Structure, Properties and Reactivity of the $Fe^{II}Fe^{III}$ and $Zn^{II}Fe^{III}$ Purple Acid Phosphatases

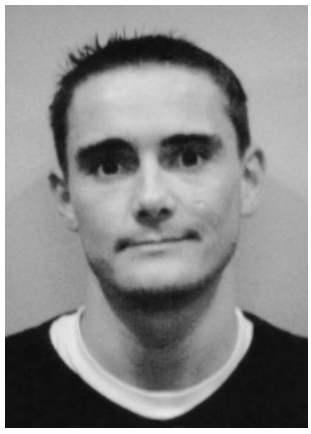
Mark B. Twitchett[a] and A. Geoffrey Sykes*[a]

Keywords: Metalloenzymes / Purple Acid Phosphatases / Phosphate Ester Hydrolysis / Dinuclear metal active sites

This microreview describes the structure, properties and mechanisms of the purple acid phosphatases (PAP). The enzyme is isolated from mammalian, plant and bacterial sources. X-ray structural information is now available for the enzyme from pig (uteroferrin), rat and kidney beans. Features of the mechanism are the concerted action of a labile M^{II} centre (Fe^{II} or Zn^{II}) alongside a more inert Fe^{III}. The latter is effective as a conjugate-base $FeOH^{2+}$, which initiates hydrolysis at the M^{II}-bound phosphate ester by a process involving OH^- replacement of OR^- at the P^V. Histidine residues near to the active site help bind the phosphate and are involved in the release of OR^-. Effects of replacement of the Fe^{II} by Mn^{II}, Co^{II}, Ni^{II}, Cu^{II} and Zn^{II}, and of Fe^{III} by Ga^{III},Al^{III} and In^{III} have been studied. The mechanistic role of the $Zn^{II}Zn^{II}$ combination in alkaline phosphatases, and other related dinuclear centres is also considered.

Introduction

Proteins having dinuclear iron centres are a well characterised category with wide-ranging biological functions.[1−3] They include ribonucleotide reductase,[4][5] methane monooxygenase,[6][7] as well as the O_2-transport/storage protein hemerythrin,[8] and Δ^9 desaturase.[9] In addition the mammalian $Fe^{II}Fe^{III}$ active site in purple acid phosphatase (PAP) is able to catalyse the hydrolysis of phosphate esters written here as $(RO)PO_3H^-$ (Equation 1) where R is an organic group.[1−3,10−13]



$$(RO)PO_3H^- + H_2O \rightarrow H_2PO_4^- + ROH \quad (1)$$

However, such phosphatase action is not restricted to dinuclear Fe centres, with plant phosphatases using the dinuclear $Zn^{II}Fe^{III}$ combination.[14] Also alkaline phosphatases have $Zn^{II}Zn^{II}$ active centres, and zinc has a prominent role in both phosphatase and phosphoryl-transfer reactions.[1] Interestingly in the case of many zinc enzymes, X-ray structures of reactant, intermediate and product states have provided a lead in determining the mechanism. [a] Department of Chemistry, University of Newcastle, Newcastle upon Tyne, NE1 7RU, UK

Professor A. G. Sykes FRS has BSc., Ph.D., and DSc. degrees in chemistry from the University of Manchester where he researched under the supervision of Professor W.C.E. Higginson. After post-doctoral work in Princeton and Adelaide, he was appointed a Lecturer at the University of Leeds, became a Reader in 1970 and moved to the Chair of Inorganic Chemistry at the University of Newcastle upon Tyne in 1980. His research is primarily in kinetic/mechanistic studies on both inorganic and bioinorganic (metalloprotein) reactions, with purple acid phosphatases a relatively recent interest.

Mark Twitchett received his undergraduate education at the University of East Anglia and University of California Santa Barbara, obtaining his BSc. in Chemistry in 1992. He remained at the University of East Anglia for a further year to obtain his MSc in Spectroscopic and Physical Methods, and then researched with Professor A.G. Mauk on biological electron transfer at the University of British Columbia where he received his Ph.D. in Biochemistry and Molecular Biology in 1998. He has just completed a UK BBSRC Postdoctoral Research Assistantship with Professor Sykes in Newcastle.

MICROREVIEWS: This feature introduces the reader to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is also included.

ever, the intense colour stemming from the Fe^{III} component of mammalian and plant PAP′s has made possible kinetic/mechanistic studies using UV/Vis spectrophotometry.[15−18] Such studies are a major contribution to this review.

Function

Purple acid phosphates are nonspecific phosphomonoesterases which can be isolated from mammalian,[19−23] plant,[24−27] and microbial sources.[28][29] They are distinguished from other acid phosphatases by their purple colours. Mammalian PAP′s are highly conserved dinuclear metal-containing enzymes produced by the osteoclasts i.e. cells that reabsorb bone. The mammalian enzymes are distinguished from lysosomal and prostatic acid phosphatases by their resistance to inhibition by L(+)tartrate, and hence are known as tartrate-resistant acid phosphatases (TRAP′s).[30−32] In the osteoclast the enzyme is believed to be involved in dephosphorylation of phosphoproteins in the bone matrix, namely osteopontin and bone sialoprotein.[33] There have also been reports of low molecular weight phosphatase activity and removal of tyrosine-linked phosphates from the epidermal growth-factor receptor.[34] A role for PAP in the spleen involving degradation of aged red blood cells has also been proposed.[35] The degradation process may correlate to the generation of O_2-related free-radicals from redox changes at the Fe^{II} centre.[36] It has also been suggested that in Alzheimer patients there is a reduction in phosphatase activity in the brain due to a decrease in protein levels. In the case of plant PAP′s a physiological function appears to be the liberation of phosphate from organophosphates, which is important following phosphate starvation.[37]

Physical Properties of PAP

Purple acid phosphatases require acidic conditions for optimum activity and are characterised by an intense purple colour. The latter is brought about by a tyrosine phenolate to iron(III) ligand to metal charge-transfer (LMCT) process, which is observed for both the $Fe^{II}Fe^{III}$ and $Fe^{III}Fe^{III}$ states.[38−41] The PAP enzymes most extensively studied are those from the porcine uterus (known as uteroferrin, Uf, or pig PAP), bovine spleen (BSPAP), and from kidney beans (KBPAP). Complete amino acid sequences for a number of mammalian PAP′s are available (Uf,[42] bovine spleen,[42] human,[43] rat,[44] and mouse PAP.[45]) These have a dinuclear $Fe^{II}Fe^{III}$ active site ($M_r \approx 38$ kDa) and greater than 80% sequence homology. The plant PAP′s have less homology with only 60% identical residues for the enzymes from kidney bean (*Phaseolus vulgaris*) and *Arabidopis thaliana*,[46] and in the former the active site is known to be the $Zn^{II}Fe^{III}$ combination.[14]

Mammalian, plant, and bacterial sequences have revealed five regions of sequence homology which have been further grouped into two signature motifs (A and B)[47] (Figure 1). Thus despite differences in overall amino acid sequences, as well as molecular mass and subunit arrangement, the enzymes have structurally similar active site regions. The mammalian PAP active sites in Uf and BSPAP are spectroscopically well characterised. The dinuclear iron site can exist in two oxidation states, $Fe^{II}Fe^{III}$ (pink) and $Fe^{III}Fe^{III}$ (purple). Of these only the $Fe^{II}Fe^{III}$ combination peak at 515 nm ($\varepsilon = 4450 M^{-1}cm^{-1}$), has significant phosphatase activity.[48][49] The $Fe^{II}Fe^{II}$ state generated by dithionite (0.5 mM) reduction (30 min) has no long term stability, and has not been studied in a similar way. Loss of Fe^{II} occurs, and after 30 min only 40% recovery of the higher oxidation states is possible.[17] The purple $Fe^{III}Fe^{III}$ form is EPR silent and gives a characteristic UV/Vis peak at 550 nm ($\varepsilon = 4300 M^{-1}cm^{-1}$). Recently magnetic susceptibility measurements on protein in the $Fe^{II}Fe^{III}$ states have indicated exchange coupling constants, J values between -5 and $-15 cm^{-1}$ for KBPAP and BSPAP in both states,[50] with the main contribution to antiferromagnetic coupling from the μ-hydroxo bridge.[51][52] Analysis of iron K-edge EXAFS data has suggested that a μ-hydroxo or alkoxy group may be present.[53] Recent CD/MCD studies on this redox state provide confirmation of antiferromagnetic coupling and suggest a μ-hydroxo group.[54] The EPR spectrum of the $Fe^{II}Fe^{III}$ enzyme, with g values at 1.94, 1.76 and 1.56 is consistent with coupling between the high-spin Fe^{II} and Fe^{III} ions.[50,55,56]

In addition to the bridging hydroxo group the existence of a coordinated aqua/hydroxo group to each Fe has been demonstrated by ESEEM (electron spin echo envelope modulation),[57] ENDOR (electron nuclear double resonance),[58] and is consistent with electrochemical studies.[59] Furthermore the remaining endogenous ligands have been

identified by a variety of spectroscopic methods. The intense purple/pink absorbance at 500−600 nm is assigned to a tyrosine phenolate to Fe^{III} charge-transfer band.[60−63] The presence of the tyrosine accounts for the retention of one Fe in the +3 state. The $Fe^{III}Fe^{III}/Fe^{II}Fe^{III}$ reduction potential (E°) is 367mV vs. NHE, whereas that required for the further reduction of $Fe^{II}Fe^{III}$ is negative.[59] Tyrosine is also a ligand in transferrin, active-site coordination $[Fe(Tyr)_2(His)(Asp)(CO_3)]$, where E° for the Fe^{III}/Fe^{II} couple is −520mV,[64] a measure of the difficulty of bringing about the reduction of a tyrosine-coordinated Fe^{III}. Additional evidence from Resonance Raman and ^1H NMR spectroscopy confirms that a tyrosine is bound to the Fe^{III} in PAP.[60−63] Coordination of imidazole and of carboxylate groups have been confirmed by ^1H NMR spectroscopy.[61][62] Pulse EPR[65] and Mossbauer[51,66,67] studies have also been carried out. A demonstration that both Fe atoms are six coordinate comes from CD/MCD investigations,[54] and all information obtained is consistent with the active site structure indicated in Figure 2. It should be noted however that the ^1H NMR studies provide no evidence for a second His coordinated to the Fe^{II}. Fast exchange of the Nε proton with bulk solvent is a possible explanation of effects observed. Studies on plant KBPAP have also been carried out.[48] Acid dissociation pK_a′s for KBPAP determined by UV/Vis absorption spectrophotometry of 4.8 and 9.5 have been assigned to H_2O ligands to the Fe^{III} and Zn^{II} respectively.[11] For BSPAP the first pK_a is also at 4.8,[48] whereas for Uf a smaller value of 3.8 is found.[16]

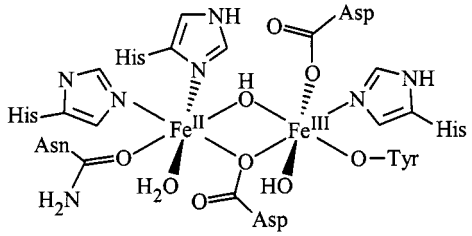

Figure 2. Structure of the $Fe^{II}Fe^{III}$ active sites of mammalian purple acid phosphatases

X-ray Structures

X-ray crystal structures of the 111 kDa homodimeric $Zn^{II}Fe^{III}$ KBPAP enzyme (resolution 2.65Å), the same protein with μ-phosphate coordinated (2.7Å), and the product with μ-tungstate(VI) inhibitor coordinated (3.0Å) have been reported.[11] More recently the structures of μ-phosphato derivatives of two mammalian PAP′s from Uf (1.55Å),[68] and from rat (2.7Å),[69] both believed to be in the $Fe^{III}Fe^{III}$ state, have been determined. The mammalian PAP enzymes are monomeric glycoproteins of ≈ 38 kDa, whereas the two monomer units of KBPAP are connected by a disulfide bridge. Sequence homologies between the monomer unit of the homodimeric KBPAP and mammalian PAP′s have been investigated.[47] With the *N*-terminal domain of KBPAP removed the two enzymes can be aligned. The C-terminal domain incorporates two sandwich βαβαβ motifs. All the ligands to the dimetal site are found within these two motifs.

The high resolution Uf structure confirms octahedral coordination at both metals.[68] The $Fe^{III}-Fe^{III}$ separation is 3.31Å and the phosphate bridges the two metals in a symmetrical manner. Strong electron density is observed consistent with the presence of a μ-hydroxo group, and there is no evidence for phosphate displacing this group. The two metals are also bridged in a monodentate manner by one of the aspartate residues, and there is confirmation that the tyrosine phenolate O-atom is bound to the Fe. The spacial arrangement of the metal ligands are very similar to those in KBPAP, and the α-carbon atoms of all seven coordinated amino acid residues superimpose. The active site is readily accessed from the surrounding solvent. The protein fold of Uf resembles that of KBPAP and some serine/threonine proton phosphatases, despite the <15% homologies.

The KBPAP structure has a $Zn^{II}Fe^{III}$ active site,[11] and unlike the $Fe^{III}Fe^{III}$ Uf and rat structures, is the only one for which the dimetal site is in the active form. The Zn^{II} is ligated to the Nε atom of His-286, the Nδ atom of His-323 and the carbonyl oxygen of Asn-201 (Figure 3). The Fe^{III} is ligated to the Nε atom of His-325, to Tyr-167 and the carboxylate of Asp-135. The Zn−Fe separation is 3.26Å. Three exogenous H_2O/OH^- ligands were modelled into the active site. These are a terminal hydroxo ligand to the Fe^{III}, a terminal H_2O to the Zn^{II}, and a μ-hydroxo bridge between the two metals. From sequence homologies and spectroscopic studies a high degree of conformity with the mammalian active site is indicated (Figures 2 and 3). The similarity of the dimetallic ligation with those of the serine/threonine protein phosphatases, calcineurin (PP2B) and PPI is noted.[70−73]

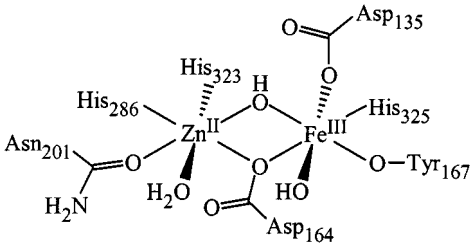

Figure 3. Structure of the $Zn^{II}Fe^{III}$ active site of kidney bean purple acid phosphatase (KBPAP) from X-ray crystallography[11]

In addition three histidine (His 202, 295 and 296) are located near to the dimetallic centre of KBPAP (Figure 4), and are in positions where they can interact with phosphate.[11] It has been proposed that the His-296 protonates the leaving alcohol group. The counterparts of these residues are His-92, Glu-194 and His-195 in the mammalian PAP′s.[68][69] In the two mammalian structures the His-92 and His-195 residues are hydrogen-bonded to the phosphate.[68] The side chain of Glu-194 is not in close contact with the phosphate, and appears to have no similar role to that of His-295 in KBPAP. The conservation of two of the

histidines (His-202 and 296), and their superposition in the different structures, suggests a mechanistic role.

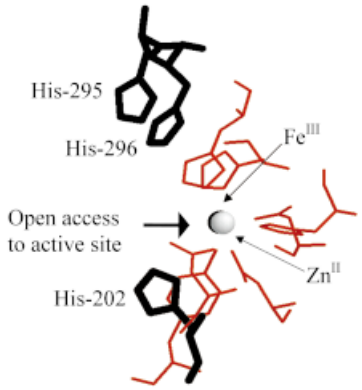

Figure 4. Structure of KBPAP illustrating the close proximity of residues His-202, -295 and -296 to the dinuclear metal active site

Structures of Other Phosphatases

The PAP′s are members of a much larger family of phosphatases recently reviewed.[1] Two other categories, the alkaline phosphatases (AP),[1][74] and the serine/theonine protein phosphatases (PP),[70−73] are mentioned here. The alkaline phosphatases are colourless and have a linear arrangement of two Zn^{II} atoms 4.1Å apart, and a Mg^{II} at 4.8Å. The structure of the native enzyme with phosphate bound (2.0Å resolution) has provided most information. The phosphate substrate bridges Zn1 and Zn2, which have no other bridging ligands, whereas Asp-51 bridges bidentately Zn2 to Mg3 (the third metal atom) (Figure 5).

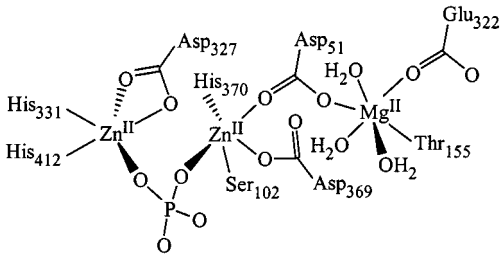

Figure 5. Structure of the $Zn^{II}Zn^{II}Mg^{II}$ active site of alkaline phosphatase with phosphate bound[1]

The Zn1 centre is pentacoordinated by bidentate Asp-327, His-331, His-412 and the O-atom of the phosphate group. The Zn2 is tetrahedral and coordinated by Asp-51, Asp-369, His-370 and phosphate. The Mg3 is ooctahedral with all O-donors, Asp-51, Thr-135, Glu-322 and three H_2O′s. The remaining two O-atoms of the phosphate are tightly held by hydrogen-bonds with the guanidinium group of Arg-166. A particular feature of the mechanism is the incorporation of $(RO)PO_3^{2-}$ into a serine phosphate-ester intermediate (Figure 6) which has been identified by X-ray crystallography.[1]

Coordination of the Ser-102 O-atom to the Zn2 facilitates deprotonation of the side chain, and the serinate nucleophile attacks the phosphate and replaces the OR^- group. The intermediate so formed reacts further with H_2O to give the hydrolysed product. AP appears unique amongst these enzymes in reacting by a two-stage mechanism. The Mg3 ion appears to have a minor role only.

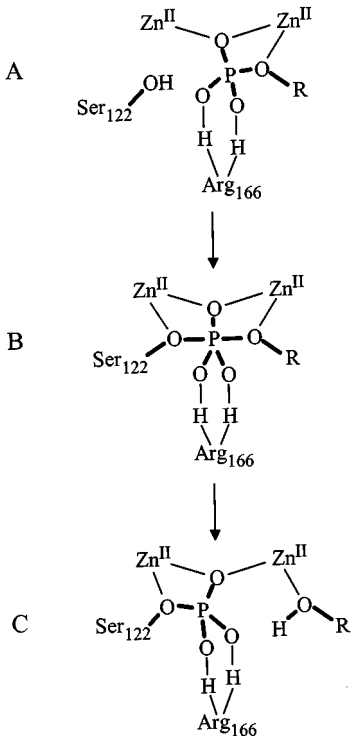

Figure 6. Schematic illustration of the conversion of $(RO)PO_3H^-$ (A) into a serine phosphate ester intermediate (C) by alkaline phosphatase

PP proteins are activated by several metal ions, and probably contain the Fe−Zn combination in the native form. The X-ray crystal structure of the phosphate bound rabbit muscle PP (PP-1) has been determined to 2.1Å resolution,[72] and the dinuclear metal site superimposes well with KBPAP, particularly with respect to the bridging ligands. The metals are both five-coordinate and are 3.3Å apart. They are bridged by an oxygen of Asp-92 and a water (very likely hydroxide). One metal has a distorted trigonal-bipyramidal geometry and additional coordination to Nε of His-173, Nδ of His-248 and the carbonyl oxygen of Asn-124. The other metal ion has a square-pyramidal geometry and additional coordination to Nε of His-66, Asp-64 and another solvent molecule (Figure 7). A notable difference is the substitution of a solvent H_2O for the tyrosine in PAP, and no purple colour is therefore observed.

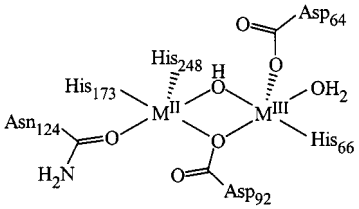

Figure 7. Structure of the active site of rabbit muscle protein phosphatase (PP-1)[72]

Activity of PAP

With the further elucidation of PAP active-site structures it is possible to consider in more detail the mechanism by which these proteins hydrolyse phosphate esters in acidic conditions. Such mechanistic studies have featured prominently in work carried out at Newcastle, with particular emphasis on kinetic analysis of UV/Vis spectrophotometric changes for the interaction of oxyanions with the enzyme.[16][18] Activity measurements are carried out by monitoring UV/Vis changes for the release of nitrophenol from *p*-nitrophenol phosphate, or α-naphthol from α-naphthyl phosphate. The initial slope of a plot of α-naphthol released against time gives the activity in nmol·min^{-1}. In previous studies unit enzyme activity was defined as the amount of enzyme catalysing the hydrolysis of 1 μmol of α-naphthyl phosphate per min. Following observations that the activity of BSPAP exhibits a bell-shaped pH dependence, Witzel and colleagues[48] proposed that two single proton equilibria were involved. One of these for the upward part of the bell-shape curve gives a pK_a of 4.8 and is catalytic, and the second for the downward part gives a pK_a of 6.9 which inhibits reaction. The lower pK_a is also observed in EPR and UV/Vis studies,[48] and has been attributed to deprotonation of the solvent H_2O coordinated to the Fe^{III}. Based on evidence that no nucleophilic residue on the enzyme appears to be involved in the catalytic reaction, and that no covalent bound intermediate is formed as in the case of the phosphotransferases, it has been concluded that a hydroxo ligand bound to the Fe^{III} induces the ester hydrolysis reaction.[16][48] Results obtained from the reaction of labelled adenosine 5′-triphosphate (ATP) with $Fe^{II}Fe^{III}$ PAP have demonstrated that there is transfer of phosphate to an H_2O position on the PAP with overall inversion at the phosphate.[75]

Reaction of Phosphate ($H_2PO_4^-$) With Uf PAP

Although reactions of the $Fe^{II}Fe^{III}$ protein with a number of oxyanions had been studied quite extensively,[19,51,54,61,65,76,77] there has until recently been no clear understanding of the precise function of the Fe^{II} and Fe^{III} combination. At 25°C acid dissociation pK_a values for H_3PO_4 are 2.1 for the formation of $H_2PO_4^-$, and 6.7−7.0 for the formation of HPO_4^{2-}. On addition of excess of phosphate ($H_2PO_4^-$) to $Fe^{II}Fe^{III}$ rapid stopped-flow formation of a phosphato product is observed. Spectrophotometric changes gave a shift in UV/Vis peaks from 515 nm for $Fe^{II}Fe^{III}$ to 535−560 nm (pH dependent) for the phosphato product. Surprisingly first-order rate constants k_{obs} obtained by monitoring absorbance changes at 620 nm indicate that the reaction is independent of $[H_2PO_4^-]$ in the range 10−50 mM (Figure 8).[16] The reactions with phenyl phosphate, pyrophosphate, tripolyphosphate and ATP (adenosine 5′-triphosphate), referred to collectively as PO_4, in which ester hydrolysis occurs, are also independent of $[PO_4]$.[16] Significantly, with $(MeO)_3PO$ no absorbance changes are observed indicating the need for two strongly nucleophilic oxo groups (and/or hydrophilic groups) for attachment to the Fe^{III} chromophore to occur. The latter does however inhibit the reaction of $H_2PO_4^-$, suggesting that an interaction of $(MeO)_3PO$ with Fe^{II} is occurring.

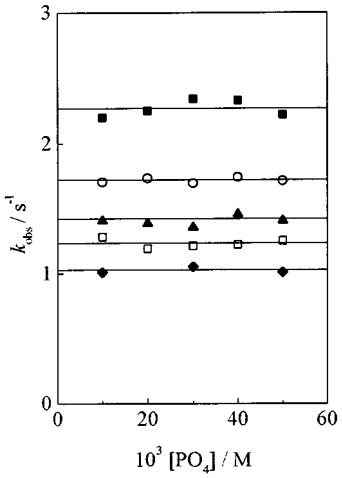

Figure 8. The phosphate concentration independence of first-order rate constants k_{obs} (25°) for the reaction of $Fe^{II}Fe^{III}$ Uf with different phosphates: $H_2PO_4^-$ (○), phenyl phosphate (□), pyrophosphate (■), tripolyphosphate (▲) and ATP (◆) at pH 4.6, I = 0.01M (NaCl)[16]

The mechanism proposed in the case of $H_2PO_4^-$ involves binding first to the Fe^{II}, in a relatively rapid process which does not contribute appreciably to changes in visible absorbance. Bridging to the strongly chromophoric Fe^{III} then occurs. Such a mechanism is consistent with general properties of high-spin Fe^{II} and Fe^{III} ions, the hexaaqua ions of which have water-exchange rate constants close to $10^6 s^{-1}$, and $10^3-10^4 s^{-1}$, respectively.[78][79] Accordingly the reaction sequence can be expressed as in Equation (2).

$$PO_4 + M^{II}\ldots Fe^{III} \underset{}{\overset{K_1.}{\rightleftharpoons}} M^{II}\ Fe^{III} \quad (2)$$
$$\quad\ |\ \ | \qquad\qquad\quad |\ \ |$$
$$\quad H_2O\ OH \qquad\qquad PO_4\ OH$$

followed by bridging to the strongly chromophoric Fe^{III}, (3).

$$M^{II}\ldots Fe^{III} \underset{k_b}{\overset{k_f}{\rightleftharpoons}} M^{II}\ldots Fe^{III} \quad (3)$$
$$|\ \ \ | \qquad\qquad\quad \backslash\ \ / \qquad\qquad$$
$$PO_4\ OH \qquad\qquad\quad PO_4$$

Assuming (2) to be relatively rapid, mass balance can be used to give (4)

$$k_{obs} = \frac{k_f K_1 [PO_4]}{K_1 [PO_4] + 1} + k_b \quad (4)$$

However the first term on the right-hand side suggests that a $[PO_4]$ dependence should be observed. Only if k_b is

dominant, or $K[PO_4] >> 1$ is this equation consistent with the observed $[PO_4]$ independence. There is no evidence for k_b being dominant, and the second possibility is therefore considered. Determination of the overall stability constant K by titration of Uf PAP with $H_2PO_4^-$ at pH 4.9 (40 mM acetate) gives a value of $165M^{-1}$,[80] in agreement with an earlier value of $151M^{-1}$ in 100 mM acetate buffer.[80] No dependence of thermodynamic and kinetic parameters on acetate in the range 25−55 mM, has been observed.[15] The overall K can be written as $K_1\ k_f/k_b$, or K_1K_2 on replacing k_f/k_b with K_2. For the 10−50 mM range of $[PO_4]$ studied no dependence on $[PO_4]$ is observed, and it is concluded that $K_1[PO_4] >> 1$, or alternatively $K_1[PO_4]$ is say > 5, which gives $K_1 > 500\ M^{-1}$. Since K has been determined as $165M^{-1}$, K_2 for the intramolecular step (3) is <0.32. It should be noted that K and K_2 have different units, and that K_1 may benefit from association at the His residues previously indicated, e.g. Figure 8.

It is not clear how the HPO_4^{2-} bridge dissociates. There are two possibilities to consider: (a) by cleavage of the $Fe^{II}-PO_4$ bond, or (b) cleavage of $Fe^{III}-PO_4$. If the first of these applies then dissociation follows a different route to formation. Two of the residues His-202, His-295 and His-296 found in KBPAP are conserved as His-92 and His-195 in mammalian forms, and may help bind the $H_2PO_4^-$ in (2). The mechanism of ester hydrolysis is considered below after sections on the reactions with other oxyanions and redox studies.

Reactions With Other Oxyanions

Further insight into the mechanism of oxyanion binding has been provided by studies on the binding of arsenate(V), molybdate(VI) and tungstate(VI) to $Fe^{II}Fe^{III}$ Uf.[18] Both phosphate and arsenate function as weak competitive inhibitors for phosphate ester hydrolysis by acting as bridging ligands between the two metal centres.[16,19,53,80−83] These oxoanions lower the protein reduction potential and increase the susceptibility of the active site to air oxidation.[58][59] Conversely, tungstate(VI) and molybdate(VI) are reported to be strong noncompetitive inhibitors which increase the reduction potential and stabilise the active site.[18,57,59] It has been suggested that the latter two oxoanions bind in a different manner to the phosphate and arsenate(V), producing a change in the active site EPR spectrum from rhombic to axial, and a change in the UV/Vis spectrum (molybdate). A low resolution structure is available for tungstate(VI) bound to KBPAP.[11] Recent CD/MCD studies on protein having bound phosphate or molybdate have led to the proposal that bound phosphate, unlike molybdate, interacts with the active site μ-OH bridge thus increasing the bond strength between the μ-OH bridge and the Fe^{II}, and producing a more rhombic Fe^{II} centre.[54] EXAFS results have also been reported on $Zn^{II}Fe^{III}$ Uf.[77] A number of anomalies remain, and further work is required in this area.

As far as the kinetics of the reactions of $Fe^{II}Fe^{III}$ Uf with oxyanions XO_4 (molybdate, tungstate and vanadate) are concerned, rate laws independent of $[XO_4]$ are similar to those obtained with $H_2PO_4^-$ phosphate.[18]

Redox Studies on Uf PAP

Two inorganic reagents, $[Fe(CN)_6]^{3-}$ (E° = 410mV) and $[Co(phen)_3]^{3+}$ (E° = 370mV) have been used as oxidants (25°C) for $Fe^{II}Fe^{III}$ Uf PAP, at pH 5.0, I = 0.10M (NaCl), overall Equations (5) and (6).[17]

$$Fe^{II}Fe^{III} + [Co(phen)_3]^{3+} \rightarrow Fe^{III}Fe^{III} + [Co(phen)_3]^{2+} \quad (5)$$

$$Fe^{II}Fe^{III} + [Fe(CN)_6]^{3-} \rightarrow Fe^{III}Fe^{III} + [Fe(CN)_6]^{4-} \quad (6)$$

With $[Co(phen)_3]^{3+}$ as oxidant first-order dependencies on both reactants are observed, giving second-order rate constants k_{Co} of $1.26M^{-1}s^{-1}$. In contrast the reaction with $[Fe(CN)_6]^{3-}$ gives saturation kinetics (Figure 9). This behaviour can be explained by the reaction sequences (7) and (8).

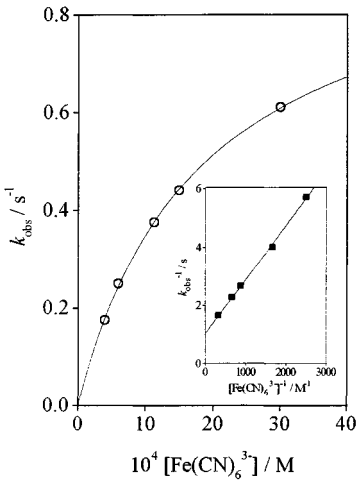

Figure 9. Saturation kinetic behaviour of first-order rate constants k_{obs} (25°C) for the reaction of $Fe^{II}Fe^{III}$ Uf with $[Fe(CN)_6]^{3-}$ at pH 5.0, I = 0.10M (NaCl). The inset shows the reciprocal plot[17]

$$Fe^{II}Fe^{III} + [Fe(CN)_6]^{3-} \overset{K_{Fe}}{\rightleftharpoons} Fe^{II}Fe^{III}\ldots[Fe(CN)_6]^{3-} \quad (7)$$

$$Fe^{II}Fe^{III}\ldots[Fe(CN)_6]^{3-} \overset{k_{Fe}}{\rightarrow} Fe^{III}Fe^{III} + [Fe(CN)_6]^{4-} \quad (8)$$

The part played in phosphate ester hydrolysis by the positive patch of His-202, His-295 and His-296 near to the active of KBPAP (Figure 4) has been discussed.[11] Two of these histidines, His-92 and His-195, are conserved in Uf. Association of $[Fe(CN)_6]^{3-}$ at this site (7), prior to electron transfer (8) is proposed therefore. For such a sequence (9) is derived,

$$k_{obs} = \frac{k_{Fe}\,K_{Fe}\,[Fe(CN)_6^{3-}]}{1 + K_{Fe}\,[Fe(CN)_6^{3-}]} \quad (9)$$

and a graph of $1/k_{obs}$ against $1/[Fe(CN)_6^{3-}]$ is linear. The slope and intercept give K_{Fe} and k_{Fe} values of $540M^{-1}$ and

$1.00s^{-1}$ respectively. Moreover competitive inhibition of the $[Fe(CN)_6]^{3-}$ oxidation by nonredox active $[Cr(CN)_6]^{3-}$ and $[Mo(CN)_8]^{4-}$ is also observed with association constants as defined in (7) of $K_{Cr} = 550M^{-1}$ and $K_{Mo} = 1580M^{-1}$. Together these studies provide support for an electrostatically controlled interaction. The magnitude of the association constants suggests an effective local protein charge as high as +4,[84] which could arise from two $HisH^+$ groups along with some contribution from the active site charge. We note that although the positively charged region on PAP favours anionic reagents, substrates which are cationic also retain an appreciable reactivity. Thus the reaction of $Fe^{III}Fe^{III}$ Uf PAP with the positively charged reductant $[Ru(NH_3)_5H_2O]^{2+}$ ($E° = 67mV$) (10),

$$Fe^{III}Fe^{III} + [Ru(NH_3)_5H_2O]^{2+} \rightarrow Fe^{II}Fe^{III} + [Ru(NH_3)_5H_2O]^{3+} \quad (10)$$

gives a second-order rate constant k_{Ru} of $2.2 \times 10^5 M^{-1}s^{-1}$. The magnitude of the rate constants k_{Co} and k_{Ru} suggest a dependence on thermodynamic driving force.

Effects of pH on PAP Reactivity

Rate constants for the reactions of $H_2PO_4^-$ and phosphate esters $(RO)PO_3H^-$ with $Fe^{II}Fe^{III}$ Uf are dependent on pH in the range 2.6−6.5 (Figure 10).[16]

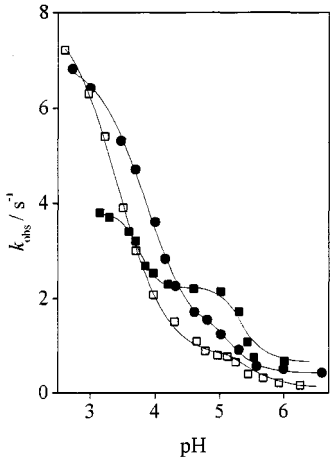

Figure 10. Variation of first-order rate constants k_{obs} (25°C) with pH for the reaction of $Fe^{II}Fe^{III}$ Uf with $H_2PO_4^-$ (●), phenyl phosphate (□), and pyrophosphate (■), $I = 0.10M$ (NaCl)[16]

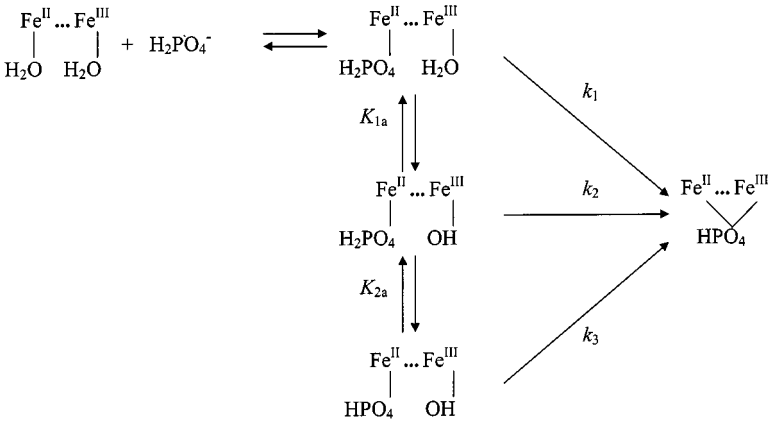


Contributions to pH effects can stem from acid-base effects involving aqua ligands, nearby protein amino acids, and/or free and monodentate phosphate species. In the reaction of $H_2PO_4^-$ rate constants k_{obs} provide evidence for a Uf pK_{1a} of 3.9, which is assigned to acid dissociation at the Fe^{III}.[16] There is some evidence (the inflection at pH ≈ 5) for a second process pK_{2a}. In all other cases (phenyl phosphate, pyrophosphate, tripolyphosphate and ATP) two pK_a values (pK_{1a} and pK_{2a}) are clearly apparent, and rate constants k_1, k_2 and k_3 can be defined for the reactions of different protonated/deprotonated forms of the adduct formed in the first step of Scheme 1.

From the mechanism proposed the rate law (11) can be derived.

$$k_{obs} = k_1 + \frac{(k_3\text{-}k_1)\,K_{1a}K_{2a} + (k_2\text{-}k_1)\,K_{1a}[H^+]}{[H^+]^2 + K_{1a}[H^+] + K_{1a}K_{2a}} \quad (11)$$

From fits to (11) values of K_{1a}, K_{2a}, k_1, k_2 and k_3 are obtained (Table 1). The pK_{1a} values determined are in the range 3.4−3.9 (average 3.8), and are attributed to deprotonation of the Fe^{III} bound H_2O. The same pK_a is obtained from the effects of pH on the UV/Vis absorbance of Uf. As a guide the first acid dissociation constant of $[Fe(H_2O)_6]^{3+}$ is 3.0, whereas $[Fe(H_2O)_6]^{2+}$ remains in the aqua form until >7.[85] The second deprotonation effect (pK_{2a}) suggests that acid dissociation at the phosphate group attached to the Fe^{II} is contributing (Figure 10). As is to be expected shifts are observed in pK_{2a} values, as compared to literature values for the free phosphate reactant (which are 0.4−0.7 pH units higher), as a result of complexing to Fe^{II} and changes in the immediate environment. In the case of $H_2PO_4^-$ this would require that the pK_a of 6.7−7.0 is shifted to 5.1 on attachment to Fe^{II}. For a full treatment the further effect of deprotonation of nearby His residues also needs to be considered.

The effects of pH on activity have been studied to higher pH′s with α-naphthyl phosphate, as illustrated in Figure 11. Maximum activity for Uf is observed at pH 4.9 whereas in the case of KBPAP and BSPAP a shift to the range pH ≈ 5.9 is observed. Earlier studies on Uf with *p*-nitrophenyl phosphate have also indicated maximum activity at pH

Scheme 1

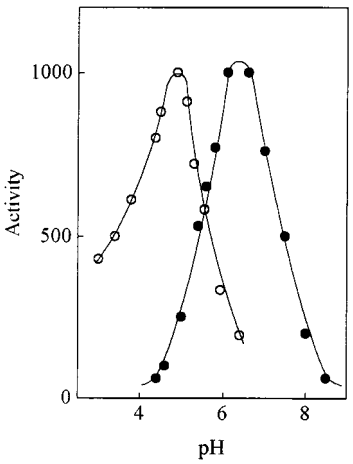
Table 1. Summary of data obtained for the reactions (25°C) of $H_2PO_4^-$, phenylphosphate, pyrophosphate with active $Fe^{II}Fe^{III}$ PAP (Uf) at pH 2.6−6.5, I = 0.10M (NaCl)[16]

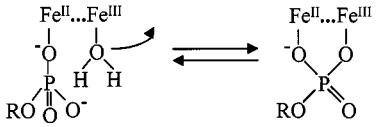
	$H_2PO_4^-$	Phenylphosphate	Pyrophosphate
pK_{1a}[a]	3.9	3.4	3.8
pK_{2a}[a]	5.1	5.0	5.4
pK_{1a}[b]	4.0		
pK_{2a}[b]	5.3		
pK_a[c]	6.9	5.6	6.0
k_1/s^{-1}	7.1	8.4	4.7
k_2/s^{-1}	1.8	1.0	2.3
k_3/s^{-1}	0.4	<0.1	0.1

[a] Recomputed using Microcal Origin 5 fitting program. − [b] Data for $Zn^{II}Fe^{III}$ Uf. − [c] Range of pK_a values for $H_2PO_4^-$ 6.7−7.0.

4.9.[86] As yet no explanation for this different behaviour of Uf as compared to BS and KBPAP has been forthcoming, although as already noted the pK_a′s assigned to $Fe^{III}-H_2O$ acid dissociation are smaller (3.9) for Uf than for BSPAP and KBPAP (4.9).

The acid dissociation process pK_{1a} giving the conjugate-base $Fe^{III}-OH$ slows down the substitution of $H_2PO_4^-$ at the Fe^{III}, but has a quite different effect on ester hydrolysis.





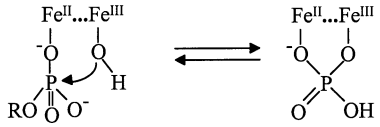


Figure 11. Variation of PAP phosphatase activity with pH, (a) for Uf (○) with 10 mM α-naphthyl phosphate (25°C) using 40 mM buffer;[16][80] and (b) for BSPAP (●), 50 mM *p*-nitrophenyl phosphate (22°C), using 100 mM buffer[100]

Phosphate Ester Hydrolysis

From the above considerations it is likely that the $Fe^{III}-OH$ conjugate-base induces phosphate ester hydrolysis. The suggestion that the μ-OH bridge might alternatively be involved,[87] seems less likely because of its less favourable nucleophilic properties. The $Fe^{III}-OH$ involvement is supported by the KBPAP catalysis of ^{18}O exchange between phosphate and solvent.[88] Rate constants k_{obs} for μ-phosphato formation are maximum at pH 3 when $Fe^{III}-H_2O$ is present exclusively. Under these conditions bridge closure can occur with displacement of the H_2O, but little or no phosphate ester hydrolysis is observed (Scheme 2). At higher pH formation and participation of $Fe^{III}-OH$ becomes more extensive, and k_{obs} decreases as the OH^- is more difficult to substitute than H_2O. However the $Fe^{III}-OH$ participates in ester hydrolysis by substitution into the P^V coordination sphere of $(RO)PO_3H^-$, with displacement of RO^- (Scheme 3). The activity plots as in Figure 11 now become relevant. The increase in activity of Uf at the lower pH′s is due to increased amounts of $Fe^{III}-OH$, which maximises at pH 4.9. The decrease in activity at the higher pH′s may relate to deprotonation of the positive patch histidines, making the binding of phosphate less effective.

Scheme 2

Scheme 3

The mechanism that emerges for PAP is thus one of repeated bridge formation and cleavage with ester hydrolysis taking place on a subsequent if not the first cycle. The reaction sequence has a number of features in common with the intramolecular phosphate hydrolysis occurring in the case of $[Co(en)_2(H_2O)\{PO_3(OC_6H_4NO_2)\}]^+$ (en = ethylenediamine), and involving the conjugate-base $[Co(en)_2(OH)\{PO_3\ (OC_6H_4NO_2\}]$.[89]

Metal Substituted PAP Derivatives

In order to clarify the role of individual metals as components of the dinuclear active site, the reactivity of metal substituted PAP′s has been studied. Work by Zerner and colleagues has shown that the Fe^{II} of active BSPAP is labile and amenable to substitution by various divalent metals (including Co^{II}, Cu^{II}, Zn^{II}, Cd^{II} and Hg^{II}).[41,76,83,90,91] The procedure used involves the reaction of PAP with dithionite for ≈ 5 minutes to remove the labile Fe^{II}, followed by reconstitution using an excess of the M^{II} salt. The effect of substitution of the Fe^{II} in Uf by Mn^{II}, Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} on UV/Vis spectra and kinetic properties has been studied. In some cases (Figure 12) substantial catalytic activity is retained by the $M^{II}Fe^{III}$ product.

The Zn^{II} substituted form of Uf is of particular interest because it resembles the KBPAP active site (Figure 13). Previous studies have shown that the properties of the $Zn^{II}Fe^{III}$ form of the BSPAP enzyme are similar to those of KBPAP.[14,40,83] In a similar manner the Zn^{II} of KBPAP can be substituted by Fe^{II} to form a catalytically active $Fe^{II}Fe^{III}$. Again the properties of the $Fe^{II}Fe^{III}$ form of the KBPAP are similar to those of native $Fe^{II}Fe^{III}$ PAP forms,[92][93] and

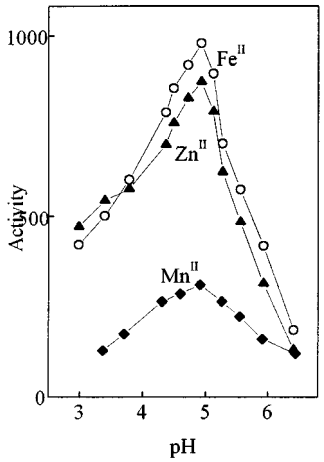

Figure 12. The variation of $M^{II}Fe^{III}$ Uf phosphatase activity (25°C) with pH (40 mM buffer) using α-naphthyl phosphate 10 mM), with M^{II} in turn Fe^{II} (○), Zn^{II} (▲), and Mn^{II} (◆)

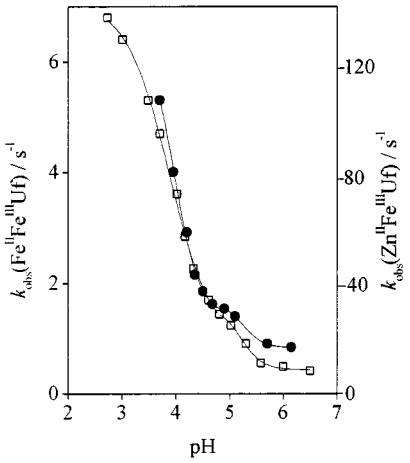

Figure 13 Variation of first-order rate constants k_{obs} (25°C) with pH for the reaction of $H_2PO_4^-$, with $Fe^{II}Fe^{III}$ Uf (□) and $Zn^{II}Fe^{III}$ Uf (●), I = 0.10M (NaCl)

vice versa for $Zn^{II}Fe^{III}$ Uf, although the reaction with $H_2PO_4^-$ is some 35 times more rapid than with $Fe^{II}Fe^{III}$ Uf at pH 4.9.[18] The $Mn^{II}Fe^{III}$ product is also of interest because Mn has been suggested as a component of sweet potato and soya bean PAP′s.[32,33,94–96] We note however that evidence for an $Fe^{II}Fe^{III}$ active site in sweet potatoes has also been reported.[97] It is unlikely that the active site contains $Mn^{II}Mn^{III}$ (as seems to be suggested), since Mn^{III}–Tyr charge transfer bands are not expected to give the same characteristic purple/pink colour as for Fe^{III} PAP′s. An appreciable blue-shift of ≈ 35 nm in phenolate to metal LMCT bands is for example observed for the Mn^{III} substituted transferrin (a lactoferrin form) as compared to the Fe^{III} form.[98]

From details of UV/Vis spectra (Table 2) it can be seen that the replacement of Fe^{II} with other divalent metals produces small but significant changes in peak positions (λ) and absorption coefficients (ε), where the products are different shades of purple. The greatest change in the peak position (λ) is for $Cu^{II}Fe^{III}$ Uf, and may indicate a different coordination of the Cu^{II}, which is known to have an affinity for *N*-donor ligands. The coupling of Fe^{II} to the Fe^{III},[45,50,51] appears to enhance ε values as compared to those for other M^{II} ions. The metal content and spectroscopic characterisation of PAP from sweet potato *Ipomea batatas* PAP has recently been carried out and establishes this as another example of a plant $Zn^{II}Fe^{III}$ protein.[99]

Table 2. UV/Vis peak positions (λ) and absorption coefficients (ε) for M^{II} substituted $M^{II}Fe^{III}$ PAP_r (Uf) (25°C), in sodium acetate buffer pH 4.9, I = 0.10M (NaCl)[80]

M^{II}	λ_{max}/nm	ε/M^{-1}cm^{-1}
Fe^{II}	510	4450[a]
Mn^{II}	514	3350
Co^{II}	518	3370
Ni^{II}	510	3260
Cu^{II}	545	3400
Zn^{II}	525	3580

Until recently metal substitution of M^{II} only was possible. In recent studies however the Fe^{III} centre has been replaced by Ga^{III} to produce $Fe^{II}Ga^{III}$ BSPAP and Zn^{II} Ga^{III} BSPAP.[100] Both forms exhibit catalytic activity similar to that of the native $Fe^{II}Fe^{III}$ BSPAP, providing evidence that diamagnetic Ga^{III} is acting as a functional analogue of Fe^{III}. Not surprisingly the gallium containing enzymes are colourless having lost the purple colour due to the tyrosine to Fe^{III} charge-transfer band. This work also provides kinetic data on the effect of substituting Fe^{II} with Zn^{II}. Thus the $Zn^{II}Fe^{III}$ BSPAP displays a 2–3 fold increase in K_M (the Michaelis constant), and nearly a twofold increase in k_{cat} relative to $Fe^{II}Fe^{III}$ BSPAP. The replacement of Fe^{II} and Fe^{III} of BSPAP to give $Zn^{II}Al^{III}$ and $Zn^{II}In^{III}$ has also been carried out.[101] There is as yet no explanation as to why the $Zn^{II}In^{III}$ form should be inactive.

Conclusions

The naturally occurring dinuclear $Fe^{II}Fe^{III}$ and $Zn^{II}Fe^{III}$ active sites of mammalian and plant purple acid phosphatases respectively make use of the M^{II} and Fe^{III} metal combination in a very subtle way to bring about phosphate ester hydrolysis. X-ray crystallographic studies on the enzyme from three different sources provides evidence for a single aqua or hydroxo ligand on each metal. The M^{II} ions are more labile, whereas Fe^{III} more readily forms conjugate-base (Fe^{III}–OH). The key roles are therefore binding of the phosphate ester to M^{II}, and the nucleophilic action of the OH^- of the Fe^{III} in bringing about phosphate ester hydrolysis. The $Fe^{III}Fe^{III}$ form of PAP has no similar enzymic action even though it does bind phosphate more strongly. The single tyrosine ligand serves to stabilise the Fe^{III} state and prevent its reduction. It also gives the enzyme its attractive colour. Other synthetic metal combinations can bring about phosphatase action although not always with the same efficiency. An essential part of the catalytic cycle is the release

of the μ-phosphate product after hydrolysis, a process which requires further investigation

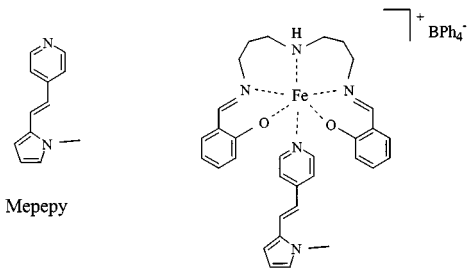
First Evidence of a Photoinduced Spin Change in an Fe^{III} Complex Using Visible Light at Room Temperature

Angélique Sour,*[a] Marie-Laure Boillot,[a] Eric Rivière,[a] and Philippe Lesot[b]



Keywords: Spin crossover / Light-induced spin change / *cis-trans* Isomerization / Visible light irradiation / Iron(III)

An iron(III) complex [Fe(salten)(Mepepy)]BPh_4 containing only one photoisomerizable ligand (Mepepy) has been synthesized, it exhibits a thermally-induced spin crossover in the solid state and in solution {H_2salten = 4-azaheptamethylene-1,7-bis(salicylideneiminate); Mepepy = 1-(pyridin-4-yl)-2-(*N*-methylpyrrol-2-yl)ethene}. The photoisomerizations of both the free and coordinated Mepepy ligand have been observed at room temperature with visible-light irradiation and monitored by UV/Vis and ^{1}H NMR spectrometries. *trans-to-cis* isomerization of only one photosensitive ligand in the iron(III) complex is sufficient to detect a partial spin change of the iron(III) ion. This photoinduced spin change is seen for the first time from a high-spin state to a low-spin state.

Spin crossover phenomena exhibited by transition metal complexes are the subject of intensive studies.[1][2] In this field, the ligand-driven light-induced spin change (LD-LISC) concept first described by our group[3] has opened up new perspectives for the purpose of optical information storage on the molecular scale. For this it is necessary to synthesize complexes in which a photoinduced modification of one or several ligands would result in a ligand field change and trigger the metal ion spin conversion.

The feasibility of the LD-LISC process was first demonstrated[3][4] at 140 K on an iron(II) complex containing four photosensitive ligands. Ultra-violet irradiation of this compound induced a *trans* ↔ *cis* isomerization of the four ligands and a subsequent low-spin (LS) ↔ high-spin (HS) conversion. More recently, the LD-LISC effect has been observed at room temperature[5] on an iron(II) complex containing two photoisomerizable ligands. A *trans* to *cis* photoconversion in this compound induced a low-spin towards high-spin change. We now want to show that the isomerization of only one photosensitive ligand is sufficient to induce a spin change. We will also show that the LD-LISC effect can be observed in an iron(III) compound. For this purpose, we present a study of an iron(III) complex containing only one photoisomerizable ligand which has the distinctive feature of absorbing visible light.

Our strategy was to coordinate an iron(III) ion to a pentadentate salten^{2-} ligand {H_2salten = 4-azaheptamethylene-1,7-bis(salicylideneiminate)}, the sixth position being occupied by a potentially photosensitive Mepepy ligand {Mepepy = 1-(pyridin-4-yl)-2-(*N*-methylpyrrol-2-yl)-ethene}.[6] The H_2salten ligand has been employed because several complexes based on this ligand are known to exhibit thermally-induced spin crossovers.[7][8] The behavior under irradiation of the Mepepy ligand has not yet been explored but the *trans* and *cis* isomers are expected to be stable and interconvertible by visible light. We report here the synthesis of [Fe(salten)(Mepepy)]BPh_4 **(1)**, its electronic and magnetic properties, and the observation of the LD-LISC effect at room temperature by suitable NMR spectroscopic experiments.

Scheme 1. The photosensitive ligand and complex made and studied

The elemental analysis, IR characterizations and the magnetic behavior allow us to propose the structure presented in Scheme 1 for [Fe(salten)(Mepepy)][BPh_4]. The magnetic susceptibility of a powdered sample of **1** was measured in the temperature range 10−320 K. The temperature dependence of the χ_M T product (χ_M = molar magnetic susceptibility) shows a gradual S = 1/2 ↔ S = 5/2 crossover of iron(III) ions (Figure 1) as expected for complexes of this family.[7][8] No thermal hysteresis was observed. The crossover taking place between 150 K and 320 K is obviously incomplete at 320 K however, due to the low thermal stability under partial vacuum, measurements at higher temperatures were not possible. The low temperature plateau around χ_M T = 0.53 $cm^3 \cdot mol^{-1} \cdot K$ indicates that nearly all molecules are in the low-spin state. In contrast, the χ_M T value at 320 K (2.68 $cm^3 \cdot mol^{-1} \cdot K$) indicates that about 55% of the molecules are in the high-spin state (assuming that χ_M T= S(S+1)/2 = 4.4 $cm^3 \cdot mol^{-1} \cdot K$ for S = 5/2).

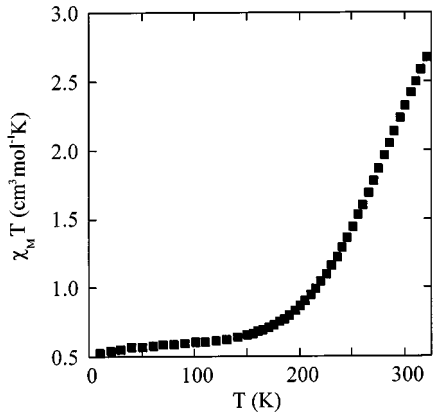

Figure 1. Temperature dependence of χ_M T of [Fe(salten)(Mepepy)]BPh_4 as a powder

Irradiation of the uncoordinated Mepepy ligand was carried out first. The experiments were performed at $\lambda = 405 \pm 5$ nm on acetonitrile solutions at room temperature and monitored by UV/Vis and NMR spectrometry. The UV/Vis spectrum of the free Mepepy ligand shows two $\pi-\pi^*$ transition bands (Figure 2a). Upon irradiation, the strongest effect is observed on the band at $\lambda_{max} = 353$ nm ($\varepsilon = 22800$ M^{-1}·cm^{-1}) which is slightly blue-shifted and decreases to about half its intensity. The band at $\lambda_{max} = 241$ nm ($\varepsilon = 7800$ M^{-1}·cm^{-1}) is less affected. An isosbestic point is observed at 300 nm. Irradiation of the ligand in an NMR tube in deuterated acetonitrile (10^{-3} M) leads to a photostationary state which is composed of 66% of the *cis* isomer and 34% of the *trans* isomer.[9] From these results it is possible to compute the absorption band for the pure *cis* isomer, which is represented in Figure 2a.

We then studied the effect of light on the complex [Fe(salten)(Mepepy)]BPh_4 under the same conditions of solvent and temperature. Irradiation of solutions at wavelengths in the range 320−405 nm leads to very similar evolutions of the UV spectra and the photostationary states are reached within a few minutes. We chose to investigate the effect of visible light at $\lambda = 405 \pm 5$ nm, as for Mepepy. The UV/Vis absorption spectrum of **1** in a 1.87×10^{-5} M acetonitrile solution (Figure 2b) shows a strong band ($\lambda_{max} = 351$ nm, $\varepsilon = 62000$ M^{-1}·cm^{-1}) which can be assigned to a "Mepepy"-centered $\pi-\pi^*$ transition and a weaker band ($\lambda_{max} = 480$ nm, $\varepsilon = 6900$ M^{-1}·cm^{-1}) arising from a ligand-to-metal charge transfer (LMCT). Irradiation of this solution (Figure 2b) leads both to a slight blue-shift of the Mepepy-centered $\pi-\pi^*$ band (from 351 to 345 nm) and to a pronounced decrease of its intensity (from $\varepsilon = 62000$ to $\varepsilon = 39000$ M^{-1}·cm^{-1} at 351 nm). In contrast, the LMCT band at 480 nm is essentially unaffected. The presence of a well defined isosbestic point at 301 nm shows the coexistence of only two molecular species upon irradiation. The parallel evolution upon irradiation of the $\pi-\pi^*$ band of uncoordinated and coordinated Mepepy strongly suggests that irradiation of **1** also causes a *trans* to *cis* photoisomerization of the coordinated Mepepy.

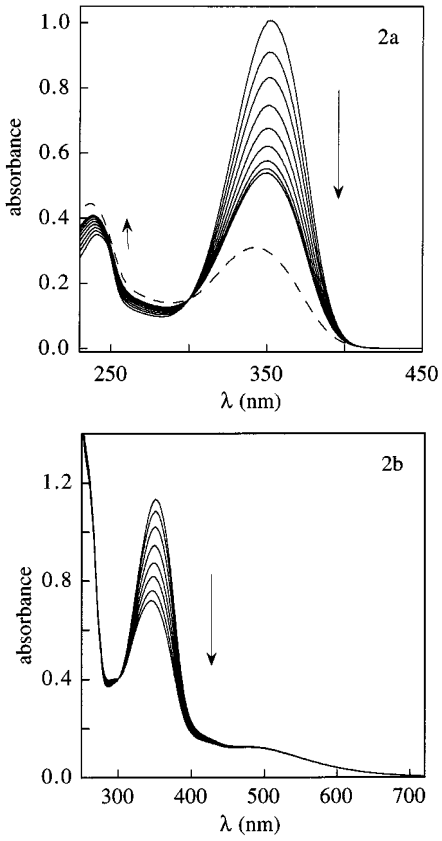

Figure 2. UV/Visible absorption spectra and evolutions upon irradiation at 405 nm of acetonitrile solutions of Mepepy (10^{-5} M) (2a) and of [Fe(salten)(Mepepy)]BPh_4 (1.87×10^{-5} M) (2b); the spectrum in dashed lines in 2a represents the calculated spectrum of pure *cis*-Mepepy

The magnetic susceptibility, and its variation under irradiation, of acetonitrile solutions of **1** were measured by the Evans method (^{1}H NMR spectrometry).[10][11] The temperature dependence of χ_M T has been obtained between 243 K and 333 K for a 10^{-2} M CD_3CN solution of **1** before irradiation. Figure 3 reveals a thermal spin-crossover behavior with χ_M T increasing from 1.48 cm^3·mol^{-1}·K at 243 K to 3.61 cm^3·mol^{-1}·K at 333 K.

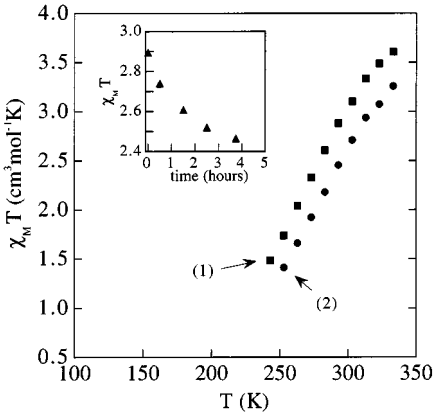

Figure 3. Temperature dependence of χ_M T of a CD_3CN solution (10^{-2} M) of [Fe(salten)(Mepepy)]BPh_4 before irradiation (1) and of a 10^{-3} M CD_3CN solution of the steady state (2); inset: time dependence of χ_M T of a 10^{-3} M CD_3CN solution of [Fe(salten)(Mepepy)]BPh_4

A 10^{-3} M CD_3CN solution of **1** in a capillary has been irradiated at room temperature. The irradiation induces a small decrease (inset of Figure 3) of χ_M T at 294 K from 2.89 to 2.46 $cm^3 \cdot mol^{-1} \cdot K$. This allows us to infer that **1** undergoes a partial HS ↔ LS change under irradiation. The temperature dependence of χ_M T of the steady state (Figure 3) reveals a thermal spin-crossover behavior with χ_M T increasing from 1.41 $cm^3 \cdot mol^{-1} \cdot K$ at 253 K to 3.26 $cm^3 \cdot mol^{-1} \cdot K$ at 333 K. The thermal spin crossovers before as well as after irradiation are reversible. Furthermore, it should be noted that solutions before and after irradiation are stable in the dark.

It is worth pointing out that the photoisomerization of a *trans* to *cis* styryl-pyridine group in an iron(II) complex[4][5] results in a spin change from a low-spin state to a high-spin state. We report here the first example where light irradiation leads to a spin change in the opposite direction. This apparent discrepancy can be explained: as the methylpyrrole moiety of the Mepepy ligand is a strong π-donor group,[6] the conversion of the *trans* isomer into the *cis* isomer results in a decrease of the π-donor character of the ligand and thus increases the ligand field strength and induces the HS ↔ LS change.

In conclusion, we have described the first Fe^{III} complex able to present a "Ligand-Driven Light-Induced Spin Change" behavior at room temperature. The complex contains only one photosensitive ligand which can be effectively photoisomerized by visible light. We have characterized the *trans* to *cis* photoisomerizations of the uncoordinated and coordinated Mepepy ligand and demonstrated that the *trans* to *cis* isomerization in complex **1** is accompanied by a small, but significant, decrease of χ_M T, which shows an unusual high-spin to low-spin change.

Attempts are currently underway to cast thin films of **1** in order to study the effect of light in the solid state.

Experimental Section

General: Starting materials were purchased from Acros. Solvents were purchased from Merck. Acetonitrile was distilled from CaH_2. The photosensitive ligand and its complexe were prepared and handled under darkness to prevent photoisomerization. Magnetic Measurements: Quantum Design SQUID Magnetometer (MPMS5S model). UV/Vis: Varian Cary 5E or Cary 300. IR: Perkin−Elmer Spectrum 1000. NMR: Bruker AM 400 (400 MHz). Evans NMR: the NMR tube is equipped with a special stem coaxial insert (Wilmad, WGS − 5BL). Irradiation: 200 W Hg (Xe) lamp (Oriel) with a standard bandpass filter 405 FS10−25 (Andover Corporation).

The ligand Mepepy[6] was prepared according to the published procedure. − ^{1}H NMR (CD_3CN, 400 MHz): δ = 8.47 (d, J = 5.9 Hz, 2 H), 7.40 (d, J = 5.9 Hz, 2 H), 7.35 (d, J = 16.2 Hz, 1 H), 6.84 (d, J = 16.2 Hz, 1 H), 6.76 (m, 1 H), 6.59 (m, 1 H), 6.11 (m, 1 H), 3.72 (s, 3 H). − IR (KBr): $\tilde{\nu}$ = 955, 965 (C=C *trans*), 1590 (pyridine) cm^{-1}.

[Fe(salten)Cl][7] was prepared according to the published procedure.

[Fe(salten)(Mepepy)][BPh_4] 1: To a solution of [Fe(salten)Cl] (360 mg, 0.84 mmol) in MeOH (16 mL) was added a solution of Mepepy (201 mg, 1.09 mmol) in MeOH (2 mL). The mixture was warmed at 60°C for 1 hour, then filtered. To the filtrate was added a solution of sodium tetraphenylborate (288 mg, 0.84 mmol) in MeOH (4 mL). The mixture was then warmed for a further 5 minutes at 60°C and allowed to stand overnight. The precipitate was filtered off, washed with cold MeOH (3 mL), water (3 × 10 mL), Et_2O (2 × 15 mL) and dried in vacuo for 2 hours to give 466 mg of a black microcrystalline powder (yield 62%). − $C_{56}H_{55}BFeN_5O_2$ (896.7): calcd. C 74.97, H 6.18, N 7.81, Fe 6.24; found C 75.01, H 6.27, N 7.82, Fe 6.00. − IR (KBr): $\tilde{\nu}$ = 3231, 3214 (N−H), 1600 (pyridine), 950 (C=C *trans*), 732, 706, 611 (BPh_4) cm^{-1}.

Acknowledgments

This work was supported by the CNRS (France) and the research fund TMR of the European Community (contract ERB − FMRX − CT 98−0199). We thank Prof. R. Clément for fruitful discussions during the preparation of this manuscript.

The First Thioallenylidene Complexes from Ruthenium-Butatrienylidene Intermediates

Rainer F. Winter*[a]

Keywords: Ruthenium / Allenylidene complexes / Butadiyne / Electrochemistry / Thio-Claisen rearrangements

Ruthenium-butatrienylidene cations *trans*-[Cl(L$_2$)$_2$Ru=C=C=C=CH$_2$]$^+$ are key intermediates in the synthesis of the first thioallenylidene complexes *trans*-[Cl(L$_2$)$_2$Ru=C=C=C(SR)R′]$^+$ (L$_2$ = dppm, R = Et, R′ = Me: **3a**, L$_2$ = dppm, R = Me, R′ = C$_4$H$_7$: **3b**, L$_2$ = dppe, R = C$_3$H$_5$, R′ = C$_4$H$_7$: **3c**). Spectroscopic and electrochemical data for **3a–c** are presented and are compared with those of their aminoallenylidene analogues. Aminoallenylidene complexes are best represented by the iminiumalkynyl resonance form, while a true cumulene description is much more appropriate for thioallenylidene complexes **3a–c**. Based on a combination of spectroscopic and electrochemical data, we present evidence that the NMR shifts of the carbon atoms of the unsaturated ligand in these allenylidene complexes are correlated to the HOMO–LUMO gap. In situ EPR-, UV/Vis-, and IR-spectro-electrochemistry reveals that the one-electron oxidation occurs at the metal center, while reduction occurs at the carbon–heteroatom terminus.

Introduction

Despite considerable progress in the field of higher homologues of carbene complexes,[1] as yet no stable mononuclear butatrienylidene complex has been reported.[2] There are, however, a growing number of instances where iron or ruthenium butatrienylidene compounds are invoked as key intermediates. Following Selegue′s initial report on the generation of such a species from a coordinated alkynyl ketone,[3] we and others have elaborated a more direct access route starting from substitutionally labile iron or ruthenium precursors [Cp*Fe(dppe)Cl], [CpRu(PPh$_3$)$_2$Cl], or *cis*-[Cl$_2$Ru(L$_2$)$_2$] (L$_2$ = dppm, depe) and butadiyne. The reactivity of the C$_4$H$_2$ ligand is dominated by the alternation of electrophilic and nucleophilic carbon centers and the easy access to the sterically unprotected terminal C=C bond. Apart from remarkable cycloaddition−cycloreversion sequences with aromatic imines,[4] two major reaction types have been identified so far: (i) regioselective addition of protic nucleophiles to the terminal C$_\gamma$=C$_\delta$ bond to give methyl-substituted allenylidene complexes,[5] and (ii) regioselective addition of aprotic nucleophiles to the electron-deficient C$_\gamma$, C$_\alpha$ being sterically protected by the bulky phosphane coligands on ruthenium.[5−7] The initial addition step may be followed by tautomerization,[5a,b] Cope-type rearrangements of quaternary vinylammonium salts resulting from the addition of allylic amines,[6a] or by a shift of the resonance stabilized ferrocenylmethyl cation to the neighbouring nucleophilic C$_\delta$ to give an aminoallenylidene complex with an appended redox-active substituent.[7] We report herein on the successful synthesis of the first thioallenylidene complexes [{Ru}=C=C=C(SR)R′]$^+$ from butatrienylidene intermediates.

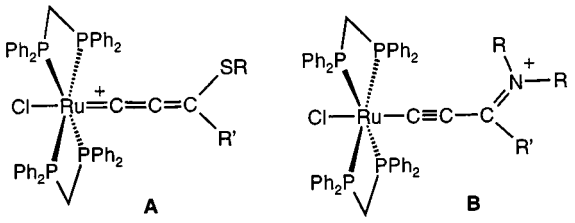
Results and Discussion

We have successfully employed both fundamental strategies, i.e. the regioselective addition of a protic nucleophile (a thiol) and the addition of aprotic nucleophiles (allylic thioethers) with subsequent [3,3] thio-Claisen rearrangement, to effect the synthesis of *trans*-[Cl(L$_2$)$_2$Ru=C=C=C(SR)R′]$^+$ X$^-$ (**3a−c**, L$_2$ = dppm, dppe, X$^-$ = SbF$_6^-$, OTf$^-$, Scheme 1), the first examples of thioallenylidene complexes. Their identities have been unequivocally established by spectroscopic means. The *trans* arrangement of the chloride and allenylidene ligands follows directly from the observation of two ABX$_2$X′$_2$ spin systems for the methylene groups of the dppm ligand and single sharp singlets in the respective ^{31}P-NMR spectra. Our spectroscopic data place the intense yellow-green (**3a**,**b**) or red (**3c**) thioallenylidene complexes close to "conventional" allenylidene analogues without a heteroatom substituent attached to C$_\gamma$. This is exemplified by the intense IR stretch of the C=C=C unit, which is found at ca. 1940 cm^{-1} for **3a−c**, at 1995 cm^{-1} for aminoallenylidene complexes,[6,7] at 1955 cm^{-1} for alkyloxy-substituted allenylidene complexes,[8] and at ca. 1920 to 1950 cm^{-1} for aryl- or alkyl-substituted allenylidene complexes of the same metal fragment.[9]



There is ample precedent that aminoallenylidene complexes are best represented by the iminiumalkynyl resonance form **B**.[6,10,11] This is not only evident from the position of the C=C=C stretch in the IR spectrum and the ^{13}C data (vide infra), but also from the two separate resonance signals seen for the identical substituents on the iminium nitrogen atom. High-temperature NMR studies on *trans*-[Cl(dppm)$_2$Ru−C≡C−C(=NMe$_2$)C$_2$H$_4$CH=CH$_2$]$^+$ PF$_6^-$ (**4a**) and its depe-substituted counterpart **4b** reveal that even at 368 K in CD$_3$NO$_2$ the two NMe resonances remain separate and sharp. From this, the barrier to rotation about this C=N bond can be estimated to be well above 71 and 76 kJ mol^{-1}, respectively. On the other hand, thioallenylidene

Scheme 1. Synthesis of the thioallenylidene complexes **3a−c**

complexes **3a−c** are adequately described by the true allenylidene resonance form **A**.

The ^{13}C-NMR signals of the carbon atoms of the unsaturated ligands in **3a−c** are readily discernible and may be assigned by virtue of the P−C coupling constants and the chemical shift values. For other *heteroatom-substituted* allenylidene complexes, both are known to decrease with increasing distance from the metal center.[5−8] ^{13}C-NMR data for a variety of allenylidene complexes containing the *trans*-$[ClRu(dppm)_2]^+$ fragment are collected in Table 1. The following trends emerge: (i) All three carbon atom signals of the cumulene chain are subject to a progressive downfield shift in the order $NR_2 < OR < SR < CR_3$. (ii) The influence of the heteroatom on the shift values *decreases* with *increasing distance* from the *metal center*, with the substituted C_γ being rather insensitive to the nature of the atom attached to it. Thus, the shift differences $\Delta\delta$ for equivalent carbon atoms in all-carbon and amino-substituted allenylidene complexes, which constitute the two extremes in Table 1, amount to ca. 120 ppm for C_α, 90 ppm for C_β, but less than 20 ppm for C_γ.

It has long been known that the characteristic low-field shifts of metal-bound carbene, vinylidene, and cumulenylidene carbon atoms (and obviously also to a lesser degree of C_β) are induced by the paramagnetic term, which itself is related to the HOMO−LUMO gap.[12] We observe a clear manifestation of this trend upon comparison of the electrochemical and optical data for the novel thioallenylidene complexes **3a−c** and those for our aminoallenylidene cations *trans*-$[Cl(dppm)_2Ru{-}C{\equiv}C{-}C(=NMe_2)C_2H_4R]^+$ [R = $CH{=}CH_2$: **4a**, R = $(\eta^5\text{-}C_5H_4)Fe(\eta^5\text{-}C_5H_5)$, Fc: **4c**, Table 2].[6,7] All the complexes undergo well-defined one-electron oxidations and one-electron reductions at potentials that are clearly dependent on the heteroatom attached

to C_γ (Table 2). As is evident from a comparison of the CV traces shown in Figure 1, replacing NR_2 by SR substituents induces significant cathodic shifts in the oxidation and reduction potentials of 0.3 and 0.8 V, respectively. As one may infer from these data, the LUMO is preferentially lowered with respect to the HOMO which, of course, reduces the HOMO−LUMO gap. As a consequence, the energies of the intense optical absorptions in the visible part of the spectra decrease considerably in this series. For aminoallenylidene complexes, this band apparently has some metal-to-ligand charge-transfer (MLCT) character, as indicated by the negative solvatochromism of the order of some 450 to 720 cm^{-1}. In contrast, no such effect is apparent for thioallenylidene complexes **3a−c**. Optical transition energies consistently exceed those measured by electrochemical methods. This is due to the vertical excitation involved in the optical transition (Franck−Condon principle) as compared to the "true" energy difference between the vibrationally relaxed ground and excited states determined by electrochemical methods. The energy difference $\Delta E_{op} - \Delta E_{ec}$ provides a measure of the vibrational excitation associated with the optical transition and therefore of the degree of structural reorganization required upon excitation, and is parameterized as the structural factor $\Delta\chi$ (Equation 1).[13]

$$\Delta E_{op} = \Delta E_{ec} + \Delta\chi \quad (1)$$

In our heteroatom-substituted allenylidene complexes of the dppm ligand, $\Delta\chi$ amounts to 0.46 to 0.47 eV, indicating a moderate degree of structural rearrangement on going from the ground to the excited states. The fact that other values of $\Delta\chi$ are found for complexes with diphosphane chelate ligands other than dppm suggests that the predominant structural change occurs at the metal fragment. Unfortunately, no UV/Vis data have been reported for any other allenylidene complexes containing the *trans*-

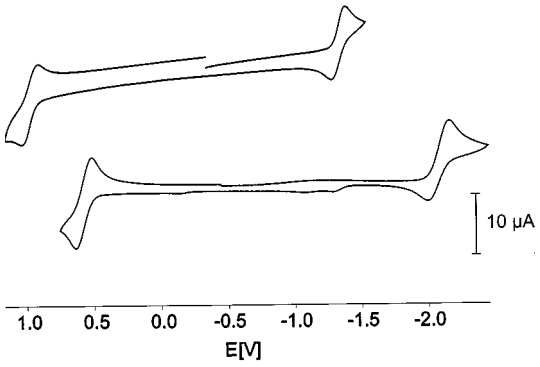

Figure 1. CV traces of *trans*-[Cl(dppm)$_2$Ru−C≡C−C=(NMe_2)C_4H_7]$^+$ (**4a**) at 231 K and *v* = 1 V/s (lower trace) and *trans*-[Cl(dppm)$_2$Ru=C=C=C=(SMe)C_4H_7]$^+$ (**3b**) at 273 K and *v* = 0.2 V/s (upper trace) in CH_3CN

[Cl(dppm)$_2$Ru]$^+$ fragment. Judging, however, from the colours (alkyloxy-substituted allenylidene complexes are orange, while all-carbon substituted analogues are violet to purple)[8,9] and the optical data for the closely related [CpRu(PPh_3)$_2$]$^+$ derivatives,[14] we conclude that the HOMO−LUMO gap decreases in the series NR_2 > OR > SR > CR_3, thus providing a rationale for the observed trends in the ^{13}C-NMR data.

The differences in redox potentials also have a bearing on the chemical stabilities of the oxidation and reduction products (see Figure 1). For the aminoallenylidene complexes **4a**, **c** and the depe derivative *trans*-[Cl(depe)$_2$-Ru−C≡C−C(=NMe_2)$C_2H_4CH=CH_2$]$^+$ (**4b**), the oxidation process is fully reversible, while for the reduction low temperature and sweep rates of about 1 V/s are required to allow the observation of an associated return peak.[7] For thioallenylidene complexes **3a−c**, on the other hand, just the opposite order of stabilities is observed. This makes the oxidation products of **4a−c** and the reduction products of

3a−c amenable to spectroscopic characterization. Such investigations can be expected to provide information on the oxidation and reduction sites within these allenylidene complexes. In their EPR spectra at 110 K and 4 K, electrochemically oxidized samples of **4c** exhibit an axial pattern at $g_{\parallel} = 2.400$ and $g_{\perp} = 2.067$, respectively. No EPR signals were observed for **4a**. The rather low intensity of the EPR signals and the considerable spread of g values are both supportive of an assignment to an Ru-based radical, such that the oxidation may be viewed as essentially involving a ruthenium(II/III) redox couple. This is also in accord with our observation that fully oxidized *trans*-$[Cl(dppm)_2Ru-C\equiv C-C(=NMe_2)C_2H_4Fc]^{3+}$ (**4c**) displays an intense triplet signal at $g = 2.0064$ arising from coupling of the ferrocinium subunit to a paramagnetic Ru(III) center, giving too weak a signal to be observed directly. The same conclusion has already been reached from UV/Vis and IR spectro-electrochemical studies of this complex.[7]

In the frozen state, the reduced form of the thio-substituted allenylidene complex **3b** exhibits a broadened isotropic signal at $g = 2.0031$, i.e. in a region characteristic of organic radicals. On warming to 295 K, the spectrum gradually resolves into a quintet of triplets, which we successfully simulated assuming coupling constants of 9.86 and 6.60 Gauss (Figure 2). This coupling pattern points to the reduction occurring at the heteroatom-substituted terminus of the allenylidene ligand. The triplet splitting then arises from coupling to the neighbouring methylene group, and the quintet from coupling to the four equivalent phosphorus nuclei across the cumulene bridge. From the resonance form for reduced **3b** shown in Figure 2, one would expect an increase in bond order of the $C_\alpha-C_\beta$ bond from C=C to C≡C upon reduction. On following this process by IR spectro-electrochemistry, the intense allenylidene band does indeed gradually disappear, which is accompanied by the concomitant formation of a new, much weaker feature at 2048 cm^{-1} (Figure 3). The position of this band is characteristic of alkynyl complexes of the *trans*-$[Cl(dppm)_2Ru]^+$ fragment.[8] A severe reduction in absorptivity on going from allenylidene to alkynyl[8] and from cationic to neutral complexes[15] has already been described in the literature. We should state that even in our best runs the reduction was accompanied by some decomposition, as indicated by the fact that only 60% of the initial band intensity was regained upon reoxidation. Nevertheless, we are certain that the observed band at 2048 cm^{-1} originates from the reduced counterpart of **3b** since, upon reoxidation, this band gradually disappears while the original band is partly restored.

In situ UV/Vis spectro-electrochemical experiments require lower concentrations and therefore shorter electrolysis times. Thus, the reduction/reoxidation cycle of **3b** proceeded with more than 90% recovery of the starting material. Upon reduction, the intense allenylidene band at $\lambda = 465$ nm disappears and is replaced by a less intense absorption (log $\varepsilon = 3.980$) at ca. 306 nm, a region characteristic for Ru(II)−alkynyl complexes (Figure 4). We have observed bands with similar positions and intensities for the related

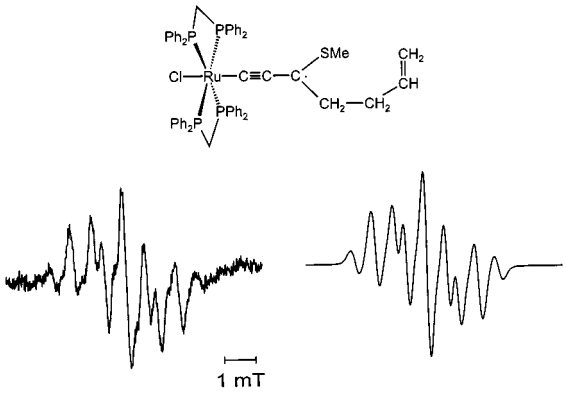

Figure 2. Experimental and simulated EPR spectra of in situ generated *trans*-$[Cl(dppm)_2Ru-C\equiv C-C=(SMe)C_4H_7]^{\bullet}$ at 295 K

ammoniobutenynyl complexes *trans*-$[ClRu(dppm)_2-C\equiv C-C-(NR_2R')=CH_2]^+$ that result from the trapping of butatrienylidene complexes with tertiary aliphatic or benzylic amines.[6b] Furthermore, the n-π* type transition originating from the dppm ligand is shifted from 271 nm to 263 nm while largely retaining its absorptivity. All this points to reduction of thioallenylidene complexes **3a−c** occurring at the C-heteroatom terminus of the unsaturated ligand, with accompanying changes in the CCC bonding mode.

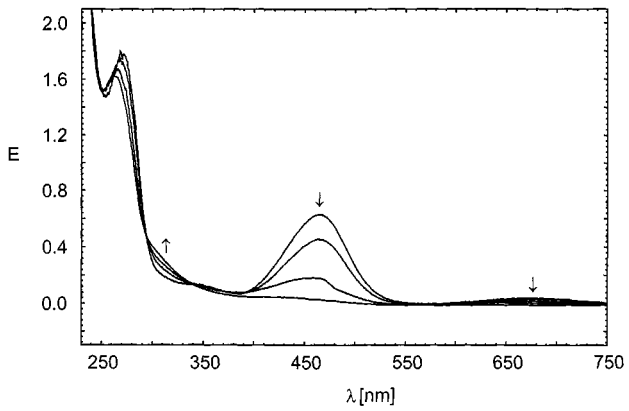

Figure 4. UV/Vis spectroscopic changes during the reduction of *trans*-$[Cl(dppm)_2Ru=C=C=C=(SMe)C_4H_7]^+$ (**3b**)

In summary, we have described the first thio-substituted allenylidene complexes. They are formed by the trapping of Ru-butatrienylidene intermediates by thiols or allylic thioethers. This provides a further example of the utilization of such intermediates in the synthesis of highly unsaturated and functionalized, yet stable ligands. A comparison of the optical, ^{13}C-NMR, and electrochemical data of a series of allenylidene complexes provides a rationale for the observed trend in the ^{13}C-NMR shifts (NR_2 < OR < SR < CR_3) as arising from the decreasing HOMO−LUMO gap within this series. In situ spectro-electrochemical investigations of the oxidized forms of amino-substituted complexes **4b**, **c** and the reduced form of the thioallenylidene complex **3b** have allowed identification of the oxidation and reduction sites within these complexes. Oxidation occurs at the metal center, while the reduction occurs at the *C*-heteroatom terminus and thus at the opposite end of the cumulenic chain. Our findings are in full agreement with EHMO calculations on the cationic allenylidene complexes $[\eta^5\text{-}C_5H_5Ru(CO)(PH_3)=C=C=CH_2]^+$[16a] and $[\eta^5\text{-}C_9H_7Ru(PH_3)_2=C=C=CH_2]^+$.[16b] Both indicate that the HOMO is dominated by contributions from the Ru d-orbitals, while the LUMO is mainly localized on the unsaturated ligand. We now aim to extend our investigations to differently substituted allenylidene complexes in order to probe the general validity of our conclusions.

Experimental Section

All manipulations were performed by standard Schlenk techniques under argon atmosphere. Dichloromethane, hexanes, and acetonitrile were dried by distillation from CaH_2. All solvents were deoxygenated either by at least three freeze-pump-thaw cycles or by saturating with argon prior to use. $[RuCl_2(dmso)_4]$[17] and *cis*-$[RuCl_2(dppm)_2]$ (**1**)[18] were obtained according to literature methods. Butadiyne was prepared from 1,4-dichlorobut-2-yne (Lancaster) on a 4 mmol scale by a slight modification of a published procedure[19] and was isolated at 195 K as a white crystalline solid. ***CAUTION:*** Butadiyne should be handled and stored under rigorous exclusion of air and at temperatures below 230 K. Prior to use, it was thawed in an ice/$CaCl_2$ cooling bath and the required amount (ca. 600 μL) was transferred via a precooled pipette. − NMR: Bruker AC 250. − IR: Elmer Paragon 1000 PC. − UV/Vis: Shimadzu UV-160 or Omega 10 from Bruins Instruments. − EPR: Bruker ESP 3000, HP frequency counter 5350 B, Bruker NMR gaussmeter ER 035 M, with a continuous flow cryostat ESR 900 from Oxford Instruments for low-temperature work. Electrochemistry was performed as described in an earlier publication.[20]

Preparation of *trans*-$[ClRu(dppm)_2=C=C=C(SEt)Me]^+$ SbF_6^- (3a): To a suspension of 171 mg (0.18 mmol) of *cis*-$[RuCl_2(dppm)_2]$ (**1**) and 379 mg (1.46 mmol) of $NaSbF_6$ in 40 mL of CH_2Cl_2, excess butadiyne (ca. 600 μL) was added by syringe. After the colour of the suspension had changed to green, 160 μL (2.16 mmol) of EtSH was added by syringe. The resulting solution was stirred under ambient conditions for 23 h, then filtered, and concentrated to dryness. The residue was thoroughly washed with hexanes. The crude product was then redissolved in chloroform and this solution was stirred at 50°C for 3 days. After evaporation of the solvent, the crude material was chromatographed on silica gel (4% H_2O, column 14 × 3 cm). The product was eluted with CH_2Cl_2/CH_3CN, 8:1, as a yellow-green band. The solvents were removed in vacuo and the remaining green solid was washed with hexanes and dried in vacuo; 72 mg (32%). − ^{1}H NMR ($CDCl_3$): δ = 0.73 [t, 3 H, SCH_2CH_3, ^3J(HH) = 7.54 Hz], 1.10 (s, 3 H, CH_3), 1.62 [q, 2 H, SCH_2, ^3J(HH) = 7.54 Hz], 5.00 [dquint, 2 H, CH_2(dppm), J(HH) = 15.46 Hz, ^2J(PH) = ^4J(P′H) = 4.10 Hz], 5.26 [dquint, 2 H, CH_2(dppm), J(HH) = 15.46 Hz, ^2J(PH) = ^4J(P′H) = 5.00 Hz], 7.13 [t, 8 H, aryl(dppm), ^3J(H-H) = 7.52 Hz], 7.29 [m, 8 H, aryl(dppm)], 7.29 [t, 16 H, aryl(dppm), ^3J(HH) = 7.47 Hz], 7.38 [m, 8 H, aryl(dppm)]. − ^{13}C{^{1}H} NMR (62.9 MHz, CD_3COCD_3): δ = 12.5 (s, SCH_2CH_3), 29.4 (s, SCH_2), 32.8 (s, CH_3), 46.1 [quint, CH_2(dppm), J(PC) = 12.05 Hz], 128.9, 129.5 (quint, *p*-C_6H_5, N = 2.5 Hz), 131.1, 131.8 (s, *m*-C_6H_5), 132.6 (quint, *ipso*-C_6H_5, N = 12.6 Hz), 133.2 (quint, *ipso*-C_6H_5, N = 11.5 Hz), 133.7 (quint, *o*-C_6H_5, N = 3.1 Hz), 134.0 (quint, *o*-C_6H_5, N = 2.9 Hz), 168.3 [quint, C_γ, ^4J(PC) = 1.65 Hz], 172.1 [quint, C_β, ^3J(PC) = 2.3 Hz], 286.2 [quint, C_α, ^2J(PC) = 13.6 Hz]. − ^{31}P{^{1}H} NMR (101.3 MHz): δ = −12.5 [s, P(dppm)]. − IR (KBr): $\tilde{\nu}$ = 1943 (vs, CCC). − UV/Vis (CH_3CN): λ_{max} (log ε) = 232 nm (4.643), 261 (4.556), 320 (sh, 3.908), 460 (3.892), 633 (sh, 3.410), 675 (3.505). Preparation of *trans*-$[ClRu(dppe)_2=C=C=C(SC_3H_5)C_4H_7]^+$ $CF_3SO_3^-$ (3c): A solution of 42 mg (41 μmol) of $[ClRu(dppe)_2]^+$ $CF_3SO_3^-$[21] in $CDCl_3$ was treated with excess butadiyne. After

30 min, 25 μL of $S(C_3H_5)_2$ (0.19 mmol) was added by means of a syringe. The progress of the reaction was monitored by ^{31}P-NMR spectroscopy. After a further 30 min, **3c** was the only identifiable product. The solution was transferred to a Schlenk tube and the solvent was removed in vacuo. Recrystallization from CH_2Cl_2/Et_2O afforded deep-red crystals. A further crop of microcrystals was obtained by concentration of the mother liquor; total yield 41 mg (84%). – ^1H NMR ($CDCl_3$): δ = 1.97 [br. d, 2 H, SCH_2, J(HH) = 6.44 Hz], 2.21 [br. t, 2 H, CH_2, J(HH) = 7.83 Hz], 2.33 (m, 2 H, CH_2), 2.76 [br. t, 2 H, CH_2 (dppe)], 3.00 [br. m, 2 H, CH_2 (dppe)], 4.76 [ddt, 1 H, =CH, ^3J(HH-*trans*) = 16.52 Hz, ^2J(HH) = ^4J(HH) = 1.4 Hz], 4.93 [ddt, 1 H, =CH, ^3J(HH-*cis*) = 9.92 Hz, ^2J(HH) = ^4J(HH) = 1.5 Hz], 4.98–5.11 (m, 3 H, =CH), 5.75 (m, 1 H, =CH), 6.92 [t, 8 H, aryl(dppe), ^3J(H-H) = 7.55 Hz], 7.04–7.14 [m, 24 H, aryl(dppe)], 7.22 [t, 8 H, aryl(dppe), ^3J(H-H) = 7.23 Hz], 7.32 [m, 8 H, aryl(dppe)]. – $^{13}C\{^1H\}$ NMR (62.9 MHz, $CDCl_3$): δ = 29.8 [quint, CH_2 (dppe), N(PC) = 11.6 Hz], 32.3, 36.5, 45.1 (s, CH_2), 116.8, 120.6 (s, $=CH_2$), 127.7, 128.6 (quint, *p*-C_6H_5, N = 2.4 Hz), 129.4 (=CH), 130.2, 131.0 (*m*-C_6H_5), 132.5 (quint, *ipso*-C_6H_5, N = 11.6 Hz), 133.1 (quint, *ipso*-C_6H_5, N = 11.0 Hz), 132.3 (quint, *o*-C_6H_5, N = 3.0 Hz), 133.8 (quint, *o*-C_6H_5, N = 2.6 Hz), 136.0 (s, =CH), 169.8, 170.2 (C_β, C_γ) 285.1 [quint, C_α, ^2J(PC) = 13.2 Hz]. – $^{31}P\{^1H\}$ NMR (101.3 MHz): δ = 42.5 [s, P(dppm)]. – IR (KBr): $\tilde{\nu}$ = 1939 (vs, CCC). – UV/Vis (CH_3CN) λ_{max} (log ε) = 231 nm (4.706), 265 (4.628), 368 (3.455), 471 (4.230), 681 (2.332); (CH_2Cl_2): λ_{max} (log ε) = 267 (4.623), 370 (3.470), 475 (4.230), 695 (2.380). – $C_{63}H_{60}ClF_3O_3P_4RuS_2$ (1246.7): calcd. C 60.70, H 4.85; found C 60.76, H 4.88.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Prof. Dr. W. Kaim, and the Institut für Anorganische Chemie der Universität Stuttgart. I also wish to thank Mr. cand. chem. Matthias Wanner for the recording of the EPR spectra and Mr. Dirk Weber for his contributions as part of an advanced laboratory course.

Molecular Precursors to Group 13 Nitrides, 14 [+]

Synthesis and Structures of $(N_3)_2Ga[(CH_2)_3NMe_2]$, $(N_3)Ga[(CH_2)_3NMe_2]_2$ and $(N_3)_3Ga(NR_3)$ (R = CH_3, C_2H_5)

Anjana Devi,[a] Harald Sussek,[a] Hans Pritzkow,[b] Manuela Winter,[a] and Roland A. Fischer*[a]

Keywords: Gallium / Azides / Chemical vapour deposition / Gallium nitride / Single source precursors

The synthesis, properties and X-ray single crystal structure analysis of the intramolecularly adduct-stabilised organogallium bisazide $(N_3)_2Ga[(CH_2)_3NMe_2]$ (**1**), the mono azide $(N_3)Ga[(CH_2)_3NMe_2]_2$ (**2**) and the trialkylamine adducts of triazidogallium of the type $(N_3)_3Ga(NR_3)$ (**3a**–**d**; R = alkyl) are reported. An unusual isomer **1b** of compound **1** is described, which was obtained by slow cooling of the analytically pure neat liquid compound **1** to 0 °C. The new and unusual structure **1b** can be regarded as a weak associate of dimers linked together by head-to-tail azide bridges. In contrast, compounds **2** and **3a**–**b** (R = CH_3, C_2H_5) are monomeric in the solid state. The suitability of the volatile compounds **1** and **2** as single source precursors to grow GaN thin films by chemical vapour deposition is compared, showing that preferentially oriented crystalline films can be obtained from compound **2** on sapphire substrates at 600–700 °C in vacuo (0.1 Pa). However the films have a grey rather than a transparent appearance, which is presumably due to N-deficiency owing to the lower N-content of the single molecule precursor **2** relative to **1**.

Introduction

The binary group 13 nitride GaN, and its ternary mixed phases with Al and In, are very promising materials for advanced microelectronic and optoelectronic devices such as light emitting diodes and lasers, high temperature and high power devices, as well as chemical sensors, acoustic surface-wave conductors and passivation layers (AlN) for GaAs[1–4] Organometallic vapour phase epitaxy (OMVPE) of these materials is currently achieved by the co-pyrolysis of ER_3 (E = Al, Ga, In; R = alkyl) with a large excess of ammonia (> 1000:1) at very high temperatures (> 1000 °C).[5–7] In order to avoid a large, background n-type carrier concentration due to nitrogen deficiencies, low temperature deposition techniques (< 850 °C) are interesting.[8][9] However, in this situation, the crystal quality of the layers, especially the concentration of point, line and planar defects which are likely to be electrically active, may be a problem. Considerable effort is currently being directed to the development of alternative molecular routes for the synthesis of group 13 nitride materials in the form of thin epitaxial films, disperse powders or nanocrystals embedded into various matrices. Recent examples include the growth of GaN single crystals (2 mm) by a solid-state reaction from sodium azide and gallium metal, the pyrolysis of various gallium amides, hydrazides or gallium azides yielding nanodisperse GaN materials.[11–19] Novel *volatile* single source precursors for use in OMVPE have also increasingly been studied.[17–19] Preformed E–N bonds in the precursor molecule lower the activation energies for the chemical vapour deposition (CVD) growth process. This could be advantageous even in the presence of ammonia as the typical (additional) nitrogen source. Azide derivatives of the group 13 metals are especially promising in this respect because the azide unit constitutes an almost ideal source for the N-component avoiding the nonselective formation of undesired side products upon fragmentation of the hydrocarbon ligands of the precursor during the growth process.[20] We are currently studying a series of adduct-stabilised organo group 13 azides of the general formula $(N_3)_{3-a}E(R)_a(L)_b$ (E = Al, Ga or In; a = 0, 1, 2; R = alkyl; L = py, b = 3; L = NR_3, b = 1), as single molecular sources for OMVPE of the group 13 nitride thin films in the absence of ammonia.[14–16] Other related works deal with the compounds $[R_2GaN_3]_3$ (R = H, CH_3, C_2H_5), $[(CH_3)_2N]_2GaN_3$ and $[X_2Ga(N_3)]_n$ (X = H, Cl.[21–24] Here we wish to report in detail on the improved synthesis and structural properties of the compounds $(N_3)_2Ga[(CH_2)_3NMe_2]$ (**1**), $(N_3)Ga[(CH_2)_3NMe_2]_2$ (**2**) and $(N_3)_3Ga(NR_3)$ (**3a**: R = CH_3; **3b**: C_2H_5) all of which have been successfully used to produce GaN materials. The results of these studies have been published elsewhere, except for the new compound **2** discussed here.[16,19,20]

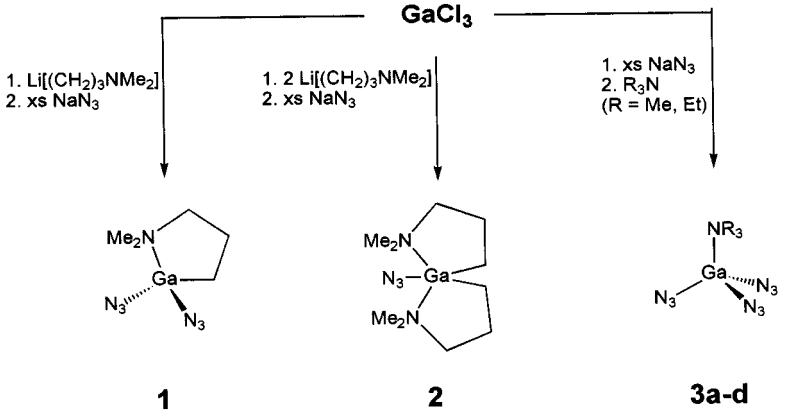
Results and Discussion

Synthesis and Properties



Molecular precursors of the materials used in electronic devices need to be very pure therefore their chemical syn-

thesis needs to be optimised for ultra high purification; a straightforward and high yield synthesis, very pure starting materials, easy scaling-up for larger quantities (multi-gram to kilogram) and very clean, e. g. oxygen and moisture-free, conditions (dry-box) are required. In the case of azide-type precursors for GaN, the compounds $GaCl_3$ and NaN_3 are the natural starting materials and are easily available in very pure forms. Furthermore, traces of chloride impurities are not a serious problem since Cl is electronically inactive in GaN. Adduct formation at the group 13 centre has also been successfully employed to reduce the incorporation of O-impurities arising from the solvents used for synthesis (e.g. ethers) or traces of moisture.[25][26] The title compounds (**1**−**3**) were thus synthesised from $GaCl_3$, NaN_3, $Li[(CH_2)_3NMe_2]$ and NR_3 (R = alkyl) according to Scheme 1. The previously reported synthesis of the bisazido derivative **1** has been significantly improved, indicated by a much higher melting point of +36(±0.1)°C (by DSC) rather than −28°C obtained earlier.[14] At temperatures above 40°C the pure compound **1** is a colourless liquid which can be repeatedly distilled in a dynamic vacuum without decomposition at 150°C (10^{-5} Torr base pressure of the turbo molecular pump system; equilibrium vapour pressure of **1** see below). Transparent single crystals suitable for X-ray crystallography were grown by slow cooling of the neat compound to 0°C. Total elemental analysis gave perfect results within the resolution of the method. NMR and mass spectrometry proved the chemical identity and the absence of any detectable trace impurities, such as Ga−O or Ga−Cl species (isotope pattern). The new monoazido compound **2** was synthesised in a similar manner (Scheme 1). Neither compound **1** nor compound **2** is pyrophoric or explosive when exposed to sudden heating (>10 K/min) or mechanical shock. Compound **2** is almost insensitive to hydrolysis, but prolonged exposure to moist air of **1** and **2** leads to decomposition and, eventually, traces of (explosive) HN_3 are formed. The synthesis of **3a**−**b** had been described previously starting from isolated $[Ga(N_3)_3]_\infty$.[14] However this is dangerous, because of the explosive nature of the polymeric triazidogallium. A one-pot synthesis of **3a**−**b** was thus developed which avoids the isolation of explosive intermediates. The treatment of a toluene suspension of the intermediately formed compound $Na[Ga(N_3)_4]$ with tertiary alkyl amines as donors is a safe way to yield the triazido congeners of type **3** (Scheme 1).[14][27]

Crystal Structures

The X-ray crystallographic data of **1** revealed that a different isomer **1b** had been obtained. The previously reported crystal data for compound **1** were obtained by zone-melting/crystallisation of a sample in a sealed Lindemann capillary mounted on the goniometer of the diffractometer and the data collection were performed at 150 K.[14] This was necessary because crystals of **1** could not be obtained by other techniques at that time, probably because of some unknown trace impurities lowering the melting point of the sample. This isomer **1a** crystallises in the triclinic space group *P*1bar and consists of centrosymmetric dimers exhibiting two asymmetric head bridging azide groups and two terminal azide units (Figure 1a).

The structure of the new isomer **1b** is rather different (Figure 1b). It crystallises from the neat liquid or concentrated toluene solutions (ice cold conditions) in the monoclinic space group *P*2(1)/*n* with four molecules attached together by loose head-to-tail azide bridges (Figure 1c). This tetramer can best be described as a dimer of dimers. Two molecules with the gallium centres Ga and Ga(A) are linked together by one single head-to-tail azide bridge {Ga(A)−N(3B) = 2.814(5) Å} and these dimers are attached to each other by rather long head-to-tail azide bridges of 3.069(6) Å. Figure 1d shows the molecular packing of **1b** in the crystal lattice. No further Ga−N distances shorter than 4.11 Å are present in the crystal lattice. The whole complex is centrosymmetric: for example, the positions of Ga and Ga(B) as well as Ga(A) and Ga(AA) are symmetrically related. All other N_{azide}−Ga contacts are well above the van-der-Waals limit of about 3.50 Å. The two (symmetry related) pairs of terminal azide groups at Ga(A) and Ga(AA), as well as the pairs of bridging azide units at Ga and Ga(B), show the typical features of covalently bonded azides: one longer N_a-N_b bond of about 1.16−1.18 Å and one shorter $N_\beta-N_\gamma$ bond of about

Scheme 1

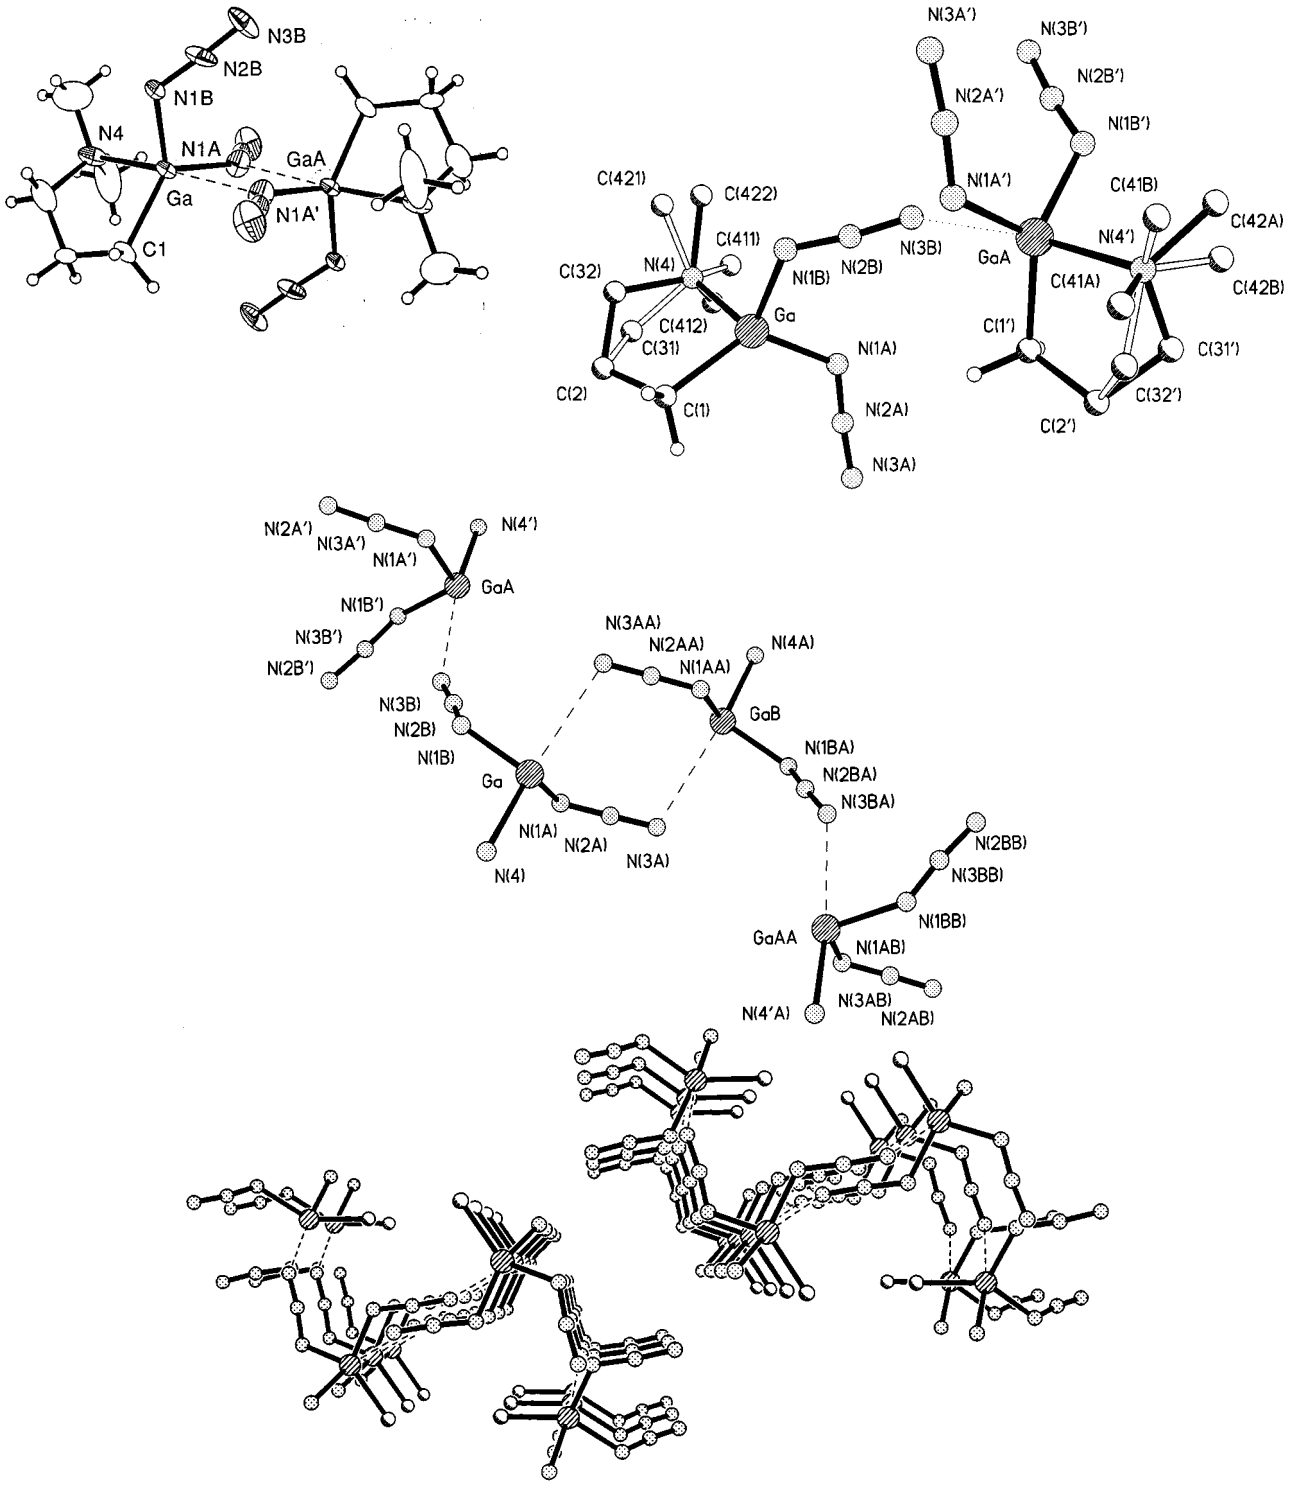


Figure 1. Molecular Structure of **1** in the solid state (ORTEP drawings, the thermal ellipsoids are at the 50% level): (a) compound **1a**;[14] (b) the two crystallographically independent centres Ga and Ga(a) of compound **1b** showing the disordering of the five-membered heterocyclic chelate rings (view of the molecular packing in the cell); (c) the characteristic tetramer (centrosymmetric dimer of dimers); (d) molecular packing of **1b** in the crystal lattice; selected bond lengths [A] and bond angles [deg] around the coordination centre Ga (the respective values for GaA are quite similar) for compound **1b**: Ga−N(1b) 188.5(4), Ga−N(1a) 190.5(4), Ga−N(4) 204.7(4), Ga−C(1) 193.8(4), N(1a)−N(2a) 116.2(5), N(2a)−N(3a) 113.9(5), N(1b)−N(2b) 118.0(5), N(2b)−N(3b) 113.8(5), N(3b)−GaA 281.4(5), Ga−N(3aa) 306.9(6); N(1b)−Ga−N(1a) 105.9(2), N(1b)−Ga−C(1) 123.2(2), N(1a)−Ga−C(1) 123.7(2), N(1b)−Ga−N(4) 101.7(2), N(1a)−Ga−N(4) 105.7(2), C(1)−Ga−N(4) 90.7, N(2a)−N(1a)−Ga 123.5(3), N(3a)−N(2a)−N(1a) 176.0(5), N(2b)−N(1b)−Ga 127.6(3), N(3b)−N(2b)−N(1b) 173.7(4)

1.14−1.15 Å; the angles Ga−N_α−N_β range around 126−129° as a consequence of the sp^2 hybridisation mode at N_α; the angles N_α−N_β−N_γ are close to 180°. There is no significant difference in the structural characteristics be-

tween terminal and bridging azide groups, again indicating the very weak interaction. On including the longer distances of 3.069(6) Å of Ga−N(3AA) compared to 2.814(5) Å for Ga(A)−N(3b), the coordination spheres of Ga and Ga(A) can be described as distorted trigonal bipyramidal. The trigonal bipyramidal coordination sphere of Ga is more distorted than that of Ga(A) as can be judged by the respective sums of their equatorial angles (356.9° vs. 352.8°). The five-membered heterocyclic chelate rings show a typical disorder because of the facile envelope flip due to intramolecular adduct formation. The positions of the involved atoms, C(31), C(32) and C(31′), C(32′) as well as the $N-CH_3$ groups are disordered (site occupation factor of 0.5). The dative Ga−N bonds, e. g. Ga−N(4) of 2.047(4) Å, are within the usual range.

Compound **2** (Figure 2a) crystallises in the monoclinic space group $P2_1$ with only one enantiomer in the asymmetric unit. In contrast to **1,** intermolecular contacts via azide bridges are absent. The structural parameters of monomeric **2** compare with the largely isostructural aluminium homologue.[20][28] Interestingly the respective indium homologue crystallises as a coordination polymer with *symmetric* head-to-tail bridging azide groups and hexa coordinated indium centres.[19] Compound **2** adopts a distorted trigonal bypyramidal structure with the two dimethylamino donor groups at the apical positions with an angle N(1)−Ga−N(2) of 178.0(8)°. The structural parameters of the equatorially coordinated azide are essentially similar to **1a** and **1b** exhibiting a somewhat more pronounced alternation of the N−N bond lengths and a longer $Ga-N_\alpha$ distance of 2.005(5) Å because of the larger covalent radius of the pentacoordinated Ga-centre. The conformational requirements of the chelating aminoalkyl groups cause an enlarged angle C1−Ga−C6 of 144.1(4)° and consequently smaller angles C6−Ga−N3 and C1−Ga−N3 of 107.6(4)° and 108.3(3)°, respectively. The Ga−C bonds are normal and the Ga−N1 and Ga−N2 dative bonds are within the usual range for related structures with penta-oordinated Ga centres, e.g. the chloro analogue of **2**.[25] Figure 2b shows the packing of compound **2** in the elementary cell.

In contrast to **1**, the compounds **3a** and **3b** crystallise as monomeric units, with no short intramolecular contacts, in the triclinic space group *P*1bar (**3a**) or in the monoclinic space group $P2_1/n$ (**3b**). Figure 3 shows the molecular structure of **3a**, which is essentially the same as for **3b** (see Experimental Section). The discussion therefore concentrates on **3a**. The only other structurally characterised compound with a triazido gallium unit is the hexacoordinated pyridine adduct $py_3Ga(N_3)_3$.[14][29] Due to the increased steric bulk of the tertiary amines only one amine ligand binds to the $Ga(N_3)_3$ moiety, rather than three (flat) pyridine ligands, yielding a trigonal pyramidal structure. Consequently the $Ga-N_{azide}$ bond lengths of **3a** and **3b** are somewhat shorter than the values obtained for the pyridine adduct (Figure 3). The short dative $Ga-NR_3$ bond of about 2.00 Å indicates a rather strong donor−acceptor bond to the $Ga(N_3)_3$ unit similar to **1** or $R_3N-GaCl_3$.[14] The structural parameters of the azide groups for **3a** and **3b** are similar to **1** and **2**.

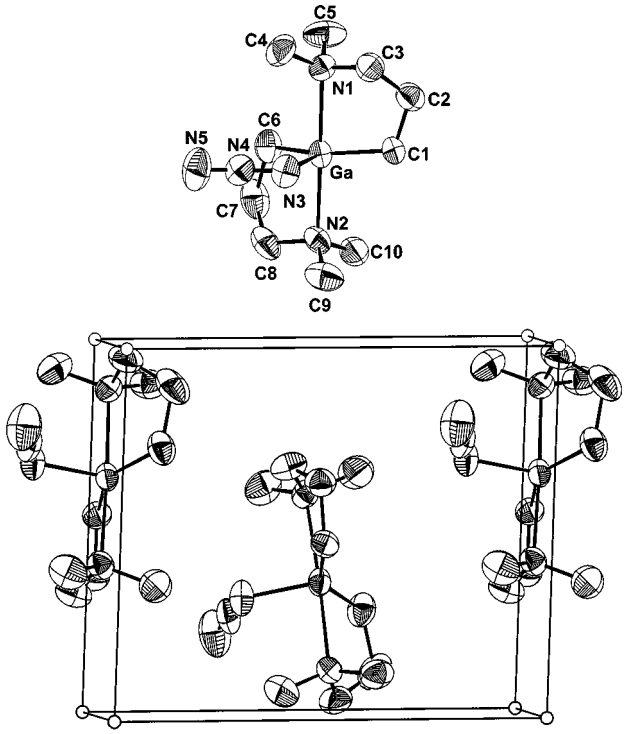

Figure. 2. Molecular Structure of **2** in the solid state (ORTEP drawings, the thermal ellipsoids are at the 50% level); (a) the monomeric unit of **2**; (b) the packing in the elementary cell; selected bond lengths [Å] and bond angles [deg]: Ga−N1 234.5(5), Ga−N2 231.1(5), Ga−N3 200.5(5), Ga−C3 197.3(5), Ga−C8 197.7(7), N3−N4 120.7(8), N4−N5 132.2(9); C3−Ga−C8 144.1(4), C3−Ga−N3 107.6(4), C8−Ga−N3 108.3, C3−Ga−N2 96.8(2), C8−Ga−N2 84.3(3), N3−Ga−N2 89.3(3), C3−Ga−N1 83.4(2), C8−Ga−N1 97.1(2), N3−Ga−N1 88.3(2), N2−Ga−N1 177.5(3), N3−N4−N5 178.0(8), N4−N3−Ga 118.7(5)

Figure 3. Materials Chemistry

Transparent, smooth (rms of 16 nm by AFM), epitaxial [full width at half maximum (FWHM) of the GaN(002) reflection of 0.72°] and stoichiometric films of GaN were grown by OMCVD on sapphire (0001) substrates at tem-

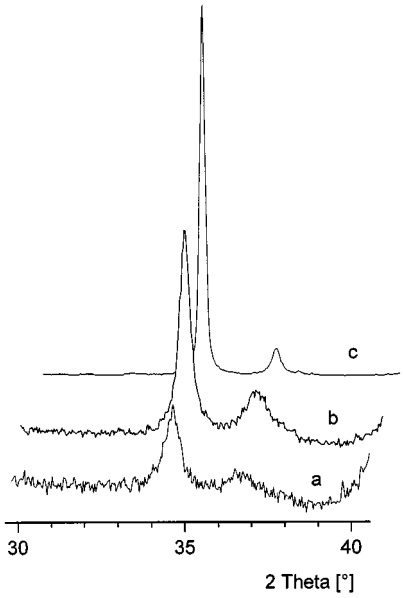

Figure 4. XRD patterns of GaN layers grown on $Al_2O_3(0001)$ using compound **2** in an isothermal horizontal hot wall tube reactor in vacuo (10^{-3} Torr) in the absence of carrier gases and additional sources of nitrogen (i.e. in the absence of ammonia) at substrate temperatures of (a) T = 600°C; (b) T = 650°C; (c) T = 750°C

peratures as low as 1070 K with growth rates up to 3−4 μm/hr from **1** with no additional source of nitrogen (ammonia) either employing an isothermal hot walled or a non-isothermal cold wall reactor system.[16] The vapour pressure of **1** between 25 (2.5 mPa) and 160°C (16 Pa) was determined by standard methods employing a Netzsch VP433 vapour pressure balance by the condensation or the impulse method.[16b] Thus, the vapour pressure of **1** can be calculated according to Equation 1. Compound **2** exhibits a vapour pressure which is an order of magnitude lower. These results show that increasing the coordinative shielding of the Ga centre by sacrificing one azide group does not improve the volatility as one might have expected on the basis of the *monomeric* structure of **2** when contrasted with the *associated* structure of **1**.

$$\ln[p(T)] = 23.7–8840/T\ [Pa] \qquad (1)$$

With a special reactor design the concentration of the fragments $HGaN_x$ and GaN_x (x = 1−6) in the boundary layer above the substrate were measured as a function of the substrate temperature showing a correlation with the growth rate of GaN.[30] We were interested in comparing the properties of the bisazido gallium compound **1** with a closely related compound with only one azide group and thus a lower nitrogen content. Compound **2** proved suitable to grow GaN films by CVD techniques employing similar hot wall conditions as for precursor **1**. The XRD pattern (Figure 4) of the films grown from **2** reveals a small shoulder for the (101) peak besides the dominant (002) reflection. The identity of the bulk material as GaN was independently established by RAMAN spectroscopy (Figure 5). The GaN thin film obtained from **2**, is only preferentially oriented on the sapphire substrate. Due to the lower nitrogen content of the monoazido precursor **2** the quality of the deposited GaN material was poor as judged by the grey appearance of the layers (Ga droplets were not detected by XRD). Also, because of the lower vapour pressure of **2** the growth rates of less than 1 μm/hr obtained were significantly lower than the growth rates obtained from precursor **1** at the same settings of the vaporiser (temperature of 80−100°C). The idea to have fewer Ga−C bonds and as many $Ga-N_3$ moieties as possible in the precursor is nicely underlined by the comparison of the films grown from **1** and **2**. Thus compound **1** seems still to be the best choice

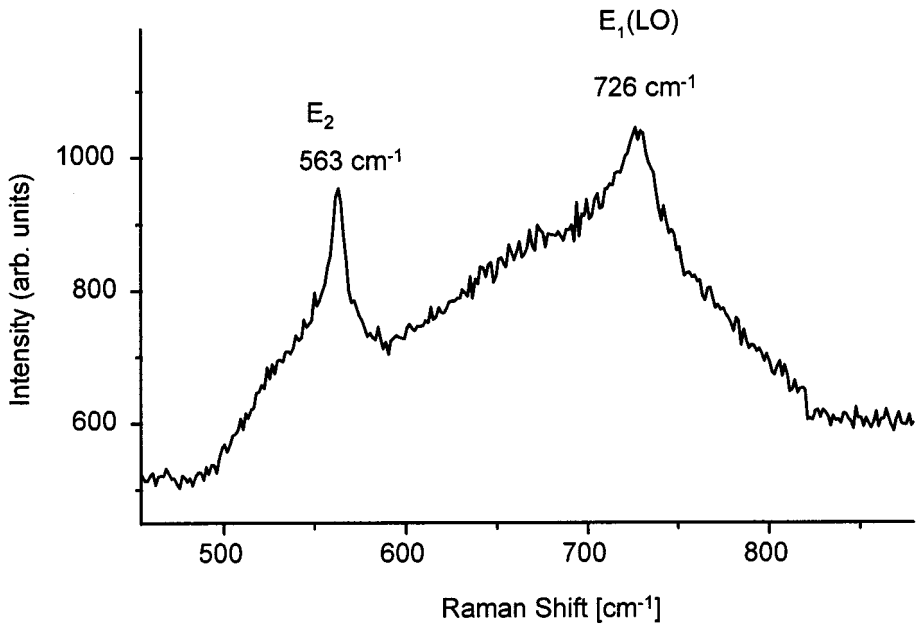

Figure 5. Raman data obtained from the GaN layer of Figure 4c; the characteristic E_2 and E_1 modes at 563 cm^{-1} and 726 cm^{-1} respectively of the GaN lattice vibrations are detected

to derive a nitrogen rich organometallic GaN precursor with an acceptable volatility for technical applications.

In contrast to **1** and **2** the triazido compounds of type **3** cannot be sublimed or volatilised at reasonable rates without the severe danger of explosion of the sample. This is probably because of the gradual loss of the volatile protecting donor ligand NR_3 and the formation of the parent compound $Ga(N_3)_3$ which is highly explosive. TG/DTA measurements were undertaken but have not yet given good quality data because of the detonation of the samples (1−2 mg). However, by taking advantage of this particular property, nanocrystalline GaN was obtained by controlled detonation of **3a** and **3b** contained in a suitable sealed stainless steel autoclave.[27,31,32] Other related adducts of long chain amines, e.g. **3c−e** were also pyrolysed under similar conditions to yield nanocrystalline GaN samples. However, it proved difficult to obtain very pure nano-GaN samples from **3a−b** due to the much higher hydrocarbon content of these precursors.[32]

Conclusions

Molecular precursors of the type $(N_3)_2Ga[(CH_2)_3NMe_2)]$ and $(N_3)Ga[(CH_2)_3NMe_2)]_2$ are single source precursors suitable for the growth of crystalline GaN films by CVD. Compound **2** is monomeric in the solid state while compound **1b** is basically a tetramer (dimer of dimers) with four molecules attached together by loose head to tail azide bridges. The testing of these compounds by CVD has demonstrated the feasibility of depositing GaN films at low temperatures (600−750°C) without any additional source of nitrogen. With respect to the accessible growth rate and thin film properties, films grown from compound **1** were of higher quality than those obtained from compound **2**.

Experimental Section

General procedures: All manipulations were performed utilising carefully oven-dried reaction vessels and Schlenk techniques under an inert atmosphere of purified argon or in a glove box. Solvents were dried under N_2 by standard methods and stored over 4 Å molecular sieves (residual water < 3 ppm, Karl-Fischer). Starting materials not available from commercial sources were synthesised according to the literature or by modified procedures, i. e. Cl_a-$Ga[(CH_2)_3NMe_2]_{3-a}$ (a = 1, 2).[25] The ^1H and ^{13}C NMR spectra were recorded on a Bruker EM 200 spectrometer and were referenced to residual protic impurities of the internal solvent and corrected to tetramethylsilane. The IR spectra were obtained in solution (toluene, pyridine) using 0.1 mm CaF_2 and NaCl cells on a Perkin−Elmer 1650 FT IR or a Bruker IFS 66. Elemental analysis were provided by the Microanalytic Laboratory of the Chemical Institute of the University of Heidelberg and the Service centre of the Faculty of Chemistry at the Ruhr-University of Bochum.

Bisazido[3-(dimethylamino)propyl]gallium (1): $Li[(CH_2)_3NMe_2]$[33] (4.2 g, 45.4 mmol) was suspended in dry ether (75 mL) and was added dropwise to a Schlenk vessel containing $GaCl_3$ (8 g, 45.4 mmol) in dry diethyl ether (75 mL) placed in a dry ice bath. After the addition was completed, the reaction mixture was allowed to stir at room temperature for 15 hours and the bis chloro[3-dimethylamino propyl] gallium formed was sublimed at 100°C to separate it from LiCl. The sublimed product (9.16 g, 40.38 mmol) was then treated with excess NaN_3 (9.72 g, 120 mmol) in toluene and refluxed at 115°C for another 15 hours. After filtration from the white residue, the solvent was removed by vacuum distillation. The product was purified by flask to flask distillation at reduced pressure using a turbomolecular pump (150°C, 10^{-5} mbar). Yield: 5.75 g (90%). − ^1H NMR (C_6D_6, 20°C): δ = 0.38 (t, 2 H, Ga−CH_2), 1.08 (m, 2 H, CH_2), 1.49 (t, 2 H, N−CH_2), 1.71 {s, 6 H, $N(CH_3)_2$}. − ^{13}C NMR (C_6D_6, 20°C): δ = 3.29 (Ga−CH_2), 21.10 (CH_2), 44.57 {$N(CH_3)_2$}, 61.70 (N−CH_2). − MS (EI, 70 eV) *m/z* = 239 [$(N_3)_2Ga\{(CH_2)_3NMe_2\}$]. − IR (toluene): $\tilde{\nu}$ = 2103 vs (N_3) cm^{-1}. − $C_5H_{12}GaN_7$: calcd. C. 25.03, H 5.04, N 40.87, Ga 29.06; found C 24.76, H 5.09, N 40.15, Ga 29.07.

Azidobis[3-(dimethylamino)propyl]gallium (2): Chlorobis[3-(dimethylamino)propyl]gallium[25] (2 g, 7.20 mmol) was dissolved in toluene (10 mL), added to a suspension of sodium azide (2.50 g, 38.45 mmol) in toluene and cooled to −78°C. The mixture was allowed to warm to room temperature after the addition and was subsequently heated to reflux for 15 h. After filtration from the white residue the solvent was removed by vacuum distillation at 25°C. The product was recrystallised from concentrated toluene solution at 5°C. Yield 1.98 g (6.99 mmol, 97.1%) as colourless needles, m.p. 40.3°C. − ^1H NMR (C_6D_6, 20°C): δ = 0.38 (m, 4 H, Ga−CH_2), 1.54 (m, 4 H, CH_2), 1.88 {s, 6 H, $N(CH_3)_2$}, 1.98 (t, 4 H, NCH_2). − ^{13}C NMR (C_6D_6, 20°C): δ = 4.86 (Ga−CH_2), 22.53 (CH_2), 44.58 {$N(CH_3)_2$)}, 61.35 (NCH_2). − MS (EI, 70 eV) *m/z* (%) = 282 (20) [M − H^+], 241 (100) [$Ga\{(CH_2)_3N(CH_3)_2\}_2^+$], 197 (8) [$(N_3)Ga\{(CH_2)_3N(CH_3)_2\}^+$]. − IR (toluene): $\tilde{\nu}$ = 2080 vs (N_3) cm^{-1}. − $C_{10}H_{24}GaN_5$ (284.05): calcd. C 42.28, H 8.51, N 24.65, Ga 24.54; found C 42.41, H 8.45, N 24.44, Ga 25.28.

General One-Pot Synthesis for Alkylamine Adducts of $Ga(N_3)_3$ of the Formula $(R_3N)Ga(N_3)_3$ (3a−d): A sample of freshly sublimed $GaCl_3$ (5.00 g, 28.40 mmol) was treated with a sample of sodium azide (9.23 g, 142.00 mmol) in 20 mL of toluene at −78°C. To this mixture 100 mL of THF was added with stirring. The suspension was allowed to warm to room temperature and was stirred for an additional 24 h. After filtration from the white residue the solution was concentrated by vacuum distillation at 25°C (removal of most of the THF) and 100 mL of toluene was added. At −78°C a sample of the respective alkylamine (113.6 mmol) was added and the mixture warmed to room temperature whilst stirring for 12 h. The reaction mixture was filtered and the solvent removed by vacuum distillation at 25°C. Compounds **3a−b** were recrystallised from concentrated toluene solutions at −30°C. The long chain alkylamine adducts **3a−d** were obtained as viscous, slightly yellow oils, which were thoroughly washed with *n*-pentane to remove excess alkylamine.

$[\{(CH_3)_3N\}Ga(N_3)_3]$ (3a): yield 6.88 g (27 mmol, 95%) m.p. 42.5°C. − ^1H NMR ([D_8]THF, 20°C) δ = 2.49 (s, CH_3) . − ^{13}C NMR ([D_8]THF, 20°C) δ = 47.30 (CH_3). − IR (toluene) $\tilde{\nu}$ = 2132 (vs), 2104 (vs), 1351 (s), 1293 (s) (N_3) cm^{-1}. − $C_3H_9GaN_{10}$ (254.86): calcd. C 14.14, H 3.56, N 54.96, Ga 27.36; found C 14.35, H 3.45, N 54.72, Ga 27.12.

$[\{(C_2H_5)_3N\}Ga(N_3)_3]$ (3b): yield 8.21 g (27.63 mmol, 97.3%) m.p. 47.5°C. − ^1H NMR (C_6D_6, 20°C) δ = 2.98 (q, 2 H, NCH_2), 1.15 (t, 3 H, CH_3). − ^{13}C NMR (C_6D_6, 20°C) δ = 49.1 (NCH_2), 10.1 (CH_3). − IR (toluene) $\tilde{\nu}$ = 2131 (vs), 2105 (vs), 1344 (s), 1291 (s) (N_3) cm^{-1}. − $C_6H_{15}GaN_{10}$ (296.97): calcd. C 24.27, H 5.09, N 47.17, Ga 23.48; found C 24.60, H 5.02, N 47.53, Ga 24.12.

X-ray Crystal Structure Determination: Crystal data and details of the structure determination of **1**, **2** and **3a** are compiled in Table 1. The data of compound **3b** are available as supplementary publication (see below). Unique sets of intensity data were collected with a four-circle diffractometer (Mo-K_α radiation, λ = 0.71073 Å), graphite monochromator, ω-scan). Empirical absorption corrections (ψ-scans) were applied. The structures were solved by direct methods[34a] and refined by least squares methods based on F^2 with all observed reflections.[34b] All non-hydrogen atoms were refined anisotropically. Crystals of **1**, **2** and **3a,b** were mounted on the goniometer using the perfluoro ether technique with cooling. Data collection were performed with a STOE-AED2 four circle instrument (University of Heidelberg, Mo-K_α radiation λ = 0.71073 Å, graphite monochromator, ω-scan). Empirical absorption correction (ψ-scans) were applied. Correction for absorption was done on the basis of ψ-scans. The structure solution was done with direct methods[34a] and the structure refinement (full matrix least squares against F^2) was undertaken with anisotropic structural parameters for all nonhydrogen atoms employing the program.[34c] The absolute structure of **2** was assigned on the basis of its Flack parameter × of −0.003(29).[36] The structure **1b** shows a disorder at the position C(31), C(32) and C(31′) and C(32′) respectively due to the facile envelope-flip of the five-membered heterocyclus defined by the atoms Ga, C(1), C(2), C(3), N(4). This disorder was fully resolved (Figure 1b). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre: CCDC-119479 (**1b**), 119673 (**2**), 119672 (**3a**) and 119671 (**3b**). Copies of the data can be obtained free of charge by application to CCDC, 12 Union Road, Cambridge CB2, 1EZ, UK [Fax: (internat.) + 44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

MOCVD of GaN Thin Films With Compound 2 as Precursor: The MOCVD experiments were conducted employing a simple horizontal hot wall reactor (heated quartz tube) described elsewhere.[35] The system was loaded with degreased single crystalline sapphire substrates (0001) heated to 450°C and evacuated to 10^{-6} mbar for several hours. After filling the reactor with argon the precursor vessel containing a sample of 0.5 g of compound **2** was attached to the quartz tube of the reactor and cooled to −30°C. The system was again evacuated down to a base pressure of 10^{-5} mbar and the oven was set to the desired temperature (600−750°C). Then the precursor reservoir was heated to vaporise the precursor. The pressure during the deposition was about 10^{-3} mbar. No carrier gas was used for the deposition. The obtained films (almost transparent to grey in appearance) were characterised by XRD using a Bruker AXS D8 ADVANCE diffractometer. RAMAN spectra of the films were recorded using a DILOR SPECTRALAB instrument equipped with a microscope using an argon ion laser operating at 514 nm.

Acknowledgments

The authors wish to thank the Deutsche Forschungsgemeinschaft for generous support and Prof. Dr. W. S. Sheldrick for his generous help rendered in solving the crystal structure of compound **1b**. A. D. is grateful to the Alexander von Humboldt Foundation for a fellowship.

Keywords: Density functional calculations / Epoxidation / Peroxo complexes / Titanium / Transition states

Epoxidation of olefins by Ti^{IV} peroxo and hydroperoxo (alkylperoxo) complexes was investigated using a hybrid DFT method (B3LYP). Reaction energies and activation barriers for direct oxygen transfer to ethylene as a model olefin were computed for various model complexes to compare the epoxidation activity of Ti(η^2-O_2) and TiOOR (R = H, CH_3) moieties. The activity of complexes with a Ti(O_2) peroxo group is shown to be essentially quenched when the coordination sphere of the complex is saturated by strongly basic (σ-donor) ligands. In contrast, the activity of a TiOOH functional group depends only weakly on the saturation of the coordination sphere of the Ti center. Substitution of methyl for hydrogen in a TiOOH group is found to slightly increase the activation barrier of epoxidation. The computational results give preference to reaction paths that involve TiOOR species. The factors governing the activity of Ti(O_2) and TiOOR groups, in particular the effects of donor ligands, are discussed on the basis of a molecular orbital analysis.

Introduction

Titanium(IV) peroxo species represent an active component in a number of homogeneous and heterogeneous oxidation reactions of organic substrates by hydrogen or alkyl peroxides.[1] Important examples of catalytic processes of this type are the homogeneous stereoselective epoxidation of allylic alcohols by alkyl peroxides catalyzed by Ti^{IV} alkoxides (Sharpless epoxidation)[2] and the heterogeneous epoxidation of olefins on titanium silicates (or silicalites) with amorphous[3] or zeolite-like structures.[4] Despite intense experimental work, the precise structure of the oxidizing active site is still a matter of controversy in most of cases, especially for heterogeneous catalytic processes on titanium silicates.[4–6]

In the known epoxidation reactions, titanium hydroperoxo or alkylperoxo groups, TiOOR (R = H, alkyl), are generally accepted as oxygen donors, while peroxo groups, Ti(η^2-O_2), with two symmetrically coordinated oxygen centers at Ti are considered inert in this reaction. For instance, a TiOO-*t*Bu species is assumed to be responsible for epoxidation in the Sharpless process,[7] and a TiOOH species for epoxidation on Ti silicalite.[4] In early reports active Ti(O_2) species have also been suggested for the latter system.[8][9] Actually, a number of stable and experimentally well-characterized Ti^{IV} η^2-peroxo complexes are not active in olefin epoxidation, e.g. (TPP)Ti(O_2)[10] (TPP = tetraphenylporphyrin) and Ti(O_2)(pic)$_2$·HMPA[11] (HMPA = hexamethylphosphoric triamide; pic = picolinato). However, there is evidence[10] that (TPP)Ti(O_2) becomes active in the epoxidation of cyclohexene once it is transformed to the *cis*-hydroxo(alkylperoxo) complex (TPP)Ti(OH)(OOR), although the latter has never been isolated.

On the other hand, the η^2-peroxo or bis-peroxo d^0 complexes of Mo, W, and Re, which are structurally similar to Ti(O_2) species, are known to epoxidize alkenes.[1,12,13] Thus far, no clear rationalization has been presented as to why η^2-peroxo complexes of Ti are not active in epoxidation. The inactivity of (TPP)Ti(O_2) has been rationalized by steric repulsion between the alkene and the porphyrin ring.[1] However, electronic effects of the porphyrin ring on the properties of the peroxo group might provide a different reason, by analogy with the inhibiting effect of strong coordinating solvents on the epoxidation activity of the bis-peroxo molybdenum complex $MoO(O_2)_2 \cdot HMPA$.[14] Here, the reactivity decrease of the peroxo group under coordination of a seventh ligand to the metal center has been attributed[15][16] to electronic effects rather than to the possibility that the reacting alkene may be prevented from coordinating to the Mo center. An inhibiting electronic effect of basic ligands on the activity of Re and Mo bis-peroxo complexes has also recently been demonstrated computationally.[17–19]

Several theoretical investigations on ethylene epoxidation catalyzed by Ti^{IV} species have been reported.[20–24] These studies presented structures of possible intermediates as well as activation energies for oxygen transfer. Most of them dealt with models of hydroperoxo complexes like $(HO)_3$-TiOOH[20–22] or closely related clusters that partially account for a silicate surrounding, e.g. $(H_3SiO)_2(HO)$-TiOOH[24] and $(H_3SiO)_3(CH_3OH)$TiOOH.[23] The activity

of $Ti(O_2)$ species was investigated only with the model peroxo complex $(HO)_2(H_2O)Ti(O_2)$.[22] Note that the Ti center of most models studied is five-coordinated. This is lower than the typical coordination (six or seven) of the experimentally characterized Ti^{IV} peroxo and alkylperoxo complexes,[11,25–27] i.e. the coordination sphere of these Ti model complexes is not saturated. Under reaction conditions the coordination of Ti centers in titanium silicalites expands beyond the initial tetrahedral structure.[28] Despite there being a number of particular cases that have been considered, a comprehensive computational comparison of properties of $Ti(O_2)$ and TiOOR species and their epoxidation activity is still lacking.

With the present work on Ti^{IV} complexes we continue our series of density functional (DF) investigations on olefin epoxidation in which we have so far studied Re, Cr, Mo, and W d^0 peroxo complexes.[17–19] Here, we compare the epoxidation activity of a number of Ti^{IV} model complexes that contain either peroxo or hydroperoxo (alkylperoxo) functional groups. For this purpose we have calculated the reaction energies and the activation barriers for direct oxygen transfer from both types of peroxo groups, $Ti(\eta^2\text{-}O_2)$ and TiOOR, to the model olefin ethylene. In addition, we pay special attention to the coordination number of the Ti center. The model study presented here will also shed light on the mechanism of epoxidation on titanium silicates.

The goals of the present study are (i) to investigate the mechanism of olefin (ethylene) epoxidation by Ti complexes with peroxo and hydroperoxo (alkylperoxo) functional groups; (ii) to determine factors that govern the reactivity of these groups and, in particular, to study the dependence of the activity on the saturation of the coordination sphere of central Ti ion; and (iii) to consider the effect of an alkyl substituent of the TiOOR moiety on the activation barrier of epoxidation.

Results and Discussion

We intend to focus on the electronic effects of ligands on the properties of the moieties $Ti(O_2)$ and TiOOR, but we want to leave aside steric effects. Therefore, we start with simple monodentate ligands like hydroxyl groups as anionic ligands and ammonia or water as (neutral) σ donors. In this way, we are able to relate the models under study to different types of titanium peroxo compounds: either to complexes with more complicated polydentate organic ligands or to Ti species incorporated in silicate structures. In order to make this relation more realistic we consider at the end models where some hydroxide ligands are replaced by either methoxide or siloxide ligands. We shall take solvent effects into account only through the coordination of additional ligands to the Ti center; no other environment effects are included. However, from studies on Re and Mo peroxo complexes it is known[17][29] that long-range solvent effects and zero-point energy corrections hardly influence reaction energies and activation barriers of oxygen transfer to olefins.

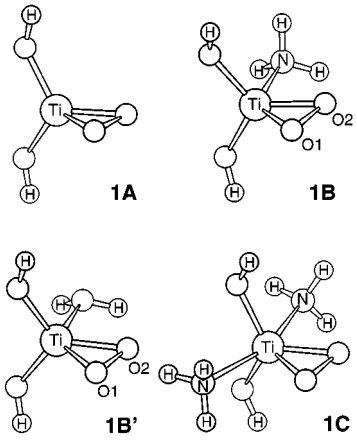

Figure 1. Model complexes with a $Ti(\eta^2\text{-}O_2)$ functional group

Model Complexes

We start by considering model η^2-peroxo complexes of Ti^{IV}. The simplest such model is $(HO)_2Ti(O_2)$, **1A** (Figure 1), with the peroxo group coordinated to Ti in a symmetric η^2 ("side-on") fashion; two hydroxyl ligands provide the oxidation state IV and electro-neutrality of the complex. The coordination sphere of complex **1A** is far from saturated and thus **1A** exhibits significant affinity to basic ligands. The binding energy of further ligands is −32.3 kcal/mol for NH_3 (complex **1B**, Figure 1) and −25.9 for H_2O (**1B′**). Addition of a second NH_3 molecule to **1B** leads to a further energy gain of −16.5 kcal/mol. The resulting complex, **1C** (Figure 1), can be considered as a model of the complex $Ti(TPP)(O_2)$ with the porphyrin ring of the latter substituted by two NH_3 and two hydroxide ligands. Geometry optimizations of the complexes **1A** and **1C** converged to structures with effective C_{2v} symmetry; thus in these complexes the two oxygen centers of the peroxo group are essentially equivalent. In complexes with one basic ligand, **1B** and **1B′**, the symmetry of the peroxo group is slightly distorted with the Ti−O distances differing by 0.02 Å (see Table 1). The calculated structural parameters of the titanium peroxo group (Table 1) are in very good agreement with X-ray data of known Ti^{IV} peroxo complexes.[11,25,26] For instance, the calculated Ti−O and O−O distances of 1.86 and 1.46 Å, respectively, in the peroxo group of complex **1C** are very close to the corresponding experimental values of 1.83 and 1.45 Å, respectively, of the complex $(OEP)Ti(O_2)$ (OEP = octaethylporphyrinato),[26] where Ti also exhibits coordination number 6.

Models of Ti hydroperoxo (alkylperoxo) complexes are shown in Figure 2. Complex **2A** has previously been used for modeling active intermediates of the Sharpless epoxidation[20] and epoxidation centers of Ti-silicalites.[21][22] Model **2B** is derived from **2A** by adding an NH_3 ligand; the calculated ligand binding energy is −13.2 kcal/mol. Model **3A** differs from **2A** by a methyl substituent in place of the hydrogen center of the peroxo group. The fact that no local symmetry in the Ti(OOR) moiety is preserved does not come as a surprise (Table 2). However, the hydroperoxo (alkylperoxo) ligand is still coordinated to Ti by both oxy-

gen centers with Ti−Oα and Ti−Oβ distances (Figure 2) of about 1.89 and 2.27 Å, respectively. The plane OOR of the TiOOR group is almost orthogonal to the plane TiOO. The O−O distance is about 1.47 Å. The calculated structure of the TiOOR group agrees very well with recently reported data for {[(η^2-*tert*-butylperoxo)titanatrane]$_2$ · 3 dichloromethane}: *r*(Ti−Oα) = 1.913 Å, *r*(Ti−Oβ) = 2.267 Å, and *r*(O−O) = 1.469 Å.[27] This is the only alkylperoxo complex of Ti reported to date for which an X-ray crystal structure is available. Although the authors[27] chose to designate this structure as η^2, we will not use this notation for TiOOR complexes in the following discussion in order to distinguish them from Ti(O_2) complexes that do exhibit almost ideal η^2 coordination. Models **1B′** and **2A** have the same stoichiometry; a formal proton transfer from the water ligand of **1B′** to the peroxo group leads to **2A**. This transfer is calculated to be exothermic by −7.0 kcal/mol; thus, the hydroperoxo complex **2A** is more stable.

Epoxidation Transition States

In the study of the epoxidation activity of the various intermediates described above we calculated in each case the transition states of oxygen transfer to the model olefin ethylene. The corresponding species will be referred to by a prefix **TS**, e.g. **TS-1A** designates the transition state of ethylene epoxidation by complex **1A**. We focus on the oxygen transfer mechanism where the ethylene double bond directly attacks an oxygen center of the peroxo (hydroperoxo) group. The activation barriers are calculated with respect to the corresponding "free" complexes and an ethylene molecule. We shall neglect the physical interaction between ethylene and a peroxo group of the reaction intermediate in the ground state; this interaction is about 2 kcal/mol.[21]

In the following text we will not discuss the insertion mechanism of Mimoun, which implies that an olefin substrate first binds to the metal center and then inserts into the peroxo-metal bond in a [2 + 2] fashion to form a metallocycle intermediate.[12][14] For **1B** this metallocycle intermediate is calculated to lie 9.7 kcal/mol higher than the reactants and the corresponding activation barrier is 27.3 kcal/mol, while a direct attack requires only 19.0 kcal/mol for activation (Table 1). These findings are very similar to those for d^0 peroxo complexes of Re[17] and Mo[19] where, at the same level of computation, [2 + 2] insertion was shown to exhibit significantly higher activation barriers than a direct transfer.

The calculated transition states of the Ti(O_2) and TiOOR (R = H, CH_3) moieties have a number of features in common and, in general, resemble the structures of transition states of direct oxygen transfer for Re, Mo, and W.[17][19] All transition structures exhibit a spiro orientation of the ethylene unit (Figures 3 and 4), i.e. the plane CCO is almost orthogonal to the plane TiOO. The structure of the ethylene moiety is only slightly distorted from the gas phase structure: the C−C bond in the transition state is elongated by 0.04 Å at most. All these transition states represent a synchronous approach of ethylene to the peroxo moiety with almost equal distances between the carbon atoms and the attacked oxygen center. The largest difference between

the O−C distances, about 0.03 Å, is found for **TS-1B′** (Table 1). The O−C distances of hydroperoxo complexes differ to a somewhat greater extent, at most by about 0.1 Å in **TS-3A** (Table 2). Similar synchronous transition states were calculated at the same level of computation (B3LYP) for the epoxidation of 1-pentene[30] and allyl alcohol[31] by peroxyformic acid. In the transition states of $Ti(O_2)$ intermediates, one of the Ti−O distances has increased by 0.05−0.14 Å whereas the other Ti−O distance has decreased by about 0.08 Å compared to the corresponding intermediates (Table 1). In the transition states of the TiOOR intermediates, the distance Ti−Oα has increased by 0.07−0.09 Å while the distance Ti−Oβ has decreased by about 0.16−0.21 Å (Table 2). The distances between the metal center and the attacked oxygen in peroxo and hydroperoxo transition states (Ti−O1 and Ti−Oα, respectively) are quite comparable and have values of about 1.9−2.0 Å (Tables 1 and 2). The most dramatic changes on the way to the transition state occur in the structure of the peroxo moiety: the O−O distance increases from about 1.47 Å in the intermediates to 1.82−1.86 Å in the peroxo transition states (Table 1) and to 1.89−1.92 Å in the hydroperoxo transition states (Table 2). A full vibrational analysis was performed for the transition state structures **TS-1B** (Figure 3) and **TS-2A** (Figure 4) as representatives of the two types of intermediates, $Ti(O_2)$ and TiOOR. Each of these structures was found to exhibit a single imaginary frequency; this confirms

the nature of the transition states as first-order saddle points on the corresponding potential energy hypersurfaces.

Oxygen transfer by epoxidation reaction involving d^0 metal peroxo complexes is generally accepted to exhibit electrophilic character.[1][12] This view is based on the fact that peroxo and alkylperoxo complexes react faster with electron-rich alkenes, e.g. with highly alkyl-substituted species. In a recent experimental study with peroxo compounds of V, Mo, and W the electrophilic nature of peroxo oxygen centers was also probed by sulfoxidation of thianthrene 5-oxide, in which an oxygen center of a peroxo complex attacks the electron-rich sulfide group rather than the electron-poor sulfoxide group.[32] In the present calculations, the electrophilic character of the oxygen transfer is manifested through the electron density transfer in the transition state, about 0.2 e, from ethylene to the peroxo (hydroperoxo) complex.

For $Ti(O_2)$ complexes the calculated activation barriers increase strongly in the sequence **1A**, **1B**, **1C**, from 11.0 to 27.4 kcal/mol (Table 1). The first complex of this family, **1A**, exhibits the lowest activation barrier, 11.0 kcal/mol, of all species considered in present work. An additional basic ligand significantly decreases the activity of the peroxo group, as deduced from the activation barriers of the complexes **1B** and **1B′**, which are 19.0 and 17.4 kcal/mol, respectively. It was found that the stronger the basic character of the ligand (ammonia vs. water), the higher the barrier. Note that in the models **1B** and **1B′** the oxygen centers of the peroxide group are not equivalent and, therefore, attacks of both centers have to be considered. We refer to attacks of the oxygen centers O1/O2, i.e. distant from/close to the NH_3 ligand (Figure 3), as "front" or "back" transition states.[17] In Table 1 we report the pertinent parameters of both transition states starting from complex **1B**. The back transition state corresponds to an attack of the more negative center O2, with the olefin in spatial proximity to the base. This situation leads to a somewhat higher barrier of 22.3 kcal/mol, which is in line with previous findings for Re, Mo, and W complexes.[17][19] The highest activation barrier of the peroxo series, 27.4 kcal/mol, is calculated for **1C** with two NH_3 ligands. Thus, saturation of the coordination sphere of the Ti center completely quenches the epoxidation activity of titanium peroxo group.

Analogous trends of increased activation energies concomitant with an increased number of basic ligands have been obtained in calculations on Re, Cr, Mo, and W mono- and bis-peroxo complexes.[17][19] A joint experimental and theoretical study[18] on different base adducts of the bis-peroxo complex $(O_2)_2(H_3C)Re{=}O$ revealed that coordination of a base to the complex induces, mediated by the metal center, additional electron density on the peroxo group; this pushes the *anti*-bonding $\sigma^*(O-O)$ level upward and results in a higher activation barrier (see below). Coordinatively saturated complexes of Re, Mo and W still exhibit moderate activation barriers ranging from 16 to 20 kcal/mol;[17–19] only Cr, which like Ti is a first row transition element, exhibits very high barriers for ethylene epoxidation. For example a barrier of about 40 kcal/mol is calculated for the model complex $(O_2)Cr(=O)_2 \cdot (NH_3)_2$,[19] which is structurally similar to our model **1C** but features oxo instead of hydroxide ligands. Experimental studies on the epoxidation activity of the bis-peroxo molybdenum complex $MoO(O_2)_2 \cdot HMPA$ have also rationalized the inhibiting effect of strongly coordinating solvents as an electronic effect of the additional (seventh) ligand on the properties of the peroxo group.[15][16] However, seven-coordinated $(L\text{-}L)MoO(O_2)_2$ complexes with bidentate L-L basic ligands were recently shown to catalyze epoxidation with *tert*-butyl hydroperoxide as an oxidant, and the formation of an MoOO*t*Bu group as an active center was proposed.[33]

For the TiOOR complexes we consider the α-attack to a peroxo group, i.e. transfer of the oxygen atom that is (closely) bound to the Ti center (Oα in Figure 2). β-attack, i.e. attack of the other oxygen center (with a substituent attached; Oβ in Figure 2), results in a higher activation energy; during this process the O−O bond breaks, accompanied by a proton transfer from Oβ to Oα. For instance, the activation barrier of ethylene epoxidation by **2A** via β-attack is calculated to be 25.7 kcal/mol, compared to 12.7 kcal/mol for α-attack. Similar differences in the barrier heights between α- and β-attack have also been found for hydroperoxo derivatives of Re and Mo.[17][19] At variance with the $Ti(O_2)$ complexes, the reaction barrier of TiOOR intermediates hardly changes upon addition of a donor ligand. Both transition states **TS-2A** and **TS-2B** feature relatively low activation energies of 12.7 and 12.4 kcal/mol, respectively. Thus, despite the additional NH_3 ligand, the activation barrier of **2B** is calculated to be slightly lower than the barrier of **2A**. This small decrease of the barrier height, by 0.3 kcal/mol, is in line with the change of the O−O distance (Table 2), although such minor changes are at the edge of computational accuracy.

