Terpyridines Functionalised with Ferrocenyl Groups of Different Redox Potential

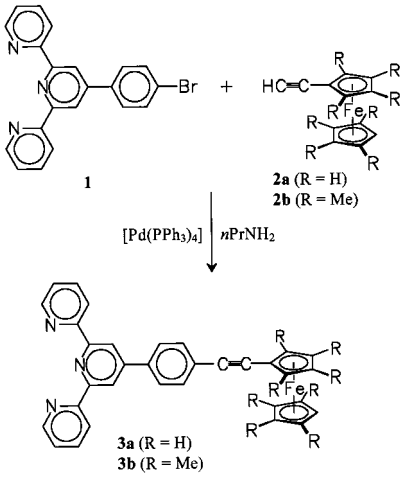
Ulrich Siemeling,*[a][1] Udo Vorfeld,[a] Beate Neumann,[a] Hans-Georg Stammler,[a] Piero Zanello,[b] and Fabrizia Fabrizi de Biani[b]

Keywords: Terpyridine ligands / Ferrocenes / Iron / Ruthenium / Cyclic voltammetry

2,2′:6′,2′′-Terpyridines bearing a substituent X in the 4′-position [**3a**: X = Fc–C≡C–*p*-C_6H_4; **3b**: X = $Fc^{\#}$–C≡C–*p*-C_6H_4; Fc = $(C_5H_5)Fe(C_5H_4)$, $Fc^{\#}$ = $(C_5Me_4H)Fe(C_5Me_4)$] were prepared by Pd^0-catalysed cross-coupling reactions. **3b** was characterised by X-ray structure analysis. [(**3a**)$RuCl_2$(DMSO)] (**4a**) and [(**3b**)$RuCl_2$(DMSO)] (**4b**) were obtained by reaction of [$RuCl_2(DMSO)_4$] with 1 equivalent of **3a** and **3b**, respectively, while the analogous reaction with 2 equivalents afforded [(**3a**)$_2$Ru][PF_6]$_2$ (**5a**) and [(**3b**)$_2$Ru][PF_6]$_2$ (**5b**), respectively, after precipitation with aqueous [NH_4][PF_6]. Similarly, [(**3a**)Ru(tpy)][PF_6]$_2$ (**6**) was isolated from the reaction of **4a** with 2,2′:6′,2′′-terpyridine (tpy). Compounds **3** and **5** were investigated by cyclic voltammetry, which revealed that the introduction of eight methyl groups leads to the expected cathodic shift of the $E^{0\prime}$ values of ca. 0.44 V for the ferrocenyl-centered redox processes.

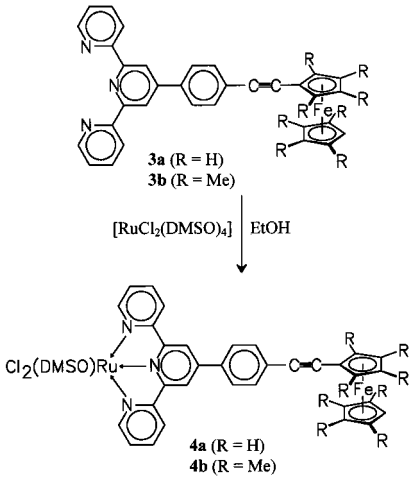
(Oligopyridine)Ru^{II} complexes exhibit unique photophysical as well as photo- and redox-chemical properties.[2] They have frequently been found to be excellent photosensitisers. Among the oligopyridine ligands 2,2′:6′,2′′-terpyridines bearing redox-active groups in the 4′-position are currently attracting much attention, since they can be used for the construction of geometrically well-defined metal complexes, which show fascinating properties based on intramolecular electron- and energy-transfer processes. For example, Ru^{II} complexes of such terpyridines have been utilised for the construction of donor/sensitiser dyads and donor/sensitiser/acceptor triads.[2a–g] These and related assemblies allow the investigation of photoinduced vectorial charge separation over large distances, which is, inter alia, of fundamental importance for solar light energy conversion.[3]

Owing to their well-behaved redox chemistry[4] as well as their chemical robustness and synthetic versatility, ferrocenyl units are very attractive donor groups in such assemblies, and several ferrocenyl-functionalised terpyridines have been synthesised for this reason.[5] However, it has turned out that ferrocenes, their (redox-)chemical advantages notwithstanding, show a serious disadvantage. [$(C_5H_5)_2$Fe] quenches photoexcited (oligopyridine)Ru^{II} complexes not only reductively, but also by triplet energy transfer.[6] The triplet energy of ferrocene has been estimated to be ca. 1.8 eV,[7] which is below the typical excited-state energy of (oligopyridine)ruthenium complexes.[2h–j] Consequently, both energy transfer and reductive quenching are thermodynamically favourable in this system. This finding has caused strong reservations as to whether ferrocenyl units can be used as donor groups in relevant assemblies, since for photoinduced charge-separation processes energy transfer is undesirable.[2g]



Undoubtedly, ferrocenyl groups could very well be utilised advantageously in this context, if it proved possible to shift the competition between energy transfer and reductive quenching in favour of the latter by judicious choice of molecular parameters. Comparative studies using ferrocene and various oligomethylferrocenes as quenchers indicate that reductive quenching can be favoured by increasing its thermodynamic driving force (i.e. by increasing the reducing power of the donor).[6][8] There is a linear relationship between the number of methyl groups and the redox potential of a ferrocene, each methyl group causing a cathodic shift of ca. 55 mV,[4][9] while leaving the triplet energy essentially unaffected.[6] However, systematic investigations of the general factors influencing the competition between energy transfer and reductive quenching in oligonuclear complexes, although of fundamental interest, have not been performed so far.[10] For such an investigation two points are of vital importance. Firstly, it is necessary to study geometrically well-defined compounds, since otherwise meaningful results, which can be compared with the predictions of current theories of electron and energy transfer,[11] cannot be obtained. Secondly, in order to obtain unequivocal results it is essential to be able to single out the effect of the variation of a single molecular parameter.

For this reason we have prepared derivatives of 2,2′:6′,2′′-terpyridine (tpy) with ferrocenyl (Fc) and octamethylferrocenyl ($Fc^{\#}$) groups attached to the 4′-position by means of a *para*-phenylene and an acetylene spacer unit.[12] In this communication we report on the synthesis of these compounds and present first results from their coordination chemistry as well as preliminary electrochemical investigations.



Sonogashira-type cross-coupling[13] of 4′-(4-bromophenyl)-2,2′:6′,2′′-terpyridine (**1**)[14] with FcC≡CH (**2a**)[15] and

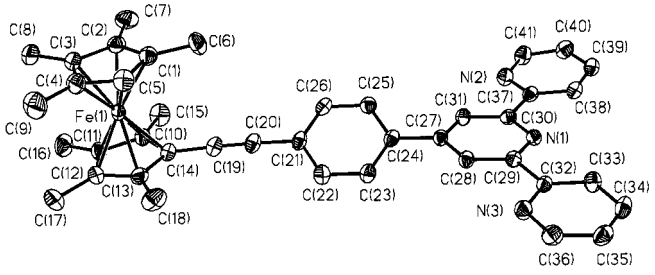
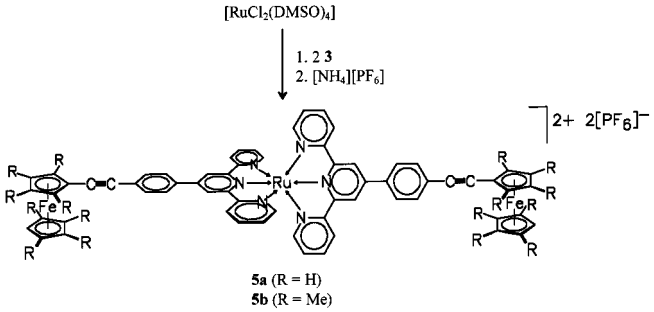
$Fc^{\#}C{\equiv}CH$ (**2b**)[16] in *n*-propylamine in the presence of $[Pd(PPh_3)_4]$[17] as catalyst[18] afforded the redox-functionalised terpyridines **3a** and **3b**, respectively (Scheme 1).

A single-crystal X-ray structure analysis was performed for **3b**. A view of the molecule is shown in Figure 1.

The cyclopentadienyl rings are arranged in an eclipsed orientation and exhibit an average Fe−C bond length of 206 pm, which is nearly identical to the value observed for decamethylferrocene (205 pm).[19] The acetylene group is almost linear [C(14)−C(19)−C(20) 177.5(3)°, C(19)−C(20)−C(21) 176.6(3)°] and has a C−C distance of 119.3(4) pm; the distance between each acetylene carbon atom and the sp^2-hybridised carbon atom attached to it is 143.1(4) [C(14)−C(19)] and 144.0(4) pm [C(20)−C(21)]. These values are unexceptional and compare well with those of other structurally characterised (phenylethynyl)ferrocenes.[20] The dihedral angle between the best planes of the C_6 ring and the central C_5N ring of the terpyridyl unit is 26.9° and that between the cyclopentadienyl ring containing the atoms C(10)−C(14) and the C_6 ring has a value of 29.1°. The three C_5N rings are almost coplanar (dihedral angles 3.3 and 7.0°) and exhibit transoid configurations about the interannular C−C bonds as is commonly observed for such compounds.[21]

We have started to develop the coordination chemistry of the new redox-functionalised terpyridines by using established methods.[18b] For example, the mono(terpyridine)ruthenium(II) complexes [(**3a**)$RuCl_2$(DMSO)] (**4a**) and [(**3b**)$RuCl_2$(DMSO)] (**4b**) were prepared by treating one equivalent of **3a** and **3b**, respectively, with $[RuCl_2(DMSO)_4]$[22] in refluxing ethanol (Scheme 2).





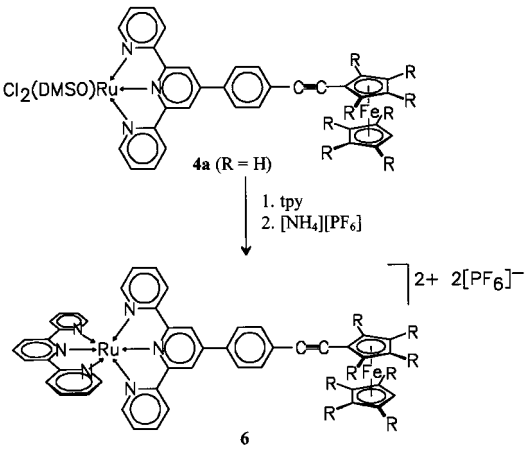


Figure 1. Molecular structure of **3b** in the crystal; selected bond lengths [pm] not discussed in the text: C(24)−C(27) 148.7(4), C(29)−C(32) 149.5(4), C(30)−C(37) 149.4(4).

Reaction of two equivalents of **3a** and **3b** with $[RuCl_2(DMSO)_4]$ in refluxing ethanol afforded the homoleptic Ru^{II} complexes $[(\mathbf{3a})_2Ru][PF_6]_2$ (**5a**) and $[(\mathbf{3b})_2Ru][PF_6]_2$ (**5b**), respectively, after precipitation with aqueous ammonium hexafluorophosphate (Scheme 3).

Scheme 3

It has also proved possible to synthesise a heteroleptic bis(terpyridine)ruthenium(II) complex, namely [(**3a**)Ru(tpy)]$[PF_6]_2$ (**6**), which was obtained by treating **4a** with one

Scheme 4

equivalent of tpy in refluxing ethanol and subsequent precipitation with aqueous ammonium hexafluorophosphate (Scheme 4).[23]

Preliminary electrochemical investigations of the terpyridine ligands **3a** and **3b** and their Ru^{II} complexes **5a** and **5b** by cyclic voltammetry demonstrate that the redox potential of the ferrocenyl moieties present in the terpyridines is not affected by complexation (Table 1). Furthermore, it is evident that the introduction of eight methyl groups in the novel redox-functionalised terpyridines and their Ru^{II} complexes leads to a cathodic shift of the $E^{0\prime}$ values of ca. 0.44 V for the ferrocenyl-centered redox processes. This is exactly the value expected for the influence of eight methyl groups (i.e. 8 × 55 mV, vide supra) and shows that in the present system oligomethylferrocenyl groups behave as reliable donors with predictable and precisely adjustable redox potentials.

[a] Conditions: 298 K; $[NBu_4][PF_6]$ supporting electrolyte (0.2 M); scan rate 0.10 V; confidence limit 0.01 V. − [b] $E^{0\prime}$ values [V] for the oxidation/reductions of the central Ru complex moiety: 1.23/ −1.22, −1.52.

In summary, we have prepared novel terpyridines functionalised with ferrocenyl and octamethylferrocenyl groups. First results indicate that both symmetrical and unsymmetrical bis(terpyridine)ruthenium complexes are accessible by established routes, which augurs well for the development of a rich coordination chemistry of these redox-functionalised ligands. Cyclic voltammetry has revealed that the ferrocenyl moieties in the new ligands and their complexes are redox-chemically well behaved. We are currently extending our studies to analogous terpyridines containing only $(C{\equiv}C)_n$ (n = 1, 2) spacer groups.[24] These and related oligomethylferrocenyl-functionalised ligands should be excellently suited for the preparation of libraries of donor/sensitiser assemblies, which for the first time will allow the detailed investigation of the competition between energy transfer and reductive quenching in a geometrically well-defined system by systematic variation of a single molecular parameter, namely the redox potential of the donor. We will report on such studies in due course.

Experimental Section

General: All manipulations were performed in an inert atmosphere (purified argon or dinitrogen) by using standard Schlenk and cannula techniques or a conventional glovebox. − Solvents and reagents were appropriately dried and purified by using standard procedures. − NMR spectra were recorded at 300 K with a Bruker DRX 500 spectrometer operating at 500.13 MHz for ^1H; TMS was used as external reference. − UV/Vis spectra were recorded with a Uvikon 860 spectrophotometer (Kontron Instruments). − Fast atom bombardment (FAB) mass spectra were obtained by the LSIMS ionisation technique (3-nitrobenzyl alcohol matrix) with a VG Autospec instrument. − Materials and apparatus used for the electrochemical investigations have been described elsewhere.[25] − Elemental analyses were performed by the Microanalytical Laboratory of the Universität Bielefeld.

Terpyridine 3a: A solution of 4′-(4-bromophenyl)-2,2′:6′,2′′-terpyridine (**1**) (1.25 g, 3.22 mmol), ethynylferrocene (**2a**) (680 mg, 3.24 mmol), and $[Pd(PPh_3)_4]$ (230 mg, 0.199 mmol) in *n*-propylamine (50 mL) placed in a thick-walled Rotaflo ampoule was stirred for 14 h at 55°C. The solution was allowed to cool to room temp. The product was filtered off, washed with diethyl ether, and dried in vacuo. A second crop was obtained by reducing the volume of the filtrate. Brownish-orange microcrystalline solid, m.p. 231°C; yield 1.40 g (84%). − ^1H NMR ($CDCl_3$): δ = 4.25 (s, 2 H, C_5H_4), 4.26 (s, 5 H, C_5H_5), 4.52 (s, 2 H, C_5H_4), 7.33 (m, 2 H, 5,5′′-H), 7.60 ("d", apparent J = 8.1 Hz, 2 H, C_6H_4), 7.84−7.87 (m, 4 H, C_6H_4 and 4,4′′-H), 8.65 (d, J = 7.9 Hz, 3,3′′-H), 8.71−8.73 (m, 4 H, 6,3′,5′,6′′-H). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 65.0, 68.9, 70.0, 71.5 (Fc); 85.5, 90.1 (C≡C); 118.6, 121.4, 123.9, 124.8, 127.2, 131.9, 136.9, 137.4, 149.1, 149.5, 156.0, 156.2 (aryl rings). − FAB MS; *m*/*z*: 518 $[M + H]^+$, 517 $[M^+]$. − $C_{33}H_{23}FeN_3$ (517.41): C 76.61, H 4.48, N 8.12; found C 76.43, H 4.81, N 8.57.

Terpyridine 3b: By a procedure analogous to that described for **3a** 1.26 g (76%) of **3b** was obtained from **1** (1.03 g, 2.64 mmol), ethynyloctamethylferrocene (**2b**) (850 mg, 2.64 mmol), and $[Pd(PPh_3)_4]$ (183 mg, 0.158 mmol) in *n*-propylamine (40 mL) as orange platelets, m.p. 221°C. − ^1H NMR ($CDCl_3$): δ = 1.69, 1.74, 1.78, 1.91 (4 s, 4 × 6 H, Me); 3.37 (s, 1 H, C_5Me_4H); 7.34 (m, 2 H, 5,5′′-H); 7.60 ("d", apparent J = 8.1 Hz, 2 H, C_6H_4); 7.86−7.88 (m, 4 H, C_6H_4 and 4,4′′-H); 8.66 (d, J = 7.9 Hz, 3,3′′-H), 8.73 (d, J = 5.2 Hz, 2 H, 6,6′′-H); 8.74 (s, 2 H, 3′,5′-H). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 8.9, 10.0, 10.6, 10.8 (Me); 71.8, 81.2, 81.3, 81.4, 82.4 (C_5-Fc[#]); 89.0, 90.5 (C≡C); 118.6, 121.4, 123.8, 125.8, 127.2, 131.5, 136.9, 149.1, 149.7, 156.0, 156.2 (aryl rings). − FAB MS; *m*/*z*: 630 $[M + H]^+$, 629 $[M^+]$. − $C_{41}H_{39}FeN_3$ (629.63): C 78.21, H 6.24, N 6.67; found C 77.88, H 6.49, N 6.76.

Complex 4a: A stirred mixture of **3a** (125 mg, 0.242 mmol) and $[RuCl_2(DMSO)_4]$ (117 mg, 0.240 mmol) in ethanol (10 mL) was refluxed for 15 h and subsequently allowed to cool to room temp. The product was filtered off, washed with ethanol, and dried in vacuo. Light-violet platelets; yield 132 mg (71%). − ^1H NMR ($[D_6]$DMSO): δ = 3.61 (s, 6 H, Me_2SO); 4.31 (s, 5 H, C_5H_5); 4.39, 4.67 (2 s, 2 × 2 H, C_5H_4); 7.53 (m, 2 H, 5,5′′-H); 7.73 ("d", apparent J = 7.9 Hz, 2 H, C_6H_4); 7.99 (m, 2 H, 4,4′′-H); 8.28 ("d", apparent J = 7.9 Hz, 2 H, C_6H_4); 8.80 (d, J = 7.5 Hz, 2 H, 3,3′′-H); 8.99 (s, 2 H, 3′,5′-H); 9.36 (d, J = 4.8 Hz, 2 H 6,6′′-H). − $^{13}C\{^1H\}$ NMR ($[D_6]$DMSO): δ = 40.4 (Me_2SO); 64.0, 67.6, 69.2, 69.8, 71.2, 85.0 (Fc and C≡C); 118.5, 123.5, 126.4, 127.8, 131.7, 132.1, 133.3, 136.7, 155.6, 157.3, 158.8 (aryl rings). − FAB MS; *m*/*z*: 767 $[M]^+$, 732 $[M - Cl]^+$, 689 $[M - Me_2SO]^+$. − $C_{35}H_{29}Cl_2FeN_3ORuS$ (767.52): C 54.77, H 3.81, N 5.47; found C 53.98, H 4.30, N 5.38.

Complex 4b: By a procedure analogous to that described for **4a** 135 mg (78%) of **4b** was obtained from **3b** (124 mg, 0.197 mmol) and $[RuCl_2(DMSO)_4]$ (95 mg, 0.196 mmol) in ethanol (10 mL) as a light-violet microcrystalline solid. − ^1H NMR ($CDCl_3$): δ = 1.70, 1.75, 1.82, 1.97 (4 s, 4 × 6 H, Me); 2.71 (s, 6 H, Me_2SO); 3.39 (s, 1 H, C_5Me_4H); 7.35 ("d", apparent J = 8.2 Hz, 2 H, C_6H_4); 7.49 (m, 2 H, 5,5′′-H); 7.67 ("d", apparent J = 8.2 Hz, 2 H, C_6H_4); 7.72 (m, 2 H, 4,4′′-H); 8.05 (d, J = 8.9 Hz, 2 H, 3,3′′-H); 8.06 (s, 2 H, 3′,5′-H); 9.33 (d, J = 5.2 Hz, 2 H, 6,6′′-H). − $^{13}C\{^1H\}$ NMR

Complex 5a: A stirred mixture of **3a** (250 mg, 0.483 mmol) and [$RuCl_2(DMSO)_4$] (117 mg, 0.241 mmol) in ethanol (30 mL) was refluxed for 15 h and subsequently allowed to cool to room temp. and filtered. 1.0 mL of a saturated aqueous solution of ammonium hexafluorophosphate was added dropwise to the red filtrate. The precipitate was filtered off, washed with ethanol and water, and dried in vacuo. Dark red microcrystalline solid; yield 130 mg (38%).− ^{1}H NMR ([D_6]DMSO): δ = 4.35 (s, 10 H, C_5H_5); 4.43, 4.67 (2 s, 2 × 4 H, C_5H_4); 7.29 (m, 4 H, 5,5′′-H); 7.56 (d, J = 5.1 Hz, 4 H, 6,6′′-H); 7.87 ("d", apparent J = 7.2 Hz, 4 H, C_6H_4); 8.07 (m, 4 H, 4,4′′-H); 8.51 ("d", apparent J = 7.1 Hz, 4 H, C_6H_4); 9.14 (d, J = 7.2 Hz, 4 H, 3,3′′-H); 9.53 (s, 4 H, 3′,5′-H). − $^{13}C\{^1H\}$ NMR ([D_6]DMSO): δ = 64.0, 69.3, 69.9, 71.3 (Fc); 85.3, 91.6 (C≡C); 120.8, 124.9, 125.1, 127.8, 128.0, 131.9, 135.2, 138.0, 152.2, 155.1, 158.0 (aryl rings). − UV/Vis (acetonitrile): λ (lg ε) = 230 nm (4.78), 272 (4.84, sh), 284 (4.86), 312 (4.97), 326 (4.94, sh), 495 (4.62). − FAB MS; *m/z*: 1281 $[\mathbf{5a} - PF_6]^+$, 1136 $[\mathbf{5a} - 2\ PF_6]^+$. − $C_{66}H_{46}F_{12}Fe_2N_6P_2Ru$ (1425.84): C 55.60, H 3.25, N 5.89; found C 56.00, H 3.56, N 6.21.

Complex 5b: By a procedure analogous to that described for **5a** 41 mg (59%) of **5b** was obtained from **3b** (53 mg, 0.084 mmol) and [$RuCl_2(DMSO)_4$] (20 mg, 0.041 mmol) in ethanol (8 mL) as a brown microcrystalline solid. − ^{1}H NMR ([D_6]DMSO): δ = 1.68−1.92 (br. m, 48 H, Me), 3.44 (s, 2 H, C_5Me_4H), 7.28 (m, 4 H, 5,5′′-H), 7.55 (d, J = 5.3 Hz, 4 H, 6,6′′-H), 7.82 ("d", apparent J = 7.4 Hz, 4 H, C_6H_4), 8.07 (m, 4 H, 4,4′′-H), 8.45 ("d", apparent J = 7.7 Hz, 4 H, C_6H_4), 9.01 (d, J = 8.0 Hz, 4 H, 3,3′′-H), 9.50 (s, 4 H, 3′,5′-H). − $^{13}C\{^1H\}$ NMR ([D_6]DMSO): δ = 8.6, 9.7, 10.4, 10.5 (Me-Fc#); 71.6, 80.4, 80.5, 81.6, 81.8 (C_5-Fc#); 88.6, 92.1 (C≡C); 120.9, 124.8, 126.0, 127.7, 128.1, 131.4, 134.8, 138.0, 152.2, 155.1, 158.0 (aryl rings). − UV/Vis (acetonitrile): λ (lg ε) = 226 nm (5.01), 272 (4.93, sh), 284 (4.94), 309 (5.01), 328 (4.93, sh), 356 (4.77), 494 (4.71). − FAB MS; *m/z*: 1505 $[\mathbf{5b} - PF_6]^+$, 1360 $[\mathbf{5b} - 2\ PF_6]^+$. − $C_{82}H_{78}F_{12}Fe_2N_6P_2Ru \times 2\ H_2O$ (1686.31): C 58.41, H 4.90, N 4.98; found C 58.57, H 5.06, N 5.12.

Complex 6: A stirred mixture of **4a** (96 mg, 0.125 mmol) and 2,2′:6′,2′′-terpyridine (29 mg, 0.124 mmol) in ethanol (25 mL) was refluxed for 15 h and subsequently allowed to cool to room temp. and filtered. 1.0 mL of a saturated aqueous solution of ammonium hexafluorophosphate was added dropwise to the red filtrate. The precipitate was filtered off, washed with ethanol and water, and dried in vacuo. Brown microcrystalline solid; yield 70 mg (49%). − ^{1}H NMR ([D_6]DMSO): δ = 4.34 (s, 5 H, C_5H_5); 4.42, 4.65 (2 s, 2 × 2 H, C_5H_4); 7.24−7.28 (m, 4 H, **3a**-5,5′′-H and tpy-5,5′′-H); 7.43 (d, J = 5.5 Hz, 2 H, **3a**-6,6′′-H); 7.54 (d, J = 5.5 Hz, 2 H, tpy-6,6′′-H); 7.86 ("d", apparent J = 8.1 Hz, 2 H, C_6H_4), 8.02−8.06 (m, 4 H, **3a**-4,4′′-H and tpy-4,4′′-H); 8.50 ("d", apparent J = 8.1 Hz, 2 H, C_6H_4); 8.54 (m, 1 H, tpy-4′-H); 8.83 (d, J = 8.0 Hz, tpy-3,3′′-H); 9.09−9.13 (m, 4 H, **3a**-3,3′′-H and tpy-3′,5′-H); 9.51 (s, 2 H, **3a**-3′,5′-H). − $^{13}C\{^1H\}$ NMR ([D_6]DMSO): δ = 64.0, 69.3, 69.9, 71.3 (Fc); 120.9, 121.0, 123.9, 124.0, 123.7, 124.8, 124.9, 127.7, 131.9, 133.5, 135.0, 135.8, 138.0, 145.8, 152.1, 154.7, 155.1, 157.7, 157.8 (aryl rings). − UV/Vis (acetonitrile): λ (lg ε) = 218 nm (4.78), 272 (4.74), 284 (4.70, sh), 308 (4.93), 326 (4.81, sh), 486 (4.48). − FAB MS; *m/z*: 852 $[\mathbf{6} - 2\ PF_6]^+$. − $C_{48}H_{34}F_{12}FeN_6P_2Ru \times H_2O$ (1159.72): C 49.71, H 3.13, N 7.25; found C 49.47, H 3.18, N 7.44.

Crystal Structure Determination of 3b[26]: An orange crystal with dimensions 1.00 × 0.60 × 0.10 mm was used for data collection at 183(2) K with a Siemens $P2_1$ four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods. Programs used were Siemens SHELXTL PLUS[27] and SHELXL 97[28]. Full-matrix least-squares refinement on F^2 was carried out anisotropically for the non-hydrogen atoms. Hydrogen atoms were included at calculated positions using a riding model. Further X-ray structure analysis data are given in Table 2.

Acknowledgments

This work was financially supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. A generous gift of ruthenium trichloride from the Degussa AG is greatfully acknowledged. U. S. thanks Prof. Dr. Johann W. Buchler and Prof. Dr. Max Herberhold for helpful discussions. U. S. and U. V. thank Prof. Dr. Peter Jutzi and Dipl.-Chem. Birgit Kleinebekel for a generous gift of ethynyloctamethylferrocene.

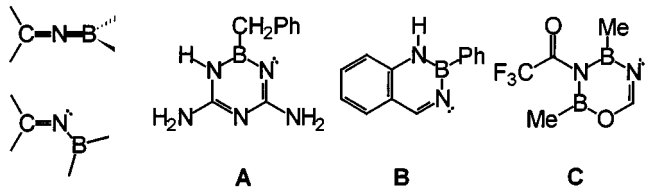
Cyclic Ketiminoboranes

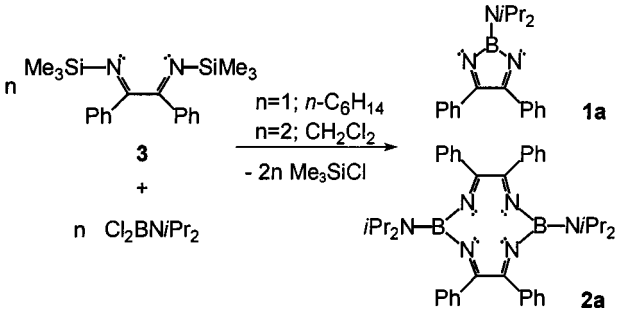


Norbert Weis,*[a] Hans Pritzkow,[a] and Walter Siebert[a]

Dedicated to Prof. M. F. Hawthorne on the occasion of his 70th birthday

Keywords: Boranes / Diazaboroles / Heterocycles / Ketiminoboranes / Crystal Structures

The cyclocondensation reaction of benzil-bis(trimethylsilylimin) (**3**) and Cl_2B–N*i*Pr_2 via silicon-boron exchange results in the solvent-dependent formation of the 1,3,2-diazaborole **1a** or the 1,3,6,8,2,7-tetraazadiborecin **2a**. Using the more rigid 9,10-bis(trimethylsilylimino)phenanthrene instead of **3** only the five-membered heterocycle 4,5-biphenylene-2-diisopropylamino-1,3,2-diazaborole (**1b**) is formed. The cyclic ketiminoboranes are characterized by NMR and X-ray diffraction data. The 1,3,2-diazaborole ring is almost planar, while the conformation of the 1,3,6,8,2,7-tetraazadiborecin has the shape of a figure-eight loop.



More than 35 years ago Hawthorne[1] synthesized the first examples of alkylideneaminoboranes. Information about their geometry and BNC bond order were obtained from IR data and X-ray structure analyses[2]. The results were complemented by theoretical studies[3], which postulate a cumulene-like arrangement for the >C=N=B< group. Geometry-optimized calculations on 6-31G niveau resulted for $HB(N{=}CH_2)_2$[4] and $B(N{=}CH_2)_3$[5] energetic differences of 74 and 12 KJ/mol, respectively, between the linear and bent CNB structure.

Scheme 1

A cumulene-like arrangement is difficult to verify in small cyclic molecules, in which the C=N−B unit may be compared with an allyl cation. To our knowledge only a few six-membered heterocycles such as **A**−**C**[6,7,8] with an incorporated C=N−B unit have been described. A dithiatetraazadiborocin[9] is an example of an eight-membered ring with B−N=S units.

Here we present the five- and ten-membered boron-nitrogen heterocycles 4,5-diphenyl-2-diisopropylamino-1,3,2-diazaborole (**1a**), 4,5-biphenylene-2-diisopropylamino-1,3,2-diazaborole (**1b**) and 2,7-bis(diisopropylamino)-4,5,9,10-tetraphenyl-1,3,6,8,2,7-tetraazadiborecin (**2a**), obtained via silicon-boron exchange reactions and characterized by X-ray structure analyses.

Scheme 2

The reaction of benzil-bis(trimethylsilylimin) (**3**)[10] with (diisopropylamino)dichloroborane in *n*-hexane leads to the formation of **1a** in 71% yield. Its composition follows from NMR and MS data. The ^{11}B-NMR signal is shifted 7 ppm to lower field (δ = 37) relative to comparable non-cyclic ketiminoboranes $R_2N{-}B(N{=}CPh_2)_2$ (R = Me, Et)[11][12]. This shift is a consequence of the orbital symmetry, which does not allow an interaction of the free electron-pair of the ketiminonitrogen atom and the p_z orbital of the boron atom in the five-membered heterocycle. With four π electrons the diazaborole **1a** should posses strong acceptor properties, however, its chemical reduction to the corresponding 6 π aromatic [**1a**]$^{2-}$ has not been succesful. The cyclovoltammogram of **1a** exhibits an irreversible reduction at $E_{1/2}$= −1.28 eV. Because single crystals of **1a** could not be obtained, crystalline **1b** was synthesized by reacting 9,10-bis(trimethylsilylimino)-phenanthrene with $Cl_2B{-}Ni Pr_2$. A dimerization of **1b** to a ten-membered ring does not take place, prevented by the syn-conformation of the fixed 1,4-diazadiene. In the ^{1}H-NMR spectrum the expected doublet and septet for the isopropyl group and four signals of the aromatic hydrogen atoms are observed in correspondence

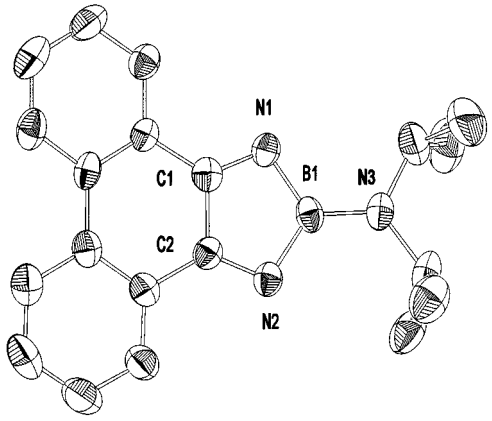

Figure 1. Molecular structure of **1b** in the crystal. Selected bond lengths [Å] and angles [°] for molecule A: B1−N3 1.383(7), B1−N1 1.505(7), B1−N2 1.506(7), C1−N1 1.296(6), C2−N2 1.295(6), C1−C2 1.513(7), N1−B1−N3 121.7(5), C1−N1−B1 101.5(4), N1−B1−N2 111.8(4), C15−N3−B1−N2 2.5.

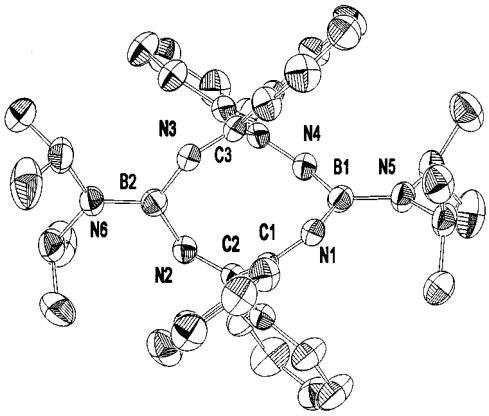

Figure 2. Molecular structure of **2a** in the crystal. Selected bond lengths [Å] and angles [°]: N5−B1 1.407(3), N6−B2 1.400(3), N1−B1 1.458(3), N4−B1 1.470(3), C1−N1 1.277(2), C2−N2 1.273(3), C3−N3 1.277(2), C4−N4 1.276(2), C1−C2 1.525(3), C3−C4 1.513(3), C1−N1−B1 128.6(2), C4−N4−B1 127.3(2), C3−N3−B2 127.9(2), C2−N2−B2 128.6(2), N1−B1−N4 121.5(2), N2−B2−N3 119.7(2), N1−B1−N5 119.9(2), N4−B1−N5 118.7(2), N2−B2−N6 120.6(2), N3−B2−N6 120.6(2), N1−C1−C2−N2 104.9, N3−C3−C4−N4 105.2.

with the symmetry of the molecule. The ^{11}B-NMR signal of **1b** is observed at the same shift (δ = 37) as for **1a**.

In methylenchloride as solvent the silicon−boron exchange reaction leads to the ten-membered 2,7-bis(diisopropylamino)-4,5,9,10-tetraphenyl-1,3,6,8,2,7-tetraazadiborecin (**2a**) in 62% yield. Its ^{11}B-NMR signal at δ = 28 appears at higher field than that of **1a**, **b**. Two signals for the methyl group of the isopropylamino substituents in the ^{1}H- and ^{13}C-NMR spectra point to a hindered rotation around the B−N(*i*Pr)$_2$ bonds.

By slow diffusion of *n*-hexane into the CH_2Cl_2 solution of **1b** single crystals suitable for an X-ray structure analysis were obtained. The two independent molecules in the cell show no significant difference.

The molecule is almost planar. The five-membered diazaborole has two short C=N double bonds [1.295(6)−1.304(6) Å] and two longer B−N bonds [1.495(7)−1.515(7) Å]. The exocyclic B−N bond lengths [1.383(7), 1.386(7) Å] are in the region of B=N double bonds. The C−C bond length [1.508(7), 1.513(7) Å] is quite short. From this point of view **1a**, **b** may be described as triazaborafulvene derivatives.

2a crystallizes in cubes; its X-ray structure analysis shows that the heterocycle deviates considerably from planarity. The arrangement of the ring can be described as a figure-eight loop, being built from two 1,4-diazadiene units in anti conformation with a torsion angle of 105°, which are bridged by two B−N*i*Pr$_2$ units. As indicated by the distances [N5−B1: 1.407(3) Å], the exocyclic B−N bonds have double-bond character. The bond lengths in the C=N−B units [C=N: 1.277(2) Å, =N−B: 1.458(3) Å] correspond to the values reported for a B(N=CH$_2$)$_3$[5]. One has to consider that the R$_2$C=N planes are turned out of the plane around the boron atoms. This geometry allows a partial interaction between the electron pair of the nitrogen atom and the p$_z$-orbital of the boron atom, as indicated by the high-field shift in the ^{11}B-NMR spectrum.

Experimental Section

General: Reactions were carried out under dry argon, using standard Schlenk techniques. Solvents were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat-gun in high vaccum. − ^{1}H-, ^{13}C-, ^{11}B NMR: BRUKER AC 200 spectrometer, NMR references are $(CH_3)_4Si$ and $BF_3 \cdot Et_2O$. − Mass spectra were obtained with a Finnigan MAT 8200 plus spectrometer using EI technique. Cyclic voltammetry data (EG&G PARC 175 potentiostat): Pt disc (1mm) working electrode, CH_2Cl_2 solution, 0.1 M Bu_4NPF_6 as supporting electrolyte, Pt-wire as auxiliar electrode, SCE as reference electrode.

1a: 362 mg (2 mmol) of Cl$_2$BN(*i*Pr)$_2$ dissolved in 10 mL of *n*-hexane was added dropwise within 50 min to a solution of 704 mg (2 mmol) **3** in 20 mL of *n*-hexane at room temp. After stirring for 14 h the yellow precipitate was filtered and washed with a small amount of cold *n*-pentane (0°C), yield: 447 mg (1.4 mmol, 71%) of **1a**. − ^{1}H NMR (δ in $CDCl_3$): 7.52−7.47 (m, 4 H, C_6H_5), 7.40−7.24 (m, 6 H, C_6H_5), 4.37 [sept, *J* = 6.8 *Hz*, 2 H, C*H*(CH$_3$)$_2$], 1.47 [d, *J* = 6.8 *Hz*, 12 H, CH(C*H*$_3$)$_2$]. − ^{13}C NMR (δ in $CDCl_3$): 178.5 (C=N), 136.3 (*i*-C, C_6H_5), 130.2, 129.1, 127.8 (CH, C_6H_5), 47.9 [*C*H(CH$_3$)$_2$], 24.5 [CH(*C*H$_3$)$_2$]. − ^{11}B NMR (δ in $CDCl_3$): 36.6. − MS (70 eV,EI): m/z (%): 317 (16) [M$^+$], 214 (27) [M − C_6H_5CN]$^+$, 171 (64) [M − C_6H_5CN, −*i*Pr]$^+$, 103 (24) [$C_6H_5CN^+$], 44 (100) [*i*PrH$^+$]. − m.p. 185−187°C.

1b: 362 mg (2 mmol) of Cl$_2$BN(*i*Pr)$_2$ dissolved in 10 mL of CH_2Cl_2 was added dropwise within 30 min to a solution of 700 mg (2 mmol) 9,10-bis(trimethylsilylimino)phenanthrene in 20 mL of CH_2Cl_2 at 0°C. After stirring for 14 h at room temp. the solvent and $ClSiMe_3$ were removed in vaccuo. The residue was dissolved in 2 mL of CH_2Cl_2 and *n*-hexane was allowed to diffuse into the solution at room temp. After 15 days crystalline **1b** was filtered, yield: 197 mg (0.6 mmol, 31%). − ^{1}H NMR (δ in $CDCl_3$): 8.37−8.33 (m, 2 H, C_6H_5), 7.95−7.92 (m, 2 H, C_6H_5), 7.53−7.44 (m, 2 H, C_6H_5), 7.36−7.28 (m, 2 H, C_6H_5), 4.38 [sept, *J* = 6.7 *Hz*, 2 H, C*H*(CH$_3$)$_2$], 1.48 [d, *J* = 6.7 *Hz*, 12 H, CH(C*H*$_3$)$_2$]. − ^{13}C NMR (δ in $CDCl_3$): 172.8 (C=N), 135.6 (*i*-C, C_6H_5), 132.7, 128.4, 124.1 (CH, C_6H_5), 48.4 [*C*H(CH$_3$)$_2$], 24.9 [CH(*C*H$_3$)$_2$]. − ^{11}B NMR (δ in $CDCl_3$): 37.1. − m.p. 202−206°C (decomp.).

2a: 905 mg (0.5 mmol) of $Cl_2BN(iPr)_2$ dissolved in 20 mL of CH_2Cl_2 was added within 1 h dropwise to a solution of 1.76 g (5 mmol) **3** in 50 mL of CH_2Cl_2 at room temp. After stirring for 14 h the solvent and $ClSiMe_3$ were removed in vaccuo. The residue was dissolved in 10 mL of CH_2Cl_2 and 5 mL of *n*-hexane was added. After 50 h at 6°C 1.91 g (3.0 mmol, 62%) **2a** was filtered. − ^{1}H NMR (δ in $CDCl_3$): 7.72−7.67 (m, 8 H, C_6H_5), 7.40−7.28 (m, 12 H, C_6H_5), 3.46 [sept, J = 6.7 *Hz*, 4 H, C*H*$(CH_3)_2$], 0.96 [d, J = 6.7 *Hz*, 6 H, CH(C*H*$_3)_2$], 0.91 [d, J = 6.7 *Hz*, 6 H, CH(C*H*$_3)_2$]. − ^{13}C NMR (δ in $CDCl_3$): 164.3 (C=N), 137.4 (*i*-C, C_6H_5), 130.4, 128.8, 127.8 (CH, C_6H_5), 45.3 [*C*H$(CH_3)_2$], 21.8 [CH(*C*H$_3)_2$]. − ^{11}B NMR (δ in $CDCl_3$): 28.2. − MS (70 eV, EI): *m/z* (%): 634 (1) [M^+], 428 (56) [M − $(C_6H_5CN)_2]^+$, 328 (100) [M − $(C_6H_5CN)_2$, − N*i*$Pr_2]^+$. − m.p. 150−152°C.

Crystal Structure Determination: Unique intensity data sets were collected at −70°C with a four-circle diffractometer (Mo-K_α radiation λ = 0.71073 Å, graphite monochromator, ω-scan). Empirical absorption corrections (ψ-scans) were applied. The structures were solved by direct methods [SHELXS86][13] and refined by least squares methods based on F^2 with all mesured reflections [SHELXL97][14]. All non-hydrogen atoms were refined anisotropically. − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center **1b**: CCDC-102512, **2a**: CCDC-102512. Copies of the data can be obtained free of charge by application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; fax: int. code +44 (0)1223/ 336-001; e-mail: deposit@ccdc.cam.ac.uk.

Formation and Structures of [1,2–Bis(*N*-*tert*-butylcarbamoyl)-cyclopentadienyl]zirconium Complexes – Coordination Chemistry of a "Fulvenologous" Malonic Amide Anion Ligand System

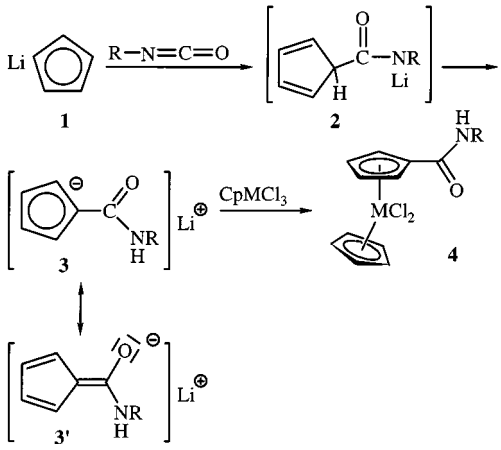
Katrin Klaß,[a] Lothar Duda,[a] Nina Kleigrewe,[a] Gerhard Erker,*[a] Roland Fröhlich,[a] and Elina Wegelius[a]

Dedicated to Professor Bernt Krebs on the occasion of his 60th birthday

Keywords: Functionalized Cp ligand / κ^2O,O′-Chelate / Carboxamido-substituted cyclopentadienides / Zirconium complexes

Treatment of sodium cyclopentadienide with two molar equivalents of *tert*-butyl isocyanate yields sodium 1,2-bis(*N*-*tert*-butylcarbamoyl)cyclopentadienide (**6**). The $[C_5H_3(1,2\text{-}CONHCMe_3)_2]Na$ reagent **6** adds to $Cp_2Zr(CH_3)Cl$ (**8**) to yield $Cp_2Zr(CH_3)[C_5H_3(CONHCMe_3)_2]$ (**9**). In **9** the $C_5H_3(CONHCMe_3)_2$ ligand is bonded to zirconium through one of its carboxamido-oxygen atoms (κ*O*-coordination). Treatment of **6** with $CpZrCl_3(THF)_2$ yields $CpZrCl_2[C_5H_3\text{-}(CONHCMe_3)_2](THF)$ **11**. In **11** the 1,2-bis(*N*-*tert*-butylcarbamoyl)cyclopentadienide moiety serves as a C_s-symmetric chelate ligand, binding to zirconium through both carbamoyl oxygens (κ^2*O,O′*-coordination). The same seven-membered metallacyclic structural type is found in the reaction products of **6** with $ZrCl_4(THF)_2$ in 1:1 and 2:1 molar ratios. The former yields the distorted octahedral complex $ZrCl_3[C_5H_3(CONHCMe_3)_2](THF)$ (**12**), the latter gives the chiral octahedral system $ZrCl_2[C_5H_3(CONHCMe_3)_2]_2$ (**13**). In solution, complex **13** undergoes a thermally induced enantiomerization process (Λ ⇌ Δ interconversion), for which a Gibbs activation energy of $\Delta G^{\ddagger}_{enant} = 14.0 \pm 0.3$ kcal mol^{-1} was determined by dynamic ^{1}H-NMR spectroscopy. The κ^2*O,O′*-coordination of the $[C_5H_3(1,2\text{-}CONHCMe_3]^-$ ligand in the complexes **11**, **12**, and **13** was secured by X-ray crystal structure analyses.

Introduction



Compounds derived from mono- and especially from bis(η-cyclopentadienyl) group 4 metal complexes have become of enormous importance in organometallic chemistry and catalysis.[1] Numerous variations at the Cp-ring systems have been devised and carried out, many of those in the development of improved homogeneous metallocene Ziegler catalysts and related systems. Most of the variations involved the attachment or anellation of hydrocarbyl moieties.[2] Functional groups have much less frequently been used for derivatising the Cp-rings, although there has been a variety of group 4 metallocene examples bearing Cp-side chains that contain amino-, phosphanyl-, or borane (and borate) substituents.[3] However, the more reactive carbonyl-derived functional groups are still very rarely found attached to Cp-type ring systems in group 4 metallocene and related chemistry. Following the pioneering work by M. D. Rausch et al.[4] we have searched for new ways of introducing reactive carbonyl substituents, especially carboxamide-derived groups at Cp-ligands, and then to attach them to the electropositive, oxophilic early transition metals.

We had previously shown that the cyclopentadienyl anion rapidly adds to a variety of alkyl- and arylisocyanates.[5][6] Subsequent to the carbon-carbon coupling step a rapid proton transfer takes place and the respective *N*-aryl- or *N*-alkylcarboxamido-substituted cyclopentadienides were obtained with moderate to good yields and selectivities. Formally these systems constitute carbamoyl-substituted cyclopentadienyl anion systems, but their fulvenoid mesomeric resonance structures must probably be taken into account for their ample structural and electronic description.[7] Nevertheless, transmetallation of the $[C_5H_4\text{–}CONHR^-]$anion equivalents to e.g. titanium straightforwardly led to the selective formation of (η^5-C_5H_4–CONHR)[Ti] complexes, such as e.g. **4**. Only coordination of the ligand system through the five cyclopentadienyl ring carbon atoms was observed. The carboxamide functional group did not participate in the bonding of this ligand type to the central group 4 metal center. This was unequivocally shown by an X-ray crystal structure analysis of a representative example.[5]

This raises the question about the structural consequences that arise from attaching more than one electron-withdrawing carboxamido-substituent at the anionic Cp ligand. Especially in the case of two "*ortho*"-positioned carbonyl substituents,[8] that can cooperatively remove cyclopentadienide electron density, a situation might arise where the remaining Cp-nucleophilicity is not sufficient to warrant binding of the carbocyclic ring system to an early transition

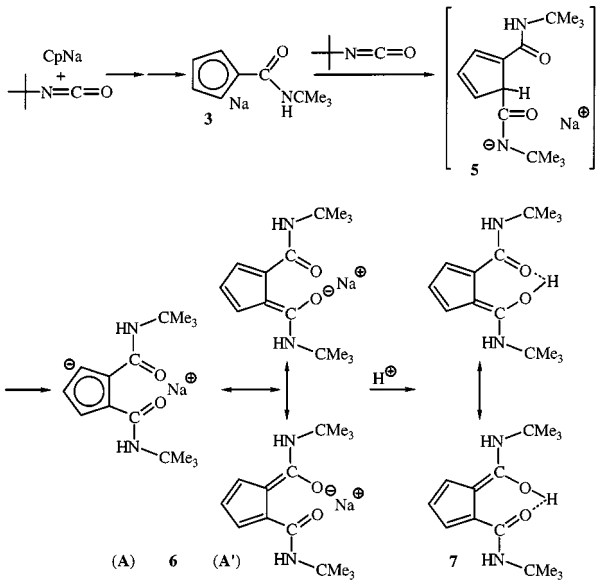
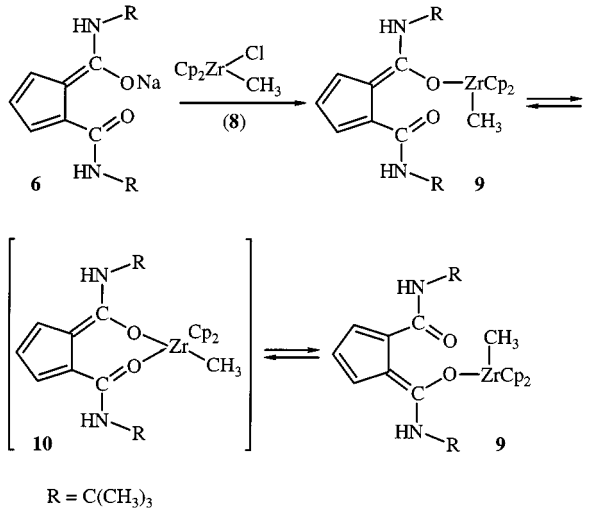


Scheme 1. Formation and metal coordination of the $[C_5H_4CONHR]^-$ ligand

metal center. Then a situation is conceivable where a switching of the preferred coordination mode from η^5-CpX_2 to potentially favored chelate bonding through the substituent nitrogen or, more likely, oxygen atoms might occur. We have prepared such a ligand system and attached it to a series of organometallic zirconium containing frameworks of decreasing overall electronic unsaturation to see which of the possible coordination modes, η^5-cyclopentadienyl or bis(carboxamide) substituent κ^2O,O'-chelate is favored.

Results and Discussion

The 1,2-biscarbamoyl-Cp ligand system employed in this study was selectively prepared by treatment of sodium cyclopentadienide with two molar equivalents of *tert*-butyl isocyanate in tetrahydrofuran. The twofold addition took place readily at temperatures between 0°C and room temperature. In view of our earlier work[5] it must be assumed that the reaction sequence proceeds through the monofunctionalized intermediates **2** and **3** (see Scheme 1, but in this case with the Na^+ counterion). Apparently, the anion **3** still contains a sufficiently nucleophilic substituted cyclopentadienide ring system to allow for a rapid subsequent attack at the strongly electrophilic sp-hybridized carbon atom of the *tert*-butyl isocyanate reagent present in the solution. Again, proton transfer seems to be rapid at the stage of the intermediate resulting from the addition reaction (compound **5** in Scheme 2) to give the doubly carbamoyl substituted anionic ligand system **6**. The twofold *tert*-butyl isocyanate addition reaction sequence is strictly 1,2-selective. This is probably due to a pronounced anion-stabilization in **6**, as it is illustrated by the fulvenoid resonance forms **6A/6A′** (see Scheme 2).[8] Indeed, the NMR spectra of **6** indicate a delocalized C_{2v}-symmetric structure in solution. There is only one set of $^1H/^{13}C$ NMR signals for the pair of symmetry-equivalent $-CONHCMe_3$ substituents (for details see the Experimental Section). Also, complex **6** exhibits an apparent AX_2 ^1H-NMR spin pattern of the central C_5H_3 unit (δ 6.73, d, 2 H; 6.25, t, 1 H; ^3J = 3.6 Hz; corresponding ^{13}C NMR ***C***H signals at δ 115.1 and 108.8). Hydrolysis of **6** gives the neutral system **7**. The spectroscopic features (e.g. ^1H NMR $-O$*H* signal at δ 19.7 in $CDCl_3$) indicate the presence of a fully enolized tautomer with $C{=}O\cdots H{-}O-$ bridging hydrogen. Again, the obtained product **7** exhibits NMR spectra that are consistent with a fully delocalized C_{2v}-symmetric species in solution. It thus seems justified to consider the compound **7** (and the anion **6** derived from it) as fulvene-expanded analogues of the respective malonic amides. One might, therefore, term such systems "fulvenologous" β-dicarbonyl compounds. The compounds **7** and **6** may then be regarded as a fulvenologous malonic amide or malonic amide anion, respectively.



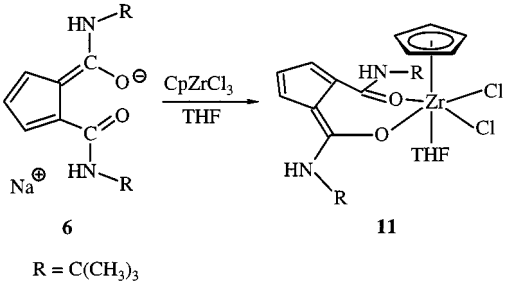
Scheme 2. Preparation of a $[C_5H_3(CONHR)_2]^-$ ligand

The anion **6** was then reacted with a variety of zirconium complexes with a varying degree of coordinative unsaturation and electrophilicity. We first treated the reagent **6** with $Cp_2Zr(CH_3)Cl$ (**8**).[9]

Complex **8** reacts rapidly with **6** in a 1:1 molar ratio in toluene solution. The product **9** of the composition $Cp_2Zr(CH_3)[C_5H_3(CONHCMe_3)_2]$ was isolated in ca. 60% yield. The NMR spectra of **9** are in accord with a C_s-symmetric structure in solution. The complex contains a pair of symmetry-equivalent η^5-cyclopentadienyl ligands ($^1H/^{13}C$ NMR signals observed at δ 6.22/112.1) and a single metal-bound CH_3 group (δ 0.38/29.7 in CD_2Cl_2 solution). The $C_5H_3(CONHCMe_3)_2$ ligand is unsymmetrically coordinated to zirconium. It exhibits two sets of ^1H- and ^{13}C-NMR resonances of the $-CONHCMe_3$ groups, five separated ^{13}C-NMR resonances of the carbon atoms of the C_5H_3 ring and an ABC-type ^1H-NMR pattern for the C_5H_3 hydrogen resonances (at 213 K, 150/600 MHz). This spectroscopic behavior is incompatible with the formation of a complex containing an η^5-$C_5H_3X_2$ ligand in addition to a pair of η^5-C_5H_5 moieties. We must assume that the $C_5H_3(CONHCMe_3)_2$ ligand in **9** is bonded to zirconium through oxygen. We assume that complex **9** contains one uncomplexed $-CONHCMe_3$ substituent, i.e. that the $C_5H_3(CONHCMe_3)_2$ ligand is only attached to the

Cp_2ZrCH_3 unit through one of the carbonyl oxygen atoms (i.e. κ^1*O*-coordination). This structural interpretation seems to be called for in view of the observation of two very different ^{1}H-NMR chemical shifts of the respective NH amido hydrogen atoms (at 213 K and 600 MHz in CD_2Cl_2 observed at δ 12.91 and 6.00, respectively). The IR spectrum is in accord with this interpretation: in this series of $[C_5H_3(CONHCMe_3)_2]$zirconium complexes (see below) only complex **9** exhibits a band (at 1643 cm^{-1}) that can be attributed to a free uncoordinated carboxamido functional group.

Complex **9** shows dynamic NMR spectra. Raising the temperature from 213 K rapidly leads to coalescence of the pairs of diastereotopic groups at the $C_5H_3(CONHCMe_3)_3$ ligand. From the ^{1}H NMR coalescence of the $C(CH_3)_2$ resonances (200 MHz, T_c = 289 K, Δν = 22 Hz) a Gibbs activation energy of $\Delta G^{\neq}_{\text{exchange}}$ = 14.9 ± 0.3 kcal mol^{-1} was determined.[10] We assume that a pentacoordinate $Cp_2Zr(CH_3)[C_5H_3(CONHCMe_3)_2]$ structure (**10**) is likely to be formed as an intermediate which has both carbonyl oxygen atoms coordinated at the available coordination sites at the front of the bent metallocene wedge.[11] Opening and closing these bonds similarly as it has been shown to proceed in $\eta^2 \rightleftarrows \eta^1 \rightleftarrows \eta^2$-acyl group 4 metallocene isomerizations and related processes[12] probably provides an ample mechanistic scheme for describing the automerization process observed to take place in complex **9** (see Scheme 3).



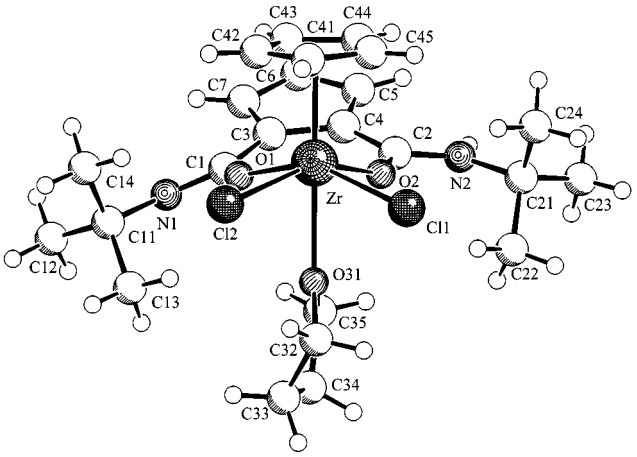
Scheme 3. Formation and dynamic behavior of **9**

We next reacted (η-cyclopentadienyl)zirconium trichloride[13] (as the bis-THF adduct) with the ligand system **6**. The chloride substitution reaction proceeds cleanly in a 1:1 stoichiometry, and we have isolated the product **11** in >70% yield as a solid from the reaction mixture. Single crystals of **11** suited for an X-ray crystal structure analysis were obtained by letting pentane diffuse through the gas phase into a toluene/dichloromethane solution of **11**. Complex **11** can be regarded as chemically C_s-symmetric, but not strictly so crystallographically. The unsubstituted cyclopentadienyl ligand is η^5-coordinated to zirconium with Zr−C(Cp) bond lengths ranging from 2.490(5) to 2.555(4) Å. The $[C_5H_3(CONHCMe_3)_2]$ ligand is bonded to the early transition metal center only through its carboxamido-oxygen atoms (Zr−O1: 2.093(3), Zr−O2: 2.081(2)Å). The ligand is part of a seven-membered metallacycle, that contains large bonding angles at the oxygen atoms[14] [C1−O1−Zr: 145.3(2)°, C2−O2−Zr: 145.0(2)°] and a rather small σ-ligand angle at zirconium (O1−Zr−O2: 82.7(1)°]. The anellated C_5H_3-ring system has no close contact to zirconium. It is in principle oriented in the C_4O_2Zr seven-membered ring plane, but bent slightly in the direction toward the adjacent η^5-cyclopentadienyl ring because of a boat-like distortion of the seven-membered metallacycle from planarity.[14a] Because of this distortion the $(\eta^5$-Cp$)[\kappa^2O,O'$-$C_5H_3(CONHCMe_3)_2]Cl_2Zr$ moiety may be regarded as a square-pyramidal subunit inside the overall octahedral coordination polyhedron around the central zirconium atom (see Figure 1). A weakly bound tetrahydrofuran ligand [Zr−O31 2.365(3)Å] trans to the η^5-Cp group completes the ligand sphere around Zr in **11**. Both the Zr−O1/O2 and the Zr−Cl1/Cl2 bonds are bent toward this THF ligand [angles O1−Zr−O31: 75.0(1)°, O2−Zr−O31: 75.2(1)°, Cl1−Zr−Cp(centroid): 104.1°, Cl2−Zr−Cp(centroid): 102.8°].

Inside the σ-bonded $C_5H_3(CONHCMe_3)_2$ ligand the double bonds are fully delocalized. There seems to be a pronounced difference in C−C bond lengths with shorter values being favored at the distal end away from zirconium, but this effect is equal for both ligand sides [e.g. C6−C5/C6−C7: 1.385(6), 1.387(3) Å; C5−C4/C7−C3: 1.398(5)/1.401(5) Å; C3−C1/C4−C2: 1.445(3)/1.436(5) Å; the length of the central conjugated C3−C4 bond is 1.440(5) Å].

The C−C(=O)−N(H)−C carboxamido groups are trans-configurated. Therefore, the bulky *tert*-butyl substituents at the carbamoyl-nitrogen atoms are oriented toward the chlorine atoms in the central O_2Cl_2Zr containing plane of the complex **11**. The corresponding bond angles at nitrogen are 128.8(4)° (C2−N2−C21) and 127.8(3)° (C1−N1−C11), respectively.

The structure of **11** in solution seems to be similar. Complex **11** shows static NMR spectra. The $C_5H_3(CONHCMe_3)_2$ ligand is C_s-symmetrically bonded to zirconium. In CD_2Cl_2 solution the single ^{1}H-NMR N*H* resonance occurs at δ 6.41 (br s, 2 H), and the C_5H_3 unit is characterized by ^{1}H-NMR resonances at δ 6.70 (d, 2 H) and 6.10 (t, 1 H, ^3J = 3.8 Hz). The observed carboxamide IR features [$\tilde{\nu}$ = 3412 and 3322 cm^{-1} (NH), 1570 and 1529 cm^{-1} (CONH)] also indicate *O*-coordination of the delocalized $C_5H_3(CONHCMe_3)_2$ ligand system to zirconium.



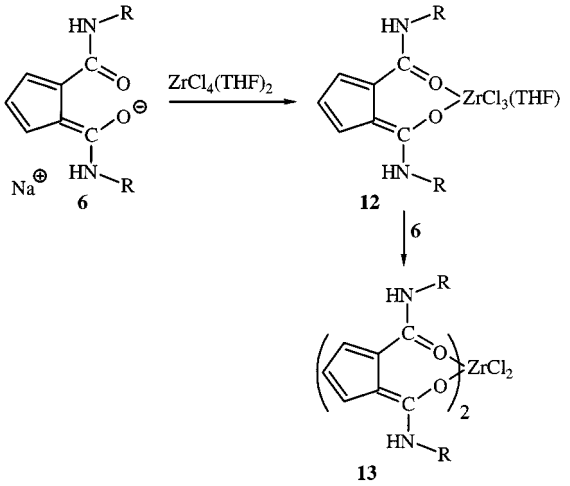


Figure 1. A view of the molecular structure of **11**; selected bond lengths and angles: Zr−O1 2.092(3), Zr−O2 2.081(2), O1−C1 1.280(4), O2−C2 1.291(4), C1−N1 1.322(5), C2−N2 1.325(5), N1−C11 1.489(5), N2−C21 1.492(5), C1−C3 1.445(5), C2−C4 1.436(5), C3−C4 1.440(5), C3−C7 1.401(5), C4−C5 1.398(5), C5−C6 1.385(6), C6−C7 1.387(5), Zr−Cl1 2.4892(11), Zr−Cl2 2.5067(10), Zr−Cp(centroid) 2.230, Zr−O31 2.365(3); O1−Zr−O2 82.73(10), O1−Zr−O31 74.96(10), O2−Zr−O31 75.18(9), O1−Zr−Cl1 152.02(8), O1−Zr−Cl2 86.07(7), O1−Zr−Cp(centroid) 103.8, O2−Zr−Cl1 91.86(6), O2−Zr−Cl2 168.54(6), O2−Zr−Cp(centroid) 102.7, O31−Zr−Cl1 77.08(7), O31−Zr−Cl2 79.18(7), O31−Zr−Cp(centroid) 177.6, Cl1−Zr−Cl2 89.93(4), Cl1−Zr−Cp(centroid) 104.1, Cl2−Zr−Cp(centroid) 102.8, Zr−O1−C1 145.3(2), Zr−O2−C2 145.0(2), O1−C1−N1 118.1(3), O2−C2−N2 117.2(3), O1−C1−C3 123.1(3), O2−C2−C4 122.6(3), N1−C1−C3 118.8(3), N2−C2−C4 120.2(3), C1−N1−C11 127.8(3), C2−N2−C21 128.8(4), C1−C3−C4 132.0(3), C2−C4−C3 129.3(3), C1−C3−C7 121.3(3), C2−C4−C5 124.1(3), C4−C3−C7 106.6(3), C3−C4−C5 106.5(3), C3−C7−C6 109.4(3), C4−C5−C6 109.7(4), C5−C6−C7 107.7(3)

We have then reacted **6** with zirconium tetrachloride. The group 4 metal halide was introduced as its tetrahydrofuran adduct (i.e. $ZrCl_4 \cdot 2$ THF), and the reaction was performed in toluene. The outcome was dependent on the chosen ratio of the reagents and it relied somewhat on the reaction conditions. Employing the reagents **6** and $ZrCl_4 \cdot 2$ THF in a 1:1 molar ratio and heating the mixture for ca. 1 d at 60°C gave a precipitate (after cooling) from which the mono-substitution product **12** was obtained by extraction with dichloromethane (35% isolated). There was a small amount of the di-substitution product **13** recovered from the toluene filtrate of this reaction. However, the complex **13** is easier prepared by treatment of **6** with $ZrCl_4 \cdot 2$ THF directly in a 2:1 molar ratio in toluene at 60°C. In this case, the product **13** was obtained in >60% yield.

Complex **12** contains a coordinated THF molecule. According to the NMR and IR spectra is exhibits very similar bonding features of the $[C_5H_3(CONHCMe_3)_2]$ ligand as found in **11**. The ligand is probably symmetrically coordinated through both oxygen atoms. The characteristic ^{1}H-NMR N*H* resonance of **12** is observed at δ 6.55 (br s, 2 H), and the IR features typical for this ligand arrangement are again observed ($\tilde{\nu}$ = 3419, 3347, 1577, 1535 cm^{-1}).

The κ^2*O,O′*-coordination of the $[C_5H_3(CONHCMe_3)_2]$ ligand of **12** was secured by the X-ray crystal structure analysis (see Figure 2). The (1,2-biscarbamoyl-Cp)Zr unit again forms a slightly boat-shaped seven-membered metallacycle.

Coordination of this ligand takes place solely through the −CONHCMe$_3$ oxygen atoms. The carbon framework is again fully delocalized and exhibits very similar bonding features as already observed for the analogously structured $[C_5H_3(CONHCMe_3)_2]$Zr unit in **11**. The in-plane oriented −CONHR groups again exhibit a trans-configurated C−C(=O)−N(H)−C(Me$_3$) framework and consequently have their bulky *tert*-butyl residues oriented towards the in-plane $ZrCl_2$ section. The coordination geometry around zirconium is almost ideally octahedral. The deviations of the O_3Cl_3Zr octahedral core from the ideal expected geometry are much smaller than e.g. observed for the $O_3Cl_2(Cp)Zr$ core in **11** (see above).

In **12** the Zr−O1 and Zr−O2 bond lengths are 2.063(2) and 2.036(2) Å, respectively.[15a] The Zr−Cl1/−Cl2 bonds are 2.426(1) and 2.448(1) Å in length, whereas the perpendicularly oriented Zr−Cl3 is shorter at 2.397(1) Å.[16] The coordinated THF molecule is located trans to it. The corresponding Zr−O31 bond length is 2.232(2) Å.[15b] This is considerably shorter than observed for the THF coordination in **11** as it is expected for a complex derived from the more electrophilic $LZrCl_3$ building block in comparison to the $LZrCl_2(Cp)$ moiety. The very close to octahedral arrangement of the core atoms of **12** around zirconium is illustrated by the close to linear arrangement of the O31−Zr−Cl3 moiety [178.62(5)°]. Also the O1−Zr−Cl1 [170.03(6)°] and O2−Zr−Cl2 [168.54(6)°] units are only slightly bent, and the deviation of the respective vectors from orthogonality is also very small [e.g.: O1−Zr−Cl2: 89.00(6)°, O2−Zr−Cl1: 91.86(6)°, O2−Zr−Cl3: 94.54(6), O1−Zr−Cl3: 95.58(6)°]. The anellated C_5H_3 ring at the C_4O_2Zr boat-shaped metallacyclic core of **12** is oriented toward the coordinated THF molecule. This is opposite of what is observed in the structurally and otherwise also conformationally related complex **11**.

Crystals of **13** were obtained by letting pentane diffuse through the gasphase into a benzene/dichloromethane solution of the 2:1 reaction product. The X-ray crystal structure analysis of **13** shows that both $[C_5H_3(CONHCMe_3)_2]$ ligands in this complex are exclusively bonded to zirconium through their carbamoyl-oxygen atoms. Again the adjacent

cyclopentadienide moiety is not involved in the bonding. Chelate coordination of both ligands leads to the occurrence of two organometallic seven-membered ring systems. Their overall bonding characteristics are very similar as has already been observed for **11** and **12** (see above). The observed bond lengths (for details see the legend of Figure 3) indicate a complete π-delocalization at both the $C_5H_3CO(N)$ frameworks with individual characteristics of bond lengths and angles that have been already discussed for the related complexes **11** and **12**.

The coordination polyhedron in **13** around the central zirconium atom is close to ideally octahedral. The respective O−Zr−O, O−Zr−Cl, and Cl−Zr−Cl angles do not deviate much from the expected values of 90° or 180°, respectively (see Figure 3). In the solid state the *cis*-chelate ligands are arranged close to C_2-symmetric to give a chiral octahedral geometry of **13** (i.e. a racemate of the respective Λ and Δ enantiomers).

Complex **13** shows the expected characteristic IR features in KBr ($\tilde{\nu}$ = 3412, 3361 (NH), 1585, 1529 (delocalized amide)). The latter bands are almost unchanged when the IR spectrum is monitored in $CDCl_3$ solution (1585, 1531 cm^{-1}). This indicates that the solution structure of **13** is very similar to that observed in the solid state.

The NMR spectra indicate that the complex $[C_5H_3(CONHCMe_3)_2]_2ZrCl_2$ **13** also attains a chiral C_2-symmetric octahedral structure in solution. The ^{1}H-NMR spectrum at 213 K in CD_2Cl_2 exhibits the signals of a pair of symmetry-equivalent $[C_5H_3(CONHCMe_3)_2]$ ligands whose "right and left sides" are diastereotopic due to the chiral octahedral molecular geometry.[17] This leads to an observation of an AMX-type ^{1}H-NMR spin pattern of the C_5H_3 protons (signals at δ 6.64, 6.59, and 5.98 with coupling constants ^3J = 4.2 Hz and ^4J = 1.8 Hz). There are two N*H* resonances at δ 6.61 and 6.42 and two separate signals of the *tert*-butyl CH_3 groups (δ 1.52 and 1.18). The ^{13}C-NMR spectrum shows the analogous diastereotopic splitting of the −CONH, C_5H_3−, and $C(CH_3)_3$ resonances (for details see the Experimental Section).

With increasing temperature the NMR signals of the respective pairs of diastereotopic groups broaden and eventu-

Scheme 4. Formation and enantiomerization of **13**

ally undergo coalescence to give a much simplified appearance of the limiting NMR spectra at high temperature. This observation indicates a rather rapid racemization of **13**, i.e. the thermally induced interconversion of the octahedral Λ ⇄ Δ configurated enantiomers of **13** in solution. From the ^{1}H-NMR coalescence of the NH resonances of **13** an enantiomerization barrier of ΔG^{+}_{enant} (298 K) = 14.0 ± 0.3 kcal mol^{-1} was determined at the coalescence temperature. Similar enantiomerization processes have previously been observed for a variety of chiral octahedral bis-chelate ligand zirconium complexes of the general types $(A-B)_2ZrX_2$ or $(A-A)_2ZrX_2$.[18] In view of the coordination properties observed in this study of the complex $[C_5H_3(CONHCMe_3)_2]$-Cp_2ZrCH_3 (**9**, see above), and of the properties of the literature systems,[18] it is likely that the Λ ⇄ Δ-isomerization of **13** is initiated by cleavage of one of the Zr−O linkages to generate a coordinatively unsaturated intermediate of a higher molecular symmetry.

Conclusions

The reaction of cyclopentadienide with two molar equivalents of the alkylisocyanate very selectively leads to the formation of the 1,2-biscarbamoyl substituted cyclopentadienide ligand system. Attachment of this ligand to a variety of zirconium centered frameworks has in most cases investigated in this study led to the formation of κ^2*O,O′*-bonded chelate zirconium complexes. In no case was the attached C_5H_3-cyclopentadienide residue involved directly in the bonding of the $[C_5H_3(CONHCMe_3)_2]$ ligand system to the oxophilic early transition metal. In contrast, we and others had previously observed that the attachment of one −COX substituent at a Cp ring does not inhibit its η^5-C_5H_4−COX attachment to a group 4 metal.[4][5] It may be that we here have crossed a borderline, being encountered when a second electron-withdrawing −COX substituent, suitably located at the Cp framework, removes too much additional electron density from the ligand core, beyond which the coordinative ability of the chelate system exceeds that of the normal η^5-Cp arrangement. It appears that 1,2-COX− (or similarly) substituted cyclopentadienides may be regarded as π-anellated cyclic vinylogues of the ubiquitous β-diketonates and systems derived thereof. Related bis(imino)C_5H_3 ligands have just recently been found to show a complexation behavior[19] analogous to our bis(carbamoyl)C_5H_3 systems **6**, forming seven-membered chelate complex systems. Also, a variety of troponolato chelate complexes have recently been described.[20] Their ligand systems may be regarded as structural isomers of the $C_5H_3(COX)_2^-$ or $C_5H_3[CR(=NR')]_2^-$ frameworks. Opening viable synthetic pathways to novel chelate systems such as those described here and in the related recent studies could be of interest in view of the actual development and the search for new homogeneous non-metallocene group 4 metal derived Ziegler systems.[21] The catalytic properties of complexes derived from $[C_5H_3(CONHR)_2]^-$ ligand systems are currently investigated in our laboratory.

Experimental Section

General Information: All reactions with organometallic reagents or substrates were carried out under argon using Schlenk-type glassware or in a glove-box. Solvents (including the deuterated solvents used for NMR spectroscopy) were dried and distilled under argon prior to use. − The following instruments were used for spectroscopic and physical characterization of the compounds: Bruker AC 200P (^{1}H: 200.13, ^{13}C: 50.3 MHz), Bruker ARX 300, and Varian Unity Plus (^{1}H: 599.2, ^{13}C: 150.8 MHz) NMR spectrometers (spectral assignments were usually secured by GCOSY, GHSQC, and

GHMBC experiments[22]); Nicolet 5 DXC FT-IR spectrometer; melting points: DSC 2010 (Texas Instruments); elemental analyses: Foss Heraeus CHN-Rapid; X-ray crystal structure analyses: Data sets were collected with Enraf Nonius CAD4 and MACH3 diffractometers, connected to sealed tube or rotating anode generators. Programs used: data reduction MolEN, structure solution SHELXS-86, structure refinement SHELXL-93 and SHELXL-97, graphics SCHAKAL-92. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102777−102779. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, CambridgeCB2 1EZ, UK [Fax: int. code +44 (1223) 336-033, E-mail: deposit@ccdc.cam.ac.uk].

The reagents $CpZrCl_3(THF)_2$[13,15a] and $Cp_2Zr(CH_3)Cl$[9] were prepared according to literature procedures.

[1,2-Bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl]sodium (6): A solution of 12.8 g (129.0 mmol, 15.2 mL) of *tert*-butyl isocyanate in 30 mL of tetrahydrofuran was added dropwise at 0°C to a solution of 5.1 g (58.0 mmol) of CpNa in 80 mL of tetrahydrofuran. The dark yellow colored reaction mixture was allowed to warm to room temperature overnight. Solvent was then removed in vacuo, and the solid residue was washed once with pentane to give the product **6** as a pale yellow solid, m. p. 178°C (DSC). − IR (KBr): $\tilde{\nu}$ = 3442 cm^{-1}, 3380 (NH), 1603, 1505 (CONH). − ^1H NMR ([D_6]benzene/[D_8]THF, 10:1.5): δ = 7.90 (br s, 2 H, NH), 6.73 (d, ^3J = 3.6 Hz, 2 H), 6.25 (t, ^3J = 3.6 Hz, 1 H, C_5H_3), 1.44 (s , 18 H, CMe_3). − ^{13}C NMR ([D_6]benzene/[D_8]THF, 10:1.5): δ = 170.7 (CONH), 116.4 (*ipso*-C, Cp), 115.1, 108.8 (CH of Cp), 50.3 and 29.6 (CMe_3). − $C_{15}H_{23}N_2NaO_2$ (286.4): calcd. C 62.92, H 8.10, N 9.78; found: C 62.53, H 8.42, N 9.12.

1,2-Bis(*N*-*tert*-butylcarbamoyl)cyclopentadiene (7): Water (50 mL) and acetic acid (1 mL) was added to an ethereal solution (50 mL) of 304 mg (1.06 mmol) of **6** at ambient temperature. The mixture was vigorously stirred and then the organic phase was separated. The aqueous phase was extracted with ether (2× 20 mL). The combined organic solutions were dried, solvent was removed in vacuo and the residue chromatographed at silicagel to give 95 mg (34%) of **7**, which was only spectroscopically characterized. − ^1H NMR (200 MHz, $CDCl_3$): δ = 19.66 (br s, 1 H, OH), 6.53 (d, ^3J = 3.9 Hz, 2 H, C_5H_3), 6.11 (t, ^3J = 3.9 Hz, 1 H, C_5H_3), 6.09 (br s, 2 H, NH), 1.46 (s, 18 H, CMe_3). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 168.2 (C=O), 117.0, 113.6 (CH of C_5H_3), 112.3 (*ipso*-C of C_5H_3), 52.4 and 29.1 (*tert*-butyl).

[1,2-Bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl]bis(η^5-cyclopentadienyl)methylzirconium (9): Chlorobis(η^5-cyclopentadienyl)methylzirconium (**8**) (500 mg, 1.8 mmol) was treated with [1,2-bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl]sodium (**6**) (530 mg, 1.8 mmol) at −78°C in 40 mL of toluene. The yellow colored mixture was stirred overnight and allowed to warm to room temperature. Filtration and solvent removal gives the yellow solid **9** in 60% yield (530 mg), m.p. 98°C (DSC). − IR (KBr): $\tilde{\nu}$ = 3443 cm^{-1}, 3091 (NH), 1643, 1586 (CONH) (in $CDCl_3$ solution: 1648, 1580). − ^1H NMR (599.9 MHz, CD_2Cl_2, 213 K): δ = 12.91 (br s, 1 H, NH), 6.44 (dd, ^3J = 3.6 Hz, ^4J = 1.8 Hz, 1 H), 6.22 (s, 10 H, Cp), 6.03 (dd, ^3J = 3.6 Hz, ^4J = 1.8 Hz, 1 H), 6.00 (br s, 1 H, NH), 5.93 (t, ^3J = 3.6 Hz, 1 H, C_5H_3), 1.33 (s, 9 H, CMe_3), 1.23 (s, 9 H, CMe_3), 0.38 (s, 3 H, Me). − ^{13}C NMR (150.8 MHz, CD_2Cl_2, 213 K): δ = 168.6 (CONH), 168.4 (CONH), 119.1, 117.5 (CH of C_5H_3), 112.1 (CH of C_5H_5), 110.6, 110.7 (*ipso*-C of C_5H_3), 109.7 (CH of C_5H_3), 51.1, 50.4 (CMe_3), 29.7 (Me), 28.5, 28.3 (CMe_3). − $C_{26}H_{36}N_2O_2Zr$ (499.8): calcd. C 62.48, H 7.26; found: C 62.38, H 7.29.

[1,2-Bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl](η^5-cyclopentadienyl)dichlorozirconium (11): $CpZrCl_3 \cdot 2$ THF (5.77 g, 14.0 mmol) was treated with [1,2-bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl]-sodium (**6**) (4.06 g, 14.0 mmol) in 50 mL of tetrahydrofuran at −78°C. The reaction mixture was stirred and allowed to warm to room temperature overnight. It was filtered and the solvent was removed in vacuo to give the product **11** as a pale yellow powder in 74% yield (5.80 g), m.p. 180°C (DSC). − IR (KBr): $\tilde{\nu}$ = 3412 cm^{-1}, 3322 (NH), 1570, 1529 (CONH) (in $CDCl_3$ solution: 1576, 1525). − ^1H NMR (CD_2Cl_2): δ = 6.70 (d, ^3J = 3.8 Hz, 2 H, C_5H_3), 6.41 (br s, 2 H, NH), 6.38 (s, 5 H, C_5H_5), 6.10 (t, ^3J = 3.8 Hz, 1 H, C_5H_3), 4.00, 1.80 (m, each 4 H, THF), 1.46 (s, 18 H, CMe_3). − ^{13}C NMR (CD_2Cl_2): δ = 169.7 (CONH), 121.4, 114.3 (CH of C_5H_3), 117.7 (CH of C_5H_5), 113.9 (*ipso*-C of C_5H_3), 71.1 (CH_2 of THF), 53.3, 29.3 (CMe_3), 25.5 (CH_2 of THF). − $C_{24}H_{36}Cl_2N_2O_3Zr$ (562.7): calcd. C 51.23, H 6.45, N 4.98; found: C 51.06, H 6.61, N 5.09.

X-ray crystal structure analysis of 11: Formula $C_{24}H_{36}Cl_2N_2O_3Zr$, M = 562.7, colorless crystal, 0.40 × 0.25 × 0.10 mm, a = 10.725(1), b = 17.410(2), c = 14.699(2) Å, β = 100.25(1)°, V = 2700.8(5) Å^3, ρ_{calc} = 1.384 g cm^{-3}, F(000) = 1168 e, μ = 6.31 cm^{-1}, empirical absorption correction via φ scan data (0.937 ≤ C ≤ 0.999), Z = 4, monoclinic, space group $P2_1/n$ (No. 14), λ = 0.71073 Å, T = 223 K, ω/2θ scans, 5789 reflections collected (-h, +k, ±l), [(sinθ)/λ] = 0.62 $Å^{-1}$, 5493 independent and 3744 observed reflections [$I \geq 2\ \sigma(I)$], 301 refined parameters, R = 0.047, wR^2 = 0.108, max. residual electron density 0.69 (-0.74) e $Å^{-3}$, hydrogens calculated and refined as riding atoms.

[1,2-Bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl]trichlorozirconium (12): [1,2-Bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl]sodium (**6**) (2.80 g, 9.8 mmol) was treated with $ZrCl_4 \cdot 2$ THF (3.70 g, 9.8 mmol) in 100 mL of toluene for 20 h at 60°C. The reaction mixture was filtered and the residue was extracted with dichloromethane to give 1.8 g (35%) of **12** as a pale yellow solid (from the toluene layer the disubstituted compound **13** was obtained as a side product). **12**: m.p. 243°C (DSC). − IR (KBr): $\tilde{\nu}$ = 3419 cm^{-1}, 3347 (NH), 1577, 1535 (CONH) (in $CDCl_3$ solution: 1575, 1530). − ^1H NMR (CD_2Cl_2): δ = 6.69 (d, ^3J = 3.9 Hz, 2 H, C_5H_3), 6.55 (br s, 2 H, NH), 6.07 (t, ^3J = 3.9 Hz, 1 H, C_5H_3), 4.16, 1.76 (m, each 4 H, THF), 1.54 (s, 18 H, CMe_3). − ^{13}C NMR (CD_2Cl_2): δ = 168.7 (CONH), 123.0, 115.3 (CH of C_5H_3), 113.1 (*ipso*-C of C_5H_3), 75.5 (CH_2 of THF), 54.3, 29.4 (CMe_3) 25.7 (CH_2 of THF). − $C_{19}H_{31}N_2O_3Cl_3Zr$ (533.0): calcd. C 42.81, H 5.86, N 5.26; found: C 42.70, H 6.50, N 5.42.

X-ray Crystal Structure Analysis of 12: Formula $C_{19}H_{31}N_2O_3Cl_3Zr$, M = 533.0, yellow crystal, 0.25 × 0.15 × 0.10 mm, a = 9.805(2), b = 15.932(4), c = 16.082(3) Å, β = 105.37(2)°, V = 2422.4(9) Å^3, ρ_{calc} = 1.462 g cm^{-3}, F(000) = 1096 e, μ = 8.06 cm^{-1}, empirical absorption correction via φ scan data (0.955 ≤ C ≤ 0.999), Z = 4, monoclinic, space group $P2_1$/n (No. 14), λ = 0.71073 Å, T = 223 K, ω/2θ scans, 5214 reflections collected (+h, +k, ±l), [(sinθ)/λ] = 0.62 $Å^{-1}$, 4923 independent and 3550 observed reflections [$I \geq 2\ \sigma(I)$], 265 refined parameters, R = 0.032, wR^2 = 0.072, max. residual electron density 0.51 (−0.57) e $Å^{-3}$, hydrogens calculated and refined as riding atoms.

Bis[1,2-bis(*N*-*tert*-butylcarbamoyl)cyclopentadienyl]dichlorozirconium (13): A reaction mixture of [1,2-bis(*N*-*tert*-butylcarbamoyl)-cyclopentadienyl]sodium (**6**, 758 mg, 2.7 mmol) and $ZrCl_4 \cdot 2$ THF (500 mg, 1.3 mmol) in 50 mL of toluene was stirred for 14 h at 60°C and then filtered. Solvent was removed in vacuo to yield 600 mg (65%) of **13** as a yellow solid, m.p. 269°C (DSC). − IR (KBr): $\tilde{\nu}$ = 3412 cm^{-1}, 3361 (NH), 1585, 1529 (CONH) (in $CDCl_3$ solu-

tion: 1585, 1531). – ^{1}H NMR ([D$_6$]benzene): δ = 6.43 (d, ^3J = 3.8 Hz, 4 H, C_5H_3), 6.36 (t, ^3J = 3.8 Hz, 2 H, C_5H_3), 6.00 (br s, 4 H, NH), 1.25 (br, 36 H, CMe_3). – ^{13}C NMR ([D$_6$]benzene): δ = 168.9 (CONH), 122.7 (CH of C_5H_3), 114.4 (*ipso*-C of C_5H_3), 114.0 (CH of C_5H_3), 53.1, 29.1 (CMe_3). – $C_{30}H_{46}N_4O_4Cl_2Zr \cdot 1/3\ C_7H_8$ (715.9): calcd. C 53.69, H 6.90, N 7.83; found: C 53.60, H 7.28, N 7.43.

X-ray Crystal Structure Analysis of 13: Formula $C_{30}H_{46}N_4O_4Cl_2Zr \cdot C_6H_6$, M = 766.9, yellow crystal, 0.25 × 0.20 × 0.10 mm, a = 13.058(2), b = 12.735(3), c = 24.172(3) Å, β = 96.43(1)°, V = 3994.4(12) Å^3, ρ_{calc} = 1.275 g cm^{-3}, $F(000)$ = 1608 e, μ = 4.49 cm^{-1}, empirical absorption correction via φ scan data (0.981 ≤ C ≤ 0.999), Z = 4, monoclinic, space group $P2_1/n$ (No. 14), λ = 0.71073 Å, T = 223 K, ω/2 θ scans, 8282 reflections collected (±h, −k, −l), [(sinθ)/λ] = 0.62 Å^{-1}, 8090 independent and 5503 observed reflections [$I \geq 2\ \sigma(I)$], 448 refined parameters, R = 0.037, wR^2 = 0.085, max. residual electron density 0.40 (−0.32) e Å^{-3}, hydrogens calculated and refined as riding atoms.

Acknowledgments

Financial support from the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Ministerium für Schule und Weiterbildung, Wissenschaft und Forschung des Landes Nordrhein-Westfalen is gratefully acknowledged. E. W. thanks the Academy of Finland for financial support.

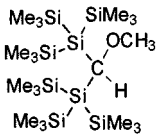
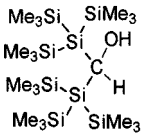
Geminal Bis(hypersilyl) Compounds – The Reaction of Tris(trimethylsilyl)silyllithium with Dialkyl(chloromethylene)ammonium Chlorides



Thoralf Gross,[a] Rhett Kempe,[b] and Hartmut Oehme*[a]

Keywords: Silicon / Silanes, sterically congested / Tris(trimethylsilyl)silanes / (Chloromethylene)ammonium chlorides



Tris(trimethylsilyl)silyllithium (**1**) reacts with dialkyl(chloromethylene)ammonium chlorides (molar ratio 2:1) to give the (dialkylamino)bis(hypersilyl)methanes $[(Me_3Si)_3Si]_2CHNR_2$ (**5a–c**; **a**: R = Me, **b**: R = Et, **c**: $R_2 = [CH_2]_5$). Due to the extreme bulkiness of the hemispherical $(Me_3Si)_3Si$ substituents, the structures of these geminal bis(hypersilyl) derivatives are characterized by tremendous distortions of their molecular skeletons. This was confirmed by X-ray structural analyses of **5a** and **5c**, which revealed considerable elongations of the central Si–C bonds (**5a**: 2.01 and 1.95 Å; **5c**: 1.99 and 1.97 Å) and an extreme widening of the Si–C–Si angles at the central sp^3-carbon atoms (**5a**: 132.6°; **5c**: 128.7°). By concentrated sulfuric acid, **5a** is converted to give, after hydrolysis, the silanol $(Me_3Si)_2Si(OH)CH_2Si(SiMe_3)_3$ (**13**). The formation of **13** is discussed as proceeding through the transient silene $(Me_3Si)_2Si{=}CHSi(SiMe_3)_3$ (**11**), generated by a formal (dimethylamino)trimethylsilane elimination from **5a** according to an acid-induced sila Peterson mechanism.

Contrary to our original expectations, the fixation of two spherically extended tris(trimethylsilyl)silyl (hypersilyl) groups at one comparatively small carbon atom proved to be surprisingly facile. Actually, geminal bis(hypersilyl) compounds are easily available by the reaction of tris(trimethylsilyl)silyllithium (**1**) with suitable C1 units. However, the experience gained from the synthesis of these compounds led to the conclusion that the approach of a second lithium silanide **1** to the α-carbon atom of a hypersilyl-substituted intermediate under conditions of a bimolecular process, i.e. with inversion of the reaction center, is hardly conceivable due to the extreme shielding of the $(Me_3Si)_3Si$ substituent in the substrate and the bulkiness of the Si nucleophile **1**. Thus, we succeeded in synthesizing methoxy–bis[tris(trimethylsilyl)silyl]methane (**2**) by consecutive replacement of the chlorine atoms of dichloromethyl methyl ether by **1**, the reaction very likely proceeding through a carbenium ion transition state.[1] Similarly, we obtained bis[tris(trimethylsilyl)silyl]methanol (**3**) from **1** and *tert*-butyl formate (2:1), as the result of the addition of **1** to the carbonyl group of the intermediate formyltris(trimethylsilyl)silane.[2] In both cases the final bis(hypersilyl) derivative is formed after attack of the lithium silanide **1** at an electrophilic planar sp^2-carbon center, thus making the steric problems, which are caused by the already fixed substituents, less significant.

A comparable stereochemical situation was expected for the reaction of **1** with dialkyl(chloromethylene)ammonium chlorides leading, as expected, to (dialkylamino)bis[tris(trimethylsilyl)silyl]methanes **5**. In this paper we describe the syntheses, the structures and the reactivity of these extremely congested functionalized geminal bis(hypersilyl) compounds. In addition, with the H_2SO_4-initiated degradation of (dimethylamino)bis[tris(trimethylsilyl)silyl]methane (**5a**) we present the first case of an acid-catalyzed sila Peterson reaction.

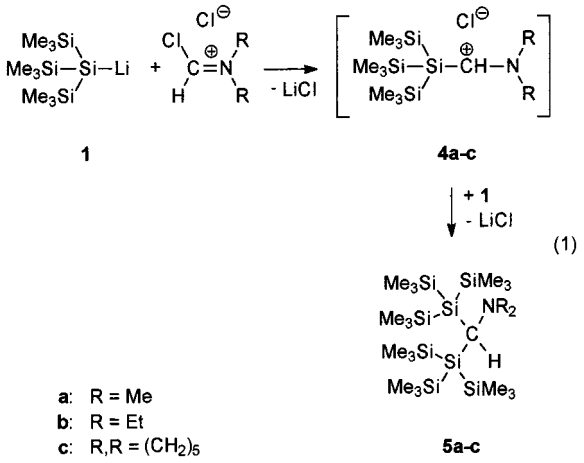
3



The Synthesis and Structure of (Dialkylamino)bis[tris(trimethylsilyl)silyl]methanes $R_2N–CH[Si(SiMe_3)_2]$ (5a–c)

The reaction of **1** with (chloromethylene)dimethylammonium chloride, (chloromethylene)diethylammonium chloride or (chloromethylene)piperidinium chloride (molar ratio always 2:1) led to the corrersponding (dialkylamino)-bis[tris(trimethylsilyl)silyl]methanes **5a–c** (Equation 1). We suppose the reaction to proceed through the intermediates **4a–c**, which are formed by nucleophilic substitution of one chlorine atom of the (chloromethylene)ammonium chlorides. Addition of a second equivalent of the silicon nucleophile **1** to the planar carbenium–immonium systems **4a–c** under elimination of lithium chloride affords the bis(hypersilyl) derivatives **5a–c**.

Actually, the gap formed by the two $(Me_3Si)_3Si$ hemispheres and the central carbon atom offers very limited space, obviously sufficient only for a small dialkylamino group. With increasing spatial demand of the amino sub-

stituent the thermal stability of the compounds decreases. Thus, **5a** is moderately stable, but recrystallization from ethanol leads to partial decomposition, producing mainly hexakis(trimethylsilyl)disilane, small quantities of tris(trimethylsilyl)silane and some unidentified material. In the case of **5c** this tendency is increased, and the diethylamino derivative **5b** could not be obtained in a really pure form and was therefore characterized only by its ^{1}H-NMR spectrum where the signals of hexakis(trimethylsilyl)disilane and tris(trimethylsilyl)silane were always also identified. Single crystals of **5a** and **5c** were obtained by recrystallization from heptane at low temperature. The reaction of **1** with (chloromethylene)diisopropylammonium chloride, performed under the same conditions, failed. Besides large quantities of unidentified material only some tetrakis(trimethylsilyl)silane was isolated. Obviously, the considerable spatial demand of the diisopropylamino group prevents the fixation of two hypersilyl substituents at the central sp^3-carbon atom.

The sterically congested tertiary amines **5a–c** are colorless solids, and are stable at low temperature towards air and moisture. The structures of the compounds **5a** and **5c** were elucidated by ^{1}H-, ^{13}C-, and ^{29}Si-NMR and MS studies; for both compounds X-ray structural analyses were also performed. As found already for **2** and **3**, the solution-NMR spectra of **5a**, **c** are very straightforward. In the ^{1}H-NMR spectra, as well as in the ^{13}C-NMR spectra, only one signal was found for the $SiMe_3$ groups. The ^{29}Si-NMR spectra also show only one signal for the $SiMe_3$ silicon atoms, indicating considerable mobility of the trimethylsilyl substituents in the extremely congested molecules of **5a**, **c**. On the other hand, at room temperature separate signals were found for the two *N*-alkyl groups, which coalesce at elevated temperature. These results were interpreted as being due to a completely hindered rotation around the Si_2C-NR_2 bond (**5a**: T_c = 329 K, $\Delta\nu$ = 30.4 Hz, calcd. rotation barrier $\Delta G^{\neq}$ = 69 kJ/mol).

The results of the X-ray structural analyses of **5a** and **5c**, demonstrated in the Figures 1 and 2, confirm the expected steric congestion of the molecules. The $(Me_3Si)_3Si$ groups form two extended hemispherical shells, separated by one sp^3-carbon atom, thus opening a narrow slit, where the di-

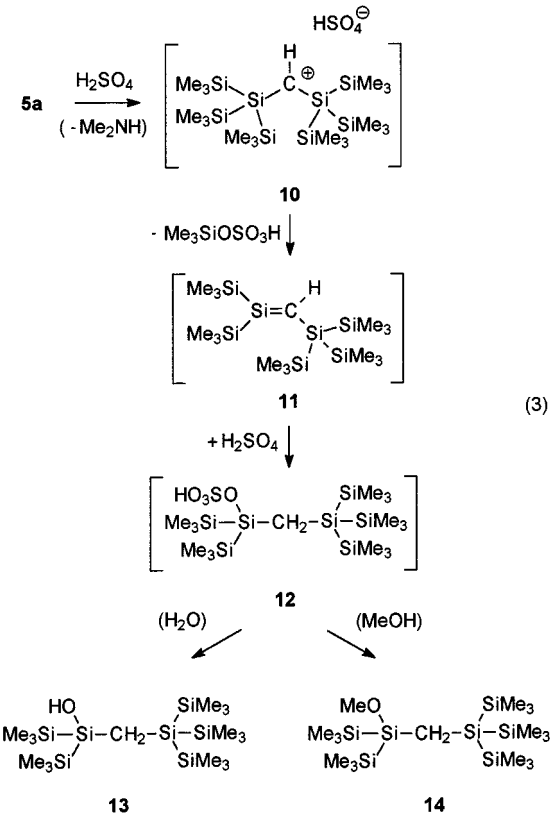
Figure 1. Figure 2. Molecular structure of **5c** in the crystal (ORTEP, 30% probability level, H atoms omitted except for C1 H, disordered atoms omitted for clarity); selected bond lengths [Å] and angles [°]: C1–Si1 1.992(3), C1–Si2 1.967(3), C1–N1 1.472(4); Si1–C1–Si2 128.7(2), C1–Si1–Si3 104.57(11), C1–Si1–Si4 120.96(11), C1–Si1–Si5 118.44(11), C1–Si2–Si6 120.76(12), C1–Si2–Si8 110.94(11), C1–Si2–Si7 109.29(11), N1–C1–Si1 107.1(2), N1–C1–Si2 114.0(2)

alkylamino groups are placed. The amino group is hidden by the two hypersilyl groups and it is quite obvious that the rotation about the Si_2C-NR_2 bond is frozen. The steric strain leads to a considerable elongation of the central C–Si bonds and, additionally, the pyramidal structure of the amino groups causes significant differences in these bond lengths (**5a**: C1–Si1 2.01 Å, C1–Si2 1.95 Å; **5c**: C1–Si1 1.99 Å, C1–Si2 1.97 Å). The central Si–C–Si angles widen to values of 132.6° for **5a** and 128.7° for **5c**. These results are in good agreement with the structural data obtained for **2** and **3**.[1][2] The spatial demand of the OCH_3 group in **2** is slightly smaller than that of the dialkylamino groups in **5a** or **5c** (**2**: Si–C 1.94 Å both, Si–C–Si 132.7°). An OH group is considerably smaller. Thus, the relevant Si–C bonds in **3** are shorter (1.91 and 1.93 Å), and the bond angle at the central sp^3-carbon atom is even wider (135.5°). The dialkylamino groups push the hypersilyl hemi-

spheres aside causing a deformation of the $CSiSi_3$ tetrahedra in **5a** and **5c**. The average C1−Si−Si bond angles in **5a** are 111.8 and 114.5°, and for **5c** 114.7 and 113.7°, but the individual angles are markedly different. At positions where the two hemispheres touch each other, the angles are widened (**5a**: C1−Si1−Si5 116.9°, C1−Si2−Si8 122.3°; **5c**: C1−Si1−Si5 118.4°, C1−Si2−Si6 120.8°). On the other hand, the small hydrogen atoms at the central sp^3-carbon atoms of **5a** and **5c** allow the trimethylsilyl groups in their neighborhood to evade the steric strain leading to comparatively small C−Si−Si angles (**5a**: C1−Si1−Si4 106.6°, C1−Si2−Si6 98.7°; **5c**: C1−Si1−Si3 104.6°, C1−Si2−Si7 109.3°). Due to the steric stress in the molecule, the trimethylsilyl groups approach at exceptionally short distances (**5a**: C9−C15 3.64 Å, C10−C18 3.82 Å; **5c**: C8−C13 3.66, C8−C16 3.51 Å). Also the distances of the *N*-methyl groups in **5a** to the neighboring *Si*-methyl groups (C3−C20 3.62 Å, C3−C21 3.56 Å, C5−C21 3.57 Å) are significantly shorter than the sum of the van der Waals radii of two methyl groups which amounts to about 4.00 Å.[3]



Extensive variation of the reaction outlined in Equation 1 is limited by the spatial demand of the dialkylamino substituent. However, an attractive aim was the synthesis of [2-(dimethylamino)ethenyl]bis[tris(trimethylsilyl)silyl]methane (**7**), which was intended to be achieved by the reaction of two equivalents of **1** with the vinylogous (3-chloro-2-propenylidene)dimethylammonium salt **6**. We hoped that both tris(trimethylsilyl)silyl groups may be drawn to the γ-position of the dimethyliminium salt. Two products, identified as 3-chloro-1-(dimethylamino)-1-[tris(trimethylsilyl)silyl]-1-propene (**8**) (50%) and 1-(dimethylamino)-1,3-bis[tris(trimethylsilyl)silyl]-1-propene (**9**) (13%) were, however, obtained as the result of the reaction of these components (Equation 2).

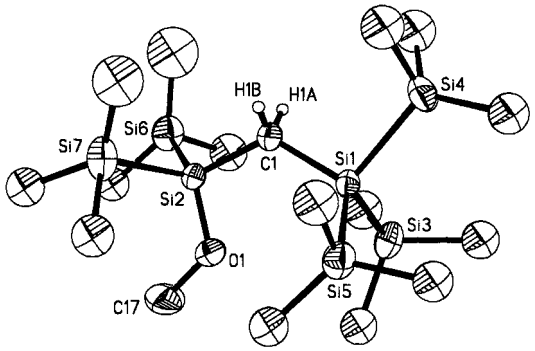
This result indicates that the first attack of the silicon nucleophile **1** occured at the α-carbon atom of the dimethyliminium chloride **6** affording **8**, and in a second reaction step the γ-chlorine atom of **8** was replaced by a further hypersilyl substituent giving **9**. A geminal bis(hypersilyl) compound could not be obtained this way.

The Conversion of 5a into the Transient 1,1-Bis(trimethylsilyl)-2-tris(trimethylsilyl)silylsilene (11) According to an Acid-Induced Sila Peterson Mechanism

Apart from their thermal instability due to the perfect shielding of the functional group, the geminal (dialkylamino)bis(hypersilyl)methanes **5a−c** were expected to be chemically rather inert. However, we noticed that **5a**, which was chosen for some studies on the reactivity of these compounds, undergoes a clean reaction with concentrated sulfuric acid. Actually, the conversion of **5a** by excess H_2SO_4 needed three days at room temperature to come to completeness, but aqueous workup afforded the silanol **13** in a yield of 60%. Workup of the same reaction mixture with methanol gave the methoxysilane **14** (30%) besides 40% of **13** (Equation 3).

The structures of **13** and **14** were proved by comprehensive spectroscopic analyses (see Experimental Section). For methoxybis(trimethylsilyl)[tris(trimethylsilyl)silylmethyl]silane (**14**) an X-ray crystal structure analysis was also performed (Figure 3), which again revealed considerable steric conges-

tion of the molecule. The central Si−C bonds are elongated (C1−Si1 1.91 Å, C1−Si2 1.87 Å) and the angle at the methylene carbon atom is widened to a value of 123.9°.



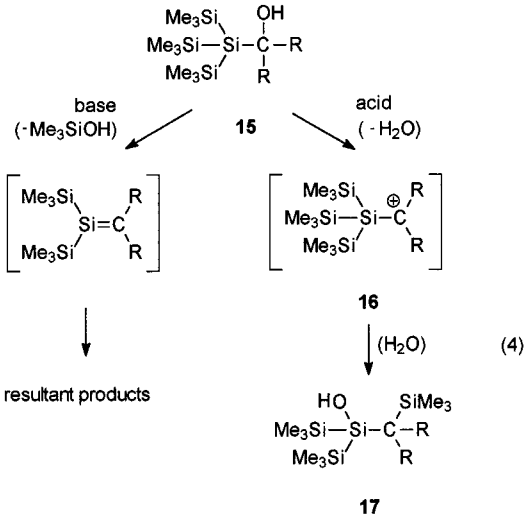


Figure 3. Molecular structure of **14** in the crystal (ORTEP, 30% probability, H atoms omitted except for C1 H_2, disordered atoms omitted for clarity); selected bond lengths [Å] and angles [°]: C1−Si1 1.914(5), C1−Si2 1.865(5), Si2−O1 1.644(4), O1−C17 1.432(7); Si1−C1−Si2 123.9(3), C1−Si1−Si3 113.2(2), C1−Si1−Si4 101.1(2), C1−Si1−Si5 115.1(2), C1−Si2−O1 106.2(2), C1−Si2−Si6 108.8(2), C1−Si2−Si7 111.5(2), Si2−O1−C17 124.1(4).

The formation of **13** and **14** is understood in terms of an acid-induced elimination of dimethylamine from **5a** under generation of the carbenium ion transition state **10**. Nucleophilic attack of the hydrogen sulfate ion at one trimethylsilyl group under cleavage of an Si−Si bond affords the silene **11**, which in the presence of excess sulfuric acid is trapped to give the silyl hydrogen sulfate **12**. Hydrolysis of **12** during the aqueous workup leads to the silanol **13**; methanolysis of **12** affords the methoxysilane **14**.

The conversion of **5a** into the silene **11** has to be interpreted as a direct Si analogue of the acid-catalyzed Peterson reaction. The original Peterson reaction, i.e. the elimination of trimethylsilanol from (2-hydroxyalkyl)trimethylsilanes with simultaneous formation of olefins, can be performed under basic as well as under acidic conditions.[4] The reaction priciple was modified in such a way, that the α-carbon atom in the (2-hydroxyalkyl)trimethylsilanes was replaced by a silicon atom. Thus, (1-hydroxyalkyl)tris(trimethylsilyl)-silanes **15**, easily available by the reaction of tris(trimethylsilyl)silylmagnesium bromide with carbonyl compounds, were subjected to the conditions of the Peterson reaction and proved to be suitable starting materials for the generation of transient silaethenes according to the base-induced sila Peterson mechanism (Equation 4).[5]

On the other hand, treatment of **15** with strong acids gives no trimethylsilanol elimination and silene generation, but the (1-hydroxyalkyl)polysilanes **15** undergo a rapid isomerisation, involving a 1,2-OH/Me_3Si exchange, under formation of the silanols **17**.[6] Similar to the reaction **5a** → **13**, this rearrangement is also supposed to proceed through a polysilanylcarbenium ion transition state **16**, but here the 1,2-trimethylsilyl migration is favored over the Me_3SiX elimination (Equation 4).

The migration of one group from a tetracoordinated silicon atom to a nascent α-carbenium ion under generation of a thermodynamically more stable transient silylium ion

appears to be a general process.[7] We suppose that this fast rearrangement generally prevents a trimethylsilanol elimination from polysilanylcarbenium ion transition states such as **16** and a silene formation along the acid-catalyzed modified Peterson mechanism. In case of the conversion **5a** → **13**, due to the extreme steric congestion of the carbenium ion **10** a shift of a trimethylsilyl group from the silicon atom to the central carbon atom is prevented or at least retarded for steric reasons, favoring in this particular case the nucleophilic attack of the hydrogen sulfate ion and the silene generation.

Experimental Section

General: All reactions involving organometallic reagents were carried out under purified argon. − NMR: Bruker AC 250 or Bruker ARX 300, tetramethylsilane as internal standard. − IR: Nicolet 205 FT-IR. − MS: Intectra AMD 402, chemical ionization with isobutane as the reactant gas. − The dialkyl(chloromethylene)ammonium chlorides were prepared using the procedure of Simchen et al.[8] applying bis(trichloromethyl) carbonate instead of phosgene as the chlorinating agent. $(Me_3Si)_3SiLi \cdot 3$ THF was prepared as reported in the literature.[9] − All yields given refer to amounts obtained after chromatographic separation and purification. − The synthesis and structure of **5a** were described in a preliminary publication.[10]

(Diethylamino)bis[tris(trimethylsilyl)silyl]methane (5b): Under stirring, 0.82 g (1.7 mmol) of **1**, dissolved in 20 mL of ether, was added dropwise into a solution of 0.14 g (0.9 mmol) of (chloromethylene)-diethylammonium chloride in 20 mL of ether at −78 °C. Stirring was continued for another hour at the same temperature and for 2 h at room temperature. After addition of water, the ethereal phase was separated, dried, and concentrated. The residue was purified by chromatography (triethylamine-treated silica gel, heptane) to obtain 0.35 g of impure **5b** containing hexakis(trimethylsilyl)disilane and tris(trimethylsilyl)silane. − ^{1}H NMR ([D_6]benzene): δ = 0.38 (s, $SiCH_3$, 54 H), 1.04 and 1.09 (2 t, ^3J = 7.3 Hz, CCH_3, 2 × 3 H), 2.48 and 2.67 (2 q, ^3J = 7.3 Hz, CH_2, 2 × 2 H), 3.82 (s, CH, 1 H).

Bis[tris(trimethylsilyl)silyl]piperidylmethane (5c): Similarly, 1.3 g (2.8 mmol) of **1** and 0.23 g (1.4 mmol) (chloromethylene)piperidinium chloride gave, after chromatographic separation (silica gel, heptane), 0.35 g (43%) of **5c**, m.p. 112−113 °C. − ^{1}H NMR

([D$_6$]benzene): δ = 0.39 (s, SiCH$_3$, 54 H), 1.41 (m, CH$_2$, 2H), 1.56 (m, CH$_2$, 4 H), 2.53 (t, ^3J = 5.2 Hz, NCH$_2$, 4 H), 3.43 (s, Si$_2$CHN, 1 H). − ^{13}C NMR ([D$_6$]benzene): δ = 4.7 (SiCH$_3$), 22.2, 25.6 and 32.2 (CH$_2$), 46.2 (CH). − ^{29}Si NMR ([D$_6$]benzene): δ = −74.6 (*Si*SiMe$_3$), −12.1 (SiMe$_3$). − MS; *m/z* (%): 590 (1) [M$^+$ − H], 344 (56) [M$^+$ − Si(SiMe$_3$)$_3$], 247 (100) [Si(SiMe$_3$)$_3^+$], 73 (64) [SiMe$_3^+$]. − $C_{24}H_{65}NSi_8$ (592.47): calcd. C 48.65, H 11.06, N 2.36; found C 46.54 (incomplete combustion), H 10.88, N 2.40.

Reaction of the Vinylogous (3-Chloro-2-propenylidene)dimethylammonium Salt 6 with 1. − Synthesis of (*E*)-3-Chloro-1-(dimethylamino)-1-[tris(trimethylsilyl)silyl]-1-propene (8) and (*E*)-1-(Dimethylamino)-1,3-bis[tris(trimethylsilyl)silyl]-1-propene (9): To a solution of 0.08 g (0.5 mmol) of **6** in 20 mL of ether, was added dropwise at −78°C, 0.49 g (1.0 mmol) of **1**, dissolved in 20 mL of ether. After warming up to room temperature, stirring was continued for 3 h. Water was added, the ethereal layer separated, dried, and concentrated. Chromatographic separation (silica gel, heptane/ethyl acetate, 20:1) gave 0.09 g (49%) of **8** (m.p. 124−126°C) and 0.04 g (13%) of **9** (m.p. 74−76°C).

8: ^{1}H NMR ([D$_6$]benzene): δ = 0.25 (s, SiCH$_3$, 27 H), 2.10 (s, NCH$_3$, 6 H), 3.14 (d, ^3J = 11.58 Hz, SiCHN, 1 H), 5.71 (d, ^3J = 13.13 Hz, CHCl, 1 H), 6.09 (dd, ^3J = 11.58 Hz, ^3J = 13.13, ClCCH, 1 H). − ^{13}C NMR ([D$_6$]benzene): δ = 1.9 (SiCH$_3$), 43.7 (NCH$_3$), 58.0 (CHN), 116.9 (ClC=*C*H), 131.8 (Cl*C*=CH). − ^{29}Si NMR ([D$_6$]benzene): δ = −73.8 (*Si*SiMe$_3$), −12.8 (SiMe$_3$). − MS; *m/z* (%): 366 (10) [M$^+$ − H], 350 (9) [M$^+$ − CH$_3$], 247 (8) [Si(SiMe$_3$)$_3^+$], 118 (100) [M$^+$ − Si(SiMe$_3$)$_3$], 73 (33) [SiMe$_3^+$]. − $C_{14}H_{36}ClNSi_4$ (366.24): calcd. C 45.91, H 9.91, Cl 9.68, N 3.82; found C 46.23, H 9.81, Cl 8.97, N 3.88.

9: ^{1}H NMR ([D$_6$]benzene): δ = 0.32 and 0.33 (2s, SiCH$_3$, 2 × 27 H), 2.30 (s, NCH$_3$, 6 H), 3.25 (d, ^3J = 10.38 Hz, SiCHN, 1 H), 5.67 (d, ^3J = 17.70 Hz, SiCH, 1 H), 6.27 (dd, ^3J = 10.38 Hz, ^3J = 17.90 Hz, NCCH, 1 H). − ^{13}C NMR ([D$_6$]benzene): δ = 1.4 and 2.2 (SiCH$_3$), 43.6 (NCH$_3$), 65.4 (CHN), 125.3 (SiC=*C*H), 145.4 (Si*C*=CH). − ^{29}Si NMR ([D$_6$]benzene): δ = −86.3 and −77.0 (*Si*SiMe$_3$), −13.1 and −12.8 (SiMe$_3$). − MS; *m/z* (%): 576 (2) [M$^+$ − H], 562 (8) [M$^+$ − CH$_3$], 533 (4) [M$^+$ − NMe$_2$], 330 (100) [M$^+$ − Si(SiMe$_3$)$_3$], 247 (9) [Si(SiMe$_3$)$_3^+$], 73 (14) [SiMe$_3^+$]. − $C_{23}H_{63}NSi_8$ (578.44): calcd. C 47.76, H 10.98, N 2.42; found C 47.91, H 10.86, N 2.66.

Bis(trimethylsilyl)[tris(trimethylsilyl)silylmethyl]silanol (13): To a solution of 0.1 g (0.18 mmol) of **5a** in 20 mL of THF, 2 mL of conc. H_2SO_4 was added gradually and the mixture was stirred for 3 d at room temperature. Then water was added, the mixture was extracted with ether and the combined extracts were neutralized with solid K_2CO_3 dried, and concentrated. Chromatographic separation (silica gel, heptane) of the residue gave 0.05 g (60%) of **13**, m.p. 65−67°C. − IR (nujol): $\tilde{\nu}$ = 3672 cm^{-1} (OH$_{free}$), 3360−3580 cm^{-1} (OH$_{ass.}$). − ^{1}H NMR ([D$_6$]benzene): δ = 0.18 (s, SiCH$_3$, 18 H), 0.31 (s, SiCH$_3$, 27 H), 0.46 (s, CH$_2$, 2 H). − ^{13}C NMR ([D$_6$]benzene): δ = −10.1 (SiCH$_2$Si), −0.93 {Si[Si(CH$_3$)$_3$]$_2$}, 1.46 {Si[Si(CH$_3$)$_3$]$_3$}. − ^{29}Si NMR ([D$_6$]benzene): δ = −83.1 [*Si*(SiMe$_3$)$_3$], −19.6 [Si(*Si*Me$_3$)$_2$], −12.6 [Si(*Si*Me$_3$)$_3$], 8.9 (SiOH). − MS; *m/z* (%): 451 (3) [M$^+$ − H], 437 (17) [M$^+$ − CH$_3$], 435 (10) [M$^+$ − OH], 379 (100) [M$^+$ − SiMe$_3$], 343 (51) [M$^+$ − HOSiMe$_3$], 247 (4) [Si(SiMe$_3$)$_3^+$]. − $C_{16}H_{48}OSi_7$ (453.16): calcd. C 42.41, H 10.68; found C 41.67 (incomplete combustion), H 10.40.

Methoxybis(trimethylsilyl)[tris(trimethylsilyl)silylmethyl]silane (14): A solution of 0.16 g (0.29 mmol) of **5a** and 2.0 mL of H_2SO_4 in 20 mL THF was stirred for 3 d at room temperature. After addition of 5 mL of dry methanol, stirring was continued for 1 h. Then water was added and the mixture was immediately extracted with ether. The ethereal extracts were dried and concentrated. Chromatographic separation of the residue (silica gel, heptane) gave 0.04 g (30%) of **14** besides 0.05 g (40%) of **13**.

14: ^{1}H NMR ([D$_6$]benzene): δ = 0.22 (s, SiCH$_3$, 18 H), 0.32 (s, SiCH$_3$, 27 H), 0.43 (s, CH$_2$, 2 H), 3.25 (s, SiOCH$_3$). − ^{13}C NMR ([D$_6$]benzene): δ = −11.7 (CH$_2$), −0.3 {Si[Si(CH$_3$)$_3$]$_2$}, 1.14 {Si[Si(CH$_3$)$_3$]$_3$}, 52.1 (SiOCH$_3$). − ^{29}Si NMR ([D$_6$]benzene): δ = −81.4 [*Si*(SiMe$_3$)$_3$], −19.9 [Si(*Si*Me$_3$)$_2$], −12.2 [Si(*Si*Me$_3$)$_3$], 13.9 (SiOMe). − MS; *m/z* (%): 465 (0.1) [M$^+$ − H], 451 (9) [M$^+$ − CH$_3$], 393 (100) [M$^+$ − SiMe$_3$], 247 (5) [Si(SiMe$_3$)$_3^+$], 73 (47) [SiMe$_3^+$]. − $C_{17}H_{50}OSi_7$ (466.22): calcd. C 43.76, H 10.81; found C 43.19, H 11.00.

Crystal-Structure Determination of 5c and 14: The crystal-structure determinations were performed with a STOE IPDS diffractometer using graphite-monochromated Mo-K_α radiation. The structures were solved by direct methods (SHELXS-86)[11] and refined by full-matrix least-squares techniques against F^2 (SHELXL-93).[12] XP (Siemens Analytical X-ray Instruments) was used for structure representations. The X-ray analysis of **5c** revealed disorder for the piperidyl ring. For **14** complete disorder for all methyl groups of the trimethylsilyl substituents was found. Further details are compiled in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-101350 (**5a**),[10] -102955 (**5c**), and -102956 (**14**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(1223)336-033; E-mail: deposit@ccdc.cam.ac.uk].

Steric and Electronic Effects on the ^{103}Rh NMR Chemical Shifts of Rh^{I}(cyclooctadiene) Compounds Bearing N-Donor Ligands

Johannes G. Donkervoort,[a] Michael Bühl,*[b] Jan Meine Ernsting,[a] and Cornelis J. Elsevier*[a]

Keywords: ^{103}Rh NMR / Rhodium complexes / Nitrogen ligands / Chemical-shift computation

In order to study electronic and steric effects on δ(^{103}Rh), the ^{103}Rh-NMR spectra of a series of [Rh(cod)L_2] complexes (with L = nitrogen, oxygen, or chloride) have been measured by gradient-enhanced HMQC (^{1}H,^{103}Rh) NMR spectroscopy. Density functional computations of representative examples have been performed at the GIAO-B3LYP level of theory. The obtained experimental values of ^{103}Rh shifts fit the generally observed trend of coordinating ligands in the first coordination sphere of the metal: P < N < O. Calculated ^{103}Rh shifts agreed to within 8 % with experimental values. The computational results indicate that the Rh–N bond distance has a larger influence on the chemical shift than the N–Rh–N angle.

Introduction

Since the development of modern inverse 2D NMR techniques, a rapid growth of available NMR data concerning insensitive metal nuclei can be discerned.[1] For example, inverse 2D X{^{103}Rh} NMR leads to a theoretical sensitivity enhancement of 360 for X = ^{31}P and 5630 for X = ^{1}H, respectively. Despite the larger amount of NMR data there is still a lack of understanding of the factors which determine the chemical shift of transition metal nuclei. From the published data it has, for instance, been concluded that changes in the first coordination sphere of the Rh nucleus result in deshielding of the metal center in the order: O > Cl ≈ N > Br > I > S ≈ Se > Te > P ≈ As ≈ Sb ≈ H ≈ C* ≈ C (C* = sp^2-carbon).[2]

It is generally accepted that the chemical shift variation of a transition metal nucleus in its coordination compound is mainly determined by the paramagnetic shielding term given by the Ramsey equation[3] which was later developed by Griffith and Orgel (Eq. 1)[4]. In this equation r_d is the expectation value of the d-orbital radius, ΣQ_N is the angular imbalance of charge and ΔE is the average excitation energy between the filled and empty d-orbitals.

$$\sigma_p = \text{const.}\ (\Delta E)^{-1} \langle r_d^{-3} \rangle \Sigma Q_N \qquad (1)$$

Changes in ΣQ_N generally bear a large influence on σ_p. Therefore this study is focused on four-coordinate, square planar Rh^I complexes of the general type [Rh(cod)L_2]. In these complexes the d-electron configuration and the symmetry at the metal are kept constant and a discussion of the observed Rh shifts can be focused on ΔE and r_d alone.[5] As earlier results indicated a dependence of the Rh shift on the applied diene,[6] only cod complexes were used in this investigation.

We have previously studied the complexes [Rh(cod)$(P)_2$][6c] and observed that variations in the first coordination sphere of the Rh nucleus indeed influenced the ^{103}Rh chemical shift according to the general order given above.[2] However, changes in the second coordination sphere, for example bite angle variations, contradicted expectations based on simple MO considerations and the Ramsey equation. This study is focussed on a series of [Rh(cod)$(N)_2$] complexes in order to evaluate changes of the ^{103}Rh shift upon a systematic variation of the nitrogen ligands. These results will be discussed in the light of theoretical calculations of δ(^{103}Rh) for several of the prepared complexes, which have recently become feasible.[7][8] Together, these efforts may result in a better insight in the factors determining variations of the δ(^{103}Rh).

Results and Discussion

Synthesis

The complexes were prepared according to literature procedures except for the new four-coordinate [Rh(cod)(*i*PrDAB)]ClO_4 (*i*PrDAB = *i*PrN=CH−CH=N−*i*Pr), **7**. Compound **7** was obtained as a dark-green solid by adding a solution of the free ligand in acetone to a solution of in situ prepared [Rh(cod)$(acetone)_x$]ClO_4 in acetone (see Experimental Section). This complex is an air-stable solid with a melting or decompostion point which lies above 300 °C. Complex **7** is readily soluble in chlorinated solvents whereas it is only slightly soluble in EtOH and MeOH.

The ^{1}H- and ^{13}C-NMR spectra of samples of **7** in $CDCl_3$ or CD_3OD at ambient temperature are consistent with a

time-average C_{2v}-symmetric molecule. No dependence on the temperature has been observed by VT-NMR spectroscopy.

GE^{103}Rh-NMR Spectroscopy

The use of gradient selection is nowadays used for most 2D $^1H\{^{13}C\}$ and $^1H\{^{15}N\}$ experiments. Here we present the use of gradient selection to reduce the measuring time of $^1H\{^{103}Rh\}$ experiment and to reduce the ^1H signals not coupled to the rhodium more effectively. In the gradient-enhanced HMQC sequence: ^1H-^{103}Rh D1 − 90°(^1H) − 1/2J − 90°(^{103}Rh) − t_1/2 − GP1 − D16 − 180°(^1H) − GP2 − D16 − t_1/2 − 90°(^{103}Rh) − GP3 − 1/2J − ACQ, the equation GP1 ($\gamma H + \gamma Rh$) + GP2 ($-\gamma H + \gamma Rh$) + GP3 ($-\gamma H$) = 0 must be fulfilled. For GP1:GP2:GP3 = 90 : 44 : 50 this is true. We have tested these gradient values and compared the results with the normal HMQC pulse sequence. It was found that the number of scans per increment can be reduced from 8 or 16 to 1 or 2 without loss of information.

The ^{103}Rh NMR spectra were measured by gradient-enhanced HMQC (^1H,^{103}Rh) as described above and in the experimental section. The compound types studied have been summarized in the drawing below and can be divided into nitrogen donor complexes (**1**−**15**), chloride compounds (**16**, **17**) and oxygen donor complexes (**18**−**23**).

In order to study steric and electronic effects on the ^{103}Rh chemical shifts, density functional computations have been performed at the GIAO-B3LYP level of theory. This level has been shown to afford transition-metal chemical-shift values in good agreement with experiment for a number of organometallic compounds.[7] In addition, it has been used to study similar steric and electronic effects on $\delta(^{103}Rh)$ in related rhodium−phosphane and −cyclopentadienyl complexes.[8] Calculations have been performed for a number of complexes of this study, comprising **1**, **2**, **5**, **6**, **7**, **13**, **14**, and **18**. The experimental ^{103}Rh chemical shifts have been collected in Table 1, together with calculated values of representative examples. The theoretical ^{103}Rh chemical shifts agree well with the corresponding experimental data, with a mean absolute deviation of 44 ppm (over a range of ca. 540 ppm). When the single large deviation in the case of **7** is excluded (see below for a more detailed dicussion), the mean absolute deviation is improved to 30 ppm.

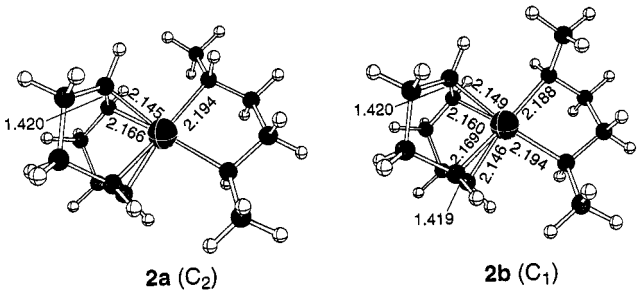
[a] Ref.[11] − [b] Ref.[6c]



The range of observed chemical shifts extends from δ = 751 to 1035 for the complexes containing nitrogen ligands and from δ = 1287 to 1372 for those containing oxygen ligands, with an intermediate value for the chloro com-

pounds **16** and **17**. Variations in the first coordination sphere of the Rh center follow the above mentioned series given by Mann. As expected, oxygen ligands (**18**−**23**) cause the Rh center to be more deshielded when compared to nitrogen ligands, while phosphorous ligands (Table 2, **24**−**30**) result in a strongly shielded Rh center. In case of P-donors, the relative energies of occupied and vacant MOs at the ligand and the metal fragments allow for a more effective overlap in terms of σ-donation and π-backdonation. These interactions result in a larger ΔE splitting, which accounts for the strong low-frequency shift of the bis(phosphane) complexes.

In earlier studies problems were reported for [Rh(cod)X(N)] (X = halogen, N = nitrogen ligand)[6a] involving exchange processes. However, for all complexes mentioned in Table 1, except for [Rh(cod)(tmeda)]-[Rh(cod)Cl_2], **6b**, the ^{103}Rh spectra recorded at 298 K were clearly resolved. For **6b** no signal is observed at 298 K, whereas upon cooling to 230 K two signals were observed at δ = 949.0 and 1065.3. These observations can be explained by assuming the presence of two species, i.e. cationic $[Rh(cod)(tmeda)]^+$ and anionic $[Rh(cod)Cl_2]^-$. Both the cationic and anionic species were also separately prepared as their perchlorate, **6a**, and tetraethylammonium, **17**, salt, respectively. Comparing the ^{103}Rh chemical shifts of **6a** and **17** with both observed signals of **6b** indicates that the signals at δ = 949.0 and 1065.3 indeed correspond to the $[Rh(cod)(tmeda)]^+$ and $[Rh(cod)Cl_2]^-$ species, respectively. The temperature dependence of the δ(^{103}Rh) of 0.42 ppm K^{-1} and 0.52 ppm K^{-1} for $[Rh(cod)(tmeda)]^+$ and $[Rh(cod)Cl_2]^-$, respectively, is consistent with values observed for related complexes.[6a,9] Although different observations have indicated the presence of two species in solution for **6b**,[10] this is the first real evidence for the presence of this cation-anion pair in solution.

For the complex $[Rh(cod)(dmeda)]ClO_4$, **2**, two resolved signals in a 5:1 ratio are observed in the ^{103}Rh spectra pointing to the presence of two rhodium species, **2a** and **2b**. This conclusion is corroborated by the observation of two not completely resolved sets of signals for the dmeda protons in the ^{1}H-NMR spectrum. Most probably these two signals arise from the presence of two stereoisomers with the methyl groups in trans (**2a**) or in cis positions (**2b**) (Figure 1). This conclusion is corroborated by results from density functional computations (vide infra), which would predict a 10:1 molar ratio for **2a** and **2b**, respectively, based on the relative energies (**2a** lower than **2b** by 5.4 kJ/mol at the B3LYP/II′ level). In addition, the calculated chemical shifts for **2a** and **2b** are in good agreement with both observed values (see Table 1).

It has been proposed that the metal shift parallels the variation of the bulk and basicity of the ligand. In a systematic study of Rh−phosphane complexes,[6c] it was shown that an increase in basicity of the phosphane ligands results in a more shielded Rh nucleus and hence a δ(^{103}Rh) shift towards higher frequencies. In addition, a larger cone-angle of the phosphane ligand also results in a shift towards higher frequencies.

2a (C_2) **2b** (C_1)

Figure 1. Optimized structures of **2a** and **2b**

For the nitrogen−rhodium complexes of this study, similar trends in the δ(^{103}Rh) can be observed when looking at one class of comparable nitrogen ligands. For example, within the class of bidentate amine-ligands a high-frequency shift is observed upon increasing the Brønsted basicity of the ligand (cf. **1**, **2**, and **6**). This trend is in contrast with expectations based on simple MO considerations combined with the above mentioned Ramsey equation. A more basic ligand is expected to result in an increased ΔE which, according to the Ramsey equation, should result in a more shielded nucleus and hence a low-frequency chemical shift. The observation that simple MO considerations do not fit the Ramsey equation were also found for phosphane-rhodium complexes.[6c]

In the series of the pyridine complexes (**12**−**15**), a strong chelate effect is observed. Replacing both pyridine ligands in **14** for the bidentate bipy ligand, resulting in a five-membered metallacycle (**13**), causes a significant low-frequency shift of 197 ppm. Variations in this ring-size affect δ(^{103}Rh) significantly, as is evident from the high-frequency shift upon increasing the ring-size by one (cf. **13** and **15**). This same trend is also observed for the amine (cf. **1** and **5**) and diimine complexes (cf. [Rh(cod)(*i*PrDAB)], **7**, [Rh(cod)-(ABK)], **8**, and [Rh(cod)(BIAN-R)], **9**−**11**). The BIAN ligand systems are known to have a relatively large bite-angle due to the rigidity of the ligand back-bone, analogous to the rigidity of the 1,2-diaminobenzene ligand. Hence, the corresponding complex **3** shows a high frequency shift as compared to **1**. A similar observation has been made for some series of phosphane rhodium complexes, e.g. $[Rh(nbd)(Ph_2P(CH_2)_nPPh_2)]^+$,[11] where the experimental shift ranged from δ = −390 for n = 2 to δ = −210 for n = 4. Hence, the chelate-ring size appears to be one of the most important factors determining the δ(^{103}Rh) value. This size effect is believed to be mediated by changes in the bite angle at the metal. Therefore, studies were performed on the model compound $[Rh(cod)(NH_3)_2]^+$ by explicitly calculating its δ(^{103}Rh) value as a function of the bite angle.

As apparent from the results displayed in Figure 2a, there is in fact a dependence on the bite angle of the computed δ(^{103}Rh) values with a minimum near ca. 90°. Variations in the bite-angle around this 90° angle result in a more deshielded metal center and hence high-frequency shifts. Similar observations were made for rhodium(phosphane) complexes, i.e. a strong deviation from the ideal geometry of square-planar d^8-complexes leads to a high-frequency

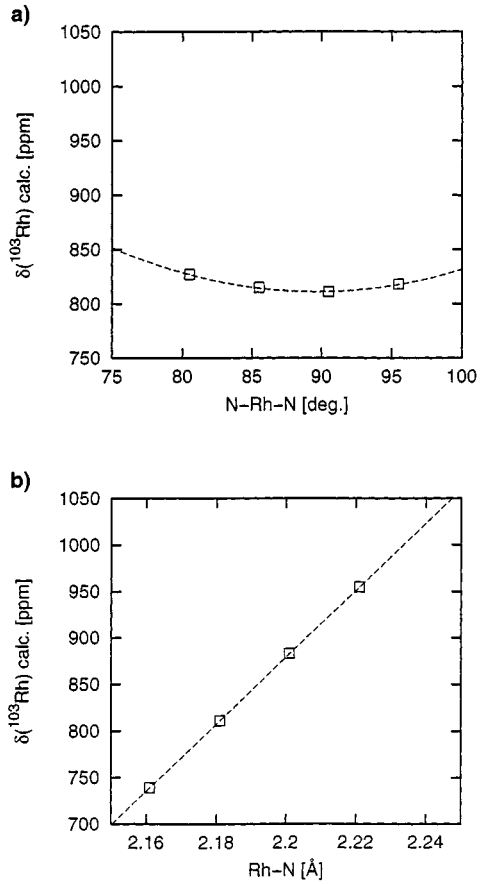


Figure 2. Calculated rhodium chemical shift of $[Rh(cod)(NH_3)_2]^+$ as a function of N−Rh−N angle and Rh−N distance

shift.[6c][11] However, for the model complex $[Rh(cod)(NH_3)_2]^+$ there seems to be only a minor variation in δ(^{103}Rh) of ca. 40 ppm in the bite-angle range between 75 and 100 typically covered in bidentate chelates. A similar result has recently been obtained in the case of rhodium(diphosphane) complexes.[8b]

According to the latter study, the ^{103}Rh chemical shifts were found to be particularly sensitive to changes in the Rh−P bond lengths, with a computed bond-length shift derivative of more than 10,000 ppm Å^{-1}. The analogous study for model compound $[Rh(cod)(NH_3)_2]^+$ now also revealed a large sensitivity of the computed δ(^{103}Rh) value to the Rh−N bond distance (see Figure 2b), albeit with a somewhat smaller slope of 3600 ppm·Å^{-1}. These results indicate that, although the bite-angle influences the δ(^{103}Rh), mainly variations in the Rh−N bond distance dominate the δ(^{103}Rh). Apparently, in rhodium−phosphane and −nitrogen complexes, variations in the chelate ring-size affect both the bite-angle and the Rh−ligand bond distance, where the latter has the larger influence on the variations in the observed δ(^{103}Rh) shift.

Using these results, we tried to separate the steric and electronic effects in the series of substituted ethylenediamine complexes **1**, **2**, and **6**, the observed ^{103}Rh chemical shifts of which cover a range of 227 ppm. Contrary to expectations based on the relative Brønsted basicity of the ligands (vide supra), a more basic ligand in this series induces a stronger deshielding of the ^{103}Rh nucleus. However, in the same series, the optimized Rh−N bond lengths increase significantly, whereas the bite angle remains essentially constant (see Table 3).[12] According to the above-mentioned results for model compound $[Rh(cod)(NH_3)_2]^+$, it is the bond-length elongation that could be responsible for the observed deshielding.

Table 3. Selected geometrical parameters of Rh(cod) complexes containing ethylenediamine derivatives and the computed d(^{103}Rh) chemical shifts

no.	ligand	Rh-N [Å]	N-Rh-N [°]	δ(with Me)[a]	δ(without Me)[b]
1	(1,2)-en	2.167	80.6	725	725
2a	dmeda (trans)	2.194	81.1	781	821
2b	dmeda (cis)	2.188/ 2.194	81.5	801	834
6	tmeda	2.239	82.2	942	974

[a] δ(^{103}Rh) computed for the fully optimized structure. [b] δ(^{103}Rh) computed for optimized structures of the respective complexes, with Me groups substituted by H atoms.

In order to assess also the effects of the added Me groups, model calculations have been performed for the parent **1** employing the geometrical parameters optimized for the derivatves **2** and **6** (i.e. by simply replacing the Me groups with H atoms). The chemical shifts computed accordingly (last column in Table 3) are thus solely the result of the structural distortions induced by the Me groups which reflect their "pure geometrical effects". Apparently, these distortions cause a strong deshielding, which is partly reduced by the "pure electronic effects" of the Me groups. The latter amounts to only ca. 30 ppm, as assessed by the difference between the entries of the last two columns in Table 3[13], compared to the overall effect of up to 227 ppm observed in going from **1** to **6**. The main origin of this deshielding is therefore a geometrical, rather than an electronic effect. A comparable shielding effect (21 ppm) is observed upon substituting bipy for 4,4′-Me_2bipy, cf. the δ(^{103}Rh) of **13** and **12**, respectively.

For more quantitative estimates of these geometrical effects, the bond-length shift derivative calculated for model compound $[Rh(cod)(NH_3)_2]^+$, 3600 ppm·Å^{-1}, was applied to **1**, **2**, and **6**. In going from **1** to **2** and from **1** to **6**, the optimized bond-length elongations are 0.026 and 0.072 Å, respectively. This corresponds to deshieldings of 94 and 259 ppm, respectively, which are in excellent accord with the calculated "pure geometrical effects" of 103 and 249 ppm, respectively.

For an interpretation of the steric and electronic influences, the above-mentioned influences have been discussed in terms of the parameters ΔE and r_d in the Ramsey equation. In general, it is possible to relate large differences in the first coordination sphere to the Ramsey equation by using a simplified MO theory, i.e. hard donor atoms result in more deshielded metal centers and hence in high-frequency shifts as compared to soft donor atoms (cf. rhodium complexes containg either oxygen (av. δ = 1300) or phos-

phorus (av. $\delta = -100$) ligating atoms, respectively). However, trends in $\delta(^{103}Rh)$ induced by second sphere variations of the applied ligands can not be related to such simplified model theories (vide supra).[6c] A more thorough investigation into the orbital symmetry and energies of the Rh complexes seems necessary. Therefore the calculated (B3LYP) molecular orbitals of complexes **1**, **2**, **6**, **13**, **14**, and model complex $[Rh(cod)(NH_3)_2]^+$ were analyzed in detail, in order to see if simple relations between appropiate ΔE values and chemical shifts could be found.

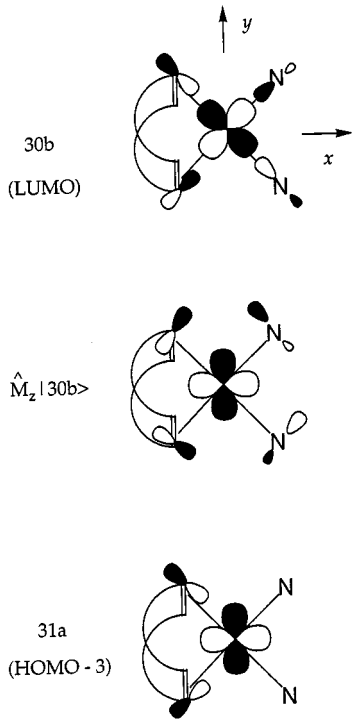

Figure 3. Highest occupied and lowest unoccupied molecular orbitals of $[Rh(cod)(NH_3)_2]^+$ fragments

The four highest occupied MOs of model complex $[Rh(cod)(NH_3)_2]^+$ are of predominant d(Rh) character, as expected, with some minor additional ligand contributions. At least one of the lowest unoccupied MOs also has large d(Rh) character [usually the LUMO, except when p-ligands are present such as in **13** and **14**; in these cases the LUMO is usually of π^*(ligand) character]. Magnetically induced coupling between suitable occupied and virtual MOs can account for paramagnetic contributions in a pictorial fashion. For example, in model compound $[Rh(cod)(NH_3)_2]^+$ the large deshielding perpendicular to the coordination plane (z direction in Figure 3) is consistent with the coupling of the LUMO (after action of the magnetic operator $\hat{M}_z$ on it, viz. the resulting orbital $\hat{M}_z|30b>$) with an occupied MO of suitable symmetry (orbital 31a, see Figure 3).[14] Unfortunately, it was not possible for the set of compounds under scrutiny, to simply relate the energy differences between the corresponding orbitals with the trends in $\delta(^{103}Rh)$. Apparently, the particular magnetic shieldings are determined by several such interactions and it is difficult to identify a single factor, such as one particular ΔE value, as the main source for the observed trends.

The same holds for complex **7** with the *i*Pr-DAB ligand where an additional deshielding is apparent in the coordination plane (corresponding to the y axis in Figure 3), consistent with paramagnetic contributions due to the coupling of the LUMO [44b, π^*(DAB) with some d_{xz}(Rh) character][15] and the HOMO [48a, d_{z2}(Rh)]. This is even more pronounced in the parent model compound, [Rh(cod)(H-DAB)]$^+$ (H-DAB = HN=CH−CH=NH), resulting in a huge predicted deshielding for the metal ($\delta_{iso} = 1505$). There is thus a huge shielding effect on $\delta(^{103}Rh)$ upon changing the substituents at the DAB nitrogen atom from H to *i*Pr ($\Delta\delta_{calc.} = -417$ ppm). Part of this effect is due to geometrical differences, but here it is the "pure electronic effect" of the *i*Pr groups which is dominating, $\Delta\delta = -262$ ppm (assessed similarly as described above for the 1,2-en derivatives). In the DAB complexes, the ^{103}Rh chemical shift is quite sensitive to subtle changes in the electronic structure, which may be one of the reasons for the unusually large deviation (more than 170 ppm) between the theoretical and experimental $\delta(^{103}Rh)$ data for **7** (see Table 1).

Conclusion

It has been found that the experimental values of the ^{103}Rh-NMR shifts of $[Rh(cod)(N)_2]^+$ complexes fit the expected trend according to the position within the spectrochemical series for substituents in the first coodination sphere of rhodium. Except for a diazabutadiene complex which turned out to be a problem case for theory, density-functional calculations have resulted in excellent numerical reproduction of the experimental shifts within 30 ppm, where the gross variation of shifts amounts to 540 ppm.

According to model calculations, it is the Rh−N distance that has a decisive influence upon the Rh chemical shift, rather than the N−Rh−N angle hitherto believed to be of prime importance for chelating ligands. These findings are consistent with recent results obtained for Rh−bis(phosphane) complexes. Effects of substituents in the second coordination sphere (e.g. alkyl vs. H substituents at the coordinating nitrogen atoms) can be partitioned computationally into geometrical and electronic contributions, the relative importance of which is depending on the ligand. Further interpretation of the origin of these secondary substituent effects on the metal shielding, e.g. in terms of the Ramsey equation, is difficult because it is hard to identify single, dominant parameters.

Experimental Section

NMR Techniques: Routine ^{1}H-NMR spectra to check purity were recorded on a Bruker AMX 300 spectrometer (300.13 MHz). All ^{103}Rh NMR measurements were carried out on a 300-MHz Bruker DRX Advance spectrometer under temperature control at 298 K using a 5-mm triple-resonance inverse probehead (^{1}H, ^{31}P{BB}) with a z gradient coil (90° ^{1}H = 7.2 ms, 90° ^{103}Rh = 19.5 ms) using the following sequence: ^{1}H-^{103}Rh GS−HMQC:[16−18] D1 − 90°(^{1}H) − 1/2J − 90°(^{103}Rh) − t_1/2 − GP1 − D16 − 180°(^{1}H) − GP2 − D16 − t_1/2 − 90°(^{103}Rh) − GP3 − 1/2J − ACQ; acqui-

sition parameters: D1 = 1 s, 1/*J*2 = 0.2−0.5 s, D16 = 50 ms, *GP* = 1 ms, 1 to 4 scans were acquired per t_1 increment, block size 2048 × 128 points for the first experiment and 2048 × 256 points for the final experiment, gradient amplitudes GP1:GP2:GP3 = 90:44:50 $G \cdot cm^{-1}$. Acquisition time 10−30 minutes for the final experiment.

The spectral width was 3000 Hz for ^1H. In the first measurement, the spectral width for ^{103}Rh was 9000 ppm which was covered by 128 t_1 increments, 16 dummy scans were used. To exclude folding and improve resolution, a second and sometimes third measurement with modified n_0(Rh) values and smaller spectral widths (at most 1900 Hz in F_1 using 256 increments) were carried out. The digital resolution of $\delta(^{103}Rh)$ was at least 3.7 Hz pt^{-1}. After zero-filling in F_1, the 512 × 512 matrix was transformed applying a sine-bell weighing function. The ^{103}Rh spectrum is obtained in F_1, and the ^1H spectrum in F_2. The absolute ^{103}Rh frequency was determined by relating it to the reference frequency Ξ = 3.16 MHz, scaled for the operating field (^1H 9 483 491 Hz) to ν_{ref} = 3.16415 MHz. Signals at higher frequencies are taken as positive.

Synthesis: All complexes, except for **7** were prepared according to published procedures: **1**−**3**, **5**−**6a**, **7**, **12**−**14**, **20**,[19] **4**,[20] **6b**,[10] **8**,[21] **9**−**11**,[22] **15**,[23] **16**,[24] **17**,[10b] **18**,[25] **19**,[20] **21**−**23**.[26]

Preparation of [Rh(cod)(*i*Pr-DAB)]ClO_4 (7): To a solution of 35.6 mg (0.1444 mmol) of $[Rh(cod)Cl]_2$ in 25 mL of acetone was added 32.5 mg (0.1444 mmol) of $AgClO_4$. The resulting mixture was stirred for 15 minutes after which the formed precipitate was filtered off. To the filtrate was added a solution of 20.2 mg (0.1444 mmol) of *i*Pr-DAB in 5 mL of acetone. The reaction mixture was stirred for 10 minutes after which the solvent was removed in vacuo. The resulting green solid was washed with pentane (2 × 10 mL) and Et_2O (2 × 10 mL), respectively, and dried in vacuo. Yield 60.9 mg (0.1350 mmol) 93%. Elem. anal. for $C_{16}H_{28}N_2O_4Rh$ found (calc.): C 42.01 (42.63), H 6.28 (6.26), N 6.14 (6.21). − ^1H NMR ($CDCl_3$, d): 8.34 (d, ^3J = 2.37 Hz, 2 H, N=C*H*), 4.40 (s br, 4 H, *H*C=C*H*), 3.32 [s, ^3J = 6.60 Hz, 2 H, C*H*$(CH_3)_2$], 2.54 (m, 4 H, CH_2), 2.02 (m, 4 H, CH_2), 1.34 [d, ^3J = 6.60 Hz, 12 H, CH(C$H_3)_2$]. $^{13}C\{^1H\}$ ($CDCl_3$, d): 87.47 and 87.31 (cod-*C*H and N=*C*H), 54.80 [*C*H$(CH_3)_2$], 30.42 (cod-*C*H_2), 22.74 [CH(*C*$H_3)_2$].

Computational Details: The same methods and basis sets as in the former theoretical studies of ^{103}Rh chemical shifts have been employed:[7b,8] Geometries have been fully optimized in the given symmetry at the BP86/ECP1 level, i.e. employing the gradient-corrected exchange-correlation functionals of Becke (1988)[27]and Perdew (1986),[28] together with a quasi-relativistic effective core potential and the corresponding [6s5p3d] valence basis set for Rh,[29]and standard 6−31G* basis[30] on the ligands (designated BP86/ECP1). Magnetic shielding tensors have been computed for the BP86/ECP1 geometries with the GIAO (gauge-including atomic orbitals)-DFT method,[31] employing a fine integration grid (75 radial shells with 302 angular points per shell), Becke′s three-parameter exchange DFT/Hartree-Fock hybrid functional[32] together with the correlation functional of Lee, Yang, and Parr[33] (denoted B3LYP), and the following basis set (denoted basis II): Rh: well-tempered [16s10p9d] basis, contracted from the 22s14p12d set[34] and augmented with two d-shells of the well-tempered series; ligands: IGLO-basis II recommended for chemical-shift calculations,[35] i.e. C,N,O: (9s5p)/[5s4p] augmented with one set of d-polarization functions; Cl: (11s7p)/[7s6p] augmented with two sets of d-polarization functions; H: (5s)/[3s] polarized with one set of p-functions. For the complexes with the N-donor ligands, the chemical shift computations employed basis II′, i.e. the same as basis II, but with a smaller DZ (double zeta) basis[35] on the hydrogen atoms. For cation **1**, the GIAO-B3LYP ^{103}Rh shieldings differed by less than 4 ppm between basis II and basis II′. Chemical shifts $\delta(^{103}Rh)$ are reported relative to σ(standard) = −878 ppm, as previously evaluated from σ(calc) vs. δ(expt) linear regressions.[7b] All calculations were performed with the Gaussian 94 program.[36]

Acknowledgments

We kindly thank Dr. P. H. M. Budzelaar, University Nijmegen, for providing us with a sample of **8**. Financial support by the Netherlands Organization for Pure Research CW-NWO under the Young Scientists Program, is gratefully acknowledged. M. B. wishes to thank Prof. W. Thiel for continuous support. Calculations were performed on a Silicon Graphics PowerChallenge (Organisch-chemisches Institut, Universität Zürich) and on IBM RS6000 workstations (C4 cluster, ETH Zürich), as well as on a NEC-SX4 (CSCS, Manno, Switzerland).

[12] No solid-state structures for the series **1**, **2**, and **6** are published; steric effects similar to those discussed here, however, can be noted in a cationic Rh(COD) complex with *N*-(2-aminoethyl)-piperidine as ligand (E. Anzuela, M. A. Garralda, R. Hernandez, L. Ibarlucea, E. Pinilla, M. A. Monge, *Inorg. Chim. Acta*, **1991**, *185*, 211): the Rh−N bond lengths to the primary and tertiary amine N atoms, 2.107(6) and 2.176(7) A, respectively, are shorter than the corresponding DFT data in Table 3 (cf. entries for **1** and **6**), but the difference between these distances is very similar in both cases, ca. 7 pm elongation from primary to tertiary amine.
[13] Somewhat counterintuitively, roughly the same effect is seen for **2** and **6** upon substituting two and four Me groups, respectively.

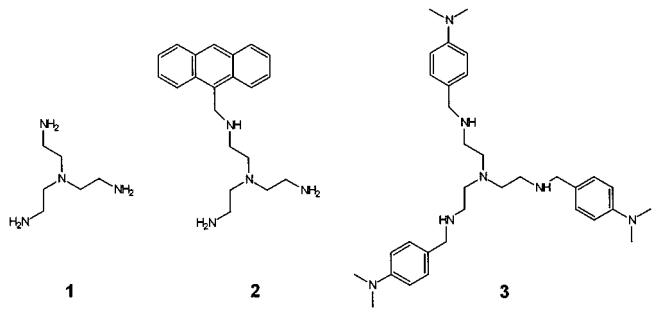
A Versatile Fluorescent System for Sensing of H^+, Transition Metals, and Aromatic Carboxylates



Luigi Fabbrizzi,*[a] Maurizio Licchelli,[a] Luisa Parodi,[a] Antonio Poggi[a], and Angelo Taglietti[a]

Keywords: Fluorescent sensors / Molecular recognition / Charge transfer excited states / Metal complexes / pH Sensors

The fluorescent emission of the *N,N*-dimethylaniline fragment of the tetramine system **3** varies with pH, displaying a maximum of the fluorescent intensity, I_F, at pH = 5. Binding of transition metals (Cu^{II}, Ni^{II}) induces fluorescence quenching and modifies the I_F vs. pH profile, giving rise to an OFF-ON-OFF type of sensor. The $[Zn^{II}(\mathbf{3})]^{2+}$ complex recognises carboxylate anions, both aliphatic and aromatic. Recognition is signalled via fluorescence quenching only for aromatic carboxylates.

In principle, a molecular fluorescent sensor for any kind of analyte can be built by following the fluorophore-spacer-receptor approach, i.e. by covalently linking a light-emitting fragment to a ligating subunit capable of recognising the desired substrate. Most importantly, an intra-molecular mechanism must exist that associates substrate binding and emitting activity of the fluorophore.[1−4] Thus, the recognition process can be signalled through either fluorescence enhancement or quenching. In this sense, a molecular fluorescent sensor can be well illustrated with the switch-light bulb metaphor, as an external input (a variation of analyte concentration, corresponding to a finger) operates the switch (the receptor subunit), thus turning on/off the light emission by the fluorescent fragment (the light bulb).[5]

We describe here a versatile fluorosensor for ionic analytes of varying kind, based on the tripodal tetramine tren, **1**.

1 **2** **3**

Tren is a quite good ligand for transition metal ions, imposing in most cases a trigonal bipyramidal coordination geometry.[6] Whereas four coordination sites are occupied by the amine groups of tren, the axial position, opposite to the tertiary nitrogen atom, is vacant and available for an anion. As a consequence, a metallo-tren subunit may behave as a receptor for ionic analytes. In this regard, we have recently reported on a Zn^{II}-tren system with a covalently appended anthracene fragment, $[Zn^{II}(\mathbf{2})]^{2+}$, which is able to recognise the $-COO^-$ residue.[7] However, recognition is signalled only for those anions displaying electron donor/acceptor tendencies, which quench the nearby fluorophore via an electron transfer mechanism.

We have now appended at each terminal amine nitrogen atom of tren an *N,N*-dimethylaniline subunit (DMA): *N*2-(4-dimethylaminobenzyl)-*N*1,*N*1-bis[2-(4-dimethylaminobenzylamino)ethyl]ethane-1,2-diamine, trenDMA$_3$, **3**. The DMA fragment, when irradiated at 300 nm, gives rise to a charge transfer (CT) excited state, which emits light at 360 nm. The interaction of the DMA-photoexcited fragment with analytes hosted by the tetramine receptor may induce drastic variations of the emission intensity, opening the way to fluorosensing of protons, transition metals and anions. Moreover, the protonation of the dimethylamine group of DMA, in strongly acidic solutions, destroys the CT-photoexcited state and quenches the fluorescence. This unique feature opens a further opportunity for selective signalling of ionic analyte recognition in aqueous solution.

Interaction with Protons

The emitting behaviour of **3** over the pH range 2−10 was investigated through a spectrofluorimetric titration experiment. In particular, a solution of **3** (10^{-4} mol L^{-1}) containing excess acid was titrated with a standard NaOH solution. The profile of the fluorescence intensity, I_F (%), vs. pH is displayed in Figure 1.

At very low pH (<2), the solution is very poorly emitting: in these acidic conditions, the dimethylamine group of each DMA fragment of **3** is protonated and the CT excited state cannot be achieved. On increasing pH, the intensity (I_F) of the emission band centered at 370 nm steeply increases, due to the stepwise deprotonation of the dimethylammonium groups and concurrent formation of the corresponding photoexcited state. At pH = 5.3, I_F reaches its maximum

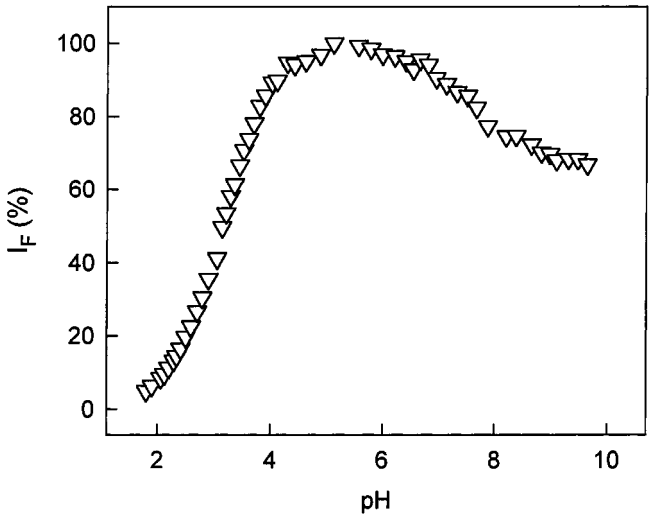

Figure 1. pH dependence of the fluorescence (λ_{exc} = 300 nm; λ_{em} = 370 nm) intensity for a solution of **3** in water

value then decreases smoothly. An emission spectrum of **3** measured at pH 8.5 is reported in Figure 2.

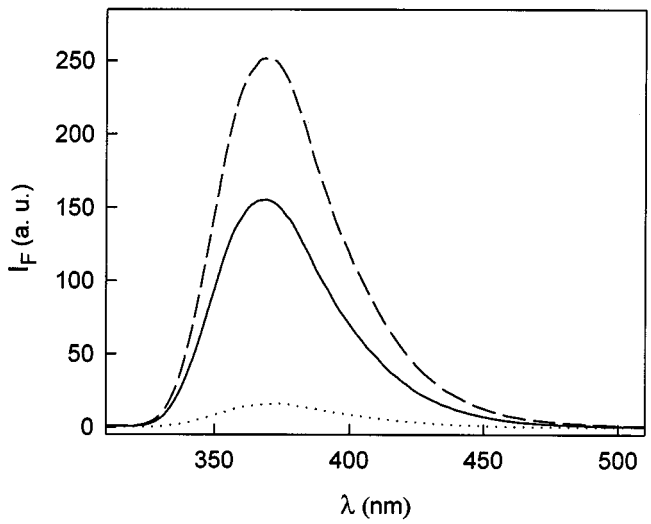

Figure 2. Emission spectra (λ_{exc} = 300 nm) in aqueous solution at pH 8.5 of: (___) free ligand **3**, (····) copper complex, (– – –) zinc complex

Progressive quenching of fluorescence after pH = 5.3 is to be ascribed to the stepwise deprotonation of the ammonium groups of the tren subunit adjacent to the DMA fragments. In fact, the amine group possesses reducing tendencies and can transfer an electron to a nearby photoexcited fluorophore, inducing fluorescence quenching.[8][9] It is possible that not only the adjacent secondary amine groups, but also the tertiary one, probably the first to deprotonate, is involved in the electron transfer process to the DMA fragment. The rather low solubility of **3** prevented a whole investigation of the stepwise protonation equilibria through potentiometric titration and determination of the pertinent pK_A values.

It should be noted that **3** belongs to the class of OFF-ON-OFF fluorosensors.[10] Sensors of this type are especially valuable, as, in contrast to usual indicators, they signal, via the fluorescent emission, the pH of the solution, within a given window. The narrower the window, the most precise and useful the sensor. In this sense, **3** is a rather poor sensor, as its peaks is poorly defined, and the window is spread over a too large pH interval.

Sensing of 3d Metal Ions

A solution of **3** containing 1 equiv. of Cu^{II} and excess acid was titrated with standard NaOH and the emission of the solution was spectrofluorimetrically monitored. In the acidic region, the I_F vs. pH profile superimposes well on the profile observed for the metal free solution. However, after reaching its maximum value at pH = 3.8, I_F decreases abruptly and full quenching is observed at pH = 5.5. The addition of Cu^{II} did not induce any changes in the shape and energy of the emission band (see Figure 3).

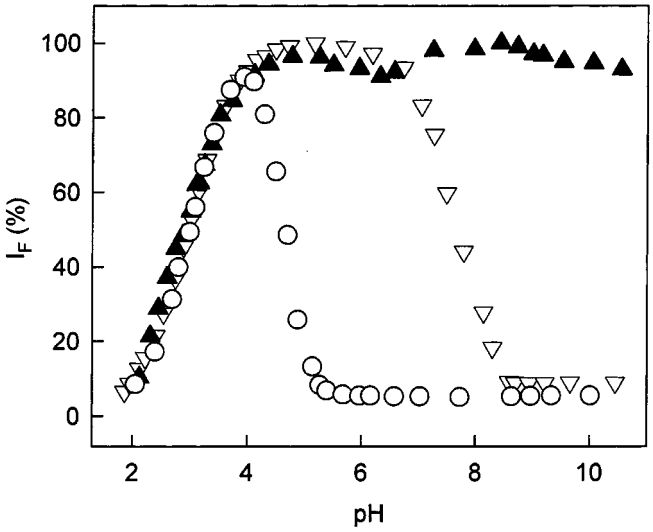

Figure 3. pH dependence of the fluorescence intensity (λ_{exc} = 300 nm; λ_{em} = 370 nm) for solutions containing equimolecular amounts of **3** in water and Cu^{II} (○); Ni^{II} (▽); Zn^{II} (▲)

Quenching is to be associated to the metal binding by the tren subunit of **3**, a process occurring in the pH = 4–5.5 interval. Transition metals typically quench proximate fluorophores via either electron transfer (eT) or energy transfer (ET) processes.[11,12] The two mechanisms can be discriminated by carrying out spectrofluorimetric studies on solutions frozen at the liquid nitrogen temperature. In fact, the occurrence of an eT process induces charge separation within the two-component system, to which a substantial rearrangement of solvent molecules is associated. Freezing prevents this rearrangement and interrupts the eT process: as a consequence, fluorescence is restored. On the other hand, an ET process induces a circular exchange of electrons, with no charge separation and no solvational rearrangement: as a consequence, the fluorophore remains quenched even when the solution is frozen at liquid nitrogen temperature and the solvent molecules are immobilised.[13] In particular, we observed that freezing at 77 K of

an equimolar solution of **3** and Cu^{II} in EtOH, did not induce any fluorescence revival, thus indicating that an ET mechanism operates. In this connection, it should be considered that Cu^{II} possesses a half-filled level of low energy (d_{z^2}, in a trigonal bipyramidal geometry), suitable for the occurrence of a double electron exchange process with a neighboring excited singlet. However other deactivation pathways (e.g. internal conversion) may be competitive in the presence of the metal ion. An intersystem crossing process could be accelerated by the proximate transition metal ion to generate a triplet state which is often non-emissive even at low temperatures.

Quite interestingly, the **3**-Cu^{II} equimolar system behaves as an extremely efficient OFF-ON-OFF pH sensor, giving rise to a well defined peak and to a narrow pH-window (2/5.5). The observed behaviour is very similar to that displayed by previously reported systems,[10] consisting of covalently linked amine, pyridine, and anthracene fragments. In those pH sensors, the quenching mechanism before and after the I_F peak (both located at pH = 6) were both of eT nature: (i) from the photoexcited anthracene subunit, An*, to the pyridinium moiety, and (ii) from the amine group to An*. In the presently investigated **3**-Cu^{II} system, the protonation of the amine group of DMA, and an ET mechanism (involving Cu^{II} and DMA*) operate.

Also when titrating **3** in presence of 1 equiv. of Ni^{II}, a peak is observed in the I_F vs. pH profile, fluorescence decrease and quenching being observed at a higher pH than in the case of Cu^{II} (see Figure 3). This is due to the intrinsically lower affinity of the tetramine subunit towards Ni^{II}, compared to Cu^{II} (constants for the M^{II} + tren = $[M^{II}(tren)]^{2+}$ equilibrium, in aqueous solution are $10^{14.95}$ and $10^{19.58}$, respectively).[14] Thus, also the **3**-Ni^{II} system gives rise to an OFF-ON-OFF behaviour even if with a rather large peak width.

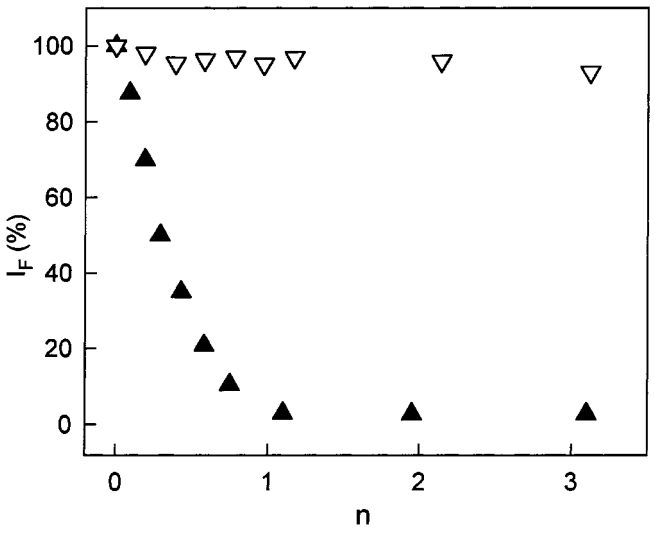

Figure 4. Discrimination of Cu^{II} and Ni^{II} by fluorescent sensor **3** in water solution buffered at pH 6 with MES buffer. Titration with Ni^{II} does not alter fluorescence (▽). On addition of Cu, I_F (λ_{exc} = 300 nm; λ_{em} = 370 nm) decreases linearly (▲); full quenching is observed with the addition of 1 equiv. *n* = number of added equivalents

On the other hand, the remarkably different affinity of the tren subunit towards Cu^{II} and Ni^{II} allows an efficient discrimination of the two metal ions to be carried out. In this connection, an aqueous solution 10^{-4} M in **3** was buffered to pH = 6 and titrated with a Ni^{II} standard solution: no alteration of the emission spectrum of the DMA fragment was observed, even after the addition of several equiv. of Ni^{II} (see Figure 4). Failure of I_F modification was due to the fact that at pH = 6 the Ni^{II} ion is not complexed by the tetramine receptor subunit. Then, the same solution was titrated with Cu^{II}. A linear decrease of I_F was observed and complete fluorescence quenching was achieved after the addition of 1 equiv. of Cu^{II}.

The Zn^{II} ion behaves quite differently with respect to Cu^{II} and Ni^{II}. In fact, on titration with standard base of an acidified solution of **3**, containing 1 equiv. of Zn^{II}, the typical increase of I_F with increasing pH was observed, which reached its maximum value at pH = 5 (see Figure 3). At this pH, the dimethylammonium group of each DMA fragment is deprotonated, which restores DMA emission. However, at pH $\geq$ 6, I_F does not begin to decrease, as observed in a metal-free solution (due to the occurrence of an eT process from the proximate amine groups) or in presence of either Cu^{II} or Ni^{II} (due to an ET mechanism involving the tetramine complexed transition metal), but maintains its maximum value until definitely basic conditions. This behaviour must be ascribed to the complexation of Zn^{II} by the tren subunit, which should occur at pH $\geq$ 6.5. In fact, metal coordination prevents the occurrence of the amine-to-DMA* eT process. On the other hand, the Zn^{II} centre, which has a d^{10} electronic configuration and does not exhibit any redox activity, cannot be involved in any ET or eT process with the nearby photo-excited fragments. The photophysical innocence of Zn^{II} as well as the coordinative unsaturation of its tren complex open the way to the design of fluorosensors for anions, whose recognition processes are based on the metal-ligand interaction (vide infra).

Sensing of Aromatic Carboxylates

The tren subunit typically imposes a trigonal bipyramidal stereochemistry to the complexed metal centre. The axial position opposite to the tertiary amine group is vacant and available for the coordination by a solvent molecule or by an anion. Thus, a metal−tren moiety can behave as a receptor for anionic substrates displaying coordinating tendencies. In this connection, the Zn^{II} derivative of a tren subunit equipped with an anthracenyl substituent (trenan, **2**) was observed to recognise aromatic carboxylates (in view of the special affinity of the $-COO^-$ group for the Zn^{II} centre), but to sense, via the anthracene fluorescence quenching, only those benzoates bearing either a donor, e.g. $-N(CH_3)_2$, or an acceptor substituent, e.g. $-NO_2$, on the 4-position of the ring.[7] Quenching was ascribed to an intra-complex eT process involving the benzoate substituent and the facing photo-excited anthracene fragment. Plain benzoate binds the Zn^{II} centre in **2**, but its recognition is not signalled by any modification of the anthracene emission.

We have tested the recognising and sensing tendencies of the Zn^{II}-**3** system towards carboxylates by carrying out spectrofluorimetric titration experiments in MeOH solution. In particular, a solution of the $[Zn^{II}(\mathbf{3})]^{2+}$ complex was titrated with a solution containing the sodium salt of the envisaged carboxylate anion. It was observed that addition of aromatic carboxylates induces quenching of the emission of the DMA fluorophore, I_F being reduced to less than 20% of the original value. I_F vs. equiv. of anion profiles for benzoate, 9-antracenoate, 4-nitrobenzoate, are reported in Figure 5.

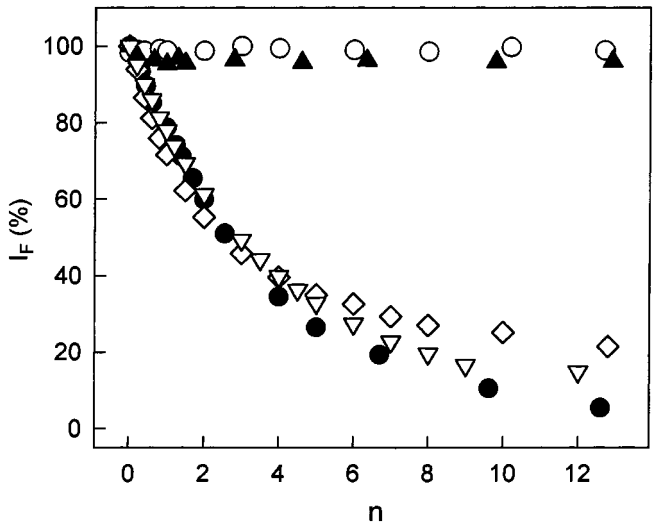

Figure 5. Spectrofluorimetric titrations (λ_{exc} = 300 nm; λ_{em} = 370 nm) of the receptor $[Zn^{II}(\mathbf{3})]^{2+}$ in methanolic solution (10^{-4} mol L^{-1}) with standard methanolic solutions of benzoate (◇); 9-anthracenoate (▽); 4-nitrobenzoate (●); acetate (▲); cyclohexylcarboxylate (○); n = number of added equivalents

Non-linear least-squares analysis of titration profiles reported in Figure 5 indicated the formation of 1:1 adducts.[15] The log$K$ values associated to the equilibrium:

$$[Zn^{II}(\mathbf{3})]^{2+} + X^- \rightleftharpoons [Zn^{II}(\mathbf{3})(X)]^+ \quad (1)$$

are reported in Table 1.

Table 1. log$K$ values for the $[Zn^{II}(\mathbf{3})(anion)]^+$ adduct formation

Anion	logK	quenching[a]
benzoate	4.69±0.04	yes
4-nitrobenzoate	4.43±0.06	yes
9-anthracenoate	4.47±0.04	yes
acetate	4.35±0.08	no
cyclohexylcarboxylate	4.08±0.08	no
chloride	3.69±0.08	no
nitrate	not bound[b]	=
perchlorate	not bound[b]	=

[a] Anion binding induces partial quenching of the emission of the DMA fragment of **3**. – [b] No alteration of titration profiles of benzoate were detected during competition experiments (see text).

Titration with aliphatic carboxylates (acetate and cyclohexylcarboxylate) did not induce any modification of the DMA emission intensity, as seen in Figure 5. However, the binding of the aliphatic carboxylates is demonstrated by competitive titration experiments involving aromatic carboxylates. As an example, titration of a solution of $[Zn^{II}(\mathbf{3})]^{2+}$ containing 10 equiv. of acetate with benzoate produces a less steep profile than that obtained in absence of acetate, indicating competition of the two substrates for the Zn^{II} site. The log$K$ values associated to the adducts of aliphatic carboxylates and other inorganic anions were calculated from the I_F vs equiv. of benzoate profiles, obtained for spectrofluorimetric titrations of solutions containing varying amounts of the investigated anion: their values are reported in Table 1. It can be seen that the values for aliphatic carboxylates are comparable with those observed for aromatic carboxylates.

It derives that the $[Zn^{II}(\mathbf{3})]^{2+}$ system is a discriminating sensor, which recognises the $-COO^-$ group, but communicates recognition only if the $-COO^-$ group is appended to an aromatic backbone. The explanation of this behaviour is not straightforward.[16] It is suggested that aromatic carboxylates interact with the DMA substituents via π stacking. This modifies the energy of the π orbitals of the DMA subunits. It should happen that the the energy of the DMA HOMO level is reduced to such an extent that its combination with the donating DMA orbital is minimized and, as a consequence, the generation of the charge transfer excited state prevented.

Experimental Section

General Considerations: All the reagents (Aldrich) were used without further purifications. – NMR data were obtained on a Bruker AMX 400 MHz. – All fluorescence measurements were carried out on a Perkin Elmer LS-50 luminescence spectrometer equipped with a 1.0 cm quartz cells. – Emission spectra at 77 K were measured in dry ethanol by using quartz sample tubes and the same luminescence accessory (Perkin-Elmer, Norwalk, CT, USA). – All pH measurements were made with an Orion 420A (Cambridge, MA, USA) digital pH meter using a combined glass-calomel electrode.

Synthesis of *N*2-(4-Dimethylaminobenzyl)-*N*1,*N*1-bis[2-(4-dimethylaminobenzylamino)ethyl]ethane-1,2-diamine (TrenDMA$_3$, **3**): 1.53 g (10.27 mmol) of 4-dimethylaminobenzaldehyde were dissolved in toluene (30 mL) and slowly added to a solution of tren (3.42 mmol) in toluene (100 mL). The reaction mixture was heated at 40°C for 24 hours. Solvent was removed under reduced pressure, and the yellow-orange oil (the imine intermediate) was dissolved in MeOH. $NaBH_4$ was carefully added in small portions, and then the reaction mixture was heated at 50°C overnight. The solvent was removed under reduced pressure and the sticky solid obtained was dissolved in 50 mL of water. The aqueous phase was extracted with CH_2Cl_2 (3× 50 mL). The organic phase was dried with $MgSO_4$ and then the solvent was distilled off, obtaining **3** as a yellow-brown oil. Yield: 70%. – MS (70 eV); *m/z* (%): 545 (6) [M^+] – ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.1 (d, J = 9 Hz, 6 H aromatic), 6.6 (d, J = 9 Hz, 6 H aromatic), 3.55 (s, 6 H) 2.8 (s, 18 H), 2.55 (t, J = 6 Hz, 6 H), 2.45 (t, J = 6 Hz, 6 H).

Spectrofluorimetric Titrations: pH titrations were performed on 10^{-4} mol L^{-1} water solutions of **3** adjusted at pH < 2 by adding small amounts of a standard solution of $HClO_4$ (1 or 0.1 mol L^{-1}). Then additions of standard solutions of NaOH (1 or 0.1 mol L^{-1}) were made until a basic pH (> 10) was obtained. Emission spectra

(excitation wavelength 300 nm) were taken after each addition of base. Titrations at buffered pH were carried out in water solutions (40 mL, 10^{-4} mol L^{-1}) . Buffered solutions were obtained with MES (pH 6). $M^{II}(ClO_4)_2$ standard (M = Zn, Cu, Ni) solutions were used and spectra recorded after every addition. Anion titrations were carried out in methanol solutions (40 mL, 10^{-4} mol L^{-1}) of an equimolecular mixture of **3** and $Zn(ClO_4)_2$. Standard solutions in methanol of sodium carboxylate salts were added, and spectra recorded after each addition.

[16] One of the Referees suggested an alternative explanation: in particular, a non-emissive exciplex between the aromatic carboxylate and the excited aminobenzene fragment could form. Such an exciplex would be expected to undergo a fast intersystem crossing due to the carbonyl oxygen lone pairs. This would not be the case for the non-aromatic carboxylates.

Synthesis and Reactivity of Subvalent Compounds, 8[+] Aromatic Phosphenium Cations[§]

Michael K. Denk,*[a] Shilpi Gupta,[a] and Alan J. Lough[a]

Dedicated to Professor Heinrich Nöth on the occasion of his 70th birthday

Keywords: Phosphorus heterocycles / Aromaticity / Phosphenium cations / Ab initio calculations

The aromatic stabilization of cyclic phosphenium cations (general type $C_2N_2P^+$) was studied by experimental methods (synthesis, multinuclear NMR, single crystal X-ray crystallography) and quantum chemical calculations (ab initio methods). The structures of the 1,3,2-diazaphosphole derivatives [(*t*BuN–CH=CH–N*t*Bu)P$^+$]Cl$^-$ (**1**), (*t*BuN–CH_2–CH_2–N*t*Bu)P–Cl (**2**), [(*t*BuN–CH=CH–N*t*Bu)P]$^+$ PF_6^- (**3**) and [(*t*BuN–CH_2–CH_2-N*t*Bu)]P$^+$ PF_6^- (**4**) were examined by single crystal X-ray diffraction. The chloro phosphane [(*t*BuN–CH=CH–N*t*Bu)P]$^+$Cl$^-$ (**1**) has an ionic P–Cl bond and contains an aromatically stabilized phosphenium cation [shortest distance P···Cl = 275.9(2) pm], while the CC-saturated compound (*t*BuN–CH_2–CH_2–N*t*Bu)P–Cl (**2**) is covalent. The two chloro-phosphanes **1** and **2** differ sharply in their volatility and solubility in organic solvents. Compound **2** is soluble in hydrocarbons and sublimes readily at 90 °C/0.1 Torr but **1** is insoluble in hexanes and not volatile below 180 °C/0.1 Torr. The degree of aromatic stabilization in the phosphenium cation **1** was investigated by ab initio methods. For the model cations [RN–CH_2–CH_2–NR]P$^+$ and [(RN–CH=CH–NR)P]$^+$, thermochemical stabilization energies of 25.8 kcal · mol^{-1} (R = H) and 28.1 kcal · mol^{-1} (R = Me) were obtained from isodesmic hydrogenation reactions at the RHF/MP2/6–31G*//RHF/6–31G* level.

Introduction

The aromatic stabilization of inorganic ring systems has seen renewed interest both by synthetic chemists and theoreticians.[1] We are currently involved in a comparative study of aromatically stabilized 1,3-diazole derivatives **A** and their non-aromatic counterparts **B**. The 1,3-diazoles **A** and 1,3-diazolidines **B** seem to have an unsurpassed capability to stabilize the heteroelement E in the coordination number 2.

The first stable carbenes[2] and silylenes[3] were indeed of type **A** and it is likely that other elements will likewise be stabilized in unusually low coordination numbers in systems of type **A** and **B**. Likely candidates for a successful isolation would be heterocycles that are isoelectronic with the stable carbenes and silylenes such as anionic diazoles featuring dicoordinate boron, aluminum, and gallium and cationic diazoles with dicoordinate nitrogen, phosphorus, and arsenic. Apart from the appeal to stabilize elements in unusual valence states, these species would make useful, presumably highly reactive building blocks of carbenoid reactivity.

The comparison of the respective unsaturated species **A** with the saturated counterparts **B** allows the systematic and independent variation for aromaticity and the heteroelement. For some elements, the experimental comparison of **A** and **B** is already possible as these species have been described in the literature. Both stable aromatic (**A**) and non-aromatic representatives (**B**) have been described for E = C,[2] Si,[3] Ge,[4] N^+[5] and P^+[6] and, most recently, As^+.[7a,11b] For the elements of the boron group, the anionic diazoles **A** and **B** would be isoelectronic to the stable carbenes and silylenes but have not been reported to our knowledge.[8]

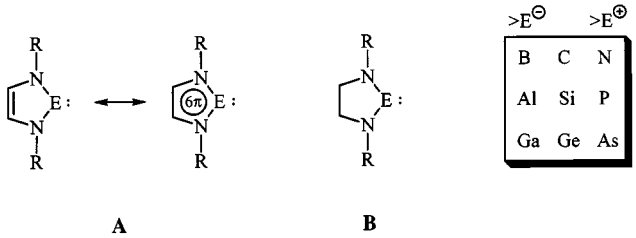

Figure 1. Aromatic 1,3-diazoles (**A**) and non-aromatic 1,3-diazolidines (**B**)

Heterocycles **A** described so far possess properties typically associated with aromatically delocalized compounds. They display unusually deshielded ring protons,[2–5] show decreased alternation in bond lengths[2–5] and exhibit reduced reactivity of **A** vs. **B**.[2–5]

For E = C,[2] Si,[3] Ge,[4] and N^+ [5] the electronic structures of **A** and **B** were investigated by ab initio methods and photoelectron spectroscopy. These studies have demonstrated substantial delocalization of the occupied π-orbitals for **A** and a stabilization of **A** vs. **B** ranging from 13 kcal·mol^{-1} for E = Ge[1] to as high as 38 kcal·mol^{-1} for E = N^+.[5] A summary of the different criteria used to

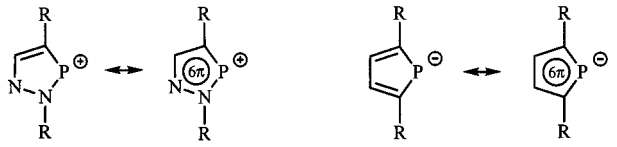
evaluate delocalization and aromaticity is available for the carbenes and silylenes.[9] Most recently, a core electron spectroscopy study by Hitchcock's group has demonstrated that the π*-orbitals of the aromatic silylenes are delocalized as well.[3e]

We have previously studied the synthesis, structure, and bonding of a series of isostructural stable carbenes,[2c] silylenes[3] and germylenes,[4] and now report on the synthesis, structure, and aromatic stabilization of the isostructural phosphenium cations **A** and **B** (R = *t*Bu in all cases).[10]

1b **1** **3** **3'**



2 **4** **4'**

Figure 2. Aromatic and non aromatic phosphenium cations and chlorophosphanes and isoelectronic stable silylenes

The compounds investigated were the chlorophosphanes $[L'P]^+Cl^-$ (**1**), LP−Cl (**2**), and the stable phosphenium salts $[L'P]^+PF_6^-$ (**3**), $[LP]^+PF_6^-$ (**4**), $[L'P]^+GaCl_4^-$ (**5**), and $[LP]^+GaCl_4^-$ (**6**). Our study was triggered by the remarkably different physical properties of **1** and **2**: the chlorophosphane **2** is soluble in benzene and hexanes but **1** is insoluble in hexanes and only sparingly soluble in benzene.[11] Compound **2** is quite volatile and sublimes readily at 80°C/0.1 Torr while **1** is not volatile under these conditions. This different behavior led us to conclude that **1** is an ionic compound composed of a phosphenium cation and a chloride counterion while **2** is a covalent compound (Figure 2).[11] The crucial role of aromatic delocalization for the stabilization of **1** in its ionic form is obvious.

The related compound **1b** had previously been obtained by a special method namely in a one step synthesis from PCl_3 and the corresponding diazadiene R−N=CH−CH=N−R (R = *cyclo*-hexyl).[6b] While the authors noticed the long P−Cl bond length of 241.6(2) pm, they fell short of describing the compound as ionic or of relating the elongated P−Cl bond to the aromatic stabilization of the corresponding phosphenium cation. Instead, the elongation was attributed to electron donation from the two nitrogen lone pairs into the P−Cl σ*-orbital. No attempt was made to compare **1b** with the corresponding CC-saturated derivative.

As our comparison of **1** and **2** shows, the postulated donation of electron density from the nitrogen lone pairs to the P−Cl σ*-orbital alone is insufficient to induce the ionicity of **2**.

C **D**

Figure 3. Aromatic 1,3 and 1,2-diazaphospholes

Remarkably, the isomeric 2,3-diaza-*P*-chlorophospholes **C** were recognized as ionic on the basis of their physical and spectral properties by Schmidpeter et al.[12] and the ionicity of the P−Cl bond was attributed to the formation of an aromatic phosphenium cation 6π system.[12] The anionic phospholes **D** that were recently obtained by the Mathey's group were also described as delocalized, aromatic 6π systems.[13]

Synthesis and Stability

The chlorophosphane **2** was first described by Wrackmeyer et al. who also investigated the formation of the corresponding tetrachloroaluminate from **2** and $AlCl_3$ by spectroscopic methods.[6] Compound **1** has been obtained by us via metathesis of the corresponding diazasilole with PCl_3[11a] and had not been reported prior to our studies. The structures of **1** and **2** were reported by Carmalt et al. while this study was in progress.[11b]

The goal of this study was a detailed comparison of the chlorophosphanes **1** and **2** with the corresponding phosphenium cations. Our attempts to use $AlCl_3$ as chloride abstractor for **1** led to side reactions and were not pursued further. The use of $GaCl_3$ as chloride abstractor often gives cleaner reactions;[14] the tetrachlorogallates $[(tBuN-CH=CH-NtBu)P]^+GaCl_4^-$ (**5**)[11a] and $[(tBuN-CH_2-CH_2-NtBu)]P^+GaCl_4^-$ (**6**)[11a] were obtained from **1** and **2** without further complications. However, extensive disordering in the cation and anion sublattices precluded the determination of accurate structural data by single crystal X-ray diffraction and led us to search for new counterions. Accurate structural data were finally obtained for the hexafluorophosphates **3** and **4**. The hexafluorophosphates are easily obtained from **1** and **2** by metathesis with $AgPF_6$ in CH_2Cl_2 as colorless crystalline solids in quantitative yield.

The PF_6 and $GaCl_4$ salts **3**−**6** are quite soluble in dichloromethane and are easily purified by precipitation (layering) of the crude reaction solutions with hexanes. The salts **3**−**6** can be stored indefinitely under exclusion of air and moisture but the stability of the salts in solution depends critically on the nature of the counterion and the solvent. The PF_6 anion in the salts **3** and **4** slowly reacts with glass to form $PO_2F_2^-$ (and SiF_4) unless moisture is rigorously excluded. The reaction is easily detected by the presence of the characteristic triplet of $PO_2F_2^-$ ($\delta^{31}P = -14.7$, $^1J(P,F) = 976$ Hz).[15] Remarkably, the phosphenium cation is unaffected by this decomposition process. The reaction of PF_6^- with glass is catalyzed by water as was

recently shown by Manzano and Otero.[15] In $CDCl_3$ solution, **3** is stable indefinitely but **4** decomposes rapidly. This difference nicely illustrates the higher reactivity (lack of aromatic stabilization) of **4**. Both phosphenium cations are significantly stabilized by the counterion $GaCl_4^-$: **5** and **6** are stable indefinitely in CD_2Cl_2 and $CDCl_3$.

Structure and Bonding

The assumption that **1** is a purely ionic compound implies a nonbonding P−Cl distance and the presence of a phosphenium cation $[(t\text{BuN}-\text{CH}=\text{CH}-\text{N}t\text{Bu})\text{P}]^+$ in the crystal lattice. To justify this assumption, a detailed comparison of the chlorophosphanes **1** and **2** with each other and also with the corresponding phosphenium cations was necessary. The structure of **1** and, for comparison, the structures of **2**−**4** were determined by single crystal X-ray crystallography.[16]

While this study was in progress, the structures of **1** and **2** were reported by Carmalt et al.[11b] For **2**, our metrical parameters differ significantly form the values reported by Carmalt et al. (see below). This is especially obvious for the P−Cl bond distance: 231.36(7) pm in this study vs. Carmalt's value of 242.5(4) pm.[11b] The value of 143(1) pm reported by Carmalt for the C−C single bond in **2** is likewise too short and results probably from an unrecognized disorder of the (nonplanar) C_2N_2P ring. The superposition of two envelope structures can present itself as structure with planar C_2N_2E geometry and artificially shortened C−C bond length resulting from projections of the true bond distances. This type of disorder is easily recognized by unusually large thermal ellipsoids for the two carbon atoms and has been described previously by us for the isoelectronic germylene.[4] The value of 150.8(3) pm that we find for the C−C distance in **2** includes a modeling of disorder of the C_2-bridge and is also in much better agreement with the ab initio structures (Table 4). Accordingly, the values of our single crystal X-ray diffraction study will be used for the remainder of this study. The P−Cl distance in **1** [275.9(2) pm] is substantially longer than in **2** [231.36(7) pm]. Both P−Cl distances are shorter than the sum of the van-der-Waals radii[18] of phosphorus (190 pm) and chlorine (181 pm). With P−Cl bond lengths of ≈ 210 pm being typical for the fragment N_2P-Cl[19], even the P−Cl bond in **2** [231.36(7) pm] must be considered as unusually elongated. A comparison of the structures of **1** and **2** with the respective genuine phosphenium (type **A** and **B**) was clearly desirable and the structures of the PF_6 salts **3** and **4** were studied to this end.

In the hexafluorophosphates **3** and **4**, the closest distance between the phosphorus in the phosphenium cation and the fluorine atom of the counterion is nonbonding (322 pm for **3**, 323 pm for **4**). The values are nearly identical to the sum of van-der-Waals radii for phosphorus (190 pm)[18] and fluorine (135 pm)[18] and confirm that **3** and **4** are ionic compounds. Further proof that **3** and **4** do indeed contain phosphenium cations that are unperturbed by the counterion is

Figure 4. Puckered C_2N_2P-ring.

the excellent agreement between their molecular structures and those calculated (6−31G* level) for the free phosphenium cations (compare Tables 4 and 5).

The experimental structures of **3** and **4** can now be used as a yardstick to measure the phosphenium cation character of **1** and **2**. The structures of the diazaphosphole rings in **1** and **3** are practically identical. This confirm that **1** is indeed a phosphenium chloride.

The structures of **2** and **4** on the other hand show distinct differences: The P−N bond lengths are significantly shorter in **4** [161.3(2) and 161.9(2) pm] than in **2** [165.2(2) pm and 165.6(2) pm] and the N−P−N angle in **4** [96.29(11)°] is larger than in **2** [92.41(8)°]. A more detailed comparison of other structural parameters reveals that the P−N bond distance is the most sensitive structural probe to measure the phosphenium cation character in **4**.

The P−N bond length in the aromatic **3** [166.1(2) pm] is significantly longer than in **4** [161.9(2) pm]. This somewhat counterintuitive result supports the description of **3** as delocalized system: the isolated allylic N_2P fragment (in **4**)

Figure 6. should experience increased delocalization and accordingly elongation of the P−N bond upon delocalization (in **3**). The nature of the phenomenon is perhaps best understood in an analogy pointed out by Sauers.[20] The C−C bond length in the cyclopentadienyl anion (141 pm) is longer than in the allyl anion (139 pm). The presence and magnitude of the effect is further evidence for a strong π-delocalization in **3**.

stable silylenes should reveal the relative extent of aromatic stabilization in the silylenes and phosphenium cations. Table 2 compares bond distances and bond angles of the phosphenium hexafluorophosphates **3** and **4** with those of the isostructural silylenes **3′** and **4′**. The P−N distances in the phosphenium cations are ca. 4 pm shorter than one would extrapolate from the Si−N distances of the silylenes and the covalent radii of Silicon and Phosphorus.[18] This is in agreement with stronger π-bonding in the N_2P^+−allyl system compared with the N_2Si−allyl system. With the exception of the element-nitrogen bond distance, the geometries of **4** and **4′** are nearly identical.

[a] Sum of nitrogen bond angles.

The relative extent of aromatic delocalization in the two aromatic species **3** and **3′** should be reflected by the difference between formal single bonds (C−N) and formal double bonds (C=C). The C−C double bond length of the silylene **3′** [134.7(21) pm] and the phosphenium cation **3** [134.1(4) pm] are nearly identical. The C−N bond length in **3** is shortened (−2.4 pm) vs. **3′**. This shortening of a formal C−N single bond, although not dramatic, is consistent with the conclusion that phosphenium cations of type **A** possess stronger aromatic delocalization than the isoelectronic silylenes. This is also in agreement with the chemical shifts of the respective ring protons and the results of ab initio calculations (see below).

Spectroscopy

NMR investigations of **1**−**6** were concerned with ring current effects[22] and the question to what extent the phosphenium cation character of **1** and **2** is reflected by the respective ^{31}P-NMR shifts. The hexafluorophosphates **3** and **4** with a fully developed phosphenium cation were used as ionic reference compounds. The phosphenium salts **1**, **3**, and **4** show the deshielded ^{31}P-NMR resonances of phosphenium cations but appear electron rich if compared with other phosphenium cations.[21] This documents the excellent dative stabilization of **1**, **3**, and **4**. The chemical shifts vary strongly with the solvent and to a lesser degree with concentration. All measurements were therefore standardized by measuring 1 M solutions at room temperature. This standardization is essential to reveal how the solvent and the counterion influence the ^{31}P-chemical shifts.

For **1**, polar solvents lead to strong deshielding of the ^{31}P signal. In CD_2Cl_2 and $CDCl_3$, the chemical shift of the phosphorus atom approaches the value found for the fully developed phosphenium cation in **3**. We interpret this solvatochromic behavior as a result of a solvent dependent polarization of the P···Cl contact in **1**. In the case of **1**, this polarization leads to a gradual increase of aromatic delocalization that can be monitored by ^{1}H NMR (deshielding of the ring protons by the ring current).[22] The extent of aromatic delocalization in **1** can thus be fine-tuned by using solvent mixtures. For example, the chemical shift δ^1H of the ring protons in **1** can be varied freely between 6.38 and 7.32 by using different mixtures of C_6D_6 and $CDCl_3$.

In $CDCl_3$, the chemical shift of the ring protons in **1** (δ = 7.32) approaches the value of the phosphenium salt **3** (δ = 7.66). This is good evidence that the P−Cl bond of **1** is dissociated in $CDCl_3$. Fully as expected, the most polar solvent used in this study ($CDCl_3$) leads to the most deshielded ^{31}P-NMR shifts for **1**−**6**. However, the salt $[L'P]^+PF_6^-$ (**3**) does not follow this trend. We tentatively attribute this deviation to the onset of a covalent interaction between the chlorine lone pair of chloroform and the phosphorus atom in **3**.

The chemical shifts ^{31}P and ^{1}H also depend on the nature of the counterion. This suggests that even the electronically highly stabilized phosphenium cations investigated in this study interact with the "non coordinating"[23] counterions $GaCl_4^-$ and PF_6^-.

The non-aromatic series of compounds (**2**, **4**, and **6**) displays the same type of solvatochromic behavior as the aromatic series **1**, **3**, and **5**, but the solvent induced shift variation is smaller.

The outlined solvatochromic behavior is presumably indicative for the tendency of a chlorophosphane to ionize to the corresponding phosphenium cation. Compounds like PCl_3 that do not give rise to well stabilized phosphenium cations do not display the same solvatochromic behavior. It seems likely, that the observed solvatochromic behavior extends to other chlorophosphanes $(Do)_2P-Cl$ with π-donor substituents Do. Further studies on the subject are in progress.

A comparison of NMR data for $[L'P]^+$ and the isostructural silylene and germylene is limited by the difficulties to find a common solvent. The PF_6 salts **3** and **4** are insoluble in C_6D_6 while the silylenes and germylenes are decomposed instantaneously by CD_2Cl_2 and $CDCl_3$.[24] If the partially developed phosphenium cation present in **1** is used instead of the fully developed phosphenium cation present in **3**, the chemical shifts of the ring protons follow the trend of thermochemical aromaticity obtained from ab initio calculations (see below):

$$L'Si < L'Ge < L'P^+$$

The solution NMR data of compound **2** do not match the symmetry of **2** in the solid state. In the crystal, the phosphorus atom in **2** is coordinated in a pseudo-tetrahedral environment. The protons of the ethylene bridge should fall into two distinct classes (*syn* and *anti* relative to the P−Cl bond) and a AA′BB′ spin system[25] should result. In $CDCl_3$ and CD_2Cl_2, the ^{1}H-NMR spectrum of **2** shows equivalent ring protons split into a well resolved doublet by ^3J coupling to the phosphorus atom. In the less polar C_6D_6, the signal of the ring protons is broadened and the ^3J coupling to the phosphorus atoms is lost. The apparent equivalence of the ring protons results from a dynamic process that is sensitive to the polarity of the solvent. A reversible dissociation of the chlorophosphane LP−Cl (**2**) into the (planar) $[LP]^+$ and Cl^- would allow the reattachment of the chloride from either sides of the planar N_2P^+ fragment. The result of this process is equivalent to an inversion at the phosphorus atom. Inversion of the phosphorus lone pair is hard to reconcile with the observed solvent effects.

Table 3. Solvatochromic behavior (δ^{31}P, δ^1H) of chloro phosphanes (**1**, **2**) and phosphenium cations (**3**− **6**). All shifts in ppm vs. TMS (^{1}H) or 85% H_3PO_4 (^{31}P).

Computational Studies

The relative degree of aromatic delocalization can be quantified by thermochemical cycles. As experimental values are not easily available for novel aromatic systems, computational approaches play an important role.

We have previously used *isodesmic* hydrogenation reactions to establish the relative stability of silylenes[3a] and germylenes[4] and now extend this approach to the isoelectronic phosphenium cations **3** and **4**.[29] Equations **a**−**d** involve the hydrogenation of the CC double bond and were chosen to investigate the degree of aromatic delocalization by testing the thermodynamic stabilities of the model compounds **7**−**10**. The *t*Bu substituent in **3** and **4** was replaced with R = H (model compounds **7H**−**10H**) or R = Me (**7Me**−**10Me**). The phosphonium cations $R_2PH_2^+$ (**9 H, 10 H, 9Me** and **10Me**) were chosen as non-aromatic reference compounds (disrupted π-delocalization). The specific combination of basis set, correlation method and isodesmic reactions used in this study is identical to the one we used to evaluate the aromatic stabilization of germylenes and silylenes. This allows a direct comparison of the calculated aromatic stabilization energies. Compounds **A** and **B** usually require bulky alkyl- or aryl substituents to be stable enough for isolation. To save computation time, these substituents are usually replaced with hydrogen in ab initio studies. We were interested to see how legitimate the replacement of alkyl substituents with hydrogen really is and thus have included the methyl compounds **7Me**−**10Me** in this study. While this study was in progress, the model compounds **7H** and **8H** were investigated by Sauers with a different basis set and a different set of isodesmic reactions.[20]

Aromatic stabilization energies (ASEs) for **7H** and **7Me** were obtained from the difference of the hydrogenation reactions **a** and **b** (|**a** − **b**| = ASE of **7H**) and **c** and **d** (|**c** − **d**| = ASE of **7Me**). It should be pointed out that an alternative system of isodesmic hydrogenation reactions (**e**−**h**) can be constructed from the oxidative addition of hydrogen to the phosphorus atom of the phosphenium cations **7** and **8** to give **9** and **10** respectively (Figure 8). Although the reaction energies for the equations **e**−**f** are different from those of the equations **a**−**d**, the aromatic stabilization energies obtained from both sets of equations are mathematically equivalent.[29b]

The results show a significant electronic stabilization of the unsaturated phosphenium cations **7H** and **7Me**. The methyl substituted phosphenium cation **7Me** possesses a slightly higher ASE (26.40 kcal·mol^{-1}) than the hydrogen derivative **7H** (25.73 kcal·mol^{-1}), a difference that is not only small but also well within the limits of the method. The use of the hydrogen substituted model compounds is thus fully adequate for the calculation of aromatic stabili-

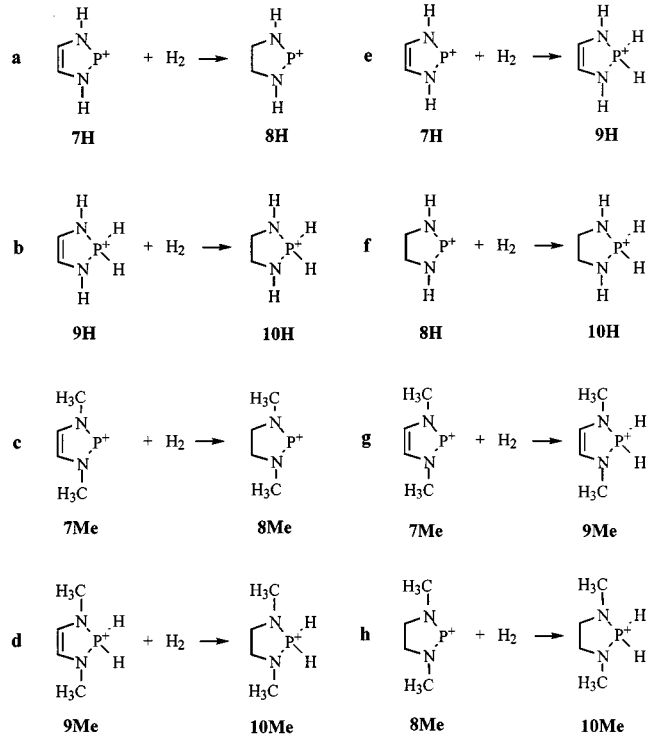

Figure 8. Isodesmic hydrogenation reactions of model compounds **7H, 9H, 7Me** and **9Me**

zation energies for the phosphenium cations and presumably for other related compounds as well.

Electron correlation at the MP2 level increases the calculated ASE values by ca. 40%. This is a good indication that the calculated ASE values represent strong differences in the degree of delocalization. Calculations at the MP4 level were restricted to the hydrogen substituted model compounds. At the MP4/6−31G*//HF/6−31G* level, a slight decrease in the ASE is observed (22.97 kcal·mol^{-1} instead of 25.73).

Table 6. Calculated reaction energies (at 0 K) for the isodesmic equations **a**−**h** and aromatic stabilization energies (ASE, **a**−**b** and **c**−**d**) in kcal·mol^{-1}

	6−31G*	MP2 / 6−31G*	MP4 / 6−31G*

h	−3.19	+11.61	−
|**a** − **b**|	18.02	25.73	22.97
|**c** − **d**|	20.11	26.44	−

The aromatic stabilization energies obtained from isodesmic equations like **a**−**d** and **e**−**h** require the construction of non-aromatic model compounds. Sauers has chosen the phosphines R_2P-H instead of the cationic species $R_2PH_2^+$ used in this study and obtained aromatic stabilization energies that are slightly smaller (24.0 kcal mol^{-1})[20] than the ones obtained from our approach.

The single crystal X-ray data obtained for **3** and **4** are in excellent agreement with the computational 6−31G* structures of the model compounds **7 H, 7Me**, **8 H,** and **8Me**. Not surprisingly, the structural agreement is slightly better (especially for the N−P−N bond angles) if methyl groups are placed on the nitrogen atoms (model compounds **7Me** and **8Me**).

Conclusion

In a series of isostructural, aromatic diamino-silylenes, -germylenes, and phosphenium cations, the phosphenium cations display the highest degree of aromatic delocalization on the basis of three independent criteria: alternation of bond lengths (least), deshielding of ring protons (most), and aromatic delocalization energy (most). The experimental structures of the phosphenium cations are reproduced with excellent agreement by ab initio calculations at the 6−31G* level. The NMR shifts of the investigated phosphenium salts are strongly dependent on the polarity of the solvent.

Experimental Section

All operations were carried out with usual Schlenk techniques under Argon (99.996) or in a nitrogen filled glove box (Braun, O_2 < 2 ppm H_2O < 2 ppm). Solvents were purified by distillation from purple benzophenone/potassium solutions (hexanes, benzene) or by 30 minutes of sonication with CaH_2 followed by deoxygenation with three freeze-pump-thaw cycles (deuterated solvents, CH_2Cl_2). $AgPF_6$ (Aldrich) and $GaCl_3$ (Alfa) were used as received and handled in an inert gas glovebox. All NMR measurements were performed with ca. 1 M solutions in flame-sealed sample tubes at room temperature. The chemical shifts δ are reported in ppm vs. 85% H_3PO_4 (^{31}P, external) or TMS (^1H, ^{13}C, internal). Capillaries of 85% H_3PO_4 in D_2O were used as internal reference for the ^{31}P-NMR measurements. Positive shift values represent deshielding relative to the standard. The NMR samples were observed over a period of 4 months for signs of decomposition. Satisfactory elemental analysis (C,H,N) were obtained for **1**−**4**. Single crystals were grown by slow sublimation (**1**, **2**) or by layering of half-saturated CH_2Cl_2 solutions with hexanes (**3**, **4**). Compounds **1** and **2** were obtained as described previously.[11]

Synthesis of 3/4: To a stirred solution of 1 mmol of the chlorophosphane (234 mg, **1** or 236 mg, **2**) dissolved in 20 mL of dichloromethane was added a solution of 1 mmol of $AgPF_6$ (253 mg) dissolved in 20 mL of dichloromethane dropwise and under exclusion of light. The mixture was stirred for 1 h, decanted from the precipitate (AgCl) with a syringe, the total volume reduced to 20 mL and the remaining solution layered with 20 mL of hexanes. The hexafluorophosphates **3/4** crystallized as analytically pure, colorless crystals and were isolated by filtration through a medium size frit and washing with 10 mL of hexanes. Yields: 95−100%. The analytically pure tetrachlorogallates **5/6** were obtained in analogous fashion from **1/2** (10 mmol) by treating with $GaCl_3$ (10 mmol 10% in benzene). The solvent was evaporated, the residue dissolved in 20 mL of CH_2Cl_2 and the resulting solution layered with 20 mL of hexanes, yields 90−95%.

The salts **3**−**6** can be stored indefinitely under exclusion of air and moisture. Single crystals for X-ray crystallography were grown by

recrystallization from boiling benzene (**1**), slow sublimation (**2**) or by layering of CH_2Cl_2 solutions with hexanes (**3**−**6**).

Spectroscopic Data

1: ^{1}H NMR (CD_2Cl_2): δ = 1.63 [d, ^4J(P,H) = 1.8 Hz, 18 H, CH_3], 6.97 [d, ^3J(P,H) = 1.5 Hz, 2 H, C*H*]. − ^{13}C NMR: δ = 30.41 [d, ^3J(C,P) = 10.3 Hz, *C*H$_3$], 57.83 [d, ^2J(C,P) = 7.4 Hz, *C*Me$_3$], 121.34 [d, ^2J(C,P) = 8.8 Hz, =*C*H]. − ^{31}P NMR (CD_2Cl_2): δ = 168.6 (s, br). − IR (Nujol, CsI, cm^{-1}): $\tilde{\nu}$ = 1201 s, 1079 s, 1020 m, 842 m, 790 m, 723 vs, 535 m. − **2**: ^{1}H NMR (CD_2Cl_2): δ = 1.39 [d, ^4J(P,H) = 1.8 Hz, 18 H, CH_3], 3.37 [d, ^3J(P,H) = 6.6 Hz, 4 H, CH_2]. − ^{13}C NMR (CD_2Cl_2): δ = 28.97 [d, ^3J(C,P) = 11.7 Hz, *C*H$_3$], 45.78 [^2J(C,P) = 10.2 Hz, *C*H$_2$*C*H$_2$], 54.10 [^2J(C,P) = 11 Hz, *C*Me$_3$]. − ^{31}P NMR (CD_2Cl_2): δ = 166.8 (s, br). − IR (Nujol, CsI, cm^{-1}): $\tilde{\nu}$ = 1222 s, 1209 s, 1125 m, 1089 w, 1041 s, 983 m, 863 m, 802 m, 723 w, 677 s, 666 s. − **3**: ^{1}H NMR (CD_2Cl_2): δ = 1.78 [d, ^4J(P,H) = 1.9 Hz, 18 H, CH_3], 8.08 (s, 2 H, =C*H*). − ^{13}C NMR (CD_2Cl_2): δ = 31.48 [d, ^3J(C,P) = 8.8 Hz, *C*H$_3$], 53.59 [d, ^2J(C,P) = 27.1 Hz, *C*Me$_3$], 132.96 [d, ^2J(C,P) = 2.9 Hz, =*C*H]. − ^{31}P NMR (CD_2Cl_2): δ = 202.3 (s, br, N_2P^+), −144.6 [hept, ^1J(P,F) = 711.1 Hz, PF_6^-]. The phosphorus chemical shift for PF_6^- is in good agreement with published values (δ = 142.1, ^1J = 717 Hz).[15] − IR (Nujol, CsI, cm^{-1}): $\tilde{\nu}$ = 1304 m, 1261 m, 1205 w, 1192 w, 1148 m, 1075 m, 1020 m, 830 vs, 803 m, 738 w, 723 m, 558 s, 476 w. − **4**: ^{1}H NMR (CD_2Cl_2): δ = 1.58 [d, ^4J(P,H) = 2.2 Hz, 18 H, CH_3], 4.10 [d, ^3J(P,H) = 4.5 Hz, 4 H, CH_2]. − ^{13}C NMR (CD_2Cl_2): δ = 29.68 [d,^3J(P,C) = 9.5 Hz, *C*H$_3$], 48.61 [d, ^2J(P,C) = 8.8 Hz, *C*H$_2$], 53.60 [d, ^2J(P,C) = 27.0 Hz, *C*Me$_3$]. − ^{31}P NMR (CD_2Cl_2): δ = +262.3 (s, br, N_2P^+), −144.6 [hept, ^1J(P,F) = 711.1 Hz, PF_6^-]. The phosphorus chemical shift for PF_6^- is in agreement with published values (δ = 142.1, ^1J = 717 Hz).[15] − IR (Nujol, CsI, cm^{-1}): $\tilde{\nu}$ = 1299 w, 1282 w, 1261 m, 1194 s, 1158 m, 1144 m, 1121 m, 1093 w, 1037 s, 1012 m, 986 w, 934 w, 876 m, 835 vs, 740 m, 723 s, 670 w, 558 vs.

Acknowledgments

We thank the National Science Engineering and Research Council of Canada (NSERC) for support of this work through an operating grant and Spaceoptix Inc. (Toronto) and the Connaught Foundation of the University of Toronto for additional support. The thoughtful comments of Dr. Ian Still and Dr. Juris Strautmanis during the preparation of this manuscript and Dr. Alfred Schmidpeter while this work was still in progress are gratefully acknowledged. We thank Prof. R. West and Dr. S. Powell for the crystallographic investigation of **1** and **2** in the University of Wisconsin Crystallography Laboratory (supported by the National Science Foundation (NSF) through grant CHE-9105497).

[16] Crystal data for $[L'P]^+Cl^-$ (**1**): The compound crystallizes with 0.5 equivalents of benzene, $C_{10}H_{20}ClN_2P \bullet 0.5\ C_6H_6$, M = 273.75, crystal size = 0.5 × 0.4 × 0.2 monoclinic, space group $P2_1/n$, a = 11.056(2), b = 11.244(2), c = 13.512(2) Å, ß = 113.872(13)°, V = 1536.0(5) Å^3, Z = 4, $d_{calc.}$ = 1.184 g·cm^{-3}, λ(Mo-K_α) = 0.71073 Å, μ(Mo-K_α) = 0.336 mm^{-1}, F(000) = 588, scan type 2θ−θ, T = 113(2) K, 2.02 < 2θ < 22.50°, total unique data 2000 (R_i = 0.039), no. of observations [(F) > 4σ(F)] 4223, R = 0.034, R_w = 0.071, maximum peak in final Fourier difference synthesis 0.232 eÅ^{-3}. − Crystal data for LPCl (**2**): $C_{10}H_{22}ClN_2P$, M = 236.72, crystal size = 0.5 × 0.4 × 0.2 orthorhombic, space group $Pbca$, a = 11.8843(8), b = 11.118(2), c = 19.899(2) Å, V = 2629.2(6) Å^3, Z = 8, $d_{calc.}$ = 1.196 g·cm^{-3}, λ(Mo-K_α) = 0.71073 Å, μ(Mo-K_α) = 0.382 mm^{-1}, F(000) = 1024, scan type 2θ−θ, T = 113(2) K, 2.02 < 2θ < 22.49 °, total unique data 1719 (R_i = 0.026), no. of observations [(F) > 4σ(F)] 3434, R = 0.027, R_w = 0.065, maximum peak in final Fourier difference synthesis −0.184 eÅ^{-3}. − Crystal data for $[L'P]^+[PF_6]^-$ (**3**): $C_{10}H_{20}F_6N_2P_2$, M = 344.22, crystal size = 0.35 × 0.45 × 0.35 orthorhombic, space group $Pnma$, a = 12.149(2), b = 8.3440(9), c = 15.431(3) Å, V = 1564.2(4) Å^3, Z = 4, $d_{calc.}$ = 1.462 g·cm^{-3}, λ(Mo-K_α) = 0.71073 Å, μ(Mo-K_α) = 0.331 mm^{-1}, F(000) = 712, scan type 2θ-θ, T = 168(2) K, 5.28 < 2θ < 59.98°, total unique data 2422 (R_i = 0.0000%), no. of observations [(F) > 4σ(F)] 1618, R = 0.045, R_w = 0.071, maximum peak in final Fourier difference synthesis 0.535 eÅ^{-3}. − Crystal data for $[LP]^+[PF_6]^-$ (**4**): $C_{10}H_{22}F_6N_2P_2$, M = 346.24, crystal size = 0.32 × 0.27 × 0.19 orthorhombic, space group $Pnma$, a = 11.6987(11), b = 8.349(2), c = 16.1957(12) Å, V = 1581.8(4) Å^3, Z = 4, $d_{calc.}$ = 1.454 g·cm^{-3}, λ(Mo-K_α) = 0.71073 Å, μ(Mo-K_α) = 0.328 mm^{-1}, F(000) = 720, scan type 2θ−θ, T = 173(2) K, 5.04 < 2θ < 60.00°, total unique data 2454 (R_i = 0.0000), no. of observations [(F) > 4σ(F)] 1656, R = 0.0495, R_w = 0.1325, maximum peak in final Fourier difference synthesis 0.513 eÅ^{-3}. Data were collected on a *Siemens P4* diffractometer. No absorption correction was applied. Lorentz and polarization corrections were applied. Systematically absent reflexions were rejected and equivalent reflexions were merged. The heavy-atom positions were determined by direct methods. Subsequent difference Fourier synthesis revealed the positions of all other non-hydrogen atoms, organic hydrogen atoms were put into idealized position. The non-hydrogen atoms were refined by the full-matrix least-squares method with the hydrogen atoms "riding" on their supporting carbon atoms. A weighting scheme ($w^{-1} = \sigma^2(F) + 0.001 \cdot F^2$) was applied and the data were corrected for the effects of anomalous dispersion and secondary extinction. Crystallographic calculations were carried out using the *Siemens SHELXS-86* program[17a] on a *Silicon Graphics Indigo2* system in the *Chemical Crystallography Laboratory, University of Wisconsin, Madison*, USA (compounds **1** and **2**) or with the SHELXTL/PC[17b] program, version 5.1, on a Pentium 133 PC in the *Chemical Crystallography Laboratory, University of Toronto*, Canada (compounds **3**−**6**).

[29] [29a] Equilibrium geometries were calculated with *Cerius*$^{2™}$[26] using *Gaussian 94*.[27] Calculations were performed without symmetry restrictions. The structures were calculated at the 6−31G* level[28] and the absence of virtual frequencies for the optimized geometries was confirmed by frequency analysis at this level. Zero-point energies were calculated at the 6−31G* level and multiplied by 0.89 to correct for anharmonicity.[28] Relative energies at 0 K were obtained by adding the corrected zero-point vibrational energies to the electronic energies. Final electronic energies were obtained by single-point calculations including electron correlation at the MP2 level in the 6−31G* basis set with the optimized RHF/6−31-G* geometries (RHF/MP2/6−31G*//RHF/6−31G*). The energies were converted to kcal·mol^{-1} using the factor 1 Hartree = 627.59 kcal·mol^{-1}. − [29b] e.g.: **a** − **b** = (**7H** + H_2 − **8H**) − (**9H** + H_2 − **10H**) = (**7H** + H_2 − **9H**) − (**8H** + H_2 − **10H**) = **e** − **f**.

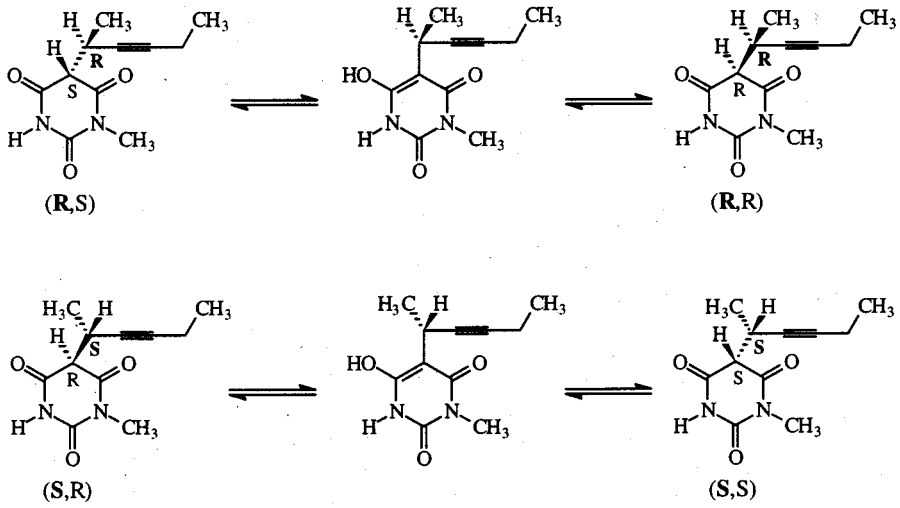
Synthesis of the Stereoisomers of Methohexital by Palladium-Catalyzed Allylation

Henri Brunner,*[a] Irmgard Deml,[a] Wolfgang Dirnberger,[a] Karl-Peter Ittner,[b] Walter Reißer,[a] and Markus Zimmermann[b]

Dedicated to Professor Bernt Krebs on the occasion of his 60th birthday

Keywords: Asymmetric catalysis / Allylic alkylation / 1-Methyl-5-(1′-methylpent-2′-ynyl)barbituric acid / Palladium catalysts / Chiral phosphane imine ligands / Methohexital / Anesthetic dose

Allylation of 1-methyl-5-(1′-methylpent-2′-ynyl)barbituric acid (MBS) with allyl acetate using in situ catalysts of palladium(II) acetylacetonate and chiral phosphane imine ligands resulted in the enantioselective formation of 5-allyl-1-methyl-5-(1′-methylpent-2′-ynyl)barbituric acid (Methohexital), an important anesthetic drug. Both, MBS and Methohexital contain two stereogenic carbon atoms. In MBS, the asymmetric centre in the barbiturate system is labile due to enolization. The asymmetric centre in the hexyne side chain is stable and racemic. The two asymmetric centres of Methohexital are stable and give rise to four stereoisomers, two diastereomeric racemates. An analysis of the isomers of MBS and Methohexital was established on the basis of ^{1}H NMR and, in particular, GC including a base-line separation of the four stereoisomers of Methohexital. The stereoselectivity of the allylation is difficult to control, because the new quaternary asymmetric centre in the barbiturate ring of Methohexital is formed within the nucleophile, attacking the η^3-allyl ligand of the catalyst from the side opposite to the palladium atom. Classical optically active ligands, such as diop or norphos, give only 2–6 % ee. Chiral phosphane imine ligands are a successful class of compounds, synthesized by Schiff base condensation of (2-formylphenyl)diphenylphosphane with optically active primary amines. The most efficient ligands have a hydroxymethyl and a bulky alkyl substituent at the asymmetric centre in the imine part, e.g. the L-*iso*-leucinol and the L-*tert*-leucinol derivatives **5** and **7**. In the Pd-catalyzed allylation of MBS a kinetic resolution and the effect of the enantioselective catalyst interplay, the contributions of which are separated. For MBS the best stereoselectivity factor of the kinetic resolution $s = k_R/k_S$ was 2.6 and 83 % "ee" were achieved. The corresponding values for Methohexital were $s = 3.5$ and 80 % ee in the α-*dl* pair. For 10 mixtures of Methohexital stereoisomers the anesthetic doses for rats were determined. With 9.1 mg/kg body weight of the animal the sample obtained from the catalysis with the D-α-phenylglycinol derivative **8** gave a much lower anesthetic dose than the widely used narcotic Brevimytal®Natrium, the sodium salt of the α-*dl* racemate of Methohexital, with 13.0 mg/kg body weight.



Introduction

Recently, we reported on the application of the enantioselective palladium-catalyzed allylic alkylation in the chemistry of barbituric acid derivatives.[2] The starting material 1,5-dimethylbarbituric acid could be converted into the product 5-allyl-1,5-dimethylbarbituric acid in an enantiomeric excess of up to 34% ee by variation of the bases and the optically active ligands.[2–4] In the present paper we transferred the experiences gained in the enantioselective allylation of the model system 1,5-dimethylbarbituric acid to the synthesis of 5-allyl-1-methyl-5-(1′-methylpent-2′-ynyl)-barbituric acid (Methohexital). Methohexital is a pharmaceutically important short-time anesthetic (Eli Lilly).[5–7] For a narcosis on an average 150 mg of substance are needed per person.[8,9] The sodium salt of the α-*dl* racemate of Methohexital is commercially available (trade name Brevimytal®Natrium).[5–11] Besides the allylic group there is a 1′-methylpent-2′-ynyl substituent in 5-position of the barbituric acid skeleton. Therefore, two asymmetric centres result, one in 5-position of the barbiturate system and one in 2′-position of the hexyne side chain. Consequently, there are four stereoisomers, two diastereomeric racemates (*R*,*R*)/(*S*,*S*) and (*R*,*S*)/(*S*,*R*). Gibson and Doran found different narcotic effects for the four stereoisomers.[12,13] The individual enantiomers can be obtained by regiospecific condensation of the enantiomers with respect to the 1′-methylpent-2′-ynyl side chain and subsequent diastereomer separation.[13] The advantage of a synthesis of Methohexital by Pd-catalyzed allylic alkylation is the accessibility of differ-

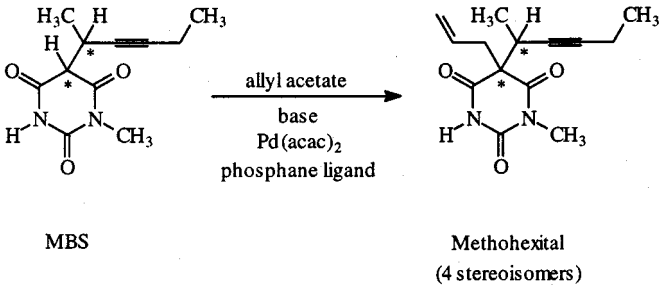
Scheme 1. Keto-enol tautomerism of the labile asymmetric centre of MBS in the barbiturate system

ently enriched diastereomeric and enantiomeric mixtures in one reaction step.

