

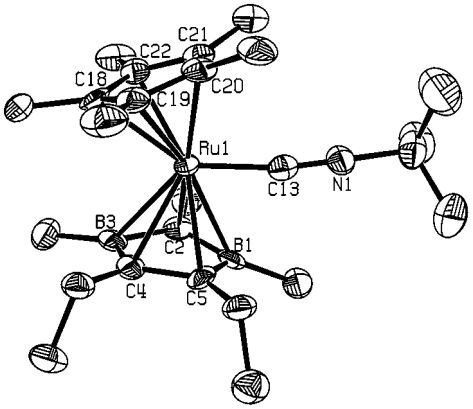

Figure 5. Molecular structure of **6*d** in the crystal

Conclusions

In contrast with our earlier findings,[6] sandwich complexes **2c−f** with less bulky groups may be obtained at low temperature using LiMe instead of NaH as reagent. The electron-poor 18 VE complexes **2*a,** and **c** react with donor ligands such as CO and $CNCMe_3$ to form donor-acceptor compounds, with different stability: CO >> $CNCMe_3$ > H_2 > THF. The complexes **2*a** and **c** activate the B−H bonds

of BH_3 to give with elimination of hydrogen the ruthenacarborane complexes **8*a** and **c**. Reaction of **2*c** $[ClRh(C_2H_4)_2]_2$ leads to the Cl-bridged pentadecker **9*c**

Experimental Section

General: Experiments were carried out under nitrogen or argon, which had been dried and purified before use. Solvents were dried by conventional methods and saturated with nitrogen. − NMR spectra were recorded on Bruker AC-200 (^{1}H: 200.13 MHz, ^{13}C: 50.32 MHz, ^{11}B: 64.21 MHz) and Bruker AC-500 (^{1}H: 500.13 MHz, ^{13}C: 125.76 MHz) in C_6D_6 as solvent. Chemical shifts are relative to that of TMS and $BF_3{\cdot}OEt_2$. − The mass spectra were recorded on Varian MAT CH7, Finnigan MAT 8230, and JEOL. The MS Station JMS 700 (reference for HRMS is perflourated Kerosin). GC mass spectra were recorded on HP-5890 II gas chromatograph with HP-5971 MSD (column HP-3, 12.5m × 0.25 mm × 0.25 μm). − IR spectra were measured on Bruker IFS 28. Neutral alumina or silica gel used for chromatography had been dried and alumina deactivated by addition of 5% water.

2-Ethyl-1,3-diiodo-4,5-dimethyl-2,3-dihydro-1,3-diborole: 2-Butyne (3.24 g, 60 mmol) was slowly added to a solution of 1,1-bisdiiodoborylpropane (33 g, 60 mmol) in 30 mL of pentane at 0°C. The reaction mixture was allowed to warm to 20°C, stirred for 1 h and then the solvent and iodine were removed in vacuum. 2-Ethyl-1,3-diiodo-4,5-dimethyl-2,3-dihydro-1,3-diborole was isolated by distillation as lightly yellow liquid. Yield 18 g (81%) − b. p. 67°C/10^{-3} Torr. − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.00 (br, 1 H, B_2CHCH_2), 1.15 (t, 3 H, $^3J_{HH}$ = 7.4 Hz, CH_2CH_3), 1.72 (s, 6 H, = CCH_3), 1.89 (m, 2 H, $CHCH_2CH_3$). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = 15.6 (=CCH_3), 16.9 (CH_2CH_3), 23.2 ($CHCH_2CH_3$), 52.7 (B_2CHCH_2, br), 175.0 (=CCH_3, br). − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 64.8.

2-Ethyl-1,3,4,5-tetramethyl-2,3-dihydro-1,3-diborole (5d): 2-Ethyl-1,3-diiodo-4,5-dimethyl-2,3-dihydro-1,3-diborole (21.5 g, 58 mmol) was dissolved in 40 mL of pentane and cooled to −5°C. 2.78 g (39 mmol) of $AlMe_3$ in 20 mL of pentane were added dropwise within 30 min. After warming to room temp. and stirring over night the solvent was removed in vacuum (80 Torr), and colorless **5d** was distilled. Yield: 6.9 g (79%). − b. p. 20°C/10^{-3} Torr. − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.69 (s, 6 H, BCH_3), 2.07 (t, 3 H, $^3J_{HH}$ = 7.1 Hz, CH_2CH_3), 2.42 (t, 1 H, $^3J_{HH}$ = 5.9 Hz, B_2CHCH_2), 2.67 (m, 2 H, $CHCH_2CH_3$), 2.78 (s, 6 H, CCH_3). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = 4.3 (BCH_3, br), 14.3 (=CCH_3), 16.9 (CH_2CH_3), 19.9 ($CHCH_2CH_3$), 51.6 (B_2CHCH_2, br), 173.0 (=CCH_3, br). − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 69.6. − GC-MS: retention time: 2.28 min. − *m/z* (%) = 148 [M^+] (35), 133 [$M^+ - CH_3$] (34), 117 [$M^+ - CH_3, - CH_4$] (33), 41 [$C_3H_5^+$] (100).

2,4,5-Trimethyl-1,3-bis(trimethylsilylmethylene)-2,3-dihydro-1,3-diborole (5e): $LiCH_2SiMe_3$ (40 mL, 1 M in pentane) was added dropwise to a solution of 7.16 g (20 mmol) of 1,3-diiodo-2,4,5-trimethyl-2,3-dihydro-1,3-diborole in 40 mL of pentane at 0°C. The yellow reaction mixture became colorless and a white solid precipitated. After warming to room temp. and stirring over night the precipitate was filtered. The solvent was removed in vacuum (50 Torr) and colorless **5e** was distilled. Yield: 3.5 g (63%). − b. p. 49°C/10^{-3} Torr. − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.09 [s, 18, $Si(CH_3)_3$], 1.01 (d, 2 H, $^2J_{HH}$ = 9.5 Hz, BCH_2Si), 1.15 (d, 2 H, $^2J_{HH}$ = 9.5 Hz, BCH_2Si), 1.27 (d, 3 H, $^3J_{HH}$ = 5.2 Hz, $CHCH_3$), 1.32 (q, 1 H, $^3J_{HH}$ = 5.2 Hz, B_2CHCH_3), 1.88 (s, 6 H, =CCH_3). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = 2.4 [$Si(CH_3)_3$], 12.2 (=CCH_3), 15.5 (BCH_2Si, br), 15.9 ($CHCH_3$), 39.2 (B_2CHCH_3, br), 172.0 (=CCH_3, br). − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 68.8. − MS (EI): *m/z* (%) = 278 [M^+] (16), 263 [$M^+ - CH_3$] (7), 190 [$M^+ - CH_2SiMe_3$] (9), 73 [Me_3Si^+] (100). − HRMS calcd. for $C_{14}H_{32}B_2Si_2$: 278.2229, found: 278.2231, Δ*m* = 0.2 mmu.

(η^5-Pentamethyl-2,3-dihydro-1,3-diborolyl)(η^5-pentamethylcyclopentadienyl)ruthenium (2*c): 1.38 mL (2.2 mmol) of 1.6 M LiMe were added dropwise to a solution of 256 mg (2.2 mmol) of **5c** in THF (35 mL) at −55°C. The reaction mixture was allowed to stir for 15 min and then transferred via canula to a flask containing 600 mg (0.55 mmol) of $[Cp^*RuCl]_4$ in 40 mL of THF, cooled to −55°C. After stirring for 12 h the solvent was removed in vacuum. The violet residue was dissolved in 5 mL of hexane and purified by chromatography, either on Al_2O_3 at −20°C or on silica gel at room temp. using hexane as eluant. **2*c** was isolated as a dark violet solid. Yield: 380 mg (47%). − m.p. 138°C (decomp.). − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.21 (s, 6 H, BCH_3), 1.46 (s, 15 H, $C_5(CH_3)_5$), 2.23 (s, 6 H, =CCH_3), 2.83 (s, 3 H, B_2CCH_3). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = −1.8 (BCH_3, br), 10.6 [$C_5(CH_3)_5$], 16.4 (=CCH_3), 20.9 (B_2CCH_3), 83.8 [$C_5(CH_3)_5$], 118.8 (=CCH_3, br), 185.8 (B_2CCH_3, br) − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 20.6−^{1}H NMR (200.13 MHz, [D$_8$]THF): δ = −0.01 (s, 6 H, BCH_3), 1.61 [s, 15 H, $C_5(CH_3)_5$], 2.25 (s, 6 H, =CCH_3), 2.59 (s, 3 H, B_2CCH_3). − ^{13}C NMR (50.32 MHz, [D$_8$]THF): δ = 11.1 [$C_5(CH_3)_5$], 16.8 (=CCH_3), 20.8 (B_2CCH_3), 84.8 [$C_5(CH_3)_5$], = CCH_3 and B_2CCH_3 not observed. − ^{11}B NMR (64.21 MHz, [D$_8$]THF): δ = 22.6. − MS (EI): *m/z* (%) = 370 [M^+] (88), 351 [$M^+ - CH_3, - 4$ H] (100), 336 [$M^+ - 2\ CH_3, - 4$ H] (74), 301 [$M^+ - C_3H_8, - BCH_3$] (77), 233 [$Cp^*Ru^+ - 4$ H] (77), 41 [$C_3H_5^+$] (89). − HRMS calcd. for $C_{18}H_{30}B_2Ru$: 370.1571, found 370.1563, Δ*m* = 0.8 mmu.

(η^5-4,5-Diethyl-1,2,3-trimethyl-2,3-dihydro-1,3-diborolyl)(η^5-pentamethylcyclopentadienyl)ruthenium (2*d): Same procedure as for **2*c**. The product, **2*d** was obtained from **5d** (162 mg, 1 mmol), LiMe (0.63 mL, 1 mmol) and $[Cp^*RuCl]_4$ (274 mg, 0.25 mmol) as a dark violet oil. Yield: 147 mg (37%). − b. p. 75°C/10^{-3} Torr. −

^{1}H NMR: δ = 0.26 (s, 6 H, BCH_3), 1.32 (t, 6 H, $^3J_{HH}$ = 7.5 Hz, = CCH_2CH_3), 1.45 [s, 15 H, $C_5(CH_3)_5$], 2.4 (m, 4 H, =CCH_2CH_3), 2.8 (s, 3 H, CCH_3), 3.15 (m, 4 H, =CCH_2CH_3). − ^{13}C NMR: δ = −0.5 (BCH_3, br), 11.7 [$C_5(CH_3)_5$], 15.1 (=CCH_2CH_3), 22.0 (B_2CCH_3), 26.3 (=CCH_2CH_3), 85.1 [$C_5(CH_3)_5$], 123.6 (=CCH_2CH_3, br), 190.6 (B_2CCH_3, br). − ^{11}B NMR: δ = 21. − MS (EI): *m/z* (%) = 397 [M^+ −H] (100), 383 [M^+ − CH_3] (98), 368 [M^+ − C_2H_6] (24), 353 [M^+ − 3 CH_3] (26), 235 [Cp*Ru^+ − H] (60). − HRMS calcd. for $C_{20}H_{34}B_2Ru$: 398.1890, found 398.1889, Δ*m* = 0.1 mmu.

[η^5-2,4,5-Trimethyl-1,3-bis(trimethylsilylmethylene)-2,3-dihydro-1,3-diborolyl](η^5-pentamethylcyclopentadienyl)ruthenium (2*e): Same procedure as for **2*c**. The product, **2*e** was obtained from **5e** (444.6 mg, 1.6 mmol), LiMe (1 mL, 1.6 mmol), and [Cp*RuCl]$_4$ (435 mg, 0.4 mmol) as a dark violet oil. Yield: 334 mg (41%). − b. p. 85°C/10−^{3} Torr. − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.01 [s, 18 H. $Si(CH_3)_3$], 0.09 (d, 2 H, $^2J_{HH}$ = 15 Hz, BCH_2Si), 0.43 (d, 2 H, $^2J_{HH}$ = 15 Hz, BCH_2Si), 1.48 [s, 15 H, $C_5(CH_3)_5$], 2.23 (s, 6 H, =CCH_3), 2.74 (s, 3 H, B_2CCH_3). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = 1.2 [$Si(CH_3)_3$], 5.7 [B$CH_2Si(CH_3)_3$, br], 10.7 [$C_5(CH_3)_5$], 16.7 (=CCH_3), 22.1 (B_2CCH_3), 83.4 [$C_5(CH_3)_5$], 118.8 (=CCH_3, br), B_2CCH_3 not observed. − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 21.7. − MS (EI): *m/z* (%) = 514 [M^+] (4), 426 [M^+ − $Si(CH_3)_3$, − CH_3] (4), 233 [Cp*Ru^+ − 4 H] (5), 73 [Me_3Si^+] (100). − HRMS calcd. for $C_{24}H_{46}B_2RuSi_2$: 514.2361, found 514.2357, Δ*m* = 0.4 mmu.

(η^5-2-Ethyl-1,3,4,5-tetramethyl-2,3-dihydro-1,3-diborolyl)(η^5-pentamethylcyclopentadienyl)ruthenium (2*f): Same procedure as for **2*c**. The product, **2*f** was obtained from **5f** (326 mg, 2.2 mmol), LiMe (1.38 mL, 2.2 mmol) and [Cp*RuCl]$_4$ (590 mg, 0.55 mmol) as a dark violet solid. Yield: 160 mg (19%). − m.p. 148°C (decomp.). − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.25 (s, 6 H, BCH_3), 1.45 (s, 15 H, C_5CH_3), 1.66 (t, 3 H, $^3J_{HH}$ = 7.6 Hz, $B_2CCH_2CH_3$), 2.20 (s, 6 H, =CCH_3), 3.20 (q, 2 H, $^3J_{HH}$ = 7.6 Hz, $B_2CCH_2CH_3$). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = −1.6 (BCH_3, br), 10.9 [$C_5(CH_3)_5$], 16.4 (=CCH_3), 16.8 ($B_2CCH_2CH_3$), 29.7 ($B_2CCH_2CH_3$), 83.8 [$C_5(CH_3)_5$], 118.4 (=CCH_3, br), $B_2CCH_2CH_3$ not observed. − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 21.5. − MS (EI): *m/z* (%) = 384 [M^+] (40), 368 [M^+ − CH_4] (100), 232 [Cp*Ru^+ − 5 H] (15). − HRMS calcd. for $C_{19}H_{32}B_2Ru$: 384.1727, found 384.1723, Δ*m* = 0.4 mmu.

(η^5-Pentamethyl-2,3-dihydro-1,3-diborolyl)(η^5-1-ethyl-2,3,4,5-tetramethylcyclopentadienyl)ruthenium (2^c): Li(Et_3BH) (1.14 mL, 1 M in THF) was added dropwise to a suspension of (Cp^ $RuCl_2$)$_2$ (365 mg, 0.57 mmol) in 40 mL of THF and then stirred for 45 min. In another flask with a cooled solution (−55°C) of **5c** (189 mg, 1.27 mmol) in 40 mL of THF 1.38 mL (2.2 mmol) of 1.6 M LiMe were added dropwise and allowed to stir for 15 min at −55°C. Subsequently the reaction mixture was transferred via canula to the likewise cooled flask of the ruthenium reaction. After stirring for 12 h the solvent was removed in vacuum. The violet residue was dissolved in 5 mL of hexane and purified by chromatography, either on Al_2O_3 at −20°C or on silica gel at room temp. using hexane as eluant. **2^c** was isolated as a dark violet solid. Yield: 88 mg (20%) − m.p. 145°C (decomp.). − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.21 (s, 6 H, BCH_3), 0.84 (t, 3 H, $^3J_{HH}$ = 7.6 Hz, $C_5CH_2CH_3$), 1.43 [s, 6 H, $C_5(CH_3)_4$], 1.50 [s, 6 H, $C_5(CH_3)_4$], 1.89 (q, 2 H, $^3J_{HH}$ = 7.6 Hz, $C_5CH_2CH_3$), 2.23 (s, 6 H, =CCH_3), 2.83 (s, 3 H, B_2CCH_3). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = −2.2 (BCH_3, br), 10.4 and 10.6 [$C_5(CH_3)_4$], 14.8 ($C_5CH_2CH_3$), 16.4 (=CCH_3), 19.1 ($C_5CH_2CH_3$), 21.0 (B_2CCH_3), 83.3, 83.9, and 89,8 ($C_5(CH_3)_4Et$), 118.9 (=CCH_3, br), 185.8 (B_2CCH_3, br). − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 20.7. − MS (EI): *m/z* (%) = 384 [M^+] (39), 243 [Cp Ru^+ − 7 H] (100), 41 [$C_3H_3^+$] (35). − HRMS calcd. for $C_{19}H_{32}B_2Ru$: 384.1727, found 384.1703, Δ*m* = 2.4 mmu.

(η^5-2-Ethyl-1,3,4,5-tetramethyl-2,3-dihydro-1,3-diborolyl)(η^5-1-ethyl-2,3,4,5-tetramethyl cyclopentadienyl)ruthenium (2^f): Same procedure as for **2^c**. The product, **2^f** was obtained from **5f** (250 mg, 1.7 mmol), LiMe (1.06 mL, 1.7 mmol) and [Cp^ $RuCl_2$]$_2$ (543 mg, 0.85 mmol), treated with 1.7 mL (1.7 mmol) of 1 M Li(Et_3BH) as a dark violet oil. Yield: 188 mg (27%). − b.p. 85°C/10^{-3} Torr. − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.25 (s, 6 H, BCH_3), 0.83 (t, 3 H, $^3J_{HH}$ = 7.4 Hz, $C_5CH_2CH_3$), 1.44 [s, 6 H, $C_5(CH_3)_4$], 1.49 [s, 6 H, $C_5(CH_3)_4$], 1.65 (t, 3 H, $^3J_{HH}$ = 7.6 Hz, $B_2CCH_2CH_3$), 1.90 (q, 2 H, $^3J_{HH}$ = 7.4 Hz, $C_5CH_2CH_3$), 2.20 (s, 6 H, =CCH_3), 3.21 (q, 2 H, $^3J_{HH}$ = 7.6 Hz, $B_2CCH_2CH_3$). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = −1.2 (BCH_3, br), 10.8 [$C_5(CH_3)_4$], 10.5 [$C_5(CH_3)_4$], 16.4 (=CCH_3), 16.8 ($B_2CCH_2CH_3$), 14.8 ($C_5CH_2CH_3$), 19.1 ($C_5CH_2CH_3$), 29.8 ($B_2CCH_2CH_3$), 83.3, 84.0, and 89.5 [$C_5(CH_3)_4Et$], 118.6 (=CCH_3, br), 190.1 (B_2CCH_2, br). − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 21.8. − MS (EI): *m/z* (%) = 398 [M^+] (52), 382 [M^+ − CH_4] (100), 368 [M^+ − C_2H_6] (22), 243 [Cp Ru^+ − 8 H] (12), 149 [Cp $^+$] (77), 41 [$C_3H_5^+$] (28). − HRMS cald. for $C_{20}H_{34}B_2Ru$: 398.1890, found 398.1881, Δ*m* = 0.9 mmu.