Comparison to Other Computational Studies

Next, we shall comment on the absolute values of the calculated activation barriers and on the accuracy of our results. From MP2 calculations,[22] activation barriers have been reported for the front attack of **1B′**, 13.2 kcal/mol, and for the α-attack of **2A**, 14.4 kcal/mol, which are similar to the corresponding values of the present study, 17.4 and 12.7 kcal/mol, respectively. However, these MP2 values have been obtained under C_s symmetry constraints.[22] Two rather different values of the activation barrier of **2A**, 9 (with C_s symmetry constraints)[20] and 21[21] kcal/mol, have been determined in DF calculations where the gradient-corrected BLYP exchange-correlation functional was employed. Significant differences of structural parameters are also worth noting. The C_s symmetry constraints enforce a planar structure of the TiOOH moiety (Figure 2) with a significantly elongated Ti−Oβ distance, 2.6−2.7 Å[20–22] (compared to about 2.27 Å calculated in the present study; Table 1). On the other hand, when used without symmetry constraints the BLYP approach yields too short a value for

Ti−Oβ, 2.1 Å.[21] To check the effect of a C_s symmetry restriction for the present B3LYP investigations, we also calculated **1B′** and **2A** as well as the corresponding transition states **TS-1B′** (front) and **TS-2A** in this way; the resulting activation barriers are 16.1 and 13.8 kcal/mol, respectively. The differences from the corresponding values of full geometry optimizations are only about 1 kcal/mol, but are of opposite sign; thus, the selectivity between the two transition state structures is reduced.

To check for possible basis set effects and to justify the use of ECPs we also performed calculations with an all-electron TZV(f) basis for Ti. Single-point calculations with the geometry optimized in the standard approach (see Computational Details) yield activation barriers of 17.9 and 13.8 kcal/mol for **TS-1B′** (front) and **TS-2A**, respectively. Further optimization of the intermediate **1B′** and the transition state **TS-1B′** (front) leads to a uniform lowering of the total energy values by 0.5 kcal/mol for both structures with almost no effect on the height of the barrier; for **2A** the barrier changes by 0.1 kcal/mol only. These results show that the computational strategy used in the present study is quite accurate. As a further supporting argument, one notes that the structure of the TiOOH group calculated here is in very good agreement with available experimental data,[27] at variance with some earlier quantum chemical investigations.[20−22] The absolute accuracy of the B3LYP approach for activation barriers is another question altogether. However, a critical comparison shows that, at least for barrier heights of organic reactions, B3LYP performs significantly better than BLYP or MP2.[34][35]

Reaction Energies

For both types of species, $Ti(O_2)$ and TiOOR, ethylene epoxidation is an exothermic reaction. By this reaction, $Ti(O_2)$ species transform into complexes with a titanyl Ti=O functional group, while TiOOH species form a TiOH group after loss of one oxygen unit. The reaction energies are computed with respect to isolated products, namely the metal complex and ethylene oxide. The calculated reaction energies for $Ti(O_2)$ species increase from −23.8 kcal/mol for **1A** to −30.7, −31.2, and −34.1 kcal/mol for **1B′**, **1B**, and **1C**, respectively. Obviously, the higher reaction energy for highly coordinated species is due to higher stabilization of Ti=O product by basic ligands compared to initial $Ti(O_2)$ intermediate, since the coordination number of Ti is lower in the product complex due to the loss of one oxygen center. The complexes **2A** and **2B** exhibit significantly higher epoxidation reaction energies of −43.2 and −44.8 kcal/mol, respectively. The reaction profiles of the various $Ti(O_2)$ and TiOOH intermediates are represented in Figure 5 where the energy of the lowest intermediate **1C** + C_2H_4 is taken as reference. Inspection of Figure 5 reveals that the intermediates **1C** and **2B** feature the lowest energies and similar thermodynamic stability. However, epoxidation by **2B** is favored for both thermodymamic (higher reaction energy) and kinetic reasons (lower activation barrier). Evidently, the kinetic argument plays the key role here: epoxidation by the $Ti(O_2)$ intermediate **1C** can be ruled out since the corresponding transition state exhibits an activation barrier of more than 27 kcal/mol; this is more than twice as high as the activation barrier for the TiOOH intermediate **2B**.

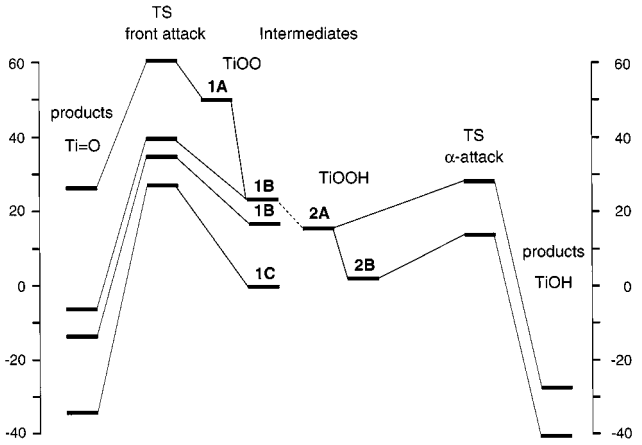

Figure 5. Total energies of intermediates with $Ti(O_2)$ or TiOOR groups and the corresponding transition states and products of ethylene epoxidation, relative to the energy of **1C** + C_2H_4. The activation barrier of proton transfer (dashed line) between the isomers **1B′** and **2A** is not shown

Molecular Orbital Analysis and Discussion

We turn to an analysis of the electronic structure of both types of the reaction intermediates, $Ti(O_2)$ and TiOOH, to rationalize the calculated activity trends. For this purpose, we consider a $Ti(O_2)$ moiety formally as an O_2^{2-} ligand coordinated to a Ti^{4+} d^0 center. The interaction between ligand and metal center can be considered as a donation from the peroxo group to the vacant d orbitals of Ti.

The energy of the unoccupied *anti*-bonding σ*(O−O) level is one of the most important of the factors that determine the activity of peroxo complex in oxygen transfer.[18] The activation of the O−O bond in the transition state is due to the interaction of this orbital in the LUMO group of the metal moiety with the HOMO π(C−C) of ethylene. The σ*(O−O) level is not the true LUMO of the complex; it lies slightly above the manifold of vacant d-levels of the metal center. The energy position of the σ*(O−O) level is expected to reflect the ability of peroxo group to accept additional electron density, which leads to breaking of O−O bond. This is indeed the case: the lower the energy of the σ*(O−O) level, the smaller is the calculated barrier for oxygen transfer. This is demonstrated in Figure 6a where the dependence of the activation barrier on the σ*(O−O) − π(C−C) gap is shown.

Coordination of a basic (σ-donor) ligand to **1A**, e.g. NH_3 in **1B**, increases the electron density at the peroxo group: the charge of the peroxo group given by a natural bond orbital analysis (NBO)[36] changes from −0.90 e in **1A** to −0.94 e in **1B** (and to −0.96 e in **1C** with two NH_3 ligands, Table 1). Concomitantly, the 1s(O) core level energies are shifted upward in **1B** by about 1.1 eV compared to **1A** (by

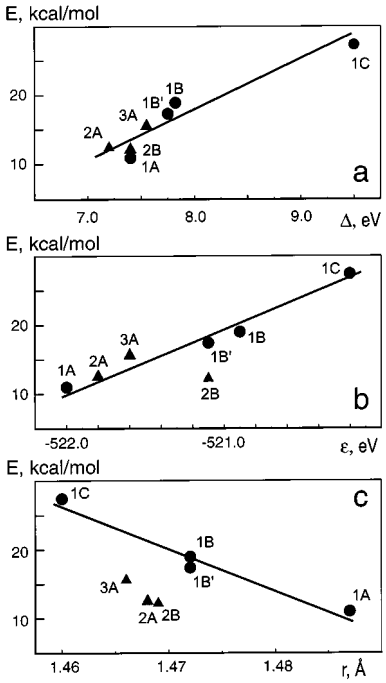

Figure 6. Calculated activation energy $\Delta E^{\#}$ (in kcal/mol) as function of (a) the HOMO−LUMO energy gap $\Delta = \sigma^*(O-O) - \pi(C-C)$ (in eV); (b) the energy ε (in eV) of the 1s(O) core level as a measure of negative charge located on the attacked oxygen center; (c) the O−O bond length (in Å). Data of peroxo group of $Ti(O_2)$ (circles) and TiOOR (triangles) complexes. Lines of linear regression on the data of the $Ti(O_2)$ complexes are also shown

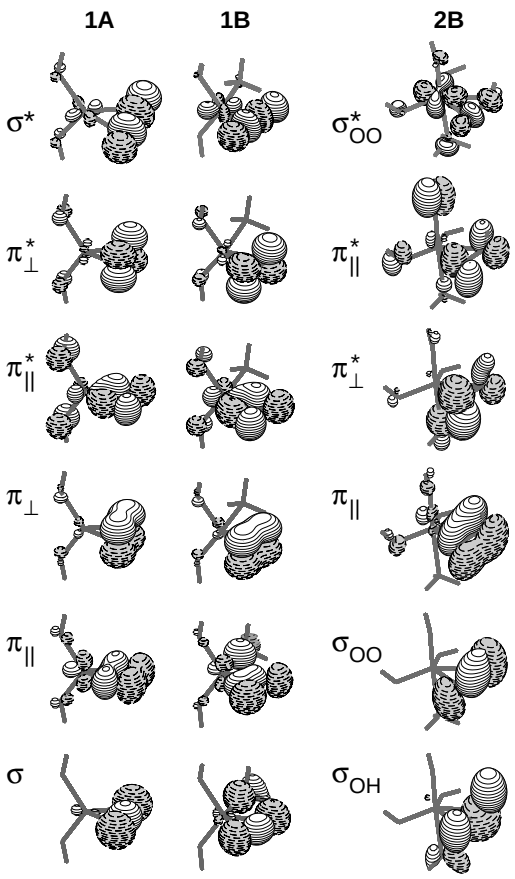

Figure 7. Structure of molecular orbitals of the intermediates **1A** (left), **1B** (center), and **2B** (right) with dominant contributions of the peroxo or hydroperoxo group

about 2.0 eV in **1C**); this is also indicative for an increase of electron density on the peroxo ligand. Thus, additional basic ligands reduce the donation from the peroxo ligand to the metal center; the electrophilic character that controls olefin epoxidation is also reduced.[1][12] Figure 6b shows how the 1s(O) core level energy as an indicator for the electron charge density of the peroxo or hydroperoxo moiety correlates with the calculated barrier of oxygen transfer.

Another factor determining the activation barrier of oxygen transfer is the strength of the O−O bond in the absence of an olefin substrate. When gauging changes in the O−O bonding based on the metal populations of the different O−O derived levels of the peroxo complex, one has to take into account their nature as O−O bonding and *anti*-bonding, respectively. Molecular orbitals of **1A** with important contributions of the peroxide group are shown in Figure 7, right-hand column. It is convenient to classify these orbitals according to the dominant σ and π character with respect to their peroxo contribution. The role of the unoccupied σ* (O−O) level has already been discussed above; let us now consider the occupied O−O orbitals. Since the peroxo group coordinates side-on to the Ti center, each pair of O−O bonding π and *anti*-bonding π* orbitals splits. We shall designate the orbitals with a dominant contribution in the TiOO plane by $\pi_{||}$ or $\pi_{||}$* and those with a dominant contribution perpendicular to that plane by π* or π*. Based on energy considerations, donation from the *anti*-bonding $\pi_{||}$* and π* orbitals of the O_2^{2-} ligand to the vacant d-orbitals of the Ti d^0 center is expected to be strongest; in particular the $\pi_{||}$* orbital exhibits a strong overlap with the d_{yz} orbital of Ti (Figure 7). There is also considerable donation from the lower lying level $\pi_{||}$ (Figure 7). The contributions of the σ(O−O) and π* orbitals to the metal-peroxide interaction are less important for overlap reasons. This analysis is corroborated by an NBO calculation of the moiety TiO_2^{2+} in the geometry of **1A**. This model, which is free of hydroxide ligand contributions, allows a facile separation of the metal-π(O−O) interaction channels according to the various irreducible representations of the point group C_{2v}; however, metal populations may be too large since the ligand sphere is incomplete. The Ti d populations due to donation from $\pi_{||}$* and π* are 0.63 and 0.60 e, respectively; donation from the in-plane $\pi_{||}$* orbital is slightly larger for overlap reasons. Donation from the bonding O−O levels is smaller: 0.20 e from π* and 0.26 e compounded from $\pi_{||}$ and σ. The (stronger) donation from the $\pi_{||}$* and π* orbitals reduces the population of these O−O *anti*-bonding levels in the complex and thus leads to a strengthening of the peroxo bond, while donation from O−O bonding levels has a weakening effect.

This analysis helps to rationalize the changes in the structure of the peroxide group; in **1A**, the O−O bond is elongated by coordination to a Ti center, 1.487 Å (Table 1), compared to a gas phase H_2O_2 molecule (calc. 1.454 Å; exp. 1.452 Å[37]). Upon addition of base the O−O bond short-

ens to 1.47 Å in **1B** and 1.46 in **1C** while the activation barrier for oxygen transfer rises significantly, by 16 kcal/mol in **1C** compared to **1A** (Table 1, Figure 6c). These indicators are consistent with the interpretation that coordination of additional bases to the complex results in a stronger O−O bond with a concomitant increase in the electronic charge of the peroxide group. The question arises as to which of the peroxide orbitals discussed above gains more population as a consequence of the additional basic ligand: the O−O bonding or *anti*-bonding orbitals. Inspection of the orbital structure of **1B** (Figure 7, center column) helps to answer this question: donation to the d-orbital of Ti significantly stabilizes the lone pair of the NH_3 ligand in the complex (Figure 8): in **1B** the energy level that represents the lone pair of NH_3 appears in the same energy region as the bonding levels of the peroxide ligand and thus partially mixes with σ and $\pi_{||}$ levels (Figure 7). Mixing with the orbitals π and π* is essentially forbidden because these orbitals have a node in the TiOO plane where the NH_3 ligand approaches the complex. However, as can be seen from Figure 7, there is also almost no interaction between the NH_3 lone pair and the peroxide *anti*-bonding $\pi_{||}$* level. This may in part be rationalized by the much higher energy of the $\pi_{||}$* level, but also the nodal structure does not favor mixing with the NH_3 lone pair. One is therefore led to conclude that a basic ligand reduces donation from the O−O bonding $\pi_{||}$ orbital more strongly than from the O−O *anti*-bonding $\pi_{||}$* orbital.

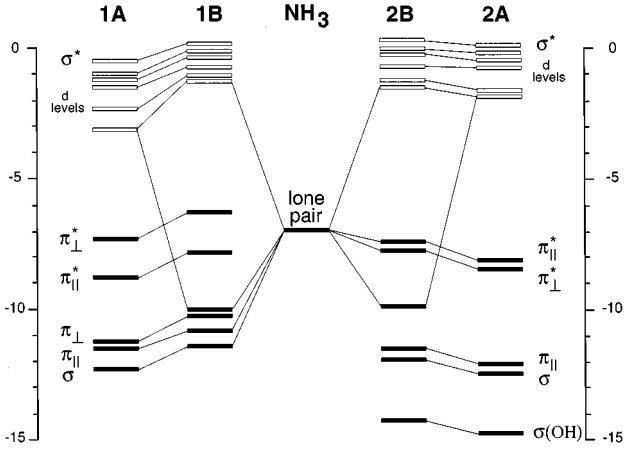

Figure 8. Orbital energy correlation diagram for peroxo and hydroperoxo derivatives

The above analysis shows that the bond between the metal center and the peroxo group plays an important role in the determination of the charge distribution over the orbitals of the peroxo moiety. This statement may be quantified with the help of an NBO charge analysis. The Ti contributions in the Ti−O σ interaction (in the TiOO plane) are 10% and 15% per bond for **1B** and **1C**, respectively. The corresponding contributions to the Ti−O π interaction (orthogonal to the TiOO plane) are 9% and 8% per bond for **1B** and **1C**, respectively. These small contributions of the metal center justify our idealized analysis focusing on the O−O derived orbitals. The increased Ti contributions in **1C** compared to **1B** indicate a strengthening of the Ti−O1 bond, in line with the calculated increase of the barrier for ethylene epoxidation. The elongation of the Ti−O1 bond from 1.84 Å in **1B** to 1.86 Å in **1C** (Table 1) may be due to stronger ligand-ligand repulsion in the highly coordinated **1C** species. However, the direct contribution of this bond to the activation energy should be considered as a second-order effect compared to the properties of the O−O bond. The main role of the Ti−O bond seems to be indirect: it influences the charge redistribution between the metal center and the peroxo group.

Figure 6 reveals that the hydroperoxo complexes follow similar general trends as the $Ti(O_2)$ complexes; however, they yield barriers of a similar height as complex **1A** despite their considerably shorter O−O bonds (Figure 6c). The orbital structure of the TiOOH species exhibits some peculiarities, which will be considered in the following discussion. When a proton is attached to the peroxo group, as in **2A** and **2B**, the electronic structure is significantly changed and a strong asymmetry is induced in the TiOO moiety (Figure 7, right-hand side). An idealized representation of the metal-ligand interaction in terms of OO orbitals has to be used with care for such species. The optimal position of the proton is in the plane almost orthogonal to the TiOO plane. Therefore, the strongest changes occur in the orbitals π and π*. The π contribution to O−O bonding is reduced and the nature of the resulting MO is better described as σ(OH) bonding; this level is the lowest in the orbital diagram of complex **2A** shown in Figure 7. In turn, the MO π* represents the lone pair of the center Oα of the hydroperoxo group (Figure 7). The other orbitals of the peroxo moiety (σ, $\pi_{||}$, and $\pi_{||}$*) remain more or less unchanged. The splitting of *anti*-bonding MOs π* and $\pi_{||}$*, with $\pi_{||}$* now being the HOMO, is significantly smaller, 0.3 eV for **2A**, than for $Ti(O_2)$ complexes where it amounts to more than 1 eV. The NBO analysis shows an almost equal charge distribution between the oxygen centers of the hydroperoxo group. The lower energy of the level 1s(Oβ) (Table 2) can be rationalized by the stabilization due to the electrostatic field of the attached proton.

As in the $Ti(O_2)$ complexes, addition of a donor ligand decreases the positive charge of the metal center, but its influence on the charge of the peroxo group is negligible (cf. the NBO charges and the core level energies of **2A** and **2B**; Table 2). At variance with the findings for "side-on" η^2-peroxo complexes, the additional ligand of the metal center has only a moderate effect on the activity of the hydroperoxo group. The calculated activation barrier of the intermediate **2B** even decreases slightly compared to **2A**. The negative charge of the peroxo group is higher in **2B** than in **2A** (Table 2) and, as a consequence, all pertinent valence levels are shifted upwards (Figure 8); however, this shift is smaller than that calculated when a ligand is introduced in **1A** to form **1B**. In particular, the vacant σ*(O−O) level shifts upwards by only 0.2 eV and its position is still rather low compared to $Ti(O_2)$ intermediates **1B** and **1C**,

which exhibit high barriers (Figure 6a). The apparently small effect of a basic ligand on the properties of the hydroperoxo complexes **2A/2B**, in particular on the oxygen transfer barrier, can be rationalized by the weaker metal-peroxo interaction in these "end-on" complexes. This follows, first of all, from the fact that only one oxygen atom, Oα, is involved in a strong interaction with the Ti center because the distance Ti−Oβ is much longer, by more than 0.3 Å (Table 2). Moreover, the Ti−Oα interaction is weaker than the corresponding interaction in the peroxo species. This can be inferred from the Ti−Oα distances in **2A** and **2B**, 1.89−1.92 Å, which are longer than the corresponding distances Ti−O of the peroxo complexes, 1.82−1.86 Å (Tables 1 and 2). Furthermore, the splitting of levels π* and $\pi_{||}$* is smaller in the hydroperoxo complexes due to reduced overlap with the orbitals of the metal center (Figure 7). The NBO analysis indicates a contribution of Ti to the Ti−Oα σ bond of 10% and 13% for **2A** and **2B**, respectively; this is slightly smaller than in the $Ti(O_2)$ complexes. However, at variance with the bonding of the $Ti(O_2)$ complexes, the π channel of the Ti−Oα interaction almost vanishes and the NBO analysis assigns the π* orbital to a lone pair located at the center Oα.

Coordination of the basic ligand NH_3 to **2A** and formation of species **2B** results in a slight decrease of the calculated activation barrier for the epoxidation of ethylene. This may be due to the fact that the lone pair of the NH_3 ligand of **2B** is stabilized in the gap between bonding and *anti*-bonding orbitals of the "peroxo" moiety. The bonding O−O levels of **2B** are lower in energy than the corresponding levels of the $Ti(O_2)$ intermediate **1B** while the NH_3 lone pair level is slightly higher (Figure 8). Inspection of the orbital structure of **2B** (Figure 7) shows that, in contrast to **1B**, this lone pair orbital of **2B** does not mix with the bonding O−O levels. In fact, this orbital even provides small contributions to the *anti*-bonding orbitals π*(OO) and $\pi_{||}$* (OO) that lie higher in energy. Thus, introduction of the additional basic ligand seems to affect the *anti*-bonding O−O levels of **2B** more than the bonding O−O levels. The resulting increased population of *anti*-bonding O−O levels leads to a weakening of the O−O bond and thus provides a rationalization for the small decrease in the barrier of the O−O bond activation in the epoxidation reaction.

Methyl Substitution of the Hydroperoxo Group

An important question is how a substituent R of the TiOOR moiety affects the epoxidation activity given that alkylhydroperoxides like *t*BuOOH are often used as oxidants.[1][3] To study this effect, we compare the epoxidation activity of the hydroperoxo complex **2A** with its methylperoxo derivative **3A** (Figure 2). Formation of **3A** according to the formal reaction **2A** + CH_3OH → **3A** + H_2O is exothermic by −4.9 kcal/mol. The calculated activation barrier for the complex **3A**, 15.8 kcal/mol, is 3 kcal/mol higher than that of **2A** (Table 2). The small increase of the negative charge on oxygen centers of the group $OOCH_3$ is in line with the weak electron-donating character of the methyl substituent; this inductive effect can also be detected from the small upward shift of 1s(O) levels (Table 2). Concomitantly, the σ*(O−O) level shifts upwards, correlating with an increase in the activation barrier (Figure 6a). The changes in the geometry of the peroxo moiety due to methyl substitution are minor.

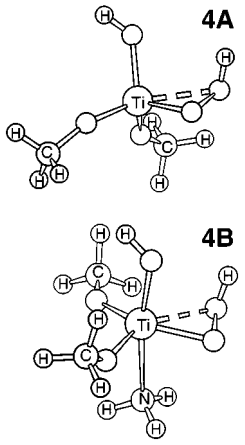

Figure 9. Model Ti hydroperoxo complexes, **4A** and **4B**, with equatorial hydroxide ligands replaced by methyloxide ligands

Methoxide and Siloxide in Comparison with Hydroxide Ligands

Finally, we consider the effects when hydroxide ligands of the model complexes are replaced by either methoxide or siloxide ligands. The methoxide derivatives **4A** and **4B** (Figure 9) are obtained from **2A** and **2B**, respectively, by formally exchanging two equatorial hydroxyl moieties by methoxide ligands. Analogous models with two $OSiH_3$ ligands will be referred to as **5A** and **5B**. These types of ligands are of interest since various titanium alkoxides, $Ti(OR)_4$, as well as titanium silicalites, are used as catalysts in epoxidation processes.[1]

In general, introduction of methoxide or siloxide ligands does not induce large structural changes in the TiOOH group (Table 2). The O−O bond length remains almost unchanged; the Ti−Oα distance becomes slightly shorter, while the Ti−Oβ distance increases somewhat. According to the NBO populations and the core level analysis, methoxide and siloxide ligands attract slightly more electron density from the Ti center than the hydroxide ligands. Thus, the electron density on the peroxo oxygen centers of the complexes **4A** and **4B** is higher (by 0.02 and 0.01 e) than on those of **2A** and **2B**, respectively; concomitantly, the 1s(O) levels shift to less negative energies by 0.2−0.3 eV. On the other hand, in complexes **5A** and **5B** there is somewhat less electron density on the peroxo group (compared to **2A** and **2B**, respectively), although for **5B** it can be detected only from the negative shift, −0.2 eV, of 1s(O) levels. Both types of ligands lead to slightly increased barriers of ethylene epoxidation. As in **2B**, the additional basic ligand NH_3 in **4B** and **5B** reduces the activation barriers by 0.9 and 1.3

kcal/mol compared to **4A** and **5A**, respectively. The corresponding transition states do not exhibit any noteworthy structural differences. Addition of NH_3 to **4A** and **5A** is exothermic by −11.0 and −12.1 kcal/mol, respectively. Based on the experience with the TiOOH models we expect similarly minor changes in the properties of the TiOO moieties due to substitution of hydroxide ligands by methoxide or siloxide.

A recent computational study of Ti silicalites[24] by Sinclair and Catlow also included a DF-BP86 calculation of ethylene epoxidation by the complex $(H_3SiO)_2Ti(OH)OOH$, which is essentially the same as the present model **5A**. For that model an activation barrier of 10.3 kcal/mol was calculated,[24] which is lower than the present result of the hybrid B3LYP, but is in agreement with the trend[34][35] of "pure" DF functionals like BLYP and BP86 in yielding lower barriers than the B3LYP hybrid method, which partially accounts for exact exchange. Sinclair and Catlow also considered the transformation of the structure $(H_3SiO)_2Ti(OH)OOH$ to $(H_3SiO)_2Ti(OH_2)(O_2)$ by an internal proton transfer, which is analogous to the transformation of **1B′** to **2A**.[24] In that study, contrary to the present results for **1B′** and **2A**, the $Ti(O_2)$ species was found to be more stable than the TiOOH analogue by about −10 kcal/mol. This difference may be due either to the different exchange-correlation potentials used or the influence of the $OSiH_3$ ligands. Sinclair and Catlow considered the structure $(H_3SiO)_2Ti(OH_2)(O_2)$ as a poisoned form of the catalyst, but they did not prove its inertness in the epoxidation process by calculating the corresponding transition state.[24] Under reaction conditions, a further base will coordinate to the Ti center; comparison with our models **1B** and **1B′** shows that adding one more basic ligand to $(H_3SiO)_2Ti(OH_2)(O_2)$ will render the activation barrier even higher.

Conclusions

We have studied the epoxidation of ethylene by model Ti^{IV} peroxo complexes with both "side-on" peroxo $Ti(\eta^2-O_2)$ and "end-on" hydroperoxo (or alkylperoxo) TiOOR (R = H, CH_3) moieties by means of hybrid B3LYP density functional calculations. The low coordinated intermediate $(HO)_2Ti(O_2)$ was found to exhibit a relatively low barrier of oxygen transfer, however it is not thermodynamically stable since it readily forms base adducts (Figure 5). Coordination of additional donor ligands to the Ti center (**1B**, **1C**) significantly increases the activation energy of a $Ti(O_2)$ group. Participation of the most stable intermediate **1C**, with its saturated coordination sphere, in the epoxidation process is ruled out for kinetic reasons since the corresponding transition state exhibits a high barrier, above 27 kcal/mol. The inhibiting effect of donor ligands was rationalized with the help of a molecular orbital analysis. Two effects were distinguished: (i) additional basic ligands reduce the electrophilicity of the peroxo group and push the σ*(O−O) orbital responsible for breaking the O−O bond to higher energies; (ii) concomitantly, the populations of the bonding levels of the peroxo group increase and strengthen the O−O bond, as deduced from shorter O−O distances in model complexes with higher coordination numbers. The high activation barrier for coordinatively saturated $Ti(O_2)$ species is in agreement with the experimentally observed chemical stability of known Ti^{IV} peroxo complexes.[10][11]

At variance with $Ti(O_2)$ moieties, the activity of a TiOOH functional group depends only very weakly on the saturation of the Ti coordination sphere. The hydroperoxo group is less sensitive to the coordination of the Ti center since there are less channels for metal-peroxo interaction for such "end-on" structures than in the case of symmetric "side-on" structures $Ti(O_2)$. Calculated reaction energies and activation barriers show that Ti hydroperoxo species are very favorable for thermodynamic *and* kinetic reasons. The hydroperoxo complex **2B**, with one basic ligand, is only slightly less stable than the η^2-peroxo complex **1C** with two basic ligands. Due to its low activation barrier, it exhibits by far the lowest lying transition state (by absolute energy, Figure 5). Substitution of hydrogen by methyl in the TiOOR group (**2A** vs. **3A**) was found to increase the activation barrier for epoxidation by 3 kcal/mol. Substitution of hydroxide anionic ligands in TiOOH model complexes by alkyloxide and siloxide increases the activation barrier by 1−2 kcal/mol. The activation barriers of oxygen transfer from a TiOOR group to an ethylene molecule are calculated in the range of 13−16 kcal/mol, thus are comparable, if not lower, than the barriers calculated at the same level of computation for various Re peroxo species.[17]

In summary, the computational results favor reaction paths that involve hydroperoxo (or alkylperoxo) titanium species over $Ti(O_2)$ species. Thus, the results of the present computational study support the interpretation of experimental and theoretical studies[4,7,10,15] that hydroperoxo intermediates are responsible for the epoxidation reactions by Ti complexes and Ti-silicalites, while the corresponding peroxo species appear (if at all) as a chemically inert structures of side reactions only.

Computational Details

In the density functional calculations[38] we employed the hybrid B3LYP exchange-correlation scheme.[39] The 1s, 2s, and 2p core shells of Ti were replaced by a LANL2 effective core potential (ECP).[40] The corresponding basis set[40] of Ti, which describes the outermost core (3s and 3p) and the valence shells, was used in the contraction (441/2111/41). For main group elements we employed a 6-311G(d,p) basis set.[33] Geometry optimizations of intermediates and transition states were performed without any symmetry constraints. Transition state structures were searched by numerically estimating the matrix of second-order energy derivatives at every optimization step and by requiring exactly one eigenvalue of this matrix to be negative. We checked typical transition state structures by performing a full vibrational analysis, using a TZV basis set for Ti (see below). Reaction energies and barrier heights were evaluated in single-point fashion with the Ti basis set augmented by a polarization f-exponent (1.506).[42]

To check how results depend on the quality of basis set and to validate the ECP for the present study, some model complexes and the corresponding transition states (including a full vibrational analysis) were re-calculated using an all-electron valence triple-ζ (TZV) basis set for Ti (842111/6311/411). Reaction energies and barrier heights were evaluated in single-point calculations with an augmented Ti basis, using the above polarization f-exponent [TZV(f)].

In preceding studies of Re and Mo oxo and peroxo complexes[17][29] zero-point energy corrections were shown to uniformly shift the calculated reaction energies and reaction barriers by small positive values. However, in no case did they change the qualitative picture when reactivity of different intermediates was compared. Therefore, in the present study we refrained from applying zero-point energy corrections to reaction energies and barrier heights.

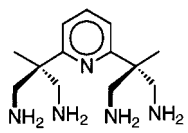
"Embroidered" Square Pyramidal Coordination Caps for Nickel(II): Mono-, Di- and Tetrafunctionalisation of a Tetrapodal Pentadentate Ligand with an NN_4 Donor Set

Christian Dietz,[a] Frank W. Heinemann,[a] and Andreas Grohmann*[a]

Dedicated to Professor Hubert Schmidbaur on the occasion of his 65th birthday



Keywords: Tetrapodal pentadentate ligand / Ligand periphery / Polydentate amine complex / Nickel / Podand / Schiff base

The tetrapodal pentaamine ligand 2,6-bis(1′,3′-diamino-2′-methylprop-2′-yl)pyridine **(1)**, which contains four equivalent primary amino groups, can be derivatised partly or completely by Schiff base condensation with suitable carbonyl compounds. The new ligands thus obtained are mononucleating, as shown by the X-ray crystal structures of their respective nickel(II) complexes. Reaction of **1** with 1 equiv. of salicylaldehyde and subsequent reduction allows the selective modification of one of the four sidearms. The resulting ligand **2** is hexadentate and uninegative in its nickel(II) complex {[(**2**)Ni]PF_6} **(3)** with both the secondary amine and the phenoxide functionalities coordinated to the metal centre. The unreduced Schiff base form of the ligand, **4**, does not form a complex with nickel(II) as readily, and only a small quantity of the mixed salt {[(**4**)Ni][(**1**)Ni(H_2O)]($Br)_2(PF_6)$} **(5)** has been obtained. While the overall coordination of **4** resembles that of **2**, there is considerably more strain in the appended chelate ring, due to the presence of the C=N double bond. Modification of one arm in **1** can also be achieved by condensation with 1 equiv. of acetylacetone, to give the new ligand **6** which, likewise, is hexadentate in its Ni^{II} complex {[(**6**)Ni]$(PF_6)_2$} **(7)**. In this case, however, the *N*/*O*-functional sidearm is not deprotonated. Rather, it is coordinated as the keto-imine tautomer, making **7** a rare example of a metal complex containing this structural fragment. Two-fold functionalisation of **1** is observed upon reaction with acetone, regardless of whether the ketone is present in stoichiometric amounts or in excess, to give the pentadentate ligand **8** with two diagonally juxtaposed isopropylidene-imine units. The complex isolated with this ligand {[(**8**)Ni]$(PF_6)_2$} **(9)** contains pentacoordinate Ni^{II}, the sixth coordination site being blocked by the rigidly positioned isopropylidene groups. When reacted with 4 equiv. of *trans*-cinnamaldehyde, all the primary amino groups in **1** condense to give the four-fold Schiff base **10**, which acts as a pentadentate podand towards nickel(II). In this complex, {[(**10**)Ni(OH_2)]Br_2} **(11),** an aqua ligand completes the coordination octahedron. All ligands are stable towards hydrolysis when coordinated to the metal, despite the presence of *alkyl*-imine groups in some cases.

Introduction

Simple tetrapodal pentadentate ligands which act as square pyramidal coordination caps towards octahedrally coordinating transition metal ions were unknown until recently.[1−5] The ligands are required to have a donor atom in the apical position of the pyramid, whose lone pair is directed towards the centre of the octahedron, as well as four donor arms pointing toward the basal positions. This leaves a sixth site on the metal ion for the coordination of a small monodentate ligand.

A prototypical pentadentate ligand with this topology is the pyridine-derived polyamine **1**, which has been shown to be mononucleating in a series of complexes of nickel(II),[4] cobalt(III),[1,6,7] copper(II)[8] and iron(II).[9] Variation of the basal functional groups to include donors other than primary amines is possible in principle. Such ligands are of basic interest in coordination chemistry, and we have set out to study this class of compounds with a view to using them as head groups in functional metal complexes. All basal donor groups are *terminal* with respect to the ligand framework. Further derivatisation aims to append a "pocket" to the tetrapodal ligand, encircling the sixth coordination site of the metal ion. Depending on the nature of the functional groups present in this pocket, we wish to explore whether the sixth ligand can engage in a two-point interaction with the complex fragment, through a combination of dative bonding to the metal and secondary bonding interactions with the ligand periphery (e.g. hydrogen bonding or π-stacking interactions). Such interactions with the sixth ligand are expected to modulate the thermodynamics and kinetics of its binding, as well as its reactivity.

1

In the case of **1**, the presence of four equivalent primary amino groups makes the molecule an attractive substrate for Schiff base condensations. The present work describes a

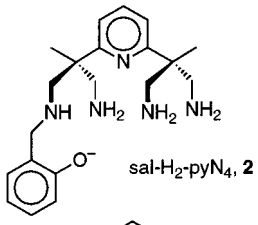
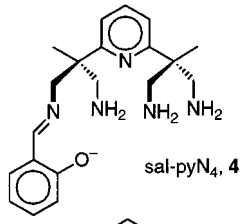
series of ligands in which one, two or all four basal amino groups have been derivatised in this manner, and the full characterisation of the Ni^{II} complexes of these "embroidered" square pyramidal coordination caps. Nickel(II) was chosen as the central metal ion as it usually gives complexes that are readily purified (crystallisation, ion exchange chromatography), thus facilitating access to the pure ligands and to complexes of a wider range of metals. This contribution presents results pertaining to Schiff base derivatives of **1** that maintain a mononuclear coordination mode.

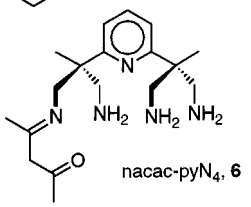
Results and Discussion



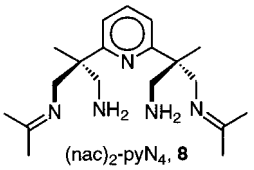
In all condensation reactions reported here, the pentaamine **1** was employed as its tetrakis(hydrobromide) salt/methanol solvate, **1**·4HBr·MeOH.[10] Methanol solutions of **1** were prepared in most cases by neutralisation of HBr with NaOMe, which was generated in situ by dissolving the appropriate amount of sodium metal. NaBr does not precipitate from methanol under the given conditions, and was not removed from solution before attempting the subsequent reactions.



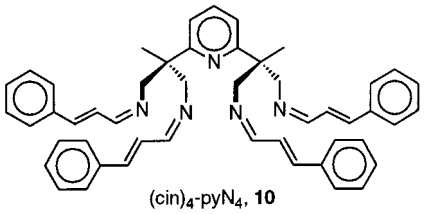
Preliminary experiments showed that the pentaamine **1** reacts readily with 4 equivalents of salicylaldehyde in methanol to give the four-fold Schiff base condensation product, and that reduction of the C=N double bonds with sodium borohydride is similarly straightforward. The Schiff base and the secondary amine derivatives are both potentially nonadentate ligands with NN_4O_4 donor sets, but the presence of four 2-hydroxy substituents in the periphery of the NN_4 pyramid is expected to induce considerable steric crowding with respect to the formation of mononuclear complexes of "small" transition metal ions such as nickel(II), utilizing only the NN_4 donor set. Indeed, we have so far not been able to isolate complexes of the type $[Ni^{II}(NN_4O_4)]$.



sal-H_2-pyN_4 (2), sal-pyN_4 (4) and Their Complexes With Ni^{II}



In light of the above observation we attempted the condensation of **1** with only one equivalent of salicylaldehyde, in the hope of obtaining asymmetric ligands of type **2** (after reduction) or **4**. These potentially hexadentate ligands may block all the coordination sites of the metal centre, but their synthesis appears to be a reasonable point of entry into the coordination chemistry of mononucleating derivatives of **1**. In accordance with the terminology used for monosubstituted diamines (so-called "half-units", which are of current interest for their potential in asymmetric catalysis), ligands such as **2** or **4** would represent "quarter-units".[11–13]



For the preparation of sal-H_2-pyN_4 (formula **2** shows its deprotonated form), one equivalent each of **1** and salicylaldehyde are reacted in methanolic solution at room temperature. The reaction is rapid, as judged by the appearance of a yellow colour which is characteristic of the Schiff base. Reduction of the condensation product in situ with sodium

borohydride gives a solution containing the ligand sal-H_2-pyN_4 (cf. **2**). After workup and addition of a suitable nickel(II) salt, followed by hexafluorophosphate anion, the desired mononuclear metal complex **3** precipitates as a purple crystalline material, in which the ligand is deprotonated and carries a negative charge. No attempt has as yet been made to optimise the yield (30% after recrystallisation). While the 1:1 condensation may not go to completion (see **4** and **5**, below), it is possibly not fully specific either, so that more highly substituted side products (sal:pyN_4 > 1:1) may form which, upon reduction, do not give the respective metal complexes as readily. In any case, nickel complexation should provide a convenient means of isolating pure **2**.

The spectroscopic characteristics of **3** (see Experimental Section) resemble those determined for a series of octahedral nickel(II) complexes of the polyamine ligand **1**, in which a monodentate ligand occupies the sixth coordination site.[4] In the UV/Vis spectrum, an absorption attributable to a d–d transition occurs at λ = 509 nm and thus at higher energy than in the aqua complex [(**1**)Ni(H_2O)]I_2 (λ = 543 nm),[4] indicating that the NN_4O ligand **2** generates a stronger ligand field than the parent NN_4 ligand **1**. The compound is paramagnetic, with shifted and broadened resonances in the ^1H NMR spectrum, as ex-

pected for a complex of octahedrally coordinated high-spin nickel(II).

Compound **3** crystallises with one molecule of water and one molecule of methanol per formula unit. The molecular structure of the cation, which has C_1 symmetry, is shown in Figure 1. The nickel(II) ion is coordinated by the NN_4 part of the ligand donor set in a pyramidal fashion, and the phenoxide oxygen atom of the peripheral arm occupies the coordination site remaining on the metal centre, the overall coordination geometry of Ni^{II} thus being octahedral. All chelate rings are six-membered. The nickel atom is displaced by 0.0397(5) Å towards the phenoxide oxygen atom, relative to the plane defined by the four equatorial amino nitrogen atoms. While the arrangement of donor atoms along the main axes of the octahedron is close to linear {176.4(1) − 177.8(1)°, see Table 1}, the NN_4 donor cap shows a slight distortion similar to that observed for a series of complexes of the type $[(\mathbf{1})Ni(X)]^{n+}$, where X is a neutral or anionic monodentate ligand.[4] The pyridine ring, itself a regular hexagon, is tilted to one side of the NN_4Ni pyramid so that the heterocycle and the aliphatic carbon atoms C18, C19, C22 and C23 are no longer coplanar {interplanar angle = 17.0(2)°}. The acute angle subtended by the lines N11−C13 and N11−Ni1 at N11 is 11.9(1)° (instead of 0°). At the same time, the nonbonded distance C16···C21 is lengthened to 5.370(5) Å, while the corresponding distance C17···C20 is shortened to 4.752(5) Å. As a consequence, the least-squares planes defined by the four methylene carbon atoms C16, C17, C20, and C21, and the four equatorial amino nitrogen atoms N12, N13, N14, and N15, are not parallel but at an angle of 8.0(1)° (Table 2). Since this kind of distortion is also observed in the parent complexes $[(\mathbf{1})Ni(X)]^{n+}$, where it has been attributed to crystal packing effects,[4] it is not necessarily caused by the presence of an additional chelating group in the ligand periphery, viz. the salicylaldehyde-derived side-arm. The accommodation of the latter into the ligand framework does not induce significant changes in any of the $Ni^{II}-N$ bond lengths ($Ni1-N_{eq}$: 2.080(3)−2.129(3) Å; $Ni1-N_{py}$: 2.075(2) Å), as compared to the range of values observed in $[(\mathbf{1})Ni(X)]^{n+}$. In particular, the bond length between Ni1 and the secondary amino nitrogen atom N15 does not differ markedly from the other values for d(Ni−N) in this structure.[14] Apparently, the only structural effect of the chelating sidearm on the NN_4 coordination cap in **3** when compared to that in $[(\mathbf{1})Ni(X)]^{n+}$ is that there are no longer matching pairs of opposite bite angles in the equatorial plane, these angles all being different and spanning the range 85.2(1)−95.3(1)° (Table 1).

The chelate ring formed by the phenoxide sidearm is a folded hexagon, the fold being along the vector O1···C30. Defining the side of the benzene ring facing the equatorial nitrogen atoms as positive, the phenoxide oxygen and methylene carbon atoms (O1 and C30) are displaced from this plane by +0.061(3) Å and −0.139(4) Å, respectively. The secondary amino nitrogen atom N15 is outside the benzene ring plane by +1.026(6) Å. The latter observation supports the notion that free rotation around the bond N15−C30 (i.e. reduction of the imine precursor) greatly facilitates the phenoxide sidearm to become a chelating group (cf. the related discussion for the Schiff base complex **5**, below). The value for d(Ni1−O1) is 2.066(2) Å and thus lies in the range observed for this type of bond in other octahedral Ni^{II} complexes.[15][16]

A nickel(II) complex of the salicylaldimine ligand **4** does not form as readily. Condensation of **1** and salicylaldehyde as described above, followed by addition of suitable Ni^{II} salts, has so far yielded only a small amount of the mixed salt $\{[(\mathbf{4})Ni][(\mathbf{1})Ni(H_2O)](Br)_2(PF_6)\}$ **(5)** the composition of which shows incomplete condensation (cf. the discussion of **2** and **3**, above.) Ligand **4** may be sluggish to form a complex with Ni^{II} because of the unfavourable conformation of the incipient chelate ring due to the presence of a C=N double bond. This ring is expected to be planar (conjugation of the aldimine and aromatic systems) and hence considerably strained. Alternatively, the phenol oxygen atom may remain an uncoordinated spectator group in the ligand periphery (see Introduction). For clarification, **5** has been characterised by X-ray crystallography.

The molecular structure of the cation $[(\mathbf{4})Ni]^+$, in which the ligand is deprotonated to the phenoxide, is shown in Figure 1. The overall coordination of **4** resembles that of **2** (see Figure 1; note the labelling schemes for $[(\mathbf{4})Ni]^+$ and $[(\mathbf{2})Ni]^+$, which reflect similar tilts of the pyridine rings, leading to different labels for the substituted equatorial nitrogen atoms). Some relevant structural parameters of the NN_4 part of the ligand are as follows; while the bond lengths $Ni-N_{py}$ and $Ni-N_{primary}$ are similar in the structures of **3** and **5** (Table 1), the Ni−N bond to the nitrogen atom carrying the appended chelate arm is significantly shorter in **5** {2.018(7) Å} than in **3** {2.119(3) Å}, as expected for an sp^2-hybridised nitrogen atom in the case of **5**. In contrast, the nickel−phenoxide bond is longer in **5** {2.115(5) Å} than in **3** {2.066(2) Å}, which is probably a manifestation of the strain imposed by the C=N double bond. The distortion of the ligand cap is of the same degree as in **3** (Table 2).

The chelate ring formed by the phenoxide sidearm is essentially planar. The maximum deviation from the best plane defined by all six ring atoms is 0.207(4) Å for O1. Selected angles in the ring are C30−N14−Ni1 127.8(7)°, C31−C30−N14 125.2(9)° and Ni1−O1−C32 123.9(5)°. The deviations from the ideal values of 120° and 109.5°, respectively, further attest to the strain in the ring. As manifest in the molecular structure of **3**, this strain is considerably relieved upon reduction of the C=N double bond. It may thus be concluded that, if the incipient chelate ring is six-membered, unsaturation does not altogether prevent its formation. For a donor group appended to the NN_4 cap to remain uncoordinated, and thus set up for interactions with a substrate coordinated to the metal (see Introduction), the donor atom should be attached to the β-, not the γ-carbon atom of the sidearm. The other cation in the structure, $[(\mathbf{1})Ni(H_2O)]^{2+}$, has parameters similar to those previously described for $[(\mathbf{1})Ni(H_2O)]I_2$.[4]

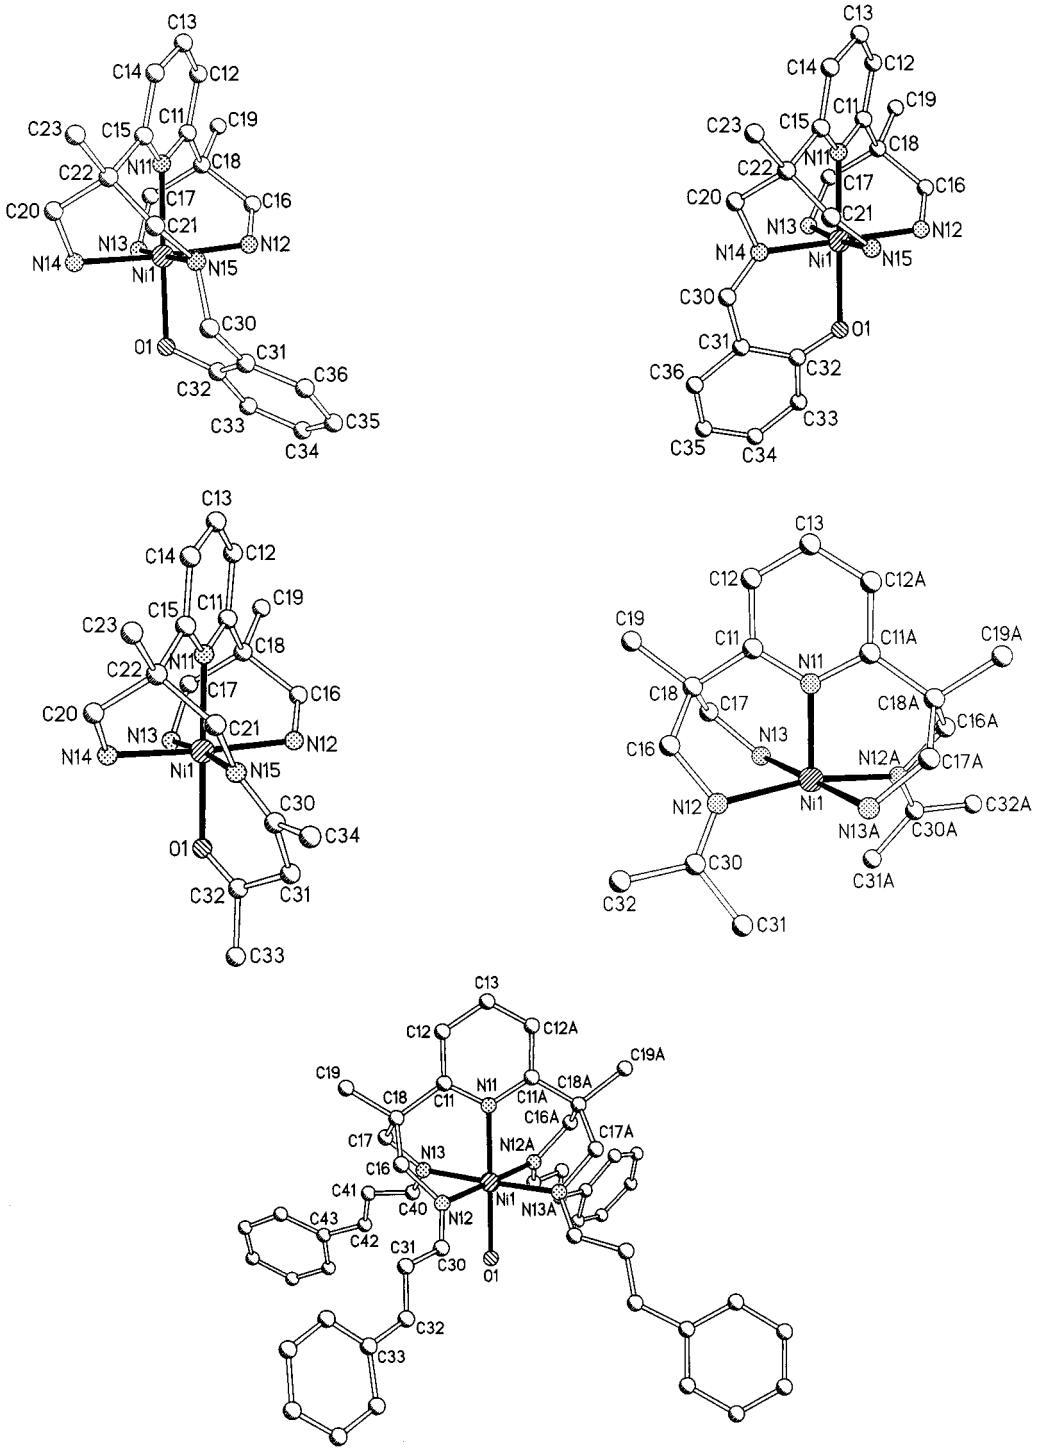


Figure 1. Molecular structures of the cations in **3** (top left), **5** (top right), **7** (middle left), **9** (middle right), and **11** (bottom); for clarity, ball-and-stick representations have been chosen, and hydrogen atoms have been omitted, the atom labelling is based on like orientations of the distortion of the NN_4 ligand cap, where applicable (see text)

nacac-pyN_4 (6), and [(6)Ni]$(PF_6)_2$ (7)

The difficulties in isolating a complex of the salicylaldimine quarter-unit **4** led us to study the condensation reaction of **1** with 1 equiv. of a related carbonyl substrate, acetylacetone (2,4-pentanedione). The expected condensation product is a β-ketoamine. While Schiff bases of salicylaldehyde can only exist as the phenol-imine tautomers, three distinct tautomeric forms are possible for β-ketoamines (enol-imine **A**, keto-enamine **B**, and keto-imine **C**).[17][18] Therefore, whereas salicylaldimines usually lose a proton upon metal complexation to become uninegative ligands, β-ketoamines may be either uninegative or neutral in their complexes, depending on whether the "central" carbon

Table 1. Selected bond lengths [Å] and angles [°] for **3**, **5**, **7**, **9** and **11** with estimated standard deviations in parentheses; the atom numbering is dictated by the tilt of the pyridine ring (see Figures and text)

atom is part of a methine or methylene group. The keto-imine tautomer **C** is expected to be a more flexible chelating ligand than **A** and **B**, since the central carbon atom is incorporated into the chain by two single bonds. At the same time, this coordination mode is expected to be disfavoured, and hence occur rarely, owing to the loss of double bond conjugation.

The ligand nacac-pyN_4 (**6**) is obtained from an equimolar mixture of **1** and acetylacetone in refluxing methanol. Addition of nickel(II) chloride, followed by hexafluorophosphate anion, yields a purple, microcrystalline precipitate which may be recrystallised from water. Its elemental analysis fits the formula [(nacac-pyN_4)Ni]$(PF_6)_2$ (**7**) in which the pyN_4 ligand has a single acetylacetone-derived sidearm. By analogy with the syntheses of **3** and **5**, compound **7** is expected to contain divalent nickel. The sidearm is thus required to be neutral, which suggests the keto-imine tautomeric form **C**. The IR spectrum is characterised by two strong bands at 1697 cm^{-1} and 1605 cm^{-1}, which may be assigned to the C=N and C=O stretching vibrations, respectively. This finding is compatible with tautomer **C**, since the C=N stretching vibration in a conjugated cyclic system occurs

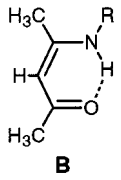

Table 2. Intramolecular angles [°] and distances [Å] illustrating the distortion of the ligand cap in complexes **3**, **5** and **7** (with estimated standard deviations in parentheses); compounds **9** and **11** do not show these distortions due to crystallographically imposed symmetry; see footnote and text for definitions of angles

A

B

C

at lower frequency (1660–1480 cm^{-1}).[19] By the same token, complexes involving ketones are expected to show especially low C=O stretching frequencies, when compared with the free ligand.[19]

The X-ray structure analysis of **7** confirms the single derivatisation of the ligand cap and the presence of a keto-imine tautomeric acetylacetone-derived sidearm (Figure 1), making **7** a rare if not the only example of a transition metal complex where this coordination mode is observed.[20] The overall coordination geometry of nickel(II) resembles that in **3**, but the NN_4 coordination cap shows a lesser distortion of the carbon backbone, as quantified by means of the parameters listed in Table 2 (cf. the structures of **3** and **5**). The bond Ni1–N15 involving the ketimine nitrogen atom {2.049(5) Å} is shorter than the other equatorial Ni–N bonds, and has the same length as the Ni–N_{py} bond (Table 1). The nickel and equatorial nitrogen atoms are not coplanar; rather, N15 is below and N14 above the plane defined by the other three equatorial atoms (Ni1, N12, N13) by 0.198(5) Å and 0.144(5) Å, respectively. The N–O chelate ring is six-membered and adopts a boat conformation, the methylene carbon atom C31 (at the "bow") and Ni1 (at the "stern") being above the best plane containing N15, C30, C32, and O1 by 0.384(8) Å and 0.635(1) Å, respectively. The bond between Ni1 and the keto oxygen atom {Ni1–O1, 2.105(4) Å} is intermediate between the corresponding axial bonds in **3** and **5** (Table 1). The coplanarity of all bonds at the imine nitrogen atom N15, the lack of planarity of the N–O chelate ring, and the differences in bond lengths within this ring (Table 1) make the assignment of the keto-imine tautomer **C** conclusive. Apparently, the geometric requirements imposed by the central nickel atom on the derivatised coordination cap are such that the ligand sidearm is best accommodated as a chelating group when in the keto-imine form, thus favouring this unusual coordination mode. The presence of the keto-imine form may also explain the remarkable hydrolytic stability of **7**. By contrast, nickel(II) complexes containing the chelating tautomers **A** or **B** (with R = alkyl) are reported to be extremely sensitive to traces of water in solution, and hence are accessible only under anhydrous conditions.[17][18]

$(nac)_2$-pyN_4 (8), and $[(8)Ni](PF_6)_2$ (9)

Initial experiments aimed at the synthesis of complex **7** yielded a crystalline by-product which analysed too high for carbon to be the acetylacetone derivative. An excess of sodium methoxide had been used for the deprotonation of **1**·4HBr·MeOH, making the solution sufficiently basic for acetylacetone to undergo a retro-aldol reaction, thereby liberating acetone. The elemental analysis data of the by-product were compatible with the nickel(II) complex of a bis(acetoneimine) derivative of the pentaamine ligand **1**, which we subsequently sought to synthesise in a directed manner.

Complex **9**, containing the ligand $(nac)_2$-pyN_4 (**8**), forms as the only isolated product in high yield as a purple, microcrystalline material when treating a methanolic solution of **1** with 4 equivalents of acetone at room temperature, followed by addition of nickel(II) acetate and ammonium hexafluorophosphate. The complex, while containing aliphatic Schiff base units, is remarkably stable towards hydrolysis. No special precautions need to be taken to exclude water from the reaction mixture, which is in fact the optimal solvent for recrystallisation. More forcing reaction conditions (reflux and/or a much larger excess of acetone) do not lead to more highly condensed products, two primary amino groups in the molecule remaining unaffected. The latter observation is in agreement with results reported by Curtis and co-workers,[21] who studied the reactivity of tris(1,3-propanediamine)-nickel(II) perchlorate in dry acetone and obtained a square-planar derivative of bis(1,3-propanediamine)-nickel(II) as an isolable intermediate, in which one acetone molecule had condensed with each of the two diamine ligands. A *trans* arrangement of the coordinated *N*-isopropylidene groups was suggested for this complex. Its hydrolytic instability, however, prevented structural

charaterisation. From this intermediate Curtis and co-workers obtained, upon prolonged reaction, a square planar nickel(II) complex of a 16-membered macrocycle containing diacetone-amine-imine linkages.[22] We have so far not observed similar reactivity for complex **9**.

The IR spectrum of **9** has a strong absorption at 1663 cm^{-1} assigned to the C=N stretching vibration, whereas the ^1H NMR spectrum is of little diagnostic value as it shows paramagnetically broadened and shifted signals (solvent: CD_3OD/D_2O). The UV/Vis spectrum of an aqueous or a methanolic solution of **9** reveals a band at 509 nm, which we assign to a d−d transition. The elemental analysis data suggest **9** to be a pentacoordinate complex, hexafluorophosphate being a very weakly coordinating ion at best. The solid-state UV/Vis spectrum (diffuse reflectance) is identical within experimental error to the solution spectrum (200−800 nm), the d−d band being recorded at 504 nm. Since the spectra of d^8 complexes are very sensitive to changes in the axial ligand positions,[23] these findings indicate the cation in **9** to be pentacoordinate both in aqueous or methanolic solution and in the solid state. The magnetic moment determined for **9** (Gouy balance) is 3.12 BM (spin only), corresponding to two unpaired electrons (theoretical value: 2.83 BM). By contrast, a diamagnetic ground state is predicted, to a first approximation, for Ni^{2+} (d^8) in a regular square pyramidal coordination environment.[24]

Compound **9** was studied by cyclic voltammetry to determine the redox potential of the $Ni^{II/III}$ couple in this less than usual coordination geometry. The cyclic voltammogram of **9** at room temperature between +1.24 and −2.36 V (Figure 2) shows a reversible redox wave in the anodic region ($E_{1/2}$ = +0.88 V) and an irreversible redox wave in the cathodic region (−1.67 V). The anodic process is assigned to the $Ni^{II/III}$ couple, whereas the cathodic process may involve irreversible reduction of the ligand, or generation of Ni^{I} and subsequent fast decomposition of the complex.

An x-ray crystallographic analysis confirms the assumed pentacoordination of the cation in **9** in the solid state. The structure of [(**8**)Ni]$^{2+}$ is shown in Figure 1. The pyridine, primary amine, and acetone-imine nitrogen atoms define a square pyramid. The molecule lies on a twofold rotation axis which contains Ni1, the pyridine nitrogen atom N11, and the *para* carbon atom of the pyridine ring, C13. As a consequence of the crystallographic symmetry, a distortion of the ligand cap as described for **3**, **5** and **7** is not observed. The primary amine nitrogen atoms (N13, N13A) and the nickel atom are on a straight line {N13−Ni1−N13A 179.3(2)°}, while the bonds connecting Ni1 with the acetone-imine nitrogen atoms N12 and N12A are at an angle of 168.2(2)° (N12−Ni1−N12A). Of the bonds involving Ni1, the axial bond Ni1−N11 to the pyridine nitrogen atom is the shortest at 1.991(4) Å, the basal bonds being somewhat longer, with bond lengths reflecting the sp^2 and sp^3 character of the nitrogen atoms, respectively {Ni1−N12: 2.041(3) Å; Ni1−N13: 2.080(3) Å}. All bonds radiating from the isopropylidene-imine nitrogen atom N12 are coplanar, as expected, and the rigidity in this donor group is accommodated by deviations of the angles at N12 and Ni1 from the expected values of 120° and 90°, respectively (see Table 1). As a consequence of this rigidity, the "inside" methyl groups (C31, C31A) approach each other to within 2.59(6) Å (C31−H···H−C31A), thereby shielding the nickel atom and blocking access to the sixth coordination site.

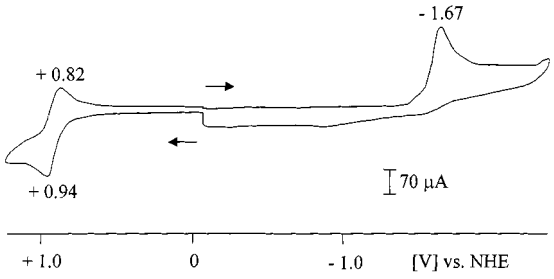

Figure 2. Cyclic voltammogram of **9** at room temperature (solvent: DMF; scan rate: 50 mVs^{-1})

$(cin)_4$-pyN_4 (10), and [(10)Ni(OH_2)]$(Br)_2$ (11)

The ligand concluding the present series is a derivative of **1** in which all four primary amino groups are condensed with a suitable carbonyl compound, namely *trans*- cinnamaldehyde (*trans*-3-phenyl-2-propenal). We expected this readily available α,β-unsaturated aromatic aldehyde to show high reactivity in the transformation at hand, as condensation would result in the formation of conjugated double bond systems in the four sidearms.[25] These would be relatively rigid, and the aromatic rings would be sufficiently removed from the metal centre for unfavourable steric interactions to prevent podand-like coordination of the ligand.

Fourfold condensation of cinnamaldehyde with the polyamine ligand is achieved by reacting the correct molar ratio of materials in refluxing methanol. Workup gives a yellow crude product which shows poorly resolved ^1H NMR spectra (see Experimental Section). In the IR spectrum, a strong band is observed at 1635 cm^{-1}, which is assigned to the C=N stretching vibration. When a methanolic solution of this product is treated with solid nickel(II) acetate, complexation is spontaneous, as jugdged by the colour change to orange. Workup of this solution gives an orange-brown microcrystalline solid whose IR and mass spectroscopic data indicate a complex containing the cation [(**10**)Ni(ac)]$^+$.

Single crystals of the aqua complex **11**, containing two molecules of methanol per formula unit, were obtained by repeated recrystallisation of the presumed acetato complex from methanol. The structure of the cation is shown in Figure 1, and relevant distances and angles are listed in Table 1. The molecule has C_2 symmetry, with Ni1, the aqua oxygen atom O1, and the pyridine nitrogen and *para* carbon atoms N11 and C13 lying on the two-fold rotational axis. The crystallographically imposed symmetry implies a regular conformation of the ligand cap; similar to the situation in compound **9**, all carbon atoms in the 2,6-diethylpyridine ligand backbone are coplanar, and the nonbonded distance between pairs of methylene carbon atoms (C16···C17A, C17···C16A) is the same {5.14(1) Å}. In contrast to the

structure of **9**, the equatorial nitrogen atoms in **11** are coplanar with the central metal, with angles N12−Ni1−N12A and N13−Ni1−N13A of 179.6(3)° and 177.9(3)°, respectively. The bond lengths Ni−N are all rather similar and lie in the range 2.076(7)−2.107(6) Å. As a consequence of the conjugated systems of double bonds, the atoms in the ligand sidearms (from the methylene carbon via the imine nitrogen atoms out to the phenyl rings) are virtually coplanar, with bonds and angles not deviating greatly from the normal values (Table 1). The aqua oxygen atom is coordinated to Ni1 at a distance of 2.148(7) Å, which is the same as in the parent complex [(**1**)Ni(OH_2)]I_2 {2.133(3) Å}.[4] The methanol molecules in this structure are situated between pairs of sidearm phenyl rings and are engaged in what seem to be weak hydrogen-bonded interactions with the bromide counterions, which are at a distance of 3.27(1) Å from the methanol oxygen atoms (sum of the van der Waals radii of O and Br: 3.37 Å[26]).

Conclusion

The series of ligands presented here may be obtained by selective or exhaustive condensation of the tetrapodal pentaamine **1** with a choice of carbonyl compounds, to give the respective Schiff bases. Derivatives obtained from **1** by introduction of *one* additional donor group into the ligand periphery are potentially hexadentate. They readily form mononuclear complexes with nickel(II) if an additional chelate ring can arise that is six-membered and sufficiently flexible (**2** and **6**). In the case of the salicylaldimine derivative **4**, this requires reduction of the C=N double bond. The derivative obtained from **1** by modification of *two* amino groups (having two diagonally juxtaposed isopropylideneimine units, **8**) forms a mononuclear complex in which these rigidly positioned substituents, while preventing the coordination of a sixth ligand, are sufficiently removed from one another so as not to prevent complexation as such. The condensation of all *four* primary amino groups in **1** with cinnamaldehyde leads to a derivative whose podand-like behaviour towards nickel(II) is facilitated by the limited steric demand of the phenylpropenylidene substituents. In all cases, nickel(II) complexation allows the isolation of pure, crystalline materials, which should make these ligands available for complexation studies with other transition metals. Also, the remaining primary amino groups of the singly derivatised square-pyramidal coordination caps make these ligands attractive subjects for further derivatisations.

Experimental Section

Materials and Instrumentation: All manipulations were performed under an atmosphere of dry nitrogen using standard Schlenk techniques, unless indicated otherwise. Solvents were dried and distilled before use. Reagents were AR grade or better and were purchased from Merck, Fluka, or Aldrich. 2,6-C_5H_3N{CMe-$(CH_2NH_2)_2$}$_2$·4HBr·MeOH (**1**·4HBr·MeOH) was prepared as described elsewhere.[10] IR (KBr discs) and UV/Vis spectra (solvent: water or methanol; solid state: diffuse reflectance) were recorded on Perkin−Elmer 16PC FT-IR or Shimadzu UV-3101 PC instruments. The cyclic voltammogram of **9** was recorded under an atmosphere of nitrogen using an EG & G PAR 246 A potentiostat equipped with a ROTEL A three-electrode cell, having a glassy carbon working electrode, a Pt counter electrode and Ag/AgCl/KCl (sat. in H_2O) as the reference electrode. The solvent was dimethylformamide, the conducting electrolyte $N^nBu_4PF_6$ (10^{-1} mol/l), scan rate 50 mV/s. Ferrocene was used as internal standard, with a potential of +0.40 V vs. NHE.[27] NMR spectra were measured on a JEOL JNM-EX 270 spectrometer, and mass spectra were obtained on JEOL MSTATION 700 and Micromass ZABSpecE spectrometers. Elemental analyses were performed using Carlo Erba Elemental Analysers 1106 (CHN) and 1108 (CHNS).

X-ray Crystallography: Crystal data for compounds **3**, **5**, **7**, **9**, and **11** are presented in Table 3, and selected distances and angles are listed in Table 1. The structures of the cations are shown in Figure 1. All structures were solved by direct methods and refined using the programme package SHELXTL 5.03.[28] All non-hydrogen atoms were refined anisotropically (full-matrix least-squares on F^2).

In the case of **3** and **9**, all hydrogen atoms were located in a difference Fourier synthesis and refined with a fixed common isotropic displacement parameter (exception for **3**: the hydrogen atoms in the methanol molecule were calculated in geometrically optimised positions). For **5**, **7** and **11**, all hydrogen atoms were positioned geometrically (exception for **5**: the hydrogen atoms of the aqua ligand in [(**1**)Ni(H_2O)]$^{2+}$ and of solvate water were located in a difference Fourier synthesis and not refined; exception for **11**: the hydrogen atoms in the aqua ligand were not included in the calculations). In the structure of **3**, the PF_6^- counterion is disordered, and two preferred orientations could be refined (occupancy factors 0.68(1) and 0.32(1), respectively). In **7**, one of the two PF_6^- anions shows rotational disorder, which was resolved with refined occupancy factors 0.61(2) and 0.39(2), respectively, for alternative sets of the four equatorial F atom sites. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-129 628 (**3**) to CCDC-129 632 (**11**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]

[(2)Ni]PF_6 (3): To a stirred suspension of pyN_4·4HBr·MeOH (0.48 g, 0.79 mmol) in methanol (50 mL) was added sodium metal (0.07 g, 3.16 mmol), which dissolved within ca. 5 minutes to give a clear solution. To this solution was added dropwise over 2 h a solution of salicylaldehyde (0.10 g, 0.79 mmol) in methanol (20 mL). The resulting yellow solution was taken to dryness, and the remaining oil taken up in ethanol (20 mL). To this mixture was added $NaBH_4$ (0.24 g, 6.32 mmol) in small portions, and the mixture heated to reflux for 1 h. Excess $NaBH_4$ was then hydrolysed by careful addition of water (10 mL). Addition of Ni$(ac)_2$·$4H_2O$ (0.23 g, 0.79 mmol) gave a purple solution, from which a purple solid crystallised upon dissolution of NH_4PF_6 (0.13 g, 0.79 mmol). The solid was separated by filtration. Recrystallisation from water/methanol (50:50 v/v) yielded crystals suitable for an X-ray structural analysis (0.15 g, 0.24 mmol, 30% relative to **1**). − IR (KBr): $\tilde{\nu}$ = 3375m, 2926m, 1594s, 1477s, 1456s, 1296s, 1086m, 1019s, 850s (PF_6), 558s cm^{-1}. − UV/Vis (water): λ_{max} (ε) = 509 nm (22 dm^3·mol^{-1}·cm^{-1}). − MS (FAB); *m/z* (%): 414 (100) [M^+]. − $C_{20}H_{30}N_5F_6NiOP$·CH_3OH·H_2O (610.23): calcd. Addition of $NiCl_2$·$6H_2O$ (0.37 g, 1.55 mmol) to the colourless mixture gave a purple solution, from which a purple crystalline solid precipitated upon dissolution of NH_4PF_6 (0.25 g, 1.55 mmol). The material was isolated and recrystallised from water to give single crystals suitable for an X-ray structural analysis (0.57 g, 0.83 mmol relative to **1**, 54%). – IR (KBr): $\tilde{\nu}$ = 3380s, 2978m, 1697s (C=N), 1605s (C=O), 1471s, 1399m, 1099m, 1024s, 851s (PF_6), 559s cm^{-1}. – MS (FAB); *m/z* (%): 390 (100) [(M – H)$^+$]. – $C_{18}H_{31}F_{12}N_5NiOP_2$ (682.13): calcd. C 31.70, H 4.58, N 10.26; found C 31.69, H 4.68, N 10.02.

[((nac)$_2$-pyN$_4$)Ni](PF$_6$)$_2$ (9): To a solution prepared as described above for **3** (20 mL MeOH; pyN$_4$·4HBr·MeOH: 0.39 g, 0.63 mmol; Na: 0.06 g, 2.52 mmol) was added dropwise over 1 h a solution of acetone (0.39 g, 2.52 mmol) in methanol (20 mL), followed by addition of solid Ni(ac)$_2$·$4H_2O$ (0.18 g, 0.63 mmol) to give a purple solution. Dissolution of NH_4PF_6 (0.21 g, 1.26 mmol) led to the precipitation of a purple microcrystalline solid which was isolated by filtration and recrystallised from water to yield, after isolation and drying in air, single crystals suitable for X-ray structure analysis (0.34 g, 0.50 mmol, 79% relative to **1**). – IR (KBr): $\tilde{\nu}$ = 3378m, 1663s (C=N), 1603m, 1470m, 1376m, 1268m, 1108m, 1016m, 848s (PF_6), 558s cm^{-1}. – UV/Vis (water): λ_{max} (ε) = 509 nm (26 dm^3·mol^{-1}·cm^{-1}). – MS (ESI$^+$); *m/z* (%): 389 (65) [M$^+$], 447 (100) [M$^+$ + 58 (acetone)]. – $C_{19}H_{33}F_{12}N_5NiP_2$ (680.15): calcd. C 33.55, H 4.89, N 10.30; found C 33.43, H 5.13, N 10.07.

[{(cin)$_4$-pyN$_4$}Ni(X)]Y (X = H$_2$O, Y = Br$_2$ 11): To a stirred suspension of pyN$_4$·4HBr·MeOH (1.90 g, 3.13 mmol) in methanol (20 mL) was added LiOMe (1M stock solution in MeOH, 12.52 mL, 12.52 mmol), resulting in a clear solution after ca. 2 min. To this was added *trans*-cinnamaldehyde (1.65 g, 12.52 mmol) in one portion. The mixture was heated to reflux for 4 h, during which time the solution became yellow. Removal of the solvent in vacuo and triturating the residue by stirring with diethyl ether (30 mL) gave a yellow solid which was separated by filtration, washed with ether and dried in vacuo. Elemental analytical results of the products of repeated preparations in a variety of solvents, although unsatisfactory, agree best with a formulation of the solid as the fourfold condensation product. In the IR spectrum, a strong band is observed at 1635 cm^{-1}, which is assigned to the C=N stretching vibration. ^{1}H NMR spectra show broad and badly resolved signals in each case. The material was therefore used in the subsequent preparations without further characterisation. No effort was made to exclude air or moisture. The yellow condensation product (presumed as py(Ncinald)$_4$; 0.26 g, ≤ 0.38 mmol) was dissolved in methanol (20 mL), and solid Ni(ac)$_2$·$4H_2O$ (0.09 g, 0.38 mmol) ad-

ded to give an orange solution. Reduction of the volume to ca. 10 mL led to the formation of an orange-brown microcrystalline precipitate which was filtered off and washed with methanol. IR and MS data indicate the solid to contain the acetato complex cation (X = ac). − IR (KBr): $\tilde{\nu}$ = 3447w, 3053w, 1627s (C=N), 1592s, 1449m, 1425m, 1262m, 1175m, 749s, 733s, 705s, 688s, 612m cm^{-1}. − MS (ESI^+); *m/z* (%): 825 (100) $[(\mathbf{10})Ni(ac)]^+$. − Repeated recrystallisation from methanol gave crystals of the aqua complex (X = H_2O; Y = Br_2) which were used in the X-ray structure analysis (0.29 g, 0.29 mmol, ≤ 75%, calculated for formula **11**). Apparently, acetate is exchanged for an aqua ligand, and lithium bromide is not removed in the course of the recrystallisations, which explains the presence of bromide counterions in the structurally characterised sample. The perchlorato perchlorate salt (X = Y = ClO_4) was obtained by recrystallisation in the presence of $NaClO_4$, but did not give satisfactory single crystals. Data for this salt are as follows: MS (FAB); *m/z* (%): 765 (75) $[(\mathbf{10})Ni]^+$; 864 (100) $[(\mathbf{10})Ni(ClO_4)]^+$. − $C_{49}H_{51}Cl_2N_5NiO_9$ {983.57, $[(\mathbf{10})Ni(ClO_4)]ClO_4 \cdot H_2O$}: calcd. C 59.83, H 5.22, N 7.12; found C 59.83, H 5.45, N 6.75.

Acknowledgments

We thank Professor D. Sellmann for generous support of this work and Mr. G. Burgeth for the measurement of a solid-state UV spectrum. Financial support from the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

[20] A recent search of the Cambridge Crystallographic Database yielded seven examples of transition metal complexes containing a keto-imine moiety [cf. Formula C]. However, all these structures are inconclusive as to the true nature of the chelate rings. The systematic names of the ligands either imply negative charges, or the number of counterions does not match the oxidation state of the central metal ion.

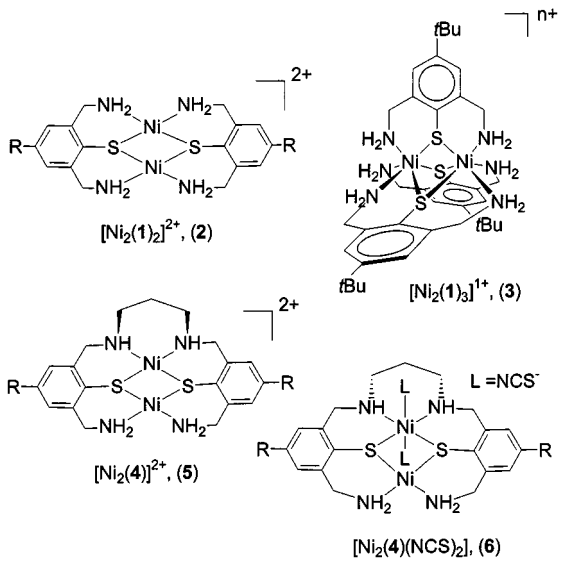
Control of Reactivity of Dinuclear Nickel(II) Amine-Thiolate Complexes

Berthold Kersting[a]



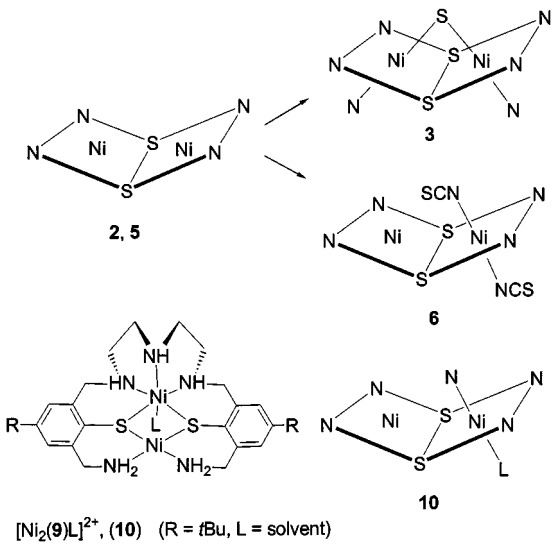
Keywords: Septadentate N_5S_2-ligand / Dinuclear complexes / Nickel / Reactivity / Redox chemistry

The coordination chemistry of a series of dinickel complexes of the new septadentate amine-thiolate ligand *N*,*N*′-bis[2-thio-3-aminomethyl-5-*tert*-butylbenzyl]diethylenetriamine, H_2**9**, has been investigated in the context of ligand binding and oxidation state changes. The complexes $[Ni_2(\mathbf{9})(L)][ClO_4]_2$ (**10**), $[Ni_2(\mathbf{9})(Cl)][Cl]$ (**11**), $[Ni_2(\mathbf{9})(L)][BPh_4]_2$ (**12**), and $[Ni_2(\mathbf{9})(NCS)][OH{\cdot}OH_2]$ (**13**) have central $N_2Ni(\mu\text{-}SR)_2NiN'_3L$ cores [L = labile solvent molecule (**10**, **12**), Cl^- (**11**), and NCS^- (**13**)] composed of dithiolate bridged planar NiN_2S_2 and six-coordinate NiN'_3S_2L units. This is demonstrated for **11** and **13** by crystal structure determinations and for **10** and **12** by UV/Vis spectroscopy and room temperature magnetic susceptibility measurements. Complexes **10**, **11**, or **12** readily add other co-ligands at the NiN'_3S_2L fragment by substitution of the solvent molecule L (**10**, **12**) or the chloride substituent (**11**). The overall structure of the parent complexes is not affected by the substitution reactions. An electrochemical study has shown that complex **10** undergoes two successive one-electron oxidations at +0.88 and +0.41 V vs SCE. The oxidized species are not thermally stable, but electronic absorption spectra and EPR spectra are indicative of the presence of Ni^{III} species.

Introduction

Polydentate Schiff base ligands derived from 2,6-diformyl-4-methylthiophenol and certain α,ω-diamines are versatile ligands in the preparation of discrete dithiolate-bridged dimetal complexes.[1] Their specific coordination mode is due to the presence of *o*,*o*′-iminomethyl substituents, which, by formation of intramolecular chelate rings, effectively block terminal metal-coordination sites and, in contrast to a variety of monodentate thiolate ligands, allow for a better control of the nuclearity and reactivity of transition metal thiolate complexes.[2] Due to the presence of the soft thiolate ligands it is also often possible to stabilize metal ions in unusually high oxidation states. The coordination chemistry of such ligands, in particular with first-row transition metals M = Fe, Ni, and Cu,[3–5] has thus been an area of considerable interest recently, since dithiolate bridged, redoxactive $M(\mu\text{-}SR)_2M$ assemblies also occur in the active sites of various enzymes.[6–8] Surprisingly, there is a paucity of information in the literature concerning the chemistry of the analogous amine-thiophenolate ligands,[9][10] although their corresponding complexes offer the further advantage of being hydrolytically more stable.[11]

Recently we reported the synthesis and characterization of coordinatively unsaturated dinuclear nickel amine-thiolate complexes $[Ni_2(\mathbf{1})_2]^{2+}$ (**2**)[12] and $[Ni_2(\mathbf{4})]^{2+}$ (**5**) (Scheme 1).[13] Both complexes exhibit $N_2Ni(\mu\text{-}SR)_2NiN_2$ core structures and both were found to readily add co-ligands resulting in total or partial change of nickel coordination numbers from four in the parent complexes (**2**, **5**) to six in the products (**3**, **6**). While the former transformation (**2** → **3**) is accompanied by severe metal/ligand donor atom rearrangements, the latter (**5** → **6**) leaves the overall core structure of the parent complex unchanged, which is due to its fixation by the hexadentate ligand. This situation, along with the (slightly) different nickel coordination environments in **3**, means that its reactions with monodentate co-ligands proceed in a well-defined manner. Scheme 2 depicts the stereochemical courses of these reactions.



Scheme 1. Structures of dinuclear nickel amine-thiolate complexes **2**,[12] **3**,[12] **5**,[13] and **6**[13]

To further explore the reactivity of thiolate-bridged complexes featuring a central $Ni(\mu\text{-}SR)_2Ni$ core, we have now focused on the reactivity of nickel complexes of the amine-thiolate ligand H_2**9** (see Scheme 2), which provides dissimilar N_2S_2 and N'_3S_2 donor sets (N and N′ denote primary

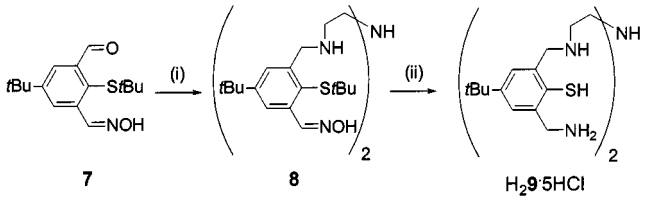
Scheme 2. Core structural changes during transformations **2** → **3** and **5** → **6** and structure of dinuclear nickel complexes of amine-thiolate ligand H_2**9**

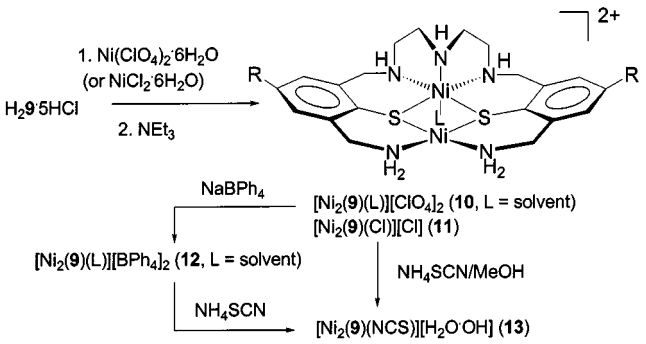


and secondary nitrogen atoms, respectively). It was assumed that the $-(CH_2)_2NH(CH_2)_2-$ chain bridging the two 2,6-bis(aminomethyl)-4-*tert*-butylthiophenol units would not distort the typical coordination observed in complexes **2** and **5**. Instead, the additional NH donor atom was anticipated to be involved in a specific *fac* coordination mode with two other secondary nitrogen and two bridging thiolate sulfur atoms, thereby yielding a six-coordinate $NiS_2N'_3L$ unit with a weakly bound solvent molecule L at the sixth coordination site. Similar strategies have been used by Sellmann et al. to control the reactivity of octahedral $MN_{5-x}S_xL$ complexes.[14]

This paper reports the synthesis of H_2**9** and some of its dinickel complexes. The crystal structures of $[Ni_2(\mathbf{9})(Cl)][Cl]$ (**11**) and of the isothiocyanate complex $[Ni_2(\mathbf{9})(NCS)][OH{\cdot}OH_2]$ (**13**), which is obtained by reaction of **11** with NH_4SCN, are also presented. The results obtained clearly demonstrate that control of the reactivity of dinuclear amine-thiolate complexes is possible, given that their core structures are assembled by specific, polydentate amine-thiolate ligands. All complexes have been further characterized by IR and UV/Vis spectroscopy and by cyclic voltammetry. Products obtained by chemical oxidation of the thiolate complexes have been characterized by UV/Vis and EPR spectroscopy.

Results and Discussion

Ligand Synthesis



The heptadentate N_5S_2 ligand, H_2**9**, was prepared following the method described in Scheme 3. In the first step, two equivalents of aldehyde **7** were condensed with one equivalent of *N*,*N*-bis(2-aminoethyl)amine. The resulting imine/thioether/oxime compound was reduced in situ with $NaBH_4$ to give the corresponding amine/thioether/oxime compound **8**. Treatment of **8** with sodium in liquid ammonia resulted in reduction of the oxime groups and reductive cleavage of the ArS−*t*Bu bonds to give, after acidic workup, the pentahydrochloride salt, $H_2\mathbf{9} \cdot 5\,HCl$, in an over-all yield of 56%. $H_2\mathbf{9} \cdot 5\,HCl$ is very soluble in protic solvents such as water or methanol. These solutions can be handled in air for short periods of time. They were, however, freshly prepared under an inert atmosphere for the synthesis of the metal complexes.

Scheme 3. Preparation of $H_2\mathbf{9} \cdot 5\,HCl$: (*i*) 0.5 equiv. $NH(CH_2CH_2NH_2)_2$, $NaBH_4$; (*ii*) Na/NH_3, HCl

Synthesis of Dinuclear Nickel Complexes

The preparations and notations of dinuclear nickel complexes of the heptadentate amine-thiolate ligand are summarized in Scheme 4. Ligand $H_2\mathbf{9} \cdot 5\,HCl$ reacted with $Ni(ClO_4)_2 \cdot 6\,H_2O$ or $NiCl_2 \cdot 6\,H_2O$ in the presence of a base such as NEt_3 in 1:2:7 molar ratios to give complexes $[Ni_2(\mathbf{9})(L)][ClO_4]_2$ (**10**) and $[Ni_2(\mathbf{9})(Cl)][Cl]$ (**11**), respectively, as red microcrystalline solids. Addition of $NaBPh_4$ to a solution of **10** in MeOH produced complex $[Ni_2(\mathbf{9})(L)][BPh_4]_2$ (**12**) in good yield. The formulation of complexes **10**, **11**, and **12** as dinuclear complexes was confirmed by X-ray crystal structure determination of **11** (see below). In contrast to **10** and **11**, the tetraphenylborate salt **12** was found to exhibit good solubility in solvents such as acetonitrile or dichloromethane, thus facilitating spectroscopic studies of the $[Ni_2(\mathbf{9})(L)]^{2+}$ complex in noncoordinating solvents (see below).

Scheme 4. Preparation of nickel complexes **10**−**13**

Reaction of complexes **10** or **11** with ammonium thiocyanate in an acetonitrile/methanol mixed solvent system resulted in the precipitation of a dark-red crystalline mate-

rial that was shown by analysis to be $[Ni_2(\mathbf{9})(NCS)][OH{\cdot}OH_2]$ (**13**). This complex could be obtained independently by reaction of the tetraphenylborate complex **12** with NH_4SCN in the same solvent system. Once precipitated, complex **13** redissolves in *N*,*N*-dimethylformamide only. Interestingly, complex **13** showed no tendency to bind further NCS^- ions − even in the presence of a 10-fold molar excess of NH_4SCN.

Complexes **10** (μ_{eff} = 3.1 μ_B), **11** (μ_{eff} = 3.1 μ_B), **12** (μ_{eff} = 3.0 μ_B), and **13** (μ_{eff} = 3.1 μ_B) are all paramagnetic in the solid state at 295 K, implying that the complexes are all composed of a planar, diamagnetic $Ni^{II}N_2S_2$ (S = 0) unit and an octahedral, paramagnetic $Ni^{II}N'_3S_2L$ center (S = 1) per molecule of complex. The presence of a six-coordinate Ni^{II} ion was confirmed for **11** and **13** by X-ray crystal structure determinations, and for **10** and **12** by electronic absorption spectroscopy (see below). In the solid state, the nature of the substituent L for complexes **10** and **12** could not be unambiguously identified. Possible candidates for L are a methanol or a water molecule.

IR spectra of **10** and **12** are very similar except for the absorptions of the anions. The ν(ClO) stretching frequency of the ClO_4^- ions in **10**, for example, is split into three very strong and sharp absorptions at 1150, 1115, and 1089 cm^{-1}. From the splitting one might conclude that a ClO_4^- ion occupies the free coordination site L in **10**. However, in $[Ni_2(\mathbf{4})][ClO_4]_2$ (**5**)[13] where a similar splitting of the $\nu_3(F_2)$ mode is observed, the ClO_4^- ions are not involved in coordination to the nickel ions. The splitting of this band might thus be caused by hydrogen bonding interactions with NH groups of the ligand. Unfortunately, it was not possible from the IR data to identify the nature of the substituent L in **10** and **12**.

Compound **13** was shown by infrared spectroscopy to contain no ClO_4^- (absence of the characteristic Cl−O stretching frequency at 1100 cm^{-1}). A new feature at 2090 cm^{-1} [ν(CN)] revealed the presence of a thiocyanate ion. Relative to the ν(CN) stretching frequency of KSCN (2053 cm^{-1}), the shift to higher frequencies implied coordination of the thiocyanate ion.[15]

Crystal Structures of 11 and 13

The X-ray crystal structure determinations of amine-thiolate complexes **11** and **13** confirm the dinuclear nature of the amine-thiolate complexes. They also demonstrate that the substitution reactions do not affect the overall structures of the parent complexes, which is in contrast to the severe ligand/donor atom rearrangements observed in the core structures during reactions of complexes **2** and **5**. The structures of the complexes are displayed in Figures 1 and 2 together with the atomic numbering schemes.

Complex **11** is composed of the dinuclear complex $[Ni_2(\mathbf{9})(Cl)]^+$, one water and two acetonitrile molecules of crystallization, and a chloride ion. Both the water molecule and the chloride ion are involved in hydrogen bonding interactions with the hydrogen atoms of nitrogen atoms N(1), N(3), and N(5) of the complex monocation. The corresponding distances are summarized in the legend to Figure 3. There are no bonding interactions between the chloride ion and the nickel atoms of the cation. The shortest distance is 3.783(3) Å for Cl(2)···Ni(2). A similar hydrogen bonding network is observed in complex **13**, where the Cl^- ion is replaced by an OH^- ion (see below).

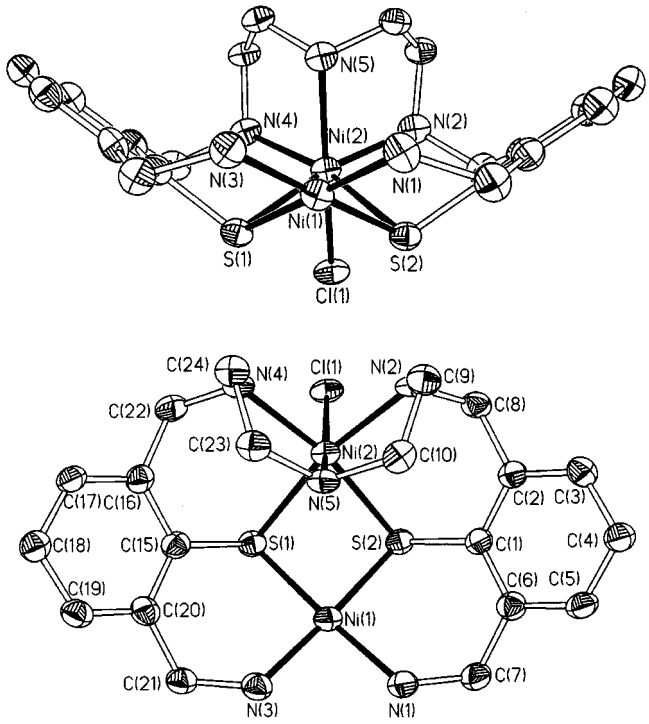


Figure 1. Molecular structure and atomic numbering of the $[Ni_2(\mathbf{9})(Cl)]^+$ cation in **11** (50% probability thermal ellipsoids). For clarity, *tert*-butyl groups and hydrogen atoms have been omitted

Table 1. Selected bond lengths [Å] in **11** and **13**

	11	**13**		**11**	**13**
Ni(1)−S(1)	2.200(2)	2.196(1)	Ni(2)−S(1)	2.414(2)	2.425(2)
Ni(1)−S(2)	2.189(2)	2.203(2)	Ni(2)−S(2)	2.429(2)	2.480(1)
Ni(1)−N(1)	1.954(4)	1.928(4)	Ni(2)−N(2)	2.090(4)	2.097(4)
Ni(1)−N(3)	1.943(4)	1.946(5)	Ni(2)−N(4)	2.095(4)	2.110(4)
			Ni(2)−N(5)	2.134(4)	2.147(4)
Ni(1)···Ni(2)	3.103(1)	3.149(1)	Ni(2)−L[a]	2.490(2)	2.070(5)

[a] L = Cl(1) in **11**, L = N(6) (NCS) in **13**.

The $[Ni_2(\mathbf{9})(Cl)]^+$ cation possesses an idealized C_s symmetry with a pseudo-mirror plane passing through the two nickel atoms and the secondary nitrogen atom N(5). Its overall structure is very similar to that of the neutral complex $[Ni_2(\mathbf{4})(NCS)_2]$ (**6**, see Scheme 1), from which it may be derived by replacing one NCS^- ion with the nitrogen atom N(5) of the lateral bis(2-aminoethyl)amine moiety. The average Ni−N and Ni−S bond lengths for the planar NiN_2S_2 (1.949 Å and 2.195 Å) and six-coordinate NiN_3S_2Cl sites (2.106 Å and 2.422 Å) show no unusual features and compare well with those in other planar NiN_2S_2[16] and octahedral NiN_4S_2 complexes,[13][17] respec-

tively. The Ni(2)−Cl(1) distance of 2.490(2) Å is likewise found in a range typical for six-coordinate NiN_xS_yCl complexes.[18] It should be noted that the Ni(2)−N(5) bond length of 2.134(4) Å *trans* to Ni(2)−Cl(1) is significantly longer than the other two Ni(2)−N distances. This bond length and the angle N(5)−Ni(2)−Cl(1) [162.9(1)°] imply that the N_3S_2 binding pocket of the ligand is too small to accommodate a nickel(II) ion in a regular octahedral coordination. The same conclusions can be drawn from the structure of **13**.

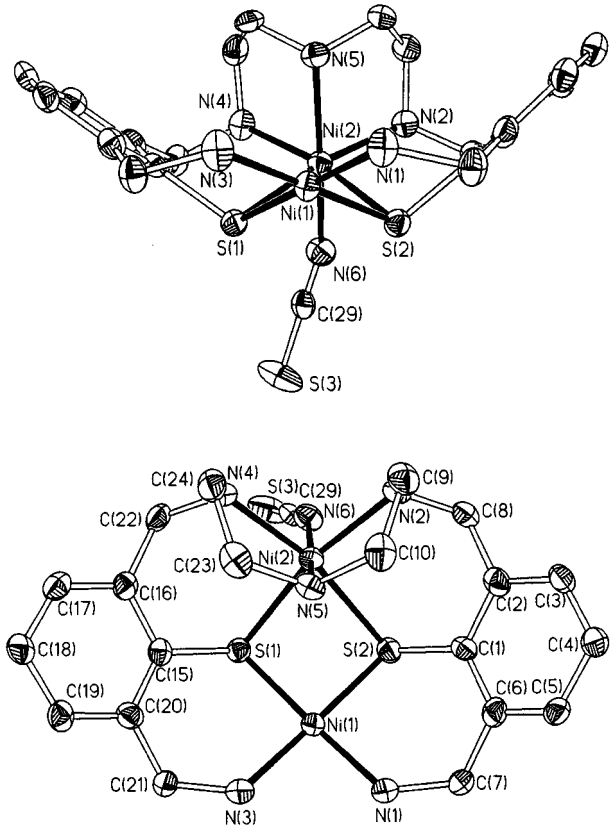

Figure 2. Molecular structure and atomic numbering of the $[Ni_2(\mathbf{9})(NCS)]^+$ cation in **13** (50% probability thermal ellipsoids). For clarity, *tert*-butyl groups and hydrogen atoms have been omitted

The isothiocyanate complex **13** is composed of the dinuclear complex $[Ni_2(\mathbf{9})(NCS)]^+$, a water molecule of crystallization, and a hydroxide ion. The hydroxide ion forms a strong $H_2O\cdots H-O$ hydrogen bonding contact to the water solvent molecule [$H_2O(1)\cdots O(2)$ 2.782(7) Å]. It should be noted that this structure is different from the $HO\cdots H\cdots OH^-$ arrangement generally found in hydrated hydroxy complexes of metals.[19] The formation of the present structure may arise from the three additional $HO^-\cdots H-N$ hydrogen bonding interactions with nitrogen atoms N(1), N(3), and N(5) of the complex monocation [O(1)···N(1) 3.239(7) Å, O(1)···N(3) 3.355(6) Å, O(1)···N(5) 3.222(7) Å]. In a similar way to **11**, there are no bonding interactions between the hydroxo or water oxygen atoms and the nickel ions of the cation. The shortest distance is 3.632(3) Å for O(1)···Ni(1). The structure of the $[Ni_2(\mathbf{9})(NCS)]^+$ cation may be simply

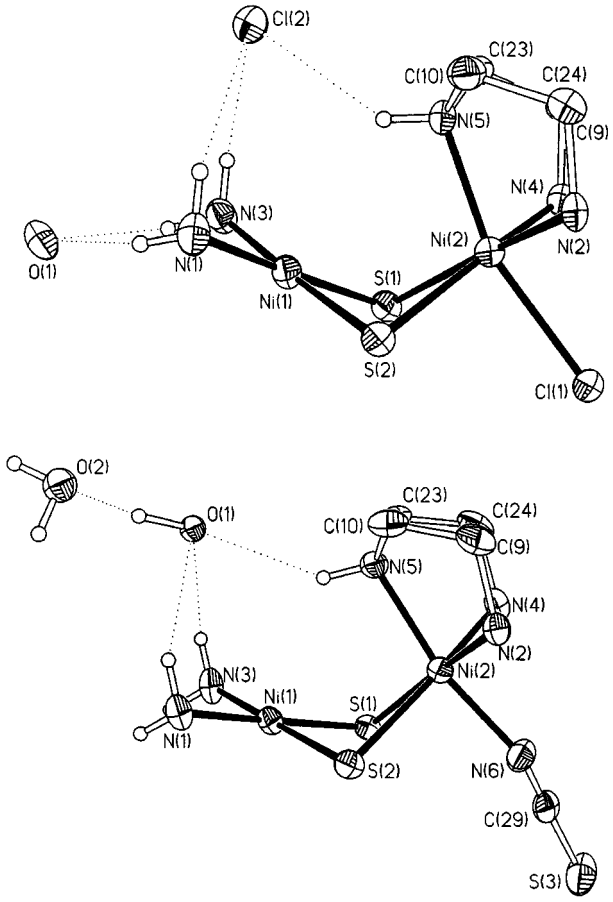

Figure 3. Core structures of complexes **11** and **13** (50% probability thermal ellipsoids). Hydrogen bonding interactions [A] in **11**: Cl(1)···N(1) 3.436(8), Cl(1)···N(3) 3.301(9), Cl(1)···N(5) 3.250(8), O(1)···N(1) 3.084(7), O(1)···N(3) 2.927(6), and in **13**: O(1)···O(2) 2.782(7), O(1)···N(1) 3.239(7), O(1)···N(3) 3.355(6), O(1)···N(5) 3.222(7). N−S and C−S bond lengths in **13**: N(6)−C(29) 1.160(7), S(3)−C(29) 1.629(6)

derived from that of $[Ni_2(\mathbf{9})(Cl)]^+$ by replacing the chloro ligand with an isothiocyanate group. There are no other gross structural changes, as evidenced by the similar shapes and similar Ni−N and Ni−S bond lengths (see Table 1).

The main difference between **5** and the complexes of the present study is the number of co-ligands that can be coordinated to the dinickel site. Dicationic **5** binds two NCS^- ligands to give complexes of the type $[N_2Ni(\mu\text{-}SR)_2NiN'_2(NCS)_2]$ (**6**) with the co-ligands in *trans* positions at the octahedral $S_2NiN'_2(NCS)_2$ site. This core structure is already partially preassembled in **10**, **11**, or **12** with an exchangeable substituent L and a nonexchangeable NH donor in place of the NCS^- ions in **5**. Hence the complexes of the present study bind only one co-ligand.

Electronic Absorption Spectra of Nickel Complexes 10−13

Although structural data for complexes **10** and **12** are currently not available, both are assumed to have a central $N_2Ni(\mu\text{-}SR)_2NiN'_3(L)$ core similar to that found for com-

[a] N and N′ denote primary and secondary nitrogen atoms.

plexes **11** and **13** in the solid-state. This is strongly supported by their electronic absorption spectral data. UV/Vis spectral data for all complexes are summarized in Table 2.

The spectra recorded for complexes **10**, **12**, and **13** are very similar − even in solvents of different donor strength. The spectrum of **10** in MeOH solution is representative of all the compounds, with an intense absorption at λ_{max} = 516 nm, a shoulder at 621 nm, and a weak absorption at 926 nm. It is noted that the position of the weak absorption in the 920 to 950 nm region appears to be dependent on the choice of the solvent.

The comparisons of the present UV/Vis spectral data with those of four-coordinate NiN_2S_2 complexes (**2**) or those of octahedral NiN_3S_3 complexes (**3**), respectively, clearly reveal the spectra of **10**−**13** to be due to superpositions of the electronic transitions of planar NiN_2S_2 and octahedral NiN_3S_2L chromophores. The intense band in the narrow range 506 to 516 nm, for example, is readily assigned to an electronic transition of a planar NiN_2S_2 unit. These bands are of approximately half the intensity of the corresponding band at 503 nm in **2**, which is consistent with the presence of only one such unit in complexes **10**−**13**. The other two bands at ca. 620 and ca. 930 to 950 nm are characteristic for an octahedral NiN_3S_2L complex.[12][20] Complex **3**, with two octahedral NiN_3S_3 units, exhibits absorptions at similar positions at 593 ($^3A_{2g}\rightarrow{}^3T_{1g}$) and 922 nm ($^3A_{2g}\rightarrow{}^3T_{2g}$), both of which again exhibit approximately twice the intensity of the respective bands of compounds **10**−**13**. This again supports the presence of only one NiN_3S_2L chromophore per dinuclear complex, as is required for complexes composed of one NiN_2S_2 and one NiN_3S_2L chromophore. The solvent dependence of the ($^3A_{2g}\rightarrow{}^3T_{2g}$) transitions around 920−950 nm is taken as an indication for the presence of an exchangeable solvent molecule in the coordination sphere of the octahedral NiN'_3S_2L fragment.

Electrochemistry

Complexes **10**, **13**, and **5** (for comparative purposes) were further characterized by cyclic voltammetry. The electrochemical properties of complex **2** have been reported previously.[12] Cyclic voltammograms (CV′s) were recorded in CH_3CN solution (for **5** and **10**) or DMF solution (for **13**) with tetra-*n*-butylammonium hexafluorophosphate as the supporting electrolyte and ferrocene as internal standard. In the following discussion, all redox potentials are referenced versus SCE.[21] Table 3 summarizes the measured potentials.

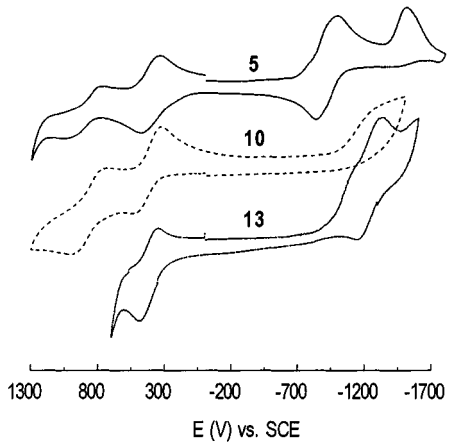

Figure 4. Cyclic voltammograms of complexes **5** and **10** in CH_3CN solution and of **13** in DMF solution at 295 K. Experimental conditions: [**5**], [**10**], [**13**] ca. $1\cdot10^{-3}$ M, Pt disk working electrode, Ag wire reference electrode, 0.1 M [nBu$_4$N][PF$_6$], scan rate 200 $mV\cdot s^{-1}$

The CV of complex **10** in acetonitrile solution is shown in Figure 4. Figure 4 shows, in the anodic potential region, two oxidation waves at $E^1_{1/2}$ = +0.88 V and at $E^2_{1/2}$ = +0.41 V vs SCE − an irreversible reduction wave occurred at ≈ −1.1 V. The electrochemical behavior of complexes **2**

[a] Solutions of complexes were ca. $1 \cdot 10^{-1}$ M in supporting electrolyte (nBu$_4$NPF$_6$) and ca. $1 \cdot 10^{-3}$ M in sample; Pt disk working electrode, Ag wire reference electrode, scan rate 200 mV s^{-1}, $E^{\times}_{1/2} = (E^{ox}_p + E^{red}_p)/2$ for reversible one-electron transfer processes; oxidation (E^{ox}_p) or reduction peak potentials (E^{red}_p) are given for irreversible (irr) processes; number in parentheses denote peak-to-peak separations $\Delta E_p = |E^{ox}_p - E^{red}_p|$, n.o. = not observed. − [b] N and N′ denote primary and secondary nitrogen atoms. − [c] Solvent = acetonitrile. − [d] Values taken from ref.[12] − [e] L^1 = macrocyclic N_4S_2 ligand,[9] reported potentials were converted into the SCE [E (V) vs SCE = E (V) vs Ag/Ag$^+$ + 0.38 V] according to Table 1 in ref.[21], peak-to-peak separations were reported as reversible (r) or quasi-reversible (qr). − [f] Solvent = *N*,*N*-dimethylformamide.

and **5** in the anodic potential region is very similar, with two well-separated oxidation waves at $E^1_{1/2} \approx +0.90$ V and at $E^2_{1/2} \approx +0.41$ V vs SCE (see Table 3). In the following, we will discuss only processes that occur in the anodic potential region.[22]

The oxidation waves at $E^1_{1/2}$ and at $E^2_{1/2}$ of all complexes exhibit very large peak-to-peak separations, indicating that the corresponding charge-transfer processes are electrochemically not reversible. Is was not possible by controlled-potential coulometry to determine the number of electrons transferred during these processes, since at ambient temperature the oxidized species of complexes **2**, **5**, and **10** are not stable on the timescale of a coulometric experiment. Electrolysis of complex **10** at an applied potential of +0.60 V vs SCE, for example, resulted in a color change from red to transient dark-green. These transient dark-green solutions were also obtained by chemical oxidation of the complexes. Figure 5 shows the UV/Vis spectra taken for complex **10** before and after its oxidation. The observed spectral changes clearly show the oxidized species to be thermally unstable at room temperature. The fate of the oxidized species is discussed below. For now we estimate the half-life $\tau_{1/2}$ of the oxidized species to be ca. 15 min (from the decrease in ε_M at 584 nm with time). Complexes **2** and **5** behaved similarly, producing transient dark-green solutions upon electrolysis or chemical oxidation.

In a similar way to transition metal phenolato complexes, the oxidation of a transition metal thiophenolato complex can, in principle, be either metal- or ligand-centered.[23] There are several points that imply that the processes at $E^2_{1/2}$ and $E^1_{1/2}$ involve metal-centered one-electron transfer reactions subsequently producing mixed-valent $Ni^{III,II}$ and $Ni^{III,III}$ species, respectively. First of all, it is well-known that thiolate ligands are powerful in stabilizing Ni in the trivalent state.[24] Secondly, the number of observed oxidation waves (N) and their separations ($\Delta E = |E^1_{1/2} - E^2_{1/2}|$) are invariably $N = 2$ and $\Delta E \approx 0.45$ V, respectively, for all complexes. N matches with the number of metal atoms per complex and the value of 0.45 V for ΔE would be consistent with the presence of a mixed-valent $Ni^{III}Ni^{II}$ complex that is very stable to disproportionation ($K_{disp.} \approx 10^{-7}$), respectively. Thirdly, the UV/Vis spectra of all the transient dark-green solutions exhibit three very strong absorptions at around 470, 600, and 900 nm, which are characteristic of trivalent NiN_xS_y complexes.[12][20] Since the spectra of the oxidized species lack any characteristic absorptions for a planar NiN_2S_2 chromophore, it is assumed that the oxidations are accompanied by changes in the coordination environment of the planar NiN_2S_2 site. The broad peak-to-peak separations noted earlier would be consistent with this view.

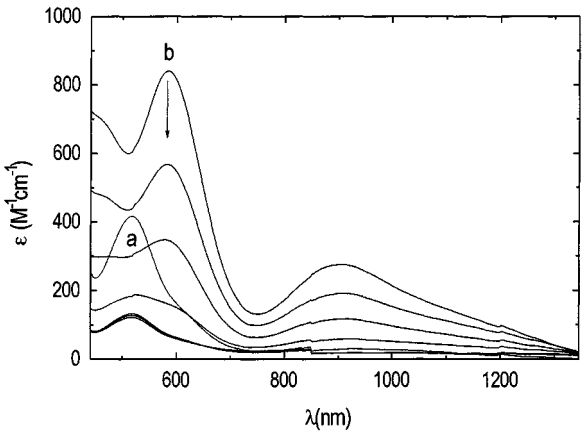

Figure 5. Oxidation of complex **10** with bromine in MeOH followed by UV/Vis spectroscopy (a: spectrum before, b: spectrum after addition of bromine). The other spectra were taken at 6 min intervals (the arrow indicates the evolution of the spectra with time)

A metal-centered nature for these oxidations is also supported by X-band EPR spectroscopic studies of frozen (77 K) solutions. Figure 6 shows the EPR spectrum of the green solution prepared by chemical oxidation of **10**. It reveals an axial signal as the main component with estimated g values of $g_\perp \approx 4.7$ and $g_\parallel \approx 2.1$, which are indicative of an $S = {}^3/_2$ spin ground state.[25] Hyperfine splitting due to ligand nitrogens could not be observed. Similar $S = {}^3/_2$ signals were previously observed for $\mathbf{3}^{2+}$ and for other mixed-valent $Ni^{III}Ni^{II}$ amine-thiolate complexes.[12] The $S = {}^3/_2$ ground states of these complexes are attained by an intramolecular ferromagnetic exchange interaction between low-spin Ni^{III} ($S = {}^1/_2$) and Ni^{II} ($S = 1$) ions. However, in the absence of more detailed spectroscopic data one can only

speculate about the electronic structure of the oxidized species.

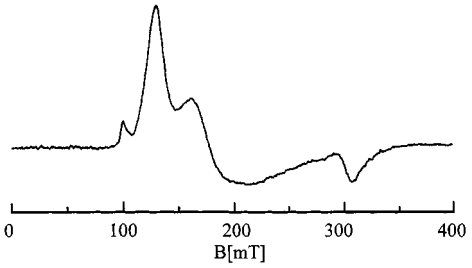

Figure 6. Frozen solution (77 K) X-band EPR spectrum of $\mathbf{10}^{+}$. Conditions: microwave frequency: ν = 9.02 GHz; microwave power: 2 mW; modulation frequency: 100 kHz; modulation amplitude: 10 gauss

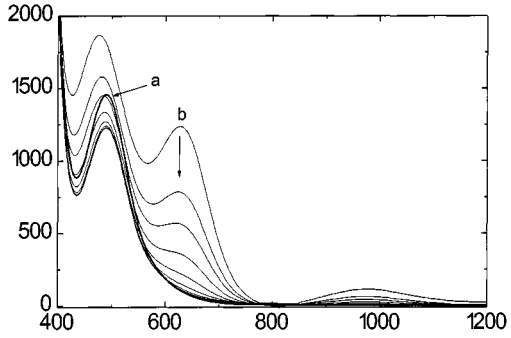
The observation of an oxidation wave at $E^{2}_{1/2}$ = +0.42 V vs SCE for the isothiocyanate complex **13** in DMF solution also deserves some comment. Although the thiocyanate ion itself is redoxactive,[26] its oxidation can be ruled out since $E_{1/2}$ for this process is at +0.77 V vs SCE.[27] It is thus likely that this oxidation also corresponds to a metal-centered oxidation forming a Ni^{III} species. It was not possible to prepare the oxidized species by chemical or electrochemical oxidation, presumably due to its very rapid decomposition.

Chemical Oxidation of Metal Complexes

Complexes **2**, **5**, and **10** could also be chemically oxidized. Whereas addition of iodine to methanolic solutions of the complexes had no effect, treatment with bromine resulted in a sudden color change from red to dark-green. It was necessary to use less than 0.2 equiv. of oxidant to observe the transient green color. Figure 7 shows the UV/Vis spectral changes that occurred upon addition of ca. 0.1 equivalent of oxidant to a solution of complex **2** in methanol. The spectrum recorded directly after sample preparation is identical to that taken for a sample prepared by electrochemical oxidation, indicating that both methods produce the same species. In a similar way to **10** the oxidation product of complex **2** is thermally unstable.



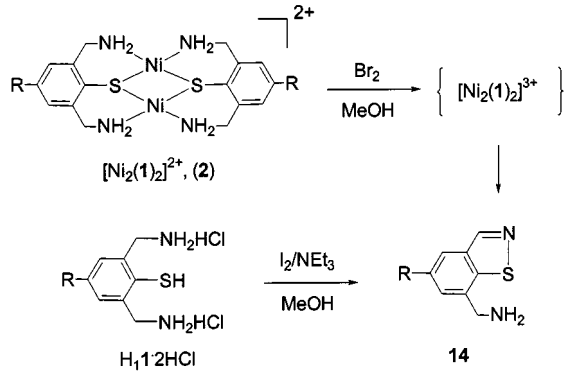


Figure 7. Oxidation of complex **2** with bromine in MeOH followed by UV/Vis spectroscopy (a: spectrum before, b: spectrum after addition of bromine). The other spectra were taken at 6 min intervals (the arrow indicates the evolution of the spectra with time)

The oxidized species of all complexes were allowed to decompose at ambient temperature. In the case of complexes **5** and **10** the resulting pale-green reaction mixtures contained a variety of new products that could not be separated. For complex **2**, however, oxidation resulted in the formation of the benzisothiazole derivative **14**[28] in high yield. The same compound is also obtained by treatment of the ligand, $H_1\mathbf{1} \cdot 2$ HCl, with iodine in methanol in the presence of base. It should be noted that the complexes could not be oxidized with iodine and this is taken as another indication that the oxidations are primarily metal-centered with the formation of intermediate Ni^{III} species.

Scheme 5. Oxidation of $H_1\mathbf{1} \cdot 2$ HCl and $[Ni_2(\mathbf{1})_2][ClO_4]_2$ (**2**)

Conclusion

The aim of controlling the reactivity of dinuclear nickel amine-thiolate complexes such as **5** has been achieved by a slight ligand modification. The constituent amine-thiophenolate units in $H_2\mathbf{9}$ retain their typical coordination mode but the additional NH donor blocks one of the two potentially free coordination sites found for **5**. The position *trans* to this donor is the reactive site of the present complexes. Solvent molecules and pseudo-halide ions bind to this site; the coordination of a halide ion has been observed for the first time. The latter substituent may be substituted by other co-ligands such as H^{-} or CN^{-}, and the influence of such substituents on the $Ni^{III,II}$ redox-potentials could be studied. These studies could also be of importance in attempts to model structural and functional features of dithiolate-bridged $[M(\mu\text{-}SR)_2M]$ structures found in metalloproteins, as for instance in [NiFe] hydrogenase from *Desulfovibrio gigas*.

Experimental Section

Materials and Methods: Compounds **7**,[13] $H_1\mathbf{1} \cdot 2$ HCl,[10] $[Ni_2(\mathbf{1})_2][ClO_4]_2$,[12] and $[Ni_2(\mathbf{4})][ClO_4]_2$[13] were prepared as previously described. All other chemicals were of reagent grade and used without further purification. Solvents were predried over molecular sieves and freshly distilled from appropriate drying agents. – ^{1}H-NMR and $^{13}C\{^{1}H\}$-NMR spectra were recorded on a Bruker AVANCE DPX 200 spectrometer. All chemical shifts are quoted on the δ scale with TMS or the solvent as internal standard. Coupling

constants are expressed in Hz. − Melting points were determined in capillaries and are uncorrected. − CHN-Analyses were determined with a Perkin−Elmer Elemental Analyzer 240. − IR spectra were recorded on a Bruker VECTOR 22 FT-IR-spectrophotometer as KBr pellets. − Absorption spectra were recorded on a Jasco V-570 UV/VIS/NIR spectrometer. − Room temperature magnetic susceptibility measurements were carried out with a Johnson Matthey model Mark II magnetic susceptibility balance. Experimental susceptibility data were corrected for the underlying diamagnetism using Pascal's constants.[29] − Cyclic voltammetry measurements were carried out at 25°C with an EG&G Princeton Applied Research Potentiostat/Galvanostat Model 263 A. The cell contained a Pt working electrode, a Pt wire auxiliary electrode, and an Ag wire as a reference electrode. Concentration of solutions were 0.1 M in supporting electrolyte ($Bu^n_4NPF_6$) and ca. 1×10^{-3} M in sample. Ferrocenium/ferrocene was used as the internal standard. All potentials were converted into the SCE reference [E (V) vs SCE = E (V) vs Fc^+/Fc − 0.38 V in CH_3CN].[21] EPR spectra were recorded using a conventional Varian X-band spectrometer with 100 kHz modulation.

***N*,*N*′-Bis[2-*tert*-butylsulfanyl-3-hydroximinomethyl-5-*tert*-butylbenzylidene]diethylenetriamine (8):** To a stirred solution of aldehyde **7** (587 mg, 2.00 mmol) in absolute ethanol (10 mL) was added a solution of *N*,*N*-bis(2-aminoethyl)amine (103 mg, 1.00 mmol) in ethanol (10 mL). After stirring for 2 h at 60°C, a solution of $NaBH_4$ (200 mg, 5.27 mmol) in ethanol (20 mL) was added, and the resulting homogeneous reaction mixture was stirred for further 12 h. Water (50 mL) was then added and the pH of the solution was adjusted to 1 by the addition of hydrochloric acid to destroy excess reducing equivalents. The mixture was stirred for an additional 30 min, the solution was made alkaline (final pH ≈ 12−13) by addition of 5 M KOH solution, and then extracted with dichloromethane (3 × 50 mL). The combined extracts were dried with $MgSO_4$, filtered, and the filtrate evaporated to dryness under reduced pressure. The pale-yellow residue was purified by column chromatography (SiO_2) using 10% MeOH in CH_2Cl_2 as eluent. Yield 521 mg (79%), m.p. 154°C. − ^{1}H NMR (5% CD_3OD/$CDCl_3$): δ = 8.88 (s, 2 H, ArC*H*), 7.79 (d, $^4J_{H,H}$ = 2.0 Hz, 2 H, Ar*H*), 7.43 (d, $^4J_{H,H}$ = 2.0 Hz, 2 H, Ar*H*), 4.00 (s br, 4 H, ArCH_2), 2.60 (s, 8 H, CH_2), 1.27 (s, 18 H, CH_3), 1.18 (s, 18 H, CH_3). − ^{13}C NMR (CD_3OD): δ = 153.8, 151.9, 147.0, 140.1, 130.2, 129.5, 123.6, 53.7, 50.4, 49.0, 47.3, 35.9, 31.9, 31.8.

***N*,*N*′-Bis[3-aminomethyl-5-*tert*-butyl-2-thiobenzyl]diethylenetriamine Pentahydrochloride ($H_2$9 · 5 HCl):** To a solution of **8** (658 mg, 1.00 mmol) in liquid ammonia (50 mL) was added sodium in small portions at −70°C, until the blue color of the reaction mixture persisted for at least 1 h (without adding further reducing equivalents). After stirring for an additional 1 h, excess sodium was destroyed by addition of solid ammonium chloride, and the solvent was evaporated at atmospheric pressure. The resulting solid was hydrolyzed with methanol (30 mL) followed by 6 M hydrochloric acid (final pH ≈ 1), and then evaporated to dryness under reduced pressure. For purification, the remaining solid was dissolved in ethanol (50 mL), filtered to remove NaCl and NH_4Cl, and evaporated to dryness. This procedure was repeated two more times. The resulting solid was sufficiently pure for metal complex syntheses. Yield 476 mg (68%). − IR (KBr): $\tilde{\nu}$ = 3417 cm^{-1} br (NH), 2400 sh (SH). − ^{1}H NMR (D_2O): δ = 7.79 (s, 4 H, Ar*H*), 4.66 (s, 4 H, ArCH_2), 4.50 (s, 4 H, ArCH_2), 3.70 (s, 8 H, CH_2), 1.39 (s, 18 H, CH_3). − ^{13}C NMR (D_2O): δ = 153.2, 136.7, 134.2, 130.1, 129.8, 127.3, 51.4, 44.0, 43.3, 42.9, 34.6, 30.7.

[Ni_2(9)(L)][ClO_4]$_2$ (10, L = H_2O): ***CAUTION!*** *Transition metal perchlorates are hazardous and may explode. Only small quantities should be prepared and great care taken.* To a solution of H_2**9** · 5 HCl (0.700 g, 1.00 mmol) and $Ni(ClO_4)_2 \cdot 6\,H_2O$ (731 mg, 2.00 mmol) in methanol (10 mL) was added a solution of NEt_3 (0.505 g, 0.500 mmol) in MeOH (1 mL). The reaction mixture was stirred for 5 min at 60°C, during which time a red crystalline precipitate formed. The solid was filtered off, washed with cold MeOH (2 × 1 mL) and ether, and dried in air. Yield: 487 mg (57%). − $C_{28}H_{45}Ni_2N_5S_2(ClO_4)_2H_2O$ (850.12): calcd. C 39.56, H 5.57, N 8.24; found C 39.64, H 5.42, N 8.18. − IR (KBr): $\tilde{\nu}$ = 3424 cm^{-1} br (OH), 3288, 3244, 3184, 3162, (NH + NH_2), 1150 s, 1115 s, 1089 vs (ClO_4^-).

[Ni_2(9)Cl][Cl] · 2 CH_3CN · H_2O (11): To a solution of H_2**9** · 5 HCl (0.700 g, 1.00 mmol) and $NiCl_2 \cdot 6\,H_2O$ (475 mg, 2.00 mmol) in acetonitrile (10 mL) was added a solution of NEt_3 (0.505 g, 0.500 mmol) in acetonitrile (1 mL). The reaction mixture was stirred for 5 min at 60°C, during which time a red crystalline precipitate formed. The solid was filtered off, washed with cold acetonitrile (2 × 1 mL) and ether, and dried in air. The crude product was recrystallized once from MeOH/CH_3CN. Yield: 530 mg (66%). − $C_{28}H_{45}Ni_2N_5S_2Cl_2(H_2O)(CH_3CN)_2$ (804.25): calcd. C 47.79, H 6.64, N 12.19; found C 47.43, H 6.42, N 11.87.

[Ni_2(9)(L)][BPh_4]$_2$ (12, L= H_2O): To a solution of complex **10** (86 mg, 0.10 mmol) in MeOH (10 mL) was added a solution of $NaBPh_4$ (50 mg, 0.15 mmol) in MeOH (1 mL). The solution was stirred for 20 min at room temperature, during which time a red crystalline precipitate formed. The solid was filtered off, washed with cold MeOH (2 × 1 mL) and dried in air. Yield: 106 mg (82%). − $C_{28}H_{45}Ni_2N_5S_2(BPh_4)_2H_2O$ (1289.68): calcd. C 70.78, H 6.80, N 5.43; found C 70.98, H 6.73, N 5.18. − IR (KBr): $\tilde{\nu}$ = 735 cm^{-1} s, 707 s (BPh_4^-).

[Ni_2(9)(NCS)][OH·H_2O] (13): To a solution of **10** (33 mg, 40 μmol) in MeOH (5 mL) was added a solution of NH_4SCN (4.6 mg, 60 μmol) in MeOH (2 mL). The resulting red solution was stirred for 1 h, during which time a dark-red microcrystalline solid precipitated. The solid was filtered off, washed with 2 mL of MeOH, and dried in air. Yield: 24 mg (83%), m.p. 344−346°C (decomp.). − IR (KBr): $\tilde{\nu}$ = 2090 cm^{-1} vs (NCS^-). − $C_{29}H_{48}Ni_2N_6S_3O_2$ (726.33): calcd. C 47.96, H 6.66, N 11.57; found C 47.83, H 6.43, N 11.18.

Oxidation of $H_1$1 · 2 HCl **(Preparation of 7-Aminomethyl-5-*tert*-butylbenzisothiazol) (14):** To a solution of H_1**1** · 2 HCl (297 mg, 1.00 mmol) and NEt_3 (556 mg, 5.50 mmol) in methanol (30 mL) was added a solution of iodine (508 mg, 2.00 mmol) in methanol (20 mL), and the reaction mixture was stirred for 2 h. The organic solvent was removed under reduced pressure, 20 mL of 1 M NaOH solution was added to the residue, and the product extracted with dichloromethane (3 × 50 mL). The combined extracts were dried with K_2CO_3, filtered, and evaporated to dryness to give 198 mg (89%) of **14** as a pale yellow solid. The crude product was purified by column chromatography using 10% MeOH in CH_2Cl_2 as eluent. M.p. 242−245°C. − ^{1}H NMR (CD_3OD/2% DCl): δ = 9.06 (s, 1 H, C*H*=N), 8.29 (d, ^4J = 1.6 Hz, 1 H, Ar*H*), 7.92 (d, ^4J = 1.6 Hz, 1 H, Ar*H*), 4.47 (s, 2 H, CH_2), 1.50 (s, 9 H, CH_3). − ^{13}C NMR (CD_3OD): δ = 158.0, 152.0, 150.5, 139.4, 128.8, 126.5, 122.7, 43.7, 36.4, 32.2.

Oxidation of [Ni_2(1)$_2$][ClO_4]$_2$: To a solution of complex [Ni_2(**1**)$_2$][ClO_4]$_2$ (200 mg, 0.262 mmol) and NEt_3 (303 mg, 0.3 mmol) in methanol (40 mL) was added a freshly prepared solution of bromine (34.2 mg, 0.214 mmol) in methanol (2 mL) at room temperature. The resulting transient dark-green solution was stirred for 30 min, during which time the color of the solution changed to dark-red. This process was repeated three more times to give a pale-green solution. The organic solvent was removed under reduced

pressure, 20 mL of 1 M NaOH solution (20 mL) was added to the residue, and the product extracted with dichloromethane (3 × 50 mL). The combined extracts were dried with K_2CO_3, filtered, and evaporated to dryness. The pale-green residue was dissolved in 2 mL of ethanol and acidified with 3 drops of 12 M HCl. Addition of ether caused precipitation of an off-white solid, which was filtered off and dried in air. Yield: 84 mg (73%). The analytical data are identical with those of compound **14**.

Crystal Structure Determination: Single crystals of complexes **11** and **13** suitable for X-ray structure analysis could be obtained by slow evaporation of acetonitrile/methanol solutions of the complexes. The crystals were mounted on glass fibers using perfluoropolyether oil. Crystal data were collected at 180(2) K, using a Bruker SMART CCD diffractometer. Graphite monochromated Mo-*K*α radiation (0.71073 Å) was used throughout. The data were processed with SAINT[30] and corrected for absorption using SADABS (transmission factors: 1.00−0.11 for **11**, 1.00−0.77 for **13**).[31]

Crystal data and refinement details for **11** ($C_{32}H_{53}Cl_2N_7Ni_2OS_2$, *M*r = 804.25): crystal size 0.52 × 0.46 × 0.32 mm, monoclinic, space group *P*2(1)/c, *a* = 14.251(3) Å, *b* = 21.351(4) Å, *c* = 12.805(3) Å, β = 94.28(3)°, *V* = 3885(1) Å^3, *Z* = 4, μ(Mo-*K*α) = 1.25 mm^{-1}, D_c = 1.375 g·cm^{-3}, *F*(000) = 1696, 24550 reflections measured, 9179 unique (R_{int} 0.1545), 5320 observed reflections [$I > 2\sigma(I)$]. The structure was solved by direct methods using the program SHELXS-86[32] and refined by full-matrix least-squares techniques against F^2 using SHELXL-93.[33] Positional and anisotropic atomic displacement parameters were refined for all nonhydrogen atoms, except for the C and N atoms of two acetonitrile molecules (refined isotropically). Hydrogen atoms were placed geometrically and positional parameters were refined using a riding model. Isotropic atomic displacement parameters for hydrogen atoms were constrained to be 1.2 (1.5 for methyl groups). Final residuals *R*1 = 0.0780, *wR*2 = 0.1846 [$I > 2\sigma(I)$], *R*1 = 0.1236, *wR*2 = 0.2126 (all data), largest difference peak, $\Delta\rho_{max}$ = 1.567 eÅ^{-3}, and hole $\Delta\rho_{min}$ = −1.265 eÅ^{-3}.

Crystal data and refinement details for **13** ($C_{29}H_{48}Ni_2N_6S_3O_2$, *M*r = 726.33): crystal size 0.75 × 0.51 × 0.16 mm, monoclinic, space group *C*c (no. 9), *a* = 11.204(2) Å, *b* = 25.651(5) Å, *c* = 12.187(2) Å, β = 98.68(3)°, *V* = 3462(1) Å^3, *Z* = 4, μ(Mo-*K*α) = 1.303 mm^{-1}, D_c = 1.393 g·cm^{-3}, *F*(000) = 1536, 12152 reflections measured, 4998 unique (R_{int} 0.0261), 4912 observed reflections [$I > 2\sigma(I)$]. The structure was solved by direct methods using the program SHELXS-86[32] and refined by full-matrix least-squares techniques against F^2 using SHELXL-93.[33] Positional and anisotropic atomic displacement parameters were refined for all non-hydrogen atoms, except for the oxygen atoms of a water molecule and a hydroxide ion (refined isotropically). Hydrogen atoms were placed geometrically and positional parameters were refined using a riding model. The OH^- and H_2O hydrogen atoms were located unambiguously from difference Fourier maps. Isotropic atomic displacement parameters for hydrogen atoms were constrained to be 1.2 (1.5 for methyl groups). The Flack *X* parameter (absolute structure parameter) was calculated to be 0.03(2) for the present structure and 0.98(2) for the inverted structure, thus providing strong evidence that the absolute structure has been assigned correctly.[34] Final residuals *R*1 = 0.0388, *wR*2 = 0.1148 [$I > 2\sigma(I)$], *R*1 = 0.0406, *wR*2 = 0.1185 (all data), largest difference peak, $\Delta\rho_{max}$ = 0.518 eÅ^{-3}, and hole $\Delta\rho_{min}$ = −0.501 eÅ^{-3}.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-132820 (**11**) and CCDC-121428 (**13**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: +44(1223) 336-033; E-mail: deposit@cam.ac.uk].

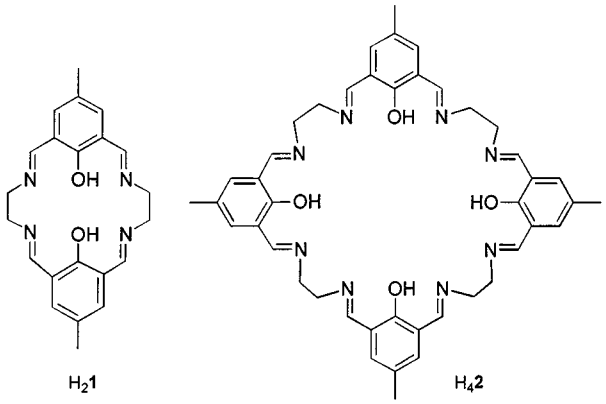
Novel Synthesis of Macrocyclic Amine-Thiophenolate Ligands: X-ray Crystal Structure of a Ni_4 Complex of an N_8S_4 Ligand



Berthold Kersting,*[a] Gunther Steinfeld,[a] Thorsten Fritz,[a] and Julia Hausmann[a]

Keywords: Macrocyclic compounds / Amine-Thiolate Donors / Polynuclear Complexes / Nickel / Condensation reactions

A novel route to macrocyclic amine-thiophenolate ligands is described. The new, air-stable thiophenolate precursor 1,2-bis(4-*tert*-butyl-2,6-diformyl-phenylsulfanyl)ethane (**4**) is readily condensed with two equivalents of 1,2-ethanediamine or 1,3-propanediamine under medium to high dilution conditions to give 2 × 4 condensation products. The smaller 1 × 2 macrocyclic compounds are not produced under these conditions. Subsequent reduction with $NaBH_4$ (reduction of imine groups) and Na/NH_3 (reductive cleavage of aryl-alkylsulfides) provides the 36- and 40-membered amine-thiophenolate ligands H_4**6a** and H_4**6b**. The macrocyclic compounds are versatile ligands for the preparation of polynuclear transition metal complexes. With divalent nickel H_4**6a** forms the di- and tetranuclear complexes $[Ni_2($**6a**$)]$ (**7**) and $[Ni_4($**6a**$)][ClO_4]_4$ (**8**). Reaction of **8** with four equivalents of NH_4SCN yields the novel isothiocyanate complex $[Ni_4^{II}($**6a**$)(NCS)_4]\cdot$10MeCN (**9**). The structure consists of well-separated molecules of the tetranuclear complex $[Ni^{II}_4($**6a**$)(NCS)_4]$ (C_i symmetry). Two symmetry-related binuclear $[N_2Ni(\mu_2\text{-}SR)_2NiN_4]$ fragments composed of thiolate-bridged distorted planar $\{N_2S_2Ni\}$- and distorted *cis*-octahedral $\{(SCN)_2N_2S_2Ni\}$ units reside within the cavity of the macrocycle. The intramolecular distance between the two binuclear units is 6.144(1) Å.

Introduction

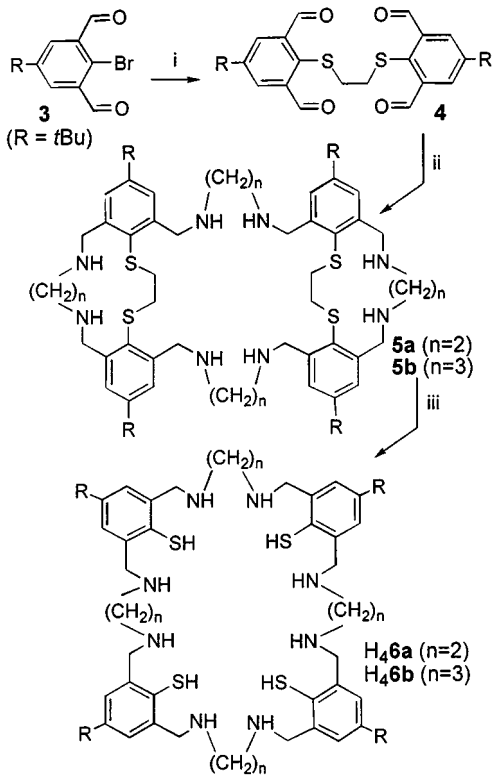
One of the most efficient syntheses of macrocyclic amine phenolate ligands such as H_2**1** (Scheme 1) involves a Schiff base condensation of 2,6-diformyl-4-methyl-phenol with an aliphatic α,ω-diamine in the presence of a labile first-row transition metal ion. Since its discovery by Robson and co-workers in 1970,[1] this reaction has been applied to a large variety of such ligands because they are ideally suited to prepare homo- and heterodinuclear and mixed-valence complexes.[2−7] Higher condensation products,[8][9] such as the 36-membered amine-phenolate ligand H_4**2**,[10] can also be obtained by this method.

Scheme 1. Macrocyclic N/O-Donor Ligands H_2**1**[1] and H_4**2**[10a]

In contrast to the large number of macrocyclic amine-phenolate ligands, there exist only a few examples of the corresponding imino- and aminothiophenolates.[11][12] This is true in particular for larger macrocyclic N_xS_y compounds.[13] To the best of our knowledge, all the macrocyclic N_xS_y compounds described to date have been obtained by metal template condensations using the air-sensitive compound 2,6-diformyl-4-methyl-thiophenol as starting material.[14]

We describe here an alternative route to macrocyclic amine-thiophenolate ligands by employing the air-stable thiophenolate precursor, 1,2-bis(4-*tert*-butyl-2,6-diformylphenylsulfanyl)ethane (**4**). The tetraaldehyde is readily condensed with aliphatic α,ω-diamines, and subsequent reduction of the intermediate thioether/imine compounds provides the 36- and 40-membered ligands H_4**6a**,**b**. This is demonstrated by the solid-state structure of $[Ni_4($**6a**$)(NCS)_4]\cdot$10MeCN.

Results and Discussion



Ligand Syntheses

The synthesis of the new octaamine-tetrathiophenol compounds H_4**6a**,**b**·8HCl was accomplished in three steps employing 4-*tert*-butyl-2,6-diformylbromobenzene **3** as starting reagent (Scheme 2). In the first step, compound **3** was reacted with dipotassium 1,2-ethanedithiolate in DMF in a 2:1 stoichiometric ratio to give the tetraaldehyde **4** in nearly quantitative yield. Condensation of **4** with two equivalents of 1,2-ethanediamine in a CH_2Cl_2/MeOH mixed solvent system under high-dilution conditions, followed by sodium borohydride reduction of the intermediate imine-thioether product, gave the amine-thioether compound **5a** in yields greater than 80%. The smaller 1 × 2−condensation product, i.e. the 18-membered N_4S_2 macrocycle, is not formed

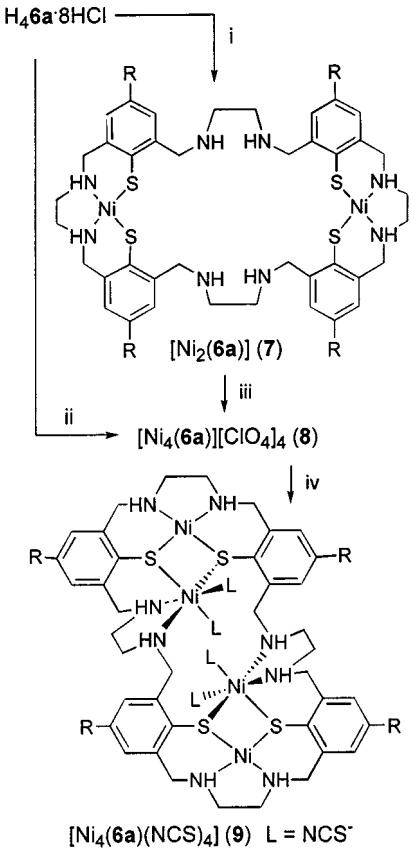
under these conditions. Attempts to obtain this compound by using more dilute solutions (and longer reaction times) were unsuccessful, but instead resulted in higher yields of **5a**. In the last step, compound **5a** was reduced with sodium in liquid ammonia (reductive cleavage of the $ArS-CH_2-CH_2-SAr$ bonds) to give, after hydrolysis with hydrochloric acid, the hydrochloride salt of the amine-thiolate ligand, H_4**6a**·8HCl. A similar reaction sequence was employed to prepare the 40-membered amine-thiolate ligand H_4**6b**·8HCl. Both ligands were stored as their hydrochloride salts under an atmosphere of dry nitrogen. The compounds H_4**6a**,**b**·8HCl are only slightly soluble in water, although the ligands dissolve in methanol in the presence of a base such as NEt_3.

Scheme 2. Preparation of macrocyclic amine-thiophenolate ligands H_4**6a**,**b**: (i). $HSCH_2CH_2SH$, K_2CO_3, DMF, 25°C; (ii). 2 equiv. $NH_2(CH_2)_nNH_2$, 10%MeOH/CH_2Cl_2; $NaBH_4$; (iii). Na/NH_3, HCl

The new compounds **4**, **5a**,**b**, and H_4**6a**,**b**·8HCl were characterized by ^{1}H NMR, ^{13}C NMR and IR spectroscopy. In the IR spectra of H_4**6a**,**b**·8HCl the N−H and S−Hstretching vibrations appear as broad bands at 2750 and 2400 cm^{-1}, respectively. The relatively low value for ν(S−H) is presumably due to intramolecular hydrogen bonding interactions with adjacent NH protons. According to the ^{1}H and ^{13}C NMR spectra, compounds H_4**6a**,**b**·8HCl exhibit fourfold symmetry in solution. Compound H_4**6a**·8HCl, for example, displays only four resonances at δ = 7.42, 4.34, 3.44, and 1.19 for the Ar*H*, $ArCH_2N$, NCH_2CH_2N, and $C(CH_3)_3$ protons, respectively. Due to fast H/D exchange, the S*H* and N*H* protons are not observed under these conditions. As expected, the ^{13}C NMR spectrum of H_4**6a**·8HCl displays eight signals for the 56 carbon atoms. The macrocyclic structure of H_4**6a**·8HCl was confirmed by an X-ray structure determination of one of its metal complexes (see below).



The strategy for the synthesis of the macrocyclic amine-thiophenolate ligands presented in this study differs from those employed by other groups for related amine-thiophenolate ligands. Such compounds have been prepared almost exclusively by metal-templated condensations between 2,6-diformyl-4-methyl-thiophenol and certain α,ω-diamines, followed by sodium borohydride reduction of the imine-thiolate complexes and hydrolysis of the resulting amine-thiolate complexes. The latter route has also been employed in the synthesis of the phenolate analogue of H_4**6a**.[10c] Our approach makes use of the air-stable tetraaldehyde/dithioether compound **4** which can be condensed with aliphatic diamines in the absence of metal ions. Since the 2 × 4 condensation products are almost exclusively formed under these conditions, it is likely that the bridging thioether unit serves as the template for macrocycle formation. However, the cyclization reactions still demand medium to high-dilution conditions (final concentration ≈ 0.01 M), since otherwise only polymeric material is obtained. It also appears that the yield of cyclization product (**5a**: > 92%, **5b**: 56%) decreases with increasing chain length of the diamine.

Synthesis and Characterization of Nickel Complexes 7−9

The preparation of nickel(II) complexes of H_4**6a**·8HCl was accomplished by reaction with nickel(II) salts in methanol or acetonitrile in the presence of a base such as triethylamine. Depending on the metal-to-ligand ratio the metalations of H_4**6a**·8HCl afforded di- or tetranuclear nickel(II) complexes (see Scheme 3). The reaction of H_4**6a**·8HCl with two equivalents of $NiCl_2·6H_2O$ produced a purple, microcrystalline solid of composition [Ni_2(**6a**)]·MeOH (**7**), whereas the reaction with four equivalents of $Ni(ClO_4)_2·6H_2O$ yielded the red-brown complex [Ni_4(**6a**)]-[ClO_4]$_4$ (**8**). Complex **8** could also be obtained by metalation of **7** with two equivalents of $Ni(ClO_4)_2·6H_2O$.

Complex **7** is diamagnetic and exhibits good solubility in most common organic solvents. Its UV/Vis spectrum in acetonitrile (Figure 1) is very similar to other planar N_2S_2Ni complexes,[15][16] indicating that both nickel ions exhibit planar N_2S_2 coordination environments in the solution state. On the basis of the ^{1}H NMR spectroscopic data (see Experimental Section) we propose a structure as shown in Scheme 3 with the two nickel ions occupying diagonally opposite sides of the macrocycle.

The metalation of **7** with nickel(II) perchlorate to form **8** is accompanied by distinct spectral changes. Isobestic points occurred at 544 and 680 nm. These spectral changes were clearly discernible until the ratio of concentrations of **7** and Ni^{2+} was 1:2 (see Figure 1). At higher Ni^{2+} concentrations the spectrum remained essentially unchanged, implying that H_4**6a** coordinates no more than four Ni^{2+} ions. The IR spectrum of **8** reveals three very strong and sharp

Scheme 3. Preparation of dinuclear and tetranuclear nickel complexes of H$_4$**6a**: (i). 2.0 equiv. $NiCl_2·6H_2O$, NEt_3/MeOH; (ii). 4.0 equiv. $Ni(ClO_4)_2·6H_2O$, NEt_3/MeOH; (iii). 2 equiv. $Ni(ClO_4)_2·6H_2O$, CH_3CN; (iv). 4 equiv. NH_4SCN, CH_3CN

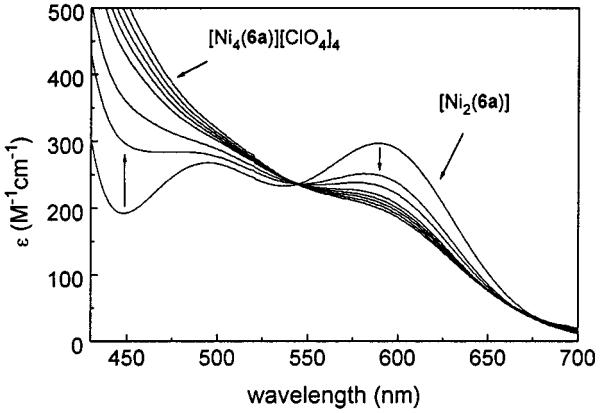


Figure 1. Titration of [Ni$_2$(**6a**)]·MeOH (**7**) ([**7**] = 1×10^{-3} M) with 10^{-3} M $Ni(ClO_4)_2·6H_2O$ in MeCN (0.0−4.0 added equiv) at 295 K followed by UV/Vis spectroscopy

absorptions for ν(ClO) at 1150, 1115, and 1089 cm^{-1} consistent with the presence of the ClO_4^- ions. It was not possible to grow single crystals of this product, although the reaction of **8** with NH_4SCN in CH_3CN yielded single crystals of [Ni$_4$(**6a**)(NCS)$_4$]·10CH_3CN (**9**) suitable for an X-ray crystal structure determination.

X-ray Crystal Structure of [Ni$_4$(6a)(NCS)$_4$]·10CH_3CN (9)

The X-ray crystal structure determination of **9** revealed the structure to consist of well-separated molecules of the tetranuclear isothiocyanate complex and acetonitrile molecules of crystallization. Figure 2 shows the molecular structure of the neutral, centrosymmetric complex [Ni$_4$(**6a**)(NCS)$_4$]. Selected bond lengths and angles are collected in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] in [Ni$_4$(**6a**)(NCS)$_4$]·10CH_3CN (**9**)[a]

[a] Symmetry transformations used to generate equivalent atoms: Ni(2a), S(2a), N(4a): 1−x, 2−y, 1−z.

All donor atoms of the 36-membered macrocycle are involved in coordination to the four nickel atoms to give two four-coordinate N_2S_2Ni and two six-coordinate N_4S_2Ni coordination units. Each Ni atom forms a five-membered chelate ring with one of the four ethanediamine moieties of the ligand. These N_2Ni units are bridged by two thiophenolate sulfur atoms to give two symmetry-related binuclear $[N_2Ni(\mu_2\text{-}SR)_2NiN_2(NCS)_2]$ units. The average Ni−N and Ni−S bond lengths within these binuclear units compare well with those of other $N_2S_2Ni^{II}$ and $N_4S_2Ni^{II}$ complexes, although the bond length Ni(1)−N(3) at 2.167(4) Å is quite long for an octahedral $N_4S_2Ni^{II}$ complex.[17] The intramolecular distance between the two distorted *cis*-octahedral and the two distorted planar nickel atoms at 6.144(1) Å and 9.005(1) Å, respectively, may be used to describe the distance between the two binuclear subunits.

An interesting feature to note is the fact that the isothiocyanate ions within each binuclear unit occupy *cis* positions at the six-coordinate nickel atom {SCN−Ni(1)−NCS at 90.8(2)°}. It is assumed that this coordination mode is enforced by the short C_2 alkyl chain which links the 2,6-

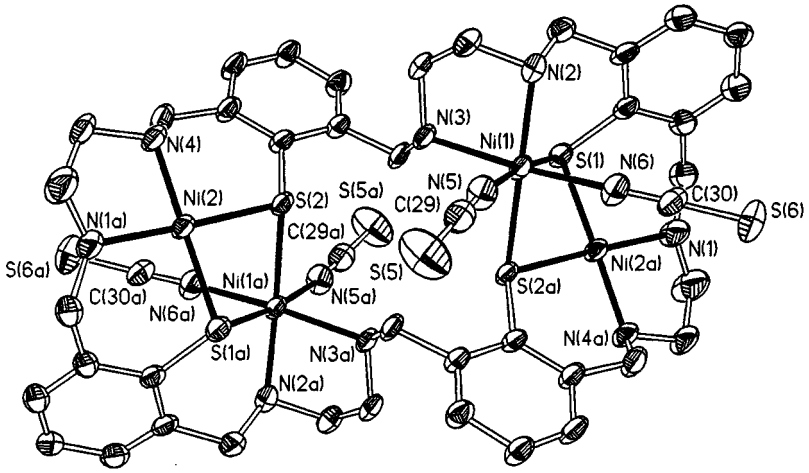

Figure 2. Perspective view of the molecular structure of the tetranuclear isothiocyanate complex $[Ni_4(\mathbf{6a})(NCS)_4]$ in **9**. Hydrogen atoms and *tert*-butyl groups are omitted for reasons of clarity

bis(aminomethyl)-4-*tert*-butylthiophenolate moieties. This is in marked contrast to coordinatively unsaturated $N_2Ni(\mu_2\text{-}SR)_2NiN_2$ complexes in which the thiophenolate moieties are connected via a C_3 alkyl chain. Here the exogenous ligands are coordinated in *trans*-axial positions (see Scheme 4).[18][19]

Scheme 4. Stereochemical courses of reactions of coordinatively unsaturated nickel complexes containing a $[N_2Ni(\mu_2\text{-}SR)_2NiN_2]$ core structure: influence of the bridging alkyl chain

Conclusion

A new synthetic route to macrocyclic amine-thiolate ligands has been developed. The air-stable thiophenolate precursor 1,2-bis(4-*tert*-butyl-2,6-diformylphenylsulfanyl)-ethane can be condensed with aliphatic α,ω-diamines $\{NH_2(CH_2)_nNH_2\}$ to give the 2 × 4 macrocyclic compounds {4·(7 + n) ring-atoms} in the absence of metal ions. By varying the building blocks it should be possible to obtain a wide range of polydentate amine-thiolate ligands which could be useful for the preparation of new polynuclear transition metal thiolate complexes

Experimental Section

General: ^1H NMR and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker AVANCE DPX 200 spectrometer. All chemical shifts are quoted on the δ scale with TMS or the solvent as internal standard. Coupling constants are expressed in Hz. Melting points were determined in capillaries and are uncorrected. CHN-Analyses were determined with a Perkin−Elmer Elemental Analyzer 240. IR spectra were recorded on a Bruker VECTOR 22 FT-IR-spectrophotometer as KBr pellets. Absorption spectra were recorded on a Jasco V-570 UV/VIS/NIR spectrometer. Compound **3**[20] was prepared as described in the literature. All other chemicals were of reagent grade and used without further purification. Solvents were predried over molecular sieves and freshly distilled from appropriate drying agents.

Compound 4: To a suspension of 1,2-ethanedithiol (2.50 g, 26.5 mmol) and K_2CO_3 (8.29 g, 60.0 mmol) in DMF (80 mL) was added solid **3** (14.3 g, 53.0 mmol), and the reaction mixture was stirred for 12 h. Water (200 mL) was then added dropwise with stirring. The resulting precipitate was isolated by filtration, washed with water (3 × 50 mL), and dried in air. The solid was purified by recrystallization from dichloromethane/cyclohexane to give 11.5 g (92%) of **4** as pale yellow crystals. M.p. 178° C. − IR (KBr): $\tilde{\nu}$ = 2872m (CH), 1687s cm^{-1} (CO). − ^1H NMR ($CDCl_3$): δ = 10.67 (s, 4 H, C*H*O), 8.11 (s, 4 H, Ar*H*), 2.96 (s, 4 H, CH_2), 1.31 (s, 18 H, CH_3). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 191.0 (*C*HO), 153.9, 138.3, 136.9, 131.3, 38.5, 35.2, 30.9.