We describe the preparation of the starting material 1-methyl-5-(1′-methylpent-2′-ynyl)barbituric acid (MBS), the analysis of its stereoisomers and its Pd-catalyzed allylation as well as the analysis of the diastereomers and enantiomers of the product Methohexital and the results of the catalytic runs (variation of base and optically active ligand). Then we report on the separation of the contributions of the kinetic resolution and the optically active catalyst, which superpose in the enantioselective Pd-catalyzed allylation of MBS. Finally, the Methohexital mixtures synthesized are tested with regard to their narcotic effect in rats.[3,4]



1-Methyl-5-(1′-methylpent-2′-ynyl)barbituric Acid (MBS) and Analysis of Its Stereoisomers

1-Methyl-5-(1′-methylpent-2′-ynyl)barbituric acid (MBS) is synthesized in five steps.[3,4,10−15] MBS contains two asymmetric centres. Therefore, it forms two diastereomeric pairs of enantiomers. The signals of the four stereoisomers of MBS appear in approximately equal intensities in the ^{1}H-NMR spectrum (*N*-methyl groups) after addition of the shift reagent (*S*)-(+)-1-(9′-anthryl)-2,2,2-trifluoroethanol. To follow the accumulation of the stereoisomers of MBS during the catalytic process a GC separation of the stereoisomers on a chiral CP-Chirasil-Dex-CB column (length 25 m), coated with permethylated β-cyclodextrin, was developed. Two peaks of equal areas were obtained, each of which contains the two stereoisomers of MBS, which interconvert by the keto-enol tautomerism of the labile asymmetric centre of the barbiturate system (Scheme 1).

This keto-enol tautomerism is only possible for these two stereoisomers, which have the same configuration in the hexyne side chain (bold configuration symbol), because only the asymmetric centre in the barbiturate system is involved in the tautomerism. Thus, the first peak arises either from the combination (***R***,*S*)/(***R***,*R*) and the second peak from the combination (***S***,*R*)/(***S***,*S*) or vice versa. The absolute configuration is not known. The difference in area between the two peaks is called "combined enantiomeric excess" and abbreviated by "ee". For a racemic MBS sample a "combined enantiomeric excess" of 0% "ee" was measured on the CP-Chirasil-DEX-CB column used for the analysis.

5-Allyl-1-methyl-5-(1′-methylpent-2′-ynyl)barbituric Acid (Methohexital) and Its Stereoisomer Analysis

In the Pd-catalyzed allylation of MBS a configurationally stable second asymmetric centre in 5-position of the barbiturate system of the product Methohexital is formed (Scheme 2).

Scheme 2. Synthesis of Methohexital by Pd-catalyzed allylation of MBS

The four stereoisomers of Methohexital were separated with a GC system consisting of an achiral and a chiral column (Figure 1a). The achiral column was a polar Durabond-DB-225 column (length 30 m) and the chiral column was a Chiraldex-B-DA column (length 30 m). The two enantiomeric pairs are designated α and β and the configuration in the hexyne side chain 1 and 2. Thus, the four stereoisomers of Methohexital are: α1, α2, β1, β2 (Figure 1a). The two α-peaks belong to one pair of enantiomers (α1 and α2) with the literature name α-*dl*[12][13] and the two β-peaks to the other pair of enantiomers (β1 and β2) with the literature name β-*dl*. These two pairs of enantiomers are either

(***R***,*R*)/(***S***,*S*) and (***R***,*S*)/(***S***,*R*) or vice versa. The indices 1 and 2 are choosen such, that stereoisomers with the same index have the same configuration in the hexyne side chain. Thus α1 and β1 have either the configuration (***R***,*R*)/(***R***,*S*) or (***S***,*S*)/(***S***,*R*) (analogously for α2 and β2).

Which of the stereoisomers of Methohexital have the same configuration in the hexyne side chain, was established from a chromatogram of a catalysis with a yield of 94%. As the starting material MBS was racemic with respect to the configuration in the hexyne side chain, the product stereoisomers can be combined to the diastereomeric pairs (***R***,*R*)/(***R***,*S*) or (***S***,*S*)/(***S***,*R*) only in this way, that the pairs do not have more than yields of 50%. Thus, the first and the fourth as well as the second and the third peak must have the same configuration in the hexyne side chain (Figure 1a).

The four stereoisomers of Methohexital could also be separated with a permethylated β-cyclodextrin column Chiraldex-B-PM (length 30 m). In this analysis the second and the fourth peak belong to the α-*dl* pair of Methohexital and the first and the third to the β-*dl* pair (Figure 1b). A Methohexital sample resulting from an achiral catalysis with the ligand triphenylphosphane (Table 1, entry 1) gave an enantiomeric excess, as expected, of 0% ee in the α and β series. The diastereomeric excess of α pair versus β pair was measured to be 8% de with the B-PM column compared to 7% de with the two-column system DB-225 + B-DA (Figure 1a). In the GC investigations of Methohexital samples care had to be taken to separate the starting material MBS completely from the product Methohexital, because both with the DB-225 + B-DA column system as well as with the B-PM column there was overlap[3,4].

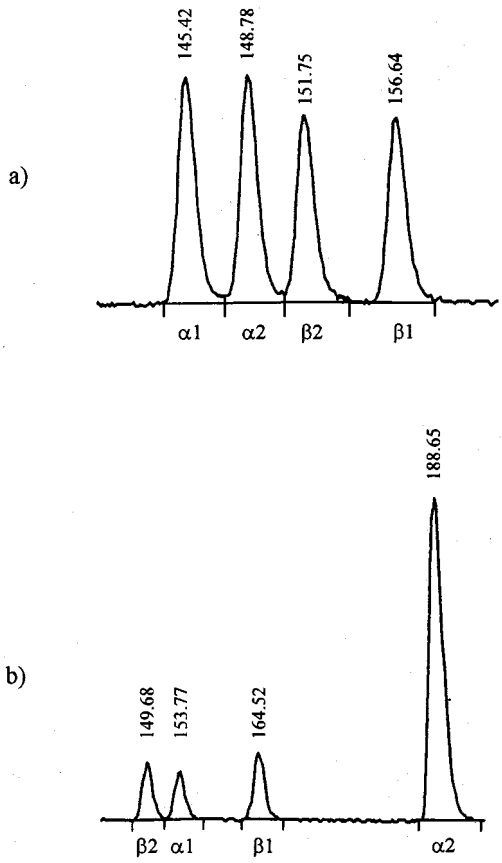


Figure 1. Separation of the four Methohexital isomers: a) on a DB-225 + B-DA column system (catalysis with ligand triphenylphosphane; Table 1, entry 1; 7% de of α pair); b) on a B-PM column (catalysis with ligand **7**; Table 2, entry 3; sample heavily enriched in α2)

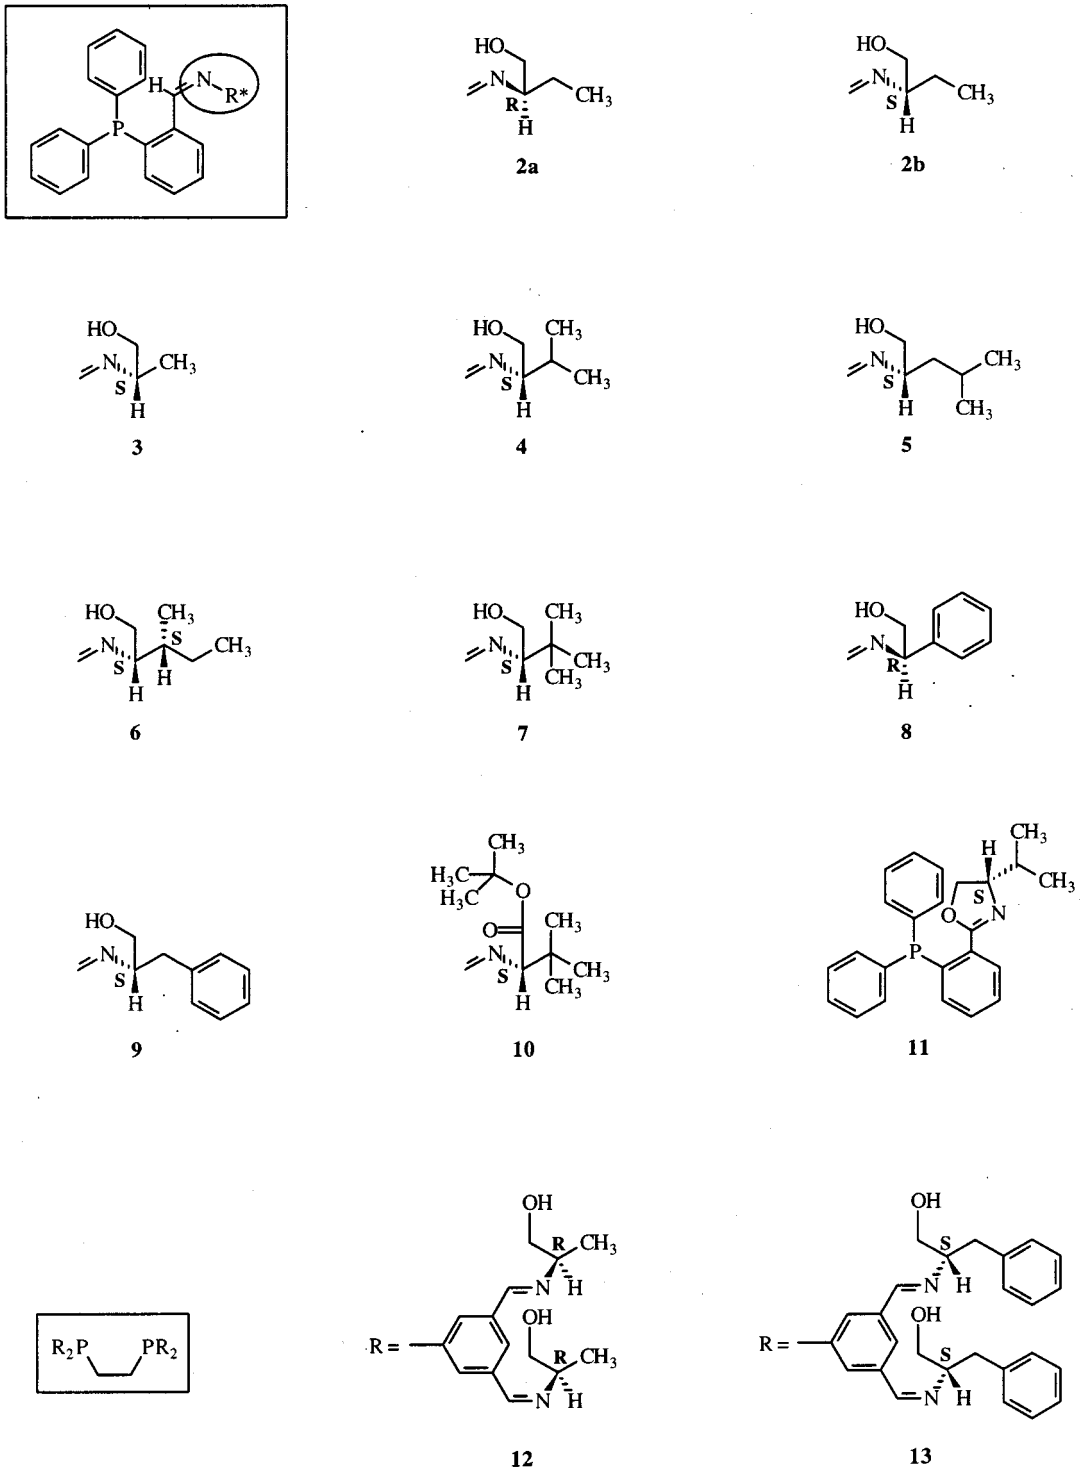
Standard Catalytic Allylation of MBS to Methohexital

In the Pd-catalyzed allylation (Scheme 2) MBS is dissolved in dichloromethane/toluene (1:1). To the clear solution a base (NEt_3 or DBU) is added in 5% excess. Then 1 mol-% of palladium(II) acetylacetonate and 4 mol-% of a monodentate or 2 mol-% of a bidentate optically active phosphane are dissolved in the reaction mixture. The reaction is started by addition of allyl acetate in 11% excess. The homogeneous solution containing the "in situ" Pd/ligand complex is stirred for 72 h at 38°C. If the ligands are not soluble in dichloromethane/toluene (1:1), the dichloromethane content is increased.



The reaction is stopped by addition of 0.2 M hydrochloric acid. From the organic layer an oily product is obtained, which is chromatographated on silica gel with dichloromethane/acetonitrile (25:1). First, the yellow (2-formylphenyl)diphenylphosphane, the hydrolysis product of the phosphane imine ligands, is eluted, then the excess of allyl acetate and small amounts of the doubly allylated by-product 3,5-diallyl-1-methyl-5-(1′-methylpent-2′-ynyl)barbituric acid (AAMBS), formed in a second allylation (*N*-allylation[2][4]). Then the product Methohexital is eluted. With a qualitative TLC test it is possible to monitor the progress of the chromatography (allyl acetate, AAMBS, Methohexital, and MBS show different yellow spots after dipping into a dilute $KMnO_4$ solution). By changing the eluent to dichloromethane/acetonitrile (3:1) the unreacted starting material MBS can be eluted. After removal of the solvent Methohexital forms a colourless oil, which crystallizes subsequently. The yield is determined by weighing. The analysis of the Methohexital stereoisomers is achieved by GC.

Chiral Ligands in the Palladium-Catalyzed Allylation of MBS

In the Pd-catalyzed allylation of MBS the achiral ligand triphenylphosphane as well as a series of chiral ligands[2] were used. The phosphane imine ligands **2a**, **2b**, **3**−**10** were obtained by Schiff base condensation of (2-formylphenyl)-diphenylphosphane with the following primary amines[2]: (*R*)-(−)-2-amino-1-butanol, (*S*)-(+)-2-amino-1-butanol, L-alaninol, L-valinol, L-leucinol, L-isoleucinol, L-*tert*-leucinol, D-α-phenylglycinol, L-phenylalaninol, L-*tert*-butyl *tert*-leucinate. Further chiral ligands were (−)-(4*S*)-2-[2′-(diphenylphosphanyl)phenyl]-4-isopropyl-1,3-oxazoline (**11**),[16,17]

(+)-1,2-bis{bis[3′,5′-bis(*N*-methyliden-(*R*)-alaninol)phenyl]phosphanyl}ethane (**12**)[2,18] and (−)-1,2-bis{bis[3′,5′-bis(*N*-methylidene-(*S*)-phenylalaninol)phenyl]phosphanyl}-ethane (**13**)[18] (Scheme 3). For a comparison the standard ligands (−)-norphos[19,20] and (−)-diop[21,22] were included. The results of the catalyses are summarized in Table 1.

mate of 7% de was obtained (Table 1, entry 1). Phosphane imine ligands induce a high diastereomeric and enantiomeric excess, if there is a hydroxymethyl substituent at the asymmetric centre near the imine group, which acts as an anchor for the incoming barbiturate anion.[2] The variation of the other side chain at the asymmetric centre leads to

[a] "ee" = "combined enantiomeric excess" (see text). − [b] s = stereoselectivity factor. − [c] After chromatography. − [d] GC analysis with the B-PM column. − [e] Pd/ligand ratio 1:2. − [f] 150 mL of CH_2Cl_2 + 25 mL of toluene was used to dissolve ligand **12**.

α-*dl* pair of 47% ee (α1) and in the β-*dl* pair of 21% ee (β1) is achieved, the diastereomeric excess for the α-*dl* pair being 40% de (entry 2). The isomers added in parentheses after the ee and de values are the favoured isomers. The analogous (*S*) ligand **2b** gives a similar enantiomeric excess of the opposite stereoisomers, a similar diastereomeric excess for the α-*dl* pair and the same chemical yield (entry 3). A shortening of the ethyl group at the asymmetric centre in the ligands **2a** and **2b** to a methyl group in the ligand **3** diminishes the diastereomeric and enantiomeric excess considerably, although the chemical yield increases (entries 4, 5).

Branching of the alkyl group as in the ligands **4**−**7** leads to the highest stereoselectivities in the Pd-catalyzed allylation of MBS observed so far similar to the Pd-catalyzed allylation of 1,5-dimethylbarbituric acid[2]. With the ligands **4** and **6**, which contain an isopropyl group and a *sec*-butyl group, respectively, a high enantiomeric excess in the α-*dl* pair of 62% ee (α2) was attained, associated with a low enantiomeric excess of 3−12% ee (β1) in the β-*dl* pair, the diastereomeric excess for the α-*dl* pair being 42 and 43% de. With NEt_3 as a base, the yields are only 26−43% (entries 6, 8, 9). Using DBU leads to an increased yield of 63%. The enantiomeric excess in the α-*dl* pair decreases to 51% ee (α2), whereas the enantiomeric excesses in the β-*dl* pair rises to 38% ee (β1) (entry 10).

The ligands **5** and **7**, which carry an isobutyl group and a *tert*-butyl group at the asymmetric centre, respectively, lead to a lower enantiomeric excess in the α-*dl* pair [33 and 40% ee (α2)] but to a higher enantioselectivity in the β-*dl* pair [55, 59, and 61% ee (β1)] with yields of up to 94% using NEt_3 as a base. The diastereoselectivities are between 25 and 29% de for the α-*dl* pair (entries 7, 11, 12). If the side chain at the asymmetric centre contains a phenyl group (ligands **8** and **9**), the induced enantiomeric excess is higher for ligand **8** than for ligand **3** and distinctly lower for ligand **9** than for ligand **2b** (entries 13−15). A substitution of the hydroxymethyl group at the asymmetric centre by a *tert*-butyl ester group in the ligand **10** reduces the enantiomeric excess appreciably independent of the base used (entry 16).

The phosphane oxazoline ligand **11** gives only a low enantiomeric excess in the product Methohexital similar to the standard ligands (−)-norphos and (−)-diop (entries 17, 20, 21). The ligands **12** and **13** belong to a different group of phosphane imine ligands with two phosphorus atoms. They afford an enantiomeric excess in the various stereoisomers of 8−19% ee using the base NEt_3 (entries 18, 19). Up to now ligand **12** is the only one, which induces a diastereomeric excess in favour of the β-*dl* pair (6% de).

The Interplay of Kinetic Resolution and Catalyst Contribution

In the allylation of 1,5-dimethylbarbituric acid the 1,5-dimethylbarbiturate anion is formed, which no longer contains an asymmetric centre. Thus, there is no kinetic resolution in this reaction and the enantiomeric excess of the product 5-allyl-1,5-dimethylbarbituric acid is only dependent on the enantioselectivity of the chiral catalyst.[2] On the contrary, the starting material 1-methyl-5-(1′-methylpent-2′-ynyl)barbituric acid (MBS) for the synthesis of Me-

[a] "ee" = "combined enantiomeric excess". – [b] s = stereoselectivity factor. – [c] After chromatography.

thohexital contains two asymmetric centres. On addition of base the asymmetric centre in the barbiturate system is removed, but the asymmetric centre in the hexyne side chain is preserved. In the present study the asymmetric centre in the hexyne side chain of the MBS used was racemic. Therefore, two different effects can influence the distribution of the stereoisomers in the Pd-catalyzed allylation of MBS, the kinetic resolution and the enantioselective catalysis, which are both concentration-dependent. The contributions of these two effects can be calculated provided the yields of Methohexital and MBS as well as the diastereomeric and enantiomeric excess of Methohexital and MBS are known. These data were obtained from a standard catalysis with ligand **7** by taking aliquots after 3, 4.5, 9, 12, and 72 h. The yields of Methohexital and MBS were determined and their stereoisomer composition was analysed by GC as described above. In Table 2 the results and calculations are summarized together with those of two other catalytic runs.

The Kinetic Resolution in the Pd-Catalyzed Allylation of MBS with Ligand 7

Due to the kinetic resolution in the reaction with the optically active catalyst there is a chiral discrimination of the MBS anions, which have opposite configurations in the hexyne side chain. One is consumed faster to give the product Methohexital, whereas the other is enriched in the unreacted starting material. This difference in reactivity shows up in the intensity ratio of the first and the second MBS GC peak (Table 2, column J). The "combined enantiomeric excess", calculated as $[(|peak1 - peak2|)/(peak1 + peak2)] \times 100\%$ reflects the reactivity difference of the MBS stereoisomers, which have opposite configurations in the hexyne side chain.

Addition of the yield of Methohexital (column A) and the amount of unreacted MBS (column I) leads to retrieval rates of 96–98%. The missing 2–4% are lost by the treatment with 0.2 M hydrochloric acid, by the chromatographic purification or by the formation of the doubly allylated byproduct AAMBS. In a reasonable approximation the yield of Methohexital can be used to represent the overall conversion.

After 3 h, the first sample taken gave a yield of 17% of Methohexital and 79% of starting material MBS (Table 2, entry 1). The yield of Methohexital increased from 20% after 4.5 h (77% MBS) via 26% after 9 h (70% MBS) and 32% after 12 h (65% MBS) to 49% after 72 h (48% MBS), as shown in columns A and I of Table 2 (entries 2–5). In comparable reactions Methohexital yields of 65% (MBS not determined) and 91% (7% MBS) were isolated after 72 h (entries 6, 7).

Figure 2 shows the correlation between the yield of Methohexital (column A) and the increase of the "combined enantiomeric excess" of MBS (column J). With the decrease of the amount of unreacted MBS down to 7% after 72 h (entry 7) the enantioselectivities of the remaining MBS rises to an enrichment of 83% "ee" (1.). The designation (1.) means an excess of the first peak of MBS in the GC chromatogram.

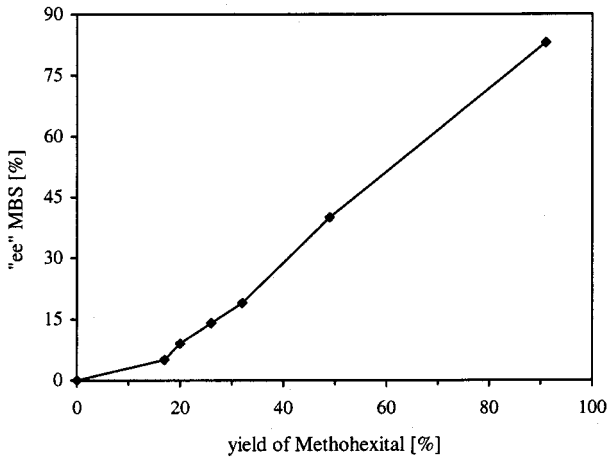

Figure 2. Correlation between the "combined enantiomeric excess" of MBS and the yield of Methohexital

With the rate constants k_R and k_S for the reaction of the two MBS anion enantiomers, the stereoselektivity factor $s = k_R/k_S$ is a measure for the kinetic resolution.[23,24] It can be calculated from the amount and the enantiomeric

excess of the unreacted starting material with Equation 1.[23,24] The values of the stereoselectivity factor *s* of MBS

$$s = \frac{\ln[(1-C)(1-ee)]}{\ln[(1-C)(1+ee)]}$$

C = conversion: 0 < C < 1 (column A); assumption: retrieval rate of 100%; ee = "ee" = "combined enantiomeric excess" in the unreacted starting material MBS: 0 < "ee" < 1 (column J)

are between 1.7 and 3.5 with an average of 2.6 (column K).

The effect of the kinetic resolution with respect to the product Methohexital can be calculated with the help of the "combined enantiomeric excess" α1 + β1 vs. α2 + β2 (vs. = versus) in column D, obtained from the four GC peaks of the Methohexital stereoisomers. The two components of each sum have the same configuration in the hexyne side chain. It decreases from 60−62% "ee" for a Methohexital yield of 17−26% via 36% "ee" for a yield of 49% to 6% "ee" for a yield of 91% (columns A and D) with increasing conversion (entries 1−5, 7). The value of 0% "ee" for a Methohexital yield of 65% does not fit into this series (entry 6). The stereoselectivity factor *s* (values between 1.7 and 5.0, column H) is calculated with Equation 2.[23,24]

$$s = \frac{\ln[1-C(1+ee)]}{\ln[1-C(1-ee)]}$$

C = conversion: 0 < C < 1 (column A); assumption: retrieval rate of 100%; ee = "ee" = "combined enantiomeric excess" in the product Methohexital: 0 < "ee" < 1 (column D)

Although the absolute configurations are not known, the starting material MBS and the product Methohexital can be correlated with respect to the configuration in the hexyne side chain. During the reaction the isomers of MBS appearing in the first GC peak are enriched. Thus, they react more slowly to the product Methohexital. The faster reacting MBS isomers lead to a growth of the GC peaks of the Methohexital stereoisomers α2 and β2. Therefore, they must have the same configuration in the hexyne side chain as the isomers of the second MBS peak.

The Contribution of the Optically Active Catalyst in the Pd-Catalyzed Allylation of MBS with Ligand 7

In addition to the kinetic resolution the optically active catalyst contributes to the stereoselectivity of the Pd-catalyzed allylation of MBS. This is reflected in the enantiomeric excess in the α series which decreases from 80% ee (α2) to 42% ee (α2) (Table 2, column B), whereas in the β series it rises from 6% ee (β1) to 72% ee (β1) (column C). Figure 1b shows the highest enantiomeric excess of 80% ee (α2) in the α-*dl* pair of Methohexital obtained up to now (entry 3).

The contribution of the optically active catalyst is concentration-dependent, because the composition of the MBS stereoisomers changes during the reaction due to the kinetic resolution. At the beginning of the reaction MBS is racemic. Thus, the influence of the optically active catalyst can be read off directly from the enantiomeric excess of Methohexital in the beginning of the MBS allylation.

Columns E and F show the diastereomeric excess α1 vs. β1 and α2 vs. β2, which involves the influence of the asymmetric centre in the hexyne side chain and the optically active catalyst on the formation of the new asymmetric centre in the barbiturate ring. For the diastereomeric excess α1 vs. β1 values between 11 and 27% de (β1) were achieved (column E) and for α2 vs. β2 values between 71 and 82% de (α2) (column F). The diastereomeric excess α1 vs. β1 and α2 vs. β2 is relatively independent of the turnover (columns A, E, F). The overall diastereomeric excess α pair vs. β pair decreases from 59 to 24% de (α pair) (column G) depending on the yield of Methohexital (column A).

Kinetic Resolution and Catalyst Contribution for the Other Ligands

The influence of the kinetic resolution in the Pd-catalyzed allylation of MBS is calculated for all the optically active ligands with Equation 2 using enantiomeric excesses α1 vs. α2 and β1 vs. β2 for Methohexital. The results are summarized in Table 1. As expected *s* is 1.0 for the achiral catalysis with triphenylphosphane, as both enantiomeric excesses α1 vs. α2 and β1 vs. β2 are 0% ee. The influence of the kinetic resolution is small for most of the ligands investigated (values for *s* between 1.0 and 1.6) except for the catalyses with the ligands **2a**, **2b**, **4**, and **6** (values for *s* from 2.3 to 3.3).

The contribution of the optically active catalyst in the Pd-catalyzed allylation of MBS for all the ligands is obvious from the enantiomeric excess in the α and β series, although most of the reactions were stopped at higher conversions. It was small for the standard ligands (−)-norphos, (−)-diop, the phosphane oxazoline ligand **11** and the phosphane imine ligand **10** containing a *tert*-butyl ester substituent with an enantiomeric excess between 1 and 6% ee. For the remaining phosphane imine ligands, which carry a hydroxymethyl substituent at the asymmetric centre, the catalyst contribution was much higher with up to 62% ee (Table 1).

Determination of the Anesthetic Doses of Methohexital Stereoisomer Mixtures in Rats

Methohexital is a common anesthetic widely used to initiate narcoses.[5−11] The four stereoisomers of Methohexital exhibit different anesthetic effects in rats, dogs and monkies.[12,13] Injected as a solution of the sodium salt into rats, the β-*l* isomer of Methohexital is the most effective of the stereoisomers with an anesthetic dose of 7 mg/kg body weight of the animal. The α-*d* stereoisomer with 11 mg/kg and the β-*d* stereoisomer with 17 mg/kg follow. For a narcosis with the α-*l* stereoisomer 35 mg/kg are necessary. With 10 mg/kg the β-*dl* racemate is more effective than the α-*dl* racemate with 15 mg/kg. However, because of undesirable stimulating post-anesthetic effects of the β-*dl* racemate caused by the β-*l* stereoisomer the extensively used narcotic is the α-*dl* racemate (Eli Lilly).

Table 3. 10 Methohexital samples and their isomer composition, the reference Brevimytal®Natrium and the anesthetic doses (AD) in Sprague Dawley rats of body weight between 560 and 720 g[25][26]

Sample	Ligand	α1 [%]	α2 [%]	β1 [%]	β2 [%]	AD [mg/kg]	Average AD [mg/kg]
1	**1**	27	27	23	23	10.8, 9.3, 11.1	10.4
2	**2a**	51.5	18.5	12	18	14.6, 13.5, 11.1	13.0
3	**2b**	17	51.5	18	13.5	15.7, 17.7, 14.8	16.1
4	**4**	13.5	58.5	14.5	13.5	17.4, 16.3, 16.4	16.7
5	**5**	22	43	27	8	16.1, 15.3, 15.7	15.7
6	**8**	41	23	13	23	8.9, 9.4, 8.9	9.1
7	**8**	41	24	12	23	17.9, 14.5, 15.6	16.0

11	reference[a]	50	50	–	–	16.3, 12.4, 10.3	13.0

[a] Protonated Brevimytal®Natrium (see Experimental Section).

For 10 mixtures of Methohexital stereoisomers, obtained by Pd-catalyzed enantioselective allylation of MBS, the anesthetic dose (AD) in rats was determined using the corneal stimulus technique[25] as described elsewhere.[26] The results were compared with those of a sample of protonated Brevimytal®Natrium (sample 11).

Table 3 summarizes the anesthetic doses obtained by standardising to 1 kg body weight of the rat. The average anesthetic dose of the samples **1**, **6**, and **9** was lower than that of Brevimytal®Natrium with 13.0 mg/kg (Table 3). In particular, sample **6** with 9.1 mg/kg had a distinctly reduced anesthetic dose. Deviations from the average value were small with this sample. However, it is conspicuous, that samples **6** and **7**, which showed marked differences in the anesthetic doses, had a closely related stereoisomer composition (Table 3).[26]

Experimental Section

The instruments used were the same as described in the preceding paper.[2] – All the syntheses and catalytic reactions were carried out with dried solvents under nitrogen. – Palladium(II) acetylacetonate and allyl acetate (Merck) were used without further purification. DBU (Fluka) was dried with $CaCl_2$, NEt_3 (Merck) with CaH_2, and distilled.

1-Methyl-5-(1′-methylpent-2′-ynyl)barbituric Acid (MBS):[3,4,13] 10.9 g (0.474 mol) of sodium was dissolved in 200 mL of refluxing absolute ethanol. After addition of 17.6 g (0.237 mol) of *N*-methylurea and stirring for 15 min, 38.0 g (0.158 mol) of diethyl (1-methylpent-2-ynyl)malonate[4,13,14] was added to the clear boiling solution within 10 min. A solid precipitated after 30 min. After 1.5 h of reflux, the solvent was removed and the product dissolved in about 750 mL of water. With vigorous stirring 80 mL of conc. hydrochloric acid was added to give an oil, which solidified. After 30 min of stirring, the product was filtered off and washed with cold water. Recrystallization from 2-propanol/water (2:1) provided colourless crystals. Yield 20.8 g (59%), m. p. 90–91.5°C. – IR (KBr): $\tilde{\nu}$ = 1754 (m), 1719 (s), 1695 (s) cm^{-1} (C=O). – ^1H NMR ($CDCl_3$, 400 MHz): δ = 8.14/8.09 (2 s, 1 H, N*H*), 3.39–3.31 (m, 2 H, OC–C*H*–C*H*), 3.303/3.298 (2s, 3 H, N–CH_3), 2.102/2.100 (2 dq, 2 H, ^5J = 2.2 Hz, ^3J = 7.5 Hz, C≡C–CH_2–CH_3), 1.444/1.440 (2d, 3 H, ^3J = 7.0 Hz, CH–CH_3), 1.040/1.038 (2 t, 3 H, ^3J = 7.5 Hz, C≡C–CH$_2$–CH_3). – $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.9 MHz): δ = 169.3/168.7 (HN–*C*O–CC$_3$), 167.5/166.8 (H$_3$C–N–*C*O–CC$_3$), 151.2/151.1 (HN–*C*O–N–CH$_3$), 86.6/86.5 (HC–*C*≡C), 76.8 (C≡*C*–CH$_2$), 54.3 (OC–*C*–CO), 31.8/31.6 (H*C*–C≡C), 27.7/27.4 (N–*C*H$_3$), 20.0/19.7 (H$_3$*C*–CH), 13.8 (CH$_2$–*C*H$_3$), 12.1 (C≡C–*C*H$_2$). – The signals appear doubled because of the two MBS diastereomers. Addition of (*S*)-(+)-1-(9′-anthryl)-2,2,2-trifluoroethanol (Super-Pirkle) to MBS in the molar rate 1:12 results also in a separationof of the enantiomers: δ = 3.059/3.054/3.043/3.035 (4s, N–CH_3), 0.940/0.938/ 0.933/ 0.927 (4 t, ^3J = 7.5 Hz, C≡C–CH$_2$–CH_3). – MS (EI, 70 eV); *m/z* (%): 222.1 (7) [M^+], 207.1 (45) [M^+ – CH_3], 193.1 (46) [M^+ – C_2H_5], 81.1 (35) [$C_6H_9^+$], 79.1 (100). – $C_{11}H_{14}N_2O_3$ (222.24): calcd. C 59.45, H 6.35, N 12.60; found C 59.52, H 6.34, N 12.63. – GC analysis of MBS: 25-m CP-Chirasil-Dex-CB column (chemically connected with permethylated β-cyclodextrin; 0.25 mm inner diameter, 0.25 µm film thickness; from Chrompack), column temp. 165°C, He pressure 1.2 bar, injector temp. 250°C, detector temp. 230°C (flame ionisation). Retention times: (1.) 23.29 min, (2.) 24.97 min; dead time t_0 (CH_2Cl_2) = 1.21 min. Separation factor: α = 1.07, resolution *R* = 3.52.

Synthesis of Methohexital by Enantioselective Palladium-Catalyzed Allylation of MBS with Allyl Acetate: 1.07 g (4.81 mmol) of MBS was dissolved in 25 mL of dichloromethane/toluene (1:1) at 38°C under nitrogen. To the clear solution 5.05 mmol of the base was added [DBU (752 µL, 769 mg) or NEt_3 (700 µL, 511 mg), respectively]. After 5 min of stirring, 14.6 mg ($4.81 \cdot 10^{-2}$ mmol) of Pd(acac)$_2$ and $19.2 \cdot 10^{-2}$ mmol of a monodentate or $9.61 \cdot 10^{-2}$ mmol of a bidentate ligand were rinsed into the reaction vessel with another 25 mL of dichloromethane/toluene (1:1). After 2.0 min, 576 µL (5.35 mmol, 536 mg) of allyl acetate was added to the clear yellow solution. Usually, the solution was stirred for 72 h at 38°C. For work-up the solution was diluted with 50 mL of dichloromethane and the reaction was stopped with 50 mL of 0.2 M hydrochloric acid. The organic layer was dried with Na_2SO_4, the Na_2SO_4 was filtered off and washed with 50 mL of dichloromethane. The solvent was removed. The remaining oily product was chromatographed on silica gel with dichlormethane/acetonitrile (25:1). If phosphane imine ligands were used in the catalysis, first the yellow (2-formylphenyl)diphenylphosphane was eluted, followed by the excess of allyl acetate and small amounts of doubly allylated MBS (AAMBS). Then the product Methohexital was eluted. The separation of the products was monitored by a qualitative TLC test (silica 60, Merck; dichloromethane/acetonitrile, 25:1), which showed how much allyl acetate, AAMBS, Methohexital and MBS were present in a specific fraction (yellow spots after dipping into a dilute $KMnO_4$ solution). All the fractions, which contained Methohexital, were combined to prevent an enrichment of the dia-

stereomers during the chromatography. After complete elution of Methohexital, the unreacted starting material MBS was eluted with dichloromethane/acetonitrile (3:1). The yield of Methohexital and unreacted MBS was determined by weighing. After about 1−2 d the colourless oil of Methohexital crystallized to a colourless solid.

Methohexital: Maximum yield 1.19 g (94%, Table 1, entry 7), m. p. 61−65°C. − IR (KBr): $\tilde{\nu}$ = 1717 (s), 1690 (s) cm^{-1} (C=O). − ^1H NMR ($CDCl_3$, 400 MHz): δ = 8.04/8.02 (2 s, 1 H, N*H*), 5.553/5.547 (2 tdd, ^3J = 7.3 Hz, $^3J_{cis}$ = 10.1 Hz, $^3J_{trans}$ = 17.0 Hz, 1 H, $H_2C{=}CH{-}CH_2$), 5.149 (md, ^3J = 17.0 Hz, 1 H, CH=CHH_{trans}), 5.084 (md, ^3J = 10.1 Hz, 1 H, CH=CHH_{cis}H), 3.293/3.286 (2 s, 3 H, N−CH_3), 3.087/3.081 (2 tq, ^5J = 2.3 Hz, ^3J = 7.0 Hz, 1 H, $H_3C{-}CH{-}C{\equiv}C{-}CH_2$), 2.864/2.852 (2 dd, ^3J = 7.3 Hz, ^2J = 13.0 Hz, 1 H, $H_2C{=}CH{-}CHH$), 2.657/2.648 (2 dd, ^3J = 7.3 Hz, ^2J = 13.0 Hz, 1 H, $H_2C{=}CH{-}CHH$), 2.102/2.099 (2 dq, ^5J = 2.3 Hz, ^3J = 7.5 Hz, 2 H, $HC{-}C{\equiv}C{-}CH_2{-}CH_3$), 1.301/1.291 (2 d, ^3J = 7.0 Hz, 3 H, $HC{-}CH_3$), 1.038/1.034 (2 t, ^3J = 7.5 Hz, 3 H, $C{\equiv}C{-}CH_2{-}CH_3$). − $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.9 MHz): δ = 171.6/170.8 (HN−*C*O−CC$_3$), 169.9/169.1 ($H_3C{-}N{-}CO{-}CC_3$), 150.4 (HN−*C*O−N−CH$_3$), 131.2 ($H_2C{=}CH$), 120.6 ($H_2C{=}CH$), 86.4 (HC−*C*≡C), 77.6 (C≡*C*−CH$_2$), 59.8 (OC−*C*−CO), 38.0 ($H_2C{=}CH{-}CH_2$), 36.0/35.6 (H*C*−C≡C), 27.6/27.5 (N−*C*H$_3$), 16.0 ($H_3C{-}CH$), 13.8 ($CH_2{-}CH_3$), 12.1 (C≡C−*C*H$_2$). Keywords: Zirconium arsenate / Crystal structure / Amine intercalation

The crystalline structure of γ-$Zr(AsO_4)(H_2AsO_4) \times 2\ H_2O$ (γ-ZrAs) has been refined by the Rietveld method. It has a monoclinic $P2_1$ layered structure built up from AsO_4 tetrahedra and ZrO_6 octahedra stacked along the 001 direction. The cell parameters are: a = 5.5752(6) Å, b = 6.8290(7) Å, c = 12.110(1) Å, and β = 103.03(1)°. The layered nature of γ-ZrAs is confirmed by the intercalation of *n*-alkylamines ($CH_3[CH_2]_nNH_2$; n = 0–5) as well as of cyclic amines (benzylamine, cyclohexylamine, piperidine, and pyridine). Among the linear amines, only with methyl-, ethyl-, and hexylamine is the maximum incorporation attained. With the cyclic amines, except in the case of pyridine, pure new phases are obtained, with the highest degree of intercalation being one mol of amine per mol of γ-ZrAs.

Introduction

Some insoluble acid salts of the general formula $M^{IV}(HXO_4)_2 \times n\ H_2O$ (M = Ti, Zr, Ce, Sn, Hf; X = P or As) have a layered structure, each layer consisting of a plane of tetravalent atoms sandwiched between tetrahedral phosphate or arsenate groups. Thus, these salts possess the typical characteristics of an intercalating agent and can be considered as hosts for the design and preparation of supramolecular solids with various functions.[1]

There are two major types of layered structures, usually denoted as α- and γ-layered forms.[1−4] The γ-compounds, presently formulated as $M(PO_4)(H_2PO_4) \times 2\ H_2O$, differ from the α-type in that half of the phosphate groups have all 4 oxygen atoms bonded to the metal atoms, while the other half are present as dihydrogen phosphate groups, bearing exchangeable protons.[4][5]

There is now an extensive body of literature dealing with the ion-exchange and intercalation chemistry of metal(IV) phosphates with α- and γ-type structures, the most studied compounds being α-$Zr(HPO_4)_2 \times H_2O$ (α-ZrP) and γ-$Zr(PO_4)(H_2PO_4) \times 2\ H_2O$ (γ-ZrP).[6−10] In contrast, the corresponding arsenates have been scarcely investigated. Only three layered α-type polyvalent metal arsenates are known: $Zr(HAsO_4)_2 \times H_2O$ (α-ZrAs), $Ti(HAsO_4)_2 \times H_2O$ (α-TiAs), and $Sn(HAsO_4)_2 \times H_2O$ (α-SnAs).

α-ZrAs was prepared by refluxing amorphous zirconium arsenate in arsenic acid[11][12] and the titration curves with hydroxides of alkali metal ions, Tl^+, Ba^{2+}, and NH_4^+ have been determined.[13] Although the windows connecting the cavities in α-ZrAs are about the same size as those in α-ZrP,[14] it seems that steric hindrance to the diffusion of large cations is less in α-ZrAs than in α-ZrP. Thus, the ion-exchange properties of the two compounds lead to differences in their abilities to function as sieves. α-TiAs has been scarcely studied to date; it is less stable than α-TiP and is strongly hydrolyzed, even in neutral media. Thus, ion-exchange experiments in aqueous solutions are restricted to acidic media, where only one proton is replaced by Li^+, Na^+, or K^+ ions.[15] α-SnAs has been prepared and the ion-exchange properties towards alkali metal ions have also been investigated.[16] This material is strongly hydrolyzed in alkaline media, hence it is a poor exchanger of limited utility, unless specific applications in acidic solution or in non-aqueous media are required.

To date, no γ-arsenates have been reported in the literature, although it is probable that the structure of Ce-$(HAsO_4)_2 \times 2\ H_2O$ is of the γ-type.[17][18] Some properties of metal(IV) arsenates are compiled in Table 1.

In a previous paper[19] we reported the hydrothermal synthesis of γ-ZrAs via its half-exchanged ammonium phase, and some preliminary data towards its characterization. In this paper, we describe the refinement of the crystal structure of γ-ZrAs by the Rietveld procedure. Furthermore, the layered nature of the compound is confirmed by the intercalation of *n*-alkylamines ($CH_3[CH_2]_nNH_2$; n = 0−5) and

cyclic amines (benzylamine, cyclohexylamine, piperidine, and pyridine).

Results and Discussion

The γ-$Zr(AsO_4)(H_2AsO_4) \times 2\ H_2O$ formula for the synthesized compound was determined by means of the analytical procedures indicated in the Experimental Section.

A summary of the crystallographic data is given in Table 2, and final positional parameters are listed in Table 3. The final Rietveld refinement plot is shown in Figure 1.

Compared with the unit cell of γ-ZrP, that of γ-ZrAs is extended in the *a* and *b* directions and compressed in the *c* direction. Accordingly, γ-ZrAs has a larger cell volume but a smaller interlayer distance (11.80 Å) than γ-ZrP (12.27 Å).

The powder pattern of γ-ZrAs reveals a certain degree of structural disorder. This is manifested by the appearance of two principal zones of extra-Bragg scattering, around 2θ = 18° and 29°. A similar effect is observed in the pattern of

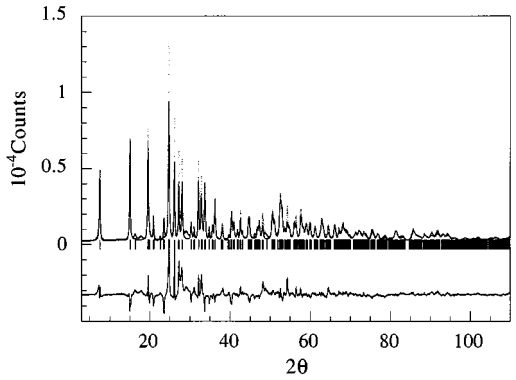

Figure 1. Rietveld refinement pattern of γ-ZrAs; points correspond to observed data; the solid line represents the calculated profile; tick marks show the positions of allowed reflections; a difference curve, on the same scale, is plotted at the bottom of the pattern

γ-TiP[20]. In the case of γ-TiP these zones appear as broad humps, whereas for γ-ZrAs sharper, better defined peaks are seen. These observations clearly indicate that both samples have a characteristic partially disordered structure.

Although the Rietveld refinement is not completely satisfactory due to the aforementioned disorder, it can clearly be stated that γ-ZrAs has a mean crystal structure akin to other known γ-phases, namely a monoclinic $P2_1$ layered structure built up from AsO_4 tetrahedra and ZrO_6 octahedra stacked along the [001] direction. A polyhedral plot of the structure is shown in Figure 2. Six-sided cavities are present between the layers. The water molecules reside inside the cavities, where they are held by hydrogen bonds.

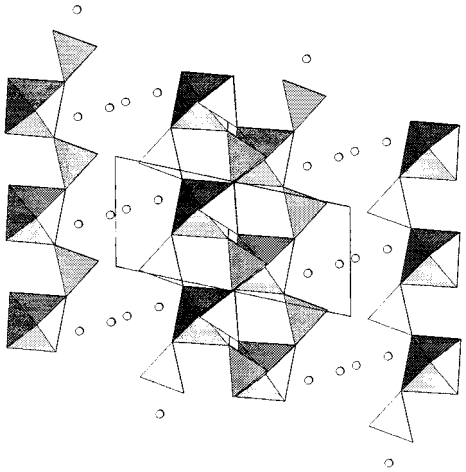

Figure 2. Polyhedral plot of the crystal structure viewed down the *b* axis; the *c* axis is vertical and the *a* axis is horizontal

Intercalation reactions of γ-ZrAs with amines were carried out in order to confirm the layered nature of the structure. The amines were chosen so as to represent the following classes: (a) primary linear amines (*n*-alkylamines), (b) primary cyclic amines (cyclohexylamine), (c) secondary cyclic amines (piperidine), (d) primary aromatic amines (benzylamine), and (e) heterocyclic amines (pyridine).

X-ray patterns of the intercalates showed the formation of new phases with basal spacings larger than in the case of γ-ZrAs (Table 4) and the total disappearance of the re-

flection at 11.80 Å, which is characteristic of the initial compound, except in the case of pyridine where this reflection persisted with a noticeable intensity. The intercalates maintain the lamellar structure, but a decrease in the order of the crystalline structure is observed.

several steps. Below 150°C, loss of water of crystallization takes place, and then between 150 and 450°C amine elimination occurs. At temperatures in excess of 500°C, ZrAs decomposition with As_2O_5 release and elimination of water due to condensation of the hydrogen arsenate groups take

Table 4. D-spacings, microanalytical data (C, N), experimental weight loss at 800°C, and tentative formulae of the intercalates

Piperidine	18.4	12.19	2.83	74.96	$Zr(AsO_4)(H_2AsO_4) \times C_5H_{11}N \times 2\ H_2O$
Pyridine	12.3	4.58	1.06	68.81	$Zr(AsO_4)(H_2AsO_4) \times 0.3\ C_5H_5N$

Figure 3 shows the X-ray patterns of some of the intercalates. It can be seen that in the case of *n*-alkylamines, the interlayer distances increase linearly with increasing number of carbon atoms in the alkyl chain (Figure 4). The resulting straight-line plot fits the equation $d_{002} = 10.0 + 2.48\ n_c$, with the slope corresponding to 2.48 Å per carbon atom. Since the increment in the alkyl chain length in a *trans-trans* conformation is generally estimated to be 1.27 Å per each additional carbon atom, the observed slope indicates, in agreement with the compositional data, that the *n*-alkylamines are arranged between the layers as a bimolecular film. The average angle α of inclination of the molecules with respect to the sheet amounts to $\sin^{-1}$ (2.48/2.54) = 77.5°. Similar behaviour has been observed for α-MP compounds (M = Zr, Ti, Hf).[21]

Tentative formulae for the intercalates were determined from elemental analysis and TG data, assuming that in all cases the final product of thermal transformations is ZrO_2 and that the change in weight is only due to amine and water losses and to γ-ZrAs decomposition with As_2O_5 release. Carbon and nitrogen contents, the total weight losses at 800°C, and the tentative formulae of the intercalates are compiled in Table 4. Analysis of these data shows that among the *n*-alkylamines, maximum uptake was only attained with methyl-, ethyl-, and hexylamine, whereas the others were only incorporated to an extent of ca. 4/3 mol of amine per mol of γ-ZrAs.

In the case of cyclic amines, the uptake does not reach the saturation level of the compound, only 1 (piperidine) and 0.3 (pyridine) mol of amine per mol of γ-ZrAs being incorporated. It was not possible to assign formulae in the case of cyclohexylamine or benzylamine since the C and N analysis values, the total weight loss at 800°C, and the apparent solidification of the amine, seemed to suggest that some amine polymerization had occurred.

Some typical TG curves for γ-ZrAs amine intercalates are reproduced in Figure 5. As can be seen, thermal decomposition on going from room temperature to 800°C occurs in

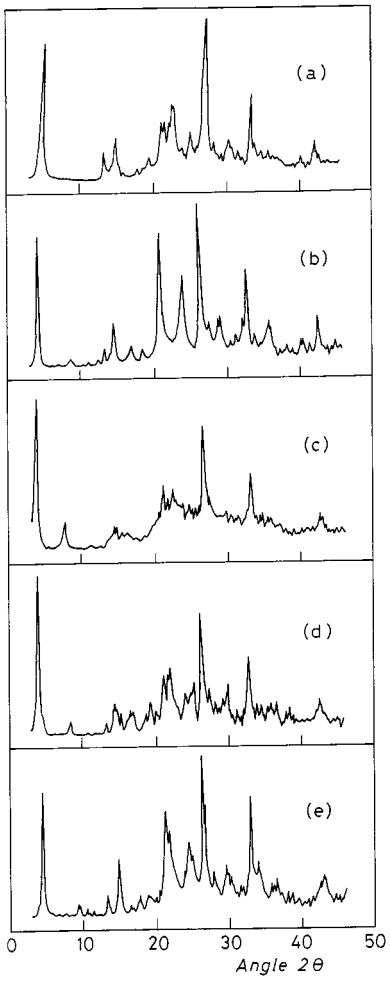

Figure 3. X-ray patterns of selected intercalates: (a) *n*-propylamine, (b) *n*-butylamine, (c) *n*-hexylamine, (d) cyclohexylamine, and (e) piperidine

place. The As_2O_5 release takes place at lower temperatures than in the case of unintercalated γ-ZrAs,[19] probably due

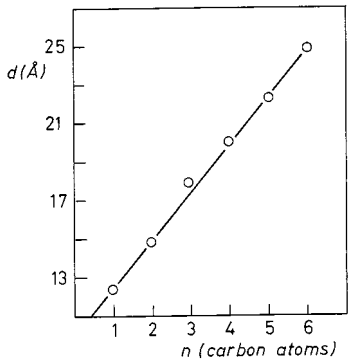

Figure 4. Interlayer distances in *n*-alkylamine intercalate compounds of γ-ZrAs as a function of the number of carbon atoms in the alkyl chain

to the loss of stability of the crystalline structure as a consequence of the presence of the amine in the interlayer space. From Figure 5, it is apparent that propylamine and butylamine intercalates do not contain water of crystallization, in contrast to the phases containing hexylamine and piperidine. For cyclohexylamine (total weight loss 93.68%) two well-differentiated losses can be observed, the first between 75 and 150°C (80.77%) corresponding to about 15.8 mol of amine per mol of γ-ZrAs, and the second at temperatures above 450°C (12.91%) corresponding to the release of As_2O_5 from γ-ZrAs and to the elimination of water upon condensation of the hydrogen arsenate groups.

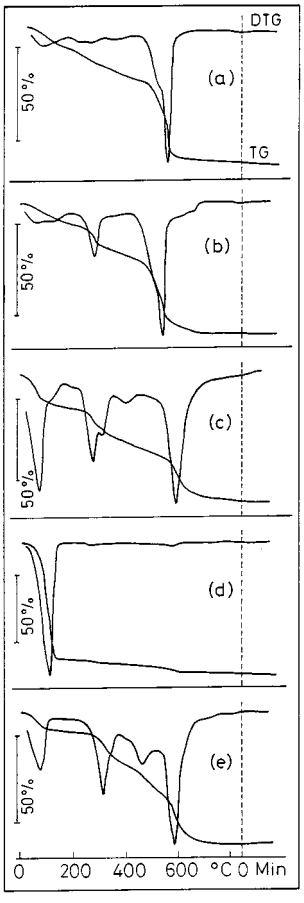

Figure 5. TG curves for selected γ-ZrAs intercalates: (a) *n*-propylamine, (b) *n*-butylamine, (c) *n*-hexylamine, (d) cyclohexylamine, and (e) piperidine

Conclusion

The crystal structure of γ-zirconium arsenate has been refined from X-ray powder diffraction data by the Rietveld method. It has a monoclinic $P2_1$ layered structure built up from AsO_4 tetrahedra and ZrO_6 octahedra stacked along the [001] direction. The final agreement factors are: R_{wp} = 0.21 and R_F = 0.068. The average As−O bond length is 1.66(1) Å.

It can be concluded that γ-ZrAs reacts readily with *n*-alkylamines, giving rise to new phases with expanded interlayer distances, which confirms its layered nature. In the case of cyclic amines, the intercalation becomes more difficult and cyclohexylamine and benzylamine form as yet uncharacterized, probably polymeric solids, the nature and composition of which will be the subject of future investigations.

Experimental Section

Synthesis: Crystalline γ-ZrAs, $Zr(AsO_4)(H_2AsO_4) \times 2\ H_2O$, was prepared by treatment of the half-exchanged ammonium phase γ-$Zr(AsO_4)[(NH_4)HAsO_4]$ with an excess of 2 M HCl, washed with deionized water, and dried in air. The half-exchanged ammonium phase was synthesized by adding a solution of $As_2O_5 \times 3\ H_2O$ and urea in an approximate mass ratio of 4:1 to zirconium propoxide (70% solution in *n*-propanol). The mixture was hydrothermally treated at 180°C for 6 d without stirring.[19] The solid obtained was characterized by X-ray diffraction, IR spectroscopy, and chemical and thermal analysis.

Structure Refinement: A sample of $Zr(AsO_4)(H_2AsO_4) \times 2\ H_2O$ (γ-ZrAs) was finely ground using an agate mortar and side-loaded onto a flat sample holder in order to minimize any preferred orientation effects. Step-scanned X-ray powder data were collected by means of a Philips PW 1050 computer-controlled automated diffractometer operating at 40 kV and 30 mA with a copper target and graphite-monochromated radiation. Data were collected in the range $3° < 2\theta < 110°$ with increments of 0.02° and a count time of 10 s per step. 22 low-angle unambiguously characterized reflections were extracted from the data and indexed by trial-and-error methods implemented in the program TREOR[22] with a monoclinic cell, giving figures of merit of M_{20} = 28[23] and F_{20} = 42(0.00837, 57).[24] Crystal data of γ-ZrAs are compared with those of γ-$M(PO_4)(H_2PO_4) \times 2\ H_2O$ (M = Ti, Zr, Hf) in Table 5.

Table 5. Crystal data for γ-phases

	γ-ZrAs	γ-HfP[25]	γ-ZrP[26]	γ-TiP[20]

a [Å]	5.5752(6)	5.3499(3)	5.3825(2)	5.186(1)
b [Å]	6.8290(7)	6.5949(4)	6.6337(1)	6.3505(8)
c [Å]	12.110(1)	12.3939(8)	12.4102(4)	11.865(3)
β [°]	103.03(1)	98.594(5)	98.687(2)	102.52(3)
V [Å^3]	449.21	432.37	438.03	381.47

In view of the similarities in the crystal data, the structural parameters of γ-ZrP[26] were used as the initial values for the Rietveld refinement using the program FULLPROF.[27] A pseudo-Voigt profile function was selected. After initial refinement of the scale, background, profile, and cell parameters, the atomic positions were refined using soft constraints for the AsO_4 tetrahedra and ZrO_6 octahedra. Additional distance constraints were needed for water molecules. All atoms were refined isotropically with a common temperature factor, $B = 1.23(8)$. No corrections were made for anomalous dispersion or absorption. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Fachinformationszentrum Karlsruhe (FIZ), D-76344 Eggenstein-Leopoldshafen, Germany, as supplementary publication No. FIZ-408717.

Intercalation Procedure: γ-ZrAs was equilibrated over a period of 7 d with the pure *n*-alkylamines or cyclic amines at 25°C according to the batch method. The solid was present in the solution in an approximate ratio of 1 g per 100 mL. The solids were subsequently separated by centrifugation, dried at 50°C for 24 h, and characterized by X-ray diffraction and thermal and chemical analysis.

Analytical Procedures: Zr and As contents of the solid samples were determined by elemental analysis using a SpectraSpec DCP-AEC spectrometer, following the dissolution of weighed amounts in HF. X-ray powder diffraction patterns were recorded with a Philips PW 1729/1720 computer-controlled diffractometer using Cu-K_α radiation ($\lambda = 1.542$ Å). Microanalytical data (C, N) were obtained with a Perkin-Elmer model 2400 elemental analyzer. The TG curves were obtained under nitrogen with a Mettler TA 4000 (TG 50) thermoanalyzer, employing a heating rate of 10°C min^{-1}.

Cobalt-Catalyzed Hydroformylation of Olefins in the Presence of Xenon: New Experimental Evidence for Metal–Xenon Adducts

Luca Rosi,*[a] Franco Piacenti,[a] Mario Bianchi,[a] Piero Frediani,[a] and Antonella Salvini[a]

Keywords: Hydroformylations / Rare gas / Homogeneous catalysis / Carbonylcobalt compounds

The rate of cobalt-catalyzed hydroformylation of cyclohexene to cyclohexanecarboxaldehyde is significantly reduced when xenon is added to the reaction mixture at a concentration similar to that of the olefin. No significant effect is produced by helium or neon under similar conditions. These experiments suggest competitive coordination of xenon to the catalytically active cobalt species.

We have recently reported that appropriate concentrations of gases such as dinitrogen or argon produce a significant retarding effect on aldehyde formation in the cobalt-catalyzed hydroformylation of olefins.[1] This behavior has been ascribed to the ability of these additional substances to compete with dihydrogen and/or the olefin for the vacant coordination site on the catalytically active carbonylcobalt intermediate. If this interpretation is correct, the effect should depend on the availability of the outer-shell electrons of the donor, as measured by its first ionization potential (IP). As the first IP decreases on going from helium to xenon,[2][3] we would expect xenon to exhibit a higher coordination ability than the lighter rare gases, although its larger size could partly counteract this tendency.[4][5][6][7][8][9][10]

As a matter of fact, available literature data on adducts of rare gases with transition metals indicate a slightly higher coordinating ability of xenon compared to both argon and krypton.[11][12] A further relevant observation is that the bond dissociation energies (BDEs) for xenon with the pentacarbonylmetal(0) fragments of Group 6 do not show any marked dependence on the nature of the metal.[12]

With this background, we reckoned that, in extension of previous studies,[1] additional evidence for xenon coordination to a transition metal could be obtained by studying its effect on the cobalt-catalyzed hydroformylation reaction. Rate retardation would be expected if the presumably coordinatively unsaturated cobalt intermediate were to be intercepted by xenon rather than by dihydrogen and/or the olefin, thereby decreasing the steady-state concentration of the catalytically active species. The magnitude of any such effect would be difficult to predict, but some insight into this matter may be gained by considering the available thermodynamic data concerning metal−dihydrogen and metal−olefin bonds.

The tungsten−dihydrogen BDE has been estimated[13] to be 83 kJ mol^{-1} in $W(CO)_3(PR_3)_2(H_2)$, which is about 50 kJ mol^{-1} higher than that reported for the W−Xe bond in $W(CO)_5Xe$ (35.1 ± 0.8 kJ mol^{-1}[11]). If a similar difference in stability between dihydrogen and xenon is maintained under hydroformylation conditions, we may expect to see an effect on the product conversion. The manganese(I)−ligand (L) bond in $Mn(\eta^5\text{-}C_5H_5)(CO)_2L$ (L = *cis*-cyclooctene) has been estimated to require 102.4 ± 10 kJ mol^{-1} for dissociation.[14]

We report here the results of our investigation into the cobalt-catalyzed hydroformylation of cyclohexene in the presence of added xenon. Toluene was chosen as the reaction medium since competitive coordination of the catalytically active species by this solvent was anticipated to be minimized by both its self-aggregation (the relatively high enthalpy of vaporization[13g] is ΔH_v = 33.2 kJ mol^{-1} at T_{bp} = 383.6 K) and owing to the disruption of resonance energy that would occur upon coordination through only part of the π electron density.

$$RCo(CO)_4 + L \rightleftharpoons RCo(CO)_3L + CO$$

for	R = H, $Co(CO)_4$	L = H_2, olefin, Ar, Xe
for	R = alkyl, acyl	L = H_2, Ar, Xe

Our results are collected in Table 1, together with those from similar experiments (see Experimental Section) carried out in the presence of helium or neon. Helium and neon have no significant effect on the rate of the hydroformylation reaction; the slight decrease in conversion observed may be attributed to the dilution effect caused by the volume increase of the liquid medium due to the gas dissolution under the reaction conditions.

The presence of xenon has a negative effect on the rate of hydroformylation of the olefin. Taking into consideration that the experimentally determined amount of argon present in the liquid phase at 1000 bar and 373 K (0.086 mol) is, on a molar basis, approximately six times as large (see Experimental Section) as the amount of xenon (0.014 mol), the 30% drop in the conversion obtained in the presence of the latter suggests a stronger coordinating ability of xenon compared to argon, as anticipated in the introductory remarks and in agreement with the literature results.

Table 1. Conversion (%) to cyclohexanecarboxyaldehyde in the hydroformylation of cyclohexene in the presence of rare gases (RG)[a]

RG	RG pressure				Ref.
	0 bar	500 bar	800 bar	1000 bar	
Helium[b]	30	29	27	–	[c]
Neon[b]	30	29	–	–	[c]
Argon[b]	30	19	10	9	[1]
	RG weight[b]				
	0 g	2.5 g	–	3.8 g	
Xenon[d]	30	25	–	21	[c]

[a] Reaction conditions: dry toluene, 7 mL; $Co_2(CO)_8$, 51 mg (0.149 mmol); cyclohexene, > 99.9% purity by GC, 504 mg (6.15 mmol); $p(CO) = 70 \pm 1$ bar (373 K); $p(H_2) = 85 \pm 2$ bar (373 K); autoclave volume, 25.4 mL; temperature, 373 K; reaction time, 3 h. – [b] Gases introduced in the following order: CO, dihydrogen, RG. – [c] This work. – [d] Gases introduced in the following order: CO (1 bar), xenon, CO (54 ± 2 bar at room temperature, 68 ± 2 bar at 373 K), H_2 (85 ± 3 bar at 373 K). Pressures are equilibrium readings after physical absorption (about 20 min).

Furthermore, in the presence of 270 bar of argon (19 mmol in the liquid phase) the conversion is not influenced, whereas in the presence the same molar amount of xenon in the liquid phase (18.5 bar, 19 mmol in the liquid phase) a reduction in the degree of conversion (16%) is observed.

In view of the BDE data mentioned above, a dihydrogen–xenon competition appears to be most likely. Catalytic hydrogenations represent another important class of reactions where indirect evidence concerning the coordinating ability of rare gases can be anticipated. Experiments along these lines, in both homogeneous and heterogeneous systems, will be undertaken in due course.

Experimental Section

The experiments in the presence of uncondensable gases (He or Ne) were carried out as follows: the catalyst, solvent, olefin, and carbon monoxide were introduced sequentially into the autoclave and the contents were heated at 373 K. Dihydrogen, followed by the additional rare gas, were then rapidly added. The reaction conditions were maintained for 3 h. In the case of xenon, which has a higher b.p. (162 K) than either helium or neon and is thus more easily condensed, the operations were carried out in the following sequence: introduction of the catalyst, solvent, olefin, xenon, and carbon monoxide at room temperature; heating to 373 K; pressurization with dihydrogen. The amount of xenon introduced was determined by the weight difference of the cylinder. At 373 K, the following equilibrium pressures (bar) were measured after introduction of xenon (weight of xenon in parentheses): 18.5 (2.5 g), 23.5 (3.8 g).

The amount of argon dissolved in the solution at 1015 bar and 373 K was experimentally determined to be about 0.086 mol; the amount of xenon (total 3.8 g) dissolved at the same temperature was estimated to be about 0.014 mol.

Acknowledgments

The authors wish to thank Prof. Fausto Calderazzo for very fruitful discussions and suggestions. This work has been partially supported by the Ministero della Università e della Ricerca Scientifica e Tecnologica (MURST).

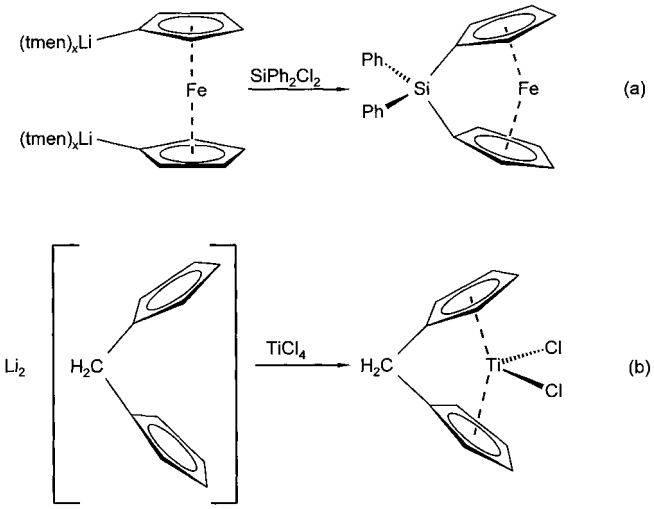
Synthesis and Structure of the First [1]Boratitanocenophanes



Holger Braunschweig,*[a] Carsten von Koblinski,[a] and Ruimin Wang[a]

Keywords: Boron / Titanium / Metallocenophanes / [1]Boratitanocenophanes

This paper presents two methods for the synthesis of the first [1]boratitanocenophanes. The novel biscyclopentadienylborane $[(Me_3Si)_2NB(C_5H_5)_2]$, the dilithio salt $Li_2[(Me_3Si)_2NB(C_5H_4)_2]$ (**1**) of which was characterized by multinuclear NMR methods, was prepared in situ, and served as starting material for several [1]boratitanocenophanes. $[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**2**) was obtained in high yield by a convenient one-pot synthesis starting from **1** and $[TiCl_3(thf)_3]$, followed by oxidation with $PbCl_2$. The highly reactive $[(Me_2N)_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**3**) was obtained by the reaction of $[(Me_3Si)_2NB(C_5H_5)_2]$, prepared in situ, with $Ti(NMe_2)_4$ and converted into the chloro derivatives $[(Me_2N)ClTi\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**4**) and $[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**2**) by treatment with one or two equivalents of a suitable diaminochloroborane. All [1]boratitanocenophanes were characterized in solution by multinuclear NMR spectroscopy, and in addition the structure of **2** in the crystalline state was determined by a single-crystal X-ray study.

Introduction

[1]Metallocenophanes have been known for almost 30 years, and since then these compounds have attracted considerable interest due to their versatile chemistry. The first example of a [1]ferrocenophane was obtained by the reaction of dilithioferrocene·tmen (tmen = tetramethylethylenediamine) with $(C_6H_5)_2SiCl_2$ (Equation 1a).[1] Due to the high ring strain of such complexes, which depends on the covalent radius of the bridging atom, [1]ferrocenophanes undergo thermal or radiation-induced ring-opening polymerization[2a,b] yielding high molecular weight polyferrocenes.[3a–d] Corresponding [1]metallocenophanes of early transition-metal complexes were obtained, for example, by the reaction of $Li_2[H_2C(C_5H_4)_2]$ with $TiCl_4$ (Equation 1b).[4] Such metallocenophanes especially of titanium and zirconium have already proven to be highly active Ziegler–Natta-type catalysts for the olefin polymerization.[5]

We have started to investigate the synthesis and properties of [1]borametallocenophanes, since we expect a particularly interesting reactivity of such compounds. On one hand, the incorporation of the small boron atom into the bridge of a [1]ferrocenophane leads to highly strained, and thus very reactive molecules. That was already demonstrated in the case of $[Fe\{(\eta^5\text{-}C_5H_4)_2BN(SiMe_3)_2\}]$, which exhibits the highest tilt angle of 32.4(2)° recorded for a [1]ferrocenophane to date.[6] On the other hand catalytic processes with metallocenophanes of early transition metals could be accelerated by a Lewis acidic atom such as boron in the bridge. Very recently, the first [1]borazirconocenophane was synthesized and structurally characterized.[7] This compound, however, exhibits SMe_2 as a boron-coordinated base, thus cancelling the Lewis acidity of the bridging boron atom. A [1]borazirconocenophane with a three-fold coordinated boron atom was reported in 1996,[8] the structure of this product in the crystal, however, is not known.

Dilithiometallocenes, which serve as starting materials for the synthesis of [1]metallocenophanes according to Equation 1a, are only available in the case of iron and ruthenium. In order to achieve a method for the preparation of various [1]borametallocenophanes we aimed at the synthesis of bis(cyclopentadienyl)boranes as versatile ligands. In contrast to the well-developed chemistry of cyclopentadienylboranes[9a–f] the knowledge of bis(cyclopentadienyl)boranes is restricted to a few examples of the type $(C_5H_4R)_2BPh$ (R = $SiMe_3$, $SnMe_3$).[8][10] Due to decomposition during distillation these products could not be isolated in pure form. Related compounds, however, with four-coordinate boron atoms include the lithium borate $Li(OEt_2)_4[(C_5H_5)_2B(C_6F_5)_2]$[11] and the borane–pyridine adduct $(C_5H_5)_2PhBNC_5H_5$.[12]

In the present paper we report the high-yield synthesis and spectroscopic characterization of the dilithiated biscyclopentadienylborane $Li_2[(Me_3Si)_2NB(C_5H_4)_2]$ and its re-

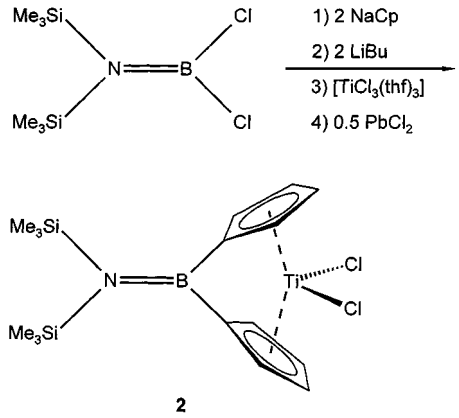
action with $[TiCl_3(thf)_3]$ giving the first [1]boratitanocenophane. An alternative route for the synthesis of such compounds starting from $[(Me_3Si)_2NB(C_5H_5)_2]$ is also described.

Results and Discussion

The reaction of $(Me_3Si)_2NBCl_2$ with a slight excess of NaC_5H_5 in hexane followed by filtration and treatment of the hexane filtrate with 2 equivalents of LiBu afforded $Li_2[(Me_3Si)_2NB(C_5H_4)_2]$ (**1**) in almost quantitative yield as a white pyrophoric solid (Equation 2).



1

The structure of **1** in solution derives from the NMR spectra showing the expected signal patterns for the monosubstituted cyclopentadienyl rings and an ^{11}B-NMR signal at $\delta = 46.6$, characteristic for an aminodiarylborane. This compound proved to be highly reactive and shows considerable signs of decomposition in thf solution, and even in the solid state at ambient temperature. Hence, for subsequent syntheses we found it convenient not to store the ligand, but rather to prepare it in situ.

According to Equation 3, the [1]boratitanocenophane $[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**2**) was obtained in a four-step one-pot synthesis. The dilithio salt **1**, which was obtained as a hexane slurry by the method described above, was treated with an equimolar amount of $[TiCl_3(thf)_3]$ at $-100\,^{\circ}C$ and the intermediate Ti^{III} species was subsequently oxidized with $PbCl_2$ according to a known procedure.[13]

Complex **2** was obtained as dark red crystals from CH_2Cl_2 in 80% yield. The compound was found to be very soluble in halogenated solvents, such as $CHCl_3$ or CH_2Cl_2, and less soluble in aromatic solvents such as benzene or mesitylene. Solutions of **2** are very sensitive to air and moisture, and an instant colour change from dark red to light green indicates decomposition.

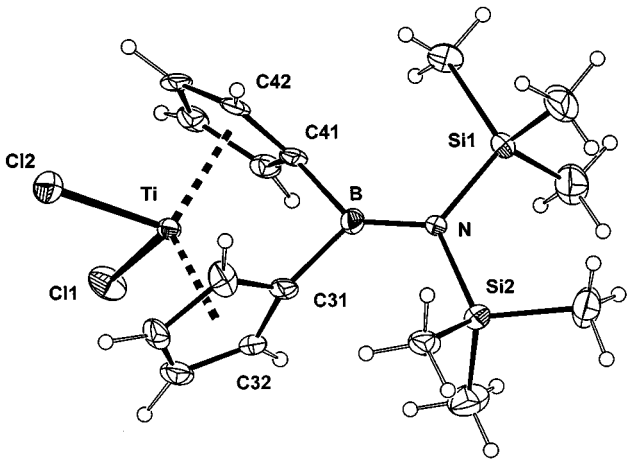
The constitution of **2** in solution is deduced from NMR spectra. The ^{1}H-NMR spectra show the expected two pseudo triplets at $\delta = 5.53$, and 7.05 for the cyclopentadienyl protons forming an AA′BB′ spin system, and the

2

80 % yield

^{11}B-NMR signal at $\delta = 46.6$ matches that of the uncoordinated ligand.

Suitable single crystals for an X-ray structure analysis were obtained by recrystallization from benzene at 7°C (Figure 1). In the solid state the molecule exhibits a slight deviation from the ideal C_{2v} symmetry, which is assumed for its structure in solution. This is demonstrated, for example, by the twisting of the Si1−N−Si2 plane with respect to the $Cp_c1-Ti-Cp_c2$ (Cp_c = ring centroid) plane; the corresponding dihedral angle was determined to be 11.5°. The comparison of the present structure with that of $[Cp_2TiCl_2]$ shows some characteristic differences, due to the albeit small strain of **2**.[14] The tilt angle between the two cyclopentadienyl rings as well as the Cl1−Ti−Cl2 angle is larger by about 3°, while the $Cp_c1-Ti-Cp_c2$ angle decreases by almost 13° with respect to the corresponding values found for $[Cp_2TiCl_2]$. While the cyclopentadienyl rings are staggered in the latter molecule, they adopt an eclipsed conformation in the present case. The boron−nitrogen distance was found to be 138(1) pm, thus being in the expected range for a B−N double bond.



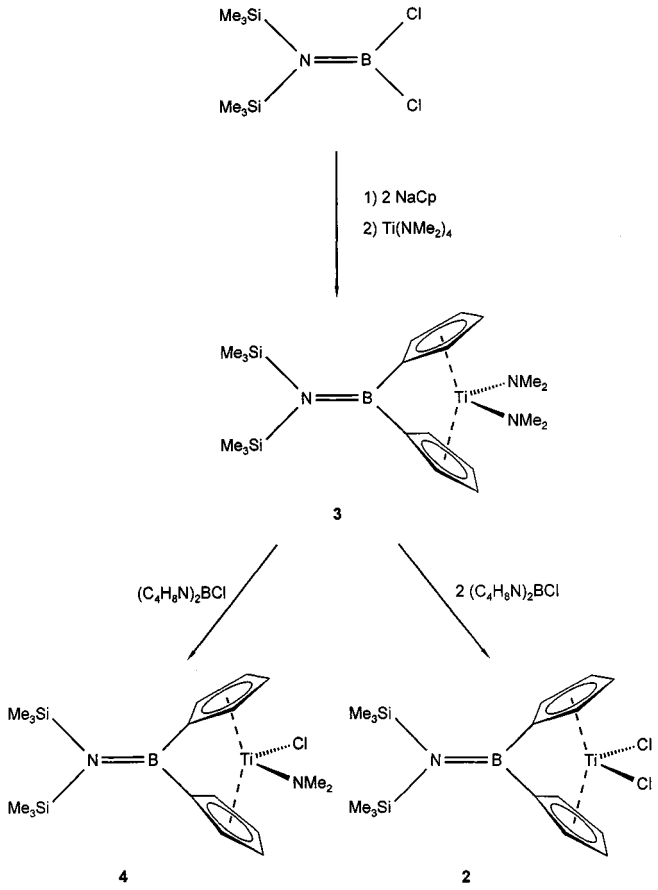


Figure 1. Structure of **2** in the crystal (ellipsoids at 30% probability); selected distances [pm] and angles [°]: Ti−Cl1 233.1(2), Ti−Cl2 233.9(2), B−N 138(1); Cl1−Ti−Cl2 97.45(9), C31−B−C41 98.3(6), C41−B−N 132.8(6), C31−B−N 128.6(6)

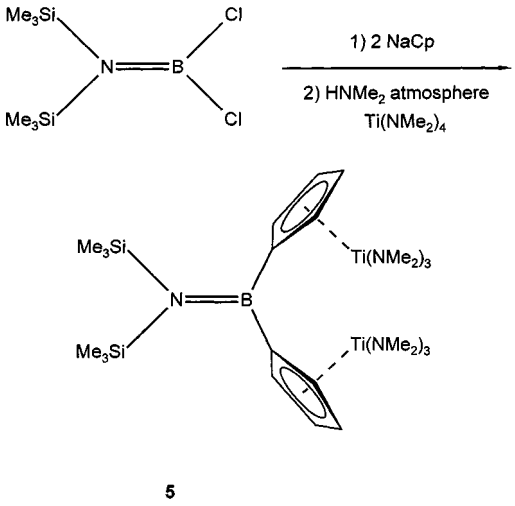
All attempts to obtain **2** directly from $Li_2[(Me_3Si)_2NB(C_5H_4)_2]$ (**1**) and $TiCl_4$ or $[TiCl_4(thf)_2]$ resulted in mixtures of several products, which could not be separated.

The reaction of $[(Me_3Si)_2NB(C_5H_5)_2]$ prepared in situ with $Ti(NMe_2)_4$, however, proved to be a suitable method for the direct preparation of a corresponding Ti^{IV} species. $[(Me_2N)_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**3**) was obtained as a dark red solid in yields of about 30% with formation of two equivalents of $HNMe_2$ (Equation 4). Due to the labile NMe_2 ligands **3** shows an even greater tendency to decompose compared to $[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**2**), and hence, cannot be stored at ambient temperature even in the solid state.



By treating this compound in situ with one or two equivalents of a chloroborane of moderate reactivity such as $(C_4H_8N)_2BCl$, however, it may be converted into the more stable chloro derivatives $[(Me_2N)ClTi\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**4**) and $[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**2**), respectively (Equation 3), which were isolated in yields of about 40% and 15%.

These reactions occurred with substitution of the titanium-bound NMe_2 groups and formation of the corresponding triaminoborane $(C_4H_8N)_2BNMe_2$, which was characterized by ^{11}B-NMR spectroscopy from the reaction mixture ($\delta = 26.0$). The use of diaminochloroboranes proved to be crucial for this synthesis, since the more reactive aminodichloroboranes always led to decomposition of **3**.

Due to its lower symmetry, $[(Me_2N)ClTi\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**4**) shows four signals for the cyclopentadienyl groups in the ^1H-NMR spectra at $\delta = 5.08$, 5.29, 6.62, and 6.83. Furthermore, the spectroscopic findings for **3** and **4**, such as the ^{11}B-NMR signals at $\delta = 46.9$, and 46.4, are comparable to those of **2**, thus proving their structure in solution.

The instability of **3** is obviously due to the cleavage of the NMe_2 ligands, and hence we attempted to synthesize this compound under an atmosphere of $HNMe_2$. The reaction of $Ti(NMe_2)_4$ with one equivalent of $[(Me_3Si)_2NB(C_5H_5)_2]$ under a constant flow of dimethylamine, however, resulted in the formation of the dinuclear half sandwich complex **5** (Equation 5), which was isolated in yields of about 45% as a red brown solid. The structure of **5** in solution was deduced from the NMR spectra, resembling those of the related chloro derivative $[(Cl_3Ti)_2\{(C_5H_4)_2BPh\}]$, which was also characterized in the crystalline state.[10]

Conclusion

The synthesis and characterization of the first [1]boratitanocenophanes was achieved by two different methods starting from the novel bis(cyclopentadienyl)borane $[(Me_3Si)_2NB(C_5H_5)_2]$.

The highly reactive bis(dimethylamido) complex $[(Me_2N)_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**3**) was achieved directly from the reaction of this ligand with $Ti(NMe_2)_4$, whereas the corresponding dichloro derivative $[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**2**) was obtained by a convenient one-pot synthesis in high yield starting from the dilithiated ligand $Li_2[(Me_3Si)_2NB(C_5H_4)_2]$ (**1**), and $[TiCl_3(thf)_3]$ followed by oxidation of the intermediate Ti^{III} species with $PbCl_2$. The latter complex was chosen as a representative example for X-ray structure analysis. Compound **3** served as starting material for the preparation of $[(Me_2N)ClTi\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**4**) and $[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (**2**) by substitution of the NMe_2 group with a suitable diaminochloroborane.

[1]Metallocenophanes of group-4 elements containing a Lewis acidic atom such as boron in the bridge should serve

as effective catalysts for Ziegler−Natta-type olefin polymerizations. Our further work will focus on the utilization of the convenient synthetic method being described in this paper and especially on the investigation of the catalytic properties of such compounds. Preliminary experiments already proved **2** and **4** to be suitable catalysts for the polymerization of ethene.

Experimental Section

All manipulations were carried out under dry nitrogen with common Schlenk techniques. Solvents and reagents were dried by standard procedures, distilled, and stored under nitrogen over molecular sieves. $(Me_3Si)_2NBCl_2$,[15] NaC_5H_5,[16] $Ti(NMe_2)_4$,[17] $[TiCl_3(thf)_3]$,[18] and $(C_4H_8N)_2BCl$[19] were synthesized according to literature procedures. NMR: Varian Unity 500 at 499.843 MHz (^1H, internal standard TMS), 150.364 MHz (^{11}B, $BF_3\cdot OEt_2$ in C_6D_6 as external standard), 125.639 MHz ($^{13}C\{^1H\}$, APT, internal standard TMS); all NMR spectra were recorded in CD_2Cl_2 as solvent unless otherwise stated. Mass spectra were recorded with a Finnigan MAT 95 (70 eV) and elemental analyses (C, H, N) were obtained from a Carlo-Erba elemental analyzer, model 1106.

$Li_2[(Me_3Si)_2NB(C_5H_4)_2]$ (1): 8.23 g (93.54 mmol) NaC_5H_5 was suspended in 100 mL of hexane and a solution of 11.13 g (46.05 mmol) of $(Me_3Si)_2NBCl_2$ in 20 mL of hexane was added dropwise at ambient temperature. After stirring for 2 h, the reaction mixture was cooled to 0°C and 57.6 mL (92.10 mmol) of a 1.6 M BuLi solution was added dropwise. A white precipitate formed immediately. The reaction mixture was allowed to warm up to ambient temperature and after stirring for 1 h, all volatiles were removed in high vacuum, and the solid residue was extracted with 150 mL of hexane overnight. The mixture was filtered and the solid dried in vacuo to give **1** as a white, pyrophoric solid in yields of 98% (14.13 g). − ^1H NMR ([D$_8$]THF): δ = 0.01 [s, 18 H, $Si(CH_3)_3$], 5.83 (m, 4 H, C_5H_4), 6.45 (m, 4 H, C_5H_4). − ^{11}B NMR: δ = 46.6 (s). − ^{13}C NMR: δ = 4.31 [s, $Si(CH_3)_3$], 103.16, 106.63, 116.63 (C_5H_4).

$[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (2) (Method A): As described for **1** 3.20 g (13.24 mmol) of $(Me_3Si)_2NBCl_2$ was treated with 2.39 g (27.17 mmol) of NaC_5H_5 and to the obtained filtrate was added 16.6 mL (26.48 mmol) of 1.6 M BuLi in hexane. The light yellow suspension was stirred at ambient temperature for 2 h, cooled to −100°C, and 4.90 g (13.24 mmol) of $[TiCl_3(thf)_3]$ and 20 mL of thf were added. The mixture was allowed to come to ambient temperature, and the colour changed from light brown to dark violet. The suspension was stirred for 3 h and then treated with 1.84 g (6.62 mmol) of $PbCl_2$. After stirring for 16 h, all volatile materials were removed in high vacuum. The remaining solid was extracted with 50 mL of CH_2Cl_2 and filtered. **2** was recovered from the filtrate at −30°C as a dark red solid (4.43 g, 80%). − ^1H NMR: δ = 0.08 [s, 18 H, $Si(CH_3)_3$], 5.53 (m, 4 H, C_5H_4), 7.05 (m, 4 H, C_5H_4). − ^{11}B NMR: δ = 46.6 (s). − ^{13}C NMR: δ = 4.89 [$Si(CH_3)_3$], 114.85, 133.44 (C_5H_4). − MS; *m/z* (%): 417 (35) [M^+], 402 (15) [M^+ − Me], 382 (25) [M^+ − Cl]. − $C_{16}H_{26}BCl_2NSi_2Ti$ (418.18): calcd. C 45.96, H 6.27, N 3.35; found C 46.56, H 7.05, N 2.87.

$[(Me_2N)_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (3): As described for **1** 2.08 g (8.60 mmol) of $(Me_3Si)_2NBCl_2$ was treated with 1.51 g (17.20 mmol) of NaC_5H_5. The obtained filtrate was cooled to −30°C, and a solution of 1.93 g (8.60 mmol) of $Ti(NMe_2)_4$ in 5 mL of hexane was added dropwise. The mixture was allowed to warm up to ambient temperature, and the colour changed from yellow to dark red. After stirring for 1 h, all volatiles were removed in high vacuum, and the remaining solid was suspended in 10 mL of hexane. After filtration and removal of all volatiles under high vacuum, compound **3** was obtained as a dark red solid (1.05 g, 28%). − ^1H NMR: δ = 0.09 (s, 18 H, $Si(CH_3)_3$), 3.14 (s, 12 H, $N(CH_3)_2$), 5.42 (m, 4 H, C_5H_4), 6.73 (m, 4 H, C_5H_4). − ^{11}B NMR: δ = 46.9 (s). − ^{13}C NMR: δ = 4.89 [$Si(CH_3)_3$], 51.11 [$N(CH_3)_2$], 112.73, 131.66 (C_5H_4). − $C_{20}H_{38}BN_3Si_2Ti$ (435.43): calcd. C 55.17, H 8.80, N 9.65; found C 55.62, H 8.22, N 9.59.

$[(Me_2N)ClTi\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (4): As describes for **1** 1.09 g (4.50 mmol) of $(Me_3Si)_2NBCl_2$ was treated with 0.88 g (10.00 mmol) of NaC_5H_5. The obtained filtrate was cooled to −30°C, and a solution of 1.01 g (4.50 mmol) of $Ti(NMe_2)_4$ in 5 mL of hexane was added dropwise. The mixture was allowed to warm up to ambient temperature, and treated with 0.84 g (4.50 mmol) of $(C_4H_8N)_2BCl$. After stirring for 1 h, all volatiles were removed in high vacuum, and the remaining solid was suspended in 20 mL of hexane, filtered and stored at −30°C to yield 0.79 g (41%) of compound **4** as a dark red crystalline solid. − ^1H NMR ($CDCl_3$): δ = 0.28 (s, 18 H, $Si(CH_3)_3$), 3.26 (s, 6 H, $N(CH_3)_2$), 5.08 (m, 2 H, C_5H_4), 5.29 (m, 2 H, C_5H_4), 6.62 (m, 2 H, C_5H_4), 6.83 (m, 2 H, C_5H_4). − ^{11}B NMR: δ = 46.4 (s). − ^{13}C NMR: δ = 7.53 [$Si(CH_3)_3$], 57.54 [$N(CH_3)_2$], 115.73, 117.57, 126.93, 128.54 (C_5H_4). − $C_{18}H_{32}BClN_2Si_2Ti$ (426.80): calcd. C 50.66, H 7.56, N 6.56; found C 50.23, H 7.59, N 6.39.

$[Cl_2Ti\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (2) (Method B): As described for **4** 1.45 g (6.00 mmol) of $(Me_3Si)_2NBCl_2$ was treated with 1.08 g (12.30 mmol) of NaC_5H_5, and to the obtained filtrate was added a solution of 1.34 g (6.00 mmol) of $Ti(NMe_2)_4$ in 5 mL of hexane. The resulting mixture was subsequently treated with 2.24 g (12.00 mmol) of $(C_4H_8N)_2BCl$ to yield 0.38 g (15%) of **2** as a dark red crystalline solid.

$[((Me_2N)_3Ti)_2\{(C_5H_4)_2BN(SiMe_3)_2\}]$ (5): As described for **1** 1.31 g (5.40 mmol) of $(Me_3Si)_2NBCl_2$ was treated with 0.97 g (11.00 mmol) of NaC_5H_5. The obtained filtrate was cooled to −30°C, and a solution of 1.21 g (5.40 mmol) of $Ti(NMe_2)_4$ in 5 mL of hexane was added dropwise under a constant stream of $HNMe_2$. After warming up to ambient temperature, the dark red solution was stirred for 1 h and then stored under an atmosphere of $HNMe_2$ at −30° C. After 3 d, compound **5** was isolated as a red brown solid (1.60 g, 45%). − ^1H NMR (C_6D_6): δ = 0.28 [s, 18 H, $Si(CH_3)_3$], 3.18 [s, 36 H, $N(CH_3)_2$], 6.14 (m, 4 H, C_5H_4), 6.78 (m, 4 H, C_5H_4). − ^{11}B NMR: δ = 46.9 (s). − ^{13}C NMR: δ = 5.79 [$Si(CH_3)_3$], 50.35 [$N(CH_3)_2$], 113.03, 121.65 (C_5H_4). − MS: *m/z* (%) = 615 (5) [M^+ − $N(CH_3)_2$], 571 (50) [M^+ − 2 $N(CH_3)_2$], 527 (50) [M^+ − 3 $N(CH_3)_2$], 347 (100) {[$(CH_3)_3Si]_2NBCp_2Ti$}. − $C_{28}H_{62}BN_7Si_2Ti_2$ (659.64): calcd. C 50.98, H 9.47, N 14.86; found C 50.56, H 9.36, N 14.77.

X-ray Structure Determination of 2: $C_{16}H_{26}BCl_2NSi_2Ti$, ENRAF-Nonius CAD4; Mo-K_α radiation (λ = 0.71073 Å, graphite monochromator); data collection with ω scan at 203 K. Dark red platelet, 0.06 × 0.24 × 0.65 mm, monoclinic space group *C*2/*c* (No. 15), M = 418.18 g mol^{-1}, unit cell dimensions a = 28.493(8) Å, b = 10.540(4) Å, c = 15.103(5) Å, β = 112.71(3)°, V = 4184(5) Å^3, Z = 8, $\rho_{calcd.}$ = 1.33 g cm^{-3}, μ(Mo-K_α) = 7.73 cm^{-1}; 5040 reflections were collected in the scan range 2° < Θ < 25°; after Lorentz and polarization corrections, an empirical absorption correction based on azimuthal scans[20] (min. transm. 0.766, max. transm. 1.000) was applied before averaging symmetry-related intensity data. Since the crystal was not stable, intensity data were corrected for the resulting decay on the basis of three regularly measured check reflections. 2510 independent observations with $I > \sigma(I)$ in structure solution by direct methods[21] and refinement with the

SDP program system[22] for 208 variables; all non-hydrogen atoms were refined with anisotropic displacement parameters, hydrogen atoms were included in riding geometry with fixed isotropic displacement parameters [C−H = 0.98 Å, U_{iso}(H) = 1.30 U_{eq}(C)]. Convergence at R = 0.092, R_w = 0.076, $w^{-1} = \sigma^2(F_o)$, GOF = 1.324. Max. residual electron density 0.722 eÅ^{-3}. Further details on the crystal structure determination can be obtained from the Cambridge Crystallographic Data Centre (CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk) on quoting the depository number CCDC-102132.

Molecular Precursors to Ceramics II[+]

[(Trichlorosilyl)dichloroboryl]ethane: Synthesis and Characterisation by Means of Experiment and Theory

Marcus Gastreich,*[a] Christel M. Marian,[b] Hardy Jüngermann,[c] and Martin Jansen[d]

Dedicated to the memory of Marco Häser

Keywords: TSDE / Ceramics / Theoretical IR-spectroscopy / RI-MP2

A new compound for the molecular synthesis route to high-demand Si/B/N/C ceramics has been found and is described in this work. We report on an elegant "one-pot" synthesis of [(trichlorosilyl)dichloroboryl]ethane (TSDE, $Cl_3Si–CH-[(CH_3)(BCl_2)]$) and its structural characterisation by means of nuclear magnetic resonance and (theoretical and experimental) infra-red spectroscopy. Density functional and Hartree-Fock calculations combined with a perturbational treatment of the electron correlation have been performed. Both methods yield good agreement of theoretical and experimental spectra, with the perturbational approach being slightly superior. In a similar way to the amino compound [(trichlorosilyl)amino]dichloroborane (TADB), TSDE exhibits a planar coordination of the dichloroboryl terminus but tetrahedral neighbourhoods for both carbon and silicon. The electronic structure has been investigated and a $\sigma - n$ order of the frontier orbitals shall be discussed.

Introduction

This paper represents the second part of a series reporting on the synthesis and characterisation of molecular precursors for covalent amorphous Si/B/N/(C) ceramics. As has been shown previously,[2] the so-called *precursor route*, i.e. the way of forming covalent networks from molecular precursors with prebuilt structural units, often leads to most useful high-demand ceramics with outstanding features such as exceptional temperature resistance, corrosion stability and hardness. As examples, we have listed three novel ceramic syntheses and the resulting thermal stabilities of the compounds obtained when using the precursor route shown in Figure 1. The interested reader may find more information on this approach to high-performance ceramics in the literature.[3–5]

In order to understand the structural principles behind these syntheses we have, in this publication, combined experimental and *ab initio* techniques to study the structural properties of [(trichlorosilyl)dichloroboryl]ethane (TSDE) for which a patent has been acquired.[6]

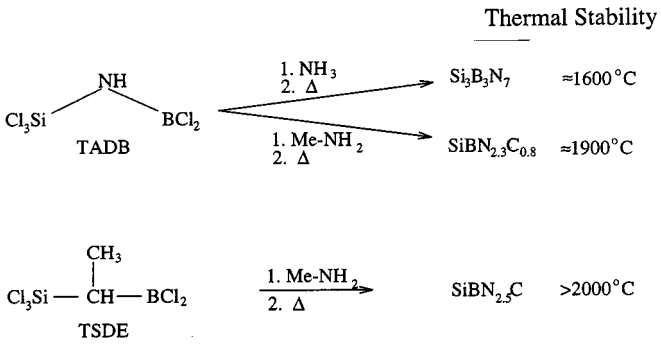

Figure 1. Novel Si/B/N/C-ceramics and their thermal stabilities

Synthesis

0.1 mol of boron trichloride was condensed at −65 °C in a round-bottomed-flask equipped with a dropping funnel and a pressure compensation valve. 0.1 mol of trichlorovinylsilane and 0.1 mol of triethylsilane were mixed and added to the boron trichloride during 15 min. The mixture was stirred for 1h and allowed to warm up to room temperature. The reaction mixture, consisting of the product and triethylchlorosilane, was distilled over a 30 cm Vigreux column. A 64.1% yield of 1-(trichlorosilyl)-1-(dichloroboryl)ethane (TSDE) was obtained at 35–40 °C/12mbar. At room temperature, the product is a colourless liquid which is extremely sensitive to moisture and air.[7]

Characterisation

Experimental Setup

Infra-Red Spectrum: The IR-spectroscopic measurements were conducted using a Fourier transform infrared (FT-IR) spectrometer (model IFS 113v, Bruker Co., Karlsruhe, Germany). The equipment has a modified interferometer by Genzel. Compared to a machine with a Michelson arrangement and the same optical unit dimensions, we obtain double resolution. A globar was used as the light source in the MIR range, and a mercury-cadmium telluride photodetector registered the transmission. No smoothing operators were applied, but a baseline correction was carried out. A liquid sample of neat TSDE was deposited in a cuvette with KBr windows and the spectrum was measured in the absence of water vapor and air at 20 °C.

NMR Spectra: The liquid NMR spectra were recorded on a Bruker AMX 300 spectrometer (Karlsruhe, Germany). The samples had been prepared by mixing neat TSDE with $CDCl_3$ for ^1H as well as for ^{13}C spectroscopy.

Theoretical Methods

Energies and Geometries: Geometry optimisations were carried out with TURBOMOLE v.4.6[8,9] and Gaussian 94.[10] We employed standard relaxation routines based on the Rational-Function or the Quasi-Newton-Raphson models; the initial Hessian matrix was updated by the BFGS algorithm throughout the calculations.[11] At points of vanishing gradient, we determined the matrix of second derivatives of the energy with respect to the nuclear coordinates (Hessian matrix) and computed its eigenvalues to check for imaginary frequencies. Our former investigations were based on molecular hypersurfaces determined on the local density functional level of theory[12] with the Slater exchange- and Vosko-Wilk-Nusair-correlation functionals.[1] These data were reasonable with the exception of hydrogen bond lengths, whose vaues were a bit too long. In the present case, we therefore used the B3LYP[13−15] density functional that employs a three-parameter hybrid functional for the exchange part of the molecular energy and a gradient-corrected functional for the electronic correlation energy. As an alternate correlation treatment to the density functional formalism, we employed the efficient RI-MP2 procedure by Feyereisen, Fitzgerald and Komornicki[16] and implemented by Weigend and Häser[17] to determine both the equilibrium structure and the vibrational spectrum of [trichlorosilyl-(dichloroboryl)]ethane. For the search of the global minimum of the potential energy surface (PES) of TSDE, we have chosen molecular conformers that differed in terms of the relative torsional positions of the BCl_2, $SiCl_3$, and CH_3 groups.

In order to validate the theoretical models with respect to further analysis of the electronic structure, we first calculated the root mean square (rms) deviations of the (scaled) vibrational frequencies for the two different levels of theory. The perturbational correlation treatment was found to be slightly inferior: For B3LYP we determined an rms value of 29 wavenumbers, the perturbational formalism yielded 36 wavenumbers). In any case, we consider the RI-MP2 model advantageous on the basis that one false ordering of frequencies was obtained with the DFT formalism (see below). Thus, subsequent examinations of bonding characteristics etc. will be based on the RI-MP2 geometries, energies and Roothaan-Self Consistent Field (SCF) molecular orbitals for those very geometries.

Basis Sets: The optimisation procedures and energy determinations involved a triple zeta split valence basis set (TZVP) for all methods. It has been taken from the TURBOMOLE v.4.6[8,9] basis set library. This basis set comprises polarisation functions on all atoms including hydrogen. For very small molecules, an RI-MP2 procedure is error-prone due to an insufficient auxiliary basis; we have, however, tested the applicability of the scheme by means of single-point energy calculations on the (full) MP2-level for ammonia, pyruvic acid, CClF(CO), and TSDE itself. Logged errors lie below one millihartree (≈ 0.03 eV); the single-point energy difference (RI- and non-RI-procedures) for the same (RI-MP2-optimised) structure of TSDE only differs by 0.3 millihartrees (≈ 0.008 eV).

Vibrational Spectra: The vibrational spectra have been determined at the corresponding equilibrium geometries by calculating the second derivatives of the electronic energy with respect to the nuclear coordinates; the same basis sets have been employed here. DFT intensities were calculated analytically from the squared derivative of the dipole moment at equilibrium geometry.[18] To calculate RI-MP2 vibrational frequencies, we employed a second derivative numeric procedure that has, amongst others, been linked to the TURBOMOLE-modules. RI-MP2 infra-red intensities have also been numerically determined by calculating the squared dipole moment derivatives with the same grid as for the frequency determination (0.02 bohr ≈ 0.0106 Å). The reliability of the resulting frequencies has, besides the plausible comparison of them with the density functional vibrational values, been tested for compounds that are still easily accessible with the standard MP2-scheme and the software available to us. For these compounds, and with our grid, deviations occur in the regime of only 1−3 wavenumbers compared to analogous analytical calculations. For the intensities, we find deviations of less than one percent. These findings shall be subject to a separate publication.

Results and Discussion

Equilibrium Structure and Stability, Bonding- and Electronic Parameters

Relaxation of the geometrical degrees of freedom of either the staggered or the eclipsed conformations leads to the equilibrium structure represented in Figure 2. We determined slightly different geometric parameters by the different methods. All values and corresponding energies obtained are listed in Table 1.

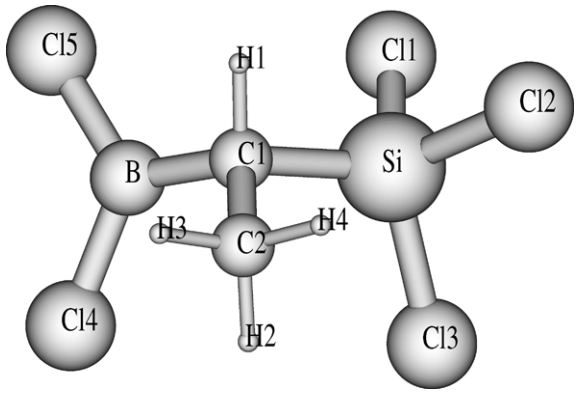

Figure 2. Equilibrium conformation of TSDE

The central carbon atom is almost perfectly tetrahedrally connected to a planar BCl_2 group and an $SiCl_3$ group that itself is tetrahedrally coordinated. A C−C distance of 1.560 Å corresponds to a typical single bond length. In addition, the Si−C and B−C bonds lie in the region of typical bond lengths for singly-bonded molecules. The single bond character of all bonds in TSDE is in contrast to the findings in TADB, which exhibits a partially doubly-bonded central pattern with its B−N bond having a length of 1.42 Å.[1]

We found a HOMO-LUMO gap for the closed-shell compound TSDE that amounts to 0.5161 hartrees, i.e. ≈ 13.9 eV. This value remains basically unaltered upon rotating the trichlorosilyl-, methyl-, or dichloroboryl groups as described below.

Graphical representations of the two SCF frontier orbitals are given in Figures 3 and 4.[19] Treating methyl and hydrogen as topologically equivalent, we may consider the plane defined by B−C−Si a mirror plane. The HOMO in this case corresponds to an *a'* molecular orbital with plain σ-type bonding interactions between (a) the central carbon and the boron atom and (b) between C and Si. A nodal plane on C separates these bonding components. This analysis already gives a clue to the low torsional barrier of $SiCl_3$ around the Si−C bond as shall be discussed in the

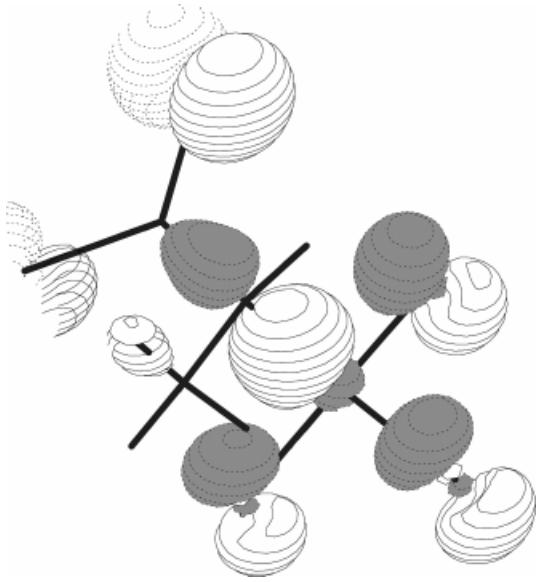

Figure 3. Highest occupied SCF-molecular orbital (HOMO) of TSDE: The BCl_2 group is in the upper left, the $SiCl_3$ group in the lower right corner

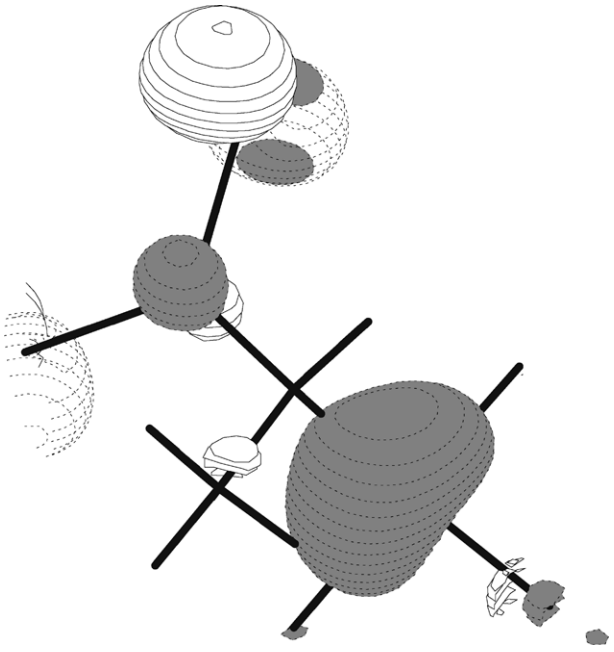

Figure 4. Lowest unoccupied SCF-molecular orbital (LUMO) of TSDE; orientation of the molcule as in Figure 3

section describing the IR spectrum. In addition, the torsion of BCl_2 around the B−C bond should be significantly easier compared to TADB. The HOMO describes the chlorine lone electron pairs as large *p atomic* orbitals that lie almost parallel to the mirror plane, resulting in non-bonded interactions with their neighbouring elements Si and B.

The LUMO, on the other hand, mainly consists of the boron and chlorine *p* atomic orbitals that are perpendicular to the BCl_2 plane. There are three nodal planes with respect to these orbitals: one within the BCl_2 plane, and the two others between B and each Cl. Thus, both B−Cl interactions are anti-bonding, which is, in fact, a very similar situation to that in TADB. The second characteristic constituent of the LUMO is a diffuse silicon atomic orbital with mostly *s* and little *p*-character, the latter being invisible in Figure 4 because of the overlying spacious *s* parts. As we did not include Rydberg or negative ion basis functions[20] in our basis set, we may not judge from this point whether this molecular orbital corresponds to a Rydberg state or not. When exciting electrons into this LUMO, one does not expect this to have a significant influence on the $SiCl_3$ and BCl_2 torsional barriers, as the corresponding interactions are nonbonding. Moreover, we have calculated that a BCl_2 torsion around B−C leaves the characteristics of the frontier orbitals mostly unaltered so that the bond distances will also remain basically the same for such a motion. In summary we can say that the electronic structure of TSDE allows a much higher flexibility when compared to TADB, and the lone pair electrons on all chlorine atoms significantly occupy the HOMO. This may well be a reason for its enhanced functionality as a network-creating agent. The fragment B−C−Si reveals a $\sigma - n$ pattern with respect to HOMO and LUMO.

Infra-Red Spectrum

Figure 5 and the enlarged detail in Figure 6 display the vibrational spectrum obtained experimentally. Embedded within each of these Figures, we have added the line spectrum from theory, and finally Table 2 lists all the data obtained in listed form.

Frequencies have been calculated without anharmonic corrections. Moreover, we have tried to minimise the effects of systematic errors during the calculation of *ab initio* frequencies by scaling the results.[21] The procedure we have applied in this context is widely known as *uniform scaling*[22] and procedes by taking a significant vibrational frequency from the theoretical spectrum and setting this to be equal to the corresponding experimental one. The resulting ratio of frequencies is then used to scale over the entire theoretical spectrum. Thus, we obtain method-specific scaling factors that are given in the header of Table 2. The reference mode was chosen to be the fifth highest in frequency at an experimental value of 1464 wavenumbers: The corresponding signal is in the mid-field region of the spectrum, it can easily be distinguished from the ones at higher wavenumbers, it is sharp, does not show any shoulders, and all theoretical models reproduce the neighbouring signal lower in energy at the experimentally observed distance of approximately ten wavenumbers. The peak chosen in this way appears to be suited best for determining a reasonable scaling factor.

In Figure 5 we have overlayed the full (scaled) RI-MP2 theoretical infra-red line spectrum with the experimental one. For the line spectrum, a ratio of $^{11}B/^{10}B \approx 80{:}20$ has been employed. Assignments from low to high frequencies are easily set up; all calculated values from theory find their

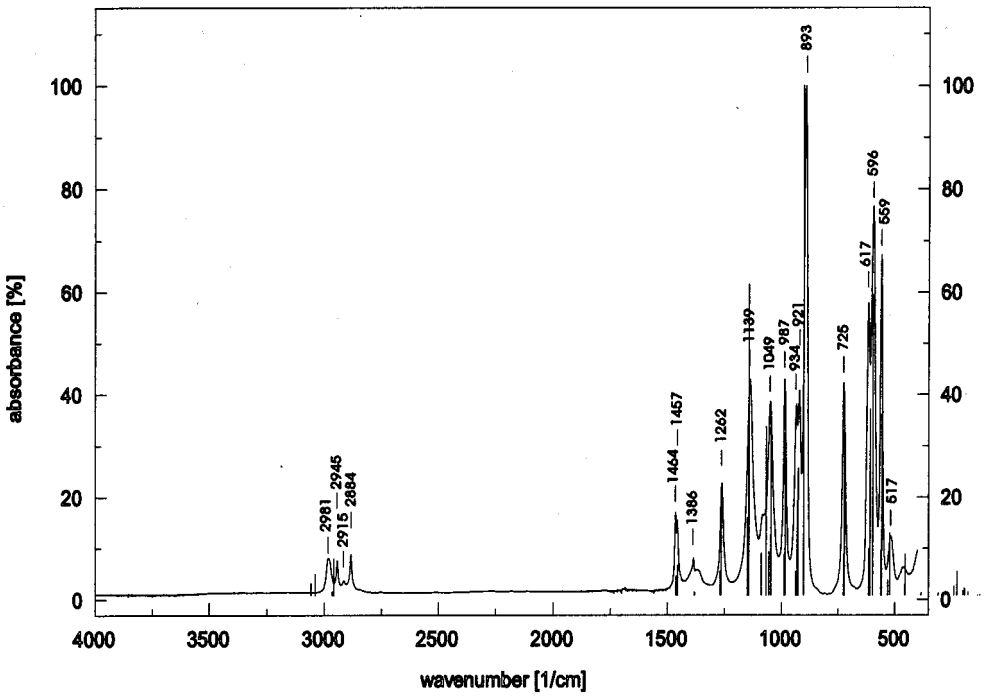

Figure 5. TSDE: Theoretical and experimental IR spectra (Overlay), theory refers to the RI-MP2 level and assumes a $^{11}B/^{10}B$ ratio of 80:20; for reasons of clarity, not all resonances are labelled

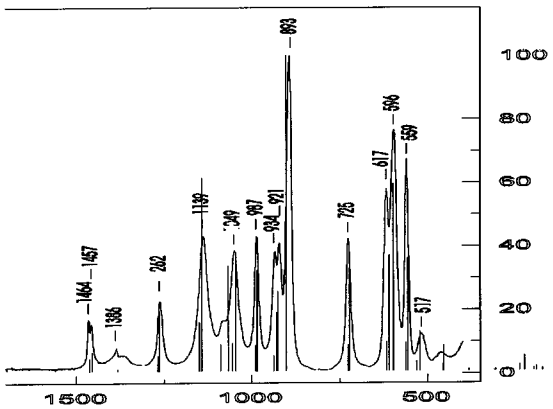

Figure 6. Infra-red spectrum as from Figure 5 − enlargement showing detail of the fingerprint region

experimental counterpart and agreement is particularly good.

Modes 1−12 are basically rocking, bending and wagging motions of the trichlorosilyl- and dichloroboryl-functions, respectively. Mode 13, which we calculate at 383 wavenumbers (scaled RI-MP2), is a combination of a breathing motion of the nuclear frame, accompanied by a slight umbrella-like motion of the methyl group. The experimental spectrum starts with its observation window at around 500 wavenumbers, so the lowest peak in energy at 467 cm^{-1} can clearly be identified with our theoretical value of 454 cm^{-1}, corresponding to mode 14, an umbrella motion of the central carbon atom, combined with symmetric Si−Cl stretching motions and a slight B−Cl stretch vibration. Mode 15 represents the strong pyramidalisation mode of boron, antiphase with Si−C stretches and the $SiCl_3$ umbrella. A theoretical value of 521 cm^{-1} nicely matches an experimental one of 517 cm^{-1}. Still, mode 16 shows a slight out-of-plane (o.o.p.) motion of a boron atom combined with a B−Cl symmetric stretch. Most characteristic for this mode though, are antisymmetric Si−Cl stretch motions and, in this case, theory and experiment agree perfectly (558 vs. 560 cm^{-1}). Mode 17 represents the strong antisymmetric Cl_2Si stretch along with a C−C−Si bending, and a calculated value of 597 wavenumbers finds its experimental counterpart at 596 cm^{-1}. Mode 18, a B−C−Si bending motion, together with an anti-symmetric stretching of the $SiCl_2$ group, shows the same agreement as before: 616 cm^{-1} from the experiment as opposed to 610 cm^{-1} from theory. Mode 19 is a Si−C stretching vibration, exhibiting frequencies of 723 cm^{-1} for the calculated model, and 725 cm^{-1} for the experimental value. This motion is certainly accompanied by a strong in-phase umbrella motion of $SiCl_3$. Mode 20

represents an antisymmetric stretching of BCl_2. We determined an experimental frequency of 893 cm^{-1} which is in accordance with theory (902 cm^{-1}) to within nine wavenumbers. As one can easily tell from looking at a model of atoms moving along this eigenvector, this should be one of the strongest modes in the infra-red spectrum, due to the fact that the dipole moment changes strongly. Indeed, both the density functional and the perturbational calculations determine this vibration as the most intense. Because of its strength we have calculated the corresponding ^{10}B isotopic shift for this mode and found a scaled RI-MP2 value of 923 cm^{-1}. Thus, we conclude that the experimental value of 921 wavenumbers corresponds to a vibration along mode 20 with a ^{10}B nucleus.

Mode 21 basically corresponds to a symmetric stretching vibration of the B−C−Si-fragment that is antisymmetric to a weak BCl_2-vibration of TSDE. A scaled theoretical value of 930 cm^{-1} is nicely reproduced by the experimentally obtained frequency at 934 cm^{-1}. Mode 22 shows the symmetric BCl_2 stretch and some C-B stretching that is antiphase with a wagging motion of the entire methyl group toward the silicon atom. Theory (985 cm^{-1}) and experiment (987 cm^{-1}) match almost perfectly. Mode 23, to which we assign an experimental value of 1049 wavenumbers (theory: 1047 cm^{-1}), shows a B−C−C antisymmetric stretching motion along with a Cl(5)−B stretch. The experimentally recorded shoulder at 1083 wavenumbers correlates with a theoretical resonance at 1069 cm^{-1}, corresponding to mode 24, a strong B−Cl stretch along with a methine-H-C−B bending. Mode 25, which we calculate at 1143 wavenumbers (in satisfactory accordance with the experimental value of 1139) appears as a strong mode in theory and experiment; the corresponding motions are (a) (SiCB) framework stretchings, mainly antisymmetric with respect to B−C and C−Si and (b) an in-plane BCl_2 bending. Mode 26 is mainly an antisymmetric C−C−B stretch. Its vibrational frequency falls into the usual region: 1262 cm^{-1} (experimental), theoretically determined at a scaled value of 1265 cm^{-1}. Mode 27 represents the pure methyl-umbrella motion. We have calculated the corresponding frequency at 1384 cm^{-1}, whereas experiment records it at 1386 cm^{-1}. Modes 28 and 29, at 1457 and 1464 (experimental) or 1456 and 1464 cm^{-1} (theory) respectively, are almost uncoupled scissoring vibrations of the methyl group. The remaining four frequencies in the region of 3000 cm^{-1} certainly belong to C−H stretches. The lowest in frequency (experimental: 2884 vs. theory: 2962) is the symmetric C−H stretch of the methyl group, and mode 31 (experimental: 2915, theory: 2969 cm^{-1}) the methine-H stretch. The density functional calculations reverse the assignment of these frequencies and only by means of a comparison of the calculated intensities (RI-MP2 vs. experiment) can these assignments safely be found. Finally, modes 32 and 33, recorded at 2945 and 2981 cm^{-1} experimentally, are the remaining antisymmetric counterparts of mode 30, the methyl stretches. We calculate these to be at 3043 and 3062 cm^{-1}. As found in most calculations, the agreement slightly deteriorates with higher energies, but the relative positions of the resonances leave assignments unambiguous. Upon turning the trichlorosilyl group through 180° around Si−C and optimising all remaining internal coordinates at the RI-MP2 level, we find a barrier with respect to the minimum of only 9 kJ/mol. Moreover, we have recalculated the vibrational spectrum after this distortion and found deviations of up to 16 wavenumbers (modes 14 and 19). Both these considerations lead us to believe that a thermal excitation should not have influenced characteristics of the experimental infra-red spectrum and that this motion is easily excited at room temperature. Similar considerations apply for the methyl group: A torsion and subsequent relaxation of the remaining internal coordinates yields an energy difference of only 12 kJ/mol above the minimum. The vibrational frequencies deviate at most by 24 cm^{-1} (mode 26) from the equilibrium values. Supported by our considerations for the bond characteristics and the frontier orbitals (see above), one should expect that, finally, a torsion of the dichloroboryl group requires less energy than in TADB (68 kJ/mol), as we had found a partially doubly bonded boron atom there. Indeed, the RI-MP2 energy difference to the minimum amounts to 38 kJ/mol, so this substituent should only be turning freely at slightly elevated temperatures.

NMR Spectrum

The ^1H-NMR spectrum (Figure 7) reveals two signals belonging to the methyl and methine groups of the precursor. The protons of the methyl group are chemically equivalent but the signal at $\delta = 1.48$ is split into a doublet because of the presence of the adjacent methine proton. Analogously, the signal of the methine proton is split into a quartet and is shifted to $\delta = 2.22$.

The signals in the ^{13}C-NMR spectrum (Figure 8) can easily be assigned to the relevant groups: The multiplet in the region of $\delta \approx 78$ belongs to solvent resonances. The methyl group produces a sharp peak at $\delta = 11.93$ whereas the resonance of the methine group is broad and flat and is shifted

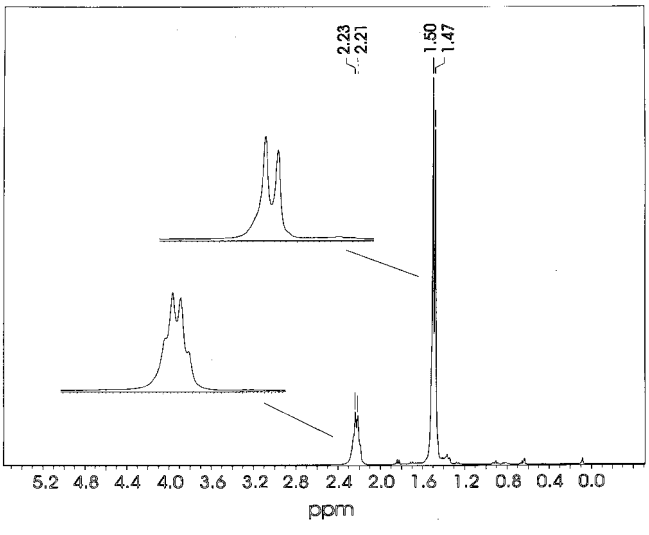

Figure 7. ^1H-NMR spectrum of TSDE

to approximately δ = 34.6. The shape of the latter signal is caused by the interaction of the ^{13}C nuclear spin (I = 1/2) with the quadrupole of the neighbouring ^{11}B (spin 3/2). Table 3 displays results of all NMR experiments conducted (^{1}H, ^{13}C, ^{29}Si, and ^{11}B).

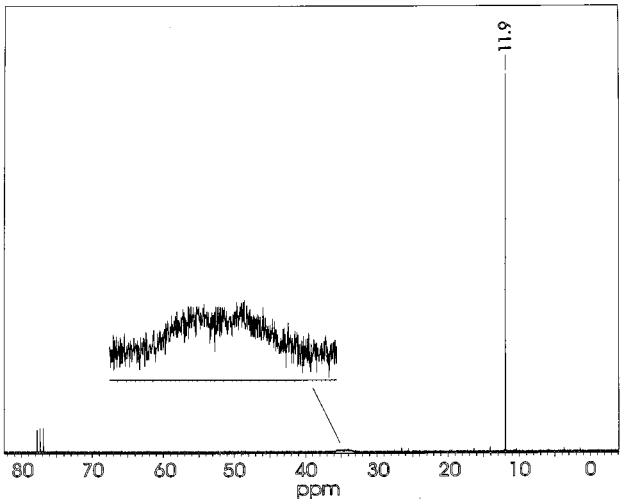

Figure 8. ^{13}C-NMR spectrum of TSDE

Table 3. NMR chemical shifts recorded for TSDE

Nucleus	Chemical shift [δ]	Assignment
^{1}H	1.48	CH_3
	2.22	CH
^{13}C	11.9	CH_3
	34.6	CH
^{29}Si	13.2	$SiCl_3$
^{11}B	67.2	BCl_2

Summary

[(Trichlorosilyl)dichloroboryl]ethane, another member of a group of molecular precursors for Si/B/N/(C) ceramics, is easily accessible through a one-pot synthesis employing boron trichloride and a mixture of trichlorovinylsilane and triethylsilane. As is the case for [(trichlorosilyl)-amino]-dichloroborane, its reasonably flexible equilibrium structure consists of a planar BCl_2 group on one side and a tetrahedral $SiCl_3$ group on the other side of the ethyl backbone. All bonds should be treated as ordinary single bonds, and the HOMO-LUMO sσquence is of $o - n$ character when focusing on the B−C−Si fragment. As far as spectroscopy is concerned, the carbon, hydrogen, boron and silicon NMR signals have been listed and are consistent with the structural analysis. Finally, we have found that second-order perturbation theory reproduces the experimental infrared spectrum with high accuracy and have made the assignments accordingly. By numerically deriving analytical RI-MP2 gradients, we are now able to determine Møller-Plesset second-order perturbational infra-red frequencies. The latter values were obtained with high accuracy for compounds that were barely accessible, or even inaccessible, to such treatment before.

Acknowledgments

This work is dedicated to the memory of Marco Häser, a very able young quantum chemist who died on August 23, 1997 − through his major contributions to the TURBOMOLE package, he substantially diminished the computational efforts we have made within this publication. We are indebted to the HLRZ Supercomputing Center in Jülich and the Cologne University Computing Center. One of us (M.G.) would like to thank Dr Stefan Grimme, Bonn, for helpful discussions. Financial support from the German Research Council (DFG) through SFB408 is gratefully acknowledged.

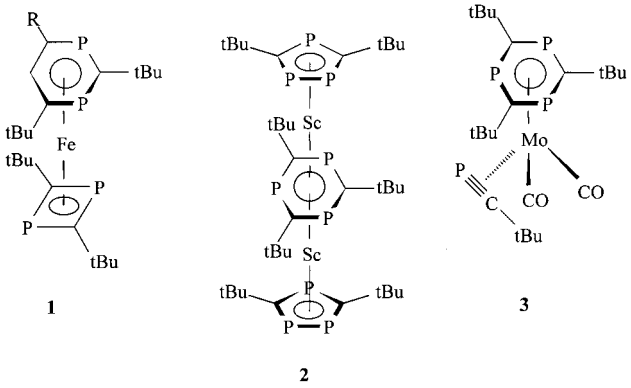
2,4,6-Tri-*tert*-butyl-1,3,5-triphosphabenzene as an η^6-Ligand in Transition Metal Complexes

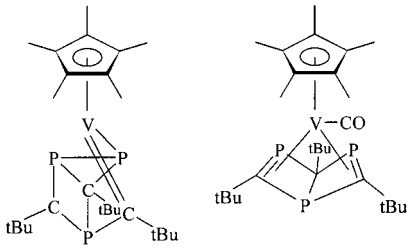
Paul Binger,*[a] Stefanie Stutzmann,[a] Jörg Stannek,[a] Barbara Gabor,[a] and Richard Mynott[a]

Keywords: 2,4,6-Tri-*tert*-butyl-1,3,5-triphosphabenzene / η^6-Triphosphabenzene transition metal complexes / Displacement reactions / Phosphorus heterocycles / Arene complexes



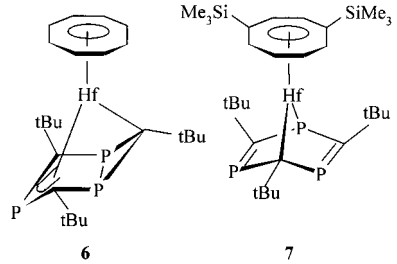
The η^6-1,3,5-triphosphabenzene transition metal complexes **12a**,**b**, **14**, and **16** have been synthesized for the first time by the displacement of η^6-arene ligands (toluene, benzene and naphthalene) with 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene (**9**). The new complexes have been fully characterized by a combination of elemental analysis, mass spectrometry, and ^{1}H-, ^{13}C- and ^{31} P-NMR spectroscopy.

The discovery of transition metal complexes bearing η^6-benzene ligands has been one of the landmarks in the development of modern organometallic chemistry.[1] Numerous π-arene complexes have since been synthesized,[2] not only containing purely carbon-aromatic systems, but arenes incorporating one or more heteroatoms such as N,[3] P,[4] As or Sb[5] as well. With these heteroarenes, a complication that often arises is that η^1-coordination of the lone pair of the heteroatom is more stable than η^6-coordination to a transition metal.[3−5] With phosphorus as the heteroatom, the preferred bonding mode is η^1-coordination; e.g. at room temperature $M(CO_5)THF$ complexes (M = Cr, Mo, W) react with phosphabenzenes (phosphinines) bearing practically any substituents to give the corresponding pentacarbonyl(η^1-phosphinine)metal complexes.[4][6] Only bulky substituents such as *tert*-butyl groups in the 2,6-positions prevent such an interaction.



η^6-Phosphinine complexes of these metals [(η^6-C_5R_5P)$M(CO)_3$] can be prepared either from the η^1-complexes by heating above 130°C or directly from phosphinine and $M(CO)_6$ at 130−150°C.[4,7a,7b] Displacement of a benzene derivative by a phosphinine represents a further possible synthetic path for preparing e.g. [(η^6-$C_5Ph_3H_2P$)Mo-$(CO)_3$].[7c]

In contrast to phosphinine complexes, only two examples are known in which 1,3-diphosphabenzene[8] and 1,3,5-triphosphabenzene[9] are η^6-bonded to a transition metal atom. In both cases the complexes are prepared by cyclotrimerization of *tert*-butylphosphaacetylene (**8**) or by cotrimerization of two equivalents of **8** with an acetylene within the coordination sphere of a metal. An earlier report in which the synthesis of the [η^6-triphosphabenzene]molybdenum complex **3** was claimed[10] is dubious for some reason (see below).[11][12]



The binding mode of a cyclic $(PC-tBu)_3$ unit to a transition metal atom appears to be very flexible, depending on the transition metal and on the other ligands connected to the metal atom. This observation is illustrated by the two vanadium complexes **4** and **5**[13] and the two hafnium complexes **6**[14b,16] and **7**.[14a]

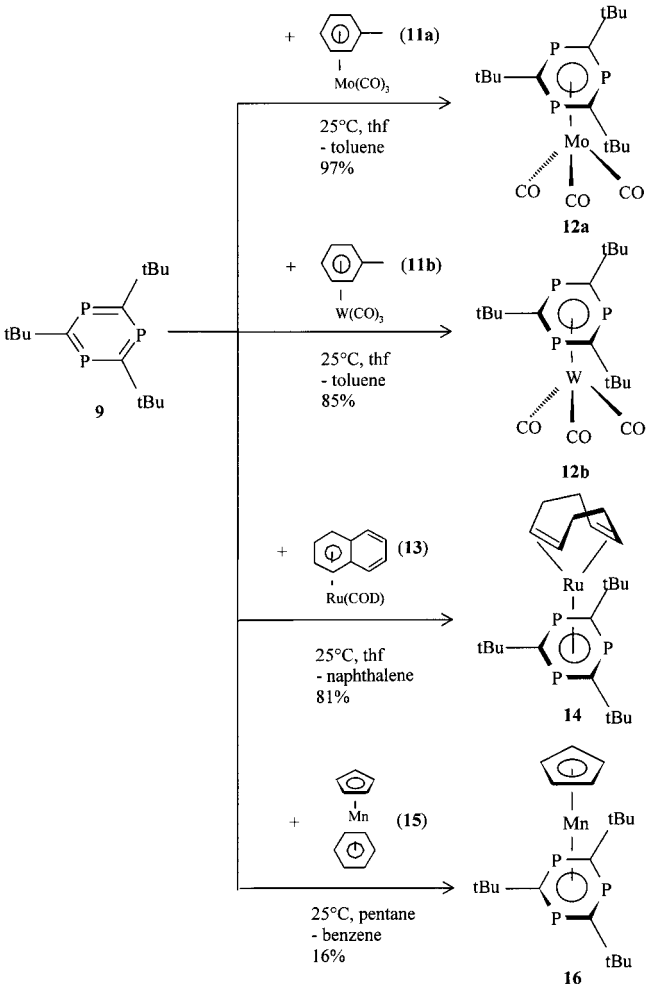
lyl)cyclooctatetraene]hafnium complex, are the starting materials for the preparation of 2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene (**9**) and 2,4,6-tri-*tert*-butyl-1,3,5-triphospha Dewar benzene (**10**), respectively, by reaction with hexachloroethane.[14a] For the synthesis of the triphosphabenzene **9**, a direct route has recently been developed, starting from **8** and trichlorovanadium *tert*-butylimide.[15]



With these procedures at hand, we were able to study the reactivity of the two new heterocycles **9**[16] and **10**.[17][18] Herein we describe the synthesis of some η^6-triphosphabenzene transition metal complexes (M = Mo, W, Ru, Mn) by the displacement of η^6-bonded aromatic ligands (benzene, toluene, naphthalene).

Reactions of tricarbonyl(η^6-toluene)molybdenum (**11a**) and tricarbonyl(η^6-toluene)tungsten (**11b**) with triphosphabenzene **9** in equimolar amounts at ambient temperature result in the displacement of toluene, yielding the molybdenum and tungsten complexes **12a** and **12b** almost quantitatively. This indicates that triphosphabenzene **9** bonds more strongly to the $Mo(CO)_3$ and $W(CO)_3$ fragments than toluene. A primary interaction between one of the lone pairs of the phosphorus atoms in **9** and the metal atom is not observed. Such coordination may be prevented by the bulkiness of the two *tert*-butyl groups in the neighbourhood of the phosphorus atoms. This may also account for the fact that it is not possible to displace nitrile or carbon monoxide from $(RCN)_3M(CO)_3$, $M(CO)_6$, or $(CO)_5M(THF)$ (M = Cr, Mo, W) by **9**. It is known that 2,6-di-*tert*-butylphosphinine does not interact with transition metals via the lone pair either.[19]

The product complexes were isolated as small orange needles (**12a**) and as an orange powder (**12b**). We have so far been unable to obtain crystals suitable for an X-ray analysis. Both complexes decompose above 100°C before reaching their melting point. It is interesting to note that it was not possible to prepare tricarbonyl(η^6-triphosphabenzene)chromium in the same manner from tricarbonyl(η^6-toluene)chromium and **9**.

For the preparation of a (η^6-triphosphabenzene)ruthenium complex, (η^4-1,5-cyclooctadiene)(η^6-naphthalene)ruthenium (**13**) is an ideal starting material. Thus, reaction with the triphosphabenzene **9** leads to substitution of the naphthalene and the new (η^4-1,5-cyclooctadiene)(η^6-triphosphabenzene)ruthenium complex **14** is formed in 81% yield as an orange powder. The product was found to decompose at 105°C.

The displacement of benzene from (η^6-benzene)(η^5-cyclopentadiene)manganese (**15**) by **9** does not reach completion. The reaction proceeds at ambient temperature in pentane only until a conversion of ca. 20% is attained. After separation of the displaced benzene, the reaction does not recommence, thus excluding the possibility of an equilibrium situation. On chromatographic work-up of the reaction mixture, ca. 80% of the starting material **15** can be recovered. Remaining **9** was detected in the distillate and the resulting complex **16** was isolated as green oil in 16% yield.

Scheme 1. Synthesis of some (η^6-triphosphabenzene)metal complexes

All of the new η^6-triphosphabenzene complexes **12a**,**b**, **14**, and **16** have been characterized by elemental analysis, mass spectrometry, and NMR spectroscopy. Elemental analytical data confirm the correct compositions, which are further corroborated by the mass spectra. The molecular ion peak is seen in the mass spectrum of each complex. The $(C_3P_3tBu_3)M$ ions give rise to characteristic fragment ion peaks in the spectra of complexes **12a**, **12b**, and **14**, while in the mass spectrum of the manganese complex **16** the ion

of triphosphabenzene **9** and fragmentation ions therefrom are prominent.

The NMR spectra provide the most diagnostic information as to the constitutions of **12a**,**b**, **14**, and **16**. All spectra exhibit the characteristic feature indicative to the free triphosphabenzene ligand **9**, i.e. the three phosphorus atoms, the three ring carbon atoms, and the hydrogen atoms of the *tert*-butyl groups each appear as single signals, indicating a delocalized 6-π-electron system. The η^6-coordination is indicated by upfield shifts, which do not vary much for the ^{13}C-NMR signals ($\Delta\delta$ = 84.8−77.8, see Table 1), whereas the ^{31}P-NMR shifts are more sensitive to the metal and to the other ligands linked to the metal atom. The coupling pattern of the carbon atoms in free triphosphabenzene **9** ($A_2A'X$) is maintained when **9** is η^6-coordinated to a metal atom. In addition, W−C coupling is observed in the spectrum of **12b**. The carbon atoms of the CO groups in **12a** and **12b** also show coupling with the metal atom and with the three phosphorus atoms of **9**.

Table 1. ^{31}P- and ^{13}C-NMR data of triphosphabenzene as an η^6-ligand in metal complexes in comparison with free triphosphabenzene **9** (δ in ppm)

Compound	**9**	**12a**	**12b**	**14**	**16**
M	−	Mo	W	Ru	Mn
P[a]	232.6	57.6	38.6	59.0	−4.7
C[b]	211.8	131.8	127.0	132.6	134.0

[a] Singlet. − [b] $A^2A'X$ system.

The electronically and coordinatively saturated η^6-triphosphabenzene complexes **12a**,**b**, **14**, and **16** are thermally stable up to ca. 100°C and are rather unreactive. Thus, it was found that the ruthenium complex **14** may be used as a catalyst for the hydrogenation of 1-hexene (THF, 20°C, 20 bar H_2, 0.5 mol-%, 90 h), although the hydrogenation rate is nine times slower than that observed using (η^6-benzene)(1,5-cyclooctadiene)ruthenium as catalyst under comparable conditions.[20][21] Complex **12a** does not react with **9** under the conditions under which Cowley et al.[9] claimed to have synthesized the first η^6-triphosphabenzene complex **3** (THF, 65°C, 10 h). This result, together with the observation of Scheer et al.,[12] led us to the conclusion that Cowley et al. did not in fact synthesize complex **3**. Therefore, the complexes **12a**,**b**, **14**, and **16** can be regarded as the first unambiguously characterized mononuclear metal complexes bearing a triphosphabenzene as an η^6-coordinated ligand.

Experimental Section

All experiments were carried out under argon in anhydrous solvents. − MS: Finnigan MAT 311 ADF, 70 eV. − ^{1}H and ^{13}C NMR: Bruker AM 200 and AMX 400; chemical shifts measured relative to solvent, numerically relative to TMS. − ^{31}P NMR: Bruker AM 200 and AMX 400; external standard H_3PO_4. − Elemental analyses: Dornis and Kolbe, Mülheim a. d. Ruhr. − 2,4,6-Tri-*tert*-butyl-1,3,5-triphosphabenzene (**9**),[14a,15] tricarbonyl(η^6-toluene)molybdenum (**11a**) and tricarbonyl(η^6-toluene)tungsten (**11b**),[22] (η^4-cyclooctadiene)(η^6-naphthalene)ruthenium (**13**),[23] and (η^6-benzene)(η^4-cyclooctadiene)manganese (**15**)[24] were prepared according to published procedures.

Tricarbonyl(η^6-2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene)-molybdenum (12a): To a solution of tricarbonyl(η^6-toluene)molybdenum (**11a**, 0.5 g, 1.8 mmol) in THF (10 mL), **9** (0.54 g, 1.8 mmol) was added at room temperature. After stirring for 4 h, the solution was concentrated to a volume of 3 mL and then cooled to −78°C. Complex **12a** precipitated as small orange needles, which were collected by filtration and dried in vacuo. Yield: 0.84 g (97%); decomp. at 103°C. − ^{1}H NMR ([D$_8$]THF, 400.1 MHz, 30°C): δ = 1.45 (s, *t*Bu). − ^{13}C NMR ([D$_8$]THF, 100.6 MHz, 30°C): δ = 215.3 ($|J_{P,P}|$ = 4.7, $J_{C,P}$ = 1.3, $J_{L,Mo}$ = 86.4 Hz, CO), 131.8 ($A_2A'X$ system, $|J_{P,P}|$ = 4.7, $^1J_{C,P}$ = 89.9, $^3J_{C,P}$ = 4.8 Hz, ring-C), 41.6 [$|J_{P,P}|$ = 4.7, $^2J_{C,P}$ = 21.7, $^4J_{C,P}$ = 0.3 Hz, ***C***$(CH_3)_3$], 36.12 [$|J_{P,P}|$ = 4.7, $^3J_{C,P}$ = 12.8, $^1J_{C,H}$ = 128 Hz, C(***C***$H_3)_3$]; all coupling constants were established by simulations. − ^{31}P NMR ([D$_8$]THF, 162 MHz, 30°C): δ = 57.6 (s). − MS (70 eV); *m/z* (%): 482 (29) [M^+], 454 (26) [M − CO^+], 398 (100) [M^+ − 3 CO], 312 (32). − $C_{18}H_{27}O_3P_3Mo$ (480.2): calcd. C 45.02, H 5.65; found C 45.04, H 5.61.

Tricarbonyl(η^6-2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene)-tungsten (12b): To a solution of **9** (200 mg, 0.67 mmol) in THF (3 mL), a solution of tricarbonyl(η^6-toluene)tungsten (**11b**, 285 mg, 0.8 mmol) in THF (2 mL) was added at room temperature. After stirring overnight, the THF was distilled off under reduced pressure (0.5 mbar) and the residue was redissolved in pentane (1 mL). At −78°C, **12b** precipitated as an orange powder, which was collected by filtration and dried in vacuo. Yield: 322 mg (85%); decomp. at 175°C. − ^{1}H NMR ([D$_8$]THF, 200 MHz, 30°C): δ = 1.64 (t, $^4J_{P,H}$ = 1.5 Hz, *t*Bu). − ^{13}C NMR ([D$_8$]THF, 50.3 MHz, 30°C): δ = 205.1 ($J_{P,C}$ = 2.0, $J_{W,C}$ = 84.4 Hz, CO), 127.0 ($^1J_{C,P}$ = 89.8, $^3J_{C,P}$ = 4.0, $J_{W,C}$ = 13.5 Hz, ring-C), 41.9 [$^2J_{P,C}$ = 21.4 Hz, ***C***$(CH_3)_3$], 36.0 [$^3J_{P,C}$ = 12.7 Hz, C(***C***$H_3)_3$]. − ^{31}P NMR ([D$_8$]THF, 81.1 MHz, 30°C): δ = 38.6 (s). − MS (70 eV); *m/z* (%): 568 (34) [M^+], 540 (100) [M − CO^+], 510 (7) [M − 210^+], 482 (46) [M − 3 CO^+]. − $C_{18}H_{27}O_3P_3W$ (568.1): calcd. C 38.06, H 4.78; found C 38.08, H 4.74.

(η^4-1,5-Cyclooctadiene)(η^6-2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene)ruthenium (14): To a solution of **9** (200 mg, 0.67 mmol) in THF (3 mL), a solution of the ruthenium complex **13** (270 mg, 0.8 mmol) in THF (2 mL) was added at room temperature. After stirring for 4 h, the THF was distilled off at 40°C/0.5 mbar, the residue was redissolved in pentane, and purified by column chromatography (glass column, diameter 2 cm, length 15 cm, silica gel 60, 70−230 mesh, Merck AG). The orange fraction was found to contain complex **14** contaminated by traces of naphthalene. The latter could be removed by sublimation at 60°C/0.5 mbar. The remaining orange powder consisted of pure complex **14**; yield: 275 mg (81%); decomp. at 105°C. − ^{1}H NMR ([D$_8$]THF, 200 MHz, 30°C): δ = 3.67 (br. s, 4 H, COD), 2.03 (br. s, 8 H, COD), 1.52 (s, *t*Bu). − ^{13}C{^{1}H} NMR ([D$_8$]THF, 50.3 MHz, 30°C): δ = 132.6 ($^1J_{P,C}$ = 87.2, $^3J_{P,C}$ = 5.4 Hz, ring C), 65.1 ($^2J_{P,C}$ = 1.5 Hz, COD), 42.7 [^2J = 22.6 Hz*, ***C***$(CH_3)_3$], 36.0 [$^3J_{P,C}$ = 13.2 Hz*, C(***C***$H_3)_3$], 33.9 (s, COD); * denotes *J* by comparison with simulated spectrum of complex **12a**. − ^{31}P NMR ([D$_8$]THF, 81.1 MHz, 30°C): δ = 59.0 (s). − MS (70 eV); *m/z* (%): 510 (25) [M^+], 453 (6) [M − *t*Bu^+], 402 (100) [M − COD^+], 169 (7) [$PC_2tBu_2^+$], 57 (10) [*t*Bu]. − $C_{23}H_{39}P_3Ru$ (509.6): calcd. C 54.21, H 7.71; found C 54.26, H 7.69.

(η^5-Cyclopentadienyl)(η^6-2,4,6-tri-*tert*-butyl-1,3,5-triphosphabenzene)manganese (16): To a solution of (η^6-benzene)(η^5-cyclopentadienyl)manganese (**15**, 170 mg, 0.86 mmol) in pentane (3 mL), a solution of **9** (200 mg, 0.67 mmol) in pentane (2 mL) was added at room temperature. From the resulting reaction mixture, complex **16** was separated by column chromatography (eluent: pentane; glass column, diameter 2 cm, length 15 cm, Al_2O_3, Merck AG). The green fraction was found to contain complex **16**, which was obtained as a green oil upon removal of the pentane by distillation. Yield: 40 mg (16%). – ^{1}H NMR ([D$_8$]THF, 200 MHz, 30°C): δ = 4.10 (s, 5 H, Cp), 1.66 (s, 27 H, *t*Bu). – ^{13}C{^{1}H} NMR ([D$_8$]THF, 50.3 MHz, 30°C): δ = 134 (ring C), 70.3 (Cp), 42.3 and 36.0 (*t*Bu). – ^{31}P NMR ([D$_8$]THF, 81.0 MHz, 30°C): δ = −4.6 (s). – MS (70 eV); *m/z* (%): 420 (42) [M$^+$], 282 (65) [M − $C_2tBu_2^+$], 258 (43) [M − P_2tBuH^+], 220 (21) [M − $P_2C_2tBu_2$], 169 (38), 120 (100) [CpMn], 57 (17), 55 (36). – $C_{20}H_{32}P_3Mn$ (420.3): calcd. C 57.15, H 7.64; found C 57.07, H 7.69.

$Ta_{11}Si_2Se_8$ – Condensed Tetrakaidecahedral Ta_9Si Clusters Arranged to an Open Network Structure

Antje Mrotzek and Bernd Harbrecht*[a]

Dedicated to Professor Edgar Niecke on the occasion of his 60th birthday

Keywords: Selenium / Silicon / Silicides / Tantalum / Condensed cluster compounds

$Ta_{11}Si_2Se_8$ was synthesized from a pre-reacted mixture of the elements in a sealed tantalum tube at 1570 K. Mo-doped crystals were obtained in a welded molybdenum crucible by a chemical transport reaction using TeI_4 as a transport agent. The structure of $Mo_{0.11}Ta_{10.89(2)}Si_2Se_8$ has been determined by single crystal X-ray means [*Pnnm*, $Z = 2$, $a = 1184.4(1)$ pm, $b = 1939.4(1)$ pm, $c = 346.48(2)$ pm, $wR_2 = 0.069$]. The structure of the ternary phase was verified by means of a Rietveld profile fit of a powder X-ray diffractogram. The silicide is isotypic with $Ta_{11}Ni_2Se_8$. The structure is composed of Si-centred, tricapped trigonal prismatic Ta_9Si clusters. The tetrakaidecahedral Ta_9Si clusters are fused into twin chains by sharing the Ta^{pr} atoms of facing triangulated prism faces and one out of three capping atoms Ta^c. Intercluster linkage of the remaining Ta^c atoms generates a microporous $^3_\infty[SiTa_2^c\ Ta_{1/2}^c\ Ta_{6/2}^{pr}]$ substructure. The channels of the metal network are sheathed by three-, four-, five-, and sixfold coordinated Se atoms. Four-probe dc resistivity measurements revealed the Mo-doped phase to be a moderate metallic conductor. The bonding interactions contributing to the stability of $Ta_{11}Si_2Se_8$ and distinctions in bonding for $Ta_{11}Si_2Se_8$ and $Ta_{11}Ni_2Se_8$ are analysed on the basis of semi-empirical extended Hückel calculations.

Introduction

Tantalum is known to form numerous metal-rich chalcogenides with very distinctive and partly exotic structural and/or physical properties. By using the versatile metal partial structure as a guideline, four groups of tantalum subchalcogenides can be distinguished:

(1) Interpenetrating metal-centred icosahedral structures: Much of the motivation for exploring low-valent tantalum chalcogenides goes back to the findings of Franzen and Smeggil[1] that tantalum can form frameworks based on interpenetrating metal-centred icosahedra. The structures of the sulfides Ta_6S_n ($n = 1$,[1][2] 3,[1] and 4[3]), $M_xTa_{6-x}S$ (M = V, Cr),[4] $AuTa_5S$,[5] $M_xTa_{15-x}S_2$ (M = Au, Al, Ga, Ge, Sn, Sb, Pd, Pt, Rh, Ir)[6] are examples of such clusters. The small-band-gap semiconductor Ta_6Te_5[7] with a unique one-dimensional pentagonal antiprismatic chain structure, the layer-type chalcogenides $Ta_3(S,Se)_2$,[8] $Ta_5(Se,Te)_3$,[9] and $Ta_3(S,Te)_2$,[10] as well as $Ta_5(S,Te)_2$[11] exhibiting a perforated Ta partial structure and the unprecedented quasicrystalline chalcogenide $Ta_{2\sqrt{3}+3}Te_4$,[7b][12] marked by a Fourier spectrum with twelvefold rotational symmetry, belong to this group of structures. They all are composed of interpenetrating, condensed, or metal−metal-bonded M_{13} icosahedra and/or fragments thereof.

(2) Body-centred cubic fragment-structures: The structures of several other low-valent tantalum chalcogenides have in common that parts of the body-centred cubic (*bcc*) arrangement of tantalum are preserved. In contrast to sulphur, tellurium, vanadium, and chromium, homologous elements like selenium, niobium, molybdenum, and tungsten promote the formation of *bcc* fragment structures. Representatives of this group are the metal-rich layer-type structures Ta_2Se, $Ta_2(S,Se)$ [n(S)/n(Se) < 4], $Ta_5(S,Se)_2$, $Ta_9(S,Se)_4$, $M_xTa_{5-x}S_2$ (M = Mo, W), $(Nb,Ta)_2S$, and $(Nb,Ta)_5S_2$[13] and the network structures of $(Nb,Ta)_{11}S_4$ and $(Nb,Ta)_9(S,Te)_5$.[14]

(3) Quasi-one-dimensional metal-rich chalcogenides: The structures of some rare examples of this third group consist of columnar metal cores completely covered with chalcogen atoms; van der Waals interactions provide the cohesion of the strings. The tellurides M_4ETe_4 (M = Nb, Ta; E = Si, Cr, Fe, Co, Ni),[15] e.g., are composed of chains of confacial square antiprismatic clusters, $^1_\infty[SiTa_{8/2}Te_{8/2}]$. Deintercalated $LiMo_3Q_3$ (Q = Se, Te)[16] and Ta_6Te_5[7] show similar structural features.

(4) Condesed tetrakaidecahedral cluster compounds: The compounds of the fourth group contain, in addition to sulphur or selenium, an iron-group metal as a second minor component. As a consequence of a substantial difference between the Ta−Q and M−Q affinities, the partial structures of the 3d-metal and chalcogen components are spatially separated by the intermediate partial structure of the major component. At low contents of the 3d metal, the M atoms are encapsulated in tricapped trigonal prismatic Ta_9 clusters confined by 14 triangular faces. All structures of this type known so far contain columns of condensed tetrakaidecahedral clusters. The columns, however, can be linked in different ways giving rise to a variety of compositionally distinct compounds: $Ta_9M_2S_6$, $Ta_{11}M_2Se_8$ (M = Fe, Co, Ni)

and Ta_8MSe_8 (M = Co, Ni),[17] $M_{1-x}Nb_6S_{2+x}$ (M = Fe, Co, Ni, Cu), $M_{2-x}Nb_9S_{3+x}$ and $M_{2-x}Nb_8S_{4+x}$ (M = Co, Ni),[18] Hf_8MTe_6 (M = Mn, Fe), Hf_5MTe_3 (M = Fe, Co), and Zr_6MTe_2 (M = Mn, Fe, Co, Ni, Ru, Pt).[19]

In an attempt to expand the structural chemistry of tantalum-rich chalcogenides by including another main-group element we explored selected ternary tantalum-selenium systems containing a group-14 element as a minor component.[20] Here we report the synthesis and structure of a tantalum-rich silicide selenide $Ta_{11}Si_2Se_8$ which is isotypic with the compounds of the $Ta_{11}M_2Se_8$ (M = Fe, Co, Ni)[17c,d] series.

Results and Discussion

Synthesis, Analyses, Electrical Properties

Microcrystalline, single-phase $Ta_{11}Si_2Se_8$ was obtained by a gas-solid reaction from a pre-reacted stoichiometric mixture of the elements in welded tantalum tubes at 1570 K within 2 days. The results of a Rietveld refinement are shown in Figure 1. Data on the profile fit are given in Table 1. Fibrous crystals up to 3 mm in length and 20 μm in diameter (Figure 2) were obtained by a chemical vapour transport reaction in welded molybdenum crucibles using TeI_4 as a transport agent. Energy-dispersive X-ray spectroscopy (EDX) and X-ray single crystal structure analyses revealed the presence of some molybdenum in the samples. No indication of an enrichment of tellurium was obtained. The results of a structure refinement of $Mo_{0.11}Ta_{10.89(2)}Si_2Se_8$ are listed in Tables 2, 3, and 4. As expected for a metal-rich compound with extended metal−metal bonding, $Ta_{11}Si_2Se_8$ is a moderate metallic conductor. The resistivity increases steadily with increasing temperature. The values for two different samples were found to be about 1 mΩcm and 1.5 mΩcm at 10 K and 1.6 mΩcm and 2.1 mΩcm at 320 K, respectively.

Table 1. Selected parameters of the Rietveld analysis of $Ta_{11}Si_2Se_8$

Measuring parameters		
Scan-range, stepwidth (2θ) [°]		5.00−95.00 / 0.03

Description of the Crystal Structure

The structure is composed of eleven crystallographically inequivalent atoms: Ta1−Ta6, Si1, and Se1−Se4. They all are located in mirror planes perpendicular to the short *c* axis at *z* = 0 and 1/2 modulo 1. Figure 3 shows the structure in a projection along the short *c* axis. The basic unit of the structure is an Si-centred tricapped trigonal prism, i.e. a tetrakaidecahedral Ta_9Si cluster that is confined by fourteen triangular faces. Strong interactions between the

[a] Occupation factors: $b_{Ta1} = 0.89(2)$, $b_{Mo1} = 0.11$.

central Si and the peripheral Ta^{pr} atoms of the prism are indicated by a mean distance of 255.2 pm. The three capping Ta^c atoms are somewhat more distant (274.8 pm). Ta–Ta bonds contribute significantly to the stability of the cluster: The mean d_{Ta1-Ta} between Ta^{pr} and Ta^c atoms is 289.3 pm in contrast to 338.1 pm between Ta atoms of adjacent prisms. The shortest Si–Si distance corresponds to the parameter *c* (346.48 pm). In contrast to the less metal-rich phase Ta_4SiTe_4[15a,b] (d_{Si-Si} = 235.3, 244.8 pm), there are no homonuclear Si–Si bonds in $Ta_{11}Si_2Se_8$.

The clusters are condensed via common trigonal prism faces into columns, according to $^1_\infty[SiTa_{6/2}{}^{pr}Ta_3{}^c]$. Furthermore, two columns share the Ta1 atom of one out of the three capping positions, $^1_\infty[(SiTa_{6/2}{}^{pr}Ta_2{}^cTa_{1/2}{}^c)_2] = Ta_{11}Si_2$. A part of such a twin column is shown in Figure 4. Adjoining twin columns are shifted relative to each other by *c*/2. Intercluster bonding contacts between Ta3 and Ta5 (318.4 pm) link the columns to an open three-dimensional network. The resulting elongated channels are sheathed by four crystallographically inequivalent Se atoms which cover and bridge the clusters in different ways: Se2 with coordination number CN 4, $<d_{Ta-Se1}> = 262.8$ pm, and Se4 (CN 6, <269.2 pm>) connect adjacent twin columns, while Se1 (CN 3, <258.2 pm>) and Se3 (CN 5, <270.8 pm>) bridge the clusters which share capping Ta atoms. As one can clearly see from Figure 5, the coordination polyhedra of the Se atoms represent distinct fragments of a Ta_9Se cluster related to the Ta_9Si cage. The one-sided coordination of all Se atoms points to a very characteristic structural functionality of the most electronegative component of the compound: the Se atoms saturate the remaining valences of the open $Ta_{11}Si_2$ network structure by completely covering its internal surfaces.

Features of the Electronic Structure

The electronic band structures of $Ta_{11}Si_2Se_8$ and $Ta_{11}Ni_2Se_8$ were calculated with the extended Hückel method.[21] Parameters were taken from the literature,[22] and are listed in Table 5. The valence-state ionization energies H_{ii} and the coefficients of the Slater-type orbitals, c_1 and c_2, for tantalum are based on charge-iterative calculations.[20] Band structure calculations were carried out using a 30 *k* point mesh lying in the representation domain of the corresponding space group. The total density of states (DOS) and the contributions of each component of the compounds are shown in Figure 6. The total DOS of the silicide can be subdivided into four blocks:

(i) The primarily Se 4s based peak around −22 eV is not shown.

(ii) The levels between −18 and −13.5 eV are dominantly of Ta 5d and Se 4p character. Mixing of these orbitals gives rise to strong heteronuclear Ta–Se interactions.

(iii) Above a deep local minimum in the DOS around −13.5 eV a third range of Si p and Ta d based states extends up to the Fermi level. A smaller portion of these states at low energy reflects strong heteronuclear Ta–Si bonds whereas the upper levels correspond basically to extended Ta–Ta bonds. Obviously, the heteronuclear bonding interactions Ta–Se and Ta–Si are segregated energetically and spatially. There are no significant Si–Se interactions ($d_{Se-Si} \geq 382.5$ pm) contributing to the stability of this compound.

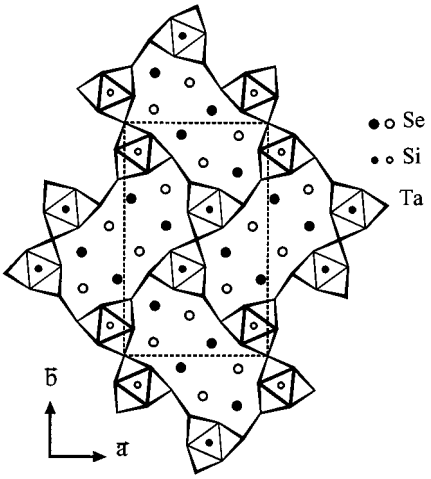

Figure 3. The structure of $Ta_{11}Si_2Se_8$ projected onto the *a,b* plane

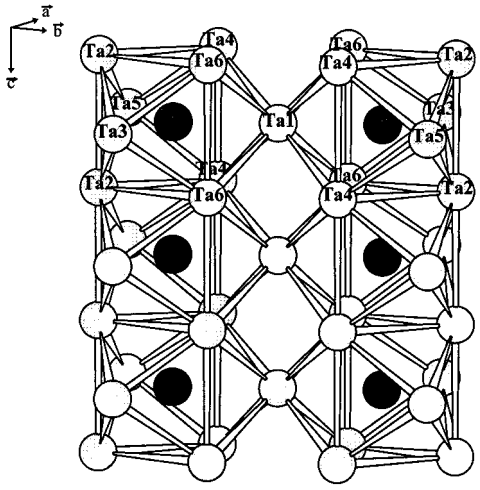

Figure 4. Part of a twin column of condensed Ta_9Si tetrakaidecahedra as present in the structure of $Mo_{0.11}Ta_{10.89(2)}Si_2Se_8$; the columns extend parallel to the short *c* axis

(iv) The states in the 6 eV wide energy window above the Fermi level (−9.8 eV) have mainly Ta d and very little Si p and Se p character. The relatively low electron concentration at the Fermi level may account for the moderate electrical conductivity of $Ta_{11}Si_2Se_8$.

Below the Fermi level the shown DOS of $Ta_{11}Ni_2Se_8$ and $Ta_{11}Si_2Se_8$ can be roughly divided into two blocks separated by a local DOS minimum at about −13.5 eV. Noticeable differences are associated with the position and influence of the states originating from the minor components, Ni and Si. Whereas the states with Ni d character are concentrated in the block at low energy, namely around −14 eV, the states with Si p character are mainly situated somewhat above the local DOS minimum at −13.5 eV in the upper block. Thus, the interactions of the low-lying Se p and Ni d with the Ta d levels give rise to a larger dispersion of the Ta d levels for $Ta_{11}Ni_2Se_8$ than for $Ta_{11}Si_2Se_8$. This difference in the dispersion is also reflected in the position of the Fermi level which resides in a local DOS minimum for the silicide but intersects a local maximum for $Ta_{11}Ni_2Se_8$.

COOP curves (crystal orbital overlap populations) of Ta−Ta, Ta−Se, and Ta−Si are shown in Figure 7. Obviously, the structure of $Ta_{11}Si_2Se_8$ affords an optimal adjustment of homonuclear Ta−Ta and heteronuclear Ta−Si interactions: these bonding states are completely populated; anti-bonding states are empty. Figure 8 illuminates the major structural distinctions of $Ta_{11}Si_2Se_8$ and $Ta_{11}Ni_2Se_8$.

Distinctions in Bonding for $Ta_{11}Si_2Se_8$ and $Ta_{11}Ni_2Se_8$

The isotypic compounds $Ta_{11}Si_2Se_8$ and, e.g., $Ta_{11}Ni_2Se_8$[17d] differ markedly in bonding, although the distances between the interstitial atoms Si and Ni and the nine Ta atoms of the cluster average 262.7 pm in each case. The *c* parameters, however, differ by 7 pm and the *a* and *b* parameter by about 10 pm. The Ta_9Si cluster is stretched along the pseudo-threefold axis and the capping atoms are closer to the centre (274.8 pm) than in the Ta_9Ni cluster (279.6 pm). A similar spectrum of Ta–Si distances for tetrakaidecahedrally coordinated Si is found in binary silicides like Ta_5Si_3 (Mn_5Si_3-type),[23] d_{Si-Ta}: 255.8–281.5 pm. As seen from Figure 8, a shortening of the Ta^c-Ta^{pr} distances in $Ta_{11}Si_2Se_8$ is associated with a shortening of the interprism contacts Ta4–Ta6 by 11.3 pm, and an extension of the intercluster Ta^c-Ta^c contacts by 6.3 pm. The changes in bond length, however, do not perfectly correlate with the changes of the respective MOP values. The distinctive "breathing modes" in the chains –(Ta2–Ta6–Ta1–Ta4–Ta2–Ta3–Ta5–)Ta2 of the two compounds can be traced back to a significant difference between the strength of the $Si-Ta^c$ (<0.27>) and $Ni-Ta^c$ (<0.13>) interactions: Evaluated according to the mean MOP values given in brackets, the bond strengths differ by a factor of two. There are obviously more valence electrons available for heteronuclear bonding in the Ta_9Si than in the Ta_9Ni cluster. Concomitantly, the average Ta–Se and Ta–Ta distances are both 1.1 pm longer for the silicide ($<d_{Ta-Se}>$ = 265.9 pm, $<d_{Ta-Ta}>$ = 316.7 pm) than for $Ta_{11}Ni_2Se_8$.

Substitution of Molybdenum for Tantalum

The major component of $Ta_{11}Si_2Se_8$ can be partly replaced by molybdenum. The partial substitution occurs at the Ta1 position where metal atoms are coordinated similarly to those in *bcc* tantalum itself. This position represents, so to speak, the most reduced centre of the Ta partial structure. It is partly occupied by about 10% molybdenum. The difference between the affinities Mo–Se and Ta–Se, which – according to our observations – is lower in the case of Mo–Se, may serve as a rationale for the enrichment of the minority component Mo at this particular position of the intermetallic framework. At this position, metal atoms have only two Se neighbours; the other crystallographically inequivalent Ta atoms are bound to three or four Se atoms, see Table 4.

Conclusion

(i) Air-sensitive $Ta_{11}Si_2Se_8$ is accessible by application of high-temperature synthesis techniques. Fibrous crystals can be grown by a chemical transport reaction.

(ii) The crystal structure is isotypic with those of

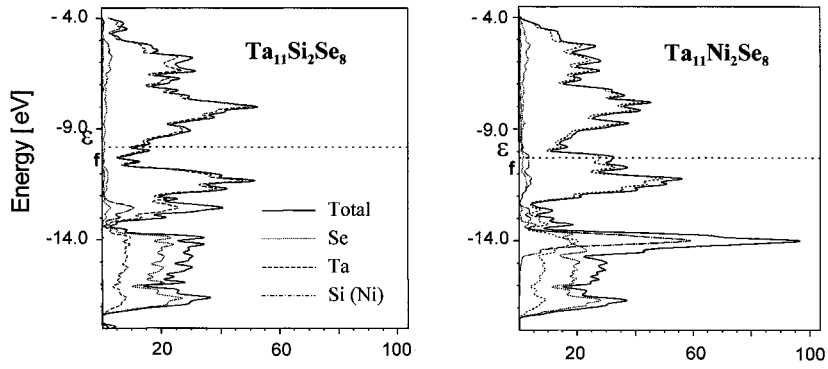

Figure 6. Total DOS and DOS projections of the constituents of (a) $Ta_{11}Si_2Se_8$ and (b) $Ta_{11}Ni_2Se_8$ in the energy window −4 to −18 eV

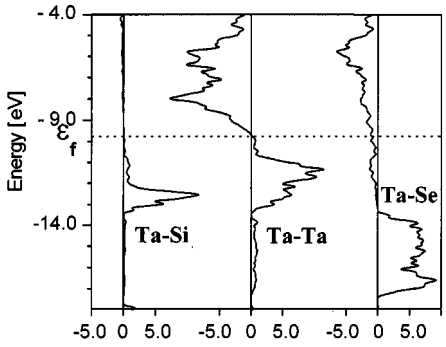

Figure 7. COOP curves of Ta−Ta, Ta−Se, and Ta−Si for $Ta_{11}Si_2Se_8$

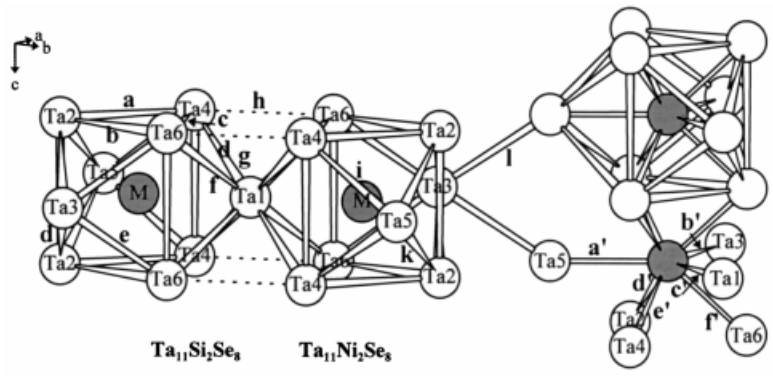
$Ta_{11}M_2Se_8$ (M = Fe, Co, Ni). It consists of an open network of condensed tetrakaidecahedral Ta_9Si clusters. The Se atoms have a single-sided Ta coordination; they cover the internal surface of the porous $Ta_{11}Si_2$ partial structure.



(iii) One out of six crystallographically inequivalent Ta atoms, namely Ta1 with the highest valence electron concentration for Ta−Ta bonding, can be partly replaced by molybdenum. The Mo-doped phase is a moderate metallic conductor.

(iv) Semi-empirical band structure calculations reveal striking differences in bonding for the two isotypic phases $Ta_{11}E_2Se_8$ (E = Si, Ni). The heteronuclear bonding interactions between the encapsulated atom and the Ta atoms of the Ta_9E cluster are substantially stronger for the silicide than for the Ni phase. The maximum of the projected DOS of Si is about 1.5 eV above the projected DOS of Ni. As a consequence, only the projected DOS of Si is − at least to a very large extent − energetically separated from the projected DOS of Se through a local minimum in the DOS at about −13.5 eV.

Experimental Section

Synthesis: $Ta_{11}Si_2Se_8$ was prepared in form of a grey, microcrystalline powder from a pre-reacted mixture of the elements in a sealed tantalum tube at 1570 K within 2 d. The pre-reacted mixtures were produced from the elements (Ta: Starck, 99.8%; Si: Heliotronic, 99.99%; Se: Chempur, 99.999%; total: 500−600 mg) in previously outgassed, evacuated quartz glass ampoules at 1170 K within 1 d. Up to 3 mm long and 20 μm thick, silver-shiny, needle-shaped crystals of Mo-doped $Mo_xTa_{11-x}Si_2Se_8$ were produced by a chemical vapour transport reaction in a welded molybdenum crucible starting from a compacted, stoichiometric mixture of $TaSe_2$, Ta, and Si (600 mg) and TeI_4 (8 mg) as a transport agent. The crucible was quickly heated up in an induction furnace, kept at 1870 K for 1 h and cooled down to 1450 K within 8 h. The furnace was then switched off. $TaSe_2$ and TeI_4 were prepared from stoichiometric mixtures of the elements in previously outgassed, evacuated quartz glass ampoules at 1270 K, 3 d ($TaSe_2$) and at 670 K, 3 d (TeI_4, I_2: Merck, 99.99%), respectively.

Phase Analyses: The phases of starting material and product were identified by powder X-ray diffraction measurements employing the Guinier technique (Guinier System 600, Huber; Cu-$K\alpha_1$ radiation). Silicon (a = 543.09 pm) was used as an internal standard. Powder diffractograms (PW1050/25, Philips; Ni-filtered Cu-K_α radiation) were recorded in the range 5° < 2θ < 95°; scan width: 0.03°; scan time per step: 90 s. Rietveld refinements were performed with the program LHPM.[24] The atomic positions as determined by the crystal structure refinement were used as starting parameters. Selected samples were analysed by energy-dispersive X-ray spectrometry (EDX, CS 4DV, CamScan; detector: Noran Instruments). The composition of the Mo-doped crystals was determined to be $Mo_{0.35(9)}Ta_{11.3(5)}Si_{1.2(5)}Se_{8.0(1)}$ by merging five independent analyses. A similar low Si content was also found for the ternary

phase probably due to the superposition of the Ta-*M* and the Si-*K* emission line.

Electrical Resistivity Measurements: Four-probe dc electrical resistivities of two needle-shaped crystals ($5 \times 10 \times 1000$ μm and $10 \times 20 \times 750$ μm) were measured as a function of temperature in the range 10–325 K. The four copper leads were attached along the needle axis with silver epoxy glue. Details concerning the measurements and the equipment are given elsewhere.[13c]

Crystal Structure Determination: Weissenberg and Buerger precession photographs of a crystal mounted along the needle axis yielded an orthorhombic unit cell. The lattice parameters, intensity modulations and the extinctions pointed unambigously to a phase that is isotypic with $Ta_{11}Ni_2Se_8$, space group symmetry *Pnnm*. Intensity data of two crystals ($0.02 \times 0.02 \times 0.31$ mm and $0.01 \times 0.01 \times 0.16$ mm) were collected employing an imaging plate diffraction system IPDS (Stoe) using Mo-K_α radiation and a graphite monochromator. Direct methods (SHELXS-96[25]) led to the anticipated structure. Application of a semi-empirical absorption correction based on symmetrically equivalent reflections (XPREP, SHELXTL[25]) improved the residual value R_{int} from 0.1047 to 0.0761 for the intensities in the case of the larger crystal. The calculations of the two data sets converged at $wR2 = 0.0631$ and 0.0691. The isotropic displacement parameter of one metal position, namely Ta1 situated in the centre of a Ta_9 cuboid was strikingly large. Nonrestricted refinements of the displacement parameter and a mixed occupation by Ta and Mo yielded in qualitative agreement with EDX analyses 89% (86%) Ta and 11% (14%) Mo and unobstrusive *U* values. Further information concerning the structure determination of the larger crystal is given in Table 2. Structural parameters are listed in Tables 3 and 4.

Substituted Tungsten Fluorides

Anton Dimitrov,[a] Stefan Seidel,[a] and Konrad Seppelt*[a]

Dedicated to Professor Bernt Krebs on the occasion of his 60th birthday

Keywords: Tungsten / Fluorine / 2,2,2-Trifluoroethoxy / Bis(2,2,2-trifluoroethyl)amino / Aza-tungsta-cyclopropane

WF_6 reacts with $HOCH_2CF_3$ to form $F_5W–OCH_2CF_3$ and *cis*-$WF_4(OCH_2CF_3)_2$. CsF is added to $F_5WOCH_2CF_3$, yielding the heptacoordinated anion $[F_6WOCH_2CF_3]^-$, which has a capped octahedral structure with the oxygen ligand in an equatorial position. The first step of the reaction of WF_6 with $HN(CH_2CF_3)_2$ results in $F_5WN(CH_2CF_3)_2$. Excess $HN(CH_2CF_3)_2$ causes deprotonation, yielding the heptacoordinated $[F_5W(\eta^2CF_3–CHN–CH_2CF_3)]^-$ anion. This can be described as a tungstaazacyclopropane derivative or a π complex between F_5W^- and $CF_3–CHN–CH_2CF_3$. The only case in which MoF_6 reacts similarly is the formation of $F_5Mo–OCH_2CF_3$.

Of the 15 known hexafluorides (SF_6, SeF_6, TeF_6, MoF_6, WF_6, TcF_6, ReF_6, RuF_6, OsF_6, RhF_6, IrF_6, PtF_6, UF_6. NpF_6, PuF_6), only a few − TeF_6, WF_6, and to some extent also UF_6 − have been considered as starting material for other hexacoordinated molecular compounds prepared by means of nucleophilic substitution. There are many reasons for the failure of such simple reactions, in particular the inertness of SF_6 and SeF_6 towards nucleophilic attack, and the oxidation strengths of most other hexafluorides, which prevents a controlled nucleophilic substitution.

In the case of TeF_6, the step-by-step replacement by OR or NR_2 ligands is well known.[1−10] For UF_6 the only thoroughly investigated case[11] seems to be the replacement of the fluorine ligand by the $OTeF_5$ group. WF_6 can be transformed step by step into WF_5OR and finally to $W(OR)_6$, although the latter is usually made from WCl_6.[12−14] CF_3CH_2OH has been treated with WF_6 to give the whole series $Cl_xW(OCH_2CF_3)_{6-x}$.[15] $F_5W−NR_2$ has been prepared in a similar manner; this is the starting point of another series that ends with the known $W(NR_2)_6$.[16−18] The ligand $−N=C(CF_3)_2$ replaces five fluorine atoms of WF_6 in $FW[NC(CF_3)]_2$.[19]

In the present study, we have chosen systems with R = CH_2-CF_3, in order to obtain some stabilization by the CF_3 group, and to avoid the inertness of fully fluorinated groups such as -C_2F_5.

$F_5WO−CH_2CF_3$, *cis*-$F_4WOCH_2CF_3]_2$, and $[F_6WOCH_2CF_3]^-$

The reaction of WF_6 and CF_3CH_2OH proceeds smoothly in two steps to F_5W-OCH_2CF_3 and *cis*-$F_4W(OCH_2CF_3)_2$. The first compound is a liquid, and is structurally characterized by the ^{1}H-, ^{19}F-, and ^{13}C-NMR spectra. The ^{19}F-NMR AB_4-type spectra for the F_5W group is, of course, typical. The same method clearly indicates the *cis* position of the two alkoxy groups in $F_4W(OCH_2CF_3)_2$ by means of the ^{19}F-NMR A_2B_2-type spectra. The latter compound can also be obtained in crystalline form, and the single-crystal structure determination gives a full account of the molecular structure (see Figure 1 and Table 1).

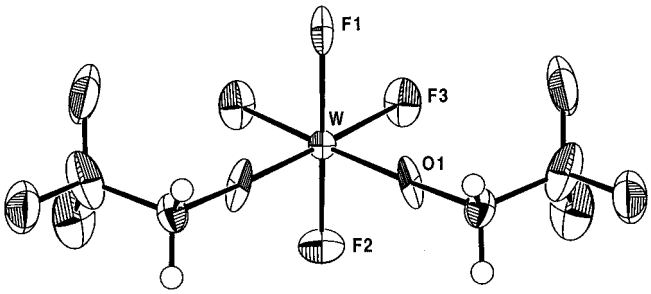

Figure 1. Structure of *cis*-$F_4W(OCH_2CF_3)_2$ in the crystal, ORTEP plot with 50% ellipsoids

Although the existence and structure of these two species is unsurprising, $F_5W−OCH_2CF_3$ is the starting material for a simple but theoretically interesting compound. It is easy to add CsF to obtain $Cs^+[WF_6OCH_2CF_3]^-$. This compound obviously has, according to a single-crystal structure determination, seven-coordinate tungsten atoms and one ligand that differs from the rest (see Figure 2 and Table 1).

WF_6 is known to add F^- to form WF_7^- and WF_8^{2-}; both anions are structurally fully characterized and turn out to be capped octahedral and square antiprismatic.[20−24] The latter structure seems to be the principle structure of the coordination number 8. For the coordination number 7 we know there are three different geometric orientations that have a very similar ligand repulsion, namely the capped octahedron, the capped trigonal prism, and the pentagonal bipyramid, listed in order of increasing ligand repulsion.[25] In the main-group series, the pentagonal bipyramid is always obtained, e.g. in IF_7 [26−29]; this is also the case for species with different ligands, such as IOF_6^-, $TeF_6OCH_3^-$

and $TeF_5(OCH_3)_2^-$.[30−33] The oxygen ligands always occupy axial positions in the pentagonal bipyramid. The pentagonal structures of XeF_5^- and $XeOF_5^-$ can be similarly explained.[34−36] Thus, in main-group compounds the overall structure (pentagonal bipyramid) is not the one with minimum interligand repulsion. However, the finer details such as the occupation of different sites by different ligands follow this ligand repulsion model. This finding calls for a theoretical explanation that is beyond the scope of this article.

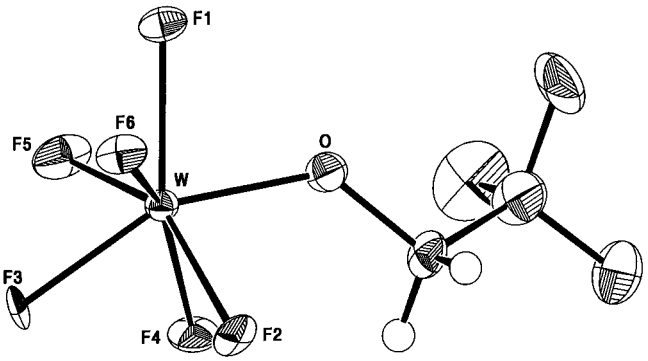

Figure 2. Structure of the $[F_6WOCH_2CF_3]^-$ anion in $Cs^+[F_6WOCH_2CF_3]^-$, ORTEP plot with 50% ellipsoid

The situation of the transition-metal compounds is also not straightforward. WF_7^- and MoF_7^- display the capped octahedral structure that the simple ligand-repulsion picture leads us to expect.[20] However, the structure of isoelectronic ReF_7 might best be described as pentagonal bipyramidal, although it is distorted into the direction of a capped octahedron.[37] ReF_7^-, with just one d electron more than WF_7^- and ReF_7, has a regular pentagonal bipyramidal structure,[38] as has $ReOF_6^-$[38], surprising results that also require a theoretical explanation beyond the interligand-repulsion model.

The reaction of $F_5W-OCH_2CF_3$ with CsF allows a test on a seven-coordinate structure, in which one ligand differs from the other six. It should be kept in mind that the analogous reaction between F_5W-OCH_3 and F^- yields only WF_5O^- and CH_3F[39] The structure of the anion $[F_6WOCH_2CF_3]^-$ is shown in Figure 2. If viewed from the direction of W−F1, the (pseudo) threefold symmetry of the anion becomes visible.

This symmetry clearly shows that the capped octahedral structure of WF_7^- is retained in $[WF_6OCH_2CF_3]^-$. A capped octahedron has three different positional sites: the capping position, three equatorial positions, and three basal positions. The $-OCH_2CF_3$ ligand occupies an equatorial position, which is obviously the site towards which the larger ligands are directed, since the W−F bond lengths of the equatorial bonds in WF_7^- are shorter than those of the basal and capping fluorine atoms.

The difference in W−F bond lengths are nearly the same as those in WF_7^-, allowing for certain small deviations induced by the one different ligand. This is also the case for the bond angles within the anion (see Table 1).

It should be kept in mind that these structures are fluxional in solution. As in WF_7^-, the different fluorine atoms in $[F_6WOCH_2CF_3]^-$ show only one signal without $^{183}W-^{19}F$ coupling, indicating rapid intermolecular fluorine exchange.

In order to check the above described structural model, we attempted to treat *cis*-$F_4W(OCH_2CF_3)_2$ with CsF. Unfortunately, however, the resulting product could not be obtained in single-crystal form.

$F_5W-N(CH_2CF_3)_2$ and $[F_5W(\eta^2CF_3-CHN-CH_2CF_3)]^-$

Like with $F_5W-N(CH_2CH_3)_2$[16], the compound $F_5W-N(CH_2CF_3)_2$ can readily be obtained from WF_6 and $HN(CH_2CF_3)_2$. It is a crystalline solid and stable at room temperature. Crystal structure investigations resulted in two different crystallizations from pentane or isopentane, a red needle-shaped modification at low temperature, and a brown one at room temperature. However, the two modifications of the $WF_5-N(CH_2CF_3)_2$ molecules are very similar (see Figure 3 and Table 1). In both cases, the nitrogen environment is completely planar, while $N(CH_2CF_3)_3$ has a pyramidally surrounded nitrogen atom. In contrast to the (alkoxy)tungsten fluorides, the different fluorine atoms on the tungsten atom are not resolved in $F_5W-N(CH_2CF_3)_2$ in the temperature range of −90 to +25°C and in different solvents.

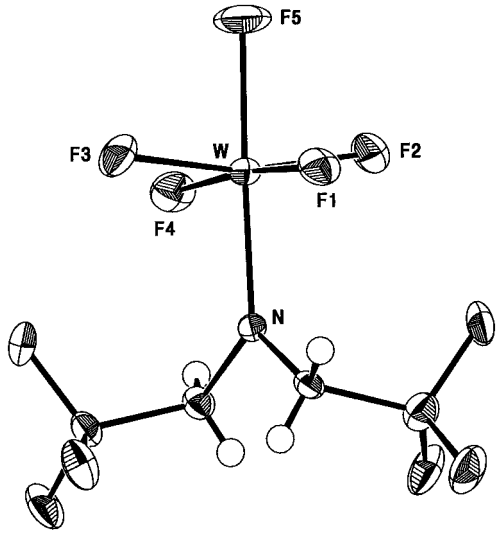

Figure 3. Structure of $F_5W-N(CH_2CF_3)_2$ in the crystal modification (1); ORTEP plot with 50% ellipsoids; overall structure and atomic numbering of modification (2) is the same

Attempts to treat $F_5W-N(CH_2CF_3)_2$ with a second equivalent of $HN(CH_2CF_3)_2$, and the reaction of WF_6 with two equivalents $HN(CH_2CF_3)_2$, do not yield the expected *cis*-$F_4W[N(CH_2CF_3)_2]_2$. Instead we obtained a red-brown compound in the form of needles or platelets; these contain an anion formed by deprotonation according to the single-crystal structure determinations, done as before on two modifications. The structure is in agreement with the complete set of ^1H-, ^{19}F-, and ^{13}C-NMR data. One remarkable feature is its tetragonal pyramidal WF_5 group, attached to a CN linkage, which forms a three-membered WNC ring (Figure 4 and Table 1). Thus, it also has a seven-coordinate tungsten atom. The counterion is $[H_2N(CH_2CF_3)_2]^+$. The anion could also be regarded as a π complex between WF_5^- and $CF_3-CHN-CH_2-CF_3$. In addition to its peculiar structure the spontaneous formation of a W−C bond with help of the weak base $HN(CH_2CF_3)_2$ is another remarkable finding.

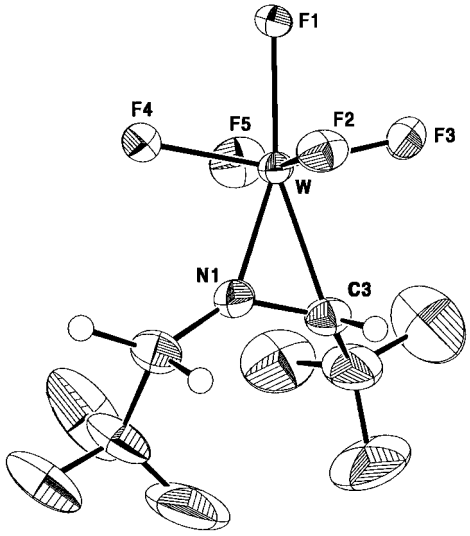

Figure 4. Structure of the anion of $[(CF_3CH_2)_2NH_2]^+[F_5W\eta_2-(CF_3-CHN-CH_2CF_3]^-$, ORTEP plot with 50% ellipsoids; overall structure and atomic numbering of modification (2) is the same

The existence of highly oxidized organometallic compounds with certain heavy transition-metal elements as central atoms, especially from Re {$(CH_3)ReO_3$, Cp^*ReO_3 [Cp* = cyclo-$(CH_3)_5C_5$]} is, of course, well known.[40] In the tungsten series recently the compounds Cp^*WF_4 and Cp^*WF_5 have been reported[41]; these may most closely resemble the tungstaazacyclopropane compound presented in this paper.

Experimental Section

General: All materials were handled in a drybox or in glass or metal vacuum systems in order to avoid hydrolysis. Reaction vessels made of FEP tubing (Perfluoro ether/propene copolymer) were often used. WF_6 and CsF were purchased from Aldrich Co.; MoF_6 and CF_3CH_2OH were purchased from Merck GmbH. $HN(CH_2CF_3)_2$ was prepared from $H_2N-CH_2CF_3$ and $C_4F_9-SO_2-O-CH_2CF_3$. Solvents were carefully dried and degassed before use.

Physical Measurements: The IR spectra were recorded with a Perkin Elmer 883 instrument, the Raman spectra with a Type 1403 of Spex Industries, 1064 nm, 300 mW; and the NMR spectra with a JEOL JNM-LA 400 instrument for ^1H, ^{19}F, and ^{13}C. Chemical shifts are given for $CFCl_3$ and tetramethylsilane as standards. Dryboxes for the use of water-sensitive compounds were obtained from Brown GmbH, Munich, Germany. Elemental analyses were performed by the Beller Co., Göttingen, Germany.

X-ray Crystallographic Procedures: When necessary, suitable single crystals were obtained as described in the experimental procedures. A suitable single crystal was cut, then mounted on an Enraf-Nonius CAD 4 four-cycle diffractometer with help of a special device (a simplified version of the one previously described).[41] Mo-K_α radiation with a graphite monochromator was used. Lattice constants were obtained by fine adjustment of 25 reflections with θ values between 20 and 25°. X-ray intensities were measured with the ω-scan method, with maximal 60 s/reflection, allowing 25% of this time for background measurements. A Lorentz polarization

and ψ absorption corrections were applied. The structures were solved and refined with the SHELX procedures.[42] All atoms were refined anisotropically, and hydrogen atoms were refined isotropically with a single vibrational parameter for all hydrogen atoms. Most hydrogen atoms could be located in difference Fourier analyses, missing hydrogen atoms were refined using a riding model. Table 2 lists further crystallographic details, while Table 1 lists selected bond lengths and angles. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102175. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44(1223)336-033; E-mail: deposit@ccdc.cam.ac.uk].

$F_5W-OCH_2CF_3$: 1.44 g (14.5 mmol) of CF_3CH_2OH and 5.34 g (17.9 mmol) of WF_6 are condensed at −196°C with the help of a metal vacuum line into an FEP tube equipped with a metal valve. The mixture is warmed to room temperature, and a slightly pink solution is formed. HF and excess WF_6 are removed by pumping all volatile material through an NaOH/CaO containing FEP tube, and pure $F_5W-OCH_2CF_5$ is trapped in a −40°C cold FEP trap. The result is 4.2 g (76% yield) of $F_5W-OCH_2CF_3$ as a colorless liquid. − IR (liquid): $\tilde{\nu}$ = 3024 w, 2967 w (C-H), 1438 m, 1395 s, 1285 vs, 1173 vs, 1113 s, 1043 s, 995 m, 951 s, 912 w, 846 w, 840 s, 712 s, 633 vs, 531 w, 486 w, 434 w cm^{-1}. − Raman (liquid): $\tilde{\nu}$ = 3020 (8), 2969 (12), 1438 (9), 1395 (5), 1279 (12), 1143 (35), 1043 (1), 951 (6), 841 (40), 771 (5), 734 (100), 638 (10), 618 (35), 529 (30), 364 (30), 306 (60), 247 (5), 185 (4), 122 (20) cm^{-1}. − ^1H NMR (400 MHz, CD_3CN): δ = 6.29 (q, $^3J_{FH}$ = 8 Hz). − ^{13}C NMR (100.4 MHz, CD_3CN): δ = 123.82 (q, $^1J_{CF}$ = 279 Hz). 80.40 (q, $^2J_{CF}$ = 39 Hz). − ^{19}F NMR: (376.0 MHz, CD_3CN): δ = 128.36 (d, $^2J_{FF}$ = 65 Hz), 102.69 (qt, $^2J_{FF}$ = 63 Hz), −72.15 (t, $^3J_{HF}$ = 8 Hz). − MS (70 eV, EI), for ^{186}W); *m/z* (%): 361 (35) [M^+ − F], 341 (20) [M^+ − H − 2 F], 311 (40) [$F_5W-OCH_2^+$], 281 (100) [F_5W^+], and smaller fragments. − $C_2H_2F_8OW$ (377.9): calcd. C 6.36, H 0.71, F 39.3; found C 7.01, H 0.71, F 40.2.

$F_5Mo-OCH_2CF_3$: 210 mg (2.1 mmol) of CF_3CH_2OH and 530 mg (2.5 mmol) of MoF_6 are treated and purified as described above. Obtained is a yellow liquid. − ^{19}F NMR: δ = 239.10 (d, $^2J_{FF}$ = 82 Hz). 223.99 (qt, $^2J_{FF}$ = 86 Hz), -69.96 (t, $^3J_{HF}$ = 8 Hz).

***cis*-$F_4W(OCH_2CF_3)_2$:** 378 mg (1.0 mmol) $F_5W-OCH_2CF_3$ is weighed into an FEP tube, equipped with a metal valve. With help of a glass vacuum line 250 mg (2.5 mmol) CF_3CH_2OH is condensed on it at −196°C. Warming to room temperature gives a light brown solution. Volatile HF is pumped off at room temperature. Obtained is 320 mg of *cis*-$F_4W(OCH_2CF_3)_2$ as a colorless liquid at room temperature, mp −5°C. − IR (liquid, KBr, νCH): $\tilde{\nu}$ = 1441 s, 1397 s, 1373 m, 1284 vs, 1167 vs, 1105 vs, 1050 m, 952 vs, 839 s, 3024 w, 2967 w, 712 s, 681 vs, 632 vs, 533 m cm^{-1}. − Raman (liquid): $\tilde{\nu}$ = 3010 (12), 2962 (30), 2869 (4), 2777 (4), 1440 (25), 1398 (12), 1280 (20), 1156 (50), 1031 (2), 962 (10), 839 (100), 732 (75), 667 (55), 649 (10), 619 (50), 531 (65), 360 (55), 307 (80), 250 (20), 183 (15) cm^{-1}. − ^1H NMR (CD_3CN): δ = 5.94 (q, $^3J_{HF}$ = 8 Hz). − ^{19}F NMR (CD_3CN): δ = 91.37 (t, $^2J_{FF}$ = 66 Hz), 76,68 (t, $^2J_{FF}$ = 66 Hz), −73.19 (t, $^3J_{HF}$ = 9 Hz). − MS (70 eV, EI for ^{186}W); *m/z* (%): 441 (15) [M^+ − F], 421 (8) [M^+ − H − 2 F], 391 (55) [M^+ − CF_3], 361 (100) [$F_4W - OCH_2CF_3^+$], and smaller fragments.

$C_4H_4F_{10}O_2W$ (457.9): calcd. C 10.49, H 0.88, F 41.49, W 40.1; found C 10.51, H 0.95, F 41.00, W 39.3. Single crystals are obtained by recrystallization at −30°C without solvent.

$Cs^+[F_6WOCH_2CF_3]^-$: In a dry-box 152 mg (1 mmol) of CsF and 275 mg (0.7 mmol) of $F_5W-OCH_2CF_3$ are weighed into an FEP tube. The tube is sealed and heated for 24 h to 60°C. The liquid phase disappears, and a light brown solid is formed. Recrystallisation from CH_3CN at -30°C affords $Cs^+F_6W(OCH_2CF_3)^-$ as colorless crystals. Under the microscope these appear as thin platelets. − IR (Nujol): $\tilde{\nu}$ = 1282 s, 1168 s, 1084 m, 1035 m, 983 s, 946 m, 916 w, 888 w, 830 w, 683 m, 598 vs, 502 s, 435 w cm^{-1}. − Raman (solid): $\tilde{\nu}$ = 1296 (10), 1112 (20), 983 (100, br), 841 (30), 733 (80), 711 (75), 663 (100) cm^{-1}. − ^1H NMR (CD_3CN): δ = 5.56 (q, $^3J_{HF}$ = 9 Hz). − ^{13}C NMR (CD_3CN): δ = 126.44 (q, $^1J_{CF}$ = 278 Hz), 73.91 (q, $^2J_{CF}$ = 36 Hz). − ^{19}F NMR (CD_3 CN): δ = 106.40 (s), −73.71 (t, J_{HF} = 8 Hz).

F_5W-N(CH_2CF_3)$_2$: 970 mg (5.3 mmol) of HN(CH_2CF_3)$_2$ is weighed into an FEP tube equipped with a metal valve. 1.7 g (5.7 mol) of WF_6 is condensed into the tube with help of a glass vacuum line at −196°C. After warming to room temperature a yellow solution and a colorless solid is formed. Excess WF_6 is pumped off, and the solution turns red. Addition of 12 mL of isopentane, centrifugation and cooling to −40°C affords red, needle-shaped crystals, yield 1.2 g (49%). − Raman (solid): $\tilde{\nu}$ = 3052 (5), 3003 (11), 1377 (12), 1022 (60), 827 m, 720 (100), 689 (35), 292 (70) cm^{-1}. − ^{19}F NMR ($CDCl_3$, r.t.): δ = −66.8 (CF_3), 143 (br., F_5W).

$H_2N(CH_2CF_3)_2^+[F_5W\text{-}\eta^2(CF_3CH_2-NCH-CF_3)]^-$: 325 mg (1.8 mol) of HN(CH_2CF_3)$_2$ is weighed into a 10-mm (inner diameter) glass tube, equipped with a teflon valve. With help of a glass vacuum line 1 mL of $CHCl_3$ as solvent and 175 mg (0.6 mmol) of WF_6 are condensed into the glass tube at −196°C. The tube is sealed and warmed to room temperature. The solution turns yellow, then orange and red due to formation of $F_5W-N(CH_2CF_3)_2$, and colorless powder precipitates. After shaking for 8 h at room temperature the color changes to yellow orange. The entire reaction mixture is kept at room temperature for 2 weeks. Brown crystals of $H_2N(CH_2CF_3)_2^+[F_5W(\eta^2CF_3CH_2-NCH-CF_3)]^-$ are formed. − Raman (solid, only peaks with at least medium intensity): $\tilde{\nu}$ = 2997 (12), 2948 (8), 1432 (10), 1413 (7), 1044 (20), 978 (10), 934 (7), 874 (30), 834 (30), 679 (28), 665 (80), 635 (10), 618 (25), 502 (35), 460 (15), 378 (15), 363 (20), 329 (25), 293 (75), 281 (75), 255 (100), 119(40) cm^{-1}. − ^{1}H NMR (CD_3CN, r.t.): δ = 5.24 (m, J_{HF} = 9 HZ, 1 H, $-CH_ACF_3$), 5.64 (m, J_{HF} = 9 Hz, 1 H, CH_BCF_3, J_{HH} = 14.7 Hz), 3.55 (s, $-CHCF_3$), 8.5 (s, $-NH_2$), 4.00 (q, $-CH_2$). − ^{13}C NMR (CD_3CN): δ = 128.9 (q, $^1J_{CF}$ = 279.5 Hz, $^2J_{CH}$ = 7 Hz, $-CH_AH_BCF_3$), 128,6 (q, $^1J_{CF}$ = 275.8 Hz, $^2J_{CH}$ = 7 Hz, $-CHCF_3$), 58.7 (q, $^2J_{CF}$ = 33.9 Hz, $^1J_{CH}$ = 146 Hz, $-CH_AH_BCF_3$), 81.7 (q, $^2J_{CF}$ = 40,5 Hz, $-CHCF_3$), 50.1 (q, $^2J_{CF}$ = 36 Hz, $^1J_{CH}$ = 149 Hz, $-CH_2CF_3$, cation), 124.1 (q, $^1J_{CF}$ = 277.8 Hz, $^2J_{CH}$ = 7 Hz, $-CH\,CF_3$ cation). − ^{19}F NMR (CF_3CN): δ = 57.5 (d, J_{FF} = 80.6 Hz, $-WF_4$), 1,2 (qt, J_{FF} = 80.6 Hz, −WF), −68.3 (t, J_{FH} = 8 Hz, $-CH_AH_BCF_3$), −62.8 (s, $-CHCF_3$), −67.8 (t, J_{FH} = 9 Hz, $-CH_2CF_3$, cation).

Selective Formation of *cis*(X)- and *trans*(X)-Ru(dmbpy)$(CO)_2X_2$ Complexes (X = Cl, Br, I, SCN) from Monomeric and Dimeric Ru−mono(dmbpy) Carbonyl Complexes (Dmbpy = 4,4′-Dimethyl-2,2′-bipyridine)

Keywords: Ruthenium / Halogens / Carbonyl complexes / Structure elucidation

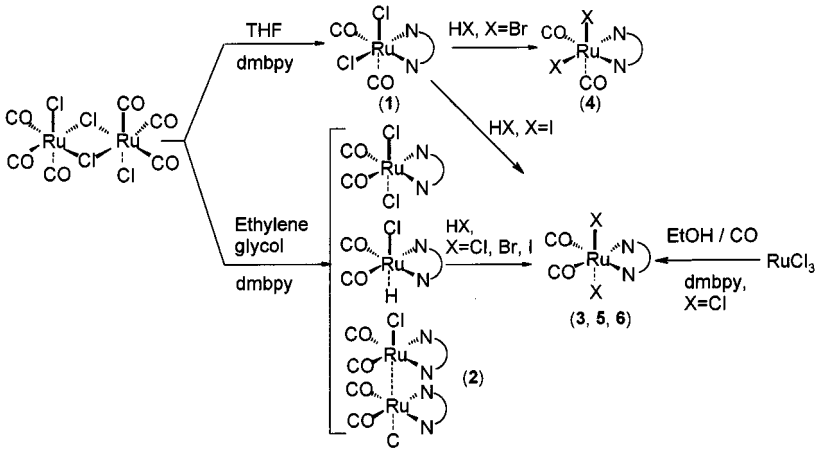
Aqueous hydrogen halides HX (X = Cl, Br, I) are shown to be excellent halogen sources for the synthesis of a series of halogen-containing ruthenium mono(2,2′-bipyridine) carbonyl complexes Ru(dmbpy)$(CO)_2X_2$ (dmbpy = 4,4′-dimethyl-2,2′-bipyridine), as well as effective reagents for the attack of the Ru–Ru bond in the dimer [Ru(dmbpy)-$(CO)_2Cl]_2$. Selective syntheses were established for both *cis*- and *trans*-halogen complexes in the case of Cl- and of Br-containing derivatives, but the only stable isomer containing iodine was *trans*(I)-Ru(dmbpy)$(CO)_2I_2$. The failure to obtain the *cis* isomer was probably due to sterical effects. Furthermore, a novel *S*-bound *trans*(SCN) analogue was synthesized and structurally characterized. In all experiments, the reaction conditions selected led to complete halogen exchange; no mixed halogen or pseudohalogen complexes were detected.

Introduction

Mononuclear ruthenium 2,2′-bipyridine complexes exhibit excellent catalytic properties in the water-gas shift reaction[1−4] and the reduction of carbon dioxide.[5−9] These catalyst-precursor complexes have been chemically modified through the use of different halogen and pseudohalogen ligands and substituted bipyridine reagents.[9−15] Most recently, the various isomeric forms of these compounds[9][16] were studied as a means of clarifying the structure of the actual catalyst, which is believed to be polymeric. Electropolymerization experiments[16] have indicated that only *trans*-halogen complexes are able to form such polymeric species, which underlines the need for isomerically pure complexes.

This paper reports isomerically selective syntheses for chemically altered monomeric ruthenium−mono(2,2′-bipyridine) complexes. On the basis of results obtained earlier,[15] we chose to use only dimethyl-substituted bpy ligands, as this was believed likely to introduce some interesting new features to complexes with direct Ru−Ru bonds. A structural study of a dimeric complex containing the 4,4′-dimethyl-2,2′-bipyridine ligand has shown that methylated bpy ligands can be used to lock the rotation of both the carbonyl and the polypyridine ligands around the ruthenium backbone in corresponding structures, which may allow structural characterization of an ordered polymeric species. In addition, the methyl groups can be converted to carboxy or trichlorosilylethyl groups to achieve chemical anchoring of Ru−bpy complexes into oxide supports.[14,17−19]

The various halogen-containing derivatives of Ru−bpy carbonyl complexes form a useful series of compounds for investigating the Ru−Ru chain-forming properties of the oligomeric complexes, since the Ru−Ru chain-forming step will also be affected by the chemical nature of the *trans* leaving group (i.e. Cl, Br, I, SCN). Furthermore, the thiocyanate ligand, as well as various halogens, have been widely used for tuning the photo- and electrochemical properties of transition metal complexes,[20][21] most recently in modern solar-cell designs.[17][18] By far, the photochemical behavior of mono(2,2′-bipyridine) complexes has remained a relatively unexplored field of ruthenium bipyridine chemistry, and the chemically altered halogen and pseudohalogen derivatives presented in this paper thus also offer an intriguing series of compounds for future photochemical investigations.



Results and Discussion

The formation of monomeric ruthenium bipyridine carbonyl complexes, such as Ru(bpy)$(CO)_2Cl_2$,[10] is complicated by the various orientations of the carbonyl and halogen ligands, which allows the coexistence of both *cis*- and *trans*-halogen isomers (third isomer with axial carbonyl groups is energetically far less favored). The choices of solvent and ruthenium reagent have been shown to determine the reaction route: synthesis with $RuCl_3$/CO/bpy[24][31] may give pure *trans*(Cl)-Ru(bpy)$(CO)_2Cl_2$, whereas syntheses based on acid-controlled $[Ru(CO)_2Cl_2]_n$/MeOH/bpy and $[Ru(CO)_3Cl_2]_2$/THF/bpy[9][10] yield both isomers. In the latter case, use of ethylene glycol instead of THF as solvent gives either hydride Ru(bpy)$(CO)_2$ClH or dimeric complex $[Ru(bpy)(CO)_2Cl]_2$. As was learned in our earlier studies,[15] methylation of the 2,2′-bipyridine ligand tends to shift the balance between *cis*- and *trans*-halogen products toward the *cis*-halogen species.

In this paper we describe the syntheses of halogen- and pseudohalogen-containing (Cl, Br, I, SCN) monomeric

Scheme 1

Ru−dmbpy (dmbpy = 4,4′-dimethyl-2,2′-bipyridine) complexes with controlled *cis*-*trans* isomerism. *trans*-Halogen complexes are achieved by treating the *trans*-chloro complex (synthesis based on "ruthenium red carbonyl solution" as starting material) or dimer **2** with the corresponding hydrogen halide. The syntheses are summarized in Scheme 1.

Ligand-Exchange Reactions Cl → Br, I based on *cis*(Cl)-Ru(dmbpy)$(CO)_2Cl_2$ (1)

Ligand-substitution reactions with aqueous hydrogen halides have previously been studied for the monomeric parent complex *trans*(Cl)-Ru(bpy)$(CO)_2Cl_2$.[12] As in the present study, the reactions were limited to halide exchange, even though decarbonylated complexes such as $[Ru(bpy)Cl_4]^-$, $[Ru(bpy)Cl_3]^-$, and $[Ru(bpy)Cl_2]^{2-}$[12] are known. The reaction conditions selected led to complete halogen exchange, i.e. no mixed-halogen complexes were detected.

Heating of complex **1** in aqueous HBr resulted in the formation of greenish yellow precipitate. The product was analyzed by spectroscopic and X-ray diffraction measurements and identified as *cis*(Br)-Ru(dmbpy)$(CO)_2Br_2$ (**4**, Figure 1). The NMR spectra of complex **4** (in $CDCl_3$) support an unchanged *cis*-halogen arrangement, the main proof being the double CO, Me, and aromatic carbon resonances detected in the ^{1}H- and ^{13}C-NMR spectra.

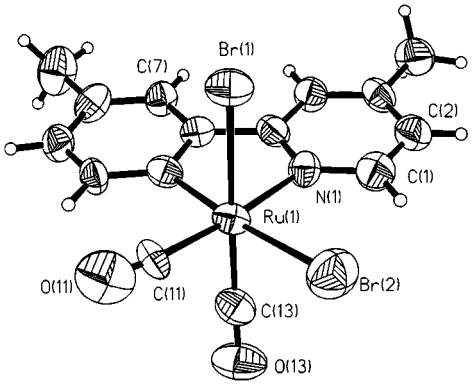

Figure 1. Structure of *cis*(Br)-Ru(dmbpy)$(CO)_2Br_2$ (**4**); the solvent molecule has been omitted for clarity

When aqueous HI was used as halogen source, the reaction changed markedly; despite several attempts, no traces of *cis*-halogen species were detected. Instead, the only product characterized (both spectroscopically and crystallographically) was *trans*(I)-Ru(dmbpy)$(CO)_2I_2$ (**6**, Figure 2). Usually, both *cis*- and *trans*-halogen forms of mono(bipyridine) complexes are highly stable, and rearrangements of coordination spheres invariably include ligand-substitution reactions. In this case, the larger size of the iodine ligand with respect to Cl and Br (ionic radii for Cl, Br, and I: 1.81, 1.95, and 2.16 Å, respectively) apparently prevents the *cis*-halogen arrangement, and strongly favors the *trans*(I) conformation.

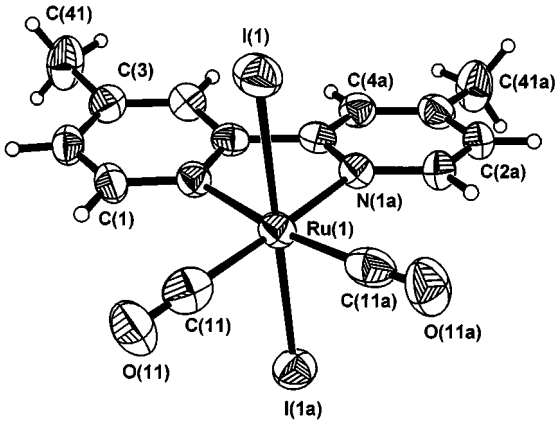

Figure 2. Structure of *trans*(I)-Ru(dmbpy)$(CO)_2I_2$ (**6**)

The structure of complex **4** does not exhibit any severe distortions compared with the chlorine-containing parent complex.[15] The bipyridine ring system is almost planar (angle between pyridine ring planes only 0.7°), although slightly bent away from the axial carbonyl group. The Ru−Br bond lengths of 2.565(1) (axial) and 2.502(2) Å (equatorial) are well within the range of bond lengths for related compounds reported earlier,[12] though, the axial halogen atom suffers slightly from the *trans* effect of the opposite carbonyl ligand. The bipyridine bite angle N(1)−Ru(1)−N(2) of 77.8(3)° is more or less typical for other Ru−bpy carbonyl complexes;[10−15] the slight distor-

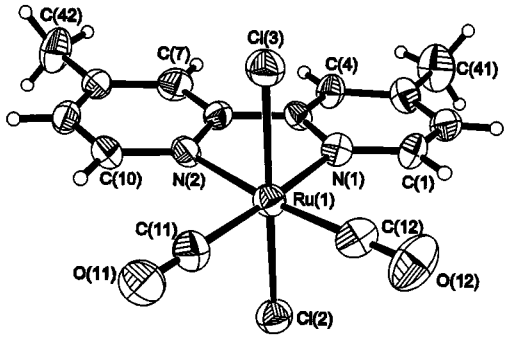

Figure 3. Structure of *trans*(Cl)-Ru(dmbpy)$(CO)_2Cl_2$ (**3**); the solvent molecule has been omitted for clarity

tion is due to the other carbonyl ligand positioned *trans* to N(1) [bond lengths Ru(1)−N(1) 2.126(8), Ru(1)−N(2) 2.076(8) Å].

Formation of Monomeric *trans*(X)-Ru(dmbpy)$(CO)_2X_2$ (X = Cl, Br, I, SCN) Complexes

Aqueous hydrogen halides proved to be excellent halogen sources in the above-described ligand-exchange reactions. In this study, we also investigated the attack of Cl^-, Br^-, and I^- on Ru−Ru bonds using dimeric [Ru(dmbpy)-$(CO)_2Cl]_2$ (**2**) as starting material. In all experiments, reactions led to breaking of the metal−metal bond and complete halogen exchange. Not surprisingly, all monomeric Ru−dmbpy compounds formed (complexes **3**, **5**, **6**) adopted *trans*-halogen configuration. This was also the case for complex **3** (Figure 3), which was synthesized by treating monomeric co-products[15] from the synthesis of complex **2**, and possibly some dimeric residues, with HCl (see Scheme 1). This experiment indicates that ethylene glycol, which was originally used to direct the complexation reaction between $[Ru(CO)_3Cl_2]_2$ and dmbpy toward dimeric species, also favors the formation of monomeric *trans*-chloride or *trans*-chloride−hydride complexes.

Since the axial positions of octahedral mono(bipyridine) complexes are sterically not hindered, they allow the *trans* coordination of relatively large ligands, such as I or *S*-bound bent SCN. Changing the halogen or pseudohalogen groups in these positions has little structural effect on the overall Ru−bpy arrangements (see Tables 2 and 3). Nevertheless, all attempts to crystallize complex **5** failed, and the identification of this complex was carried out instead by elemental analysis and interpretation of spectroscopic data. Once again, the most valuable proof came from ^{13}C-NMR data; single resonances for CO, Me, and aromatic carbon atoms supporting the *trans*-halogen arrangement were detected for all three complexes **5**, **6**, and **7**. Probably the main reason for the difficulty in obtaining single crystals from complex **5** was the tendency to form solvated crystalline species. As in the case of complex **3**, the solvent molecules eventually escape from the solid structure, destroying the crystals. Consequently, a decent X-ray diffraction analysis requires very fast data collection.

The coordination of thiocyanate ligands in complex **7** results in a strong ν_{SC-N} single band at 2116 cm^{-1} (in CH_2Cl_2), a value close to that found for both the *S*- and the *N*-bound Ru^{II} mono(2,2′-bipyridine) thiocyanate complexes reported earlier[13] (ν_{SC-N} values: 2116 for *S*-bound and 2109 cm^{-1} for *N*-bound, showing an unexpectedly weak tendency of the *N*-bound thiocyanate ligand to shift the SC−N stretching bands toward lower frequencies). A weak resonance at δ_{SCN} = 120 found in the ^{13}C-NMR spectrum of complex **7** matched that of the *S*-bound thiocyanate analogue [δ_{SCN} = 118 for *trans*(SCN)-Ru(bpy)-$(CO)_2(SCN)_2$], and other *S*-bound Ru−SCN complexes[21] assigned spectroscopically. The coordination mode of the SCN ligands in complex **7** was verified by X-ray crystallography (Figure 4). Since there is no severe steric hindrance, both terminal thiocyanates are bent [angles Ru−S(13)−C(13) 102.2(1)°, Ru−S(14)−C(14) 104.8(1)°]; in crystalline form the rotation of the groups is locked roughly between the two carbonyl ligands and the opposite bipyridine ring halves. The bond lengths of 2.429(1) and 2.432(1) Å for Ru(1)−S(13) and Ru(1)−S(14) are almost identical with those of the above-mentioned Ru−bpy analogue, but long relative to the range reported for other Ru^{II}−S bond lengths [2.262(1)−2.393(3) Å[32]]. The longer distances most probably are due to the competition of the carbonyl ligands for the π-electron density of the central metal atom.

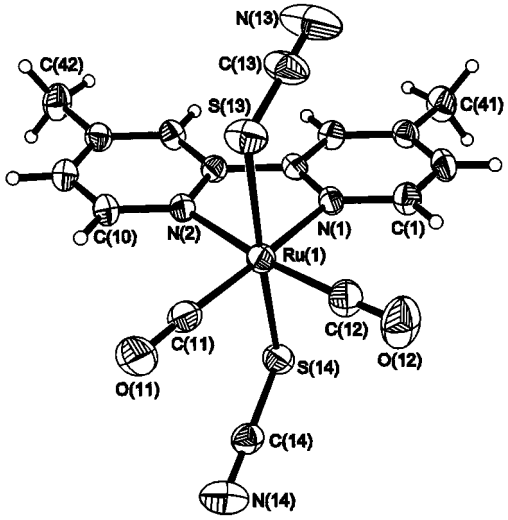

Figure 4. Structure of *trans*(SCN)-Ru(dmbpy)$(CO)_2(SCN)_2$ (**7**)

The ligand-exchange reaction Cl → SCN was also checked for complex **1** with reaction conditions similar to those used in the synthesis of complex **7**. Elemental analysis and heavily shifted ν_{CO} frequencies in the IR spectrum of the brownish-yellow product indicated the coordination of thiocyanate ligands in the complex (ν_{CO} in CH_2Cl_2: 2074 and 2020 cm^{-1}). The appearance of a strong ν_{SC-N} band at 2103 cm^{-1} with shoulder at 2117 cm^{-1} suggested the restored *cis*(CO)-*cis*(X) arrangement in this compound, where, owing to steric hindrance, the equatorial coordination position most probably was occupied by a linear NCS ligand. The poor X-ray-crystallographic data collected for the brownish-yellow disordered crystal supported the *N*-bound (linear) coordination mode for the equatorial, and *S*-bound (bent) arrangement for the axial thiocyanate. Unfortunately, poor solubility of this complex prevented detailed NMR study.

The ν_{CO} bands in the IR spectrum of a transition metal complex may be taken as a measure of backdonation from the metal atom to the ligand, where the higher the electron density of the central metal, the lower the ν_{CO} frequency. The ν_{CO} values recorded for the complexes studied here showed a slightly increasing trend for σ-bonding ligands in the order Cl ≥ Br > I, while a considerably higher value was recorded for the π-accepting SCN group. Similarly, change in the monodentate ligand affected the CO resonances in the ^{13}C-NMR spectra. A slight upfield shift was

detected in the order Cl > Br > I, which strictly follows the increasing electron affinities and decreasing ionic radii of these halogens. Interestingly, the thiocyanate ligands high-shifted the δ(CO) value of complex **7** relative to the halogen-containing derivatives, evidently due to effective shielding of the equatorial carbonyl groups by rotating SCN groups.

Conclusions

In this paper we have described synthetic procedures for obtaining chemically altered Ru(dmbpy) species and presented the basic crystallographic and spectroscopic data for identification. The complexes were modified by fundamentally simple ligand-exchange reactions and with use of substituted polypyridine ligands. Aqueous hydrogen halides were shown to serve as effective halogen sources and as suitable reagents attacking Ru−Ru bonds in dimeric [Ru(bpy)$(CO)_2Cl]_2$, which consequently led to selective formation of monomeric *trans*-halogen species. The particular combination of ruthenium reagent and solvent used in the synthesis, as well as the sterical properties of the chromophore and non-chromophore ligands, were suggested to direct the complexation reaction toward mononuclear *cis*- or *trans*-halogen species.

Experimental Section

Materials: $[Ru(CO)_3Cl_2]_2$ was purchased from Johnson and Matthey and 4,4′-dimethyl 2,2′-bipyridine (dmbpy) from Aldrich Chemicals. All solvents were of analytical grade and used as received. The parent complexes *cis*(Cl)-Ru(dmbpy)$(CO)_2Cl_2$, and $[Ru(dmbpy)(CO)_2Cl]_2$[15] were synthesized under exclusion of air with use of traditional N_2/vacuum-line techniques. The ligand-exchange reactions with aqueous hydrogen halide solutions (HCl, 37%; HBr, 48%; HI, 67%, all from Merck) were carried out in a 60-mL Berghof digestive pressure vessel[22] with PTFE liner. All product manipulations were performed in air.

Spectroscopic Studies: Infrared spectra were measured in CH_2Cl_2 solutions with a Nicolet Magna 750 FTIR spectrometer. ^{1}H- and ^{13}C-NMR spectra were recorded with a Bruker AMX 400 spectrometer with $CDCl_3$ as solvent.

Syntheses: Parent complexes *cis*(Cl)-Ru(dmbpy)$(CO)_2Cl_2$ (**1**) and $[Ru(dmbpy)(CO)_2Cl]_2$ (**2**) were synthesized from $[Ru(CO)_3Cl_2]_2$ and 4,4′-dimethyl 2,2′-bipyridine with THF or ethylene glycol used as solvent in 72% and 68% yield[15], respectively.

***trans*(Cl)-Ru(dmbpy)$(CO)_2Cl_2$ (3):** Complex **3** was synthesized by using "ruthenium red" carbonyl solution[23][24] as starting material. $RuCl_3 \cdot 3\ H_2O$ (1 g, 3.82 mmol) and 70 mL of dry ethanol were placed in a reaction vessel under nitrogen. The reaction mixture was refluxed for 8 h under CO flow, and cooled to room temperature, after which 4,4′-dimethyl-2,2′-bipyridine (0.63g, 3.82 mmol) was added. The solution was refluxed under nitrogen for an additional 2 h, and cooled to room temperature. The yellow precipitate was filtered, washed with small amounts of ethanol, and dried in vacuo (yield 83%). Additionally, a sample of complex **3** (300 mg, 0.73 mmol) was prepared as follows: A brownish-yellow mixture of monomeric by-products (ca. 500 mg) from the synthesis of complex **2**[15] was added to 15 mL of 37% hydrochloric acid and the mixture was allowed to stand at room temperature for several days. A yellow precipitate was formed during the concentration of the aqueous solution. This was washed with water and small amounts of methanol, dried in air, and analyzed by IR and NMR spectroscopy, X-ray diffraction [single crystals obtained from CH_2Cl_2 as solvated Ru(dmbpy)$(CO)_2Cl_2 \cdot CH_2Cl_2$], and elemental analysis. − $C_{14}H_{12}Cl_2N_2O_2Ru$ (412.24): calcd. C 40.8, H 2.9, N 6.8; found C 40.9, H 2.9, N 6.6. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2063 (vs), 2001 cm^{-1} (vs) (both CO). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 155.5−124.6 (five peaks, aromatic rings in dmbpy), 196.8 (CO), 22.0 (Me). − ^{1}H NMR ($CDCl_3$): δ = 8.99 (d, 6-H), 8.02 (s, 3-H), 7.44 (d, 5-H) (all aromatic H); 2.58 (s, Me).

Halogen-Ligand Exchange Reactions: The halogen-ligand exchange reactions were carried out in a Berghof pressure vessel using aqueous HBr (2 mL of 48% HBr/2 mL of H_2O) or HI (1.25 mL of 67% HI/3.25 mL of H_2O) and complexes **1** and **2** as starting materials.

***cis*(Br)-Ru(dmbpy)$(CO)_2Br_2$ (4):** Complex **4** was synthesized by weighing 80 mg (0.19 mmol) of complex **1** into the pressure vessel, adding 4 mL of aqueous HBr, and heating the mixture to 200°C. The temperature was maintained at 200°C for 6 h, after which the reaction vessel was cooled to room temperature. A light green precipitate was separated from the greenish solution, washed several times with water, and air-dried (yield ca. 70%). Complex **4** was analyzed by spectroscopic methods, elemental analysis, and X-ray diffraction analysis [single crystals obtained from CH_2Cl_2/$CDCl_3$ mixture as solvated Ru(dmbpy)$(CO)_2Br_2 \cdot CDCl_3$]. − $C_{14}H_{12}Br_2N_2O_2Ru$ (501.14): calcd. C 33.6, H 2.4, N 5.6; found C 33.9, H 2.4, N 5.6. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2063 (vs), 2000 cm^{-1} (vs) (both CO). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 156.5−124.2 (ten peaks, aromatic rings in dmbpy); 197.4, 191.2 (both CO); 22.0 (Me). − ^{1}H NMR ($CDCl_3$): δ = 8.97 (d, 6-H), 8.68 (d, 6′-H), 8.01 (s, 3-H), 7.99 (s, 3′-H), 7.49 (d, 5-H), 7.43(d, 5′-H) (all aromatic H); 2.63 (s), 2.59 (s) (both Me).

***trans*-Br−Ru(dmbpy)$(CO)_2Br_2$ (5):** Dimer **2** (60 mg, 0.08 mmol) was dissolved in 4 mL of aqueous HBr, and the mixture was heated at 200°C for 10 h. A greenish yellow precipitate was filtered off from the yellow solution, washed with water, and dried in air (yield 49%). Complex **5** was analyzed by spectroscopic methods and elemental analysis. − $C_{14}H_{12}Br_2N_2O_2Ru$ (501.14): calcd. C 33.6, H 2.4, N 5.6; found C 33.7, H 2.4, N 5.8. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2062 (vs), 2000 cm^{-1} (vs) (both CO). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 155.4−124.6 (five peaks, aromatic rings in dmbpy); 197.4 (CO); 22.0 (Me). − ^{1}H NMR ($CDCl_3$): δ = 8.97 (d, 6-H), 8.01 (s, 3-H), 7.43 (d, 5-H) (all aromatic H); 2.60 (s, Me).

***trans*(I)-Ru(dmbpy)$(CO)_2I_2$ (6):** Complex **6** was synthesized similarly to the Br-containing derivatives of complexes **1** and **2**, except that 4.5 mL of an aqueous HI solution was used as halogen source in each synthesis and the reaction temperature was maintained at 200°C for 20 h. The bright yellow precipitate, yields ca. 65% (from complex **1**) and 72% (from complex **2**), was analyzed by spectroscopic methods and elemental analysis, and identified as pure complex **6** in both syntheses. Crystals suitable for X-ray diffraction analysis were obtained from CH_2Cl_2 solution. − $C_{14}H_{12}I_2N_2O_2Ru$ (595.13): calcd. C 28.3, H 2.0, N 4.7; found C 28.7, H 2.0, N 4.9. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2056 (vs), 1999 cm^{-1} (vs) (both CO). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 155.3−124.6 (five peaks, aromatic rings in dmbpy); 198.7 (CO); 22.1 (Me). − ^{1}H NMR ($CDCl_3$): δ = 8.94 (d, 6-H), 8.00 (s, 3-H), 7.38 (d, 5-H) (all aromatic H); 2.60 (s, Me).

***trans*(SCN)-Ru(dmbpy)$(CO)_2(SCN)_2$ (7):** 70 mg (0.17 mmol) of complex **3**, 200 mg (2.0 mmol) of KSCN, and 3 mL of water were placed in an autoclave, and the mixture was heated at 140°C for 8

h. The reaction mixture was cooled slowly to room temperature, and the bright yellow precipitate was separated by filtration and washed thoroughly with water [yield 42 mg (0.09 mmol), 54%]. The product was dried under vacuum, and analyzed by spectroscopic measurements and X-ray diffraction analysis (single crystals obtained directly from the reaction vessel without recrystallization). – $C_{16}H_{12}N_4O_2S_2Ru$ (457.49): calcd. C 42.0, H 2.6, N 12.3; found C 41.7, H 2.7, N, 11.9. – IR (CH_2Cl_2): $\tilde{\nu}$ = 2069 (vs), 2016 (vs) (both CO); 2116 cm^{-1} (SCN). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 155.5–125.4 (five peaks, aromatic rings in dmbpy); 195.0 (CO); 22.3 (Me); 119.6 (SCN). – ^1H NMR ($CDCl_3$): δ = 8.76 (d, 6-H), 8.11 (s, 3-H), 7.51 (d, 5-H) (all aromatic H); 2.63 (s, Me).