(η^5-1,3,4,5-Tetraethyl-2-methyl-2,3-dihydro-1,3-diborolyl)(η^5-pentamethylcyclopentadienyl)ruthenium *tert*-Butylisocyanide (6*a): Compound **2*a** (100 mg, 0.24 mmol) was dissolved in hexane (15 mL) and CNC_4H_9 (19.5 mg, 24 mmol) was added dropwise. The color changed immediately from violet to yellow. After partial removal of the solvent in vacuum **6*a** crystallized at −20°C. Yield: 80 mg (66%) − m.p. 75°C (diss. to the starting materials). − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.17 (t, 3 H, $^3J_{HH}$ = 7.3 Hz, = CCH_2CH_3), 1.24 [s, 9 H, $CNC(CH_3)_3$], 1.34 (t, 3 H, $^3J_{HH}$ = 7.3 Hz, =CCH_2CH_3), 1.38−1.49 (m, 10 H, BCH_2CH_3), 1.51 (s, 3 H, B_2CCH_3), 1.55 [s, 15 H, $C_5(CH_3)_5$], 1.83−2.22 (m, 4 H, = CCH_2CH_3). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = 6.8 (BCH_2CH_3, br), 9.6 [$C_5(CH_3)_5$], 10.5 (BCH_2CH_3, br), 12.2 and 12.9 (BCH_2CH_3), 15.6 (B_2CCH_3), 17.2 and 17.6 (=CCH_2CH_3), 21.5 and 22.6 (=CCH_2CH_3), 31.5 [$CNC(CH_3)_3$], 56.4 [$CNC(CH_3)_3$], 67.5 (B_2CCH_3, br), 90.8 [$C_5(CH_3)_5$], 102.6 and 121.7 (=CCH_2CH_3, br), 166.5 [$CNC(CH_3)_3$]. − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 29.6. − MS (EI): *m/z* (%) = 509 [M^+] (44), 425 [M^+ − $CNC(CH_3)_3$] (53), 396 [M^+ − C_2H_5, − $CNC(CH_3)_3$] (100), 367 [M^+ − 2 C_2H_5, − $CNC(CH_3)_3$] (30), 236 [Cp*Ru^+ − H] (15), 57 [$C_4H_9^+$] (40). − HRMS calcd. for $C_{27}H_{47}B_2NRu$: 509.2938, found 509.2953, Δm = 1.5 mmu. − FT-IR (hexane): $\tilde{\nu}_{CN}$ = 2048 cm^{-1}, 2088 cm^{-1} (weak).

(η^5-4,5-Diethyl-1,2,3-trimethyl-2,3-dihydro-1,3-diborolyl)(η^5-pentamethylcyclopentadienyl)ruthenium *tert*-Butylisocyanide (6*d): Same procedure as for **6*a**. The product, **6*d** was obtained from **2*d** (95.5 mg, 0.24 mmol) in 15 mL of hexane and 19 mg (0.24 mmol) of $CNC(CH_3)_3$ as yellow crystals. Yield: 76.3 mg (66%) − m.p. 65°C (diss. to the starting materials). − ^{1}H NMR (200.13 MHz, C_6D_6): δ = 0.80 (s, 3 H, BCH_3), 0.84 (s, 3 H, BCH_3), 1.16 (t, 3 H, $^3J_{HH}$ = 7.5 Hz, =CCH_2CH_3), 1.25 [s, 9 H, $CNC(CH_3)_3$], 1.30 (t, 3 H, $^3J_{HH}$ = 7.5 Hz, =CCH_2H_3), 1.47 (s, 3 H, B_2CCH_3), 1.55 [s, 15 H, $C_5(CH_3)_5$], 1.85−2.19 (m, 4 H, = CCH_2CH_3). − ^{13}C NMR (50.32 MHz, C_6D_6): δ = −1.6 (BCH_3, br), 1.9 (BCH_3, br), 10.5 [$C_5(CH_3)_5$], 16.4 (B_2CCH_3), 17.7 (= CCH_2CH_3), 18.4 (=CCH_2CH_3), 22.3 (=CCH_2CH_3), 23.5 (= CCH_2CH_3), 32.5 [$CNC(CH_3)_3$], 57.0 [$CNC(CH_3)_3$], 70.1 (B_2CCH_3, br), 91.6 [$C_5(CH_3)_5$], 109.8 (=CCH_2CH_3, br), 121.9 (=CCH_2CH_3, br), 164.4 [$CNC(CH_3)_3$]. − ^{11}B NMR (64.21 MHz, C_6D_6): δ = 29.4 − MS (EI): *m/z* (%) = 481 [M^+] (40), 397 [M^+ − H, − CN*t*Bu]

(30), 382 [$M^+ - H, - CNtBu, - CH_3$] (100). – HRMS calcd. for $C_{25}H_{43}B_2NRu$: 481.2625, found 481.2650, Δm = 2.5 mmu. – FT-IR (hexane): $\tilde{\nu}_{CN}$ = 2084 cm^{-1}, 2031 cm^{-1} (weak).

(η⁵-1,3,4,5-Tetraethyl-2-methyl-2,3-dihydro-1,3-diborolyl)(η⁵-pentamethylcyclopentadienyl)ruthenium Dihydride (7*a): Complex **2*a** (50 mg, 0.12 mmol) was dissolved in 20 mL of hexane, and H_2 gas was bubbled through the solution for 4 min at a flow rate of 10 mLmin^{-1}. The color changed reversibly at −50°C from violet to yellow. For NMR studies, the deuterated solvents were used instead of hexane. – ^{1}H NMR (200.13 MHz, C_6D_6): δ = −12.49 (s, 2 H, Ru−H), 1.21−1.35 (m, 10 H, BCH_2CH_3), 1.43 (t, 6 H, $^3J_{HH}$ = 8.3 Hz, =CCH$_2$CH_3), 1.53 [s, 15 H, C$_5$(CH$_3$)$_5$], 1.66 (s, 3H, B$_2$CCH$_3$), 1.93 and 2.14 (m, 2H, =CCH_2CH$_3$). – ^{13}C NMR (50.32 MHz, C_6D_6): δ = 5.1 (BCH$_2$CH$_3$, br), 9.7 (BCH$_2$CH$_3$), 10.5 [C$_5$(CH$_3$)$_5$], 13.7 (=CCH$_2$CH$_3$), 22.2 (=CCH$_2$CH$_3$), 30.2 (B$_2$CCH$_3$), 94.6 [C$_5$(CH$_3$)$_5$], 114 (=CCH$_2$CH$_3$, br), B$_2$CCH$_3$ not observed. – ^{11}B NMR (64.21 MHz, C_6D_6): δ = 20.1.

(η⁵-1,2,3,4,5-Pentamethyl-2,3-dihydro-1,3-diborolyl)(η⁵-pentamethylcyclopentadienyl)ruthenium Dihydride (7*c): Same procedure as for **7*a**. The product, **7*c** was formed as a yellow solution from **2*c** (40 mg, 0.11 mmol) in 20 mL of hexane and H_2 gas (10 mLmin^{-1}) at −50°C. – ^{1}H NMR (200.13 MHz, [D$_8$]THF): δ = 0.40 (s, 6 H, BCH$_3$), 1.85 [s, 15 H, C$_5$(CH$_3$)$_5$], 1.62 (s, 6 H, =C−CH$_3$), 1.19 (s, 3 H, B$_2$CCH$_3$), −12.25 (s, 2 H, Ru−H). – ^{13}C NMR (50.32 MHz, [D$_8$]THF): δ = −4.9 (BCH$_3$, br), 10.9 [C$_5$(CH$_3$)$_5$], 14.7 (=CCH$_3$), 31.2 (B$_2$CCH$_3$), 96.7 [C$_5$(CH$_3$)$_5$], =CCH$_3$ and B$_2$CCH$_3$ not observed. – ^{11}B NMR (64.21 MHz, [D$_8$]-THF): δ = 22.9.

(η⁵-1,2,3,4,5-Pentamethyl-2,3-dihydro-1,3-diborolyl)(η⁵-pentamethylcyclopentadienyl)ruthenium Hydride Deuteride [7*c(HD)]: It was obtained from **2*c** (40 mg, 0.11 mmol) in 0.6 mL of [D$_8$]THF and HD gas (10 mLmin^{-1} for 4 min) as a yellow solution at −50°C. – ^{1}H NMR (200.13 MHz, [D$_8$]THF): δ = 0.40 (s, 6 H, BCH$_3$), 1.85 [s, 15 H, C$_5$(CH$_3$)$_5$], 1.63 (s, 6 H, =CCH$_3$), 1.18 (s, 3 H, B$_2$CCH$_3$), −12.21 and −12.24 (s, 1 H, Ru−H). – ^{11}B NMR (64.21 MHz, [D$_8$]THF): δ = 22.8.

[η⁵-2,4,5-Trimethyl-1,3-bis(trimethylsilylmethylene)-2,3-dihydro-1,3-diborolyl](η⁵-pentamethylcyclopentadienyl)ruthenium Dihydride (7*e): Same procedure as for **7*a**. The product, **7*e** was obtained as a yellow solution from **2*e** (50 mg, 0.1 mmol) in 20 mL of hexane and H_2 gas (10 mLmin^{-1}) at −50°C. – ^{1}H NMR (200.13 MHz, C_6D_6): δ = −11.91 (s, 2 H, Ru−H), 0.25 [s, 18 H, Si(CH$_3$)$_3$], 0.64 (d, 2 H, $^2J_{HH}$ = 3.1 Hz, BCH$_2$Si), 0.83 (d, 2 H, $^2J_{HH}$ = 3.1 Hz, BCH$_2$Si), 1.42 (s, 3 H, B$_2$CCH$_3$), 1.53 (s, 15 H, C$_5$(CH$_3$)$_5$), 1.76 (s, 6 H, =CCH$_3$). – ^{13}C NMR (50.32 MHz, C_6D_6): δ = 1.5 [Si(CH$_3$)$_3$], 10.3 [C$_5$(CH$_3$)$_5$], 16.5 (=CCH$_3$), 23.0 (B$_2$CCH$_3$), 96.0 [C$_5$(CH$_3$)$_5$], =CCH$_3$ and B$_2$CCH$_3$ not observed. – ^{11}B NMR (64.21 MHz, C_6D_6): δ = 22.5.

(1,2,3,6-Tetraethyl-5-methyl-4-hydrido-2,3,5-tricarbahexaboranyl)-(η⁵-pentamethylcyclopentadienyl)ruthenium (8*a): BH_3 in THF (0.24 mL, 1 M, 0.24 mmol) was added dropwise to a solution of **2*a** (100 mg, 0.24 mmol) in 40 mL of hexane at room temp. After the yellow reaction mixture had been stirred for 15 min, the solvents were removed in vacuum and the yellow solid was sublimed. Yield: 30 mg (29%). – m.p. 130°C. – ^{1}H NMR (500.13 MHz, C_6D_6): 0.07 (m, 1 H, BCH_2CH$_3$), 0.20 (m, 1 H, BCH_2CH$_3$), 0.83 (t, 3 H, $^3J_{HH}$ = 7.9 Hz, BCH$_2$CH_3), 1.02 (t, 3 H, $^3J_{HH}$ = 7.6 Hz, CCH$_2$CH_3), 1.23−1.34 (m, 5 H, BCH_2CH_3), 1.36 (t, 3 H, $^3J_{HH}$ = 7.5 Hz, CCH$_2$CH_3), 1.64 (s, 3 H, B$_2$CCH$_3$), 1.73 [s, 15 H, C$_5$(CH$_3$)$_5$], 1.75−1.89 (m, 3 H, CH_2CH$_3$), 2.14 (m, 1 H, CCH_2CH$_3$). – ^{13}C NMR (125 MHz, C_6D_6): 4.0 (BCH$_2$CH$_3$, br), 8.9 (BCH$_2$CH$_3$, br), 10.6 (B$_2$CCH$_3$), 11.3 [C$_5$(CH$_3$)$_5$], 12.3 (BCH$_2$CH$_3$), 12.7 (BCH$_2$CH$_3$), 14.4 (CCH$_2$CH$_3$), 14.6 (CCH$_2$CH$_3$), 21.0 (CCH$_2$CH$_3$), 21.4 (CCH$_2$CH$_3$), 68.5 (B$_2$CCH$_3$, br), 78.4 (CCH$_2$CH$_3$, br), 80.7 (CCH$_2$CH$_3$, br), 84.4 [C$_5$(CH$_3$)$_5$]. – ^{11}B NMR (64.21 MHz, C_6D_6): −0.4 (1 B, BH, $^1J_{BH}$ = 156 Hz), 3.9 (1 B, BCH$_2$CH$_3$), 6.6 (1 B, BCH$_2$CH$_3$). – MS (EI): *m*/*z* (%) = 438 [M^+] (100), 423 [$M^+ - CH_3$] (10), 235 [Cp*Ru$^+$ − 2 H] (15).

(1,2,3,5,6-Pentamethyl-4-hydrido-2,3,5-tricarbahexaboranyl)(η⁵-pentamethylcyclopentadienyl)ruthenium (8*c): Same procedure as for **8*a**. The complex **8*c** was obtained as a yellow solid from **2*c** (180 mg, 0.49 mmol) in 50 mL of hexane and BH_3 (0.5 mL, 1 M, 0.5 mmol). Yield: 90 mg (48%). – m.p. 110°C. – ^{1}H NMR (200.13 MHz, C_6D_6): δ = −0.55 (s, 3 H, BCH$_3$), 1.44 (s, 3 H, BCH$_3$), 1.73 [s, 15 H, C$_5$(CH$_3$)$_5$], 1.89 (s, 3 H, B$_2$CCH$_3$), 1.99 (s, 3 H, =CCH$_3$), 2.12 (s, 3 H, =CCH$_3$). – ^{13}C NMR (75.46 MHz, C_6D_6): δ = 11.9 [C$_5$(CH$_3$)$_5$], 12.9 (=CCH$_3$), 13.4 (=CCH$_3$), 17.3 (B$_2$CCH$_3$), 83.5 [C$_5$(CH$_3$)$_5$], BCH$_3$, B$_2$CCH$_3$, and =CCH$_3$ not observed. – ^{11}B NMR (64.21 MHz, C_6D_6): δ = 1.1 (1 B, BH, $^1J_{BH}$ = 159 Hz), 2.3 (1 B, BCH$_3$), 6.0 (1 B, BCH$_3$). – MS (EI): *m*/*z* (%) = 382 [M^+] (100), 367 [$M^+ - CH_3$] (20), 233 [Cp*Ru$^+$ − 4 H] (15). – HRMS calcd. for $C_{18}H_{31}B_3Ru$: 381.1761, found 381.1761, Δm = 0.0 mmu.

Dimer of [(η⁵-Pentamethyl-2,3-dihydro-1,3-diborolyl)(η⁵-pentamethylcyclopentadienyl)ruthenium]rhodium Chloride (9*c): To a suspension of μ-dichlorotetraethylenedirhodium (180 mg, 0.46 mmol) in 30 mL of THF 380 mg of **2*c** (1.03 mmol) dissolved in 15 mL of THF was added. After stirring for 12 h the reaction mixture was filtered and the solvent was removed in vacuum. The black residue was purified by chromatography (silica gel, hexane/toluene, 50:50) to give a dark brown solid. Yield: 210 mg (44%). – m.p. 170°C (decomp.). – ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.28 [s, 15 H, C$_5$(CH$_3$)$_5$], 1.39 (s, 6 H, BCH$_3$), 1.97 (s, 3 H, B$_2$CCH$_3$), 2.23 (s, 6 H, =CCH$_3$). – ^{11}B NMR (64.21 MHz, C_6D_6): δ = 21.8. – MS (EI): *m*/*z* (%) = 1016 [M^+] (100), 779 [M^+ − **2*c**] (4), 509 [M^+ − **2*c** − Rh − Cl] (45), 473 [**2*c**Rh$^+$] (35), 233 [Cp*Ru$^+$ − 4 H] (8).

Crystal Structure Determinations for 6*a,d: Diffraction data were collected on a Siemens-Stoe AED2 diffractometer (Mo-K_α radiation, graphite monochromator) in the ω-scan mode at −70°C. Crystal data and details of the measurements are summarized in Table 2. The structures were solved by direct methods (SHELXS86)[20] and refined by full-matrix least-squares methods (SHELXL93)[20] based on F^2 with all reflections. Non-hydrogen atoms were refined anisotropically, hydrogen atoms were added in calculated positions. − Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center: CCDC-116376 (**6*a**), CCDC-116377 (**6*d**). Copies of the data can be obtained free of charge by application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-001; E-mail: deposit@ccdc.cam.ac.uk].

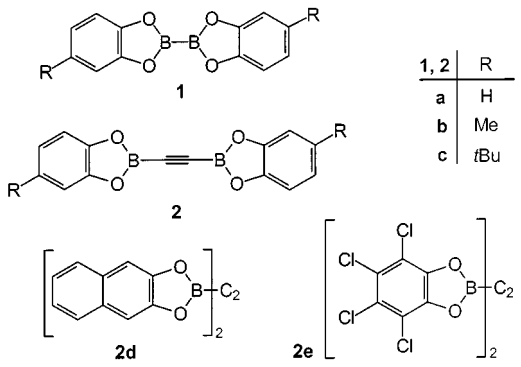
Synthesis of Tetraborylethenes and 1,1,1′,1′-Tetra- and Hexaborylethanes; Electronic Interactions in Tetraborylethenes and 1,1,1′,1′-Tetraborylethanes, and HF-SCF Calculations

Martin Bluhm,[a] Andreas Maderna,[a] Hans Pritzkow,[a] Sabine Bethke,[b] Rolf Gleiter,*[b] and Walter Siebert*[a]

Dedicated to Prof. Wolf-Peter Fehlhammer on the occasion of his 60th birthday



Keywords: Boranes / Homogeneous catalysis / Ab initio calculations / Donor-acceptor systems / X-ray analysis

The catechol-substituted diboranes(4) **1** react with the catechol-substituted diborylacetylenes **2**, in the presence of $[Pt(PPh_3)_2(C_2H_4)]$ or $[Pt(PPh_3)_4]$, to give tetra- and hexaborylethane derivatives. When $[Pt(cod)_2]$ is used as catalyst, the tetraborylethene **5a** is formed exclusively. Catalytic hydrogenation of **5a** affords the 1,1,1′,1′-tetraborylethane **4a**, which has been studied by an X-ray structure analysis. Natural Bond Orbital (NBO) analyses for the RHF/3–21G optimized geometries of **4a** and **5a** reveal intramolecular stabilization of the boron p_z orbital. This covers B–O, B–B, and agostic interactions. The photoelectron spectrum of **5a** is reported

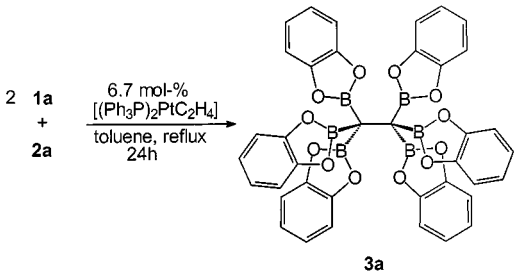
Introduction

The platinum-catalyzed diboration reaction of acetylenes was reported by Suzuki and Miyaura in 1993.[1] Mechanistic studies[2−4] revealed that, in the first step, an oxidative addition of diborane(4) to the platinum occurs followed by the insertion of a π-bonded acetylene into the Pt−B σ bond. Subsequent reductive elimination leads to the 1,2-diborylethene derivatives. Catechol-substituted diboranes(4), which are air-stable and easy to handle, have also been used. The highly reactive tetrachlorodiborane(4) (B_2Cl_4) readily adds, without a catalyst, to acetylene or acetylene derivatives to give (*Z*)-1,2-bis(dichloroboryl)ethenes.[5] Further reaction of $(CH)_2(BCl_2)_2$ with B_2Cl_4 affords tetrakis(dichloroboryl)ethane in excellent yield.[6] Recently a tetraborylethane was proposed as an intermediate in the hydroboration of bis(diethylboryl)acetylene, which rearranges to give carborane clusters.[7] Diboration of ethenes to 1,2-diborylethanes can be achieved by using bis(1,5-cyclooctadiene)platinum[8] $[Pt(cod)_2]$, tris(norbornene) platinum[8] $[Pt(nbe)_3]$ or bis(dibenzylideneacetone)platinum[9] $[Pt(dba)_2]$.