Compound 5a: A solution of 1,2-ethanediamine (493 mg, 8.20 mmol) in 10% MeOH/CH_2Cl_2 (100 mL) and a solution of **3**

(2.05 g, 4.36 mmol) in CH_2Cl_2 (100 mL) were simultaneously added within 3 h to 300 mL of CH_2Cl_2 with stirring. After the reaction mixture was stirred for further 12 h at room temperature, the solvents were removed at reduced pressure to obtain a white solid. The solid was dissolved in MeOH/CH_2Cl_2 (100 mL, 1:1), a solution of $NaBH_4$ (1.20 g, 31.7 mmol) in 50 mL of MeOH was added, and the resulting homogeneous reaction mixture was stirred for further 2 h. After the excess reducing agent was destroyed by acidification with 1M HCl, the pH was readjusted to 11 by addition of 2M NaOH solution, and the aqueous phase extracted with CH_2Cl_2 (3 × 200 mL). The combined organic phases were dried over K_2CO_3, filtered, and the solvent removed under reduced pressure. The pale-yellow residue was purified by column chromatography (SiO_2) using MeOH/NEt_3/CH_2Cl_2 (10:5:85) as eluting solvent to give 2.12 g (92%) of the product as a white foam. − IR (KBr): $\tilde{\nu}$ = 3310w cm^{-1} (NH). − ^1H NMR ($CDCl_3$): δ = 7.34 (d, ^4J = 2.0 Hz, 4 H, Ar*H*), 7.24 (d, ^4J = 2.0 Hz, 4 H, Ar*H*), 4.02 (s, 8 H, BzCH_2), 3.97 (s, 8 H, BzCH_2), 3.25 (s, 8 H, SCH_2), 2.91 (s, 8 H, NHCH_2), 2.81 (s, 8 H, NHCH_2), 1.90 (s br, 8 H, NH), 1.30 (s, 36 H, CH_3). − ^{13}C NMR ($CDCl_3$): δ = 151.7, 144.3, 144.0, 130.3, 127.0, 126.4, 53.9, 53.3, 48.7, 37.4, 34.4, 31.1.

Compound 5b: Analogously to the preparation of **5a**, compound **5b** was prepared from **3** (2.05 g, 4.36 mmol) and 1,3-propanediamine (608 mg, 8.20 mmol). Yield: 1.35 g (56%). − IR (KBr): $\tilde{\nu}$ = 3295w cm^{-1} (NH). − ^1H NMR ($CDCl_3$): δ = 7.25 (d, ^4J = 2.0 Hz, 4 H, Ar*H*), 7.14 (d, ^4J = 2.0 Hz, 4 H, Ar*H*), 3.95 (s, 8 H, BzCH_2), 3.85 (s, 8 H, BzCH_2), 3.03 (s, 8 H, SCH_2), 2.73 (m, 16 H, NHCH_2), 1.72 (m, 8 H, NHCH_2), 1.23 (s, 36 H, CH_3). − ^{13}C NMR (D_2O/2%DCl): δ = 155.9, 136.9, 136.6, 131.9, 130.8, 126.3, 50.7, 49.9, 45.4, 44.6, 37.8, 34.9, 30.5, 23.0, 20.9.

Compound $H_4$6a·8HCl: To a solution of sodium (1.00 g, 43.0 mmol) in liquid ammonia (100 mL) was added a solution of **5a** (2.00 g, 1.90 mmol) in THF (30 mL) and the deep-blue reaction mixture was stirred for 1 h. After the excess reducing equivalents were destroyed by careful addition of NH_4Cl, the suspension was evaporated to dryness, and the resulting pale yellow residue was taken up in water (40 mL). The yellow solution was cooled to 0° C, and the pH of the solution adjusted to 1 by addition of 12M hydrochloric acid. The pale yellow solid was collected by filtration and recrystallized from 1M HCl to give H_4**6a**·8HCl (1.79 g, 73%) as white crystals. − IR (KBr): $\tilde{\nu}$ = 3423, 2750br (N−H), 2400br cm^{-1} (S−H). − ^1H NMR (D_2O): δ = 7.41 (s, 8 H, Ar*H*), 4.36 (s, 16 H, BzCH_2N), 3.45 (s, 16 H, NCH_2), 1.23 (s, 36 H, CH_3). − ^{13}C NMR (D_2O): δ = 152.0, 133.9, 131.9 (CH), 130.7, 51.5, 43.0, 34.5, 30.7.

Compound $H_4$6b·8HCl: Analogously to the preparation of H_4**6a**·8HCl, this compound was prepared by reduction of **5b** (2.11 g, 1.90 mmol) with sodium (1.00 g, 43.0 mmol) in liquid ammonia (100 mL). Recrystallization from 1M HCl afforded H_4**6b**·8HCl (1.56 g, 61%) as white crystals. − ^1H NMR (D_2O): δ = 7.47 (s, 8 H, Ar*H*), 4.38 (s, 16 H, BzCH_2N), 3.12 (t, ^3J = 7.5 Hz, 16 H, NCH_2), 2.17 (qnt, ^3J = 7.5 Hz, 8 H, CH_2), 1.16 (s, 36 H, CH_3). − ^{13}C NMR (CD_3OD): δ = 154.1, 136.6, 131.8 (CH), 129.3, 51.5, 45.8, 35.8, 31.4, 23.9.

[Ni_2(6a)]·MeOH (7): To a solution of H_4**6a**·8HCl (129 mg, 0.100 mmol) in MeOH (3 mL) was added $NiCl_2·6H_2O$ (47 mg, 0.200 mmol) in MeOH (1 mL) and NEt_3 (121 mg, 1.20 mmol). The purple solution was stirred overnight, during which time a purple, microcrystalline precipitate of **7** deposited. The crystals were filtered, washed with cold MeOH (1 mL), and dried in vacuum. Yield: 58 mg (51%). − IR (KBr): $\tilde{\nu}$ = 3129w cm^{-1} (NH). − UV/Vis (MeCN): λ_{max} (ε_M) = 495 (270), 588 nm (298 $M^{-1}cm^{-1}$). − ^1H NMR (200 MHz, $CDCl_3$/CD_3OD, 1:1): δ = 7.22 (d, ^4J = 2.0 Hz, 4 H, Ar*H*), 6.90 (d, ^4J = 2.0 Hz, 4 H, Ar*H*), 4.42 (d, ^2J = 12.0 Hz, 4 H, CH_2), 3.90 (d, ^2J = 12.0 Hz, 4 H, CH_2), 3.27 (d, ^2J = 12.0 Hz, 4 H, CH_2), 3.04 (m, 8 H, CH_2), 2.95 (m, 4 H, CH_2), 2.50 (m, 8 H, CH_2), 1.26 (s, 36 H, CH_3). − $C_{56}H_{84}N_8Ni_2S_4·CH_3OH$ (1147.00): calcd. C 59.69, H 7.73, N 9.77; found C 59.42, H 7.33, N, 9.52.

[Ni_4(6a)][ClO_4]$_4$·3MeOH (8): To a solution of **7** (115 mg, 0.100 mmol) in MeOH (3 mL) was added $Ni(ClO_4)_2·6H_2O$ (76 mg, 0.20 mmol) in MeOH (1 mL). The brown solution was stirred for 12 h, during which time a microcrystalline precipitate of **8** deposited. The crystals were filtered, washed with cold MeOH (1 mL), and dried in air. Yield: 128 mg (74%). − IR (KBr): $\tilde{\nu}$ = 3200w (NH), 1142, 1113, 1087vs cm^{-1} [ClO_4^-, $\nu_3(F_2)$]. − UV/Vis (MeCN): λ_{max} (ε) = 586 (204), 1017 nm (10 $M^{-1}cm^{-1}$). − $C_{56}H_{84}N_8Ni_4S_4·Cl_4O_{16}·3CH_3OH$ (1726.27): calcd. C 41.05, H 5.61, N 6.49; found C 41.32, H 5.45, N 6.36.

[Ni_4(6a)(NCS)$_4$]·10CH_3CN (9): To a solution of **8** (36 mg, 0.021 mmol) in MeCN (5 mL) was added a solution of NH_4SCN (6.5 mg, 0.085 mmol) in MeOH (1 mL). The brown solution was filtered and kept at room temp. for 12 h, during which time the tetranuclear isothiocyanate complex **9** deposited as brown-red crystals. Yield: 25 mg (63%). Crystals of **9** quickly lose the MeCN molecules of crystallization upon storage in air at 298 K. − IR (KBr): $\tilde{\nu}$ = 3200w (NH), 2075vs cm^{-1} (CN). − UV/Vis (DMF): λ_{max} (ε) = 520sh (317), 975 nm (65 $M^{-1}cm^{-1}$). − $C_{60}H_{84}N_{12}Ni_4S_8$ (1464.65): C 49.20, H 5.78, N 11.48; found C 48.93, H 5.31, N 11.01.

X-ray Crystal Structure Determination: Single crystals of complex **9** were obtained by the procedure described above. A red-brown crystal of [Ni_4(**6a**)(NCS)$_4$]·10MeCN measuring 0.42 × 0.35 × 0.09 mm was mounted with some mother-liquor in a glass capillary. Intensity data were collected at −60 °C using a STOE IPDS diffractometer with graphite-monochromatized Mo Kα radiation (λ = 0.71073 Å). The data were corrected for Lorentz and polarization effects. An empirical absorption correction was applied. Of 8518 unique reflections 5890 measured $F_o > 4\sigma(F_o)$. Structure solution (direct methods) and refinements were carried out with SHELXS-86 and SHELXL-93 software,[21] respectively. The complex [Ni_4(**6a**)(NCS)$_4$]·10MeCN crystallizes in the triclinic space

group $P\bar{1}$. The asymmetric unit contains one half of the atoms of the formula unit ($Z = 1$). The disordered *tert*-butyl methyl carbon atoms and C- and N-atoms of the MeCN solvates were refined isotropically. All other non-hydrogen atoms were refined anisotropically. An isotropic split-atom model was applied for the disordered *tert*-butyl methyl carbon atoms. The multiplicities of the respective orientations C(20a)−C(21a)−C(22a): 0.68, C(20b)−C(21b)−C(22b): 0.32 were refined. In the final stages of anisotropic refinement, hydrogen atoms were included at calculated positions and refined by using a riding model. The final difference Fourier maps showed no unusual features. Final *R* factors are given in Table 2. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-128515. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Trovacene Chemistry, 3[+]

The Mono-, Di-, and Tri([5]trovacenyl)boranes: A Study of Intermetallic Communication Across an sp^2-Hybridized Boron Atom

Christoph Elschenbroich,*[a] Matthias Wolf,[a] Olaf Burghaus,[a] Klaus Harms,[a] and Jürgen Pebler[a]

Dedicated to Professor Christoph Rüchardt on the occasion of his 70th birthday

Keywords: EPR spectroscopy / Metallocenylboranes / Organovanadium radicals / Redox chemistry (CV) / X-ray diffraction

The paramagnetic complexes di(mesityl)([5]trovacenyl)-borane (**5**$^{\cdot}$), (mesityl)di([5]trovacenyl)borane (**6**$^{\cdot\cdot}$), and tri([5]trovacenyl)borane (**7**$^{\cdot\cdot\cdot}$) were prepared from [5]trovacenyllithium, (η^5-C_7H_7)V(η^5-C_5H_4Li), and $(Mes)_2BF$, $(Mes)BF_2$, and BF_3, respectively. The propeller-shaped species **5**$^{\cdot}$, **6**$^{\cdot\cdot}$, and **7**$^{\cdot\cdot\cdot}$ were subjected to X-ray diffraction with the aim of possibly correlating the twist angles with intramolecular intermetallic communication. Cyclic voltammetry points to successive vanadium-centered oxidation processes and boron-centered reduction, a small redox splitting $\delta E_{1/2}$[(2+/+), (+/0)] being observed for **6**$^{\cdot\cdot}$. According to EPR spectroscopy, performed in fluid solution, the exchange interaction J in the diradical **6**$^{\cdot\cdot}$ approaches the fast-exchange region and is attenuated significantly by quaternization at boron in [**6**$^{\cdot\cdot}$–*n*Bu]$^-$. Although EPR spectroscopy of the triradical **7**$^{\cdot\cdot\cdot}$ also indicates an extensive exchange interaction, the exchange parameters, derived from spectral simulation, follow the gradation J(**7**$^{\cdot\cdot\cdot}$) $\approx$ 1/3 J(**6**$^{\cdot\cdot}$). The magnetic susceptibility of **6**$^{\cdot\cdot}$ and **7**$^{\cdot\cdot\cdot}$ follows the same trend. As expected, compound **7**$^{\cdot\cdot\cdot}$ exhibits spin frustration because it contains three antiferromagnetically coupled S = 1/2 systems that are arranged in an equilateral triangle.

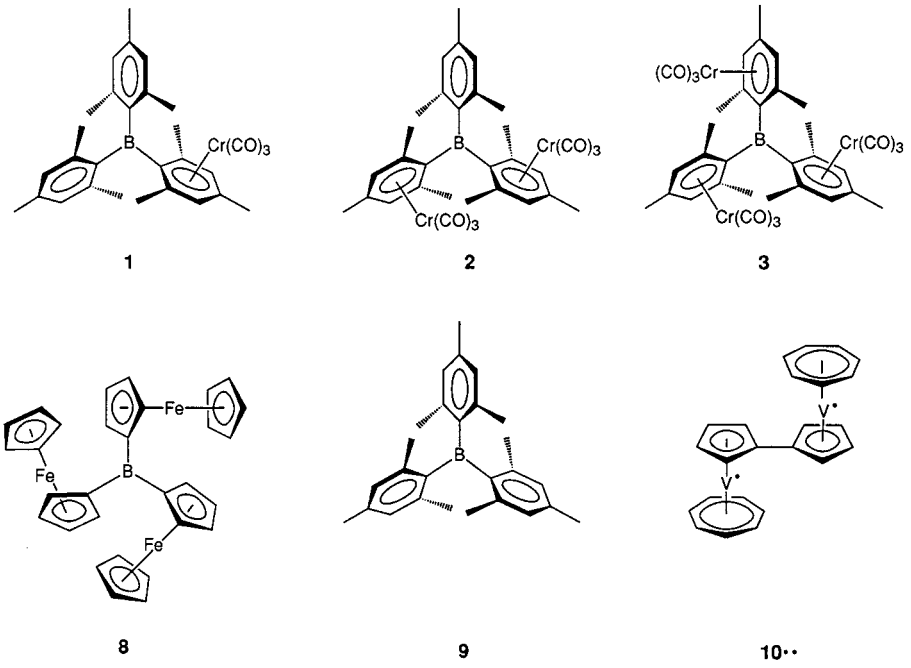
Introduction

The screening of diverse inorganic and organic groups for their potential as spacers, capable of mediating electronic and magnetic interactions between metal centers, remains a topic of intense investigation.[2] With this aim in mind, we previously prepared the half-sandwich complexes $Mes_2B[(\eta^6\text{-Mes})Cr(CO_3)]$ (**1**), $MesB[(\eta^6\text{-Mes})Cr(CO)_3]_2$ (**2**), and $B[(\eta^6\text{-Mes})Cr(CO)_3]_3$ (**3**), determined their molecular structures by X-ray diffraction, and studied their IR-, redox-, and EPR properties.[3]

Structurally, these propeller-shaped complexes differ in the dihedral angle between the η^6-arene planes and the reference plane which is spanned by the three carbon atoms bonded to boron. If interactions between these complex moieties were governed by conjugation between the aromatic π-systems and the vacant p_z orbital of the boron atom, compounds **1**, **2**, and **3** would be expected to exhibit characteristic spectral and electrochemical differences. However, IR spectroscopy and cyclic voltammetry indicated almost no discernible communication between the $Cr(CO)_3$ units of either **2** or **3**. A more sensitive tool for probing intramolecular communication is provided by EPR spectroscopy, which may either be applied to mixed valence species, to search for spin delocalization, or it may be used for oligoradicals, to assess the extent of exchange coupling. We have used both methods in the past for related cases;[1][4] they failed for **1**–**3**, however, because the requisite paramagnetic species could not be obtained either chemically or electrochemically.

Our recent research[1][5] with the paramagnetic, neutral complex (η^7-C_7H_7)V(η^5-C_5H_5) (**4**$^{\cdot}$) [or trovacene, for (η^7-tropylium)vanadium(η^5-cyclopentadienyl)[6]] caused us to synthesize the mono-, di-, and tri([5]trovacenyl)boranes **5**$^{\cdot}$–**7**$^{\cdot\cdot\cdot}$ in order to study their electrochemical and EPR spectroscopic characteristics. The redox splitting $\delta E_{1/2}$, i.e., the difference in the potentials of subsequent redox steps, as well as the exchange coupling constant J, for diradical **6**$^{\cdot\cdot}$ and triradical **7**$^{\cdot\cdot\cdot}$, should both provide information on the extent of intermetallic communication via the central boron atom. The results from this investigation should also complement those obtained previously for the related complex tri(ferrocenyl)borane, $[(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4)Fe]_3B$ (**8**).[7]

Results and Discussion



Synthesis

Trovacene undergoes selective monolithiation at the cyclopentadienyl ring.[8][9] Subsequent reaction with the B–F functionality affords di(mesityl)([5]trovacenyl)borane

(**5**•), (mesityl)di([5]trovacenyl)borane (**6**••) and tri([5]trovacenyl)borane (**7**•••) (Scheme 1). The mesityl group was chosen as an auxiliary ligand to sterically protect the boron atom in order to improve the kinetic stability of R_3B anions,[10] which are also targets of the present investigation. Compounds **5**• and **6**•• crystallized as green cubes, and **7**••• formed green needles. The solubility in aromatic solvents decreases in the order **5**• > **6**•• > **7**•••.

Molecular Structures of $5^{\cdot}$, $6^{\cdot\cdot}$, and $7^{\cdot\cdot\cdot}$ in the Crystal

While it may not be assumed that the structures of $\mathbf{5}^{\cdot}-\mathbf{7}^{\cdot\cdot\cdot}$ in the solid state are identical to those in fluid solution, where CV and EPR spectroscopic studies are performed, X-ray diffraction studies were nevertheless carried out to extract trends in the torsional angles which characterize these molecules. The structures of $\mathbf{5}^{\cdot}-\mathbf{7}^{\cdot\cdot\cdot}$ are shown in Figures 1−3; bond lengths and bond angles are collected in the captions.

Because of their propeller shape, $\mathbf{5}^{\cdot}-\mathbf{7}^{\cdot\cdot\cdot}$ are chiral; a few peculiarities of the respective unit cells deserve to be noted. Di(mesityl)([5]trovacenyl)borane ($\mathbf{5}^{\cdot}$) crystallizes in the space group $P\bar{1}$, i.e., the two enantiomorphic forms are crystallographically indistinguishable. (Mesityl)di([5]trovacenyl)borane ($\mathbf{6}^{\cdot\cdot}$) crystallizes in the space group $P2_1$ as a single enantiomer since a mirror plane and a center of symmetry are absent. Finally, $\mathbf{7}^{\cdot\cdot\cdot}$ (space group $P1$) incorporates two independent, chiral molecules in the racemic unit cell.

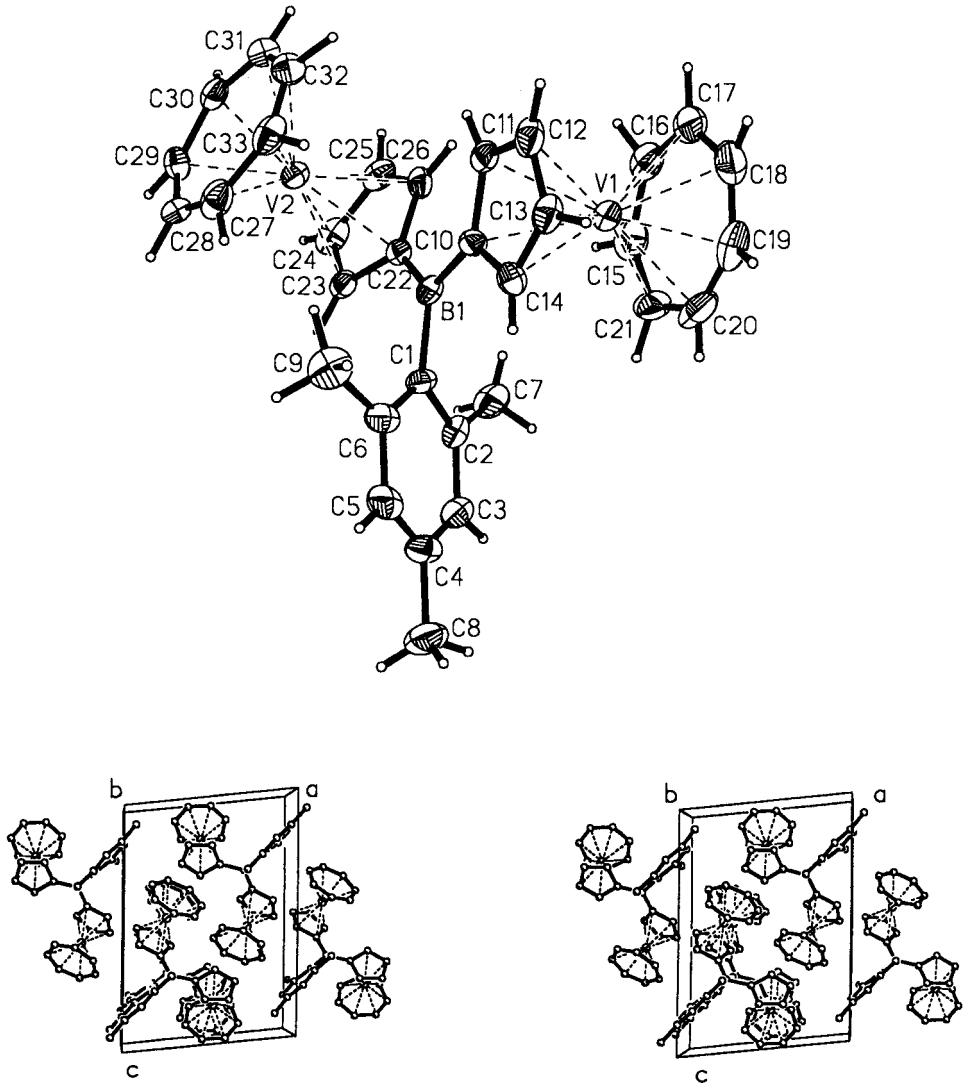

Figure 2. Molecular structure and numbering scheme of compound **6**¨: (top) SHELXTL/LP drawing with 50% probability ellipsoids; (bottom) stereoplot; selected bond lengths (pm) and bond angles (°): B−C1 158.4 (9), B−C10 154.9 (9), B−C22 155.4 (9), C−C (η^5−Cp, mean value) 142.3, C−C (η^7-Tr, mean value) 140.4, V−C (Cp, mean value) 226.1, V−C (Tr, mean value) 218.5, V−Cp (centroid) 191.0 (3), V−Tr (centroid) 146.9 (1), C1−B−C10 117.5 (5), C1−B−C22 119.2 (5), C10−B−C22 123.2 (5). V1···V2 589.3; important dihedral angles are collected in Table 1

The following remarks focus on those structural features that may be relevant to the extent of intramolecular communication between the sandwich moieties. The B−C_{ipso} bond lengths involving the organometallic (156 pm) and organic (159 pm) substituents at boron (mean values) differ only marginally. More important are the dihedral angles between the η^5-cyclopentadienyl and the aryl- and B(C_{ipso})$_3$ reference planes PR1, listed in Table 1. The twist of the mesityl plane, with regard to PR1, always surpasses that of the Cp planes. Furthermore, the dihedral angles between the planes Cp and PR1 differ considerably, encompassing the range 4.1−41.7°. This contrasts markedly with the structures of tri(ferrocenyl)borane (**8**), for which these angles lie in the narrow range of 25.8−28.1°[7c] and those of triarylboranes (45−55°[11]). In the context of intersandwich conjugation, the dihedral angles between the cyclopentadienyl planes of the trovacene units connected to boron are of interest: they amount to 25.6° for **6**¨ and to 20.8, 27.3, and 48.1° in the case of **7**‴. However, the torsional angles may be different in fluid solution. Finally, within the error limits, the bond angles about boron add up to 360°, although individual angles differ from 120° (maximal deviation 3°). Consequently, the boron atom is only slightly displaced from the plane defined by the three carbon atoms (3.3 pm for **5**˙; 1.3 pm for **6**¨; 6.6, 4.5 pm for **7**‴).

Electrochemical Properties

Cyclovoltammetric traces for compounds **5**˙−**7**‴ are depicted in Figure 4, the pertinent data are collected in Table 2. As for the parent complex **4**˙, the trovacenyl boranes **5**˙−7‴ each show one reversible oxidation and one reversible reduction step. Assignment of the redox sites, which are

responsible for these processes, is based on a comparison with the redox potentials of the components. Thus, the waves at positive potential involve oxidation of the trovacene units. The corresponding potential for the mono(trovacenyl) derivative **5**$^{\cdot}$ underwent a 171 mV anodic shift relative to that of parent **4**$^{\cdot}$, to reflect the electron-accepting properties of the $(Mes)_2B$ substituent.

For the di(trovacenyl) derivative **6**$^{\cdot\cdot}$, a redox splitting $\delta E_{1/2}$-[(2+/+), (+/0)] = 138 mV is clearly resolved, indicating intersandwich communication in **6**$^{\cdot\cdot}$. The value $\delta E_{1/2}$ for **6**$^{\cdot\cdot}$ is very similar to that found for [5−5]di(trovacene) (**10**$^{\cdot\cdot}$) ($\delta E_{1/2}$ = 147 mV[1]), showing that a (Mes)B spacer does not constitute a significant barrier to intramolecular communication between two trovacene units − at least with regard to their mutual influence on the ease of vanadium ionization. Interestingly, the mean value, $[E_{1/2}(2+/+) + E_{1/2}(+/0)]/2$, for dinuclear **6**$^{\cdot\cdot}$ is identical to $E_{1/2}(+/0)$ for mononuclear **5**$^{\cdot}$: primary oxidation of **6**$^{\cdot\cdot}$ is more facile due to the presence of a second, electron-donating trovacene unit; secondary oxidation is less favorable because of the positive charge on **6**$^{+\cdot}$.

Somewhat surprisingly, this behavior is not found for trinuclear **7**$^{\cdots}$ − this complex displays no redox splitting, and despite the presence of three trovacenyl groups, the cathodic shift, relative to the parent, trovacene, is very small. This finding is reminiscent of the redox behavior of molecules containing multiple noninteracting ferrocene units; in this case a CV curve typical for a diffusion-controlled, reversible, one-electron process is obtained (ΔE_p = 60 mV) where the wave height indicates the number of electrons transferred sequentially.[12] The latter criterion is fulfilled for **7**$^{\cdots}$, since the peak current, relative to the wave at −2.067 V which represents a one-electron process (vide infra), is larger by a factor of three. For **5**$^{\cdot}$ this peak−current ratio (cathodic process: anodic process) is 1:1, for **6**$^{\cdot\cdot}$ it is approximately 1:(1 + 1).

Table 1. Dihedral angles (°) between the reference plane PR1 = $B(C_{ipso})_3$, the planes of the mesityl substituents (Mes), and those of the cyclopentadienyl rings (Cp) of **5**$^{\cdot}$, **6**$^{\cdot\cdot}$, **7**$^{\cdot\cdot\cdot}$ and **7**$^{\cdot\cdot\cdot\prime}$

Why, within the framework of the CV experiment, do the trovacene units appear to be interacting in **6**$^{\cdot\cdot}$ but noninteracting in **7**$^{\cdot\cdot\cdot}$? If one assumes that trovacenyl groups are sterically more demanding than mesityl groups, it is conceivable that, in fluid solution, the twisting of the trovacene units relative to the BC_3 reference plane is more extensive in **7**$^{\cdot\cdot\cdot}$ than in **6**$^{\cdot\cdot}$. Since, arguably, an intersandwich interaction requires conjugation, a large twist distortion in **7**$^{\cdot\cdot\cdot}$ would explain the absence of an observable redox splitting. In this context it is worth mentioning that the solid-state and fluid-solution structures of the related molecule tri(ferrocenyl)borane (**8**) were found to be disparate,[7c] in the fluid solution, one ferrocenyl group is oriented opposite to the other two with respect to the central BC_3 plane. Since its electrochemical data were unavailable, we resynthesized **8** and recorded its cyclovoltammogram. As for **7**$^{\cdot\cdot\cdot}$, no redox splitting is resolved for **8** and, relative to ferrocene [$E_{1/2}(+/0)$ = 0.49 V], the potential $E_{1/2}(+/0)$ = 0.42 V for **8** represents a small cathodic shift.

In the strongly cathodic region of the potential, **5**$^{\cdot}$−**7**$^{\cdot\cdot\cdot}$ give rise to waves which signalize one-electron processes. This is inferred when their peak currents are compared to those representing the oxidation of the trovacene groups (vide supra). Furthermore, the numerical values of the potentials $E_{1/2}$ = −2.067 (**5**$^{\cdot}$), −2.095 (**6**$^{\cdot\cdot}$), −2.067 V (**7**$^{\cdot\cdot\cdot}$) are closer to $E_{1/2}(0/-)$ = −1.94 V[10] of 1,3,5-tri(mesityl)borane (**9**), than that of trovacene(**4**) [$E_{1/2}(0/-)$ = −2.55 V]. The cathodic shift observed for **5**$^{\cdot}$ (0/−), **6**$^{\cdot\cdot}$ (0/−) and **7**$^{\cdot\cdot\cdot}$ (0/−) relative to **9** (0/−) reflects the superior electron-donating properties of trovacenyl versus mesityl. Reduction of trovacenylboranes therefore must be regarded as boron-centered. Subsequent vanadium-centered reductions of the [5]trovacenylborane anions **5**$^{-}$−**7**$^{-}$ probably lie close to or outside the electrochemical window, i.e., at potentials < −2.9 V.

EPR Spectroscopy and Magnetic Susceptibility

The availability of the mono-, di-, and tri([5]trovacenyl)boranes **5**$^{\cdot}$−**7**$^{\cdot\cdot\cdot}$ permits a systematic study of the substituent effect of an R_2B group, as well as of the relative mediating properties of the RB< and −B< units. EPR spectra of **5**$^{\cdot}$−**7**$^{\cdot\cdot\cdot}$ are shown in Figures 5−7, the parameters, confirmed by simulation, are collected in Table 3.

The most remarkable feature in the fluid-solution spectrum of di(mesityl)([5]trovacenyl)borane (**5**$^{\cdot}$) is the fairly large coupling constant $a(^{51}V)$ = −7.35 mT, which exceeds the value for parent **4**$^{\cdot}$ by 6%. As for phenyl([5]trovacene),[1] this increase can be rationalized by a π-electron donation [η^5-$C_5H_4(e_2) \rightarrow B(sp^2)$] which raises the positive partial charge on the central vanadium atom with concomitant V{3d(z^2)} orbital contraction. This will have the effect of decreasing V{3d(z^2)}/ligand(a_1) overlap, thereby diminishing metal → ligand spin delocalization and slightly raising the coupling constant $a(^{51}V)$. The electronic perturbation of the trovacene unit by the dimesitylboryl substituent is insufficient, however, to effect an observable change of the g tensor from axial (**4**$^{\cdot}$) to orthorhombic (**5**$^{\cdot}$) which would be required by symmetry.

(Mesityl)di([5]trovacenyl)borane (**6**$^{\cdot\cdot}$) in fluid solution gives rise to a typical diradical EPR spectrum; the 15-line hyperfine pattern approaches a binomial intensity distribution with splitting that amounts to half the value of a (^{51}V) for the monoradical **5**$^{\cdot}$. Spectral simulation furnished optimal agreement for the exchange coupling constant J_{EPR} = |1.43| cm^{-1} which represents half the magnitude of J obtained for [5−5]di(trovacene) (**10**$^{\cdot\cdot}$).[1] In conditions close to the "fast-exchange limit", however, two caveats are called for: (1) spectral simulation does not provide the sign for J (magnetic susceptibility suggests that J < 0, vide infra), and (2) not too much confidence should be placed on the numerical value of J in this situation. Yet, the qualitative conclusion, that the incorporation of an −(R)B− spacer

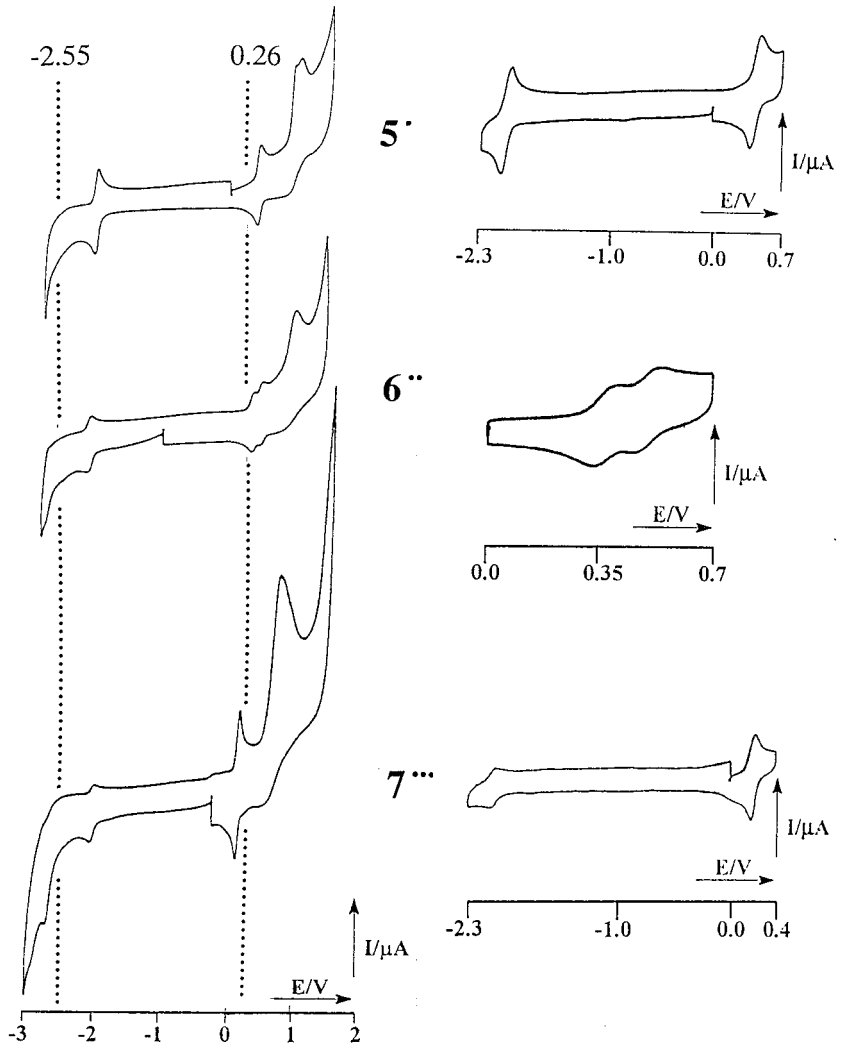

Figure 4. Cyclic voltammetric traces for compounds $\mathbf{5}^{\cdot}-\mathbf{7}^{\cdot\cdot\cdot}$ (1,2-dimethoxyethane/0.1 M tetrabutylammonium perchlorate, at glassy carbon versus SCE, $v = 100$ mV s^{-1}, −40 °C); the dotted lines mark the potentials for the processes $\mathbf{4}^{\cdot}$ (+/0) and $\mathbf{4}^{\cdot}$ (0/−) of the parent trovacene

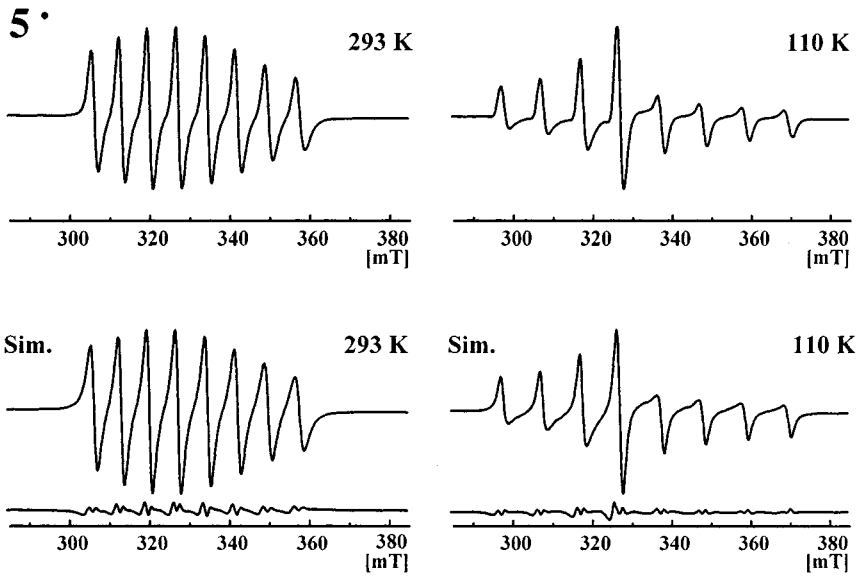

Figure 5. EPR spectra (X-band) of $\mathbf{5}^{\cdot}$, fluid (293 K) and rigid (110 K) solution in toluene, with simulated traces (bottom)

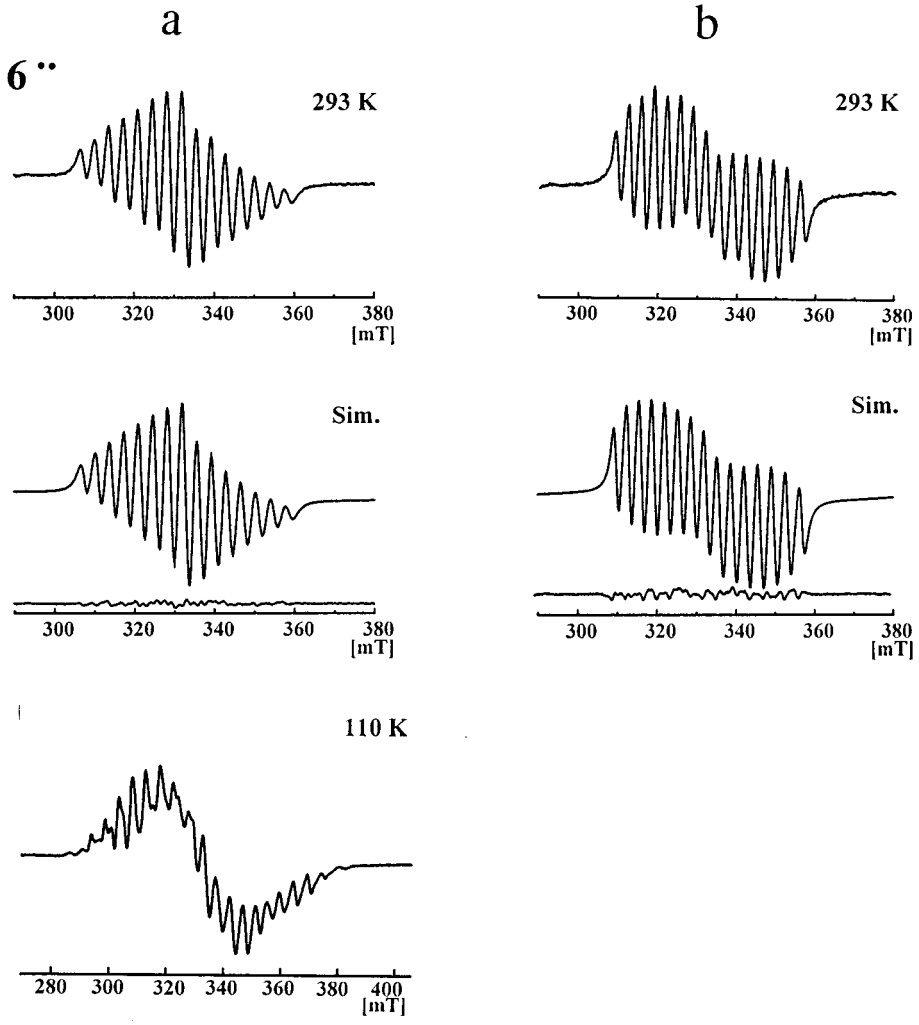

Figure 6. EPR spectra (X-band) of **6**··, fluid (293 K) and rigid (110 K) solution in THF (a), and spectra obtained after addition of *n*-butyllithium in hexane (b)

between two [5]trovacenyl units attenuates exchange coupling to a small degree only, is warranted. If conjugation between the η^5-C_5H_4 π-perimeters and the vacant B($2p_z$) orbital contributes to the exchange interaction, this result does not come as a surprise, since for **6**·· the dihedral angles between the ligand- and reference planes are small in the crystal structure (Table 1) and, due to conformational mobility, they are variable in fluid solution. However, as in the case of [5−5]di(trovacene),[1] the detailed coupling path between the two V(d^5) centers is not clear. Overlap of the V{3d(z^2)} orbitals, which dominate the SOMOs of the trovacene units, with the σ-backbone of the μ[η^5:η^5-$C_5H_4B(Mes)C_5H_4$] bridge, is small, as demonstrated by the small hyperfine coupling constant $a(^1H_{Cp})$ = 0.18 mT in the EPR spectrum of **4**·. Therefore, the direct coupling mechanism and the indirect one, which operates by polarization of filled π-orbitals of the ligands by the singly occupied V{3d(z^2)} orbitals, may be of comparable magnitude. Both mechanisms are of low efficiency, though, and the resulting type of interaction − ferromagnetic or antiferromagnetic − is difficult to predict.

Information concerning the spin-exchange path between the two vanadium centers was also expected from the influence that coordination of a Lewis base to boron would exert on the EPR spectrum of **6**··. The EPR trace for **6**·· in the presence of *n*-butyllithium is shown in Figure 6, where the spectral parameters, verified by computer simulation, are also given. Formation of the adduct [**6**··−*n*Bu]$^-$ clearly affects the EPR spectrum, from which the reduced value J_{EPR} = |0.97| cm^{-1} for the exchange coupling constant can be derived by simulation. No discernible change is observed on the addition of triethylamine, indicating that, probably due to steric hindrance, no adduct formation occurs. Exchange interaction is attenuated in [**6**··−*n*Bu]$^-$, presumably because the exchange path is modified in two ways: (1) The vacant boron p_z orbital, which potentially may engage in conjugative interactions between the trovacenyl units, is transformed into an orbital used for σ-bonding to the Lewis base, and (2) The boron atom is rehybridized from sp^2 to sp^3 during the process **6**·· → [**6**··−*n*Bu]$^-$. Both effects, elimination of a vacant p-orbital in the bridge and decrease of the B(2s) content in the σ-orbitals radiating from boron

may contribute to the observed reduction in exchange coupling, but apportioning their relative contributions is unfeasible. The gradation in J values of the diradicals containing B(sp^2) or B(sp^3) atoms in the spacer is an empirical observation which, for a detailed analysis, must await additional evidence. It is noteworthy, however, that a similar trend is encountered in the ^{1}H NMR spectra of boranes, in that nuclear spin coupling across boron is weakened if boranes R_3B are converted into borates $[R_3BR']^-$.[13]

Additional interesting aspects are offered by tri([5]trovacenyl)borane $\mathbf{7}^{\cdot\cdot\cdot}$. Whereas numerous organic triradicals have been prepared and studied in great detail,[14] and inorganic species possessing three paramagnetic centers are also familiar,[15] very few organometallic triradials have been reported so far.[16] This is surprising, since the choice of open-shell metal atoms whose nuclei bear magnetic moments suitable for EPR study, and the almost unlimited variability of organic frameworks serving as potential spacers, should provide a rich playground for investigation. Further assets of organometallic oligoradicals include the feasability of EPR studies in fluid solution (most organometallics contain mainly covalent bonds that suppress dissociation in solution), as well as their attenuated reactivity, compared to that of organic radicals. The synthesis and characterization of organometallic oligoradicals is interesting both from a fundamental point of view (study of competing interactions and spin frustration) as well as from an applied perspective (generation of high-spin molecules with ferromagnetic properties).

The fluid-solution EPR spectrum of tri([5]trovacenyl)borane $\mathbf{7}^{\cdot\cdot\cdot}$ exhibits a 22-line multiplet whose ^{51}V splitting corresponds to one third of the hyperfine coupling for mononuclear trovacene $\mathbf{4}^{\cdot}$ (Figure 7). The intensity distribution and the line shapes deviate markedly from the simple binomial case (fast-exchange limit) so that deriving the parameter J by computer simulation appears practicable. The numerical value $J = |0.53|$ cm^{-1} thus obtained for the exchange interaction in $\mathbf{7}^{\cdot\cdot\cdot}$ is somewhat unreliable, though, because it exceeds the coupling constant $a(^{51}\mathrm{V})$ by a factor of 100 which means that the fast-exchange limit is very close. A comparison of the exchange interactions of $\mathbf{6}^{\cdot\cdot}$, $\mathbf{7}^{\cdot\cdot\cdot}$, and $\mathbf{10}^{\cdot\cdot}$ will therefore be based on J values gathered from magnetic susceptibility studies.

Magnetic susceptibilities of crystalline powders of diradical $\mathbf{6}^{\cdot\cdot}$ and triradical $\mathbf{7}^{\cdot\cdot\cdot}$ were measured on a SQUID magnetometer in the temperature range 1.8−250 K and at constant magnetic fields of 500 and 5000 G. Plots of the dependence of the inverse susceptibility, χ^{-1}, vs temperature, T, for both radicals are shown in Figure 8.

The Bleaney−Bowers type equation, Equation 1[15d] was fitted to the experimental data of the diradical $\mathbf{6}^{\cdot\cdot}$ (Figure 8a) to give the best-fit parameters for the factor $g = 1.99(1)$, the exchange constant $J/k = -1.38(2)$ K (-0.96 cm^{-1}) and the Curie−Weiss temperature $\Theta = -9.5(5)$ K. Therefore, the interaction in $\mathbf{6}^{\cdot\cdot}$ is antiferromagnetic.

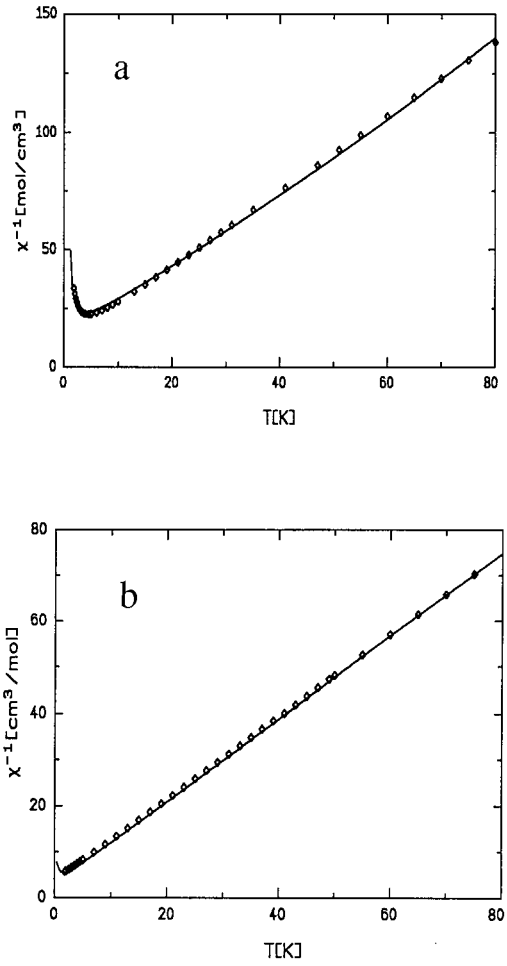

Figure 8. Temperature-dependence of the inverse molar susceptibility of the diradical **6**·· and the triradical **7**···

$$\chi_{mol} = \frac{2N g^2 \mu_B^2}{kT[3+\exp(-J/kT)]} \quad \frac{T}{(T-\Theta)} \qquad (1)$$

This is also the case for triradical **7**··· whose susceptibility data (Figure 8b) were fitted by Equation 2, which applies to the case of an equilateral triangular disposition of identical $S = 1/2$ centers.[17] Optimal fit of the curve was obtained by means of the parameters $g = 1.99(1)$, $J/k = -0.5(2)$ K (-0.35 cm^{-1}), $\Theta = -2.7(5)$ K. From an inspection of the least-squares fit in Figure 8b one has to conclude that the derived exchange constant J can only be interpreted as an upper limit of the interaction parameter. If the local spins present in **7**··· are denoted as S_1, S_2, and S_3, the spin Hamiltonian describing the low-lying states in zero field may be expressed as Equation 3.

$$\chi_{mol} = \frac{N g^2 \mu_B^2}{2kT} \quad \frac{1+5\exp(-3J/kT)}{1+\exp(-3J/kT)} \quad \frac{T}{(T-\Theta)} \qquad (2)$$

$$H = -2J(S_1S_2+S_1S_3+S_2S_3) \qquad (3)$$

The interaction between the three local doublets leads to a molecular quartet and two degenerate doublets, the latter forming the ground state as implied by the antiferromagnetic nature of the interaction. Here, the separation between the degenerate doublets and the quartet amounts to 3*J*. The analysis of the susceptibility data reveals that J(**7**···) for the triradical falls considerably short of J(**6**··) obtained for the diradical. The same gradation was found for the EPR spectra of **7**··· and **6**··. This finding reflects the spin frustration in **7**··· where three spins $S = 1/2$ that are coupled antiferromagnetically, reside in an equilateral triangular arrangement (Figure 3, Figure 9). The reduced J value results because, in the doublet ground state of **7**···, two spins need to be aligned parallel, the opposite of the tendency towards spin pairing (as demonstrated by the susceptibility curve for diradical **6**··).

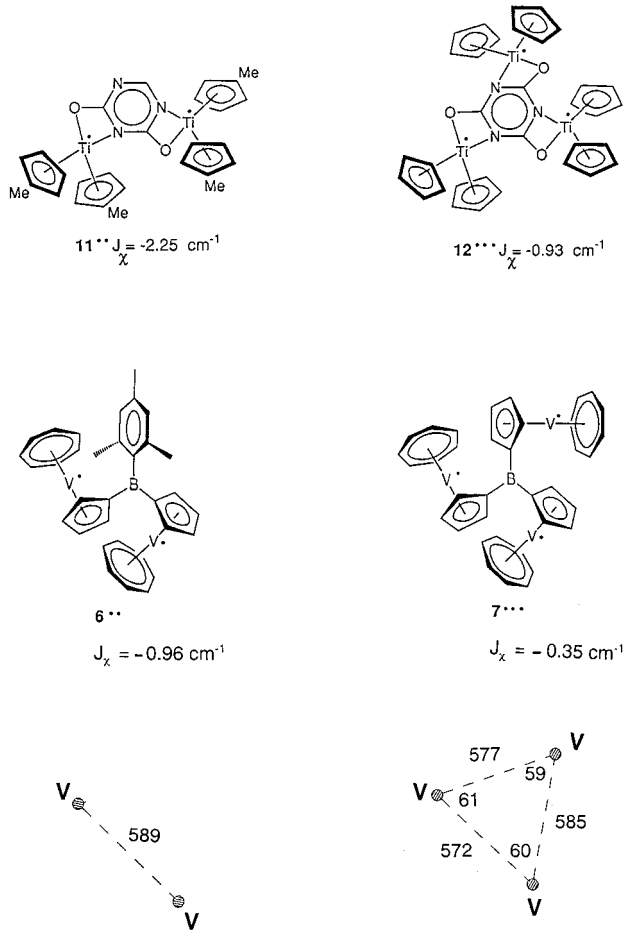

Figure 9. Structures of the organometallic diradicals/triradicals 11··/12··· and 6··/7···, and their exchange coupling constants $J_{\χ}$; intervanadium distances (pm) in 6·· and 7··· are also given

The characteristic decrease in the magnitude of J on going from a diradical to a triradical of triangular structure, while keeping the exchange path identical, is limited to cases where the pairwise interactions are antiferromagnetic. Organic triradicals with the requisite trigonal symmetry are usually based on 1,3,5-benzenetriyl as backbone, where the 1,3-connection effects ferromagnetic coupling.[18] Therefore, to the best of our knowledge, spin frustration has as yet only been observed once for an organic triradical.[14d] In

contrast, several examples of spin-frustrated coordination compounds[19] are known, and there are also a few cases known in the field of organometallic chemistry.[20,5a] Since the pair **11**$^{\cdot\cdot}$/**12**$^{\cdot\cdot\cdot}$[20] resembles the pair **6**$^{\cdot\cdot}$/**7**$^{\cdot\cdot\cdot}$ reported here, they are represented in Figure 9 together with their respective *J* values, determined by susceptometry. What both pairs have in common is the presence of two or three paramagnetic sandwich complex units ($S = 1/2$) whose open-shell central metal atoms, Ti(d^1) or V(d^5), are linked by bridges which effect antiferromagnetic coupling. Furthermore, in the trinuclear complexes **7**$^{\cdot\cdot\cdot}$ and **12**$^{\cdot\cdot\cdot}$, the central metal atoms are placed at the corners of an equilateral triangle so that the pairwise magnetic interactions are governed by a single exchange parameter *J*. Thus, the stage is set for spin frustration which is actually observed in both cases since, despite identical coupling paths, *J* for the triradicals **7**$^{\cdot\cdot\cdot}$ and **12**$^{\cdot\cdot\cdot}$ falls short of *J* exhibited by diradicals **6**$^{\cdot\cdot}$ and **11**$^{\cdot\cdot}$. It may come as a surprise that the *J* values for **11**$^{\cdot\cdot}$ and **12**$^{\cdot\cdot\cdot}$ exceed those for **6**$^{\cdot\cdot}$ and **7**$^{\cdot\cdot\cdot}$ considerably, despite the fact that, in both cases, the interacting metal atoms are separated by four bonds. One should bear in mind, however, that a detailed description of the exchange pathway must be based on the symmetry relationship between the metal- and ligand bridge orbitals and their energies. The two systems compared here differ significantly in that the singly occupied titanium orbitals in **11**$^{\cdot\cdot}$ and **12**$^{\cdot\cdot\cdot}$ are thought to be located in the plane of the bridging cyanurato trianion,[20] whereas in the [5]trovacenyl derivatives **6**$^{\cdot\cdot}$ and **7**$^{\cdot\cdot\cdot}$, the singly occupied vanadium orbitals are perpendicular to the cyclopentadienyl plane of the $\mu[\eta^5{:}\eta^5\text{-}C_5H_4B(R)C_5H_4]$ bridge (R = mesityl, trovacenyl). A simple count of the atoms intervening between the two paramagnetic centers can therefore not account for the gradation of the experimental *J* values.

Experimental Section

General: All manipulations were performed with exclusion of air under dinitrogen or argon (CV) unless stated otherwise. Physical measurements were carried out with equipment specified previously.[22] Trovacene $(\eta^7\text{-}C_7H_7)V(\eta^5\text{-}C_5H_5)$,[6a] di(mesityl)fluoroborane, and (mesityl)difluoroborane[23] were prepared as described in the literature.

Bis(mesityl)([5]trovacenyl)borane (5$^{\cdot}$): To a solution of trovacene (290 mg, 1.4 mmol) in 80 mL of diethyl ether was added, at room temperature, 1.4 mL of a solution of *n*-butyllithium in hexane (1.55 mol L^{-1}). After being stirred for 14 h, the reddish-brown solution was cooled to −40 °C, and 187 mg (0.7 mmol) of di(mesityl)fluoroborane, dissolved in 30 mL of diethyl ether, was slowly added to it. The mixture was allowed to reach room temperature, whereby a color change to green occurred. After the reaction mixture was stirred for 20 h, the solvent was removed in vacuo, the residue was taken up in toluene and subjected to column chromatography (Al_2O_3, 0% H_2O, elution with toluene). From the first fraction, 290 mg (0.65 mmol, yield: 46%) of **5**$^{\cdot}$ was obtained as a green product. Single crystals suitable for X-ray diffraction were grown from benzene/*n*-pentane (supernatant). MS (EI, 70 eV) *m*/*z* (%): 456

[16] To the best of our knowledge the only organometallic triradicals which have been isolated are cyanuratotris[bis(η^5-methylcyclopentadienyl)titanium(III)][19] and 1,3,5-tri([5]trovacenyl)benzene.[5a] Formally, certain paramagnetic termetallocene cations, generated during electrochemical oxidations in CV experiments,[21] also belong to this class.

[17] Equation 2 was derived from the more general expression valid for an equilateral triangular configuration with nonidentical coupling pathways, described by the parameters J and J', where the ratio $J'/J = \alpha$ was set to one (see Ref.[14d]). Apart from the structural information about **7**$^{+\cdot\cdot\cdot}$, gathered by X-ray crystallography, the simplification inherent in Equation 2 is justified by the fact that the fit based on the more general expression given in Ref.[14d] was optimal for $\alpha = 1$.

Chiral Chelate Ligands Based on a Neopentane Framework; Introducing Indenyl and Fluorenyl Donor Groups

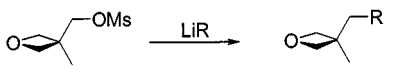
Joachim Vogelgesang,[a] Gottfried Huttner,*[a] Elisabeth Kaifer,[a] Peter Kircher,[a] Peter Rutsch,[a] and Sven Cunskis[a]

Dedicated to Prof. Dr. H. Schmidbaur on the occasion of his 65th birthday

Keywords: Ansa compounds / Cp-derived chelate ligands / Neopentane chemistry / Spiro compounds / Tripodal ligands / Cyclopentadienyl compounds

The neopentane-derived functionalized oxetane $O(CH_2)_2C(CH_3)(CH_2OMs)$, **1**, reacts with indenyllithium (LiInd) or fluorenyllithium (LiFlu) to produce the derivatives $O(CH_2)_2C(CH_3)(CH_2R)$ (R = indenyl, fluorenyl), **2**. The oxetane ring of **2** undergoes nucleophilic ring-opening by reaction with $LiPR'_2$ to give the chiral chelate ligands $(HOCH_2)(CH_3)C(CH_2R)(CH_2PR'_2)$ (R = indenyl, fluorenyl), **5**. Nucleophilic ring-opening by LiInd or LiFlu is possible too, resulting in the functionalized *ansa*-Cp ligands $(HOCH_2)(CH_3)C(CH_2R)(CH_2R')$ (R, R′ = indenyl, fluorenyl), **12**. Electrophilic ring-opening of **2** with HBr to give $(HOCH_2)(CH_3)C(CH_2R)(CH_2Br)$ (R = indenyl, fluorenyl), **3**, is also possible. The alcohol function of **3** may be activated directly, whereas activation of this group in **5** is only possible after BH_3 protection of the phosphane function. The mesylates $(MsOCH_2)(CH_3)C(CH_2R)(CH_2Br)$ (R = indenyl, fluorenyl), **4**, undergo, under basic conditions, spiro cyclization to produce spirocyclobutane derivatives **9** with the α-carbons of the five-membered cycles acting as the spiro centres. Substitution of the mesylate group of **4** by PR_2 nucleophiles is therefore not possible. *Ansa*-Cp derivative $(MsOCH_2)(CH_3)C(CH_2Ind)(CH_2Flu)$, **12c** also reacts with $LiPPh_2$ with spiro cyclization to produce **9d**, instead of giving the substitution product. Tripodal ligands $(CH_3)C(CH_2R)(CHPPh_2)_2$ (R = indenyl, fluorenyl), **11**, are accessible by the reaction of $(MsOCH_2)(CH_3)C(CH_2PPh_2)_2$ with LiInd or LiFlu. All compounds are fully characterized by the usual spectroscopic and analytical techniques including single-crystal X-ray analyses in several cases.

Introduction



The coordination chemistry of neopentane-based tripodal ligands was extensively developed by L. Sacconi[1] and his school,[2] on the basis of $CH_3C(CH_2PPh_2)_3$ as the prototype ligand. The peculiar type of reactivity of the corresponding tripodal metal templates $CH_3C(CH_2PR_2)_3M$[1][2] indicates potential for this type of ligand, and modification of the donor groups appears to be a worthwhile goal. A number of methods have been developed for the introduction of different donor groups in $CH_3C(CH_2X)(CH_2Y)(CH_2Z)$ (X, Y, Z = PR_2, PR'_2, NR_2, SR, OR),[3−5] even enantioselectively.[3c,3e,3h] Introducing a Cp moiety as a constituent of this type of tripodal ligand calls for special procedures which have been worked out in some cases.[6] The ligands $[R'CH_2C(CH_2C_5H_4)(CH_2X)(CH_2Y)]^-$ (Y, Z = PR_2) lend themselves to the construction of $CpML_2$ templates in which the Cp ligand and the L donors are covalently linked by a neopentane scaffolding. The importance of $CpML_2$ templates in the metal-mediated transformation of organic substances is a stimulus for the interest in such tripodal CpL_2 ligands.[7] It is shown in this paper that the routes developed for the introduction of Cp donor groups into the tripodal ligands cannot be directly transferred to the synthesis of tripodal ligands containing indenyl or fluorenyl groups, due to complications arising from internal cyclization processes. Reaction sequences are nevertheless developed, which allow the introduction of these Cp derivatives into neopentane-based tripodal ligands.

Results and Discussion

Ligand Synthesis

The following reaction sequence was shown to be effective for converting functionalized oxetane **1** to Cp-functionalized tripodal ligands: 1. Substituting OMs by Cp. 2. Electrophilic opening of the oxetane ring by HBr. 3. Mesylation of the OH group resulting from step 2. 4. Nucleophilic substitution of the two leaving groups (OMs, Br) by PR_2.[6a]

The first step of this sequence (Scheme 1) also works when indenyl or fluorenyl needs to be introduced. Compound **2a** is obtained as a colourless oil, which tends to

1 **2a** R = Indenyl **2b** R = Fluorenyl

Scheme 1

crystallize at −20°C. Compound **2b** forms a colourless microcrystalline powder, from which crystals, suitable for X-ray analysis, could be grown by slow evaporation from CH_2Cl_2/*n*-pentane solutions. NMR spectroscopic data (Table 1) and analytical data (Table 2) are consistent with the assigned constitution which is further proved by an X-ray analysis of **2b** (Figure 1, Table 3 and Table 4).

There are two independent molecules of **2b** in the unit cell (only one is shown in Figure 1). The scalar geometric parameters of these individual molecules are almost identical (Table 3). Even the relative orientation of the fluorenyl entity with respect to the oxetane moiety is closely similar in both molecules (see torsion angles C1−C2−C5−C6 in Table 3). The only significant difference is in the folding angles of the oxetane ring which is definitely different in the two independent species (cf. torsion angles C1−C2−C3−Y and C1−C2−C4−Y Table 3).

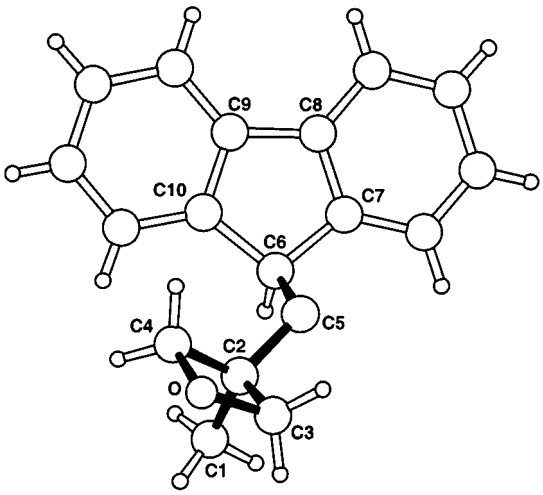

Figure 1. Structure of **2b**

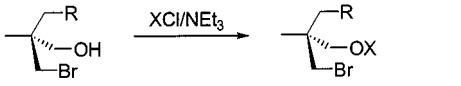


Electrophilic opening of the oxetane rings of **2** by HBr results in compounds **3**; **3a** is obtained as a colourless oil and **3b** as a colourless microcrystalline material (Scheme 2). Analytical (Table 2) and spectroscopic data (Table 1) confirm the identity of **3**.

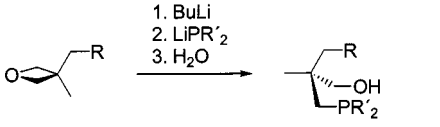
2a R = Indenyl
2b R = Fluorenyl

3a R = Indenyl
3b R = Fluorenyl

Scheme 2

3a R = Indenyl
3b R = Fluorenyl

4a R = Indenyl, X = Ms
4b R = Indenyl, X = SO_2Ph
4c R = Indenyl, X = $SiMe_3$
4d R = Fluorenyl, X = Ms



Scheme 3

Activation of the OH group of **3** by different reagents leads to compounds **4** (Scheme 3). Transformation of the $OSiMe_3$ group of **4c** into an iodine substituent by reaction with NaI/$ClSiMe_3$/acetonitrile was unsuccessful. The silyl derivative **4c** is obtained as a colourless oil, while the other compounds **4** form colourless microcrystalline solids. The analytical (Table 2) and the spectroscopic (Table 1) data are in accord with the assigned constitutions, which are further corroborated by single-crystal X-ray analyses of **4a** and **4b** (Figure 2, Table 3 and Table 4). The single crystals of **4a** and **4b** could be grown in test tubes from saturated CH_2Cl_2/*n*-pentane solutions by slow diffusion of the solvent into rubber stoppers.

Both these chiral neopentane derivatives crystallize in racemic form (Table 4). The arrangement of the individual substituents is such that steric congestion within the molecules is avoided by spreading out of the bulky groups (Figure 2). In both compounds the indenyl substituents are connected to the scaffolding via the α-carbon centre (C6) of the five-membered cycle. The alternating double and single bonds between the carbon atoms of these five-membered cycles are clearly evident from the corresponding distances (Table 3). The solid-state structures are in agreement with the NMR spectroscopic data (Table 1) which show that indenyl substitution is fully stereoselective with only C_α acting as the linking atom.

Nucleophilic opening of the oxetane group of **2** is also possible. This is done according to a procedure developed for Cp-substituted oxetanes.[6a] After deprotonation of the Cp-containing residue by *n*-butyllithium in THF, a THF solution of $LiPR_2$ is slowly added to the reaction mixture. After hydrolysis, the products **5** are extracted with diethyl ether and are obtained as colourless oils after evaporation of the solvent (Scheme 4). The crude products **5a** and **5b** are separated from the excess diphenylphosphane by chromatography while excess diethylphosphane is removed from **5c** in vacuo. The NMR spectroscopic data of **5** (Table 5) are consistent with the formulae given, as are the mass spectra and the elemental analyses (Table 2).

Protection of the PR_2 group of **5** by BH_3 leads to the derivatives **6**, which are also fully characterized (Scheme 5, Table 5 and Table 2). [3f,8] Single crystals of **6b** were grown from saturated CH_2Cl_2/*n*-pentane solutions by slow diffusion of the solvent into rubber stoppers. X-ray analysis data of **6b** (Figure 3, Table 3 and Table 4) are in accord with the assigned constitution. In contrast to **4a**/**4b**, the bulky substituents are not spread out as far as possible; the fluorenyl substituent is apparently preferentially close to the phenyl groups, with a face to edge arrangement of these two groups resulting. Individual angles and distances within the compound are normal (Table 3); the P−B distance

2a R = Indenyl
2b R = Fluorenyl

[a] The numbering scheme used refers to the graphic given here and is different from the numbering schemes for the individual atoms in the deposited data. − [b] X (Y) designates the atom which is directly bonded to the relevant carbon atom. − [c] C_{ar}−C_{ar} designates the distances within the annelated cycles, excluding C7−C8 (fluorenyl) and C9−C10 which are given explicitly.

The synthesis of tripodal ligands containing one indenyl- or fluorenyl group and two phosphorus donors appears straightforward from starting compounds such as **4**: with $CH_3C(CH_2C_5H_5)(CH_2Br)(CH_2OMs)$ as the starting material, substitution of the leaving groups by phosphorus donors is easily achieved through reaction with $KPPh_2$.[6a] When the same procedure is applied to **4a**, internal cyclization with formation of the spiro compounds **9a** ***syn***/**9a** ***anti*** occurs (Scheme 7). The higher nucleophilicity of the indenyl residue compared to that of the Cp residue apparently favours the reaction leading to internal cyclization rather than the one leading to external substitution by PPh_2. With C_α of the indenyl group forming the spiro centre, there are two diastereomeric forms of **9a**, one in which the CH_2PPh_2 residue and the annelated benzene part of the indenyl residue are on the same side of the cyclobutane ring (*syn*) and one

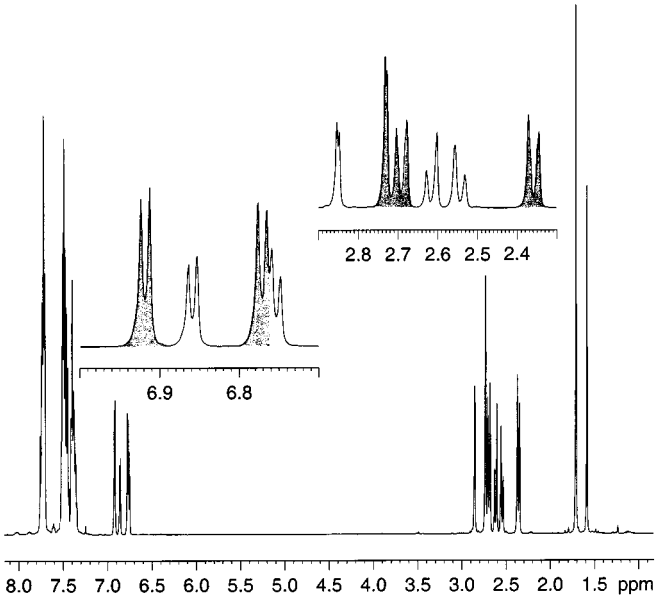
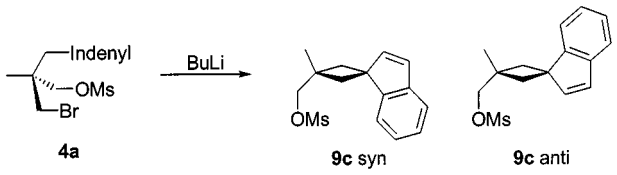
in which they are on opposite sides (*anti*). These two diastereomers are formed in a ratio of *syn*:*anti* = 7:4, as shown by NMR. Assignment of individual signals (Table 6) to the *syn*- and *anti* forms is based on the signals characterizing the CH_2 groups of the four-membered cycle. While the two CH_2 groups in each specific diastereomer are symmetrically equivalent, the protons of these groups are not so and this gives rise to two doublets. The type of spectrum observed for the indenyl spiro compounds **9** is exemplified in Figure 4 for **9a**. The resonances useful for the attribution of the structures of the *syn*- and *anti* isomers are shown as magnified inserts in Figure 4 (*syn* isomer in grey).





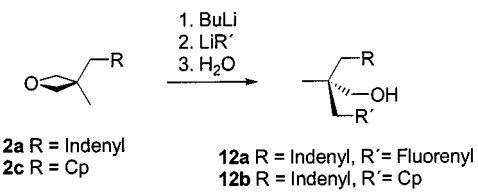


Figure 4. ^{1}H NMR spectrum of **9a** in $CDCl_3$

Assignment of the NMR resonances to individual diastereomers is based on the assumption that, within the *syn* diastereomer, two of these protons are in close vicinity of the CH_2PPh_2 group and the annelated benzene ring, whereas the other two protons stick out to the far less congested side of the four-membered cycle, so that the environments of these two pairs of protons are very different. The proton signals corresponding to these protons should therefore have significantly different shift values. With the *anti* isomer, both sides of the ring are congested, so that the

the protons that are on the same sides of the four-membered cycles as the methyl groups show a strong correlation (Figure 5).

The spectroscopic and analytical properties of the fluorenyl residue of **9b** (due to the symmetry of the fluorenyl spiro substituent only one isomer is possible) are in accordance with the assigned constitution (Table 6 and Table 2).

The formation of the spiro compounds **9a/9b** is not due to any specific properties of $LiPPh_2$ as a base; the same type of reaction is observed when **4a** is treated with *n*-butyllithium.

The *syn*- and *anti* isomers of **9c** are formed in a ratio of 2:1 (Scheme 8); **9c** gives rise to a ^{1}H NMR spectrum (Table 6) similar to that of **9a** shown in Figure 4.

Towards the synthesis of tripodal ligands, the formation of the spiro products **9** is a dead end. Spiro cyclization appears to be the more favoured reaction for the more sterically congested compounds such as these neopentane-derived ones, which contain an indenyl or a fluorenyl group together with an electrophilically activating group. Here substitution by an external nucleophile is slowed down, whereas internal substitution is not drastically retarded by steric crowding. Taking this into account, it is not really probable that nucleophilic oxetane-ring-opening reaction sequences starting with the substituted oxetane **2**, shown to lead to **8** (Scheme 4, Scheme 5, and Scheme 6) might finally lead to the desired tripodal ligands. If, on the other hand, the oxetane ring of **2** would be amenable to nucleophilic ring-opening by indenyl- or fluorenyllithium, this would give a simple access to *ansa*-Cp ligands containing a functionalizable -CH_2−$C(CH_3)(CH_2OH)$−CH_2- linker. Compounds **2** were found to undergo this type of ring-opening reaction when treated with indenyl- or fluorenyllithium (Scheme 9). The OH group of **12** may be activated as shown by the transformation of **12a** into the corresponding mesylate **12c**, or trimethylsilyl ether **12d** (Scheme 10). Compounds **12** are fully characterized by their spectroscopic (Table 7) and analytical (Table 2) data. Except for **12b**, which is a colourless oil, compounds **12** are obtained as colourless microcrystalline solids. Single crystals suitable for X-ray analysis could be grown for **12a** (Figure 6, Table 3, and Table 4). The crystals were grown from saturated

CH_2Cl_2/*n*-pentane solutions by slow diffusion of the solvent into rubber stoppers.

The constitution of **12a** as derived from spectroscopy (Table 7) is confirmed by its structure. The angles and distances are in the normal ranges (Table 3). In contrast to **6b** where the fluorenyl substituent and the bulky PPh_2BH_3 group are in close vicintity to each other, the fluorenyl and indenyl substituents of **12a** are as distant from each other as possible (Figure 6) with a well spread-out molecular shape as had also been observed for **4a**/**4b**. As expected, phosphinylation of **12c** is not possible: When **12c** is treated with $LiPPh_2$ (Scheme 11), the spiro compound **9d** is formed which is characterized analytically (Table 2) as well as by its typical NMR pattern (Table 6). The transformation **12c** → **9d** is selective. No indication of spiro cyclization involving the indenyl substituent is observed.

The above results suggest that, in order to introduce an indenyl or a fluorenyl group into a tripodal ligand, this group has to be introduced last. This contrasts strongly to the synthesis of tripodal ligands containing a C_5H_5 group, where the optimal reaction route relies upon introducing the Cp group at the very beginning of the sequence.[6a] The reason for this difference is the inherent tendency of fluorenyl- and indenyl derivatives to undergo spiro cyclization.

Tripodal ligands containing an indenyl or a fluorenyl donor group are accessible from **10**, which is obtained from **10**•$2BH_3$ by deprotection with morpholine.[8c,9] The deprotected form **10** has to be used because using **10**•$2BH_3$ itself as the starting compound reduces yield and selectivity. Compound **10** reacts with indenyllithium to produce **11a** and with fluorenyllithium to give the tripodal ligand **11b** (Scheme 12). To obtain acceptable yields, the lithium reagents have to be activated by the addition of TMEDA or 18-crown-6. Under these conditions, the yields of **11** after chromatographic workup are around 30%. Compounds **11** are off-white solids, which are obtained in microcrystalline form. Depending on the handling procedure, **11b** may be orange, presumably due to some very minor dyestuff impurity which is not apparent from the analytical and spectroscopic data (Table 7 and Table 2). Both products **11a**/**11b** and starting material **11** are fully characterized by spectroscopy (Table 7) and elemental analysis (Table 2).

Conclusion

Neopentane-based tripodal ligands $CH_3C(CH_2PR_2)_2(CH_2R')$ (R = aryl, alkyl; R′ = indenyl, fluorenyl) are accessible by a synthetic procedure in which the indenyl or fluorenyl residues are introduced in the last step. This contrasts to the synthesis of the analogous Cp-containing tripodal ligands $[CH_3C(CH_2PR_2)_2(CH_2C_5H_4)]^-$, where the Cp group had to be the first one to be introduced.[6a]

Neopentane derivatives of the type $(RCH_2)(CH_2R')C(CH_2Indenyl)(CH_2X)$ (X = electrophilically activating group) undergo spiro cyclization when treated with bases, to produce spiro cyclobutanes with the indenyl α-carbon atom acting as the spiro centre. The basic nucleophiles (e.g., $KPPh_2$) therefore do not react by substitution, they act as bases, initiating spiro cyclization. The same type of reactivity is observed with fluorenyl as the neopentane-bound substituent.

Neopentane-derived oxetanes $O(CH_2)_2C(CH_3)(CH_2R)$ (R = Cp, indenyl) react with indenyl- or fluorenyllithium by nucleophilic opening of the oxetane ring to produce functionalizable chiral *ansa*-Cp ligands $(HOCH_2)(CH_3)C(CH_2R)(CH_2R')$ (R, R′ = Cp, indenyl, fluorenyl), in fair yields

Experimental Section

General: All manipulations involving phosphanes were carried out under argon by means of standard Schlenk techniques and were monitored by TLC (Macherey−Nagel Co., Polygram SIL G/UV_{254}). All solvents were dried by standard methods[10] and distilled under argon. The solvents $CDCl_3$ and CD_2Cl_2 used for NMR spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried with 4-Å molecular sieves. − NMR: Bruker Avance DPX 200 at 200.12 MHz (^1H), 50.323 MHz ($^{13}C\{^1H\}$), 81.015 MHz ($^{31}P\{^1H\}$), T = 298 K; chemical shifts (δ) with respect to $CHCl_3$ (^1H: δ = 5.32; ^{13}C: δ = 53.5) as internal standards. ^{31}P chemical shifts (δ) with respect to 85% H_3PO_4 (^{31}P: δ = 0) as external standard. − MS: Finnigan MAT 8320, EI (70 eV) − Melting points: Gallenkamp MFB-595010; uncorrected values. − Elemental analyses: Microanalytical Laboratory of the Organisch-Chemisches Institut, Universität Heidelberg.

Materials: Silica gel (Kieselgel z.A. 0.06−0.2 mm, J. T. Baker Chemicals B. V.) used for chromatography was degassed at 1 mbar for 24 h and saturated with argon. A solution of 2.5 M *n*BuLi in hexane was used for deprotonations. $HPEt_2$,[11] $HPPh_2$,[12] 3-methanesulfonoxymethyl-3-methyloxetane (**1**),[13] 1-methanesulfonoxymethyl-2,2-bis(diphenylphosphanylmethyl)propane−*P,P*-bis(borane) (**10**•$2BH_3$)[3f] and 3-cyclopentadienylmethyl-3-methyloxetane (**2c**)[6a] were prepared according to or by adaptation of literature procedures. All other chemicals were obtained from commercial suppliers and were used without further purification.

General Procedure for the Synthesis of Compounds 2: Indene or fluorene (37 mmol, 1.3 equiv.) was dissolved in 100 mL of THF and was deprotonated by the dropwise addition of *n*BuLi at 0°C. This solution was stirred for 2 h at room temperature; after this period the solution was heated to 60°C and a solution of 3-methanesulfonoxymethyl-3-methyloxetane (28 mmol) in THF (50 mL) was added dropwise over a period of 45 min. The resulting mixture was then heated to reflux for 3 h. After cooling to room temperature, the mixture was hydrolysed by addition of 30 mL water. The organic phase was separated, and the aqueous layer was extracted with three 30 mL portions of diethyl ether. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield given in Table 2).

General Procedure for the Synthesis of Compounds 3: Compound **2** (10 mmol) was dissolved in 50 mL THF and cooled to 0°C. At this temperature 30 mmol (3 equiv.) of a 48% aqueous solution of hydrobromic acid was added dropwise. After it was stirred for 1 h at 0°C, the reaction mixture was allowed to warm to room temperature and stirred for 1 h.

For 3a: The mixture was again cooled to 0°C and 15 mL of 10% caustic soda solution was added to reverse the HBr addition at the

double bond of the indene residue, which had occurred in part during the first step (c.f.[6a]). Stirring was continued for 1 h at 20°C. The organic phase was separated, and the aqueous layer was extracted with three 30 mL portions of diethyl ether. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

For 3b: The organic phase was separated, and the aqueous layer was extracted with three 30 mL portions of diethyl ether. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

General Procedure for the Synthesis of Compounds 4a, 4d, 7, and 12c: The starting material (10 mmol) was dissolved in CH_2Cl_2 (60 mL)and 1.5 equiv. of triethylamine was added to the solution. The mixture was cooled to 0°C and 1.3 equiv. of methanesulfonyl chloride was added dropwise. After half the amount of methanesulfonyl chloride had been added, a white precipitate formed. After 20 min at 0°C, stirring was continued for another 6 h at 20°C. The mixture was hydrolysed by the addition of 20 mL of water. The organic phase was separated, and the aqueous layer was extracted with three 30 mL portions of CH_2Cl_2. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue purified by column chromatography (eluent, R_f, and yield are given in Table 2).

General Procedure for the Synthesis of Compounds 5: Oxetane **2** (6−15 mmol) was dissolved in THF (40−60 mL)and deprotonated by the dropwise addition of 1 equiv. *n*BuLi at 0°C. The solution was stirred for 1 h. The phosphane HPR'_2 (1.2 equiv.) was dissolved in THF (40−60 mL) and was deprotonated in the same manner by the dropwise addition of 1 equiv. *n*BuLi at 0°C. This solution was stirred for 30 min at 20°C. The phosphide solution was added dropwise to the deprotonated oxetane over a period of 45 min. The resulting mixture was stirred for 6 h at room temperature and heated to reflux (**5a**, **5c** 1 h; **5b** 3 h). After it had cooled to room temperature, the mixture was hydrolysed by addition of 20 mL of water. The organic phase was separated, and the aqueous layer was extracted with three portions of 30 mL diethyl ether. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (not in case of **5c**, which seems to decompose on silica gel) (eluent, R_f, and yield are given in Table 2).

General Procedure for the Synthesis of Compounds 6: Compound **5** (5−12 mmol) was dissolved in THF (50 mL) and cooled to 0°C. At this temperature, BH_3 (1.3 equiv.) in THF was added dropwise. The reaction mixture was stirred for 45 min. The solvent was removed in vacuo and the remaining residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

General Procedure for the Synthesis of Compounds 8 and 10: The starting material was dissolved in a sufficient amount of morpholine (no undissolved parts remained). The mixture was heated 15 min at 70°C. All volatile components were removed in vacuo and the remaining residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

General Procedure for the Synthesis of Compounds 9a and 9b: Diphenylphosphane (12 mmol, 3 equiv.) was dissolved in THF (30 mL) and deprotonated by the dropwise addition of 1 equiv. *n*BuLi at 0°C. This solution was stirred for 1 h at room temperature, after which a solution of 4 mmol starting material (**4a**, **4d**) in 30 mL THF was added dropwise over a period of 2 min. The resulting mixture was stirred for 2 h at room temperature and heated to reflux (**9a** 2 h; **9b** 3 h). After cooling to room temperature the mixture was hydrolysed by addition of 20 mL of water. The organic phase was separated and the aqueous layer was extracted with three portions of 20 mL diethyl ether. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

Synthesis of Compound 9c: Compound **4a** (1.4 mmol) was dissolved in 10 mL of THF and deprotonated by the dropwise addition of 1 equiv. *n*BuLi at −70°C. This solution was stirred for 2 h at room temperature and heated to reflux for 2 h. After cooling to room temperature the mixture was hydrolysed by addition of 10 mL of water. The organic phase was separated and the aqueous layer was extracted with three portions of 10 mL diethyl ether. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

Synthesis of Compound 9d: Diphenylphosphane (2.8 mmol, 2.5 equiv.) was dissolved in 15 mL of THF and deprotonated by the addition of 1 equiv. KO*t*Bu at 0°C. This solution was stirred for 1 h at room temperature, then a solution of 1.9 mmol **12c** in 20 mL THF was added dropwise over a period of 1 min. The resulting mixture was stirred for 12 h at room temperature. The mixture was hydrolysed by addition of 10 mL of water. The organic phase was separated and the aqueous layer was extracted with three portions of 20 mL diethyl ether. The combined organic phases were washed with saturated NaCl solution (pH: neutral) and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography. Elution with PE/Et_2O = 1/1 removed contaminants while **9d** did not migrate at all. It was subsequently eluted with toluene/THF 1/1. On evaporation of the solvent from the eluate, the purified compound **9d** was obtained in microcrystalline form (yield are given in Table 2).

General Procedure for the Synthesis of Compounds 4c and 12d (Silylation): Starting material (5 mmol) was dissolved in 40 mL CH_2Cl_2 and 1.5 equiv. of triethylamine was added. The solution was cooled to 0°C and 1.3 equiv. of trimethylsilyl chloride was added dropwise. After the reaction mixture was stirred for 1 h, all volatile parts were removed in vacuo. The remaining residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

Synthesis of Compound 4b: Compound **3a** (10 mmol) was dissolved in a solution consisting of 20 mL CH_2Cl_2 and 20 mmol pyridine (2 equiv.). The mixture was cooled to 0°C and 14 mmol benzenesulfonyl chloride (1.4 equiv.) was added dropwise. Stirring was continued at 20°C for 15 h. The mixture was hydrolysed by addition of 20 mL water. The organic phase was separated, and the aqueous layer was extracted with three portions of 30 mL CH_2Cl_2. The combined organic phases were washed and neutralized with saturated NaCl solution and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

Synthesis of Compound 11a: Indene (4.6 mmol, 2.2 equiv. related to **10**) was dissolved in 40 mL THF and deprotonated by the dropwise addition of an equimolar amount *n*BuLi at 0°C. This solution was stirred for 10 min. Dibenzo-18-crown-6-ether (4.6 mmol) was ad-

ded. Stirring was continued for another 2 h at 20°C. The mixture was heated to 60°C and a solution of **10** (2.1 mmol) in 10 mL THF was added dropwise over a period of 5 min (After the first drops the reaction mixture turned a deep violet colour). The mixture was heated to reflux for another 5 h. After cooling to 20°C, it was hydrolysed by the addition of 20 mL water. The precipitated white substance (crown ether) was filtered off and washed twice with diethyl ether. The organic phase was separated, and the aqueous layer was extracted with three portions of 30 mL diethyl ether. The combined organic phases were washed and neutralized with saturated NaCl solution until neutral pH was obtained, and it was then dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

Synthesis of Compound 11b: Fluorene (5.6 mmol, 3 equiv. with respect to **10**) was dissolved in 40 mL THF and deprotonated by the dropwise addition of an equimolar amount *n*BuLi at 0°C. After stirring for 10 min, TMEDA (5.6 mmol) was added. Stirring was continued for another 2 h at 20°C. The mixture was heated to 60°C and a solution of 1.9 mmol **10** in 10 mL THF was added dropwise over a period of 5 min (after the first drops the reaction mixture adopted a deep violet colour). The mixture was then heated to reflux for 5 h. The mixture was hydrolysed by addition of 20 mL water. The organic phase was separated and the aqueous layer was extracted with three portions of 30 mL diethyl ether. The combined organic phases were washed and neutralized with saturated NaCl solution and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

General Procedure for the Synthesis of Compounds 12a and 12b: Indene (in the case of **12b**) or fluorene (in the case of **12a**) (30 mmol, 3 equiv. with respect to **2**), for the generation of the nucleophile, was dissolved in 40 mL THF and deprotonated by the dropwise addition of 30 mmol *n*BuLi at 0°C. Stirring was continued 2 h at 20°C. Compound **2c** (in case of **12b**) or **2a** (in case of **12a**) (10 mmol) was dissolved in 30 mL THF and deprotonated by the dropwise addition of 10 mmol *n*BuLi at 0°C. The solution was stirred at 20°C (**2c** 1 h, **2a** 2 h). To this solution the nucleophile was added dropwise. The reaction mixture was heated to reflux for 4 h. The mixture was hydrolysed by the addition of 20 mL water. The organic phase was separated, and the aqueous layer was extracted with three portions of 30 mL diethyl ether. The combined organic phases were washed and neutralized with saturated NaCl solution and dried with Na_2SO_4. The solvent was evaporated in vacuo and the residue was purified by column chromatography (eluent, R_f, and yield are given in Table 2).

X-ray Structure determinations: Suitable crystals were taken directly out of the mother liquor, immersed in perfluorinated polyether oil and fixed to a glass capillary at 200 K. The measurements for **2b**, **4a**, and **4b** were carried out on a Siemens P4 four-circle diffractometer (equipped with a low temperature unit) with graphite-monochromated Mo-K_α radiation. The measurements for **6b** and **12a** were carried out on a Nonius-Kappa CCD diffractometer (low temperature unit, graphite-monochromated Mo-K_α radiation). In case of the Siemens P4 four-circle diffractometer measurements, the intensities of three control reflections (measured every 100 reflections) remained constant throughout the data collection, thus indicating crystal and electronic stability. The data collected on a Siemens P4 four-circle diffractometer were corrected in the standard manner, including experimental absorption correction. The data from the Nonius Kappa CCD device were processed by standard Nonius software.[14] All Calculations were performed using the SHELXT-PLUS software package.[15] Structures were solved by direct methods with the SHELXS-97 program[15a] and refined with the SHELXL-97 program.[15b] Graphical handling of the structural data during solution and refinement was performed with XPMA.[16] Atomic coordinates and anisotropic thermal parameters of the non-hydrogen atoms were refined by full-matrix least-squares calculations. Data for the structure determinations are compiled in Table 3. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-124896 (**2b**), CCDC-124900 (**4a**), CCDC-124899 (**4b**), CCDC-124897 (**6b**), and CCDC-124898 (**12a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +44-(0)1223/336 033; E-mail: deposit@ccdc.cam.ac.uk].

An Inorganic Helix $[Mn(IPG)(MeOH)]_n[PF6]_n$[‡]: Structural and Magnetic Properties of a *syn-anti* Carboxylate-Bridged Manganese(II) Chain Involving a Tetradentate Ligand

Clotilde Policar,*[a] François Lambert,[a] Michèle Cesario,[b] and Irène Morgenstern-Badarau[a]

Keywords: Carboxylate *syn-anti* / *N*-centered tripodal ligand / Manganese / Imidazole / Helicoïdal inorganic chiral chain / Magnetism / π-π interaction

The crystal structure of an infinite inorganic chain consisting of Mn^{II} and an *N*-centered tripodal ligand *N*,*N*-(2-pyridylmethyl)[(1-methylimidazol-2-yl)-methyl]glycinate is presented. It exhibits a chiral helical structure with a pitch of two monomeric units (each monomeric unit containing one Mn atom). Each manganese is connected to its neighbor through a carboxylate bridge in a *syn-anti* geometry. Around each manganese center, two carboxylates bind in a *cis* geometry. This peculiar bridging geometry (*syn-anti cis*) provides a broken-line chain, running in a zig-zag manner along the *b* axis of the $P2_1$ space group. The magnetic properties have been investigated. They show a pseudo-2D magnetic structure, with one major pathway along the chain and an inter-chain minor one. The intrachain coupling is a weak antiferromagnetic interaction (J/k = –0.25). This low value is entirely consistent with the geometry of the bridge. The interchain coupling is a weaker antiferromagnetic coupling (J′/k = –0.11) and could be mediated through π-π interactions between pyridine and imidazole from two adjacent helixes.

Introduction

Carboxylate ligands play an important role in coordination chemistry. They are known to adopt binding modes as diverse as terminal monodentate, chelating to one metal center and bridging bidentate in a *syn-syn*, *syn-anti* or *anti-anti* configuration to two metal centers. The *syn-anti* bridge appears to be a rather uncommon binding mode.[1][2] In the past fifteen years, there has been a flow of interest in carboxylate complexes as models for metalloproteins. The carboxylate can be incorporated as an external ligand, usually as an acetate. However, in the metallic cores of metalloproteins, the carboxylato ligand is provided by the side chain of an aspartate or a glutamate making polydentate chelating ligands bearing a carboxylate and some other donor biologically relevant.[2][3] We have prepared several nitrogen-centered tripodal ligands with three appended moities, one being a carboxylate. Mononuclear iron complexes have previously been obtained and described with a monodentate carboxylate. They have been studied as models for nonheme enzymes.[4][5] Surprisingly, with one of these ligands, *N*,*N*-(2-pyridylmethyl)[(1-methylimidazol-2-yl)-methyl)]glycinate (IPG)[6] **(2)**, Mn^{II} forms infinite chains through carboxylato-bridges in a *syn-anti* geometry. Here, the results of structural and magnetic susceptibility studies on these Mn^{II} chains are described.

Results

Synthesis

Ligand Synthesis − A given tripod can be synthesized by several different methods depending on the order chosen for the introduction of the different moieties. Several strategies were investigated and we report here the higher yield one. In the synthesis of a nitrogen-centered tripod, the yield-limiting step is usually the tertiarization of the amine. Here, the first step is an *N*-alkylation of a primary amine to give a secondary amine which is easily purified by distillation. This compound then reacts quantitatively with an aldehyde by reductive amination. The overall yield is 70% (see Scheme 1). If the first two steps are switched, the overall yield drops to 35% due to the poor yield of the last step (less than 40%).

complex, the ligand was used as a mixture of the potassium salt and the free acid (**2K/2H** mixture) with a pH controlled ratio (see Experimental Section). Crystals suitable for an X-ray diffraction study were grown from a methanol solution.

Description of the Structure

An X-ray diffraction study was carried out on complex **3**. Experimental details are reported in the Experimental Section (Table 1). The crystal structure has been found to consist of a polymeric sequence of Mn^{II} cations, bridged by *syn-anti* carboxylato groups. The charge of the $[\{Mn^{II}IPG(MeOH)\}^{+}]_n$ chain is balanced by n (PF_6^-) anions. The polymeric chain extends along the *b* axis of the $P2_1$ chiral space group. An ORTEP representation of a succession of three monomeric units is shown in Figure 1. The three units are labeled 0 for the central one, corresponding to the crystallographic unit [*x, y, z*], −1 and +1 for the two adjacent ones along the chain, with the symmetry transformations [$-x$, $-0.5 + y$, $1 - z$] and [$-x$, $0.5 + y$, $1 - z$] respectively. Selected bond lengths and angles are presented in Table 2.

Mn^{II} is hexacoordinated with a pseudo-octahedral environment. Four of the donors are provided by the ligand **2**, through the imidazole nitrogen N1A, the pyridine nitrogen N1B, the tripodal nitrogen N and one carboxylato oxygen O2. The fifth donor is provided by the carboxylato oxygen O1 from the carboxylato of unit (−1). The final coordination site is filled by a molecule of methanol. The $Mn-N_{tripodal}$ distance [2.35(3) Å] is longer than the other Mn−N bonds, but shorter than the corresponding sum of the van der Waals radii (2.82 Å), indicating that the metal is hexacoordinated. The Mn−N1A distance [2.13(2) Å] is significantly shorter than the Mn−N1B distance [2.23(2) Å], suggesting a stronger bond with the imidazole ligand. Such small $Mn-N_{imidazole}$ distances were reported to be characteristic of bridged structures.[7] Imidazole and pyridine are in the trans positions with regard to Mn and the two aromatic rings are parallel to each other [$\Phi = 5(1)°$]. The Mn atom and the three oxygens O1, O2′ and O3 (see Figure 1) (carboxylate and methanol) are coplanar (mean

displacement 0.006 Å), the tripodal nitrogen N being located at 0.34(2) Å from this mean plane.

The carboxylates bridge two mononuclear units with a *syn-anti* pattern, forming an infinite chain. The manganese from unit 0 is slightly closer to the carboxylato oxygen O1 belonging to a ligand from the adjacent unit (−1) than to O2 [see Figure 1; 2.13(2) Å (Mn−O1) versus 2.18(2) Å (Mn−O2)]. O1 interacts with the manganese through its *syn* lone pair and O2 through its *anti* lone pair. All distances and angles (see Table 2) are consistent with those previously found in manganese *syn-anti* μ-carboxylato systems.[8−16] Although the H-atom of the coordinated methanol could not be located on difference Fourier-syntheses, it seems clear that a strong internal hydrogen bond occurs between the acceptor oxygen O2 of the carboxylate group and the oxygen donor of the methanol of the adjacent unit +1 [see Figure 1; d(O2−O3″) = 2.63(2) Å]. This hydrogen bond involves the *syn* lone pair of O2.

The two oxygens O1 and O2 are in a *cis* conformation with regard to Mn, with a (O1−Mn−O2) angle of 88.3(6)°. The chain develops in a zig-zag manner, with an (Mn_{-1}−Mn_0−Mn_{+1}) angle of 125.3° and a nonplanar Mn−O−C−O−Mn pattern. From unit −1 to unit 0, the plane of the two aromatic rings is tipped over by 64° (see Figure 2). The third unit along the chain can be deduced from the first one by translation (10.84 Å). The structure can be described as a chiral helix-like chain running parallel to the *b* axis and with a pitch of two complexes (see Figure 2). The Mn−Mn distance is 5.42 Å and is in the typical range which has previously been described for such *syn-anti* bridges between Mn^{II} [5.2−5.8 Å].[9−16]

The spatial arrangement of the complex **3** is displayed in Figure 3. The packing diagram reveals a layer organisation with entangled parallel helixes. A pyridine moiety from one helix is parallel to an imidazole from the next, with a small interplanar distance (3.8 Å). The closest distance between two Mn from two adjacent helixes is 8.42 Å.

Magnetic Properties

The results of susceptibility measurements are shown in Figure 4. At very low temperature, the experimental susceptibility is smaller than that predicted by a Curie law for S = 5/2 and g = 2 (see inset, dash line). This indicates some small antiferromagnetic coupling between two metallic centers in **3**. The magnetic properties of such a chain can be explained by the Heisenberg linear-chain model. The Hamiltonian used here is:

$$\boldsymbol{H} = -2J\sum_i \mathbf{S}_i \cdot \mathbf{S}_{i+1}$$

where the summation is all along the chain and J is the exchange coupling between two adjacent paramagnetic centers. An analytical law has been derived by Fisher for infinite chains and large spins.[17][18] For an infinite S = 5/2 chain, the expression of the chain molar magnetic susceptibility χ_c is:[19−21]

$$\chi_c = (35/32)*(1/T)*g^2(1+u)/(1-u)$$

$$\text{with } u = \coth[(35/32)*(1/T)*(J/k)]-[(2/35)*T*(k/J)]$$

Fitting the data to that expression provided an estimate of J (J/k = −0.27). However, the g value thus obtained was too small for a Mn^{II} high spin complex (g = 1.946, with an agreement factor for the fitting $R = 1.51 \times 10^{-4}$). The fitting was improved by taking into account interchain interactions via a mean-field.[18][22] The expression used to fit the data was:

$$\chi = \frac{\chi_c}{1-\frac{2zJ'\chi_c}{Ng^2\beta^2}} = \frac{\chi_c}{1-\frac{16}{3}\,z\,\frac{J'}{k}\,\chi_c}$$

where J′ is the interchain-exchange coupling and z the number of nearest neighbors. The best fit of Equation 2 in the temperature range 2−300 K was found for J/k = −0.25 (−0.17 cm^{-1}), zJ′/k = −0.11 (−0.078 cm^{-1}) and g = 1.970 with an agreement factor $R = 2.17 \times 10^{-5}$. All three parameters were allowed to vary during the fitting process. As can be seen in Figure 4, the experimental points and theoretical curve are superimposed in all the temperature range. The J and J′ values obtained are very small and thus the precision on their absolute value must be rather low. Moreover the ratio zJ′/J = 0.4 is at the high limit for the mean-field model to be valid.[22−24] This increases the uncertainty on J′ although the order of magnitude both for J and J′ is still meaningful.

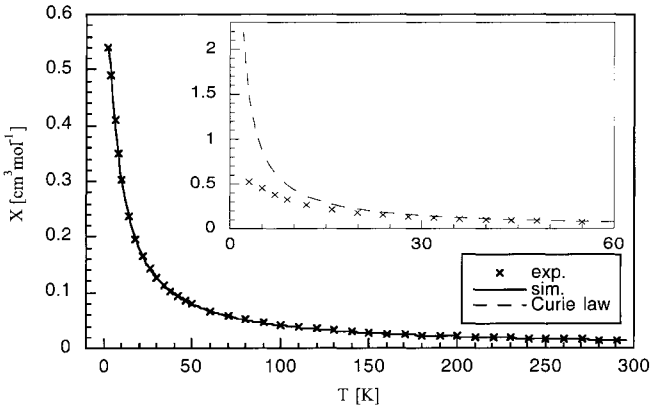

Figure 4. Experimental and calculated temperature dependences of χT; for clarity only 50% of the experimental points are shown; the dashed line was generated with a Curie law for S = 5/2 and g = 2 (see text); the solid line is the best fit obtained including the mean-field correction (see text for parameters)

Discussion

A *syn-anti* bridging configuration is rare by comparison with a *syn-syn* configuration.[2] The former is made easier by steric congestion[25][26] and is more frequently found when the carboxylate is part of a polydentate ligand[27−30] or a substituted acetate,[13,15,16,25] including amino acids.[14][31] It has been reported for discrete complexes,[15] polymeric chains and networks with manganese.[9−14,16,31]

The main structural feature of compound **3** is the chiral helix-like structure with a nonlinear bridging network. This is due both to the *syn-anti* bridging mode of the carboxylato ligand and to the *cis* position of the two oxygens O1 and O2 in the octahedron around Mn. IR spectroscopic data are consistent with a bridging carboxylate and not a unidentate one: the small value of $\Delta\nu = (\nu_{asCO}) - (\nu_{sCO}) = 131 cm^{-1}$ is characteristic of a bridging carboxylate.[1] Another important feature is the layer organisation. In the crystal packing, the chains are stacked by π-interactions with an interplanar spacing of 3.8 Å between the pyridine from one helix and the imidazole from the next.

Very little is known about the magnetic properties of such carboxylato *syn-anti* manganese chains. On the contrary, the magnetic properties of manganese chains involving halogen bridges have been extensively described and are classical examples of linear chain compounds (see Table 3).[19−21,32] The carboxylato *syn-anti* bridge has received some attention because it allows a large variety of structural and magnetic features.[23,29,33] Without being exhaustive, the magnetic behavior has been studied for *syn-anti* carboxylato bridges in chain structures involving homonuclear[23,28,29,33−35] Cu^{II}, heterodinuclear[36] Mn^{II} and Cu^{II} or in discrete complexes[27] (Fe^{III}). The magnetic properties have also been studied for a 2D-polymer with a *syn-anti* carboxylato network[16] between Mn^{II}, and on a discrete Mn^{II} homodimer involving a mono *syn-anti* carboxylato bridge (see Table 3).[15]

The intrachain coupling constant in compound **3** is at least one order of magnitude smaller than that reported for halogenated Mn^{II} chains (see Table 3). The exchange coupling through the carboxylato moiety is highly dependent on the conformation of the bridge between the metal centers that are interacting.[18,34,37] A *syn-syn* pattern provides small metal−metal distances and a good overlap of magnetic orbitals. It induces high antiferromagnetic coupling, as has previously been reported in $Cu_2(CH_3COO)4{\cdot}2H2O$ where the four acetates are in a *syn-syn* configuration with J = −150 cm^{-1}.[38][39] *Syn-anti* carboxylato bridges induce much smaller J values because of the expanded metallic core and a mismatch in the orientation of magnetic orbitals.[23,29,34,36] For compound **3**, the Mn−Mn intrachain distance is 5.42 Å, which is rather large. Moreover, the bridging network displays a "zig-zag" structure (see description of the structure). To the best of our knowledge, there are considerably fewer examples involving two carboxylato *syn-anti* ligands in a *cis* position than in a *trans* position. The four closest structures, studied from a magnetic point of view, found in the literature are: (a)[29] and

Table 3. Antiferromagnetic couplings for several Mn^{II} compounds (including chains, one 2D-polymer and one dimer) and related Mn−Mn distances

3	5.42	Carboxylato *syn-anti*	−0.25	this work

[a] 5-NO_2-salimH = 4-(2-[(5-nitrosalicylidene)amino)ethyl]imidazole. − [b] MCPA = 2-methyl-4-chlorophenoxyacetic acid. − [c] For chains, intrachain distance; for polymer, closest distance.

(b)[40][41] two copper(II) chains, (c) a copper tetranuclear cluster[28] and (d) a copper(II) ladder-like chain of dimer units with a di-μ-carboxylato.[35] Both (a) and (b) show a helix-like structure that bears a great number of structural similarities with compound **3** with a ferromagnetic coupling J/k = 2.4 and J/k = 4.0, respectively. Compound (c) also displays a ferromagnetic coupling J/k = 3.8. In compound (d), a very small antiferromagnetic coupling was estimated at −0.7 K.

The importance of the *syn-anti* conformation on the magnitude of J has previously been stressed for copper(II) compounds.[28−30] It can also be illustrated for compound **3** by some relevant comparisons. First, two structures with *syn-anti* carboxylato bridges between Mn^{II} have previously been reported and studied from a magnetic point of view: (e) a 2D-polymer[16] containing a *syn-anti* carboxylato lozenge-shaped network between Mn^{II} and (f) a discrete Mn^{II} dimer involving a mono *syn-anti* carboxylato bridge.[15] In (e), the Mn−Mn distance is 5.40 Å and an antiferromagnetic coupling J/k of −0.3 to −0.4 was estimated. In (f), the intermetallic distance is 5.67 Å with an antiferromagnetic coupling J/k = −0.27. These exchange coupling constants are of the same order and are very close to that obtained for compound **3**.[42] Another comparison can be made with a Mn^{II} chain with a dipodal *N*-centered ligand bearing one imidazole and one phenolate involving a formate bridge in a *anti-anti cis* binding mode (see Table 3).[7] The Mn−Mn distance along the chain is 5.92 Å and J/k = −0.36. Despite a larger distance, the antiferromagnetic coupling is greater than in compounds **3** and (f).[43] Presumably this is related to the *anti-anti* pattern inducing better orbital overlap.[30] The geometric characteristics of **3** (*syn-anti* carboxylato bridges, "zig-zag" structure with nonplanar Mn−O−C−O−Mn pattern) account for the very low value determined for the intrachain coupling constant (J/k = −0.25).

The value of the ratio zJ′/J = 0.4 suggests a pseudo-2D magnetic structure. The shortest Mn−Mn interchain distance is 8.42 Å, each Mn having two closest neighbors (z = 2). Two adjacent helixes seem to be connected through π-π interactions between a pyridine moiety and the imidazole group (see Figure 3). Despite the large Mn−Mn interchain distance (8.42 Å), a π-π interaction provides an effective pathway for interchain exchange interaction.

Conclusions

In this article, we have reported the structure and magnetic study of a polymeric Mn^{II} compound involving carboxylato *syn-anti cis* bridges. The compound described here is of interest for several reasons. First, it involves a carboxylato bridge that is part of a polydentate ligand and not a separate acetate. This carboxylate has been shown to be coordinated to the Mn^{II} centers in a *syn-anti* mode, affording a chiral helix-like polymeric structure. It also displays a pseudo-2D magnetic structure with a weak exchange interaction through intrachain *syn-anti cis* carboxylato bridges and a weaker interaction through interchain π-interactions. Finally, it presents a potentially open-shell. The ligand **2** is tetradentate. In the solid state, the coordination sphere of each Mn^{II} center of compound **3** is completed by a molecule of methanol and an oxygen atom (O1) from a carboxylato group from a neighboring molecule of **2**. Compound **3** is soluble in several solvents, indicating a disrupture of the polymeric structure. This probably occurs by the replacement of O1 by a further solvent molecule,[7][44] thus keeping the usual octahedral environment of Mn^{II} complexes. In solution, this compound thus bears two labile coordination sites available for substrate binding. Its reactivity towards superoxide is now under investigation.

Experimental Section

General: IR spectra (KBr) were recorded on a Bruker IFS 66 FT-IR spectrometer. ^1H NMR spectra were recorded on Brüker AM 200 and AM 250 spectrometers. X-band electron paramagnetic resonance (EPR) was recorded on a Bruker ER 200E spectrometer. Variable temperature magnetization measurements were collected on ground crystals with a Quantum Design SQUID magnetometer at a magnetic field of 1 T within the temperature range 300−2 K. Data were corrected for diamagnetism of the ligand estimated to -2.431500×10^{-4} $cm^3 \cdot mol^{-1}$ from Pascal's constant.[48] Chemical reagents were purchased either from Aldrich or Acros and used without further purification.

Synthesis and Characterization

***N*-(2-pyridylmethyl)aminoethyl acetate (1):** To a solution of 2-aminomethylpyridine (18.38 g) in 100 mL of anhydrous THF at 0°C, ethylbromoacetate (14.19 g) in 100 mL of anhydrous THF was ad-

ded dropwise. The reaction mixture was left for 30 min. at 0°C and then allowed to warm to room temperature. After 15 h, the solution was filtered and the filtrate evaporated to dryness. The residual oil was distilled under reduced pressure (0.4 Torr, 100°C), to give a colorless liquid. Yield: 75%. − ^{1}H NMR ($CDCl_3$): δ = 1.28 (t, 3 H, CH_3), 2.81 (s, 1 H, NH), 3.48 (s, 2 H, N−CH_2−COOEt), 3.96 (s, 2 H, py−CH_2−N), 4.20 (q, 2 H, O−CH_2), 7.17 (t, 1 H, H_{py}), 7.33 (d, 1 H, H_{py}), 7.64 (t, 1 H, H_{py}), 8.56 (d, 1 H, H_{py}).

Potassium *N*,*N*-[2-pyridylmethyl)(1-methylimidazol-2-yl)-methyl]-glycinate (2K): A solution of **1** (3.88 g) and *N*-methyl-2-imidazolcarboxaldehyde[45] (2.2 g) in MeOH (100 mL) was hydrogenated over (Pd/C, 10%) for 24 h. After filtration and evaporation to dryness, **2K** was obtained by hydrolysis at room temperature in H_2O/EtOH (3:1) with K_2CO_3 (2.2 equiv.) for 48 h. Residual potassium salts were partially removed by extracting the carboxylate **2K** with anhydrous MeOH. Compound **2K** was recrystallized from MeOH/EtOEt. Yield: 95%. − ^{1}H NMR (CD_3OD): δ = 2.95 (s, 2 H, N−CH_2COOK), 3.30 (s, 3 H, CH_3), 3.52 and 3.57 (2s, 2 × 2 H, N−CH_2−py and N−CH_2−Im), 6.54 and 6.64 (2s, 2 × 1 H, H_{Im}), 7.03 (t, 1 H, H_{py}), 7.14 (d, 1 H, H_{py}), 7.52 (t, 1 H, H_{py}), 8.15 (d, 1 H, H_{py}). − IR (KBr): $\tilde{\nu}$ = 1591 (ν_{asCO}), 1396 (ν_{sCO}), 771 ($\nu_{pyr.\ deform.}$), 742 ($\nu_{imid.\ deform.}$) cm^{-1} (strong bands only).

[Mn(IPG)(MeOH)]$_n$(PF$_6$)$_n$ (3): The pH of a 2 × 10^{-3} M solution of **2K** in water was adjusted by HCl addition in the 8−8.5 range. After evaporation, the solid was dried under reduced pressure for one night in the presence of P_2O_5 and KCl was removed by extraction of the ligand in anhydrous methanol. Typically, chain crystals were obtained as followed. $MnBr_2$ (330 mg) in deoxygenated MeOH (20 mL) was added to a solution of the ligand (400 mg) in deoxygenated MeOH (20 mL). It was allowed to stand for two hours at 40°C. Then, after cooling, a deoxygenated solution of NH_4PF_6 (3 equivalents) in MeOH (40 mL) was added dropwise. The solution was allowed to stand for a week during which time crystals were formed. Yield: 50%. − $C_{14}H_{19}F_6MnN_4O_3P$ (491.2): calcd C 34.2, H 3.9, N 11.4, P 6.3, Mn 11.2; found C 33.9, H 3.8, N 11.3, P 5.9, Mn 10.6. − IR (KBr): $\tilde{\nu}$ = 1606 (sh), 1571 (ν_{asCO}), 1440 (ν_{sCO}), 770 ($\nu_{pyr.\ deform.}$) 755 ($\nu_{imid.\ deform.}$) cm^{-1} (strong bands only). − The EPR spectrum was recorded on ground crystals at room temperature and 100 K. It shows a broad signal centered at g = 1.98, with no resolved hyperfine structure.

All measurements were performed with crystals or ground crystals from the same batch of crystallization.

Crystal Data, Data Collection and Refinement

Several crystals were tested for their suitability for X-ray diffraction studies. Most of them were twinned. A very thin fragment was found to be a single crystal. This pale yellow-pink crystal of 0.2 × 0.15 × 0.07 mm was mounted on an Enraf−Nonius Cad 4 diffractometer with graphite monochromated Mo-K_α radiation [λ = 0.7107Å]. The unit cell dimensions were refined from setting angles of 25 reflections [5.2 < Θ <11.6°]. Structure determination and refinement data are reported in Table 1. Data collection was performed at room temperature with Θ−2Θ scan technique mode, in the 2Θ range from 4 to 32°. Three standard reflections were measured every hour, to monitor instrument and crystal stability. A 28% decay was observed. A total of 568 reflections was collected [$-6 \le h \le 6$; $0 \le k \le 7$; $0 \le l \le 9$]. From 531 independent reflections, 509 were used [$I > 2\sigma(I)$]. These data were corrected for Lorentz and polarization factors but not for absorption factors.

The structure was solved by direct methods (program SHELXS86)[46] and refined on F^2 for all reflections by least-squares method using SHELXL-93.[47] Hydrogen atoms were calculated and included in the refinement at their ideal positions (C−H_{ar} = 0.93Å, C−H_{Me} = 0.96Å) with an isotropic thermal parameter of 1.2 for the bonded atoms. Only the manganese atom was refined anisotropically to limit the number of parameters versus the number of data.

The asymmetric unit consists of one monomeric complex cation and one counteranion (PF_6). The latter shows disorder; two different sites were found on a difference Fourier-syntheses. A better convergence was obtained with an occupancy factor of 50% and refinement was pursued with restraints. A selection of bond lengths and angles is presented in Table 2 and the crystallographic number scheme is presented in Figure 1 which shows three adjacent units along the axis *b*.

Crystallographic data (excluding structure factors) for the structure included in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-125980. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

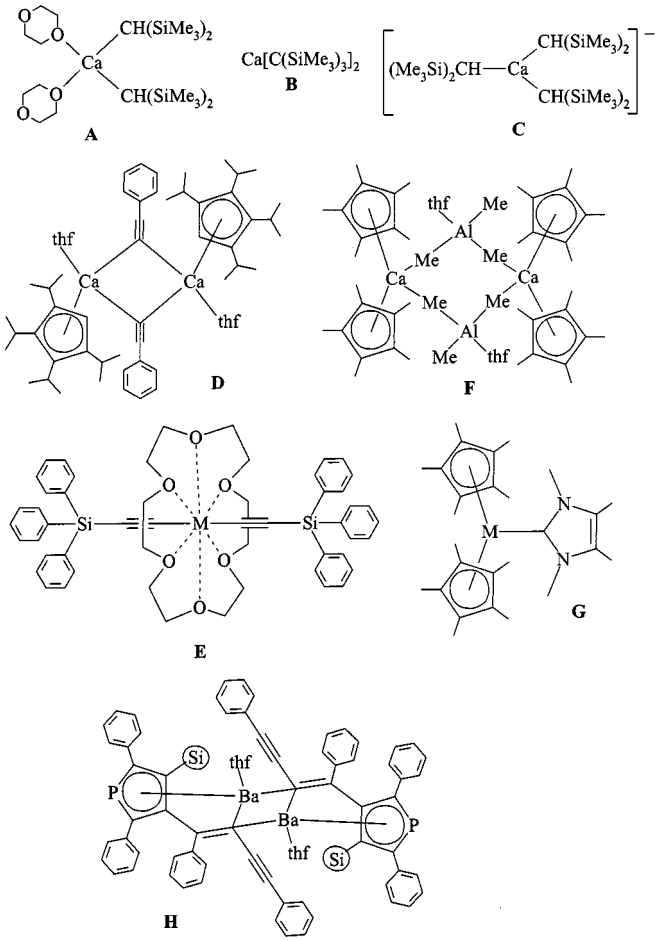
Formation of Calcium–Carbon Bonds From a Lewis Acid-Base Reaction of Calcium Bis[bis(trimethylsilyl)amide] and Tris(trimethylsilylmethyl)alane



Matthias Westerhausen,*[a] Christin Birg,[a] Heinrich Nöth,[a][+] Jörg Knizek,[a][+] and Thomas Seifert[a][+]

Keywords: Aluminium / Amides / Calcium / Metallacycles / Phosphorus

Treatment of calcium bis[bis(trimethylsilyl)amide] with two equivalents of tris(trimethylsilylmethyl)alane yields $(Me_3SiCH_2)_2Al–N(SiMe_3)_2$ (**1**) and the dimer $[(Me_3Si)_2N–Ca(\mu–CH_2SiMe_3)_2Al(CH_2SiMe_3)2]_2$ (**2**). The five-coordinate bridging carbon atoms show Ca–C bond lengths of 264 and 268 pm. A similar reaction with calcium bis[bis(trimethylsilyl)phosphanide] gives the dimer $[(Me_3SiCH_2)_2Al–P(SiMe_3)_2]_2$ (**3**) with crystallographic *C*2 symmetry. A calcium-containing species is not isolable, however, in the presence of DME – ether cleavage reactions and the formation of the centrosymmetric dimer $[(Me_3SiCH_2)_2Al–OCH_2CH_2OMe]_2$ (**4**) are observed. The central moiety is an Al_2O_2 cycle with fivefold coordinated aluminium centers.

Introduction

In contrast to the well-developed chemistry of organo lithium compounds and the widely used Grignard reagents, only a few examples of compounds with σ-bonds between carbon and the heavier alkaline earth metals have been structurally characterized (Scheme 1). Several years ago Lappert and co-workers[1] reported the bis(1,4-dioxane) complex of bis[bis(trimethylsilyl)methyl] calcium **(A)** with Ca−C bond lengths of 248 pm. Solvent-free bis[tris(trimethylsilyl)methyl] calcium **(B)** crystallizes with a bent C−Ca−C moiety of 150° and Ca−C distances of 246 pm.[2] Compound **A** was prepared by a co-condensation reaction of calcium and bis(trimethylsilyl)methyl bromide. The metathesis reaction of $KC(SiMe_3)_3$ and calcium diiodide gave compound **B**. The reaction of alkaline earth metal arenesulfonates with bis(trimethylsilyl)methyl lithium or potassium yields alkali metal [tris(alkyl)alkaline earth metalates] **C**.[3] The metalation reaction is only applicable to organic substrates with acidic hydrogen atoms such as phenylacetylene as shown by Burkey and Hanusa[4] for the synthesis of $[(\eta^5\text{-}i\text{Pr}_4C_5H)Ca–C\equiv C–Ph]_2$ **(D)**. The crown ether complexes of the heavier alkaline earth metal bis(triphenylsilylacetylides) **E** display bent M−C≡C fragments.[5] The tetrahydrofuran complex of trimethylaluminium, which can act as a bridging ligand between the metal centers of decamethylcalcocene **F**, shows very long Ca−C distances of 295 and 300 pm.[6] Recently, the structures of the carbene complexes **G** were published by Arduengo and co-workers.[7] The dimeric barium compound **H** contains a central planar Ba_2C_2 cycle with Ba−C bond lengths of 288 and 307 pm.[8] In contrast to these rare examples of M−C σ-bonds numerous alkaline earth metallocenes have been reported.[9]

Scheme 1. Well-characterized molecules with alkaline earth metal−carbon σ-bonds (M = Ca, Sr, Ba); alkaline earth metallocenes and similar compounds are not considered

The reaction of trialkylalanes with alkaline earth metal bis(amides)[10] and bis(phosphanides)[10] seems to be an-

other promising access to alkaline earth metal−carbon bonds. Magnesium bis(dialkylamide) reacts with trialkylaluminium to give the heteroleptic, dimeric alkylmagnesium dialkylamide and a dialkylamino dialkylalane.[11] Herein we report the results of the Lewis acid-base reaction between $Ca[E(SiMe_3)_2]_2$ (E = N, P) and tris(trimethylsilylmethyl)alane.

Results and Discussion

Synthesis

The addition reaction of tris(trimethylsilylmethyl)alane[12] and solvent-free calcium bis[bis(trimethylsilyl)amide][13] in a 2:1 molar ratio in toluene leads to a Lewis acid-base complex, although this compound could not be isolated. According to Equation 1 the elimination of bis(trimethylsilylmethyl)aluminium-bis(trimethylsilyl)amide **(1)** occurs spontaneously. Compound **1** can be removed from the reaction mixture in vacuo at elevated temperatures. Cooling of the concentrated reaction solution leads to the precipitation of crystalline dimeric calcium bis(trimethylsilyl)amide-tetrakis(trimethylsilylmethyl)aluminate **(2)**. The steric shielding of the central Ca_2N_2 cycle prevents another Lewis acid-base reaction even with a large excess of tris(trimethylsilylmethyl)alane in the reaction mixture. To allow the spectroscopic characterization of analytically pure compound **1** the metathesis reaction was performed with $[(Me_3SiCH_2)_2AlCl]_2$[14] and two equivalents of lithium bis(trimethylsilyl)amide according to Equation 2. The NMR spectra show three chemically different trimethylsilyl groups, which could be due to dimerization of **1**. However, in the mass spectrum the molecular ion of the monomer is the highest peak.

Equation 1. Synthesis of calcium aluminate **2**

$$(RCH_2)_2Al(\mu\text{-}Cl)_2Al(CH_2R)_2 + 2\ LiNR_2 \rightarrow 2\ (RCH_2)_2AlNR_2 + 2\ LiCl$$

R = $SiMe_3$ **1**

Equation 2. Synthesis of bis(trimethylsilylmethyl)aluminium bis(trimethylsilyl)amide **1**

Thus far, the use of calcium bis[bis(trimethylsilyl)phosphanide][10][15] as a synthon for the preparation of calcium−carbon bonds has failed. Solvent-free $Ca[P(SiMe_3)_2]_2$ is insoluble in aromatic and aliphatic hydrocarbons. The addition of $Al(CH_2SiMe_3)_3$ to a suspension of this calcium bis(phosphanide) in toluene leads to a clear solution. A $^{31}P\{^1H\}$ NMR spectroscopic investigation of the reaction reveals the formation of $[(Me_3SiCH_2)_2Al-P(SiMe_3)_2]_2$ **(3)**.[16] Nonetheless, an aluminate or a trimethylsilylmethyl calcium moiety could not be isolated. Compound **3** crystallizes from toluene and has a melting point of 218°C, approximately 20°C higher than reported by Wells and coworkers.[16] The spectroscopic data are consistent with a dimeric molecule of **3**. Performing this Lewis acid-base reaction in the presence of ethers such as tetrahydrofuran (THF) or 1,2-dimethoxyethane (DME) as solvents leads to an ether cleavage reaction. With DME, $[(Me_3SiCH_2)_2Al-OCH_2CH_2OMe]_2$ **(4)** with a central Al_2O_2 cycle was formed as one of the reaction products, although the isolation of an analytically pure product was not possible. The use of ether complexes and ether solutions seems to limit these Lewis acid-base reactions as a suitable pathway to calcium−carbon σ-bonds. The reactivity of alanes towards ethers has already been reported by Uhl[17] and Roesky.[18] Similar ether cleavage reactions have also been observed for bis[tris(trimethylsilyl)methyl] calcium **(B)**.[2] Treatment of **3** with DME also gives such reactions. Besides compound **4**, some unidentified substances were detected, although purification failed due to co-crystallization with side products.

Spectroscopic Characterization

The aluminate anion of **2** shows simple NMR spectra consistent with a free rotation. Even at temperatures of −70°C it is not possible to halt the exchange process of the bridging and terminal trimethylsilylmethyl substituents. The negative charge leads to a high-field shift of the CH_2 group relative to compounds **1** and **3**. The $^{29}Si\{^1H\}$ NMR chemical shift (δ = −8.47) of the bis(trimethylsilyl)amido ligand bridging the calcium atoms clearly proves that this complex remains dimeric in toluene solution. One would expect a value of approximately δ = −15 for terminally bonded $(Me_3Si)_2N$ substituents[10][13] whereas a low-field shift of 6 to 8 ppm is characteristic of a bridging ligand with a quadruply coordinated nitrogen atom at calcium.

Molecular Structures

Compound **2** crystallizes in the monoclinic space group $P2_1/n$. Figure 1 shows the molecular structure and the numbering scheme. The bonding situation of the bridging tri-

methylsilylmethyl group with the freely refined hydrogen atoms is depicted in Figure 2. The central, planar Ca_2N_2 cycle with Ca1−N1 and Ca1−N1′ bond lengths of 240.7(2) and 248.7(2) pm, respectively, is slightly distorted although the values lie within the expected range.[10][13] The Ca1−C1 and Ca1−C2 distances [267.8(3) and 263.8(3) pm] are approximately 20 pm longer than in the above mentioned dialkyl calcium derivatives **A**[1] und **B**.[2] Similar values were obtained by Hanusa and co-workers[19] for bis[1,3-bis(trimethylsilyl)allyl]calcium. The bridging Me_3SiCH_2 substituents of **2** also show longer Al1−C distances [206.9(3) and 208.1(3) pm] compared to the terminal Al1−C3 and Al1−C4 bond lengths [198.9(3) and 199.7(3) pm]. The values for the terminal Al−C distances are in agreement with those in Al_2Me_6 [196(1) and 198(1) pm[20]] and are larger than in Al_2Ph_6 [195.6(5) and 196.0(5) pm[21]] as well as in Al2^{i}Pr6 [mean value 193(1) pm].[22] The rather large Ca−C distances and the short Al−C bonds to the bridging Me_3SiCH_2 groups in **2** compared to Al_2Me_6 [213(1) and 215(1) pm[20]] and Al_2Ph_6 [218.0(5) and 218.4(5) pm[21]] are a consequence of the distorted trigonal bipyramid coordination polyhedron of C1 and C2. The aluminium atom is located in the equatorial plane whereas the calcium atom is in an axial position. The other axial bonded group is the trimethylsilyl substituent. Therefore, the C1−Si1 and C2−Si2 bond lengths (mean value 189.6 pm) are elongated compared to C3−Si3 and C4−Si4 (mean value 185.2 pm).

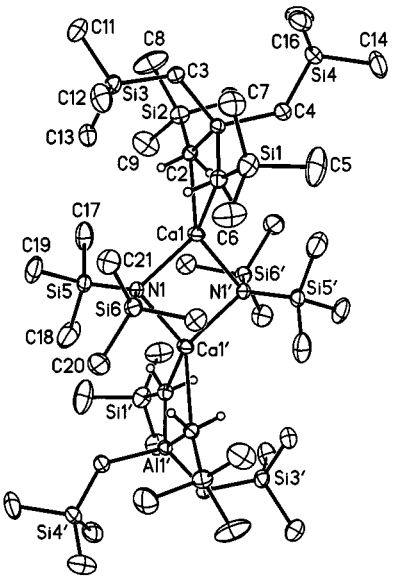

Figure 1. Molecular structure and numbering scheme of **2**; the ellipsoids represent a probability of 40%; hydrogen atoms with the exception of those at C1 and C2 are omitted for clarity reasons; symmetry-related atoms ($-x + 2, -y, -z$) are marked with an apostrophe; selected bond lengths (pm) and angles (°): Ca1−N1 240.7(2), Ca1−N1′ 248.7(2), Ca1−C1 267.8(3), Ca1−C2 263.8(3), Al1−C1 206.9(3), Al1−C2 208.1(3), Al1−C3 198.9(3), Al1−C4 199.7(3), C1−Si1 190.1(3), C2−Si2 189.2(3), C3−Si3 185.3(3), C4−Si4 185.0(3), N1−Si5 175.3(2), N1−Si6 174.1(2); N1−Ca1−N1′ 90.88(7), Ca1−C1−Al1 85.5(1), Ca1−C1−Si1 153.3(2), Al1−C1−Si1 117.8(2), Ca1−C2−Al1 86.3(1), Ca1−C2−Si2 154.2(1), Al1−C2−Si2 119.1(1), Al1−C3−Si3 123.6(2), Al1−C4−Si4 127.0(2)

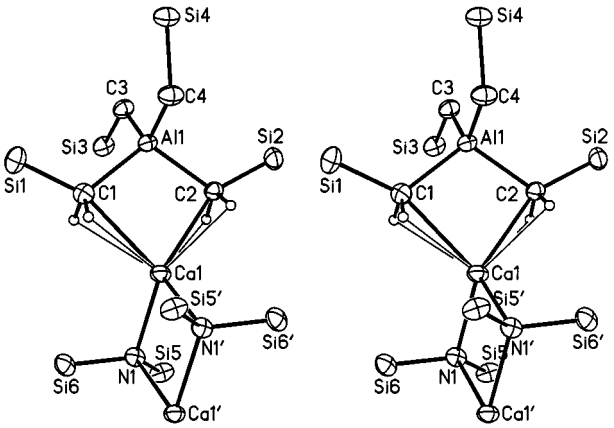

Figure 2. Stereoscopic representation of the coordination sphere at Ca1 of compound **2**; selected H-atoms are drawn with arbitrary radii, whereas all non-hydrogen atoms are represented on a 40% probability level; symmetry-related atoms ($-x + 2, -y, -z$) are marked with an apostrophe; the Ca−H interactions are represented by thin lines

The close contact Ca1···Al1 of 325.38(9) pm as well as the small bond angles Ca1−C1−Al1 and Ca1−C2−Al1 of 85.5(1)° and 86.3(1)°, respectively, can be described as two electron-three center bonds. On the other hand, an ionic arrangement with the calcium dication bonding to the C1−H as well as C2−H bonds (agostic interactions) could also explain the geometry of these bridging methylene fragments. As a consequence of these attractions small Ca1−C−H angles of between 57(2)° and 74(2)° as well as short Ca1···H contacts of between 232(3) and 258(3) pm are observed.

Figure 3 shows the molecular structure of **3**. Wells and co-workers[16] previously deduced the dimeric nature of **3** from NMR spectroscopic data. The Al1−P1 bond length of 248.0(1) pm is shorter than the Al−P distance of the adduct $(Me_3SiCH_2)_3Al-P(SiMe_3)_3$ [268.1(4) pm[16]] but in the same range as for $(Me_3SiCH_2)_2Al(Br)-P(SiMe_3)_3$ [249.8(7) pm[16]] and in the dimer $[(Me_3SiCH_2)Al(Br)-P(SiMe_3)_2]_2$ [243.6(2) pm[16]] with four-coordinate aluminium and phosphorus atoms. In comparison with the dimer with ethyl groups at the aluminium atom, the endocyclic bond lengths in **3** are elongated and a slight distortion is observed {$[Et_2Al-P(SiMe_3)_2]_2$: P−Al 246.0(1) and 245.4(1) pm, Al−P−Si: 114.21(5) and 114.46(5)°;[23] **3**: P−Al 248.0(1) and 248.6(1) pm, Al−P−Si: 112.07(4) and 115.93(5)°}.

The molecular structure of compound **4** is represented in Figure 4. The aluminium centers exhibit a trigonal bipyramidal geometry with the atoms O1′ and O2 in apical positions. Ring strain leads to a bent O1′−Al1−O2 geometry of 150.73(4)°. Due to the anionic charge on O1 (alcoholate oxygen), the Al1−O1 distance is smaller than the Al1−O2 distance [226.8(1) pm]. In agreement with the Gillespie−Nyholm rules the apical Al1−O1′ bond [190.3(1) pm] is slightly lengthened relative to the equatorial Al1−O1 bond [184.6(1) pm]. The Al−O distances lie in the range of known alkyl-substituted aluminium alkoxides obtained from ether cleavage reactions. There are a few reports of

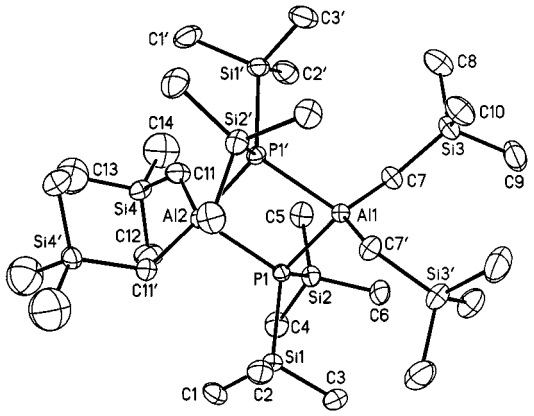

Figure 3. Molecular structure and numbering scheme of **3**: the ellipsoids are drawn at a 40% probability level and the hydrogen atoms omitted for clarity. Symmetry-related atoms ($-x$, y, $-z$ + 0.5) are marked with an apostrophe; selected bond lengths (pm) and angles (°): P1−Al1 248.0(1), P1−Al2 248.6(1), P1−Si1 226.7(1), P1−Si2 226.8(1), Al1−C7 196.9(4), Al2−C11 196.3(4), C7−Si3 186.8(3), C11−Si4 183.6(3); Al1−P1−Al2 91.48(4), Si1−P1−Si2 104.55(5), C7−Al1−C7′ 119.6(2), C11−Al2−C11′ 121.9(2)

the cleavage of DME[17] and THF[18] during reduction of trimethylsilyl-substituted alkyl aluminium halides and the formation of the corresponding alkyl aluminium alcoholates. The Al1−C1 and Al1−C5 distances of 198.3(1) and 196.9(1) pm in **4** are similar to the values observed for **2**.

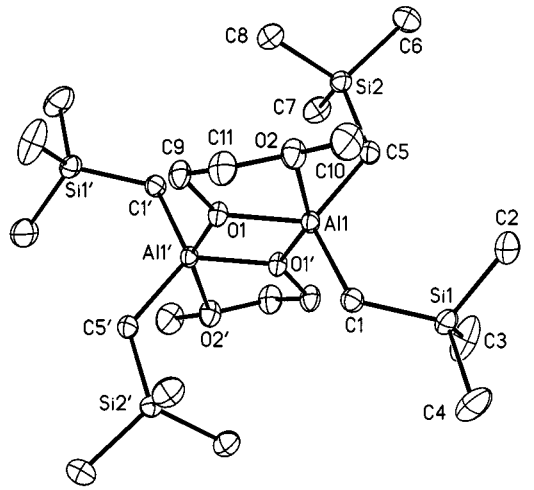

Figure 4. Molecular structure and numbering scheme of **4**; the ellipsoids represent a probability of 40%; the hydrogen atoms are omitted for clarity; symmetry-related atoms ($-x$ + 1, $-y$, -$-z$) are marked with an apostrophe; selected bond lengths (pm) and angles (°): Al1−O1 184.6(1), Al1−O1′ 190.3(1), Al1−O2 226.8(1), Al1−C1 198.3(1), Al1−C5 196.9(1); O1−Al1−O1′ 75.68(5), O1−Al1−O2 75.32(4), O1−Al1−C1 115.19(5), O1−Al1−C5 124.72(5), O1′−Al1−O2 150.73(4), O1′−Al1−C1 103.20(6), O1′−Al1−C5 103.69(6), O2−Al1−C1 92.59(6), O2−Al1−C5 89.67(6), C1−Al1−C5 118.43(6)

Conclusion

These experiments show that ether has to be excluded during the Lewis acid-base reactions of calcium bis(amides) and bis(phosphanides) with alanes. Furthermore, only calcium bis[bis(trimethylsilyl)amide] seems to be a valuable synthon for the strategy presented here because the heavier homologous phosphanides are insoluble in common organic solvents in the absence of ether. Thus far it has not been possible to eliminate another molecule of **1** from heteroleptic **2** to obtain bis(trimethylsilylmethyl)calcium

Experimental Section

General Remarks: All experiments and manipulations were carried out under argon or nitrogen purified by passage through BTS catalyst and P_4O_{10}. Reactions were performed with standard Schlenk techniques. All solvents were dried and thoroughly deoxygenated prior to use. The starting materials $Ca[N(SiMe_3)_2]_2$,[13] $(THF)_2Ca[P(SiMe_3)_2]_2$,[15] $ClAl(CH_2SiMe_3)_2$[14] and $Al(CH_2SiMe_3)_3$[12] were prepared according to literature procedures. NMR spectra were recorded on Jeol GSX270 and EX400 spectrometers. A Perkin−Elmer Paragon 1000 PC spectrophotometer was used to record the IR spectra; solid compounds were examined as Nujol mulls between CsBr plates (vs very strong, s strong, m medium strong, w weak, vw very weak, sh shoulder). The frequencies in the region of the Nujol vibrations are not listed. The low carbon values in the elemental analysis originate from carbide and carbonate formation during combustion of the compounds.

Bis(trimethylsilylmethyl)aluminium-bis(trimethylsilyl)amide (1). − Method 1: $Al(CH_2SiMe_3)_3$ (2.1 g; 8.96 mmol) was dropped slowly at 0°C into a solution of calcium bis[bis(trimethylsilyl)amide] dimer (1.62 g, 2.24 mmol) in 25 mL of toluene. After complete addition, the solution was heated under reflux for five hours. Vacuum distillation yielded pyrophoric **1** (1.1 g, 1.52 mmol, 68%). The residue consisted mainly of compound **2**.

Method 2: At room temp. $ClAl(CH_2SiMe_3)_2$ (1.15 g, 4.87 mmol) was added to a solution of lithium bis(trimethylsilyl)amide (0.82 g, 4.88 mmol) dissolved in 12 mL of toluene. Colorless LiCl precipitated immediately. After heating for four hours at approximately 100°C the NMR spectra showed a quantitative reaction. After removal of the solid materials vacuum distillation gave **1** (2.64 g, 3.65 mmol, 75%), b.p. 86°C/0.15 Torr. − ^{1}H NMR ([D$_8$]toluene): δ = −0.51 (broad) and −0.45 [CH_2], 0.11 [$CSiMe_3$], 0.13 and 0.18 [$NSiMe_3$]. − ^{13}C NMR ([D$_8$]toluene): δ = 2.40 [$NSiMe_3$, ^1J(H−C) = 117.8 Hz]. − ^{29}Si{^{1}H} NMR ([D$_8$]toluene): δ = −0.24 and −2.50, 0.11. − IR: $\tilde{\nu}$ = 2953 vs, 2901 m, 1647 vw, 1616 vw, 1587 vw, 1436 w, 1408 w, 1346 vw, 1250 vs, 1182 m, 1133 vw, 1056 m, 985 m, 934 s, 915 s, 887 s, 839 vs, 750 s, 682 m, 618 m, 575 m cm^{-1}. − MS (70 eV); *m*/*z* (%): 362 (3)[M^+], 347 (9)[M^+ − Me], 274 (70)[$Me_9Si_3CH_2AlN^+$ or $Me_9Si_3(CH_2)_2Al^+$], 201 (85)-[$Me_6Si_2CH_2AlN^+$ or $Me_6Si_2(CH_2)_2Al^+$], 160 (93) [$NSi_2Me_6^+$], 146 (100), 128 (100) [$Me_3SiCH_2AlN^+$]. − $C_{14}H_{40}AlNSi_4$ (361.81): calcd. C 46.47, H 11.14, N 3.87; found C 45.48, H 11.15, N 3.55.

Calcium Bis(trimethylsilyl)amide-tetrakis(trimethylsilylmethyl)aluminate (2): At 0°C tris(trimethylsilylmethyl)alane (2.4 g, 10.32 mmol) was added slowly to a solution of dimeric calcium bis[bis(trimethylsilyl)amide] (1.92 g, 2.67 mmol) in 25 mL of toluene. This solution was stirred at room temp. for an additional four days. During this time the solution turned slightly cloudy. After evaporation of solvent to 15 mL colorless crystals of **2** (1.1 g, 0.95 mmol, 36%) precipitated at 0°C, m.p. 81°C (dec.). − ^{1}H NMR ([D$_8$]toluene): δ = −0.89 [CH_2], 0.27 [$NSiMe_3$], 0.28 [$CSiMe_3$]. − ^{13}C{^{1}H} NMR ([D$_8$]toluene): δ = 3.04 [$CSiMe_3$], 5.53 [$NSiMe_3$], 10.09 [CH_2]. − ^{29}Si{^{1}H} NMR ([D$_8$]toluene): δ = −8.47 [$NSiMe_3$], 2.07

This compound has already been described by Wells and co-workers,[16] however, the spectroscopic data differ slightly.

X-ray Structure Determinations of 2, 3 and 4:[24] The single crystals were covered with nujol[25] and mounted on a Siemens P4 diffractometer with graphite monochromated Mo-K_α radiation (λ = 71.073 pm). A Siemens SMART−CCD area detector was used to monitor the reflections. Crystallographic parameters and details of data collection are summarized in Table 1.

All structures were solved by direct methods and refined with the software packages SHELXL-93 and SHELXL-97.[27] Neutral scattering factors were taken from Cromer and Mann[28] and for the hydrogen atoms from Stewart et al.[29] The non-hydrogen atoms were refined anisotropically. The H-atoms were considered with a riding model under restriction of ideal symmetry at the corresponding atom.

Acknowledgments

We thank the "Deutsche Forschungsgemeinschaft" (DFG) and the "Fonds der Chemischen Industrie" for generous financial support. C. B. is also grateful to the German state of Bavaria for a scholarship.

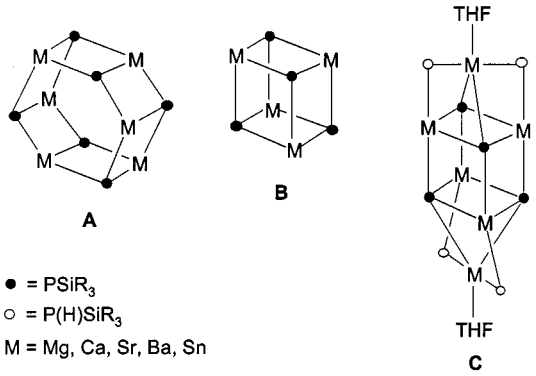
Magnesiation of Triisopropylsilylphosphane: Synthesis and Structures of New $Mg_{2n}P_{2m}$ Polyhedra

Matthias Westerhausen,*[a] Stefan Schneiderbauer,[a] Jörg Knizek,[a] Heinrich Nöth,[a] and Arno Pfitzner[b]



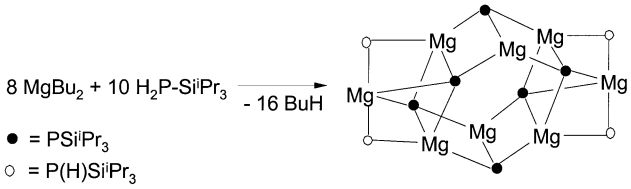
Dedicated to Prof. Alfred Schmidpeter on the occasion of his 70th birthday

Keywords: Magnesium / Metalation / Phosphorus / Polyhedra / X-ray structures

The magnesiation of triisopropylsilylphosphane with dibutylmagnesium in toluene yields the octanuclear complex $[Mg_8(PSi^iPr_3)_6\{P(H)Si^iPr_3\}_4]$ **(1)** which consists of $MgPSi^iPr_3$ units forming a hexagonal Mg_6P_6 prism, with two opposite Mg_2P_2 moieties capped by additional $Mg[P(H)Si^iPr_3]_2$ groups. If a small amount of THF is present during the metalation reaction $[(THF)_4Mg_6(PSi^iPr_3)_6]$ **(2)** also containing a hexagonal Mg_6P_6 prism can be isolated. The magnesiation of $H_2P–Si^iPr_3$ in tetrahydrofuran leads to the formation of the tetrameric complex $[(THF)MgPSi^iPr_3]_4$ **(3)** with a slightly distorted Mg_4P_4 cubane-like structure.The structures depend strongly on the steric strain caused by the trialkylsilyl substituents and the neutral coligands at the magnesium center. The highest steric strain, which is induced by coordination to every magnesium atom, leads to the smallest Mg_nP_n polyhedron – the central Mg_4P_4 heterocubane moiety. In compounds **1** and **2** the hexagonal Mg_6P_6 prism is formed, however, with reduced steric strain as observed for **2** where the Mg–P bond lengths become more similar.

Introduction

The synthesis of phosphandiides of the main group metals has been attracting increasing interest over the last few years due to their expected synthetic potential. Bulky substituents at the phosphorus atoms are necessary to avoid polymerization and to obtain oligomers soluble in common organic solvents. One of the most favored groups is the tri(*tert*-butyl)silyl[1] moiety, which is able to stabilize the negative charge and to shield the reactive center effectively. Therefore, solvent-free hexameric $[MgPSi^tBu_3]_6$ **(A)**[2] and tetrameric $[SnPSi^tBu_3]_4$ **(B)**[3] are well-known (Scheme 1). With regard to the heavier alkaline earth metals, the complete deprotonation of $H_2P-Si^tBu_3$ to a phosphandiide has not yet been achieved. Even in the presence of an excess of metalating reagent, bis(tetrahydrofuran-*O*)hexakisbarium tetrakis[tri(*tert*-butyl)silylphosphanide] tetrakis[tri(*tert*-butyl)silylphosphandiide] **(C)** with an $RP(H)^-/RP^{2-}$ ratio of 1:1 was isolated.[4] Smaller substituents such as triisopropylsilyl groups yield higher oligomers as shown for the solvent-free hexameric $[SnPSi^iPr_3]_6$ with a hexagonal Sn_6P_6 prism[5] similar to **A**. Herein we report on the magnesiation of triisopropylsilylphosphane with dibutylmagnesium and the influence of the THF content on the structures of the magnesiated phosphanes.

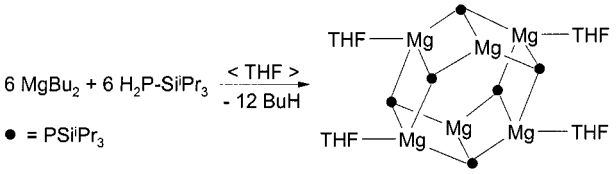


Scheme 1. Known phosphandiides of selected divalent main group metals (see text)

Results and Discussion

Synthesis

The metalation of triisopropylsilylphosphane[6] in toluene with dibutylmagnesium in the absence of Lewis bases such as THF yields compound **1** as shown in Scheme 2. Heating of the reaction solution to approximately 100°C and subsequent cooling to 6°C lead to the precipitation of colorless crystals of **1** with a melting point of 272°C and a decomposition point of 297°C.



Scheme 2. Synthesis of **1**

The ^{31}P NMR spectrum shows three chemically different phosphorus nuclei; however, the coupling pattern was not resolved and the assignment was not obvious. The resonance at $\delta = -265$ shows a doublet splitting due to a $^{1}J(P-H)$ coupling, whereas the other two signals originate from phosphandiide ligands. For these reasons a crystal structure determination was performed at −80°C (see below). The central moiety is a hexagonal Mg_6P_6 prism with two $Mg[P(H)Si^iPr_3]_2$ molecules coordinating above two opposite square planes. These magnesium bis(phosphanide) molecules can be substituted by Lewis bases such as THF. If a small amount of this ether is present during the magnesiation reaction compound **2** is instead obtained (Scheme 3). Again the Mg_6P_6 prism is formed; however, in this case, four THF molecules are bonded to the magnesium atoms of the two opposite square planes.

Scheme 3. Synthesis of **2**

Whereas ladder structures were reported for the hexamer $[LiP(SiMe_3)_2]_6$[7] and the polymeric compounds $[AP(SiMe_3)_2]_\infty$ (A = K, Rb, Cs),[8] the hexagonal prism of **2** can be described as a closed (cyclic) ladder structure. Open ladder structures such as those observed for the alkali metal bis(trimethylsilyl)phosphanides have not yet been found in alkaline earth metal phosphanide and phosphandiide complexes. The $^{31}P\{^1H\}$ NMR spectrum of **2** shows a single resonance due to a rapid interchange of the THF molecules on the NMR time scale. If the magnesiation of triisopropylsilylphosphane is performed in THF, the formation of $[(THF)MgPSi^iPr_3]_4$ **(3)** is observed (Scheme 4).

Scheme 4. Sythesis of **3**

Molecular Structures

The molecular structure of **1** and the atom numbering scheme is shown in Figure 1. The molecule has a crystallographic C_2 axis through the atoms Mg2 and Mg5; the symmetry-related atoms are marked with apostrophes. Selected bond lengths are summarized in Table 1.

The central moiety is a hexagonal Mg_6P_6 prism as already described for the hexamer $[MgPSi^tBu_3]_6$.[2] Due to the fact that the triisopropylsilyl groups are less effective in shielding the metal atoms than tri(*tert*-butyl)silyl substituents, coordination gaps appear at the magnesium centers. Two molecules of $Mg[P(H)Si^iPr_3]_2$ are bonded above two opposite Mg_2P_2 planes. These magnesium bis(phosphanide)

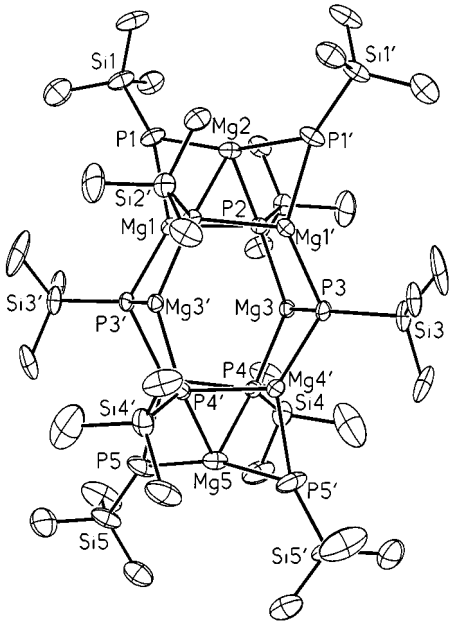

Figure 1. Molecular structure and numbering scheme of **1**; the methyl groups and the hydrogen atoms are omitted for clarity; the ellipsoids represent a probability of 40%; the atoms marked with an apostrophe are generated by C_2 symmetry; selected bond angles [°]: P1−Mg1−P2 100.59(7), P1−Mg1−P2′ 87.71(6), P1−Mg1−P3′ 139.0(1), P2−Mg1−P2′ 79.48(6), P2−Mg1−P3′ 120.40(7), P1−Mg2−P2 99.18(5), P1−Mg2−P1′ 163.0(1), P1−Mg2−P2′ 93.63(5), P2−Mg2−P2′ 82.46(8), P2−Mg3−P3 107.12(6), P2−Mg3−P4 134.59(8), P3−Mg3−P4 106.25(7), P4−Mg4−P5 98.17(8), P4−Mg4−P3′ 123.00(8), P4−Mg4−P4′ 80.21(7), P5−Mg4−P3′ 138.8(1), P5−Mg4−P4′ 89.02(7), P4−Mg5−P5 96.70(6), P4−Mg5−P4′84.29(8), P4−Mg5−P5′ 95.87(6), Mg1−P1−Mg2 71.05(7), Mg1−P2−Mg2 69.88(5), Mg1−P2−Mg3 107.12(7), Mg2−P2−Mg3 135.89(6), Mg1−P2−Mg1′ 100.22(6), Mg2−P2−Mg1′ 65.21(4), Mg3−P2−Mg1′ 72.56(5), Mg3−P3−Mg1′ 79.97(6), Mg3−P3−Mg4′ 81.22(7), Mg1′−P3−Mg4′ 123.65(9), Mg3−P4−Mg4 105.22(7), Mg3−P4−Mg5 135.82(7), Mg4−P4−Mg5 70.11(6), Mg3−P4−Mg4′ 73.12(6), Mg4−P4−Mg4′99.30(7), Mg5−P4−Mg4′ 64.87(5), Mg4−P5−Mg5 71.40(7)

[a] Atoms marked with an apostrophe are generated by C_2 symmetry ($-x + 1, y, -z + 0.5$). − [b] Coordination number.

units have P1−Mg2−P1′ and P5−Mg5−P5′ bond angles of 163.0(1)°. The Mg2−P1−Si1 and Mg5−P5−Si5 values amount to 137.5(1) and 139.6(1)°, respectively. These structural data, together with the rather short Mg2−P1 and Mg5−P5 bond lengths of 254.8(2) pm, allow us to consider the idea of coordinated magnesium bis(phosphanide) molecules.