X-ray Data Collection and Structure Solutions: X-ray diffraction data were collected at 20°C with a Nicolet R3m (complexes **4** and **6**) or an Enraf–Nonius Kappa CCD (complexes **3** and **7**) diffractometers using graphite Mo-K_α radiation (λ = 0.71073 Å). Crystals suitable for X-ray diffraction studies were carefully chosen by microscopic examination and mounted on glass fibers. For **4** and **6**, cell parameters were obtained from 25 automatically centered reflections. Intensities were corrected for background, polarization, and Lorentz factors. Data collection, data reduction and cell refinement were carried out with the P3/P4 diffractometer program V 4.27.[25] The structures were solved by direct methods. The structure solution was carried out with the SHELXS 86 program[26] and structure refinement with the SHELXL 93 program.[27] For compounds **3** and **7**, data were collected using ϕ or combined ϕ-ω scan mode with a kcd program (Enraf–Nonius). Denzo and Scalepack programs[28] were used for cell refinements and data reductions. The structure solutions (direct methods) were carried out with the SHELXS 97 program,[29] and structure refinements with the SHELXL 97.[30] For complexes **3**, **4**, **6,** and **7**, all non-hydrogen atoms were refined anisotropically. Aromatic hydrogen atoms and methyl group hydrogen atoms were placed in idealized positions (aromatic C–H = 0.93 Å, methyl C–H = 0.96 Å). Decomposition of the solvated crystalline complex **3** was relatively rapid, requiring fast data collection with the X-ray diffractometer. The crystallographic data are collected in Table 1, the selected bond lengths and angles in Tables 2–3. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102482 (**3**), -102483 (**4**), -102484 (**6**), -102485 (**7**). Phosphinidene Transition Metal Complexes: A Combined Ab Initio MO-DFT Study of $Cr(CO)_5$–PR

Steven Creve,[a] Kristine Pierloot,[a] Minh Tho Nguyen,*[a] and Luc G. Vanquickenborne[a]

Keywords: Ab initio calculations / Density functional calculations / Phosphinidene / Carbonyl complexes

Ab initio MO and DFT calculations have been performed on phosphinidene complexes of the type $Cr(CO)_5$–PR, with R = H, CH_3, SiH_3, NH_2, PH_2, OH, and SH. The formation of the Cr–P bond essentially arises from a ligand-to-metal charge transfer. While a significant π backdonation is also observed for the $Cr(CO)_5$–PH, $Cr(CO)_5$–PCH_3, and $Cr(CO)_5$–$PSiH_3$ complexes, this is less the case for $Cr(CO)_5$–POH, $Cr(CO)_5$–PSH, and $Cr(CO)_5$–PNH_2, and the backbonding almost disappears for $Cr(CO)_5$–PPH_2. In both the lowest lying singlet and triplet states, all complexes exhibit a staggered conformation. CASSCF/CASPT2 calculations performed with the ANO basis sets indicate a closed-shell singlet ground state along the whole series. The binding energy between $Cr(CO)_5$ and PR ranges from 216 kJ/mol for $Cr(CO)_5$–PNH_2 to 127 kJ/mol for $Cr(CO)_5$–$PSiH_3$ (B3LYP values). In general, the B3LYP-DFT scheme yields reasonable qualitative and quantitative results when compared with CASPT2(12/12).

1 Introduction

Phosphinidenes (R−P) are known as important transient species in phosphorus chemistry that can be stabilized through complexation with transition metal fragments. In contrast to analogous transient intermediates such as carbenes, nitrenes, and silylenes, spectroscopic information on free phosphinidenes is rather scarce. In fact, the ESR spectrum of an aryl derivative (Mes−P) has only recently been recorded.[1] In most cases, these short-lived and highly reactive species have been trapped in transition metal complexes and can be used in this way as starting materials in organophosphorus syntheses.[2]

Recently, we[3−6] and others[7][8] have shown by high-level ab initio calculations, that phosphinidenes exhibit an inherent triplet electronic ground state but that the singlet counterparts can be stabilized strongly by substituents through both electronic and steric effects. For example, amino (R_2N−P) and phosphino (R_2P−P) derivatives containing large alkyl groups are likely to possess a closed-shell singlet ground state.[3]

Mathey[9][10] and Lammertsma[11] suggested from numerous experimental observations of the complexed species that the phosphinidene ligand within the coordination sphere of a metal fragment behaves as a typical singlet monovalent intermediate giving a higher and cleaner reactivity. Nevertheless, the identity of the ground state of complexed phosphinidenes still remains an open question.

To our knowledge, only three theoretical studies of terminal phosphinidene complexes have yet been reported. The first one dealt with an Extended Hückel study of a number of substituted phosphinidene ligands (PCH_3, PNH_2, PPH_2, ...).[12] Idealized geometries were used throughout, based on parameters chosen from experimental data on parent species. Although very useful, this study only yields a qualitative picture of the considered complexes. In two other studies, partial geometry optimizations of the $Cr(CO)_5$−PH complex were performed.[13][14] However, the P−Cr bond length turned out to be 1.9 Å at the Extended Hückel level[13] while it was found to be 2.33 Å by ROHF calculations.[14] Disagreement concerning the singlet or triplet nature of the ground state of $Cr(CO)_5$−PH also arose. In our previous study on $Cr(CO)_5$−PH,[15] high-level ab-initio calculations have been applied, removing these discrepancies. We showed that $Cr(CO)_5$−PH has a singlet ground state with a P−Cr distance of 2.268 Å. The lowest lying triplet was 35 kJ/mol higher in energy. In this work, an extension is made to $Cr(CO)_5$ complexes of different phosphinidenes PR, yielding a deeper understanding of the singlet-triplet energy problem in these species. Furthermore, the backbonding phenomenon usually observed in metal complexes will be addressed, since it is not well characterized yet for phosphinidene complexes.[16]

The theoretical study presented here, includes full geometry optimizations and high-level energy calculations on a series of simple carbonylchromium complexes, $Cr(CO)_5$−PR, in which R = H, CH_3, SiH_3, NH_2, PH_2, OH, and SH.

2 Details of the Calculations

2.1 Computational Methods

All geometries were fully optimized with density functional theory, using the B3LYP functional[17][18] in combination with 6-31G(d,p) basis sets for all atoms, except for Cr. For the latter element we used a (14*s*,9*p*,5*d*)/[8*s*,5*p*,3*d*] basis set,[19] augmented by two *p*-functions[20] with exponents 0.120675 and 0.038610, one *d*-function[21] with exponent 0.09720, and one *f*-function with exponent 1.0,

respectively. This [8*s*,7*p*,4*d*,1*f*] basis set for Cr will be denoted hereafter as "TZ+2PDF".

In our preliminary study on the $Cr(CO)_5-PH$ complex,[15] it was found that the (U)HF, (U)MP2 or CASSCF/PT2(2/2) methods are not reliable in treating this kind of systems. Therefore, we now only consider the higher level CASSCF(12/12) and CASPT2(12/12) calculations, using the B3LYP optimized geometries. ANO basis sets were used[22] for these calculations, following the contraction scheme shown below.

	primitive	contracted
H	*7s3p*	*2s1p*
C	*10s6p3d*	*3s2p1d*
N	*10s6p3d*	*3s2p1d*
O	*10s6p3d*	*3s2p1d*
Si	*13s10p4d*	*4s3p2d*
P	*13s10p4d*	*4s3p2d*
S	*13s10p4d*	*4s3p2d*
Cr	*17s12p9d4f*	*6s4p3d1f*

Our previous study[15] pointed out that a more flexible contraction with the same primitive set does not significantly alter the results.

All B3LYP optimizations were performed using the Mulliken software,[23] while the CASSCF/CASPT2 calculations were done with the MOLCAS-4.0 code.[24]

2.2 Notations

Figure 1 gives a schematic overview of the geometries for the different complexes and their proposed shorthand notations. For the $Cr(CO)_5-PH$, $Cr(CO)_5-POH$, and $Cr(CO)_5-PSH$ complexes, two forms were considered, an "eclipsed" conformation, indicating that the P−R bond is eclipsed with one of the $Cr-C_{eq}$ bonds, and a staggered form which has its P−R bond in between two $Cr-C_{eq}$ bonds. For the $Cr(CO)_5-PCH_3/Cr(CO)_5-PSiH_3$ and $Cr(CO)_5-PNH_2/Cr(CO)_5-PPH_2$ cases, additional specifications are needed to indicate the rotational orientation of the CH_3/SiH_3 and NH_2/PH_2 groups, respectively. They are referred to as **A** and **B**, following the convention of Figure 1. As a shorthand notation for use in tables, we will, for instance, designate an eclipsed structure of the **A** type as **ec-A** and a staggered structure as **st-A**. Note from Figure 1 that the **B**-types of $Cr(CO)_5-PNH_2$ and $Cr(CO)_5-PPH_2$ have a pyramidal NH_2 or PH_2 unit, in contrast to their corresponding **A**-types.

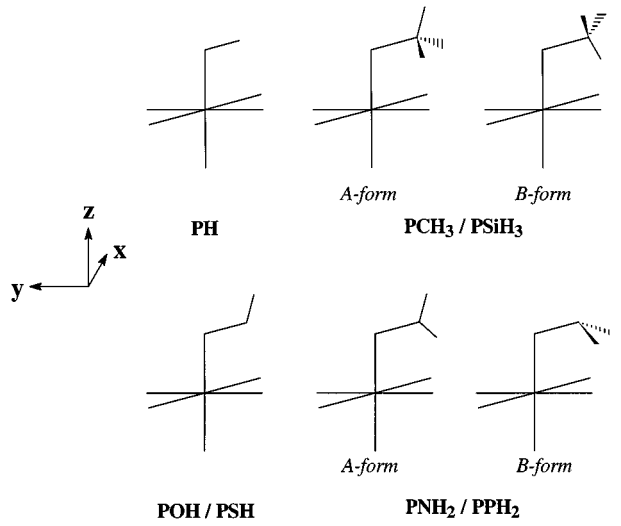

Figure 1. Schematic representation of the different $Cr(CO)_5-PR$ complexes considered, along with the naming convention; only eclipsed forms are shown in this figure

2.3 Choice of the Active Space

The quality of a CASSCF calculation on a transition metal system critically depends on the choice of the active space. This space needs to include all valence orbitals necessary for an adequate description of the metal−ligand bonding. In a previous study,[25] it was demonstrated that the ground state electronic structure of $Cr(CO)_6$ is well described by a (10/10) space, built up from the metal 3*d* orbitals and their bonding and antibonding counterparts. For $Cr(CO)_6$ this amounts to an occupied e_g (CO σ) and t_{2g} (Cr *3d*) shell, and a virtual e_g (Cr *3d*) and t_{2g} (CO π*) shell. By replacing one CO ligand by a phosphinidene unit, however, an additional difficulty arises. The PR ligand has a triplet ground state with two singly occupied $p(\pi)$ orbitals. As a consequence, both π orbitals have to be added to the original (10/10) space. This means that the active space needed for an adequate description of $Cr(CO)_5-PR$ consists of at least 12 electrons in 12 orbitals.

In the CASPT2 calculations, all valence electrons as well as the Cr semi-core 3*s*, 3*p* electrons were correlated, whereas the rest of the core (C, N, O 1*s*; Si, P, S 1*s*, 2*s*, 2*p*; Cr 1*s*, 2*s*, 2*p*) was kept frozen. Finally, first-order relativistic corrections (mass-velocity and Darwin term) have been added to the CASPT2 energies.

A remark has to be made for triplet **st-A** $Cr(CO)_5-PPH_2$. In this case, it has not been possible to perform the CASSCF/PT2(12/12) calculation with the active space specified above. It turns out that one of the active orbitals (representing the Cr−P σ bond) spontaneously leaves the active space, in favor of the entering $3p_z$(Cr) orbital. Therefore, two additional calculations have been performed on the triplet **st-A** $Cr(CO)_5-PPH_2$ species. The first was to force the calculation to keep the Cr−P σ bond in its active space, by freezing the orbitals during the CASSCF run up to 3*p*(Cr). In another calculation, a reduced (10/11) space was used, containing neither the Cr−P σ bonding orbital, nor the $3p_z$(Cr) orbital. The relative energies obtained from both approaches differed by only 1.2 kJ/mol.

3 Results and Discussion

3.1 Electronic Structure

As quite a number of geometrical effects and properties of the relative energies cannot be fully understood without

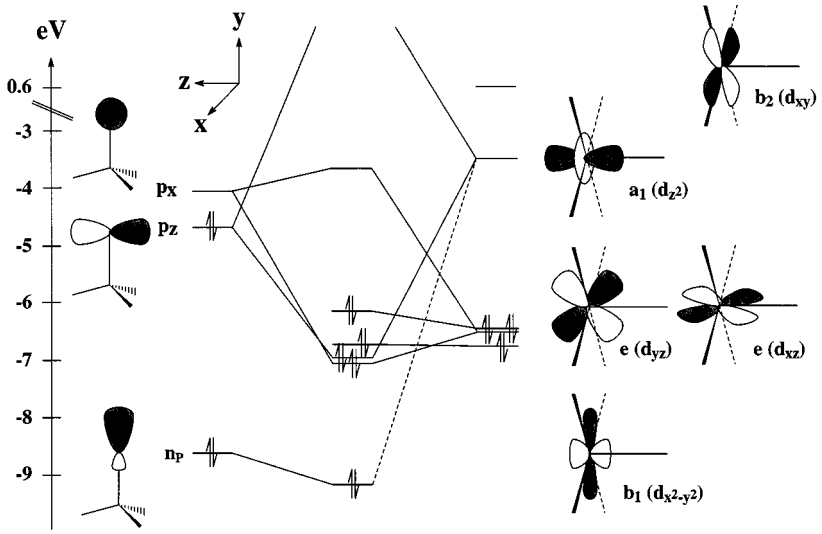

Figure 2. Schematic drawing of the orbital interactions in singlet **st-A** $Cr(CO)_5-PCH_3$

having the electronic structure of the considered complexes in mind, the latter will be discussed first.

A careful analysis of the bonding situation in $Cr(CO)_5-PH$ has already been reported.[15] Therefore, we will recall briefly here the most important features. As a guideline, the orbital correlation diagram for the singlet **st−A** $Cr(CO)_5-PCH_3$ complex shown in Figure 2, together with contour plots of the most important orbitals shown in Figure 3 are used in what follows. The highest occupied orbitals of the d^6 $Cr(CO)_5$ fragment are the *e* orbitals (d_{xz}, d_{yz}) and a b_1 ($d_{x^2-y^2}$) orbital, which are stabilised through π backbonding with the empty CO π* orbitals. The lowest unoccupied orbital is of a_1 symmetry (d_{z^2}), followed by a b_2 (d_{xy}) orbital. Both point directly towards the CO ligands and constitute the antibonding combinations arising from a σ-interaction with the CO 5σ orbitals. The PR molecule has a σ orbital directed along the P−R bond containing the phosphorus lone pair, n_P. Two phosphorus *p* orbitals, perpendicular to the P−R bond, contain another pair of electrons, usually in a triplet ground state configuration. However, the bonding is best understood by considering a singlet PR. In this case, one *p* orbital, perpendicular to the P−R bond and doubly occupied, is used to form a σ bond with the empty a_1 orbital of the $Cr(CO)_5$ fragment. The remaining empty p_x orbital of PR is in an orientation suited to π backbonding with the doubly occupied d_{xz}(Cr) orbital. The antibonding combination arising from this interaction constitutes the LUMO of the resulting complex. For clarity, the phosphinidene complex in Figure 2 is represented with a Cr−P−R angle of 90°. Optimized structures, on the other hand, have an Cr−P−R angle of 105−130°. This can be understood by considering the secondary stabilizing interaction between the phosphorus n_P lone pair and the d_{z^2}(Cr) orbital (HOMO-4 of Figure 3) which increases if the Cr−P−R angle gets larger than 90°.

It is interesting to look at the evolution of the π backbonding through the series of complexes. Figure 4 shows contour plots of the bonding orbital [with predominant d_{xz}(Cr) character] involved in the π backdonation. Immediately perceptible is the decrease of the p_x(P) orbital contribution in the series $Cr(CO)_5-PCH_3 \rightarrow Cr(CO)_5-POH \rightarrow Cr(CO)_5-PNH_2$. The same trend is seen for the analogous series of second-row R groups. There, the decrease of the *p* orbital contribution is even more pronounced (an extreme case is shown as HOMO-1 of $Cr(CO)_5-PPH_2$ in Figure 6. In order to have a more physical picture of the π backbond strength, density difference plots have also been made and are shown in Figure 5. This difference corresponds to the deformation density upon bond formation and is obtained as follows.

$$\Delta\rho = \rho_{tot}(\text{complex}) - [\rho_{tot}(\text{singlet PR}) + \rho_{tot}(Cr(CO)_5)]$$

To compute Δρ, the geometries of the fragments are frozen to their corresponding geometries in the complex. Full lines in Figure 5 correspond to an increase in total density, dotted lines to a decrease. As expected, one can see that charge is transferred from the d_{xz}(Cr) orbital to the p_x(P) orbital. Again, the extent of this charge transfer decreases as R varies in the order $CH_3 \rightarrow OH \rightarrow NH_2$. The same is also seen for the second-row series, but to a slightly higher extent. How can we understand such a weakening of the π back transfer? Table 1 shows the energy difference (Δ*E*) between the LUMO of the different PR fragments − the orbital which is involved in π backbonding − and the d_{xz}(Cr) orbital of $Cr(CO)_5$. The larger the energy difference between both partners involved in the π bond, the weaker this bond. In more chemical terms, one could say that in PNH_2, PPH_2, POH, and PSH the empty phosphorus p_x orbital is already used by the neighboring heteroatom to delocalize its lone pair, making this orbital less available for backbonding with the d_{xz}(Cr) orbital. O and S, which have a larger electronegativity than N and P, respectively, delocalize their lone pair to a lesser extent, such that the phos-

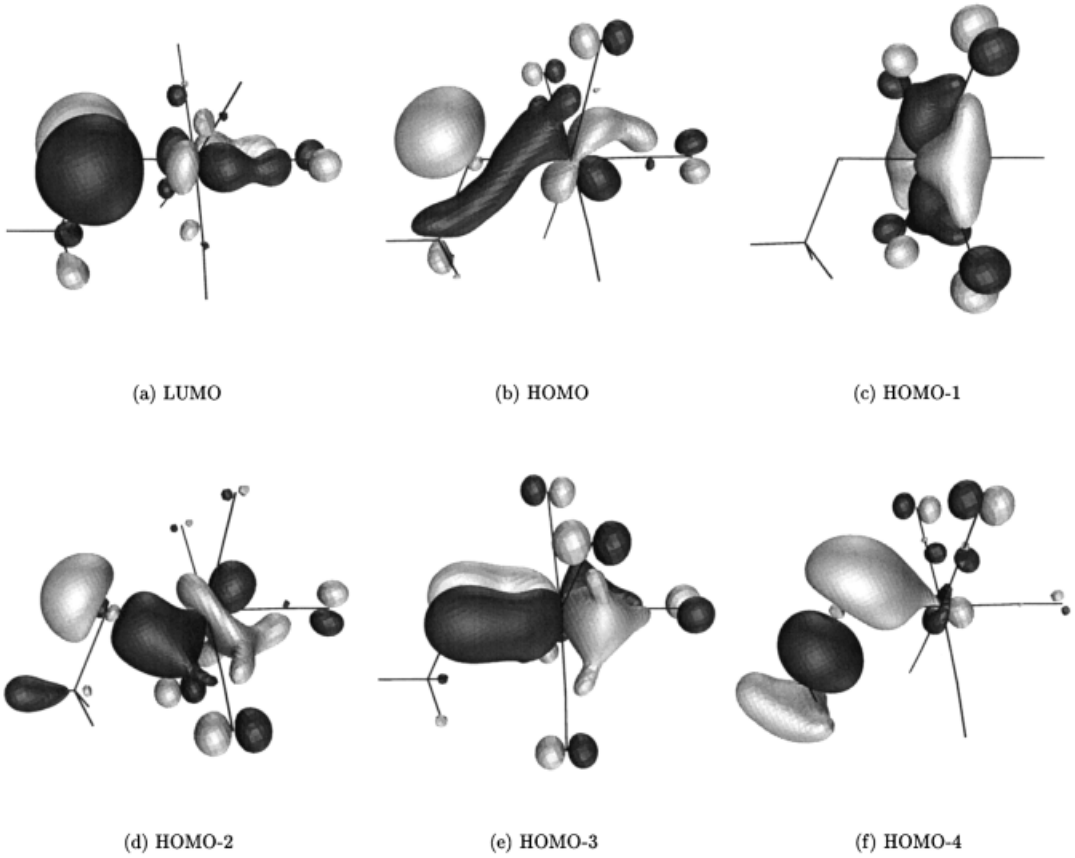

Figure 3. Molecular orbitals of the **st-A** $Cr(CO)_5-PCH_3$ molecule; the isosurfaces are plotted at a value of 0.05 a.u.

phorus p_x orbital remains more suited to backbonding with Cr in the $Cr(CO)_5-POH$ and $Cr(CO)_5-PSH$ complexes. This explains the fact that the π bond strength of $Cr(CO)_5-POH$ lies in between that of $Cr(CO)_5-PCH_3$ and $Cr(CO)_5-PNH_2$. The same applies to $Cr(CO)_5-PSH$.

For all complexes considered, the LUMO is the antibonding orbital involved in the π backbond discussed above. For R = PH, PCH_3, $PSiH_3$, this orbital is a simple antibonding combination of the p_x(P) orbital and the d_{xz}(Cr) orbital. However, for the internally conjugated PR fragments, this orbital is also antibonding between P and R. As an example, Figure 6 shows the LUMO of **st-A** $Cr(CO)_5-PPH_2$.

Calculated Mulliken charges show that the most electrophilic phosphinidene centers are found for $Cr(CO)_5-POH$ (q_P = 0.57 e^-) and $Cr(CO)_5-PNH_2$ (q_P = 0.48 e^-), whereas $Cr(CO)_5-PSiH_3$ has the least electrophilic P (q_P = 0.14 e^-). In general, the charge at the P center is considerably reduced upon excitation to the triplet state, due to an occupation of the LUMO, which is an orbital mainly localized on the PR unit. The charges at the Cr center are nearly constant throughout the series (−1.5 e^- for singlets and −1.3 e^- for triplet species). The total PR fragment charge (sum of the Mulliken charges) gives an estimate of the total charge transfer from PR to $Cr(CO)_5$. It is seen that this charge transfer is largest for $Cr(CO)_5-PNH_2$ (0.45 e^-) and smallest for $Cr(CO)_5-PSiH_3$ (0.20 e^-). As shown in a further section, these compounds also have the largest and smallest binding energy, respectively. For the triplet species, calculations show that the spin density is mainly locacted on both the Cr and P centers [ρ^S(Cr) varies from 0.61 to

0.99 e^-, while $\rho^S(P)$ lies between 1.23 and 1.45 e^-]. An extremely low $\rho^S(P)$ value is found in $Cr(CO)_5-PPH_2$, probably caused by the fact that in this molecule, a considerable amount of spin density is also found on the phosphanyl P. A full table containing the calculated mulliken charges and spin densities is supplied as supporting information (available on the WWW under http://www.wiley-vch.de/home/eurjic or from the author).

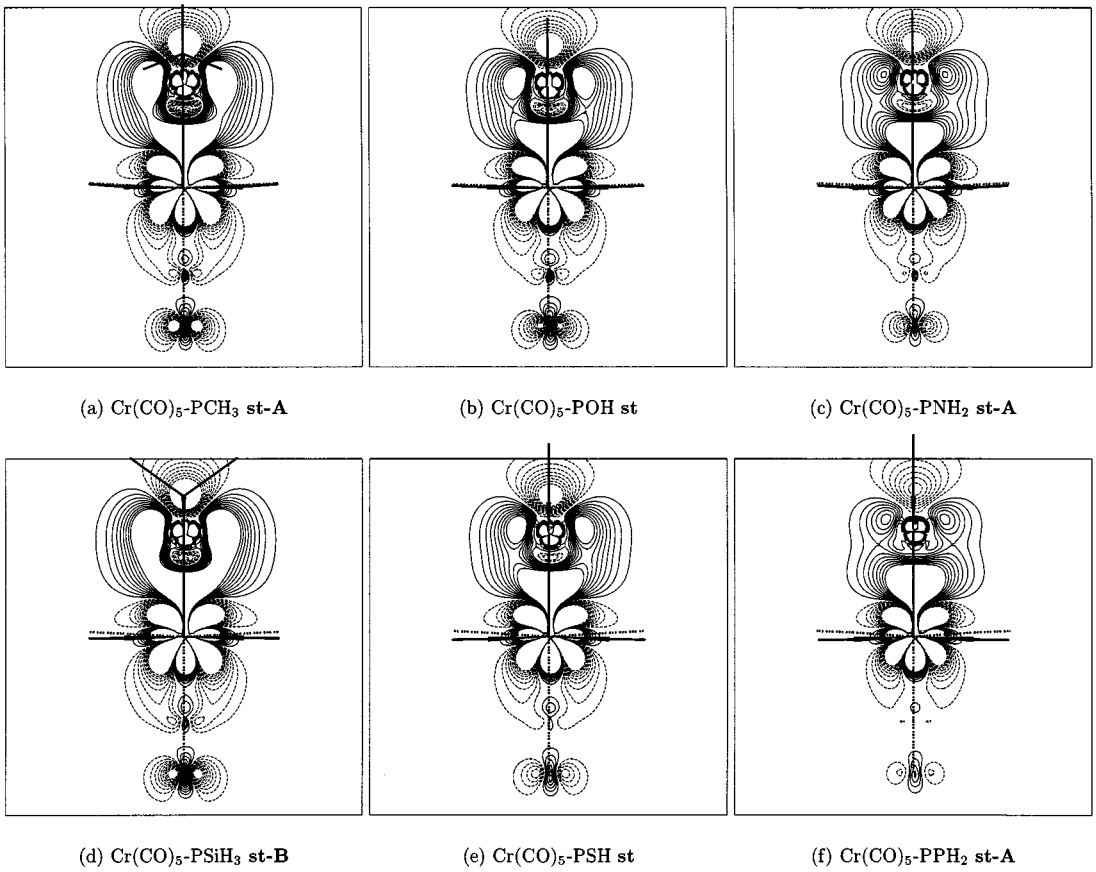

Figure 5. Density difference plots $\Delta\rho = \rho_{tot}(\text{complex}) - \{\rho_{tot}(\text{singlet PR}) + \rho_{tot}[Cr(CO)_5]\}$ of the various complexes, made in the plane containing the π backbond; full lines correspond to an increase in electron density upon bond formation, dotted lines to a decrease; the maximum and minimum contour levels are 0.009 and −0.009 a.u., respectively, with intervals of 0.001 a.u.

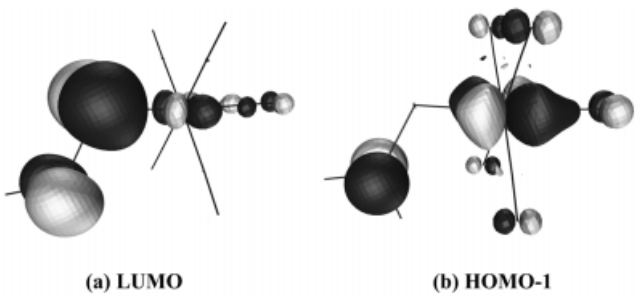

Figure 6. Some selected orbitals of the singlet **st-A** $Cr(CO)_5-PPH_2$ complex

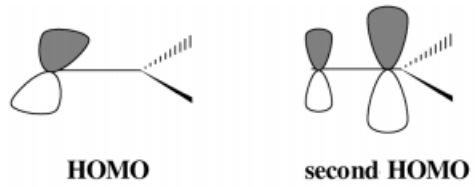
3.2 Geometries

Optimized P−R bond lengths of free phosphinidenes are listed in Table 2. The B3LYP values are consistently slightly larger than UMP2 values obtained in previous work.[3] However, on the average, the difference in the calculated P−R distances is only about 0.01 Å, which is too small to be significant. This, together with previous work on phosphorus-containing species,[5][26] shows that B3LYP is a reliable tool to obtain geometries of phosphinidenes.

Selected geometrical parameters of the complexes of interest are shown in Table 2. Included are the P−Cr and P−R distances. For singlet $Cr(CO)_5$−PH, a P−Cr bond length of 2.27 Å was found, as compared to previously reported values of 1.9 Å (Extended Hückel)[13] and 2.33 Å (ROHF).[14] For triplet $Cr(CO)_5$−PH, a P−Cr distance of about 2.37 Å was found, significantly shorter than the 2.67 Å of the ROHF result reported earlier.[14] Hence, the need for a careful geometry optimization before obtaining accurate electronic energies of these complexes is evident. In view of the successes of DFT in the last decade[27−32] we felt that a full geometry optimization using B3LYP and the basis set specified above is a very reasonable choice.



As can be seen from Table 2, in all singlet complexes the P−Cr distance is close to 2.3 Å. For the phosphane complexe $Cr(CO)_5-PH_3$, an experimental P−Cr distance of 2.35 Å was found.[33] Our calculated P−Cr distances thus suggest that the P−Cr bond in the presently studied phosphinidene complexes has nearly single bond character.

The P−Cr bond lengths of the various molecules also seem to correlate with the observed π bond strengths discussed in the previous section and shown in Figures 4 and 5. As expected, the P−Cr bond becomes shorter as the π bond strength increases. Only $Cr(CO)_5$−POH and $Cr(CO)_5$−PSH do not follow this trend. However, in view of the small differences in these bond lengths, such an apparent correlation might be questionable.

Immediately apparent from Table 2 is the lengthening of the P−Cr distances following electronic transition from the $^1A'$ to the $^3A''$ state. This effect is mainly due to the exci-

tation of an electron into the LUMO, which is strongly anti-bonding between Cr and P.

Upon closer inspection of Table 2, a number of points deserve some comment. While for $Cr(CO)_5-PCH_3$ and $Cr(CO)_5-PSiH_3$ no significant geometry differences are found between the **A** and **B** forms, the **B** forms of $Cr(CO)_5-PNH_2$ and $Cr(CO)_5-PPH_2$ exhibit considerably shorter P−Cr bonds than the corresponding **A** conformations. This effect is related to the electronic structure of singlet PNH_2 and PPH_2. In these molecules, the amino or phosphanyl π lone pair is conjugated with the empty *p* orbital on the phosphinidene P, resulting in a planar structure with sp^2 hybridization of the tricoordinated N and P atoms (see for instance ref.[3]). As a consequence, the second phosphinidene lone pair is found in a *p* orbital in the plane of the molecule. A schematic drawing of the two highest occupied molecular orbitals of both singlet PNH_2 and PPH_2 is shown in Scheme 1.

Scheme 1

The most important difference between the **A** and **B** forms of the PNH_2 or PPH_2 complexes, as can be seen from Figure 1, is not the rotation of the amino or phosphanyl group, but the fact that these groups are pyramidal in the **B** conformation, in contrast to their **A** counterparts. As such, the **B**-coordinated PNH_2 or PPH_2 phosphinidenes are no longer internally conjugated. As a consequence, the empty *p*-orbital on the ligating P-atom becomes more available for accepting a π backdonation of the metal, which results in a shorter P−Cr bond as compared to the **A** conformations.

One additional point has to be noted about the structures of $Cr(CO)_5-PNH_2$ and $Cr(CO)_5-PPH_2$. It is well known[3] that triplet PNH_2 and PPH_2 are characterized by a pyramidal structure. The triplet **A** conformations, however, were optimized within C_s symmetry where the phosphinidene unit is prevented from becoming pyramidal. It was found that, when re-optimizing the triplet **ec-A** form in C_1 symmetry, the molecule converged to the triplet **st-B** form. As such, the triplet **A** forms of $Cr(CO)_5-PNH_2$ and $Cr(CO)_5-PPH_2$ might be transition states for inversion at the pyramidal phosphinidene center or rotation around the P−R bond. Since we are not able to perform vibrational analyses of these structures, the identity of the triplet **A** $Cr(CO)_5-PNH_2$ and $Cr(CO)_5-PPH_2$ (minimum or transition structure) remains an open question.

While for $Cr(CO)_5-PCH_3$ and $Cr(CO)_5-PSiH_3$ the P−R distances are systematically shorter in the triplet structures − in contrast to the situation in free phosphinidenes (Table 2) − a reverse trend is seen for $Cr(CO)_5-POH$ and $Cr(CO)_5-PSH$ as well as for the **A** forms of $Cr(CO)_5-PNH_2$ and $Cr(CO)_5-PPH_2$. Since in these molecules the LUMO is also anti-bonding between P and R (see, for example, the LUMO in Figure 6), excitation of one electron to the LUMO causes the P−R bond to become longer with respect to the corresponding singlet form.

3.3 Relative Energies

In our previous study[15] on $Cr(CO)_5-PH$ a detailed analysis of the relative energy of the **A** and **B** forms using different methods and basis sets was performed. Here, we present only results obtained at the B3LYP and CASPT2(12/12) (including relativistic corrections) levels. The obtained relative energies are shown in Table 3. At each optimized singlet or triplet geometry, both lowest lying singlet and triplet states were calculated.

3.3.1 Conformational Behavior

We will focus on a few general characteristics of the relative energies. In every case, both B3LYP and CASPT2 methods predict a singlet staggered conformation for the ground state, except for $Cr(CO)_5-PNH_2$, where CASPT2 gives a singlet **st-A** ground state, lying 1.6 kJ/mol below the **ec-A** structure, in contrast to B3LYP, which gives a singlet **ec-A** ground state, 1.2 kJ/mol below the **st-A** form. For a given conformation, the energy difference between eclipsed and staggered is rather small; the largest value amounts to 10.7 kJ/mol [$Cr(CO)_5-PSiH_3$, **ec-B** − **st-B**, CASPT2]. Since frequency analyses were beyond the scope of this work, it is impossible to say whether the eclipsed forms are true minima on the potential energy surface. They might as well be transition structures for rotation of one staggered form to another. For the **A** and **B** forms of $Cr(CO)_5-PCH_3$ and $Cr(CO)_5-PSiH_3$ no large deviations are seen. This is, however, not true for $Cr(CO)_5-PNH_2$ and $Cr(CO)_5-PPH_2$. The important difference in coordination mode of PR for these complexes (**A** or **B**) has already been highlighted in the previous section on geometries. As expected, it is now confirmed that, for singlet complexes, the most favorable conformation is **A** while it turns out to be **B** for triplet forms.

3.3.2 Singlet-Triplet Energy Difference

Table 1 contains the singlet-triplet energy differences [$\Delta(T - S)$] for both free and complexed phosphinidenes. The $\Delta(T - S)$ values shown refer to E(lowest lying triplet) − E(lowest lying singlet). For free PR species, QCISD(T) values are also given.[3] It is seen that, on the average, B3LYP results are about 10−20 kJ/mol higher than the QCISD(T) values. Since a detailed discussion of the variation of $\Delta E(T-S)$ throughout the PR series has already been given elsewhere,[3] it will not be discussed any further in this work. While all free phosphinidenes considered have a triplet ground state, all their complexed counterparts have a singlet

Table 3. Relative energies of the complexed species considered

ground state. For the complexed forms, B3LYP apparently underestimates the CASPT2 values. It is seen that the larger the absolute value of the singlet-triplet splitting of the free PR, the smaller this quantity for $Cr(CO)_5-PR$. One exception to this rough tendency, is $Cr(CO)_5-PPH_2$. Based upon the analysis of the π bond strength of the previous section, we can tentatively say that in this case, the singlet form is less stable (ralative to other complexes) due to its very weak π backbonding. Note, however, that a direct comparison between $\Delta(T - S)$ values for free and complexed phosphinidenes might not be legitimate, since in free phosphinidenes it concerns an excitation within PR orbitals, while in complexed phosphinidenes, the excitation is from the HOMO, which is an orbital with mainly d_{yz}(Cr) character, to the LUMO, having mainly p_x(P) character.

At this point, the high relative energy of triplet **st-A** $Cr(CO)_5-PPH_2$ should be noted. As explained in the section on the choice of the active space, problems were encountered for this molecule. The most probable reason is the relatively long P−Cr bond length obtained by B3LYP for this molecule.

In summary, in order to obtain $Cr(CO)_5-PR$ complexes with singlet ground states well below the triplet state, the phosphinidene ligand should have an internally stabilized singlet state through π donation of the R group. However, if this internal π donation becomes too strong, the P-center is no longer sufficiently able to accept π donation from the $Cr(CO)_5$ fragment. As such, two opposing effects are present, yielding − for the series presently studied − an optimum for $Cr(CO)_5-PNH_2$. The latter complex has a $\Delta(T - S)$ value of 108.7 kJ/mol at the CASPT2 level.

3.3.3 Overall Stability

The main parameter to judge the overall stability of a complex is the binding energy listed in Table 1, which is defined as B.E. = E[$Cr(CO)_5-PR$] − {E(triplet PR) + E[$Cr(CO)_5$]}. As discussed in our previous study[15] on $Cr(CO)_5-PH$, CASPT2(12/12) turns out to be somewhat problematic for the B.E. of this type of compounds. Upon dissociation of the phosphinidene ligand, the (12/12) space reduces to a (10/10) space on the $Cr(CO)_5$ fragment and a (2/2) space on the PR unit. A (2/2) space on triplet PH, in fact, is a simple ROHF calculation. Considerably different CASPT2 energies were obtained when instead a (6/10) space on PH was used, including all valence orbitals and the *3d*(P) orbitals (about 34 kJ/mol). After correcting the CASPT2(12/12) binding energy for the shortcomings of the (2/2) active space and for basis set superposition errors (BSSE), values very close to the B3LYP results were obtained. Therefore, we present here only the B.E. obtained using B3LYP. The $Cr(CO)_5-PNH_2$ complex has a B.E. of 216 kJ/mol, followed by $Cr(CO)_5-POH$ (186 kJ/mol) and $Cr(CO)_5-PSH$ (173 kJ/mol). Then the B.E. drops by about 36 kJ/mol for the remaining complexes, with $Cr(CO)_5-PSiH_3$ having the lowest B.E. of 127 kJ/mol. It is thus seen that the complex having the highest $\Delta(T - S)$ also has the highest B.E.

4 Concluding Remarks

$Cr(CO)_5$ complexes of differently substituted phosphinidenes (PR, R = H, CH_3, SiH_3, NH_2, PH_2, OH, and SH) have been studied by high level ab initio (CASPT2 + relatvistic corrections) and density functional (B3LYP) methods. It is shown that the P−Cr bond is essentially formed by a ligand-to-metal σ charge transfer; π backbonding is also manifested in the complexes of PH, PCH_3, and $PSiH_3$, but its importance systematically decreases in $Cr(CO)_5-POH$, $Cr(CO)_5-PSH$, and $Cr(CO)_5-PNH_2$, and is almost absent in $Cr(CO)_5-PPH_2$. Both B3LYP and CASPT2 methods show that all complexes have a singlet, staggered ground state conformation. There is only one case [$Cr(CO)_5-PNH_2$] where B3LYP predicts a different ground state conformation from CASPT2, but the energy difference is rather small − the eclipsed-staggered energy differences are small in general. One of the most intriguing parameters, both from an experimental and theoretical point of view, is the singlet-triplet energy difference [$\Delta(T - S)$] in these complexes. While the largest gap is found for $Cr(CO)_5-PNH_2$ amounting to 103 kJ/mol at the B3LYP level and 109 kJ/mol at the CASPT2 level, $Cr(CO)_5-PSiH_3$ exhibits the smallest gap of only 4 kJ/mol at B3LYP and 11 kJ/mol at CASPT2. The binding energies (B.E.) for P−Cr bond cleavage, as computed by the B3LYP method, show a similar behavior; the largest value is 216 kJ/mol for $Cr(CO)_5-PNH_2$, while $Cr(CO)_5-PSiH_3$ has the smallest B.E. of 127 kJ/mol. The trends in $\Delta(T-S)$ and B.E. can be understood in terms of electronic structure.

The qualitative trends emphasized by CASPT2 calculations are well reproduced by the B3LYP method and, in most cases, a quantitative agreement between the two methods is found as well.

Acknowledgments

Zinc Complexes of Aldehydes and Ketones, 2[+] Zinc-Aldehyde Complexes with Weakly Coordinating Anions

Bodo Müller[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Aldehyde ligands / Weakly coordinating anions / Structural chemistry

Zinc salts of low or zero water content were obtained from the hexahydrates of zinc nitrate, zinc perchlorate, and zinc tetrafluoroborate by dehydration with triethoxymethane or by solvation with acetonitrile or nitromethane. The compounds incorporated aldehydes as ligands when treated with an excess of the aromatic aldehydes benzaldehyde, mesitylaldehyde, 2-chlorobenzaldehyde, and 4-fluorobenzaldehyde. Eighteen zinc-aldehyde complexes were isolated and identified by crystal structure determinations. All contain octahedral zinc to which 2, 3, 4, 5, or 6 aldehyde ligands are bound. Water, ethanol, and acetonitrile molecules act as coligands. Of the anions employed, BF_4^- and $SbCl_6^-$ were found to be only noncoordinating and NO_3^- only coordinating, whereas complexes with one or two perchlorate ligands were obtained in addition to perchlorate salts.

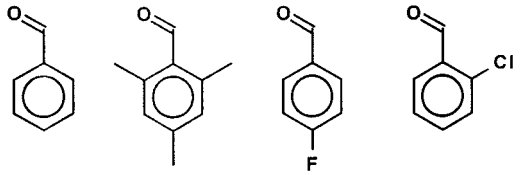
It is widely known that countless reactions of organic carbonyl compounds (esters, amides, aldehydes, ketones, etc.) can be catalyzed by metal salts or complexes. Zinc species play a dominant role in this context for preparative organic chemistry[2] as well as for enzyme-catalyzed transformations[3]. The basic function of the metal ion in these reactions is its attachment to the carbonyl oxygen to induce Lewis-acidic activation. However, since carbonyl compounds are only weak donors and since the important reactions are catalytic, metal complexes of organic carbonyl compounds are rarely isolated. Therefore, in sharp contrast to the many mechanistic proposals involving metal activation of the carbonyl function, the coordination chemistry of this function is rather underdeveloped[4].

We became interested in zinc coordination of CO-containing species during our model studies and mechanistic interpretations of zinc enzyme-catalyzed hydrolyses of esters, amides, and CO_2 by Zn−OH complexes[5]. Our attention focused on aldehydes and alkoxides as ligands when trying to reproduce the biological function of zinc-containing alcohol dehydrogenase[6] by stepwise reactions with zinc complexes[7]. We therefore set out to undertake a comprehensive study of zinc complexation by aldehydes, which led to the results presented in this and the two succeeding[8][9] papers.

The literature on metal complexation of plain aldehydes contains a few papers describing zinc complexes, i.e. hexaaldehyde solvates of zinc salts[10][11], the benzaldehyde adduct of zinc chloride[12], mono- and bis-aldehyde adducts of zinc chalcogenolates[13], chelate complexes of pyridine-2-carbaldehyde[14−16], and two zinc porphyrin complexes with η^1-coordinated benzaldehyde[17][18]. Of these examples only the latter two[17][18] and the $Zn(SeR)_2$(anisaldehyde) dimer[13] were characterized by structure determinations. Likewise, for all other metals the number of well-characterized aldehyde complexes is small, and the level of information is noteworthy only for complexes of salicylic aldehyde and its derivatives as well as for organometallic complexes of η^2 (side-on)-coordinated simple aldehydes[4]. A search of the Cambridge Crystallographic Data File has yielded just six further structures of classical metal complexes with monodentate O-coordinated aldehyde ligands.

Our systematic approach to the chemistry of zinc aldehyde complexes followed four lines: (a) monodentate plain aldehydes and zinc salts of weakly coordinating anions; (b) monodentate plain aldehydes and zinc halides; (c) chelating aldehydes derived from nitrogen heterocycles; (d) aldehyde complexes of zinc thiolates. The aims of this study were: (a) to obtain as many different compound types as possible; (b) to confirm their composition and constitution by structure determinations; (c) to elucidate the donor qualities of the aldehydes as compared to those of competing ligands like water and anions; (d) to find relationships between the complex properties and catalytic phenomena; (e) to model the structure and function of the active site of horse liver alcohol dehydrogenase. We have published a short communication describing the initial stages of this work[1]. This manuscript is the first in a series of full papers describing zinc complexes with predominant or exclusive aldehyde coordination.

Preparations and Structures



It was clear after our preliminary studies[1] that water, donor solvents, and anions with donor properties, like halides, are better ligands for the zinc ion than aldehydes. Furthermore, aliphatic aldehydes were preferentially condensed, polymerized, or underwent disproportionation to carboxylic esters rather than being incorporated into stable

complexes. This fact dictated the working procedures and the choice of aldehydes. All reactions were carried out in water-free nonpolar solvents containing high concentrations of the aldehydes or using the neat aldehydes as solvents. The water content of the zinc salts was controlled by using triethoxymethane as a dehydrating agent[19] or by starting from water-free zinc hexachloroantimonate solvates[20][21]. Thus the starting zinc compounds were $[Zn(H_2O)_6]X_2$ (X = ClO_4, BF_4, NO_3), $[Zn(CH_3CN)_6](SbCl_6)_2$, and $[Zn(CH_3NO_2)_6](SbCl_6)_2$. These compounds were treated with various aromatic aldehydes of which the following allowed the isolation of pure complexes:

benz-aldehyde **BA** | mesityl-aldehyde **MA** | 4-fluoro-benzaldehyde **FA** | 2-chloro-benzaldehyde **CA**

The hydrated zinc salt was always first dissolved in triethoxymethane before the reaction was started. For each water molecule to be removed, one equivalent of triethoxymethane was applied, plus one additional equivalent for completion of the dehydration. After drying the (partially) dehydrated zinc salt in vacuo it was treated with a large excess of the aldehyde. The resulting clear solutions were diluted with petroleum ether, which caused the aldehyde-containing zinc salts to precipitate. This process worked in all cases. However, the precipitates were never crystalline (e.g. oily) or pure when the precipitation was performed by adding petroleum ether. It was therefore essential to prepare the products by slow crystallization. This was achieved by layering the neat or dichloromethane-diluted aldehyde solutions with petroleum ether and keeping the mixture in a vibration-free place at or slightly below room temperature. In this way all products that could be obtained pure were crystalline and immediately suitable for X-ray crystallography. Due to their extremely hygroscopic nature, all handling of the compounds required the rigorous exclusion of water.

Tetraaqua-bisaldehyde complexes were obtained from zinc perchlorate and tetrafluoroborate with mesitylaldehyde. Compounds **1** and **2** were originally believed to be tetraaldehyde complexes, and only the structure determinations revealed that they contain, in the solid state, two non-coordinating aldehyde molecules that are linked by hydrogen bridges to water ligands.

$[Zn(MA)_2(H_2O)_4]X_2 \bullet 2\ MA$
1: X = ClO_4, **2**: X = BF_4

Figure 1 shows the coordination pattern of **1** and **2**. In both cases the two aldehyde ligands are in *trans* positions, and the Zn−O(aldehyde) bonds are longer than the Zn−O(water) bonds.

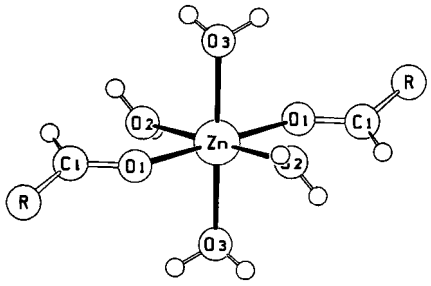

Figure 1. Zinc coordination in **1** and **2**. Bond lengths [Å] and angles [°] for **1/2**: Zn−O1 2.125(1)/2.129(2), Zn−O2 2.069(1)/2.052(2), Zn−O3 2.053(1)/2.075(2), O1−C1 1.227(2)/1.227(3), Zn−O1−C1 135.2(1)/135.5(2), O−C−C 126.0(1)/125.4(2).

Diaqua-tetraaldehyde complexes were again obtained only from $Zn(ClO_4)_2$, $Zn(BF_4)_2$ and mesitylaldehyde. Of these complexes, compound **3** again contains two aldehyde molecules in the second coordination sphere, while **4** has only zinc-coordinated aldehyde. The structure determinations showed that zinc is again *trans*-configured in both compounds (Figure 2). In these cases the Zn−O(aldehyde) and Zn−O(water) bond lengths are spread irregularly over their range from 2.04 to 2.13 Å.

$[Zn(MA)_4(H_2O)_2](ClO_4)_2 \bullet 2\ MA$ **3** $[Zn(MA)_4(H_2O)_2](BF_4)_2$ **4**

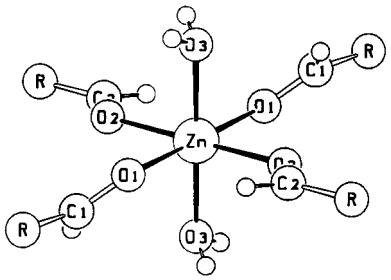

Figure 2. Zinc coordination in $[Zn(MA)_4(H_2O)_2](ClO_4)_2 \bullet 2$ MA (**3**) and $[Zn(MA)_4(H_2O)_2](BF_4)_2$ (**4**). Bond lengths [Å] and angles [°] for **3/4**: Zn−O1 2.061(3)/2.128(1), Zn−O2 2.086(2)/2.102(1), Zn−O3 2.109(2)/2.036(1), O1−C1 1.225(3)/1.233(2), O2−C2 1.226(4)/1.225(2), Zn−O1−C1 130.7(2)/122.6(1), Zn−O2−C2 132.7(2)/129.3(1), O1−C−C 125.9(3)/126.5(2), O2−C−C 125.1(3)/125.1(2).

In order to make these partially solvated zinc salts available for a wider range of aldehydes, two equivalents of ethanol were added to solutions of the bis-hydrates in various aldehydes. However, in only two cases did this lead to pure compounds, and these products were **5** and **6**. In all other cases the precipitates were non-crystalline and non-uniform. The structure determinations (Figure 3) showed that the two aldehyde, alcohol, and water ligands are each bound to zinc in an all-*trans* fashion. There is no noteworthy distinction between the Zn−O bond lengths for the aldehyde, alcohol, or water ligands.

$[Zn(A)_2(EtOH)_2(H_2O)_2]\ (ClO_4)_2$
5: A = MA; **6**: A = CA

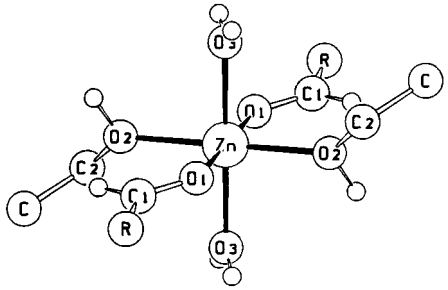

Figure 3. Zinc coordination in $[Zn(A)_2(EtOH)_2(H_2O)_2](ClO_4)_2$ (**5**: A = MA, **6**: A = CA). Bond lengths [Å] and angles [°] for **5**/**6**: Zn−O1 2.083(5)/2.098(3), Zn−O2 2.080(5)/2.057(4), Zn−O3 2.079(5)/2.011(4), O1−C1 1.230(8)/1.225(5), O2−C2 1.440(9)/1.496(9), Zn−O1−C1 130.1(5)/135.1(3), Zn−O2−C2 128.0(4)/127.0(4), O1−C−C 125.4(7)/122.1(4).

Further removal of water allowed the isolation of monoaqua complexes. In the case of 2-chlorobenzaldehyde, four aldehyde molecules and one perchlorate ion were the other ligands in complex **7**. **7** has the water and perchlorate ligands *trans* to each other (Figure 4). Although the Zn−O(aldehyde) bonds are of average length, there is a *trans* effect for the two other Zn−O bonds: the weak (long) Zn−perchlorate interaction has a strong (short) Zn−water interaction *trans* to it.

$[Zn(CA)_4(H_2O)(ClO_4)]ClO_4$
7

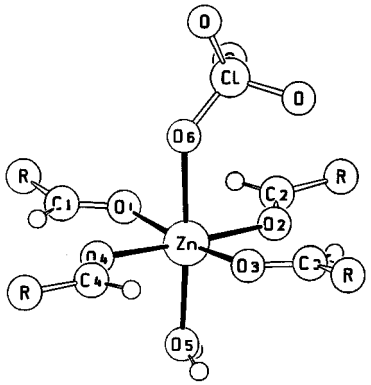

Figure 4. Zinc coordination in $[Zn(CA)_4(H_2O)(ClO_4)]ClO_4$ (**7**). Bond lengths [Å] and angles [°]: Zn−O1 2.078(4), Zn−O2 2.093(5), Zn−O3 2.068(4), Zn−O4 2.095(4), Zn−O5 2.032(6), Zn−O6 2.188(5), O1−C1 1.203(7), O2−C2 1.218(7), O3−C3 1.201(7), O4−C4 1.214(7), Zn−O1−C1 127.8(4), Zn−O2−C2 127.8(4), Zn−O3−C3 127.2(4), Zn−O4−C4 130.0(4), O1−C−C 123.8(6), O2−C−C 123.2(6),O3−C−C 123.4(6), O4−C−C 123.1(6), Zn−O6−Cl 132.4(3).

Five benzaldehyde ligands are present in complex **8**. This time there is no *trans* effect associated with the water ligand, but the average Zn−O(aldehyde) bond length of 2.09 Å is significantly longer than the average Zn−O(water) bond length of 2.02 Å (Figure 5).

$[Zn(BA)_5(H_2O)](BF_4)_2$
8

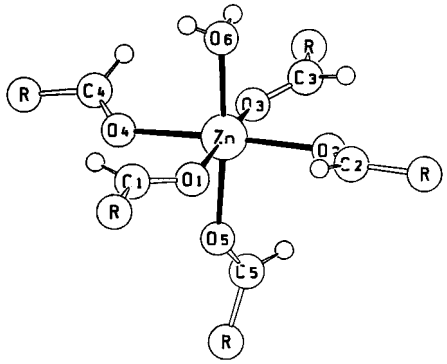

Figure 5. Zinc coordination in $[Zn(BA)_5(H_2O)](BF_4)_2$ (**8**). Bond lengths [Å] and angles [°] in the two independent molecules: Zn−O1 2.091(3)/2.118(3), Zn−O2 2.080(3)/2.079(3), Zn−O3 2.105(3)/2.078(3), Zn−O4 2.096(3)/2.086(3), Zn−O5 2.070(4)/2.080(3), Zn−O6 2.017(4)/2.031(4), O1−C1 1.215(6)/1.217(6), O2−C2 1.215(6)/1.213(6), O3−C3 1.211(6) /1.224(6), O4−C4 1.212(6)/1.213(5), O5−C5 1.216(6)/1.231(6), Zn−O1−C1 127.0(3)/129.6(3), Zn−O2−C2 127.4(3)/126.4(3), Zn−O3−C3 132.3(3)/130.3(3), Zn−O4−C4 126.6(3)/128.7(3), Zn−O5−C5 135.1(4)/127.9(3), O1−C−C 123.5(4)/124.3(4), O2−C−C 123.0(5)/123.6(4), O3−C−C 122.6(5)/122.5(5), O4−C−C 124.5(4)/124.5(4), O5−C−C 122.1(5)/123.5(4).

While no hydrated aldehyde complex of zinc nitrate could be obtained in a pure state, this was the case for the water-free complexes. In the reaction with mesitylaldehyde, complex **9** was isolated. The composition of **9** indicated that three coordination positions would be used for the zinc−nitrate interactions, i.e. one nitrate ligand would be monodentate and the other bidentate, a situation observed many times in octahedral zinc complexes. This was borne out by the structure determination (Figure 6). The three

$[Zn(MA)_3(NO_3)_2]$
9

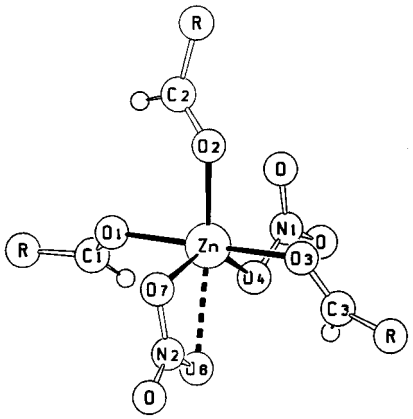

Figure 6. Zinc coordination in $[Zn(MA)_3(NO_3)_2]$ (**9**). Bond lengths [Å] and angles [°]: Zn−O1 2.075(2), Zn−O2 2.032(2), Zn−O3 2.120(2), Zn−O4 2.017(2), Zn−O5 2.098(2), Zn−O6 2.400(2), O1−C1 1.231(3), O2−C2 1.218(2), O3−C3 1.228(3), O1−C−C 125.2(2), O2−C−C 124.7(2), O3−C−C 126.7(2), Zn−O1−C1 127.7(2), Zn−O2−C2 130.7(1), Zn−O3−C3 119.2(1), O2−Zn−O4 125.1(1), O2−Zn−O5 96.3(7), O2−Zn−O6 150.9(1).

aldehyde and the three nitrate oxygen atoms are all arranged meridionally. The unsymmetrically bidentate nature of one nitrate ligand causes a severe distortion of the octahedral ligand arangement (cf. angles involving O2), and the lack of a direct *trans*-ligand makes Zn−O2 an unusually short Zn−O(aldehyde) bond.

Attempts to prepare hexa-aldehyde complexes by way of quantitative dehydration of the zinc salts did not lead to the desired products. Instead tetraaldehyde-bisperchlorate complexes were obtained from $Zn(ClO_4)_2 \bullet 6\ H_2O$. These compounds were isolated in a crystalline form by reaction with benzaldehyde, 4-fluorobenzaldehyde and mesitylaldehyde as **10**, **11**, and **12**. **12** represents another example that contained two equivalents of co-crystallized aldehyde. All three complexes have the four aldehyde ligands in a planar arrangement and the two perchlorate ligands in a *trans*-axial orientation (Figure 7). The presence of two additional aldehyde molecules per formula unit in the crystals of **12** has no influence on bond lengths or angles around zinc. By comparison the Zn−O(aldehyde) bonds are relatively short and the Zn−O(perchlorate) bonds typically long.

$[Zn(A)_4(ClO_4)_2]$
10: A = BA; **11**: A = FA; **12**: A = MA

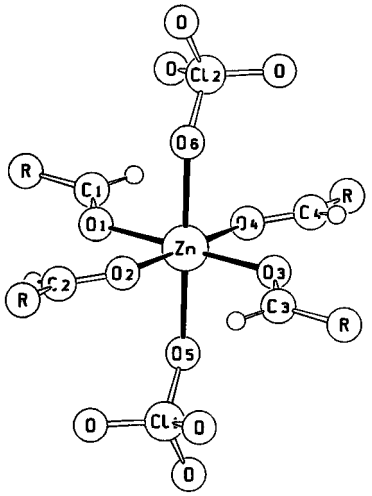

Figure 7. Zinc coordination in **10**, **11**, and **12** (**10** and **11** have zinc on an inversion center). Bond lengths [Å] and angles [°] for **10**/**11**/**12**: Zn−O1 2.063(1)/2.068(1)/2.072(3), Zn−O2 2.057(1)/2.044(1)/2.052(2), Zn−O3 −/−/2.084(3), Zn−O4 −/−/2.043(2), Zn−O5 2.143(1)/2.159(1)/2.134(3), Zn−O6 −/−/2.230(3), O1−C1 1.229(2)/1.227(2)/1.235(4), O2−C2 1.234(2)/1.231(2)/1.233(4), O3−C3 −/−/1.229(4), O4−C4 −/−/1.233(4), Zn−O1−C1 129.0(1)/128.3(1)/121.2(2), Zn−O2−C2 127.0(1)/128.9(1)/123.8(2), Zn−O3−C3 −/−/125.1(2), Zn−O4−C4 −/−/125.2(2), O1−C−C 123.3(2)/123.1(2)/126.9(3), O2−C−C 122.9(2)/122.2(2)/125.4(3), O3−C−C −/−/125.9(3), O4−C−C −/−/125.3(2), Zn−O5−Cl 132.8(3)/133.6(1)/135.0(2), Zn−O6−Cl −/− 142.4(2).

In complexes like **10**−**12** the perchlorate ligands seem to be more difficult to replace than the aldehyde ligands. This became evident when two equivalents of ethanol were added to solutions of the fully dehydrated zinc salts in the neat aldehydes. Complex **13** could be crystallized from its solution in mesitylaldehyde. Figure 8 shows the all-*trans* arrangement of its pairs of aldehyde, alcohol, and perchlorate ligands. The Zn−O(aldehyde) and Zn−O(alcohol) bond lengths are not significantly different in **13**, and all of its Zn−O bond lengths are quite similar to those in **10**−**12**.

$[Zn(MA)_2(EtOH)_2(ClO_4)_2]$
13

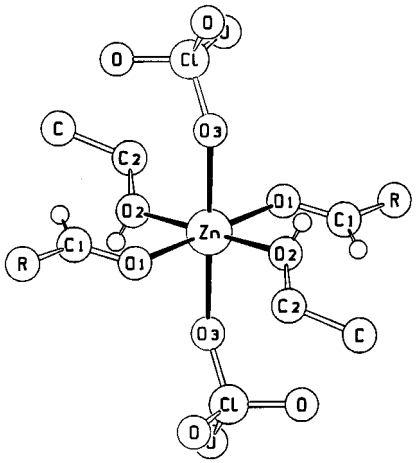

Figure 8. Zinc coordination in **13**. Bond lengths [Å] and angles [°]: Zn−O1 2.069(2), Zn−O2 2.045(3), Zn−O3 2.151(3), O1−C1 1.225(4), O2−C2 1.447(4), Zn−O1−C1 125.6(2), Zn−O2−C2 130.5(2), Zn−O3−Cl 143.1(2), O1−C−C 126.4(3).

It was thus obvious that the aldehydes are not strong enough as donors to occupy all six coordination positions at the zinc ion in the presence of the weakly coordinating anions NO_3^-, BF_4^-, or ClO_4^-. We therefore resorted to solvated zinc hexachloroantimonate as a starting material. By dissolving $[Zn(CH_3CN)_6](SbCl_6)_2$[20] in the aldehydes we found that not more than two of the acetonitrile ligands could be replaced. Complexes **14**−**16** were isolated.

trans-$[Zn(A)_2(MeCN)_4]\ (SbCl_6)_2$
14: A = BA; **15**: A = MA

cis-$[Zn(CA)_2(MeCN)_4]\ (SbCl_6)_2$
16

The structure determinations revealed that **14** and **15** are *trans*-configured (Figure 9). The mediocre quality of the data set for **14** prohibits a detailed comparison, but it is obvious that the Zn−O and Zn−N bond lengths in both complexes are practically identical and that the equatorially arranged acetonitrile ligands show a variable deviation from linearity (157−177°) at their nitrile carbon atoms.

In contrast, complex **16** is *cis*-configured (Figure 10). This time there is a distinction between the Zn−O and Zn−N bond lengths, the latter being shorter, and the acetonitrile ligands are closer to being linear. The structural features do not offer an indication as to why **14** and **15** should be *trans*- and **16** *cis*-configured.

A complete replacement of solvate by aldehyde ligands could be achieved by starting with $[Zn(CH_3NO_2)_6](SbCl_6)_2$[21], as previously reported by Driessen et al.[10][11]. The problem of fast decomposition of the products could

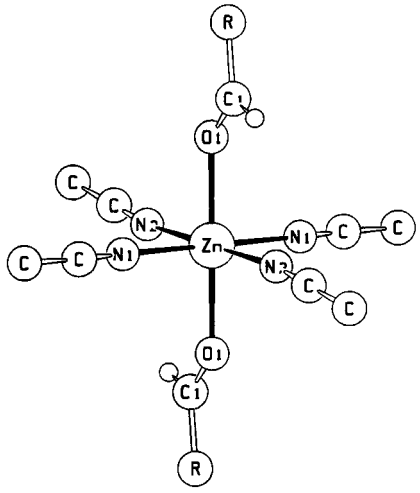

Figure 9. Zinc coordination in **14** and **15**. Bond lengths [Å] and angles [°] in **14/15**: Zn−O1 2.116(9)/2.103(3), Zn−N1 2.113(11)/2.137(4), Zn−N2 2.117(12)/2.106(5), O1−C1 1.20(1)/1.23(1), Zn−O1−C1 136(1)/129.2(3), O1−C−C 123(1)/126.4(4), Zn−N1−C 174(1)/157.3(4), Zn−N2−C 172(1)/165.1(4).

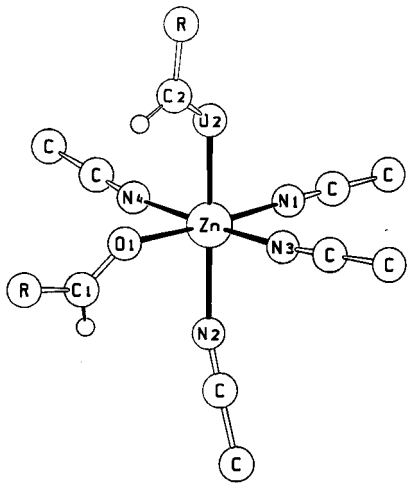

Figure 10. Zinc coordination in **16**. Bond lengths [Å] and angles [°]: Zn−O1 2.168(2), Zn−O2 2.149(2), Zn−N1 2.087(3), Zn−N2 2.165(3), Zn−N3 2.087(3), Zn−N4 2.082(3), O1−C1 1.215(4), O2−C2 1.216(4), Zn−O1−C1 131.0(2), Zn−O2−C2 128.0(2), O1−C−C 123.1(4), O2−C−C 123.8(3), Zn−N1−C 177.4(3), Zn−N2−C 164.3(3), Zn−N3−C 168.4(3), Zn−N4−C 171.5(3).

be overcome for fluoro- and chlorobenzaldehyde, making compounds **17** and **18** accessible in a pure and crystalline form.

$[Zn(FA)_6](SbCl_6)_2$ $[Zn(CA)_6](SbCl_6)_2 \bullet 4\ CA$
17 **18**

Structurally **17** and **18** are symmetrical octahedral complexes (Figure 11). Specifically, **18** shows very uniform bond lengths and angles for the aldehyde ligands and a very narrow spread of 88−92° for the angles at zinc. The lower data quality for **17** seems to have caused a wider spread of bond lengths and angles, the averages of which, however, agree well with those for **18**. The two complexes define the structural standards for homoleptic zinc-aldehyde complexes with bond lengths of ca. 2.08 Å for Zn−O and ca. 1.23 Å for C−O.

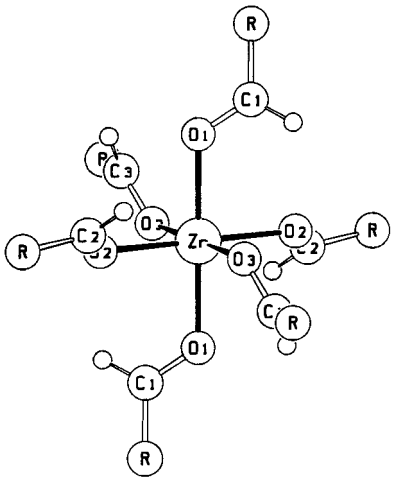

Figure 11. Zinc coordination in **17** and **18** (**18** has zinc on an inversion center). Bond lengths [Å] and angles [°] for **17/18**: Zn−O1 2.07(1)/2.073(2), Zn−O2 2.05(1)/2.078(2), Zn−O3 2.15(1)/2.075(2), Zn−O4 2.11(1)/−, Zn−O5 2.09(1)/−, Zn−O6 2.08(1)/−, O1−C1 1.26(2)/1.219(4), O2−C2 1.24(2)/1.219(4), O3−C3 1.21(2)/1.222(4), O4−C4 1.25(2)/−, O5−C5 1.19(2)/−, O6−C6 1.28(2)/−, Zn−O1−C1 122(1)/124.6(2), Zn−O2−C2 130(1)/124.5(2), Zn−O3−C3 119(1)/127.3(2), Zn−O4−C4 125(1)/−, Zn−O5−C5 130(1)/−, Zn−O6−C6 130 (1)/−.

Discussion of the Structures

All these aldehyde complexes are octahedral to a very good approximation. In most cases the valence angles at zinc deviate by not more than ±3° from 90° or ±5° from 180°, with the extremes being ±6° and ±8°, respectively. The aldehyde ligands are attached to zinc in a strict anti fashion, as expressed by the dihedral angles Zn−O−C−R, which range from 158° to 180° with an average over all structures of 174°. Furthermore, and despite some steric hindrance, the aromatic rings of the aldehydes are always coplanar with the RCHO functions, again expressed by dihedral angles ranging from 166° to 179° with an average of 176°.

Details of the Zn−O bond lengths and some internal comparisons were mentioned above for the complex types. Table 1 gives the data for a general comparison. The most interesting question is whether the bonding strength of the aldehydes can be deduced from their Zn−O distances. An inspection of Table 1 reveals that for a given complex type there is no distinction between Zn−O bond lengths according to the type of aldehyde. Instead the coligands seem to have the major influence on the strength of the zinc-aldehyde interaction. When two or more water (**1**−**6**) or acetonitrile ligands (**14**−**16**) are present the Zn−O(aldehyde) bonds are long. In turn, when only aldehyde ligands are present (**17**, **18**) or when only perchlorate is the coligand (**10**−**12**), the Zn−O(aldehyde) bonds are short. This is another demonstration of the fact that the aldehydes are very weak ligands.

Table 1. Bonding features (average values of bond lengths [Å] and angles [°]) for the zinc−aldehyde interactions

	aldehyde			coligands	
	Zn−O	O−C	Zn−O−C	X	Zn−X
1	2.13	1.23	135	$O(H_2O)$	2.06
2	2.13	1.23	136	$O(H_2O)$	2.06
3	2.10	1.23	132	$O(H_2O)$	2.06
4	2.12	1.23	126	$O(H_2O)$	2.04
5	2.08	1.23	130	$O(H_2O)$	2.08
				O(EtOH)	2.08
6	2.10	1.23	135	$O(H_2O)$	2.01
				O(EtOH)	2.06
7	2.08	1.21	128	$O(H_2O)$	2.03
				$O(ClO_4)$	2.19

9	2.08	1.23	126	$O(NO_3)$	2.02
				$O(NO_3)$	2.10, 2.40
10	2.06	1.23	128	$O(ClO_4)$	2.14
11	2.06	1.23	129	$O(ClO_4)$	2.16
12	2.06	1.23	124	$O(ClO_4)$	2.18
13	2.07	1.23	126	O(EtOH)	2.05
				$O(ClO_4)$	2.15
14	2.12	1.20	136	N(MeCN)	2.12
15	2.10	1.23	129	N(MeCN)	2.12
16	2.16	1.22	130	N(MeCN)	2.11
17	2.09	1.24	126	−	−
18	2.08	1.22	126	−	−

The spread of the Zn−O distances finds no reflection in the other structural features of the aldehydes. The details of the aldehyde orientation (cf. dihedral angles, see above) show no systematic relation with the Zn−O(aldehyde) bond lengths. The range of the aldehyde C=O bond lengths is too small to warrant a discussion. There is just a barely noticeable proportionality between the Zn−O−C angles and the Zn−O(aldehyde) bond lengths. When compared to the three other reported structures of zinc-aldehyde complexes[13][17][18] the structural features listed in Table 1 span the range observed there.

The coligands in complexes **1**−**16** bind to zinc in a fashion that is known to occur in such complexes[22]. Specifically the bonding alternatives for the nitrate ligand between strictly monodentate and symmetrically bidentate and the weak and variable zinc−perchlorate interactions are well known. Similarly the Zn−N(acetonitrile) bond lengths in **14**−**16** are in the reported range, as are the deviations of the Zn−N−C units from linearity found here (157−177°) in comparison to the reported range (156−178°)[22].

Complexes **17** and **18** are of general significance as they define the standard of ZnO_6 coordination by aldehydes. Their Zn−O distances of 2.08−2.09 Å compare very well with the average values for Zn−O in $Zn(H_2O)_6^{2+}$ (2.09 Å)[23] and in $Zn(alcohol)_6^{2+}$ (2.08 Å)[24]. Other reported complexes with a homoleptic ZnO_6 coordination belong to the types $Zn(pyridine\ oxide)_6^{2+}$[25], $Zn(urea)_6^{2+}$[26], and $Zn(DMSO)_6^{2+}$[27] with average Zn−O bond lengths of 2.10, 2.10, and 2.11 Å, respectively. The Zn−O bond length for the aldehyde complexes is at the lower end of all these ZnO_6 species, indicating again that donor strength and bond distances are not clearly correlated for such compounds. Instead the very narrow spread of all these Zn−O bond lengths (2.08−2.11 Å) indicates that the packing of six oxygen atoms around one zinc ion does not allow shorter contacts irrespective of the variation of the attractive forces.

Spectroscopy

The most important indication for the formation of the aldehyde complexes was the observation of the aldehyde ν(CO) IR bands at their typical locations. As shown in Table 2, the bands for coordinated aldehydes are shifted by ca. 50−80 cm^{-1} to lower wavenumbers, which is in agreement with previous observations on zinc-hexaaldehyde complexes[10][11]. In contrast, those complexes that contain cocrystallized uncoordinated aldehyde display additional ν(CO) bands that are practically unshifted.

Contrary to expectation, the ν(CO) band shifts are neither proportional to the donor strength (i.e. electron richness of the aromatic system) of the aldehydes nor inversely proportional to the donor power of the coligands (i.e. water stronger than perchlorate). Indeed complex **10**, containing benzaldehyde as one of the better aldehyde donors together with only the very weak donor perchlorate, shows the smallest Δν, and complex **6**, containing electron-poor 2-chlorobenzaldehyde together with two water and two ethanol ligands, shows the largest Δν. There seem to be, however, rather uniform Δν values for each aldehyde, e.g. −50 cm^{-1} for BA, −55 cm^{-1} for MA, −65 cm^{-1} for FA, and −80 cm^{-1} for CA. This trend should be of diagnostic value.

The IR data of the coligands and anions also yield some information (Table 2). While the water and ethanol ligands

Table 2. IR data (KBr, cm^{-1}) of the complexes

display a broad and unspecific absorption between 3400 and 3550 cm^{-1}, the ν(CN) bands of the acetonitrile ligands are characteristically shifted by 25−40 cm^{-1} to higher wavenumers[28] as compared to those of free CH_3CN. The ν(NO) bands of the nitrate ligands, as is usual[29], give no clear indication of their bonding mode (uni- or bidentate). The BF_4^- and ClO_4^- ions show their strong absorptions near 1100 cm^{-1}. For perchlorate, a medium-intensity band near 940 cm^{-1}, assignable to a fully symmetrical stretch[19], is observed only in complexes **1**, **3**, **5**, and **6**, in accord with the structural data showing that these complexes contain uncoordinated ClO_4^-.

The suitability of NMR spectroscopy for bonding discussions of the aldehyde complexes is hampered by the fact that, other than in the neat aldehydes, they dissolve only in polar organic solvents that may be stronger donors for zinc than the aldehydes. Accordingly, only small shift effects were observed when recording the spectra in [D_6]acetone. Table 3 lists the data.

Table 3. ^{1}H- and ^{13}C-NMR data for the aldehyde CHO functions (in [D_6]acetone, δ)

Metal coordination of the aldehyde function should lead to deshielding of both the H and C of RCHO. Such a deshielding is actually observed with Δδ values of 1−2 ppm for the ^{13}C resonances while the ^{1}H resonances are so close to those of the free aldehydes that they cannot be discussed. The extent of deshielding decreases in the order MA > BA > FA > CA, which can be correlated with the donor strengths. The NMR spectra, however, do not show a distinction between coordinated and uncoordinated aldehydes in complexes **1**−**3**, **12**, and **18**.

The coligands ethanol and acetonitrile seem to stay coordinated to zinc in acetone solutions. Their ^{1}H-NMR resonances are shifted by 0.5−1 ppm to lower field in comparison to those of the free ligands. Likewise the ^{13}C-NMR signals are shifted downfield by up to 2.5 ppm for ethanol-CH_2, but show almost no shift for the acetonitrile resonances.

Conclusions

This work has shown that two to six aldehyde molecules can be coordinated to zinc under carefully controlled conditions. The complexes described here are those that were isolated in an analytically pure form. Many more have been prepared in a less pure form, and it is to be assumed that the various structural types can be realized by most of the aldehydes. The aldehydes are completely expelled from the ligand sphere of zinc when excess water is present. In the presence of strongly coordinating anions like the halides, completely different structural types are observed[8].

All isolated complexes were found to be octahedral. Normally they contain one to four coligands together with the aldehyde ligands. In addition to water, ethanol and acetonitrile can also not be completely replaced by the aldehydes. Under anhydrous conditions the nitrate and perchlorate anions are preferred over the aldehydes as ligands. Hexaaldehyde complexes could only be obtained by replacement of the very weak donor nitromethane and by applying an anion ($SbCl_6^-$) of extremely low donor strength.

X-ray structure determination was found to be the only method of unambiguous product identification. It has provided the structural features of zinc−aldehyde bonding. It has delivered examples of the basic ZnL_6 structure for L = aldehyde, which need to be complemented for other L, e.g. alcohol, acetone, ethers, nitromethane, acetonitrile, etc. It has been shown that slight variations in the reaction conditions can lead to quite different compositions of the complexes. Together with the low donor strength of the aldehydes this means that there exists a high degree of uncertainty when mechanistic conclusions are drawn from such structures or even from the composition of reaction solutions.

With respect to modelling the zinc enzyme alcohol dehydrogenase, this work has provided some elementary information. On the one hand it was shown that aldehydes can be bound to zinc in the presence of water, i.e. zinc can be involved in the process of aldehyde reduction. On the other hand it has become very clear that excess water replaces zinc-bound aldehydes very easily, e.g. the last step of alcohol oxidation is facile. Furthermore, the possible coexistence of alcohol and aldehyde ligands in the same complex was demonstrated. With respect to the chemical reactions happening in the enzyme, the findings of this work are of little relevance as neither the low coordination number of zinc nor the presence of a redox reagent were reproduced. It was partly for this reason that we extended our studies of zinc−aldehyde coordination to further types of ligands and coligands[8][9].

Experimental Section

The general working and measuring techniques were as described previously[30]. All experiments were carried out using carefully dried atmospheres (nitrogen or argon) and solvents. As some of the products were too moisture-sensitive for ordinary C/H/N analyses, all compounds were also characterized by zinc and anion analyses

(Table 5). All starting compounds were obtained commercially, recrystallized or distilled prior to use, and stored under anhydrous conditions. The acetonitrile[20] and nitromethane[21] complexes of zinc were prepared as described. Although none of the perchlorate-containing materials were found to be explosive, all of them were handled in small quantities and with the appropriate safety precautions. The new complexes were prepared following two procedures that are outlined below and the details for which are given in Table 4. Table 5 gives data of the analytical characterizations.

Preparation of Complexes 1−13: The hydrated zinc salt was dissolved in the appropriate amount of triethoxymethane (n + 1 equivalents for removal of n equivalents of water). The solution was heated to reflux using a hot air blower for a few seconds. After cooling to room temperature, all volatiles were removed in vacuo and the residue dried in vacuo at 40−50°C for 2 h. An approximately 10-fold excess of the aldehyde was then added and the mixture stirred with warming until all reactants had dissolved. After cooling the solution to room temperature the aldehyde solution was layered carefully with 30 mL of petroleum ether (b.p. 60−70°C). Within one to two days the colourless product complex had precipitated. In those cases where the product was crystalline it was also found to be pure. The complex was filtered off, washed with a small amount of petroleum ether (b.p. 60−70°C) and dried in vacuo.

Preparation of Complexes 14−18: The solvated zinc salt was suspended in 5 mL of dichloromethane. 5 mL of the aldehyde was added with stirring upon which a clear solution was formed. This solution was layered carefully with 40 mL of petroleum ether (b.p. 60−70°C). Within a few days the product complex had precipitated as colourless crystals, which were filterd off, washed with a few mL of petroleum ether (b.p. 60−70°C) and dried for a short time in vacuo.

Structure Determinations[31]: Crystals were obtained from the reaction solutions. The crystals were then immersed in perfluorinated polyether oil for protection and attachment to the goniometer head and immediately subjected to the nitrogen flow from the diffractometer's cooling system. Diffraction data were recorded at low temperatures with the ω/2θ technique on a Nonius CAD4 dif-

Zinc Complexes of Aldehydes and Ketones, 3[+]
Aldehyde Complexes of Zinc Halides

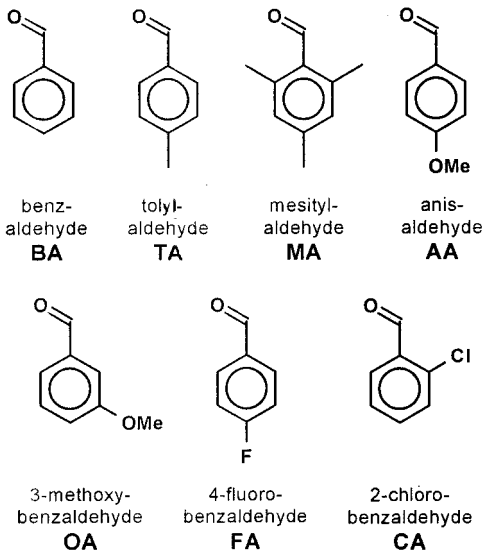
Bodo Müller[a] amd Heinrich Vahrenkamp*[a]

Keywords: Zinc / Aldehyde ligands / Halide ligands / Structural chemistry

Aldehyde complexes of the zinc halides were obtained by treating $ZnCl_2$, $ZnBr_2$, and ZnI_2 under anhydrous conditions with large excesses of benzaldehyde and various substituted benzaldehydes. Their constitutions were determined by a total of 12 X-ray structure analyses. Three product types were found: $ZnHal_2(aldehyde)_2$ (**A**), $[ZnHal_2(aldehyde)]_\infty$ (**B**), and $[Zn(aldehyde)_6]$ $[Zn_2Hal_6]$ (**C**). All three dissolve readily in the corresponding aldehyde or in polar nonprotic solvents indicating the presence of solvated zinc species in solution.

In the preceding paper[1] we outlined the motivation for our studies of zinc complexation by aldehydes and ketones. The sharp discrepancy between the importance of metal ion catalysis for reactions of carbonyl-containing compounds and the scant knowledge on the chemical interactions between metal ions and carbonyl functions calls for the gathering of basic information upon which mechanistic insight is to be built. The fact that so little is known about metal complexes (other than organometallic species) of simple carbonyl compounds is a reflection of the low donor strength of these compounds. Thus for their exploration not only are anhydrous reaction conditions essential but also are all reaction media of moderate donor strength to be avoided.

While catalytic zinc in biochemical systems is never bound to halides and in fact halide ions are known to be inhibitors of some zinc enzymes[2], zinc halides are typical activators for reactions of organic carbonyl compounds. Examples in which zinc chloride is employed in higher than stoichiometric amounts are sugar acetylations, the Fischer indole synthesis, Friedel–Crafts acetylations, and various condensations[3]. After studying the coordination of carbonyl compounds to halide-free zinc species[1] we therefore turned to the corresponding studies of the pure zinc halides.



This paper, like the preceding one[1], describes aldehyde complexes. We are aware of only one related publication, i.e. one containing some data on $ZnCl_2$•benzaldehyde[4]. We scanned the coordination abilities of a broad range of aldehydes towards the zinc halides $ZnCl_2$, $ZnBr_2$, and ZnI_2. Again we observed that aliphatic aldehydes undergo condensation or polymerization reactions after addition of the zinc halide. Benzaldehyde and various substituted benzaldehydes, however, were found to be suitable as ligands. A preliminary account of our findings was published in 1994[5].

Preparations

In order to obtain the aldehyde complexes as pure, solid materials the aldehyde had to be present in a large excess and in a high concentration. In practice this meant using the aldehyde as the reaction medium which restricted the reaction to only those aldehydes that are low-melting or liquid. Pure and crystalline products were obtained with the following aldehydes:

The water-free zinc halides $ZnCl_2$, $ZnBr_2$, and ZnI_2 were prepared in diethyl ether from zinc and HCl, Br_2, and HI prior to use. They were dissolved in the aldehydes. After complete dissolution an equal volume of dichloromethane was added. The products precipitated on addition of petroleum ether. Crystalline complexes were obtained in lower yields after careful layering with petroleum ether. The resulting zinc complexes belong to one of the three classes **A**, **B**, and **C**.

$[ZnHal_2(aldehyde)_2]$ **A** $[-Hal-ZnHal(aldehyde)-]_\infty$ **B**

$[Zn(aldehyde)_6][Zn_2Hal_6]$ **C**

Class **A** type complexes, i.e. monomolecular tetrahedral $ZnHal_2(aldehyde)_2$ species, were obtained from the five aldehydes BA, TA, MA, AA, and OA. Compounds **1b** to **5c** respesent the total of 12 complexes that were isolated analytically pure. They are all extremely hygroscopic, and they should be stored at low temperatures as some of them decompose within a few days at room temperature. Eight of the complexes were subjected to crystal structure determinations; the high structural similarity between them is discussed below.

$[ZnHal_2(aldehyde)_2]$

	1b	**1c**	**2b**	**2c**	**3a**	**3b**	**3c**	**4a**	**4b**	**4c**	**5b**	**5c**
Hal	Br	I	Br	I	Cl	Br	I	Cl	Br	I	Br	I
aldehyde	BA	BA	TA	TA	MA	MA	MA	AA	AA	AA	OA	OA

The alternative class **B** type complexes, i.e. mono-aldehyde−$ZnHal_2$ species, were obtained for almost all cases in which class **A** type complexes did not result. Compounds **6a**−**9c** were isolated. Structure determinations of three of them showed them to be halide-bridged polymers in the solid state (see below). These compounds do not differ in their behaviour (solubility, hygroscopicity, thermal stability) from the monomolecular complexes, which indicates inter alia that they are molecular bis-aldehyde complexes in aldehyde solution. So far we have found no indication for the alternative constitution of the mono-aldehyde complexes as halide-bridged dimeric units.

$[ZnHal_2(aldehyde)]_\infty$

	6a	**7a**	**8a**	**9a**	**9b**	**9c**
Hal	Cl	Cl	Cl	Cl	Br	I
aldehyde	BA	MA	FA	CA	CA	CA

Quite unexpectedly, two compounds of composition $ZnHal_2 \cdot 2$ aldehyde (**10b**, **c**) were found to belong to class **C** rather than class **A**. This was proved for **10b** by structure determination and assumed for **10c** by analogy of composition and spectra. **10b** and **c** share the property of all zinc halide complexes reported here, namely, they contain only covalently bound halide. There is no obvious reason, however, why in this case dismutation into a fully aldehyde-coordinated cation and a fully halide-coordinated anion has occurred. Just like in the cases of benzaldehyde and tolylaldehyde, also in the case of fluorobenzaldehyde reaction with $ZnCl_2$ yields a 1:1 complex (**8a**) whereas reaction with $ZnBr_2$ and ZnI_2 yield 2:1 (aldehyde/zinc) complexes (**10b**, **c**).

$[Zn(FA)_6]\ [Zn_2Hal_6]$
10b: Hal = Br; **10c**: Hal = I

Structures

Eight complexes of class **A** were subjected to structure determinations. Their molecular shapes are remarkably uniform, including the fact that with the exception of **3a** they all have a crystallographic twofold axis. Figure 1 and Table 1 summarize the bonding features. All complexes are distorted tetrahedral with the O−Zn−O angle typically small (94−106°), the Hal−Zn−Hal angle typically large (122−131°), and the O−Zn−Hal angles close to the tetrahedral value (105−111°). The aldehydes are attached to zinc in a strictly anti fashion (dihedral angle Zn−O−C−C average 178°), and the aromatic rings and the CHO groups are coplanar (dihedral angle O−C−C−C average 175°).

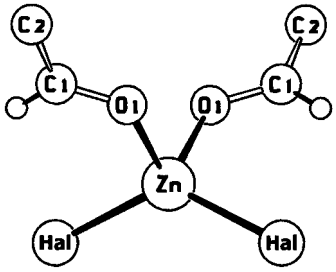

Figure 1. Zinc coordination of class **A** complexes

The zinc halide bond distances are typical and uniform for Zn−Cl, Zn−Br, and Zn−I, cf. Table 1. The Zn−O bond lengths vary only 0.03 Å about their average value of 2.035 Å. Compared to the average value of 2.09 Å for octahedral zinc-aldehyde complexes they are typically shorter. There is only one reference value in the literature for Zn−O(aldehyde) in tetrahedral complexes: in Bochmann's $[Zn(SeR)_2(AA)]_2$ it measures 2.06 Å[6]. The spread of the aldehyde C=O bond lengths is negligible. Relative to the standard value for aromatic aldehydes of 1.22 Å[7] they are only very slightly elongated due to the coordination to the metal.

Three structures of class **B** type complexes were determined. They were found to belong to two different structural types. Compound **6a** has a screw type arrangement of the polymeric backbone made up of Zn and Cl (Figure 2). Compounds **7a** and **9b** crystallize with a linear zig-zag array of zinc and halide (Figure 3). Table 2 compares the structural details of the three complexes.

Like the complexes of class **A**, those of class **B** are distorted tetrahedral, yet with a different kind of distortion. Their O−Zn−Hal angles are near the tetrahedral value, their Hal1−Zn−Hal2 angles are near 118−120°, and the Hal2−Zn−Hal2′ angles (i.e. those involving both bridging halides) are near 102°. The anti orientation of the zinc-bound aldehydes (dihedral angles 171−179°) and the coplanarity of the arene and CHO groups (dihedral angles 171−176°) are as before. In Table 2 comparison of **6a** and **7a** shows that the backbone structure of the polymers (screw-like or zigzag) is not reflected in the basic bond lengths and angles. The Zn−Hal distances have typical values for the terminal halides, cf. Table 1, but are characteristically elongated for the bridging halides. The Zn−O(al-

[a] Average of two values each.

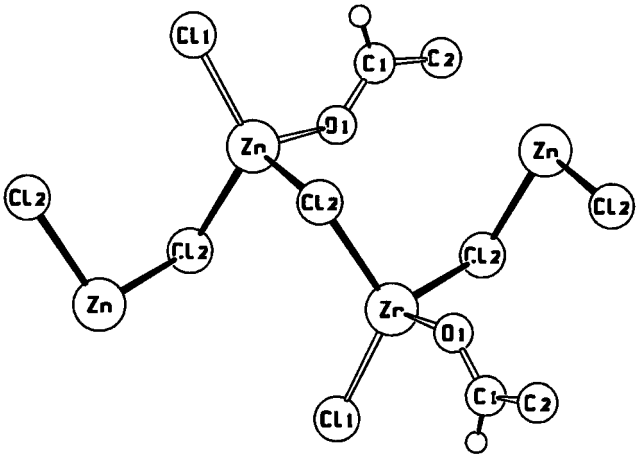

Figure 2. Polymer backbone and zinc coordination of complex **6a**

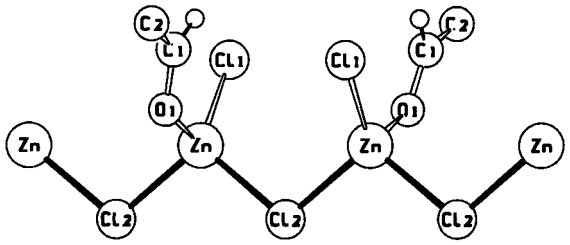

Figure 3. Polymer backbone and zinc coordination of complexes **7a** and **9b**

dehyde) bonds are still a bit shorter than those for class **A**. This must be related to the fact that only one aldehyde ligand per zinc ion is present and that the donor capacity of two of the three halide ligands is reduced because of their bridging nature.

The unexpected class **C** constitution of complexes **10b** and **c** became obvious only after the structure determination of **10b**, cf. Figure 4. The hexaaldehyde−zinc cation of **10b** corresponds to the ones structurally characterized by us for 4-fluorobenzaldehyde and 2-chlorobenzaldehyde with $SbCl_6^-$ counterions[1]. Its structural features, typically its Zn−O bond length of 2.08 Å (av.), are as observed before[1]. The $Zn_2Br_6^{2-}$ anion of **10b** belongs to the well-established class of $Zn_2Hal_6^{2-}$ complexes. While quite a number of these with Hal = Cl have been structurally characterized[8], there is just one structure each for X = Br[9] and X = I[10] in the literature. The structural details of the $Zn_2Br_6^{2-}$ ion in **10b** compare well with the reported ones. Typically both the terminal and bridging Zn−Br bonds are longer than in the neutral complexes like **9b**, and the Zn_2Br_2 rectangle is characterized by rather acute angles both at zinc and bromine.

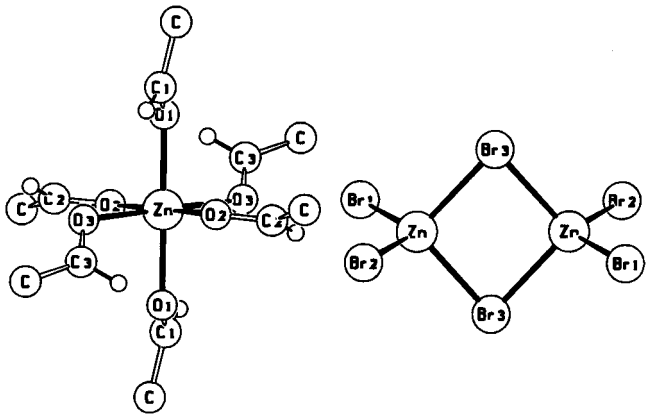

Figure 4. Coordination of zinc in the cation and anion of complex **10b**

Spectra

The characteristic IR bands of the complexes, i.e. the aldehyde ν(CO) bands, are listed in Table 3. A significant shift to lower wavenumbers occurs upon coordination to zinc. There is no correlation between this shift and the bonding type (i.e. classes **A**, **B**, and **C**). Instead it seems to be correlated with the electron density of the aldehydes: for electron-rich aldehydes (BA, AA), the shift is small, and for electron-poor aldehydes (FA, CA) it is large. The same observations were made for zinc-aldehyde complexes with weakly coordinating anions[1].

Table 3. ν(CO) IR bands (KBr, cm^{-1}) and their relative shifts

4c	1638	−52	**10c**	1636	−64

The characteristic ^{1}H- and ^{13}C-NMR resonances result from the aldehyde CHO functions. In the complexes these resonances are shifted by small, yet significant, amounts. The ^{1}H signals are moved upfield and downfield in an irregular fashion, the ^{13}C signals are all shifted downfield, as expected due to deshielding resulting from coordination. While for the zinc−aldehyde complexes with noncoordinating anions[1] the ^{1}H-NMR shifts were so small that the possibility of aldehyde substitution by [D_6]acetone upon dissolution could not be ruled out, this is not the case here. Obviously the molecular nature and the lower coordination number of the zinc-halide complexes reported here result in a tighter binding between the cation and the aldehyde ligands.

Discussion

The strict maintenance of anhydrous conditions has made it possible to isolate zinc halide complexes of seven different aromatic aldehydes. In all compounds obtained the halides are attached covalently to zinc. Two compositions have been observed, represented by the formulae $ZnHal_2$•aldehyde and $ZnHal_2$•2 aldehyde. They appear in three structural types, monomolecular $ZnHal_2$•2 aldehyde (**A**), polymeric and halide-bridged $ZnHal_2$•aldehyde (**B**), and ionic $[Zn(aldehyde)_6][Zn_2Hal_6]$ (**C**). Notably the dimeric halide-bridged structural type $[ZnHal_2$•aldehyde$]_2$ is missing.

The NMR spectra prove the compositions of the products, and the solid-state IR data prove the aldehyde coordination by large Δν values for the aldehyde CO bands. They give no indication of the complex structures which could only be obtained by crystal structure determinations. Typically complex **10b** of type **C** does not differ spectroscopically from other $ZnBr_2$ complexes like **3b** or **5b**. Altogether the uniformity within groups of spectra or structures does not allow conclusions on structure and bonding to be drawn.

There seems to be a relation between the composition of the complexes and the electron-donor properties of the ligands. Both electron-rich aldehydes (MA, AA) and low-electronegativity halides (Br, I) favour the $ZnHal_2$•2 aldehyde composition. Conversely zinc chloride yields only polymeric 1:1 complexes with the "normal" aldehydes BA and TA, and the most electron-poor aldehyde CA appears only in the polymeric 1:1 complexes. The formation of the 1:1 complexes even in the neat aldehydes is a demonstration of the low donor strength of the aldehydes, which cannot compete with bridging halide for the coordination to zinc. The formation of complexes **10** is an unusual result of this competition in that both aldehyde and halide get their own zinc ions.

With the exception of the cation of **10** all complexes described here are tetrahedral. This can be related to the soft character of the halide ligands, while the homoleptic aldehyde complexes in **10** and the other complexes with hard coligands (water, alcohol, oxoanion) are octahedral[1]. The tetrahedral complexes are of relevance for zinc-catalyzed reactions of organic carbonyl compounds, as in organic synthesis the catalyst is most often $ZnCl_2$[3] and in the enzyme alcohol dehydrogenase the catalytic zinc has a tetrahedral $ZnNS_2O$ environment[2].

The challenge to improve this relevance faces two problems. One of them is the mostly unpredictable composition and structure of the zinc halide/aldehyde complexes. This means that reaction intermediates and catalytic pathways of zinc halide catalyzed carbonyl reactions are equally unpredictable as yet. The other is the weak attachment of the

aldehydes, which should render $ZnNX_2O$ complexes (i.e. structural models of alcohol dehydrogenase) unstable when N represents a good nitrogen donor. We have been working to overcome the latter problem, and the succeeding paper presents one possible solution[11].

Experimental Section

All preparations required strictly anhydrous conditions. The general working and measuring conditions were as in ref.[12], and the specific ones as in ref.[1]. The aldehydes were obtained commercially and distilled prior to use. The anhydrous zinc halides were prepared from zinc and HHal or Hal_2 in diethyl ether[13][14]. The new complexes were prepared following the general procedure below, details for which are given in Table 5. When they were too hygroscopic for ordinary C/H/N analysis, they were also characterized by zinc and halide analyses. Table 6 gives the analytical characterizations.

Preparation of the Complexes: The zinc halide was dissolved in a 10−20 fold excess of the aldehyde with stirring and heating. After cooling to room temp. 10 mL of dichloromethane was added. By adding 50 mL of petroleum ether (b.p. 60−70°C) a colourless precipitate was obtained, which was filtered off, washed with the petroleum ether, and dried in vacuo.

Structure Determinations[15]: Crystals were obtained by careful layering of the reaction solutions with petroleum ether (b.p. 70−90°C). They were immersed in perfluorinated polyether oil for protection and attachment to the goniometer head and immediately subjected to the nitrogen flow of the diffractometer's cooling system. Diffraction data were recorded at low temperatures with the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator. No absorption corrections were applied. The structures were solved with direct methods and refined anisotropically with the SHELX program suite[16]. The aldehyde C-H hydrogen atoms were located and refined freely. All other hydrogen atoms were in-

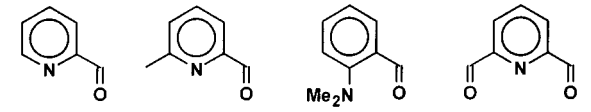
Zinc Complexes of Aldehydes and Ketones, 4[+]
Zinc Complexes of Chelating Aldehydes

Bodo Müller[a] and Heinrich Vahrenkamp*[a]

Keywords: Zinc / Aldehyde ligands / N,O Chelate ligands / Structural chemistry / Chelates



The reactions of various zinc salts with the chelating aromatic aldehydes pyridine-2-carbaldehyde, 6-methylpyridine-2-carbaldehyde, pyridine-2,6-dicarbaldehyde, and 2-dimethylaminobenzaldehyde were studied. The monoaldehydes and zinc halides yielded the tetrahedral chelate complexes $ZnHal_2$·aldehyde. Pyridine-2-carbaldehyde also formed the octahedral bis-chelate complexes $ZnHal_2$·2 aldehyde. The octahedral tris-chelate complexes $[Zn(aldehyde)_3]^{2+}$ were obtained from $[Zn(CH_3CN)_6](SbCl_6)_2$. Pyridine-2,6-dicarbaldehyde was found to be tridentate in the trigonal-bipyramidal complexes $ZnHal_2$·aldehyde. The structural variability in this system was underlined by the identification of the two unusual complexes [(pyridine-2-carbaldehyde)$_2$(H_2O)Zn–Cl–$ZnCl_3$] and [ZnI(pyridine-2-carbaldehyde)$_2$]$_2$[ZnI_4].

The importance of metal catalysis for reactions of organic carbonyl compounds in chemistry and biology, specifically by zinc compounds, has motivated us to undertake a systematic study of the interactions between the zinc ion and carbonyl-containing species. We started this study with an investigation of zinc−aldehyde complexes. The justification and scope of our work, as well as the relevant information from the literature, are summarized in our first full paper on this subject[2]. It can be stated that, to date, surprisingly little is known about the composition, structure, and bonding of metal-aldehyde adducts, be it in solution or in the solid state.

Our investigations with various zinc salts and plain aldehydes[1][2] gave rise to the conclusion that many complexes can be isolated and that they have a very rich structural chemistry, but that they are of low stability, very labile, and do not persist in solution in the presence of water or solvents of even low donor ability. We therefore sought to improve the situation by ligand design in terms of the aldehydes as well as of the coligands. Complex stabilization by chelation could be predicted to be advantageous for this purpose. We therefore used aldehydes bearing an additional nitrogen donor function, suitable for N,O chelation. A second motivation for this choice came from our attempts to model the structure and function of the enzyme alcohol dehydrogenase, in which the reacting aldehyde or alkoxide are attached to zinc as part of a ZnS_2NO donor set[3].

A search of the literature revealed that, just as for the plain aldehydes, there is very little information on the metal complexation of N,O chelating aldehydes. The only reported structural study showed that pyridine-2-carbaldehyde coordinates to CuCl only through the nitrogen atom[4]. For zinc the complex types $ZnBr_2$•2 aldehyde[5] and $Zn(SR)_2$•aldehyde[6] were described for pyridine-2-carbaldehyde, but these compounds were not structurally characterized. Structural information exists only for the somewhat related zinc halide complexes of pyridine-2-carboxylic acid esters, which contain N,O chelate rings[7]. Some work from a mechanistic point of view was reported for the zinc salt-catalyzed reduction of acyl-substituted pyridines and isoquinolines by hydride donors of the NADH type[8−10].

In order to provide a basis of isolated and structurally characterized complexes we investigated the coordinating abilities of the four typical chelating aldehydes PA, MPA, ABA, and PDA towards zinc salts. We found all four of these compounds to be suitable ligands for zinc, making ZnL, ZnL_2, and ZnL_3 complexes accessible. A small number of these results have already been described briefly[11].

2-pyridine-carbaldehyde **PA** | 6-methylpyridine-2-carbaldehyde **MPA** | 2-dimethylamino benzaldehyde **ABA** | 2,6-pyridine-dicarbaldehyde **PDA**

Preparations

The zinc halides formed 1:1 as well as 1:2 complexes with the chelating aldehydes. When a solution of the zinc halide in diethyl ether was treated dropwise with an ethereal solution of one equivalent of the aldehyde, the 1:1 complexes **1**−**3** precipitated. With pyridine-2-carbaldehyde it could be shown that the accessibility of the 1:1 complexes depends on the presence of sub-stoichiometric amounts of the aldehyde in solution and on its removal by precipitation. However, when the zinc halide and the aldehyde were dissolved simultaneously in the better solvent acetonitrile, the sub-

sequent crystallization yielded the 1:2 complexes **4a**−**c** regardless of the stoichiometric ratio of the reagents. Near quantitative conversion to **4a**−**c** occurred when the required 1:2 ratio was employed. Complexes **1**−**4** are stable enough to be recrystallized from organic donor solvents. Complex **4b** is the only zinc complex of a chelating aldehyde that has been described before[5].

	$ZnHal_2$•A			$ZnHal_2$•2 PA
	Hal	A		Hal
1a	Cl	PA	**4a**	Cl
1b	Br	PA	**4b**	Br
2a	Cl	MPA	**4c**	I
2b	Br	MPA		
2c	I	MPA		
3a	Cl	ABA		
3b	Br	ABA		
3c	I	ABA		

Two unexpected results pointed to the subtleties inherent in these reaction systems, despite the higher stabilities of the chelating aldehyde complexes in comparison to those of the plain aldehydes. When water was accidentally present in the reaction solution for the preparation of **1a**, complex **5** was isolated instead. **5** was subsequently prepared from $ZnCl_2$, PA, and H_2O in the ratio 2:2:1. Just like complexes **4** in comparison to complex **1**, complex **5** shows a preference for higher coordination numbers in the presence of oxygen-containing ligands. In a similar fashion complex **6**, which was isolated instead of the expected yet elusive ZnI_2•PA, shows the PA ligands to be part of the five-coordinate $[ZnL_2I]^+$ cation. In both **5** and **6** the bonding preferences of the hard and soft ligands are realized by dismutation into an N,O-coordinated zinc cation and a halide-coordinated zincate anion, albeit in quite different ways and yet different from the way chosen by the compound of composition $ZnBr_2$(4-fluorobenzaldehyde)$_2$[1].

$(PA)_2(ZnCl_2)_2{\cdot}H_2O$

5

$[(PA)_2ZnI]_2\ (ZnI_4)$

6

Exclusive coordination of zinc by the chelating aldehydes could be achieved when starting with zinc compounds with weakly coordinating anions. After some futile attempts with fully dehydrated zinc nitrate, tetrafluoroborate, or perchlorate[2] or the hexaethanol zinc complex, it was found that hexa(acetonitrile)−zinc−bis(hexachloroantimonate)[12] is a suitable starting material. Treatment of this compound with the aldehydes PA and MPA resulted in the formation of the 1:3 complexes **7** and **8**. Although **7** and **8** could not be obtained as X-ray quality crystals, their constitution is confirmed by the spectra (see below), which indicate coordination of all N and O donors to zinc, thus implying octahedral ZnL_3 cations.

$[Zn(A)_3][SbCl_6]_2$

7: A = PA; **8**: A = MPA

As expected, the doubly chelating bis-aldehyde ligand PDA formed 1:1 complexes with the zinc halides. Complexes **9a**−**c** resulted from adding a solution of the ligand to a solution of the halide in ether. While we are aware of no other metal complex of PDA, the corresponding Schiff bases are popular ligands, and some zinc halide complexes are known from them[13]. As could be predicted, such complexes, like **9a**−**c**, are trigonal-bipyramidal with the halide ligands in equatorial positions.

$ZnHal_2$•PDA

9a: Hal = Cl; **9b**: Hal = Br; **9c**: Hal = I

Structures

The simplest complex type, $ZnHal_2$•aldehyde, was characterized by the structure determinations of **2b** and **2c**. Figure 1 shows that the aldehyde acts as a symmetrically chelating ligand with similar Zn−N and Zn−O bond lengths. The chelate ring is planar and is also coplanar with the aromatic ring. The $ZnHal_2$ plane is perpendicular to the ZnNO plane, i.e. tetrahedral coordination is realized to a good approximation. However, as is usual due to the geometrical restraints of the chelate ring, the N−Zn−O angle has a typically small value, which is compensated by a rather large Hal−Zn−Hal angle.

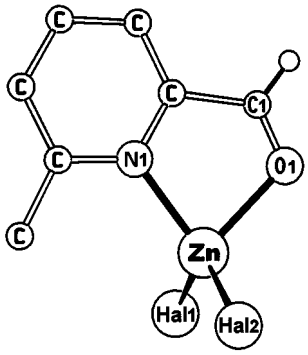

Figure 1. Molecular structure of complexes **2b** and **2c**
Relevant bond lengths [Å] and angles [°] (**2c** has two independent molecules in the asymmetric unit for which average values are given): Z−N1 2.05(2)/2.06(1), Zn−O1 2.10(1)/2.11(1), Zn−Hal1 2.334(4)/2.530(2), Zn−Hal2 2.314(3)/2.513(1), O1−C1 1.18(3)/1.21(1), N1−Zn−O1 80.3(6)/80.2(6), Hal1−Zn−Hal2 119.1(1)/122.8(3.0).

Complex **3c** shares the basic structural features of **2b** and **2c**, i.e. similar Zn−N and Zn−O bond lengths and the symmetrically distorted tetrahedral coordination of zinc (Figure 2). The six-membered chelate ring allows a larger N−Zn−O angle that is still considerably smaller than the tetrahedral angle. The six-membered chelate ring is characteristically folded along the N−O line, allowing the aromatic ring and the aldehyde function to be coplanar. This situation, however, means that unlike in all other aldehyde complexes characterized by us in this study[1][2], the zinc ion is displaced from this plane by the considerable distance

of 1.1 Å. Compared to the tetrahedral zinc halide complexes of plain aldehydes[1] the Zn−Hal distances in **2b**, **2c**, and **3c** are in the normal range, but the Zn−O distances are elongated by roughly 0.05 Å. This must be related to the presence of N donors in the molecules, which serve to better satisfy the electron-acceptor properties of the zinc ions.

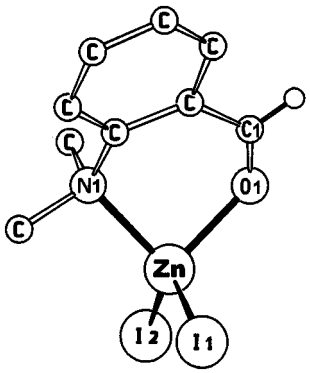

Figure 2. Molecular structure of complex **3c**
Relevant bond lengths [A] and angles [°]: Zn−N1 2.099(4), Zn−O1 2.051(3), Zn−I1 2.518(1), Zn−I2 2.518(1), O1−C1 1.222(6), N1−Zn−O1 89.3(1), I1−Zn−I2 122.07(2).

The $ZnHal_2$•2 aldehyde complexes **4a−c** crystallize with unusual molecular shapes (Figure 3). These compounds are not octahedral, as can be seen from the severe angular distortions, but their oxygen atoms are visibly oriented towards the zinc ions despite their extremely long Zn−O distances. In addition, the oxygen atoms are positioned cleanly in *trans*-positions opposite to the halide ligands such that they cannot be excluded from the ligand sphere, a situation that would render the complexes tetrahedral. Tetrahedral ZnN_2Hal_2 complexes are commonplace and, just like the tetrahedral ZnN_2S_2 complexes, define a highly preferred coordination mode. Thus it must again be concluded that the good donor qualities of the pyridine nitrogens saturate the electronic demands of the zinc ions and render further coordination by the aldehyde oxygens almost unnecessary. A similar situation was observed for zinc halide complexes of pyridine-2-carboxylic esters[7] with Zn−O distances ranging from 2.38 to 2.50 Å as compared to 2.48−2.54 Å seen here. In the pyridine-ester complexes, just as in our pyridine-aldehyde complexes, the zinc−halide distances are characteristically longer than in the tetrahedral zinc halide complexes, e.g. of the plain aldehydes[1], in accord with the higher coordination number of zinc.

The weak N−O coordination characteristic of **4a−c** is not observed in the unique complexes **5** and **6**, see Figures 4 and 5. Both **5** and **6** contain cationic units bearing two chelating aldehyde ligands attached to zinc of coordination number 5 or 6 together with anionic $ZnHal_4$ units. In **5** cation and anion are halide bridged, in **6** the ZnI_4 anions are isolated. The Zn−O distances in **5** and **6**, with an average length of 2.25 Å, are longer than those in the tetrahedral complexes **2** and **3** (see above) and also those in octahedral complexes of the plain aldehydes[2], but they are not significantly outside the range for octahedral zinc. Thus,

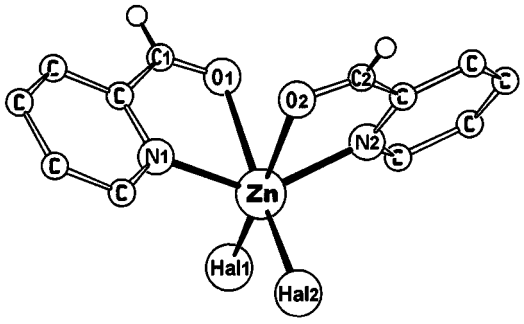

Figure 3. Molecular structures of complexes **4a−c**
Relevant bond lengths [A] and angles [°] for **4a/4b/4c**: Zn−N1 2.108(7)/2.102(15)/2.102(5), Zn−N2 2.108(7)/2.111(14)/2.117(4), Zn−O1 2.481(6)/2.498(14)/2.483(4), Zn−O2 2.544(7)/2.525(14)/2.532(4), Zn−Hal1 2.301(3)/2.450(3)/2.661(1), Zn−Hal2 2.300(3)/2.441(3)/2.665(1), O1−C1 1.20(1)/1.19(3)/1.21(1), O2−C2 1.22(1)/1.20(2)/1.21(1), N1−Zn−N2 137.7(3)/135.9(6)/136.8(2), O1−Zn−O2 80.8(2)/83.3(5)/85.8(2), Hal1−Zn−Hal2 130.7(1)/102.9(1)/101.92(3), N1−Zn−O1 72.2(2)/71.7(5)/72.1(2), N2−Zn−O2 71.0(2)/70.9(5)/71.6(2).

although the weakening of the Zn−O bonds due to the presence of the Zn−N bonds is observed, it is less pronounced because the zinc ions, due to the cationic nature of the complexes, are better electron acceptors than those in complexes **2**, **3**, or **4**. Although complexes **5** and **6** are both the first examples of their kind, their structural patterns are not singular. Both halide bridging between octahedral and tetrahedral zinc[14] and bis(chelate)-mono(halide)-zinc cations of square-pyramidal geometry[15] have been observed before.

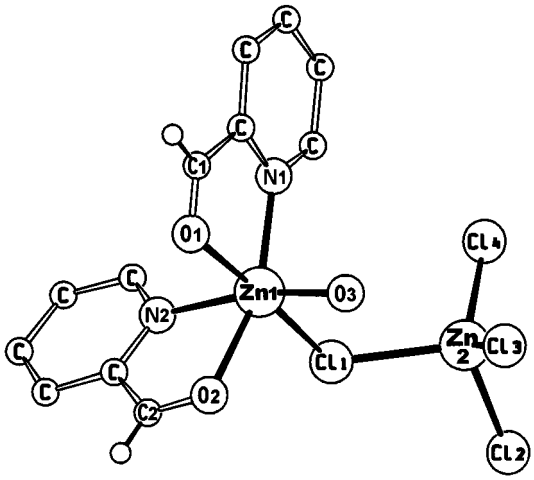

Figure 4. Molecular structures of complex **5**
Relevant bond lengths [Å] and angles [°]: Zn1−N1 2.087(3), Zn1−N2 2.108(3), Zn1−O1 2.244(3), Zn1−O2 2.267(3), Zn1−O3 2.024(3), Zn1−Cl1 2.394(1), Zn2−Cl1 2.366(1), Zn2−Cl2 2.258(1), Zn2−Cl3 2.259(1), Zn2−Cl4 2.202(1), O1−C1 1.201(5), O2−C2 1.209(5), N1−Zn1−O1 77.1(1), N2−Zn1−O2 75.3(1), N1−Zn1−O2 156.7(1), N2−Zn1−O3 163.8(1), O1−Zn1−Cl1 176.0(1).

Complexes **9a** and **9b** belong to the group of trigonal-bipyramidal $LZnX_2$ complexes in which L represents a doubly chelating tridentate ligand. Close relatives of **9a** are $LZnCl_2$ with L = terpyridyl[16] and L = 2,6-diacetylpyridinedioxime[17]. These complexes share the coplanar nature of the whole ligand L and the severe deviation of the axial

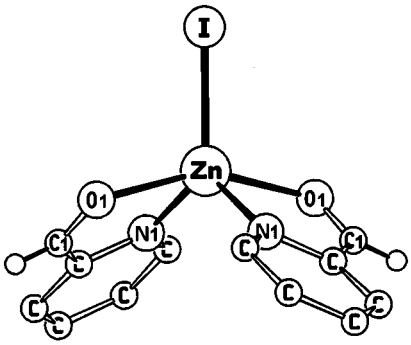

Figure 5. Structure of the cations of compound **6**
Relevant bond lengths [Å] and angles [°]: Zn−N1 2.06(1), Zn−O1 2.25(1), Zn−I 2.515(4), O1−C1 1.19(2), N1−Zn−O1 76.8(5), N1−Zn−N1′ 116.5(8), O1−Zn−O1′ 154.6(8), N1−Zn−O1′ 89.8(5), N1−Zn−I 121.8(4), O1−Zn−I 102.7(4).

ligand arrangement from linearity. However, while in the latter two complexes the axial zinc-ligand bonds (in both cases Zn−N) are not significantly longer than the equatorial Zn−N bond, the opposite is the case for **9a** and **b** (Figure 6). The Zn−O bonds are, on average, 2.34 Å long and are therefore halfway between those in tetrahedral **2** or **3** and octahedral **4**. As in complex **2** or **3** only a single nitrogen donor is present, but as is the case in **4** two aldehyde oxygen donors compete for the remaining acceptor strength of the zinc ion. Like in all other complexes described in this paper, the aldehyde C=O bond lengths do not reflect the variable strength of the Zn−O interactions. They all have lengths of around 1.21 Å with very little variation.

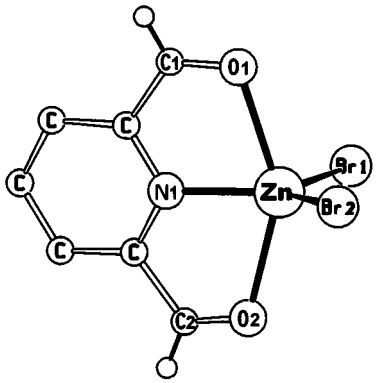

Figure 6. Molecular structure of complexes **9a** and **9b**

Spectroscopy

Upon coordination to transition metals, the intense IR ν(CN) band of pyridine-derived ligands is shifted by about 10 to 50 cm^{-1} to higher wavenumbers[18][19]. This shift is observed in the +20 cm^{-1} category here, proving the expected Zn−N coordination of the pyridine-derived aldehydes (Table 1). Conversely, the aldehyde-ν(CO) band is shifted by about 50 cm^{-1} to lower wavenumbers in zinc complexes of the plain aldehydes[1][2]. Shifts to lower wavenumbers are also observed here. They are in the 40−50 cm^{-1} range for those complexes (**1**−**3**, **5**, **6**) in which, according to the structure determinations, the Zn−O interactions are strong or medium. The shifts are typically smaller when the Zn−O interactions are known to be weak (complexes **4**, **9**). For the presumably octahedral ZnN_3O_3 complexes **7** and **8** there seem to be good interactions according to the IR data. Some spectra are further complicated as far as this interpretation is concerned by showing ν(CO) bands that are split into two maxima. As this occurs irregularly and the intensity of the second band varies significantly we refrain from interpreting this observation in terms of structural details or crystal packing phenomena.

[a] NMe_2 signal.

tra that are almost identical to those of the free aldehydes, thereby supporting the suspicion that the complexes dissociate in solution, all pyridine-aldehyde complexes display significant coordination shifts for the signals of the groups in the vicinity of the donor atoms N and O. In particular, the proton resonances of the aldehyde CHO groups and the ^{13}C resonances of the pyridine-C_α carbon atoms provide important evidence that the aldehyde function is coordinated to zinc in all cases, even in solution.

Discussion

The results of this work have verified the assumption that the chelate effect will lead to more stable and more inert zinc−aldehyde complexes. Unlike the complexes of the plain aldehydes, compounds **1**−**9** do not require a large excess of the aldehyde to be isolable, they result from stoichiometric amounts of the reagents in solution, they can be recrystallized from donor solvents (e.g. THF), and their NMR spectra indicate the persistence of the zinc-aldehyde binding in solution. With the exception of **5** and **6** their structures can be deduced from their compositions by assuming coordination of all donor groups. Accordingly, the structure proposed for **4b**, the only previously reported zinc complex of a pyridine aldehyde[5], was confirmed.

While the Zn−N coordination is essential for the existence of the complexes, it is also the reason for weaker Zn−aldehyde interactions. Only in the 1:1 complexes **1**−**3** are the Zn−O bonds as strong (i.e. short) as in the Zn-aldehyde complexes without N-donor ligands[1][2]. These complexes can, however, only be isolated by precipitation from solutions with low pyridine aldehyde concentrations, and when dissolved complexes **1** undergo dismutation with formation of complexes **4**. Similarly, compound **6**, having a 1:2 (zinc/aldehyde) composition in its complex cation, was the only isolable product in attempts to prepare the elusive ZnI_2•PA. This preference for the 1:2 over the 1:1 composition is a reflection of the high stability of ZnN_2X_2 species, where N represents a heteroaromatic nitrogen donor and X e.g. a halide, in zinc complex chemistry.

By adjusting the reaction conditions and the nature of the coligands, zinc complexes with one, two, or three chelating aldehydes were accessible, e.g. **1a**, **4a**, and **7** for pyridine-2-carbaldehyde. Tetrahedral, square-pyramidal, and octahedral coordination of zinc has been observed. Most typical for the chelating aldehydes are the distorted coordination geometries between tetrahedral and octahedral, as exemplified by complexes **4**, and this phenomenon is caused by the strong Zn−N and weak Zn−O interactions. The distortion is most pronounced for complexes **4** because without Zn−O interactions these complexes would be very stable tetrahedral complexes of the ZnN_2Hal_2 type. On the other hand, the absence of a second nitrogen donor makes Zn−O binding stronger and hence complexes **1**−**3** are less distorted, and likewise complexes like **5** or **7**, bearing the chelating aldehyde bound to a cationic ZnL_6 species, have stronger Zn−O interactions and hence more symmetrical coordinations due to the higher electron acceptor strength of the zinc ion. Similar observations have been made for zinc halide complexes of pyridine-2-carboxylic esters[7].

The structural variability of the complexes reported here is much greater than that of the complexes of the plain aldehydes[1][2]. The latter invariably form octahedral complexes in the absence of halide and tetrahedral complexes with halides as coligands. In the compounds reported here, halide can be coligand in tetrahedral (**1**−**3**), five-coordinate (**6**), and octahedral (**5**) complexes. As discussed above, the composition of the compounds as well as the reaction conditions influence the specific geometry. The subtleties governing this are demonstrated by the formation of **6** instead of the elusive ZnI_2•PA as well as the fact that 2-dimethylaminobenzaldehyde forms only the 1:1 complexes **3** but not 1:2 complexes like **4**. A variation of this theme concerns the dismutation reactions of some of the zinc halide complexes into cationic zinc-aldehyde and anionic zinc halide constituents, of which the latter again show structural variability by existing as isolated $ZnHal_4^{2-}$ (**6**), halide bridged $ZnHal_4^{2-}$ (**5**) or even isolated $Zn_2Hal_6^{2-}$ [together with a $Zn(aldehyde)_6^{2+}$ cation][1].

In terms of activation of the carbonyl function for catalytic reactions, the complexes described here offer important information by their variable Zn−O (aldehyde) interactions. In the complexes of the plain aldehydes, octahedral coordination agrees with Zn−O distances close to the average of 2.09 Å[2] and tetrahedral coordination with Zn−O distances averaging 2.04 Å[1]. In contrast, in the compounds reported here Zn−O bond lengths ranging from 2.05 to 2.54 Å are observed with no systematic correlation between distance and coordination number. There is, however, a correlation between Zn−O bond length and the donor/acceptor situation at the zinc ion. In complexes **1**−**3** a single nitrogen donor provides the zinc ion with insufficient electron density and hence the Zn−O bonds are short (ca. 0.05 Å above the tetrahedral reference value). On the other hand

complexes **4** would be able to exist as four-coordinated ZnN_2Hal_2 species, i.e. Zn−O coordination is not required and hence is weak (Zn−O distances ca. 0.40 Å above the octahedral reference value). Complexes **5** and **6**, as discussed above, are intermediate cases (with Zn−O distances ca. 0.15 Å above average). Complexes **9** can be referenced against complexes **1**−**3**. In the latter compounds one nitrogen and one oxygen donor both experience good Zn−O(N) interactions, while in **9** two oxygen donors have to share the remaining bonding capacity, resulting in clearly weaker Zn−O interactions (bond lengths ca. 0.25 Å above average). These variations in the Zn−O interactions are in part reflected by the IR data, which demonstrate a congruous variation of the C=O bond strengths. Thus the electronic situation of the "catalytic" zinc ion visibly influences the electronic modification of the aldehydic C=O functions, which should become effective in terms of reaction rates or reaction pathways.

In terms of modelling the enzyme alcohol dehydrogenase, complexes **1**−**3** represent an advancement as they contain Zn−O(aldehyde) together with Zn−N(heteroaromatic) coordination in the tetrahedral $ZnHal_2NO$ pattern. The realization of the enzyme-like ZnS_2NO pattern with the pyridine-aldehyde ligands calls for a replacement of the halide ligands by thiolate ligands. This has already been reported by Bochmann[6], yet without the support of a structure determination. Our own work using the chelating aldehydes and $Zn(SC_6F_5)_2$, including X-ray structural studies, will be published shortly[20].

Experimental Section

The general working and measuring conditions were as in ref.[21], the specific conditions as in ref.[2]. The aldehydes were obtained commercially and distilled or recrystallized prior to use. The anhydrous zinc halides were prepared from zinc and HHal or Hal_2, respectively, in diethyl ether[22][23], $[Zn(CH_3CN)_6]$ $[SbCl_6]_2$ was prepared according to the published procedure[12]. The new complexes were prepared following the general procedure below, details for which are given in Table 4. Table 5 gives details of the analytical characterizations.

Preparation of the Complexes: The zinc salt was dissolved in the organic solvent. The chelating aldehyde was added as a solution in diethyl ether with stirring. The resulting complex either precipitated immediately or after cooling the hot solutions to room temperature. After filtration the product was washed with petroleum ether (b.p. 60−70°C) and dried in vacuo.

Structure Determinations[24]: Crystals of **3a**−**c** were obtained by dissolution in CH_2Cl_2, all others by dissolution in THF/CH_2Cl_2

(1:1). Careful layering with petroleum ether (b.p. 70−90°C) and storage of the sample in a vibration-free place yielded well-shaped crystals. These crystals were immersed in perfluorinated polyether oil for protection and attachment to the goniometer head and immediately subjected to the nitrogen flow of the diffractometer's cooling system. Diffraction data were recorded at low temperatures with the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator. No absorption corrections were applied. The structures were solved by direct methods and refined anisotropically with the SHELX program suite[25]. The aldehyde C−H hydrogen atoms were located and refined freely. All other hydrogen atoms were in-

cluded with fixed distances and isotropic temperature factors 1.2 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma F_o - F_c / \Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL[26]. Table 6 lists the crystallographic data.

1,1′-Bis(stannyl)- and 1,1′-Bis(chlorostannyl)ferrocenes Studied by Multinuclear Magnetic Resonance, Temperature-Dependent ^{57}Fe- and ^{119}Sn-Mössbauer Spectroscopy, and Electrochemistry

Max Herberhold,*[a] Wolfgang Milius,[a] Udo Steffl,[a] Klaus Vitzithum,[a] Bernd Wrackmeyer,*[a] Rolfe H. Herber,[b] Marco Fontani,[c] and Piero Zanello[c]

Keywords: Sandwich complexes / Iron / Tin / NMR spectroscopy / Mössbauer spectroscopy / Electrochemistry

The 1,1′-bis(chlorostannyl)-substituted ferrocenes $Fe(C_5H_4–SnMe_2Cl)_2$ (**2**), $Fe(C_5H_4–SnMeCl_2)_2$ (**3**) and $Fe(C_5H_4–SnCl_3)_2$ (**4**) were prepared, starting from 1,1′-bis(trimethylstannyl)ferrocene (**1**). Treatment of the chlorides with $Li[AlH_4]$ afforded the 1,1′-bis(hydridostannyl)-subsituted ferrocenes $Fe(C_5H_4–SnMe_2H)_2$ (**5**), $Fe(C_5H_4–SnMeH_2)_2$ (**6**) and $Fe(C_5H_4-SnH_3)_2$ (**7**), respectively. All complexes **1**–**7** were studied by ^{1}H-, ^{13}C-, and ^{119}Sn-NMR spectroscopy with 1D and 2D techniques. The compounds **1**–**4** were investigated by temperature-dependent ^{119}Sn- and ^{57}Fe-Mössbauer spectroscopy. The electrochemistry of **1**–**5** gave evidence of reversible one-electron oxidation processes. The molecular structure of 1,1′-bis(trichlorostannyl)ferrocene (**4**) was determined by X-ray structural analysis, and there was no indication of intra- or intermolecular Sn···Cl···Sn interactions. This direct structural information proved to be consistent with both the Mössbauer and the solution NMR spectroscopic data.

1. Introduction

In spite of the multifaceted chemistry of organotin compounds,[1] ferrocene derivatives bearing stannyl substituents at the cyclopentadienyl rings have received only scant attention.[1−4] Recent interest has focused on ferrocenophanes with one,[5] two,[6] and three[6,7] diorganostannylene moieties in the bridge. Other [3]ferrocenophanes with tin atoms in 1,3-positions and chalcogen,[7,8] nitrogen,[9] phosphorus,[9] or arsenic[9] in 2-position have been reported. The 1-stanna-[1]ferrocenophane undergoes ring-opening polymerization,[5,10] and transition-metal fragments can be inserted into the Sn−C(1) bond by oxidative addition.[11] The reaction of 1,2-distanna-[2]ferrocenophane with $Pt(C_2H_4)(PPh_3)_2$ provides access to 1,3-distanna-2-platina-[3]ferrocenophanes,[12,13] which are examples of the active intermediates in the Pt^0-catalyzed distannation of alkynes.[6,14,15]

In the present work we report on the synthesis and properties of potential precursors of ferrocenophanes containing two tin atoms, the 1,1′-disubstituted ferrocenes **1** bearing trimethylstannyl groups ($SnMe_3$), **2**−**4** bearing chlorostannyl groups ($SnMe_2Cl$, $SnMeCl_2$, and $SnCl_3$), and **5**−**7** bearing hydridostannyl groups ($SnMe_2H$, $SnMeH_2$, SnH_3) (Scheme 1). Obviously, all these ferrocene derivatives can serve as starting materials for novel organotin compounds. Their structures are of interest with respect to intra- and intermolecular interactions through chloro or hydrido bridges between tin atoms. Therefore, we have studied the compounds **1**−**7** by NMR spectroscopy in solution, by temperature-dependent ^{57}Fe- and ^{119}Sn-Mössbauer spectroscopy (**1**−**4**), by X-ray crystallography (**4**) and by electrochemical techniques (**1**−**5**).

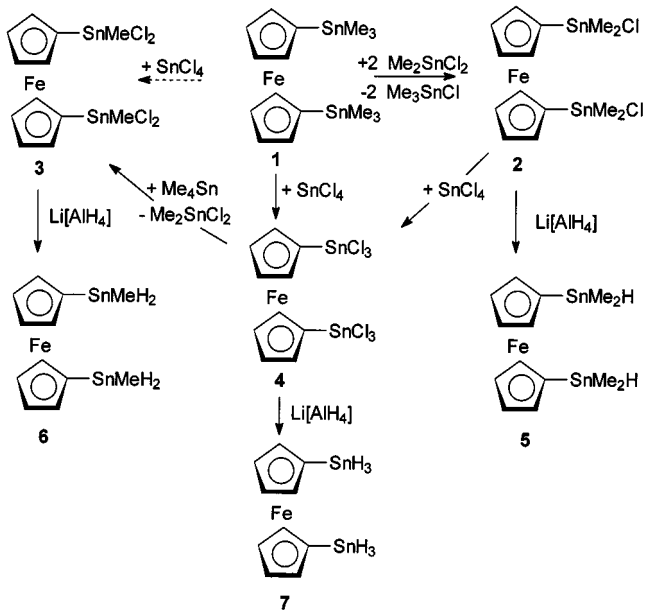
2. Results and Discussion

2.1. Syntheses



1,1′-Bis(trimethylstannyl)ferrocene (**1**) served as starting material for all preparative work. It reacts with tin tetrachloride to give the complexes **2**−**4** as stable products which can be isolated and purified by recrystallization from hexane or pentane. However, as shown in Scheme 1, the compounds **2**−**4** are obtained in higher yield and purity by using a slightly different approach. Thus, the reaction of **1** with dimethyltin dichloride affords **2** in ca. 90% yield; the properties of **2** are in agreement with those reported previously.[3f] Both **1** or **2** react with an excess of tin tetrachloride to give **4**, whereas **3** is best accessible in the pure state by the reaction of **4** with tetramethyltin in a 1:1 ratio.

Treatment of the chlorides **2**−**4** with $Li[AlH_4]$ in ether at 0°C (**5**) or −30°C (**6**, **7**) affords the tin hydrides **5**−**7**. These are more labile than the parent chlorides and were isolated as orange-yellow oils. Although they were pure according to the NMR spectra, they could not yet be crystallized.

2.2. NMR-Spectroscopic Studies

All NMR spectra (Table 1) support the proposed structures of **1**−**7**. No indication of intermolecular association can be found in C_6D_6 or $CDCl_3$ solutions. Chemical shifts and coupling constants vary in such a regular way that intramolecular interactions between the stannyl groups also

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434−1948/99/0101−0145 $ 17.50+.50/0

Scheme 1. Synthesis of complexes **2**−**7**

appear to be unlikely. Thus, intramolecular hydride exchange between the two tin atoms in **5**−**7** must be slow on the NMR time scale, since the magnitude of the coupling constants $|^1J(^{119}Sn,^1H)|$ is observed in the usual range [e.g. $PhSnH_3$: $^1J(^{119}Sn,^1H)$ = 1920 Hz[16]]. $^1H/^1H$-NOE difference spectra[17] show the proximity of the methyltin groups to the hydrogen atoms in 2,5- and 2′,5′-positions of the cyclopentadienyl rings, as expected, but also to the hydrogen atoms in 3′,4′- and 3,4-positions. This indicates that the stannyl groups on average avoid close mutual contacts.

^1H- and ^{13}C-resonance signals of the ferrocene unit were assigned on the basis of 2D heteronuclear $^{13}C/^1H$ shift correlations, of ^{13}C-^{13}C coupling constants (e.g. in **4**, as has been described for **1**[4]), and of the consistent trend in the ^{119}Sn-^{13}C coupling constants. The signal-to-noise ratio of the ferrocene-$^{13}C(1,1')$ resonances was much improved by using the refocused INEPT pulse sequence[18] based on $^{2,3}J(^{13}C,^1H)$, as has been suggested previously.[19] The observation of relevant cross peaks for ^{119}Sn satellites in the 2D experiments[20] revealed that the signs of the coupling constants $^3J[^{119}Sn,^1H(2,5)]$, $^4J[^{119}Sn,^1H(3,4)]$, $^2J[^{119}Sn,^{13}C(2,5)]$, and $^3J[^{119}Sn,^{13}C(3,4)]$ are alike. A typical example is shown in Figure 1. Taking into account the negative sign of $\gamma(^{119}Sn)$ and the presumably negative sign of $^3J(^{119}Sn,^1H)$ or $^3J(^{119}Sn,^{13}C)$ (reduced coupling constants $^3K > 0$), all these coupling constants should be < 0.

The changes in the coupling constants $^1J(^{119}Sn,^{13}C)$ in **1**−**4** are best explained by the concept of rehybridization[21] as a consequence of replacing the methyl groups in **1** by the more electronegative chloro substituents. The "s character" of the remaining Sn−C hybrid orbitals increases with increasing number of Sn−Cl bonds. The analogous trend, although less pronounced, is found in the case of the hydrides. An increasing number of Sn−H bonds leads to larger coupling constants $^1J(^{119}Sn,^{13}C)$. At the same time, the magnitude of $^1J(^{119}Sn,^1H)$ increases from **5**−**7**.

The tin chemical shifts $\delta^{119}Sn$ are known to be extremely sensitive even to weak associative interaction.[16] In the case of compounds **1**−**7**, only small changes in the $\delta^{119}Sn$ values result from solvent effects, dilution, or changes in temperature. The similarity between phenyl and ferrocenyl groups is reflected by the $\delta^{119}Sn$ data, e.g. of **1** (−4.2) and $PhSnMe_3$ (−28.6[16]), **4** (−23.2) and $PhSnCl_3$ (−63[16]), and **7** (−330.7) and $PhSnH_3$ (−320[16]). Spin-spin coupling between ^{119}Sn and ^{117}Sn nuclei was not observed in the complexes **1**−**7**. Altogether, the $\delta^{119}Sn$-NMR data indicate negligible inter- or intramolecular interactions in **1**−**7**.

2.3. X-ray Structural Analysis of 1,1′-Bis(trichlorostannyl)ferrocene 4

In addition to the ferrocenophanes mentioned in the introduction, there is only one report of an X-ray analysis of a 1,1′-bis(stannyl)ferrocene, namely 1,1′-bis(triphenylstan-

nyl)ferrocene.[22] In this complex, the stannyl groups are in *trans* positions, and the torsional angle τ between the cyclopentadienyl rings is 163.4(4)° (with respect to the positions of the substituted cyclopentadienyl carbon atoms). To the best of our knowledge, there is also just one example of a molecular structure of an organotin trichloride, namely methyltin trichloride, in which the surroundings of the tin atoms correspond to compressed tetrahedrons [CSnCl 120.3(3), 113.5(1)°; ClSnCl 103.58(6)°], and weak intermolecular Sn···Cl···Sn interactions [d_{Sn-Cl} = 371.4(2) pm] are proposed in order to account for the arrangement of the $MeSnCl_3$ molecules in infinite chains.[23] The molecular structure of **4** is depicted in Figure 2 together with selected bond lengths and angles.[24] The $SnCl_3$ groups are not in *trans* positions; the torsional angle τ between the cyclopentadienyl rings is 85.3°. All intramolecular Sn···Cl···Sn contacts must be extremely weak [shortest distance d_{Sn-Cl} = 526 pm], and the same is true for intermolecular contacts [shortest distance d_{Sn-Cl} = 395 pm] in spite of the infinite chains built by molecules of **4**, as shown in Figure 3. Figure 3 also shows the separation of the $SnCl_3$ from the ferrocene parts in the crystal structure. The distortion from tetrahedral symmetry around the tin atoms in **4** is even less than in $MeSnCl_3$. The complete absence of intramolecular Sn···Cl···Sn bridging in **4** is surprising, since this type of

bonding is well established in other organotin halides, e.g. in tris(dialkylhalostannyl)amines.[25]

2.4. ^{57}Fe- and ^{119}Sn-Mössbauer Spectroscopy

The Mössbauer parameters at 90 K as well as their temperature dependencies are summarized in Table 2. All of the ^{57}Fe-resonance spectra consist of well-resolved doublets having isomer shifts (I.S.) of about 0.52−0.53 mm s^{-1} at 90 K and quadrupole splittings (Q.S.) of 2.3 mm s^{-1}. These values are characteristic[26] of ferrocenyl moieties in which each cyclopentadienyl ring is ligated by a single σ bond to a main-group atom, including Sn, and are otherwise not remarkable. A typical spectrum (of **4** at 90 K) is shown in the upper part of Figure 4. The M_{eff} values, calculated[27] from the temperature dependence of the I.S. parameter fall in the range of 112−142 Da, consistent with the predomi-

nantly covalent character of the ferrocenyl ligand bond. As noted previously,[28] the Q.S. is temperature-insensitive and reflects primarily the thermal expansion coefficients of the covalent lattice.

With the exception of the results for **1**, the ^{119m}Sn-Mössbauer spectra also consist of well-resolved doublets, and these data (at 90 K) are again summarized in Table 2. A representative spectrum (of **4** at 90 K) is shown in the lower half of Figure 4. In contrast, the ^{119m}Sn-Mössbauer spectrum of **1** appears to consist of a single resonance maximum, despite the obvious lack of cubic symmetry around the metal atom. This lack of a resolvable quadrupole splitting in the case where the Sn^{IV} atom is ligated to nearest-neighbor atoms lacking nonbonding lone pairs has been extensively discussed in the literature.[29−33] When lone-pair electrons are present on the atom(s) σ-bonded to the Sn, a π-electron back donation into empty 6p orbitals of the tin atom is assumed to give rise to a large electric field gradient at the metal center. In the present case, the three $Sn-CH_3$ and the single $Sn-C_{Cp}$ bonds, although clearly not of T_d symmetry, give rise to four sp^3-hybrid orbitals on the tin atom which are sufficiently similar to produce a very small field gradient at the Mössbauer-active atom site. Using a Lorentzian line shape minimization procedure, the quadrupole splitting at 90 K is calculated to be ca. 0.30(2) mm s^{-1}; that is less than the natural line width.

The other three compounds **2**−**4** represent an interesting series of bonding interactions, especially with respect to the field gradients generated by the σ and π bonds around the metal center. In previous studies of organotin chlorides, the question of the effect of coordination around the Sn atom has always posed a complication in the interpretation of the relevant Mössbauer data. Thus, Me_3SnCl, which is monomeric in the vapor phase,[34] is polymeric in the solid[35] with a distorted trigonal-bipyramidal environment around the Sn atom. Similarly, the X-ray diffraction data for Me_2SnCl_2[36] reflect a sixfold coordination around the Sn atom, in which two chlorine atoms bridge adjacent Sn atoms and the two methyl groups occupying axial positions around the quasi-octahedral metal atom. Recent X-ray diffraction data[23] for $MeSnCl_3$ have been referred to above and indicate weak intermolecular Sn−Cl−Sn bonding to

Representative Mössbauer spectra for **4** at 90 K; the upper trace is that of the ^{57}Fe-resonance effect, while the lower trace is that for the ^{119}Sn resonance; the full lines are the fitted data to the experimental points with each component of the doublet fitted separately; the velocity scales are relative to the centroid of a metallic iron absorbance (upper trace) and a $BaSnO_3$ absorber spectrum absorbance (lower trace) at room temperature

account for the infinite chain formation suggested by the NQR data of Petrosyan et al.,[37] but the theoretical calculations of Manning and Grodzicki[38a] and Grodzicki et al.[38b] have assumed four-coordinate metal centers in their discussion of the Q.S. and I.S. parameters of this molecule. Clearly, these variable coordinations around Sn complicate the interpretation of the Mössbauer parameters of the methyl Sn halides. In the present series of compounds, in which the bulky nature of the ferrocenyl ligand(s) clearly precludes coordination numbers larger than 4, this complication is obviated. The absence of a resolvable Q.S. in the Sn spectra of **1** has already been noted (above). The readily observed non-zero Q.S. parameter for **2**, **3**, and **4** is readily accounted for by the π back-donation effect, and the relative similarity of the Q.S. parameters for **2** and **4**, and its much smaller value for **3**, is consistent with this rationalization. Thus, **2** has one Sn−Cl and three Sn−C and **4** has three Sn−Cl and one Sn−C bond. The distortion from tetrahedral symmetry arising from one and three π bonds to the metal atom should have similar influences but with opposite sign on the field gradient at the metal center. The

effect of the bonding in **3** (i.e. two Sn−Cl bonds and one $Sn-C_{CH3}$ and one $Sn-C_{Cp}$ bond) is reflected in the ca. 40% reduction in the Q.S.

Finally, with respect to both the ^{57}Fe- and the ^{119}Sn-Mössbauer data, it is appropriate to observe that the temperature dependencies of the I.S., Q.S. and resonance effect (as reflected in the area under the resonance curve for optically "thin" absorbers) are all smooth, continuous functions in the temperature range from 90 to ca. 300 K. Thus, there is no evidence of either structural or crystallographic phase transitions in this interval for any of the compounds examined in this study. As can be noted in Table 2, the $-d\ln A/dT$ parameter of the ^{57}Fe resonance for **1** is significantly larger than for **2**, which in turn is larger than the value of this parameter for **3** and **4**, indicating a larger mean-square amplitude of vibration of the iron atom in **1** than in **4** under comparable conditions. Similarly (but less pronounced) is the decrease of the $-d\ln A/dT$ parameter extracted from the ^{119}Sn spectra, again reflective of a larger mean-square amplitude of vibration of the Sn atom in **1** than in **4**. This observation is clearly consistent with the fact that **1** is a liquid at room temperature, **2** is a low-melting solid, and **3** and **4** are crystalline materials, and thus the lattice temperature (as reflected in the lattice phonon spectrum) increases with the ratio of the number of chlorine to methyl group ligands in this series. However, there is persuasive evidence from the Mössbauer hyperfine parameters and their temperature dependencies that there are no significant intermolecular interactions in these complexes in the solid state, in agreement with the solution (C_6D_6 or $CDCl_3$) NMR data cited above.

2.5. Electrochemistry of 1−5

The typical redox behavior of the stannylferrocenes **1**−**5** is shown in Figure 5 for the example of $Fe(C_5H_4-SnMe_3)_2$ (**1**).

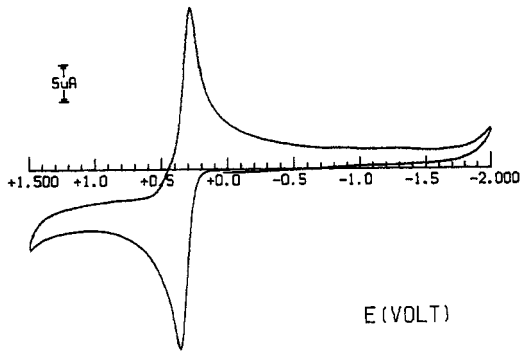

Figure 5. Cyclic voltammetric response recorded at a platinum electrode in a CH_2Cl_2 solution containing **1** ($1.1\ 10^{-3}$ mol dm^{-3}) and $[NBu_4][PF_6]$ (0.2 mol dm^{-3}); scan rate 0.2 Vs^{-1}

As expected, it is only the oxidation of the ferrocene unit which can be observed, and it is a chemically reversible process. As a matter of fact, controlled potential coulometric tests ($E_W = +0.7$ V) show the consumption of one electron per molecule. The originally yellow solution turns blue and exhibits an absorption band at $\lambda_{max} = 636$ nm which confirms the iron-centered oxidation to the ferricenium cation. The chemical reversibility of the one-electron removal is proven by the fact that the exhaustively oxidized solution of **1** displays a cyclic voltammetric profile quite complementary to that shown in Figure 5.

Analysis of the cyclic voltammetric responses with scan rates varying from 0.02 to 1.00 Vs^{-1} is diagnostic for an essentially electrochemically reversible anodic step: The current ratio i_{pe}/i_{pa} is constantly equal to unity; the current function $i_{pa}v^{-1/2}$ remains constant; the peak-to-peak separation ΔE_p slightly departs from the theoretical value of 60 mV.[41]

The same behavior is exhibited by the complexes **2**, **3**, and **5**. In contrast, although the oxidation process of **4** also appears uncomplicated on the cyclic voltammetric time scale ($E^{0\prime} = +0.73$ V), its monocation $\mathbf{4}^+$ proved to be unstable on the longer time scale of macroelectrolysis, and the electrogenerated blue solution gives rise to a reversible reduction process at $E^{0\prime} = +0.37$ V (ferrocene).

Table 3 compiles the electrochemical parameters for the oxidation process of the complexes **1**−**5**, together with some related parameters. It is easy to conclude that the formal electrode processes are exclusively governed by the inductive effects of the methyl and chloro substituents of the stannyl groups. As a matter of fact, a plot of $E^{0\prime}$ values vs. the inductive (Hammett) parameters F[42] of these substituents affords a linear correlation coefficient of 0.99, according to the equation

$$E^{0\prime}\ [V] = 0.16\ \Sigma F + 0.33$$

Table 3. Electrochemical and spectroscopic characteristics for the oxidation process of the complexes **1**−**5** in dichloromethane solution; ΣF represents the inductive effects of the substituents present in the stannyl groups

$Fe(C_5H_4-X)_2$ X =	$E^{0\prime}(0/+)$ [V]	ΔE_p[a]	λ_{max}[b] [nm]	ΣF
$SnMe_3$ (**1**)	+0.32	76	636	0.06
$SnMe_2Cl$ (**2**)	+0.46	73	634	0.88
$SnMeCl_2$ (**3**)	+0.65	92	−	1.70
$SnCl_3$ (**4**)	+0.73	70	[c]	2.52
$SnMe_2H$ (**5**)	+0.36	80	635	0.04
H	+0.37	78	620	−

[a] Measured at 0.1 Vs^{-1}. − [b] Referred to the oxidized species. − [c] See text.

3. Conclusions

Synthetic routes to 1,1′-bis(stannyl)ferrocenes are straightforward, both for chlorostannyl and hydridostannyl groups. These functionally substituted compounds should be useful starting materials for ferrocenophanes and other 1,1′-bis(stannyl)ferrocenes. There are no indications for intra- or intermolecular interactions between the stannyl groups, neither by Sn···Cl···Sn nor Sn···H···Sn bridging. This is obvious from investigations in the solid state by temperature-dependent ^{119}Sn- and ^{57}Fe-Mössbauer spec-

troscopy (**1**−**4**) and X-ray crystallography (**4**), and also in solution by multinuclear magnetic-resonance spectroscopy (**1**−**7**). The electrochemistry of **1**−**5** revealed the expected result by reversible one-electron oxidation processes involving the respective ferricenium cations.

Experimental Section

General: All compounds were handled in dry argon, and carefully dried solvents were used for syntheses and preparation of the samples for NMR measurements. Starting materials were either used as commercial products without further purification (ferrocene, Me_3SnCl, Me_2SnCl_2, $SnCl_4$, *n*-butyllithium 1.6 M in hexane) or prepared as described [$Fe(C_5H_4SnMe_3)_2$ (**1**)[4]].In general, all reactions were monitored by ^{119}Sn-NMR spectroscopy. − Electron impact (EI) mass spectra: Finnigan MAT 8500 with direct inlet. − NMR measurements: Bruker ARX 250 or DRX 500 {^{1}H, ^{13}C, ^{119}Sn NMR [inverse gated ^{1}H-decoupled or refocused INEPT spectra,[19] based on $^2J(^{119}Sn,^1H)$ = 55−75 Hz]}. Chemical shifts are given relative to Me_4Si [$\delta^1H(CHCl_3/CDCl_3)$ = 7.24, $\delta^1H(C_6D_5H)$ = 7.14, $\delta^{13}C(CDCl_3)$ = 77.0, $\delta^{13}C(C_6D_6)$ = 128.0, $\delta^{13}C(C_6D_5CD_3)$ = 20.4], and Me_4Sn [(δ^{119}Sn = 0 for $\Xi(^{119}Sn)$ = 37.290665 MHz].

X-ray Structural Analysis of 4: $C_{10}H_8Cl_6FeSn_2$; M = 634.1; orange crystal of irregular shape; size [mm] 0.35 × 0.20 × 0.18, monoclinic; space group *C*2/c, a = 12.859(2), b = 11.867(2), c = 12.212(2) Å, β = 109.21(2)°, V = 1759.6(5) Å^3, Z = 4, ρ(calcd.) = 2.394 Mg/m^3; absorption coefficient μ = 4.523 mm^{-1}, F(000) = 1184. − Data collection: Siemens *P*4 diffractometer, Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, 296 K; the single crystal was mounted in a Lindemann capillary; 2θ range 3.0−55.0°; scan type ω; reflections collected 4406, independent reflections 2026, observed reflections 1982 [$F > 2.0\ \sigma(F)$]; semi-empirical absorption correction; min./max. transmission 0.5335/1.000. − Structure solution: direct methods [SHELXTL PLUS (VMS)]; extinction correction χ = 0.00059(3), all atoms except the hydrogen atoms are described with anisotropic temperature factors, all hydrogen positions were refined by using the riding model and fixed U; weighting scheme $w^{-1} = \sigma^2(F)$; number of parameters refined 88; R = 3.29%, wR = 3.30% (observed data); largest difference peak/hole 1.74/−0.53 e/Å^3.

Mössbauer Spectra: The experimental details relating to the acquisition of both ^{57}Fe- and ^{119}Sn-Mössbauer data have been described previously.[39][40] All samples were prepared as optically thin absorbers, and mixed with BN to minimize preferential crystallite orientation with respect to the γ-ray axis of the spectrometer. The isomer shift standards used in this study are the centroids of metallic iron and $BaSnO_3$ spectra at room temperature. Spectrometer calibration was effected by the use of a 1.85 mg m cm^{-2} metallic iron absorber at room temperature. Temperature control over the period of data acquisition (generally 4−24 h, depending on temperature) was stable to better than ±0.5 K. To minimize statistical errors, more than 10^6 counts per channel were accumulated at each temperature point.

Electrochemistry: Materials and apparatus for electrochemistry have been described elsewhere.[43] All potential values are referred to the Saturated Calomel Electrode (SCE).

1,1′-Bis(chlorodimethylstannyl)ferrocene (2): A Schlenk tube was filled with $Fe(C_5H_4SnMe_3)_2$ (**1**) (1.41 g; 2.8 mmol) and Me_2SnCl_2 (1.23 g; 5.6 mmol) was added at 0°C. The mixture was heated at 140°C for 3 h while Me_3SnCl sublimed and was collected at a cooling finger (15°C). Then the mixture was cooled to room temperature and remaining traces of Me_3SnCl und Me_2SnCl_2 were removed in vacuo. A viscous dark orange oil was left which crystallized upon cooling in hexane to give an orange solid (1.4 g; 90%; m.p. 85°C). − EI MS; *m*/*z* (%): 554 (100) [M$^+$].

1,1′-Bis(dichloromethylstannyl)ferrocene (3): A two-necked flask containing $Fe(C_5H_4SnCl_3)_2$ (**4**) (1.79 g; 2.82 mmol) was cooled to 0°C and tetramethyltin (0.429 ml; 3.10 mmol, slight excess) was added. After warming slowly to 60°C, the mixture was stirred at this temperature for 4 h. After cooling, Me_2SnCl_2 and Me_3SnCl were removed in vacuo. Extraction with toluene (15 ml), filtration, removal of toluene, and washing with hexane afforded 0.79 g (65%) of a yellow solid (m.p. 126°C, dec.). − EI MS; *m*/*z* (%): 594 (100) [M$^+$].

1,1′-Bis(trichlorostannyl)ferrocene (4): Tin tetrachloride (0.9 ml; 7.54 mmol) was added to a solution of $Fe(C_5H_4SnMe_2Cl)_2$ (**2**) (1.60 g; 2.90 mmol) in CH_2Cl_2 (5 ml) and hexane (15 ml) at 0°C. The color of the reaction mixture changed rapidly from yellow to green; the mixture was stirred for 2 h at 30°C. Then all volatile material was removed in vacuo and CH_2Cl_2/hexane (1:10, v/v; 20 ml) was used to extract the product. After filtration of the yellow solution and removal of the solvents, the product **4** (1.56 g; 85%; m.p. 122°C dec.) was obtained as a yellow solid. Recrystallization from hexane afforded single crystals suitable for X-ray analysis. − EI MS; *m*/*z* (%): 634 (100) [M$^+$].

1,1′-Bis(dimethylstannyl)ferrocene (5): A solution of $Fe(C_5H_4SnMe_2Cl)_2$ (0.73 g; 1.3 mmol) in ether (20 ml) was added to a suspension of $LiAlH_4$ in ether (30 ml) at −30°C. The mixture was stirred for 5 h at room temperature. After filtration and removal of ether, a yellow oil was left (6.07g; 96%). − EI MS; *m*/*z* (%): 486 (100) [M$^+$].

1,1′-Bis(methylstannyl)ferrocene (6): A solution of $Fe(C_5H_4SnMeCl_2)_2$ (490 mg; 0.83 mmol) in ether (20 ml) was added dropwise to a suspension of $LiAlH_4$ (120 mg; 3.16 mmol) in ether (30 ml) at −30°C. The mixture was stirred for 2 h at room temperature. After removal of the solvent in vacuo, the residue was extracted with hexane, insoluble material was filtered off and hexane was removed in vacuo from the yellow-orange solution. A yellow-orange oil was left (0.37 g; 98%). − EI MS; *m*/*z* (%): 456 (30) [M$^+$].

1,1′-Bis(stannyl)ferrocene (7): The same procedure with **4** as starting material, as described for **6**, afforded **7** in almost quantitative yield as a yellow-orange oil. − EI-MS; *m*/*z* (%): 429 (30) [M$^+$].

Organometallic Compounds of Group 13, 55[+]

Novel Organoaluminum Lewis Acids via Selective Aluminum-Tin Exchange Processes – Electrophilic Initiation by the Aluminum Halide and Ensuing Complexation by the Resulting Tin Halide

John J. Eisch,*[a] Katrin Mackenzie,[a] Harald Windisch,[a] and Carl Krüger[b]

Dedicated to the memory of our most esteemed colleague, the late Professor Wilhelm P. Neumann, master of organotin chemistry[c]

Keywords: Organometallics / Aluminum / Tin / Metal-metal exchange / Electrophilic reagents / Lewis acid-base complexes

With the goals of preparing novel carbaluminating reagents and mono- and bidentate organoaluminum Lewis acids, the scope and limitations of synthesizing the requisite organoalanes by the aluminum-tin exchange between an aluminum halide and the appropriate organostannane have been examined in detail. The interactions of such tin precursors as 1,2-bis(trimethylstannyl)ethyne, allyltri-*n*-butyltin, benzyltrimethyltin, and 1,2-bis(trimethylstannyl)benzene and various aluminum chlorides of the type, R_nAlCl_{3-n} (R = Me, Et), gave selective aluminum-tin exchange at the sp- or sp^2-hybridized carbon–tin bond and produced such organoalanes as allyl(methyl)aluminum chloride, benzylaluminum dichloride, 1,2-bis(diethylalumino)ethyne, 1,2-bis(dimethylalumino)benzene, 1,2-bis[chloro(methyl)alumino]benzene, and 1,2-bis(dichloroalumino)benzene in high yield. A complicating factor was the tendency of the R_3SnCl by-product to complex with the resulting organoalane. In some cases, exemplified by allyl(methyl)aluminum chloride, such complexation did not interfere with the carbaluminating action of the reagent; in other cases, exemplified by 1,2-bis[chloro(methyl)alumino]benzene, the R_3SnCl could be removed by means of π-bases and reduced pressures; and in still other structures, as with 1,2-bis(dichloroalumino)benzene, the tin chloride could not be dislodged at moderate temperatures. The structure and bonding in such tin halide–aluminum halide complexes in solution were investigated with the 1:1 adducts of $AlCl_3$ with Me_3SnCl and with nBu_3SnCl, respectively, by means of multinuclear NMR spectroscopy. Furthermore, an XRD of the solid complex, $Me_3SnCl \cdot AlCl_3$, was carried out. Such complexes were shown to consist of 1:1 ion pairs of the type $[R_3Sn^+][AlCl_4^-]$ in dilute solution and of a chiral polymeric helix in the solid state wherein planar Me_3Sn^+ units are linked to each other via bridging tetrachloroaluminate anions, $Cl–(AlCl_2)–Cl^-$. Treatment of such complexes with either benzyltriethylammonium chloride (one or two equivalents) or tetramethylphosphonium chloride leads to the displacement of Me_3SnCl and the formation of the expected ionic complexes. Finally, the importance of such novel reagents and chelating Lewis acids to organic synthesis and olefin polymerization is discussed and elucidated.

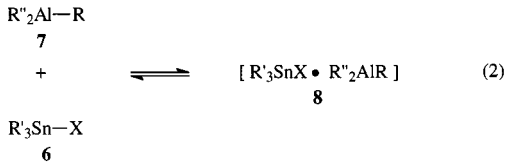
[c] Professor W. P. Neumann was born in Würzburg, Germany, on October 29, 1926. Upon the completion of studies on pyrimidopyrimidines with Professor F. G. Fischer at the University of Würzburg in 1952, he was awarded the degree Dr. rer. nat. Thereafter, he was postdoctoral research associate with Nobel Laureate Karl Ziegler with whom he embarked on his lifelong study of organotin chemistry. After habilitation on this theme at the University of Gießen in 1960, he served on the same faculty as Außerplanmäßiger Professor until 1968. He joined the faculty of the University of Dortmund in 1969 as Ordinary Professor of Organic Chemistry and until his formal retirement in 1992 he was chiefly responsible for developing the Organic Chemistry Institute of this new university. His research and scholarly work on the organometallic chemistry of tin and germanium and on organic intermediates, such as free radicals and carbenes, were reported in over 250 articles and reviews. At the time of his death on August 3, 1993 he was still at the forefront of the organic chemistry of tin, a research area on which he had composed a monograph as a young scientist (1970, Wiley) and whose high relevance to the whole field of organic chemistry his career in research has made manifest. We, his colleagues, will always fondly remember his great scientific zest and his extraordinary human warmth.

In continuing investigations directed toward the synthesis of novel Group 13 Lewis acids suitable as cocatalysts with cyclopentadienyl transition metal derivatives for Ziegler−Natta olefin polymerization catalysis, we have sought ways of preparing unsymmetrical organometallics of Group 13 whose Lewis acidity might be enhanced either by the electron-withdrawing nature of the substituent E in **1** or by the chelating effect of two proximally arrayed Lewis acid metal centers M in **2**. In the previous article of this series the possible effect of such Lewis acidity enhancing factors in selected organoboranes was examined.[1] This present study has explored the Lewis acidity of analogous unsymmetrical organoaluminum compounds in the well-established expectation that such organoaluminum analogs would exhibit greater Lewis acidities than their boron counterparts for steric and electronic reasons:[2] the smaller covalent radius of boron versus aluminum (B, 81 pm versus Al, 125 pm) increasing the steric hindrance or F-strain upon complexation (**3**) and any $p_\pi-p_\pi$ back-bonding from ligands (E) on the boron center, such as unshared electron pairs (E = X, RO, or R_2N), decreasing the boron center's Lewis acidity.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434−1948/99/0101−0153 $ 17.50+.50/0

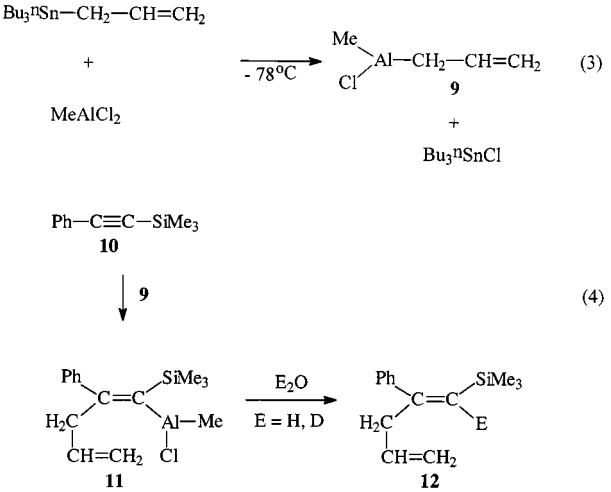


As a preparative route to such unsymmetrical organoaluminum reagents, we have availed ourselves of the selective exchange occurring between organotin compounds and aluminum halides (Equation 1).[3] Such exchanges are potentially reversible depending on the nature of the organyl substituents and on experimental conditions. Where R, R′, and R′′ are alkyl, the reaction proceeds to the left and produces tetraalkyltin compounds.[4] In the present case of interest, the reaction has been found to lead selectively to the right, producing **7**, when R in **4** is an organyl group more electronegative than alkyl, such as allyl, benzyl, aryl, or 1-alkynyl. Furthermore, the extent of tin-aluminum exchange can in some instances be feasibly controlled by removing one of the components of the equilibrium in Equation 1 from the reaction zone by volatization or complexation, in accord with LeChatelier′s principle.[5]

(1)

Because of the greater Lewis acidity of such organoaluminum derivatives, compared with their organoboron analogs, a serious complication occurs when utilizing such tin-aluminum exchanges for preparing unsymmetrical organoalanes (**7**, Equation 1): namely the organoalane **7** usually complexes more or less firmly with the organotin halide byproduct **6** (Equation 2). Such complexation (**8**) generally does not interfere in preparative tin-boron exchanges,[1] most likely because of destabilizing F-strain in such complexation (cf. **3**). This complexation in tin-aluminum exchanges (**8**) has been of dual interest to us: not only did we seek mild experimental conditions to disrupt such complexation and to isolate **7** in satisfactory yield, but also we wished to elucidate the structure and bonding in complex **8**.

(2)



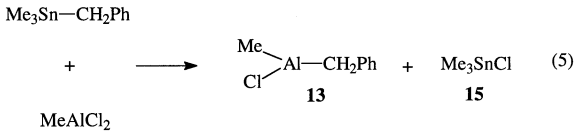
Results

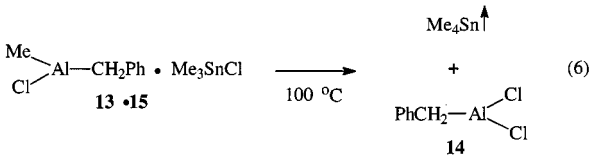
Preparation of Organoalanes by Aluminum−Tin Exchange Reactions

Previous studies on generating organoboranes by boron-tin exchange processes had revealed that selective exchange of groups is achievable when the C−Sn bond is attached to an sp- or sp^2-hybridized group.[1] In addition, by combining what has been established by Neumann in his pioneering work on aluminum-tin exchanges[6] with what is known about lithium-metal exchanges,[7] it was considered likely that aluminum-tin exchanges would proceed selectively at C−Sn bonds to allylic and benzylic groups as well. The driving force for such exchanges appears to lead to the more electropositive metal atom (Li, Al) being bonded to the more electronegative carbon atom (sp-, sp^2-, or allylic-bonded organyl group) in the favored product.

Allyl(methyl)aluminum Chloride (9)

This reagent could be readily generated from the interaction of allyltri-*n*-butyltin with methylaluminum dichloride at −78°C but the high autoreactivity of such allylic alanes precluded its isolation at room temperature (Equation 3). Hence, reagent **9** was generated at −78°C in the presence of trimethyl(phenylethynyl)silane (**10**); subsequent hydrolytic work-up led to a high yield of (*Z*)-2-phenyl-1-trimethylsilyl-1,4-pentadiene (**12**). Work-up with D_2O yielded **12** deuteriated at C-2. The exclusive formation of **12** establishes that **9** had carboaluminated **10** with regio- and stereo-selectivity to form precursor **11** (Equation 4).[8]

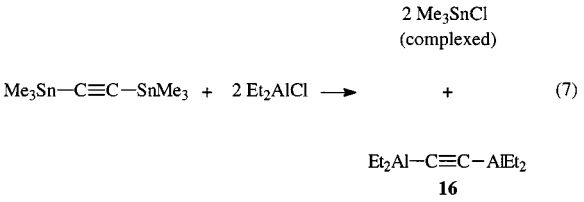




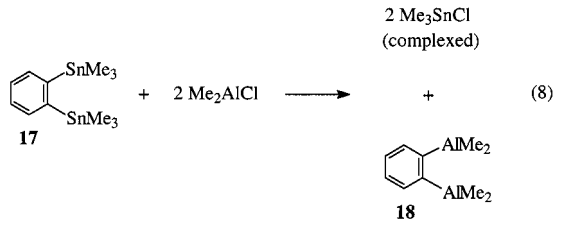
(3)

(4)

Benzylaluminum Dichloride (14)

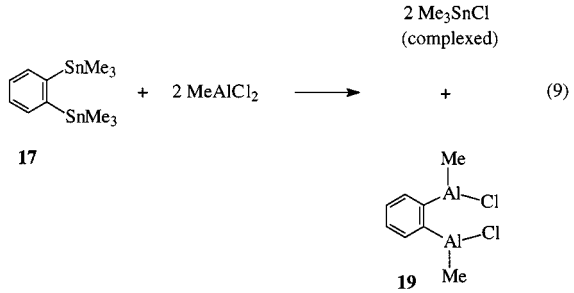


The attempted exchange between benzyltrimethyltin and methylaluminum dichloride to produce benzyl(methyl)aluminum chloride (**13**, Equation 5) took an unexpected course when the separation of **13** from its complex with **15** was undertaken. Under the conditions expected to lead to the dissociation of the complex, **13** · **15**, and the selective volatilization of **15** (100°C in mesitylene), further tin-aluminum exchange occurred with the formation of pure **14** and the volatilization of tetramethyltin (Equation 6).[9]



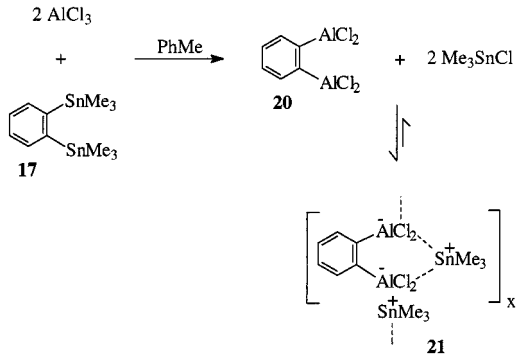
1,2-Bis(diethylalumino)ethyne (16)

The interaction of 2 equivalents of diethylaluminum chloride with one equivalent of bis(trimethylstannyl)ethyne in pentane at −30°C led to the deposition of 95% of the pale yellow **16**, which was highly pyrophoric and insoluble in benzene or chloroform. The ^{1}H-NMR spectrum of **16** from the reaction mixture from Equation 7 in THF is consistent with complexation of **16** with the ether solvent and the liberation of free Me_3SnCl: The triplet and quadruplet ethyl signals of **16** are shifted downfield from those of unsolvated Et_3Al and the singlet due to free Me_3SnCl is visible at δ = 1.2.



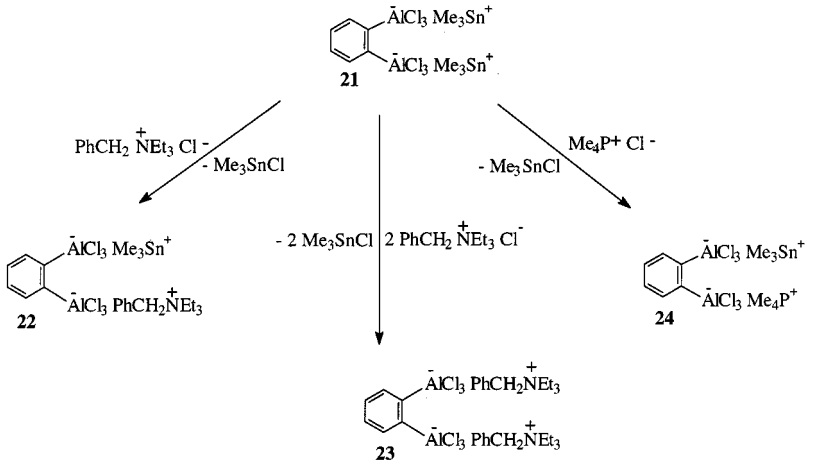
1,2-Bis(dimethylalumino)benzene (18)

The interaction of 1,2-bis(trimethylstannyl)benzene (**17**) with 2 equivalents of dimethylaluminum chloride in hexane at 25°C produced the *ortho*-dimethylalumino derivative **18** as its 1:1 and 1:2 complexes with Me_3SnCl (Equation 8), as evidenced by Me_3Sn group singlets in the δ = 0.02 to −0.02 region in the ^{1}H NMR, as well as by extra aromatic doublets in the δ = 7.0−8.0 region. Such Me_3SnCl was largely removed by warming under reduced pressure and by the distillative removal of added heptane at ordinary pressure to yield essentially free **18**.



1,2-Bis[chloro(methyl)alumino]benzene (19)

Similarly, the interaction of **17** with 2 equivalents of methylaluminum dichloride in toluene at 25°C yielded the analogous *ortho*-dichloro(methyl)alumino derivative **19**, which was even more strongly complexed with the Me_3SnCl by-product than was **18**. Here the use of the π-base, toluene, for the reaction aided the dissociation and removal of Me_3SnCl from **19**. Evaporation of the toluene solvent and repeated evaporation of several added portions of toluene under vacuum served to chase off almost all of the remaining Me_3SnCl (Equation 9).[8]



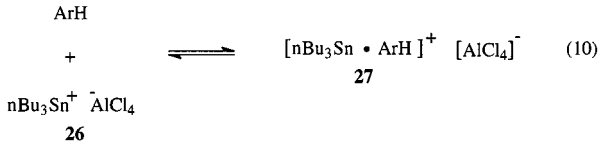
1,2-Bis(dichloroalumino)benzene (20)

Finally, the interaction of **17** with 2 equivalents of aluminum trichloride in toluene suspension led to the aluminum-tin exchange product, **20**, but in this situation the Me_3SnCl by-product remained firmly complexed with **20** to form a polymeric ion pair **21** (Scheme 1).

Scheme 1

The presence of the trichloroaluminate anion is consistent with a ^{27}Al-NMR resonance signal at δ = 105, as is the presence of a planar trimethylstannyl cation supported by the low-field ^{119}Sn-NMR peak at δ = 357.5. (More structural information on such ion-pairs follows below). Thermal dissociation of **21** under high vacuum or by use of π-basic solvents under 100°C has thus far proved to be ineffectual in removing the complexed Me_3SnCl.[8]

Scheme 2



Complexation of Organotin Halides with Aluminum Halides

Trimethyltin Chloride with 1,2-Bis(dichloroalumino)benzene in a 2:1 Ratio (21)

Although Me_3SnCl is difficult to remove from complex **21**, the trimethylstannyl cation can readily be displaced either singly or dually by the benzyltriethylammonium ion (**22** and **23**, Scheme 2) or by the tetramethylphosphonium ion (**24**). In all cases, the ^{27}Al-NMR spectra display a resonance peak in the $\delta = 103$ region; in **22** and **24** the ^{119}Sn-NMR spectra have a peak in the $\delta = 317-320$ region; and in each complex the appropriate ^{1}H- and ^{13}C-NMR peaks corroborate the ionic structures and compositions.

Complexes of Trimethyltin Chloride with Aluminum Chloride (Complex 25) and of Tri-*n*-butyltin Chloride with Aluminum Chloride (Complex 26)

These 1:1 complexes were first described by Neumann, Schick, and Köster almost 35 years ago and upon the basis of the relatively high electrical conductivity of such complexes and their formula weight in dilute solution, they were depicted as ion pairs. Above 1 mol/L concentrations higher degrees of association (2−6) became significant.[9] To add to our insight into the structure of complexes **25** and **26**, a multinuclear NMR study was undertaken in solution. Noteworthy are the following observations: 1) the ^{27}Al-NMR signals occur at $\delta = 104-105$, almost identical with the reported peak for $AlCl_4^-$;[10] 2) the ^{119}Sn-NMR peaks are displayed at $\delta = 358$ and 380, respectively, consistent with the presence of a planar R_3Sn^+ cation;[11][12] and 3) the ^{119}Sn-NMR signal of complex **26** shows a significant upfield shift with increasing π-basicity of the medium: $\delta = 380$ ([D_6]benzene), 375 (toluene), 356 (mesitylene), and 338 (saturated solution of hexamethylbenzene in pentane). This last observation is consistent with such increasing π-basicity enhancing the coordination and hence the shielding of the nBu$_3$Sn$^+$ cation (**27** in Equation 10).

X-ray Crystallographic Structure of [$Me_3SnCl \cdot AlCl_3$]$_n$, Complex 25, and Its Formulation as Polymeric Trimethyltin Cationic-Tetrachloroaluminate Anionic Pairs

As shown in Figure 1 [$Me_3SnCl \cdot AlCl_3$]$_n$ (**25**) consists in the solid state of trigonal bipyramidal trimethyltin fragments and tetrahedral coordinated tetrachloroaluminate fragments forming a chiral polymeric helix.[13] The three equatorial methyl groups bonded to the tin atoms are completely planar, the Sn−C bond lengths (average, 2.109 Å, compare Tables 1−3) are within the usual range for Sn−CH_3 bonds.[14−22] The two axial positions are occupied by chlorine atoms of the tetrachloroaluminate fragments. The Sn−Cl distances are much longer than usual,[16,17,20,21] especially more than 0.30 Å longer than the Sn−Cl bond in Me_3SnCl (2.430 Å).[16][17] These values show that **25** can best be understood as a contact ion pair of trimethyltin cations and tetrachloroaluminate anions, as was already indicated by the results of the NMR-spectroscopic measurements. Therefore it would be more accurate to write an ionic formula like [Me_3Sn^+][$AlCl_4^-$] for compound **25**. Furthermore it is worth mentioning that the Sn−Cl distances alternate, each tin atom [except Sn5 with equal distances of 2.790(4) Å] has a short (average, 2.772 Å) and a long bond length (average, 2.832 Å) to a chlorine atom. The Cl−Sn−Cl angles are on an average 172.9° instead of 180°

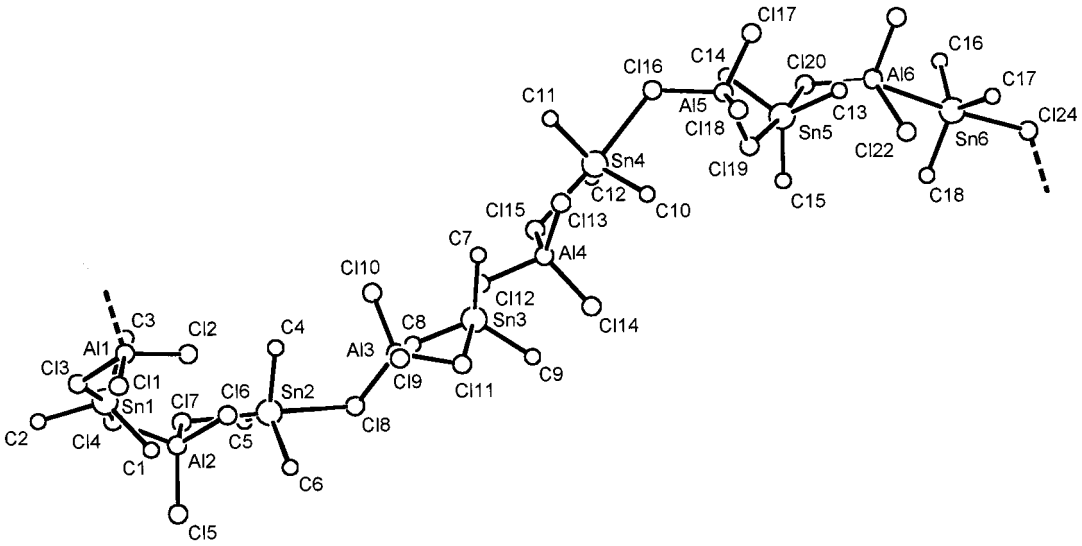


Figure 1. Structure of the polymeric chiral helix of $[Me_3SnCl \cdot AlCl_3]$ (**25**)

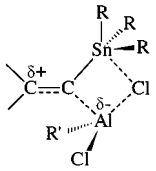
Table 1. Selected bond lengths and angles of $[Me_3SnCl \cdot AlCl_3]$ (**25**)

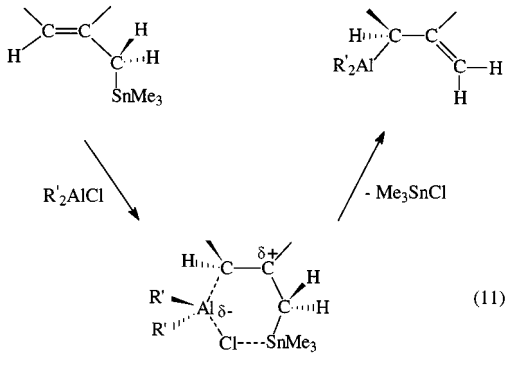
	Minimum value	Maximum value	Average value
Bond lengths [Å]			
Sn−C	2.02(2)	2.15(2)	2.109
Sn−Cl (short)	2.738(4)	2.792(5)	2.772
Sn−Cl (long)	2.800(4)	2.887(4)	2.832
Sn−Cl terminal	2.065(8)	2.109(6)	2.090
Sn−Cl bridging	2.143(7)	2.205(6)	2.171
Bond angles [°]			
C−Sn−C	116.4(7)	123.6(7)	120.0
Cl−Sn−Cl	168.1(1)	175.7(1)	172.9
Cl(terminal)−Al−Cl(terminal)	114.0(3)	116.8(3)	114.9
Cl(bridging)−Al−Cl(bridging)	103.4(2)	106.6(2)	104.8
Sn−Cl−Al	111.1(2)	122.1(2)	115.8



as one would expect for an ideal trigonal bipyramidal configuration.

The tetrachloroaluminate fragments show different distances from the aluminum atoms to its chlorine atoms (average, 2.090 Å) and to the bridging chlorine atoms (average, 2.171 Å), but both bonds are only 0.04 Å shorter or longer than those found for $NaAlCl_4$ (2.13 Å).[23] Also the Cl−Al−Cl angles are slightly different. The angles including the terminal chlorine atoms are on average 114.9°, whereas the Cl−Al−Cl angles for the bridging chlorine atoms are on average 104.8° compared to 109.5° for an ideal tetrahedral configuration. These structural differences at the tetrachloroaluminate fragments in this particular complex can be explained by the interactions of the bridging chlorine atoms with the trimethyltin fragments.

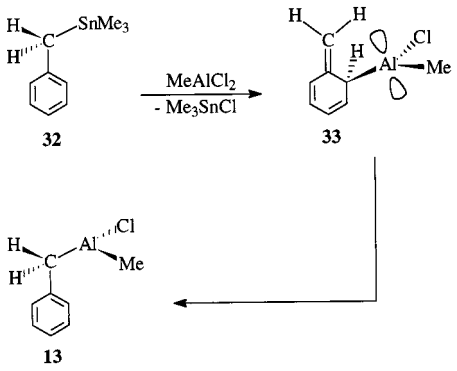
Discussion



Selectivity of Aluminum-Tin Exchange

With organotin derivatives having both sp- or sp^2-hybridized and sp^3-hybridized carbon−tin bonds, such as 1,2-bis(trimethylstannyl)ethyne (**28**) and 1,2-bis(trimethylstannyl)benzene (**17**), attack by the aluminum chloride, R'_nAlCl_{3-n} (**29**), occurs cleanly and exclusively at the carbon−tin bond of higher *s*-character (Equations 7−9 and Scheme 1). This preference for aluminum-tin exchange at such sites accords with a fostered electrophilic attack of **29** at such sites through transition states similar to **30**. Attack of **29** at the α-carbon atom of the C−Sn bond is favored by the σ-bond hyperconjugation stabilizing the positive charge at the β-carbon atom.[25]

30



The preferential reactivity of allylic or benzylic C−Sn bonds over alkyl C−Sn bonds can be explained by similar electrophilic attack by R'_nAlCl_{3-n} (**29**) (Equations 4 and 5) except that such attack occurs at the γ-carbon atom with rearrangement (**31**, Equation 11). Here again, the favored transition state **31** is dually stabilized by σ-bond hyperconjugation of the β-carbon atom′s positive charge.

(11)

31

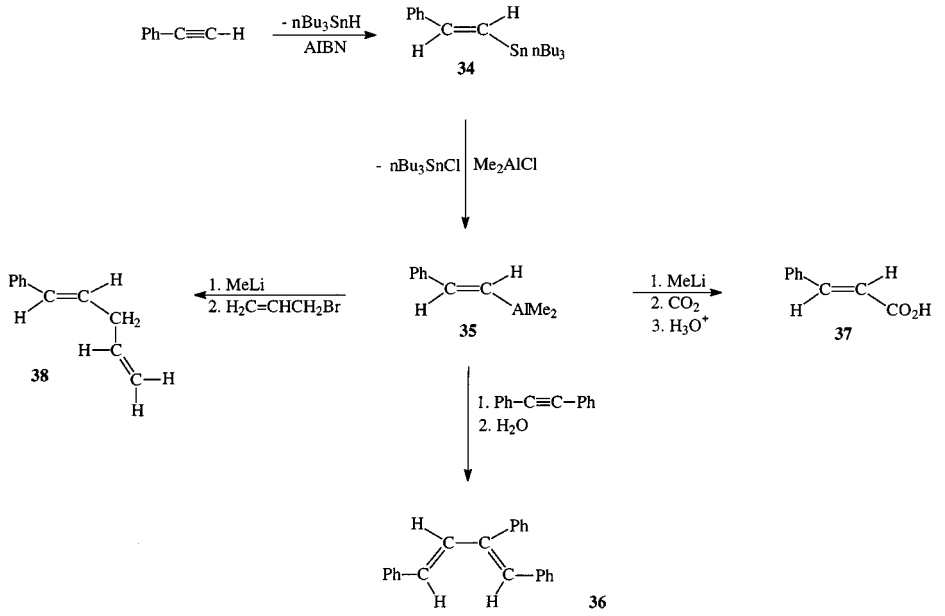
Applicability of this mechanism to the reaction of benzyltrimethyltin (**3**) with $MeAlCl_2$ (Equation 5) would require that the initial reaction product **33** would have to undergo facile rearrangement to **13** (Scheme 3). Transformation of **33** to **13** would involve a 1,3-suprafacial sigmatropic rearrangement which should be thermally allowed via the available p-orbital on the sp^2-hybridized aluminum atom in **33**.[25]

Scheme 3

Lewis Acidity of Aluminum Halides towards Trialkyltin Chlorides and the Structure of the Resulting Lewis Complexes

From the evidence on the spectral properties of complexes **25** and **26**, $R_3SnCl \cdot AlCl_3$, in solution (R = Me, Bu), it is clear that $AlCl_3$ can heterolyze the tin−chlorine bond completely to form the ion pair, $[R_3Sn]^+[AlCl_4]^-$. In dilute solutions of π-basic hydrocarbons such as arenes, the trialkyltin cation is probably solvated by arenes and exists as a simple solvated ion pair with the tetrachloroaluminate anion, as corroborated by ^{119}Sn- and ^{27}Al-NMR spectroscopy. The decreasing chemical shift of the ^{119}Sn signal of **26** as the π-basicity of the arene solvent increases, from δ = 380 in [D_6]benzene to 375 in toluene to 356 in mesitylene to 338 in hexamethylbenzene dissolved in pentane, is consistent with an increasing complexation of the Bu_3Sn^+ with the arene π-electron cloud and thus an increasing diamagnetic shielding of the tin cation by the π-electrons. In more concentrated solutions (> 0.01 mol/L) and especially in the solid state, planar R_3Sn cations are linked to each other by $AlCl_4$ anions through Cl−($AlCl_2$)−Cl bridges (Figure 1), whereby the bridging Sn−Cl separations are some 30 pm longer (12%) than the Sn−Cl bond in the original Me_3SnCl (at δ = 243). Such relatively weak coordination by the two chlorine atoms means that the planar R_3Sn unit is essentially still cationic.

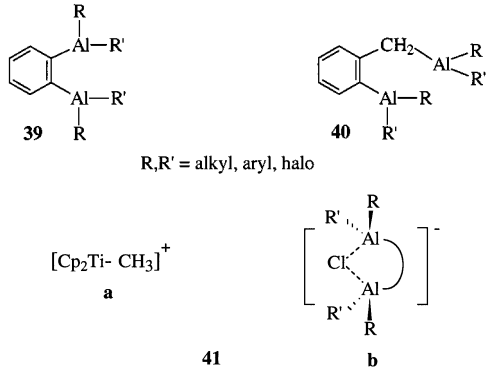
The stability of the complex **21** between 1,2-bis(dichloroalumino)benzene (**20**) and 2 equivalents of Me_3SnCl demonstrates that an arylaluminum dichloride is still a strong enough Lewis acid to heterolyze Me_3SnCl completely. Presumably the structure of viscous **21** consists of intramolecular and intermolecular bridging of Me_3Sn^+ units between arene $AlCl_3^-$ sites (Scheme 1). The 1,2-bis(dimethylalumino)benzene (**18**) and 1,2-bis[chloro(methyl)alumino]benzene (**19**) are clearly weaker Lewis acids than **20** because the complexed Me_3SnCl can be removed by use of high vacuum and the addition of π-basic arenes (Equations 8 and 9).



However, there is one structural feature of compounds **18**, **19**, and **20** that make them especially appealing as novel Lewis acids, and this is their potential as structurally rigid, chelating Lewis acids in Ziegler−Natta olefin polymerization. This attractive prospect motivates our continuing efforts to prepare **19** and **20** free of any complexation with Lewis bases. In the final section our recent progress in this research is outlined.

Novel Applications of Unsymmetrical Organoalanes in Organic Synthesis and Polymerization

Such aluminum-tin exchange processes constitute a most useful selective route to vinylic, allylic, acetylenic, aryl, and benzylic organoalanes in their unsolvated form. Illustrative are the preparations depicted in Equations 3, 5, 7, 18, and 19. Since the requisite organotin precursor reacts readily with $RAlCl_2$ or R_2AlCl in alkanes, toluene or dichloromethane, the organoalane can be generated free of any coordinated ether solvent and despite its auto-association, in its more electrophilic form. The weakly coordinated R_3SnX by-product can often be removed by a combination of π-basic hydrocarbons and high vacuum. In some cases, as with allyl(methyl)aluminum chloride (**9** in Equation 3), the presence of the R_3SnX does not interfere with the carbaluminating action of the organoalane.



Since many organotin derivatives can be prepared by Grignard and organolithium reactions or by hydrostannations, subsequent aluminum-tin exchanges permit access to the more reactive organoalanes (Scheme 4).[26] Typical is the stereoselective generation of organoalane **35** from organotin precursor **34**. Reagent **35** can carbaluminate alkynes with selective *syn* addition (**36**),[27] undergoes carboxylation via an ate complexation with retention of configuration (**37**)[28][29] and yields the corresponding allyl derivative (**38**) by ate-complex-assisted allylation.[30] These selective reactions at the vinylic C−Al bonds, rather than at the methyl C−Al bonds, highlight the great utility of such vinylalanes in organic synthesis.

Finally, the first successful synthesis of the structurally rigid, chelating Lewis acids of types **39** and **40** from the corresponding organotin precursors has led to their evaluation as potential cocatalysts with transition metal metallocenes for the polymerization of olefins. Indeed, such cocatalysts, when employed with titanocene methyl chloride, $Cp_2Ti(Me)Cl$, in a 1:8 Ti/Al ratio, have been found decidedly superior to other aluminum cocatalysts such as $MeAlCl_2$ and even MAO, in polyethylene productivity numbers at comparable Ti/Al ratios. Productivity numbers (PN) of 2000−3000 g of polyethylene per g Ti × per h × per atm are attained with **39** and **40**, compared with PN values of 800 for MAO and 200 for $MeAlCl_2$.[31] The greater cocata-

Scheme 4

lytic efficacy of **39** and **40** may well stem from the greater binding of the chloride ion through their chelating ability (**41b**) and thus the cleaner generation and separation of the solvent-separated cation **41a**, which has been established as the active site in the metallocene polymerization of olefins.[32–34]

Experimental Section

General Techniques: All preparations and purification procedures involving manipulations with oxygen- and moisture-sensitive reagents were carried out under anhydrous, oxygen-free argon or nitrogen employing Schlenk techniques.[35] Those procedures which did not require a protective atmosphere but involved working with toxic chemicals (such as boron and tin compounds) were carried out in an exhaust hood evacuating air at 100 cubic ft/min. For the operations under reduced pressure the required vacuum was provided either by a rotary vacuum oil pump (down to 0.1 Torr) or by a water pump (down to 10 Torr) and toxic volatiles were condensed in cold traps. Commercially available solvents of reagent grade were purified according to the recommended methods.[35] Solvents used in reactions were always freshly distilled under argon or nitrogen from the appropriate drying agents: aliphatic hydrocarbons from $LiAlH_4$; toluene from sodium; dichloromethane from CaH_2; and ethers from sodium/benzophenone combinations. Deuteriated solvents (Cambridge Scientific) for NMR measurements of oxygen- and moisture-sensitive substances were vacuum-transferred to the Schlenk glass vessels and stored over Molecular Sieves (4 Å) under argon. Gas chromatographic analysis (GC) was performed with a Hewlett-Packard Chromatograph, model 5880A, with helium as the carrier gas. The ^1H- (360.1 MHz) and ^{13}C- (90.6 MHz) NMR spectra were recorded with a Bruker AM 360 spectrometer and the ^{27}Al- (78.2 MHz) and ^{119}Sn- (111.9 MHz) NMR spectra with a Bruker AC 300 spectrometer. Solid-state NMR spectra were recorded with a Bruker AC 300 spectrometer at 75.4 (^{13}C), 78.2 (^{27}Al) and 111.9 MHz (^{119}Sn). The ^1H- and ^{13}C-NMR chemical shifts are referred to resonances of the solvent [D_6]benzene. For ^{27}Al-NMR spectra aqueous $AlCl_3$ ($\delta = 0$) and for ^{119}Sn-NMR spectra Me_3SnCl (16.4% in C_6D_6: $\delta = 159.7$[28]) were used as external reference standards.

Preparation of Aluminum-Tin Complexes with Trialkyltin Chlorides

Complex 25 of Trimethyltin Chloride and Aluminum Trichloride in a 1:1 Ratio: To a suspension of 1.94 g (14.5 mmol) of aluminum trichloride in 20 mL of toluene was added 7.95 mL (7.95 mmol) of a 1.0 M solution of trimethyltin chloride in toluene via a syringe at room temperature. The resulting suspension was stirred for 3 d, filtered, and the solvent removed under reduced pressure. The remaining yellow crystals were washed with 10 mL of pentane, the pentane layer was decanted and the product dried in vacuo. In this way 2.55 g (7.7 mmol) of the crude product was obtained (97%). For further purification the crystals of **25** were again dissolved in 10 mL of toluene, the solution was filtered and cooled to −78°C. After standing overnight the solvent was decanted at a temperature of −78°C and the crystalline product was washed at room temperature with a mixture of 8 mL of pentane and 4 mL of toluene and finally dried in vacuo. − ^1H NMR (C_6D_6): $\delta = 0.88$ (s, $SnCH_3$, $^2J_{Sn-H} = 56.2/58.5$ Hz). − ^{13}C NMR (C_6D_6): $\delta = 5.7$ ($SnCH_3$, $^1J_{Sn-C} = 334.4/350.1$ Hz). − ^{27}Al NMR (C_6D_6): $\delta = 104.6$ ($W_{1/2} = 960$ Hz). − ^{119}Sn NMR (C_6D_6): $\delta = 342.0$.

Complex 26 of Tri-*n*-butyltin Chloride and Aluminum Trichloride in a 1:1 Ratio: To a suspension of 1.94 g (14.5 mmol) of aluminum trichloride in 20 mL of pentane was added 1.5 mL (5.5 mmol) of

tributyltin chloride via a syringe at room temperature. The resulting suspension was stirred for 2 d, filtered, and the solid was extracted three times with 10 mL of pentane. The solvent of the combined extracts and filtrate was removed in vacuo to leave 2.38 g of a yellow oil which was identified as the pure complex **26** by NMR spectroscopy (94%). – ^{1}H NMR (C_6D_6): δ = 0.86 (t, CH_3, 3 H), 1.29 (sext, CH_2, 2 H), 1.72 (m, CH_2, 4 H). – ^{13}C NMR (C_6D_6): δ = 13.6 (CH_3), 25.7 (CH_2, $^1J_{Sn-C}$ = 266.0/278.3 Hz), 27.0 (CH_2, $^2J_{Sn-C}$ = 75.9 Hz), 28.0 (CH_2, $^3J_{Sn-C}$ = 27.7 Hz). – ^{27}Al NMR (C_6D_6): δ = 103.7 ($W_{1/2}$ = 3000 Hz). – ^{119}Sn NMR (C_6D_6): δ = 380.4.

Complex 21 of Trimethyltin Chloride and 1,2-Bis(dichloroalumino)-benzene (20) in a 2:1 Ratio: To a suspension of 4.43 g (33.2 mmol) of aluminum trichloride in 25 mL of toluene was added 2.03 g (5.0 mmol) of 1,2-bis(trimethylstannyl)benzene[1] via a syringe at room temperature. The resulting yellow reaction mixture was stirred for 3 d and then filtered. The solvent was evaporated from the filtrate. In order to remove all volatile material the residue was heated in vacuum up to 50°C. The resulting yellow oil was washed with 10 mL of pentane, the pentane layer was decanted and the residual oil dried in vacuum. In this way 3.25 g (4.8 mmol) of the pale yellow oil of **21** was obtained in 97% yield. – ^{1}H NMR (360.1 MHz, C_6D_6, 25°C): δ = 0.86 (s, 6 H, $SnCH_3$, $^2J_{Sn-H}$ = 58.1 Hz), 6.98 (d, 2 H, C_6H_4, J_{H-H} = 7.8 Hz), 7.08 (d, 2 H, C_6H_4, J_{H-H} = 7.8 Hz). – ^{13}C NMR (90.6 MHz, C_6D_6, 25°C): δ = 5.9 ($SnCH_3$, $^1J_{Sn-C}$ = 346.3/331.7 Hz), 125.6 (C_6H_4), 128.6 (C_6H_4), 129.4 (C_6H_4). – ^{27}Al NMR (78.2 MHz, C_6D_6, 25°C): δ = 105 ($W_{1/2}$ = 20000 Hz). – ^{119}Sn NMR (111.9 MHz, C_6D_6, 25°C): δ = 357.5.

Displacement of Trimethyltin Chloride from Complex 21

Displacement of One Equivalent of Me_3SnCl by Benzyltriethylammonium Chloride. – Complex 22: To 211 mg (0.93 mmol) of benzyltriethylammonium chloride was added 3.1 mL of a 0.3 M of solution of the 2:1 complex of Me_3SnCl and 1,2-bis(dichloroalumino)benzene (**21**) (0.93 mmol) at room temperature. Stirring of the reaction mixture overnight resulted in the formation of two layers. While the upper layer was a clear yellow solution, the lower layer was a brown oil. After removal of solvent, the residue was heated in vacuum up to 40°C in order to remove all volatile material. Addition of C_6D_6 resulted again in the formation of the two layers which were separately investigated by NMR spectroscopy. The spectra of the upper layer showed no signals corresponding to starting materials or to an adduct of bis(dichloroalumino)benzene with benzyltriethylammonium chloride, but did exhibit signals for Me_3SnCl. In the spectra of the lower layer signals corresponding to the presence of the benzyltriethylammonium cation and consistent with the formation of the complex **22** were observed. – ^{1}H NMR (360.1 MHz, C_6D_6, 25°C): δ = 0.65 (t, CH_3CH_2N), 1.08 (s, $SnCH_3$), 2.13 (q, CH_3CH_2N), 3.27 (s, $C_6H_5CH_2N$), 6.80–6.90 (m, C_6H_4), 7.14–7.25 (m, C_6H_4). – ^{13}C NMR (90.6 MHz, C_6D_6, 25°C): δ = 5.9 ($SnCH_3$), 7.5 (CH_3CH_2N), 52.4 (CH_3CH_2N), 60.5 ($C_6H_5CH_2N$), 125.6 (C_6H_5), 128.5 (C_6H_4), 129.3 (C_6H_4), 129.8 (C_6H_5), 131.3 (C_6H_5), 132.0 (C_6H_5).

Displacement of Two Equivalents of Me_3SnCl by Benzyltriethylammonium Chloride. – Complex 23: To a suspension of 340 mg (1.50 mmol) of benzyltriethylammonium chloride in 2 mL of toluene was added 2.5 mL of a 0.3 M solution (0.75 mmol) of the 2:1 complex of Me_3SnCl and 1,2-bis(dichloroalumino)benzene (**21**) in toluene at room temperature. Stirring of the reaction mixture overnight resulted in the formation of two layers. While the upper layer was a pale yellow solution, the lower layer was a bright yellow oil. The separated upper layer was shown by NMR spectroscopy to contain only Me_3SnCl. The separated lower layer was washed with pentane and the residue was then heated in vacuum up to 40°C in order to remove all volatile materials. The remaining yellow residue was treated with C_6D_6 which caused again the formation of two layers, which were individually investigated by NMR spectroscopy. The spectra of the lower layer showed all signals corresponding to the reaction product, namely bis(benzyltriethylammonium) 1,2-phenylenebis(trichloroaluminate) (**23**). – ^{1}H NMR (360.1 MHz, C_6D_6, 25°C): δ = 0.75 (t, CH_3CH_2N), 2.28 (q, CH_3CH_2N), 3.46 (s, $C_6H_5CH_2N$), 6.92–6.95 (m, C_6H_5), 6.98–7.10 (m, C_6H_4), 7.22–7.26 (m, C_6H_5). – ^{13}C NMR (90.6 MHz, C_6D_6, 25°C): δ = 7.6 (CH_3CH_2N), 52.5 (CH_3CH_2N), 60.5 ($C_6H_5CH_2N$), 125.5 (C_6H_4), 125.9 (C_6H_5), 128.5 (C_6H_4), 129.2 (C_6H_4), 129.7 (C_6H_5), 131.0 (C_6H_5), 132.2 (C_6H_5). – ^{27}Al NMR (78.2 MHz, C_6D_6, 25°C): δ = 103.5 ($W_{1/2}$ = 14 Hz).

Displacement of One Equivalent of Me_3SnCl by Tetramethylphosphonium Chloride. –Complex 24: To 152 mg (1.2 mmol) of tetramethylphosphonium chloride was added 4 mL of a 0.3 M solution of complex **21** (1.2 mmol) at room temperature. Stirring the reaction mixture overnight resulted in the formation of two layers: the upper layer was a clear yellow solution and the lower layer was a golden-colored oil. After evaporating the solvent, the residue was heated in vacuum up to 40°C in order to remove all volatile materials. Addition of C_6D_6 resulted in the formation of the two layers which were individually investigated by NMR spectroscopy. The spectra of the upper layer showed only signals corresponding to Me_3SnCl, while in the spectra of the lower layer the signals of the reaction product were found, namely the 1:1 complex of tetramethylphosphonium trichloro(2-dichloroaluminophenyl)aluminate with Me_3SnCl (**24**). – ^{1}H NMR (360.1 MHz, C_6D_6, 25°C): δ = 0.82 (d, CH_3P, $^2J_{P-H}$ = 14.1 Hz), 1.04 (s, CH_3Sn, $^2J_{Sn-H}$ = 58.8 Hz), 6.96–7.22 (m, C_6H_4). – ^{13}C NMR (90.6 MHz, C_6D_6, 25°C): δ = 5.9 (CH_3Sn, $^1J_{Sn-C}$ = 345.0/358.2 Hz), 9.3 (CH_3P, $^1J_{P-C}$ = 56.0 Hz), 130.1 (C_6H_4), 134.3 (C_6H_4), 139.6 (C_6H_4). – ^{27}Al NMR (78.2 MHz, C_6D_6, 25°C): δ = 103 ($W_{1/2}$ = 1500 Hz). – ^{13}P NMR (121.4 MHz, C_6D_6, 25°C): δ = 21.4. – ^{119}Sn NMR (111.9 MHz, C_6D_6, 25°C): δ = 317.0 ($W_{1/2}$ = 30 Hz).

Aluminum-Tin Exchange Reactions

1,2-Bis(diethylalumino)ethyne (16): To a stirred solution of 0.80 g (2.3 mmol) of 1,2-bis(trimethylstannyl)ethyne (**28**), dissolved in 20 mL of dry pentane and cooled to –30°C, was added 5.0 mmol of diethylaluminum chloride in 30 mL of hexane. A pale yellow precipitate appeared almost immediately. The reaction suspension was stirred and brought to room temperature over 60 min. After removal of the volatiles in vacuo, the residue was found to be insoluble in alkanes, benzene or $CDCl_3$ but readily dissolved in THF or ether. The ^{1}H-NMR spectrum in THF showed the absence of **28** and the presence of free Me_3SnCl. Furthermore, in [D_8]THF the broaded triplet and quadruplet of the ethyl groups of **16** appeared at δ = 1.3 and 0.8, consistent with coordination of THF, rather than Me_3SnCl, at aluminum.

1,2-Bis(dimethylalumino)benzene (18): To a solution of 6.0 g (14.9 mmol) of 1,2-bis(trimethylstannyl)benzene (**17**)[1] in 20 mL of heptane was added 2.76 g (29.8 mmol) of pure dimethylaluminum chloride by syringe. The resulting solution was stirred at room temperature for 72 h and thereupon the solvent and the Me_3SnCl by-product were evaporated in vacuo without heating. The residue was redissolved in heptane and volatiles again removed under reduced pressure; this addition and evaporation of heptane was repeated to remove all traces of residual Me_3SnCl. The residual viscous pale yellow oil was essentially pure 1,2-bis(dimethylalumino)benzene (**18**) in 89% yield, as evidenced by spectral data. – ^{1}H NMR (360.1 MHz, C_6D_6, 25°C): δ = –0.41 (br., 6 H, $AlCH_3$), –0.32 (br., 6 H,

$AlCH_3$), 6.96 (dd, 2 H, C_6H_4), 7.96 (2 H, dd, C_6H_4). – ^{13}C NMR (90.6 MHz, C_6D_6, 25°C): δ = −7.7 ($AlCH_3$), 6.4 (br., $AlCH_3$), 129.7 (C_6H_4), 144.9 (C_6H_4), 160.3 (C_6H_4). – ^{27}Al NMR (78.2 MHz, C_6D_6, 15°C): δ = 174 ($W_{1/2}$ = 3200 Hz); (−8°C): δ = 179 ($W_{1/2}$ = 5200 Hz).

1,2-Bis[chloro(methyl)alumino]benzene (19): To a solution of 6.0 g (14.9 mmol) of 1,2-bis(trimethylstannyl)benzene in 20 mL of toluene were added 29.8 mmol of a solution of methylaluminum dichloride in hexane at room temperature. After stirring for 72 h, the solvents were evaporated in vacuo. In order to remove the more tightly complexed Me_3SnCl, the procedure of adding 20 mL of toluene to the reaction residue and evaporating all volatiles at 25°C in high vacuum had to be performed four times. The residue thus obtained was a pale yellow waxy substance (85% yield) whose NMR spectra corroborate that it is rather pure **19**, existing as a bridging isomeric mixture. – ^1H NMR (360.1 MHz, C_6D_6, 25°C): δ = 0.25 (br., $AlCH_3$, 2 H), 0.8 (br., $AlCH_3$, 4 H), 6.8−7.3 (m, br., C_6H_4, 2 H), 7.4−7.9 (m, br., C_6H_4, 2 H). – ^{13}C NMR (90.6 MHz, C_6D_6, 25°C): δ = −6.6 ($AlCH_3$), 4.3 (br., $AlCH_3$), 129.5 (br., C_6H_4), 137.0 (C_6H_4), 150.4 (C_6H_4). – ^{27}Al NMR (78.2 MHz, C_6D_6, 25°C): δ = 101 ($W_{1/2}$ = 5000 Hz).

Benzylaluminum Dichloride (14):[36] A solution of 7.6 g (30.0 mmol) of benzyl(trimethyl)tin in 200 mL of mesitylene was treated with 30 mL of a 1.0 M solution of methylaluminum dichloride in hexane and the resulting clear solution was stirred at 20°C for 15 h and then heated at 100−110°C for 3 h. The mesitylene was slowly evaporated at 100°C under a low pressure and caught in a cold trap. By ^1H- and ^{13}C-NMR spectroscopy the mesitylene was shown to contain tetramethyltin but not trimethyltin chloride. Spectral analysis of the residual viscous oil showed it to be pure benzylaluminum dichloride (**14**), free of any organotin by-product. – ^1H NMR (C_6D_6): δ = 2.15 (s, 2 H), 6.71 (br. s, 2 H), 6.95 (t, 1 H), 7.10 (t, 2 H). – ^{13}C NMR (C_6D_6): δ = 29 (CH_2 by DEPT), 123.6, 127.8, 127.86, 127.93.

Allyl(methyl)aluminum Chloride (9):[37] To a solution of 1.87 mL (6.0 mmol) of allyltri-*n*-butyltin and 1.13 mL (5.8 mmol) of trimethyl(phenylethynyl)silane (**10**) in 6.0 mL of toluene, cooled to −78°C, was added dropwise 6.1 mL of a 1.0 M solution of $MeAlCl_2$ in hexane. The reaction mixture was slowly brought to 0°C over 4 h. Hydrolytic work-up with aqueous NaOH and ether extraction of the organic product allowed the isolation of a mixture of tri-*n*-butyltin chloride and (*Z*)-2-phenyl-1-trimethylsilyl-1,4-pentadiene; no starting tin compound or **10** remained. The adduct **12** was cleanly separated from the nBu_3SnCl by column chromatography on silica gel with hexane eluent (90% yield). – ^1H NMR ($CDCl_3$): δ = −0.15 (s, 9 H), 3.15 (d, 2 H), 5.00 (m, H), 5.59 (s, H), 5.84 (m, H), 7.15−7.35 (m, 5 H).[7] – ^{13}C NMR ($CDCl_3$): δ = 0.0, 46.76, 116.41, 126.97, 127.75, 127.98, 135.91, 144.06, 157.43. – When a similar reaction mixture was worked up with NaOD in D_2O, the ^1H singlet at δ = 5.59 was absent in the spectrum of **12**.

X-ray Crystallographic Study of Trimethylstannyl Tetrachloroaluminate, $Me_3SnAlCl_4$ (25). – Crystal Mounting and Data Collection: A pale yellow-brown crystal of **25**, 0.25 × 0.53 × 0.42 mm in size, was mounted with a perfluorinated polyether oil on the tip of a glass fiber on the goniometer head and cooled immediately by an argon current to −173°C. Intensity data were collected with an Enraf-Nonius CAD4 diffractometer by a coupled ω-2θ scan technique with speeds varying from 1.0 to 10.0°/min depending on the standard deviation to intensity ratio of a preliminary 10°/min scan. The radiation employed was Mo-K_α with a graphite monochromator. The crystals of molecular weight 332.6 g mol^{-1} have 6 molecules per unit cell and have a calculated density of 1.97 g cm^{-3}; they belong to the triclinic crystal system and the space group of *P*l, No. 1. The absorption corrections were made by the ψ-scan method. Observed reflections were defined as those reflections with $I \geq 2\sigma(I)$. Only these were used in the solution and refinement of the structure (*F* refinement). For refinement based on F^2 all reflections were used. Refinement was done by least-squares; the quantity minimized was $\Sigma\, w(|Yo| - |Yc|)^2$, with $Y = F$ or F^2. Computations were done using VAX, Sun4, and Silicon Graphics computers. In addition to several locally written programs, the following software was used: S. L. Lawton, R. A. Stabilization of Copper(III) Ions with Deprotonated Hydroxyiminoamide Ligands: Syntheses, Structures, and Electronic Properties of Copper(II) and Copper(III) Complexes

Jan Hanss,[a] Alexander Beckmann,[a] and Hans-Jörg Krüger*[a]

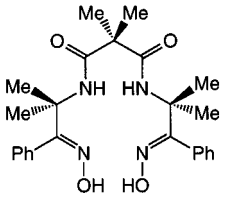
Keywords: Copper / Deprotonated amide ligands / Oxime ligands / Redox chemistry / High valent metal ions

Copper(II) and copper(III) complexes were prepared with two novel ligands, *N*,*N*′-bis(2-(1-hydroxyimino-2-methyl-1-phenyl)propyl)dimethylmalondiamide (H_4mal55) and *N*,*N*′-bis(2-(1-hydroxyiminoethyl)phenyl)dimethylmalondiamide (H_4mal66), both of which contain two amide and two oxime functionalities as potential ligand donor groups. The two copper(II) complexes (NEt_4)[Cu(Hmal55)] (**1**) and (NEt_4)[Cu(Hmal66)] (**2**) can be reversibly oxidized in acetonitrile at a redox potential of –0.120 and –0.075 V vs. the Fc/Fc^+ redox couple, respectively. While the quantitative electrolysis of **1** results in the preparation of the oxidized complex [Cu(Hmal55)] (**3**), which is sufficiently stable to be isolated, isolation of the oxidation product of **2** was not attempted because of its long-term instability. The properties of the complexes were investigated by means of various spectroscopic methods (UV-vis, ESR, NMR, and IR spectroscopy) and by X-ray structure analysis. The structure determinations and the spectroscopic investigations of the complexes reveal a square-planar CuN_4 coordination environment for each complex in the solid state and in acetonitrile solution. In both the oxidized and reduced oxidation states of the complexes, the coordinated ligands remain triply deprotonated with a hydrogen atom bridging both oxime oxygen atoms. The ligands can therefore be regarded as pseudo-macrocyclic. The characterization of the oxidation products clearly identifies the electron-transfer reaction as being metal-centered. For the first time, the structure of a copper(III) complex with a ligand containing oximes as donor groups was determined. The redox potentials of the copper complexes are compared to related Cu^{III}/Cu^{II} redox couples.

Introduction

The stability of highly oxidized metal ions in complexes is determined for the most part by the type of donor functions provided by the ligand. In general, anionic and highly polarizable donor groups are needed to achieve high oxidation states at the metal sites. For example, deprotonated amides as part of a multidentate ligand are well known to stabilize the trivalent oxidation state of the central ion in mononuclear copper and nickel complexes.[1] Thus, copper(III) complexes have been synthesized *and* successfully isolated with ligands which contain carboxylate,[2] amine,[2] thiolate,[3] alcoholate, and phenolate[4] or further amide groups[5] in addition to the deprotonated amide functions.

Another type of ligand donor function that has been demonstrated to generate high-valent metal ions is the deprotonated oxime group.[6] While ligand systems with oximato groups produce stable nickel(III) and even nickel(IV) complexes,[7] this ligand donor group seems to be considerably less well-established in the coordination chemistry of copper(III) ions. To our knowledge, the Cu^{III}/Cu^{II} redox chemistry has only been reported for two mononuclear copper complexes containing such ligand donor functions.[8] In these complexes the metal ion is coordinated to two imine and two oxime nitrogen atoms in a square-planar geometry.



Further, since metal ions can be bound by the deprotonated oximate group via the nitrogen as well as via the oxygen atom, this type of ligand donor group has an advantage: multinuclear complexes which display interesting magnetic properties[9] can be prepared and may, therefore, be potentially useful for the development of new materials in the field of molecular magnetism.[10]

In light of the low Ni^{III}/Ni^{II} redox potentials obtained for nickel complexes with either amidate or oximate groups in the ligand environment,[11] some years ago we initiated an investigation of the complexation properties of tetradentate ligands comprised of two deprotonated amide and two oxime groups. The ligands used in this study, H_4mal55 and H_4mal66, are depicted below. They contain two amide and two oxime functions for the complexation of metal ions. Until recently[12] complexes with such a combination of donor groups in a ligand were unknown. In a recent complexation study of copper(II) ions,[12a] Kozlowski et al. employed the tetradentate amide-oxime ligand H_4pap, in which the oxime function is adjacent to the carboxylate portion of the amide group. In contrast, in both the acyclic amide-oxime ligands used in our investigation, the oximate groups lie on the side of the amine residues of the amide functions. In addition, the ligands H_4mal55 and H_4mal66 are designed to contain no hydrogen atom attached to a carbon atom in the α position to any donor atom; this feature has been shown to be very helpful in abolishing or at least in retarding possible decomposition reaction pathways of amidato complexes after the metal ion is oxidized.[2][13][14] The two ligands H_4mal55 and H_4mal66 dis-

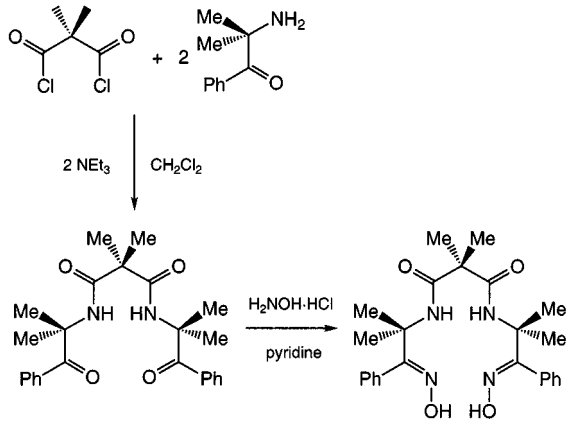
tinguish themselves by the different carbon chain lengths of the two hydroxyliminoamine components. Therefore, while ligand H_4mal55 is expected to form two five- and one six-membered chelate rings with the metal ion upon complexation, ligand H_4mal66 will render only six-membered chelate ring sizes.

H_4mal55

H_4mal66

H_4pap



Here we introduce the results of the complexation reactions of the two novel amide-oxime ligands, H_4mal55 and H_4mal66, with copper ions, emphasizing the effects of the distinctive structural features of the ligands on the properties of the resulting complexes. The syntheses, as well as the structural and electronic properties of the copper(II) complexes, are described. The results of an electrochemical investigation, from which the isolation and first structural characterization of a copper(III) complex with oxime donor groups in the ligand environment ensued, are presented.

Results and Discussion

Preparation of the Ligands and the Copper(II) Complexes

Scheme 1 illustrates the synthesis of the ligand H_4mal55 $\times$ 0.5 H_2O, which was obtained from dimethylmalonyl dichloride and α-amino-isobutyrophenone in two reaction steps with an overall yield of 54%. Using a similar procedure, the ligand H_4mal66 $\times$ H_2O was synthesized from dimethylmalonyl dichloride and 2-amino-acetophenone in a 62% overall yield.

The red copper(II) complexes (Et_4N)[Cu(Hmal55)] (**1**) and (Et_4N)[Cu(Hmal66)] (**2**) were prepared by refluxing the corresponding ligand with one equivalent of $Cu(OAc)_2$ $\times$ H_2O in the presence of two equivalents of Et_4NOAc $\times$ 4 H_2O in absolute ethanol. The elemental analyses of both compounds suggest that the coordinated ligand is triply deprotonated. The absence of N−H stretching vibrations between 3310 and 3370 cm^{-1} in the IR spectra of the complexes indicates that both amide nitrogen atoms are deprotonated upon complexation.

Scheme 1. Synthesis of the ligand H_4mal55

Structures of the Copper(II) Complexes

Perspective views of the copper(II) complex anions are displayed in Figures 1 and 2. A comparison of selected bond lengths and angles is listed in Table 1. In the crystal lattice of **1** · 0.5 Et_2O, two crystallographically distinct, but otherwise chemically equivalent complexes are found. In both complexes **1** and **2**, the copper(II) ions are bound to two deprotonated amide and two oxime nitrogen atoms in essentially square-planar arrangements. The copper ions of the two symmetry-unrelated complex anions in the crystal lattice of **1** · 0.5 Et_2O deviate by 0.052 and 0.075 Å, respectively, from the calculated least-squares-plane of the four nitrogen donors. A similar deviation of the copper ion from the least-squares N_4-plane (0.052 Å) is observed in **2**. In both complexes, the dihedral angle between opposing CuN_2 planes does not exceed 6.5°. The structure analysis of both copper(II) complexes provides further evidence that the two oximate oxygen atoms are bridged by a proton; this is in agreement with the previously mentioned elemental analyses and IR spectra. Similar to the crystal structure of the related complex anion $[Cu(Hpap)]^-$,[12a] the hydrogen-bridging is found to be asymmetric. This feature of a hydrogen atom bridging both oximate oxygen atoms gives the ligands a pseudo-macrocyclic appearance with only six-membered chelate rings occurring in **2**, while in **1** the chelate ring sizes alternate between five and six. The interatomic O−O distance between the oxime oxygen atoms measures 2.427 ±0.005 Å and 2.417 Å for **1** and **2**, respectively.

The different fused chelate-ring sizes have a profound effect on the degree of ruffling of the pseudo-macrocyclic ring as well as on the Cu−N bond lengths. Thus, while most of the atoms of the ligands backbone in **1** (except those of the methyl and the phenyl groups) lie approximately in the same plane as the CuN_4 unit, the ligand backbone in **2** exhibits a more saddle-like appearance in order to still be capable of accommodating the copper ion. The two phenylene rings in **2** are positioned under the CuN_4 plane, forming interplanar angles of 45.0−49.2° with the CuN_4 plane, while the two oxime oxygen atoms and the atoms of the malonyl bridge are located above the CuN_4 plane. Values of 36.5° and 31.7° are calculated for the interplanar angle

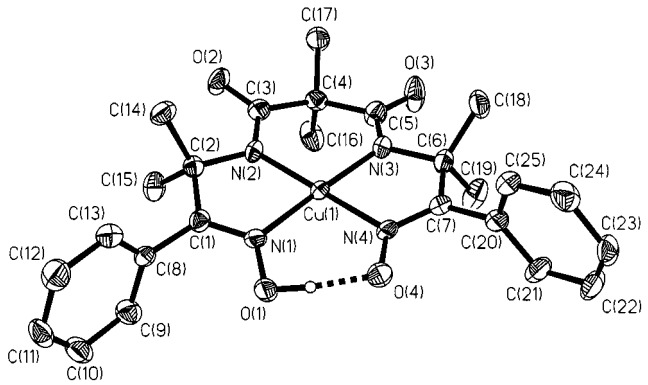


Figure 1. Perspective view of the structure of one of the two crystallographically independent $[Cu(Hmal55)]^-$ anions in **1** · 0.5 Et_2O showing thermal ellipsoids at 50% probability and the atom-numbering scheme

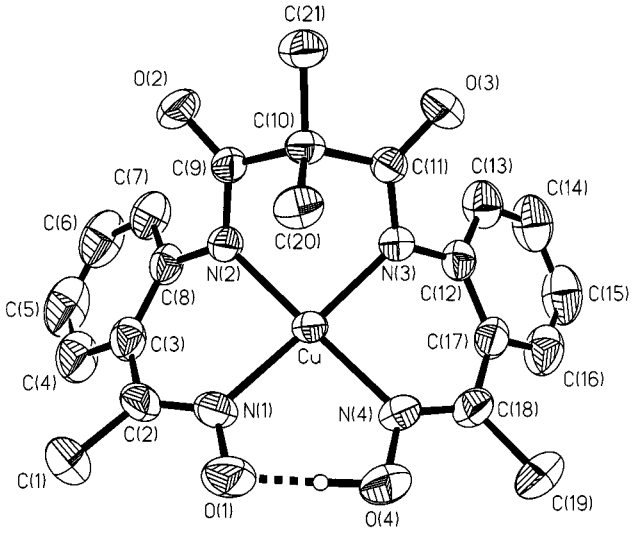

Figure 2. Perspective view of the structure of the $[Cu(Hmal66)]^-$ anion in **2** showing thermal ellipsoids at 50% probability and the atom-numbering scheme. The location of the hydrogen atom which asymmetrically bridges both oxime oxygen atoms is disordered over two positions; the present view shows only one of these positions

enclosed by the CuN_4-plane and the least-squares planes passing through the atoms N(2), C(9), C(11), and N(3) and through the atoms O(1), N(1), N(4), and O(4), respectively. In addition, the average $Cu-N_{amide}$ and $Cu-N_{oxime}$ distances in **1** of 1.906 ±0.005 Å and 1.950 ±0.011 Å, respectively, increase to 1.946 ±0.006 Å and 2.000 ±0011 Å in **2**.