Tetraborylethenes are useful building blocks for the synthesis of new heterocycles, carboranes and for functionalized ethenes. The first example was synthesized in low yields by gas-phase reaction of carbon with B_2F_4.[10] Here we wish to report a detailed investigation into the platinum-catalyzed reactions of catechol-substituted diboranes **1** with the corresponding diborylacetylenes **2,** whereby access to air-stable tetraborylethenes, and tetraboryl- and hexaborylethanes is achieved.

Results and Discussion

Hexaborylethanes 3



In refluxing toluene, an excess of the diborylacetylene **2a** reacts with the diborane(4) **1a** in the presence of (ethene)-bis(triphenylphosphane)platinum catalyst, and **3a** is isolated in 71% yield.[11] This compound is insoluble in nonprotic solvents but slightly soluble in methanol with slow decomposition. The molecule ion of **3a** can be detected by mass spectrometry (EI, CI and FD). In the ^{11}B NMR spectrum (CD_3OD) a broad signal at δ = 34 for **3a** and a sharp one at δ = 19 for the methanolysis product $C_6H_4O_2BOCD_3$ appear. The boron-bound carbon atom is found as a broad signal at δ = 23 in the ^{13}C NMR spectrum (T = 203 K).

Other hexaborylethane derivatives are obtained from the substituted diborylacetylene **2d**[12] and the diborane(4) **1a**. Due to steric hindrance in the starting compounds, the

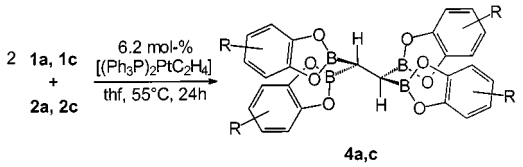
yields of the hexaborylethane derivatives $\mathbf{3a_nd_{6-n}}$ (n = 2−5) are low. During the formation of these compounds an unexpected exchange of the boryl substituents takes place, as indicated by mass spectrometric studies of the products. As shown in Scheme 2, the reaction of **2d** with **1a** in the presence of $[Pt(PPh_3)_2(C_2H_4)]$ leads to a mixture of the derivatives $\mathbf{3a_nd_{6-n}}$ (n = 2−5), in which between five and two boryl substituents of **1a** and between one and four substituents of **2d** are incorporated. It is unknown whether the exchange occurs before or after the formation of the hexaborylethanes.

Scheme 1

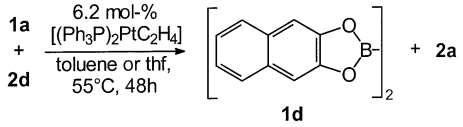
These results clearly demonstrate that in refluxing toluene the platinum compounds $[Pt(PPh_3)_2(C_2H_4)]$ or $[Pt(PPh_3)_4]$ catalyze the double diboronation of the diborylacetylene **2a** with the diborane(4) **1a** to give the hexaborylethane **3a**.[11][13] Under these conditions the reaction does not stop at the expected tetraborylethene **5a**,[14] but leads to **3a**. Such a double diboronation of an alkyne in the presence of platinum phosphane catalysts has not previously been described and its formation had been disclaimed on the basis of theoretical calculations.[15] Our findings of a high reactivity of the diborylacetylene **2a** may be due to its flat shape[16] and to the easy formation of catecholboryl platinum compounds[3] relative to that of other derivatives.



Scheme 2

Tetraborylethanes 4

Surprisingly, the formation of tetraborylethanes[17][18] occurs by catalysis with $[Pt(PPh_3)_2(C_2H_4)]$ or $[Pt(PPh_3)_4]$ under mild conditions (55°C). A 1:1 mixture of **1a** and **2a** reacts in the presence of these platinum complexes to give 1,1,1′,1′-tetra(benzo-1,3-dioxa-2-borol-2-yl)ethane (**4a**) in low yield. The reaction proceeds in tetrahydrofuran and in toluene. Purification of **4a** is achieved by sublimation under high vacuum. Under the same reaction conditions **1c** and **2c** form the tetraborylethane **4c** in very low yield.

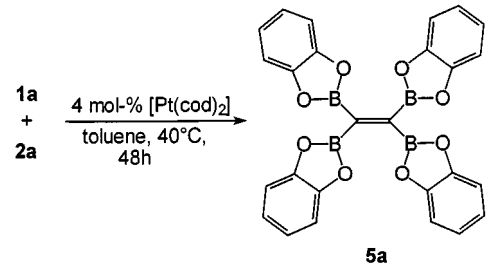


The molecular formula of **4a,c** follows from the molecular ions of **4a** and **4c** found in the EI mass spectrum and from the NMR spectroscopic data. The ^{11}B NMR spectrum (CD_3OD) shows a broad signal at δ = 32.5 for **4a,c** and a

Scheme 3

sharp one at δ = 19 for the methanolysis product. The signal in the ^{13}C NMR spectrum for the boron-bound carbon atoms of **4a** is observed at δ = 10. In the ^1H NMR spectrum, the two hydrogen atoms of the ethane unit appear as a broad singlet at δ = −0.1, which is in the same range for similar compounds.[19]

Attempts have been made to elucidate the origin of the hydrogen atoms in the ethane derivatives **4**. There is no incorporation of deuterium when the reaction is carried out in dry $[D_8]$thf. As the formation of a tetraborylethane also takes place in dry CCl_4 the hydrogen atoms must originate from other sources. Compound **1a** also reacts with the octachloro derivative **2e** to give the tetraborylethane derivative $\mathbf{4a_2e_2}$, which indicates that the hydrogen atoms cannot come from the diborylacetylene **2e**. We assume that a transfer of hydrogen atoms from the aryl substituents of the platinum phosphane catalysts occurs by an *ortho*-metalation reaction. The formation of tetraborylethanes most likely occurs by the intermediate formation[14,18,20,21] of 1,3-benzodioxa-2-borole followed by double hydroboration of the diborylacetylene.



Scheme 4

A different reaction takes place when **1a** and **2d** react in the presence or absence of $[Pt(PPh_3)_2(C_2H_4)]$ at 55°C in tetrahydrofuran, in toluene or in a mixture of both solvents. The expected bis(naphthalene-1,3-dioxa-2-borol-2-yl)-bis(benzo-1,3-dioxa-2-borol-2-yl)ethane does not form but, instead, the new compound 1,1:2,2-bis(2,3-naphthalenedioxy)diborane(4) (**1d**) is formed by an exchange of the boryl groups. The colorless air-stable solid **1d** is obtained in 74% yield. Its mass and NMR spectra prove the formation of the new diborane(4) derivative **1d**, which could not be obtained from the reaction between $B_2(NMe_2)_4$ and naphthalene-1,2-diol.[22] In the ^1H NMR spectrum **1d** shows a multiplet for the naphthol substituents and in the ^{13}C NMR spectrum, five signals for the naphthol carbon atoms. The ^{11}B NMR spectrum of **1d** in CD_3OD exhibits a signal at δ = 31.6 and a sharp one at δ = 19 for the methanolysis product of **1d**.

Tetraborylethene 5a

As outlined above, the attempt to synthesize tetraborylethene derivatives leads to the formation of tetraborylethane

compounds **4** when triphenylphosphane-platinum catalysts are used. The previously elusive tetraborylethene **5a** is obtained, however, from **1a** and **2a** with the base-free platinum catalyst [Pt(cod)$_2$] under mild conditions in toluene. Compound **5a** is formed in 70% yield as a colorless solid which sublimes at 160°C under high vacuum.

Scheme 5

The molecule ion of **5a** is detected in the EI and CI mass spectra whereas the M^+ ion for **4a** is not observed. The boron-bound carbon atoms of the double bond are found as a broad singlet at $\delta = 165$ in the low-temperature ^{13}C NMR spectrum ($T = 203$ K). The ^{11}B NMR spectrum (CD_3OD) shows a broad signal at $\delta = 30$ for **5a** and a sharp one at $\delta = 19$ for the methanolysis product of **5a**. The Raman spectrum of **5a** exhibits a band at 1549 cm^{-1} for the stretching vibration of the double bond. The IR spectrum of **5a** and Raman spectrum of the reference substance **1a** do not contain this band.

At temperatures above 40°C the hexaboryl derivative **3a** forms in toluene, because **1a** adds across the double bond of **5a**. By catalytic hydrogenation of **5a** (palladium/active carbon, 5 bar pressure) **4a** is formed in 35% yield.

Crystal Structure and Geometrical Parameters for 4a

To elucidate the structure of **4a**, an X-ray diffraction study was carried out (crystal data and structure refinement for **4a** are listed in Table 6). A single crystal of **4a**(thf)$_2$ was grown from a tetrahydrofuran solution at 4°C. Table 1 shows some of the structural parameters of **4a** as obtained from the X-ray diffraction structure analysis and the HF/3−21G geometry optimization. The crystal structure determination (Figure 1) shows a staggered conformation for the substituents at the central C−C single bond. The large substituents and the hydrogen atoms adopt the *anti* position. This result is in agreement with ab initio calculations (see Table 1). In the crystal structure, two tetrahydrofuran molecules are coordinated to the boron atoms. The C1−C1′ distance is elongated (1.585 Å, calcd. 1.575 Å), and comparable with that of other characterized tetraborylethane derivatives.[6]

The angles around the carbon atoms of the ethane unit are nearly tetrahedral, the B1−C1−B2 angle being larger (113.30°, calcd. 113.80°) than the H1−C1−B1 angle (107.78°, calcd. 107.15°) and the H1−C1−B2 angle (109.65°, calcd. 107.27°) due to steric reasons. The distances O5−B1 (2.728 Å) and O5−B2 (2.673 Å) confirm a bonding interaction between the tetrahydrofuran molecules and the boron atoms.

Computational Details for 4a and 5a

The geometries of **4a** and **5a** were fully optimized with GAUSSIAN94[23] at the Hartree−Fock level of theory using the split-valence 3−21G basis set. Compound **4a** was optimized in the point group symmetries C_i and C_{2h}, and **5a** in C_{2v}, C_{2h}, D_2 and D_{2h} symmetries. HF/3−21G frequency calculations were performed to verify that the structures are minima on the potential energy hypersurface, i.e. the eigenvectors of the Hessian matrix were all positive. The electronic structures of **4a** and **5a** were analyzed by means of a Natural Bond Orbital (NBO) analysis.[24]

Calculated Geometrical Parameters for 5a

Since there are no structural data available for **5a**, geometry optimizations were computed in several point groups. The global minimum on the HF/3−21G potential energy surface of **5a** belongs to the point group C_{2h} (see Figure 2, conformer **A**). In this structure two diametrically

opposed catechol rings are twisted by 90° out of the molecular plane while the remaining two are located in the molecular plane containing the four boron atoms. Conformation **A** favors an additional interaction between the lone pairs of the oxygen atoms and the boron centers lying opposite them, as shown in Figure 3.

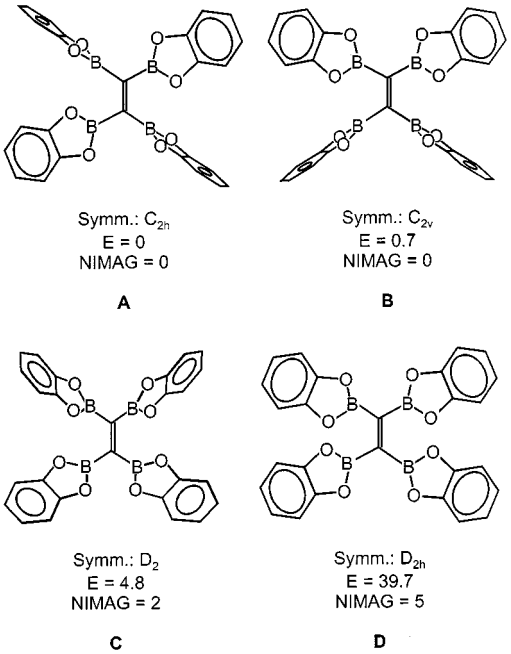

Figure 2. Calculated conformers of **5a**. E: relative energies [kcal/mol] corrected with zero-point energies and thermal enthalpies. NIMAG: number of imaginary frequencies

A conformation which is closely related to that just described belongs to point group C_{2v} (see Figure 2, conformer **B**). It is a local minimum, which is 0.7 kcal/mol less favored than **A**. In **B**, two geminal catechol rings are twisted by 90° to provide a donor-acceptor interaction between two vicinal catechol rings. The other two conformations shown in Figure 2 belong to point groups D_2 (**C**) and D_{2h} (**D**). Both represent higher order saddle points. In conformation **C** all rings are twisted propeller-like 42° out of the molecular plane. This conformation no longer allows donor-acceptor interactions as in the previously discussed conformations. In the case of conformation **D** all four catechol rings are coplanar to the ethylene fragment. This arrangement causes severe steric repulsion between the lone pairs at the oxygen atoms of vicinal catechol rings.

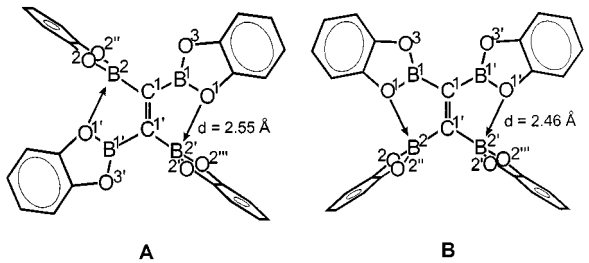

Figure 3. Intramolecular B−O interactions for conformers **A** and **B** (**5a**)

Table 2 summarizes some of the structural parameters of **5a** as obtained from the HF/3-21G geometry optimization in C_{2h}, C_{2v}, D_2 and D_{2h} symmetry. Structure **A** shows two types of boron atoms which are coordinated differently: B1 and B1′ are part of an extensive π system which is delocalized over two catechol moieties connected by the ethylene unit. However, the catechol groups of B2 and B2′ (see Figure 3) are oriented perpendicular to the plane containing the ethylene group and therefore experience a smaller stabilization by π-electron density delocalization from only one catechol group. This is compensated by intramolecular donation of electron density from the oxygen lone pairs of O1 and O1′ to the p_z orbitals of B2 and B2′, which is shown by short B2−O1′ and B2′−O1 interactions for conformers **A** (2.55 Å) and **B** (2.46 Å). The variations in B−O bond lengths in **A** and **B** (1.398−1.415 Å) are in line with electron density being donated from the lone pairs of O1 and O1′thus causing a lengthening of the B1−O1 bond and a shortening of the B1−O3 bond. The length of the B2−O2 bond (of the acceptor boron atom) is slightly longer than the averaged B1−O1 and B1−O3 bond lengths, due to electron donation from O1′ to B2.

Table 2. Calculated structural parameters for **5a**

	C1−C1′[a]	B2−O1′[a]	B2−O3[a]	B1−O1[a]	B1−O3[a]	B2−O2[a]	D1[b]	D2[b]
A	1.347	2.552	3.202	1.409	1.398	1.406	90.0	0.0
B	1.352	2.464	3.353	1.415	1.398	1.405	90.0	0.0
C	1.346	3.000	3.250	1.402	1.406	1.40	139.3	139.3
D	1.366	3.151	2.937	1.402	1.412	1.40	0.0	0.0

[a] Bond lengths in Å. − [b] Dihedral angles D are in degrees; D1 = O2B2C1C1′, D2 = O1B1C1C1′. For the atomic numbering see Figure 3.

To quantify these stabilizing B−O-interactions, a second-order perturbation theory treatment according to the Weinhold Natural Bond Orbital (NBO) localization procedure[23] was performed. As shown in Table 3, there is a stabilization of the empty boron p_z orbital by delocalized π electrons, especially from the neighboring oxygen atoms. The intramolecular donor-acceptor interaction O1−B2′ and O1′−B2 can be clearly seen. Each interaction stabilizes **A** by 15.5 kcal/mol. Although the stabilization is even higher in **B** (21.0 kcal/mol for each interaction) due to shorter O1−B2′ and O1′−B2 distances, this configuration does not represent the global minimum energy structure of **5a** because of repulsive interactions of these geminal catechol rings, which are coplanar with the ethylene fragment. No intramolecular O3−B2 or O3′−B2′ donor-acceptor interactions can be seen, because the distance is too long (3.2 Å in **A**, 3.4 Å in **B**) for an interaction, although the orientation is the same for O3−B2 and O1′−B2. Stabilization by π-electron density from the ethylene fragment can only exist for the boryl groups which are located in this plane (B1 and B1′). Although in close proximity, the

amount of stabilization is not much larger than the amount of intramolecular stabilization. The largest stabilization is due to π-electron density donation from the lone pairs of the neighboring oxygen atoms (Table 3).

PE Spectrum of 5a

The He^I PE spectrum of **5a** is shown in Figure 4. RHF/3−21G calculations were carried out in order to assign the bands to individual ionization processes. In the range 8.3−9.7 eV there is a broad band of overlapping ionization events (bands 1−3), followed by band 4 at 11.2 eV. The recorded vertical ionization energies agree very well with calculated negative orbital energies, according to Koopmans′ theorem.[25] The bands 1−3 (exp. 8.3−9.7 eV; calcd. 8.8−9.7 eV) are assigned to ionization processes from the eight highest occupied molecular orbitals, which are shown in Figure 5. These orbitals can be described as linear combinations between the π system of the catechol rings and the ethylene π system. The recorded energy differences Δ between band 3 and 4 compare well with the results of the calculations [Δ (exp.) 1.7 eV; Δ (calcd.) 1.5 eV]. Band 4 is assigned to ionization processes from the ethylene π-orbital.

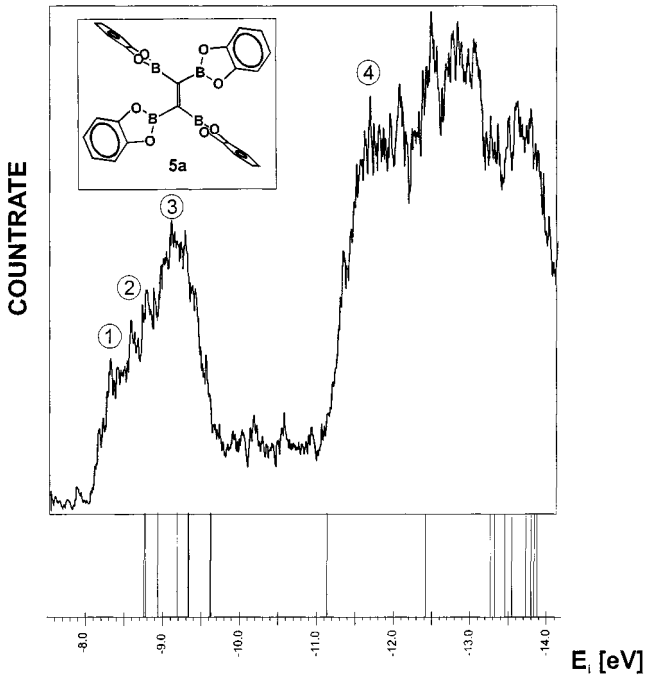

Figure 4. Photoelectron spectrum of **5a**

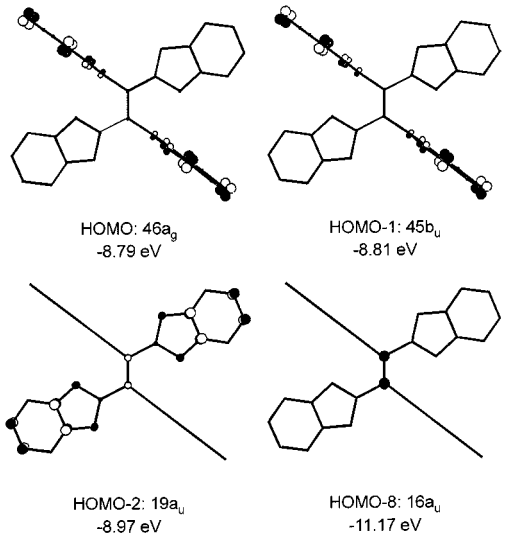

Figure 5. Selected occupied RHF/3−21G orbitals of **A** (**5a**)

Calculated Geometrical Parameters for 4a

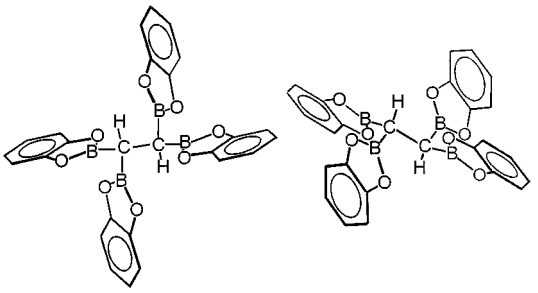

Figure 6 shows the most favorable conformations of **4a**, calculated without the coordinated tetrahydrofuran molecules. The global minimum on the HF/3−21G potential energy surface belongs to point group C_i (conformer **E**). In this structure the geminal catechol rings are twisted by 53° to provide a B−O donor-acceptor interaction between two vicinal catechol rings (Table 4). Additionally, there is a B−B interaction between the boron atoms of two geminal catechol rings and an agostic interaction between one boron p_z orbital and the C−H bond of the ethane fragment. In point group C_{2h} (conformer **F**, Figure 6) there is a mirror plane, spanned by the two C−H bonds of the ethane moiety, which disables donor-acceptor interactions. As a consequence, this structure represents a second-order saddle point, which is disfavored by 4.2 kcal/mol (corrected with zero-point energies and thermal energies) relative to **E**.