Another description of the structure can be derived from considering the trigonal bipyramid with the magnesium atoms in apical positions as the basic polyhedron. Two bipyramids are joined through common faces (Mg2, P2, P2′, and Mg5, P4, P4′, respectively); two of these polyhedra are joined again through two $MgPSi^iPr_3$ units. Regarding the structure of **1** in this way, the similarity to the barium compound **D** is obvious; in **D** the $MPSiR_3$ moieties are missing and the dimerization occurs through M_2P_2 planes. The molecule has three- and four-coordinate magnesium atoms.

From this structure we can now identify the three different kinds of phosphorus atoms already found in the $^{31}P\{^1H\}$ NMR spectrum: the four-coordinate phosphorus atoms of the phosphanide ligands bound to two Mg atoms, one Si and one H atom (P1 and P5); the hexagonal prism containing one fourfold- (P3) and two fivefold coordinated P atoms (P2 and P4).

Figure 2 shows the molecular structure of **2** and the atom numbering scheme. Although the molecule displays no crystallographically enforced symmetry, the central moiety is very similar to the Mg_6P_6 polyhedron of **1**. Selected structural parameters are summarized in Table 2. The substitution of both $Mg[P(H)Si^iPr_3]_2$ molecules by four THF ligands leads to steric relief at the metal center; consequently the Mg−P bond lengths become more equal varying between 248.7 and 259.9 pm; bond lengths of this magnitude are already known for magnesium bis(phosphanides).[9] The Mg−O bond lengths are characteristic[10][11] of four-coordinate magnesium.

Figure 3 shows a comparison of the central moieties of the structures of **1**, **2** and $[MgPSi^tBu_3]_6$ ignoring the carbon and hydrogen atoms. The distortions of the hexagonal prism due to the coordination of two additional molecules of $Mg[P(H)Si^iPr_3]_2$ or THF are rather small. Whereas in the hexamer $[MgPSi^tBu_3]_6$ the Mg−P bond lengths vary in the rather narrow range of 247 to 260 pm, in **1** Mg−P distances of up to 298 pm are observed.

Figure 4 shows the molecular structure of **3** and the atom numbering scheme. The central moiety consists of a slightly distorted Mg_4P_4 cube with four-coordinate magnesium and phosphorus atoms. Table 3 contains selected bond lengths. In this polyhedron the Mg−P distances vary in a very narrow range around 254 pm.

The P(n)−Si(n) bond lengths differ in a characteristic manner. The P3−Si3 distance in **1** is the smallest due to the low coordination number of four at P3, whereas the P2−Si2 and P4−Si4 bond lengths are elongated due to the higher coordination number at the phosphorus atoms P2 and P4. The phosphanide ligands show further elongated bond lengths because the lower charge on P1 and P5 leads to a reduced electrostatic attraction between the negative phosphorus and the positively polarized silicon atoms. In **2** the P−Si bond lengths lie in a narrow range around 221 pm. In **3** the P−Si values of 218.4 pm are clearly smaller due to the reduced steric strain as a consequence of small Mg−P−Mg angles. The negative charge on the phosphorus atoms leads to decreased P−Si bond lengths relative to tris(trialkylsilyl)phosphanes[12−14] and bis(triisopropylsilyl)phosphane.[6]

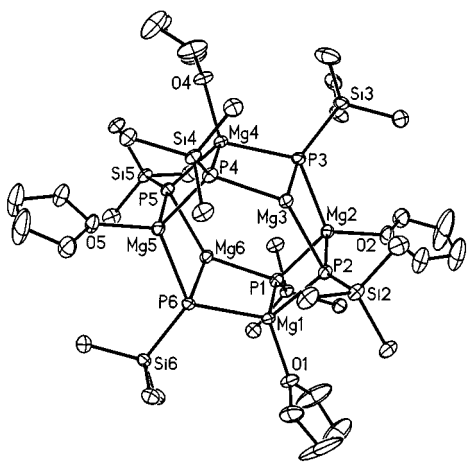

Figure 2. Molecular structure and numbering scheme of **2**; the methyl groups of the triisopropylsilyl substituents and the hydrogen atoms are omitted for clarity; the ellipsoids are drawn on a 40% probability level; selected bond angles [°]: P1−Mg1−P2 94.71(4), P1−Mg1−P6 99.75(4), P2−Mg1−P6 118.83(4), P1−Mg2−P2 94.76(4), P1−Mg2−P3 115.85(4), P2−Mg2−P3 100.88(4), P2−Mg3−P3 102.68(4), P2−Mg3−P4 138.58(4),P3−Mg3−P4 103.01(5), P3−Mg4−P4 100.44(4), P3−Mg4−P5 116.91(5), P4−Mg4−P5 94.96(4), P4−Mg5−P5 94.88(4), P4−Mg5−P6 117.33(4), P5−Mg5−P6 100.22(4), P1−Mg6−P5 139.70(4), P1−Mg6−P6 102.56(4), P5−Mg6−P6 102.37(4), Mg1−P1−Mg2 84.75(4), Mg1−P1−Mg6 78.07(4), Mg2−P1−Mg6 104.88(4), Mg1−P2−Mg2 85.52(4), Mg1−P2−Mg3 104.50(4), Mg2−P2−Mg3 78.00(4), Mg2−P3−Mg3 77.43(4), Mg2−P3−Mg4 125.39(4), Mg3−P3−Mg4 77.57(4), Mg3−P4−Mg4 77.84(4), Mg3−P4−Mg5 104.93(4), Mg4−P4−Mg5 84.37(4), Mg4−P5−Mg5 85.55(4), Mg4−P5−Mg6 104.38(4), Mg5−P5−Mg6 78.26(4), Mg1−P6−Mg5 123.08(4), Mg1−P6−Mg6 77.90(4), Mg5−P6−Mg6 77.62(4)

Table 2. Selected bond lengths of **2**

$Mg_{2n}P_{2m}$ Polyhedra

These new $Mg_{2n}P_{2m}$ polyhedra are missing links in a series of phosphandiides of divalent metals such as the alkaline earth metals and tin(II). An overview is given in

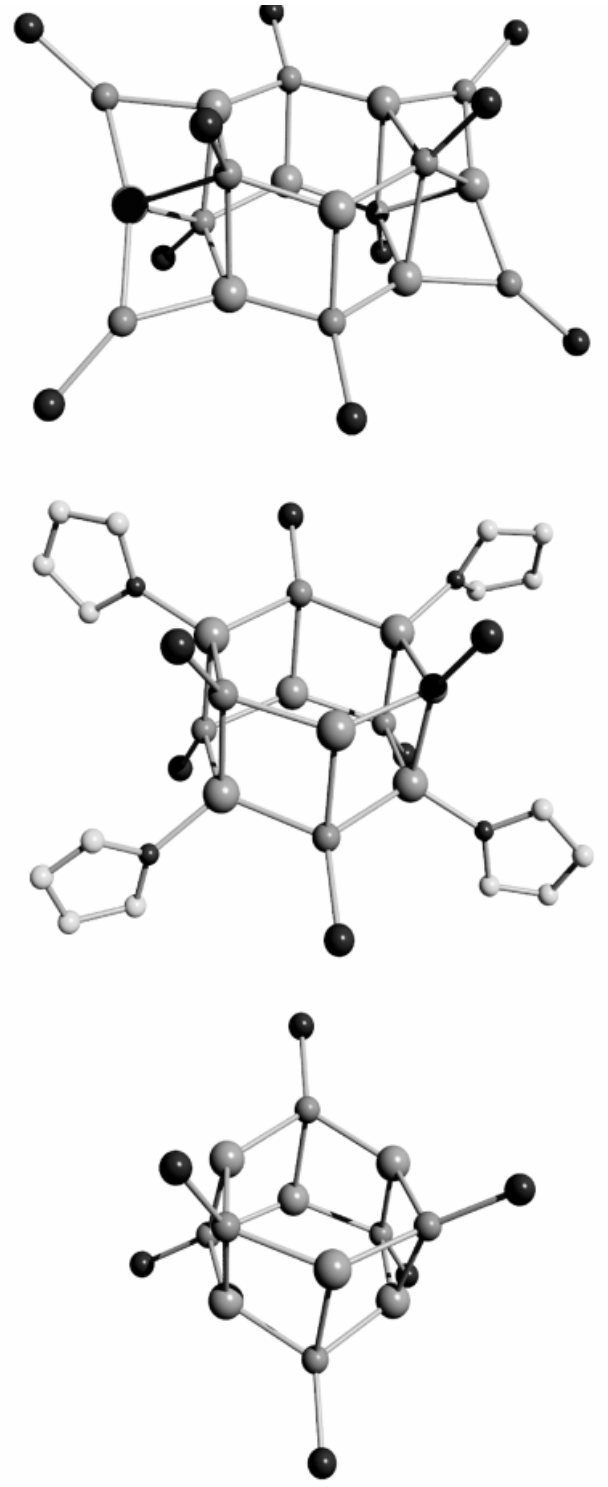

Figure 3. Comparison of the hexagonal prisms of **1** (on the top), **2** (in the middle) and hexakis(magnesium tri-*tert*-butylsilylphosphandiide) $[MgP-Si^tBu_3]_6$ (on the bottom); all hydrogen atoms are omitted for clarity; carbon atoms are omitted with the exception of those of the THF ligands; the atoms are shown with arbitrary radii

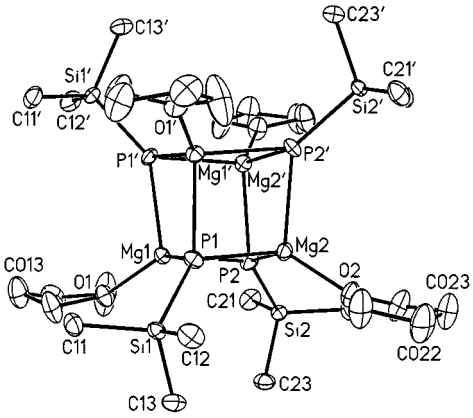

Figure 4. Molecular structure and numbering scheme of **3**. The methyl groups and the H atoms are omitted for clarity. The ellipsoids represent a probability of 40%. The atoms marked with an apostrophe are generated by C_2 symmetry. Selected bond angles [°]: P1−Mg1−P2 98.87(2), P1−Mg1−P1′ 98.78(2), P2−Mg1−P1′ 97.83(2), P1−Mg2−P2 99.16(2), P1−Mg2−P2′ 97.70(2), P2−Mg2−P2′ 97.78(2), Mg1−P1−Mg2 80.37(2), Mg1−P1−Mg1′ 80.54(2), Mg2−P1−Mg1′ 81.46(2), Mg1−P2−Mg2 80.57(2), Mg1−P2−Mg2′ 81.35(2), Mg2−P2−Mg2′ 81.53(2)

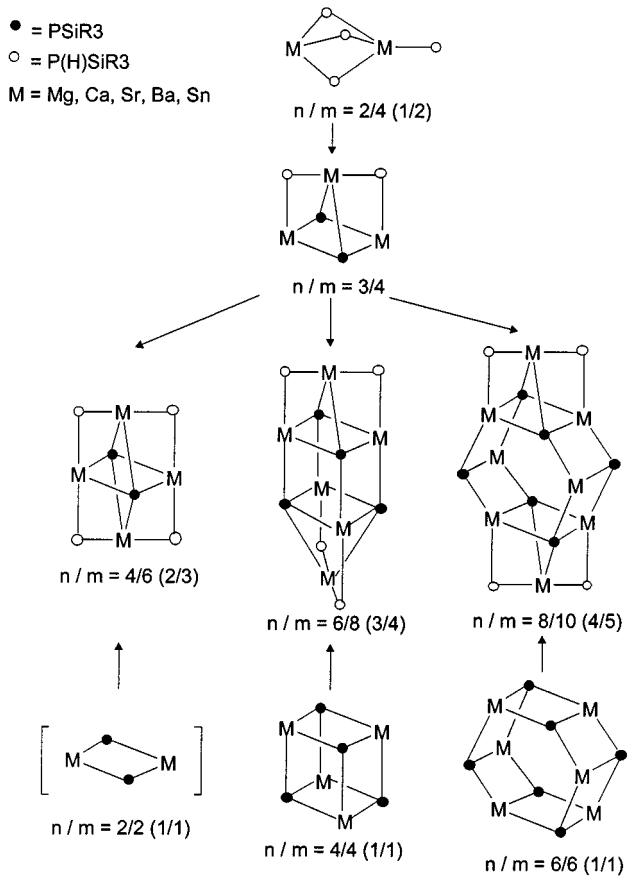

Table 3. Selected bond lengths of **3**[a]

Atom	Mg1	Mg2	Si(n)
P1	254.16(7)	253.97(7)	218.39(6)
P2	253.99(7)	253.08(7)	218.37(6)
P1′	254.66(7)		
P2′		255.19(7)	
O(n)	203.5(1)	203.0(1)	

[a] Atoms marked with an apostrophe are generated by C_2 symmetry ($-x$, y, $-z + 0.5$).

Scheme 5, where two basic types of polyhedra with m = n and $m = n + 1$ are shown, namely $M_{2n}P_{2n}$ (n = 2 and 3) and $M_{2n}P_{2n+2}$ (n = 3 and 4). The class of the $M_{2n}P_{2n}$ polyhedra consists of oligomeric alkaline earth metal phosphandiides where the dimer $[MgPSiR_3]_2$ with $n = 1$ − which would be the smallest unit − is still unknown. Dimerization leads to the formation of a cube (n = 2) and trimerization to the hexagonal prism (n = 3). These oligomeric alkaline earth metal phosphandiides are represented in the bottom row of Scheme 2.

In the group of $M_{2n}P_{2n+2}$ polyhedra the molecules contain both phosphanide and phosphandiide ligands, however the compound with n = 2 cannot be stabilized with triisopropylsilyl groups at the phosphorus atoms, although the steric strain introduced by tri(*tert*-butyl)silyl substituents is enough to allow the isolation of a dimer with the formula $Mg_4(PSi^tBu_3)_2[P(H)Si^tBu_3]_4$[15] whose structure is shown in Scheme 5. The upper part of Scheme 5 shows the alkaline earth metal bis(phosphanides) with n = 1 which contain only phosphanide substituents. These molecules are bicyclic in the case of the heavier alkaline earth metals with small groups at the phosphorus atoms.[4,9,14,16,17] In Scheme 5 the M/P ratio changes from 1:2 on the top to 1:1 on the bottom, which are the extreme values in this substance class. The middle row of Scheme 5 shows the compounds with M/P ratios of 2:3, 3:4 and 4:5, which crystallize as dimers.

Scheme 5. Schematic construction of $Mg_{2n}P_{2n}$ polyhedra starting from a dimeric alkaline earth metal bis(phosphanide) on the top (Mg/P ratio of 1:2) or starting from the alkaline earth metal phosphandiide at the bottom (Mg/P ratio of 1:1); the compounds in the middle row belong to polyhedra of the type $Mg_{2n}P_{2n+2}$ (see text)

Conclusion

The steric strain incorporated by the trialkylsilyl substituents and/or by the coordination of Lewis bases such as THF to the metal dications defines the polyhedron which is formed in the magnesiation of bulky trialkylsilylphosphanes. Tri(*tert*-butyl)silyl groups lead to the formation of a hexagonal Mg_6P_6 prism. If the less crowded triisopropylsilylphosphane is magnesiated in the absence of Lewis bases, two $Mg[P(H)Si^iPr_3]_2$ molecules cap two opposite square Mg_2P_2 planes of a hexagonal prismatic $(MgPSi^iPr_3)_6$ and **1** precipitates. The presence of Lewis bases such as THF is necessary to achieve a complete deprotonation of triisopropylsilylphosphane. The magnesium bis(phosphanide) molecules of **1** can be substituted by four THF ligands to yield **2**. Coordination of a THF molecule to each magnesium atom allows the isolation of $[(THF)MgPSi^iPr_3]_4$ with a slightly distorted Mg_4P_4 cube.

Experimental Section

General Remarks: All experiments and manipulations were carried out under argon or nitrogen purified by passage through BTS catalyst and P_4O_{10}. Reactions were performed with standard Schlenk techniques and dried, thoroughly deoxygenated solvents. $H_2PSi^iPr_3$[6] was prepared by a literature procedure. NMR spectra were recorded on Jeol spectrometers GSX270 and EX400. A Perkin–Elmer Paragon 1000 PC spectrophotometer was used to record the IR spectra; solid substances were measured in nujol between KBr plates (vs very strong, s strong, m medium strong, w weak, vw very weak, sh shoulder). The low carbon values for the elemental analysis result from carbide and carbonate formation as well as loss of neutral coligands during handling and combustion of the compounds.

$Mg_8(PSi^iPr_3)_6[P(H)Si^iPr_3]_4$ (1): Triisopropylsilylphosphane (1.12 mL, 5.0 mmol) was dissolved in 40 mL of toluene. A heptane solution of dibutylmagnesium (4.0 mL of a 1M solution) was dropped into this solution and a yellow precipitate formed immediately. Heating to approximately 100°C for 15 min. and subsequent cooling to 6°C led to the crystallization of 1.03 g of colorless **1** (0.49 mmol, 97%); m.p. 272°C, dec. above 297°C. – ^{1}H NMR ([D$_8$]toluene, 30°C): δ = 0.65 (m), 1.06 (m), 1.23 (m), 1.28 (m), 1.35 (m). – ^{31}P{^{1}H} NMR ([D$_8$]toluene, 30°C): δ = −265.0 (br, PH), −266.8 (br, P with C.N. = 4), −331.2 (br, P with C.N. = 3). – IR: $\tilde{\nu}$ = 316 vw, 372 w, 427 w, 444 w, 482 m, 515 m, 539 w, 576 m, 636 w, 656 m, 732 w, 784 vw, 802 vw, 819 vw, 882 s, 918 m, 993 s, 1015 m, 1064 s, 1161 w, 1197 w, 1230 w, 1289 w, 1313 w, 1368 w, 1386 w, 1465 m, 1686 w, 1768 w, 2300 m, 2364 vw, 2719 vw, 2732 vw, 2869 s, 2893 m, 2946 s. – $C_{90}H_{214}Mg_8P_{10}Si_{10}$ (2081.69): calcd. C 51.97, H 10.36; found C 51.23, H 10.35.

$(THF)_4Mg_6(PSi^iPr_3)_6$ (2): To a solution of triisopropylsilylphosphane (1.12 mL, 5.0 mmol) and 0.41 mL of THF in 30 mL of toluene a 1M heptane solution of dibutylmagnesium (5.0 mL, 5.0 mmol) was added dropwise. A yellow solution forms. During stirring for additional 19 h at room temp. a colorless solid precipitated which redissolved upon heating to approximately 80°C. Cooling to 6°C led to the crystallization of 1.18 g of **2**·2C_7H_8 (0.67 mmol, 81%); dec. above 300°C. – ^{1}H NMR ([D$_8$]toluene, 30°C): δ = 1.16 [sept, ^3J(H,H) = 7.0 Hz, C*H*Me$_2$], 1.37 (d, CH*Me*$_2$), 1.51 and 4.20 (br, THF). – ^{13}C{^{1}H} NMR ([D$_8$]toluene, 30°C): δ = 15.89 (m, CH), 20.58 (m, CH$_3$), 24.89 and 69.97 (m, THF). – ^{29}Si{^{1}H} NMR ([D$_8$]toluene, 30°C): δ = 24.13 (m). – ^{31}P{^{1}H} NMR ([D$_8$]toluene, 30°C): δ = −331.59 (s). – IR: $\tilde{\nu}$ = 327 w, 337 w, 462 m, 477 m, 487 m, 558 m, 678 m, 806 w,820 w, 884 s, 921 w, 991 m, 1013 s, 1061 m, 1093 s, 1162 m, 1193 m, 1260 w, 1366 w, 1386 w, 1465 m, 1631 w, 1638 w, 2865 s, 2894 m, 2953 s. – $C_{84}H_{174}Mg_6O_4P_6Si_6$ (1748.48): calcd. C 57.70, H 10.03; found C 57.48, H 10.04.

$[(THF)Mg]_4(PSi^iPr_3)_4$ (3): Dibutylmagnesium in heptane (5.0 mL of a 1M solution) was added dropwise to a solution of triisopropylsilylphosphane (1.12 mL, 5.0 mmol) in 25 mL of THF. After stirring for an additional 15 h at room temp. the volatile materials were removed in vacuum and the residue recrystallized from toluene at 90°C. Storage of this solution at 6°C led to the precipitation of 0.75 g of large colorless cuboids of **3** (0.66 mmol, 53%); dec. above 320°C. – ^{1}H NMR ([D$_8$]toluene, 30°C): δ = 1.21 [sept, ^3J(H,H) = 7.2 Hz, C*H*Me$_2$], 1.37 (d, CH*Me*$_2$), 1.51 and 4.20 (br, THF). – ^{13}C{^{1}H} NMR ([D$_8$]toluene, 30°C): δ = 15.86 (s, CH), 20.52 (s, CH$_3$), 25.46 and 67.77 (THF). – ^{29}Si{^{1}H} NMR ([D$_8$]toluene, 30°C): δ = 23.37 (m). – ^{31}P{^{1}H} NMR ([D$_8$]toluene, 30°C): δ = −330.8 (s). – IR: $\tilde{\nu}$ = 466 m, 485 m, 496 m, 557 m, 615 w, 680 m, 804 w, 819 w, 884 m, 921 w, 994 m, 1012 s, 1060 s, 1089 s, 1160 m, 1262 w, 1367 w, 1384 w, 1465 m, 1632 m, 1638 m, 2865 s, 2894 m, 2945 s. – $C_{36}H_{84}Mg_4P_4Si_4$ (850.51, THF-free compound): calcd. C 50.84, H 9.95; found C 50.46, H 9.87.

X-ray Crystal Structure Determinations of 1, 2 and 3:[18] Data were collected on a Siemens P4 diffractometer with a Siemens SMART-CCD area detector (**1** and **2**) or on a STOE-IPDS diffractometer

(**3**) with graphite monochromated Mo-K_α radiation (λ = 71.073 pm) from oil-coated[19][20] rapidly cooled single crystals. Crystallographic parameters, details of data collection and refinement procedures are summarized in Table 4.

All structures were solved by direct methods and refined with the software packages SHELXL-93 and SHELXL-97.[22] The asymmetric unit of **2** contains two toluene molecules without coordination to magnesium atoms. Neutral scattering factors were taken from Cromer and Mann[23] and for the hydrogen atoms from Stewart et al.[24] The non-hydrogen atoms were refined anisotropically. The H-atoms were considered with a riding model under restriction of ideal symmetry at the corresponding atoms.

Syntheses, Molecular Structures, and Bonding of Molybdenum and Tungsten Calix[4]arene Imido Complexes

Udo Radius*[a] Juri Attner[a]

Dedicated to Professor Dr. H. Werner on the occasion of his 65th birthday

Keywords: Calixarenes / Inclusion compounds / Imido Complexes / Molybdenum / Tungsten

Syntheses, spectroscopic properties, molecular structures, and bonding of novel calix[4]arene imido compounds are described. Treatment of $M(NtBu)_2(NHtBu)_2$ **Ia** (M = Mo), **Ib** (M = W) or $M(NMes)_2Cl_2(dme)$ **IIa** (M = Mo), **IIb** (M = W) (Mes = 2,4,6-Me_3-C_6H_2) with *p*-*t*Bu-calix[4]arene LH_4 affords calix[4]arene metal complexes LM(NR) **1a**, **b** (M = Mo, W; R = *t*Bu) and **2a**, **b** (M = Mo, W; R = Mes). Analytical and spectroscopic data are consistent with monomeric structures for **1** and **2**, retaining a local C_{4v} symmetry for the calix[4]arene metal fragment. These complexes are well-suited to bind small molecules like acetonitrile, *t*Bu-isonitrile, or water within their macrocyclic pockets. The spectroscopic data of some inclusion compounds and the crystal structures of LMo(N*t*Bu)(NCMe) **1a(NCMe)**, LW(N*t*Bu)(OH_2) **1b(OH_2)**, LW(N*t*Bu)(CN*t*Bu) **1b(CN*t*Bu)**, LMo(NMes)(NCMe) **2a(NCMe)**, and LW(NMes)(NCMe) **2b(NCMe)** are reported. All complexes contain a group VI metal imido [M=NR] moiety mounted on the phenoxide rim of the calix[4]arene ligand as well as an incorporated guest molecule within the cavity. Some insights into the structures of complexes of the type L′W(NR′) (L′ = *p*-H-calix[4]arene; R′ = H, Me) and into bonding in these compounds are provided by density functional theory, applying the B-P86 density functional and an all SVP basis set within the RI-J-DFT approximation. At least one π bond is of importance for calix[4]arene-metal bonding in these compounds. The metal-imido bond can be described as a triple bond. A geometrically optimized minimum structure of L′W(NMe) **4** shows a calix[4]arene ligand only slightly distorted from a local C_{4v} symmetry and an almost linear tungsten-imido moiety.

Introduction

The role of transition metal imido complexes[1] as reactive intermediates in industrial and laboratory organic synthesis[2][3] has received increased attention in recent years. The selective ammoxidation of propylene to acrylonitrile over bismuth molybdate catalysts with a minimal composition $Bi_2O_3 \cdot n\,MoO_3$ is one of the most significant reactions of this type.[4] With approximately four million tons of worldwide acrylonitrile production, this process constitutes the largest volume example of an allylic oxidation process in industrial practice. Similar reactions employing methylbenzenes are used in the manufacture of benzonitriles and terephthalonitriles. It is known that in the ammoxidation ammonia is activated by the formation of a bismuth oxide supported imido species [Mo=NH], and so this system has been the subject of industrial research and mechanistic studies.[5]

One approach leading to model oxo surfaces that bind metals on a molecular level is to employ ligands with a preorganized set of oxygen donor atoms in a quasiplanar arrangement as provided, for example, by calixarenes.[6] The simplest of the calixarenes, the calix[4]arene system, usually binds in tetradentate fashion to transition metals and often retains its cone-like appearance.[7] As part of our ongoing studies on metal-metal and metal-element multiple bonding supported by calix[4]arene ligands and calix[4]arene metal fragments,[8] we report here on the syntheses, molecular structures, and bonding of new molybdenum and tungsten calix[4]arene imido complexes.

Results and Discussion

Synthesis

There are, in principle, several ways to prepare *p*-*t*Bu-calix[4]arene organoimido complexes. Basic strategies are (i) to introduce the imido fragment into *p*-*t*Bu-calix[4]arene complexes and (ii) to introduce the *p*-*t*Bu-calix[4]arene fragment into imido complexes. Preparative ways for the former approach could be the reaction of *p*-*t*Bu-calix[4]arene metal chlorides $LMCl_2$ with amines RNH_2 in the presence of a base or the reaction of *p*-*t*Bu-calix[4]arene metal oxides LM=O with isocyanates RN=C=O.[1] Introduction of the *p*-*t*Bu-calix[4]arene fragment into imido complexes might be achieved by reacting imidochlorides $M(NR)Cl_4$ with *p*-*t*Bu-calix[4]arene LH_4. We decided to follow a similar method to that described by Gibson and co-workers for the preparation of a calix[4]arene imido molybdenum complex with the parent *p*-H-calix[4]arene. These authors reported the reaction of $M(NR)_2(OtBu)_2$ with *p*-H-calix[4]arene $L'H_4$.[9] In the case of M = Mo and R = 2,6(iPr)$_2$Ph (Dip),[9a] formation of the calix[4]arene imido complex

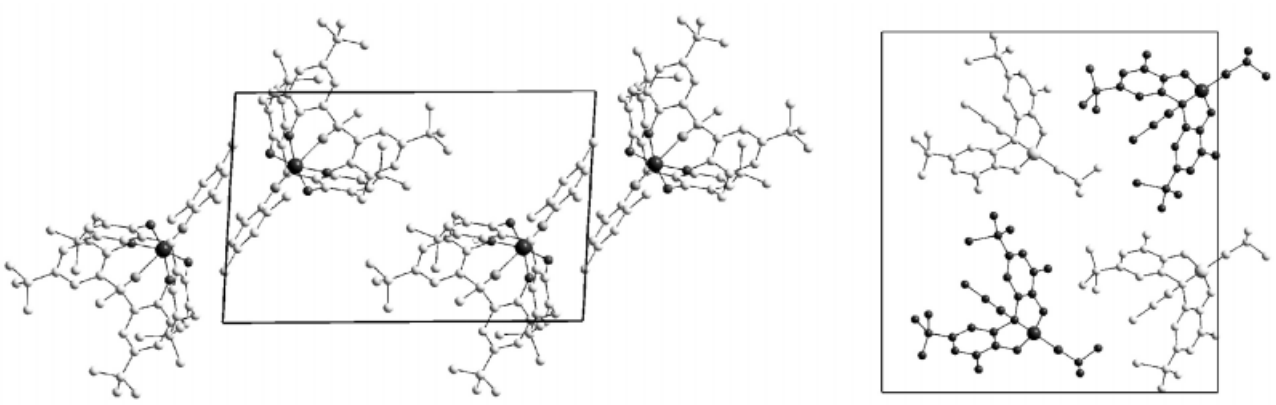

Figure 1. Packing diagram of LMo(NMes)(NCMe) **2a(NCMe)** (left side) and LMo(N*t*Bu)(NCMe) **1a(NCMe)** (right side). Projections down the a axis are shown. Molecules with the metal atom at (0.5, *y*, *z*) are light gray colored while those with metal atoms at (0, *y*, *z*) are dark gray colored in the cellplot of **1a(NCMe)**.

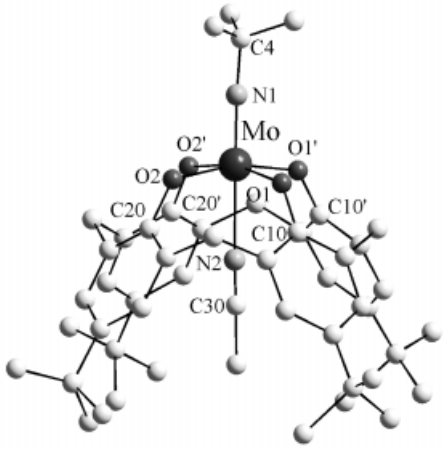
L′Mo(NDip) was observed, whereas in the case of M = Cr and R = *t*Bu all imido and alkoxy ligands were sacrificed to yield a mononuclear complex with two calix[4]arene molecules in the coordination sphere of the central chromium atom.[9b]

The *p*-*t*Bu-calix[4]arene *t*Bu-imido complexes LM(N*t*Bu) **1a** (M = Mo) and **1b** (M = W) are prepared by amide and imido replacement from compounds $M(NtBu)_2(NHtBu)_2$, which is a convenient starting material, especially for tungsten imido chemistry. Treatment of $M(NtBu)_2(NHtBu)_2$ **Ia** (M = Mo)[10a,10b] and **Ib** (M = W)[10c,10d] with one equivalent of *p*-*t*Bu-calix[4]arene LH_4 in toluene affords the monoimido complexes LMo(N*t*Bu) **1a** and LW(N*t*Bu) **1b**, after work up, as high melting solids in moderate to good yield (see Scheme 1).

Since preliminary studies on the reactivity of **1a**, **b** revealed that these compounds do not readily decompose with traces of HCl,[11] we tried to access calix[4]arene imido complexes by chloride and imido replacement from molybdenum and tungsten diimido dichlorides. These starting materials are also readily prepared and, especially for the molybdenum chemistry, more straightforward to synthesize than the amido imide **Ia**. Treatment of $M(NMes)_2Cl_2(dme)$ **IIa** (M = Mo) and **IIb** (M = W) (Mes = 2,4,6-$Me_3C_6H_2$)[12] with one equivalent of *p*-*t*Bu-calix[4]arene LH_4 in refluxing toluene results in the formation of calix[4]arene imido complexes LMo(NMes) (**2a**) and LW(NMes) (**2b**) in good yield. We believe this route to be general for the synthesis of compounds of the type LM(NR) (M = Mo, W).



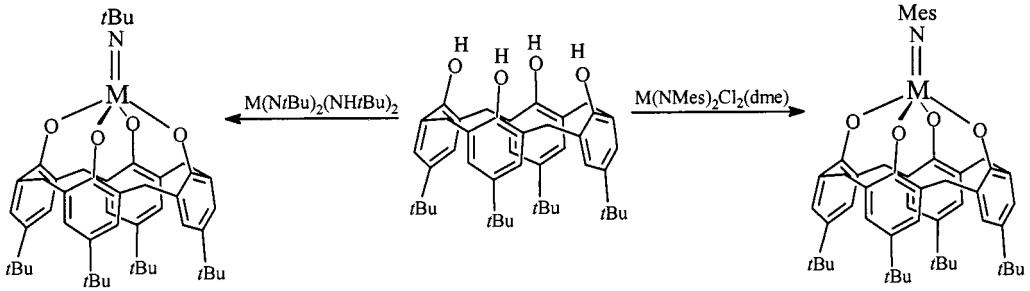


Figure 2. The molecular structure of LMo(N*t*Bu)(NCMe) **1a(NCMe)** with hydrogen atoms omitted for clarity. Disorders in *t*Bu groups are not resolved in the drawing. Selected bond lengths [pm] and angles [°]: Mo−N1: 171.8(10), Mo−O1: 194.0(5), Mo−O2: 194.0(5), Mo−N2: 234.3(9), N1−C4: 139.7(17), O1−C10: 134.0(9), O2−C20: 137.5(9), C4−N1−Mo: 176.9(11), N1−Mo−O1: 97.4(3), N1−Mo−O2: 97.6(3), O1−Mo−O2′: 165.0(2), O2−Mo−O1′: 165.0(2), N1−Mo−N2: 179.4(4), C10−O1−Mo: 129.6(5), C20−O2−Mo: 128.6(4).

Scheme 1

Unlike the calix[4]arene molybdenum oxide LMo=O,[13] which coordinates an additional molecule LH_4 to the LMoO core and is almost insoluble in common organic solvents, the imido compounds are readily soluble in organic solvents like benzene or toluene and sparingly soluble in hexane. The nature of the products was determined by ^{1}H- and ^{13}C-NMR spectroscopy as well as IR spectroscopy, mass spectroscopy, and elemental analysis. Analytical and spectroscopic data are consistent with a monomeric structure for **1** and **2** in the solid state and in solution. In all cases, intense signals for the molecular peaks were observed in the electron impact mass spectra at m/z = 813 (**1a**), 899 (**1b**), 875 (**2a**), and 961 (**2b**).

The monomeric nature of these compounds in solution is also evident from NMR spectroscopy. The proton NMR spectra are typical for calix[4]arene complexes with a pseudo C_{4v} symmetry of the macrocyclic ligand, showing a singlet for the calix[4]arene *tert*-butyl protons, two doublets for the diastereotopic protons of the methylene bridges with a coupling constant between 12.1 and 12.5 Hz, and one resonance for the aromatic protons of the aryloxy groups. ^{1}H-NOE measurements reveal that the doublet at lower field, for example at δ = 4.47 for the tungsten compound **1b**, is due to methylene hydrogen atoms closer to the metal atom, whereas the resonances at higher field, e.g. at δ = 3.25 for **1b**, have to be attributed to methylene protons in close proximity to the aryl hydrogen atoms. The proton NMR spectrum of a possible dinuclear imido-bridged species of the type LM(μ-NR)$_2$ML, in solution, should reveal the typical features of a calix[4]arene complex with local C_{2v} symmetry, i.e. a splitting of the signals of the *t*Bu protons of the inequivalent phenoxide rings. The local C_{4v} symmetry of the [LM] group is also reflected in the ^{13}C{^{1}H}-NMR spectra of **1** and **2**, where we observed two signals for the calix[4]arene *tert*-butyl carbon atoms, one signal for the methylene bridges and four signals for the carbon atoms of the phenoxide ring.

Calixarenes have attracted some attention for their ability to include small guest molecules in the solid state.[6][14] In the X-ray structure determination of *p*-*t*Bu-calix[4]arene LH_4, for example, there was a toluene molecule incorporated into the *endo* calix position.[15] Despite considerable effort, we were unable to obtain good quality crystals of compound **1** or **2** without any guest molecule in the *endo* calix position or with toluene included into the calixarene basket. However, this situation changes when we allow **1** or **2** to react with small donor molecules like water, acetonitrile, or isonitrile.

Accordingly, the complexes LMo(N*t*Bu)(NCMe) **1a(NCMe)**, LMo(N*t*Bu)(CN*t*Bu) **1a(CN*t*Bu)**, LW(N*t*Bu)(NCMe) **1b(NCMe)**, LW(N*t*Bu)(CN*t*Bu) **1b(CN*t*Bu)**, LW(N*t*Bu)(OH_2) **1b(OH_2)**, LMo(NMes)(NCMe) **2a(NCMe)**, and LW(NMes)(NCMe) **2b(NCMe)** can be prepared by dissolving **1** or **2** in acetonitrile or by reaction of toluene solutions of **1** or **2** with nucleophiles like water, acetonitrile or isonitrile.

The IR spectra of the acetonitrile complexes show two bands in the characteristic region between 1700 and 2800 cm^{-1}, one at approximately 2320 cm^{-1}, the other at approximately 2295 cm^{-1}. These bands may be assigned to a C≡N stretching frequency and a combination band, which results from coupling of a symmetric CH_3 deformation mode and a C−C stretching frequency. The ^{1}H-NMR spectra reveal one additional signal in the region of δ = −0.1 to −0.2, shifted upfield from the resonance of uncoordinated acetonitrile dissolved in $CDCl_3$ at δ = 1.90. Although coordination to transition metals might lead to upfield shifting of the acetonitrile resonances, these shifts are most probably due to shielding effects inside the cavity of the calix[4]arene ligand.

Similar shifts can be obtained for the isonitrile ligated to **1a** and **1b**. The resonances for the isonitrile CH_3 groups at δ = −0.17 and −0.20 are shifted significantly compared to the resonance of the uncoordinated molecule at δ = 1.37. Bands at 2211 and 2218 cm^{-1}, respectively, in the IR spectra of **1a(CN*t*Bu)** and **1b(CN*t*Bu)** are in the characteristic region of C≡N stretches. The bound H_2O molecule of **1b(OH_2)** gives rise to two OH stretches at 3519 and 3448 cm^{-1} in the IR spectrum, and a singlet at δ = 1.54 in the proton NMR spectrum.

^{13}C-NMR spectroscopy has an exceptional position in the characterization of *tert*-butyl imido compounds.[1] The difference in the chemical shifts of α- and β-*t*Bu-carbon atoms, Δδ, can serve as an experimental probe for the electron density on the metal atom of imido complexes. A decrease of electron density on the metal atom leads to a strengthening of the metal-nitrogen bond and therefore to a decrease of electron density on the imido nitrogen atom. This decrease can be experimentally observed as a downfield shift of the α-carbon atom resonance and a small upfield shift of the β-carbon atom resonance, and therefore by an increase of Δδ. We observe a Δδ value for LW(N*t*Bu) **1b** of 44.61 ppm and lower values for the adducts: 40.47 ppm for **1b(NCMe)**, 41.07 ppm for **1b(OH_2)**, and 41.36 ppm for **1b(CN*t*Bu)**. Electron density on the metal atom increases upon coordination of the guest molecule and weakens the tungsten nitrogen bond of the calix[4]arene imido compound. This weakening is mainly due to σ bond effects (vide infra).

Molecular Structures

Single crystal X-ray diffraction studies confirm the structural assignments for the calix[4]arene imido compounds of the type LM(NR) deduced from spectroscopic data. Suitable crystals for X-ray analyses of the compounds LMo(N*t*Bu)(NCMe) **1a(NCMe)**, LW(N*t*Bu)(OH_2) **1b(OH_2)**, LW(N*t*Bu)(CN*t*Bu) **1b(CN*t*Bu)**, LMo(NMes)(NCMe) **2a(NCMe)**, and LW(NMes)(NCMe) **2b(NCMe)** can either be grown from acetonitrile solutions (acetonitrile adducts) or toluene solutions (water adduct, isonitrile adduct). Projections of the cells down the a axis of LMo(N*t*Bu)(NCMe) **1a(NCMe)** and LMo(NMes)(NCMe) **2a(NCMe)** are given in Figure 1. The molecular structures of the compounds are shown in Figures 2 to 6, while selected bond lengths and

bond angles are given in the figure captions. Some important structural parameters are summarized and compared in Table 1.

Compound **2a(NCMe)** crystallizes in the triclinic space group $P\bar{1}$, **2b(NCMe)** in *C*c, and the isostructural *tert*-butyl imido compounds **1a(NCMe)**, **1b(OH_2)**, and **1b(CN*t*Bu)** in the orthorhombic space group $Cmc2_1$. As shown on the left side of Figure 1, the molecules of the molybdenum mesityl imido compound **2a(NCMe)** are in a head-to-head arrangement connected through π stacking of the aryl rings of the imido ligand. The carbon-carbon distances of the mutually

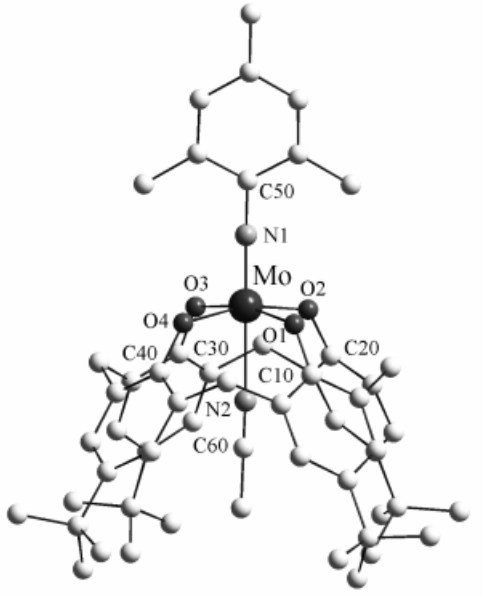

Figure 5. The molecular structure of LMo(NMes)(NCMe) **2a(NCMe)** with hydrogen atoms omitted for clarity. Disorders in *t*Bu groups are not resolved in the drawing. Selected bond lengths [pm] and angles [°]: Mo−N1: 172.4(3), Mo−O1: 194.8(3), Mo−O2: 193.7(2), Mo−O3: 193.9(3), Mo−O4: 195.3(2), Mo−N2: 230.3(3), N1−C50: 137.9(3), N2−C60: 113.3(4), O1−C10: 136.0(3), O2−C20: 137.1(4), O3−C30: 136.8(3), O4−C40: 136.3(3), Mo−N1−C50: 172.3(2), Mo−N2−C60: 177.8(4), N1−Mo−O1: 95.87(11), N1−Mo−O2: 98.07(11), N1−Mo−O3: 98.11(11), N1−Mo−O4: 97.04(11), O1−Mo−O3: 165.92(8), O2−Mo−O4: 164.85(8), N1−Mo−N2: 177.56(10), C10−O1−Mo: 128.99(17), C20−O2−Mo: 128.4(3), C30−O3−Mo: 125.80(16), C40−O4−Mo: 131.38(17).

opposite atoms are in a narrow range between 371.7−372.5 pm. The other structurally characterized compounds are close to isostructural and show molecules isolated from each other in the unit cell, as presented for **1a(NCMe)** at the right side of Figure 1.

All complexes contain a group VI metal imido M=NR moiety mounted on the phenoxide rim of the calix[4]arene ligand. The four oxygen atoms of the calix[4]arene ligand and the nitrogen atom of the imido ligand span a flat square pyramidal environment around the transition metal atom. A sixth coordination site is occupied by a neutral donor molecule, i.e. acetonitrile, isonitrile, or water, respectively. Thus, the metal atoms adopt distorted octahedral coordination spheres.

The donor atoms of the guest molecules are almost linearly coordinated to the metal atoms with respect to the metal−(imido)nitrogen vector and all N1−M−D angles are larger than 177°. The distances and angles of the coordinated acetonitrile molecules suggest minimal changes in the bonding of these ligands compared to the uncomplexed molecules, because the d^0 metal centers cannot π backdonate into the carbon-nitrogen triple bonds. The carbon−nitrogen distances of 111.4(15) pm in **1a(NCMe)**, 113.3(4) pm in **2a(NCMe)**, and 112.0(6) pm in **2b(NCMe)**, as well as almost linear [N−C−C] entities, indicate carbon-nitrogen bond orders of approximately three. The bond lengths of the acetonitrile adducts compare well with other aceto-

nitrile adducts of group VI imido complexes of metals in their highest oxidation state.[16] The N−C bond lengths of the acetonitrile molecules in **2a(NCMe)**, **2b(NCMe)**, and **1a(NCMe)** correlate with the lengths of the M−N2 bonds of 230.3(3) pm in **2a(NCMe)**, 231.4(3) pm in **2b(NCMe)**, and 234.4(9) pm in **1a(NCMe)**.

Compound **1b(CN*t*Bu)** is the first structurally characterized terminal isonitrile complex of a d^0-group VI metal complex. The observed W−C bond length in **1b(CN*t*Bu)** of 241.7(13) pm is very long compared to homoleptic W^{II} complexes $[W(CNtBu)_7]^{2+}$. In these compounds, W−C distances are in a range between 206.9(6) pm and 214.2(8) pm.[17] The W−OH_2 bond length of 230.3(4) pm in **1b(OH_2)** is significantly shorter than the Mo−OH_2 distance of 240.8(16) pm in the calix[4]arene molybdenum oxide $(LH_4)LMoO(OH_2)(PhNO_2)$,[13] but comparable to other tungsten complexes with a water molecule coordinated *trans* to σ,π donor ligands. In tungsten(V) anions of the type $[W(=O)X_4(OH_2)]^-$ prepared by Atwood and co-workers, for example, the W−OH_2 bond length comes to 226.2(9) pm (X = Cl) and 231(2) pm (X = Br), respectively, and in an anion of higher nuclearity prepared in Jeannin′s group the W−OH_2 bond length was determined to be 229(1) pm.[18]

The calix[4]arene metal fragments of all the imido compounds LM(NR)(donor) that were investigated by X-ray crystallography retain pseudo C_{4v} symmetry in the solid state and produce circular calix[4]arene cavities similar to those in the uncoordinated ligand. The molybdenum−oxygen and tungsten−oxygen bond lengths are in a very narrow range between 192.5(6) pm and 195.3(2) pm, with three exceptions at 194.0±0.6 pm, and are comparable with average metal−oxygen bond lengths in molybdenum or tungsten aryloxy complexes.[19] The angles N1−M−O are between 97° and 99°, the angles M−O−C are approximately 130° and all *endo* calix angles O−M−O between two *trans* oxygen atoms are in a narrow range between 163.5° and 165.9°.

The short Mo−N1 and W−N1 contacts of 171.8(5)−174.3(4) pm and the almost linear M−N1−C entities with angles larger than 170° suggest sp hybridized imido nitrogen atoms with triple bond character of the metal-(imido)-nitrogen bond.[1] These bonding parameters are also in good agreement with other monoimido complexes of the type Mo(NR)X_4 · L, for example in Mo(NTolyl)Cl_4 · THF [Mo−N bond length 171.7(3) pm, angle Mo−N−C 174.6(3)°],[20] in $(H_2NSO_2N)WCl_4$ · NCMe [W−N bond length 173.0(12) pm, angle W−N−S 168.3(7)°],[16b] in (ClN)WCl_4 · NCMe [W−N bond length 172(1) pm, angle W−N−C 175.5(10)°][16c] or in L′Mo(NDip) [Mo−N bond length 172.9(3) pm, angle Mo−N−C 179.2(2)°].[9a]

Theoretical Studies

In order to gain some insight into the bonding situation of calix[4]arene imido complexes, as well as their donor adducts, we performed density functional calculations[21] on

model compounds of the characterized complexes. We wanted to understand calix[4]arene−metal bonding, bonding of the imido fragment [RN] to the calix[4]arene metal fragment [LM] and the influence of the donor molecule on metal−imido bonding. The *t*Bu groups of the calix[4]arene ligands were replaced by hydrogen atoms and the organic groups of the imido ligands were replaced by hydrogen or methyl groups to reduce computational cost. The models under investigation were the tungsten compounds L′W(NH) **3** and L′W(NMe) **4** (L′ = *p*-H-calix[4]arene).

For an electron count of calix[4]arene imido complexes, we opted to cleave all metal ligand bonds heterolytically and end up with $[L']^{4-}$, a metal center in the formal electron configuration d^0 and a closed shell imido anion $[NR]^{2-}$. Counting the imido ligand − in agreement with the M−N bond lengths (vide supra) − as a six-electron donor,[1] the calix[4]arene ligand has to provide 12 electrons for an 18 VE count on the central atom. For the acetonitrile- and isonitrile-stabilized complexes, 10 electrons are sufficient since these donor molecules act as neutral two electron donors. Eight electrons are provided by four σ bonds. Thus, one [for LM(NR)(D) type complexes] and two [for LM(NR) type complexes] calix[4]arene−metal π bonds are necessary to fulfill the 18 VE rule for the central atom. In the evaluation of π bonding in this type of compound, we want to preface our analysis with simple considerations emerging from group theory.

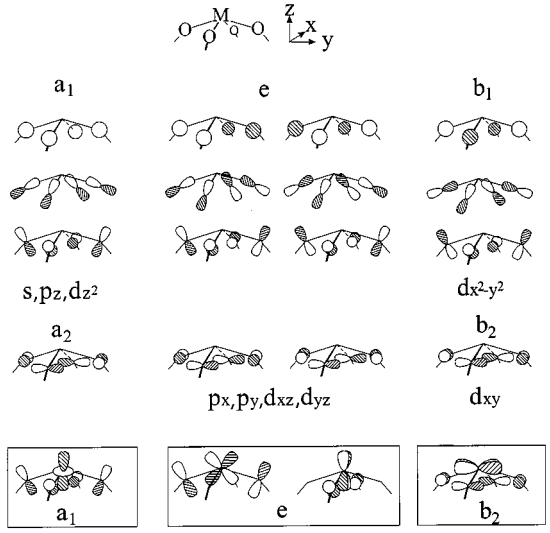

Figure 7. Symmetry-adapted linear combinations of oxygen s and p orbitals of a C_{4v} $[O_4]$ set

One possibility to generate symmetry adapted combinations of oxygen s and p orbitals of an $[O_4]$ fragment in C_{4v} symmetry is shown in Figure 7. Combination of the oxygen s orbitals gives four symmetry adapted orbitals that transform as a_1, e, and b_1, which are shown as the first entry in Figure 7. For the p orbitals on each oxygen atom, one can think of a basis set independent from the cartesian coordinate system, one radial p orbital pointing in the direction of the M−O vector and two sets of tangential p orbitals, which are perpendicular to each other and to the M−O vector (second and third entry in Figure 7). The radial p orbitals and one of the tangential sets transform as a_1, e, and b_1. The second set of tangential orbitals, those lying in the O_4 plane, transforms as a_2, e, and b_2 (fourth entry in Figure 7). The counterparts on the metal atom, which can interact with these combinations, are s, p_z, and d_{z2} for a_1 ligand orbitals, p_x, p_y, d_{xz}, and d_{yz} for ligand orbitals of e symmetry, d_{x2-y2} for b_1, and d_{xy} for b_2 ligand orbitals. Within this simplified scheme, linear combinations of radial ligand p orbitals and ligand s orbitals are responsible for metal ligand σ bonding, whereas π bonding comes from overlap of tangential ligand orbitals with metal orbitals of appropriate symmetry. The most important interactions for π bonding are shown in the lowest part of Figure 7. There is one π interaction of a_1 symmetry, one of e symmetry and one of b_2 symmetry. For the C_{4v} calix[4]arene metal fragment we observe M−O−C angles of approximately 130°, a value that is significantly smaller than 180°. Thus, there will be mixing of radial and tangential orbitals of the same symmetry resulting in a good O−C overlap and, as a consequence of this, in worse overlap of the a_1 and e π-type orbitals shown at the bottom of Figure 7.

In order to check these qualitative considerations, DFT calculations were carried out on geometrically optimized C_{4v} L′W(NH) **3** and on the complex fragment C_{4v} $[L'W]^{2+}$. The imido complex **3** optimizes at W−O distances of 195.8 pm, a W−N distance of 174.8 pm and angles W−O−C of 135.6°. These bonding parameters are in good agreement with the experimental results. The imido group is kept linear to retain overall C_{4v} symmetry. A Mulliken population analysis of the tungsten-oxygen bond reveals a strong π bond for the b_2 orbital shown at the bottom of Figure 7. The contribution of the irreducible representation b_2 is 0.106 to a total W−O overlap population of 0.420. In contrast, contributions from e-type orbitals are almost negligible. Similar results can be obtained from an SEN (shared electron number) analysis[22] of covalent contributions to the W−O bond. Orbitals of b_2-type symmetry contribute significantly to the W−O bond (0.169 out of a total of 0.611), whereas the contributions of e symmetry are approximately 0.03. Calculations on the complex fragment $[L'W]^{2+}$ confirm these results. The b_2 interaction shown in the lowest part of Figure 7 is an important π interaction that helps to stabilize metal d orbitals in calix[4]arene metal complexes.

A truncated fragment molecular orbital (FMO) scheme for the interaction of a C_{4v} calix[4]arene tungsten fragment $[L'W]^{2+}$ with a linear dianionic imido group $[NR]^{2-}$ is shown in Figure 8. The frontier orbitals of the $[L'W]^{2+}$ complex fragment are shown schematically on the left side. A group of highest occupied orbitals indicated as a dashed box are centered on the calix[4]arene ligand, mainly on the carbon atoms of the phenoxide. The highest unoccupied orbitals are metal-centered and give a typical M(ligand)$_4$ pattern: there is a low lying $1a_1$ orbital, mainly d_{z^2} in character, a degenerate set of d_{xz} and d_{yz} orbitals of e symmetry, a W−O antibonding orbital of b_2 symmetry (d_{xy}), and two orbitals $2a_1$ (p_z) and b_1 ($d_{x^2-y^2}$) that are high in energy. Im-

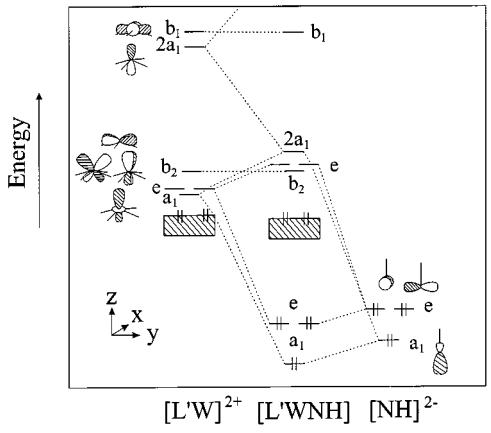

Figure 8. Schematic FMO diagram for C_{4v} L′W≡NH built up from the components $[L'W]^{2+}$ (left side) and $[NR]^{2-}$ (right side). The important frontier orbitals of the fragments and the combined molecule are shown. The HOMO region of $[L'W]^{2+}$ and L′W≡NH is indicated by a dashed box.

portant orbitals of the linear imido fragment $[NR]^{2-}$ are an sp hybrid orbital of a_1 symmetry and a degenerate e set of nitrogen p_x and p_y orbitals, and these are shown on the right side of Figure 8. The W−N σ bond is built up from interactions of the a_1 orbitals depicted in Figure 8, with some additional admixture of tungsten s. The orbitals of e symmetry combine to give a degenerate set of π orbitals for the tungsten nitrogen bond. The net result of this interaction is a metal-nitrogen triple bond resulting from one σ−(a_1) and two π−(e) interactions. This qualitative picture is confirmed by our DFT results on C_{4v} L′W(NH) **3**. From a total shared electron number (SEN) of 1.59 electrons for the tungsten nitrogen bond, 0.83 electrons are due to contributions of a_1 symmetry and 0.76 electrons are due to contributions of e symmetry.

A detailed analysis of the frontier orbitals of C_{4v} L′W(NH) **3** shows that HOMO 30e is a ligand centered orbital, whereas LUMO $13b_2$ is tungsten d_{xy} in character. The LUMO + 1, a degenerate orbital 31e is W−N antibonding and can be considered a W−N π* orbital. The LUMO + 2, which is also W−N antibonding, is an a_1 hybrid orbital with contributions from tungsten d_{z^2}, p_z, and s, as well as some nitrogen s and p_z. This orbital is responsible for binding an *endohedral* donor molecule, such as nitriles or isonitriles, to the metal atom. Calculations on **3(NCH)** show that the W−(imido)N bond should be weaker in comparison to **3**, mainly due to a lower a_1 contribution to the W−(imido)N bond.

An X-ray crystal structure of L′Ta(η^5-C_5Me_5),[23] which is isoelectronic to L′W(NR), shows a significant distortion from pseudo C_{4v} to pseudo C_{2v} symmetry for the macrocycle bound to the CpTa unit, and this results in an *elliptical* cone section for the calix[4]arene ligand. This distortion can be traced by two sets of different Ta−O bond lengths (189 pm and 200 pm), two sets of Ta−O−C angles (one set with angles larger than 160°, the other with angles of approximately 125°) and two different *endo* calix angles (127° and 155°). Lippard and co-workers attributed this distortion to favorable oxygen-to-metal π bonding for the distorted molecule. The opening of one pair of the M−O−C angles should lead to a better overlap for one of the π bonds of the e set depicted at the bottom of Figure 7. However, the optimization of L′W(NH) **3** under C_{2v} symmetry restriction leads to a geometry that is only 0.03 kcal/mol lower in energy than C_{4v} L′W(NH), and only minor deviations from the C_{4v} structure can be observed. The calculated bond lengths and angles in C_{2v} L′W(NH) are 174.8 pm [in C_{4v} L′W(NH): 174.8 pm] for the W−N bond, 196.5 pm and 194.8 pm (195.8 pm) for the different W−O bonds, 104.0 and 102.6° (103.2°) for the angles N−W−O, and 131.9° and 140.0° (135.6°) for the W−O−C angles.

Since we were not able to obtain high quality crystals of compounds **1** and **2** without any guest in the calix[4]arene cavity, we decided to optimize an extended model system, L′WNMe **4**, without any symmetry restraints in order to answer the question as to whether the calix[4]arene ligand in these group VI imido compounds adopts pseudo C_{4v} symmetry or distorts to a pseudo C_{2v}-type structure with an *elliptical* cone section. The geometrically optimized minimum structure of L′W(NR′) **4** shows the calix[4]arene ligand to be only slightly distorted from a local C_{4v} structure and an almost linear tungsten-imido moiety. We calculate a W−N distance of 174.91 pm and an angle W−N−C of 179.95°, W−O distances of 196.33±2 pm, W−O−C angles of 134.74±2°, and N−W−O angles of 102.62±2°. The bond lengths obtained are in good agreement with those of the experimentally determined structures (see Table 1), while the angles N−W−O and W−O−C are significantly smaller in the observed structures due to coordination of an additional molecule inside the calix[4]arene cavity. However, there is no driving force for a significant distortion in these systems as reported for the tantalum compound. The tungsten d_{xz} and d_{xy} orbitals of e symmetry are significantly stabilized by interaction with a good σ, π donor, i.e. the imido ligand, and do not contribute to tungsten calix[4]arene bonding.

Conclusions

Group VI calix[4]arene imido complexes LM(NR) **1a**, **b** (M = Mo, W; R = *t*Bu) and **2a**, **b** (M = Mo, W; R = Mes) have been prepared and characterized. Treatment of $M(NtBu)_2(NHtBu)_2$ or $M(NMes)_2Cl_2$(dme) (M = Mo, W) with *p*-*t*Bu-calix[4]arene LH_4 affords calix[4]arene metal imido complexes LM(NR) **1a, b** (M = Mo, W; R = *t*Bu) and **2a**, **b** (M = Mo, W; R = Mes). These molecules are well suited to bind small molecules, like acetonitrile, *t*Bu-isonitrile, or water within their macrocyclic pockets, and some of those adducts have also been characterized. The monomeric nature of these compounds in solution is demonstrated by NMR spectroscopy. ^{1}H- and ^{13}C-NMR spectra are typical for calix[4]arene complexes with a pseudo C_{4v} symmetry of the macrocyclic ligand. The signals of the acetonitrile and isonitrile molecules incorporated into the *endo* calix site are shifted significantly in the ^{1}H-NMR spectra as compared to the uncoordinated guest molecules.

The crystal structures of LMo(N*t*Bu)(NCMe) **1a(NCMe)**, LW(N*t*Bu)(OH_2) **1b(OH_2)**, LW(N*t*Bu)(CN*t*Bu) **1b(CN*t*Bu)**, LMo(NMes)(NCMe) **2a(NCMe)**, and LW(NMes)(NCMe) **2b(NCMe)** show a group VI metal imido M=NR moiety mounted on the phenoxide rim of the calix[4]arene ligand and an incorporated guest molecule within the cavity. The metal atoms in these compounds adopt a distorted octahedral coordination sphere. The calix[4]-arene ligands also retain a pseudo C_{4v} symmetry in the solid state and thus produce circular calix[4]arene cavities. The imido group [M−N−R] is almost linear with M−N distances of 171.8(5)−174.3(4) pm. In the solid state, molecules of LMo(NMes)(NCMe) **2a(NCMe)** are assembled head-to-head through van der Waals forces between the aryl rings of the imido ligands.

Some insights into the structures of compounds of the type L′W(NR′) **3** and **4** (L′ = *p*-H-calix[4]arene; R′ = H, Me) and into bonding in calix[4]arene imido complexes are provided by density functional theory. Simple symmetry considerations show that there is one π bond of b_2 symmetry, which is very important for calix[4]arene−metal bonding in these compounds. This is confirmed by population analyses of C_{4v} L′W(NH) **3**. The geometrically optimized minimum structure of L′W(NR′) **4** shows the calix[4]-arene ligand only slightly distorted from a local C_{4v} structure and an almost linear tungsten-imido moiety. According to our DFT results, calix[4]arene-tungsten π interactions of e symmetry do not contribute significantly to the net stabilization of this compound

Experimental Section

General: All reactions and subsequent manipulations involving organometallic reagents were performed under an argon atmosphere using standard Schlenk techniques. The preparation of samples for spectroscopy was undertaken using a glove box (Braun MB 150 BG-I). Solvents were dried according to standard procedures, stored over activated 4-Å molecular sieves and degassed prior to use. Deuterated solvents were obtained from Aldrich Inc. (all 99 atom% D), dried according to standard procedures, and stored over activated 4-Å molecular sieves. − NMR spectra were recorded on a Bruker AC 250 at 298 K. ^{13}C-NMR spectra are broad-band proton decoupled ($^{13}C\{^1H\}$). Standard DEPT-135 experiments were recorded to distinguish $-CH_3$- and −CH-type carbons from −C- or $-CH_2$-type carbons in the ^{13}C-NMR spectrum. NMR data are listed in parts per million (ppm) and are reported relative to tetramethylsilane. Coupling constants are quoted in Hertz. Residual solvent peaks used as internal standards were as follows: $CDCl_3$: δ = 7.24 (^{1}H), CD_2Cl_2: δ = 5.32 (^{1}H) or natural-abundance carbon signal at δ = 77.0 for $CDCl_3$ and δ = 54.0 for CD_2Cl_2. − EI-MS spectra were recorded on a Varian MAT 3830 (70 eV). − Elemental analyses were performed by the microanalytical laboratory of the author′s department. − Infrared spectra were recorded as KBr pellets on a Bruker IFS 28 and are reported in cm^{-1}. − The compounds *p*-*t*Bu-calix[4]arene,[24] Mo(NH*t*Bu)$_2$(N*t*Bu)$_2$,[10a,10b] W(NH*t*Bu)$_2$(N*t*Bu)$_2$,[10c,10d] and [M(NMes)$_2$Cl$_2$(dme)] (M= Mo, W)[12] were prepared as described in the literature. All other reagents were purchased from commercial sources and purified by standard techniques.

Preparation of *p-tert*-Butylcalix[4]arene-*tert*-butylimidomolybdenum(VI) (1a): A solution of 250 mg (0.65 mmol) of Mo(NH-*t*Bu)$_2$(N*t*Bu)$_2$ and 485 mg (0.65 mmol) of *p*-*t*Bu-calix[4]arene toluene adduct in 40 mL of toluene was stirred for 8 h at 80°C. All volatile material was removed in vacuo. The red-brown residue was washed with 20 mL of hexane, collected, and dried in vacuo. Yield: 435 mg, 82%. m.p 345°C (dec.). Crystals suitable for X-ray analysis were grown from a saturated acetonitrile solution of **1a** to yield **1a(NCMe)**. **1a(CN*t*Bu)** was obtained as a red-brown powder by addition of an excess of *t*Bu-isocyanide to a toluene solution of **1a** and removal of all volatiles in vacuo. − ^{1}H NMR ($CDCl_3$) [**1a**]: δ = 7.10 (s, 8 H, aromatic *H*), 4.36 (d, 4 H, $^2J_{HH}$ = 12.3 Hz, CH_2), 3.24 (d, 4 H, $^2J_{HH}$ = 12.3 Hz, CH_2), 1.85 [s, 9 H, NC(CH_3)$_3$], 1.25 [s, 36 H, C(CH_3)$_3$]. − ^{13}C NMR ($CDCl_3$) [**1a**]: δ = 29.28 [s, NC(*C*H$_3$)$_3$], 31.49 [s, C(*C*H$_3$)$_3$], 33.86 (s, *C*H$_2$), 34.09 [s, *C*(CH$_3$)$_3$], 81.99 [s, N*C*(CH$_3$)$_3$], 124.96 (s, aromatic *C*H), 130.22 (s, aromatic *C*), 145.76 (s, aromatic C*t*Bu), 153.96 (s, aromatic *C*O). − EI/MS (70 eV) *m*/*z* (%): 813 [M]$^+$ (87), 798 [M − CH_3]$^+$ (3), 756 [M − C_4H_9]$^+$ (49), 741 [M − NC_4H_9]$^+$ (21), 57 [C(CH$_3$)$_3$]$^+$ (38), 41 [C_3H_5]$^+$ (100). − $C_{48}H_{61}O_4MoN$ (811.96) calcd. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-114936 to CCDC-114940. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44 1223/336 033; E-mail: deposit@ccdc.cam.ac.uk).

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie (Liebig fellowship for U. R.). U. R. kindly thanks Professor D. Fenske for his continued support and interest in our work. Furthermore, we would like to thank Dr. S. Elliott for helpful discussions as well as Dr. E. Matern and H. Berberich for recording NMR spectra. A gift of metal chlorides from Fa. H. C. Starck GmbH, Goslar, is gratefully acknowledged.

Synthesis, X-ray Crystal Structures and Reactivity Towards Alkynes of Gold(I)–Phosphinine Complexes

Nicolas Mézailles,[a] Louis Ricard,[a] François Mathey,*[a] and Pascal Le Floch*[a]

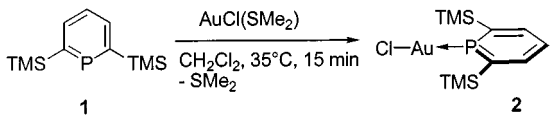
Keywords: Phosphorus / Heterocycles / Phosphinines / Gold / Cycloadditions

The coordination behaviour of 2,6-disilyl-substituted phosphinines towards gold(I) has been examined. The reaction of the bis(trimethylsilyl)phosphinine **1** with [AuCl(SMe_2)] gives the corresponding AuCl derivative **2**. X-ray crystal structure analysis reveals that the aromaticity of the phosphinine ring is slightly reduced as a result of the poor π-back bonding ability of the AuCl fragment. The same phenomenon is observed in the cationic complex [Au(**1**)$_2$][$GaCl_4$] (**3**) which was readily prepared by reaction of two equivalents of **1** with [AuCl(SMe_2)] followed by treatment with $GaCl_3$ at low temperature. Reaction of 2,6-bis(phenylethynyldimethylsilyl)phosphinine (**4**) with the same precursor leads similarly to the complex [AuCl(**4**)] (**5**). Interestingly, this complex dimerizes upon crystallization to give the bis(phosphabarrelene) complex **6**, also structurally characterized. The formation of **6** results from a [4 + 2] cycloaddition between one alkynyl group of each phosphinine with the other phosphinine subunit. The formation of the cationic complex [Au(**4**)][$GaCl_4$] (**8**) occurs under classical conditions but it disproportionates to give the cationic complex [Au(**4**)$_2$][$GaCl_4$] (**9**) and colloidal gold deposition. The formation of **9** has been ascertained by treating **8** with one equivalent of ligand **4**. Additionally, **9** can also be obtained in a straightforward fashion by treating two equivalents of **4** with [AuCl(SMe_2)] followed by treatment with $GaCl_3$ at low temperature. The structure of **9** has been elucidated. Despite a particular arrangement of the alkyne groups which encapsulate the gold coordination sphere, no gold–alkyne interactions are visible.

Introduction

It is now well established that phosphinines are strong π-acceptor ligands whose electronic properties markedly differ both from their nitrogen counterparts, pyridines, and classical tertiary phosphanes (R_3P).[1] This singularity, which mainly results from the presence of an electropositive sp^2-phosphorus atom, has recently been exploited to stabilize electron-rich transition-metal species which are usually unstable with other ligands, except CO. The studies of Elschenbroich et al. on the synthesis of homoleptic complexes of the parent compound C_5H_5P[2] and our work with 2,2′-biphosphinine complexes are illustrative of such uncommon reactivity.[1][3] Although significant progress has recently been achieved in this direction, our knowledge of the coordination chemistry of phosphinines still remains to be improved. Indeed, the understanding of phosphinine−metal interactions is a prerequisite to the use of these ligands in more applied projects such as homogeneous catalysis, an area which has just been explored,[4] and for the elaboration of sophisticated supramolecular edifices using, for example, phosphinine-based macrocycles.[5] Furthermore, it is clear that this useful information could be transposed to other species containing sp^2-hybridized P atoms (heterocycles or acyclic derivatives) whose properties are quite similar to those of phosphinines.

The study presented here, which deals with the synthesis of a series of gold(I) complexes of phosphinines, was also motivated by the fact that phosphinine complexes of group 11 are rather rare. Indeed, whereas some derivatives of copper(I) have been described,[6] very little is known of silver and gold derivatives. As far as we are aware, only one gold complex of the 2,4,6-triphenylphosphinine has been mentioned by Schmidbaur et al. but its spectroscopic and structural data remain unknown.[7] Another important motivation concerns the highly specific properties exhibited by phosphane−gold complexes[8] in different areas such as homogeneous catalysis,[9] photochemistry (luminescence)[10] and medicine (cytotoxic and antitumour activity).[11] Furthermore, the coordination of strong π-acceptor ligands such as phosphinines raises the problem of π-back-donation from gold. Experimental results and calculations made on carbonyl complexes tend to show that this back-donation is rather weak in gold(I) and gold(0) complexes.[12] As the stability of complexed phosphinines was shown to be dramatically dependent on the electron density available at the metal centre for π-back-donation,[13] it was also interesting to probe whether the coordination to gold(I) would enhance the reactivity of phosphinines or not. Herein, we present the results of these investigations.



Results and Discussion

All our experiments were conducted with 2,6-disilylphosphinines. This choice was dictated by their availability and by the fact that we had recently developed a very efficient synthetic approach to polydentate ligands such as bis(trisphosphinines)[14] and phosphinine-based macrocycles[5] in which phosphinine units are linked by dimethylsilyl groups. Consequently, before extending our investigations to these sophisticated species, it seemed logical to focus our work on these simple models.

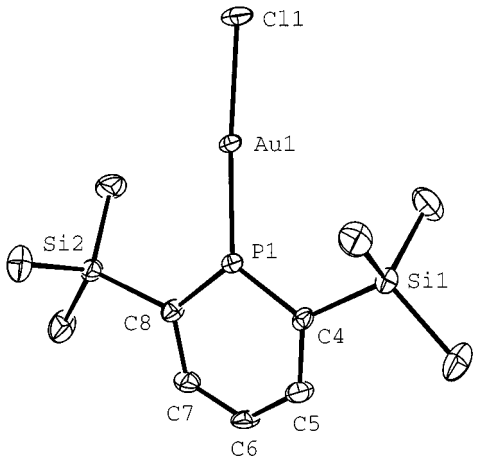
As a preliminary experiment, to assess the effects of gold coordination to the phosphinine, we investigated the reaction of the 2,6-bis(trimethylsilyl)phosphinine (**1**) with AuCl(SMe$_2$). The reaction proceeded cleanly in dichloromethane affording complex **2** which was obtained as a pale yellow solid after precipitation with hexanes (Scheme 1).

Scheme 1. Synthesis of complex **2**

The NMR data of **2** deserves comment. In the ^{31}P-NMR spectrum, **2** displays a singlet [δ (CD_2Cl_2) = 199.50] as expected since no $^1J(^{197}Au-^{31}P)$ coupling constants can be observed because of the large value of the quadrupole moment of gold ($Q = 0.59 \times 10^{-28}$ m^2)[15] which leads to a short value of the relaxation time. The strong shielding of the ^{31}P signal [δ ($CDCl_3$) = 254.50 for **1**, $\Delta\delta$ = 55.00 ppm) is difficult to rationalize and a similar effect has already been observed for (2,2′-biphosphinine)copper(I) complexes.[6] Apart from group-6 metal complexes of phosphinines, where a trend in the shielding has been noted, variations of ^{31}P-NMR chemical shifts of phosphinine complexes have not, so far, been correlated with electronic effects on the ligands. As observed for copper(I) complexes, ^{1}H signals of the β and γ protons (3,3′-H and 4,4′-H) in **2** are shifted towards lower field compared to those of the free ligand **1**. This phenomenon is accompanied by a significant increase in the corresponding coupling constant ^3J(P−H) from 9.39 Hz in **1** to 31.20 Hz in **2**. Similar effects are generally observed for other phosphinine complexes. In the ^{13}C-NMR spectrum, the coordination induces an upfield shift which correlates with the distance to the phosphorus atom. Thus, the chemical shift of C-4 is not modified (δ = 127.50 in **1** vs. δ = 127.00 in **2**), but C-3 and C-2 are more shielded by 4.50 and 11.00 ppm, respectively. This steady increase in shielding of the nuclei closest to the metal atom, which has already been observed for group-6 metal complexes, reflects that the shielding constant σ of these nuclei is mainly governed by the shielding contribution of the metal atom. Also noteworthy is the magnitude of the ^1J(P−C) coupling constant which varies from 84.40 Hz in **1** to 4.0 Hz in **2**. This very large variation, also observed to a lesser extent in other phosphinine complexes, is caused by two competing factors which are generally encountered in the case of classical complexes of tertiary phosphanes:[16] the higher degree of coordination of the P atom (decrease of the magnitude of the coupling) and the loss of the lone-pair effect (algebraic increase of the coupling). Finally, we also note the very large magnitude of the ^3J(P−C4) coupling constant indicating that the electronic delocalisation within the ring has been strongly perturbed. In order to gain structural information, an X-ray crystal analysis of **2** was carried out. An ORTEP drawing of **2** is presented in Figure 1.



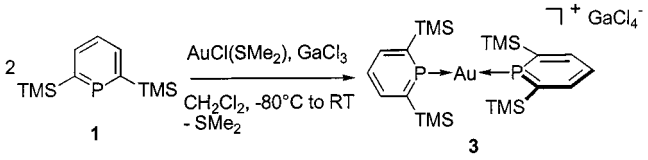


Figure 1. ORTEP drawing of **2** as determined by a single-crystal X-ray diffraction analysis; ellipsoids are drawn to enclose 50% of the electron density; hydrogen atoms are omitted for clarity; the crystallographic labelling is arbitrary and different from the numbering used for assignments of the ^{13}C-NMR spectra; selected bond lengths [Å] and angles [°]: Au1−Cl1 2.281(2), Au1−P1 2.211(2), P1−C4 1.710(6), P1−C8 1.702(7), C4−C5 1.406(9), C5−C6 1.38(1), C6−C7 1.38(1), C7−C8 1.41(1); Cl1−Au1−P1 175.36(7), Au1−P1−C4 122.6(2), C4−P1−C8 110.4(3), P1−C4−C5 117.5(5), C4−C5−C6 125.3(6), C5−C6−C7 123.7(6), C6−C7−C8 125.7(6), P1−C8−C7 117.2(5), P1−C4−Si1 120.6(4)

As expected for an [LAuX] complex, the geometry around the metal atom is perfectly linear. Whereas the Au−Cl bond length [2.281(2) Å] falls in the normal range, the Au−P(1) bond length [2.211(2) Å] appears to be slightly shorter than that observed for [AuCl(phosphane)] complexes [2.227(2) Å in the AuCl(DMPP) complex].[17] Nevertheless, this shortening cannot be considered as reflecting a better π-back-donation from the metal centre to the ligand since the hybridization of the phosphorus atom in **2** is sp^2 versus sp^3 in tertiary phosphanes.[16] More interesting information can be retrieved from an examination of bond lengths and angles within the ring. The value of the internal angle [Θ(CPC) = 110.4°] is quite large when compared to values usually recorded for free phosphinines (between 101° and 103°).[18] However, part of the effect is due to the disubstitution by silyl groups. Indeed, although the X-ray structure of ligand **1** is unknown (**1** is a liquid), we can compare this value to the angle recorded for the silacalix[4]phosphinine macrocycle which includes four dimethylsilylphosphinine units [Θ = 106.3(2)°].[5] In general, a similar increase in Θ(CPC) values is observed for phosphinines upon complexation.[19] The P=C bond lengths also allow the estimation of the extent of aromaticity within the ring. In **2**, it clearly appears that these bonds are shortened [1.710(6) and 1.702(7) Å] when compared to the parent phosphinine [1.73 Å] and to the dimethylsilyl derivative quoted above [1.734(5) and 1.746(5) Å]. This phenomenon, which has also been observed in other complexes such as Mo(C_5H_5P)$(CO)_5$[20] and homoleptic [M($C_5H_5P)_6$] (M = Cr, Mo, W) derivatives,[2d] indicates that the P−C bonds are more localized and acquire a higher double-bond character. As expected, this effect reflects a poor π-back-donation from the gold atom to the phosphinine ligand.

Indeed, a strong electronic transfer from the metal centre would tend to increase the P−C bond length since the lowest unoccupied π* molecular orbital (LUMO) of phosphinines is P−C-antibonding.[21] Another piece of data corroborates this fact. The C−C bond lengths present a significant disymmetry, $C_\alpha-C_\beta$ [1.406(9) and 1.41(1) Å] bonds being slightly longer than $C_\beta-C_\gamma$ [1.38(1) Å] bonds.

These effects are not specific to the chloride complex and similar results are also observed in the cationic $[Au(\mathbf{1})_2][GaCl_4]$ complex **3**. This complex was readily obtained by treating two equivalents of ligand **1** with $[AuCl(SMe_2)]$, followed by $GaCl_3$, which was used as a chloride abstractor at low temperature (see Scheme 2).

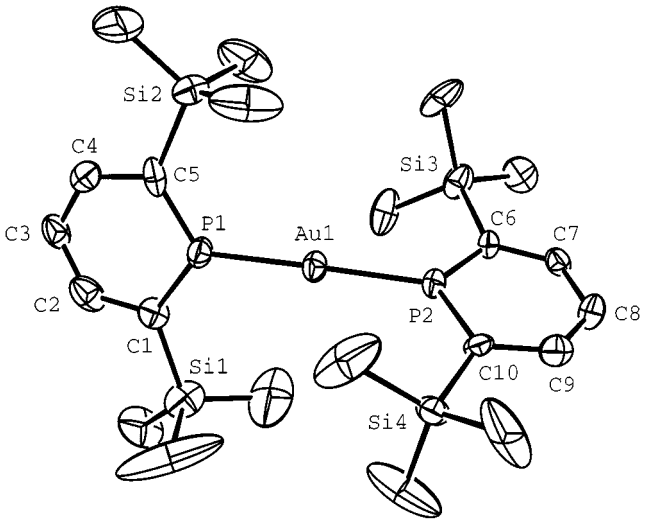
Scheme 2. Synthesis of complex **3**

Complex **3**, which was characterized as a pale yellow solid, exhibits NMR data which are overall similar to those recorded for **2**. Although a slight downfield shift is observed in the ^{31}P-NMR spectrum, the signal of **3** [$\delta(CD_2Cl_2) = 206.00$] remains shielded compared to that of the free ligand **1**. Apparently, the replacement of the chloride ion by a second phosphinine unit does not modify the electronic effects within the rings, also consistent with very poor π-back-donation from the gold atom.

To ascertain this point, the structure of **3** was elucidated by an X-ray diffraction study. An ORTEP view of **3** is presented in Figure 2. As in **2**, the geometry around the gold centre is linear[22] with the two ligands lying in two nearly perpendicular planes ($\Theta = 70.57°$). Very likely, this particular conformation allows through-space interactions between bulky trimethylsilyl groups to be minimized. The structure of **3** is comparable to that of **2** and the same trends are observed: an increase of the internal angle (mean Θ = 112.2°), short P−C bond lengths and a disymmetry between C−C bond lengths.

We then attempted to synthesize trigonal-planar Au^I species. Unfortunately, reaction of a large excess of ligand **1** with $[AuCl(SMe_2)]$, followed by treatment with $GaCl_3$ at low temperature, only led to the recovery of complex **3** and no traces of the desired $[Au(\mathbf{1})_3][GaCl_4]$ complex could be observed whatever experimental conditions were used. Very likely, this failure results from the strong steric hindrance generated by the bulky trimethylsilyl groups.

In view of these quite disappointing results, we focused our work on the preparation of hemilabile complexes of phosphinines. A recent report has demonstrated the affinity of Au^I centres for strained alkynes which are coordinated in an η^2-fashion.[23] Postulating that cationic trigonal-planar complexes incorporating two η^2-bonded alkynes and an η^1-bonded phosphinine could be prepared, we first investigated the reaction of the bis(phenylethynyldimethylsilyl)-



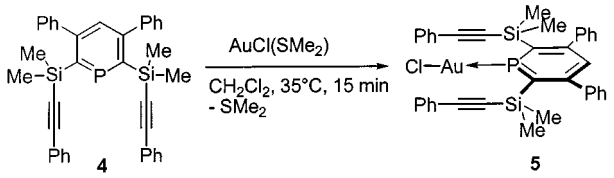


Figure 2. ORTEP drawing of **3** as determined by a single-crystal X-ray diffraction analysis; ellipsoids are drawn to enclose 50% of the electron density; hydrogen atoms are omitted for clarity; the crystallographic labelling is arbitrary and different from the numbering used for assignments of the ^{13}C-NMR spectra; selected bond lengths [Å] and angles [°]: Au1−P1 2.274(4), Au1−P2 2.290(4), P1−C1 1.73(1), P1−C5 1.69(2), P2−C(6), 1.71(1), P2−C10 1.71(1), C1−C2 1.41(2), C2−C3 1.39(2), C3−C4 1.37(2), C4−C5 1.44(2), C6−C7 1.38(2), C7−C8 1.40(2), C8−C9 1.35(2), C9−C10 1.43(2); P1−Au1−P2 175.3(2), Au1−P1−C1 123.5(5), Au1−P1−C5 123.9(5), C1−P1−C5 112.3(7), Au1−P2−C6 122.6(5), Au1−P2−C10 125.0(5), C6−P2−C10 112.1(6), P1−C1−C2 115.1(1), C1−C2−C3 127.0(1), C2−C3−C4 125.0(1), C3−C4−C5 125.0(1), P1−C5−C4 117.1(1), P2−C6−C7 116.0(1), C6−C7−C8 126.0(1), C7−C8−C9 123.0(1), C8−C9−C10 128.0(1)

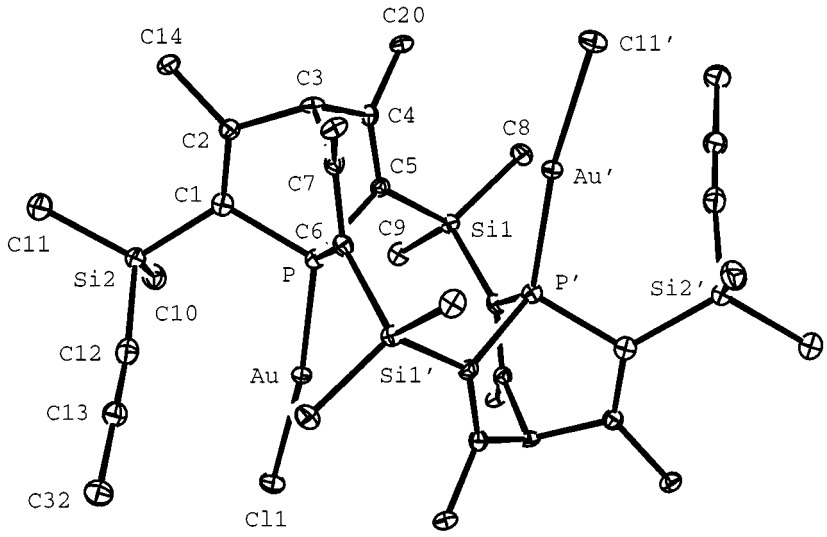
phosphinine **4** towards $[AuCl(SMe)_2]$. As previously described for the synthesis of **3**, the reaction proceeds smoothly in dichloromethane at room temperature. Complex **5** was isolated in a 95% yield as a yellow solid after a simple precipitation with hexanes (Scheme 3).

Scheme 3. Synthesis of complex **5**

Whereas ^{13}C-NMR data of the ring carbon atoms compare in every respect to those recorded for **2** and **3**, the ^{31}P-NMR signal of **5** appears at low field [δ (CD_2Cl_2) = 222.00]. This deshielding does not reflect a particular electronic situation since the signal of the free ligand is also strongly downfield shifted [δ (CD_2Cl_2) = 273.00] from that of **2**. It must be noted that chemical shifts of the alkyne moiety are not significantly perturbed when compared to those recorded for the bis(phenylethynyl)dimethylsilane. This observation indicates that no η^2-alkyne coordination to the AuCl fragment occurs in **5**.

Before studying the formation of the corresponding cationic derivative $[Au(\mathbf{4})]^+$, we performed an X-ray crystal structure analysis of **5** to probe whether the structure observed in solution is maintained in the solid or not. This

experiment led to a quite unexpected result. Every attempt to crystallize **5** failed and each experiment systematically led to insoluble microcrystals whose structure was established by an X-ray diffraction study. The structure of complex **6** is a symmetrical dimer consisting of two (1-phosphabarrelene)AuCl complex units which are connected by two $SiMe_2$ bridges. An ORTEP drawing of **6** is presented in Figure 3.



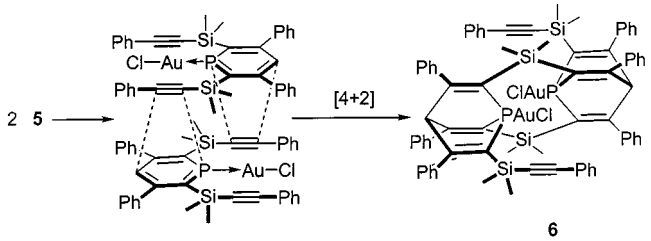


Figure 3. ORTEP drawing of **6** as determined by a single-crystal X-ray diffraction analysis; ellipsoids are drawn to enclose 40% of the electron density; hydrogen atoms are omitted for clarity; the crystallographic labelling is arbitrary and different from the numbering used for assignments of the ^{13}C-NMR spectra; selected bond lengths [Å] and angles [°]: Au−Cl1 2.286(1), Au−P2.218(1), P−C1 1.834(5), P−C5 1.835(5), P−C(6) 1.825(6), C1−C2 1.333(7), C2−C3 1.546(6), C3−C4 1.538(9), C3−C7 1.533(7), C4−C5 1.347(7), C6−C7 1.352(7); Cl1−Au−P 171.87(4), Au−P−C1 110.9(1), Au−P−C5 120.9(2), Au−P−C6 121.2(1), C1−P−C5 100.6(2), C1−P−C6 100.5(3), C5−P−C6 99.2(2), P−C1−C2 11.5(3), C1−C2−C3 116.3(4), C2−C3−C4 106.5(4), C2−C3−C7 108.1(4), C4−C3−C7 11.8(4), C3−C4−C5 118.1(4), P−C5−C4 109.4(4), P−C6−C7 109.4(4), C3−C7−C6 118.2(5)

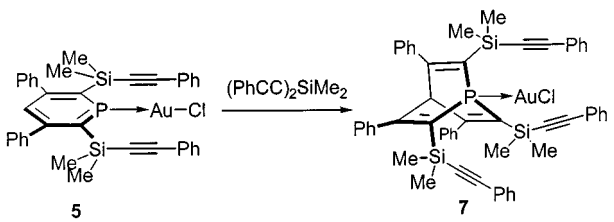


Unfortunately, due to its insolubility in common organic solvents, no NMR data of **6** could be recorded. The formation of **6** results from two [4 + 2] Diels−Alder reactions between two molecules of complex **5**, each phosphinine unit playing the role of a 1-phosphadiene (see Scheme 4).

Scheme 4. Intermolecular [4+2] cycloaddition leading to complex **6**

Apparently, this transformation only occurs during the formation of crystals and parallel experiments aimed at reproducing the synthesis of **6** under dilution conditions failed and led to colloidal Au^0 deposition. The formation of 1-phosphabarrelenes is not totally unprecedented. Usually, phosphinines do not react with alkynes, except when the latter are substituted by strongly electron-withdrawing groups (e.g. CF_3, CN) or when the triple bond is included into a strained structure.[24] Activated phosphinines in which CH unit(s) have been replaced by phosphorus or nitrogen such as 1,4-diphospha-[25a,25b] or monoaza- and diazaphosphinines[14,25c−25f] display a particular ability to react with various alkynes to give the corresponding aza- and diazabarrelenes. Moreover, it was also reported that $P-W(CO)_5$ complexes give [4 + 2] cycloadditions with activated alkynes such as dimethyl acetylenedicarboxylate or *N*-phenylmaleimide to afford 1-phosphabarrelenes and 2,3-dihydrobarrelenes complexes, respectively.[26] However, this was the first time that this kind of reaction has been observed in such mild conditions. Interestingly, as noted above, similarities are observed between the structure of these complexes and that of gold(I) studied here.

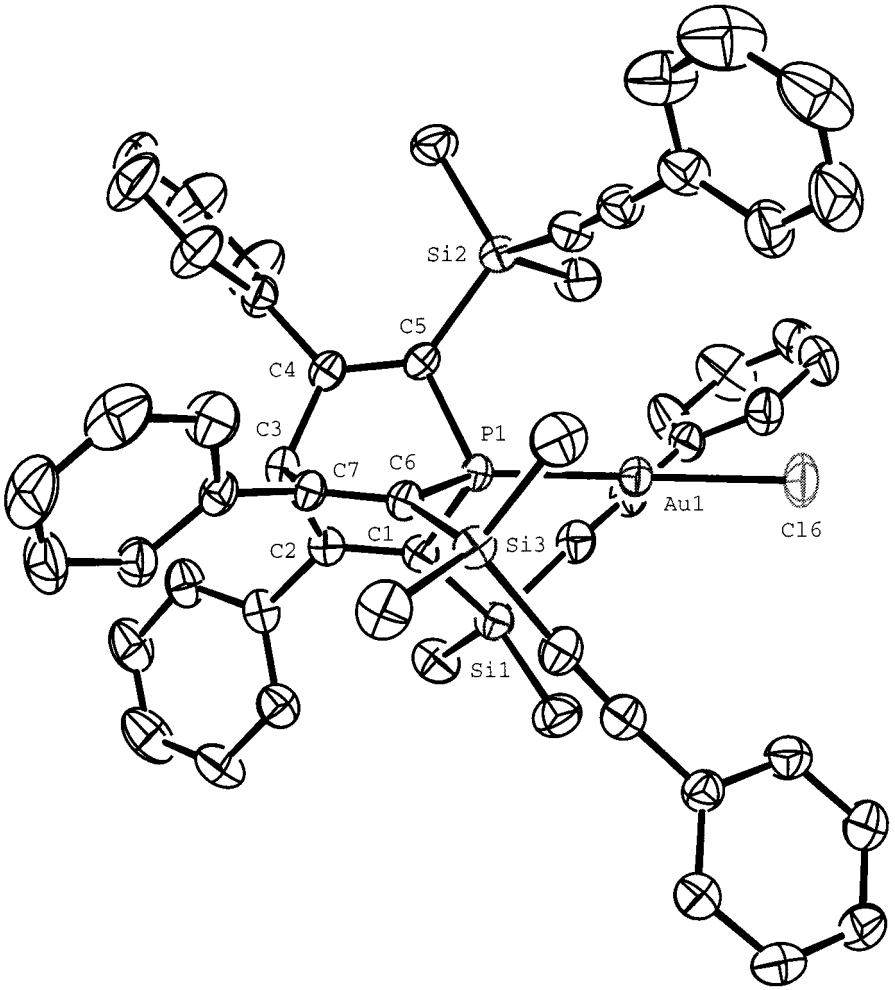
To validate the hypothesis of the double [4 + 2] Diels−Alder reaction, we decided to investigate the reaction of phosphinine **4** towards an alkyne with the hope of obtaining a soluble [4 + 2] cycloadduct. For obvious reasons, we chose the bis(phenylethynyl)dimethylsilane whose reaction with **4** should provide a symmetrical barrelene. In order to reproduce the conditions of crystallization of **6**, the reaction was carried out in concentrated medium, at room temperature. It led to total conversion into the desired symmetrical barrelene **7** within 48 h [δ (CD_2Cl_2) = −7.00] (see Scheme 5). The remarkable ease of this reaction explains why complex **5** could not be crystallized.

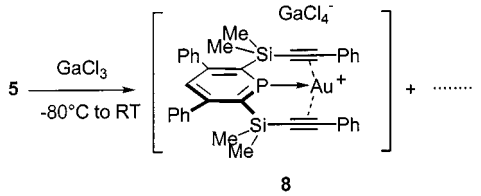
Scheme 5. Trapping of complex **5** with $(PhCC)_2SiHe_2$

To the best of our knowledge, **7** is the first example of a gold(I) barrelene complex. All NMR data (see Experimental Section) are in good agreement with the symmetrical structure proposed, thus confirming the regioselectivity of the Diels−Alder reaction. The fact that the alkyne carbon atom bearing the silicon group is attached to the P atom confirms that this latter bears a substantial positive charge.[14] Indeed, the observed regioselectivity compares with that observed in the case of 1,2 and 1,3,2-diazaphosphinines which are known to behave as strongly polarized [1,4] dipoles. To ascertain its formulation, an X-ray crystal structure analysis was carried out. An ORTEP drawing of **7** is presented in Figure 4. The structure of **7** reveals no particular features and no interactions between gold and alkynyl groups (C8−C9, C24−C25 and C40−C41) can be noted. Indeed, gold−carbon bond lengths appear to be quite long between 3.444 and 3.890 Å] and C≡C triple bond lengths fall in the expected range [from 1.203(8) to 1.212(8) Å].

Unfortunately, the isolation of the cationic derivative $[Au(\mathbf{4})]^+$ turned out to be more complicated than expected. The reaction of **5** with one equivalent of $GaCl_3$ at low temperature proceeds cleanly in dichloromethane to give complex **8** which was identified by ^{31}P-NMR spectroscopy only [δ (CH_2Cl_2) = 227.00] (see Scheme 6). Cationic complex **8** displays a poor stability in solution and after several minutes standing in dichloromethane, a purple color typical of the formation of colloidal gold can be observed concomitant with the appearance of a new signal in ^{31}P NMR at δ = 231.70.

Postulating that the latter could be the cationic complex $[Au(\mathbf{4})_2]^+$ **9**, resulting from the disproportionation of two molecules of **8**, we studied the reaction of **8** with one equivalent of ligand **4**. Indeed, complex **9**, which exhibits the expected ^{31}P-NMR resonance, was produced as pale yellow solid with a 90% yield. It must be noted that **9** can also be readily obtained by reacting two equivalents of **4** with





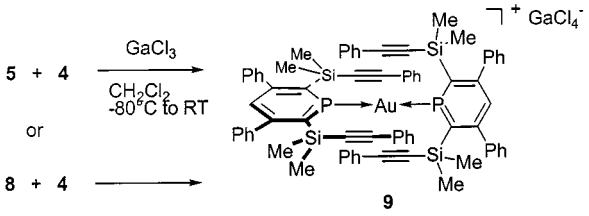


Figure 4. ORTEP drawing of **7** as determined by a single-crystal X-ray diffraction analysis; ellipsoids are drawn to enclose 50% of the electron density; hydrogen atoms are omitted for clarity; the crystallographic labelling is arbitrary and different from the numbering used for assignments of the ^{13}C-NMR spectra; selected bond lengths [Å] and angles [°]: Au1−Cl 2.273(2), Au1−P1 2.211(1), P1−C1 1.829(5), C1−C2 1.354(7), C2−C3 1.534(7), C4−C5 1.344(7), C6−C7 1.331(7), C8−C9 1.212(8), C24−C25 1.203(8), C40−C41 1.205(8); Cl−Au1−P1 176.92(7), Au1−P1−Cl6 176.92(7), Au−P1−C1 119.6(2), Au1−P1−C5 118.7(2), Au1−P1−C6 115.2(2), P1−C1−C2 109.8(4), C1−C2−C3 118.1(4), C2−C3−C4 111.1(4), Si(1)−C(8)−C(9) 174.9(5), Si2−C24−C25 174.3(5), Si(3)−C40−C41 169.8(5)

Scheme 6. Possible structure of complex **8**

$[AuCl(SMe_2)]$ in the presence of $GaCl_3$ as previously described for the synthesis of complex **3** (see Scheme 7).

Scheme 7. Synthesis of complex **9**

All the NMR data, which is comparable with those of **3**, confirm the proposed structure. An X-ray crystal structure analysis was undertaken. An ORTEP view of **9** is shown in Figure 5. As observed in the structure of **3**, P=C bond lengths appear to be rather short at 1.72(1) and 1.71(1) Å (compared to those of free silylphosphinines) and the presence of the two bulky silyl groups at the α positions of the phosphorus atom implies that the two phosphinines are twisted against each other [interplane angle Θ = 66.7(3)°]. The most interesting feature of **9** is provided by the arrangement of the four alkynyl substituents which encapsulate the gold coordination sphere. Despite this particular geometry, no interactions between the gold centre and these alkynyl groups are noted. Indeed, although shorter than in complex **7**, all Au−C bonds appear to be too long (between 3.043 and 3.308 Å) to favour an overlap between the filled 5d orbitals of the gold atom and the π* system of the triple bond. Besides, this assumption is confirmed by the C≡C triple-bond lengths which fall in the expected range [from 1.19(1) to 1.21(2) Å]. Additionally, it must be noted that no π overlap occurs between the phenyl groups and the phosphinine units.

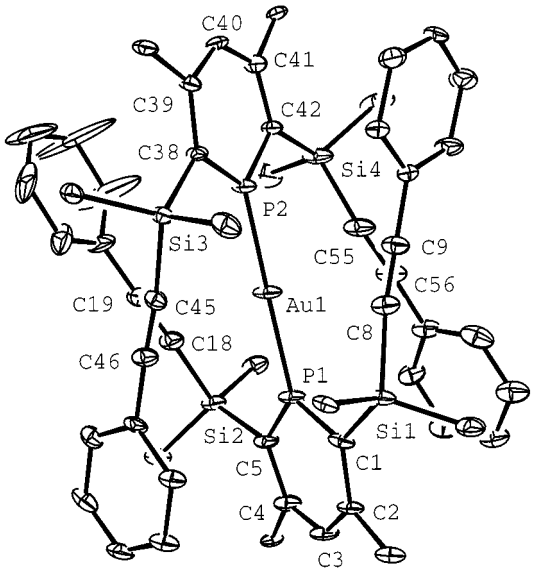

Figure 5. ORTEP drawing of **9** as determined by a single-crystal X-ray diffraction analysis; ellipsoids are drawn to enclose 50% of the electron density; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Au1−P1 2.263(2), Au1−P2 2.262(2), P1−C1 1.72(1), C1−C2 1.41(1), C2−C3 1.40(1), C3−C4 1.38(1), C4−C5 1.42(1), P1−C5 1.71(1), Si1−C8 1.861(9), C8−C9 1.19(1), C18−C19 1.21(1), C45−C46 1.20(1), C55−56 1.21(2); P1−Au1−P2 177.1(1), P1−C1−C2 117.0(7), C1−C2−C3 123 (1), C2−C3−C4 128.0(8), C3−C4−C5 123 (1), C4−C5−P1 116.4(8), C5−P1−C1 112.4(4), Si1−C8−C9 165(1), Si2−C18−C19 168(1), Si3−C45−C46 167.7(8), Si4−C55−C56 168(1)

In conclusion, we have shown that the poor π-back-donating ability of gold(I) significantly increases the dipole [1,4] character of monophosphinine ligands which are able to react under very mild conditions with alkynes to give phosphabarrelenes [4 + 2] cycloadducts. On the other hand, the existence and the appreciable stability of cationic derivatives such as **3** and **9** opens the way for a systematic investigation of the coordination chemistry of multidentate ligands including phosphinine units. Accordingly, studies aimed at including Au^+ into phosphinine-based macrocycles are currently under investigation.

Experimental Section

General: All reactions were routinely performed under nitrogen using Schlenk techniques and dry, oxygen-free solvents. Dry toluene, hexane, and *n*-pentane were obtained by distillation from sodium/benzophenone and dry CH_2Cl_2 was obtained by distillation from P_2O_5. Dry Celite was used for filtration. − NMR: Bruker AC-200 SY operating at 200.12 MHz for ^1H, 50.32 MHz for ^{13}C, and 81.91 MHz for ^{31}P; chemical shifts (ppm) are relative to TMS (^1H and ^{13}C) or 85% H_3PO_4 (^{31}P). List of abbreviations used: s, singlet; d, doublet; t, triplet; q, quadruplet; p, pseudo. − Elemental analyses: "Service d'analyse du CNRS", Gif-sur Yvette, France. Phosphinines **1**[14b] and **4**,[14b] $AuCl(SMe_2)$[27] were prepared according to published methods.

Synthesis of Complex 2: Phosphinine **1** (0.046 g, 1.9×10^{-4} mol) and $AuCl(SMe_2)$ (0.056 g, 1.9×10^{-4} mol) were weighed in air and placed under N_2. Freshly distilled CH_2Cl_2 (3 mL) was then added by syringe into the Schlenk flask, and the mixture allowed to stir at 35°C. ^{31}P-NMR spectroscopy indicated that the reaction was finished within 15 min. Reduction of the volume, followed by hexane precipitation and filtration yielded a pale yellow solid (0.085 g, 95%). Crystallization was achieved by layering hexanes onto a CH_2Cl_2 solution of complex, m.p. 120°C. − ^{31}P NMR (CD_2Cl_2): δ = 199.50 (s). − ^{13}C NMR (CD_2Cl_2): δ = 0.50 (d, $^3J_{C,P}$ = 4.31 Hz, 2 × $SiMe_3$), 127.00 (d, $^3J_{C,P}$ = 50.0 Hz, C-4), 143.50 (d, $^2J_{C,P}$ = 18.00 Hz, C-3,5), 160.00 (d, $^1J_{C,P}$ = 4.00 Hz, C-2,6). − ^1H NMR (CD_2Cl_2): δ = 0.50 (s, 18 H, 2 × $SiMe_3$), 7.51−7.62 (td, 1 H, $^4J_{H,P}$ = 6.70 Hz, $^3J_{H,H}$ = 8.20 Hz, 4-H), 8.20−8.40 (dd, 2 H, $^3J_{H,P}$ = 31.20 Hz, $^3J_{H,H}$ = 8.20 Hz, 3,5-H). − $C_{11}H_{21}AuClPSi_2$ (472.85): calcd. C 27.94, H 4.48; found C 28.15, H 4.66.

Synthesis of Complex 3: Phosphinine **1** (0.060 g, 2.5×10^{-4} mol) and $AuCl(SMe_2)$ (0.037 g, 1.25×10^{-4} mol) were weighed in air and placed under N_2. Freshly distilled CH_2Cl_2 (3 mL) was then added by syringe into the Schlenk flask, and the mixture allowed to stir at room temperature for 10 min. In a glove box, $GaCl_3$ (0.022 g, 1.25×10^{-4} mol) was weighed and put in a second

Schlenk flask. Outside the box, CH_2Cl_2 was added by syringe into the flask and the solution added to the first flask at −78°C using a cannula. The mixture was warmed to room temperature and stirred. ^{31}P-NMR spectroscopy indicated that the reaction was finished within 15 min. Reduction of the volume, followed by hexanes precipitation and filtration yielded a pale yellow solid (0.10 g, 90%). Crystallization was achieved by layering hexanes onto a CH_2Cl_2 solution of the complex, m.p. 140°C. − ^{31}P NMR (CD_2Cl_2): δ = 206.10 (s). − ^{1}H NMR (CD_2Cl_2): δ = 0.57 (s, 36 H, 4 × $SiMe_3$), 7.80−7.89 (m, 2 H, 2 × 4-H), 8.50−8.71 (ptd, 4 H, $\Sigma J_{H,P}$ = 42.35 Hz, 2 × 3,5-H). − ^{13}C NMR (CD_2Cl_2): δ = 0.85 (s, 4 × $SiMe_3$), 129.90 (pt AXX′, $\Sigma J_{C,P}$ = 50.60 Hz, 2 × C-4), 144.40 (pd AXX′, $\Sigma J_{C,P}$ = 14.75 Hz, 2 × C-3,5), 164.55 (s, 2 × C-2,6). − $C_{22}H_{42}AuCl_4GaP_2Si_4$ (889.37): calcd. C 29.71, H 4.76; found C 30.05, H 4.96.

Synthesis of Complex 5: Phosphinine **4** (0.200 g, 3.55 × 10^{-4} mol) and AuCl(SMe_2) (0.104 g, 3.55 × 10^{-4} mol) were weighed in air and placed under N_2. Freshly distilled CH_2Cl_2 (5 mL) was then added by syringe into the Schlenk flask, and the mixture allowed to stir at 35°C. ^{31}P-NMR spectroscopy indicated that the reaction was finished within 15 min. Reduction of the volume, followed by hexanes precipitation and filtration yielded a pale yellow solid (0.269 g, 95%), m.p. 160°C. − ^{31}P NMR (CD_2Cl_2): δ = 222.00 (s). − ^{13}C NMR (CD_2Cl_2): δ = 2.20 (d, $^3J_{C,P}$ = 4.20 Hz, 2 × $SiMe_2$), 94.60 (d, $^3J_{C,P}$ = 8.90 Hz, 2 × CCPh), 110.70 (s, CCPh), 123.0−129.70 (m, CH of Ph), 127.05 (d, $^3J_{C,P}$ = 50.0 Hz, C-4), 144.20 (d, $^2J_{C,P}$ = 12.000 Hz, C-3,5), 151.20 (d, $^2J_{C,P}$ = 12.00 Hz, Cq of C_6H_5), 158.40 (d, $^1J_{C,P}$ = 15.85 Hz, C-2,6). − ^{1}H NMR (CD_2Cl_2): δ = 0.30 (s, 12 H, 2 × $SiMe_2$), 7.10−7.60 (m, 21 H,4 × Ph, 4-H). − $C_{37}H_{33}AuClPSi_2$ (797.24): calcd. C 55.74; H 4.17; found C 55.95, H 4.46.

Synthesis of Complex 6: A CH_2Cl_2/hexane solution of gold complex **5** was placed in a tube and left under a static N_2 pressure. Pale yellow crystals slowly grew out of the solution together with a slight purple precipitate of colloidal gold. These crystals were very insoluble which prevented spectrocopic analysis. The crystal gave a combustion analysis consistent with the starting complex, m.p. 200°C. − $C_{37}H_{33}AuClPSi_2$ (797.24): calcd. C 55.74 H 4.17; found C 55.95, H 4.46.

Synthesis of Complex 7: Complex **5** (0.239 g, 3.00 × 10^{-4} mol) and bis(phenylethynyl)dimethylsilane (0.078 g, 3.00 × 10^{-4} mol) were weighed in air and placed under N_2. Freshly distilled toluene (5 mL) was then added by syringe into the Schlenk flask, and the mixture stirred at room temperature for 48 h. Purple gold(0) colloids were removed by filtration through a pad of Celite. Reduction of the volume and hexanes precipitation yielded a pale yellow solid (0.269 g, 85%). Suitable crystals for X-ray analysis were grown by slow diffusion of hexanes into a concentrated CH_2Cl_2 solution of the complex, m.p. 175°C. − ^{31}P NMR (CD_2Cl_2): δ = −7.00 (s). − ^{13}C NMR (CD_2Cl_2): δ = 1.10 (d, $^3J_{C,P}$ = 2.20 Hz, 3 × $SiMe_2$), 78.90 (d, $^3J_{C,P}$ = 44.11 Hz, C-4), 92.50 (s, 3 × CCPh), 109.30 (s, 3 × CCPh), 127.60−132.90 (m, CH of Ph), 141.50 (d, $^2J_{C,P}$ = 12.14 Hz, C-3), 173.80 (d, $^1J_{C,P}$ = 9.85 Hz, C-2). − $C_{55}H_{49}AuClPSi_3$ (1057.65): calcd. C 62.46, H 4.67; found C 62.58, H 4.93.

Synthesis of Complex 9: Phosphinine **4** (0.141 g, 2.5 × 10^{-4} mol) and AuCl(SMe_2) (0.037 g, 1.25 × 10^{-4} mol) were weighed in air and placed under N_2. Freshly distilled CH_2Cl_2 (3 mL) was then

added by syringe into the Schlenk flask, and the mixture allowed to stir at room temperature for 10 min. In a glove box, $GaCl_3$ (0.022 g, 1.25×10^{-4} mol) was weighed and placed into a second Schlenk flask. Outside the box, CH_2Cl_2 was added by syringe into the flask and the solution added to the first flask at −78°C using a cannula. The mixture was warmed to room temperature and stirred. ^{31}P-NMR spectroscopy indicated that the reaction was finished within 15 min. Reduction of the volume, followed by hexane precipitation and filtration yielded a pale yellow solid (0.10 g, 90%). Crystallization was achieved by layering hexanes onto a CH_2Cl_2 solution of the complex, m.p. 165°C. − ^{31}P NMR (CD_2Cl_2): δ = 231.70 (s). − ^{1}H NMR (CD_2Cl_2): δ = 0.25 (s, 24 H, 4 × $SiMe_2$), 7.10−7.60 (m, 42 H,8 × Ph, 2 × H-4). − ^{13}C NMR (CD_2Cl_2): δ = 2.60 (s,4 × $SiMe_2$), 95.35 (pt, AXX′, $\Sigma J_{C,P}$ = 4.60 Hz, 4 × CCPh), 113.90 (s, CCPh), 128.20−132.50 (m, CH of Ph), 133.90 (pt, AXX′, $\Sigma J_{C,P}$ = 18.25 Hz, 2 × C-4), 143.40 (pt, $\Sigma J_{C,P}$ = 6.10 Hz, 2 × C-3,5), 151.40 (pt, AXX′, $\Sigma J_{C,P}$ = 4.60 Hz, 2 × Cq of C_6H_5), 158.75 (pt, AXX′, $\Sigma J_{C,P}$ = 6.10 Hz, 2 × C-2,6). − $C_{74}H_{66}AuCl_4GaP_2Si_4$ (1538.13): calcd. C 57.79, H 4.33; found C 55.85, H 4.46.

X-ray Structural Analysis: For compounds **2**, **3, 6** and **9**, data were collected at 123 ± 0.5 K with an Enraf Nonius CAD4 diffractometer; data collection for **7** was conducted at room temperature using a KappaCCD diffractometer. Mo-K_α (λ = 0.71073 Å) radiation and a graphite monochromator were used in all cases. The crystal structures were solved and refined using the Enraf Nonius MOLEN package (maXus for the kappaCCD). In the case of **7**, final refinement was made with SHELX-97.[28] The structure of **9** calls for an additional comment. The asymmetric unit contains two dichloromethane molecules of crystallization. While one molecule can be directly modelled, the second one is very highly disordered. To address this problem, we used the Platon[29] SQWEEZE function and completed refinement using SHELX-97, thus leading to an acceptable *R* value. Other experimental details are given in Table 1 (compounds **2** and **3**) and 2 (compounds **6**, **7** and **9**) . Crystallographic data (excluding structure factors) for the structures reported have been deposited with the Cambridge Data Centre as supplementary publications CCDC-115213 to -115217. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

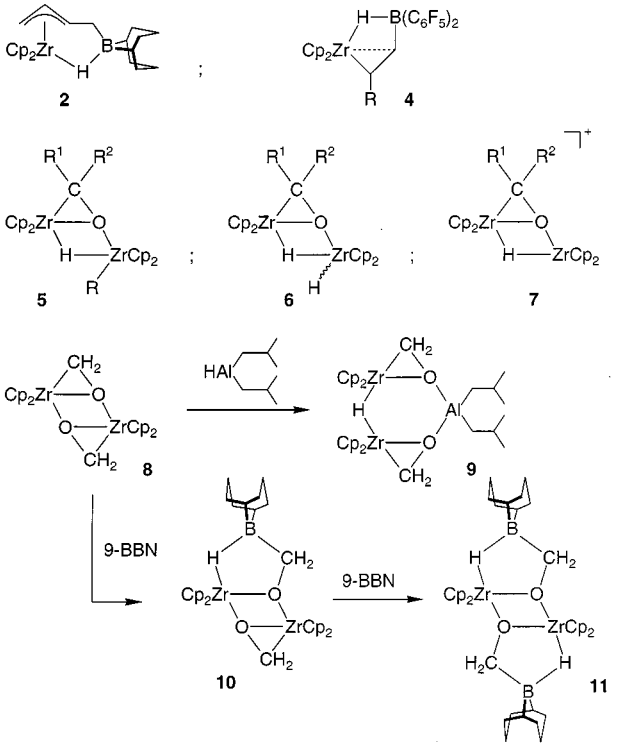
Borane Insertion into Group-4 Metal-to-Carbon Bonds: The Reaction of $HB(C_6F_5)_2$ with (η^2-Formaldehyde)zirconocene Dimer and with (Butadiene)zirconocene



Ulrich Blaschke,[a] Gerhard Erker,*[a] Roland Fröhlich,[a][+] and Oliver Meyer[a][+]

Keywords: Metallaoxirane / HBR_2 addition / (Formaldehyde)zirconocene / (Butadiene)zirconocene / Heterocycles / Boron

(η^2-Formaldehyde)zirconocene dimer (**8**) cleanly adds one or two molar equivalents of the borane $HB(C_6F_5)_2$ by insertion of the H–[B] unit into the zirconium–carbon bond of the metallaoxirane moieties to form the mono- and bis-insertion products **16** and **17**, respectively. These systems contain five-membered heterocyclic rings that are built up by connecting five different elements, namely H, B, C, O, and Zr. The bis(borane) insertion product **17** was characterized by an X-ray crystal structure analysis. (Butadiene)zirconocene reacts with $HB(C_6F_5)_2$ in a similar way by insertion of the H–[B] unit into the (butadiene)C4–Zr linkage to form the metallacycle **18**.

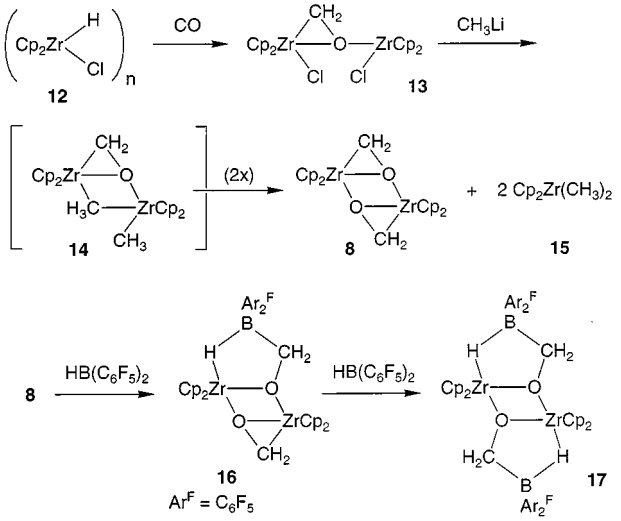
Introduction

Main-group and transition-metal hydrides react in various ways with (η^2-alkene) group-4 metallocene complexes and with their heteroatom analogues, the (η^2-aldehyde- and -ketone)metallocenes. 9-BBN adds cleanly to (butadiene)zirconocene (**1**)[1] to yield **2**;[2] similarly the electrophilic $H-B(C_6F_5)_2$ (**3**) ("Piers' borane")[3] adds to (η^2-alkene)zirconocenes, generated in situ, to yield **4** (see Scheme 1).[4–6] (η^2-Ketone and η^2-aldehyde)zirconocenes show a more diverse reactivity. They form the 1:1 addition products with $Cp_2M^{IV}H_2$ or $Cp_2M^{IV}(R)H$ units, and even with the elusive monomeric Cp_2Zr-H^+ cation (to yield the dinuclear systems **5**, **6**, and **7**, respectively).[7][8] (η^2-Formaldehyde)zirconocene dimer (**8**) is known to add diisobutylaluminium hydride to form **9**, which exhibits the intact metallaoxirane subunits,[9][10] whereas 9-BBN reacts differently with **8** and inserts sequentially into the $Zr-CH_2$ bond of the metallaoxirane to give the respective HBCOZr-containing five-membered heterocyclic systems **10** and **11** (see Scheme 1).[11][12] We have now extended this series of studies and reacted (η^2-formaldehyde)zirconocene dimer (**8**) as well as (butadiene)zirconocene (**1**) with $HB(C_6F_5)_2$ (**3**). The outcome of these reactions is described in this article.

Scheme 1. Previously reported main-group and transition-metal hydride adducts to (diene-, alkene-, and η^2-ketone and -aldehyde)zirconocene complexes

Results and Discussion

Reaction of (η^2-Formaldehyde)zirconocene Dimer with $HB(C_6F_5)_2$



(η^2-Formaldehyde)zirconocene was prepared starting from $[Cp_2Zr(H)Cl]_n$ (**12**). Carbonylation resulted in the formation of the dinuclear complex **13**, as described by C. Floriani et al.[13] Subsequent treatment with two molar equivalents of methyllithium led to the direct formation of $[Cp_2Zr(OCH_2)]_2$ (**8**) and dimethylzirconocene (**15**), as we had described previously.[9] The reaction probably proceeded via the unstable adduct $[Cp_2Zr(OCH_2) \cdot Me_2ZrCp_2]$ (**14**).

The borane $HB(C_6F_5)_2$ (**3**) was added to the (η^2-formaldehyde)zirconocene dimer at ambient temperature. The reaction was first carried out in deuterated solvent ([D_6]benzene or [D_2]dichloromethane) and monitored directly by

NMR spectroscopy. Combination of the two components in a ca. 1:1 ratio at room temperature resulted in the instantaneous formation of a single new compound, showing two Cp singlets at δ = 6.23 and 5.99 (^{1}H)/113.8 and 108.9 (^{13}C NMR) in a 10:10 ratio in addition to signals of two CH_2 groups [^{1}H/^{13}C NMR: δ = 4.26 (br., 2 H)/78.2 (br., B−CH_2) and δ = 3.22 (s, 2 H)/72.0 (Zr−CH_2)]. Although the B−*H* signal was not located, we assumed that insertion of the HB moiety of the $HBAr^F_2$ reagent into the Zr−CH_2 linkage of one of the metallaoxirane subunits of **8** had taken place with formation of the unsymmetrical dimetallatricyclic product **16**. In agreement with this interpretation was the observation of a ^{11}B-NMR resonance of **16** at δ = −13.5 − at a typical tetracoordinate borate chemical shift value − as a doublet with a $^1J_{BH}$ coupling constant of 65 Hz. This value was markedly reduced from a typical $HB(R)_3^-$ coupling constant (ca. 80−85 Hz), which probably indicated a reduced B···H bond order of the bridging Zr−(μ-H)−B situation in the heterocyclic addition complex **16**.

Scheme 2. Preparation of (η^2-formaldehyde)zirconocene dimer and its reaction with $HB(C_6F_5)_2$

Further addition of $HB(C_6F_5)_2$ to the solution rapidly resulted in HB insertion into the remaining ($ZrOCH_2$) moiety with formation of the double insertion product (**17**). The reaction was carried out in toluene solution (5 min at ambient temperature) to give **17** in ca. 50% yield. The rather poorly soluble product **17** exhibited a Cp singlet at δ = 6.43 (20 H) in [D_2]dichloromethane in addition to a CH_2 singlet (4 H) at δ = 4.45. The *H*−B signal was not located. The ^{11}B-NMR resonance is at δ = −13.2 (very broad signal, $\nu_{1/2} \approx 170$ Hz).

Single crystals suitable for X-ray structure determination of **17** were obtained from [D_2]dichloromethane. The Zr−(μ-H)−B hydrogen atoms could be located in the difference Fourier map. Figure 1 shows a view of the structure of **17** that contains a (disordered) molecule of the [D_2]dichloromethane solvent in the crystal.

The X-ray crystal structure analysis (see Figure 1) shows that the H−$B(C_6F_5)_2$ reagent has inserted into the Zr−CH_2 linkage of each of the metallacyclic three-membered rings of the dinuclear starting material **8** to form the 2:1 addition product **17**. A planar dimetallatricyclic framework has resulted in which two exceptional heterocyclic ring systems − each exhibiting a five-membered ring system made up by the five different core atoms Zr, O, C, B, and H − are connected by two Zr−O linkages. Actually, the connecting metal−oxygen bonds in the central four-membered Zr_2O_2 ring[15] (i.e. O1−Zr1A) are shorter [2.127(2) Å] than the respective Zr1−O1 bonds [2.148(2) Å] inside the lateral five-membered heterocycles. The bond angles at O inside the central four-membered ring are 111.2(1)° (Zr1−O1−Zr1A), the adjacent angle at Zr (O1−Zr1−O1A) is much smaller at 68.8(1)°. This indicates the presence of an additional coordination at the bent metallocene unit, which is formed by the B−(μ-H)−Zr bridge inside the five-membered ring.[14] The overall arrangement of the ZrOCBH ring system in **17** is very similar, as observed in the **8** + 9-BBN addition product **11** (see Scheme 1 and Table 1),[11] only that the bridging hydrogen atom in **17** seems to be located significantly closer to the boron atom. This might reflect the increased electrophilicity of the

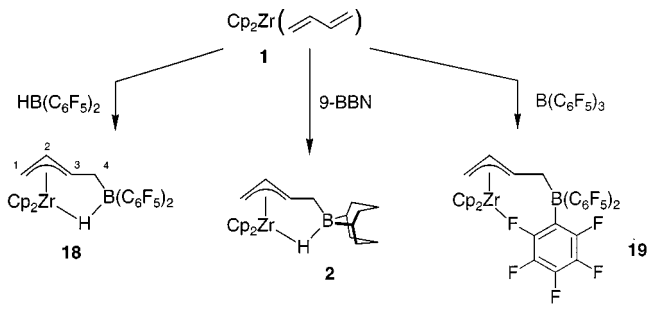
boron atom bonded to the two strongly electron-withdrawing C_6F_5 substituents as compared to the 9-BBN subunit, but in view of the general uncertainty of H-atom location by X-ray diffraction, such an effect should not be overemphasized.[14]



Reaction of (Butadiene)zirconocene with $HB(C_6F_5)_2$

(Butadiene)zirconocene (**1**) reacted rapidly with $HB(C_6F_5)_2$ to form a 1:1 addition product (75% isolated). It showed the ^1H-/^{13}C-NMR resonances of a pair of diastereotopic Cp ligands at zirconium (δ = 5.23, 5.08/107.8, 106.9 in [D_6]benzene), a pair of diastereotopic C_6F_5 substituents at B, a broad Zr−(μ-H)−B ^1H-NMR signal at δ = −3.3, and a very broad ^{11}B-NMR resonance at δ = −32 ($\nu_{1/2} \approx 170$ Hz). The ^1H- and ^{13}C-NMR resonances of the C_4H_6[B] unit of **18** are listed in Table 2. A comparison with the respective NMR signals of the complexes **2** and **19**, previously obtained from the addition reaction of (butadiene)-zirconocene with 9-BBN[2] and $B(C_6F_5)_3$,[16][17] respectively, show a number of subtle differences, but a similar overall spectroscopic environment.[18] This indicates the occurrence of an analogous product structure in the $HB(C_6F_5)_2$ + (butadiene)$ZrCp_2$ addition reaction. We must assume that the H−B functional group of the reagent **3** has also added the electrophilic boron center to the butadiene terminus and the hydride to the zirconium center to give the metallacyclic (π-allyl)Zr(μ-H)B complex **18**.

Table 2. A comparison of selected ^1H- and ^{13}C-NMR data of the (butadiene)zirconocene borane adducts **18**, **2**, and **19**

Scheme 3. Reaction of (butadiene)zirconocene with $HB(C_6F_5)_2$ and related electrophilic borane reagents

Conclusions

We conclude that the electrophilic borane $H-B(C_6F_5)_2$ has probably added to (butadiene)zirconocene in an analogous way as has 9-BBN. In the reaction with the (η^2-formaldehyde)zirconocene dimer there was the attractive alternative reaction possibility of $HB(C_6F_5)_2$ to add in a similar fashion as had been observed for the $H-AlR_2$ reagent or $H-ZrCp_2^+$,[8][10] namely by addition of the H−M unit to the dipolar Zr−O edge of the metallaoxirane template. However, our experiment has shown that the electrophilic boron center in the reagent **3** shows no tendency to add to the nucleophilic metallaoxirane oxygen atom to form such an adduct. Instead, insertion of the HB moiety into the $Zr-CH_2$[O] bond of the metallacyclic three-membered ring of **8** is observed, leading to the formation of the respective five-membered heterocycle, as was observed in the analogous case of the 9-BBN addition to (η^2-formaldehyde)zirconocene (**8**).[11] From these experiments, it appears that $HB(C_6F_5)_2$ behaves as an example of an ordinary borane reagent, just as 9-BBN or $HBEt_2$,[3b] despite the presence of two strongly electron-withdrawing $-C_6F_5$ substituents at the boron atom.

Experimental Section

Reactions were carried out under argon using Schlenk-type glassware or in a glovebox. Solvents were dried and distilled under argon prior to use. For more general information including a list of spectrometers and instruments used for the physical characterization of the compounds see ref.[8] The starting materials $HB(C_6F_5)_2$ (**3**),[3a] (η^2-formaldehyde)zirconocene dimer (**8**),[9] and (η^4-butadiene)zirconocene (**1**)[1] were prepared according to literature procedures.

Reaction of (η^2-Formaldehyde)zirconocene Dimer (8) with $HB(C_6F_5)_2$ (3) in a 1:1 Ratio. − Formation of 16 (NMR Experiment): Complex **8** (15.0 mg, 29.6 μmol) and the borane **3** (10.3 mg, 29.8 μmol) were suspended in 1 mL of [D_6]benzene. Within 5 min, the starting materials had dissolved to give a pale yellow solution. NMR-spectroscopic analysis revealed the formation of **16**. − ^1H NMR (200.1 MHz, [D_6]benzene): δ = 5.79, 5.52 (s, each 10 H, Cp), 4.27 (br., 2 H, $B-CH_2$), 2.81 (s, 2 H, $Zr-CH_2$), $B-H$ signal not observed. − ^{11}B NMR (64.2 MHz, [D_6]benzene): δ = −13.0 (br., d). − The reaction was analogously carried out in [D_2]dichloromethane to also generate **16**: ^1H NMR (200 MHz, [D_2]dichloromethane): δ = 6.23, 5.99 (s, each 10 H, Cp), 4.26 (br., 2 H, $B-CH_2$), 3.22 (s, 2 H, $Zr-CH_2$), $B-H$ signal not observed. − ^{13}C NMR (50.3 MHz, [D_2]dichloromethane): δ = 148.2, 139.3, 137.5 [each d, $^1J_{CF}$ = 240 Hz, *o*-, *p*-, *m*-$B(C_6F_5)_3$], 113.8, 108.9 (Cp), 78.2 (br., $B-CH_2$), 72.0 ($Zr-CH_2$), *ipso*-C resonance of C_6F_5 not observed. − ^{11}B NMR (64.2 MHz, [D_2]dichloromethane): δ = −13.5 (d, $^1J_{BH}$ = 65 Hz).

Reaction of 8 with 3 in a 1:2 Stoichiometry. − Preparation of 17: The addition reaction was carried out as an NMR experiment in both [D_6]benzene and [D_2]dichloromethane, and on a preparative scale. Typical NMR experiment: Complex **8** (15.0 mg, 29.6 μmol) and $HB(C_6F_5)_2$ (20.6 mg, 58.1 μmol) were suspended in 1 mL of [D_6]benzene. The mixture was stirred for 5 min, then the precipitated product was collected by filtration and characterized by NMR spectroscopy in a 1:1 [D_6]benzene/[D_8]toluene mixture [^1H

NMR: δ = 6.21 (s, 20 H, Cp), 4.36 (br., 4 H, B−CH_2−Zr), B−H resonance not observed; ^{11}B NMR: δ = −13.0 (br., $\nu_{1/2} \approx 210$ Hz]. The reaction between **8** and **3** in a 1:2 ratio was also carried out in [D_2]dichloromethane: ^{1}H NMR (200.1 MHz): δ = 6.43 (s, 20 H, Cp), 4.45 (br., 4 H, B−CH_2−Zr), B−H resonance not observed; ^{13}C NMR (50.3 MHz): δ = 115.5 (Cp), other signals not detected due to the low solubility of **17**; ^{11}B NMR (64.2 MHz): δ = −13.2 (br., $\nu_{1/2} \approx 170$ Hz).

Reaction of 8 with 3 on a Preparative Scale: (Formaldehyde)zirconocene dimer (**8**, 60 mg, 119 μmol) and $HB(C_6F_5)_2$ (**3**, 85 mg, 246 μmol) were introduced as solids into a Schlenk tube. Toluene (3 mL) was added at ambient temperature and the mixture vigorously stirred. The solid reagents dissolved within ca. 1 min, and within a reaction time of ca. 5 min a precipitate of the product **17** formed. It was allowed to settle, the supernatant liquid was decanted, the remaining solid was washed with toluene (1 mL) and dried in vacuo to give 78 mg (51%) of **17**. The product contained one equivalent of toluene, m.p. 99°C, 178°C (decomp.). − $C_{46}H_{26}B_2F_{20}O_2Zr_2 \cdot C_7H_8$ (1286.9): calcd. C 49.47, H 2.66; found: C 49.47, H 3.36.

X-ray Crystal Structure Analysis of 17: Single crystals were obtained from [D_2]dichloromethane solution at room temperature. Formula $C_{46}H_{26}B_2F_{20}O_2Zr_2 \cdot 2\ CD_2Cl_2$, M = 1368.58, light yellow crystal, 0.25 × 0.20 × 0.05 mm, a = 14.295(1), b = 15.430(1), c = 11.513(1) Å, β = 103.12(1)°, V = 2473.2(3) Å^3, $\rho_{calcd.}$ = 1.832 g cm^{-3}, F(000) = 1344 e, μ = 7.55 cm^{-1}, absorption correction by SORTAV (0.834 ≤ T ≤ 0.963), Z = 2, monoclinic, space group $P2_1/c$ (No. 14), λ = 0.71073 Å, T = 198 K, ω and φ scans, 22325 reflections collected (±h, ±k, ±l), [(sinθ)/λ] = 0.71 Å^{-1}, 7495 independent and 5756 observed reflections [$I \geq 2\ \sigma(I)$], 365 refined parameters, R = 0.049, wR^2 = 0.134, max. residual electron density 1.93 (−1.46) e Å^{-3} in the region of the solvent molecule, hydrogen atoms at boron atoms from difference Fourier map and refined free, all other hydrogen atoms calculated and refined as riding atoms. The data set was collected with a Nonius KappaCCD diffractometer, placed on a Nonius rotating anode generator FR591.[19] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-120189. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat. + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk].

Reaction of (Butadiene)zirconocene (1) with $HB(C_6F_5)_2$ (3). − Preparation of 18: A mixture of (butadiene)zirconocene (**1**) (199 mg, 0.72 mmol) and of $HB(C_6F_5)_2$ (**3**) (250 mg, 0.72 mmol) in toluene (10 mL) was stirred for 30 min at room temperature. Solvent was removed from the red-brown solution. The resulting solid was stirred up in pentane (10 mL). The solid product was collected by filtration, washed with 10 mL of pentane and dried in vacuo to give 335 mg (75%) of **18**, m.p. 162°C (decomp.) − ^{1}H NMR (360.1 MHz, [D_6]benzene): δ = 5.23, 5.08 (s, each 5 H, Cp), 5.15 (m, 1 H, 2-H), 4.38 (m, 1 H, 3-H), 3.64 (m, 1 H, 4-H), 1.81 (m, 1 H, 1-H), 1.69 (m, 1 H, 1-H′), 1.46 (m, 1 H, 4-H′), −3.3 (br., 1 H, B-*H*). − ^{13}C NMR (90.6 MHz, [D_6]benzene): δ = 149.3 and 148.3, 140.3 and 139.9, 137.7 and 137.5 [each d, $^1J_{CF}$ = 240 Hz, *o*-, *p*-, *m*-$B(C_6F_5)_3$], 120.1 (C-2), 107.8, 106.9 (Cp), 96.2 (C-3), 49.1 (C-1), 25.5 (br., C-4). − GCOSY (360.1 MHz, [D_6]benzene): δ = 5.15/4.38 (2-H/3-H), 5.15/1.81 (2-H/1-H), 5.15/1.69 (2-H/1-H′), 4.38/3.64 (3-H/4-H), 4.38/1.46 (3-H/4-H′), 3.46/1.46 (4-H/4-H′), 1.81/1.69 (1-H/1-H′). − HETCOR (360.1 MHz, [D_6]benzene): δ = 120.1/5.15 (C-2), 107.8/5.08 (Cp), 106.9/5.23 (Cp), 96.2/4.38 (C-3), 49.1/1.81 (C-1/1-H), 49.1/1.69 (C-1/1-H′). − ^{11}B NMR (64.2 MHz, [D_6]benzene): δ = −32.4. − ^{19}F NMR (282.4 MHz, [D_6]benzene): δ = −131.1, −131.8 [*o*-$B(C_6F_5)_3$], −156.9, −159.0 [*p*-$B(C_6F_5)_3$], −162.7, −163.5 [*m*-$B(C_6F_5)_3$]. − IR (KBr): $\tilde{\nu}$ = 3128, 2962, 2916, 2875, 2843, 1782, 1643, 1515, 1464, 1376, 1278, 1207, 1096, 1017, 971, 816, 734 cm^{-1}. − $C_{26}H_{17}BF_{10}Zr$ (621.44): calcd. C 50.25, H 2.76; found C 48.99, H 2.87.

Synthesis and Characterisation of New Arsonium Salts and Crystal Structures of Trimethylarsonium Undecafluorodiarsenate $(CH_3)_3AsH^+As_2F_{11}^-$ and Trimethylarsonium Hexafluoroantimonate $(CH_3)_3AsH^+SbF_6^-$

Rolf Minkwitz,*[a] Claudia Hirsch,[a] and Thorsten Berends[a]

Keywords: Arsonium salts / Superacidic systems / Structure elicidation

The reaction of trimethylarsane in the superacidic systems hydrogen/fluoride antimony pentafluoride and hydrogen fluoride/arsenic pentafluoride leads to trimethylarsonium fluorometallates. These salts are stable up to 60 °C and 5 °C, respectively. Structures were successfully elucidated in the cases of trimethylarsonium undecafluorodiarsenate and trimethylarsonium hexafluoroantimonate. $(CH_3)_3AsH^+As_2F_{11}^-$ crystallizes in the monoclinic space group $P2_1/n$ with four formula units per unit cell with the dimensions a = 7.362(1), b = 12.589(1), c = 13.598(1) Å and β = 95.37(1)°. $(CH_3)_3AsH^+SbF_6^-$ crystallizes in the monoclinic space group $P2_1/m$ with four formula units per unit cell with the dimensions a = 8.313(1), b = 8.855(1), c = 13.285(1) Å and β = 94.358(1)°.

Introduction

Arsanes are much weaker bases than amines, although they do demonstrate nucleophilic properties. For instance, arsane is protonated during the reaction with hydrogen bromide or hydrogen iodide (Equation 1).[1]

$$AsH_3 + HX \rightarrow AsH_4^+X^- \quad X = Br, I \qquad (1)$$

However, these salts are only stable up to −123 °C (Br^-) and −83 °C (I^-), respectively.

Stabilisation to −40 °C (SbF_6^-) and −75 °C (AsF_6^-) is achieved by exchanging the anions by hexafluoroantimonate or hexafluoroarsenate (Equation 2).[2]

$$AsH_3 + HF + MF_5 \rightarrow AsH_4^+MF_6^- \quad M = As, Sb \qquad (2)$$

Dimethylarsane reacts with hydrogen chloride with formation of dimethylarsonium chloride (Equation 3), which is completely dissociated into the starting materials at 20 °C.[3]

$$(CH_3)_2AsH + HCl \rightleftharpoons (CH_3)_2AsH_2Cl \qquad (3)$$

Trimethylarsane and, for example, methyl halogenides (CH_3Cl, CH_3Br, CH_3I) form stable tetramethylarsonium salts i.e. $(CH_3)_4As^+Br^-$ and $(CH_3)_4As^+I^-$ which have been identified by their crystal structures.[4][5]

Although attempts to protonate triphenylarsane in sulfuric acid failed, the reaction of triphenylarsane with hydrogen chloride, yielding the triphenylarsonium salt (Equation 4), nevertheless succeeded.[6][7]

$$Ph_3As + HCl \xrightarrow{HCl} Ph_3AsH^+Cl^- \qquad (4)$$

Hence, the protonation of trimethylarsane in the superacidic systems hydrogen fluoride antimony pentafluoride and arsenic pentafluoride, respectively, should lead to salts which are more stable than dimethylarsonium chloride but less stable than the tetramethylarsonium salts.

Not only will the series of $(CH_3)_nAsH_{4-n}^+$ salts with n = 1−4 be completed but new pnikogenium salts which are analogous to trimethylphosphonium salts will also be formed. The crystal structure of trimethylphosphonium hexachloroantimonate is well-known and could be compared to the structures of prepared trimethylarsonium undecafluorodiarsenate and trimethylarsonium hexafluoroantimonate.[8]

Moreover, a structure elucidation of a undecafluorodiarsenate salt succeeded. This anion was firstly mentioned by Brownstein in 1969, who examined the reaction of various hexafluoroantimonate and hexafluoroarsenate salts with AsF_5.[9] Further investigations by Raman spectroscopy, IR spectroscopy, NMR spectroscopy, cryoscopic and conductimetric measurements followed.[10−13] In spite of the fact that this kind of salt has been known since 1969, structural data, in comparison to the undecafluorodiantimonate, are scarce. Only a few crystal structures of salts with undecafluorodiarsenate as the anion are known up to now. To date, Christe has been able to determine the crystal structure of an $As_2F_{11}^-$ salt,[14] whilst we have crystallized salts of $HPCl_3^+As_2F_{11}^-$ (to be published), $(MeS)_2CSX^+As_2F_{11}^-$ (X = H, D) and $(CH_3)_3AsH^+As_2F_{11}^-$ reported now.[15]

Results and Discussion

Formation of $(CH_3)_3AsH^+$ Salts

The salts are prepared by protonation of trimethylarsane in superacidic media, hydrogen fluoride and antimony pentafluoride (Equation 5) or arsenic pentafluoride (Equation 6).

$$As(CH_3)_3 + HF + SbF_5 \xrightarrow{HF/-78\,^\circ C} (CH_3)_3AsH^+SbF_6^- \quad (5)$$

$$As(CH_3)_3 + HF + 2AsF_5 \xrightarrow{HF/-78\,^\circ C} (CH_3)_3AsH^+As_2F_{11} \quad (6)$$

The fine colourless solids are stable for several months at −70°C under a nitrogen atmosphere, decomposing at 5°C in the case of the undecafluorodiarsenate and at 60°C in the case of the hexafluoroantimonate. The salts dissolve well in sulfur dioxide at −40°C.

Vibrational Spectra

The Raman and IR spectra of $(CH_3)_3AsH^+SbF_6^-$ are shown in Figure 1 and all observed wavenumbers of the salts are summarised in Table 1. The vibrational spectra are assigned according to C_{3v} symmetry for the $(CH_3)_3AsH^+$ cation. The cation has twenty-four fundamental modes consisting of eight A_1 vibrations, four A_2 vibration and twelve E vibrations. The A_2 modes are inactive in both Raman and IR spectra. The twenty active fundamentals can be divided into six modes which are largely associated with $HAsC_3$ skeletal vibrations and the remaining modes which can be considered as motions of the methyl group. The CH_3 stretching modes are found in the range of 3042 to 2949 cm^{-1} and the corresponding deformation modes from 1433 cm^{-1} to 1180 cm^{-1}. The As−H and As−D stretching modes are detected at 2290 cm^{-1} and 1650 cm^{-1}, respectively.

The assignment of the skeletal vibrations is much more difficult because both anion and cation have the same anticipated range of vibrations. However, the possible assignment is carried out by comparison with the AsH_4^+ cation and the isoelectronic trimethylgermane.[2][16] Only four modes of the expected six could be assigned. In the range of 950 cm^{-1} to 880 cm^{-1} the CAsH and CAsD deformation modes are observed. They are shifted up to 90 cm^{-1} to higher wavenumber in comparison to the analogous vibration in trimethylgermane. The out-of-phase stretching modes of the AsC_3 skeleton are assigned to the lines and bands around 655 cm^{-1} and the in-phase stretching modes to those at 600 cm^{-1}. The corresponding deformation modes are detected at 220 cm^{-1}. The remaining vibrations are possibly modes of the anions.

Crystal Structure of $(CH_3)_3AsH^+As_2F_{11}^-$

$(CH_3)_3AsH^+As_2F_{11}^-$ crystallises in the monoclinic space group $P2_1/n$ (no. 14) with a = 7.362(1), b = 12.589(1), c = 13.598(1) Å, β = 95.37(1)° and four formula units per unit cell. The crystal structure was solved via the Patterson method and successive difference Fourier syntheses. For refinement full-matrix least-squares methods were applied. All hydrogen atoms were taken from Fourier maps and refined with isotropic displacement parameters and all non-hydrogen atoms with anisotropic displacement parameters. For the data reduction, structure solution, and refinement, programs in the SHELXTL package, PLATON, MISSYM, and PARST were used.[17−21] The crystal data are summarised in Table 2. The cation has the shape of a trigonal pyramid and the anion has a distorted edge-linked dioctahedral structure. Bond lengths and selected angles are shown in Table 3. The structure of trimethylarsonium cation with weak hydrogen bonds [H···F: 2.44(7) Å to 2.55(5) Å] to the nearest fluorine atoms of the anions is shown in Figure 2.

For comparison, the sum of the van der Waals radii of fluorine and hydrogen amounts to 2.67 Å.[22] Only the hydrogen atoms of the methyl groups are involved in hydrogen bonds and not the hydrogen atom which is directly bonded to the arsenic atom. No contact between arsenic and fluorine atoms, which is significantly below the sum of the van der Waals radii of 3.32 Å, is formed. The weak hydrogen bonds result in a formation of ribbons and two "As−F contacts", in the range of the sum of the van der Waals radii, of 3.304(3) Å and 3.399(3) Å, lead to a weak linkage of these ribbons. The As−C lengths of 1.894(5) Å, 1.907(5) Å and 1.908(5) Å are comparable to those found in methyltrifluoroarsonium hexafluoroarsenate of 1.886(4) Å and dimethyldifluoroarsonium hexafluoroantimonate of 1.894(7) Å, but are significantly shorter than that in trimethylarsane of 1.98(2) Å.[23−25] Comparison of the C−As−C angles of 109.5(3)°, 109.8(3)° and 111.1(3)° to the analogous C−P−C angles in trimethylphosphonium hexachloroantimonate of 109.7(4)°, 110.4(4)° and 111.0(3)° show no significant difference.[8]

The undecafluorodiarsenate anion with hydrogen bonds is shown in Figure 3. The As−F bond lengths involving the "bridging" fluorine atom are asymmetrical and amount to 1.855(3) Å and 1.983(3) Å. They are significantly longer than the other As−F bond lengths of 1.675(3) Å up to 1.696(3) Å, which are in the normal range of As−F bond lengths of hexafluoroarsenate anions.[26−28] The As−F bond lengths involving the "bridging" fluorine atom in $(CH_3S)_2CSH^+As_2F_{11}^-$ of 1.867(4) Å and 1.920(6) Å are in the same range as in the presented salt.[15] By projection along the As(1)−As(2) axes of the $As_2F_{11}^-$ anion (Figure 4) the gauche arrangement of the two octahedral AsF_6 units is visible, the overage torsion angle F−As−As−F of 45.0° being comparable to that found in $(CH_3S)_2CSH^+As_2F_{11}^-$.[15] The As(1)−F(1)−As(2) angle of 146.1(2)° is comparable to the Sb−F−Sb angle of 146.2(4)° and 147.6(3)° found in $(CF_3)_2C(F)OH_2^+$ $Sb_2F_{11}^-$ and $[Hg(CO)_2][Sb_2F_{11}]_2$, respectively, but smaller than the As−F−As angle of 159.1(6)° in $(CH_3)_2CSH^+$-$As_2F_{11}^-$.[15,29,30]

Crystal Structure of $(CH_3)_3AsH^+SbF_6^-$

$(CH_3)_3AsH^+SbF_6^-$ crystallises in the monoclinic space group $P2_1/m$ (no. 14) with a = 8.313(1), b = 8.855(1), c = 13.285(1) Å, β = 94.358(1)° and four formula units per unit cell. The crystal structure was solved via direct methods and successive difference Fourier syntheses. For refinement full-matrix least-squares methods were applied. All hydro-

gen atoms were taken from Fourier maps and refined with isotropic displacement parameters and all nonhydrogen atoms with anisotropic displacement parameters. For the data reduction, structure solution, and refinement the same programs were used as for the structure solution of $(CH_3)AsH^+As_2F_{11}^-$.[21] The monoclinic unit cell consists of two crystallographically independent cations and anions. The crystal data are summarised in Table 2 and bond lengths and selected angles are shown in Table 3.

The arsenic−carbon bond lengths of 1.779(10) and 1.765(9) Å in the two cations are significantly shorter than the remaining arsenic−carbon bond lengths of 1.910(9) and 1.935(9) Å and the analogous bond lengths of 1.894(5), 1.907(5) and 1.908(5) Å in trimethylarsonium undecafluorodiarsenate. The C−As−C angles of average 107.7(4) and 109.1(6)° are comparable to the C−P−C angles found in trimethylphosphonium hexachloroantimonate [110.4(4)°]. The interionic contacts are stronger than in trimethylarsonium undecafluorodiarsenate. The two independent cations form different contacts to fluorine atoms of neighbouring anions. In one case hydrogen fluorine contacts of 2.36(9) up to 2.47(6) Å and one arsenic fluorine contact of 3.060(5) Å result in formation of ribbons in the *ac* plane without connection along the *b* axes. In the other case only one hydrogen fluorine contact of 2.36(10) Å leads to a connection of cations and anions

Experimental Section

Caution: Avoid contact with these compounds and note that the hydrolysis of $As_2F_{11}^-$ salts and SbF_6^- salts form HF, which burns the skin and causes irreparable damage. Safety precautions should be taken when using and handling these materials.

General: All synthetic work and sample handling was performed by employing standard Schlenk techniques and standard vacuum line (stainless steel or glass, respectively). Nonvolatile materials were handled under dry nitrogen and experiments in anhydrous HF were handled in Kel-F reactors with valves made of the same material. − The synthesis of $As(CH_3)_3$ was carried out by known literature methods out of $AsCl_3$ (Merck) and CH_3I (Merck).[31][32] Di-*n*-butyl ether (Fluka) was dried with sodium. AsF_5 was synthesised from As and F_2. SbF_5 (Merck) was distilled repeatedly before use. HF was dried in a stainless steel bomb using 1.5 bar of F_2. − The Raman spectra were recorded on a Jobin Yvon T64000 spectrometer using an Ar^+ laser (514.5 nm) from Spectra Physics. The spectra were obtained in a glass cell cooled with solid CO_2.[33] − Infrared spectra were recorded on a Bruker ifs 113v spectrophotometer. Spectra were obtained from a coated CsBr plate in a low-temperature cuvette.[34] − NMR spectra were recorded with a Bruker DPX 300 spectrometer. − Single crystals were obtained by slowly removing HF at −78°C under vacuum and placed in Lindemann capillaries in a cooled stream of dry nitrogen. − X-ray diffraction studies were carried out using a Nonius Kappa CCD diffractometer.

Preparation of $(CH_3)_3AsH^+As_2F_{11}^-$ [$(CH_3)_3AsH^+SbF_6^-$]: In a typical reaction, 3 mL of HF was distilled into a Kel-F reactor at −196°C, followed by 2 mmol (1 mmol) of AsF_5 (SbF_5). The mixture was warmed to 20°C to form the superacid. The reactor was then cooled to −196°C, and $As(CH_3)_3$ (1 mmol) was added. The mixture was warmed to −70°C. After removing the volatile compounds at −78°C colourless solids, stable up to 5°C (60°C) were obtained. − NMR spectra were recorded in SO_2 at −40°C, standards are ^{75}As: 10% $KAsF_6$ in D_2O; ^{19}F: F11; $^{1\,H,\ 13}C$: TMS. The obtained data are as follows. **$(CH_3)_3AsH^+As_2F_{11}^-$:** ^1H NMR: δ = 1.92 (s), 10.27 (s). − ^{13}C NMR: δ = 4.13 (s). − ^{19}F NMR: δ = −52.24 (s). − ^{75}As NMR: δ = 138 (d), 131.1 (J_{AsH} = 507 Hz). − **$(CH_3)_3AsH^+SbF_6^-$:** ^1H NMR: δ = 2.00 (s). − ^{13}C NMR: δ = 4.42 (s). − ^{75}As NMR: δ = 138.6 (d, J_{AsH} = 498 Hz).

Preparation of $(CH_3)_3AsD^+As_2F_{11}^-$ [$(CH_3)_3AsD^+SbF_6^-$]: The preparations were analogous to those of the protonated species, but DF was used instead of HF. The colourless solids were stable up to 5°C (60°C).

Synthesis and Characterisation of a Dioxo-μ-Oxo Molybdenum Dimer: An Unusual case of a μ-Oxo Conformational Equilibrium

Henri Arzoumanian,*[a] Robert Bakhtchadjian,[a] Giuseppe Agrifoglio,[b] Heinz Krentzien,[b] and Jean-Claude Daran[c]

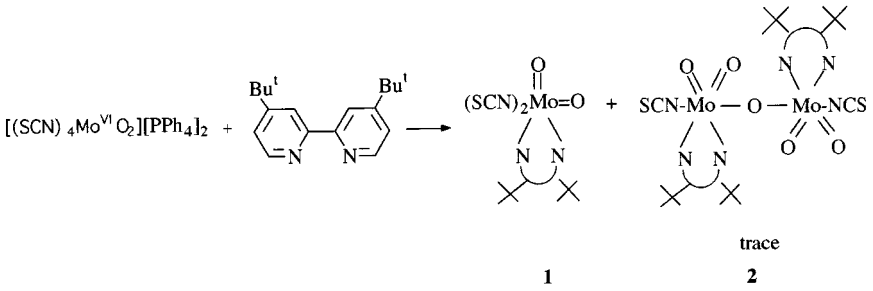
Keywords: Molybdenum / μ-Oxo / Conformational equilibrium / X-ray diffraction / NMR spectroscopy

A new thiocyanatomolybdenum(VI) dioxo-μ-oxo complex dimer bearing a 4,4′-di-*tert*-butyl-2,2′-bipyridine ligand (**2**) is shown to exist in the crystal cell unit as a meso (Mo-O–Mo angle of 180°) and d,l, pair (Mo–O–Mo angle of 155.7°). These conformers are in equilibrium in solution and have been observed clearly by ^{1}H NMR spectroscopy.