The $Cu-N_{amide}$ bond lengths compare well with those found in other square-planar amidato copper(II) complexes.[3][12a][15] Reference values for $Cu-N_{oxime}$ distances in square-planar copper(II) complexes containing *vic* dioximate ligand donor groups are rare; the copper(II) ion is five-coordinate in most complexes with this type of donor function.[16] The $Cu-N_{oxime}$ bond lengths (1.954 and 1.962 Å) in the square-planar complex anion $[Cu(Hpap)]^-$, which possesses the same sequence of fused chelate ring sizes as **1**, resemble those observed in **1**.[12a]

Electronic Properties of the Copper(II) Complexes

The magnetic moments of **1** and **2** were determined to be 1.81 and 1.85 μ_B, respectively, which is consistent with the $S = 1/2$ state of the mononuclear copper(II) complexes. The ESR spectra of the complexes dissolved in an acetonitrile/toluene mixture (*v*/*v* = 1:4) and in pure ethanol were recorded at room temperature and at 100 K, respectively. The spectra are shown in Figure 3 and the ESR parameters obtained by simulation of the spectra are listed in Table 2. Thus, the solution of **1** at room temperature renders an isotropic ESR signal at $g_{iso} = 2.075$, which is split into four lines by the hyperfine coupling to the $I = 3/2$ spin of the copper nucleus. Further, superhyperfine splitting is observed due to the coupling to the nuclear spins $I = 1$ of the four nitrogen donor atoms of the ligand. The values for g_{iso} and $A^{Cu}_{iso} = 94.0 \cdot 10^{-4}$ cm^{-1} are typical for square planar or for tetragonally elongated octahedral compounds of copper(II) ions with an equatorial N_4-ligand donor environment. Through the interpretation of the powder spectrum of a frozen ethanolic solution of **1**, one arrives at the same conclusion. Thus $g_z = 2.170$ and $A^{Cu}_z = 210 \cdot 10^{-4}$ cm^{-1} have values that are predicted by a scatter plot of g_z vs. A^{Cu}_z for a monoanionic complex with a square planar or tetragonally distorted octahedral CuN_4-coordination core.[17] The *g*-values and the hyperfine coupling constants

Table 1. Selected bond lengths [Å] and angles [deg] in $(NEt_4)[Cu(Hmal55)]$ (**1**), $(NEt_4)[Cu(Hmal66)]$ (**2**), and $[Cu(Hmal55)]$ (**3**)

	$(NEt_4)[Cu(Hmal55)]$[a]		$(NEt_4)[Cu(Hmal66)]$	$[Cu(Hmal55)]$[b]

N(3)−Cu−N(4)	83.3(2)	[83.0(2)]	87.5(1)	83.1(1)[b]

[a] The corresponding bond lengths and angles in the crystallographically distinct second complex anion in **1** are listed in square brackets. – [b] The atom numbering scheme of $[Cu(Hmal55)]$ (**3**) (cf. Figure 6) is adapted to that of $(NEt_4)[Cu(Hmal55)]$ (**1**). Thus, the atoms N(1′) and N(2′) in Figure 6 correspond to the atoms N(4) and N(3) in Table 1, respectively.

indicate further that the unpaired electron resides in the d_{xy}-orbital of the copper(II) ion if the coordinate system is arranged in such a way that the z axis lies perpendicular to the CuN_4 plane and the x axis bisects the $N_{amide}-Cu-N_{amide}$ angle. The ESR spectra of **2** have rather similar appearances except that the g_z value is slightly larger and the $A^{Cu}{}_z$ value is smaller than that of **1**. A smaller g_z value and a larger $A^{Cu}{}_z$ value is correlated to the greater ligand field strength that the ligand $Hmal55^{3-}$ exerts on the copper ion. Thus, the ESR data confirm the presence of weaker Cu−N bonds in **2** as compared to those in **1**, a fact which has already been established by the structure determinations.

The electronic absorption spectra of the copper(II) complexes **1** and **2** are shown in Figure 4. The visible region of the spectrum corresponding to **1** comprises two absorption bands at 405 and 509 nm. Based on their positions and intensities, the bands are attributed to d−d transitions. The energy range of the absorption bands indicates either that the coordination geometry observed in the solid state is preserved in solution or that any possible axial coordination by solvent molecules must be rather weak.[18] Electrochemical evidence[19] supports the notion that, in acetonitrile, solvent molecules are, if at all, extremely weakly coordinated to the axial coordination sites. Similar d−d transitions appear as shoulders with slightly higher intensities in the spectrum of **2**; the lower energies of the absorption bands agree with the previously stated proposition that a smaller ligand field strength is exerted by the ligand $Hmal66^{3-}$ as compared to $Hmal55^{3-}$. The intense absorption around 280 nm is attributed to an amidato-to-copper(II) charge transfer transition.[20]

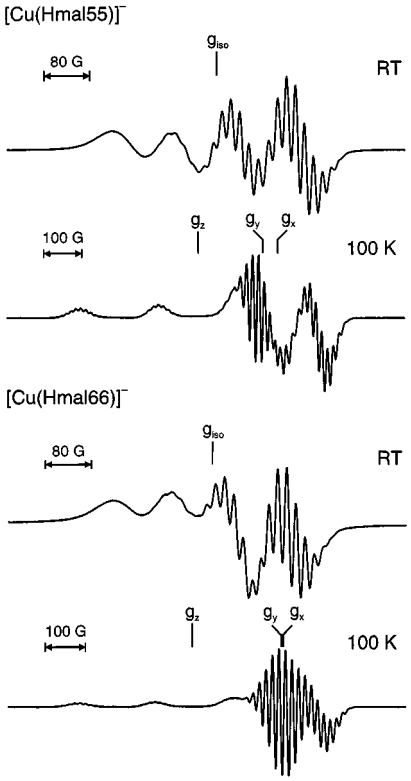

Figure 3. X-Band ESR spectra of $(Et_4N)[Cu(Hmal55)]$ (**1**) (top) and $(Et_4N)[Cu(Hmal66)]$ (**2**) (bottom) in acetonitrile/toluene (v/v = 1:4) at room temperature and as frozen glass in ethanol at 100 K (g-values are indicated)

Electrochemical Properties

The electrochemical properties of the copper(II) complexes were investigated by cyclic voltammetry and by coulometry in acetonitrile solution. The cyclic voltammograms of **1** and **2** are depicted in Figure 5. Both complexes reveal electrochemically reversible oxidation reactions (the current ratio $|i_{p,a}/i_{p,c}| \approx 1$; $i_p/v^{1/2}$ and the separation of the peak-potentials ΔE_p are independent of the scan rate v) at −120 and −75 mV vs. the ferrocene/ferrocenium (Fc/Fc^+) redox couple in acetonitrile, respectively. No reversible reductions are observed. Coulometric oxidations of the complexes at an applied potential of 80 mV for **1** and 125 mV for **2** produce dark brown-red solutions. Quantitative electrolysis demonstrates that the complexes are oxidized by one electron; immediate re-reduction results in the recovery of 98 and 95% of the reduced complexes **1** and **2**. The long-term stability of the oxidized species was examined spectrophotometrically. Thus, 95% of the oxidation product of **1** are still present after 3 d and 91% after six days, indicating that isolation of the oxidized compound should be feasible. In contrast, only 67% and 51% of the oxidized species of **2** can be detected after 3 and 6 d, respectively.[21] Due to this

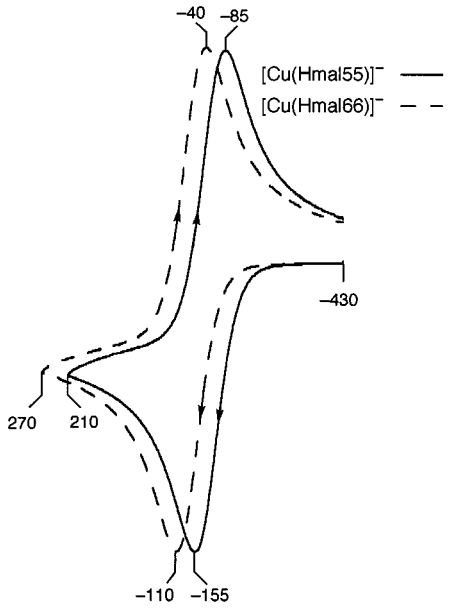

Figure 5. Cyclic voltammograms (50 mV/s) of **1** (solid line) and **2** (dashed line) at a Pt-foil electrode in acetonitrile at room temperature; peak potentials in mV vs. Fc/Fc^+ redox couple are indicated

apparent instability, no isolation of the oxidation product of **2** was attempted.

In water containing 0.05 M $NEt_4(ClO_4)$ as supporting electrolyte, the oxidation potentials for **1** and **2** were determined to be 750 and 770 mV vs. NHE, respectively. The electrochemical behavior of the complexes in water is, however, less ideal than that in acetonitrile, as demonstrated by the peak current ratio and by the incipient appearance of adsorption phenomena for the oxidation product of **1**. Addition of NEt_4OH effectuates a shift of the potential of **2** by 60 mV to a more negative value, indicating that the coordinated ligand looses its bridging proton in a more basic medium. However, the shape of the electrochemical response demonstrates decomposition of the oxidized species; for **1** oxidation was no longer observed upon addition of base; this means that the stability of the fully deprotonated copper(II) complex $[Cu(mal55)]^{2-}$ is very limited in water.

Preparation of Copper(III) Complexes

Indeed, consecutive coulometric oxidation of complex **1** in acetonitrile, evaporation of the acetonitrile, and recrystallization of the obtained residue from toluene/hexane affords analytically pure product. The elemental analysis of the compound is consistent with its formulation as [Cu(Hmal55)] (**3**). The IR spectrum of **3** is very similar to that of **1** except that the features corresponding to the counter cation NEt_4^+ are now absent. For the purpose of comparing spectroscopic data, solutions of the oxidation product of **2** were electrochemically generated in situ and, in light of the apparent instability of the oxidized species, immediately used for the respective measurements.

Structure of the Copper(III) Complex [Cu(Hmal55)]

A crystal structure determination was carried out on a single crystal of **3**. A perspective view of the complex is presented in Figure 6. In Table 1 some selected bond lengths and angles of compound **3** are compared to those of the reduced complex. Overall, the ligand environment, as well as the coordination geometry at the center ion, is preserved upon oxidation of **1**. The copper ion in **3** deviates by approximately the same amount (0.073 Å) from the least-squares N_4-plane as in **1** and also the dihedral angles between opposing CuN_2-planes are still under 6.5°. The structure analysis provides evidence that the H-bridging between the oxime oxygen atoms still persists in complex **3**. Compared to complex **1**, the Cu−N distances are reduced by 0.05 Å, indicating metal-centered oxidation. The decrease of the copper-donor atom bond lengths upon oxidation of the metal ion is, however, considerably smaller than that observed in other square-planar copper(II)/copper(III) couples with acyclic ligands.[2,3,5] In our opinion, the modest reduction of Cu−N bond lengths, despite the loss of a strongly σ-antibonding electron, can be attributed to the pseudo-macrocyclic nature of the coordinated ligand, which does not allow a tighter enclosure of the metal ion by the ligand without introduction of steric strain on the ligand backbone. A closer inspection of the structural parameters of the ligand reveals no major differences between complex **1** and **3** except that the ruffling of macrocyclic ring seems to be a little bit more pronounced in the oxidized complex. This observation is also manifested by the rather small decrease of the interatomic O−O distance between the oxime oxygen atoms from 2.427 ±0.005 Å in **1** to 2.400 Å in **3**. The $Cu^{III}-N_{amide}$ bond length of 1.860 Å is at the high end of the range of values observed for a bond length between a copper(III) ion and a deprotonated amide nitrogen donor atom.[2−5]

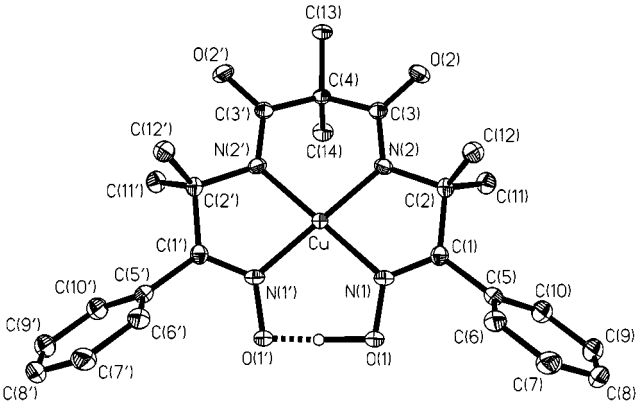

Figure 6. Perspective view of the structure of [Cu(Hmal55)] (**3**) showing thermal ellipsoids at 50% probability and the atom-numbering scheme. The location of the hydrogen atom which asymmetrically bridges both oxime oxygen atoms is disordered over two positions; the present view shows only one of these positions

As previously noticed for other amidato copper(III) complexes,[2−5] in response to the higher positive charge on the copper ion upon oxidation, the partial double bond charac-

ter of the C−N bond in the deprotonated amide function is reduced in order to provide the amide nitrogen atom with a higher negative charge. Thus, the average C−N and C−O bond lengths change from 1.325 and 1.240 Å in **1** to 1.358 and 1.233 Å in **3**, respectively. The strengthening of the C−O bond upon oxidation of the metal ion is accompanied by an increase of the C=O stretching frequency by 28 cm^{-1} in the IR spectra.

Spectroscopic Properties of the Copper(III) Complex

The diamagnetism of complex **3** which would be expected for a complex with a copper(III) ion is confirmed by NMR spectroscopy. The NMR spectrum of **3** in CD_2Cl_2 clearly establishes that the ligand is still bound to the metal ion in its triply deprotonated form, i.e. the oxime oxygen atoms are still bridged by a proton. A similar result is obtained when the oxidation product of **2** is examined by NMR spectroscopy immediately after its electrochemical generation.

Addition of a base like triethylamine to a solution of complex **3** in deuterated acetonitrile or dichloromethane seems to cause deprotonation of the oxime group, which is, however, accompanied by decomposition reaction(s) of the complex.

Intense absorption bands with extinction coefficients between 1000 and 8000 M^{-1} cm^{-1} are present in the visible regions of the electronic absorption spectra of both oxidized complexes (Figure 7). These bands are tentatively attributed to LMCT transitions. In general, two strong absorption bands are observed in the spectra of copper(III) peptide complexes at 260−280 nm and at 380−400 nm attributed to the σ and π N(peptide)-to-copper(III) charge transfer transitions, respectively.[1,22] Copper(III) imine-oximate complexes yield a LMCT band between 515 and 581 nm. The absorption bands in the electronic absorption spectra of the complexes [Cu(Hmal55)] and [Cu(Hmal66)] occur at rather similar energies. Except for the intense band around 773 nm for [Cu(Hmal66)], the visible regions in the spectra of both oxidized complexes resemble each other. The reason for the additional appearance of an intense band around 773 nm for [Cu(Hmal66)] is attributed to a LMCT transition involving the phenylene moieties of the ligand. Such LMCT transition are likely to occur with the oxidized copper ion in [Cu(Hmal66)], since here the sp^2-hybridized donor atoms are part of π-molecular orbital systems extending over the phenylene units.

Comparison of Redox Potentials

In Figure 8a, the redox potentials of compounds **1** and **2** are compared with those of some selected copper complexes in aqueous solutions. With the exception of complex **12**,[8a] all complexes contain at least two deprotonated amide functions as ligand donor groups, while complexes **1**, **2**, and **12** possess two vicinal dioximate ligand donor groups as a common feature.

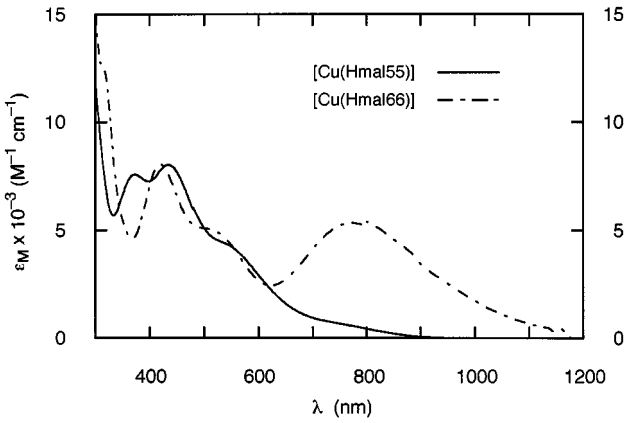

Figure 7. Electronic absorption spectra of a solution of [Cu(Hmal55)] (**3**) and an electrochemically generated solution of [Cu(Hmal66)] in acetonitrile

Complexes **4**−**12**[8a,19b,23−26] have the same square-planar CuN_4 coordination environment as complexes **1** and **2**. In addition, complexes **1**−**10** all contain a malondiamide bridge in the ligand.[19b,23,24] The type of nitrogen donor group of the two other coordination sites causes the potential to vary by approximately 0.7 V. Thus, a relatively high redox potential (1.34 V) is achieved with π-acceptor ligand donor functions such as pyridine units (**4**),[23] while the introduction of further negatively charged donor groups in addition to the two already provided by the malondiamide unit affords low potentials (e.g. complex **10**).[19b] In accordance to this general trend, the redox potentials of **1** and **2** lie between those complexes containing amine donor groups[19b,23,24] in addition to the malondiamide moiety and that of complex **10**.

The effect of the ring size of the macrocycle on the redox potential is illustrated by the complexes **6**, **8**, and **9**, which contain fifteen-, fourteen-, and thirteen-membered rings, respectively.[19b,24] Thus, the copper(III) ion is best accommodated by a small ring size, as demonstrated by the low redox potential. A similar trend is also observed in complexes with acyclic ligands where the lowest redox potentials are found with 5-5-5 fused ring systems.[23] In general agreement with this tendency, the redox potential of **2**, containing a sixteen-membered pseudo-macrocyclic ring, is 20 to 45 mV (depending on the employed solvent) higher than that of **1**, in which the pseudo-macrocyclic ring is fourteen-membered. Thus, the difference in the redox potential of 45 mV observed in acetonitrile corresponds to a 4.3 kJ mol^{-1} stabilization of the trivalent oxidation state relative to the divalent oxidation state upon changing the ring size of the pseudo-macrocycle from sixteen in **2** to fourteen in **1**. The long-term instability of the oxidation product of **2** is very likely also related to the facts that the cavity in the sixteen-membered macrocyclic ring is too large to accommodate the rather small copper(III) ion and that the already substantially ruffled ligand in copper(II) complex **2** cannot sustain any further ruffling in order to reduce the cavity size after the oxidation of the metal ion.

With respect to the dioximato complex **12**,[8b] the redox potential of complex **1**, which possesses the same pseudo-

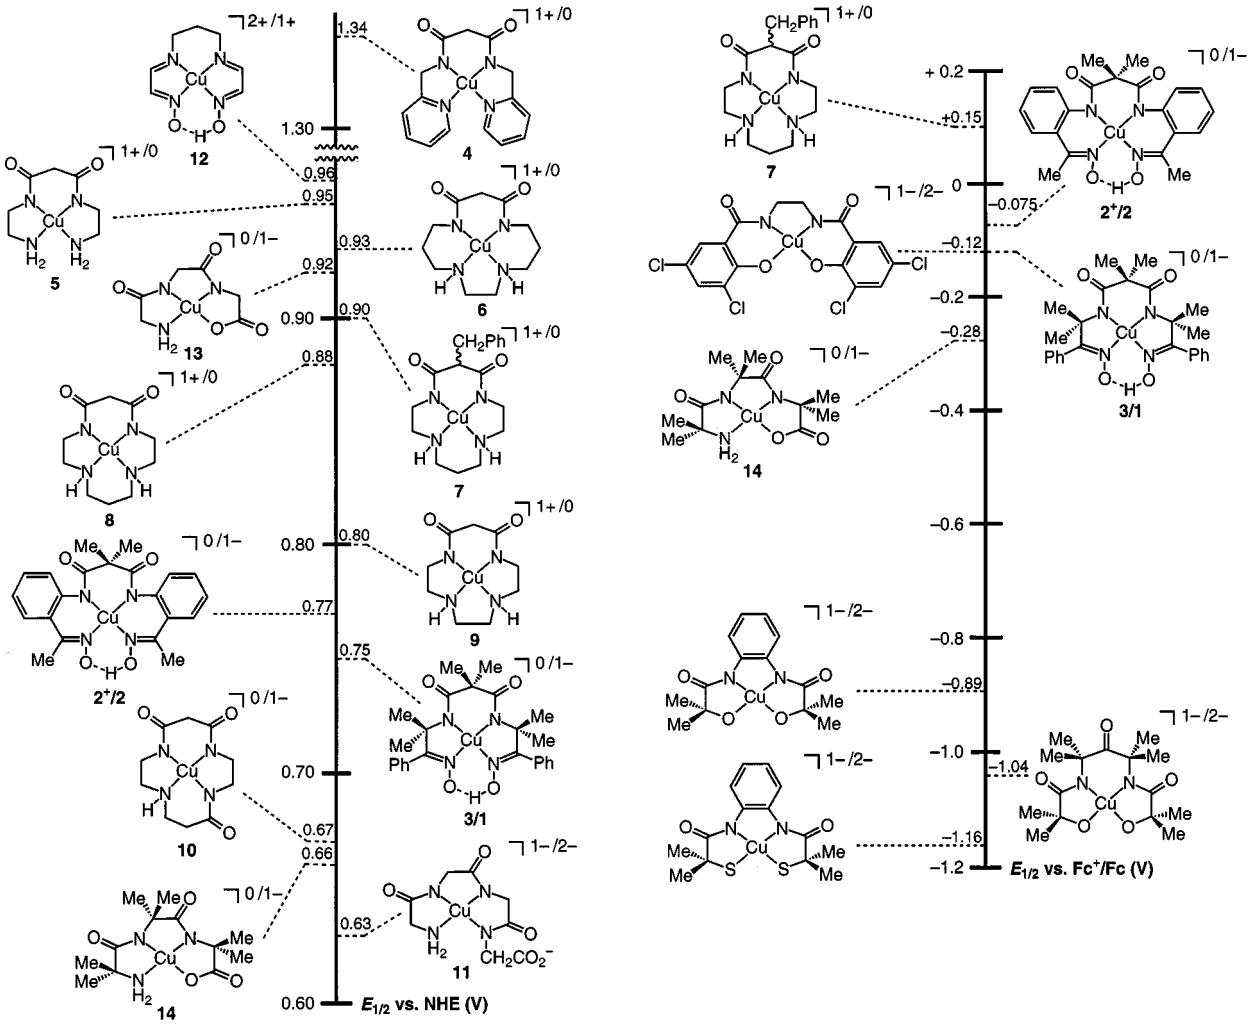

Figure 8. Schematic presentation of the redox potentials of **1** and **2** compared to those of related Cu^{III}/Cu^{II} redox couples in a) water (left) and b) acetonitrile (right). Data are taken from this work and other investigations[3,4,8a,19b,23−26]

macrocyclic ring size, is lowered by more than 200 mV. This substantial decrease is a testimony of the considerable stabilizing influence that two deprotonated amide functions exert on the high oxidation state of copper ions.

The redox properties of copper(II) peptide complexes were extensively surveyed by Margerum and coworkers.[25][26] The copper(II) complex of the triply deprotonated triglycine ligand (**13**) with a CuN_3O coordination environment is oxidized at 0.92 V.[25] Substitution of all hydrogen atoms by methyl groups (cf. **14**) causes a substantial decrease of the Cu^{III}/Cu^{II} redox potential.[26] The presence of methyl groups in α-position to ligand donor atoms may therefore be regarded as another contributing factor to the stabilization of the oxidized complex **3**.

In Figure 8b, the influence on the Cu^{III}/Cu^{II} redox potential of various donor types in combinations with two deprotonated amide donor functions is examined for square planar copper complexes dissolved in acetonitrile. Granting that chelate ring sizes are not always comparable for these complexes, a general trend, however, can still be discerned. Thus, the stabilizing influence of donor groups on the trivalent oxidation state increases in the order amine[24] < oximate ≈ phenolate[4] < deprotonated amide[26] < alcoholate[4] < alkylthiolate.[3]

Conclusion

Two novel ligands containing two amide and two oxime donor groups were synthesized and their coordination properties were investigated with copper ions. The structure analyses reveal a square-planar coordination geometry around the copper(II) ion in the solid state; this geometry is preserved upon dissolving the complexes in acetonitrile, as indicated by spectroscopic and electrochemical methods. While both amide nitrogen atoms are deprotonated, only one oxime donor group is deprotonated upon coordination of the ligand. The residual oxime hydrogen atom bridges the two *vicinal* oxime oxygen atoms, thereby furnishing the ligand with a pseudo-macrocyclic appearance.

Special emphasis was given to the investigation of the redox properties of the complexes. Thus, both copper(II) compounds can be oxidized to their corresponding copper(III) oxidation states. However, only the oxidation prod-

uct of complex **1** displays sufficient stability to be isolated, resulting in the first structural characterization of a copper(III) complex containing oximes donor functions in its ligand sphere. The coordination geometry around the copper(III) ion is essentially the same as in the reduced complex.

Experimental Section

Methods: ^{1}H-NMR: Varian Gemini 200 and Bruker AM 360, TMS as internal standard. − UV-vis: Varian Cary 5 E. − IR: Perkin-Elmer 1720 FT-IR. − ESR: Bruker ESP 300E. The ESR spectra were analyzed with the programs ESR V1.0 of Frank Neese (Diploma, University of Konstanz, June 1993) and SimFonia 1.2 of Bruker. − Electrochemistry: PAR Model 270 Research Electrochemistry Software controlled Potentiostat/Galvanostat Model 273A with the electrochemical cell placed in a glovebox. Electrochemical experiments were performed on 1−2 mM acetonitrile solutions containing 0.2 M $(Bu_4N)ClO_4$ as supporting electrolyte unless otherwise mentioned; a higher than normal electrolyte concentration was applied to minimize solution resistance. All potentials were measured vs. a SCE reference electrode at 25°C. The potentials were not corrected for junction potentials. A Pt-foil electrode was employed as the working electrode. Under these conditions the potential for the ferrocene/ferrocenium ion couple was 0.43 V. Coulometric experiments were performed using a Pt-gauze electrode. − Magnetic susceptibilities: Johnson Matthey Magnetic Susceptibility Balance at room temperature. The values for the diamagnetic susceptibilities of the ligands and the other components of the complexes were taken from the literature.[27] − Chemical analyses: Chemical analyses were carried out by the analytical laboratory of the authors′ institute and by H. Kolbe, Mülheim.

Preparation of Ligands and Complexes. − Materials: 2-Aminoacetophenone (Aldrich), dimethylmalonic acid (Merck), copper(II)-acetate monohydrate (Riedel), and tetraethylammonium acetate tetrahydrate (Fluka) were purchased from the indicated sources and used without further purification. Dimethylmalonyl dichloride[28] and 2-amino-2-methylpropiophenone hydrochloride[29] were prepared according to previously published procedures.

***N,N′*-Bis[2-(1-hydroxyimino-2-methyl-1-phenyl)propyl]dimethylmalondiamide Hemihydrate (H_4mal55 × 0.5 H_2O). − (a) *N,N′*-Bis[2-(2-methyl-1-oxo-1-phenyl)propyl]dimethylmalondiamide Monohydrate:** At room temperature, dimethylmalonyl dichloride (2.5 g, 15 mmol) was added dropwise to a stirred solution containing 2-amino-2-methylpropiophenone hydrochloride (7.2 g, 36 mmol) and triethylamine (10.4 mL, 75 mmol) in dichloromethane (150 mL). Stirring of the reaction mixture was continued for 12 h. After the addition of water (30 mL), dichloromethane was added until a clear solution was produced. The organic phase was separated and subsequently washed with 2 N HCl (200 mL), saturated sodium carbonate solution, and water before it was dried over $MgSO_4$. Removal of the solvent in vacuo yielded the product as a white solid (4.8 g, 73% yield) which was further recrystallized in EtOH in order to obtain an analytically pure sample. − $C_{25}H_{32}N_2O_5$ (440.54): calcd. C 68.16, H 7.32, N 6.36; found C 68.21, H 7.38, N 6.58. − ^{1}H NMR (200 MHz, $[D_6]Me_2SO$): δ = 0.92 (s, CH_3, 6 H), 1.43 (s, CH_3, 12 H), 7.32−7.56 (m, Ph−H, 6 H), 7.89 (d, Ph−H, 4 H), 8.00 (s, N−H, 2 H). − IR (KBr): $\tilde{\nu}$ = 3344, 1684, 1644, 1514, 1466, 1447, 1385, 1258, 1217, 1174, 1160, and 718 cm^{-1} (strong bands only). −

b) *N,N′*-Bis[2-(1-hydroxyimino-2-methyl-1-phenyl)propyl]dimethylmalondiamide Hemihydrate: A suspension consisting of *N,N′*-Bis[2-(2-methyl-1-oxo-1-phenyl)propyl]dimethylmalondiamide monohydrate (2.2 g, 5.0 mmol) and hydroxylammonium chloride (14 g, 201 mmol) in pyridine (150 mL) was stirred for 12 h at 60°C. After removal of the solvent in vacuo, the resulting solid was redissolved in chloroform (200 mL). The chloroform solution was first washed with water (200 mL), then three times with 2 N HCl (100 mL) and finally with water (100 mL). After drying the solution over $MgSO_4$, the solvent was evaporated in vacuo to yield the product (1.7 g, 74% yield) as a white solid. − $C_{25}H_{33}N_4O_{4.5}$ (461.56): calcd. C 65.06, H 7.21, N 12.14; found C 65.02, H 7.00, N 11.83. − ^{1}H NMR (200 MHz, $[D_6]Me_2SO$): δ = 1.03 (s, CH_3, 6 H), 1.42 (s, CH_3, 12 H), 7.02−7.07 (m, Ph−H, 4 H), 7.25−7.37 (m, Ph−H, 6 H), 7.95 (s, 2 H), 10.57 (s, 2 H). − IR (KBr): $\tilde{\nu}$ = 3456, 3312, 2983, 2933, 1663, 1644, 1539, 1512, 1455, 1444, 1420, 1387, 1358, 1216, 1014, 959, 771, 723, and 705 cm^{-1} (strong bands only).

***N,N′*-Bis[2-(1-hydroxyiminoethyl)phenyl]dimethylmalondiamide Monohydrate (H_4mal66 · H_2O). − (a) *N,N′*-Bis[2-(1-oxoethyl)phenyl]dimethylmalondiamide:** Dimethylmalonyl dichloride (2.02 g, 12 mmol) was slowly dropped into a solution of 2-aminoacetophenone (6.48 g, 48 mmol) in absolute toluene (50 mL) at 0°C. The reaction mixture was warmed to room temperature and stirred for 3 h. The resulting solid was collected by filtration and washed twice with toluene (30 mL). Afterwards, the solid was resuspended under intense stirring for 20 min in an aqueous solution (400 mL) saturated with sodium hydrogen carbonate. After filtration, the solid was washed with copious amounts of water and dried in vacuo at room temperature. Recrystallization of the raw product (3.02 g, 69% yield) from glacial acetic acid yields analytically pure product as a white solid. − $C_{21}H_{22}N_2O_4$ (366.42): calcd. C 68.84, H 6.05, N 7.65; found C 68.54, H 6.25, N 7.62. − ^{1}H NMR (200 MHz, $[D_6]Me_2SO$): δ = 1.62 (s, CH_3, 6 H), 2.65 (s, CH_3, 6 H), 7.23 (ddd, Ph−H_c, 2 H, J_{ac} = 1.0 Hz, J_{bc} = 7.2 Hz, J_{cd} = 8.1 Hz), 7.63 (ddd, Ph−H_b, 2 H, J_{ab} = 8.6 Hz, J_{bc} = 7.2 Hz, J_{bd} = 1.4 Hz), 8.08 (dd, Ph−H_d, 2 H, J_{bd} = 1.4 Hz, J_{cd} = 8.1 Hz), 8.55 (dd, Ph−H_a, 2 H, J_{ab} = 8.6 Hz, J_{ac} = 1.0 Hz), 11.92 (s, N−H, 2 H). − IR (KBr): $\tilde{\nu}$ = 3215, 1668, 1655, 1607, 1584, 1517, 1479, 1452, 1441, 1384, 1364, 1355, 1314, 1298, 1251, 1226, 1167, 1150, 1122, 961, 910, 762, and 605 cm^{-1} (strong bands only).

(b) *N,N′*-Bis[2-(1-hydroxyiminoethyl)phenyl]dimethylmalondiamide Monohydrate: Using a similar procedure as in the synthesis of *N,N′*-Bis[2-(1-hydroxyimino-2-methyl-1-phenyl)propyl]dimethylmalondiamide hemihydrate, *N,N′*-Bis[2-(1-hydroxyiminoethyl)-phenyl]dimethylmalondiamide monohydrate was prepared in a 90% yield (3.11 g) in the form of a white solid from *N,N′*-bis[2-(1-oxoethyl)phenyl]dimethylmalondiamide (3.02 g, 8.3 mmol) and hydroxylammonium chloride (21 g, 302 mmol) in pyridine (180 mL). An analytically pure sample was obtained by recrystallization from ethanol. − $C_{21}H_{26}N_4O_5$ (414.46): calcd. C 60.86, H 6.32, N 13.52; found C 60.53, H 6.53, N 13.67. − ^{1}H NMR (200 MHz, $[D_6]Me_2SO$): δ = 1.55 (s, CH_3, 6 H), 2.20 (s, CH_3, 6 H), 7.16 (ddd, Ph−H_c, 2 H, J_{ac} = 1.1 Hz, J_{bc} = 7.6 Hz, J_{cd} = 7.7 Hz), 7.34 (ddd, Ph−H_b, 2 H, J_{ab} = 8.1 Hz, J_{bc} = 7.6 Hz, J_{bd} = 1.4 Hz), 7.54 (dd, Ph−H_d, 2 H, J_{bd} = 1.4 Hz, J_{cd} = 7.7 Hz), 8.27 (dd, Ph−H_a, 2 H, J_{ab} = 8.1 Hz, J_{ac} = 1.1 Hz), 11.01 (s, 2 H), 11.52 (s, 2 H). − IR (KBr): $\tilde{\nu}$ = 3368, 2925, 1664, 1624, 1580, 1526, 1447, 1394, 1369, 1310, 1295, 1270, 1246, 1124, 1009, 922, and 756 cm^{-1} (strong bands only).

(NEt_4)[Cu(Hmal55)] (1): A solution was prepared from H_4mal55 × 0.5 H_2O (231 mg, 0.5 mmol), tetraethylammonium acetate tetrahydrate (261 mg, 1.0 mmol), and copper(II) acetate monohydrate (100 mg, 0.5 mmol) in absolute ethanol (50 mL). After the reaction mixture was heated at reflux for a short time, the solvent was com-

Table 3. Summary of Crystal Data, Intensity Collection and Refinement Parameters for (NEt_4)[Cu(Hmal55)]·0.5 Et_2O (**1**), (NEt_4)[Cu(Hmal66)] (**2**), and [Cu(Hmal55)] (**3**)

pletely removed in vacuo. The residue was treated with acetonitrile (40 mL) and the resulting red solution was filtered. Slow diffusion of ether into the acetonitrile solution afforded analytically pure product in the form of orange-red needles, which, upon standing, easily lost the ether molecules incorporated in the crystal lattice (234 mg, 73% yield). − $C_{33}H_{49}CuN_5O_4$ (643.33): calcd. C 61.61, H 7.68, N 10.89; found C 61.31, H 7.68, N 10.81. − Absorption spectrum (acetonitrile): λ_{max} (ε_M) 509 (84,4), 405 (141), 260 (sh, 14100), 225 (sh, 25700), and 203 (42500) nm. − IR (KBr): $\tilde{\nu}$ = 2968, 1589, 1493, 1451, 1393, 1362, 1341, 1320, 1199, 1173, 1151, 1089, 1036, 1018, 1010, 923, 886, 825, 785, 737, 699, 656, and 537 cm^{-1} (strong bands only).

(NEt_4)[Cu(Hmal66)] (2): In a procedure similar to that described for the synthesis of complex **1**, complex **2** was prepared from H_4mal66 × H_2O (207 mg, 0.5 mmol), tetraethylammonium acetate tetrahydrate (261 mg, 1.0 mmol), and copper(II) acetate monohydrate (100 mg, 0.5 mmol) as dark red blocks (202 mg, 69% yield). − $C_{29}H_{41}CuN_5O_4$ (587.22): calcd. C 59.32, H 7.04, N, 11.93; found C 59.30, H 7.06, N 11.93. − Absorption spectrum (acetonitrile): λ_{max} (ε_M) 547 (307), 430 (sh, 501), 310 (sh, 9790), 272 (35500), 251 (sh, 30000), and 223 (24200) nm. − IR (KBr): $\tilde{\nu}$ = 2985, 2950, 1617, 1597, 1586, 1573, 1481, 1439, 1394, 1350, 1304, 1262, 1245, 1174, 1083, 1000, 957, 942, 867, 841, 772, 765, 744, and 530 cm^{-1} (strong bands only).

[Cu(Hmal55)] (3): A solution of (NEt_4)[Cu(Hmal55)] (163 mg, 0.25 mmol) in acetonitrile (20 mL) containing 0.1 M $NaClO_4$ as supporting electrolyte was oxidized at +0.08 V vs Fc/Fc^+ in an electrochemical cell placed in a glove box. The electrolysis was carried out at a platinum net electrode with a PAR Model 273A Potentiostat/Galvanostat controlled by the PAR Model 270 Research Electrochemistry Software. After the oxidation was completed, the solvent was completely removed in vacuo. The solid was treated with toluene (30 mL) and the resulting dark red-brown solution was filtered. Hexane (120 mL) was layered upon the solution. Slow mixing of the two layers by diffusion afforded analytically pure product in the form of dark red blocks (64.5 mg, 51% yield). − $C_{25}H_{29}CuN_4O_4$ (513.08): calcd. C 58.52, H 5.70, N 10.92; found C 58.38, H 5.76, N 10.88. − ^{1}H NMR (360 MHz, CD_2Cl_2): δ = 1.36 (s, CH_3, 6 H), 1.64 (s, CH_3, 12 H), 7.27 (m, Ph−H, 6 H), 7.48 (m, Ph−H, 4 H), 16.68 (s, N=OH, 1 H). − Absorption spectrum (acetonitrile): λ_{max} (ε_M) 700 (sh, 944), 533 (sh, 4460), 436 (8030), 373 (7590), 279 (17700), and 242 (15900) nm. − IR (KBr): $\tilde{\nu}$ = 2986, 2937, 1617, 1593, 1560, 1452, 1394, 1371, 1362, 1351, 1224, 1200, 1124, 879, 747, and 700 cm^{-1} (strong bands only).

Solutions of [Cu(Hmal66)]: For the purpose of comparing spectroscopic data, solutions of the oxidation product of **2** in acetonitrile were electrochemically generated in situ at an applied potential of 0.125 V vs Fc/Fc^+ and, in light of the apparent instability of the oxidized species, immediately used for the respective measurements. Absorption spectrum (acetonitrile): λ_{max} (ε_M) 773 (5350), 500 (sh, 5100), 420 (8040), 313 (sh, 12600), 269 (35200), and 243 (35400) nm.

Crystal Structure Analyses of the Copper Complexes: Table 3 contains the cell parameters of the crystals and experimental details on the data collections and structure refinements. The positions of the non-hydrogen atoms were determined by SHELXS 86[30] and by Fourier difference maps using the program SHELXL-93 (**1** and **2**) or SHELXL-97 (**3**).[30] The structural parameters were refined with the program SHELXL-93 or SHELXL-97, using F^2 of all symmetry-independent reflections except those with very negative F^2-values. Empirical absorption correction on the data set of **3** was applied by using the program DIFABS. All non-hydrogen atoms were refined anisotropically unless stated otherwise. The ether molecule in **1**·0.5 Et_2O is disordered and the atoms of this crystal solvent are therefore ill defined, resulting in large temperature factors and somewhat distorted bond lengths. The non-hydrogen atoms of this molecule were therefore refined isotropically. The tetraethylammonium cation in **2** is disordered and was modeled by two separate

molecules. Half of the complex **3** is related to the other half by a symmetry plane passing through the copper atom and the atoms of the dimethylmethylene group of the dimethylmalondiamide unit. Hydrogen atoms were assigned idealized locations and their isotropic temperature factors were refined, except for those bound to the oxime oxygen atoms in **1**, in which complex the positions and the isotropic temperature factors were refined. The locations of the hydrogen atoms which asymmetrically bridge both oxime oxygen atoms in **2** and **3** are disordered over two positions.

The largest peaks (holes) in the final difference Fourier maps correspond to 1.13 (−1.12) e $Å^{-3}$, 0.56 (−0.45) e $Å^{-3}$, and 0.68 (−0.67) e $Å^{-3}$ for structures analyses of **1**, **2**, and **3**, respectively.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-101423. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: Int. code +44 (1223) 336-033; E-mail: deposit@chemcrys.cam.ac.uk).

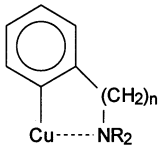
The Deprotonated Iminophosphorane *o*-$C_6H_4PPh_2P{=}NSiMe_3$ as a Novel Chelating Ligand in Organocopper(I) and -zinc(II) Chemistry

Stefan Wingerter,[a] Heinz Gornitzka,[b] Guy Bertrand,[b] and Dietmar Stalke*[a]

Dedicated to Professor Edgar Niecke on the occasion of his 60th birthday



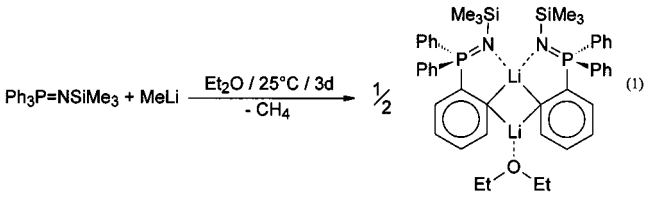
Keywords: P Ligands / N Ligands / Copper / Zinc / Structure elucidation

Lithiation of triphenyl(trimethylsilylimino)phosphorane $Ph_3P{=}NSiMe_3$ with MeLi gives the *ortho*-metallated species $[Li(o\text{-}C_6H_4PPh_2NSiMe_3)]_2{\cdot}Et_2O$ (**1**), which exhibits all the requirements of an organometallic ligand capable of side-arm donation. The deprotonated *ortho*-phenyl carbon atom gives access to metal–carbon σ bonds in transmetallation reactions, while the $Ph_2P{=}NSiMe_3$ moiety can donate to the same metal center through the imine nitrogen atom. In transmetallation reactions with CuBr, the dimeric organocopper complex $[Cu(o\text{-}C_6H_4PPh_2NSiMe_3)]_2$ (**2**) is obtained, while application of $ZnCl_2$ yields the monomeric zinc complex $[Zn(o\text{-}C_6H_4PPh_2NSiMe_3)_2]$ (**3**). Reaction with $CuCl_2$ gives access to the new diiminophosphorane $(o\text{-}C_6H_4PPh_2NSiMe_3)_2$ (**4**) through oxidative coupling at the *ortho* positions. In all the metal complexes, the $Ph_2P{=}NSiMe_3$ residue acts as a side-arm donating group through the nitrogen atom. The intermolecular N→Cu donor bond in **2** is as short as copper–amide bonds, while the N→Zn bond lengths in **3** are in the region normally found for donor bonds. Compound **4** is a molecule, possessing two $Ph_2P{=}NSiMe_3$ moieties bridged by a biphenylene group.

Introduction

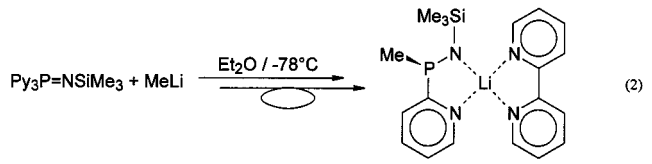
Since the landmark synthesis of $LiCuMe_2$ in 1952,[1] the application of organocopper reagents in organic synthesis has continued to increase exponentially.[2] Among the d-block metals, Cu^I species play the most prominent role in regio- and stereoselective synthesis.[3] The growing number of cuprates and organocopper compounds characterized by X-ray structure analysis is clearly evident.[4] Organocopper(I) compounds CuR are generally encountered as polynuclear species, which exist either as discrete aggregates or as polymers. Transformation of these aggregates and polymers into units of lower nuclearity can either be achieved by employing very bulky groups R, or by the action of suitable Lewis bases.[5] N, P, O, or S donor centers, as well as alkynes, have been reported to stabilize copper(I) species in low aggregation states.[6] The combination of both approaches leads to the side-arm donation concept pioneered by van Koten.[7] α-Metallated aryl ligands are substituted with $R_2N(CH_2)_n$ amido groups, permitting intramolecular complexation (Scheme 1).

In the compounds discussed in this paper, the $R_2N[CH_2]_n$ amido group is formally replaced by an $Me_3SiN{=}PPh_2$ imido group within the deprotonated triphenyl(trimethylsilylimino)phosphorane $Ph_3P{=}NSiMe_3$.



Scheme 1

The lithiation and reactivity of the trimethyl(trimethylsilylimino)phosphorane $Me_3P{=}NSiMe_3$ has been studied previously by Schmidbaur et al.[8] and the structure of the $[LiCH_2(Me_2)P{=}NSiMe_3]_4$ tetramer was recently determined by Dehnicke et al.[9] In analogy to this lithiation, the reaction of triphenyl(trimethylsilylimino)phosphorane $Ph_3P{=}NSiMe_3$ with MeLi gives $[Li(o\text{-}C_6H_4PPh_2\text{-}NSiMe_3)]_2{\cdot}Et_2O$ (**1**) according to Equation 1.[10] The C_2-symmetric dimer contains a tetrahedrally coordinated and a trigonal-planarly coordinated lithium atom. The tripyridyl(trimethylsilylimino)phosphorane $Py_3P{=}NSiMe_3$ reacts completely differently. In a reductive coupling reaction of the substituents, the phosphorus(V) center is reduced to phosphorus(III), substituted by one pyridyl, one methyl, and an Me_3SiN group. The P−N double bond in the starting material is thus converted into a single bond (Equation 2).[10]



We embarked on the synthesis of organometallic compounds using lithiated triphenyl(trimethylsilylimino)phosphorane, $[Li(o\text{-}C_6H_4PPh_2NSiMe_3)]_2{\cdot}Et_2O$ (**1**), as a starting material, as this species exhibits all the requirements of a ligand capable of side-arm donation. The deprotonated *ortho*-phenyl carbon atom should give access to metal−carbon σ bonds in transmetallation reactions, while the $Ph_2P{=}NSiMe_3$ moiety should be capable of donation to the same metal center through the imine nitrogen atom.

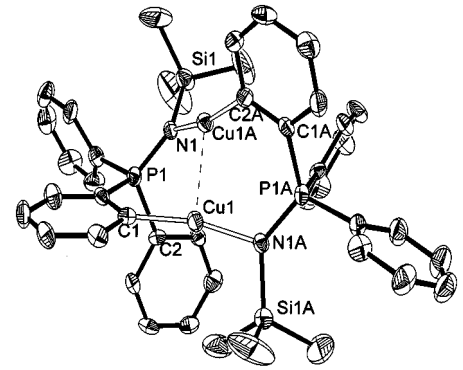
Results and Discussion

Preparation of 2−4

As synthetically important metals, we decided to employ monovalent Cu^{I} and divalent Zn^{II} and Cu^{II}. In a transmetallation reaction of $[Li(o\text{-}C_6H_4PPh_2NSiMe_3)]_2{\cdot}Et_2O$ (**1**) with CuBr, the dimeric organocopper complex $[Cu(o\text{-}C_6H_4PPh_2NSiMe_3)]_2$ (**2**) was obtained (Equation 3). Transmetallation using $ZnCl_2$ yielded the monomeric zinc complex $[Zn(o\text{-}C_6H_4PPh_2NSiMe_3)_2]$ (**3**) (Equation 4), while reaction with $CuCl_2$ led to the new diiminophosphorane $(o\text{-}C_6H_4PPh_2NSiMe_3)_2$ (**4**) as a result of oxidative coupling at the *ortho* positions (Equation 5).



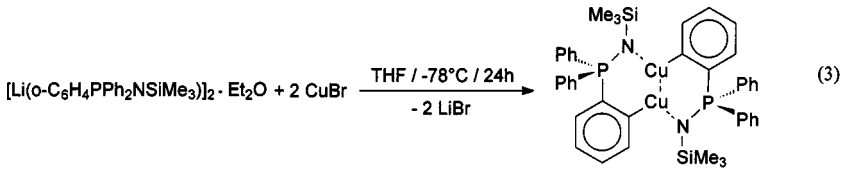


Figure 1. Solid-state structure of $[Cu(o\text{-}C_6H_4PPh_2NSiMe_3)]_2$ (**2**); anisotropic displacement parameters are depicted at the 50% probability level

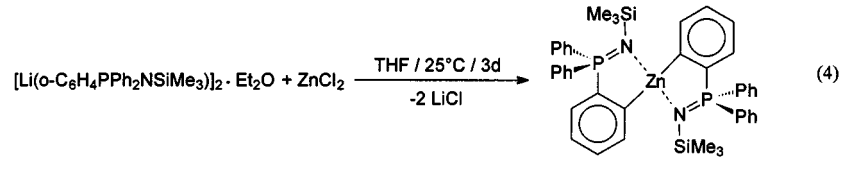
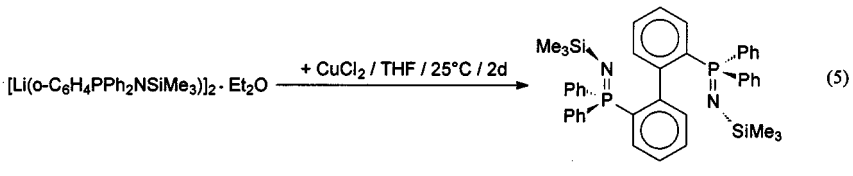


Crystal Structure of $[Cu(o\text{-}C_6H_4PPh_2NSiMe_3)]_2$ (2)

In the organocopper complex $[Cu(o\text{-}C_6H_4PPh_2NSiMe_3)]_2$ (**2**), both lithium atoms of the C_2-symmetric starting material are replaced by copper atoms to give a C_i-symmetric dimer (Figure 1).



Each copper atom is coordinated to an *ortho*-carbon atom and the nitrogen atom of the $Ph_2P{=}NSiMe_3$ side-arm of a second ligand. Hence, this moiety acts as an intermolecular rather than as an intramolecular donor function. The Cu−C distance in **2** is 190.5(5) pm (Table 1), which is comparable with the Cu−C(aryl) bond length determined in monomeric $Me_2SCuC_6H_3$-2,6-bis(2,4,6-triisopropylphenyl) [Cu−C: 189.4(6) pm].[11] Both distances fall at the short end of the range observed in organocopper com-

2

3

4

pounds (mean Cu−C: 205.5 pm).[12] On average, the Cu−C(alkyl) distances appear to be slightly longer, because an sp^2 carbon atom is about 4 pm smaller than an sp^3 carbon atom.[13] The dinuclear organylcopper complex $[CuC(SiMe_3)_2C_5H_4N]_2$ shows almost the same structural motif as complex **2**. However, the Cu−C(alkyl) bond length in the former complex is 195.0(4) and 195.4(2) pm[14] in $[CuLi\{CH(Me)P(Et)_2NSiMe_3\}_2]$.[15] The Cu−N distances in both complexes are very similar; 191.1(4) pm in **2** and 191.0(3) pm in $[CuC(SiMe_3)_2C_5H_4N]_2$. Both values correspond very closely to the value of Cu−N distances in secondary copper amides $[CuNR_2]_4$, which is generally close to 191 pm.[12][16] Hence, the Cu−imide donor bond in **2** is as short as a Cu−amide bond. The latter is probably extended by the higher coordination number at the copper centers (coordination number 4−6) compared to the coordination number 2 at the copper center in **2**. Although the P=N bond [159.1(4) pm] in **2** is 2.9 pm longer than that in the starting material **1** [156.2(3) pm][10] and 4.9 pm longer than that in the parent iminophosphorane $Ph_3P{=}NSiMe_3$ [154.2(2) pm],[17] the distance falls within the range normally observed in iminophosphoranes (147−162 pm).[18]

The Cu···Cu distance of 248.79(14) pm in complex **2** is rather short, both as a consequence of the bite of the bridging chelating ligand,[19] which forces the metal centers into close proximity, as well as metal d^{10}-d^{10} closed-shell attraction.[20] Although this distance is not remarkably short (in comparison with 240.3(2) pm in $[Li(thf)_4][Cu_5Cl_4\{Si(SiMe_3)_3\}_2]$[21] and 236.9(1) pm in $[Cu_2\{Si(SiMe_3)_3\}_2BrLi(thf)_3]$[22]), the non-linear C···Cu−N angle of 167.8(2)° clearly indicates metal−metal interaction. This angle is caused by a close metal−metal contact. One would expect the metals to be pushed further out of the center (i.e. further away from the center of inversion located in the middle of the Cu···Cu vector) and a bend of the C−Cu−N unit in the opposite direction if there was no "sticky" interaction. This could easily be achieved by rotation of the metallated phenyl rings about the P−C(*ipso*) bonds. Steric requirements do not constrain the tilt of the two monomeric units and the observed lean would be maximized if the two metal cations were to favour separation.

Organozinc Compounds

The chemistry of organozinc compounds has a long history. They are used as intermediates in organic synthesis, specifically as mild alkylation or arylation agents in organometallic reactions. Organozinc reagents are generally less reactive than Grignard reagents, a property that is a distinct advantage when more gentle reaction conditions are required.[23] Furthermore, they do not tend to associate via μ_2-bridging alkyl or aryl groups like organocopper compounds. All known diarylzinc compounds are colourless solids made up of monomeric units, and are of good to moderate solubility in apolar organic solvents. Diorganozinc compounds bearing functional groups can be divided into two categories, i.e. compounds bearing substituents that do not interact directly with the central zinc atom, and compounds in which coordination of the heteroatoms of the substituents is observed.

Crystal Structure of $[Zn(o\text{-}C_6H_4PPh_2NSiMe_3)_2]$ (3)

The complex $[Zn(o\text{-}C_6H_4PPh_2NSiMe_3)_2]$ (**3**) belongs to the second group, because the two nitrogen atoms of the two $Ph_2P{=}NSiMe_3$ side-arms coordinate to the zinc atom. Hence, the o-$C_6H_4PPh_2NSiMe_3$ substituent in **3** is closely related to other bidentate monoanionic C,N-chelating ligands.[24]

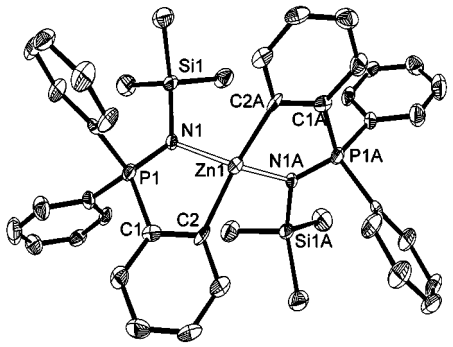


Figure 2. Solid-state structure of $[Zn(o\text{-}C_6H_4PPh_2NSiMe_3)_2]$ (**3**); anisotropic displacement parameters are depicted at the 50% probability level

The zinc atom in **3** is tetrahedrally coordinated by both carbon and nitrogen atoms of the two ligands. The metal atom resides at a center of inversion. The Zn−C distance in **3** [200.8(5) pm, Table 1] is comparable with the Zn−C distances in other diarylzinc species (194.9−201.2 pm).[25] Zn−N distances span a wide range from 182 to 232 pm.[13][26] The Zn−N dative bond in **3** measures 215.8(4) pm and is thus considerably longer than Zn−N bonds in zinc amides (182 pm for $[Zn\{N(SiMe_3)_2\}_2]$ in the gas phase[27]). In the structure of $[HZnN(Me)C_2H_4NMe_2]_2$,[28] the two zinc−amide bonds within the central Zn_2N_2 four-membered ring are 206.1 pm in length, while the two Zn←$N(Me_2)$R donor bonds measure 218.6 pm. The P=N bond in **3** [157.4(4) pm] is 1.7 pm shorter than that in **2** [159.1(4) pm].

The Coupling Product $[(o\text{-}C_6H_4PPh_2NSiMe_3)_2]$ (4)

The application of oxidative coupling to generate C−C bonds via organocopper compounds has a venerable history.[7] A large number of CuR and $CuLiR_2$ species bearing alkyl or functionalized alkyl, alkenyl, alkynyl, aryl or heteroaryl groups have been oxidatively dimerized to the symmetrical coupling products RR.[29] These oxidations have been accomplished by using $CuCl_2$, O_2 or nitrobenzene. In general, the best yields have been obtained employing $CuCl_2$ as the oxidizing reagent. Numerous reactions have been reported in which copper(II) salts have been treated with organometallic compounds [MR] to give organocopper(I) compounds [CuR] and reductive coupling products

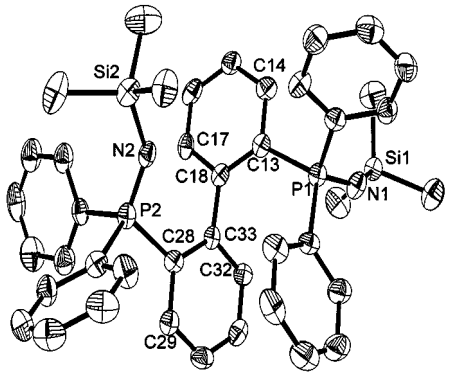

Figure 3. Solid-state structure of (o-$C_6H_4PPh_2NSiMe_3)_2$ (**4**); anisotropic displacement parameters are depicted at the 50% probability level

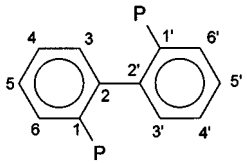
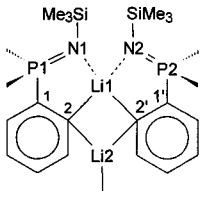
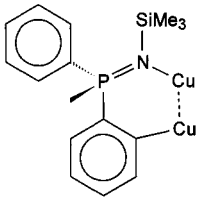
RR (reactions in which the CuX_2:MR molar ratio is 1:2). Reactions of species containing several M−C bonds in close proximity, such as $[Li_nR_n]$ or MgR_2 with CuX_2 afford exclusively the reductive elimination product RR. Thus, it was not surprising that we obtained the coupling product (o-$C_6H_4PPh_2NSiMe_3)_2$ (**4**) from the reaction of [Li(o-$C_6H_4PPh_2NSiMe_3$)]$_2$·Et_2O (**1**) with $CuCl_2$.

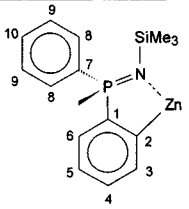
In **4**, the distances are almost identical to the corresponding distances in the iminophosphorane $Ph_3P{=}NSiMe_3$.[9] It is worthy of note that the two symmetry-independent P−N−Si angles in the iminodiphosphorane **4** are significantly different [P1−N1−Si1: 145.1(3)° and P2−N2−Si2: 138.7(3)°, see Figure 3, Table 1], as a result of the steric demand of the bulky groups.

In 1,1′-phosphorus-substituted biphenylenes, the central C2−C2′ distances range from 146.8 to 153.3 pm.[12] The $P-C_{biphenylene}$ distances are found between 182.0 and 187.5 pm, the angles P−C1−C2 vary from 114.5 to 124.2°, and the P−C1−C6 angles from 115.7 to 125.1°. The corresponding distances in **4** are 149.3(7) pm for the C2−C2′ distance of the biphenylene (C18−C33 in Figure 3), and 181.9(6) and 184.6(5) pm for the $P-C_{biphenylene}$ distances (P2−C28 and P1−C13), while the angles amount to 122.9(4) and 127.5(4)° (P−C1−C2) (P2−C28−C33 and P1−C13−C18), and 117.9(4) and 112.2(4)° (P−C1−C6) (P2−C28−C29 and P1−C13−C14). It seems worthy of note that the extreme values for the bond angle of 127.5(4)° and the angle of 112.2(4)° do not fall within the range previously observed in 1,1′-P-substituted biphenylenes. The best planes of the two phenyl rings of the biphenylene unit intersect at an angle of 64.7°.









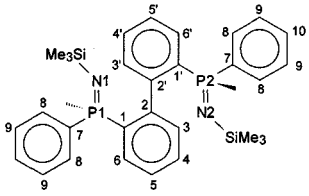


Figure 4

In conclusion, the transmetallation of the *ortho*-lithiated triphenyl(trimethylimino)phosphorane [Li(o-$C_6H_4PPh_2$-$NSiMe_3$)]$_2$·Et_2O gives access to side-arm *N*-donating chelating ligands in organometallic chemistry. The nitrogen donor bond can be as short as a metal−amide bond, as observed in the dimeric copper(I) complex.

Experimental Section

All experiments were performed under nitrogen, either by using modified Schlenk techniques or in a drybox. Solvents were freshly

Crystallographic Measurements: Crystal data for structures **2**–**4** are presented in Table 2. Data of **2** were collected using an Enraf-Nonius CAD4 diffractomer and data of **3** and **4** were collected with a Stoe AED 2 diffractometer fitted with a classical scintillation counter using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). All data were collected at low temperatures using oil-coated shock-cooled crystals.[30] A semiempirical absorption correction was applied for structure **2**.[31] The structures were solved by Patterson or direct methods using SHELXS-90.[32] All structures were refined by full-matrix least-squares procedures on F^2, using SHELXL-93.[33] All non-hydrogen atoms were refined anisotropically, and a riding model was employed in the refinement of the hydrogen atom positions. Although the anisotropic displacement parameters of the trimethylsilyl group in **2** indicate slight rotational disorder, refinement to split occupation sites of the methyl groups was not successful. The elongation of the anisotropic displacement parameter of the *ipso*-carbon atom C2 in **3** along the Zn–C bond is due to the lack of absorption correction. Unfortunatelly, the crystal of **3** decomposed right after data collection of the unique set. Further details of the structure investigation may be obtained from CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K., on quoting the supplementary publication nos. CCDC-102400, -102401, -102402.

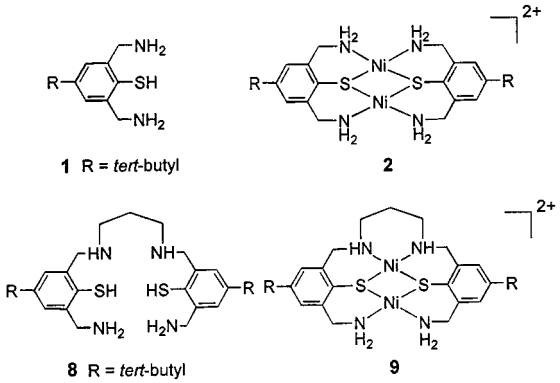
Reactions at the $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ Core in Dinuclear Nickel(II) Amine-Thiolate Complexes

Berthold Kersting,*[a] Gunther Steinfeld,[a] and Julia Hausmann[a]



Keywords: Hexadentate N/S-ligand / Dinuclear complexes / Nickel / Redox chemistry

A discrete dinickel complex with a central $N_2Ni^{II}(\mu_2\text{-}SR)_2Ni^{II}N_2$ core has been synthesized and investigated in the context of ligand binding and oxidation state changes. Reaction of the hexadentate amine-thiolate ligand *N,N′*-bis-[2-thio-3-aminomethyl-5-*tert*-butylbenzyl]propane-1,3-diamine (**8**) with $Ni(ClO_4)_2 \cdot 6\ H_2O$ in methanol affords $[Ni^{II}_2\mathbf{8}][ClO_4]_2 \cdot 3\ CH_3OH$ (**9**), the structure of which has been determined by X-ray crystallography. Complex **9** contains a central $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ core with two approximately planar *cis*-N_2S_2Ni coordination polyhedra bridged at the thiolate sulfur atoms. The *cis*-N_2S_2Ni units differ in that one nickel atom forms a six-membered chelate ring with the two secondary amine nitrogen atoms of **8** whereas the other nickel atom is bound to the remaining primary nitrogen atoms. Complex **9** binds a variety of substrates. Binding of anions to the $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ core in **9** occurs selectively at the Ni atom bound to the secondary nitrogen atoms because of a slightly weaker ligand-field strength. This is demonstrated by X-ray structure determination of the isothiocyanate complex $[Ni^{II}_2\mathbf{8}(NCS)_2] \cdot MeOH$ (**10**) formed by the reaction of **9** with 2 equiv. of KSCN in methanol. Complex **10** is the first example of a complex with adjacent octahedral *cis*-N_4S_2Ni and planar *cis*-N_2S_2Ni sites. The overall dinuclear structure of the parent complex **9** is retained in **10**, except for *trans*-axially bound isothiocyanate ions at Ni(1) and an as yet unexplained inversion of configuration at both secondary amine nitrogen atoms. In DMF solution both complexes undergo two successive reductions at potentials of –0.95 V and –1.53 V vs SCE, assigned to the formation of mixed-valent $[Ni^{I}Ni^{II}\mathbf{8}]^{1+}$ and $[Ni^{I}_2\mathbf{8}]^{0}$ species, respectively. The similar electrochemical properties of **9** and **10** suggest that the *trans*-axially bound isothiocyanate ions in **10** are replaced by DMF molecules in DMF solution. Upon reduction, these solvent molecules decoordinate to produce an unsolvated $[Ni^{I}Ni^{II}\mathbf{8}]^{1+}$ species with two planar N_2S_2Ni units.

Introduction

Discrete first-row transition-metal complexes featuring central $M(\mu_2\text{-}SR)_xM$ cores ($x = 1-3$) have come under increased investigation in the past several years owing to their unusual electronic and magnetic properties[1] and their occurrence in biological systems.[2–4] There are numerous $M(\mu_2\text{-}SR)_2M$ type complexes,[5] which, for the most part, have been studied in attempts to mimic the bonding, spectral, and redox properties of the active site of certain metalloenzymes.[6–9] By contrast, chemical reactivity studies of such species are extremely rare because of the paucity of stable complexes.[10]

The apparent nonuniformity of dinuclear thiolate complexes of labile metal ions with mono- or bidentate thiolate ligands, especially in the solution state, renders desirable the synthesis of well-defined complexes by use of multidentate thiolate ligands containing additional donor atoms such as amine nitrogen or imine nitrogen atoms. However, the synthesis of such N/S-based ligands is a relatively recent development in coordination chemistry and often involves a multi-step reaction sequence. Thus, there are only few reports in which a $M(\mu_2\text{-}SR)_2M$ core is solely assembled by the donor atoms of a multidentate N/S based ligand. An early example of such a system involved the template synthesis of a dinuclear nickel amine-thiolate complex with formaldehyde and nitroethane in aqueous basic solution to give a hexadentate N_4S_2 ligand.[11] Since then the use of metal-directed template reactions between derivatives of 2,6-diformylthiophenol[12] and α,ω-diamines has been an important new source of macrocyclic Schiff-base ligands containing imine nitrogen and thiolate sulfur donor atoms.[13,14]

Scheme 1. Structures of ligands and complexes **1**, **2**,[15] **8**, and **9**

Recently we reported the syntheses and characterization of dinuclear, dithiolate-bridged nickel complexes of the tridentate amine-thiolate ligand **1** (see Scheme 1).[15] The dicationic nickel complex **2**, for example, was found to react with another one equivalent of the ligand, resulting in the

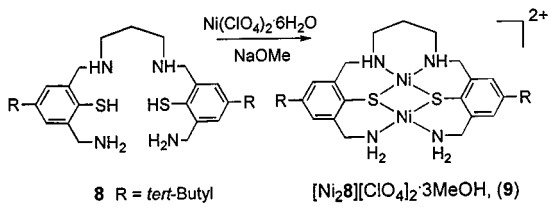
formation of a novel, face-sharing bioctahedral complex with a unique $N_3Ni^{II}(\mu_2\text{-}SR)_3Ni^{II}N_3$ core.[16] While these results unambiguously revealed the ability of the $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ site to expand both nickel coordination spheres from square-planar (*cis*-N_2S_2) to octahedral (*fac*-S_3N_3), an important point that has not been addressed previously was whether unidentate substrates could similarly bind to this dinickel site. Unfortunately, reactions of complex **2** with unidentate substrates did not proceed in a well-defined manner and all attempts to isolate well-defined products have not yet been successful.

In anticipating that a more rigid ligand backbone would allow the dicationic complex to retain its dinuclear structure upon binding of further ligands, we have now prepared the novel hexadentate amine-thiolate ligand **8**, in which two 2,6-bis(aminomethyl)-4-*tert*-butylthiophenolate moieties are joined by one lateral 1,3-propylene chain at the amine nitrogen atoms. We here report the synthesis of **8** and its dinickel complex $[Ni^{II}_2\mathbf{8}][ClO_4]_2 \cdot 3$ MeOH (**9**), the solid-state structure of which has been determined by X-ray structure analysis. We also present the crystal structure of the isothiocyanate complex $[Ni^{II}_2\mathbf{8}(NCS)_2] \cdot$ MeOH (**10**), which is obtained by reaction of **9** with KSCN in methanol. To the best of our knowledge, this result represents the first unambiguous example for substrate binding to a $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ site without affecting the dinuclear structure of the parent complex.[14,17] Both complexes, **9** and **10**, were further characterized by cyclic voltammetry.

Results and Discussion



Syntheses

The preparation of the hexadentate N_4S_2 ligand **8** is very similar to that described previously for the tridentate amine-thiolate ligand **1**[15] and required only slight modifications (Scheme 2). In the first step *tert*-butyl-protected thiolate compound **4** was prepared instead of the benzyl-protected derivative benzyl (4-*tert*-butyl-2,6-diformylphenyl)sulfide used in the preparation of **1**, since reductive cleavage of the ArylS$-$C$(CH_3)_3$ bond by Na/NH_3 (last step) was found to proceed more smoothly than cleavage of the ArylS$-$$CH_2$Ph bond (by virtue of higher yields and easier workup conditions). Key step of this reaction sequence is the reaction of dialdehyde **4** with hydroxylamine in a 1:1 molar ratio, which, besides unreacted **4** and the dioxime as side product, affords the desired monoaldehyde **5** in 69% yield. Reaction of **5** with 1,3-propanediamine in a 2:1 molar ratio in ethanol then furnishes the diimine derivative **6**. This compound precipitates from the reaction mixture in analytically pure form. Subsequent reductions employing $NaBH_4$ and Na/NH_3 as reducing agents gave the hexadentate amine-thiolate ligand **8**. The hydrochloride salt **8** $\cdot$ 4 HCl is a pale yellow solid that can be handled in air for short periods of time without any sign of oxidative decomposition. For long term usage the compound was stored under an atmosphere of dry nitrogen.

Scheme 2. Preparation of the hexadentate amine-thiolate ligand **8**

Reaction of $Ni(ClO_4)_2 \cdot 6\ H_2O$ with **8** $\cdot$ 4 HCl in methanol in the presence of sodium methanolate (Scheme 3) in a 2:1:6 molar ratio gives the dinickel(II) complex $[Ni^{II}_2(\mathbf{8})][ClO_4]_2$ as a dark-red microcrystalline solid. Recrystallization from methanol solution affords this complex as the methanol solvate $[Ni^{II}_2(\mathbf{8})][ClO_4]_2 \cdot 3$ MeOH (**9**), the structure of which has been determined by X-ray crystal-structure determination (below).

Scheme 3. Reaction of **8** with $Ni(ClO_4)_2 \cdot 6\ H_2O$

Complex **9** is an air-stable crystalline solid which is very soluble in polar aprotic solvents like acetonitrile and *N*,*N*-dimethylformamide (DMF). It is less soluble in methanol and practically insoluble in H_2O or dichloromethane. In the IR spectrum the most prominent feature is the strong ClO_4^- absorption at 1090 cm^{-1}, and ν(NH) and $\nu(NH_2)$ stretching frequencies also occur as one broad feature at 3222 cm^{-1} in the usual 3170$-$3225 cm^{-1} region.[18] The O$-$H stretching vibrations of the methanol solvates appear as one broad feature at a relatively low frequency of 3415 cm^{-1} which is due to N$-$H$\cdots$O hydrogen bonding interactions in the solid state.

The UV/Vis spectrum of **9** in acetonitrile is very similar to that of **2** and related planar $N_2S_2Ni^{II}$ complexes with an intense ligand-to-metal charge-transfer band at 501 nm (ε = 1005 $M^{-1}cm^{-1}$) (Figure 1).[19] However, a discrete ^{1}H-NMR spectrum for **9** could not be obtained in CD_3CN solution, presumably due to a paramagnetic species which is formed by coordination of the ClO_4^- anions or solvent molecules. This is also supported by distinct UV/Vis spectral changes for **9** in other donor solvents. DMF solutions of **9**, for example, give rise to new absorption bands at 523 nm (ε = 580 $M^{-1}cm^{-1}$) and 616 nm (sh, ε = 269). Under these conditions, **9** is assumed to exist as discrete dinuclear species with at least one nickel atom being five-coordinate (N_2S_2ONi).[13a,b] A six-coordinate structure can be ruled

out, since the spectrum does not reveal the ν_1 ($^3A_{2g} \rightarrow {}^3T_{2g}$) absorption band around 900−1000 nm characteristic for octahedral, six-coordinate Ni^{II} complexes.[20][21]

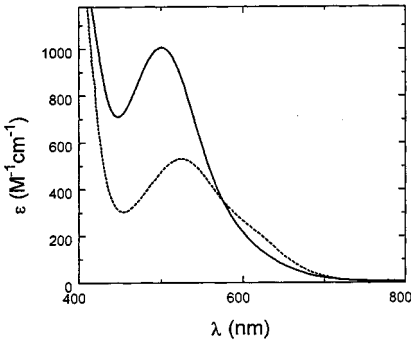


Figure 1. UV/Vis spectra of **9** in CH_3CN (—) and DMF (---) at 295 K

Crystal Structure of $[Ni_2\mathbf{8}][ClO_4]_2 \cdot 3\ CH_3OH$ (9)

The X-ray crystal structure determination of **9** revealed the structure to consist of well-separated molecules of the dinickel complex, two perchlorate anions, and three molecules of methanol of crystallization. Two of the three solvates form hydrogen-bonds with the primary nitrogen atoms of the dication [N(2)−H(2A)···O(9) 2.978 Å, N(4)−H(4A)···O(10) 3.030 Å] whereas the third one is involved in hydrogen-bonding interactions with both secondary nitrogen atoms [N(1)−H(1)···O(11) 3.067 Å, N(3)−H(3)···O(11) 2.987 Å]. However, there are no close contacts between methanol molecules and nickel atoms of the complex cation. Perspective views of the dication of **9** are shown in Figure 2. Bond lengths and angles are summarized in Tables 1 and 2.

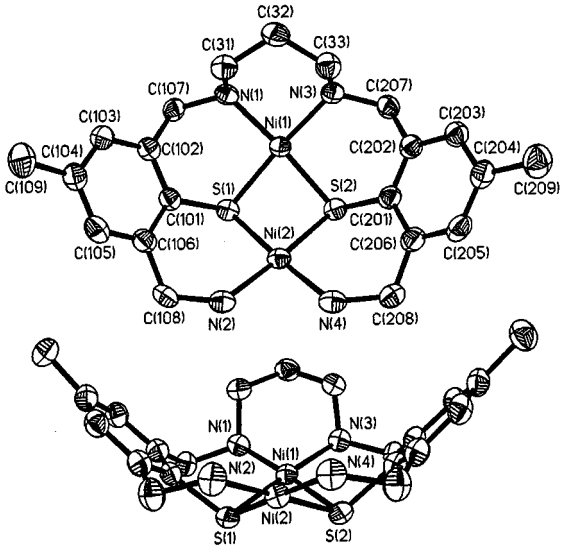

Figure 2. Two different views of the molecular structure of the $[Ni^{II}_2\mathbf{8}]^{2+}$ cation in **9** (50% probability thermal ellipsoids). Hydrogen atoms and *tert*-butyl methyl carbon atoms have been omitted for reasons of clarity. Selected bond lengths and angles are collected in Tables 1 and 2

S(6)−C(6)	−	1.638(10)	C(6)−N(6)	−	1.152(12)

The dication $[Ni_2\mathbf{8}]^{2+}$ possesses idealized C_s symmetry with a pseudo mirror plane passing through the metal atoms and the methylene carbon atom C(32) of the 1,3-diazacyclohexane ring. Its overall structure is very similar to that of **2**,[16] with two approximately planar *cis*-N_2S_2Ni coordination units joined by the thiolate sulfur atoms, with almost identical Ni−N and Ni−S bond lengths, and with a similar bowl-shaped molecular structure. The Ni−N bond lengths at Ni(1) and Ni(2) do not differ significantly, despite the fact that Ni(1) is coordinated by two secondary amine nitrogen atoms. A major structural difference is the six-membered nickela-1,3-diazacyclohexane chelate ring involving the atoms Ni(1), N(1), N(3), C(31), C(32), and C(33). The chelate ring adopts the typical chair conformation[22][23] with enantiomeric configurations (*R*) and (*S*) for asymmetric nitrogen atoms N(1) and N(3), respectively. While this isomer seems to be the thermodynamically most stable form (or the least soluble form), it is likely that the other possible isomers coexist with (*RS*)-**9** in the solution-state (Chart 1). In compound **10**, for example, the 1,3-diazacyclohexane ring adopts the (*S*)-N(1), (*R*)-N(3) set of nitrogen configurations (see below). Similar equilibria between isomers related by (*SR*) ↔ (*RS*) N-inversions within 1,3-diazacyclohexane rings have also been observed in nickel(II) complexes of macrocyclic secondary amine ligands, for example, in $[Ni(cyclam)]^{2+}$ (cyclam = 1,4,8,11-tetraazacyclotetradecane).[24]

Properties of 9

While the molecular structures of **2** and **9** reveal only slight differences, the substitution of two of the tridentate N_2S ligands **1** in **2** by the hexadentate N_4S_2 ligand **8** in **9** affords a kinetically and conformationally more stable complex, as demonstrated by the reactions and electrochemical properties detailed below. Most important, binding of anionic ligands to coordinatively unsaturated **9** does not affect its overall bowl-shaped dinuclear structure. This is in contrast to complex **2** which has been shown to undergo significant structural changes upon coordination of further ligands.[16]

Binding of Anionic Ligands to 9

The red complex **9** reacts cleanly with a variety of substrates such as NaCN, NH_4SCN, NaN_3, or NaHS. In the

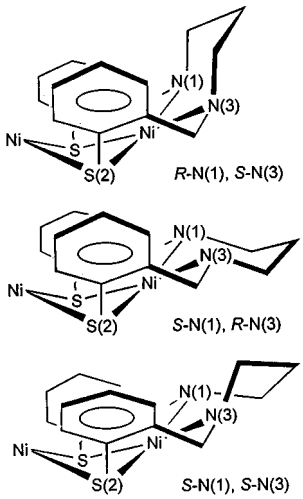

Chart 1. Possible conformations of the six-membered chelate rings in **9** and **10** and the respective configurations at secondary nitrogen atoms N(1) and N(3)

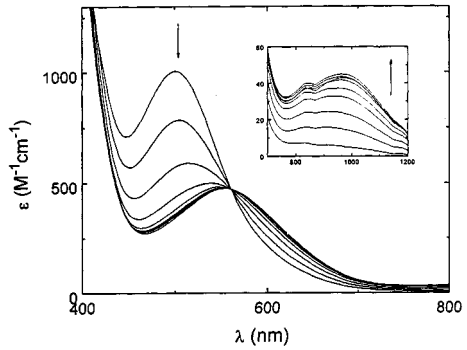
following we will concentrate on the reaction with thiocyanate.[25] Binding of the thiocyanate ion is facile and is accompanied by distinct spectral changes (Figure 3).



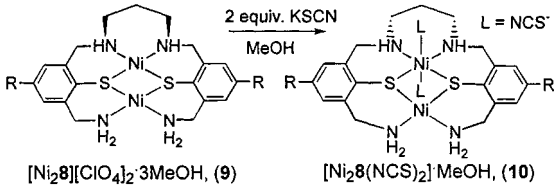


Figure 3. UV/Vis spectral titration of complex **9** ([**9**] = 1×10^{-3} M) with NH_4SCN (0.0−4.0 added equiv.) in acetonitrile at 295 K

Thus, addition of NH_4SCN to **9** in acetonitrile resulted in disappearance of the 501 nm band with concomitant evolution of new absorption bands at 555 nm and 968 nm. An isosbestic point occurred at 561 nm. The 555 nm band exhibited its maximum absorption at a complex to SCN^- ratio of 1:2, and remained essentially unchanged at higher SCN^- concentrations, consistent with binding of two thiocyanate ions. The weak absorption at 968 nm (ε = 48 $M^{-1}cm^{-1}$) is tentatively assigned to the ν_1 band ($^3A_{2g} \rightarrow {}^3T_{2g}$) characteristic for a six-coordinate nickel(II) ion (S = 1), implying that both substrates bind to the same nickel atom. When **9** was allowed to react with KSCN in methanol solution, the complex $[Ni^{II}_2\mathbf{8}(NCS)_2]\cdot CH_3OH$ (**10**) was obtained as a microcrystalline solid (Scheme 4).

Scheme 4. Reaction of **9** with KSCN

Complete replacement of the ClO_4^- anions in **9** by thiocyanate anions in **10** is indicated by the absence of the characteristic ν_3F_2 stretching frequency of the ClO_4^- ion and by the presence of two strong ν(CN) absorptions at 2084 and 2071 cm^{-1}. Compared to the ν(CN) frequencies of KSCN (2053 cm^{-1}),[18] the shift to higher ν(CN) frequencies in **10** clearly indicates the coordination of the thiocyanate ion. However, from the values and numbers of the observed ν(CN) stretching frequencies one cannot a priori distinguish between an S-bonded (thiocyanato complex) or an N-bonded (isothiocyanato complex) or whether both coordination modes occur at the same time. To elucidate the exact bonding mode the crystal structure of **10** was determined.

Crystal Structure of $[Ni_2\mathbf{8}(NCS)_2] \cdot CH_3OH$ (10)

The X-ray crystal structure determination of **10** confirmed coordination of the two thiocyanate anions. Both thiocyanate anions are N-bonded to one nickel atom of the dinuclear isothiocyanate complex. To the best of our knowledge this is the first structurally characterized example of a discrete nickel amine-thiolate complex with adjacent planar *cis*-N_2S_2Ni and octahedral *cis*-N_4S_2Ni units. Figure 4 shows

the molecular structure of the C_s-symmetric neutral complex with the individual atoms displayed as thermal ellipsoids drawn at the 50% probability level. Tables 1 and 2 summarize selected bond lengths and angles.

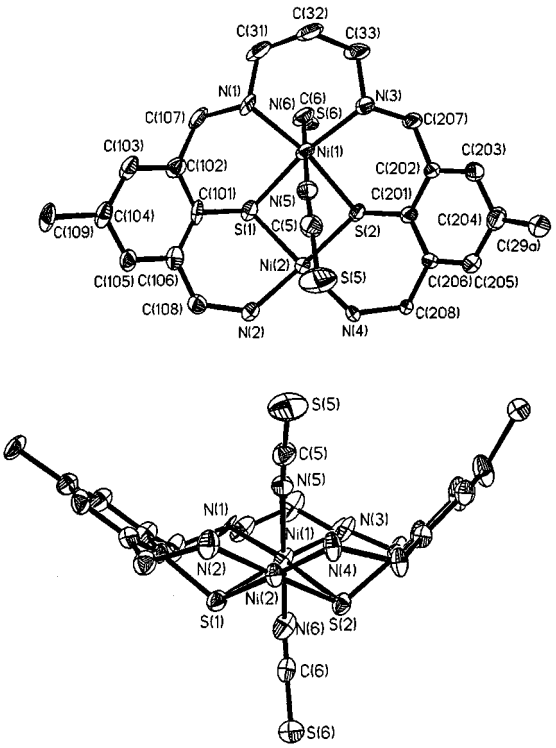

Figure 4. Perspective views of the molecular structure of **10**. Hydrogen atoms and *tert*-butyl methyl carbon atoms are omitted for reasons of clarity. Selected bond lengths and angles are summarized in Tables 1 and 2

The linear isothiocyanate ions occupy *trans*-positions in the $N_4S_2Ni(1)$ octahedron with Ni−N bond lengths of 2.108(7) and 2.095(8) Å, an SCN−Ni−NCS angle of 179.7(3)°, and C−N−Ni angles of 159.4(7) and 149.8(7)°. These values and the average CN and CS distances compare well with those of other isothiocyanato complexes.[26] The remaining coordination sites at Ni(1) are occupied by two bridging thiolate sulfur atoms and by two secondary amine nitrogen atoms. The average Ni−S (2.429 Å) and Ni−N bond lengths (2.098 Å) of six-coordinate Ni(1) are longer than those of four-coordinate Ni(2) and compare well with those of other six-coordinate $N_{6-n}S_nNi^{II}$ complexes. In *cis*-$[Ni(bpy)_2(SPh)_2] \cdot 2\ D_2O$,[27] for example, the average Ni−S and Ni−N bond lengths are at 2.445 Å and 2.091 Å. The average Ni−S (2.208 Å) and Ni−N bond lengths (1.963 Å) for the four-coordinate atom Ni(2), on the other hand, are only slightly longer in comparison with the corresponding values of the four-coordinate nickel atoms in **9**.

As can be seen in Figure 5, the neutral complexes stack in pairs with relatively short [Ni(2)···Ni(2a) 3.904 Å, Ni(2)···S(1a) 3.994 Å, and Ni(2)···S(2a) 3.777 Å] but nonbonding intermolecular interactions. The intramolecular Ni(1)···Ni(2) separation in **10** is shorter at 3.124(1) Å, but likewise out of range of bonding interactions.[28]

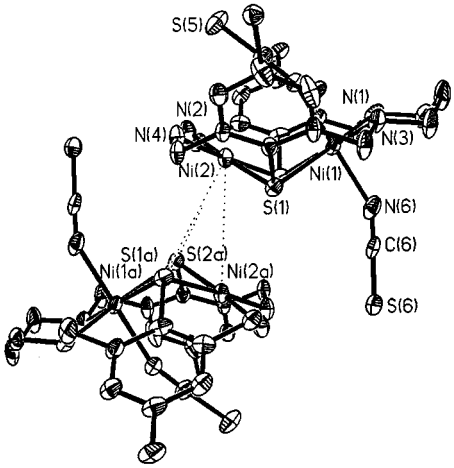

Figure 5. Intermolecular contacts between the neutral molecules in the crystal structure of **10**

It is interesting to note that the isothiocyanate ions have not selected to coordinate to the nickel atom Ni(2). This is surprising because the primary amine nitrogen atoms N(2) and N(4) bound to Ni(2) appear to be sterically less demanding than the secondary nitrogen atoms N(1) and N(3) bound to Ni(1). It thus appears that steric effects play only a minor role for this site-selective binding. This then favors the other explanation that the thiocyanate ions sense the slightly weaker ligand field strength exerted by the secondary amine nitrogen donors at Ni(1) when coordinating to coordinatively unsaturated complex **9**. Consistent with this are observations that the ligand field strength steadily decreases for amine ligands as the number of *N*-alkyl groups is increased.[29]

Another interesting feature is the fact that the 1,3-diazacyclohexane chelate ring now adopts a conformation with (*S*)-N(1) and (*R*)-N(3) nitrogen configurations. That is (*R*)-N(1) and (*S*)-N(3) nitrogen configurations in **9** change to (*S*)-N(1) and (*R*)-N(3) in **10**. However, in the absence of a more detailed kinetic study, one can only hypothesize about the likely mechanism for the inversions.[30,31]

Comparison with other Structures

Compound **10** is unique because it is a crystallographically characterized dinickel(II) amine-thiolate complex where adjacent square-planar N_2S_2Ni and octahedral N_4S_2Ni sites are assembled via the N_4S_2 donor set of a hexadentate N_4S_2 ligand and through the nitrogen atoms of two *N*-bound thiocyanate ions. The dinuclear complex $[Ni(terpy)(SPh)_2]_2 \cdot 6\ H_2O$[17] features a central $N_3SNi(\mu_2\text{-}SR)_2NiSN_3$ core, but this structure is not assembled by a multidentate amine-thiolate ligand. Complex **10** is also an important addition to the series of dinuclear nickel complexes of tridentate aliphatic amine-thiolate,[32] hexadentate macrocyclic amine-thiolate,[11] and imine-thiolate ligands.[13][14] However, these ligands tend to form almost

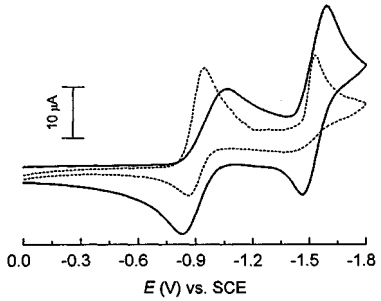

Figure 6. Cyclic voltammograms of complexes **9** (—) and **2** (---) in DMF solution at 295 K. Experimental conditions: [**9**] ca. 1×10^{-3} M, Pt disk working electrode, Ag wire reference electrode, 0.1 M [nBu$_4$N][PF$_6$], scan rate = 200 mV·s^{-1}

exclusively complexes with square-planar N_2S_2Ni units because of the stronger ligand fields of the aliphatic thiolate or the imine donors and, therefore, lack a reactivity pattern similar to that observed for the compounds examined in this study. Binding in the compounds $[Ni_2L(NCCH_3)_2]^{2+}$ and $[Ni_2L(NCS)_2OCN(CH_3)_2]^{2+}$, for example, has been reported to occur only after replacing one half of the N_4S_2 imine-thiolate donor set by an N_2O amine-phenolate donor set.[14c,d] Such compounds have recently attracted interest in connection with the Ni(μ_2-SR)$_2$(X)Fe dinuclear active site in hydrogenase from *Desulfovibrio gigas* (X = unknown ligand).[33]

Electrochemistry

Complexes **9** and **10** were further characterized by cyclic voltammetry. Cyclic voltammograms have been recorded in DMF solution with tetra-*n*-butylammoniumhexafluorophosphate as the supporting electrolyte. All potentials are referenced to the SCE (Table 3).

The CV of **9** in DMF in the cathodic potential region 0.0 to −1.8 V reveals two reduction waves at $E^1_{1/2} = -0.95$ V and at $E^2_{1/2} = -1.53$ V vs SCE. Similar but less well-defined reduction waves were previously observed for complex **2**[15] at −0.97 and −1.48 V (Figure 6). Since the number of observed reduction waves matches with the number of N_2S_2Ni units in **2** and **9** and since the ligands are unlikely to undergo ligand-centered redox reactions, it is assumed that these processes correspond to metal-centered redox reactions with successive formation of mixed valent $Ni^{II,I}$ and $Ni^{I,I}$ species (Eqs. 1a, b). This is also supported by the electrochemical properties of related nickel amine-thiolate complexes featuring planar N_2S_2Ni units which have been reported to undergo $Ni^{II/I}$ reductions at similar potentials.[9a,34]

$$[Ni^{II}_2\mathbf{8}]^{2+} + e^- \rightleftharpoons [Ni^{II}Ni^{I}\mathbf{8}]^{1+} \qquad E^1_{1/2} \qquad (1a)$$

$$[Ni^{II}Ni^{I}\mathbf{8}]^{1+} + e^- \rightleftharpoons [Ni^{I}_2\mathbf{8}]^{0} \qquad E^2_{1/2} \qquad (1b)$$

It is worthwhile to note that the CV of compound **2** is not so well defined in comparison to that of **9**. The second reduction wave at $E^2_{1/2}$, for example, is electrochemically irreversible for **2** (no anodic peak current present) whereas

Table 3. Electrochemical data (E (V)) for **2**,[15] **9**, and **10**[a]

	9	**10**	**2**
$E^1_{1/2}$	−0.95 (230)	−0.96 (192)	−0.97 (irr.)
$E^2_{1/2}$	−1.53 (110)	−1.50 (120)	−1.48 (irr.)
$E^3_{1/2}$		+0.52 (114)	

[a] DMF solutions of **2**, **9**, and **10** were 0.1 M in nBu$_4$NPF$_6$ and ca. 1×10^{-3} M in sample, Pt disk working electrode, Ag wire reference electrode, scan rate 200 mV·s^{-1}, $E^{\times}_{1/2} = (E^{ox}_p + E^{red}_p)/2$ for reversible one-electron-transfer processes; oxidation (E^{ox}_p) or reduction peak potentials (E^{red}_p) are given for irreversible (irr) processes; number in parentheses denote peak-to-peak separations $\Delta E_p = |E^{ox}_p - E^{red}_p|$.

for complex **9** it is quasi-reversible with cathodic and anodic peak potentials separated by 110 mV. It follows that the reduced $[Ni_2\mathbf{8}]^{1+}$ and $[Ni_2\mathbf{8}]^{0}$ species, presumably as a result of a more rigid ligand structure of the hexadentate ligand **8**, exhibit greater stability than the Ni^I species, $[Ni_2\mathbf{1}_2]^{1+}$ and $[Ni_2\mathbf{1}_2]^{0}$, of the tridentate N_2S ligand **1**. The results predict that incorporation of the N_4S_2 donor set into a fully cyclized ligand system would further increase the stability of the dinickel(II,I) or dinickel(I,I) species such as to probably allow for their isolation and an investigation of their properties.

Another important feature of the cyclic voltammogram of complex **9** is the rather broad peak-to-peak separation of the first reduction wave at $E^1_{1/2}$ ($\Delta E_{1/2} = 220$ mV), possibly because of changes in axial ligation upon reduction or oxidation or slight differences in the coordination environments of both nickel ions.[35] This is not unreasonable since the UV/Vis spectral properties of $[Ni_2\mathbf{8}]^{2+}$ in CH_3CN or DMF solution (Figure 2) implicated coordination of solvent molecules to the dinickel(II,II) complex in the latter solvent. It is assumed that these Ni-bound DMF molecules, irrespective of the site of reduction, decoordinate upon the first one-electron-transfer to give a monocationic $[Ni_2\mathbf{8}]^{1+}$ species with unoccupied axial coordination sites at both N_2S_2Ni units (Eq. 2).

$$[Ni_2\mathbf{8}(DMF)_x]^{2+} + e^- \rightleftharpoons [Ni_2\mathbf{8}]^{1+} + x\ DMF \qquad E^1_{1/2} \qquad (2)$$

There are several points which strongly argue for such a structure of the mixed-valent complex. First, the overall charge of the parent complex $[Ni^{II}_2\mathbf{8}(DMF)_\times]^{2+}$ decreases by one unit to give the monocationic complex $[Ni^{I}Ni^{II}\mathbf{8}]^{1+}$ which is expected not to bind substrates as readily as the dicationic $[Ni^{II}_2\mathbf{8}]^{2+}$ species. Second, the rather narrow peak-to-peak separation of the second reduction wave at $E^2_{1/2}$ departs not so strongly from reversibility as observed for the first one-electron-transfer process at $E^1_{1/2}$, implicating that this process does not involve changes in axial ligation. Finally, nearly all structurally characterized Ni^I complexes (d^9 electronic configuration) have been shown to be four-coordinate with a planar coordination around Ni^I.[36] Similar conclusions can be drawn from a comparison of the electrochemical properties of complex **9** and the isothiocyanate complex **10**.

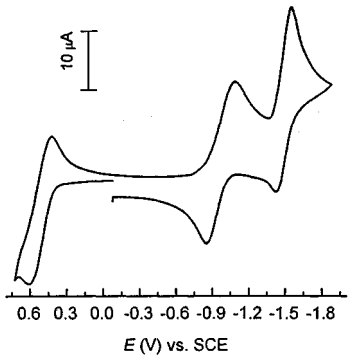

Figure 7. Cyclic voltammogram of complex **10** in DMF solution at 295 K. Experimental conditions: [**10**] ca. 1×10^{-3} M, Pt disk working electrode, Ag wire reference electrode, 0.1 M $[n\text{Bu}_4\text{N}][\text{PF}_6]$, scan rate = 200 mV·s^{-1}

As shown in Figure 7 the CV of complex **10** reveals, besides two reduction waves in the cathodic potential region, an additional oxidation wave at $E^3_{1/2} = 0.52$ V vs SCE in the anodic potential region. Since this feature was not present in the CV of **9**, it is assigned to oxidation of free thiocyanate (Eq. 3b) which is deliberated from **10** by DMF substitution (Eq. 3a). The reported values of $E_{1/2} = 0.77$ V (vs SCE, H_2O) for the process indicated in Eq. 3b is in good agreement with this assignment.[37] It thus appears that in DMF solution the solvent molecules compete successfully with the thiocyanate ions for the axial coordination sites at the dimetal centrum.

$$[\text{Ni}_2\mathbf{8}(\text{NCS})_2]^{2+} + x\ \text{DMF} \rightleftharpoons [\text{Ni}_2\mathbf{8}(\text{DMF})_x]^{2+} + 2\ \text{NCS}^- \quad (3a)$$

$$\text{NCS-SCN} + 2\ e^- \rightleftharpoons 2\ \text{NCS}^- \quad (3b)$$

The fact that complexes **10** and **9** reduce at nearly the same potentials with similar peak-to-peak separation characteristics reveal that both complexes in DMF solution exist presumably as the same DMF-solvated $[\text{Ni}_2\mathbf{8}(\text{DMF})_x]^{2+}$ species. Finally, the presence of free thiocyanate in the electrolyte medium has obviously no effect on the reduction of the mixed-valent $[\text{Ni}^{\text{II}}\text{Ni}^{\text{I}}\mathbf{8}]^{1+}$ species at $E^2_{1/2}$, indicating little, if any, affinity for binding of anions.

Conclusion

Two novel thiolate-bridged dinickel complexes have been synthesized and crystallographically characterized. Both compounds represent important additions to the series of similar structures previously established with hexadentate imine-thiolate ligands. However, the hexadentate N_4S_2 amine-thiolate ligand described in this study exerts a weaker ligand field strength such that binding of exogenous substrates occurs to the central $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ core in **9**. In contrast to **2**, complex **9** represents a thermodynamically and configurationally more stable dinuclear nickel amine-thiolate complex that coordinates further anions without affecting its overall dinuclear structure. We expect further exciting coordination chemistry with **9** and **10** and with other first-row transition metal complexes of this ligand.

Experimental Section

Materials and Methods: Compound **3**[15] was prepared as previously described. All other chemicals were of reagent grade and used without further purification. Solvents were predried over molecular sieves and freshly distilled from appropriate drying agents. − ^{1}H-NMR and ^{13}C{^{1}H}-NMR spectra were recorded on a Bruker AC 200 spectrometer. All chemical shifts are quoted on the δ scale with TMS or the solvent as internal standard. Coupling constants are expressed in Hz. − Melting points were determined in capillaries and are uncorrected. − CHN-Analyses were determined with a Perkin Elmer Elemental Analyzer 240. − IR spectra were recorded on a Bruker IFS25 spectrophotometer as KBr pellets. − Absorption spectra were recorded on a Jasco V-570 UV/VIS/NIR spectrometer. − Cyclic voltammetry measurements were carried out at 25°C with an EG&G Princeton Applied Research Potentiostat/Galvanostat Model 263 A. The cell contained a Pt working electrode, a Pt wire auxiliary electrode, and an Ag wire as reference electrode. Concentration of solutions were 0.1 M in supporting electrolyte ($n\text{Bu}_4\text{NPF}_6$) and ca 1×10^{-3} M in sample. Ferrocenium/ferrocene was used as internal standard. All potentials were converted to the SCE reference.

***tert*-Butyl (4-*tert*-Butyl-2,6-diformylphenyl) Sulfide (4):** To a suspension of *tert*-butylthiol (4.78 g, 53.0 mmol) and K_2CO_3 (8.29 g, 60.0 mmol) in DMF (80 mL) was added solid 1-bromo-4-*tert*-butyl-2,6-diformylbenzene (**3**) (14.3 g, 53.0 mmol). After stirring the reaction mixture for 12 h, the product precipitated upon dropwise addition of water (200 mL). The solid was isolated by filtration, washed with water (100 mL), and dried in vacuum. The crude product was used without further purification. Yield: 14.0 g (95%). − ^{1}H NMR (200 MHz, $CDCl_3$, 25°C, TMS): δ = 10.80 (s, 2 H, C*H*O), 8.18 (s, 2 H, Ar*H*), 1.30 (s, 9 H, CH_3), 1.21 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR (50.2 MHz, $CDCl_3$, 25°C): δ = 192.4, 153.3, 140.2, 136.4, 130.2, 49.2, 35.0, 30.7.

***tert*-Butyl (4-*tert*-Butyl-2-formyl-6-hydroximinomethylphenyl) Sulfide (5):** To a solution of **4** (27.8 g, 100 mmol) in $CHCl_3$ (300 mL) was added a solution of $NH_2OH\cdot HCl$ (6.95 g, 100 mmol) and NEt_3 (10.1 g, 100 mmol) in $CHCl_3$ (100 mL). The reaction mixture was stirred for 12 h and then reduced in volume to 150−200 mL by evaporation under reduced pressure. As indicated by TLC chromatography, the reaction mixture contains **5** as the main product (second spot), the dioxime as side product (third spot), and unreacted **2** (first spot). For easier workup, most of the dioxime was precipitated by addition of hexanes and separated by filtration. The filtrate was then taken to dryness to leave a pale yellow oil. The oil was loaded on a SiO_2 column and the product (second fraction) eluted by using CH_2Cl_2/C_6H_{12} (1:1, v:v) as eluent. Removal of the solvent afforded 20.2 g (69%) of **5** as colorless crystals. − ^{1}H NMR (200 MHz, $CDCl_3$, 25°C, TMS): δ = 10.77 (s, 1 H, C*H*O), 9.00 (s, 1 H, C*H*N), 8.15 [d, ^4J(H,H) = 2 Hz, 1 H, Ar*H*], 8.01 [d, ^4J(H,H) = 2 Hz, 1 H, Ar*H*], 7.58 (br. s, 1 H, NO*H*), 1.30 (s, 9 H, CH_3), 1.18 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR (50.2 MHz, $CDCl_3$, 25°C): δ = 193.4, 152.8, 147.3, 140.3, 139.8, 132.0, 127.9, 125.7, 49.5, 35.0, 31.0, 30.9.

***N,N′*-Bis-[2-*tert*-butylsulfanyl-3-hydroximinomethyl-5-*tert*-butylbenzylidene]propane-1,3-diamine (6):** To a solution of **5** (587 mg, 2.00 mmol) in ethanol (10 mL) was added a solution of propane-1,3-diamine (71 mg, 0.96 mmol) in ethanol (3 mL). The solution was heated to 60°C for 10 min. On cooling **6** precipitated as a white solid. The solid was isolated by filtration, washed with ether (3 × 2 mL), and dried in air to give 557 mg (93%, based on 1,3-propanediamine) of analytically pure product. Compound **6** exhibits only poor solubility in organic solvents. − ^{1}H NMR (200 MHz,

[D$_6$]DMSO, 35°C): δ = 11.32 (s, 2 H, NO*H*), 9.10 (s, 2 H, C*H*=N), 8.81 (s, 2 H, C*H*=N), 8.13 [d, ^4J(H,H) = 2 Hz, 2 H, Ar*H*], 8.01 [d, ^4J(H,H) = 2 Hz, 2 H, Ar*H*], 3.71 [t, ^3J(H,H) = 7 Hz, 4 H, NCH_2], 1.98 [qnt, ^3J(H,H) = 7 Hz, 2 H, CH_2], 1.31 (s, 18 H, CH_3), 1.13 (s, 18 H, CH_3).

***N,N′*-Bis-[2-*tert*-butylsulfanyl-3-hydroximinomethyl-5-*tert*-butylbenzyl]propane-1,3-diamine (7):** To a suspension of **6** (5.0 g, 8.0 mmol) in MeOH/CH_2Cl_2 (100 mL, 1:1) was added a solution of $NaBH_4$ (1.06 g, 28.0 mmol) in MeOH (50 mL). After the reaction mixture was stirred for 2 h, the resulting homogeneous solution was acidified with concentrated HCl to destroy the excess reducing agent. Then water (100 mL) was added and the reaction mixture was made alkaline by addition of 6 M KOH solution (final pH = 13). The organic phase was separated, and the aqueous phase extracted with CH_2Cl_2 (3 × 200 mL). The combined organic phases were dried with K_2CO_3, filtered, and the solvent removed in vacuum to give 4.6 g (91%) of the product as a white foam. The product was used without further purification. – ^{1}H NMR (200 MHz, CD_3OD, 25°C): δ = 8.83 (s, 2 H, C*H*=NO), 7.91 [d, ^4J(H,H) = 2 Hz, 2 H, Ar*H*], 7.57 [d, ^4J(H,H) = 2 Hz, 2 H, Ar*H*], 4.84 (s, 4 H, ArCH_2N), 2.66 [t, ^3J(H,H) = 7 Hz, 4 H, NCH_2], 1.75 [qnt, ^3J(H,H) = 7 Hz, 2 H, CH_2], 1.31 (s, 18 H, CH_3), 1.13 (s, 18 H, CH_3). – ^{13}C{^{1}H} NMR (50.2 MHz, CD_3OD, 25°C): δ = 153.1, 151.3, 146.3, 139.5, 129.5, 128.9, 123.0, 53.1, 49.6, 48.2, 35.3, 31.4, 31.2, 29.6

***N,N′*-Bis-[2-thio-3-aminomethyl-5-*tert*-butyl-benzyl]propane-1,3-diamine (8):** A solution of **7** (6.29 g, 10.0 mmol) in THF (50 mL) was added dropwise to a solution of sodium (6.51 g, 28.3 mmol) in liquid ammonia (100 mL). During addition the temp. was kept below −60°C by cooling with a dry ice/2-propanol bath. After the deep blue reaction mixture was stirred for further 3 h at −50°C, solid ammonium chloride was added to destroy excess reducing equivalents. The ammonia was allowed to evaporate at atmospheric pressure, and then the remaining THF was evaporated in vacuum. The solid residue was dissolved in 30 mL of water and the pH of the solution adjusted to 1 by addition of 1 M HCl. After stirring for 30 min, the precipitate was collected by filtration, and recrystallized from 1 M HCl to give 4.32 g (68%) of **8** · 4 HCl as a pale yellow solid. – ^{1}H NMR (200 MHz, D_2O, 25°C): δ = 7.45 (s, 4 H, Ar*H*), 4.26 (s, 4 H, ArCH_2N), 4.16 (s, 4 H, ArCH_2N), 3.31 [t, ^3J(H,H) = 7 Hz, 4 H, NCH_2], 1.75 [qnt, ^3J(H,H) = 7 Hz, 2 H, CH_2], 1.31 (s, 18 H, CH_3). – ^{13}C{^{1}H} NMR (50.2 MHz, D_2O, 25°C): δ = 152.7, 136.3, 134.2, 129.7, 129.2, 127.0, 57.4, 50.4, 44.4, 34.3, 30.2, 22.5.

[Ni_2(8)][ClO_4]$_2$ · 3 MeOH (9): ***Caution! Transition-metal perchlorates are hazardous and may explode. Only small quantities should be prepared and great care taken.*** To a suspension of **8** · 4 HCl (635 mg, 1.00 mmol) in methanol (5 mL) was added a solution of $Ni(ClO_4)_2$ · 6 H_2O (731 mg, 2.00 mmol) in methanol (5 mL). The resulting pale green suspension was allowed to stir for further 10 min. Then a 1.00 M solution of NaOMe in methanol (6.00 mL, 6.00 mmol) was added. The dark red solution was stirred over night to obtain the product as a red microcrystalline powder. Filtration and recrystallization from methanol affords the complex as the methanol solvate **9** · 3 MeOH. Further product may be obtained by addition of $LiClO_4$ to the mother liquor to give a total yield of 580 mg (70%) of **9** · 3 MeOH. The crystals lose the methanol molecules of crystallization upon storage in air at 298 K. – IR (KBr): $\tilde{\nu}$ = 3415s (OH), 3222s (NH), 1090vs cm^{-1} [ClO_4^-, $\nu_3(F_2)$]. – UV/Vis (CH_3CN): λ_{max} (ε): 312 (6858), 374 (5821), 501 nm (1005 M^{-1} cm^{-1}). – $C_{27}H_{42}Cl_2N_4Ni_2O_8S_2$ · 3 CH_3OH (899.18): calcd. C 40.07, H 6.05, N 6.23; found C 39.08, H 5.82, N 5.88.

[Ni_2(8)($NCS)_2$] · MeOH (10): A solution of NH_4SCN (10 mg, 0.13 mmol) in methanol (2 mL) was added to a solution of **9** (45 mg, 0.050 mmol) in methanol (5 mL) resulting in the precipitation of a purple solid. After the suspension was stirred for further 30 min, the product was isolated by filtration, washed with 2 mL of methanol, and dried in air. Single crystals suitable for study by X-ray diffraction were grown by slow evaporation of an acetonitrile/methanol solution (2:1) of **10**. – IR (KBr): $\tilde{\nu}$ = 3277w, 3208sh, 3193 br s, 3150sh (NH), 2084vs, 2072vs cm^{-1} (NCS^-). – UV/Vis (CH_3CN): λ_{max} (ε): 555 (478), 968 nm (45 M^{-1}cm^{-1}). – $C_{29}H_{42}N_6Ni_2S_4$·CH_3OH (752.35): calcd. C 47.89, H 6.16, N 11.17; found C 47.81, H 6.02, N 10.88.

Crystal-Structure Determinations: Crystals of **9** suitable for X-ray structure analysis were obtained by recrystallization from methanol. Black crystals of **10** suitable for single-crystal X-ray determination were obtained by the procedure described above.

Crystal data and refinement details for **9** ($C_{30}H_{54}Cl_2N_4Ni_2O_{11}S_2$, M_r 899.18): crystal size 0.18 × 0.16 × 0.08 mm^3, STOE IPDS diffractometer, T = 213(2) K, monoclinic, space group $P2_1/n$, a = 11.408(2), b = 17.396(3), c = 20.342(4) Å, β = 92.29(3)°, V = 4033.7 Å^3, Z = 4, ρ_{calcd} = 1.48 g·cm^{-3}, μ(Mo-K_α) = 0.64 mm^{-1}, empirical absorption correction, transmission factors 0.92–0.97, 56797 reflections collected, 7806 unique reflections (R_{int} = 0.1058), 6233 observed reflections [$I > 2\sigma(I)$]. The structure was solved by direct methods (SHELXS-86)[38] and refined by full-matrix least-squares techniques against F^2 (SHELXL-93). All non-hydrogen atoms were refined anisotropically except the methyl carbon atoms of one disordered *tert*-butyl group and the oxygen atoms of the disordered perchlorate ions. An isotropic split-atom model was applied for the disordered methyl carbon and oxygen atoms. The multiplicities of the respective orientations [C(110)–C(112)/C(113)–C(115), O(1A)–O(4A)/O(1B)–O(4B), O(5A)–O(8A)/O(5B)–O(8B)] were refined as follows: 0.68/0.32, 0.55/0.45, 0.49/0.51. Hydrogen atoms were placed at calculated positions and were refined using a riding model with isotropic thermal parameters fixed at 1.2 times the equivalent isotropic U of the atom to which they were bonded. Final residuals: $R1$, $wR2$ [$F_o > 4\sigma(F_o)$]: 0.0715, 0.1778, $R1$, $wR2$ (all data): 0.0889, 0.2007, goodness-of-fit on F^2: 1.08, residual electron density: 1.16/-0.79 e·Å^{-3}.

Crystal data and refinement details for **10** ($C_{30}H_{46}N_6Ni_2OS_4$, M_r 752.39): crystal size 0.21 × 0.12 × 0.11 mm^3, Enraf-Nonius CAD4 diffractometer, T = 183(2) K, triclinic, space group $P\bar{1}$, a = 12.051(2), b = 12.117(2), c = 13.139(3) Å, α = 99.39(3), β = 110.88(3), γ = 100.66(3)°, V = 1705.9 Å^3, Z = 2, ρ_{calcd} = 1.47 g·cm^{-3}, μ(Mo-K_α) = 1.38 mm^{-1}, empirical absorption correction based on ψ-scans, transmission factors 0.96–0.91, 7001 reflections collected, 6665 unique reflections (R_{int} = 0.0917), 3891 observed reflections [$I > 2\sigma(I)$]. The structure was solved by the heavy atom method (SHELXS–86) and refined by full-matrix least-squares techniques against F^2 (SHELXL-93). All non-hydrogen atoms were refined anisotropically except the methyl carbon atoms of the disordered *tert*-butyl groups and the atoms of the methanol solvate. An isotropic split-atom model was applied for the disordered methyl carbon atoms of the *tert*-butyl groups. The multiplicities of the respective orientations [C(110)–C(112)/C(113)–C(115), C(220)-C(212)/C(213)-C(215)] were refined as follows: 0.64/0.36 and 0.48/0.52. Hydrogen atoms were placed at calculated positions and were refined using a riding model with isotropic thermal parameters fixed at 1.2 times the equivalent isotropic U of the atom to which they were bonded. Final residuals: $R1$, $wR2$ [$F_o > 4\sigma(F_o)$]: 0.0652, 0.1706, $R1$, $wR2$ (all data): 0.1613, 0.2463, goodness-of-fit on F^2: 1.05, residual electron density: 0.86/–0.97 e·Å^{-3}. Crystallo-

graphic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102781 (**10**) and CCDC-102782 (**9**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: +44 (1223) 336-033; E-mail: deposit@cam.ac.uk].

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft. We thank Prof. Dr. H. Vahrenkamp for his generous support, and Prof. Dr. B. Krebs for the use of the STOE-IPDS diffractometer. We are grateful to S. Höck and A. Trösch for help in collecting the X-ray data.

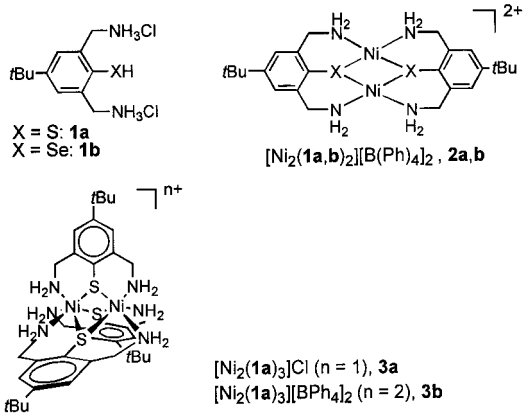
Preparation, Structure, and Properties of a Mixed-Valent $Ni^{II}Ni^{III}$ Amine-Selenolate Complex

Berthold Kersting*[a] and Dieter Siebert[b]

Dedicated to Prof. Dr. Bernt Krebs on the occasion of his 60th birthday

Keywords: Mixed-valent compounds / Nickel / N_2Se ligand / Cyclic voltammetry / EPR spectroscopy



Two dinuclear nickel amine-selenolate complexes of the tridentate amine-selenolate ligand, 4-*tert*-butyl-2,6-di-(aminomethyl)selenophenol (**1b**), have been synthesized and their properties characterized. The green complex $[Ni^{II}_2(\mathbf{1b})_3]Cl$ (**4a**) is readily prepared from **1b**, $NiCl_2 \cdot 6\,H_2O$, and NaOMe in methanol or by reaction of coordinatively unsaturated $[Ni^{II}_2(\mathbf{1b})_2][BPh_4]_2$ (**2b**) with another one equivalent of **1b** in the presence of triethylamine. The face-sharing, bioctahedral structure of **4a** is derived from UV/Vis spectroscopy, cyclic voltammetry, and single-crystal X-ray diffraction of its oxidation product, $[Ni^{II}Ni^{III}(\mathbf{1b})_3]^{2+}$. The dication was prepared by air-oxidation of **4a** in MeOH and isolated as the dark-brown BPh_4^- salt, $[Ni^{II}Ni^{III}(\mathbf{1b})_3][BPh_4]_2 \cdot CH_3OH$ (**4b**). Mixed-valent complex **4b** consists of a dinuclear, face-sharing bioctahedral dication with a central $N_3Ni^{II}(\mu_2\text{-}SeR)_3Ni^{III}N_3$ core and well-separated tetraphenylborate anions. Distortions from D_{3h} symmetry suggest that **4b** is a trapped-valence compound in the solid-state. On the CV time scale complex **4a** undergoes two reversible one-electron oxidations at $E^1_{1/2} = -0.15$ and at $E^2_{1/2} = +0.29$ V vs SCE, affording **4b** and the thermally not stable trication $[Ni^{III}_2(\mathbf{1b})_3]^{3+}$, respectively. The EPR spectrum of a powdered sample of **4b** reveals an $S = {}^3/_2$ ground state of the mixed-valent $Ni^{II}Ni^{III}$ complex.

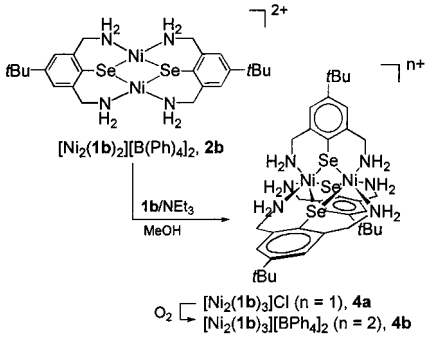
Introduction

In contrast to the considerable chemistry of nickel thiolate complexes,[1] the coordination chemistry of nickel selenolate complexes has been less extensively developed.[2] The majority of the structurally characterized complexes contain divalent, four-coordinate nickel with planar[3] or tetrahedral coordination environments.[4] Recently, higher coordination numbers have been realized by partial selenolate ligand replacement through multidentate N-based coligands.[5][6] Structurally characterized selenolate complexes of trivalent[7] and quadrivalent[8] nickel are known as well, most of them with unsaturated selenolate ligands, as for instance with benzene-1,2-diselenol.[9] However, attempts to prepare nickel(III) complexes of monodentate aliphatic or aromatic selenolate ligands have not yet been successful.

Recently we have reported the synthesis, solution- and solid-state structures of dinuclear nickel complexes **2a**,**b** of amine-thiolate and -selenolate ligands **1a**,**b**.[10] In contrast to many other $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ type complexes, the amine-thiolate complex **2a** was shown to readily react with another one equivalent of **1a** to afford the dinuclear, face-sharing bioctahedral complex **3a**. Furthermore, complex **3a** could be reversibly oxidized to afford the mixed-valent dication $[Ni^{II}Ni^{III}(\mathbf{1a})_3]^{2+}$ in **3b** with distinct localized Ni^{III} ($S = {}^1/_2$) and Ni^{II} ions ($S = 1$).[11] Such dinuclear, face-sharing octahedral complexes have attracted considerable attention in regards to their electronic structures.[12,13]

We now present the synthesis, structural, spectral, and redox properties of the selenium analogs of **3a**,**b**.

Scheme 1. Structures of ligands and complexes **1a**,**b**, **2a**,**b**, and **3a**,**b**



Results and Discussion

Syntheses

The synthesis of amine-selenolate complexes **4a**,**b** is shown in Scheme 2. Analogously to the preparation of amine-thiolate complex **3a**, complex **4a** was obtained by reaction of **2b** with another one equivalent of **1b** in the presence of triethylamine. Alternatively, complex **4a** could also

Scheme 2. Preparation of amine-selenolate complexes **4a**,**b**

be obtained by the direct reaction between **1b** and $Ni(ClO_4)_2 \cdot 6\ H_2O$ in a 3:2 molar ratio. The face-sharing, bioctahedral structure of **4a** is derived from UV/Vis spectroscopy, cyclic voltammetry, and single-crystal X-ray diffraction of its oxidation product **4b** (see below).

Complex **4a** is a pale-green, air-sensitive solid that is insoluble in most common organic solvents, but a suspension of **4a** in methanol, when exposed to air, produces a clear deep brown solution. From the resulting clear solution, upon addition of $NaBPh_4$, the dicationic salt $[Ni_2(\mathbf{1b})_3][BPh_4]_2 \cdot MeOH$ (**4b**) is obtained as black crystals.

Crystal Structure of 4b

The crystal structure determination of **4b** confirms the dinuclear structure and the mixed-valent nature of the $[Ni_2(\mathbf{1b})_3]^{2+}$ dication. The crystal structure consists of well-separated dications $[Ni_2(\mathbf{1b})_3]^{2+}$, BPh_4^- anions, and one methanol molecule of crystallization. Complex **4b** is isostructural with the amine-thiolate complex **3b**.[11] The molecular structure of the $[Ni_2(\mathbf{1b})_3]^{2+}$ dication is displayed in Figure 1 along with important bond lengths and angles.

Both nickel ions are facially coordinated to three amine nitrogen atoms and three bridging selenolate selenium atoms of three amine-selenolate ligands. The N_3Se_3 octahedra around Ni(1) and Ni(2) are different, and consequently, the local symmetry of the $[Ni_2(\mathbf{1b})_3]^{2+}$ dication is distorted from D_{3h} symmetry. These distortions are manifested in three different Ni−Se distances at Ni(1) at 2.456(1), 2.427(1), and 2.533(1) Å and similarly at Ni(2) at 2.443(1), 2.391(1), and 2.529(1) Å. Likewise, the Ni−N distances at Ni(1) at 2.042(4), 2.102(4), and 2.061(4) Å and similarly at Ni(2) at 2.011(4), 2.107(4), and 2.087(4) Å are not equidistant. It is noted that the Ni−N and Ni−Se bond lengths appear to be shorter at Ni(2).

As expected, the average Ni−Se bond length at 2.463(1) Å is longer than the average Ni−S bond length in **3b** at 2.380(1) Å. The average Ni−N bond length, on the other hand, has decreased from 2.089(3) Å in **3b** to 2.068(4) Å in **4b**. Both, Ni−Se and Ni−N distances should be compared with Ni−Se and Ni−N distances of 2.440(3) and 2.063(5) Å, respectively, in $[Ni(terpy)(SeC_6H_2\text{-}2,4,6\text{-}Me_3)_2]$, which contains five-coordinate Ni^{II} in a distorted trigonal-bipyramidal coordination environment.[6] As a consequence of

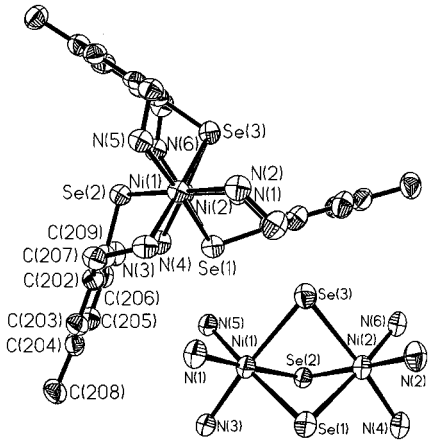

Figure 1. Molecular structure of the $[Ni^{II}Ni^{III}(\mathbf{1b})_3]^{2+}$ dication and the structure of the central $N_3Ni(\mu_2\text{-}SeR)_3NiN_3$ core in **4b** (50% probability thermal ellipsoids). Hydrogen atoms and *tert*-butyl methyl carbon atoms have been omitted for reasons of clarity. Selected bond lengths [Å] and angles [°]: Ni(1)−N(1) 2.042(4), Ni(1)−N(3) 2.102(4), Ni(1)−N(5) 2.061(4), Ni(2)−N(2) 2.011(4), Ni(2)−N(4) 2.107(4), Ni(2)−N(6) 2.087(4), Ni(1)−Se(1) 2.456(1), Ni(1)−Se(2) 2.427(1), Ni(1)−Se(3) 2.533(1), Ni(2)−Se(1) 2.443(1), Ni(2)−Se(2) 2.391(1), Ni(2)−Se(3) 2.529(1); Ni(1)−Se(1)−Ni(2) 80.96, Ni(1)−Se(2)−Ni(2) 82.63(1), Ni(1)−Se(3)−Ni(2) 77.84(1), N−Ni−N 89.0(2)−92.7(2), Se−Ni−Se 80.40(3)−85.99(3), N−Ni−Se_{cis} 91.4(1)−93.8(1), N−Ni−Se_{trans} 172.1(1)−174.7(7), Ni−Se−Ni 77.84(1)−82.63(1)

longer Ni−Se distances, the Ni(1)···Ni(2) separation in **4b** is 3.181(1) Å. The corresponding value in **3b** was determined to be 3.064(1) Å. In both compounds, however, wide Ni−S−Ni [mean 80.16(3)°] and Ni−Se−Ni angles [mean 80.48(3)°] preclude any attraction between the metal atoms.[14]

The individual bond lengths and angles within the three amine-selenolate ligands show no unusual features ruling out the possibility of a ligand-centered oxidation of **4a** with one of the ligands being coordinated as a selenyl radical in **4b**. A metal-centered rather than a ligand-centered oxidation is also supported by infrared spectroscopy. From the apparent distortions from D_{3h} symmetry complex **4b** appears to be a trapped-valence $Ni^{II}Ni^{III}$ compound with distinct localized Ni^{II} and Ni^{III} sites (Class I in Robin and Day's classification of mixed-valent species).[15] A delocalized species would be expected to have structurally identical nickel sites.[16] The greater extent of distortion in Ni−N and Ni−Se distances at Ni(2) may be due to a Jahn−Teller distortion, which is expected for an octahedral Ni^{III} ion with low-spin d^7 electronic configuration. Thus, Ni(2) is presumably a Ni^{III} ion.

Infrared and UV/Vis Spectra of 4a, b

The most characteristic features in the infrared spectrum of **4a** are two strong absorptions at 3328 and 3250 cm^{-1}. These bands are assigned to $\nu_{as}(NH_2)$ and $\nu_s(NH_2)$ stretching vibrations of the RNH_2 groups.[17] In the infrared spectrum of **4b**, the $\nu(NH_2)$ stretching frequencies are shifted by ca. 20 cm^{-1} to lower wavenumbers. This further supports the metal-centered oxidation of **4a** and the ground state of

4b, since the decrease in Ni−N bond lengths upon passing from $Ni^{II}-NH_2$ to $Ni^{III}-NH_2$ is expected to give a more polarized $Ni^{III}N-H$ bond, causing a weakening of the N−H bonds. Furthermore, the increase in the number of $\nu(NH_2)$ stretching vibrations from two in **4a** to five in **4b** nicely corroborates with the notion of distinct localized Ni^{II} and Ni^{III} oxidation states in the mixed-valent compound **4b**.

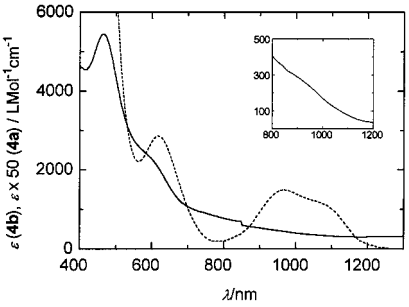

Figure 2. UV/Vis spectra of **4a** (···) and **4b** (—) in DMF at 295 K. The inset displays the spectrum of **4b** in the 800-to-1200 nm region

The pale-green complex **4a** exhibits typical weak d-d transitions of octahedral nickel(II) (d^8) in the 500 to 1200 nm region (Figure 2). Compared to the thiolate complex **3a**, the ligand field transitions ν_2 ($^3A_{2g} \rightarrow {}^3T_{1g}$) at 617 nm and ν_1 ($^3A_{2g} \rightarrow {}^3T_{2g}$) at 966 and 1065 nm (splitting due to lower symmetry) are shifted by 24 and 44 nm to lower energies, consistent with a weaker ligand field strength of the amine-selenolate ligand. The electronic spectrum of **4b** is dominated by two intense, spin-allowed charge transfer (CT) transitions at 465 and 604 nm. Similar intense absorptions were observed for complex **3b** at 473 and 580 nm. Other than the two intense CT bands, the UV/Vis spectrum of **4b** reveals no further characteristic features.

Electrochemistry

The cyclic voltammogram of **4a** in DMF solution reveals two one-electron oxidation waves at $E^1_{1/2} = -0.15$ V and $E^2_{1/2} = +0.29$ V vs SCE both closely approaching the characteristics of reversible charge transfer processes; that of **4b** using the same experimental conditions is identical to that of **4a** (Figure 3).

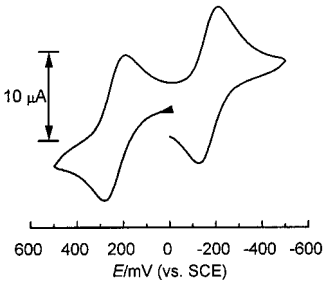

Figure 3. Cyclic voltammogram of **4b** in DMF at 295 K. Experimental conditions: [**4b**] ca. 1×10^{-3} M, 0.1 M [nBu$_4$N][PF_6], Pt disk working electrode, Ag wire reference electrode, scan rate = 200 mV·s^{-1}

At all scan rates (50−500 mV·s^{-1}), the ratio i_{pc}/i_{pa}, $i_p/\nu^{1/2}$ is independent of scan rate, and $\Delta E^1_p = 85$ mV and $\Delta E^2_p =$ 79 mV (at 100 mV·s^{-1}) increase slightly with scan rate. Controlled-potential coulometry of **4a** in DMF at an applied potential of 0.0 V vs SCE consumed $n = 0.96 \pm 2$ e$^-$/complex. The brown solution contains the $[Ni_2(\mathbf{1b})_3]^{2+}$ dication as shown by UV/Vis spectroscopy. Rereduction at −0.45 V vs SCE reforms the pale-green complex **4a**. Accordingly, the respective one-electron-transfer processes are assigned to Eqs. 1a, b producing the mixed-valent complex **4b** and subsequently the thermally instable dinickel(III) selenolate species.

$$[Ni^{III}Ni^{III}(\mathbf{1b})_3]^{3+} + e^- \rightleftharpoons [Ni^{III}Ni^{II}(\mathbf{1b})_3]^{2+} \quad E^2_{1/2} \qquad (1a)$$

$$[Ni^{III}Ni^{II}(\mathbf{1b})_3]^{2+} + e^- \rightleftharpoons [Ni^{II}Ni^{II}(\mathbf{1b})_3]^{1+} \quad E^1_{1/2} \qquad (1b)$$

$$[Ni^{III}Ni^{III}(\mathbf{1b})_3]^{3+} + [Ni^{II}Ni^{II}(\mathbf{1b})_3]^{1+} \rightleftharpoons [Ni^{III}Ni^{II}(\mathbf{1b})_3]^{2+} \quad K_{com}$$

From the redox potentials $E^x_{1/2}$ the comproportionation constant K_{com} is calculated to be 1.1×10^7, which is slightly smaller than the corresponding constant determined for **3b** (1.4×10^8). Relative to the amine-thiolate complexes **3a**,**b**, the $Ni^{III/II}$ redox potentials of the amine-selenolate complexes **4a**,**b** are cathodically shifted by 0.18 V and 0.13 V, respectively.

EPR Spectroscopy

The mixed-valent nature of **4b** is further confirmed by EPR-Spectroscopy. The EPR spectrum of a powdered sample of **4b** at 77 K exhibits a rhombic signal with three resonances at 1230, 2210, and 3350 G, indicating an $S = {}^3/_2$ ground state. Closer inspection reveals a further resonance at 1080 G, which is also present in the single-crystal EPR spectra. This resonance is tentatively assigned to the $M_s = -{}^3/_2$ to $M_s = +{}^3/_2$ transition, which is forbidden in axial environments, but gains intensity by the rhombic distortion. Unfortunately, hyperfine coupling to nitrogen atoms (^{14}N) could not be observed.

Thus, mixed-valent complex **4b** exhibits an $S = {}^3/_2$ ground state, which is most likely attained by an intramolecular ferromagnetic exchange interaction between a low-spin Ni^{III} ion ($S = {}^1/_2$) and a Ni^{II} ion ($S = 1$). It is interesting to note that an intramolecular ferromagnetic exchange interaction between adjacent Ni^{III} and Ni^{II} ions has also been observed in the trinuclear $Co^{III}Ni^{III}Ni^{II}$ complex $[LCo^{III}Ni^{III}Ni^{II}L][PF_6]_2$ [L = 1,4,7-tris(4-*tert*-butyl-2-mercaptobenzyl)-1,4,7-triazacyclononane], which contains a central $N_3Co^{III}(\mu_2\text{-}SR)_3Ni^{III}(\mu_2\text{-}SR)_3Ni^{II}N_3$ core with three face-sharing octahedra.[12] We anticipate a more detailed study of the electronic spin systems of **3b** and **4b** by magnetic susceptibility measurements.

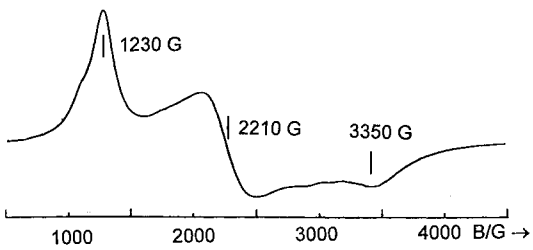

Figure 4. X-Band EPR powder spectrum of **4b** (9 GHz) at 78 K

In the present study it was shown that the coordinatively unsaturated amine-selenolate complex **2b**, upon reaction with **1b**, forms the dinuclear, face-sharing bioctahedral complex **4a** with a central $N_3Ni^{II}(\mu_2\text{-}SeR)_3Ni^{II}N_3$ core. Similarly to the electrochemical properties of isostructural amine-thiolate complex **3a**, complex **4a** undergoes an electrochemically and chemically reversible one-electron oxidation to produce a stable $Ni^{II}Ni^{III}$ amine-selenolate complex. Hence, the amine-chalcogenolate ligands **1a**,**b** both allow for the preparation of discrete dinuclear complexes and the stabilization of unusual nickel oxidation states. Further studies will focus on the isolation of the analogous tellurolate derivatives.

Experimental Section

Materials and Methods: Compounds **1b** and $[Ni_2(\mathbf{1b})_2][BPh_4]_2 \cdot CH_3OH \cdot CH_3CN$[10a] were prepared as previously described. All reactions were carried out under dry nitrogen with standard Schlenk techniques. Solvents were predried over molecular sieves and freshly distilled from appropriate drying agents. – CHN Analyses were determined with a Perkin-Elmer Elemental Analyzer 240. – IR spectra were recorded on a Bruker IFS25 spectrophotometer as KBr pellets. – Electronic spectra were recorded on a Jasco V-570 UV/VIS/NIR spectrometer. – Cyclic voltammetry measurements were carried out at 25°C with an EG&G Princeton Applied Research Potentiostat/Galvanostat Model 263 A. The cell contained a Pt working electrode, a Pt wire auxiliary electrode, and an Ag wire as reference electrode. Concentration of solutions were 0.1 M in supporting electrolyte (nBu$_4$NPF$_6$) and ca 1×10^{-3} M in sample. Ferrocenium/ferrocene was used as internal standard. All potentials were converted to the SCE reference. – EPR spectra were recorded by a conventional Varian X-band spectrometer with 100 kHz modulation.

$[Ni_2(\mathbf{1b})_3][Cl]\cdot EtOH$ (4a). – Method A: To a solution of $[Ni_2(\mathbf{1b})_2][BPh_4]_2 \cdot CH_3OH \cdot CH_3CN$ (137 mg, 0.100 mmol) in acetonitrile (5 mL) was added a solution of **1b** (34 mg, 0.10 mmol) in methanol (2 mL). Addition of 3 drops of NEt_3 initiated the precipitation of a pale-green solid, which was isolated by filtration, washed with methanol (2 mL) and ether (1 mL). The solid was recrystallized from ethanol. Yield: 62 mg (62%). – UV/Vis (DMF): λ_{max} (ε) = 617 (203), 966 (150), 1065 nm (137 $M^{-1}cm^{-1}$). – IR (KBr): $\tilde{\nu}$ = 3328s (NH_2), 3250s cm^{-1} (NH_2). – CV (DMF, 295 K, 0.1 M nBu$_4$NPF$_6$, E [V] vs SCE): $E^1_{1/2} = -0.15$ V, $E^2_{1/2} = +0.29$ V. – $C_{36}H_{57}N_6Se_3Ni_2Cl\cdot EtOH$ (1009.67): calcd. C 45.20, H 6.29, N 8.32; found C 44.83, H 5.87, N 7.94.

Method B: To a solution of $Ni(ClO_4)_2 \cdot 6\,H_2O$ (244 mg, 0.67 mmol) and the hydrochloride salt of the ligand **1b** (344 mg, 1.00 mmol) in ethanol (10 mL) was added a solution of triethylamine (303 mg, 3.00 mmol) in ethanol (3 mL). The mixture was stirred for 30 min at 20°C during which time a pale-green microcrystalline of **4a** formed which was filtered off, washed with ethanol and ether, and dried in vacuum. Yield: 240 mg (72%).

$[Ni_2(\mathbf{1b})_3][BPh_4]_2\cdot MeOH$ (4b): A suspension of **4a** (101 mg, 0.100 mmol) in methanol (30 mL) was stirred for 6h in the presence of air to ensure complete oxidation of **4a**. To the resulting brown solution was added dropwise a solution of $NaBPh_4$ (0.20 g, 0.58 mmol) in methanol (2 mL). The solution was filtered and was allowed to stand for 2d at room temperature during which time **4b** precipitated as black crystals. Yield: 86 mg (54%). – IR (KBr): $\tilde{\nu}$ = 3302 m, 3289 w, 3268 w, 3242 s, 3229 s cm^{-1} (NH_2). – UV/Vis (DMF): λ_{max} (ε) = 350 (8710), 399 (4644), 465 (4978), 604 nm (1554 $M^{-1}cm^{-1}$). – CV (DMF, 295 K, 0.1 M nBu$_4$NPF$_6$, E [V] vs SCE): $E^1_{1/2} = -0.15$ V, $E^2_{1/2} = +0.29$ V. – $C_{85}H_{101}B_2N_6Ni_2OSe_3$ (1598.66): calcd. C 63.86, H 6.37, N 5.26; found C 63.83, H, 6.22, N 5.11.

Crystal-Structure Determination: Black crystals of **4b** suitable for single-crystal X-ray determination were obtained by the procedure described above. Crystal data and refinement details for **4b** ($C_{85}H_{101}B_2N_6Ni_2OSe_3$, M_r 1598.66): crystal size 0.52 × 0.44 × 0.32 mm^3, STOE IPDS diffractometer, T = 193(2) K, monoclinic, space group $P2_1/c$, a = 23.552(5), b = 19.384(4), c = 16.701(3) Å, β = 105.79(3)° , V = 7507(3) Å^3, Z = 4, ρ_{calcd} = 1.41 g·cm^{-3}, μ(Mo-K_α) = 2.007 mm^{-1}, $2\theta_{max}$ = 48.6°, 63669 reflections collected, 11924 unique reflections (R_{int} = 0.1051), 8926 observed reflections [$I > 2\sigma(I)$]. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SHELXS-86)[18] and refined by full-matrix least-squares techniques against F^2 (SHELXL-93). All non-hydrogen atoms were refined anisotropically except the methyl carbon atoms of one disordered *tert*-butyl group. An isotropic split-atom model was applied for the disordered methyl carbon and oxygen atoms. The multiplicities of the respective orientations C(210)–C(212)/C(213)–C(215) were refined as follows: 0.73(1)/0.27(1). Hydrogen atoms were placed at calculated positions and were refined using a riding model with isotropic thermal parameters fixed at 1.2 times the equivalent isotropic U of the atom to which they were bonded. Final residuals: $R1$, $wR2$ [$F_o > 4\sigma(F_o)$]: 0.0446, 0.0963, $R1$, $wR2$ (all data): 0.0701, 0.1137, goodness-of-fit on F^2: 1.05, residual electron density: 0.58/−0.62 e·Å^{-3}. The quality of the structure could not be improved with an absorption correction. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102536 (**4b**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: +44 (1223) 336-033; E-mail: deposit@cam.ac.uk].

Supramolecular Assemblies of 1,2-Dicarbadodecaborane(12) with Bowl-Shaped Calix[5]arene

Michaele J. Hardie[a] and Colin L. Raston*[a]

Keywords: Calixarene / Carboranes / Host-guest chemistry / Non-classical hydrogen bonding / Supramolecular chemistry

Treatment of globular 1,2-dicarbadodecaborane(12) (*o*-carborane) **1** with the bowl-shaped container molecule calix[5]arene **2** affords either the crystalline 1:1 or 1:2 host-guest complexes (*o*-carborane)(calix[5]arene)(CH_2Cl_2) **3**, (*o*-carborane)(calix[5]arene)(toluene) **4** and (*o*-carborane)-(calix[5]arene)$_2$(CH_2Cl_2)$_{0.5}$ **5**. The three complexes show a remarkable range of different supramolecular interplay beyond the common structural unit, a ball-and-socket nanostructure or supermolecule [(*o*-carborane)∩(calix[5]arene)]. Complex **3** forms dimeric [(*o*-carborane)∩(calix[5]arene)]$_2$ units, and **5** has an additional edge on interaction between the supermolecule and a secondary calix[5]arene host.

Introduction

Carbon-containing polyhedral boranes, the carboranes, are extremely stable cage molecules known for over 30 years. Carboranes and their derivatives have applications in a number of diverse fields such as boron neutron capture therapy, boron carbide-type ceramics, complexing agents for extraction of metal ions, nonlinear optics, conducting polymers and more.[1] The carboranes *o*-, *m*-, and *p*-$C_2B_{10}H_{12}$[1,2-, 1,7-, 1,12-dicarbadodecaborane(12)] (hereafter *o*-, *m*-, and *p*-carborane) are twelve-vertex icosahedral cages whose potential as components or building blocks in supramolecular systems is beginning to be explored.[2−6][9−12] Rigid rod-like and trigonal carborane-based molecular building units have been synthesised,[2] as well as metallodendrimers.[3] A number of carborane derived macrocyles are known, with the clusters linked through their carbon centres by both organic groups[4] and mercury centres.[5] The mercury linked macrocycles show host-guest complexation of halide ions, and the tetrameric macrocycle can complex *closo*-$B_{10}H_{10}^{2-}$.[6]

Carboranes have high C−H acidity[7] and consequently show potential for hydrogen bonding.[8] Supramolecular complexes involving such weak intermolecular interactions are known. The first examples to be reported were the series of inclusion complexes with cyclodextrin host molecules and *o*-carborane as the guest.[9] Thermally stable 1:1 cyclodextrin/carborane complexes were formed with α-, β-, and γ-cyclodextrin, and a 2:1 complex was also found for α-cyclodextrin. More recently the crystal structures of the 1:1 complexes of hexamethylphosphoramide (HMPA) with *o*-, *m*-, and *p*-carboranes have been reported.[10] The three complexes show extensive C−H···O hydrogen bonding and all adopt quite different supramolecular structures, commensurate with their differing arrangement of C−H sites. These complexes represent the first structures of unsubstituted carboranes in a crystal lattice. *o*-Carborane forms 1:1 complexes with diaza-18-crown-6 and aza-18-crown-6 again with distinct supramolecular structures.[11] The (*o*-carborane)(diaza-18-crown-6) complex associates through C−H···O hydrogen bonds at distances similar to those found for the HMPA complexes, whereas the aza-18-crown-6 complex has a layered structure with no close intermolecular contacts. The bowl-shaped container molecule cyclotriveratrylene (CTV) can act as a host for *o*-carborane guest molecules and a 2:1 CTV/*o*-carborane complex is formed.[12] In the solid state one CTV molecule complexes a carborane guest while the other forms a π interaction with the host CTV. Each $C-H_{carborane}$ is directed towards the centroid of an aromatic ring in the cavity of the CTV as a Coulumbic interaction between a polarised C−H bond and the basic π-electrons of an aromatic ring. The energy of such an interaction between benzene with *o*-carborane, shown schematically in Figure 1, is calculated to be energetically favoured by 2.74 kcal mol^{-1},[12] and this type of interaction is usually described as a weak non-classical C−H···π hydrogen bond. NMR studies were uninformative, except to suggest that *o*-carboranes can bind *endo*- and *exo*-to the cavity of the CTV.[12]

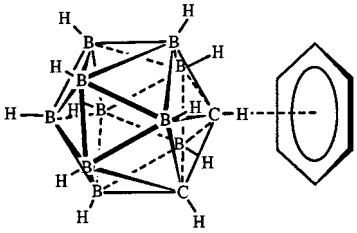

Figure 1. Schematic representation of non-classical hydrogen bonding between *o*-carborane and an aromatic ring

The complexation of *o*-carborane by a bowl-shaped container molecule such as CTV is reminiscent of much of the host-guest chemistry of the fullerene C_{60}[13][14] Both the carboranes and C_{60} are thermally stable, icosahedral clusters with diameters of about 8 and 10 Å respectively. Fullerene C_{60} forms inclusion complexes with the bowl-shaped CTV[13] and a number of calixarenes,[14] indeed the selective

complexation of C_{60} by *p*-*t*Bu-calix[8]arene is a simple and efficient means of C_{60} extraction from a mixture of fullerenes. The supramolecular chemistry of carboranes with bowl-shaped potential host molecules is, by comparison, in its infancy and may also lead to simplified separation procedures, currently reliant on chromatographic techniques.[7] The work reported herein further develops host-guest chemistry between carboranes and bowl-shaped molecules with the formation of 1:1 and 1:2 complexes of *o*-carborane with calix[5]arene. The solid state structures have been established from low-temperature X-ray diffraction data. These three complexes show a remarkable range of supramolecular interactions and, despite being constructed from similar or the same supramolecular synthons/molecular building blocks, form different nano-structures. The ability to control weak intermolecular interactions underpins much of the basic aims and ideals of supramolecular chemistry,[15] yet the range of possible interactions is often extensive even for simple systems, illustrated by the quite distinct nano-structures formed here.

Results and Discussion

Slow evaporation of toluene solutions of 1:1, 1:2 mixtures of *o*-carborane **1** and calix[5]arene **2**, and subsequent recrystallisation from dichloromethane/hexane affords the colourless crystalline complexes, (*o*-carborane)(calix[5]arene)(CH_2Cl_2) **3** and (*o*-carborane)(calix[5]arene)$_2$-(CH_2Cl_2)$_{0.5}$ **5**, see Scheme 1. Heating a 3:1 mixture of **1** and **2** in toluene at ca. 70°C for one hour and subsequent cooling gave crystals of the toluene solvated 1:1 complex (*o*-carborane)(calix[5]arene)(C_7H_8) **4**. The complexes were characterised by IR spectroscopy, microanalysis and single crystal X-ray crystallography. The IR showed a clear a shift to lower energy (by 11 cm^{-1}) for ν_{C-H} of the carborane in **5**. Similar shifts in the IR were seen for the previously reported 2:1 complex (*o*-carborane)(CTV)$_2$ where the carborane ν_{C-H} shifts 13.5 cm^{-1} to lower energy.[12] Such an energy shift is indicative of the involvement of the carborane C−H in hydrogen bonding, with dispersal of the extra charge on the carbon resulting in the strengthening of the B−H bonds. Smaller shifts of 6 and 3 cm^{-1} respectively were seen in the 1:1 complexes **3** and **4**.

Scheme 1

(*o*-Carborane)(calix[5]arene)(CH_2Cl_2) 3

X-ray diffraction data was collected for **3** at −123(1)°C. The crystal structure was solved in the monoclinic space group $P2_1/n$. As was seen for (*o*-carborane)(CTV)$_2$,[12] a ball-and-socket supermolecule is formed between the host calix[5]arene and guest *o*-carborane.

The calix[5]arene adopts a bowl-conformation, with an average torsion angle between an aromatic ring and the plane formed by hydroxy oxygens of around 50°. The ball-and-socket supermolecule is shown in Figure 2. The carborane guest sits close to the middle of the calixarene cavity, with distances from C or B vertices of the carborane to aromatic ring centroids of the calixarene of 3.44, 3.55, 3.78, 3.93, and 4.08 Å. Both C−H vectors of the carborane are directed towards aromatic rings of the host molecule, albeit in an unsymmetrical fashion. As was seen for (*o*-carborane)(CTV)$_2$,[12] this interaction is most likely non-classical C−H···π hydrogen bonding, with the two interactions having $C_{carborane}$···aromatic centroid separations of 3.55 and 3.44 Å, and $C-H_{carborane}$···centroid angles of 11.8 and 24.8° respectively; the closer contact having the lesser C−H···π interaction, indicated by the greater angle at the hydrogen.

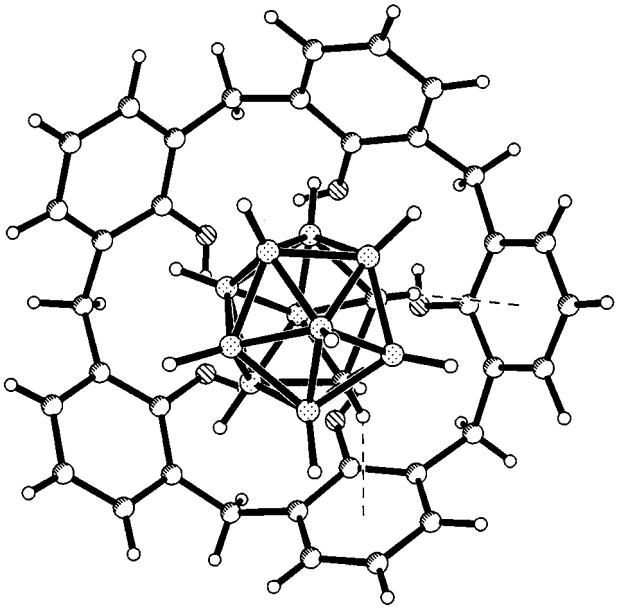

Figure 2. Ball-and-socket (*o*-carborane)∩(calix[5]arene) assembly of (calix[5]arene)(*o*-carborane)(CH_2Cl_2) **3**. Potential non-classical C−H π hydrogen bonds are indicated as dashed lines

The ball-and-socket (*o*-carborane)∩(calix[5]arene) units organise into larger dimeric supramolecules within the crystal lattice. The dimers have the calixarene hydroxy groups facing each other, forming a hydrophilic core shown in Figure 3. The X-ray data obtained did not allow for the location of the hydroxy hydrogens, and those shown in Figures are at calculated positions. This makes it difficult to ascertain the exact hydrogen-bonding pattern. The O···O contacts between the calixarenes are quite close at 2.96, 3.01, 3.09, 3.14, and 3.22 Å. There are no close contacts between dimers within the crystal lattice. The dimers occur in two layers, each running in the *b* direction and alternat-

ing in the *c* direction, with disordered dichloromethane molecules positioned between individual dimers.

(*o*-Carborane)(calix[5]arene)(C_7H_8) 4

X-ray diffraction data was collected for **4** at −150(1)°C. The crystal structure was solved in the monoclinic space group $P2_1/n$. Although the basic structural unit of **4** − a ball-and-socket type (*o*-carborane)∩(calix[5]arene) − is similar to that of **3**, the crystal packing is quite distinct.

The (*o*-carborane)∩(calix[5]arene) supermolecule of **4** is similar to that of **3**, although the *o*-carborane sits slightly closer to the host molecule. The calix[5]arene adopts a bowl-conformation, with an average torsion angle between an aromatic ring and the plane formed by hydroxy oxygens of around 48°. The C−H vectors of the carborane point towards the edges of aromatic rings of the calix[5]arene host at $C_{carborane}$···aromatic centroid separations of 3.40 and 3.49 Å, and $C-H_{carborane}$···centroid angles of 20.2 and 31.4°. The dimeric units evident in **3** are not formed, however, with the (*o*-carborane)∩(calix[5]arene) supermolecules stacking in the same orientation along the *b* direction (Figure 4) to form columns of the supermolecule. The orientation of these columns alternates along the *c* direction. The

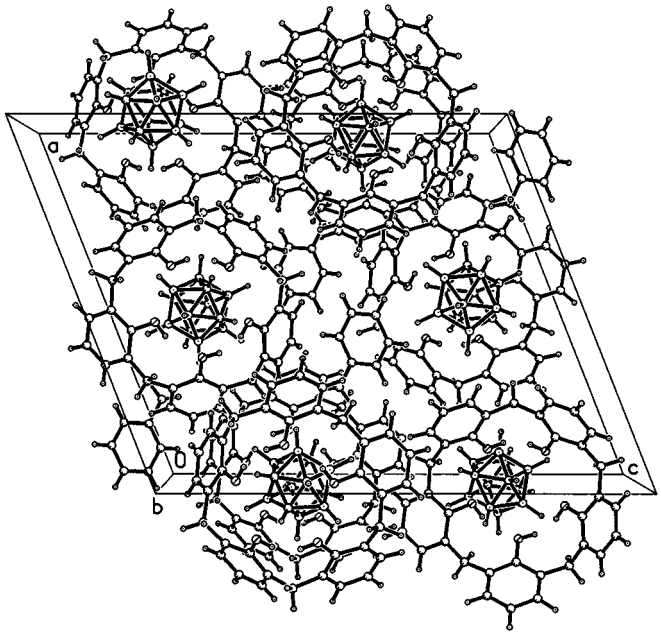

Figure 4. Packing diagram of (calix[5]arene)(*o*-carborane)(C_7H_8) **4** along the *b* axis. Columns of (calix[5]arene)]∩(calix[5]arene) supermolecules are formed along *b*

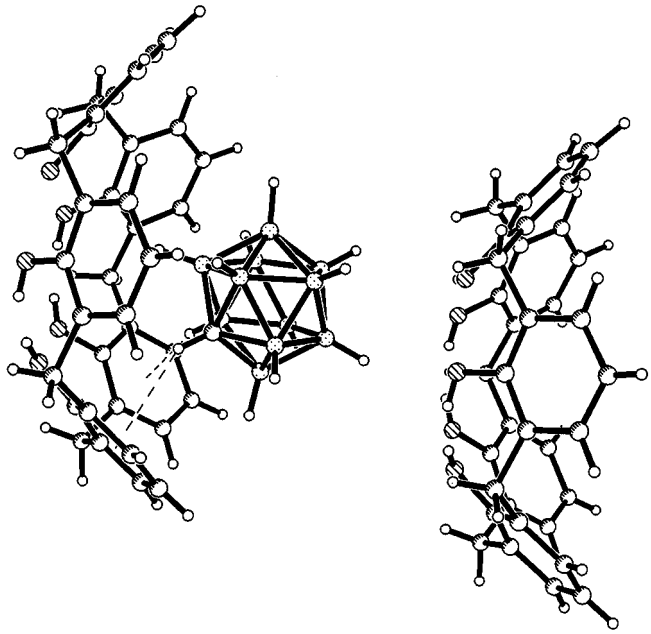

Figure 5. Side view of the ball-and-socket (*o*-carborane)∩(calix[5]arene) supermolecule and calixarene of next supermolecule along *b*, of (calix[5]arene)(*o*-carborane)(C_7H_8) **4**. Potential non-classical C-H π hydrogen bonds are indicated as dashed lines

included *o*-carborane of one supermolecule has contacts to the hydroxy groups of the next (*o*-carborane)∩(calix[5]arene) at a closest B···O distance of 3.55 Å (Figure 5).

Each toluene molecule within the crystal lattice forms close contacts to two calix[5]arene molecules (Figure 6). The plane of the toluene is almost exactly perpendicular to the plane of an aromatic ring of one calix[5]arene (torsion angle 89.1°). An aromatic C−H of the toluene, *ortho* to the methyl group, is directed towards the centre of this arene at

a H···centroid distance of 2.6 Å. One of the toluene C-Hs *meta* to the methyl group is directed towards a hydroxy oxygen of the calix[5]arene at an H···O distance of 2.5 Å. The toluenes effectively bridge between the supramolecular columns in the direction of the *c* axis.

(*o*-Carborane)(calix[5]arene)$_2$(CH_2Cl_2)$_{0.5}$ 5

X-ray diffraction data was collected for **5** at room temperature and −100°C. The crystals were observed to undergo a phase change from primitive monoclinic (room temperature, $P2_1/m$: a = 11.679(1), b = 18.128(2), c = 16.394(1) Å, β = 97.12(1)°) to triclinic [−100°C: a = 11.6151(13), b = 16.3617(17), c = 18.014(2) Å, α = 90.699(9), β = 91.612(9), γ = 96.739(9)] on cooling. The room-temperature and low-temperature structures are essentially the same, although the carborane displays some positional disorder in the room temperature structure. Data from the low temperature study is presented here. The structure was solved in space group $P\bar{1}$, and features two types of calixarene molecule and one carborane.

Both calix[5]arene molecules adopt a bowl conformation, and their ability to act as host molecules manifests itself in two distinct manners. The curvature of the two calixarenes is quite different. One calixarene has torsion angle between an aromatic ring and the plane formed by hydroxy oxygens between 46.5 and 49.0° (average 48°). The second calixarene is considerably more puckered with torsion angles between 34.4 and 64.2° (average 49°). The shallower calixarene acts as a host molecule for the *o*-carborane, forming the familar ball-and-socket arrangement seen in **4**. The more puckered calixarene acts as a secondary host for the (*o*-carborane)∩(calix[5]arene) assembly forming the [(*o*-carborane)∩(calix[5]arene)]∩(calix[5]arene) nano-structure illustrated in Figure 7. The complexation of a host-guest species by a secondary host is, to out knowledge, relatively uncommon. Other examples of such supramolecular interactions include the complexation of alkali metal-crown ethers by cyclodextrins.[16] These form entirely different nano-structures to that seen here.

The (*o*-carborane)∩(calix[5]arene) arrangement in **5** is similar to the analogous supermolecule in **3**, with both C−H vectors of the included *o*-carborane directed towards aromatic rings of the host calix[5]arene to form non-classical hydrogen bonds. In the case of **5**, however, the C−H$_{carborane}$ vectors point more directly to the centre of the aromatic rings with C···aromatic centroid separations of 3.51 and 3.57 Å, and a C−H$_{carborane}$···centroid angles of 0.8

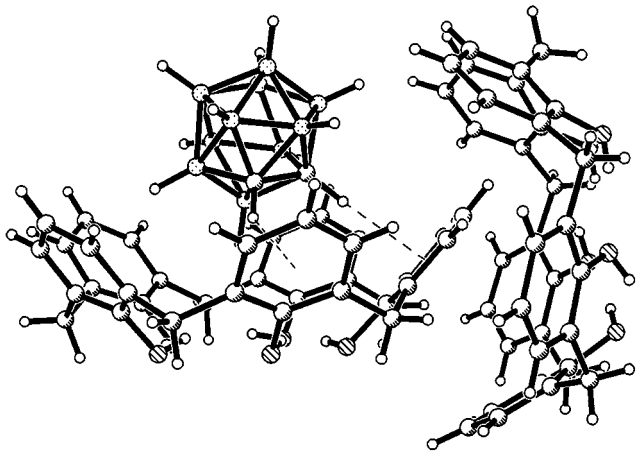

Figure 7. The (*o*-carborane)∩[(calix[5]arene)]∩(calix[5]arene) nano-structure of (calix[5]arene)$_2$(*o*-carborane)(CH_2Cl_2)$_{0.5}$ **5**. Potential non-classical C−H π hydrogen bonds are indicated as dashed lines. The two aromatic rings shown side-on show π-π stacking at a centroid separation of 3.920 Å and torsional angle of 18.8°

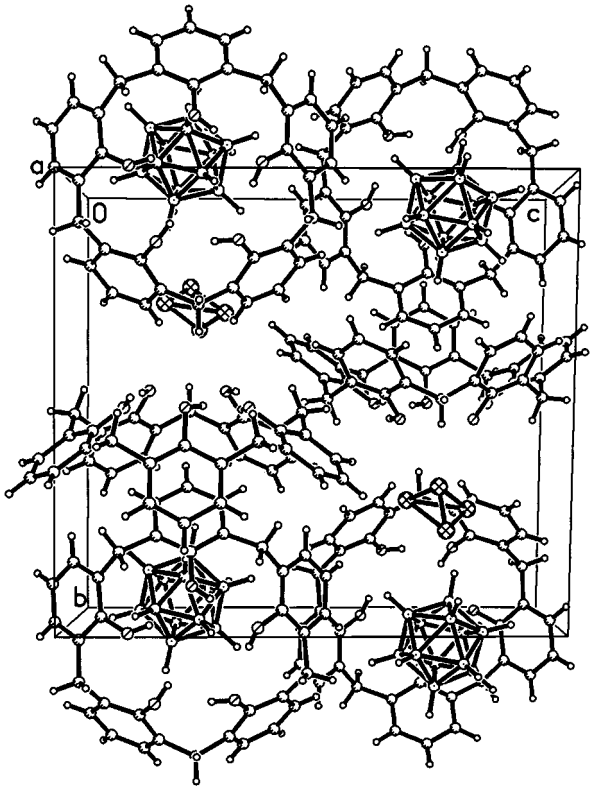

Figure 8. Packing diagram of (calix[5]arene)$_2$(*o*-carborane)(CH_2Cl_2)$_{0.5}$ **5** shown down the *a* axis

and 9.1° (Figure 7). The closest B···aromatic ring centroid distances are 3.80, 3.90, and 4.22 Å. It is evident from this that the carborane is positioned to one side of the calixarene bowl − not surprisingly, the side featuring C-$H_{carborane}$···π interactions (Figure 7). The (*o*-carborane)∩-(calix[5]arene) supermolecule.

The presence and identity of solvent molecules also plays a vital role in determining the crystal packing and overall topology of the systems. The crystallisation from CH_2Cl_2 instead of toluene, for instance, results in a dimer of the 1:1 complex being formed. We also note that calixarenes are known to form inclusion complexes with dichloromethane through the formation of non-classical hydrogen bonds.[17] Chlorinated solvents such as chloroform are known to break up analogous fullerene-calixarene complexes through such bonds competing with fullerene-calixarene associations.[14] In the carborane-based supramolecular systems reported here, however, carborane-calixarene and calixarene-calixarene interactions appear to form the preferred interactions.

Experimental Section

Synthesis of 3 and 5: Calix[5]arene and *o*-carborane were mixed in toluene in 1:1, 2:1, and 1:3 proportions and the solution slowly evaporated to dryness. The residues were taken up in dichloromethane then hexane vapour was diffused into the solutions to give colourless crystals. (*o*-Carborane)(calix[5]arene)(CH_2Cl_2) **3**; $C_{38}H_{44}B_{10}Cl_2O_5$. − IR 3284, 3061, 2577, 1594, 1489, 1451, 1386, 1245, 1212, 1150, 1089, 1016, 907, 841, 803, 754, 714, 637, 559, 472 cm^{-1}; microanalysis C 60.50% (60.07), H 5.91% (5.83); (*o*-carborane)(calix[5]arene)$_2$(CH_2Cl_2)$_{0.5}$. − **5**; IR 3286, 3059, 2946, 2875, 2556, 2280, 1612, 1468, 1450, 1386, 1244, 1210, 1152, 1086, 906, 841, 803, 755, 698, 639, 558, 486; microanalysis C 69.69% (69.78), H 6.07% (5.90). − **4**: Calix[5]arene and *o*-carborane were mixed in toluene in 1:3 proportions and the solution heated at ca. 70°C for one hour then cooled to room temperature to give colourless crystals of (*o*-carborane)(calix[5]arene)(C_7H_8); IR 3260, 3066, 2572, 2362, 1611, 1468, 1449, 1398, 1243, 1210, 1151, 1085, 841, 756, 714, 559, 468 cm^{-1}.

X-ray Crystallography: Details of data collections and structure refinements for **3** to **5** are given in Table 1. All data sets were collected on an Enraf-Nonius KappaCCD diffractometer with MoK_α radiation (λ = 0.71073 Å). Data was corrected for Lorentzian, polarisation but not absorption. The structures were solved by direct methods using SHELXS-97[18] and refined by full matrix least-squares on $|F^2|$ using SHELXL-97.[19] Carbon atoms within the carborane molecules were assigned by analysis of atomic displacement parameters. As the X-ray scattering factors for B and C are very similar these assignments should be regarded as tentative. Only neutron diffraction data would allow for unequivocal discrimination between C and B. Treatment of hydrogen atoms was mixed. The hydroxy hydrogens for **3** to **5** were fixed at geometrically estimated positions with a riding refinement. The hydrogen positions of the disordered CH_2Cl_2 molecule in **3**, and the toluene molecule of **4** were fixed at geometrically estimated positions with a riding refinement. All other hydrogen atoms were fully refined. The disordered CH_2Cl_2 molecule in **3** was modelled with two carbon positions each with an occupancy of 0.5. The disordered CH_2Cl_2 molecule in **5** was refined with an overall occupancy of 0.5, four disordered chlorine positions (with occupancies of 0.15 or 0.35), forming a rough tetrahedron, were modelled, however the central carbon atom was not located. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-101900, CCDC-101901, and CCDC-101902 Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (+44) 1223/ 336-033; E-mail: deposit@ccdc.cam.ac.uk]

The Reaction of Diazomethane Derivatives with the Dielement Compounds $R_2Al–AlR_2$ and $R_2Ga–GaR_2$ [R = $CH(SiMe_3)_2$] − Insertion versus Fragmentation

Werner Uhl*[a] and Frank Hannemann[a]

Keywords: Aluminium / Gallium / Low-valent compounds / Insertion reactions

Tetrakis[bis(trimethylsilyl)methyl]dialane(4) **1** reacted with trimethylsilyldiazomethane and bis(trimethylsilyl)diazomethane at room temperature by the insertion of the terminal nitrogen atoms into its aluminium–aluminium bond. As shown by a crystal structure determination, one of the aluminium atoms of each product enhanced its coordination number to four by the interaction with the central nitrogen atom of the C=N–N group, which results in the formation of a three-membered AlN_2 heterocycle bearing an exocyclic N=C double bond. The reactions of the corresponding gallium compound (**2**) containing a gallium–gallium single bond needed more drastic conditions. Mixtures of many unknown products were formed, and only on treatment with trimethylsilyldiazomethane two compounds could be isolated after repeated recrystallization in yields below 10%, which were characterized by crystal structure determinations. One was identified as the trimeric dialkylgallium cyanide (**8**) with a nine-membered $Ga_3C_3N_3$ heterocycle, and the other one (**9**) has a dialkylgallium fragment coordinated by both terminal nitrogen atoms of the chelating ligand $NH_2–N=C(SiMe_3)–NH^-$. Due to the NMR spectroscopic characterization, **8** seems to be tetrameric in solution with an asymmetric structure containing four different gallium atoms. With this unusual structure, the IR spectrum of tetrameric dimethylgallium cyanide could now completely be interpreted, which was published more than 20 years ago.

Tetrakis[bis(trimethylsilyl)methyl]dielement(4) compounds with aluminium−aluminium (**1**)[1], gallium−gallium (**2**)[2], and indium−indium bonds (**3**)[3] were isolated and completely characterized for the first time about ten years ago in our group. They showed a remarkable and unprecedented chemical reactivity, and up to now we observed six different types of reaction[4]. Among these, the insertions of atoms, molecules, and molecular fragments are quite outstanding owing to the number and the structural variety of the isolated products. At present, we are much interested in the insertion of carbenes into the element−element bonds, which may lead to the formation of methylene-bridged dielement compounds with two coordinatively unsaturated aluminium, gallium, or indium atoms. Such compounds are of particular interest in current organoelement chemistry, because they are potentially useful as chelating Lewis acids[5]. However, only once before we unexpectedly succeeded in inserting a carbene, when we treated the dialuminium derivative **1** with $LiCH_2SMe$[6]. In the course of this reaction, the thiomethyl compound was cleaved to yield CH_2, which was inserted into the Al−Al bond by the formation of an $Al–CH_2–Al$ group, and the remaining thiomethanolate was coordinated in a chelating manner by both aluminium atoms to give compound **4** (Scheme 1). A similar reaction was not observed for the gallium (**2**) or indium analogues (**3**), which on similar conditions gave a complete fragmentation[6]. In order to obtain the uncoordinated methylene bridged dielement compounds by the insertion of carbenes, we treated **1** to **3** with diazomethane derivatives.

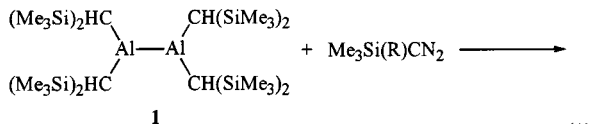
Scheme 1



Reactions of the Dialuminium(4) Compound 1 with Trimethylsilyl and Bis(trimethylsilyl) Diazomethane

One equivalent of each of the diazomethane derivatives was added to solutions of **1** in hexane at room temperature, and **1** was completely consumed after stirring for about one day in both cases. Trimethylsilyldiazomethane gave only a highly viscous fluid (**5**), which could not be purified by recrystallization. Its purity was, however, high enough to allow the complete NMR spectroscopic characterization. In contrast, product (**6**) obtained by the reaction of **1** with bis(trimethylsilyl)diazomethane was isolated as a yellow crystalline solid by recrystallization from *n*-hexane. Both products have a similar constitution, as was easily derived from some very characteristic NMR data. In **5**, the resonance of one proton was observed at very low field (δ = 7.95) indicative for a N=C(H)R group, and the protons of the trimethylsilyl groups attached to the diazomethane carbon atom of compound **6** gave two resonances in accord-

ance with the differing chemical vicinity at each side of a C=N double bond. The corresponding central carbon atoms revealed ^{13}C-NMR shifts of δ = 152.9 (**5**) and δ = 179.0 (**6**) characteristic of imines[7]. Thus, the diazomethane derivatives did not react as a carbene donor, but they were completely inserted into the Al−Al bond of the starting compound **1** by the formation of energetically favored Al−N bonds (Eq. 1).

1 (1)

5: R = H
6: R = SiMe$_3$

The constitution of **5** and **6** given in Equation (1) was verified also by a crystal structure determination of compound **6** (Figure 1). Bis(trimethylsilyl)diazomethane inserted into the Al−Al bond of **1** with its terminal nitrogen atom N1, and by the interaction of the nitrogen lone pair at N2 with the aluminium atom Al1 a three-membered AlN_2 heterocycle results. The compound may be described as a hydrazone derivative with both N−H hydrogen atoms replaced by dialkylaluminium groups. The shortest Al−N bond is observed to the coordinatively unsaturated exocyclic atom Al2 [183.5(2) pm], while the bond Al1−N1 in the ring is little lengthened to 189.6(2) pm. Both are within the characteristic range of Al−N single bonds[8]. As expected, the dative bond[8] between the imine nitrogen atom N2 and Al1 is much elongated to 198.9(2) pm. The N1−N2 bond [141.7(2) pm] is shorter than in hydrazine or derivatives of hydrazine[9], but similar to some N−N distances observed in hydrazones with a more comparable bonding situation[10]. The length of the C=N double bond (131.5 pm) corresponds to the standard value of 128 pm[11]. The angle Al1−N1−Al2 is 141.5°, an even closer approach to linearity is observed for the group Al1−N2−C including the C=N double bond (159.3°).

The structures of **5** and **6** have two chemically different dialkylaluminium groups, one with a tricoordinated, coordinatively unsaturated and one with a tetracoordinated, saturated aluminium atom. Thus, two different types of bis(trimethylsilyl)methyl groups should be detectable in the NMR spectra. But at room temperature only one singlet was observed for the $SiMe_3$ or methine protons indicating a fast exchange process of the imine nitrogen atom (N2) between both aluminium atoms. The chemical shifts of the methine resonances, which are very indicative for the coordination number at the aluminium atoms[12], are intermediate [δ = −0.51 (**5**) and −0.44 (**6**)] between the range of tetracoordinated (δ < −0.7) and tricoordinated (δ > −0.2) bis(trimethylsilyl)methyl aluminium compounds. On cooling to −70°C a complicated splitting of all resonances was observed indicating, that all bis(trimethylsilyl)methyl groups became different. The signals of the methine protons splitted into four resonances of equal intensity at δ = −0.26, −0.45, −0.47, and −0.78, from which only the last one was in that region characteristic for tetracoordinated aluminium atoms. For the trimethylsilyl groups a multiplet with nine maxima in the range between δ = 0.16 and 0.43 was observed. The behavior of the diazomethane insertion products is thus quite different from that of the related products (**7**) obtained by the insertion of isonitriles into the Al−Al bond of **1**[13]. The structure of **7** in the solid state is quite similar to that of compound **6** with one tricoordinated and one tetracoordinated aluminium atom and a three-membered heterocycle; but a C=N double bond is included in the ring (Scheme 2). This structure was retained in solution, and we observed the resonances of the different $CH(SiMe_3)_2$ groups even at +100°C. The much faster exchange process detected for **5** and **6** is favored by the easy rotation around the N−N single bond of the heterocycle after opening of the Al−N2 bond, while an exchange with the isontrile products requires the energetically unfavorable inversion of the nitrogen atom, which is part of the C=N double bond. Furthermore, it seems, that the dative nitrogen−aluminium interaction in **5** or **6** is weaker than that in the isonitrile insertion products. The Al−N2 distance is much lengthened to 198.9 pm in the hydrazone derivative **6** compared to 186.4 pm of the isonitrile product **7**.

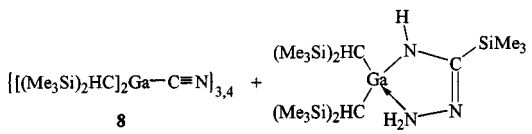
7

Scheme 2



Compound **6** melts at 110°C without decomposition. UV irradiation in *n*-pentane gave no reaction after five minutes. After 60 minutes, complete decomposition occurred with the formation of a mixture of many unknown products, from which no one could be isolated in a pure form.

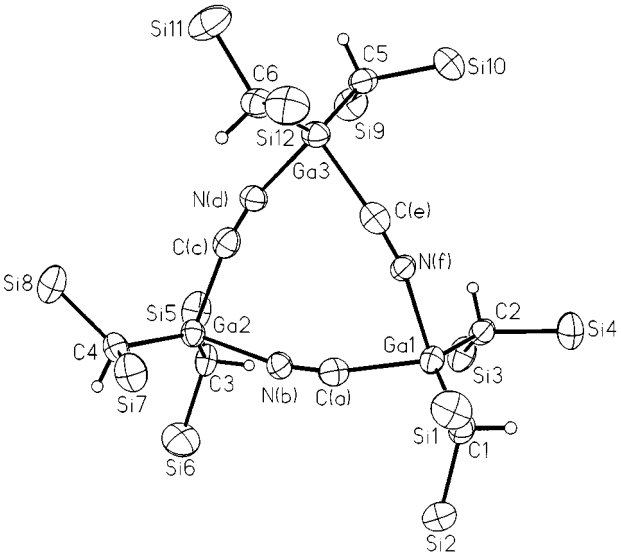
Reaction of the Digallium(4) Compound 2 with Trimethylsilyldiazomethane

In contrast to the easy reactions of the Al−Al bond, the insertion into the Ga−Ga bond of **2** usually needs more drastic reaction conditions with longer reaction times or does not occur at all[14]. In accordance with these observations, **2** did not react with trimethylsilyl or bis(trimethylsilyl) diazomethane at room temperature. Even in boiling solvents no reaction was observed with the last one, but on UV irradiation in a quartz apparatus **2** was completely consumed within 35 minutes. The main product of the obtained mixture was, however, formed by the disproportionation reaction of **2** and was spectroscopically identified as the trialkylgallium compound $Ga[CH(SiMe_3)_2]_3$[2]. Sterically less shielded trimethylsilyldiazomethane reacted in boiling *n*-hexane with **2**, but the reaction time was 24 h. A complicated mixture of products was formed, from which after repeated recrystallization from toluene two components (**8** and **9**) could reproducibly be isolated in a pure form and in a very low yield below 10% (Eq. 2). They were identified by crystal structure determinations.

2 (2)

8 **9**

Compound **8** was isolated in a yield of 6% and identified as the trimeric dialkylgalliumcyanide (Figure 2). The isotypic aluminium compound was recently obtained in our group[15]. **8** has a nine-membered $Ga_3C_3N_3$ heterocycle, in which three gallium atoms are bridged by three cyanide groups. This is an unusual structure for alkyl metal cyanides, which often polymerize like Me_2In-CN[16] or Me_3Sn-CN[17]. A tetrameric structure was reported for a dialkylgold compound[18]. Some other dialkylelement cyanides with the heavier elements of the third main group are known in literature, their degree of association between four and eight was, however, detected only by mass spectroscopy or molecular weight determinations[19]. The heterocycle of **8** deviates from planarity and adopts almost a boat conformation with the atom Ga1 furthest above the mean plane (34.3 pm). The GaC_2 planes with the central atoms of the $CH(SiMe_3)_2$ groups are not exactly perpendicular to the heterocycle, the angles between their normals are 102.6° (Ga1), 71.7° (Ga2), and 105.2° (Ga3). The bond lengths of the C−N triple bonds is 115.2 pm on average, they lie within the range observed for covalent or ionic cyanides[11][16−18][20]. The cyanide groups are not exactly linear coordinated by the gallium atoms, and angles of 164° on average are detected at the carbon or nitrogen atoms. The bonds Ga−N and Ga−C (208.8 pm on average) are much lengthened compared with the corresponding aluminium compound (202.2 pm)[15], which may be caused by a lower ionic contribution to the Ga−C or Ga−N bonds.



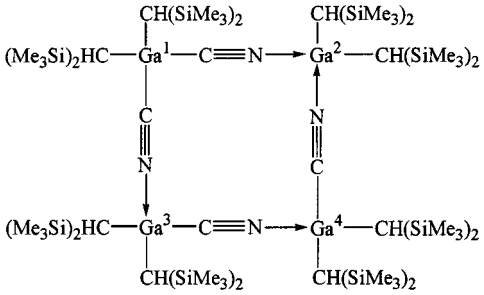


Figure 2. Molecular structure and numbering scheme of compound **8**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity; the atoms of the cyanide groups are statistically disordered, the labels of the atoms are idealized; selected bond lengths [pm] and angles [°]: Ga1−C1 197.0(4), Ga1−C2 198.3(3), Ga2−C3 197.4(4), Ga2−C4 197.5(4), Ga3−C5 197.7(4), Ga3−C6 198.2(4), Ga1−(C,N)(a) 208.1(4), Ga1−(C,N)(f) 209.3(4), Ga2−(C,N)(b) 209.5(4), Ga2−(C,N)(c) 207.7(4), Ga3−(C,N)(d) 208.7(4), Ga3−(C,N)(e) 209.2(4), (C,N)(a)−(C,N)(b) 115.0(5), (C,N)(c)−(C,N)(d) 115.7(5), (C,N)(e)−(C,N)(f) 114.9(4), Ga−(C,N)−(C,N) 164.4 (average), (C,N)−Ga−(C,N) 85.1 (average)

The aluminium analogue of **8** was a dimer in solution and showed three resonances in the ^{1}H-NMR spectrum in the ratio of 1 to 2 to 1 for the $SiMe_3$ and methine protons. These observations were interpreted in terms of a different coordination of the aluminium atoms, one by two carbon and one by two nitrogen atoms of the cyanide ligands. Both bis(trimethylsilyl)methyl groups of one aluminium atom

gave two separate resonances possibly owing to a hindered rotation and the usually observed molecular conformation with the methine hydrogen atom of one substituent pointing between both trimethylsilyl groups of the second one[15]. The NMR spectra of **8** are much more complicated. The ^{1}H-NMR spectrum shows four different methine protons of equal intensity at $\delta = -0.23$, -0.33, -0.34, and -0.50 in a range characteristic of tetracoordinated gallium atoms[6][21]. Furthermore, six different $SiMe_3$ groups with the integration ratio of 1 to 1 to 2 to 2 to 1 to 1 are observed; one of the more intensive signals has a shoulder possibly indicating a poorly resolved further splitting. A similar ^{13}C-NMR spectrum is observed with six resonances of the $SiMe_3$ groups and four resonances of the methine carbon atoms. Most striking is the occurrence of four different ^{13}C resonances of the cyanide groups in the characteristic range of about $\delta = 143$; these resonances were difficult to detect due to the low solubility of these dialkyl cyanides. The appearance of the NMR spectra clearly cannot be explained by the formation of a single dimer in solution. For two isomeric dimers in an equilibrium with four different cyanide groups, an even more complicated pattern of resonances of the methine and trimethylsilyl protons has to be expected, and despite their different structures and energy those two isomers must be present in absolutely identical concentrations to account for the observed NMR spectra, which seems to be quite unlikely. A tetrameric structure was formulated for dimethylgallium cyanide owing to molecular mass determinations[19], and a similar structure may be adopted by compound **6** in solution. A complete interpretation of the NMR spectra succeeds, however, only by the assumption of a asymmetric constitution with one gallium atom coordinated by two carbon atoms of cyanide, one by two nitrogen atoms, and the remaining two by one carbon and one nitrogen atom, as shown in Scheme 3. This structure has four different cyanide carbon atoms and four different methine groups. Furthermore, two resonances are expected for those bis(trimethylsilyl)methyl groups, which have diastereotopic trimethylsilyl groups owing to the asymmetric coordination of the gallium atoms by one carbon and one nitrogen atom of the ring. In contrast, only one singlet should be observed for the $CH(SiMe_3)_2$ groups attached to the gallium atoms, which are symmetrically coordinated by two carbon or two nitrogen atoms of the ring with a local mirror plane bisecting the C−Ga−C or N−Ga−N as well as the Si−C−Si angles. All these expectations are in accordance with the experimental ^{1}H- and ^{13}C-NMR spectra described above. The question arose, whether this asymmetry was observed in the IR spectra of dimethylgallium cyanide, too, which was intensively investigated by the group of Dehnicke 23 years ago[19]. Six absorptions were observed for the Ga-(C,N) stretching vibrations of the ring between 316 and 365 cm^{-1}, this number was too high for a symmetric structure. They originally were explained by the intermolecular coupling of vibrations. A calculation now done by Dehnicke with the asymmetric structure proposed by us for compound **6** gave, however, an excellent agreement with the experimental spectrum. It was based on a local C_{2v} symmetry of those gallium atoms coordinated by two carbon or two nitrogen atoms of the heterocycle (Ga^1 and Ga^2), which result in two IR active stretching vibrations (A_1, B_2) for each of the groups $Ga^1-(CN)_2$ and $Ga^2-(NC)_2$. The local C_s symmetry at both gallium atoms asymmetrically coordinated by one carbon and one nitrogen atom of the heterocycle (Ga^3 and Ga^4) leads to two indistinguishable stretching vibrations for Ga−(CN) and Ga−(NC) of the symmetry type A′, which gives a total of six IR active stretching vibrations for the $(GaCN)_4$ group. This result impressively confirms our interpretation of compound **6** as a tetramer in solution and the asymmetric structure of the tetramers.

Scheme 3

Upon heating solutions of **8**, the splitting of the $SiMe_3$ resonances disappeared and only one singulet was observed at $\delta = 0.31$. The methine protons gave three resonances with an intensity ratio of 1 to 2 to 1 with similar chemical shifts as observed at room temperature. The temperature of coalescence was at about 40°C. Probably, the resonances of different $SiMe_3$ groups coincided, and there is not enough information for a sensible interpretation. In the IR spectra, the CN stretching vibration was observed in an expected range[22] at 2172 cm^{-1} similar to the aluminium analogue (2185 cm^{-1})[15].

The second product of the reaction of **2** with trimethylsilyldiazomethane was identified as compound **9**, which was isolated in a yield of 4%. A dialkylgallium fragment is coordinated by the ligand $H_2N-N=C(SiMe_3)-NH-$ (Figure 3), which to the best of our knowledge has never been used before in coordination chemistry. However, few derivatives of the neutral compound with two terminal NH_2 groups (amidrazones) are reported in literature[23]. The gallium atom in **9** has a distorted tetrahedral coordination sphere with normal Ga−C bond lengths of 200.0 pm on average. The Ga−N distances differ with 204.8(2) pm to the nitrogen atom N1 of the NH_2 group and 192.7(2) pm to the amide nitrogen atom N3. The N1−N2 single bond length [149.5(2) pm] is longer than in the diazomethane insertion product **6** discussed above, in which both nitrogen atoms were part of a three-membered heterocycle and coordinated by aluminium. The carbon−nitrogen double bond C3−N2 has a length of 130.9(3) pm in the normal range similar to that observed in compound **6**. Also, the C−N bond between C3 and the NH group (N3) is short [134.0(2) pm] and has some π character due to the delocalization of elec-

tron density. A five-membered heterocycle is formed by the coordination of the gallium atom by both terminal nitrogen atoms of the ligand (N1 and N3), which is almost ideally planar. The atom N1 deviates furthest from the average plane by only 4.9 pm. Also, the silicon atom Si5 bound to the carbon atom C3 and the hydrogen atom at N3 lie within this plane with small deviations of 9.1 and 3.5 pm, respectively.

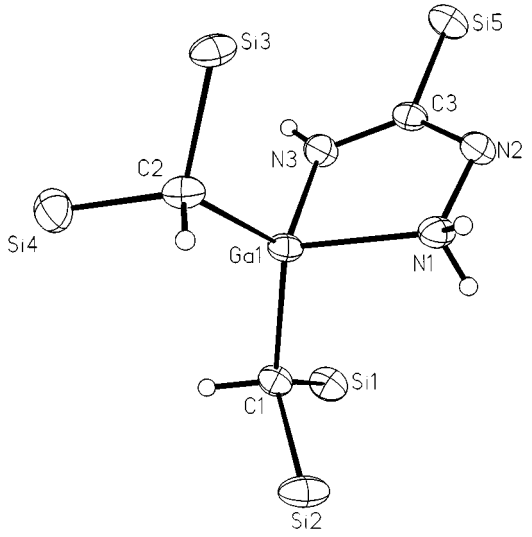

Figure 3. Molecular structure and numbering scheme of compound **9**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity; selected bond lengths [pm] and angles [°]: Ga1−N1 204.8(2), Ga1−N3 192.7(2), N1−N2 149.5(2), N2−C3 130.9(3), N3−C3 134.0(2), C3−Si5 190.1(2), Ga1−C1 199.9(2), Ga1−C2 200.0(2), N1−Ga1−N3 80.11(8), Ga1−N1−N2 111.3(1), N1−N2−C3 110.1(2), N2−C3−N3 122.6(2), C3−N3−Ga1 115.3(2)

The trimethylsilyl groups of the $CH(SiMe_3)_2$ substituents are diastereotopic due to the molecular symmetry and give two resonances in the ^{1}H- and ^{13}C-NMR spectra. The methine protons show a resonance at very high field ($\delta = -0.75$), which is characteristic for a coordination number of four at the gallium atom[21], and the N−H protons give two broad signals in the intensity ratio of 1 to 2 at $\delta = 4.51$ and 4.20. The carbon atom of the chelating ligand has, as expected, a resonance at low field ($\delta = 176.7$) similar to the bis(trimethylsilyl)diazomethane product **6** discussed above. In the IR spectrum, two absorptions are observed at 1584 and 1501 cm^{-1}, which can be attributed to the N−C−N moiety with a delocalized π bond in the chelate ligand.

The diindium compound **3** with an In−In single bond did not react with the diazomethane derivatives at room temperature. Complete disproportionation by the formation of elemental indium and the corresponding InR_3 compound occurred upon heating in boiling *n*-hexane or under irradiation with UV light, and no product of a reaction with the diazomethanes could be detected by NMR spectroscopy.

Experimental Section

General: All procedures were carried out under purified argon in dried solvents (toluene with Na/benzophenone, *n*-hexane with $LiAlH_4$). Compounds **1**, **2**, and **3** were synthesized as described in ref.[1−3]. A commercially available solution of trimethylsilyldiazomethane in *n*-hexane was used without further purification; bis(trimethylsilyl)diazomethane was synthesized according to ref.[24].

Reaction of 1 with Trimethylsilyldiazomethane. − Synthesis of 5: A solution of trimethylsilyldiazomethane in *n*-hexane (2 M, 0.77 ml, 1.53 mmol) was added to a solution of dialane(4) **1** (0.960 g; 1.39 mmol) in 50 ml of *n*-hexane at room temperature. The mixture was stirred for 24 h. The color changed from pale-yellow to orange. The solvent was removed in vacuo, and the residue was thoroughly dried in vacuo. The product (**5**) could not be purified by recrystallization. − ^{1}H NMR (C_6D_6, 300 MHz): δ = 7.95 (1 H, CH of azomethane), 0.32 [72 H, $SiMe_3$ of bis(trimethylsilyl)methyl], 0.26 (9 H, $SiMe_3$ of diazomethane), −0.51 (4 H, $AlCHSi_2$). − ^{13}C NMR (C_6D_6, 75.5 MHz): δ = 152.9 (C=N), 6.0 ($SiMe_3$ of diazomethane), 5.2 [$SiMe_3$ of bis(trimethylsilyl)methyl], −0.6 ($AlCSi_2$).

Reaction of 1 with Bis(trimethylsilyl)diazomethane. − Synthesis of 6: A solution of 0.796 g (1.15 mmol) dialane(4) **1** in 60 ml of *n*-hexane was added to 0.294 g (1.58 mmol) bis(trimethylsilyl)diazomethane at room temperature. The mixture was stirred for 18 h. The solvent was removed in vacuo. The residue was recrystallized from *n*-hexane. Yield: 0.761 g (75%), yellow crystals. − M. p. (argon, sealed capillary): 110°C. − ^{1}H NMR (C_6D_6, 300 MHz, 300 K): δ = 0.43 (9 H, $SiMe_3$ of diazomethane), 0.36 [72 H, $SiMe_3$ of bis(trimethylsilyl)methyl], 0.32 (9 H, $SiMe_3$ of diazomethane), −0.44 (4 H, $AlCHSi_2$). − ^{1}H NMR ([D$_8$]toluene, 300 MHz, 203 K): δ = 0.43, 0.40, 0.39, 0.36, 0.34, 0.30, 0.24, 0.19, 0.16 ($SiMe_3$), −0.26, −0.45, −0.47, −0.78 (each 1 H, $AlCHSi_2$). − ^{13}C NMR (C_6D_6, 75.5 MHz): δ = 179.0 (C=N), 5.9 [$SiMe_3$ of bis(trimethylsilyl)methyl], 5.1 ($SiMe_3$ of diazomethane), 4.0 ($AlCSi_2$), 2.1 ($SiMe_3$ of diazomethane). − IR (CsBr, paraffin): $\tilde{\nu}$ = 1289 vw cm^{-1}, 1248 vs δCH_3; 1187 vw, 1154 vw, 1071 w, 1045 m νNN; 1007 m δCH; 951 m, 922 m, 845 vs, 777 m, 752 m, 723 m ρCH_3(Si); 675 s ν_{as}SiC; 646 w, 631 w ν_sSiC; 594 vw, 557 w, 527 w, 515 m, 502 w, 465 w, 451 w νAlC, νAlN; 401 vw, 378 vw, 339 vw δSiC. − UV (*n*-hexane): λmax (lg ε) = 260 nm (br., 3.5), 360 (3.5), 370 (sh, 3.3). − $C_{35}H_{94}N_2Si_{10}Al_2$ (878.0): calcd. Al 6.1, found Al 6.0. − Mol. mass: 825 (cryoscopically measured in benzene).

Reaction of 2 with Trimethylsilyldiazomethane − Synthesis of 8 and 9: A solution of trimethylsilyldiazomethane (2 ml; 2 M; 4.00 mmol) was added to a solution of 0.953 g (1.23 mmol) digallane(4) **2** in 50 ml of *n*-hexane. The mixture was refluxed for 24 h. After cooling to room temperature, the solvent was removed in vacuo, and the brown residue was dissolved in 1.5 ml of toluene. An amorphous solid crystallized on storing the solution at −50°C for 14 d, which was isolated and recrystallized from 2 ml of toluene at −50°C for seven days. Three compounds were detected in the solid by NMR spectroscopy, one could not be isolated in a pure form and was not identified. Compound **8** [$(R_2GaCN)_3$] was isolated after dissolution of the solid in 2.5 ml of toluene and slow cooling to 0°C. The mother liquor was cooled to −50°C to obtain a colorless solid, which was dissolved in *n*-hexane and gave product **9** upon slow cooling to −20°C.

Characterization of 8: Yield: 0.06 g (6%, based on **2**), colorless crystals. − M. p. (argon, sealed capillary): 224−226°C (dec.). − ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 0.369 (9 H), 0.362 (9 H), 0.353 (18 H), 0.346 (sh) and 0.342 (18 H), 0.335 (9 H), 0.325 (9 H, all $SiMe_3$), −0.225, −0.332, −0.339, −0.504 (each 1 H, $GaCHSi_2$).

Characterization of 9: Yield: 0.052 g (4%, based on **2**), colorless crystals. − M. p. (argon, sealed capillary): 124°C (dec.). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 4.51 (1 H, AlNH), 4.20 (2 H, $AlNH_2$), 0.22 (9 H, $SiMe_3$ of the chelating ligand), 0.19 and 0.10 [each 18 H, $SiMe_3$ of bis(trimethylsilyl)methyl], −0.75 (2 H, $GaCHSi_2$). − ^{13}C NMR (C_6D_6, 75.5 MHz): δ = 176.7 (C=N), 4.9 ($SiMe_3$ of the chelating ligand), 4.0 and 3.8 [$SiMe_3$ of bis(trimethylsilyl)methyl], −2.4 ($GaCSi_2$). − IR (CsBr, paraffin): $\tilde{\nu}$ = 3428 m, 3273 m, 3185 m, 3098 m νNH; 2922 vs, 2853 vs paraffin; 1584 s cm^{-1}, 1501 s νNCN; 1462 vs, 1373 vs paraffin; 1289 w, 1256 sh, 1246 vs δCH_3; 1192 m, 1155 s νCN; 1017 s δCH; 936 s, 909 m, 843 vs, 785 s, 774 s, 754 s, 725 m ρCH_3(Si); 669 m ν_{as}SiC; 629 w, 619 m ν_sSiC; 583 m, 525 m, 517 m, 498 s νGaC, νGaN; 368 m δSiC. − $C_{18}H_{50}N_3Si_5Ga$ (518.8): calcd. Ga 13.4, found Ga 13.3.

Crystal Structure Determinations: Single crystals of the compounds **6**, **8**, and **9** were obtained by recrystallization from *n*-hexane, toluene, and *n*-hexane, respectively. Crystal data and structure refinement parameters are given in Table 1[27]. In compound **8**, the atoms of the cyanide groups are statistically disordered as often observed before; each position was refined by the occupation with a half nitrogen and a half carbon atom. The positions of the hydrogen atoms bound to nitrogen in **9** were taken from a difference Fourier-map and isotropically refined. All other hydrogen atoms were calculated on ideal positions and refined by using the riding model.

Acknowledgments

We are very indepted to Prof. Dr. K. Dehnicke (University of Marburg) for the discussion of the IR spectra of tetrameric dimethylgallium cyanide. Further, we are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for generous financial support.

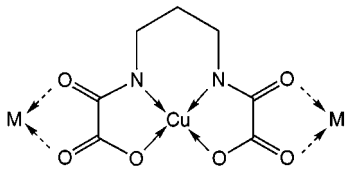
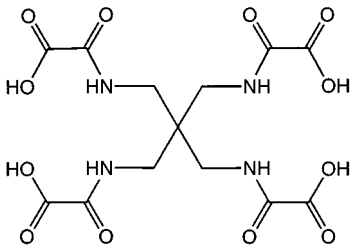
An Na_8 Cluster in the Structure of a Novel Oxamato-Bridged Na^ICu^{II} Three-Dimensional Coordination Polymer



Ally Aukauloo,[a] Xavier Ottenwaelder,[a] Rafael Ruiz,[a][+] Yves Journaux,*[a] Yu Pei,[a] Eric Rivière,[a] Beatriz Cervera,[b] and M. Carmen Muñoz[c]

Keywords: Amides / Chirality / Clusters / Copper / Sodium

The new heterometallic sodium(I)-copper(II) compound Na_4Cu_2 (**2**) · 10.5 H_2O (**3**), where H_8[**2**] stands for *N*,*N*′,*N*″,*N*‴-methanetetrayltetrakismethylenetetrakis(oxamic acid), has been synthesized and its crystal structure determined by single-crystal X-ray diffraction. The structure of **3** consists of cationic $[Cu_2(\eta^4{:}\eta^4\text{-}\mathbf{2})]^{4-}$ dinuclear units, coordinated sodium cations, and water molecules. In the crystal, the dinuclear copper entities are joined through discrete aggregates of eight sodium atoms linked by oxamato and water bridges, leading to a three-dimensional polymeric network.



The chemistry of polymetallic coordination compounds (clusters or cages) has received much attention during the last two decades because of their fundamental role in redox metalloenzymes[1] and metal storage proteins.[2] The recent finding that polymetallic complexes could exhibit intrinsically original magnetic properties, such as high-spin molecules (nanomagnets), has further enhanced the interest in cluster chemistry.[3] Metal clusters with different kinds of bridging ligands (both organic and inorganic) are known for almost all transition metals throughout the periodic table,[4] including among them the class of polyoxometalates.[5] The preparation of these clusters has been frequently based on the use of organic terminal ligands to prevent the formation of undesired polymeric solids. Otherwise, the use of metal complexes as ligands in the preparation of cluster compounds is an attractive approach to obtain heterometal aggregates. This can be realized using suitable precursor complexes with exposed donor atoms which ligate another metal site.

We have always been interested in the coordination chemistry of oxamato ligands like H_4[**1**], the parent acid of the polychelating ligand *N*,*N*′-propane-1,3-diylbis(oxamate). The fully deprotonated ligand forms a stable copper(II) complex $[Cu(\eta^4\text{-}\mathbf{1})]^{2-}$, where the tetradentate ligand coordinates to Cu^{II} through the two strongly basic amide-N and the two carboxylate-O atoms,[6] while the four carbonyl-O atoms are still sufficiently basic to coordinate to another metal ion in a bischelate fashion (Scheme 1). That provides diverse examples of heterometallic compounds with both first-row transition[7] and rare-earth lanthanide metal ions.[8] In particular, this family of compounds ranges from discrete mononuclear[6] or small oligonuclear complexes[7b,7c] (dimers and trimers) to extensive infinite chain arrays[7a,8c] and layers,[8a,8b] although no three-dimensional networks are reported.

Scheme 1. Coordination modes of the *N*,*N*′-propane-1,3-diylbis(oxamato) ligand: tetradentate-*N*,*N*,*O*,*O* (full arrows) and bis(bidentate-*O*,*O*) (dashed arrows)

In the scope of our continuous research in this field we prepared the related binucleating ligand H_8[**2**], the parent acid of the ligand *N*,*N*′,*N*″,*N*‴-methanetetrayltetrakismethylenetetrakis(oxamate). Potentially, this ligand can bind two Cu^{II} ions to give a dimeric copper(II) complex $[Cu_2(\eta^4{:}\eta^4\text{-}\mathbf{2})]^{4-}$, which in turn can act as ligand, as its monomeric counterpart. We report herein the synthesis and general physical and structural characterization of the sodium salt of this oxamatocopper(II) complex of formula $Na_4[Cu_2(\eta^4{:}\eta^4\text{-}\mathbf{2})]$ · 10.5 H_2O (**3**).

H_8[**2**]

The structure of **3** comprises dimeric copper(II) complex anions $[Cu_2(\eta^4{:}\eta^4\text{-}\mathbf{2})]^{4-}$, complexed sodium metal cations and solvent water molecules, both coordinated and non-coordinated (Figure 1). Within the dinuclear copper anion,

the Cu(1) and Cu(2) atoms are coordinated to the two deprotonated amide-N and two carboxylate-O atoms of the bistetradentate ligand in a nearly square-planar geometry [metal deviations from the mean basal planes are 0.020(4) and 0.188(5) Å, respectively], with Cu(2) showing a weak axial interaction with the oxygen atom O(16) from water (2.80 Å). The average Cu−N and Cu−O bond lengths (1.92 and 1.97 Å, respectively) and the copper bond angles (84.0−96.6°) are similar to those found for the related monomeric complex $(PPh_4)_2[Cu(\eta^4\text{-}\mathbf{1})] \cdot 2\ H_2O$.[6] The conformation of the ligand is such that the two mean copper basal planes form a dihedral angle of 44.0°, thus a global butterfly-folded shape to the dinuclear copper molecule.

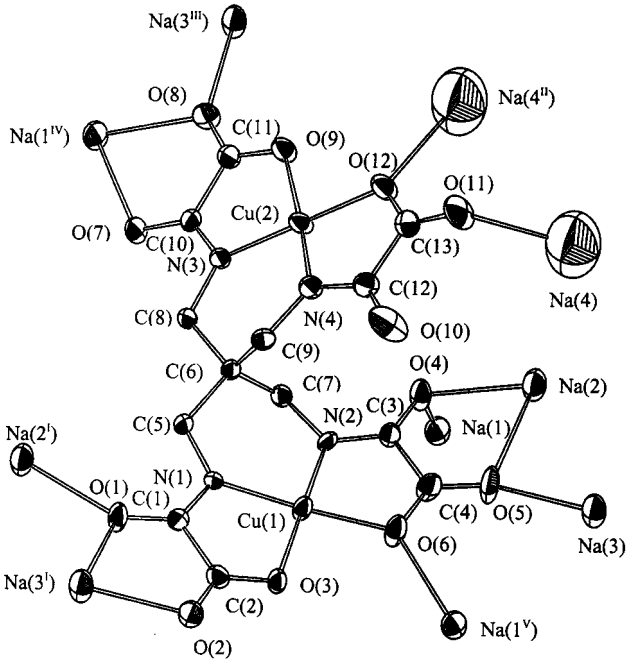

Figure 1. Perspective drawing of the assymetric unit of **3** with the atom-numbering scheme; thermal ellipsoids are representted at the 30% probability level (all hydrogen atoms and oxygen atoms from water molecules have been omitted for clarity); selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Cu(1)−N(1) 1.926(5), Cu(1)−N(2) 1.919(5), Cu(1)−O(3) 1.961(4), Cu(1)−O(6) 1.964(4), Cu(2)−N(3) 1.929(5), Cu(2)−N(4) 1.921(5), Cu(2)−O(9) 1.963(4), Cu(2)−O(12) 1.983(4); N(2)−Cu(1)−N(1) 96.6(2), O(3)−Cu(1)−N(1) 84.5(2), O(6)−Cu(1)−N(1) 173.3(2), N(2)−Cu(1)−O(3) 176.8(2), N(2)−Cu(1)−O(6) 84.2(2), O(6)−Cu(1)−O(3) 95.1(2), N(3)−Cu(2)−N(4) 95.1(2), O(9)−Cu(2)−N(3) 84.4(2), O(12)−Cu(2)−N(3) 178.9(2), N(4)−Cu(2)−O(9) 172.4(2), N(4)−Cu(2)−O(12) 84.0(2), O(12)−Cu(2)−O(9) 96.4(2)

The dinuclear copper anion molecule is dissymmetric both (*R*) and (*S*) optical isomers are present in the crystal due to the existence of an inversion center according to the *P*−1 space group]. In fact, the central carbon atom C(7) connecting the two mononuclear copper fragments turns out to be the center of dissymmetry of the molecule because of the four independent oxamato substituents are involved in distinct coordinative interactions with the metal sodium cations (i.e., the central C atom in the free ligand H_8[**2**] can be seen as being "prochiral"). Actually, almost all twelve oxygen atoms [but O(10)] from the four oxamato groups of the dicopper complex anion participate in coordination of the sodium metal cations. These sodium cations form in turn molecular aggregates comprising of eight Na^+ which are connected through the $[Cu_2(\eta^4\text{:}\eta^4\text{-}\mathbf{2})]^{4-}$ moieties, thus leading to an intricate three-dimensional structure in the solid-state (Figure 2). The Cu(1)···Cu(2) intramolecular separation is 5.92 Å, while the shortest intermolecular ones $Cu(1^V)\cdots Cu(1^{VI})$ and $Cu(2^{II})\cdots Cu(2^{VI})$ are 5.28 and 4.08 Å, respectively (II = 1 − *x*, 2 − *y*, 2 − *z*; V = −*x*, 1 − *y*, 1 − *z*; VI = *x*, 1 + *y*, *z*).

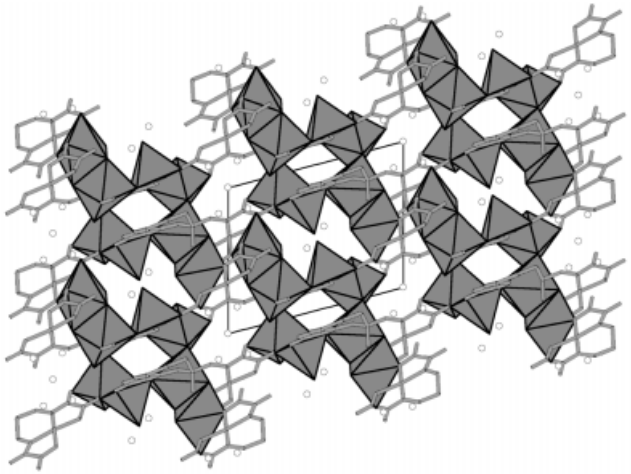

Figure 2. Projection view of the unit cell of **3** along the *b* axis, showing the formation of octanuclear sodium aggregates in the solid state; sodium cations are represented by shaded octahedra and all remaining atoms are represented by spheres of arbitrary radii

The octanuclear sodium cationic entity (Figure 3) is made up of two tetranuclear propeller-like molecular units with an approximate three-fold symmetry related by an inversion center (V = −*x*, 1 − *y*, 1 − *z*). The central tris(chelate) sodium complex of one tetrameric fragment and its symmetry related one have opposite chirality, one isomer being Δ and the other Λ (i.e., the centrosymmetric octanuclear moiety is mesomorphic). Alternatively, the resulting cluster can also be viewed as a ring of six sodium atoms with two edge-bridged sodium atoms. Therefore, all but two pairs of neighboring sodium polyhedra in the aggregate share an edge, while Na(1) and $Na(3^V)$ atoms (and their symmetry-related pair) share a corner. The central hexasodium ring is reminiscent to that found in some cyclic hexairon(III)[9a] and hexamanganese(III) complexes.[9b] The six sodium atoms which form the ring are situated at the vertices of an almost regular hexagon [Na(1)−Na(2), Na(2)−Na(3) and Na(3)−$Na(1^V)$ distances of 3.52, 3.44 and 3.70 Å, respectively, and Na(2)−Na(1)−$Na(3^V)$, Na(3)−Na(2)−Na(1) and Na(2)−Na(3)−$Na(1^V)$ angles of 118.9, 116.9 and 105.4°, respectively], with a diameter of about 6.92 Å (average distance between two opposing symmetry-related sodium atoms). The remaining Na(4) and $Na(4^V)$ atoms are connected to the ring through Na(2) and $Na(2^V)$ atoms, respectively [Na(2)−Na(4) distance of 3.50 Å]. The intraring sodium atoms lie essentially in a plane with a maximum deviation of ±0.467(2) Å for Na(2) and $Na(2^V)$, whereas the extraring ones are ±2.58(1) Å out of the ring plane.

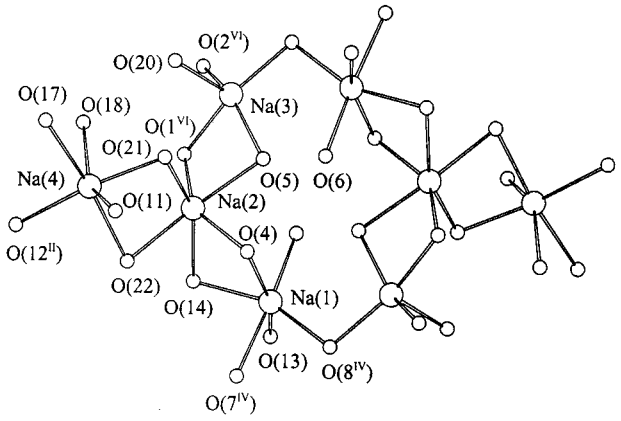

Figure 3. Perspective drawing of the cationic octasodium cluster of **3** with the atom-numbering scheme; an inversion center relates one tetranuclear unit to the other one; atoms are represented by spheres of arbitrary radii; selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Na(1)−O(4) 2.513(6), Na(1^V)−O(6) 2.368(5), Na(1)−O(7^{IV}) 2.384(5), Na(1)−O(8^{IV}) 2.379(5), Na(1)−O(13) 2.421(7), Na(1)−O(14) 2.395(6), Na(2)−O(1^{VI}) 2.299(5), Na(2)−O(4) 2.358(5), Na(2)−O(5) 2.485(5), Na(2)−O(14) 2.463(6), Na(2)−O(21) 2.366(10), Na(2)−O(22) 2.539(9), Na(3)−O(1^{VI}) 2.357(5), Na(3)−O(2^{VI}) 2.386(5), Na(3)−O(5) 2.346(5), Na(3^V)−O(8^{IV}) 2.291(5), Na(3)−O(20) 2.345(10), Na(4)−O(11) 2.532(10), Na(4)−O(12^{II}) 2.615(9), Na(4)−O(17) 2.532(10), Na(4)−O(18) 2.540(14), Na(4)−O(21) 2.302(14), Na(4)−O(22) 2.52(2); Na(2)−O(4)−Na(1) 92.3(2), Na(1)−O(14)−Na(2) 92.7(2), Na(2)−O(1^{VI})−Na(3) 95.4(2), Na(3)−O(5)−Na(2) 90.8(2), Na(4)−O(21)−Na(2) 97.0(5), Na(4)−O(22)−Na(2) 87.4(4), Na(3^V)−O(8^{IV})−Na(1) 104.7(2) [symmetry codes: (II) 1 − x, 2 − y, 2 − z; (IV) − x, 1 − y, 2 − z; (V) − x, 1 − y, 1 − z; (VI) x, 1 + y, z]

Focusing on the core skeleton of the cationic Na_8 cluster, the six sodium atoms which define the central ring are linked by ten bridging oxygen atoms: four carboxylate-O and four carbonyl amide-O atoms from the oxamato groups and only two water molecules. Bis(aquo) bridges connect the two extraring sodium atoms to the central Na_6 skeleton. The remaining sites of the six [NaO_6] octahedra and two [NaO_5] trigonal bipyramids which form the octasodium aggregate are occupied by oxygen atoms from additional water molecules and oxamato ligands. The Na−O bond lengths are not all equivalent (2.29−2.66 Å), and the O−Na−O angles lie in the large range 69.6−166.7°. The architecture of the sodium cluster is issued from the bridging modes of the oxamato groups: each of the two μ_4-O_3C_2NR moieties link four Na^+ ions in the inner rim of the cyclic ring, while each of the four μ_2-O_2C_2ONR moieties link two Na^+ ions in the outer rim. In addition, two bidentate bridging carboxylate moieties from two μ_2-O_2C_2ONR groups connect the extraring Na^+ ions from two neighboring aggregates.

In summary, compound **3** provides a clear evidence of self-assembly in the solid-state of an unprecedent octanuclear sodium cluster which serves as the molecular fragment of a three-dimensional supramolecular complex. In that case, the formation of the octasodium cluster relies on the multidentate character of the novel dicopper oxamato complex $[Cu_2(\eta^4{:}\eta^4\text{-}\mathbf{2})]^{4-}$, acting as both terminal and bridging ligand. We are currently focusing our attention on the ability of this novel organometallic assembling block to bind more relevant cations in the field of magnetochemistry, such as iron and manganese, in order to elaborate new materials with interesting magnetic properties (molecular-based magnets)

Experimental Section

Preparation of H_8[2]: The tetraethyl ester Et_4H_4[**2**] ligand resulted from the condensation of tetrakis(aminomethyl)methane prepared according to a literature procedure[10] and diethyl oxalate in tetrahydrofuran: A solution of the tetraamine (4.0 g, 30 mmol) in THF (100 mL) was added dropwise through a dropping funnel to a large excess of diethyl oxalate (250 mL). The resulting mixture was stirred for 0.5 h at room temp. and then filtered through paper. The solvent was removed in a rotatory evaporator and the remaining oil was treated with diethyl ether to give a white solid which was collected by filtration and dried under vacuum (90%). − ^{1}H NMR ([D_6]DMSO): δ = 1.29 (t, 12 H, CH_3), 3.02 (d, 8 H, CH_2N), 4.27 (q, 8 H, CH_2O), 8.89 (t, 4 H, NH). − IR (KBr): $\tilde{\nu}$ = 3330 cm^{-1} (NH), 1740 and 1695 (C=O).

Synthesis of 3: The sodium salt of the copper(II) complex **3** was obtained by reaction of the tetraethyl ester Et_4H_4[**2**] with Cu^{2+} in basic aqueous media: To a suspension of Et_4H_4[**2**] (1.33 g, 2.5 mmol) in water (50 mL) was added an aqueous solution (25 mL) of NaOH (1.00 g, 25 mmol). After stirring for 15 min at room temp. until complete dissolution, an aqueous solution (25 mL) of $Cu(NO_3)_2 \cdot 3\ H_2O$ (1.20 g, 5 mmol) was added dropwise. The deep-blue solution was then filtered to eliminate the rest of solid particles and the solvent volume was reduced to 25 mL in a rotatory evaporator when a solid began to appear. Slow addition of absolute ethanol to the mother liquor gave a purple-blue crystalline solid which was collected by filtration and air-dried. Upon standing a second crop separated which was also collected and dried (95%). − IR (KBr): $\tilde{\nu}$ = 1640 and 1608 cm^{-1} (C=O). − $C_{13}H_8Cu_2N_4Na_4O_{12} \cdot 8\ H_2O$ (775): calcd. C 20.14, H 3.12, N, 7.23; found C 19.35, H 2.85, N 7.01. − The purple-blue crystalline solid is readily soluble in water but insoluble in common solvents (even in DMSO or DMF). Well-shaped large purple prisms of **3**, suitable for X-ray diffraction, were obtained by recrystallization from concentrated aqueous solutions after two weeks of slow concentration at room temp.

X-ray Crystallographic Study for 3:[11] Crystal data: $C_{13}H_{29}Cu_2Na_4N_4O_{22.5}$, mol. mass = 820, triclinic, space group $P\bar{1}$, a = 10.507(1), b = 10.958(2), c = 13.438(2) Å, α = 109.17(1), β = 99.21(1), γ = 103.11(1)°, V = 1376.3(3) Å^3, d = 1.99 g mL^{-1}, Z = 2. − Data collection: Enraf-Nonius CAD-4 diffractometer, Mo-K_α radiation, λ = 0.71069 Å, graphite monochromator, 293 K, ω-2θ, Lorentz and polarization effects and absorption correction, μ = 1.72 mm^{-1}, 2.0° ≤ θ ≤ 22.5°, crystal size 0.05 × 0.20 × 0.05 mm. 3498 unique reflections, and 3428 assumed as observed with $I > 2\sigma(I)$. Structural analysis and refinement: standard Patterson methods with subsequent full-matrix least-squares method refinement, SHELX93.[12] The hydrogen atoms from the organic ligand were located from a difference synthesis and refined with an overall isotropic thermal parameter. The hydrogen atoms from the water molecules were neither found nor calculated. Refinement of 414 variables with anisotropic thermal parameters for all non-hydrogen atoms gave R = 0.051 and R_w = 0.123 with S = 1.05. The crystal drawings were carried out with the SCHAKAL[13] and CRYSTAL MAKER[14] programs.

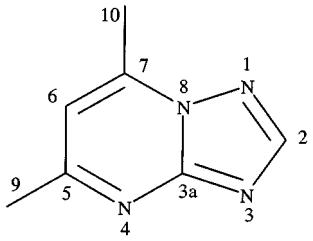
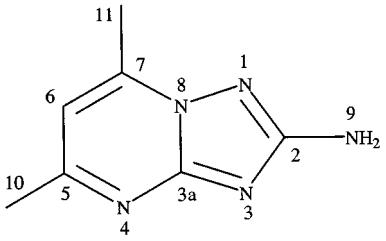
A Unique Fourfold Intramolecular Hydrogen Bonding Stabilises the Structure of *trans*-Bis(2-amino-5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine-N^3)-aquatrichlororuthenium(III) Monohydrate



Aldrik H. Velders,[a] Franco Ugozzoli,[b] Marina Biagini-Cingi,[b] Anna M. Manotti-Lanfredi,[b] Jaap G. Haasnoot,[a] and Jan Reedijk*[a]

Keywords: Ruthenium / Nitrogen heterocycles / Hydrogen bonds / Antitumor agents / Crystal structures



The X-ray structure of the potential antitumour complex *trans*-[$RuCl_3(H_2O)(admtp)_2$] · H_2O (admtp = 2-amino-5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine) shows unique and very interesting intramolecular hydrogen-bonding properties with the non-bridgehead pyrimidinic nitrogen atom of admtp acting as hydrogen acceptor and the amino group acting as hydrogen donor.

In the search for new chemotherapeutic antitumour agents, ruthenium(III) complexes of the type *trans*-(LH)[$RuCl_4(L)_2$] (where L is an aromatic N-heterocycle like imidazole or indazole and HL the protonated heterocycle) have shown promising activity in preclinical tests against different (platinum-resistant) tumour models.[1] As yet no clear structure−activity relationship has been reported for ruthenium(III) complexes, like for platinum compounds;[2] therefore, the hydrolysis properties[3] and DNA binding[4] are important factors to analyse. In vivo the ionic *trans*-(LH)[$RuCl_4(L)_2$] complexes with bicyclic ligands like indazole appear to be prodrugs that hydrolyze rapidly to form relatively stable neutral complexes of the type *trans*-[$RuCl_3(H_2O)(L)_2$].[5] However, the consecutive extracellular and intracellular reactions of these monoaquatrichlororuthenium(III) complexes that finally lead to the antitumour activity, and the role of the heterocyclic ligands therein, are not yet understood[3,6] and are currently under investigation.

Recently, we have reported the synthesis and characterisation of the neutral trichlororuthenium(III) complex *trans*-[$RuCl_3(H_2O)(dmtp)_2$] · H_2O, in which the azapurine 5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine (dmtp) (Scheme 1), is coordinated to the ruthenium(III) centre through the N(3) nitrogen atom of the triazole moiety, whilst the pyrimidinic (N4) nitrogen atoms of both coordinated ligands are involved in intramolecular hydrogen bonds with the two hydrogen atoms of the coordinated water molecule.[7] The hydrogen-bonding interactions of the dmtp suggested the possibility of fine-tuning in the investigations of the hydrolysis reactions and hydrolysis products of ruthenium(III) antitumour complexes, on use of heterocyclic ligands with the capacity to form intramolecular donor and/or acceptor hydrogen bonds.

dmtp

admtp

Scheme 1

In the past two decades several triazolopyrimidines have been used to synthesise complexes with different metals and purposes,[8,9] and recently a platinum complex with two triazolopyrimidine ligands has been reported which has interesting antimour activity.[9c] To our knowledge, the 2-amino-5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine,[10] (admtp) (Scheme 1), has not been reported yet as a ligand for metal coordination. We now present the synthesis and characterisation of a ruthenium complex, in which admtp acts as a monodentate ligand with unique intramolecular hydrogen-bonding properties, and its possible role in the search for a structure−activity relationship of antitumour-active ruthenium(III) complexes is discussed.

The new neutral monoaquatrichlororuthenium(III) compound *trans*-[$RuCl_3(H_2O)(admtp)_2$] · H_2O (**1**) was synthesised by a procedure analogous to *trans*-[$RuCl_3(H_2O)(dmtp)_2$] · H_2O[7] (**2**) and characterised by elemental analysis, and NMR and IR spectroscopy. The crystal structure of **1** (Figure 1) was determined by X-ray diffraction analysis and shows a six-coordinated ruthenium(III) ion with three chloride ions in a *mer* configuration, two admtp molecules, coordinated by their N(3) nitrogen atoms, in a parallel "face-to-face" *trans* orientation, and a water molecule coordinated in the plane of the chloride ions and lying in between the pyrimidinic rings of the two admtp ligands. The Ru−N, Ru−Cl, and Ru−O bond lengths are comparable with those found in related complexes, like *trans*-[$RuCl_3(H_2O)(dmtp)_2$][7] and *trans*-[$RuCl_3(H_2O)(1\text{-MeInd})_2$][5] which also display a quasi-octahedral stereochemistry with two *trans*-located heterocyclic ligands.

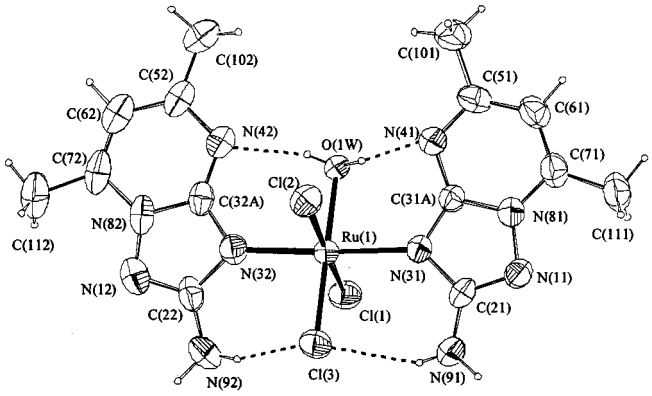

Figure 1. X-ray structure and numbering scheme of **1** with the thermal ellipsoids drawn at a 50% probability level (PLATON); intramolecular hydrogen bondings are indicated with dotted lines; the crystal water is omitted for clarity; selected metal−ligand bond lengths [Å] and angles [°]: Ru(1)−N(31) 2.117(4), Ru(1)−N(32) 2.131(5), Ru(1)−O(1W) 2.098(4), Ru(1)−Cl(1) 2.339(2), Ru(1)−Cl(2) 2.348(2), Ru(1)−Cl(3) 2.358(2), N(32)−Ru(1)−N(31) 175.7(2), Cl(1)−Ru(1)−Cl(2) 175.08(5), Cl(3)−Ru(1)−O(1W) 176.5(1); donor···acceptor (D···A) and hydrogen···acceptor (H···A) distances [Å], and donor−hydrogen···acceptor (D−H···A) angles [°] of the intramolecular hydrogen bonds: O(1W)−H(1WA)···N(41) 2.650(6), 1.81(9), and 154(8); O(1W)−H(1WB)···N(42) 2.662(6), 1.95(7), and 165(8); Cl(3)···H(91A)−N(91) 3.126(6), 2.51(6), and 141(6); Cl(3)···H(92A)−N(92) 3.077(7), 2.35(10), and 155(10)

The most striking feature of the structure of **1** is that a fourfold intramolecular hydrogen-bond system is present. In addition to the hydrogen-bonding acceptor properties of the pyrimidinic N(4) nitrogen atoms to the coordinated water hydrogen atoms, the amino groups of the two admtp ligands are both involved as hydrogen donors in intramolecular hydrogen bonding to the chloride ion Cl(3) lying *trans* to the coordinated water molecule. This special hydrogen bonding is probably also the origin of the elongated Ru(1)−Cl(3) distance (2.358 Å), which is slightly longer than the other two ruthenium−chloride bonds (2.339 and 2.348 Å). It is more difficult to draw conclusions about differences in the stability of the coordinated water molecule from the crystallographic data of **1** and **2** as the water molecule in the former is also involved in intermolecular hydrogen bonds.