Table 4. Calculated structural parameters for **4a** (without coordinated thf)

4a	C1−C1′[a]	B1C1B2[a]	H1C1B1[a]	H1C1B2[a]	C1O1C1′O1′[a]	NIMAG[b]
E	1.582	112.97	107.31	108.02	51.3	0
F	1.573	115.00	106.50	106.50	0.0	2

[a] RHF/3−21G-optimizations, bond lengths are in Å, angles are in degrees. − [b] NIMAG: number of imaginary frequencies. For the atomic numbering see Figure 7.

To quantify these stabilizing B−O, B−B and agostic interactions, a second-order perturbation theory treatment according to the Weinhold Natural Bond Orbital (NBO) localization procedure[24] was performed. The relative orientation of the "empty" boron p_z orbital to the C−H bond of the ethane fragment is nearly coplanar and thus enables a stabilization by an agostic interaction. The acceptor boron p_z orbital has an occupation number of 0.318 and stabilizes the geminal boron p_z orbital, which shows an occupation number of 0.323. The larger occupation number

E F

Figure 6. Calculated conformers of **4a**. E: relative energies corrected with zero-point energies and thermal enthalpies. NIMAG: number of imaginary frequencies

is due to an additional intramolecular donor-acceptor interaction from the σ-type oxygen lone pair of the *cis* vicinal catechol group. As for **5a**, the large stabilization by π-electron density donation from the lone pairs of the neighboring oxygen atoms can also be seen (Table 5).

Experimental Section

General: Reactions were carried out under dry nitrogen, with standard Schlenk techniques. Solvents were dried, distilled and saturated with nitrogen. Glassware was dried with a heat-gun under high vacuum. ^{1}H, ^{13}C, ^{11}B NMR: Bruker AC 200 and 500 spectrometers; NMR references are $(CH_3)_4Si$ and BF3·Et2O. Mass spectra were obtained on a Finnigan MAT 8200 plus (EI technique) and ZAB-2F VG-Micromass CTD spectrometer (EI and HR-EI techniques) and on a Jeol MS station JMS 700 (EI, HR-EI and CI techniques). − Bis(benzo-1,3-dioxa-2-borol-2-yl)acetylene **2a,**[16] bis(naphthalene-1,3-dioxa-2-borol-2-yl)acetylene **2d,**[12] diborane(4)-compounds **1a−c,**[26] $[Pt(PPh_3)_2(C_2H_4)]$,[27] and $[Pt(cod)_2]$[28] were prepared according to literature procedures.

Bis[(4-*tert*-butylbenzo)-1,3-dioxa-2-borol-2-yl]acetylene (2c): (4-*tert*-Butylbenzo)-2-chloro-1,3-dioxa-2-borole (10 g, 47.6 mmol) in toluene (40 mL) and bis(trimethylstannyl)acetylene (7.6 g, 21.6 mmol) in toluene (40 mL) were simultaneously added dropwise to 200 mL of toluene at −78°C. The mixture was allowed to warm to room temp. and stirred for 24 h. The solvent was removed, the residue was stirred in pentane, filtered and dried in vacuum. Yield: 5.5 g (68%), sbp. 145°C/10^{-3} Torr. − ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 1.32 (s, 18 H, CH_3), 7.18−7.31 (m, 6 H, H_{ar}). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 31.7 (CH_3), 34.9 [*C*$(CH_3)_3$], 110.1, 111.9, 120.4, 145.2, 147.4, 147.5 (C_6H_3). − ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 24.1 (s). − EI-MS: *m*/*z* (%) 374 (54) [M^+], 359 (100) [$M^+ - CH_3$], 200 (17) [$M - (C_4H_9)C_6H_3O_2B + H]^+$. − HR-MS: *m*/*z* 374.18655 (M^+), calcd. $^{12}C_{22}{}^1H_{24}{}^{11}B_2{}^{16}O_4$: 374.18607 (Δ = 0.48 mmu).

Bis[(tetrachlorobenzo)-1,3-dioxa-2-borol-2-yl]acetylene (2e): (Tetrachlorobenzo)-2-chloro-1,3-dioxa-2-borole (18.3 g, 63 mmol) in toluene (60 mL) and bis(trimethylstannyl)acetylene (10 g, 29 mmol) in toluene (60 mL) were simultaneously added dropwise to 250 mL of toluene at −78°C. The mixture was allowed to warm to room temp. and stirred for 24 h. The precipitate was filtered and dried in vacuum. Yield: 11.6 g (74%), sbp. 190°C. − ^{13}C NMR (50.3 MHz, [d_4]MeOH): δ = 102 (B*CC*B, br.), 120.4, 123.3, 144.2 (C_6Cl_4). − ^{11}B NMR (64.2 MHz, [d_4]MeOH): δ = 22.1 (s), 19.1 (s, $Cl_4C_6O_2$-$BOCD_3$). − EI-MS: *m*/*z* (%) 538 (18.9) [M^+], 282 (70.0) [$M^+ - Cl_4C_6O_2B$]. − HR-MS: *m*/*z* 537.74298 (M^+), calcd. $^{12}C_{14}{}^{11}B_2{}^{16}O_4{}^{35}Cl_6{}^{37}Cl_2$: 537.74316 (Δ = 0.18 mmu).

Hexa(benzo-1,3-dioxa-2-borol-2-yl)ethane (3a): Compound **2a** (472 mg, 1.8 mmol), **1a** (431 mg, 1.8 mmol) and (ethene)bis(triphenylphosphane)platinum (83 mg, 0.12 mmol, 6.7 mol-%) were refluxed in 15 mL of toluene for 24 h. The precipitate was then filtered and purified by washing several times with THF and CH_2Cl_2. The colorless solid was dried in vacuum. Yield: 522 mg (71%), sbp. 457°C. Under the same conditions the catalyst tetrakis(triphenylphosphane)platinum gives **3a** in 57% yield. − ^{1}H NMR (200.1 MHz, [d_4]MeOH): δ = 6.61−6.77 (m, H_{ar}). − ^{13}C NMR (50.3 MHz, [d_4]MeOH): δ = 146.3, 120.9, 116.4 (C_6H_4). − ^{13}C NMR (125.8 MHz, [d_4]MeOH, 203 K): δ = 23 (B_3C, br.). − ^{11}B NMR (64.2 MHz, [d_4]MeOH): δ = 34 (s), 19 (s, $C_6H_4O_2BOCD_3$). − HR-MS: *m*/*z* 738.1860 (M^+), calcd. $^{12}C_{38}{}^1H_{24}{}^{16}O_{12}{}^{11}B_6$: 738.1826 (Δ = 3.4 mmu). − $C_{38}H_{24}O_{12}B_6$ (737.47): calcd. C 61.88, H 3.28; found C 61.93, H 3.57.

Mixture of Naphthalene- and Benzo-1,3-dioxa-2-borol-2-ylethanes $3a_nd_{6-n}$ (n = 2−5): A solution of **2d** (1.00 g, 2.76 mmol), **1a** (660 mg, 2.76 mmol) and (ethene)bis(triphenylphosphane)platinum (128 mg, 0.17 mmol) in 20 mL of toluene was refluxed for 48 h. The precipitate was filtered and purified by washing several times with THF and CH_2Cl_2. The colorless solid was dried in vacuum. Yield: 428 mg. − ^{1}H NMR (200.1 MHz, [d_4]MeOH): δ = 6.62−6.85 (m, C_6H_4), 7.10−7.63 (m, $C_{10}H_6$). − ^{13}C NMR (50.3 MHz, [d_4]MeOH): δ = 110.5, 116.7, 121.2, 124.4, 127.0, 131.0, 146.5, 147.8. − ^{11}B NMR (64.2 MHz, [d_4]MeOH): δ = 31 (s), 19 (s, $C_6H_4O_2BOCD_3$ and $C_{10}H_6O_2BOCD_3$). − EI-MS *m*/*z* (%) 937 (5.7) [M(**3a$_2$d$_4$**) − H]$^+$, 887 (23.6) [M(**3a$_3$d$_3$**) − H]$^+$, 838 (63.4) [M(**3a$_4$d$_2$**)]$^+$, 787 (68.3) [M(**3a$_5$d$_1$**) − H]$^+$, 720 (28.5) [M(**3a$_4$d$_2$**) −

$C_6H_4O_2B + H]^+$, 670 (27.6) [M(**3a$_4$d$_2$**) − $C_{10}H_6O_2B + H]^+$ and [M(**3a$_5$d$_1$**) − $C_6H_4O_2B + H]^+$.

Tetra(benzo-1,3-dioxa-2-borol-2-yl)ethane (4a). − Method A: Compound **2a** (1.54 g, 5.9 mmol), **1a** (1.29 g, 5.4 mmol) and tetrakis(triphenylphosphane)platinum (330 mg, 0.27 mmol, 5 mol-%) were heated in 35 mL of THF at 55°C for 24 h. The solvent was evaporated in vacuum and the precipitate was stirred in diethyl ether and filtered. Washing with diethyl ether gave a yellowish solid that was dried in vacuum. Further purification was performed by sublimation under high vacuum. Yield: 220 mg (11.5%) colorless solid, sbp. 170°C/10^{-5} Torr. − **Method B:** In a pressure apparatus 300 mg (0.6 mmol) of **5a** was suspended with 70 mg of a palladium/active carbon catalyst in 100 mL of toluene. The apparatus was filled with hydrogen gas (5 bar). After stirring the mixture for 24 h the catalyst was filtered and the solvent was evaporated in vacuum. The remaining solid was dried in vacuum. Yield: 130 mg (43.2%) colorless solid. − ^{1}H NMR (200.1 MHz, [d$_6$]DMSO): δ = 6.36−6.91 (m, 16 H, H_{ar}), −0.11 (s, 2 H, B_2CH). − ^{13}C NMR (50.3 MHz, [d$_4$]MeOH): δ = 116.4, 121.0, 146.3. − ^{13}C NMR (125.8 MHz, [d$_4$]MeOH, T = 203 K): δ = 10 (B_2C, br.). − ^{11}B NMR (64.2 MHz, [d$_4$]MeOH): δ = 32.5 (s), 19 (s, $C_6H_4O_2BOCD_3$). − HR-MS: *m/z* 502.1390 (M^+), calcd. $^{12}C_{26}{}^1H_{18}{}^{16}O_8{}^{11}B_4$: 502.1374 (Δ = 1.6 mmu).

Tetra[(4-*tert*-butylbenzo)-1,3-dioxa-2-borol-2-yl]ethane (4c): 672 mg (1.8 mmol) of **2c**, 630 mg (1.8 mmol) of **1c**, and 82 mg (0.1 mmol, 6.2 mol-%) of (ethene)bis(triphenylphosphane)platinum were heated in 20 mL of thf at 55°C for 40 h. The precipitate was filtered and dried in vacuum. Yield: 33 mg (2.5%). − ^{1}H NMR (200.1 MHz, [d$_4$]MeOH): δ = 6.67−6.82 (m, 12 H_{ar}), 1.24 (s, 36 H, CH_3), 0.10 (s, 2 H, B_2CH). − ^{13}C NMR (50.3 MHz, [d$_4$]MeOH): δ = 32.3 (CH_3), 35.1 ($C(CH_3)_3$), 114.1, 116.1, 117.7, 144.0, 144.5, 145.9 (C_6H_3). − ^{11}B NMR (64.2 MHz, [d$_4$]MeOH): δ = 32.5 (s), 19 (s, $C_6H_4O_2BOCD_3$). − CI-MS: *m/z* (%) 726 (64.7) [M^+], 727 (62.7) [M + H]$^+$, 552 (21.4) [M − $(C_4H_9)C_6H_3O_2B$ + H]$^+$, 377 (38.0) [M − 2 $(C_4H_9)C_6H_3O_2B$ + H]$^+$. − HR-MS: *m/z* 726.3903 (M^+), calcd. $^{12}C_{42}{}^1H_{50}{}^{16}O_8{}^{11}B_4$: 726.3878 (Δ = 2.5 mmu).

Bis(benzo-1,3-dioxa-2-borol-2-yl)-bis[(tetrachlorobenzo)-1,3-dioxa-2-borol-2-yl]ethane (4a$_2$e$_2$): Compound **2e** (1.00 g, 1.86 mmol), **1a** (42 mg, 1.86 mmol) and bis(triphenylphosphane)(ethene)platinum (97 mg (0.12 mmol, 7 mol-%) were refluxed in 20 mL of toluene for 48 h. The precipitate was filtered and dried in vacuum. Yield: 289 mg (20%). − ^{1}H NMR (200.1 MHz, [d$_4$]MeOH): δ = 6.60−6.77 (m, 8 H, H_{ar}), 0.1 (s, 2 H, B_2CH). − ^{13}C NMR (50.3 MHz, [d$_4$]MeOH): δ = 146.3, 121.0, 116.4 (C_6H_4), 144.2, 123.4, 120.5 (C_6Cl_4). − ^{11}B NMR (64.2 MHz, [d$_4$]MeOH): δ = 32.4 (s), 19 (s, $C_6H_4O_2BOCD_3$ and $Cl_4C_6O_2BOCD_3$). − EI-MS: *m/z* (%) 778 (18) [M^+], 254 (100) [$C_{12}H_8O_5B_2{}^+$], 392 (48) [$C_{12}H_4O_5B_2Cl_4{}^+$].

1,1:2,2-bis(2,3-naphthalenedioxy)diborane(4) (1d): Compound **2d** (600 mg, 1.66 mmol), **1a** (394 mg, 1.66 mmol) and bis(triphenylphosphane)(ethene)platinum (77 mg, 0.1 mmol, 6.2 mol-%) were heated in 20 mL of toluene at 50°C for 72 h. The colorless precipitate was filtered, washed with toluene and dried in vacuum. Yield: 416 mg (74%), sbp. 150°C/10^{-3} Torr. − ^{1}H NMR (200.1 MHz, [d$_4$]MeOH): δ = 7.14−7.55 (m, H_{ar}). − ^{13}C NMR (50.3 MHz, [d$_4$]MeOH): δ = 110.8, 124.5, 127.0, 131.1, 147.9 ($C_{10}H_6$). − ^{11}B NMR (64.2 MHz, [d$_4$]MeOH): δ = 31.6 (s), 19 (s, $C_{10}H_6O_2$-$BOCD_3$). − EI-MS: *m/z* (%) 338 (100) [M^+], 169 (12) [M^+ − $C_{10}H_6O_2B$], 355 (6) [$(C_{10}H_6O_2B)_2O^+$]. − HR-MS: *m/z* 338.09237 (M^+), calcd. $^{12}C_{20}{}^1H_{12}{}^{16}O_4{}^{11}B_2$: 338.09216 (Δ = 0.21 mmu). − $C_{20}H_{12}O_4B_2$ (338.09): calcd. C 71.08, H 3.57; found C 69.34, H 3.62.

Tetra(benzo-1,3-dioxa-2-borol-2-yl)ethene (5a): Compound **2a** (3.00 g, 11.5 mmol), 1a (2.725 g, 11.5 mmol) and of bis(1,5-cyclooctadiene)platinum (188 mg, 0.46 mmol, 4 mol-%) were heated in 55 mL of toluene at 40°C for 24 hours. The precipitate was then filtered and washed with CH_2Cl_2 and dried in vacuum. Yield: 4.025 g (70%), sbp. 160°C/10^{-5} Torr. − ^{1}H NMR (200.1 MHz, [d$_4$]MeOH): δ = 6.60−6.79 (m, H_{ar}). − ^{13}C NMR (50.3 MHz, [d$_4$]MeOH): δ = 146.3, 120.9, 116.4 (C_6H_4), 165 (B_2C, br., weak). − ^{13}C NMR (125.8 MHz, [d$_4$]MeOH, T = 203 K): δ = 165 (B_2C, br.). − ^{11}B NMR (64.2 MHz, [d$_4$]MeOH): δ = 29.9 (s), 19 (s, $C_6H_4O_2BOCD_3$). − CI-MS: *m/z* (%) 500 (100) [M^+], 501 (78.4) [M + H]$^+$, 557 (1.8) [M + C_4H_9]$^+$ − HR-MS: *m/z* 500.12158 (M^+), calcd. $^{12}C_{26}{}^1H_{16}{}^{11}B_4{}^{16}O_8$: 500.12173 (Δ = 0.15 mmu). − Raman: $\tilde{\nu}$ = 1549 cm^{-1} (C=C), 1620 cm^{-1} (ar.), 1471, 1330, 1230, 1150, 1002, 818, 611 cm^{-1}, 3066 cm^{-1} (C−H). − $C_{26}H_{16}O_8B_4$ (499.65): calcd. C 62.50, H 3.23; found C 62.33, H 3.65.

X-ray Crystal Structure Determinations of 4a: Crystal data and details of the structure determination are listed in Table 1. Unique sets of intensity data were collected at −70°C with a four-circle diffractometer (Mo-K_α radiation λ = 0.7107 Å, graphite monochromator, ω scan). Empirical absorption corrections (ψ-scans) were applied. The structure was solved by direct methods [SHELXS86][29] and refined by least-squares methods based on F^2 with all measured reflections [SHELXL97].[30] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-116696. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) + 44-1223/336-001; E-mail: deposit@ccdc.cam.ac.uk

PE spectrum of 5a: The He^{I} PE spectrum was recorded on a Perkin–Elmer PS18 spectrometer. The recording temperature was 230°C. The calibration was performed with Ar (13.76 and 15.94 eV) and Xe (12.13 and 13.44 eV). A resolution of 20 meV on the $^2P_{3/2}$ Ar line was obtained.

Acknowledgments

We thank A. Flatow for recording the PE spectrum and Dr. S. Lebedkin, Forschungszentrum, Karlsruhe, for the Raman spectrum of **5a**. We are grateful to the Graduiertenkolleg der Universität Heidelberg, the Deutsche Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie.

Te...Te Interlayer Interactions, Te → Metal Electron Transfer and Electrical Conductivity in the $MM'Te_5$ Phases (M = Nb, M′ = Ni, Pd; M = Ta, M′ = Ni, Pt)

Pere Alemany*[a] and Enric Canadell*[b]

Keywords: Ternary Tellurides / Conductivity / Electronic structure / Layered compounds / Low-dimensional metals.