Introduction

Oxygenated complexes of transition metals are of utmost importance in catalytic oxidation processes. Among these complexes, metal-oxo species, found in a wide range of systems from metal-oxide surfaces to metalloenzymes, have received considerable attention.[1]

Two structural features describe the metal-oxo function: terminal-oxo (M=O) and bridging μ-oxo (M−O−M). Although most studies deal implicitly with the former type, binuclear oxo-metal entities have been shown to be key intermediates in many catalytic systems. For example, among the innumerable compounds known with μ-oxo ligands, ruthenium oxo-bridged complexes have already been shown to be active in the catalytic oxidation of water.[2] Later, high valent bimetallic μ-oxo species of Cu and Fe were found to take part in C−H bond activation.[3] Very recently some novel Co^{III} and Ni^{III} bis(μ-oxo) complexes have been isolated and characterized foreboding high oxidation capability.[4]



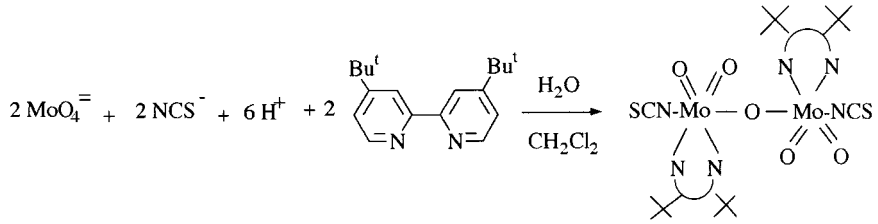
Polyoxometallates are well-defined anionic, oligomeric metal oxides featuring both terminal and bridging oxygen atoms. Among these, vanadium, molybdenum and tungsten anions are the most common and are often involved in oxidation reactions.[5]

This paper presents the synthesis and characterization of a molybdenum(VI) complex bearing both terminal and bridging oxo ligands which, in solution, exhibits a new μ-oxo conformational equilibrium which can be clearly observed by ^{1}H NMR spectroscopy.

Results and Discussion

In the course of a study of reactions of tetrathiocyanatodioxomolybdenum(VI) anions with substituted bipyridines,[6] a molybdenum(VI) dioxo complex (**1**) exhibiting exceptional oxidizing ability was obtained with the bulky 4,4′-di-*tert*-butyl-2,2′bipyridine (Scheme 1). This reaction was accompanied by the formation of traces of a μ-oxo dimer (**2**) thought to arise by an oxo-ligand redistribution process.

The remarkable properties of **1**[7] prompted us to develop a better method to synthesize compound **2** directly in order



Scheme 1

to test it also as a potential oxygen atom transfer agent. One plausible route consisted of replacing one thiocyanato group of **1** by a hydroxyl group, followed by dehydration. This reaction appeared to work but was not optimized. Instead a less cumbersome biphasic system was chosen starting directly from an aqueous solution of molybdate and thiocyanate, with the bipyridine in dichloromethane (Scheme 2).

Scheme 2

The product was obtained as a light yellow crystalline solid exhibiting, in the IR spectrum, the characteristic bands for both terminal and μ-oxo functions, and those for the thiocyanato and the bipyridyl ligands.[8] An X-ray

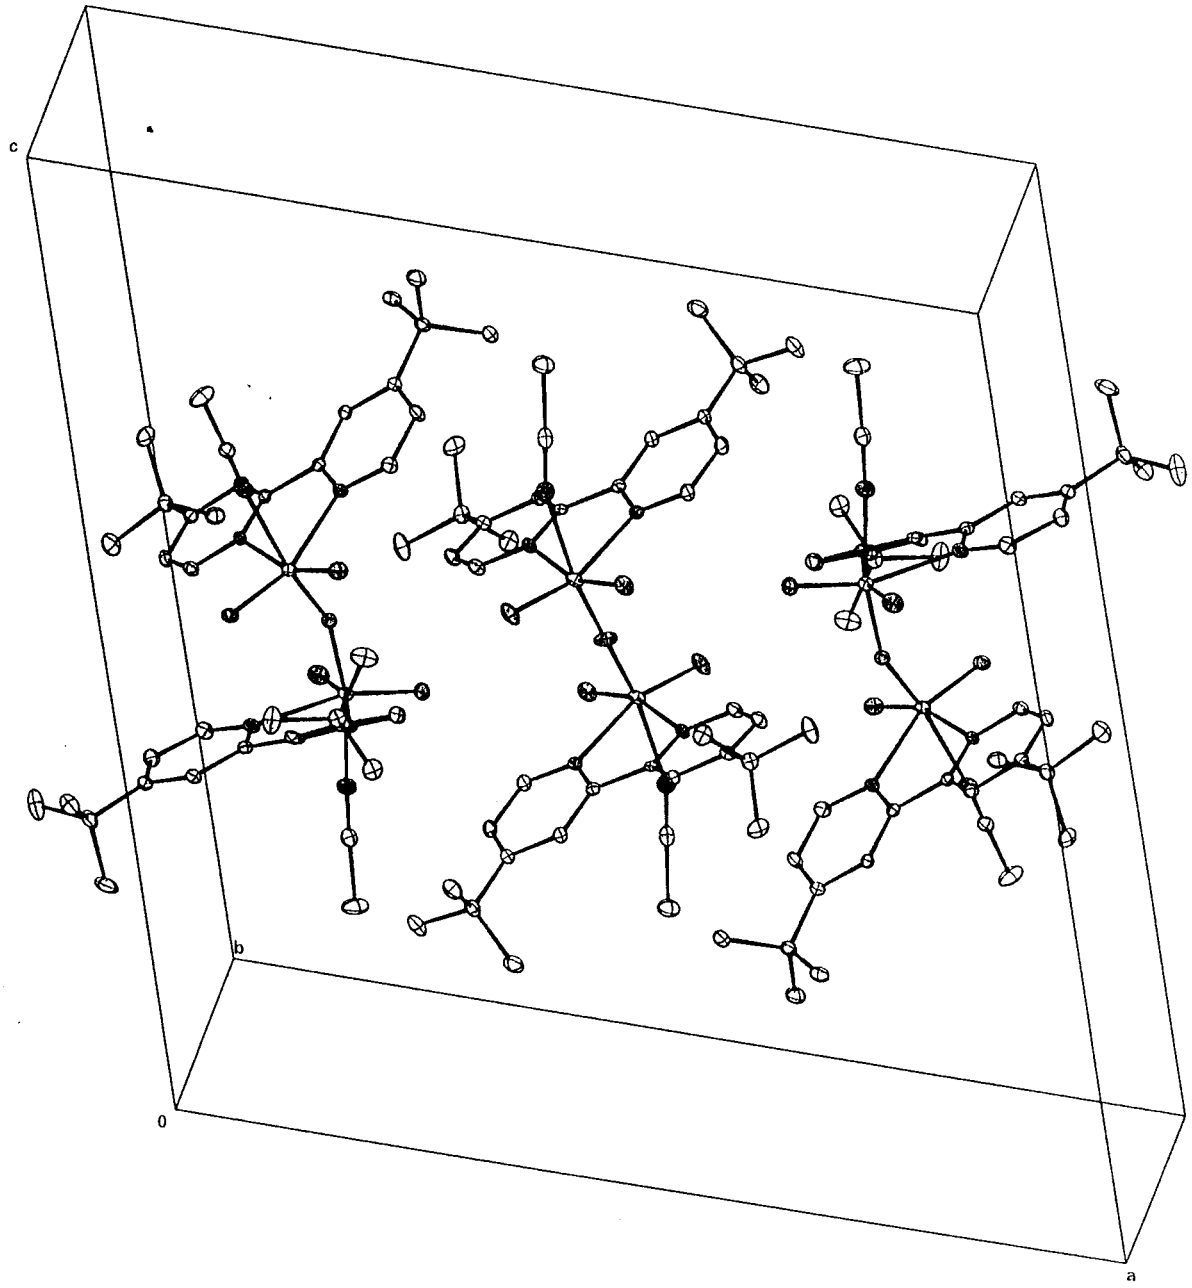

Figure 1. Unit cell of **2**

analysis of a suitable crystal confirmed these observations and, furthermore, uncovered an interesting feature − the cell unit was found to contain three molecules of **2** (see Figure 1), one with a Mo−O−Mo angle of 180°, with a center of symmetry located at the μ-oxo oxygen atom, and two others with a Mo−O−Mo angle of 155.7°, each totally unsymmetrical, with each of the four nitrogen-containing heterocycles in a different environment.

A closer examination reveals that these two molecules are enantiomers and, thus, the unit cell consists of a d,l, pair ($\mathbf{2}_{d,l,}$) and a meso isomer ($\mathbf{2}_{meso}$). Taken separately (see Figures 2 and 3) each molecule exhibits some interesting features; as expected, the two dioxo moieties are trans to each other in both the meso and the d,l conformers, however the thiocyanato ligands are slightly bent away from the molybdenum dioxo plane in the $\mathbf{2}_{meso}$ conformer whereas they appear to be slightly bent towards the molybdenum dioxo plane in the case of the d,l pair $\mathbf{2}_{d,l}$. The bipyridyl moiety is always coplanar with the molybdenum dioxo plane; however, all four nitrogen heterocycles are equivalent in the $\mathbf{2}_{meso}$ conformer, whereas they are found in different environments in the $\mathbf{2}_{d,l}$ conformer, with the consequence of having, in this case, four tertiary butyl groups also in a different environment. Finally the metal to oxygen bond lengths, either terminal or μ-oxo, have values similar to those reported for related compounds.[1a] Such a mixture of conformers in the solid state, although not unique, is quite scarce and could conceivably be rationalized by constraining stacking forces during crystallization.[9]

Much more unexpected and unusual, however, was the ^{1}H NMR spectrum in solution. Contrary to the NMR spectrum of the monomeric dioxomolybdenum(VI) complex **1** which exhibits, as expected, the pattern for the bipyridyl moiety of three signals in the aromatic region and a singlet for the *tert*-butyl group, the spectrum of **2** ($CDCl_3$ 25°C) showed five well-separated "sets" of bipyridyl signals. One integrating for 44% and the other four, of equal intensity, integrating for a total of 56% (Figure 4).

The presence of five anisotropically different tertiary butyl groups was also observed; one major signal integrating for 44% and four others, of equal intensity, integrating jointly for 56%. The interpretation of such spectra can only be done in terms of an unprecedented μ-oxo conformational equilibrium between the $\mathbf{2}_{meso}$ conformer, with four equal pyridyl rings (44%), and the $\mathbf{2}_{d,l}$ conformer, with four distinct pyridyl rings resonating at different fields due to their anisotropically different environment (56%). The presence of such an equilibrium was confirmed in various ways. First, changing the NMR solvent from $CDCl_3$ to CD_2Cl_2 resulted in a slightly, but significantly, different ratio of conformers ($\mathbf{2}_{meso}/\mathbf{2}_{d,l}$ = 44:56 in $CDCl_3$ and 55:45 in CD_2Cl_2). Second, a variable temperature NMR spectroscopic analysis added supporting evidence: upon lowering the temperature (from 25°C to −60°C) the signals sharpened, but the $\mathbf{2}_{meso}/\mathbf{2}_{d,l}$ ratio varied only very slightly (44:55 at 25°C vs 40:60 at −60°C). This is not unexpected for a conformeric mixture close to 50:50. However, upon increasing the temperature (from 25°C to 130°C), the signals corresponding to the four distinct pyridyl ring hydrogens of the $\mathbf{2}_{d,l}$ conformer quickly broaden, collapse and then slowly coalesce with the signals of $\mathbf{2}_{meso}$. The energy barrier estimated from this analysis is about 75 kJ·mol^{-1}. It is noteworthy that upon cooling the solution back to 25°C the original spectrum was obtained thus indicating the presence

of an equilibrium. The ^{95}Mo NMR spectrum also supports the presence of two distinct species in solution; it exhibits two resonances at −45 and −57 ppm. The relatively small difference between these two signals indicates that the electronic density at the metallic center is very slightly perturbed in going from one conformer to the other, es-

Figure 3. pecially if one compares the value of + 63 ppm for compound **1**.[6]

Although the interconversion between $\mathbf{2}_{meso}$ and $\mathbf{2}_{d,l}$ can easily be described, based on molecular models, by a bending of the Mo−O−Mo bond accompanied by a slight tilting of the bipyridyl moiety, the real reason for the existence of *two* stable conformers remains unclear. Studies are in progress to establish which oxygen atom in **2** is most prone to be transferred to a substrate. The dynamics of this μ-oxo conformational equilibrium, although never directly observed before, could be implied in numerous isomerisation processes of oxometallate anions and, in turn, give a better insight to the more general oxygen atom transfer reactions.

Experimental Section

Synthesis of 2: To an aqueous solution (30 mL) containing Na_2MoO_4 (0.50 g, 2.4 mmol) and KSCN (0.92 g, 9.6 mmol) was slowly added 9.6 mL of 1N HCl (9.6 mmol). The resulting yellow solution was stirred for 15 min followed by the addition of a CH_2Cl_2 solution (60 mL) containing 4,4′-di-*tert*-butyl-2,2′-bipyridine (0.64 g, 2.4 mmol). Vigorous stirring for an additional 30 min resulted in a yellow organic layer which was separated, dried and evaporated to give **2** (0.95 g, 76%) as a yellow solid. Recrystallization (−15°C) from CH_2Cl_2/*n*-hexane (2:1) afforded light yellow needles (m.p. > 180°C). − IR(KBr): $\tilde{\nu}$ = 2065 (-NCS), 940, 905 (= O), 775 (-O-) cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$, 21°C, TMS): δ = 1.36 (s), 1.41 (s), 1.43 (s), 1.48 (s), 7.45 [d, *J*(H-H) = 6 Hz], 7.57 [dd, *J*(H-H) = 6 Hz, 1.6 Hz], 7.69 [t, *J*(H-H) = 6 Hz], 7.98 [d, *J*(H-H) = 6 Hz], 8.14[d, *J*(H-H) = 1.6 Hz], 8.24[d, *J*(H-H) = 6 Hz], 8.51[d, *J*(H-H) = 6 Hz], 8.78 [d, *J*(H-H) = 6 Hz], 8.89 [d, *J*(H-H) = 6 Hz], 9.36 [d, *J*(H-H) = 6 Hz], 9.406 [d, *J*(H-H) = 6 Hz]. − ^{13}C NMR (101MHz, $CDCl_3$, 21°C, TMS): δ = 30.2, 30.3, 35.8, 118.6, 118.8, 119.1, 123.7, 124.1, 124.3, 124.5, 148.9, 149.7, 150.0, 150.5, 151.0, 151.7, 152.8, 165.4, 165.7. − ^{95}Mo NMR (26MHz, $CDCl_3$, 21°C, Na_2MoO_4, pH = 11): δ = −45, −57. − $C_{38}H_{48}Mo_2N_6O_5S_2$ (924): calcd. Keywords: Macrocycles / Lithium / Fluorescence / Cryptands / Coordination

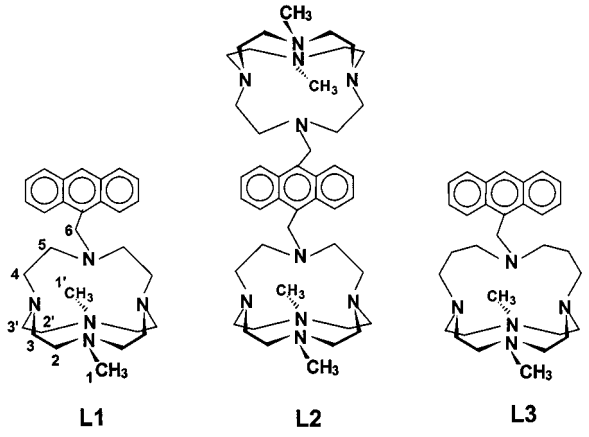
Three aza-cages with the anthracene-containing photoactive groups **L1**, **L2**, and **L3** have been synthesized. All compounds are able to selectively encapsulate a lithium ion and solid complexes have been isolated. The formation equilibria have been investigated by UV/Vis and ^{1}H, ^{13}C and ^{7}Li NMR spectroscopic techniques. The fluorescence emission of both free ligands and lithium complexes have been investigated. Results indicate that the CHEF (chelation enhancement of the fluorescence) effect obtained by lithium coordination exits although lower than that occurring upon full protonation.

Introduction

The design of new ligands with the ability to bind metal ions, and capable of recognizing the presence of these ions in solution, is of great interest in a wide variety of chemical fields ranging from the study of transport processes in biological systems to industrial and technological applications.[1−6] Macrocyclic compounds are a particularly attractive class of ligands and have thus received much attention in the last few years.[7−10] The development of new synthetic strategies has led to the real possibility of merging theory and experimentation in the design of chemical compounds with specific properties. Lithium is one target of this research and much effort has been dedicated to the synthesis of ligands able to bind it.[11−12] The interest in this ion is due to its significant role not only in industrial applications, but also in medical and biological chemistry.[13][14] Lithium salts have, in fact, been extensively and successfully used in the treatment of manic depression and other neurological and psychiatric disorders.[15][16] Lithium also exhibits antiviral activity against DNA-type viruses.[17] However, the use of lithium salts as drugs is limited by their side effects and toxicity. The mechanisms by which Li^{+} is involved in biological systems are unknown. No natural molecules are known, nor have any synthetic receptors been prepared, that would be selective enough to preferentially bind lithium ions at physiological concentration. Furthermore, easy determination of the lithium level in patients, using selective reactants would be very important. The elucidation of synthetic strategies and coordination properties of Li^{+} should lead to an improved understanding of its biological activity and to the design of better ligands as ionophores for it.

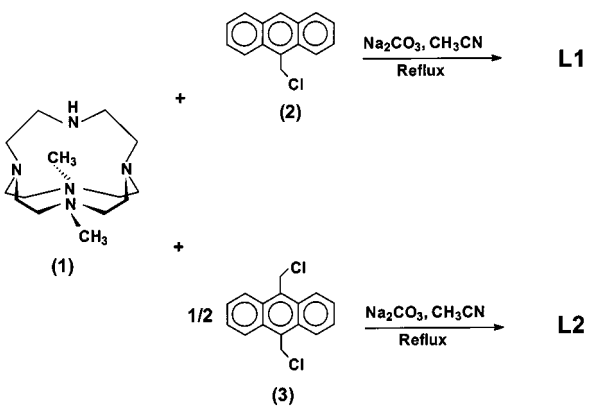
So far, fluorescence methods have proved to be useful in assaying metal ions. The design of molecular systems which combine binding ability and photochemical properties, displaying photoactive features, therefore have a great attraction.[18−20] One of the most used sensors is the anthracene moiety, which presents high fluorescence that could be affected by the molecular surroundings. In this context, three new aza-criptands bearing the anthracene function and characterized by different macrocyclic molecular topologies were synthesized (Chart I). All the ligands present a small three-dimensional cavity able to selectively encapsulate the lithium ion; the aromatic sensor is situated in an external position outside the macrocyclic cavity but in such a way that its optical properties could be perturbed by metal complexation.

The main aim of the present work was to investigate the possibility of employing these anthracene-functionalized aza-cages as selective lithium receptors and chromoionophores. The acid-base behavior of such ligands and their lithium complexation, performed by potentiometric titration, are reported, along with ^{13}C, ^{1}H and ^{7}Li NMR spectroscopic analysis.



Results and Discussion

Synthesis



All three of the new ligands contain the macrocycle 1,7-dimethyl-1,4,7,10-tetraazacyclododecane; nevertheless, the synthesis was carried out with two different methods, one to obtain **L1** and **L2**, and the other for **L3**. Scheme 1 shows the synthetic pathways for **L1** and **L2**, which were obtained starting from the previously synthesized aza-cage **1** as already reported.[21] To obtain **L1**, compound **1** was functionalized in acetonitrile with the chloroanthracene derivative **2** in an equimolar ratio in the presence of sodium car-

bonate as a base. The reaction gave **L1** in almost quantitative yield and the ligand was transformed into its diperchlorate salt by adding $HClO_4$ during the purification step. The same procedure was adopted to achieve **L2** but, in this case, the dichloroanthracene derivative **3**[22] was added to functionalize cryptand **1** in acetonitrile and employing a molar ratio of 1:2; again, cryptand **L2** was obtained as its perchlorate salt in good yield.

Scheme 1. Synthetic pathway for **L1** and **L2**

Ligand **L3**, however, was synthesized from the tetraaza monocyclic base **8**[23] (see Scheme 2) by reaction with the synthesized dimesyl-*N*-(9-methylanthracene)dipropanolamine (**7**); the complete synthetic pathway is depicted in Scheme 2. Aldehyde **4** was reacted with 3-aminopropanol in a solvent mixture of acetonitrile/ethanol/chloroform in the classic formation of a Schiff base. This compound was not isolated, but the crude solid obtained after evaporating the solvent was reduced in absolute ethanol with sodium borohydride to give compound **5**. This compound was transformed into the dialcohol **6** by *N*-alkylation with 3-bromo-propanol in acetonitrile in the presence of K_2CO_3 as base. Attempts to perform direct dialkylation of 9-aminomethylanthracene with two equivalents of 3-bromopropanol to give the dialcohol **6** failed. The methylsulfonyl derivative **7** was obtained using standard methods. Reaction of **7** with the base **8** in the presence of Na_2CO_3, a modification of Richman and Atkins′ method gave, after purification, the cryptand **L3**, in quite good yield. The need to use different synthetic pathways to obtain the three ligands is due to the different properties of the precursor cryptand. In fact, while **1** is present as a free amine in alkaline solution, the analogous cryptand with two propylenic (instead of all ethylenic) chains behaves as a proton-sponge and is present as a mono-protonated species in solution; its *N*-alkylation with the compound **2** is thus impeded.

Scheme 2. Synthetic pathway for **L3**

It was possible to isolate the monoprotonated species of the ligand **L1** as its perchlorate salt by extraction of an alkaline suspension of the ligand in chloroform and subsequent precipitation with hexane. The same treatment for **L3** afforded the free amine. The synthesis of the lithium complexes was carried out by reaction of an excess of LiOH with the ligands in methanol at room temperature. The complexes can be easily isolated after removal of the methanol by extracting the solid mixture with chloroform. It should be noted that the Li^+ complexes of all the ligands under investigation are very soluble in organic solvents (*ca.* 0.1 M).

Absorption and Emission Spectroscopy

Absorption Spectra

The absorption spectra in aqueous solution of the compounds **L1**, **L2** and **L3** present an identical pattern, being characterized by a structured absorption band in the near UV/Visible region of the spectrum. This absorption band can be immediately assigned to the anthracene chromophore. The shape of the absorption spectra of these compounds is only slightly affected by the pH of the solution, allowing us to conclude that the absorption of light by the anthracene moiety occurs independently of the protonation state of the cavity.

Fluorescence Emission

Excitation of acidic aqueous solutions of the compounds **L1**, **L2** and **L3** into the first singlet state gives rise to a fluorescence emission band which can also be attributed to the anthracene fluorophore. In contrast to the absorption, the fluorescence emission spectra are very dependent on the protonation state of the cavity (see Figure 1). Determination of the protonation constants of these compounds is difficult due to their low solubilities which preclude direct potentiometric measurements. Moreover, as the pH-dependent variations in the absorption spectra are very small, the error associated is large.

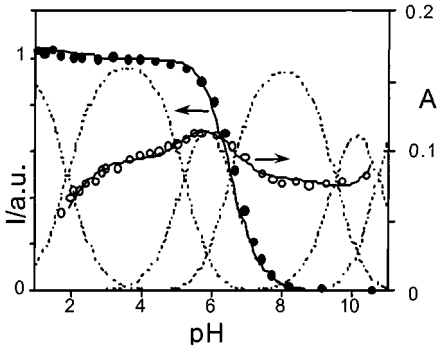

Figure 1. Fluorescence emission (•) and absorption (o) titration, distribution curves of the species (- -), for the compound **L2** in aqueous solution, 5×10^{-5} M, $\lambda_{exc} = 398$ nm, $\lambda_{em} = 429$ nm, absorbance at 323 nm

A fitting to the experimental curves was also performed and the protonation constants thus obtained are reported in Table 1. The best situation was obtained in the case of the compound **L2**. For **L1**, a protonation constant, $pK_a = 6.5$, can only be obtained with sufficient accuracy from fluorescence emission. The most interesting characteristic of the fluorescence emission titration curves of **L1**, **L2** and **L3** is the quenching effect that occurs in the pH 6−9 region. This type of quenching has been described before in chemosensors possessing aromatic units linked to a polyaza chain, and was attributed to an intramolecular electron-transfer process from the deprotonated amine to the excited aromatic moiety.[24] According to the structure of the compounds **L1**, **L2** and **L3** it is likely that quenching occurs upon deprotonation of the apical nitrogen functionalized by the photoactive group, which is the one in the best position to carry out the electron-transfer process. This interpretation is also compatible with the protonation constants obtained by means of the fluorescence data (see Table 1). The log *K* values are very similar for **L1** and **L2** ($pK_a = 6.5$ and 6.8, respectively) and higher for **L3** ($pK_a = 8$). Analyzing these values we propose that the apical nitrogen is involved in the protonation only from the second protonation step of each cage subunit. Furthermore, while **L1** and **L2** have the same cavity, in the case of **L3** it is larger, and the apical nitrogen more basic, because the charge repulsion of the other protonated nitrogen is smaller.

Potentiometric and NMR Spectroscopic Studies

Due to the presence of the hydrophobic anthracene fragment, the ligands do not show good solubility in aqueous solution. However, in the case of **L2**, and given its topology, it was possible to measure some protonation constants by direct potentiometric methods. The measurements performed in aqueous solution (0.15 M Me_4NCl ionic medium) are summarized in Table 1. The similar log *K* values for the addition of the third and fourth proton, together with the ligand topology, suggest that, in the $[H_4\mathbf{L2}]^{4+}$ species, both amine subunits bind two protons. This hypothesis is also confirmed from a comparison of the log K_2 values obtained for **L1** by spectrophotometric methods. Furthermore the basicity constants evaluated with the two different method are in good agreement.

Table 1. Protonation constants of **L1**, **L2** and **L3** (log K) in aqueous solution (298 ± 0.1 K, I = 0.15 M NMe_4Cl)

Reaction	**L1**	**L2**	**L3**
$L + H^+ = HL^+$	Insoluble	10.7[a]	Insoluble
$HL^+ + H^+ = H_2L^{2+}$	6.5[a]	9.5[a]	8.0[a]
$H_2L^{2+} + H^+ = H_3L^{3+}$	–	6.8[a] – 7.0 (1)[b, c]	6.0[a]
$H_3L^{3+} + H^+ = H_4L^{4+}$	–	6.2[a] – 6.4 (1)[b]	1.9[a]
$H_4L^{4+} + H^+ = H_5L^{5+}$	–	1.9[a] – 1.8(1)[b]	–

[a] From spectrophotometric measurements. – [b] From potentiometric measurements. – [c] Values in parentheses are standard deviations to the last significant figure.

From a ^1H and ^{13}C NMR spectroscopic analysis, it was possible to obtain additional information about the chemical properties of **L1** and of the other two ligands. As explained in the "synthesis" section, the free ligand **L1** could not be obtained. The ^1H NMR spectrum of the $[H\mathbf{L1}]^+$ species, recorded in $CDCl_3$, is shown in Figure 2a. The spectrum also shows a peak at 10.84 ppm assignable to the deshielded acidic proton. Upon addition of H_2O or CH_3OH to the chloroform solution, the signal at 10.85 ppm did not disappear, indicating a slow exchange on the NMR time scale with the labile protons of the solvent. However, the resonance did disappear when D_2O or CD_3OD were added. The chemical shift, together with the experimental evidence, suggests that the proton is stabilized inside the macrocyclic cavity by a strong hydrogen-bonded network with the amine functions. The other resonance in the ^1H NMR spectrum of the $[H\mathbf{L1}]^+$ species in CD_3OD (Figure 2b) is similar to that recorded in $CDCl_3$. It did not change even when a solution of NaOD in methanol was added, thus proving that the acidic proton cannot be removed in alcoholic alkaline solutions. Under the conditions described above, and as reported in the experimental section, **L2** and **L3** are present as free amines. Again, the chemical shift of the ^{13}C NMR resonance shows a C_{2V} time-averaged symmetry for **L2** and **L3** in $CDCl_3$ solution. In conclusion, **L2** and **L3** show a lesser basicity in alcoholic solution than **L1** in the first protonation step as evidenced by spectrophoto-

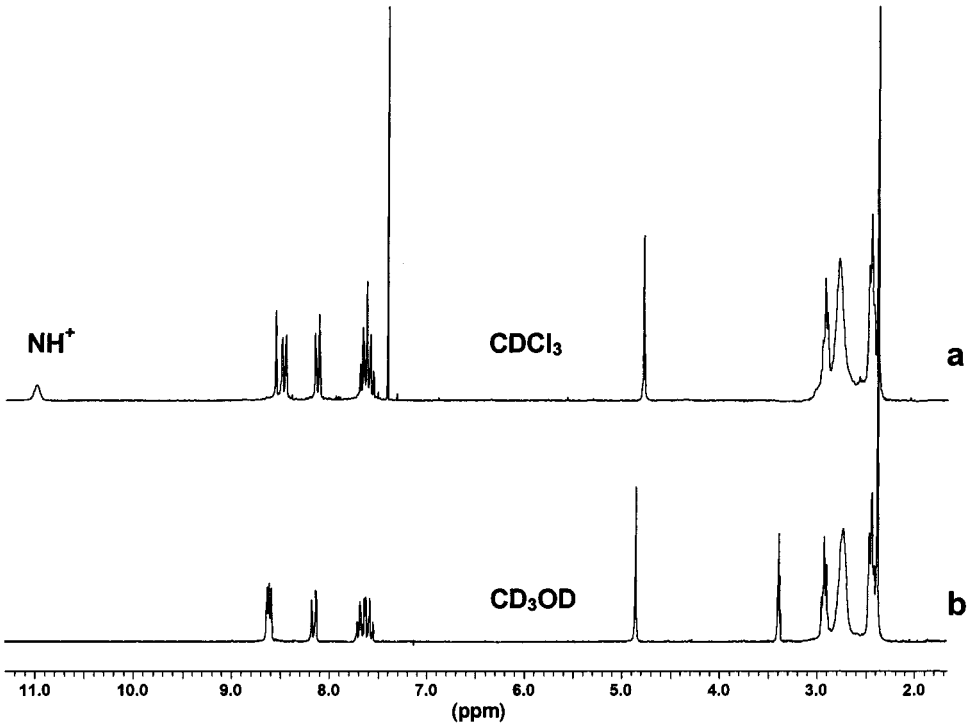

Figure 2. ^{1}H NMR spectra of $[HL1]^{+}$ species in $CDCl_3$ (a); in CD_3OD (b)

metric and NMR spectra, this could be ascribed to the larger three-dimensional cavity for **L3**, but other factors like the inductive effect of the methylanthracene group could be important to explain the different behavior of **L1** vs. **L2** and **L3**.

Lithium Complexation

The coordination of the alkaline metal ions by ligands **L1**, **L2** and **L3** was studied by ^{1}H, ^{13}C and ^{7}Li NMR spectroscopic techniques in alcoholic solution. With ^{1}H and ^{13}C

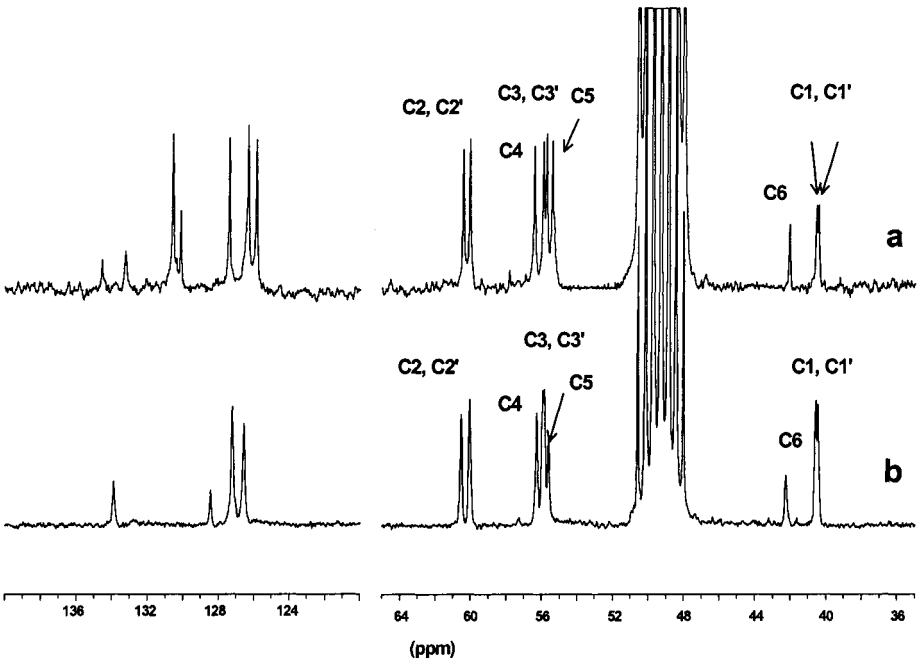

Figure 3. ^{13}C NMR spectra in CD_3OD of: $[LiL1]^{+}$ complex (a); $[Li_2L2]^{2+}$ complex (b)

spectroscopy as diagnostic techniques, no evidence was found for complex formation with sodium and potassium ions in alcoholic solution. Instead, all the ligands readily bound the smaller Li^+ ion and the solid complexes were isolated as reported in the experimental section. These solid compounds are soluble in organic solvents such as $CDCl_3$ and their ^7Li NMR spectra present a sharp peak, shifted downfield with respect to the free ion. Li^+ coordination is clearly shown by the ^{13}C and ^7Li NMR spectra of a methanol solution containing **L1**, **L2** or **L3** and Li^+ in the presence of a base. In all three cases, upon the addition of an excess of Li^+ to an alkaline solution of the ligands, the ^7Li NMR spectrum shows two sharp peaks, one due to the free lithium ion and the other, shifted downfield, due to the complexed lithium ion. The changes in chemical shift of the complexed ion are 3.29, 3.26, and 1.39 ppm with respect to the solvated ion, for **L1**, **L2**, and **L3**, respectively. The simultaneous presence of the two peaks denotes a slow exchange of the complexed lithium ion with the free ion on the NMR time scale. These chemical shifts were conserved when the solvent was changed to CD_3CN or $CDCl_3$, and are the same as observed by solubilizing the solid complexes.

The solvent-independence of the ^7Li chemical shift and the slow exchange on the NMR time scale between free and bound lithium indicate that the ion is encapsulated inside the macrocyclic cavity and thus quite isolated from the medium. Comparison of the ^{13}C NMR spectra of the free amines with those of the lithium complexes, as shown for example in the case of **L1** (Figure 3a), revealed that the complexation of the Li^+ ion produces a decrease in molecular symmetry, on the NMR time scale, for all three ligands. In fact while the free ligand **L1** presents fourteen peaks for a C_{2v} time-averaged symmetry, the spectrum of the complex presents seventeen peaks indicating a C_s symmetry. Analyzing the spectrum of the complex, the element of symmetry lost is the plane passing through the bridgehead nitrogen and the nitrogen atom having the anthracene group, while the other plane, which contains the methylated nitrogen atoms, is preserved.

For ligand **L1** the coordination of the lithium ion leads to removal of the acidic proton resonance at 10.85 ppm which is not present in the ^1H NMR spectrum of the complex. Ligand **L2** is able to bind two lithium ions but only one resonance was obtained in the ^7Li spectra, with the same value as for the **L1** complex. The aliphatic resonances for the $[Li_2\mathbf{L2}]^{2+}$ complex (Figure 3b), show the same environment around the lithium ions from the two subunits, and are similar to those found for the $Li\mathbf{L1}^+$ species (Figure 3a). These experimental data provide evidence that, for **L2**, only one ion is lodged in the subunit and the coordination around the ion is equal in the two subunits on the NMR time scale and similar to that of the **L1** complex. It is noteworthy that these spectral features do not change even in the presence of a large excess of Na^+. In other words, lithium complexation is not influenced by the presence of the Na^+ ion, even at high concentrations, indicating that ligands **L1**–**L3** are able to discriminate completely between Li^+ and Na^+. Such selectivity is related to the small dimensions of the macrobicyclic cavity, in which the larger Na^+ cannot be encapsulated.

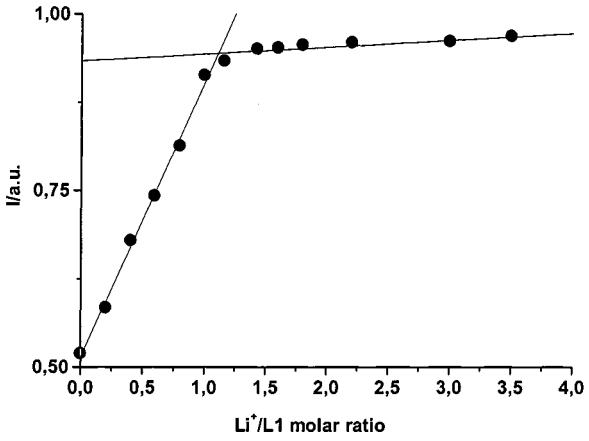

Figure 4. Variation of the fluorescence emission intensity of **L1** (1×10^{-5} M) in methanol with tetrabutylammonium hydroxide, at λ_{em} = 412 nm, as a function of Li^+/**L1** molar ratio

Sensing Lithium

A plot of the fluorescence emission variations that occur upon addition of different concentrations of lithium to an alkaline methanol solution of compound **L1**, at 25°C is shown in Figure 4. A similar behavior was also observed for **L2**. The fit of the experimental data points is in good agreement with a Li^+:L ratio of 1:1 for the lithium complex of **L1** and a 2:1 ratio for **L2**. The trend of chelation enhancement of the fluorescence (CHEF) effect, obtained by coordination of Li^+ into the cavity by increasing the lithium equivalents, shows that the complexes are completely formed by the addition of one or two equivalents of ion for **L1** and **L2,** respectively. The spectrum of the lithium complexes is quite similar to the sensor in the absence of lithium, but is approximately twice as intense and slightly shifted to the red, as shown in Figure 5 for the $[Li\mathbf{L3}]^+$ species.

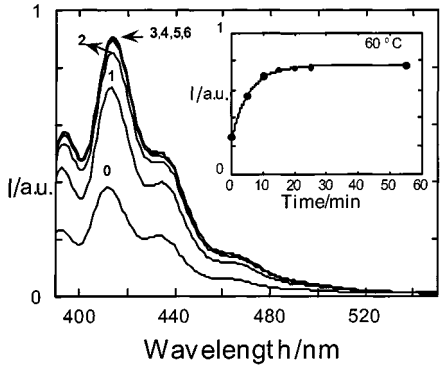

Figure 5. Spectral variations of the fluorescence emission of **L3** in methanol with addition of tetrabutylammonium hydroxide (0); immediately after addition of lithium excess(1); after 5 min (2); 10 min (3); 15 mim (4); 20 min (5); 55 min (6). λ_{exc} = 380 nm. Inset variation of the fluorescence emission intensity at λ_{em} = 420 nm as a function of time

In this case the coordination of the lithium is time-dependent but the equilibrium state is reached in less than twenty minutes at 60°C. In the equilibrium state, a behavior similar to that of the previous two ligands was also observed for **L3**. The CHEF effect obtained by coordination of lithium into the cavity is, however, much lower than that occurring upon full protonation. A possible explanation for this behavior is the fact that coordination of the metal has only a small influence on the quenching mechanism.

Conclusions

The molecular topology of the polyamines **L1**-**L3** is characterized by the presence of both a three-dimensional cavity and an anthracene moiety. It has been shown that **L1** behaves as a "proton sponge" in alcoholic solution. All three ligands are able to selectively bind the lithium ion in alcoholic solution while the other alkali metal ions are not complexed. Such remarkable selectivity is due to the small dimensions of the macrocyclic cavity, in which alkali metals larger than lithium cannot be encapsulated. The solid lithium complexes, which were isolated and fully characterized, are soluble in organic solvents such as $CDCl_3$. **L2** forms a binuclear lithium complex with each ion lodged in a single cage subunit. The photochemical properties of the ligands are strongly influenced by protonation; moreover, on lithium complexation an increase in the fluorescence emission of the sensor, relative to that of the free ligand, is observed in methanol. Unfortunately, the presence of the anthracene moiety renders the ligands insoluble in aqueous solutions preventing the complexation of the lithium in this medium.

Experimental Section

General: ^1H, ^{13}C and ^7Li NMR spectra were recorded on a Bruker AC-200 instrument, operating at 200.13, 50.33 or 77.78 MHz, respectively. ^1H NMR peak positions are reported relative to HOD (4.75 ppm), dioxane was used as reference standard in ^{13}C NMR spectra (δ = 67.4 ppm). For the spectra recorded in $CDCl_3$, the peak positions are reported relative to TMS. ^7Li NMR peaks are reported relative to free $LiClO_4$. ^1H-^1H and ^1H-^{13}C correlation experiments were performed to assign the signals. Solvents and starting material were used as purchased.

Spectrophotometric and Spectrofluorimetric Titrations: Absorption spectra were recorded on a Perkin–Elmer Lambda 6 spectrophotometer and fluorescence emission on a SPEX F111 Fluorolog spectrofluorimeter. HCl and tetrabutylammonium hydroxide were used to adjust the pH values, which were measured on a Metrohm 713 pH meter. The acidification constants were obtained from a fit of the theoretical equations to the experimental titration data by least-squares analysis using the bracketing technique.

Potentiometric Measurements: All potentiometric measurements were carried out in 0.15 M Me_4NCl at 298.1 ± 0.1 K, in the pH range 2.5–10, using the fully automatic equipment that has been already described.[25] The acquisition of the emf data was performed with the PASAT computer program. The electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free Me_4NOH solutions and determining the equivalent point by Gran's method,[26] which gives the standard potential E° and the ionic product of water K_w. At least three measurements were performed. The HYPERQUAD computer programs were used to process the potentiometric data and calculate the protonation constants.[27]

Compounds **1**, **3**, **8** were synthesized as reported in the literature.[21–23] Compounds **2** and **4** were purchased from Aldrich Chemical Co. All reactions were carried out under an inert atmosphere.

Caution: Perchlorate salts of organic compounds are potentially explosive; these compounds must be handled with great caution!

(1,7,-Dimethyl-1,4,7,10,15-pentaazabicyclo-[5.5.5]-heptadecan-15-yl)-9-methylanthracene Diperchlorate (L1·2HClO$_4$): Cryptand **1** (0.54 g, 2 mmol) and Na_2CO_3 (0.64 g, 6 mmol) were suspended in refluxing CH_3CN (100 mL). To this mixture, a solution of **2** (0.68 g, 3 mmol) in 50 mL of acetonitrile was added dropwise in 2 h. After the addition was completed, the suspension was refluxed for 2 h. The mixture was evaporated to dryness under vacuum, and the solid obtained was suspended in chloroform. The organic layer was filtered and solvents removed under vacuum to give a yellow solid, which was dissolved in ethanol. The suspension was filtered to eliminate the excess of **2,** and then treated with 65% perchloric acid to give the diperchlorate salt as a yellowish solid. Yield: 0.85 g (90%). – $C_{29}H_{43}Cl_2N_5O_8$: calcd. C 52.73, H 6.56, N 10.60; found C 52.6, H 6.6, N 10.5.

L1·HClO$_4$: The monoprotonated species was obtained by suspending the diperchlorate salt in 1 M NaOH aqueous solution and extraction of the resulting suspension with chloroform. The volume of the organic phase was reduced and the H**L1**$^+$ was precipitated with hexane in almost quantitative yield. – $C_{29}H_{42}ClN_5O_4$: calcd. C 62.18, H 7.56, N 12.50; found C 62.0, H 7.5, N 12.3. – MS (ESI) m/z = 461 $[M + H]^+$. – ^1H NMR ($CDCl_3$): δ = 2.24 (s, 6 H) 2.30 (t, 4 H), 2.64 (bb, 16 H), 2.78 (t, 4 H), 4.65 (s, 2 H), 7.46 (m, 4 H), 7.97 (d, 2 H), 8.32 (d, 2 H), 8.41 (s, 1 H), 10.84 (bb, 1 H). – ^{13}C NMR ($CDCl_3$): δ = 43.5, 49.4, 50.2, 52.9, 53.0, 53.5, 124.2, 125.1, 126.5, 128.3, 128.4, 129.5, 130.9, 131.3.

(1,7,-Dimethyl-1,4,7,10,15-pentaazabicyclo-[5.5.5]-heptadecan-15-yl)-9,10-dimethylanthracene Tetraperchlorate (L2·4HClO$_4$): Cryptand **1** (1.1 g, 4 mmol) and Na_2CO_3 (1.3 g, 12 mmol) were suspended in refluxing CH_3CN (100 mL). To this mixture, was added a solution of **3** (0.55 g, 2 mmol) in CH_3CN (100 mL) dropwise in 2 h. After the addition was completed, the suspension was refluxed for 3 h. The mixture was vacuum evaporated, and the solid obtained was suspended in chloroform. The organic layer was filtered and vacuum evaporated to give a yellow solid. The solid was dissolved in a minimum amount of chloroform and chromatographated on neutral alumina with CH_2Cl_2/MeOH mixture (10:1) as eluent. The eluted fractions were collected and evaporated to dryness to obtain a yellow solid. The solid was further purified by dissolving it in ethanol and the solution treated with 65% perchloric acid to give the tetraperchlorate salt in almost quantitative yield. Yield: 1.65 g (72%). – $C_{44}H_{76}Cl_4N_{10}O_{16}$: calcd. C 46.24, H 6.70, N 12.26; found C 46.0, H 6.6, N 12.1. – MS (ESI) m/z = 742 $[M + H]^+$. – ^1H NMR (D_2O, pD = 3):δ = 2.56 (s, 12 H) 2.69 (t, 8 H), 2.87 (bb, 32 H), 2.95 (t, 8 H), 4.70 (s, 4 H), 7.39 (d, 4 H), 8.26 (d, 4 H), 10.68 (bb, 2 H). – ^{13}C NMR (D_2O, pD = 3):δ = 42.2, 49.1, 50.6, 53.0, 53.2, 53.7, 127.1, 128.9, 129.4, 136.2.

***N*-(Anthracene-9-methyl)-aminepropanol (5):** Reagent **4** (20.6 g, 0.10 mol) was added together with 3-amino-propanol to 150 mL of $CH_3CN/CH_3CH_2OH/CHCl_3$ mixture (5:15:70). This solution was kept stirred at room temperature for 24 h and then vacuum evapo-

rated to give a yellow solid, which was dissolved in hot absolute ethanol (500 mL). The solution was cooled at room temperature and then added of $NaBH_4$ (8 g, 0.2 mol). The suspension obtained was refluxed for 4 h and then vacuum evaporated. The solid was suspended in water (120 mL) and extracted with chloroform (3×100 mL). The organic phase was dried over anhydrous Na_2SO_4, and its volume vacuum reduced. Ethyl ether was added to this solution to complete precipitation of a yellow solid, which was recrystallized from hot CH_3CN. Yield: 20.5 g (77%). − $C_{18}H_{19}NO$: calcd. C 81.48, H 7.22, N 5.28; found C 81.6, H 7.3, N 5.2. − M.p., 79−81°C. − ^{1}H NMR ($CDCl_3$): δ = 1.82 (m, 2 H), 2.41 (t, 2 H), 3.38 (t, 2 H), 3.51 (b, 1 H), 4.26 (s, 2 H), 4.76 (b, 1 H) 7.47 (m, 4 H), 8.04 (d, 2 H), 8.29 (d, 2 H), 8.44 (s, 1 H). − ^{13}C NMR ($CDCl_3$): δ = 28.5, 48.5, 53.6, 62.4, 124.0, 124.8, 126.0, 128.6, 129.7, 131.1, 131.3.

***N*-(Anthracene-9-methyl)-dipropanolamine (6):** A sample of **5** (5.3 g, 0.02 mol) was added with 3-bromine-propanol (2.8 g, 0.02 mol) and K_2CO_3 (3.0 g, 0.022 mol) to 80 mL of CH_3CN. This mixture was slowly warmed to 50°C and kept with stirring over a period of 5 h. After this period the suspension was refluxed for 2 h. The reaction mixture was allowed to cool to room temperature and then 100 mL of 0.1 mol dm^{-3} NaOH aqueous solution added. The extracted organic phase, was dried over sodium sulfate. The solvent was removed under reduced pressure to obtain a solid which was recrystallized from CH_3CN. Yield 3.6 g (56%). − $C_{21}H_{25}NO_2$: calcd. C 77.98, H 7.79, N 4.33; found C 78.2, H 7.9, N 4.3. − ^{1}H NMR ($CDCl_3$): δ = 1.79 (p, 4 H), 2.76 (t, 4 H), 3.48 (t, 4 H), 3.62 (b, 2 H), 4.53 (s, 2 H), 7.51 (m, 4 H), 8.01 (d, 2 H), 8.37 (d, 2 H), 8.45 (s, 1 H). − ^{13}C NMR ($CDCl_3$): δ = 28.7, 51.4, 52.5, 62.2, 124.3, 125.0, 126.2, 128.9, 129.3, 131.3, 131.4.

***N*-(Anthracene-9-methyl)-*O*-dimesyl-dipropanolamine (7):** A sample of **6** (3.2 g, 0.01 mol) and triethylamine (5.1 g, 0.05mol) in 60 mL of anhydrous dichloromethane was cooled at −5°C. To this solution was added dropwise over a period 3 h, with stirring, a solution of methanesulfonil chloride (2.9 g, 0.025 mol). The reaction mixture was kept to −5°C for further 30 min and then was allowed to warm up to room temperature. The resulting suspension was washed twice with a 0.1 M NaOH aqueous solution and then with water. The organic phase was dried over anhydrous Na_2SO_4 and evaporated to dryness to obtain **7** as a yellowish solid. Yield: 4.4 g (91%). − $C_{23}H_{29}NO_6S_2$: calcd. C 57.60, H 6.09, N 2.92; found C 57.7, H 6.1, N 3.0. − ^{1}H NMR ($CDCl_3$): δ = 1.52 (m, 4 H), 2.71 (t, 4 H), 2.83 (s, 6 H), 3.38 (s, 2 H), 4.25 (t, 4 H), 7.53 (dd, 2 H), 7.72 (dd, 2 H), 8.07 (d, 2 H), 8.33 (dd, 2 H), 8.59 (s, 1 H). − ^{13}C NMR ($CDCl_3$): δ = 24.3, 37.5, 39.7, 54.1, 59.7 123.1, 125.7, 127.2, 129.0, 129.5, 129.9, 132.2, 132.8.

1,7,-Dimethyl-1,4,7,10,16-pentaazabicyclo-[5.5.7]-nonadecan-16-yl-9-methylanthracene (L3): To a refluxing suspension of **8** (1.8 g, 0.009 mol) and Na_2CO_3 (5.3 g, 0.05 mol) in 150 mL of acetonitrile was added, over a period of 6 h, a solution of **7** (4.3 g, 0.009 mol) in 100 mL of acetonitrile. The reaction mixture was maintained at reflux for a further 2 h. After the mixture was cooled to room temperature, the resulting suspension was filtered and evaporated under reduced pressure to give a yellowish solid, which was dissolved in a minimum amount of $CHCl_3$ and chromatographed on neutral alumina with an eluent mixture of $CHCl_3/CH_3OH$ (100:5). The eluted fractions were collected and evaporated to dryness to obtain a yellow solid. The solid was further purified by dissolving it in ethanol and the solution treated with 65% perchloric acid to give the diperchlorate salt in almost quantitative yield. Yield: 3.6 g (58%). − $C_{31}H_{45}N_5$: calcd. C 76.34, H 9.30, N 14.36; found C 76.2, H 9.3, N 14.3. − MS FAB *m/z* = 489 $[M + H]^+$. − ^{1}H NMR ($CDCl_3$): δ = 1.56 (m, 4 H) 2.52 (s, 6 H), 2.58 (t, 4 H), 2.66 (t, 4 H), 2.92 (m, 16 H), 4.48 (s, 2 H) 7.43 (m, 4 H), 7.95 (d, 2 H), 8.36 (s, 1 H), 8.40 (d, 2 H). − ^{13}C NMR ($CDCl_3$): δ = 25.2, 41.5, 50.6, 51.4, 53.2, 54.8, 55.5, 124.7, 124.8, 125.6, 127.5, 129.1, 130.0, 131.1, 131.3.

Preparation of the Complexes. [LiL1]ClO_4 (9): A solution of LiOH (10 mg, 0.44 mmol) and $NaClO_4 \cdot H_2O$ (100 mg, 0.7 mmol) in 15 mL of methanol was added to a solution of **L1**· $HClO_4$ (56 mg, 0.1 mmol) in methanol (15 mL). The reaction mixture was stirred for 15 min and then evaporated to dryness. The yellow solid was suspended in 20 mL of $CHCl_3$, and the mixture filtered to separate the inorganic excess and the organic solution dried over Na_2SO_4. On addition of cyclohexane (25 mL) a yellow precipitated formed, yield 41 mg (73%). − $C_{29}H_{41}ClLiN_5O_4$: calcd. C 61.53, H 7.30, N 12.37; found C 61.4, H 7.4, N 12.3. − MS (ESI) *m/z* = 467 $[Li\mathbf{L1}]^+$. − ^{13}C NMR ($CDCl_3$):δ = 39.8, 39.9, 41.0, 54.3, 54.4, 54.5, 55.1, 58.6, 58.9, 124.0, 124.7, 125.1, 126.5, 129.0, 129.2, 131.3, 132.8.

[Li_2L2](ClO_4)$_2$ (10): This compound was synthesized from **L2**·2$HClO_4$ (47 mg, 0.05 mmol) following the same procedure reported for **9** giving **10** as a yellowish solid, yield 36 mg (76%). − $C_{44}H_{72}Li_2Cl_2N_{10}O_8$: calcd. C 55.40, H 7.61, N 14.68; found C 55.5, H 7.6, N 14.8. − MS (ESI) *m/z* = 854 ($Li_2\mathbf{L2}ClO_4^+$). − ^{13}C NMR ($CDCl_3$):δ = 40.1, 40.3, 42.2, 55.4, 55.6, 55.8, 55.1, 60.2, 60.8, 126.3, 127.1, 128.4, 134.0.

[LiL3]ClO_4 (11): This compound was synthesized from **L3**·2$HClO_4$ (34 mg, 0.05 mmol) following the same procedure reported for **9** giving **11** as a yellowish solid, yield 36 mg (76%). − $C_{31}H_{45}ClLiN_5O_4$: calcd. C 62.67, H 7.63, N 11.79; found C 62.5, H 7.6, N 11.7. MS (ESI) *m/z* = 495 $[Li\mathbf{L3}]^+$. − ^{13}C NMR ($CDCl_3$):δ = 26.4, 44.4, 52.2, 53.0, 53.5, 54.4, 54.9, 126.1, 126.2, 126.6, 129.7, 130.1, 130.3, 132.8, 134.2.

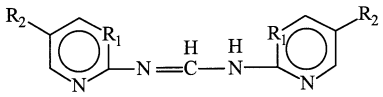
Synthesis, Structure, Spectroscopy, and Magnetism of Unique Propeller-Type Linear Trinuclear Cu^{II} Complexes with In-situ Prepared Formamidine Ligands

Gerard A. van Albada,[a] Petra J. van Koningsbruggen,[c] Ilpo Mutikainen,[b] Urho Turpeinen,[b] and Jan Reedijk*[a]

Keywords: Copper / Trinuclear complexes / Formamidines / Magnetism

Three new copper(II) linear trinuclear compounds are reported, all of which were synthesized in-situ, with the general formula $[Cu_3(L)_4](CF_3SO_3)_2(Y)_x$, where L is the dehydronated ligand: *N*,*N*′-bis(pyridine-2-yl)formamidine (abbreviated as Hpdf), *N*,*N*′-bis(pyrimidine-2-yl)formamidine (abbreviated as Hpmf) and *N*,*N*′-bis(5-methylpyridine-2-yl)formamidine (abbreviated as Hmpdf), Y = EtOH or H_2O and x = 0.5–1.5. The compounds were characterized by X-ray diffraction, IR, LF, and EPR spectroscopy and by magnetic susceptibility down to 4 K. The structure of the compound $[Cu_3(pmf)_4](CF_3SO_3)_2(H_2O)_{1/2}$ was determined by X-ray crystallography; it was found to crystallise in the triclinic space group *P*–1 with *a* = 8.529(5), *b* = 15.760(5), *c* = 19.639(5) Å, α = 101.793(5), β = 101.263(5), γ = 102.389(5)°, *Z* = 2. The structure [Cu–Cu–Cu angle 174.96(11)°] consists of four nearly flat molecules of the ligand, which contribute to the propeller-type structure around the Cu–Cu–Cu axis. A strong antiferromagnetic interaction between the Cu^{II} ions is observed with calculated *J* values, based on the Hamiltonian $H = -2J(\mathbf{S}_1\cdot\mathbf{S}_2 + \mathbf{S}_2\cdot\mathbf{S}_3) - 2J'\cdot\mathbf{S}_1\cdot\mathbf{S}_3$, of –174(1) cm^{-1}, –120(1) cm^{-1}, and –167(1) cm^{-1} for the compounds studied with L = pdf, pmf, and mpdf, respectively. These values are in agreement with an *S* = 1/2 ground state below temperatures of 120–160 K.

Introduction



Dinuclear and polynuclear exchange-coupled copper(II) complexes have been extensively studied, although the number of trinuclear compounds investigated magnetically and structurally is still quite limited.[1][2]

Dinuclear systems are well documented not only because of their interesting magnetic interactions,[1] but also because of their relevance for bioinorganic model systems for copper in enzymes.[3] The theory for dinuclear systems is adequate for interpreting the relationship between the isotropic exchange constant and the structural parameters, but linear trinuclear compounds have been discussed to a much lesser extent, mainly due to the fact that the number of such copper(II) compounds is relatively small.

The majority of the known linear trinuclear Cu^{II} compounds of which the structures have been characterised by X-ray crystallography contain an oxygen bridge[4][5] or a mixed (N, Cl, O) bridge[2,6,7] between the Cu^{II} atoms, and only a few contain a nitrogen bridge. In fact a very small number of compounds contain a CuN_{4-6} chromophore around all three copper sites[8] and, of these compounds, two are from external azide bridges.[8b,8d] Of all known trinuclear linear Cu^{II} compounds a limited number of copper(II) complexes have been fully studied magnetically *and* also characterised by X-ray crystallography (see Table 2).

Trinuclear compounds that have a $[Cu-N-Cu-N-Cu]_x$ bridge (with an N belonging to a heterocyclic ligand) are rare and, in fact, only two structures have been reported in the literature.[8b,9,10a] Several mixed Mn−Cu−Mn linear trinuclear compounds are also known.[11]

In a preliminary communication[9] we described a novel template synthesis of a new N_4-donor ligand and, as an example, the X-ray structure of such a compound.

N,*N*′-bis(pyridine-2-yl)formamidine (Hpdf) R_1 = CH, R_2 = H

N,*N*′-bis(pyrimidine-2-yl)formamidine (Hpmf) R_1 = N, R_2 = H

N,*N*′-bis(5-methylpyridine-2-yl)formamidine (Hmpdf) R_1 = CH, R_2 = CH_3

In the present study we describe three formamidine compounds synthesized in a similar way, in situ, from 2-aminopyridine, 2-aminopyrimidine, and 2-amino-5-methylpyridine ligands, copper(II) triflate, and triethylorthoformate in alcohol. The study also includes a second X-ray structure of such a compound. To the best of our knowledge this method for the preparation of such formamidine compounds in situ is unique.

The general formula of the new compounds is $[Cu_3(L)_4](CF_3SO_3)_2(Y)_x$, where L is the dehydronated ligand: *N*,*N*′-bis(pyridine-2-yl)formamidine (abbreviated as Hpdf), *N*,*N*′-bis(pyrimidine-2-yl)formamidine (abbreviated as Hpmf) and *N*,*N*′-bis(5-methylpyridine-2-yl)formamidine (abbreviated as Hmpdf), Y = EtOH or H_2O and

$x = 0.5-1.5$. Recently a number of related compounds have been reported with the formula $[M_3(pdf)_4][PF_6]_2$ [where M = Cu^{II}, Co^{II}, Fe^{II}, Cr^{II}], and these were prepared by a different synthetic method[10] involving the initial synthesis of the pdf ligand followed by treatment with PF_6^- as an anion. The structural features of these systems will be compared and discussed.

Synthesis of the Complexes

The compounds are formed in situ by an easy one-step template synthesis of 2-aminopyridine, 2-aminopyrimidine, and 5-methyl-2-aminopyridine for pdf, pmf, and mpdf, respectively, using anhydrous copper(II) triflate in dry ethanol. Upon standing, deep dark green (almost black) crystals of formula $[Cu_3(L)_4](CF_3SO_3)_2(Y)_x$ were formed (Y = EtOH or H_2O, L = dehydronated ligand).

Three Cu^{II} compounds with different formamidine ligands are shown in Table 1 together with some spectral and magnetic features. It must be noted that only a very weak non-coordinating anion like triflate can be used, as stronger binding anions, like perchlorate or nitrate, do not give the same results. Attempts to use this synthetic method to prepare compounds with metals other than Cu^{II} have failed so far. Spectroscopic, magnetic and analytical characterisation showed that all three compounds must have a similar molecular structure. The structure of **1** was reported previously and the structure of **2** is discussed below.

Crystal Structure of Compound 2

X-ray structural analysis of **2** shows a linear arrangement of three Cu^{II} ions surrounded by four ligand molecules in a propeller mode, each of which is tetracoordinated to the three copper atoms. A plot representing this complex, together with the atom labelling scheme, is given in Figure 1 and distances and angles are given in Table 2. The central copper atom Cu2 has a distorted square-planar geometry [with *trans* angles of 168.7(6) and 159.2(6)°] and normal Cu−N distances of about 2.0 Å. The outer copper ions are six-coordinated with, in general, a distorted square-based geometry and a different geometry for each copper. The angles of the basal plane of Cu3 (formed by N117−N217−N317−N423) are 170.7(6)° and 160.9(6)°. The short Cu−N distances Cu3 vary from 2.002(12) to 2.124(14) Å. The axial sites of the geometry are occupied by the nitrogen atoms N223 and N417 with Cu−N distances of 2.31(2) to 2.49(2) Å. The geometry of the copper atoms Cu3 and Cu2 is comparable with those in compound **1**.[9]

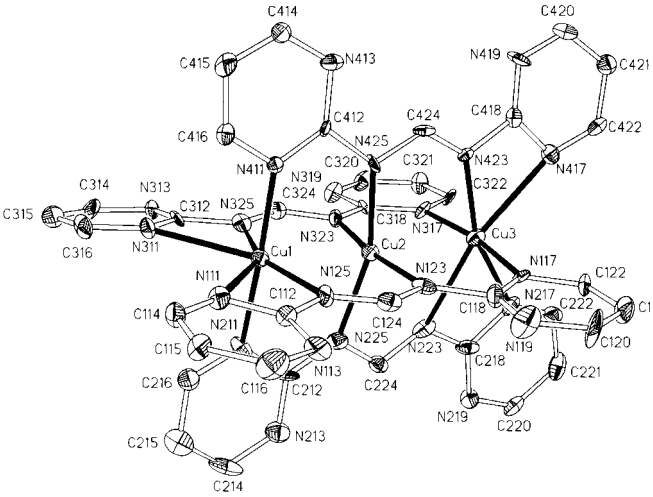

Figure 1. Plot of structure **2** with atom-labelling scheme. H atoms, the non-coordinating triflate anions, and the disordered water molecule are omitted for clarity

The octahedral geometry of the Cu1 atom is unusual (and is in contrast to compound **1**) in that it has four short Cu−N distances [2.004(13)−2.072(13) Å] and two *cis* elongated Cu−N distances of 2.546(13) and 2.538(12) Å. One angle is normal [N211−Cu1−N411 = 177.5(5)°], but two angles have very large deviations from 180° [N311−Cu1−N125 = 151.5(5), N325−Cu1−N111 = 151.0(5)°]. Such an unusual geometry has been observed previously[12] in a few cases like for the mononuclear species

$Cu(edtb)^{2+}$. The Cu−Cu distances of 2.637(3) and 2.652(3) Å are slightly shorter than in the comparable pdf compound **1** [which are 2.6618(8) and 2.6676(8) Å],[9] and are close to the shortest known distances for Cu^{II} linear trinuclear compounds (see Table 3). Only in Cu^{I} compounds are shorter distances known in some cases.[13] The linear angle Cu1−Cu2−Cu3 is 174.96(11)° and is close to those for other species[9,10a] of this type.

On viewing the compound along the Cu−Cu−Cu axis a propeller-type arrangement is visible in which the ligands are almost perpendicular to the axis with angles between the 2 rings of each ligand that vary from 7.21 to 2.10°. These variations are significantly smaller than in compound **1**, in which they vary from 27.73 to 8.19°, as can been seen from Figure 2. Further stabilisation of the lattice is achieved by stacking of pyrimidine rings between different units (ring-ring distances 3.648−3.889 Å), as can be seen in Figure 3.

Hydrogen bonds between the oxygen atoms of the disordered water molecule and the fluorine of the tetrafluoroborate anion are present, with contacts O···F of 2.73 and 3.16 Å.

An X-ray structure of compound **3** could not be obtained due to the very small crystal size, but this compound very closely resembles **1** and **2** both spectroscopically and magnetically, so a very similar structure is anticipated.

Spectroscopy

The ligand field spectra of compounds **1** to **3** all show a broad band with a double maximum at 16.1−17.3 and 20.0−22.0 $\times 10^3 cm^{-1}$. In addition, a charge transfer band is observed near $29 \cdot 10^3$ cm^{-1}. The two low-energy absorptions are both assigned to d-d transitions,[14] and it is tempting to assume that the highest energy band originates from the square-planar central Cu atom (even though Cu2 is not perfectly square-planar) and the lowest energy band from the outer six-coordinated Cu atoms.[8c,15]

The IR spectra of the compounds are rather featureless. In the mid-infrared section the characteristic C=N is still observed in the free Hpdf ligand at 1671 cm^{-1} as a strong broad band. In compound **1** a double band occurs at 1604, 1587 cm^{-1}. As the free ligand also has a band at 1602 cm^{-1}, the last band is probably the C=N stretching vibration. This band occurs at 1586 cm^{-1} and 1589 cm^{-1} for **2** and **3**, respectively.

In the far-infrared region a strong and broad vibration is predominant at 364 cm^{-1}, 381 cm^{-1}, and 377 cm^{-1} for compounds **1**, **2**, and **3**, respectively; this band can be assigned to the asymmetric Cu−N vibration.[16] Other weak bands present at lower wavenumbers have not been assigned.

EPR

The EPR spectra of powdered polycrystalline samples of the compounds at room temperature show a very broad absorption (peak to peak separation 36 mT) centered around $g = 2.11$ and a weaker broad absorption which lies around $g = 3.6$ for compounds **1** and **3** and at $g = 4.1$ for compound **2**. These latter absorptions disappear upon cooling to 77 K or lower. The main EPR signal ($g = 2.07$) sharpens upon cooling to 77 K (peak-to-peak separation 9.5 mT) and a very weak $g_{//}$ at ca. $g = 2.3$ becomes visible (no $A_{//}$ resolved) (Figure 4). Such signal sharpening upon cooling is not uncommon with trinuclear compounds.[5f,7c,17] The EPR signals at room temperature at ca. $g = 3.6-4.1$ can be assigned to the parallel transitions of the quadruplet state,[18] a state that is almost completely depopulated at 77 K. The narrowing of the other signal seems to be in agreement with this view because only the ground doublet is populated in these conditions. The energy of these signals also varies with the J values (vide infra), a fact that confirms this assignment.

Frozen solution spectra in DMF show (for compounds **2** and **3**) only a broad signal at $g = 2.07$ and a very weak unresolved $g_{//}$ section. Compound **1**, however, shows a well-resolved $g_{//}$ of 2.30 with an $A_{//}$ of 15.8 mT and this is indicative of Cu^{II} in an axial symmetry.[2,14a] This signal is likely to originate from a mononuclear species resulting from dissociation.

Magnetism

The magnetic susceptibility of powdered samples was measured from 4 to 300 K. The magnetic properties of the compounds are summarized in Table 1 and the inverse susceptibility vs. temperature is shown in Figure 5. The inverse susceptibility vs. temperature is almost linear at high temperature, exhibits a broad shoulder and a bend at ca.

Table 3. Linear Cu^{II} trinuclear compounds for which the X-ray structure and magnetism has been published[d,e]

Compound[a]	Bridging atom(s) between adjacent copper atoms[b]	Cu−Cu distance(s)	Cu−Cu−Cu angle	*2J* value [cm^{-1}]	Reference (s = structure, m = magnetism)

[a] L1 = *N*-Methyl-*N*′-(4-methoxysalicylidene)-1,3-propanediamine; amat = 4,4,9,9-tetramethyl-5,8-diazadodecane-2,11-diol; LH = 2-tolylsulfonylamido-7-hydroxy-1,8-naphthyridine; L2 = 3-[{2-(2-pyridinyl)ethyl}imino]-2-butanone oximato; adeH = adenine; H_2ahmt = 4-amino-3,5-bis(hydroxymethyl)-1,2,4-triazole; attn = 1,9-bis(3-amino-4*H*-triazol-5-yl)-3,7-dithianonane; dbae = 2-dibutylaminoethanol; deae = 2-diethylaminoethanol; Hpdf = *N*,*N*′-bis(pyridine-2-yl)formamidine; Hpmf = *N*,*N*′-bis(pyrimidine-2-yl)formamidine. − [b] When nothing is mentioned the N, O, and C atoms belong to an organic molecule. − [c] Another structure with bridging azide ions has been published recently, although only limited magnetic observations were given. The structure has the formula $[Cu_3(\mu\text{-}N_3)_4(L)_2]$ (in which L = hydridotris(3,5-dimethylpyrazolyl)borate, Cu−Cu distances of 3.082(3), 3.03(3) Å and reported to have a weak antiferromagnetic coupling. − [d] Structures with a copper distances > 5.5 Å and/or Cu−Cu−Cu angles < 170° are excluded, see for instance ref.[17] and ref.[22] − [e] After submitting the manuscript three more compounds were published for which the X-ray structure and the magnetic properties were measured; compound $[Cu_3(pytrz)_{10}(H_2O)_2](ClO_4)_6 \cdot 7\,H_2O$ (pytrz = 4-(2-pyridyl)-1,2,4-triazole), Cu−Cu distance 3.8540(7) Å and $J = -5.41$ cm^{-1}[26] and the compounds: $[Cu_3(L)_2(Me_2en)_2(H_2O)_2] \cdot 7\,H_2O$,$[Cu_3(L)_2(MeOH)_6(H_2O)_4]$ (H_3L = 3,5-pyrazoledicarboxylic acid, Me_2en = *N*,*N*-dimethylethylenediamine) with Cu−Cu distances of 4.3992(13) and 4.4532(12) Å, respectively, and *J* values of −15 cm^{-1} and −19 cm^{-1}, respectively.[27]

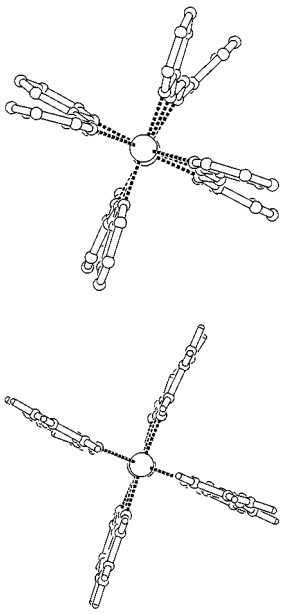

Figure 2. View along the Cu−Cu−Cu axis of structure **1**[9] and **2**

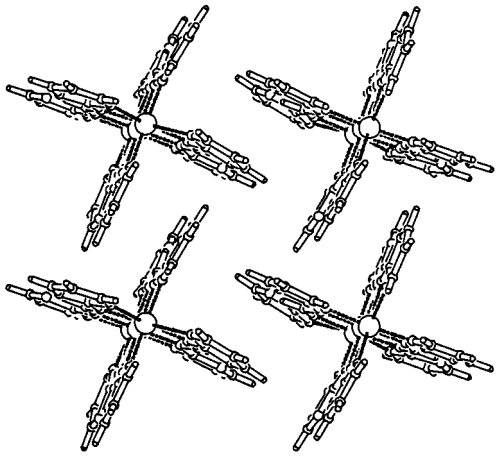

Figure 3: Packing of structure **2**, showing the stacking of the molecules. Uncoordinated triflate and water molecules are ommitted for clarity

120−160 K and is again linear at low temperatures; this behaviour is characteristic of linear trinuclear compounds

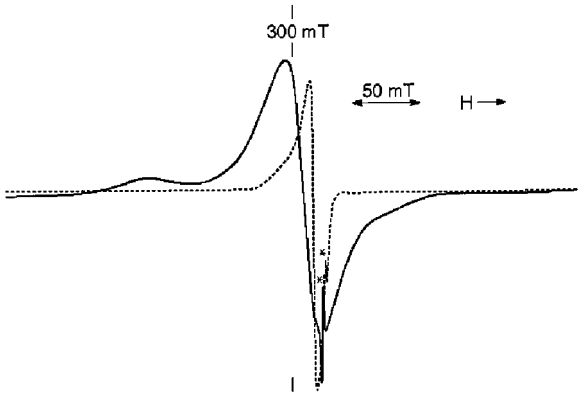

Figure 4. EPR signal of (**2**) as a powdered solid at room temperature (straight line) and at 77 K (dotted line) ("*" denotes dpph); for an explanation see text

with a strong antiferromagnetic exchange interaction between neighbouring paramagnetic metal ions.[5f,7b,19]

The effective magnetic moment μ_B per Cu at room temperature is 1.35, 1.50, 1.35 for compounds **1**, **2**, and **3**, respectively, and decreases gradually until it becomes almost constant with a value of ca. 1.05−1.10 μ_B, which is appropriate for a system with a spin = 1/2 ground state; such values have also been found for other linear Cu trinuclear compounds.[4f,5c,5f,8a,8c]

The magnetic data were fitted to the theoretical expression for the magnetic susceptibility of linear trinuclear $S = 1/2$ systems, which was based on the Hamiltonian:[5f,7b,7c,20]

$$H = -2J(\mathbf{S1}\cdot\mathbf{S2} + \mathbf{S2}\cdot\mathbf{S3}) - 2J'\cdot\mathbf{S1}\cdot\mathbf{S3}$$

in which J is the interaction between adjacent nuclei (J_{12}) and J' the interaction between terminal nuclei (J_{13}). In a trinuclear linear Cu compound the magnetic interaction (J_{12}) between neighbouring copper ions is the dominant pathway of the interaction, and the interaction between the terminal copper ions (J_{13}) can be neglected (i.e. J_{13} is almost zero).[2,5f,7b,10a] Only if the linearity is far from 180°, or in triangular cases, can the value for J_{13} not be neglected.[21]

The magnetic susceptibility is then defined by Equation (1):

$$\chi_m = (Ng^2m_B^2/4\,kT) \times [1 + \exp(-2J/kT) + 10\exp(J/kT)] / [3 + 3\exp(-2J/kT) + 6\exp(J/kT)] \quad (1)$$

(N, g, μ_B, k, and T have their usual meanings, the exchange parameter is denoted as J. The g tensor was assumed to be equal for all individual metal ions).

A good fit has been obtained for the parameters J = −174(1) cm^{-1}, −120(1) cm^{-1}, and −167(1) cm^{-1}, for compounds **1**, **2**, and **3**, respectively.

From these values, and also from Figure 5, it can be seen that compounds **1** and **3** have almost the same behaviour and probably also a very similar structure, which is not surprising as the methyl group will fall at the outer ends of the trinuclear structure and the Cu1−Cu2−Cu3 chromophore can remain the same. Compound **2** has a quite different ligand and, therefore, some other differences (e.g. geometry) in the structure (see Figure 2) and J value are also observed.

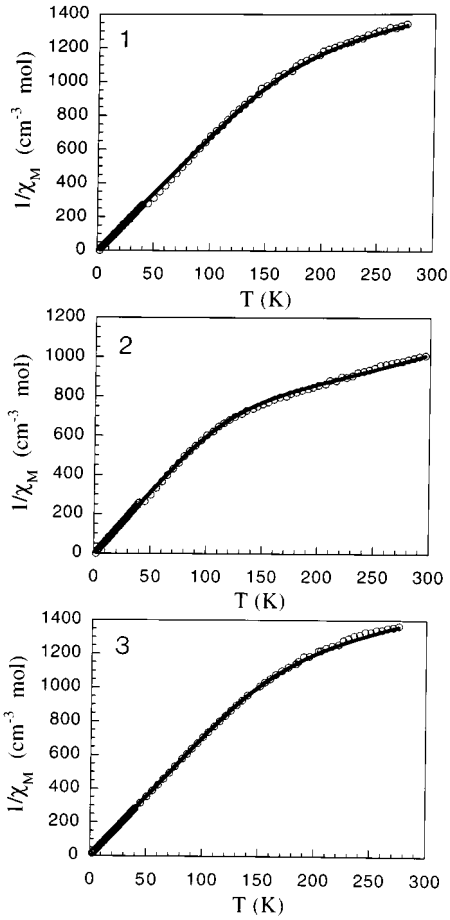

Figure 5. Inverse molar susceptibility ($1/\chi$) (O) as a function of the temperature of compounds **1**, **2**, and **3**. The full curves represent the theoretical curves (see text and Table 1)

Concluding Remarks

In Table 3, a number of the copper(II) compounds is listed with decreasing Cu−Cu distances, studied both magnetically *and* by use of X-ray crystallography. A number of relevant crystallographic and magnetic parameters are also listed. By comparing these magnetic values it can be concluded that the metal-metal distance is one of the important factors, except when the bridging unit is azido,[5d] oxamido,[17] or thiooxamido.[22] The (relatively) strong antiferromagnetism (J = −98.7 and −483 cm^{-1}) for these last two ligands has been attributed to the superexchange by the orbitals of oxygen and/or sulfur, although the Cu−Cu distances are large (about 5−5.5 Å), but it must also be noted that the Cu−Cu−Cu angle deviates markedly from linearity (154−165°)[17,22,23] in these cases. The strong antiferromagnetic coupling (J = −212 cm^{-1}, Cu−Cu distance 2.940 Å) in the compound $[Cu_3(racemo\text{-amat})_2](ClO_4)_2$ (in which amat = 4,4,9,9-tetramethyl-5,8-diazadodecane-2,11-

diol) has been attributed to the same superexchange of the p orbitals of the oxygen.[5e]

Two Cu^{II} compounds have been described with a smaller Cu−Cu separation than that reported in this paper. The compounds $[Cu_3(bipyam)_4X_2]\cdot H_2O$ [in which bipyam = bis(2-pyridyl)amide and X = Cl or Br] have a Cu−Cu separation of 2.471 and 2.468 Å and a strong antiferromagnetism has been suggested of < -500 cm^{-1},[8a,8c] although their magnetism has not been reported. The only linear trinuclear compounds (of which the X-ray structure has been measured) that exist with short Cu−Cu distances between 2.466−2.348 Å involve Cu^{I}, and there are several examples.[13] Only two compounds, which are related to each other, have a ferromagnetic coupling.[5a] In order to understand more about magnetism further research will be needed on strictly linear trinuclear Cu^{II} compounds.

Experimental Section

General: C, H, N, and Cu determinations were performed by the Microanalytical Laboratory of University College, Dublin, Ireland. − UV/Vis spectra were obtained on a Perkin−Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. − X-band powder EPR spectra were obtained on a Jeol RE2x electron spin resonance spectrometer using DPPH (g = 2.0036) as a standard. − FTIR spectra were obtained on a Perkin−Elmer Paragon 1000 FTIR spectrophotometer by using KBr pellets or films between KBr disks.

FIR-FTIR spectra were obtained on a Bruker 113v infrared spectrophotometer as polyethylene mulls (600−100 cm^{-1}, mirror velocity 0.099 cm/sec, resolution 2 cm^{-1}, Mylar 3.5 Å beam splitter). Magnetic susceptibility measurements (4−300 K) were carried out using a Quantum Design MPMS-5 5T SQUID magnetometer (measurements carried out at 1000 Gauss). Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.

Synthesis of the Compounds: 2-aminopyridine, 2-amino-5-methylpyridine, and 2-aminopyrimidine were obtained from Acros Organics; Anhydrous copper(II) triflate was obtained from Strem Chemicals. The solvents were commercially available and used without further purification. Ethanol was dried with magnesium sulfate.

General Synthesis: 1.2 mmol of dry $Cu(CF_3SO_3)_2$ and 1.2 mmol of the ligand were each dissolved in ca. 10 mL of dry ethanol. The solutions were carefully heated to about 40 °C on a lamp-heating device. To each solution ca. 5 mL of triethylorthoformate was added. The copper solution was added carefully to the amino compound solution and filtered to remove any un-dissolved material. After a few days a blackish (green) crystalline material was obtained, which was filtered off and air-dried. Yields varied from 55 to 65%.

Compound **1** $\{[Cu_3(pdf)_4](CF_3SO_3)_2(EtOH)_{1.5}\}$ could also be synthesized directly from the copper(II) triflate salt and the ligand Hpdf (which is known from a synthesis reported in the literature[24]) in dry ethanol, with triethylorthoformate used to remove any water from the ethanol.

Elemental Analysis: Compound **1:** $[Cu_3(pdf)_4](CF_3SO_3)_2(EtOH)_{1.5}$, $(C_{49}H_{45}Cu_3F_6N_{16}O_{7.5}S_2)$; calcd. C 43.70, H 3.37, N 16.64, Cu 14.16; found C 43.21, H 3.19, N 16.56, Cu 13.64; Compound **2:** $[Cu_3(pmf)_4](CF_3SO_3)_2(H_2O)0.5$, $(C_{38}H_{29}Cu_3F_6N_{24}O_{6.5}S_2)$; calcd. C 35.26, H 2.26, N 25.97, Cu 14.73; found C 35.71, H 2.46, N 25.62, Cu 13.95; Compound **3:** $[Cu_3(mpdf)_4](CF_3SO_3)_2(EtOH)_1$, $(C_{56}H_{58}Cu_3F_6N_{16}O_7S_2)$; calcd. C 46.84, H 4.07, N 15.61, Cu 13.28; found: C 46.19, H 3.95, N 15.64, Cu 13.27.

X-ray Crystallographic Studies: Crystal data for $[Cu_3(pmf)_4](CF_3SO_3)_2(H_2O)_{0.5}$: $C_{38}H_{28}Cu_3F_6N_{24}O_{6.5}S_2$, M = 1293.6, triclinic, space group $P-1$ (no. 2), a = 8.529(5), b = 15.760(5), c = 19.639(5) Å, α = 101.793(5), β = 101.263(5), γ = 102.389(5)°, V = 2444(2) Å^3, Z = 2, D_c = 1.759 g cm^{-3}, T = 193(2) K, μ = 1.477 mm^{-1}, F (000) = 1300, 6141 reflections measured, 5939 independent (R_{int} = 0.0423), (range $2.53 < \theta < 24.00°$), refined data/parameters: 5939, 686; largest difference peak and hole 1.658 and −0.803 e·Å^{-3}.

A blackish (green) crystal with dimensions of 0.14 × 0.10 × 0.03 mm was selected, mounted onto the glass fibre using the oil drop method[25a] and measured with a Rigaku AFC-7S diffractometer, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å), $\omega - 2\theta$ scans. Data reduction was performed using the TEXSAN[25b] package. The intensity data were corrected for Lorentz and polarization effects and for absorption and extinction. All non-H atoms were refined anisotropically. The disordered water atoms O1 and O2 with a population parameter of 0.25 were refined isotropically. The H atoms, except those of the disordered water, were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms. The structure was solved using direct methods SHELXS-97.[25c] The weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.1197P)^2 + 3.4200P]$, where $P = (F_o^2 + 2F_c^2)/3$ was adopted. The refinement method was full-matrix least-squares on F^2 using the SHELXL97[25d] package converged to $R1$ [$I > 2\sigma(I)$] = 0.109, $wR2$ = 0.255 (all data), S = 1.034.

Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-116049. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44(1223)336−033, E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

The work described in this paper was supported by the Leiden University Study group WFMO (Werkgroep Fundamenteel Materialen Onderzoek). Use of the services and facilities of the Dutch National NWO/SURF Expertise Center CAOS/CAMM, under grant numbers SON 326−052 and STW NCH99.1751, is gratefully acknowledged. The authors are indebted to the EU for a grant as Host Institute in the EU Programme Human Capital and Mobility (1994−1997). Dr. J. G. Haasnoot and Prof. Dr. D. Gatteschi are thanked for their helpful suggestions.

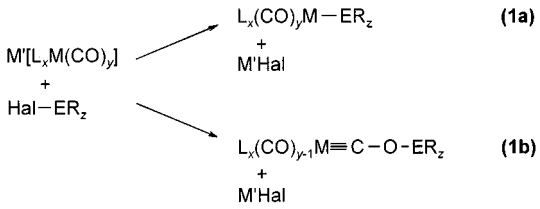
Synthesis and Structure of Trinuclear Boryloxycarbyne Complexes

Holger Braunschweig,*[a] Carsten Kollann,[a] Margot Koster,[a] Ulli Englert,[a] and Matthias Müller[b]

Keywords: Boron / Iron / Nickel / Carbyne complexes



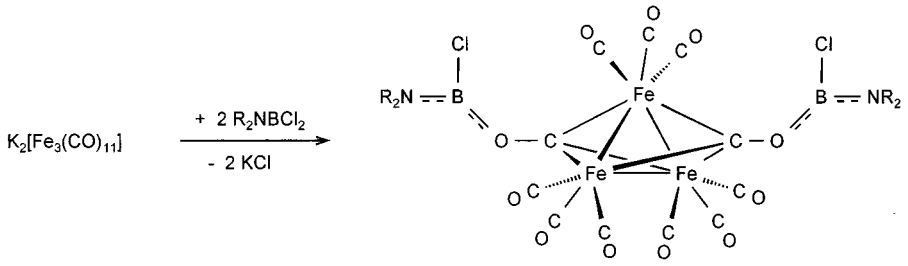
The μ^3-boryloxycarbyne complexes $[\{Fe(CO)_3\}_3\{\mu^3\text{-}COBCl\{NtBu(SiMe_3)\}\}_2]$ (**1**) and $[\{(\eta^5\text{-}C_5H_5)Ni\}_3\{\mu^3\text{-}COBX(NR_2)\}\mu^3\text{-}CO]$ (**2a**: $NR_2 = NtBu(SiMe_3)$, X = Cl; **2b**: $NR_2 = N(SiMe_3)_2$, X = Cl; **2c**: $NR_2 = NMe_2$, X = $BNMe_2Cl$) were obtained by reaction of the anionic complexes $K_2[\{Fe(CO)_3\}_3\{\mu^3\text{-}CO\}_2]$ and $K[\{(\eta^5\text{-}C_5H_5)Ni(CO)]$ with the corresponding chloroboranes Cl_2BNR_2 {$NR_2 = NtBu(SiMe_3)$, $N(SiMe_3)_2$}, or 1,2-dichlorodiboranes(4) $B_2(NMe_2)_2Cl_2$, respectively. The products are formed by a nucleophilic attack of the CO oxygen atom at the boron centres with subsequent salt elimination. All compounds were characterized by IR and multinuclear NMR spectroscopy, and the structures of **1** and **2c** in the solid state were determined by single-crystal X-ray diffraction studies.

Introduction

A large number of complexes $[L_x(CO)_yM-ER_z]$ with transition metal element bonds have been obtained over the last decades by salt elimination reactions between anionic complexes of the type $M'[L_xM(CO)_y]$ and element halides $HalER_z$ according to Equation 1a.[1a,b] More recently, this fundamental reaction has also been very successfully employed for the synthesis of transition metal complexes of boron, especially for boryl and borylene complexes.[2a,b] In the course of our investigations in this field we found that the mononuclear anionic complexes $K[(\eta^5\text{-}C_5H_5)M(CO)_3]$ (M = Mo, W) undergo salt elimination reactions with 1,2-diiododiboranes(4) by nucleophilic attack of the CO oxygen atom at the boron centre with formation of oxycarbyne complexes of the type $[1,2\text{-}\{(\eta^5\text{-}C_5H_5)M(CO)_2CO\}_2B_2(NMe_2)_2]$.[3] Despite the spectroscopic and experimental evidence for the nucleophilic character of the CO atom in anionic carbonyl complexes,[4a–d] this alternative pathway, with formation of the corresponding oxycarbyne complexes of the type $[L_x(CO)_{y-1}M{\equiv}C-O-ER_z]$ according to Equation 1b, has only been observed once before.[5] In the present paper we describe the syntheses of some trinuclear μ^3-boryloxycarbyne complexes, which were obtained from anionic carbonyl complexes and suitable haloboranes; these compounds are also formed by nucleophilic attack of CO oxygen atoms at boron and salt elimination.

Results and Discussion

The reaction of the trimeric dianion $[Fe_3(CO)_{11}]^{2-}$, which was used as the corresponding dipotassium salt, with two equivalents of $Cl_2BNtBu(SiMe_3)$ afforded the μ^3-oxycarbyne complex **1** according to Equation 2.



(1a) (1b)

The product was isolated as red crystalline platelets in yields of about 62%. It is readily soluble in nonpolar solvents, extremely sensitive to air and moisture, and melts without decomposition at 124°C. The structure of **1** in solution derives from IR and NMR spectroscopic data. A distinct high-field shift of the ^{11}B NMR signal at $\delta = 28.1$ relative to that of the starting material $Cl_2BNtBu(SiMe_3)$ ($\delta = 36.6$)[6] indicates the formation of an oxoborane derivative, and all other spectroscopic findings, such as the CO stretching frequencies in the IR spectrum ($\tilde{\nu}$ = 2040, 2007 and 1942 cm^{-1}), confirmed our expectations.[7] An X-ray structure analysis was carried out on a single crystal of **1**, which was grown from a hexane solution at −30°C. Although the quality of the structure refinement suffers from incorporated and disordered solvent molecules, the results unambigously prove the constitution of $[\{Fe(CO)_3\}_3\{\mu^3\text{-}COBCl\{NtBu(SiMe_3)\}\}_2]$ (**1**) in the crystalline state (Figure 1).

The compound crystallizes in the space group $P\bar{1}$ (no. 2), and the molecule adopts C_1 symmetry. The three iron atoms form an almost regular triangle with iron-iron distances ranging between 250 and 253 pm. This $Fe_3(CO)_9$ moiety is capped by two μ^3-$COBCl\{NtBu(SiMe_3)\}$ carbyne ligands resulting in a central trigonal-bipyramidal Fe_3C_2 core with iron-carbon distances of about 195 pm. The boron-oxygen {B1–O1 = 138(1) pm, B2–O2 = 135(1) pm} and boron-nitrogen {B1–N1 = B2–N2 = 141(1) pm} bond lengths are in the expected range for B–O and B–N linkages with partial double bond character.[8]

1; NR_2 = N*t*Bu(SiMe$_3$)

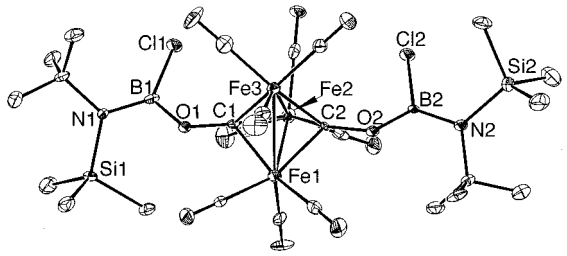

Figure 1. PLATON[21] representation of **1** in the crystal (displacement ellipsoids scaled to 30% probability, hydrogen atoms omitted); selected bond lengths (pm) and angles (deg): Fe1−Fe2 250.6(2), Fe1−Fe3 250.1(2), B2−O2 135(1), B1−O1 139(1), B1−N1 141(1), B2−N2 141(1); Fe2−Fe1−Fe3 60.80(5)

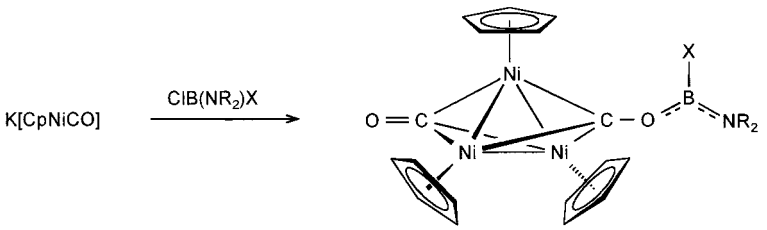

Related trinuclear nickel carbyne complexes were obtained from the reaction of mononuclear K[{(η^5-C_5H_5)NiCO] with monoborane- or diborane(4)chlorides, respectively (Equation 3).

The formation of [{(η^5-C_5H_5)Ni}$_3${μ^3-COBX(NR_2)}μ^3-CO] (**2a**, NR_2 = N*t*Bu($SiMe_3$), X = Cl; **2b**, NR_2 = N($SiMe_3$)$_2$, X = Cl; **2c**, NR_2 = NMe_2, X = $BNMe_2Cl$) was again achieved from nucleophilic attack of a CO oxygen atom at the boron centre. All three boryloxycarbyne complexes were isolated in 12%−15% yields as black, crystalline solids that dissolve readily in nonpolar solvents such as hexane. Solutions of **2a−c** are stable for several days at ambient temperature under an inert gas atmosphere, but exposure to air immediately leads to decomposition.

The compounds [{(η^5-C_5H_5)Ni}$_3${μ^3-COBX(NR_2)}μ^3-CO] (**2a**, NR_2 = N*t*Bu($SiMe_3$), X = Cl; **2b**, NR_2 = N($SiMe_3$)$_2$, X = Cl; **2c**, NR_2 = NMe_2, X = $BNMe_2Cl$) are obviously the products of a complex, nonstoichiometric reaction, and hence, attempts were made to obtain the nickel complexes directly from the corresponding trinuclear monoanion [{(η^5-C_5H_5)Ni}$_3${μ^3-CO}$_2$]$^-$.[9] Interestingly, these reactions always resulted in mixtures of several boron-containing species and the formation of compounds **2a−c** could not be observed.

The molecular structure of the trinuclear nickel complexes in solution was deduced from IR and multinuclear NMR spectroscopic measurements. The boryl compounds **2a,b** show the expected shift to higher field for the ^{11}B NMR signals [δ = 26.0 (**2a**) and δ = 25.9 (**2b**)], whereas the diboran(4)yl derivative **2c** is characterized by two signals at δ = 30.9 and 38.0. The position of the latter signal is almost unaltered with respect to that of the starting diborane(4) $B_2(NMe_2)_2Cl_2$,[10] and is assigned to the chloride-substituted boron atom, while the distinct high-field shift of the other signal clearly indicates the boron-oxygen linkage. Due to a restricted rotation around the boron-nitrogen double bonds the four methyl groups exhibit four signals in the ^{1}H and ^{13}C NMR spectra. The CO stretching frequencies in the IR spectra at $\tilde{\nu}$ = 1719 (**2a**), 1716 (**2b**) and 1734 cm^{-1} (**2c**) are in the expected range for μ^3-CO ligands. An X-ray structure analysis was carried out for the diborane(4) derivative **2c** (Figure 2).

This compound crystallizes in the monoclinic space group $P2_1/n$, and the molecule adopts C_1 symmetry. The three nickel atoms form a regular triangle, with Ni−Ni bond lengths of about 243 pm, which is capped on one side by a μ^3-CO ligand and on the other side by a μ^3-oxycarbyne

(3)

2a, NR_2 = N*t*Bu($SiMe_3$), X = Cl

2b, NR_2 = N($SiMe_3$)$_2$, X = Cl

2c, NR_2 = NMe_2, X = $BNMe_2Cl$

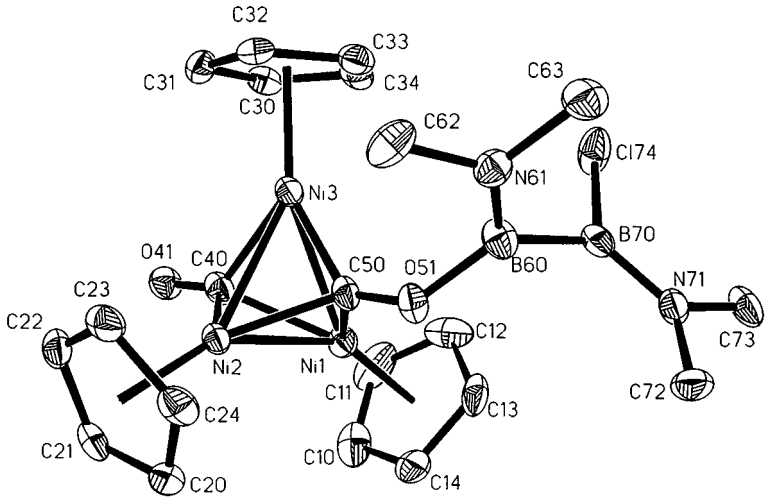

Figure 2. CAMERON[22] representation of **2c** in the crystal (displacement ellipsoids scaled to 30% probability, hydrogen atoms omitted); selected bond lengths (pm) and angles (deg): Ni1−Ni2 243.19(9), Ni1−Ni3 243.33(9), B60−B70 172.2(7), B70−N71 135.3(7), B60−N61, 137.7(8), B60−O51 143.4(7); Ni2−Ni1−Ni3 59.98(3)

moiety. The structural parameters of the central Ni_3C_2 core resemble those of the trimeric monoanion $[\{(\eta^5\text{-}C_5H_5)Ni\}_3\{\mu^3\text{-}CO\}_2]^-$,[9] and the geometry of the boryloxycarbyne moiety C−O−B(NMe$_2$)−B(NMe$_2$)Cl is similar to that of the related mononuclear complex $[1,2\text{-}\{(\eta^5\text{-}C_5H_5)Mo(CO)_2CO\}_2B_2(NMe_2)_2]$.[3] In both cases the boron-nitrogen bond lengths range from 135 to 137 pm, thus indicating double bonds, whereas the boron-oxygen bond lengths of about 144 pm are evidence for B−O linkages without significant π-interactions. These observations with respect to the bonding situation of the boron atom to the neighbouring RO- and R_2N groups of **2c** are in contrast to the results described for $[\{Fe(CO)_3\}_3\{\mu^3\text{-}COBCl\text{-}\{NtBu(SiMe_3)\}\}_2]$ (**1**). The hindered rotation of the Me_2N groups in **2c**, which was not observed for the monoborane derivatives **1** and **2a**,**b**, gives further evidence for less effective boron-nitrogen π-interaction bond in the latter complexes, which may be due to the electron-withdrawing effect of the $SiMe_3$ groups.

Experimental Section

All manipulations were carried out under a dry nitrogen atmosphere with common Schlenk techniques. Solvents and reagents were dried by standard procedures, distilled, and stored under nitrogen over molecular sieves. $B_2(NMe_2)_2Cl_2$,[10] $Cl_2BN(SiMe_3)_2$,[11] $Cl_2BNtBu(SiMe_3)$,[6] $K_2[Fe_3(CO)_{11}]$,[12] and $K[(\eta^5\text{-}C_5H_5)Ni(CO)]$[13] were synthesised according to literature procedures. − NMR: Varian Unity 500 at 499.843 MHz (^{1}H, internal standard TMS), 150.364 MHz (^{11}B, BF3·OEt2 in C_6D_6 as external standard), 125.639 MHz ($^{13}C\{^1H\}$, APT, internal standard TMS); all NMR spectra were recorded in C_6D_6 as solvent unless otherwise stated. − Elemental analyses (C, H, N): Carlo−Erba elemental analyzer, model 1106. − IR: Perkin−Elmer FT-IR 1720x

$[\{Fe(CO)_3\}_3\{\mu^3\text{-}COBCl\{NtBu(SiMe_3)\}\}_2]$ (1): Neat $Cl_2BN(tBu)SiMe_3$ (1.70 g, 7.52 mmol) was added to a dark red suspension of $K_2[Fe_3(CO)_{11}]$ (2.08 g, 3.76 mmol) in 30 mL benzene at ambient temperature. The reaction mixture was stirred for 15 min and the solvent was subsequently removed under high vacuum. The orange-red residue was extractet with 30 mL of hexane, and after filtration and cooling to −30°C, compound **1** (1.99 g, 61.7%) was obtained as an extremely air-sensitive red solid. Recrystallisation from hexane at −30°C yielded dark red platelets of **1**, m.p. 124°C (sealed tube). − ^{1}H NMR: δ = 0.46 (s, 18 H, $SiMe_3$), 1.53 (s, 18 H, CMe_3). − ^{11}B NMR: δ = 28.1 (s). − ^{13}C NMR: δ = 5.4 ($SiMe_3$), 32.8 (CMe_3), 56.6 (CMe_3), 209.8 (CO), no signals for μ^3-carbyne were found. − IR (toluene): $\tilde{\nu}$ = 2040, 2007, 1942 cm^{-1} (CO). − $C_{25}H_{36}B_2Cl_2Fe_3N_2O_{11}Si_2$ (856.78): calcd. C 35.04, H 4.24, N 3.27; found C 34.55, H 4.36, N 3.02.

$[\{(\eta^5\text{-}C_5H_5)Ni\}_3\{\mu^3\text{-}COBCl\{NtBu(SiMe_3)\}\}\mu^3\text{-}CO]$ (2a): Neat $Cl_2BNtBu(SiMe_3)$ (1.01 g, 4.45 mmol) was added to a suspension of $K[(\eta^5\text{-}C_5H_5)Ni(CO)]$ (0.85 g, 4.45 mmol) in 20 mL of toluene at 0°C. The black reaction mixture was stirred for 20 min, warmed to ambient temperature and all volatiles were removed under high vacuum. The remaining solid was extracted with 20 mL of hexane and the resulting black suspension was filtered. The residue was discarded after rinsing with two portions of 5 mL of hexane. After evaporating the dark red filtrate to ca. 20 mL and cooling to −30°C, compound **2a** (0.38 g, 14%) was obtained as a black microcrystalline solid, no m.p. observed, decomposition above 200°C (sealed tube). − ^{1}H NMR: δ = 0.47 (s, 9 H, $SiMe_3$), 1.51 (s, 9 H, CMe_3), 5.11 (s, 15 H, C_5H_5). − ^{11}B NMR: δ = 26.0 (s). − ^{13}C NMR: δ = 5.4 ($SiMe_3$), 32.8 (CMe_3), 56.1 (CMe_3), 92.6 (C_5H_5), no signals for μ^3-CO and μ^3-carbyne observed. − IR (toluene): $\tilde{\nu}$ = 1719 cm^{-1} (s, μ^3-CO). − $C_{24}H_{33}BClNNi_3O_2Si$ (617.69): calcd. C 46.64, H 5.38, N 2.27; found C 45.97, H 5.45, N 2.36.

$[\{(\eta^5\text{-}C_5H_5)Ni\}_3\{\mu^3\text{-}COBCl\{N(SiMe_3)_2\}\}\mu^3\text{-}CO]$ (2b): As described above for **2a** neat $Cl_2BN(SiMe_3)_2$ (1.48 g, 6.13 mmol) was treated with $K[(\eta^5\text{-}C_5H_5)Ni(CO)]$ (1.17 g, 6.13 mmol). to give **2b** (0.47 g, 12%) as a black microcrystalline solid, no m.p. observed, decomposition above 200°C (sealed tube). − ^{1}H NMR: δ = 0.42 (s, 18 H, $SiMe_3$), 5.10 (s, 15 H, C_5H_5). − ^{11}B NMR: δ = 25.9 (s). − ^{13}C NMR: δ = 3.5 (s, $SiMe_3$), 92.7 (C_5H_5), no signals for μ^3-CO and μ^3-carbyne observed. − IR (toluene): $\tilde{\nu}$ = 1716 cm^{-1} (s, μ^3-CO). − $C_{23}H_{33}BClNNi_3O_2Si_2$ (634.10): calcd. C 43.56, H 5.24, N 2.21; found C 43.01, H 5. 38, N 2.32.

$[\{(\eta^5\text{-}C_5H_5)Ni\}_3\{\mu^3\text{-}COBNMe_2\{BNMe_2Cl\}\}\mu^3\text{-}CO]$ (2c): As described above for **2a** neat $B_2(NMe_2)_2Cl_2$ (1.07 g, 5.92 mmol) was treated with $K[(\eta^5\text{-}C_5H_5)Ni(CO)]$ (1.13 g, 5.92 mmol). to give **2c** (0.44 g, 13%) as a black microcrystalline solid, m.p. 87°C (sealed

tube). – ^{1}H NMR: δ = 2.48, 2.62, 2.65, 2.73 (s, 6 H, NMe), 5.18 (s, 15 H, C_5H_5). – ^{11}B NMR: δ = 30.9 (s, BO), 38.0 (s, BCl). – ^{13}C NMR: δ = 36.3, 37.9, 38.7, 42.4 (NMe), 92.2 (C_5H_5), no signals for μ^3-CO and μ^3-carbyne observed. – IR (toluene): $\tilde{\nu}$ = 1734 cm^{-1} (m, μ^3-CO). – $C_{21}H_{27}B_2ClN_2Ni_3O_2$ (572.63): calcd. C 44.01, H 4.75, N 4.89; found C 43.39, H 5.10, N 4.74.

X-ray Crystal Structure Determination of Compound 1·0.5 hexane

Experimental: Crystals of **1**·0.5 hexane were grown from a hexane solution at −30°C. A dark red rod of approximate dimensions 0.60 × 0.32 × 0.24 mm^3 was selected and mounted on a glass fibre in a cold (203 K) stream of nitrogen.

Crystal Data: $C_{28}H_{43}B_2ClFe_3N_2O_{11}Si_2$, M = 899.90 g mol^{-1}, triclinic, a = 8.432(2) Å, b = 12.591(4) Å, c = 19.067(2) Å, α = 78.68(2)°, β = 85.00(2)°, γ = 88.32(3)°, V = 1977(1) Å^3, space group P1bar (no. 2), Z = 4, D_X = 1.51 g cm^{-3}, μ = 13.34 cm^{-1}.

Data Collection and Processing: Intensity data were collected at 203 K on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). 8318 reflections were measured in the scan range 3° < θ < 26° and corrected for Lorentz and polarization effects. An empirical absorption correction based on azimuthal scans[14] was applied before averaging over symmetry related reflections. Of 7763 independent reflections 4741 data with $I > 1.0\ \sigma(I)$ were considered observed.

Structure Solution and Refinement: The structure was solved by direct methods[15] and refined on structure factors with the SDP program suite.[16] The crystal structure exhibits a large void of ca 100 Å^3 close to the crystallographic inversion centre, which contains a disordered hexane molecule. All non-hydrogen atoms, except those of the disordered solvent were refined with anisotropic displacement parameters, and hydrogen atoms for the nondisordered part of the structure were included as riding with C–H = 0.98 Å, U_{iso}(H) = 1.3 U_{eq}(C). The C atoms of the hexane moiety were assigned isotropic displacement parameters. Convergence was obtained for 440 variables and 4741 observations at R = 0.10, R_w = 0.095 and GOF = 1.774. A final difference Fourier synthesis showed a local maximum of 3.5 e Å^{-3} close (0.9 Å) to Fe1; residual electron density was still located in the region of the disordered solvent.

X-ray Crystal Structure Determination of Compound 2c

Experimental: Crystals of **2c** were grown from a hexane solution at −30°C. A crystal was immersed in highly viscous perfluoropolyether under argon to exclude oxygen. It was mounted on a glass fibre and plunged into a cold (100 K) nitrogen stream.

Crystal Data: $C_{21}H_{27}B_2ClN_2Ni_3O_2$, M = 572.66 g mol^{-1}, monoclinic, a = 12.722(1) Å, b = 9.463(1) Å, c = 19.309(2) Å, β = 92.477(6)°, V = 2322 Å^3, space group $P2_1/n$, Z = 4, D_X = 1.624 g cm^{-3}, μ = 25.35 cm^{-1}, black crystals, crystal dimensions 0.26 × 0.21 × 0.16 mm^3.

Data Collection and Processing: The data were collected at 100 K on an Enraf–Nonius DIP2020 image plate diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). 32395 Reflections were measured (1 < θ < 26°, −15 ≤ h ≤ 15, −11 ≤ k ≤ 11, −24 ≤ l ≤ 24). The 4646 unique reflections obtained gave 2618 reflections with $I > 3\sigma(I)$. The images were processed with the DENZO and SCALEPACK programs.[17] Corrections for Lorentz and polarisation effects were made. No corrections for anomalous scattering, absorption or extinction were performed.

Structure Solution and Refinement: The crystal structure was solved by direct methods and refined by the full-matrix least-squares method. Subsequent difference Fourier analysis revealed the terminal (Cl)(Me_2N)B fragment to be disordered over two sites. The refinement of the occupancies of the two disordered groups converged at a ratio of 0.17 to 0.83. The atoms B80 and N81 of the isomer with the smaller occupancy factor were refined with isotropic displacement parameters. All non-hydrogen atoms with the exception of B80, N81, C82 and C83 were refined anisotropically. The B–B bond lengths, the B–Cl bond lengths and the B–N bond lengths of the B–B(Cl)(NMe_2) fragment were restrained to have the same lengths in both isomers. The carbon atoms C82 and C83 of the isomer with minor occupancy could not be found in difference maps. Towards the final stage of the structure determination C82, C83 and all hydrogen atoms were added geometrically (N–C = 1.47 Å, C–H = 1.00 Å) after each refinement cycle. Their isotropic temperature factors were chosen to be equal to U[iso] of the heavy atom to which they are linked. During refinement the geometrically added atoms were treated with fixed thermal and positional parameters. They were included in the structure factor calculations. The 298 refined parameters and 2624 observations resulted in an observation/refined parameter ratio of 8.8. A Chebyshev weighting scheme[18] with parameters 2.27, 0.679 and 1.68 was applied. Refinement on F converged at R = 0.038, R_w = 0.048 and GOF = 0.84. A final difference Fourier synthesis showed minimum and maximum residual electron densities of −0.43 and 0.45 e Å^{-3}. All crystallographic calculations were carried out with the CRYSTALS program package.[19] Neutral atom scattering factors were taken from the International Tables for Crystallography.[20]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-121748 (**1**) and -121749 (**2c**). Complexes of Group 3 Metals and Lanthanides That Contain Siloxane-Bridged Bisaminopyridinato Ligands: Synthesis, Structure, and Application in the Ring-Opening Polymerization of Lactones

Henrik Noss,[a] Markus Oberthür,[a] Christine Fischer,[a] Winfried P. Kretschmer,[b] and Rhett Kempe*[a]

Keywords: N-ligands / Yttrium / Samarium / Ring-opening polymerization / Lactones

The reaction of one equivalent of dilithiated $O(SiMe_2\text{-}Ap\text{-}H)_2$ [Ap-H = -N(2-amino-4-methylpyridine)] (**1**), generated in situ, with $LnCl_3$ (Ln = Y, Sm) in THF affords $O(SiMe_2\text{-}Ap)_2YCl(THF)_2$ (**2**) or $O(SiMe_2\text{-}Ap)_2SmCl(THF)_3$ (**3**). In contrast, the reaction of one or two equivalents of dilithiated **1**, again generated in situ, with $LaBr_3$ in THF affords $O(SiMe_2\text{-}Ap)_2)_2LaLi(THF)_3$ (**4**). An X-ray structural analysis of **2** and **3** reveal the $O(SiMe_2\text{-}Ap)^{2-}$ ligand to bind in a planar tetradentate manner. Equivalent Sm–N distances in **3** indicate a delocalized binding mode. Compound **2** reacts with Bu_4NBH_4, $NaBH_4$ or $LiCH(SiMe_3)_2$ to give the corresponding "ate" complexes $O(SiMe_2\text{-}Ap)_2Y(BH_4)\text{-}Cl(THF)$ Bu_4N (**5**), $O(SiMe_2\text{-}Ap)_2Y(BH_4)_2Na(THF)_2$ (**6**) and $O(SiMe_2\text{-}Ap)_2Y(CH(TMS)_2)_2Li(THF)_3$ (**7**), respectively. The steric demand of the $O(SiMe_2\text{-}Ap)^{2-}$ ligand is not large enough to stabilize monoalkyl or monoborohydride complexes. Complex **4** has been used as an initiator for the ring-opening polymerization of ε-caprolactone or δ-valerolactone. In both cases an almost linear relation between the monomer-to-initiator ratio and the molecular weight of the obtained polyester is observed. By conducting the polymerization in neat ε-caprolactone at room temperature a solid polyester block is formed after 3 min (300000 $g \cdot mol^{-1}$, M_w/M_n 2.3).

Introduction

The most popular amido ligands in lanthanide chemistry are the silyl-substituted benzamidinates (Scheme 1, left).[1] Related to these ligands are deprotonated 2-aminopyridines (aminopyridinato ligands) when they are bound in a strained η^2 coordination mode (Scheme 1, right).

Scheme 1. Benzamidinate (left) and aminopyridinato (right) ligands

Only a few examples of such group 3 metal complexes (including lanthanides) have been described so far.[2] An advantage of aminopyridinato over amidinato ligands is the opportunity to connect two of them easily by a bridge between the amido nitrogen atoms,[3] thus giving additional possibilities in ligand and complex design. Furthermore, an increase in the stability of the metal-ligand bond (chelating effect) might be established, which would extend the active lifetime of such compounds when employed as catalysts. However, a disadvantage of the aminopyridinato ligands might be the lower steric demand of these ligands, since steric shielding is considered to be very important to prevent the formation of "ate" complexes. Recently, "ate" complexes have been shown to have very interesting applications in homogeneous catalysis[4][5] and coordination chemistry.[2][6] In this paper we report on the synthesis and structure of group 3 and lanthanide complexes that contain siloxane-bridged bisaminopyridinato ligands. Furthermore, the application of selected examples of such compounds in the ring-opening polymerization of lactones is described. Recently, the preparation of siloxane-bridged bisaminopyridinato complexes of the group 4 metals, including ethylene polymerization studies of these compounds, was reported.[7]

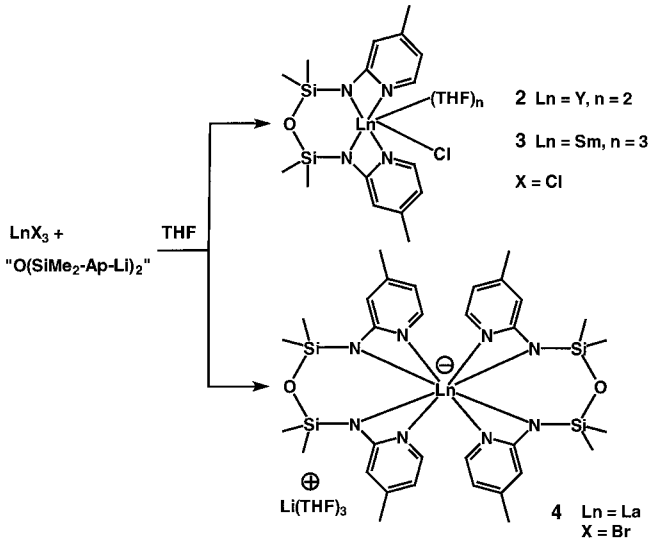
Results and Discussion



Metal Complex Syntheses and Structures

1. Monochloro and Bis(bisaminopyridinato) Complexes

The reaction of one equivalent of dilithiated $O(SiMe_2\text{-}Ap\text{-}H)_2$ [Ap-H = -N(2-amino-4-methylpyridine)][7] (**1**), generated in situ, with $LnCl_3$ (Ln = Y, Sm) in THF affords **2** or **3** by a salt metathesis reaction (Scheme 2, above). Compounds **2** and **3** could be isolated from THF/ether solution after removal of the precipitated LiCl. They form crystals which are colorless (**2**) or light orange (**3**).

From the NMR spectroscopic data of **2** and **3** it can be inferred that the ligand array coordinates to the metal in a planar fashion. The ^1H and ^{13}C NMR spectra are consistent with C_{2v} monomeric structures in which the nuclei measured show a single set of signals. Single crystal X-ray diffraction analyses of **2** and **3** reveal each to have a monon-

Scheme 2. Synthesis of monochloro and bis(bisaminopyridinato) lanthanoid complexes

uclear structure with the symmetry proposed from the NMR studies (see Figure 1 and 2, respectively).

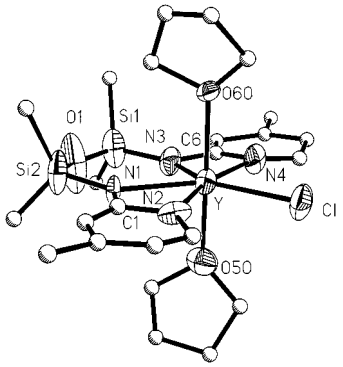

Figure 1. Structural representation of **2**; hydrogen atoms and disorders of the THF ligands are omitted for clarity; the thermal ellipsoids correspond to 30% probability; selected bond lengths [pm] and angles [deg]: Y−N1 246.5(14), Y−N2 249(2), Y−N3 227(2), Y−N4 236(2), Y−O50 221(2), Y−O60 240.9(13), Y−Cl 264.6(3), N1−C1 129(4), N2−C1 144(3), N3−C6 144(2), N4−C6 134(3); Si1−O1−Si2 148.2(9), N1−Y−N3 83.2(3), O50−Y−O60 178.6(4), O50−Y−Cl 89.1(5), O60−Y−Cl 92.1(4)

The X-ray analysis of **2** clearly shows that the ligand array coordinates to the metal in a planar fashion. The metal atom is surrounded by four nitrogen atoms within the equatorial plane of a pentagonal bipyramid. The apices of the pyramid are occupied by two molecules of solvent (THF), which appear to be rather loosely bound, since complex **2** readily loses coordinated THF. Experimental evidence for this was gained by a combined elemental analysis and ^{1}H NMR spectroscopic investigation. In contrast to the spectroscopic data showing two molecules of THF coordinating to the metal atom, the elemental analysis of a sample dried in vacuo indicates the presence of a single molecule of solvent. After drying at 150°C in vacuo for 15 min not a single THF ligand was found residing at the metal complex (by ^{1}H NMR spectroscopy). The presence of two coordinated THF ligands is shown by the X-ray analysis of **2** (Figure 1). Due to the larger ionic radius of Sm an increase in coordination number from Y to Sm is observed (Figure 2).

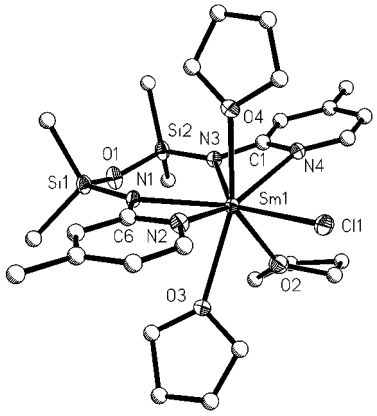

Figure 2. Structural representation of **3**; hydrogen atoms and disorder of one of the three THF ligands are omitted for clarity; the thermal ellipsoids correspond to 30% probability; selected bond lengths [pm] and angles [deg]: Sm1−N1 244.1(4), Sm1−N2 247.9(5), Sm1−N3 245.9(4), Sm1−N4 251.5(4), Sm1−O2 251.4(4), Sm1−O3 258.6(4), Sm1−O4 252.6(4), Sm1−Cl1 271.5(2), N1−C6 135.7(6), N2−C6 135.9(7), N3−C1 136.8(7), N4−C1 137.3(7); Si1−O1−Si2 141.2(3), N1−Sm1−N3 83.10(14), O2−Sm1−O3 65.45(14), O2−Sm1−Cl1 84.69(11), O3−Sm1−Cl1 92.83(10), O4−Sm1−Cl1 85.65(10)

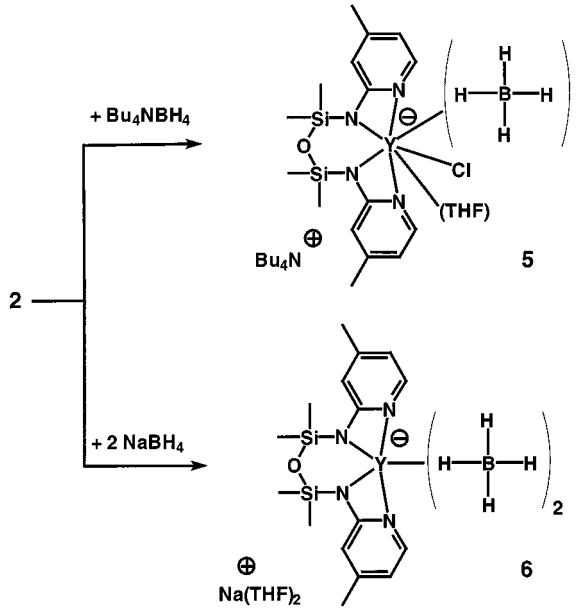
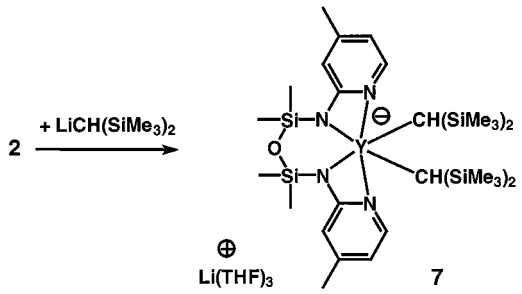
The latter metal center has three additionally coordinated THF ligands. The equivalence of the samarium−nitrogen bond lengths indicates the existence of a delocalized binding mode, thus showing that the negative charge of the aminopyridinato moieties is not localized on the amido nitrogen atom. The reaction of one or two equivalents of dilithiated $O(SiMe_2\text{-}Ap\text{-}H)_2$, generated in situ, with $LaBr_3$ in THF affords **4** (see Scheme 2). The formation of **4** is independent of the ratio of **1** and $LaBr_3$ used as only the bis(bisaminopyridinato) complex was isolated. NMR spectroscopic data of **4** indicate a highly symmetric molecule, as only one set of signals is seen in the proton NMR spectrum.



2. Yttrium Borohydride Complexes

The reactivity of **2** towards borohydride ions was examined by using either one equivalent of Bu_4NBH_4 (Scheme 3) or an excess of $NaBH_4$ in THF (Scheme 3). The reactions proceeded at room temperature within a few hours (see Experimental Section for details). The reaction of **2** with Bu_4NBH_4 gave **5**, while from the reaction with $NaBH_4$ complex **6** was isolated.

In contrast to sodium borohydride, which is insoluble in THF, compound **6** displays a high solubility in THF. Similarly, while **5** is very soluble in ether, Bu_4NBH_4 is nearly insoluble in this solvent. Compounds **5** and **6** were characterized by standard analytical methods. No resonances for the BH_4 groups could be seen in the ^{1}H NMR spectrum, probably due to the quadrupole moment of the boron nucleus. The IR signals in the range 2380−2130 cm^{-1} are characteristic of BH_4 vibrations.



3. Alkyl Complexes

For the alkylation of **2** and **3**, a salt elimination route was chosen. As shown in Scheme 4, compound **2** was reacted

Scheme 3. Syntheses of yttrate complexes **5** and **6**

with an equimolar amount of $LiCH(SiMe_3)_2$ at low temperature. The reaction mixture was filtered to remove precipitated LiCl, concentrated in vacuo and cooled to promote crystallization, after which complex **7** was obtained as colorless needles at −40°C. Since **7** is prone to thermal decomposition it has to be stored at −30°C. The ^1H NMR spectrum of **7** contained a single signal set for the aromatic protons indicative of a symmetric molecule. The presence of three THF ligands can be concluded from the integration of the resonances in the NMR spectrum. The IR data is consistent with that of a coordinating bisaminopyridinato ligand and, together with the results of the elemental analysis, is in accordance with the proposed structure of **7** in Scheme 4.

Scheme 4. Synthesis of the yttrate complex **7**

The reaction of **3** with PhLi leads to biphenyl. The progress of this reaction at −40°C can easily be followed by the change of color of the reaction mixture from red to yellow and the precipitation of LiCl . On warming to 15°C the solution suddenly changed color . The clear, light yellow solution became dark brown, a color which is characteristic for Sm^{II} compounds. We tentatively ascribed this to a redox reaction in which samarium was reduced from Sm^{III} to Sm^{II} and the phenyl anion was oxidized. The reaction mixture was therefore examined for products of phenyl radicals, which one can assume were intermediates. By GC/MS, biphenyl was identified as a product of the reaction and this was confirmed by NMR spectroscopic studies. Recently, Fryzuk et al. have reported a similar reaction, which started with the attempted arylation of an yttrium(III) chloro complex by PhLi but yielded a biphenyl-dianion coordinated to two yttrium(III) complex fragments.[8] Since yttrium is not as easily reduced as samarium this reaction stops after phenyl coupling. The yttrium arene complex may be considered as a model for the intermediate in the reaction of **3** with PhLi.

Ring-Opening Polymerization of Lactones

The ring-opening polymerization of lactones is a useful method to produce biodegradable aliphatic polyesters.[9] Well-defined polymers of this sort have interesting applications, for instance, as surgical sutures and drug delivery systems.[10] Common polyesters are made from a condensation polymerization reaction starting from diols and dicarboxylic acids. A disadvantage of this method is that high temperatures and long reaction times are required to obtain high molecular weights. Furthermore, broad molecular weight distributions are observed. Lanthanocene complexes have been found to be initiators for the ring-opening polymerizations of ε-caprolactone and δ-valerolactone.[11] Recently, lanthanide "ate" complexes have been introduced as very efficient initiators.[5] However, the preferred linear relationship between the monomer to initiator ratio and the molecular weight was not observed, although molecular weights of up to 30000 $g \cdot mol^{-1}$ were obtained. Thus, the behavior of the aminopyridinato "ate" complex **4** as an initiator was investigated with regard to a linear relation between the monomer to initiator ratio and the molecular weight of the polyester, as well as the production of high molecular weights. Tables 1 and 2 show the results of these polymerization studies.

Table 1. Ring opening polymerization of ε-caprolactone with **4** as an initiator

$[M_0]/[I_0]$	M_n [$g \cdot mol^{-1}$]	M_w/M_n	Yield%
100	25000	1.7	61
200	40000	1.7	59
300	51000	1.7	70
400	54000	1.7	74

Table 2. Ring opening polymerization of δ-valerolactone with **4** as an initiator

$[M_0]/[I_0]$	M_n [$g \cdot mol^{-1}$]	M_w/M_n	Yield%
100	12000	1.7	39
200	15000	1.8	35
300	19000	2.0	48
400	27000	1.6	50

ε-Caprolactone and δ-valerolactone were used as monomers. In both cases an almost linear relation between the

monomer to initiator ratio and the molecular weight was observed. The high efficiency of the system is remarkable. By performing the polymerization in neat ε-caprolactone at room temperature a solid polyester block (300000 g·mol^{-1}, M_w/M_n 2.3) is formed after 3 min. Nevertheless, the thermodynamically stable γ-butyrolactone could not be polymerized with **4** as an initiator.

Conclusion

Several conclusions can be drawn from this study. Firstly, the monochloro complexes are readily accessible by salt metathesis reactions. Secondly, these metal complexes smoothly react with borohydrides and standard alkylating reagents to yield the corresponding "ate" complexes. The steric demand of the siloxane-bridged bisaminopyridnato ligands is not large enough to stabilize monoalkyl or monoborohydride complexes. Thirdly, bis(bisaminopyridinato) complexes are highly efficient initiators for the ring-opening polymerization of lactones.

Experimental Section

Materials and Procedures: Bis(trimethylsilyl)methyl lithium[12] and the bisaminopyridine O(SiMe$_2$-Ap-H)$_2$[7] were prepared according to literature procedures. All other reagents were obtained commercially and used as supplied. All manipulations of air-sensitive materials were performed with rigorous exclusion of oxygen and moisture in dried Schlenk-type glassware on a dual manifold Schlenk line interfaced to a high-vacuum line, or in an argon-filled glovebox (mBraun labmaster 130) with a high-capacity recirculator (<1.5 ppm O_2). Reaction solvents (Aldrich) and NMR solvents (Cambridge Isotope Laboratories all 99 atom% D) were freshly distilled from sodium tetraethylaluminate.

Physical Measurements: NMR spectra were recorded on a BRUKER ARX 400 instrument with a variable temperature unit. ^{1}H and ^{13}C chemical shifts are referenced to the solvent resonances and reported relative to TMS. ^{29}Si chemical shifts are reported relative to TMS. Melting points were determined in sealed capillaries on a BÜCHI 535 apparatus. Elemental analysis were performed with a Leco CHNS-932 elemental analyzer. X-ray diffraction data were collected on a STOE-IPDS diffractometer using graphite monochromated MoK_α radiation. The crystals were mounted in a cold nitrogen stream (**3**) or sealed inside a capillary (**2**). The structure was solved by direct methods (SHELXS-86)[13] and refined by full-matrix least-squares techniques against F^2 (SHELXL-93).[14] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations. See also Table 3. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-121918 (compound **2**) and CCDC-121919 (compound **3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (internat. + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk]. Number-average molecular weights and molecular weight distributions of the isolated polymers were determined by gel permeation chromatography on a HP Liquid Chromatograph 1090 at 40°C using THF as the eluent and a universal calibration relative to polystyrene standards.

Syntheses of the Complexes 2−7. O(SiMe$_2$-Ap)$_2$YCl(THF)$_2$ (2): O(SiMe$_2$-Ap-H)$_2$ (3.11 g, 8.98 mmol) was dissolved in a mixture of 20 mL of hexane and 10 mL of THF and cooled to −78°C. While stirring, 17.96 mmol of *n*-butyllithium was added. This mixture was warmed to −40°C and stirred for 30 minutes to yield a colorless suspension. YCl_3 (1.76 g, 8.98 mmol) was added to 30 mL of THF and the mixture heated to reflux for 10 minutes. The resulting suspension was cooled to −40°C and at this temperature added to the suspension of the lithiated ligand. The reaction mixture was allowed to warm to ambient temperature and stirred for another 12 h; the solvent was then removed in vacuo. The residue was washed with 10 mL of hexane, filtered through a frit (G 4), and then washed with 20 mL of ether and filtered again. The combined filtrates were reduced in volume to 15 mL by vacuum evaporation, to give a colorless precipitate . Having stood for 12 h, the mixture was filtered and the filtrate cooled to −78°C. The crystalline product was obtained by filtration and dried in vacuo. Yield: 3.27 g (6.05 mmol, 67%), m.p. 233°C, (240°C dec.). − ^{1}H NMR (293 K, C_6D_6): δ = 7.69 (s, 2 H, broad, 6-H), 6.22 (s, 2 H, 3-H), 5.83 (broad, 2 H, 5-H), 3.65 (t, 8 H, *J* = 6.4 Hz, THF), 1.90 (s, 6 H, Me-pyridine), 1.12 (m, 8 H, THF), 0.59 (s, 12 H, Me−Si). − ^{13}C NMR (293 K, C_6D_6): δ = 170.6 (C-2), 150.1 (C-4), 145.2 (C-6), 112.4 (C-5), 110.3 (C-3), 69.8, 25.3 (THF), 21.6 (Me-pyridine), 1.9 (Me−Si). − ^{29}Si NMR (293 K, C_6D_6): δ = −15.5. − IR (nujol): $\tilde{\nu}$ = 1604 s, 1532 m (C=C), 1330 s, 1290 s, 1252 s (Me−Si), 1174 s, 1055, 1027, 999 vs (Si−O−Si), 891 s, 871 s (Me$_2$Si), 748 s, 583 s cm^{-1}. − $C_{24}H_{40}ClN_4O_3Si_2Y$ (613): calcd. C 47.01, H 6.58, N 9.14; found C 45.81, H 6.49, N 9.51. The lower value found for carbon is due to the loss of coordinated solvent (THF).

O(SiMe$_2$-Ap)$_2$SmCl(THF)$_3$ (3): To a solution of O(SiMe$_2$-Ap-H)$_2$ (2.92 g, 8.44 mmol) in 20 mL of THF was added 16.88 mmol *n*-butyllithium, dissolved in hexane, at −78°C. After stirring for 1 h at −78°C this solution was warmed to 20°C within another hour and then added to a suspension of $SmCl_3$ (3.25 g, 12.7 mmol) in 40 mL of THF. The reaction mixture was stirred for 12 h, and the solvent was then removed in vacuo to yield a viscous yellow oil which was redissolved in a mixture of 30 mL of ether and 10 mL of THF. A colorless microcrystalline solid precipitated. The supernatant solution was filtered and reduced in volume to 20 mL. Cooling to −30°C yielded light orange needles, which were collected

and dried in vacuo. The crystals easily lose coordinating solvent on vacuum drying. Yield: 1.27 g (2.11 mmol, 25%), mp: 82−86°C (solvent loss), 110−130°C, (230°C dec.). − ^{1}H NMR (293 K, [D$_8$]THF): δ = 10.76 (d, 2 H, *J* = 5.2 Hz, 6-H), 7.59 (s, 2 H, 3-H), 6.90 (d, 2 H, *J* = 5.2 Hz, 5-H), 3.61−3.55 (m, 8 H, THF), 2.70 (s, 6 H, Me-pyridine), 1.79−1.76 (m, 8 H, THF), 0.82 (s, 12 H, Me−Si). − ^{13}C NMR (293 K, [D$_8$]THF): δ = 186.1 (C-2), 150.4 (C-4), 148.3 (C-6), 115.6 (C-5), 110.0 (C-3), 68.3 (THF), 26.4 (THF), 22.4 (Me-pyridine), 2.4 (Me−Si). − ^{29}Si NMR (293 K, [D$_8$]THF): δ = −10.9. − IR (nujol): $\tilde{\nu}$ = 1605 s, 1532 m (C=C), 1324 m, 1288 m, 1249 s (Me−Si), 1174 s, 1056, 1025 vs (Si−O−Si), 888, 870 s, 785 vs (Me$_2$Si), 737 m, 583 m cm^{-1}. − $C_{20}H_{32}ClN_4O_2Si_2Sm$ (602): calcd. C 39.87, H 5.35, N 9.30; found C 39.63, H 5.24, N 9.13.

O(SiMe$_2$-Ap)$_2$)$_2$LaLi(THF)$_3$ (4): To a solution of O(SiMe$_2$-ApH)$_2$ (4.03 g, 11.5 mmol) in 50 mL of THF was added 23.4 mmol of BuLi at −78°C. After stirring for 30 min at this temperature the solution was allowed to warm to 20°C within 30 min. The solution was then added to a suspension of $LaBr_3$ (2.20 g, 5.82 mmol) in 50 mL of THF. The reaction mixture was stirred for 16 h at 20°C. After removal of precipitated LiBr by filtration the volume of solvent was reduced to 30 mL, and 20 mL of diethyl ether was added. Cooling the solution to −30°C yielded colorless crystals which were collected and dried in vacuo. Yield: 4.7 g (4.5 mmol, 77%), mp: 203−205°C. − ^{1}H NMR (293 K, [D$_8$]THF): δ = 7.55 (d, *J* = 4.9 Hz, 2 H, H-6), 5.69 (s, 2 H, H-3), 5.59 (d, *J* = 5.3 Hz, 2 H, H-5), 3.62 (m, 4 H, THF), 1.89 (s, 6 H, Me-pyridine), 1.77 (m, 4 H, THF), 0.11 (s, 6 H, Me−Si). − ^{13}C NMR (293 K, [D$_8$]THF): δ = 170.4 (C-2), 146.4 (C-4), 146.1 (C-6), 113.9 (C-5), 107.1 (C-3), 67.4 (THF), 26.3 (Me-pyridine), 25.2 (THF), 2.1 (Me−Si). − ^{29}Si NMR (293 K, [D$_8$]THF): δ = −19.8. − IR (nujol): $\tilde{\nu}$ = 1601 vs, 1530 s (arom.), 1377 s, 1331 m, 1294 s, 1245 s (Me−Si), 1178 s, 1026 s, 990 s (Si−O−Si), 881 s, 839 s, 792 vs (Me$_2$Si), 674 m, 574 s cm^{-1}. − $C_{44}H_{72}LaLiN_8O_5Si_4$ (1051): calcd. C 50.27, H 6.90, N 10.66; found C 49.81, H 7.06, N 10.82.

O(SiMe$_2$-Ap)$_2$Y(BH$_4$)Cl(THF) Bu$_4$N (5): Compound **2** (567 mg, 1.05 mmol) and tetrabutylammonium boranate (540 mg, 2.10 mmol) were dissolved in 10 mL of THF with stirring. The solution was reduced in volume to 2 mL, then 20 mL of ether was added and the solution was stirred for 1 h. After filtration a clear colorless solution with a characteristic blue fluorescence was obtained. The solvent was removed in vacuo within 2 h to furnish a highly viscous, sticky product. Yield: 330 mg, 0.414 mmol, 39%. − ^{1}H NMR (293 K, [D$_8$]THF): δ = 7.87 (d, *J* = 5.2 Hz, 2 H, 6-H), 5.86−5.84 (m, 4 H, 3-H, 5-H), 3.61 (m, 6 H, THF), 3.29 (m, 8 H, 1′-H), 2.01 (s, 6 H, Me-pyridine), 1.75−1.71 (m, 6 H, THF), 1.65−1.62 (m, 8 H, 2′-H), 1.38−1.32 (m, 8 H, 3′-H), 0.93 (t, *J* = 7.2 Hz, 12 H, 4′-H), 0.09 (s, 12 H, Me−Si). − ^{13}C{^{1}H} NMR: δ = 170.3 (C-2), 148.6 (C-4), 145.9 (C-6), 112.5 (C-5), 108.1 (C-3), 68.2 (THF), 59.1 (C-1′), 26.2 (THF), 21.5 (Me-pyridine), 20.4 (C-3′), 14.0 (C-4′), 1.5 (Me−Si). − ^{29}Si NMR: δ = −15.6. − IR (THF): $\tilde{\nu}$ = 2278 m, 2206 m, 2135 m (B-H), 1642 w, 1603 vs, 1563 m (aromat.) cm^{-1}. − $C_{36}H_{72}BClN_5O_2Si_2Y$ (797): C 54.16, H 9.09, N 8.77, Cl 4.44; found C 54.26, H 10.21, N 8.82, Cl 4.55.

O(SiMe$_2$-Ap)$_2$Y(BH$_4$)$_2$Na(THF)$_2$ (6): With stirring NaBH$_4$ (107 mg, 2.81 mmol) was added to a solution of **2** (759 mg, 1.40 mmol) in 10 mL of THF. The resulting mixture was stirred for 72 h at 20°C and then filtered. The colorless filtrate was reduced in volume to 5 mL by vacuum evaporation. Cooling to −30°C afforded colorless needles. Yield: 292 mg, 0.523 mmol, 37%, mp: 164°C: subl. − ^{1}H NMR (293 K, C_6D_6): δ = 8.42 (broad, 2 H, 6-H), 6.17 (s, 2 H, 3-H), 6.03 (d, *J* = 5.0 Hz, 2 H, 5-H), 3.74 (t, *J* = 6.5 Hz, 8 H, THF), 1.86 (s, 6 H, Me-pyridine), 1.10 (m, 8 H, THF), 0.46 (s, 12 H, Me−Si). − ^{13}C NMR (293 K, C_6D_6): δ = 170.9 (C-2), 150.6 (C-4), 146.1 (C-6), 112.7 (C-5), 110.2 (C-3), 70.7 (THF), 25.2 (THF), 21.5 (Me-pyridine), 1.8 (Me−Si). − ^{29}Si NMR (293 K, C_6D_6): δ = −15.6. − IR (nujol): $\tilde{\nu}$ = 3316 w, 2374, 2297, 2223 m (BH$_4$), 1605 vs, 1566 w, 1532 m (C=C), 1377 m, 1329 s, 1290, 1252 s (Me−Si), 1175 s, 1057, 1028 vs (Si−O−Si), 999 m, 970 m, 892, 872 s (Me$_2$Si), 785, 776 s, 585 m cm^{-1}. − $C_{20}H_{40}B_2N_4NaO_2Si_2Y$ (558): calcd. C 43.03, H 7.22, N 10.04, Cl 0.00; found C 43.88, H 7.55, N 9.15, Cl 0.16.

O(SiMe$_2$-Ap)$_2$Y(CH(TMS)$_2$)$_2$Li(THF)$_3$ (7): An ethereal solution of bis(trimethylsilyl)methyllithium (0.973 mmol) was added dropwise to a solution of **2** (526 mg, 0.973 mmol) in 10 mL of ether. A colorless solid precipitated. After standing for 16 h at 4°C the supernatant solution was filtered through a frit (G 4). The filtrate was evaporated to dryness and the residue redissolved in a mixture of 20 mL of pentane and 3 mL of ether and filtered again. Cooling the filtrate to −78°C afforded a yellowish crystalline product. Yield: 224 mg, 0.367 mmol, 38%, mp: 175°C subl. (dec.). − ^{1}H NMR (293 K, C_6D_6: δ = 7.67 (s, broad, 2 H, 6-H), 6.22 (s, 2 H, 3-H), 6.02 (d, *J* = 4.8 Hz, 2 H, 5-H), 3.42 (broad, 12 H, THF), 1.84 (s, 6 H, Me-pyridine), 1.20 (s, 12 H, THF), 0.51 (s, 12 H, Me−Si−O), 0.40−0.35 (m, 36 H, Me−Si−C), −0.36 (s, 1 H, HC-Y), −0.82 (s, 1 H, HC−Y). − ^{13}C NMR (293 K, C_6D_6): δ = 169.6 (C-2), 150.7 (C-4), 144.2 (C-6), 113.8 (C-5), 110.9 (C-3), 69.2 (THF), 65.8 (ether), 25.2 (THF), 21.5 (Me-pyridine), 15.3 (ether), 6.6 (Me−Si), 4.4 (Me−Si), 1.7 (Me−Si), 1.5 (Me−Si). − ^{29}Si NMR (293 K, C_6D_6: δ = −0.12 (Me$_2$Si), −7.9 (Me$_3$Si), −9.1 (Me$_3$Si). − IR (nujol): $\tilde{\nu}$ = 1606 vs, 1533 w (C=C), 1377 m, 1329 m, 1296 m, 1247 s (Me−Si), 1178 m, 1045 vs, 1027 vs (Si−O−Si), 994 m, 968 w, 892 s, 862, 844, 826, 781 vs (Me$_2$Si), 676 m, 656 m, 588 m, 428 m cm^{-1}. − $C_{42}H_{86}LiN_4O_4Si_6Y$ (1114): calcd. C 51.71, H 8.89, N 5.74; found: C 51.36, H 8.30, N 5.94.

Polymerization: In a typical run ε-caprolactone/δ-valerolactone was added by syringe to a solution of **4** (24 μmol) in 10 mL THF at 20°C with vigorous magnetic stirring. After 30 min the polymerization was quenched by addition of 200 mL methanol. The precipitated polymer was redissolved in THF and precipitated again from methanol (250 mL). The polymer was filtered and dried in vacuo.

Water/Ethanol Displacement Reactions in Vanadyl Phosphate

Ludvík Beneš,*[a] Klára Melánová,[a] Miroslava Trchová,[b] Pavla Čapková,[b] and Pavel Matějka[c]

Keywords: Intercalations / Vanadyl phosphate / Ethanol / Hydration / Kinetics

The course of the replacement of ethanol by water molecules in the $VOPO_4{\cdot}2C_2H_5OH$ intercalate, and of water by ethanol in $VOPO_4{\cdot}2H_2O$ has been studied by X-ray diffraction and infrared and Raman spectroscopy. Formation of mixed phase $VOPO_4{\cdot}C_2H_5OH{\cdot}H_2O$ was not observed. The shape of the kinetics curves indicates a transition of at least one reaction zone through the crystal. A delay in formation of the product in comparison with the decrease in the amount of starting material can be explained by the existence of non-diffracting advancing phase boundary. In a $VOPO_4$/ethanol/water system, $VOPO_4{\cdot}2C_2H_5OH$ is formed as the only product when the system contained more than 96 vol% of ethanol, whereas in the system with less than 94 vol% of ethanol only $VOPO_4{\cdot}2H_2O$ is present.

Introduction

Compounds based on vanadyl phosphate are of great interest because of their catalytic properties for oxidation. The structure of vanadyl phosphate dihydrate, $VOPO_4{\cdot}2H_2O$, has been determined by Tietze using X-ray diffraction[1] as tetragonal, space group *P*4/*nmm*, a = 6.202 Å and c = 7.410 Å. Tachez et al.[2] used neutron powder diffraction of the deuterated compound in order to determine the positions of hydrogen atoms and determined the space group *P*4/*n*, a = 6.215 Å and c = 7.403 Å. The layers are built up of PO_4 tetrahedra linked to distorted VO_6 octahedra by sharing four equatorial oxygen atoms. VO_6 octahedra are completed by axial oxygens, one of which is a vanadyl oxygen, and the second of which belongs to the interlayer water molecule coordinated to vanadium. The second water molecule is bonded by weak H-bridges between the $VOPO_4$ layers.

Vanadyl phosphate is a good host structure for intercalation of organic molecules with suitable functional groups.[3] Intercalation compounds of vanadyl phosphate with aliphatic and aromatic amines,[4–6] heterocycles,[7] alcohols and diols,[8] carboxylic acids[9] and their amides[10] have been studied. From this point of view, vanadyl phosphate dihydrate can be regarded as an intercalate of α_I-$VOPO_4$ with water.

The time course of intercalation of water into α_I-$VOPO_4$ has been followed by TMA, XRD[11] and infrared and Raman spectroscopy.[12] Formation of vanadyl phosphate monohydrate was not observed during hydration of the anhydrous form under ambient conditions. Instead, the broadening and the shift of positions of the (00*l*) diffraction lines were observed. These phenomena were explained by formation of a Hendricks–Teller disordered layered structure, which is composed of the α_I-$VOPO_4$ and $VOPO_4{\cdot}2H_2O$ layers. The vanadyl stretching band appears to be especially sensitive to atoms coordinated to the vanadium within an octahedral arrangement in the host lattice structure. During the intercalation, the position of this band at 1035 cm^{-1} in the anhydrous form changes to 995 cm^{-1}, which are typical values for mono- and dihydrates. The additional peak at 1017 cm^{-1} occurring in the initial stages of intercalation was explained in terms of a random stacking of intercalated and non-intercalated layers in the sample.

Ethanol can be intercalated into anhydrous vanadyl phosphate[13] or it can replace the water molecules in $VOPO_4{\cdot}2H_2O$.[8] The kinetics of intercalation of ethanol into anhydrous vanadyl phosphate were studied by XRD and a volumetric method, and the kinetics curves obtained were found to have a sigmoidal shape.[14] During intercalation, the original host and the intercalate are present in one crystal. Both phases are separated by an advancing phase boundary.[15] A molecular mechanics simulation, combined with X-ray diffraction and supported by vibrational spectroscopy, was used to investigate the layered structure of vanadyl phosphate $VOPO_4$ intercalated with ethanol.[16] The bilayer arrangement of ethanol molecules in the interlayer was found, giving the calculated basal spacing d = 13.21 Å; the experimental d value obtained from X-ray diffraction is 13.17 Å. One half of the total number of CH_3CH_2OH molecules is anchored by their oxygen to $VOPO_4$ layers to complete the vanadium octahedra and their orientation is not very strictly defined. The second half of the ethanol molecules are linked by hydrogen bonds to the anchored ethanol and sometimes also to the layer oxygen. The position and orientation of this anchored ethanol with respect to $VOPO_4$ layers exhibits a certain degree of disorder, resulting in the disorder in the layer stacking.

Owing to the instability of $VOPO_4{\cdot}2C_2H_5OH$ when exposed to air, the water molecules intercalate into this system at room temperature by simply keeping the compounds under ambient conditions. The course of reintercalation of water molecules into vanadyl phosphate intercalate with ethanol was studied by X-ray diffraction and infrared and Raman spectroscopy. The aim of this work is to contribute to the elucidation of the mechanism of water/ethanol displacement in vanadyl phosphate.

Results and Discussion

X-ray Study

In order to study an equilibration in a $VOPO_4$/ethanol/water system, $VOPO_4{\cdot}2H_2O$ was contacted with ethanol containing a known amount of water. The dependence of the basal spacing of solid products on the concentration of ethanol is shown in Figure 1. It is evident that only two phases are formed in this system. A mixture of $VOPO_4{\cdot}2C_2H_5OH$ and $VOPO_4{\cdot}2H_2O$ phases is formed in the ethanol/water solvent containing from 94 to 96 vol% of ethanol. Above 96 vol% of ethanol, only $VOPO_4{\cdot}2C_2H_5OH$ (basal spacing 13.17Å) is present, whereas below 94 vol% of ethanol in the solvent mixture only $VOPO_4{\cdot}2H_2O$ (7.41 Å) is formed. These results were obtained from the properties of the binary alcohol/water mixture, where an azeotrope with 96 vol% of ethanol is formed as a mixture with the most stable structure. Ethanol containing a lower content of water is hygroscopic and tends to take up water. Therefore, water is taken from $VOPO_4{\cdot}2H_2O$ and the water molecules in the interlayer space are replaced by ethanol molecules. The solvent with more than 6% of water, on the other hand, can provide water molecules to replace ethanol in $VOPO_4{\cdot}2C_2H_5OH$ and leads to the formation of $VOPO_4{\cdot}2H_2O$. This means that the co-intercalate $VOPO_4{\cdot}C_2H_5OH{\cdot}H_2O$ containing molecules of ethanol and water together was not observed. The co-intercalate of this type was reported by Matsubayashi as a starting material for the intercalation of ferrocene into $VOPO_4$.[17] Practically the same result is obtained when $VOPO_4{\cdot}2C_2H_5OH$ is contacted with ethanol/water mixtures.

In situ X-ray diffraction was employed to follow the reaction of polycrystalline $VOPO_4{\cdot}2H_2O$ with ethanol vapors. The lines observed in the diffractograms belong to either vanadyl phosphate dihydrate or ethanol-intercalated vanadyl phosphate, indicating that there is no intermediate product such as $VOPO_4{\cdot}C_2H_5OH{\cdot}H_2O$. In the region investigated, four sharp (00*l*) lines of the intercalate were observed, which gave the same value for the basal spacing. The interlayer distances calculated from the (00*l*) reflections of both phases remain constant. Small changes of linewidths during reintercalation can be explained by a decrease in the size of an area of the dihydrate and an increase in the size of an area of the intercalate formed in the crystals. It can be assumed from the XRD results that the intercalate is formed directly in the majority of the crystals,

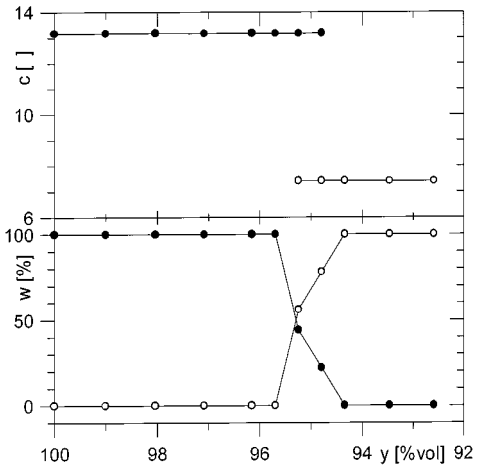

Figure 1. Basal spacing and content of the solid products in the $VOPO_4$/water/ethanol system

without any occurrence of random stacking of the layers (Hendricks–Teller effect).

The dependence of the extent of reaction of dihydrate (α_H) and ethanol intercalate (α_E) on reaction time is shown in Figure 2. The reintercalation process starts very quickly. The kinetics curves do not have a sigmoidal shape. Their shape could probably be described as exponential or, better still, as a combination of parabolic and linear dependences. This type of kinetic curve has been found for some heterogeneous oxidations of metals with gaseous oxygen[18–20] or during reactions of metals with sulfur vapors.[21–23] This type of reaction is supposed to be a two-step process. In our case, the first step may involve replacement of the water molecules by ethanol and the second step could be a rearrangement of the ethanol molecules to form bilayers in the interlayer space. This idea is supported by the existence of the non-diffracting phase, which separates pristine and intercalated parts of the crystals as an advanced phase boundary.[15][24] In this very disordered zone of the crystals, the host layers are bent so that segments with variable interlayer distance containing a mixture of both guests are formed. In addition, interlayer spaces filled with water or ethanol molecules can vary along the *c* axis in this zone. The amount of this non-diffracting phase corresponds to a difference of $\alpha_H - \alpha_E$, which is shown in Figure 2 (open circles). This phase is formed very quickly and then slowly transforms to the product during the reaction.