Double intramolecular hydrogen bonding of heterocyclic ligands with both hydrogen atoms of a coordinated water molecule has been observed before for metal complexes,[7,9a,11a] and also double intramolecular hydrogen bonding of N−H groups with one coordinated halide ion is not an unknown feature for coordination compounds. However, the combination of (intramolecular) hydrogen-accepting and hydrogen-donating bonds of one ligand in a coordination compound, like in this case for admtp [via the N(4) nitrogen atom and the amine moiety, respectively] is to our knowledge unique.[11b] As both admtp ligands in **1** bind in a similar way, complex **1** is an as yet unique example of a coordination compound in which four square-planar coordinated monodentate ligands, linked to each other by a fourfold intramolecular hydrogen bond, form a pseudo-chelating tetradentate ligand which is organised by the heterocyclic ligand.

Due to the (non-symmetric) intermolecular hydrogen bonds of the two amino groups and the two water molecules in the crystal structure of **1** no twofold symmetry is present. However, it is likely that in solution **1** does have a twofold symmetry, in agreement with the single set of admtp signals found in NMR. Time-dependent UV/Vis absorption, NMR, and conductivity measurements of **1** in coordinating solvents (Solv), like DMSO and acetonitrile, indicate the formation of complexes of the type *trans*-[$RuCl_3(Solv)(admtp)_2$]. This type of reactions is related to those seen in the *trans*-[$RuCl_3(H_2O)(dmtp)_2$] · H_2O chemistry[7] and will be published in detail in a full paper. Preliminary results indicate that the solvolysis of **1**, in acetonitrile for example, is slightly faster than that of **2**, but still much slower than in analogous complexes that do not have double intramolecular hydrogen bonds that can stabilise the coordinated water molecule.[12] Although the water-substitution reactions are not directly correlated to in vivo reactions of this type of ruthenium complexes, these results do indicate that the ruthenium−ligand properties have been slightly changed by a small modification of the ligand.

As hydrolysis properties play a key role in the antitumour mechanism of chemotherapeutic platinum complexes, it is useful to study these properties of ruthenium complexes, too. The structure of complex **1** indicates that the use of the triazolopyrimidine admtp offers the possibility to stabilise, isolate, and study the first hydrolysis product of antitumour-active ruthenium(III) complexes of the type *trans*-(LH)[$RuCl_4(L)_2$]. Furthermore, the intramolecular hydrogen bonds of admtp are likely to influence hydrolysis properties through interactions with incoming (water molecules), as well as with leaving ligands (chloride ions). Also the consecutive in vivo reactions of the aquated ruthenium species, in which the water molecules are thought to be substituted by DNA bases, are likely to be influenced by the presence of hydrogen-donating as well as hydrogen-accepting moieties of the heterocyclic ligands. Finally, the amine group of the ligand admtp is also interesting for its potential intermolecular hydrogen-bonding properties, which for antitumour-active platinum compounds have been proven to be a crucial factor for the in vivo DNA binding and

distortion that finally lead to cell death.[2]

In summary, the hydrogen-bonded stabilised structure of *trans*-[$RuCl_3(H_2O)(admtp)_2$] proves the possibility to design and synthesise new ruthenium complexes with specific ligands that can fine-tune the chemical and physical properties of potential antiumour complexes via multiple intramolecular hydrogen bondings. The easy synthesis and interesting hydrogen-bonding properties of admtp give it promise as a useful ligand for the synthesis of complexes with other transition metals in different fields of coordination chemistry, too. Although the amine group of the admtp is not as reactive as a primary amine, due to the delocalisation of the electron pair in the triazolopyrimidine ring system,[10] it is a useful functional group for the design and synthesis of other triazolopyrimidine derivatives that might also be successful ligands.

Experimental Section

General: NMR: Bruker WM 300 MHz spectrometer. For [D_6]acetone as solvent, δ_H = 2.06 at 295 K. ^{1}H-NMR data of **1** were obtained using an inversion recovery pulse sequence, *π-τ-π/2-acquisition*, with τ (the variable delay time between the inversion and the acquisition pulse, respectively) in the order of 100 ms. The ^{1}H-NMR signals of **1** could be identified as the paramagnetically shifted and broadened signals with relaxation times in the order of ms.

***trans*-[$RuCl_3(H_2O)(admtp)_2$] · H_2O (1):** The ligand 2-amino-5,7-dimethyl[1,2,4]triazolo[1,5-*a*]pyrimidine (admtp) was prepared by a method slightly different method from the one by Kreutzberger[10] by condensation of 3,5-diamino-1,2,4-triazole (Aldrich) with a small excess of 2,4-pentanedione (Merck) in boiling ethylene glycol. After gentle heating at 75°C for 3 h of a ruthenium(III) chloride solution (5 mmol in 50 mL 1 M HCl) with admtp (15 mmol in 50 mL of ethanol), *trans*-[$RuCl_3(H_2O)(admtp)_2$] · H_2O was obtained as a brick-red powder; recrystallisation from acetone/water (5:1) yielded orange-red prismatic crystals. — $C_{14}H_{22}Cl_3N_8O_2Ru$ (569.8): calcd. C 29.50, H 3.86, N 24.58, Cl 18.67; found: C 29.52, H 3.86, N 24.58, Cl 18.6. − The effective magnetic moment, μ_{eff}, of the complex was determined to be 1.9 Bohr magneton at 20°C. − ^{1}H NMR ([D_6]acetone): δ (peak width at half height) = +1.4 (20 Hz) [H(61/62)], +4.7 (35 Hz) and −3.5 (15 Hz) [CH_3(101/102) and CH_3(111/112)], and +53 (2000 Hz) [coordinated H_2O].

X-ray Crystallographic Study of 1: $C_{14}H_{20}Cl_3N_{10}ORu \cdot H_2O$; M = 569.823; monoclinic, space group $P2_1/c$; a = 8.292(5), b = 26.289(5), c = 10.175(5) Å, β = 97.16(2)°; V = 2201(2) Å^3; Z = 4; $D_{calcd.}$ = 1.720 g cm^{-3}; graphite-monochromated Cu-K_α radiation (λ = 1.54178 Å); μ = 9.421 mm^{-1}; T = 293 K. Data were collected with a Siemens AED and corrected for Lorentz and polarisation effects: 4150 unique data in the range 6° < θ < 70°. Refinement on F^2 values of all data with SHELXL96.[13] Final $R1 = \Sigma ||F_o| - |F_c||/\Sigma|F_o| = 0.0566$ for 3140 $F_o > 4\sigma(F_o)$ and 0.0689 for all data, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{1/2} = 0.1605$, $\Sigma = [\Sigma w(F_o^2 - F_c^2)^2/(n - p)]^2 = 1.073$ for 303 parameters. Residual electron density extrema are 2.49 and −1.5 eÅ^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication number CCDC-103269. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The authors thank Johnson & Matthey (Reading, UK) for their generous loan of $RuCl_3 \cdot 3\ H_2O$. This research is sponsored by the Netherlands Organisation for Chemical Research (SON), with financial aid of the Netherlands Organisation for the Advancement of Research (NWO), and support by COST Action D8/0017/97 (Metals in medicine) is also kindly acknowledged. Spontaneous Assembly of a Novel Tetranuclear Ni–Fe Complex by Complete Reshuffling of Ligands and Oxidation States

Elisabeth Bouwman,*[a] Richard K. Henderson,[a] Anthony L. Spek,[b] and Jan Reedijk[a]

Keywords: Nickel / Iron / Clusters / Carbonyl complexes / S ligands

Upon reaction of the mononuclear nickel dithiolate complex [Ni(dsdm)] (H_2dsdm = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-sulfanylethyl)ethylenediamine) with K[HFe(CO)$_4$] in ethanol a unique reshuffling of ligands and of oxidation states takes place. This results in the formation of a novel tetranuclear complex [Fe^{II}(dsdm)Ni^0(CO)$_3$]$_2$, in which a linear array of Ni–Fe–Fe–Ni is formed. The inner core of this complex consists of the dinuclear [Fe(dsdm)]$_2$, and two Ni(CO)$_3$ groups are bound at the periphery through one of the thiolate sulfurs.

The [NiFe] hydrogenases consist of enzymes, which, apart from iron, also contain nickel in the active site. The first crystal structure of a [NiFe] hydrogenase enzyme, extracted from *Desulfovibrio gigas*, has been published by Volbeda et al. in 1995.[1] The active site was shown to contain an unexpected disulfur-bridged heterobimetallic Ni−Fe core. There are two further cysteine groups bound to the nickel and three small non-protein ligands bound to the iron. These diatomic ligands are nowadays considered to be one carbon monoxide and two cyanide molecules, based on isotopic enrichment experiments and FT-IR measurements.[2] The publication of the crystal structure has renewed interest in the chemical modelling of the active site of [NiFe] hydrogenases. A large amount of modelling chemistry had already been reported prior to the publication of the X-ray structure,[3][4] when it was believed that the active site contained mononuclear nickel.

The compound described in the present paper was synthesised as part of research in modelling the heterodinuclear Ni−Fe active site of hydrogenases. It was decided that ligands containing mixed N/S donor groups would be used preferentially to provide greater synthetic control. In view of the new structural information, the ligand *N*,*N*′-dimethyl-*N*,*N*′-bis(2-sulfanylethyl)ethylenediamine (H_2dsdm) was considered useful in our synthetic modelling studies. The mononuclear [Ni(dsdm)] and trinuclear [Ni_3(dsdm)$_2$]-Cl_2 complexes with this ligand have previously been reported from this laboratory.[5] The mononuclear nickel compound was reinvestigated as it contains two *cis* sulfur atoms from thiolate groups, which have potential in forming heterodimetallic complexes in which sulfur bridges to iron compounds.[6]

The complex [Fe(dsdm)Ni(CO)$_3$]$_2$ (**1**) was prepared from a reaction of the mononuclear dithiolate complex [Ni(dsdm)] with K[HFe(CO)$_4$], and was characterised by IR spectroscopy, elemental analysis and single-crystal X-ray crystallography. A fully labelled representation of the molecular structure of the tetranuclear compound **1**, is given in Figure 1. The asymmetric unit contains one half of the molecule, the other half is generated by a centre of symmetry. The compound is built up in an array of Ni^0−Fe^{II}−Fe^{II}−Ni^0. The ligand dsdm is folded around the Fe^{II} ion, and one of the thiolate groups of the dsdm ligand bridges to the second (symmetry generated) iron ion, thus forming the dinuclear [Fe(dsdm)]$_2$ core of the complex. The other thiolate group of the ligand is bridging to a Ni^0 tricarbonyl group, thus forming the tetranuclear complex.

Initially, the structure was refined as "[Ni(dsdm)Fe(CO)$_3$]$_2$", in view of the composition of the starting materials. However, substitution of Fe^{II} for Ni^{II}, thus giving a tetranuclear Fe_4 cluster, resulted in significantly better *R* values and lower residual electron densities in the refinement of the structure, and substitution of the peripheral iron by nickel resulted in even better refinement of the crystal data. Ultimately, this also explained the "16-electron" count for the, initially, Fe^0 moieties, which can now be rationalised as 18-electron Ni^0 species. The coordination around the iron is distorted trigonal bipyramidal, and the nickel atoms are in a tetrahedral geometry. The Fe−N and the Fe−S distances in this unique tetranuclear compound are significantly longer than the Ni−N and Ni−S distances observed in the Ni-dsdm trinuclear species characterised by Turner et al.[5] Instead, the Fe−N and Fe−S bond distances and angles in **1** are comparable to those found in [Fe(dsdm)]$_2$,[7] deviating by less than 0.04 Å and 5.6° from this "parent" compound.

Reactivity studies of nickel thiolate complexes in binding with other metal ions have been reported for several years. In particular mononuclear nickel complexes with *cis* dithiolate groups are regarded as very reactive in forming thiolate bridged polynuclear compounds. Reactions of such nickel complexes with $FeCl_2$,[8] Fe(ClO$_4$)$_2$,[9] $Fe_2(CO)_9$,[10] or (norbornadiene)M(CO)$_4$ (with M = Cr, Mo, W)[6] have been carried out at room temperature with stirring only.

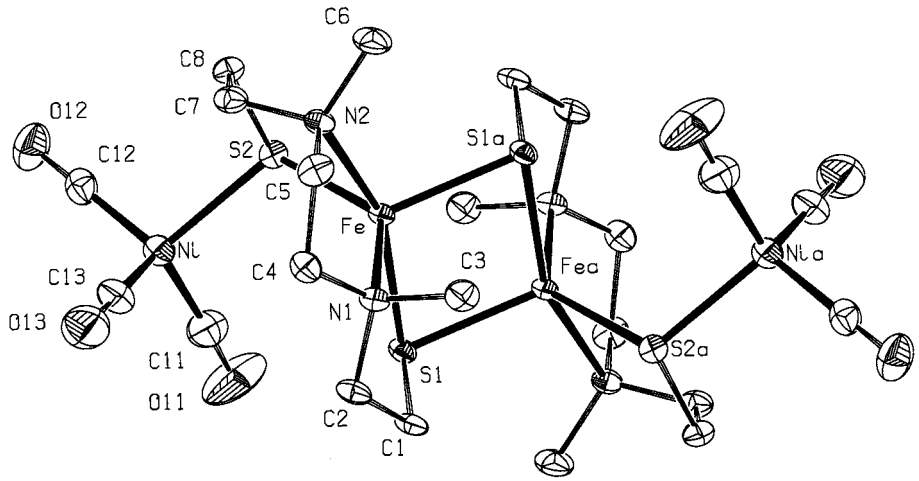

Figure 1. ORTEP view at 50% probability level of the molecular structure of **1** with the atomic labelling. Hydrogen atoms have been omitted for clarity; selected bond lengths [Å] and angles [°]: Ni−Fe 3.899(1), Fe−Fea 3.098(1), Ni−S2 2.317(1), Ni−C11 1.789(6), Ni−C12 1.773(4), Ni−C13 1.786(5), Fe−S1 2.444(1), Fe−S2 2.346(1), Fe−N1 2.168(3), Fe−N2 2.330(3), Fe−S1a 2.363(1), S2−Ni−C11 103.9(2), S2−Ni−C12 104.5(2), S2−Ni−C13 110.8(2), C11−Ni−C12 110.8(2), C11−Ni−C13 113.7(2), C12−Ni−C13 112.5(2), S1−Fe−S2 97.79(4), S1−Fe−N1 83.58(9), S1−Fe−N2 156.20(8), S1−Fe−S1a 99.75(4), S2−Fe−N1 132.48(10), S2−Fe−N2 82.98(8), S2−Fe−S1a 115.56(4), N1−Fe−N2 78.7(1), N1−Fe−S1a 110.87(9), N2−Fe−S1a 101.32(8)

These reactions resulted in various heteropolynuclear complexes, in which the original nickel thiolate complexes act as monodentate or didentate ligands towards the newly introduced metal ion. In our hands, the mononuclear compound [Ni(dsdm)] did not react with either $Fe_2(CO)_9$ or $Fe(CO)_5$ under similar mild reaction conditions. However, more severe conditions such as described above, leads to complete scrambling of the reactants.

Although the initial aim of the reaction was to form a heterodinuclear NiFe compound as a model for hydrogenase, such as the one reported by Darensbourg et al.,[10] the tetranuclear complex which was obtained instead is interesting by itself for other research areas. Numerous examples are known of iron carbonyl compounds, which are bridged by thiolates to other transition metals, but to our knowledge such compounds have not been reported with nickel carbonyl groups. The tetranuclear **1** is the first compound in which a $Ni(CO)_3$ group is bound to a transition metal thiolate complex. Only a few organometallic clusters with bridging inorganic sulfide, in which the nickel monocarbonyl is part of the cluster core, have been reported.[11]

The observation and characterisation of this reshuffled complex may draw the attention to the fact that a tetradentate chelating ligand may not be enough to hold on and stabilize a divalent metal ion. The reshuffling of ligands and oxidation states may have been triggered by the strong reducing power of $K[HFe(CO)_4]$ species, leading to "$[Ni(0)(dsdm)]^{2-}$", which then falls apart and causes a cascade of other reactions. Another scrambled compound which could be isolated from the reaction mixture is the dinuclear [Fe(dsdm)Fe(dmes)$(CO)_2$] (H_2dmes = bis(sulfanylethyl)sulfide).[12]

Experimental Section

General: Infrared spectra (KBr pellets) were recorded in the range 4000−400 cm^{-1} using a Perkin−Elmer FT-IR Paragon spectrophotometer controlled by a PC using PE Grams Analyst software.

Synthesis: All experiments were performed in an argon atmosphere. Solvents were dried according to standard procedures. The ligand H_2dsdm was synthesised according to a literature procedure.[13] [Ni(dsdm)] was synthesized by reaction of $Ni(acac)_2$ with H_2dsdm in toluene.

Iron pentacarbonyl (1 mmol, 0.131 mL) was added to an ethanolic solution of potassium hydroxide (2 mmol, 0.112 g in 5 mL of absolute ethanol) and stirred overnight until a red solution of $K[HFe(CO)_4]$ was obtained.[14] The solution was filtered to remove precipitated $KHCO_3$, which was washed with 10 mL of absolute ethanol. To the red solution was added solid [Ni(dsdm)] (1 mmol, 0.26 g) and the mixture was heated under reflux for 2 hours during which time the solution became very dark. After cooling the reaction mixture was filtered to remove any precipitated solids, and the resulting solution was left to crystallize. Orange-brown crystals suitable for X-ray diffraction were obtained after a few days. − Infrared Spectrum (KBr pellet): 3443 (br) 2919 (m), 2861 (m), 2048 (vs), 1968 (vs), 1949 (vs), 1648 (m,br), 1465 (m), 1295(m), 1273(m), 1079 (m), 1046 (m), 1029 (m), 939 (s), 882 (w), 764 (m), 740 (w), 668 (w), 519 (w), 450 (m) cm^{-1}. The compound gets slightly sticky when in contact with air. Satisfactory elemental analysis was obtained for $[C_{22}H_{36}Fe_2N_4Ni_2O_6S_4] \cdot 3\ H_2O$.

X-ray Crystal Structure Analysis: Crystal data for [Fe(dsdm)Ni$(CO)_3]_2$: $[C_{22}H_{36}Fe_2N_4Ni_2O_6S_4]$, M = 809.89, orange-brown needle (0.12 × 0.12 × 0.55 mm), triclinic, space group $P-1$ with a = 8.2339(17), b = 8.3530(15), c = 12.729(3) Å, α = 79.683(18), β = 74.661(18), γ = 75.532(16)°, U = 811.5(3) $Å^3$, Z = 1, D_c = 1.657 $g \cdot cm^{-3}$, $F(000)$ = 416, μ(Mo-K_α) = 23.2 cm^{-1}, 7392 reflections measured, 3717 independent (R_{av} = 0.05). Mo-K_α radiation, graphite monochromator, λ = 0.71073 Å, θ_{max} = 27.5°, T = 150 K, CAD4T diffractometer on rotating anode. Data were corrected for absorption (analytical). The structure was solved by Patterson techniques (DIRDIF)[15] and refined on F^2 using SHELXL96.[16] Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were located at calculated positions and refined riding on their carrier atoms. Convergence was reached at R_1 = 0.0415 [for 2653 reflections with $I > 2\sigma(I)$] and wR_2 = 0.0892 (S = 0.98). A final difference map did not show any features outside $-0.54 < \Delta\rho < 0.70$ e·$Å^{-3}$. Structure graphics and checking for higher symmetry were performed with the program PLATON.[17]

Crystallographic data (excluding structure factors) for the structure in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102783. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44(1223) 336-033, E-mail: deposit@ccdc.cam.ac.uk].

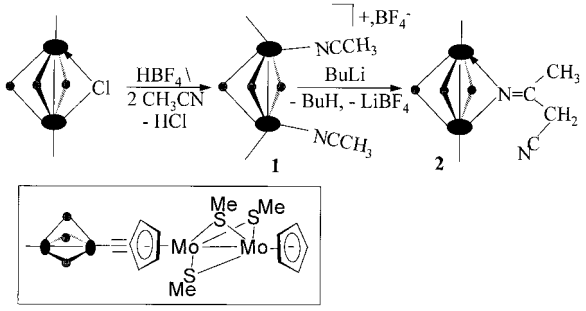
A μ-η¹-Azavinylidene Complex: Intramolecular Condensation of Two Acetonitrile Ligands at a Dinuclear Molybdenum(III) Site

Philippe Schollhammer,[a] Mael Pichon,[a] Kenneth W. Muir,*[b] François Y. Pétillon,*[a] Roger Pichon,[a] and Jean Talarmin[a]

Keywords: Dimolybdenum(III) complexes / Azavinylidene / C–C coupling / Acetonitrile ligands / X-ray crystal structure



Removal of a proton from one of the two coordinated acetonitrile ligands in $[Mo_2Cp_2(\mu\text{-}SMe)_3(CH_3CN)_2](BF_4)$ (**1**) initiates its intramolecular condensation with the second of the acetonitrile ligands attached to the bimetallic $[Mo_2Cp_2(\mu\text{-}SMe)_3]$ core, thereby giving rise to the novel μ-η¹-azavinylidene complex $\{Mo_2Cp_2(\mu\text{-}SMe)_3[\mu\text{-}\eta^1\text{-}N{=}C(CH_3)\text{-}CH_2CN]\}$ (**2**). Complex **2** has been characterized by NMR and X-ray methods.

Bimetallic complexes with direct M−M bonds permit the simultaneous activation of neighbouring ligands. The ensuing reactions are often different from those that occur with polymetallic systems[1] or with bimetallic species in which there is little or no direct communication between the metal atoms.[1−3] Here, we show that a well-known organic reaction, the self-condensation of an alkyl cyanide, can still occur when both substrate molecules are attached to the neighbouring metal atoms of a binuclear complex. Moreover, the product represents a new type of N-donor bridging ligand.

We are currently extensively developing the chemistry of bimetallic complexes with an $[Mo_2Cp_2(\mu\text{-}SMe)_3]$ core by using the bis(acetonitrile) compound $[Mo_2Cp_2(\mu\text{-}SMe)_3(CH_3CN)_2](BF_4)$ (**1**) as a starting material for the coordination of other substrates, such as alkynes and hydrazines, at the bimetallic site. However, we have found that the coordinated nitriles can themselves undergo reaction. We report here their transformation into a novel bridging azavinylidene ligand in the presence of a base.

Electrophilic abstraction of the chloride bridge in the complex $[Mo_2Cp_2(\mu\text{-}SMe)_3(\mu\text{-}Cl)]$ by HBF_4 proceeded in acetonitrile solution and was followed by the coordination of one acetonitrile molecule to each molybdenum atom (Scheme 1).[4] Reaction of the resulting bis(acetonitrile) compound $[Mo_2Cp_2(\mu\text{-}SMe)_3(CH_3CN)_2](BF_4)$ (**1**) with butyllithium in THF afforded the complex $\{Mo_2Cp_2(\mu\text{-}SMe)_3[\mu\text{-}\eta^1\text{-}N{=}C(CH_3)CH_2CN]\}$ (**2**) which was isolated in good yield (Scheme 1). Complex **2** was characterized by IR, one- and two-dimensional NMR, mass spectrometry, and elemental analysis.

The IR stretching frequency of the C≡N bond was detected at 2220 cm^{-1}, while the ^{1}H-NMR spectrum exhibited a set of resonances characteristic of the $[Mo_2Cp_2(\mu\text{-}SMe)_3]$ core. Two additional signals, a single resonance at δ = 2.05 and an AB spin system at δ = 3.02, could be attributed to the CH_3 and CH_2 groups, respectively, of a fourth bridging ligand. Two-dimensional heteronuclear ^{1}H-^{15}N and ^{1}H-^{13}C inverse-correlation experiments were carried out to further characterize **2**. The correlation peaks in the HMBC ^{1}H-^{15}N spectrum were characteristic of $^3J(^1H\text{-}^{15}N)$ couplings. This spectrum showed the AB pattern at δ = 3.02 to be coupled with two nitrogen atoms with signals at δ = −132.5 and δ = −14.2, relative to nitromethane, and the methyl group with signal at δ = 2.05 to be correlated only with the second nitrogen atom with signal at δ = −14.2. The signal at δ = −132.5 suggested the presence of a free nitrile group in the molecule (see Experimental Section).[5] Such a pattern was consistent with an N≡C−CH_2−C(CH_3)=N backbone. Full assignment of the ^{13}C chemical shifts was achieved by means of HMQC ^{1}H-^{13}C and HMBC ^{1}H-^{13}C experiments, which were also in accord with an N≡C−CH_2−C(CH_3)=N ligand.

Scheme 1. Synthesis of complex **2**

The structure of the new complex was confirmed by X-ray analysis of the orange crystals of **2**, which were obtained by cooling a dichloromethane/pentane/carbon disulfide (1:1:1, v/v/v) solution to −15°C (Figure 1). It was found to consist of a typical $[Mo^{III}_2Cp_2(\mu\text{-}SMe)_3]$ unit[6] bridged by the nitrogen atom of the 3-iminobutyronitrile ligand N≡C−CH_2−C(CH_3)=N, namely an η¹-azavinylidene group. The p orbitals on sp²-hybridized N1 and C5 are seen to overlap [Mo1−N1−C5−C6 = −5.4(5)°], so that the C5−N1

bond [1.266(6) Å] has appreciable multiple character. The Mo−N1 bond lengths [2.101(4) and 2.114(4) Å] are nearly equal.

A mechanism involving an intramolecular carbon−carbon attack accounts for the formation of the 3-iminobutyronitrile ligand in this reaction (Scheme 2). Initial deprotonation of the methyl group of one of the coordinated acetonitriles by a strong base leads to a resonance-stabilized $[Mo{-}N{\equiv}C{-}CH_2^-]$ carbanion.[7] This is then attacked by the electrophilic nitrile carbon atom of the second acetonitrile ligand $[Mo{-}N{\equiv}C{-}CH_3]$. The imino nitrogen atom moves to a bridging position as the second C≡N group decoordinates, finally giving the bridging azavinylidene ligand $[\mu\text{-}\eta^1\text{-}N{=}C(CH_3)CH_2CN]$ present in **2**. Evidently, coordination to molybdenum does not impair the ability of acetonitrile to undergo Thorpe−Ziegler-type activation through α-hydrogen abstraction, while the electronic and geometric properties of the bimetallic site ensure a specific intramolecular condensation in preference to an intermolecular reaction[2] or other types of coupling.[8] Moreover, the two bonded metal atoms confer stability on the azavinylidene ligand.

Scheme 2. Possible pathway to the formation of **2**

In view of the role of azavinylidene species as postulated intermediates in the reduction of nitriles to amines[9] and the importance of cyanoenamine in the synthesis of heterocycles,[10] we now intend to investigate the redox behaviour of complex **2** and to extend these preliminary results to other bis(nitrile) complexes.

Experimental Section

Experimental Procedure: At −70°C, 0.5 mL of a 2.5 M solution of butyllithium in hexane (1.25 mmol) was added to a red solution of **1** (600 mg, 0.9 mmol) in THF (50 mL). When the temperature reached 25°C, the solution became orange. After evaporation of the solvent, the product **2** was extracted with toluene (5 × 15 mL). The toluene was then removed from the pooled extracts in vacuo, and after washing of the residue with cold pentane, **2** was obtained as an orange powder (424 mg, 85%). − $C_{17}H_{24}N_2Mo_2S_3$ (544.44): calcd. Sidechain Functionalizations by Cuprate Additions to Phosphorylallenyl-Substituted Arenetricarbonylchromium Complexes

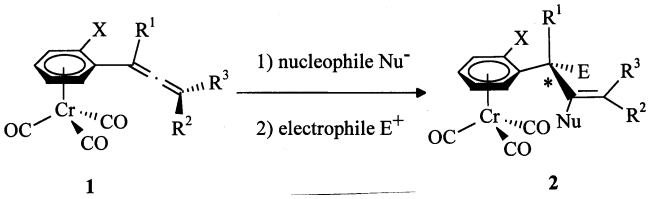
Markus Ansorge,[a] Kurt Polborn,[a] and Thomas J. J. Müller*[a]



Keywords: Arene complexes / Chromium / Sidechain functionalization / Allenes / Cuprates

The cuprate addition to (arene)$Cr(CO)_3$-substituted phosphorylallenes **1** gives rise to the regioselective formation of complexed allylphosphane oxide derivatives **3a–c** and allylphosphonate derivatives **3d–j** in good yields. In the case of racemic planar chiral *ortho*-substituted complexed (arylallenyl)phosphonates **1c**, **d** the protonation of the intermediate allyl anion proceeds diastereoselectively due to the hindered rotation around the C_{ipso}–C_α bond. This diastereoselective protonation is discussed on the basis of the conformational analysis as deduced from the X-ray structure analyses of the allenylphosphonate **1d** and the allylphosphonates **3i**, **j**.

Introduction

Planar chiral (arene)$Cr(CO)_3$ complexes bear a plethora of opportunities for diastereoselective transformations and thus have become well-established building blocks in natural products syntheses.[1,2] Besides stereochemical issues the carbonylchromium complexation alters the reactivity of the arene ligands significantly and therefore opens new reaction pathways. In particular, the activation of the benzylic position has received the most attention and has been intensively studied.[3] Complexed benzylic anions stabilized by the strong electron-withdrawing nature of the (arene)$Cr(CO)_3$ fragment[4] basically can be generated in two different ways: (a) by deprotonation of toluene complexes[5] or (b) by addition of a nucleophile to the β-position of styrene or dihydronaphthalene complexes.[1b,6] Especially, the addition of nucleophiles to an alkenyl side chain of an arene complex represents an extremely useful reaction allowing a subsequent trapping of the complexed benzylic anion by a suitable electrophile. Unfortunately, this process is only limited to stabilized carbanions.[1b,6] Presumably, the nucleophilic susceptibility of the β-carbon atom in styrene complexes is not very strong. In order to overcome these severe limitations we have started to investigate the syntheses, structure and reactivity of allenyl-substituted arene complexes[7] which upon nucleophilic addition to the β-carbon atom of the allenyl side chain give rise to (arene)$Cr(CO)_3$-stabilized allyl anions. This interesting class of ambident nucleophiles opens new opportunities to extended sidechain functionalizations (Scheme 1).

Recently, we could show that allenylphosphonate complexes **1** [R^1 = $PO(OEt)_2$, R^2 = R^3 = Me, X = H] can be successfully applied to metal-template-directed syntheses of 5- and 6-membered heterocyclic dienes by a nucleophilic addition/intramolecular olefination sequence.[7b] So far,

Scheme 1

there are only very few examples of diastereoselective functionalizations initiated by an attack on the homobenzylic position of the tricarbonylchromium-substituted arene sidechain.[1b,8] Here we report on conformational aspects of allenylphosphonate-substituted (arene)$Cr(CO)_3$ complexes **1** in the solid state, cuprate additions to these allenylphosphonates and subsequent regio- and diastereoselective protonations of the ambident planar chiral complexed arylallyl anions to give allylphosphonate-substituted (arene)$Cr(CO)_3$ complexes. The diastereoselectivity of the protonations is discussed on the basis of conformation analyses as deduced from relative stereochemistry by X-ray crystal structure analyses of the organometallic allylphosphonates.

Results and Discussion

Conformational Aspects of (Arene)$Cr(CO)_3$-Substituted Phosphorylallenes

(Arene)$Cr(CO)_3$-substituted allenes have proven to be easily accessible by displacement rearrangements of the corresponding arene complex substituted propargylic alcohols.[7] Although, the structure in solution of some planar chiral organometallic allenes has been elucidated by NMR spectroscopy,[7b] conformational aspects, i.e. the mutual arrangement of the allenyl substituent and the arene(carbonyl)chromium fragment, have not been addressed yet. In the case of the allene derivatives **1a** and **1d** the crystal structures[9] have been elaborated by X-ray structure analysis.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434–1948/99/0202–0225 $ 17.50+.50/0

The linear allenyl sidechain [C10−C11−C12: 177.1(3)°] of the benzene complex substituted allenylphosphane oxide **1a** (Figure 1, Table 4) is arranged almost coplanarily with the complexed phenyl ring (torsional angle C9−C4−C10−C11: 164.9°) indicating an ideal overlap of the proximate allenic double bond and the complexed arene π-system. One of the phenyl rings on the phosphane oxide group shields the *endo* face of the allenyl substituent. Therefore, a nucleophilic attack to this conformer will occur from the *exo* face.

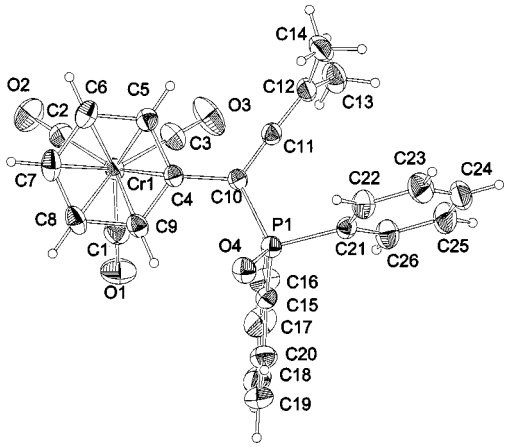

Figure 1. ORTEP plot of **1a**; selected bond lengths [Å], angles [°], and torsional angles [°]: C(10)−C(11) 1.318 (3), C(11)−C(12) 1.291 (4), C(4)−C(10) 1.489(3); C(10)−C(11)−C(12) 177.1(3), C(4)−C(10)−C(11) 122.3(2), C(4)−C(10)−P(1) 119.6(2); C(9)−C(4)−C(10)−P(1) −19.8(3), C(9)−C(4)−C(10)−C(11) 164.9 (2), C(4)−C(10)−P(1)−O(4) −47.4(2), C(7)−C(8)−C(9)−C(4) 0.5(4)

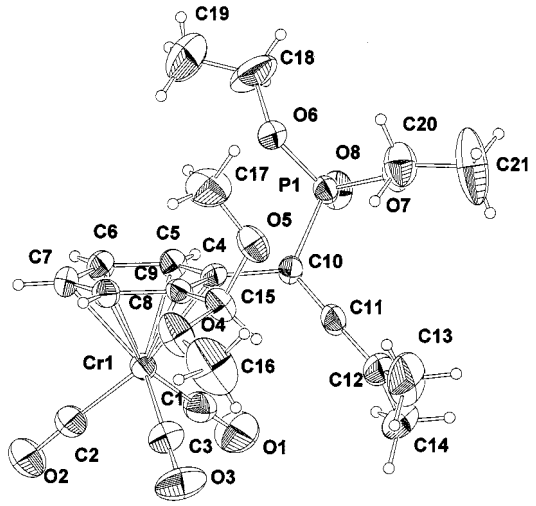
The introduction of a sterically demanding *ortho* substituent into the complexed arene causes significant changes in the mutual arrangement of the allenyl and the arene(carbonyl)chromium fragments. The X-ray structure analysis of **1d** (Figure 2 and Table 4) reveals that the torsion of the allene substructure deviates from coplanarity with the arenetricarbonylchromium fragment by almost 60° (torsional angle C9−C4−C10−C11: 59.3°). Interestingly, the phosphonate group at the linear allenyl fragment (C10−C11−C12: 178°) and carbonylchromium tripod are arranged in an *anti* conformation and the *P*-oxygen atom is arranged *anti* with respect to the acetal group. According to MM2 calculations[10] the *anti* conformer is by 1.0 kcal/mol lower in energy than the corresponding *syn* conformer and the rotation barrier can be estimated by 3.3 kcal/mol. Thus, an attacking nucleophile preferably will add in an *anti* fashion with respect to the carbonylchromium tripod and the *ortho* substituent but with only a small preference for either conformers.

Cuprate Addition and Diastereoselective Protonation

Organocuprates are known to add to allenylphosphonates in a 1,4-fashion to give allylphosphonates.[11] Thus, various Gilman and Normant cuprates easily add to the allenylarene complexes **1** to give after aqueous workup the



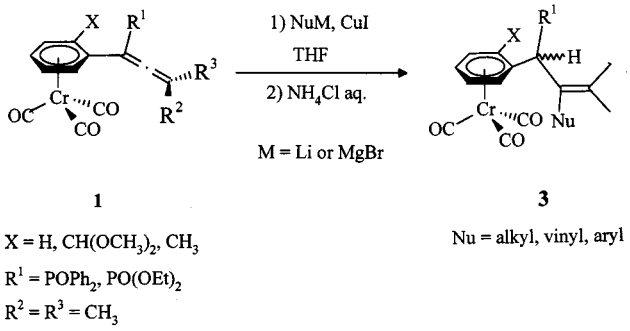


Figure 2. ORTEP plot of **1d**; selected bond lengths [Å], angles [°], and torsional angles [°]: C(10)−C(11) 1.297(9), C(11)−C(12) 1.314(11), C(4)−C(10) 1.492(9); C(10)−C(11)−C(12) 178.2(8), C(4)−C(10)−P(1) 117.9(5), C(4)−C(10)−C(11) 124.3(6); C(9)−C(4)−C(10)−C(11) 59.3(11), C(9)−C(4)−C(10)−P(1) −123.6(6), O(8)−P(1)−C(10)−C(4) −92.4(6), C(4)−C(9)−C(15)−O(5) 69.7(9), C(7)−C(8)−C(9)−C(4) 0.9(10)

regioselectively protonated allylarene complexes **3** in moderate to good yields as light yellow crystalline solids (Scheme 2 and Table 1). All transformations were performed with racemic planar chiral complexes.

Scheme 2. Cuprate addition/protonation sequence

In the NMR spectra the regioselective protonation of the allyl derivatives **3** is supported by the appearance of characteristic $^2J_{P,H}$ and $^1J_{P,C}$ coupling constants of the benzylic protons and carbon atoms. For the phosphane oxide derivatives **3a**−**3c** (R^1 = Ph, X = H) the benzylic methine proton appears in the proton NMR spectra as a doublet ($^2J_{P,H}$ = 10.0−11.6 Hz) at δ ≈ 4.6−4.7. The corresponding signals for the phosphonates **3d**−**3j** [R^1 = OEt, X = H, Me, and $CH(OMe)_2$] are found at δ ≈ 4.1−4.4 as doublets ($^2J_{P,H}$ = 25.2−27.7 Hz). In the proton-decoupled ^{13}C-NMR spectra the benzylic carbon resonances of the phosphane oxides **3a**−**3c** appear as doublets ($^1J_{P,C}$ = 63.0−67.1 Hz) at δ ≈ 46.1−46.8 and the corresponding resonances of the phosphonates **3d**−**3j** at δ ≈ 42.2−45.0 display characteristic large $^1J_{P,C}$ coupling constants (139.9−145.9 Hz).

In addition, the allylphosphonate structure was elaborated and supported by X-ray structure analyses[9] of **3f** and **3j** (Figures 3, 4 and Table 4). The benzylic carbon atom

[a] The yields reported were determined after chromatography on silica gel. – [b] The diastereomers could be separated by chromatography. – [c] The other diastereomer was not detected by NMR spectroscopy. – [d] The major diastereomer can be enriched by recrystallization from dichloromethane/pentane (2:1 to 85:15)

C10 is pyramidalized, in agreement with the formation of an sp^3-hybridized phosphonate moiety upon regioselective protonation of an allyl anion. In the case of the planar chiral complex **3j** only the major of two possible diastereomeric racemates was crystallized and the relative configuration was determined to be (*S*,*S*) or (*R*,*R*). The benzylic and the acetal hydrogen atoms are arranged in a *syn* conformation whilst the 2-isoprenyl substituent is oriented in an antiperiplanar fashion with respect to the tricarbonylchromium tripod.

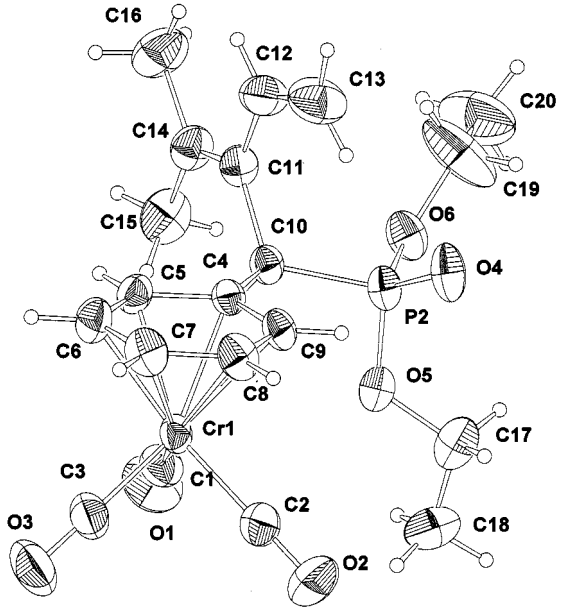

Figure 3. ORTEP plot of **3f**; selected bond lengths [Å], angles [°], and torsional angles [°]: C(4)–C(10) 1.531(4), C(10)–C(11) 1.546(5), C(11)–C(14) 1.332(5); C(4)–C(10)–C(11) 111.3(3), C(11)–C(10)–P(2) 114.2(2); C(9)–C(4)–C(10)–C(11) –122.5(3), C(9)–C(4)–C(10)–P(2) 11.0(4), C(10)–C(11)–C(14)–C(15) –2.5(6), C(6)–C(7)–C(8)–C(9) 0.5(6)

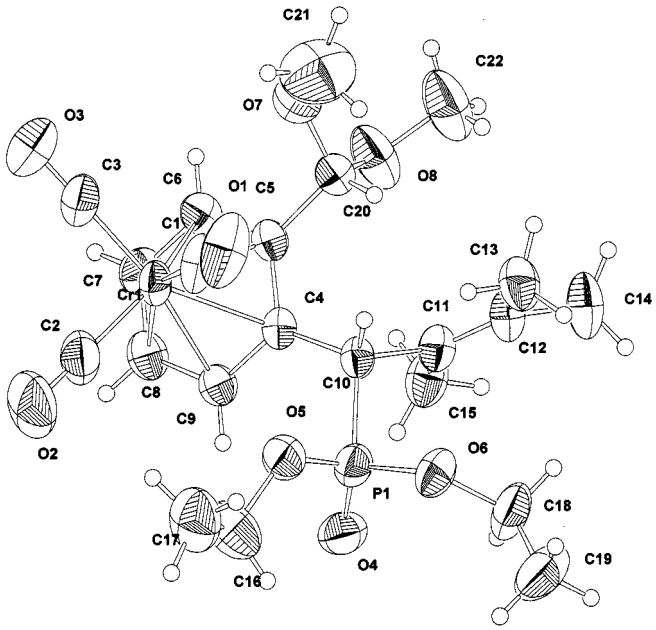

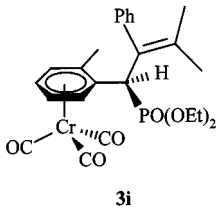

Figure 4. ORTEP plot of **3j**; selected bond lengths [Å], angles [°], and torsional angles [°]: C(4)–C(10) 1.533(6), C(10)–C(11) 1.541(6), C(11)–C(12) 1.329(7); C(4)–C(10)–C(11) 111.4(4), C(11)–C(10)–P(1) 108.5(3), C(9)–C(4)–C(10)–C(11) 110.7(5); C(9)–C(4)–C(10)–P(1) –14.0(6), C(10)–C(11)–C(12)–C(14) –0.7(10), C(7)–C(8)–C(9)–C(4) 0.9(9)

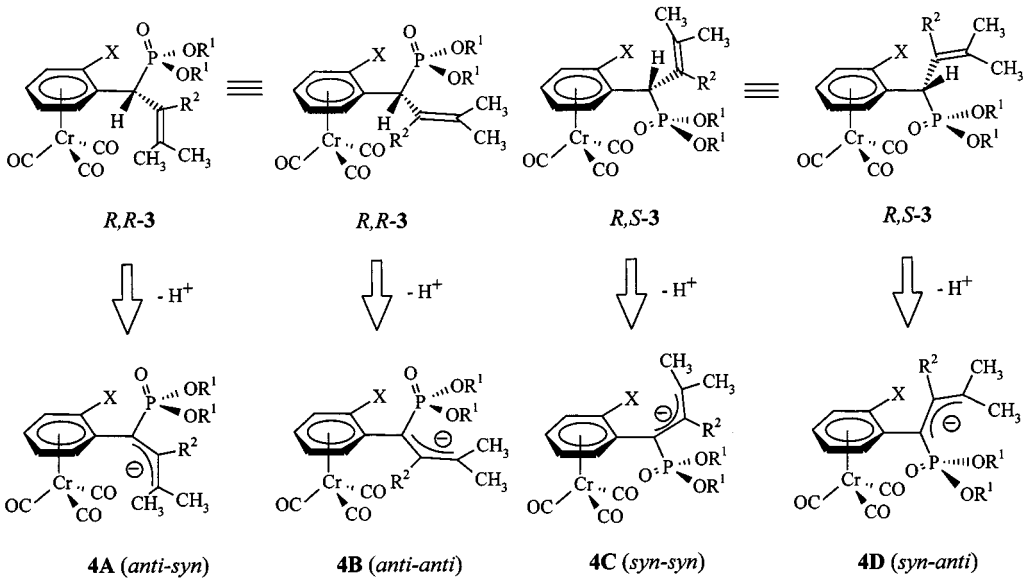
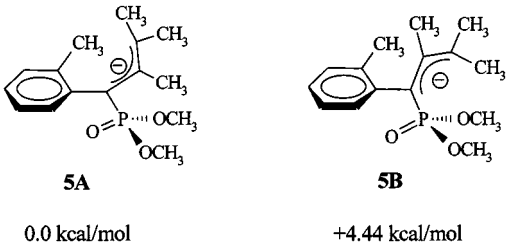
The X-ray crystal structure[9] of the pure racemic diastereomer **3i** (Figure 5 and Table 4) clearly reveals the relative configuration of the product to be (*R*,*R*) or (*S*,*S*). Unfortunately, the ethoxy group in **3i** was strongly disordered and a pentane molecule was incorporated in the crystal lattice both giving rise to an insufficient wR_2 value for all data (Table 4).



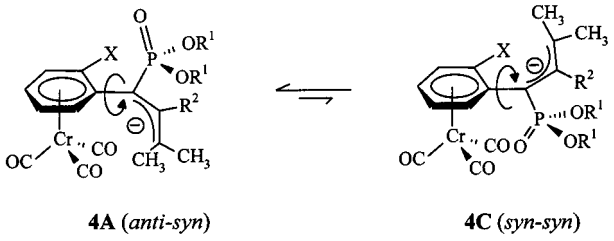
3i

Figure 5. Relative configuration of **3i**



Obviously, the protonation of the allyl anions that form upon the cuprate addition to the allenyl derivatives proceeds with a facial diastereoselection. Aqueous ammonium chloride as proton source guarantees a protonation under kinetic control and excludes a base-catalyzed epimerization at the benzylic carbon atom. Based upon the relative configurations of **3i** and **3j** as established by the X-ray structure analyses the structure of the diastereomeric conformations of the allyl anions can be deduced (Scheme 3).

Assuming a diastereofacial protonation[12] of the allyl anions from the less hindered *endo* face the major diastereomer (*R*,*R*)-**3** (or *S*,*S*-**3**) can be derived from two diastereomeric allyl anions where the phosphonate group



Scheme 3. Stereochemical correlation of the allylphosphonates **3** and the allylphosphonate anions **4**

orientation is *anti* to the carbonylchromium tripod and the mutual stereochemistry of the phosphonate group and the substituent R^2 is either *syn* (**4A**) or *anti* (**4B**). In analogy, the minor diastereomer (*R*,*S*)-**3** (or *S*,*R*-**3**) stems from the protonation of diastereomeric allyl anions **4C** or **4D** where the phosphonate and the chromium fragment are in a *syn* conformation whereas the substituent R^2 can be either *syn* (**4C**) or *anti* (**4D**) with respect the phosphonate group. According to PM3 calculations[10] performed on the free ligands (**5A** and **5B**, Scheme 4) the phosphonate/methyl *syn* isomer (**5A**) is by 4.44 kcal/mol lower in energy than the phosphonate/methyl *anti* isomer (**5B**). The depicted structures are also the corresponding lowest energy conformations of **5A** and **5B**, respectively.

Scheme 4. Relative energies (PM3) of the configurational isomers of the free ligand **5**

The activation enthalpy for the *anti*-*syn* isomerization of these allyl anions is represented by a rotation around the $C_\alpha - C_\beta$ bond and can be estimated to be 2.4 kcal/mol. This relatively low rotation barrier is caused by an efficient resonance stabilization of the benzylic phosphonate carbanion. In turn, the *anti*-*syn* equilibration proceeds rapidly to give the thermodynamically more stable *syn* isomer almost exclusively. Thus, it is reasonable to assume that the corresponding complexed diastereomers **4A** and **4C** (Scheme 5) with a *syn* orientation of the substituent R^2 with respect the phosphonate moiety are also low-energy isomers. Therefore, the cuprate addition to the allenylphosphonates **1** very likely leads to the formation of the diastereomers **4A** and **4C**. Since the allyl anions **4A** and **4C** are diastereomeric conformers their interconversion proceeds by a rotation around the $C_{ipso} - C_\alpha$ bond. Therefore, the temperature dependence of this rotation should be reflected in the **4A**/**4C** ratio, ultimately in the diastereomeric ratio of the protonation products **3**.

Scheme 5. The **4A**/**4C** equilibration by rotation around the $C_{ipso} - C_\alpha$ bond

In a number of cuprate addition/protonation sequences to planar chiral complexes the dependence on the temperature, the reaction time and the cuprate was investigated (Table 2). In case of the *ortho*-methyl-substituted complex **1c** (entries 1–4) the diastereoselectivities depend on the reaction temperature and the nature of the cuprate. Obviously, the fast cuprate addition to the allenylphosphonate **1c** predominantly leads to the kinetically controlled formation of the conformer **4A** (entries 2 and 3). The free rotation of the allyl anion moiety around the $C_{ipso} - C_\alpha$ bond is facilitated as the temperature rises and the allylanion conformers **4A** and **4B** equilibrate to give after protonation the observed thermodynamic diastereoselectivity (entry 1). This indicates that the energy difference between the allyl anion conformers **4A** and **4B** is 0.4 kcal/mol. In the case of complex **1d** (entries 5 and 6) the resulting diastereoselectivity is rather poor and not temperature-dependent. Presumably, the coordinating ability of the *ortho*-acetal facilitates the

thermodynamic equilibration very rapidly, even at low temperatures.

Table 2. Diastereotopic cuprate addition/protonation experiments

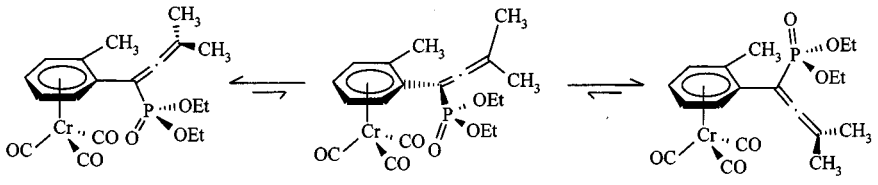
Entry	Allene	R	Temperature	Reaction time	Yield (diastereomeric ratio)
1	**1c**	Me	−40 to 20°C	3 h	68% (2:1) **3h**
2	**1c**	Me	−50 to −40°C	3 h	70% (5:1) **3h**
3	**1c**	Me	−78 to −70°C	7 h	67% (5:1) **3h**
4	**1c**	Ph	−78 to −70°C	3 h	68% (> 15:1) **3i**
5	**1d**	Me	−40 to −15°C	3 h	85% (2:1)[a] **3j**
6	**1d**	Me	−78 to −40°C	8 h	80% (2:1)[a] **3j**

[a] The major diastereomer can be enriched by recrystallization (2:1 to 85:15)

Finally, the initial step of this sequence, i.e. the cuprate addition to the allenylphosphonates **1** has to be discussed. According to MM2 calculations[10] the conformers **6A** and **6C** (Scheme 6) are almost equal in energy and are interconverted by a low rotation barrier (i.e. **6B**) indicating a rapid preequilibrium.

The cuprates add to the allenylphosphonates **1** from the *exo* face with respect to the carbonylchromium tripod and the *ortho* substituent to give preferentially the conformer **4A** under kinetic control (vide supra). Considering the bulky nature of a Gilman or Normant cuprate[13] the precoordination to the phosphonate oxygen atoms in conformer **6C** from the *exo* face with respect to the carbonylchromium fragment is sterically less biased than the corresponding attack to conformer **6A** from the *exo* face. Once the phosphonate-substituted allyl anion has formed and the organocopper group has dissociated, the conformational stability and thus the diastereoselective protonation is influenced by the temperature-dependent rotation around the $C_{ipso}-C_{\alpha}$ bond. Thus, the generation and the electrophilic trapping reactions of conformationally and configurationally stable (arene)$Cr(CO)_3$-substituted allyl anions without additional anion-stabilizing functionalities for diastereoselective sidechain functionalizations are currently under investigation.

Conclusion



(Arene)$Cr(CO)_3$-substituted allenylphosphane oxides and allenylphosphonates readily react with organocuprates in a 1,4-addition to give after protonation 1-(arene)$Cr(CO)_3$-substituted (2-propen-1-yl)phosphane oxides and (2-propen-1-yl)phosphonates in good yields. With planar chiral *ortho*-substituted complexed allenes this cuprate addition/protonation sequence gives rise to the diastereoselective formation of complexed allylphosphane oxide and allylphosphonate derivatives. The conformation analysis of the intermediate arene complex substituted allyl anions reveals that the crucial origin of the observed diastereoselectivity stems from the hindered rotation around the $C_{ipso}-C_{\alpha}$ bond. Therefore, future studies will be directed towards the study of the reactivity and selectivity of (arene)$Cr(CO)_3$-stabilized allyl anions in intra- and intermolecular electrophilic trapping reactions.

Experimental Section

All reactions involving tricarbonylchromium complexes were carried out in flame-dried Schlenk flasks under nitrogen by using septum and syringe techniques. Solvents were dried and distilled according to standard procedures.[14] − Column chromatography: Silica gel 60 (Merck, Darmstadt), mesh 70−230. TLC: Silica gel plates (60 F_{254} Merck, Darmstadt). Melting points (uncorrected values): Reichert-Jung Thermovar. − The *ortho*-iodobenzaldehyde dimethylacetal complex,[15] the complexed allenylphosphane oxide **1a** and the complexed allenylphosphonates **1b** and **1c** were prepared in analogy to our published procedures.[7] The organolithium and vinylmagnesium chloride solutions were purchased from Aldrich. Chlorodiethoxyphosphane (Aldrich) was used without further purification. Chlorodiphenylphosphane (Aldrich) was distilled under reduced pressure prior to use. All crystalline arenechromium complexes can be handled in air. − ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra: Bruker ARX 300, Varian VXR 400S [D_6]DMSO. The assignments of quaternary C, CH, CH_2, and CH_3 has been made by using DEPT spectra. − IR: Perkin Elmer Models Lambda 16. − MS: Finnigan MAT 90 and MAT 95 Q. − Elemental analyses were carried out in the Microanalytical Laboratory of the Institut für Organische Chemie, Ludwig-Maximilians-Universität München.

X-ray Structure Determination of Compounds 1a, 1d, 3f, 3i, and 3j: Suitable crystals were mounted on a capillary and transferred to an Enraf-Nonius CAD4 diffractometer. The structures were solved by direct methods and refined anisotropically on F^2 (G.M. Sheldrick, SHELXS-86, SHELXL-93 programs, University of Göttingen). Hydrogen atoms were found from differential Fourier synthesis and refined. The data of the X-ray structure analyses are summarized in Table 4.

Tricarbonyl{η^6-1-[3-hydroxy-3-methylbut-1-yn-1-yl]-2-(dimethoxymethyl)benzene}chromium(0): 1.00 g (2.40 mmol) of the *o*-iodobenzaldehyde dimethylacetal complex,[15] 33 mg (0.04 mmol) of bis(triphenylphosphane)palladium dichloride and 5 mg (0.02 mmol) of

Scheme 6. Relative energies (MM2) of the conformations **6A,6B** and **6C**

copper iodide were dissolved in a degassed mixture of 15 mL of THF and 7 mL of triethylamine. A solution of 0.28 mL (2.90 mmol) of 3-methylbutyn-3-ol, dissolved in 10 mL of THF, was added over a period of 1 h. After complete addition, the solution was heated to reflux temperature for 5 h and then cooled to room temperature. Diethyl ether was added, the mixture was filtered and the solvents were evaporated. Chromatography on silica gel with diethyl, ether/pentane afforded 0.65 g (73%) of the propargyl alcohol complex. Recrystallization from pentane gave yellow crystals, m.p. 68−70°C. − ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 1.46 (s, 6 H), 3.33 (s, 3 H), 3.53 (s, 3 H), 5.21 (s, 1 H), 5.54 (s, 1 H), 5.64 (t, *J* = 6.1 Hz, 1 H), 5.71−5.78 (m, 2 H), 5.85 (d, *J* = 6.5 Hz, 1 H). − ^{13}C NMR ([D$_6$]DMSO, 75 MHz): δ = 31.53 (CH$_3$), 54.01 (CH$_3$), 57.18 (CH$_3$), 63.80 (C$_{quat.}$), 74.75 (C$_{quat.}$), 91.27 (C$_{quat.}$), 91.85 (CH), 92.19 (CH), 94.67 (CH), 96.08 (CH), 99.88 (C$_{quat.}$), 101.71 (CH), 109.18 (C$_{quat.}$), 233.07 (C$_{quat.}$, CO). − MS (70 eV, FAB); *m/z* (%): 370 [M$^+$] (7), 314 [M$^+$ − 2 CO] (2), 286 [M$^+$ − 3 CO] (100), 52 [Cr$^+$] (14). − IR (KBr): $\tilde{\nu}$ = 3089 cm^{-1}, 2983, 2935, 2837, 1977, 1898, 1879, 1629, 1527, 1494, 1449, 1418, 1364, 1341, 1271, 1249, 1201, 1187, 1170, 1111, 1096, 1082, 1044, 983, 962, 912, 829, 808, 662, 624, 534, 469. − UV/Vis (DMSO): λ$_{max}$ (ε) = 325 (9500). − $C_{17}H_{18}CrO_6$ (370.31): calcd. C 55.14, H 4.89; found C 55.98, H 5.08.

Tricarbonyl{η^6-1-[1-diethoxyphosphoryl)-3-methylbuta-1,2-dien-1-yl]-2-(dimethoxymethyl)benzene}chromium(0) (1d): In a two-necked round-bottomed flask 0.49 g (1.35 mmol) of the previously prepared propargyl alcohol and 0.20 mL (1.50 mmol) of triethylamine were dissolved in 15 mL of THF under nitrogen. The resulting mixture was cooled to −78°C and 0.19 mL (1.40 mmol) of chlorodiethoxyphosphane, dissolved in 5 mL of THF, was added over a period of 5 min. After 1 h at −78°C, the cooling bath was removed and stirring was continued for further 20 h at room temperature. To the mixture was added 20 mL of water and the aqueous layer was extracted several times with dichloromethane. The combined organic phases were dried with anhydrous magnesium sulfate and the solvents were removed in a rotary evaporator under reduced pressure. After chromatography on silica gel [diethyl ether/pentane (1:1), diethyl ether, methanol/dichloromethane (1:10)], the yellow band was isolated to give 0.55 g (84%) of **1d**. Recrystallization from dichloromethane/pentane afforded yellow crystals, m.p. 70°C. − ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 1.21 (m, 6 H), 1.82 (m, 6 H), 3.11 (s, 3 H, OMe), 3.47 (s, 3 H, OMe), 3.98 (m, 4 H), 5.38 (s, 1 H), 5.68 (m, 2 H), 5.81 (m, 2 H). − ^{13}C NMR ([D$_6$]DMSO, 75 MHz): δ = 16.24 (CH$_3$, *J* = 6.1 Hz), 17.97 (CH$_3$, *J* = 6.1 Hz), 19.69 (CH$_3$, *J* = 6.1 Hz), 50.28 (CH$_3$, OMe), 56.27 (CH$_3$, OMe), 62.43 (CH$_2$, *J* = 6.1 Hz), 62.71 (CH$_2$, *J* = 6.1 Hz), 89.48 (C$_{quat}$, *J* = 191.6 Hz), 90.03 (CH), 92.12 (CH), 95.18 (CH), 97.86 (CH), 98.28 (C$_{quat}$), 98.53 (CH), 105.48 (C$_{quat}$, *J* = 15.8 Hz), 109.27 (C$_{quat}$, *J* = 4.8 Hz), 208.49 (C$_{quat}$, *J* = 4.3 Hz), 233.18 (C$_{quat}$, CO). − ^{31}P NMR ([D$_6$]DMSO, 121 MHz) : δ = 13.46. − MS (70 eV), *m/z* (%): 490 [M$^+$] (1), 434 [M$^+$ − 2 CO] (5), 406 [M$^+$ − 3 CO] (22), 354 [M$^+$ − Cr(CO)$_3$] (3), 52 [Cr$^+$] (12). − IR (KBr): $\tilde{\nu}$ = 3069 cm^{-1}, 2988, 2937, 2910, 2833, 1967, 1886, 1866, 1630, 1525, 1444, 1414, 1392, 1367, 1340, 1254, 1195, 1159, 1112, 1082, 1063, 1029, 975, 925, 907, 874, 834, 801, 753, 717, 679, 665, 627, 579, 553, 534, 479, 427. − UV/Vis (DMSO): λ$_{max}$ (ε) = 324 (8800). − $C_{21}H_{27}CrO_8P$ (490.40): calcd. C 51.43, H 5.55; found C 51.54, H 5.57.

General Procedure (GP) for the Preparation of the Complexed Allylphosphane Oxides and Allylphosphonates 3

1) Preparation of the Cuprate: A stirred suspension of 104 mg (0.550 mmol) of copper iodide in 10 mL of THF was cooled (exact conditions see below) and 1.10 mmol of a solution of a commercially available organolithium or organomagnesium halide was added over a period of 1 min by syringe. The temperature of the solution had to be adjusted exactly due to the thermal lability of some cuprates. For the preparation of the cuprates the solution was cooled to 0°C when methyllithium was used, to −60°C for butyllithium and to −78°C for phenyllithium and for vinylmagnesium chloride. The resulting cuprate solution was stirred for further 40 min at the given temperature.

2) Nucleophilic Addition/Protonation: To the stirred and cooled solution of the cuprate (temperatures see below) a solution of 0.50 mmol of **1** in 5 mL of THF was added over a period of 5 min. Stirring was continued at the indicated temperatures for 3−7 h (Tables 2 and 4). Then 20 mL of saturated ammonium chloride solution was added to the reaction mixture at the final temperature. The aqueous layer was extracted several times with diethyl ether. The combined organic phases were dried with magnesium sulfate, filtered, and concentrated in a rotary evaporator. After chromatography on silica gel (diethyl ether/pentane to diethyl ether) the yellow bands were collected to give the products **3**. The experimental details and yields are summarized in Table 3.

Tricarbonyl{η^6-[1-(diphenylphosphoryl)-2,3-dimethylprop-2-en-1-yl]benzene}chromium(0) (3a): Yellow crystals, m.p. 178−180°C. − ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 1.42 (s, 3 H), 1.73 (s, 3 H), 1.87 (s, 3 H), 4.60 (d, *J* = 10.3 Hz, 1 H), 5.29 (t, *J* = 6.2 Hz, 1 H), 5.51 (t, *J* = 6.3 Hz, 1 H), 5.63 (t, *J* = 6.1 Hz, 1 H), 5.76 (d, *J* = 6.2 Hz, 1 H), 6.01 (d, *J* = 6.4 Hz, 1 H), 7.48−7.88 (m, 10 H). − ^{13}C NMR ([D$_6$]DMSO, 75 MHz): δ = 17.22 (CH$_3$), 20.64 (CH$_3$), 21.31 (CH$_3$), 46.81 (CH, $J_{P,C}$ = 64.5 Hz), 91.07 (CH), 91.86 (CH), 96.29 (CH), 98.29 (CH, $J_{P,C}$ = 4.6 Hz), 99.72 (CH, $J_{P,C}$ = 5.6 Hz), 110.55 (C$_{quat}$), 123.62 (C$_{quat}$, $J_{P,C}$ = 5.5 Hz), 128.51 (CH, $J_{P,C}$ = 11.1 Hz), 128.74 (CH, $J_{P,C}$ = 11.1 Hz), 130.50 (CH, $J_{P,C}$ = 9.0 Hz), 131.25 (CH, $J_{P,C}$ = 9.0 Hz), 131.48 (C$_{quat}$), 131.99 (CH), 132.11 (C$_{quat}$, $J_{P,C}$ = 94.3 Hz), 132.47 (C$_{quat}$, $J_{P,C}$ = 128.3 Hz), 233.63 (C$_{quat}$). − ^{31}P NMR ([D$_6$]DMSO, 121 MHz) : δ = 31.28. − MS (70 eV, *EI*), *m/z* (%): 468 [M$^+$ − CO] (8), 440 [M$^+$ − 2 CO] (9), 412 [M$^+$ − 3 CO] (89), 360 [M$^+$ − Cr(CO)$_3$] (11), 52 [Cr$^+$] (18). − IR (KBr): $\tilde{\nu}$ = 3056 cm^{-1}, 2924, 1964, 1883, 1628, 1590, 1524, 1483, 1456, 1438, 1377, 1312, 1233, 1180, 1116, 1101, 1072, 998, 847, 816, 741, 721, 700, 660, 632, 568, 547, 534, 517, 507, 482, 427. − UV/Vis (DMSO): λ$_{max}$ (ε) = 319 (8900). − $C_{27}H_{25}CrO_4P$ (496.46): calcd. Nanostructuring Titania: Control over Nanocrystal Structure, Size, Shape, and Organization

Abdelkrim Chemseddine*[a] and Thomas Moritz[b]

Dedicated to Professor J. Rouxel in recognition of his important contributions to the chemistry of solids

Keywords: TiO_2 / Growth / Self-organisation / Polytitanate / Nanocrystals / Nanostructure / Superlattice / Films

Control over crystal structure, size, shape, and organization of TiO_2 nanocrystals has been achieved by means of wet chemistry. Hydrolysis and polycondensation of titanium alkoxide [$Ti(OR)_4$] has been performed in the presence of tetramethylammonium hydroxide (Me_4NOH). This base both catalyzes the reaction and provides an organic cation that stabilizes the anatase polyanionic cores formed in this medium. These anatase clusters are organized so as to favour self-assembly into intermediate nanocrystals, which, in turn, self-assemble into superlattices. This self-assembling process has been exploited for the processing of highly structured titania films. Furthermore, larger anatase TiO_2 nanocrystals of different sizes and shapes have been obtained by adjusting the relative concentrations of titanium alkoxide and Me_4NOH, the reaction temperature, and the pressure. HRTEM, XRD, and EXAFS have been used to characterize the various samples and to elucidate the growth of titania anatase. Our observations are in accordance with theoretically predicted condensation and growth pathways. The formation of mesoscopic structures through a self-assembling process of the multiply charged polytitanate anions in the presence of Me_4N^+ is also discussed.

Introduction

The chemistry of titania has been the subject of much scientific and technological attention. This material is used as a white pigment in making paints and cosmetics, in the electroceramics industry, as a support in catalysis, and as a photocatalyst.[1,2] Nanostructuring of titania is of great interest with regard to the construction of membranes for gas-phase separations,[3] its use as a nanoporous electrode material in the development of new types of solar cells,[4] and its use as an active layer in the design of electrochromic devices.[5] Recently, TiO_2 coatings on glasses have been shown to exhibit interesting antifogging and self-cleaning properties.[6] The performance of titania in applications such as these could be optimized with specific microstructural and macrostructural control over the morphology of the material. Progress in this area depends on our understanding of the fundamental details by which chemical reactivity is related to nucleation and growth of titania. These processes need to be controlled at the earliest stages of production and arrested at the appropriate stage so as to furnish titania particles with the desired crystal structure and a well-defined size, shape, and surface structure. Furthermore, control over the surface chemistry of nanocrystals and their functionalization through the attachment of organic ligands may lead to organized assemblies[7] and provide new types of precursors for the processing of highly nanostructured titania-based materials.[8]

The fundamental physical properties of such nanoscale materials are of interest, since their small size and large surface area can lead to unexpected or dramatically differing properties.[9] The need for high-quality titania systems in order to achieve a quantitative understanding of size effects on the physical properties is another motivating factor in this work.[9]

In techniques such as CVD, MOCVD, and simple thermal pyrolysis, molecular precursors are allowed to react at rather high temperatures in the gas phase or as molecular solids.[10] Control over particle size, size distribution, shape, and crystalline orientation is inherently difficult to achieve. In contrast, in wet chemical methods, a solvent is used as the reaction medium or vehicle, and the reaction is performed at low temperature. There are many advantages in using wet chemistry for the synthesis of nanomaterials.[7] Reaction, nucleation and growth can be easily monitored and influenced. The growth can be arrested by controlling the stoichiometry or by using appropriate ligands.[11] In contrast to growing clusters on solid substrates or in solid matrices, in the liquid phase the mobility and dynamics of the growing phase is assured, allowing structural arrangement of the core and growth termination by surface restructuring and capping. By variation of the synthesis conditions or reactants and characterization of the materials obtained, the production of nanocrystals can be rationalized.[11,12] Nanocrystals can be isolated according to size in the form of soluble, processable, manageable powders, or used as precursors in the processing of films.[13]

Furthermore, a major line of development of this chemistry concerns the spontaneous generation of well-defined architecture by the self-assembly of suitably designed and functionalized nanocrystals.[7] This issue of ordered nano-

structured arrays of functional nanocrystals is of central importance for the evaluation of the competitiveness of wet chemistry, i.e. sol-gel processes or solution techniques, since through the size, shape, and organization of particles, organic species can be confined within well-defined inorganic structures, allowing control over their thermal removal.[8,14] One of the problems encountered in making titania is the high reactivity of the available precursors, such alkoxides or chlorides, toward water.[15] The reaction invariably leads to a mixture of different polymeric species, which assume a variety of structures and sizes, and finally to an amorphous solid. Although certain chemical modifications have been successful in controlling the reactivity of titanium alkoxides and have permitted the isolation of intermediate polyoxoalkoxides,[16,17] none of these species resemble the structure of the bulk dioxide and any further hydrolysis again leads to gels and amorphous precipitates. In both cases, a peptization process is required to convert these polymers into crystalline particles. Control over size, size distribution, and shape is difficult during these dissolution-growth processes.[3] The present approach involves performing the reaction in a purely aqueous medium in the presence of a base, so as to achieve a complete hydrolysis and to provide conditions similar to those used in the aforementioned peptization process. Thus, hydrolysis and polycondensation of titanium alkoxide [$Ti(OR)_4$] is performed in the presence of tetramethylammonium hydroxide (Me_4NOH). This base both catalyzes the reaction[15,17] and provides an organic cation that is known to stabilize polyanionic cores in basic media, e.g. polyanions of tungsten, molybdenum, and vanadium.[18]

Results

Figure 1 shows an overview image of titania nanocrystals from a first sample, denoted as sample A. The nanocrystals are uniform in shape and are not aggregated. The particles are single nanocrystals and exhibit a triangular prismatic shape with a relatively narrow size distribution. The high resolution micrograph clearly shows lattice planes. All images of sample A show particles with an interplanar distance of 3.52 Å in the tetragonal [101] planes, which corresponds to the anatase phase. The lateral dimensions of the particles can be estimated by counting the number of lattice planes (about 30 LP in this case, which amounts to 10.5 nm). The average length measured directly from the micrograph is about 20 ± 1 nm. A careful analysis of the particles reveals structural features that can be utilized for the study of surface morphologies of small particles and the changes that occur during growth. Thin edges of TEM samples represent surfaces that can be viewed in profile by HRTEM.[20] The steps on the particle edges are in the [101] crystallographic directions and the height of each step can be taken as an indication of a cluster-cluster growth (see below). The triangular shape is in fact due to the presence of stepped [101] surfaces.

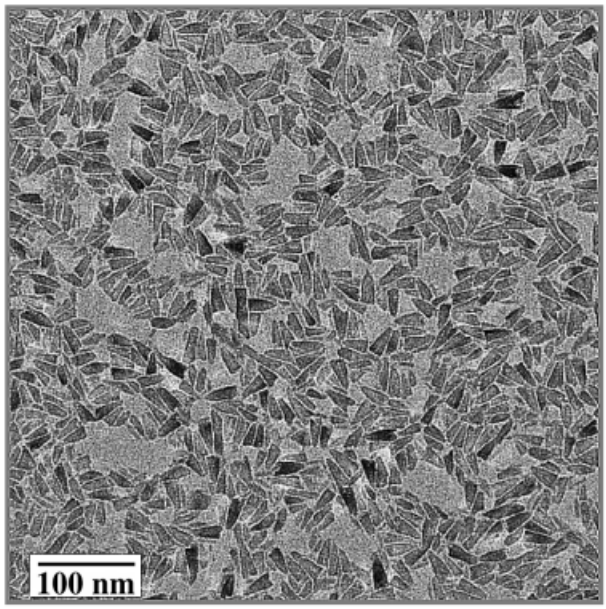

Figure 1. TEM micrograph of TMA-capped TiO_2 particles obtained for $R = 3$; the particles are homogeneous in size and triangular in shape

The X-ray diffraction pattern (Figure 2b) of sample A confirms the single anatase phase. However, all the Bragg peaks are relatively broad due to the finite size of the nanocrystals. The sizes calculated from the half-widths of the peaks using the Scherrer equation amount to 11.1 nm for the [101] peak, 20.8 nm for the [004] peak, and 20.7 nm for the [200] peak. These values are in accordance with the lateral dimensions measured from the TEM micrographs of these triangular prismatic nanocrystals.

Autoclaving of solution A leads to a shape transformation from triangular to rectangular particles, which have lengths of about 28 ± 3 nm and widths of about 12 ± 2 nm (Figure 3). The autoclaving leads to nanocrystals of uniform shape, which are non-aggregated and conform to a single anatase phase, according to TEM and XRD analysis. The morphological transformation of particles can be attributed to the thermal decomposition of the organic cations under the autoclaving conditions. The loss or decomposition of the organic cations probably induces chemical etching, which is followed by further growth and elimination of steps, ultimately leading to a shape transformation from triangular to rectangular.

Figure 4a shows a typical TEM image at low magnification of titania particles obtained in the case of sample B. A homogeneous fibrous or rod-like texture is achieved, although a relatively marked polydispersity in terms of length and width is apparent. Figure 4b shows a high-resolution image of a selected titania nanocrystal from sample B. The nanocrystal is viewed along the [010] direction. The surface profile image of the nanocrystal B shows stepped terraces on the [101] surface, which are marked with arrows. Its height is measured as a multiple of 3.52 Å, in accordance with the $d_{[101]}$. The corrugated sides are structural features that have not previously been observed in the case of titania

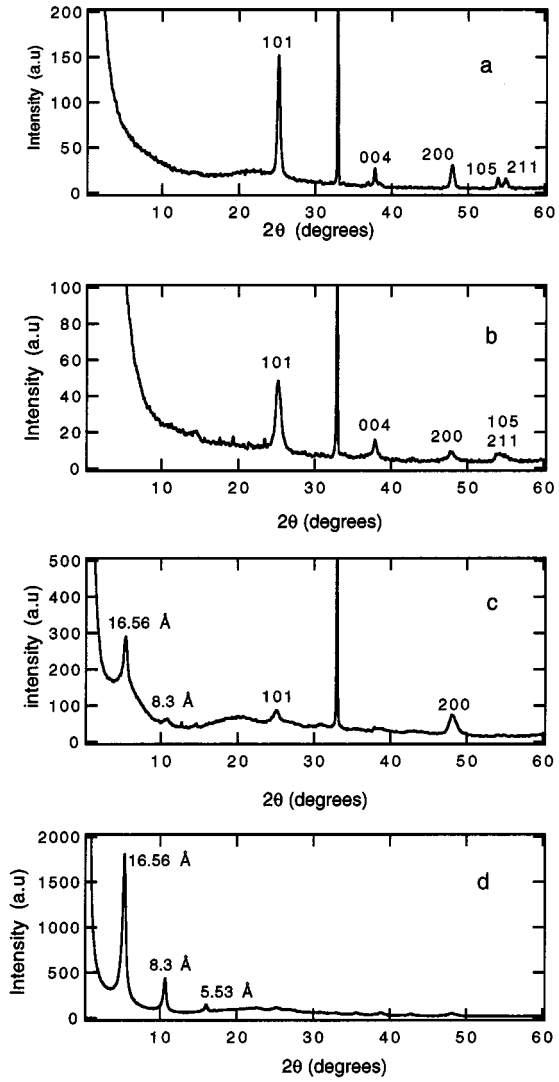

Figure 2. X-ray powder diffractograms of TiO_2 nanocrystals made with various Ti/Me_4N^+ ratios R; Figures b, c, and d correspond to solutions A (R = 4), B (R = 1.25), and E (R = 0.84); Figure a was obtained after autoclaving solution B under a saturated vapor pressure of water at 200°C and 2500 kPa; large-angle peak assignments are based on anatase titania; peak broadening indicates a decrease of nanocrystal size with increasing R; in addition to the perfect organization in the lateral dimensions shown in Figure 10, the series of harmonics in d indicates ordering of the growing anatase cluster in the nanocrystals forming a layered nanostructure; the sharpness of the peaks indicates a high degree of structural communication between the nanocrystals

and are a consequence of cluster-cluster growth and condensation of skewed octahedra in the case of anatase (see Discussion). The two sets of lattice fringes give two interplanar distances, which correspond to the [101] and the [002] of the anatase crystal structure (Figure 5). The elongated particles lie in the [010] plane.

XRD measurements on films obtained by the deposition of sample B solution onto a silicon wafer (Figure 2c) yield further information on the polydispersity of the sample. The low-angle peaks correspond to the presence of smaller titania clusters (cf. sample E). The relatively high intensity of the [200] peaks compared to the [101] peak is indicative

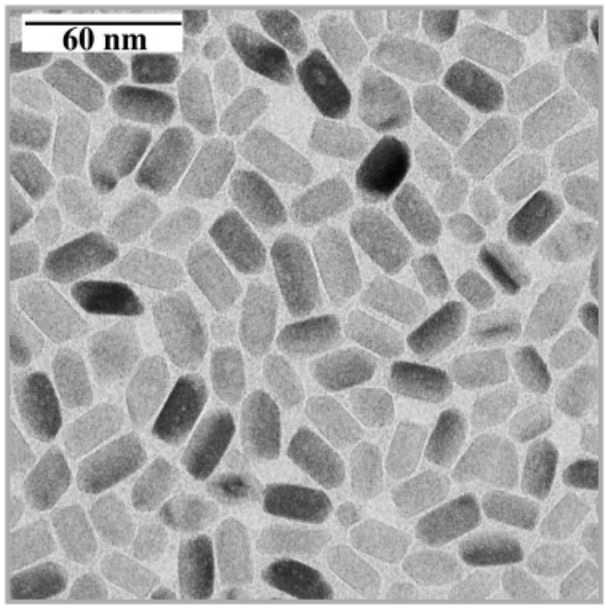

Figure 3. Overview of titania nanocrystals prepared by autoclaving solution A; the nanocrystals are homogeneous in both shape and size

of film anisotropy and confirms a preferred orientation of the crystallites. The Scherrer equation leads to 92.9 Å for the [101] peak and to 79.6 Å for the [200] peak.

Figure 6 shows TEM images of particles obtained after autoclaving sample B. The rod-like morphology is maintained. The diameter of the rods varies between 15 and 20 nm, but a large polydispersity in terms of rod length is apparent ($76 < L < 177$ nm). The adopted procedure of adding the titanium alkoxide solution in a dropwise fashion is mainly responsible for the observed polydispersity. In contrast to sample A, where a shape transformation was seen to occur, further growth in length and diameter takes place during the autoclaving of solution B without a change in the rod-like morphology. However, the structural features on the surface, such as sharp edges and steps, are no longer present. Again, the surface reconstruction can be related to the thermal decomposition of the organic cations under the autoclaving conditions. This confirms the role of the Me_4N^+ cation as a good capping ligand in stabilizing the surface structure of titania nanocrystals.

The size of the particles can also be fine-tuned by changing the autoclave temperature. Autoclaving of portions of sample B at 175°C and 200°C for a duration of 5 h resulted in particle sizes, calculated using the Scherrer equation, of 18 nm and 12 nm, respectively, for the [101] peak, and of 15.6 nm and 14 nm, respectively, for the [200] peak. The average width of nanocrystals measured from the TEM images is of the same order (about 12.32 nm). The average length of 63 nm reflects the nanocrystal dimension in the [002] direction, as shown in Figure 6b.

As mentioned above, the adopted procedure of adding the titanium alkoxide solution in a dropwise fashion accounts for the observed polydispersity in samples A and B. Figures 7a and 7b show two typical images obtained from

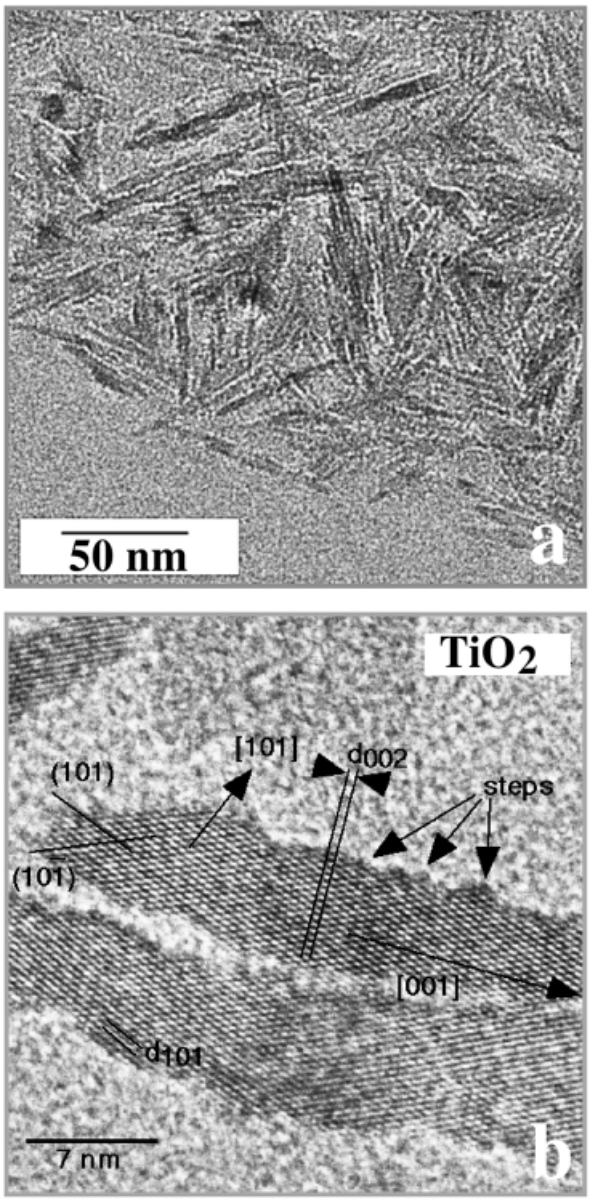

Figure 4. a) Elongated nanocrystals prepared with $R = 1.25$ (solution B); b) HRTEM of nanocrystals lying in the [010] plane and elongated in the [001] direction; the corrugated sides shown by arrows are due to oscillatory repetition of [1 0 1] and [1 0 −1] planes

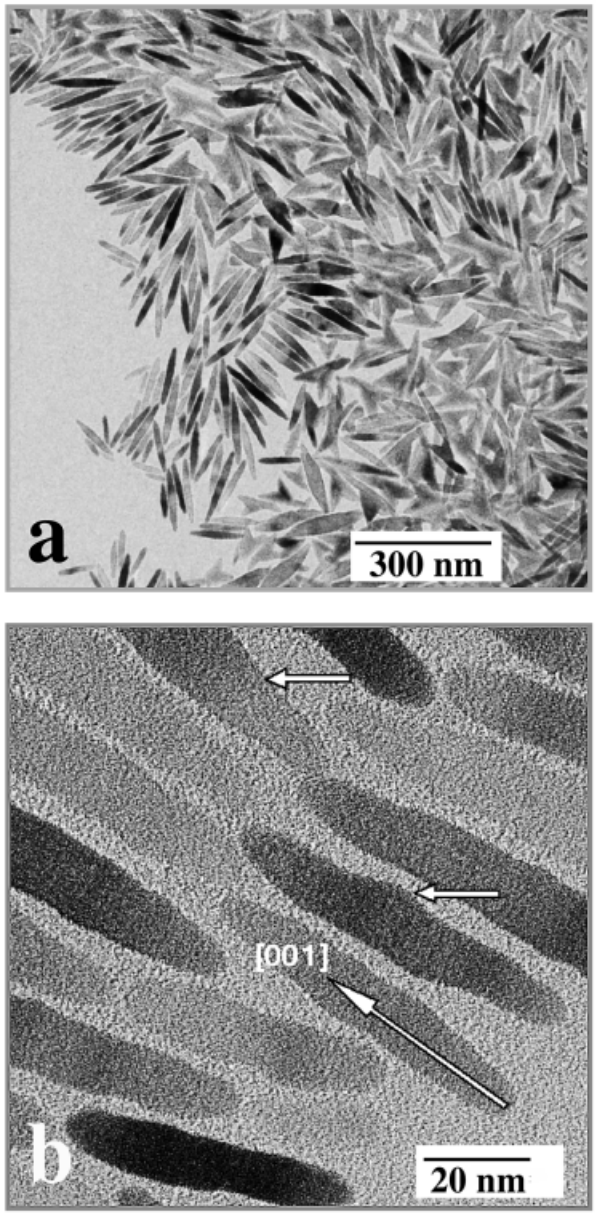

Figure 6. a) Overview of nanocrystals obtained after autoclaving B at 200°C, 2500 pKa for 5 hours; b) HRTEM shows no sharp edges and no clear surface steps after NMe_4^+ decomposition

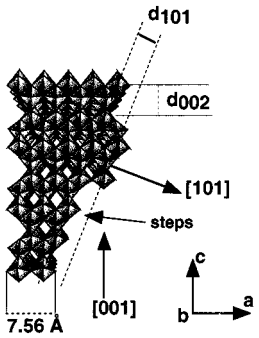

Figure 5. Polyhedral and packing drawing of anatase, TiO_2 in the [010] projection; [101] and [001] growth directions and a stepped [101] surface are shown

sample C ($Ti/Me_4NOH = 2$), made by adding the titanium alkoxide solution in a single portion. The sample has a relatively homogeneous appearance at low magnification. Particles of two distinct shapes are formed. These two particle types represent unique morphologies, in the sense that they are themselves the products of a self-assembling process (aggregation) of smaller elongated titania particles (slabs), as indicated by arrows in Figure 7b.

Particles with a triangular prismatic shape are also present in sample C, as indicated by arrows in Figure 7a. In contrast to sample A, where the particles are single nanocrystals, particles in sample C are composed of smaller ti-

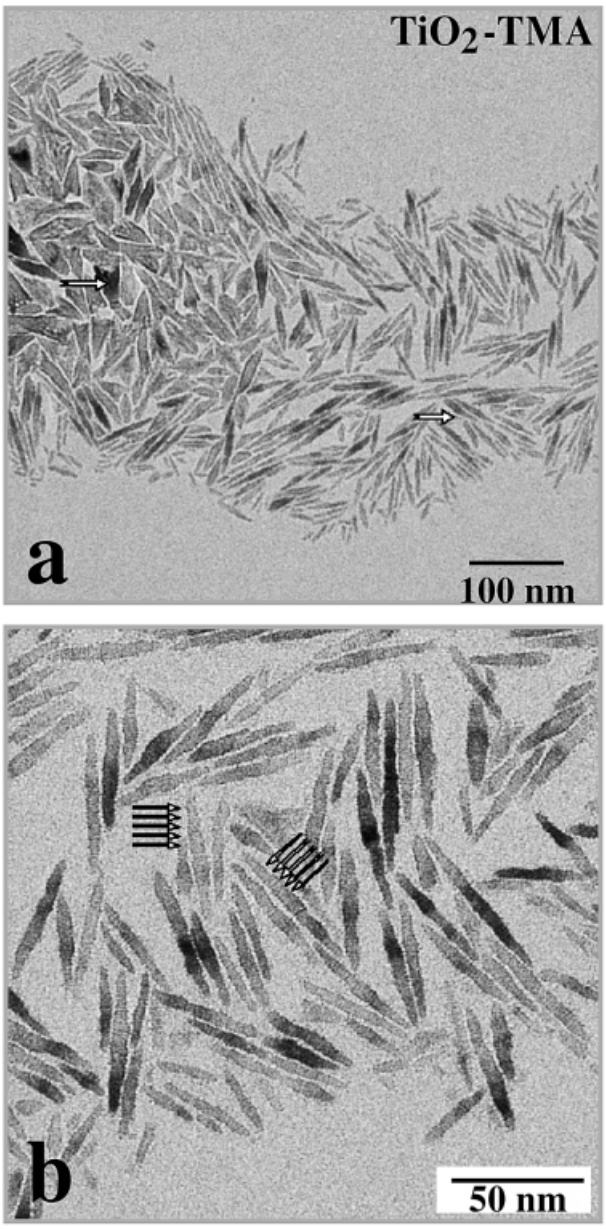

Figure 7. a) Two type of particles, shown by arrows, are obtained in solution C; b) These particles are composed of self-assembled smaller slabs as indicated by arrows

tania particles (slabs) self-assembled into aggregates of triangular shape.

Figure 8 shows images obtained from sample D (Ti/Me_4NOH = 1). At low beam intensities, the particles exhibit an internal structure as that in the case of sample C. Slabs are disposed parallel to one another along the [001] direction. At high magnification (higher electron fluxes), a coalescence (condensation) is induced by the loss of the organic cations (see Figure 8). The nanocrystals are viewed along the [010] axis, oriented parallel to the electron beam. The coalescence of these slabs (building units) leads to particles with corrugated sides or stepped [101] surfaces, as shown by black arrows in Figure 8. In addition to these thin slabs, as already observed in the case of sample C, spherical particles are formed. Particles of this type form at R = Ti/$Me_4NOH \leq 1$ and they show a propensity to self-assemble into organized structures. Their concentration increases, at the expense of their elongation, with the TMA concentration.

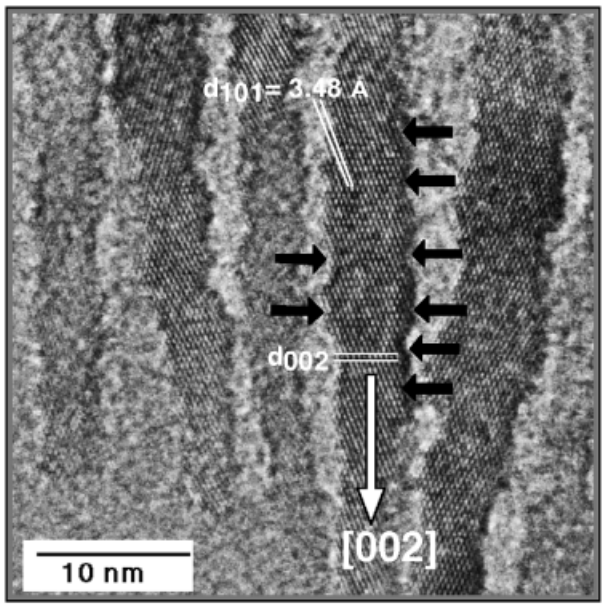

Figure 8. Titania clusters made in solution D; elongated slabs self-assemble into aggregates; at high magnification (higher electron fluxes) the particles coalesce into elongated nanocrystals presenting the same corrugated sides shown by arrows

Figures 9a and 9b show TEM images obtained in the case of sample E. The particles are seen to be organized in an ordered structure (2D superlattice). TEM provides a real-space imaging of the superlattice. In addition, small-angle electron diffraction can be used to probe the superlattice structure on the micrometer scale, while small-angle XRD allows insight into the structures of individual titania/Me_4N^+ nanocrystals on the Ångström scale. Figure 9 shows an array of nanocrystals with a mean inter-particle (center-to-center) distance of 15.7 nm, determined by direct imaging and confirmed from the power spectrum. The high magnification Figure 9b reveals well-faceted hexagonal crystals that form a hexagonal close-packed sheet. The crystals measure 13.5 nm in diameter. The high regularity in terms of size and shape, and long-range translational and orientational order is confirmed by the relatively sharp spots seen in the power spectrum (see inset in Figure 9a).

Further structural information is provided by X-ray diffraction (XRD). Measurements performed on thin films obtained by solution deposition on various supports, particularly on silicon wafers, are very sensitive to the periodicity perpendicular to the substrate (Figure 2d).

The diffraction intensity appears in two distinct scattering regions, the small-angle and large-angle. A series of harmonics at inter-plane distances of 16.56, 8.3, and 5.53 Å indicates an orientation in the direction normal to the substrate. The titania clusters are stacked in columns directly on top of one another, forming a multilayered struc-

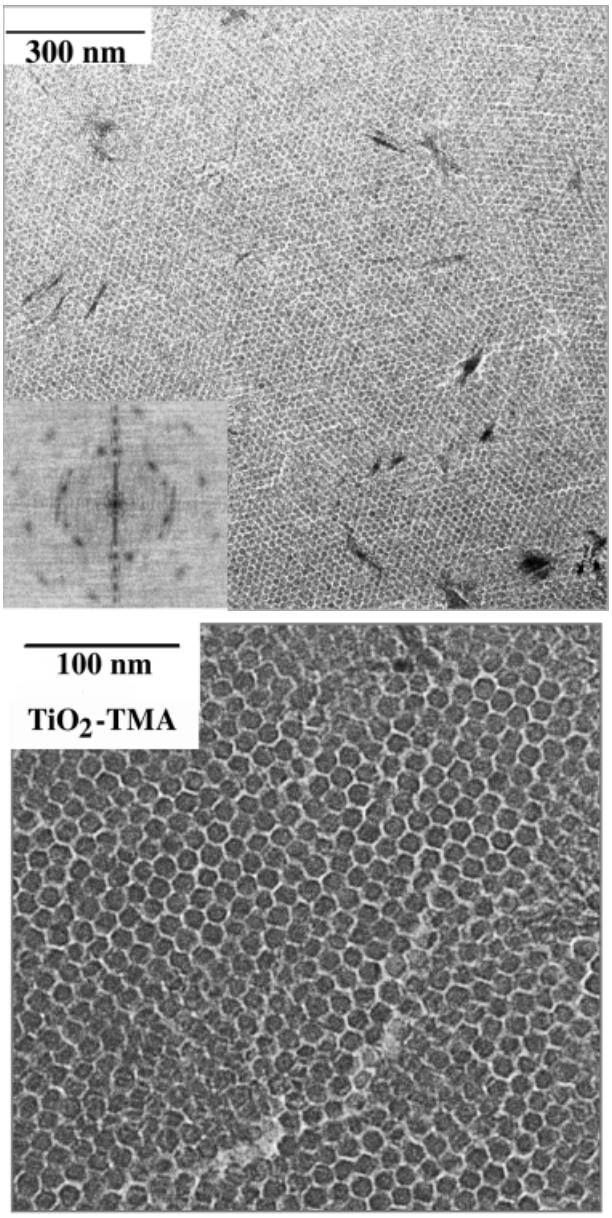

Figure 9. a) Transmission electron micrograph of titania/Me_4N^+ nanocrystals self-assembled into a superlattice with dimensions of the order of μm; the power spectrum (inset) confirms the long-range translational and orientational order of the superlattice; b) high magnification shows well-faceted hexagonal nanocrystals

ture. The majority of the nanocrystallites have the same orientation of their layered structures, which accounts for the sharpness of the XRD peaks.The white space observed around the nanocrystals in Figure 9 is probably occupied by organic cations.

Figure 10 shows TEM images of particles obtained in the case of sample F, which corresponds to solution E kept under reflux for an additional hour. The arrays obtained exhibit less regular geometries on a large scale. In comparison with sample E, changes in particle shape and in their organization, as well as in the internal structures of the nanocrystals are observed. Instead of the hexagonal shape observed in E, the drying leads to a rectangular shape and the nanocrystals are differently packed (Figure 10). Furthermore, two types of internal structures are observed. This can be explained in terms of the presence of two competing structures, since one type of nanocrystal is seen to be composed of slabs disposed parallel to one another, while the other type does not have any discerning features. Another explanation is that in a few nanocrystals a condensation process takes place, leading to slabs. These local transformations will affect the self-assembling process, thereby leading to new structures. A very interesting observation is that the high magnification images reveal that the newly formed slabs adopt a zig-zag structure. This is an indication of the presence of *cis*-skewed chains, characteristic of the anatase crystal structure (Figure 10). In fact, these anatase slabs are the condensation products of smaller ones (sample E), the anatase structure of which was shown by EXAFS and XRD experiments.

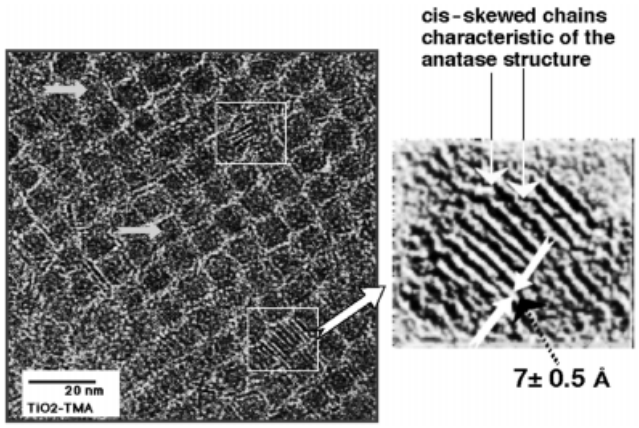

Figure 10. Nanocrystals obtained from solution F: Arrow shows nanocrystal composed of slabs disposed parallel to one another; high magnification indicates structural features that can be related to the *cis*-skewed chains in the [001] direction of the anatase crystal structure; the neighboring nanocrystals do not exhibit the same internal structure; arrows point to small clusters that probably did not condense to give slabs; a competing structure, where the slabs are differently oriented, is present

Figure 11 shows particles obtained in the case of sample G, using the same composition as in sample D, but with $(C_5H_{11})_4NOH$ as the base instead of Me_4NOH. The particles obtained are also elongated and relatively homogeneous, with widths of about 3.6 nm and lengths of about 42 nm. The important difference is the absence of the corrugated sides observed with Me_4N^+. The sharp edges indicate a relatively flat [100] surface. High-resolution microscopy shows most particles to be single nanocrystals, and a structural regularity where only [101] lattice planes are observed for most particles. The use of $(C_5H_{11})_4N^+$ illustrates the influence of cation size on the growth of titania, the larger ion leading to [100] surfaces instead of [101] surfaces.

Figure 12 depicts an electron micrograph of particles of sample H. The particles are almost spherical in shape and display a large size distribution (102 nm < diameter < 5 nm). Besides the spherical particles, a few elongated forms (or slabs) are also present, as indicated in Figure 12. By

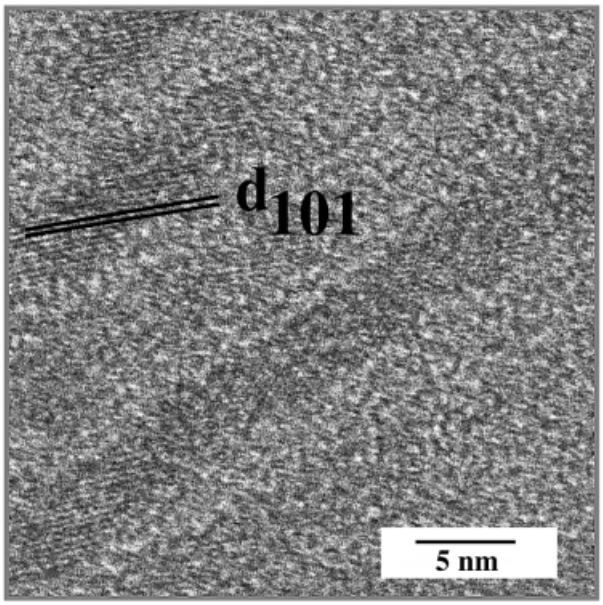

Figure 11. Elongated nanocrystals made with TPA; HRTEM showing no corrugated sides but relatively sharp edges corresponding to flat [100] surfaces

comparison with sample E, this experiment shows the importance of stirring with regard to the size distribution of particles.

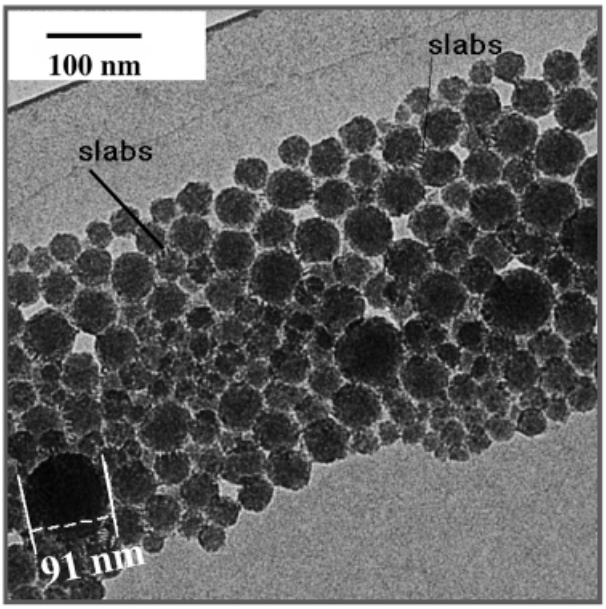

Figure 12. Overview of nanocrystals obtained without continuous stirring; in addition to the wide distribution of sizes, some slabs are observed (arrows), which seem to bridge or to interact with neighboring spherical nanocrystals

Figure 13 shows particles of sample I, made using the same procedure as in the case of sample E but with titanium tetrabutoxide Ti(O*n*Bu)$_4$ as the titanium source in butanol. The particles are almost spherical in shape and display a very narrow size distribution, having a mean diameter of about 7 nm. In this overall view of the particles, some small organized domains can be observed. However, no long-range order is apparent. The difference in size and shape of the particles compared to those in sample E can be attributed to the nature of the alkoxide groups.

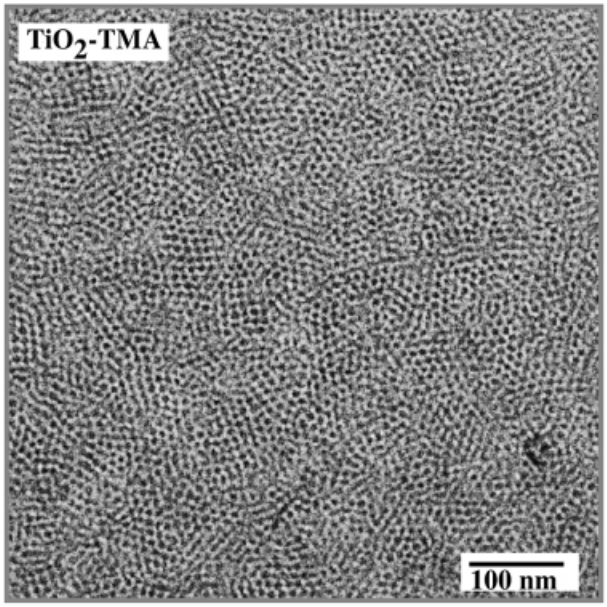

Figure 13. A new type of nanocrystal is obtained with titanium tetrabutoxide in butanol; monodisperity is achieved but the nanocrystals are smaller compared to those in sample E

Sample J was prepared using a 10-fold more concentrated titanium alkoxide solution. The condensation products are titania fibres or slabs of uniform width (7.5 ± 1 Å). However, polydispersity in slab length is in evidence ($1 < L < 18$ nm), as can be seen in Figure 14.

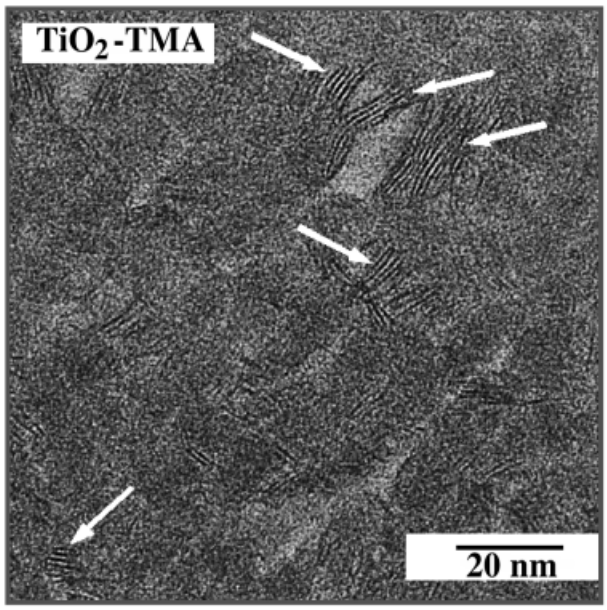

Figure 14. A further increase in titanium concentration leads to the formation of longer and relatively stable slabs, or of polymers with a polydispersity in length; the same width is observed for all polymers

Discussion

As far as we are aware, the work reported herein represents the first incidence of the tailoring of the morphologies of titania nanocrystals with the anatase crystal structure under homogeneous conditions by variation of the hydrolysis conditions and control of the hydrothermal treatment. In this approach, relatively high concentrations of the alkoxide [$Ti(OR)_4$] are used. The hydrolysis is performed in the presence of excess water and a base is employed to catalyze the complete hydrolysis of all OR groups. The effects of unhydrolyzed OR groups on the condensation pathway or on the structure of the primary polycondensed species are therefore avoided. Moreover, hydrolysis and condensation are not separated due to the high titanium concentrations.[17] This methodology leads to a totally new type of clusters and nanocrystals, exhibiting exclusively the anatase crystal structure, with stabilization by tetramethylammonium cations (Me_4N^+).

The hydrolysis and condensation of titanium alkoxide or titanium cations in solution has been the subject of a great deal of attention.[17,21] Particularly relevant to the present results is the theoretical work based on the partial charge model by Henry and Livage, developed to understand and predict inorganic polymerization in the case of transition metal oxide precursors,[21] as well as the work by Bradley on the hydrolysis of titanium alkoxides in the presence of a base.[22] According to these authors, the presence of a base influences the condensation by favouring the formation of the highly nucleophilic TiO^-. This reactive condensation precursor reacts with the positively charged titanium, leading to the formation of polymeric materials.[17]

In the case of a highly dilute alcoholic solution of the alkoxide, the overall hydrolysis reaction after the addition of excess water can be written as:

$$Ti(OR)_4 + 4\ H_2O \rightarrow Ti(OH)_4 + 4\ ROH \quad (a)$$

However, at the high titanium concentrations used in the present study, it is difficult to separate the hydrolysis (Equation a) and condensation (Equation b) processes. These two primary processes are accelerated by the presence of Me_4NOH as a result of the formation of the highly nucleophilic TiO^- according to Equation c. The cation also plays a role in preventing further condensation and stabilizing condensed species according to Equation d.

$$Ti{-}OH + XO{-}Ti \rightarrow Ti{-}O{-}Ti + XOH\ (X = H, R) \quad (b)$$
$$Ti{-}OH + Me_4NOH \rightarrow Ti{-}O^- + Me_4N^+ + H_2O \quad (c)$$
$$Ti_xO_yH_z + Me_4NOH \rightarrow (Ti_xO_yH_{z-1})Me_4N + H_2O \quad (d)$$

The Me_4NOH concentration will also determine the x and y values and therefore the size of the condensed species. According to refs.[17][22] reaction according to Equation c leads to polymers, which is consistent with the formation of stable polymeric material in Figure 14, or of slabs in Figure 7b. In terms of the partial charge model,[21] the formation and stabilization of a totally new type of clusters, slabs, polymers, or nanocrystals, exhibiting exclusively the anatase crystal structure, can be explained by considering a condensation process dominated by an olation pathway, which is seemingly favoured under the present experimental conditions.[17][21] It is generally accepted that early in the condensation process, the coordination number of titanium changes from 4 to 6, and that the basic building unit in the polymerization process is an octahedral arrangement of six oxygen atoms around a titanium centre.[17][21] These octahedra link together by sharing edges, so as to form dimers. According to the partial charge model, these dimers condense to form skewed chains as a result of olation processes, as illustrated in Figure 15.[21] In the presence of Me_4N^+, the condensed species can be stabilized allowing their isolation, or may be forced to condense into larger particles by further heat treatment. In the early stages of condensation, the linear growth (polymerization) leads to skewed chains,[21] which corresponds to growth in the [001] direction of the anatase phase (main stem). Then, through an oxolation process, the nuclei can grow in one of the two equivalent directions.[21] The shape of the particle will be determined by the difference in growth velocities in the [101] and [001] directions, as indicated in Figure 5. At low concentrations of Me_4N^+, growth is favoured in the the [101] direction (Figure 1), while at high concentrations the growth velocity is favoured in the [001] direction (Figure 4). Therefore, the shape of nanocrystals can be fine-tuned by changing the ratio Ti/Me_4NOH, denoted as R.

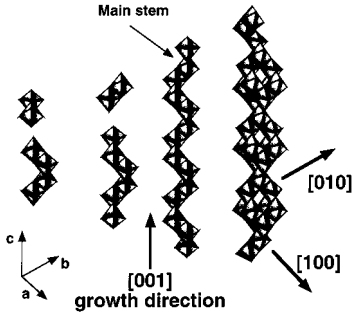

Figure 15. Model to explain condensation and growth of titania anatase; the mode of linking dimers imposes restriction on the growth direction leading to *cis*-skewed chains (main stem) and this is favoured by the physicochemical conditions of the present reaction; [100] and [010] are the first branching directions; then, depending on the organic cation present and its concentration, the secondary branching can be parallel to [101] or can remain parallel to [100] and [010]

The HRTEM micrograph shown in Figure 4b and the illustration in Figure 5 relate to titania nanocrystals where the [101] and [010] are the predominant surfaces. The corrugated sides are due to oscillatory repetition of [1 0 1] and [1 0 −1]. In terms of the mechanism discussed above, the main stem of the nanocrystal is seemingly in the [001] direction. The [100] and [010] directions are equivalent in the case of the anatase crystal phase, and both can be primary branching directions. Sample B, heat-treated for only 2 h, was found to contain small slabs and very thin elongated particles in the [001] crystallographic direction; in Figure 1 nanocrystals also show stepped [101] surfaces. The surface steps are of a height equivalent to the cluster size. Growth

will take place by the building-up of these steps so as to form new cluster layers, and the rate of this process will depend on the concentration of Me_4N^+. The crystal surface in contact with the building units can be influenced by Me_4N^+. This cation seems to interact preferentially with the [101] surface, leading to the favoured development of these surfaces, as shown in Figures 4b.

The decomposition of Me_4N^+ at higher temperatures and pressures leads to surface reconstruction and further growth. The structural features observed on the surface, such as steps, corrugated sides, and sharp edges are, in fact, stabilized by Me_4N^+. However, no corrugated sides or steps are observed in the presence of $(C_5H_{11})_4N^+$ cations (Figure 11). The [100] surfaces of the particles are relatively flat. The observed effect of cation size on nanocrystal shape can be explained in terms of the role of the cations during the early stages of condensation, and thereafter during the crystal growth. Preliminary attempts to stabilize smaller clusters by replacing Me_4N^+ with $(C_5H_{11})_4N^+$ were not successful.

The Me_4N^+-stabilized clusters are able to self-assemble to form nanocrystals, which can be identically replicated in unlimited quantities provided that vigorous stirring of the solution is maintained during the hydrothermal reaction (see Figure 9, and to some extent Figures 10 and 13 as well). Without stirring, a wide size distribution is generally obtained, as shown in Figure 12, where arrows indicate the additional presence of slabs. In fact, the monodispersity of the primary clusters determines the monodispersity of the intermediate nanocrystals formed by a self-assembling process and, therefore, the formation of the superlattice observed in Figures 9 and 10. These results clearly indicate the construction of a superlattice in 3 steps. This was called a progressive condensation process in our preliminary report.[23] The overall process first involves the formation of the monodispersed primary building units. Secondly, they self-assemble into nanocrystals with a diameter of 13.5 nm. Finally, these nanocrystals are made to self-assemble in a uniform manner to form a superlattice. These clusters and nanocrystals are negatively charged and their electrostatic repulsion accounts for the stability of the solutions inasmuch as it prevents flocculation. On the other hand, these interactions and the monodispersity are responsible for the long-range ordering observed after evaporation of the solvent (Figure 10). The charged titania nanocrystals are aligned in a periodic array, rather like in a crystal.[24]

The very broad peaks seen in Figure 2d and the preliminary EXAFS experiments performed on our samples, particularly on sample E, are indicative of the anatase crystal structure.[25] The structural changes observed after an additional heat-treatment of E to make F clearly indicate a further condensation among a few nanocrystals to form slabs, with the *cis*-skewed chains being characteristic of the anatase crystal phase. Further structural information could be gleaned from the XRD pattern of cluster films prepared by simple deposition of solution E onto a silicon wafer followed by drying in air (Figure 2d). A similar procedure was used to obtain TEM measurements, where one drop of the solution was applied to a carbon film. A series of peaks at low angular range with the spacings 16.56 Å, 8.3 Å, and 5.53 Å was observed, attributable to [001], [002], and [003] reflections, respectively, of a spacing of 16.56 Å. These XRD data suggest that the clusters are arranged inside the nanocrystal such as to form a layered structure. Packing of this type has been observed in the case of colloidal nanosheets made from exfoliated titanate. The exfoliation/reassembly process in the presence of tetrabutylammonium hydroxide Bu_4N^+ leads to a comparable XRD pattern.[26] In both cases, drying of the aggregate leads to textured films, in which reflections are suppressed due to the preferred orientation of the nanosheets or, in this case, clusters or slabs. The thickness of the nanosheets is 7.5 Å, which is comparable to the thickness of the slabs (sample F), while their lateral dimension is in the range 0.3−1 μm.[26] Figure 10 shows nanocrystals composed of slabs disposed parallel to one another with a repeating distance of about 16 ± 1 Å. This distance falls within the range of the spacings estimated from the XRD pattern of sample F, which is analogous to Figure 2d.

The observed stepped surfaces in Figures 1 and 4b give indications of a cluster-cluster growth of titania anatase nanocrystals, especially the corrugated sides observed in the case of sample B. According to XRD, these particles are already formed at the reflux stage, i.e. in solution. In the case of samples C and D, particles are seen to be composed of aggregated small slabs at low magnification, which subsequently coalesce into elongated particles also having corrugated sides (Figure 8) like those of sample B grown in solution (Figure 4). This direct observation suggests that a cluster-cluster growth takes place in solution. The coalescence process that takes place under the electron beam still has to be carefully investigated.

The nature of the intermediate nanocrystals observed in Figure 9 proved to be sensitive to the OR group of the alkoxide. Figure 13 shows smaller nanocrystals formed when titanium tetrabutoxide in butanol was used (particle diameter ca. 8−9 nm). The difference in size, and probably in the internal structure as well, highlights the importance of the OR group in the hydrolysis and condensation processes.

The ordering observed in Figure 9 is due to electrostatic interactions between the multiply charged titanium polyanions and the Me_4N^+ cations and leads to intermediate nanocrystals. In turn, through inter-nanocrystal interactions, these form a long-range ordered array, comparable to arrays of pores typically observed in mesophases. In the case of polysilicates, the self-assembly process can be accompanied by a condensation-polymerization process, leading to the formation of three-dimensionally structured arrays, which are stable even after calcination.[27,28]

The present synthetic technique furnishes titania clusters of various sizes and shapes in solution. These clusters may be used to grow transparent thin films, allowing control over both the orientation of superlattices and that of individual nanocrystals. The exact internal structure of the superlattice still has to be determined, and this will be addressed once single crystals are obtained. However, EXAFS

results, XRD, HRTEM, and elemental analysis indicate the presence of anatase clusters and Me_4N^+ cations. Optical measurements and X-ray photoelectron spectroscopy (XPS) indicate dramatic changes in the electronic properties of the titania nanocrystals according to their size and shape.[25]

Conclusion

We have presented a new method for preparing titania nanocrystals with exclusively the anatase crystal structure. Small titania clusters or polytitanate anions have been prepared and stabilized in solution for the first time. Cluster-cluster growth has been shown to take place, leading to larger nanocrystals. The growth can be influenced by controlling the hydrolysis and condensation with Me_4NOH. There is an apparent preference for interaction between [101] surfaces and Me_4N^+, which would account for the differential growth velocities in the [101] and [001] directions. The monodispersity of the negatively charged clusters renders them suitable for the progressive formation of titania/Me_4N^+ superlattices. Thin-film growth allows control over the orientations of superlattices, individual nanocrystals, and individual clusters. The polycondensation and growth processes observed and discussed in this study are in accordance with theoretical predictions. These new results should motivate further investigations of titania and polytitanates in solution.

Experimental Section

General: All hydrolysis reactions were conducted in air, whereas the refluxing of solutions was carried out under argon.

Chemicals: All chemicals used were analytical grade or of the highest purity available and were used as purchased. 2-Propanol and butanol from Merck; titanium isopropoxide $Ti(OiPr)_4$ and butoxide $Ti(OnBu)_4$ from Aldrich, and tetramethylammonium hydroxide Me_4NOH and tetrapentylammonium hydroxide $(C_5H_{11})_4NOH$ from Fluka.

Synthesis of TiO_2 Clusters and Nanocrystallites: A 250-mL three-necked flask was placed in a large crystallizing dish on top of a magnetic stirrer, and the side necks were fitted with a thermometer and a gas inlet tube. A magnetic stirrer bar and 150 mL of aqueous Me_4NOH solution were placed in the flask and the crystallizing dish was filled with ice. When the temperature of the Me_4NOH solution had reached 2°C, a solution of 0.333 mL of titanium isopropoxide in 10 mL of 2-propanol was added dropwise by means of a dropping funnel (1 drop/s) while the mixture was stirred vigorously. During the course of the addition, a white precipitate formed. After the addition was complete, the mixture was left to stand for 10 min, then the ice bath was replaced by a heating mantle, and the mixture was heated. On refluxing, the precipitate dissolved after about 3 h, but after 6 h the solution became slightly turbid once more (sample A).

Sample B was prepared according to the same procedure, but using different concentrations (see Table 1); the mixture became slightly turbid only after all the titanium alkoxide solution had been added (about 5 min). In this case, aliquots were withdrawn from the refluxing solution after 2 h and 6 h in order to carry out TEM observations.

Aliquots of solutions A and B (8 mL each) were heat-treated in a titanium autoclave at 175 and 200°C for a period of 5 h under a saturated vapor pressure of water (about 2500 kPa) in a titanium-coated reactor.

For the preparation of all other samples, the procedure adopted was similar to that described above, except that the titanium alkoxide solution was added in a single portion rather than dropwise to the Me_4NOH solution (see Table 1).

Table 1. Stoichiometry of the reactions

Sample	$Ti(OR)_4$ x µmol[a]	Me_4NOH y µmol[a]	Reflux [h]	Temperature [°C]
A	1.14	0.26	6	90−100
B	1.14	0.82	6	90−100
C	1.14	0.57	6	90−100
D	1.14	1.09	6	90−100
E	1.14	1.36	6	90−100
F	1.14	1.42	7	90−100
G	1.14[b]	1.17	6	90−100
H	1.14	1.36	13 d	50−60
I	1.06[b]	1.42	6	90−100
J	11.4	11.6	6	90−100

[a] x µmol of titanium isopropoxide in 10 mL of 2-propanol, y µmol of Me_4NOH in 150 mL of water. − [b] Sample G was prepared with tetrapentylammonium hydroxide (TPA) and sample I with titanium tetrabutoxide in butanol. Sample H was left for 13 d without stirring.

Elemental Analysis of Sample E was carried out commercially at the microanalytical laboratory Pascher in Remagen-Bahndorf, Germany. Elemental analysis of powder E, dried at room temperature in air: C 18.22, H 5.5, N 4.9, O 42.87, Ti 33.3. The composition can be roughly written as $Ti_4O_{15}[N(CH_3)_4]_2H_{12}$.

Film Growth: The samples were prepared by depositing freshly prepared solutions on a silicon [100] wafer or on glass. In some cases, the solutions were first concentrated in a rotary evaporator prior to deposition in order to accelerate thick-film processing. Optically transparent films of ordered titania nanocrystals could be prepared by controlling the rate of evaporation of the solvent. Slow evaporation leads to thin film growth, which allows orientation of the superlattice and of the individual layered structures. Such deposition on solid substrates produces ordered and oriented films.

The titania clusters and nanocrystals were investigated with a Philips CM12 transmission electron microscope. Samples were prepared by placing a drop of the freshly prepared nanocrystal solution on a carbon film supported on a Cu grid. The advantages of investigating crystal growth in the case of nanocrystals is that the specimens are already thin to the point of electron transparency, and are thus readily amenable to TEM examination. High resolution is quite easily achieved nowadays and image processing is straightforward, allowing a stimulating interplay between synthesis and TEM observation.[19] A careful analysis of the micrographs can provide unique periodical and morphological information to aid in the understanding of the effects of additives on crystal growth. The NIH image-processing program was used to enhance the data obtained from some samples.

X-ray Powder Diffraction and Small-Angle X-ray Scattering were carried out with a Siemens D500/5000 diffractometer, operating with a Cu anode at 45 kV and 30 mA. A secondary graphite monochromator was used to select the K_a1 and K_a2 lines.

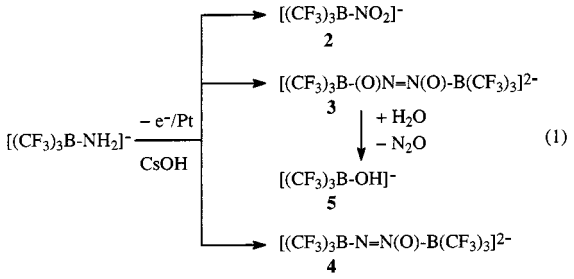
Electrochemical and Ozone Oxidation of $(CF_3)_3B \cdot NH_3$: Formation and Characterization of Products with Nondegradated $(CF_3)_3B$ Groups

David J. Brauer,[a] Hans Bürger,*[a] Yonas Chebude,[a] and Gottfried Pawelke[a]

Keywords: Boron / Fluorine / Oxidation / Nitrogen / Molecular structures



$(CF_3)_3B \cdot NH_3$ (**1**) has been oxidized in aqueous solution using a platinum anode. At pH = 8–9 in $CsOH/Cs_2CO_3$ solution $Cs[(CF_3)_3B–NO_2]$ (**2**), $Cs_2[(CF_3)_3B–N(O)=N(O)–B(CF_3)_3]$ (**3**) and $Cs_2[(CF_3)_3B–N=N(O)–B(CF_3)_3]$ (**4**) are formed. Compound **3** slowly hydrolyses to yield the hydroxyborate $Cs[(CF_3)_3B–OH]$ (**5**). Compound **2** and traces of **3** and **5** were also formed by oxidation of **1** or $(CF_3)_3B \cdot NHEt_2$ with ozone. The constitution of the novel borates has been deduced from multinuclear NMR, IR and mass spectra. The structures of **2**–**5** have been investigated by single-crystal X-ray diffraction.

Introduction

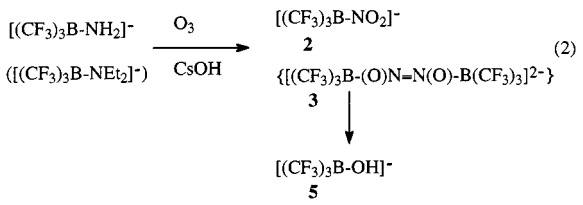
Homoleptic, donor-free (perfluoroalkyl)boranes, e. g. $(R_f)_3B$ (R_f = CF_3, C_2F_5, ...), are still unknown in spite of considerable efforts made in the past towards their synthesis.[1] The simplest species tris(trifluoromethyl)borane, $(CF_3)_3B$, is expected to readily decompose under elimination of difluorocarbene and formation of BF_3. However, various amine adducts of $(CF_3)_3B$ are accessible, and they have been shown to be amazingly stable.[2a–2d] As a result of the presumed high Lewis acidity of the $(CF_3)_3B$ moiety and despite its relative bulkiness, the B–N bond in amine–tris(trifluoromethyl)boranes is thermodynamically extraordinarily strong. Attempts to selectively cleave this bond have failed so far. Such amine–boranes withstand e. g. concentrated hydrochloric acid as well as concentrated solutions of KOH. SbF_5 or superacids like $HSbF_6/HF$ react at 10°C with e. g. $(CF_3)_3B \cdot NHEt_2$ with cleavage of the B–N bond and formation of BF_3, perfluoropropene or HCF_3. Since the isolation of the donor-free tris(trifluoromethyl)-borane remains a challenge, we have focused our continuing interest on the synthesis of alternative promising precursor molecules. We decided to start from ammine–tris-(trifluoromethyl)borane, $(CF_3)_3B \cdot NH_3$ (**1**), the synthesis of which has been improved.[3] We hoped that oxidation of its nitrogen atom might favor low-temperature B–N cleavage reactions.

Results

Ammine–tris(trifluoromethyl)borane (**1**) is a hygroscopic compound which forms a crystalline tetrahydrate when exposed to moist air. Dissolved in water it is a weak acid with a pK_a = 5 and behaves like an ammonium cation. Attempts to electrochemically oxidize the nitrogen atom on platinum anodes in acidic solution failed, only H_2 and O_2 being evolved. On raising the pH to 8–9, the nitrogen atom in **1** is deprotonated to form the aminotris(trifluoromethyl)borate anion $[(CF_3)_3B–NH_2]^-$. In view of planned X-ray crystal studies a $CsOH/Cs_2CO_3$ mixture was used to adjust the pH to 8.5 because cesium salts of the oxidation products were expected to crystallize well. Under these alkaline conditions the nitrogen atom was found to be readily oxidized at a 4.5 V potential difference between electrodes. The progress of the oxidation was monitored by measurement of ^{19}F-NMR spectra of the solution. The electrolysis was interrupted every two hours in order to isolate the insoluble, colorless material which accumulated on the anode and at the bottom of the cell. Work-up of the precipitated material revealed that it consisted mainly of a mixture of cesium azodioxybis[tris(trifluoromethyl)borate] $Cs_2[(CF_3)_3B–N(O)=N(O)–B(CF_3)_3]$ (**3**) and cesium azoxybis[tris(trifluoromethyl)borate] $Cs_2[(CF_3)_3B–N=N(O)–B(CF_3)_3]$ (**4**) (Equation 1).

(1)

The main product of the anodic oxidation, however, was the nitroborate $Cs[(CF_3)_3B–NO_2]$ (**2**) which precipitated when the concentrated solution was cooled to 4°C. Concentration of the solution to dryness gave a residue which contained substantial quantities of $Cs[(CF_3)_3B–OH]$ (**5**). Besides these main products, which according to ^{19}F-NMR spectra account for 95% of all formed from **1**, several other (trifluoromethyl)borates were detected. These include compounds with either three or two CF_3 groups attached to the boron atom. However, separation and characterization of these species failed.



The origin of **5** became apparent from a study of the hydrolysis of **3**. This compound slowly reacts with water at

room temperature − the elimination of N_2O, which was confirmed by IR spectroscopy, and formation of **5** being completed within one week. We are sure that this pathway accounts for all of **5** produced.

Besides the electrochemical oxidation, attempts were also undertaken to oxidize compound **1** chemically. The results of such oxidation reactions will be reported later, but one case is mentioned here. Ozone reacts readily with **1** in cesium hydroxide solution to form **2** and **5** in a ratio of 7:2. Moreover, we found that $(CF_3)_3B\cdot NHEt_2$, the precursor molecule for **1**, is also directly converted into similar quantities of **2** and **5** (Equation 2). The fate of the *N*-ethyl groups has not yet been elucidated.

(2)

Spectra and Properties

The NMR chemical shifts and coupling constants of **2**−**5** are set out in Table 1 and are consistent with the proposed structures. For **3** and one of the $B(CF_3)_3$ groups of **4** the resonances of the CF_3 groups were not found in the ^{13}C-NMR spectra due to quadrupolar broadening by the boron nucleus.

Infrared and Raman spectra of **2**−**5** were recorded. All of these novel borates contain a $(CF_3)_3B-X$ (X = N, O) moiety, the vibrational frequencies of which fall into well-defined ranges. First the bands in the range of 1300−1280 cm^{-1} and 1140−1060 cm^{-1} are assigned to ν(CF_3) vibrations which are associated with very strong infrared absorptions but medium to weak Raman lines. Then, the $\delta_s(CF_3)$ mode is found at ca. 720 and 690 cm^{-1} where the former mode appears as a strong Raman line and the latter as a medium to strong infrared band. Near 500 cm^{-1} $\delta_{as}(CF_3)$ features with medium infrared and weak Raman intensity occur while ρ(CF_3) is associated with weak infrared bands and medium to strong Raman lines at 350−280 cm^{-1}. The BC_3 and B−X stretching vibrations are strongly coupled and may be assigned to several infrared bands between 950 and 860 cm^{-1} showing $^{10/11}$B isotopic patterns. Compound **2** has an NO_2 group, which exhibits characteristic frequencies. Thus, the infrared bands/Raman lines [cm^{-1}] were assigned as follows: 1471 vs/1484 m (ν_{as} NO_2), 1400 w/1400 vs (ν_s NO_2), 795 s/797 s (δ_s NO_2), 595 m/− (δ_{op} BNO_2). Compound **3** has *trans* configuration with C_i symmetry in the crystal. Consequently, backbone vibrations which occur in characteristic ranges obey the mutual exclusion principle of the infrared and Raman frequencies. These vibrations were assigned to infrared bands/Raman lines [cm^{-1}] at: −/1415 vs (ν NN), −/1125 m (ν NO i.p.), 685 −/m (δ NNO), ca. 1100 s/− (ν NO o.p.), 620 s/− (δ NNO). Compound **4** has strongly coupled N−N and N−O stretching vibrations which were assigned to infrared bands/Raman lines [cm^{-1}] at 1511 m/1514 m (ν NN) and 1258 vs/1265 m (ν NO). The N−N−O bending mode is associated with features in the IR and Raman spectrum at 800 m/805 w cm^{-1}. The O−H stretching and B−O−H bending vibrations of **5** were unambiguously assigned to IR bands at 3650 and 1520 cm^{-1}.

The molecular masses of **2** and **5** were determined by ESI/neg. spectra (CH_3CN + 10% H_2O). Compound **2** showed the peak of the anion $[(CF_3)_3B-NO_2]^-$, 100%, and the cluster peak $[Cs[(CF_3)_3B-NO_2]_2]^-$, 10%, whereas **5** gave only the anion peak $[(CF_3)_3B-OH]^-$, 100%.

The cesium borates **2**−**5** are colorless solids. Their approximate decomposition temperatures determined thermogravimetrically are 260°C (**2**), 80°C (**3**), 190°C (**4**), and 150°C (**5**). Because the decomposition of **3** is violent, reliable elemental analyses were difficult to obtain.

Compound **2** is stable towards acids like HCl, H_3PO_4, or H_2SO_4. Dissolved in neat CF_3SO_3H **2** reacts within 1 d under elimination of difluorocarbene. This subsequently inserts into the O−H bond to form the ester $CF_3SO_2OCF_2H$, which was identified by its NMR spectra. Reaction of **2** with ethereal HCl forms the sublimable ether adduct $(CF_3)_3B-NO_2H \times Et_2O$. The latter is hydrolyzed by moist air to form what appears to be a pentahydrate **2a** $(CF_3)_3B-NO_2H \times 5\ H_2O$. Titration of **2a** revealed a pK_a of ca. 1.9 and a molecular mass of 359 g/mol which is in line with a pentahydrate (355.93 g/mol), while elemental analyses were in agreement both with a penta- or a hexahydrate. Compound **2a** is stable at room temperature and decomposes according to thermogravimetric experiments at 75°C without leaving any residue. Compound **2** reacts with zinc in aqueous KOH to form **1** (Equation 3) and it is reduced by sodium amalgam in ether to form, according to NMR spectra, a mixture of **3** and **4** (Equation 4).

(3)

$$[(CF_3)_3B\text{-}NO_2]^- \xrightarrow{Na/Hg} \begin{matrix}[(CF_3)_3B\text{-}N(O)\text{=}N(O)\text{-}B(CF_3)_3]^{2-} \\ + \\ [(CF_3)_3B\text{-}N\text{=}N(O)\text{-}B(CF_3)_3]^{2-}\end{matrix} \quad (4)$$

We were unable to isolate **3** and **4** from this reduction because the ethereal solutions decomposed violently upon concentration. This might be ascribed to precipitation of the salts $Na_2[(CF_3)_3B-N(O)=N(O)-B(CF_3)_3]$ and $Na_2[(CF_3)_3B-N=N(O)-B(CF_3)_3]$ from this sodium-rich system. Such salts might be thermally less stable than their cesium counterparts; that is, small cations are stronger Lewis acids than Cs^+ and tend to abstract fluoride from the CF_3 groups. This is underscored by the rather low decomposition temperature of $Li[(CF_3)_3B-NO_2]$, 70°C, compared with that of $Cs[(CF_3)_3B-NO_2]$, 260°C.

Only little information on the chemical properties of **3** and **4** has been gathered. We have no evidence for an equilibrium $[(CF_3)_3B-N(O)=N(O)-B(CF_3)_3]^{2-} \rightleftarrows 2\,[(CF_3)_3B-N=O]^-$ which is known to exist for aliphatic nitroso compounds. Since monomers of the latter compounds are intensely colored whereas solutions of **3** are colorless, any such equilibrium for **3** must be shifted far to the left. The protonation of **5** has been investigated in more detail. Upon treatment with ethereal HCl, protonation and formation of a sublimable ether adduct $(CF_3)_3B-OH_2 \times Et_2O$, which is analogous to compound **2**, was observed. The ether is readily replaced by water on contact with moist air to form an oily product which, according to thermogravimetric analysis, is a pentahydrate **5a**. This behaves as an acid, with a pK_a of 1.6, and is thermally stable up to 70°C.

Discussion

Hydroxyborate anions of the general formula $[R_3BOH]^-$ with R = F,[4] H,[5] CH_3,[6] C_6H_5[7] are well known, and compound **5** might be regarded as a further homologue with R = CF_3. Unlike **5**, such anions for R = alkyl or aryl are only stable under alkaline conditions, and species with R = F or H are of limited thermal and kinetic stability which decompose upon protonation. Compounds **2**, **3** and **4** have, to our knowledge, no real counterparts in boron chemistry. The formation of the $[F_3BNO_2]^-$ anion in solution has been reported.[8] This anion, only characterized by ^{19}F-NMR spectra, was found prone to disproportionation into $[BF_4]^-$ and $[F_2B(NO_2)_2]^-$. The stability of **2** towards dissociation gives an impression of the Lewis acid strength of illusive free $(CF_3)_3B$.

Borate ions with $N_2O_2^{2-}$ or N_2O^{2-} as coordinating ligands as revealed in **3** and **4** are unknown whereas a Lewis acid/base complex with SO_3, $[O-N=N(O)-SO_3]^{2-}$, has been characterized. The latter anion is formed when NO is introduced into an alkaline SO_3^{2-} solution,[9] and the structure of the ammonium salt has been determined.[10] This salt hydrolyses slowly in water to form SO_4^{2-} and N_2O, and experiments with ^{15}N-labeled material proved that the hyponitrite anion is an intermediate.[11] Therefore the slow hydrolysis of **3** with elimination of N_2O and formation of **5** is in line with the behavior of $[O-N=N(O)-SO_3]^{2-}$.

The stability of the $(CF_3)_3BN$ skeleton towards oxidation is remarkable. This results in part from the steric bulk of three CF_3 groups, which efficiently shield the boron atom, the boron−carbon bonds as well as the boron−nitrogen bond in **1**, **2**, and **4**. In the course of the oxidation reactions, the nitrogen atom changes its oxidation state in alkaline solution from −3 in **1** over "average" ±0 in **4** to +1 in **3** and finally to +3 in **2**. One of the oxidizing reagents that is able to accomplish this oxidation is ozone. Its oxidation strength in alkaline solution is clearly larger than is that of hydrogen peroxide; for example, the standard reduction potential for the half reaction $O_3 + H_2O + 2e^- \rightarrow O_2 + 2OH^-$, +1.24 V, is much larger than for $HO_2^- + H_2O + 2e^- \rightarrow 3OH^-$, +0.87 V. Whereas O_3 readily oxidizes **1** to **2**, concentrated H_2O_2 in alkaline solution is unable to perform an oxidation. Apparently, the lower limit for oxidation of **1** in alkaline solution must lie between +0.87 V and +1.24 V; so in the absence of kinetic hindrance, any other reagent with standard reduction potentials higher than +1.24 V should be able to convert **1** into **2**. Similar to ozone, fluorine reacts in alkaline solution readily with **1** to form **2** whereas in acidic solution only water is oxidized. The oxidation of $Cs[(CF_3)_3B-NH_2]$ in acetonitrile has been studied by cyclic voltammetry. The anion is irreversibly oxidized at a potential against an Ag reference electrode of ca. 1.82 V which is close to the limit dictated by the acetonitrile solvent. This high potential might explain why XeF_2 failed to react with $Cs[(CF_3)_3B-NH_2]$ in acetonitrile.

The oxidation of **1**, which leads ultimately to the formation of a nitro group, resembles the oxidation of aniline to nitrobenzene which also can be performed with ozone[12] or electrochemically.[13] Diazene bis(oxides) R−N(O)=N(O)−R (azodioxy compounds) or diazene *N*-oxides R−N=N(O)−R (azoxy compounds) with R = alkyl, aryl are also formed both by oxidation or reduction of precursor molecules. For example *cyclo*-C_6H_{11}−(O)N=N(O)−*cyclo*-C_6H_{11} is formed from *cyclo*-$C_6H_{11}NH_2$ using peracetic acid[14] while $C_6H_5-N=N(O)-C_6H_5$ is obtained by reduction of nitrobenzene with Zn[15] or Pb.[16] On the other hand azoxybenzene is prepared more conveniently by oxidation of aniline with a mixture of hydrogen peroxide and acetonitrile.[17] In this respect compound **1** behaves like an ammonium cation which is deprotonated in alkaline solution to form an "amine" before it is oxidized. Consequently, compounds **2**, **3** and **4** correspond to a nitroalkane, a diazene bis(oxide) and a diazene *N*-oxide, respectively, bearing overall negative charges.

Crystal Structures

In the anion of **2** (Figure 1) the nitro group is coplanar with the boron atom to within 0.002 Å. Despite the sp^2 hybridization of the nitrogen atom, the B−N bond length [1.606(4) Å] is more typical for a linkage of a $B(CF_3)_3$ group to an sp^3-hybridized nitrogen atom such as in $(CF_3)_3B \cdot NH_3$, 1.595(8) Å,[2d] than to an sp^2-hybridized nitrogen

atom such as in $(CF_3)_3B \cdot NHCHNMe_2$, 1.541(4) Å.[2d] Similarly, an average distance between a nitro group and a quaternary carbon atom is given as 1.533(13) Å,[18] which compares well with the C−N distance reported for the *tert*-butylammonium cation, 1.506(3) Å.[19] The average value of the B−C bond length in **2**, 1.618(10) Å, is normal, as are the respective averages of the C−B−C and N−B−C bond angles, 111.5(8) and 107.4(14)°. The small but significant spread in these angles [1.5(4) and 2.7(4)°, respectively] results in part from the mismatch in the symmetries of the $B(CF_3)_3$ (C_{3v}) and BNO_2 (C_{2v}) groups. Thus, the symmetry of the anion can not exceed C_s, and the magnitude of the O(2)−N−B−C(2) torsion angle, 19.6(5)°, shows that the structure is even less symmetric.

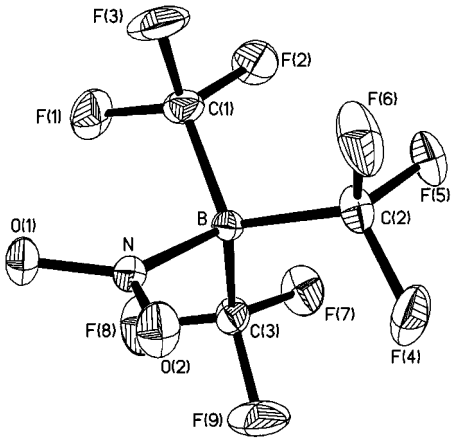

Figure 1. A perspective drawing of the $[(CF_3)_3BNO_2]^-$ anion with 20% probability thermal ellipsoids

While all atoms of **3** occupy general positions in the crystal, the midpoint of the N−N bond of the anion (Figure 2) lies on an inversion center. The $B_2N_2O_2$ fragment is planar to within 0.004 Å, and the N−N′ and N−O bond lengths of 1.30(2) and 1.30(1) Å, respectively, indicate delocalized π bonding in the azodioxy anion. These atom distances agree to within experimental error with the corresponding values for the azodioxysulfonate $[O-N=N(O)-SO_3]^{2-}$.[10] In **3** the B−N bond length is 1.59(2) Å, and the B−N−N′ angle [123(1)°] is significantly larger than the B−N−O angle [117(1)°].

In crystals of **4**, the two crystallographically unique Cs cations as well as the B(1), B(2), C(2), C(4), F(5) and F(10) atoms of the anion (Figure 3) lie on a crystallographic mirror plane. Since the azoxy group is oriented perpendicular to this plane, the positions of its atoms are disordered. A further consequence of this disorder is that the locations found for the $B(CF_3)_3$ groups are superpositions of two distinct orientations; for example, the C_3 axis of the $B(CF_3)_3$ group of the B(1) atom will either lie along the B(1)−N(2) or B(1)−N(2′) directions − the angle between these C_3 axes being 33.7(9)°. Therefore the atom distances and angles in this structure should not be taken too seriously although the agreement factors (Table 2) are acceptable. The N(1)−N(2) bond length [1.25(1) Å] should not be prejudiced by the disorder, and this value does not differ significantly from that of the analogous linkage in *p*-azoxyanisole, 1.218(5) Å.[20]

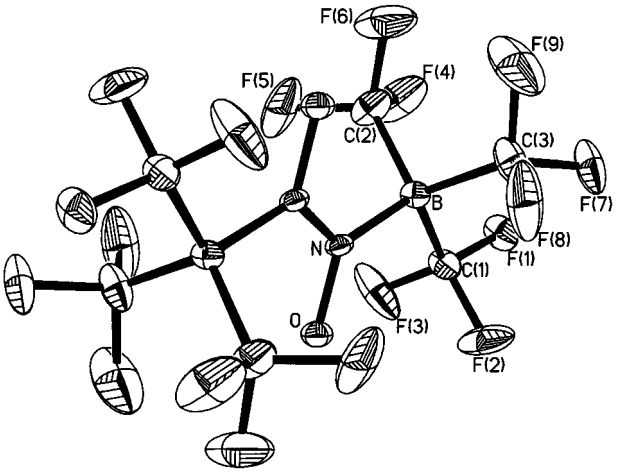

Figure 2. A perspective drawing of the $[(CF_3)_3B-N(O)=N(O)-B(CF_3)_3]^{2-}$ anion with 20% probability thermal ellipsoids

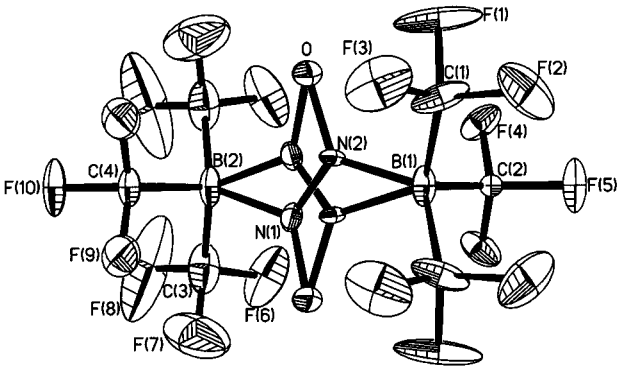

Figure 3. A perspective drawing of the $[(CF_3)_3B-N=N(O)-B(CF_3)_3]^{2-}$ anion with 20% probability thermal ellipsoids showing the disorder of the azoxy group

Crystals of **5** contain the cations Cs(1) and Cs(2) in C_3 and S_6 symmetry sites, respectively, while the H, O, B, C(2) and F(4) atoms of the anion (Figure 4) lie on a mirror plane. The B−O bond length of 1.447(7) Å falls in the range, 1.432(3)−1.465(3) Å, found for hydroxyborates bearing two boron-bonded trifluoromethyl substituents.[21] In **5** the average B−C bond length, 1.617(6) Å, is in excellent agreement with that found in **2**. While the length determined for the O−H bond, 0.76(7) Å, is obviously too short, the B−O−H angle albeit imprecise seems to be acceptable, 109(5)°. No interionic hydrogen bonding is present since no oxygen or fluorine atom in a neighboring ion lies within 2.50 Å of the hydrogen atom even after extension of the O−H bond to 0.973 Å. The hydrogen atom lies in the plane which bisects the C(1)−B−C(1′) angle. The latter angle, 111.7(6)°, is larger than its C(1)−B−C(2) counterpart, 108.0(3)°. Furthermore, the O−B−C(1) angle, 111.4(3)°, is markedly larger than O−B−C(2), 106.1(4)°. Thus, significant deviations from C_{3v} symmetry are apparent at the boron atom, and although they correlate with the orientation of the hydroxy group, they may well have resulted from packing forces.

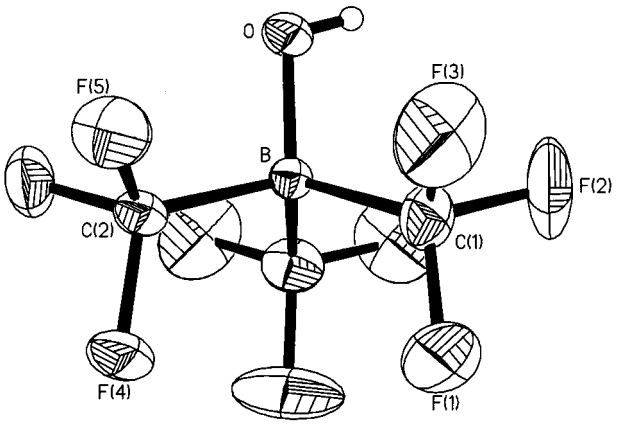

Figure 4. A perspective drawing of the $[(CF_3)_3BOH]^-$ anion with 20% probability thermal ellipsoids for the nonhydrogen atoms

The coordination polyhedra of the cesium cations in **2**−**5** are mostly irregular. The shortest Cs−O and Cs−F contacts are 3.054(9) and 3.049(5) Å, respectively, and most cations form between four and eight contacts shorter than 3.25 Å. If all contacts with oxygen and fluorine atoms which are less than 3.80 Å are counted, then the cation coordination numbers are 12 in **3** and **5** (both cases) and 14 in **2** and **4** (both cases). High coordination numbers imply low bonding strength for the cations,[22] and these weakly acidic centers are apparently well matched to the weakly basic CF_3 donors. The condensation of the coordination polyhedra in **5** is particularly fascinating. First, coordination spheres of the Cs(1) cations are bridged across their O_3 faces to dimers which possess crystallographic C_{3h} symmetry (Figure 5). This bridging gives rise to a Cs−Cs distance [4.616(2) Å], which is shorter than the 5.25 Å value found in the metal. Second, the symmetry of the complexation of the Cs(2) cation is higher (S_6); that is, it is surrounded by two interpenetrating trigonal antiprisms of fluorine atoms. These polyhedra are fused along F_3 faces to form infinite chains of C_3 symmetry parallel to the *c* axis (Figure 6). However, the interactions which bridge the Cs(2) cations [Cs(2)−F(4), 3.518(2) Å] are much longer and weaker than those which link the Cs(1) cations to dimers [Cs(1)−O, 3.182(3) Å]; as a result, the Cs(2)−Cs(2) separations along the chain are much longer, 6.180(2) Å, than the Cs(1)−Cs(1) contacts in the dimers. In addition to the long bridging distances, the other contacts involving the second cation [Cs(2)−F(1), 3.546(6) Å] are also relatively long. Indeed the cavity enclosed by the Cs(2) coordination polyhedron is large enough to allow marked rattling of the cation. Thus, the equivalent isotropic temperature factor of the Cs(2) cation, 0.0881(3) $Å^2$, is much larger than is that of Cs(1), 0.0559 $Å^2$, and is in fact the largest of all cations studied.

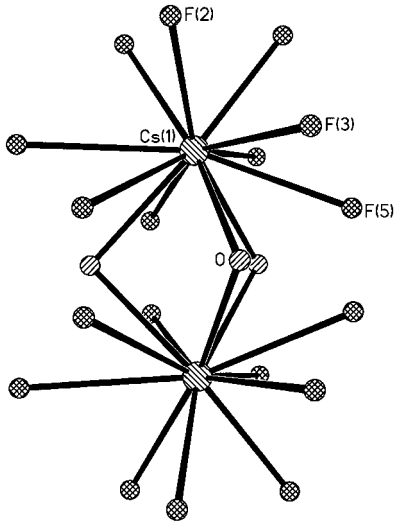

Figure 5. A perspective drawing of a Cs(1) dimer in **5** with atoms not bonded to Cs(1) omitted; selected bond lengths in [Å]: Cs(1)−O 3.182(3), Cs(1)−F(2) 3.131(4), Cs(1)−F(3) 3.599(6), Cs(1)−F(5) 3.440(4)

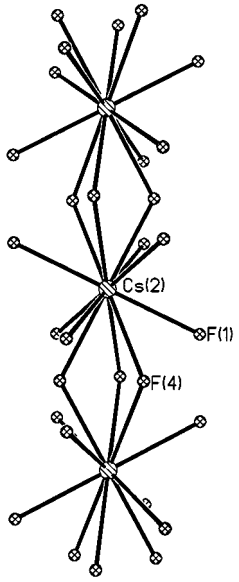

Figure 6. A perspective view of a segment of the infinite Cs(2) chain in **5** with atoms not bonded to Cs(2) omitted; selected distances in [Å]: Cs(2)−F(1) 3.546(6), Cs(2)−F(4) 3.518(2)

Experimental Section

General: NMR: Bruker ARX 400 (400 MHz, 100.6 MHz and 376.5 MHz, for ^1H, ^{13}C and ^{19}F, respectively), Bruker AC 250 (79.8 MHz for ^{11}B). [D_3]acetonitrile as solvent and internal standard ^1H: δ_H = 1.95, ^{13}C: δ_C = 1.30, ^{19}F: external standard $CFCl_3$, ^{11}B: external standard $BF_3 \cdot OEt_2$. − IR: Bruker IFS 25. − Raman: Cary 82 Kr^+ 647.1 nm. − MS: Varian MAT 311 (70 eV). − Thermogravimetry: Mettler TA4000. − Ozone Generator: Fischer 501.

X-ray Crystallographic Studies: Crystals were glued to glass fibers and transferred to a Siemens P3 diffractometer, which was equipped with a graphite monochromator. Intensities were determined from the profiles of the θ-2θ scans and corrected either by integration (**2**, **4** and **5**) or empirically (**3**) for absorption. The structures of **2**, **3** and **5** were solved by direct methods − the hydrogen atom of **5** being located with a difference Fourier synthesis and refined freely. In order to avoid unreasonable geometries for the CF_3 groups of **3**, C_3 restraints were applied to these groups with the C−F bond length and intra-group F···F contact being refined. The heavy-atom method was used to develop the structure of **4** −

the NNO group being disordered over the mirror plane. Treatment of the structure as a pseudo-merohedral twin space group *Cc*, twinning plane (100)] gave comparable final residuals but poor convergence; thus, the disordered model in $Cmc2_1$ will be presented here. The absolute structure parameter for **4**, 0.02(5), implies that the polarity of the *c* axis has been chosen correctly. An extinction correction was only necessary for **3**. The structures were solved, refined and illustrated with the SHELXTL program package. Additional crystal data are given in Table 2. Further details of the crystal-structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-410079, -410078, -410077, and -410076 for **2**, **3**, **4** and **5**, respectively.

Preparation of Compounds: Cesium Tris(trifluoromethyl)nitroborate (2), Cesium Azodioxybis[tris(trifluoromethyl)borate] (3), Cesium Azoxybis[tris(trifluoromethyl)borate] (4), Cesium Tris(trifluoromethyl)hydroxyborate (5): $(CF_3)_3B \cdot NH_3 \times 4\ H_2O$ was prepared from $(CF_3)_3B \cdot NHEt_2$ according to ref.[3] 10 g ($33 \cdot 10^{-3}$ mol) of $(CF_3)_3B \cdot NH_3 \times 4\ H_2O$, 20 g ($61 \cdot 10^{-3}$ mol) of Cs_2CO_3 and 10 g ($60 \cdot 10^{-3}$ mol) of $CsOH \times H_2O$ were dissolved in 300 mL of water. This mixture was electrolyzed at 4.5 V/0.15 A for ca. 2 h using platinum net electrodes (DEGUSSA 303, diameter 35 mm, height 50 mm). Compounds **3** and **4**, which are poorly soluble in water, accumulated at the bottom of the reaction vessel as well as on the anode and were isolated and dried. The electrolysis was then continued until all starting material was consumed as indicated by ^{19}F-NMR spectroscopy. The solution was concentrated and upon cooling in an ice bath most of compound **2** precipitated (plates). After all of **2** had been isolated (ca. 50%), the mother liquor was concentrated in vacuo and the residue stirred with dry acetonitrile. The slurry was filtered, and the filtrate slowly concentrated until **5** crystallized (needles) (ca. 5%).

Separation of 3 and 4: When the mixture of **3** and **4**, dissolved in dry acetonitrile at 20°C, was cooled to −30°C, most of **3** crystallized (ca. 10%). After stripping off the acetonitrile, the residue **4** was recrystallized from methanol/acetone (yield ca. 24%).

Compounds **2** and **5** were formed by oxidation of $(CF_3)_3B \cdot NH_3 \times 4\ H_2O$ or $(CF_3)_3B{\cdot}NHEt_2$ in CsOH solution in a flow of ozone/oxygen in a ratio of 7:2. In a typical experiment $20 \cdot 10^{-3}$ mol of reactant was mixed with 50 mL 25% CsOH solution and a flow of ozone/oxygen (ca. 2 g O_3/h) was introduced into the stirred reaction mixture at 20°C through a Teflon PFA tube. The progress of the reaction was monitored by running ^{19}F-NMR spectra from the solution. In case of $(CF_3)_3B \cdot NHEt_2$, which is only slightly soluble in CsOH solution, the reaction was stopped when a clear solution was obtained. Work-up and separation as described above yielded ca. 65% of **2**. − **2:** $C_3BCsF_9NO_2$ (396.74): calcd. C 9.08, N 3.53; found C 9.0 N, 3.8. − **3:** $C_6B_2Cs_2F_{18}N_2O_2$ (761.48): calcd. C 9.46, N 3.68, F 44.91; found C 9.4, N 3.6, F 46.4. − **4:** $C_6B_2Cs_2F_{18}N_2O$ (745.48): calcd. C 9.67, N 3.76, F 45.87; found C 9.6, N 3.6, F 44.4. − **5:** C_3HBCsF_9O (367.74): calcd. C 9.80, H 0.27; found C 9.3, H 0.3.

Protonation of 2 and 5: To a stirred suspension of $12 \cdot 10^{-3}$ mol (4 g) of **2** in 20 mL of diethyl ether, 5 mL of 1 M ethereal HCl was added dropwise at 20°C. The reaction mixture was stirred for 20 min and the CsCl formed removed by filtration in air. Ether and HCl were removed in vacuo at 0.1 mbar/20°C and **2a** was purified by repeated sublimation at 60°C/10^{-2} mbar, yield 2.7 g (85%). Compound **5** was analogously protonated to yield 88% of **5a**. − MS (70 eV); *m/z*(%): **2a:** 99 (100) [CBF_4^+], 69 (78) [CF_3^+], 81 (36) [$C_2F_3^+$], 47 (13) [HNO_2^+], 246 (11) [$M^+ - F$]; **5a:** 66 (100) [F_2BOH^+], 46 (57) [FBO^+], 96 (20) [CF_3BO^+], 108 (16) [$C_2F_3BO^+$], 216 (16) [$M^+ - HF$]. − IR film: **2a**: $\tilde{\nu}$ = 3669 cm^{-1} (OH), 1624

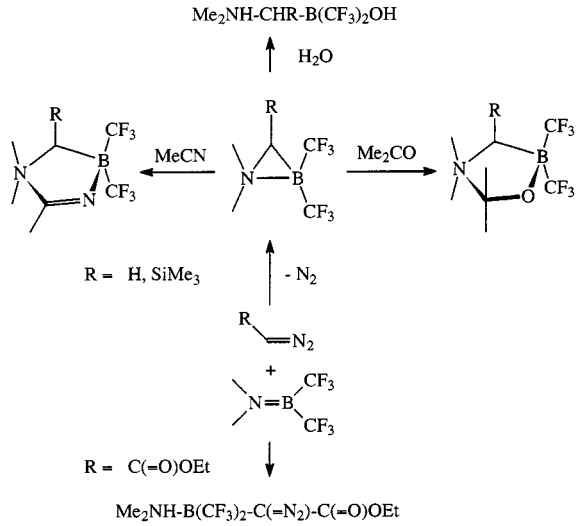
New Azoniaboratacyclopropanes from $(F_3C)_2BNMe_2$ and Diazomethane Derivatives – Structure of *cyclo*-$(F_3C)_2B–CPh_2–NMe_2$ and $HOB(CF_3)_2–CHC_6F_5–NHMe_2$

David J. Brauer,[a] Hans Bürger,*[a] Silke Buchheim-Spiegel,[a] and Gottfried Pawelke[a]

Dedicated to Professor H. D. Lutz on the occasion of his 65th birthday



Keywords: Boron / Small rings / Trifluoromethyl group / Crystal structure

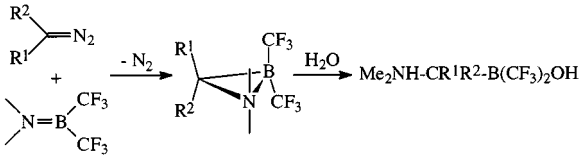
1,1-Dimethyl-2,2-bis(trifluoromethyl)azoniaboratacyclopropanes, *cyclo*-$(F_3C)_2B–CR^1R^2–NMe_2$ [$R^1 = R^2 = C_6H_5$ (**2a**); $R^1/R^2 = C_{12}H_8$ (**2b**); R^1 = H, $R^2 = C_6H_5$ (**2c**), 4-FC_6H_4 (**2d**), 3-FC_6H_4 (**2e**), 2-FC_6H_4 (**2f**), C_6F_5 (**2g**), *i*Pr (**2h**), *t*Bu (**2i**); R^1 = Me, R^2 = C(=O)OMe (**2j**), C(=O)OEt (**2k**)] have been obtained from $(F_3C)_2BNMe_2$ (**1**) and diazomethanes $R^1R^2CN_2$. In contrast to compound **2a**, the B–N bonds of **2b**–**2k** hydrolyze to form the zwitterionic species $Me_2NH–CR^1R^2–B(CF_3)_2OH$ (**3b**–**3k**). The diazoacetic acid esters $HC(N_2)C(=O)OMe$ and $HC(N_2)C(=O)OtBu$ react with **1** to form three-membered rings, which hydrolyze rapidly to form $Me_2NH–CR^1R^2–B(CF_3)_2OH$ [R^1 = H, R^2 = C(=O)OMe (**3l**), C(=O)O*t*Bu (**3m**)]. F_3CSiF_3 reacts under elimination of CF_2 with **1** to form the acyclic derivative $(F_3C)_2BF–CF=NMe_2$ (**4**). The structures of **2a** and **3g** have been investigated crystallographically. A nearly eclipsed conformation is found for the central B–C bond of **3g**, which is 0.097(7) Å longer than the B–C bond length in the three-membered ring of **2a**.

(Dimethylamino)bis(trifluoromethyl)borane, $(F_3C)_2BNMe_2$ (**1**), possesses chemical properties that are unique in aminoborane chemistry.[1] Owing to a balance of pronounced electrophilic character and steric protection of the boron atom, the reactivity of its strong B=N bond bears a degree of resemblance to an olefinic C=C bond. On the other hand its polarity is related to that of a C=N bond in a dimethyliminium cation. In a preceding paper we reported on reactions of diazomethane derivatives with **1**.[2] While diazomethane itself, trimethylsilyldiazomethane and trimethylsilyl(benzyl)diazomethane formed novel heterocyclopropane derivatives, diazoacetic acid ethyl ester underwent an ene-type reaction to form an extraordinary stable, borylated diazomethane species (Scheme 1). In contrast to the B−N bond in dimethylamine−bis(trifluoromethyl)boranes, $R(F_3C)_2B \cdot NMe_2H$, which is not only stable to dissociation but also to displacement reactions at room temperature, the B−N bond in the azoniaboratacyclopropanes, which are formed from reactions of **1** with diazomethane or trimethylsilydiazomethane, is rather reactive.

Thus, water cleaves their B−N bonds to form $Me_2NH–CHR–B(CF_3)_2OH$ while nitriles like H_3CCN or carbonyl compounds like acetone insert into the B−N bond to yield the five-membered heterocycles *cyclo*-$Me_2N–CHR–B(CF_3)_2N=CMe$ and *cyclo*-$Me_2N–CHR–B(CF_3)_2O–CMe_2$, respectively.[3] On the other hand *cyclo*-$(F_3C)_2B–C(SiMe_3)(CH_2C_6H_5)–NMe_2$ was far less reactive than the other three-membered rings.

The reasons for the varying reactivity were not fully understood, and there were questions left unanswered: (1) What is the influence of the substituents R^1 and R^2 on the formation, reactivity and stability of azoniaboratacyclopropanes? (2) Can other potential carbene sources (e. g., F_3CSiF_3) be used to form such three-membered rings? (3) Will diazoacetic acid esters other than $HC(N_2)C(=O)OEt$ also enter into ene-type reactions or will they form three-membered rings? Here we report on our results.

Scheme 1. Diazomethane derivatives and (dimethylamino)bis(trifluoromethyl)borane



Results

The reactivity of compound **1** towards many solvents and reagents prohibits in situ generation of diazomethanes. Furthermore the diazomethanes must be accessible as neat ma-

terial in high purity. These demands limit the number of possible candidates to a small number of stable, isolable diazomethanes. Of these candidates, $R^1R^2CN_2$, those with R^1 and R^2 as defined in Scheme 2 were prepared and dissolved in dry pentane. Compound **1** was condensed onto these frozen solutions at −196°C. Upon warming decolorization and evolution of nitrogen was observed as soon as **1** melted and mixed with the diazomethane solutions.

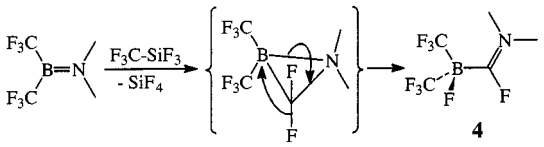
	H	C(=O)O*t*-Bu	**3m**

Scheme 2. Formation of azoniaboratacyclopropanes and hydrolytic cleavage of their B−N bond



All of the investigated diazomethanes act as carbene sources, and though their reactivity towards **1** varied, no competing reactions were observed. The relatively stable diphenyldiazomethane and fluorenyldiazomethane react less rapidly than the less stable phenyl and alkyldiazomethanes. On the other hand trifluoromethyldiazomethane, F_3CHCN_2, did not react with **1**.

While $HC(N_2)COOEt$ undergoes an ene-type reaction with **1**, the corresponding diazoacetic acid esters $HC(N_2)COOMe$ and $HC(N_2)COOtBu$ reacted differently − three-membered rings were formed with elimination of N_2. Due to their sensitivity towards water, these ring compounds were not isolated in a pure state and therefore are missing in the list of Scheme 2. However, their hydrolysis products **3l** and **3m** were obtained in high yields.

The reactivity of **2a**−**2k** was tested by reaction with water (Scheme 2). Except for compound **2a** all of the three-membered rings hydrolyze within minutes to form the zwitterionic species **3b**−**3m**. Because neat $F_2C{=}N_2$ is difficult to prepare and because all of the diazomethanes tested here reacted as carbene sources, we were interested in testing the reactivity of a suitable difluorocarbene source with compound **1**. Such a difluorocarbene source is trifluoro(trifluoromethyl)silane, F_3CSiF_3, which is known to decompose at 30°C according to Equation 1.[4]

$$F_3C\text{-}SiF_3 \rightarrow \{CF_2\} + SiF_4 \quad (1)$$

Indeed trifluoro(trifluoromethyl)silane reacts rapidly with **1** at −60°C; however, instead of the expected three-membered ring, the acyclic isomer $(F_3C)_2BF{-}CF{=}NMe_2$ (**4**) was obtained (Scheme 3). We assume that difluorocarbene adds primarily to the B=N bond of **1**; however, the three-membered ring is unstable and rearranges by a 1,2-dyotropic shift to form **4**.

Scheme 3. Difluorocarbene and (dimethylamino)bis(trifluoromethyl)borane

Properties and Spectra

Compounds **2a**−**4** are colorless solids. Except for compound **2a** the three-membered heterocycles **2b**−**2k** are sensitive to moisture − their B−N bond being cleaved. At first it is surprising that **2a** is stable to water whereas **2b** hydrolyses readily. In both species two phenyl rings are bonded to the ring carbon atom. However, electronically both groups in the ring are different. Heterolytic breaking of the C−N bond in **2a** and **2b** would generate either a borylated diphenylmethyl (**2a**) or a borylated fluorenyl cation (**2b**). If it is accepted that the diphenylmethyl cation is more stable than the fluorenyl cation and that this is also true for a borylated species, then the $C_{13}H_8$ substituent attracts more electron density from the B−N bond in **2b** than the $C(C_6H_5)_2$ group does in **2a**. Thus, the B−N bond in **2b** is more polar than in **2a** and hence more reactive towards water.

The ^{1}H-, ^{19}F-, ^{11}B- and ^{13}C-NMR spectra of **2a**−**4** were recorded. The shift data which are set out in Table 1 are consistent with the proposed structures, and only a few comments will be necessary. The ^{13}C resonances of the CF_3 groups in **2a**−**2k** are not detectable due to quadrupolar broadening by the boron atom. In **3b**−**4** they appear as extremely broadened signals. Therefore these resonances are not included in Table 1. Compounds **2c**−**2k** and **3c**−**3m** have an asymmetric carbon atom which causes a splitting of the NMR signals of both the $N(CH_3)_2$ and $B(CF_3)_2$ groups. For compound **3g** five ^{19}F and five ^{13}C resonances are found for the pentafluorophenyl ring. This splitting is due to hindered rotation of the ring relative to the NMR time scale which was confirmed by recording the NMR spectra at different temperatures. While **2a**−**2k** show only broad signals for the ring carbon atoms, in the zwitterions **3b**−**3m** the ^{13}C resonances of these carbon atoms appear as 1:1:1:1 quadruplets with ^1J(BC) = 42−51 Hz. The ^{19}F chemical shift of the boron-bonded fluorine atom in **4** occurs at unusually high field, δ = −220.9. This shift is larger than that for $Mes(F_3C)BF{-}CF{=}NMe_2$ [δ(B*F*) = −202.7][5]

which was previously believed to be the upper limit for a fluorine bonded directly to boron.

EI mass-spectral data are set out in Table 2. M^+ peaks are generally weak, but the fragments [$M^+ - CF_3$] and [$M^+ - C_2F_5$] give reliable indications of the molecular mass. The base peak of the three-membered rings **2c**−**2h** is [$(CH_3)_2NCHR^+$], which is less prominent in **2i** due to the instability of the *t*Bu group. In the corresponding hydrolyzed products **3c**−**3h** the fragment [CH_3NHCHR^+] is in general the base peak.

Description of the Crystal Structures of 2a and 3g

The structure of **2a** is shown in Figure 1. The three-membered ring defines a non-crystallographic mirror plane, which is obeyed by the exocyclic bonds to within experimental error and is followed by the angles and the magnitude of the torsion angles to within 4°. The phenyl groups are oriented parallel to the B−N bond and are thus not capable of conjugation with the tangential Walsh ring orbitals.[6]

Several features of the ring geometry deserve comment. Firstly, the B−N bond length [1.568(6) Å] is clearly shorter than those reported between quaternary nitrogen atoms and $(F_3C)_2B$ entities in four-, five- and six-membered rings − all of which exceed 1.61 Å.[7−9] Secondly, the N−C(1) linkage [1.556(5) Å] is markedly longer than the N−CH_3 bonds [av. 1.484(5) Å], but examples of long bonds between quaternary nitrogen and carbon atoms have been registered in five-membered heterocycles involving the $(F_3C)_2B$ group such as *cyclo*-$(F_3C)_2B-NMe_2-CMe_2-S(=O)-O$ [1.543(3) Å[8]] and *cyclo*-$(F_3C)_2B-CH(SiMe_3)-NMe_2-CMe_2-O$ [1.582(4) Å[3]]. In this connection we note that the B−C, B−N and N−C(1) [1.556(5) Å] bond lengths in **2a** agree to within experimental error with the values [1.595(5), 1.560(5) and 1.567(4) Å] found for the corresponding linkages in *cyclo*-$(F_3C)_2B-C(SiMe_3)(CH_2C_6H_5)-NMe_2$ (**5**).[2] Thirdly, the exocyclic substituent planes of the B and C(1) atoms do not bisect the N−B−C(1) and B−C(1)−N angles, respectively, but rather are pivoted away from the bisecting positions by 8.8(5)° and 9.7(5)°, respectively, towards the NMe_2 group. A similar distortion was found in **5**. Fourthly, the bond angles defined at the ring atoms by their two exocyclic substituents average 109.1(8)°, which is similar to the 108.0(3)° value found in **5**. These angles seem small in view of the relatively high s character ascribed to the hybrid orbitals used by a cyclopropyl ring atom in its exocyclic bonds.[10]

A drawing of **3g** is given in Figure 2. The nearly eclipsed conformation about the B−C(3) bond and its great length,

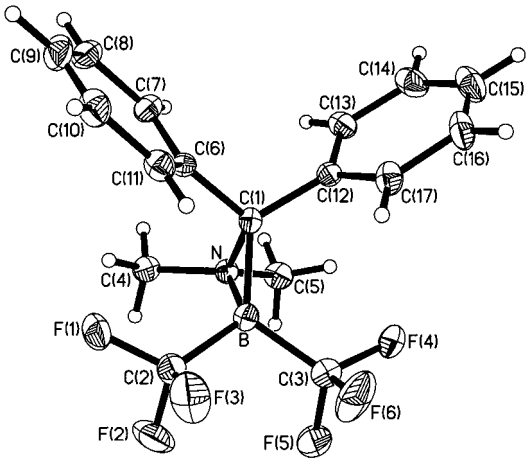

Figure 1. A perspective drawing of **2a**

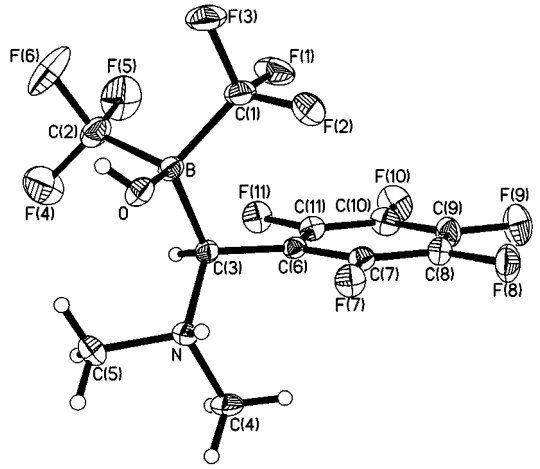
1.683(4) Å, are reminiscent of the structures reported previously for $B(CF_3)_2(OH)CH(Ph)NH(Bz)(tBu)$ (**6**)[11] and $B(CF_3)_2(OH)CH(SiMe_3)NHMe_2$ (**7**)[3] − the corresponding B−C bond lengths being 1.673(4) and 1.690(4) Å, respectively. Each compound exhibits a synperiplanar O−B−C(3)−N torsion angle − their values of 20.3(5)° and 19.6(5)° in **6** and **7**, respectively, being significantly larger than in **3g**, 11.6(3)°. While the conformation in **6** and **7** is stabilized by moderately strong intramolecular N−H···O hydrogen bonds of 1.88(2) and 1.82(3) Å, respectively, the corresponding distance in **3g**, 2.41(3) Å, is too long to be bonding. Here the nitrogen atom donates its proton to an oxygen atom of an inversion-related molecule, 2.03(3) Å; thus, centrosymmetric, hydrogen-bonded dimers are formed in the solid state. Perhaps the absence of intramolecular hydrogen bonding in **3g** accounts for its O−B−C(3) and B−C(3)−N angles [110.2(2)° and 111.4(2)°, respectively] being on the average 5(1)° larger than the analogous angles of **6** and **7**.

Because hindered rotation was detected by NMR spectroscopy for the C_6F_5 group, we note that the aryl group in **3g** is oriented roughly parallel to the C(3)−H(3) bond − the H(3)−C(3)−C(6)−C(11) torsion angle being 17(2)°. A similar orientation was found for the corresponding phenyl substituent of **6**. In **3g** the aryl group protrudes into a cavity



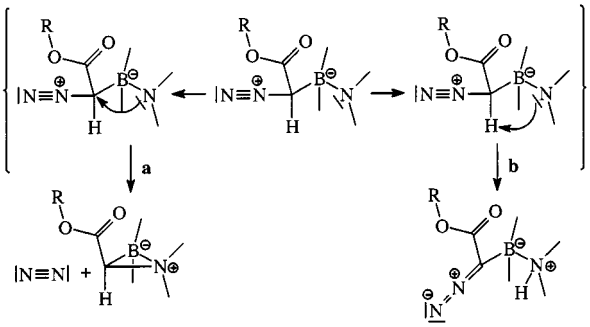


Figure. 2. A perspective drawing of **3g**

in which the CH_3 group of C(4) and the CF_3 group of C(1) are on opposites sides of the ring plane.

Discussion

The divergent behavior of the three diazoacetic acid esters $HC(N_2)COOR$ (R = *t*Bu, Et and Me) is not fully understood. The acetic acid esters H_3CCOOR with R = *t*Bu, Et undergo an ene-type reaction with **1** regardless of their substituent R. Therefore we speculate that the mechanism which leads to ene-type products of acetic acid esters and the diazoacetic acid ethyl ester are different. The reaction of all diazomethane derivatives with **1** is obviously initiated by a nucleophilic attack of boron at the diazo carbon atom (Scheme 4). The transient complex thus formed has two ways to gain stabilization. In pathway **a** the nitrogen lone pair attacks the diazomethane carbon atom, dinitrogen is eliminated and the three-membered ring is fused. In pathway **b** the lone pair abstracts a proton bonded to the diazomethane carbon atom − the diazo group being preserved.

Scheme 4. Formation of azoniaboratecyclopropanes and ene-type reaction products with **1** and diazomethane derivatives

A small conformational change in the transition complex, as determined by the N−B−C−H torsional angle, is presumably responsible for the formation of azoniaboratacyclopropanes (route **a**) or ene-products (route **b**). The conformation about the B−C bond should be affected by the varying shape of the groups R [R = Me, *t*Bu (C_3 symmetry) and R = Et (C_s symmetry)], and the conformation governs the distances between the lone pair, the carbon atom and the hydrogen atom and thus the reaction pathway. Route **b** is, however, also dependent on the acidity of the abstracted proton. Therefore this route is only observed for diazocarbonyl derivatives.

The failure to synthesize the three-membered ring *cyclo*-$(F_3C)_2B-CF_2-NMe_2$ animated us to compare the difference in its calculated energy and that of **4** to the analogous difference of *cyclo*-$(F_3C)_2B-CH_2-NMe_2$ versus $(F_3C)_2BH-CH=NMe_2$. According to semi-empirical AM1 calculations the energy of *cyclo*-$(F_3C)_2B-CH_2-NMe_2$ is ca. 2 kcal/mol lower than that of $(F_3C)_2BH-CH=NMe_2$ while **4** is ca. 30 kcal/mol more stable than *cyclo*-$(F_3C)_2B-CF_2-NMe_2$

Experimental Section

General: NMR: Bruker ARX 400 (400 MHz, 100.6 MHz and 376.5 MHz, for ^1H, ^{13}C and ^{19}F respectively), Bruker AC 250 (79.8 MHz for ^{11}B). [D_3]Acetonitrile as solvent and internal standard (^1H: $\delta_H = 1.95$; ^{13}C: $\delta_C = 1.30$), $CDCl_3$ as solvent and internal standard (^1H: $\delta_H = 7.27$; ^{13}C: $\delta_C = 77.0$), [D_6]acetone as solvent and internal standard (^1H: $\delta_H = 2.05$; ^{13}C: $\delta_C = 29.8$), CD_2Cl_2 as solvent and internal standard (^1H: $\delta_H = 5.35$; ^{13}C: $\delta_C = 53.8$), ^{19}F external standard $CFCl_3$, ^{11}B external standard $BF_3 \cdot OEt_2$. − IR: Bruker IFS 25. − MS: Varian MAT 311 (70 eV).

X-ray Structure Determinations: Crystals of **2a** and **3g** were grown from solutions in $CHCl_3$ and acetone/H_2O, respectively. While crystals of **2a** were sealed in glass capillaries under nitrogen, those of **3g** were glued to glass fibers. The structures were solved and refined using absorption-corrected X-ray data with the SHELXTL program package.[12] While the H(N) and H(O) atoms of **3g** were refined freely, the positions of all other hydrogen atoms were idealized. Crystal data are summarized in Table 3. Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102694 for **2a** and -102695 for **3g**. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44(1223)336-033; E-mail: deposit@ccdc.cam.ac.uk].

1,1-Dimethyl-3,3-diphenyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2a), 3-Fluorenyl-1,1-dimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2b), 1,1-Dimethyl-3-phenyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2c), 3-(4-Fluorophenyl)-1,1-dimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2d), 3-(3-Fluorophenyl)-1,1-dimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2e), 3-(2-Fluorophenyl)-1,1-dimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2f), 1,1-Dimethyl-3-(pentafluorophenyl)-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2g), 3-Isopropyl-1,1-dimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2h), 3-*tert*-Butyl-1,1-dimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2i), 3-(Methoxycarbonyl)-1,1,3-trimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2j), 3-(Ethoxycarbonyl)-1,1,3-trimethyl-2,2-bis(trifluoromethyl)-1-azonia-2-boratacyclopropane (2k). − General Procedure: 10×10^{-3} mol of the respective neat diazomethane (Scheme 2) and 10−15 ml of pentane (stored over P_4O_{10}) were condensed at −196°C into a U-shaped reaction vessel connected to a vacuum line. By warming the vessel, pentane and the diazomethane were mixed. The vessel was cooled

again to −196°C and 2 g (11 × 10^{-3} mol) of $(F_3C)_2BNMe_2$ and ca 10 ml of pentane were condensed onto the diazomethane/pentane mixture. The reaction vessel was gassed with dry nitrogen and allowed to warm to room temperature under stirring. After 10 min at 20°C, all volatile material was removed in vacuo. According to NMR spectra the reaction was quantitative and the products were analytically pure.

3-Fluorenyl-5,5,5-trifluoro-4-hydroxy-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3b), 5,5,5-Trifluoro-4-hydroxy-2-methyl-3-phenyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3c), 5,5,5-Trifluoro-3-(4-fluorophenyl)-4-hydroxy-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3d), 5,5,5-Trifluoro-3-(3-fluorophenyl)-4-hydroxy-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3e), 5,5,5-Trifluoro-3-(2-fluorophenyl)-4-hydroxy-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3f), 5,5,5-Trifluoro-4-hydroxy-2-methyl-3-(pentafluorophenyl)-4-(trifluoromethyl)-2-azonia-4-boratapentane (3g), 5,5,5-Trifluoro-4-hydroxy-3-isopropyl-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3h), 3-*tert*-Butyl-5,5,5-trifluoro-4-hydroxy-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3i), 5,5,5-Trifluoro-4-hydroxy-3-(methoxycarbonyl)-2,3-dimethyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3j), 3-(Ethoxycarbonyl)-5,5,5-trifluoro-4-hydroxy-2,3-dimethyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3k), 5,5,5-Trifluoro-4-hydroxy-3-(methoxycarbonyl)-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3l), 3-(*tert*-Butoxycarbonyl)-5,5,5-trifluoro-4-hydroxy-2-methyl-4-(trifluoromethyl)-2-azonia-4-boratapentane (3m). − General Procedure: A solution (3 × 10^{-3} mol) of the corresponding azoniaboratacyclopropane in 10 ml of CH_2Cl_2 was stirred with 20 × 10^{-3} mol of H_2O for 12 h at ambient temperature. After removal of the solvent and the water in vacuo, pure **3b**−**3m** were obtained in quantitative yield.

3b: M.p. 160°C. − IR: $\tilde{\nu}$ = 3636 cm^{-1} (OH), 3270 (NH), 1078 (CF).

3c: M.p. 96°C. − IR: $\tilde{\nu}$ = 3638 cm^{-1} (OH), 3278 (NH), 1107, 1083 (CF).

Square-Planar and Octahedral Nickel(II) Complexes of Isomeric *cis*-2,9-Bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecanes

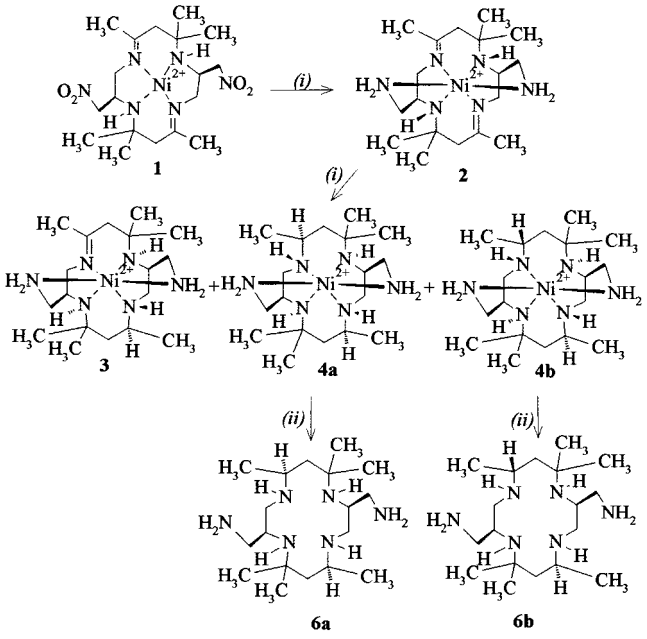
Bohdan Korybut-Daszkiewicz,*[a] Przemysław Gluziński,[a] Janusz Krajewski,[a] Andrejas Kemme,[b] and Anatolij Mishnev[b]

Keywords: Macrocyclic ligands / N ligands / Nickel complexes

Isomeric *cis*-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecanes (**6a** and **6b**) and their octahedral (**4**) and square-planar nickel(II) complexes (**5**) have been prepared and characterized. X-ray crystallographic investigations of the octahedral complexes have confirmed a folded conformation of the macrocyclic ring. Protonation of the pendant amino groups results in a change in the Ni configuration, which is accompanied by a concomitant change of the macrocycle conformation from a folded to a planar one. The structures of the protonated, square-planar complexes and of the free ligands have been established mainly on the basis of their ^{1}H- and ^{13}C-NMR spectra.

Introduction

Tetraaza macrocyclic ligands functionalized with pendant donor groups form diamagnetic square-planar nickel(II) complexes when the donor groups are protonated and cannot coordinate, whereas at higher pH coordination of the pendant donors leads to paramagnetic, octahedral complexes.[1,2] In the case of monosubstituted ligands, coordination of the pendant donor occurs at one of the axial sites, and the second axial site is occupied by an anion or solvent molecule.[3,4] Pendant methylnitronato[5] or carboxylate[6] groups, by virtue of their ability to offer two possible donor oxygen atoms, may also fill this coordination site and act as a bridge between nickel(II) ions forming one-dimensional polymers.



Nickel(II) complexes of cyclam derivatives substituted with two pendant amino groups are subject to similar pH-dependent equilibria. *trans*-Substituted ligands form octahedral complexes, with the nitrogen atoms of the macrocycle occupying an equatorial plane and the pendant groups in axial positions.[7–9] However, coordination of both pendant groups in the case of *cis*-substituted cyclam derivatives requires folding of the macrocycle conformation. Such folding occurs upon coordination of the pendant amino groups in *cis*-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene nickel(II) diperchlorate (**2**).[8] Hydrogenation of complex **2** gave two violet nickel(II) complexes of isomeric *cis*-2,9-bis(aminomethyl)-substituted cyclam derivatives, **4a** and **4b**. Crystallographic data for these two octahedral nickel(II) complexes, as well as the spectroscopic characterization of their diamagnetic square-planar protonation products and free ligands, are described in the present paper.

Results and Discussion

Synthesis

The synthesis of the isomeric complexes **4a**, **4b** and the free ligands **6a**, **6b** is outlined in Scheme 1.

Scheme 1. Reagents: (*i*) zinc amalgam and HCl; (*ii*) NaCN in water under reflux

Reduction of the nitro groups in the *cis*-2,9-bis(nitromethyl)-substituted complex **1**, followed by hydrogenation of the C=N double bonds with zinc amalgam and hydrochloric acid led to the isomeric 2,9-bis(aminomethyl)-substituted Ni complexes **4a**, **4b** and the intermediate product **3**. Work-up of the mixture after a shorter reaction time allowed isolation of the previously described, unsaturated complex **2**. The use of zinc amalgam in place of the zinc dust used in published procedures[9,10] proved advantageous

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434–1948/99/0202–0263 $ 17.50+.50/0

since the degree of decomposition accompanying reduction of the nitro groups was lower. The two isomeric, fully saturated, octahedral Ni^{II} complexes were separated by chromatography on an SP Sephadex C-25 column and were isolated in the form of their diperchlorate salts **4a** and **4b**.

Upon acidification with 72% perchloric acid, violet nitromethane solutions of complexes **4a** and **4b** gave deep-red and orange solutions of the square-planar tetraperchlorates **5aα** and **5b**, respectively, with protonated pendant arms. Complexes **5aα** and **5b** were found to readily undergo isomerization in protic solvents and thus they were characterized only in nitromethane solution. *N*-Isomeric **β** and **γ** forms of complex **5a** were isolated in solid form, but only an oily mixture of isomers was precipitated upon addition of diethyl ether to an ethanolic solution of complex **5b**.

Demetallation of **4a** and **4b** in aqueous solution using an excess of sodium cyanide gave the free ligands **6a** and **6b**.

Crystal Structures of 4a and 4b

Selected bond lengths and valence angles in cations **4a** and **4b**, as shown in Figures 1 and 2, are listed in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] for cations **4a** and **4b**

Both cations have an irregular octahedral Ni^{II} coordination sphere with the macrocycle coordinated in a folded conformation, with fold angles (N1−Ni−N8) of 106° and 101° in **4a** and **4b**, respectively. All N−Ni−N angles in the five-membered chelate rings are rather small (79−83°). The angles in the six-membered chelate rings incorporating the macrocyclic nitrogen atoms are large (95−98°), while those incorporating the aminomethyl pendant arms are small (84−87°). The Ni−N distances fall in the range typical for octahedral coordination (2.10−2.14 Å for **4a**; 2.08−2.13 Å for **4b**).

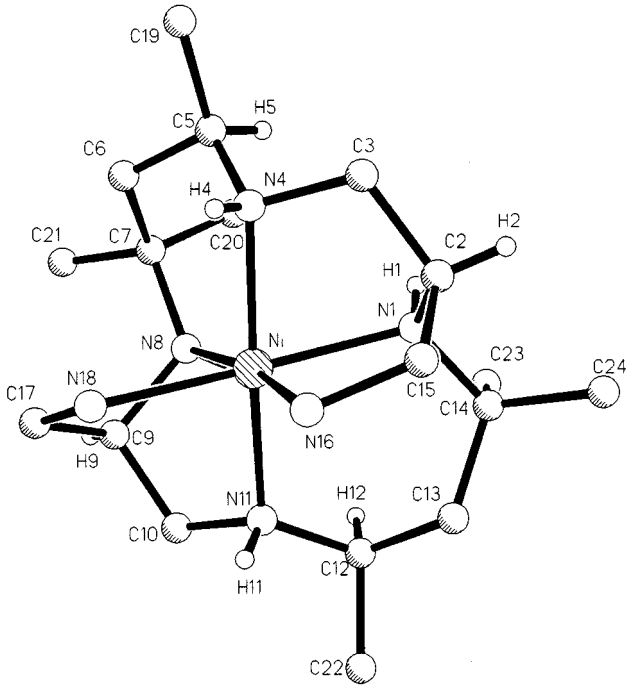

Figure 1. Molecular structure together with atomic labelling for cation **4a**

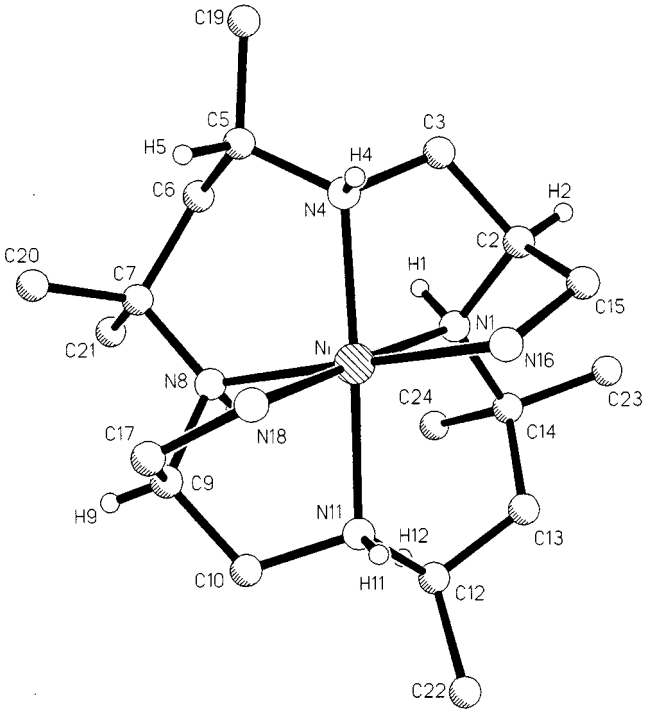

Figure 2. Molecular structure together with atomic labelling for cation **4b**

The shape and symmetry of any given ring is precisely described by its set of endocyclic torsion angles (ETAs) and

the sequence of their signs.[11] The ETAs of complexes **4a** and **4b** are collected in Table 2, together with the appropriate *n*-butane conformational codes.

The folded macrocycle of cation **4a** has C_2 symmetry and its conformation according to Boeyens notation[12] can be assigned as type V [3434]. The macrocycle forms two five-membered chelate rings in E_2 (*envelope*) and two six-membered rings in ^4E (*sofa*) conformation. In the isomeric cation **4b**, both of the endomacrocyclic five-membered rings and one of the six-membered chelate rings adopt similar E_2 (*envelope*) and ^4E (*sofa*) conformations, respectively. The second six-membered ring [N(4)−N(8)] adopts a $^3H_4$ (*half-chair*) conformation and the folded cyclam macrocycle assumes a type V [21434] form.

The 5,12-dimethyl and 2,9-bis(aminomethyl) substituents in isomer **4a** are located on the same side of the macrocyclic ring and the relative configuration of the chiral N and C atoms, according to Cahn−Ingold−Prelog rules,[13] is assigned as (1*R*2*S*4*R*5*S*8*R*9*S*11*R*). The methyl group attached to C-5 in cation **4b** is located on the opposite side of the macrocycle and the configuration of this isomer is assigned as (1*R*2*S*4*R*5*R*8*R*9*S*11*R*). The 5,12-dimethyl groups assume *equatorial* positions and the coordinated pendant arms are *axially* arranged in both isomeric complexes.

Structures of Square-Planar Complexes 5

The structures of the free ligands and of the diamagnetic complexes were established mainly on the basis of their ^{13}C- and ^{1}H-NMR spectra (Tables 3 and 4).

Under acidic conditions in nitromethane solution, the amino groups on the side-chains of complexes **3**, **4a** and **4b** are protonated, leaving the Ni^{II} ions in a square-planar configuration. This change in the Ni^{II} configuration is accompanied by a concomitant change in the conformation of the macrocycle from a folded to a planar one. However, the secondary nitrogen atoms in the ring retain their configurations in the course of this process. This can clearly be seen in the ^{1}H-NMR spectra of protonated complex **5aα** and its *N*-isomeric forms (**5aβ** and **5aγ**), most notably in the chemical shifts of the 7- and 14-geminal methyl substituent signals (Table 4).

The conformations of the methyl groups and of the six-membered chelate rings can be assigned on the basis of the known deshielding effects observed for axially oriented substituents in the ^{1}H-NMR spectra of square-planar macrocyclic Ni^{II} complexes.[14−17] The 5,12-dimethyl groups retain an *equatorial* arrangement in all the isomeric **5aα**, **5aβ** and **5aγ** complexes (Scheme 2).

The geminal 7,14-dimethyl groups in complex **5aα**, due to the non-chair conformation of the six-membered chelate

Scheme 2. Isomerization pathway and configurations of square-planar complexes **5a**

rings, resonate at almost the same frequency. This indicates that the macrocycle in **5aα** retains a type-V conformation. The inversion at N(1) causes a switch in the N(1)−N(11) six-membered chelate-ring conformation to the chair form. This is reflected in the large separation of *axial* and *equatorial* 14-methyl group signals in the spectrum of **5aβ** and indicates a type-II conformation of the macrocycle. The second isomerization, caused by inversion at N(8), followed by conformational change in the second six-membered ring, results in formation of the cation **5aγ**. The macrocycle in **5aγ** adopts a type-I conformation, with all secondary amino protons and substituents in 2,5,9,12-positions on the same side of the ring.

Addition of perchloric acid to a nitromethane solution of the octahedral complex **4b** results in the formation of an orange square-planar complex, **5b**. The chemical shifts of the geminal methyl groups indicate a non-chair conformation of both six-membered chelate rings and a type-V conformation of the macrocycle. This complex also undergoes isomerization upon addition of protic solvents, but attempts to isolate and characterize the individual species as solids were not successful.

Electronic spectra in nitromethane solution, acidified with perchloric acid, show d−d transition bands at 506 nm (ε = 188) and 476 nm (ε = 122) for **5aα** and **5b**, respectively. The wavelengths of the bands are substantially longer and the molar absorption coefficients are higher than typically observed for Ni^{II} complexes of cyclam derivatives ($\lambda_{max} \approx$ 450 nm, ε ≈ 80).[18] This indicates strong distortion of the square-planar $Ni^{II}N_4$ geometry,[19] especially in the case of isomer **5aα**, which has six substituents on the same side of the macrocyclic ring. After isomerization, the less strained complex **5aβ** absorbs at 462 nm and the most stable cation **5aγ** at 454 nm, close to the usual wavelength for Ni^{II} square-planar complexes.

Conclusion

In Ni^{II} complexes of *cis*-2,9-bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecanes, coordination of the two pendant amino groups located on the same side of the tetraaza macrocyclic ring forces the ring to adopt a folded conformation. Protonation of the pendant donor groups by perchloric acid in nitromethane solution is accompanied by a concomitant return of the macrocycle to a preferred planar arrangement around the central Ni^{II} ion. Steric crowding in **5aα** and **5b**,

as well as the unusual type-V conformation of the cyclam ring, leads to severe distortion of the square-planar geometry and to weakening of the ligand field. In the presence of protic solvents, consecutive inversions at chiral nitrogen atoms, accompanied by conversion of the macrocyclic ring conformation, lead to the more stable isomers **5aβ** and **5aγ**.

Experimental Section

General Remarks: IR spectra (paraffin oil mulls) were recorded with a Perkin-Elmer 1600 FT-IR spectrometer. NMR spectra were obtained with a Bruker AM 500 spectrometer using TMS as internal standard. Electronic spectra were recorded using a Cary 1E UV/Vis spectrophotometer and mass spectra with an AMD 604 spectrometer.

Synthesis: ***Caution! Perchlorate salts are potentially explosive!*** Preparation of complex **1** and its reduction with zinc dust and hydrochloric acid has been described previously.[8−10] Zinc amalgam was prepared according to the standard procedure.[20] Hydrochloric acid, perchloric acid, and solvents were commercial materials and were used without further purification.

Reduction of [5,7,7,12,14,14-Hexamethyl-2,9-*cis*-bis(nitromethyl)-1,4,8,11-tetraazacyclotetradeca-4,11-diene]nickel(II) Diperchlorate (1): Concentrated hydrochloric acid (75 mL) was added dropwise to a vigorously stirred mixture of zinc amalgam (25 g) and complex **1** (35 g) in a 1:1 water/methanol solution (400 mL), while the temperature was maintained below 20°C. After 24 h, the mixture was filtered, the filtrate was diluted with water (400 mL) and applied to a Dowex 50WX2 cation-exchange column (H^+ form). The column was washed with 1 M HCl (1 L) and then eluted with 3 M HCl. An orange eluate was obtained, which was concentrated to dryness. The residue was dissolved in 1 M perchloric acid and the solution was made alkaline by the addition of 50% sodium hydroxide solution. The violet precipitate thus obtained was filtered off, redissolved in 0.02 M perchloric acid, and the resulting orange solution was filtered and applied to an SP Sephadex C-25 column (12 × 60 cm). The column was washed with water and eluted with 0.2 M sodium sulfate solution. Four orange bands were collected, which were each absorbed onto Dowex 50WX2 columns and, after washing with 1 M HCl, were eluted with 3 M HCl. Orange eluates were obtained, which were concentrated to dryness. The respective residues were dissolved in 1 M perchloric acid and neutralized with NaOH (50%). On cooling, violet crystals formed, which were filtered off and recrystallized from water. Minor fractions 1 and 2 were found to contain two isomeric products **4a** (0.5 g, 1.7%) and **4b** (0.3 g, 1%), respectively, in which besides the nitro groups both of the C=N double bonds were reduced. The third fraction contained product **3** (3.2 g, 10%) with two aminomethyl groups and one C=N double bond. The major fourth fraction contained complex **2** (12.5 g, 39%).

[2,9-Bis(aminomethyl)-5,7,7,12,14,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane]nickel(II) Diperchlorates 4a and 4b: Concentrated hydrochloric acid (30 mL) was added dropwise over a period of 30 min to a vigorously stirred mixture of zinc amalgam (10 g) and complex **2** (4 g) in water (200 mL), while the temperature was maintained below 20°C. Stirring was continued for 72 h and then the mixture was applied to a Dowex 50WX2 cation-exchange column (H^+ form). The column was washed with 1 M HCl and eluted with 3 M HCl. An orange eluate was collected, which was concentrated to dryness. The residue was dissolved in water and the resulting solution was applied to an SP Sephadex C-25 column (5 × 50 cm). Four fractions were eluted with 0.2 M sodium sulfate solution and were worked up according to the same procedure as described above. 2.3 g (58%) of **4a**, 0.9 g (22%) of **4b**, 0.5 g (12%) of **3**, and 0.2 g (5%) of **2** were isolated and crystallized from water. − **3**: $C_{18}H_{40}Cl_2N_6NiO_8$ (598.2): calcd. C 60.0, H 12.3, N 23.3; found C 60.2, H 12.0, N 23.1. − HR MS: calcd. for $C_{18}H_{42}N_6$ 342.3471; found 342.3457.

X-ray Crystallography: Well-shaped crystals of compounds **4a** and **4b** were selected for X-ray-diffractometric measurements. In both cases, the cell constants were obtained from least-squares refinement based on 25 setting angles. The stabilities of the crystals were checked by monitoring 2 control reflections at 50 reflection intervals; no appreciable decay was observed. Lorentz and polarization corrections were applied to all collected data. No absorption corrections were performed at the measurement stage. Table 5 shows the crystal data and measurement conditions for **4a** and **4b**. Models of the two structures were obtained by direct methods using the program SHELXS-86[21] and a series of subsequent Fourier difference syntheses (program SHELX-93[22]) revealed the positional parameters for all non-hydrogen atoms. The same refinement procedure was applied in both cases: Initially, the positional and isotropic temperature factors for non-hydrogen atoms were refined by full-matrix, least-squares procedures (program SHELX-93). Further refinement steps were performed in anisotropic mode for the non-hydrogen atoms. The positional parameters for *C*-attached hydrogen atoms were calculated from assumed geometries. They were added to parameter sets and refined in isotropic mode in separate blocks. The highest residual electron density peaks observed in each case on final difference maps were below 0.4 eÅ^{-3}.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101460. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Investigation of Chalcogen Atom Substituted Dinitriles and Porphyrazines

Anthony E. Pullen,* Christophe Faulmann, and Patrick Cassoux*

Keywords: Phthalocyanines / Porphyrazines / Macrocycles / Chalcogen atom substitution

A series of chalcogen atom substituted porphyrazines have been assembled and characterized. Oxygen and sulfur chalcogen atoms have been substituted for peripheral methylene groups. Heteroatom-enriched, seven-membered ring dinitriles (**1**–**3**) were synthesized and characterized by IR, MS, UV-vis, ^{1}H NMR, elemental analysis, and X-ray analysis to examine the ring conformations. They were template cyclized in the presence of Mg^{II} to form the Mg^{II} containing porphyrazine macrocycles. The Mg^{II} and metal-free macrocycles (**4**–**9**) were synthesized for all peripherally substituted porphyrazines. The unchalcogen-substituted Ni^{II}, Cu^{II}, and Zn^{II} containing porphyrazine derivatives (**10**–**12**) were also synthesized because of the higher solubility of the metal-free porphyrazine **7**. The macrocycles were characterized and studied using such techniques as UV-vis, IR, elemental analysis, cyclic voltammetry, and electrical conductivity measurements.

Introduction

Phthalocyanines and porphyrins have received considerable attention due to the number of applications that these two families of compounds have been employed, and also for their interesting properties.[1] Among their many applications, phthalocyanines have often been studied for their electrical conductivity,[2] liquid-crystalline properties[3] and use as pigments.[4] Porphyrins for example, have been studied for their magnetic[5] and catalytic[6] properties and their role in biomolecular processes.[7] Another family of similar conjugated macrocycles that have received considerably less attention than the phthalocyanines or porphyrins, are the porphyrazines (also called tetraazaporphyrazines).[8][9] Recently, a significant amount of work has been made with these systems. Hoffman and coworkers for example, have reported the synthesis of polymetallic porphyrazines and a novel metal-linked porphyrazine dimer.[10–13]

Efforts have also been made studying porphyrazines substituted with long alkyl chains for applications in liquid crystals and Langmuir–Blodgett layers.[14] Hemiporphyrazines, a slightly different class of porphyrazines which exhibit a box-like geometry, have also been recently reported. They have been used in the assembly of Langmuir–Blodgett layers[15] and ladder polymers and oligomers.[16]
Bryce and coworkers have applied porphyrazines in supramolecular chemistry by synthesizing pyrazinoporphyrazines with pendant TTF (tetrathiafulvalene) units.[17] Along a similar line, other modifications to the porphyrazine system may be envisioned, for example, a synthetic goal would be to incorporate chalcogen atoms with large diffuse atomic orbitals directly into the periphery of the planar, conjugated porphyrazine macrocycle. An additional related goal would be also to determine their feasibility for use in chalcogen-rich electrically conducting complexes. Despite the enormous amount of research currently being carried out worldwide in the areas of phthalocyanines, porphyrins, and porphyrazines, to our knowledge only the work recently reported by Swager and coworkers[18] has chalcogen-atom incorporation been investigated for these types of macrocycles. This idea has been extensively utilized in the field of the synthesis of chalcogen-rich, planar and fully conjugated organic donor and acceptor molecules. Such well-known examples are TTF, BEDT-TTF (bisethylenedithiotetrathiafulvalene), and square planar metal bis-dmit (dmit = 2-thione-1,3-dithiole-4,5-dithiolato) complexes, which have been used in the assembly of superconducting partial-oxidation state materials.[19] In this paper, we report the findings of a study of the synthesis and characterization of a series of chalcogen-enriched porphyrazine macrocycles and their possible use for future incorporation into electrically conductive materials. Four methylene groups in the periphery of the porphyrazine molecule have been substituted by oxygen and sulfur atoms. Seven-membered ring dinitrile compounds were first synthesized with a methylene (**1**), sulfur (**2**), or oxygen (**3**) group in the five position. Single crystal X-ray structures were obtained for compounds **1**–**3** to understand the ring conformations. The Mg^{II} and

Scheme 1. Synthesis of chalcogen atom substituted dinitriles and related porphyrazines

H_2 containing porphyrazines (**4**−**9**), which were cyclized from the dinitriles, have been synthesized along with the Ni^{II}, Cu^{II}, and Zn^{II} containing macrocycles of the methylene derivative (**10**−**12**). Their electronic spectra and electrochemical properties have been examined and compared to similar reported systems. Also, two-probe pressed-pellet electrical conductivity measurements have been carried out on some of the compounds.

Synthesis of the Porphyrazine Macrocycles

The syntheses of compounds **1**−**12** are shown in Scheme 1. Dinitriles 3,7-dithiacycloheptamaleonitrile (**1**) and 3,7-dithia-5-oxocycloheptamaleonitrile (**3**) were assembled by the reaction of mnt^{2-} ligand with the corresponding dihalide in high dilution conditions in refluxing dioxane over a period of 3 days to obtain yields of 14 and 25% respectively.

3,5,7-trithiacycloheptamaleonitrile (**2**) was synthesized in 67% yield by the reaction of $S(CH_2Br)_2$ with the labile $(Bu_4N)_2[Zn(mnt)_2]$ complex in acetone at room temperature over the same period of time. All three dinitriles had to be purified by column chromatography due to the large amount of dimeric, trimeric and oligomeric side products with similar solubilities. In a previous paper by Spannenberg et al.,[20] compound **1** was synthesized, isolated, and characterized along with the dimeric and trimeric cyclization products. The dimeric and trimeric forms were not of interest in this work. The crystal structures of the three dinitriles **1**−**3** are shown in Figure 2 and selected bond lengths and angles are listed in Table 1.

Their structures were obtained to examine the conformation of the seven-membered rings due to the inability to obtain crystal structures of the ensuing porphyrazine macrocycles. In Figures 2a for 3,7-dithiacycloheptamaleonitrile (**1**) and 2b for 3,5,7-trithiacycloheptamaleonitrile (**2**), both compounds exhibit similar twisted ring conformations. In compound **1**, the dihedral angle between the S1′−C3′−C3−S1 and C2′−C1−C2 planes is 45.48(8)° while for **2** the dihedral angle between the S1−C1−C2−S2 and C5−S3−C6 planes is almost the same at 45.44(17)°. Figures 2c and d each show a different view of the same compound 3,7-dithia-5-oxocycloheptamaleonitrile (**3**). Figure 2c is in the same perspective as for compounds **1** and **2** while Figure 2d is a profile view down the axis of the C1=C2 bond showing a chair-like conformation of the ring unlike that seen for **1** and **2**. This is in contrast to the twisted ring conformations of compounds **1** and **2**. The S1−C5−C6−S2 plane is folded at the sulfur atoms at an angle of 56.76(6)° from the S1−C1−C2−S2 plane and 70.12(15)° from the C5−C6−O1 plane. The square planar metal complexes $(Et_4N)[Cu(pddt)_2]$ (where pddt = $C_5H_6S_4^{2-}$ = 1,3-propanediyldithioethylene-1,2-dithiolato),[21] $(Bu_4N)[Pd(dtdt)_2]$ (where dtdt = $C_4H_4S_5^{2-}$ = 5,7-dihydro-1,4,6-trithiin-2,3-dithiolato),[22] and $(Ph_4P)[Cu(diod)_2]$ (where diod = $C_4H_4OS_4^{2-}$ = 1,4-dithia-6-oxa-2,3-dithiolato)[23] have been reported and the ligands contain the seven-membered rings as compounds **1**−**3** do respectively. It is interesting to note that in every instance, the rings are in a chair-like conformation like compound **3**. For $(Ph_4P)[Cu(diod)_2]$, the fold angles of the planes at the ring sulfur atoms was reported as 61.2° which is greater than for **3** [56.76°(6)]. The angle of the C−O−C plane reported for $(Ph_4P)[Cu(diod)_2]$ is 65.9°, smaller than that found in compound **3** of 70.12(15)°.[23]

The conversion of the dinitriles to the Mg^{II} porphyrazine macrocycles Mg(dtchp) (**4**), Mg(ttchp) (**5**) and Mg(dochp) (**6**) were achieved following slightly modified procedures by Linstead and Whalley[8b] in refluxing Mg alkoxide suspensions. To remove Mg^{II} and to synthesize the metal-free porphyrazines H_2(dtchp) (**7**), H_2(ttchp) (**8**), and H_2(dochp) (**9**),

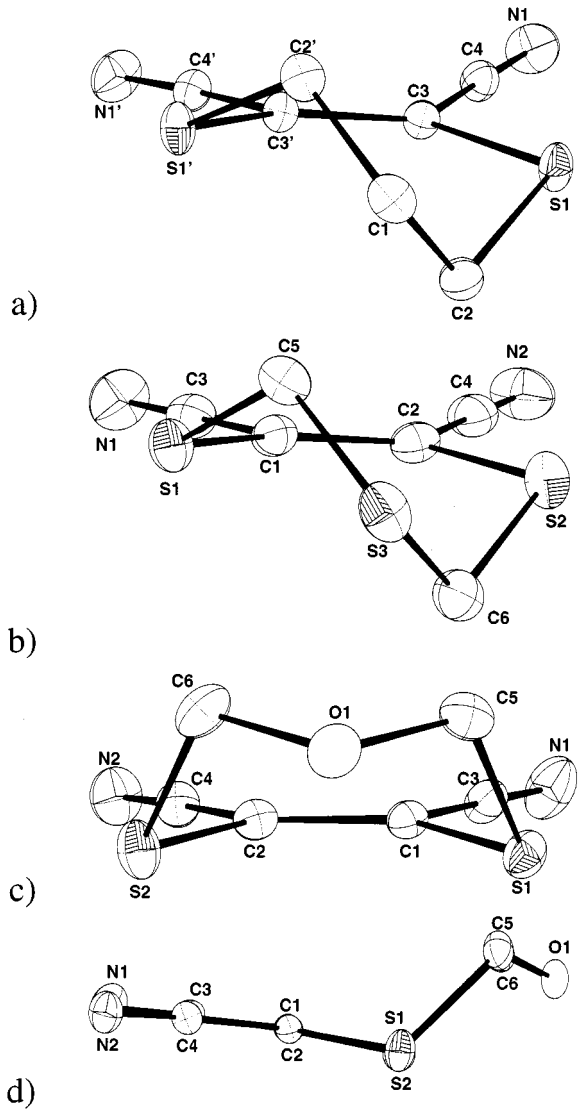

Figure 2. Thermal ellipsoids drawings (30% probability) and numbering schemes for the dinitriles (a) 3,7-dithiacycloheptamaleonitrile (**1**), (b) 3,5,7-trithiacycloheptamaleonitrile (**2**), (c) 3,7-dithia-5-oxocycloheptamaleonitrile (**3**), (d) Profile view down the axis of the C1−C2 double bond of **3** showing the chair-like conformation of the seven-membered ring. Hydrogen atoms have been omitted for clarity.

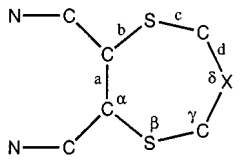
compounds **4**−**6** were treated with trifluoroacetic acid followed by aqueous precipitation and neutralization with ammonia.[10b] This method resulted in clean demetallation and yielded compounds **7**−**9** in up to 83% yield.

Purification of H_2(dtchp) (**7**) was achieved using column chromatography. The sulfur and oxygen peripherally substituted compounds H_2(ttchp) (**8**) and H_2(dochp) (**9**) could not be purified with column chromatography due to their rather low solubility in common organic solvents. Sublimation was attempted as it has been shown to purify phthalocyanines.[16] In both cases though, black insoluble materials resulted and no sublimation products were observed. Nevertheless, **8** and **9** can be purified through exhaustive washing.



Due to the adequate solubility of H_2(dtchp) (**7**), facile insertion of Ni^{II}, Cu^{II}, and Zn^{II} ions into the core of the macrocycle was accomplished to assemble compounds **10**−**12**. This was completed by refluxing anhydrous $Ni(OAc)_2$, $Cu(OAc)_2$, and ZnI_2 respectively with the metal-free porphyrazine in a mixture of PhCl/DMF over a period of 20 hours.[12]

Electronic Absorption Spectroscopy

Phthalocyanines and porphyrazines give similar and characteristic absorption spectra as it is a valuable tool in determining their synthesis.[4b] This is important in this study due to the inability to obtain single-crystal X-ray structures of the macrocycles. Table 2 lists the electronic band maxima for all compounds synthesized. Figure 3 shows the spectra for compounds **4** and **7** which are representative of all of the Mg^{II} and metal-free compounds assembled in this study along with the Ni^{II}, Cu^{II} and Zn^{II} containing macrocycles of the methylene derivative, **10**−**12**.

The optical spectra for the four-fold symmetric Mg^{II} derivatives Mg(dtchp) (**4**), Mg(ttchp) (**5**), and Mg(dochp) (**6**) are nearly identical. They exhibit an intense single Soret band at approximately 368−370 nm, a weak shoulder absorption at 510−538 nm and an intense Q band at 656−664 nm. This is similar to that seen for metal phthalocyanines.[1] The Soret and Q band region absorptions are attributed to

[a] Measured in pyridine. − [b] In DMF. − [c] In chloronapthalene. − [d] In chlorobenzene.

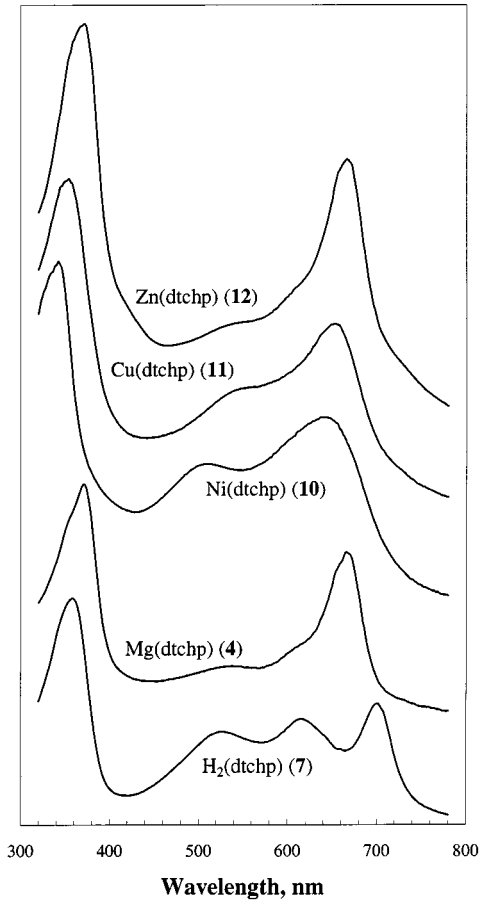

Figure 3. Comparison of the UV-vis absorption spectra for the metal-free derivative H_2(dtchp) (**7**) and metal-containing derivatives Mg(dtchp) (**4**), Ni(dtchp) (**10**), Cu(dtchp) (**11**), and Zn(dtchp) (**12**)

π→π* transitions from the a_{1u}, a_{2u} HOMOs to the doubly degenerate (e_g) LUMOs.[12] The optical spectra of H_2(dtchp) (**7**), H_2(ttchp) (**8**), and H_2(dochp) (**9**) which are also very similar, show a splitting of the Q band found at 656−664 nm for compounds **4**−**6**. This is due to the lowering of symmetry from four-fold (D_{4h}) to two-fold (D_{2h}) symmetry for the metal-free derivatives **7**−**9**, and removal of the degeneracy of the e_g LUMOs.[4b] Also observed in each is a slight red-shift of the Soret band in the metal-free compounds. This behavior observed in the Soret and Q band regions is typical for substituted porphyrazines.[8][10−12][14][24] In difference to metal and metal-free phthalocyanines, we observe a definite broadening of the absorptions in compounds **4**−**9**.[4b] This has also been observed in several instances in other sulfur-containing porphyrazines. With 8 sulfur atoms in the periphery of the CH_2 derivative and more so with 12 sulfur and oxygen atoms in the periphery of the other new porphyrazine derivatives reported here, there are probably significant contributions to the spectra from underlying n→π* transitions from the lone pair electrons of the heteroatoms.[12] Like Mg(dtchp) (**4**), the D_{4h} Ni^{II}, Cu^{II}, and Zn^{II} derivatives, Ni(dtchp) (**10**), Cu(dtchp) (**11**), and Zn(dtchp) (**12**), show similar spectra with an intense Soret band and Q band with a weaker absorption in the 500−560 nm region. In the case of the Ni^{II} derivative, the Soret band at 342 nm, the weak absorption at 508 nm and the Q band region absorption at 640 nm are the most red-shifted absorptions of all the new metal derivatives presented here. In comparison to the Mg^{II} derivative, this is not observed in metal phthalocyanines as the Mg^{II} and Ni^{II} derivatives give absorptions at nearly the same wavelengths (Table 2). This effect has been seen in other thio-substituted porphyrazines.[24]

Redox Properties of H_2(dtchp) (7)

The redox properties of H_2(dtchp) (**7**) have been investigated with cyclic voltammetry. The $E_{1/2}$ values are found in Table 3 along with other related porphyrazine and phthalocyanine systems for comparison. Potentials as high as +0.90 V were reached (vs. SCE, CH_2Cl_2, 0.1 M Bu_4NPF_6) with **7** but no oxidation process were found. Upon scanning cathodically, two low-potential redox couples were observed with $E_{1/2}$ values of −0.95 and −1.29 V (vs. Fc/Fc^+ couple; $E_a - E_c$ = 120 and 250 mV and $i_{p,a}/i_{p,c}$ = 0.80 and 0.91 respectively).

Table 3. Cyclic voltammetric half-wave potentials (V, reported vs. Fc/Fc^+ couple) for the reduction of H_2(dtchp) (**7**)[a] and similarly related compounds for comparison

Compound	$E_{1/2}{}^1$	$E_{1/2}{}^2$
H_2(dtchp) (**7**)	−0.95	−1.29
H_2(obtp)[b]	−0.85	−1.19
H_2(obcbp)[c]	−0.8	−1.2
H_2(pc)[d]	−1.20	−1.54

[a] Conditions: scan rate, 100 mV/s; reference electrode, standard calomel; working electrode, Au plate; 0.1 M Bu_4NPF_6 electrolyte in CH_2Cl_2 under argon at room temperature. − [b] Ref.[11b] − [c] Ref.[12] − [d] Ref.[25]

These values are slightly lower than the tetrathioether-substituted porphyrazines H_2(obcbp) [obcbp = octa(4-butyloxycarbonylbenzylthio) porphyrazine, −0.8 and −1.2 V] and H_2(obtp) [obtp = octa(benzylthio) porphyrazine, −0.85 and −1.19 V] reported by Hoffman and coworkers.[11b][12] These compounds were also reported to exhibit no oxidation processes as seen in the H_2(dtchp) (**7**) system. This is in contrast to phthalocyanines which can exhibit oxidation processes that are typically irreversible along with their reversible reduction couples. The $E_{1/2}$ values for the ring reductions for H_2(pc) (−1.20 and −1.54 V) are lower than the values for the porphyrazines reported and discussed here.[12,25]

Conductivity Measurements

As said above, one side goal of this work was to determine the feasibility for use of the chalcogen-rich porphyrazines studied here in the preparation of electrically conducting complexes. Preliminary electrical conductivity studies have been completed and measurements of compounds H_2(dtchp) (**7**), Ni(dtchp) (**10**), and Cu(dtchp) (**11**) exhibited pressed-pellet conductivities of $<10^{-12}$ S/cm. It is thus clear that this result doesn't live up the expectations. Moreover, even the metal-free H_2(dtchp) is not oxidized at potentials below 0.9 V/SCE, and the lack of solubility of most of the studied porphyrazines severely limits a more detailed analysis.

Conclusions

We have synthesized a series of chalcogen-substituted dinitrile isologues and they have been characterized and investigated using a variety of techniques including single-crystal X-ray analysis. Compounds **1** and **2** show a twisted conformation of the seven-membered rings while **3** exhibits a chair conformation. The dinitriles were cyclized in Mg propoxide suspensions to assemble the macrocyclic Mg^{II} porphyrazines. The metal-free porphyrazines were obtained by treatment with trifluoroacetic acid. The electronic spectra of the Mg^{II} and metal-free porphyrazines show very little variance with the substitution of O or S for a methylene group in the periphery. Due to the low-solubility of the peripherally substituted oxygen and sulfur derivatives, only the higher soluble methylene substituted porphyrazine H_2(dtchp) (**7**) could be further studied. Compound **7** could be purified via column chromatography and cyclic voltammetry studies showed it exhibits two low-potential reduction couples. The Ni^{II}, Cu^{II}, and Zn^{II} containing porphyrazines were then assembled and characterized. Due to the fact that the solubility of the porphyrazines studied here is lowered when chalcogen atoms are incorporated into the structure, future directions must also consist of the addition of solubility improving groups, such as long alkyl chains. This may then allow chalcogen atom enhanced porphyrazine derivatives to be further studied for metal coordination, electrochemical, and electrical conductivity studies.

Experimental Section

General Procedures and Chemicals: All reactions unless otherwise noted were carried out under an argon atmosphere. All solvents were purified following standard procedures. Compounds Na_2mnt and $(Bu_4N)_2[Zn(mnt)_2]$ were synthesized according to Davison et al.[26] Bis(chloromethyl) ether and bis(bromomethyl) thioether were synthesized following Buc[27] and Komoto et al.,[28] respectively. − Column chromatography was carried out using silica gel 60 (Merck, 63−200 μm particle size), and POLGRAM SIL G/UV 254 (Macherey-Nagel, 0.25 mm thickness) was used for TLC experiments. − Elemental analyses were performed by the Microanalysis Service at the LCC-CNRS, Toulouse. − Mass spectra were obtained at the Joint Mass Spectrometry Service at Paul Sabatier University, Toulouse. − Melting points were obtained using a Stuart Scientific SMP1 melting point apparatus and are uncorrected. − UV-vis spectra were recorded on a Hewlett Packard 8452A spectrophotometer. − IR spectra were obtained on a Perkin Elmer 1725X FT-IR spectrometer as KBr pellets. − NMR spectra were recorded on a Bruker AC 200 MHz instrument.