The layered ternary tellurides $NbNiTe_5$, $TaNiTe_5$, $TaPtTe_5$ and $NbPdTe_5$ are all metallic, but the conductivity of the latter is between one and two orders of magnitude smaller. A tight binding study of the electronic structure of these phases suggests that the large conductivity difference results from the different Te···Te interlayer interactions and the Te → M (M = Nb, Ta) electron transfer that they induce.

Introduction

Several ternary transition metal tellurides are layered materials and exhibit metallic behavior.[1][2] Thus, one could expect that these materials may show the low temperature structural modulations and resistivity anomalies characteristic of many low-dimensional metals.[3][4] However this seems not to be the case.[5] The most likely reason for this unexpected behavior lies in the many short Te...Te interactions which these materials possess. As shown by several theoretical studies,[6–8] such interactions exert a strong control over the electronic structure in the region around the Fermi level. The mechanism by which the interlayer Te...Te interactions control the structural or transport properties of these materials is by raising the top of the tellurium bands which, as a consequence, overlap (or increase the overlap) with the transition metal d-block bands. This has two consequences. First, there is a Te → metal electron transfer so that the transition metal atom is really in an oxidation state somewhat lower than that expected from the stoichiometric formula and usual ideas concerning transition metal and chalcogen oxidation states. For instance, the layered binary telluride $NbTe_2$, in which the Nb atoms are formally d^1, exhibits a structure with double zigzag chains which would be expected if Nb was really $d^{4/3}$.[9] Theoretical calculations have shown that the Te → Nb electron transfer does indeed occur.[6b,9] Second, the density of states at the Fermi level, which has a strong control over the conductivity of these metallic systems, can be significantly affected. We have recently suggested that the large difference in the metallic conductivity (one order of magnitude) of the two structurally related tellurides $Ta_3Pd_3Te_{14}$ and $Ta_4Pd_3Te_{16}$, can be rationalized on the basis of the different density of states at the Fermi level for the two phases, and that such a difference is largely imposed by the interlayer Te...Te interactions.[7]

A series of ternary layered tellurides exhibiting interesting conducting properties is that of the $MM'Te_5$ (M = Nb, M′ = Ni, Pd; M = Ta, M′ = Ni, Pt) phases.[1] All of these systems are metallic but one of them, $NbPdTe_5$, is between one and two orders of magnitude less conducting than the other three. The $NbNiTe_5$, $TaNiTe_5$ and $TaPtTe_5$ phases have similar conductivities. The layers of the four salts are of the same type but, interestingly, the interlayer stacking is the same for the three phases with similar conductivity and differs from that of the less conducting phase.[1] This immediately suggests that the Te...Te interlayer interactions must exert a strong control over the conductivity of these phases also.[1d] Thus, we felt it would be interesting to study the possible relationship between the interlayer Te...Te interactions and the conductivity of the four $MM'Te_5$ phases.

The calculations reported here are of the extended Hückel type[10] with the exponents and parameters summarized in Table 1. The electronic structure of $NbNiTe_5$ and $NbPdTe_5$ was studied by Halet et al[8] some years ago. However, as briefly discussed above, the understanding of the role of the Te...Te interactions in determining the electronic structure of ternary tellurides has considerably progressed in recent years so that we thought it was of interest to reexamine some aspects of the electronic structure of these phases. Here we will concentrate on the possible relationship between the Te...Te interlayer interactions, Te → metal electron transfer and conductivity for this interesting family of solids and refer the reader to the work of Halet et al[8] for a more complete discussion of the relationship between the geometrical and electronic structure of the $MM'Te_5$ layers.

Results and Discussion

Crystal Structure and Te···Te Short Contacts

The electronic structure of these materials is very complex[8] so that it is very important to clearly understand

what are the key aspects of the crystal structure on which we must concentrate when trying to understand the band structure calculations to be reported in the next sections. There are different ways to describe the crystal structure of a solid depending on the particular aspect one wishes to examine. Since the conductivity of a metal is dominated by the levels near the Fermi level, the appropriate structural description should be that leading to a qualitative feeling of the nature and structural dependency of such levels. As shown in Figure 1a, the $MM'Te_5$ layers present in the $MM'Te_5$ phases can be considered to result from the condensation of MTe_3 face sharing trigonal prismatic chains and $M'Te_3$ edge sharing octahedral chains. Because of the condensation, the M atoms form two additional bonds with the Te atoms of the adjacent octahedral chains so that they are really in a bicapped trigonal prismatic environment. Consequently, the $MM'Te_5$ layers can be simply described as a series of bicapped trigonal prismatic MTe_5 chains glued by the M′ atoms which reside in the octahedral holes in between them.

The previous description has an important implication. As already discussed,[7] these bicapped trigonal prismatic (btp) chains lead to five chains of direct Te...Te short contacts (see Figure 1a) as well as to four zigzag chains of Te...Te short contacts formed by the capping Te atoms and those of the triangular basis of the prisms (i.e., the four zigzag chains, two of *n* contacts and two of *o* contacts, shown in Figure 1b). The Te p orbitals parallel to these chains (both along the zigzag and direct chains) are very well oriented to make very strong overlaps and lead to very strongly dispersive Te-based bands which cross the Fermi level and are responsible for the above mentioned Te → metal electron transfer. Thus, it is tempting to consider the pentagonal shaped columns of Te atoms glued together by the M and M′ atoms as the essential building blocks that we should use in order to try to understand what happens near the Fermi level.

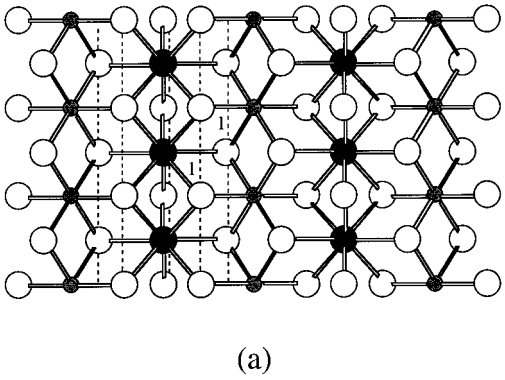

Figure 1a. View of a $MM'Te_5$ layer along a direction perpendicular to the slab.

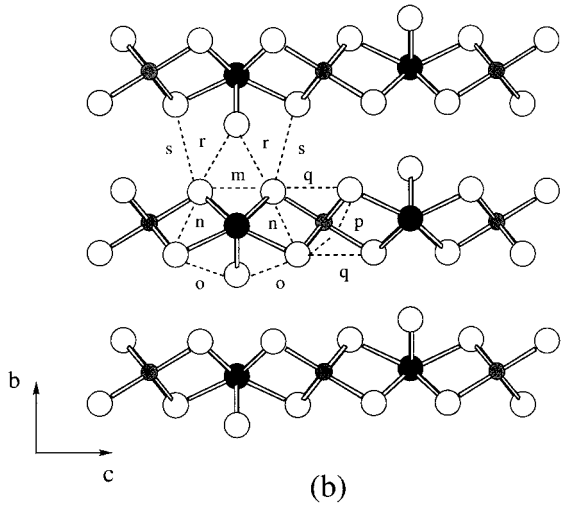

Figure 1b. Projection view of the crystal structure of $NbNiTe_5$, $TaNiTe_5$ and $TaPtTe_5$ along the *a* axis.

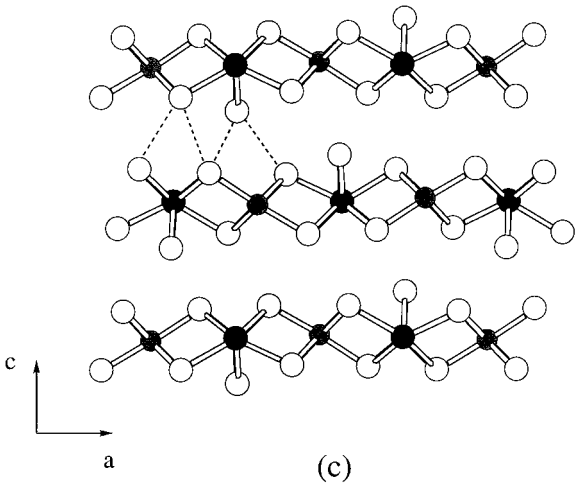

Figure 1c. Projection view of the crystal structure of $NbPdTe_5$ along the *b* axis. Large black circles represent the M atoms (Nb, Ta), large open circles the Te atoms and smaller grey circles the M′ atoms (Ni, Pd, Pt). The Te···Te contacts discussed in the text have been shown as dotted lines.

If we proceed along this line, we should next consider how these Te columnar units interact. Obviously, they interact along the intralayer intercolumn direction through the M′−Te bonds. However, the bonding and antibonding M′−Te levels are far from the Fermi level. The levels of the columnar units crossing the Fermi level must be Te-based so that the intercolumn interactions along the layer must be dominated by the direct Te...Te intercolumn contacts. There are five Te...Te short contacts of this type per formula unit. If for instance we look at the $NbNiTe_5$ structure these contacts are 3.623 Å and 3.788 Å(×4) (see contacts *p* and *q* in Figure 1b, respectively). Of course, these contacts should have a non-negligible but comparatively smaller influence than the intracolumn ones on the dispersion of the above mentioned Te very wide bands. Not only the orbital orientation is much better along the columns but there are more and considerably shorter intracolumn Te...Te contacts: 3.331 Å (×4), 3.460 Å (×4), 3.656 Å (×5) for $NbNiTe_5$ (see contacts *o*, *n* in Figure 1b and *l* in Figure 1a, respectively). There is another very short intracolumn Te...Te contact (3.196 Å in $NbNiTe_5$, see *m* in Figure 1b) which is perpendicular to the chain direction and is going to play an important role in our discussion (see later).

The way in which the layers order relative to each other for $NbNiTe_5/TaNiTe_5/TaPtTe_5$ and $NbPdTe_5$ is shown in Figures 1b and 1c, respectively. The btp chains in one layer are aligned with those in the next layer in Figure 1b ($NbNiTe_5/TaNiTe_5/TaPtTe_5$) whereas this is not the case in Figure 1c ($NbPdTe_5$). Of course, this leads to somewhat different Te...Te contacts, those in $NbPdTe_5$ being shorter. However, at this point, the important aspect we would like to scrutinize is the possible strength of these Te...Te contacts with respect to the intercolumn intralayer ones. In $NbNiTe_5$ there are six interlayer contacts: 3.789 Å (×4) and 3.931 Å (×2) (see contacts *r* and *s* in Figure 1b, respectively). Thus, for the time being, and just on the basis of the crystal structure information, we may suggest that the influence of the Te...Te intralayer and interlayer intercolumn contacts on the dispersion of the Te levels near the Fermi level should not be that different. We conclude that around the Fermi level there should be Te bands with very large dispersion along the direction of the Te columns and only a moderate one along *both* the intralayer and interlayer intercolumn directions.

Can the M and M′ levels be completely neglected as seems to be suggested by the previous discussion? As already mentioned, the M′-based bands (M′ being a very electronegative metal atom) will be far from the Fermi level and thus we can ignore them in our qualitative scheme. However this is not the case for the low-lying M-based ones. The very wide Te-based bands will cross some of the low-lying M-based bands, which would be empty if it were not for the existence of such wide Te bands, and lead to the Te → metal electron transfer. Thus, some of the low-lying *d* levels of the M atoms can play a very important role in understanding the electronic structure of the $MM'Te_5$ phases near the Fermi level and this is why, coming back to the beginning of this section, we propose that the MTe_5 btp chains are the more convenient building blocks to be used in discussing the relationship between the electronic structure and electrical conductivity of the $MM'Te_5$ phases.

Band Structure of the $MM'Te_5$ Phases

The calculated band structures for a single layer and the three dimensional structure of $TaNiTe_5$ are shown in Figures 2a and 2b, respectively. It should be remembered that the unit cell of $TaNiTe_5$ contains two $TaNiTe_5$ layers. Because of the overall similarity of the results we will only discuss here those concerning $TaNiTe_5$, although a similar study has been carried out for all the phases of this family.

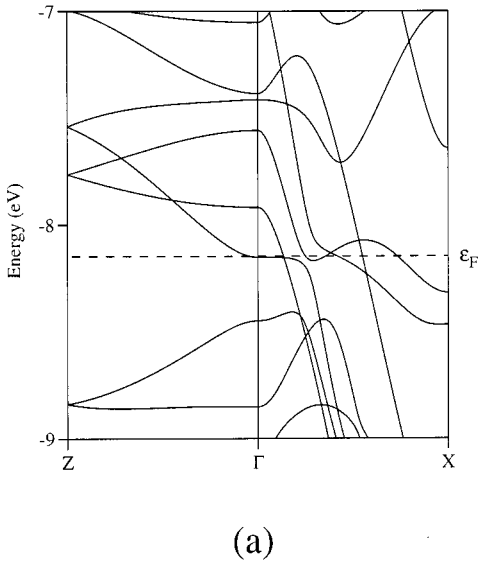

Figure 2a. Calculated dispersion relations for a single layer of $TaNiTe_5$.The Γ, X and Z labels in refer to the wave vector points (0, 0), (*a**/2, 0) and (0, *c**/2), respectively. The dashed line refers to the Fermi level.

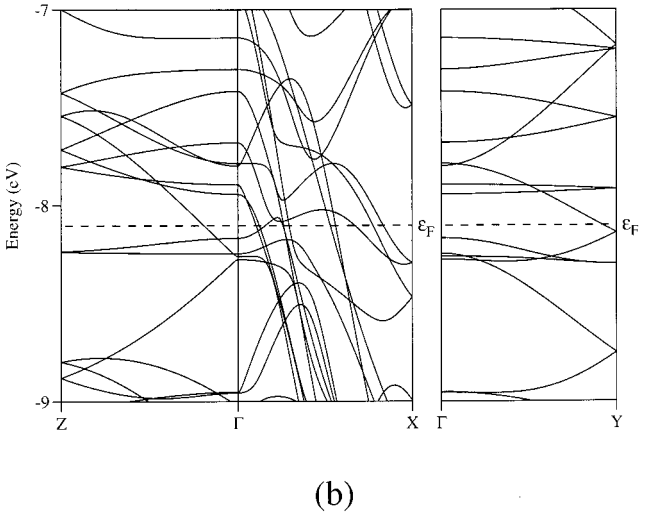

Figure 2b. Calculated dispersion relations for the 3D structure of $TaNiTe_5$, where the dashed lines refer to the Fermi level. The labels Γ, X, Y and Z refer to the wave vector points (0, 0, 0), (*a**/2, 0, 0), (0, *b**/2, 0) and (0, 0, *c**/2), respectively.

The most important observations based on the calculated band structures are the following. First, the 3D band structure is not just the superposition of twice that of a single layer. Indeed, some bands split considerably when introducing the interlayer interactions (compare for instance the two band structures along the $\Gamma \rightarrow Z$ direction). This is also clear when looking at the $\Gamma \rightarrow Y$ direction in Figure 2b (i.e., along the b^*-direction, b being the interlayer direction): some bands which cross or lie near the Fermi level have a quite sizeable dispersion. Thus, it is clear that the interlayer Te...Te interactions cannot be neglected. Second, there are several extremely wide bands along the $\Gamma \rightarrow X$ direction (i.e., along the a^*-direction, a being the propagation direction of the btp chains) which are mainly Te in character and which cross the Fermi level, as expected from the presence in these phases of Te-based btp chains. Third, in the region around the Fermi level these wide bands cross two bands per layer which are much less dispersive and are mainly Ta (or Nb in the $MNbTe_5$ phases) in character. Fourth, the dispersion of most of the bands along the $\Gamma \rightarrow X$ direction is very large but those along the $\Gamma \rightarrow Y$ and $\Gamma \rightarrow Z$ directions (i.e., the interlayer and intralayer interchains directions, respectively) are smaller but non-negligible and of the same order of magnitude along both directions.

The first and fourth observations make the importance of the interlayer Te...Te interactions clear and, maybe more surprisingly, the fact that the interlayer interactions are as strong as the intralayer interchain interactions. The second and third observations clearly show that there is an important electron transfer from Te to Ta (or Nb in the $MNbTe_5$ phases). Of course, this transfer is something inherent to the $MM'Te_5$ layers (see Figure 2a) but it is importantly affected by the interlayer Te...Te interactions. These conclusions are common to the four $MM'Te_5$ phases and completely validate the qualitative discussion of the previous section. From the viewpoint of the electrical conductivity our study suggests that these phases must be 3D metals although with a strong anisotropy, i.e., the conductivity should be much higher along the btp chain direction. The only difference between the $NbPdTe_5$ and the $NbNiTe_5$/$TaNiTe_5$/$TaPtTe_5$ phases is that the Fermi level does not cut bands along the interlayer $\Gamma \rightarrow Y$ direction for $NbPdTe_5$; there is a relatively small band gap along this direction. This fact is probably inherent to the different interlayer stacking and is not a parameter dependent feature because it was also noted by Halet et al[8] who used a different set of parameters in their calculations. Thus, $NbPdTe_5$ should have a weaker 3D metallic character than the other three $MM'Te_5$ phases. However, we should not conclude that the smaller conductivity of $NbPdTe_5$ originates from this fact because the conductivity of these phases is largely dominated by the Te...Te interactions along the btp chain direction. We must look in more detail at the electronic structure before discussing this point.

Our previous work[7] on the ternary tellurides $Ta_3Pd_3Te_{14}$ and $Ta_4Pd_3Te_{16}$ showed how the interlayer Te...Te interactions are responsible for the large difference in the density of states at the Fermi level [$N(\varepsilon_f)$] between the two phases and we proposed that this fact was at the heart of the large difference in conductivity between the two phases. Both the qualitative discussion of section 2 and the band structure calculations, suggest that the interlayer Te...Te interactions must also be very important in determining the conductivity of the $MM'Te_5$ phases whereas the nature of the M′ transition metal atom should not play a major role. That the conductivity and the strength of the Te...Te interlayer interactions should be correlated can be seen in Figure 3a where we have plotted the room temperature conductivity of the four $MM'Te_5$ phases vs the shortest Te...Te interlayer contact (such a correlation has already been noted previously[1a]). The four $MM'Te_5$ phases appear perfectly aligned in this plot and $NbPdTe_5$ is clearly separated from the other three phases, the shorter interlayer Te...Te contacts being associated with the smaller conductivities.

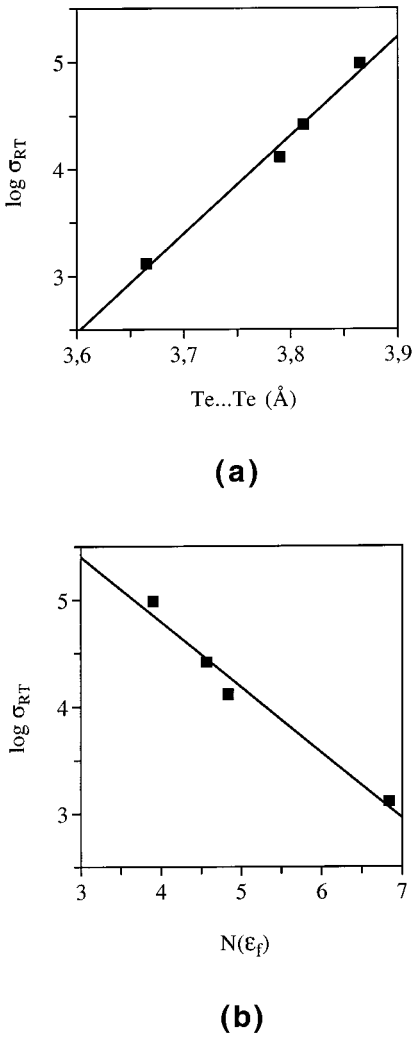

Figure 3. (a) Plot of the log σ_{RT} (σ_{RT}: room temperature conductivity) vs the shortest Te···Te interlayer contact for the $MM'Te_5$ phases. (b) Plot of the log σ_{RT} vs the calculated density of states at the Fermi level $N(\varepsilon_f)$ for the $MM'Te_5$ phases.