A progressive hydration of the intercalate $VOPO_4{\cdot}2C_2H_5OH$ was studied by XRD at several relative humidities (r.h.). The course of hydration is similar for relative humidities lower than 75%. The exchange of ethanol molecules for water is also fast and the reaction time depends on the relative humidity used and sample thickness. The lines observed in the diffractograms belong to either vanadyl phosphate dihydrate or ethanol-intercalated vanadyl phosphate, indicating that, as in the reaction of $VOPO_4{\cdot}2H_2O$ with ethanol, there is no crystalline intermediate product such as $VOPO_4{\cdot}C_2H_5OH{\cdot}H_2O$. All diffraction lines (00*l*) are sharp and their positions do not change.

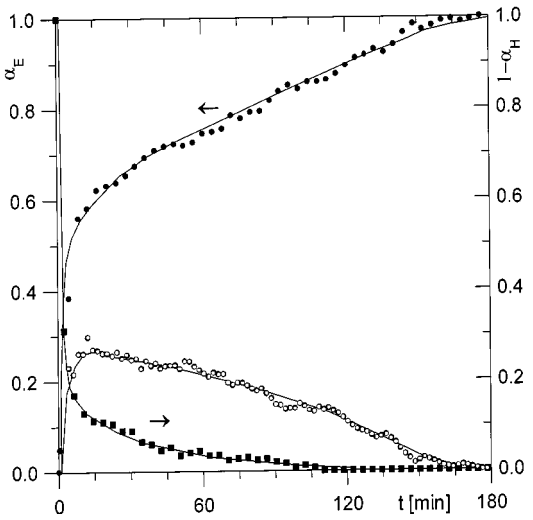

Figure 2. Dependence of the extent of reaction of the parent vanadyl phosphate dihydrate α_H and the product α_E on time t obtained by XRD during reintercalation of $VOPO_4{\cdot}2H_2O$ with ethanol vapours; the difference $\alpha_H-\alpha_E$ (open circles) corresponds to the amount of non-diffracting phase

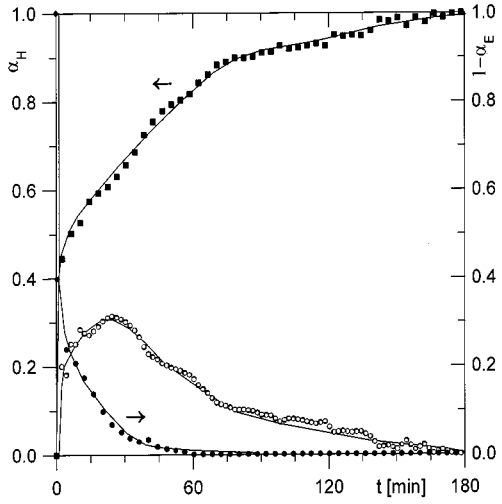

Figure 3. Dependence of the extent of reaction of the ethanol intercalate α_E and the product α_H on time t obtained by XRD during hydration of the ethanol intercalate at 11% r.h; the difference $\alpha_E-\alpha_H$ (open circles) corresponds to the amount of non-diffracting phase

The dependence of the extent of reaction of ethanol intercalate and dihydrate at r.h. = 11% on the reaction time is shown in Figure 3. The shape of the kinetic curves is very similar to those in the case of the formation of ethanol intercalate and, indeed, a similar mechanism is presumed to be operating. The formation of non-diffracting phases was also observed.

A different course of reaction was observed at high humidities. Changes in the diffractograms during hydration at 92% r.h. are shown in Figure 4. The ethanol intercalate is transformed to vanadyl phosphate pentahydrate (basal spacing 10.5 Å) very quickly. The intensity of the series of three (00*l*) lines of $VOPO_4{\cdot}5H_2O$ decreases during hydration and the dihydrate is formed. This process is supported by two factors: the large interlayer distance in $VOPO_4{\cdot}2C_2H_5OH$ (compared with $VOPO_4{\cdot}2H_2O$) and the high concentration of water molecules in air at 92% r.h. The attacking water molecules fill the interlayer space after the release of ethanol before the layers are able to move closer together. The unstable pentahydrate formed then slowly decomposes to the dihydrate.

FTIR Spectroscopy

IR spectra of $VOPO_4{\cdot}2C_2H_5OH$ and its spectra upon progressive hydration by atmospheric water are shown in Figure 5 together with the spectrum of pure ethanol. One can easily identify the bands corresponding to the ethanol molecules. The ethanol bands maintain the same position in the IR spectra of the intercalate as in pure ethanol. This

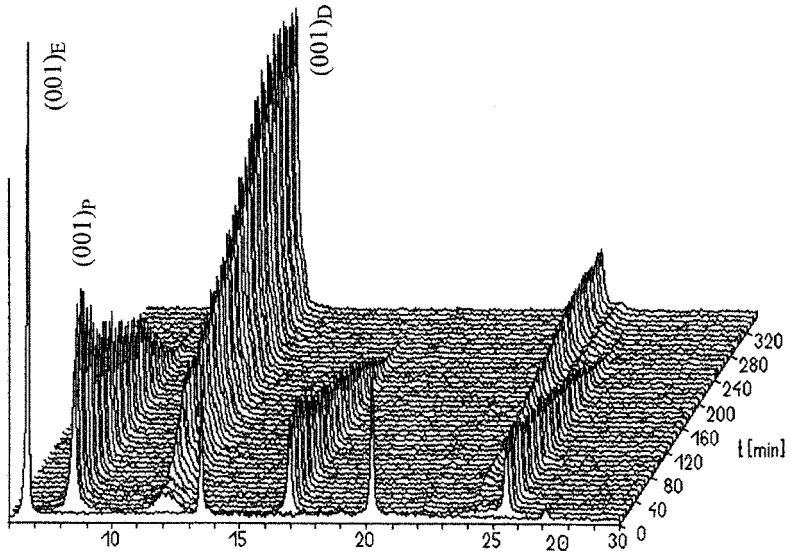

Figure 4. The changes of the diffractograms during hydration of $VOPO_4{\cdot}2C_2H_5OH$ at 92% r.h.

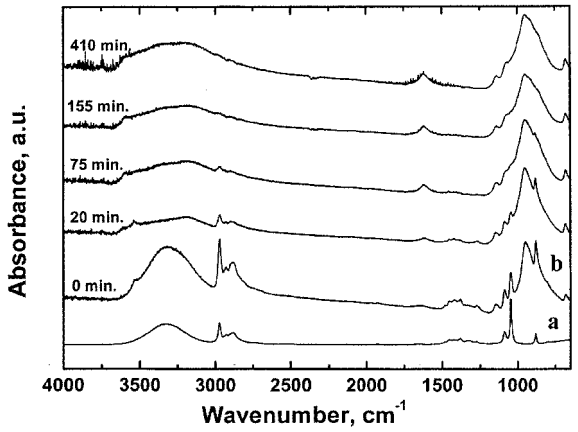

Figure 5. IR spectrum of pure ethanol (a) and $VOPO_4{\cdot}2C_2H_5OH$ (b) as a function of time of hydration by atmospheric water molecules

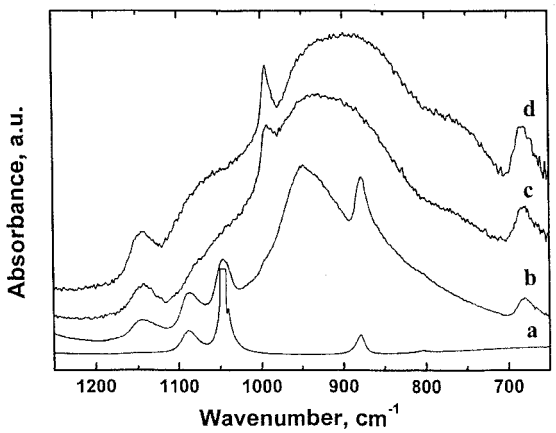

Figure 6. IR spectra of pure ethanol (a), $VOPO_4{\cdot}2C_2H_5OH$ (b), this intercalate upon 24 hours of hydration by atmospheric water (c) and $VOPO_4{\cdot}2H_2O$ (d)

is due to the weak ethanol−layer bonding.[25] IR spectra of $VOPO_4{\cdot}2C_2H_5OH$ and $VOPO_4{\cdot}2H_2O$ are given in Figure 6. In the IR spectra of the dihydrate and intercalate we can see the same bands at the same positions (see Table 1). The broadened band in the spectrum of the $VOPO_4{\cdot}2H_2O$ (with the center of gravity at about 920 cm^{-1}) contains a mixture of overlapping bands: $\nu_1(PO_4)$, $\delta(P-O-V)$ and $\rho(H_2O)$. It is evident that this band changes its profile on going from $VOPO_4{\cdot}2C_2H_5OH$ to the dihydrate. Evidence for this is that $\rho(H_2O)$ bands are absent and $\delta(P-O-V)$ deformation bands are suppressed in the intercalate due to the smaller number of hydrogen bonds between ethanol and the host layers in comparison with the network of hydrogen bonds in $VOPO_4{\cdot}2H_2O$. The band due to the degenerate asymmetric stretching vibration $\nu_3(PO_4)$ is active only in the IR spectra and its position at 1143 cm^{-1} is the same as in the intercalate. Only one band of a stretching V=O vibration is observed in the spectra of $VOPO_4{\cdot}2C_2H_5OH$ and $VOPO_4{\cdot}2H_2O$ and this occurs at the same position (995 cm^{-1}). The same is valid for the lattice vibration at 681 cm^{-1}.

In agreement with other authors[26] we believe that the sharp bands near 3600 and 1620 cm^{-1} in the spectrum of $VOPO_4{\cdot}2H_2O$ (see Figure 5) are due to strongly bonded water molecules within the crystalline lattice associated with the water molecule bound to vanadium. The additional lattice water is indicated by the broad bands near 3300 and 1620 cm^{-1} in the spectrum of the dihydrate. In the bending vibration at 1620 cm^{-1}, sharp and broad bands are superimposed. In the spectrum of intercalate at the beginning of the hydration process (0 min.) we can assign the sharp bands near 3600 cm^{-1} to the ethanol molecule that is strongly bonded to vanadium (this peak is absent in the spectrum of pure ethanol). The broad band at 3350 cm^{-1} corresponds to the stretching vibration of OH groups in ethanol molecules.

During the hydration process of $VOPO_4{\cdot}2C_2H_5OH$ in air the ethanol vibration bands gradually disappear and the bands corresponding to the water molecules in $VOPO_4{\cdot}2H_2O$ appear. After 24 hours of exposure to air the IR spectrum of the intercalate had completely changed to give the IR spectrum of the dihydrate (see Figure 6). Intermediate phases were not observed during the hydration process of $VOPO_4{\cdot}2C_2H_5OH$.

Raman Spectroscopy

The Raman spectra of anhydrous $VOPO_4$, $VOPO_4{\cdot}2C_2H_5OH$, the intermediate states obtained by hydration with atmospheric water, and $VOPO_4{\cdot}2H_2O$ are shown in Figure 7. The ethanol bands in the Raman spectrum of $VOPO_4{\cdot}2C_2H_5OH$ are in exactly the same positions as in the spectrum of pure ethanol. Consequently, the ethanol spectrum can be subtracted from the spectrum of the intercalate. As a result of this subtraction we obtained the spectrum of the intercalate without ethanol bands, which is more convenient for the comparison of bands corresponding to the $VOPO_4$ layers in the dihydrate, anhydrous, and intercalated structure. The most intense band of the Raman spectrum, with a maximum at about 929 cm^{-1} in the anhydrous form, at 937 cm^{-1} in $VOPO_4{\cdot}2C_2H_5OH$, and at 945 cm^{-1} in $VOPO_4{\cdot}2H_2O$, corresponds to the symmetric stretching vibration $\nu_1(PO_4)$. This band is especially active in the Raman spectra. The bands of the degenerate asymmetric stretching vibration $\nu_3(PO_4)$ are not observed in the Raman spectra. In addition, the bands due to symmetric bending vibrations [$\nu_4(PO_4)$ at 579 cm^{-1} and 541 cm^{-1}] and bands due to asymmetric bending vibrations [$\nu_2(PO_4)$ at 460 and 433 cm^{-1}] are observed in the Raman spectra of the samples. Two bands can be observed at 1029 and 990 cm^{-1} in the Raman spectrum of the host structure and these correspond to the V=O stretching mode. The vanadyl stretching band is especially sensitive to the local coordination of vanadium and two peaks indicate the presence of anhydrous and hydrated forms of $VOPO_4$. Only one peak at 1036 cm^{-1} is observed in the anhydrous form. The partial escape of water in the hydrated form is due to the heating caused by a laser beam during the measurements (for a detailed explanation see ref.[12]). In the case of $VOPO_4{\cdot}2C_2H_5OH$, these bands are slightly shifted and broadened. This broadening of V=O stretching bands reflects the disorder in the position of ethanol molecules found by molecular simulations.[25] The irregularity in hydrogen bonding of ethanol to PO_4 oxygen atoms also affects the PO_4 stretching and bending modes.

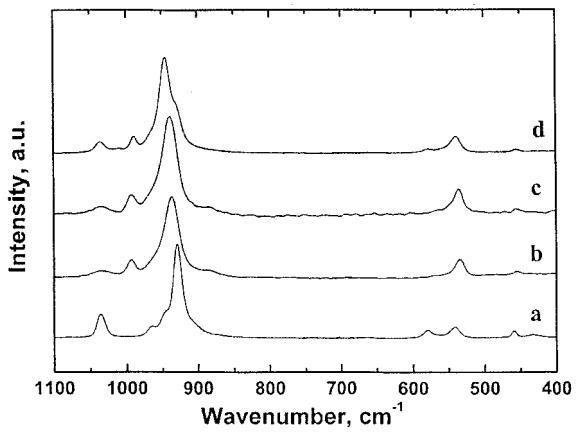

Figure 7. Raman spectra of anhydrous $VOPO_4$ (a), $VOPO_4{\cdot}2C_2H_5OH$ (b), the intermediate state of hydration (c) and $VOPO_4{\cdot}2H_2O$ (d). The ethanol spectrum was subtracted from the spectrum of $VOPO_4{\cdot}2C_2H_5OH$

Conclusions

A progressive hydration of $VOPO_4{\cdot}2C_2H_5OH$ has been studied by X-ray analysis and ATR FTIR and Raman spectroscopy. The mixed intercalate $VOPO_4{\cdot}C_2H_5OH{\cdot}H_2O$ is not formed during hydration of $VOPO_4{\cdot}2C_2H_5OH$. During this hydration, only vanadyl phosphate dihydrate or pentahydrate (at high relative humidity) are formed. In contrast to the intercalation of ethanol into anhydrous vanadyl phosphate, the kinetic curves of reintercalation of dihydrate do not have a sigmoidal shape. The shape of the kinetic curve indicates a transition of at least one reaction zone through the crystal. A similar course is also observed for the reintercalation of $VOPO_4{\cdot}2H_2O$ with ethanol. A delay in the formation of the product in comparison with the decrease in the amount of starting material is explained by the existence of very disordered phase.

The reintercalation reactions are very fast and their activation energy is presumed to be very low compared with that of intercalation of water or ethanol into anhydrous $VOPO_4$. This is due to the sufficient interlayer distance in the starting materials. Moreover, no energy is needed for V=O···V bond breaking, as is seen in the case of intercalation into anhydrous $VOPO_4$.[14] As inferred from the constant position of the stretching V=O vibration during hydration of $VOPO_4{\cdot}2C_2H_5OH$, both guests are anchored to the host layers by similar bonds and therefore no large change in the bond energy is expected during the reaction.

Experimental Section

The samples of $VOPO_4{\cdot}2C_2H_5OH$ for the IR and Raman measurements were prepared by suspending solid $VOPO_4{\cdot}2H_2O$ in dry ethanol for two hours. After filtration, the product was dried in nitrogen and kept in sealed ampoules. The study of the equilibration in the $VOPO_4$/ethanol/water system was carried out by contacting $VOPO_4{\cdot}2H_2O$ or $VOPO_4{\cdot}2C_2H_5OH$ (0.25 g) with 10 mL of ethanol/water mixture (from 92.5 to 100 vol% of ethanol) for two hours. The powder data of the intercalates with a small excess of the guest were obtained with an X-ray diffractometer HZG-4 (Präzisionsmechanik, Germany) using Cu-K_α radiation with discrimination from Cu-K_β by a Ni-filter. The exchange reactions were performed in the following way: the sample of $VOPO_4{\cdot}2H_2O$ or $VOPO_4{\cdot}2C_2H_5OH$ was placed on the surface of a thermostated (25°C) corundum target plate under dry nitrogen, whereupon the stream (ca. 0.5 $Lmin^{-1}$) of nitrogen saturated with vapors of ethanol or water was introduced onto the sample. The reaction taking place in the solid phase was monitored by recording the diffractograms (from $6 < 2\theta < 30$) at 8 minute intervals. The intensities of the (001) reflections of $VOPO_4{\cdot}2H_2O$ and $VOPO_4{\cdot}2C_2H_5OH$ were obtained from diffractograms measured from $5.5 < 2\theta < 15$ at 4 minute intervals. The extent of reaction, α_P, for the product at time t is given by the equation:

$$\alpha_P = B/B_\infty$$

where B is the intensity of the (001) line of the product at time t and B_∞ is this intensity at infinite time. Analogously, the equation:

$$\alpha_S = 1 - A/A_0$$

describing the extent of the reaction, α_S, for the decrease in the amount of the starting material at time t can be defined, where A

is the intensity of the (001) line of the starting material at time t and A_0 is this intensity at time $t = 0$. Depending on the direction of the reaction, $\alpha_P = \alpha_E$ and $\alpha_S = \alpha_H$ when the starting material is dihydrate, whereas $\alpha_P = \alpha_H$ and $\alpha_S = \alpha_E$ when the starting material is the ethanol intercalate.

Infrared measurements were carried out using a NICOLET IMPACT 400 Fourier transform infrared (FTIR) spectrophotometer in an H_2O-purged environment. An ambient-temperature deuterated triglycine sulfate (DTGS) detector was used for the wavelength range from 400 to 4000 cm^{-1}. A Happ-Genzel apodization function was used in the whole region and the spectral resolution was 2 cm^{-1}. Approximately 300 scans were coadded to achieve the signal-to-noise ratio shown. The Baseline Horizontal Attenuated Total Reflection (ATR) accessory with ZnSe crystal ($n = 2.4$ at 1000 cm^{-1}) was used for measurements of infrared spectra of the samples. In our experiments the effective path length was approximately a few μm (angle of incidence = 60°, number of reflections = 7). The ATR correction was performed in order to eliminate the dependence of the effective path length on the wavelength. After some trials it was found that the best results were obtained, if a sample is exposed for a definite time to the external conditions without removing the sample from the crystal between the subsequent spectral measurements. In this situation the water molecules arrive at the surface of the ZnSe crystal from the bulk volume and the adsorption of water at the measured surface of the sample is avoided.

FT Raman spectra were collected using an Equinox 55/S Fourier transform near-infrared (FT-NIR) spectrometer (Bruker) equipped with FT Raman module FRA 106/S (Bruker). The samples were irradiated by the focused laser beam (power 100 mW) of an Nd-YAG laser (1064 nm, Coherent). The scattered light was collected in backscattering geometry. A quartz beamsplitter and Ge detector (liquid N_2 cooled) were used to obtain interferograms. 128 interferograms were co-added and then processed by Fourier transformation with Blackman-Harris 4-term apodization and a zerofilling factor of 8 to obtain final FT Raman spectra in the range 4000−1000 cm^{-1} with 4 cm^{-1} resolution.

The FT Raman spectra of pure species ($VOPO_4$, $VOPO_4 \cdot 2H_2O$, $VOPO_4 \cdot 2C_2H_5OH$) were obtained from samples in sealed glass ampoules. In each case the glass ampoule was placed in the sample holder and aligned by the motorized x-y-z sample stage to achieve the optimal optical condition of irradiation of the sample and of the collection of the scattered light. The FT Raman spectra collected during the intercalation of water were obtained from the samples placed in the aluminium cup. The aluminium cup was optically pre-aligned using sulfur as a sample, and then sulfur was replaced by the particular sample studied.

Acknowledgments

We are grateful to Professor J. Votinský from University of Pardubice for fruitful discussions and Professor B. Strauch from Charles University for help with interpretation of spectra. The Dramatic Influence of Diamidoamine Ligands on the Structure and Reactivity of Low-Valent Tin and Bismuth Derivatives

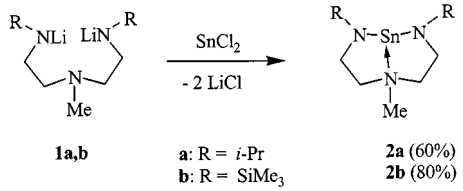
Jean-Luc Fauré,[a] Heinz Gornitzka,[a] Régis Réau,[a] Dietmar Stalke,[b] and Guy Bertrand*[a]

Keywords: Lewis acids / Bismuth / Aluminum / Phosphorus / Tin



The dilithium salts of *N*-methyl-*N*′,*N*′′-bis(diisopropyl)- and -(trimethylsilyl)-diethylenetriamine **1a**,**b** react with $SnCl_2$ affording the corresponding stannylenes **2a,b** in 60 and 80% yield, respectively. Compound **1b** also reacts with $BiCl_3$ to give the bismuth chloride **5** (90% yield). Derivatives **2b** and **5** have a symmetrical bicyclic structure and are monomeric both in solution and in the solid state. When **2b** is treated with $BiCl_3$ or PCl_3, an oxidation reaction leads to the hypercoordinated tin(IV) dichloride **3** (58% yield), or a transmetallation gives rise to the oniophosphane **4** (95% yield), respectively. Transmetalation reactions also occurred when **5** was treated with $AlCl_3$, $GaCl_3$ or $SnCl_2$ affording the corresponding aluminum chloride **6** (81% yield), gallium chloride **7** (38% yield) or tin dichloride **3** (38% yield). The observed reactivity for **2** and **5** is compared to that reported for Veith's stannylene or bismuth chloride.

Introduction

Compounds containing low-valent group 14 and 15 elements have attracted interest in recent times not only because of their inherently high reactivity,[1] but also because of their importance as heterogeneous catalysts[2] and as precursors for superconducting materials in MOCVD processes.[3] One of the main problems has been with the ligand design, balancing the duality between stability and reactivity.[4] We have recently shown that diamidoamino ligands $[(RNCH_2CH_2)_2NR']^{2-}$, initially developed by Cloke,[5] are powerful tools for stabilizing a large variety of group 13 Lewis acids.[6] Here we report the synthesis and reactivity of diamidoamino-stannylene and -bismuth(III)chloride derivatives, which are monomeric even in the solid state. The reactivity of these derivatives appears to be totally different from that observed with diamido-stannylenes (**I**) and -bismuth chloride derivatives (**II**) as reported by Veith et al.

Results and Discussion

The dilithium salts **1a,b**[6a] react in ether at −78°C with $SnCl_2$ to give the corresponding stannylenes **2a,b**, which were isolated in 60 and 80% yields, respectively (Scheme 1). The ^{13}C NMR spectra show the presence of only two types of CH_2 groups, which is consistent with monomeric structures. The high field ^{119}Sn NMR chemical shifts [(C_6D_6, 298 K): **2a**, +129; **2b**, +158] strongly suggest the coordination of the amino nitrogen to the tin center, leading to a bicyclic structure.[7] This is confirmed by the presence of tin satellites for the N−Me signals in the ^1H and ^{13}C NMR spectra [**2a**: $\delta(^{13}C) = 49.0$, $^2J(^{119}SnC) = 50.2$ Hz; $\delta(^1H) = 2.11$, $^3J(^{119}SnH) = 20.0$ Hz]. Both the monomeric nature and the intramolecular coordination are retained in the solid state as shown by the molecular structure of **2b** (Figure 1). The geometric parameters around the tin center approach those of a trigonal monopyramidal geometry, indicating significant s-character for the lone pair.

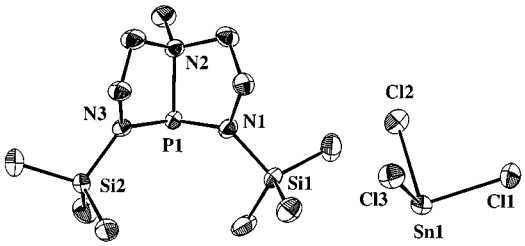
Scheme 2. Compared reactivity of **2b** and **I**

The reactivity of **2b** is "opposite" to that observed for Veith's stannylene **I**[8] (Scheme 2). An oxidation reaction occurs upon addition of an equimolar amount of $BiCl_3$ to a thf solution of **2b** leading to the hypercoordinate tin(IV)dichloride **3** (58% yield), whereas with **I** a transmetalation reaction was observed[8c] giving rise to the bismuth chloride **II**. In contrast, an exchange reaction occurs on treatment of **2b** with one equivalent of PCl_3 leading to **4** (95% yield), while Veith[8d] noticed the oxidation of the stannylene **I** into **III**.

Interestingly, the ^1H and ^{13}C NMR spectra suggest the coordination of the amino nitrogen to the phosphorus center [CH_3N: $\delta(^1H) = 2.74$, $^3J_{PH} = 13.5$ Hz; $\delta(^{13}C) = 51.7$, $^2J_{PC} = 5.9$ Hz]. A single crystal X-ray diffraction study not only confirmed the bicyclic structure but also showed the ionic nature of **4** (Figure 2).

In order to further compare diamidoamino ligands with diamido ligands we focused our attention on the corresponding bismuth(III) chloride derivative **5**. This product was obtained in 90% yield by treatment of a toluene solution of the dilithium salt **1b** with $BiCl_3$ at −78°C (Scheme 3). Both the monomeric and bicyclic structure of **5** were supported by the ^1H and ^{13}C NMR spectroscopic data in solution. In the solid state, the closest intermolecular Bi···Cl contact is of 3.725 Å. This value is not appreciably larger than those observed in the polymeric (3.047 Å) and dimeric (3.554 Å) bismuth chlorides **II** and **IV**, prepared by Veith[8b] and Raston,[9] respectively. However, since in **5** the intermolecular Bi···Bi distance is short (3.731 Å) and the value of the Bi−Cl−Bi angle is small (69.13°), this compound is best regarded as a monomeric species. The coordination geometry around the bismuth center approaches a trigonal bipyramid (Figure 3). The equatorial N1−Bi−N3 angle is small (101.8°) indicating that the lone pair has a strong s-character and the N2−Bi−Cl1 angle is large (159.6°) which indicates that the amino group interacts with a vacant Bi d-type orbital.[10]



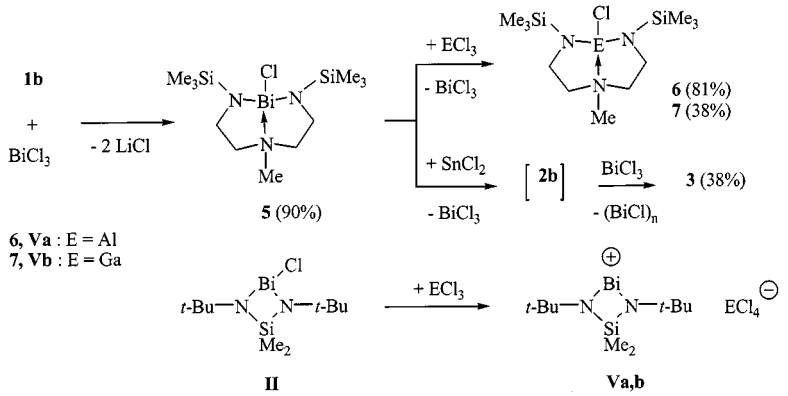


Figure 2. Molecular structure of **4**; selected bond lengths [Å] and angles [°]: N1−P1 1.684(3), N2−P1 1.897(3), N3−P1 1.664(3), N1−Si1 1.755(3), N3−Si2 1.765(3); N1−P1−N2 89.86(13), N2−P1−N3 90.05(13), N1−P1−N3 111.17(13).

It has been reported that treatment of **II** with Lewis acids such as aluminum and gallium trichloride yielded the corresponding bismuth salt **Va,b** by abstraction of chloride.[8h] In marked contrast, **5** reacted at −78°C in thf with $AlCl_3$ to give the corresponding aluminum chloride derivative **6** (81% yield). This transmetallation reaction even occurred

Scheme 3. Synthesis and reactivity of **5**

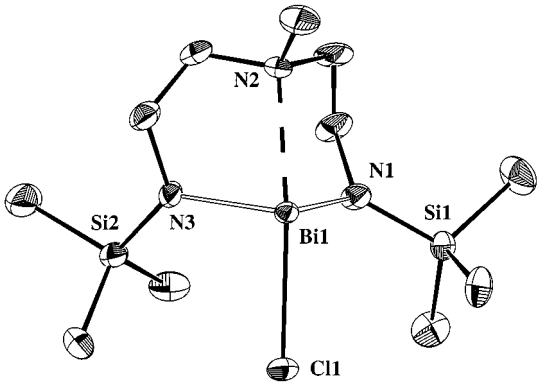

Figure 3. Molecular structure of **5**; selected bond lengths [Å] and angles [°]: N1−Bi1 2.123(5), N2−Bi1 2.496(6), N3−Bi1 2.138(6), Cl1−Bi1 2.6727(17), N1−Si1 1.714(6), N3−Si2 1.719(6); N1−Bi1−N2 75.6(2), N2−Bi1−N3 74.8(2), N1−Bi1−N3 101.8(2), N1−Bi1−Cl1 90.78(16), N2−Bi1−Cl1 159.60(14), N3−Bi1−Cl1 93.71(16).

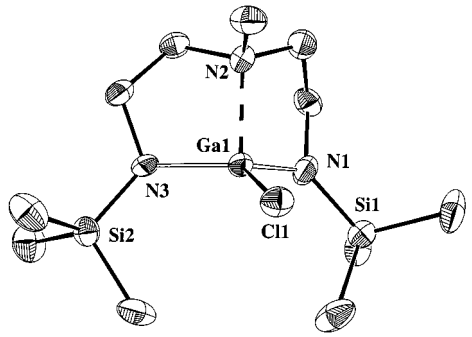

Figure 4. Molecular structure of **7**; selected bond lengths [Å] and angles [°]: N1−Ga1 1.839(16), N2−Ga1 2.043(3), N3−Ga1 1.870(15), Cl1−Ga1 2.1935(13), N1−Si1 1.711(9), N3−Si2 1.712(9); N1−Ga1−N2 90.2(4), N2−Ga1−N3 91.1(4), N1−Ga1−N3 126.08(17), N1−Ga1−Cl1 113.8(6), N2−Ga1−Cl1 111.62(10), N3−Ga1−Cl1 115.5(6).

with a strong Lewis acid such as $GaCl_3$, in toluene at −78°C; the gallium derivative **7** being isolated in 38%. According to an X-ray diffraction study, the gallium chloride **7** is monomeric and presents a trigonal-pyramidal geometry similar to that observed for the corresponding aluminum chloride **6**[6] (Figure 4).

Since the diamidoaminobismuth chloride **5** undergoes novel transmetallation reactions with group 13 Lewis acids, it was of interest to extend this reactivity to group 14 Lewis acids. A thf solution of **5** reacted at −78°C with an equimolar amount of $SnCl_2$, to give the tin dichloride derivative **3** in 38% yield. Since we have shown above (Scheme 2) that the stannylene **2b** reacts with $BiCl_3$ to give **3**, it is quite clear that a transmetallation reaction also occurs between **5** and $SnCl_2$ to give the stannylene **2b**, which is subsequently oxidized to **3** by the resulting $BiCl_3$. Therefore, this exchange reaction (**5**→**2b**) is the opposite of that observed by Veith (**I** →**II**).[8]

Conclusion

The dramatic difference observed in the reactivity of stannylene **2** and bismuth chloride **5** with that of **I** and **II**, respectively, can be rationalized by the electron donation from the axial nitrogen, which decreases the electrophilicity of the metal centers. The transmetalation reactions observed for bismuth chloride **5** with group 13 and 14 halides which occur under very mild conditions, suggest they could probably be generalized, especially for the synthesis of transition metal complexes.

Experimental Section

All experiments were performed under dry argon. Melting points are uncorrected ^1H, ^{13}C, and ^{119}Sn NMR spectra were recorded with Bruker AC80, AC200, WM250 or AMX400 spectrometers. ^1H and ^{13}C chemical shifts are reported in ppm relative to Me_4Si as external standard. ^{119}Sn NMR downfield chemical shifts are expressed with a positive sign, in ppm, relative to external Me_4Sn. Conventional glassware was used.

2a: To an ether solution (20 mL) of the lithium salt of *N*-methyl-*N′,N′′*-bis(diisopropyl)diethylenetriamine **1a** (4.7 mmol) was added an ether suspension (20 mL) of $SnCl_2$ (0.891 g, 4.7 mmol) at −78°C. The solution became golden yellow, and was allowed to warm to room temperature and stirred overnight. After filtration, and removal of the solvent under vacuum, **2a** was obtained as a yellow oil (0.89 g, 60%). − ^1H NMR (C_6D_6, 250.134 MHz): δ = 1.49 (d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH_3CH), 1.54 (d, $^3J_{HH}$ = 6.2 Hz, 6 H, CH_3CH), 2.11{s, $^3J(^{119}SnH)$ = 20 Hz, 3 H, CH_3N}, 2.37 (m, 4 H, CH_2), 3.11 (m, 2 H, CH_2), 3.47 (m, 2 H, CH_2), 3.67 (sept, $^3J_{HH}$ = 6.2 Hz, 2 H, CH). − $^{13}C\{^1H\}$ NMR (C_6D_6, 62.896 MHz): δ = 26.64, 26.93 (CH_3CH), 49.05 {$^2J(^{119}SnC)$ = 50.2 Hz, CH_3N}, 54.64 (CH_2NCH_3), 55.04 (CH), 63.32 (CH_2NCH). − $^{119}Sn\{^1H\}$ NMR (C_6D_6, 32.248 MHz): δ = +129. − $C_{11}H_{25}N_3Sn$: calcd. C 41.54, H 7.92, N 13.21; found C 41.10, H 7.65, N 13.42.

2b: Using the same experimental procedure as above employing the lithium salt of *N*-methyl-*N′,N′′*-bis(trimethylsilyl)diethylenetriamine **1b** (3.6 mmol) and $SnCl_2$ (0.682 g, 3.6 mmol), colorless crystals (1.15 g, 80%) were obtained from a toluene solution (6 mL) at −20°C. − m.p. < 20°C. − ^1H NMR (C_6D_6, 400.135 MHz): δ = 0.41 (s, 18 H, $SiCH_3$), 2.02 {s, $^3J(^{119}SnH)$ = 19 Hz, 3 H, CH_3N}, 2.15 (m, 4 H, CH_2), 3.35 (m, 2 H, CH_2), 3.44 (m, 2 H, CH_2). − $^{13}C\{^1H\}$ NMR (C_6D_6, 100.624 MHz): δ = 2.25 ($SiCH_3$), 48.32 {$^2J(^{119}SnC)$ = 54.0 Hz, CH_3N}, 50.09 (CH_2NCH_3), 65.99 (CH_2NSi). − $^{29}Si\{^1H\}$ NMR (C_6D_6, 79.495 MHz): δ = +0.03. − $^{119}Sn\{^1H\}$ NMR (C_6D_6, 149.248 MHz): δ = +158. − $C_{11}H_{29}N_3Si_2Sn$: calcd. C 34.93, H 7.73, N 11.11; found C 34.67, H 7.76, N 11.22.

3: A thf solution (5 mL) of $BiCl_3$ (0.123 g, 0.38 mmol) was added dropwise to a thf solution (5 mL) of stannylene **2b** (0.147 g, 0.38 mmol) at −78°C. The color of the solution changed from dark brown to black after the solution was allowed to warm to room temperature. After filtration, the solvent was removed under vacuum. The residue was treated with toluene (20 mL) and, after filtration, the solvent was removed under vacuum. Colorless crystals were obtained from a pentane solution (4 mL) at −20°C (0.101 g, 58%). − m.p. < 20°C. − ^1H NMR (C_6D_6, 250.133 MHz): δ = 0.43 (s, 18 H, $SiCH_3$), 1.87 (ddd, J_{HH} = 9.4, 5.1 and 3.5 Hz, 2 H, CH_2), 2.02 (s, 3 H, CH_3N), 2.04 (ddd, J_{HH} = 9.4, 5.6 and 3.4 Hz, 2 H, CH_2), 2.86 (m, 4 H, CH_2). − $^{13}C\{^1H\}$ NMR (C_6D_6, 62.896 MHz):

δ = 3.10 ($SiCH_3$), 41.41 (CH_3N), 44.00 (CH_2NCH_3), 57.86 (CH_2NSi). – $^{119}Sn\{^1H\}$ NMR (C_6D_6, 29.881 MHz): δ = −228. – $C_{11}H_{29}Cl_2N_3Si_2Sn$: calcd. C 29.41, H 6.51, N 9.36; found C 29.64, H 6.22, N 9.33.

4: Neat freshly distilled PCl_3 (0.072 mL, 0.8 mmol) was added dropwise to a toluene solution (6 mL) of diamidoaminostannylene **2b** (0.315 g, 0.8 mmol) at −90°C. The solution was allowed to warm to room temperature and became yellow after 30 min. The solvent was removed under vacuum and the yellow-orange oil obtained was washed with pentane (5 mL) and ether (5 mL). Colorless crystals were obtained from a C_6D_6 solution (1 mL) at room temperature (0.315 g, 95%). – m.p. 110°C. – ^1H NMR (C_6D_6, 250.134 MHz): δ = −0.02 (s, 18 H, $SiCH_3$), 2.61 (m, 2 H, CH_2), 2.74 {d, J_{PH} = 13.5 Hz, 3 H, CH_3N}, 3.03 (m, 2 H, CH_2), 3.43 (m, 2 H, CH_2), 4.70 (m, 2 H, CH_2). – $^{13}C\{^1H\}$ NMR (C_6D_6, 62.896 MHz): δ = 1.01 ($SiCH_3$), 51.70 {d, J_{PC} = 5.9 Hz, CH_3N}, 53.39 (CH_2NCH_3), 64.67 (CH_2NSi). – $^{31}P\{^1H\}$ NMR (C_6D_6, 81.02 MHz): δ = +169. – $C_{11}H_{29}Cl_3N_3PSi_2Sn$: calcd. C 25.63, H 5.67, N 8.15; found C 25.30, H 5.58, N 8.22.

5: Using the same procedure as for **2a**, but with toluene instead of ether, and $BiCl_3$ (0.232 g, 0.73 mmol), colorless crystals were obtained from a toluene solution (2 mL) at −20°C (0.334 g, 90%). – m.p. 133°C (dec.). – ^1H NMR (C_6D_6, 200.132 MHz): δ = 0.46 (s, 18 H, $SiCH_3$), 1.56 (ddd, J_{HH} = 12.1, 6.6 and 3.3 Hz, 2 H, CH_2), 1.65 (s, 3 H, CH_3N), 1.91 (ddd, J_{HH} = 12.1, 6.6 Hz and 3.3 Hz, 2 H, CH_2), 3.95 (ddd, J_{HH} = 14.5, 6.6 and 3.3 Hz, 2 H, CH_2), 4.16 (ddd, J_{HH} = 14.5, 6.6 and 3.3 Hz, 2 H, CH_2). – $^{13}C\{^1H\}$ NMR (C_6D_6, 62.896 MHz): δ = 2.98 ($SiCH_3$), 44.76 (CH_3N), 47.92 (CH_2NCH_3), 65.80 (CH_2NSi). – $C_{11}H_{29}BiClN_3Si_2$: calcd. C 26.22, H 5.80, N 8.34; found C 26.34, H 5.70, N 8.39.

6[6a] was prepared following the same procedure as for **7**.

7: A toluene solution (6 mL) of $GaCl_3$ (0.201 g, 1.12 mmol) was added dropwise to a toluene solution (10 mL) of bismuth chloride **5** (0.569 g, 1.12 mmol) at −78°C. The pale yellow solution was allowed to warm to room temperature. After filtration, the solvent was removed under vacuum, and colorless crystals (0.157 g, 38%) were obtained from a toluene solution (2 mL) at −20°C. – m.p. 180°C (dec.). – ^1H NMR ($CDCl_3$, 200.132 MHz): δ = 0.41 (s, 18 H, $SiCH_3$), 1.79 (ddd, J_{HH} = 11.3, 6.1 and 5.1 Hz, 2 H, CH_2), 1.91 (s, 3 H, CH_3N), 2.05 (ddd, J_{HH} = 11.3, 6.1 and 4.8 Hz, 2 H, CH_2), 2.83 (m, 4 H, CH_2). – $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.896 MHz): δ = 0.84 ($SiCH_3$), 41.77 (CH_2NCH_3), 41.99 (CH_3N), 58.40 (CH_2NSi). – $C_{11}H_{29}ClGaN_3Si_2$: calcd. C 36.22, H 8.01, N 11.52; found C 36.26, H 8.05, N 11.48.

X-ray Crystal Structure Determination of 2b, 4, 5 and 7:

2b: $C_{11}H_{29}N_3Si_2Sn$, M = 378.24, triclinic, $P\bar{1}$, a = 9.047(2) Å, b = 10.209(2) Å, c = 11.906(2) Å, α = 103.62(2)°, β = 100.02(2)°, γ = 113.71(2)°, V = 932.8(3) Å^3, Z = 2, ρ_c = 1.347 Mg m^{-3}, $F(000)$ = 388, λ = 0.71073 Å, T = 173(2) K, μ (Mo K_α) = 1.487 mm^{-1}, crystal size 0.7 × 0.6 × 0.6 mm, 2.42° < θ < 23.25°, 9933 reflections (2523 independent, R_{int} = 0.1104) were collected at low temperatures using an oil-coated shock-cooled crystal[11] on a STOE-IPDS diffractometer. The structure was solved by direct methods (SHELXS-97)[12] and 201 parameters using 71 restraints were refined using the least-squares method on F^2.[13] Largest electron density residue: 1.606 e Å^{-3}, R_1 {for $F>2\sigma(F)$} = 0.058 and wR_2 = 0.134 (all data) with $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $wR_2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2\}0.5$. The disorder of a trimethylsilyl group was refined anisotropically on two positions with the occupancy 0.64/0.36 using ADP and distance restraints.

4: $C_{11}H_{29}Cl_3N_3PSi_2Sn$, M = 515.56, triclinic, $P\bar{1}$, a = 6.374(1) Å, b = 12.868(2) Å, c = 13.913(2) Å, α = 100.39(2)°, β = 98.47(2)°, γ = 93.07(2)°, V = 1106.4(3) Å^3, Z = 2, ρ_c = 1.548 Mg m^{-3}, $F(000)$ = 520, λ = 0.71073 Å, T = 173(2) K, μ (Mo K_α) = 1.695 mm^{-1}, crystal size 0.4 × 0.3 × 0.1 mm, 1.99° < θ < 23.53°, 8463 reflections (3113 independent, R_{int} = 0.0375) were collected at low temperatures using an oil-coated shock-cooled crystal[11] on a STOE-IPDS diffractometer. The structure was solved by direct methods (SHELXS-97)[12] and 197 parameters were refined using the least-squares method on F^2.[13] Largest electron density residue: 0.475 e Å^{-3}, R_1 {for $F>2\sigma(F)$} = 0.025 and wR_2 = 0.065 (all data) with $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $wR_2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2\}0.5$.

5: $C_{11}H_{29}BiClN_3Si_2$, M = 503.98, monoclinic, $P2_1/n$, a = 10.063(1) Å, b = 13.280(2) Å, c = 15.006(2) Å, β = 109.16(1)°, V = 1894.3(4) Å^3, Z = 4, ρ_c = 1.767 Mg m^{-3}, $F(000)$ = 976, λ = 0.71073 Å, T = 173(2) K, μ (Mo K_α) = 9.566 mm^{-1}, crystal size 0.6 × 0.5 × 0.5 mm, 2.10° < θ < 23.25°, 15301 reflections (2718 independent, R_{int} = 0.0883) were collected at low temperatures using an oil-coated shock-cooled crystal[11] on a STOE-IPDS diffractometer. A numerical absorption correction was employed and the min./max. transmissions are 0.0857 and 0.2607. The structure was solved by direct methods (SHELXS-97)[12] and 171 parameters were refined using the least-squares method on F^2.[13] Largest electron density residue: 1.022 e Å^{-3}, R_1 {for $F>2\sigma(F)$} = 0.029 and wR_2 = 0.074 (all data) with $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $wR_2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2\}0.5$.

7: $C_{11}H_{29}ClGaN_3Si_2$, M = 364.72, monoclinic, $P2_1/m$, a = 6.472(2) Å, b = 18.624(5) Å, c = 7.688(3) Å, β = 96.64(4)°, V = 920.5(5) Å^3, Z = 2, ρ_c = 1.316 Mg m^{-3}, $F(000)$ = 384, λ = 0.71073 Å, T = 153(2) K, μ (Mo K_α) = 1.760 mm^{-1}, crystal size 0.5 × 0.4 × 0.1 mm, 2.67° < θ < 24.21°, 6014 reflections (1514 independent, R_{int} = 0.0445) were collected at low temperatures using an oil-coated shock-cooled crystal[11] on a STOE-IPDS diffractometer. A numerical absorption correction was employed and the min./max. transmissions are 0.5865 and 0.7727. The structure was solved by direct methods (SHELXS-97)[12] and 164 parameters using 71 restraints were refined using the least-squares method on F^2.[13] Largest electron density residue: 0.273 e Å^{-3}, R_1 {for $F>2\sigma(F)$} = 0.024 and wR_2 = 0.055 (all data) with $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $wR_2 = \{\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2\}0.5$. The mirror leads to a disorder of the whole molecule, which was refined anisotropically by ignoring the symmetry (PART-1) using ADP and distance restraints. A refinement in $P2_1$ gives the same disorder.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Data Centre as supplementary publication no. CCDC-112754 (**2b**), CCDC-112755 (**4**), CCDC-112756 (**5**) and CCDC-112757 (**7**). Silicon Compounds with Strong Intramolecular Steric Interactions, 71[+]

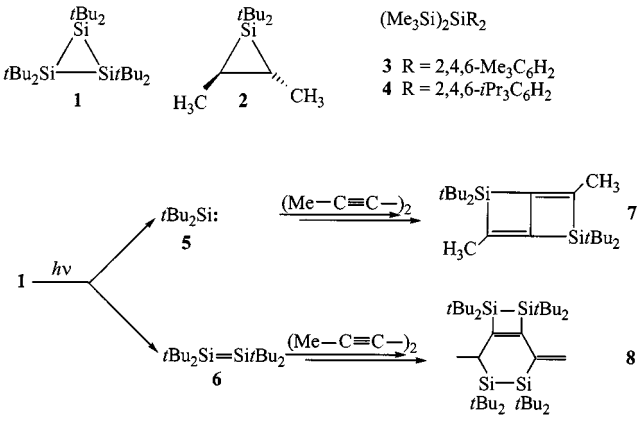
Silylene Reactions with Buta-1,3-diynes: Cycloadditions, Insertions, and Rearrangements



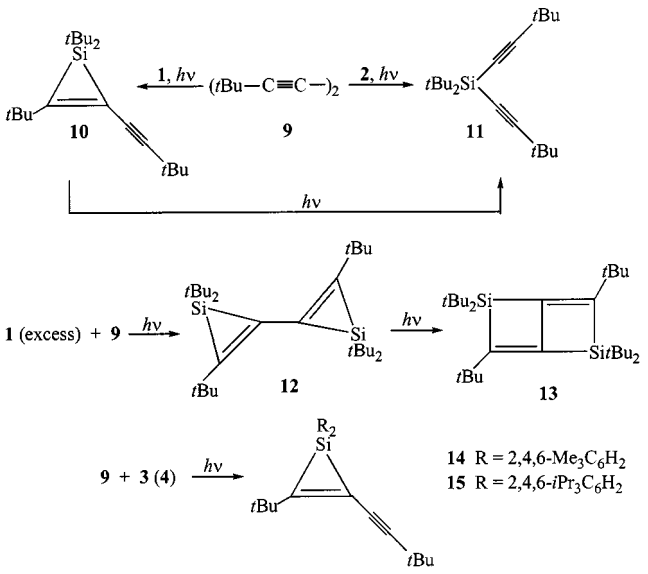
Detlev Ostendorf,[a] Lars Kirmaier,[a] Wolfgang Saak,[a] Heinrich Marsmann,[b] and Manfred Weidenbruch*[a]

Keywords: Multiple bonds / Silicon / Silylene / Cycloadditions / Insertions

Di-*tert*-butylsilylene, generated by photolysis of hexa-*tert*-butylcyclotrisilane **1** or 1,1-di-*tert*-butyl-*trans*-2,3-dimethylsilirane (**2**), reacts with the 1,3-diyne (*t*Bu–C≡C–)$_2$ **9** to furnish the dialkynylsilane **11** via the isolable alkynylsilirene **10**. Photolysis of excess **1** in the presence of **9** furnishes the C–C linked 2,2′-disilirene **12** which, upon prolonged irradiation, rearranges to the 2,5-disilabicyclo[2.2.0]hexa-1(6),3-diene (**13**). Treatment of **9** with diarylsilylenes, formed by irradiation of hexamethyl-2,2-dimesityltrisilane (**3**) or hexamethyl-2,2-bis(2,4,6-triisopropylphenyl)trisilane (**4**), gives the corresponding alkynylsilirenes **14** and **15**, respectively. Photolysis of **1** or **2** in the presence of (Me$_3$Si–C≡C–)$_2$ **16** yields the dialkynylsilane **17** which, on further reaction with **2**, yields the 2,5-disilabicyclo[2.2.0]hexa-1(6),3-diene (**18**). Irradiation of **3** in the presence of **16** affords the *cis*- and *trans*-isomeric 1,3-dimethylene-2,4-disilacyclobutane derivatives *cis*-**21** and *trans*-**21**, presumably via a 1-silaallene intermediate. The structures of **12**, **15**, **18**, *cis*-**21**, and *trans*-**21** have been determined by X-ray crystallography.

Dialkyl- and diarylsilylenes (silanediyls), R$_2$Si:, are highly reactive intermediates capable of undergoing numerous addition and insertion reactions. When the groups R on silicon are small, the initial products are usually unstable and often undergo a series of subsequent transformations before the thermodynamically stable final products are reached.[1] Silylenes bearing bulky substituents behave differently and, for example, undergo smooth addition reactions with multiple bond systems to furnish three-membered ring compounds that can often be isolated in spite of their high degrees of ring strain.[2]

Examples of silylenes of this type are di-*tert*-butylsilylene, generated photolytically from the cyclotrisilane **1**[3] or the silirane **2**,[4] and the 2,4,6-trialkylphenyl-substituted silylenes, also accessible from the acyclic trisilanes **3**[5] and **4**[6] under the action of light. We recently studied the photolysis of **1**, which decomposes under these conditions to give di-*tert*-butylsilylene **5** and tetra-*tert*-butyldisilene **6**, in the presence of hexa-1,3-diyne. From these experiments, the bicyclic compounds **7** and **8** were isolated as the final products and their structures were confirmed by X-ray crystallography.[7] In order to obtain further information relating to the formation of these compounds, especially the bicyclic system **7**, we have now examined the reactions of the 1,3-diynes 1,4-bis(trimethylsilyl)buta-1,3-diyne **16** and 2,2,7,7-tetramethylocta-3,5-diyne **9** with the silylene sources **1**−**4** and report here on the resultant cycloaddition, formal insertion, and rearrangement reactions leading to the formation of novel mono- and bicyclic systems.



Photolysis of the cyclotrisilane **1** in the presence of the diyne **9** in a ratio of approximately 1:1 furnished the alkynylsilirene **10** as a colorless oil in 30% yield; the constitution of this product was confirmed by a complete NMR analysis. The position of the ^{29}Si-NMR signal is of particular diagnostic value: it appears upfield at $\delta = -63.3$, which is typical for silirenes with *tert*-butyl substituents at the silicon atom.[7][8]

When the silirane **2** is used instead of **1** for the generation of di-*tert*-butylsilylene, colorless crystals are obtained in 52% yield, the analytical and mass spectral data of which

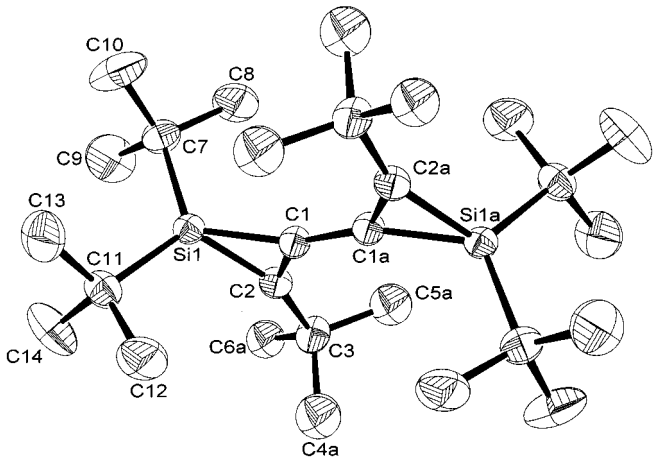

Figure 1. Molecular structure of **12** in the crystal (hydrogen atoms omitted); ellipsoids are drawn at a 50% probability level; selected bond lengths [pm] and angles [°]: C(1)−C(2) 133.8(3), C(1)−C(1a) 145.1(4), Si(1)−C(1) 182.2, Si(1)−C(2) 181.9(2); C(2)−C(1)−Si(1) 68.3(1), C(2)−Si(1)−C(1) 43.1, C(2)−C(1)−C(1a) 137.4(3), C(1a)−C(1)−Si(1) 154.3(2)

again point to the formation of **10**. However, the NMR data are not compatible with structure **10**. Thus, no signals attributable to olefinic carbon atoms can be seen in the ^{13}C-NMR spectrum and the ^{29}Si-NMR spectrum features a singlet at $\delta = -20.04$. These data, as well as an X-ray crystallographic analysis,[9] showed that, instead of the silirene **10**, the dialkynylsilane **11** had been formed as the product of a formal silylene insertion into the central C−C single bond. The X-ray crystal structure did not exhibit any unusual features compared to those of other alkynylsilanes.[10]

The formation of different products from the photolysis of **1** or **2** in the presence of **9** is presumably due to the impeded liberation of **5** from the silirane **2**, as is reflected in the appreciably longer photolysis time. In order to obtain information on the mode of formation of the formal insertion product **11**, the silirene **10** was subjected to a further photolysis, which afforded the silane **11** in almost quantitative yield. The isomerization **10** → **11** can most simply be rationalized by a 1,2-migration of the alkynyl group in combination with a cleavage of the three-membered ring. Ishikawa et al.[11] have previously observed a similar rearrangement on heating a dimesitylsilacyclopropene to 250°C, which also furnished the corresponding dialkynylsilane.

The reaction to afford **10** from the cyclotrisilane **1** and the diyne **9** also furnished a second crystalline product in 15% yield, the spectral data of which showed it to be the C−C linked bis(silirene) **12**. The yield of this compound could be increased to 37% by increasing the proportion of **1** in the photolysis mixture to a ratio of 1:1.5. An X-ray crystallographic analysis (Figure 1) confirmed not only the constitution of **12**, but also revealed some interesting features.

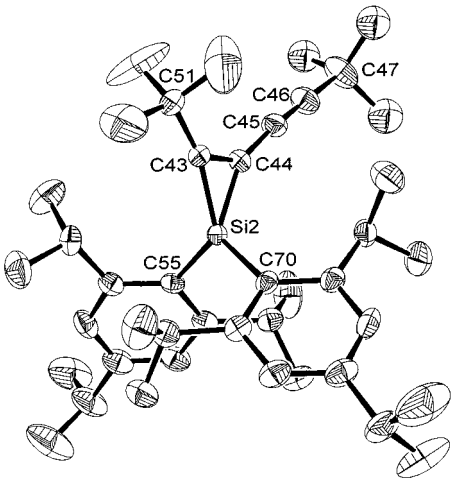
Compound **12** not only represents the first C−C linked bis(silirene),[12] but is also a *trans*-butadiene with both double bonds bridged by silylene units. A comparison of the structure with that of the parent butadiene[13] reveals a somewhat shortened C−C single bond length of 145.1(4) pm instead of 148.3 pm in the butadiene. The difference in the C=C−C angles is more pronounced; 137.4(3)° in **12** is markedly larger than the 122.4° in the parent compound. Furthermore, the endocyclic Si−C bond lengths, with an average of 182 pm, are short and the C1−Si1−C2 angle of 43.1(1)° is very small.

The bis(silirene) **12** is thermally stable and, for example, is recovered unchanged after 30 d at 120°C. Its behavior under photochemical conditions is completely different: after only 6 h at room temperature the 2,5-disilabicyclo[2.2.0]hexa-1(6),3-diene **13** is isolated from the reaction mixture in 52% yield. The formation of **13** is thought to proceed through cleavage of two Si−C bonds in **12**, followed by reformation of two σ-bonds to afford the rearranged bicyclic compound. The constitution of **13** was confirmed by comparison of its NMR data with those of compounds **7** and **18**, the structures of which have been verified by X-ray crystallography. Thus, we have unambiguously demonstrated all intermediate steps involved in the formation of **13** and have also found a feasible explanation for the formation of the bicyclic compound **7**, which remained as an open question from a previous publication.[7]

The photochemical lability of the Si−C bonds in **12** is also manifested in the concomitant formation of the molecules **10** and **11**, clearly showing that cycloreversion with cleavage of a silylene molecule **5** is possible besides the rearrangement **12** → **13**.

Although the dialkylsilylene **5** can participate in a variety of cycloaddition and rearrangement reactions, analogous photolyses of the 1,3-diyne with the trisilanes **3** and **4**, which also readily liberate the corresponding diarylsilylene under these conditions, merely furnish the [2+1] cycloadducts **14** and **15**, as indicated by the typical highfield signals in the ^{29}Si-NMR spectra at $\delta = -106$ (**14**) and $\delta = -109.5$ (**15**). Since the reaction of **3** with the 1,4-bis(trimethylsilyl)-1,3-diyne **16** gives rise to a completely different palette of products (see below), we have determined the structure of

15 by X-ray crystallography (Figure 2). The structure revealed a very small endocyclic C−Si−C angle of 43.2(2)°, very short Si−C1 and Si−C2 bond lengths in spite of the steric crowding, as well as a short exocyclic C2−C3 bond. All other features were unremarkable.



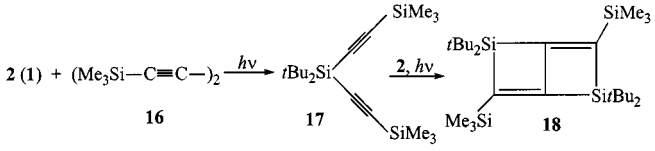


Figure 2. Molecular structure of **15** in the crystal (hydrogen atoms omitted); ellipsoids are drawn at a 50% probability level; selected bond lengths [pm] and angles [°]: C(1)−C(2) 134.5(5), Si−C(1) 181.9(3), Si−C(2) 181.7(3); C(2)−Si−C(1) 43.4(1), C(2)−C(1)−Si 68.2(2), C(1)−C(2)−Si 68.4(2)

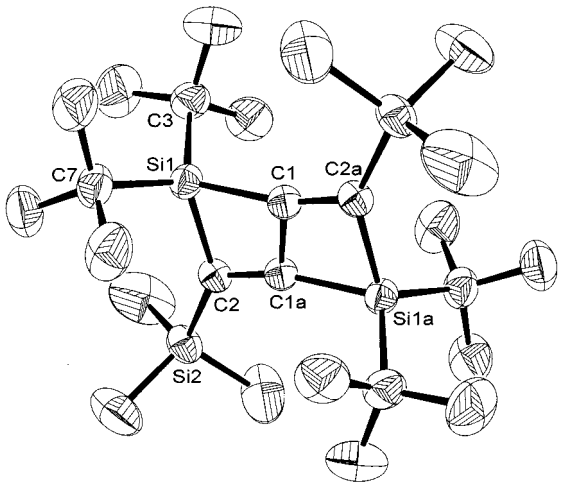
An unusual result, however, was that dark-yellow crystals of tetrakis(2,4,6-triisopropylphenyl)disilene were isolated together with the colorless crystals of **15**. This compound had previously been obtained by dehalogenation of dichlorobis(2,4,6-triisopropylphenyl)silane[14] and by photolysis of the trisilane **4**.[15] The fact that the dimerization process of the silylene accessible from **4** to give the disilene proceeds in competition with the [2+1] cycloaddition is possibly due to steric repulsion between the *tert*-butyl and triisopropylphenyl groups in the cycloaddition process. This hypothesis was supported by the photolysis of **4** in the presence of hexa-2,4-diyne, which gave an appreciably higher yield of the corresponding alkynylsilirene (**15**; Me instead of *t*Bu).

Analogously performed reactions of the cyclotrisilane **1** or − preferentially − the silirane **2** with the trimethylsilyl-substituted 1,3-diyne **16** seem to proceed according to the same pattern as observed for the 1,3-diyne **9**, except that in no case was a [2+1] cycloadduct of the type **10** isolated. Presumably as a consequence of the greater mobility of the trimethylsilylethynyl group,[11] the formal insertion product **17** is obtained in 46% yield; its structure, like that of **11**, was confirmed by X-ray crystallography.[16] Further treatment of the dialkynylsilane **17** with the silirane **2** led to an unexpected result: light-yellow crystals of the bicyclic product **18** were obtained in 32% yield. Similar reactions have previously been observed when zirconocene was treated with a dialkynylsilane[17] or a dialkynylzirconocene derivative;[18] these reactions also furnished bicyclic products in which one or two zirconium atoms had been incorporated into the ring skeletons. However, these results cannot be directly compared with the silylene situation because of the different bonding possibilities available to the 14-electron zirconocene complex.



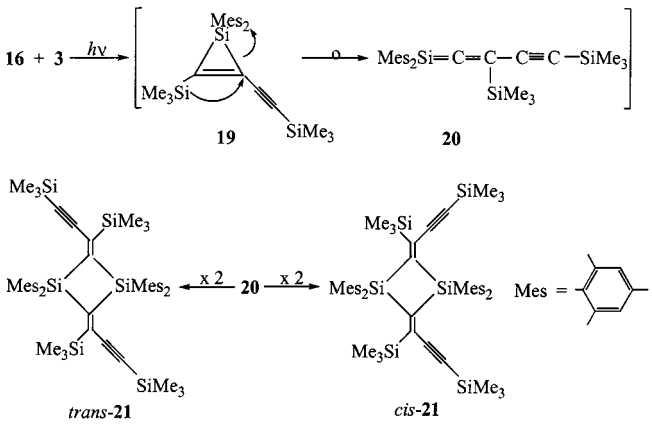


Figure 3. Molecular structure of **18** in the crystal (hydrogen atoms omitted); ellipsoids are drawn at a 50% probability level; selected bond lengths [pm] and angles [°]: Si(1)−C(1) 189.9(2), Si(1)−C(2) 189.9(2), C(1)−C(2a) 136.2(3); C(1)−Si(1)−C(2) 76.2(1), C(1)−C(1a)−C(2) 110.0(2), Si(1)−C(2)−C(1a) 88.8(1), Si(1)−C(1)−C(1a) 85.1(2), C(1a)−C(2)−Si(2) 128.5(2), Si(1)−C(2)−Si(2) 142.7(1)

A plausible mechanistic sequence leading to formation of the bicyclic compound **18** consists of the [2+1] cycloaddition of a silylene molecule **5** to one of the C/C triple bonds, followed by a 1,2-shift of a trimethylsilyl group with intermediate formation of a 1-silaallene derivative. A subsequent intramolecular [2+2] cycloaddition can then furnish the bicyclic system of **18**. The constitution of **18** was confirmed by X-ray crystallography (Figure 3). This revealed that **18** possess a crystallographic center of inversion in the middle of the C1−C1a bond. In spite of the sterically voluminous *tert*-butyl groups, both the endo- and the exocyclic Si−C bonds are only slightly extended. However, the steric influence of these groups is apparent in the Si1−C2−Si2 angle of 142.7°, which reflects the repulsion of the trimethylsilyl groups.

In order to obtain further support for the postulated sequence proceeding via a 1-silaallene, we subjected trisilane **3** to photolytic conditions in the presence of the 1,3-diyne **16**. Fractional crystallization of the reaction mixture first gave colorless, high-melting crystals composed, according to NMR and mass spectral data, of two molecules each of the diyne and the diarylsilylene. The ^{13}C-NMR spectrum revealed the presence of both olefinic and acetylenic carbon atoms. The ^{29}Si-NMR spectrum featured three signals of equal intensity at $\delta = -2, -19$, and -22.

An X-ray crystallographic analysis of the isolated crystals (Figure 4) showed that the compound *trans*-**21** had been

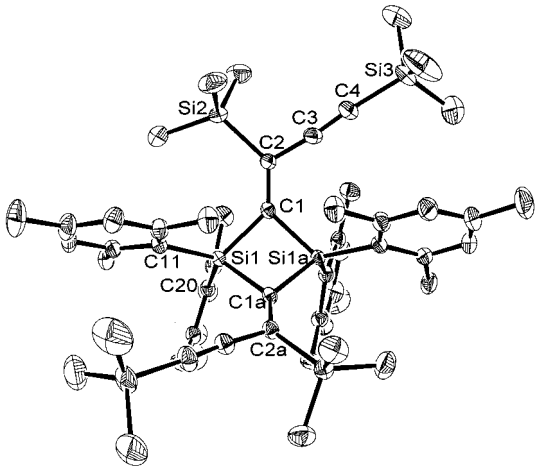

Figure 4. Molecular structure of *trans*-**21** in the crystal (hydrogen atoms omitted); ellipsoids are drawn at a 50% probability level; selected bond lengths [pm] and angles [°]: Si(1)−C(1) 192.1(2), Si(1a)−C(1) 191.9(2), C(1)−C(2) 135.7(3), C(3)−C(4) 120.4(3); C(1)−Si(1)−C(1a) 83.1(1), Si(1)−C(1)−Si(1a) 91.70(9), C(1)−C(2)−C(3) 120.0(2)

formed. This structure has a C_2 symmetry axis perpendicular to the middle of the four-membered ring, which accounts for the fact that only three signals are observed in the ^{29}Si-NMR spectrum. The four-membered ring is folded, with an angle of 33° between the planes formed by the atoms Si1−C1−Si1a and Si1a−C1a−Si1. Within the ring, the smaller angles are found at the silicon atoms and the larger ones at the carbon atoms. This situation, together with the slightly extended Si−C bond lengths of all substituents on the four-membered ring, results in a strain-free structure. The 1,3-dimethylene-2,3-disilacyclobutane structure described here is novel. Barton, Gordon et al.[19] recently reported on a similar ring obtained by dehalogenation of α-(bromovinyl)chlorodimethylsilane, although without an unambiguous structural characterization.

After several weeks standing at −30 °C, a second fraction was obtained from the above mentioned reaction mixture, also as colorless crystals with a high melting point. The mass, ^{1}H-, and ^{13}C-NMR spectral data of this fraction did not show any major changes in comparison with those of *trans*-**21**. However, in the ^{29}Si-NMR spectrum, two signals at δ = −2.6 and −18.87 with higher intensity and another

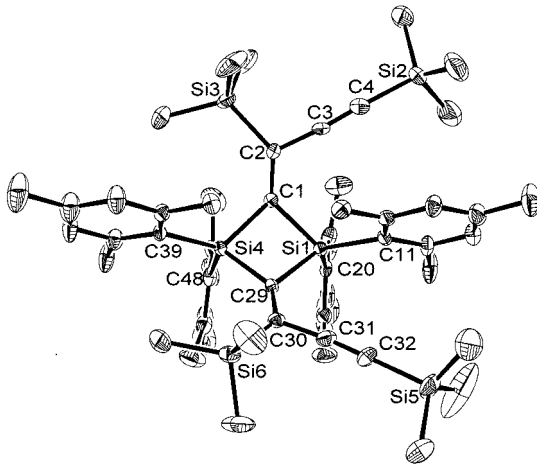

Figure 5. Molecular structure of *cis*-**21** in the crystal (hydrogen atoms omitted); ellipsoids are drawn at a 50% probability level; selected bond lengths [pm] and angles [°]: Si(1)−C(1) 192.1(6), C(1)−Si(4) 191.9(4), Si(4)−C(29) 191.6(4), C(29)−Si(1) 192.3(4), C(1)−C(2) 135.8(6), C(2)−C(3) 144.0(7), C(3)−C(4) 122.1(7), Si(1)−C(1)−Si(4) 91.4(2), C(1)−Si(1)−C(2) 82.7(2), C(29)−Si(4)−C(1) 82.9(2), Si(4)−C(29)−Si(1) 91.5(2)

two at δ = −21.74 and −24.04 with lower intensity were observed, indicating a different structure. Again, X-ray crystallography (Figure 5) allowed an unequivocal structural assignment and revealed that *cis*-**21** had been obtained. As in the case of the *trans* isomer, the central ring is not planar, but has a folding angle of 34.7°. The molecule possesses a mirror plane dissecting the folding angle, which explains the number (four) and relative intensities of the ^{29}Si-NMR signals. The remaining structural parameters are more or less the same as those of the *trans* form.

The isolation of both *cis*- and *trans*-isomers of **21** supports the assumption that their mechanisms of formation do indeed proceed via a 1-silaallene derivative. The reaction sequence may be initiated by the [2+1] cycloaddition of the diarylsilylene to one of the triple bonds in **16** to form the silirene **19**, which is then transformed to the 1-silaallene **20** through 1,2-silyl group migration and concomitant cleavage of a ring Si−C bond. In contrast to alkyl groups, the silyl groups in this and related systems are able to undergo such 1,2-migrations.[19] Although 1-silaallenes with sterically demanding groups can be isolated as thermally stable molecules,[20][21] the steric shielding in **20** is not sufficient so that intermolecular [2+2] cycloaddition occurs to furnish the *cis*- and *trans*-isomers of compound **21**.

The results presented here serve not only to clarify the individual steps in the formation of the bicyclic systems **7**, **13**, and **18**, but also to illustrate the sensitivity with which the reaction system 1,3-diyne/silylene can depend on the terminal groups of the diacetylene, the substituents of the silylene, and the duration of photolysis

Experimental Section

General: All manipulations were performed using standard Schlenk techniques under dry argon. − ^{1}H and ^{13}C NMR: Bruker AM 300 or Bruker ARX 500. The assignments of the ^{1}H- and ^{13}C-NMR

signals were confirmed with the aid of COSY and COLOC spectra. − ^{29}Si NMR: Bruker AMX 300. − MS: Finnigan MAT 212. −Elemental analyses: Analytische Laboratorien, D-51789 Lindlar, Germany. − IR spectra: Bio-Rad FTS-7. − Photolyses: High-pressure mercury immersion lamp (Heraeus TQ 150).

1,1,3-Tri-*tert*-butyl-2-(3,3-dimethylbut-1-ynyl)-1*H*-silacyclopropene (10): A solution of **1** (1.5 g, 3.5 mmol) and **9** (0.65 g, 4.0 mmol) in *n*-hexane (80 mL) was irradiated for 5 h at room temperature. After this time, TLC monitoring showed the reaction to be complete as **1** had been fully consumed. The solvent was removed and the oily residue was transferred to a molecular still. Distillation at 60°C/1.5 mbar yielded 0.32 g (30%) of **10**. − ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 1.04 (s, 18 H), 1.22 (s, 9 H, *t*BuC≡C), 1.34 (s, 9 H, *t*BuC=C). − ^{13}C NMR (C_6D_6, 75.5 MHz, 298 K): δ = 21.59 (C_q), 28.89 (C_q), 30.00 (C_p), 30.25 (C_p), 31.24 (C_p), 36.67 (C_q), 74.16 (C_q, C≡*C*tBu), 111.01 (C_q, *C*≡CtBu), 131.33 (C_q, *C*=C*t*Bu), 172.07 (C_q, C=*C*tBu); C_p and C_q refer to primary and quaternary carbon atoms; the assignment of the ^{13}C-NMR signals was confirmed by a COLOR spectrum. − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = −63.3. − MS (CI, isobutane): *m*/*z* (%) = 305 (100) [MH^+]. − $C_{18}H_{36}Si$ (304.4): calcd. C 78.88, H 11.92; found C 78.62, H 12.00.

The residue was dissolved in the minimum volume of *n*-pentane and this solution was kept at −65°C for 12 h to afford 0.075 g (10% yield) of colorless crystals of **12**. For spectroscopic data, see below.

Di-*tert*-butylbis(3,3-dimethylbut-1-ynyl)silane (11): A solution of **2** (1.20 g, 6.05 mmol) and **9** (0.76 g, 4.68 mmol) in *n*-hexane (80 mL) was irradiated for 11 h at room temperature. The solvent was then removed by vacuum distillation and the brown oily residue was transferred to a molecular still. Distillation at 60°C/0.4 mbar yielded 0.89 g of a colorless oil, which was redissolved in the minimum volume of *n*-hexane. Cooling of this solution to −17°C furnished 0.74 g (52%) of colorless, transparent crystals of **11**; m.p. 45−46°C. − ^{1}H NMR (C_6D_6, 500 MHz, 298 K): δ = 1.09 (s, 18 H, *t*Bu$_2$Si), 1.30 (s, 18 H, *t*BuC≡C). − ^{13}C NMR (C_6D_6, 125.75 MHz, 298 K): δ = 19.59 (C_q), 28.13 (C_p), 28.33 (C_q, C≡C−CCH_3), 30.78 [C_p, $(CH_3)_3$CC≡C], 77.36 (C_q, *C*≡C*t*Bu), 117.50 (C_q, C≡*C*t*Bu*). − ^{29}Si NMR: (C_6D_6, 59.6 MHz, 298 K): δ = −20.04. − MS (CI, isobutane): *m*/*z* (%) = 305 (100) [MH^+]. − $C_{18}H_{36}Si$ (304.4): calcd. C 78.88, H 11.92; found C 78.69, H 12.07.

Rearrangement 10 → 11: A solution of **10** (0.11 g, 0.36 mmol) in C_6D_6 (0.5 mL) was irradiated for 8 h in a sealed quartz NMR tube. After this time, the ^{1}H- and ^{13}C-NMR spectra showed that **10** had been almost quantitatively converted into **11**.

1,1,1′,3,3′-Hexa-*tert*-butyl-1*H*,1′*H*-2,2′-bis(silacyclopropene) (12): A solution of **1** (2.51 g, 5.88 mmol) and **9** (0.69 g, 4.25 mmol) in *n*-hexane (80 mL) was irradiated for 4.5 h at room temperature. The solvent was removed and then 0.47 g (36%) of a mixture of the volatile compounds **10** and **11** was distilled off at 50−60°C/0.03 mbar. The distillation residue was redissolved in the minimum volume of *n*-hexane and this solution was kept at −65°C for 12 h. Recrystallization of the precipitate from *n*-hexane at −20°C yielded 0.70 g (37%) of colorless crystals of **12**; m.p. 124°C. − ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 1.19 (s, 36 H), 1.30 (s, 18 H). − ^{13}C NMR (C_6D_6, 125.7 MHz, 298 K): δ = 22.08 (C_q, Si*t*Bu$_2$), 30.50 (C_p, Si*t*Bu$_2$), 31.13 (C_p, CCH_3), 35.06 (C_q, *C*CH_3), 143.46 (C_q, *C*=C*t*Bu), 153.05 (C_q, C=*C*t*Bu*). − ^{29}Si NMR: δ = −64.0. − MS (CI, isobutane): *m*/*z* (%) = 446 (100) [M^+].

2,2,3,5,5,6-Hexa-*tert*-butyl-2,5-disilabicyclo[2.2.0]hexa-1(6),3-diene (13): A solution of **12** (0.60 g, 1.3 mmol) in *n*-hexane (80 mL) was irradiated for 6 h at room temperature. The solution was then concentrated to a volume of 10 mL and cooled for 6 d at −25°C. The precipitate was subsequently filtered off and recrystallized from the minimum volume of *n*-hexane to provide 0.31 g (52% yield) of colorless crystals of **13**; m.p. 328−330°C (sealed tube). − ^{1}H NMR (C_6D_6, 500 MHz, 298 K): δ = 1.18 (s, 36 H), 1.19 (s, 18 H). − ^{13}C NMR (C_6D_6, 125.7 MHz, 298 K): δ = 20.90 (C_q), 28.95 (C_p), 31.62 (C_p), 34.09 (C_q), 166.50 (C_q, *C*=C*t*Bu), 170.78 (C_q, C=*C*t*Bu*). − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = 36.7. − MS (CI, isobutane): *m*/*z* (%) = 446 (64) [M^+], 389 (100) [M^+ − *t*Bu]. − $C_{28}H_{54}Si_2$ (446.6): calcd. C 75.25, H 12.18, found C 74.97, H 12.01.

3-*tert*-Butyl-2-(3,3-dimethylbut-1-ynyl)-1,1-bis(2,4,6-trimethylphenyl)-1*H*-silacyclopropene (14): A solution of **3** (0.87 g, 2.1 mmol) and **9** (0.77 g, 4.2 mmol) in *n*-hexane (80 mL) was irradiated for 5 h at room temperature. After this time, TLC monitoring showed the reaction to be complete as **3** had been fully consumed. The dark-yellow solution was concentrated to a volume of 10 mL and kept at −30°C for 12 h. The resulting precipitate was filtered off and recrystallized from toluene to afford 55 mg (8% yield) of colorless **14**; m.p. 100°C. − ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 1.26 (s, 9 H), 1.32 (s, 9 H), 2.06 (s, 6 H, *p*-CH_3), 2.60 (s, 12 H, *o*-CH_3), 6.67 (s, 4 H). − ^{13}C NMR (C_6D_6, 75.5 MHz, 298 K): δ = 21.09 (C_p), 24.02 (C_p), 28.99 (C_q), 30.00 (C_p), 31.17 (C_p), 37.29 (C_q), 73.70 (C_q, *t*Bu−*C*≡C-), 113.68 (C_q, *t*Bu−C≡*C*-), 128.72 (C_t), 132.49 (C_q, *ipso*-C), 136.14 (C_q, *t*Bu−C=*C*), 139.19 (C_q), 143.97 (C_q), 173.26 (C_q, *t*Bu−*C*=C). − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = −106. − MS (CI, isobutane): *m*/*z* (%) = 429 (100) [MH^+].

3-*tert*-Butyl-2-(3,3-dimethylbut-1-ynyl)-1,1-bis(2,4,6-triisopropylphenyl)-1*H*-silacyclopropene (15): A solution of **4** (1.50 g, 2.58 mmol) and **9** (0.42 g, 2.59 mmol) in *n*-hexane (80 mL) was irradiated for 9 h at room temperature. After this time, TLC control showed the reaction to be complete as **4** had been fully consumed. The solution was concentrated to a volume of 20 mL and kept at −60°C for 4 d. Repeated crystallization of the resulting solid from *n*-hexane furnished 0.47 g (32% yield) of colorless crystals of **15**; m.p. 117°C. − ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 1.18 (d, 12 H, ^3J = 6.9 Hz), 1.22 (d, 24 H, ^3J = 6.8 Hz), 1.26 (s, 9H, *t*BuC≡C), 1.38 (s, 9 H, *t*BuC=C), 2.75 (sept, 2 H), 3.89 (sept, 4 H), 7.07 (s, 4 H). − ^{13}C NMR (C_6D_6, 75.5 MHz, 298 K): δ = 24.06 (C_p), 24.63 (C_p), 25.05 (C_p), 28.98 (C_q), 29.87 (C_p), 31.23 (C_p), 34.69 (C_t), 35.51 (C_t), 37.28 (C_q), 73.73 (C_q, *t*Bu−*C*≡C), 114.58 (C_q, *C*≡C*t*Bu), 121.35 (C_t), 132.96 (C_q, *ipso*-C), 138.02 (C_q, *C*=C*t*Bu), 150.78 (C_q), 154.91 (C_q), 174.04 (C_q, C=*C*t*Bu*). − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = −109.6. − MS (CI, isobutane): *m*/*z* (%) = 597 (42) [MH^+], 393 (100) [MH^+ − TipH].

On prolonged cooling at −20°C, yellow crystals (90 mg, 12%) of tetrakis(2,4,6-triisopropylphenyl)disilene were isolated, which were identified by comparison of their ^{1}H- and ^{13}C-NMR spectra with those of an authentic sample.

Di-*tert*-butylbis(3-trimethylsilylethynyl)silane (17): A solution of **2** (1.05 g, 5.3 mmol) and **16** (1.03 g, 5.3 mmol) in *n*-hexane (80 mL) was irradiated for 11 h at room temperature. After this time, NMR monitoring showed the reaction to be complete as **2** had been fully consumed. The solvent was distilled off and the oily residue was transferred to a molecular still. Distillation at 53°C/0.04 mbar afforded a pale-yellow oil, which was recrystallized twice from the minimum volume of *n*-hexane to yield 0.82 g (46%) of colorless **17**; m.p. 35°C. − ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 0.08 (s, 18 H), 1.28 (s, 18 H). − ^{13}C NMR (C_6D_6, 75.5 MHz, 298 K): δ = −0.29 (C_p), 19.36 (C_q), 27.94 (C_p), 108.26 (C_q, *C*≡CSiMe_3), 116.79 (C_q, C≡*C*SiMe_3). − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = −20.94, −18.36. − MS (CI, isobutane): *m*/*z* (%) = 337 (30) [MH^+].

− $C_{18}H_{36}Si_3$ (336.4): calcd. C 64.20, H 10.78; found C 64.05, H 10.91.

2,2,5,5-Tetra-*tert*-butyl-3,6-bis(trimethylsilyl)-2,5-disilabicyclo-[2.2.0]hexa-1(6),3-diene (18): A solution of **17** (0.48 g, 1.43 mmol) and **2** (0.34 g, 1.71 mmol) in *n*-hexane (80 mL) was irradiated for 5 h at room temperature. After this time, the solution was concentrated to a volume of 5 mL and kept at −30°C for 3 d. The resulting precipitate was filtered off and recrystallized from *n*-hexane to afford 0.14 g (32% yield) of pale-yellow crystals of **18**; m.p. 269−272°C. − ^{1}H NMR (C_6D_6, 300 MHz, 298 K): δ = 0.23 (s, 18 H), 1.15 (s, 18 H). − ^{13}C NMR (C_6D_6, 75.5 MHz, 198 K): δ = 0.16 (C_p), 20.89 (C_q), 28.50 (C_p), 162.66 (C_q, *C*=CSiMe$_3$), 196.19 (C_q, C=*C*SiMe$_3$). − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = −12.66, 46.00. − MS (CI, isobutane): *m*/*z* (%) = 478 (100) [M$^+$]. − $C_{26}H_{54}Si_4$ (479.05): calcd. C 65.19, H 11.36; found C 64.99, H 11.48.

Photolysis of 3 in the Presence of 16 − Formation of *cis*- and *trans*-21: A solution of **3** (1.78 g, 4.3 mmol) and **16** (0.84 g, 4.3 mmol) in *n*-hexane (80 mL) was irradiated for 15 h at room temperature. After this time, TLC monitoring showed the reaction to be complete as **3** had been fully consumed. The solution was concentrated in vacuo to a volume of 10 mL and kept at −25°C. After 3 weeks at this temperature, 0.40 g of a solid had precipitated, which was recrystallized from *n*-hexane to provide 0.33 g (17% yield) of colorless crystals of *trans*-**21**; m.p. 265°C. − ^{1}H NMR (C_6D_6, 500 MHz, 298 K): δ = −0.01 (s, 18 H), 0.18 (s, 18 H), 1.92 (s, 6 H), 2.09 (s, 6 H), 2.11 (s, 6 H), 2.37 (s, 6 H), 2.74 (s, 6 H), 3.01 (s, 6 H), 6.18 (s, 2 H), 6.60 (s, 2 H), 6.61 (s, 2 H), 6.83 (s, 2 H). − ^{13}C NMR (C_6D_6, 125.7 MHz, 298 K): δ = −0.41 (C_p), −0.18 (C_p), 20.92 (C_p), 21.23 (C_p), 25.55 (C_p), 25.70 (C_p), 26.07 (C_p), 26.95 (C_p), 106.68 (C_q, *C*≡CSiMe$_3$), 109.62 (C_q, C≡*C*SiMe$_3$), 129.23 (C_t), 129.35 (C_t), 130.48 (C_q, *ipso*-C), 131.13 (C_t), 137.04 (C_q), 137.90 (C_q), 139.52 (C_q), 144.53 (C_q), 144.60 (C_q), 146.87 (C_q), 147.92 (C_q), 152.44 (C_q, *C*=CSiMe$_3$), 175.89 (C_q, C=*C*SiMe$_3$). − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = −22.17, −18.90, −2.24. − MS (CI, isobutane): *m*/*z* (%) = 923 (25) [MH$^+$]. − $C_{56}H_{80}Si_6$ (921.74): calcd. C 72.97, H 8.75; found C 71.82, H 8.93.

The *n*-hexane was then replaced by an *n*-hexane/DME mixture and the resulting solution was cooled for 2 weeks at −30°C. After this time, 0.22 g (11% yield) of colorless crystals of *cis*-**21** were obtained; m.p. 268−270°C. − ^{1}H NMR (C_6D_6, 500 MHz, 298 K): δ = −0.02 (s, 18 H), 0.21 (s, 18 H), 1.92 (s, 3 H), 1.94 (s, 3 H), 2.02 (s, 3 H), 2.09 (s, 3 H), 2.11 (s, 3 H), 2.17 (s, 3 H), 2.51 (s, 6 H), 2.61 (s, 6 H), 2.95 (s, 3 H), 2.97 (s, 3 H), 6.38 (s, 2 H), 6.41 (s, 2 H), 6.59 (s, 1 H), 6.61 (s, 1 H), 6.79 (s, 1 H), 6.81 (s, 1 H). − ^{13}C NMR (C_6D_6, 125.7 MHz, 298 K): δ = −0.42 (C_p), −0.17 (C_p), 20.91 (C_p), 21.24 (C_p), 25.33 (C_p), 25.62 (C_p), 25.70 (C_p), 25.78 (C_p), 27.02 (C_p), 106.22 (C_q, *C*≡CSiMe$_3$), 109.87 (C_q, C≡*C*SiMe$_3$), 127.72 (C_t), 128.47 (C_t), 128.69 (C_t), 128.78 (C_t), 130.87 (C_t), 131.55 (C_t), 131.66 (C_q, *ipso*-C), 136.60 (C_q), 137.54 (C_q), 138.34 (C_q), 138.53 (C_q), 140.34 (C_q), 143.81 (C_q), 144.89 (C_q), 146.53 (C_q), 146.98 (C_q), 147.17 (C_q), 148.25 (C_q), 152.80 (C_q, C=*C*SiMe$_3$), 176.84 (C_q, *C*=CSiMe$_3$). − ^{29}Si NMR (C_6D_6, 59.6 MHz, 298 K): δ = −2.60 (2 Si, C=C−SiMe$_3$), −18.87 (2 Si, C≡C−SiMe$_3$), −21.74 (1 Si), −24.04 (1 Si). − MS (CI, isobutane): *m*/*z* (%) = 922 (16) [MH$^+$], 461 (100) [M$^+$/2]. − $C_{50}H_{80}Si_6$ (921.74): calcd. C 72.97, H 8.75; found C 72.72, H 8.92.

X-ray Structure Analyses of 12, 15, 18, *trans*-21, and *cis*-21: Crystal data and numerical data of the structure determinations are given in Table 1. In each case, the crystal was mounted in an inert oil. Data collection was performed with a Siemens Stoe AED 2 diffractometer (**18**) or a Stoe IPDS area detector (**12**, **15**, *trans*-**21**, *cis*-**21**) using graphite-monochromated Mo-K_α radiation (λ = 71.073 pm). The structures were solved by direct phase determination and refined by full-matrix least-squares against F^2 using the SHELXL-93/97 program systems.[22] Hydrogen atoms were placed in calculated positions, while all other atoms were refined anisotropically.[23]

Keywords: Ruthenium / Triazole / Titanium / Electron Transfer / Sensitizers

The complexes $[Ru(dcb)_2(L)]$ {L = 3-(2-hydroxyphenyl)-5-(pyridin-2-yl)-1,2,4-triazole (2-ppt), 3-(4-hydroxyphenyl)-5-(pyridin-2-yl)-1,2,4-triazole (4-ppt), 3,5-bis(pyrazin-2-yl)-1,2,4-triazole (bpzt), 3-(2-hydroxyphenyl)-5-(pyrazin-2-yl)-1,2,4-triazole (2-ppzt) and dcb = 4,4′-$(CO_2H)_2$-2,2′-bipyridine} have been synthesized, spectroscopically characterized and anchored to nanocrystalline TiO_2 electrodes for the conversion of light into electricity in regenerative solar cells. The different efficiencies observed have been rationalized on the basis of an analytical expression relating the incident photon-to-current conversion efficiency (IPCE) to the kinetic parameters of the relevant electron transfer processes involved in the solar cell.

Introduction

In the search for new solar energy conversion systems, dye-sensitized wide bandgap semiconductors have attracted much attention.[1−14] Solar cells containing photoanodes based on highly porous nanocrystalline TiO_2 films with adsorbed ruthenium dyes have demonstrated photon-to-current conversion efficiencies in the range 7−10% at AM 1.5.[6,12,15,16] The general mechanism of sensitization in a regenerative dye solar cell is shown in Scheme 1.[10,17,18] Excitation of an adsorbed dye molecule (D*) is followed by electron injection (k_2) to the semiconductor conduction band (CB). The oxidized dye molecule is reduced by an electron donor (k_4), which is present in the electrolyte. Reduction of the oxidized dye molecule (D^+) takes place via the sacrificial donor I^-, which is regenerative at the counterelectrode (k_7) (Pt/SnO_2). Losses in efficiency can occur by radiative and nonradiative decay of the excited state (k_1), by recombination of electrons in TiO_2 with oxidized dye molecules (k_3), and by electrons in TiO_2 which react with oxidants in solution (k_6).

Measuring the monochromatic incident photon-to-current efficiency, IPCE, gives the overall efficiency of the processes involved in the photovoltaic cell. IPCE is directly related to the absorption characteristics of the dye, the surface coverage of the TiO_2 electrode (LHE), the quantum yield for charge injection to the semiconductor (ϕ), and the efficiency of collecting electrons in the external circuit (η).[6][12]

Scheme 1

$$IPCE = (LHE)(\Phi)(\eta) \qquad (1)$$

Several studies have focused on the role played by the different electron transfer processes in determining cell performances.[5,19−21] It has been shown that charge injection processes (k_2) take place in the femto- and/or picosecond time domain[8][22] with $\phi = 1$, and that an important factor decreasing the conversion efficiency is the electron transfer from the sensitized TiO_2 film to the relay electrolyte (k_6).[5] Recently, examples of the limiting role of iodide oxidation by oxidized dye (k_4) on the conversion efficiencies have been reported.[21]

The understanding of the key parameters affecting cell performances is of relevance to the design of the molecular sensitizer. A strong absorption in the visible part of the absorption spectrum is clearly beneficial. In addition, the excited-state properties and the redox potentials of the molecular dyes have to be tuned with respect to the level of the conduction band in the TiO_2 and to the redox potential of the sacrificial donor I^-, to increase the driving force of the corresponding electron transfer processes. The complexes which so far have shown the most promising characteristics, are based on ruthenium polypyridyl moieties incorporating

negative monodentate ligands such as NCS^-.[6,10,16,23] The presence of monodentate ancillary ligands can, however, lead to some photochemical instability of the dye molecule which, in principle, can be reduced by using chelating ligands. We have therefore started a systematic investigation of potential dyes based upon triazole-type ligands.

Mixed-ligand Ru^{II} complexes with electron rich 1,2,4-triazole-and 2,2′-bipyridine (bpy) containing ligands have been investigated in detail. Upon coordination the triazole ring is deprotonated, leaving a negative charge on the triazole ligand. It is well established that for complexes incorporating deprotonated triazole ligands the excited state is localized on the bpy moieties.[24−33]

In this study, the synthesis and characterization of complexes of the type $[Ru(dcb)_2(L)]$ {L = 3-(2-hydroxyphenyl)-5-(pyridin-2-yl)-1,2,4-triazole (2-ppt), 3-(4-hydroxyphenyl)-5-(pyridin-2-yl)-1,2,4-triazole (4-ppt), 3,5-bis(pyrazin-2-yl)-1,2,4-triazole (bpzt), 3-(2-hydroxyphenyl)-5-(pyrazin-2-yl)-1,2,4-triazole (2-ppzt); dcb = 4,4′-$(CO_2H)_2$-2,2′-bipyridine} is reported. The general structure of the complexes and ligands are depicted in Figure 1. The excited-state properties of the complexes in solution and when immobilized on TiO_2 have also been investigated by means of laser flash photolysis. The efficiency of the complexes as dyes in regenerative photoelectrochemical cells has been assessed and rationalized on the basis of an analytical expression correlating the IPCE to the relevant kinetic parameters schematized in Scheme 1.

Results

Electronic Absorption Spectra in Solution

Figure 2 shows the UV-Vis spectra of the complexes $[Ru(dcb)_2(L)]$ (L = 4-ppt, 2-ppt, bpzt or 2-ppzt) in aqueous solution at pH 7 (see also Table 1). At this pH both the triazole and dcb ligands are deprotonated (see discussion). The UV-Vis spectra for the complexes with 4-ppt or 2-ppt are nearly identical. The spectra obtained for the complexes containing the pyrazine-based ligands bptz and 2-ppzt are also very similar. The 4-ppt and 2-ppt complexes are characterized by absorption bands at 487, 437 and 367 nm, while the complexes containing bptz and 2-ppzt show a significant blue shift of the lowest energy absorption, with bands at about 461 and 433 nm. Lowering the pH to ca. 3 gives a characteristic blue shift for the 4-ppt and 2-ppt complexes, resulting in only two absorption bands each at 465, 433 and 473, 435 nm, respectively. The complexes with bpzt and 2-ppzt only showed band broadening. These changes are due to protonation of the triazole ring, and similar shifts have been observed for the corresponding mixed-ligand complexes containing bpy.[24−33] Decreasing the pH further resulted in precipitation of the compounds because of protonation of the carboxy ligands. The emission spectra were recorded in aqueous solution at pH 7, and the maxima are summarized in Table 1.

Electrochemistry in Solution

The electrochemical properties of the complexes were measured in DMF/0.1 M $LiClO_4$. The redox potentials obtained are listed in Table 1. For the complexes $[Ru(dcb)_2(L)]$ (L = 4-ppt, 2-ppt or 2-ppzt) the voltamograms are complicated by the irreversible oxidation of the phenol ligand at about 1.3 V vs SCE. By comparison with data observed for the corresponding bpy complexes, the quasi reversible process at about 1 V vs Ag/AgCl can be assigned to the Ru^{II}/Ru^{III} redox couple. The dcb-based reduction processes are irreversible. As observed before for other triazole-based ruthenium polypyridyl complexes, partial protonation of the triazole ring is observed when the potential is first cycled through the bpy-based reductions. In that case an additional redox wave at about 1.3 V is observed.[34]

Photophysics in Solution

Flash photolysis experiments were carried out in degassed aqueous solution at pH 7, employing a 532 nm excitation pulse (6.5 mJ). The transient-absorption difference spectra of the complexes are shown in Figure 3. The spectra are characterized by a bleaching process in the 400–500 nm region and the formation of a new transition in the 350–400 nm region. The excited-state lifetime obtained from the transient spectra were identical to the lifetimes obtained from independent time-resolved emission measurements. The decay of the emission intensity was, in all cases, single exponential. The lifetimes of the various complexes are summarized in Table 1.

Absorption spectra on TiO_2

The complexes $[Ru(dcb)_2(L)]$ were absorbed as a monolayer onto a ca. 7 μm thick nanocrystalline TiO_2 film. The UV-Vis spectra of two complexes (L = 2-ppt or bptz) on a TiO_2 film are shown in Figure 4. The absorption spectrum of $[Ru(dcb)_2(2\text{-ppt})]/TiO_2$ is mainly a superposition of the complex and the TiO_2. The absorption spectrum of the corresponding bpzt complex closely resembles the absorption spectrum in solution, but with different intensities of the absorption maxima. At 491 nm (2-ppt) and 475 nm (bptz) the absorbances were 1.60 and 1.84, respectively. Using the extinction coefficients at this wavelength, 1.0×10^4 $M^{-1}\cdot cm^{-1}$ (2-ppt) and 1.4×10^4 $M^{-1}\cdot cm^{-1}$ (bpzt),[25][35] and considering for the surface requirement of one adsorbed molecule the value of 100 Å^2, for a complete monolayer coverage, an average roughness factor of ca. 800 can be calculated.

Photoelectrochemistry

The dye-molecules were tested in a standard photovoltaic cell (see experimental). Figure 5 shows a plot of the incident-photon-to-current efficiency (uncorrected for light absorption by the conductive glass) *vs.* the excitation wavelength, IPCE(λ), for the complexes. The IPCE(λ) is defined by Equation (2).[6][10]

Figure 5 demonstrates that the IPCE(λ) closely resembles the absorption spectra of the dye molecules attached to the TiO_2.

$$IPCE(\lambda) = \frac{1.24\ (eV\cdot nm)\ x\ photocurrentdensity\ (\mu A\cdot cm^{-2})}{wavelength\ (nm)\ x\ photonflux\ (\mu W\cdot cm^{-2})} \qquad (2)$$

Photophysics on TiO_2

The transient-absorption difference spectra of the complexes $[Ru(dcb)_2(L)]$ anchored to TiO_2 are shown in Figure 6. The striking difference with the spectra recorded in solution (Figure 3) is the lack of the absorption band in the 350–400 nm region. The time-resolved absorbance changes of the complexes measured at 480 nm are depicted in Figure 7 [traces marked with **(1)**].

The traces were obtained by excitation with P = 0.3 $mJ\cdot cm^{-2}$. The back electron transfer between the electrons in the TiO_2 particle and the Ru^{III} centers typically takes place in the nano- and microsecond time domain and is power dependent. At low excitation power, the back electron transfer is slower than at excitation with higher powers

(spectra not shown). A detailed study[36] and description of the complexes kinetics is beyond the scope of this paper.

In order to get a better insight into the processes determining the efficiency of the photovoltaic cell, experiments in the presence of I^- were employed. The quenching of oxidized dye molecules by 0.3 M I^-, giving rise to the parent complex, the iodine radical[19] and TiO_2-nanoparticle with an electron excess, are depicted in Figure 7 [traces marked with (2)]. The concentration of I^- was the same as in a typical photovoltaic cell (0.3 M LiI) and the Li^+ concentration was kept constant with respect to the recombination experiments (0.3 M $LiClO_4$). The transient-absorption difference spectra in the presence of I^- show a broad band (360−450 nm), most probably due to radical products of I^- (spectrum not shown).[19] The quenching of $[Ru^{III}(dcb)_2(NCS)_2]$ by I^- was observed to take place in the laser pulse (< 10 ns), while, under the same experimental conditions, the quenching of all $[Ru^{III}(dcb)_2(L)]$ dye molecules was slower and completed within ca. 100 ns.

Discussion

In metal complexes with the triazole ligands reported here, the coordination mode of the triazole ring has to be considered. As Figure 1 shows, coordination of the triazole ring can occur through the N1 or the N4 atom. HPLC analysis of the reaction products shows that only one major product is obtained. It has been shown in the past that proton NMR spectroscopy can be used to determine the coordination mode of these ligands.[31−33,35,37,38] The spectra obtained for the compounds strongly indicate that for all compounds coordination of the triazole ring is through the N1 atom. N1 coordination is also to be expected from steric considerations. It is also important to note that the spectra

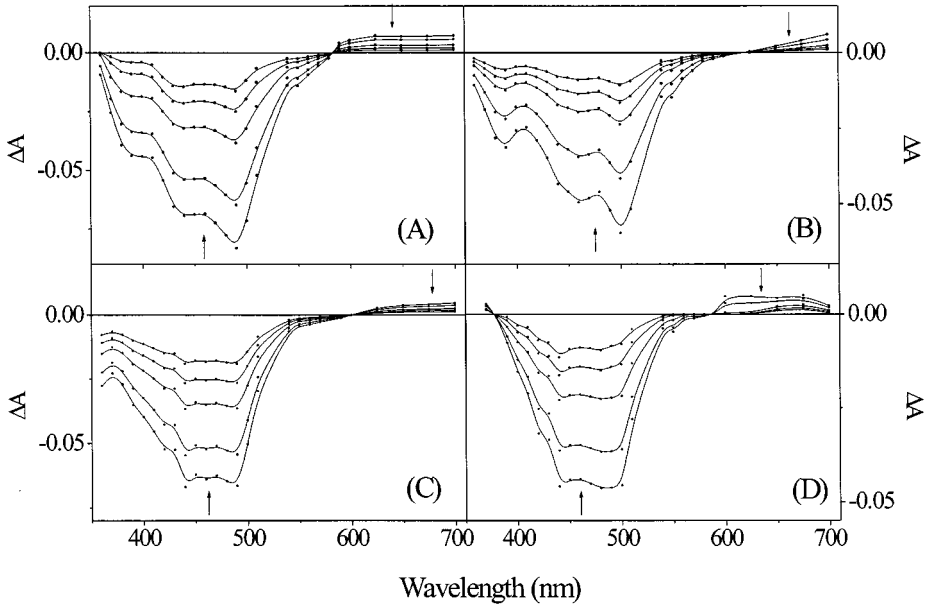

Figure 6. Time-resolved transient-absorption spectra of the TiO_2 films in MeCN/0.1 M $LiClO_4$ (room temp.), covered with (A) [Ru(dcb)$_2$(4-ppt)], (B) [Ru(dcb)$_2$(2-ppt)], (C) [Ru(dcb)$_2$(bpzt)] and (D) [Ru(dcb)$_2$(2-ppzt)] at τ_d = 0, 50, 250, 1000 and 2000 ns, respectively (λ_{exc} = 532 nm, P = 0.5 mJ·cm^{-2})

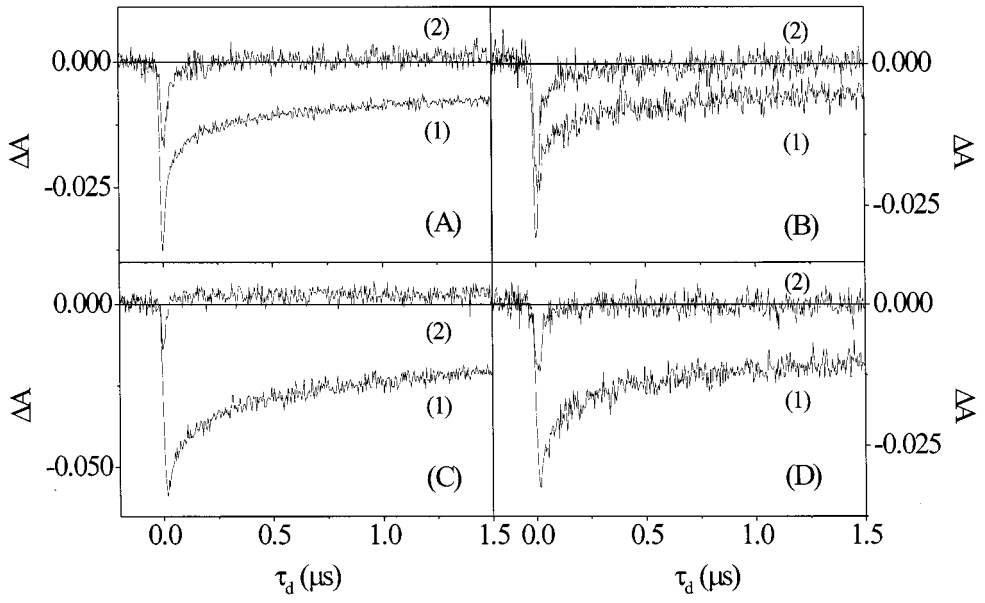

Figure 7. The microsecond decay kinetics measured at 480 nm of (A) [Ru(dcb)$_2$(4-ppt)], (B) [Ru(dcb)$_2$(2-ppt)], (C) [Ru(Hdcb)$_2$(bpzt)] and (D) [Ru(dcb)$_2$ (2-ppzt)] measured in the presence of (1) MeCN/0.3 M $LiClO_4$ and (2) MeCN/0.3 M LiI, respectively (λ_{exc} = 532 nm, P = 0.3 mJ·cm^{-2})

are recorded in DMSO/NaOD and, therefore, under these conditions, the complexes are completely deprotonated. The overall charge of the complexes is then 3−.

Intrinsically, the complexes reported here have very complicated acid-base properties. First of all the deprotonation steps of the dcb ligand have to be considered. The ligand shows two protonation steps for the complexes [Ru(bpy)$_{3-n}$(dcb)$_n$] (n = 1,2,3) with pK_{a2} values around 1.7−1.75 and pK_{a1} values between 2.2−2.85.[39−42] For the excited states a pK_a*$_2$ value of 1.75 was estimated, while the pK_a*$_1$ value was found to increase from the corresponding ground-state value to between 4.6−4.25.[39−42] Secondly, the triazole ligands have their own acid-base properties. The ground-state pK_a values for the closely related triazole complexes are between 2.0 and 5.5.[25,31−33,35,37,38] The pyridyltriazole-containing complexes are slightly more acidic in the excited state than in the ground state.[31][32] This is in agreement with resonance Raman, time-resolved resonance Raman, and excited-state absorption studies, which all support an excited state localized on the bpy ligands and triazole ligands that do not actively participate in the lowest excited state of the compounds.[24,26,27] For pyrazinetriazoles the

situation is even more complicated. The acid-base chemistry of these compounds together with resonance Raman data strongly suggest that when the triazole moiety is deprotonated (with a pK_a of about 2.0) the excited state is based on the bpy ligand, while in complexes where protonation of the triazole ring has occurred the lowest energy excited state is based upon the pyrazine ring.[24][34] Furthermore, the complexes with 4-ppt, 2-ppt or 2-ppzt have a phenol group with a pK_a of about 11.[25] These intricate acid-base properties make it impossible to isolate solid materials with a well-defined state of protonation. However, in solution under pH control, well-defined species are obtained as is shown in the NMR and UV-Vis spectra. For this reason we have used the $[Ru(dcb)_2(L)]$ formula to describe the solid complexes. All the photophysical measurements have been carried out under conditions where the triazole moiety is deprotonated. This ensures that the lowest energy excited state is based on the dcb ligands. This is also the case for the pyrazine based systems.

Analogous to the corresponding bpy complexes, the lowest absorption bands at ca. 470 nm, can be assigned to MLCT transitions between the metal and the dcb ligands. The complexes with the pyridine-based ligands 4-ppt and 2-ppt show MLCT bands at lower energy than those observed for the pyrazine-containing complexes. Since the lowest MLCT transitions originate from the $d_{Ru} \rightarrow \pi^*_{dcb}$ orbitals,[24] the observed red-shift for the pyridine-based complexes can be explained by the stronger σ-donor effect of the pyridine ring, resulting in an increase in energy of the d-orbitals of the metal center.[35] The UV-Vis spectra of the $Ru(dcb)_2$ pyridyltriazoles measured in aqueous solution at pH 7, where both the triazole and the polypyridyl ligands are deprotonated, show the same spectral properties as those of the corresponding $[Ru(bpy)_2(2\text{-ppt})]$ complex.[30] The spectral features of the $Ru(dcb)_2$ pyrazinetriazole compounds are similar to the spectra of $[Ru(bpy)_2(bpzt)]^+$.[33][35] All the absorption spectra show a typical red-shift of ca. 15−20 nm on going from bpy to dcb.[39][41] Under these circumstances, at pH 7, the emission maxima of the complexes are found at ca. 680 nm, which is a red-shift of 20 nm with respect to the values observed for the bpy derivatives, further supporting the proposition that the excited state is localized exclusively on the dcb ligand. The spectral changes observed on changing the pH to 3 correspond to the protonation of the triazole and dcb ligands.[30−33,35,37−42] An extensive study of the protonation behavior of the compound was not possible because further decreasing of the pH results in precipitation of the complexes.

The transient-absorption difference spectra of the $[Ru(dcb)_2(L)]$ complexes in aqueous solution (pH 7) show a bleach in the region 400−500 nm. This can be attributed to the disappearance of the MLCT transitions in the excited state. The strong absorption in the region 350−400 nm can be assigned to intraligand transitions of the dcb radical-anion. This behavior is typical for those Ru-complexes with a bpy/dcb ligand-localized excited state.[43−45] A comparable spectrum was found for $[Ru(bpy)_2(bpzt)]^+$.[24] The lifetimes of the excited states of the various complexes are in the range of 30−60 ns (see Table 1), which is shorter than the lifetimes observed for the corresponding bpy complexes, i.e. $[Ru(bpy)_2(bpzt)]^+$ (290 ns) and $[Ru(dcb)_2(bpzt)]$ (45 ns).[24] A red-shift of the absorption and emission maxima leads, in general, according to the energy gap law, to a decrease in lifetime.[46−48]

The complexes were absorbed on TiO_2 for photoelectrochemical measurements. Figure 4 shows that the optical properties of the dye molecules bound to TiO_2 and in solution (at pH 7) are comparable. The spectra also show that the triazole ligands are in the deprotonated form. The photoaction spectra (Figure 5 and Table 2) indicate that the complexes act as efficient sensitizers with $IPCE_{470nm}$ in the range 0.55−0.65 (0.68−0.80; values corrected for light absorption by the ITO glass). The fact that under similar experimental conditions the $[Ru(dcb)_2(NCS)_2]$ complex was shown to give better performances [$IPCE_{500nm} = 0.77$ (0.95; value corrected for light absorption by the ITO glass)] was unexpected, since the ground- and excited-state redox properties of these species are very similar. As shown in Equation 1, IPCE depends on the three terms Φ **(i)**, LHE **(ii)**, and η **(iii)**, [6][12] which will be discussed separately:

(i) The absence of $^3[Ru(dcb)_2(L)]^*$ in the transient-absorption spectra of the dye on TiO_2, clearly shows that electron injection to the semiconductor is efficient (>95%) and takes place within the laser pulse (< 10 ns) or faster, which is in agreement with earlier reported data.[8][22]

(ii) Under the experimental conditions used, the LHE term for $[Ru(dcb)_2(NCS)_2]$ and the $[Ru(dcb)_2(L)]$ (L = 2-ppt, bpzt or 2-ppzt) complexes are the same, since for the examined photoanodes the incident light absorption was in the range 0.96−0.99 (see Table 2). Due to the low solubility of $[Ru(dcb)_2(4\text{-ppt})]$, the surface coverage on TiO_2 of the latter complex was lower than the other compounds, resulting in LHE = 0.90.

(iii) Significant differences are found for the quenching rate of Ru^{III} by I^- (k_4). For $[Ru(dcb)_2(NCS)_2]$ this process takes place in the laser pulse (less than 10 ns), while the quenching of $[Ru^{III}(dcb)_2(L)]$ is completed within less than 100 ns. The quenching of $[Ru^{III}(dcb)_2(bpzt)]$ by I^- [Figure 7 (C) trace (2)] is completed in 30 ns, resulting in the highest IPCE value. The reaction of the $[Ru^{III}(dcb)_2(L)]$ (L = 4-ppt, 2-ppt or 2-ppzt) with I^- is slower (100 ns), resulting in lower IPCE values. Furthermore, one should realize that any formation of Ru^{III} in the presence of I^- directly leads to losses in efficiency. Apparently, the quenching rate of Ru^{III} by I^- is an important parameter in the efficiency of the photovoltaic cell. Differences in IPCE values, therefore, most likely reflect a variation in η values, which reflects the processes k_3, k_4 and k_5. The traces obtained from the quenching experiments [Figure 7 (C) trace (2)] do not give the rate constant (k_4) for the quenching of the Ru^{III} by I^-.

$$S^+ + e^- \xrightarrow{k_3} S$$
$$S^+ + I^- \xrightarrow{k_4} S + I^{\bullet} \qquad (3)$$

$$[S^+] = [S^+]_0 e^{-(k_3+k_4)t} \qquad (4)$$

From Equations 3 and 4 it can easily be seen that the observed rate constant is the sum of the quenching rate constant (k_4) and the back electron transfer (k_3).

Analogous to the quantum yield of injection (Φ), the efficiency of quenching (defined as) η, of Ru^{III} by I^- is described by Equation 5 or 6. These equations describe the interplay between the quenching of Ru^{III} by I^- (k_4) and the recombination of the electrons in the conduction band with the Ru^{III} center (k_3). The appendix shows the full derivation for all the processes involved in the IPCE under steady-state conditions, resulting in the same terms for η if $k_6[e^-] << k_7[e^-_{ex}]$,[49−53]

$$\eta = \frac{k_4[I^-]}{k_3[e^-] + k_4[I^-]} \quad \text{or} \quad \eta = 1 - \frac{k_3[e^-]}{k_3[e^-] + k_4[I^-]} \qquad (5) \text{ and } (6)$$

$$\eta = \frac{k_4}{k_3 + k_4} \quad \text{or} \quad \eta = 1 - \frac{k_3}{k_3 + k_4} \qquad (7) \text{ and } (8)$$

Application of these formulae is not straightforward, since the experimental k_3 and (k_3 + k_4) are not first or second order. For the estimation of η, the simplified first order formulae (Equation 7 and 8) and the following parameters were used: (i) (k_3 + k_4) is equal to k_{obs} in the Ru^{III}/I^- quenching experiment (see Equations 3 and 4), and was treated as a single exponential; (ii) the traces of the recombination of the electron in TiO_2 with the oxidized dye molecule (k_3) can be fitted with a bi-exponential function (see Table 2), which indicates a fast component ($k \approx 1 \times 10^7$ s^{-1} and a slow component ($k \approx 4 \times 10^5$ s^{-1}). Since the quenching of Ru^{III} by I^- is completed within 100 ns, only the fast exponential component of k_3 is considered. Using these rate constants and Equation 7 or 8 we calculated values for η (Table 2). For the steady-state measurements, η can be calculated (Table 2) from Equation 1, the LHE term and $\phi = 1$. The values for the η term obtained by this transient-absorption study are in good agreement with the values found in the steady-state experiments. As a consequence, the delicate interplay between the quenching of Ru^{III} by I^- (k_4) and the recombination of the electrons in the conduction band with the Ru^{III} center (k_3) apparently determines the efficiency of a regenerative solar cell based on ruthenium dyes.

Experimental Section

Materials and Apparatus and Preparations: [$RuCl_3 \cdot H_2O$] (Oxkem Ltd), 4,4′-dimethyl-2,2′-bipyridine (Aldrich) were used without further purification. The solvents for the spectroscopic measurements, acetonitrile (Aldrich), methanol (Aldrich) were of spectroscopic grade and were used as received. 4,4′-Dicarboxy-2,2′-bipyridine (dcb) was prepared by the method of Oki et al.[54] The ligands 4-ppt,[37] 2-ppt,[30] bpzt[35] and 2-ppzt[38] were prepared as previously described. The complexes [$Ru(dcb)_2Cl_2$] and [$Ru(dcb)_2(NCS)_2$] were prepared according to literature procedures.[55] UV-Vis spectra were recorded with a Kontron Uvikon 860 spectrophotometer. Emission spectra were measured on a SPEX Fluoromax 2 spectrofluorimeter equipped with a Hamamatsu R3896 tube. The emission spectra were corrected for the instrumental response. The NMR spectra were recorded on a Bruker AMX 400. HPLC was carried out on a Waters system equipped with a 990 photodiode array detector with a SAX anionic exchange column (8 × 100 mm) and 50:50 (MeCN/H_2O) 0.05 M phosphate buffer as the mobile phase. The TiO_2 films were prepared as described by Nazeeruddin et al.[6] For the IPCE measurement the TiO_2 was deposited on conductive fluorine-doped SnO_2 glass (LOF ≈ 10Ω/□), while for the transient-absorption measurement normal glass was used. The films were heated at 450°C for 30 min. Coating of the TiO_2 surface with the dye was carried out by soaking the film for 3 h (transient-absorption experiments) and 24 h (IPCE measurements) in a ca. 1×10^{-4} M methanol solution of the complexes. After completion of the dye adsorption, the film was rinsed with acetone and dried (10 min. at 60°C). The measurements were performed directly after the preparation of the film. The complexes [$Ru(dcb)_2(L)$] (L = 4-ppt, 2-ppt, bpzt or 2-ppzt) were stable towards daylight and oxygen in methanol solution as well as when bound to the TiO_2 surface. Photoelectrochemical measurements were performed in a two-electrode sandwich cell arrangement by using SnO_2/TiO_2/dye as the photoanode (active area 0.5 cm^2) and a SnO_2/Pt-coated glass as counterelectrode. The sandwich cell was filled with an acetonitrile solution containing 0.3 M LiI and 0.03 M I_2. The current measurements were performed with a Kontron DDM4021 Digital Multimeter. The excitation source was a 150 W Xe lamp coupled to a 0.22 m monochromator. Incident light flux was measured with a UDT-calibrated Si-diode. In order to minimize errors in the IPCE measurements, the complexes and [$Ru(dcb)_2(NCS)_2$] are measured in at least two different cells, resulting in an estimated error of 5%. Nanosecond flash photolysis transient-absorption spectra were measured by irradiating the sample with 6−8 ns (fwhm) of a Continuum Surelight Nd:Yag laser (10 Hz repetition rate) and using as probe light a pulsed Xe-lamp perpendicular to the laser beam. The excitation wavelength was

[a] Kinetic data from the traces (1) of Figure 7. − [b] Kinetic data from the traces (2) of Figure 7, $k_{obs} = k_3 + k_4$. − [c] Calculated from Equation 8. − [d] LHE = $1-10^{-A}$, where A is the absorbance of the dye on the TiO_2 layer, see also ref.[6][12] − [e] Calculated from Equation 1, with $\phi = 1$.

obtained by frequency doubling (532 nm). The 150 W Xe lamp was equipped with an Applied Photophysics Model 408 power supply and Applied Photophysics Model 410 pulsing unit (giving pulses of 0.5 ms). A shutter, Oriel Model 71445, placed between the lamp and the sample was opened for 100 ms to prevent PMT fatigue. Suitable pre- and post-cutoff and bandpass filters were used to minimize the probe light and scatter light of the laser. The films were oriented at 45° to the laser and probe light and set up in such a way that the scattered light was reflected to the probe light. In this way we were also able to measure in the early time domain (t < 50 ns) without registering artifacts due to scattered light. The sampling rate was kept at a relatively long time (intervals of 10 s) to prevent electron accumulation in the conduction band of the semiconductor. The light was collected in a LDC Analytical monochromator, detected by a R928 PMT (Hamamatsu), and recorded on LeCroy 9360 (600 MHz) oscilloscope. The laser oscillator, Q-switch, lamp, shutter and trigger were externally controlled with a digital logic circuit, which allowed synchronous timing. The absorption transients were plotted as $\Delta A = \log(I_o/I_t)$ *vs* time, where I_o was the monitoring light intensity prior to the laser pulse and I_t was the observed signal at delay time t. The same setup as described above was employed for the time-resolved emission experiments, with the exception that the probe lamp was not used.

Synthesis of Metal Complexes: The complexes containing the triazole ligands were prepared by the following procedure. The ligand (4×10^{-4} M) was heated under reflux in a basic solution of 2:1 ethanol/water (ca. 20 mL) to which the $[Ru(dcb)_2Cl_2]$ (3.2×10^{-4} M) was added. The mixture was further heated at reflux for 3−4 h and the reaction was monitored by HPLC. The product was precipitated by lowering the pH to 2.7 with HCl (ca. 2 mL, 0.2 M) and purified after resolution in water at pH 7 by column chromatography with Sephadex LH20 resin. Isolation of the product after chromatography was achieved by adjusting the pH with HCl as before. In the molecular formulas given below, the degree of protonation and therefore the charge of the complexes has not been defined. Protonation is strongly dependent on the pH of the solution and the pK_a values of the various ligands. The materials obtained have been characterized by proton NMR and anion exchange HPLC.

[Ru(dcb)$_2$(4-ppt)]: ^{1}H NMR ([D$_6$]DMSO/NaOD, 293 K) δ = 8.80−8.76 (d, 4 H, dcb-H$_6$), 8.15 (d, 1 H, H$_{3'}$), 7.92 (t, 1 H, H$_{4'}$), 7.79 (d, 1 H, H$_{6''}$), 7.67 (d, 1 H, H$_{2''}$), 7.74−7.66 (m, 8 H, dcb-H$_3$ and dcb-H$_5$) 7.41 (d, 1 H, H$_{6'}$), 7.20 (t, 1 H, H$_{5'}$), 6.71 (d, 2 H, H$_{3''}$ and H$_{5''}$). − UV/Vis (aqueous solution pH 7): λ_{max} = 487, 437, 367. − Yield 60%.

Appendix

According to Scheme 1, the following chemical reactions can be summarized:

$$S \xrightarrow{h\nu,\phi} S^+ + e^-$$
$$S^+ + e^- \xrightarrow{k_3} S$$
$$S^+ + I^- \xrightarrow{k_4} S + I^\bullet$$
$$e^- \xrightarrow{k_5} e^-_{ex}$$
$$e^- + I^\bullet \xrightarrow{k_6} I^-$$
$$e^-_{ex} + I^\bullet \xrightarrow{k_7} I^-$$

Under steady-state conditions of for $[S^+]$,$[I^\bullet]$, and$[e^-]$ follows:

$$(A.1) \quad \frac{\partial[S^+]}{\partial t} = \phi I_{abs} - k_3[S^+][e^-] - k_4[S^+][I^-] = 0$$

$$(A.2) \quad [S^+] = \frac{\phi I_{abs}}{k_3[e^-] + k_4[I^-]}$$

$$(A.3) \quad \frac{\partial[I^\bullet]}{\partial t} = k_4[S^+][I^-] - k_6[I^\bullet][e^-] - k_7[I^\bullet][e^-_{ex}] = 0$$

$$(A.4) \quad [I^\bullet] = \frac{k_4[S^+][I^-]}{k_6[e^-] + k_7[e^-_{ex}]}$$

$$(A.5) \quad \frac{\partial[e^-]}{\partial t} = \phi I_{abs} - k_3[S^+][e^-] - k_5[e^-] - k_6[I^\bullet][e^-] = 0$$

Substitution of (A.2) and (A.4) in (A.5), with $J_{ex} = k_5[e^-]$, results in:

$$(A.6) \quad J_{ex} = \phi I_{abs}\left(\frac{k_4[I^-]}{k_3[e^-] + k_4[I^-]} \cdot \frac{k_7[e^-_{ex}]}{k_6[e^-] + k_7[e^-_{ex}]}\right)$$

Since $I_{abs} = I_o(LHE)$, (A.6) becomes:

$$(A.7) \quad IPCE = \frac{J_{ex}}{I_0} = (LHE)(\phi)(\eta) \text{ with } \eta = \left(\frac{k_4[I^-]}{k_3[e^-] + k_4[I^-]} \cdot \frac{k_7[e^-_{ex}]}{k_6[e^-] + k_7[e^-_{ex}]}\right)$$

If $k_6[e^-] << k_7[e^-_{ex}]$ then η can be written as:

$$(A.8) \quad \eta = \frac{k_4[I^-]}{k_3[e^-] + k_4[I^-]} \quad \text{or} \quad \eta = 1 - \frac{k_3[e^-]}{k_3[e^-] + k_4[I^-]}$$

Oxidation of Dichloroanilines and Related Anilides Catalyzed by Iron(III) Tetrasulfonatophthalocyanine

Anke Hadasch[a] and Bernard Meunier*[a]

Keywords: Dichloroanilines / Propanil / Iron(III) tetrasulfonatophthalocyanine / Oxidations / Catalysts

We investigated the degradation of polychlorinated pollutants, such as dichloroanilines and related anilides, catalyzed by iron(III) tetrasulfonatophthalocyanine (FePcS) with potassium monopersulfate or hydrogen peroxide as oxidant. The reaction is influenced by the positions of the two chloro-substituents and by the nature of the oxidant. The FePcS-catalyzed oxidation of 3,5-dichloroaniline with potassium monopersulfate leads to the formation of more biodegradable products (carboxylic acids) and to potentially toxic dimers (azo and azoxy compounds). The oxidation of 3,4-dichloroaniline by FePcS/H_2O_2 converts this pollutant into coupling products. The formation of dimers in the catalytic oxidation of dichloroanilines can be avoided by acylation of the amine function.

Introduction

Dichloroanilines (DCAs) are used as precursors on a large scale in the industrial synthesis of pesticides, plastics and dyes.[1] The contamination of aquatic environments by DCAs can occur directly through their accidental release during industrial processing or indirectly by microbial degradation of DCA-derived pesticides in soil. The herbicide Propanil (3,4-dichloropropionanilide, 3,4-DCPA) is used extensively around the world for control of weeds in rice cultures.[2] Although Propanil itself has a low toxicity, its conversion into 3,4-DCA by microorganisms in soil is a problem, since the acute exposure to this DCA isomer results in renal and hepatic toxicity in vivo.[3] In order to solve this problem several investigations have been carried out to find efficient systems for DCA degradation by reductive or oxidative dehalogenation. Using the latter method, Pieper et al. reported the degradation of 3,4-DCA by lignin peroxidase from *Phanerochaete chrysosporium*.[4] Whereas 60% of the pollutant was degraded to a quinoneimine, 10−15% of 3,4-DCA was transformed into the more toxic tetrachloroazobenzene.

We recently developed a new catalytic system for the oxidative degradation of recalcitrant pollutants, such as polychlorinated phenols[5] and polycyclic aromatic hydrocarbons,[6] using iron(III) tetrasulfonatophthalocyanine (FePcS) as a catalyst. We found that the FePcS-catalyzed oxidation of 2,4,6-trichlorophenol (TCP) with hydrogen peroxide leads to the formation of chloromaleic acid as the main product and also to carbon dioxide.[5a−5d] Because of its high catalytic activity in the degradation of TCP, we decided to investigate the FePcS-catalyzed oxidation of other poorly biodegradable compounds such as dichloroanilines.

In order to investigate the chemical degradation of dichloroanilines (DCA) we studied the catalytic oxidation of the following two isomers: 3,4-dichloroaniline (3,4-DCA) and 3,5-dichloroaniline (3,5-DCA). 3,4-DCA is formed during the biodegradation of the herbicide Propanil (3,4-dichloropropionanilide).[2] From 1970 to 1987, on average, 3−7 kg of Propanil/ha were applied each year to about 70 to 100% of rice culture in the United States.[7] 3,5-DCA, which is the most toxic DCA isomer, is a relevant precursor in the industrial synthesis of azo dyes.

Results

We first investigated the oxidative degradation of the two different dichloroanilines 3,5-DCA and 3,4-DCA using FePcS as the catalyst and potassium monopersulfate or hydrogen peroxide as the oxidant. The final concentrations of DCA and oxidant (H_2O_2 or $KHSO_5$) in the reaction mixture were 1 mM and 5 mM, respectively. The solution contained 0.03 mM of FePcS, which corresponds to a molar ratio of catalyst to substrate of 3%. The reactions were carried out at room temperature at pH 7 in an aqueous mixture of acetone/phosphate buffer (v/v = 1:9) with a final volume of 4 mL. The results are reported in Table 1.

Table 1. Oxidation of 3,4-DCA and 3,5-DCA

Run	Substrate	Oxidant	Conversion [%] after 10 min	30 min	Cl^-/DCA[a]
1	3,4-DCA	$KHSO_5$[b]	100	100	0.4
2	3,4-DCA	H_2O_2[b]	41	100	0.5
3	3,4-DCA	$KHSO_5$[c]	90	100	0
4	3,4-DCA	H_2O_2[c]	0	0	−
5	3,5-DCA	$KHSO_5$[b]	100	100	0.6
6	3,5-DCA	H_2O_2[b]	38	78	0.4
7	3,5-DCA	$KHSO_5$[c]	80	100	0.1
8	3,5-DCA	H_2O_2[c]	0	0	−

[a] Number of released chloride ions per converted DCA molecule (determined after 60 min). − [b] Reactions carried out with FePcS, molar ratio FePcS/DCA = 3%. − [c] Reactions carried out without FePcS.

Under these conditions 3,4-DCA and 3,5-DCA were completely converted by the FePcS/$KHSO_5$ system within 10 min (runs 1 and 5). When hydrogen peroxide was used instead of potassium monopersulfate, the reaction rates decreased and the conversions of 3,4-DCA and 3,5-DCA were 41% and 38% after 10 min and increased to 100% and 78% within 30 min, respectively (runs 2 and 6). The average dechlorination values of these reactions corresponded to 0.5 released chloride ions per converted substrate molecule. In other words, one covalent chlorine atom of 50% of DCA molecules was transformed into a chloride ion.

In control reactions we tested the behavior of these DCA molecules without FePcS catalyst. Surprisingly, we observed fast reactions of DCAs with $KHSO_5$ and the pollutants were completely converted within 30 min (runs 3 and 7). Despite full substrate conversions, the dechlorination values were negligible, suggesting the formation of oxidation products different to those obtained in the catalyzed reaction with FePcS/$KHSO_5$. A similar oxidation reaction was also observed on replacing acetone by ethanol, suggesting that a dioxirane was not entirely responsible for this noncatalyzed oxidation of DCAs (see ref.[8] for a review article on the formation of dioxiranes from ketones and monopersulfate). The absence of chloride release suggested that the amine function was the only oxidation site in these noncatalyzed oxidations with monopersulfate. The control reactions with hydrogen peroxide gave no substrate conversions without catalyst (runs 4 and 8).

These results indicate that the catalytic activity of FePcS is higher with potassium monopersulfate than with hydrogen peroxide. Nevertheless, full substrate conversion of 3,4-DCA could also be reached using the clean oxidant H_2O_2 (water being the only by-product after reaction). The dechlorination values in these catalyzed oxidations of DCA derivatives with $KHSO_5$ or H_2O_2 were similar and suggested the same level of pollutant degradation regardless of the nature of the oxidant.

In order to identify the reaction products we extracted the aqueous mixture after the oxidation of 3,5-DCA by FePcS/$KHSO_5$ and analyzed the organic phase by ^{1}H NMR spectroscopy and GC-MS. Three groups of oxidation products could be distinguished: (i) ring cleavage products, (ii) products resulting from oxidation of the amine function and (iii) oxidative coupling products (Figure 1). The formation of ring cleavage products probably occurred via the intermediates 2,6-dichloro-1,4-quinoneimine (**1**) and 2,6-dichloro-1,4-benzoquinone (**2**). Their respective reduced forms, 2,6-dichloro-4-aminophenol and 2,6-dichloro-1,4-hydroquinone, were identified by GC-MS. The ring cleavage of intermediates **1** and **2** can lead to the formation of chloromaleic acid (**3**) and formic acid (**4**) as occurs in the degradation of 2,4,6-trichlorophenol by FePcS/H_2O_2.[5] Carboxylic acids **3** and **4** were identified by ^{1}H NMR spectroscopy after extraction of the reaction mixture in the manner previously described for the TCP oxidation products.[5c] 3,5-Dichloronitrosobenzene (**5**) and 3,5-dichloronitrobenzene (**6**) resulted from the oxidation of the amine function. Both compounds are minor products of the catalytic oxidation reaction, since only traces of these compounds were detected by GC-MS and HPLC. Most of the 3,5-DCA was transformed into coupling products such as 3,5,3′,5′-tetrachloroazobenzene (**7**) and 3,5,3′,5′-tetrachloroazoxybenzene (**8**). A third dimer was also detected by GC-MS. The MS data for this compound ([M^+] = 316, isotopic peaks indicating four chlorine atoms) are in agreement with 1,3,6,8-tetrachlorophenazine (**9**).

In order to compare the distribution and the structure of the degradation products obtained with FePcS/$KHSO_5$ and the oxidation compounds of the noncatalyzed reaction, the oxidation of 3,5-DCA was carried out with $KHSO_5$ only. In this case, 38% of 3,5-DCA was transformed into 3,5-dichloronitrobenzene (**6**), which is the major reaction product quantified by HPLC. In accordance with the negligible dechlorination value (0.1 Cl^-/3,5-DCA), the other products

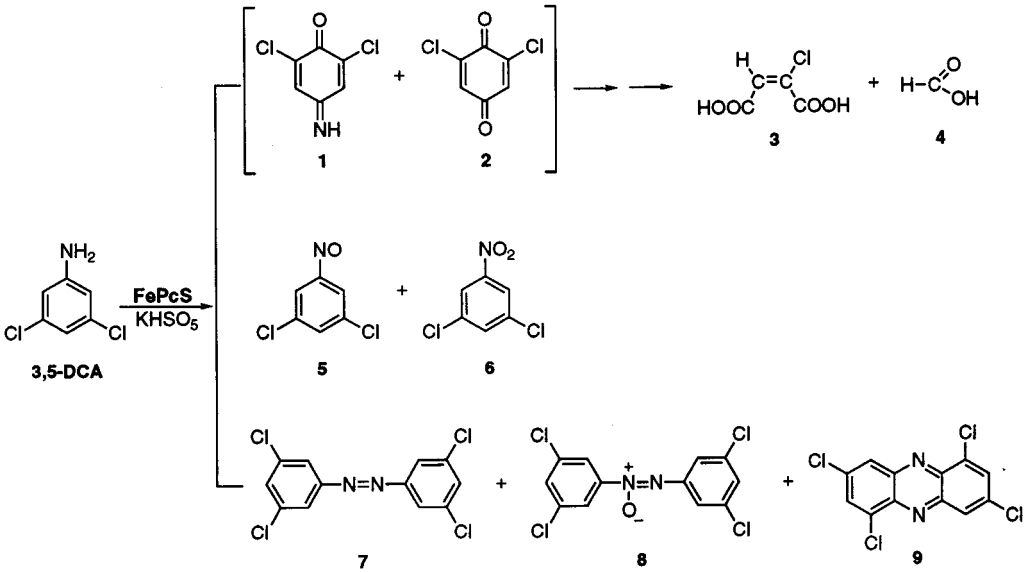

Figure 1. Products formed in the oxidation of 3,5-DCA by FePcS/$KHSO_5$

identified by GC-MS were 3,5-dichloronitrosobenzene (**5**) and small amounts of dimers **7** and **8**. It should be noted that no ring cleavage products could be identified by GC-MS in this noncatalyzed oxidation of 3,5-DCA.

We subsequently characterized the reaction products of the FePcS-catalyzed oxidation of 3,4-DCA with hydrogen peroxide as the oxidant (Figure 2). After a reaction time of 1 h, 69% of the pollutant was transformed into more hydrophobic products, which precipitated from the aqueous mixture. The separation of the precipitated components by column chromatography allowed the isolation and quantification of products **10**−**13**. As shown in Figure 2, this dichloroaniline was mainly transformed into tetrachloroazobenzene **10** (22%), whereas the tetrachloroazoxybenzene **11** (7%) and the two tetrachlorophenazine isomers **12** and **13** (3%) were isolated in lower yields. We also analyzed the aqueous phase after filtration, but no ring cleavage products could be identified.

The oxidation of chlorinated aromatic amines leads to the formation of chlorinated azo and azoxy compounds, which are cytotoxic and teratogenic molecules.[1] In order to avoid the formation of these dimers during the oxidation of DCA we decided to protect the amine function with an acetyl or a propionyl group and we synthesized the 3,4-dichloropropionanilide 3,4-DCPA (Propanil) and the 3,5-dichloroacetanilide 3,5-DCAA. To compare the reaction behavior of these anilides with that of the corresponding anilines, we checked the degradation of 3,4-DCPA and 3,5-DCAA with hydrogen peroxide or potassium monopersulfate using FePcS as a catalyst. The reaction conditions were identical to those of DCA oxidations and the results are shown in Table 2.

The FePcS-catalyzed oxidations of 3,4-DCPA and 3,5-DCAA with potassium monopersulfate led to conversions of 34% and 22% within 30 min, respectively (runs 1 and 5). The catalytic system using hydrogen peroxide as the oxidant was able to convert 34% of 3,4-DCPA, while only a small amount of 3,5-DCAA was oxidized (runs 2 and 6). We also checked the reaction behavior of the anilides in the absence of a catalyst: the control reactions with $KHSO_5$ led to negligible conversions (runs 3 and 7) and no reaction occurred with H_2O_2 (runs 4 and 8).

Table 2. Oxidation of 3,4-DCPA and 3,5-DCAA

Run	Substrate	Oxidant	Conversion [%] after 10 min	30 min	Cl^-/DCA[a]
1	3,4-DCPA	$KHSO_5$[b]	31	34	0.3
2	3,4-DCPA	H_2O_2[b]	15	34	1.0
3	3,4-DCPA	$KHSO_5$[c]	1	2	0
4	3,4-DCPA	H_2O_2[c]	0	0	0
5	3,5-DCAA	$KHSO_5$[b]	22	22	0
6	3,5-DCAA	H_2O_2[b]	1	3	0
7	3,5-DCAA	$KHSO_5$[c]	4	8	0
8	3,5-DCAA	H_2O_2[c]	0	0	0

[a] Number of released chloride ions per converted 3,4-DCPA or 3,5-DCAA molecule (determined after 60 min). − [b] Reactions carried out with FePcS, molar ratio FePcS/3,4-DCPA and FePcS/3,5-DCA**A** = 3%. − [c] Reactions carried out without FePcS.

The dechlorination value of the oxidation of 3,4-DCPA by $FePcS/H_2O_2$ corresponded to one released chloride ion per converted substrate molecule and indicated an advanced degradation of the anilide. In order to identify the degradation products, the reaction mixture was extracted after the oxidation of 3,4-DCPA by $FePcS/H_2O_2$ and the organic phase was analyzed by ^1H NMR spectroscopy and GC-MS. Four oxidation products were distinguishable and the proposed structures have to be considered as current working hypotheses (Figure 3).

3,4-DCPA was degraded to 2-chloro-hydroxy-*N*-propionyl-1,4-quinoneimine (**14**), which is the most oxidized product that was identified by GC-MS. The additional oxygen atom is probably introduced into the ring as the mass fragment of the propionyl group was unchanged after the oxidation. The GC-MS data of another product indicated the oxidation of the aromatic ring of 3,4-DCPA. In accordance with a molecular peak $[(M_{3,4\text{-DCPA}} + 16)^+]$ and a mass fragment suggesting an unchanged amide function we propose the formation of 3,4-dichlorohydroxypropionanilide (**15**). We detected a second product having a molecular peak

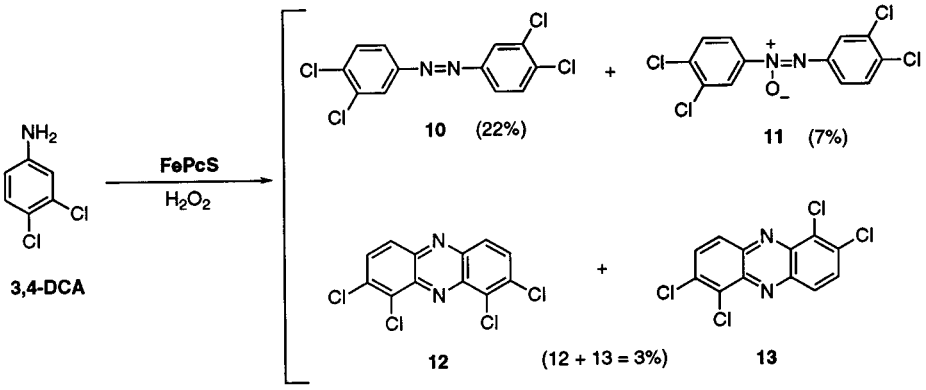

Figure 2. Products formed in the oxidation of 3,4-DCA by $FePcS/H_2O_2$; indicated percentages are isolated yields after a 69% conversion of the substrate

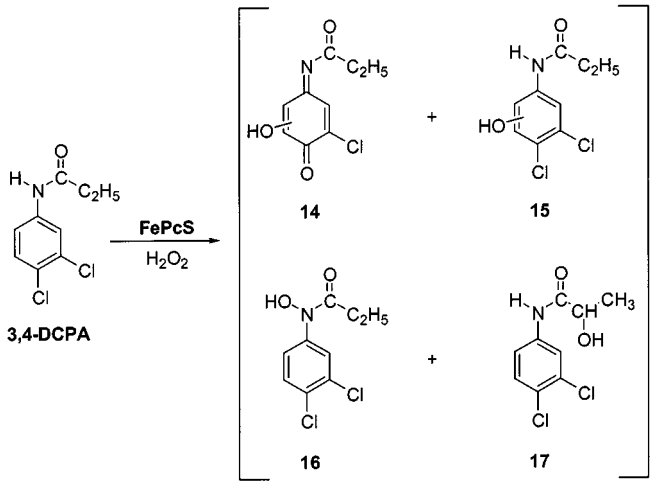

Figure 3. Proposed structures for the products of the oxidation of 3,4-DCPA by FePcS/H_2O_2

$[(M_{3,4\text{-DCPA}} + 16)^+]$. The corresponding mass spectrum indicated that oxidation on the aromatic ring or on the propionyl group had not taken place. These characteristics are in agreement with the proposed formula of 3,4-dichloro-*N*-hydroxypropionanilide (**16**). Furthermore, we detected a product with a mass spectrum suggesting the incorporation of an oxygen atom into the propionyl substituent. The following structural hypotheses have to be considered: (i) formation of an ester by insertion of an oxygen atom, (ii) oxidation of the methylene group or (iii) oxidation of the methyl group. A carbonyl group can be oxidized to the corresponding ester by an oxygen atom donor such as *m*-chloroperbenzoic acid or $KHSO_5$ through a Bayer−Villiger reaction.[9] This kind of reaction is rather unexpected in the presence of hydrogen peroxide even if a nucleophilic Fe^{III}-peroxo species is formed with FePcS.[5c] Therefore, we propose the oxidation of the acyl methylene group, since secondary C−H bonds of a methylene group in the α-position with respect to a carbonyl group should be weaker than tertiary C−H bonds of a methyl group. The proposed product is the 3,4-dichloro-2-hydroxy-propionanilide **17**. Coupling products, such as the azobenzene **10** and the azoxybenzene **11**, were not detected in the degradation of 3,4-DCPA by FePcS/H_2O_2.

Discussion

In the first part of this work we investigated the behavior of two dichloroanilines, 3,4-DCA and 3,5-DCA, in oxidations catalyzed by FePcS. In order to check the influence of the chloro-substituents on the reaction rate we compared the conversions obtained for these two dichloroaniline isomers. The reactions catalyzed by FePcS with potassium monopersulfate as oxidant were too fast to detect differences in the reaction rates by HPLC analyses. However, in the catalytic oxidations with hydrogen peroxide, 3,4-DCA is converted faster than 3,5-DCA, suggesting a lower oxidation potential for the isomer with chloro-substituents in positions 3 and 4.

The oxidation of both DCA derivatives catalyzed by FePcS is faster with potassium monopersulfate than with hydrogen peroxide. Sorokin et al. reported that the oxidation of 2,4,6-trichlorophenol (TCP) catalyzed by FePcS was also remarkably influenced by the oxidant and occurred much faster with $KHSO_5$.[5] This characteristic could be explained by the formation of different active species of the catalyst with potassium monopersulfate or hydrogen peroxide. The authors proposed that the activation of $KHSO_5$ by FePcS leads to the formation of an iron(IV)-oxo species ($Fe^{IV}=O$), which is able to abstract electrons from aromatic substrates such as DCA or TCP, but unable to transfer the oxygen atom of the iron(IV)-oxo species to an olefin, styrene or cyclohexene.[5c] Furthermore, recent data regarding the oxidation of polycyclic aromatic hydrocarbons by FePcS/H_2O_2 indicate that the activation of H_2O_2 by FePcS probably generates two different kinds of active species: an iron(IV)-oxo entity ($Fe^{IV}=O$) and an iron(III)-hydroperoxo species ($Fe^{III}-OOH$).[6] The oxidation potential of the iron(IV)-oxo species is expected to be higher than that of the lower valent iron(III)-hydroperoxo entity. When potassium monopersulfate is used as the oxidant, the concentration of iron(IV)-oxo species is higher than with hydrogen peroxide and, consequently, we obtained faster substrate conversions.

The formation of the oxidation products from 3,5-DCA can be explained in terms of the mechanism depicted in Figure 4. Two successive one-electron oxidations of 3,5-DCA and a deprotonation lead to the formation of the cation **A**, with a positive charge delocalized on the nitrogen atom and on the *ortho* or *para* positions of the ring. The nucleophilic addition of a water molecule to the nitrogen atom and further deprotonation gave the 3,5-dichloro-hydroxylaniline **B** (pathway a). As proposed by Pothuluri et al.,[2] compound **B** can react with another substrate molecule to form the 3,5,3′,5′-tetrachlorohydrazobenzene **C**, which is then oxidized to the 3,5,3′,5′-tetrachloroazobenzene (**7**) and to the 3,5,3′,5′-tetrachloroazoxybenzene (**8**). The addition of a water molecule at the *para* position of the cation **A** (pathway b in Figure 4) generates intermediate **D**, which is transformed into 2,6-dichloro-1,4-quinoneimine (**1**) by deprotonation and removal of two electrons. The proposed reaction mechanism suggests that the degradation of dichloroanilines and their transformation into dimers proceeds via the same intermediate **A**. In the case of 3,5-DCA, two successive one-electron oxidations are necessary to generate the 3,5-dichloro-hydroxylaniline **B**, whereas four electrons have to be abstracted from 3,5-DCA to produce the 2,6-dichloro-1,4-quinoneimine **1**. This electrophilic compound can then be further oxidized to ring-cleavage products by addition of peroxidic oxidants, either activated or not activated by FePcS, as shown in quinone intermediates observed in the oxidative degradation of 2,4,6-trichlorophenol.[5c]

In the second part of this work we investigated the catalytic oxidation of the dichloroanilides 3,4-DCPA and 3,5-

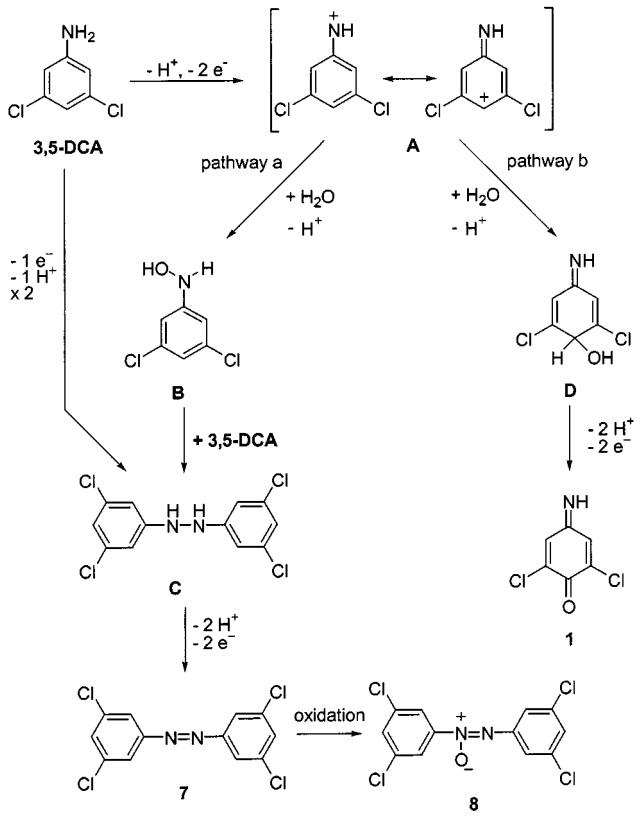

Figure 4. Proposed mechanism for the oxidation of 3,5-DCA by FePcS/$KHSO_5$; compounds indicated by numbers have been identified whereas derivatives assigned by capital letters are only putative intermediates

DCAA, prepared by reacting the respective DCA isomers with propionic or acetic anhydride. The results of the catalytic oxidations indicate that the introduction of an electron-withdrawing substituent such as a propionyl or an acetyl group reduced the conversion rates of these anilides compared with the corresponding amines. In addition, the anilide 3,5-DCAA, with two chloro-substituents on positions 3 and 5 of the aromatic ring, is more difficult to oxidize than the 3,4-isomer 3,4-DCPA. It should be noted that we observed the same tendency in the oxidations of 3,5-DCA and 3,4-DCA because only the latter was fully converted by FePcS/H_2O_2 (Table 1, runs 2 and 6).

The oxidation of 3,4-DCPA by FePcS/H_2O_2 gave the hydroxylated *N*-propionyl-quinoneimine **14**, which is formed after release of one chloride. The analytical data suggest that the formation of products **15**, **16** and **17** resulted from oxidations of the aromatic ring, the amide function or the acyl chain of 3,4-DCPA, respectively. The dechlorination value (1.0 Cl^-/converted 3,4-DCPA) indicates that other unidentified dechlorinated products should be formed, since **14** is the only mono-chlorinated compound observed.

Coupling products such as azo or azoxy compounds were not detected in the catalytic oxidation of 3,4-DCPA by FePcS/H_2O_2. The presence of the propionyl substituent on the aniline derivative blocked the formation of toxic dimers such as the azobenzene **10** and the azoxybenzene **11**, which were always produced in the catalytic oxidations of DCA derivatives under similar conditions.

Conclusion

The present study indicates that the catalytic systems FePcS/$KHSO_5$ and FePcS/H_2O_2 are able to oxidize recalcitrant pollutants such as dichloroanilines and related anilides. One part of the pollutant 3,5-DCA was partially transformed by FePcS/$KHSO_5$ into more biodegradable products such as chloromaleic acid (**3**) and formic acid (**4**), whereas the other part of 3,5-DCA was oxidized to toxic dimers such as the azobenzene **7** and the azoxybenzene **8**. The FePcS-catalyzed oxidation of 3,4-DCA with hydrogen peroxide gave mainly coupling products without ring cleavage products.

The noncatalyzed oxidations of DCA isomers with $KHSO_5$ led to fast conversions of the pollutants without chlorine release, indicating that the FePcS catalyst is necessary for the oxidative ring cleavage of the dichloroaniline derivatives.

The oxidation of DCA by these bio-inspired systems is, like the degradation of 3,4-DCA by lignin peroxidase from *Phanerochaete chrysosporium*,[4] a double-edged sword, since the formation of more biodegradable compounds and toxic dimers occurs simultaneously. The formation of oligomers could be avoided when these amines were converted into amides before the catalytic oxidation. Unfortunately, the electron-withdrawing acyl substituents are responsible for slower substrate conversions, but the optimization of the reaction conditions might be able to produce full substrate conversions without the formation of toxic coupling products in these catalytic degradation reactions of dichloroaniline derivatives.

Experimental Section

Materials: Potassium monopersulfate (the triple salt $[KHSO_5]_2[KHSO_4][K_2SO_4]$, Curox®) was a gift from Peroxid Chemie GmbH. Hydrogen peroxide was obtained from Acros as a 35 wt.% solution. 3,4-DCA, 3,5-DCA, 3,5-dichloronitrobenzene and 2,6-dichloro-1,4-benzoquinone were purchased from Aldrich. Iron tetrasulfonatophthalocyanine (FePcS) was prepared according to the modified method of Weber and Busch.[11][12]

Analytical procedures: The conversions of substrates were monitored by HPLC (Waters 510 pump, Waters 486 detector) using a μ-Bondapak C18 column. The eluent was a mixture of acetonitrile/phosphate buffer 0.05 M (pH 7.0) in proportions 55:45 (v/v) for oxidations of 3,5-DCA and 3,4-DCPA and 40:60 (v/v) for oxidations of 3,4-DCA and 3,5-DCAA. The flow rate was 1 mL/min and the detection was performed at 220 nm. Gas chromatography-mass spectrometry data (GC-MS), except for compounds **1** and **2**, were recorded on a Hewlett-Packard 5890 instrument by electron-impact ionization at 70 eV. The carrier gas for GC-MS was helium and a non polar capillary column (12 m × 0.2 mm HL-1, crosslinked methylsilicone) was used. The injector temperature was 250°C, and analyses were performed at 80°C for 2 min, then up to 250°C (10°C/min) for a further 15 min. The GC-MS data for

compounds **1** and **2** were obtained using a Hewlett-Packard 5890 spectrometer with a nonpolar capillary column (50 m × 0.22 mm BPX5). The injector temperature was 250°C, and analyses were performed at 100°C for 0.5 min, then up to 325°C (6°C/min) for a further 30 min. ^{1}H NMR spectra were recorded with a Bruker WM 250 spectrometer. The concentration of chloride ions was determined by the mercuric thiocyanate method.[10]

General Procedure for Catalytic Oxidations: The reaction mixture, with a final volume of 4 mL, contained 4 μmol of substrate, 0.12 μmol of FePcS and 5 μmol of $KHSO_5$ or 6 μmol of H_2O_2. The reaction mixtures were prepared as follows: 80 μL of a substrate solution (50 mM) in acetone was mixed with 80 μL of an internal standard (4-fluoronitrobenzene, 50 mM) in acetone. 1.5 mL of an aqueous FePcS solution (80 μM) was added and the reaction mixture was adjusted to a final volume of 4 mL with 400 μL of phosphate buffer (500 mM, pH 7), 240 μL of acetone and 1.7 mL of water for 3,5-DCA, 3,4-DCA and 3,4-DCPA (acetone/water = 1:9, v/v) or with 400 μL of phosphate buffer (500 mM, pH 7), 640 μL of acetone and 1.3 mL of water for 3,5-DCAA (acetone/water = 2:8, v/v). Finally, 175 μL of H_2O_2 (0.12 M) or 50 μL of $KHSO_5$ (0.4 M) was added and the reaction mixture was stirred at room temperature.