Preparation of 3,7-Dithiacycloheptamaleonitrile (1): Compound **1** was prepared, isolated, and purified according to Spannenberg et al.,[20] and its elemental analysis was in agreement with that reported.

3,5,7-Trithiacycloheptamaleonitrile (2): An 8.0 g ($9.63\cdot10^{-3}$ mol) amount of $(Bu_4N)_2[Zn(mnt)_2]$ was dissolved in 350 ml of acetone. Dropwise was added 4.30 g (0.020 mol) of bisbromomethyl thioether to the rapidly stirring solution. The stirring was continued and the solution turned from a pale yellow to a deep red color after 3 days. At this time, the solvent was evaporated to leave a dark-red oil. The product was isolated with column chromatography using CH_2Cl_2 as eluent (R_f = 0.73). The solid was recrystallized using CH_2Cl_2/hexane to yield 2.60 g of **2** (67%) as yellow platelets, m. p. 91−92°C. − $C_6H_4N_2S_3$ (200.29): calcd. C 35.98, H 2.01, N 13.99; found C 35.95, H 1.55, N 13.69. − ^{1}H NMR ($CDCl_3$): δ = 4.82 (s, 4 H). − IR (KBr): $\tilde{\nu}$ = 2996 cm^{-1} m, 2937 m, 2220 m, 1496 s, 1386 s, 1227 s, 1198 s, 1158 vs, 1117 m, 1033 m, 1008 m, 984 w, 850 m, 780 m, 734 vs, 490 vs. − UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 256 nm (4.46), 300 (4.46), 364 (4.43), 386 (4.42). − MS (FAB); *m/z* (%): 201 (100) [M + H^+].

3,7-Dithia-5-oxocycloheptamaleonitrile (3): Compound **3** was prepared similar to **1**. A 5.58 g (0.030 mol) sample of Na_2mnt was placed in 600 ml of dioxane under an argon atmosphere allowed to react with 3.45 g (0.030 mol) of bis(chloromethyl) ether. The crude product was purified by column chromatography using CH_2Cl_2 as eluent (R_f = 0.88). The pale yellow microcrystalline product was recrystallized in CH_2Cl_2/hexane to yield 1.09 g (25%) of **3** as cream-colored plates, m. p. 133−134°C. $C_6H_4N_2OS_2$ (184.23): calcd. C 39.12, H 2.19, N 15.21; found C 39.36, H 1.64, N 15.13. − ^{1}H-NMR ($CDCl_3$): δ = 5.45 (s, 4 H). − IR (KBr): $\tilde{\nu}$ = 3006 cm^{-1} m, 2927 m, 2220 m, 1511 s, 1441 vs, 1401 sh, 1335 s, 1322 s, 1242 s, 1147 vs, 1067 vs, 998 s, 970 vs, 932 vs, 682 vs, 510 s. − UV/Vis (CH_2Cl_2): λ_{max} (lg ε) = 258 nm (2.38), 300 (2.40), 358 (2.38). − MS (EI, 70 eV); *m/z* (%): 184 (100) [M^+].

[Tetrakis(dithiacyclohepta)porphyrazinato]magnesium(II) [Mg(dtchp) (4)], [Tetrakis(trithiacyclohepta)porphyrazinato]magnesium(II) [Mg(ttchp) (5)], and [Tetrakis(dithiaoxocyclohepta)porphyrazinato]magnesium(II) [Mg(dochp) (6)]: The synthesis of the following Mg containing derivatives **4**−**6** were completed following previously reported procedures.[8b] Under an argon atmosphere, magnesium (Aldrich, 98%) was refluxed with 15 ml of 1-propanol with

a crystal of iodine as initiator for 24 hours. To the grayish suspension was then added the dicyano compound **1**−**3** as a slurry in a small amount of 1-propanol. The mixture was stirred and refluxed for a minimum of 12 hours. The solution was filtered hot and the precipitate was washed with CH_2Cl_2 until the washings were pale blue. The filtrate and washings were combined and evaporated to dryness to give a blue-black product. The product was washed with water until the washings were clear followed by copious amounts of EtOH also until the washings were clear. The solid was dried under vacuum and recrystallized in CH_2Cl_2/2-propanol. − Mg(dtchp) (**4**): Yield 33%, dark-blue microcrystals. − IR (KBr): $\tilde{\nu}$ = 2962 cm^{-1} m, 2926 m, 1654 m, 1560 m, 1459 m, 1384 m, 1300 m, 1255 w, 1220 w, 1104 m, 1026 s, 802 s, 560 w. − $C_{28}H_{24}MgN_8S_8$ (753.34): calcd. [Tetrakis(dithiacyclohepta)porphyrazinato]nickel(II) [Ni(dtchp) (10)], [Tetrakis(dithiacyclohepta)porphyrazinato]copper(II) [Cu(dtchp) (11)], and [Tetrakis(dithiacyclohepta)porphyrazinato]zinc(II) [Zn-(dtchp) (12)]: Compounds **10**−**12** were synthesized similar to previously reported procedures found in refs.[10−12] After the reaction of **7** with anhydrous $Ni(OAc)_2$, $Cu(OAc)_2$, or ZnI_2 respectively in a 3:1 mixture of PhCl/DMF at 100°C for 20 hours under an argon atmosphere, the solvents were removed under vacuum. The remaining solids were washed thoroughly with water and 5% HCl/MeOH to remove excess metal salts followed by MeOH until the washings were clear then dried under vacuum. − Ni(dtchp) (**10**): Yield 92%, blue-black powder. − IR (KBr): $\tilde{\nu}$ = 2993 cm^{-1} m, 2922 m, 1683 m, 1538 w, 1517 m, 1412 m, 1302 m, 1254 s, 1244 s, 1078 m, 1047 vs, 875 m, 815 s, 750 s, 690 w. − $C_{28}H_{26}NiN_8S_8$ (787.72): calcd. C 42.69, H 3.33, N 14.23, S 32.56; found C 42.21, H 3.04, N 14.13, S 32.40. − UV/Vis (PhCl): λ_{max} (lg ε) = 342 nm (4.85), 508 (4.55), 640 (4.61). − Cu(dtchp) (**11**): Yield 95%, blue-black powder. − IR (KBr): $\tilde{\nu}$ = 2960 cm^{-1} m, 2923 m, 1654 w, 1560 w, 1488 w, 1414 m, 1302 s, 1260 s, 1236 m, 1091 s, 1043 s, 907 w, 864 w, 805 vs, 745 s, 678 w, 503 w. − $C_{28}H_{26}CuN_8S_8$ (792.58): calcd. C 42.43, H 3.05, N 14.14, S 32.36; found C 42.05, H 2.98, N 14.10, S 32.15. − UV/Vis (DMF): λ_{max} (lg ε) = 354 nm (4.80), 550 (4.49), 654 (4.60). − Zn(dtchp) (**12**): Yield 94%, green-black powder. − IR (KBr): $\tilde{\nu}$ = 2963 cm^{-1} m, 1653 m, 1613 m, 1413 w, 1380 w, 1262 s, 1098 s, 1022 s, 864 w, 800 vs, 687 w. − $C_{28}H_{26}N_8S_8Zn$ (794.41): calcd. C 42.33, H 3.05, N 14.11; found C 42.10, H 2.98, N 14.02. − UV/Vis (DMF): λ_{max} (lg ε) = 372 nm (4.73), 556 (4.20), 666 (4.56).

Electrochemical Methods: Cyclic voltammetry was performed using a ISMP Model Elektrokemat 400 potentiostat equipped with microcomputer-controlled instrumentation with positive feedback ohmic resistance compensation following previously described techniques.[29] Methylene chloride was dried, distilled, and degassed with argon prior to use and tetrabutylammonium hexafluorophosphate was used as the supporting electrolyte (0.1 M). A standard calomel electrode was used for the reference electrode with a 2 mm gold plate as the working electrode and the electrochemical experiments were completed under an argon atmosphere.

Electrical Conductivity Measurements: Two-probe pressed powder, AC electrical resistance measurements were carried out with an in-house assembled powder press using a Hewlett Packard 4263A LCR meter.

Crystal Structure Determinations: Suitable crystals of compounds **1** (pale green diamonds), **2** (yellow plates), and **3** (clear hexagons) were obtained from slow evaporation of 1:1 solutions of hexane/dichloromethane. Data were collected on an imaging plate IPDS-STOE diffractometer [Mo-K_α radiation, λ(Mo-K_α) = 0.71073 Å]. The cell parameters were determined from 5000 reflections over the whole θ range. Data for all structures were corrected for Lorentz-polarization effects. Data reduction were performed with X-Red.[30] The structures were solved by direct methods (SHELXS-86)[31] followed by normal heavy-atom procedures. For every compound, full matrix least-squares refinement on F^2 with all non-H atoms anisotropic. H-atoms were placed geometrically at 0.99 Å and included in the calculations as riding the adjacent C atom with an isotropic displacement parameter 50% higher than the one of the adjacent C atom. All crystallographic calculations were performed using SHELXL-97 (Sheldrick, 1997)[32] Neutral atom scattering factors were taken from ref. 33. Molecular graphics were obtained using Cameron.[34] The crystallographic data are compiled in Table 4. Crystallographic data (excluding structure factors) for the structures reported in this manuscript have been deposited with the Cambridge Crystallographic Data Centre. The deposition number for compounds **1**, **2**, and **3** is 101472. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, GB-Cambridge CB12 1EZ [Fax: (internat.) +44 (0)1223/ 336-033, E-mail: deposit@ccdc.cam.ac.uk].

Equilibria Between Gas and Liquid Phases for Concentrated Aqueous Solutions of Nitric Acid

Fanny Balbaud,*[a] Gérard Sanchez,[a] Gérard Santarini,[a] and Gérard Picard[b]

Keywords: Nitric acid / Nitrogen oxides / Electrochemistry / Thermodynamics

Calculated diagrams, representing chemical and electrochemical properties of concentrated aqueous nitric acid mixtures, have been drawn for temperatures of 25 °C and 100 °C using vapor pressures and thermochemical data of related gaseous species. Electrochemical measurements have permitted the establishment of an experimental potential scale (referenced to the saturated mercurous sulfate electrode at 25 °C) incorporated in the diagram at 100 °C. These measurements also allowed the determination of the Gibbs free energy of formation of dissolved nitrous acid for various nitric acid solutions at 100 °C, leading to a value of $\Delta G_f(HNO_2)$ = –36.31 kJ mol^{-1}, for the whole nitric acid concentration range.

Introduction

Nuclear fuel reprocessing is achieved in France using nitric acid as the dissolution reaction medium. Nitric acid acts as an oxidizing agent and is currently used over a large range of concentration, e.g. 1 mol L^{-1} to 14.4 mol L^{-1}, and temperature, from room temperature to boiling point (at atmospheric pressure). The corrosive nature of these nitric mixtures leads to the use of corrosion-resistant materials such as austenitic stainless steels and zirconium. Corrosion studies of selected materials have previously been performed in the CEA-CEREM laboratories in an attempt to answer many practical industrial problems.[1,2] A more fundamental study of corrosion in these mixtures was undertaken some years ago[3] and showed the necessity of investigating thoroughly the corrosive nature of the reaction medium as had been performed for fused sodium nitrate−nitrite mixtures.[4a,4b]

The main objective of the study presented in this paper is to build up a synthetic thermodynamic representation of the chemical properties of concentrated nitric media. This representation connects with the Pourbaix diagram[5] for solutions of positive pH and gives a picture of the medium for more concentrated solutions. The construction of this thermodynamic representation involves knowledge of the thermochemical data of all the species present in the medium. As the value of the Gibbs free energy of formation of nitrous acid (one of the major soluble nitrogenous species apart from nitric acid) in nitric acid at 100 °C appeared to be uncertain, electrochemical measurements were performed to determine this datum. These measurements also allowed the establishment of an experimental potential scale for the diagram.

Analysis of Available Literature Data and Graphic Representation of the Chemical Properties of Nitric Media

Nitric acid and water vapor pressures for acid concentrations varying from 0% to 95% and temperatures from 0 °C to 140 °C may be found from an analysis of literature data [Tables 1 and 2; all the pressures are given in bar (1 bar = 10^5 Pa)].[6−15]

The major interest in considering the gaseous forms of the different substances is that it makes possible the use of thermochemical data associated with the gaseous pure substances instead of those of soluble species which are generally not known with a great accuracy for concentrated media. Thermochemical data used for the calculations are presented in Table 3.[16−19]

Principle of the Construction of a Potential−Acidity-Type Diagram

All species are gaseous, including water and nitric acid, and thermochemical data used are those of pure substances under a pressure of 1 bar. The diagram was drawn using the coordinates $\log(P_{O_2}) = f[-\log(P_{HNO_3})$ or pH]. The curves represent the calculated values of the oxygen pressure for which the partial pressures of the various gaseous species are equal to 1 bar and 0.1 bar. For pH < 0, the x axis is plotted as $-\log(P_{HNO_3})$; this parameter allows the scale to be expanded and avoids the problems of proton activity in a concentrated medium. For pH > 0 the classical pH scale is used and the representation becomes equivalent to a Pourbaix diagram. The y axis is in $\log(P_{O_2})$. This choice allows the exclusive use of gaseous species, without making any approximation concerning the nitric acid dissociation

or the proton activity. The partial pressures of the gases are considered to be equal to their fugacities.

Calculated Diagrams at 25°C and 100°C (Involving Only Gaseous Species)

The following equilibria were considered in order to represent the variations of oxygen pressure for the different gases:

$$2\ HNO_3 \rightleftharpoons N_2 + \frac{5}{2}O_2 + H_2O \quad (a)$$

$$2\ HNO_3 \rightleftharpoons N_2O + 2O_2 + H_2O \quad (b)$$

$$2\ HNO_3 \rightleftharpoons 2\ NO + \frac{3}{2}O_2 + H_2O \quad (c)$$

at 100°C: $$2\ HNO_3 \rightleftharpoons 2\ NO_2 + \frac{1}{2}O_2 + H_2O \quad (d)$$

at 25°C: $$2\ HNO_3 \rightleftharpoons N_2O_4 + \frac{1}{2}O_2 + H_2O \quad (e)$$

At 25°C, the dimer N_2O_4 is the predominant form whilst at 100°C the monomer NO_2 is the predominant form for pressures of 1 bar and 0.1 bar.

For each reaction, the equilibrium constant can be written as a function of the pressures of the different gases. For reaction (a), the equilibrium constant may be expressed as:

$$K_a = \frac{P_{N_2} P_{O_2}^{5/2} P_{H_2O}}{P_{HNO_3}^2}$$

For a given temperature, the equilibrium constant K_a can be calculated, as the Gibbs free energies of formation of the different gases are known in the literature. The variation of the logarithm of the oxygen pressure can then be expressed as:

$$\log P_{O_2} = \frac{2}{5}\log K_a - \frac{2}{5}\log P_{H_2O} - \frac{4}{5}\log P_{HNO_3} - \frac{2}{5}\log_{N_2} \quad (7)$$

For given nitric acid concentration and temperature, the nitric acid and water vapor pressures are known and it is

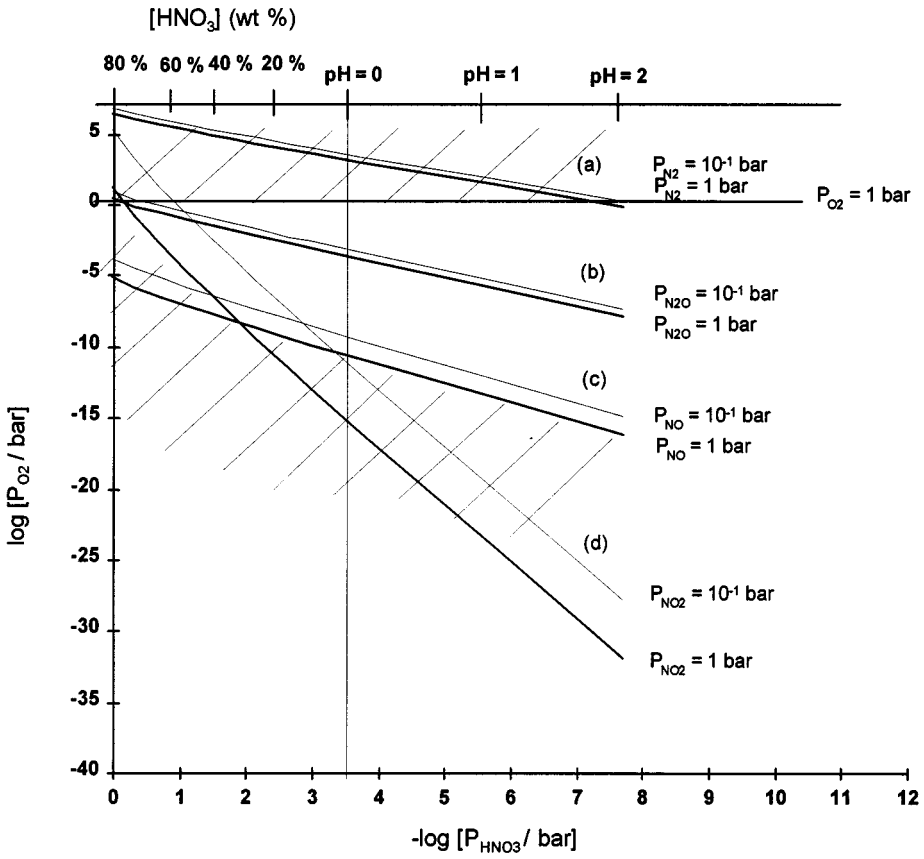

Figure 1. Calculated thermochemical diagram of nitric acid at 100°C involving gaseous species − stability domain of nitric acid under a pressure of 1 bar

therefore possible to determine the variation of the oxygen pressure with the nitric acid vapor pressure, for a given nitrogen pressure. For the other equilibria, the same calculation method may be used.

Theoretical representations in [log (P_{O_2})] − [−log (P_{HNO_3})] were calculated from the thermochemical data available in the literature at 100°C and 25°C (Figures 1 and 2).

Experimental Results and Discussion

In order to determine the missing datum of the free energy of formation of nitrous acid in nitric acid solutions at 100°C, potentiometric measurements were performed. All the measurements were referenced to the saturated mercurous sulfate electrode at 25°C (SSE).

Potentiometric Study; Determination of the Standard Potentials of the HNO_3/HNO_2 Electrochemical System at 100°C

To determine the standard potential of the HNO_3/HNO_2 system, the potential of the platinum electrode was measured at 100°C as a function of the concentration of nitrite (nitrous acid) in different nitric acid solutions (Figure 3). Initially, with no addition of nitrite, the concentration of nitrous acid in the nitric acid solution was approximately of 10^{-6} mol L^{-1}.

Nitrite ions were added as $NaNO_2$ in a 2.3 mol L^{-1} aqueous solution. In concentrated nitric acid, nitrite ions exist in the form of nitrous acid, HNO_2. During the potential measurements, the concentration of nitrous acid in nitric acid solution was considered equal to the concentration of nitrite added. This assumption was verified by analyzing the solutions for an expected value of 10^{-3} mol L^{-1}. The results obtained are given in Table 4 and show a good agreement. The following reduction reaction was considered:

$$HNO_{3(g)} + 2H^+_{(aq.)} + 2\bar{e} \rightleftharpoons HNO_{2(aq)} + H_2O_{(g)} \quad (1)$$

For this reaction, the Nernst equation can be written as:

$$E = E_1^0 + \frac{RT}{2F} \ln\left(\frac{P_{HNO_3}[H^+]^2}{P_{H_2O}[HNO_2]}\right)$$

The experimental measurements of the potential of the platinum electrode, as a function of the nitrous acid concentration, lead to the determination of the apparent standard potential $E_1{}^{0'}$ of the HNO_3/HNO_2 system. This apparent standard potential is the potential measured for a nitrous acid concentration of 1 mol L^{-1}, the concentrations of the other species being fixed by the solution. It can be expressed as:

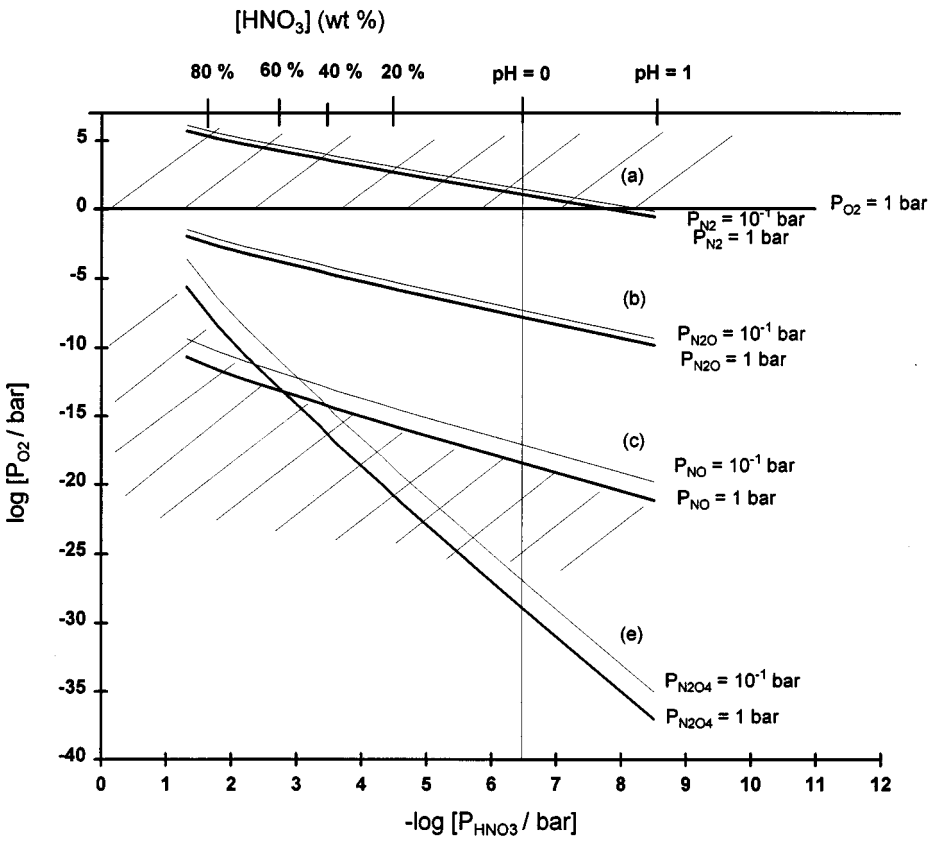

Figure 2. Calculated thermochemical diagram of nitric acid at 25°C involving gaseous species − stability domain of nitric acid under a pressure of 1 bar

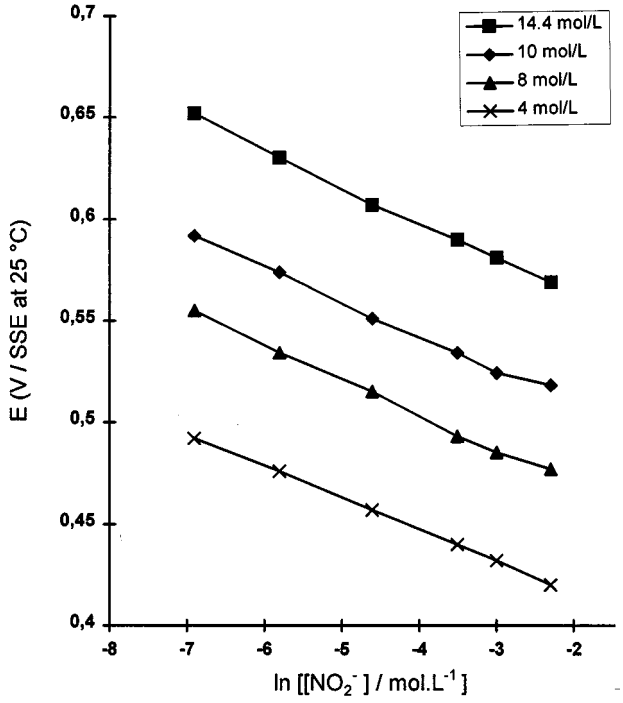

Figure 3. Potential of the platinum working electrode as a function of the concentration of nitrite added in solution and of the nitric acid concentration at 100°C

Table 4. Experimental measurement of the nitrite (nitrous acid) concentration in solution as a function of the nitric acid concentration; $[HNO_2]_{added} = 10^{-3}$ mol L^{-1} (theoretical concentration)

$[HNO_3]$/mol L^{-1}	$[HNO_2]$/mol L^{-1} measured in solution
4	$8.9 \cdot 10^{-4}$
8	$8.7 \cdot 10^{-4}$
10	$9.6 \cdot 10^{-4}$
14.4	$1.2 \cdot 10^{-3}$

$$E_1^{0'} = E_1^0 + \frac{RT}{2F} \ln\left(\frac{P_{HNO_3}[H^+]^2}{P_{H_2O}}\right)$$

The potential can then be written as:

$$E = E_1^{0'} - \frac{RT}{2F} \ln[HNO_2]$$

The variations of the potential of the platinum electrode, as a function of the nitrous acid concentration, are represented in Figure 3 for four nitric acid solutions of concentrations of 4 mol L^{-1}, 8 mol L^{-1}, 10 mol L^{-1}, and 14.4 mol L^{-1}. The experimental slope obtained with the linear regression analysis varies from 0.0178 for 14.4 mol L^{-1} to 0.0156 for 4 mol L^{-1}. The theoretical slope being equal to 0.0161, it can be inferred that the HNO_3/HNO_2 system follows the Nernst law.

Table 5 gives the experimental apparent standard potentials for the different solutions, $E_1{}^{0\prime}$. The values were determined by a linear regression analysis performed by fixing the value of the slope at the Nernst value.

Table 5. Experimental apparent standard potentials of HNO_3/HNO_2 and HNO_3/NO_2 systems as a function of nitric acid concentration at 100°C

$[HNO_3]$ [mol L^{-1}]	$E^0_{app.}(HNO_3/HNO_2)$ (V/SSE) = $E_1{}^{0\prime}$	$E^0_{app.}(HNO_3/NO_2)$ (V/SSE) = $E_2{}^{0\prime}$

Determination of the Standard Potentials of the HNO_3/NO_2 Electrochemical System at 100°C

To determine the standard potential of the HNO_3/NO_2 system, the potential of the platinum electrode was measured at 100°C as a function of the nitrogen dioxide pressure (Figure 4). The nitrogen dioxide pressure was fixed and controlled by a continuous flow of NO_2 in the reactor. The measurement was performed after stabilization of the potential. No measurement was performed for a nitric acid concentration of 10 mol L^{-1}.

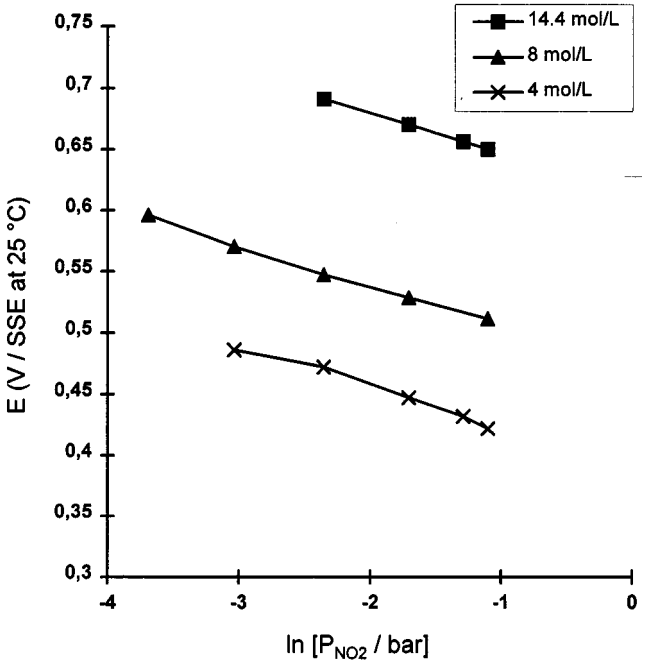

Figure 4. Potential of the platinum working electrode as a function of the nitrogen dioxide pressure and of the nitric acid concentration at 100°C

The following reaction was considered:

$$HNO_{3(g)} + H^+_{(aq.)} + \bar{e} \rightleftharpoons NO_{2(g)} + H_2O_{(g)} \quad (2)$$

According to this reaction, the Nernst equation can be written:

$$E = E_2^0 + \frac{RT}{F} \ln\left(\frac{P_{HNO_3}[H^+]}{P_{H_2O}\, P_{NO_2}}\right)$$

As previously, it is possible to define an apparent standard potential:

$$E_2^{0\prime} = E_2^0 + \frac{RT}{F} \ln\left(\frac{P_{HNO_3}[H^+]}{P_{H_2O}}\right)$$

Then:

$$E = E_2^{0\prime} - \frac{RT}{F} \ln(P_{NO_2})$$

The variations of the potential as a function of the nitrogen dioxide pressure are represented in Figure 4 for three nitric acid concentrations, 4 mol L^{-1}, 8 mol L^{-1}, and 14.4 mol L^{-1}. The experimental slope varies from 0.0325 for 8 mol L^{-1} to 0.0330 for 4 mol L^{-1}. In this case the theoretical slope is equal to 0.0321; therefore HNO_3/NO_2 shows Nernst-like behavior. The values of the apparent standard potentials of HNO_3/NO_2 are reported in Table 5.

Calculation of the Gibbs Free Energy of Formation of Nitrous Acid at 100°C

Combining the expressions of the equilibrium potential obtained for the HNO_3/HNO_2 and for the HNO_3/NO_2 systems, the following equation can be written:

$$E_2^{0\prime} = E_1^{0\prime} + \frac{RT}{2F} \ln\left(\frac{P^2_{NO_2}}{[HNO_2]}\right)$$

The ratio of the square nitrogen dioxide pressure to the nitrous acid concentration (right term) is linked to the equilibrium constant, K_3, of the following reaction, by the ratio of the partial pressure of nitric acid to the partial pressure of water:

$$HNO_{3(g)} + HNO_{2(aq.)} \rightleftharpoons 2\,NO_{2(g)} + H_2O_{(g)} \quad (3)$$

Therefore, the constant K_3, for a given nitric acid solution (concentration and temperature fixed), can be deduced from the apparent standard potentials according to the expression:

$$K_3 = \frac{P_{H_2O}}{P_{HNO_3}} \exp\left(\frac{2F}{RT}(E_2^{0\prime} - E_1^{0\prime})\right)$$

Experimentally, the standard apparent potentials of the systems HNO_3/HNO_2 and HNO_3/NO_2 have been determined for nitric acid concentrations of 4 mol L^{-1}, 8 mol L^{-1}, and 14.4 mol L^{-1}. Therefore the constant K_3 for these concentrations can be easily calculated, without making any assumption of the proton activity or of the reference system used. Moreover, with this calculation method, uncertainties in the potential measurements, linked to an eventual liquid-junction potential, are avoided if this potential is supposed to be constant for all the measurements.

As the Gibbs free energies of formation of gaseous nitric acid, gaseous water and nitrogen dioxide are known, and as for a given nitric acid solution, the partial pressures of water and nitric acid are also known, it is possible to calculate the Gibbs free energy of formation of dissolved nitrous acid in 4 mol L^{-1}, 8 mol L^{-1}, and 14.4 mol L^{-1} solutions. The results are reported in Table 6 in which the three values obtained from the calculations on the apparent standard potentials are given with all the figures obtained. The three values are quite close and therefore a mean value of the Gibbs free energy of formation of nitrous acid at 100°C was determined as $\Delta G_f(HNO_2) = -36.3 \pm 1$ kJ mol^{-1}.

This value is considered constant for the whole nitric acid concentration range. The error of 1 kJ mol^{-1} corresponds to a potential measurement error of ± 5 mV. In Table 6, two literature values corresponding to the Gibbs free energy of formation of dissolved nitrous acid in water at 100°C, are reported.[20,21] These values are quite different and the experimental datum determined above is intermediate between them.

Table 6. Experimental values of the free energy of formation of nitrous acid in various nitric acid solutions (results obtained by a calculation made with the experimental standard potentials); literature values in water at 100°C[20,21]

Joint Use of Thermochemical and Potentiometric Data for Establishing an Improved Potential−Acidity Diagram for Nitric Media

Calculated Diagrams at 25°C and 100°C

The curves on the diagrams (Figures 1 and 2) represent the calculated values of the oxygen pressure for which the partial pressures of the various gaseous species are equal to 1 bar and 0.1 bar. For concentrated media (around 65%), the curves tend to deviate from a linear evolution; this phenomenon is due to the variation of the water vapor pressure.

The oxygen pressure is directly linked to the oxidizing power of the medium. Therefore, the curves relative to the different gases delimit the stability domain of nitric acid solutions in oxidation and in reduction under a pressure of 1 bar.

According to the diagrams at 25°C, as well as at 100°C, nitric acid should not be stable and should decompose into nitrogen and oxygen. In practice, the curves corresponding to the variation of the oxygen pressure for a pressure of 1 bar of nitrogen, N_2, and for a pressure of 1 bar of dinitrogen monoxide, N_2O, are found at much lower oxygen pressures than the values calculated. Literature results report that nitrogen and dinitrogen monoxide are formed at potentials lower than 0.7 V/NHE i.e. 0 V/SSE.[22] This potential gives a value of the oxygen pressure of $\log(P_{O_2}) \approx -30$, which is much lower than the values obtained by calculations. This behavior is probably due to the slow kinetics of the reactions involving N_2 or N_2O.

If N_2 and N_2O are not considered, the curves relative to the gaseous nitrogen oxides, NO and NO_2, delimit the stability domain of nitric solutions when the medium is reduced (under a pressure of 1 bar). This domain is equivalent to the electroactivity domain for cathodic potentials in a Pourbaix diagram. In oxidation, the domain is limited by the formation of oxygen. In the diagram at 25°C, the reduction of nitric acid leads to the formation of NO for nitric acid concentrations lower than 60 wt-% ($P_{HNO3} = 1.58 \cdot 10^{-3}$ bar) and to the formation of N_2O_4 for higher concentrations. At 100°C, the electroactivity domain of nitric acid in reduction under a pressure of 1 bar is also divided into two parts. The formation of NO limits the stability domain of nitric acid for concentrations lower than 40 wt-% ($P_{HNO3} = 0.0115$ bar) and the formation of NO_2 limits the stability domain for higher concentrations.

The junction between the $[-\log(P_{HNO3})]$ scale and the pH scale is made with the dissociation constant of nitric acid. Consider the equilibrium:

$$HNO_{3(g)} \rightleftharpoons H^+_{(aq.)} + NO^-_{3(aq.)} \quad (4)$$

For pH = 0, the activity of protons is considered to be equal to its concentration, and the equilibrium constant of reaction (4), known in the literature,[18,19] can be written as:

$$K_{diss.} = \frac{[H^+][NO_3^-]}{P_{HNO_3}}$$

This expression leads to:

$$-\log(P_{HNO_3}) = 2\,pH + \log(K_{diss.})$$

Therefore the junction between pH and nitric acid vapor pressure can be established.

Incorporation of Experimental Measurements into the Calculated Diagram at 100°C

In Figure 5, the variation of the oxygen pressure for the various gaseous species is represented. Moreover, the variation of the oxygen pressure is drawn for a concentration of nitrous acid of 10^{-2} mol L^{-1}. To represent this variation, the mean experimental value of the free energy of formation of nitrous acid in a nitric acid solution at 100°C, $\Delta G_f(HNO_2) = -36.3 \pm 1$ kJ mol^{-1}, is used and the equilibrium (f) is considered:

$$HNO_{3(g)} \rightleftharpoons HNO_{2(aq.)} + \frac{1}{2} O_{2(g)}$$

Then, the variation of the oxygen pressure can be written as:

$$\log P_{O_2} = 2\log K_f + 2\log P_{HNO_2} - 2\log[HNO_2]$$

Here all the terms are known for a given nitric acid concentration and temperature. The experimental curve is represented with error bars corresponding to a potential measurement error of ± 5 mV [or 1 kJ mol^{-1} in terms of $\Delta G_f(HNO_2)$].

For pH > 0, the variations of the oxygen pressure, for a concentration of nitrous acid of 10^{-2} mol L^{-1}, obtained with literature values of $\Delta G_f^0(HNO_2)$, are also represented. The experimental variation is located between those curves.

An experimental potential scale, referenced to the saturated sulfate electrode at 25°C, has been superimposed on the $\log(P_{O2})$ scale for each nitric acid concentration. It is necessary to be aware that this experimental potential scale is not a thermodynamic scale because of the temperature gradient. The working electrode was in the nitric acid solution at 100°C and the reference electrode in a compartment of the electrochemical bridge at 25°C for practical considerations. However, all the measurements were performed in the same conditions and are reproducible, and can therefore be compared between with other.

The correspondence between the oxygen pressure and the potential scale is established in the following way. The potential can be expressed according to the system O_2/H_2O:

$$E = E^0_{O_2/H_2O} + \frac{RT}{2F}\ln\frac{P_{O_2}^{1/2}[H^+]^2}{P_{H_2O}}$$

For a given nitric acid concentration and temperature, the concentration of protons and the water vapor pressure are fixed. They can be included in an apparent standard potential, $E^{0\prime}{}_{O2/H2O}$, and the potential can be written as:

$$E = E^{0\prime}_{O_2/H_2O} + 2.303\frac{RT}{4F}\log P_{O_2}$$

For a variation of 1 of the $\log(P_{O2})$ scale for a given nitric acid concentration at 100°C, the apparent standard potential, $E^{0\prime}{}_{O2/H2O}$ is constant and the corresponding variation of the potential is equal to 18.5 mV according to:

$$\Delta E = 2.303\frac{RT}{4F} = 18.5\ \text{mV}$$

The electrochemical measurements led to the determination of the apparent standard potential of the HNO_3/NO_2 system, $E_2{}^{0\prime}$, at nitric acid concentrations of 4 mol L^{-1}, 8 mol L^{-1}, and 14.4 mol L^{-1}. Therefore, the values of $E_2{}^{0\prime}$ could be placed on the diagram, for each nitric acid concentration, on the curve representing the variation of the oxygen pressure for a nitrogen dioxide pressure of 1 bar.

At a given nitric acid concentration, knowing the value of $E_2{}^{0\prime}$, all the other potentials can be determined with the

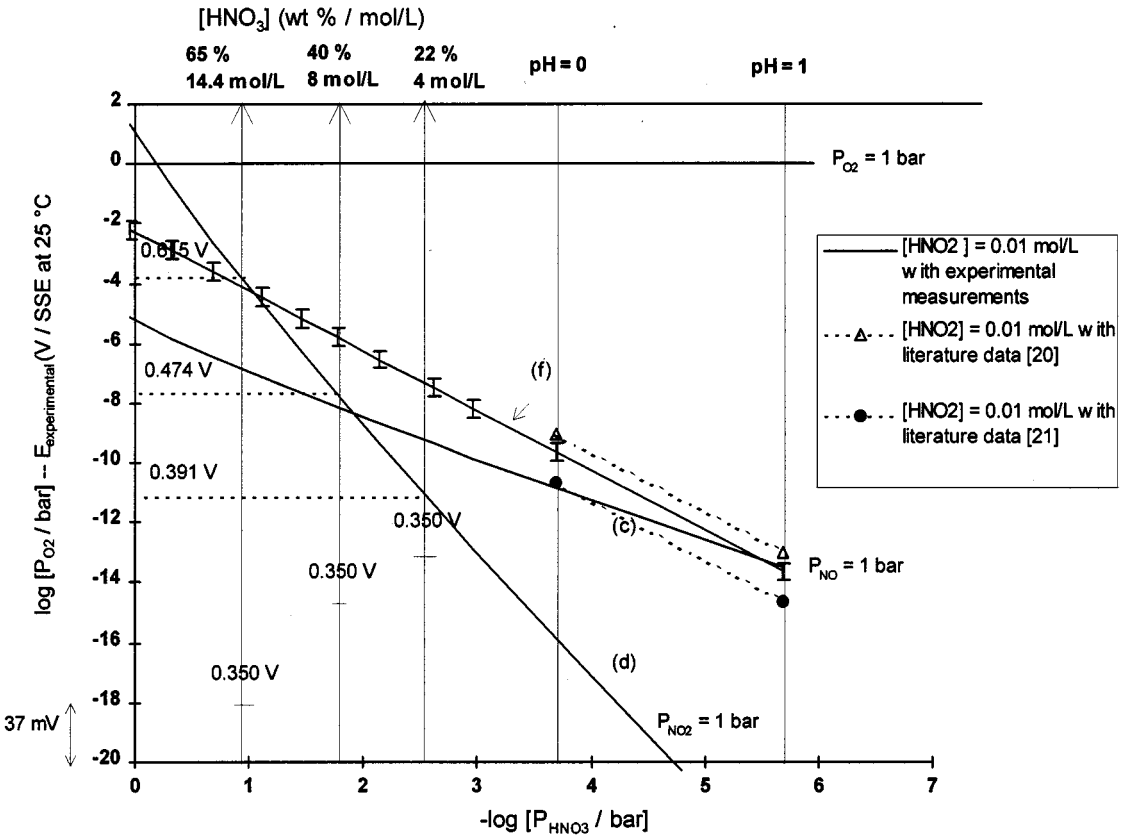

Figure 5. Incorporation of the experimental results into the calculated thermochemical diagram at 100°C; determination of an experimental potential scale referenced on the nitrogen dioxide curve for a pressure of 1 bar

correspondence between the $\log(P_{O2})$ axis and the experimental potential axis.

In Figure 5, the potential value of 0.350 V/(SSE at 25°C) for the three nitric acid concentrations is represented in order to show the variation of the experimental potential scale with the nitric acid concentration. For each nitric acid concentration, an experimental potential scale has then been established. This scale allows any experimental measurement to be placed on the diagram.

Conclusion

The method used in this study to represent the nitric acid chemical properties can be extended to any concentrated medium. The choice of an *x* scale linked to a gaseous species avoids the use of uncertain data on the dissociation of concentrated acid and of thermochemical data of soluble species which are often unknown in the working medium. Moreover, working with vapor pressures in concentrated media allowed us to obtain a more expanded scale.

In the case of nitric acid, the major soluble species apart from nitric acid is nitrous acid. For this substance, uncertainties remained in the value of the Gibbs free energy of formation in solution at 100°C. Values of the free energy of formation of nitrous acid in solution have, however, now been determined experimentally for nitric acid concentrations varying from 4 mol L^{-1} to 14.4 mol L^{-1}. These values led to the determination of the free energy of formation of nitrous acid in solution for the whole nitric acid concentration range. Knowledge of this value allowed us to place the variation of the oxygen pressure for a concentration of nitrous acid of 10^{-2} mol L^{-1} into the diagram.

Finally, the major species found when nitric acid is reduced at potentials close to the equilibrium potential have been determined: NO for nitric acid concentration lower than 40% (ca. 8 mol L^{-1}) and NO_2 for higher concentrations. An experimental potential scale, referenced to the saturated mercurous sulfate electrode at 25°C, was also established with the experimental determination of the HNO_3/HNO_2 and HNO_3/NO_2 systems.

This representation appears to be a useful tool to understand and clarify the behavior of concentrated nitric acid. In the subsequent part of the study, corresponding to an electrokinetic investigation of the reduction of concentrated nitric acid at 100°C, this diagram will help us to understand reduction mechanisms of nitric acid occurring at a platinum electrode.

Experimental Section

Reactor Cell: The reactor was regulated at 100°C and contained 1 L of solution with the volume of the vapor phase approximately 0.6 L. The size of reactor was chosen for the measurements under a flow of nitrogen dioxide as a large volume of solution avoided a significant variation in the composition of the liquid medium with the gaseous flow. The working electrode was a platinum plate of 0.25 cm^2 polished to a mirror finish. The following circuit was set up for measuring the electrode potential: working electrode/HNO_3 solution, 100°C/HNO_3 solution, 25°C/saturated KNO_3 solution, 25°C/saturated K_2SO_4 solution, 25°C/saturated sulfate electrode, 25°C. The reference electrode was a saturated mercurous sulfate electrode and may be described as: Hg/Hg_2SO_4/saturated K_2SO_4 solution. The potential of this reference electrode relative to the standard hydrogen electrode at 25°C is equal to E_{SSE} = 0.640 V/SHE.[23] The difference in temperature between the working electrode and the reference electrode prevented us from measuring thermodynamic potentials: The potential scale established was not a thermodynamic scale but rather, was purely experimental allowing us to compare values obtained in the same conditions.

Electrochemical Apparatus and Procedure: The potential measurements were made with an EG&G PAR Model 273 potentiostat as other electrochemical experiments, which are not presented here, were performed in the same time. Measurements were performed in 22 wt-% (4 mol L^{-1}), 40 wt-% (8 mol L^{-1}), 48 wt-% (10 mol L^{-1}), and 65 wt-% (14.4 mol L^{-1}) nitric acid solutions at 100°C with addition of nitrites (nitrous acid in concentrated medium) in the solution or under a controlled atmosphere performed with a gas flow imposing a specific NO_2 pressure. The NO_2 flow was performed by combining air and NO at specific rates to form NO_2 at the desired pressures according to:

$$NO(g) + {}^1/_2\ O_2(g) \rightleftharpoons NO_2(g)$$

The NO_2 pressure was verified by bubbling NO_2 for one hour through a sodium hydroxide solution and measuring the concentration of nitrites as NO_2 reacts with NaOH to form nitrites according to:

$$2\ NO_2(g) + 2\ NaOH \rightleftharpoons NaNO_2(aq.) + NaNO_3(aq.) + H_2O$$

The concentration of nitrous acid (nitrite ions) in solution was measured by colorimetry with a Perkin−Elmer UV/Vis spectrometer according to the Griess method.[24]

Interactions Between Cyclodextrins and Tm^{III} Chelates of Polyazamacrocycles as Studied by NMR in Aqueous Solution

Emrin Zitha-Bovens,[a] Herman van Bekkum,[a] Joop A. Peters,*[a] and Carlos F. G. C. Geraldes*[b]

Keywords: MRI contrast agents / Macrocyclic ligands / Cyclodextrins / Host-guest chemistry / Lanthanides

The interactions between α-, β-, and γ-CD and the Tm^{III} chelates of the macrocyclic polyaminopolycarboxylates DOTA and NOTA were studied with the use of ^1H- and ^{13}C-NMR shift and relaxation rate measurements. Interactions were only observed between $Tm(DOTA)^-$ and γ-CD. The structure and the stability of the concerning supramolecular structures was elucidated by fitting of the NMR titration curves to a theoretical model. It appears that an inclusion compound is formed, where the hydrophobic macrocyclic part of the chelate sits in the γ-CD cavity. This inclusion compound binds a second $Tm(DOTA)^-$ molecule at the outside lower rim of the CD cone. The binding occurs probably via hydrogen bonds between non-chelated carboxylate oxygen atoms of the concerning $Tm(DOTA)^-$ and CH_2OH groups of the γ-CD molecule, which are in a favorable position due to opening of the γ-CD cone angle as a result of the inclusion of the first γ-CD.

Introduction

A number of stable lanthanide(III) complexes with polyazamacrocyclic ligands are utilized in biomedical diagnosis, for example as paramagnetic shift reagents for in vivo NMR,[1] and specially as contrast agents for Magnetic Resonance Imaging (MRI).[2−4] One of the currently applied contrast agents is $Gd(DOTA)^-$ (Dotarem®) (H_4DOTA = 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*′′,*N*′′′-tetraacetic acid) (For structures of the ligands see Figure 1).[5] The efficacy of MRI contrast agents is determined by their ability to enhance the solvent water proton relaxation rate. Among the strategies to improve this, optimisation of the inner-sphere relaxivity, through slowing down of the rotational dynamics, has proved to be quite useful.[2−4] This has been achieved by either covalent conjugation[2,6] or non-covalent binding[7] of the Gd^{III} complexes to high molecular weight aggregates or macromolecules, such as Human Serum Albumin (HSA).

Cyclodextrins (CDs) are cyclic oligosaccharides made up of six, seven, or eight α-1,4-linked D-glucopyranoside units (α-, β-, and γ-CD, respectively).[8,9] They have a cone-like shape with a hydrophobic cavity, the size of which depends on the number of glucopyranose units constituting the CD. Many NMR studies of the solution thermodynamic stability and structure of host-guest compounds of α-, β-, and γ-CDs with organic molecules have recently been published.[10−14] Several inclusion complexes of γ-CD with crown ethers, azamacrocycles and their complexes with metal cations such as Li^+, Ca^{2+}, and Ba^{2+}, have been characterized.[15−17] Inclusion compounds with cyclodextrins have drawn attention as enzyme model systems and found a wide range of applications, such as in drug delivery systems.[8,9,18] Formation of a stable inclusion compound between a contrast agent and a cyclodextrin would possibly increase its relaxivity and also alter its in vivo biodistribution. Aime et al. have studied inclusion compounds of β-benzyloxy-α-propionic substituted DOTA and DTPA-Gd^{III} complexes.[19] The benzyl groups of these compounds are included in the small CD cavity, which resulted in an increase of the relaxivity. Sherry et al. have observed the formation of weak inclusion compounds between γ-CD and $Tm(DOTP)^{5-}$ (H_8DOTP = 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*′′,*N*′′′-tetrakis(methylenephosphonic acid).[20]

The present paper reports an NMR study on the stability and structure of the inclusion compound(s) formed between γ-CD and $Tm(DOTA)^-$. The latter complex has a lower net charge than $Tm(DOTP)^{5-}$ and, therefore, is probably less hydrophilic. Tm^{III} was selected as Ln^{III} ion for these studies because this Ln^{III} ion induces both large chemical shifts and relaxation rate enhancements.[4] The geometry of the inclusion compounds was studied by measuring the cyclodextrin ^1H- and ^{13}C-NMR Lanthanide Induced Shifts (LIS) and spin-lattice (T_1) relaxation rate enhancements induced by the paramagnetic cation in the supramolecular system(s) formed. A one-step procedure is presented for the fitting of the measured LIS data to model the complexes formed. We also investigated the effect of a change in the size of the macrocyclic Tm^{III} complex [by using Tm(NOTA) complexes, H_3NOTA = 1,4,7-triazacyclononane-*N*,*N*′,*N*′′-tri-

Results and Discussion

Referencing of NMR Chemical Shifts

Referencing of NMR chemical shifts in a study of the interaction between CDs and a paramagnetic complex is a non-trivial problem. Any internal reference used should not interfere with the equilibria between these species. ^{1}H-NMR spectra of γ-CD referenced with respect to the potential internal references *tert*-butyl alcohol, 1,4-dioxane, pentaerythritol, or tetramethylammonium bromide showed concentration dependence of the chemical shifts, which suggests an interaction between the CD and the "standard". To avoid these problems, we decided to use a solution of TMS in $CDCl_3$ in a coaxial tube inside the sample tube as external standard. Introduction of paramagnetic complexes into the outer compartment of the NMR samples causes large changes of bulk magnetic susceptibility (BMS), which are not felt in the inner tube containing the standard.[21] Therefore, corrections for these BMS effects are required. The BMS for a system with a coaxial cylindrical sample tube parallel to the main magnetic field is given by Equation (1), where Δ_χ is the paramagnetic contribution to the BMS in ppm, c is the concentration of the Tm^{III} complex in mol dm^{-3}, and T is the temperature.[21]

$$\Delta_\chi = 29\,997 \cdot c/T \quad (1)$$

Experimentally determined BMS values, determined with samples containing $Tm(DOTA)^-$ and *tert*-butyl alcohol as internal reference, were, within the experimental error, the same as those calculated with Equation (1). All chemical shifts mentioned below are corrected for BMS contributions.

Screening of the Interactions Between Macrocyclic Tm^{III} Complexes and α-, β-, and γ-Cyclodextrin

We started by titrating Tm(NOTA) or $Tm(DOTA)^-$ into 5 mM solutions of α-, β-, and γ-CD in D_2O at 25°C. Interactions were monitored by the ^{1}H resonances of the CD in question. Only upon addtion of $Tm(DOTA)^-$ to γ-CD, significant induced ^{1}H shifts were observed (after subtraction of the BMS contribution, see above). For all other combinations the induced shifts were less than 0.1 ppm when the concentration of the Tm^{III} chelate was increased up to a molar ratio Tm^{III} complex/CD (ρ) of 10. Only some line broadening was observed in these cases and the longitudinal ^{1}H relaxation rate enhancements were of the same order of magnitude as those observed for *tert*-butyl alcohol in a sample containing the same concentration of the Tm^{III} chelate. For example, ^{1}H relaxation rate enhancements ranging between 2.4 and 4.5 s^{-1} were measured for β-CD in the presence of $Tm(DOTA)^-$ at ρ = 3, whereas for *tert*-butyl alcohol under similar conditions an enhancement of 2.8 s^{-1} was observed. Therefore, it can be concluded that these relaxation rate enhancements are due to intermolecular effects, i.e. to effects resulting from diffusion of substrate molecules past the paramagnetic chelate complexes. Any direct binding of a Tm^{III} chelate to a CD molecule would lead to additional specific and substantial relaxation rate enhancements. Binding of the Tm^{III} chelates to the outer surface of the CD cones, therefore, does not play an important role.

The internal diameters of the three CD cavities are: α-CD: 4.7−5.2 Å; β-CD: 6.0−6.4 Å; γ-CD: 7.5−8.3 Å, where the smaller value is for the ring 5-H and the larger value is for the ring 3-H.[8,22] The size of the Tm^{III} chelates was evaluated by measuring (using standard molecular modelling software) the maximum distance between two ring ethylenediamino protons or acetate arm protons oppositely placed in the chelate structure. For Tm(NOTA) these distances are 5.82 and 6.76 Å, respectively.[23] A comparison of the approximate sizes of the potential host cavities and

the chelate guest indicates that the α-CD and β-CD cavities are too small to accomodate Tm(NOTA), while the γ-CD cavity is already too large to interact with the bottom macrocyclic ring hydrophobic surface of that chelate. Similarly, molecular models show that $Tm(DOTA)^-$ (distances 7.5 and 8.3 Å) fits exactly into the cavity of γ-CD, but is too bulky for inclusion in α- or β-CD.

Thus, the observation of significant Tm^{III}-induced ^1H shifts corresponds with the ability of the Tm^{III} chelate to form a well-fitting inclusion compound with the CD. Apparently, a very fine geometry fitting is needed for a reasonable host-guest interaction, perhaps due to the need of the guest to expel the hydrogen-bonded network of water molecules from inside the host CD cavity. Similar phenomena have been reported for $Tm(DOTP)^{5-}$, which induces paramagnetic ^1H shifts in γ-CD nuclei, but not in β-CD nuclei.[20]

Interactions between $Tm(DOTA)^-$ and γ-CD; Tm^{III}-Induced NMR Shifts

The interaction between $Tm(DOTA)^-$ and γ-CD was studied in more detail. Upon titration of $Tm(DOTA)^-$ into a 25 mM γ-CD solution, all ^1H and ^{13}C resonances of the CD molecule, after correction for the BMS shift contribution (see above), show Tm^{III}-induced shifts, some to high and others to low frequency. The magnitude of each (corrected) LIS was sensitive to the amount of $Tm(DOTA)^-$ added, indicating fast exchange between free and bound γ-CD. Figure 2 illustrates the plots of experimental LIS values versus ρ for some ^1H and ^{13}C CD resonances. In a similar NMR titration performed with the diamagnetic $La(DOTA)^-$ no induced shifts were observed for the γ-CD resonances. Therefore, it can be concluded that diamagnetic contributions to the shifts induced by the Tm^{III} complex are negligible.

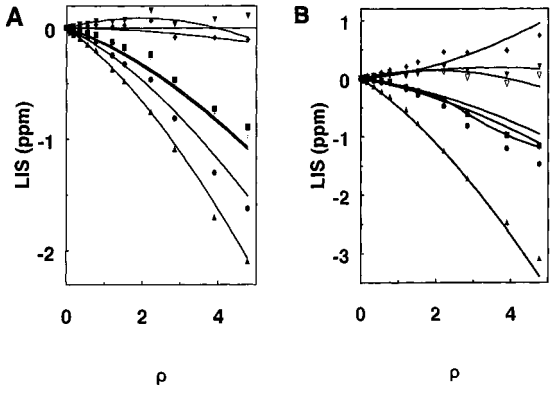

Figure 2. ^{13}C (A) and ^1H-NMR titration curves (B) for the addition of $Tm(DOTA)^-$ to a 25 mM solution of γ-CD in D_2O; the curves are calculated using the parameters given in Table 1 (see text); + C-1/1-H, ● C-2/2-H, ▲ C-3/3-H, ■ C-4/4-H, ◆ C-5/5-H, ▼ C-6/6-H, ▽ 6′-H; the experimental points of 2-H and 4-H coincide

It is known that Ln^{III} ions have only weak interactions with carbohydrates.[24] The Tm^{III} ion in $Tm(DOTA)^-$ is strongly chelated by the bulky macrocyclic ligand in an eight-dentate fashion[25] and, therefore, it may be assumed that additional coordination of a CD in the first coordination sphere of Tm^{III} does not occur. As a result, the contact contributions to the LIS can be neglected; the LIS are determined exclusively by the pseudo-contact mechanism.[4] Furthermore, the $Ln(DOTA)^-$ complexes have 4-fold symmetry and, consequently, the pseudo-contact contributions to the fully bound LIS values (LIS_{pc}) of each ligand nucleus is related to the structure of the chelate through Equation (2).[26] Here, the geometric term G depends on the spherical coordinates r and θ of the nucleus under study with respect to Ln^{III} at the origin and with the principal symmetry axis of the system as the z axis.

$$LIS_{pc} = D \cdot G = D \cdot \frac{3\cos^2\theta - 1}{r^3} \qquad (2)$$

The magnetic proportionality constant D is characteristic of the Ln^{III} ion and the chelate. Brittain and Desreux have reported that the D value for the major isomer of $Yb(DOTA)^-$ is 5082 ± 209 ppm·Å^3.[27] The ratio of the pseudocontact shifts of isostructural Yb^{III} and Tm^{III} complexes is known to be 53:22.[4][28] Therefore, the value of D of the major $Tm(DOTA)^-$ complex can be estimated to be 12243 ppm·A^3 (= 5082×53/22). From Equation (2) it follows that the magnitude and direction of the LIS is determined by the position of the nucleus relative to the paramagnetic center. The LIS is zero in spatial positions on a cone centered on the metal, with an axis coinciding with the magnetic axis of the chelate and with a cone angle of 54.7°, where the geometrical factor G and the shift change sign. We assume that the position of the principal axis and the value of D of adducts of the Tm^{III} chelates and γ-CD are the same as those in the free $Tm(DOTA)^-$ complexes, and also that binding to γ-CD does not affect the isomer equilibrium of $Tm(DOTA)^-$.[25]

The initial slopes of the titration curves of protons 1-H to 4-H, as well as the corresponding carbon atoms C-1 to C-4 are negative (shifts to lower frequencies, negative LIS values), whereas the atoms 5-H, 6-H, 6′-H, C-5, and C-6 have positive LIS values. This change in sign of the LIS between the C-4-H and C-5-H moieties of the γ-CD ring determines, through the change of sign of the geometrical term for the $Tm(DOTA)^-$ (see Equation 2), the depth at which the chelate sits inside the γ-CD cavity, and thus gives a qualitative picture about the relative position of the chelate and the cyclodextrin molecule (see Figure 3). This is quite similar to what has been previously found for $Tm(DOTP)^{5-}$/γ-CD.[20]

Surprisingly, almost all titration curves of Figure 2 show an increase of slope upon an increase of ρ, whereas for $Tm(DOTP)^{5-}$ the titration curves have been reported to to be linear up to ρ = 50.[20] Therefore, it can be concluded that besides the 1:1 adduct of $Tm(DOTA)^-$ and γ-CD [ML, M = $Tm(DOTA)^-$, L = γ-CD] another species is present, most likely M_2L. Furthermore, it can be noted from Figure 2 that, even at ρ = 5, the LIS values have not reached a

limiting value. This indicates that the association constant for the stability constants of the adducts are very low.

The most common procedure for the elucidation of solution structures of Ln^{III} complexes in the case of fast exchange between the free and bound substrate on the NMR time scale involves two steps.[4,29] First fully bound shifts of the ligand nuclei are evaluated from fitting titration curves or relative bound shifts are determined from the initial slopes of the titration curves. The bound shifts are then entered into a fitting to, for example, Equation (2) to give the molecular structure. In the present case, however the determination of bound shifts is difficult because of the curvature of the plots and because the limiting values of the shifts are not reached at high ρ-values. Therefore, we performed the two fitting procedures simultaneously. Since both the geometries of the host and the guest are rather rigid and well-known, structural constraints can be applied in the fitting procedure, which results indirectly in constraints on the calculated bound shifts. In a simultaneous fitting these constraints, on their turn, reduce the uncertainty in the resulting stability constants.

The experimental LIS data for the titration of γ-CD with $Tm(DOTA)^-$ were fitted with a model taking into account the ML and M_2L adducts. It was assumed that the ML adduct is an inclusion compound in which the main symmetry axis of the host and the guest coincide. Any location of the second chelate M at the surface of the CD cone is less likely, because then averaging over the various equivalent positions in the eight sugar units would lead to averaging out of the angular term in Equation (2) and, therefore, to very small LIS values. Most likely, the second M is near one of the rims and its position probably coincides with the main symmetry axis of γ-CD. For this situation, equivalent nuclei of the various sugar units have equal θ values and averaging out of the induced shifts does not occur.

Reported crystal coordinates for γ-CD[30] were submitted to molecular mechanics with the MM+ force field, after docking of a model of the $Eu(DOTA)^-$ structure obtained from reported crystal coordinates[31] in the cavity. The geometry of the guest was fixed during these calculations. The resulting coordinates of the γ-CD moiety were used in the elucidation of the solution structure of ML and M_2L. From an initial guess of the location of the two Tm^{III} ions on the symmetry axis of γ-CD, the bound shifts of the γ-CD nuclei of ML and M_2L (Δ_{ML} and Δ_{M2L}) were calculated using Equation (2). The *D* value in Equation (2) was fixed at 12243 ppm·Å^3 (see above). It is assumed that the *D* values of the adducts ML and M_2L are the same as that of the parent compound M. The equilibrium constants of the species in question were defined as in Equations (3) and (4).

$$\beta_{ML} = \frac{[ML]}{[M][L]} \quad (3)$$

$$\beta_{M_2L} = \frac{[M_2L]}{[M]^2[L]} \quad (4)$$

From an initial guess of β_{ML} and β_{M2L}, Equations (3) and (4) and the mass balances, the concentrations of the various species were obtained by an iteration following a procedure outlined previously.[32] With these concentrations the fractions of L bound as ML and M_2L were calculated (f_{ML} and f_{M2L}, respectively). Then the induced shifts $\delta_{calcd.}$ at the various ρ values were calculated using Equation (5).

$$\delta_{calcd.} = f_{ML}\Delta_{ML} + f_{M2L}\Delta_{M2L} \quad (5)$$

The agreement between the calculated and experimental shifts was optimized using an iteration with the location of the two Tm^{III} centers on the symmetry axis of the γ-CD host, and β_{ML} and β_{M2L} as variables. An optimal fit was obtained for the parameters reported in Table 1. The corresponding bound shifts for ML and M_2L calculated with these parameters are included in Table 1. The Tm^{III} of the included $Tm(DOTA)^-$ chelate is located 2.7 Å above the plane formed by the anomeric oxygen atoms of the glucose units of the CD host. A similar position of Tm^{III} has been reported for $Tm(DOTP)^{5-}$ included in γ-CD.[20] The second Tm^{III} ion in the M_2L complex is found 5.1 Å below this plane, the second $Tm(DOTA)^-$ molecule is thus located at the lower rim of the host (see Figure 3). An inspection of molecular models of this complex shows that such a location is favorable for the formation of hydrogen bonds between the non-chelated carboxylate oxygens of the $Tm(DOTA)^-$ molecule and CH_2OH functions of the glucose units of γ-CD.

Table 1. Stabilities of 1:1 and 2:1 $Tm(DOTA)^-$: γ-CD complexes as obtained from Tm^{III}-induced shift measurements,[a] location of the Tm^{III} cations, and calculated bound shifts

	ML	M_2L
β [M^{-1}]	0.33 ± 0.03	3.4 ± 0.3
distance Tm^{III}−O-1 plane [Å][c]	2.67 ± 0.05	−5.14 ± 0.09
bound shifts [ppm]		
C-1	−14.5	−15.5
C-2	−22.4	−20.3
C-3	−32.6	−26.0
C-4	−16.3	−14.4
C-5	−0.3	−3.1
C-6	12.4	−13.1
1-H	−11.1	−15.5
2-H	−15.0	−16.3
3-H	−55.3	−41.2
4-H	−11.3	−15.3
5-H	6.1	19.7
6-H	19.5	−20.9
6′-H	14.1	−7.9

[a] Calculated with *D* = 12243 (see text). Agreement factor *R* = 0.16. − [b] M = $Tm(DOTA)^-$, L = γ-CD. − [c] Plane through the anomeric oxygen atoms of the glucose units of γ-CD, the direction towards the upper (wide) rim of γ-CD is denoted positive.

The calculated locations of the Tm^{III} centers are not very sensitive to the choice of the value of *D* in Equation (2). If the value of this parameter was fixed at 7434, a value derived from that reported for the minor isomer of $Yb(DOTA)^-$,[27] positions 2.6 Å above and 5.2 Å below the plane of the anomeric glucose oxygen atoms were obtained.

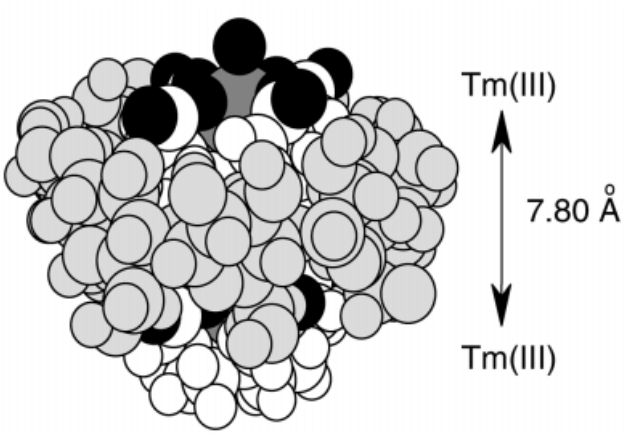

Figure 3. Schematic representation of the M_2L complex [M = $Tm(DOTA)^-$, L = γ-CD]

The calculated formation constants were, however, somewhat higher (β_{ML} = 0.51 M^{-1}; β_{M2L} = 6.6 M^{-2}).

Iterations with a model including a second 1:1 adduct with M bound at the outside of the cone at the lower rim rather than inside the CD cavity, did not lead to a better agreement between the calculated and observed titration curves. Furthermore, the resulting stability constant for the concerning complex was relatively small (β = 0.10 ± 0.05 M^{-1}). This is in line with the observation that α- and β-CD, which are not able to include $Tm(DOTA)^-$, also do not show interaction with this chelate at the outside surface of their cones. Furthermore, it should be noted that the stepwise formation constant of M_2L is larger than the formation constant of ML. Apparently, inclusion of the first $Tm(DOTA)^-$ chelate leads to a situation that is favorable for binding of the second one. It is known that inclusion of bulky guests into CDs results in adaption of the cone-angle of the CD host.[17] We assume that the inclusion of $Tm(DOTA)^-$ in γ-CD brings the CH_2OH functions of the CD in a position that is more favorable for the formation of multiple hydrogen bonds with a second $Tm(DOTA)^-$ molecule. This also explains, why an M_2L complex was not observed with $Tm(DOTP)^{5-}$,[20] as the distance between the oxygen atoms of the phosphonate functions is too large for the formation of hydrogen bonds with CH_2OH functions. Also the high negative charge of the Tm(DOTP) chelate (about −3 at pH = 7) causes it to hinder the binding of the second one at the lower rim through electrostatic repulsion.

Interactions between $Tm(DOTA)^-$ and γ-CD; Tm^{III}-Induced Relaxation Rate Enhancements

The longitudinal ^1H relaxation rate enhancements of γ- and β-CD upon addition of $Tm(DOTA)^-$ at ρ = 3 are given in Table 2. The ^{13}C relaxation rate enhancements are at least an order of magnitude smaller and are not taken into consideration. Various relaxation enhancing mechanisms contribute to the total effect. Two contributions resulting from the binding of the $Tm(DOTA)^-$ to the CD molecule should be envisaged: (i) a dipolar one ($1/T_{1,p}$) caused by through space interactions due to the random fluctuations of the electronic field of Tm^{III}[33,34] and (ii) the Curie contribution ($1/T_{1,Curie}$), which arises from the interaction of the nuclear spin with the thermal average of the electronic spins[35−38] (Equation 6).

Table 2. Contributions to the Tm^{III}-induced longitudinal relaxation rate enhancements of a 0.023 M solution of γ-CD nuclei in D_2O at ρ = 2.8[a]

	$1/T_{1,p} + 1/T_{1,Curie}$ [s^{-1}][a]	$1/T_{1,inter}$ [s^{-1}][b]	$1/T_{1,calcd.}$ [s^{-1}][c]	$1/T_{1,exp}$ [s^{-1}]
1-H	0.51	5.79	6.30	5.23
2-H	0.41	4.95	5.36	7.25
3-H	4.39	7.15	11.54	12.44
4-H	0.64	4.16	4.80	4.59
5-H	4.05	4.41	8.46	5.01
6-H/6′-H	3.03	3.85	6.88	4.90

[a] Calculated with Equations 6−9 (see text). − [b] Estimated from relaxation rate measurements on a 0.013 M solution of β-CD in D_2O at ρ = 3.0. A correction for the difference in the $Tm(DOTA)^-$ concentrations between the two samples was applied. − [c] Sum of $1/T_{1,p}$, $1/T_{1,Curie}$, and $1/T_{1,inter}$.

$$\frac{1}{T_{1,b}} = \frac{1}{T_{1,p}} + \frac{1}{T_{1,Curie}} \tag{6}$$

Tm^{III} has a very short electronic relaxation time ($T_{1e} \approx 10^{-13}$ s). If zero-field splitting (ZFS) effects are neglected,[38] $1/T_{1,p}$ can be given by the simplified Solomon-Bloembergen Equation (7).[33,34]

$$\frac{1}{T_{1,p}} = \frac{4}{3}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\gamma_I^2 \mu_{eff}^2 \beta^2}{r^6} T_{1e} \tag{7}$$

Here, $\mu_0/4\pi$ is the magnetic permeability of a vacuum, γ_I is the magnetogyric ratio of the nucleus under study, μ_{eff} is the effective magnetic moment of Tm^{III}, β is the Bohr magneton, and r is the distance between the nucleus under study and Tm^{III}. The Curie spin contribution can be expressed by Equation (8) where H_0 is the magnetic field strength, k is the Boltzmann constant, T is the temperature, τ_R is the rotational tumbling time of the complex and ω_I is the Larmor frequency of the nucleus under study.[35,36]

$$\frac{1}{T_{1,Curie}} = \frac{6}{5}\left(\frac{\mu_0}{4\pi}\right)^2 \left(\frac{\gamma_I^2 H_0^2 \mu_{eff}^4 \beta^4}{(3kT)^2 r^6}\right)\left(\frac{\tau_R}{1+\omega_I^2 \tau_R^2}\right) \tag{8}$$

Merbach et al. have reported a value of 77 ps for the rotational correlation time (τ_R) of $Gd(DOTA)^-$ at 298 K[39] and Aime et al. have reported values of 72 and 80 ps for the Gd^{III} and Lu^{III} complexes of DOTA, respectively.[40] The rotational correlation times are, according to the Debye-Stokes-Einstein equation, proportional to a^{-3} for spherical complexes, where a is the molecular diameter. On this basis, we have used 80, 268, and 339 ps as estimates for the τ_R values of M, ML, and M_2L, respectively. Values of T_{1e} of lanthanides other than Gd^{III} are usually not very

dependent on the structure of bound ligands. The T_{1e} values reported by Aime et al. for DOTA chelates of Tb^{III}, Dy^{III}, and Ho^{III}[40] are close to those tabulated for the aquo complexes.[41] It should be noted, however, that T_{1e} values obtained with data processing including ZFS effects are about 2−3 times higher,[38] although the same nuclear relaxation rates were calculated as with a procedure in which ZFS effects were neglected. Therefore, we have used T_{1e} = 0.369 ps for $Tm(DOTA)^-$ and its complexes with γ-CD. With the use of these parameters and Equations (5−8) the $1/T_{1,b}$ values for ML, and M_2L were calculated. The exchange of γ-CD between ML, M_2L, and L is fast on the NMR time scale and, therefore, the relaxation rate enhancement due to binding of $Tm(DOTA)^-$ to γ-CD can be estimated with Equation (9).

$$\frac{1}{T_{1,calc}} = \frac{f_{ML}}{T_{1,ML}} + \frac{f_{M_2L}}{T_{1,M_2L}} \qquad (9)$$

The relaxation rates have no angular dependence, and therefore, in contrast to the LIS values the effects of random diffusion controlled encounters between the paramagnetic complexes and the γ-CD moieties do not average out. These intermolecular contributions ($1/T_{1,inter}$) were estimated from the longitudinal relaxation rate enhancements of β-CD upon addition of $Tm(DOTA)^-$ (see Table 2), since inclusion does not occur there. It can be seen that this mechanism plays a major role in the present case. After inclusion of $1/T_{1,inter}$ the order of magnitude of the resulting calculated relaxation rates is the same as that of the experimental ones and the large relative value of the relaxation rate of 3-H is reproduced. The agreement between the calculated and experimental values is reasonable, considering the many assumptions that have been made in the course of these calculations.

Conclusion

$Tm(DOTA)^-$ forms a weak inclusion complex with γ-CD. The hydrophilic carboxylate groups remain outside the cavity. The resulting inclusion compound is able to bind a second $Tm(DOTA)^-$ chelate at the outer surface of the CD molecule at the lower rim. The binding occurs probably by hydrogen bonding between the carboxylate oxygen atoms of $Tm(DOTA)^-$ and the CH_2OH functions of the glucose units of γ-CD. Similar complexes are not formed with α- or β-CD or with the less bulky chelate $Tm(NOTA)^-$. Apparently, a good spatial fit of the guest in the cavity of the CD is required for the formation of an inclusion compound. The stability of the inclusion compound is even lower than that of the previously reported inclusion compound of $Tm(DOTP)^{5-}$ and γ-CD.[20] For that compound, however, binding of a second chelate molecule was not observed. Because of the low stability constants of the inclusion compounds, it can be concluded that inclusion of $Gd(DOTA)^-$ into γ-CD is not a useful approach to increase its efficacy as contrast agent for MRI.

Experimental Section

General Remarks: $TmCl_3 \cdot 6\ H_2O$ was purchased from Aldrich, and α-, β-, and γ-cyclodextrin from Fluka. All reagents were used without further purification. The macrocyclic ligands H_4DOTA and H_3NOTA were synthesized according to known procedures.[42−44] The respective Tm^{III} complexes [$Tm(DOTA)^-$ and Tm(NOTA)] were prepared by adding stoichiometric amounts of $TmCl_3 \cdot 6\ H_2O$ to a ligand solution, while maintaining the pH at about 6. The solution was kept at 80°C for about 6 h to ensure complete complex formation, and was tested for free lanthanide ions using xylenol orange and arsenazo III as indicators.[45,46] Salts were removed by nanofiltration through a Toray "Romembra" UTC-60 membrane under 20 bar nitrogen pressure. The final solutions were freeze-dried. The Tm^{III} content of the products was determined from the induced Bulk Magnetic Susceptibility (BMS) shift.[47,48] The latter was measured in a 5-mm sample tube equipped with a 2-mm coaxial inner cell (New Era Enterprises, Vineland, NJ, USA). The inner cell was filled with a 1% solution of TMS in $CDCl_3$ and the outer compartment with a 1% solution of *tert*-butyl alcohol in D_2O. The BMS was determined from the increase of the separation between the TMS and *tert*-butyl alcohol signals upon addition of the Tm^{III} complex.

The NMR titrations were performed by adding weighted amounts of the Tm^{III} complexes to 5 mM or 25 mM CD solutions in D_2O at pH = 6−7, using 10-mm NMR tubes. A 2-mm coaxial tube containing a solution of TMS in $CDCl_3$ was used as external reference for ^1H- and ^{13}C-NMR shifts.

All pH measurements were made at room temperature using a Corning 125 pH meter and a calibrated microcombination electrode purchased from Aldrich Chemical Co. Adjustments of the pH of the solutions were made with DCl and NaOD solutions in D_2O (all supplied by Merck), and no correction was made for the deuterium isotope effect.

NMR spectra were obtained with Varian VXR-400S or Unity 500 spectrometers. Spin-lattice relaxation rates were measured using the inversion recovery method. The ^1H- and ^{13}C-NMR spectra of γ-CD were assigned by two-dimensional homonuclear (COSY) and heteronuclear (HETCOR) correlated spectra, and agreed with the literature.[10−15,20] Molecular mechanics was performed with the use of the HyperChem program (version 3, MM+ force field, HyperCube Inc., Gainsville, FL, USA).Computer fitting of the LIS data was carried out with a homemade computer program using the Micromath Scientist version 2.0 (Salt Lake City, UT, USA) program. The speciations used in this program were evaluated following procedures outlined previously.[32] The equation file used in this program is available from the authors upon request.

Tetracarboxylatodirhenium Complexes Linked by Axial Cyano Bridges to Metalpentacarbonyl Ligands − Synthesis and Characterization

Fritz E. Kühn,*[a] Isabel S. Gonçalves,[b,c] André D. Lopes,[b] João P. Lopes,[b] Carlos C. Romão,[b] Wolfgang Wachter,[a] Janos Mink,[d,e] Làszló Hajba,[e] A. Jorge Parola,[f] Fernando Pina,[f] and João Sotomayor[f]

Keywords: Chromium / Carboxylate complexes / Metal–metal multiple bonds / Molybdenum / Rhenium / Tungsten

Reaction of $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4Cl_2$ with $[(CO)_5M–CN]Na$ (M = Cr, Mo, W) leads to tetranuclear complexes of formula $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4[–NC–M(CO)_5]_2$ (M = Cr, Mo, W). These complexes were characterized by ^1H-, ^{13}C-, and ^{95}Mo-NMR, IR and Raman spectroscopy, elemental analysis and examined by cyclic voltammetry. The applied methods show the donor capabilities of the $[(CO)_5M–CN]^-$ ligands which shift electron density towards the Re centers weakening the Re–Re quadruple bond. The Re–Re bond lengths and the ν(Re–Re) force constants are estimated based on the FT-IR and Raman examinations. Photochemical examinations and TG/MS experiments have also been conducted. The latter method shows that the product complexes decompose around 100 °C, by first loosing their carbonyl substituents; as do the Cr, Mo, W precursor compounds. The dirhenium tetrapivalate unit decomposes only at higher temperatures in a distinct second step.

Introduction

Dirhenium carboxylates of the general formula $Re_2(\mu\text{-}O_2CR)_4X_2$ were among the first molecules containing metal−metal quadruple bonds to be correctly described.[1] Their recognition followed closely upon the heels of the structural characterization of the $[Re_2Cl_8]^{2-}$ anion and the correct treatment of its bonding.[2] However, the first reports of rhenium carboxylates appeared before this, but failed to take into account the possibility of metal−metal bonding.[3] In the interim a very extensive chemistry of $Re_2(\mu\text{-}O_2CR)_4X_2$ complexes has been developed.[1] Nevertheless, the variation of the ligands in axial position (X) remained rather limited. In particular, halides and pseudohalides, e.g. Cl, Br, I, NCS etc. have been reported.[4] Ligands containing transition metals are rare. To our knowledge, only one such compound with perrhenate as axial ligand has been structurally characterized.[4c] During the course of our own work on mixed transition metal complexes linked by nitrile and cyano groups[5] we came to examine the reactivity of $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4Cl_2$ with $[(CO)_5M–CN]Na$ (M = Cr, Mo, W). The latter complexes have gained considerable interest in recent times due to their ability to form cyano bridges to other molecules.[6] The results of these reactions and the characterization of the products are reported in this work.

Results and Discussion

Synthesis and Spectroscopic Characterization

Mixing of a suspension of dichlorodirhenium tetrapivalate (**1**) with $[(CO)_5M–CN]Na$ [M = Cr (**2**) , Mo (**3**), W (**4**)] in THF at room temperature leads to a color change from brown to very dark red. A white precipitate is formed. According to Scheme 1, molecules of composition $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4[–NC–M(CO)_5]_2$ [M = Cr (**5**), Mo (**6**), W (**7**)] and sodium chloride as stoichiometric byproduct are formed. After extraction with dichloromethane to remove the NaCl, the compounds **5**−**7** can be precipitated by the addition of *n*-pentane. The yields of isolated compounds obtained in this way are nearly quantitative. Compounds **5**−**7** can be handled in air at room temperature.

As it might be expected, the ^1H-NMR spectra are not very informative. Both complex **1** and complexes **5**−**7** display a singlet at $\delta(^1H) = 1.52$. The ^{13}C-NMR spectra clearly indicate the formation of the complexes **5**−**7**. The ^{13}C-NMR data are summarized in Table 1. All signals are influenced by the coordination. The strongest shift difference can be seen in the signal corresponding to the carbon atom of the bridging cyano group. This signal is shifted ca. 15−25 ppm to higher field, depending on the central metal atom of the coordinating axial ligand. Interestingly, the shifts of the corresponding signals are very similar in all product molecules in remarkable contrast to the Cr, Mo, W

Scheme 1

precursor compounds. The carboxylate carbon atoms are nearly uninfluenced by the coordination, the ^{13}C signals of the carbonyl C atoms are only slightly (ca. 5 ppm) shifted upfield. The influence of the coordination is also clearly reflected in the ^{95}Mo-NMR spectrum of compound **6** when compared with that of compound **3**. The signal is shifted more then 270 ppm to lower field and is significantly broadened (ca. 130 Hz in the starting material **3**, more than 5000 Hz in compound **6**). The ^{95}Mo-NMR data also display a temperature dependence as depicted in Table 2. A temperature decrease of 100°C causes a downfield shift of ca. 100 ppm in the complex **6**. This seems to be due to the somewhat reduced electron-transfer capability of the complexes at elevated temperatures, probably due to an increase of the thermal movements of the ligands. The latter is reflected in the significantly increasing half widths of the ^{95}Mo-NMR signals at higher temperatures. As can be also concluded from the ^{13}C NMR the electron density in compound **6** is withdrawn from the Mo core. The axial Cr, Mo, W ligands therefore act as donors, which is in good agreement with the expectations and earlier examinations of the behavior of the $[(CO)_5M-CN]^-$ moiety.[6]

IR and Raman Spectroscopy

The characteristic IR and Raman bands of the complexes **2**−**7** are summarized in Table 3. The vibrational symmetry of the complexes **5**−**7** is D_{4h} which leads to the alternativity of the IR and Raman bands especially for the skeletal modes involving displacements of the Re atoms. The infrared spectra of the starting pentacarbonylmetal complexes **2**−**4** are also tabulated for a better understanding of the vibrational assignment. According to theoretical considerations of the vibrations, the very characteristic and important stretching modes of the linear CN−ReRe−NC moiety has no interaction with the ReO vibrations which involve displacements perpendicular to the linear molecular axis. According to the selection rules the Re−Re and the inphase symmetric stretchings of the Re−N and C−N are Raman-active and the antisymmetric contribution of Re−N and C−N stretches are IR-active. Since the vibrational interactions via the heavy Re atoms should be very weak, the IR and Raman stretching frequencies are expected to be rather close to each other. Because of the above-mentioned very weak or negligible vibrational coupling through Re−Re groups, the assignment of the $[NC-M(CO)_5]^-$ moieties can be performed on the basis of C_{4v} local symmetry (see Table 3). The general features reflected by the experimental observations can be summarized as follows:

The IR data of the complexes **5**−**7** show that the ν(CO) vibrations are shifted to higher wavenumbers relative to the starting materials **2**−**4**. However, in both types of complexes the carbonyl−metal bond is dominated by the back donation of the metal core to the carbonyl groups. The

back-donating effect to the π* orbitals of the carbonyl groups is decreased in the product molecules because part of the electron density at the metal centers is now shifted towards the CN units.[7] Accordingly, the ν(CN) vibrations are shifted ca. 10−20 cm^{-1} to lower wavenumbers. Electron density is withdrawn from the C≡N bond to the rhenium atoms.

The vibrational frequencies of the $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4$ unit are only slightly influenced by the new metalpentacarbonyl ligands. Characteristic bands were observed at 1550 (w), 1430 (s) and 1220 (vs) cm^{-1}, referring to one asymmetric and two symmetric COO stretching vibrations, respectively. The COO deformational mode is observed as a strong IR band at 630 cm^{-1}. The ReO stretching modes appear in the range of 360−480 cm^{-1} assigned to a_{1g}, e_u, a_{2u} and e_g species (see Table 3).

The very strong Raman bands at 275, 277 and 288 cm^{-1} can unambiguously be assigned to stretching frequencies of the quadruple bond between the rhenium atoms for the complexes **5**−**7**. The position and intensity of this Raman bands[8] suggests that coupling occurs between the metal−metal stretching mode and the rhenium−cyanide stretching mode. The Re−Re stretching vibraton of these complexes are shifted to higher energies relative to that of $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4Cl_2$ (**1**) in accord with the occurrence of less ReRe→(N≡CR) π back-bonding. We can observe a slight strengthening of the Re−Re bond in the Re-Re←N≡CM(CO)$_5$ moiety in the order M = Cr < Mo < W.

Simplified force-constant calculations have been performed using the linear CN−ReRe−NC moiety of the complexes. On the basis of literature values of bond lengths and Re−Re stretching frequencies the metal−metal stretching force constants have been calculated for the compounds shown in Table 4. A clear correlation has been observed between bond lengths and force constants. This relation can be used to predict bond lengths for the newly synthesized complexes **5**−**7**. As the Re−Re force constants are increasing from 4.15 to 4.55 Ncm^{-1}, consequently the predicted bond lengths are shortened from 226 to 223.6 pm for complexes **5**−**7** (see Table 4).

Electrochemical Studies

Complexes **5**−**7** have a chain of 12 atoms along the Re−Re axis, with four triple bonds (2 C≡O and 2 C≡N) and one quadruple Re−Re bond which will show some degree of conjugation due to π back-donation. Cyclovoltammetric studies have shown that both the organometallic ligands $[(CO)_5M-CN]^-$, and the $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4X_2$ moiety are electrochemically active. The former undergo 1-e^- oxidations which are only reversible for M = Cr.[9a] The latter undergo 1-e^- reduction to give the paramagnetic anions $[Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4X_2]^-$ possessing a $(\sigma)^2(\pi)^4(\delta)^2(\delta^*)^1$ electronic configuration.[9b] These facts suggested the possibility of obtaining interesting redox activities for such complexes and, therefore, an electrochemical survey was carried out. The cyclic voltammograms (CV) of the tetranuclear complexes **5**−**7** were measured in a CH_2Cl_2 solution in the presence of $N[CC(CH_3)_3]_4BF_4$ as supporting electrolyte and the data are presented in Table 5. For sake of comparison, the same table presents the data collected for the organometallic ligands **2**−**4**. These could not be obtained in the same solvent due to insolubility and were, therefore, measured in $NCCH_3$ in good agreement with reported values.[9a] The values obtained under our conditions for complex **1** in CH_2Cl_2 are also in agreement with those reported in ref.[9b]

The voltammograms of **6** and **7** are essentially similar. They only present a totally irreversible oxidation wave at $E_{pa} \approx 1.15$ V without any cathodic response. In the case of **5**, this wave is better defined and a small cathodic response at $E_{pa} = 0.82$ V is already present, as depicted in Figure 1. A second irreversible oxidation in the CV of **5** is indicated by the anodic peak at $E_{pa} = 1.39$ V. Lowering of the temperature to −50°C increases the reversibility of the former wave ($i_a/i_c \approx 1$) suggesting that its lack of reversibility at room temperature results from a chemical decomposition process taking place after oxidation. In agreement, the anodic peak at $E_{pa} = 1.39$ V disappears completely at −50°C. No wave was present in the region expected for the oxidation of free, uncoordinated ligands $[(CO_5)M-CN]^-$ which attests to the stability of the adducts **5**−**7**.

In complex systems like these tetranuclear species it is obviously difficult to assign the part of the molecule whereupon the oxidation is based. However, we assign these oxidations to the $[(CO_5)M-CN]$ center (M = Cr, Mo, W), in the case of the Cr derivative **5** ($E_{pa} = 1.15$ V) this corresponds to a shift of the E_{pa} signal to more positive potentials by ca. 0.3 V since the anion **2** undergoes a reversible oxidation in that region at $E_{pa} = 0.73$ in $NCCH_3$. The irreversible anodic waves of **3** and **4** also undergo a similar shift towards higher potentials in their corresponding complexes **6** and **7**. In this case a more accurate comparison of potentials is not possible because of the insolubility of the complexes **2**−**4** are in CH_2Cl_2. Although the lack of reversibility does not allow an accurate interpretation, these results suggest that the organometallic ligands $[M(CO)_5-CN]^-$ (**2**−**4**) donate electronic density to the ReRe core, therefore becoming more difficult to be oxidized.

As we mentioned above, the complexes $Re_2\{O_2CC(CH_3)_3)\}_4X_2$ undergo a 1-e^- reduction to their monoanions. This reduction presents a linear dependence on the nature of the halogen X, being more difficult in the case of X = Cl relative to X = I by only 0.1 V.[9b] In view of the reversible voltammetric behavior of these halides and the ready acceptance of an anti-bonding electron by the Re−Re quadruple bond molecular orbital framework, the absence of a corresponding reduction wave in all three complexes **5**−**7** is quite surprising. All experimental modifications attempted (lowering the temperature to −70°C, changing the sweep rate, increasing the sample concentration) failed to reveal any reduction wave. At present we cannot offer a sound explanation for the absence of this reduction although it may be considered consistent with a significant electron transfer from the axial ligands capable of modifying the

electronic framework of the Re−Re bond to such an extent as to shift the reduction potential to the outside of the solvent window. A more detailed study of the electrochemical behavior of axially substituted ReRe complexes of type $[Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4L_2]^{n+}$ as well as a theoretical investigation of the orbital interactions in complexes **5**−**7** is currently under way. Preliminary results show that the analogous nitrile complexes $[Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4(NCR)_2]^{2+}$ (R = Me, Ph) undergo irreversible reductions in the expected region, ca. $E_{pa} \approx -0.5$ V.

Thermogravimetry and Thermal Decomposition

The Re precursor compound **1** is thermally very stable, subliming at ca. 380°C (onset temperature) leaving a residue of only 3.6%. Possibly only those parts of the compound decompose which cannot sublime quickly enough. Lowering the amount of compound in the crucible also lowers the amount of the remaining residue. The mass spectrometer we used, which is able to detect only masses of $m/z < 400$, does not record any species.

The Mo precursor **3**, of which the thermal decomposition behavior was examined, starts to decompose quickly at ca. 160°C (onset 158.3°C). Carbonyl ligands can be detected as volatile fragments in the mass spectrometer. Only traces of $[Mo(CO)_6]^+$ (m/z = 264) have been detected. This molecule has also been detected during the thermal decomposition of related complexes.[6e] The remaining residue contains 54.6% of the original mass of the compound. Thus, 45.4% of the sample mass is lost during the heating process. This is in good agreement with the total mass of CO in the starting material (48.8%).

The decomposition behavior of the product molecules **5**−**7** is rather similar and the appearance of the curve depends on the total mass of the metal atoms (Figure 2). All product compounds first loose their carbonyl ligands. The total mass loss during the first decomposition step is roughly comparable to the CO content of the molecules, as also observed in the case of the $[NCMo(CO)_5]Na$ precursor molecule. The onset temperatures for the first decomposition step are ca. 100, 110 and 160°C respectively, in the case of **5**, **6** and **7**. In the first decomposition step no indication for the formation of $M(CO)_6$ as a thermal decomposition product has been detected. During the second decomposition step fragments of the pivalate ligand can be observed, especially $[C(CH_3)_3]^+$, $[H_2CCCH_2]^+$, $[H_2CCH]^+$ and $[CH_3]^+$. Carbon dioxide can also be found in significant amounts during the second decomposition step. Trace amounts of HCN^+ (m/z = 27) have also been detected during the second decomposition step of the complexes **5**−**7**. The onset temperatures for the second step are ca. 360, 390 and 270°C, respectively, for **5**, **6** and **7**. A small amount of pivalate fragments, however, can already be found during the first decomposition step. The intensity is nearly one order of magnitude smaller than during the second decomposition step. The remaining mass at the end of the measurement at 550°C is 44.6%, 49.3% and 61.9%, respectively. The mass of the metal atoms and the CN groups together is 43.5%, 47.4% and 53.7% in the cases of **5**−**7**. Taking into account the results of the simultaneous mass spectrometry this shows that the majority of the CO and the pivalate ligands is removed during the heating process. Replacement of the axial Cl ligands by $[(CO)_5M-CN]^-$ ligands clearly lowers the thermal stability of the resulting complex in comparison to its precursor.

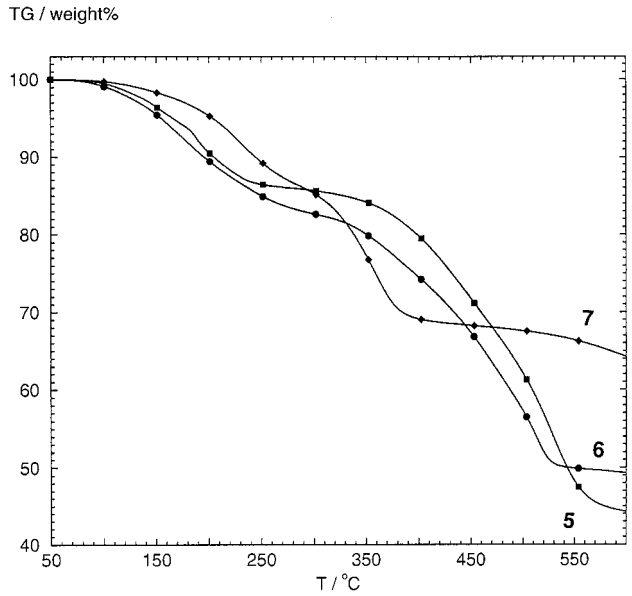

Figure 2. TG curves of $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4[-NC-M(CO)_5]_2$ [M = Cr (**5**), Mo (**6**), W (**7**)]

Absorption Spectra

The UV/Vis absorption spectra of the compounds **5**−**7** are represented in Figure 3. The trace lines correspond to the absorption spectrum of the dichlorodirhenium tetrapivalate **1**, the point lines to the absorption spectra of the mononuclear complexes $[(CO)_5M-CN]Na$ [M = Cr (**2**), Mo (**3**), W (**4**)], and the full lines to the respective tetranuclear compounds. Comparison of the absorption spectra of these last species with the sum of the spectra of their components (two $[(CO)_5M-CN]^-$ units plus the dirhenium moiety) shows the appearence of new absorption bands that extend to the near-infrared region. These types of bands have been observed in similar compounds[6j] and can be attributed to MMCT transitions from the $[(CO)_5M-CN]^-$

units to the Re^{III} centers, on the basis of the NMR, IR and CV data.

Irradiation on these MMCT bands does not give any significant reaction followed in the visible spectral region.

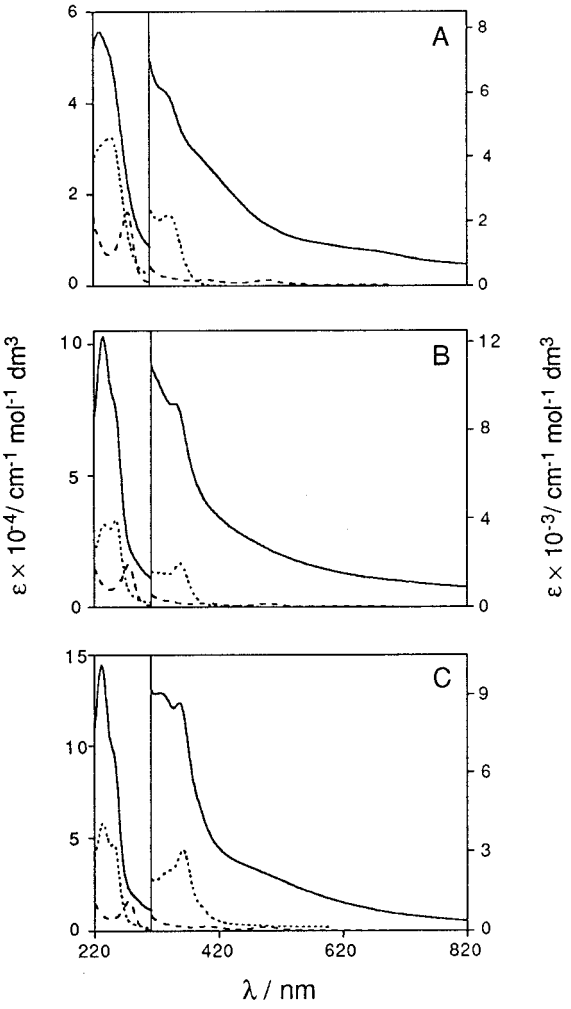

Figure 3. Absorption spectra of compounds **5** (**A**, full line), **6** (**B**, full line) and **7** (**C**, full line and their components **1** (**A**,**B**,**C**, point line), **2** (**A**, trace line), **3** (**B**, trace line) and **4** (**C**, trace line), in CH_3CN

Conclusions

Molecules of the type $[(CO)_5M-CN]^-$ not only form complexes with mononuclear metal centers, as described in the literature during the recent years, but also with dinuclear complexes containing metal−metal multiple bonds. Charge transfer between the ligands and the multiple bonded core unit takes place as can be judged from the optical absorption spectra. Significant charge donation from the $[(CO)_5M-CN]^-$ ligands to the ReRe core is also implied by ^{13}C- and ^{95}Mo-NMR as well as by cyclic voltammetry data. The Re−Re quadruple bond is only slightly weakened due to the donor influence of the organometallic ligand in the axial position. The synthesis of the described molecules is straightforward. An introduction of more NC functions in the ligands could therefore lead to long chained molecules with conjugated multiple bonds. It can also be assumed that it is easily possible to substitute other compounds of the type $[M_2(O_2CR)_4][X_2]$ or $[M_2(CH_3CN)_{10}][X_4]$ (M = Re, Rh, Mo, Tc, etc., X = BF_4, SF_6 etc.) with $[(NO)_xM(CO)_{6-x}]^-$ ligands. Work in this direction is currently under way in our laboratories and will be reported elsewhere.

Experimental Section

General: All preparations and manipulations were performed with standard Schlenk techniques under oxygen- and water-free argon. Solvents were dried by standard procedures: THF, Et_2O, *n*-pentane, and *n*-hexane with sodium benzophenone ketyl; acetonitrile and dichloromethane were distilled from P_2O_5 after refluxing for several hours. Acetone was distilled from K_2CO_3 and kept over 4-Å molecular sieves. − Microanalyses were performed at the ITQB (Oeiras). −^1H-NMR spectra were obtained with a Bruker CXP 300 spectrometer, ^{13}C-NMR spectra were measured at 100.28 MHz with a JEOL JNM GX-400 and a Bruker Avance DPX-400, ^{95}Mo-NMR spectra were measured at 26.07 MHz with a Bruker Avance DPX-400. − Infrared spectra were recorded with a Unican Mattson Mod 7000 FTIR spectrophotometer using KBr pellets and/or solutions. − The TG/MS studies were performed using a Perkin Elmer TGA 7 thermobalance coupled with a Balzers QMG 420 mass spectrometer. The thermolysis experiments were carried out in a dynamic helium atmosphere (purity 5.0, 45 sccm) using a 50 to 600°C temperature program at a rate of 10°C/min. The temperature of the capillary interface was 280°C. − The electrochemical instrumentation consisted of a BAS CV 50W−1000 Voltammetric Analyzer connected to BAS/Windows data acquisition software. All the electrochemical experiments were run under argon at room temperature. Tetrabutylammonium hexafluorophosphate (Aldrich) was used as supporting electrolyte after being recrystallized from ethanol. Cyclic voltammetry experiments were performed in a glass cell MF-1082 from BAS in a C-2 cell enclosed in a Faraday cage. The reference electrode was SSC (MF-2063 from BAS). In all cases the calibration of the reference eletrode was performed with a solution of ferrocene (1mM) to obtain a potential in agreement with the literature value. The auxiliary electrode was a 7.5-cm platinum wire (MW-1032 from BAS) with a gold-plated connector. The working electrode was a disk of platinum (MF-2013 from BAS) with ca. 0.022 cm^2 sealed in Kel-F plastic. Solvents were dried as previously described.

Photochemical Studies: All solutions (ca. 10^{-3} M) were prepared and handled in the dark. Electronic absorption spectra were run using a Perkin Elmer lambda 6 UV/Vis spectrophotometer. The photochemical reactivity was initially tested at $\lambda \geqslant 600$ nm, $\lambda \geqslant 540$ nm. Even after longer irradiation times (> 24 h), no significant spectral changes were observed. Further irradiations were than carried out to check the photochemical reactivity at $\lambda = 436$ nm and $\lambda = 366$ nm. Irradiation experiments at $\lambda \geqslant 600$ nm and $\lambda \geqslant 540$ nm were carried out with a tungsten lamp and filters with cut-off at 600 and 540 nm, respectively. Irradiation experiments at 436 nm and 366 nm, were carried out in PTI instrumentation, using a medium-pressure Hg lamp (HBO 100 W) mounted in a lamphouse (Model A1010) connected to an LPS-220 Lamp Arc Supply. The light, whose intensity was of the order of 10^{-7} Einstein min^{-1},was isolated from the medium-pressure Hg lamp by means of interference filters P/N 56450 with $\lambda_{max} = 435.8$ nm, and P/N 56430 9 BAGT with $\lambda_{max} = 367$ nm, both from Allied Electro Optics

(Italy). − Raman spectra were measured at room temperature with a Renishaw imaging microscope 2000, equipped with a 25-mW Spectra Physics 127 HeNe excitation laser (632.8 nm); resolution of 1 cm^{-1}. − $[(CO)_5M-CN]Na$ (M = Mo, Cr, W)[10] and $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4Cl_2$[11] complexes were prepared as described in the literature.

Spectroscopic data already given in the Tables 1−5 are not repeated in the Experimental Section.

Preparation of Complexes of General Formula $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4[-CN-M(CO)_5]_2$ [M = Cr (5), Mo (6), W (7): A suspension of $Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4Cl_2$ (0.43 g, 0.50 mmol) in THF (15 mL), was treated with 1.00 mmol of $[(CO)_5M-CN]Na$ (M=Mo, Cr, W). The mixture turned dark red. After 90 min at room temperature, the resulting solution was concentrated to dryness, extracted with dichoromethane and concentrated. Upon addition of *n*-pentane, a dark red microcrystalline powder precipitated The mother liquor was filtered off and the remaining solid was dried in oil-pump vaccuum. Yield: 91% (**5**), 89% (**6**), 86% (**7**).

$Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4[-CN-Cr(CO)_5]_2$ (5): $C_{32}H_{36}Cr_2N_2O_{18}Re_2$ (1213.05): calcd. C 31.69, H 2.99, N 2.31; found C 31.78, H 3.13, N 2.02. − ^1H NMR (CD_2Cl_2, 300 MHz, +25°C): δ = 1.52 (s, 9 H, 3 Me).

$Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4[-CN-Mo(CO)_5]_2$ (6): $C_{32}H_{36}Mo_2N_2O_{18}Re_2$ (1300.91): calcd. C 29.54, H 2.79, N 2.15; found C 29.77; H 3.10; N 2.06. − ^1H NMR (CD_2Cl_2, 300 MHz, room temp.): δ = 1.52 (s, 9 H, 3 Me). − ^{95}Mo NMR (CD_2Cl_2, 400 MHz, +25°C): δ = −1690.

$Re_2\{\mu\text{-}O_2CC(CH_3)_3\}_4[-CN-W(CO)_5]_2$ (7): $C_{32}H_{36}N_2O_{18}Re_2W_2$ (1476.76): calcd. C 26.03, H 2.46, N 1.90; found C 26.09; H 2.65; N 1.83. − ^1H NMR (CD_2Cl_2, 300 MHz, +25°C): δ = 1.52 (s, 9 H, 3 Me).

Comparison of Electrochemically and Photochemically Induced Electron-Transfer Processes of a Series of Copper(II) Schiff Base Complexes with Thiolate Coordination

Stephan Knoblauch,[a] František Hartl,*[b] Derk J. Stufkens,[b] and Horst Hennig*[a]

Dedicated to Professor Arnd Vogler on the occasion of his 60th birthday

Keywords: Spectroelectrochemistry / Cyclic voltammetry / Photochemistry / Copper(II) complexes / Thiolate complexes

The electrochemical and photoredox properties of copper(II) thiopyrazolone Schiff base complexes **1**–**9** with imine and thiolate coordination, showing variable degrees of tetrahedral distortion, were investigated by means of combined electrochemical and spectroscopic techniques in the temperature range of 193−293 K. The cyclic voltammograms of **1**–**9** in butyronitrile revealed that the reduction and oxidation paths are strongly dependent on the geometry of the CuN_2S_2 moiety. Due to the strong delocalization of the singly occupied redox orbital (SOMO) the oxidations and reductions occur in a narrow potential range. The one-electron-reduced **1(r)**–**9(r)** and oxidized **1(o)**–**9(o)** products were electrogenerated and stabilized inside optically transparent thin-layer electrochemical (OTTLE) cells at variable temperatures and could be characterized for the first time by UV/Vis spectroscopy. The reduced formal d^{10} copper(I) species absorb only weakly in the visible region. The oxidized products **1(o)**–**9(o)** show several strong absorptions in the visible region due to the presence of formal d^8 copper(III) species. The spectral information allowed assignment of the initial photoproducts. Irradiations in donor media such as THF or EtOH initially produces **1(r)**–**9(r)**. No photoreduction was observed in *t*BuOH which cannot liberate reducing H_α. The primary oxidized species **1(o)**–**9(o)** were formed in chlorinated acceptor solvents ($CHCl_3$) on UV irradation. Fast relaxation to the ground state prevents the photoredox reactions from CT or LF excited states.

Introduction

Recently we have shown that the photocatalytic oxygenation of terpenes like α-pinene induced by iron(III) porphyrins leads in the presence of copper(II) complexes with $[CuN_2S_2]$ constitution to rearrangement of α-pinene to limonene (beside the formation of oxygenation products).[1] $[CuN_2S_2]$ complexes containing Schiff base ligands with imine and thiolate coordination sites (Figure 1) are of particular significance in that photocatalytic rearrangement. Because it is assumed that photoinduced electron-transfer processes between iron(III) porphyrins, $[CuN_2S_2]$ complexes and α-pinene occur, the spectroscopic, electrochemical, and photochemical properties of the copper(II) complexes themselves were investigated to obtain more insight into the rather intricate function of these complexes. This paper summarizes results obtained from combined electrochemical and photochemical investigations of copper(II) complexes of Schiff base ligands with imine and thiolate coordination sites.

The well-known procedure of the synthesis of these ligands by condensation of the 4-benzoyl-5-mercapto-3-methyl-1-phenylpyrazole with selected diamines has been applied to derivatives of phenylene-1,2-diamine[2][3] with the intention of studying the influence of a coupling π-system between the pyrazole units on the redox behavior. The investigated systems complete a series of tetrahedrally distorted complexes reported by L. Hennig et al.[4]. The reduction potentials were expected to be strongly dependent on the geometry of the donor sphere surrounding the copper ion but this trend could not be experimentally confirmed by L. Hennig et al. It appeared, therefore, necessary to extend the series by more planar complexes to recognize the trends in the redox properties and reactivity of the singly reduced and oxidized species.

The investigated complexes **1**−**9** belong to the comparatively few examples of stable copper(II) thiolate complexes studied so far.[5] In general, previous research done on these compounds was focused on aspects of biomimetic modelling of the active site behavior of biological *Type I* copper centres with regard to their structural and reduction properties. However, oxidation of these compounds has recieved little attention. Further investigation is required in this field. Notably, the first stable copper(III) thiolate complex [Cu(phmi)](PPh_4)] [phmi = 1,2-phenylenebis(2-mercapto-2-methylpropionamide)] has recently been described in the literature.[6]

Ferraudi and Muralidharan reviewed the photochemistry of copper complexes in 1981.[7] A review of research until the early 1990s is given by Horváth and Stevenson.[8] Only little is known, however, about photochemical properties of

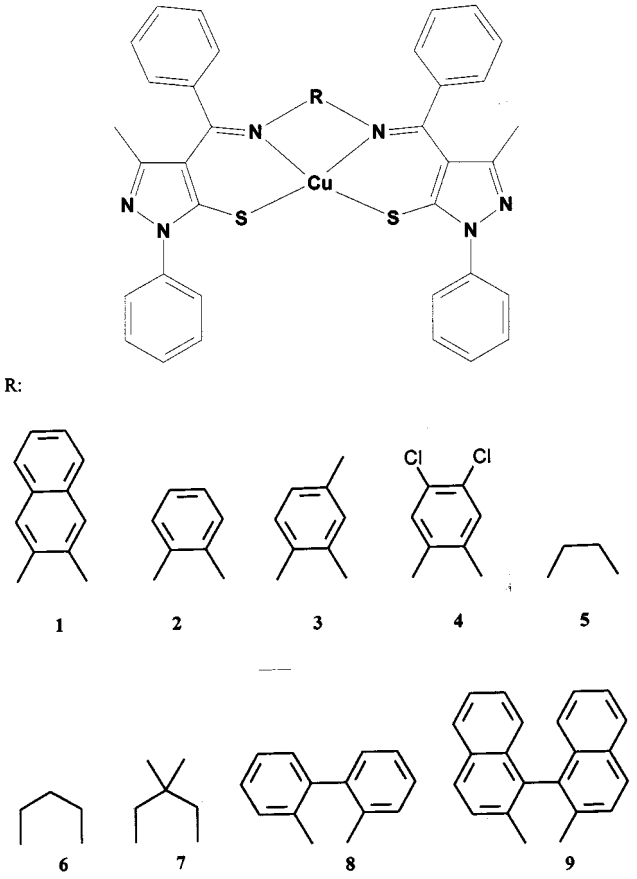

Figure 1. Structural scheme of the Cu^{II} Schiff base complexes used displaying the different backbones R

copper(II) thiolate complexes with large chelating ligands.[9] To our knowledge, only copper(II) complexes with thioethers[10] or dithiolate derivatives (dithiocarbamate,[11–14] maleonitriledithiolate,[15–19] dithiooxalate[20,21] etc.) have been studied photochemically so far.

The detailed spectroscopic and photochemical characterization of large systems like the studied Schiff base complexes **1**–**9** is complicated by strong delocalization of the frontier orbitals and low symmetry.[22] Nevertheless, the presence of intense low-energy charge-transfer absorption bands and the accessibility of two or more oxidation states suggest a variety of photoredox reactions. A redshift of the CT absorptions correlated to the tetrahedral distortion of the CuN_2S_2 moiety is observed.[3] Due to the better separation of the charge-transfer bands, it was important to find out whether redox reactions can be initiated by electronic excitation into the corresponding electronic transitions, or from other excited states, with regard to potential application of these light-sensitive compounds as catalysts in homogeneous photocatalytic systems.[1]

Results and Discussion

Electronic Absorption Spectra

The electronic absorption spectra of the Schiff base ligands employed feature an intense band system in the UV region (see Figure 1). The spectral data of the ligands are listed in Table 1. These transitions are, in accordance with their intensities, attributable to $\pi\rightarrow\pi^*$ transitions within the aromatic system and the azomethine or the thiolate chromophores. They occur at lower energies for the Schiff bases with aromatic coupling between the two imine groups linked by phenylene or biphenylene units. The less intense bands in the near ultraviolet may also arise from $\pi\rightarrow\pi^*$ transitions since they are too intense to be assigned to $n\rightarrow\pi^*$ bands. These absorptions disappear on deprotonation of the ligands during coordination of the metal ion.

Table 1. UV/Vis-spectroscopic data of the free ligands $\mathbf{H}_2$**1**–$\mathbf{H}_2$**9** in $CHCl_3$ at 293 K

Ligand	Band λ_{max} [nm] (ε [$M^{-1}cm^{-1}$])
$\mathbf{H}_2$**1**	271 (37300), 321 (34000), 419 (11700)
$\mathbf{H}_2$**2**	276 (35500), 318 (35800), 421 (11900)
$\mathbf{H}_2$**3**	275 (34800), 317 (35100), 419 (12300)
$\mathbf{H}_2$**4**	271 (36000), 321 (36000), 426 (10900)
$\mathbf{H}_2$**5**	277 (26100), 314 (31200), 399 (11700)
$\mathbf{H}_2$**6**	281 (24500), 310 (29900), 394 (11100)
$\mathbf{H}_2$**7**	282 (25600), 311 (31200), 394 (11400)
$\mathbf{H}_2$**8**	271 (32800), 321 (26300), 419 (10600)
$\mathbf{H}_2$**9**	284 (37900), 344 (28300), 446 (12100)

The electronic absorption spectra of the copper(II) complexes **1**–**9** exhibit UV absorption bands that can be assigned to intraligand (IL) transitions. They are only slightly shifted relative to those of the corresponding uncoordinated Schiff base ligands (Table 2). The UV/Vis region displays bands or shoulders which have been assigned to ligand-to-metal (σ,π-SR$\rightarrow Cu^{II}$) charge-transfer transitions (LMCT)[4] as reviewed by Schugar.[37] For example, **5** shows a shoulder at 346 nm and a relatively strong and broad absorption at 438 nm with a shoulder at 520 nm. In contrast to that, two intense bands in the visible region are observed for **9** (530 nm and 659 nm), together with a shoulder at 355 nm (Table 2). These bands exhibit a red shift on going from a square-planar to a pseudotetrahedral geometry of the CuN_2S_2 chromophores, i.e. from **1** to **9**.[22,29] It should be recalled that strict assignment cannot be given due to strong delocalization of the frontier orbitals.[22]

Ligand field transitions (LF or d-d) at Cu^{II} could not be localized due to strong overlap with CT bands in the visible region. This is not surprising, as the LF transitions are also expected to shift to lower energy with increasing tetrahedral distortion.[30,33]

Cyclic Voltammetry

Cyclic voltammograms of the complexes **1**–**9** were recorded in butyronitrile, as this solvent is also suitable for spectroelectrochemical studies at variable temperatures (described hereinafter). In selected cases THF was employed. All complexes **1**–**9** can be oxidized and reduced within the

potential window available in these solvents. The corresponding redox potentials (vs. Fc/Fc$^+$) are summarized in Table 3. The representative cyclic voltammograms of **2**, **5**, and **9** in butyronitrile are shown in Figures 2A−C, respectively. The cathodic and anodic steps will be described separately.

Reduction

In *butyronitrile*, the reduction of the complexes **5**−**9** on the time scale defined by scan rates $v \geq 50$ mV/s is chemically reversible already at room temperature (see Figure 2C). The electron transfer is electrochemically reversible for **7**−**9**, but quasi-reversible for **5** and **6** (see Figure 2B and Table 3). On the other hand, the reduction of the complexes **1**−**4** at room temperature is chemically totally irreversible, as no anodic counterpeak was observed on the reverse anodic scan (see Figure 2A). The reduction in the latter case produces species, denoted **1(ir)**−**4(ir)** in Table 3, which oxidize on the reverse scan ca. 0.7 V more positively in comparison with the reduction potentials of the parent complexes **1**−**4**. The complexes **1**−**9** could be reduced completely with one equivalent of cobaltocene, which agrees with the transfer of one electron. The cobaltocenium salts of the anionic products **5(r)**−**9(r)** persisted in the solution for several minutes without any decomposition and could be oxidized back completely to parent **5**−**9** by one equiva-

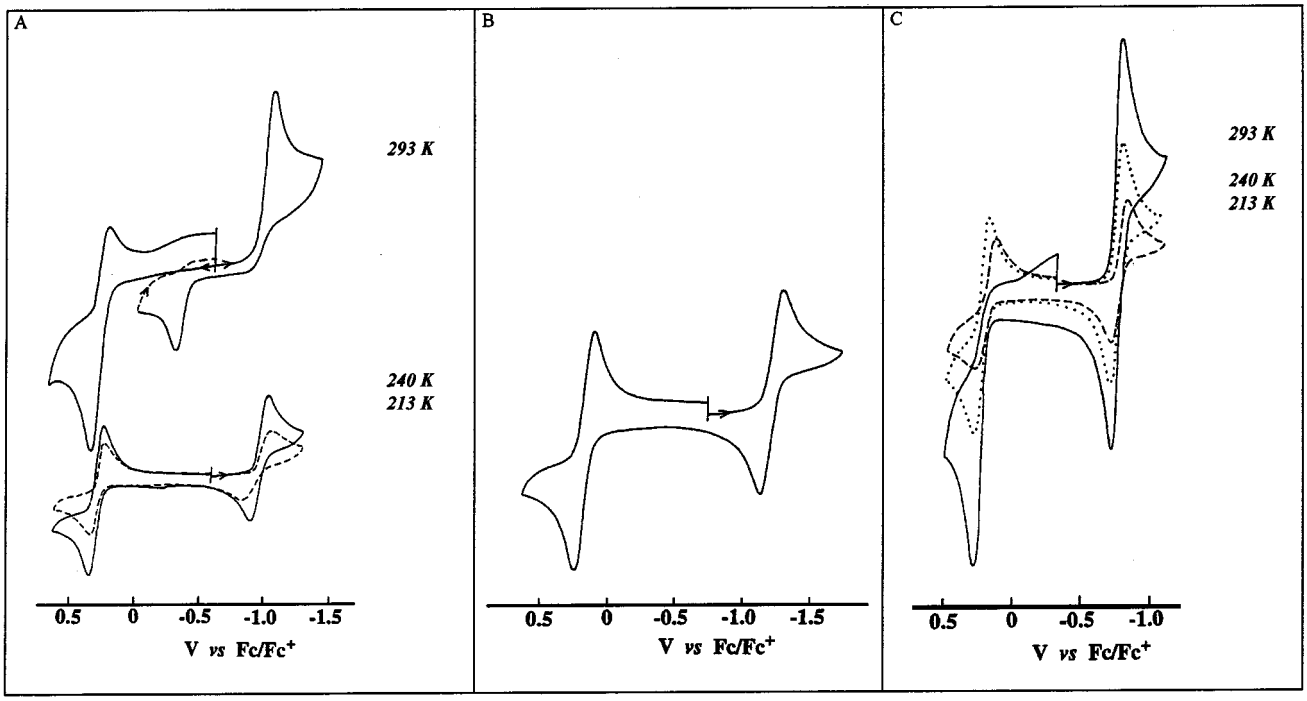

Figure 2. Cyclic voltammograms of the complexes (A) **2** at 293, 240, and 213 K; (B) **5** at 293 K; (C) 9 at 293, 240, and 213 K (butyronitrile/ $3 \cdot 10^{-1}$ M Bu_4NPF_6, Pt disk microelectrode with 0.42 mm^2 disk area, scan rate v = 100 mV/s)

lent of $FcBF_4$. The secondary anionic reduction products **1(ir)−4(ir)** are also inherently stable, as confirmed by cyclic voltammetry. Scan reversal beyond their anodic peaks (see Table 3) led to the reappearance of the cathodic peaks due to the reduction of **1**−**4**. The recovery of **1** and **2** on oxidation of **1(ir)** and **2(ir)**, respectively, was further documented by corresponding UV/Vis spectroelectrochemical experiments (see below). This behavior points to rapid conversion of the primary one-electron reduction products **1(r)−4(r)** to **1(ir)−4(ir)** at room temperature, resulting in a reversible conformational change (see below). Oligomerization or polymerization reactions induced by the reduction are less likely due to the limited conformational flexibility of the ligand framework in the parent complexes **1**−**4** (see Figure 1). As reported recently by Rasmussen et al.,[34] a tetranuclear cluster (Cu_4L_4) is produced in the course of the reaction between the more flexible deprotonated ligand *N*,*N*′-(2,2′-biphenyldiyl)bis(4-aminomethyl-1,3-diphenyl-5-thiopyrazole) and $[Cu(CH_3CN)]^+$ in DMF.

All stable reduction products **1(ir)−4(ir)** and **5(r)−9(r)** are EPR-silent. This result is consistent with the formation of one-electron-reduced, formal Cu^I complexes; although, the Extended-Hückel calculations on the fragments of the parent complexes **2**, **5**, and **6** and the average imine N−C distances (1.31 Å for **8**[3,14]) in the middle of the N=C/N−C bond-length range[38] (1.25−1.39 Å) show that the singly occupied redox orbital (SOMO) is strongly delocalized over the *cis*-CuN_2S_2 moiety.[22] It cannot be excluded, however, that in the anionic reduction products **1(r)−9(r)** the added electron density resides more on the central Cu atom, for example due to the mixing of the HOMO of the anions with close-lying empty orbitals (LUMO and LUMO +1) which are largely localized[22] on the electron-withdrawing imine functions and the thiopyrazolone rings.

Within the series of the parent compounds **1**−**9** the geometry around the central ion strongly depends on the flexibility of the backbone R connecting the two imine nitrogen atoms (see Figure 1). Thus, the rather rigid naphthylene and phenylene backbones in **1**−**4** impose only slightly distorted square planar geometry, as documented by the crystal structures of **1** and **2** showing θ = 3.3° and 9.3°, respectively (θ is the dihedral angle between the two N−Cu−S planes in the crystal). In contrast to this, in **5** and **6** with the more flexible ethylene and propylene backbones, the value for θ increases to 34.7° and 42.5°, respectively, and θ = 52.1° was determined for **8** (L. Hennig et al.[4]) with the flexible 2,2′-biphenylene backbone enforcing a large tetrahedral twist on the coordination polyhedron. Even larger tetrahedral distortion from the planar geometry was recently observed for a novel complex **10** with the backbone R = butylene, where θ = 56°.[36] In general, Cu^I complexes will prefer the tetrahedral coordination, which also applies for the studied primary one-electron reduction products **1(r)−9(r)**. We have indeed observed that the one-electron reduction at room temperature is chemically irreversible for the nearly square planar complexes **1**−**4**, while the thermal stability of **5(r)−9(r)** nicely correlates with the increased tetrahedral distortion in **5**−**9**. We therefore propose that the secondary chemical reactivity of **1(r)−4(r)** producing **1(ir)−4(ir)** has its origin in a tetrahedral twist induced by the electron-transfer step. The electrochemically quasireversible character of the reduction of **5** at room temperature may indicate some small conformational change on going to **5(r)** while the geometry of the

coordination polyhedron of **6(r)−9(r)** with respect to that of the parent complexes **6−9** remains unchanged. It is noteworthy that the size of the chelate ring, the nature (aromatic, aliphatic) and steric demands of the bridging system in **1−7** possess rather limited influence on the reduction potential. Only for the pseudotetrahedral complexes **8** and **9** an apparent positive shift of the reduction potential was observed (see Table 3). This shift may arise from a stabilizing overlap between the π systems of the twisted 2,2′-biphenylene and 2,2′-binaphthylene backbones, respectively, and the π system of the "4-benzyl" substituent at the thiopyrazolone rings, as judged from the crystal structure of **8**.[4,35] For example, the tetrahedrally most twisted complex **10** with the aliphatic butylene backbone R reversibly reduces at $E_{p,c} = -1.03$ V,[36] i.e. again more negatively than **8** and **9** but identical to nearly planar **1−3** and less twisted **6** and **7**.

Cyclic voltammetry performed at moderate scan rates has revealed that the reduction of **2** becomes chemically reversible at $T = 230$ K, as judged from $I_{p,a}/I_{p,c} = 1$ and disappearance of the anodic peak due to the oxidation of **2(ir)** on the reverse scan. Between 243 and 213 K the ΔE_p value gradually increases relative to that of the Fc/Fc^+ internal standard and the voltammetric response broadens, while $I_{p,a}/I_{p,c}$ again becomes less than 1 and $I_p v^{-1/2}$ is virtually independent of v (see Figure 2A). This behavior is characteristic for an electrochemically quasireversible charge transfer and suggests that, likewise **5(r)** and **6(r)** (see above), also **2(r)** and parent **2** may slightly differ in the coordination geometry. A similar temperature dependent voltammetric response was recorded for **3** and **4**; chemical reversibility of the reduction in the latter cases was, however, only achieved at $T = 213$ K (see Table 3). In contrast to this, the one-electron reduction of the nearly square planar complex **1** ($\theta = 3.3°$) remains chemically irreversible even at $T = 213$ K.

No significant difference in the reduction path was observed when cyclic voltammograms of **2**, **6**, and **9** were recorded in *THF* at $T = 293$ K, besides a shift of the reduction potentials to lower values by 40−160 mV (see Table 3).

Oxidation

Oxidation of **1−9** in *butyronitrile* occurs, independently of the geometry of the CuN_2S_2 core, in a narrow potential range (see Table 3). At $v = 100$ mV/s oxidation of the nearly square planar complex **1**, in contrast to its reduction, is a both chemically and electrochemically reversible one-electron process independently of the applied temperature between 293 and 213 K. Of course, at $T = 330$ K for example, the oxidized species of **1** will decompose. In consequence of the increasing tetrahedral distortion of the coordination polyhedron, the oxidation of the complexes **2−10** at $T = 293$ K is chemically irreversible at $v = 100$ mV/s (see Table 3). The oxidation of the complexes **2−4** on this subsecond time scale is still an one-electron process and the primary oxidation products **2(o)−4(o)** are detectable on the reverse anodic scan ($I_{p,c}/I_{p,a} \approx 0.4-0.5$). At $T = 255$ K the secondary chemical reactivity of **2(o)−4(o)** becomes completely suppressed, as judged from $I_{p,c}/I_{p,a} = 1$ (see Figure 2A). The one-electron-oxidized complex **5(o)** does not fit within the series, being exceptionally stable even at room temperature (see Figure 2B). On the other hand, complex **6** is oxidized in a chemically totally irreversible step which corresponds with transfer of two electrons ($n_{app} = 2$). Proceeding to **7−9** the oxidation remains chemically irreversible but the number of transferred electrons at $v = 100$ mV/s again decreases to $n_{app} \approx 1.5$ for **7** and $n_{app} = 1$ for **8** and **9** (see Figure 2C). Scanning at low temperatures revealed that the oxidation of **6** at $T = 230$ K becomes chemically reversible ($n_{app} = 1$) while for **9** $T = 220$ K is required to stabilize the cation **9(o)** at $v = 100$ mV/s. The corresponding cations **7(o)** and **8(o)** remain unstable even at $T = 213$ K. It is noteworthy that, opposite to **1−4**, the one-electron oxidation of **6−9** producing **6(o)−9(o)** is electrochemically quasireversible while the one-electron reduction of these complexes under identical conditions is electrochemically reversible (see Table 3). This redox behavior may indicate that, likewise **1−4** and **1(r)−4(r)** (see above), also **6−9** and **6(o)−9(o)** in butyronitrile slightly differ in the coordination geometry of the CuN_2S_2 core. In the case of **5** the little conformational change applies both for **5(r)** and **5(o)**.

In sharp contrast to the cyclic voltammetric response in butyronitrile, the complexes **2**, **6**, and **9** oxidize in THF at room temperature in a both chemically and electrochemically reversible one-electron step (see Table 3). Addition of an excess of PPh_3 to the THF solution of **9** converts the oxidation of the latter complex to a chemically totally irreversible two-electron process while the chemically reversible one-electron reduction remains unaffected.

The one-electron-oxidized complexes **1(o)−9(o)** can be viewed in first approach formally as d^8-Cu^{III} species. Their preference for the square-planar geometry of the CuN_2S_2 polyhedron may explain the electrochemically quasireversible character of the one-electron oxidation of the strongly tetrahedrally distorted parent complexes **5−9**. This description is, however, too oversimplified as the SOMO of **1−9** is known to be strongly delocalized over the whole CuN_2S_2 moiety, with a major contribution from the two sulfur atoms.[22] For example, oxidation of the derivative of **2** with the thiolate donors replaced by oxygen functions occurs significantly more positively [**2-O**: $E_{p,a}(ox) = 0.9$ V and $E_{p,c}(red) = -1.38$ V vs. Fc/Fc^+ in butyronitrile at $T = 293$ K; the one-electron reduction is chemically reversible at $v = 100$ mV/s]. It can therefore be accepted that the one-electron oxidation mainly affects the stability of the Cu−S bond(s). The chemical irreversibility of the oxidation and its overall two-electron character have probably its origin in the cleavage of the Cu−S bonds, followed by closure of intra- or intermolecular disulfide S−S bonds in **1(io)−9(io)**, the secondary oxidation products. The latter processes become significantly accelerated for the tetrahedrally twisted complexes **6−9**, pointing to the role of conformational change induced by the electron transfer to the anode, and

in the presence of strongly coordinating ligands like butyronitrile or PPh_3, which may occupy the coordination sites abandoned by the sulfur atoms. This anodic path explains the increased chemical reversibility of the primary one-electron oxidation step in weakly coordinating THF.

UV/Vis Spectroelectrochemistry

UV/Vis spectra of primary and secondary redox products of **1**−**9**, detected by cyclic voltammetry were recorded in situ at variable temperatures by using appropriate OTTLE cells. The main goal of these experiments was to obtain spectroscopic information needed for correct assignment of species generated on photo-induced reduction and oxidation of selected complexes under study. The UV/Vis spectroelectrochemical data are collected in Table 2.

Reduction

The one-electron reduction of **5** (Figure 3A), **6** and **9** (Figure 3B) in butyronitrile at 293 K, and **2** in butyronitrile at 190 K (Figure 3C) in the course of the OTTLE experiments yielded the stable species **5(r)**, **6(r)**, **9(r)**, and **2(r)** as single products. This assignment was based on the thin-layer cyclic voltammograms recorded during the reduction and reverse reoxidation steps, which corresponded with the chemically reversible redox couples observed in ordinary cyclic voltammograms under identical conditions. In all of these cases retention of isosbestic points was observed and the reoxidation of the anionic products resulted in full recovery of the parent complexes. The UV/Vis spectra of the anions are characterized by the presence of an intense band between 230 and 275 nm with an apparent shoulder at ca. 330 nm. The charge-transfer absorption bands of the parent complexes in the visible region disappeared. Instead, the anions **2(r)**, **5(r)**, **6(r)**, and **9(r)** absorb only weakly between 380 and 500 nm.

The UV/Vis spectrum of square-planar **2(r)** also shows a weak absorption at 510 nm (see the insert to Figure 3C). This band is missing in the UV/Vis spectrum of the secondary reduction product **2(ir)** generated during the one-electron reduction of **2** in butyronitrile at 293 K (see Figure 3C). The rest of the UV/Vis spectrum of **2(ir)** closely resembles that of **2(r)**, pointing to a very similar bonding situation in both anions. For example, oxidation at the positively shifted anodic potential of **2(ir)** (see Table 3) also led to the complete reappearance of the UV/Vis spectrum of **2**, in agreement with the cyclic voltammetric behavior (see above). Almost identical spectroscopic responses were observed for the chemically irreversible one-electron reduction of nearly square planar **1** at 293 K and for the reverse oxidation of **1(ir)** (see Table 2 and Figure 3C).

Oxidation. Electrochemical oxidation of **2**, **5**, **6**, and **9** in butyronitrile at 193 K within the UV/Vis OTTLE cell produced stable cations **2(o)**, **5(o)**, **6(o)**, and **9(o)**. As depicted in Figure 4 and summarized in Table 2, the electronic absorption spectra of these cations typically exhibit several

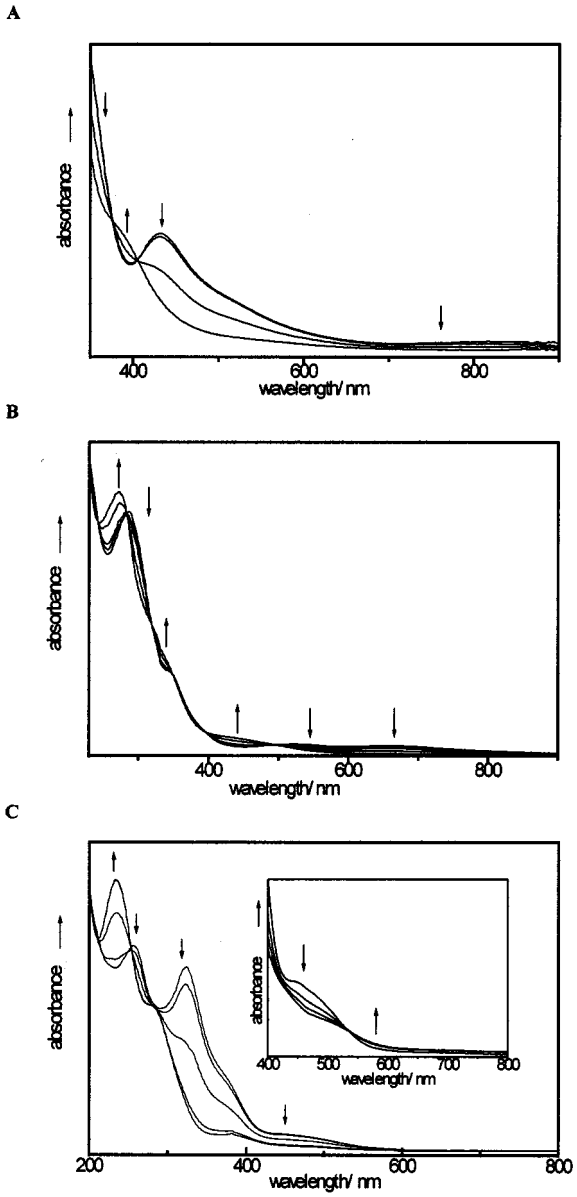

Figure 3. UV/Vis-spectroscopic changes accompanying electrochemical reduction of **5** (A), **9** (B), and **2** (C) in butyronitrile at 293 and 193 K (inset) within an OTTLE cell[27,28]

absorption bands covering the whole visible region between 400 and 900 nm. Their assignment was not attempted, particularly due to the strong electronic delocalization of the parent complexes, which probably also persists in the one-electron-oxidized species. The cation **2(o)** was still observable at 230 K whereas **5(o)** existed a few minutes even at 293 K. The oxidation of **2** at room temperature only yielded the stable secondary product **2(io)** which does not absorb in the visible region (see Table 2). Interestingly, reverse reduction of **2(io)** directly resulted in full recovery of the parent complex **2**. The same result was obtained for the corresponding planar complex **1**, regardless of the chemically reversible one-electron oxidation of the latter complex at 293 K on the subsecond time scale of cyclic voltammetry. Provided **1(io)**−**9(io)** contain intra- or intermolecular disulfide linkages, as argued above, their reduction is then largely

localized on this function, resulting in rapid recoordination of the reduced thiolate appendages and the recovery of **1**−**9**.

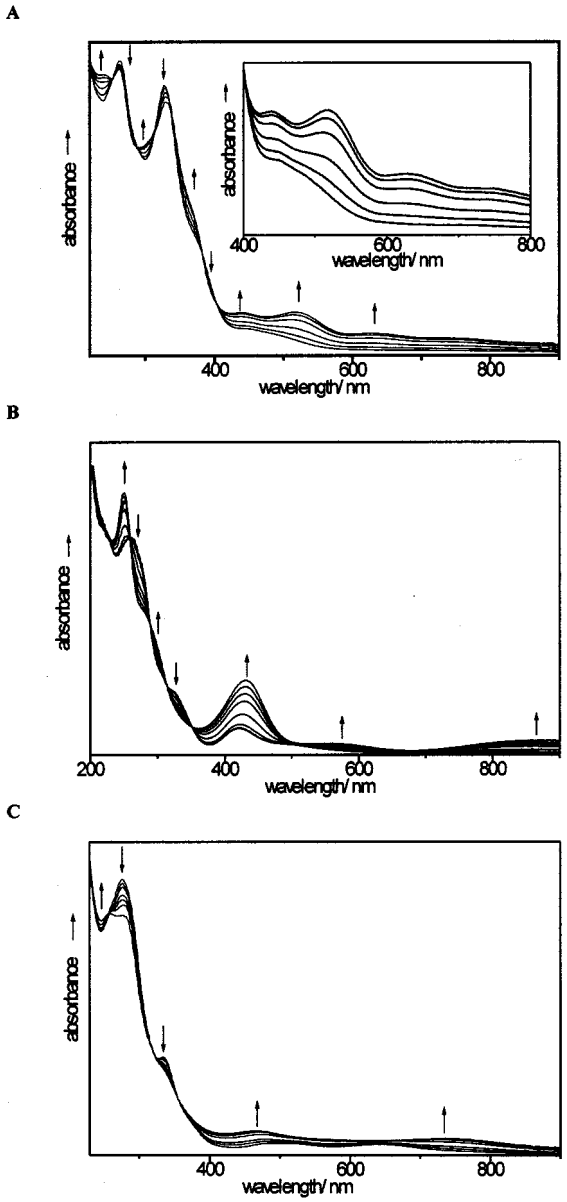

Figure 4. UV/Vis-spectroscopic changes accompanying electrochemical oxidation of **2** (A), **5** (B), and **9** (C) in butyronitrile at 193 K within an OTTLE cell[28]

Photochemistry

The photochemical experiments have been carried out to investigate the possibility to initiate photoinduced electron-transfer processes producing oxidized or reduced species from the parent copper(II) complexes.

Photoreduction

Continuous photolysis of complexes **1**−**9** with full output of the mercury lamp in donor solvents EtOH or THF at room temperature led to bleaching of the bands in the visible region within approximately 30 min. Identical spectral changes were monitored when wavelengths $\lambda_{irr} < 310$ nm were excluded. The photoreactions became accelerated in the presence of electron donors such as $N(CH_2CH_2OH)_3$ (TEA). No photoreduction took place in *t*BuOH within 30 min ($T = 303$ K), presumably because this solvent does not liberate α-hydrogen atoms, in contrast to THF and EtOH.

The UV/Vis-spectral changes accompanying the photoreduction of complex **9** at 293 K are depicted in Figure 5A ($\lambda_{irr} > 315$ nm). Identical spectral changes were monitored upon the electrochemical one-electron reduction of this complex within the OTTLE cell. The same behavior was observed for **8**. The increase of absorbance around 450 nm is a characteristic feature of the primary reduced anions **8(r)** and **9(r)**. The conversion is complete within ca. 60 min. The photoreduction requires strictly anaerobic conditions. Full recovery of the starting complexes was observed on air exposure of the photogenerated anions **8(r)** and **9(r)** if the irradiation was stopped before side reactions started.

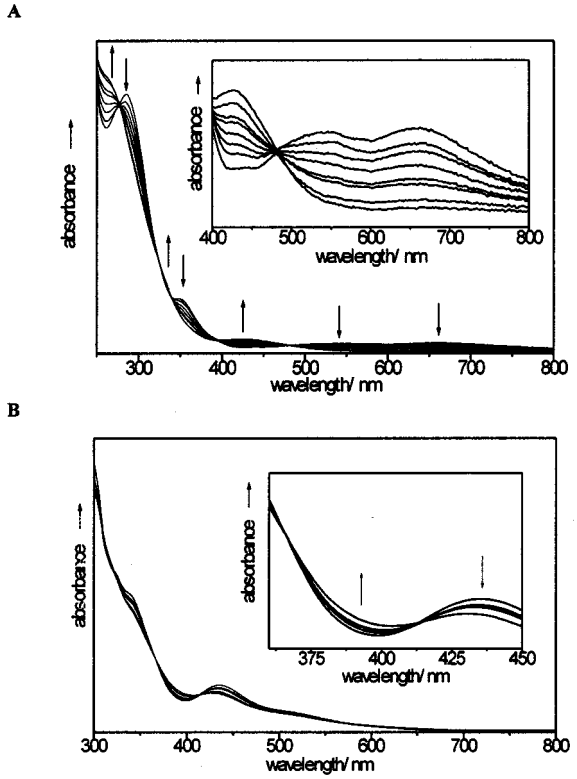

Figure 5. UV/Vis-spectroscopic changes accompanying continuous photolysis of **9** (A) at 293 K, **5** (B) at 193 K in THF ($\lambda_{irr} > 310$ nm, $t_{irr} = 0, 10, 20, 35, 50, 70$ s)

Photochemical generation of the reduced complexes **5(r)**−**7(r)** failed at room temperature, though the spectroelectrochemical investigations reveal their thermal stability. Continuous photolysis in THF at low temperatures ($T \leq 213$ K), however, yielded the expected anionic complexes. The formation of **5(r)** at $T = 193$ K is shown in Figure 5B.

The application of low temperature was not successful in the case of **2(r)**. The absence of the weak absorption of **2(r)** at 500 nm arising in the course of the electrochemical

reduction, reveals that only the secondary product **2(ir)** was formed on irradiation of **2** in EtOH and THF, even at T = 193 K. This finding obviously fits with the lower stability of the primary reduced complex **2(r)** in comparison with **5(r)−9(r)**, as discussed in previous sections.

Photooxidation

Irradiation of **1**−**9** in $CHCl_3$ at 546, 436, and 366 nm did not lead to any measurable photoreaction, although intense CT absorption bands dominate in this region (see Table 2). With λ_{irr} = 332 nm only minor spectral changes could be detected within 60 min. A considerable acceleration of the photoreaction was observed when shorter irradiation wavelengths (λ_{irr} = 313 , 302 , and 254 nm) were applied, though the absorbance of **1**−**9** does not deviate significantly at the latter wavelengths from that at 334 or 366 nm. Notably, a week absorbance ($A \approx 0.004$ vs. H_2O; d = 1 cm) of the solvent $CHCl_3$ was measurable already at λ = 313 nm (cut off at ca. 250 nm).

Continuous photolysis (λ_{irr} = 254 , 302 , and 313 nm) of the complexes **1**−**9** in $CHCl_3$ only resulted in disappearance of the visible and UV absorption bands. The bleaching reactions may indicate formation of secondary oxidized products as studied in the course of the corresponding UV/Vis-spectroelectrochemical experiments (see Table 2).

In order to obtain evidence for the formation of the primary one-electron-oxidized species **1(o)**−**9(o)** upon irradiation in $CHCl_3$, flash photolysis experiments were carried out at room temperature. The samples were excited with 266 nm and 355 nm laser pulses. The ns transient absorption spectra were recorded in 10-nm steps for deaerated, as well as oxygen-saturated solutions (Figure 6). The expected increase of absorption in the visible region due to the cationic species **1(o)**−**9(o)** was indeed observed independent of the exclusion of oxygen, as displayed in Figure 7 for **2**. Following the decay of this transient absorption on the ns time scale showed that the cationic complexes exist at room temperature only a few hundred ns. The lifetimes τ of **1(o)**−**9(o)** in oxygen-free $CHCl_3$ were estimated assuming a first- or pseudo-first-order decay. Values for τ are given in Table 4. The longer lifetimes of **2(o)** and particularly **1(o)** relative to those of **6(o)**, **9(o)**, and particularly **8(o)** nicely agree with the cyclic voltammetric trends (see above).

In general, the photochemical reactivity of **1**−**9** in $CHCl_3$ tracks the absorbance spectrum of the solvent $CHCl_3$. The observed reactions are therefore assigned to be solvent initiated or to take place from CTTS excited states, which are not manifested in the electronic spectrum of these compounds in $CHCl_3$.[38]

No spectral changes could be monitored on excitation of the complexes **1**−**9** with visible light (λ > 400 nm) within 30 min. This behavior appears to be a result of relaxation processes from CT excited states via LF excited states.

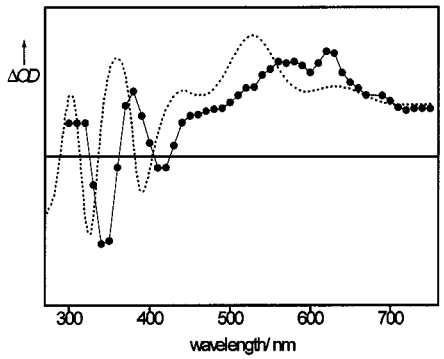

Figure 6. Transient absorption spectrum of **2** in *CHCl*$_3$ measured point-by-point 0.4 μs after laser excitation at 266 nm (••••), compared with UV/Vis absorbance difference spectrum recorded on one-electron oxidation of **2** in *butyronitrile* at 193 K (----) (see also Figure 3C)

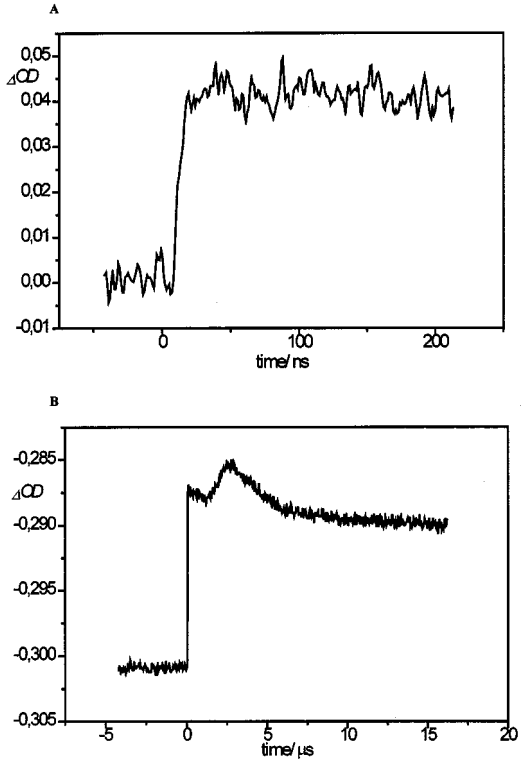

Figure 7. Transient decay following flash excitation of **2** in $CHCl_3$ at 266 nm on nanosecond (A) and microsecond (B) time scales

Table 4. Estimated lifetimes τ of the photooxidized complexes

Cation	**1(o)**	**2(o)**	**5(o)**[a]	**6(o)**	**8(o)**	**9(o)**
τ [μs]	3.1	1.2	–	0.5	0.2	1.0

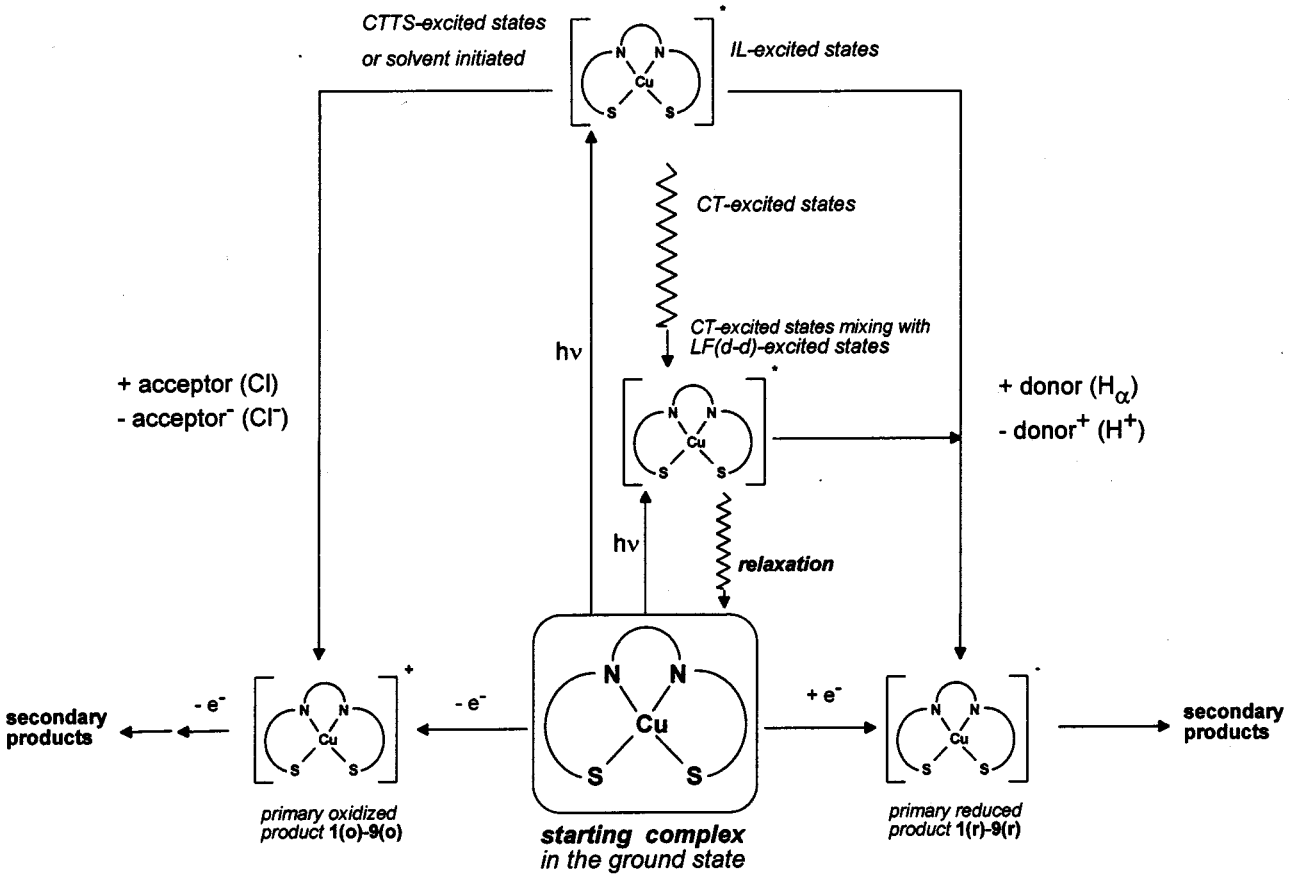
[a] The lifetime of **5(o)** could not be estimated due to very weak decrease of optical density accompanying the formation of secondary product sfrom **5(o)**.

Conclusions

The thiolate sulfur atom of the complexes under study is bound to an sp^2-hybridized carbon atom. The coupling of the pyrazole-ring carbon atom and the sulfur p-orbitals provides an easily conjugable framework to stabilize the thiolato copper(II) linkage. This electronic coupling results in a strong delocalization crucially influencing the electro-

chemical and photochemical properties of **1**−**9**. This kind of strong delocalization seems to be responsible that photochemical reactions can only be initiated by exciting intraligand excited states whilst excitation of low-energy electronically excited states leads to fast radiationless deactivation via d-d excited states.

Both thermally and photochemically induced reaction pathways of **1**−**9** are summarized in Scheme 1. In general, the same primary redox products, as studied by spectroelectrochemistry, are initially formed on photolysis in the appropriate reducing and/or oxidizing media. Photoreduction occurs in solvents bearing H_α atoms. Photooxidation in chlorinated solvents like $CHCl_3$ are solvent-initiated or initiated by population of CTTS-excited states.



The oxidation takes place on the copper−sulfur moiety. Obviously, the strong delocalization is responsible for the similar values of the oxidation potentials. The primary one-electron-oxidized products of copper(II) thiolate complexes could be characterized by UV/Vis spectroscopy at low temperature.

The reduction behavior is strongly dependent on the geometry of the pseudotetrahedral N_2S_2 donor set surrounding the Cu^{II} ion. The stability of the primary one-electron-reduced products increases with stronger tetrahedral distortion. An opposite trend applies for the primary one-electron-oxidized species (formally d^8-Cu^{III}) which prefer square-planar geometry of the coordination sphere.

The effect of different substituents on the redox behavior of the nearly planar complexes **1**−**4** containing aromatic backbones is not significant. The influence of the ligand flexibility on the reduction of the complexes with aliphatic backbones is reflected in the two-electron oxidation of the complexes **6** and **7** in comparison with **8** and **9** on the time scale of cyclic voltammetry. The oxidation path is significantly influenced by the kind of donor solvents used. Thus, strongly coordinating butyronitrile facilitates cleavage of the Cu−S bonds in the primary one-electron-oxidized species, followed by transfer of a second electron. This reactivity can be supressed in weakly coordinating THF.

Experimental Section

Synthetic Methods and Materials: All chemicals were of analytical grade and were used as received from Aldrich [Bu_4NPF_6, ferrocene (Fc), cobaltocene ($CoCp_2$), cobaltocenium hexafluorophosphate ($CoCp_2PF_6$), PPh_3]. Ferrocenium tetrafluoroborate ($FcBF_4$) was prepared according to a literature procedure.[23] THF (Acros) was dried with NaOH pellets, followed by distillation from Na/benzophenone under nitrogen. Butyronitrile (Fluka) was freshly distilled from CaH_2 under nitrogen. Solvents for photoredox reactions ($CHCl_3$, ethanol), from Merck (Uvasol) or Aldrich (*t*BuOH), were degassed by means of ultrasound or bubbling solvent-saturated N_2 through the solutions before use. The complexes **1**−**9** (Figure 1) were synthesized according to literature procedures.[2,4,22] Their purity was checked by elemental analysis and mass spectrometry.

Scheme 1. General scheme of the electron-transfer pathway of the complexes **1**−**9**

Instrumentation

Spectroelectrochemistry: Cyclic voltammetry was performed in butyronitrile or THF using a standard vacuum-tight single-compartment cell equipped with a Pt disk working electrode of 0.42 mm^2 apparent surface area polished carefully with a 0.25 μm diamond paste. Pt gauze auxiliary and coiled Ag wire pseudoreference electrodes were used. The redox potentials are reported versus the $E_{1/2}$ potential of the ferrocene/ferrocenium (Fc/Fc^+) couple used as the recommended internal standard.[24] Occasionally, the cobaltocene/cobaltocenium ($CoCp_2^{+/0}$) couple was employed instead of Fc/Fc^+, using $E_{1/2}(CoCp_2^{+/0}) = -1.34$ V vs. Fc/Fc^+.[25] In butyronitrile $E_{1/2}(Fc/Fc^+) = +0.43$ V vs. SCE.[26] The cyclic voltammetric samples contained one of the $5\cdot10^{-4}$ M complexes **1**−**9** and $3\cdot10^{-1}$ M Bu_4NPF_6 as supporting electrolyte. UV/Vis spectroelectrochemistry at variable temperatures was carried out with previously described optically transparent thin-layer electrochemical (OTTLE) cells[27][28] placed into a Perkin-Elmer Lambda 5 spectrophotometer equipped with a 3600 data station. The solutions were typically $5\cdot10^{-3}$ M in the copper complexes **1**−**7** or less concentrated (near saturation) due to limited solubility of **8** and **9**, and $3\cdot10^{-1}$ M in the supporting electrolyte. Potential control during spectroelectrochemical experiments was achieved with a PA4 potentiostat (*EKOM*, Czech Republic).

Photochemistry: The photochemical experiments were carried out in 1-cm quartz cuvettes. The solutions typically contained ca. $5\cdot10^{-5}$ M **1**-**9**. As light source served a high-pressure mercury lamp USH 102DH (Ushio) equipped with appropriate filters or a monochromator (AMKO). Electronic absorption spectra were recorded in the course of the photochemical experiments with Cary 3 (Varian) and Perkin-Elmer Lambda 900 spectrophotometers.

Time-Resolved Spectroscopy: The third or fourth harmonic outputs (355 or 266 nm) of an Nd-Yag laser (GCR-11, Quanta-ray) were used for photoexcitation and a Xenon lamp (XBO 500, Narva) for probing the transient absorption in the ns and μs experiments. The light source for the ms experiments were two high-pressure mercury flash lamps operating parallel (Narva). The absorption was probed with an HBO 500 lamp (Narva). After each pulse, the sample solutions were replaced to avoid accumulation of photoproducts.

Acknowledgments

Financial support by the Deutsche Forschungsgemeinschaft, the Netherlands Foundation for Chemical Research (SON) and the Netherlands Organization for Pure Research (NWO) is gratefully acknowledged. We wish to thank Prof. O. Brede and his group (University of Leipzig) for the ns and μs time-resolved spectroscopic experiments.

Synthesis, Electrochemistry, and Oxygen-Atom Transfer Reactions of Dioxotungsten(VI) and -molybdenum(VI) Complexes with N_2O_2 and N_2S_2 Tetradentate Ligands

Yee-Lok Wong,[a] Jian-Fang Ma,[a] Wing-Fong Law,[a] Yan Yan,[a] Wing-Tak Wong,[b] Ze-Ying Zhang,[a] Thomas C. W. Mak,[a] and Dennis K. P. Ng*[a]

Keywords: Tungsten complexes / Molybdenum complexes / Tetradentate ligands / Oxygen-atom transfer

A series of N_2O_2 tetradentate ligands with a range of substituents attached to the nitrogen atoms have been prepared (H_2L^n) (n = 1–9). Treatment of these ligands and the N_2S_2 tetradentate ligand H_2L^{10} with [WO_2Cl_2(DME)] (DME = 1,2-dimethoxyethane) in the presence of triethylamine leads to the formation of *cis*-dioxotungsten(VI) complexes [$WO_2(L^n)$] (n = 1–10). Reaction of the N_2O_2 tetradentate ligands H_2L^n (n = 1, 3–7) with ammonium molybdate tetrahydrate and dilute hydrochloric acid gives the corresponding molybdenum(VI) analogs [$MoO_2(L^n)$] (n = 1, 3–7). These compounds have been spectroscopically characterized and the molecular structures of [$WO_2(L^n)$] (n = 1, 2, 9) and [$MoO_2(L^5)$] have been established by X-ray diffraction analysis. These high-valent compounds participate in oxygen-atom transfer reactions and can catalyze the oxidation of benzoin with dimethyl sulfoxide. The complex [$WO_2(L^{10})$], which contains an S-donor ligand, has lower reduction potential and higher reactivity toward oxo-transfer reactions than analogous tungsten complexes having N_2O_2 ligands. The kinetics of these catalytic processes along with the structure and electrochemistry of these dioxotungsten and -molybdenum complexes are described and compared.

Introduction

Atom-transfer chemistry of tungsten has recently attracted considerable attention because of its relevance to some important oxidation processes promoted by high-valent tungsten species[1] and biological reactions mediated by tungsten oxotransferase enzymes, which catalyze the oxo-transfer reactions for a range of substrates such as aldehydes and carbon dioxide.[2] In contrast to the related molybdenum chemistry that has been well documented,[3] tungsten-mediated atom-transfer reactions have been little studied and, to our knowledge, not more than a dozen examples have been reported so far.[4] Of much current interest are those containing bidentate dithiolene-type ligands which mimic the pterin cofactors found in the tungstoenzymes.[4][5] Although the oxomolybdenum complexes with tetradentate N-, O- and S-donor ligands have been studied extensively and some of them participate in various atom-transfer reactions,[6] very little has been accomplished with regard to the analogous tungsten chemistry.[7] We describe herein the synthesis and characterization of a new series of dioxotungsten(VI) complexes with N_2O_2 and N_2S_2 tetradentate ligands. These compounds undergo an irreversible reduction at highly negative potentials, but are still active toward oxygen-atom transfer reactions. The structural, electrochemical and oxo-transfer properties of these tungsten complexes are discussed and compared with those of their molybdenum counterparts, some of which have also been synthesized for the first time.

Results and Discussion

Synthesis and Characterization

Deprotonation of the readily available tetradentate ligand H_2L^1[8] with *n*BuLi followed by *N*-methylation with methyl iodide or *N*-benzylation with various benzyl bromides led to the formation of a series of N_2O_2 tetradentate ligands H_2L^n (n = 2−7) in good yield (Scheme 1). These substituents, having different steric and electronic properties, were introduced to the nitrogen atoms with the goal of examining their effects on complex formation and properties of the resulting complexes. The ligand H_2L^2 was prepared previously by reductive amination from formaldehyde and glyoxalbis(2-hydroxyanil).[9] The new ligands H_2L^n (n = 3−7) were found to be rather unstable and the yellow oily liquids darkened gradually upon exposure to air over 1−2 days. The ligands should therefore be freshly prepared for complex formation. The ligands H_2L^n (n = 8−10) were synthesized according to literature methods.[10,11]

Treatment of these ligands with [WO_2Cl_2(DME)] in the presence of triethylamine gave the corresponding dioxo complexes [$WO_2(L^n)$] (n = 1−10, Scheme 2). In contrast to the commonly used starting material [WO_2Cl_2],[12] this DME adduct, which can be prepared readily from [$WOCl_4$], $(Me_3Si)_2O$ and DME,[13] possesses good solubility in or-

ganic solvents and undergoes facile ligand-substitution reactions.[14] It therefore appears to be a more versatile precursor to other high-valent tungsten complexes. The molybdenum counterparts $[MoO_2(L^n)]$ (n = 1, 3−7) were also prepared in moderate yield by treating ammonium molybdate tetrahydrate with the ligands H_2L^n (n = 1, 3−7) in the presence of HCl and EtOH (Scheme 2).[15] The complex $[MoO_2(L^1)]$ was prepared previously from $[MoO_2(acac)_2]$ (acac = acetylacetonate) and H_2L^1 by Spence et al.[16] All these air-stable dioxotungsten and -molybdenum complexes could be purified by column chromatography and/or recrystallization, and were characterized with elemental analyses or accurate mass measurements, along with a range of spectroscopic methods.

Scheme 2. Preparation of dioxotungsten(VI) and -molybdenum(VI) complexes

All the tungsten compounds showed two characteristic *cis*-dioxo $[WO_2]$ vibrational bands at 895−921 and 936−958 cm^{-1} in their IR spectra,[17] except $[WO_2(L^8)]$ the IR spectrum of which exhibited only the higher frequency band at 941 cm^{-1} while the lower frequency band was embedded in a broad signal at 885 cm^{-1}. The IR spectra of the molybdenum analogs showed similar asymmetric and symmetric Mo=O stretches at 905−919 and 928−938 cm^{-1}, respectively; the latter band occurred at a 15−25 cm^{-1} lower frequency than that for the tungsten congeners. The ^{1}H- and ^{13}C-NMR spectra of these dioxo compounds were in accord with an octahedral structure having a C_2 rotation axis. Take compounds $[WO_2(L^n)]$ (n = 8, 9) as examples; the two methylene protons next to the aromatic ring are no longer equivalent. Two doublets with a geminal coupling constant of ca. 14 Hz appeared at $\delta \approx 3.9$ and 4.7 in their ^{1}H-NMR spectra recorded in [D$_6$]DMSO. The two methylene protons in the benzyl groups in $[MO_2(L^n)]$ (M = Mo, W; n = 3−6) are also diastereotopic and an AB quadruplet was observed for these protons in all the spectra. All these dioxo compounds were also characterized by fast atom bombardment (FAB) or liquid secondary ion (LSI) mass spectrometry. The M^+ or $[M+H]^+$ species were identified in all cases with predicted isotopic distribution pattern.

Molecular Structures

Single-crystal X-ray diffraction studies of $[WO_2(L^2)]$ and $[MoO_2(L^5)]$ revealed that the asymmetric unit consists of two crystallographically independent molecules. The former also contains solvated dichloromethane. Figures 1 and 2 display the molecular structure of one of the independent molecules for $[WO_2(L^2)]$ and $[MoO_2(L^5)]$, respectively. For $[WO_2(L^9)]$ (Figure 3), the tungsten atom lies on a crystallographic 2-fold axis so that one-half of the molecule is present in the asymmetric unit. A perspective view of $[WO_2(L^1)]$ is also presented in Figure 4. Each of these structures possesses C_2 {for $[WO_2(L^9)]$} or approximate C_2 symmetry and adopts distorted octahedral geometry, with the N atoms *trans* to the terminal oxo groups. The bond lengths and angles of these complexes are unexceptional and resemble those found in other six-coordinate dioxo−W^{VI}[12d,14a,17b,18] and −Mo^{VI} complexes.[9,10,19] Selected bond lengths and angles for these compounds, along with a brief description is available as Supporting Information on the WWW or from the author.

Electrochemistry

The electrochemical behavior of $[MoO_2(L^1)]$ in *N*,*N*-dimethylformamide (DMF) was studied previously by cyclic voltammetry.[16] The voltammogram displayed an irreversible one-electron reduction peak at −1.41 V vs. SCE coupled to an oxidation peak at −0.02 V, together with a reversible one-electron reduction peak at −1.70 V assignable to the Mo^{VI}/Mo^V and Mo^V/Mo^{IV} couples, respectively. An oxo−Mo^V species with deprotonated amino ligand was postulated as the intermediate. The electrochemistry of $[MoO_2(L^n)]$ (n = 4, 5, 7), which do not have ionizable protons, is somewhat different. Their voltammograms recorded in DMF showed only one redox couple attributable to a metal-based reduction. A weak cathodic peak at around −1 V was also observed for $[MoO_2(L^n)]$ (n = 5, 7) but its origin is unclear at this stage. The electrochemical data are summarized in Table 1. Ferrocene was added in all measurements as an internal reference and its half-wave potential ($E_{1/2}$ = 0.08 V vs. Ag/Ag^+ in MeCN) remained virtually unchanged. By comparing the values of ΔE_p of the reduction couples of $[MoO_2(L^n)]$ (n = 4, 5, 7) (102−160 mV) with that of ferrocene which ranges from 66 to 71 mV, and on considering the i_{pa}/i_{pc} values which are less than unity, these couples can be described as quasi-reversible processes. It is worth noting that the substituents attached to the nitrogen atoms of the ligands only have marginal effects on the redox potentials. The $E_{1/2}$ values follow the order

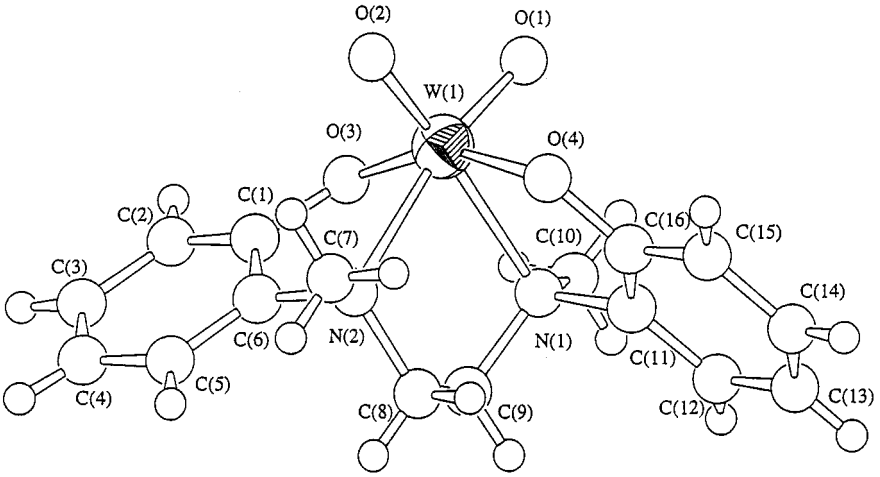

Figure 1. Molecular structure and atom-labeling scheme for $[WO_2(L^2)]$; the hydrogen atoms are shown with small arbitrary radii

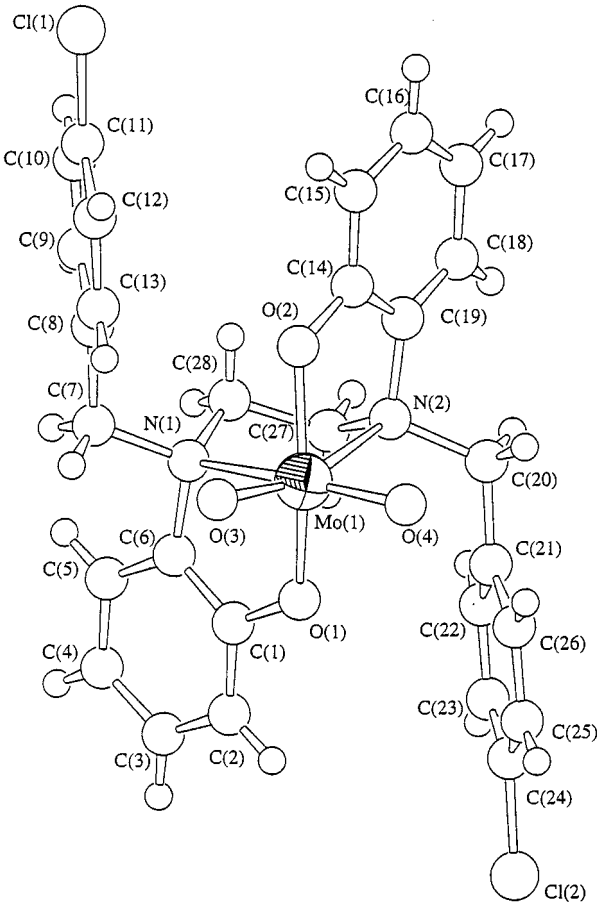

Figure 2. Molecular structure and atom-labeling scheme for $[MoO_2(L^5)]$; the hydrogen atoms are shown with small arbitrary radii

$[MoO_2(L^5)] > [MoO_2(L^4)] > [MoO_2(L^7)]$ as a result of the different electron-withdrawing abilities (Cl > Me > *t*Bu).

The voltammograms of the tungsten analogs $[WO_2(L^n)]$ (n = 1, 4, 5, 8) revealed a major irreversible process at highly negative potentials (E_{pc} ranged from −2.07 to −2.32 V vs. SCE) assignable to the reduction of the W^{VI} metal center. Some weak and unidentified signals were also seen for some of these complexes (Table 1). In accordance with previous studies,[5a,17b,20] the metal-based reduction potentials for the tungsten complexes were more negative than those of the corresponding molybdenum counterparts and the redox processes were less reversible.

The electrochemical behavior of $[WO_2(L^{10})]$ was remarkably different from that of other tungsten analogs. Its voltammogram recorded at a scan rate of 100 mV s^{-1} showed a reduction couple centered at −1.90 V and an oxidation peak at −0.06 V, both vs. SCE (Figure 5a). The anodic peak for the reduction couple was not observed at slower scan rates but this peak emerged and the peak current ratio (i_{pa}/i_{pc}) for this couple approached unity as the scan rate was increased. The peak-to-peak separation (ΔE_p) fell in the region 100 to 105 mV at scan rates between 100 and 700 mV s^{-1}. The value increased gradually to 197 mV with increasing scan rate to 10,000 mV s^{-1}. These results suggested that the reduction changed from an irreversible to a quasi-reversible process as the scan rate was increased. The peak current function ratio {peak current function: $i_p\nu^{-1/2}C^{-1}$, where i_p = peak current [A], ν = scan rate [V s^{-1}], C = concentration [M]} for the reduction of $[WO_2(L^{10})]$ with respect to the one-electron oxidation of ferrocene under identical conditions was 1.25 at 20 mV s^{-1}, which decreased to 0.76 at 800 mV s^{-1}. These data together with the plot showing the variation of $i_{pc}\nu^{-1/2}$ with ν (Figure 6) indicated that the process approaches an overall two-electron reduction at slow scan rates. This plot implied that the one-electron reduction product is somewhat unstable and a further removal of one electron occurs readily to the W^{IV} state. This will happen if the $W^{VI/V}$ potential is more negative than the $W^{V/IV}$ potential, as was observed for related molybdenum complexes.[10,21] It is also worth noting that the intensity of the oxidation peak at −0.06 V decreases with increasing scan rate and eventually vanishes at 800 mV s^{-1} (Figure 5b). This peak may thus be attributed to an electrochemically generated W^{IV} species and a purely one-electron quasi-reversible reduction seems to occur at scan rates over 800 mV s^{-1}. This behavior is very similar to that of the molybdenum counterpart $[MoO_2(L^{10})]$ with the ex-

[a] Recorded with $[Bu_4N][ClO_4]$ as electrolyte in DMF (0.1 M) at ambient temp. Scan rate = 100 mV s^{-1}. Potentials are expressed in V vs. SCE. – [b] $\Delta E_p = \lvert E_{pc} - E_{pa}\rvert$ in mV.

ception that the reduction of the latter occurs at a much more positive potential (−1.34 V vs. SCE).[22] It is interesting to note that incorporation of sulfur-containing ligand such as L^{10} lowers the reduction potential of the complex and increases its reversibility relative to the analogous oxygen-containing ligands. The reduction potential of $[WO_2(L^{10})]$ (E_{pc} = −1.96 V vs. SCE or −2.27 V vs. Ag/Ag^+ in MeCN), however, is still more negative than those of the synthetic models for tungstoenzymes such as $[Et_4N]_2[WO_2(bdt)_2]$ (bdt = 1,2-benzenedithiolate) (E_{pc} = −1.34 V vs. SCE)[5a] and $[Et_4N]_2[WO_2(mnt)_2]$ (mnt = 1,2-dicyanoethylenedithiolate) (E_{pc} = −1.50 V vs. Ag/Ag^+ in MeCN).[5c] It appears that these unsaturated dithiolene-type ligands are crucial for the complexes to reach physiologically accessible potentials.

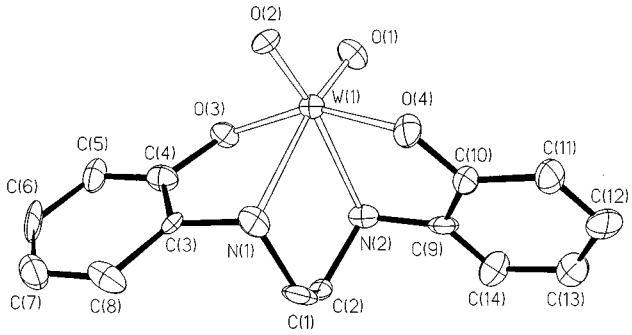

Figure 4. Molecular structure of $[WO_2(L^1)]$ showing the atom-labeling scheme

Oxo-Transfer Reactions

As tungsten-mediated oxo-transfer reactions had been little studied, we were interested to examine the oxo-transfer properties of some of these dioxotungsten(VI) compounds, namely $[WO_2(L^n)]$ (n = 1, 8, 10) using benzoin as the common reductant. Typically, 7×10^{-3} mmol of the complexes and 20 equiv. of benzoin were dissolved in deoxygenated $[D_6]$DMSO (0.5 ml). The mixtures were sealed in NMR tubes and heated at 100°C. The kinetics of the systems were analyzed by ^{1}H-NMR spectroscopy which allowed the quantification of benzoin and its oxidized product, benzil, as well as the complexes. The concentration ratios of {[benzoin] + [benzil]} to $\{[WO_2(L^n)]\}$ (n = 1, 8, 10) remained constant during the course of the reactions. In the absence of the complexes, no reaction between benzoin and $[D_6]$DMSO was detected. The percentage conversion of benzoin to benzil was about 90% after 36 h when compound $[WO_2(L^{10})]$ was used. Reactions involving complexes $[WO_2(L^n)]$ (n = 1, 8) proceeded slowly and only ca. 50% of benzoin was consumed after 1 week. These results indicated that these dioxotungsten(VI) complexes can catalyze the

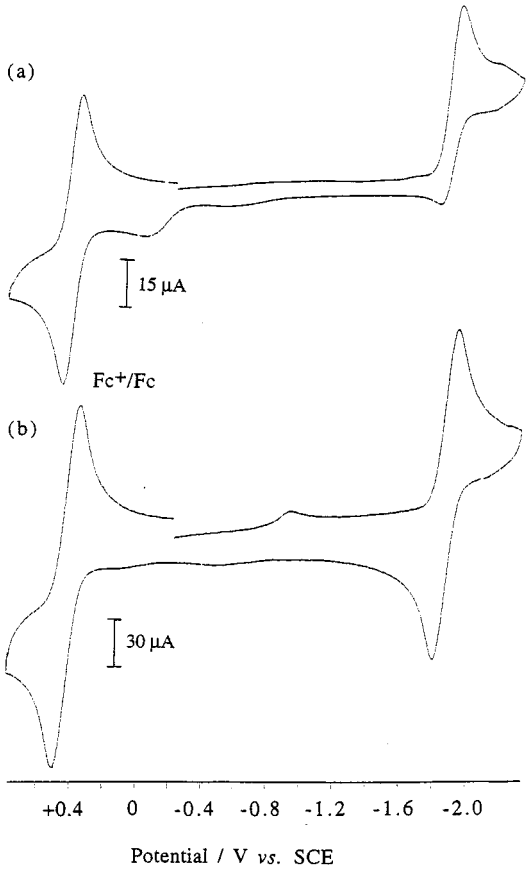

Figure 5. Cyclic voltammograms of $[WO_2(L^{10})]$ in DMF containing 0.1 M $[Bu_4N][ClO_4]$ recorded at (a) 100 mV s^{-1} and (b) 800 mV s^{-1}

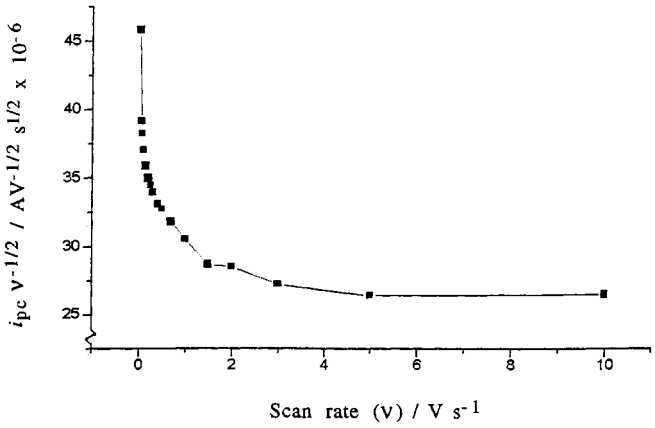

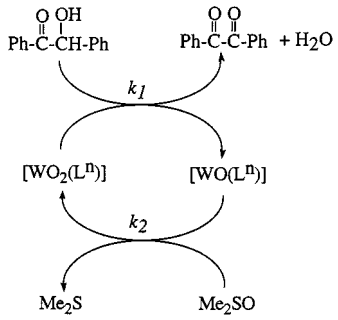

Figure 6. Plot of $i_{pc}v^{-1/2}$ vs. v for $[WO_2(L^{10})]$

oxidation of benzoin with $[D_6]$DMSO. The use of DMSO as oxo donor in this study has biological relevance to the molybdenum-containing DMSO reductases, which are able to utilize a variety of dialkyl- and alkylarylsulfoxides as oxidizing substrate.[23]

A plausible mechanism for this oxidation is suggested in Scheme 3 by analogy to that proposed for related catalytic systems.[24] Presumably, the W^{VI} complexes are reduced by benzoin to yield monomeric oxotungsten(IV) species, benzil and water. The W^{IV} complexes are then oxidized back to their parent dioxo compounds with $[D_6]$DMSO. Assuming that the regeneration of the W^{VI} species is fast ($k_2 \gg k_1$), their concentration should be essentially constant throughout the reactions. The rate of consumption of benzoin can thus be regarded as a pseudo-first-order reaction ($-$d[benzoin]/dt = k_{obs} [benzoin], where k_{obs} = k_1 {[WO(L^n)]}). Figure 7 shows the variation of ln{[benzoin]$_o$/[benzoin]} with time for $[WO_2(L^{10})]$, where [benzoin]$_o$ is the initial concentration of benzoin. From the slope of the best-fit straight line (1.86×10^{-5} s^{-1}), the value of k_1 can be determined (1.31×10^{-3} M^{-1} s^{-1}). For the other two N_2O_2 complexes $[WO_2(L^n)]$ (n = 1, 8), a gradual decrease in the catalytic activities was observed after prolonged heating. The respective k_1 values were calculated to be 1.28×10^{-4} and 9.43×10^{-5} M^{-1} s^{-1} based on the data collected in the first 85 h. The *S*-ligated complex $[WO_2(L^{10})]$ is therefore a better oxo donor than the *O*-ligated complexes $[WO_2(L^n)]$ (n = 1, 8) which is fully consistent with the electrochemical data (Table 1). A comparison of these dioxo complexes shows that the anionic complexes $[WO_2(bdt)_2]^{2-}$[5a,25] and $\{WO_2[O_2CC(S)Ph_2]_2\}^{2-}$[24a] are very efficient in promoting the oxidation of benzoin, while the complexes $[WO_2LX]$ [L = hydrotris(3,5-dimethyl-1-pyrazolyl)borate; X = OPh, S_2PPh_2-*S*] are inert toward oxygen-atom transfer reactions.[17b]

Scheme 3. Proposed mechanism for the oxidation of benzoin with DMSO using $[WO_2(L^n)]$ as a catalyst

In order to reveal whether the W^{IV} species $[WO(L^{10})]$ or the W^V dimer $[W_2O_3(L^{10})_2]$ were actually formed, a mixture of $[WO_2(L^{10})]$ and one equiv. of benzoin in deoxygenated $[D_7]$DMF was sealed in an NMR tube and heated at 100°C. The reaction was monitored by ^{1}H-NMR spectroscopy. Surprisingly, the spectra were essentially unchanged and no significant amount of benzil was detected even after 1 week.

The oxo-transfer properties of the molybdenum analogs $[MoO_2(L^n)]$ (n = 5, 6) were also investigated under identical conditions for comparison. These molybdenum-mediated reactions proceeded considerably faster and ca. 75% of benzoin was consumed after 25 h at 100°C. However, the {[benzoin] + [benzil]}-to-{$[MoO_2(L^n)]$} (n = 5, 6) ratios increased gradually during the course of the reactions indicating that part of the catalysts was deactivated and consumed. Some unidentified signals were also observed in the NMR spectra which precluded a detailed kinetic analysis. Lowering the temperature to 50°C greatly retarded the oxo-transfer reactions; the benzoin conversion was only 5−7% after 95 h. The higher oxo-transfer reactivity of molybdenum

complexes relative to their tungsten counterparts may be attributed to their lower reduction potentials and weaker M=O bond (bond dissociation energy = ca. 410 kJ mol^{-1} for Mo=O and > 580 kJ mol^{-1} for W=O).[4,17b]

In summary, we have synthesized a new series of dioxotungsten complexes with N_2O_2 and N_2S_2 tetradentate ligands which represent rare examples of tungsten compounds showing oxo-transfer activity. The S-donor atoms in the ligand seem to play an important role in lowering the reduction potential of the complex and thereby increasing its oxo-transfer reactivity toward the oxidation of benzoin with DMSO. The analogous molybdenum complexes are more active in this oxygen-atom transfer reaction which is in accord with the electrochemical data.

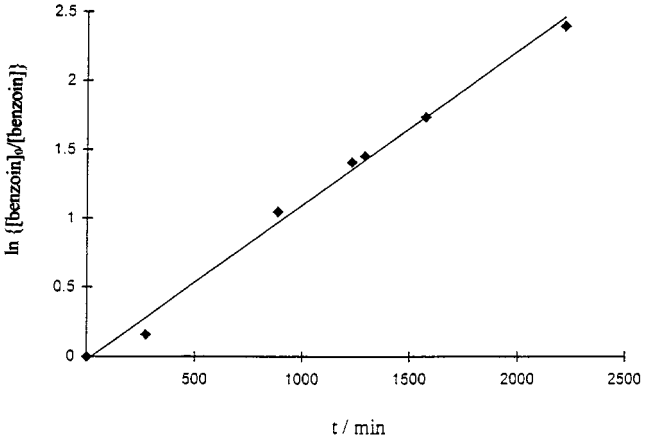

Figure 7. Plot of ln{[benzoin]$_o$/[benzoin]} vs. time for a system containing initially 0.28 M benzoin and 0.014 M [$WO_2(L^{10})$] in [D_6]DMSO at 100°C

Experimental Section

All reactions were carried out with standard Schlenk-line techniques under nitrogen; workups were performed in air. Dichloromethane was dried with 4-Å molecular sieves and distilled from calcium hydride. Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl. DMF for voltammetric studies was dried with barium oxide and distilled under reduced pressure. The electrolyte [Bu_4N][ClO_4] was recrystallized from dry acetone three times prior to use. All other reagents and solvents were of reagent grade and used as received. The ligands H_2L^n (n = 1,[8] 8, 9,[10] 10[11]) and the tungsten complex [WO_2Cl_2(DME)][13] were prepared by previously described methods. − NMR: Bruker WM 250 (^{1}H, 250; ^{13}C, 62.9 MHz), Bruker DPX 300 (^{1}H, 300; ^{13}C, 75.4 MHz) and Bruker ARX 500 (^{1}H, 500; ^{13}C, 125.8 MHz), $CDCl_3$ as solvent and TMS as internal standard unless otherwise stated, for [D_6]DMSO as solvent δ_H = 2.50, δ_C = 39.7, coupling constant J in Hz. − IR: Perkin Elmer 1600 FT-IR and Nicolet 550 FT-IR as KBr pellets. − MS: Hewlett Packard 5989B (FAB) and Bruker APEX 47e FT-ICR (LSI) with 3-nitrobenzyl alcohol as matrix. − Elemental analyses: Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences. − Electrochemical measurements were carried out with a BAS CV-50W voltammetric analyzer. The cell comprised inlets for a platinum-sphere working electrode, a silver-wire counter electrode and an Ag/$AgNO_3$ (0.1 M in MeCN) reference electrode which was connected to the solution by a Luggin capillary whose tip was placed close to the working electrode.[26] Typically, a 0.1 M solution of [Bu_4N][ClO_4] in DMF containing 1.0 mM of sample was purged with nitrogen for 20 min, then the voltammograms were recorded at scan rates ranging from 20 to 3000 mV s^{-1} at ambient temp. unless otherwise stated. All potentials were referred internally to the ferrocene/ferrocenium couple at +0.39 V vs. SCE.[27]

General Procedure for the Preparation of H_2L^n (n = 2−7): To a colorless solution of H_2L^1 (0.24 g, 1.0 mmol) in THF (10 ml) was added *n*BuLi (1.6 M solution in *n*-hexane, 2.6 ml, 4.1 mmol) dropwise at 0°C. The mixture was stirred at this temp. for 1 h, then allowed to warm to room temp. Iodomethane (0.13 ml, 2.0 mmol) or differently substituted benzyl bromides (2.0 mmol) were added slowly and stirring was continued for 18 h (only 6 h was required for the reaction with iodomethane). The volatiles were removed under reduced pressure and water (20 ml) was added. The mixture was extracted with CH_2Cl_2 (3 × 50 ml) and the combined extracts were dried with sodium sulfate and the solvent was removed using a rotary evaporater. The ligand H_2L^2 was collected as a white solid by washing the residual light brown solid with CH_2Cl_2/hexane (1:3), while the other ligands were purified by column chromatography using hexane followed by CH_2Cl_2 as eluent. These ligands were obtained as a pale yellow oil.

General Procedure for the Preparation of $[MoO_2(L^n)]$ (n = 1, 3−7): A mixture of ammonium molybdate tetrahydrate $[NH_4]_6[Mo_7O_{24}] \times 4\ H_2O$ (0.18 g, 0.14 mmol), H_2L^n (n = 3−7, 1.0 mmol) and dilute hydrochloric acid (0.1 M, 5 ml, 0.5 mmol) in ethanol (30 ml) was stirred at room temp. overnight. $[MoO_2(L^1)]$ was collected by filtration as a yellow solid which was washed with ethanol and hexane, and dried in vacuo. For the other molybdenum complexes, the solid was collected by filtration and the filtrate was extracted with CH_2Cl_2 (3 × 20 ml). The solid and the extracts were combined, dried with sodium sulfate and the solvent removed using a rotary evaporator. The residue was chromatographed with $CHCl_3$ as eluent to develop a bright yellow band which was collected and evaporated to give a yellow solid.

X-ray Crystallographic Analysis of [$WO_2(L^1)$] and [$WO_2(L^9)$] · MeCN · EtOH: Crystal data and data-processing parameters are given in the Supporting Information on the WWW or may be obtained from the author. Data collection was performed in the variable ω-scan mode with a Rigaku AFC7R diffractometer using Mo-K_α radiation (λ = 0.71073 Å) at 294 K. Unit-cell parameters were calculated from least-squares fitting of the 2θ angles for 25 selected strong reflections. Three standard reflections were monitored periodically after every 150 reflections and showed no significant decay during the data collection. The tungsten atom {of site symmetry 2 for [$WO_2(L^9)$] · MeCN · EtOH} was located by the Patterson method and the remaining non-hydrogen atoms were derived from subsequent Fourier difference syntheses. For [$WO_2(L^9)$] · MeCN · EtOH, both *tert*-butyl groups exhibit twofold orientational disorder, and the ethanol molecule is likewise twofold disordered with a common methylene group. The acetonitrile molecule lies on a crystallographic twofold axis. All non-hydrogen atoms were refined with anisotropic thermal parameters by full-matrix least-squares procedures. The hydrogen atoms were placed in idealized positions (C−H 0.96 Å, N−H 0.90 Å) with fixed isotropic thermal parameters and allowed to ride on their respective parent carbon and nitrogen atoms. All calculations were performed with a PC-486 computer using the SHELXL-PLUS program package.[28] Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[29]

X-ray Crystallographic Analysis of [$WO_2(L^2)$ · 1/4CH_2Cl_2] and [$MoO_2(L^5)$]: All pertinent crystallographic data and other experimental details are also summarized in the Supporting Information. Intensity data were collected at 298 K with an Enraf-Nonius diffractometer using graphite monochromated Mo-K_α radiation and the ω-2θ scan technique. Three checked reflections were monitored periodically throughout data collection and showed no significant variations. All intensity data were corrected for Lorentz and polarization effects. An absorption correction by the ψ-scan method[30] was applied for [$WO_2(L^2)$ · 1/4CH_2Cl_2]. Both structures were solved by direct methods (SIR 92)[31] and expanded using Fourier techniques.[32] Some non-hydrogen atoms were refined anisotropically, while the rest was refined isotropically by full-matrix least-squares analysis. Hydrogen atoms were generated in their idealized positions but not refined. All calculations were performed with a Silicon-Graphics computer using the program package TEXSAN.[33]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication nos. CCDC-102337 {for [$WO_2(L^2)$]}, 101953 {for [$WO_2(L^2)$ · 1/4CH_2Cl_2]}, 102338 {for [$WO_2(L^9)$] · MeCN · EtOH} and 101952 {for [$MoO_2(L^5)$]}. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int.code + 44(1223)336-033; E-mail: deposit@ccdc.cam.ac.uk].

An Experimental and Theoretical Study of Gaseous Products in the Radiolysis of Germane/Ethylene Mixtures

Paola Antoniotti,[a] Paola Benzi,[a] Mario Castiglioni,[a] and Paolo Volpe*[a]

Keywords: Semiconductors / Germanium carbide / Radiolysis / Ab initio calculations / Gas-phase reactions

Gas-phase radical reactions of germane/ethylene mixtures have been investigated using theoretical calculations and radiolysis techniques. Ab initio quantum chemical calculations have been performed on reactions starting from GeH_x (x = 0–3) radicals and C_2H_4. The geometrical structure and relative stability of isomeric GeC_2H_n (n = 4–7) radicals have been investigated and restricted to the species in which a C–C bond is present, at the MP2(FROZEN) level of calculation with double-ζ quality basis sets. To better evaluate the relative stability of the investigated species, single-point calculations at the QCISD(T) level were performed with a 6-311G(3df,2p) basis set. Reaction enthalpies and heats of formation of the species have also been determined using theoretical calculations. From irradiation of GeH_4/C_2H_4 mixtures, condensed products and volatile species were obtained. Composition, amount, and characteristics of the condensed phase products are reported. The volatile compounds were identified and their amounts determined. From experimental results and theoretical calculations some hypotheses on the reaction mechanisms are presented.

Introduction

In the last few years much work has been done on the photovoltaic applications of amorphous materials, as they are less expensive and more direct in use than the crystalline ones. Amorphous alloys, such as Si−C, Si−Ge, and Ge−C, are very interesting because they can be obtained with variable compositions, and hence with tunable physical properties, by varying the nature and concentration of the reagents. Si−C and Si−Ge have been widely studied[1−9] while Ge−C has been generally neglected, even though the Davis and Mott equation[10] suggests that amorphous Ge−C can have good photovoltaic properties, depending on the Ge/C ratio.[11] This is probably due to the difficulties encountered in its preparation using simple methods, although many different synthetic paths have been exploited.[12−18] One of these methods is the radiolysis of gas mixtures of GeH_4 and hydrocarbons. The use of high-energy radiation (namely X-rays) overcomes the problem of the activation of compounds having very different bond energies (Ge−H, C−H, and C−C).

In our laboratory, studies on the decomposition of gas-phase mixtures of germane and saturated hydrocarbons using high-energy radiation have been performed. By this method, powders and thin films of materials containing Ge and C in different ratios have been obtained,[19−21] but even at high mol fraction of alkane in the reacting mixture, the C content of the solids is generally low.[22] A study of radiolysis of germane/unsaturated hydrocarbon mixtures is now in progress which has been undertaken because of the presence of the more reactive double bond which may lead to an increase in the number of carbon atoms incorporated into the solid.

This paper will deal with the gas-phase reactivity of monogermane/ethylene mixtures. In order to find a relationship between the gaseous reactant molar fraction and the abundance of the corresponding atoms in the solid, it is of fundamental importance to know the gas-phase behaviour of the reacting molecules. The combination of experimental and theoretical investigations is becoming a useful approach to the study of gas-phase chemistry.[23,24] In fact, in this paper, we report results of ab initio theoretical calculations to determine the structure, relative stability, and thermochemical data of the ground state of some products of the more probable gas-phase reactions proposed as a consequence of the experimental results. These calculations can help in some qualitative speculation on the whole mechanism involved.

Radiolysis of GeH_4/C_2H_4 Mixtures

Following irradiation of germane/ethylene mixtures gaseous and solid products are obtained, the latter being deposited on the bottom of the irradiation ampoules. For the samples containing more than of 15% ethylene, small amounts of a viscous liquid phase are formed which easily dissolve some of the volatile products making sampling and analysis of the gas phase products difficult.

Besides unreacted germane and ethylene, analysis of the gas-phase products indicates the presence of variable amounts of species containing both Ge and C. Only traces of volatile hydrocarbons, formed by polymerization of ethylene and mainly containing eight C atoms, is sometimes observed. The amounts of volatile species (other than GeH_4 and C_2H_4) as a function of ethylene percentage are reported in Table 1.

From Table 1 it appears that (i) apart from in the 30% ethylene mixture, the percentage of Ge found in the gas-

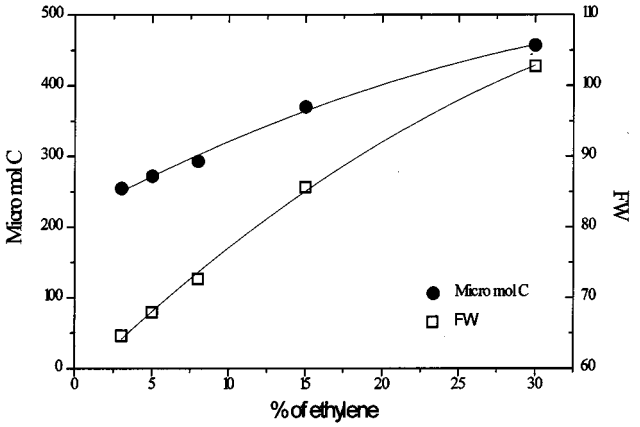

Figure 1. Absolute amounts of carbon and formula weight (FW) of the condensed-phase products vs. C_2H_4 percentage

phase products compared with Ge present in the reacting mixture is quite constant at about 0.1%, probably because of the formation of compounds of very low volatility and/or the solubility of the gases in the liquid phase; and (ii) the percentage of C found in the volatile products with respect to its starting amount is constant at about 0.6%, except for the samples at 30% ethylene, for the same reasons given above. The volatile products may be obtained from addition of GeH_x ($x = 1-3$) species with germane molecules or with ethylene or ethylene derivatives. It can be observed that with increasing amounts of ethylene in the reacting mixture, the amounts of the products containing only Ge and H decrease. In contrast, the amounts of the compounds containing both Ge and C increase, though for the latter the quantity decreases as the number of Ge atoms in the compound increases.

The low amounts of volatile products observed seems to indicate that the reactions which lead to condensed-phase products are favoured. In Table 2, amounts, composition and other characteristics of the condensed phases products obtained by irradiation of GeH_4/C_2H_4 mixtures with various ethylene percentages are reported. Ge/C and H/(Ge + C) atomic ratios observed for the condensed phase products are also reported.

Table 2 and Figure 1 show that both the absolute amount and the formula weight of the condensed-phase products increase as C_2H_4 increases. Moreover from Table 2 it can be observed that the Ge/C ratio decreases while the H/(Ge + C) ratio increases as the ethylene percentage is enhanced.

It is noteworthy that even if both volatile compounds and condensed-phase products (reported in Table 1 and 2) are considered, the decomposition of the GeH_4 is low with respect to the analogous germane/alkane mixtures.[22] In fact, the percentage of germane decomposed with respect to the germane initially present in the mixture varies from 0.5% to 2.0% when ethylene ranges from 3.0% to 30.0% corresponding to G ($-GeH_4$) values (μM/J) ranging from 1.4 to 5.2. In the GeH_4/alkane systems previously studied, the G ($-GeH_4$) values are 11.7 and 10.7 with ethane and propane, respectively, for mixtures with 25% of alkane. To explain this decomposition with respect to that observed when GeH_4 is irradiated alone, G ($-GeH_4$) = 1.26, the poor energy transfer between excited molecules of GeH_4 and hydrocarbon molecules has been invoked.[22] In fact, in such conditions the collisional quenching decreases and an excited GeH_4 molecule may therefore suffer decomposition after a few collisions. In the present study, ethylene is generally a minor component of the irradiated mixture and it is

generally present in too low percentage to prevent the energy transfer from excited germane molecules to germane molecules in the ground state.

As far as the condensed-phase products are concerned, it is interesting to study the hydrogen content as a function of the C_2H_4 percentage in the starting mixture, as shown in Figure 2.

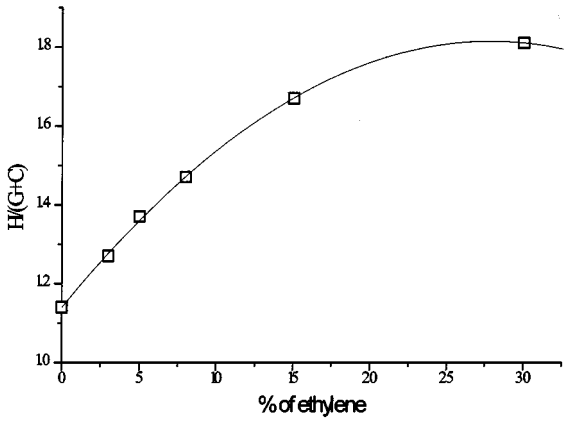

Figure 2. H/(Ge + C) atomic ratio in the condensed-phase obtained by irradiation of GeH_4/C_2H_4 mixtures with different ethylene percentages; the point on the *y* axis is an extrapolated value

Extrapolation to 0% ethylene, gives a value of H/Ge = 1.14 which is very close to the 1.29 value found in the γ radiolysis of pure GeH_4, measured using a radioisotopic technique.[25] The agreement improves considering the higher irradiation dose used in those experiments and that the extent of hydrogenation slowly increases with the dose.

During the irradiation both ionic and radical species may be involved in the formation of volatile and condensed-phase products. The ionic contribution to these processes can be investigated by mass-spectrometric experiments of both single reactants and their mixtures. The most important ions in the mass spectrum of pure ethylene are $C_2H_4^+$, $C_2H_3^+$, and $C_2H_2^+$ with abundances of 38, 23, and 22%, respectively, and other ions such as $C_2H_5^+$,$C_3H_n^+$ (n = 5, 7), and $C_5H_n^+$ (n = 7, 9) are also formed by ion−molecule reactions.[27] In germane the most abundant ionic species are GeH_3^+, GeH_2^+, GeH^+, and Ge^+. In addition, the formation of dimeric, trimeric, and tetrameric ions in ion−molecule reactions has been also observed.[28,29]

In a Fourier-transform mass-spectrometric study[27] of GeH_4/C_2H_4 mixtures it has been observed that reaction between $C_2H_4^+$ ions and GeH_4 molecules gives GeH_3^+ and, to a lesser extent, GeH_2^+ ions. Further reactions of GeH_3^+ ion species with GeH_4 or C_2H_4 neutrals lead to the formation of mixed species or ions containing two Ge atoms, respectively (Equations. 1, 2, and 3).

$$GeH_3^+ + GeH_4 \rightarrow Ge_2H_3^+ + 2\,H_2 \quad (1)$$
$$GeH_3^+ + GeH_4 \rightarrow Ge_2H_5^+ + H_2 \quad (2)$$
$$GeH_3^+ + C_2H_4 \rightarrow GeC_2H_5^+ + H_2 \quad (3)$$

Moreover, it is reasonable to suppose that ions obtained from the above reactions react further with GeH_4 and/or C_2H_4 leading to products with longer chains. This hypothesis is supported by the finding that in mass-spectrometric experiments performed under chemical ionization conditions on GeH_4/C_2H_4 mixtures, several ions containing one Ge and up to four C atoms were detected with relatively high abundance. Ions with two Ge and two to four C atoms were also observed.[27]

In summary, the ionic reaction mechanisms reported in a previous study,[27] using Fourier-transform and high-pressure mass-spectrometric methods, are in satisfactory agreement with the observations of this work.

In the radiolysis a great contribution to the products is, however, given by radical species. In order to evaluate the relative contribution of ions and radicals, the energy required for ionization and for the formation of a radical should be considered. The average energy absorbed for the formation of an *ion pair* (W)[26] in GeH_4 is about 22.0 eV ($8.41 \cdot 10^{-22}$ kcal)[22] and because the ionization potential (I) of GeH_4 is only 10.7 eV ($4.08 \cdot 10^{-22}$ kcal),[25,31] there is an excess energy ($W - I$) of about 11.3 eV ($4.33 \cdot 10^{-22}$ kcal) available for the formation of excited molecules and/or radicals. Considering the germylene radical (which from energetic data reported below, is the more probable primary radical) the energy required is 2.16 eV ($8.27 \cdot 10^{-23}$ kcal).[32] It follows that about four radicals can be formed in addition to each ion. It can therefore be concluded that radical reactions should give the major contribution to the product formation.

In previous experiments on GeH_4/alkane mixtures, high amounts of gaseous products were obtained and none of the product yields seemed to be affected by the addition of oxygen as a radical scavenger.[22] In contrast, in mixtures where ethylene is used instead of an alkane, a very low abundance of volatile products is formed. In particular, the amount of Ge_2H_6 is low and decreases with increasing concentration of ethylene, whereas the amount of GeC_2H_8 species increases with ethylene pressure showing that ethylene strongly competes with germane in the reactions with the GeH_x (x = 1−3) radicals and that germane−alkene reactions are mainly scavenging processes.

This hypothesis is supported by the data of Tables 1 and 2 which show that while the fraction of carbon in the products (gas and condensed phase) is about 6% of carbon in the reactant over the whole range of ethylene concentration, the fraction of germanium present in the products increases from about 0.5 to about 2% with increasing concentration of C_2H_4.

The radicals formed during the germane radiolysis are germyle, GeH_3, and germylene, GeH_2; it has been proposed that their formation occurs by decomposition of excited molecules according to the Equations 4 and 5.[33]

$$GeH_4^* \rightarrow GeH_3 + H \quad (4)$$
$$GeH_4^* \rightarrow GeH_2 + H_2 \quad (5)$$

The formation of GeH_3 and GeH_2 radicals requires an activation energy of $2.27 \cdot 10^{24}$ eV mol^{-1} (87.20 kcal mol^{-1})

and $1.30 \cdot 10^{24}$ eV mol^{-1} (49.80 kcal mol^{-1}), respectively,[32] so the reaction forming GeH_2 radicals should be energetically favoured. Moreover, it has been observed that GeH_2 further decomposes according to Equations 6 and 7, which compete with each other in the ratio 9:1[32] and suggest that the Ge and GeH species must also be considered in the products formation.

$$GeH_2 + M \rightarrow Ge + H_2 + M \quad (6)$$
$$GeH_2 + M \rightarrow GeH + H + M \quad (7)$$
M = neutral molecule

Therefore, it can be proposed that the germane radicals react with ethylene molecules leading to mixed species according to Equations (8) to (15). In these reactions ethylene addition or addition followed by elimination of hydrogen molecules or atoms occurs.

$$Ge + C_2H_4 \rightarrow GeC_2H_4 \quad (8)$$
$$GeH + C_2H_4 \rightarrow GeC_2H_5 \quad (9)$$
$$GeH_2 + C_2H_4 \rightarrow GeC_2H_4 + H_2 \quad (10)$$
$$GeH_2 + C_2H_4 \rightarrow GeC_2H_5 + H \quad (11)$$
$$GeH_2 + C_2H_4 \rightarrow GeC_2H_6 \quad (12)$$
$$GeH_3 + C_2H_4 \rightarrow GeC_2H_5 + H_2 \quad (13)$$
$$GeH_3 + C_2H_4 \rightarrow GeC_2H_6 + H \quad (14)$$
$$GeH_3 + C_2H_4 \rightarrow GeC_2H_7 \quad (15)$$

Because the long-chain products derive from the light ones, the same mechanisms for beginning a chain may be invoked to explain the formation of both volatile species and condensed-phase products. In fact, the species obtained from the above reactions may further react (by analogous mechanisms) with germane or ethylene with chain propagation leading to condensed-phase products, but the chain can be stopped by reaction with hydrogen radicals leading to the observed volatile species.

Considering the hydrogenation extent of the condensed-phase products, two hypotheses on the product formation can be proposed: (i) the main radicals which contribute to the Ge−C mixed compounds are the ones poor in hydrogen (Ge and GeH) and (ii) if germyle and germylene are the reactants, then in the reactions H (or H_2) is released. Some evidence supports the first hypothesis; in fact Figure 2 shows that the extent of condensed-phase hydrogenation increases with the carbon content. It is possible to think that the hydrogen enters in the chain mainly bonded to carbon atoms. This is because when an ethylene molecule leads upon a radical addition reaction it incorporates four hydrogen atoms, i.e. two hydrogen atoms for each carbon atom. To reach the empirical formula reported in Table 2 any germanium atom must lead, on average, to less then two hydrogen atoms. Moreover, even if from the above energetic considerations the germylene is the more probable primary radical, it must undergo an extensive decomposition leading to Ge and GeH. Thus, even Ge and GeH radicals have an important function in chain propagation leading to condensed-phase products which should, as a result, be poor in hydrogen.

Theoretical Study of the GeC_2H_n ($n = 4-7$) Species

In order to determine the most probable reaction pathways leading to the formation of the condensed-phase products, ab initio theoretical calculations on the products obtained from the previous reactions have been performed. Since in the radiolysis of ethylene the products maintaining the C−C bond predominate,[34] only the GeC_2H_n ($n = 4-7$) species in which such a bond is present were considered.

The enthalpies[35] of reactions leading to the most stable isomer have been calculated at the QCISD(T)/6-311G(3df,2p) level of theory and are reported in Table 3. Formation enthalpies $\Delta H°_f$ for the most stable GeC_2H_n ($n = 4-7$) species considered in this paper have also been computed and are reported in Table 4. They have been obtained by the method proposed by Pople et al.[36] The method was used with the following modifications: (i) The QCISD(T)/6-311G(3df,2p) energies (reported in Table 5) have been directly used throughout in order to evaluate the energy difference relevant to the isogyric reaction; (ii) instead of the ZPE correction to the energy, the full thermal correction at the MP2/BS level of theory has been applied (as outlined in ref.[35]).

Table 3. Enthalpies of reactions leading to the most stable products [kcal mol^{-1}]

Equation	Reaction	$\Delta H°$
(8)	$Ge + C_2H_4 \rightarrow GeC_2H_4$	−31.5
(10)	$GeH_2 + C_2H_4 \rightarrow GeC_2H_4 + H_2$	−3.0
(9)	$GeH + C_2H_4 \rightarrow GeC_2H_5$	−19.4
(11)	$GeH_2 + C_2H_4 \rightarrow GeC_2H_5 + H$	49.0
(13)	$GeH_3 + C_2H_4 \rightarrow GeC_2H_5 + H_2$	5.8
(12)	$GeH_2 + C_2H_4 \rightarrow GeC_2H_6$	−35.2
(14)	$GeH_3 + C_2H_4 \rightarrow GeC_2H_6 + H$	23.6
(15)	$GeH_3 + C_2H_4 \rightarrow GeC_2H_7$	−25.2

GeC_2H_4

The investigation of the potential-energy surface of singlet and triplet GeC_2H_4 radicals suggested the existence of three distinct species. The geometrical parameters are shown in Figure 3 and the total and relative energies are reported in Table 5. The structure **3a**, a singlet species with C_S symmetry, obtained from the reaction of the Ge radical with the ethylene molecule (reaction 8), is the global minimum on the potential-energy surface. This structure contains a Ge atom bridging the two carbon atoms. The exo-

thermicity of the reaction (-31.5 kcal mol^{-1}) suggests that the formation of these radicals are rather probable. The structure **3b,** also with C_S symmetry, is a triplet state, less stable than structure **3a** by 17.6 kcal mol^{-1} at the QCI level of theory. Once again, the results of the calculations suggest that reaction is rather probable. The structure **3c** can probably be obtained from the reaction of the GeH_2 radical with the ethylene molecule with a subsequent elimination of a hydrogen molecule. Structure **3c** is a cyclic species calculated to lie 38.4 kcal mol^{-1} above **3a** at the highest level of calculation. Results for the enthalpy calculations for the **3c** formation reaction show that more than 35.4 kcal mol^{-1} are necessary to overcome the barrier for dissociation of a H_2 molecule.

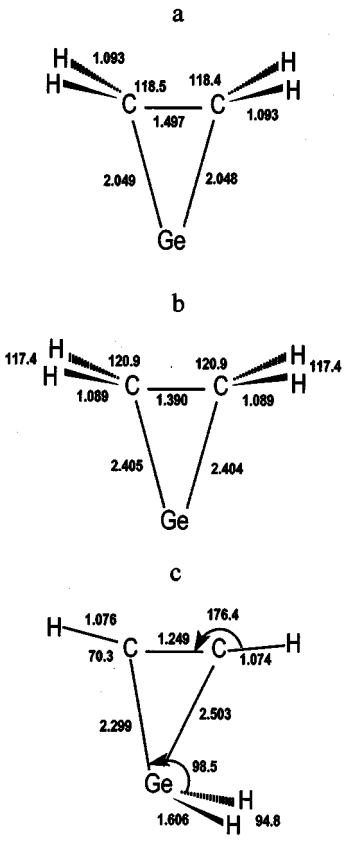

Figure 3. MP2/BS geometrical parameters of the GeC_2H_4 isomers with bond lengths [Å] and bond angles [°]

GeC_2H_5

Six different critical points have been located on the GeC_2H_5 potential-energy surface corresponding to a minimum or first-order saddle point. The optimized geometries and the total and relative energies of GeC_2H_5 isomers are reported in Figure 4 and Table 5.

The allyl-like structure **4c** with C_S symmetry, obtained most easily from Equation (11) (endothermic by 49.0 kcal mol^{-1}), was found to be a first-order saddle point corresponding to a transition structure for the rotation of the germylene group around the Ge−C bond. The activation energy of the rotation process was computed as 3.3 kcal mol^{-1} at the QCI level of calculation. This is not in agreement with that found for $GeC_2H_5^+$ ions where the allyl-like planar structure corresponds to the most stable absolute minimum.[37] The other two structures **4a** and **4b**, which can be obtained from Equation (11), have been characterized as minima on the potential-energy surface. The **4a** species, with C_1 symmetry, the most stable at the MP2 level of theory, becomes less stable by 1 kcal mol^{-1} at the QCI level with respect to **4b** which has C_S symmetry. Although these isomers are stable, the calculated enthalpy change for Equation (11) is very high (49.0 kcal mol^{-1}) and it follows that formation of these radicals from the reaction considered becomes more difficult than from Equations (9) or (13).

Only one 1-propenyl-like species, corresponding to a minimum, has been located on the potential-energy surface, indicated as **4f**. This product, derived probably from Equation (13) (endothermic by 5.8 kcal mol^{-1} compared to species **4a**), was found to be the less stable isomer at all levels of calculation. In fact, it is 27.2 kcal mol^{-1} less stable than **4b** at the QCI level. Moreover, in order to obtain this product it is probably necessary to overcome a barrier for dissociation of a H_2 molecule.

The 2-propenyl-like species **4e** has been located and characterized as a minimum on the potential-energy surface of GeC_2H_5 radicals, as a product of Equation (13). In this case too, in addition to the reaction endothermicity, the energy of this species was found to be rather high (22.5 kcal mol^{-1} with respect to the species **4a**). This is probably due to the contamination of the spin state (see Table 5).

The only thermally allowed reaction according to Equation (9) (-19.4 kcal mol^{-1}), which follows from the junction of a GeH radical and an ethylene molecule, gives rise to the species **4d**. Although this product was found to be less stable by 21.2 kcal mol^{-1} with respect to structure **4a**, the reaction remains feasible.

GeC_2H_6

Five critical points have been located on the potential-energy surface of the singlet GeC_2H_6 species. The geometrical parameters are shown in Figure 5 and the absolute and relative energies are collected in Table 5.

The staggered and eclipsed (C_s symmetry) conformations of vinylgermane have been located on the potential-energy surface. They are indicated as **5b** and **5c**, respectively. The former corresponds to a minimum and the latter corresponds to a first-order saddle point for rotation of GeH_3 around the Ge−C bond. The energy difference between **5b** and **5c** is computed to be as large as 1.2 kcal mol^{-1} at the QCI level of calculation. Moreover, the staggered conformation of vinylgermane results to be more stable than **5a** by 4.3 kcal mol^{-1} at the QCI level of theory and the global minimun on the GeC_2H_6 potential-energy surface. The species **5b** can probably be obtained from Equation (14) (but this process is endothermic) following a hydrogen atom dissociation, or from equation (12) (exothermic by 35.2 kcal

mol^{-1}) through a hydrogen-atom migration. The ethylgermylene **5a**, the most stable at the MP2 level of theory, becomes less stable at the QCI level. This product cannot be obtained directly from the exothermic reaction according to Equation (12), but through a rearrangement of the structure after this reaction or a rearrangement and a loss of a

hydrogen atom after the reaction according to Equation (14). The 2-methyl-1-germaethylene **5e** was found to be 14.7 kcal mol^{-1} above the most stable species **5b**. This structure, which can be derived from the more feasible process according to Equation (12), requires a transposition of a hydrogen atom. The germacyclopropane **5d** can only be obtained directly from the thermally favoured formation reaction of GeC_2H_6. Although the energy of the germacyclopropane was found to be higher by 10.0 kcal mol^{-1} with respect to that of **5a**, the reaction remains thermally allowed.

The investigation of the potential-energy surface of the triplet GeC_2H_6 species provides four other structures that are shown also in Figure 5 (**5f** to **5i**). The total and relative energies are collected in Table 5. The products obtained directly from the process according to Equation (12) correspond to the species **5g** and **5h**, the former being a minimum on the potential-energy surface, the latter a first-order saddle point for rotation of a methylene group around the C−C bond. The activation energy of the rotation process was calculated to be 3.4 kcal mol^{-1}. The energy of the minimum **5g** was found to be 42.6 kcal mol^{-1} higher than that of the most stable GeC_2H_6 species **5a**.

The other two species **5f** and **5i** can be obtained from the exothermic reaction according to Equation (12) only through rearrangements of the molecular structure that require overcoming energy barriers. Moreover, if the energy of the **5f** species was found to be only 24.6 kcal mol^{-1} higher than that of **5a**, the **5i** species is 60.3 kcal mol^{-1} higher in energy. The energy required for these reactions is very high which therefore are the least feasible.

GeC_2H_7

Four different critical points have been located on the potential-energy surface of the GeC_2H_7 radical obtained from Equation (15). The main geometrical parameters are shown in Figure 6, absolute and relatives energies are collected in Table 5.

Two different 1-propyl-like structures can be conceived, i.e. $CH_3CH_2GeH_2$ and $GeH_3CH_2CH_2$.

Both the bisected and the eclipsed conformations of $GeH_3CH_2CH_2$, henceforth indicated as **6d** and **6b**, have been located in the C_S symmetry on the potential-energy surface. The bisected conformation (Figure 6d) has been characterized as a first-order saddle point for rotation of the methylene group around the C−C bond, the activation energy of this process being computed as 3.1 kcal mol^{-1} at the QCI level of calculation. The eclipsed conformation **6b** was found to be a minimum on the potential-energy surface with an energy 17.0 kcal mol^{-1} higher with respect to the most stable $CH_3CH_2GeH_2$ radical **6a** in the C_1 symmetry. Since the reaction enthalpy corresponds to −25.2 kcal mol^{-1} this process is thermochemically feasible. However, species **6a**, the global minimum on the potential-energy surface of the GeC_2H_7 radical, cannot be obtained directly from Equation (15) but only through a rearrangement of an H atom from a Ge to a C atom.

Only one 2-propyl-like structure can be conceived for the GeH_3CHCH_3 radicals. The structure obtained is reported in Figure 6c; the energy was found 16.4 kcal mol^{-1} higher than that of **6a**. In this case, the structure cannot be obtained directly from Equation (15) but a migration of an H atom over a C−C bond is necessary.

Comparing these results with those for the $GeC_2H_7^+$ ions[38] the 1-propyl-like species appears to be the most stable structure, which is in agreement with the available data concerning the $GeC_2H_7^+$ ions. However, there is a difference between the ions and radicals as, in the latter case, a cyclic structure has not been obtained.

Conclusions

The results of the mass-spectrometric study outlined above, together with the composition of the condensed-phases products and the low yield of volatile species observed in the radiolysis of GeH_4/C_2H_4 mixtures seem to suggest a propensity for ethylene to react with both neutral or ionic GeH_x species. The above findings appear to solve the problems regarding the poor content of carbon of the solid obtained from GeH_4/alkane mixtures.

The theoretical calculations indicate that, among the considered reactions, the most probable are those which take place without atomic or molecular hydrogen dissociation. Moreover, among the reactions whose products are obtained by addition of the two reagent species, the processes without molecular rearrangements are favoured. In particular, for the species GeC_2H_4 and GeC_2H_5 the **3a**, **3b**, and **4d** isomers, from Equations (8) and (9), can be easily obtained. With regard to the GeC_2H_6 species, the structure **5d** is the most probable isomer which originates from Equation (12), but it is a closed-shell structure without free electrons. The most probable GeC_2H_7 radical obtained from reaction 15 is the **6b** isomer.

As reported above, the more abundant radical species derived from GeH_4 radiolysis seem to be Ge and GeH and so the most abundant primary mixed compounds are the GeC_2H_4 isomers **3a** and **3b**obtained from Equation (8) and the GeC_2H_5 isomer **4d** from Equation (9). These mixed products are probably the species which result from reactions with germane radicals and/or with ethylene molecules, leading to formation of condensed-phase products and also to volatile compounds with longer chains. This is consistent with the low hydrogen content of the products in the condensed phase and it is in agreement with the trend of the H/(Ge + C) ratio as a function of ethylene percentage, reported in Figure 2. It seems to indicate that the hydrogen atoms present in the chain are those of ethylene which remain bonded to carbon atoms.

Experimental Section

Radiolysis: Monogermane was prepared according to the literature[39] and purified by bulb-to-bulb distillation. Ethylene was high-purity SIAD (Società Italiana Acetilene e Derivati) gas and was

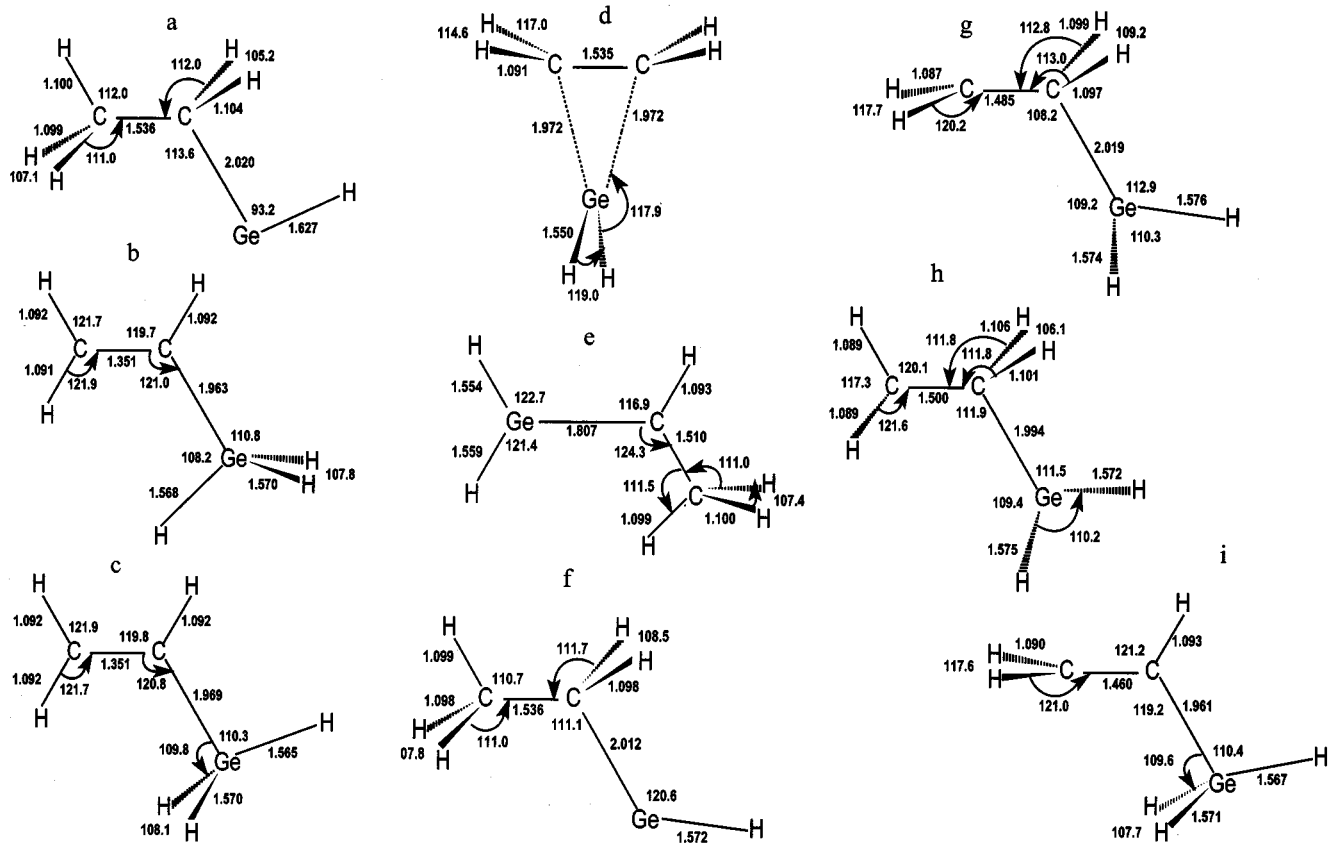

Figure 5. MP2/BS geometrical parameters of the GeC_2H_6 isomers with bond lengths [Å] and bond angles [°]

used without purification. Samples of GeH_4/C_2H_4 mixtures of different compositions were irradiated with 250-keV X-rays in 365-ml Pyrex vessels at a total pressure of 700 Torr. Standard vacuum techniques were used to handle both reactants and gaseous products. The X-ray source was a CPXT-320 tube (GILARDONI) with a maximum output of 320-keV X-ray. The dose absorbed by each sample was evaluated to be $5.0 \cdot 10^4$ Gy at a rate of $1.0 \cdot 10^4$ Gy h^{-1}. During the irradiation the temperature did not exceed 320 K. The gaseous product analysis was performed by gas chromatography and mass spectrometry using a VARIAN 3400/Finnigan ITD instrument equipped with Alltech AT-1 chromatographic column (polydimethylsiloxane, length 30 m, i.d. 0.25 mm, film thickness 1.0 μm). The temperature ranged from 243 to 523 K at 10 K/min. A 10 psi He carrier front column was used. Ionisation in the ion trap was achieved by electron impact at 70eV and acquisition of ions was obtained in the 20−650 unit mass range. Quantitative determination of volatile compounds was effected by calibrating the gas chromatograph with GeH_4. The values reported are the averages of at least four experiments.