Figure 3b shows a plot of the room temperature conductivity versus the calculated $N(\varepsilon_f)$ for the $MM'Te_5$ phases. Contrary to intuitive expectations, the conductivity increases as $N(\varepsilon_f)$ decreases. This result is also obtained when

the $N(\varepsilon_f)$ calculated for a single layer is used. Thus, it is clear that the situation in the $MM'Te_5$ series is very different from that in the $Ta_3Pd_3Te_{14}$ and $Ta_4Pd_3Te_{16}$ phases: the $N(\varepsilon_f)$ cannot be taken as a basis for understanding the conductivity differences in the $MM'Te_5$ phases. In fact, these results should not be that surprising given that there are many bands crossing the Fermi level and that some of them are quite flat for large zones of the Brillouin zone. In other words, with such a complex situation, an increase in $N(\varepsilon_f)$ does not necessarily mean that the conductivity must increase because the mobility of the different types of electrons can be rather different. A fraction of the electrons may be very mobile and delocalized making a strong contribution to the electrical conductivity of the phase and another fraction can behave as localized electrons having a very weak contribution to the electrical conductivity. As a matter of fact, the magnetic susceptibility of the metallic phases $NbNiTe_5$ and $TaNiTe_5$ is temperature dependent[1d] as if there were localized electrons as well as delocalized electrons in these phases. For $TaPtTe_5$ and $NbPdTe_5$ the magnetic susceptibility is temperature independent as expected for a normal metal.[1d] Thus, there seems to be a strong competition between a localized vs delocalized behavior for some of the electrons near the Fermi level in the $MM'Te_5$ phases so that it is not really surprising that there is no correlation between the calculated values of the $N(\varepsilon_f)$ and the conductivity.

Te...Te Interlayer Interactions, Te → M (M = Nb, Ta) Electron Transfer and Conductivity of the $MM'Te_5$ Phases

At this point we would like to have a closer look at the Te → metal electron transfer induced by the Te...Te interlayer interactions mentioned above. As expected, the Te → M′ electron transfer (M′ = Ni, Pd, Pt) is very small (0.014, 0.017, 0.021 and 0.041 electrons per M′ atom for $TaPtTe_5$, $TaNiTe_5$, $NbNiTe_5$ and $NbPdTe_5$, respectively). The Te → M electron transfer (M = Nb, Ta) is quite strong (0.129, 0.157, 0.189 and 0.267 electrons per M atom for $TaPtTe_5$, $TaNiTe_5$, $NbNiTe_5$ and $NbPdTe_5$, respectively). As shown in Figure 4a, there is a clear correlation between the strength of this Te → M electron transfer and the shorter Te...Te interlayer contacts. The transfer increases when the Te...Te interlayer contacts become shorter, i.e., the interlayer Te...Te interactions become stronger. Interestingly, the four $MM'Te_5$ phases appear perfectly aligned in this plot and $NbPdTe_5$ is clearly separated from the other three phases. These results make clear the relationship between the Te...Te interlayer interactions and the very important electron transfer that they induce. Since we noted the excellent correlation between the conductivity and the Te...Te interlayer interactions (see Figure 3a) it is not surprising to find also an excellent correlation between the conductivity and the strength of the Te → M electron transfer (see Figure 4b).

In order to analyze the nature of this electron transfer we carried out calculations in which the Te...Te interlayer

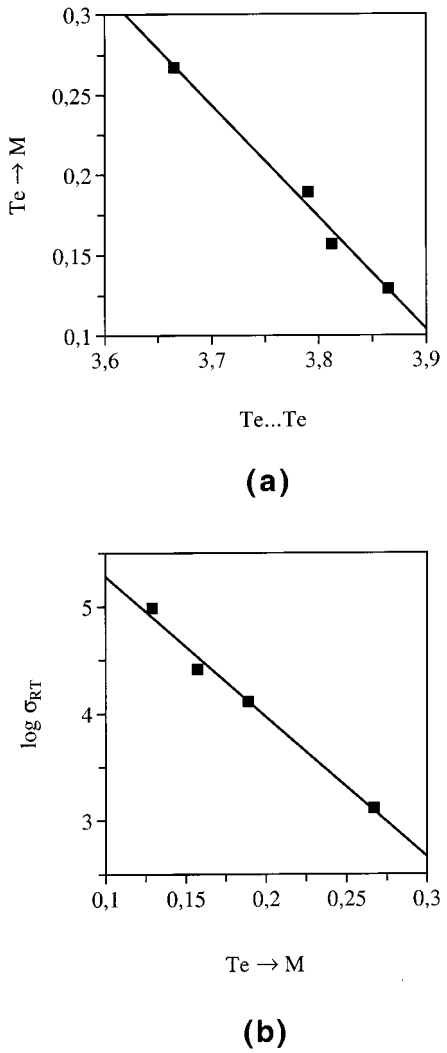

Figure 4. (a) Plot of the Te → M (M = Nb, Ta) electron transfer due to the interlayer Te···Te interactions vs the shortest Te···Te interlayer contact for the $MM'Te_5$ phases. (b) Plot of the log σ_{RT} vs the Te → M (M = Nb, Ta) electron transfer induced by the interlayer Te···Te interactions for the $MM'Te_5$ phases.

overlaps were deleted and we compared the results with those for the full calculations. The electrons are mainly transferred from the two Te atoms forming the shorter side (3.196 Å in $NbNiTe_5$) of the triangular faces of the prisms (see contact *m* in Figure 1b). In fact they are transferred from the bonding combination of the two p orbitals of these atoms perpendicular to the layer, i.e., from a bonding π-type orbital. These Te p orbitals interact very well with the p orbital of the two capping Te atoms which is parallel to the direction of the btp chain. They are also those pointing towards the next layer and implicated in the shorter interlayer Te...Te short contacts. Of course, the overlap population of the shorter Te−Te triangular side decreases when the Te...Te interlayer interactions are switched on. Assuming that the local x, y and z coordinates point approximately towards the *a*, *b* and *c* directions of Figure 1b, the electrons are transferred towards an M orbital which can be described as x^2-y^2 which mixes in some z^2 character, in

other words, an orbital which is in between an x^2-y^2 orbital and a z^2 orbital.

Coming back to our main purpose, we suggest that it is the Te → M electron transfer induced by the interlayer interactions which lies behind the conductivity differences for the $MM'Te_5$ phases. The reason is the following: because of the Te → M electron transfer, the electrons dominating the conductivity of the $MM'Te_5$ phases, i.e., the Te-based electrons near the Fermi level, are less screened from the core attractive forces of the Te atoms engaged in the Te → M electron transfer. Consequently, they are more tightly bound and their contribution to the conductivity is reduced.[11] In chemical terms, the Te atoms engaged in the electron transfer behave as ′more electronegative′ because of the electron transfer and attract more strongly their electrons. This effect will increase with the strength of the Te...Te interlayer interactions making less metallic the $MM'Te_5$ phases with stronger interlayer Te...Te interactions.

Let us remember that the electrons transferred leave a Te−Te bonding orbital located in the shorter side of the triangular faces of the prisms. Thus, the conductivity of the $MM'Te_5$ phases and the length of this Te...Te short contact should be correlated: as the Te → M electron transfer increases, the Te...Te short contact should increase and the conductivity decrease. In fact, this is the case. According to the presently available crystal structures[1] this Te...Te short contact is 3.153 Å for $TaPtTe_5$, 3.183 Å for $TaNiTe_5$, 3.196 Å for $NbNiTe_5$ and 3.242 Å for $NbPdTe_5$. This is in excellent agreement with the conductivity of these phases which decreases in the same order. Thus, we believe that even if our argument is very simple and naive, it grasps the essential feature underlying the conductivity behavior of these phases.

Finally, concerning the two structurally related $Ta_3Pd_3Te_{14}$ and $Ta_4Pd_3Te_{16}$ phases, we would like to point out that the former, which has a conductivity one order of magnitude smaller than the latter, also has a larger Te → M electron transfer and the shortest interlayer Te...Te contacts. Thus, the argument developed here should also work for these phases. However, $Ta_3Pd_3Te_{14}$ also has a considerably smaller density of states at the Fermi level so that it is not clear which of the two effects really leads to the difference in conductivity. Magnetic susceptibility measurements could be helpful in scrutinizing this point.

Conclusions

In summary, we believe that the present work provides a simple explanation for the long standing problem of the conductivity differences in the $MM'Te_5$ phases. It also provides additional evidence for the important role that interlayer Te...Te interactions can play in modulating the conductivity of metallic layered tellurides.

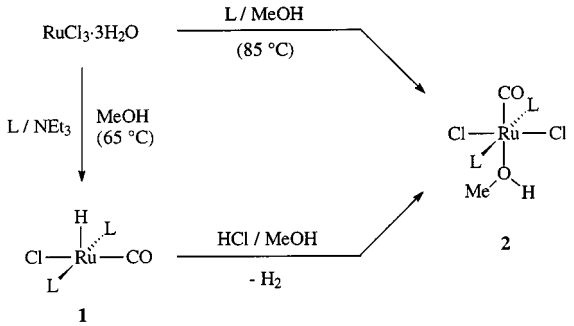
Hydrido(carbonyl) and Hydrido(carbene) Complexes of Ruthenium

Helmut Werner,*[a] Wolfram Stüer,[a] Birgit Weberndörfer,[a] and Justin Wolf[a]

Dedicated to Professor Dirk Walther on the occasion of his 60th birthday

Keywords: Carbene complexes / Carbonyl complexes / Diazoalkanes / Hydrido complexes / Ruthenium



The five-coordinate compound [RuHCl(CO)(P*i*Pr$_2$Ph)$_2$] (**1**), which was prepared from $RuCl_3 \cdot 3\ H_2O$ and P*i*Pr$_2$Ph in methanol in the presence of NEt_3, reacts with CO and with diazoalkanes $RCHN_2$ (R = Ph, H) to give the six-coordinate complexes [RuHCl(CO)$_2$(P*i*Pr$_2$Ph)$_2$] (**4**) and [RuHCl(CO)(=CHR)(P*i*Pr$_2$Ph)$_2$] (**5**, **6**), respectively. If the reaction of **1** with CH_2N_2, which at –78 °C affords **6**, is carried out at room temperature, the ionic compound [MeP*i*Pr$_2$Ph][RuHCl$_2$(CO)(P*i*Pr$_2$Ph)$_2$] (**7**) is formed. The corresponding PPN salt was obtained from **1** and [PPN]Cl. The X-ray crystal structure analysis of **7** revealed, that the anionic species [RuHCl$_2$(CO)(P*i*Pr$_2$Ph)$_2$]$^-$ contains the chloro ligands in *cis* and the phosphanes in *trans* disposition. The Ru=CH$_2$ bond of compound **6** is quite labile and, therefore, the CH$_2$ unit is easily displaced by CO or pyridine. From **1** and pyridine, an isomeric mixture of [RuHCl(CO)(py)(P*i*Pr$_2$Ph)$_2$] (**9a**, **b**) is formed. Treatment of **1** with HC≡CR (R = H, Ph) yields the five-coordinate vinylruthenium(II) complexes [Ru(CH=CHR)Cl(CO)(P*i*Pr$_2$Ph)$_2$] (**12**, **13**) by insertion of the alkyne into the Ru–H bond. The preparation of [RuHX(CO)(P*i*Pr$_2$Ph)$_2$] (X = CF_3CO_2, I) is also reported.

In the search for coordinatively unsaturated complexes with M(P*i*Pr$_3$)$_2$ as a molecular unit, we previously found that treatment of $RuCl_3 \cdot 3\ H_2O$ and $OsCl_3 \cdot 3\ H_2O$ with triisopropylphosphane in methanol leads to the formation of the five-coordinate hydrido(carbonyl)metal compounds [MHCl(CO)(P*i*Pr$_3$)$_2$] (M = Ru, Os) in good to excellent yields.[1] Owing to the free coordination site, these complexes react smoothly with CO, PMe_3, and $P(OMe)_3$ to give the corresponding six-coordinate hydridoruthenium(II) and -osmium derivatives. Further studies revealed that the starting materials [MHCl(CO)(P*i*Pr$_3$)$_2$] are also highly reactive toward terminal acetylenes; however, in this case instead of the anticipated alkyne(hydrido) compounds [MHCl(CO)(HC≡CR)(P*i*Pr$_3$)$_2$] the isomeric insertion products [M(CH=CHR)Cl(CO)(P*i*Pr$_3$)$_2$] are formed.[2]

When we attempted to insert *carbenes* into the M–H bond of the five-coordinate precursors [MHCl(CO)(P*i*Pr$_3$)$_2$], we recently discovered that the complex with M = Os reacts not only with CH_2N_2 but also with substituted diazomethanes $RCHN_2$ by addition of the respective carbene CHR (R = Ph, CO_2Et, $SiMe_3$) to the metal affording the octahedral carbene(hydrido)osmium(II) compounds [OsHCl(CO)(=CHR)(P*i*Pr$_3$)$_2$].[3] In contrast, the ruthenium complex [RuHCl(CO)(P*i*Pr$_3$)$_2$] catalyses the decomposition of diazoalkanes $RCHN_2$ to give olefins RCH=CHR and N_2.[4] Since we knew from our recent work in rhodium chemistry,[5] that both the bulkiness *and* the donor/acceptor capabilities of tertiary phosphanes influences the stability of a carbene-metal bond, we set out to prepare complexes of the general composition [RuHCl(CO)(PR$_3$)$_2$] with phosphanes other than P*i*Pr$_3$. In this paper we report the synthesis of both five-coordinate [RuHCl(CO)(P*i*Pr$_2$Ph)$_2$] and a series of 1:1 adducts including those with CH_2 and CHPh as the additional ligand.

Results and Discussion

Following the procedure used for the preparation of [RuHCl(CO)(P*i*Pr$_3$)$_2$],[1] treatment of a solution of $RuCl_3 \cdot 3\ H_2O$ in methanol with a sixfold excess of P*i*Pr$_2$Ph in the presence of NEt_3 at 65 °C leads to the formation of the analogous chloro(hydrido)ruthenium(II) derivative [RuHCl(CO)(P*i*Pr$_2$Ph)$_2$] (**1**). The yellow, only slightly air-sensitive solid precipitates from the solution in analytically pure form. The ^{1}H-NMR spectrum of **1** displays for each of the four diastereotopic methyl groups of the phosphane ligands a doublet of virtual triplets which is in agreement with the proposed structure. The presence of the hydrido ligand is indicated by the high-field resonance at δ = –24.67 which is split into a triplet due to P-H coupling.

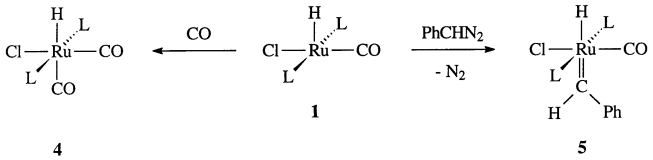
When we changed the reaction conditions in order to increase the yield of compound **1**, we discovered that from $RuCl_3 \cdot 3\,H_2O$, P*i*Pr_2Ph and methanol a by-product is formed besides **1**, which is the six-coordinate dichlororuthenium(II) complex **2** (Scheme 1). After raising the temperature to 85 °C and the time of reaction to 70 h, the isolated yield of **2** was improved to 41%. Moreover, compound **2** is obtained quantitatively upon treatment of the hydrido complex **1** with gaseous HCl in CH_2Cl_2/CH_3OH (1:1). Hereby, the evolution of H_2 is observed. Although it is known that the related hydridoosmium compound $[OsHCl(CO)(P\textit{i}Pr_3)_2]$ reacts with HCl to afford the rather stable dihydrogen complex $[OsCl_2(H_2)(CO)(P\textit{i}Pr_3)_2]$,[6] our attempts to isolate or detect spectroscopically the corresponding 1:1 adduct of **1** and H_2 failed.

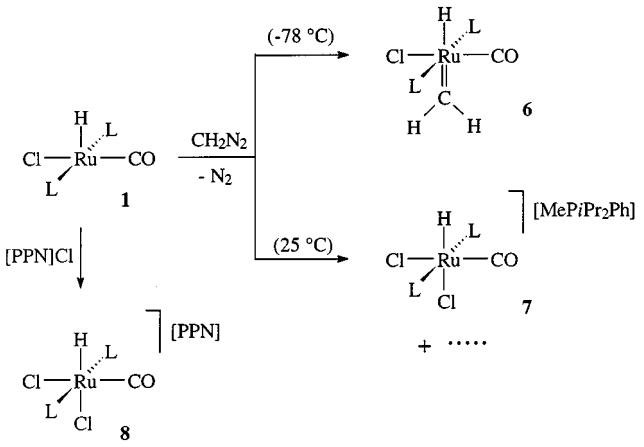
With regard to the mechanism of formation of compound **2** from $RuCl_3 \cdot 3\,H_2O$, P*i*Pr_2Ph, and methanol, we assume that initially the chloro(hydrido)ruthenium(II) derivative **1** is generated as an intermediate which, subsequently, reacts with the phosphonium chloride [HP*i*Pr_2Ph]Cl (formed from an excess of P*i*Pr_2Ph) to give **2**. The coordination of methanol to the ruthenium center in **2** is indicated by the appearance of a strong $\tilde{\nu}$(OH) band at 3563 cm^{-1} in the IR spectrum and of a broad singlet (with a relative intensity of 3 H) at $\delta = 2.48$ in the ^{1}H-NMR spectrum. Since the ^{1}H-NMR spectrum of **2** displays only two signals for the PCHC*H*$_3$ protons instead of four as in the case of **1**, we conclude that not only the two phosphanes but also the two chloro ligands are *trans* disposed. A structurally related 1:1 adduct of a dichlororuthenium(II) complex with a weakly bound solvent molecule of the composition $[RuCl_2(H_2O)(CO)(PEt_3)_2]$ was recently isolated by Carty et al. and characterized by an X-ray crystal structure analysis.[7]



The labile methanol ligand of compound **2** is easily displaced by CO to give the six-coordinate dicarbonyl complex $[RuCl_2(CO)_2(P\textit{i}Pr_2Ph)_2]$ (see Scheme 2). The orange product **3a** initially formed is relatively stable in the solid state but rearranges in solution to the thermodynamically preferred yellow isomer **3b**. An independent synthesis of **3a** consists of the reduction of $RuCl_3 \cdot 3\,H_2O$ by CO in the presence of ethanol, followed by addition of P*i*Pr_2Ph. Since the IR spectrum of **3a** exhibits *one* and that of **3b two** CO stretching frequencies, we assume that **3a** is the *all-trans* and **3b** the *cis,cis,trans* isomer. A similar conclusion was drawn by Nelson et al. who prepared, also from $RuCl_3 \cdot 3\,H_2O$ as the starting material, two isomeric forms of the ruthenium(II) compound $[RuCl_2(CO)_2(PPh_3)_2]$.[8]

The five-coordinate chloro(hydrido) complex **1** is also highly reactive toward CO and affords in the presence of carbonmonoxide in ether the dicarbonyl derivative **4** in quantitative yield (Scheme 3). The open coordination site of the precursor compound **1**, however, cannot only be occupied by CO but also by phenylcarbene. If a solution of **1** in toluene is treated dropwise with a solution of $PhCHN_2$ in hexane, a change of color from yellow to orange occurs and the evolution of gas (N_2) is observed. After removal of the solvent and recrystallization from toluene an orange

Scheme 2. L = P*i*Pr_2Ph



solid is isolated which according to the elemental analysis and the spectroscopic data represents the six-coordinate ruthenium(II) complex **5**. The fact, that the carbene(hydrido) and not the isomeric benzyl compound $[Ru(CH_2Ph)Cl(CO)(P\textit{i}Pr_2Ph)_2]$ is formed, is clearly indicated by the ^{1}H-NMR spectrum, which displays besides the signals for the two phosphanes a doublet of triplets for the hydrido ligand at high field ($\delta = -2.77$) as well as a broadened singlet for the carbene C*H*Ph proton at low field ($\delta = 18.22$). The ^{13}C-NMR spectrum of **5** exhibits resonances at $\delta = 343.4$ and 203.3 which are assigned to the Ru=*C*HPh and Ru-*C*O carbon atoms, respectively.