Characterization of the Oxidation Products of 3,5-DCA: The reaction was carried out under the conditions described for run 5 in Table 1 with a larger (25 times) reaction volume (100 mL). The reaction mixture was stirred for 1 h at room temperature. The acetone and water were then evaporated under vacuum at 50°C and the residue was dried for 1 h under vacuum at room temperature. The residue was dissolved in 10 mL of 1 M HCl saturated with NaCl (resulting pH = 2). The products were extracted with diethyl ether (4 × 60 mL). After evaporation of the ether, the dark brown residue was dried under vacuum for 2 h at room temperature and dissolved in 1 mL of diethyl ether. The resulting solution was analyzed by GC-MS. In order to analyze the product mixture by ^{1}H NMR spectroscopy the diethyl ether was evaporated and the residue was dissolved in 1 mL of deuterated dimethyl sulfoxide ([D_6] DMSO).

In order to identify the intermediate products, we modified the work-up described above and acidified the reaction mixture after 5 min of reaction time without prior evaporation of water and acetone. After extraction with 2 × 60 mL of diethyl ether and evaporation of the ether, the residue was contaminated with buffer salts because of their solubility in acetone. The residue was dissolved in 20 mL of diethyl ether and filtered to separate the salts from oxidation products.

2,6-Dichloro-1,4-quinoneimine (1): The mass spectrum corresponded to the 2,6-dichloro-4-aminophenol, which is the reduced form of compound **1**. GC-MS: m/z = 180 [$(M + 2)^+$], 178 [M^+], 144 [$(M + 2 - HCl)^+$], 142 [$(M - HCl)^+$], 116 [$(M + 2 - HCOCl)^+$], 114 [$(M - HCOCl)^+$].

2,6-Dichloro-1,4-benzoquinone (2): The mass spectrum corresponded to the 2,6-dichloro-1,4-hydroquinone, which is the reduced form of compound **2**. GC-MS: m/z = 179 [$(M + 2)^+$], 177 [M^+], 143 [$(M + 2 - HCl)^+$], 141 [$(M - HCl)^+$], 115 [$(M + 2 - HCOCl)^+$], 113 [$(M - HCOCl)^+$].

Chloromaleic acid (3): ^{1}H NMR ([D_6] DMSO): δ = 6.67 (s, CH). Chloromaleic acid formed an adduct with traces of unchanged 3,5-DCA under the conditions of GC-MS analysis. GC-MS data of the adduct: m/z = 277 [$(M + 2)^+$], 275 [M^+], 242 [$(M + 2 - Cl)^+$], 240 [$(M - Cl)^+$], 198 [$(M + 2 - CO_2Cl)^+$], 196 [$(M - CO_2Cl)^+$], 161 [$(M + 2 - CHCCl(CO)_2)^+$], 159 [$(M - CHCCl(CO)_2)^+$]. We verified the GC-MS data by co-injection of a solution containing 3,5-DCA and chloromaleic acid, and the same adduct (retention time and mass spectrum) was formed during the analysis. Chloromaleic acid was prepared according to the method of Gruzdev and Gruzdev.[13]

Formic acid (4): ^{1}H NMR ([D_6] DMSO): δ = 8.24 (s, CH). Formic acid formed an adduct with traces of unchanged 3,5-DCA under the conditions of GC-MS analysis. GC-MS data of the adduct: m/z = 191 [$(M + 2)^+$], 189 [M^+], 163 [$(M + 2 - CO)^+$], 161 [$(M - CO)^+$]. We verified the data by co-injection of a solution containing 3,5-DCA and formic acid, and the same adduct (retention time and mass spectrum) was formed during the analysis.

3,5-Dichloronitrosobenzene (5): GC-MS: m/z = 177 [$(M + 2)^+$], 175 [M^+], 147 [$(M + 2 - NO)^+$], 145 [$(M - NO)^+$], 111 [$(M + 2 - HNOCl)^+$], 109 [$(M - HNOCl)^+$].

3,5-Dichloronitrobenzene (6): GC-MS: m/z = 193 [$(M + 2)^+$], 191 [M^+], 163 [$(M + 2 - NO)^+$], 161 [$M - NO)^+$], 147 [$(M + 2 - NO_2)^+$], 145 [$(M - NO_2)^+$]. – HPLC: product **6** was also characterized by co-injection of an authentic commercial sample which had the same retention time. The quantification of compound **6** in the oxidation of 3,5-DCA with $KHSO_5$, corresponding to run 7 in Table 1, was recorded by HPLC with 4-fluoronitrobenzene as an internal standard.

3,5,3′,5′-Tetrachloroazobenzene (7): GC-MS: m/z = 322 [$(M + 4)^+$, 12], 320 [$(M + 2)^+$, 20], 318 [M^+, 14], 175 [$(M + 2 - C_6H_3Cl_2)^+$, 18], 173 [$(M - C_6H_3Cl_2)^+$, 30], 147 [$(M + 2 - C_6H_3N_2Cl_2)^+$, 55], 145 [$(M - C_6H_3N_2Cl_2)^+$, 82].

3,5,3′,5′-Tetrachloroazoxybenzene (8): GC-MS: m/z = 338 [$(M + 4)^+$, 3], 336 [$(M + 2)^+$, 7], 334 [M^+, 6], 322 [$(M + 4 - O)^+$, 13], 320 [$(M + 2 - O)^+$, 24], 318 [$(M - O)^+$, 20], 175 [$(M + 2 - C_6H_3Cl_2O)^+$, 20], 173 [$(M - C_6H_3Cl_2O)^+$, 33], 147 [$(M + 2 - C_6H_3Cl_2N_2O)^+$, 64], 145 [$(M - C_6H_3Cl_2N_2O)^+$, 100].

1,3,6,8-tetrachlorophenazine (9): GC-MS: m/z = 320 [$(M + 4)^+$, 48], 318 [$(M + 2)^+$, 100], 316 [M^+, 76], 283 [$(M + 2 - Cl)^+$, 17], 281 [$(M - Cl)^+$, 20], 248 [$(M + 2 - Cl_2)^+$, 6], 246 [$(M - Cl_2)^+$, 9].

Characterization of the Oxidation Products of 3,4-DCA. – Procedure for the catalytic oxidation: The reaction mixture, with a final volume of 200 mL, contained 2 mmol of 3,4-DCA, 80 μmol of FePcS (catalyst/substrate ratio: 4%) and 10 mmol of H_2O_2. The reaction mixture was prepared as follows: 324 mg of 3,4-DCA and 82 mg of FePcS (M = 1022) were dissolved in a previously prepared solvent mixture containing 40 mL of acetone and 110 mL of water. Phosphate buffer (50 mL, pH 7, 500 mM) was added. Finally, 1 mL of H_2O_2 (12 M, 35 wt.%) was added in five aliquots (5 × 200 μL every 5 min) and the reaction mixture was stirred at room temperature.

Isolation of the Oxidation Products: After a reaction time of 60 min, the mixture was filtered and the remaining precipitate was dried for 3 h under vacuum. Yield: 223 mg (69%). In order to separate the hydrophobic products from paramagnetic iron salts, the precipitate was dissolved in diethyl ether and filtered. The filtrate was evaporated under vacuum and 155 mg (48%) of organic products were isolated. Afterwards, the products were separated by liquid chromatography (column on silica, eluent: dichloromethane/hexane = 65:35) and analyzed by GC-MS and ^{1}H NMR spectroscopy.

3,4,3′,4′-Tetrachloroazobenzene (10): Yield: 71 mg (22%). – GC-MS: m/z = 322 [$(M + 4)^+$, 10], 320 [$(M + 2)^+$, 19], 318 [M^+, 14], 175 [$(M + 2 - C_6H_3Cl_2)^+$, 18], 173 [$(M - C_6H_3Cl_2)^+$, 28], 147 [$(M + 2 - C_6H_3N_2Cl_2)^+$, 53], 145 [$(M - C_6H_3N_2Cl_2)^+$, 82]. – ^{1}H NMR ($CDCl_3$): δ = 7.61 (d, 1 H, J = 7.5 Hz, C_5-H, $C_{5'}$-H), 7.79

(dd, 1 H, J = 7.5 Hz, J = 2.5 Hz, C_6-H, $C_{6'}$-H), 8.00 (d, 1 H, J = 2.5 Hz, C_2-H, $C_{2'}$-H).

3,4,3′,4′-Tetrachloroazoxybenzene (11): Yield: 22 mg (7%). − GC-MS: m/z = 338 [(M + 4)$^+$, 3], 336 [(M + 2)$^+$, 7], 334 [M$^+$, 6], 322 [(M + 4 − O)$^+$, 13], 320 [(M + 2 − O)$^+$, 25], 318 [(M − O)$^+$, 20], 175 [(M + 2 − $C_6H_3Cl_2O$)$^+$, 21], 173 [(M − $C_6H_3Cl_2O$)$^+$, 32], 147 [(M + 2 − $C_6H_3Cl_2N_2O$)$^+$, 64], 145 [(M − $C_6H_3Cl_2N_2O$)$^+$, 100]. − ^{1}H NMR ($CDCl_3$): δ = 7.52 (d, 1 H, J = 7.5 Hz, $C_{2'}$-H), 7.57 (d, 1 H, J = 7.5 Hz, C_2-H), 7.98 (dd, 1 H, J = 10 Hz, J = 2.5 Hz, $C_{6'}$-H), 8.12 (dd, 1 H, J = 10 Hz, J = 2.5 Hz, C_6-H), 8.38 (d, 1 H, J = 2.5 Hz, $C_{2'}$-H), 8.39 (d, 1 H, J = 2.5 Hz, C_2-H).

Tetrachlorophenazines 12 and 13: Yield: 9.5 mg (3%). − GC-MS: m/z = 320 [(M + 4)$^+$, 48], 318 [(M + 2)$^+$, 100], 316 [M$^+$, 76], 283 [(M + 2 − Cl)$^+$, 17], 281 [(M − Cl)$^+$, 20], 248 [(M + 2 − Cl_2)$^+$, 6], 246 [(M − Cl_2)$^+$, 9]. − **3,4,6,7-tetrachlorophenazine 12:** ^{1}H NMR ($CDCl_3$): δ = 7.87 (d, 1 H, J = 9 Hz, C_2-H, C_8-H), 8.09 (d, 1 H, J = 9 Hz, C_1-H, C_9-H). − **1,2,6,7-tetrachlorophenazine 13:** ^{1}H NMR ($CDCl_3$): δ = 7.93 (d, 1 H, J = 9 Hz, C_3-H, C_8-H), 8.25 (d, 1 H, J = 9 Hz, C_4-H, C_9-H).

Preparation of 3,4-Dichloropropionanilide (3,4-DCPA): Propionic anhydride (20 mL, 156 mmol) was added to 3,4-dichloroaniline (600 mg, 3.7 mmol). The mixture was stirred at 60 °C for 4 h and then at 100 °C for 2 h. The propionic acid and unreacted propionic anhydride were removed by distillation (bath temperature: 70 °C) under vaccum. The remaining orange oil was dissolved in 5 mL of dichloromethane and the product was precipitated by addition of 100 mL of hexane. The white powder was filtered off and dried under vacuum for 4 h at 25 °C. − Yield: 550 mg (68%). − ^{1}H NMR ([D_6] DMSO): δ = 1.19 (t, 3 H, CH_3), 2.44 (q, 2 H, CH_2), 7.59 (dd, 1 H, C_6-H), 7.67 (d, 1 H, C_5-H), 8.12 (d, 1 H, C_2-H), 10.29 (s, 1 H, NH). − GC-MS: m/z = 219 [(M + 2)$^+$], 217 [M$^+$], 163 [(M + 2 − $COCH_2CH_2$)$^+$], 161 [(M − $COCH_2CH_2$)$^+$]. − $C_9H_9Cl_2NO$ (218): calcd. C 49.54, H 4.13, N 6.42; found C 49.62, H 3.79, N 6.38.

Preparation of 3,5-Dichloroacetanilide (3,5-DCAA): Acetic anhydride (10 mL, 102 mmol) was added to a solution of 3,5-dichloroaniline (300 mg, 1.85 mmol) in 10 mL of acetonitrile. The reaction mixture was stirred for 2 h at 100 °C. The acetic acid and unreacted acetic anhydride were removed by distillation (bath temperature: 100 °C) under vaccum. The remaining beige oil was dissolved in 5 mL of dichloromethane and the product was precipitated by the addition of 100 mL of hexane. The white powder was filtered off and dried under vacuum for 3 h at 25 °C. − Yield: 310 mg (82%). − ^{1}H NMR ([D_6] DMSO): δ = 2.18 (s, 3 H, CH_3), 7.36 (s, 1 H, C_4-H), 7.76 (s, 2 H, C_2-H, C_6-H), 10.41 (s, 1 H, NH). − GC-MS: m/z = 205 [(M + 2)$^+$], 203 [M$^+$], 163 [(M + 2 − $COCH_2$)$^+$], 161 [(M − $COCH_2$)$^+$]. − $C_8H_7Cl_2NO$ (204): calcd. C 47.06, H 3.43, N 6.86; found C 47.17, H 3.15, N 6.91.

Characterization of the Oxidation Products of 3,4-DCPA: The reaction was carried out under the conditions as described for run 2 in Table 2 with a larger (25 times) reaction volume (100 mL). The workup was identical to that used for the characterization of the oxidation products of 3,5-DCA.

2-Chloro-hydroxy-*N*-propionyl-1,4-quinoneimine (14): GC-MS: m/z = 215 [(M + 2)$^+$], 213 [M$^+$], 185 [(M − C_2H_4)$^+$], 161 [(M + 2 − CNC_2H_4)$^+$], 159 [(M − CNC_2H_4)$^+$].

3,4-Dichlorohydroxypropionanilide (15): GC-MS: m/z = 235 [(M + 2)$^+$], 233[M$^+$], 179 [(M + 2 − COC_2H_4)$^+$], 177 [(M − COC_2H_4)$^+$].

3,4-Dichloro-*N*-hydroxypropionanilide (16): GC-MS: m/z = 235 [(M + 2)$^+$], 233[M$^+$], 217 [(M + 2 − H_2O)$^+$], 215 [(M − H_2O)$^+$], 179 [(M + 2 − COC_2H_4)$^+$], 177 [(M − COC_2H_4)$^+$].

3,4-Dichloro-2-hydroxypropionanilide (17): GC-MS: m/z = 235 [(M + 2)$^+$], 233 [M$^+$], 191 [(M + 2 − CO_2)$^+$], 189 [(M − CO_2)$^+$], 163 [(M + 2 − $CO_2C_2H_4$)$^+$], 161 [(M − $CO_2C_2H_4$)$^+$].

Novel Condensed Thionated Bis(phosphonic) Acid Salts with a Rigid Naphthalene-1,8-diyl Backbone

Petr Kilian,[a] Alexandra M. Z. Slawin,[a] and J. Derek Woollins*[a]

Keywords: Heterocycles / Organo-phosphorus compounds / Dithiadiphosphetane disulfides / Phosphonates

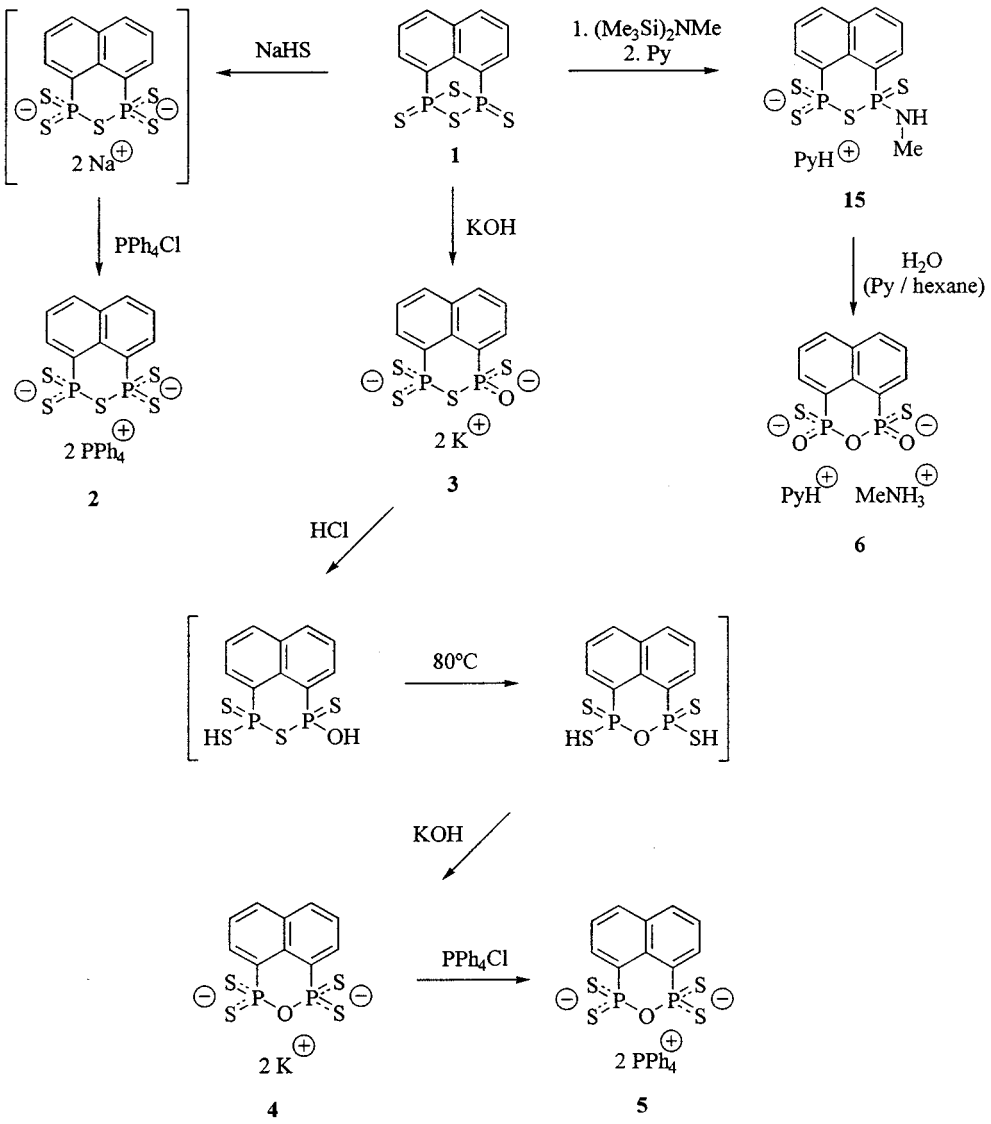
New salts of thionated (naphthalene-1,8-diyl)bis(phosphonic) acid monoanhydrides $[PPh_4^+]_2[C_{10}H_6PS_2(\mu\text{-}S)PS_2^{2-}]$ (**2**) and $[K^+]_2[C_{10}H_6PS_2(\mu\text{-}S)POS^{2-}]\cdot H_2O$ (**3**) both containing the C_3P_2S ring, were prepared in high yields by the reaction of 2,4-(naphthalene-1,8-diyl)-1,3,2,4-dithiadiphosphetane 2,4-disulfide (**1**) with NaHS and PPh_4Cl, or KOH, respectively, in water. The derivative **3**, containing a P=O terminal bond as well as P–S–P bridge, undergoes, in acid conditions, a rearrangement reaction leading to the O,S-symmetrically substituted derivative $[K^+]_2[C_{10}H_6PS_2(\mu\text{-}O)PS_2^{2-}]$ (**4**) containing a C_3P_2O heterocycle. Dipotassium salt 4 was converted into the bis(tetraphenylphosphonium) salt **5** by the treating with PPh_4Cl. Hydrolysis of $[PyH^+][C_{10}H_6P(S)(NHMe)(\mu\text{-}S)PS_2^{2-}]$ (**15**) led to $[CH_3NH_3^+][PyH^+][C_{10}H_6POS(\mu\text{-}O)POS^{2-}]\cdot 1.5$ Py (**6**). New compounds were characterised by $^{31}P\{^1H\}$-, ^1H- and $^{13}C\{^1H\}$-NMR, FT-IR, ES-MS and in the cases **2**–**6** by X-ray structure determination. The $^{31}P\{^1H\}$-NMR spectra of these mixed O,S-derivatives are briefly discussed.

Introduction

Phosphonic acids and their esters form the largest group of compounds containing P−C linkages. Esters of thionated phosphonic acids have been extensively studied because of their use as oil additives and in pesticide chemistry.[1] 2,4-dialkyl(aryl)-1,3,2,4-dithiadiphosphetane 2,4-disulfides $(RPS_2)_2$, especially that with R = C_6H_4OMe (An), well-known as Lawesson reagent (LR), are commonly used for their preparation. In some cases they are converted into intermediates − alkali metal salts of dithio- and trithiophosphonic acids or their monoesters. These salts are either isolated as pure compounds[2][3] or without isolation from the reaction mixture they are directly alkylated to diesters.[4,5,6,7]

As a continuation of our interest in the chemistry of 2,4-(naphthalene-1,8-diyl)-1,3,2,4-dithiadiphosphetane 2,4-disulfide **1** we studied its reactions with potassium hydroxide and sodium hydrogen sulfide, leading to salts of the composition described above. Because of the presence of a rigid organyl backbone in **1**, which fixes its phosphorus atoms in the sterically strained 1,8-positions of the naphthalene ring, we obtained condensed products − bis(phosphonates), containing a P−X−P bridge built into six-membered C_3P_2X (X = S or O) heterocycles.

Several examples of thionated bis(phosphonates) have been reported. In the form of their alkali metal salts RP(S)(OM)(μ-S)P(S)(OM)R they were obtained from $(RPS_2)_2$, where R = alkenyl with long chain, by mild alkalic hydrolysis by potassium and sodium hydroxide.[3] Partially thionated diesters RP(S)(OR′)(μ-S)P(S)(OR′)R were obtained in low yield by the reaction of $(RPS_2)_2$ with primary and secondary alcohols at higher temperatures,[5][8] particularly in boiling xylene. The more sulfur rich diester AnP(S)(SEt)(μ-S)P(S)(OEt)An was obtained in good yield by the reactions of LR with 1,1,1-triethoxyethane, tri- and tetraethoxymethane.[9][10] The fully thionated bis(phosphonate) diester AnP(S)(SPh)(μ-S)P(S)(SPh)An was obtained in low yield by the action of thiophenol on LR.[5] In these systems the ease of sulfur loss occurring on contact of thionated phosphonates with water requires the work to be performed with the exclusion of water.[2][7] However the substantially lower reactivity of **1** compared to common dithiadiphosphetane disulfides $(RPS_2)_2$ allowed us to prepare salts of perthionated as well as partially dethionated phosphonic acids in water.



Results and Discussion

The bis(tetraphenylphosphonium) salt of bis(trithiophosphonic acid) monoanhydride **2** was prepared in a good yield by the action of excess NaHS on **1** and consequent treatment of the resulting disodium salt (without its isolation from reaction mixture) with PPh_4Cl (Scheme 1). $^{31}P\{^1H\}$-NMR of the reaction mixture after the first step showed a singlet at δ = 69.0 ppm, belonging to the disodium salt $[Na^+]_2[C_{10}H_6PS_2(\mu\text{-}S)PS_2^{2-}]$. When a stoichiometric amount or only a small molar excess of NaHS was used, the larger amount of the side product, the anion of **3**, was observed by $^{31}P\{^1H\}$-NMR. Reaction of the disodium salt with PPh_4Cl afforded pure **2**, which is insoluble in many common solvents. Its slight solubility in CD_3CN/[D_6]DMSO allowed us to measure its $^{31}P\{^1H\}$- and ^1H-NMR spectra, however the concentration of such saturated solution was too low to obtain a good quality $^{13}C\{^1H\}$-NMR spectrum.

By the action of small excess of KOH on **1** (molar ratio 2.3:1) we obtained the potassium salt of the unsymmetrically O,S-substituted naphthalene-1,8-diyl bis(phosphonic)

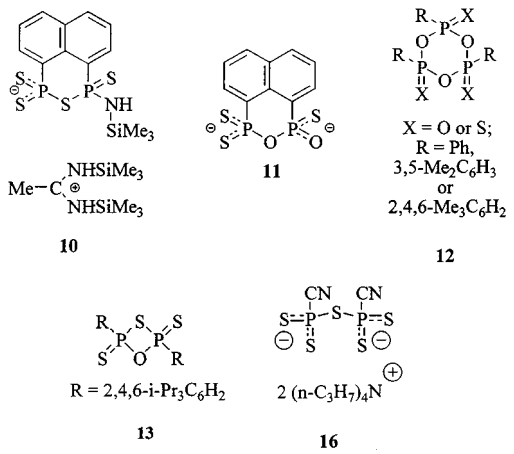
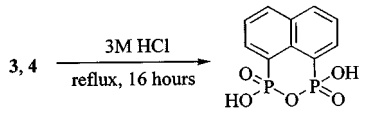


Scheme 1

acid, **3** (Scheme 1). The $^{31}P\{^1H\}$-NMR spectrum of the reaction mixture showed an AX system with δ 69.2 and 58.6 ppm. The magnitude of $J(PP) = 11.6$ Hz indicates that a P−S−P bridge is preserved in the product.[11][12] Both the ^1H and $^{13}C\{^1H\}$-NMR spectra showed unsymmetrical substitution of the naphthalene ring, whilst in the IR a very strong band at 1112 cm^{-1} corresponding to ν(P=O) was found. The position of this band in the lower frequency range for a P=O bouble bond valence vibration is due to the lowered bond order given by delocalisation of the negative charge between more terminal atoms. All these facts are in accord with the structure of **3** shown in Scheme 1, which was confirmed by X-ray structure determination (Figure 2). Signals in the ^1H and $^{13}C\{^1H\}$-NMR spectrum of **3** were assigned by analogy with **10**, where unambiguous assignment was performed by both 1D- and 2D-NMR.[11] Recrystallization of the crude product from non dried ethanol/methanol mixture afforded hygroscopic material, which after six hours of drying *in vacuo* was identified by elemental analysis as **3**, monohydrate, whilst 2.5 molecules of water per naphthalene entity were found in the crystal structure of **3** by X-ray structure determination. On attempts to convert the potassium salt **3** to its tetraphenylphosphonium relative by the reaction of **3** with PPh_4Cl a mixture of the desired product together with reorganised product **5** was obtained.

The potassium salt **3** is indefinitely stable in the solid state. However, when it is in the form of its conjugated acid, [obtained by the addition of diluted mineral acid (HCl) to the water solution of **3**], it undergoes a rearrangement reaction leading to O,S-symmetrically substituted acid, containing a P−O−P bridge (Scheme 1). Treatment of the crude mixture of the bis(phosphonic) acid and KCl with dry methanol allows the removal of a majority of KCl together with other methanol insoluble side products by filtration. Stripping off methanol, dissolving the resulting solid in water and titration with KOH afforded the potassium salt **4**. In its $^{31}P\{^1H\}$-NMR spectrum we found signals due to



three distinct compounds. Besides the major signal of **4** (s, δ = 101.4) and minor signals of the starting material **3** (2 × d, δ = 69.2 and 58.6, ^2J(PP) = 11.6 Hz) other minor signals (2 × d, δ = 102.7 and 59.7, ^2J(P−O−P) = 47 Hz) were found, probably belonging to the dianion **11**. After another purification step (recrystallization from ethanol), pure **4** was obtained. Signals in the ^{1}H- and ^{13}C{^{1}H}-NMR spectrum of **4** were assigned on the basis of analogy with **10**.[11] The second order signals of carbons C1 and C9 (for numbering of atoms see Figure 4) represent AXX′ systems, where A is the carbon atom and X and X′ are phosphorus atoms. Magnitudes of their ^2J(PP), ^1J(PC) and ^3J(PC) coupling constants were obtained using the LAOCOON III simulation program.[13] The magnitude of ^2J(PP) = 51.2 Hz is comparable with the corresponding ^2J(PP) values found in thiotrimetaphosphonates **12**[14] (32−62 Hz) whilst it is substantially larger when compared with ^2J(PP) = 14.2 Hz in **13**[14] or with ^2J(PP) = 6.5 Hz in **1**.[15] In the IR spectrum of **4** no strong band was found in the 1100−1400 cm^{-1} region, which would be expected for ν(P=O) vibrations, whilst a very strong band, belonging to ν_{as}(P−O−P) was found at 825 cm^{-1}.

10 11 12 13 16

Figure 1. Structural formulas of compounds **10**, **11**, **12**, **13** and **16**

By the reaction of **1** with excess of ethylene glycol at 140°C a completely desulfurated compound **14** was obtained.[16] Compounds **3** or **4** respectively can be used for preparation of **14** as well. These desulfuration reactions were performed by prolonged boiling with 3 M HCl (Scheme 2). The identity of resulting products was confirmed by ^{31}P{^{1}H}-NMR and IR spectroscopy.

14

Scheme 2

To improve the solubility of the potassium salt **4** in organic solvents we converted it into the bis(tetraphenylphosphonium) salt **5** by the reaction of **4** with PPh_4Cl (Scheme 1). **5** shows good solubility in hot acetonitrile, whilst it is much less soluble at room temperature; this allowed very good yields when recrystalized from this solvent.

In our previous paper[17] we described the preparation of pyridinium salt **15** by the treatment of **1** with bis(trimethylsilyl)methylamine and pyridine (Py). An attempt to recrystallize **15** by diffusion of hexane into its pyridine solution led to hydrolysis with formation of **6** (Scheme 1). The product, obtained in the form of several crystals, was identified by X-ray structure analysis, but the small amount available only allowed further characterization by ^{31}P{^{1}H}- and ^{1}H-NMR. The latter showed 1:1.2 ratio of naphthalene and pyridine hydrogens, whilst in the crystal ratio 1:2.5 was found by X-ray structure analysis, the lower ratio found in solution is due to partial evaporation of solvated Py from crystals. The integral of the broad signal at 3.4 ppm, belonging to $MeNH_3^+$ and PyH^+ hydrogens was lower than the expected value from its comparison with integral value of CH_3 hydrogens of methylamine, probably due to their fast chemical exchange.

Discussion of ^{31}P{^{1}H}-NMR Spectra

When comparing ^{31}P-NMR shifts in dianionic O,S-mixed derivatives of (naphthalene-1,8-diyl)bis(phosphonic) acid, the following conclusions can be drawn:[2,3,10,11] In such systems it is common, that substitution of an O atom by a S atom leads to the lower field shift. This rule is obeyed very well when a series of compounds containing oxygen as a bridging atom between both phosphorus atoms is taken into account, compounds **5** (δ = 100 ppm), **6** (δ = 59 ppm) and **14** (δ = 7 ppm) contain moieties C−P(μ-O)S_2, C−P(μ-O)OS and C−P(μ-O)O_2, respectively. A second group, for which the above rule applies as well, is formed by compounds containing sulfur as a bridging atom between both phosphorus atoms. Members of this group are compounds **2** (δ = 73 ppm, C−P(μ-S)S_2 moiety) and **3** (δ = 69 ppm, C−P(μ-S)S_2 moiety; 59 ppm C−P(μ-S)OS moiety), the missing member is a compound containing a C−P(μ-S)O_2 moiety, no example of this type has been described yet. The above rule obviously does not apply, when comparing compounds with C−P(μ-S)S_2 moiety (**2**, δ = 73 ppm) with C−P(μ-O)S_2 moiety (**5**, δ = 100 ppm), thus both groups with different P-X−P bridging atoms should be judged separately.

Discussion of X-ray Structure Analysis

X-ray structures of compounds **2**−**6** were measured, see Figure 2−6 and Tables 1−6. The naphthalene part and the phosphorus atoms lie very close to the mean plane fitted to these atoms in case of the anion of **2** [P(1) 0.05 Å above and P(9) 0.13 Å below the mean plane] and **6** both P(1) and P(9) lie 0.08 and 0.01 Å, respectively, above the mean plane], whilst in **3**, **4** and **5** the distortion is more significant and phosphorus atoms in each anion lie above and below the mean plane in distances between 0.31 and 0.44 Å.

The C_3P_2X (X = S or O) rings are hinged, the C_3P_2 and P_2X planes in anions of **2** and **3** (where X = S) are inclined by 52 and 48°, respectively. In **4** and **5** (where X = O) these angles are 32 and 36°, in **6** (X = O) the corresponding value of 50° was found.

The nonbonding P···P distances as well as internal P−S−P angles in **2** and **3** are very similar [3.31 and 3.27 Å; 103.31(7) and 101.5(1)°], substitution of sulfur bridging atom by oxygen led to shortening of P···P distances in **4** and **5** to 2.97 and 2.99 Å, the internal P−O−P angles are enlarged to 131°. The most compact P_2 environment is in **6**, where the Pψree dots aboveP distance 2.89 Å and corresponding internal P−O−P angle 125.2(1) is found.

As expected, the bond lengths of exocyclic substituents of phosphorus atoms reflect delocalisation of the negative charge in the $P(X_{exo})_2$ groups (X_{exo} = S, O). When comparing P−S_{exo} distances in **2**, **3**, **4**, **5** and **6** [range 1.945(2)−1.990(2) Å] with endocyclic P−S_{endo} distances in **2** and **3** [range 2.102(3)−2.116(2) Å], the difference is substantial due to their different bond order. Similarly, the P−O_{exo} distances in **3** and **6** [range 1.505(2)−1.521(5) Å] are substantially shorter than P−O_{endo} distances in **4**, **5** and **6** [range 1.623(2)−1.650(4) Å], however they are significantly longer than conventional P=O double bond as found for example in phosphoric acid triesters (average value 1.45 Å).[18]

In the structure of the anion in **2** (Figure 2, Table 1 and 2) there is surprisingly no mirror plane along the S(19)C(5)C(10) plane, sulfur atoms S(1) and S(9) lie in substantially different distances from the mean plane fitted to naphthalene part and phosphorus atoms (1.40 and 0.95 Å). The steric effect of the naphthalene backbone results in a short P···P distance 3.31 Å in **2**, compare to P···P distance 3.50 Å in **16**,[19] where phosphorus atoms are not bridged by any organic substituent.

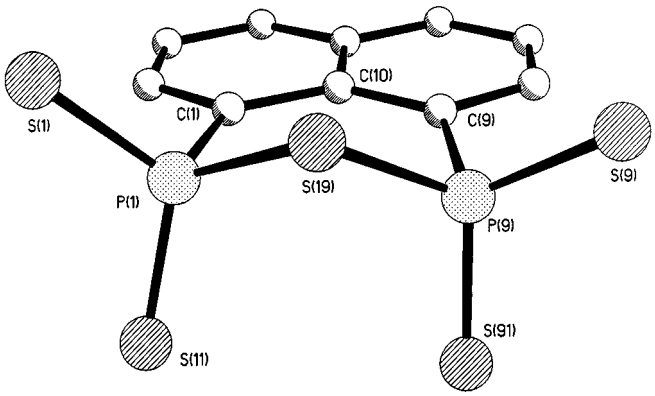


Figure 2. Molecular diagram of **2**

Table 2. Selected bond lengths (Å) and angles (°) in compound **2**

P(1)−S(19)	2.116(2)	P(9)−S(19)	2.108(2)
P(1)−S(1)	1.985(2)	P(1)−S(11)	1.968(2)
P(9)−S(9)	1.990(2)	P(9)−S(91)	1.955(2)
P(1)−C(1)	1.831(4)	P(9)−C(9)	1.841(5)
P(1)−S(19)−P(9)	103.31(7)		
S(1)−P(1)−S(11)	117.97(8)	S(9)−P(9)−S(91)	117.31(9)
S(1)−P(1)−S(19)	100.59(7)	S(11)−P(1)−S(19)	116.06(8)
S(9)−P(9)−S(19)	102.88(8)	S(91)−P(9)−S(19)	114.67(8)
C(1)−P(1)−S(1)	110.3(2)	C(1)−P(1)−S(11)	107.7(1)
C(9)−P(9)−S(9)	110.8(2)	C(9)−P(9)−S(91)	108.3(2)
C(1)−P(1)−S(19)	103.3(2)	C(9)−P(9)−S(19)	101.7(2)

In the structure of the anion in **3** (Figure 3, Table 1 and 3) the K^+ cations interact with all the sulfur atoms [including S(19)] with K···S distances in the range 3.24−3.75 Å, oxygen atom O(1) interacts with K···O distances in the range 2.76−3.02 Å. The water solvate molecules (2.5 molecule per naphthalene entity) coordinate to the K^+ centres.

Because of the close similarity of anionic parts in the structures of **4** (Figure 4, Table 1 and 4) and **5** (Table 1 and 5), only the former is discussed here. As well as in the structure of the anion of **2**, in the structure of anion of **4**, there is no mirror plane along the 0(19)C(5)C(10) plane, even when the substitution pattern is symmetric. Atoms in *trans* positions [e.g. S(1) and S(91)] are approximately in the same distance from the plane fitted to carbon and phosphorus atoms, thus when disregarding the O(19) atom (lying 0.37 Å above mean plane), the anion has approximate C_2 symmetry. The K^+ ions in **4** form close contacts with the sulfur atoms in the range 3.18−3.43 Å, and there is a K(1)···O(19) distance of 2.83Å.

In the structure of the anion in **6** (Figure 5, Table 1 and 6) the exocyclic substituents are in the *cis* position and the molecule possesses an approximate mirror plane along the O(19)C(5)C(10) plane, which is in contrast with *trans* geometry of **14**.[16] The NH protons in the $MeNH_3^+$ counterion are hydrogen-bonded to a solvated pyridine nitrogen atom [H(20a)···N(41) 1.94 Å, N(20)−H(20a)−N(41) 169°], to O(9) atom [H(20b)···O(9) 1.79 Å, N(20)−H(20b)−O(9) 175°] and to O(9′) atom in adjacent anion [H(20c)···O(9′) 1.95 Å, N(20)−H(20c)−O(9′) 167°]. The pyridinium NH proton strongly bonds to the anion O(1) atom [H(31)···O(1) 1.64 Å, N(31)−H(31)−O(1) 175°].

Conclusion

In this paper we have gained access to almost all possible permutations of O,S-substituted phosphorus environments in salts of (naphthalene-1,8-diyl)bis(phosphonic) acids. The only missing member in this group of environments of general formula C−P(μ-X)X_2, where X = either O, S, or their permutations, is the C−P(μ-S)O_2 moiety. All other members were characterised by $^{31}P\{^1H\}$-NMR and by X-ray structure analysis either in this paper or elsewhere.[16] Current investigations are focusing on the preparation of other interesting main group derivatives of 1,8-bis(phosphorus) substituted naphthalenes

Experimental Section

General Remarks: 1 was prepared by the reaction of P_4S_{10} with 1-bromonaphthalene[20][21] and recrystallized from dichloromethane, tetraphenylphosphonium chloride was obtained from Aldrich. Methanol was dried by boiling with CaH_2 and subsequent distillation under nitrogen. In vacuo refers to a pressure of 0.1 Torr at 20°C. NMR spectra were recorded on a Bruker DPX-400 spectrometer. For ^1H- and ^{13}C-NMR spectroscopy TMS or TSPSA [(4-trimethylsilyl)propane sulfonic acid Na salt, $\delta(^1H) = 0.015$ ppm] were used as internal standards, for ^{31}P-NMR 85% H_3PO_4 was used as an external standard. IR spectra were recorded as a pellets with KBr on a Perkin−Elmer system 2000. Mass spectra were measured by the EPSRC National Mass Spectrometry Service Centre, University of Wales, Swansea. Microanalyses were carried out by the Departmental service.

$[PPh_4^+]_2[C_{10}H_6PS_2(\mu\text{-}S)PS_2^{2-}]$ (2): 1 (200 mg, 0.63 mmol) was added to a solution of NaHS.H_2O (220 mg, 3.0 mmol) in water (5 cm^3) and refluxed with stirring until all the solid **1** dissolved (ca. 10 min). The resulting cloudy solution was filtered using a sintered glass funnel with a plug of celite. The filtrate was added with vigorous stirring to a solution of PPh_4Cl (472 mg, 1.26 mmol), the resulting yellow solid was filtered off, washed with water (5 × 20 cm^3) and dried in vacuo. The crude product was of sufficient purity, however for recrystalisation acetonitrile can be used. Crystals of **2** suitable for X-ray structure determination were obtained by slow cooling of its hot saturated solution in acetonitrile. Yield 531 mg (82%) before recrystalisation. − $C_{58}H_{46}P_4S_5$: calcd. C 67.8, H 4.5; found C 67.6, H 4.6. − M.p. 271−273°C (decomp.). − IR (cm^{-1}): $\tilde{\nu}$ = 690vs and 669vs [ν(P=S)]. − $^{31}P\{^1H\}$-NMR (CD_3CN/[D_6]DMSO 3:1; for numbering of atoms see Figure 2): δ = 72.8 (s, anion), 29.1 (s, PPh_4^+). − ^1H-NMR (CD_3CN/[D_6]DMSO 3:1; for numbering of atoms see Figure 2): δ = 8.64 (2 H, m, 2-H and 8-H), 7.92 (8 H, m, PPh_4^+), 7.79−7.65 (34 H, m, 4-H, 6-H and PPh_4^+), 7.40 (2 H, m, 3-H and 7-H). − Mass spectrum (ES+): *m/z* 339 (PPh_4^+), 262 (PPh_3); (ES−): *m/z* 687 (anion + PPh_4^+), 349 (anion + H), 317 (anion − S), 253 (anion − 3S + H), 189 ($C_{10}H_6P_2$ + H), 174 (anion, z = 2).

$[K^+]_2[C_{10}H_6PS_2(\mu\text{-}S)POS^{2-}]\cdot H_2O$ (3): 1 (500 mg, 1.58 mmol) was added to a solution of KOH (204 mg, 3.64 mmol) in water (5 cm^3) and refluxed with stirring for 1 hour. The resulting cloudy solution was filtered using a sintered glass funnel with a plug of celite and the filtrate was evaporated on a rotavapor. The resulting light yellow hygroscopic solid was recrystalised from mixture of ethanol/methanol (4:1) and dried in vacuo at room temperature. Crystals of **3** suitable for X-ray structure determination (in the form of hydrate with 2.5 molecule of water per naphthalene entity) were obtained by evaporation of its saturated solution in an ethanol/methanol mixture. Yield 489 mg (72%) of monohydrate. − $C_{10}H_6K_2OP_2S_4\cdot H_2O$: calcd. C 28.0, H 1.9; found C 28.0, H 1.9. − Decomp. above 200°C. − IR (cm^{-1}): $\tilde{\nu}$ = 1112vs [ν(P=O)], 650vs [ν(P=S)]. − $^{31}P\{^1H\}$-NMR (D_2O; for numbering of atoms see Figure 3): δ = 69.2 (d, P-2), 58.6 (d, P-1), ^2J(PP) = 11.6 Hz. − ^1H NMR (D_2O; for numbering of atoms see Figure 3): δ = 8.75 [1 H, ddd, ^3J(PH) = 20.8, ^3J(HH) = 7.3, ^4J(HH) = 1.4 Hz, 2-H or 8-H], 8.60 [1 H, ddd, ^3J(PH) = 18.9, ^3J(HH) = 7.3, ^4J(HH) = 1.4 Hz, 2-H or 8-H], 8.04 (2 H, m, 4-H and 6-H), 7.64 (2 H, m, 3-H and 7-H). − $^{13}C\{^1H\}$-NMR (D_2O; for numbering of atoms see Figure 3): δ = 140.0 [dd, ^1J(PC) = 80.4, ^3J(PC) = 3.1 Hz, C-9], 137.6 [dd, ^1J(PC) = 106.5, ^3J(PC) = 3.9 Hz, C-1], 134.0 [t, ^3J(PC) = 10.6 Hz, C-5], 133.5 (m, C-4 or C-6), 133.3 (m, C-4 or C-6), 131.4 [d, ^2J(PC) = 11.6 Hz, C-8], 130.1 [d, ^2J(PC) = 14.0 Hz, C-2], 126.8 [t, ^2J(PC) = 8.9 Hz, C-10], 125.6 [d, ^3J(PC) = 12.2 Hz, C-3 or C-7], 125.4 [d, ^3J(PC) = 12.8 Hz, C-3 or C-7]. − Mass spectrum (ES+): *m/z* 449 (M + K), 317 (anion − O + H); (ES-): *m/z* 371 (anion + K), 333 (anion + H).

$[K^+]_2[C_{10}H_6PS_2(\mu\text{-}O)PS_2^{2-}]$ (4): To **3** (monohydrate, 500 mg, 1.17 mmol) 0.5M HCl (5 cm^3) was added, resulting solution was heated to 70°C for 1 hour and then filtered using a sintered glass funnel with a plug of celite. The filtrate was evaporated on a rotavapor and the resulting solid was dried in vacuo. The following purification process for crude product was used: To the solid dry methanol (10 cm^3) was added, the resulting suspension was well mixed, filtered and the filtrate was evaporated on a rotavapor. The solid was then dissolved in water (8 cm^3) and titrated by 1M KOH to pH 7. The resulting light yellow hygroscopic solid obtained after stripping off water was recrystalised from non-dried ethanol. Crystals of **4** suitable for X-ray structure determination were obtained by cooling of its hot saturated solution in ethanol. Yield 249 mg (52%). − $C_{10}H_6K_2OP_2S_4$: calcd. C 29.2, H 1.5; found C 28.8, H 1.5. − M.p. 310°C. − IR (cm^{-1}): $\tilde{\nu}$ = 825vs [ν_{as}(P−O−P)], 678s, 661vs [ν(P=S)]. − $^{31}P\{^1H\}$-NMR (D_2O; for numbering of atoms see Figure 4): δ = 101.4 (s), ^2J(PP) = 51.2 Hz (calculated value).

− ^{1}H NMR (D_2O; for numbering of atoms see Figure 4): δ = 8.39 (2 H, m, 2-H and 8-H), 8.07 (2 H, m, 4-H and 6-H), 7.66 (2 H, m, 3-H and 7-H). − $^{13}C\{^1H\}$-NMR (D_2O; for numbering of atoms see Figure 4): δ = 137.8 [m, ^1J(PC) = 103.4, ^3J(PC) = 3.6 Hz, C-1 and C-9], 133.1 [t, ^3J(PC) = 9.9 Hz, C-5], 132.3 (s, C-4 and C-6), 131.3 (m, C-2 and C-8), 126.5 (m, C-3 and C-7), 125.7 [t, ^2J(PC) = 8.0 Hz, C-10]. − Mass spectrum (ES+): *m*/*z* 449 (M + K), 317 (anion − O + H); (ES-): *m*/*z* 371 (anion + K), 333 (anion + H), 317 (anion − O + H), 237 (anion − 3S + H), 205 (anion − 4S + H), 189 ($C_{10}H_6P_2$ + H), 166 (anion, z = 2).

$[PPh_4^+]_2[C_{10}H_6PS_2(\mu\text{-}O)PS_2^{2-}]\cdot 0.5\ CH_3CN$ (5): To a solution of PPh_4Cl (365 mg, 0.97 mmol) in water (10 cm^3) a solution of **4** (200 mg, 0.49 mmol) in water (10 cm^3) was added with vigorous stirring. The resulting yellow solid was filtered off, washed with water (5 × 20 cm^3), dried in vacuo and recrystalised from acetonitrile. Crystals of **5** suitable for X-ray structure determination were obtained by slow cooling of its hot saturated solution in acetonitrile. Yield 397 mg (79%) of acetonitrile hemisolvate. − $C_{58}H_{46}OP_4S_4.1/2CH_3CN$: calcd. $[CH_3NH_3^+][PyH^+][C_{10}H_6POS(\mu\text{-}O)POS^{2-}]\cdot 1.5$ Py (6): A solution of **15** (20 mg) in pyridine/hexane was left in an open test tube at room temperature. After 5 days colourless crystals suitable for X-ray structure determination were formed. M.p. 102−104°C. Several crystals were examined by NMR. $^{31}P\{^1H\}$-NMR (D_2O): δ = 59.4 (s). − ^{1}H NMR (D_2O): δ = 8.60−7.58 (protons of naphthalene and pyridinium entity), 3.4 (br s, acid protons of $CH_3NH_3^+$ and PyH^+), 2.51 (s, CH_3).

$C_{10}H_6P(O)(OH)(\mu\text{-}O)P(O)(OH)]$ (14): To **3** (monohydrate, 500 mg, 1.17 mmol) 3M HCl (20 cm^3) was added, resulting solution was refluxed for 16 hours and then filtered using a sintered glass funnel with a plug of celite. The volume was reduced to 2 cm^3 on rotavapor and the solid **14** precipitated aftef cooling to 0°C was filtered off and dried in vacuo. Yield ca 65%. − $^{31}P\{^1H\}$-NMR (MeOH): δ = 7.1 (s). A similar procedure was applied when **4** was used as a starting material.

X-ray Crystallographic Study: Details of the data collections and refinements are summarised in Table 1. Data were collected at room temperature using graphite-monochromatized Mo-K_α (λ = 0.71073 Å) radiation on a Siemens SMART CCD diffractometer. Full hemisphere of data with 0.3° steps was collected. Sadabs corrections were applied. All of the non-hydrogen atoms were refined anisotropically, calculations employed the SHELXTL program system.[22] Atomic coordinates, thermal parameters and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre (CCDC) under deposition numbers 120586−120590, see http://www.ccdc.cam.ac.uk.

Amino Alcohol Coordination in Ruthenium(II)-Catalysed Asymmetric Transfer Hydrogenation of Ketones

Daniëlle G. I. Petra,[a] Paul C. J. Kamer,[a] Piet W. N. M. van Leeuwen,*[a] Kees Goubitz,[a] Arjen M. Van Loon,[b] Johannes G. de Vries,[c] and Hans E. Schoemaker[a,c]

Keywords: Asymmetric catalysis / Transfer hydrogenation / Ruthenium / Amino alcohol ligands / X-ray structure

The nature of ruthenium-amino alcohol precursors in the catalytic cycle of asymmetric hydrogen transfer reactions was studied using two C_2-symmetrical tetradentate ligands (**1** and **2**) that were synthesised from (nor)ephedrine. The structure of the catalyst precursor was examined through catalysis and NMR experiments. It was shown that the active catalyst contains one ligand per metal, which coordinates in a didentate N,O fashion (**9**). In addition, a $Ru^{II}Cl_2$ complex, in which *N*,*N*′-bis(2-hydroxy-1-methyl-2-phenylethyl)-1,2-diaminoethane (**1**) coordinates through two nitrogen atoms, was structurally characterised by X-ray diffraction (**8**). – Based on the results of this study a series of new amino alcohol ligands was synthesised from easily available starting materials. Optimisation of the amino alcohol ligand structure resulted in the most effective chiral amino alcohol ligand (**5**) so far that is capable of reducing acetophenone at 0 °C with up to 97% ee in the Ru^{II}-catalysed transfer hydrogenation.

Introduction

Transfer hydrogenation of ketones is a highly efficient method for the synthesis of chiral alcohols, owing to low fractional yields of side products and high product yields in high enantiomeric excess. The reaction conditions are relatively mild and the costs are low as a result of the operational simplicity of this method.

As a consequence, much effort has been devoted to the development of new chiral catalysts tailored to the transfer hydrogenation of prochiral ketones. Recently, rapid progress in this area has been made, mainly due to Noyori's work.[1−5] One of the highest catalyst activities so far was observed in ruthenium(II)-catalysed transfer hydrogenation with simple amino alcohols as ligands. Diamines and chiral phosphorus and nitrogen ligands gave rise to lower reaction rates.[5]

Despite these high activities obtained for Ru^{II} amino alcohol catalysts there are only a few reports on the use of simple amino alcohols as chiral ligands.[3,6,7] Amino alcohols are easily accessible and it would seem worthwhile optimising their performance in terms of activity and enantioselectivity by varying the structure. To this end we started to elucidate the nature of ruthenium amino alcohol catalysts. The chiral shielding around the metal centre is highly dependent on the ligand structure and the number of ligand donor atoms that coordinate to the metal.

From the work of Noyori and co-workers it is clear that for their Ru^{II}-TsDPEN [TsDPEN = *N*-(*p*-tolylsulfonyl)-1,2-diphenylethylenediamine] system the active catalyst contains one ligand per metal.[4] However, for weakly coordinating amino alcohol ligands, which give rise to much higher reaction rates in the Ru^{II}-catalysed reduction of ketones using 2-propanol as an H-donor,[5] the ligand to ruthenium ratio has proven to be critical.[6] For these systems the ligand stoichiometry and the mechanism have not been elucidated as yet. In all cases reported so far two equivalents of amino alcohol ligand per ruthenium were used to maintain a high selectivity.

Other mechanistic studies concerning the ligand-to-metal ratio were limited to rhodium catalysts containing didentate nitrogen ligands. Gladiali's pioneering work resulted in a proposed catalytic cycle in which the active complex is a metal hydride complex containing two phenanthroline ligands.[8] In contrast to this, Bernard et al. postulated that the active catalyst is a rhodium complex having only one diamine ligand coordinated to the metal.[9]

In order to gain more insight into the mechanism of hydrogen transfer reactions and especially the influence of the ligand stoichiometry, two potentially tetradentate ligands (**1** and **2**) were synthesised and applied in enantioselective transfer hydrogenation. The preferred mode of coordination (i.e. either two, three or four donating atoms per metal) and the ligand stoichiometry were examined in catalysis. The catalytic results were compared with those of the didentate analogues **3** and **4**. ^{1}H-, ^{13}C-, and ^{15}N-NMR spectroscopy were used to study the catalyst in situ. The molecular structure of a ruthenium(II) catalyst precursor complex containing **1** was determined by X-ray diffraction.

Based on the results of the study towards the preferred mode of coordination of the ligands, a series of new amino alcohol ligands was synthesised to create higher selectivities in the transfer hydrogenation of ketones using ru-

thenium(II) amino alcohol catalysts. Various substituents in the backbone and on the amine functionality were introduced to determine possible factors that influence the enantioselectivity of the reaction. We were able to develop the most effective chiral amino alcohol ligand to date for Ru^{II}-catalysed hydrogen transfer of acetophenone.

Results and Discussion

In order to elucidate the mode of coordination and the ligand stoichiometry in ruthenium(II) amino alcohol-catalysed transfer hydrogenations, ligands **1** and **2** were used (Figure 1). These ligands are suitable for this study as they can coordinate in a tetradentate manner, using two nitrogen and two oxygen donor atoms, in a tridentate manner or in a didentate manner, using either two nitrogen atoms or a nitrogen and an oxygen donor atom. In addition, these tetradentate ligands can possibly form a deeper chiral concave pocket around the metal centre compared to the corresponding didentate ligands, which might result in higher selectivities. Examples in which this effect was found are catalysts for hydrogen transfer reactions containing the chiral bis(oxazolinyl)pyridine ligand (pybox) and the bis(oxazolinyl)amine ligand (ambox).[10][11]

The synthesis of **1** {*N*,*N*′-bis[(1*S*,2*R*)-2-hydroxy-1-methyl-2-phenylethyl]-1,2-diaminoethane} and **2** {*N*,*N*′-bis[(1*S*,2*R*)-2-hydroxy-1-methyl-2-phenylethyl]-1,3-dimethylaminopropane} is analogous to that described by Soai et al.[12]

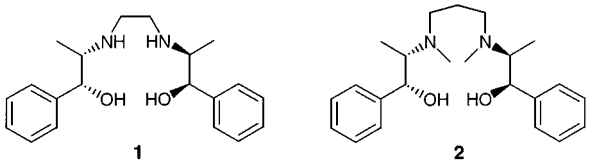

Figure 1. Tetradentate ligands **1** and **2**

The results of the use of catalysts generated in situ from ligands **1** and **2** (Figure 1) and various ruthenium(II) precursors in the reduction of acetophenone (Scheme 1) are depicted in Table 1. In a typical catalysis experiment a solution of ketone (0.1 M in dry 2-propanol), the ruthenium complex ($[RuCl_2(arene)]_2$, 0.5 mol-%), the chiral amino alcohol (1 mol-%) and *t*BuOK (2.5 mol-%) was stirred at room temperature under argon in dry 2-propanol. Conversions and enantioselectivities were monitored during the reaction. At lower conversions (i.e. < 60%) a zero order rate dependency in substrate concentration was found. The enantioselectivity proved to be constant in time for all catalytic reactions described here unless otherwise stated.

The use of **1** in combination with $[RuCl_2(p\text{-cymene})]_2$ and base in propan-2-ol resulted in reduction of acetophenone to (*S*)-phenethyl alcohol in 88% ee at 67% conversion after 44 hours (entry 1, Table 1). Under the same reaction conditions ligand **2** gave rise to 24% conversion and 82% ee after 44 hours (entry 2, Table 1). Both the lower reaction rate and asymmetric induction of **2** can be explained by the fact that at least one primary or secondary amine functionality is essential to obtain high yields and high enantiomeric excess. This has been observed before and Noyori et al. suggested that an NH-moiety in the ligand may promote a cyclic transition state through hydrogen bonding to a ketone substrate.[5]

Table 1. Hydrogen transfer reduction of acetophenone using ligands **1**−**7**[a]

13	complex **8**	1/1	44	78	87	(*R*)

[a] The reaction was carried out at room temperature using a 0.1 M solution (5 mmol) in propan-2-ol. Substrate:$[RuCl_2(p\text{-cymene})]_2$/ligand/*t*BuOK = 200:1:1.1−4:10. − [b] Conversions were determined by GLC analysis. − [c] Determined by capillary GLC analysis using a chiral cycloSil-B column. − [d] The reaction was carried out at 0°C. − [e] Ru = $[RuCl_2(benzene)]_2$. − [f] Ru = $RuCl_2(PPh_3)_3$.

The use of another ruthenium arene complex, the (benzene)ruthenium(II) chloride dimer in combination with amino alcohol **1**, resulted in a large decrease of the enantiomeric excess and in a higher reaction rate (88% conversion and 56% ee, after 44 h; entry 11, Table 1). The increase in reactivity by decreasing steric bulk on the arene has been observed in other systems. As in our case, this is often accompanied by a decrease in enantioselectivity.[3][6] High selectivities have been observed using $RuCl_2(PPh_3)_3$ as a catalyst precursor in combination with tridentate nitrogen ligands.[10][11] This catalyst precursor does not contain an arene moiety and therefore offers additional coordination sites for amino alcohol coordination. Hardly any conversion was observed using this catalyst precursor in combination with ligand **1** (entry 12, Table 1).

In order to study the coordination fashion of ligand **1** during catalysis (i.e. either didentate, tridentate or tetradentate) it was compared to its corresponding didentate analogues (1*R*,2*S*)-(−)-norephedrine (**3**) and (1*R*,2*S*)-(−)-ephedrine (**4**) in the reduction of acetophenone (Figure 4) (see also Takehara et al.).[3] The use of **3** gave rise to a very fast reaction, but a lower selectivity compared to the use of **1** (95% conversion and 77% ee, after 0.5 h; entry 3, Table 1). On using amino alcohol **4**, however, a much higher reaction rate was found compared to the use of **1**, with similar enantioselectivity (91% conversion and 87% ee, after 0.5 h; entry 4, Table 1). These results show that no increase of enantioselectivity is observed on using the tetradentate ligand **1**, which contains additional donor atoms, compared to the use of **4**.

With the aim of resolving the mode of coordination for the tetradentate ligand **1** a series experiments was performed in which the ratio of ligand **1** to ruthenium was varied. When the ligand to ruthenium ratio was changed from two to one half, the initial selectivity of the reaction did not change. However, on using half an equivalent of ligand the enantioselectivity of the reaction dropped to 78% after 44 hours, probably due to catalyst deactivation (entry 6, Table 1). When 1 or 2 equivalents of ligand are in solution the excess of donating atoms of the amino alcohol must stabilise the complex, preventing the formation of black particles of ruthenium. The increasing reaction rate can be explained by the formation of a sterically less hindered bimetallic ruthenium complex containing only one tetradentate ligand that coordinates in a didentate fashion. From these results it is concluded that the active catalyst is most likely a ruthenium complex with one ligand coordinating to the metal in a didentate mode, because catalysis using a ligand stoichiometry of one half results in identical initial enantioselectivities and a higher reaction rate. Thus, half an equivalent of ligand suffices for the control of enantioselectivity, assuming a coordination mode similar to that of ligands **3** and **4** (i.e. coordination through one nitrogen and one oxygen donor atom). The remaining part of the C_2-symmetric molecule merely acts as a large substituent at the nitrogen atom which slows down the reaction and does not further increase the selectivity.

In order to confirm the conclusions we have drawn above, i.e. that ligand **1** prefers a didentate *N,O*-coordination fashion to ruthenium(II), we now describe our attempts to identify two different (1:1) ruthenium−amino alcohol complexes and establish their coordination mode.

When an equimolar mixture of $[\{RuCl_2(\eta^6\text{-}p\text{-cymene})\}_2]$ and **1** was stirred in dichloromethane for one hour at room temperature, the ruthenium(II) complex **8** was isolated and was crystallised from benzene.

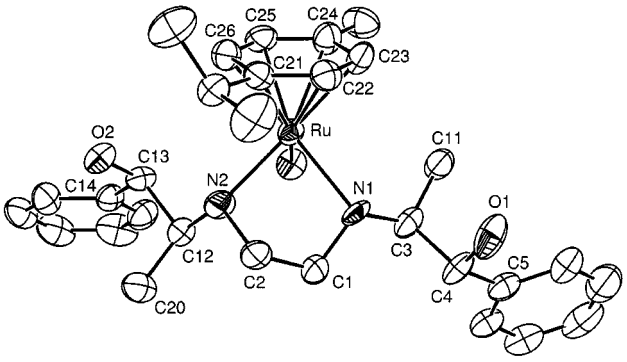

Figure 2. Crystal structure of **8**

The crystals were isolated and characterised by X-ray diffraction. A number of neutral complexes of the type [Ru(arene)Cl(amino−amido ligand)] have been crystallographically characterised.[10] The cationic complex **8** of the type [Ru(arene)Cl(neutral amino−amino ligand)]$^+$ described here contains a neutral amino−amino ligand. The single crystal X-ray analysis indicates that this cationic ruthenium(II) complex has a distorted octahedral coordination environment (see Figure 2). The metal centre is coordinated to two neutral nitrogen atoms, which are involved in a five-membered chelate ring displaying an envelope conformation with C1 and C2. A chloride anion and a *p*-cymene molecule, acting as a neutral six electron donor, complete the coordination sphere of the ruthenium atom. A second chloride anion is present as a noncoordinating counterion. Selected bond lengths and angles are collected in Table 2.

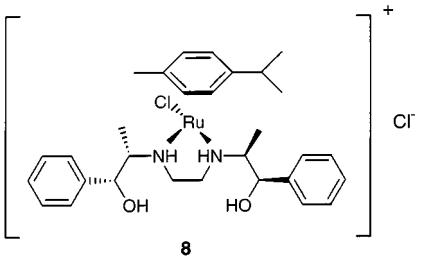

Table 2. Selected bond lengths [Å] and angles [°] for [Ru{*N,N′*-bis[(1*S*,2*R*)-2-hydroxy-1-methyl-2-phenylethyl]-1,2-diaminoethane}{*p*-cymene}Cl]Cl (**8**) (with esd′s in parentheses)

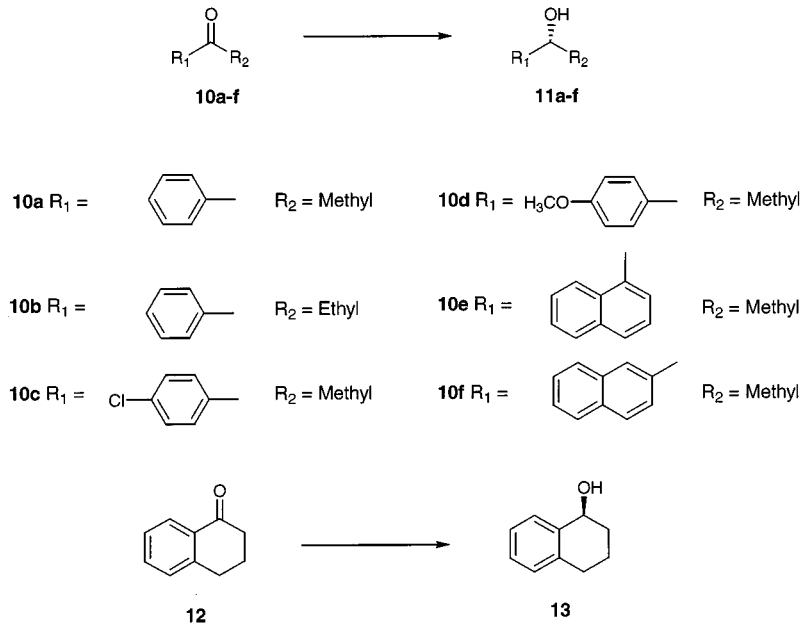
The ruthenium complex **8**, which catalyses the asymmetric transfer hydrogenation of acetophenone in 2-propanol containing *t*BuOK (entry 13, Table 1), is merely a catalyst precursor. Upon addition of base the most acidic protons are eliminated. Due to deprotonation of the OH group, N,O coordination will be preferred to didentate *N,N′* coordination. An unsymmetrical complex with a chiral metal centre is formed.

In order to elucidate the structure of this complex in solution, ^{1}H-NMR and ^{15}N-NMR experiments were performed on the in situ catalyst in CD_3OD. Upon mixing (*p*-cymene)ruthenium(II) chloride dimer and ligand **1**, complex **8** is formed as the major product. All the ^{1}H-NMR signals of the hydrogen atoms near the nitrogen atoms are shifted downfield in comparison to those of the free ligand. The two methyl signals become inequivalent. The NH protons in complex **8** show very slow H, D exchange in CD_3OD; the signal that is visible at $\delta = 6.45$, slowly decreases in size when the compound stands at room temperature in CD_3OD (i.e. to 50% of its original value after 7 days). After two hours at 60°C in CD_3OD the NH signal completely disappears. The ^{15}N-NMR spectrum shows two peaks at $\delta = -357$ and $\delta = -358$, while the free ligand shows a peak at $\delta = -336$. Upon addition of 2 equivalents of base a new complex (**9**) formed (see Figure 3). This complex showed two peaks in the ^{15}N-NMR spectrum at $\delta = -355$ and at $\delta = -343$. The ^{15}N-NMR spectrum did not change upon stepwise cooling to −40°C. In the ^{1}H-NMR spectrum, broadened signals were observed, which suggests fluxional behaviour. Under these basic conditions no NH

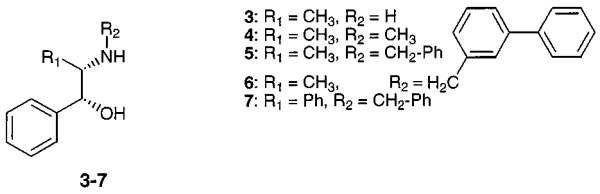
protons were observed for this compound in CD_3OD. It is concluded that in complex **9** one nitrogen atom coordinates to the ruthenium atom as in complex **8**; the chemical shift that is found at $\delta = -355$ is typical for a coordinated nitrogen atom.[13] The chemical shift of the second nitrogen atom is characteristic of a noncoordinated amine moiety; the position of the ^{15}N signal at $\delta = -343$ is comparable to the nitrogen resonance of $\delta = -336$ for the free ligand.[14] The presence of the hydride in **9** was proven by ^1H-NMR measurements in deuterated benzene, which showed a hydride signal at $\delta = -5.50$. In addition, the molecular formula of **9** was confirmed by electrospray mass spectrometry, which showed a signal for M^+ at 564.230 (calcd. 564.228).

8



9

Figure 3. Ruthenium amino alcohol complexes **8** and **9**



Since it now seems clear that a didentate coordination of amino alcohol ligands is preferred to either tridentate or tetradentate coordination, the design of new amino alcohols as ligands to create high selectivities should be directed towards didentate ligands. From Table 1 it can be seen that the selectivity of the reaction is influenced by the substitution pattern on the nitrogen (cf. **1**, **3**, and **4**). It is shown that the secondary amine gives rise to better selectivities than the corresponding primary amine or tertiary amine without decrease of reaction rate. In contrast, Palmer et al. reported that the substitution of the primary amine functionality with a methyl group resulted in a decrease of both the reaction rate and the enantioselectivity, when (1*R*,2*S*)-(+)-*cis*-1-amino-2-indanol was used as a ligand.[6]

In order to optimise the amino alcohol ligand structure both the substituents in the backbone and the substituents on the nitrogen atom were varied. Amino alcohols **5**, **6**, and **7** were synthesised in one step by reacting either (1*R*,2*S*)-(−)-2-aminodiphenyl ethanol or (1*R*,2*S*)-(−)-norephedrine with benzyl bromide and/or 3-phenylbenzyl bromide, respectively, under slightly basic conditions (see Figure 4). The effect of a bulky substituent on the nitrogen atom was assessed by using amino alcohols **5** and **6** as ligands in catalysis (Figure 4). The use of **5** in combination with $[\{RuCl_2(p\text{-cymene})\}]_2$ under the standard conditions gave an excellent result (95% ee at 88% conversion after 1 h; entry 7, Table 1). The selectivity could be further improved by lowering the reaction temperature to 0°C. The beneficial temperature effect resulted in the highest enantioselectivity observed so far in the Ru^{II} amino alcohol-catalysed reduction of acetophenone, i.e. 97% (entry 8, Table 1). A longer reaction time was required to reach high conversion. Changing the substituent from a benzyl to a 3-phenylbenzyl group did not improve the results any further. Both the conversion and the enantioselectivity decreased (91% ee at 64% conversion after 2 hours; entry 9, Table 1). Ligand **7** was synthesised to investigate the effect of an additional bulky

Scheme 1. Asymmetric transfer hydrogenation of ketones **10a**−**12**

substituent in the carbon backbone. Changing the substituent at the 1-position from a methyl to a phenyl group did not result in higher enantioselectivities (entry 10, Table 1). The phenyl substituent is clearly too bulky because the conversion dropped drastically.

3-7

Figure 4. Amino alcohol ligands **3**−**7**

A variety of other substrates could also be transformed to the corresponding secondary alcohols with high enantiomeric purity, using ligand **5** under optimised conditions (Table 3, Scheme 1). Changing the electronic and steric properties of the substrate did not clearly affect the enantioselective outcome of the reaction. In these catalytic experiments only one equivalent of ligand was required to obtain high enantioselectivities.

Table 3. Hydrogen transfer reduction of ketones **10a**−**12** using ligand **5**[a]

Entry	Ketone	*t*[h]	Conv. [%] of ketone[b]	ee [%] alcohol[c]	Confign.

Conclusion

In the ruthenium-catalysed transfer hydrogenation of prochiral ketones using tetradentate ligand **1** the amino alcohol prefers a didentate coordination fashion, as was shown by catalysis experiments (see Table 1) and NMR experiments. The extra donor atoms in the ligand do not enhance the selectivity of the reaction but only give rise to lower reaction rates. In contrast to results in other reports, a ligand-to-metal ratio of one is sufficient to maintain selectivity.

The best amino alcohol ligand structure turned out to be NH-benzyl-(1*R*,2*S*)-(−)-norephedrine (**5**), which proved to be an excellent ligand for the control of asymmetric ruthenium-catalysed transfer hydrogenation of prochiral ketones.

Experimental Section

General Remarks: Reactions were performed under an atmosphere of argon in flame-dried Schlenk flasks and using anhydrous solvents. Propan-2-ol was freshly distilled from CaH_2 prior to use. − Column chromatography was performed with silica gel 60, 70−230 mesh ASTM (Merck). Thin layer chromatography was carried out on TLC aluminium foil, silica gel 60 G/UV_{254} and spots were detected with UV light or iodine vapour. − Melting points were taken on a Gallenkamp melting point apparatus and are uncorrected. − Optical rotations were measured on a Perkin−Elmer 241 automatic polarimeter. − IR spectra were recorded on a BioRad FT-IR (FTS-7) spectrophotometer. − ^{1}H- and ^{13}C-NMR spectra were recorded on a Bruker AMX 300 spectrometer. Chemical shifts are on the δ scale (ppm) relative to TMS as internal standard. ^{15}N-NMR spectra were recorded on a Bruker DRX 300 instrument. Chemical shifts are relative to nitromethane as external standard. − Mass spectra were recorded on a JEOL JMS SX/SX102A four sector mass spectrometer, coupled to a JEOL MS-MP7000 data system. − Microanalyses (C, H, N) were performed on an Elementar Vario EL apparatus (Foss Electric). − Gas chromatography was performed using a Carlo Erba GC 6000 Vega 2 instrument, 25 m column: CycloSil-B (chiral) and a Carlo Erba HRGC Mega 2 instrument, 25 m column: BPX 35 (SGE) (achiral). HPLC chromatography was performed using a Gilson HPLC apparatus and a Chiracel OD column.

***N*,*N*′-Bis[(1*S*,2*R*)-2-hydroxy-1-methyl-2-phenylethyl]-1,2-diaminoethane (1):** Compound **1** was synthesised in analogy with the procedure of Soai et al.[12] 1,2-Dibromoethane (3.1 g, 16.5 mmol) was added to (1*R*,2*S*)-(−)-norephedrine (5.0 g, 33 mmol) and finely powdered Na_2CO_3 (7.0 g, 66 mmol) in ethanol (25 mL). The mixture was heated at reflux for 20 h. The salts that formed were filtered off and the solvent was evaporated in vacuo. The product was extracted with dichloromethane, the organic phases were dried with Na_2SO_4 and evaporated to dryness. After dissolving the residue in a minimal amount of ethanol and addition of HCl, a white precipitate formed, which was collected by filtration and recrystallised from water (40 mL) with a few drops of HCl. The HCl salt was dissolved in water and 0.1 M NaOH was added until pH = 12 was reached. The mixture was extracted three times with diethyl ether. The organic layers were combined and evaporated to dryness. Yield: 4.4 g (81%). M.p.: 108−110°C (free amine). − IR (neat): $\tilde{\nu}$ = 3387 cm^{-1}, 2976, 2927, 1452. − ^{1}H NMR (CD_3OD): δ = 0.94 (d, 6 H, *J* = 6.4 Hz, CH_3), 2.62 (m, 2 H, C*H*NH), 2.75 (m, 4 H, CH_2), 4.61 (d, 2 H, *J* = 4.8 Hz, C*H*OH), 7.21−7.34 (m, 10 H, C_6H_5). − ^{13}C NMR (CD_3OD): δ = 14.92 (*C*H$_3$), 59.85 (*C*HNH), 47.25 (*C*H$_2$), 76.17 (*C*HOH), 127.55 [*C*H$_{arom}$ (*o*)], 128.32 [CH$_{arom}$ (*p*)], 129.26 [*C*H$_{arom}$ (*m*)], 144.07 (*C*$_q$). − ^{1}H{^{15}N} NMR (CD_3OD): δ = −336. − HRMS (FAB$^+$): *m*/*z* calcd. for $C_{20}H_{29}N_2O_2$ [M + H]$^+$: 329.2229; found 329.2227. − $C_{20}H_{28}N_2O_2$ (328.458): calcd. C 73.14, H 8.59, N 8.53; found C 73.12, H 8.56, N 7.96. − $[\alpha]_D^{20}$ = +9.6 (*c* = 0.8, EtOH).

***N*,*N*′-Bis[(1*S*,2*R*)-2-hydroxy-1-methyl-2-phenylethyl]-1,3-dimethylaminopropane (2):** Compound **2** was prepared from (1*R*,2*S*)-(−)-ephedrine according to a literature procedure[12] and in an analogous way to **1**. Yield: 2.6 g (78%). IR (neat, HCl salt): $\tilde{\nu}$ = 3407 cm^{-1}, 2978, 2940, 2800, 1451, 754, 700. − ^{1}H NMR (CD_3OD): δ = 0.88 (d, 6 H, *J* = 6.8 Hz, CH_3), 1.69 (dt, 2 H, *J* = 6.7 Hz, *J* = 6.8 Hz, CH_2), 2.31 (s, 6 H, NCH_3), 2.41, 2.63 (each dt, 4 H, *J* = 6.4 Hz, *J* = 6.4 Hz, CH_2), 2.77 (dq, 2 H, *J* = 3.1 Hz, *J* = 6.8 Hz, C*H*N), 4.95 (d, 2 H, *J* = 3.6 Hz, C*H*OH), 7.20−7.32 (m, 10 H, C_6H_5). − ^{13}C NMR ($CDCl_3$): δ = 8.08 (*C*H$_3$), 23.59 (N*C*H$_3$), 38.65 (*C*HNH), 52.05, 64.81 (*C*H$_2$), 73.15 (*C*HOH), 126.07 [*C*H$_{arom}$ (*o*)],

C 57.56, H 7.77, N 5.84; found C 57.52, H 8.04, N 5.78. − $[\alpha]_D^{20}$ (HCl salt) = +5 (*c* = 0.6, EtOH).

NH-Benzyl-(1*R*,2*S*)-norephedrine (5): K_2CO_3 (234 mg, 1.70 mmol) was added to (1*R*,2*S*)-(−)-norephedrine (250 mg, 1.65 mmol) in acetonitrile at room temperature. At 0°C, benzyl bromide (171 mL, 1.65 mmol) was added and the resulting mixture was stirred for 16 h at 60°C. The reaction mixture was filtered through Celite and the filtrate evaporated to dryness. The crude compound was purified by column chromatography (silica gel 60, eluent: ethyl acetate, R_f value: 0.33). Yield: 200 mg (50%), colourless oil. − IR (neat): $\tilde{\nu}$ = 3334 cm^{-1}, 3062, 3028, 2973, 2871, 1603, 1494, 1452, 744, 700. − ^{1}H NMR ($CDCl_3$): δ = 0.87 (d, 3 H, *J* = 6.6 Hz, C*H*$_3$), 2.48 (s, 1 H, O*H*), 3.02 (dq, 1 H, *J* = 3.8 Hz, *J* = 6.6 Hz, C*H*NH), 3.90 (s, 2 H, CH_2), 4.82 (d, 1 H, *J* = 3.8 Hz, C*H*OH), 7.33 (m, 5 H, C_6H_5). − ^{13}C NMR ($CDCl_3$): δ = 14.81 (*C*H$_3$), 51.44 (*C*H$_2$), 58.01, 73.57 (2 *C*H), 126.39, 127.27, 127.36, 128.31, 128.76 (10 CH_{arom}), 140.33, 141.77 (2 C_q). − HRMS (FAB$^+$): *m*/*z* calcd. for $C_{16}H_{20}NO$ [M + H]$^+$: 242.1545; found 242.1545. − $C_{16}H_{19}NO{\cdot}0.5H_2O$ (250.344): calcd. C 76.77, H 8.05, N 5.59; found C 76.80, H 7.94, N 5.58. − $[\alpha]_D^{20}$ = +16 (*c* = 0.70, EtOH).

NH-3-Phenylbenzyl-(1*R*,2*S*)-norephedrine (6): This compound was synthesised analogously to **5**. The crude compound was purified by column chromatography (silica gel 60, eluent: ethyl acetate, R_f value: 0.29). Yield: 620 mg (61%), yellow oil. − IR (neat): $\tilde{\nu}$ = 3397 cm^{-1}, 3059, 3031, 2974, 2872, 1601, 1480, 1453, 757, 738, 701. − ^{1}H NMR ($CDCl_3$): δ = 0.95 (d, 3 H, *J* = 5.5 Hz, C*H*$_3$), 2.53 (s, 2 H, N*H*, O*H*), 3.05 (dq, 1 H, *J* = 3.9 Hz, *J* = 5.5 Hz, C*H*NH), 3.96 (s, 2 H, CH_2), 4.84 (d, 1 H, *J* = 3.9 Hz, C*H*OH), 7.33−7.69 (m, 9 H, C_6H_5). − ^{13}C NMR ($CDCl_3$): δ = 14.48 (*C*H$_3$), 51.12 (*C*H$_2$), 57.71, 73.24 (2 *C*H), 125.85, 126.01, 126.76, 126.86, 126.93, 127.02, 127.21, 127.95, 128.68, 128.82 (*C*H_{arom}), 140.43, 140.87, 141.31, 141.35 (4 C_q). − HRMS (FAB$^+$): *m*/*z* calcd. for $C_{22}H_{24}NO$ [M + 1]$^+$: 318.1858; found 318.1850. − $[\alpha]_D^{20}$ = −17 (*c* = 1.75, $CHCl_3$).

(1*R*,2*S*)-2-(Benzylamino)-1,2-diphenylethanol (7): This compound was synthesised analogously to **5**. The crude compound was purified by crystallisation from ethyl acetate/hexane. Yield: 760 mg (59%), white solid. M.p.: 154−155°C. − IR ($CHCl_3$): $\tilde{\nu}$ = 3020 cm^{-1}, 2977, 1524, 1424, 1453, 734, 670. − ^{1}H NMR ($CDCl_3$): δ = 3.13 (s, 2 H, N*H*, O*H*), 3.60 (d, 1 H, *J* = 13.4 Hz CH_2), 3.82 (d, 1 H, *J* = 13.4 Hz CH_2), 3.97 (d, 1 H, *J* = 5.3 Hz, C*H*OH), 5.03 (d, 1 H, *J* = 5.3 Hz, C*H*NH), 7.11−7.38 (m, 15 H, C_6H_5). − ^{13}C NMR ($CDCl_3$): δ = 50.57 (*C*H$_2$), 67.57, 75.76 (2 *C*H), 126.56, 127.26, 127.48, 127.73, 127.80, 128.08, 128.30, 128.44 (*C*H_{arom}), 137.14, 137.95, 139.96 (3 C_q). − HRMS (FAB$^+$): *m*/*z* calcd. for $C_{21}H_{22}NO$ [M + 1]$^+$: 304.1701; found 304.1696. − $C_{21}H_{21}NO$ (303.408): calcd. C 83.13, H 6.98, N 4.62; found C 82.10, H 7.01, N 4.39. − $[\alpha]_D^{20}$ = −229 (*c* = 1.00, $CHCl_3$).

[Ru{*N*,*N*′-bis[(1*R*,2*S*)-2-hydroxy-1-methyl-2-phenylethyl]-1,2-diaminoethane}{*p*-cymene}Cl]Cl (8): Complex **8** was prepared in analogy with a literature procedure.[15] To a solution of [{$RuCl_2(\eta^6$-*p*-cymene)}$_2$] (100 mg, 0.16 mmol) in CH_2Cl_2 (5 mL) was added *N*,*N*′-bis[(1*S*,2*R*)-2-hydroxy-1-methyl-2-phenylethyl]-1,2-diaminoethane (**1**) (108 mg, 0.33 mmol). After stirring the reaction mixture for 1 h at room temperature the solvent was removed in vacuo. The orange solid was washed twice with diethyl ether (10 mL) and dried in vacuo. Recrystallisation from chloroform/pentane afforded yellow needle-shaped crystals. − IR (neat): $\tilde{\nu}$ = 3287 cm^{-1}, 2959, 2927, 2855, 1452, 1216, 758. − ^{1}H NMR (CD_3OD): δ = 0.90 (d, 3 H, *J* = 6.6 Hz, C*H*$_3$), 1.06 (d, 3 H, *J* = 6.8 Hz, C*H*$_3$), 1.24, 1.25 [each d, 6 H, *J* = 6.9 Hz, CH(C*H*$_3$)$_2$], 2.02 (s, 3 H, C*H*$_3$ in *p*-cymene), 2.48 [m, 1 H, C*H*(CH$_3$)$_2$], 2.79 (m, 4 H, CH_2), 5.17 (d, 2 H, *J* = 2.5 Hz, C*H*), 5.41 (broad s, 2 H, C*H*), 5.56, 5.65, 5.75, 5.77 (each d, 4 H, *J* = 5.9 Hz, CH_{arom} in *p*-cymene), 6.45 (broad s, 2 H, N*H*), 7.13−7.46 (m, 10 H, C_6H_5). − ^{13}C NMR (CD_3OD): δ = 12.55, 18.61, 20.09, 25.11, 25.61 (5 *C*H$_3$), 53.57 (*C*H$_2$), 34.68, 60.83, 64.00, 72.96, 77.90 (5 *C*H), 118.34 (C_q), 129.26, 129.56, 129.60, 129.90, 130.74, 130.87 (8 *C*H_{arom}), 131.81, 132.00 (2 C_q). − ^{15}N{^{1}H} NMR (CD_3OD): δ = −357, −358. − HRMS (FAB$^+$): *m*/*z* calcd. for $C_{30}H_{42}ClN_2O_2Ru$ [M$^+$]: 599.1972; found 599.1979. − $C_{30}H_{43}Cl_3N_2O_2$ (570.048): calcd. C 53.69, H 6.46, N 4.17; found C 53.07, H 6.80, N 3.71.

Enantioselective Reduction of Ketones (General Procedure for [ketone]/[Ru] = 200): A solution of (*p*-cymene)ruthenium(II) chloride dimer (7.7 mg, 0.0125 mmol) and the amino alcohol as a ligand (0.030 mmol) in dry propan-2-ol (5 mL) was heated at 80°C for 1 h under argon. After cooling the mixture to room temperature, it was diluted with propan-2-ol (43.75 mL) and *t*BuOK (1.25 mL, 0.1M in propan-2-ol, 0.125 mmol) was added. The resulting solution was stirred for 30 min before the ketone (5 mmol) was added. The reaction was performed at room temperature under argon for the time indicated and monitored by GC and/or HPLC.

X-ray Structure Analysis of 8: A crystal with the approximate dimensions 0.05 × 0.08 × 0.80 mm was used for data collection on an Enraf−Nonius CAD-4 diffractometer with graphite-monochromated Cu-K_α radiation and ω-2θ scan. A total of 3449 unique reflections was measured within the range −13 < *h* < 12, 0 < *k* < 33, 0 < *l* < 17. Of these, 2964 were above significance level of 5σ(*F*) and were treated as observed. The range of (sinθ)/λ was 0.032−0.625 Å (2.9 < θ < 74.6°). Two reference reflections ([1 2 0], [0 0 10]) were measured hourly and showed no decrease during the 76 h collecting time. Unit-cell parameters were refined by a least square fitting

Table 4. Selected crystallographic data of [Ru{*N*,*N*′-bis[(1*R*,2*S*)-2-hydroxy-1-methyl-2-phenylethyl]-1,2-diaminoethane}{*p*-cymene}Cl]Cl (**8**)

Crystal Data		Data Collection

μ(Cu-K_α) [cm^{-1}]	61.6	$(\Delta/\sigma)_{max}$	0.30

procedure using 23 reflections with $80 < 2\theta < 84$. Corrections for Lorentz and polarisation effects were applied. Absorption correction was performed with the program PLATON,[16] following the method of North et al. using Ψ-scans of three reflections, with coefficients in the range of 0.484−0.989.[17] The structure was solved by the PATTY option of the DIRDIF96 program system.[18] After isotopic refinement a ΔF synthesis revealed one peak, which was interpreted as a chloride ion. The hydrogen atoms were calculated. The hydrogen atoms on the alcohol and amine groups were located by Fourier synthesis. Full matrix least-squares refinement on F, anisotropic for the non-hydrogen atoms and isotropic for the hydrogen atoms restraining the latter in such a way that the distance to their carrier remained constant at approximately 1.0 Å, converged to $R = 0.057$, $R_w = 0.063$, $(\Delta/\sigma)\text{max} = 0.30$, $S = 0.93$. A weighting scheme $w = \{10 + 0.01 \times [\sigma(F\text{obs})]^2 + 0.0001/[\sigma(F\text{obs})]\}^{-1}$ was used. The secondary isotropic extinction coefficient refined to Ext = 0.015(6).[19][20] The absolute structure was determined by refining the inverse structure, which converged to $R = 0.068$, $R_w = 0.073$, thus confirming the correct enantiomer. A final difference Fourier map revealed a residual electron density between −1.7 and 1.9 eÅ^{-3} in the vicinity of the heavy atoms. Scattering factors were taken from Cromer and Mann; *International Tables for X-ray Crystallography*.[21] The anomalous scattering of Ru and Cl was taken into account.[22] All calculations were performed with XTAL, unless otherwise stated.[23]

Acknowledgments

We thank the Innovation Oriented Research Programme (IOP-Catalysis) for their financial support of this research. Solvay Pharmaceuticals is acknowledged for the gift of 3-phenylbenzyl bromide. Jan Fraanje is gratefully acknowledged for measuring the crystallographic data. Jan Meine Ernsting is kindly acknowledged for measuring the ^{15}N-NMR data. We are grateful to Wim G. J. de Lange for his help with the HPLC measurements. We thank Murat Ünal for his experimental efforts.

Pairing Energy Effects in Cyanide Complexes of $CpCr^{III}$

Rinaldo Poli*[a] and Kevin M. Smith[a]

Keywords: Chromium / Cyanides / Density-functional calculation / Electronic structure / Spin state

The steric and electronic factors responsible for the reactivity differences between CN and Cl complexes of $CpCr^{III}$ were examined by DFT/B3LYP computational techniques. The energy difference between quadruplet and doublet $[CpCr(CN)_2(PH_3)]$, ΔE_{D-Q}, was calculated to be 21.2 kcal mol^{-1} with the LanL2DZ basis set. Although the high-spin configuration is still the ground state for the cyanide complex, the energy gap is 8.7 kcal mol^{-1} less than that found for the corresponding chloride species. The difference between quadruplet $[CpCr(CN)_2(PH_3)]$ and doublet $[CpCr(CN)_2(PH_3)_2]$ less free PH_3, ΔE_{Cr-P}, is also smaller than for the Cl system. The components of ΔE_{Cr-P} for CN and Cl were analyzed by calculating energies at fixed geometries in both spin states, which indicated that the influence of the cyanide group on the pairing energy was more important than changes in Cr–PH_3 bond strength or steric effects.

Introduction

The study of transition metal compounds containing cyanide ligands has experienced a recent resurgence due in large part to the ability of these ligands to form M−CN−M′ bridges.[1] Extending these bridges in one, two, or three dimensions results in novel materials often possessing microporous structures and interesting magnetic properties.[2] As an alternative to homoleptic cyanometalates, anionic $[CpM(CN)_n]^-$ complexes have also been investigated in which the Cp or Cp* ligand serves to enhance the overall inertness of the complex as well as to limit polymerization.[3][4]

We have recently examined the reactivity of cyanide complexes of $CpCr^{III}$ as part of our ongoing investigation of spin-state effects in organometallic chemistry.[5] Cyanide ligands confer a greater stability on the resulting highly coordinated monometallic compounds than the halide ligands on the corresponding, relatively unsaturated analogues. For example, in the case of complexes of $CpMo^{IV}$, the cyanometalate exists as the 18-electron dianion,[6] $[CpMo(CN)_5]^{2-}$, while with the chloride ion the 16-electron monoanion,[7] $[CpMoCl_4]^-$, is observed. The same trend between CN and Cl ligation is observed for $CpCr^{III}$ complexes.[8] For cyanide, equilibrium concentrations of the 17-electron spin-doublet $[CpCrL_4]$ species $[CpCr(CN)_2(PR_3)_2]$ and $[CpCr(CN)_4]^{2-}$ have been detected in solution by ESR spectroscopy,[9] whereas similar 17-electron species were *not* spectroscopically observed for the analogous chloride complex.[10] A kinetic and theoretical investigation of the PR_3 exchange reactions for $[CpCrCl_2(PR_3)]$ complexes demonstrated that, although exchange proceeds by an associative pathway, the reaction proceeds solely on the quadruplet spin hypersurface by an S_N2-type mechanism.[11] Previously, density functional theory (DFT) calculations have been used to compare the relative energies of $[CpCrX_2(PH_3)_n]$ (X = Cl, CH_3; n = 1, 2) and $[CpMoCl_2(PH_3)_n]$ systems in the doublet and quadruplet spin states.[12] In this study, DFT calculations were used to determine the relative importance of the possible factors which contribute to the anomalous stability of the 17-electron doublet CN species relative to the Cl analogues. Possible factors which we have previously considered include: (a) steric considerations (since CN is smaller than Cl), (b) the Cr−L bond strength (the relative electron-withdrawing ability of CN could increase the relative strength of the additional Cr−PR_3 bond in the 17-electron species), (c) changes in ΔE_{D-Q} (by modifying the orbital splitting and/or the pairing energy, CN could influence the relative stabilities of the doublet and quadruplet spin states).[9]

Results and Discussion

Optimized LanL2DZ Geometries and Energies

The geometries of doublet $[CpCr(CN)_2(PH_3)_2]$, and doublet and quadruplet $[CpCr(CN)_2(PH_3)]$ were optimized in the C_s symmetry with DFT using the three-parameter form of the Becke, Lee, Yang and Parr functional (B3LYP)[13a] and the LanL2DZ basis set.[13b−d] The bond lengths and angles are shown in Table 1. A comparison of the two 15-electron monophosphane compounds reveals that the doublet complex has slightly shorter bond lengths and deviates further from an idealized three-legged piano-stool structure.[14] The relative difference between the two geometries is comparatively small and is much less pronounced than the difference between doublet and quadruplet $[CpCrCl_2(PH_3)]$.[11,12b]

The relative energies calculated for the $CpCr^{III}$ cyanide compounds are depicted in Figure 1. As expected, based on 15-electron $CpCr^{III}$ monophosphane compounds containing halide or alkyl groups,[15] the quadruplet state is favored over the doublet. In the present case, the high-spin configuration is 21.2 kcal mol^{-1} more stable than the ΔE_{D-Q} value

of 29.9 kcal mol^{-1} previously calculated for $[CpCrCl_2(PH_3)]$ with the same functional and basis set.[11] Similar differences between cyanide and chloride complexes are observed when comparing the energy of doublet $[CpCrX_2(PH_3)_2]$ to the sum of quadruplet $[CpCrX_2(PH_3)]$ and free PH_3. This energy difference, labelled ΔE_{Cr-P} in Figure 1, provides an indication of how readily the quadruplet species will accommodate another *phosphane* ligand. In qualitative agreement with experimental results, ΔE_{Cr-P} is smaller for X = CN (10.3 kcal mol^{-1}) than for X = Cl (ΔE_{Cr-P} = 21.2 kcal mol^{-1}).

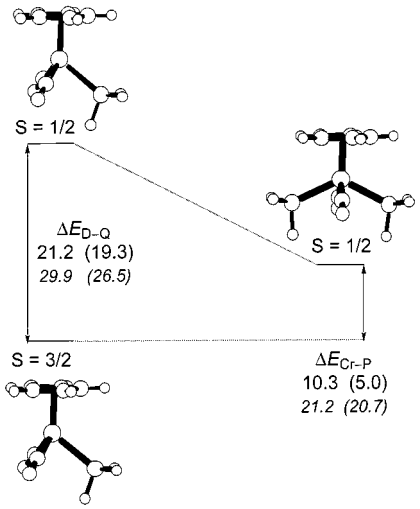

Figure 1. Relative energies of doublet and quadruplet $[CpCr(CN)_2(PH_3)_n]$ (n = 1, 2); energies calculated at the B3LYP/LanL2DZ level of theory, with B3LYP/6−311+G(2d,2p) values indicated in parentheses, and the corresponding $[CpCrCl_2(PH_3)_n]$ energies in italics

Larger Basis Set Calculations

Recent work with $[CpCo(PH_3)_n]$ complexes (n = 1, 2) has showed the importance of the size of the basis set on $[ML_n]$ ligand dissociation energies.[16] Smaller basis sets tend to underestimate metal−ligand bond strengths, thereby causing the relative stability of unsaturated compounds to be overstated. To account for this effect, the energies of the $[CpCr(CN)_2(PH_3)_n]$ compounds optimized at the B3LYP/LanL2DZ level were recalculated with the larger 6−311+G(2d,2p) basis set; the resulting energies are indicated in parentheses in Figure 1. The energy difference between the quadruplet and doublet 15-electron compounds decreased slightly to 19.3 kcal mol^{-1}, and the expected decrease in ΔE_{Cr-P} was also observed, from 10.3 to 5.0 kcal mol^{-1}. For comparison, the B3LYP/LanL2DZ geometries previously obtained for $[CpCrCl_2(PH_3)_n]$ were used to recalculate their energies at the B3LYP/6−311+G(2d,2p) level, and the resulting values are also displayed in Figure 1.

Fixed Geometry Calculations

In order to analyze the various components that make up ΔE_{Cr-P}, single-point calculations were performed at the B3LYP/LanL2DZ level as illustrated in Figure 2. One PH_3 ligand was removed from the optimized structure of doublet $[CpCr(CN)_2(PH_3)_2]$ without altering any of the other structural parameters. The single-point calculations on these complexes with one or three unpaired electrons yield energies for the doublet-fixed and quadruplet-fixed complexes, respectively, as indicated in Table 2. The Bond Energy Term (BET) is equal to the difference between the 17-electron doublet-optimized and 15-electron doublet-fixed structures plus free PH_3, and provides an indication of the $Cr-PH_3$ bond strength without additional factors due to spin-state change. Since the doublet-fixed and quadruplet-fixed energies are based on exactly the same geometry, the difference in energy between these species reflects the Pairing Energy (PE). The Relaxation Energy (RE), obtained from the difference between quadruplet-fixed and quadruplet-optimized energies, accounts for the reorganization required for the 15-electron species to accommodate an additional phosphane ligand, and is directly related to the steric bulk of the adjacent cyanide ligands. These energies were also calculated for the chloride species, and the values obtained are collected in Table 2.

Direct comparison of the factors that contribute to ΔE_{Cr-P} for the two $[CpCrX_2(PH_3)_n]$ systems helps identify the ligand properties responsible for the observed experimental differences between the cyanide and chloride compounds. The BET is only slightly greater for X = CN than for X = Cl, a variation which might be attributable to the

different electron-withdrawing capacity of the two X ligands which affects the ability of the metal center to accommodate the strong σ-donor phosphane ligand. The anticipated difference in steric requirements for CN vs. Cl apparently does not play an appreciable role, since the RE is roughly the same in each case. The key factor seems to be the ability of the cyanide ligand to facilitate the electron pairing required to cross over from the quadruplet-spin to the doublet-spin potential energy surface, as reflected in the PE which is −17.1 kcal mol^{-1} for X = CN in contrast to −25.5 kcal mol^{-1} for X = Cl. The same trend is seen in the values obtained for ΔE_{D-Q} in the two systems.

The relative energies of the frontier orbitals for the $[CpCrX_2(PH_3)]$ (X = CN, Cl) fixed-doublet and fixed-quadruplet species are shown in Figure 3. While it is imprudent to assign too much physical significance to the Kohn-Sham orbitals arising from the current DFT calculations,[17] the qualitative trends in orbital energies appear to support our interpretation. The significantly greater energy gap for X = CN than for X = Cl between the highest and lowest energy frontier orbitals for both spin states accounts for the enhanced stability of the doublet spin-state for the cyanide complex. As well as influencing the orbital splitting, the CN group may also favor the doublet species by decreasing the pairing energy, consistent with the known large nephelauxetic effect of the cyanide ligand.[18]

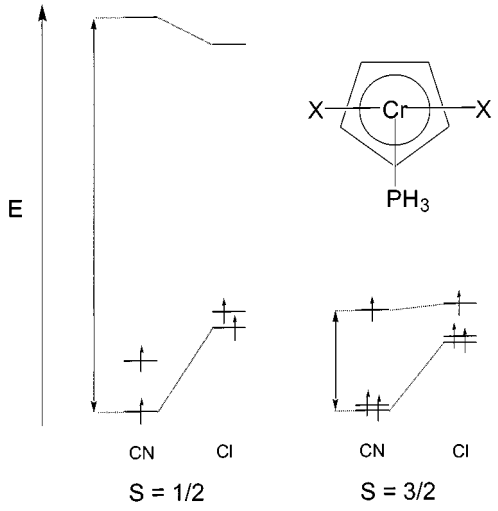

Figure 3. Orbital energies (α orbitals) and occupancies of fixed geometry $[CpCrX_2(PH_3)]$ (X = CN, Cl) species in doublet and quadruplet spin states

Conclusions

Several possible explanations were initially forwarded to rationalize the observation of $[CpCr(CN)_2(PR_3)_2]$ complexes by EPR although the corresponding Cl complexes were not detected. Calculations at the DFT/B3LYP level indicate that the steric differences and variation in Cr−P bond strength are not adequate to account for this discrepancy. The observed differences are best explained by the relative ability of the CN group to encourage spin pairing, as demonstrated by the smaller ΔE_{D-Q} than in the chloride system for both fixed and optimized geometries.

Experimental Section

General Remarks: All calculations were performed with GAUSSIAN 94[19] on an SGI Origin 200 workstation. The geometries of the $[CpCrX_2(PH_3)_2]$ and $[CpCrX_2(PH_3)]$ species and free PH_3 were optimized with B3LYP,[13a] a DFT type of calculation, employing the LanL2DZ basis set. The LanL2DZ basis set includes both Dunning and Hay's D95 sets for H and C and the core potential sets of Hay and Wadt for the heavy atoms.[13b–d] Electrons outside the core were all those for H and C, the 3s and 3p electrons for P, and the 3s, 3p, 3d and 4s electrons for Cr. All geometries were optimized at the B3LYP/LanL2DZ level with imposed C_s symmetry. The B3LYP energy calculations were performed separately with both the LanL2DZ basis set and the larger 6−311+G(2d,2p) basis set, which has two sets of polarization functions on all atoms including two f-sets on the Cr, and also diffuse functions.

The mean value of the first-order electronic wavefunction, which is not an exact eigenstate of S^2 for unrestricted calculations on the open shell systems, was considered suitable for unambiguous identification of the spin state. Spin contamination was carefully monitored and the value of $<S^2>$ for the unrestricted B3LYP (UB3LYP) calculations on the $[CpCrX_2(PH_3)_n]$ species indicated minor

spin contamination in most cases. With the exception of doublet $[CpCr(CN)_2(PH_3)]$, $<S^2>$ was in the range of 0.7651 to 0.7783 for doublet species, and 3.8196 to 3.8692 for quadruplets. As previously observed for doublet $[CpCr(CH_3)_2(PH_3)]$,[12b] the 15-electron doublet cyanide complex exhibited anomalously large $<S^2>$ values: 1.7257 to 1.5558 for fixed and optimized geometries with both basis sets. The energies shown in the Results and Discussion section correspond to UB3LYP calculations, and the frontier orbital energies are those of the occupied (α) orbitals.

Homogeneous and Supported Copper Complexes of Cyclic and Open-Chain Polynitrogenated Ligands as Catalysts of Cyclopropanation Reactions

F. Adrián,[a] M. I. Burguete,[a] J. M. Fraile,[b] J. I. García,[b] J. García,[b] E. García-España,[c] S. V. Luis,*[a] J. A. Mayoral,*[b] A. J. Royo,[a,b] and M. C. Sánchez[b]

Keywords: Cyclopropanation / Copper / N ligands / Macrocycles / Supported catalysts

Cu^{I} and Cu^{II} complexes of cyclic and open-chain polyaza compounds have been tested as catalysts in the benchmark cyclopropanation reaction of styrene with ethyl diazoacetate. In general, only small amounts of copper are needed to promote the reaction. The catalytic activity depends on the structure of the ligand, e.g. amine–amides are more efficient than polyamines, and on the oxidation state of copper, Cu^{II} being more active than Cu^{I}. Given that Cu^{I} is the active species, these changes of behavior must be related to the stabilities of the complexes. The nature of the counterion also has a noticeable influence on the catalytic activity, the role of which is discussed. XAS measurements suggest the formation of oligomeric species. Some of the chiral ligands lead to small enantiomeric excesses. Open-chain ligands can easily be supported on organic polymers and their complexes can be used as catalysts. Furthermore, cyclic and acyclic complexes can be supported on clays by cation exchange and the solids obtained tend to promote the reaction with a decrease in the *trans*/*cis* ratio.

Introduction

The search for new ligands suitable for incorporation into homogeneous and heterogeneous catalysts for organic reactions is a field of considerable interest. As far as possible, such ligands should be easy to prepare and they should be amenable to facile chemical modification so as to obtain chiral derivatives from simple, accessible starting materials. On the other hand, their incorporation into a heterogeneous support has to be easily accomplished with minimum structural modification. In this regard, polynitrogenated compounds fulfil such requirements. These ligands can selectively bind metal cations and can distinguish between oxidation states.[1] They can be obtained as open-chain or macrocyclic compounds, and also in chiral forms by the incorporation of chiral diamines, amines, or amino acid derivatives. Furthermore, the chiral auxiliaries can be incorporated at different sites in the molecules leading to ligands with different symmetries. In particular, they can easily be obtained with C_2 symmetry.[2] They can also be supported on organic or inorganic materials, which opens up the possibility of using their complexes as solid catalysts in the fine chemicals industry.[3] The chiral compounds would, of course, open the way to chiral heterogeneous catalysts.[4] Given the presence of nitrogen atoms related by the symmetry elements of the molecule, they can be grafted onto a flexible support without losing their symmetry.[5] It is important to note that in a significant number of examples of heterogeneous chiral catalysts, the symmetry of the chiral ligand is lost when it is grafted onto the support, which may be one of the reasons for the lower efficiency of these catalysts in inducing asymmetry.[4]

Porphyrin complexes have been described as catalysts in several reactions,[6] including cyclopropanations.[7] Complexes of other cyclic polynitrogenated systems have also been used.[8] Since open-chain polynitrogenated compounds have not been used in this context, we felt that it would be interesting to compare several of these ligands (cyclic and open-chain, non-chiral and chiral, amines and amides, unsupported and supported) in a benchmark reaction. In this paper, we present the results obtained using copper complexes of these polyaza derivatives (Figure 1) as catalysts of the cyclopropanation reaction between styrene and ethyl diazoacetate. The effect of the oxidation state of the copper and the nature of the counterion are also analyzed.

Results and Discussion

Polyamines as Ligands

We first tested a cyclic ligand, 14,15,17,18-tetramethyl-2,5,8,11-tetraaza[12]paracyclophane (**L_1**, Figure 1) since ligands of this type have been show to stabilize Cu^{I} with respect to its disproportionation into Cu^{II} and Cu^{0}.[10] We prepared its Cu^{I} complex in situ and used it as a catalyst in the cyclopropanation reaction of styrene (**1**) with ethyl diazoacetate (**2**) (Scheme 1). The results obtained are presented in Table 1.

[a] Reactions carried out under argon atmosphere using a twofold excess of **1**. − [b] **2** was slowly added over a period of 45 min.; the time is given from the beginning of the addition. − [c] Determined by gas chromatography.

Copper(I) compounds are known to be very active catalysts in the cyclopropanation of alkenes with diazo compounds.[9] However, addition of the ligand in an almost equimolecular ratio results in the appearance of a period of induction. After this period, the color of the solution changes to yellow and the reaction ultimately yields a final result comparable to that obtained with CuOTf. This period of induction is reduced when the ligand/copper molar ratio is decreased. The addition of an excess of the ligand is of little consequence. Such an induction period is only observed when the complex is used in a ratio of 0.001:1 with respect to the styrene and is no longer seen when it is used in a ratio of 0.01:1 (see entry 14, Table 1). This result indicates the formation of a stable complex of the ligand with Cu^I,[10] which reduces the rate of formation of the reactive copper−carbene intermediate. The most rational explanation for this behavior is the formation of aggregates of the Cu^I-L_1 complexes, in which the copper cation is much less accessible for the interaction with the reagents to give the active metal−carbene species. The formation of aggregates has recently been reported to hamper the hydrolytic catalytic activity of some copper−polyamine complexes.[14] A key feature of tetraaza[*n*]paracyclophanes is that a maximum of three of the four nitrogen atoms can be simultaneously coordinated to a metal cation. This leaves a noncoordinated benzylic nitrogen atom, which can interact with another metal cation (see structure **5**, Figure 2), thereby favoring the formation of complex aggregates. This is particularly the case when the solvent is changed from water to a less polar medium such as CH_2Cl_2. The formation of species such as **5** has been observed in the solid state and has also been inferred from the results of NMR spectroscopic studies.[11][12] As a matter of fact, it has been shown that, in water, tetraaza[12]paracyclophanes such as $\mathbf{L_1}$ can form dinuclear copper(II) complexes (see **6**, Figure 2) which, at least in the solid state, are polymerically associated.[13] The involvement of complexes of the general structure **6** accounts for the fact that even at low $\mathbf{L_1}$/Cu ratios (≈0.5) (entry 9, Table 1) the induction period persists. Only below this ratio is some free copper available and hence the induction period drastically decreases (entry 12, Table 1).

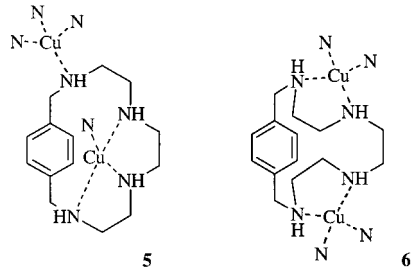

Figure 2. Binuclear structural patterns found for tetraaza[*n*]paracyclophanes

In order to improve the yields, we added a fresh aliquot of ethyl diazoacetate (**2**) (0.5 mol for each mol of remaining styrene) (Table 2). Surprisingly, the period of induction was no longer observed after the second addition. This kinetic behavior is characteristic of product-accelerated reactions, in which a side product, formed via a non-catalytic pathway, is the species involved. In this context, we have to consider that decomposition of ethyl diazoacetate gives rise to the formation of coordinating species, namely ethyl fumarate and maleate. These by-products are produced in large excess with respect to $\mathbf{L_1}$ and, once formed, should favor disruption of aggregates through coordination to the metal cation. Displacement of these kinetically labile ligands from the coordination sphere of the metal by the carbene-forming species thus becomes easier and so the induction period is much decreased or is not seen at all. To check this hypothesis, we stirred a solution of CuOTf and $\mathbf{L_1}$ for 3 h in CH_2Cl_2 with 50 equiv. of ethyl acetate (the same ratio of ethyl diazoacetate used in the reactions) prior to addition of the ethyl diazoacetate. Following this treatment, the period of induction was not seen (entry 5, Table 2).

[a] After this time, an additional amount of **2** was added over a period of 45 min. – [b] The Cu–L_1 complex was stirred with ethyl acetate prior to use.

In order to study the influence of ligand topology on the catalyst activity, we tested several open-chain tri- and tetraamines ($\mathbf{L_2}$–$\mathbf{L_5}$). The results obtained (Table 3) show that the effect of these ligands is to increase the period of induction compared to that observed using $\mathbf{L_1}$ under the same conditions. Furthermore, this period is longer with triamines, and in particular with $\mathbf{L_3}$ (entries 5–6, Table 3). Again, the formation of aggregates has to be considered. Clearly, this phenomenon has to be more important for those ligands ($\mathbf{L_2}$ and $\mathbf{L_3}$) providing a smaller number of nitrogen donor atoms. The presence of bulky C-substituents ($\mathbf{L_4}$ and $\mathbf{L_5}$) should also be reflected in a decreased tendency for aggregation.

Although the design of efficient chiral auxiliaries was not the main aim of this work, the enantiomeric excesses achieved in the reactions using the chiral ligands $\mathbf{L_4}$ and $\mathbf{L_5}$ were examined. In neither case was any asymmetric induction observed.

Table 3. Results obtained in the reactions promoted by CuOTf–linear polyamine ($\mathbf{L_2}$–$\mathbf{L_5}$) = 1:1.1 complexes, using 0.1% catalyst with respect to styrene in CH_2Cl_2 at 25 °C

[a] Determined by gas chromatography using a chiral stationary phase. – [b] After this time, the reaction mixture was heated under reflux.

Amides as Ligands

A further structural change was considered by using the diamides $\mathbf{L_6}$–$\mathbf{L_{10}}$. The results obtained with $\mathbf{L_6}$ and $\mathbf{L_7}$, when compared to those with $\mathbf{L_4}$ and $\mathbf{L_5}$ (entries 2 and 6, Table 4 *vs.* entries 8 and 11, Table 3), show that the presence of carbonyl groups leads to a decrease in the induction period and, in the case of the (*S*)-phenylalanine derivative ($\mathbf{L_7}$), to a decrease in the *trans*/*cis* ratio and a measurable enantioselectivity. These data suggest that, for $\mathbf{L_6}$ and $\mathbf{L_7}$, the changes in geometry and donor characteristics associated with the presence of the amide functionalities lead to an increased rate of copper–carbene intermediate formation.

Table 4. Results obtained in the reactions promoted by CuOTf–linear amide–amine ($\mathbf{L_6}$–$\mathbf{L_{10}}$) = 1:1.1 complexes, using 0.1% catalyst with respect to styrene in CH_2Cl_2 at 25 °C

[a] In cases with asymmetric induction, (1*R*)-cycloadducts are preferably obtained.

In comparison to $\mathbf{L_6}$ and $\mathbf{L_7}$, the period of induction is clearly reduced with $\mathbf{L_8}$, which has a longer bridge, but the *trans*/*cis* ratio and enantioselectivity remain unchanged. Two diastereomeric ligands ($\mathbf{L_9}$ and $\mathbf{L_{10}}$) were also tested and showed very different behaviors. Whereas the reaction is very fast with $\mathbf{L_9}$, use of $\mathbf{L_{10}}$ leads to an extremely long period of induction. Clearly, the *cis,trans,cis*-arrangement of the substituents in complexed $\mathbf{L_9}$ disfavors aggregation, while the opposite is true for the all-*trans* diastereomer formed from $\mathbf{L_{10}}$, for which the access for the formation of the carbene−copper species should again be restricted. The introduction of chirality in the central bridge is always detrimental for the enantioselectivity.

The Effect of the Oxidation State of Copper: The Use of $Cu^{I}L$ vs. $Cu^{II}L$ Complexes

It is known that Cu^{I} is the active species in these reactions and that Cu^{II} is reduced to Cu^{I} in the presence of diazoacetate.[9] Thus, Cu^{II} complexes can also be used as catalysts. In view of this, we tested the cyclic ligand ($\mathbf{L_1}$), two open-chain polyamines ($\mathbf{L_3}$ and $\mathbf{L_5}$), and an amide-containing ligand ($\mathbf{L_7}$) in the same reaction using $Cu(OTf)_2$. The results obtained (entry 1, Table 5) show that the induction period with $\mathbf{L_1}$ decreases and that it is very short even on halving the amount of catalyst (entries 3−4, Table 5). The induction period is no longer seen with $\mathbf{L_5}$ and $\mathbf{L_7}$, but persists with $\mathbf{L_3}$. Therefore, other than in the case of $\mathbf{L_3}$, the metal center in the Cu^{II} complexes is much more accessible to the additional exogenous ligands. Once Cu^{II} is reduced to Cu^{I}, i.e. in the presence of diazoacetate, the strongly active yellow complex is immediately formed.

Table 5. Results obtained in the reactions promoted by $Cu(OTf)_2$−L = 1:1.1 complexes in CH_2Cl_2 at 25 °C

Entry	Ligand	Cu/**1** (%)	*t* (h)	% yield	**4**:**3**	% *ee* (**3**)[a]	% *ee* (**4**)[a]

13			1.5	33	1.7	10	6

[a] In cases with asymmetric induction, (1*R*)-cycloadducts are preferably obtained.

In the reactions promoted by $\mathbf{L_7}$−Cu^{I} and Cu^{II} complexes, the *trans*/*cis* ratios and enantioselectivities are the same, and so it would seem reasonable to assume that the reactive intermediate is the same $\mathbf{L_7}$−Cu^{I} carbene complex.

It can be concluded that the only difference between Cu^{I} and Cu^{II} is the decrease in the induction period, whereas the selectivities and the relative catalytic activities of the different complexes are the same.

Structural XAS/EXAFS Studies

In order to gain further insight into the structural characteristics of these complexes, we studied the structures of the species derived from three representative ligands, $\mathbf{L_1}$, $\mathbf{L_5}$ and $\mathbf{L_7}$, and $CuCl_2$ by X-ray absorption spectroscopy (XAS). The use of $CuCl_2$ instead of $Cu(OTf)_2$ leads to complexes with lower catalytic activity (Table 6) and this has been attributed to the presence of the chloride counterion.[15] However, we decided to use $CuCl_2$ in order to be able to distinguish between the anion (Cl) and the coordinating groups in the ligand (N, O).

[a] Reaction at room temperature. – [b] Reaction under reflux conditions after the initial period at room temperature.

The experimental EXAFS signal was extracted from the raw spectra according to standard methods.[16] The threshold energy E_0, defining the zero wavevector, was taken at the inflection point of the absorption edge. Figure 3 shows the Fourier transform (FT) of the Cu-*K* edge $k\,\chi(k)$ spectra of the three complexes. The FT was calculated using a Gaussian window in the range 2.2−12.5 $Å^{-1}$. EXAFS spectra of the three samples are very similar and show little resolution of structure, indicating structural disorder. The moduli of the FTs of the $\mathbf{L_1}$ and $\mathbf{L_5}$ complexes show two main peaks, while that of the $\mathbf{L_7}$ complex shows an additional peak in the region of 3−4 Å.

[a] Considering Cu−N contributions only. − [b] Considering Cu−N and Cu−O contributions.

The first-shell contribution was extracted by Fourier filtering of the FT spectra in the range 0.8−2.2 Å, and the corresponding structural parameters were obtained by least-squares fitting of the filtered k-weighted spectrum to the EXAFS formula:[16]

$$(k) = \Sigma\ (\rho/k)\ (N_i/R_i^2)\ A_i(k)\ \sin[2kR_i+\phi_i(k)]$$

The amplitudes $A_i(k)$ and phase shifts $\phi_i(k)$ used in the best fit were generated from the FEFF3.11 code.[16e] The best-fit parameters obtained for the different complexes are reported in Table 7. The data for the $\mathbf{L_1}$ and $\mathbf{L_5}$ complexes were found to be very similar and showed the copper to be surrounded by five nitrogen or/and oxygen atoms at an average distance of 2.02 Å. For the second shell, the best fit was obtained solely with carbon atoms at 2.93 Å. We did not observe Cu−Cl contributions in these complexes. On the other hand, the high DW values obtained for both the first and second shells, together with the large error margins associated with the fit of structural parameters of the second shell indicate a high degree of structural disorder in these compounds. The absence of a Cu−Cl contribution in these complexes may be accounted for in terms of the significant structural disorder, the presence of different Cu−Cl and Cu−C distances in the second shell, or a very long Cu−Cl distance with a large vibrational DW factor. The presence of a large number of donor atoms in close proximity to the metal supports the formation of aggregate species with more than one ligand being involved in the complexation of the copper.

The best-fit results for the $\mathbf{L_7}$ complex reveal a slightly different structure. Cu−O and Cu−N cannot be clearly distinguished by EXAFS, hence we considered both possibilities in the theoretical fit of the experimental spectra. If we consider only Cu−N contributions, we obtain 6 nitrogen atoms at a distance of 2.02 Å. A similar fit is obtained considering Cu−N and Cu−O contributions at two different distances. An important difference between $\mathbf{L_7}$ and $\mathbf{L_1}$ and $\mathbf{L_5}$ is the observation of two distant chlorine atoms in the complex of the former. The presence of these chlorine atoms suggests less structural disorder and a higher accessibility of the copper in this complex. These structural changes, which may be due to the planarity imposed by the amide system, the presence of oxygen atoms, or both these factors, must also be responsible for the changes in the *trans*/*cis* ratio and the enantioselectivity.

After background subtraction from the raw spectra, the XANES spectra were normalized taking unity to indicate atomic absorption. The XANES spectra of the complexes of $\mathbf{L_1}$ and $\mathbf{L_5}$ with $CuCl_2$ were found to be almost superimposable, which was not the case with the $\mathbf{L_7}-CuCl_2$ complex. This fact is in good agreement with the differences observed by EXAFS.

The formation of copper−$\mathbf{L_7}$ oligomeric species might suggest that each amine−amide moiety of the ligand participates in the complexation of different copper atoms. This suggestion led us to examine the behavior of the simplest ligand $\mathbf{L_{11}}$. Unfortunately, the corresponding XAS spectrum could not be obtained. However, the close similarity of their catalytic behavior (Table 5) lends support to this hypothesis.

The results obtained from the EXAFS measurements show the absence of chlorine atoms in close proximity to the copper ions, which would seem to be at variance with the influence of this counterion on the catalytic activity. Thus, we investigated whether the same structural behavior is observed with other ligands, such as bis(oxazolines), where the same influence of the counterion has been described.[15] To this end, we studied the EXAFS spectrum of the $\mathbf{L_{12}}-CuCl_2$ complex. The EXAFS and the FT of the Cu-K edge $k\ \chi(k)$ spectrum is shown in Figure 3 and the best-fit parameters are given in Table 7. As can be seen, the spectra show clear differences and chlorine is observed at a distance of 2.21 Å from the copper, justifying its strong influence on the catalytic activity.

Comparison of this result with those obtained for the polynitrogenated compounds shows that the use of the latest ligands leads to oligomeric complexes with considerable disorder in the environment of the copper, and with chlorine at greater distances. In spite of these differences, the counterion has the same influence on the catalytic activity. It may be speculated that, in accordance with the period of induction, the oligomeric species are fragmented to yield the reactive copper−carbene intermediate, and that the reactivity of this intermediate depends on the nature of the counterion. Unfortunately, it has not been feasible to design an EXAFS experiment to check this hypothesis.

Supported Complexes as Catalysts

As a final avenue of investigation, we tested the behavior of some of these ligands supported in various ways. The

formation of aggregates should be disfavored when using such immobilized ligands. This, along with the changes in the micro-environments of the ions, could lead to significant changes in reactivity. Open-chain systems can be grafted onto polystyrene−divinylbenzene through the primary amine functionalities and ligands $\mathbf{L}_{13}$ and $\mathbf{L}_{14}$ were obtained in this way.[5] In accordance with our expectations, the reactions took place without an induction period. The results obtained (Table 8) show that the stereochemical course of the reaction is influenced by the presence of the support. A decrease in the *ee*, relative to that achieved with the same ligand in solution, was observed. Similar changes in the stereochemical course of reactions upon immobilization of a chiral auxiliary have repeatedly been observed.[3]

Table 8. Results obtained in the reactions promoted by Cu^{II} using polymeric ligands ($\mathbf{L_{13}}$−$\mathbf{L_{14}}$) in CH_2Cl_2 at 25 °C

Entry	Ligand	Cu/**1** (%)	*t* (h)	% yield	**4**:**3**	% *ee* (**3**)	% *ee* (**4**)
1	$\mathbf{L_{13}}$[a]	0.1	1.5	12	2.0	−	−
2			2.0	19	2.0	−	−
3			24.0	28	1.8	0	0
4	$\mathbf{L_{14}}$[a]	0.1	1.0	17	1.6	−	−
5			23.0	31	1.6	4	3

[a] $\mathbf{L_{12}}$ contains 0.30 mmol ligand g^{-1} and $\mathbf{L_{13}}$ 0.46 mmol ligand g^{-1}.

Given that the complexes used as catalysts are cationic, they can also be supported using of a different strategy, i.e. they can be electrostatically entrapped using anionic solids. To test this approach, we used a synthetic laponite with a high swelling ability. Cation exchange was carried out in methanol using the $CuCl_2$ complexes of a cyclic ($\mathbf{L_1}$) and an open-chain ($\mathbf{L_3}$) ligand. Table 9 shows the results of analyses of the clays. In both cases, 0.1 mmol Cu g^{-1} are introduced, the Li:Cu stoichiometry is 1:1, and the presence of the complex produces a decrease in the surface area. With $\mathbf{L}_1$, the basal spacing increases, indicating that the complex is accommodated into the interlamellar space, at least in part. With $\mathbf{L_3}$, no change in basal spacing is observed, which may either be due to the smaller size of the complex or to a disposition of this complex on the external surface of the clay. In view of the result obtained with $\mathbf{L_1}$, the first explanation seems more plausible.

Table 9. Analysis of the laponites exchanged with the complexes of $CuCl_2$ with $\mathbf{L_1}$ and $\mathbf{L_3}$

Entry	Ligand	Cu (mmol g^{-1})	N/Cu	d_{001} (•)	S (m^2 g^{-1})
1	−	−	−	16	289
2	$\mathbf{L_1}$	0.1	3.9	19	245
3	$\mathbf{L_3}$	0.1	3.8	16	239

Table 10 shows the results obtained with these clay-supported catalysts. As can be seen in Table 6, the use of chloride in place of triflate significantly reduces the catalytic activity in solution and it is necessary to carry out the reaction under reflux. This can only be related to the effect of the more coordinating chloride counterion. In the case of $\mathbf{L_3}$, the catalytic activity of the supported catalyst is similar to that seen for the homogeneous complex, while for $\mathbf{L_1}$ it is even superior. However, a simple comparison cannot be made because in the supported catalyst the counterion is changed from chloride to the clay surface, and the nature of the counterion has a decisive influence on the catalytic activity. The *trans*/*cis* ratio decreases, hence the proportion of the less stable product increases. This has previously been observed with clay catalysts and has been explained in terms of the isolation of the catalytic sites and the dimensionality of the clay, which should also be related to the higher catalytic activity.[17]

Table 10. Results obtained in the reactions promoted by $CuCl_2$−$\mathbf{L_1}$ and $\mathbf{L_3}$ (1:1.1) complexes exchanged in laponite, in CH_2Cl_2 using a Cu/**1** ratio of 0.001

Conclusions

The results presented here open the way for the design of novel polynitrogenated ligands for use in copper-catalyzed processes and for understanding the different factors affecting the activity of such species. The copper(I) and copper(II) complexes of some cyclic and non-cyclic polyamines, as well as of some diamides, have been assayed in the benchmark cyclopropanation reaction of styrene with ethyl diazoacetate. First and foremost, all the complexes examined showed an appreciable catalytic activity, even at very low catalyst concentrations. All data suggest that formation of the carbene−copper complex is the rate-limiting step. For polyamines, aggregation hinders the formation of the active carbene−copper complexes and as a result induction periods are observed in non-coordinating solvents (CH_2Cl_2). The addition or the *in situ* generation of kinetically labile coordinating species such as EtOAc or ethyl fumarate (formed by decomposition of the diazoacetate) disrupts aggregation and allows the facile formation of the active complexes. Aggregation is more significant with polyamines having a smaller number of nitrogen donor atoms and with less bulky ligands, and is much reduced with amides.

The induction periods are more important for Cu^{I} than for Cu^{II} complexes, according to the different coordination geometries. This seems to be associated with the formation of more accessible Cu^{II} sites that readily interact with the carbene-forming species and are reduced to Cu^{I} complexes, which are the active catalytic species. No other differences (e.g. in terms of selectivity) are associated with the use of Cu^{I} or Cu^{II} and, accordingly, the use of the more stable Cu^{II} compounds is clearly favored.

Polyamine or amide ligands of this type can easily be supported by anchoring on functionalized polymers or by cation exchange in clays. The resulting supported Cu^{II} complexes show higher activities than their homogeneous analogues. This can be rationalized in

terms of the pseudodilution effects operative in the solid materials, which will disfavor the aggregation processes.

Finally, small enantioselectivities have been observed on using some of the chiral ligands. However, more work is needed in this regard if novel chiral ligands able to improve the observed enantioselectivities are to be developed

Experimental Section

Preparation of the Ligands: $\mathbf{L_2}$ and $\mathbf{L_3}$ are commercial compounds. $\mathbf{L_1}$,[12] $\mathbf{L_4}-\mathbf{L_7}$[18] and $\mathbf{L_{13}}-\mathbf{L_{14}}$[5] were prepared as described previously. $\mathbf{L_8}$, $\mathbf{L_9}$ and $\mathbf{L_{10}}$ were obtained by reaction of the *N*-hydroxysuccinimide esters of the *N*-Cbz protected amino acids with the corresponding diamines, followed by deprotection of the *N*-Cbz groups.

General Procedure for the Preparation of *N*-Hydroxysuccinimide Esters of Amino Acids: The appropriate *N*-Cbz-protected amino acid (3.34 mmol) and *N*-hydroxysuccinimide (3.34 mmol) were suspended in anhydrous DME at 0°C. Once a clear solution had been obtained, DCC (3.67 mmol) was added and the resulting solution was stirred at 0−5°C for 20 h. The dicyclohexylurea formed was filtered off and the filtrate was concentrated to dryness. The crude product was recrystallized from propan-2-ol to furnish the pure product. *N*-Hydroxysuccinimide ester of *N*-Cbz-L-phenylalanine: yield 87%; m.p. 137−140°C. − ^{1}H NMR: δ = 2.80 (br. s, 4 H), 3.13−3.41 (m, 1 H), 5.09 (s, 4 H), 7.29−7.4 (m, 10 H). − ^{13}C NMR: δ = 25.4, 37.8, 52.9, 67.2, 127.3, 128.0, 128.2, 128.5, 128.7, 129.5, 134.3, 167.5, 168.7. − $[\alpha]_D^{25}$ = −11.1 (*c* = 2, dioxane). − $C_{21}H_{20}N_2O_6$: calcd. C 63.6, H 5.1, N 7.1; found C 63.5, H 5.5, N 7.4.

General Procedure for the Preparation of *N,N′*-Bis(*N*-Cbz-aminoacyl)diamines: The *N*-hydroxysuccinimide ester of the appropriate amino acid (7.44 mmol) was dissolved in anhydrous DME cooled in an ice bath, and the diamine (3.72 mmol) was added dropwise. The reaction mixture was stirred at room temp. for 18 h. The white solid formed was filtered off and washed with water and cold methanol.

Deprotection of *N*-Cbz Groups: The *N,N′*-bis(*N*-Cbz-aminoacyl)-1,3-diaminopropanes were added to HBr/AcOH (33%) and the respective mixtures were stirred at room temp. until CO_2 evolution ceased. At this point, diethyl ether was added to the clear solution, which led to the deposition of a white precipitate. This was filtered off and dried to afford the pure product.

$\mathbf{L_8}$: M.p. 140−143°C. − $[\alpha]_D^{20}$ = −89.42 (*c* = 1, $CHCl_3$). − ^{1}H NMR: δ = 1.5 (m, 4 H), 2.7 (dd, J_1 = 9.2, J_2 = 14 Hz, 2 H), 3.25 (m, 6 H), 3.6 (dd, J_1 = 3.8, J_2 = 9.2 Hz, 2 H), 7.3 (m, 10 H). − ^{13}C NMR: δ = 27.0, 38.7, 41.1, 56.5, 126.8, 128.7, 129.4, 138.0, 174.3. − $C_{22}H_{30}N_4O_2$: calcd. C 69.1, H 7.9, N 14.6; found C 69.3, H 8.3, N 15.0.

C 75.6, H 7.1, N 11.0; found C 75.5, H 7.1, N 11.3.

Preparation of the Cationic Complexes Supported on Clays: A solution of the complex was first prepared by stirring CuCl2•2H2O (1 mmol) and the appropriate ligand ($\mathbf{L_1}$ or $\mathbf{L_3}$, 1 mmol) in methanol (50 mL) for 45 min. To this green solution, laponite (10 g) was added and the mixture was shaken for 22 h. After this time, the blue clay was separated by filtration and washed with methanol. The residue obtained by evaporation of the solvent from the colorless solution was found to contain NaCl.

The copper content was analyzed by plasma emission spectroscopy using a Perkin−Elmer Plasma 40 emission spectrometer. Carbon and nitrogen analyses were carried out using a Perkin−Elmer 2400 elemental analyzer. Step-scanned X-ray diffraction patterns of oriented samples were collected at room temperature from 3° in 2& thetas; up to 60° using a D-max Rigaku system with a rotating anode. The diffractometer was operated at 40 kV and 80 mA and Cu-K_α radiation was selected using a graphite monochromator. Surface areas were calculated from BET nitrogen isotherms determined at 77 K.

Cyclopropanation Reactions with Homogeneous Catalysts: Under argon, a mixture of the requisite amount of the ligand (Tables 1−5) and CuOTf•1/2C_6H_6 or $Cu(OTf)_2$ (0.1 mmol) in dry CH_2Cl_2 (60 mL) was stirred at room temperature for 30 min. Then, a solution of styrene (100 mmol) and *n*-decane (2 g) in dry CH_2Cl_2 (50 mL) was added and the resulting solution was stirred for 10 min. After this time, ethyl diazoacetate (50 mmol) was slowly added by means of a syringe pump over a period of 45 min. The reactions were monitored by gas chromatography using *n*-decane as an internal standard; FID from Hewlett-Packard 5890 II; cross-linked methyl silicone column 25 m × 0.2 mm × 0.33 μm; helium as carrier gas, 20 psi; injector temperature 230°C; detector temperature 250°C; over temperature program: 70°C (3 min)−15°C/min−200°C (5 min); retention times: ethyl diazoacetate (**2**) 4.28 min, styrene (**1**) 5.03 min, *n*-decane 6.93 min, diethyl fumarate 8.73 min, diethyl maleate 9.04 min, *cis*-cyclopropanes (**3**) 11.84 min, *trans*-cyclopropanes (**4**) 12.35 min.

Asymmetric induction in the reactions using chiral ligands was also assessed by gas chromatography; cyclodex-B column 30 m × 0.25 mm × 0.25 μm; oven temperature program: 125°C isothermal; retention times: (1*S*,2*R*)-cyclopropane 28.9 min, (1*R*,2*S*)-cyclopropane 29.8 min, (1*R*,2*R*)-cyclopropane 34.3 min, (1*S*,2*S*)-cyclopropane 34.9 min. The peaks were assigned to the corresponding enantiomers by comparison with previous results.

In general, the onset of the reactions is signified by a color change from green to yellow. In one case (entry 4, Table 3), the reaction did not take place at room temperature and had to be carried out under reflux. In another case (entry 2, Table 2), after the consumption of the ethyl diazoacetate an additional amount of this reagent was added in the same manner. In another reaction (entry 5, Table 2), the $\mathbf{L_1}$−CuOTf complex was stirred with ethyl acetate (5 mmol) for 3 h prior to addition of the reagents.

Cyclopropanation Reactions with Polymeric Catalysts: The appropriate amount of polymer (0.37 g of $\mathbf{L_{12}}$ or 0.24 g of $\mathbf{L_{13}}$) was

stirred under argon in a solution of $Cu(OTf)_2$ (1 mmol) in CH_2Cl_2 for 24 h. After this time, the solution was decanted off and the remaining solid was washed with CH_2Cl_2. To a suspension of the catalyst in dry CH_2Cl_2 (60 mL), the internal standard and the reagents were added and the reaction was monitored as described above.

Cyclopropanation Reactions with Clay-Supported Catalysts: To a suspension of the clay (1 g) in dry CH_2Cl_2 (60 mL), the reagents and the internal standard were added and the reaction was monitored as described above.

EXAFS and XANES Experiments: X-ray absorption experiments at the Cu-*K* edge were carried out at the synchroton radiation source, Daresbury, U.K. A double-crystal Si(111) monochromator was used. The storage ring operated at 2 GeV with an average beam current of 150 mA. The experiments were performed at room temperature in the transmission mode, and the signal was collected by means of ion chambers. For the XAS measurements, solid samples of the $\mathbf{L_1}$, $\mathbf{L_5}$, $\mathbf{L_7}$ and $\mathbf{L_{12}}-CuCl_2$ complexes were pressed into thin pellets. The thickness of the samples was optimized in order to obtain the best signal-to-noise ratio.

Samples were prepared using the ligand and $CuCl_2$ in an equimolar ratio; the amounts of the two components were adjusted in order to obtain 100 mg of complex. To a solution of the ligand in CH_2Cl_2 (5 mL), the requisite amount of CuCl2•2H2O was added. The resulting suspension was stirred at room temperature for 5 h, which led to the gradual disappearance of the solid $CuCl_2$. After this time, the solution was filtered through a plug of cotton wool and the solvent was evaporated from the filtrate under reduced pressure. The solid complexes were dried in vacuo for 24 h at 50°C. All complexes showed the expected IR bands and gave appropriate elemental analyses.

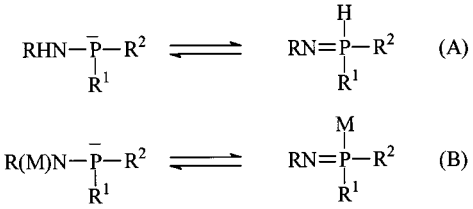
(*N*-lithioamino)diorganophosphanes and Bis(*N*-Lithioamino)organophosphanes: Synthesis and Structures

Bettina Eichhorn,[a] Heinrich Nöth,*[a] and Thomas Seifert[a]

Dedicated to Professor Alfred Schmidpeter on the occasion of his 70th birthday

Keywords: Phosphane complexes / Lithium / Aminophosphanes / Hydrazides / (*N*-lithioamino)diorganophosphanes



Butyllithium (*n*BuLi) deprotonates Ph_2P–NH*t*Bu in ether to give $(Ph_2P–NLi{t}Bu)_2{\cdot}OEt_2$. There is no Li···P interaction in this molecule. Three compounds of the type $R'P(NLiR)_2$ have been obtained by lithiation of $R'P(NHR)_2$, isolated as $[BuP(NLi{t}Bu)_2{\cdot}OEt_2]_2$, $[PhP(NLiPh)_2{\cdot}OEt_2]_2$ and $[PhP(NLiPh)_2]_2$. Reaction of *n*BuLi with $MeP(NH{i}Pr)_2$ in hexane/THF leads to $[MeP\{N(Li){i}Pr]_2{\cdot}THF\}_4$ with an asymmetric cluster structure comprising one LiP_3, three $LiPN_2$, three LiP_2N and one LiN_3 cluster units. The molecular structures of these compounds as determined by X-ray structure analysis show that they are best depicted as *N*-lithioaminophosphanes and not as the isomeric *P*-lithioiminophosphoranes.

Introduction

The chemistry and particularly the structural chemistry of alkali metal hydrazides has recently been the subject of great interest. They are versatile reagents and offer surprising structural features.[1] Amongst the series $R_2N-N(R)M$, R_2N-NM_2, $R(M)N-N(M)R$, $R(M)N-NM_2$ and M_2N-NM_2 (M = alkali metal), so far only the first three members are known.[1] Furthermore, only very few derivatives with the heavier alkali metals have been described, a typical example being $CsMeN-N(SiMe_3)_2$.[1d] All these metal hydrazides are dimers, trimers or oligomers in spite of the fact that the alkali metal cations coordinate donor solvent molecules. The most significant feature of the hydrazide units is that the two nitrogen atoms are present in a planar or almost planar coordination sphere in which the planes around the N atoms are more or less perpendicularly oriented to one another.

Monoaminophosphanes $R_{2-n}H_nN-PR_2$ are the mixed higher homologues of hydrazines $R_{2-n}H_nN-NR_2$. Upon lithiation, amidophosphanes $RLiN-PR_2$ form.[2] Association of these molecules should preferentially occur by means of intermolecular Li···N interactions, although Li···P interactions may also be present;[2] these should, however, not be preferential due to the softer base character of the phosphorus(III) atom. Moreover, it is well-known that aminophosphanes may be involved in prototropism (A) which can lead to imido-phosphoranes;[3] metallotropism, as described in Equation (B), might therefore also be observable.[2]

As far as aminophosphanes are concerned, the analogy between hydrazines and mono-aminophosphanes can be readily expanded because a P^{III} atom allows for the formation of the series of compounds $RHN-PR_2$, $(RHN)_2PR$ and $(RHN)_3P$ and all these should be amenable to deprotonation. Another extension includes bis(phosphanyl)amines $(R_2P)_2NH$ and their metallation to $(R_2P)_2NM$ compounds (M = Li, Na, K, Cs) where it has been found that for M = Li, a dimeric species with Li–N bonds is formed, while the sodium salt shows only Na–P bonds.[4] Therefore it is interesting, but difficult to predict, what kind of metal–ligand interaction can be expected for bis-metallated di(amino)phosphanes. For this reason we have not only investigated the metalation of monoaminophosphanes[5] but also the bis(amino)organophosphanes. Because tris(amino)phosphanes $P(NHR)_3$[6] (R = Me, *t*Bu, Ch_2Ph, $C_{12}H_{25}$) condense too readily to give cyclophosphazanes $[RHN-P=NR]_2$ or $P_4N_6R_6$, we did not include a study of the deprotonation of tris(amino)phosphanes.

Results

Bis(organoamino)organophosphanes, $R'P(NHR)_2$

Aminophosphanes $R'_{3-n}P(NHR)_n$ bearing primary amino groups are amenable to condensation. This tendency increases with the number of amino groups attached to the phosphorus atom and decreases with increasing bulk of the *P*- and *N*-substituents. The first compound of type $R'P(NHR)_2$ such as $C_5F_5P(NHR)_2$ (R = *t*Bu, CH_2Ph) was reported in 1966.[7] Another series of compounds $PhP(NHR)_2$ (R = Me, Et, *n*Pr, *i*Pr, *t*Bu) was described in 1967.[8] They can be oxidized to $PhP(X)(NHR)_2$ (X = O, S) or alkylated to their phosphonium salts $[PhR'P(NHR)_2]X$[8] which are thermally more stable than

the parent compounds. Furthermore, bis(arylamino)arylphosphanes seem to be less prone to condensation[9] and, therefore, several bis(anilido)arylphosphanes have been characterized by spectroscopic methods.[9][10] Moreover, the structure of mes*P[NH(mes*)]$_2$ (mes* = 2,4,6-tris-*tert*-butylphenyl = supermesityl) has been determined by X-ray diffraction techniques.[10] Scherer[11] and Payne[8] were able to isolate MeP(NH*t*Bu)$_2$ as the most stable species amongst bis(monoorganoamino)methylphosphanes. Even MeP(NH*i*Pr)$_2$ **(1)**, can be isolated like MeP(NH*t*Bu)$_2$ **(2)** as the product of aminolysis of MePCl$_2$, as described by Equation (1).[8] The aminolysis method has been used to prepare compounds **1** to **5**.

$$R'PCl_2 + 4NH_2R \longrightarrow R'P(NHR)_2 + 2(NHR_3)Cl \quad (1)$$

$$mesP(NH^tBu)_2 + H_2O \xrightarrow{CH_2Cl_2} mes{-}P(=O)(H){-}NH^tBu + iPrNH_2 \quad (4)$$

9

It is interesting to note that amination of MePCl$_2$ with LiNHR or Me$_3$SiNHR was unsuccessful in our hands. Moreover, aminolysis of MePCl$_2$ with aniline or mesidine to MeP[NH(aryl)]$_2$ was equally unsuccessful; this contrasts with the aminolysis of PhPCl$_2$ which provided the series of bis(organoamino)phenylphosphanes **3**–**5** as shown in Equation (1). While ether is a good solvent for these reactions, toluene is required for the preparation of **5** in order to circumvent solubility problems.

In contrast, the bis(monoorganoamino)mesitylphosphanes **6** and **7** were readily obtained by allowing mesPCl$_2$ (mes = mesityl) to react with aminosilanes Me$_3$Si–NHR as described in Equation (2). However, the formation of **7** was always accompanied by the formation of the di-phosphetidine **8** (Equation 3). The ratio of **7**:**8** before distillation was ≈4:1. Slow hydrolysis of **7** yielded the phosphonic acid amide **9** as described by Equation (4), a compound that was not obtained by direct hydrolysis of **7**.

NMR Spectra

Chemical shifts for ^{31}P and ^{15}N NMR, as well as coupling constants, of compounds **1**–**8** are summarized in Table 1 and additional data (^{1}H, ^{13}C) are reported with the individual compounds in the Experimental Section.

Table 1. Chemical shifts ^{31}P and ^{15}N and P-N coupling constants for bis(organoamino)organophosphanes **1**–**8** and related compounds measured in C_6D_6

	δ^{31}P	δ^{15}N	^1J(P-N) (Hz)
MeP(NH^{i}Pr)$_2$ **(1)**	51.7	−302.1	65.3
MeP(NH*t*Bu)$_2$ **(2)**	39.2	−289.9	65.7
PhP(NH*i*Pr)$_2$ **(3)**	58.9	−304.8	67.9
PhP(NH*t*Bu)$_2$ **(4)**	42.0	−292.2	68.2
PhP(NHPh)$_2$ **(5)**	46.8	−294.6	66.4
mesP(NH*i*Pr)$_2$ **6**	58.7	−303.5	63.4
mesP(NH*t*Bu)$_2$ **7**	44.1	−298.9	59.9
[mesP−N*i*Pr]$_2$ **8**	242.0	−374.1	t 37.5
mes*P(NHmes*)$_2$	82	–	–

mes* = 2,4,6-tris-*tert*-butylphenyl.

All compounds exhibit a single ^{31}P NMR signal, and the ^2J(P-C) coupling constants were calculated from the satellites. Shielding of the P nucleus increases from 12.5 to 16.9 ppm by replacing *i*Pr groups with *t*Bu groups, and this difference decreases in the series R = Me > mes > Ph. On the other hand, the nitrogen nuclei are better shielded by *i*Pr groups than by *t*Bu groups. The shift differences are $\Delta\delta(^{15}N)$ = 12.2 for the pair **1** and **2**, 12.6 for the pair **3** and **4,** but only 4.6 for the pair **6** and **7**.

Both, ^{1}H and ^{13}C NMR spectra of all bis(isopropylamino)phosphanes **1**, **3** and **6** show nonequivalent CH$_3$ groups with different ^3J(H-H) coupling due to the prochirality of the *i*Pr groups. The corresponding signal for the CH proton is a multiplet of higher order. On the other hand, four ^{13}C NMR signals for the phenyl group reveal free rotation about its P–C bond.

There are two signals for the NH protons of bis(isopropylamino)phenylphosphane which are fairly broad. These signals do not stem from a doublet due to coupling of the protons with ^{31}P because the two signals did not collapse into a single line on ^{31}P decoupling, nor were they affected by proton decoupling. This is in contrast to the observation by Payne et al.[8] who found for their compounds that the NH signals collapsed to a singlet on irradiation at the frequency of the methine proton implying ^3J(H-H) coupling. On the other hand, there are also two NH signals in compound **4** where there is no methine proton available for a ^3J(H-H) coupling. On heating, a [D$_8$]toluene solution of **3** led to coalescence of the two NH signals at 80 °C, while all other ^{1}H NMR signal remain unchanged. A $^{13}C\{^1H^{31}P\}$ double resonance experiment clearly demonstrates that two doublets for the CH*Me*$_2$ groups are due to ^3J(P-C) because this gives rise to two singlets. Thus, the temperature-dependence of the NH proton signals suggests hindered rotation about the P–N bond. However, there was no indication of hindered rotation in the *tert*-butylaminophosphane **6**, although the steric requirement of the *tert*-butyl group would certainly be more demanding than that of the prochiral isopropyl group. However, the height of the rotational barrier has not been determined experimentally

A **B** **C** **D**

Two ^{1}H and ^{13}C NMR signals for the isopropyl groups were also observed in the cyclophosphazane **8**, appearing as doublets in the ^{1}H NMR spectrum due to ^{3}J(H-H) coupling. In addition, the *O*-methyl groups of the mesityl substituents are also not magnetically equivalent, which also became apparent for the *m*-H atoms which appear as two signals and, therefore, also indicated hindered rotation. The four-membered ring structure of **8** was ascertained by NMR spectroscopy, with a triplet for the ^{15}N NMR signal due to coupling to the P atoms [^{1}J(P-N) = 37.5 Hz], as well as by its molecular weight, and finally, by an X-ray structure analysis.

Ab initio Calculations

Hindered rotation about the P−N bond of bis(organoamino)organophosphanes may result in chirality at the phosphorus center. As depicted in formulae **A**−**D**, four different rotamers result as limiting cases. The conformers **A** and **C** are chiral, while **B** and **D** are achiral due to a plane of symmetry.

In order to obtain information on compound **3**, our best-studied bis(amino)phenylphosphane, single point calculations were performed. A simulation of the NMR spectrum of **3**, taking its solid state structure into account, must consider 19 spins (^{1}H, ^{15}N, ^{31}P). This would be technically quite demanding. Therefore, we turned to NBO analysis as implemented in the Gaussian 94 program package,[12] and Figure 1 depicts calculated Mulliken charges and Wiberg bond orders. The latter renders bond orders usually as too large.

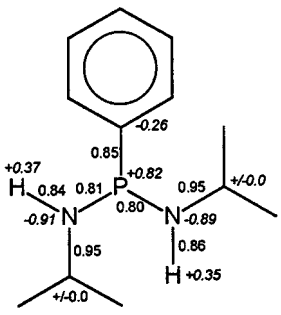

Figure 1. Wiberg bond orders and Mulliken charges for PhP(NH*i*Pr)$_2$

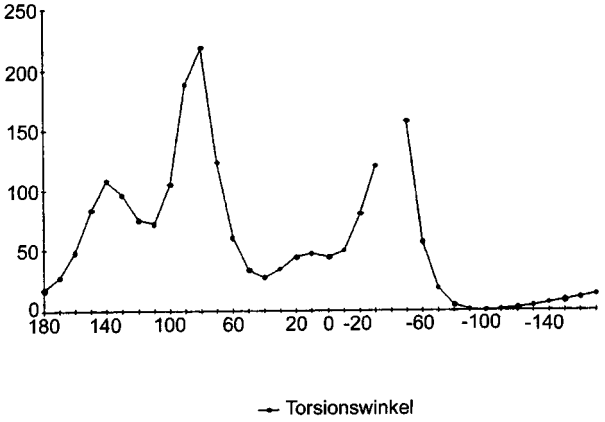
In spite of this, P−N bond order values of ≈ 0.80 correspond to a single bond, and calculated negative charges are associated with the nitrogen centers as well as the *ipso* carbon atoms. Positive charges are centered at the P atom and the hydrogen atoms. This implies localized pairs of electrons at the P and N centers. Surprisingly, the lone pair at the P atom resides in an orbital close to sp^3 while the lone pairs at the nitrogen atoms are of *p*-type, resulting from an almost planar environment of the substituents at the nitrogen atoms. This result already excludes any discussion that a hindered rotation about the P−N bond originates from π-bonding. Taking the molecular parameters into account, as obtained from the X-ray structure determination (see below), single point calculations (basis set 31G*) have been performed by rotating one isopropyl amino group by 360° leaving the rest of the molecular structure untouched. The result of these calculations is depicted in Figure 2.



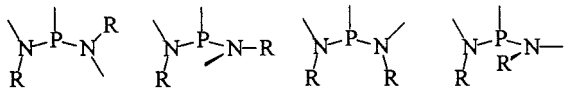


Figure 2. Rotational barrier calculated for PhP(NH*i*Pr)$_2$, using its structural data as found for the solid state; one isopropyl group was kept fixed, the second one was rotated about its P−N bond

E **F** **G** **H**

As can be seen, there are four minima on the hypersurface corresponding to the following rotational angles: −100°, 130°, 40° and 0°. The corresponding conformations are shown by structures **E**−**H**. At a torsion angle of −50°, the isopropyl groups overlap. In going from a *cis*- to a *trans*-structure, an energy of 200 kcal mol^{-1} is required. This barrier cannot be surpassed at ambient temperature. On the other hand, a cogwheel rotation of both isopropyl groups will most likely lower this barrier significantly.