Computational Details: Ab initio quantum-mechanical calculations were performed using an IBM RISC/6000 and a DIGITAL α STATION version of Gaussian 94 set of programs.[40] The geometries of investigated species were optimized by gradient-based techniques[41] at the unrestricted Möller−Plesset level of theory[42] truncated at the second order and with the frozen-core approximation (UMP2/FROZEN). The basis set (BS) used was obtained as follows. For the germanium atoms, starting with Huzinaga (4333/433/4) basis,[43] the last s and p atomic orbitals were decontracted to the double-ζ level to give (43321/4321/4); in addition, a set of polarization functions[43] was added with exponent α = 0.246. For the carbon atom, starting with the Huzinaga (43/4/1) basis, the last s and p atomic orbitals were decontracted to the double-ζ level to give (421/31/1). For the hydrogen atom, the 6-31G basis set was employed.[44] The critical points were characterized as minima at this level through diagonalization of analytically calculated Hessian matrices (vibrational frequencies calculation). The UMP2/(FROZEN)/BS geometries were employed to recompute the relative energies by quadratic configuration-interaction calculations at the QCISD(T) level[45] with the more extended basis set 6-311G (3df,2p).[46a−46d] Zero-point vibrational energies were computed at the UMP2(FROZEN)/BS level.[47]

Transition Metal Complexes with Sulfur Ligands, 134[+]

Synthesis of the Tetradentate Thioether Amine and Thioether Thiolate Ligands ′tpS$_2$(NH$_2$)$_2$′ and ′tpS$_4$′-H$_2$ and Some Representative Six-Coordinate Ruthenium and Osmium Complexes [′tpS$_2$(NH$_2$)$_2$′ = 1,2-Bis(2-aminophenylthio)phenylene; ′tpS$_4$′$^{2-}$ = 1,2-Bis(2-mercaptophenylthio)phenylene(2–)]

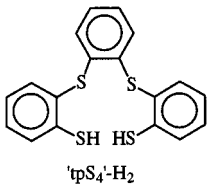
Dedicated to Professor Bernt Krebs on the occassion of his 60th birthday

Keywords: Cleavage reactions / C–S cleavage / Ligand synthesis / Osmium / Ruthenium / S ligands

In search of a tetradentate thioether thiolate ligand that is more stable toward reductive C–S bond cleavage than the parent ligand ′S$_4$′-H$_2$ [′S$_4$′-H$_2$ = 1,2-bis(2-mercaptophenylthio)ethane], the novel tris-phenylene ligand ′tpS$_4$′-H$_2$ (**3**) [′tpS$_4$′-H$_2$ = 1,2-bis(2-mercaptophenylthio)phenylene] was synthesized via the nitro and amine compounds ′tpS$_2$(NO$_2$)$_2$′ (**1**) and ′tpS$_2$(NH$_2$)$_2$′ (**2**). The coordination of ′tpS$_4$′$^{2-}$ to ruthenium centers resulted in the formation of six-coordinate [Ru(L)(PR$_3$)(′tpS$_4$′)] complexes (R = Et, L = PEt$_3$ **4**; R = Ph, L = PPh$_3$ **5**, CO **6**, DMSO **7**). The X-ray structure analyses of **4** and **6** revealed that the thiolate donors occupy trans positions; consequently the ′tpS$_4$′$^{2-}$ ligand coordinates in the same way as the ′S$_4$′$^{2-}$ ligand. The stability of the ′tpS$_4$′$^{2-}$ ligand toward reductive C–S cleavage reactions was shown by the synthesis of [Os(PEt$_3$)$_2$(′tpS$_4$′)] (**8**). In contrast to [Os(PEt$_3$)$_2$(′S$_4$′)], **8** is stable for unlimited periods of time. The X-ray structure analysis of [Ru(Cl)$_2$(PPh$_3$)(′tpS$_2$(NH$_2$)$_2$′)] (**9**) demonstrates that the potentially tetradentate ligand ′tpS$_2$(NH$_2$)$_2$′ coordinates in **9** through three donors leaving one NH$_2$ donor dangling.

The tetradentate thioether thiolate ligand ‘S$_4$’−H$_2$ [= 1,2-bis(2-mercaptophenylthio)ethane] exhibits a rich coordination chemistry. It binds to numerous transition metals, e.g. Fe, Ru, Os, Cr, Mo, W, Ni, and the resulting [M(′S$_4$′)] complex fragments are able to coordinate a large variety of coligands to give six-coordinate complexes of the type [M(L)(L′)(′S$_4$′)].[1]

[M(L)(L')('S$_4$')]



The coligands L or L′ range from hard ligands such as halides or oxide to soft ligands such as CO or phosphanes. The coligands also include a large number of biologically relevant small species, for example, N$_2$H$_2$, N$_2$H$_3$, N$_2$H$_4$, NH$_3$, NO$^+$, NO, NH$_2$O, H$_2$, H$^-$, CH$_3^-$, CH$_3$CO$^-$, H$_2$S, or S$_2$. The activation or stabilization and the reactivity of these small species is strongly influenced by the [M(′S$_4$′)] cores. In some of these reactions, the ′S$_4$′$^{2-}$ ligand appears to behave as a ′spectator′ ligand only, yielding a robust [M(′S$_4$′)] core, although in all reactions involving protons, the Brønsted basicity of the thiolate donors has been shown to be pivotal.[1b,1g,2,3] In other reactions, the ′S$_4$′$^{2-}$ ligand can experience severe changes. Coordination of the ′S$_4$′$^{2-}$ ligand to very electron-rich metal centers and UV irradiation or treatment of [M(′S$_4$′)] complexes with strongly reducing reagents frequently causes the reductive elimination of the C$_2$H$_4$ bridge as ethylene. For example, the reaction of ′S$_4$′$^{2-}$ with [MoCl$_2$(PMe$_3$)$_4$] gives the Mo^{IV} complex [Mo(PMe$_3$)$_2$(S$_2$C$_6$H$_4$)$_2$] and C$_2$H$_4$,[4] [Os(PEt$_3$)$_2$(′S$_4$′)] readily releases C$_2$H$_4$ to give [Os(PEt$_3$)$_2$(S$_2$C$_6$H$_4$)$_2$],[1e] UV irradiation of [Ru(CO)(PCy$_3$)(′S$_4$′)] yields [Ru(PCy$_3$)(S$_2$C$_6$H$_4$)$_2$] and C$_2$H$_4$,[5] and the reduction of [Fe(CO)$_2$(′S$_4$′)] by metallic sodium gives the Fe^{II} complex [Fe(S$_2$C$_6$H$_4$)$_2$]$^{2-}$ and C$_2$H$_4$.[6] The partial cleavage of S−C bonds is observed when [Ru(PPh$_3$)$_2$(′S$_4$′)] is treated with NO.[7] In this case, [Ru(NO)(PPh$_3$)(S$_2$C$_6$H$_4$)(CH$_2$=CH−SC$_6$H$_4$S)] forms, which contains a vinyl thioether thiolate ligand. All these reactions represent the reversal of the ′S$_4$′$^{2-}$ formation, which is synthesized via template alkylation of S$_2$C$_6$H$_4^{2-}$ by 1,2-C$_2$H$_4$Br$_2$.[1a] The ′S$_4$′$^{2-}$ cleavage reactions are usually unwanted. They can be traced back to the π acidity of the thioether donor functions and the partial occupation of antibonding C−S(thioether) σ* orbitals by metal d-electrons.[8] We have now tried to synthesize a ligand which

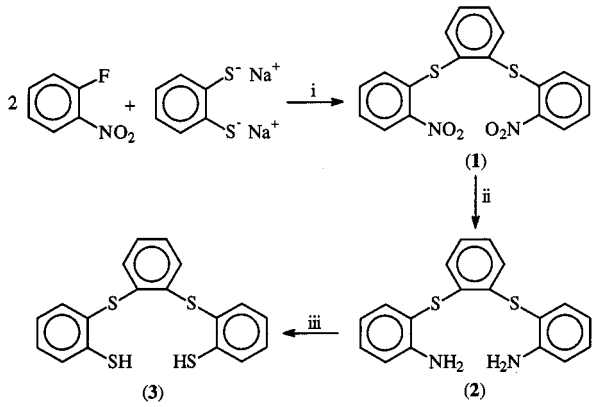
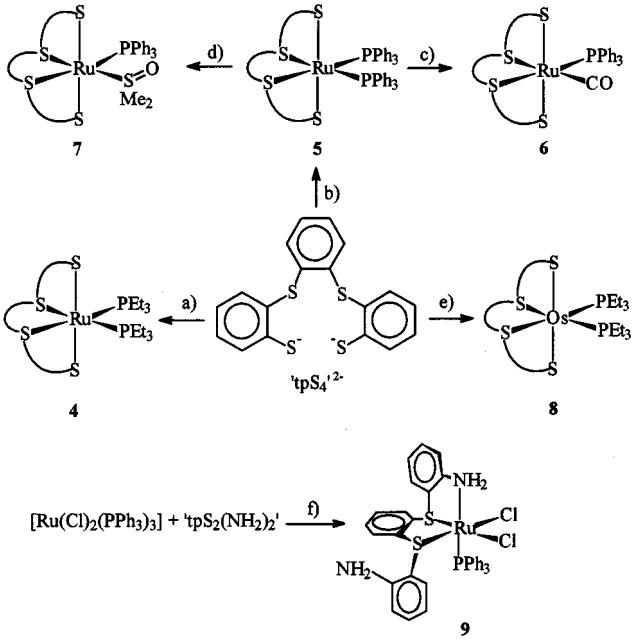
maintains the donor functions and coordination pattern of the $'S_4'^{2-}$ ligand, but is stable toward strong reducing reagents and photolysis. For this purpose, the C_2H_4 bridge in $'S_4'^{2-}$ has been replaced by an *o*-phenylene bridge. In order to clearly distinguish the target from the parent ligand and for indicating the presence of the phenylene entities, we use the acronym $'tpS_4'$-H_2.



$'tpS_4'$-H_2

In orienting experiments, the coordination of $'tpS_4'^{2-}$ to electron-rich Ru^{II} and Os^{II} complexes was tested.

Results



The target ligand $'tpS_4'$-H_2 (**3**) was synthesized by the route given in Scheme 1.

Scheme 1. Synthesis of $'tpS_4'$-H_2; i: MeOH/12 h/reflux; ii: Zn/NH_4Cl/THF/12 h/reflux; iii: 1. $NaNO_2/H_2SO_4/H_2O$/0°C; 2. KSC(S)OEt/H_2O/85°C; 3. KOH/EtOH/12 h/reflux; 4. HCl/H_2O, 5. LiOMe/$Niac_2 \cdot 4\ H_2O$, 6. HCl

Nucleophilic substitution of fluorine in 1,2-C_6H_4(F)-(NO_2)[9] by the thiolate functions of $Na_2S_2C_6H_4$ yielded the tris-phenylene nitro compound $'tpS_2(NO_2)_2'$ (**1**) in practically quantitative yield. Reduction of the nitro groups in **1** by Zn/NH_4Cl[10] gave the diamine-dithioether $'tpS_2(NH_2)_2'$ (**2**). Diazotisation of the NH_2 groups of **2** and subsequent reaction of the resulting bis-diazonium salt with KSC(S)(OEt), hydrolysis and acidification[11] yielded a brown oil containing $'tpS_4'$-H_2 (**3**) and a mixture of other compounds. Purification of this brown oil proved difficult. After many unsuccessful attempts applying conventional techniques, isolation of pure $'tpS_4'$-H_2 (**3**) was finally achieved by coordination to Ni^{II} salts and subsequent hydrolysis of the resulting nickel complex. Treatment of the brown oil with LiOMe and $Niac_2 \cdot 4\ H_2O$ yielded a red-brown microcrystalline solid which was analyzed as $[Ni('tpS_4')]_2 \cdot THF \cdot 0.5$ MeOH. Hydrolysis with hydrochloric acid gave a colorless analytically pure oil of $'tpS_4'$-H_2 (**3**). The compounds **1**, **2**, and **3** were characterized by elemental analysis and spectroscopic methods. The molecular structures of **1** and **2** were determined by X-ray diffraction.

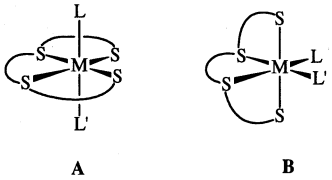
Scheme 2 summarizes the syntheses of ruthenium and osmium complexes which were obtained with $'tpS_4'^{2-}$. In one experiment also the coordination of $'tpS_2(NH_2)_2'$ (**2**) was investigated.

Scheme 2. Synthesis of $'tpS_4'^{2-}$ ruthenium and osmium complexes and of $[Ru(Cl)_2(PPh_3)('tpS_2(NH_2)_2')]$; (a) $[Ru(Cl)_2(DMSO)_4]$/PEt_3/MeOH/1 h reflux; (b) $[RuCl_2(PPh_3)_3]$/THF/4 h at room temperature/5 min reflux; (c) CH_2Cl_2/CO/12 h/room temperature; (d) DMSO/5 min at 40°C; (e) $OsCl_3 \cdot \mathbf{x}\ H_2O$/$PEt_3$/MeOH/2 h reflux; (f) THF/1 h reflux

The reaction of dianionic $'tpS_4'^{2-}$, which was routinely obtained from $'tpS_4'$-H_2 (**3**) and NaOMe or BuLi, with $[Ru(Cl)_2(DMSO)_4]$ in the presence of excess PEt_3 yielded $[Ru(PEt_3)_2('tpS_4')]$ (**4**). Heating to reflux was necessary in order to drive the reaction to completeness. Treatment of $[RuCl_2(PPh_3)_3]$ with $'tpS_4'$-Li_2 in boiling THF gave $[Ru(PPh_3)_2('tpS_4')]$ (**5**). Complex **5** shows that also two sterically demanding phosphanes can bind to the $[Ru('tpS_4')]$ fragment. One PPh_3 ligand in **5** is labile and readily exchanges for CO at ambient temperatures to give $[Ru(CO)(PPh_3)('tpS_4')]$ (**6**). The PPh_3 ligand also exchanges for DMSO at slightly elevated temperature (40°C) to give $[Ru(DMSO)(PPh_3)('tpS_4')]$ (**7**). The DMSO ligand in **7** is also labile. ^{1}H-NMR spectra of **7** in [D_6]DMSO show only one DMSO signal at $\delta = 2.57$ indicating exchange of coordinated DMSO and [D_6]DMSO solvent molecules, which is rapid on the NMR time-scale.

A critical test for the inertness of $'tpS_4'^{2-}$ toward C−S cleavage reactions was its reaction with $OsCl_3 \cdot \mathbf{x}\ H_2O$ in the presence of excess PEt_3. It yielded, although in low yield, $[Os(PEt_3)_2('tpS_4')]$ (**8**). Subsequent NMR spectroscopic investigations showed that **8** is stable in solution for unlimited periods of time and contrasts $[Os(PEt_3)_2('S_4')]$

which rapidly releases C_2H_4 to give $[Os(PEt_3)_2(S_2C_6H_4)_2]$.[1e]



The comparison of the reactions b) and f) in Scheme 2 shows that $'tpS_2(NH_2)_2'$ (**2**) has poorer coordinating capabilities than $'tpS_4'^{2-}$ (**3**). Even after prolonged heating to reflux, the THF mixture of $RuCl_2(PPh_3)_3$ and $'tpS_2(NH_2)_2'$ yielded exclusively $[Ru(Cl)_2(PPh_3)('tpS_2(NH_2)_2')]$ (**9**) in which the potentially tetradentate $'tpS_2(NH_2)_2'$ (**2**) utilizes only three of its four donor functions.

Characterization of the Compounds and Complexes

All compounds were characterized by elemental analysis and spectroscopic methods, the molecular structures of $'tpS_2(NO_2)_2'$ (**1**), $'tpS_2(NH_2)_2'$ (**2**), $[Ru(PEt_3)_2('tpS_4')]$ (**4**), $[Ru(CO)(PPh_3)('tpS_4')]$ (**6**), and $[Ru(Cl)_2(PPh_3)('tpS_2(NH_2)_2')]$ (**9**) were also determined by X-ray diffraction.

Characteristic IR absorptions of the nitro compound **1** are ν(NO) bands of the asymmetric and symmetric ν(NO) vibrations at 1511, 1333, and 1303 cm^{-1}. The $'tpS_4'$-H_2 ligand (**3**) exhibits a medium intensity ν(SH) band at 2526 cm^{-1}. All $[M('tpS_4')]$ complexes show a nearly identical IR pattern for the $[M('tpS_4')]$ cores. Strong ν(CO) (1965 cm^{-1}) and ν(SO) (1087 cm^{-1}) bands are suited to readily identify $[Ru(CO)(PPh_3)('tpS_4')]$ (**6**) and $[Ru(DMSO)(PPh_3)('tpS_4')]$ (**7**). The ν(SO) band of **7** indicates *S*-bound DMSO.[12a]

A major concern was the coordination mode of the $'tpS_4'^{2-}$ ligand and the question whether, despite of the rigid phenylene bridge, $[M('tpS_4')]$ cores assume the same helical configuration as $[M('S_4')]$ cores. Formulas A and B schematically show the two potential configurations of $[M('tpS_4')]$ cores.

The X-ray structure analysis of **4** and **6** revealed that configuration B is assumed. When the $[M('tpS_4')]$ cores bind two different coligands L and L′ also ^{13}C-NMR spectra allow to distinguish between A and B.

Identical coligands L = L′ result in any case either in C_{2v} (formula A) or in C_2 symmetrical structures (formula B). When L ≠ L′, formula A exhibits (approximately) C_S symmetry, formula B, however, C_1 symmetry. Consequently, in complexes assuming the structure B, all aromatic C atoms are chemically non equivalent. The ^{13}C-NMR spectrum of $[Ru(CO)(PPh_3)('tpS_4')]$ (**6**) exhibits 22 aromatic ^{13}C signals and thus allows to unambiguously assign structure B. In contrast, the ^{13}C-NMR spectrum of **4** exhibits only 9 aromatic ^{13}C signals which do not allow to distinguish between structures A and B.

The coordination of $'tpS_2(NH_2)_2'$ (**2**) in $[Ru(Cl)_2(PPh_3)('tpS_2(NH_2)_2')]$ (**9**) leaving one amino donor dangling could be concluded from the ^1H-NMR spectrum of **9**. The protons of the uncoordinated NH_2 group give rise to a singlet, while the protons of the coordinated NH_2 group give rise to two doublets, because the NH protons are nonequivalent in C_1-symmetrical **9**. In addition, only the uncoordinated NH_2 group shows H^+/D^+ exchange with D_2O.

The molecular structures of $'tpS_2(NO_2)_2'$ (**1**), $'tpS_2(NH_2)_2'$ (**2**) $[Ru(Cl)_2(PPh_3)('tpS_2(NH_2)_2')]$ (**9**), $[Ru(PEt_3)_2('tpS_4')] \cdot 0.5\ Et_2O$ (**4** · 0.5 Et_2O), and $[Ru(CO)(PPh_3)('tpS_4')] \cdot CH_2Cl_2$ (**6** · CH_2Cl_2) are depicted in Figure 1. Table 1 lists selected distances and angles.

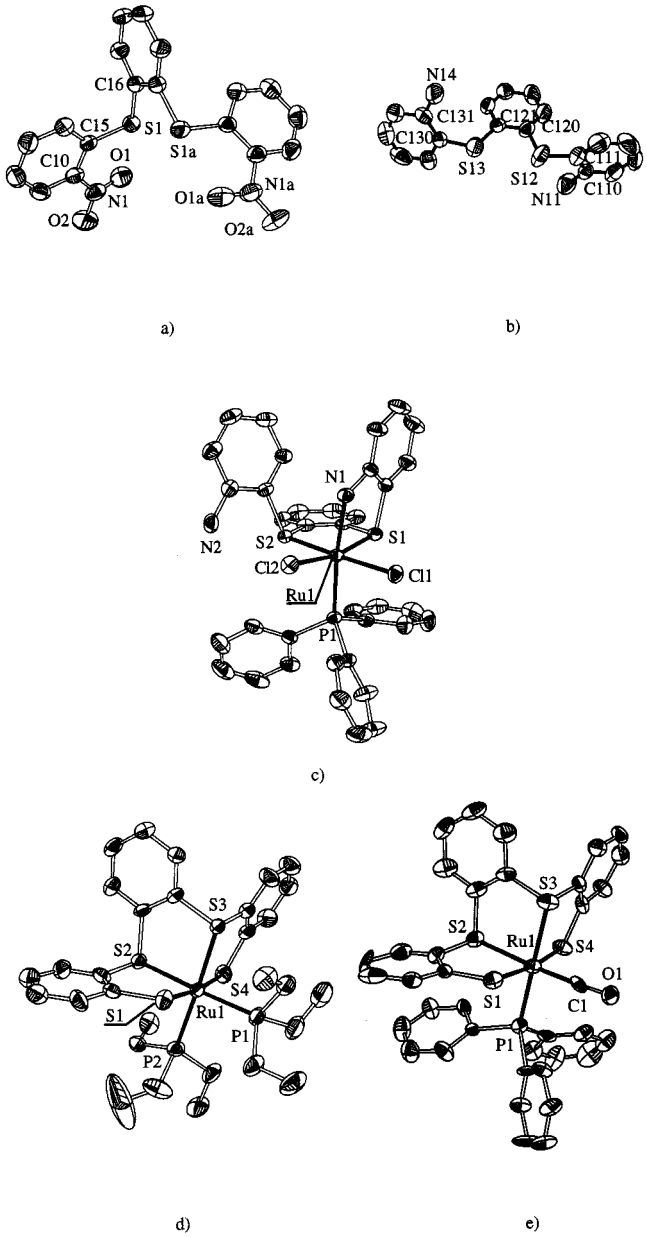


Figure 1. Molecular structures of (a) $'tpS_2(NO_2)_2'$ (**1**), (b) $'tpS_2(NH_2)_2'$ (**2**), (c) $[Ru(Cl)_2(PPh_3)('tpS_2(NH_2)_2')]$ (**9**), (d) $[Ru(PEt_3)_2('tpS_4')] \cdot 0.5\ Et_2O$ (**4** · 0.5 Et_2O), and (e) $[Ru(CO)(PPh_3)('tpS_4')] \cdot CH_2Cl_2$ (**6** · CH_2Cl_2) (50% probability ellipsoids, H atoms and solvent molecules omitted)

The compound $'tpS_2(NO_2)_2'$ (**1**) exhibits crystallographically imposed C_2 symmetry and shows that the two thioether S atoms lead to a helical preorganization of the three

Table 1. Selected distances [pm] and angles [°] of $'tpS_2(NO_2)_2'$ (**1**), $'tpS_2(NH_2)_2'$ (**2**), $[Ru(Cl)_2(PPh_3)('tpS_2(NH_2)_2')]$ (**9**), $[Ru(PEt_3)_2('tpS_4')] \cdot 0.5\ Et_2O$ (**4** · 0.5 Et_2O), and $[Ru(CO)(PPh_3)('tpS_4')] \cdot CH_2Cl_2$ (**6** · CH_2Cl_2)

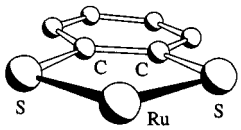
phenylene units as found in **4** and **6**. The NO_2 groups bind approximately coplanar to the phenylene rings. Distances and angles show no anomalies.

The thioetheramine compound $'tpS_2(NH_2)_2'$ crystallizes with 2 independent molecules per asymmetric unit, having practically identical distances and angles. The thioether distances and angles compare with those of **1**, and **2** is also characterized by well-approximated C_2 symmetry.



The metal centers of all three ruthenium complexes exhibit pseudo-octahedral coordination. The molecular structure of **9** unambiguously shows that one NH_2 group remains uncoordinated. Distances and angles of **9** lie in the same range as found in other Ru^{II} thioether ammine complexes, for example, $[Ru(Br)(PPh_3)('Bz_2S_2N_2H_2')]Br$ ($'Bz_2S_2N_2H_2'$ = 1,10-dibenzyl-2,3,8,9-dibenzo-1,10-dithia-4,7-diazadecane).[12b]

The $'tpS_4'^{2-}$ ligand in **4** and **6** coordinates in the same helical configuration as the $'S_4'^{2-}$ ligand in analogous $[Ru('S_4')]$ complexes. As a result, the thiolate donors assume trans positions. Also worth being noted is that the distances of **4** and **6** are virtually identical to those found in the analogous $[Ru(PR_3)_2('S_4')]$[1d] or $[Ru(L)(PR_3)('S_4')]$ complexes (L = Cl, I).[13] For example, C_2-symmetrical $[Ru(PnBu_3)_2('S_4')]$ exhibits Ru−S(thiolate) [239.8(2) pm] and Ru−S(thioether) [236.8(2) pm] distances.[1d] This suggests that the small difference in the Ru−S(thioether) distances of **4** [236.1(2) pm; 234.3(2) pm] is due to crystal packing effects. It is further noted that the differences either in the Ru−S(thiolate) or the Ru−S(thioether) distances of C_1-symmetrical **6** remain very small and are certainly due to coligand effects.

The only significant difference between $[Ru('S_4')]$ and $[Ru('tpS_4')]$ cores thus is the central five-membered chelate ring formed by the metal, the two thioether donors and the C_2H_4 or C_6H_4 bridge. In $[Ru('S_4')]$ cores, this chelate ring invariably assumes the chair conformation C, in both $[Ru('tpS_4')]$ complexes it is found to be virtually planar (D). The deviation of the two phenylene C atoms from the plane defined by the Ru and the two S atoms is only 7(1) pm and 12(1) pm in **4** · 0.5 Et_2O and 7(1) and 11(1) pm in **6** · CH_2Cl_2 respectively.

C

D

Concluding Discussion

Aim of this work was the synthesis of a tetradentate thioether thiolate ligand which shows a coordination chemistry as rich as that of the $'S_4'^{2-}$ ligand but is stable toward the reductive elimination of the C_2 bridge connecting the $C_6H_4S_2$ units. The new ligand $'tpS_4'^{2-}$ coordinates to metal centers in six-coordinate complexes in the same way as the $'S_4'^{2-}$ ligand. The resulting $[M('tpS_4')]$ cores exhibit two *trans*-positioned thiolate donors and two *cis* positions which can be occupied by ligands such as PEt_3, PPh_3, CO,

or DMSO. Orienting experiments indicate that, for example, $[Ru(PPh_3)_2('tpS_4')]$ shows a PPh_3 substitution chemistry similar to that of $[Ru(PPh_3)_2('S_4')]$. X-ray structure analyses further demonstrate that the RuS_4 distances and core angles remain invariant when the C_2H_4 bridge in $[Ru('S_4')]$ is replaced by a phenylene bridge in $[Ru('tpS_4')]$. The only and significant difference of $[Ru('S_4')]$ and $[Ru('tpS_4')]$ fragments is the central $[RuS_2C_2]$ chelate ring, which is virtually planar in $[Ru('tpS_4')]$, but exhibits a chair conformation in $[Ru('S_4')]$. The stability of the $'tpS_4'^{2-}$ ligand toward reductive cleavage could be demonstrated by the synthesis of $[Os(PEt_3)_2('tpS_4')]$ (**8**). Complex **8** is stable in solution for unlimited periods of time and thus contrasts $[Os(PEt_3)_2('S_4')]$ which readily eliminates ethylene.

Experimental Section

General Methods: Unless noted otherwise, all reactions and operations were carried out under nitrogen using standard Schlenk techniques. Solvents were dried and distilled before use. As far as possible, reactions were monitored by IR or NMR spectroscopy. − Spectra were recorded with the following instruments: IR (KBr discs or CaF_2 cuvettes, solvent bands were compensated): Perkin Elmer 983, 1620 FT IR, and 16PC FT-IR. − NMR: Jeol FT-JNM-GX 270, EX 270, and Lambda LA 400 with the protio-solvent signal used as a reference. Chemical shifts are quoted on the δ scale (downfield shifts are positive) related to tetramethylsilane (^1H, $^{13}C\{^1H\}$ NMR) or 85% H_3PO_4 ($^{31}P\{^1H\}$ NMR). Spectra were recorded at 25°C. − Mass spectra: Varian MAT 212 and Jeol MSTATION 700 spectrometers. − Elemental analysis: Carlo Erba EA 1106 or 1108 analyzer. − $[RuCl_2(DMSO)_4]$,[14] $[RuCl_2(PPh_3)_3]$,[15] and *o*-benzenedithiol ($'S_2'$-H_2)[16] were prepared as described in the literature, potassiumethylxanthogenate, 1-fluoro-2-nitrobenzene, LiOMe, and *n*BuLi (2.5 M in *n*-hexane) were purchased from Aldrich.

$'tpS_2(NO_2)_2'$ (1): A red-orange solution containing NaOMe (2.70 g, 50 mmol), $'S_2'$-H_2 (3 mL, 23.7 mmol), and 1-fluoro-2-nitrobenzene (5 mL, 47.4 mmol) in MeOH (100 mL) was heated under reflux for 20 h. A bright yellow solid precipitated that was separated, washed with MeOH (100 mL) and H_2O (150 mL), and dried in vacuo. Yield: 9.00 g of **1** (99%). − $C_{18}H_{12}N_2O_4S_2$, **1** (384.42): calcd. C 56.24, H 3.15, N 7.29, S 16.68; found C 56.41, H 3.12, N 7.33, S 16.28. − IR (KBr): $\tilde{\nu}$ = 1511, 1333, 1303 cm^{-1} ν(NO). − ^1H NMR (269.6 MHz, CD_2Cl_2): δ = 8.20 (m, 2 H, C_6H_4), 7.70−7.20 (m, 8 H, C_6H_4), 6.90 (m, 2 H, C_6H_4). − $^{13}C\{^1H\}$ NMR (67.7 MHz, CD_2Cl_2): δ = 137.52, 137.10, 136.55, 133.57, 131.15, 129.39, 129.35, 125.96, 125.78 [C(aryl)]. − EI MS (70 eV); *m/z*: 385 $['tpS_2(NO_2)_2']^+$.

$'tpS_2(NH_2)_2'$ (2): A yellow-grey suspension of **1** (6.0 g, 15.6 mmol), zinc powder (15.4 g, 235.5 mmol), and NH_4Cl (8.0 g, 149.6 mmol) in THF (120 mL) was heated under reflux for 20 h yielding a grey suspension. The grey solid was filtered off and washed with hot THF (100 mL), the colorless filtrate was concentrated to dryness. The remaining oily residue was recrystallized from hot EtOH (20 mL) yielding white crystals that were washed with EtOH (15 mL) and dried in vacuo. Yield: 4.00 g of **2** (79%). − $C_{18}H_{16}N_2S_2$, **2** (324.46): calcd. C 66.63, H 4.97, N 8.63, S 19.76; found C 66.67, H 5.21, N 8.65, S 19.37. − IR (KBr): $\tilde{\nu}$ = 3448, 3360 cm^{-1} ν(NH). − ^1H NMR (269.6 MHz, CD_2Cl_2): δ = 7.45 (m, 2 H, C_6H_4), 7.25 (m, 2 H, C_6H_4), 6.95 (m, 2 H, C_6H_4), 6.80−6.70 (m, 6 H, C_6H_4), 4.35 (s, 4 H, NH_2). − $^{13}C\{^1H\}$ NMR (67.7 MHz, CD_2Cl_2): δ = 149.32, 137.25, 135.49, 131.42, 128.01, 126.73, 118.94, 115.69, 114.69 [C(aryl)]. − FD MS (CH_2Cl_2); *m/z*: 324 $['tpS_2(NH_2)_2']^+$.

Synthesis of Crude $'tpS_4'$-H_2 (3): At 0°C, $'tpS_2(NH_2)_2'$ (**2**) (3.0 g, 18.5 mmol) was suspended in a mixture of H_2SO_4 (2.2 g, 22.4 mmol) and H_2O (35 mL). After addition of ice (12 g), a solution of $NaNO_2$ (1.34 g, 19.4 mmol) in H_2O (12 mL) was added dropwise to the suspension. The resulting yellow suspension was stirred for 1 h at 0°C and subsequently added slowly to a hot solution (85°C) of KSC(S)OEt (12.0 g, 74.9 mmol) in H_2O (30 mL), whereupon a red oil separated. The mixture was stirred for 45 min at 85°C, cooled to room temperature, and extracted with CH_2Cl_2 (150 mL). The CH_2Cl_2 extract was evaporated in vacuo. The remaining red oil was dissolved in EtOH (50 mL), solid KOH (6.0 g) was added, and the mixture was heated under reflux for 12 h. Evaporation of the solvent yielded a yellow residue which was suspended in H_2O (100 mL) and extracted with CH_2Cl_2 (75 mL). To the remaining aqueous solution hydrochloric acid was added until pH = 1 was reached and an orange oil separated. The oil was extracted from the aqueous phase with CH_2Cl_2 (125 mL), and the CH_2Cl_2 extract was dried with Na_2SO_4. Removal of CH_2Cl_2 yielded a brown oil. Yield: 1.5 g of **3** (46%). − IR (Film): $\tilde{\nu}$ = 2526 cm^{-1} (SH). − ^1H NMR (269.6 MHz, CD_2Cl_2): δ = 7.40 (m, 2 H, C_6H_4), 7.30 (m, 2 H, C_6H_4), 7.35−6.95 (m, 8 H, C_6H_4), 4.20 (s, 2 H, S*H*). − $^{13}C\{^1H\}$ NMR (67.7 MHz, CD_2Cl_2): δ = 137.43, 135.94, 134.54, 131.42, 130.67, 130.04, 129.32, 128.05, 126.71 [C(aryl)]. − FD MS (CH_2Cl_2); *m/z*: 358 $['tpS_4'$-$H_2]^+$.

Purification of Crude $'tpS_4'$-H_2 (3)

$[Ni('tpS_4')]_2$: The brown oil containing crude $'tpS_4'$-H_2 (1.5 g, 4.2 mmol) was dissolved in THF (40mL). LiOMe (8.4 mL, 8.4 mmol of a 1 M solution in MeOH) was added and stirred for 1 h. Removal of the THF yielded a yellow brown solid which turned into a white powder upon digestion with CH_2Cl_2 (150 mL). After drying, the white powder was characterized as $Li_2'tpS_4'$ by ^1H- and ^{13}C-NMR spectroscopy. − $Li_2'tpS_4'$ (330 mg, 0.89 mmol) in 20 mL of THF and $Niac_2 \cdot 4\ H_2O$ (222 mg, 0.89 mmol) in 20 mL MeOH were combined and stirred for 12 h. A microcrystalline red brown solid resulted which was separated, washed with MeOH (20 mL), THF (50 mL), Et_2O (20 mL), and dried in vacuo. It analyzed as $[Ni('tpS_4')]_2 \cdot THF \cdot 0.5\ MeOH$. Yield: 290mg (70%). − $C_{40.5}H_{34}O_{1.5}S_8Ni_2$ (918.60): calcd. C 52.95, H 3.74, S 27.92; found C 52.98, H 3.64, S 27.93.

$'tpS_4'$-H_2 (3): A red brown suspension of $[Ni('tpS_4')]_2 \cdot THF \cdot 0.5$ MeOH (280 mg, 0.30 mmol) in CH_2Cl_2 (15 mL) was combined with concentrated aqueous hydrochlorid acid (10 mL) and stirred for 1 h. A colorless CH_2Cl_2 and a light-green aqueous phase formed. The CH_2Cl_2 phase was separated, dried with Na_2SO_4, and concentrated to dryness, yielding a colorless oil of **3**. Yield: 120 mg of **3** (56%).− $C_{18}H_{14}S_4$, **3** (358.55): calcd. C 60.30, H 3.94, S 35.77; found C 60.51, H 3.99, S 35.47.

$[Ru(PEt_3)_2('tpS_4')]$ (4): A yellow suspension of $'tpS_4'$-H_2 (**3**) (120 mg, 0.33 mmol), NaOMe (38 mg, 0.7 mmol), and $[Ru(Cl)_2(DMSO)_4]$ (161 mg, 0.33 mmol) in MeOH (10 mL) was combined with PEt_3 (0.23 mL, 1.69 mmol) and heated under reflux for 1 h. After cooling to room temperature, the precipitated yellow solid was separated, washed with MeOH (10 mL) and Et_2O (10 mL), dried in vacuo for 5 min, and redissolved in CH_2Cl_2 (5 mL). The yellow CH_2Cl_2 solution was layered with MeOH (15 mL) and stored at room temperature. In the course of 4 d, yellow crystals precipitated that were separated, washed with MeOH (10 mL) and Et_2O (10 mL), and dried in vacuo. Yield: 100 mg of **4** · 0.5 CH_2Cl_2 (41%). − $C_{30.5}H_{43}ClP_2RuS_4$, **4** · 0.5 CH_2Cl_2 (736.41): calcd. C 49.75, H 5.89, S 17.42; found C 49.70, H 6.26, S 17.13. − IR (KBr):

$\tilde{\nu}$ = 1086 cm^{-1} δ(PCH). − ^1H NMR (269.6 MHz, CD_2Cl_2): δ = 7.90 (m, 2 H, C_6H_4), 7.75 (m, 2 H, C_6H_4), 7.30 (m, 2 H, C_6H_4), 7.20 (m, 2 H, C_6H_4), 6.90−6.70 (m, 4 H, C_6H_4), 1.85 (m, 12 H, PCH_2), 1.05 (m, 18 H, CH_3). − $^{13}C\{^1H\}$ NMR (67.7 MHz, CD_2Cl_2): δ = 159.02, 138.48, 136.66, 132.00, 131.58, 130.10, 129.68, 128.81, 121.06 [C(aryl)], 19.23 (vt, PCH_2CH_3), 8.49 (PCH_2CH_3). − $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2): δ = 18.5 (s). − FD MS (CH_2Cl_2, ^{102}Ru); *m/z*: 694 $[Ru(PEt_3)_2('tpS_4')]^+$.

[Ru(PPh$_3$)$_2$('tpS$_4$')] (5): A yellow solution of 'tpS$_4$'-H$_2$ (**3**) (102 mg, 0.28 mmol) in THF (15 mL) was combined with *n*BuLi (0.23 mL, 0.58 mmol) at −78 °C and subsequently warmed to room temperature. Addition of $[Ru(Cl)_2(PPh_3)_3]$ (281 mg, 0.28 mmol) resulted in an orange solution which was stirred for 4 h at room temperature, heated to reflux for 5 min, and cooled to room temperature. Yellow microcrystals precipitated which were separated, washed with THF (20 mL) and Et_2O (10 mL), dried in vacuo for 5 min, and redissolved in CH_2Cl_2 (15 mL). The yellow CH_2Cl_2 solution was filtered, THF (50 mL) was added to the filtrate, and the mixture was reduced in volume to 10 mL. The precipitated yellow microcrystals were separated, washed with THF (20 mL), MeOH (20 mL), and Et_2O (20 mL), and dried in vacuo. Yield: 145 mg of **5** · 0.25 CH_2Cl_2 (51%). − $C_{54.25}H_{42.5}Cl_{0.5}P_2RuS_4$, **5** · 0.25 CH_2Cl_2 (1003.44): calcd. [Ru(Cl)$_2$(PPh$_3$)('tpS$_2$(NH$_2$)$_2$')] (9): 'tpS$_2$(NH$_2$)$_2$' (**2**) (168 mg, 0.52 mmol) was added to a brown solution of [Ru(Cl)$_2$(PPh$_3$)$_3$] (495 mg, 0.52 mmol) in THF (25 mL). An orange solution formed which was heated under reflux for 1 h, cooled to room temperature, and reduced in volume to 15 mL. Yellow microcrystals precipitated which were separated, washed with THF (15 mL) and Et_2O (25 mL), and dried in vacuo. Yield: 330 mg of **9** · THF (76%). – $C_{40}H_{39}Cl_2N_2OPRuS_2$, **9** · THF (759.93): calcd. C 57.83, H 4.73, N 3.37, S 7.72; found C 57.90, H 4.64, N 3.37, S 7.45. – IR (KBr): $\tilde{\nu}$ = 1616 cm^{-1} δ(NH). – ^1H NMR (269.6 MHz, $CDCl_3$): δ = 7.85 (m, 7 H, C_6H_5), 7.15 (m, 1 H, C_6H_4), 7.40–7.05 (m,13 H, C_6H_4), 7.00 (m, 1 H, C_6H_4), 6.75 (m, 1 H, C_6H_4), 6.00 (m, 1 H, N*H*), 5.95 (m, 1 H, C_6H_4), 5.00 (s, 2 H, N*H*), 4.80 (m, 1 H, C_6H_4), 4.50 (m, 1 H, N*H*). – $^{13}C\{^1H\}$ NMR (67.7 MHz, $CDCl_3$): δ = 148.03, 144.16, 142.12, 139.86, 138.60, 135.90, 135.24, 134.50 (d), 133.38, 132.09, 131.56, 131.50, 131.24, 130.86, 130.45, 129.83, 129.02, 128.22 (d), 119.31, 119.11, 119.03 [C(aryl)]. – $^{31}P\{^1H\}$ NMR (109.38 MHz, CD_2Cl_2): δ = 43.5 (s). – FD MS (CH_2Cl_2, ^{102}Ru); *m/z*: 721 [Ru(Cl)(PPh$_3$)('tpS$_2$(NH$_2$)$_2$') − 2 H]$^+$.

X-ray Structure Analyses of 'tpS$_2$(NO$_2$)$_2$' (1), 'tpS$_2$(NH$_2$)$_2$' (2), [Ru(Cl)$_2$(PPh$_3$)('tpS$_2$(NH$_2$)$_2$')] (9), [Ru(PEt$_3$)$_2$('tpS$_4$')] · 0.5 Et$_2$O (4 · 0.5 Et$_2$O), and [Ru(CO)(PPh$_3$)('tpS$_4$')] · CH$_2$Cl$_2$ (6 · CH$_2$Cl$_2$): Yellow cubes of **1** crystallized from a hot saturated solution of **1** in THF upon cooling to room temperature, colorless cubes of **2** from a satured $CHCl_3$ solution. Orange cubes of **9** formed in the course of 7 d, when a saturated CH_2Cl_2 solution of **9** was stored at room temperature. Yellow plates of **4** and **6** were grown by layering CH_2Cl_2 solutions of **4** and **6** with Et_2O and MeOH, respectively, at room temperature. In the case of **4**, spontaneous separation of racemic **4** occured. Both independent molecules present in the asymmetric unit of **4** · 0.5 Et_2O represent the same enantiomer. Distances and angles of the two independent molecules differ only marginally. Suitable single crystals were sealed under N_2 in glass capillaries. Data were corrected for Lorentz and polarization effects, no absorption correction. The structures were solved by direct methods (SHELXTL 5.03[17]). Full-matrix least-squares refinement was carried out on F^2 (SHELXTL 5.03). All non-hydrogen atoms were refined anisotropically, the positions of the hydrogen atoms of **1**, **2**, and **9** were taken from the difference Fourier map and were either refined isotropically (**1**, **9**) or kept fixed with a common isotropic displacement parameter (**2**). In the case of **4** and **6** the hydrogen atoms were geometrically positioned with isotropic displacement parameters fixed at 1.5 times *U*(eq) of the preceding carbon atom. In the case of **2** and **4**, there are two crystallographically independent molecules per asymmetric unit. Selected crystallographic data are summarized in Table 2.[18]

Transition Metal Complexes with Sulfur Ligands, 135[+]

Electron-Rich Fe and Ru Complexes with the New Trisamine Dithiolate Ligand $'N_3H_3S_2'$-H_2 [2,2′-Bis(2-mercaptophenylamino)diethylamine]

Dieter Sellmann,*[a] Jürgen Utz,[a] and Frank W. Heinemann[a]

Keywords: N ligands / S ligands / Iron / Ruthenium / Pentadentate ligands

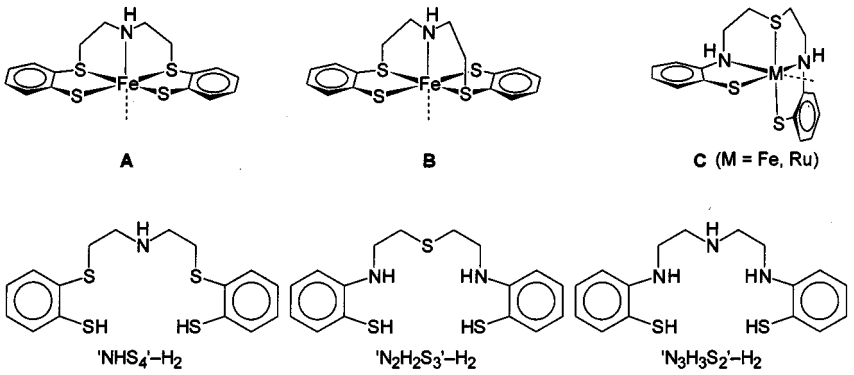
In order to obtain iron and ruthenium complexes which are analogous to [M(L)($'NHS_4'$)] and [M(L)($'N_2H_2S_3'$)] complexes [$'NHS_4'^{2-}$ = 2,2′-bis(2-mercaptophenylthio)diethylamine(2–), $'N_2H_2S_3'^{2-}$ = 2,2′-bis(2-mercaptophenylamino)diethylsulfide-(2–)] but have electron-richer metal centers, the new pentadentate amine thiolate ligand $'N_3H_3S_2'$-H_2 [= 2,2′-bis(2-mercaptophenylamino)diethylamine] (**4**) was synthesized. The dianion $'N_3H_3S_2'^{2-}$ reacted with Fe^{II} salts to give high-spin [Fe($'N_3H_3S_2'$)] (**5**) [μ_{eff} (293 K) = 3.94 μ_B], which yielded diamagnetic [Fe(CO)($'N_3H_3S_2'$)] (**6**) upon reaction with CO. Complex **6** exhibits a low-frequency ν(CO) band (1934 cm^{-1} in THF) indicating an electron-rich Fe center and a strong Fe–CO bond. In spite of this, **6** readily dissociated in solution to **5** and CO. The reaction of $[RuCl_2(PPh_3)_3]$ with $'N_3H_3S_2'^{2-}$ yielded [Ru(PPh_3)($'N_3H_3S_2'$)] (**7**), which proved inert with respect to PPh_3 substitution but could be methylated at the thiolate donors. The resulting [Ru(PPh_3)($'N_3H_3S_2'$-Me_2)]I_2 (**8**) proved as inert towards substitution as **7**. Complex **8** could reversibly be deprotonated to give [Ru(PPh_3)($'N_3H_2S_2'$-Me_2)]I (**11**), in the course of which the $[RuPN_3S_2]$ cores rearrange from C_S to C_1 symmetry. Reversible protonation/deprotonation was also found with [Ru(NO)($'N_3H_2S_2'$)] (**9**) which formed from $[RuCl_3(NO)(PPh_3)_2]$ and $'N_3H_3S_2'^{2-}$ in the presence of one additional equivalent of LiOMe. Protonation of **9** with HBF_4 gave [Ru(NO)($'N_3H_3S_2'$)]BF_4 (**10**). The NMR spectra and the X-ray structure analysis of **8** proved that the $[RuPN_3S_2]$ cores of **7** and **8** exhibit a C_S-symmetrical *meso* structure. In all other complexes, however, the $[MLN_3S_2]$ cores exhibit a C_1-symmetrical structure. It results from the *fac-mer* coordination mode of the $'N_3H_3S_2'^{2-}$ ligand and favors the planarization of amide donors when NH functions are reversibly deprotonated.

Structure–function relationships of transition metal complexes are primarily determined by the metal oxidation state, type and number of the donor atoms, and the structure of the metal ligand core.[1] In quest of metal complexes that combine structural (metal sulfur sites) and functional (reactivity) features of nitrogenase centers, our interest focusses on complexes with multidentate ligands which contain amine N, thioether S, and thiolate S donors. In this search the [Fe($'NHS_4'$)] fragment (Scheme 1) was found to exist in the diastereomeric forms **A** and **B** and to bind N_2H_2, N_2H_4, NH_3, and CO, but not N_2.[2] As high electron densities at the metal centers usually favor the coordination of N_2,[3] we tried to increase the iron electron density in the [Fe($'NHS_4'$)] cores through a systematic substitution of σ-donor–π-acceptor thioether functions by σ-donor amine functions.

The first target ligand $'N_2H_2S_3'$-H_2[4] yielded the CO complex [Fe(CO)($'N_2H_2S_3'$)], whose ν(CO) frequency of 1932 cm^{-1} indicated a higher Fe electron density when compared with to that of [Fe(CO)($'NHS_4'$)] (1960 cm^{-1}). However, despite the low-frequency ν(CO) indicating strong Fe–CO π-back-bonding, [Fe(CO)($'N_2H_2S_3'$)] proved much more labile than [Fe(CO)($'NHS_4'$)], and neither N_2 nor N_2H_2, N_2H_4, or NH_3 complexes could be obtained with the [Fe($'N_2H_2S_3'$)] fragment. Beyond that all [Fe(L)($'N_2H_2S_3'$)] and corresponding [Ru(L)($'N_2H_2S_3'$)] complexes were shown to exhibit the core structure **C** having thiolate donor atoms in *cis* positions. The core structure **C** distinctly differs from the [Fe($'NHS_4'$)] core structure **B** having *trans*-thiolate donors. *trans*-Thiolate donors, however, proved to be essential for the stabilization of molecules such as N_2H_2 in [μ-N_2H_2{Fe($'NHS_4'$)}$_2$], because only a *trans* coordination of thiolate donors allows the formation of strong N–H···$(S)_2$ bridges.[2a,2c]

In the series of systematically varied ligands, our next target ligand was $'N_3H_3S_2'$-H_2. It is comparable with the $'NHS_4'^{2-}$ ligand in so far as all thioether donors are exchanged for amine donors. Simultaneously, the terminal thiolate donors are maintained in a coordination mode that enables them to occupy, at least in principle, *trans* positions in six-coordinate metal complexes.

Results



Ligand Synthesis

As in the case of the $'N_2H_2S_3'^{2-}$ ligand synthesis, the requirement of terminal thiolate functions in the target ligand $'N_3H_3S_2'^{2-}$ necessitated a specific synthetic route (Scheme 2).

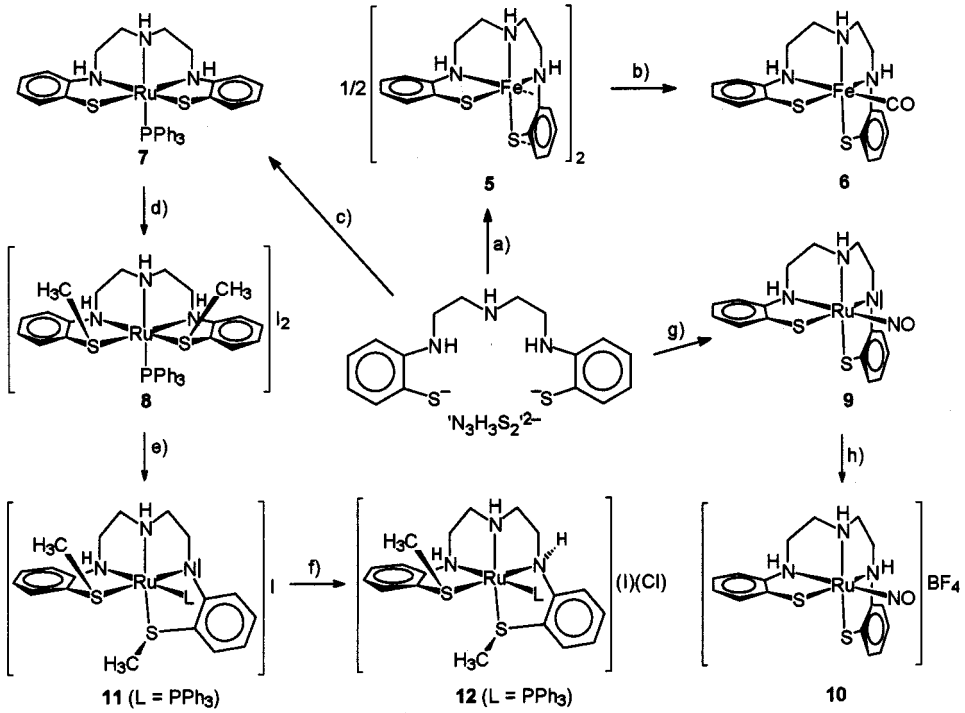
Scheme 1. Ligands and core structures of metal complex fragments

Scheme 2. Synthesis of $'N_3H_3S_2'$-H_2 (**4**)

Alkylation of 2(3*H*)-benzothiazolone (**1**) with $TsN(C_2H_4I)_2$ in the presence of K_2CO_3 yielded **2** as major product. The rather unusual N-lost derivative $TsN(C_2H_4I)_2$ had to be applied because all other and more common alkylation reagents such as $NH(C_2H_4Br)_2$ or amides of the type $R(CO)N(C_2H_4Br)_2$ failed. For example, $NH(C_2H_4Br)_2$ gave piperazine derivatives[5] instead of alkylating **1**, the amides $R(CO)N(C_2H_4Br)_2$ rearranged.[6] From the crude product of **2**, traces of by-products resulting from oxygen alkylation of **1**[7] could readily be removed by extraction with EtOH. Compound **2** is soluble in CH_2Cl_2 and THF and moderately soluble in EtOH or MeOH; it was characterized by the usual spectroscopic methods and by elemental analysis. The $^{13}C\{^1H\}$-NMR CO signal (δ = 170.6) and the IR ν(CO) band (1678 cm^{-1} in KBr) are particularly suited to confirm alkylation of the N atom in **1** and to identify **2**.



Alkaline hydrolysis of **2** by aqueous NaOH in EtOH and subsequent acidification with hydrochloric acid yielded **3** as yellow powder in nearly quantitative amounts. The final step, the reductive detosylation of the central N atom in **3** with sodium in liquid NH_3 gave **4**, which was isolated after recrystallization from EtOH in form of beige needles.

Syntheses of Fe and Ru Complexes

Scheme 3 summarizes the syntheses and reactions of $[M('N_3H_3S_2')]$ complexes.

The reaction a) of Fe^{II} salts with $'N_3H_3S_2'^{2-}$, which was routinely obtained from $'N_3H_3S_2'$-H_2 and two equivalents of LiOMe, gave grey-white $[Fe('N_3H_3S_2')]$ (**5**). The structure of **5** remains unknown, but in analogy to the closely related dinuclear $[Fe('N_2H_2S_3')]_2$ complex, **5** is suggested to exhibit a dinuclear structure resulting from thiolate bridging. In solid state, **5** is paramagnetic [μ_{eff} (293 K) = 3.94 μ_B]. The μ_{eff} value is compatible with four unpaired electrons per Fe center, which are partially coupled antiferromagnetically through Fe−S−Fe bridges.

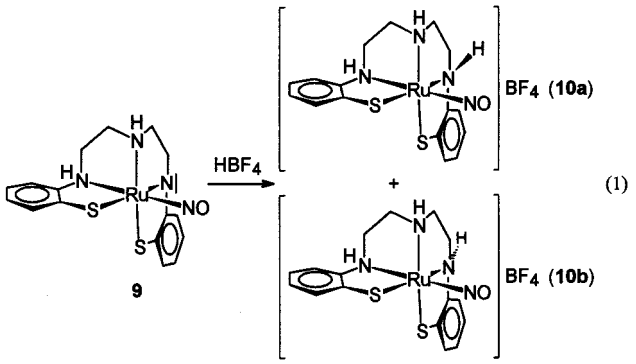
All attempts to obtain $[Fe(L)('N_3H_3S_2')]$ derivatives by treating **5** with N_2H_4, NEt_4N_3, or PMe_3 in MeOH or THF solutions remained unsuccessful and yielded only the starting complex **5**. Exclusively CO could be added to give red $[Fe(CO)('N_3H_3S_2')]$ (**6**) (Scheme 3, reaction b). Complex **6** is diamagnetic and probably exhibits the C_1-symmetric structure indicated in Scheme 3. The C_1 symmetry is concluded from the NMR spectra of **6** (see below), and it corresponds with that of the related $[Fe(CO)('N_2H_2S_3')]$ whose structure has been determined by X-ray diffraction. Complex **6** exhibits a low-frequency ν(CO) IR band at 1934 cm^{-1} (in THF) indicating strong Fe−CO π-back-bonding. In accordance with this, solid **6** is stable at room temperature for unlimited periods of time. In solution, however, **6** rather unexpectedly readily loses CO within a few hours and yields the starting complex **5**. In this respect, the properties of **6** resemble very closely those of the related

Scheme 3. Syntheses and reactions of [M('$N_3H_3S_2$')] complexes (M = Fe, Ru)

[Fe(CO)('$N_2H_2S_3$')]. For this reason, we tried to obtain the kinetically less labile ruthenium homologue of **6**. As in the case of the '$N_2H_2S_3$'$^{2-}$ ligand, all efforts to obtain the corresponding monocarbonyl complex [Ru(CO)('$N_3H_3S_2$')] remained unsuccessful. The composition of the complexes resulting from reactions of precursors such as $[Ru(H)(Cl)(CO)(PCy_3)_2]$[8] or $[Ru(Cl)_2(CO)_3(THF)]$[9] with '$N_3H_3S_2$'$^{2-}$ suggested that only four of the five '$N_3H_3S_2$'$^{2-}$ donors had become coordinated.

However, coordination of all five '$N_3H_3S_2$'$^{2-}$ donors could be achieved when $[RuCl_2(PPh_3)_3]$ was treated with '$N_3H_3S_2$'$^{2-}$ in refluxing THF (Scheme 3, reaction c). Yellow [Ru(PPh_3)('$N_3H_3S_2$')] (**7**) resulted, which interestingly also formed when $[RuCl_2(PPh_3)_3]$ was treated with the *N*-tosylated ligand '$^{Ts}N_3H_2S_2$'$^{2-}$ (**3**). This indicates that coordination of **3** facilitates its detosylation. Detosylation of amides normally needs much more drastic reaction conditions.[10] The C_S symmetry of **7** indicated in Scheme 3 is concluded from the ^{1}H-NMR signal pattern of the aliphatic '$N_3H_3S_2$'$^{2-}$ protons. It consists of two pseudo triplets and a multiplet and characteristically differs from the pattern observed consisting of two pseudo triplets. This signal pattern characteristically differs from that observed for the aliphatic protons in C_1-symmetrical [Fe(CO)('$N_3H_3S_2$')]. A ^{13}C-NMR spectrum confirming this conclusion could not be recorded due to insufficient solubility of **7**. However, the C_S symmetry assumed for **7** is further supported by the C_S-symmetrical structure of the *S*-methylated derivative of **7**. Alkylation of **7** by CH_3I yielded [Ru(PPh_3)('$N_3H_3S_2$'-Me_2)]I_2 (**8**) (reaction d), whose molecular structure could be determined by X-ray structure analysis.

Coordination of the '$N_3H_3S_2$'$^{2-}$ ligand to (nitrosyl)ruthenium complexes resulted in deprotonation of one aromatic amine function. Treatment of $[RuCl_3(NO)(PPh_3)_2]$ with '$N_3H_3S_2$'$^{2-}$ and LiOMe yielded neutral, deep green [Ru(NO)('$N_3H_2S_2$')] (**9**), which exhibits one amide donor (reaction g). The formation of the amide could further be substantiated by protonation of **9** with HBF_4 (reaction h). It yielded red [Ru(NO)('$N_3H_3S_2$')]BF_4 (**10**). The protonation is accompanied by a shift of the ν(NO) band from 1779 cm^{-1} in **9** to 1855 cm^{-1} in **10**. The ^{1}H- and ^{13}C-NMR spectra indicate that **10** exists in two diastereomeric forms (see below).

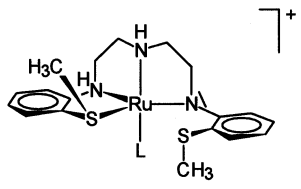


Substitution and Acid−Base Reactions

The reactivity of the complexes containing [M('$N_3H_3S_2$')] or [M('$N_3H_2S_2$')] cores paralleled that of complexes with [M('$N_2H_2S_3$')] or [M('N_2HS_3')] cores. The [Fe(CO)('$N_3H_3S_2$')] complex proved unexpectedly labile with respect to CO loss.

The ruthenium complexes proved extremely inert towards substitution. For example, the PPh_3 ligand in [Ru(PPh_3)('$N_3H_3S_2$')] (**7**) could neither be substituted by CO (50 bar, 2 d, THF) nor by N_2H_4 which was used as solvent (40°C, 1 d). With the intention to labilize the Ru−PPh_3 bond by converting the thiolate into thioether

functions, **7** was alkylated. The resulting [Ru(PPh_3)-($'N_3H_3S_2'$-Me_2)]I_2 (**8**) proved to be as inert towards substitution as **7**.



As in the case of [M($'N_2H_2S_3'$)] complexes, protonation−deprotonation reactions of the [M($'N_3H_3S_2'$)] cores could be observed. Protonation of the amide donor in [Ru(NO)($'N_3H_2S_2'$)] yielded two diastereomers of [Ru(NO)($'N_3H_3S_2'$)]BF_4. The formation of two diastereomers could be concluded from the $^{13}C\{^1H\}$-NMR spectrum and is explained by the stereogenicity of the amine function that results from either a "front"- or a "back"-side attack of the proton upon the prochiral amide donor (Equation 1).

(1)

The protonation−deprotonation reactions of [Ru(PPh_3)($'N_3H_3S_2'$-Me_2)]I_2 (**8**) differ from those of the analogous [Ru(PPh_3)($'N_2H_2S_3'$-Me_2)]I_2. The ^{1}H-NMR spectrum and X-ray structure determination established that **8** formed in isomerically pure form as C_S-symmetrical species when synthesized from **7** and CH_3I. Complex **8** can be deprotonated by bases such as N_2H_4 to give [Ru(PPh_3)($'N_3H_2S_2'$-Me_2)]I (**11**), which is converted into [Ru(PPh_3)($'N_3H_3S_2'$-Me_2)](I)(Cl) (**12**) when treated with HCl. The ^{1}H- and ^{13}C-NMR spectra unambiguously show that **11** and **12** have C_1 symmetry only. Thus, the deprotonation−protonation reactions [steps e) and f) in Scheme 3] lead to a configurational rearrangement of **8**.

The rearrangement could occur via the five-coordinate intermediate [Ru(PPh_3)($'N_3H_2S_2'$-Me_2)]$^+$ in which one thioether donor has dissociated. Driving force of this rearrangement probably is the planarization tendency of amide N atoms[11] and, in addition, the capability of amide donors to stabilize five-coordinate intermediates by π donation.[2e] The rearrangement further indicates that, like [M($'N_2H_2S_3'$)] cores, also [M($'N_3H_3S_2'$)] cores prefer the C_1-symmetrical configuration. It is noteworthy that the protonation of **11** yields only one diastereomer of **12** (cf. ref.[4]).

Characterization of Complexes

All complexes except [Fe($'N_3H_3S_2'$)]$_2$ (**5**) are diamagnetic and exhibit similar solubilities. They are soluble in DMF and DMSO, moderately soluble in CH_2Cl_2, THF, and acetone, and virtually insoluble in all other common organic solvents. The phosphane complex [Ru(PPh_3)($'N_3H_3S_2'$)] (**7**) is only very moderately soluble even in DMSO. All complexes have been characterized by elemental analysis, IR, NMR, and mass spectra. The FD mass spectra of the complexes showed the molecular ions except in the case of **6** in which only the decarbonylated species [Fe($'N_3H_3S_2'$)]$^+$ could be observed. As expected the IR (KBr) spectra show numerous bands. One broad or up to three weak- to medium-intensity ν(NH) bands in the region of 3293 to 3102 cm^{-1} can be used as an IR probe for the complexes containing [M($'N_3H_3S_2'$)] cores. In contrast, [Ru(NO)($'N_3H_2S_2'$)] (**9**) containing one amide donor gives rise to two medium ν(NH) bands at 3245 and 3224 cm^{-1}. The complexes **6**, **9**, and **10** can further readily be identified by their strong ν(CO), ν(NO), and ν(BF_4) bands which appear at 1934 cm^{-1} (**6** in THF), 1779 cm^{-1} (**9** in KBr), and 1855 and 1084 cm^{-1}, respectively (**10** in KBr). $^{13}C\{^1H\}$-NMR spectra are the most suitable probe for distinguishing between C_1 or C_S symmetry of the complexes[4][12]. Twelve aromatic ^{13}C-NMR signals in the range δ = 160−108 and four aliphatic ^{13}C-NMR signals of the *N*-bonded C atoms in the range δ = 65−45 indicate C_1 symmetry of the complexes **6** and **9** containing [M($'N_3H_3S_2'$)] or [M($'N_3H_2S_2'$)] cores. Two sets of this signal pattern in the $^{13}C\{^1H\}$-NMR spectrum of **10** suggest the presence of two diastereomers. Only six aromatic and two aliphatic (*N*-bonded C_2H_4 groups) ^{13}C-NMR signals for the [M($'N_3H_3S_2'$)] core indicate the C_S symmetry of **8**, which was confirmed by X-ray structure analysis. The C_S symmetry of **8** is also reflected in the appearance of only one SCH_3 singlet in the ^{1}H-NMR spectrum.

X-ray Structure Analysis of [Ru(PPh_3)($'N_3H_3S_2'$-Me_2)]I_2 · 2 CH_2Cl_2 (**8** · 2 CH_2Cl_2)

The molecular structure of [Ru(PPh_3)($'N_3H_3S_2'$−Me_2)]I_2 · 2 CH_2Cl_2 (**8** · 2 CH_2Cl_2) (Figure 1) was determined by X-ray structure analysis. Table 1 lists selected distances and angles.

The ruthenium center of **8** is pseudo-octahedrally surrounded by the phosphane and the $'N_3H_3S_2'$-Me_2 donors. Both the aromatic amine and the thioether donor atoms assume *cis* positions, and the aliphatic amine donor N3 and the phosphane donor occupy *trans* positions such that **8** exhibits approximate C_S symmetry. Distances and angles show no anomalies and are typical for this type of Ru^{II} complexes.[4,13] Within the crystal, the complex cations, iodide anions, and CH_2Cl_2 solvate molecules are connected by hydrogen bonds. The shortest interionic contact is observed between the N2, H2, and I2 atoms [N2−H2···I2: N2−H2 86(6), N2···I2 352.8(4), H2···I2 274(5) pm; N2−H2···I2 153(4)°].

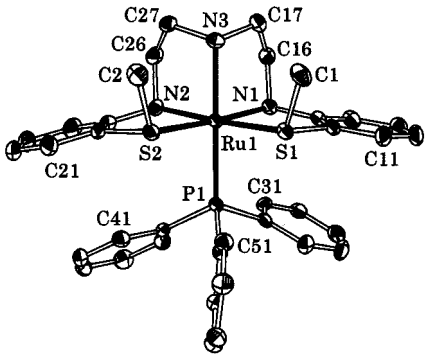


Figure 1. Molecular structure of the cation of $[Ru(PPh_3)('N_3H_3S_2'\text{-}Me_2)]I_2 \cdot 2\ CH_2Cl_2$ (**8** · 2 CH_2Cl_2) (50% probability ellipsoids, H atoms and solvate molecules omitted)

Table 1. Selected distances [pm] and angles [°] of $[Ru(PPh_3)('N_3H_3S_2'\text{-}Me_2)]I_2 \cdot 2\ CH_2Cl_2$ (**8** · 2 CH_2Cl_2)

Concluding Discussion

In the course of a study aiming at the series of $'NHS_4'^{2-}$, $'N_2H_2S_3'^{2-}$, and $'N_3H_3S_2'^{2-}$ ligands and transition metal complexes with increasing electron density at the transition metal centers, the new pentadentate ligand $'N_3H_3S_2'\text{-}H_2$ was prepared.

A special synthetic route which warranted the NH and the terminal thiolate donors of $'N_3H_3S_2'\text{-}H_2$ was developed. The low-frequency ν(CO) of $[Fe(CO)('N_3H_3S_2')]$ (**6**) (1934 cm^{-1}) shows that the iron center indeed exhibits a high electron density. However, the Fe electron density is not higher than in the related $[Fe(CO)('N_2H_2S_3')]$ (1932 cm^{-1}), the CO ligand is very labile and no small molecules other than CO could be coordinated to the $[Fe('N_3H_3S_2')]$ fragment. With respect to $[Fe('NHS_4')]$ fragments, a further serious shortcoming of $[M(L)('N_3H_3S_2')]$ complexes is their core structure. Like $[M(L)('N_2H_2S_3')]$ complexes, $[M(L)('N_3H_3S_2')]$ complexes appear to prefer C_1-symmetrical structures and thiolate donors in *cis* position. Only $[Ru(PPh_3)('N_3H_3S_2')]$ (**7**) and its *S*-methylated derivative $[Ru(PPh_3)('N_3H_3S_2'-Me_2)]I_2$ (**8**) exhibit C_S-symmetrical structures which are comparable with the C_S-symmetrical diastereomer of the $[Fe('NHS_4')]$ fragment. However, the deprotonation−protonation reactions of **8** lead to the C_1-symmetrical diastereomer **12** and indicate that also the $[Ru('N_3H_3S_2')]$ fragment prefers the C_1-symmetrical core structure. Thus, with respect to structure, $[M(L)('N_3H_3S_2')]$ and $[M(L)('N_2H_2S_3')]$ complexes show largely similar properties. The same holds for the electronic and reactivity features. The corresponding carbonyliron complexes exhibit high electron density at the metal centers, but are labile. The ruthenium complexes are virtually substitution inert. The reversible deprotonation of one amine NH function to give an amide donor is their only significant reaction. It has previously been discussed in detail that this formation of π-donor amides can lead to either labilization or stabilization of *trans*-metal−ligand bonds.[4,14]

Experimental Section

General: Unless noted otherwise, all procedures were carried out under N_2 at room temperature by using Schlenk techniques. Solvents were dried and distilled before use. As far as possible the reactions were monitored by IR spectroscopy. − Spectra were recorded with the following instruments: IR: Perkin Elmer 16 PC FT-IR. − NMR: JEOL JNM-GX 270 and JNM-EX 270 [^{1}H NMR (269.6 MHz) and ^{13}C NMR (67.7 MHz): The protio-solvent signal was used as an internal reference. Chemical shifts are quoted on the δ scale (downfield shifts are positive) relative to tetramethylsilane; ^{31}P NMR (109.38 MHz): external standard H_3PO_4]. − Mass spectra: Varian MAT 212 and JEOL JMS 700. − Magnetic moments: Johnson Matthey magnetic susceptibility balance (293K). − $[RuCl_3(NO)(PPh_3)_2]$,[15] $[RuCl_2(PPh_3)_3]$,[16] *N*,*N*-bis[2-(*p*-tolylsulfonyloxy)ethyl]-*p*-toluolsulfonamide,[17] and 2(3*H*)-benzothiazolone[18] were prepared by literature methods. *N*,*N*-bis(2-iodoethyl)-*p*-toluenesulfonamide[19] was prepared in situ and directly used afterwards. Hydrazine was obtained by twofold distillation of $N_2H_4 \cdot H_2O$ over solid potassium hydroxide under reduced pressure.

Alkylation of 2(3*H*)-Benzothiazolone (1) with *N*,*N*-Bis(2-iodoethyl)-*p*-toluenesulfonamide To Give 2: A solution of *N*,*N*-bis[2-(*p*-tolylsulfonyloxy)ethyl]-*p*-toluenesulfonamide (2.03 g, 3.58 mmol) and NaI (2.50 g, 10.68 mmol) in acetone (40 mL) was refluxed for 14 h and concentrated to dryness. The resulting residue was dissolved in CH_2Cl_2 (30 mL), insoluble material was removed by filtration, and the filtrate was concentrated to dryness, yielding *N*,*N*-bis(2-iodoethyl)-*p*-toluenesulfonamide (1.52 g, 89%). − A suspension of 2(3*H*)-benzothiazolone (0.96 g, 6.35 mmol) and K_2CO_3 (0.88 g, 6.37 mmol) in 2-butanone (20 mL) was refluxed for 30 min and then combined with a solution of *N*,*N*-bis(2-iodoethyl)-*p*-toluenesulfonamide (1.52 g, 3.17 mmol) in 2-butanone (10 mL). The resulting white suspension was refluxed for 14 h and concentrated to dryness to give a foamy white residue. It was redissolved in EtOH (30 mL). Addition of water (50 mL) precipitated a white powder, which was separated, digested with EtOH (30 mL), and dried in vacuo. Yield: 1.39 g (74%). − $C_{25}H_{23}N_3O_4S_3$ (525.67): calcd. C 57.12, H 4.41, N 7.99, S 18.30; found C 56.71, H 4.47, N 7.98, S 18.11. − IR (KBr): $\tilde{\nu}$ = 1678 vs ν(CO), 1327, 1153 w ν(SO_2) cm^{-1}. − MS (FD, CH_2Cl_2); *m/z*: 525 [**2**]$^+$. − ^{1}H NMR ($CDCl_3$): δ = 7.59 (d, 2 H, C_6H_4), 7.40 (d, 2 H, C_6H_4), 7.34 (d, 2 H, C_6H_4), 7.25−7.10 (m, 6 H, C_6H_4), 4.14 (t, 4 H, C_2H_4), 3.50 (t, 4 H, C_2H_4), 2.35 (s, 3 H, CH_3, Ts). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 170.6 (CO), 144.6, 137.3, 135.8, 130.6, 127.7, 127.4, 124.0, 123.4, 123.3, 111.3 (C, aryl), 46.9, 42.2 (C_2H_4), 22.2 (CH_3, Ts).

$'^{Ts}N_3H_2S_2'\text{-}H_2$ (3): A suspension of **2** (1.83 g, 3.48 mmol) in EtOH (20 mL) was combined with a solution of NaOH (1.39 g, 34.8 mmol) in H_2O (20 mL) and refluxed for 18 h. Concentrated hydrochloric acid was added until pH = 3 was reached, the solution was concentrated in volume to one half, diluted with H_2O (60 mL), and extracted with CH_2Cl_2 (60 mL). The combined CH_2Cl_2 phases were dried with anhydrous Na_2SO_4 and concentrated to dryness, yielding **3** as a yellow powder. Yield: 1.60 g (97%). − $C_{23}H_{27}N_3O_2S_3$ (473.69): calcd. C 58.32, H 5.75, N 8.87, S 20.31; found: C 58.10, H 5.90, N 8.91, S 19.99. − IR (KBr): $\tilde{\nu}$ = 3385, 3364 w ν(NH), 2522 w ν(SH), 1323 s, 1159 vs ν(SO_2) cm^{-1}. − MS (FD, CH_2Cl_2);

m/z: 474 [$'^{Ts}N_3H_2S_2'$-H_2]$^+$. – ^{1}H NMR ($CDCl_3$): δ = 7.62 (d, 2 H, C_6H_4, Ts, *ortho* to SO_2), 7.23 (d, 2 H, C_6H_4, *ortho* to SH), 7.17 (d, 2 H, C_6H_4, Ts, *meta* to SO_2), 7.03 (dd, 2 H, C_6H_4, *para* to SH), 6.50 (dd, 2 H, C_6H_4, *para* to NH), 6.42 (d, 2 H, C_6H_4, *ortho* to NH), 4.80 (s, br., 2 H, NH), 3.27 (s, 8 H, C_2H_4), 2.70 (s, br., 2 H, SH), 2.30 (s, 3 H, CH_3, Ts). – ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 147.6, 143.7, 135.5, 135.2, 129.8, 129.4, 127.1, 117.2, 111.6, 109.8 (C, aryl), 48.8, 42.9 (C_2H_4), 21.4 (CH_3, Ts).

$'N_3H_3S_2'$-H_2 (4): Metallic sodium was added in small portions to a solution of $'^{Ts}N_3H_2S_2'$-H_2 (**3**) (1.0 g, 2.1 mmol) in refluxing liquid NH_3 (100 mL) until the blue color of dissolved sodium persisted for 10 min. Ammonium chloride was added until the blue color disappeared, and the liquid NH_3 was allowed to evaporate. The resulting beige residue was dissolved in aqueous NaOH (0.4 g NaOH in 100 mL H_2O). The resulting H_2O solution was extracted with CH_2Cl_2 (70 mL) and filtered through filter pulp. Concentrated hydrochloric acid was added to the H_2O filtrate. When pH = 8 was reached, a white solid precipitated which was separated and washed with H_2O (40 mL). Recrystallization from EtOH yielded beige needles of **4**. The pH = 8 proved critical, because further lowering of the pH led to formation of yellow material, which had a gummy consistency, proved insoluble in all common organic solvents, and was not characterized in detail. Yield: 0.51 g (66%) of **4** · EtOH. – $C_{18}H_{27}N_3OS_2$ (365.57): calcd. C 59.14, H 7.44, N 11.49, S 17.54; found C 58.86, H 7.61, N 11.74, S 17.69. – IR (KBr): $\tilde{\nu}$ = 3376, 3317 m ν(NH), 2588 w, br. ν(SH) cm^{-1}. – MS (FD, CH_2Cl_2); *m/z*: 319 [$'N_3H_3S_2'$-H_2]$^+$. – ^{1}H NMR (CD_2Cl_2): δ = 7.35 (d, 2 H, C_6H_4), 7.15 (t, 2 H, C_6H_4), 6.68–6.53 (m, 4 H, C_6H_4), 3.50–3.10 (s, br., superimposed by t, 9 H, SH, NH, C_2H_4), 2.97 (t, 4 H, C_2H_4). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 148.8, 135.1, 129.3, 117.3, 110.8, 110.8 (C_6H_4), 48.4, 43.6 (C_2H_4).

[Fe($'N_3H_3S_2'$)]$_2$ (5): A yellow solution of $'N_3H_3S_2'$-H_2 · EtOH (**4** · EtOH) (0.22 g, 0.60 mmol) and LiOMe (1.20 mmol, 1.20 mL of a 1 M solution in MeOH) in THF (10 mL) was combined with a solution of $FeCl_2 \cdot 4\ H_2O$ (0.12 g, 0.60 mmol) in MeOH (10 mL). A white solid precipitated which was separated, washed with MeOH (15 mL), and dried in vacuo, in the course of which the color of the solid changed from white to grey. Yield: 0.20 g (89%). – $C_{32}H_{38}Fe_2N_6S_4$ (746.66): calcd. C 51.48, H 5.13, N 11.26, S 17.18; found C 51.19, H 5.29, N 11.17, S 16.98. – IR (KBr): $\tilde{\nu}$ = 3145 m, br. ν(NH) cm^{-1}. – MS (FD, DMSO); *m/z*: 373 [Fe($'N_3H_3S_2'$)]$^+$. – μ_{eff} (293 K) = 3.94 μ_B.

[Fe(CO)($'N_3H_3S_2'$)] (6): CO was continuously bubbled through a solution of $'N_3H_3S_2'$-H_2 · EtOH (**4** · EtOH) (0.135 g, 0.37 mmol) and LiOMe (0.75 mmol, 0.75 mL of a 1 M solution in MeOH) in MeOH (15 mL). A solution of $FeCl_2 \cdot 4\ H_2O$ (0.074 g, 0.37 mmol) in MeOH (15 mL) was added and a red suspension formed. After 15 min, the resulting red solid was separated, washed with MeOH (20 mL), and dried in vacuo. Yield: 0.15 g (97%) **6** · 0.5 MeOH. – $C_{17.5}H_{21}FeN_3O_{1.5}S_2$ (417.36): calcd. C 50.36, H 5.07, N 10.07, S 15.37; found C 50.35, H 4.88, N 10.27, S 15.59. – IR (KBr): $\tilde{\nu}$ = 3241, 3157, 3102 w ν(NH), 1930 s, 1910 vs ν(CO) cm^{-1}. – IR (THF): $\tilde{\nu}$ = 1934 vs ν(CO) cm^{-1}. – MS (FD, DMSO); *m/z*: 373 [Fe($'N_3H_3S_2'$)]$^+$, 317 [($'N_3H_3S_2'$)]$^+$. – ^{1}H NMR ([D$_6$]DMSO): δ = 7.26–6.50 (m, 9 H, C_6H_4 and NH superimposed), 5.86 (s, br., 1 H, NH), 5.78 (s, br., 1 H, NH), 3.70–2.20 (m, 8 H, C_2H_4). – ^{13}C{^{1}H} NMR ([D$_6$]DMSO): δ = 221.3 (CO), 153.6, 152.1, 151.1, 149.1, 129.0, 128.2, 124.7, 124.5, 122.4, 119.5, 119.4, 119.0 (C_6H_4), 62.2, 58.9, 46.2, 45.0 (C_2H_4).

[Ru(PPh$_3$)($'N_3H_3S_2'$)] (7): [$RuCl_2(PPh_3)_3$] (0.79 g, 0.82 mmol) was added to a solution of $'N_3H_3S_2'$-H_2 · EtOH (**4** · EtOH) (0.30 g, 0.82 mmol) and LiOMe (1.65 mmol, 1.65 mL of a 1 M solution in MeOH) in THF (30 mL). The reaction mixture was stirred for 24 h and then refluxed for 3 h. The yellow solid precipitating from the green solution was separated, washed with THF (15 mL) and MeOH (60 mL), and dried in vacuo. [Compound **7** was obtained in equally high yields, when instead of **4** · EtOH the ligand $'^{Ts}N_3H_2S_2'$-H_2 (**3**) was used]. Yield: 0.18 g (32%). – $C_{34}H_{34}N_3PRuS_2$ (680.84): calcd. C 59.98, H 5.03, N 6.17, S 9.42; found C 59.63, H 5.19, N 6.29, S 9.34. – IR (KBr): $\tilde{\nu}$ = 3288 w, 3258, 3247 m ν(NH) cm^{-1}. – MS (FD, DMSO, ^{102}Ru); *m/z*: 681 [Ru(PPh$_3$)($'N_3H_3S_2'$)]$^+$. – ^{1}H NMR ([D$_6$]DMSO): δ = 7.35–6.17 [m, 23 H, C_6H_4 and P(C_6H_5) superimposed], 5.77 (d, 2 H, NH), 4.41 (s, br., 1 H, NH), 3.75 (pseudo-t, 2 H, C_2H_4), 2.90 (pseudo-t, 2 H, C_2H_4), 2.75–2.20 (m, 4 H, C_2H_4). – ^{31}P{^{1}H} NMR ([D$_6$]DMSO): δ = 52.6 [s, P(C_6H_5)].

[Ru(PPh$_3$)($'N_3H_3S_2'$-Me$_2$)]I$_2$ (8): Addition of MeI (0.50 mL, 8.0 mmol) to a yellow suspension of [Ru(PPh$_3$)($'N_3H_3S_2'$)] (**7**) (0.13 g, 0.19 mmol) in THF (20 mL) yielded a beige suspension. The beige solid was separated after 2 d, washed with THF (10 mL), and dried in vacuo. Yield: 0.19 g (96%) **8** · THF. – $C_{40}H_{48}I_2N_3OPRuS_2$ (1036.83): calcd. C 46.34, H 4.67, N 4.05, S 6.19; found C 46.18, H 4.85, N 3.92, S 6.48. – IR (KBr): $\tilde{\nu}$ = 3284 w, br. ν(NH) cm^{-1}. – MS (FD, CH_2Cl_2, ^{102}Ru); *m/z*: 838 {[Ru(PPh$_3$)($'N_3H_3S_2'$–Me$_2$)](I)}$^+$, 711 [Ru(PPh$_3$)($'N_3H_3S_2'$-Me$_2$)]$^+$. – ^{1}H NMR ([D$_6$]DMSO): δ = 7.73–6.96 [m, 23 H, C_6H_4 and P(C_6H_5) superimposed], 6.85 (d, 2 H, NH arom.), 6.46 (s, br., 1 H, NH aliphat.), 4.06 (m, 2 H, C_2H_4), 2.92 (s, 6 H, SCH_3), 2.87–2.72 (m, 6 H, C_2H_4). – ^{13}C{^{1}H} NMR ([D$_6$]DMSO): δ = 148.3 (C_6H_4), 133.2, 132.7 [d, P(C_6H_5)], 131.7, 131.2, 130.6 (C_6H_4), 129.8 [s, br., P(C_6H_5)], 128.2 (C_6H_4), 127.8 [d, P(C_6H_5)], 126.4 (C_6H_4), 60.0, 51.8 (C_2H_4), 25.3 (d, SCH_3). – ^{31}P{^{1}H} NMR ([D$_6$]DMSO): δ = 37.5 [s, P(C_6H_5)].

[Ru(PPh$_3$)($'N_3H_2S_2'$-Me$_2$)]I (11): [Ru(PPh$_3$)($'N_3H_3S_2'$-Me$_2$)]I_2 · THF (**8** · THF) (0.10 g, 0.10 mmol) was suspended in N_2H_4 (1.0 mL). The yellow reaction mixture was stirred for 4 h and then concentrated to dryness. The resulting yellow residue was dissolved in CH_2Cl_2 (5 mL), insoluble material was removed by filtration, and the filtrate was concentrated to dryness yielding a yellow powder. Yield: 0.07 g (84%). – IR (KBr): $\tilde{\nu}$ = 3275 m ν(NH) cm^{-1}. – MS (FD, DMSO, ^{102}Ru); *m/z*: 694 [Ru(PPh$_3$)($'N_3H_2S_2'$-CH$_2$)]$^+$. – ^{1}H NMR (CD_2Cl_2): δ = 7.57 [t, 2 H, CH(aryl)], 7.47–7.19 [m, 17 H, CH(aryl)], 6.97 [t, 1 H, CH(aryl)], 6.75 [d, 1 H, CH(aryl)], 6.31 [d, 1 H, CH(aryl)], 6.09 [t, 1 H, CH(aryl)], 5.72 (t, br., 1 H, NH), 5.46 (t, br., 1 H, NH), 3.46–2.60 (m, 8 H, C_2H_4), 2.36 (s, 3 H, CH_3), 1.75 (s, 3 H, CH_3). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 158.6, 147.3, 138.1 (d) (C_6H_4), 133.8, 133.6 [d, P(C_6H_5)], 131.9, 131.3, 131.0 (C_6H_4), 130.1 [s, br., P(C_6H_5)], 130.0, 129.6 (C_6H_4), 129.2 [d, P(C_6H_5)], 127.2, 120.0, 111.4, 110.7 (C_6H_4), 58.7, 57.4, 55.8, 49.2 (C_2H_4), 28.2, 23.1 (d) (SCH_3). – ^{31}P{^{1}H} NMR (CD_2Cl_2): δ = 43.7 [s, P(C_6H_5)].

[Ru(PPh$_3$)($'N_3H_3S_2'$-Me$_2$)](I)(Cl) (12) by Protonation of 11: Hydrochloric acid (0.50 mmol, 5 mL of a 0.1 M solution of HCl in H_2O) was added to a yellow suspension of [Ru(PPh$_3$)($'N_3H_2S_2'$-Me$_2$)]I (**11**) (0.04 g, 0.05 mmol) in MeOH (15 mL). The reaction mixture was stirred for 5 min. Removal of the solvents yielded a yellow powder (0.04 g). – MS (FD, CH_2Cl_2, ^{102}Ru); *m/z*: 711 [Ru(PPh$_3$)($'N_3H_3S_2'$-Me$_2$)]$^+$, 695 [Ru(PPh$_3$)($'N_3H_2S_2'$-Me)]$^+$, 681 [Ru(PPh$_3$)($'N_3H_3S_2'$)]$^+$. – ^{1}H NMR (CD_2Cl_2): δ = 9.57 (t, br., 1 H, NH arom.), 9.37 (s, br., 1 H, NH arom.), 7.80–7.04 [m, 24 H, C_6H_4, P(C_6H_5) and NH superimposed], 3.96–2.82 (m, 8 H, C_2H_4), 2.29 (s, 3 H, SCH_3), 1.84 (s, 3 H, SCH_3). – ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 151.9, 151.4, 136.8, 134.3, 134.1 (d), 133.5 (d), 132.1, 131.9, 131.8, 131.2, 130.9, 129.6 (d), 129.2 (d), 128.8, 125.4, 125.1

Table 2. Selected crystallographic data of [Ru(PPh$_3$)('$N_3H_3S_2$'-Me$_2$)]I$_2$ · 2 CH$_2$Cl$_2$ (**8** · 2 CH$_2$Cl$_2$)

X-ray Structure Analysis of [Ru(PPh$_3$)('$N_3H_3S_2$'-Me$_2$)]I$_2$ · 2 CH$_2$Cl$_2$ (8 · 2 CH$_2$Cl$_2$): Bright green columns of [Ru(PPh$_3$)('$N_3H_3S_2$'-Me$_2$)]I$_2$ · 2 CH$_2$Cl$_2$ (**8** · 2 CH$_2$Cl$_2$) were grown from a saturated CH_2Cl_2 solution of **8** which was layered with *n*-hexane. A suitable single crystal was sealed under N_2 in a glass capillary, and data were collected with a Siemens P4 diffractometer. The structure was solved by direct methods (SHELXTL-PLUS).[20] Full-matrix least-squares refinement was carried out on F^2 values (SHELXL-93).[21] The hydrogen atoms were located in a difference Fourier synthesis and isotropically refined. The hydrogen atoms of the CH_2Cl_2 solvate molecules were calculated for ideal geometries. Their isotropic temperature factors were fixed at 1.5 times the value for the C atoms attached to them. For the atom Cl41, an obvious alternative position exists, which, however, could not be refined. Table 2 contains selected crystallographic data for [Ru(PPh$_3$)('$N_3H_3S_2$'-Me$_2$)]I$_2$ · 2 CH$_2$Cl$_2$ (**8** · 2 CH$_2$Cl$_2$).[22]

Local Density Functional Study of Copper Clusters: A Comparison between Real Clusters, Model Surface Clusters, and the Actual Metal Surface

Xavier Crispin,*[a] Christophe Bureau,*[b] Victor Geskin,[a] Roberto Lazzaroni,[a] and Jean-Luc Brédas*[a]

Keywords: Copper clusters / Cu(100) surface / Chemical hardness / Relaxation energy / Size effect

Density Functional Theory is used to study the influence of the size of copper clusters modeling the Cu(100) surface, on the electronic properties: ionization potential, electron affinity, electronic chemical potential, and chemical hardness. The model clusters are chosen to have a bilayer structure and range in size from 9 to 20 copper atoms. The chemical hardness being identified as the relaxation energy of the frontier levels when an electron is removed or added to the system, a simple expression is proposed to estimate its value from the eigenenergies of the frontier levels in neutral and partially ionized systems. A detailed comparison of the geometric and electronic structures is made between the model surface copper clusters, real copper clusters, and the actual metal surface; it is seen that the model surface clusters provide an easy extrapolation to the properties of the metal surface.

Introduction

Metal clusters are increasingly exploited as surface models to study surface reactions. The size dependence of their electronic properties and reactivities therefore attracts major interest from both fundamental and applied standpoints, especially since clusters provide a bridge between the properties of metal atoms and those of the infinite metallic solid, between homogeneous catalysis and heterogeneous catalysis.[1−6] To study the mesoscopic world between the metal atom and the metal solid, a traditional approach is to evaluate the properties of *real* metal clusters with intermediate sizes and to build a rationalization of the evolution of these properties. With real metal clusters, direct comparison between theory and experiment is possible; however, real clusters are shape-distorted spheres and thus present geometric structures (interatomic distances, packing structures) and electronic properties that can be much different from those of (infinite) metal surfaces. As we ultimately aim at studying reactions at metal surfaces, we have investigated size effects for metal clusters modeling metal surfaces; the geometric structure of such *model* clusters is chosen to represent a portion of the surface: they are flat (generally bilayered) and extended into two dimensions. The comparison between such an approach based on flat *model* clusters and the traditional approach using *real* clusters is interesting since both must extrapolate to the same limit at infinite size.

Among transition metal clusters, copper clusters are probably those that are most studied because of the apparent simplicity of the copper atom, which can be seen in a first approximation as monovalent (the 3d bonding and antibonding orbitals in a copper cluster are all filled). Numerous experimental measurements and theoretical studies of increasing sophistication have been performed on the size evolution of the properties of real copper clusters, such as ionization potential, electron affinity, and band gap.[7−12] Early theoretical approaches, such as the corrected classical model,[13] in which the cluster is considered as a perfect conducting sphere, fail to reproduce the behavior of electron affinity and ionization potential with cluster size.[14] Hence, a quantum mechanical treatment is needed to obtain a reliable average evolution of cluster properties, as shown in the semi-classical model of Brack.[14,15] The latter method is able to explore the properties of huge clusters (up to 10^6 atoms) since the nuclei are not explicitly considered; however, it only gives an average evolution of the properties as a function of the cluster size, fails for small clusters, and does not provide other electronic features (bond description, charge distributions, etc.). The semi-classical model can be refined within jellium models to take into account shell effects, where the valence electrons move in a spherical or a perturbed spherical potential modeling the positive charge due to the nucleus screened by core electrons, such as the Clemenger−Nilsson model.[3,4,16] Such jellium methods reproduce the shell effect and even-odd oscillations typical of real copper clusters,[7,9,12] which are not explained by the classical or semi-classical models; however, they are not reliable for very small metallic clusters (< 7 atoms) since the nuclei cannot be modeled with a jellium. Methods that take into account the positions of the nuclei are therefore necessary; they are more computationally demanding but adequate to study small copper clusters. Among these are the effective-medium methods[17] and other semi-empirical methods[18,19] as well as Hartree−Fock ab initio methods[20−23] and density functional theory-based methods.[24−29]

In the first part of this work, a density functional approach is used to analyze the size evolution of electronic

properties (ionization potential and electron affinity) of copper clusters as surface models. In contrast to previous theoretical works,[23,24,28,29] the clusters studied here are designed to model an adsorption site of the Cu(100) surface. Therefore, copper cluster systems studied here do not have the quasi-spherical shape of real copper clusters. The consequences of such a difference are analyzed, on the one hand, on the validity of the surface model, and on the other hand, on the ability to extrapolate the evolution of ionization potential and electron affinity with cluster size.

In the second part, the copper clusters are characterized in terms of global properties as defined within Density Functional Theory (DFT): the electronic chemical potential (μ) and chemical hardness (η). One of the highlights of the present work is to point out the relationship between hardness and relaxation energy of the valence levels when one electron is removed or added to the system; an estimate of hardness is proposed on the basis of the eigenenergies of the frontier levels of neutral and partially ionized systems. The evolutions of the chemical potential and hardness are analyzed with respect to the size of the clusters. Bureau et al.[30] have shown that the DFT chemical potential, μ, is particularly relevant to describe the interaction of a molecule with a metallic surface, should it be polarized or not: μ is the pertinent parameter both for mimicking the setting of a metallic surface under voltage under electrochemical conditions, and for the description of the charge transfer between the adsorbed species and the surface. The latter aspect is based on the relationship between DFT and the Lewis concept of acids and bases, as introduced by Pearson and Parr;[31,32] within this scheme, the hardness of the surface and the molecule, and the difference in their chemical potentials are essential parameters for the understanding of adsorption phenomena.[32–34] It is thus of primary interest to analyze the behavior of these properties (chemical potential, chemical hardness) with cluster size since we ultimately aim at using metal clusters as surface models to study the interaction between an organic molecule and a metal surface.

We emphasize that we have deliberately chosen to adopt a very pedagogical pace to introduce the concepts touched upon in this work. The validity and merits of our methodological approach can in this way be best assessed.

Methodology

The (100) Copper Surface

An adsorption site of the fcc crystal (100) surface is modeled with various copper clusters by considering sizes ranging from nine to twenty copper atoms (Figure 1). The interatomic distances are fixed at the bulk crystal values, so that all reconstruction phenomena are neglected. This choice of interatomic distances for the copper clusters designed to model the surface is obviously taken to simulate at best a site on the surface. Indeed, it is well known that the atomic density at the surface and thus the interatomic

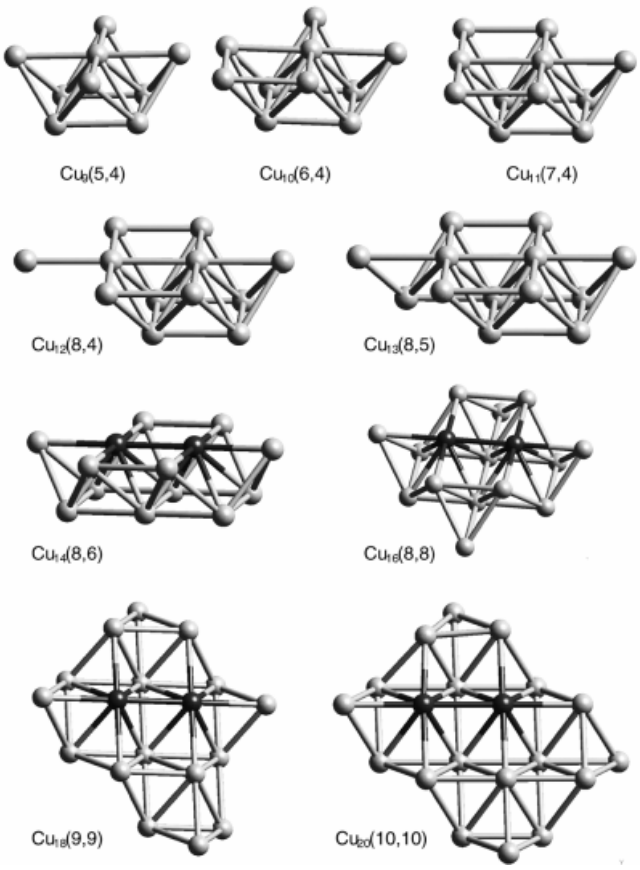

Figure 1. Representation of the copper clusters $Cu_n(y,w)$ used as models of the Cu(100) surface. The clusters are composed of two atomic layers; one containing *y* atoms and the other *w* atoms; from the fourteen-atom cluster, the two copper atoms in dark have the same nearest neighbors as a surface atom on the actual Cu(100) surface

distances can have a strong influence on the chemisorption energy of an adsorbate. This is illustrated by the different reactivities of different crystalline surfaces of transition metals.[35–37]

The clusters are bilayered; the smallest one is $Cu_9(5,4)$ (where the subscript indicates the total number of copper atoms in the cluster and the numbers in parentheses denote the composition of its layers, in this case, 5 atoms in the upper layer and 4 in the bottom layer); in $Cu_9(5,4)$, the central atom of the upper layer has the same number of nearest neighbors as on the actual (100) surface. Clusters $Cu_{10}(6,4)$, $Cu_{11}(7,4)$, and $Cu_{12}(8,4)$ are obtained by extending the upper layer; extending the bottom layer then leads to $Cu_{13}(8,5)$ and $Cu_{14}(8,6)$; $Cu_{14}(8,6)$ has two central atoms which have the same number of nearest neighbors as on the actual (100) surface. Larger clusters built from $Cu_{14}(8,6)$ are also considered: $Cu_{16}(8,8)$, $Cu_{18}(9,9)$, and $Cu_{20}(10,10)$.

Computational Approach

The calculations are performed in the framework of the density functional theory.[38,39] This method is a nonempirical approach, alternative to Hartree–Fock-based theories,

that presently enjoys a wide range of applications to chemical problems due to the possibility of including a significant part of the electron correlation energy; correlation is essential for a correct description of transition metal compounds. An extension of the Kohn−Sham theory describes the energy as a continuous function of the occupation of the monoelectronic levels;[40,41] this allows one to use fractional occupations to evaluate the derivatives of energy with respect to the number of electrons in the system. The evaluation of such derivatives is a way to estimate the electronic chemical potential and chemical hardness of copper clusters.

All the calculations were performed with the DMol program.[42,43] The basis set is DNP (double zeta numeric with polarization). The core orbitals are frozen during the SCF iterations and we choose a "MEDIUM" mesh size of the numerical grid for the calculations.[42,44,45] The calculations are performed within the local spin density approximation (LSD) with the Vosko−Wilk−Nusair exchange-correlation potential.[46] The ionization potential and electron affinity are calculated from total energy differences: $IP(n) = E_{tot}(Cu^+) - E_{tot}(Cu_n)$ and $EA(n) = E_{tot}(Cu_n) - E_{tot}(Cu^-_n)$ [note that, when using this convention, $EA(n) > 0$ means the anionic species is more stable than the neutral species]; the ions are maintained in the same geometry as the neutral copper clusters. The LSD approximation is known to give electron affinities and ionization potentials that are better than those obtained with Hartree−Fock methods[47,48] and in reasonable agreement with experimental data. Therefore, reliable trends for the evolution of electronic properties with respect to the size of the copper clusters can be expected from LSD calculations. Note that since the method is less computationally demanding than the gradient-corrected approximations, it allows us to consider relatively large clusters with all 3d, 4s and 4p atomic orbitals of Cu included in the basis set. The charge analysis used in this work comes from the Hirshfeld scheme, which is directly based on electronic density.[49,50]

Results and Discussion

The presentation of the results is divided into two parts. Firstly, we compare the electronic properties of the model clusters [representing a site of the copper (100) surface] to those of real copper clusters; the evolution of ionization potential (*IP*) and electron affinity (*EA*) as a function of cluster size is analyzed. Secondly, the electronic chemical potential (μ) and the chemical hardness (η) of copper clusters are evaluated and their evolution with cluster size is discussed.

Comparison between Real Copper Clusters, Surface-Model Clusters, and the Metal Surface

In this section, the $Cu_n(y,w)$ clusters modeling the Cu(100) surface are compared to the corresponding real clusters Cu_n, in terms of geometric structure and behavior of *EA* and *IP* with cluster size. The main geometric differences are the interatomic distances and the overall shape of the clusters; their consequences on the electronic properties are described below.

Small real copper clusters (<10 atoms) have significantly shorter interatomic distances[22,27,28] than those in the bulk (nearest-neighbor distance of 2.55 Å). The mean interatomic distance in real copper clusters tends to increase when the cluster grows. As far as the atomic packing is concerned, the fcc structure is found to be the most stable for clusters larger than thirteen atoms with interatomic distances close to those of the bulk metal.[51] Hence, the contraction of the interatomic distances is significant only for small clusters.

The interatomic distances used in the model clusters are the same as those in the bulk (thus larger than the distances of the corresponding real clusters), and their structure is fcc. Note that the use of non-optimized clusters has some unexpected consequences: in the spin-unrestricted calculations, some clusters with an even number of atoms are more stable in their triplet state, whereas real copper clusters with an even number of atoms are expected to be singlet. The total spin of the most stable states found in the odd-clusters (i.e., having an odd number of atoms), namely Cu_9(5,4), Cu_{11}(7,4), and Cu_{13}(8,5), is always 1/2. For the even-clusters, the spin of the most stable state is one for Cu_{10}(6,4), zero for Cu_{12}(8,4), one for Cu_{14}(8,6), one for Cu_{16}(8,8), and zero for Cu_{18}(9,9) and Cu_{20}(10,10). Nevertheless, it must be noted that the total energy of the first singlet state for Cu_{10}(6,4), Cu_{14}(8,6), and Cu_{16}(8,8) is always very close to that of the first triplet state. The fact that we obtain triplet states for these clusters results from the quasi-degeneracy of the one-electron levels near the highest occupied molecular orbital, which is a consequence of the large interatomic distances used and the non quasi-spherical symmetry of the clusters, as explained below.

The ionic species Cu^-_n and Cu^+_n used to calculate $EA(n)$ and $IP(n)$ are more stable in a state having a spin multiplicity of either one or two. The spin multiplicity is one for the anionic or cationic odd-clusters, and two when the ionic species have an even number of copper atoms. No spin-multiplicity difference among the charged even-clusters is observed, in contrast to the neutral clusters.

1. Size Dependence of EA and IP: We now consider the evolution of electron affinity and ionization potential with the size of copper clusters. These two properties are expected to converge on increasing the cluster size since both become equal to the workfunction at infinite size where the cluster is truly metallic, with no electronic gap. In Figure 2, we compare the *EA* values calculated for the $Cu_n(y,w)$ clusters to those measured experimentally from the ionization threshold of real anionic clusters.[7,9] In the experimental work, the energy needed to remove an electron from the anionic cluster was associated to the opposite of the electron affinity of the neutral cluster; as it is a vertical evaluation of *EA*, these experiments in fact provide the *EA* of the neutral cluster in the geometry of the anionic cluster. Note that the presence of an extra electron globally increases the interatomic distances; this is closer to our theo-

retical situation since the interatomic distances of the $Cu_n(y,w)$ clusters are those of the bulk (known to be larger than in small neutral clusters). It can be seen in Figure 2 that the theoretical values of *EA* and the experimental data lie in the same energy range; such an overall agreement is an indication of the ability of our method to evaluate *EA*.

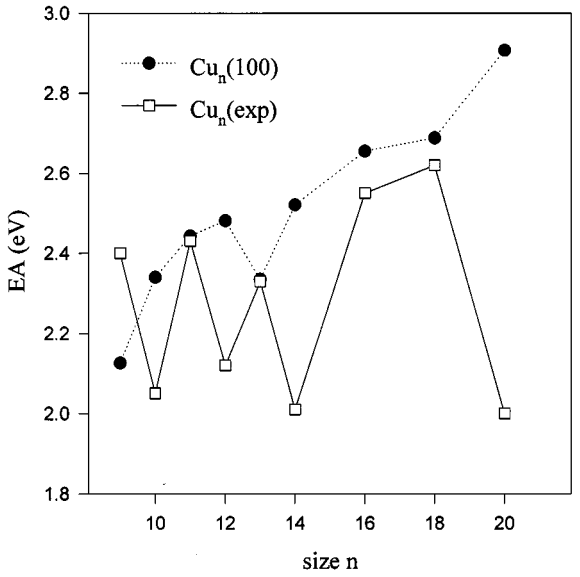

Figure 2. Comparison between the calculated electronic affinities (*EA*) of the copper clusters $Cu_n(y,w)$ ($n = 9 - 20$) modeling the (100) surface and the experimental values for the corresponding real copper clusters

Some errors are expected to be introduced by the LSD and frozen-core approximations used in our calculations. The magnitude of this error can be estimated by comparing the experimental vertical *EA* provided by ultraviolet photoelectron spectroscopy (UPS) measurements on the anionic copper dimer[8] to the calculated value EA_{cal}. EA_{cal} is the difference between the total energy of the anionic copper dimer whose geometry was optimized and the total energy of the neutral copper dimer in the geometry of the anionic species. The experimental vertical *EA* of Cu_2 is 0.89 ±0.01 eV, while the calculated *EA* is 0.80 eV. That the error in the evaluation of the electron affinity for Cu_2 is small (0.1 eV), again illustrates the ability of the method we apply to calculate such a property.

The most striking feature of Figure 2 is the oscillating behavior of the experimental curve, which is not reproduced in the calculations. In order to understand this difference, it is necessary to briefly recall basic theoretical models describing real copper clusters. Real copper clusters (>7 atoms) tend to adopt an equilibrium geometry consisting of either a sphere or a distorted sphere. This was demonstrated theoretically for copper clusters up to 29 atoms by searching the most stable geometry using a simulated annealing approach coupled to an effective-medium method.[17] Although strong 3d-4s hybridization occurs for some small copper clusters, which affects their electronic structure and geometry,[27] it has been shown that the Cu−Cu bonds are mainly due to the overlap of 4s atomic orbitals, as mentioned for Cu_2.[26,52] Various theoretical studies aiming at explaining experimental data have used the following crude but reasonable approximation (e.g. refs.[9] and[12]): copper atoms are considered as monovalent in clusters; as a consequence, the number of valence electrons involved in a cluster is the same as the number of copper atoms in the cluster. In this approximation, the 4s valence electrons of an ideal spherical copper cluster are confined in a spherically symmetric potential (spherical jellium model). Because of its symmetry, such a potential gives rise to a spherical shell structure where the valence electrons successively fill the degenerate levels. The electronic system of a cluster with exactly the right number of electrons to complete a shell is very stable. This is the case when the number of 4s electrons is for instance 8 or 20; the corresponding clusters (Cu_8, Cu_{20}) are thus very stable: this is called the "shell effect" and the numbers 8 and 20 are called "magic numbers (n_g)". This can be experimentally related to the high relative abundance in the mass spectrum for the anionic species of ($n_g - 1$) atoms, like 7 and 19,[7,8] and for cationic species of ($n_g + 1$) copper clusters, like 9 and 21;[53] such stable ions have a completely filled shell. When one atom is added to a Cu_8 or Cu_{20} neutral cluster, its valence electron occupies a degenerate state with considerably higher energy, and hence the stability of the cluster is reduced. In such a case, the cluster symmetry is reduced into a distorted sphere in order to minimize the energy (Jahn−Teller-like effect).[17,54] For each system, the structure distorts to maximize the gap at the Fermi level under the constraints set up by other energy contributions. For even-numbered clusters, there are two electrons in the HOMO and thus the energy gain due to the distortion is larger, resulting in a larger gap.[17] This interplay between the electronic system and the geometry of the cluster allows some clusters to be very stable without having a "magic number" of atoms.

As shown by Pettiette et al.,[9] the low electron affinity of magic-size copper clusters with respect to the *EA* of the neighboring sizes, as well as the even-odd oscillations of experimental *EA* values, can be explained qualitatively within a monoelectronic scheme with Koopmans' theorem thanks to jellium models:

(i) The sudden decrease in *EA* for magic sizes (Cu_{20}) can be understood by considering the shell structure appearing when valence electrons move in a spherical potential; the *EA* for $n = 20$ is lower than that for size $n - 1 = 19$, since an additional electron must occupy a new shell of higher energy. For surface models $Cu_n(y,w)$, no shell structure is expected since the shape is not spherical but flat. This explains why $Cu_{20}(10,10)$, corresponding to a magic size for real clusters, does not have a low calculated *EA*. As a consequence, *EA* for size 20 differs most importantly with respect to experiment (ca. 1 eV) (Figure 2).

(ii) The magnitude of the even-odd oscillations is about 0.5 eV in small real copper clusters; these oscillations decrease when the size increases and disappear at the bulk limit. To qualitatively understand the even-odd oscillations, Taylor et al.[12] refer to the case of monovalent, non-fully symmetrical clusters, thus with no degeneracy in the energy levels. In the even-numbered neutral clusters, the HOMO is

doubly occupied while the odd-numbered neutral clusters are open-shell species. To a first approximation, the extra electron, which makes the cluster negative, would either occupy the lowest unoccupied molecular orbital (LUMO) of the even-numbered clusters or fill the HOMO of the odd-numbered clusters. Such an effect will result into lower *EA* for the even-atom clusters.

The lack of even-odd oscillations in the theoretical curve (Figure 2) can be understood on the basis of the density of valence states (DOS) of the $Cu_n(y,w)$ surface models. The calculated DOS of the model $Cu_{10}(6,4)$ cluster and that of the real $Cu_{10}^{D_{4d}}$ cluster (both shown in Figure 3), as well as the experimental photoemission spectrum of Cu(100),[19,55] are presented in Figure 4 [the DOS of the copper clusters are obtained by enveloping the DFT eigenvalue spectrum with Gaussians of width 0.1 eV and we use Löwdin's decomposition[56] to obtain local DOS (LDOS); note also that the Fermi level is set at zero energy]. The comparison between these DOS and the experimental spectrum shows, on the one hand, strong differences between the DOS of $Cu_{10}^{D_{4d}}$ and that of $Cu_{10}(6,4)$, and, on the other hand, the similarity between the DOS of $Cu_{10}(6,4)$ and the experimental photoemission spectrum of Cu(100). For both copper clusters, the most important region of d monoelectronic states lies in the −4,0 to −1,3 eV range, between hybridized s-p states. Two main differences appear between the DOS of the two copper clusters: the global shape and the electronic gap. The DOS spectrum of the real cluster $Cu_{10}^{D_{4d}}$ shows weakly overlapping peaks, while the DOS of the 3 d states of $Cu_{10}(6,4)$ is non-vanishing in the entire −3 to −1 eV energy range, where these states are almost exclusively concentrated; these features are present in the total DOS of all $Cu_n(y,w)$ clusters studied here. The lower symmetry of $Cu_n(y,w)$ relative to spherical clusters, is responsible for the more uniform, in general, distribution of the monoelectronic states, i.e. the absence of the degenerate levels. The fact that the 3d states of $Cu_{10}(6,4)$ are mainly localized at higher energy is related to the chemical saturation (the number of the nearest neighbors) of the copper atoms in the clusters. Indeed, Figure 5 shows that the lower the saturation of the copper atoms, the more they are involved in 3d states of high energy: the local DOS corresponding to molecular orbitals involving 3d atomic orbitals centered on the peripheral atoms of the top layer (3 or 4 nearest neighbors) are mainly in a range of higher energy than the local DOS related to the peripheral atoms of the bottom layer (5 or 6 nearest neighbors); it is the local DOS related to the most saturated atom, i.e. the central atom with 8 nearest neighbors, that spreads over the widest range of energy. Hence, since every atom is saturated almost equally in $Cu_{10}^{D_{4d}}$, its DOS does not display the specific concentration of 3d valence states in a range of high energy as for $Cu_{10}(6,4)$.

The other main difference between the eigenvalue spectrum of $Cu_{10}^{D_{4d}}$ and that of $Cu_{10}(6,4)$ is the significant electronic gap for the real cluster (Figure 4), while for our surface model the electronic gap is vanishingly small; extremely small gaps are actually observed for all $Cu_n(y,w)$ surface models, since these clusters do not have spherical or quasi-spherical symmetry. This is why the evolution of $IP(n)$ and $EA(n)$ for these clusters does not show shell effects and even-odd oscillations. The removal of such strong oscillations in $EA(n)$ [and also in $IP(n)$] is actually a major advantage when the average behavior of these properties needs to be extrapolated to larger cluster sizes.

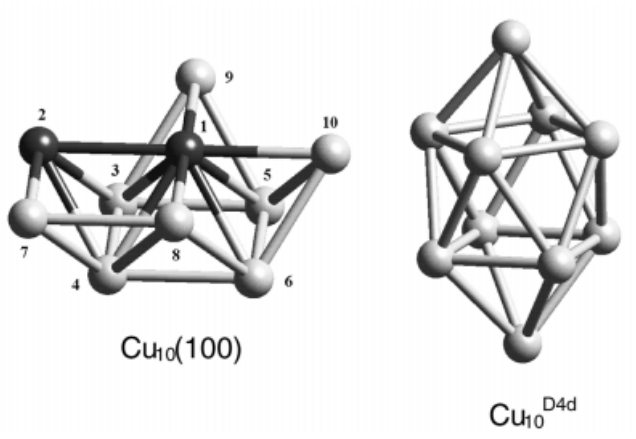

Figure 3. Geometric structures of the surface model $Cu_{10}(6,4)$ and of the corresponding real cluster $Cu_{10}^{D_{4d}}$

In Figure 4, we observe a narrower distribution of the 3d and 4s states in the DOS of $Cu_{10}(6,4)$, relative to that in the experimental spectrum of Cu(100). This is due to two major reasons: first, the model cluster is not large enough to represent the metal; secondly, the application of Koopmans' theorem is not strictly valid for the DFT eigenvalues, since Janak has shown that these eigenvalues rather correspond to the derivative of the total energy with respect to the occupation of orbitals[40]. However, the striking similarity between the DOS of $Cu_{10}(6,4)$ and the experimental spectrum for Cu(100), along with the difference relative to the DOS of $Cu_{10}^{D_{4d}}$, is a favorable argument for considering the $Cu_n(y,w)$ surface models appropriate (and better than real clusters) to model the (100) copper surface.

2. Exploration of the Mesoscopic Size Copper Clusters: Here, we take advantage of the weak oscillations observed in the evolution of $EA(n)$ and $IP(n)$ for the $Cu_n(y,w)$ surface models to explore the mesoscopic region. Properties of large copper clusters are thus deduced from the properties calculated for small model copper clusters.

It has been shown that the evolution of the properties of real clusters, such as the cohesive energy, ionization potential, and electron affinity, can be described with a convergent series whose variable is the number of atoms (n) in the cluster.[57] When neglecting high-order terms, the truncated expansion contains only one unknown coefficient (A) and shows that a property G(n) evolves as a function of $n^{-1/3}$:

$$G(n) = G(\infty) + A \cdot n^{-1/3} \quad (1)$$

The exponent of n is thought to be related to the ratio between the surface and the volume of the cluster, as suggested by Müller et al.[57]. The exponent is therefore ap-

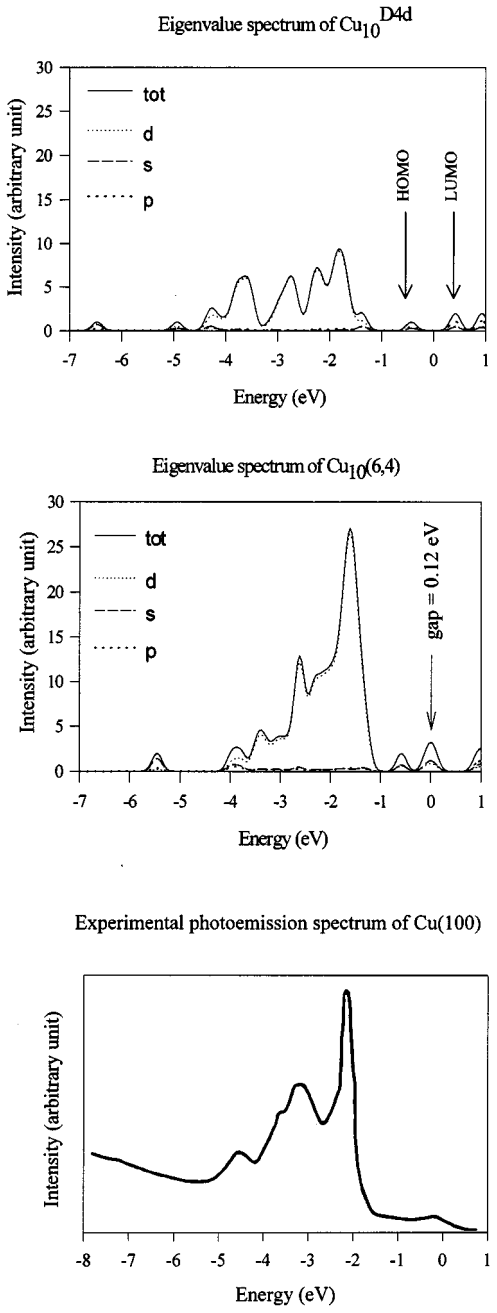

Figure 4. Comparison between the calculated total density of valence states (DOS) of $Cu_{10}^{D_{4d}}$, that of $Cu_{10}(6,4)$ and the experimental photoemission spectrum of Cu(100).[19,55] The total densities of valence states are enveloped with Gaussians of width 0.1 eV and their decomposition in local density of states (LDOS) is obtained from the scheme by Löwdin. The local density of states corresponding to molecular orbitals including 4s atomic orbitals is shown as a dashed line, the 4p component as a thick-dotted line and the 3d component as a thin-dotted line. The Fermi level is set at zero energy.

proximately $-1/3$ for real clusters, which are often almost spherical. Although the $Cu_n(y,w)$ surface models are not spherical, we also use $-1/3$ as the exponent, for the sake of simplicity and to allow a comparison with previous work dealing with real copper clusters[7–9,11]. The average behavior of $IP(n)$ or $EA(n)$ as a function of size (n) of the clusters can thus be expressed as follows: $EA(n) = W_{Cu} + B \cdot n^{-1/3}$ and $IP(n) = W_{Cu} + C \cdot n^{-1/3}$, where W_{Cu} is the workfunction of polycrystalline copper (4.65 eV).

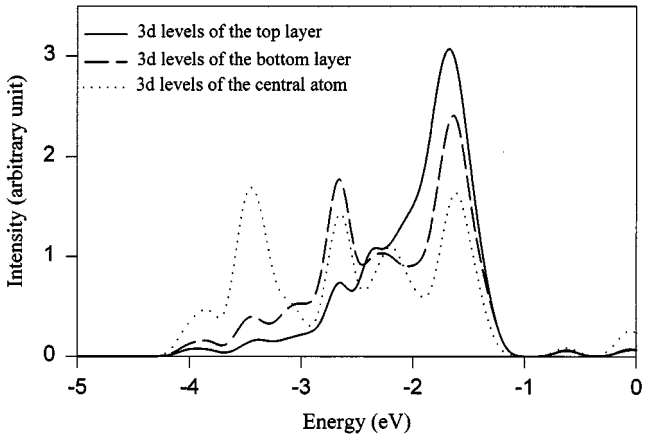

Figure 5. Local density of states (LDOS) from the d component of $Cu_{10}(6,4)$ localized on different regions of the cluster: (i) the peripheral atoms of the top layer (atoms labeled 2, 7, 8, 9, 10 in Figure 3) (full line); (ii) the peripheral atoms of the bottom layer (3, 4, 5, 6) (dashed line); and (iii) the central atom (1) (dotted line).

Accurate descriptions of the average evolution of $EA(n)$ and $IP(n)$ are obtained by imposing the condition that the curves $EA(n) = W_{Cu} + B{*}n^{-1/3}$ and $IP(n) = W_{Cu} + C \cdot n^{-1/3}$ pass through the experimental bulk limit ($n^{-1/3} = 0$, $W_{Cu} = 4.65$ eV), see Figure 6. Coefficients B and C are determined from linear regressions, which yields the following expressions:

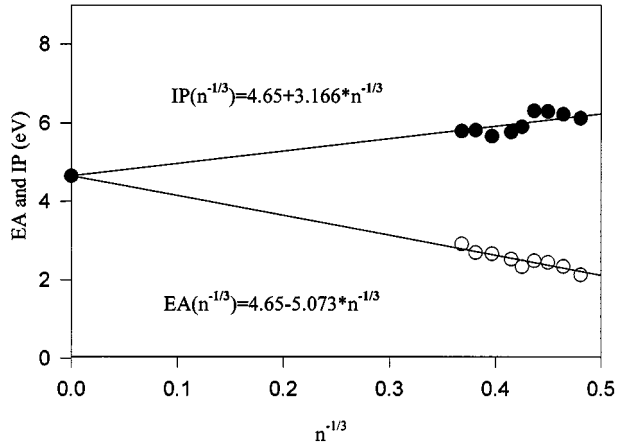

Figure 6. Evolution of calculated $EA(n)$ (open circles) and $IP(n)$ (full circles) with the size n of the cluster $Cu_n(y,w)$. The straight lines represent the average evolution of these properties with size, as obtained by the method described in the text. The intersection point between the average evolution of $IP(n)$ and that of $EA(n)$ is set at the workfunction of polycrystalline copper ($W_{Cu} = 4.65$ eV).

$$EA(n) = 4.65 - 5.073 \cdot n^{-1/3} \quad (2a)$$

$$IP(n) = 4.65 + 3.166 \cdot n^{-1/3} \quad (2b)$$

Note that if the linear regressions are performed without imposing the curve to pass through ($n^{-1/3} = 0$, $W_{Cu} = 4.65$ eV), the extrapolated values for the workfunction of copper is found to be 4.34 eV; this is as good an estimate as those found for the workfunction of other metals from jellium calculations in the LSD approximation (VWN func-

tional).[58,59] Since oscillations are very weak for large copper clusters, the average evolution of $EA(n)$ or $IP(n)$ given by these expressions is expected to follow closely the real evolution. Therefore, we believe that calculations on small copper clusters can provide valuable estimates of the properties of large copper clusters, by means of the above interpolation formulae.

An argument in favor of the validity of the calculated coefficients is that the ratio between coefficient B for $EA(n)$ and C for $IP(n)$, i.e. B/C = −5.073/3.166, is very close to that observed in various experimental studies (−5/3)[8,11]. The average behavior of $IP(n)$ and $EA(n)$ can be evaluated from the limited sample of $Cu_n(y,w)$ (n = 9−20) clusters studied here because the absence of spherical symmetry induces small electronic gaps and thus a rather linear evolution of $IP(n)$ and $EA(n)$ vs. $n^{-1/3}$. The simple expressions describing the average evolution of $IP(n)$ and $EA(n)$ will thus be used below to describe the behavior of the chemical potential of the clusters.

Size Dependence of Chemical Potential μ(n) and Hardness η(n)

1. Evaluation of Chemical Potential and Hardness; Relation with Other Electronic Properties: The chemical potential and the hardness or softness of the clusters are important parameters for describing the physics and chemistry of metal clusters. Firstly, various studies have shown that the softness, a global property measuring the response of a system to the change in the number of electrons at fixed external potential, is directly related to the static dipole polarizability α, a measure of the response of the electron cloud to the change in external potential (modification of external electric field) at a fixed number of electrons.[60−66] Secondly, the chemical potential and the hardness are related to the reactivity and the charge transfer between the metal cluster and an adsorbate upon chemical bond formation.[34,67] Moreover, Ghanty et al. noticed that the condition of maximum hardness, which can be regarded as a criterion of stability,[68] can in general be associated to the minimum polarizability.[69] Thus, the chemical reactivity could be guided by the evolution of hardness or polarizability upon reaction.

In this section, we show the relation between hardness and relaxation of valence levels when an electron is added or removed from the electronic system. We then propose various ways to estimate these properties and calculate the hardness $\eta(n)$ and chemical potential $\mu(n)$ for the $Cu_n(y,w)$ copper clusters.

We first consider a neutral cluster containing n copper atoms, with N_0 electrons explicitly taken into account in the calculations; here, $N_0 = 11 \cdot n$, since 11 electrons per atom are not frozen. Janak showed that the DFT total energy can be seen as a continuous function of the occupation vector and thus of the number of electrons, N, in the system.[40] The total energy of Cu_n^{+x}, $E(n, N = N_0 - x)$, obtained by the removal of a negative charge $x|e|$ (x is not necessarily an integer), can be expressed from the total energy of the neutral cluster, $E(n,N_0)$, by means of a series:[38,67]

$$E(n, N = N_0 - x) = E(n, N_0) - x\left(\frac{\partial E}{\partial N}\right)_{N=N_0} + (x^2/2)\left(\frac{\partial^2 E}{\partial N^2}\right)_{N=N_0} - R(x^3) \quad (3)$$

$R(x^3)$ contains the higher-order terms of the series. An analogous expression can be written when considering the addition of a partial charge x. We recall that, in DFT, the first derivative of the expansion, $(\delta E/\delta N)_{N = N_0}$, considering either charge removal or addition, is defined as the electronic chemical potential $\mu(n)$;[70] while half of the second derivative, $1/2(\delta^2 E/\delta N^2)_{N = N_0}$, corresponds to the absolute hardness[32] $\eta(n)$ or half of the inverse of the softness $[2S(n)]^{-1}$. The chemical potential, i.e., the opposite of the electronegativity, and the hardness can also be obtained in the finite difference approximation:[32]

$$\mu(n) \approx -\frac{IP(n) + EA(n)}{2} \; ; \quad \eta(n) \approx \frac{IP(n) - EA(n)}{2} \quad (4)$$

As discussed by several authors,[41,71−74] electronic open-shell systems have a single chemical potential while closed-shell systems do not have a unique chemical potential. Indeed, for the latter, the removed electron comes from the HOMO level while the added electron goes to the LUMO level. As a consequence, the derivative (at x = 0) of the energy with respect to the charge removed from the system, i.e. the chemical potential denoted μ^+, corresponds to the HOMO energy, according to Janak′s theorem;[40] similarly, the derivative of the energy with respect to the charge added to the system, i.e. μ^-, corresponds to the LUMO energy.

$$\mu^+(n) = \left(\frac{\partial E(n,N)}{\partial(N_0 - x)}\right)_{N_0^+} = \varepsilon_{HOMO}(n, N_0) \quad (5a)$$

$$\mu^-(n) = \left(\frac{\partial E(n,N)}{\partial(N_0 + x)}\right)_{N_0^-} = \varepsilon_{LUMO}(n, N_0) \quad (5b)$$

For closed-shell systems, the injection of Equations 5 into Equation 3 allows the definition of the ionization potential and electron affinity:

$$IP(n) = E(n,N_0 - 1) - E(n,N_0) = -\varepsilon_{HOMO}(n,N_0) + E^+_{rel}(n) \quad (6a)$$
$$-EA(n) = E(n,N_0 + 1) - E(n,N_0) = \varepsilon_{LUMO}(n,N_0) + E^-_{rel}(n) \quad (6b)$$

$E^+_{rel}(n)$ and $E^-_{rel}(n)$ are the relaxation energy when an electron is removed from the HOMO level and the relaxation energy when an electron is added to the LUMO of the cluster of size n, respectively. The relaxation energies, as defined here, are expressed as follows:

$$E^+_{rel(n)} = \eta^+(n) + R^+(n) = IP(n) + \varepsilon_{HOMO}(n,N_0) \quad (7a)$$
$$E^-_{rel(n)} = \eta^-(n) + R^-(n) = -EA(n) + \varepsilon_{LUMO}(n,N_0) \quad (7b)$$

where $R^+(n)$ and $R^-(n)$ are the values of the higher-order terms $R(x^3)$ in the series (Eq. 3) for $x = 1$ when the electron is removed or added to the system, respectively:

$$R^+(n) = \sum_{i=3} \frac{(-1)^i}{i!} \left(\frac{\partial^i E}{\partial N^i} \right)_{N=N_0} \quad (8a)$$

$$R^-(n) = \sum_{i=3} \frac{1}{i!} \left(\frac{\partial^i E}{\partial N^i} \right)_{N=N_0} \quad (8b)$$

When $R^+(n)$ and $R^-(n)$ can be neglected, the relaxation energy of the valence levels is directly related to the hardness of the electronic system. In this approximation, *we propose a new expression for the hardness*, which can be written as:

$$\eta_{ED}{}^+(n) = \frac{1}{2} \left(\frac{\partial^2 E(n,N)}{\partial (N_0 - x)^2} \right)_{N_0^+} \cong IP(n) + \varepsilon_{HOMO}(n,N_0) \quad (9a)$$

$$\eta_{ED}{}^-(n) = \frac{1}{2} \left(\frac{\partial^2 E(n,N)}{\partial (N_0 + x)^2} \right)_{N_0^-} \cong -EA(n) - \varepsilon_{LUMO}(n,N_0) \quad (9b)$$

The hardnesses estimated using Equation 9 are denoted $\eta_{ED}(n)$, since the ionization potential and electron affinity are evaluated as total energy differences (ED).

The *IP* and *EA* values can also be calculated using Slater's transition state concept;[75−77] the simplest approach is to consider the opposite of the eigenenergy of the HOMO-[LUMO] coming from the neutral system, when this orbital is occupied by half of an electron, as the value of the ionization potential [electron affinity]. Consequently, the hardnesses of a system can be estimated only from the eigenvalues of the frontier orbitals for neutral and partially ionized systems:

$$\eta^-{}_{Slater}(n) \approx -\varepsilon_{HOMO}(n,N_0 - 1/2) - \varepsilon_{HOMO}(n,N_0) \quad (10a)$$
$$\eta^+{}_{Slater}(n) \approx -\varepsilon_{LUMO}(n,N_0 + 1/2) - \varepsilon_{LUMO}(n,N_0) \quad (10b)$$

Since, for the copper clusters we study here, the HOMO −LUMO gap is very small (as discussed above), we may consider in a first good approximation that unique (average) first and second derivatives of the energy can satisfactorily characterize the chemical potential and absolute hardness of the copper clusters (closed-shell and open-shell). Hence, the HOMO and LUMO eigenenergies written in the above relations can be replaced by the chemical potential of the copper clusters. This approximation becomes increasingly accurate for closed-shell systems as the size of the cluster expands, the electronic structure then approaching that of the metal, for which the chemical potential of the electrons and hardness are well-defined concepts[33]. Taking this approximation and neglecting the high-order terms $R(x^3)$ of the series in Eq. 3, the total energy difference, $[E(n, N_0 - x) - E(n, N_0)]$, displays a parabolic dependence on charge x:

$$[E(n,N_0 - x) - E(n.N_0)] = -\mu(n)x + \eta(n)x^2 \quad (11)$$

For $x = -1|e|$ and $x = 1|e|$, i.e. in the finite-difference approximation, Equation 11 provides $EA(n)$ and $IP(n)$ values that can be recombined to express $\mu(n)$ and $\eta(n)$ as in Equation 4. In order to improve on the accuracy of $\mu(n)$ and $\eta(n)$ with respect to the definitions given in Equation 4, we have considered a set of charges x ($x = -1|e|$; $x = -0.5|e|$; $x = 0|e|$; $x = 0.5|e|$; $x = 1|e|$) and interpolated the SCF total energy difference $[E(n,N_0 - x) - E(n,N_0)]$ through the second-order polynomial of Equation 11, for each size n of the clusters. The chemical potential and hardness of $Cu_n(y,w)$ clusters resulting from the above interpolation are denoted below $\mu(n)$ and $\eta(n)$ (without any indices).

Figure 7 shows the calculated $[E(n,N_0 - x) - E(n,N_0)]$ for $Cu_{20}(10,10)$ carrying different charges, together with the second-order fit. The value of the first derivative of this expression for $x = 0$ gives an estimate of the electronic chemical potential of the cluster $[-\mu(20)]$ while the curvature of the parabola (Eq. 10) is an estimate of the hardness of the cluster $[\eta(20)]$. The graph of Figure 7 provides the values of *EA*, *IP*, and μ for $Cu_{20}(10,10)$: respectively 2.9 eV, 5.8 eV, and −4.4 eV. We obtain the trend that the differences between $IP(20)$ and $-\mu(20)$ or between $-EA(20)$ and $\mu(20)$ are mainly related to the hardness $\eta(20)$ and only weakly depend on the higher terms R in the expressions 7a and 7b: $\{IP(20) - [-\mu(20)]\} = 1.43$ eV and $[-\mu(20) - EA(20)] = 1.45$ eV are both very close to the curvature of the parabola $\eta(20) = 1.44$ eV.

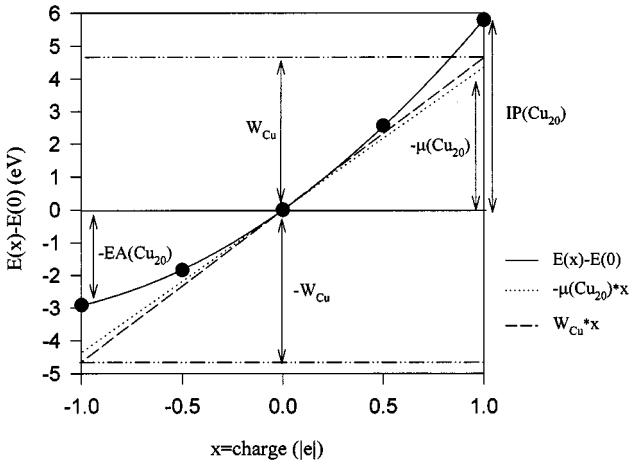

Figure 7. Calculated total energy of $Cu_{20}(10,10)$ as a function of charge x (full circles). The parabola interpolated from the calculated points (Equation 11) is represented by a full line. The dotted line represents the tangent of the parabola at the origin, which corresponds to $[-\mu(Cu_{20}) \cdot x]$, and the dashed line represents $[W_{Cu} \cdot x]$. The arrows point to specific values, such as $IP(Cu_{20})$, $EA(Cu_{20})$, and $\mu(Cu_{20})$.

We now apply the relations defined above and compare the results to those obtained from the interpolation using Equation 11. Table 1 lists the energies of the HOMO and LUMO levels as a function of cluster size as well as the chemical potentials estimated from the slope at the origin of the interpolated parabola (Eq. 11). The μ values are very close to the HOMO or LUMO energies of the neutral $Cu_n(y,w)$ clusters. This confirms that Equation 11 is a

reasonable way to determine the chemical potential [we note that both frontier orbital energies are given in Table 1 since: (i) the calculations were performed at the unrestricted level; and (ii) the copper clusters having an even number of atoms are not necessarily closed-shell systems].

Table 1. Comparison between the chemical potential $\mu(n)$, estimated as the slope at the origin of the interpolated parabola described by Equation 11, and the eigenenergies of the frontier orbitals of the neutral copper clusters $Cu_n(y,w)$ with $n = 9-20$. All the electronic properties are given in eV.

n	$\mu(n)$	$\varepsilon_{HOMO}(n,N_0)$	$\varepsilon_{LUMO}(n,N_0)$
9	−4.13	−4.13	−4.02
10	−4.29	−4.30	−4.18
11	−4.37	−4.41	−4.26
12	−4.36	−4.51	−4.19
13	−4.12	−4.16	−4.03
14	−4.16	−4.18	−4.15
16	−4.17	−4.21	−4.07
18	−4.25	−4.23	−4.17
20	−4.36	−4.41	−4.38

Table 2 compares the energies of the frontier levels when they are occupied by half an electron with the electron affinity and ionization potential coming from total energy differences. The results show that the use of Slater′s transition state gives the right order of magnitude for the ionization potential and electron affinity. However, this simple approximation introduces some inaccuracy in the estimates of EA [err$|EA - \varepsilon_{LUMO}| = 0.28$ eV] and IP [err$|IP - \varepsilon_{HOMO}| = 0.14$ eV] and, consequently, also in Equations 10 which gives the hardness η_{Slater}.

Table 2. Comparison between the electron affinity (EA) and ionization potential (IP) of the $Cu_n(y,w)$ clusters, calculated using total energy differences and with the eigenenergies of the HOMO and LUMO levels occupied by half of an electron and coming from those of the neutral system (Err is the mean error). All the electronic properties are given in eV.

n	$EA(n)$	$\varepsilon_{LUMO}(n,N_0 + 1/2)$	$IP(n)$	$\varepsilon_{HOMO}(n,N_0 - 1/2)$
9	2.13	−2.82	6.12	−6.22
10	2.34	−2.38	6.22	−6.13
11	2.44	−3.06	6.29	−5.97
12	2.48	−2.42	6.31	−6.20
13	2.33	−2.77	5.90	−5.75
14	2.52	−2.54	5.77	−5.81
16	2.66	−2.46	5.66	−5.67
18	2.69	−2.60	5.82	−5.83
20	2.91	−3.26	5.79	−6.21
Err $\lvert EA - \varepsilon_{LUMO}\rvert = 0.28$ eV $\lvert IP - \varepsilon_{HOMO}\rvert = 0.14$ eV				

In Table 3, we compare the hardness values calculated in various ways. These all provide the right order of magnitude. However, the results from Equation 10 miss what appears as the reasonable evolution of the relaxation energy and hardness, i.e. their decrease with cluster size; it is likely that an improved approximation, such as the Generalized Slater′s Transition State method,[76] would give the right evolution.

A relationship between the polarizability and the electronic relaxation of valence levels also exists since, as we have mentioned above, the hardness is related to the polarizability. In fact, a low relaxation energy implies a low energy cost of the deformation of the electronic cloud. Hence, the smaller the relaxation energy of valence molecular orbitals, the smaller the hardness and the higher the polarizability of the system.

Table 3. Comparison among: (i) the hardness, η, evaluated as the curvature of the interpolated parabola described by Equation 11; (ii) the hardness, η^+_{ED} and η^-_{ED}, estimated from Equations 9a and 9b; and (iii) the hardness, η^+_{Slater} and $\eta^-_{Slater}(n)$, coming from Equations 10a and 10b. The values are in eV.

n	$\eta^+_{ED}(n)$	$\eta^-_{ED}(n)$	$\eta^+_{Slater}(n)$	$\eta^-_{Slater}(n)$	$\eta(n)$

2. Evolution of the Chemical Potential and Hardness with the Size of Copper Clusters: The knowledge of the chemical potential and hardness of the copper clusters allows us to characterize the evolution of these properties with size, from a small metal cluster to bulk metal. Since the relationship between hardness, polarizability, and relaxation energy of the valence levels has been pointed out above, we also discuss the evolution of these properties.

The evolution of the parameters μ and η of the parabola (Equation 11) has been analyzed as a funtion of the size of the cluster. The results are presented in Figure 8. We first discuss the behavior of the first derivative in the expansion, $-\mu(n)$. Figure 8 indicates that $-\mu$ remains close to the value of W_{Cu} whatever the size; it slowly converges towards the workfunction of the metal surface for an infinite size, as found within the jellium model.[78] The oscillation of the chemical potential of the metal clusters is weaker than that of IP or EA since the chemical potential can be seen as an average of these properties (Eq. 4). Hence, the slope of the average evolution of $IP(n)$, $EA(n)$ and $-\mu(n)$ should also be correlated. The average evolutions were found above for $EA(n) = 4.65 - 5.073 \cdot n^{-1/3}$ and $IP(n) = 4.65 + 3.166 \cdot n^{-1/3}$. The slope D of $-\mu(n) = 4.65 - D \cdot n^{-1/3}$ can be directly evaluated by using the interpolation formulae (Eq. 2) of $IP(n)$ and $EA(n)$ in Equation 4; it appears that $D = (5.073 - 3.166)/2 = 0.954$, which is in good agreement with the value of $D = 0.938$ calculated from a linear regression of $-\mu(n)$ for $n = 9-20$:

$$-\mu(n) = 4.65 - 0.954 \cdot n^{-1/2} \quad (12)$$

The small value of coefficient D leads to a relatively weak dependence of μ on n, in the range of n studied; this rationalizes the proximity between $-\mu$ and W_{Cu} and the slow convergence of $-\mu$ towards W_{Cu}, i.e. the quasi-constant character of μ in the clusters studied here. The HOMO energy of copper clusters (Table 1), and thus the chemical potential as calculated here (since the gap is very small), is then a

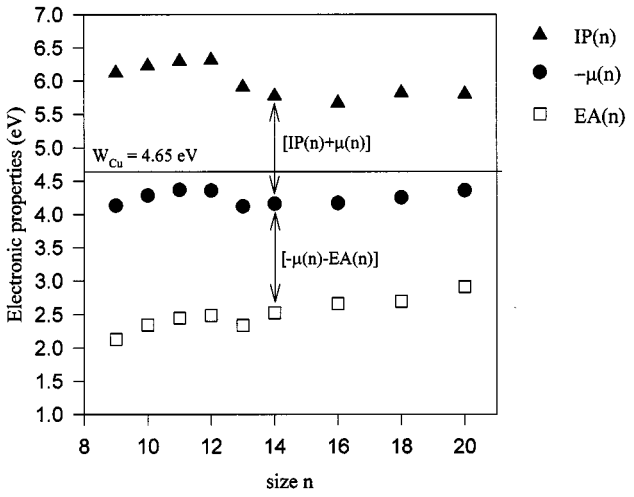

Figure 8. Evolution of the electronic properties of $Cu_n(y,w)$ with size n: (i) opposite of the chemical potential $-\mu(n)$ (full circles); (ii) $IP(n)$ (full triangles); and (iii) $EA(n)$ (open squares). The solid line indicates the workfunction of the metal.

good approximation of the workfunction of the metal. This result was first observed by Russier et al. for other transition metal clusters such as those of palladium.[79]

The hardness, $\eta(n)$, decreases as a function of size of the cluster (Figure 9). This trend is similar to that found for sodium clusters (Na_n).[63,65] The curvature of the parabola $\eta(n)$ (represented in Figure 7 for $n = 20$) decreases with increasing size n, hence the edges of the parabola for $x = -1$ and 1, i.e. EA and IP respectively, tend to become equal to the workfunction W, as shown in Figure 6. The decrease in hardness with cluster size is fully consistent with the expected evolution of the polarizability and relaxation energy. As the copper clusters grow, the number of valence levels that are close in energy increases, which induces a smaller relaxation energy and a higher polarizability.[63,80]

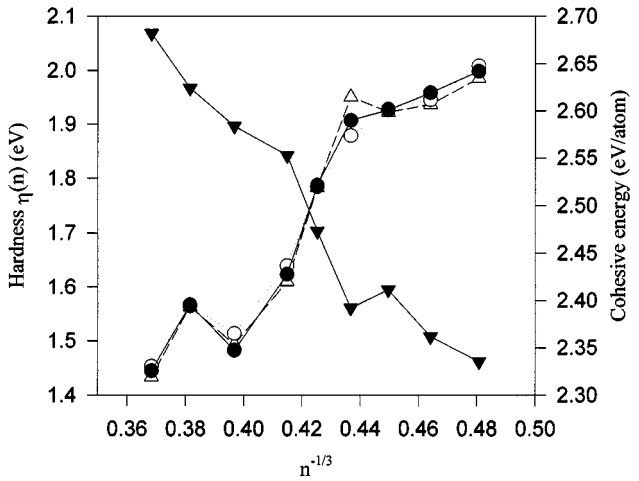

Figure 9. Evolution of the cohesive energy per atom (full triangles) and chemical hardness of the copper clusters $Cu_n(y,w)$. The full circles represent the hardness evaluated from the curvature of the polynomial expression (Eq. 11, Figure 7); the other two curves represent the evolution of $[IP(n) + \mu(n)]$ (open triangles) and $[-\mu(n) - EA(n)]$ (open circles).

For bulk metals, n is considered to be infinite and the relaxation energy when removing an electron at the Fermi energy is zero [for $n = \infty$, IP becomes the workfunction and the HOMO level corresponds to the Fermi level; Equation 7a then becomes: $E^+_{rel}(n = \infty) = 0$]. Equation 7a shows that the non-zero value of the hardness of a metal surface exactly corresponds to the opposite of the higher-order terms in the series of Eq. 3, $-R^+(n = \infty)$. Hence, as the hardness is also the inverse of the density of states at the Fermi level $g(E_F)$,[33] we obtain the following equalities:

$$\eta(n = \infty) = -R^+(n = \infty) = 1/[2g(E_F)] \quad (13)$$

This shows the direct relationship, for a bulk metal, between the higher-order terms in the series of Eq. 3 and the density of states at the Fermi level.

It has been demonstrated that hardness modifications with size are related to the shell structure in atoms or metal clusters.[65,81] The hardness of real copper clusters possessing a magic size is expected to be larger than that of the neighboring sizes, as observed for Li_n clusters;[82] clusters with a magic size adopt a geometric structure such that a shell is filled, so that hardness is maximized according to the maximum hardness principle.[68] Consequently, as for the other properties [$IP(n)$, $EA(n)$], the absence of shell structure in the model copper clusters can be advantageous to evaluate the average evolution of hardness with size. Figure 9 indicates that the $[-\mu(n) - EA(n)]$ and $[IP(n) + \mu(n)]$ curves are similar to that of $\eta(n)$; this shows that the simple relation (Eq. 4) defining the hardness from EA and IP is valuable for finite copper clusters $Cu_n(y,w)$. Of course, Equation 4 is not valid for infinite metal clusters (according to it, the hardness would be zero, whereas the hardness of a metal is non-zero); nevertheless, since the hardness of a metal is small [$g(E_F)$ is large], it is reasonable to use Equations 4 and 2 to estimate the hardness of large clusters; injecting Equation 1 into 3 gives the following relation:

$$\eta(n) = 4.120 \cdot n^{-1/3} \quad (14)$$

The comparison between the evolutions of chemical potential (Eq. 12) and hardness (Eq. 14) illustrates that the hardness varies much more strongly than the chemical potential with size. In the expression of the total energy as a series (Eq. 3), it is the second-derivative term, related to the relaxation energy (Eq. 8) and hardness, that is mostly responsible for the variation of $IP(n)$ and $EA(n)$ when the size n is changed, as already indicated for IP by Russier[41].

We have also calculated the cohesive energy of the $Cu_n(y,w)$ copper clusters (binding energy per atom); it is found to evolve in a roughly linear manner with respect to $n^{-1/3}$ (Figure 9). This is in good agreement with the previous study by Delley et al. on quasi-spherical copper clusters.[25] Figure 9 clearly shows that when the cluster size increases, the cohesive energy increases while the hardness decreases. The same kind of observation was made by Ghanty et al.[63] for Na_n clusters; these authors pointed out a polarizability increase as well as a cohesive energy increase with size of the Na_n clusters. To the best of our

knowledge, no analytical relation between cohesive energy and hardness has been established. Such a relationship would probably be linked to another concept (which is not related to size dependence): the maximum hardness principle,[68] which is a stability criterion and could be associated to a minimum polarizability condition, as has been suggested by Ghanty.[69]

Synopsis

Density Functional Theory has been used to study the dependence of the size of copper clusters $Cu_n(y,w)$ (n = 9−20) modeling the Cu(100) surface on their electronic properties. A comparison has been made between real quasi-spherical clusters, flat clusters modeling the surface, and the actual metal surface. We can draw the following major conclusions:

(i) The electronic structure of the copper clusters modeling the surface involves the absence of shell effect and even-odd oscillation in the evolution of *EA* and *IP* with size. Consequently, the evolution of *IP* and *EA* with $n^{-1/3}$ is quasi-linear, which allows the extrapolation of these properties to large copper clusters, for which such DFT calculations are intractable.

(ii) The DOS analysis of the model $Cu_{10}(6,4)$ cluster, compared to that of the quasi-spherical $Cu_{10}^{D_{4d}}$, shows that the absence of shell structure in the flat copper clusters is due to their geometric structure. The DOS of the surface-modeling clusters are similar to the photoemission spectrum of the actual Cu(100) surface, indicating the better adequacy of such surface models to simulate the metal surface, compared to real copper clusters.

(iii) Another important feature of the electronic structure of the $Cu_n(y,w)$ model surfaces is the small HOMO-LUMO gap. This allows one to consider energy derivatives with respect to charge removal or addition to be equal for closed-shell systems. Hence, it is possible to define global properties such as the chemical potential, μ, and the absolute hardness, η, whatever the size and the closed or open shell character. These properties are estimated as derivatives of the total energy versus charge, where the energy function is a second-order polynomial interpolated from SCF total energies calculated for partially negatively and positively charged clusters.

(iv) By exploiting the newly established relationship between hardness and relaxation energy of the valence levels when an electron is added to or removed from the system, it becomes possible to estimate the hardness from the eigenenergies of the frontier levels of the neutral and partially ionized systems.

(v) The average evolutions of the chemical potential and hardness can be extrapolated vs. $n^{-1/3}$ from the expressions of *IP* and *EA* vs. $n^{-1/3}$. The chemical potential of small copper clusters is close to the workfunction of a polycrystalline copper surface and is already a good estimate of this macroscopic property. The hardness decreases significantly with size; this is directly related to the decrease in relaxation energy of the valence levels and the increase in polarizability when increasing the size towards the metal.

In a forthcoming paper, we intend to exploit the knowledge base obtained in the present work to study the influence of the copper cluster size on the adsorption of organic molecules such as acrylonitrile; the adsorption of acrylonitrile on copper surfaces and copper electrodes has indeed been identified as the initial step leading to the grafting of polyacrylonitrile on a copper cathode through electropolymerization, a process that holds much promise for the surface protection of commodity metals.[83−85]

Acknowledgments

The Mons−Saclay collaboration is conducted in the framework of the "TOURNESOL" bilateral programme between Belgium and France (contract 98.026). The work in Mons is partly supported by the Belgian Federal Government "Service des Affaires Scientifiques, Techniques et Culturelles (SSTC)" in the framework of the "Pôle d'Attraction Interuniversitaire en Chimie Supramoléculaire et Catalyse Supramoléculaire (PAI 4/11)", FNRS-FRFC, and an IBM Academic Joint Study. XC is a grant holder of "Fonds pour la Formation à la Recherche dans l'Industrie et dans l'Agriculture (FRIA)". RL is Maître de Recherches of the Belgian "Fonds National de la Recherche Scientifique (FNRS)".

Modification of the Adsorption and Catalytic Properties of Molecular Sieves by Reaction with Organometallic Complexes

Frédéric Lefebvre,[a] Aimery de Mallmann,[a] and Jean-Marie Basset*[a]

Keywords: Zeolites / Transition metals / Organometallic compounds / Adsorption properties

Molecular sieves can be modified by organometallic complexes using two different methods: (i) OMCVD (organometallic chemical vapor deposition), where a multilayered organometallic fragment is calcined and transformed into an oxide of rather indefinite composition, and (ii) SOMC (surface organometallic chemistry), where an organometallic fragment is grafted with retention of its molecular integrity. Both methods may lead to a grafting, which can occur at the external surface and/or inside the channels of the zeolites. In the case of SOMC, by judicious choice of both the reaction conditions and the organometallic complexes, it is possible to modify only the external surface of the sieve, for example, of a mordenite. This can lead to a decrease of the surface acidity, allowing greater selectivity in catalytic reactions (such as xylene isomerization). Another application is the modification of the pore openings of the channels by grafting organometallic compounds near the pore entrances. This results in a modification of the adsorption characteristics of the molecular sieve, allowing a fine tuning of its properties. Depending on the size of the adsorbed molecule, two effects can be observed: (i) a total exclusion of the molecule from the channels of the molecular sieve, due to steric effects ("thermodynamic" control); (ii) a modification of the adsorption kinetics of the adsorbed molecule, depending greatly on its size and on the size of the organometallic fragment ("kinetic" control). Finally, the grafting reaction can, in some cases, occur inside the channels, thereby leading to effects similar to those described above and to a reduction of the adsorption capacity due to the presence of the grafted organometallic moieties within the pores.

Jean-Marie Basset was born in 1943. After studies at the ESCIL, he joined the Institut de Recherches sur la Catalyse at Lyon in 1965. He received his PhD in 1969 from the University of Lyon. After a postdoctoral period at the University of Toronto in 1969−1970 he returned to the Institut de Recherches sur la Catalyse where he developed a research group on olefin metathesis and organometallic chemistry on surfaces. He created an new laboratory called L.C.O.M.S. (Laboratoire de Chimie Organométallique de Surface) at the ESCPE-Lyon in 1993. His was elected to the French Academy of Sciences as Correspondent Member at the same period. He is at present developing the application of Surface Organometallic Chemistry to the design of catalysts and to new reactions such as alkanes metathesis.

Frédéric Lefebvre was born in Arras, France in 1956. He received the Agrégation in Chemistry in 1979. He worked first in the field of heteropolyanions with Prof. Hervé and after a 3rd cycle thesis he washired by CNRS and joined the Institut de Recherches sur la Catalyse in 1981 where he received his PhD in 1985. After a postdoctoral period at the University of Namur (Belgium) with Prof. Derouane, he returned to the Institut de Recherches sur la Catalyse where he was responsible of the solid-state NMR group until 1993. At this period he joined the group of Dr. Basset. He is actually in charge of the solid-state NMR and of the SOMC on zeolites and metathesis groups in the L.C.O.M.S. laboratory.

Aimery de Mallmann was born in Paris, France in 1960. He worked in the field of zeolites with Denise Barthomeuf and, after a 3rd cycle thesis in 1986, he was hired by CNRS and received a new thesis from University Paris VI in 1989. After a postdoctoral period at Texas A&M University with Jack Lunsford and one year spent at an industrial research center for Elf-Atochem, he joined L.C.O.M.S. group in 1993. His research in the field of zeolite, catalysis and organometallic chemistry is aimed at the rational design of heterogeneous catalysts for a variety of chemical transformations.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

Introduction

Molecular sieves, and more specifically zeolites, offer many applications, including catalysis (e.g. catalytic cracking, isomerization of xylenes, alkylation of aromatic compounds), separation processes (e.g. the preparation of oxygen or the removal of water from gases, solvents, etc.), not to mention one of their most important applications as bulk materials to replace phosphate compounds in detergents. Their cage-like structures of precise geometry, with pores of uniform shape running throughout the entire crystal, render them very useful for all these applications. Indeed, the limited size of the channels may prevent the formation of certain intermediates in catalytic reactions, thereby leading to unexpected selectivities (shape−form selectivity). Furthermore, the fixed dimensions of the channels lead to similar properties over the whole crystal.

Although more than fifty naturally occurring species have been characterized and more than 120 synthetic zeolites have been prepared,[1] it is not yet possible to vary the size of the pores and of the cages in a continuous, systematic manner. A zeolite is mainly composed of SiO_4 and AlO_4 tetrahedra and has a well-defined crystallographic structure. For a given zeolite, the size of the pores can be varied by cation exchange or by replacement of the Si or Al atoms by other atoms. This has led to numerous techniques for modification of the zeolitic pore system in a controlled manner, with the aim of improving their performances in catalysis and/or molecular separations. These techniques can generally be classified into three groups:[2]

(i) Modification by a Cation-Exchange Process: The zeolitic pore size can be altered, in a controlled manner, by a replacement of the exchangeable cations, which are normally located near the pore openings. This can lead to a significant alteration of the zeolitic pore structure.[3] A typical example is the adsorption of 2-methylpentane and 2,2-dimethylbutane on mordenite: both alkanes are adsorbed on a calcium mordenite, but only 2-methylpentane is adsorbed on a strontium- or barium-exchanged mordenite.[4] This observation can be simply explained in terms of a pore size reduction on going from the calcium-exchanged mordenite to the strontium and barium ones. As 2,2-dimethylbutane has a kinetic diameter slightly larger than that of 2-methylpentane, it will be excluded from the strontium- and barium-exchanged mordenites.

(ii) Modification by Preadsorption of Polar Molecules: Another method for modifying the molecular sieving effect of a zeolite is to preadsorb polar molecules. Indeed, these molecules will bind around the exchangeable cations and thereby modify the diffusion of adsorbed hydrocarbons. A typical example is the adsorption of butanes on a CaA zeolite, which shows a marked dependence on the amount of preadsorbed water or amines.[5]

(iii) Modification of the Zeolite Framework: Finally, pore size "engineering" in zeolites can be achieved by a modification of the zeolitic framework. This can be performed in various ways:

(a) Firstly, crystallographic changes can be obtained by thermal treatment. For example, thermal treatment of zeolites in the presence of water results in a modification of the pore sizes.[6] Indeed, steam treatment leads to migration and hydrolysis of the exchangeable cations. We will not describe this process in more detail here, as such modifications are not relevant in the realm of organometallic compounds.

(b) Another method is the internal and external structure modification of the zeolite framework by the incorporation of additional atom groups. Various methods have been described in the literature[7] such as silylation, disilylation, boration, etc. As silanes are organometallic compounds, we will briefly discuss these methods in the final part of this review, but we will describe more extensively the reactions of organotin compounds with cloverite, a recently discovered gallophosphate.[8]

(c) A third way of modifying the zeolite framework is to selectively modify the external surface of the zeolite crystal, leaving the internal channels or cavities unaffected. This is typically achieved by reaction with organometallic compounds (including silicon compounds) and will be reported in detail in the next section, in particular the modification of mordenite by reaction with organotin or -germanium compounds.

Modification of the External Surface of Zeolite Crystals

The first example of a variation of the properties of a zeolite by modification of the external surface was reported by Niwa et al. in 1984.[9] The principle of the method was relatively simple, its purpose being the deposition of an organometallic moiety on the zeolite surface that could not enter the pore system. The great advantage of this modification method was that the internal properties of the zeolite remained unchanged after the grafting reaction, in contrast to what was observed when the modification occurred inside the pores as well (see the next part of this review). In most cases, the zeolite used in these studies was mordenite. Indeed, mordenite has monodimensional channels (Figure 1)[6] and so, even if not all the pore openings were modified, an effect could still be observed. Indeed, modification of only 50% of the pore openings should lead, statistically, to 25% of the channels remaining unmodified, 25% of them being modified at both ends, and 50% of them having only one extremity modified. For zeolites with bi- or tri-dimensional channel systems (e.g. ZSM-5 or faujasite), modification of 50% of the channel apertures will have no effect on the adsorption properties since the molecules can enter via the unmodified channel apertures and occupy all the voids in the solid. Significant effects can only be observed when more than 95% of the pore openings are modified, a result which in practice is difficult to achieve. This accounts for the fact that, in most cases, the studies have been carried out on mordenite.

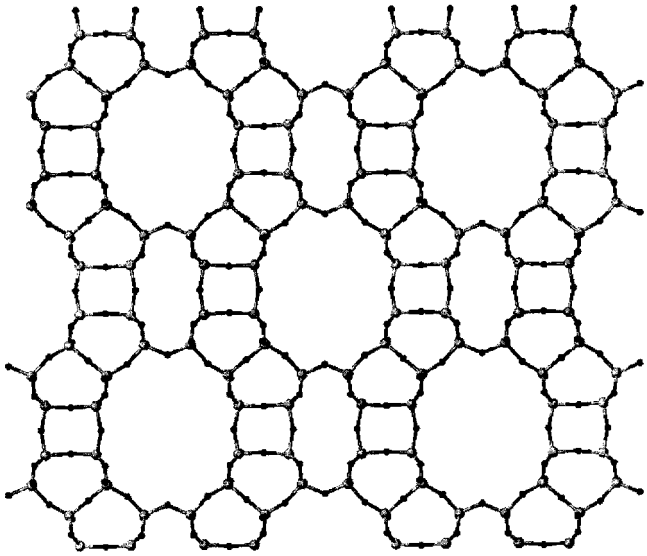

Figure 1. Schematic representation of the channels of mordenite

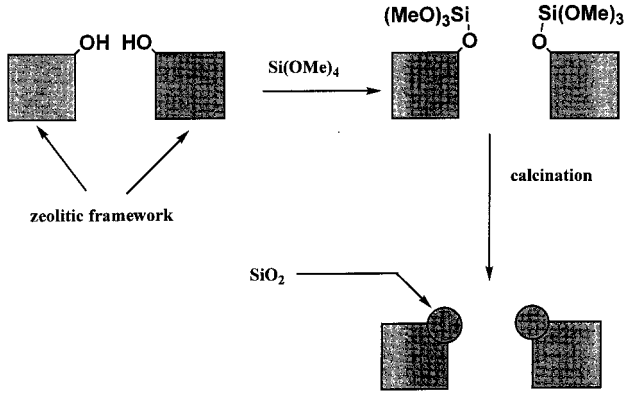
Niwa et al.[9] deposited $Si(OCH_3)_4$ on mordenite by chemical vapor deposition (C.V.D.). The C.V.D. technique differs quite significantly from surface organometallic chemistry (S.O.M.C.), which will be discussed later. In C.V.D., there is no control of the grafting process at the molecular level. Once one, or more typically, several layers of an organometallic have been grafted on a surface, thermal or chemical treatment leads to an inorganic material (usually an oxide, but possibly also a carbide, a nitride, etc.), which has a definite composition. In S.O.M.C., only one (or less than one) monolayer of an organomolecular fragment is grafted onto the surface, which thus retains, at least in part, its molecular integrity. In the case of the Niwa approach by OMCVD, $Si(OCH_3)_4$ was allowed to react with the hydroxy groups present on the external surface of the zeolite, thereby leading to a surface organometallic complex:

$$\equiv T-OH + Si(OCH_3)_4 \rightarrow \equiv T-O-Si(OCH_3)_3 + CH_3OH$$



where T represents a framework atom such as Si or Al. This surface complex was then able to undergo further reactions with the hydroxy groups of the surface, leading to multigrafted species:

$$\equiv T-O-Si(OCH_3)_3 + x \equiv T-OH \rightarrow (\equiv T-O)_{1+x}Si(OCH_3)_{3-x} + x\ CH_3OH$$

$$T = Si, Al;\ x = 1, 2$$

The resulting materials were subsequently calcined under oxygen, leading to the formation of silica-coated zeolites by the elimination of the hydrocarbon residues (ligand and alcohol) as shown in Scheme 1.

Repetition of this process reduced the dimensions of the pore entrances by 0.1 nm for a single-step modification or by 0.2 nm for a multistep OMCVD modification. Adsorption of *p*-xylene was greatly modified on these materials;

Scheme 1. Modification of the pore entrance of a zeolite by reactions with $Si(OMe)_4$

while this molecule was easily adsorbed on unmodified mordenite (Large pore from Norton), it was totally excluded from the same zeolite modified by grafting $Si(OCH_3)_4$ (2.7 wt.-% complex) and subsequent calcination. A study of the reaction on the surface of mordenites with various Si/Al ratios was carried out, the results of which showed that the amount of adsorbed methoxysilane depended on this parameter, the "epitaxial" growth of the SiO_2 layer on the external surface being perturbed by the aluminium atoms.[10]

Various other silicon-containing molecules have been used, for example $(C_3H_7)_3Si(OCH_3)$, which led only to a monografted complex, the Si−C bond being very stable,[11] or chlorosilanes.[12] With the latter, the reaction led to the formation of hydrochloric acid, thus it was necessary to use zeolites with a high Si/Al ratio in order to avoid the local destruction of the framework by HCl.

As these modifications did not affect the internal catalytic properties of the zeolites, the modified solids could be used in catalysis, often showing increased selectivity for the desired products. There have been numerous reports of such applications, although most of them deal with the formation of dibranched aromatic compounds and the production of *para*-substituted aromatic compounds. For example, such systems are used in the alkylation of toluene by methanol.[13] The deposition of silica onto the zeolite leads to a large decrease in the catalytic activity, but to a concomitant marked increase in the *p*-xylene selectivity. These results were explained in terms of a decrease of the diffusivity inside the channels due to the silica deposit, together with a deactivation of the acid sites on the external surface due to reaction with the silicon compound. Similar results were obtained for toluene disproportionation and *o*-xylene isomerization;[9c] the larger the amount of silica deposited on the catalyst, the higher the selectivity towards *p*-xylene and the lower the catalytic activity.

However, the main problem of these studies was that the reaction of the organometallic compound with the surface was performed by OMCVD, which does not offer control at the molecular level. Numerous surface species were most probably obtained which, by calcination and migration,

gave rise to poorly defined solids. It was thus difficult to correlate the catalytic properties with the modification of the zeolite.

More recently, numerous studies have been undertaken using the SOMC technique, which preserves the molecular structure on the surface. Various organometallic compounds have been reacted with mordenite and the grafted fragments thus obtained have been fully characterized by in situ IR spectroscopy, volumetric measurements, elemental analysis, and ^{13}C-CP-MAS solid-state NMR.[14−18] The grafting of organometallic derivatives of various metals has also been studied, including magnesium ($MgNp_2$), zirconium ($ZrNp_4$), germanium ($GeBu_4$), and, most thoroughly, tin (SnR_4 compounds with R = Me, Et, *i*Pr, *n*Pr, *n*Bu, Ph, Cy; $HSnBu_3$). In the case of the alkyltin compounds, the solids were also characterized by ^{119}Sn-MAS-NMR. In each case, reaction of the organometallic compound with the external surface hydroxy groups occurred, which can be described in terms of the following equations:

$$\equiv Si-OH + MR_4 \rightarrow \equiv Si-O-MR_3 + RH$$
$$M = Sn, Ge, Zr; R = Me, Et, nPr, iPr, nBu, Np, Cy, Ph$$
$$\equiv Si-OH + HSnBu_3 \rightarrow \equiv Si-O-SnBu_3 + H_2$$
$$\equiv Si-OH + MgNp_2 \rightarrow \equiv Si-O-MgNp + NpH$$

These results were confirmed by further studies on various oxides (silica, alumina, silica/alumina, etc.).[19] For all organometallic compounds, the reaction occurred only at the external surface and near the pore entrances, the starting organometallic compounds being too large to enter inside the channels (with the sole exception of $SnMe_4$, which probably reacted very rapidly at the pore entrances, thereby preventing other molecules of tetramethyltin from penetrating inside the channels, XPS showing a considerable tin enrichment on the surface). The main interest in this approach stemmed from the fact that the organometallic compounds were not calcined after the grafting reaction. As a consequence, the reduction of the pore openings was under a *strict molecular control* and was also much larger than that achieved in the previously mentioned studies, where calcination and formation of an oxide layer typically resulted in only a ca. 5% decrease in the dimensions of the pore entrance. Figure 2 shows a pore entrance of mordenite after grafting of a tributyltin organometallic fragment. It can readily be seen that the pore entrance is reduced by ca. 30−40%. This significant obstruction of the pore entrance results in a marked change in the adsorption properties of the modified zeolite. In studies of these systems, the adsorption capacities were determined by a dynamic method, the apparatus being shown in Figure 3. It could be described as a chromatographic method, the zeolite being placed in a small chromatographic column. Pulses of the desired hydrocarbon were introduced at the entrance of the column and the gaseous phase was analyzed at the output. The adsorption capacity was determined from the quantity of hydrocarbon present in the pulses that did not appear in the output from the column.

Figure 4 shows the adsorption capacities for *n*-hexane, 2-methylpentane, 2,3-dimethylbutane, and isooctane (2,2,4-trimethylpentane) of mordenite and of mordenite modified by grafting various organometallic complexes. Clearly, the adsorption capacities (as determined by this method) were greatly modified after the grafting reaction, although the data were not so easy to explain quantitatively. In principle, the role of the organometallic fragment should be very simple; the incoming molecule either can or cannot enter the pore system, depending on the bulkiness of the organometallic fragment. This may be evaluated, for example by molecular modelling. Experimentally, however, the results are more complicated:

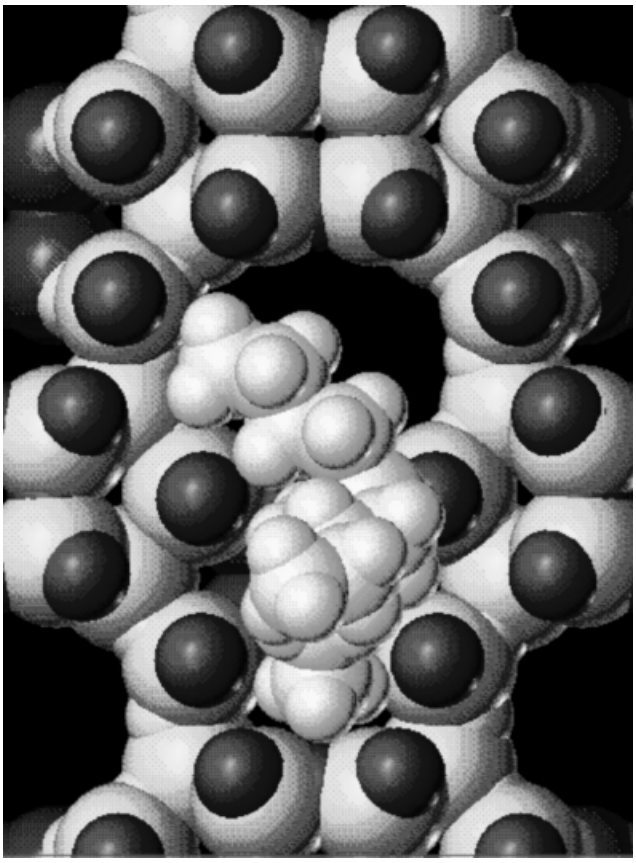


Figure 2. Molecular modelling representation of the pore entrance of mordenite after the grafting reaction of an organometallic tributyltin fragment

In some cases, molecules which were experimentally found to enter into the pore system of mordenite (e.g. isooctane) could no longer penetrate into mordenites modified by bulky organotin compounds (e.g. SnR_3; R = Cy, *n*Bu).

In other cases, molecules experimentally found to enter the pore system of mordenite were also found to penetrate mordenite modified by organotin fragments, albeit more slowly. This was the case for 2,3-dimethylbutane. Here, the actual adsorption capacity of the mordenite was not modified by the grafting reaction, which occurred only on the external surface of the solid without modification of the bulk.

These results are best explained as follows:

(a) A "thermodynamic" effect is observed when a hydrocarbon molecule, which can be adsorbed by the unmodified

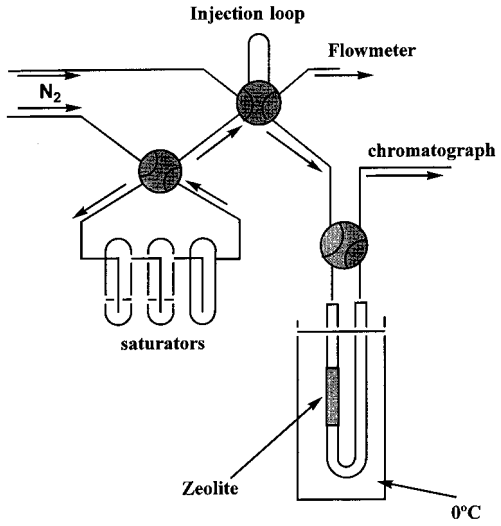

Figure 3. Schematic representation of the apparatus used for the determination of adsorption capacities by a dynamic method ("pulse" method)

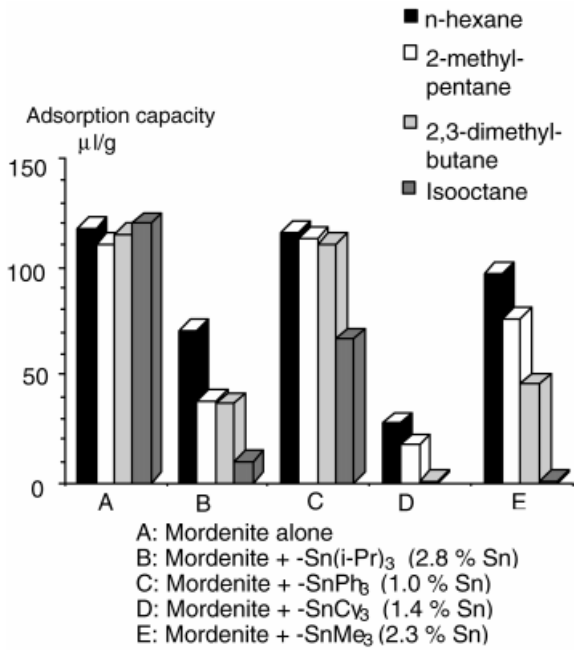

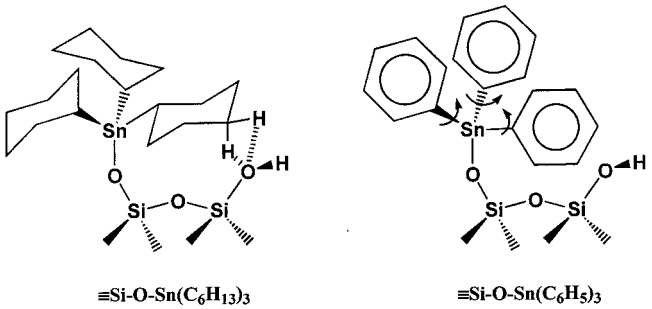

Figure 4. Adsorption capacities (determined by the pulse method) of *n*-hexane, 2-methylpentane, 2,3-dimethylbutane, and isooctane in unmodified mordenite and in mordenite modified by grafting various organometallic complexes

zeolite, can no longer pass through the partially obstructed pore entrance following grafting of the complex, due to steric interactions. A typical example is provided by isooctane, which is adsorbed by mordenite, but is totally excluded from mordenite modified by trimethyltin or tricyclohexyltin. In this case, the new adsorption capacity is zero.

(b) A "kinetic" effect, which is attributable to a decrease in the diffusion rate of molecules able to pass through the modified pore entrances. Indeed, at the pore entrances, the hydrocarbon molecules can interact with the alkyl ligands of the grafted organometallic complexes, resulting in a decrease of their diffusion rate and so to an apparently lower adsorption capacity. These effects were relatively straightforwardly predicted by Monte Carlo theoretical calculations.[20]

Another interesting conclusion of these studies was obtained by comparing the effects of the tricyclohexyltin and triphenyltin grafted fragments (Figure 4). While mordenite modified by tetracyclohexyltin readily discriminated the four hydrocarbons, no effect was observed for the samples modified by reaction with tetraphenyltin. This was explained by assuming, in agreement with ^{13}C-CP-MAS NMR data,[19c] that the phenyl ligands were able to rotate freely about the C−Sn bonds, while the cyclohexyl moieties interacted with remaining hydroxy groups on the surface, thereby leading to a more efficient reduction of the dimensions of the pore entrances (Scheme 2).

Scheme 2. Structure of ≡Si−O−SnR_3 (R = C_6H_{13}, C_6H_5) grafted on mordenite

Most of the modified zeolites were found to be unstable at high temperature (decomposition of the organometallic fragment at temperatures above 200 °C). However, a significant exception to this rule was observed with mordenite modified by organogermanes; the grafted fragment was stable up to ca. 400 °C, allowing the possibility of using this material for practical applications.[15]

These materials were also studied with regard to the direct separation of a mixture of the aforementioned four hydrocarbons. For this purpose, a different experimental setup was used (Figure 5). The mixture of hydrocarbons was passed continuously through the zeolite in the form of chromatographic column and the gases were analysed sequentially by GC. Figure 6 shows typical results obtained by this method: while the four hydrocarbons (*n*-hexane, 2-methylpentane, 2,3-dimethylbutane and isooctane) were not discriminated by unmodified mordenite, they were easily separated by mordenite modified by grafting organometallic complexes. These experiments thus represented a real case of separation of hydrocarbon mixtures by a zeolite. It should be pointed out that, with the exception of isooctane, even if the hydrocarbons could enter the pores, they were discriminated by their van der Waals interactions with the grafted organometallic fragment (combination of thermodynamic and kinetic effects).

Finally, a study was undertaken of the zeolite properties as a function of the organometallic loading, in order to gain a better understanding of the grafting mechanism.[21] Vari-

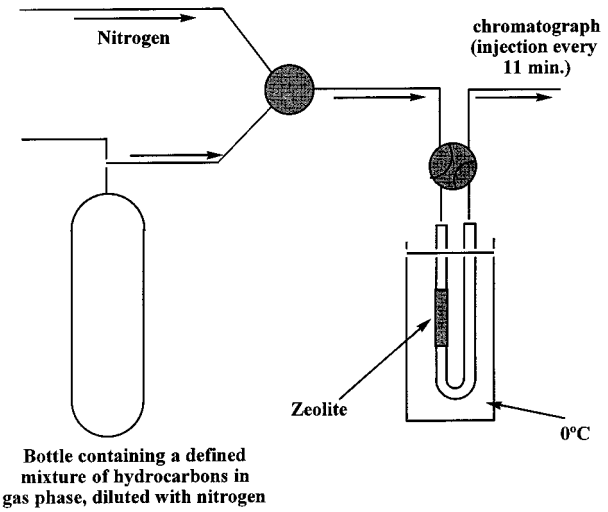

Figure 5. Schematic representation of the apparatus used for the separation of mixtures of hydrocarbons

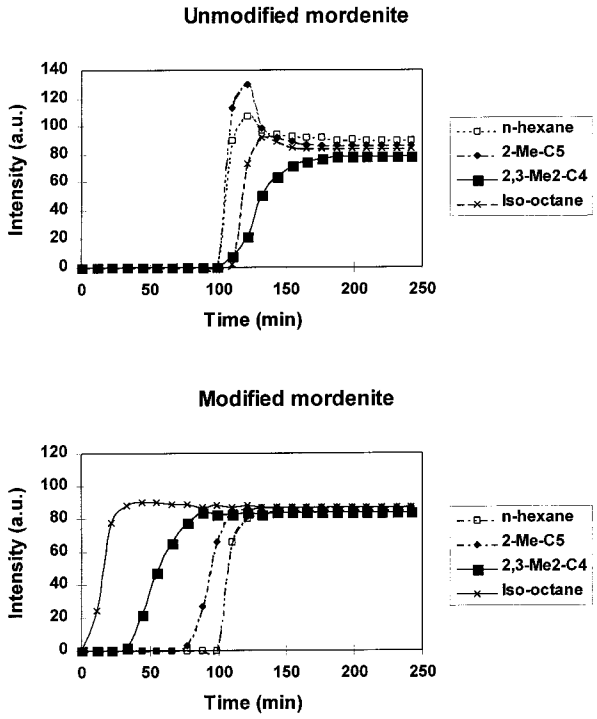

Figure 6. Separation of a mixture of hydrocarbons (*n*-hexane, 2-methylpentane, 2,3-dimethylbutane, and isooctane) by unmodified mordenite and by mordenite modified by grafting tributyltin fragments

ous organometallic complexes of tin (SnR_4; R = Me, Et, *n*Pr, *n*Bu) were used. The adsorption properties of these modified materials towards *n*-hexane, 2-methylpentane, 2,3-dimethylbutane, and isooctane were studied (Figure 7).

It was shown that a total exclusion of isooctane could be achieved with tin loadings greater than 0.5 wt.-%, while 2-methylpentane and 2,3-dimethylbutane were only discriminated with tin loadings in excess of 0.9 wt.-%. No detectable effect was observed in the case of *n*-hexane, even with tin loadings as high as 1.5 wt.-%. These results can be interpreted by assuming that the grafting reaction of the tin fragments occurs on different hydroxy sites of the mordenite, depending on the degree of tin loading. There are four possible grafting sites on an idealized external surface of mordenite (Figure 8), reaction at which should lead to differential reductions of the pore sizes. It has been proposed that for low tin loadings (below 0.5 wt.-%), the grafting reaction occurs only at site 1. A molecular modelling study showed that under these conditions only isooctane would be totally excluded and that the other hydrocarbons would still be able to enter. For tin loadings between 0.5 and 1.0 wt.-%, it is proposed that the grafting reaction occurs at sites 3 or 4, resulting in the exclusion of both 2-methylpentane and 2,3-dimethylbutane.

These modified mordenites have also been used in catalysis experiments, for the selective isomerization of C_8 aromatic mixtures to xylenes.[16] These C_8 aromatic mixtures contained *ortho*-, *meta*- and *para*-xylenes and a non-negligible amount of ethylbenzene (10−40%), of which *para*-xylene is the most useful component. This is removed from the reaction mixture in an aromatic separation unit and the *p*-xylene-depleted mixture is then fed to a unit where the *o*- and *m*-xylenes are isomerized into an equilibrium mixture of *p*-, *o*- and *m*-xylenes. This mixture is then recycled to the *p*-xylene recovery unit together with fresh feed. As the C_8 mixture contains ethylbenzene, the catalyst has to be able to convert it with a minimum loss of xylenes, in order to avoid an increase of its concentration in the recycle loop. Consequently, the objectives of the isomerization units are to isomerize xylenes and to convert ethylbenzene into valuable products. Usually, this is accomplished industrially by the use of a bifunctional catalyst consisting of a large-pore acid zeolite (typically mordenite) and a hydrogenating metal (platinum). It was thus interesting to study the applicability of mordenites modified by organometallic complexes in this reaction. However, such reactions are performed at high temperatures (410°C) and under these conditions the organometallic fragment is not stable: a dealkylation of the grafted species occurs, resulting in a mordenite bearing only dealkylated species. The modified mordenites were therefore calcined prior to use. They were then mixed mechanically with a hydrogenation catalyst, in the form of Pt/Al_2O_3 (0.3 wt.-% Pt). Mordenites modified by various organometallic complexes [$MgNp_2$, $ZrNp_4$, $Sn(n\text{Bu})_4$, $Ge(n\text{Bu})_4$] were used. It was observed that the disproportionation reactions, which lead to undesirable products and to a loss of some of the xylenes, were, in some cases, greatly reduced compared to the situation using an unmodified mordenite. When the mordenite was modified by $Ge(n\text{Bu})_4$ or $ZrNp_4$, the isomerization selectivity (between xylenes, and for the transformation of ethylbenzene into xylenes) was increased, while the disproportionation reactions became less significant. When mordenite was modified by $Sn(n\text{Bu})_4$ or $MgNp_2$, no difference was observed compared to unmodified mordenite.

These results were compared to XPS data: XPS showed that in the case of magnesium and tin complexes there was migration of these metals into the interior of the zeolite

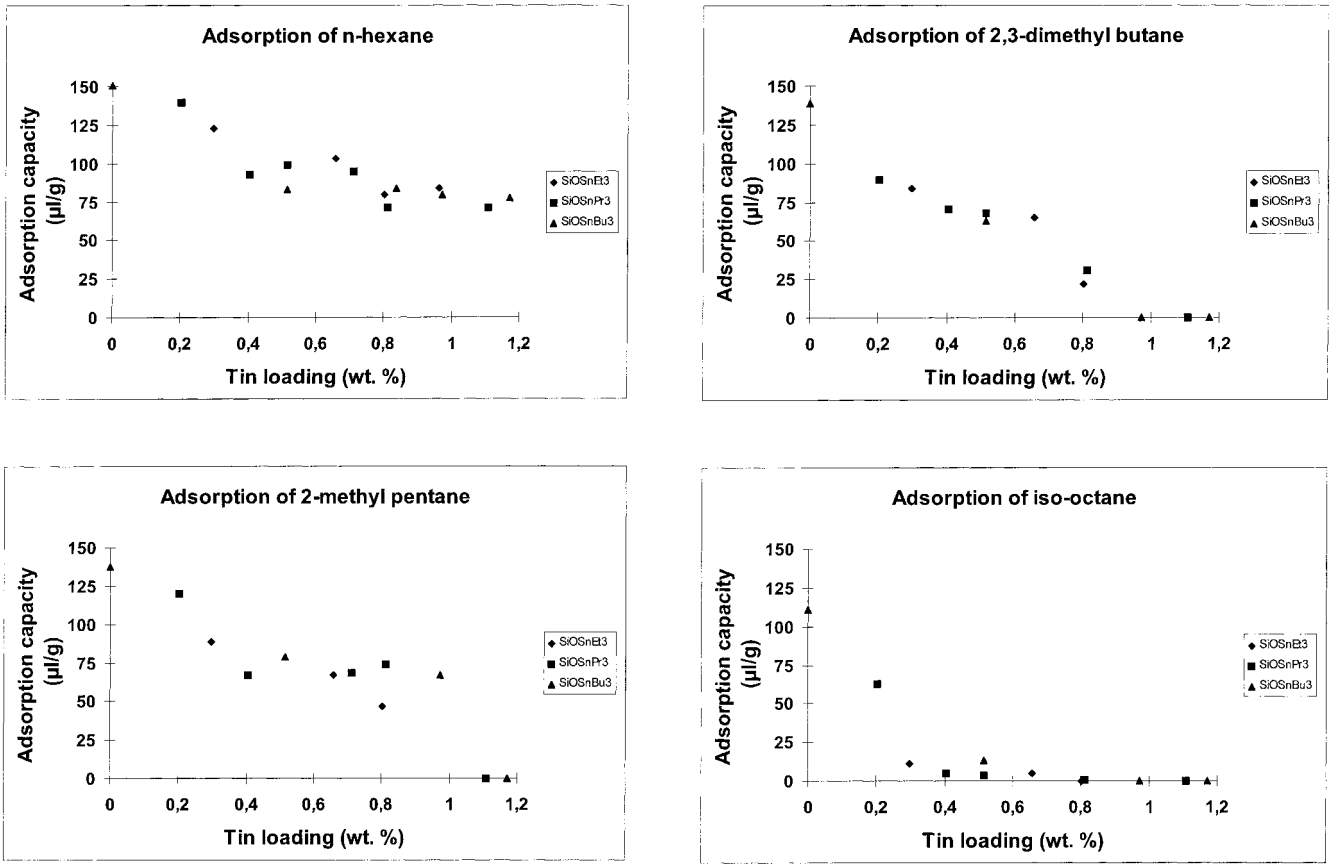

Figure 7. Adsorption capacities towards various hydrocarbons, determined by the pulse method, of mordenite modified by reaction with tetraalkyltin complexes, as a function of the tin loading

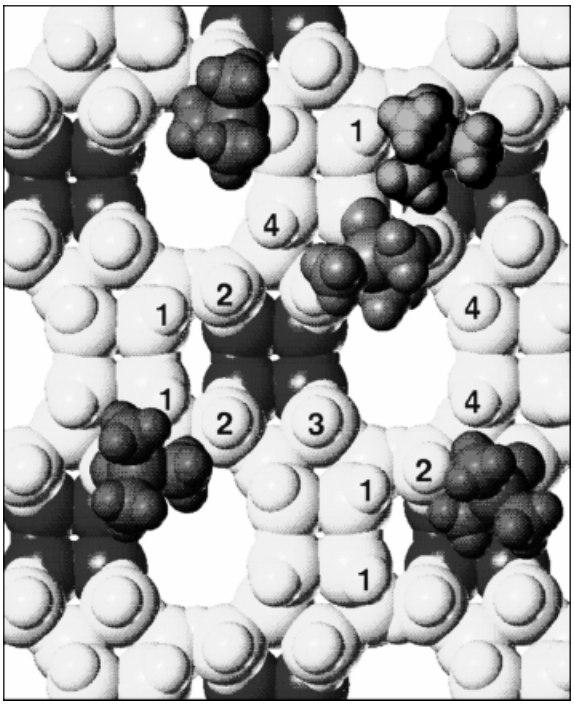

Figure 8. Grafting sites at the pore entrances of mordenite

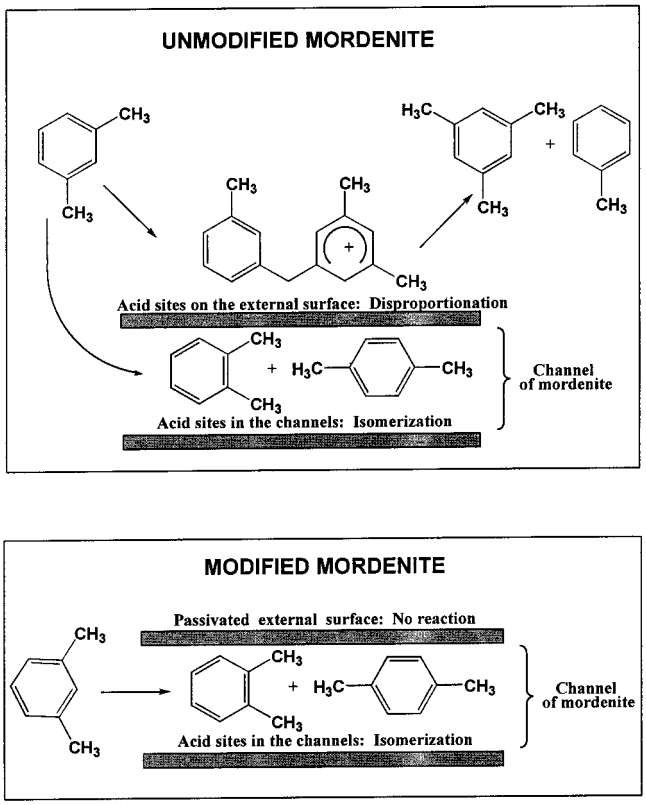

grains during calcination, whereas in the case of germanium and zirconium there was no migration, resulting in the formation of a disperse layer of Ge or Zr "oxide" on the external surface of the zeolite crystals. It was thus logical to suppose that the disperse layer was responsible for the observed decrease in disproportionation.

The interpretation of this experimental correlation between catalytic and XPS results is shown in Scheme 3. The disproportionation reaction is bimolecular; it requires the formation of a bulky reaction intermediate. This intermediate, in view of the channel dimensions of the mordenite zeolite framework, should be formed preferentially by the intervention of the acid sites present at the channel entrances, or preferably at the external surface of the zeolite crystals. The grafting of the organometallic complexes at the external surface leads to the elimination or poisoning of such "non-selective" acid sites, which leads to an overall reduction of the disproportionation reactions.

These studies were also extended to other microporous materials, such as mesoporous silicas and cloverite. However, in these cases, the modification occurred not only on the external surface but also inside the channels. These results are presented in the following part of this review.

Modification of the Internal and External Surfaces of Molecular Sieves

Before describing the modification of the properties of molecular sieves by true organometallic compounds, we will

Scheme 3. Isomerization of xylenes on unmodified and modified mordenite

briefly overview the modification by the other compounds, essentially silanes and boranes.[2,22]

Acidic zeolites can be modified by reaction with silanes, due to the reactivity of the Si−H bond. Reactions with hydroxy groups of the zeolite can thus be written as:

$$\equiv T{-}OH + SiH_4 \rightarrow \equiv T{-}O{-}SiH_3 + H_2$$
$$\equiv T = Si, Al$$

This chemisorbed group can react further with another hydroxy group, resulting in a silicon dihydride species linked to the surface via two σ-bonded oxygen atoms:

$$\equiv T{-}OH + \equiv T{-}O{-}SiH_3 \rightarrow (\equiv T{-}O)_2SiH_2 + H_2$$
$$\equiv T = Si, Al$$

In all cases, the samples were further hydrolyzed in order to obtain stable compounds that could not react with the adsorbents:

$$(4-x)\,H_2O + (\equiv T{-}O)_xSiH_{4-x} \rightarrow (\equiv T{-}O)_xSi(OH)_{4-x} + (4-x)\,H_2$$
$$\equiv T = Si, Al;\ x = 1, 2$$

Thus, a total of 4 hydrogen molecules were evolved per grafted silicon. In principle, the greatest number of silanes that could react with the zeolite (very often a mordenite) could not exceed the number of hydroxy groups (typically around 2 mmol per gram). In practice, the experimental value was invariably lower, owing to several factors: (i) heterogeneous reactivity of the hydroxy groups (depending on their crystallographic localization), (ii) a decrease of the diffusion rate of the silane molecules in the channels, following the reduction of the dimensions of the pore openings after modification by an initial SiH_4 molecule (this effect is somewhat analogous to that described above as a kinetic effect in the case of zeolites modified only at the external surface).

Another modification method involved the use of disilanes such as $H_3Si{-}SiH_3$ rather than simple silanes of the type SiR_4. Two reactions occurred simultaneously, depending on whether the Si−Si or an Si−H bond was broken:

$$2 \equiv T{-}OH + Si_2H_6 \rightarrow H_2 + 2 \equiv T{-}O{-}SiH_3$$
$$\equiv T{-}OH + Si_2H_6 \rightarrow H_2 + \equiv T{-}O{-}Si_2H_5$$

In the case of silanes, the chemisorbed species could undergo further reactions with the hydroxy groups, leading to multigrafted species. Finally, the residual ≡Si−H and ≡Si−Si≡ bonds were hydrolysed to ≡Si−OH groups:

$$\equiv Si{-}H + H_2O \rightarrow H_2 + \equiv Si{-}OH$$
$$\equiv Si{-}Si\equiv + 2\,H_2O \rightarrow H_2 + 2 \equiv Si{-}OH$$

The resulting solids were often characterized by adsorption kinetics of Xe, Kr, O_2 or N_2. In all cases, a pore size reduction was observed, leading to a decrease of the pore volume. It was also observed that the hydrolysis reaction led to a marked decrease in the pore volume, resulting, in some cases, in a complete exclusion of *n*-butane. This was not due to a destruction of the framework, since smaller molecules such as rare gases and oxygen could still fill the pores, but solely due to the reduction of the pore size by the grafted fragments (thermodynamic effect).

Similar modifications of zeolites were carried out using B_2H_6 but, as above, changes in the adsorption properties were only significant after treatment under severe conditions.[2]

Recently, the reaction of organometallic compounds with the internal hydroxy groups of molecular sieves has been studied. Due to the non-negligible size of the organometallic complexes, only some molecular sieves could be used, namely cloverite[23] and mesoporous silica (MCM-41 or MS-1).[24]

Cloverite is a synthetic microporous gallophosphate with a 20-tetrahedral pore opening, the synthesis and structure of which was reported in 1991.[8] Its crystal structure contains two non-intersecting channel systems with 8-ring (8-T, 3.8 Å) and 20-ring (20-T, 13.2 Å) pore openings. The diagonal dimension of the supercages formed at the intersections of the 20-ring channels amounts to 23−30 Å (Figure 8).[25] Furthermore, hydroxy groups can only be found at the windows of these supercages (4 hydroxy groups per window, 6.2 Å apart). The reactions of $SnMe_4$, $SnEt_4$ and $HSnBu_3$ with this solid were studied by numerous methods and the resulting materials were fully characterized by physicochemical techniques such as ^{13}C-CP-MAS- and ^{119}Sn-MAS-NMR, EXAFS, X-ray powder diffraction, XPS, etc.[23] In all cases, it was shown that the grafting reaction had occurred both on the external surface and inside

the channels, most of the tin being found in the bulk. Depending on the starting organometallic species, different solids were obtained, with a mean value of one grafted organometallic fragment per window of the supercages when $SnEt_4$ or $HSnBu_3$ were used (corresponding to ca. 3.5 wt.-% tin) or four grafted organometallic fragments per window in the case of $SnMe_4$ (corresponding to ca. 14 wt.-% tin). In the latter case, all hydroxy groups in the solid had reacted. For all samples, the grafted organometallic fragment was fully characterized as a $\equiv T-O-SnR_3$ complex, in which tin was tetracoordinated. The reaction was not selective and both $\equiv P-OH$ and $\equiv Ga-OH$ hydroxy groups reacted:

$$\equiv T-OH + SnR_4 \rightarrow \equiv T-O-SnR_3 + RH$$
$$R = Me, Et$$
$$\equiv T-OH + HSnBu_3 \rightarrow \equiv T-O-SnBu_3 + H_2$$

As an example, Figure 9 shows a molecular modelling representation of a supercage window before and after modification by $SnEt_4$.

The adsorption properties of unmodified cloverite and of cloverite modified by grafted $-SnR_3$ fragments were studied. The adsorption properties towards *n*-hexane, benzene and isooctane were determined using a static method. The apparatus used for these studies is shown schematically in Figure 10. The cloverite sample was connected to a pressure gauge and a vacuum line via a break-seal. A known amount of the appropriate hydrocarbon was introduced into the system as a liquid and immediately vaporized. The break-seal was then broken and the variation of the hydrocarbon pressure was analyzed as a function of time, thereby allowing determination of the adsorption capacity.

The values obtained for unmodified cloverite showed that benzene and isooctane filled only the 20-T channel system, while *n*-hexane filled both the 8-T and 20-T channel systems. When cloverite was modified by tetramethyltin (14 wt.-%), tetraethyltin, or tributyltin hydride (3.5 wt.-%), the following features were observed: (a) Total exclusion of isooctane from all materials. (b) Reduction of the adsorption capacities towards *n*-hexane and benzene, which became very similar after the grafting reaction.

The exclusion of isooctane was explained in terms of the reduction of the size of the windows of the supercages, which prevented passage of this molecule. This was also the case for butane after reaction with disilane. These observations are nicely predictable by molecular modelling.

The reduction of the adsorption capacities towards *n*-hexane and benzene was due to two factors: (i) *n*-Hexane could only fill the 20-T channel system, owing to a blocking of the pore openings of the 8-T channels by the organometallic fragments grafted onto the external surface. (ii) The decrease of the adsorption capacity corresponds to a reduction in the pore volume due to the presence of the grafted organometallic complexes inside the channels. This effect was also predictable by simple molecular modelling calculations.

Unfortunately, no difference was observed between cloverites modified by reaction with tetramethyltin, tetraethyltin, or tributyltin hydride, even though the sizes of the windows were reduced to varying extents. This was probably related to the limited range of hydrocarbons adsorbed on these materials. However, such a modification of the adsorption characteristics of a molecular sieve is very interest-

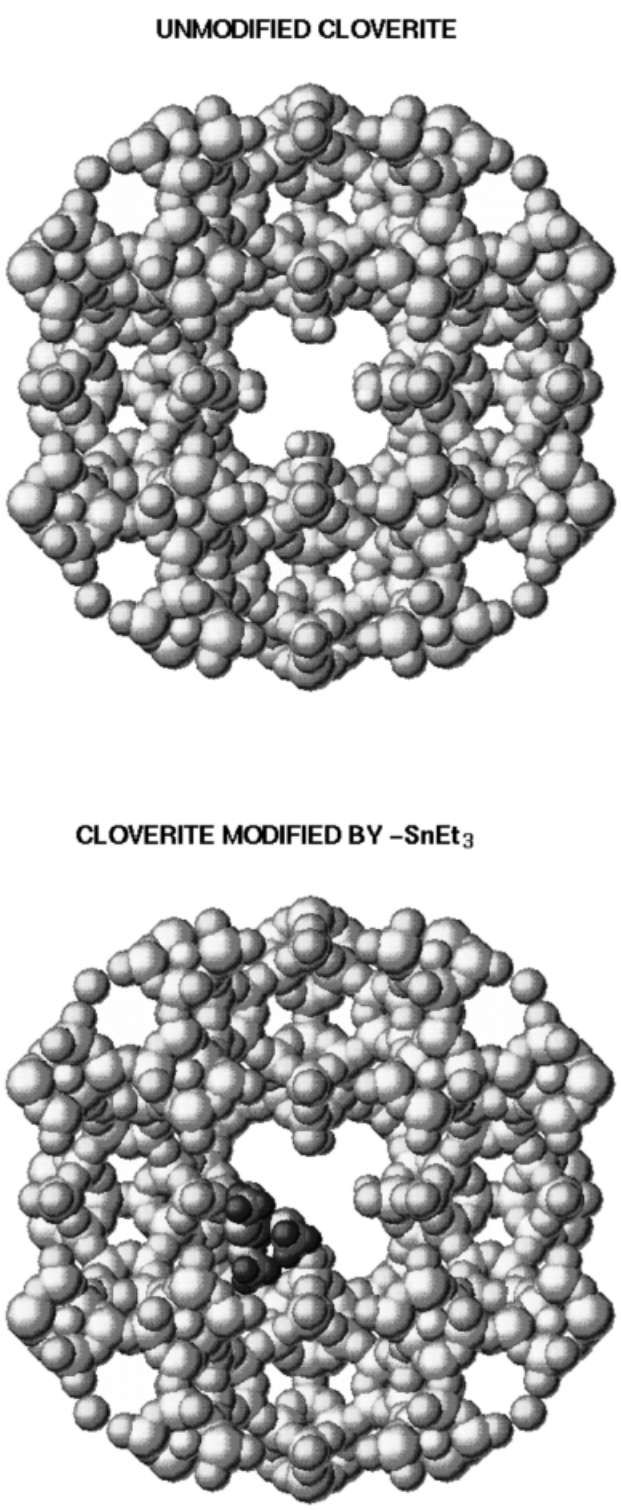

Figure 9. Molecular modelling representation of a supercage window of cloverite before and after modification by reaction with tetraethyltin

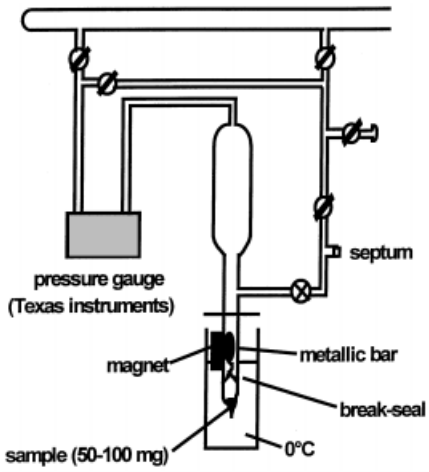

Figure 10. Schematic representation of the apparatus used for the determination of the adsorption capacities by a static method

ing as there are many more steric interactions between the adsorbed molecule and the grafted organometallic complex than in the case of mordenite, where the grafting reaction occurs only on the external surface (there is not just one interaction with the organometallic compound as the hydrocarbon is adsorbed onto the solid, but numerous interactions along the channels).

Analogous studies were also performed on MCM-41, a recently discovered mesoporous silica.[26] MCM-41 has pores with a very sharp diameter distribution, rendering this material useful for separation processes of large molecules. Depending on the template used during the synthesis, the diameter of the pores can be varied from ca. 20 to 100 Å. The reactions of various alkyltin complexes with this solid were studied using the same physicochemical techniques as mentioned above.[24] As with mordenite and cloverite, a reaction was observed with the surface hydroxy groups. However, in contrast to what was observed in the previous examples, the main surface product when the mesoporous silica was pretreated at 200°C was not $\equiv Si-O-SnR_3$ but $(\equiv Si-O)_2SnR_2$, obtained by reaction of two hydroxy groups with SnR_4. This result was tentatively attributed to the concavity of the walls in the pores, which probably induced a stabilization of the multi-grafted species. When the mesoporous silica was initially dehydroxylated at 500°C, the mono-grafted species was predominant (more than 90% of the tin was present in the form of $\equiv Si-O-SnR_3$ species) and all the hydroxy groups were consumed. For this material, the grafting reaction completely modified the shapes of the hydrocarbon adsorption isotherms (Figure 11). Indeed, the isotherm of unmodified mesoporous silica showed a great increase of the adsorbed alkane (for example, *n*-hexane) at low P/P_0 ratios, while the isotherm of the modified material increased only slowly as a function of P/P_0. This phenomenon was independent of the hydrocarbon, all alkanes with the same number of carbon atoms giving the same curves. It was explained by assuming that for the unmodified material the adsorption curve was due to hydrogen bonding between the

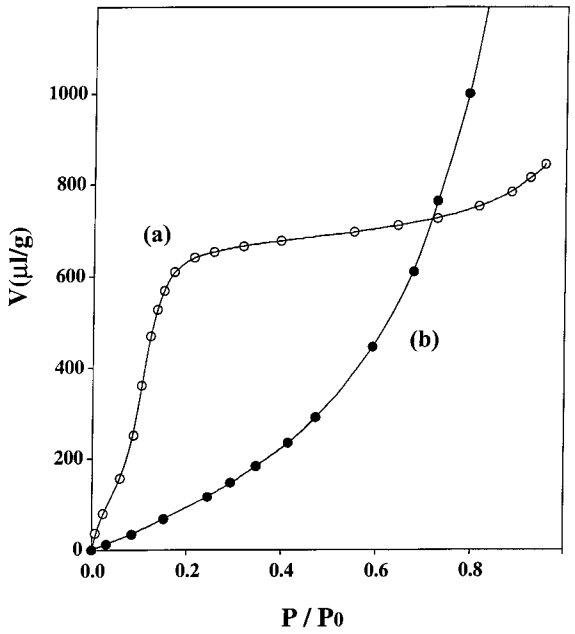

Figure 11. Adsorption isotherms at 0°C of *n*-hexane on MCM-41 dehydroxylated at 500°C before (a) and after (b) reaction with tetrabutyltin

hydroxy groups of the surface and the C−H bonds of alkanes, while in the modified material the hydroxy groups were absent and the aforementioned interactions were replaced by van der Waals interactions between the alkyl groups of the grafted organometallic fragments and the hydrocarbons.

Conclusion

This short review article has shown the great advantages of the modification of molecular sieves by grafting organometallic compounds. Two different methods can be used: OMCVD, where the grafted organometallic fragment is calcined and transformed into an oxide of rather indefinite composition, and SOMC, where the grafted organometallic fragment is well-characterized and retains its molecular integrity. Both methods can lead either to a grafting reaction only on the external surface, or to grafting inside the channels of the molecular sieve as well, depending on the reaction conditions and on the size of the organometallic complex used for the modification. In the case of SOMC, it is possible to modify only the external surface of molecular sieves such as mordenites, leading to an increased selectivity, e.g., in xylene isomerization. Grafting of the organometallic complex near the pore entrances permits a fine tuning of the adsorption properties of the zeolite. Two effects can be observed, depending on the size of the adsorbed molecule: (i) a total exclusion of the molecule from the channels of the molecular sieve, due to steric constraints ("thermodynamic effect"); (ii) a retardation of the adsorption kinetics of the adsorbed molecule, due to steric interactions with the grafted organometallic fragments at the pore entrances ("kinetic control").

These properties of the modified materials can be envisaged as being useful in catalysis. For this purpose, it would be necessary to first introduce the catalytically active species into the channels of the molecular sieve and then to graft the organometallic complex onto the external surface in order to reduce the dimensions of the pore entrances. Two effects could then be expected: (i) The leaching of the catalyst could be completely avoided, allowing easy recycling. (ii) By judicious choice of the organometallic complex, only some reaction products could be desorbed from the molecular sieve containing the homogeneous catalyst, resulting, in line with the principle of microreversibility, to an increase in the selectivity towards these products.

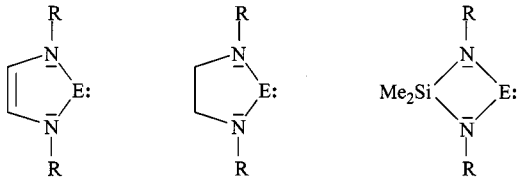
Some Silicon, Germanium, Tin, and Lead Analogues of Carbenes, Alkenes, and Dienes

Manfred Weidenbruch[a]



Keywords: Silicon / Germanium / Tin / Lead / Carbene analogues / Multiple bonds

The isolation and characterization of thermally stable diaminocarbenes and diaminosilylenes has reawakened interest in the low-coordinated compounds of group-14 elements. The existence of these species is presumably due to interactions between the free electron pairs on the nitrogen atoms and the carbene carbon atom or the silicon atom. The present review is mainly concerned with the heavier analogues R_2Ge**:**, R_2Sn**:**, and R_2Pb**:**, systems without intramolecular donor stabilization that owe their existence principally to steric shielding by the voluminous alkyl or aryl groups R. Dimerizations of these electron-sextet molecules give rise to the double-bond systems of the digermenes, distannenes, and diplumbenes; the latter species have for a long time been considered as being incapable of existence. The properties of these molecules are compared with the results of quantum chemical calculations. A separate section is devoted to the isomers of Si_4R_6, which include novel tetrasilacyclobutenes and the diene analogues, the tetrasilabuta-1,3-dienes.

Introduction

One of the most interesting developments in organo-element chemistry of the past few years has been the preparation and complete characterization of the diaminocarbenes **1**, which were soon supplemented by the saturated ring compounds **4** and even the corresponding acyclic compounds.[1] Shortly thereafter, the stable or marginally stable silylenes **2** and **5**,[2] as well as germylenes with the same substitution pattern,[1] were successfully prepared. The diaminogermylenes **7**, -stannylenes **8**, and -plumbylenes **9** have been known for a longer time and have since been shown to possess an extensive chemistry.[3] A correspondingly substituted silylene has now also been detected, although it is only stable in a matrix up to 77 K.[4]

A common feature of all these compounds is the presence of a free electron pair on the nitrogen atom, or on other donor atoms as well, which can either allow delocalization, as in the five-membered rings of **1**−**3** or, in the case of saturated systems, can participate in π-interactions with electron-deficient centers, as in compounds **4**−**9**.[5] As a result, the tendency of these species to undergo dimerization with formation of homonuclear double bonds is rather low. The dialkyl, diaryl, or disilyl derivatives of silicon, germanium, tin, and lead behave differently: They do not experience any intramolecular donor stabilization and can thus undergo dimerization to afford the homonuclear double-bond systems of the disilenes, digermenes, and distannenes with varying degrees of ease.

Manfred Weidenbruch studied chemistry at the Technical University of Aachen and received his Dr. rer. nat. in 1965 under the guidance of the late Professor Martin Schmeisser. After his habilitation at Aachen in 1971 he was appointed Außerplanmäßiger Professor in 1973. In 1978 he moved as Full Professor of Inorganic Chemistry to the University of Oldenburg. His research interests lie in the general field of main-group chemistry, particularly group-14 compounds, with emphasis on synthetic and structural studies.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

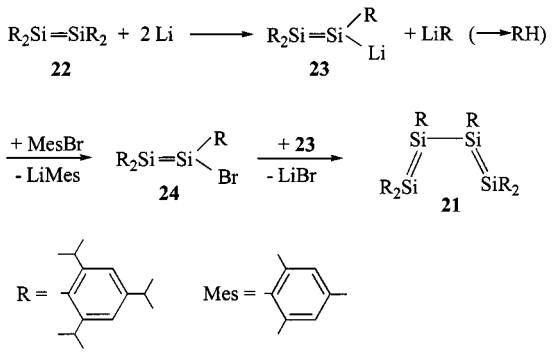
While most disilenes **11** are sufficiently stable towards dissociation into the silylenes **10**,[6] the tendency of the double-bond systems in **15** and **16** to undergo cleavage to the carbene analogues **12**–**14** increases on descending group 14 towards the heavier elements.[7] Thus, for example, only one distannene that retains its structural integrity in solution is known. In the case of lead, until recently merely a few dialkyl-, disilyl-, and diarylplumbylenes, but no diplumbenes $R_2Pb{=}PbR_2$, had been isolated. This behavior – which clearly deviates from that of alkenes – has been explained theoretically in terms of the varying nature of the double bond on descending the series. Thus, carbenes have either a triplet ground state (T) or a singlet ground state (S), with relatively small S → T transition energies. The familiar picture of a C–C double bond results from the approach of two triplet carbenes in the manner shown in Scheme 1.

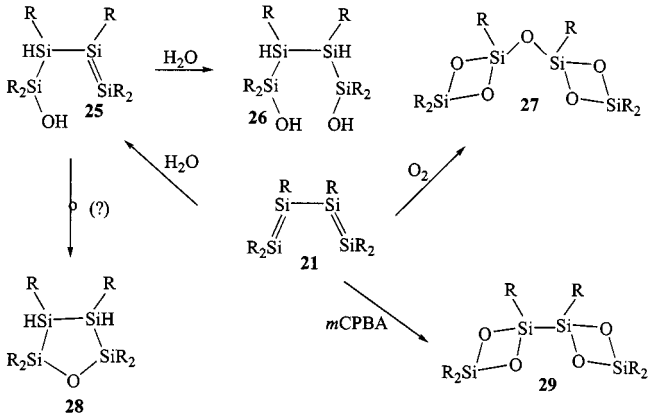
Scheme 1. Double-bond formation from two carbenes and their analogues

In contrast to the carbenes, all silylenes, germylenes, stannylenes, and plumbylenes characterized to date have exclusively singlet ground states, with the energy of the S → T separation increasing with increasing atomic mass of the group-14 element.[8] Thus, approach of two such singlet species in the manner shown in Scheme 1 should result in repulsion rather than in bond formation. However, if the two electron-sextet species are rotated with respect to one another, interactions between the doubly-occupied s orbitals and the vacant p orbitals can also lead to the creation of a double bond, which, in contrast to that in alkenes, arises by way of a double donor–acceptor adduct formation. This is accompanied by a *trans* bending of the substituents about the E=E vector, with the *trans*-bending angle Θ increasing appreciably on going to heavier elements.[9–12]



Since the results obtained up to 1994/1995 in the field of multiple bonding of group-14 elements have been covered in numerous review articles,[6,7] only some more recent developments, including the first diplumbene, the first tetrasilabutadiene, and some other isomers with the composition Si_4R_6, are included in the present survey.

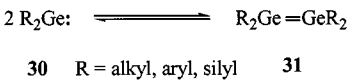
The Si_4R_6 Isomers



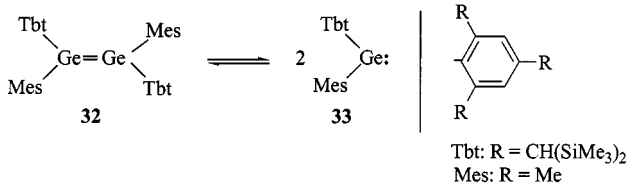
Since the isolation of tetramesityldisilene as the first molecule containing an Si–Si double bond in 1981,[13] numerous other compounds belonging to this class have been reported, although fundamentally new bonding systems are still rare. Recently, Kira et al. described the isolation of the first thermally stable cyclooligosilene **19** incorporating an Si=Si bond in the ring, albeit in very low yield, which was obtained by coupling of two oligosilanes.[14] Although compound **19** was found to be stable in the dark for an indefinite period, the action of visible light resulted in conversion to the tetrasilabicyclo[1.1.0]butane derivative, the butterfly-like skeleton of which had been described about 15 years earlier by Masamune et al. in relation to compound **17**.[15] Trapping experiments at low temperature indicated that the primary product of the coupling reaction was not the tetrasilacyclobutene **19**, but rather the tetrasilabicyclobutane **18**, which underwent conversion to **19** by 1,2-silyl group migration during work-up.[16] Although ring systems of this type are relatively new in molecular chemistry, the corresponding butterfly anions have long been known in solid-state chemistry. Thus, addition of two electrons to the tetrahedral anion $[Si_4]^{4-}$ leads smoothly to the tetrasilabicyclobutane system $[Si_4]^{6-}$ through cleavage of one bond, as is realized in the compound Ba_3Si_4.[17] By way of the same principle, Wiberg et al. recently obtained the tetrasilacyclobutene **20** in almost quantitative yield by reaction of the *tetrahedro*-tetrasilane $(tBu_3SiSi)_4$[18] with iodine.[19]

The isomer formed seemingly depends strongly not only on the nature of the substituents but also on the chosen synthetic route. The missing link in the series of simple compounds with the composition Si_4R_6, i.e. the tetrasilabuta-1,3-diene **21**, has been prepared in this laboratory in the following way. The action of excess lithium on the disilene **22**,[20] prepared photolytically from the trisilane $R_2Si(SiMe_3)_2$ by the method of West and co-workers,[21] presumably furnishes the disilenyllithium compound **23**. Half of the formed **23** is converted by reaction with mesityl bromide to the bromodisilene **24**, which spontaneously reacts with the remainder of the formed **23** through intermolecular cleavage of LiBr to afford the tetrasilabutadiene **21** in 60% yield.[22,23]

Interestingly, a crystal structure analysis of the brownish-red compound **21** revealed that it adopts the *s-cis* arrangement in the solid state, which is rather less favorable[24] than the *s-trans* form, with a dihedral angle of 51° within the Si_4 skeleton. The Si–Si double bonds are slightly lengthened in comparison with the corresponding bonds in disilenes, while the formal single bond is markedly shortened in spite



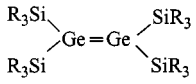
of the bulky substituents. These data, together with the electronic spectrum in solution, which reveals a bathochromic shift of the longest wavelength absorption of 100 nm compared with that of the tetraaryldisilenes, indicate that a conjugation between the Si−Si double bonds is present in both phases.



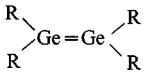
Although the *s-cis* form of compound **21** would appear to be ideally suited for Diels−Alder reactions, all attempts to achieve a [4 + 2] cycloaddition with C−C multiple bonds have failed.[25] The reason for this is probably the high steric shielding of the Si atoms in **21**, as well as the large 1,4 separation of about 540 pm. However, compound **21** does react readily with small molecules, as illustrated. For example, an initial 1,2-addition to furnish compound **25** occurs with water, which can be followed by a second 1,2-addition to afford **26**. Somewhat surprisingly, however, compound **26** does not exhibit any tendency to undergo condensation. Although the constitution of compound **28** has been confirmed by an X-ray crystal structure analysis, it cannot as yet be stated whether it is formed by rearrangement of **25** or by another route. The reaction of *meta*-chloroperbenzoic acid (*m*CPBA) with **21** proceeds through a three-membered ring intermediate [a bis(disilaoxirane)] to furnish bis(2,4-disila-1,3-dioxetane) **29** as the final product. With atmospheric oxygen, an additional insertion of oxygen into the formal Si−Si single bond with formation of **27** occurs; considering the steric shielding of this bond, this is a somewhat unexpected reaction.[23,26]

Germylenes, Digermenes

Stable dialkyl- or diarylgermylenes R_2Ge**:** (**30**), apart from Lappert's compound[27] $[(Me_3Si)_2CH]_2Ge$**:**, have only become known in the past few years. Examples include, among others, the structurally confirmed molecules $(Me_3Si)_3C[(Me_3Si)_2CH]Ge$**:**[28] and $(2,4,6\text{-}tBu_3C_6H_2)_2Ge$**:**[29], of which the latter is converted in the presence of a Lewis acid or at high temperatures to a germaindane derivative by insertion of the germanium atom into one of the methyl groups of the *ortho-tert*-butyl substituents,[30] as well as the sterically extremely crowded $(2,6\text{-}Mes_2C_6H_3)_2Ge$**:** (Mes = $2,4,6\text{-}Me_3C_6H_2$).[31] The compound $[2,4,6\text{-}(CF_3)_3C_6H_2]_2Ge$**:** can only be mentioned with reservations since it has to be classified as an intramolecularly donor-stabilized germylene on account of the weak F···Ge contacts between the electron-poor germanium atom and the fluorine atoms of the *ortho*-CF_3 groups.[32]

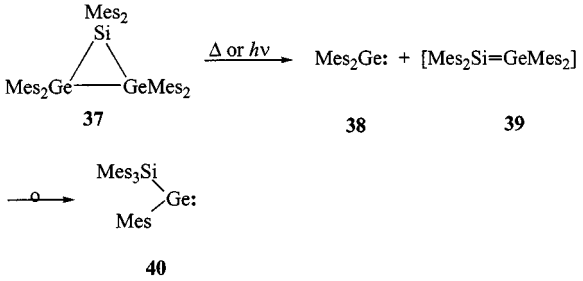


A comparatively large number of germylenes are stable in solution since some of the digermenes **31**, although stable in the solid state, dissociate to germylene molecules in solution. Whether monomeric germylenes with larger Ge···Ge separations or digermenes with a formal Ge−Ge double bond exist in the solid state probably depends on both the spatial requirements of the substituents bonded to the germanium atom and the possible donor properties of these groups. Thus, the aforementioned germylenes either bear very bulky substituent groups or, as in the case of the 2,4,6-$(CF_3)_3C_6H_2$-substituted compound, experience a weak donor stabilization. Lappert's germylene is an exception: It is stable in solution but exists as a digermene in the crystalline state in spite of the presence of very bulky substituents.[33]



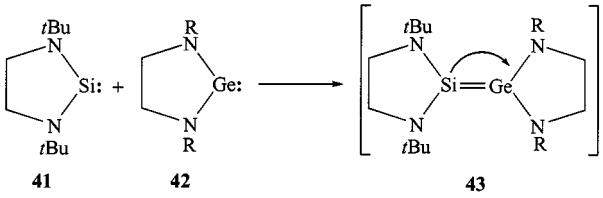
The usually facile cleavage of the Ge−Ge double bond to furnish two germylene molecules is most probably due to the low bond dissociation energy. Thus, a bond dissociation energy of merely 61.5 kJ mol^{-1} has recently been determined for the cleavage **32** → 2 **33** by variable-temperature electronic spectroscopy.[34] This is in accord with the variable Ge−Ge bond lengths in digermenes, which range from 221 to 246 pm, as well as with the *trans*-bent angles, which range from 45° to almost 0° (i.e. a planar structure). The shortest Ge−Ge bond length is observed in the digermene $Dep_2Ge{=}GeDep_2$ (Dep = $2,6\text{-}Et_2C_6H_3$), where the substituents have the lowest spatial requirements.[35] The *trans*-bent angle in this compound, 12°, is also small, and represents one of the lowest values yet found for a tetraaryldigermene. Even the slightest changes in the spatial require-

ments of the substituents can result in markedly different bond lengths and angles: Thus, the compound (*E*)-MesDipGe=GeMesDip (Dip = 2,6-$iPr_2C_6H_3$) has a Ge−Ge bond length of 230.1(1) pm and a bending angle of 36°.[36] These examples illustrate the difficulties in predicting the lengths and deformations of Ge−Ge double bonds, which can again be explained in terms of the flat potentials for bending angles and E=E bond lengths in homonuclear multiple bonds between the heavier elements of group 14.