Scheme 3. L = P*i*Pr_2Ph

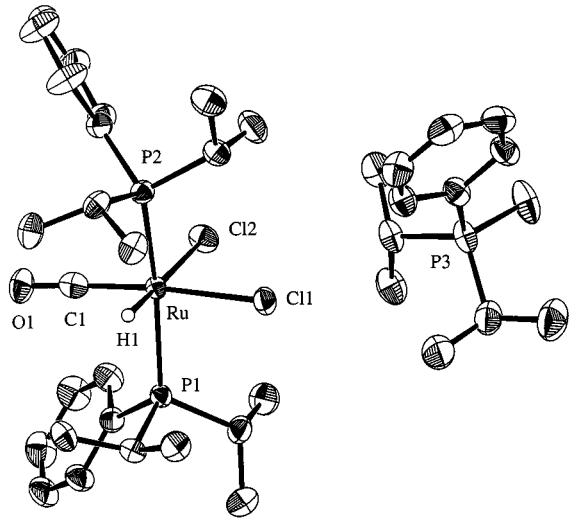
The parent diazoalkane CH_2N_2 behaves similarly to $PhCHN_2$ and reacts with the starting material **1** to yield the hydrido(methylene) complex **6** (Scheme 4). However, while the phenylcarbene derivative **5** is thermally stable as a solid up to 138 °C and can be stored under argon at room temperature for weeks, the $RuH(CH_2)$ compound **7** decomposes above −50 °C. Thus it could not be characterized by elemental analysis but only by spectroscopic means. Similarly to **5**, the ^{1}H-NMR spectrum of **6** displays a hydride resonance at $\delta = -2.60$ and two signals for the nonequivalent Ru=CH_2 protons at $\delta = 17.38$ and 16.36. The chemical shifts for these signals differ only slightly to those of the related osmium complex $[OsHCl(=CH_2)(CO)(P\textit{i}Pr_3)_2]$, which is, however, in contrast to **6** significantly more stable.[3]

At room temperature, the reaction of **1** with CH_2N_2 led to a different result. If the solution of the two reacting substrates in toluene/ether is stirred for ca. 12 h, a white precipitate is formed which is easily soluble in dichloromethane but almost insoluble in benzene and ether. These properties, together with the analytical data, indicate that an ionic complex of the composition [MeP*i*Pr_2Ph][$RuHCl_2$(CO)(P*i*Pr_2Ph)$_2$] (**7**) is formed. Based on control measurements (in CD_2Cl_2) in an NMR tube we assume that initially the methylene compound **6** is formed as an intermediate which rapidly decomposes to give inter alia the starting material **1** and [MeP*i*Pr_2Ph]Cl. Both compounds then react to afford

Scheme 4. L = P*i*Pr_2Ph

7. The most typical spectroscopic features of **7** are the two resonances in the ^{31}P-NMR spectrum (in CD_2Cl_2) at δ = 40.6 (sharp singlet) and 47.0 (broad singlet) which are assigned to the phosphorus nuclei of the cation and anion, respectively. Since the hydride signal in the ^{1}H-NMR spectrum at 28 °C is also rather broad (but sharpens in CD_2Cl_2 at −50 °C to a triplet with a P-H coupling of 22.4 Hz), we suppose that at room temperature the anion $[RuHCl_2(CO)(PiPr_2Ph)_2]$ partially dissociates in $[RuHCl(CO)(PiPr_2Ph)_2]$ (**1**) and Cl^-. This proposal is in agreement with the observation that upon cooling at −50 °C the ^{31}P-NMR resonance of the anion of **7**, although still relatively broad, is shifted from δ = 47.0 to 43.5, this process being reversible. A similar phenomenon was observed by measuring the ^{31}P-NMR spectrum of $[OsHCl_2(CO)(PiPr_3)_2]^-$ at different temperatures.[4] We note (see Scheme 4) that the PPN-salt **8** of the anion $[RuHCl_2(CO)(PiPr_2Ph)_2]^-$ is obtained as a white solid from **1** and [PPN]Cl in nearly quantitative yield. The IR as well as the ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra of **8** differ only slightly to those of **7** and thus deserves no further comment.

In order to substantiate the exact composition of **7**, a single-crystal X-ray structure analysis was carried out. As Figure 1 reveals, the coordination geometry around the metal center of the anion is distorted octahedral, with the two phosphanes in *trans* and the two chloro ligands in *cis* disposition. The P1−Ru−P2 axis is considerably bent, the bond angle of 163.49(3)° being comparable to that in the related neutral osmium complex $[OsCl_2(=CHPh)(CO)(PiPr_3)_2]$ [167.5(2)°].[3] The most notable detail of the structure of the anion, however, is the significant difference of the Ru−Cl bond lengths. While the bond length between ruthenium and the chloride *trans* to CO is 2.499(1) Å, that between the metal and the chloride *trans* to hydride is 2.618(1) Å. This difference (which is hard to understand owing to the similar *trans* influence of CO and hydride) could be used as an argument to explain the assumed dissociation of the anion $[RuHCl_2(CO)(PiPr_2Ph)_2]$ into **1** and Cl^-. We note that for the two carbonyl(hydrido)iridium(III) complexes $[IrHCl_2(CO)(PiPr_3)_2]$ and $[IrHCl_2(CO)(PPh_3)\{PPh_2(o\text{-}C_6H_4OH)\}]$, both containing a planar $IrHCl_2(CO)$ unit with *cis*-disposed chloro ligands, a similar difference in the Ir−Cl bond lengths of about 0.10 and 0.18 Å, respectively, has been observed.[9][10]



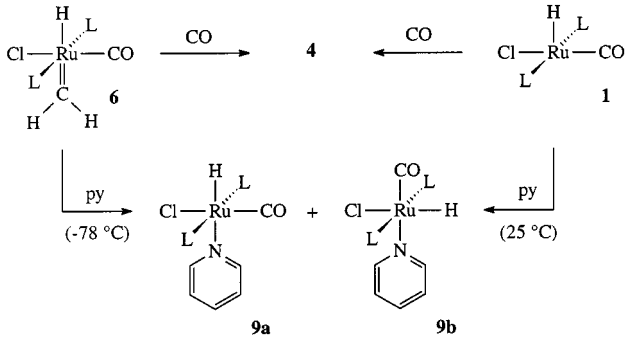


Figure 1. Molecular structure (ORTEP plot) of **7**; the hydrogen atoms besides H1 are omitted for clarity; selected bond lengths [Å] and angles [°]: Ru−P1 2.351(1), Ru−P2 2.358(1), Ru−Cl1 2.499(1), Ru−Cl2 2.618(1), Ru−H1 1.53(2), Ru−C1 1.806(3), C1−O1 1.137(3); P1−Ru−P2 163.49(3), C1−Ru−Cl1 172.71(8), P2−Ru−Cl1 90.81(4), P2−Ru−Cl2 98.41(4), P2−Ru−C1 90.2(1), Cl2−Ru−Cl1 90.31(4), Cl2−Ru−C1 96.67(9), Cl2−Ru−P1 97.97(4), Cl1−Ru−P1 87.04(4), C1−Ru−P1 89.9(1), H1−Ru−P1 84.0(1), H1−Ru−P2 79.5(1), H1−Ru−C1 88.5(1), H1−Ru−Cl1 84.6(1), H1−Ru−Cl2 174.5(1), Ru−C1−O1 176.1(2)

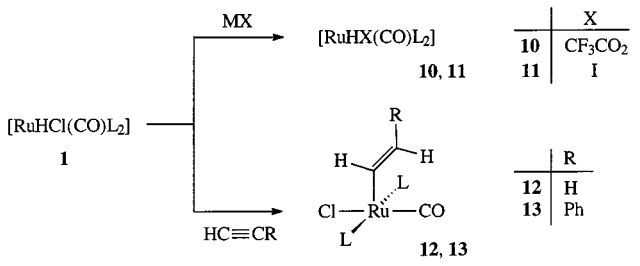

Attempts to initiate an insertion of the carbene ligand into the Ru−H bond of compound **6** by treatment of **6** with Lewis bases such as CO or pyridine led to a displacement of the CH_2 unit. This finding differs with ab initio calculations which predict that for the model system $RuH(=CH_2)Cl$ the conversion into $Ru(CH_3)Cl$ proceeds with a rather low barrier of 11.5 kcal/mol and is exothermic by 7.1 kcal/mol.[11] The model system, however, is coordinatively unsaturated while compound **6** is not. As shown in Scheme 5, the reaction of **6** with CO affords the dicarbonyl complex **4** together with traces of ethene. In contrast, treatment of **6** with pyridine gives a mixture of two isomers **9a** and **9b**, which are also obtained from the five-coordinate starting material **1** and pyridine. Regarding the ligand arrangement of **9a** and **9b**, a plausible assumption is that in one isomer the pyridine is *trans* to hydride and in the other *trans* to CO. The fact, that both the chemical shifts of the hydride signals in the ^{1}H NMR (at δ = −13.54 and −14.41) and of the two resonances in the ^{31}P-NMR spectrum (at δ = 48.9 and 43.8) differ only slightly, seems to be in agreement with this proposal. The alternative, that the hydride and the carbonyl ligands are *trans* to each other, is less likely since in this case, which corresponds to the situation in compound **4**, the hydride signal should be observed at considerably lower field (for **4**: δ = −5.23). In this context we note that Caulton and co-workers recently reported that treatment of $[RuH(OR_F)(CO)(PtBu_2Me)_2]$ (R_F = CH_2CF_3) with pyridine

also produces a mixture of two isomers of the composition $[RuH(OR_F)(CO)(py)(PtBu_2Me)_2]$.[12]

Scheme 5. L = P*i*Pr$_2$Ph

Similarly to $[RuHCl(CO)(PiPr_3)_2]$ and $[OsHCl(CO)(PiPr_3)_2]$, which react with MX by salt metathesis to give the ruthenium(II) and osmium(II) derivatives $[MHX(CO)(PiPr_3)_2]$ (X = Br, I, N_3, OR, SR),[13] the five-coordinate compound **1** can be converted with CF_3CO_2Tl and KJ to the related hydrido(trifluoracetato) and hydrido(iodo) complexes **10** and **11**, respectively (see Scheme 6). While the orange-yellow $RuH(O_2CCF_3)$ species **10**, in analogy to the starting material **1,** is only slightly air-sensitive, the brown hydrido(iodo) compound **11** smoothly decomposes (in solution as well as in the solid state) in the presence of air. Despite the different behavior of **1** and **11** toward O_2, the spectroscopic data of both complexes are quite similar. This is illustrated by the chemical shifts both of the hydride signal (**1**: $\delta = -24.67$; **11**: $\delta = -25.0$) in the ^{1}H-NMR and of the CO resonance (**1**: $\delta = 197.7$; **11**: $\delta = 198.7$) in the ^{13}C-NMR spectra. In contrast, the corresponding NMR spectra of **10** exhibit the signal for the RuH moiety at $\delta = -18.23$ and that for the CO ligand at $\delta = 205.1$. Owing to these data we assume that the CF_3CO_2 unit of **10** is coordinated in a chelating fashion, which increases the coordination number for ruthenium(II) from five (in **1**) to six (in **10**). This structural proposal is supported by the IR spectrum of **10**, in which the symmetrical and the antisymmetrical OCO stretching vibrations appear at 1597 and 1410 cm^{-1}, respectively. According to extensive studies, particularly by Robinson et al.,[14][15] the observed difference of 187 cm^{-1} clearly points to a bidentate, not a monodentate, linkage of the trifluoracetate to the ruthenium center.

Scheme 6. L = P*i*Pr$_2$Ph

As mentioned above, the chloro compound **1** reacts readily with $PhCHN_2$ at room temperature to give the phenylcarbene complex **5** in 42% isolated yield. Contrary to this result, the trifluoracetato and iodo derivatives **10** and **11** are less reactive toward $PhCHN_2$ and upon stirring a solution of the two respective substrates in toluene for 2−4 h a complex mixture of products is formed. We not only failed to separate the mixture but also found no evidence for the presence of a Ru=CHPh species among the various components.

Completely inert toward $PhCHN_2$ are the vinyl complexes **12** and **13**, which have been obtained likewise to the corresponding ruthenium and osmium compounds $[M(CH=CHR)Cl(CO)(PiPr_3)_2]$ (M = Ru, Os; R = H, Ph)[2] from the starting material **1** and acetylene or phenylacetylene, respectively (Scheme 6). Both complexes, **12** and **13**, are moderately air-sensitive solids which are easily soluble in common organic solvents (with the exception of hexane and pentane). The *trans* stereochemistry at the C=C bond of **13** is strongly supported by the large H−H coupling constant for the vinyl protons, which is 14.0 Hz.[16] The ^{13}C-NMR resonances for the $CH=CH_2$ carbon atoms of **12** appear at $\delta = 152.5$ and 120.5, the chemical shifts being quite similar to those of $[Ru(CH=CH_2)Cl(CO)(PiPr_3)_2]$.[2] Attempts to convert compound **12** to the π-allyl complex $[RuCl(\eta^3\text{-}C_3H_5)(CO)(PiPr_2Ph)_2]$ by treatment with CH_2N_2, in analogy to the preparation of $[RuCl(\eta^3\text{-}C_3H_5)(CO)(PPh_3)_2]$ by Hill and co-workers,[17] remained unsuccessful.

In summary, the present investigations have shown that in contrast to $[RuHCl(CO)(PiPr_3)_2]$ the related five-coordinate bis(diisopropylphenylphosphane) complex **1** reacts with CH_2N_2 and $PhCHN_2$ to generate the six-coordinate carbeneruthenium(II) derivatives **5** and **6**. Although theoretical calculations reveal that an insertion of the carbene unit into the Ru−H bond is conceivable, attempts to prepare alkylruthenium compounds from **5** or **6** as a precursor failed. As recent studies by Caulton and Eisenstein indicate,[18] the conversion of a $RuH(CH_2)$ to a $RuCH_3$ unit could be strongly influenced by the phosphane ligands linked to the ruthenium center, the more bulky P*t*Bu$_2$Me being more suitable than P*i*Pr$_3$. We finally note that despite the lability of the carbene−ruthenium bond, which is most obvious in **6,** the complexes **5** and **6** are catalytically inactive in olefin metathesis. Whether this is due to the octahedral geometry, that hinders the addition of an olefin, or to the presence of a Ru−H bond, is open to speculation.

Experimental Section

All operations were carried out under argon using Schlenk techniques. The diazoalkanes CH_2N_2 and $PhCHN_2$[19] were prepared as reported in the literature. All other starting materials were commercial products from Aldrich, Strem and ABCR. − NMR: Bruker AC 200 and AMX 400 [dvt = doublet of virtual triplets; $N = {}^3J(PH) + {}^5J(PH)$ or $^1J(PC) + {}^3J(PC)$, respectively]. − Melting points determined by DTA.

1. Preparation of [RuHCl(CO)(P*i*Pr$_2$Ph)$_2$] (1): A solution of 1.00 g (3.98 mmol) of $RuCl_3 \cdot 3\,H_2O$ in 35 mL of methanol was treated dropwise with 4.63 g (23.8 mmol) of P*i*Pr$_2$Ph. After the solution was stirred for 10 min at room temperature, 1.09 mL (7.88 mmol)

of NEt_3 were added and the mixture was heated for 5 h at 65 °C. After the solution was cooled to room temperature, a yellow precipitate was formed which was filtered, washed twice with 5 mL of methanol, then with 10 mL of pentane and dried in vacuo; yield 1.43 g (65%); m.p. 194 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 2100 cm^{-1} (RuH), 1900 (CO). − ^1H NMR (400 MHz, C_6D_6): δ = 7.72 (m, 4 H, C_6H_5), 7.11 (m, 6 H, C_6H_5), 3.22, 2.62 (both m, 2 H each, PC*H*CH_3), 1.33 [dvt, *N* = 14.4, *J*(HH) = 6.8 Hz, 6 H, PCHC*H*$_3$], 1.25 [dvt, *N* = 16.0, *J*(HH) = 6.8 Hz, 6 H, PCHC*H*$_3$], 1.15 [dvt, *N* = 15.2, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 0.87 [dvt, *N* = 13.2, *J*(HH) = 6.6 Hz, 6 H, PCHC*H*$_3$], −24.67 [t, *J*(PH) = 20 Hz, 1 H, RuH]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 197.7 [t, *J*(PC) = 10 Hz, CO], 135.0, 127.9 (both vt, *N* = 11 and 8 Hz, *ortho*- and *meta*-C of C_6H_5), 130.5 (s, *para*-C of C_6H_5), 129.4 (vt, *N* = 35 Hz, *ipso*-C of C_6H_5), 22.5, 20.8 (both vt, *N* = 23 and 22 Hz, P*C*HCH$_3$), 18.5, 18.3, 17.8, 15.5 (all s, PCH*C*H$_3$). − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 55.5 (s). − $C_{25}H_{39}ClOP_2Ru$ (554.1): calcd. C 54.20, H 7.10, Ru 18.24; found C 53.92, H 7.00, Ru 18.45.

2. Preparation of [$RuCl_2$(CO)(MeOH)(P*i*Pr_2Ph)$_2$] (2): a) A solution of 1.00 g (3.98 mmol) of $RuCl_3 \cdot 3\,H_2O$ in 10 mL of methanol was treated dropwise with 1.95 g (10.0 mmol) of P*i*Pr_2Ph and heated for 70 h at 85 °C. After the reaction mixture was cooled to room temperature, the resulting pale yellow precipitate was filtered, washed twice with 10 mL of methanol, and dried in vacuo; yield: 1.01 g (41%). − b) A slow stream of dried HCl was passed through a solution of 83 mg (0.15 mmol) of **1** in 4 mL of dichloromethane-methanol (1:1) for ca. 1 min. The solvent was removed and the resulting yellow solid was dried in vacuo; yield: 92 mg (99%); m.p. 138 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 3563 cm^{-1} (OH), 1918 (CO). − ^1H NMR (400 MHz, C_6D_6): δ = 7.58 (m, 4 H, C_6H_5), 7.20−6.82 (m, 6 H, C_6H_5), 3.50 (m, 4 H, PC*H*CH_3), 2.48 (s, 3 H, C*H*$_3$OH), 1.72 [dvt, *N* = 15.6, *J*(HH) = 7.6 Hz, 12 H, PCHC*H*$_3$], 1.09 [dvt, *N* = 12.8, *J*(HH) = 6.4 Hz, 12 H, PCHC*H*$_3$], signal of CH_3OH not observed. − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 36.7 (s). − $C_{26}H_{42}Cl_2O_2RuP_2$ (620.5): calcd. C 50.32, H 6.82; found C 50.38, H 6.88.

3. Preparation of *trans,trans,trans*-[$RuCl_2$(CO)$_2$(P*i*Pr_2Ph)$_2$] (3a): A solution of 100 mg (0.40 mmol) of $RuCl_3 \cdot 3\,H_2O$ in 5 mL of ethanol was stirred in a pressure bottle under CO atmosphere (1 bar) for 5 h at 65 °C. After the reaction mixture was cooled to 0 °C, it was treated under CO dropwise with a solution of 155 mg (0.80 mmol) of P*i*Pr_2Ph in 1.3 mL of chloroform. The solution was stirred for 15 h at room temperature, the resulting orange precipitate was filtered, washed with 5 mL of ethanol and dried in vacuo; yield: 186 mg (79%). − IR (KBr): $\tilde{\nu}$ = 1975 cm^{-1} (CO). − ^{31}P NMR (81.0 MHz, $CDCl_3$): δ = 32.7 (s).