Crystal and Molecular Structures

The molecular structures of two primary bis(amino)phosphanes were determined by X-ray structure analysis. PhP(NH*i*Pr)$_2$ **3**, crystallizes as needles in the orthorhombic

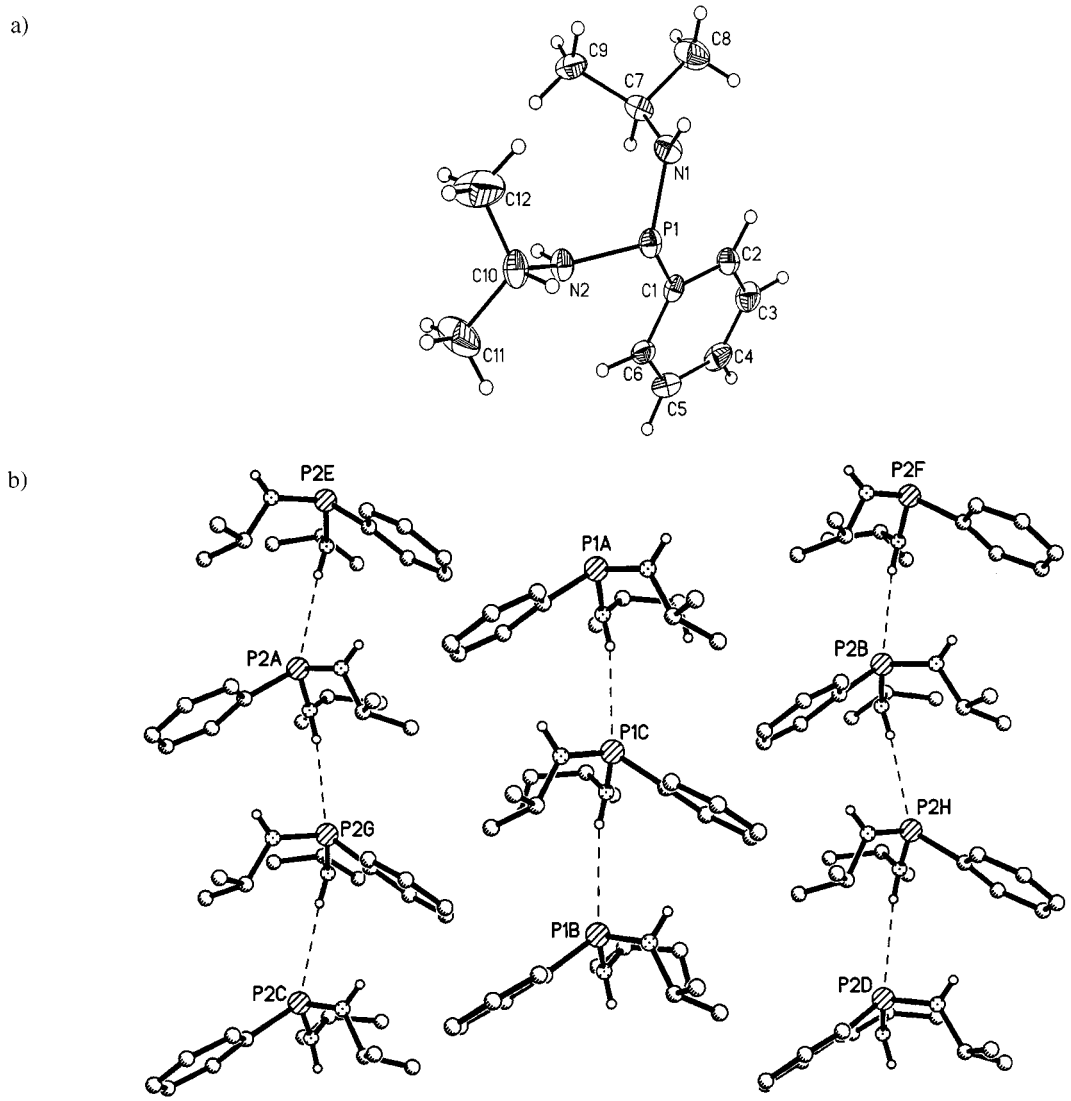

Figure 3. a) The molecular structure of the two independent $PhP(NHiPr)_2$ molecules in ORTEP representation; thermal ellipsoids are drawn on a 25% probability scale; selected bond lengths (Å) and angles (°): P1−N1 1.687(4), P1−N2 1.875(4). P1−C1 1.844(5), N1−C7 1.448(7), N2−C10 1.476(6); − N1−P1−N2 113.7(2), N1−P1−C1 100.2(2), N2−P1−C1 99.2(2), C10−N2−P1 120.1(4), C7−N1−P1 127.9(4); P2−N3 1.674(5), P2−N4 1.684(5), P2−C13 1.836(5), N3−C19 1.471(6), N4−C22 1.465(7); N3−P2−N4 113.0(2), N3−P2−C13 99.6(2), N4−P1−C22 100.0(2); b) Stereoplot of the contents of the unit cell of $PhP(NHiPr)_2$ **1**, along the b−axis; N3−H3 0.88 Å, H3···P 1.99 Å; angle N3−H3−P2 172.6°

system, space group $Pca2_1$ with $Z = 8$. Therefore, there are two independent molecules in the asymmetric unit, (see Figure 3a). Both molecules differ only slightly in bond lengths and possess almost the same conformation. However the pyramidalization at the P atoms is significantly different as shown by the sum of bond angles at atom P1 (325.9°) and atom P2 (319.7°). Each of these independent molecules are arranged in the unit cell by forming chains resulting from N−H···P hydrogen bonding as shown in Figure 3b.

The N atoms deviate only slightly from a planar environment because the sum of bond angles for N1 is 355.4°, for N2, 352.5°, for N3, 355.4° and for N4, 352.1°. The plane of the phenyl group does not stand perpendicular to the respective N_2P plane but is twisted against it by ≈ 65°. Association of the molecules results from weak hydrogen bonding between N and P atoms of neighboring molecules with a N1(X)···P1(X) distance of 3.789 Å and a N2(X)···P2(X) distance of 3.740 Å. The respective P···H distances are 2.98 and 2.87 Å, and the P−H−N angles are 160.1° and 172.6°, respectively.

In contrast to $PhP(NHiPr)_2$ whose amino groups are present in an *anti*-conformation, a *syn*-conformation is found for $PhP(NHPh)_2$ **5** in the solid state as shown in Figure 4. This compound crystallizes in the centrosymmetric monoclinic space group *Cc*; the molecule itself, however only shows C_1 point group symmetry.

The sum of bond angles at the P1 atom (300.7°), and those at the N atoms (N1: 360°, N2: 358°) are indicative of sp^2 hybridization. An interplanar angle of the phenyl group bonded to atom P1 with respect to the PN_2 plane is 73.5°; so the latter plane is not bisected. As a consequence, the

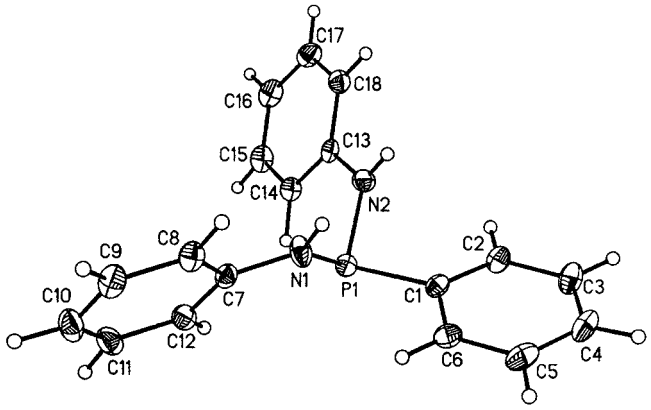

Figure 4. ORTEP representation of a molecule of $PhP(NHPh)_2$ **5**, in the crystal; thermal ellipsoids are drawn on the 25% probability level; bond lengths (Å): P1−N1 1.695(2), P1−N2 1.708(2), P1−C1 1.828(2), N1−C7 1.401(3), N2−C13 1.399(3), N1−H1 0.83, N2−H2 0.81; bond angles (°): N1−P1−N2 105.4(1), N1−P1−C1 97.6(1), N2−P1−C1 97.7(1), P1−N1−C7 127.7(1), P1−N2−C13 126.0(2), H1−N1−P1 118, H2−N2−P1 115

interplanar angles between the C1−C6 phenyl plane with respect to the other two phenyl planes are 62.3° (C7−C12) and 121.2° (C13−C18), respectively, and it should be noted that the phenyl groups of the aniline units are practically in plane with the respective CNH planes (2.6°, 2.4°) allowing for good π-overlap with the π-system of the phenyl groups. This can also be deduced from the short C−N bonds.

In contrast to compound **3**, no NH···P or NH···N hydrogen bonds are present in the crystal of **5**. This may be due to the pronounced pyramidal geometry at the P center and the near planarity of the nitrogen atoms with their phenyl rings resulting in π-interaction. Thus $PhP(NHPh)_2$ is a true molecular compound in the solid state.

As indicated, slow hydrolysis of $mesP(NHiPr)_2$ **7** led to the mesitylphosphonic acid amide mesP(O)H(NH*i*Pr), **9**. Its structure was determined by X-ray methods. The molecule crystallizes in the centrosymmetric monoclinic space group $P2_1/c$. Figure 5a depicts the molecule. Association of the molecules in the solid state can occur by means of NH···P, NH···O and NH···N bonding as well as, but less likely, by PH···O or PH···N bonding. Figure 5b, which shows four molecules, demonstrates that an intermolecular interaction occurs by means of NH···O hydrogen bonding with an intermolecular N···O atom distance of 2.665 Å and an N−H···O bond angle of 175.1°.

The molecular structure of the cyclophosphazane **8** (see Figure 6) is another example of the less preferred *trans*-conformation of the substituents in a centrosymmetric structure.[13] Its bonding parameters fall into the same range as observed for many other derivatives with a P_2N_2 ring. Due to steric effects, the mesityl groups are perpendicular to the P_2N_2 ring. Moreover, the ring nitrogen atoms are slightly pyramidal (sum of bond angles 351.5°). This is a stronger deviation from planarity than usually observed for *trans*-diazadiphosphetidines (358−360°)[14] and is probably a result of the bulky mesityl group.

N-Lithioaminophosphanes

Synthesis

It is to be expected that *N*-lithioaminophosphanes are better nucleophiles than the parent aminophosphanes and therefore might be useful reagents for the synthesis of new ring and chain compounds based on N−P−N structural units. Besides this aspect, the question as to whether these *N*-metallated bis(amino)phosphanes will be present as *N*-metal aminophosphanes or as *P*-metaliminophosphoranes requires the determination of their structures. According to ab initio calculations by Ashby and Trinquier[15] the $RN-PR_2^-$ isomer is favored over the $RN=PR_2^-$ isomer. The stabilization of the latter requires strongly eletronegative substituents such as F or CF_3 bonded to the P atom. Anions of type $RN=PR_2^-$ can probably only be detected if the Li counter ion is separated from the anion by complexation or if replaced by a non-coordinating cation. Otherwise one has to expect association of the *N*-lithioaminophosphanes which raises the question as to whether this will occur through the N or/and P atoms. Indeed, compounds **10**−**14** are associated in the solid state as revealed by X-ray structure determinations.

However, NMR spectroscopic data of these compounds in solution usually showed more ^{31}P NMR signals than expected; even when the solutions had been prepared from well defined crystalline material. This suggests that several solution species are formed from the dimeric and tetrameric species. Therefore, the ^1H and ^{13}C NMR spectra were complex, and it is quite evident that a detailed study of the NMR spectra is required to characterize the solution state of compounds **10**−**14**. So far, this has not yet been achieved successfully.

Metallation of $mesP(NHtBu)_2$ with *n*BuLi yielded no $mesP[N(Li)tBu]_2$ but the *P*-butyl derivative **11**. Therefore, *n*BuLi not only deprotonated the aminophosphane but also induced an exchange of the *P*-bonded organo group.

Reactions

The *N*-lithio derivatives of bis(amino)organophosphanes are expected to be versatile reagents particularly for the synthesis of new heterocycles. Here we describe only a single example as a prototype, namely the synthesis of a 1,3-diaza-2-phospha-4,5-diboretidine **15**.

This new heterocycle can be considered to be a 6π-electron system provided that the P atom resides in a planar moiety. However, the X-ray structure (vide infra) clearly disproves this because the P atom is pyramidal. Nevertheless, this example demonstrates that many other new heterocyclic systems will be accessible via the new reagents, and we will report on these later.

Crystal and Molecular Structures

Compound **10** crystallized at −30°C from its ether solution in the monoclinic space group *C*2/*c*. It proved to be

$\{MeP[N(Li)iPr]_2\}_4$ **14**

the hemietherate of $[Ph_2P-N(Li)tBu]_2$ whose molecular structure is depicted in Figure 7. The molecule shows a crystallographically imposed C_2 point group symmetry.

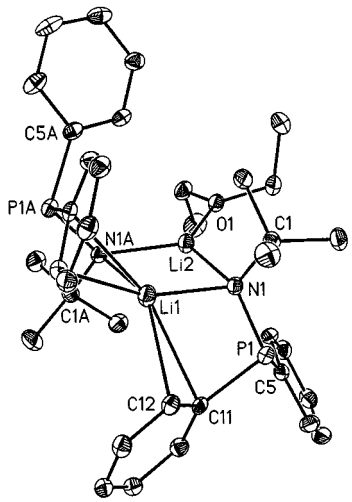

Figure 7. ORTEP representation of the molecular structure of **10** in the crystal; hydrogen atoms are omitted for clarity; thermal ellipsoids are drawn on a 25% probability level; selected interatomic distances (Å): Li1−N1 2.018(5), Li2−N1A 2.075(5), Li2−O1 2.034(7), P1−N1 1.686(3), P1−C5 1.848(3), P1−C11 1.849(3), N1−C1 1.504(4); bond angles (°): C5−P1−C11 99.7(1), C5−P1−N1 112.6(2), C11−P1−N1 103.0(1), P1−N1−Li1 106.9(2), P1−N1−Li2 139.4(1); other interatomic distances (Å): Li1···C11 2.700(3), Li1···C12 2.602(6), Li2···C2 2.602(6); Li1···P1 2.983(2), Li1···Li2 2.42(1); torsion angle C1−N1−P1−N1a −148.8°

Because the structure of $Ph_2P-NHtBu$ is still unknown, no direct comparison of **10** to changes in bonding parameters with the parent compound can be made. The P−N bonds of **10** are shorter than in $Ph_2P-NHmes$ [1.730(2)Å][16] but not as short as in $Ph_2P-NmesLi\cdot 2OEt_2$ [1.661(2) Å]. Only the nitrogen atoms are involved in coordination with the Li atoms. The Li−N bond to the ether-bearing Li atom is 0.057 Å longer than the Li−N bond to the ether-free atom Li1. However, this atom has two close contacts with H atoms of two methyl groups. Moreover, atom Li1 is also shielded sterically by the two phenyl groups as there are four η-Li−C interactions. These are sufficient to prevent the addition of an ether molecule to the atom Li1, and also to inhibit Li−P coordination. The two phenyl groups are mutually oriented at an interplanar angle of 110.9° to one another, and the coordination of the phenyl groups C11 to C16 and C11a to C16a to the atom Li1 form an interplanar angle of 45.6°. A torsion angle of 15.8° for the four-atom arrangement Li2−N1−C1−C2 reveals an almost optimal orientation for the Li2···H2C and Li2···H10A "agostic" interactions with distances of 2.44 Å. Thus the structure of the anion shows an *anti*-conformation of the substituents at the PN unit (torsion angles C1−N1−P1−C5: −121°, C1−N1−P1−C11: 134°).

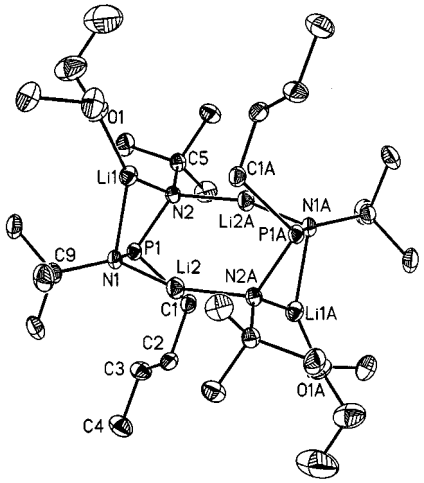

Figure 8. The molecular structure of $\{BuP[N(Li)tBu]_2\}_2\cdot 2OEt_2$ **(11)** in the crystal; hydrogen atoms omitted for clarity; thermal ellipsoids are represented on a 25% probability scale; selected bond lengths and atom distances (Å): Li1−N1 2.034(5), Li1−N2 1.983(5), Li2−N1 1.930(5), Li2−N2a 1.962(5), Li1−O1 1.926(5), P1−N1 1.707(2), P1−N2 1.715(2), P1−C1 1.876(3); P1···Li1 2.543(5), Li2···C5A 2.785(5), Li2···P1 3.046(5); bond angles (°): C1−P1−N1 100.9(1), C1−P1−N2 100.9(1), N1−P1−N2 98.7(1), N1−Li1−N2 80.5(2), O1−Li1−N2 142.7(3), O1−Li1−N1 135.9(2), N1−Li2−N2A 160.0(3), 85.2(2), Li1−N1−P1 85.2(2), Li2−N1−P1 113.6(2), Li1−N2−P1 86.6(2)

The dilithio compound **11** crystallizes as a dimer of composition $BuP[N(Li)tBu]_2\cdot OEt_2$. Its molecular structure is shown in Figure 8. The molecule is centrosymmetric due to a crystallographically-imposed center of inversion at the center of an eight-membered ring. The two non-equivalent P−N bonds are slightly but significantly different and somewhat longer than in **10**. They can be considered as P−N single bonds. All nitrogen atoms are involved in coordination to Li atoms. There are two kinds of Li atoms. Atom Li1 is coordinated to one oxygen atom and two N atoms, and the sum of bond angles at the tricoordinated atom Li1 is 359°. In addition, there is a fairly short Li1···P1 contact [2.543(5) Å]. However, this is a consequence of the geometry of the four-membered ring because the lone pair of the atom P1 presumably points outwards from the four-membered butterfly-shaped Li1−N1−P1−N2 ring. Taking the sum of bond angles at P1 (300.5°) into account, one can assume that hybridization at this atom is halfway between p^3 (270°) and sp^3 (330°) so that the lone pair at the P atom no longer has pure s character. While the N1−Li1−N2 bond angle of the four-membered ring is rather sharp [81.5(2)°] the N1−Li2−N2a bond angle is quite open (144.9°). Atom Li2 is, however, sterically shielded by two Li···H interactions ranging from 2.37 to 2.39 Å. While the folding angle of the four-membered ring Li1−N1−P1−N2 is 32.7°, the N1Li1N2 plane adopts an interplanar angle of 85° with the N1Li2N2a plane. Figure 9 shows the closest intramolecular Li···H contacts (2.4−2.7 Å) of molecule **11** which contribute to the steric shielding

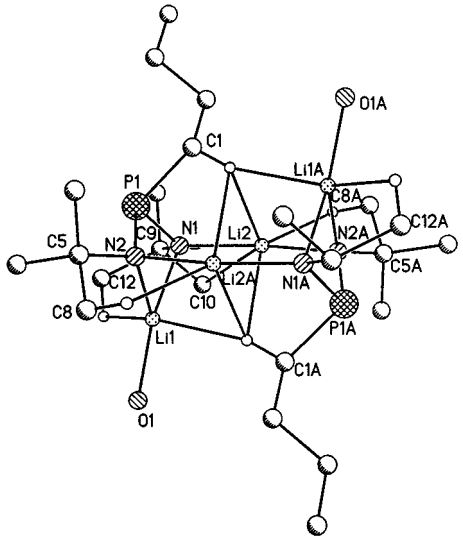

Figure 9. View almost along the Li_2N_4 plane on the structural core of molecule **11** including short H−Li contacts

of the Li atoms. A structure similar to **11** is observed for the solvent-free centrosymmetric molecule $\{PhP[N(Li)-tBu]_2\}_2$ **12**, as shown in Figure 10. There are two independent "monomers" in the asymmetric unit. The dimeric molecules exhibit eight-membered Li_4N_4 rings with the P atoms bridging adjacent pairs of N atoms, or, alternatively, two N_2PLi four-membered rings are connected by two Li atoms, with the formation of a total of four Li−N bonds.

Two Li centers are η^6-coordinated to phenyl groups. As a result of this coordination, the Li2−N2−Li1 bond angle is only 93.3° (100.1° in **11**), and the interplanar angle N1−Li1−N2/N2−Li2−N1a is now 99.1°. Moreover, the folding angle between the N_2Li and the N_2P plane of the four-membered ring is 16.5°, and, therefore the ring is closer to planarity than the analogous ring in **11**. As ex-

Figure 10. pected for a four-membered LiN_2P ring, a short Li···P distance of 2.559(5)Å is observed.

Although compound **13** is formally related to both **11** and **12**, as it is a dimeric dimetallated bis(monoorganoamino)organophosphane (see Figure 11), its structure turned out to be vastly different to **12**, obviously due to solvation by diethyl ether. There is (formally) one ether molecule per Li atom. However the structure determination revealed that there are altogether *four* different Li centers, one of which binds two ether molecules, two others only one, while the fourth Li center carries no ether molecule at all as seen in Figure 11.

There are two molecules of **13** in the asymmetric unit of the triclinic unit cell of space group $P\bar{1}$. The differences between their bonding parameters are insignificant therefore only one molecule is depicted in Figure 11. Formally, the structure can be described as $[(Et_2O)_2Li]$-$[Li_3(NPh)_4(PPh)_2\ OEt_2]$, and the anionic cage as being built from two PN_2Li four-membered rings joined by two LiN bonds to result in a structure of three condensed four-membered rings whose open faces are bridged by a $Li(OEt_2)$ unit by two nitrogen atoms. On the other hand, the $(Et_2O)_2Li$ unit is joined to atom P1 with a comparatively short Li−P distance of 2.54 Å while the Li4−P1 distance in the four-membered ring is 0.1 Å longer. In contrast, the four-membered ring P2N3N4Li1 is characterized by a longer and therefore weaker Li1−N3 interaction, and this causes a lengthening of the Li1−P2 distance to 2.746(5)Å.

P−N bonds to atom P1 are shorter than in the parent compound $PhP(NHPh)_2$, but are of equal lengths, while those at atom P2 seem to be slightly different but are on average only 0.01 Å longer than those at P1. These bonds correspond to those found for $PhP(NHPh)_2$.

The lithiation of $MeP(NH\textit{i}Pr)_2$ led to $MeP[N(Li)\textit{i}Pr]_2$ which turned out to be the *tetramer* **14**, crystallizing with 5 molecules of THF. Four of these THF molecules are bonded to Li centers, the fifth remains uncoordinated in the triclinic lattice. Thus the composition of compound **14** can be described as $\{MeP[N(Li{\cdot}THF)\textit{i}Pr]\ [N(Li)\textit{i}Pr]\}_4$ THF but it is surprisingly asymmetric as depicted in Figure 12.

Inspection of Figures 12 and 13 reveals that the Li atoms are coordinated quite differently. While Figure 12 gives an overview of the structure, Figure 13 represents more clearly its cage structure. Atoms Li2, Li4 and Li6 are tricoordinated by two N atoms and one O atom; they form a rhombus with another Li atom which coordinates to the two N atoms. Atoms Li1 and Li7 have three nitrogen atoms as coordination partners and these are arranged in a plane including the Li atoms (sum of bond angles 359.9 and 360° respectively). Two of the N−Li−N angles subtending at Li are comparatively small, ranging from 100.5 to 113.5°.The others are rather wide (144.8 and 149.6°). On the other hand, atom Li3 has two nitrogen atoms and a phosphorus atom as coordination partners. The same number of bonded atoms are observed for atom Li5 which is, however,

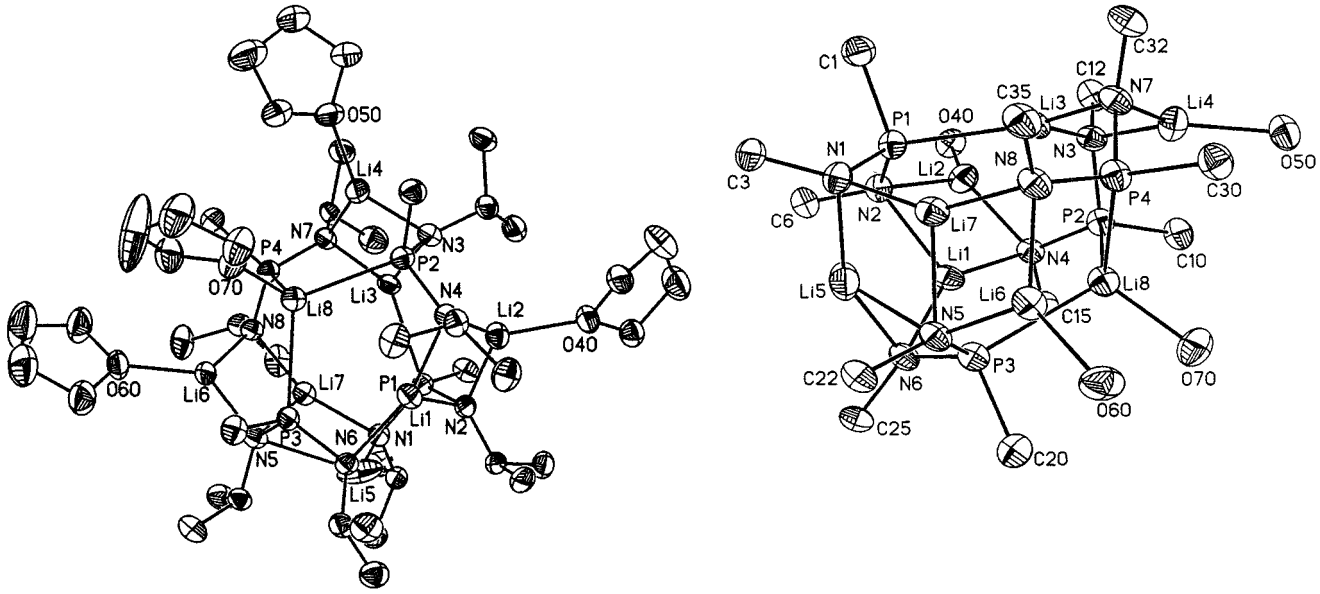

Figure 12. a) ORTEP molecular structure of {MeP[N(Li)*i*Pr]2·thf}$_4$ **(14)**; hydrogen atoms are omitted; thermal ellipsoids are represented at a 25% probability level; selected bond lengths and atom distances (Å): P1−N1 1.671(4), P1−N2 1.683(4), P1···Li3 2.514(8), P1···Li5 2.76(2), P1···Li7 2.854(8), P2−N3 1.677(5), P2−N4 1.686(4), P2···Li8 2.656(9), P3−N5 1.687(4), P3−N6 1.674(4), P3···Li8 2.629(9), P4−N7 1.656(5), P4−N8 1.682(4), P4···Li8 2.677(9), C1−P1 1.871(7), N1−Li5 1.96(2), N1−Li7 2.082(9), N2−Li1 2.17(1), N2−Li2 2.043(9), N3−Li3 2.006(9), N3−Li4 2.05(1), N4−Li1 2.105(9), N4−Li2 1.97(1), N5−Li6 1.999(9), N5−Li7 2.17(1), N6−Li1 2.03(1), N6−Li5 1.96(1), N7−Li3 2.004(9), N7−Li4 1.98(1), N8−Li6 2.01(1), N8−Li7 2.036(9); bond angles (°): N1−P1−N2 112.5(2), Li3−P1−N2 107.5(2), Li3−P1−N1 121.5(2), C1−P1−N1 105.1(2), C1−P1−N2 108.7(2), N2−Li1−N4 10.5(4), N2−Li1−N6 113.6(4), N4−Li1−N6 144.8(5), P1−N1−Li5 68.1(2), P1−N1−Li7 98.4(2), Li5−N1−Li7 80.3(6), P1−N2−Li2 112.2(3), P1−N2−Li1 102.9(3), Li1−N2−Li2 72.2(4),N2−Li2−N4 111.1(5), N2−Li2−O40 123.0(4), N4−Li2−O40 116.1(4), C10−P2−N4 105.2(2) C10− P2−N3 106.2(3), C10−P2−Li8 118.6(3), N3−P2−N4 109.4(2) Li8−P2−N3 107.3(3), Li8−P2−N4 109.8(2), P2−N3−Li3 103.9(4), P2−N3−Li4 96.6(4), P2−N4−Li1 105.8(3), P2−N4−Li2 104.7(4), C20−P3−N5 109.9(2), C20−P3−N6 105.6(3), N5−P3−N6 111.3(2), P3−N5−Li6 110.8(3), P3−N5−Li7 104.4(3), P3−N5−Li5 72.6(3), P3−N6−Li5 91.3(5), P3−N6−Li1 96.3(3), C30−P4−N7 103.0(3), C30− P4−N8 104.8(2), N7−P4−N8 116.7(2), C30−P4−Li8 121.6(3), P4−N7−Li4 109.9(4), P4−N8−Li7 107.9(3), P4−N8−Li6 99.7(3), N3−Li3−N7 107.1(4), N3−Li3−P1 118.5(4), N7−Li3−P1 134.3(4), O50−Li4−N7 128.8(5), O50−Li4−N3 125.1(5), O50−Li4−P2 107.8(4), N1−Li5−N6 148.5(7), N1−Li5−P3 120.7(5), O60−Li6−N5 124.0(6), O60−Li6−N8 128.1(5), O60−Li6−P4 117.0(4), N1−Li7−N5 109.9(4), N1−Li7−N8 149.6(6), N5−Li7−N8 160−4(5), O70−Li8−P3 109.1(5), O70−Li8−P2 109.8(3), O70−Li8−P4 109−2(4), P2−Li8−P3 111.3(3), P2−Li8−P4 110.3(4); b) The core structure of **14** was obtained by removing all the substituents from the N and P atoms and the C atoms of the THF molecules

not part of a Li_2N_2 rhombus. Finally, atom Li8 binds to three phosphorus atoms and one oxygen atom. Li8 represents the only Li center which is tetracoordinated. Amongst the tricoordinated Li centers, atoms Li2 and particularly Li5 are unusual because the sum of bond angles at Li2 is 350° but for Li5 only 323° (without including a possible weak Li5−P3 interaction (2.605(4).Å). One may see this atom as being dicoordinated, particularly because the Li2−N5 distance is 2.551(6) Å and the N6−Li5−N1 bond angle is rather open [148.5(7)°]. Similar angles are also observed in the structures of **11** and **12**.

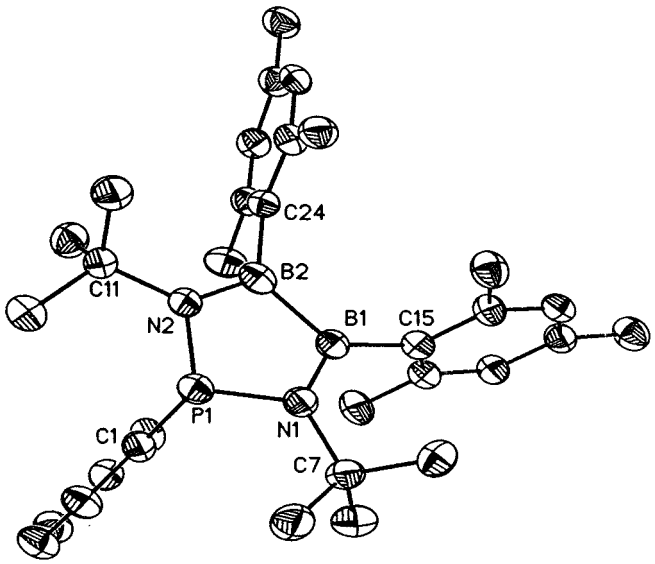
The five-membered ring of the 1,3,2,4,5-diazaphosphadiboretidine **15** is almost planar (sum of bond angles 539.8°). It contains a pyramidal P1 atom, and planar N and B atoms. The B−N bond lengths are characteristic of π-bonds. The B−B bond length is typical for a single bond and lies in the usual range for diborane(4) derivatives. The two mesityl groups include an interplanar angle of 64°.

Discussion

The stability of primary bis(amino)organophosphanes depends on the steric shielding at the P center. This is an indication that the elimination of RNH_2 from these molecules to form, e.g. 1,3,2,4-diazadiphosphetidines[13][14] occurs by intermolecular steps. An intramolecular amine elimination to form an iminophosphane RP=NR′ followed by dimerisation could be an alternative. This process, however, might be less influenced by steric effects. An intramolecular process should be dependent on the conformation of the $R'P(NHR)_2$ molecules. It is evident that a mechanistic study is required to settle this question.

The synthesis of the bis(organoamino)organophosphanes is readily achieved by aminolysis of the respective chloride $R'PCl_2$ or by silazane cleavage. The latter method is versatile and quite useful, particularly if steric effects are not too pronounced.

As demonstrated for $P(NHPh)_3$ ($\delta^{31}P = 73.8$)[6f] the ^{31}P nucleus is better shielded in compound $PhP(NHPh)_2$. Replacement of an *i*Pr group by a *t*Bu group at the N atom also results in a better shielding of the ^{31}P nucleus by 14 ppm. It is also surprising that the ^{31}P nucleus is better shielded in $PhP(NHPh)_2$ than in $PhP(NHiPr)_2$. This may be due to the larger N−P−N bond angle in $PhP(NHiPr)_2$ relative to $PhP(NHPh)_2$, due to a higher s-character of the P atom in $PhP(NHPh)_2$. However, this may be due to the longer P−N bond lengths resulting from hydrogen bonding but we have not determined the degree of association in



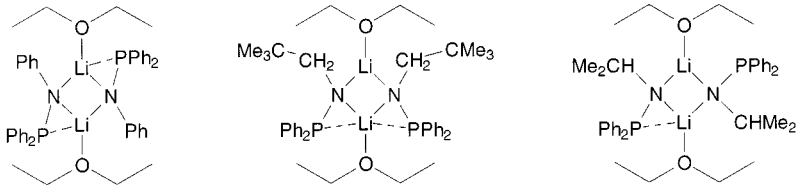


Figure 13. The molecular structure of **15** in the solid state; thermal ellipsoids are represented at a 25% probability level; hydrogen atoms are omitted for clarity; selected bond lengths (Å): P1−N1 1.743(5), N1−B1 1.436(7), B1−B2 1.71(1), B2−N2 1.428(7), N2−P1 1.732(5), P1−C1 1.841(6), B1−C15 1.585(8), B2−C24 1.605(8); bond angles (°): C1−P1−N12 100.9(2), C1−P1−N2 101.5(2), N1−P1−N2 95.7(2), P1−N1−B1 114.8(4), P1−N1−C7 115.7(3), C7−N1 B1 129.4(5), N1−B1−B2 106−6(4), N1−B1−C15 125.3(5), B1−B2−N2 108.4(5), B1−B2−C24 128.1(5), B2−N2−P1 114.3(4); torsion angle: C1−P1 N1−C7 −80.4°; interplanar angle: N1N2P1/C1 to C6 92.8°; C15 to C20/C24 to C29 71.1°

solution. On the other hand, there is only a small variation both in the shielding of the ^{15}N nuclei as well as in the coupling constant ^{1}J(P-N), irrespective of the substituent at the P atom (Me, Ph, mes) or the N atoms (*i*Pr, *t*Bu, Ph). This suggests that in solution the structural differences observed for the structure of $PhP(NHiPr)_2$ and $Ph(NHPh)_2$ in the solid state, particularly with respect to the pyramidal geometry at the P atom, but also at the N atoms, becomes less significant or even negligible. This also holds for the mesityl bis(amino)phosphanes, although the coupling constants ^{1}J(P-N) are noticeably smaller (by 4.5 and 8.3 Hz, respectively, for the isopropyl and *tert*-butyl derivative), probably due to steric effects particularly for the sterically-crowded $mesP(NHtBu)_2$.

It would be most interesting to compare the structural parameters and their changes in the aminophosphanes with those of the respective *N*-lithio compounds. Unfortunately there are, at the moment, too few pairs of compounds to be compared in this respect. Nevertheless, the structural aspects of *N*-lithioaminophosphanes are attracting increasing interest [2,4,15,16] since the determination of the X-ray structure of $[Ph_2P-NPh(Li\cdot OEt_2)]_2$.[2] So far, $Ph_2P-N(Li)mes^*\cdot 2OEt_2$[16] is the only monomeric *N*-lithio-monoaminophosphane known which shows a *trans*-conformation with respect to the P−N bond. A related compound is the lithium salt of the bis(diphenylphosphanyl)amine $Ph_2P-NH-PPh_2$.[4] Therefore, bulky groups are necessary besides supporting ligands such as THF or Et_2O which coordinate to the Li centers. The *trans*-conformation in monoaminophosphanes inhibits any intramolecular P···Li interaction. However, this kind of interaction is observed in $Ph_2P-N[Li(THF_3)]-PPh_2$ where a *cis*-conformation was determined, a result also supported by ab initio calculations.[4a] Besides these two structurally-characterized compounds, there are three dimeric *N*-lithioaminophosphanes of type $Ph_2P-N(Li\cdot OEt_2)R$ (formulae **I**−**L**) where the *cis*-conformation prevails. These compounds exhibit different degrees of P···Li interactions.[16] Thus, **I** and **K** show weak Li···P interactions, while there is only a single one in **L**. Thus an increasing steric effect due to the nitrogen substituents decreases the probability of Li···P interactions. These conclusions are supported by the molecular structure of **10** where a *trans*-conformation is observed for the $Ph_2P-NtBu$ unit which inhibits a Li···P interaction. The *trans*-conformation results from the N−Li coordination, and the η^6-coordination of two phenyl groups of two different $Ph_2P-NtBu$ units. The consequence of this is, in addition, that only a hemietherate is formed. The P−C bond lengths in **11** are similar to those in **6** and **L**, a situation that does not allow one to draw the conclusion as to whether the orbitals at nitrogen mix with the P−C* orbitals or not.[15][16]

For dimetallated bis(amino)organophosphanes, structures different to monometallated monoaminodiorganophosphanes are to be expected. It is, however, somewhat surprising that out of the four examples investigated, three are dimeric. Of these, two have rather similar structures in spite of the fact that **11** is an ether solvate and **12** is non-solvated. Moreover, the formation of **11** was also not expected because the nucleophilic exchange of *P*-bonded organo groups is an exception in phosphorus chemistry. This kind of reaction has been observed, for instance, in the reaction of tris(2-pyridinyl)-trimethylsilylamino-phosphoranes with methyl lithium.[17] Since this exchange of R groups has only been observed during the metallation of $mesP(NHtBu)_2$ and not of phenyl-bis(monoorganoamino)-phosphanes it appears that the mesityl group acts as a better leaving group than a phenyl group. Thus the butyl anion not only acts as a base for NH deprotonation, but also as a nucleophile, attacking the P^{III} center.

The conformation of the $CP(NC)_2$ units in **11** and **12** can be considered as representing a *trans* conformation with dihedral C−P−N−C angles of −122.2° and 102.2° for **11** and −126.1° and 123.2° for **12.** Four-membered LiN_2P rings are formed which are connected by two Li−N−Li bonds, making all nitrogen atoms tetracoordinated. Although the Li···P distances in **11** and **12** are 2.543 and 2.559 Å, respectively, and are therefore shorter than the "secondary" Li−P bonding in **I,** the short distances are certainly a consequence of the geometry of the four-membered ring, and reflect no Li−P single bond interaction. The rather sharp N−Li−N bond angle (80.5° in **11** and 81.5° in **12**) is also an indication that Li−P bonding is avoided. However, the N−P−N bond angles are 98.7 and 102.8° in **11** and **12**. In addition, the lone pair of electrons at the P atoms cannot be of an s-type because the sum of bond angles at these atoms is 291° and 303.4°, respectively. There is only a change of 2.7° for the N−P−N bond angles in **12**, com-

I **K** **L**

pared to the non-metalated aminophosphane, and only a slight elongation of the P−N bond lengths (average 0.01 Å), which has to be considered as almost negligible. However, the P−C bond length in **12** is 0.05 Å longer than in **11,** and this is an indication of a negative hyperconjugative effect.[8,15,16] Most interesting is the presence of dicoordinated Li atoms both in **11** and **12**, a situation that is similar to that found in tetrameric lithium tetramethylpiperidine[10] or trimeric $LiN(SiMe_3)_2$.[18] Another feature of **12** is that two of its Li centers are η^6-coordinated to phenyl rings. This mode of coordination saturation does not occur very often, but is nevertheless not uncommon,[19] and found, for instance, in $[(Me_3Si)_2N-N(Li)Ph]_4$[1d] or $[Ph(Li)N-N(Li)SiMe_3]_4$[1c] the latter also containing $(\eta^6\text{-}C_6H_5)_2Li$ units.

No η^6-PhLi groups are present, however, in $\{PhP[N(Li)Ph]_2\}_2 \cdot 4OEt_2$, **(13)**. The rather unsymmetrical structure of this compound having four different kinds of Li centers is unique. Once again there is a Li···P distance (2.55 Å) across a LiN_2P ring that might indicate weak bonding, but we regard this as a consequence of the ring structure. One may also look upon this molecule as a contact ion pair because one Li atom is not used for completing the $Li_3P_2N_4$ cage. The Li−P atom distance of this unique Li center, formally a $(Et_2O)_2Li^+$ unit, is 2.64 Å. This distance is similar to that found in lithiumphosphides,[20] e.g. [(TMEDA·Li)PPh_2 (2.61 Å)][21] or $[LiP(SiMe_3)_2]4\cdot 2THF$ (2.48−2.64 Å).[22] While the P−N bond lengths at the atom P2 are not influenced by the metallation, obviously because the P atom remains tricoordinate, the P−N bonds at P1, the atom which can be considered as tetracoordinated become shorter. This is unusual insofar as an increase in coordination normally causes bond lengthening. Therefore, this can be taken as an indication of π-bonding in the P−N bond, as supported by the observation that the P−C bond length is not affected and remains the same as in **12**.

Even more unsymmetrical is the structure of **14**. The most interesting feature is the presence of a P_3LiO unit besides a planar N_3Li unit. By maximizing the number of Li−N contacts, it is obvious that one LiN_3 unit must finally lead also to Li−P contacts. The first principle leads to three four-membered Li_2N_2 rhombi, a structural unit typical for lithium amides.[19] Of the eight Li centers, seven are tricoordinate, and only the Li atom of the LiP_3 unit becomes tetracoordinated by also binding a THF molecule. Although one can rationalize that Li−N contacts in lithiated aminophosphanes are preferred as a result of the principle of hard/soft acid-base character, LiP interactions cannot be totally avoided particularly in the lithiated bis(amino)phosphanes $[R'P(NLiR)_2]_n$ for n > 2. Due to the association of the lithiated aminophosphanes, the question as to whether these might contain the structural unit of a *P*-metallated iminophosphorane can be discarded, as there is no indication of short P−N bonds (higher bond order) where Li···P coordination is observed. It is evident that bis-metallated bis(amino)phosphanes have structures completely different to bis-metallated hydrazines. The reason that they must have different geometries is due to their composition, which is $RP(NLiR)_2$ for the former and R(Li)N−N(Li)R for the latter with the P atom offering at least potentially, an additional coordination site

Experimental Section

All experiments were performed under anhydrous conditions with standard Schlenk techniques and nitrogen as the protecting gas. Solvents were dried by standard procedures, distilled under a nitrogen atmosphere and stored under N_2. The amines and the phosphorus halides used were commercial products, whose purity was checked by NMR methods. $Ph_2P-NHtBu$ was prepared as described in the literature.[2] − M.p.′s were determined with a Mel-Temp apparatus. − Elemental analysis was performed at the institute′s microanalytical laboratory. − NMR: Jeol 270, Jeol 400 with $SiMe_4$ or C_6D_6 internal standard for ^1H and ^{13}C, internal 1M aqueous $^{15}NH_4^+$ solution for ^{15}N, 85% H_3PO_4 internal for ^{31}P; 1M LiCl solution external for ^7Li. − IR: Nicolet FT 320 (samples in Nujol/Hostaflon mulls); MS: Atlas CH7. − X-ray: Siemens P4 diffractometer equipped with a CCD area detector and LT2 low temperature device; Mo-K_α radiation, graphite monochromator.

Bis(isopropylamino)methylphosphane (1): $iPrNH_2$ (14.7 g, 249 mmol) was dissolved in diethyl ether (250 mL) and a solution of $MePCl_2$ (5.84 g, 50.3 mmol) in ether (50 mL) was added at 0°C while stirring. A precipitate formed. Stirring was continued overnight, the solid was removed by filtration, and washed three times with 150 mL of ether. The solutions were combined, and the solvent and excess amine were removed in vacuo. The residue was then subjected to distillation. Yield: 6.3 g of **1** (78%), colorless oil b.p. 52°C/2 Torr. − ^1H NMR (C_6D_6, 400 MHz): δ = 0.9 (d, $^3J_{HH}$ = 6.4 Hz, 6 H, CH−CH_3), 1.0 (d, $^3J_{HH}$ = 6.4 Hz, 6 H, CH−CH_3), 1.1 (d, $^2J_{PH}$ = 5.8 Hz, 3 H, P−CH_3), 1.6 (s, broad, 2 H, N*H*), 3.1−3.2 (m, 2 H, C*H*−CH_3). − ^{13}C NMR (C_6D_6, 100 MHz): δ = 18.7 (d, $^1J_{PC}$ = 2.8 Hz, P−CH_3), 26.4 (d, $^3J_{PC}$ = 6.0 Hz, CH−CH_3), 26.9 (d, $^3J_{PC}$ = 3.7 Hz, CH−CH_3), 44.7 (d, $^2J_{PC}$ = 12.6 Hz, *C*H−CH_3). − ^{15}N NMR (C_6D_6, 27.4 MHz): δ = −302.1 (d, $^1J_{PN}$ = 65.3 Hz). − ^{31}P NMR (C_6D_6, 81 MHz): δ = 51.7 (s). − $C_7H_{19}N_2P$ (162.22): calcd. C 51.83, H 11.81, N 17.27; found C 49.24, H 11.96, N 16.82.

Bis (*tert*-butylamino)methylphosphane (2): Prepared in a similar manner to **1** from $tBuNH_2$ (17.3 g, 243 mmol) and $MePCl_2$ (5.0 g,

43 mmol) in a total of 200 mL of diethyl ether. Yield: 7.6 g (84%), colorless oil, b.p. 53°C/5 Torr. – ^{1}H NMR (C_6D_6, 400 MHz): δ = 1.1 (d, $^2J_{PH}$ = 6.6 Hz, 3 H, P–CH_3), 1.2 (s, 18 H, C–CH_3), 1.4 (s, broad, 1 H, N*H*), 1.5 (s, broad, 1 H, N*H*). – ^{13}C NMR (C_6D_6, 100 MHz): δ = 23.7 (d, $^2J_{PC}$ = 3.5 Hz, P–CH_3), 32.4 (d, $^3J_{PC}$ = 9.6 Hz, C–CH_3), 50.8 (d, $^2J_{PC}$ = 13.7 Hz, *tert*-*C*). – ^{15}N NMR (C_6D_6, 27.4 MHz): δ = –289.9 (d, $^1J_{PN}$ = 65.7 Hz). – ^{31}P NMR (C_6D_6, 80 MHz): δ = 39.2 (s). – $C_9H_{23}N_2P$ (190.27): calcd. C 56.81, H 12.18, N 14.72; found C 55.72, H 12.07, N 14.01.

Bis(isopropylamino)phenylphosphane (3): Prepared analogously to **1** from *i*PrNH$_2$ (20.9 g, 350 mmol) in ether (250 mL) and PhPCl$_2$ (12.7 g, 70 mmol) in ether (50 mL). Isolated by distillation, b.p. 76–78°C /0.2 Torr as an oily liquid. On standing at 4°C, crystals formed with m.p. 6°C. Yield: 12.6 g of **3** (79%). – ^{1}H NMR (C_6D_6, 400 MHz): δ = 1.0 (d, $^3J_{HH}$ = 6.2, CH-CH_3), 1.1 (d, $^3J_{HH}$ = 6.3 Hz, 6 H, CH–CH_3), 1.7 (s, broad, 1 H, N*H*), 1.75 (s, broad, 1 H, N*H*), 3.2 (m, 2 H, C*H*–CH_3, 7.1–7.7 (m, 5 H, C_6H_5). – ^{13}C NMR (C_6D_6, 67.9 MHz): δ = 26.5 (d, $^3J_{PC}$ = 6.1 Hz, CH–CH_3), 26.8 (d, J_{PC} = 4.1 Hz, CH–CH_3), 46.2 (d, $^2J_{PC}$ = 7.5 Hz, *C*H–CH_3), 127.7 (s, *p*-C_6H_5), 128.1 (d, $^3J_{PC}$ = 4.1 Hz, *m*-C_6H_5), 131.1 (d, $^2J_{PC}$ = 15.3 Hz, *o*-C_6H_5), 148.0 (d, $^1J_{PC}$ = 5.1 Hz, *ipso*-C_6H_5). – ^{15}N NMR (C_6D_6, 27.4 MHz): δ = –304.8 (d, $^1J_{PN}$ = 67.9 Hz). – ^{31}P NMR (C_6D_6, 81 MHz): δ = 58.9 (s). – $C_{12}H_{21}N_2P$ (224.29), calcd. C 64.26, H 9.44, N 12.49; found C 63.72, H 8.94, N 12.47.

Bis(*tert*-butylamino)phenylphosphane (4):[7] Prepared analogously to **1** from *t*BuNH$_2$ (15.0 g, 210 mmol) and PhPCl$_2$ (5.7 g, 32 mmol) in 200 mL of ether. Yield: 5.9 g of **4** (73%), slightly yellow oil, b.p. 98°C/0.8 Torr. – ^{1}H NMR (C_6D_6, 400 MHz): δ = 0.0 (d, $^4J_{PH}$ = 0.5 Hz, 18 H, C–CH_3), 1.5 (s, broad, 1 H, NH), 1.7 (s, broad, 1 H, NH), 6.9–7.3 (m, 5 H, C_6H_5). – ^{13}C NMR (C_6D_6, 100 MHz): δ = 32.7 (d, $^3J_{PC}$ = 8.2 Hz, C–CH_3), 51.1 (d, $^2J_{PC}$ = 16.1 Hz, *tert*-C), 127.2 (s, *p*-C_6H_5), 127.7 (d, $^3J_{PC}$ = 4.2 Hz, *m*-C_6H_5), 130.1 (d, $^2J_{PC}$ = 17.2 Hz, *o*-C_6H_5, 148.0 (d, $^1J_{PC}$ = 3.5 Hz, *ipso*-C_6H_5). – ^{15}N NMR (C_6D_6, 27.4 MHz): δ = 292.3 (d, $^1J_{PN}$ = 68.2 Hz). – ^{31}P NMR (C_6D_6, 81 MHz): δ = 42.0 (s). – $C_{14}H_{25}N_2P$ (252.34), calcd. C 66.64, H 9.99, N 11.27; found C 66.36, H 9.75, N 11.10.

Bis(anilido)phenylphosphane (5): PhPCl$_2$ (4.5 g, 25 mmol) was dissolved in toluene (50 mL), and a solution of aniline (9.3 g, 100 mmol) in toluene (100 mL) was added with stirring in such a manner that the temperature of the resulting suspension never exceeded 25°C. After stirring overnight, the insoluble material was removed by filtration and washed with a total of 100 mL of diethyl ether. (The solution may turn turbid.) The solid was then removed after several hours. The combined solutions were reduced to 30 mL in volume. The remaining solution was layered with pentane. After cooling to 0°C a crystalline solid separated, m.p. 70–72°C. Yield: 3.0 g of **5** (42%). – ^{1}H NMR (C_6D_6, 400 MHz): δ = 4.4 (s, broad, 2 H, N*H*), 6.6–7.7 (m, 15 H, C_6H_5). – ^{13}C NMR (C_6D_6, 100 MHz): δ = 117.0. (d, $^3J_{PC}$ = 11.7 Hz, *m*-C_6H_5), 120.3, s, 128.7 (d, $^3J_{PC}$ = 4.0 Hz, *m*-C_6H_5), 129.0, s, 129.5, s, 130.2 (d, $^2J_{PC}$ = 17.0 Hz, *o*-C_6H_5), 141.7, s, 145.7 (d, $^1J_{PC}$ = 13.8 Hz, *ipso*-C_6H_5). – ^{15}N NMR (C_6D_6, 27.4 MHz): δ = –294.6 (d, $^1J_{PN}$ = 66.4 Hz). – ^{31}P NMR (C_6D_6, 81 MHz): δ = 46.8 (s). – $C_{18}H_{17}N_2P$ (297.32): calcd. C 73.96, H 5.86, N 9.58; found C 72.15, H 5.87, N 9.36.

Bis(*tert*-butylamino)mesitylphosphane (6): Prepared analogously to **7** from mesPCl$_2$ (1.2 g, 5.5 mmol) and *t*BuHN–SiMe$_3$ (3.2 g, 22 mmol) in 30 mL of toluene. Yield: 1.17 g of **6** (4.0 mmol, 72%), b.p. 100°C/0.1 Torr, yellow oil. – ^{1}H NMR (C_6D_6, 400 MHz): δ = 1.2 (s, 18 H, C- CH_3), 2.3 (s, 3 H, *p*-CH_3), 2.2 (s, broad, 1 H, NH), 2.3 (s, broad, 1 H, NH), 2.6 (s, 6 H, *o*-CH_3), 6.8 (s, 2 H, *m*-C_6H_2). – ^{13}C NMR (C_6D_6, 100 MHz): δ = 20.9 (s, *p*-CH_3), 22.5 (d, $^3J_{PC}$ = 21.4 Hz, *o*-CH_3), 32.2 (d, $^3J_{PC}$ = 10.0 Hz, C–CH_3), 51.2 (d, $^2J_{PC}$ = 21.7 Hz, *tert*-C), 129.6 (d, $^3J_{PC}$ = 4.2 Hz, *m*-C_6H_5), 137.4 (s, *p*-C_6H_5), 139.3 (d, $^2J_{PC}$ = 18.7 Hz, *o*-C_6H_5), 140.4 (d, $^1J_{PC}$ = 13.4 Hz, *ipso*-C_6H_5). – ^{15}N NMR (C_6D_6, 27.4 MHz): δ = –298.9 (d, $^1J_{PN}$ = 59.9 Hz). – ^{31}P NMR (C_6D_6, 81 MHz): δ = 44.1 (s). – $C_{17}H_{31}N_2P$ (294.42): calcd. C 69.35, H 10.61, N 9.51; found C 69.06, H 9.70, N 9.32.

Di(isopropylamino)mesitylphosphane (7) and 1,3-Diisopropyl-2,4-dimesityl-1,3,2,4-diazadiphosphetidine (8): A solution of mesPCl$_2$ (1.7 g, 7.6 mmol) in toluene (20 mL) was added to a stirred solution of *i*PrHN–SiMe$_3$ (3.90 g, 29.3 mmol) in toluene (30 mL). The mixture was heated at reflux for 14 h. Me$_3$SiCl and toluene were then stripped off from the clear orange-colored solution. The oily residue yielded 1.7 g of **7** (35 mmol), b.p. 109°C/0.1 Torr. – ^{1}H NMR (C_6D_6, 400 MHz): δ = 1.0 (d, $^3J_{HH}$ = 6.3 Hz, 6 H, CH–CH_3), 1.3 (d, $^3J_{HH}$ = 6.3 Hz, 6 H, CH–CH_3), 2.1 (s, broad, 1 H, N*H*), 2.2 (s, broad, 1 H, N*H*), 2.3 (s, 3 H), 2.6 (s, 6 H), 3.3 (m, 2 H, C*H*CH$_3$), 6.7 (2, 2 H, C_6H_2). – ^{13}C NMR (C_6D_6, 67.9 MHz): δ = 20.8 (s, *p*-CH_3), 22.7 (d, $^3J_{PC}$ = 19.8 Hz, *o*-CH_3), 26.3 (d, $^3J_{PC}$ = 4.6 Hz, CH–CH_3), 26.5 (d, $^3J_{PC}$ = 7.7 Hz, CH–CH_3), 47.8 (d, $^2J_{PC}$ = 32.1 Hz, *C*H–CH_3), 129.5 (d, $^3J_{PC}$ = 3.8 Hz, *m*-C_6H_5), 17.8 (s, *p*-C_6H_5), 139.2 (s, *o*-C_6H_5), 139.4 (d, $^1J_{PC}$ = 17.6.1 Hz, *ipso*-C_6H_5). – ^{15}N NMR (C_6D_6, 27.4 MHz): δ = –303.5 (d, $^1J_{PN}$ = 63.4 Hz). – ^{31}P NMR (C_6D_6, 81 MHz): δ = 58.7 (s). – $C_{15}H_{27}N_2P$ (266.37): calcd. C 67.64, H 10.22, N 10.52; found C 64.75, H 9.90, N 10.11.

From a similar reaction, using (4.0 g of *i*PrHN–SiMe$_3$, 30 mmol), 1.7 g of MesPCl$_2$, 7.6 mmol) in toluene (20 mL), 1.7 g of **7** was obtained by distillation. A non-volatile oil remained which was dissolved in CHCl$_3$ (5 mL). On cooling large red needles of **8** separated, m.p. 155°C. Yield: 0.5 g of **8** (30%). – ^{1}H NMR (CDCl$_3$, 400 MHz): δ = 0.8 (d, $^3J_{HH}$ = 6.4 Hz, 6 H, CH–CH_3), 0.81 (d, $^3J_{HH}$ = 6.4 Hz, 6 H, CH–CH_3), 2.3 (s, mesityl–CH_3), 2.7 (s, mesityl–CH_3), 3.1 (s, mesityl–CH_3), 2.9 (m, 2 H, C*H*–CH_3). – ^{13}C NMR (CDCl$_3$, 100 MHz): δ = 3.4 (d, $^3J_{PC}$ = 7.4 Hz, SiCH$_3$), 25.6 (d, $^3J_{PC}$ = 7.5 Hz, CH–CH_3), 25.8 (d, $^3J_{PC}$ = 7.6 Hz, CH–CH_3), 48.6 (d, $^2J_{PC}$ = 10.9 Hz, CH), 127.1 (d, $^3J_{PC}$ = 2.5 Hz, *m*-C_6H_5), 128.1 (s, *p*-C_6H_5), 130.7 (d, $^2J_{PC}$ = 18.6 Hz, *o*-C_6H_5), 147.2 (d, $^1J_{PC}$ = 20.6 Hz, *ipso*-C_6H_5). – ^{15}N NMR (CDCl$_3$, 27.4 MHz): δ = –374.1 (t, $^1J_{PN}$ = 37.5 Hz). – ^{31}P NMR (CDCl$_3$, 81 MHz): δ = 242.0 (s). – MS (70 eV); *m*/*z* (%): 414 (75) [M$^+$], 371 (5) [M$^+$ – *i*Pr], 295 (100) [M$^{\bullet+}$ – mes], 207 (25) [M$^+$ – mesNP*i*Pr], 149 (35). – $C_{12}H_{30}N_4P_2$ (290.): calcd. C 69.54, H 8.75, N 6.76; found C 68.48, H 8.33, N 6.68.

Mesitylphosphinic Acid *tert*-Butylamide (9): From a solution of **7** in C_6D_6 which was kept in a NMR tube fitted with a plastic cap, a few crystals separated within 5 weeks which were characterized as **9** by X-ray structure analysis only. Attempts to hydrolyze **7** with an ether solution saturated with water gave no **9** on attempts to crystallize the product from benzene.

***N*-Lithio(organoamino)phosphanes**

These compounds were prepared from the (organoamino)organophosphanes Ph$_2$P–NH*t*Bu, MeP(NHR)$_2$, PhP(NHR)$_2$ and MesP(NHR)$_2$ by treating ether or toluene solutions with an equivalent amount of *n*BuLi in hexane at –78°C. The solutions were then kept at reflux for 1 h, reduced in volume and kept at low temperature for crystallization.

Since the crystals deteriorated quite rapidly when the solvent was removed, no elemental analysis was performed. Their composition follows from the crystal structure analysis.

Hemietherate of *N*-Lithio-*N*-*tert*-butylamino-diphenylphosphane (10): Ph$_2$P–NH*t*Bu (540 mg, 2.1 mmol) dissolved in ether (10 mL)

[a] $w^{-1} = \sigma^2 F_o^2 + (xP)^2 + yP$; $P = (F_o^2 + 2F_c^2)/3$.

was treated at −70°C with 1.4 mL of a BuLi solution in hexane (2.2 mmol). After refluxing and volume reduction to ca. 1/3, crystals were grown at −30°C, and selected at this temperature for X-ray crystal structure analysis. NMR (supernatant solution): ^{31}P NMR (ether, 81 MHz): several signals in the range δ = 43.6−55.9, − ^{7}Li NMR (77.8 MHz): δ = 1.4 (s, broad).

Dimeric Bis(*N*-lithio-*tert*-butylamino)butylphosphane (11): mesP(NH*t*Bu)$_2$ (0.34 g, 1.7 mmol) dissolved in 10 mL of ether was metallated with 2.24 mL of a 1.56 M solution of *n*BuLi in hexane. The yellow solution was reduced under vacuum, and was kept for 3 weeks at −30°C for crystallization. Clear yellow crystals of **11** had then separated. NMR (supernatant solution): ^{31}P NMR (ether/hexane, 81 MHz): δ = 96.9 (s), 93.6 (s), 89.6 (s) − ^{7}Li NMR (77.8 MHz): δ = 2.5 (s, broad), 2.2 (s, broad).

Dimeric Bis(*N*-lithio-*tert*-butylamino)phenylphosphane (12): PhP(NH*t*Bu)$_2$ (990 mg, 3.9 mmol) dissolved in toluene (30 mL) was metallated with *n*BuLi in hexane (5.2 mL, 8.27 mmol). The yellow solution was reduced to ≈ 10 mL. Yellow crystals grew at −30°C. Yield: 900 mg of **12** (86%). NMR (supernatant solution): ^{31}P NMR (C_6D_6, 81 MHz): δ = 94 (s). − ^{7}Li NMR (77.8 MHz): δ = −2.3 s, 1.4 (s, broad), 2.2 (s, broad).

Dimeric Bis(*N*-lithioanilino)phenylphosphane bis(ether) (13): PhP(NHPh)$_2$ (690 mg, 2.4 mmol) dissolved in ether (20 mL) was metallated at −78°C with *n*BuLi (3.2 mL, 4.96 mmol) in a hexane/ether mixture (3.2 mL hexane, 5 mL ether). A solid formed which dissolved on heating. Yellow crystals of **13** separated from the yellow solution at −30°C. NMR (supernatant solution): ^{31}P NMR (ether, 81 MHz): several signals in the range of δ = 16−88.2 (m). − ^{7}Li NMR (77.8 MHz): δ = −0.2 (s, broad), 1.1 (s, broad), 1.7 (s, broad), 2.8 (s, broad).

Tetrameric Bis(*N*-lithio-isopropylamino)methylphosphane-tetrahydrofuran (14): MeP(NH*i*Pr)$_2$ (830 mg, 5.1 mmol) in THF (20 mL) was treated with *n*BuLi (6.71 mL, 10.8 mmol). A clear yellow solution formed on heating at reflux. Crystals separated at −30°C. Yield: 910 mg of **14** (72%). NMR (supernatant solution and crystals): ^{31}P NMR (C_6D_6, 81 MHz): several signals in the range δ = 24.0 to 39, main signal at 26.5 (m, *J* = 68.5 Hz). − ^{7}Li NMR (77.8 MHz): δ = 1.7 (s, broad).

X-ray Structure Determinations

Crystals from the solutions were transferred at about −30°C in precooled perfluorether oil, and single crystals were selected. The selected crystal was quickly mounted on the tip of a glass fiber and then rapidly transferred to the goniometer head flushed with a gas stream of N_2 cooled to −90°C. The crystal quality was checked by reflection profiles. The unit cell dimensions were calculated from the data on 4 different sets of data of 15 frames each recorded at different φ and χ angles, by rotating φ by 0.3°. Having obtained satisfactory results, data collection was started (10s exposure per frame, 1480 frames collected in the hemisphere mode). Data were reduced by the program SAINT.[23] No absorption correction was applied. The structures were solved by direct methods (SHELXL programs[24]) and non-hydrogen atoms were given anisotropic thermal parameters. Although most H positions could be detected, these were calculated and refined with a riding model and isotropic U_i adopted to U_{eq} of the respective carbon atom. It should be noted that the refinement of the structure of compounds *N*-lithioamidophosphanes **12**, **13**, and **14** converged at comparatively high *R* values. This is due to the fact that the crystal quality was not an optimum, leading also to rather high R_{int} values; moreover the diffracting power was not excellent, e. g. there were only few

reflection at $2\Theta > 40°$ with $I > 3\sigma(I)$. Several crystals of these compounds had been measured without improving the result. Table 4 contains relevant information on the crystallographic data and structure refinement. Additional material (without structure factor tables) are deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers CCDC 102 977 to 102 986. Copies of the data can be obtained on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U. K. by quoting the authors, the journal citation [Fax: (internat.)+44-1223/336-033; E-mail: deposit@ccdc.cam.uk].

Acknowledgments

We thank Chemetall GmbH for generous support, Mrs D. Ewald for recording the mass spectra, Dipl.-Chem. M. Vosteen and Mr. P. Mayer for recording numerous NMR spectra and Dipl.-Chem. W. Lippert for help with the MO calculations.

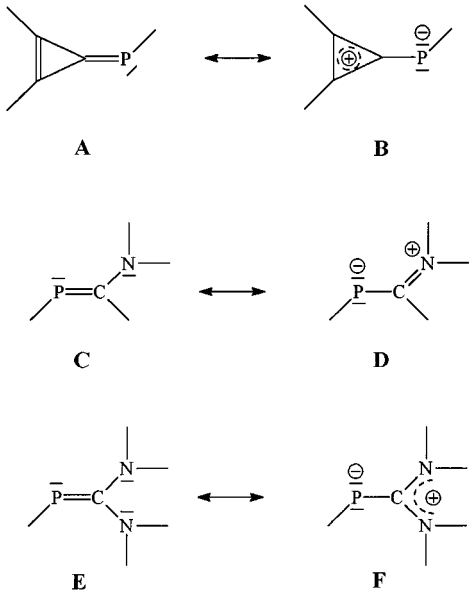
Reactivity of Carbonyl-Functionalized Phosphaalkenes RC(O)P=C(NMe$_2$)$_2$ (R = *t*Bu, Ph) towards Electrophiles

Lothar Weber,*[a] Stefan Uthmann,[a] Hans-Georg Stammler,[a] Beate Neumann,[a] Wolfgang W. Schoeller,[a] Roland Boese,[b] and Dieter Bläser[b]

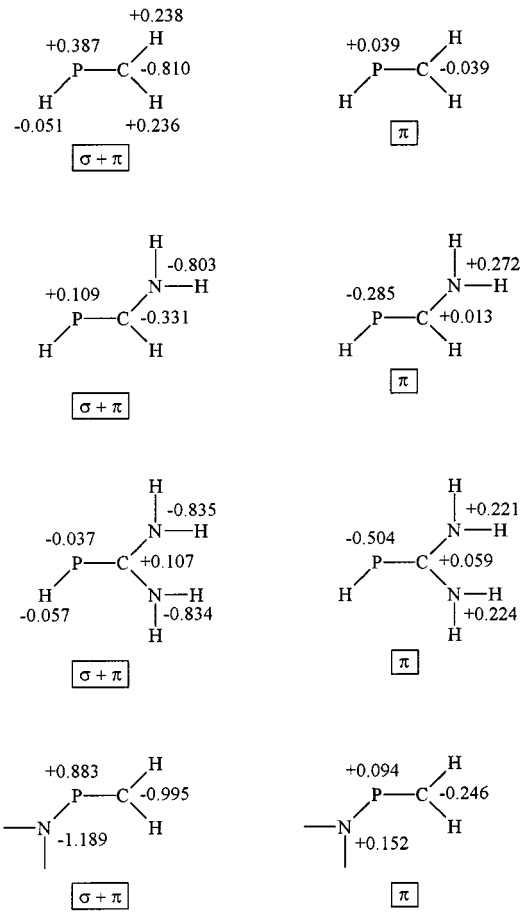


Dedicated to Professor Dirk Walther on the occasion of his 60th birthday

Keywords: Alkylation / Carbonyl complexes / Lewis acids / Phosphaalkenes / Protonation

The reaction of the carbonyl-functionalized phosphaalkenes RC(O)P=C(NMe$_2$)$_2$ [R = *t*Bu (**2a**), Ph (**2b**)] with protic acids and alkylating reagents occurred at the two-coordinate phosphorus atom to give the phosphanyl-substituted carbocations **3a,b** and **4a,b**. In contrast, treatment with Me$_3$SiOSO$_2$CF$_3$ resulted in attack at the oxygen atom by the silyl group, and the formation of [RC(OSiMe$_3$)=PC(NMe$_2$)$_2$]SO$_3$CF$_3$ (**5a,b**). Similarly, the Lewis acids B(C$_6$F$_5$)$_3$, Al(*t*Bu)$_2$Cl and AlMe$_3$ were ligated to the oxygen atom of the carbonyl group. Two equivalents of GaMe$_3$ were added to the oxygen and phosphorus atom of the phosphaalkene to yield the thermolabile complexes [RC(OGaMe$_3$)=P(GaMe$_3$)C(NMe$_2$)$_2$] (**10a,b**). In contrast, one molecule of InMe$_3$ was bound to the phosphorus center of the phosphorus compound. Reaction of the phosphaalkenes with [Ni(CO)$_4$], [Fe$_2$(CO)$_9$] or [{(*Z*)-cyclooctene}Cr(CO)$_5$] also took place at the pnictogen atom, resulting in complexes of the type [RC(O)P{M(CO)$_n$}C(NMe$_2$)$_2$] (R = *t*Bu, Ph; M = Ni, *n* = 3; Fe, *n* = 4; Cr, *n* = 5). The chemical transformations reported here underline the versatile chemistry of phosphaalkenes and emphasize a relationship between carbonyl-functionalized phosphaalkenes and the well-investigated class of phosphorus ylides. X-ray structures of compounds **6b**, **7b***, **10a**, **11a** and **12a** are reported.

Introduction



The chemistry of low-coordination phosphorus compounds is a rapidly expanding field that highlights the remarkable ability of phosphorus to mimic the chemistry of carbon.[1] In the vast majority of phosphaalkenes R^{1}P=CR^{2}R^3 and phosphaalkynes RC≡P, the multiple bonds are polarized in the sense P$^{\delta+}$···C$^{\delta-}$, as anticipitated by the different electronegativities of phosphorus and carbon. It was pointed out by Regitz et al. that in phosphatriafulvenes **A** (Scheme 1) the P=C bond has an inverse electron density;[2] this was substantiated by quantum chemical calculations in comparison to the parent compound HP=CH$_2$. The latter molecule has a σ + π Mulliken charge distribution of +0.154 electrons at the phosphorus and −0.564 electrons at the carbon atom, whereas the PC π-bond is essentially nonpolar (+0.021 e$^-$ at P; 0.021 e$^-$ at C). In the cyclopropylidene phosphane **A** a σ + π Mulliken charge distribution of −0.037 e$^-$ at the phosphorus and of −0.177 e$^-$ at the carbon atom of the exocyclic double bond were calculated. Here the PC π-bond is clearly polarized towards the phosphorus atom as the negative end of the dipole with an excess of 0.369 e$^-$ at the P atom and a deficiency of 0.084 e$^-$ at the C-atom. The positive charge is stabilized by incorporation into the Hückel aromatic cyclopropenium unit (formula **B** in Scheme 1).

Grobe et al. discovered that the introduction of one dialkylamino group at the carbon atom of the double bond in molecules such as F$_3$CP=C(F)NR$_2$ also resulted in an inverse electron distribution of the P=C π-bond.[3] In order to uncover the role of an amino group on the electron distribution in a phosphaalkene we performed quantum chemical calculations at a density functional level [B3LYP/6−31 g(d)].[4a−4e]

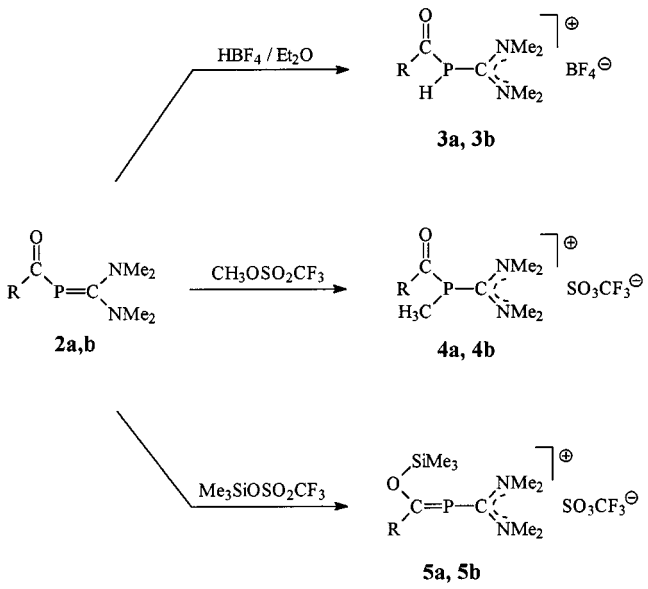
Scheme 2. Charge distribution in $HP{=}CH_2$ and amino-substituted phosphaalkenes

As has been found previously[2] the calculations predict that the parent phosphaalkene should have a nonpolar π-bond (NBO charges and populations),[4d] although one amino group or, to a greater extent, two amino groups at the carbon atom[5] induce an inverse electron-density distribution at the π-bond, i.e. the charge at the phosphorus is increased relative to the parent methylenephosphane. Alternatively, an amino group at the phosphorus does the opposite, it enhances π-electron density at the carbon atom. Phosphaalkenes with an inverse electron density exhibit pecularities in their coordination behavior towards 18 VE transition metal fragments. In η^1-complexes of normally polarized phosphaalkenes ($P^{\delta+}{=}C^{\delta-}$) such as [$(MesP{=}CPh_2)Cr(CO)_5$] a trigonal planar phosphorus atom is linked to the methylene carbon atom by a P=C double bond of 1.679(4) Å.[6a] In the complex [$(\eta^5\text{-}C_5Me_5)(CO)_2FeP[Cr(CO)_5]C(NMe_2)_2$], however, where the inversely polarized phosphaalkene [$(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}C(NMe_2)_2$] is η^1-ligated to the [$Cr(CO)_5$] group, a trigonal-pyramidal phosphorus atom (sum of angles 346.1°) forms a single bond of 1.793(5) Å to the planar carbon atom.[7] For comparison, in the free phosphaalkene a P=C double bond of 1.709(5) Å was measured.[7c] Obviously the zwitterionic structures of inversely polarized phosphaalkenes are stabilized by ligation to metal centers.

In the $W(CO)_5$ complex of the inversely polarized phosphatriafulvene $MesP{=}C^aC^b(t\text{Bu}){-}C^ct\text{Bu}(C^a{-}C^c)$, however, the PC double bond [1.679(5) Å] is retained, and the phosphorus atom is pyramidalized to a lesser extent (sum of angles 352.9°).[2b]



From carbanion and ylide chemistry[8] it is well documented that the negative charge on a carbon center is effectively stabilized by adjacent carbonyl groups via π-delocalization. In keeping with this, stabilization of the negative charge on the P-atom in phosphatriafulvenes[2b] and amino-functionalized phosphaalkenes has been achieved by acyl, dithiocarboxy, and thiocarbamoyl groups.[9] A significant charge transfer from phosphorus to the acyl-substituents was documented in the IR spectra, where the ν(CO) bands exhibited marked shifts to lower wavenumbers. Thus, in the IR spectrum of $RC(O)P{=}C(NMe_2)_2$, ν(CO) bands at 1563 cm^{-1} (R = *t*Bu) and 1546 cm^{-1} (R = Ph) are found;[9] the IR spectrum of the "normally polarized" phosphaalkene $t\text{BuC(O)P}{=}\text{C(OSiMe}_3)(t\text{Bu})$ shows a ν(CO) band at 1664 cm^{-1},[10] which is well within the range of $\tilde{\nu}$ = 1630−1690 cm^{-1} usually encountered in acyl phosphanes.[11] Although a number of P-acyl phosphaalkenes with an inverse electron density have been prepared, information on the chemistry of these molecules is scarce. Thus, only dimerization and isomerization processes of several phosphatriafulvenes, as well as the formation of the complex [$t\text{BuC(O)P}\{W(CO)_5\}{=}C^a{-}C^b(t\text{Bu}){=}C^ct\text{Bu}](C^a{-}C^c$) have been investigated.[2b]

We decided to study in more detail the chemical reactivity of $t\text{BuC(O)P}{=}\text{C(NMe}_2)_2$ (**2a**) and $\text{PhC(O)P}{=}\text{C(NMe}_2)_2$ (**2b**), which are readily available from $Me_3SiP{=}C(NMe_2)_2$ (**1**) and carboxylic acid chlorides, especially with respect to the related carbonyl-stabilized phosphorus ylides $RC(O)CH{=}PPh_3$. Here we report on the reactions of **2a** and **2b** with protic acids, alkylating and silylating reagents, organometallic compounds of group 13 elements, and transition metal carbonyl complexes.

Results and Discussion

Reaction of 2a,b With Protic Acids, $ROSO_2CF_3$ (R = Me, $SiMe_3$) and $B(C_6F_5)_3$

The reaction of the P-acyl phosphaalkenes **2a** and **2b** with equimolar amounts of ethereal HBF_4 in diethyl ether at −50°C led to the formation of the phosphanyl carbenium salts $[RC(O)P(H)C(NMe_2)_2][BF_4]$ **3a** (R = *t*Bu) and **3b** (Ph) (Scheme 3). Salt **3a** was obtained as a colorless solid and **3b** as a yellow viscous oil. Both compounds are highly soluble in CH_2Cl_2 and $CHCl_3$. In chloroform, however, slow decomposition occurred at ambient temperature. Methylation of **2a** and **2b** was effected by methyl trifluoromethanesulfonate (methyl triflate) in diethyl ether at −50°C. Compounds **4a** and **4b** were isolated as orange, air- and moisture-sensitive powders, which are highly soluble in

2-5: R = *t*Bu (**a**), Ph (**b**)

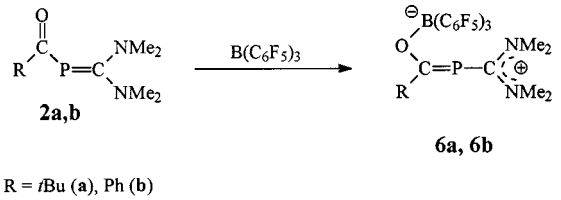
Scheme 3. Reaction of **2a,b** with HBF_4, $CH_3OSO_2CF_3$ and $Me_3SiOSO_2CF_3$

halogenated hydrocarbons. In the ^{31}P NMR spectrum, the protonated products **3a** and **3b** display doublets at δ = −53.7 ($^1J_{PH}$ = 245 Hz) and δ = −46.6 ($^1J_{PH}$ = 257.7 Hz) which are significantly shifted to high field with respect to the corresponding signals in **2a** (δ = 26.4) and **2b** (δ = 31.3). The size of the $^{31}P\{^1H\}$ coupling constants furthers the idea that the protonation occurred at the phosphorus center of the phosphaalkene. The resonances of the ^{13}C nuclei of the PCN_2 and the PC=O groups of the starting materials **2a** [δ = 201.4 (d, $^1J_{PC}$ = 80.5 Hz), 231.4 (d, $^1J_{PC}$ = 90.8 Hz)] and **2b** [δ = 199.3 (d, $^1J_{PC}$ = 78.5 Hz), 215.6 (d, $^1J_{PC}$ = 78.7 Hz)] are also high-field shifted upon protonation, and are observed in **3a** as broad singlets at δ = 178.1 and δ = 220.0 and in **3b** at δ = 177.9 and 204.8, respectively. In the ^1H NMR spectrum a doublet at δ = 6.02 ($^1J_{PH}$ = 245 Hz) (**3a**) and at δ = 6.23 ($^1J_{PH}$ = 257.7 Hz) (**3b**) accounts for the PH unit.

The IR spectrum of **2a** shows a very strong ν(CO) absorption at $\tilde{\nu}$ = 1563 cm^{-1}, which is hypsochromically shifted in the carbenium ion of **3a** [ν(CO) = 1680, 1597 cm^{-1}]. Similar observations were made with **2b** and **3b**. The methylation of **2a** and **2b** to yield the phosphanyl carbenium salts **4a** and **4b**, gave rise to high-field shifts of only 30−33 ppm in the ^{31}P NMR spectra. In the $^{13}C\{^1H\}$ NMR spectra the ^{13}C nuclei of the methyl groups of **4a** and **4b** were observed as doublets at δ = 6.0 ($^1J_{PC}$ = 13.3 Hz) and δ = 5.0 ($^1J_{PC}$ = 11.7 Hz), respectively, which is consistent with an alkylation at the P-atom of the P-acyl phosphaalkenes. Upon methylation, the ^{13}C nuclei of the CN_2 and the PCO units of precursors **2a** and **2b** are shielded by 21.8−23.8 and 5.6−8.7 ppm, and the $^1J_{PC}$ coupling constants decreased from 80.5 and 90.8 Hz in **2a** to 44.0 and 60.6 Hz in **4a** and from 78.5 and 78.7 Hz in **2b** to 39.4 and 37.7 Hz in **4b**. Again the ν(CO) bands in the IR spectra of the salts **4a** ($\tilde{\nu}$ = 1644, 1588 cm^{-1}) and **4b** ($\tilde{\nu}$ = 1647, 1587 cm^{-1}) are observed at higher wavenumbers than in the neutral phosphaalkenes **2a** and 2**b**.

These observations compare well with carbonyl-stabilized ylides $RC(O)CH{=}PPh_3$, their corresponding phosphonium salts $[RC(O)CH_2PPh_3]^+X^-$, and their transition metal complexes, where the position of the ν(CO) band in the IR spectra serves as a sensitive probe for their electronic situation. Thus, the IR spectra of the ylides $MeC(O)CH{=}PPh_3$ and $PhC(O)CH{=}PPh_3$ display strong carbonyl bands at $\tilde{\nu}$ = 1540 and 1500 cm^{-1}, which upon protonation to the corresponding phosphonium ions were shifted to 1710 and 1665 cm^{-1}, respectively.[12]

The silylation of **2a** and **2b** with equimolar amounts of trimethylsilyl triflate in diethyl ether gave the extremely air- and moisture-sensitive salts **5a** and **5b**, which were isolated as pale yellow oils (Scheme 3). Here, in contrast to the protonation and methylation of **2a** and **2b**, a deshielding of the ^{31}P NMR resonances to δ = 109.2 (**5a**) and δ = 101.0 (**5b**) was observed.



In the region typical for the stretching vibrations of acylic carbonyl groups in the IR spectra of **5a** and **5b** no intense bands are present. This situation is best explained by an attack of the hard acid "Me_3Si" at the hard oxygen center of the carbonyl group with the formation of a Si−O and a P=C bond. Thus, the products can be regarded as salts with unsymmetrical phosphaallyl cations or, alternatively, as phosphaalkenyl-functionalized carbocations. Symmetrical phosphaallyl cations such as $[(Me_2N)_2CPC(NMe_2)_2]^+$[13] or $[\{t\mathrm{BuC}^c{-}(t\mathrm{Bu})\mathrm{C}^b{-}\mathrm{C}^a\}_2\mathrm{P}]^+(C^a{-}C^c)$[2b] were described several years ago. In the low-field region of the $^{13}C\{^1H\}$ NMR spectra of **5a** and **5b**, doublets at δ = 180.8 ($^1J_{PC}$ = 75.5 Hz) and δ = 181.0 ($^1J_{PC}$ = 72.4 Hz) were attributed to the diaminocarbenium center, whereas the ^{13}C nuclei of the PCOSi units were observed as doublets at δ = 226.1 ($^1J_{PC}$ = 77.3 Hz) (**5a**) and δ = 211.8 ($^1J_{PC}$ = 61.4 Hz) (**5b**),respectively.

Thus, the main spectroscopic evidence for an electrophilic attack at the P- or O-atom of P-acyl phosphaalkenes with inverse electron density is taken from the direction in which the ^{31}P NMR resonance of the product is shifted. With this in mind, we decided to react **2a** and **2b** with the hard Lewis acids $B(C_6F_5)_3$, tBu_2AlCl, and $(AlMe_3)_2$.

Treatment of **2a** or **2b** with tris(pentafluorophenyl)borane in toluene solution at room temperature gave the adducts **6a** or **6b** as yellow solids (Scheme 4).

The air- and moisture-sensitive compounds are only slightly soluble in dichloromethane or chloroform, but dissolve well in acetonitrile. In ethereal and hydrocarbon solvents **6a** and **6b** are insoluble. Low-field shifted singlets in the $^{31}P\{^1H\}$ NMR spectra at δ = 68.3 (**6a**) (Δδ = 41.9) and 72.6 (**6b**) (Δδ = 41.5), and the absence of ν(C=O) bands in the IR spectra of the adducts agree with the ligation of the phosphaalkenes to the electron-deficient boron center via the oxygen atom. Doublets in the $^{13}C\{^1H\}$ NMR spectra at δ = 188.4 ($^1J_{PC}$ = 89.0 Hz) and 190.9 ($^1J_{PC}$ = 80.6 Hz) are

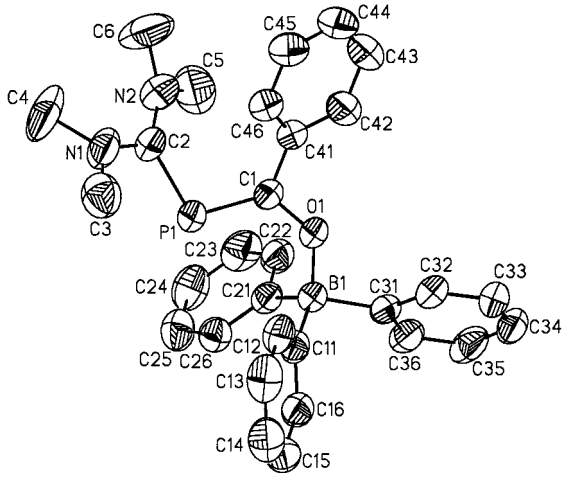
readily assigned to the three-coordinate ^{13}C nuclei of the diaminocarbenium units in **6a** and **6b**. Low-field resonances at δ = 228.8 (d, $^1J_{PC}$ = 81.4 Hz, **6a**) and δ = 223.4 ($^1J_{PC}$ =

Scheme 4. Reaction of **2a,b** with $B(C_6F_5)_3$

71.1 Hz, **6b**) are due to the ^{13}C nuclei of the PCOB units.

X-ray Structural Analysis of 6b

To confirm the spectroscopic evidence for the ligation of the phosphaalkene to the borane, an X-ray structural analysis of **6b** was performed (Figure 1, Table 1). Single crystals of **6b** were grown from toluene at −30°C. The analysis confirms the presence of a tetracoordinate boron atom, which is attached to the carbonyl group via a single bond of 1.506(3) Å. Delocalization of the negative charge into the C=O bond is obvious from an elongation from 1.240(2) Å (as measured in **2b**)[14] to 1.315(3) Å and by the bond length P(1)−C(1) of 1.735(2) Å, which is similar to the P=C bond length in $HP=C(NMe_2)_2$ [1.740(1) Å].[5] The trigonal-planar carbon atom C(1) (sum of angles 359.9°) is linked to atom C(41) by a single bond of 1.482(3) Å. The former PC(N) bond in **2b** [1.800(1) Å] is lengthened to 1.838(3) Å in **6b**. The trigonal-planar carbon atom C(2) (sum of angles 359.4°) shows multiple bonding to the planarly configured nitrogen atoms [N(1)−C(2) = 1.333(4); N(2)−C(2) = 1.327(4) Å]. The bond angle C(1)−P(1)−C(2) [102.3(1)°] is close to the value found in $HP=C(NMe_2)_2$ [103(1)°].[5] This is presumably because of the steric hinderance between the *cis*-oriented diaminocarbenium group and the phenyl ring which means that the valence angle P(1)−C(1)−C(41) [127.5(2)°] is markedly more obtuse than P(1)−C(1)−O(1) [121.4(2)°]. The very bulky $B(C_6F_5)_3$ moiety is directed towards the P-atom of the PC multiple bond, giving rise to torsion angles B(1)−O(1)−C(1)−P(1) and B(1)−O(1)−C(1)−C(41) of 2.5° and −179.4°, respectively. The torsion angle C(2)−P(1)−C(1)−O(1) was determined to be −175.1°. Thus, the atoms B(1), O(1), C(1), C(41), P(1) and C(2) are located in one plane, and the molecule may be described as a zwitterionic phosphaalkene, where the positive charge is formally centered at the diaminocarbenium substituent, and a negative charge at the boron atom.



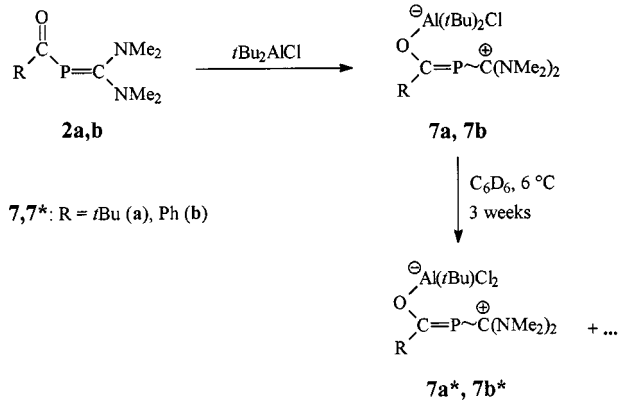


Figure 1. Molecular structure of **6b** in the crystal (fluorine atoms at the borane unit are omitted for clarity); selected bond lengths [Å] and angles [°]: P(1)−C(1) 1.735(2), P(1)−C(2) 1.838(3), O(1)−C(1) 1.315(3), O(1)−B(1) 1.506(3), B(1)−C(11,21,31) av. 1.649(4), C(1)−C(41) 1.482(3), N(1)−C(2) 1.333(4), N(2)−C(2) 1.327(4), N(1)−C(3) 1.459(4), N(1)−C(4) 1.481(4), N(2)−C(5) 1.465(5), N(2)−C(6) 1.474(5); C(1)−P(1)−C(2) 102.3(1), C(1)−O(1)−B(1) 130.2(2), O(1)−C(1)−C(41) 111.0(2), P(1)−C(1)−O(1) 121.4(2), P(1)−C(1)−C(41) 127.5(2), P(1)−C(2)−N(1) 115.6(2), P(1)−C(2)−N(2) 123.6(2), N(1)−C(2)−N(2) 120.2(3), C(2)−N(1)−C(3) 122.7(2), C(2)−N(1)−C(4) 122.8(3), C(3)−N(1)−C(4) 113.8(3), C(2)−N(2)−C(5) 122.7(3), C(2)−N(2)−C(6) 122.3(4), C(5)−N(2)−C(6) 114.0(4), O(1)−B(1)−C(11) 111.1(2), O(1)−B(1)−C(21) 115.4(2), O(1)−B(1)−C(31) 107.0(3), C(11)−B(1)−C(21) 115.4(2), C(11)−B(1)−C(31) 107.0(2), C(21)−B(1)−C(31) 112.1(2).

Reaction of 2a and 2b With tBu_2AlCl

Di-*tert*-butylaluminium chloride smoothly reacted with an equimolar amount of **2a** or **2b** in toluene at −30°C to afford the adducts **7a** or **7b** (Scheme 5). They were obtained as extremely moisture-sensitive orange solids. Attempts to grow crystals of **7a** and **7b** from C_6D_6 solution at 6°C within a period of 3 weeks led to the formation of crystalline $RC[OAl(tBu)Cl_2]=PC(NMe_2)_2$ [R = *t*Bu (**7a***), Ph (**7b***)] instead.

Scheme 5. Reaction of **2a,b** with tBu_2AlCl

In the IR spectra of the adducts **7a** and **7b**, no unambigious identification of ν(CO) bands was possible. The ^1H NMR spectrum of **7a** was characterized by a singlet for the nine protons of the *tert*-butyl group at the P=C function, and by another singlet accounting for the 18 protons of the *tert*-butyl groups at the aluminium atom. A singlet at δ = 2.63 was assigned to the protons of the dimethylamino groups.

In the low-field region of the $^{13}C\{^1H\}$ NMR spectra of **7a** and **7b**, doublets at δ = 184.4 ($^1J_{PC}$ = 76.5 Hz) and

185.3 ($^1J_{PC}$ = 71.8 Hz) were found for the carbon atoms of the diaminocarbenium unit. Again, adduct formation is accompanied by a high-field shift [Δδ = 17.0 (**7a**) and 14.0 (**7b**)] for the signals of these nuclei. The carbon atoms adjacent to the oxygen atoms of **7a** and **7b** appeared as doublets at δ = 233.8 ($^1J_{PC}$ = 86.5 Hz) and 220.3 ($^1J_{PC}$ = 69.8 Hz). Diagnostic for the mode of coordination are the $^{31}P\{^1H\}$ NMR resonances of both adducts which were observed at lower field (**7a**: δ = 72.9 s; **7b**: 78.2 s) than in **2a** and **2b**. Thus, the presence of dative Al−O bonds in **7a** and **b** was inferred.

X-ray Structural Analysis of 7b*

Unfortunately, the initially obtained compounds **7a** and **b** were converted into **7a* and b*** during attempts to grow crystals for an X-ray diffraction analysis. A yellow crystal of **7b*** [PhC{OAl(*t*Bu)Cl$_2$}=PC(NMe$_2$)$_2$] was studied by X-ray diffraction (Figure 2, Table 1). The molecule was found to be a *Z*-configured phosphaalkene with a P=C double bond of 1.728(2) Å between the phosphorus atom and the carbonyl carbon atom. The distance C(5)−O(1) is lengthened to 1.309(2) Å. The bond Al(1)−O(1) of 1.776(1) Å is quite short if compared to aluminium−carbonyl oxygen contacts in alane-ketone and -aldehyde adducts[15] such as the AlMe(O-2,6-*t*Bu$_2$-4-MeC$_6$H$_2$)$_2$·O=CPh$_2$ [1.903(6) Å] but clearly elongated relative to the Al−O (alkoholate) bonds in the molecule [1.733(5); 1.721(6) Å].[15]

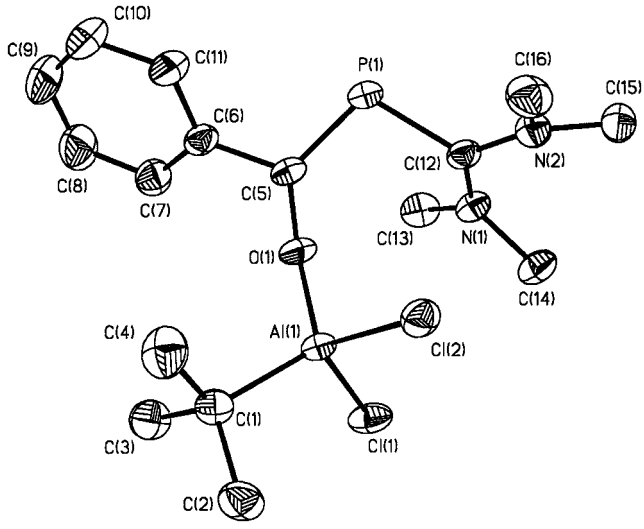

Figure 2. Molecular structure of **7b*** in the crystal; selected bond lengths [Å] and angles [°]: P(1)−C(5) 1.728(2), P(1)−C(12) 1.844(2), O(1)−C(5) 1.309(2), O(1)−Al(1) 1.776(2), Al(1)−C(1) 1.969(2), Al(1)−Cl(1) 2.173(1), Al(1)−Cl(2) 2.170(1), C(5)−C(6) 1.492(3), N(1)−C(12) 1.336(2), N(2)−C(12) 1.343(2), N(1)−C(13) 1.465(3), N(1)−C(14) 1.473(2), N(2)−C(15) 1.472(3), N(2)−C(16) 1.462(3); C(5)−P(1)−C(12) 104.1(1), C(5)−O(1)−Al(1) 139.2(1), O(1)−C(5)−C(6) 115.3(2), P(1)−C(5)−O(1) 128.4(1), P(1)−C(5)−C(6) 116.0(1), P(1)−C(12)−N(1) 123.5(1), P(1)−C(12)−N(2) 116.3(1), N(1)−C(12)−N(2) 119.5(2), C(12)−N(1)−C(13) 123.9(2), C(12)−N(1)−C(14) 122.3(2), C(13)−N(1)−C(14) 113.7(2), C(12)−N(2)−C(15) 123.2(2), C(12)−N(2)−C(16) 122.3(2), C(15)−N(2)−C(16) 114.3(2), O(1)−Al(1)−C(1) 114.8(1), O(1)−Al(1)−Cl(1) 102.8(1), O(1)−Al(1)−Cl(2) 106.0(1), C(1)−Al(1)−Cl(1) 110.7(1), C(1)−Al(1)−Cl(2) 111.8(1), Cl(1)−Al(1)−Cl(2) 110.4(1)

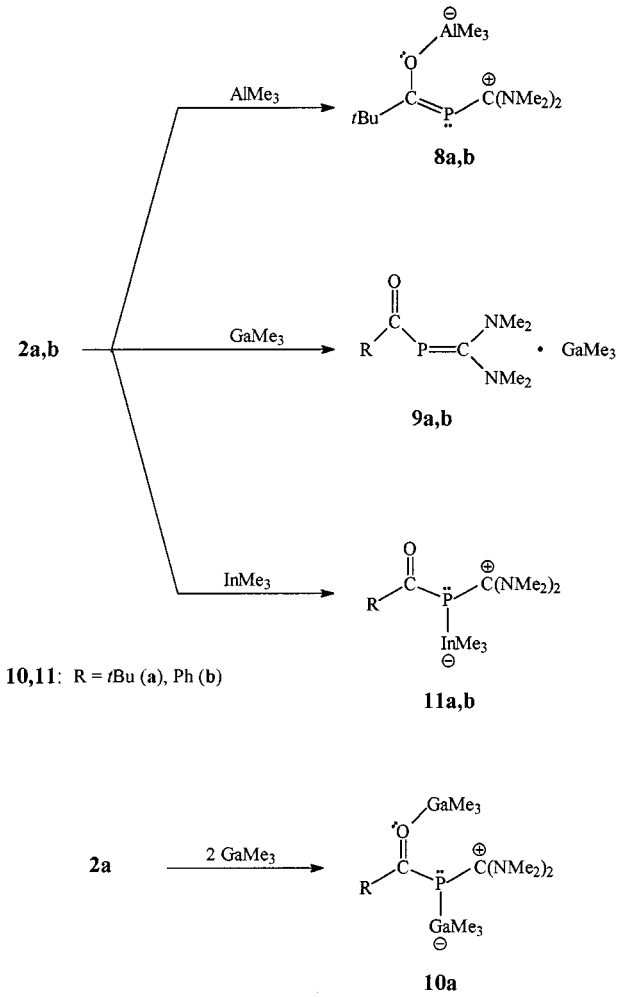

The coordination sphere at the aluminium atom is completed by one *tert*-butyl substituent and two chlorine atoms, which are directed towards the diaminocarbenium center. The trigonal-planar carbon atom C(12) of the latter forms a single bond of 1.844(2) Å with the P-atom. Short bonds N(1)−C(12) [1.336(2) Å] and N(2)−C(12) [1.343(3) Å] reflect multiple bonding between the amino groups and the tricoordinate carbon atom. The valence angle at phosphorus [104.1(1)°] is comparable to that in **6b**. The angle at the planar carbon atom C(5) P(1)−C(5)−O(1) [128.4(1)] is significantly open relative to the remaining two angles P(1)−C(5)−C(6) [116.0(1)°] and O(1)−C(5)−C(6) [115.3(2)°]. This can be rationalized by the steric repulsion between the *cis*-located substituents at the P=C double bond.

The atoms O(1), C(5), P(1) and C(12) are located in nearly the same plane, as is obvious from torsion angle C(12)−P(1)−C(5)−O(1) = 2.4°. In contrast to the molecular structure of **6b**, the *ipso*-carbon atom C(6) and the group 13 metal deviate from this plane [C(12)−P(1)−C(5)−C(6) = −171.6°; P(1)−C(5)−O(1)−Al(1) = 78.8°]. Moreover, it is obvious that **6b** and **7b*** differ in the configuration at the P=C double bond.

Reaction of 2a and 2b With MMe$_3$ (M = Al, Ga, In)

The following section deals with the reactivity of the P-acyl phosphaalkenes **2a** and **2b** towards the homologous Lewis acids AlMe$_3$, GaMe$_3$ and InMe$_3$ (Scheme 6).

Reaction of equimolar amounts of **2a** and trimethylaluminium in *n*-pentane yielded adduct **8a** as a pale-yellow moisture-sensitive oil. The $^{31}P\{^1H\}$ NMR spectrum of the compound displayed a singlet at δ = 62.7, which is deshielded by Δδ = 36.3 with respect to free **2a**. Thus, the alu-

Scheme 6. Reaction of **2a,b** with $AlMe_3$, $GaMe_3$ and $InMe_3$

minium atom is attached to the oxygen atom of the carbonyl group, as it was in the case of the adducts **7**. In the low-field region of the $^{13}C\{^1H\}$ NMR spectrum doublets at $\delta = 184.4$ ($^1J_{PC} = 76.6$ Hz) and $\delta = 233.8$ ($^1J_{PC} = 86.5$ Hz) are readily assigned to the ^{13}C nuclei of the CN_2 and OCP moieties, respectively. Signals due to the methyl groups at the metal atom were observed at $\delta = -5.2$ in the ^{13}C NMR spectrum and $\delta = -0.37$ in the ^1H NMR spectrum. Similar results are obtained with **2b** and $AlMe_3$.

Under analogous conditions, one equivalent of trimethylgallium was added to **2a** and **2b**. The products were a very thermolabile yellow oil (**9a**) and a yellow powder (**9b**). Both compounds can easily be freed from Me_3Ga in vacuum at room temperature. Broad singlets in the $^{31}P\{^1H\}$ NMR spectra at $\delta = 38.7$ (**9a**) or $\delta = 48.1$ (**9b**) did not allow for unambigious assignment of the structure to one of the modes of coordination under discussion. In the presence of excess trimethylgallium, the NMR resonances did not shift significantly. However, when the mixture of **2a** and 2 equivalents of Me_3Ga in *n*-pentane was carefully concentrated to ca 2 mL, and this solution stored for 24 h at −30°C, yellow crystals of the 1:2 adduct **10a** were isolated. The NMR spectra of **10a** in C_6D_6 did not differ significantly from those already registered for **9a**. As observed for **9a**, adduct **10a** easily lost the two molecules of Me_3Ga in a vacuum.

The coordination chemistry of **2a** and **b** towards the "soft" Lewis base $InMe_3$ is more straightforward (Scheme 6). The yellow solid adduct **11a** and the yellow oily adduct **11b** were obtained under similar conditions, and display singlets in their $^{31}P\{^1H\}$ NMR spectra at $\delta = 15.6$ and 36.8. A high-field coordination shift of $\Delta\delta = 10.8$ for **11a**, and a low-field shift of $\Delta\delta = 5.5$ is consistent with an In−P contact rather than with the alternative In−O ligation. In the low-field part of the $^{13}C\{^1H\}$ NMR spectrum, doublets at $\delta = 195.5$ ($^1J_{PC} = 68.4$ Hz) and 234.0 ($^1J_{PC} = 84.5$ Hz) (**11a**) and $\delta = 196.2$ ($^1J_{PC} = 76.6$ Hz) and 219.9 ($^1J_{PC} = 76.7$ Hz) (**11b**) are caused by the ^{13}C atoms of the diaminocarbenium- and the carbonyl-groups, respectively. In the IR spectrum of **11a**, strong ν(CO) bands appears at $\tilde{\nu} = 1594$ and 1546 cm^{-1}, and in the spectrum of **11b**, a medium intense ν(CO) band at 1540 cm^{-1} with a shoulder at 1597 cm^{-1} was observed.

X-ray Structural Analysis of 10a

The crystal structure analysis of **10a** shed some light on the nature of the 1:2 adduct (Figure 3, Table 1). The backbone of the molecule constitutes a P-acyl unit with a trigonal-pyramidal P-atom (sum of angles 333.26°), which is connected to the atoms C(4), C(12) and Ga(2) by single bonds. The bond length P(1)−C(4) [1.784(3) Å] is shorter than P(1)−C(12) [1.831(3) Å], which was determined to be 1.800(1) Å in **2b**. A pronounced bond strengthening of the $P-C_{(CO)}$ bond as encountered in **6b** and **7b*** did not occur. The atomic distance Ga(2)−P of 2.635(2) Å is markedly longer than in the complex $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP\{GaMe_3\}C(NMe_2)_2]$ [2.503(2) Å].[16] Generally, Ga−P bonds in molecules with tetracoordinate gallium and phosphorus range from 2.347(5) Å in $[(Me_3Si)_3P\rightarrow GaI_3]$[17] up to 2.683(5) Å in $[Ph_2(H)P\rightarrow Ga\{CH_2(tBu)\}_3]$.[18][19] The second molecule of $GaMe_3$ is bound to the oxygen atom of the carbonyl group by a long dative bond [Ga(1)−O(1) = 2.109(2) Å]. As the covalent radii of Al (1.25 Å) and Ga (1.26 Å)[20] are similar, it is obvious from the comparison with the Al−O contact in **7b*** that only a weak gallium−oxygen bond is present in **10a**.

The bond length of the carbonyl group [1.249(3) Å] is similar to that of the P-acyl function in **2b** [1.240(2) Å]. The weak contact between the oxygen atom and the gallane may also be inferred from the small deviation of the $Ga(CH_3)_3$ unit from planarity [sum of angles C(1)−Ga(1)−C(2), C(1)−Ga(1)−C(3), C(2)−Ga(1)−C(3) = 350.3°]. For comparison, a more pronounced perturbation of the planar configuration of the borane by adduct formation with **2b** is evident by the corresponding sum of angles C(11)−B(1)−C(21), C(11)−B(1)−C(31) and C(21)−B(1)−C(31) of 334.5° in **6b**. In the aluminium adduct **7b***, the respective sum of angles (332.94°) is similar to **6b**. Moreover, the angle at the carbonyl oxygen atom opens up in going from **6b** [130.2(2)°] through **7b*** [139.2(1)°] to **10a** [148.7(2)°].

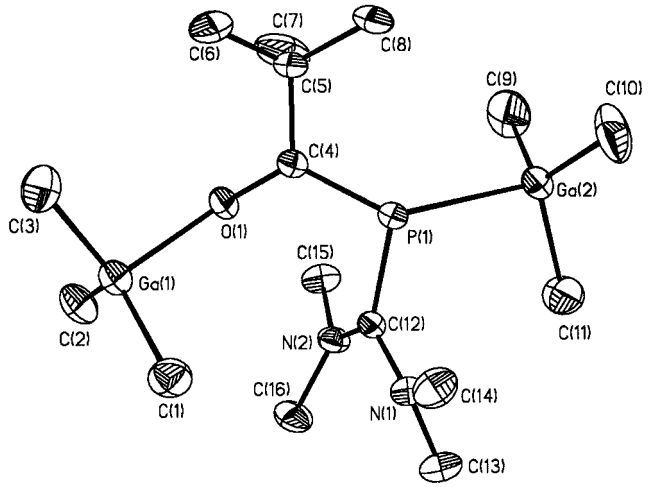

Figure 3. Molecular structure of **10a** in the crystal; selected bond lengths [Å] and angles [°]: P(1)−C(4) 1.784(3), P(1)−C(12) 1.831(3), P(1)−Ga(2) 2.635(2), O(1)−C(4) 1.249(3), O(1)−Ga(1) 2.109(2), C(4)−C(5) 1.537(3), Ga(1)−C(1) 1.985(3), Ga(1)−C(2) 1.972(3), Ga(1)−C(3) 1.962(3), Ga(2)−C(9) 1.976(3), Ga(2)−C(10) 1.965(3), Ga(2)−C(11) 1.980(3), N(1)−C(12) 1.337(3), N(2)−C(12) 1.337(3), N(1)−C(13) 1.465(3), N(1)−C(14) 1.470(3), N(2)−C(15) 1.462(3), N(2)−C(16) 1.470(3); C(4)−P(1)−C(12) 102.9(1), C(4)−P(1)−Ga(2) 127.7(1), Ga(2)−P(1)−C(12) 102.6(1), P(1)−C(4)−O(1) 124.2(2), P(1)−C(4)−C(5) 118.4(2), O(1)−C(4)−C(5) 117.5(2), Ga(1)−O(1)−C(4) 148.7(2), P(1)−C(12)−N(1) 116.7(2), P(1)−C(12)−N(2) 123.5(2), N(1)−C(12)−N(2) 119.4(2), C(12)−N(1)−C(13) 123.3(2), C(12)−N(1)−C(14) 122.3(2), C(13)−N(1)−C(14) 113.5(2), C(12)−N(2)−C(15) 123.0(2), C(12)−N(2)−C(16) 123.2(2), C(15)−N(2)−C(16) 113.2(2), O(1)−Ga(1)−C(1) 103.5(1), O(1)−Ga(1)−C(2) 97.0(1), O(1)−Ga(1)−C(3) 101.1(1), C(1)−Ga(1)−C(2) 117.6(1), C(2)−Ga(1)−C(3) 117.5(1), C(1)−Ga(1)−C(3) 115.2(1), P(1)−Ga(2)−C(9) 107.6(1), P(1)−Ga(2)−C(10) 99.8(1), P(1)−Ga(2)−C(11) 98.8(1), C(9)−Ga(2)−C(10) 118.8(2), C(9)−Ga(2)−C(11) 112.8(2), C(10)−Ga(2)−C(11) 115.5(2)

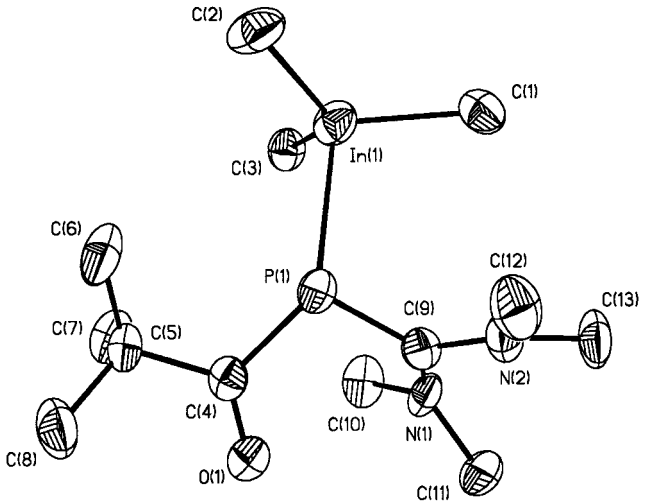
X-ray Structural Analysis of 11a

The X-ray structural analysis of **11a** has fully confirmed the conclusions drawn from the spectra (Figure 4, Table 1). A trigonal pyramid configured phosphorus atom is coordinated to the indium atom by a single bond of 2.774(4) Å. This value is similar to those measured in $(Me_3In)_2(Ph_2PCH_2CH_2PPh_2)$ [2.755(4) C].[21] For indane-phosphane adducts In−P bond lengths in the range of 2.575(3) to 2.819(2) Å have been reported.[19a] The coordination of **2a** to the planar acceptor molecule $InMe_3$ causes only a small pyramidalization of the InC_3-unit, as may be concluded from the sum of the angles C(1)−In(1)−C(2), C(1)−In(1)−C(3) and C(2)−In(1)−C(3) (349.8°). The environment of carbon atom C(4) is trigonal-planar, a C=O double bond of 1.238(10) Å and a C−C single bond of 1.552(11) Å to the *tert*-butyl substituent clearly exclude π-conjugation of the carbonyl group with the lone pair on phosphorus in **11a**. Whereas similar C=O bond lengths were encountered in acyl phosphanes such as $[(\eta^5\text{-}C_5Me_5)(CO)_2Ru-C(O)P(t\text{Bu})(SiMe_3)]$ [1.219(4) Å][22] or *t*BuC(O)P(Ph)P(Ph)C(O)*t*Bu (1.21 Å),[23] the P−C(CO) single bonds in these molecules are considerably longer [1.952(3) Å and 1.89 Å, respectively] than in **11a** [P(1)−C(4) = 1.851(9) Å]. The structural features of the diaminocarbenium unit are similar to those in **6b**, **7b*** and **10a**. Again this group is linked to the P-atom through a single bond [P(1)−C(9) = 1.823(8) Å].



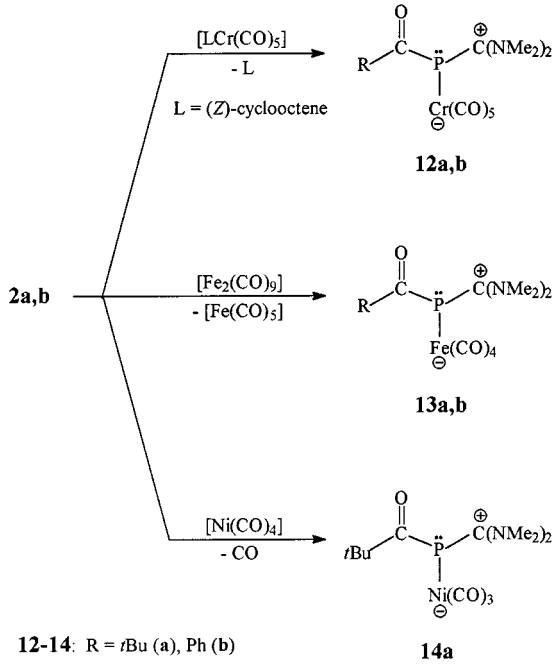


Figure 4. Molecular structure of **11a** in the crystal; selected bond lengths [Å] and angles [°]: P(1)−C(4) 1.851(9), P(1)−C(9) 1.823(8), P(1)−In(1) 2.774(4), O(1)−C(4) 1.238(10), C(4)−C(5) 1.552(11), N(1)−C(9) 1.334(10), N(2)−C(9) 1.374(10), N(1)−C(10) 1.483(10), N(1)−C(11) 1.483(10), N(2)−C(12) 1.452(12), N(2)−C(13) 1.497(12), In(1)−C(1) 2.198(9), In(1)−C(2) 2.189(9), In(1)−C(3) 2.216(8); C(4)−P(1)−C(9) 101.2(4), C(4)−P(1)−In(1) 125.9(3), In(1)−P(1)−C(9) 102.3(3), P(1)−C(4)−O(1) 122.2(6), O(1)−C(4)−C(5) 119.8(7), P(1)−C(4)−C(5) 118.0(6), P(1)−C(9)−N(1) 125.5(6), P(1)−C(9)−N(2) 117.3(6), N(1)−C(9)−N(2) 117.1(7), C(9)−N(1)−C(10) 122.7(7), C(9)−N(1)−C(11) 123.6(7), C(10)−N(1)−C(11) 112.7(7), C(9)−N(2)−C(12) 124.4(8), C(9)−N(2)−C(13) 122.0(8), C(12)−N(2)−C(13) 113.1(8), P(1)−In(1)−C(1) 97.6(3), P(1)-In(1)−C(2) 98.9(3), P(1)−In(1)−C(3) 105.5(2), C(1)−In(1)−C(2) 115.8(4), C(2)−In(1)−C(3) 119.9(4), C(1)−In(1)−C(3) 114.1(3)

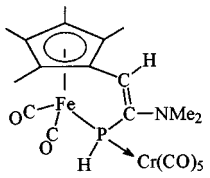
Reaction of 2a and 2b With [{(*Z*)-cyclooctene}Cr(CO)$_5$], [Fe$_2$(CO)$_9$] and [Ni(CO)$_4$]

With regard to the concept of hard and soft acids and bases, and under consideration the coordination chemistry of carbonyl-stabilized ylides, the reaction of β-acyl phosphaalkenes with low valent transition metal carbonyls should lead to complexes with metal-phosphorus bonding. To further substantiate this idea the phosphaalkenes **2a** and **b** were reacted with equimolar amounts of [{(*Z*)-cyclooctene}Cr(CO)$_5$] for 2 h in diethyl ether (**2a**) or *n*-pentane (**2b**). The pentacarbonylchromium complexes **12a** and **12b** were isolated as yellow or orange-red microcrystalline solids in 79% and 71% yield, respectively.

The red microcrystalline tetracarbonyliron complexes **13a** and **13b** (73−76% yield) resulted from the treatment of **2a** and **b** with equimolar amounts of solid [Fe$_2$(CO)$_9$] in diethyl ether at room temperature for 18−20 h.

Compound **2a** and [Ni(CO)$_4$] underwent reaction in diethyl ether to afford complex **14a** as an orange crystalline,



Scheme 7. Complexation of **2a,b** with transition metal carbonyls

extremely light-sensitive solid. Purification of this product was effected by recrystallization from diethyl ether at −30°C. Attempts to synthesize the analogous nickeltricarbonyl complex of **2b** failed (Scheme 7).

High-field shifts of the $^{31}P\{^1H\}$ NMR resonances of complexes **12a, 12b**, **13a, 13b**, and **14a** in the range of δ = −26.4 to 1.9 are consistent with metal−phosphorus ligation. In the low-field region of the $^{13}C\{^1H\}$ NMR spectra of **12a**, **13a** and **14a** the ^{13}C atoms of the pivaloyl substituents were observed as doublets at δ = 232.2 to 235.3 ($^1J_{PC}$ = 70.6 to 80.0 Hz). Doublets at δ = 195.2 to 198.7 ($^1J_{PC}$ = 48.0 to 55.4 Hz) are readily assigned to the tricoordinate carbon atoms of the carbenium building block. Similar observations have been made in the $^{13}C\{^1H\}$ NMR spectra of P-benzoyl analogoues.

Informations on the σ-donor/π-acceptor properties of **2a** and **b** were provided by the IR spectra of the carbonylmetal complexes. Three intense bands at $\tilde{\nu}$ = 2054, 1976 and 1966 cm^{-1} in the IR spectrum of **14a** (KBr) are attributed to the stretching modes of the CO ligands of the $[Ni(CO)_3]$ moiety. The local symmetry of the latter is lower than that of the point group C_{3V}. The donor capacity of the inversely polarized phosphaalkene is similar to that of $PtBu_3$ in $[(tBu_3P)Ni(CO)_3]$ [ν(CO) (CH_2Cl_2) = 2056, 1971 cm^{-1}].[24] It is interesting to note that the metallophosphaalkene $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP{=}C(NMe_2)_2]$ of inverse electron density behaves as a much stronger donor ligand towards the $[Ni(CO)_3]$ group in $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP\{Ni(CO)_3\}C(NMe_2)_2]$ [ν(NiCO) (KBr) = 2034, 1957, 1917 cm^{-1}].[7b] The observation of three intense carbonyl bands in the IR spectrum of the tetracarbonyliron complex **13a** ranging from 2028 to 1927 cm^{-1} is consistent with the local symmetry of the point group C_{3V} for the $[Fe(CO)_4]$-unit with an additional donor ligand in the axial position at the trigonal bipyramid. Intense carbonyl absorptions at $\tilde{\nu}$ = 2051, 1987, 1919 and 1900 cm^{-1} in the IR spectrum of **12a** (KBr) correspond to the ν(CO) bands in phosphane complex **15** ($\tilde{\nu}$ = 2051, 1989, 1927, 1894 cm^{-1}.[7b]). Similar absorptions occur in compounds **12b** and **13b**.

15

In the IR spectra of complexes **12a**, **13a**, and **14a**, medium to intense bands at $\tilde{\nu}$ = 1584 to 1596 and 1542 to 1560 cm^{-1} are tentatively assigned to the ν(CO) modes of the pivaloyl substituent. Thus they are found between those of free **2a** and its protonation and methylation products **3a** and **4a**. For comparison, coordination of the ylides MeC(O)CH=PPh_3 and PhC(O)CH=PPh_3 to AuCl via the C-atom has also led to hypsochromic shifts of the ν(CO) bands from 1540 to 1645 and from 1500 to 1620 cm^{-1}.[12]

X-ray Structural Analysis of 12a

An ORTEP drawing of **12a** is shown in Figure 5; selected bond lengths and angles are given in the caption and in Table 1. The molecule exhibits octahedral geometry at the metal atom; one coordination site is occupied by an η^1-ligated phosphaalkene. The complexation of $tBuC(O)P{=}C(NMe_2)_2$ to the $[Cr(CO)_5]$ moiety is accompanied by a severe distortion of the organophosphorus ligand. A single bond of 1.833(2) Å is found between the trigonal pyramidal phosphorus atom (sum of angles 332.9°) and the planar carbon atom C(6) (sum of angles 359.9°). Both nitrogen atoms are also planar (sum of angles 359.9 and 358.5°). The bond length P(1)−C(1) [1.848(2) Å] is as long as the other P−C single bond in the molecule. The carbon atom C(1) is trigonal planar configured (sum of angles 359.4°) featuring a C=O double bond of 1.225(2) Å and a C−C single bond of 1.541(2) Å to the *tert*-butyl substituent, which clearly excludes any significant π-conjugation between the carbonyl group and the lone pair on phosphorus in **12a**. The Cr−P bond length [2.516(1) Å] is similar to that in $[(\eta^5\text{-}C_5Me_5)(CO)_2FeP\{Cr(CO)_5\}C(NMe_2)_2]$ [2.533(2) Å],[7a] but clearly exceeds the Cr−P atomic distances in complexes such as $[2,4,6\text{-}Me_3C_6H_2P\{Cr(CO)_5\}{=}CPh_2]$ [2.356(1) Å][6a] or $[CF_3P\{Cr(CO)_5\}{=}C(F)NMe_2]$ [2.454(1) Å].[3a] A view perpendicular to the $[Cr(CO)_4]$ plane indicates an almost eclipsed conformation with torsion angles C(1)−P(1)−Cr(1)−C(14) = 11.3° and C(6)−P(1)−Cr(1)−C(13) = −11.2° (Figure 6).

Presumably due to steric hindrance, the ideal local C_{4V}-symmetry of the $[Cr(CO)_5]$ unit is slightly perturbed, as it is evident from the angles C(11)−Cr(1)−C(15) [86.8(1)°],

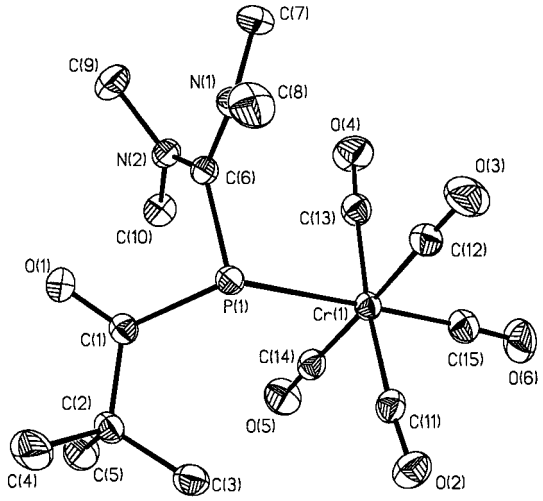


Figure 5. Molecular structure of **12a** in the crystal; selected bond lengths [Å] and angles [°]: Cr(1)−P(1) 2.516(1), Cr(1)−C(11) 1.897(2), Cr(1)−C(12) 1.889(2), Cr(1)−C(13) 1.899(2), Cr(1)−C(14) 1.924(2), Cr(1)−C(15) 1.853(2), P(1)−C(1) 1.848(2), C(1)−O(1) 1.225(2), C(1)−C(2) 1.541(2), P(1)−C(6) 1.833(2), C(6)−N(1) 1.347(2), C(6)−N(2) 1.339(2); N(1)−C(7) 1.471(2), N(1)−C(8) 1.466(3), N(2)−C(9) 1.469(2), N(2)−C(10) 1.465(2), C(2)−C(1)−P(1) 120.5(1), C(2)−C(1)−O(1) 118.0(2), P(1)−C(1)−O(1) 120.9(1), C(1)−P(1)−Cr(1) 130.0(1), C(1)−P(1)−C(6) 98.5(1), Cr(1)−P(1)−C(6) 104.4(1), P(1)−C(6)−N(1) 117.7(1), P(1)−C(6)−N(2) 124.3(1), N(1)−C(6)−N(2) 118.0(2), C(6)−N(1)−C(7) 123.1(2), C(6)−N(1)−C(8) 123.5(2), C(7)−N(1)−C(8) 113.3(2), C(6)−N(2)−C(9) 122.5(2), C(6)−N(2)−C(10) 123.4(1), C(9)−N(2)−C(10) 112.6(2), P(1)−Cr(1)−C(11) 90.9(1), P(1)−Cr(1)−C(12) 87.6(1), P(1)−Cr(1)−C(13) 92.1(1), P(1)−Cr(1)−C(14) 91.1(1), P(1)−Cr(1)−C(15) 177.6(1), C−Cr−C 86.8(1)−92.4(1), Cr−C−O 175.0(2)−178.2(2)

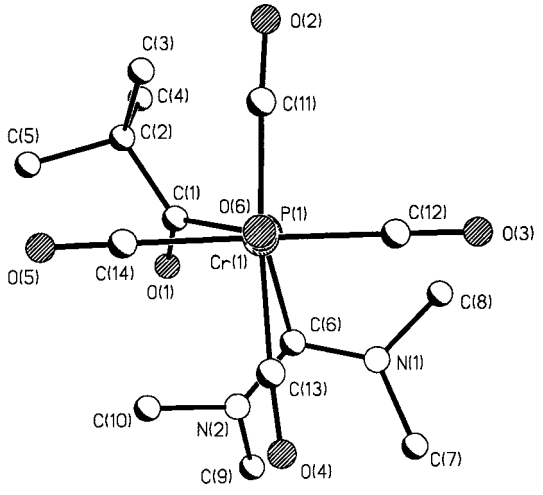

Figure 6. Newman projection of **12a** along the Cr(1)−P(1) vector

P(1)−Cr(1)−C(13) [92.1(1)°] and C(11)−Cr(1)−C(13) [174.6(1)°]. It is also remarkable that one of the equatorial Cr−C(CO) bonds [Cr(1)−C(14) = 1.924(2) Å] is elongated in comparison to the remaining equatorial carbonyl ligands [Cr−CO = 1.889(2) to 1.899(2) Å]. As usual in $[Cr(CO)_5]$ complexes with donor ligands, the axial Cr−CO bond is markedly shortened [Cr(1)−C(15) = 1.853(2) Å]

Experimental Section

All reactions were performed by Schlenk techniques under an atmosphere of dry nitrogen. The phosphaalkenes $Me_3SiP{=}C(NMe_2)_2$ **1**,[25] **2a,b**,[9] tBu_2AlCl,[26] and the complexes $[Fe_2(CO)_9]$[27] and [{(*Z*)-cyclooctene}$Cr(CO)_5$][28] were prepared as described in the literature. $[Ni(CO)_4]$, $HBF_4{\cdot}OEt_2$, $MeOSO_2CF_3$, $Me_3SiOSO_2CF_3$, $(AlMe_3)_2$, $GaMe_3$ and $InMe_3$ were purchased commercially. − Infrared spectra were recorded with a Bruker FTIR IFS 66 spectrometer. − NMR Spectra: Bruker AC 100, AM Avance DRX 500. Standards: $SiMe_4$ (^1H, ^{13}C), external 85% H_3PO_4 (^{31}P).

[*t*BuC(O)P(H)C(NMe$_2$)$_2$]BF$_4$ (3a): A solution of pivaloyl chloride (0.18 g, 1.47 mmol) in diethyl ether (10 mL) was added dropwise to a chilled solution (−50°C) of **1** (0.30 g, 1.47 mmol) in diethyl ether (30 mL). The reaction mixture was warmed to −20°C and stirred for 30 min. After cooling to −50°C a solution of 20 mL (1.47 mmol) of ethereal HBF_4 (54%) in diethyl ether (10 mL) was added dropwise. The solution was slowly warmed to room temp. and stirred for 1 h. A colorless precipitate was formed, filtered off and washed with diethyl ether (20 mL) to afford 0.33 g (74% yield) of **3a**. − IR (KBr): $\tilde{\nu}$ = 1680 s, 1597 [s, (C=O)] cm^{-1}. − ^1H NMR (CD_2Cl_2): δ = 1.18 [s, 9 H, $C(CH_3)_3$], 3.24 (s, 12 H, NCH_3), 6.02 (d, J_{PH} = 245 Hz, 1 H, PH). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 28.5 [s, $C(CH_3)_3$], 44.6 (s, NCH_3), 49.9 [s, $C(CH_3)_3$], 178.1 (s, br, CN_2), 220.0 (s, br, C=O); − ^{31}P NMR (CD_2Cl_2): δ = −53.7 (d, J_{PH} = 245 Hz). − $C_{10}H_{22}BF_4N_2OP$ (304.07): calcd. C 39.50, H 7.29, N 9.21; found C 39.43, H 7.03, N 9.23.

[PhC(O)P(H)C(NMe$_2$)$_2$]BF$_4$ (3b): A solution of **2b** was prepared analogously from benzoyl chloride (0.26 g, 1.81 mmol) and **1** (0.37 g, 1.81 mmol) in diethyl ether (40 mL). At −50°C 0.29 g (1.81 mmol) of ethereal HBF_4 (54%) in 10 mL of the same solvent was added dropwise. It was warmed to room temp. and stirred for 1 h. The supernatant solvent was decanted from a light-yellow oil. The latter was kept under vacuum (10^{-1} Torr, 1 h) to afford 0.56 g (95%) of **3b** as a light yellow viscous oil. − IR (CsI, film): $\tilde{\nu}$ = 1653 (s), 1599 [s, (C=O)] cm^{-1}. − ^1H NMR (CD_2Cl_2, 22°C): δ = 3.34 (s, 12 H, NCH_3), 6.36 (s, br, 1 H, PH), 7.55 (m, 2 H, *m*-Ph*H*), 7.70 (m, 1 H, *p*-Ph*H*), 7.80 (m, 2 H, *o*-Ph*H*). − ^1H NMR (CD_2Cl_2, −70°C): δ = 3.36 (s, 12 H, NCH_3), 6.23 (d, J_{PH} = 257.7 Hz, 1 H, PH), 7.65 (m, 3 H, *m*,*p*-Ph*H*), 7.80 (m, 2 H, *o*-Ph*H*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 45.0 (s, NCH_3), 127.0 s, 129.6 s, 135.5 s, 138.1 (d, J_{PC} = 31.8 Hz, Ph*C*), 177.9 (s, br, CN_2), 204.8 (s, br, C=O). − ^{31}P NMR (CD_2Cl_2, −70°C): δ = −46.6 (d, J_{PH} = 257.1 Hz). − $C_{14}H_{30}BF_4N_2OP$ (324.06): calcd. C 44.48, H 5.60, N 8.64; found C 44.38, H 5.69, N 8.40.

[*t*BuC(O)P(CH$_3$)C(NMe$_2$)$_2$][SO$_3$CF$_3$] (4a): As described before, **2a** was generated from equimolar amounts of **1** (0.38 g, 1.86 mmol) and pivaloyl chloride (0.23 g, 1.86 mmol) in 40 mL of diethyl ether. At −50°C a solution of methyl triflate (0.31 g, 1.86 mmol) in diethyl ether (10 mL) was added dropwise to the mixture, thereafter it was warmed to room temp. and stirred for 1 h. The orange precipitate formed was filtered off and washed with diethyl ether (30 mL) to give 0.53 g (75% yield) of **5a** as a moisture-sensitive solid. − IR (KBr): $\tilde{\nu}$ = 1644 s, 1588 [s, (C=O)] cm^{-1}. − ^1H NMR (CD_2Cl_2): δ = 1.20 [s, 9 H, $C(CH_3)_3$], 1.69 (d, J_{PH} = 4.5 Hz, 3 H, PCH_3), 3.32 (s, 12 H, NCH_3). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 6.0 (d, J_{PC} = 13.3 Hz, PCH_3), 26.4 [s, $C(CH_3)_3$], 45.2 (s, NCH_3), 49.8 [d, J_{PC} = 30.4 Hz, $C(CH_3)_3$], 121.2 (q, J_{CF} = 321.0 Hz, CF_3], 177.6 (d, J_{PC} = 44.0 Hz, CN_2), 222.7 (d, J_{PC} = 60.6 Hz, C=O). − $^{31}P\{^1H\}$ NMR: δ = −3.8 s. − $C_{12}H_{24}F_3N_2O_4PS$ (380.36): calcd. C 37.89, H 6.36, N 7.36; found C 36.62, H 5.82, N 7.34.

[PhC(O)P(CH$_3$)C(NMe$_2$)$_2$][SO$_3$CF$_3$] (4b): A solution of **2b**, prepared from **1** (0.32 g, 1.57 mmol) and benzoyl chloride (0.22 g,

1.57 mmol) in 40 mL of diethyl ether was treated with methyl triflate (0.25 g, 1.57 mmol) in diethyl ether (10 mL) at −50°C and then allowed to warm to room tmperature with stirring. A pale orange solid formed, which was filtered off and washed with diethyl ether (30 mL) to afford 0.56 g (89%) of **4b**. − IR (CsI): $\tilde{\nu}$ = 1647 m, 1587 [m, (C=O)] cm^{-1}. − ^1H NMR (CD_2Cl_2): δ = 1.78 (d, J_{PH} = 3.7 Hz, PCH_3), 3.16 (s, 12 H, NCH_3), 7.57 (m, 3 H, Ph*H*), 7.74 (m, 2 H, Ph*H*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 5.0 (d, J_{PC} = 11.7 Hz, PCH_3), 44.6 (s, NCH_3), 121.1 (q, J_{CF} = 321.2 Hz, CF_3), 127.2 (d, J_{PC} = 6.9 Hz, PhC), 129.7 s, 136.0 s, 138.1 (d, J_{PC} = 35.9 Hz, Ph*C*), 177.5 (d, J_{PC} = 39.4 Hz, CN_2), 210.0 (d, J_{PC} = 37.7 Hz, C=O). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = −2.3 s. − $C_{14}H_{20}F_3N_2O_4PS$ (400.35): calcd. C 42.00, H 5.04, N 7.00; found C 42.00, H 5.00, N 6.70.

[*t*BuC(OSiMe$_3$)=PC(NMe$_2$)$_2$][SO$_3$CF$_3$] (5a): A solution of **2a**, obtained from **1** (0.28 g, 1.37 mmol) and pivaloyl chloride (0.17 g, 1.37 mmol) in 40 mL of diethyl ether was treated at −50°C with a solution of trimethylsilyl triflate (0.30 g, 1.37 mmol) in diethyl ether (10 mL). Thereafter it was warmed to room temp. whereupon a pale yellow oil separated. The solvent was decanted, and the remaining oil was kept in vacuo (10^{-2} Torr) for 1 h to afford 0.53 g (88% yield) of **5a** as a viscous, very air- and moisture-sensitive liquid. − IR (CsI, film): $\tilde{\nu}$ = 1221 [m, δ($SiMe_3$)], 836 [m, ρ($SiMe_3$)] cm^{-1}. − ^1H NMR (CD_2Cl_2): δ = 0.33 (s, 9 H, $SiCH_3$), 1.24 [s, 9 H, $C(CH_3)_3$], 3.33 (s, 12 H, NCH_3). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 1.7 (s, $SiCH_3$), 28.5 [s, $C(CH_3)_3$], 45.0 (s, NCH_3), 51.1 [s, br, $C(CH_3)_3$], 121.2 (q, J_{CF} = 321.3 Hz, CF_3), 180.8 (d, J_{PC} = 75.5 Hz, CN_2), 226.1 (d, J_{PC} = 77.3 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 109.2 s. − $C_{14}H_{30}F_3N_2O_4PSSi$ (438.52): calcd. C 38.35, H 6.90, N 6.39; found C 36.91, H 6.36, N 6.44.

PhC(OSiMe$_3$)=PC(NMe$_2$)$_2$][SO$_3$CF$_3$] (5b): A solution of **2b**, prepared from **1** (0.25 g, 1.23 mmol) and benzoyl chloride (0.17 g, 1.23 mmol), in 40 mL of diethyl ether was treated with a solution of 0.27 g (1.23 mmol) of trimethylsilyl triflate in the same solvent (10 mL) at −50°C. It was warmed to room temp., whereupon a colorless oil separated. Decanting the solvent and liberating the oil from volatile compounds in vacuo (10^{-2} Torr) gave 0.48 g of **5b** as an extremely air- and moisture-sensitive colorless oil. − IR (CsI, film): $\tilde{\nu}$ = 1223 [m, δ($SiMe_3$)], 839 [m, ρ($SiMe_3$)] cm^{-1}. − ^1H NMR (CD_2Cl_2): δ = 0.15 (s, 9 H, $SiCH_3$), 3.39 (s, 12 H, NCH_3), 7.42 (m, 3 H, Ph*H*), 7.59 (m, 2 H, Ph*H*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 0.8 (s, $SiCH_3$), 45.1 (s, NCH_3), 127.1 s, 129.5 s, 139.5 (s, Ph*C*), 181.0 (d, J_{PC} = 72.4 Hz, CN_2), 211.3 (d, J_{PC} = 61.4 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 101.0 s. − $C_{16}H_{26}F_3N_2O_4PSSi$ (458.51): calcd. C 41.91, H 5.72, N 6.11; found C 40.14, H 5.55, N 6.59.

***t*BuC[OB(C$_6$F$_5$)$_3$]=PC(NMe$_2$)$_2$ (6a):** A 10% solution of tris(pentafluorophenyl)borane (5.52 g, 1.08 mmol) in toluene was added dropwise to a chilled solution (−30°C) of **2a** (0.23 g, 1.08 mmol) in toluene (40 mL). The mixture was slowly warmed to room temp., whereupon the slow formation of a precipitate occurred. After 3 h of stirring the bright yellow solid was filtered and washed with 5 mL of *n*-pentane. Yield: 0.52 g (66%) of yellow **6a**. − ^1H NMR (CD_2Cl_2): δ = 1.13 [s, 9 H, $C(CH_3)_3$], 3.13 (s, 12 H, NCH_3). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 28.8 [s, $C(CH_3)_3$], 45.4 (s, NCH_3), 48.4 [s, $C(CH_3)_3$], 137.0 (d, J_{CF} = 247.7 Hz, aryl-C), 139.5 (d, J_{CF} = 247.2 Hz, aryl-C), 147.5 (d, J_{CF} = 237.9 Hz, aryl-C), 147.9 (d, J_{CF} = 240.1 Hz, aryl-C), 188.5 (d, J_{CP} = 89.0 Hz, CN_2), 228.8 (d, J_{CP} = 81.4 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 68.3 s. − $C_{28}H_{21}BF_{15}N_2OP$ (728.24): calcd. t*BuC[OAl(*t*Bu)$_2$Cl]=PC(NMe$_2$)$_2$ (7a):** 15.7 mL of a 0.1M solution of tBu_2AlCl in toluene (1.57 mmol) was added dropwise at −40°C to a freshly prepared solution of **2a** (0.37 g, 1.57 mmol) in 40 mL of toluene. While warming to room temp. the color of the solution changed from yellow to orange. After 1 h of stirring the solvent was removed in vacuo and the oily residue was extracted with *n*-pentane (5 × 10 mL) to give **7a** as an orange, very moisture- and air-sensitive solid. Attempts to crystallize **7a** led to dismutation. A few crystals of *t*BuC[OAl(*t*Bu)Cl_2]=PC(NMe_2)$_2$ (**7a) were obtained after storing a solution of pure **7a** in C_6D_6 at +6°C for 3 weeks. − **7a:** ^1H NMR (C_6D_6): δ = 1.34 [s, 9 H, $(CH_3)_3CC$], 1.38 [s, 18 H, $(CH_3)_3CAl$], 2.63 (s, 12 H, NCH_3). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 29.4 [s, $CC(CH_3)_3$], 31.6 [s, $AlC(CH_3)_3$], 44.2 (s, NCH_3), 46.3 [d, J_{PC} = 35.5 Hz, $CC(CH_3)_3$], 184.4 (d, $^1J_{PC}$ = 76.5 Hz, CN_2), 233.8 (d, J_{PC} = 86.5 Hz, PCO), the signal of $AlC(CH_3)_3$ was not detectable. − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 72.9 (s). − $C_{18}H_{39}AlClN_2OP$ (392.92): calcd. C 55.02, H 10.01, N 7.13; found C 54.89, H 10.13, N 7.05. − **7a*:** $C_{14}H_{30}AlCl_2N_2OP$ (371.26): calcd. C 45.29, H 8.14, N 7.55; found 45.27, H 8.16, N 7.36.

PhC[OAl(tBu)$_2$Cl]=PC(NMe$_2$)$_2$ (7b): Analogously, reaction of **2b** (0.34 g, 1.42 mmol) and tBu_2AlCl (14.2 mL of a 0.1M solution in toluene, 1.42 mmol) in 40 mL of toluene led to the orange solid **7b** (0.38 g, 64%). Attempts to grow single crystals of **7b** from C_6D_6 at 6°C resulted in a dismutation and the isolation of a few crystals of PhC[OAl(*t*Bu)Cl_2]=PC(NMe_2)$_2$ (**7b***) after 2 weeks. − **7b:** ^1H NMR (C_6D_6): δ = 1.37 [s, 18 H, $C(CH_3)_3$], 2.63 (s, 12 H, NCH_3), 7.09 (m, 3 H, Ph*H*), 8.07 (m, 2 H, Ph*H*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 29.7 [s, $C(CH_3)_3$], 31.3 [s, $C(CH_3)_3$], 44.1 (s, NCH_3), 125.5 s, 128.7 s, 131.7 s, 143.5 (d, J_{PC} = 39.0 Hz, Ph*C*), 185.3 (d, J_{PC} = 71.8 Hz, CN_2), 220.3 (d, J_{PC} = 69.8 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 78.2 (s). − $C_{20}H_{35}AlClOP$ (412.92): calcd C 58.18, H 8.54, N 7.78; found C 57.50, H 8.04, N 8.20.

***t*BuC(OAlMe$_3$)=PC(NMe$_2$)$_2$ (8a):** At −30°C 13.2 mL of a 0.1M solution of $AlMe_3$ in *n*-hexane (1.32 mmol) was added dropwise to a solution of **2a** (0.29 g, 1.32 mmol) in *n*-pentane (40 mL). The yellow color of the solution faded rapidly as it warmed up. The solvent was then removed in vacuo to leave **8a** as a pale-yellow very air- and moisture-sensitive oil. − ^1H NMR (C_6D_6): δ = −0.37 (s, 9H, $AlCH_3$), 1.39 [s, 9 H, $C(CH_3)_3$], 2.50 (s, 12 H, NCH_3). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = −5.2 (s, $AlCH_3$), 28.5 [s, $C(CH_3)_3$], 43.6 (s, NCH_3), 46.3 [d, J_{CP} = 34.7 Hz, $C(CH_3)_3$], 189.9 (d, J_{CP} = 78.3 Hz, CN_2), 239.6 (d, J_{CP} = 86.4 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 62.7 (s). − $C_{13}H_{30}AlN_2OP$ (288.41): calcd. C 54.14, H 10.48, N 9.71; found C 53.48, H 10.42, N 9.49.

PhC(OAlMe$_3$)=PC(NMe$_2$)$_2$ (8b): Similarly, 0.31 g (90%) of **8b** was obtained as an orange air- and moisture-sensitive oil from 1.12 mmol of $AlMe_3$ and 0.26 g (1.12 mmol) of **2b**. − ^1H NMR (C_6D_6): δ = −0.33 (s, 9H, $AlCH_3$), 2.47 (s, 12H, NCH_3), 7.12 (m, 3H, Ph*H*), 8.23 (m, 2H, Ph*H*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ =

−5.7 (s, $AlCH_3$), 43.5 (s, NCH_3), 125.6 (s, Ph*C*), 131.7 (s, Ph*C*), 143.0 (d, $^2J_{CP}$ = 40.4 Hz, *i*-PhC), 189.9 (d, $^1J_{CP}$ = 76.3 Hz, CN_2), 223.5 (d, $^1J_{CP}$ = 73.4 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 64.9 s. − $C_{15}H_{26}N_2AlOP$ (308.40): calcd. C 58.42, H 8.50, N 9.08; due to the extreme sensibility of **8b** no reliable elemental analyses could be obtained.

***t*BuC(O)PC(NMe$_2$)$_2$·GaMe$_3$ (9a):** At −30°C 11.5 mL of a 0.1M solution of $GaMe_3$ in *n*-hexane (1.15 mmol) was added dropwise to a solution of **2a** (0.25 g, 1.15 mmol) in *n*-pentane (40 mL). After warm up to ambient temp. the solvent was carefully removed in vacuo to afford **9a** (0.32 g, 84%) as a yellow, very moisture- and air-sensitive oil. In vacuo (10^{-3} Torr) the adduct can be liberated completely from $GaMe_3$. − ^1H NMR (C_6D_6): δ = 0.08 (s, 9 H, $GaCH_3$), 1.37 [s, 9 H, $C(CH_3)_3$], 2.46 (s, 12 H, NCH_3). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = −2.0 (s, $GaCH_3$), 28.2 [s, $C(CH_3)_3$], 42.9 (s, NCH_3), 47.1 [d, J_{CP} = 38.6 Hz, $C(CH_3)_3$], 195.6 (d, J_{CP} = 76.3 Hz, CN_2), 237.3 (d, J_{CP} = 88.8 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 38.7 (s, br). − $C_{13}H_{30}GaN_2OP$ (331.09): calcd. C 47.16, H 9.13, N 8.46; found C 45.21, H 8.52, N 8.06.

***t*BuC(O)PC(NMe$_2$)$_2$·2GaMe$_3$ (10a):** Analogously, 23.0 mL (2.30 mmol) of a 0.1M solution of $GaMe_3$ in *n*-hexane was reacted with 0.25 g (1.15 mmol) of **2a** in 40 mL of *n*-pentane. After warming to room temp. the mixture was concentrated to 2 mL and stored at −30°C for 24 h, whereupon yellow crystalline **10** (0.24 g, 63%) separated. The air- and moisture-sensitive adduct can be freed from $GaMe_3$ in vacuo. The chemical shifts in the NMR spectra of **10a** are essentially the same as of **9a** − a phenomenon, which is presumeably caused by dissociation.

PhC(O)PC(NMe$_2$)$_2$·GaMe$_3$ (9b): A 0.1M solution of $GaMe_3$ in *n*-hexane (7.8 mL, 0.78 mmol) was added dropwise to a cooled solution of **2b** (0.18 g, 0.78 mmol) in *n*-pentane (40 mL). After warming to ambient temp. the solvent was carefully removed in vacuo. Adduct **9b** (0.25 g, 91% yield) was obtained as an extremely air- and moisture-sensitive residue. Continued evacuation led to a complete removal of $GaMe_3$. − ^1H NMR (C_6D_6): δ = 0.05 (s, 9 H, $GaCH_3$), 2.47 (s, 12 H, NCH_3), 7.13 (m, 3 H, Ph*H*), 8.19 (m, 2 H, Ph*H*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = −2.2 (s, $GaCH_3$), 43.1 (s, NCH_3), 126.7 s, 126.8 s, 133.0 s, 144.3 (d, J_{CP} = 43.9 Hz, Ph*C*), 194.0 (d, J_{CP} = 79.5 Hz, CN_2), 225.4 (d, J_{PC} = 76.7 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 48.1 (s, br). − $C_{15}H_{26}GaN_2OP$ (351.08): calcd.C 51.32, H 7.46, N 7.98; found C 49.80, H 7.52, N 7.75.

***t*BuC(O)P(InMe$_3$)C(NMe$_2$)$_2$ (11a):** Analogously, a 0.1M solution of $InMe_3$ in *n*-hexane (9.6 mL, 0.96 mmol) was added at −40°C dropwise to a solution of **2a** (0.21 g, 0.96 mmol) in 40 mL of *n*-pentane. The mixture was slowly warmed up to room temp. and the solvent was carefully removed in vacuo. Crude adduct **11a** was obtained as a yellow oily residue, which was redissolved in *n*-pentane (5 mL) and stored at −30°C. Pure **11a** was isolated as orange crystals (0.29 g, 80%). − IR (KBr): $\tilde{\nu}$ = 1594 (s, CO), 1546 (s, CO) cm^{-1}. − ^1H NMR (C_6D_6): δ = 0.09 (s, br, 9 H, $InCH_3$), 1.36 [s, 9 H, $C(CH_3)_3$], 2.45 (s, 12 H, NCH_3). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = −4.6 (s, $InCH_3$), 27.9 [s, $C(CH_3)_3$], 43.1 (s, NCH_3), 47.7 [d, J_{CP} = 39.8 Hz, $C(CH_3)_3$], 195.5 (d, J_{CP} = 68.4 Hz, CN_2), 234.0 (d, J_{CP} = 84.5 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 15.6 (s, br). − $C_{13}H_{30}InN_2OP$ (376.18): calcd. C 41.51, H 8.04, N 7.45; found C 41.16, H 8.21, N 7.41.

PhC(O)P(InMe$_3$)C(NMe$_2$)$_2$ (11b): Adduct **11b** (0.40 g, 91%) was isolated as an air- and moisture-sensitive solid from the reaction of $InMe_3$ (1.12 mmol of a 0.1M solution in *n*-hexane, 11.2 mL,) and **2b** (0.28 g, 1.12 mmol) in 40 mL of *n*-pentane at −30°C and after an analogous workup. − IR (KBr): $\tilde{\nu}$ = 1597 (sh, CO), 1540 (m, CO) cm^{-1}. − ^1H NMR (C_6D_6): δ = 0.06 (s, br, 9 H, $InCH_3$), 2.53 (s, 12 H, NCH_3), 7.13 (m, 3 H, Ph*H*), 8.26 (m, 2 H, Ph*H*). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = −4.7 (s, $InCH_3$), 42.2 (s, NCH_3), 126.4 s, 131.1 s, 133.0 s, 144.6 (d, J_{CP} = 46.7 Hz, Ph*C*), 196.2 (d, J_{CP} = 76.6 Hz, CN_2), 219.9 (d, J_{CP} = 76.7 Hz, PCO). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ = 36.8 (s). − $C_{15}H_{26}InN_2OP$ (396.17): calcd. [*t*BuC(O)P{Ni(CO)$_3$}C(NMe$_2$)$_2$] (14a): A solution of [Ni(CO)$_4$] (0.23 g, 1.37 mmol) in 10 mL of diethyl ether was added dropwise to the chilled solution (−30°C) of 1.37 mmol **2a**, prepared from 0.28 g **1** and 0.17 g of pivaloyl chloride, in diethyl ether (30 mL). The mixture was allowed to warm to room temp. and was stirred for 1 h, whereupon its color changed from orange to red-brown. Volatile components were removed in vacuo, and the red solid residue was washed with 20 mL of cold *n*-pentane (−30°C). Recrystallization from diethyl ether afforded orange crystalline **14a** (0.26 g, 50%). Upon exposure to daylight, the crystals turned brown rapidly. – IR (KB): $\tilde{\nu}$ = 2054 [s, (NiCO)], 1976 [s, (NiCO)], 1966 [s, (NiCO)], 1584 [s, $(CO)_{acyl}$], 1542 [m, $(CO)_{acyl}$] cm^{-1}. – ^{1}H NMR (C_6D_6): δ = 1.38 [s, 9 H, $C(CH_3)_3$], 2.53 (s, 12 H, NCH_3). – $^{13}C\{^1H\}$NMR (C_6D_6): δ = 27.6 [s, $C(CH_3)_3$], 42.5 (s, NCH_3), 48.1 [d, J_{PC} = 41.5 Hz; $C(CH_3)_3$], 196.7 (s, NiCO), 198.4 (d, J_{PC} = 48.9 Hz, CN_2), 232.2 (d, J_{PC} = 70.6 Hz, PCO). – $^{31}P\{^1H\}$NMR (C_6D_6): δ = −11.7 (s). – $C_{13}H_{21}N_2NiO_4P$ (358.99): calcd. C 43.50, H 5.90, N 7.80; found C 43.47, H 5.80, N 7.79.

X-ray Crystallography: Data collection for **6b** was performed on a 1 K-Siemens (Bruker) AXS-CCD-diffractometer using omega-scan techniques; integration and absorption correction with Siemens-Saint program, structure solution with direct methods and refinement on F^2 with Siemens SHELXTL Vers. 5.03 with riding models for hydrogen atoms.

For **7b***, **10a**, **11a** and **12a** crystallographic data (Table 2) were collected with a Siemens $P2_1$ four-circle diffractometer using graphite-monochromated Mo-K_α radiation. Semi-empirical absorption corrections using ψ-scans were applied. Crystallographic programs used for structure solutions and refinements were SHELXTL PLUS and SHELXL-97. The structures were solved by direct methods and refined by using full-matrix least squares on F^2 and all unique reflections and attributing anisotropic thermal parameters to all non-hydrogen atoms. Hydrogen atoms were included at calculated positions using a riding model.[29] Crystal data collection and refinement parameters are given in Table 2. ORTEP drawings of the solid state structures of **6b**, **7b***, **10a**, **11a** and **12a** are shown in Figures 1–6. Bonding parameters are given in the captions and in Table1.