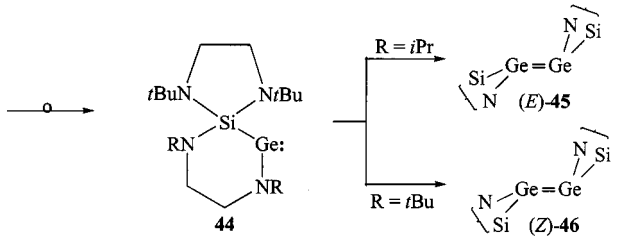


34 $SiR_3 = iPr_2MeSi$
35 $SiR_3 = iPr_3Si$

36 R = 2-*t*Bu-4,5,6-Me_3C_6H

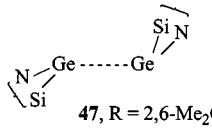


Recently, Kira et al. described some tetrasilyldigermenes, among which the structures of compounds **34** and **35** were characterized by X-ray crystallography. In agreement with theoretical calculations, which predict that electropositive substituents should favor a planar arrangement, these molecules exhibit small bending angles of 5.9° and 16.4°, while the Ge−Ge double bond lengths are surprisingly short in view of the bulky substituents, 226.8(1) pm in **34** and 229.8(1) pm in **35**.[37] However, the presence of electropositive substituents is not an essential prerequisite for such an arrangement, as demonstrated by the tetraaryldigermene **36**, which has an almost planar structure and a short Ge−Ge bond length of 225.21(8) pm.[38]



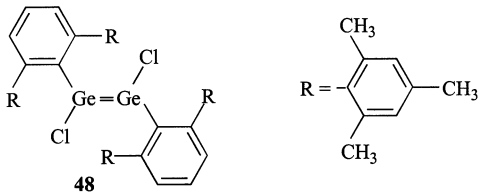
37 **38** **39**

40

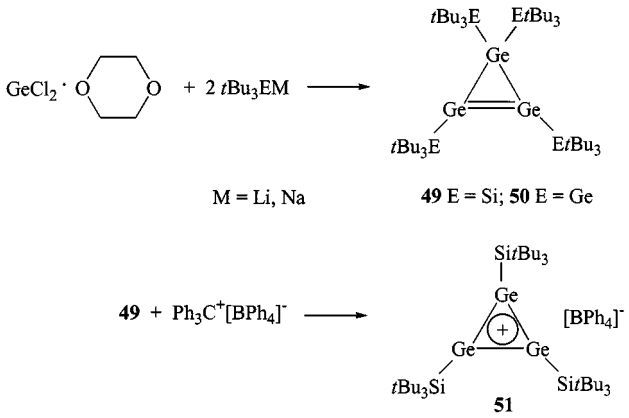


These examples further illustrate how difficult it is to correlate the substitution pattern about the Ge−Ge double bond with the molecular structure. Nevertheless, the existence of Si−Si and Ge−Ge double bonds cannot be questioned. On the other hand, stable compounds with heteronuclear double bonds between these elements are still unknown. In a series of papers, Baines et al. reported on the photolysis and thermolysis of the siladigermirane **37**, which resulted in regioselective conversion to the germylene **38** and the germasilene **39**, although the latter compound underwent rapid isomerization to the silylgermylene **40**. The presence of compounds **38**, **39**, and **40** in the reaction mixture was confirmed by isolation of the corresponding products of trapping reactions.[39−42]

41 **42** **43**

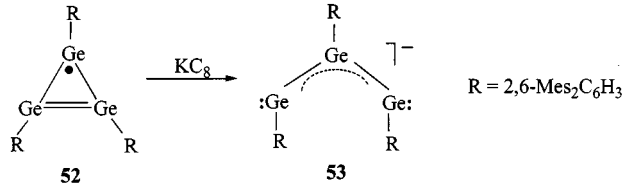


44 **(*E*)-45** **(*Z*)-46**



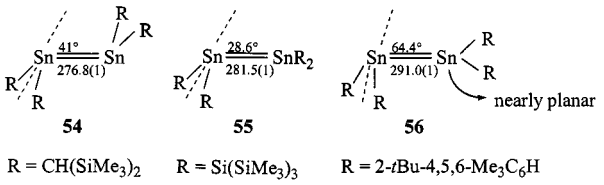
47, R = 2,6-$Me_2C_6H_3$

The potentially promising idea of allowing the marginally stable diaminosilylene **41**[2] to react with various diaminogermylenes **42**[1] as an approach to germasilenes yielded surprising results. It seems that in all cases an initial, loosely bound adduct **43** is formed between the electron-sextet species, which is then transformed into the novel aminosilylgermylenes **44** by insertion of the silicon atom into one of the Ge−N bonds. The conceivable subsequent reactions are again strongly influenced by the nature of the substituents R at the germanium atom. In the case of R = *t*Bu, the digermene (*Z*)-**46** is formed; this compound has a very long Ge−Ge bond of 245.4(2) pm and pronounced *trans*-bent angles of 41.3° and 42.3°, which clearly exceed all previously known θ values.[43] On the other hand, with R = *i*Pr the digermene (*E*)-**45** is obtained, which has an even longer Ge−Ge bond length than that in (*Z*)-**46**, as well as a markedly larger bending angle.[44] Finally, with the aryl substituent R = 2,6-$Me_2C_6H_3$, the germylene **47** is isolated. The Ge−Ge separation of 410 pm and the *trans*-bent angle of 14° are indicative of weak dispersive forces between neighboring germylene molecules.[44] In parallel to the investigations performed in this laboratory, Lappert et al. reported on an analogous insertion of a diaminosilylene into one of the Ge−N bonds of $Ge[N(SiMe_3)_2]_2$; the final product in this case being a germane.[45] The large Ge−Ge bond lengths in (*E*)-**45** and (*Z*)-**46**, and the only very weak interactions in **47**, are probably attributable to the substitution patterns in these compounds. Although the Ge−Si bond in the intermediate **44** promotes the formation of a Ge−Ge double bond, the Ge−N bonds also present hinder Ge−Ge contacts, with the overall result that the structural param-



eters described above represent a compromise between these opposing effects.

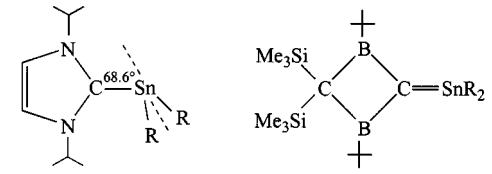
A similar situation is found in compound **48**, where each germanium atom bears an aryl group and a chlorine atom; in the solid state it exists as a dimer with a Ge−Ge bond length of 244.3(2) pm and a *trans*-bending angle of Θ = 39°.[31] A further candidate for an analogous dimer could be the germylene RGeCl (R = 2,4,6-tBu$_3$C$_6$H$_2$), which is monomeric in solution but has yet to be examined in the solid state by X-ray crystallography.[46]



The cyclotrigermenes **49** and **50**, the first compounds with endocyclic Ge−Ge double bonds, were reported by Sekiguchi et al.,[47] who also generated and isolated the cation **51** from compound **49** by treatment with trityl tetraphenylborate.[48] An X-ray crystal structure analysis of the cyclotrigermenium salt revealed the presence of free germyl cations with a delocalized 2π-electron system, reminiscent of the cyclopropenium ion, with an equilateral triangular form.[48] The Ge−Ge bond lengths of 232.5 pm are intermediate between those of a single and a double bond.

Power et al. obtained another unusual compound similar to the cation **51** by dehalogenation of RGeCl (R = 2,6-Mes$_2$C$_6$H$_3$) with KC$_8$; the reaction furnished the cyclotrigermyl radical **52**. Although X-ray crystal structure analysis of **52** provided only limited details because of disorder problems, the EPR spectrum of the compound indicated the localization of the unpaired electron on one germanium atom. Further action of KC$_8$ on **52** led to the trigermyl anion **53**, with a structure comparable to that of the allyl anion but with a very large Ge−Ge−Ge angle of 159.2°.[49]

Stannylenes, Distannenes

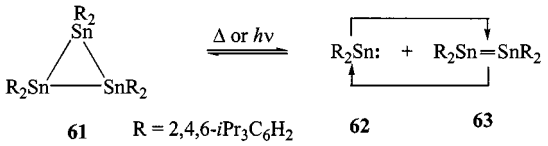


Lappert's distannene **54** was the first compound with a homonuclear multiple bond between two heavier atoms of group-14 elements to be prepared; however, its classification was at first difficult on account of the lack of suitable data for comparison.[9,50] The successful syntheses of stable disilenes and digermenes,[6,7] as well as the results of quantum chemical calculations,[9−12] were additionally needed to show that this molecule, with its *trans* bending of the substituents by 41° and the Sn−Sn bond length of 276.8(1) pm, a value approaching that of an Sn−Sn single bond, fits almost ideally into the series of homonuclear bonds between atoms of elements of this group.

Although compound **54** was first prepared and characterized by X-ray crystallography in 1976,[50] almost twenty years passed before the isolation of **55** and **56**, two further distannenes that are also stable in the solid state. These three distannenes differ considerably in their spatial structures. While the parameters for **54** are akin to those theoretically calculated for the parent compound Sn_2H_4, the highly distorted compound **55** avoids the strain arising from the bulky substituents by means of a considerable torsion about the double bond of 63.2° and a small *trans*-bent angle of 28.6°.[51] The structure of **56** is even more unusual: The long Sn−Sn bond, the length of which even exceeds that of an Sn−Sn single bond by about 13 pm, as well as the differing environments of the substituents on the two tin atoms, are indicative of a zwitterionic character of the molecule according to $R_2Sn^+ \rightarrow {}^-SnR_2$, which may arise through a single donor−acceptor interaction between the fully occupied s orbital of one tin atom and the empty p orbital of the other. This hypothesis is supported by the observation that the Sn−C bond lengths at the formally negatively charged tin atom are appreciably longer than those at the tin atom bearing the positive charge.[52] However, these observations are apparently at variance with the ^{119}Sn CP-MAS NMR spectrum of crystalline **56**, which features only one signal at δ_{iso} = 819.[53]

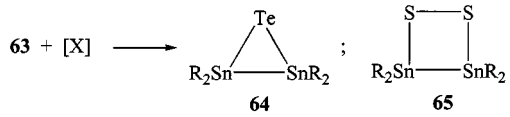
In order to simulate the bonding situation in solid **56**, a nucleophilic carbene of the Arduengo type[1] was prepared in this laboratory according to the method of Kuhn and Kratz,[54] and was allowed to react with a diarylstannylene. In spite of the different binding partners, the resulting compound **57** exhibited great similarity to the distannene **56**.

Thus, the tin atom in **57** exhibits a strong pyramidalization, with a bending angle of 68.6°, and the molecule has



57 R = 2,4,6-*i*Pr$_3$C$_6$H$_2$ **58** R = 2-*t*Bu-4,5,6-Me$_3$C$_6$H

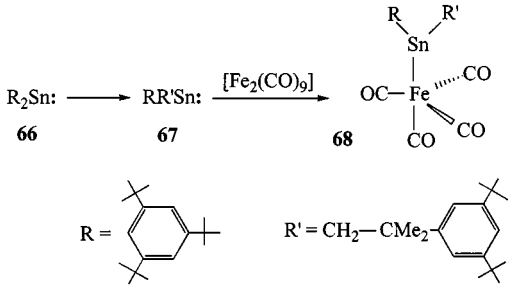
an extremely stretched Sn−C bond length of 237.9(5) pm.[55] In contrast, the stannaethene **58**, prepared for comparison purposes from an electrophilic cryptodiborylcarbene and a diarylstannylene, has completely planar environments at both the tin and the carbon atoms, with an Sn−C bond length of only 203.2(5) pm.[56]



$R_2Sn{=}SnR_2 \rightleftharpoons 2\ R_2Sn:$

59 crystal **60** solution

A common feature of all distannenes **59**, including the recently reported compound RR′Sn=SnRR′ [R = Si(SiCH$_3$)$_3$, R′ = 2,4,6-(CF$_3$)$_3$C$_6$H$_2$],[57] is their stability in the crystalline state, even though they largely dissociate into stannylenes **60** in solution. An exception is the distannene **63**, first prepared by Masamune and Sita by thermolysis or photolysis of the cyclotristannane **61**, which retains its structural integrity in solution.[58]

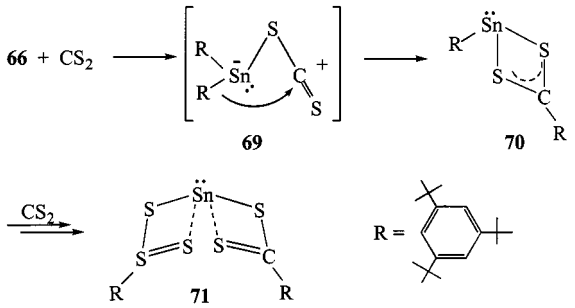


61 R = 2,4,6-*i*Pr$_3$C$_6$H$_2$ **62** **63**

64 **65**

The existence of the Sn−Sn double bond in solution was demonstrated not only by variable-temperature ^{119}Sn-NMR spectroscopy,[58,61] but also by trapping reactions with the heavier chalcogens to give, for example, the new ring systems of the telluradistannirane **64,**[59] or the unusual 1,2-dithiadistannetane **65**.[60] However, compound **63** cannot be isolated as a solid because at room temperature there is invariably some reversion to cyclotristannane **61** through generation of the stannylene **62** and its addition to **63**. Since the steric crowding of the aryl groups in distannene **63** is insufficient to prevent this reversion to cyclotristannane **61**, the isopropyl substituents in **63** were replaced by *tert*-butyl groups, and, after numerous unsuccessful attempts, dark-red crystals of the stannylene **66** were obtained by reaction of 2,4,6-*t*Bu$_3$C$_6$H$_2$Li with Sn[N(SiMe$_3$)$_2$]$_2$. This compound was found to exist as the monomeric stannylene both in solution and in the solid state. The spatial requirements of the substituents are apparently too great to allow a dimerization to the distannene in this case.[62]

Although the diarylstannylene **66** is stable in the crystalline state for an indefinite length of time, in solution a slow

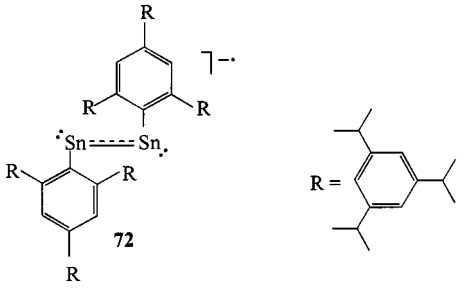


66 **67** **68**

R = R′ = CH$_2$—CMe$_2$

isomerization occurs, leading to the alkylarylstannylene **67**. Accordingly, all reactions with heavier chalcogens or transition metal substrates furnish exclusively products containing an aryl/alkyl-isomerized group R′.[63] One unusual result arose from the reaction of the stannylene with [Fe$_2$(CO)$_9$] or [Fe$_3$(CO)$_{12}$]: In the resulting iron complex **68** the stannylene **67** occupies an axial site, indicative of a strong σ-donor but weak π-acceptor character.[64,65]

It is of interest to note that **66** represents the first structurally characterized diarylstannylene that lacks donor stabilization. However, the stannylene [2,4,6-(CF$_3$)$_3$C$_6$H$_2$]$_2$Sn:, stabilized by weak F···Sn contacts, was known previously and had been observed in a second crystalline form involving weak Sn···Sn interactions.[66,67] Recently, Power et al. described the sterically crowded stannylene (2,6-Mes$_2$C$_6$H$_3$)$_2$Sn:, which, like **66**, cannot form a distannene in the solid state for steric reasons.[31] Structurally confirmed dialkylstannylenes are also rare, of which the cyclic compound SnC(SiMe$_3$)$_2$[CH$_2$]$_2$C^a(SiMe$_3$)$_2$(*Sn*−*C*^{a}) is mentioned as an example.[68]

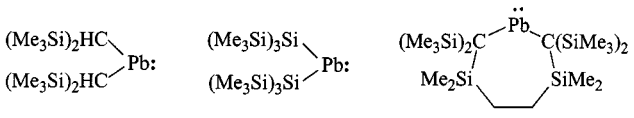


69 **70**

71

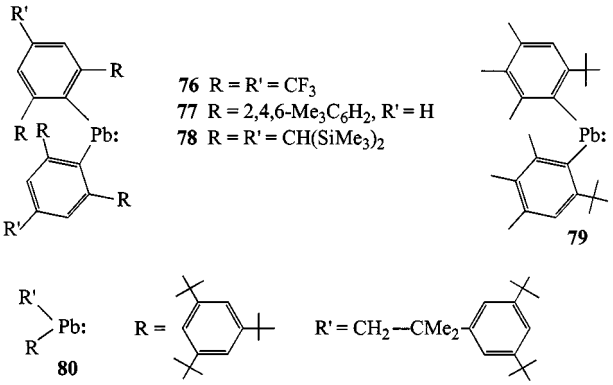
The only reaction of **66** to proceed without isomerization is that with carbon disulfide. This is probably due to the primary formation of an end-on or side-on adduct of the reacting species, **69**, followed by an aryl group migration to afford the tricoordinated stannylene **70**. A repetition of this process then leads to the final product, the tetracoordinated stannylene **71**; the structures of both compounds **70** and **71** were confirmed by X-ray crystallography.[69]

The trend towards decreasing E=E bond energies, which first becomes apparent in the digermenes, becomes more pronounced in the distannenes with the result that all distannenes, with the exception of compound **63**,[58] largely exist as the corresponding stannylenes in solution. Accordingly, the activation barrier determined for the equilibrium **59** ⇄ **60** (R = 2-*t*Bu-4,5,6-Me$_3$C$_6$H) amounts to just 34 kJ mol^{-1}.[53] As illustrated by the facile isomerization of **66**,

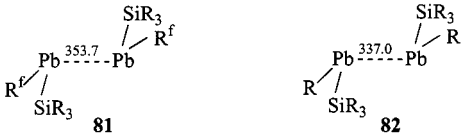


the Sn−C bonds are also appreciably more labile on account of their relatively large bond lengths.

Power et al. have recently reported on a novel Sn−Sn bonding situation: Reaction of a sterically extremely crowded arylchlorostannylene with KC_8 furnished the radical anion **72**, which could be crystallized with $[K(THF)_6]^+$ or $[K(dibenzo\text{-}18\text{-}crown\text{-}6)(THF)_3]^+$ as the counterion. The anion exhibits an Sn−Sn bond length of 281.2(1) pm and a *trans*-bent angle of 95.2°. Together with the spectral data, these values are indicative of a molecular ion with an Sn−Sn bond order of 1.5 and a localization of the free electron pairs on the two tin atoms.[70]

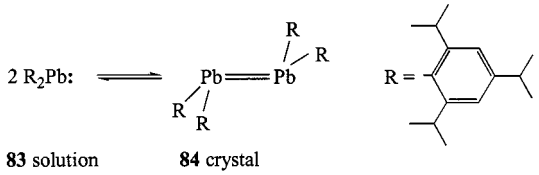


The Elusive Diplumbenes



On account of their thermal lability and sensitivity to light, dialkyl- and diarylplumbanes were virtually unknown until recently. Although Lappert et al.[27][71] reported the isolation of the purple plumbylene **73** as early as 1973, its structure has only recently been determined.[72] In the solid state, compound **73** exists as a loosely bound dimer with a second plumbylene molecule and has a Pb···Pb separation of 412.9 pm with a *trans*-bent angle of 34.2°.

In contrast, the not too dissimilar cyclic plumbylene **75**[73] and the disilyl compound **74**[51] are strictly monomeric. The same holds for the diarylplumbylene **76**, which represents a borderline case between non-stabilized and donor-stabilized systems as a consequence of its weak Pb···F contacts,[74] and for the sterically extremely crowded diarylplumbylenes **77**[31] and **78**.[75]



The sterically less crowded diarylplumbylene **79** and the heteroleptic alkylarylplumbylene **80** do not interact with neighboring plumbylene molecules either.[76] The formation of **80** is of interest since it allows a comparison to be made with the molecules $(2,4,6\text{-}t\text{Bu}_3C_6H_2)_2\text{Ge:}$[29] and **66**,[62] which were prepared by similar routes. The germanium compound is only stable at low temperature, while **66**, although stable for an indefinite length of time in the solid state, undergoes a slow isomerization in solution to furnish an alkylarylstannylene with the same substitution pattern as that in **80**. There is some evidence that the diarylplumbylene is formed initially in the reaction of $2,4,6\text{-}t\text{Bu}_3C_6H_2MgBr$ with lead(II) chloride, but then undergoes rearrangement to compound **80** at temperatures above −30°C.[76]

$SiR_3 = Si(SiMe_3)_3$; $R^f = 2,4,6\text{-}(CF_3)_3C_6H_2$; R = 2-*t*Bu-4,5,6-$Me_3C_6H$

The plumbylenes **73**−**80** all exist as V-shaped monomers in the crystal, with C−Pb−C angles ranging from 96.5° (**80**) to 117.1° (**75**). A first breakthrough with regard to lead−lead contacts between plumbylene molecules was realized with the recent isolation of the heteroleptic plumbylene dimer **81**, which has a Pb···Pb separation of 353.7(1) pm and a *trans*-bent angle of 40.8°.[57] Since intramolecular interactions between the fluorine atoms of the *ortho*-CF_3 groups and the lead atoms should weaken rather than favor a possible lead−lead interaction, another heteroleptic plumbylene has been prepared in this laboratory by reaction of the plumbylenes **74** and **79**. In the solid state, the thus formed plumbylene dimer **82** exhibits a short lead−lead separation of 337.0(1) pm and a *trans*-bent angle of 46.5°.[76] However, the observed lead−lead separations in **82**, and especially in **81**, are still markedly larger than the bond length of 295−300 pm calculated for the parent compound $H_2Pb{=}PbH_2$.[10,12,57]

Since sterically less demanding aryl groups apparently favor lead−lead contacts between plumbylene molecules, the reaction of $2,4,6\text{-}i\text{Pr}_3C_6H_2MgBr$ with lead(II) chloride at low temperature has been examined. This led to a violet solution of the plumbylene **83**, from which red crystals of the diplumbene **84** could be obtained. The existence of the first molecule with a lead−lead double bond is supported by the Pb−Pb bond length of 305.15(3) pm and the *trans*-

bent angles of 43.9° and 51.2°, which agree rather well with the calculated values.[77] Thus, with the discovery of compound **84**, homonuclear double bonds between all elements of group 14 are now known.

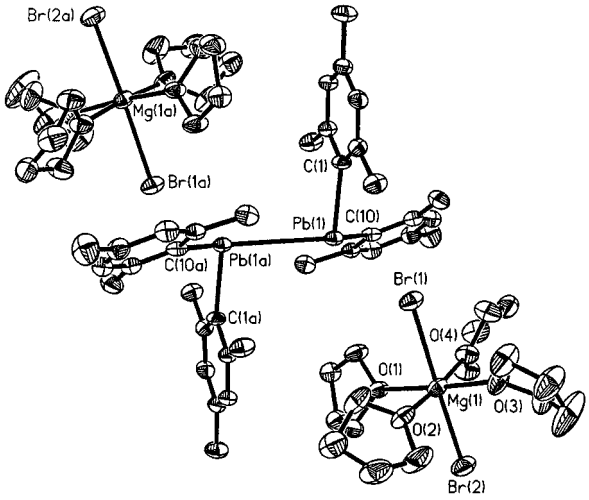


Figure 1. Molecular structure of the $MgBr_2(thf)_4$-stabilized plumbylene dimer $(Mes_2Pb)_2$

In order to examine whether even smaller aryl groups are capable of protecting a possible diplumbene from subsequent reactions, 2,4,6-$Me_3C_6H_2MgBr$ was allowed to react with lead(II) chloride under otherwise identical conditions. Black crystals of compound **85** were obtained, a plumbylene dimer stabilized by $MgBr_2(THF)_4$, as shown in Figure 1. Although the Pb···Br contact is about 50 pm longer than a Pb−Br bond, it does have an appreciable influence on the molecular structure of **85**, as manifested in the *trans*-bent angle of 71.2° and the Pb···Pb separation of 335.49(6) pm.[78] These examples indicate that more interesting results may be expected in the field of plumbylene dimers and diplumbenes.

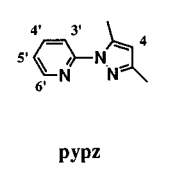
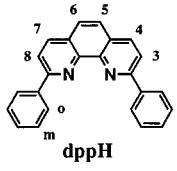
Efficient and Selective Photochemical Labilization of a Given Bidentate Ligand in Mixed Ruthenium(II) Complexes of the $Ru(phen)_2L^{2+}$ and $Ru(bipy)_2L^{2+}$ Family (L = Sterically Hindering Chelate)

Anne-Chantal Laemmel,[a] Jean-Paul Collin,*[a] and Jean-Pierre Sauvage*[a]

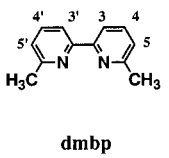
Keywords: Ruthenium / Photochemistry / Photosubstitution / Diimine chelates / Sterically hindered ligands



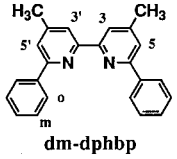
Mixed ruthenium(II) complexes containing 1,10-phenanthroline (or 2,2′-bipyridine) and a sterically congested bidentate ligand such as 2,9-diphenyl-1,10-phenanthroline, 6,6′-dimethyl- or 6,6′-diphenyl-2,2′-bipyridine, or 1-(2′-pyridyl)-3,5-dimethylpyrazole undergo clean and selective ligand substitution under irradiation with visible light. For instance, $Ru(phen)_2(dmbp)^{2+}$ in CH_3CN is quantitatively converted to $Ru(phen)_2(CH_3CN)_2{}^{2+}$ in a photochemical reaction accompanied by expulsion of the sterically hindering chelate dmbp (phen = 1,10-phenanthroline; dmbp = 6,6′-dimethyl-2,2′-bipyridine). Interestingly, 2,2′-bipyridine was found to be photochemically ejected in one case, probably as a consequence of its greater flexibility.



The development of new molecular devices relying on electronic and photonic processes is an attractive challenge. Signal processing and information storage at the molecular level could be based on molecules able to exist in two stable states,[1] with the interconversion between these states having to be fast and quantitative.



Ruthenium(II) complexes display photochemical properties that permit their use as photoactive electron- or energy-transfer components,[2] photochemical stability of the complex being an essential requirement. On the other hand, *the photolabilization of a ligand followed by its recoordination in the dark could be the key steps in the construction of photoswitchable molecular devices.* Interesting photochemically labile ruthenium(II) complexes have been reported, some of which are capable of clean photo-expulsion of a given ligand with a high quantum efficiency.[3]



Herein, we describe the quantitative photosubstitution reactions that occur in four tris-chelated ruthenium(II) complexes. These complexes (**1**, **2**, **5**, **6**), incorporating two identical bidentate ligands (bipy or phen; bipy = 2,2′-bipyridine, phen = 1,10-phenanthroline) and a suitable third ligand, are shown in Scheme 1.

The choice of the third ligand was made with the help of models, which predicted that photolabilization would be most likely to occur on the weakest ligand field axis.[4] Hindering bidentate ligands such as dppH, dmbp, and dm-dphbp (dppH = 2,9-diphenyl-1,10-phenanthroline; dmbp = 6,6′-dimethyl-2,2′-bipyridine; dm-dphbp = 4,4′-dimethyl-6,6′-diphenyl-2,2′-bipyridine) or disymmetrical ligands with poor σ-donor character such as pypz [pypz = 1-(2′-pyridyl)-3,5-dimethylpyrazole] are considered to decrease the ligand field. Excitation in the MLCT region leads to a charge-transfer excited state, allowing the thermal

$Ru(bipy)_2(pypz)(PF_6)_2$	**1**
$Ru(bipy)_2(dppH)(PF_6)_2$	**2**
$Ru(bipy)(dppH)(CH_3CN)_2(PF_6)_2$	**3**
$Ru(bipy)(dpp)(CH_3CN)(PF_6)$	**4**
$Ru(phen)_2(dmbp)(PF_6)_2$	**5**
$Ru(phen)_2(dm\text{-}dphbp)(PF_6)_2$	**6**

Scheme 1. The various ligands used and the ruthenium(II) complexes made and studied

population of low-lying dissociative d-d states.[5] As expected, visible (300 nm ≤ λ ≤ 800 nm) light irradiation of **1**, **2**, **5**, and **6** in degassed acetonitrile led very selectively to a substitution of one bidentate ligand by two molecules of solvent (reactions 1, 2, and 3 in Scheme 2). The photoproduct was unambiguously identified as $[Ru(bipy)_2(CH_3CN)_2](PF_6)_2$ or $[Ru(phen)_2(CH_3CN)_2](PF_6)_2$ depending on the starting complex.

However, contrasting behavior between the various complexes could also be observed. Since the tris complex $Ru(pypz)_3{}^{2+}$, previously studied by Marzin et al.,[6] undergoes photosubstitution in acetonitrile to produce $Ru(pypz)_2(CH_3CN)_2{}^{2+}$,[7] it was not unexpected that irradiation of **1** led efficiently to $Ru(bipy)_2(CH_3CN)_2{}^{2+}$. On the contrary,

$$Ru(bipy)_2(pypz)^{2+} \xrightarrow[CH_3CN]{h\nu} Ru(bipy)_2(CH_3CN)_2{}^{2+} + pypz \quad (1)$$

$$Ru(bipy)_2(dppH)^{2+} \xrightarrow[CH_3CN]{h\nu} Ru(bipy)(dppH)(CH_3CN)_2{}^{2+} + bipy \quad (2)$$

$$Ru(phen)_2(L)^{2+} \xrightarrow[CH_3CN]{h\nu} Ru(phen)_2(CH_3CN)_2{}^{2+} + L \quad (3)$$

L = dmbp or dm-dphbp

Scheme 2. Photochemical subtitution of a given bidentate chelate by CH_3CN

compound **2** formed from the same $Ru(bipy)_2$ core and disubstituted 1,10-phenanthroline (dppH) displayed unexpected behavior. In this case, a bipyridine was photolabilized rather than the hindering dppH ligand. This finding may be related to the distorted structure of the complex. Indeed, the coordination of dppH in this complex may be quite normal in terms of Ru−N distances and the N−Ru−N angle. On the other hand, strong steric interactions between the phenyl groups and the bipy ligands could result in extension of the Ru−N(bipy) distances or to a twisting of the pyridine moieties. Such a distortion has been found in the solid state for the closely analogous complex $Ru(phen)_2(dmp)^{2+}$ (dmp = 2,9-dimethyl-1,10-phenanthroline).[8] An alternative argument hinges on the different rigidities of the bipyridine and phenanthroline ligands. Intuitively, the decoordination of phenanthroline must be more difficult than that of bipyridine, since after the first Ru−N bond breaking, the pyridine ring can rotate about the $C^2-C^{2'}$ bond in the case of bipy, whereas the aromatic plane of phen is almost impossible to distort. Indeed, intermediates with η^1-bipyridine ligands have been previously postulated[3a,5b] and recently identified[9] in the photosubstitution of $Ru(bipy)_2(3,3'\text{-dmbp})^{2+}$ in acidic media (3,3′-dmbp = 3,3′-dimethyl-2,2′-bipyridine). Unfortunately, complex **2** does not fulfil the requirements of reversibility because the photoproduct $Ru(bipy)(dppH)(CH_3CN)_2{}^{2+}$ is highly base-sensitive. During its attempted purification on an alumina column or in the presence of a trace of base, an orthometallation reaction takes place at one phenyl group leading to the very stable $Ru(bipy)(dpp)(CH_3CN)^+$ complex. This complex was fully characterized by ^{1}H NMR, FAB MS, and cyclic voltammetry. In order to avoid this reaction, and in view of the behavior of the disubstituted phenanthroline in complex **2**, complexes **5** and **6**, based on the $Ru(phen)_2$ core and incorporating a disubstituted bipyridine (dmbp or dm-dphbp), were prepared and irradiated in acetonitrile. These two systems were found to undergo very efficient photolabilization of the hindering bipyridine ($t_{1/2}$ = 28 and 390 s for **5** and **6**, respectively). As illustrated in Figure 1, after 140 s of irradiation, the electronic spectrum of a degassed acetonitrile solution of **5** is transformed to the characteristic spectrum of the $Ru(phen)_2(CH_3CN)_2{}^{2+}$ species.[10]

The presence of marked isosbestic points at 342 and 404 nm demonstrates the selectivity of the photosubstitution.

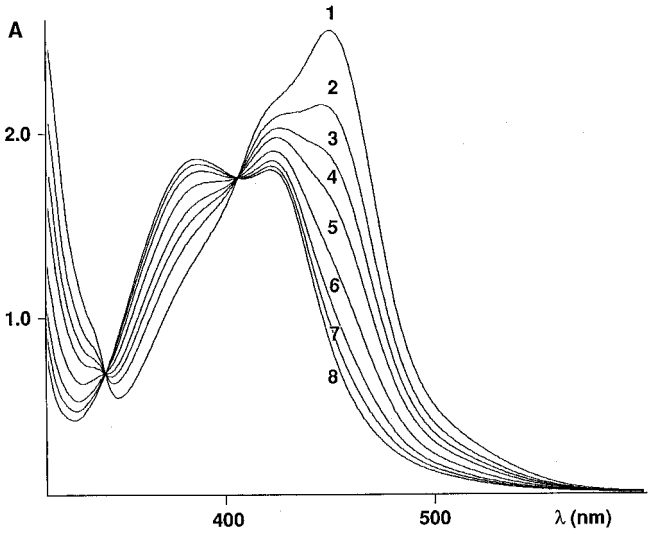

Figure 1. Visible spectra of a CH_3CN solution of **5** (1-cm cell; [**5**] = $2.4\cdot10^{-4}$ molL^{-1}) after various irradiation times: 0 s (1), 15 s (2), 25 s (3), 35 s (4), 55 s (5), 80 s (6), 105 s (7), 140 s (8)

The same result was also obtained by ^{1}H-NMR spectroscopy with direct light irradiation of the NMR tube. As suggested by the behavior of **2** and confirmed in the case of **5** and **6**, phenanthrolines are seen to be much more difficult to photolabilize than bipyridine ligands, regardless of which type of ligand is the hindering one. This conclusion can be related to the different quantum yields of photoanation found for $Ru(bipy)_3Cl_2$ and $Ru(phen)_3Cl_2$ (0.1 and 0.014, respectively) in CH_2Cl_2, which differ almost by one order of magnitude.[5b]

In conclusion, we have shown that by combining ligands with precisely defined electronic and steric properties in the same ruthenium(II) complex, it is possible to prepare photochemically active compounds that undergo quantitative and selective decoordination of a given ligand under light irradiation. Work currently in progress is concerned with the use of the present photolabile complexes as building blocks and their incorporation into multi-component systems. Preliminary experiments demonstrate that the recoordination reaction of dmbp onto the ruthenium centre, starting from $Ru(phen)_2(CH_3CN)_2{}^{2+}$ is indeed quantitative.

Experimental Section

Physical Measurements: ^{1}H NMR: Bruker WP200 SY (200 MHz) and Bruker AM 400 (400 MHz) instruments; the reported chemical shifts are referenced to Me_4Si as an internal standard. − UV/Vis: Kontron Uvikon 860. − MS: VG ZAB-HF, Thomson THN 208. − Irradiation: Hanimex slide projector (150-W halogen lamp). − Cyclic voltammetry: PAR model 273A potentiostat, Pt disc as working electrode, CH_3CN solution, 0.1 M Bu_4NBF_4 as supporting electrolyte, Pt wire as auxiliary electrode, SCE as reference electrode.

Photolysis Experiments − Representative Photolysis of 1: In a round-bottomed Pyrex Schlenk flask, 30 mg (0.034 mmol) of **1** was dissolved in 50 mL of CH_3CN. The resulting solution was stirred under argon and irradiated for 8 h. In order to obtain a crystalline

product, the solution was first concentrated to half of its original volume, 30 mL of toluene was added, and then the remaining CH_3CN was evaporated with the temperature not exceeding 40°C. Orange crystals were obtained, which were filtered off on a porosity grade 4 glass frit and washed with diethyl ether. The product was dried in vacuo to give 26 mg of $[Ru(bipy)_2(CH_3CN)_2](PF_6)_2$ (96%). The remaining 4% was accounted for by recovered starting material **1**. − UV/Vis (CH_3CN): λ_{max} (ε) = 425 nm (8460 $Lmol^{-1}cm^{-1}$). − ^1H NMR ([D_6]acetone, 200 MHz): δ = 9.7 (d, *J* = 5.05 Hz, 2 H, 6-H), 8.9 (d, *J* = 7.88 Hz, 2 H, 6′-H), 8.76 (d, *J* = 7.87 Hz, 2 H, 3-H), 8.51 (td, *J* = 7.93, 1.55 Hz, 2 H, 5-H), 8.19 (td, *J* = 7.87, 1.48 Hz, 2 H, 4-H), 8.07 (td, *J* = 6.58, 1.35 Hz, 2 H, 5′-H), 7.96 (d, *J* = 4.92 Hz, 2 H, 3′-H), 7.52 (td, *J* = 6.64, 1.47 Hz, 2 H, 4′-H), 2.59 (s, 6 H, 2 CH_3CN). − The photolysis of **2** was performed following the same method (yield 81%). The photolyses of **5** and **6** were realized in a Schlenk cell on an analytical scale.

Synthesis of Ligands and Complexes: The ligands dppH,[11] pypz,[6] dmbp,[12] and dm-dphbp,[13] and the complexes *cis*-$Ru(L)_2Cl_2$ (L = bipy or phen),[14] were prepared according to literature procedures.

$[Ru(bipy)_2(pypz)](PF_6)_2$ (1): The complex *cis*-$Ru(bipy)_2Cl_2$ (145 mg, 0.3 mmol) was dissolved in 20 mL of EtOH/H_2O (3:1) and the resulting solution was refluxed for 1 h. The ligand pypz (52 mg, 0.3 mmol) was then slowly added and refluxing was continued for a further 4 h, in the course of which the colour of the solution changed from purple-red to orange-red. The mixture was then filtered, the filtrate was concentrated to dryness, and the residue was redissolved in water (20 mL). The complex was precipitated as the hexafluorophosphate by the dropwise addition of concentrated KPF_6 solution. The product was filtered off (grade 4 glass frit) and recrystallized from EtOH/H_2O to give an orange-red microcrystalline powder (210 mg), yield 80%. − UV/Vis (CH_3CN): λ_{max} (ε) = 449 nm (9200 $Lmol^{-1}cm^{-1}$). − ^1H NMR (CD_3CN, 200 MHz): δ = 8.45 (m, 4 H), 8.2−7.9 (m, 7 H), 7.77 (m, 2 H), 7.60 (d, *J* = 5.42 Hz, 1 H), 7.53−7.28 (m, 5 H), 7.22−7.14 (m, 1 H), 6.35 (s, 4-H), 2.82 (s, 5-CH_3), 1.48 (s, 3-CH_3).

$[Ru(bipy)_2(dppH)](PF_6)_2$ (2): In a 100-mL round-bottomed flask fitted with a reflux condenser, a mixture of 145 mg (0.3 mmol) of *cis*-$Ru(bipy)_2Cl_2$ and 120 mg (0.36 mmol) of dppH in 25 mL of ethylene glycol was heated under reflux for 3 h. After cooling to room temperature, the orange solution was filtered through a porosity grade 4 glass frit. Then, at 100°C, the filtrate was treated dropwise with a saturated aqueous solution of KPF_6. The resulting solution was allowed to cool and left to stand overnight at 0°C, whereupon the complex crystallized. It was filtered off, washed with a copious amount of water, and air-dried. The crude red product was purified by chromatography on silica gel, eluting with acetonitrile/water/saturated aqueous KNO_3 (100:5:0.5). After anion exchange, 243 mg (76%) of **2** was obtained. − UV/Vis (CH_3CN): λ_{max} (ε) = 451 nm (13300 $Lmol^{-1}cm^{-1}$). − ^1H NMR (CD_3CN, 400 MHz): δ = 8.66 (d, *J* = 8.04 Hz, 4-H, 7-H), 8.34 (s, 5-H, 6-H), 8.24 (d, *J* = 7.76 Hz, 2 H), 8.05 (td, *J* = 7.88, 1.53 Hz, 2 H), 7.89 (d, *J* = 5.08 Hz, 2 H), 7.84 (d, *J* = 7.76 Hz, 2 H), 7.54 (d, *J* = 8.28 Hz, 3-H, 8-H), 7.45 (t, *J* = 7.9 Hz, 2 H), 7.34 (t, *J* = 6.44 Hz, 2 H), 7.13 (br. s, 2 H, *o*-H), 7.02 (t, *J* = 7.5 Hz, 2 H, *p*-H), 6.86 (br. s, 2 H, *o*-H), 6.74 (br. s, 2 H, *m*-H), 6.66 (d, *J* = 5.64 Hz, 2 H), 6.56 (td, *J* = 6.68, 1.5 Hz, 2 H), 6.12 (br. s, 2 H, *m*-H). − Redox potential (V vs. SCE): $E°(Ru^{III/II})$ = 1.3 V, $E°(Ru^{II/I})$ = −1.3 V, irreversible wave.

$Ru(bipy)(dppH)(CH_3CN)_2(PF_6)_2$ (3): In a round-bottomed Schlenk flask, 20 mg (0.019 mmol) of **2** was dissolved in 30 mL of acetonitrile and the resulting orange-red solution was stirred under argon and irradiated for 8 h. The yellow solution thus obtained was chromatographed on a silica gel column, eluting with acetonitrile/water/saturated aqueous KNO_3 (100:5:0.5). After anion exchange, 0.15 g of **2** (81%) was obtained. − UV/Vis (CH_3CN): λ_{max} (ε) = 401 nm (4720 $Lmol^{-1}cm^{-1}$), 424 nm (4690 $Lmol^{-1}cm^{-1}$). − ^1H NMR (CD_2Cl_2, 200 MHz): δ = 8.80 (d, *J* = 8.36 Hz, 7-H or 4-H), 8.37 (d, *J* = 8.36 Hz, 4-H or 7-H), 8.27 (d, *J* = 8.62 Hz, 5-H or 6-H), 8.25 (d, *J* = 6.4 Hz, 1 H), 8.10 (t, *J* = 8.12, 8.36 Hz, 3-H or 8-H, 6-H or 5-H), 8.02 (d, 7.88 Hz, 1 H), 7.92 (d, *J* = 7.62 Hz, 1 H), 7.83−7.71 (m, 4 H), 7.58 (m, 4 H), 7.44 (d, *J* = 8.36 Hz, 8-H or 3-H), 7.36 (td, *J* = 3.66, 1.47 Hz, 2 H), 7.14 (td, *J* = 6.64, 1.48 Hz, 2 H), 7.05 (td, *J* = 6.4, 1.48 Hz, 1 H), 6.95 (t, *J* = 7.62 Hz, 1 H), 6.70 (d, *J* = 5.66 Hz, 1 H), 6.44 (d, *J* = 7.62 Hz, 1 H), 2.77 (s, 3 H, CH_3CN), 1.50 (s, 3 H, CH_3CN). − Redox potential (V vs. SCE): $E°(Ru^{III/II})$ = 1.49 V, $E°(Ru^{II/I})$ = −1.3 V, irreversible wave.

$Ru(bipy)(dpp)(CH_3CN)(PF_6)$ (4): 40 mg (0.039 mmol) of **3** was subjected to chromatography on 5 successive alumina columns, eluting with CH_2Cl_2/MeOH (99.3:0.7), to give 25.5 mg of **4** (85%). − UV/Vis (CH_3CN): λ_{max} (ε) = 458 nm (7900 $Lmol^{-1}cm^{-1}$), 520 (9681 $Lmol^{-1}cm^{-1}$). − ^1H NMR (CD_3CN, 200 MHz): δ = 8.99 (d, *J* = 6.4 Hz, 1 H), 8.47 (d, *J* = 8.38 Hz, dpp-H), 8.40 (d, *J* = 8.86 Hz, dpp-H), 8.28 (d, *J* = 8.86 Hz, dpp-H), 8.15 (d, *J* = 8.86 Hz, dpp-H), 8.07 (d, *J* = 8.84 Hz, dpp-H), 8.03 (t, *J* = 7.12, 7.64 Hz, 2 H), 7.89 (m, 1 H), 7.85 (dd, *J* = 7.74, 1.35 Hz, 1 H), 7.76 (td, *J* = 7.75, 1.48 Hz, 1 H), 7.61 (d, *J* = 8.36 Hz, dpp-H), 7.54 (td, *J* = 7.5, 1.48 Hz, 1 H), 7.36 (m, 2 H), 7.20 (d, *J* = 4.92 Hz, 1 H), 7.01 (m, 3 H), 6.87−6.62 (m, 4 H), 5.95 (d, *J* = 6.4 Hz, 1 H), 1.99 (s, 3 H, CH_3CN). − FAB-MS; *m*/*z*: 589 [M^+ − bipy], 630.1 [M^+ − bipy + CH_3CN]. − Redox potential (V vs. SCE): $E°(Ru^{III/II})$ = 0.5 V, $E°(Ru^{II/I})$ = −1.68 V.

$Ru(phen)_2(dmbp)(PF_6)_2$ (5): A mixture of *cis*-$Ru(phen)_2Cl_2$ (0.2 g, 0.38 mmol), dmbp (0.1 g, 0.54 mmol), and degassed ethylene glycol (5 mL) was heated at 160°C under argon for 4 h. After cooling to room temperature, 20 mL of saturated aqueous KPF_6 solution was added. The yellow precipitate thus obtained was collected by filtration, washed with water (30 mL), and redissolved in the minimum volume of CH_3CN. This solution was subjected to column chromatography on silica, using CH_2Cl_2/MeOH (0 to 4%) as eluent. Complex **5** was obtained as a red powder (0.18 g, 51%). − UV/Vis (CH_3CN): λ_{max} (ε) = 449 nm (12200 $Lmol^{-1}cm^{-1}$). − ^1H NMR (CD_3CN, 200 MHz): δ = 8.71 (dd, *J* = 8.37, 1.23 Hz, 2 H, 2-H), 8.43 (dd, *J* = 7.62 Hz, 1.23 Hz, 2 H, 9-H), 8.40 (dd, *J* = 5.41, 1.23 Hz, 2 H, 4-H), 8.38 (m, 2 H, bipy-H), 8.28 (d, *J* = 8.86 Hz, 2 H, 5-H or 6-H), 8.17 (d, *J* = 8.84 Hz, 2 H, 6-H or 5-H), 7.92 (m, 2 H, bipy-H), 7.88 (dd, *J* = 8.24, 5.3 Hz, 2 H, 8-H or 3-H), 7.58 (dd, *J* = 5.16, 1.22 Hz, 2 H, 7-H), 7.31 (dd, *J* = 8.24, 5.3 Hz, 2 H, 3-H or 8-H), 7.21 (dd, *J* = 7.62, 0.98 Hz, 2 H, bipy-H), 1.46 (s, 6 H, 2 CH_3).

$Ru(phen)_2(dm\text{-}dphbp)(PF_6)_2$ (6): A mixture of *cis*-$Ru(phen)_2Cl_2$ (0.15 g, 0.28 mmol), dm-dphbp (0.93 g, 0.28 mmol), and degassed ethylene glycol (5 mL) was refluxed under argon for 3 h. After cooling, addition of aqueous KPF_6 solution (20 mL) afforded a brown precipitate, which was collected by filtration, washed with water (50 mL) and diethyl ether (50 mL), and finally dried. The product was purified by chromatography (silica gel) using CH_2Cl_2/MeOH (0 to 2%) as eluent, to give a red powder (0.25 g, 81%). − UV/Vis (CH_3CN): λ_{max} (ε) = 454 nm (12100 $Lmol^{-1}cm^{-1}$). − ^1H NMR (CD_3CN, 200 MHz): δ = 8.67 (dd, *J* = 5.29, 1.23 Hz, 2 H, 2-H), 8.70 (dd, *J* = 8.24, 1.12 Hz, 2 H, 4-H), 8.54 (s, 2 H, bipy-H), 8.15 (d, *J* = 8.86 Hz, 5-H), 7.96 (dd, *J* = 8.23, 4.66 Hz, 2 H, 3-H), 7.88 (d, *J* = 8.86 Hz, 2 H, 6-H), 7.87 (dd, *J* = 8.11, 1.23 Hz, 2 H, 7-H), 7.05 (br. s, 2 H, phenyl-H), 6.98 (s, 2 H, bipy-H), 6.64

(m, 4 H, phenyl-H), 6.60 (dd, J = 8.12, 5.42 Hz, 2 H, 8-H), 6.47 (dd, J = 5.29, 1.24 Hz, 2 H, 9-H), 6.11 (br. s, 2 H, phenyl-H), 5.36 (br. s, 2 H, phenyl-H), 2.54 (s, 6 H, 2 CH_3).

Acknowledgments

This work was performed with the aid of financial support from the CNRS. We thank C. O. Dietrich-Bucheker and G. Mieslin for providing a sample of dm-dphbp.

Organometallic Compounds Containing the *cis*-$[MoO(NNPhR)]^{2+}$ Core (R = Me, Ph) – X-ray Structures of $[MoO(NNPh_2)Me_2(o\text{-phen})]$ and $[MoO(NNPh_2)Ph_2(o\text{-phen})]$

Keywords: Molybdenum / Hydrazido complexes / Organometallic complexes / Phenanthroline / X-ray structure determination

New organometallic compounds containing the *cis*-$[MoO(NNPhR)]^{2+}$ core have been synthesized by means of a two-step procedure involving: (i) functionalization of the precursor $[MoO_2Br_2(o\text{-phen})]$ (**1**) with $MePhNNH_2$ and Ph_2NNH_2 to afford the intermediates $[MoO(NNMePh)Br_2(o\text{-phen})]$ (**2**) and $[MoO(NNPh_2)Br_2(o\text{-phen})] \cdot MeCN$ (**3**), respectively, and (ii) reaction of these intermediates with Grignard reagents to give $[MoO(NNPhR)Me_2(o\text{-phen})]$ [R = Me (**4**), R = Ph (**5**)], $[MoO(NNPhMe)Ph_2(o\text{-phen})]$ (**6**), and $[MoO(NNPh_2)Ph_2(o\text{-phen})] \cdot CH_2Cl_2$ (**7**). These compounds have been characterized by ^{1}H-NMR, IR, and UV/Vis spectroscopy and the crystal and molecular structures of **5** and **7** have been determined by X-ray diffraction analysis.

Much of the current interest in coordination of the hydrazido ligand, NNH_2, at transition-metal centers stems from the expectation that its geometric and electronic structure, as well as its reactivity, may provide some insight into the mechanism of metal-catalysed reduction of dinitrogen into ammonia.[1−6] Organohydrazido ligands, NNRR′ (RR′ = alkyl and/or aryl; H and alkyl/aryl), are considered as potential models of NNH_2 because of their structural similarities. Accordingly, in the last few years increasing attention has been paid to transition-metal complexes containing NNRR′ ligands and, consequently, several studies have been carried out involving chemical and electrochemical cleavage of the N−N bond,[7−11] *N*-alkylation,[10,12] protonation−deprotonation reactions,[13,14] and hydrolysis of the Mo−NNRR′ group.[15] Very recently, we have studied the electronic structures of hydrazido and organohydrazido ligands using Extended Hückel Molecular Orbital (EHMO) and ab initio calculations, with the aim of resolving uncertainties regarding the assignment of hydrazido(2−) or isodiazene character to NNH_2 and NNRR′ groups (RR′ = alkyl and/or aryl) in coordination compounds.[16]

As part of an ongoing investigation into (organohydrazido)molybdenum complexes, we have previously described the synthesis, characterization, and the chemical properties of a number of inorganic complexes containing the *cis*-$[Mo(NNPhR)_2]^{2+}$ and *cis*-$[MoO(NNPhR)]^{2+}$ cores with a wide range of ancillary ligands, e.g. acetylacetonate,[14,17−21] tertiary phosphanes,[14,21,22] 2,2′-bipyridine,[15] 1,10-phenanthroline,[15] hydridotris(pyrazolyl)borate,[23,24] hydridotris(3,5-dimethylpyrazolyl)borate,[23] and mercaptobenzoate.[25] However, recent work in our laboratories has focused on the synthesis of organometallic molybdenum compounds containing these cores; the new piano-stool compounds formulated as $[(\eta^5\text{-}C_5H_5)Mo(NNPhR)_2(PPh_3)]^+CF_3SO_3^-$ (R = Me, Ph) represent the first two members of this new class of organometallic compounds.[26] This paper deals with a convenient synthesis of the first members of a new class of organometallic molybdenum compounds containing the *cis*-$[MoO(NNPhR)]^{2+}$ core. Functionalization of the novel precursor $[MoO_2Br_2(o\text{-phen})]$ (**1**) with neutral organohydrazines leads to the stable intermediates $[MoO(NNMePh)Br_2(o\text{-phen})]$ (**2**) and $[MoO(NNPh_2)Br_2(o\text{-phen})] \cdot MeCN$ (**3**). Subsequent reaction of these with Grignard reagents affords the organometallic compounds formulated as $[MoO(NNPhR)Me_2(o\text{-phen})]$ [R = Me (**4**), R = Ph (**5**)], $[MoO(NNPhMe)Ph_2(o\text{-phen})]$ (**6**), and $[MoO(NNPh_2)Ph_2(o\text{-phen})] \cdot CH_2Cl_2$ (**7**). We also report the X-ray crystal and molecular structures of compounds **5** and **7**.

Results and Discussion

The preparations of the organometallic compounds **4**−**7** were carried out starting from the inorganic precursor $[MoO_2Br_2(o\text{-phen})]$ (**1**), according to a two-step procedure: (i) functionalization of complex **1** with neutral 1,1-disubstituted hydrazines, $PhRNNH_2$ (R = Me, Ph), to obtain the inorganic intermediates $[MoO(NNMePh)Br_2(o\text{-phen})]$ (**2**) and $[MoO(NNPh_2)Br_2(o\text{-phen})] \cdot MeCN$ (**3**), and (ii) reaction of the intermediate complexes **2** and **3** with Grignard reagents R′MgBr (R′ = Me, Ph), to afford the organometallic compounds formulated as $[MoO(NNPhR)Me_2(o\text{-phen})]$ [R = Me (**4**), R = Ph (**5**)], $[MoO(NNMePh)Ph_2(o\text{-phen})]$ (**6**), and $[MoO(NNPh_2)Ph_2(o\text{-phen})] \cdot CH_2Cl_2$ (**7**).

Precursor **1** was synthesized in excellent yield (86%) by oxidation of $[Mo(CO)_6]$ with bromine in the presence of 1,10-phenanthroline, using a mixture of CH_2Cl_2/EtOH (1:1) as solvent (for further details, see Experimental Section). This one-pot procedure, developed in our laboratories, is essentially a modification of that described in the literature for obtaining $[MoO_2Br_2(bpy)]$[27] (bpy = 2,2′-bipyridine) through: (i) photochemical reaction of $[Mo(CO)_6]$ with bpy in hexane[28] to generate the precursor $[Mo(CO)_4(bpy)]$, and (ii) oxidation of this precursor with an excess of bromine in CH_2Cl_2/EtOH (1:1).

Step 1. Synthesis and Characterization of the Intermediate Complexes $[MoO(NNMePh)Br_2(o\text{-phen})]$ (2) and $[MoO(NNPh_2)Br_2(o\text{-phen})] \cdot MeCN$ (3)

The syntheses of complexes **2** and **3** were performed in acetonitrile by reaction of precursor **1** with the neutral 1,1-disubstituted hydrazines $PhRNNH_2$ (R = Me, Ph), respectively, in a 1:2 molar ratio (Equation 1).

$$[MoO_2Br_2(o\text{-phen})] + PhRNNH_2 \rightarrow [MoO(NNPhR)Br_2(o\text{-phen})] + H_2O \quad (1)$$

We have found that the use of an excess of organohydrazine in these reactions does not lead to the bis(organohydrazido) complexes, but rather the yields of **2** and **3** are increased somewhat. We have observed that in similar molybdenum complexes the *cis*-$[Mo(NNPhR)_2]^{2+}$ group undergoes hydrolysis with loss of one NNPhR ligand if water is present.[15] As is apparent from Equation 1, the formation of the *cis*-$[MoO(NNPhR)]^{2+}$ group is accompanied by the elimination of one water molecule.

Complexes **2** and **3** were obtained as orange, air-stable crystalline solids in yields of 91% and 80%, respectively, and were characterized by ^{1}H-NMR, IR, and UV/Vis spectroscopy (see Experimental Section). The ^{1}H-NMR spectra of both complexes feature a complex multiplet in the range δ = 6.85−10.20, attributable to the phenyl and phenanthroline proton resonances. The spectrum of complex **2** containing the NNMePh ligand, which had to be recorded in [D$_6$]DMSO solution owing to the low solubility of this complex in $CDCl_3$, CD_3COCD_3, and CD_3NO_2, exhibits three proton resonances in the region δ = 3.65−4.50. These resonances may be attributed to the unmodified complex, $[MoO(NNMePh)Br_2(o\text{-phen})]$, and the cationic species $[MoO(NNMePh)Br(Me_2SO)(o\text{-phen})]^+$ and $[MoO(NNMePh)(Me_2SO)_2(o\text{-phen})]^{2+}$, formed by successive substitutions of the Br^- ligands by Me_2SO solvent molecules.

Step 2. Synthesis and Characterization of the Organometallic Compounds $[MoO(NNPhR)Me_2(o\text{-phen})]$ [R = Me (4), R = Ph (5)], $[MoO(NNMePh)Ph_2(o\text{-phen})]$ (6), and $[MoO(NNPh_2)Ph_2(o\text{-phen})] \cdot CH_2Cl_2$ (7)

The syntheses of the organometallic compounds **4**−**7** were carried out at 0°C in dry THF by reaction of the inorganic intermediates **2** and **3** with the corresponding Grignard reagents, R′MgBr (R′ = Me, Ph; Equation 2). Under the experimental conditions used, an excess of the Grignard reagent was added to the solution in order to solubilize the inorganic intermediates **2** and **3**.

$$[MoO(NNPhR)Br_2(o\text{-phen})] + 2R'MgBr \rightarrow [MoO(NNPhR)R'_2(o\text{-phen})] + 2MgBr_2 \quad (2)$$

Compounds **4**, **5** and **7** were obtained in yields of 41−80%, while compound **6** was isolated in only 17% yield. All compounds were obtained as orange, air-stable crystalline solids, and were characterized by ^{1}H-NMR, IR, and UV/Vis spectroscopy. The ^{1}H-NMR spectra each feature a complex multiplet in the range δ = 6.65−10.15, attributable to the phenyl proton resonances of the NNMePh ligand and the proton resonances of the *o*-phenanthroline ligand. The spectra of compounds **6** and **7** are more complicated than those of **4** and **5** owing to the proton resonances of the phenyl ligands bonded to the molybdenum center in *trans* positions (vide infra). The spectra of compounds **4** and **6** also feature methyl proton resonances due to the NNMePh ligand at δ = 4.00 and δ = 4.23, respectively. In addition, the spectra of **4** and **5** exhibit methyl proton resonances at δ = 0.17 and δ = 0.19, attributable to the methyl ligands bonded to the molybdenum center in *trans* positions. The spectrum of compound **7**, which crystallizes with a CH_2Cl_2 solvent molecule, exhibits a methylene proton resonance at δ = 5.30.

Structural Results

ORTEP drawings of $[MoO(NNPh_2)Me_2(o\text{-phen})]$ (**5**) and $[MoO(NNPh_2)Ph_2(o\text{-phen})]$ (**7**), in similar perspectives for the sake of comparison, are presented in Figures 1 and 2. In both compounds, the molybdenum center displays distorted octahedral geometry, with the two methyl and two phenyl ligands occupying mutually *trans* positions, and with the equatorial plane being defined by the oxo group, the N(1) and N(2) atoms of the *o*-phenanthroline, and the N(3) atom of the organohydrazido ligand. The geometric parameters observed in the *cis*-$[MoO(NNPhR)]^{2+}$ cores of these com-

pounds are quite similar to those reported in the literature for other (organohydrazido)oxomolybdenum complexes.[16,29] An extensive delocalization of the electron density throughout the $Mo(NNPh_2)$ units is supported by (i) the short Mo−N(3) and N(3)−N(4) bond lengths of 1.770(3) and 1.330(4) Å in **5**, and of 1.770(6) and 1.307(9) Å in **7**; (ii) the almost linear Mo−N(3)−N(4) bond angles of 171.7(2)° and 173.6(5)° in **5** and **7**, respectively, and (iii) the almost planar Mo−N(3)−N(4)C(31)C(41) moiety, the sum of the bond angles about N(4) being 358.7(3)° and 360.0(5)° in **5** and **7**, respectively. On the other hand, the Mo−O bond lengths of 1.711(2) and 1.711(4) Å in **5** and **7**, respectively, fall within the normal range[29] and, in line with expectation,[15] the *trans* influence exerted by this group is clearly far more important than that exerted by the organohydrazido ligands, e.g. Mo−N(2) = 2.361(3) Å vs. Mo−N(1) = 2.302(3) Å for **5**, and Mo−N(2) = 2.368(5) Å vs. Mo−N(1) = 2.302(6) Å for **7**. Finally, one more salient feature of the structures of these compounds is the preferential inclination of the two methyl (**5**) and the two phenyl (**7**) ligands toward the N(2) atom of the *o*-phenanthroline ligand; thus, in **5** the C(51)−Mo−N(2) and C(61)−Mo−N(2) bond angles are 74.5(1) and 76.1(1)° while the C(51)−Mo−N(1) and C(61)−Mo−N(1) bond angles are 84.7(1) and 79.8(1)°; likewise, in **7** the C(51)−Mo−N(2) and C(61)−Mo−N(2) bond angles are 76.7(2) and 78.6(2)° while the C(51)−Mo−N(1) and C(61)−Mo−N(1) bond angles are 89.5(2) and 81.5(2)°. These differences can most probably be ascribed to repulsions between the methyl and phenyl ligands and the oxo group. As a further consequence of these repulsions, the C(51)−Mo−C(61) bond angles are 149.9(1) and 155.3(2)° in compounds **5** and **7**, respectively. For comparison purposes, it is noteworthy that the methyl and *p*-anisyl ligands in the related organometallic compounds $[MoO_2R_2(bpy)]$ (R = Me,[30] C_6H_4OMe[31]) are also bent toward the midpoint of the N,N vector of the bpy ligand, the C−Mo−C bond angles in these cases amounting to 149.03(10) and 153.6(1)°, respectively. On the other hand, in the related inorganic complexes $[MoO(NNPh_2)Cl_2(o\text{-phen})]$ and $[MoO(NNPh_2)Cl_2(bpy)]$, this folding effect is less pronounced and the Cl−Mo−Cl

Figure 1. bond angles are found to be 161.5(1)° and 160.2(1)°, respectively.[15]

With reference to our recent study concerned with molecular orbital analysis of hydrazido(2−)−metal bonding in coordination chemistry,[16] if formally considered as a dianion, the hydrazido ligand represents a six-electron donor when it is coordinated in a linear mode in monohydrazido complexes. Accordingly, the molybdenum center in the organometallic compounds described herein attains an 18-electron configuration.

Conclusion

The present study highlights the potential utility of the new inorganic precursor $[MoO_2Br_2(o\text{-phen})]$ (**1**) for the preparation of organometallic *trans*-dialkyl and *trans*-diaryl compounds containing the *cis*-$[MoO(NNPhR)]^{2+}$ core, where R = Me, Ph. The readiness with which the *cis*-MoO_2^{2+} fragment can be monofunctionalized with neutral 1,1-disubstituted hydrazines opens a facile synthetic route for the preparation of stable inorganic intermediates, further reaction of which with Grignard reagents, as in the present investigation, allows access to organometallic compounds formulated as $[MoO(NNPhR)Me_2(o\text{-phen})]$ and $[MoO(NNPhR)Ph_2(o\text{-phen})]$ (R = Me, Ph). These derivatives containing the *cis*-$[MoO(NNPhR)]^{2+}$ core represent the first members of a new class of organometallic molybdenum compounds, the chemical and electrochemical properties of which, associated with cleavage of the N−N bond, will be the subject of further investigations in our laboratories.

Experimental Section

General: All operations were performed under inert atmosphere using standard vacuum/nitrogen line (Schlenk) techniques. Hexacarbonylmolybdenum, bromine, 1-methyl-1-phenylhydrazine, 1,1-

diphenylhydrazine hydrochloride, methylmagnesium bromide (3.3 M in diethyl ether), phenylmagnesium bromide (0.79 M in THF), and 1,10-phenanthroline, were purchased from commercial sources and used as received. Solvents were dried and distilled under nitrogen by standard methods prior to use. − Microanalytical data were obtained with a Perkin-Elmer Model 2400 elemental analyzer. − IR spectra were obtained from KBr disks with a Perkin-Elmer Model 1600 FT-IR spectrophotometer. − Electronic spectra were recorded in CH_2Cl_2 solutions with a Hewlett Packard 8452A spectrophotometer. − ^{1}H-NMR spectra were recorded in $CDCl_3$ or [D_6]DMSO with a Bruker FT AC/200P spectrometer; chemical shifts are reported in ppm relative to tetramethylsilane, with the residual solvent proton resonances as internal standards. − Melting points were determined using a Kofler apparatus.

Preparation of [MoO_2Br_2(*o*-phen)] (1): To a vigorously stirred solution of [$Mo(CO)_6$] (3.95 g, 15.0 mmol) and 1,10-phenanthroline (2.70 g, 15.0 mmol) in 200 mL of CH_2Cl_2/EtOH (1:1), excess bromine was added dropwise. Following the addition, the mixture was warmed to 40°C and stirred for 45 min, whereupon a microcrystalline orange solid was deposited. The crude material was filtered off, washed with diethyl ether, dried in vacuo, and finally recrystallized from CH_3CN. Yield before recrystallization: 6.04 g (86%), m.p. 195°C (dec.). − $C_{12}H_8Br_2MoN_2O_2$ (467.96): calcd. C 30.80, H 1.72, N 5.99; found C 29.83, H 1.76, N 5.89. − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 266 nm (4.47). − IR (KBr): $\tilde{\nu}$ = 3052 cm^{-1} (vw), ν(CH); 2921 (vw), ν(CH); 2818 (vw), ν(CH); 935 (vs) and 901 (vs), ν(MoO_2). − ^{1}H NMR ($CDCl_3$): δ = 9.90 (dd, 2 H, $^3J_{HH}$ = 8.2 Hz), 8.67 (dd, 2 H, $^3J_{HH}$ = 4.9 Hz), 8.12 (s, 2 H), 8.06 (dd, 2 H, $^3J_{HH}$ = 1.4 Hz).

Preparation of [MoO(NNMePh)Br_2(*o*-phen)] (2): To 1.83 g (3.91 mmol) of **1**, dissolved in 180 mL of acetonitrile, was added 0.96 g (7.82 mmol) of 1-methyl-1-phenylhydrazine, $MePhNNH_2$. The mixture was stirred vigorously under reflux for 2 h, in the course of which a microcrystalline solid was deposited. The pink solid was filtered off, washed with acetonitrile and diethyl ether, and dried in vacuo. Yield 2.04 g (91%), m.p. 315°C (dec.). − $C_{19}H_{16}Br_2MoN_4O$ (572.11): calcd. C 39.89, H 2.81, N 9.79; found C 38.66, H 2.70, N 9.76. − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 535 (4.13), 388 (4.60), 298 sh (5.13), 276 (5.40). − IR (KBr): $\tilde{\nu}$ = 3052 cm^{-1} (w), ν(CH); 2932 (w), ν(CH); 2856 (vw), ν(CH); 1583 (m), ν(NN); 902 (s), ν(MoO). − ^{1}H NMR ([D_6]DMSO): δ = 10.17−6.87 (m, 13 H, $C_{12}H_8N_2$ and C_6H_5), 4.47, 4.42, 3.67 (s, 3 H, CH_3).

Preparation of [MoO($NNPh_2$)Br_2(*o*-phen)]·MeCN (3): The procedure adopted was similar to that described for **2**, using in this case 1.34 g (6.08 mmol) of 1,1-diphenylhydrazine hydrochloride, $Ph_2NNH_3^+Cl^-$, previously neutralized with triethylamine, and 1.42 g (3.04 mmol) of **1**. The product was obtained as a red microcrystalline solid. Yield 2.16 g (80%), m.p. 290°C. − $C_{26}H_{21}Br_2MoN_5O$ (675.23): calcd. C 46.25, H 3.13, N 10.37; found C 46.44, H 3.10, N 9.38. − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 520 nm (3.28), 388 (3.70), 298 sh (4.19), 278 (4.48). − IR (KBr): $\tilde{\nu}$ = 3044 cm^{-1} (w), ν(CH); 2922 (vw), ν(CH); 2856 (vw), ν(CH); 1585 (m), ν(NN); 899 (s), ν(MoO). − ^{1}H NMR ($CDCl_3$): δ = 10.19−6.99 (m, 18 H, $C_{12}H_8N_2$ and 2 C_6H_5 hydrazido), 2.01 (s, 3 H, CH_3CN).

Preparation of [MoO(NNMePh)Me_2(*o*-phen)] (4): To 0.30 g (0.52 mmol) of **2** suspended in 20 mL of dry THF at 0°C, 0.38 g (3.15 mmol) of methylmagnesium bromide in Et_2O was added dropwise. After stirring for 1 h, the reaction mixture was allowed to warm to room temperature and then concentrated to dryness in vacuo. The residue was partitioned between 20 mL of CH_2Cl_2 and 20 mL of saturated aqueous ammonium chloride solution, the aqueous phase was extracted with further CH_2Cl_2, and the combined organic extracts were dried with magnesium sulfate. After concentrating the dried extract to a volume of 10 mL, it was allowed to stand at −18°C, resulting in the deposition of an orange microcrystalline solid. This was filtered off, washed with diethyl ether, dried in vacuo, and finally recrystallized from CH_2Cl_2 layered with diethyl ether. Yield before recrystallization: 0.094 g (41%), m.p. 173°C. − $C_{21}H_{22}MoN_4O$ (442.37): calcd. C 56.96, H 4.97, N 12.65; found C 56.11, H 5.09, N 12.19. − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 380 nm br (3.83), 326 (4.24), 270 (4.60). − IR (KBr): $\tilde{\nu}$ = 3056 cm^{-1} (w), ν(CH); 2945 (m), ν(CH); 2878 (w), ν(CH); 1592 (s), ν(NN); 886 (vs), ν(MoO). − ^{1}H NMR ($CDCl_3$): δ = 10.17−6.97 (m, 13 H, $C_{12}H_8N_2$ and C_6H_5 hydrazido), 4.00 (s, 3 H, CH_3 hydrazido), 0.17 (s, 6 H, $2CH_3$).

Preparation of [MoO($NNPh_2$)Me_2(*o*-phen)] (5): The synthesis of this yellow crystalline complex was carried out using a procedure similar to that described for complex **4**, adding in this case 0.56 g (4.66 mmol) of methylmagnesium bromide to 0.49 g (0.73 mmol) of **3** in 20 mL of dry THF. Suitable single crystals for X-ray diffraction studies were obtained from CH_2Cl_2 layered with diethyl ether. Yield 0.58 g (80%), m.p. 215°C. − $C_{26}H_{24}MoN_4O$ (504.44): calcd. C 61.91, H 4.80, N 11.11; found C 61.22, H 4.70, N 10.98. − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 380 nm br. (4.32), 310 (4.92), 270 (5.32). − IR (KBr): $\tilde{\nu}$ = 3056 cm^{-1} (vw), ν(CH); 2951 (w), ν(CH); 2889 (w), ν(CH); 1586 (m), ν(NN); 892 (vs), ν(MoO). − ^{1}H NMR ($CDCl_3$): δ = 10.20−7.20 (m, 18 H, $C_{12}H_8N_2$ and 2 C_6H_5 hydrazido), 0.19 (s, 6 H, 2 CH_3).

Preparation of [MoO(NNMePh)Ph_2(*o*-phen)] (6): To 0.31 g (0.54 mmol) of **2**, dissolved in 20 mL of dry THF, 0.59 g (3.20 mmol) of phenylmagnesium bromide in THF was added dropwise. After stirring for 1 h at 0°C, the reaction mixture was allowed to warm to room temperature and then concentrated to dryness in vacuo. The residue was partitioned between 20 mL of CH_2Cl_2 and 20 mL of saturated aqueous ammonium chloride solution. The CH_2Cl_2 solution containing the product was dried with magnesium sulfate and concentrated to a volume of 10 mL. On leaving the concentrated solution to stand at −18°C, a brown crystalline solid was deposited, which was filtered off, washed with diethyl ether, and dried in vacuo. Yield 0.052 g (17%), m.p. 165°C. − $C_{31}H_{26}MoN_4O$ (566.51): calcd. C 65.73, H 4.63, N 10.07; found C 64.85, H 4.48, N 9.82. − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 420 nm br. (4.27), 334 (4.90), 270 (5.33). − IR (KBr): $\tilde{\nu}$ = 3041 cm^{-1} (w), ν(CH); 2964 (vw), ν(CH); 2922 (vw), ν(CH); 1592 (m), ν(NN); 896 (s), ν(MoO). − ^{1}H NMR ($CDCl_3$): δ = 10.48−6.67 (m, 23 H, $C_{12}H_8N_2$, C_6H_5 hydrazido and 2 C_6H_5), 4.23 (s, 3 H, CH_3 hydrazido).

Preparation of [MoO($NNPh_2$)Ph_2(*o*-phen)]·CH_2Cl_2 (7): This yellow crystalline complex was synthesized according to the procedure described above, adding in this case 1.08 g (5.95 mmol) of phenylmagnesium bromide to 0.31 g (0.46 mmol) of **3** in 20 mL of dry THF. Suitable single crystals for X-ray diffraction studies were obtained from CH_2Cl_2 layered with hexane. Yield before recrystallization: 0.22 g (67%), m.p. 185°C. − $C_{37}H_{30}Cl_2MoN_4O$ (713.52): calcd. C 62.28, H 4.24, N 7.85; found C 61.46, H 4.23, N 7.99. − UV/Vis (CH_2Cl_2): λ_{max} (log ε) = 368 nm br. (4.07), 332 (4.45), 256 (4.75). − IR (KBr): $\tilde{\nu}$ = 3047 cm^{-1} (w), ν(CH); 3000 (vw), ν(CH); 2956 (vw), ν(CH); 1586 (m), ν(NN); 889 (vs), ν(MoO). − ^{1}H NMR ($CDCl_3$): δ = 10.52−6.68 (m, 28 H, $C_{12}H_8N_2$, 2 C_6H_5 hydrazido and 2 C_6H_5), 5.30 (s, 2 H, CH_2Cl_2).

1032, crystal size [mm]: 0.50 × 0.28 × 0.20. Siemens R3m/V four-circle diffractometer; Mo-K_α radiation (λ = 0.71073, graphite monochromator), 2θ range 3.0−50.0° at 298 K, scan type θ-2θ, reflections collected 4338, independent reflections 4077 (R_{int} = 2.45%), observed reflections 3435 [$F > 4.0\sigma(F)$]. Convergence at R = 0.0355, R_w = 0.0526, $w^{-1} = \sigma^2(F) + gF^2$. Cell parameters were determined from least-squares fits of 25 reflections with 15° ≤ 2θ ≤ 30°. Two standard reflections, monitored every 98 reflections, showed no significant variation of intensity during data collection. Intensities were corrected for Lorentz and polarization effects, and semiempirical corrections based on ψ scans were applied for absorption.

X-ray Structure Determination for 7: $C_{37}H_{30}Cl_2MoN_4O$, M_r = 713.5 g mol^{-1}, unit cell dimensions: a = 11.951(2), b = 19.850(3), c = 14.135(2) Å, β = 100.97(1)°, V = 3292(1) Å^3, monoclinic, $P2_1/n$, Z = 4, $D_{calcd.}$ = 1.440 g cm^{-3}, μ(Mo-K_α) = 0.597 mm^{-1}, F(000) = 1456, crystal size [mm]: 0.20 × 0.18 × 0.06. Siemens R3m/V four-circle diffractometer; Mo-K_α radiation (λ = 0.71073 Å, graphite monochromator), 2θ range 3.0−45.0° at 298 K, scan type θ-2θ, reflections collected 4562, independent reflections 4324 (R_{int} = 2.29%), observed reflections 2261 [$F > 4.0\sigma(F)$]. Convergence at R = 0.0387, R_w = 0.0378, $w^{-1} = \sigma^2(F) + gF^2$. Cell parameters were determined from least-squares fits of 30 reflections with 15° ≤ 2θ ≤ 30°. Two standard reflections, monitored every 98 reflections, showed no significant variation of intensity during data collection. Intensities were corrected for Lorentz and polarization effects, and semiempirical corrections based on ψ scans were applied for absorption.

Both structures were solved by direct methods and refined on F by full-matrix least-squares calculations (see Table 1). The function minimized was $\Sigma w(F_o - F_c)^2$. All non-H atoms were refined anisotropically. A riding model was applied to H atoms, which were placed at calculated positions with C−H = 0.96 Å, with the equivalent isotropic thermal parameters of their parent C atoms. All calculations were performed with the Siemens SHELXTL-PLUS system of programs.[32] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-102552 (**5**) and -102553 (**7**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (int. code) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

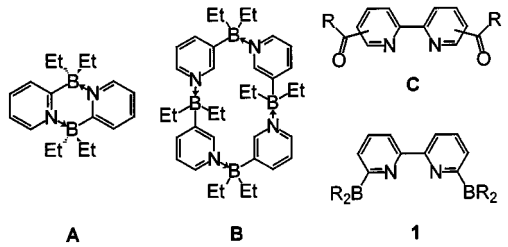
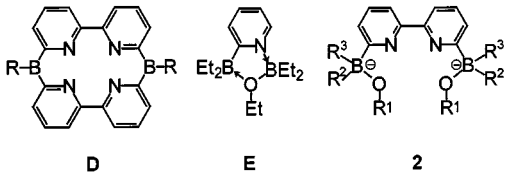
Syntheses, Structures, and Coordination of Diborylbipyridines and Bipyridinediborates



Norbert Weis,[a] Hans Pritzkow,[a] and Walter Siebert*[a]

Dedicated to Prof. Dr. Günter Wächtershäuser on the occasion of his 60th birthday

6,6′-Bis(diethylboryl)-2,2′-bipyridine (**1a**) was obtained in low yield by in situ deprotonation of 2,2′-bipyridine in the presence of diethyl(methoxy)borane. 6,6′-Dilithio-2,2′-bipyridine reacts with various alkoxyboranes leading to bipyridinediborates **2** in good yields. The derivatives **2b** and **2c** allow the formation of the free diborylbipyridines **1b** and **1c**. The coordination properties of the diboryl–bipyridines as tetrafunctional donor–acceptor compounds have been used for the formation of the copper complex **4** and of the adduct **5** which is built from diborylbipyridine and a dihydroxydiboroxan derivative. The composition of the products follows from spectroscopic data and from X-ray structure analyses for **2f**, **4**, and **5**.



Introduction

The intramolecular presence of Lewis basic (nitrogen) and Lewis acidic centers (boron) results in interesting properties of borylated pyridines and bipyridines. A small number of borylpyridines has been reported,[1] which were synthesized as starting compounds for Suzuki coupling reactions.[2] 2-(Diethylboryl)pyridine[3] and 3-(diethylboryl)-pyridine[4] are known for their stability towards moisture and oxygen. The reason for this is their assembly by intermolecular boron−nitrogen coordination. 2-(Diethylboryl)-pyridine exists as a dimer (**A**) in solution and in the solid state,[5] and 3-(diethylboryl)pyridine as a cyclic tetramer (**B**).

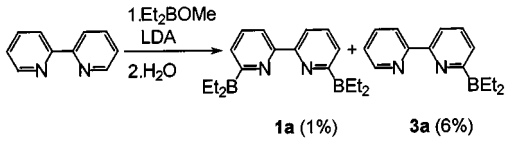
Scheme 1

Bipyridines have been the subject of many studies.[6][7] The π-acceptor properties of this bidentate σ-donor are weak. By introducing electron-withdrawing groups the π*-level is lowered as has been demonstrated with acyl- and carboxybipyridines (**C**).[8] The dπ→π* absorption bands in L_3Ru^{II} complexes (L = bipyridines) are shifted toward the red region of the spectra and this shift increases the quality of these metal complexes as sensitizers in solar energy converting processes.[9] 6,6′-Diboryl-2,2′-bipyridines **1** should also have increased π-acceptor qualities relative to that of non-substituted bipyridines. We are in particular interested in 6,6′-diborylated bipyridines with respect to their donor-acceptor properties and their potential of forming the macrocycle **D**.

Scheme 2

From spectroscopic data the formation of the cyclic adduct **E**, based on the donor−acceptor pattern of 2-(diethylboryl)pyridine was postulated.[3] For the tetrafunctional 6,6′-diboryl-2,2′-bipyridines **1** one may expect a complex donor−acceptor behavior due to their geometric requirements. In the following the coordination properties of the donor−acceptor molecules **1** will be presented. In addition the formation of bipyridinediborates **2** and their behavior as N_2O_2 tetradentate ligands are studied, of which numerous examples have been reported.[10−13]

Results and Discussion



Synthesis

Following a general procedure,[14] we synthesized the diborylbipyridine **1a** by in situ deprotonation of 2,2′-bipyridine with lithium diisopropylamide (LDA) in the presence of an excess of diethyl(methoxy)borane. In this reaction **1a** was obtained in very low yield (1%) besides the monoborylated product **3a** (6%). **1a** is a colorless, high-melting solid of low solubility whereas **3a** is a viscous oil. Both substances are stable toward moisture and air. Their ^{11}B-NMR spectra (δ = 3) indicate tetracoordinate boron atoms in as yet unknown assembly, most likely **1a** and **3a** form donor−acceptor compounds similar to **A**. In the EI mass spectra the fragments of the monomeric species with loss of one

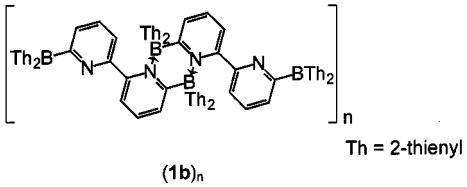
ethyl group appear as highest masses at m/z = 263 [**1a** − Et]$^+$ and 195 [**3a** − Et]$^+$.

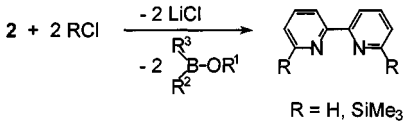
Scheme 3



To improve the yields a stepwise synthesis was carried out. 6,6′-Dilithio-2,2′-bipyridine, obtained by a metal/halogen exchange,[15] was treated with various alkoxyboranes to give the borate derivatives **2a−f**.

Scheme 4

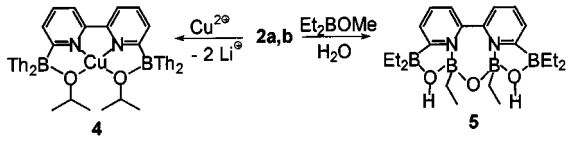
Regardless of the steric and electronic properties of the substituents, the products **2a−f** are thermally stable and isolated in 64−89% yields. All are colorless, crystalline substances, which, however, are very sensitive toward hydrolysis to give bipyridine and the corresponding boron compounds. They are characterized by ^{1}H-, ^{13}C-, ^{11}B-NMR spectroscopy and by an X-ray structure analysis of **2f** (see below). In these molecules the expected leaving groups LiOR are bound to the diborylbipyridines. There are interactions between the acceptor function (boron) with the alkoxy group and between the donor function (nitrogen) with the lithium ion. The formation of this five-membered heterocyclic arrangement enhances the stability of the adducts.



Attempts to synthesize **1a** from **2a** failed. Reaction of **2b** with $ClSiMe_3$ yields the 6,6′-bis-di(2-thienyl)boryl]-2,2′-bipyridine (**1b**) in 36% yield. The combination of steric (*i*Pr) and electronic effects (thienyl) of the substituents destabilizes the coordination in the dianionic borate **2b** and thus allows the formation of the free diborylbipyridine **1b**. Based on the ^{11}B-NMR spectrum in thf (δ = −1), its low solubility and high melting point (> 250°C) we propose an aggregation via N−B donor acceptor interactions to give an oligomer of unknown structure and number of diborylbipyridine units. The appearence of only one ^{11}B-NMR signal may indicate a cyclic arrangement. In a chain-like donor−acceptor compound $(\mathbf{1b})_n$ the two terminal BTh_2 groups could be stabilized by thf molecules forming donor−acceptor adducts.

Scheme 5

The reaction of the diisobutoxy derivative **2c** with chlorobis(dimethylamino)borane results in the formation of 6,6′-bis[bis(dimethylamino)boryl]-2,2′-bipyridine (**1c**). It is obtained in 64% yield as a red oil of limited solubility in thf. In comparison to bis(dimethylamino)organoboranes (δ = 34−36)[16] the ^{11}B-chemical shift of **1c** appears at higher field (δ = 31). Most likely this is caused by π-interaction between the p_z orbital of the boron atom and the π system of the heterocycle. In the ^{1}H NMR there is only one signal for the dimethylamino groups which indicates a free rotation around the B−N and the B−C bonds on the NMR time scale.



In general the reactivity of **2a−f** is high toward HCl/Et_2O and $ClSiMe_3$ (except **2b**), resulting in the cleavage of the boron−bipyridine bond. Because of their high sensitivity toward moisture, no satisfactory C,H,N analysis could be obtained.

Scheme 6

Complex Formation

In the borates **2** the bipyridine has an *anti* conformation and acts as a tetradentate ligand toward two lithium cations. Treatment of **2b** with one equivalent of $(Et_4N)_2CuCl_4$ results in the formation of the deep green-blue coordination compound **4**. The copper ion is coordinated by two nitrogen and two oxygen atoms of the alkoxy groups. Because of the paramagnetism of the d^9-Cu^{II} ion the NMR spectra of **4** could not be used for characterization. The cyclovoltammetry of **4** shows a reversible oxidation at $E_{1/2}$ = 0.65 V and an irreversible reduction at −1.1 V.

Scheme 7

An unprecedented coordination mode is observed in the adduct **5**. It is formed by the interaction of **1a** with 1,3-diethyl-1,3-dihydroxydiboroxane. The unknown dihydroxy-

diboroxane molecule is stabilized by the intermolecular aggregation. Treatment of 6,6′-dilithio-2,2′-bipyridine with an excess of diethyl(methoxy)borane and aqueous workup leads to **5** in 42% yield. The Lewis donor−acceptor pattern of **1a** induces the formation of the matching partner with the inverted Lewis functionality. Hydrolysis of the diethyl(methoxy)borane yields 1,3-diethyl-1,3-dihydroxydiboroxane coordinated to the diborylbipyridine **1a**. The free dihydroxydiboroxane is unstable and is expected to give give cyclic 1,3,5-boroxine. **5** is characterized by ^{1}H-, ^{13}C-, ^{11}B-NMR spectroscopy and an X-ray structure analysis (see below). In the ^{11}B-NMR spectrum appears only one broad signal at $\delta = 9$. Therefore all four boron atoms are quaternized. The Lewis acidic diethylboryl groups act as acceptor for the terminal oxygen atoms and the electron pair of the nitrogen atoms donate to the boron atoms of the dihydroxydiboroxane. The chemical shift of the methylene groups of the diethylboroxane at $\delta = -0.2$ corresponds with the high electron density at the boron atoms.

Crystal Structures

Single crystals of **2f** were grown from a tetrahydrofuran solution at room temperature. Figure 1 shows a molecule of **2f**, its lithium centers are tetracoordinated. Besides the bonding to the oxygen atom of the alkoxy group [Li−O: 1.87(1) Å] there is an interaction with the nitrogen atom [Li−N: 2.08(1) Å] of the bipyridine unit. The coordination sphere is completed by two thf molecules [Li−O: 1.97(1) Å]. The five-membered heterocycles are approximately planar with deviations from the best plane being less than 0.02 Å. The bond length B1−C1 is 1.64 Å. The two pyridine units are twisted by 149.6°.

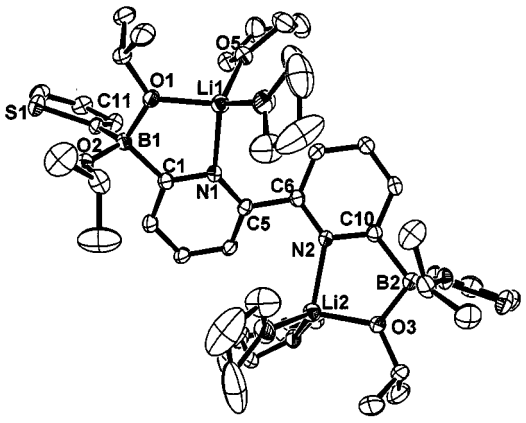


Figure 1. Structure of **2f** in the crystal; selected bond lengths [Å] and angles [°]: B1−C1 1.642(8), B1−O1 1.506(7), B1−O2 1.479(7), Li1−O1 1.87(1), Li1−N1 2.08(1), Li1−O5 1.97(1), C1−B1−O1 106.4(4), C1−B1−O2 112.5(5), C1−B1−C11 107.0(4), N1−C5−C6−N2 30.6

The large variety of possible coordination modes of Cu^{II}[17] are known. Therefore it is of interest to obtain structural information on the copper coordination in **4**. Single crystals suitable for an X-ray diffraction study were grown by slow diffusion of *n*-hexane into the solution of **4** in CH_2Cl_2. Figure 2 shows its structure in the crystal. The copper center has a distorted square-planar coordination by two nitrogen and two oxygen atoms. One of the oxygen atoms (O2) deviates strongly from the plane. The geometry around O2 differs much from that around O1. The distance Cu1−O2 [2.016(3) Å] is larger than Cu1−O1 [1.962(3) Å]. The oxygen atom O1 shows a planar coordination, while O2 is pyramidalized. The five-membered cycle of O1 is planar, that of O2 has an envelope form. The isopropyl group at O1 lies approximately symmetrical to the plane through the ring, while in the case of O2 it is strongly bent to one side, and one of the methyl groups reaches a position above the copper ion. A weak agostic interaction with one of its hydrogen atoms to the copper ion [Cu1−H 2.48(4) Å] is observed. The distances between the boron atoms and the bridging oxygen atoms [1.558(5), 1.575(5) Å] are about 0.1 Å longer than in regular B−O bonds of uncoordinated borates.

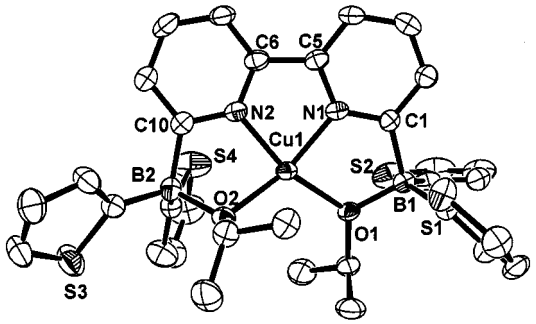

Figure 2. Structure of **4** in the crystal; selected bond lengths [Å] and angles [°]: B1−C1 1.630(6), B1−O1 1.558(5), B2−O2 1.575(5), Cu1−N1 1.938(3), Cu1−N2 1.938(3), Cu1−O1 1.962(3), Cu1−O2 2.016(3), C5−C6 1.483(6), C1−B1−O1 103.7(3), C10−B2−O2 104.8(3), N1−Cu1−N2 80.8(1), N1−Cu1−O1 83.1(1), O1−Cu1−O2 114.8(1), O2−Cu1−N2 83.4(1), B1−O1−C27 116.6(3), C27−O1−Cu1 126.5(3), Cu1−O1−B1 116.9(2), N1−C5−C6−N2 7.4, N1−C1−B1−O1 2.1, N2−C10−B2−O2 23.7

Figure 3 shows the molecule structure of **5** in the crystal. Crystals suitable for X-ray structure analysis were obtained by slow diffusion of *n*-hexane in a CH_2Cl_2 solution of **5**. The molecules of **5** form dimers in the solid state by hydrogen bonds. There are two independent dimers (four molecules) in the cell. They may be described as a donor−acceptor coordination product of **1a** with 1,3-diethyl-1,3-dihydroxydiboroxane, with the nitrogen atoms of the bipyridine and the hydroxy groups of the boroxane acting as donors to the boron atoms. All boron atoms are tetrahedrally coordinated. Three groups of B−O bonds are found, which are clearly distinguished in their distances: One type in the seven-membered ring with the two-coordinated oxygen atoms varying from 1.415−1.445 Å, two types in the five-membered rings with three-coordinated oxygen atoms, where they differ in the coordination of the boron atoms; 1.503−1.536 Å for the boron atoms connected to the nitrogen atoms, and 1.561−1.620 Å for the boron atoms connected to three carbon atoms.

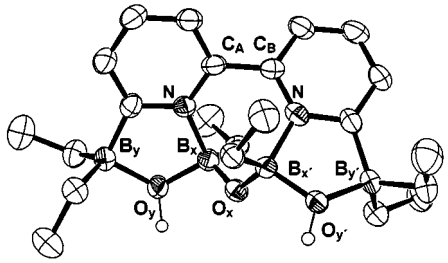

Figure 3. Structure of **5** in the crystal; selected bond lengths [Å] [mean values and range given (esd. 0.006−0.009 Å)]: B_X-O_X 1.440 (1.415−1.445), B_X-O_Y 1.525 (1.503−1.536), B_Y-O_Y 1.595 (1.561−1.620), B_X-N 1.626 (1.611−1.650), C_A-C_B 1.486 (1.479−1.494)

Experimental Section

General: Reactions were carried out under dry argon, using standard Schlenk techniques. Solvents were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat-gun in high vaccum. − ^{1}H, ^{13}C, ^{11}B NMR: Bruker AC 200 spectrometer, NMR references are $(CH_3)_4Si$ and $BF_3 \cdot Et_2O$. − Mass spectra were obtained with a Finnigan MAT 8200 plus spectrometer using EI technique. − Melting points (uncorrected) were obtained with a Büchi apparatus, using capillaries which were filled under argon and sealed.

Crystal-Structure Determination: Unique sets of intensity data were collected at −70°C with a four-circle diffractometer (Mo-K_α radiation λ = 0.71073 Å, graphite monochromator, ω-scan). Empirical absorption corrections (ψ-scans) for **2f** and **4** were applied. The structures were solved by direct methods [SHELXS86][18] and refined by least-squares methods based on F^2 with all measured reflections [SHELXL97].[19] All non-hydrogen atoms were refined anisotropically.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center: CCDC-102722 (**2f**), -102723 (**4**), and -102724 (**5**). Copies of the data can be obtained free of charge and by application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-001; E-mail: deposit@ccdc.cam.ac.uk].

6,6′-Bis(diethylboryl)-2,2′-bipyridine (1a) and 6-Diethylboryl-2,2′-bipyridine (3a): 3.00 g (30 mmol) of Et_2BOMe and 900 mg (7.5 mmol) of 2,2′-bipyridine were dissolved in 30 ml of Et_2O and cooled to −75°C. 15 mmol of $LiNiPr_2$ in 30 ml of Et_2O was added dropwise within 1 h. The resulting yellow solution was stirred for 6 h at −75°C and was allowed to warm up to room temp. overnight. The red solution was hydrolysed with 100 ml of brine (saturated NaCl solution) and the organic layer was extracted with ethyl acetate (3 × 100 ml). The combined extracts were dried with anhydrous sodium sulfate and the solvent was removed in high vacuo. The residue was column-chromatographed with silica gel (2 × 30 cm) with a mixture of *n*-hexane and ethyl acetate (4:1) to give 27 mg (0.09 mmol, 1%) **1a** and 97 mg (0.4 mmol, 6%) of **3a**. − **1a:** ^{1}H NMR (200.1 MHz, [D$_8$]thf): δ = 0.55 (t, 12 H, CH_2CH_3), 0.82 (q, 8 H, CH_2CH_3), 6.93 (m, 2 H, $C_{10}H_6N_2$), 7.63 (m, 2 H, $C_{10}H_6N_2$), 8.02 (m, 2 H, $C_{10}H_6N_2$). − ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 3.2. − ^{13}C NMR (50.3 MHz, [D$_8$]thf): δ = 8.7 (CH_2CH_3), 10.5 (CH_2CH_3), 16 (br., CH_2CH_3), 123.8, 127.7, 139.0, 147.4 ($C_{10}H_6N_2$). − MS (70 eV, EI); *m*/*z* (%): 263 (26) [M − Et]$^+$, 235 (8) [M − Et − C_2H_4]$^+$, 167 (100) [M − BEt_2 − HCN]$^+$, 78 (16) [C_5H_4N]$^+$. − M. p. > 250°C. − **3a:** ^{1}H NMR (200.1 MHz, [D$_8$]thf: δ = 0.50 (t, 6 H, CH_2CH_3), 0.78 (q, 4 H, CH_2CH_3), 7.24 (m, 1 H, $C_{10}H_7N_2$), 7.50 (m, 1 H, $C_{10}H_7N_2$), 7.96 (m, 1 H, $C_{10}H_7N_2$), 8.06 (m, 1 H, $C_{10}H_7N_2$), 8.40 (m, 2 H, $C_{10}H_7N_2$), 8.52 (m, 1 H, $C_{10}H_7N_2$). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 9.9 (CH_2CH_3), 13.4 (br., CH_2CH_3), 118.9, 123.1, 124.5, 136.9, 138.1, 139.8, 141.9, 146.9, 149.2 ($C_{10}H_7N_2$). − ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 3.4. − MS (70 eV, EI); *m*/*z* (%): 195 (40) [M − Et]$^+$, 180 (3) [M − Et − Me]$^+$, 167 (100) [M − HCN − C_2H_4]$^+$,78 (4) [$C_5H_4N^+$].

6,6′-Bis-di(2-thienyl)boryl]-2,2′-bipyridine (1b): 630 mg (0.68 mmol) of **2b** was dissolved in 5 ml of CH_2Cl_2. 147 mg (1.36 mmol) of $ClSiMe_3$ in 5 ml of CH_2Cl_2 was added dropwise at 0°C. The yellow solution was stirred at room temp. for 15 h. The mixture was filtered and 20 ml of thf was added to the precipitate. The mixture was again filtered from LiCl. After recrystallisation in thf, 124 mg (0.24 mmol, 36%) of **1b** was obtained as an amorphus solid. − ^{1}H NMR (200.1 MHz, [D$_8$]thf): δ = 7.39 (dd, 2 H, C_4H_3S), 7.65 (dd, 1 H, $C_{10}H_6N_2$), 7.82−7.89 (m, 3 H, $C_{10}H_6N_2/C_4H_3S$), 8.05 (dd, 2 H, C_4H_3S), 8.42 (dd, 1 H, $C_{10}H_6N_2$). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 120.4, 126.1, 131.0, 133.5, 138.5, 140.1, 141.6 ($C_{10}H_6N_2/C_4H_3S$). − ^{11}B NMR (64.2 MHz, [D$_8$]thf): δ = 1.0. − MS (70 eV, EI): *m*/*z* (%): 342 (28) [M − 2 (C_4H_3S)]$^+$, 259 (11) [M − 3 (C_4H_3S)]$^+$, 84 (100) [$C_4H_4S^+$]. − MS (FAB); *m*/*z* (%): 509 [M + 1$^+$]. − M.p. > 250°C.

6,6′-Bis[bis(dimethyamino)boryl]-2,2′-bipyridine (1c): To a solution of 500 mg (0.79 mmol) of **2c** in 5 ml of thf 211 mg (2 mmol) of $ClB(NMe_2)_2$ in 5 ml of Et_2O was added dropwise at room. temp. After some min, a red solid started to precipitate. After stirring at room temp. overnight, the mixture was filtered. The residue was destilled in high vacuo (10^{-2} mbar, 220°C) yielding 179 mg (0.51 mmol, 64%) of **1c** as a red oil. − ^{1}H NMR (200.1 MHz, [D$_8$]thf): δ = 2.52 (s, 12 H, NMe_2), 7.60 (d, 2 H, $C_{10}H_6N_2$), 7.76 (dd, 2 H, $C_{10}H_6N_2$), 8.38 (d, 2 H, $C_{10}H_6N_2$). − ^{13}C NMR (50.3 MHz, [D$_8$]thf): δ = 40.4, [$N(CH_3)_2$], 120.9, 129.8, 140.8, 142.6 ($C_{10}H_6N_2$). − ^{11}B NMR (64.2 MHz, [D$_8$]thf): δ = 31.0. − EI-MS; *m*/*z* (%): 253 (25) [M − $B(NMe_2)_2$]$^+$, 226 (46) [M − $B(NMe_2)_2$ − HCN]$^+$, 79 (100) [$C_5H_5N^+$].

2,2′-Bipyridine-6,6′-diborates 2: 1.57g (5 mmol) of 6,6′-dibromo-2,2′-bipyridine, dissolved in 75 ml of thf, was added dropwise within 20 min to a solution of 10 mmol *n*BuLi in 50 ml of thf at −80°C. After stirring for 45 min, the alkoxyborane, dissolved in 30 ml of Et_2O, was added dropwise within 30 min to the red solution The mixture was allowed to warm up to room temp. overnight. Half of the solvent was removed in vacuo and 30 ml of *n*-hexane was added. After 36 h at 0°C, the mixture was filtered. The borates were obtained as colorless solids.

2a: (2.10 g, 3.2 mmol, 64%). − ^{1}H NMR (200.1 MHz, [D$_8$]thf): δ = 0.19 (q, 4 H, CH_2CH_3), 0.71 (t, 6 H, CH_2CH_3), 3.14 (s, 3 H,

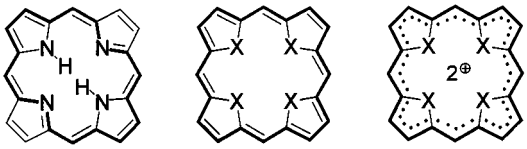
Syntheses, Structures, and Reactivity of 2,5-Diboryl-1-alkylpyrroles and Di(1-alkyl-2-pyrrolyl)boranes

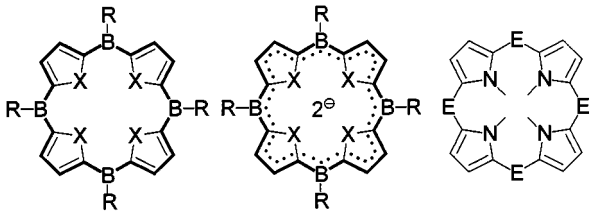
Jürgen Faderl,[a] Bernd Deobald,[a,b] Roger Guilard,[b] Hans Pritzkow,[a] and Walter Siebert*[a]



Dedicated to Prof. Wolfgang Sundermeyer on the occasion of his 70th birthday

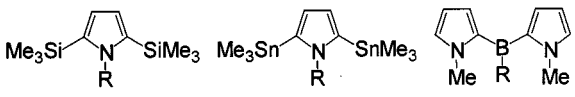
Keywords: Boranes / 1-Alkylpyrroles / Porphyrinogenes / Lithiation / Tin–boron exchange

Reactions of 2,5-dilithiated 1-methylpyrrole (**1a**) with $ClB(NR_2)_2$ lead to the novel 2,5-diboryl-1-methylpyrroles **2a** and **2b**. Accordingly, 2,5-diboryl-1-benzylpyrrole **2d** is obtained. **1a** and Cl_2BNiPr_2 form the aminochloroboryl-substituted derivative **2c** and the di(5-boryl-2-pyrrolyl)borane **4** in 29% and 15% yield, respectively. The 2,5-distannyl-1-methylpyrrole **1c** is used for the synthesis of the aryloxy-boryl derivative **2e**. Reacting monolithiated 1-methyl- and 1-benzylpyrroles with Cl_2BNiPr_2 yields the di(2-pyrrolyl)boranes **3e** and **3f**, respectively. NMR and MS data are in agreement with the compositions of the compounds, which are confirmed by X-ray structure analyses for **2a**, **2b**, **2d**, und **3e.**



Introduction

Since 1960 the hypothetical isophlorin (*N,N′*-dihydroporphyrin) **B**, X = NH,[1] as well as its heteroatom analogs have become a matter of interest. They may be regarded as bridged [20]annulenes. While the [18]annulene porphyrin **A** is very stable and shows a diatropic ring current[2] the tetraoxa macrocycle **B**, X = O, is less stable and exhibits a paratropic ring current.[3] Its dicationic precursor **C**, X = O, is an aromatic compound with a diatropic ring current.[4] In the octaethyl, tetramethyl derivatives of the tetraaza compounds **B** and **C**, X = NMe, the steric interference of the methyl groups causes non-planarity of both molecules. This yields for **C**, X = NMe, only to a small diatropic ring current,[5] whereas the paratropic ring current of **B**, X = NMe, is almost zero.[3]



A **B** X = NH, NR, O, S **C** X = NH, NR, O, S

We are interested in the electronic structure and ligand properties of the tetrabora porphyrinogenes **D**, which formally derive from **B** by exchange of the *meso*-carbon for boron atoms. In **D** the empty p_z orbitals of the boron atoms may allow macrocyclic conjugation, when **D** (16 π electrons) is reduced to the dianion **E**. As a first example of a tetrabora porphyrinogene **D** we recently synthesized the tetrathia macrocycle **D**, X = S, R = N*i*Pr$_2$.[6] The formation of the silyl- and stannyl-bridged macrocycles **F**, E = $SiMe_2$, $SnMe_2$, has been reported.[7]

D X = NH, NR, O, S **E** X = NH, NR, O, S **F** E = $SiMe_2$, $SnMe_2$

Possible building blocks for the synthesis of **D**, X = NR, may be 2,5-diborylpyrroles **2** and di(2-pyrrolyl)boranes **3**, which when suitably functionalized should be precursors for ring-closure reactions. However, 2,5-diborylpyrroles **2** are not yet known. Only a few 2,5-disilylpyrroles **G**[8] and the 2,5-distannylpyrrole **H**[9] have been reported. The di(1-methyl-2-pyrrolyl)boranes **3a–d** were synthesized via tin–boron exchange and characterized by NMR.[10] In the following we report on the syntheses of novel 2,5-diborylpyrroles **2** as well as the preparation of the di(2-pyrrolyl)boranes **3e** and **3f** via lithiated 1-alkylpyrroles.

G R = Me, CO_2tBu, CONH*t*Bu **H** R = CO_2tBu **3a-d** R = NMe_2, Et, Cl, C_4H_3NMe

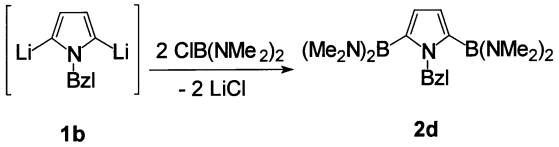
Results and Discussion

Syntheses and Reactivity

2,5-Dilithio-1-methylpyrrole (**1a**) is formed by treating 1-methylpyrrole with 2.4 equivalents of *n*-butyllithium in the presence of *N,N,N′,N′*-tetramethylethylendiamine (tmeda) in refluxing hexane. The grey-brown suspension of **1a** is very sensitive and immediately turns dark on air contact. Due to its high reacticity **1a** was used in situ for the preparation of the compounds **2a−c**. Presumably the lithium centers of **1a** are coordinated and stabilized with tmeda.

The reaction of **1a** with $ClB(NMe_2)_2$ leads to the novel 2,5-bis[bis(dimethylamino)boryl]-1-methylpyrrol (**2a**) in 47% yield as colorless, crystalline solid, which is sensitive to air and moisture. The composition of **2a** follows from spectroscopic data and is confirmed by an X-ray structure analysis (see below). The ^{1}H-NMR spectrum shows the expected three singulets. The ^{11}B-NMR spectrum exhibits a signal at $\delta = 30.1$, which corresponds with that of 2-bis(dimethylamino)boryl-1-methylpyrrole ($\delta = 29.8$).[10a] In the ^{13}C-NMR spectrum the signals of the ring carbon atoms appear at $\delta = 116.2$ for those in 3- and 4-position and at $\delta = 137$ as a broadened signal[11] for the boron-bound ring atoms. The ^{13}C signals of the ring atoms reveal a low-field shift of 7 and 15 ppm compared with those of 1-methylpyrrole,[12] which may be explained by π-interaction of the heterocycle with the boryl substituent as discussed by Nöth et al.[10] A thermogravimetric analysis of **2a** shows a continuous loss of mass with no hint for condensation reactions, expected to be accompanied with elimination of $B(NMe_2)_3$. An analogous reaction is known to occur with 2,5-bis(dimethylboryl)thiophene[13] even at room temperature. Treatment of **2a** with $AlMe_3$, MeOH, or PCl_5 did not lead to the projected exchange of substituents at the boron atoms.



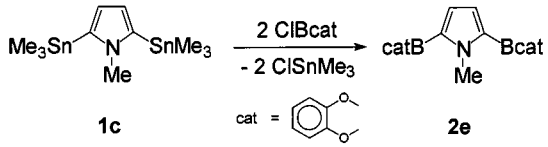
Scheme 1

The reaction of **1a** with $ClB(N\textit{i}Pr_2)_2$ yields only 6% of 2,5-bis[bis(diisopropylamino)boryl]-1-methylpyrrole (**2b**) as a colorless, crystalline solid, which is sensitive to air and moisture. The difference in the yield of **2a** and **2b** is probably caused by the greater steric impact of the diisopropylamino in comparison to the dimethylamino group. The spectroscopic and structural data of **2b** are similar to those of **2a**. Treatment of **2b** with BCl_3 did not yield the appropriate bis(dichloroboryl) derivative.

By adding the suspension of **1a** slowly into a cooled solution of $Cl_2BN\textit{i}Pr_2$ the 2,5-bis(chlorodiisopropylaminoboryl)-1-methylpyrrole (**2c**) is obtained in 29% together with 15% of bis[5-(chlorodiisopropylaminoboryl)-1-methyl-2-pyrrolyl]diisopropylaminoborane (**4**). Most likely the latter is formed, when the intermediate 5-(chlorodiisopropylamino)-2-lithio-1-methylpyrrole reacts with **2c** to give **4**.

2c is a colorless, crystalline solid, sensitive to air and moisture. Its ^{1}H-, ^{11}B-, and ^{13}C-NMR shifts are very similar to that of **2b** with exception of the shifts for the isopropyl groups. They appear in the ^{1}H-NMR spectrum as two sets of broadened signals with equal intensity, which indicates a B−N double bond.

4 is a colorless, air- and moisture-sensitive crystalline solid, which decomposes when heated to 130°C. The ^{1}H-NMR spectrum of **4** shows three sets of isopropyl groups in equal intensity. The signals for the aminochloroboryl substituents are identical with that of **2c**, the third set belongs to the isopropylamino group between the two heterocycles and is resolved as doublet and septet. The ring protons appear as two doublets at $\delta = 6.51$ and 6.63 with a coupling constant of 3.5 Hz. The ^{11}B-NMR spectrum shows one broad unsymmetrical signal at $\delta = 35$, formed by superposition of the two signals of the different boron atoms. In the ^{13}C-NMR spectrum only one broad signal at $\delta = 23$ for the two methyl groups of the outer isopropyl group is found, the corresponding methyne signals are separated. For the heterocycles four signals are found, two at $\delta = 114.1$ and 116.7 for the carbon atoms in 3- and 4-position and two broad ones[11] at $\delta = 137$ and 141 for the two different boron-bound carbon atoms. The composition of **4** is confirmed by a high resolution mass spectrum.

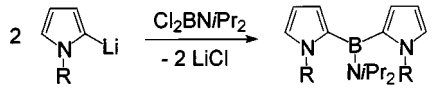


Scheme 2

Treating 1-benzylpyrrole with 2.4 equivalents of *n*-butyllithium and tmeda in refluxing hexane leads to the formation of 1-benzyl-2,5-dilithiopyrrole (**1b**). It is in situ treated with $ClB(NMe_2)_2$ to yield 34% of 2,5-bis[bis(dimethylamino)boryl]-1-benzylpyrrole (**2d**) as a colorless, crystalline solid, which is sensitive to air and moisture. Beside the benzyl group its spectroscopic data are similar to **2a**. A high resolution mass spectrum and an X-ray structure analysis confirm the composition of **2d**.

Attempts to synthesize 2,5-bis(dimethylboryl)-1-methylpyrrole (**2f**) from **1a** and Me_2BBr failed. The alternative route via the ditin derivative **1c** was tested to obtain **2e** as precursor for **2f**. Reaction of **1a** with trimethyltinbromide leads to the formation of 2,5-bis(trimethylstannyl)-1-methylpyrrole (**1c**), a colorless solid, characterized by multinuclear NMR spectroscopy (^{1}H, ^{13}C, and ^{119}Sn) and mass spectrometry. It is transformed into 2,5-bis(1,3,2-benzodioxaborol-2-yl)-1-methylpyrrole (**2e**) by the reaction of **1c**

with 2-chloro-1,3,2-benzodioxaborole. The tin−boron exchange leads to colorless **2e** in 75% yield.



The 200-MHz ^{1}H-NMR spectrum of **2e** shows only two multiplets in the aromatic region. A 300-MHz spectrum reveals that the singulet for the pyrrole ring protons (δ = 7.09) superposes with one of the multiplets of the benzo ring protons at δ = 7.11. The ^{11}B-NMR shift of **2e** is δ = 30. In the ^{13}C-NMR spectrum a signal for the boron-bound carbon atoms could not be observed.[11] As recently shown the benzodioxaborole ring is easily cleaved by LiMe or $AlMe_3$ to yield dimethylboryl groups.[14] The reaction of **2e** with $AlMe_3$ at −70°C indicated the formation of 2,5-bis(dimethylboryl)-1-methylpyrrole (**2f**), which could not be isolated. Most likely a polycondensation of the projected **2f** occured with elimination of BMe_3.

1c **2e**

Scheme 3

The reaction of monolithiated 1-methylpyrrole (**1d**) with Cl_2BNiPr_2 yields diisopropylaminodi(1-methyl-2-pyrrolyl)-borane (**3e**) as a colorless, crystalline solid. **3e** is stable up to 210°C, but sensitive to air and moisture. The ^{1}H-NMR spectrum shows next to the signals of the isopropyl group and the ring methyl group three multiplets for the ring protons at δ = 6.31, 6.48, and 6.56. The signal at δ = 6.31 is resolved as doublet of doublets with coupling constants of 2.4 and 3.5 Hz. They are ^3J coupling constants and hence the signal is assigned to the ring proton in 4-position. According to Nöth et al.[10b] the signals for the ring atoms in 4-position (proton and carbon atom) appear at high field, compared with those of the other ring atoms. This fact is based on the mesomeric effect of the boryl group in 2-position, which leads to partially postive charged 1-, 3-, and 5-positions. Accordingly, in the ^{13}C-NMR spectrum the signal for the carbon atom in 4-position appears at δ = 107.7 with the other ring signals at δ = 116.7, 125.4, and 138, the latter being the broadened signal[11] for the boron-bound carbon atoms. The ^{11}B-NMR spectrum shows a signal at δ = 35.6, which is comparable to dimethylamino derivative **3a** (δ = 31.8).[10a] The composition of **3e** is confirmed by a high resolution mass spectrum and an X-ray structure analysis.

1d R = Me **3e** R = Me
1e R = Bzl **3f** R = Bzl

Scheme 4

Analogously, di(1-benzyl-2-pyrrolyl)diisopropylamino-borane (**3f**) is synthesized from **1e**. The colorless solid is sensitive to air and moisture. Its chemical shifts are very similar to those of **3e** with exception of the benzyl group.

Crystal Structures

To elucidate the structure of the novel 2,5-diborylpyrroles **2** X-ray diffraction studies of the amino-substituted derivatives **2a**, **2b**, and **2d** were carried out (crystal data and structure refinement including **3e** are shown in Table 1).

The molecule of **2a** has almost C_s-symmetry with the mirror plane perpendicular to the ring plane. The bond lengths and angles are equal within the *esd*s.

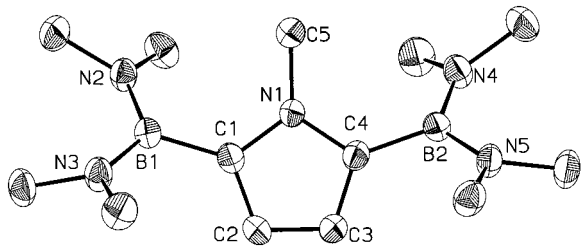


Figure 1. Molecular structure of **2a** in the crystal; selected bond lengths [Å] and angles [°]: N1−C1 1.390(2), N1−C4 1.391(2), C1−C2 1.383(3), C4−C3 1.381(3), C2−C3 1.402(3), N1−C5 1.457(2), C1−B1 1.577(3), C4−B2 1.575(3), B1−N2 1.419(2), B1−N3 1.429(3), B2−N4 1.429(3), B2−N5 1.424(3), C4−N1−C1 111.0(1), N1−C1−C2 105.6(1), C1−C2−C3 108.8(2), C2−C3−C4 108.8(2), C3−C4−N1 105.7(1), N1−C1−B1 127.8(1), N1−C4−B2 127.4(1).

2b has a crystallographic two-fold axis through the molecule and **2d** a crystallographic mirror plane perpendicular to the pyrrole ring.

The geometries of the three molecules are very similar. The distances and angles of the pyrrole rings are almost equal (within 3σ), but show significant deviations from the unsubstituted pyrrole ring,[12] especially for the endocyclic angles (values for the unsubstituted pyrrole in parantheses): C−N−C 111.0−111.6° (109.8°), N−C−C 105.4−105.7° (107.7°), C−C−C 108.7−108.8° (107.4°). The reason for this difference is not clear.

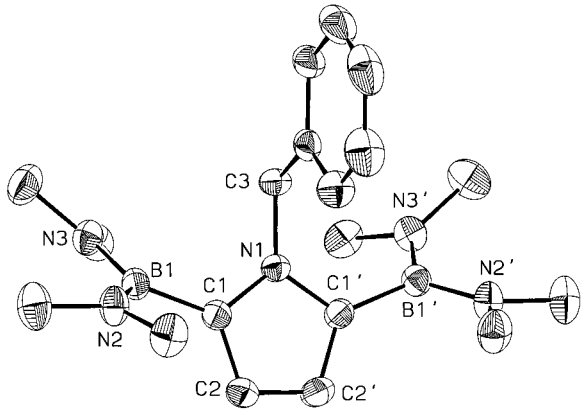

Figure 2. Molecular structure of **2d** in the crystal. − Selected bond lengths [Å] and angles [°] of **2d**: N1−C1 1.390(2), C1−C2 1.382(2), C2−C2′ 1.411(4), N1−C3 1.456(3), C1−B1 1.578(2), B1−N2 1.419(2), B1−N3 1.427(2), C1′−N1−C1 111.4(2), N1−C1−C2 105.6(1), C1−C2−C2′ 108.7(1), N1−C1−B1 125.5(1). − Selected bond lengths [Å] and angles [°] of **2b**: N1−C1 1.384(3), C1−C2 1.373(3), C2−C2′ 1.405(5), N1−C3 1.447(4), C1−B1 1.584(4), B1−N2 1.425(4), B1−N3 1.438(4), C1′−N1−C1 111.6(3), N1−C1−C2 105.4(2), C1−C2−C2′ 108.7(1), N1−C1−B1 127.0(2).

The pyrrole rings are almost planar with max. deviations of 0.006 Å for **2a** and 0.010 Å for **2b** and **2d**. The substituents deviate only slightly from the ring plane. The boron atoms have an almost planar coordination, but the CBNN planes are twisted against the ring planes. The interplanar angles increase from 43.0 and 48.2° for **2a** to 57.8° for **2d** (caused by the benzyl ligand) and up to 71.5° for **2b** with the bulky isopropyl groups. The planes through the amino groups are not coplanar with the CBNN planes, but rotated by 19.0−35.1°. The B−N distances (1.419−1.438 Å) are somewhat greater than in other aminoboranes.[15]

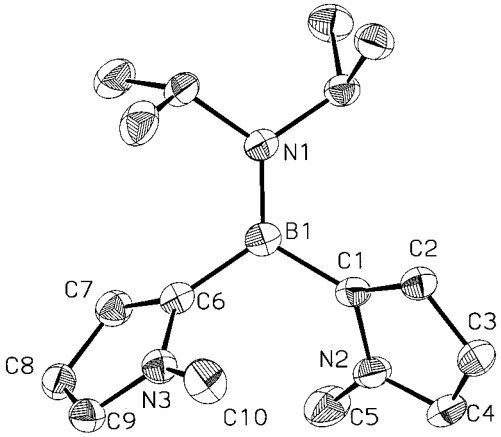

Figure 3. Molecular structure of **3e** in the crystal; selected bond lengths [Å] and angles [°]: N2−C1 1.389(2), N3−C6 1.392(2), C1−C2 1.387(2), C6−C7 1.384(2), C2−C3 1.409(3), C7−C8 1.406(3), C3−C4 1.357(3), C8−C9 1.363(3), C4−N2 1.366(2), C9−N3 1.367(2), N2−C5 1.456(3), N3−C10 1.456(3), C1−B1 1.577(3), C6−B1 1.574(3), B1−N1 1.406(2), C4−N2−C1 109.7(1), C9−N3−C6 110.3(1), N2−C1−C2 105.3(1), N3−C6−C7 105.0(2), C1−C2−C3 109.2(2), C6−C7−C8 109.5(2), C2−C3−C4 106.5(2), C7−C8−C9 106.9(2), C3−C4−N2 109.1(2), C8−C9−N3 108.3(2), N2−C1−B1 124.6(1), N3−C6−B1 122.5(1).

3e is the first di(2-pyrrolyl)borane, whose structure was determined. The coordination at the boron and the N1 nitrogen center is almost planar, but the molecule ist twisted by 17.8° around the B−N bond. The B−N distance is smaller than in the 2,5-diborylpyrroles **2**. The two pyrrole rings show only small deviations (max. 0.008 Å) from planarity and are rotated by 45.9 and 58.1° against the plane through B1, C1, C6, and N1. The pyrrole rings are not symmetrically substituted and show significant differences of the distances and angles compared with the unsubstituted pyrrole[12] and the 2,5-diborylpyrroles **2**.

Experimental Section

General: Reactions were carried out under dry nitrogen using standard Schlenk techniques. Solvents and chemicals were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat-gun in high vacuum. − ^{1}H, ^{11}B, ^{13}C, ^{119}Sn NMR: Bruker AC 200 spectrometer, shift references are $(CH_3)_4Si$, $BF_3 \cdot Et_2O$, and $(CH_3)_4Sn$. − Mass spectra were obtained with a Varian MAT CH7 spectrometer, high resolution mass spectra with a Jeol JMS-700 spectrometer both using the EI technique. − Melting points (uncorrected) were measured with a Büchi apparatus using a capillary, which was filled under nitrogen and sealed. − 1-Benzylpyrrole,[16a] $ClB(NMe_2)_2$,[16b] $ClB(NiPr_2)_2$,[16c] Cl_2BNiPr_2,[16d] 2-chloro-1,3,2-benzodioxaborole (ClBcat),[16e] and $(CH_3)_3SnBr$[16f] were prepared according to literature procedures.

2,5-Dilithio-1-methylpyrrole (1a): To a solution of 3.6 mL (24.0 mmol) of tmeda in 40 mL of hexane 9.6 mL (24.0 mmol) of *n*-butyllithium (2.5 M in hexane) were added with cooling and stirred for 15 min at room temp. After the addition of 0.9 mL (10.1 mmol) of 1-methylpyrrole the mixture was refluxed for 9 h. A grey-brown suspension was formed.

2,5-Bis(trimethylstannyl)-1-methylpyrrole (1c): To a suspension of **1a** (10.3 mmol) in 50 mL of hexane a solution of 5.86 g (24.0 mmol) of $(CH_3)_3SnBr$ in 10 mL of hexane was added dropwise at −30°C. The mixture was allowed to warm to room temp. and stirred for 15 h. Volatile compounds were removed in vacuum, the residue was dissolved in hexane and filtered. The solvent was evaporated in vacuum and the colorless solid obtained was recrystallized from hexane at −80°C. Yield: 2.88 g (69%) colorless **1c**. − ^{1}H NMR (C_6D_6, 200.1 MHz): δ = 0.22 [s, 18 H, ^2J(H,^{117}Sn) = 53.4 Hz (7,1%), ^2J(H,^{119}Sn) = 55.9 Hz (7,7%), SnCH_3], 3.41 (s, 3 H, $^4J_{H,Sn}$ = 2.4 Hz, NCH_3), 6.65 (s, 2 H, $^3J_{H,Sn}$ = 10.5 Hz, C*H*). − ^{13}C NMR (C_6D_6, 50.3 MHz): δ = −8.8 ($^1J_{C,Sn}$ = 348.3 Hz and 364.3 Hz, Sn*C*H$_3$), 39.4 (N*C*H$_3$), 120.1 ($^2J_{C,Sn}$ = 50.5 Hz and 60.5 Hz, *C*H), 136.3 (ring-*C*Sn). − ^{119}Sn NMR (C_6D_6, 74.6 MHz): δ = −33.0. − MS: *m*/*z* (%): 407 (26) [M$^+$], 392 (62) [M$^+$ − Me], 230 (100).

2,5-Bis[bis(dimethylamino)boryl]-1-methylpyrrole (2a): To a suspension of **1a** (10.1 mmol) in 50 mL of hexane a solution of 2.75 g (20.5 mmol) of $ClB(NMe_2)_2$ in 15 mL of hexane was added within 25 min at −30°C. The mixture was allowed to warm to room temp. and stirred for 14 h. After 20 min of refluxing the volatile compounds were evaporated in vacuum, the residue was dissolved in hexane and filtered. The solvent was removed in vacuum and **2a** was sublimed. A single crystal was grown from a pentane solution at −30°C. Yield: 1.32 g (47%) colorless **2a**, subl.p.: 72°C/5·10^{-2} mbar. − ^{1}H NMR (C_6D_6, 200.1 MHz): δ = 2.65 (s, 24 H, BNCH_3), 3.44 (s, 3 H, CNCH_3), 6.52 (s, 2 H, C*H*). − ^{11}B NMR (C_6D_6, 64.2 MHz): δ = 30.1. − ^{13}C NMR (C_6D_6, 50.3 MHz): δ = 34.4 (CN*C*H$_3$), 40.8 (BN*C*H$_3$), 116.2 (*C*H), 137 (br, *C*B). − MS: *m*/*z* (%): 277 (7) [M$^+$], 233 (3) [M$^+$ − NMe_2], 58 (100).

2,5-Bis[bis(diisopropylamino)boryl]-1-methylpyrrole (2b): To a suspension of **1a** (10.1 mmol) in 50 mL of hexane a solution of 5.10 g (20.7 mmol) of $ClB(NiPr_2)_2$ in 20 mL of hexane was added within 20 min at room temp. The mixture was stirred for 14 h and refluxed for 8 h. Volatile compounds were removed in vacuum, the residue was dissolved in hexane and filtered. The solvent was evaporated in vacuum and **2b** was sublimed. A single crystal was grown from a hexane solution at −30°C. Yield: 0.30 g (6%) colorless **2b**, subl.p.: 140°C/1.2·10^{-2} mbar. − ^{1}H NMR (C_6D_6, 200.1 MHz): δ = 1.17 [d, 48 H, $^3J_{H,H}$ = 6.9 Hz, CH(CH_3)$_2$], 3.58 [sept, 8 H, $^3J_{H,H}$ = 6.9 Hz, C*H*(CH$_3$)$_2$], 3.70 (s, 3 H, NCH_3), 6.39 (s, 2 H, ring-C*H*). − ^{11}B NMR (C_6D_6, 64.2 MHz): δ = 33.7. − ^{13}C NMR (C_6D_6, 50.3 MHz): δ = 25.1 [CH(*C*H$_3$)$_2$], 37.3 (N*C*H$_3$), 47.8 [*C*H(CH$_3$)$_2$], 116.7 (ring-*C*H), *C*B signal not observed. − MS: *m*/*z* (%): 501 (47) [M$^+$], 458 (39) [M$^+$ − *i*Pr], 401 (43) [M$^+$ − N*i*Pr$_2$], 211 (100) [B(N*i*Pr$_2$)$_2^+$].

2,5-Bis(chlorodiisopropylaminoboryl)-1-methylpyrrole (2c) and Bis[5-(chlorodiisopropylaminoboryl)-1-methyl-2-pyrrolyl]diisopropylaminoborane (4): To a solution of 4.43 g (24.3 mmol) of Cl_2BNiPr_2 in 20 mL of hexane a suspension of **1a** (10.3 mmol) in 50 mL hexane was added dropwise at −50°C. The mixture was allowed to warm to room temp. and stirred for 15 h. Volatile compounds were removed in vacuum, the residue was dissolved in hexane and fil-

tered. The solvent was evaporated and the residue treated with 20 mL of hexane. **4** was crystallized from the solution at −30°C, filtered, and dried. The remaining solution was evaporated in vacuum to half the volume and **2c** was crystallized at −30°C, separated, and dried. Yield: 1.12 g (29%) of colorless **2c**. − ^{1}H NMR (C_6D_6, 200.1 MHz): δ = 0.84, 1.34 [each br, 12 H, CH(CH_3)$_2$], 3.38, 4.07 [each br, 2 H, CH(CH$_3$)$_2$], 3.81 (s, 3 H, NCH_3), 6.48 (s, 2 H, ring-CH). − ^{11}B NMR (C_6D_6, 64.2 MHz): δ = 33.8. − ^{13}C NMR (C_6D_6, 50.3 MHz): δ = 22.1, 23.0 [each CH(*C*H$_3$)$_2$], 37.1 (N*C*H$_3$), 47.0, 51.6 [each *C*H(CH$_3$)$_2$], 115.0 (ring-*C*H), 137 (br, *C*B). − MS: *m*/*z* (%): 371 (13) [M$^+$], 328 (18) [M$^+$ − *i*Pr], 84 (100). − Yield: 422 mg (15%) of colorless **4**, m.p.: 187°C (decomp.). − ^{1}H NMR (C_6D_6, 200.1 MHz): δ = 0.94, 1.32 [each br, 12 H, CH(CH_3)$_2$ (outer)], 1.17 [d, 12 H, $^3J_{H,H}$ = 6.8 Hz, CH(CH_3)$_2$ (inner)], 3.31 (s, 6 H, NCH_3), 3.37 [br, 2 H, CH(CH$_3$)$_2$ (outer)], 4.07 [sept, 2 H, $^3J_{H,H}$ = 6.8 Hz, CH(CH$_3$)$_2$ (inner) and br, 2 H, CH(CH$_3$)$_2$ (outer)], 6.51, 6.63 (each d, 2 H, $^3J_{H,H}$ = 3.5 Hz, ring-CH). − ^{11}B NMR (C_6D_6, 64.2 MHz): δ = 35. − ^{13}C NMR (C_6D_6, 50.3 MHz): δ = 23 [br, both CH(*C*H$_3$)$_2$ (outer)], 24.8 [CH(*C*H$_3$)$_2$ (inner)], 36.2 (N*C*H$_3$), 46.9, 51.5 [each *C*H(CH$_3$)$_2$ (outer)), 49.1 (*C*H(CH$_3$)$_2$ (inner)], 114.1, 116.7 (each ring-*C*H), 137, 141 (each br, *C*B). − MS: *m*/*z* (%): 561 (56) [M$^+$], 518 (27) [M$^+$ − *i*Pr], 292 (100). − HR-MS: *m*/*z* (%): 561.3915 (9) [M$^+$, calc. for $^{12}C_{28}$ $^1H_{52}$ $^{11}B_3$ $^{35}Cl_2$ $^{14}N_5$: 561.3879].

2,5-Bis[bis(dimethylamino)boryl]-1-benzylpyrrole (2d): To a solution of 3.6 mL (24.0 mmol) of tmeda in 50 mL of hexane 9.2 mL (23.0 mmol) of *n*-butyllithium (2.5 M in hexane) was added with cooling. After stirring for 20 min at room temp. 1.58 g (10.0 mmol) of 1-benzylpyrrole was added with cooling and the mixture was heated under reflux for 14 h. To the resulting suspension 2.77 g (20.6 mmol) of ClB(NMe$_2$)$_2$ in 20 mL of hexane was added dropwise at −30°C. After the mixture was allowed to warm to room temp. and stirred for 4 h, it was refluxed for 2 h. Volatile compounds were evaporated in vacuum, the residue was dissolved in hexane and filtered. The solvent was removed in vacuum and the colorless solid washed with pentane. A single crystal was grown from a solution of pentane and CH_2Cl_2 (4:1) at −30°C. Yield: 1.21 g (34%) colorless **2d**, m.p.: 103°C. − ^{1}H NMR ($CDCl_3$, 200.1 MHz): δ = 2.59 (s, 24 H, CH_3), 4.91 (s, 2 H, CH_2), 6.17 (s, 2 H, pyrrole-CH), 6.92 (m, 2 H, phenyl-CH), 7.17 (m, 3 H, phenyl-CH). − ^{11}B NMR ($CDCl_3$, 64.2 MHz): δ = 30.8. − ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 40.6 (*C*H$_3$), 51.1 (*C*H$_2$), 116.1 (pyrrole-*C*H), 126.5, 127.2, 127.9 (each phenyl-*C*H), 141.4 (phenyl-*C*$_{ipso}$), *C*B signal not observed. − MS: *m*/*z* (%): 353 (69) [M$^+$], 309 (9) [M$^+$ − NMe$_2$], 99 (100) [B(NMe$_2$)$_2^+$]. − HR-MS: *m*/*z* (%): 353.2907 (22) [M$^+$, calc. for $^{12}C_{19}$ $^1H_{33}$ $^{11}B_2$ $^{14}N_5$: 353.2922].

2,5-Bis(1,3,2-benzodioxaborol-2-yl)-1-methylpyrrole (2e): A solution of 1.13 g (2.8 mmol) of **1c** in 10 mL of toluene was cooled to −75°C and the solution of 878 mg (5.7 mmol) of ClBcat in 10 mL of toluene was added. The mixture was allowed to warm to room temp. and stirred for 15 h. After 1 h of refluxing the resulting solid was separated by filtration, washed with hexane and CH_2Cl_2, and dried. Yield: 661 mg (75%) colorless **2e**. − ^{1}H NMR ([D$_8$]thf, 200.1 MHz): δ = 4.38 (s, 3 H, CH_3), 7.09 (s, 2 H, pyrrole-CH), 7.11, 7.31 (each m, 4 H, benzo-CH). − ^{11}B NMR ([D$_8$]thf, 64.2 MHz): δ = 30. − ^{13}C NMR ([D$_8$]thf, 50.3 MHz): δ = 37.3 (*C*H$_3$), 113.3, 123.9 (each benzo-*C*H), 124.2 (pyrrole-*C*H), 149.6 (*C*O), *C*B signal not observed. − MS: *m*/*z* (%): 317 (28) [M$^+$], 58 (100).

Diisopropylaminodi(1-methyl-2-pyrrolyl)borane (3e): To a solution of 2.6 mL (29.2 mmol) of 1-methylpyrrole in 20 mL of thf 12.5 mL (31.2 mmol) of *n*-butyllithium (2.5 M in hexane) was added at −35°C. After the mixture was allowed to warm for 1 h, and stirred at room temp. for 3 h. At −70°C a solution of 2.60 g (14.3 mmol) of Cl_2BNiPr_2 in 10 mL of thf was added. The mixture was allowed to warm to room temp. and stirred for 16 h. Volatile compounds were removed in vacuum, the residue was dissolved in hexane and filtered. The solvent was evaporated in vacuum and the colorless

solid recrystallized from hexane at −30°C. A single crystal was grown from a solution of hexane and CH_2Cl_2 (6:1) at room temp.. Yield: 1.50 g (38%) colorless **3e**, m.p. > 210°C. − ^{1}H NMR (C_6D_6, 200.1 MHz): δ = 1.17 [d, 12 H, $^3J_{H,H}$ = 6.7 Hz, CH(CH_3)$_2$], 2.82 (s, 6 H, NCH_3), 4.07 [sept, 2 H, $^3J_{H,H}$ = 6.7 Hz, CH(CH$_3$)$_2$], 6.31 [dd, 2 H, $^3J_{H,H}$ = 2.4 Hz, $^3J_{H,H}$ = 3.5 Hz, ring-CH(C4)], 6.48 (m, 2 H, ring-CH), 6.56 (dd, 2 H, $^3J_{H,H}$ = 3.5 Hz, $^4J_{H,H}$ = 1.5 Hz, ring-CH). − ^{11}B NMR (C_6D_6, 64.2 MHz): δ = 35.6. − ^{13}C NMR (C_6D_6, 50.3 MHz): δ = 24.8 [CH(*C*H$_3$)$_2$], 35.3 (N*C*H$_3$), 49.0 [*C*H(CH$_3$)$_2$], 107.7 [ring-*C*H(C4)], 116.7, 125.4 (each ring-*C*H), 138 (br, *C*B). − MS: *m*/*z* (%): 271 (65) [M$^+$], 147 (100). − HR-MS: *m*/*z* (%): 271.2226 (38) [M$^+$, calc. for $^{12}C_{16}$ $^1H_{26}$ ^{11}B $^{14}N_3$: 271.2220].

Di(1-benzyl-2-pyrrolyl)diisopropylaminoborane (3f): To a solution of 1.8 mL (12.0 mmol) of tmeda in 40 mL of hexane 4.8 mL (12.0 mmol) of *n*-butyllithium (2.5 M in hexane) was added with cooling and stirred for 30 min at room temp.. After the addition of 1.55 g (9.9 mmol) of 1-benzylpyrrole the mixture was refluxed for 2 h. To the brown suspension a solution of 1.04 g (5.7 mmol) of Cl_2BNiPr_2 in 25 mL of hexane was added within 45 min at −30°C. After the mixture was allowed to warm to room temp. and stirred for 18 h, it was refluxed for 30 min. Volatile compounds were removed in vacuum, the residue was dissolved in toluene and filtered. The solvent was evaporated in vacuum and the colorless solid recrystallized from pentane at −80°C. Yield: 662 mg (31%) colorless **3f**. − ^{1}H NMR ($CDCl_3$, 200.1 MHz): δ = 1.11 [d, 12 H, $^3J_{H,H}$ = 6.8 Hz, CH(CH_3)$_2$], 4.04 [sept, 2 H, $^3J_{H,H}$ = 6.8 Hz, CH(CH$_3$)$_2$], 4.57 (s, 4 H, CH_2), 6.28 [dd, 2 H, $^3J_{H,H}$ = 2.4 Hz and 3.4 Hz, pyrrole-CH(C4)], 6.47 (dd, 2 H, $J_{H,H}$ = 3.4 Hz, $^4J_{H,H}$ = 1.5 Hz, pyrrole-CH), 6.85 (dd, 2 H, $^3J_{H,H}$ = 2.4 Hz, $^4J_{H,H}$ = 1.5 Hz, pyrrole-CH), 7.08 (m, 4 H, phenyl-CH), 7.26 (m, 6 H, phenyl-CH). − ^{11}B NMR ($CDCl_3$, 64.2 MHz): δ = 36.4. − ^{13}C NMR ($CDCl_3$, 50.3 MHz): δ = 24.6 [CH(*C*H$_3$)$_2$], 48.9 [*C*H(CH$_3$)$_2$], 51.7 (*C*H$_2$), 107.4 [pyrrole-*C*H(C4)], 116.7, 124.5 (each pyrrole-*C*H), 126.9, 127.3, 128.1 (each phenyl-*C*H), 137 (br, *C*B), 139.5 (phenyl-C_{ipso}). − MS: *m*/*z* (%): 423 (100) [M$^+$], 408 (18) [M$^+$ − Me], 91 (88) [CH$_2$ − Ph$^+$].

X-ray Structure Determinations of 2a, 2b, 2d, and 3e: Crystal data and details of the stucture determinations are listed in Table 1. Unique sets of intensity data for **2a**, **2d**, and **3e** were collected at −70°C with a Siemens Stoe AED2 diffractometer and for **2b** at room temp. with a Syntex R3 diffractometer (Mo-K_α radiation, λ = 0.7107 Å, graphite monochromator, ω-scan). Empirical absorption corrections (ψ-scans) were applied. The structures were solved by direct methods (SHELXS-86)[17a] and refined by least-squares methods based on F^2 with all measured reflections (SHELXL-93)[17b]. All non-hydrogen atoms are refined anisotropically. For **2a** and **2b** hydrogen atoms were inserted in calculated positions, for **2d** and **3e** they were located in difference Fourier maps and refined isotropically.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publications no. CCDC-102879 (**2a**), CCDC-102880 (**2b**), CCDC-102881 (**2d**), and and CCDC-102882 (**3e**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: int. code +44 (0)1223/ 336-001; E-mail: deposit@ccdc.cam.ac.uk

Keywords: Epichlorohydrin / Chiral diphos ligands / Diphos rhodium complexes / Conformation analysis / Chelates / Asymmetric synthesis

Enantiomerically pure chelate ligands L_2 = $XCH_2CH(OH)CH_2Y$ (**1**) are obtained from epichlorohydrin in a two-step synthesis. X and Y may be different types of R_2P donor groups, NR_2 or SR donors. The OH function of **1** may be transformed into an ether function under specialized conditions. Ligands **1** react with $[Rh(COD)Cl]_2$ in the presence of KPF_6 to give the coordination compounds **2**, $[L_2Rh(COD)]^+PF_6^-$, as orange, microcrystalline salts. The structures adopted by compounds **2** in the solid state have been analysed by X-ray crystallography in selected cases, and it has been found that the six-membered chelate cycles adopt twist as well as chair conformations depending on the nature of X and Y. In solution, compounds **2** generally show dynamic behaviour, which is in part due to the conformational flexibility of the six-membered cycles. In cases where one of the PR_2 donor groups contains *ortho*-substituted phenyl substituents, rotational isomerism of these groups is an additional dynamic process. For some of these compounds, the nature of the dynamic behaviour has been analysed by variable-temperature NMR experiments. Compounds **2** are found to be precatalysts in the hydrogenation of (*Z*)-2-acetamidocinnamic acid. The rate of conversion is strongly influenced by the steric bulk of the substituents, with smaller substituents leading to higher rates. Enantiomeric discrimination is high only for those ligands that contain *ortho*-substituted aryl groups at their PR_2 donors. The maximum enantiomeric excess observed was 85% for X = PPh_2, Y = $P(2\text{-MeOPh})_2$.

Introduction

Enantioselective hydrogenation mediated by chiral bis(phosphane)rhodium templates is a well-established process.[1,2] Even though the major steps of the relevant catalytic cycles are well known,[3] there is still no means of predicting which properties of the ligands will induce a high enantioselectivity. It has been found that chelate diphosphane ligands are generally a good choice.[4,5] From the data available to date, it appears that five-membered and seven-membered cycles are superior to six-membered chelate rings in this respect.[2] In almost all of the relevant chelate ligands, chirality is embedded in the backbone, and this again appears to be a good principle, in particular because building blocks for the chiral backbones are often readily available from the chiral pool.[5] Despite the existence of a large amount of relevant literature,[6] there is no straightforward way of predicting the efficiency of a specific ligand.

As far as six-membered chelate cycles are concerned, their generally low efficiency has been attributed to the particular conformational flexibility of these cycles, which allows both chair and twist conformations, although only the twist conformations induce strong enantiomeric discrimination.[7] In solid-state structures, both conformations have been observed, even with the same chelate ligand. Thus, (2*S*,4*S*)-2,4-bis(diphenylphosphanyl)pentane $Ph_2PCH(CH_3)CH_2CH(CH_3)PPh_2$ (skewphos) forms a chelate chair with norbornadiene (NBD) as a coligand in the catalyst precursor skewphosRh(NBD)$^+$, while it is found in the twist conformation with cyclooctadiene (COD) as a coligand in skewphosRh(COD)$^+$.[8,9] Even though the chair conformation is thus available to this specific chelate cycle, it holds the record for enantioselectivity (*ee* > 90%) achieved in hydrogenation experiments.[8,9] From an analysis of the conformational properties of chirally substituted 1,3-diaminopropanes, it has been argued that with these amino ligands, which have a substitution pattern equivalent to that of skewphos, the twist conformation should be preferred on energetic grounds.[10] For chiral 1,3-diphosphanylpropane chelate cycles, the experimental material available so far[6,9] is not sufficient to deduce any general trends in this respect, nor are reliable force-field calculations available for isolated cycles.[11] In an attempt to create a structural database of chirally substituted 1,3-bis(phosphanyl)propane chelate cycles, with the ultimate aim of deriving a reliable force-field description by global optimization[12] of the relevant force-field parameters, a series of chiral 1,3-bis(phosphanyl)propanes (L_2) has been synthesized. Their rhodium complexes $[L_2Rh(COD)]PF_6$ (**2**) have been prepared and, where possible, structurally characterized as

well. The catalytic activities of these complexes and the associated enantioselectivities have been probed and it has been found that [(**1g**)Rh(COD)]PF_6 [**1g** = $Ph_2PCH_2CH(OH)CH_2P(2\text{-}MeOPh)_2$] permits up to 85% *ee* in the rhodium-mediated hydrogenation of (*Z*)-2-acetamidocinnamic acid (AAC).

Results and Discussion

Ligands

It has been reported that epichlorohydrin $H_2C(O)CHCH_2Cl$ (**A**) permits a simple and fully stereoselective synthesis of chiral tripod ligands $X_2POCH(CH_2PR_2)(CH_2PR'_2)$.[13] The corresponding tripod rhodium compounds, on the other hand, have been shown to be rather sluggish catalysts offering only slight enantiomeric discrimination.[14] Their reduced reactivity and low enantioselectivity has been explained on the basis of the hypothesis that in order to form active catalyst precursors, η^2-diphos species first have to be generated from the η^3-coordinated compounds by dissociation of one of the "legs" of the tripod ligands.[14,15] This hypothesis is well supported by a series of observations made for catalytic systems involving tripod metal entities.[14–17] In the light of this hypothesis, a logical course of action is to probe diphos ligands $HOCH(CH_2PR_2)(CH_2PR'_2)$, which differ from the above tripod ligands simply by the absence of the third oxygen-supported "leg". Such ligands are easily accessible by the same sequence of reactions as that used for the synthesis of the above tripod ligands.

Scheme 1. Reaction scheme

The reaction scheme shown for the consecutive addition of two phosphorus-centred nucleophiles (**1a–1l**) may be adapted to allow the incorporation of sulfur- or nitrogen-centred nucleophiles as well (**1m**, **1n**). Compounds **1** were purified by column chromatography and were obtained as colourless oils of modest to low viscosity. In no case could a crystalline product be obtained. In most cases it proved difficult to completely remove the solvent and successive cycles of freezing and drying had to be applied to overcome this problem. The microanalytical data were in agreement with the assigned constitutions with only a few exceptions (Tables 8 and 11). In these cases, high-resolution mass spectrometry was used as an analytical tool (Tables 8 and 11).

The ^{31}P-, ^{13}C-, and ^{1}H-NMR spectra provided further unequivocal evidence for the identity of the compounds (Tables 9, 10, 12, and 13). The assignment of the individual signals was in part based on the observation that chemically different PR_2 groups give rise to ^{31}P resonances in distinct and different ranges [dibenzophospholyl (DBP): δ = −20 to −23; PPh_2: δ = −21 to −25; PEt_2: δ = −26 to −30; $PMes_2$: δ = −30 to −33; $P(C_6H_4OMe)_2$: δ = −41 to −45; $P(o\text{-}Tol)_2$: δ = −44 to −47 (Tables 10 and 13)]. Comparing the whole set of spectra of compounds **1**, assignments based on these shift ranges were thus possible, whereas owing to the narrow range of shifts of specific organic groups, individual assignments of all the ^{13}C and ^{1}H resonances were not possible in all cases. The shifts and patterns observed leave no doubt as to the identity of **1** (Tables 9, 10, 12, and 13). The chirality of **1** gives rise to a range of specific rotations of $|[\alpha]_D^{20}| = 1–79$ (Tables 8 and 11).

With the donor groups $PMes_2/PEt_2$ (**1j**) and $P(o\text{-}Tol)_2/PEt_2$ (**1k**), the synthesis was performed by two alternative routes, as shown for **1j** in Scheme 2.

Scheme 2. Alternative syntheses of (*S*)-**1j**

Either (*R*)-**A** was used as the starting compound and the phosphane donors were introduced in the sequence: 1. $PMes_2$, 2. PEt_2, to obtain **1j** [or: 1. $P(o\text{-}Tol)_2$, 2. PEt_2, to produce **1k**], or alternatively (*S*)-**A** was used with the inverse

Scheme 3. Synthesis of ether derivatives **1**

sequence of addition. Both reactions lead to the same compound with the same chirality provided they are, as documented,[13,18] fully stereoselective. In line with expectation, the optical rotations of the two pairs of samples prepared by these two routes were in fact equal (**1j**: $[\alpha]_D^{20} = +46.2$, **1k**: $[\alpha]_D^{20} = +15.7$, Table 8).

All of the ligands **1a−1n** contain a hydroxy function. Etherification of this type of function in the presence of phosphane groups may be problematic.[19] For tripod ligands $HOCH_2C(CH_2PPh_2)_3$, a strategy that circumvents the problems caused by the nucleophilicity of the phosphorus functions in the course of a Williamson-type etherification has been developed.[20] The same type of reaction protocol works equally well with the diphos ligands **1**. The compound $Ph_2PCH_2CH(OH)CH_2PPh_2$, prepared by literature methods,[13] reacts with methyl iodide after depro-

tonation with KO*t*Bu at temperatures below 20°C to produce **1o**. In the same way, **1b** is transformed into **1p**. Stringent temperature control is necessary to avoid alkylation at the phosphorus atom.[20] With **1g** as the starting material, however, exclusive methylation at the oxygen position with methyl iodide proved impossible, even under these controlled conditions. The increased nucleophilicity of the $(2\text{-MeOPh})_2P$ function leads to partial quaternization of this phosphorus centre during the course of the reaction. On the other hand, etherification by the tosylate H_3CCH_2-$CH(CH_3)CH_2OTs$ could be achieved both for **1b** (→ **1r**) and for **1g** (→ **1t**). Silylation (**1b** → **1q**, **1g** → **1s**) did not present any problems of this kind.

With longer-chain tosylates, problems tend to arise in the separation of the ligands from the long-chain alcohols. Thus, when **1d** was treated with $H_2C{=}CH(CH_2)_9OTs$, the corresponding ether derivative (**1u**) was obtained, which could, however, not be obtained in an analytically pure state as such (Table 11), but was unequivocally characterized by the data obtained for its coordinated derivative **2u** (Table 3).

Coordination Compounds

Ligands **1** react with $[Rh(COD)Cl]_2$ under standard conditions to give the coordination compounds **2** [(**1a**–**u**)Rh-(COD)]PF_6.

Scheme 4. Constitution of compounds **2**

The labelling scheme used is such that coordination compound **2**"label" contains ligand **1**"label". Coordination compounds **2v** (R = R′ = Ph) and **2w** (R = *p*-Tol, R′ = Ph) were obtained from the appropriate ligands, the preparation of which has been described previously.[13] Compounds **2** were obtained as orange, microcrystalline solids.

The identities of compounds **2** were evident from their analytical data (Table 3), as well as from several X-ray analyses (see below). Elemental analyses, as well as the mass numbers as determined by FAB mass spectrometry, were in agreement with the constitutions as given. The optical rotations of the chiral compounds (all compounds except **2o**, **2v**) were found to be in the absolute range $|[\alpha]_D^{20}| = 5.4-79$ (Table 3).

The ^{1}H-NMR spectra are cumbersome to interpret. In most cases, broad signals are found at room temperature and the spectra are strongly temperature-dependent, indicating a dynamic behaviour of the chelate cycles. This is clearly borne out by analysis of the ^{31}P-NMR spectra (see

below). Individual assignment of groups of signals is nevertheless possible in the ^1H- (Table 14) as well as in the ^{13}C-NMR spectra (Table 15). Full interpretation of the spectra would, however, require an intricate analysis of the dynamic behaviour. The spectra of **2a**, **2m**, **2o**, **2v**, **2w** are comparatively sharp at room temperature and indicate the presence of one single species, at least over the time average. Sharp signals are also observed for compounds **2d−f**, **2j**, and **2u**, which contain $PMes_2$ groups. For these species, however, the presence of two different conformers (see below) leads to an overlap of signals, which hampers the unambiguous assignment of their ^1H and ^{13}C data.

The most clear-cut information is provided by the ^{31}P-NMR spectra. They are in agreement with the given constitutions in that they show the appropriate signals for each of the differently substituted PR_2 entities within the chelate cycle (Table 4). The signal pattern characteristic for each of the phosphorus nuclei consists of a doublet of doublets with $^1J_{PRh} \approx 140$ Hz, $^2J_{PP} \approx 40$ Hz (Table 4). There are only two compounds where the PR_2 groups are equal (**2o**, **2v**), and only one kind of phosphorus signal (doublet, $^1J_{PRh} \approx 145$ Hz) is observed in these cases at 293 K (Table 4).

The dynamic behaviour of the compounds is in some cases already apparent at or above room temperature, and is a rather general phenomenon. In the cases of **2d−f**, **2j**, and **2u**, which contain $PMes_2$ groups, the behaviour is static already at room temperature, where two different conformers give rise to two sets of signals. Two conformers are sometimes observed for compounds **2** in the solid state as well (see below).

The kind of dynamic behaviour is not always directly evident from the spectra, since there are a number of conceivable dynamic processes. In some cases, hindered rotation of *ortho*-substituted aryl groups as well as conformational changes of the chelate cycles seem to be simultaneously operative in the same system. Not all of the dynamic processes have yet been delineated, hence the types of process will be described here only for especially clear-cut cases.

With **2b**, the only dynamic process observed on the timescale of the experiment is the hindered rotation of the *ortho*-tolyl groups of the P(*o*-Tol)$_2$ moiety. At 273 K, broad multiplets are observed (Figure 1). Upon heating, one clear doublet of doublets structure is observed (Figure 1), which indicates that one of the phosphorus nuclei is not influenced by a change of the environment. The signal of the other phosphorus atom, however, is completely broadened into the baseline at 313 K; its signal starts to reappear at 328 K and a clear doublet of doublets pattern is observed at 388 K. Above this temperature, the compound starts to decompose and so the high-temperature limit can only be approached (Figure 1). The structure of the new signal observed at 388 K leaves no doubt that it has to be assigned to the second phosphorus atom ($^1J_{PRh} = 145$ Hz, $^2J_{PP} = 43$ Hz).

The signals also sharpen at temperatures below 273 K, giving rise to two patterns, each composed of two doublet of doublets structures. The innermost pattern (Figure 1, 213 K) corresponds to one set of two chemically different phosphorus nuclei, and the outer one characterizes another pair of chemically different phosphorus atoms. The coherence of the outer set of signals is evident from PPCOSY experiments (Figure 2). The inner set of signals is of higher order, and its coherence is clear from the type of pattern as well as from the coupling constants.

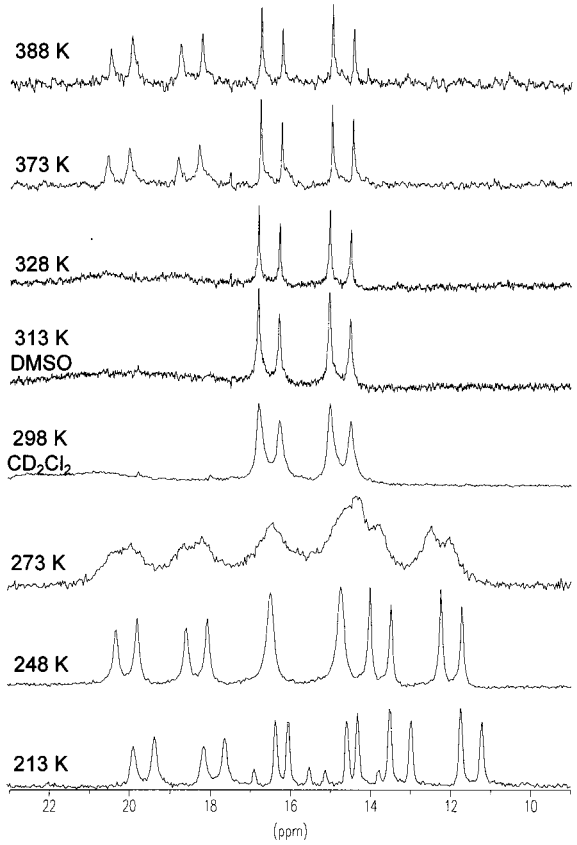

Figure 1. Temperature dependence of the $^{31}P\{1H\}$-NMR spectrum of **2b**

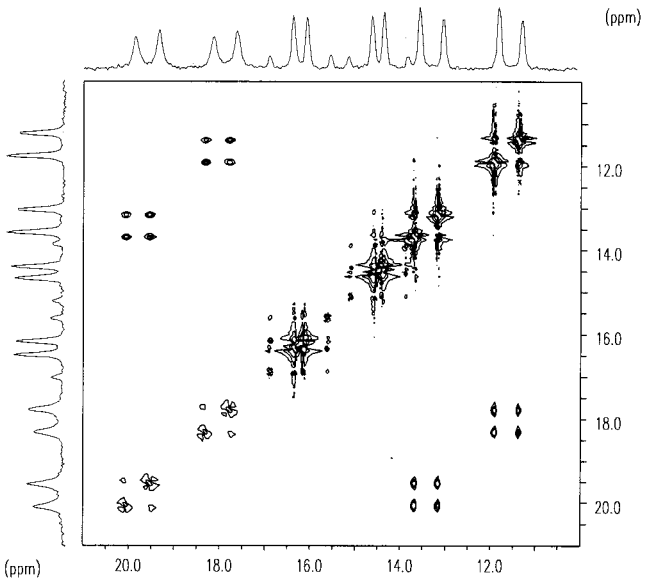

Figure 2. ^{31}P-^{31}P COSY experiment on **2b** at 213 K

These observations can be interpreted as follows. The tolyl groups of the P(*o*-Tol)$_2$ fragment of the compound are fixed in two different positions at the low temperature limit and are, focusing only on a single P(*o*-Tol)$_2$ group, mirror images of one another. Either the left-hand aryl group has its methyl substituent pointing forward while the right-hand group has it pointing backwards (Figure 3), or vice versa. Thus, there are two conformers present at the low-temperature limit. Evidently, the conformation of the chelate cycle is either still fully dynamic at this temperature, or the different conformations which it might adopt (chair, twist) do not significantly influence the phosphorus resonances.

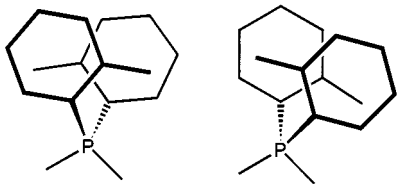

Figure 3. Conformations of the P(*o*-Tol)$_2$ fragment

The conformational enantiomerization of the P(*o*-Tol)$_2$ group, which is the rationale for the fact that two different species are observed at the low-temperature limit, also accounts for the changes observed in the spectra at higher temperatures. Just above 273 K (Figure 1), a clear doublet of doublets structure evolves for one of the constitutionally different PR_2 groups. The second one is not observable at all. This indicates that the environment of the "unobservable" phosphorus atom changes at such a rate that no signal is observed. At higher temperatures, this change speeds up and the signal appears as a doublet of doublets. The change of environment is due to the enantiomerization of the P(*o*-Tol)$_2$ conformation. The phosphorus atom of the P(*o*-Tol)$_2$ group itself does not take much notice of this conformational change, whereas the PPh_2 "spectator" group well feels it.

The validity of the above interpretation is corroborated by the observation of analogous behaviour in a case where there is no doubt as to which phosphorus signal is from which group. The ^{31}P-NMR spectra of the whole series of compounds $H_3C(CH_2PPh_2)_n[CH_2P(o\text{-}Tol)_2]_{3-n}Mo(CO)_3$ have been thoroughly analysed with regard to their dynamic behaviour.[21] The conformational enantiomerization (see above) of the P(*o*-Tol)$_2$ groups lies at the basis of the dynamic processes observed for these species. For $H_3C(CH_2PPh_2)_2[CH_2P(o\text{-}Tol)_2]Mo(CO)_3$, it has been found that the signal of the phosphorus atom of the P(*o*-Tol)$_2$ group is undisturbed by the enantiomerization of the P(*o*-Tol)$_2$ conformation, while the phosphorus nuclei at the two spectator PPh_2 groups are strongly influenced.[21]

Compound **2c** is an analogue of **2b**, the only difference being that the phenyl groups of the PPh_2 moiety of **2b** are linked by a carbon−carbon bond in its dibenzophosphole donor group. The dynamic behaviour of **2c** is found to be qualitatively analogous to that of **2b** in the high-temperature range (Figure 4). In the low-temperature range between 298 K and 218 K, the behaviour is again similar with the signals of two different species gradually evolving. At the lowest accessible temperature (185 K), however, there is seemingly only one species. This implies that one of the diastereomers generated by the conformational isomerism of the P(*o*-Tol)$_2$ group is decidedly more stable than its epimeric form.

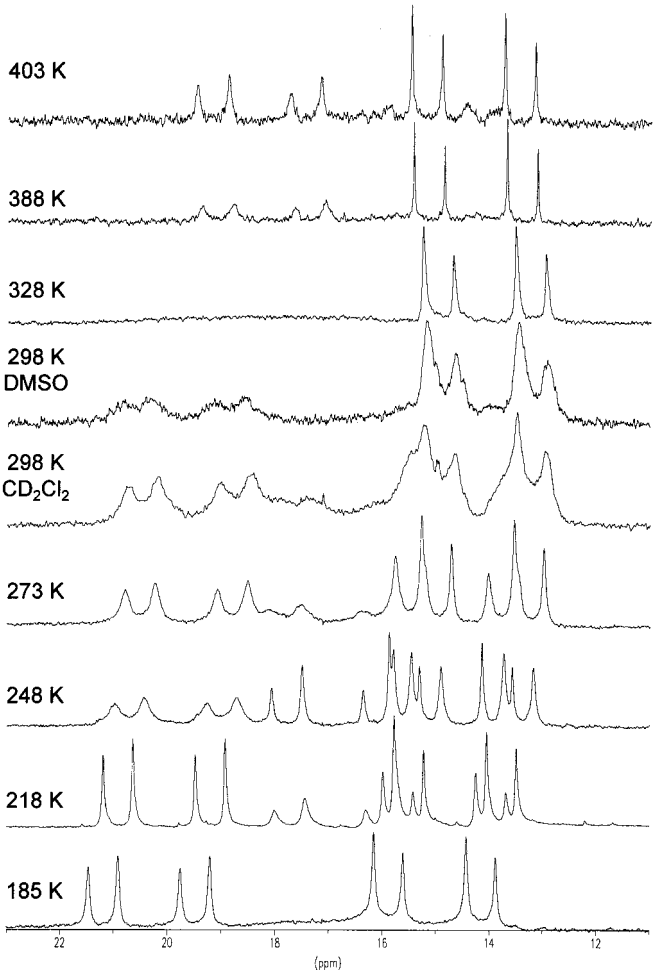

Figure 4. Temperature dependence of the $^{31}P\{^1H\}$-NMR spectrum of **2c**

X-ray Analyses

The kind of dynamic behaviour indicated by the NMR observations has not yet been fully delineated for all compounds **2**. It will in part be associated with the conformational flexibility of the chelate cycles, and the X-ray data obtained for **2** (Table 5) clearly show that these can adopt chair as well as twist conformations.

Considering structurally equivalent moieties, the scalar properties (distances, angles) are rather similar for the whole group of compounds (Table 6). The real difference between the compounds is apparent from the torsion angles (Table 5). There are five independent molecules that adopt chair conformations (Table 5), with the crystal structure of **2b** containing two crystallographically independent molecules of this type. The torsion angles within this group of

conformationally similar molecules are not too dissimilar within each set of conformationally equivalent groups (cf. columns φ_{2345}, φ_{6543} in Table 5; these angles should be equal in size but opposite in sign for a mirror-symmetric chair. The signs of the torsion angles of **2c** are the opposite of those of **2b**; this is not a physically relevant difference but arises because of the priority rules used to assign chirality). The different conformational classes are most clearly apparent from the pseudo torsion angle φ_{3265} (Table 5), which is close to zero for the chair conformations and +/−51−56° for the δ or λ conformations (Table 5).

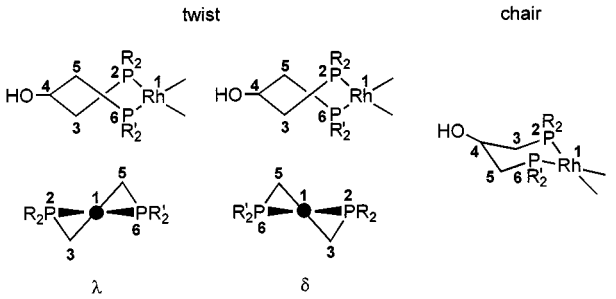

Figure 5. Schematic illustration of the conformations adopted by the chelate cycles in **2**

To illustrate the twist conformation the structures of the δ and λ conformations, both of which are found in the crystal of **2d**, are illustrated in Figure 6. The two molecules are conformational diastereomers. Even though the chirality defined by the substitution pattern at the ligand is the same for both molecules, the additional chirality induced by the twist of the chelate cycle is opposite in sense for the two

[a] The numbering scheme adopted refers to Figure 5 throughout and is different from the schemes used to label individual atoms in the deposited data.[36] − [b] C_{COD} *cis* to PR_2 (PR'_2). − [c] The structure of **2v** is rather inaccurate, disorder is observed for the COD ligand and for the aryl substituents of one of the PPh_2 groups. Only items involving solely P and Rh are therefore given in the table. The overall geometry is nevertheless clearly evident, as is the chair-type conformation of the chelate cycle (Table 5).

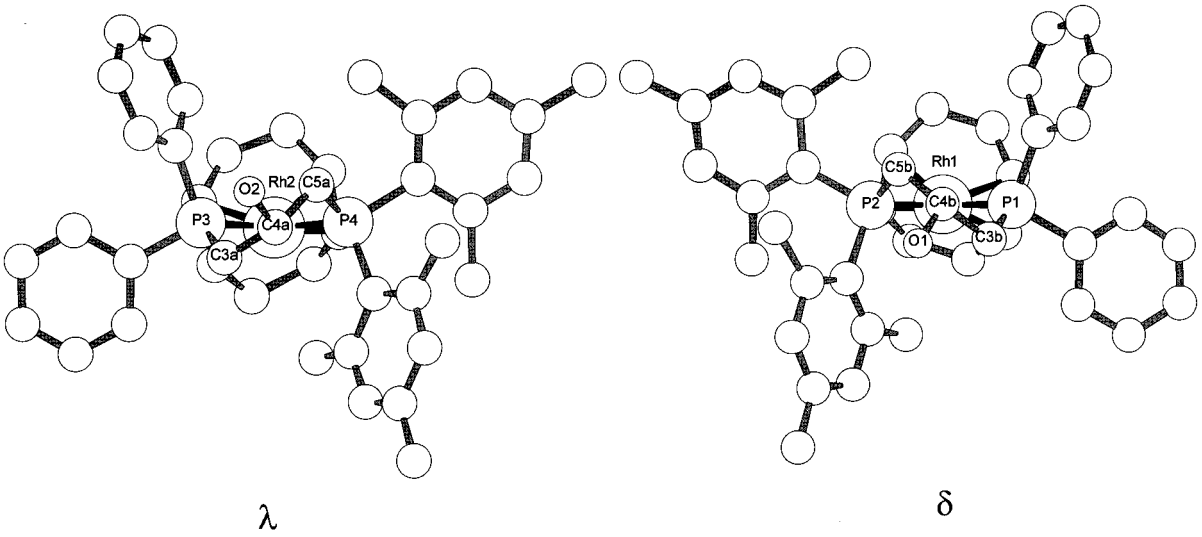

Figure 6. Conformations of the cation of **2d** as observed in the solid state; the numbering scheme refers to Figure 5; the designators *a* and *b* are used to differentiate between the two different molecules in the crystal of **2d**

species. It appears that with the substituents used, enantioselective discrimination is not sufficient to make one of the ring conformations much more stable than the other. The ^{31}P-NMR spectra of **2d** (see above, Table 4) show that two conformers are also present in solution at room temperature. In contrast to **2b**, **2c** (see above), it is not clear, however, whether the conformational isomerism observed in solution is due to an inversion of the ring conformation or to the hindered rotation of the mesityl groups.

The results presented in Table 5 suggest that sterically more demanding substituents at the phosphorus centres favour twist conformations. Chair conformations are found for **2b**, **2c**, **2o**, **2v**, and their overall geometry is illustrated for **2b** (Figure 7). Only one of the two geometrically almost equivalent independent molecules in the crystal of **2b** is shown in Figure 7. Despite the fact that **2b** adopts a chair conformation in the solid state, two conformers are observed in solution at low temperatures, which are attributed to a rotational isomerism of the P(*o*-Tol)$_2$ group (see above). In the crystal, the P(*o*-Tol)$_2$ groups of the two independent molecules adopt the same orientation.

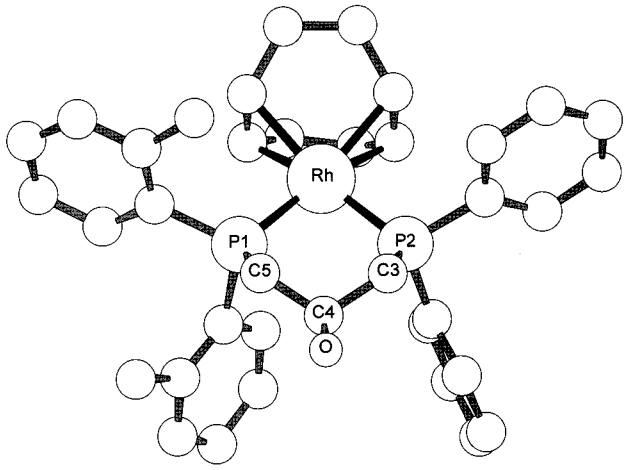

Figure 7. Conformation of the cation of **2b** as observed in the solid state; the numbering scheme refers to Figure 5

Catalysis

Compounds **2** act as precatalysts in the catalytic hydrogenation of (*Z*)-2-acetamidocinnamic acid (AAC). Table 7 shows the relative efficiencies of the various compounds **2**, together with the *ee* values observed in each case. The highest rate is observed for **2v**, i.e. for the sterically least demanding ligand, $Ph_2PCH_2CH(OH)CH_2PPh_2$, of the series. The activity of **2v** is similar to that observed for $[Ph_2PCH_2C(CH_3)_2CH_2PPh_2]Rh(COD)^+$.[22] The reactivity is not significantly reduced by *para* substitution of one of the PPh_2 groups [P(*p*-Tol)$_2$, **2w**], nor by *meta* substitution [P(*m*-Xyl)$_2$, **2a**], see Table 7. The enantiodiscriminating influence of this type of substitution is also low (*ee* = 3% and 6%, respectively). Replacing one of the PPh_2 groups by a P(*o*-Tol)$_2$ group (**2b**) has virtually no effect on the reactivity, but the enantiomeric excess is found to rise to 36% (*S*) at 20°C, 40% at 50°C, and 49% at 30 bar, 25°C. To examine the influence of the OH substituent on the backbone of the ligand, *O*-alkylated and *O*-silylated derivatives of **2b** were analysed. It was found that **2p** (substituent OCH_3), **2q** (substituent $OSiMe_3$), and **2r** [substituent (*S*)-H_3CCH_2-$CH(CH_3)CH_2O$] required longer reaction times in order to reach full conversion (Table 7). The enantiomeric excess, however, proved to be almost independent of this type of substitution (Table 7).[22]

Replacing the PPh_2 group in **2b** by a DBP group (**2c**) greatly reduces the reactivity. The enantioselectivity becomes inverted such that the product is of (*R*) configuration. Increasing either the temperature or the pressure results in reduced selectivity. Replacing one of the PPh_2 groups in **2v** by an SPh donor (**2m**) also reduces the reactivity, with the observed *ee* value lying at the lower end of the range. Although the large difference between the properties

[a] 1 mol-% catalyst. – [b] For the high-pressure experiments the reaction time was set to the values given and thus has no immediate relation to the reactivity of the catalyst. – [c] 4 mol-% catalyst.

of the donor groups PPh_2 and SPh might be expected to increase enantiomeric discrimination, this expectation is counterbalanced by the fact that the reaction "pocket" accessible to the substrate with the SPh substituent will be larger than that formed by a PPh_2 substituent. Moreover, the coordinated sulfur centre is itself a centre of chirality, the configuration of which could be such as to counteract enantioselectivity.

When one of the PPh_2 groups in **2v** is replaced by a $PMes_2$ group (**2d**), the reactivity is drastically reduced, such that complete conversion could not be achieved under any of the conditions employed (Table 7). Enantioselectivity leading to favoured formation of the (*R*) product is found. Etherification of the OH position (**2u**) again has no significant influence. Replacing the PPh_2 group of **2d** by DBP (**2e**) results in reduced reactivity, but the enantiomeric excess is found to increase to 64% (*R*).

The results of the experiments described so far indicate that in order to obtain sufficient reactivity, a low degree of substitution at the PR_2 entities is favourable. With regard to the enantiomeric excess, it appears that *ortho* substitution of the aryl groups is effective. Etherification at the OH position of the ligands does not appear to have strong influence on the *ee*, but it is found to reduce the reactivity.

With these findings in mind, **2h**, the ethyl-substituted analogue of **2b**, was prepared and screened for its catalytic activity. The reactivity was found to be somewhat lower than that observed with **2b**, but higher enantioselectivity was achieved, rising to 62% *ee* at 30 bar (Table 7). Replacing the ethyl substituents in **2h** by methoxy groups (**2g**) reduces the reactivity, but increases selectivity (Table 7); 77% *ee* (*S*) is observed at 20°C, 1 bar H_2. Increasing the pressure reduces the selectivity to 67% (*S*) at 30 bar H_2. Reducing the temperature to 0°C and compensating for the reduced reactivity by using 4 mol-% catalyst instead of the standard 1 mol-% leads to quantitative conversion in less than 3 h, with an *ee* of 85% (*S*) (Table 7). While enantioselectivities much higher than this have been observed with analogous rhodium complexes derived from five- or seven-membered chelate ligands, to the best of our knowledge there has only been one report to date where a six-membered chelate cycle has led to an *ee* in excess of 80%. The corresponding ligand was skewphos, $Ph_2PCH(CH_3)CH_2CH(CH_3)PPh_2$, which contains two chiral carbon centres in its backbone. On the other hand, the efficiency of *ortho*-alkyloxy substitution in phosphorus-bound aryl groups with regard to enantiomeric discrimination has been known for a long time.[23] In **2g**, both effects, i.e. the skew of the chelate cycle and the activity of the methoxy substituent, may lie at the basis of its enantioselectivity. Further modifications of **2g** by either etherification of its OH group (**2s**, **2t**) or by replacing the PPh_2 group by a $PMes_2$ group (**2f**) did not increase enantioselectivity, but reduced the reactivity to varying extents (Table 7).

Conclusion

The following conclusions can be drawn from the results presented in this paper:

1. Enantiomerically pure chelate ligands $L_2 = XCH_2CHOHCH_2Y$ are easily accessible for a broad range of donor groups X and Y by a two-step synthesis starting from epichlorohydrin. Under specialized conditions, ether derivatives of L_2, $XCH_2CHORCH_2Y$ may be prepared, even with X, Y = PR_2.

2. The chelate cycles in $L_2Rh(COD)^+$ may adopt twist or chair conformations with dynamic equilibria between the different conformations being operative in solution.

3. Compounds $L_2Rh(COD)^+$ act as precatalysts for the homogeneous hydrogenation of AAC. Depending on the nature of the donor groups X and Y, *ee* values of up to 85% can be achieved.

Experimental Section

General: All manipulations involving phosphanes were carried out under argon by means of standard Schlenk techniques and were monitored by TLC (Macherey Nagel Co., Polygram SIL G/UV_{254}). All solvents were dried by standard methods[24] and distilled under argon. The solvents $CDCl_3$, CD_2Cl_2, [D_6]DMSO, and [D_8]THF used for NMR-spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried with 4-Å molecular sieves. − NMR: Bruker Avance DPX 200 at 200.12 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 81.015 MHz (^{31}P{^{1}H}), T = 298 K, unless stated otherwise; chemical shifts (δ) in ppm with respect to $CHCl_3$ (^{1}H: δ = 7.27; ^{13}C: δ = 77.0) and CH_2Cl_2 (^{1}H: δ = 5.32; ^{13}C: δ = 53.5) as internal standards. ^{31}P chemical shifts (δ) in ppm with

[a] Due to dynamic phenomena (see text) most of the signals are rather broad. Depending on the appearance of the spectra, either ranges are given in the table, or, if predominant peaks are observed in the corresponding ranges, the shifts of these peaks are given. – [b] For complexes **2i**, **2n** see Experimental Section.

− Catalytic hydrogenations were performed in a hydrogenation apparatus according to Marhan (Normag) (1 bar) or in an HR 250 stainless steel high-pressure laboratory reactor (Berghof/Maasen GmbH) (30 bar). Yields were determined by ^{1}H-NMR analysis; the *ee* values were determined by GC/MS (column: Chirasil L-Val, Chrompack GmbH).

Materials: Silica gel (Kieselgel z.A. 0.06−0.2 mm, J. T. Baker Chemicals B.V.) used for chromatography was degassed at 1 mbar for 24 h and saturated with argon. A solution of 2.5 M *n*BuLi in hexanes was used for deprotonations. (*S*)- and (*R*)-epichlorohydrin (A) (Aldrich, 97% *ee*) were degassed (see above) and checked for optical purity by measurement of their specific rotations ($|[\alpha]_D^{20}|$ = 34.3[25]). $HPEt_2$,[26] $HPPh_2$,[27] HP(*p*-Tol)$_2$,[27] HP(*o*-Tol)$_2$,[28] HP(*m*-Xyl)$_2$,[29] $HPMes_2$,[30] HP(2-EtPh)$_2$,[31] HP(2-MeOPh)$_2$,[32] HP(2-Me_2NPh)$_2$,[32,33] DBPH,[34] and [Rh(COD)Cl]$_2$[35] were prepared according to or by adaptation of literature procedures. All other chemicals were obtained from commercial suppliers and used without further purification.

Ligand Synthesis

General Procedure for the Synthesis of Ligands 1a−1n: 5−12 mmol of phosphane R_2PH for the generation of nucleophile I (Table 8) was dissolved in 30 mL of THF and deprotonated by the dropwise addition of *n*BuLi at −70°C. This solution was stirred for 10 min. Meanwhile, 5−12 mmol of epichlorohydrin was dissolved in 20 mL of THF and the solution was cooled to −70°C. At this temperature, the previously prepared phosphide solution was added in a dropwise manner over a period of 30 min. After warming to room

temperature, the orange solution was stirred for 30−120 min (Table 8) and then cooled to −70°C once more. Then, a solution of 1 equiv. of nucleophile II (phosphane, thiol, or amine), generated by a deprotonation procedure analogous to that described for nucleophile I, was added in a dropwise manner to the cooled reaction mixture over a period of 30 min. The resulting mixture was stirred at room temperature for 2−16 h (Table 8). The solvent was then evaporated in vacuo (10^{-1} mbar) and the residue was suspended in 30 mL of diethyl ether. 20 mL of acetate buffer was added, the organic phase was separated, and the aqueous layer was extracted with three 20-mL portions of diethyl ether. The combined organic phases were dried with Na_2SO_4, the solvent was evaporated in va-

[a] The crystals of **2** tend to contain solvate molecules. The number and type of solvate molecules found per formula unit is given in the column header. − [b] Disorder of the COD ligand and of two of the aryl groups greatly reduces the accuracy of the structure determination. − [c] Disorder of the two PF_6 counterions. − [d] Disorder of one PF_6 counterion.

cuo, and the oily white residue was purified by column chromatography (silica gel, eluent and R_f as given in Table 8). Analytical difficulties arose in part due to the hygroscopic nature and the sensitivity to oxidation of the ligands when analytical samples were prepared without inert gas protection.

General Procedure for the Etherification of Ligands 1a−1n: 1 mmol of ligand was dissolved in 50 mL of freshly dried THF and the resulting solution was cooled to −5°C. At this temperature, 2 equiv. of KO*t*Bu were added and the solution was stirred for 2 min.

Methylation: 2 equiv. of methyl iodide were added to the above solution and the progress of the reaction was monitored by TLC. After completion of the reaction (maximum reaction time 30 min), the solvent and excess methyl iodide were evaporated in vacuo. The residue was dissolved in 30 mL of diethyl ether and the solution was filtered to remove potassium chloride. Removal of the solvent yielded the methylated ligands in an analytically pure state (Table 11).

Silylation: 1.6 equiv. of Me_3SiCl were added to the above solution and the progress of the reaction was monitored by TLC. After completion of the reaction (maximum reaction time 30 min), the solvent and excess Me_3SiCl were evaporated in vacuo. The residue was dissolved in 30 mL of CH_2Cl_2 and the solution was filtered to remove potassium chloride. If, after removal of the solvent, the products were not found to be analytically pure, they were further purified by column chromatography (Table 11).

Alkylation: 1.5 equiv. of alkyl tosylate were added to the reaction mixture and the ensuing reaction was monitored by TLC. The solution was stirred for 30 min, allowed to warm to room temperature, and then stirred for 6 h. If the conversion was not complete, the reaction mixture was cooled to −5°C once more, 0.5 equiv. of KO*t*Bu and alkyl tosylate were added and, after warming to room temperature, the solution was stirred for a further 4 h. The solvent was then evaporated in vacuo and the residue was purified by column chromatography (silica gel, eluent and R_f as given in Table 11). Compound **1u** could not be obtained in an analytically pure state because of identical R_f values for both the product and the corresponding long-chain alcohol. Therefore, the crude product **1u** was used to synthesize **2u**, which could be purified by column chromatography.

General Procedure for the Synthesis of Complexes 2: 0.5 equiv. of di-μ-chlorobis(η^4-1,5-cyclooctadiene)dirhodium(I) ($[Rh(COD)Cl]_2$) was dissolved in 10 mL of CH_2Cl_2 and a solution of 1.2 equiv. of potassium hexafluorophosphate in 5 mL of THF/acetone (1:1) was added. The mixture was stirred for 2 min. 1 mmol (1 equiv.) of the appropriate ligand was dissolved in 30 mL of CH_2Cl_2 and the resulting solution was added to the above mixture in a dropwise manner. After stirring for 30 min, the solvent was evaporated in vacuo, the residue was redissolved in 5 mL of CH_2Cl_2, and the solution was filtered through Na_2SO_4. Complexes **2** were precipitated as orange powders upon addition of 20 mL of diethyl ether. Further purification was generally not necessary but could be achieved by washing with diethyl ether, by recrystallization, or by chromatography. Chromatography on silica gel was possible when CH_2Cl_2 solutions of **2** were applied to a column with CH_2Cl_2 as the mobile phase. Elution with CH_2Cl_2 removed contaminants while compounds **2** did not noticeably migrate under these conditions. They were subsequently eluted with CH_2Cl_2/Et_2O or THF/Et_2O mixtures. On evaporation of the solvent from the eluate, the purified compounds **2** were obtained in microcrystalline form. The syntheses of the complexes containing an amine donor function (**2i**, **2n**), even under varied reaction conditions, invariably resulted in a mixture of different coordination products, as was clearly evident from the ^{31}P-NMR spectra. In none of these cases could a single product be separated by recrystallization or column chromatography.

X-ray Structure Determinations:[36] Single crystals were obtained by the layering technique. Exploratory experiments with various solvents (CH_2Cl_2, THF, Et_2O) and mixtures thereof had to be performed in order to obtain crystals of sufficient quality. Suitable crystals were taken directly from the mother liquor, immersed in perfluorinated polyether oil, and fixed to a glass rod at 200 K. In the case of **2g**, for which the data were collected at 298 K, the crystal was fixed in a Lindemann capillary. The measurements were made with a Siemens P4 four-circle diffractometer (equipped with a low-temperature device) using graphite-monochromated Mo-K_α radiation. All calculations were performed using the SHELXTPLUS[37] software package. Structures were solved by direct methods with the SHELXS-86 program[37a] and refined with the SHELX-93 program.[37b] Graphical handling of the structural data during solution and refinement was performed with XPMA.[38] Absorption corrections (ψ scan, $\Delta\psi = 10°$) were applied to the data. Atomic coordinates and anisotropic parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data pertaining to the structure determinations are compiled in Table 16.

Acknowledgments

We are indebted to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support. A generous loan of rhodium(III) chloride by the DEGUSSA AG is gratefully acknowledged. We wish to thank T. Jannack for mass-spectrometric analysis and Dr. J. Groß for his help with high-resolution mass spectra. The continued enthusiasm and patience of Dr. Laszlo Zsolnai in solving crystal structures over more than two decades has helped a lot. Dr. Zsolnai died April 26, 1998.

Addition of Stabilized Carbanions to Cationic (η^6-Arene)tricarbonylmanganese Complexes: Syntheses of Homo (Mn–Mn) and Hetero (Mn–Cr) Dinuclear Complexes

Eric Rose,*[a] Claudine Le Corre-Susanne,[a] Françoise Rose-Munch,[a] Christophe Renard,[a] Vanessa Gagliardini,[a] Fatima Teldji,[a] and Jacqueline Vaissermann[b]

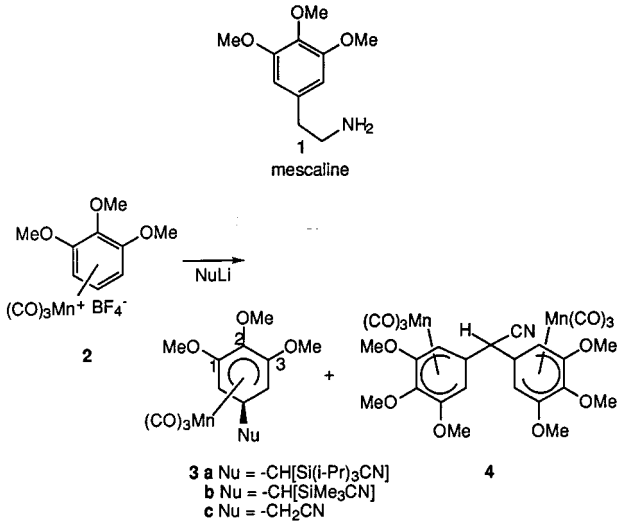
Keywords: Arene complexes / Chromium / Cyclohexadienyl complexes / Dinuclear complexes / Manganese

The reaction of secondary α-cyano or α-sulfonyl carbanions with cationic (η^6-arene)tricarbonylmanganese complexes affords neutral mono- and dinuclear tricarbonyl(η^5-cyclohexadienyl)manganese complexes. The X-ray analyses of three (η^5-cyclohexadienyl)Mn complexes (two mononuclear and one dinuclear) obtained by addition of α-cyano carbanion to cationic (η^6-arene)manganese complexes are reported. The addition of benzylic carbanions of (η^6-arene)tricarbonylchromium complexes to cationic (η^6-arene)manganese complexes gives rise to the formation of the corresponding heterodinuclear [(η^5-cyclohexadienyl)-manganese–(η^6-arene)chromium] complexes.

Introduction

The air-stable [(η^6-arene)$Mn(CO)_3$] cations are quite electrophilic and the addition of nucleophiles to the arene ring affording thermally stable cyclohexadienyl complexes has been the subject of numerous studies.[1] Among them, a mere handful of papers describes the use of organometallic derivatives as nucleophiles[2−4] towards (η^6-arene)tricarbonylmanganese complexes giving rise to the formation of homo- and heteropolymetallic complexes.

Our studies concerning the structure and reactivity of (η^6-arene)tricarbonylmanganese complexes and their application in organic synthesis, led us to discover the possibility of synthesizing di- or even trinuclear complexes by the simple addition of stabilized carbanions to cationic manganese complexes. In particular, during the course of our work on the synthesis of mescaline (**1**), a natural product with hallucinogenic properties, we undertook the study of the regioselectivity of the addition of primary and secondary stabilized carbanions to tricarbonyl(1,2,3-trimethoxybenzene)manganese complex **2**[5] (Equation 1). We observed the formation of mononuclear complex **3** and unexpected dinuclear complex **4**.



We report an extension of this work as well as a complete study of the addition of stabilized carbanions, α-cyano and α-sulfonyl carbanions to the simplest complex: the benzene manganese complex, and the structures of one dinuclear and two mononuclear complexes obtained by this method. In addition, we describe an extension of this method to the preparation of new heteropolymetallic Mn−Cr complexes.

Results and Discussion

Addition of Silylated α-Cyano Carbanions to (1,2,3-Trimethoxybenzene)manganese Complex

Our first attempt at functionalizing the trisubstituted arene ring of complex **2**, in order to synthesize a precursor of mescaline (**1**), involved the reaction of lithioacetonitrile (Equation 1). Unfortunately, the reaction mixture turned black and decomposition occured very quickly. Since more substituted carbanions have previously been shown to be nucleophiles of optimum reactivity for addition to arene−Cr complexes,[6] we anticipated that the same would apply to Mn complexes. We thus decided to study the reactivity of more crowded nucleophiles such as silylated α-cyano carbanions.

tion of one equivalent of (triisopropylsilyl)acetonitrile in THF under N_2 at −78°C, reacted with complex **2** to give the neutral complex **3a**, Equation 1, in 38% yield. An analogous reaction occured with the anion of (trimethylsilyl)acetonitrile as nucleophile, yielding complex **3b** as the major product. Unexpectedly, a silicon−carbon bond cleavage occurred after silica gel column chromatography, affording complex **3c**. We noticed also the formation of a minor dinuclear complex **4** in 12% yield, whose formation will be discussed later (vide infra, mechanism involved in the synthesis of complex **7a**).

In the case of the two mononuclear neutral complexes **3a** and **3c** we were able to obtain crystals suitable for X-ray determinations. The structures appear in Figures 1 and 2 whereas the crystallographic data, selected bond lengths and bond angles can be found in Table 1.

Table 1. Selected bond lengths [Å] and bond angles [°] for **3a** and **3c**

Bond lengths	Complex **3a**	Complex **3c**
Mn−C1	2.178(6)	2.19(1)
Mn−C2	2.143(6)	2.15(1)
Mn−C3	2.194(6)	2.19(1)
Mn−C4	2.169(6)	2.18(1)
Mn−C6	2.201(6)	2.20(1)
Bond angles	**Complex 3a**	**Complex 3c**
C4−C5−C6	104.3(5)	103.8(9)
C2−Mn−C6	68.1(2)	67.8(4)
C2−Mn−C4	68.3(2)	68.4(4)
C2−O2−C8	118.0(2)	113.8(10)

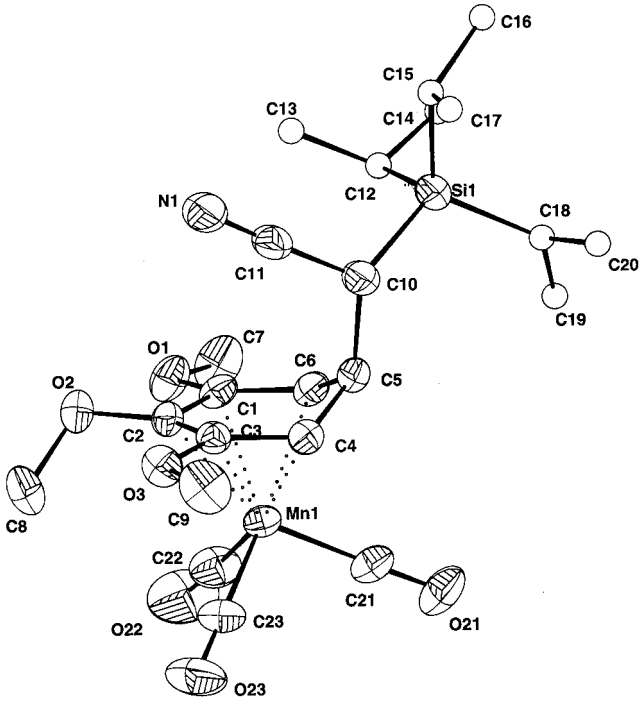

Figure1. ORTEP diagram of complex **3a**

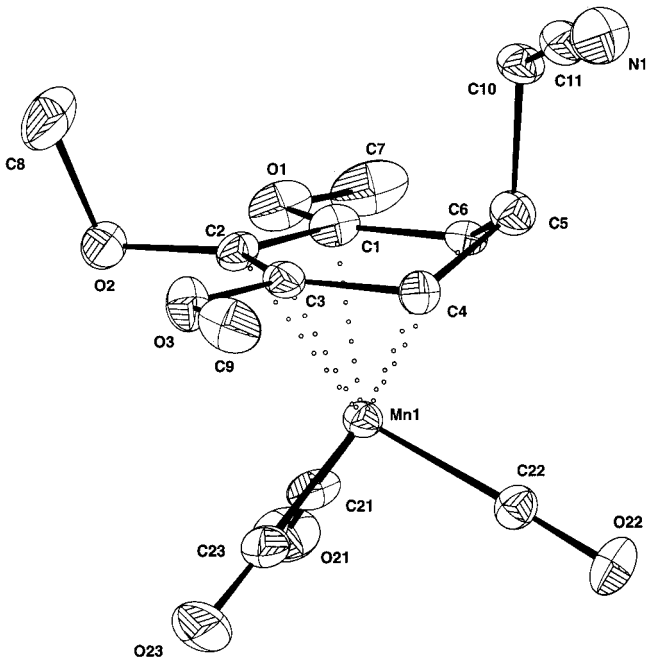

Figure 2. ORTEP diagram of complex **3c**

The ORTEP views show classical (η^5-cyclohexadienyl) structures with the five ring atoms C^1, C^2, C^3, C^4, C^5, almost coplanar while the remaining atom C^6 lies in a $C^4-C^5-C^6$ plane making an angle of 40° with the other one (in both complexes). It is worth noting the completely different position adopted by the OMe groups attached to the C^2 atoms: in the case of complex **3a**, this methoxy group is pointing away from the bulky silylated substituent attached to the sp^3 carbon atom, and thus it is located on the same side of the ring plane with respect to the $Mn(CO)_3$ moiety. The reverse is observed for the corresponding methoxy group of complex **3c**: it is opposite to the organometallic entity.

The ^{1}H- and ^{13}C-NMR data of complexes **3a**, **3b**, **3c**, and **4** are presented in Tables 2 and 3. We noticed that the ^{13}C-NMR data of the C^1, C^2, C^3 atoms of the four complexes (Table 3) were in good agreement with those observed in the case of unsubstituted neutral η^5-cyclohexadienyl−Mn complexes[7] or even in the case of η^5-Cr complexes.[8] This feature was attributed to a strong charge alternation in such η^5 systems as it was shown by charge density calculations at the individual carbon atoms.[9] Thus, the C^2 signals are shielded by roughly 20 ppm with respect to the C^1 and C^3 signals (Table 3).

Also interesting to note are the more shielded signals of H^4, H^5, H^6 of dinuclear complex **4** when compared to the corresponding proton signals of the mononuclear complex **3c** (Table 2).

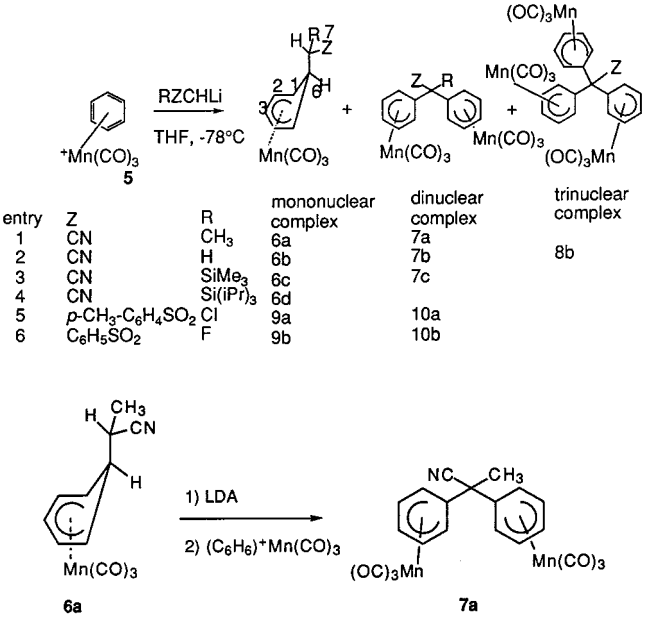
No significant effect could be dectected comparing the chemical shifts of the OMe groups attached to the C^2 atoms of the complexes **3a** and **3c** (δ = 4.02 and 4.06, respectively, Table 2). Therefore, it was clear that the methoxy groups did not keep the same orientation in solution as in the solid state because of the free rotation of the methoxy groups.

Table 2. ^{1}H-NMR data of complexes **3a**, **3b**, **3c**, **4** (in $CDCl_3$)

	$H^{4[a]}$	$H^{6[a]}$	H^5	H^7	OMe^2	$OMe^{1[b]}$	$OMe^{3[b]}$
3a	2.83	3.14	2.93	1.44	4.02	3.43	3.58
3b	2.84	3.09	2.77	1.28	4.06	3.47	3.58
3c	2.90	2.90	2.90	1.67	4.06	3.48	3.48
4	2.66	2.76	2.52	0.98	3.99	3.50	3.59

[a] H^4 or H^6. – [b] OMe^1 or OMe^3.

In order to better understand the mechanism of formation of dinuclear complexes such as **4**, we extended this study to the reactivity of α-cyano carbanions towards the simplest arene−Mn complex: that of benzene.



Addition of α-Cyano Carbanions to the (η^6-Benzene)manganese Complex 5

2-Lithiopropionitrile (prepared in situ by addition of LDA to a solution of one equivalent of propionitrile in THF under N_2 at −78°C) reacted with one equivalent of (η^6-benzene)tricarbonylmanganese complex **5** to give the mononuclear complex **6a** and the dinuclear complex **7a** (Table 4) in 76% and 11% yield, respectively. These complexes were purified by flash chromatography on an alumina column. An analogous reaction in the presence of an excess of **5** (two equivalents) and an excess of LDA (two equivalents) allowed us to isolate complex **7a** as the major product (61% yield) as well as complex **6a** (24% yield). It is interesting to note that, although some additions of α-cyano carbanions to (η^6-arene)manganese complexes have already been reported,[10−12] no formation of dinuclear complexes was described.

The formation of the dinuclear complex **7a** was easily explained. Indeed, in this basic medium, the acidic proton, α to the cyano group of complex **6a** could be abstracted, giving rise to a new carbanion which could, in turn, add to the arene ring of complex **5**. Two points support this mechanism: 1. The higher yield of complex **7** obtained when an excess of complex **5** and LDA were used; this is in good agreement with our mechanism proposal. 2. In a separate experiment which was carried out starting from complex **6a** itself, the addition of one equivalent of LDA to complex **6a** and further reaction with cationic complex **5**, gave complex **7a** in almost quantitative yield (Equation 2).

The ^{1}H-NMR spectrum of complex **6a** in $CDCl_3$ showed expected signals at δ = 5.80 (H^3), δ = 4.97 and 4.92 (diastereotopic protons H^2 and H^4), δ = 3.34 and 3.15 (diastereotopic protons H^1 and H^5) whose multiplicities could be unambigously interpreted (Table 5). The difference between the chemical shifts of the H^1 and H^5 signals is larger than the one between the H^2 and H^4 signals, certainly due to the proximity of the chiral center.

Table 4. Nucleophilic addition of a nucleophile to benzenetricarbonylmanganese complex

Equation 2. Preparation of dinuclear complex **7a**

The ^{1}H-NMR spectrum of complex **7a** showed the same features due to the η^5-cyclohexadienyl structure but two points warranted comment (Table 5): 1. An overall deshielding effect was observed for the protons of the dinuclear structure relative to those of the mononuclear structure. This effect can reach 1.44 ppm in the case of the H^1 signal. An opposite effect was noticed in the case of complexes **3c** and **4**, clearly showing the effect of the three methoxy groups. 2. Although the H^2 and H^4 atoms did not present distinct signals for complex **7a**, the H^1 and H^5 atoms showed two signals with a very important difference − a shift of 1.43 ppm was observed instead of 0.19 ppm for the corresponding protons of complex **6a**.

Recrystallization of complex **7a** in an acetone/ether mixture afforded yellow single crystals suitable for X-ray analysis. As can be seen from the ORTEP view in Figure 3 the structure showed a classical (η^5-cyclohexadienyl) struc-

Table 5. ^{1}H-NMR data of complexes **6a**, **7a** (in [D_6]acetone)

	H^3	H^2 or H^4	H^4 or H^2	H^1 or H^5	H^5 or H^1
Complex **6a**	5.80, t J = 6.1	4.97, t J = 6.1	4.92, t J = 6.1	3.34, tt J = 6.1 and 1.5	3.15, tt J = 6.1 and 1.5
Complex **7a**	5.98, tt J = 5.7 and 1.3	5.25, m	5.25, m	4.78, tt J = 5.7 and 1.3	3.35, tt J = 5.7 and 1.3

ture.[7] The sp^3 carbon atoms (C^6 and $C^{6'}$) of the rings are each eclipsed by a Mn−CO bond. The anion added on the *exo* face with respect to the manganese atom. The cyclohexadienyl rings are nearly planar and fold about $C^1C^6C^5$ and $C^{1'}C^{6'}C^{5'}$ with the same angle of 36°. The two metal centers are 7.556(6) Å apart. Crystallographic data, selected bond lengths and bond angles are listed in Table 6. It is worth noting that the two metal centers are not directly bonded to each other and could not be linked: our trials to form a metal−metal bond by irradiating, for example, complex **7a**, failed.

2-Lithioacetonitrile (prepared by addition of LDA to a solution of acetonitrile in THF under nitrogen at −78°C) reacted with (η^6-benzene)manganese complex **5** giving rise to the formation of three compounds (Table 4, entry 2) (overall yield 58%): the mononuclear complex **6b**, the dinuclear complex **7b** and the unexpected complex **8b** in a 80:18:2 ratio. This "caroussel-like" complex **8b** was very dif-

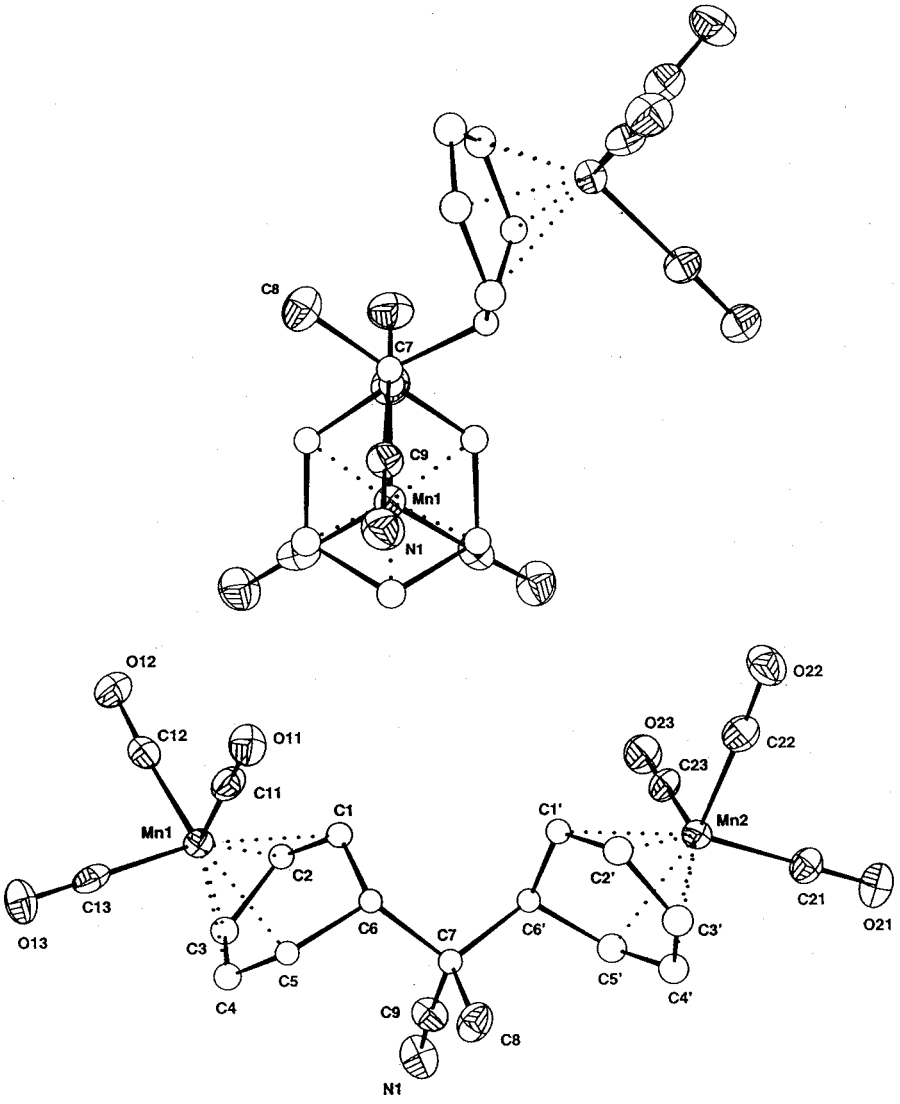

Figure 3. ORTEP diagram of complex **7a**

Table 6. Selected bond lengths [Å] and bond angles [°] for **7a**

Bond lengths	Bonds angles
Mn1−C3: 2.14 (1)	C8−C7−C9: 108.5 (11)
Mn2−C3′: 2.12 (1)	C1−C6−C5: 103.1 (10)
C7−C6: 1.58 (2)	C1′−C6′−C5′: 103.6 (10)
C7−C6′: 1.57 (2)	

ficult to isolate from the mixture of **6b** and **7b**; nevertheless we succeeded in obtaining **8b** in 11% yield by using 1.2 equivalents of LDA and 0.4 equivalents of nitrile. All attempts to obtain crystals of **8b** suitable for X-ray crystallography were unsuccessful: the sharp needles obtained so far are too small to be studied.

In solution, the ^{1}H-NMR spectrum of the "caroussel" complex **8b** showed also the atom H^3 as the less shielded one at $\delta = 5.85$, the atoms $H^{2,4}$ at $\delta = 5.04$ and the atoms $H^{1,5}$ at $\delta = 3.12$ in $CDCl_3$ (Table 7). The ^{13}C-chemical shifts of the carbon atom bearing the cyano group are in good agreement with the substitution of this bridge carbon atom. Indeed this carbon atom, which resonates at $\delta = 29$ in the case of complex **6b**, is deshielded by 26.4 ppm in the case of complex **7b** ($\delta = 55.4$) and by 37.2 ppm in the case of **8b** ($\delta = 66.2$) (Table 8).

Table 7. ^{1}H-NMR data of complexes **6b**, **7b**, **8b** (in $CDCl_3$)

	H^3	H^4	H^5	H^6
6b	5.84	4.94	3.23	2.94
7b	5.81	4.93	3.12	2.68
8b	5.85	5.04	3.12	2.79

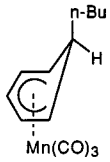

Table 8. ^{13}C-NMR data of complexes **6b**, **7b**, **8b** (in [D_6]acetone)

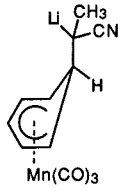
	C^1	C^2	C^3	C^6	CN	C(CN)
6b	53.2	96.9	80.7	31.7	116.7	29.0
7b	54.3	99.2	83.5	34.6	119.7	55.4
	56.4	99.0				
8b	55.4	98.0	81.7	36.7	120.0	66.2



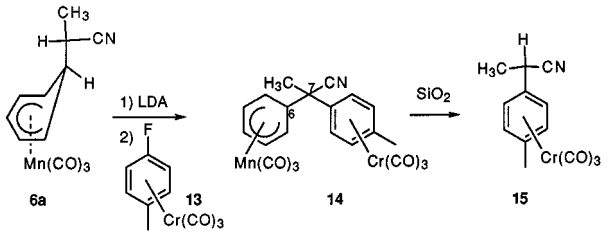
Under the same conditions, 2-lithio-2-(trimethylsilyl)-acetonitrile (2.2 equivalents) reacted with one equivalent of complex **5** (Table 4, entry 3) to give a mixture of complexes **6c**, **7c**, **6b**, and **7b** in a 64:28:7:1 ratio in 66% overall yield after a very fast silica gel column chromatography to avoid C−Si bond cleavage. Using a bulkier anion such as 2-lithio-2-(triisopropylsilyl)acetonitrile (2.2 equivalents), the same reaction gave only complex **6d** (Table 4, entry 4). No C−Si bond scission was noticed, even after silica gel column chromatography.

Addition of α-Sulfonyl Carbanions to the (η^6-Benzene)manganese Complex 5

Lithiation of chloromethyl *p*-tolyl sulfone $CH_3-C_6H_4-SO_2-CH_2Cl$ with *n*BuLi gave the corresponding α-sulfonyl carbanion[13,14] which reacted with one equivalent of complex **5** in a THF suspension. Two complexes **9a** and **10a** were isolated in a 1:1 ratio (73% yield) (Table 4, entry 5). The ^{1}H-NMR spectra were in good agreement with an η^5-cyclohexadienyl mononuclear structure for complex **9a** and with a dinuclear structure for complex **10a**. Indeed, in the case of complex **9a**, the atom H^7 attached to the sp^3 carbon atom resonates as a doublet at $\delta = 3.65$ and is absent in the case of complex **10a**. With the phenylsulfonylfluoromethyl carbanion $C_6H_5-SO_2-CHFLi$,[15] analogous results were obtained: Two complexes **9b** and **10b** were isolated in a 9:1 ratio (48% yield) (Table 4, entry 6). When two equivalents of complex **5** and two equivalents of *n*BuLi were used, three complexes **9b**, **10b**, and **11** were isolated in 3, 52, and 16% yield, respectively. The less polar complex **11**, which was eluted first by silica gel flash column chromatography, appeared to be the neutral 6-*exo*-butyl-η^5-cyclohexadienyl derivative whose preparation by a different method was previously reported by Chung et al.[16] In a separate experiment, complex **11** could be obtained in almost quantitative

11

12

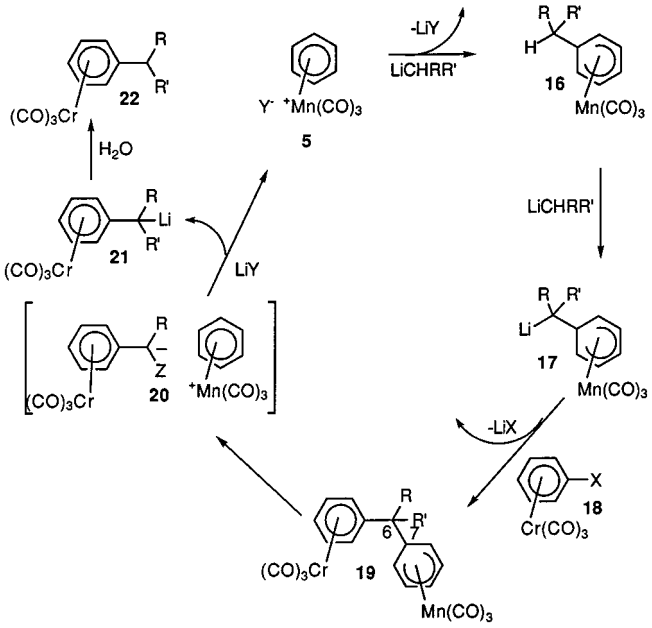


yield by treating one equivalent of *n*BuLi with complex **5**.[4]

We thus demonstrated the high reactivity of the α-cyano carbanion of complex **6a** towards benzene complex **5** (Equation 2), allowing us to synthesize, by this original way, homonuclear dimetallic complexes. We then tried to take advantage of these results in treating the same carbanion with other organometallic electrophilic complexes, such as chromium complexes, to obtain an access to heterodinuclear complexes.

Heterodinuclear Complex Syntheses

It is well known that arenes coordinated to the tricarbonylchromium entity are very electrophilic and the corresponding complexes, substituted by a good leaving group, readily undergo *ipso*,[17] *cine*,[18] or *tele*[19] nucleophilic aromatic substitutions. Addition of tricarbonyl(*p*-fluorotoluene)chromium complex **13** to the carbanion **12** of complex **6a** yielded the heterodinuclear complex **14**, detected by NMR spectroscopy in the crude mixture. However, when the reaction mixture was filtered through a silica gel chromatography column, a new unexpected *para*-disubstituted arenetricarbonylchromium complex **15** was isolated (Equation 3). This tricarbonyl[2-(*para*-tolyl)propionitrile]chromium complex **15** was obtained by cleavage of the C^6-C^7 bond and subsequent rearomatization of the (η^5-cyclohexadienyl)manganese part of complex **14**. It is worth noting that this complex **14** could be obtained in 37% yield along with complex **15** (63% yield) by adding the lithium salt of

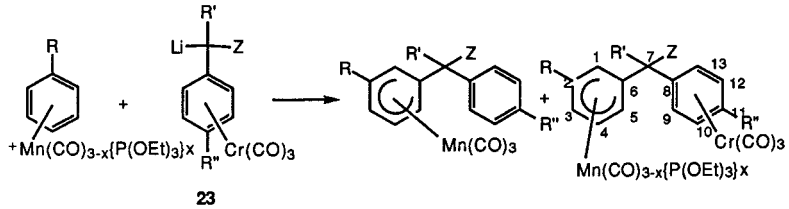


complex **15** to the arene complex **5**, followed by a simple extraction without further purification. When the mixture was subjected to chromatography, only complex **15** was obtained.

Equation 3. Synthesis of *para*-disubstituted complex **15** from **6a** and **13**

Treating the tricarbonyl(*p*-flurorotoluene)chromium complex **13** with the lithium salt **12** gave a new *para*-disubstituted arenetricarbonylchromium complex **15** and the cationic benzene complex **5**. The carbanion **12** plays an unexpected role because it is an unusual way to render the reaction of the propionitrile carbanion with (η^6-benzene)tricarbonylmanganese cation **5** reversible, by an indirect process! We can point out that *ipso* substitution of the fluoro group of **13** by a propionitrile carbanion can also give complex **15**. Thus, the carbanion **12** is a formal precursor of the carbanion of the propionitrile. It is obvious that this reaction would be of great interest if we could apply it to the addition of anions which do not react with arenechromium complexes but which react easily with arenemanganese complexes. Indeed it is well known that manganese complexes are much more reactive than chromium complexes. The reaction could maybe work in the presence of a catalytic amount of complex **5** according to the mechanism represented in Scheme 1. Indeed a primary or secondary carbanion LiCHRR′ in the presence of complexes **5** (catalytic amount) and **18** (X being a good leaving group) could react faster with the more electrophilic complex **5**, giving a catalytic amount of complex **16**. Complex **16**, in this medium, could be deprotonated yielding a catalytic amount of the complex **17** which could react with complex **18** giving complex **19** and LiX. Cleavage of the C^6-C^7 bond of the binuclear complex **19** could afford the zwitterionic complex **20**. In the presence of LiY, the complexes **22** (after hydrolysis of **21**) and **5** could be obtained; thus **5** might play a catalytic role in this process.

Having thus established the easy addition of benzylic anions such as **15-Li** to complex **5**, we turned our attention to modifications of the nature of the substituents at the bridgehead carbon atom of dinuclear complexes such as **14**, so as to increase the stability of the newly-formed C^6-C^7 bond. For this purpose, we assumed that it would be interesting to replace the electron-withdrawing cyano group by an electron-donating group such as methoxy.[20] For this reason, we treated the benzylic carbanion **23** (Z = OMe, R′ = R″ = H) with the cationic benzene complex **5** (Table 9, entry 1). We were pleased to find that the dinuclear complex **24a** could be obtained almost quantitatively (according to the ^{1}H-NMR spectrum of the crude mixture), and that



Scheme 1. Tranformation of **18** into **22**: possible mechanism for the carbon−carbon bond formation catalyzed by benzenetricarbonylmanganese complex **5**

it could be purified by silica gel chromatography without any cleavage of the C^6-C^7 bond. However, some decoordination of chromium occured giving rise to the formation of the product **25** (29%), free of Cr, besides the expected complex **24a** (41%). It is thus clear that the nature of the substituent at the benzylic position of the nucleophile plays an important role with respect to the stability of the bridge of these dinuclear complexes.

We were interested in the fate of this reaction (Table 9) when other ligands around the manganese atom were used. Indeed, it has been demonstrated that substitution of one or two CO ligands of arene manganese complexes by phosphane or phosphite could lead to cleaner reactions during the nucleophilic addition process[4,7a,24,25] and, in some cases, could even modify the regioselectivity of the addition.[23] We thus prepared complexes $\mathbf{5P}_1$ and $\mathbf{5P}_2$ by substituting one and two carbonyl groups by one and two triethyl phosphito groups, respectively. After addition of carbanion **23** (Z = OMe, R′ = R″ = H) to $\mathbf{5P}_1$ (or $\mathbf{5P}_2$), we isolated, after column chromatography, the complex **24b** in 55% yield (or **24c** in 47% yield) and starting Cr complex **23** in 16% yield (28% in the case of $\mathbf{5P}_2$) (Table 9, entries 2 and 3). In both cases, no sign of chromium decoordination was detected. The NMR study of the η^5-cyclohexadienyl rings of complexes **24** reflected the electronic influence of the phosphito ligands on the cycle coordinated to the Mn entity. A shielding effect was detected in the ^{1}H- and ^{13}C-NMR spectra (Table 10). No modification of chemical shifts of chromium ring proton signals was observed.

The role of the phosphito ligands with respect to the manganese atom could thus be two-fold: 1. The phosphito ligands, being weaker π-acceptors than CO ligands, lead to an increase of the electron density of the cycle and lower the activation of the manganese complex towards nucleophilic

Table 9. Addition of benzylic anions prepared from tricarbonylchromium complexes to cationic Mn complexes

		Cr complex			mononuclear	dinuclear
entry	Mn complex	Z	R'	R"	complex	complex
1	5 R=H, x=0	OMe	H	H	25	24a
2	$5P_1$ R=H, x=1	OMe	H	H		24b
3	$5P_2$ R=H, x=2	OMe	H	H		24c
4	26a R=OMe, x=0	OMe	CH_3	H		27a
5	26b R=OMe, x=1	OMe	CH_3	H		27b

Table 10. Shielding effect of phosphito ligands on the η^5-cyclohexadienyl ring of complexes **24**

Complexes **24**	**24a**	**24b**	**24c**
H^1 and H^5	3.30, 2.83	3.04, 2.54	2.61, 2.05
H^2 and H^4	4.91	4.73	4.53
H^3	5.79	5.53	5.18
H^6	2.60	2.62	2.51
C^1 and C^5	51.7, 54.6	48.5, 51.4	45.2, 47.8
C^2 and C^4	96.8, 97.0	95.3, 95.5	93.2, 93.7
C^3	80.4	79.5	76.8
C^6	87.0	87.0	87.2

addition. Thus, 16% and 28% of starting material was recovered when $\mathbf{5P_1}$ and $\mathbf{5P_2}$, respectively, were used. 2. Although the phosphito−manganese complexes were less electrophilic, better yields in **24b** and **24c** were observed (55% and 47%, respectively) due to an overall stabilization of these dinuclear complexes, which is as yet difficult to explain.

To further investigate the regioselectivity of the addition of α-benzylic carbanions to manganese complexes, we treated the carbanion **23** (Z = OMe, R′ = CH_3, R′′ = H) with the cationic (η^6-anisole) complex **26a**. We observed the formation of only one regioisomer **27a** in 47% yield as a mixture of two diastereoisomers in a 1:1 ratio (measured by integrating the methoxy protons at C2), and some Cr complex starting material (26%) (Table 9, entry 4). Addition occured, as expected, *meta* to the methoxy group.[21,22] No formation of a mononuclear Mn complex due to the decoordination of the chromium entity was observed.

An analogous reaction was carried out with the anisole dicarbonyl mono-phosphito complex **26b** in order to gain insight into the influence of the nature of manganese ligands. Thus, complex **26b** treated with the benzylic carbanion **23** (Z = OMe, R′ = CH_3, R′′ = H) yielded complex **27b** as a unique regioisomer in 64% yield (2 diastereoisomers in a 1:1 ratio) (Table 9, entry 5) and some Cr starting material was recovered. In this example again, substitution of a CO ligand by a phosphito ligand led to a significant increase of the yield of the dinuclear complex. As already observed for complexes **24**, the ^{1}H- and ^{13}C-NMR spectra of complex **27b** showed shielded signals compared to those of complex **27a**: for example, the H^3 and H^4 atoms are shielded by 0.34 and by 0.26 ppm and the C^3 and C^4 atoms are shielded by 1.3 and 0.9 ppm, respectively.

Conclusion