4. Preparation of *cis,cis,trans*-[$RuCl_2$(CO)$_2$(P*i*Pr_2Ph)$_2$] (3b): A solution of 186 mg (0.30 mmol) of **3a** in 5 mL of chloroform was heated for 15 min at 80 °C. After the reaction mixture was cooled to room temperature, the solvent was removed and the yellow solid was dried in vacuo; yield: 186 mg, (99%); m.p. 69 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 2020 cm^{-1} (CO), 1960 (CO). − ^1H NMR (400 MHz, $CDCl_3$): δ = 8.12 (m, 4 H, C_6H_5), 7.45 (m, 6 H, C_6H_5), 3.25 (m, 4 H, PC*H*CH_3), 1.36 [dvt, *N* = 15.2, *J*(HH) = 7.2 Hz, 12 H, PCHC*H*$_3$], 1.19 [dvt, *N* = 14.4, *J*(HH) = 7.2 Hz, 12 H, PCHC*H*$_3$]. − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 195.2 [t, *J*(PC) = 11 Hz, CO], 134.2, 128.1 both vt, *N* = 7 and 8 Hz, *ortho*-C and *meta*-C of C_6H_5), 130.4 (s, *para*-C of C_6H_5), 127.7 (vt, *N* = 36 Hz, *ipso*-C of C_6H_5), 23.4 (vt, *N* = 24 Hz, P*C*HCH$_3$), 18.5, 17.7 (both s, PCH*C*H$_3$). − ^{31}P NMR (162.0 MHz, $CDCl_3$): δ = 30.6 (s). − $C_{26}H_{38}Cl_2O_2RuP_2$ (616.5): calcd. C 50.65, H 6.21; found C 50.56, H 6.01.

5. Preparation of [$RuHCl(CO)_2$(P*i*Pr_2Ph)$_2$] (4): A slow stream of CO was passed at room temperature through a suspension of 124 mg (0.22 mmol) of **1** in 5 mL of ether until a clear, almost colorless solution was formed. The solvent was removed and the remaining white solid was dried in vacuo; yield 130 mg (99%); m.p. 161 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 2010 cm^{-1} (RuH), 1950, 1900 (CO). − ^1H NMR (400 MHz, CD_2Cl_2): δ = 7.85 (m, 4 H, C_6H_5), 7.50 (m, 6 H, C_6H_5), 2.99, 2.89 (both m, 2 H each, PC*H*CH_3), 1.28 [dvt, *N* = 16.1, *J*(HH) = 7.1 Hz, 6 H, PCHC*H*$_3$], 1.22 [dvt, *N* = 16.8, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 1.12 [dvt, *N* = 13.8, *J*(HH) = 7.1 Hz, 6 H, PCHC*H*$_3$], 1.01 [dvt, *N* = 15.9, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], −5.23 [t, *J*(PH) = 20 Hz, 1 H, RuH]. − ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 200.8, [t, *J*(PC) = 8 Hz, CO], 198.3 [t, *J*(PC) = 11 Hz, CO], 134.9, 128.2 (both vt, *N* = 10 and 9 Hz, *ortho*-C and *meta*-C of C_6H_5), 130.5 (s, *para*-C of C_6H_5), 128.8 (vt, *N* = 35 Hz, *ipso*-C of C_6H_5), 23.3, 22.5 (both vt, *N* = 29 and 23 Hz, P*C*HCH$_3$), 18.3, 17.8, 17.4, 16.8 (all s, PCH*C*H$_3$). − ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 59.6 (s). − $C_{26}H_{39}ClO_2P_2Ru$ (582.1): calcd. C 53.65, H 6.75; found C 53.74, H 7.06.

6. Preparation of [RuHCl(CO)(=CHPh)(P*i*Pr_2Ph)$_2$] (5): A solution of 156 mg (0.28 mmol) of **1** in 10 mL of toluene was treated dropwise with 0.27 mL of a 1.5 M solution of $PhCHN_2$ (0.42 mmol) in hexane. A change of color from yellow to orange occurred and the evolution of gas was observed. After the reaction mixture was stirred for 30 min at room temperature, the solvent was removed in vacuo, and pentane was added to the oily residue. Ultrasonic irradiation of this mixture gave an orange precipitate, which was filtered, washed three times with 2 mL of pentane and dried in vacuo. The crude product (yield ca. 80%) still contained ca. 5% of compound **1**. After recrystallization from toluene at −20 °C, a pure orange solid was obtained; yield 76 mg (42%); m.p. 138 °C (dec.). − IR (KBr): $\tilde{\nu}$ = 1930 cm^{-1} (CO). − ^1H NMR (400 MHz, C_6D_6): δ = 18.22 (m, 1 H, Ru=C*H*Ph), 8.22 (m, 2 H, C_6H_5), 7.74 (m, 4 H, C_6H_5), 7.12 (m, 9 H, C_6H_5), 3.14, 2.81 (both m, 2 H each, PC*H*CH_3), 1.49 [dvt, *N* = 16.8, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 0.99 [dvt, *N* = 14.8, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 0.96 [dvt, *N* = 16.8, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 0.95 [dvt, *N* = 14.8, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], −2.77 [dt, *J*(PH) = 21, *J*(HH) = 2 Hz, RuH]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 343.4 (s, Ru=*C*HPh), 203.3 [t, *J*(PC) = 12 Hz, CO], 154.3 [s, *ipso*-C of Ru=CH(*C*$_6$H$_5$)], 135.0 (vt, *N* = 9 Hz, C_6H_5), 133.2, 132.1, 130.0, 129.6, 127.6, 125.6 (all s, C_6H_5), 23.8, 23.6 (both vt, *N* = 22 and 31 Hz, P*C*HCH$_3$), 18.5, 17.1, 17.0, 16.8 (all s, PCH*C*H$_3$). − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 75.2 (s). − $C_{32}H_{45}ClORuP_2$ (644.2): calcd. C 59.67, H 7.04; found C 59.23, H 6.80.

7. Preparation of [RuHCl(CO)(=CH_2)(P*i*Pr_2Ph)$_2$] (6): A suspension of 123 mg (0.22 mmol) of **1** in 5 mL of toluene was treated dropwise at −78 °C with 1.5 mL of a ca. 0.5 M solution of diazomethane (ca. 0.75 mmol) in ether. Almost instantaneously, a pale yellow solid precipitated, the formation of which was facilitated upon addition of 10 mL of pentane (−78 °C). The mother liquor was removed, the remaining residue washed with 5 mL of pentane (−78 °C) and dried at −78 °C in vacuo. Since the pale yellow solid decomposed at −50 °C, it was characterized spectroscopically. − ^1H NMR (400 MHz, [D_8]THF, −53 °C): δ = 17.36, 16.38 (both br s, 1 H each, Ru=CH_2), −2.60 [t, *J*(PH) = 20 Hz, RuH], signals of C_6H_5 and C_3H_7 protons overlap with those of the solvents used for preparation.

8. Preparation of [MeP*i*Pr_2Ph][$RuHCl_2$(CO)(P*i*Pr_2Ph)$_2$] (7): A solution of 100 mg (0.18 mmol) of **1** in 10 mL of toluene was treated dropwise with 1 mL of a ca. 0.5 M solution of diazomethane in ether (ca. 0.5 mmol) at room temperature. The color of the reaction

mixture changed from yellow to dark red and the evolution of gas was observed. After the reaction mixture was stirred for ca. 15 h, a white precipitate was formed, which was filtered, washed twice with 5 mL of pentane, and dried in vacuo; yield 41 mg (30%); m.p. 138 °C (dec.). – IR (KBr): $\tilde{\nu}$ = 2085 cm^{-1} (RuH), 1940 (CO). – ^{1}H NMR (400 MHz, CD_2Cl_2); signals for $[RuHCl_2(CO)(P$-$i Pr_2Ph)_2]^-$: δ = 8.08 (m, 4 H, C_6H_5), 7.70 (m, 2 H, C_6H_5), 7.38 (m, 4 H, C_6H_5), 2.99, 2.82 (both m, 2 H each, PC*H*CH_3), 1.22 [br d, *J*(HH) = 6.7 Hz, 6 H, PCHC*H*$_3$], 1.17 [br d, *J*(HH) = 6.7 Hz, 6 H, PCHC*H*$_3$], 1.08 [dvt, *N* = 11.6, *J*(HH) = 5.8 Hz, 6 H, PCHC*H*$_3$], 1.01 [dvt, *N* = 13.4, *J*(HH) = 6.7 Hz, 6 H, PCHC*H*$_3$], −17.8 (br s, 1 H, RuH); signals for $[MeP$-$i Pr_2Ph]^+$: δ = 7.84−7.59 (m, 5 H, C_6H_5), 3.18 (m, 2 H, PC*H*CH_3), 2.26 [d, *J*(PH) = 12.4 Hz, 3 H, PC*H*$_3$], 1.29 [dd, *J*(HH) = 7.2, *J*(PH) = 10.8 Hz, 6 H, PCHC*H*$_3$], 1.34 [dd, *J*(HH) = 6.8, *J*(PH) = 10.8 Hz, 6 H, PCHC*H*$_3$]. – ^{13}C NMR (100.6 MHz, CD_2Cl_2); signals for $[RuHCl_2(CO)(Pi Pr_2Ph)_2]^-$: δ = 203.0 [t, *J*(PC) = 13.1 Hz, CO], 135.8, 127.3 (both vt, *N* = 10.0 and 8.0 Hz, *ortho*- and *meta*-C of C_6H_5), 132.4 (vt, *N* = 27.3 Hz, *ipso*-C of C_6H_5) 129.2 (s, *para*-C of C_6H_5), 23.9, 22.7 (both vt, *N* = 26.1 and 20.2 Hz, P*C*HCH$_3$), 19.0, 18.3, 18.1, 17.6 (all s, PCH*C*H$_3$); signals for $[MeP$-$i Pr_2Ph]^+$: δ = 135.0 [d, *J*(PC) = 3 Hz, *para*-C of C_6H_5], 133.0, 130.6 both d, *J*(PC) = 8 Hz and 11 Hz, *meta*- and *ortho*-C of C_6H_5], 115.7 [d, *J*(PC) = 78 Hz, *ipso*-C of C_6H_5], 21.5 [d, *J*(PC) = 47 Hz, P*C*HCH$_3$], 15.9, 15.8 both d, *J*(PC) = 2 Hz, PCH*C*H$_3$], −0.5 [d, *J*(PC) = 52 Hz, P*C*H$_3$]. – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 47.0 (s, PiPr$_2$Ph), 40.6 (s, $[MeP$-$i Pr_2Ph]^+$). – $C_{38}H_{61}Cl_2OP_3Ru$ (798.8): calcd. C 57.14, H 7.70; found C 57.32, H 7.70.

9. Preparation of [PPN][$RuHCl_2(CO)(Pi Pr_2Ph)_2$] (8): A solution of 104 mg (0.19 mmol) of **1** in 10 mL of benzene was treated with 108 mg (0.19 mmol) of [PPN]Cl. The color of the solution changed gradually from yellow to pale yellow. After the reaction mixture was stirred for ca. 18 h at room temperature, a white solid precipitated, which was filtered, washed three times with 5 mL of benzene, and dried in vacuo; yield 187 mg (88%); m.p. 125 °C (dec.). – IR (KBr): $\tilde{\nu}$ = 2062 cm^{-1} (RuH), 1890 (CO). – ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 8.32 (m, 4 H, C_6H_5), 7.66−7.36 (m, 36 H, C_6H_5), 3.11, 2.70 (both m, 2 H each, PC*H*CH_3), 1.33 [dvt, *N* = 14.1, *J*(HH) = 7.0 Hz, 6 H, PCHC*H*$_3$], 1.20 [dvt, *N* = 14.9, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 1.03 (m, 12 H, PCHC*H*$_3$), −16.1 (br s, 1 H, RuH). – ^{13}C NMR (50.3 MHz, CD_2Cl_2): δ = 203.3 [t, *J*(PC) = 15.7 Hz, CO], 135.0 (s, PC_6H_5), 134.1 (s, PPN), 132.9, 128.6 both vt, *N* = 26.2 and 25.7 Hz, PC_6H_5), 132.4, 129.7, 128.4, 126.2 (all m, PPN), 127.1 (s, PC_6H_5), 24.0, 22.3 (both vt, *N* = 26.8 and 19.5 Hz, P*C*HCH$_3$), 18.8, 18.3, 18.0, 17.1 (all s, PCH*C*H$_3$). – ^{31}P NMR (81.0 MHz, CD_2Cl_2): δ = 45.7 (br s, PiPr$_2$Ph), 21.6 (s, PPN). – $C_{61}H_{69}Cl_2NOP_4Ru$ (1128.1): calcd. C 64.95, H 6.17, N 1.24; found C 64.73, H 6.11, N 1.20.

10. Preparation of [$RuHCl(CO)(py)(Pi Pr_2Ph)_2$] (9a, b): A suspension of 82 mg (0.15 mmol) of **1** in 5 mL of hexane was treated with 0.05 mL (0.62 mmol) of pyridine at room temperature. After the reaction mixture was stirred for ca. 3 min, a white solid precipitated, which was filtered, washed three times with 5 mL of pentane and dried in vacuo; yield 89 mg (95%); m.p. 115 °C (dec.). The same compound was formed upon addition of ca. 0.1 mL of pyridine to a solution of 80 mg (0.14 mmol) of **6** in 1 mL of [D_8]THF at −78 °C. After the solution was warmed to room temperature, the ^{1}H-NMR spectrum indicated the complete conversion of **6** to **9a**, **b**. – ^{1}H NMR (400 MHz, C_6D_6); signals for **9a**: δ = 8.20, 7.07, 6.16 (all m, NC_5H_5 and C_6H_5) 3.19, 2.83 (both m, 2 H each, PC*H*CH_3), 1.41 [dvt, *N* = 13.6, *J*(HH) = 6.8 Hz, 6 H, PCHC*H*$_3$], 1.22 [dvt, *N* = 13.2, *J*(HH) = 6.6 Hz, 6 H, PCHC*H*$_3$], 1.10 [dvt, *N* = 14.0, *J*(HH) = 7.0 Hz, 6 H, PCHC*H*$_3$], 0.89 [dvt, *N* = 15.0, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], −13.54 [t, *J*(PH) = 22.0 Hz, 1 H, RuH]; signals for **9b**: δ = 7.57, 7.07, 6.51 (all m, NC_5H_5 and C_6H_5), 2.67, 1.81 (both m, 2 H each, PC*H*CH_3), 1.35 [dvt, *N* = 16.4, *J*(HH) = 7.0 Hz, 6 H, PCHC*H*$_3$], 1.29 [dvt, *N* = 13.6, *J*(HH) = 6.8 Hz, 6 H, PCHC*H*$_3$], 1.21 [dvt, *N* = 13.6, *J*(HH) = 6.8 Hz, 6 H, PCHC*H*$_3$], 0.99 [dvt, *N* = 13.4, *J*(HH) = 6.7 Hz, 6 H, PCHC*H*$_3$], −14.41 [t, *J*(PH) = 21.8 Hz, 1 H, RuH]. – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 48.9, 43.8 (both s). – $C_{30}H_{44}ClONP_2Ru$ (633.2): calcd. C 56.91, H 7.00, N 2.21; found C 56.62, H 7.04, N 2.23.

11. Reaction of Compound 6 with CO: A slow stream of CO was passed through a solution of 80 mg (0.14 mmol) of **6** in 1 mL of [D_8]THF at −80 °C. After the solution was warmed to room temperature, the ^{1}H-NMR spectrum indicated the complete conversion of **6** to **4**.

12. Preparation of [$RuH(CF_3CO_2)(CO)(Pi Pr_2Ph)_2$] (10): A solution of 192 mg (0.35 mmol) of **1** in 10 mL of toluene was treated with 111 mg (0.35 mmol) of CF_3CO_2Tl and stirred for 15 h at room temperature. The solution was decanted from the solid residue and then brought to dryness in vacuo. An orange-yellow microcystalline solid was obtained; yield 188 mg (86%); m.p. 177 °C (dec.). – IR (KBr): $\tilde{\nu}$ = 2090 cm^{-1} (RuH), 1910 (CO), 1597 ($OCO_{as.}$), 1410 ($OCO_{sym.}$). – ^{1}H NMR (400 MHz, C_6D_6): δ = 7.89 (m, 4 H, C_6H_5), 7.31−7.17 (m, 6 H, C_6H_5), 2.54 (m, 4 H, PC*H*CH_3), 1.42 [dvt, *N* = 15.9, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 1.33 [dvt, *N* = 15.0, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 1.24 [dvt, *N* = 14.6, *J*(HH) = 7.1 Hz, 6 H, PCHC*H*$_3$], 1.01 [dvt, *N* = 13.3, *J*(HH) = 6.7 Hz, 6 H, PCHC*H*$_3$], −18.23 [t, *J*(PH) = 20 Hz, 1 H, RuH]. – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 205.1 [t, *J*(PC) = 10 Hz, CO], 164.2 [q, *J*(FC) = 38 Hz, CF_3CO_2] 134.7, 128.1 (both vt, *N* = 10 and 14 Hz, *ortho*-C and *meta*-C of C_6H_5), 130.1 (s, *para*-C of C_6H_5], 128.7 (vt, *N* = 34 Hz, *ipso*-C of C_6H_5), 115.0 [q, *J*(FC) = 287 Hz, CF_3CO_2], 24.5, 24.3, (both vt, *N* = 24 and 23 Hz, P*C*HCH$_3$), 19.1, 18.4, 18.1, 17.2, (all s, PCH*C*H$_3$). – ^{19}F NMR (376.4 MHz, C_6H_6): δ = −75.4 (s). – ^{31}P NMR (162.0 MHz, C_6D_6): δ = 53.7 (s). – $C_{27}H_{39}F_3O_3P_2Ru$ (631.6): calcd. C 51.34, H 6.22; found C 51.03, H 5.98.

13. Preparation of [$RuHI(CO)(Pi Pr_2Ph)_2$] (11): A solution of 200 mg (0.36 mmol) of **1** in 10 mL of dichloromethane was treated with 600 mg (3.61 mmol) of KI and stirred for 15 h at room temperature. The reaction mixture was filtered and the filtrate was brought to dryness in vacuo. The brown microcrystalline residue was washed with methanol and dried; yield 116 mg (50%); m.p. 122 °C (dec.). – ^{1}H NMR (400 MHz, C_6D_6): δ = 7.70 (m, 4 H, C_6H_5), 7.46 (m, 6 H, C_6H_5), 3.33, 3.02 (both m, 2 H each, PC*H*CH_3), 1.35 [dvt, *N* = 15.2, *J*(HH) = 7.6 Hz, 6 H, PCHC*H*$_3$], 1.19 [dvt, *N* = 15.2, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 1.14 [dvt, *N* = 16.8, *J*(HH) = 8.0 Hz, 6 H, PCHC*H*$_3$], 1.04 [dvt, *N* = 13.2, *J*(HH) = 6.8 Hz, 6 H, PCHC*H*$_3$], −25.0 (br s, 1 H, RuH). – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 198.7 [t, *J*(PC) = 12 Hz, CO], 134.9, 127.8 (both vt, *N* = 10 and 8 Hz, *ortho*-C and *meta*-C of C_6H_5), 130.1 (s, *para*-C of C_6H_5), 130.3 (vt, *N* = 36 Hz, *ipso*-C of C_6H_5), 25.1, 24.4 (both vt, *N* = 27 and 23 Hz, P*C*HCH$_3$), 19.6, 19.5, 19.1, 17.8 (all s, PCH*C*H$_3$). – ^{31}P NMR (162.0 MHz, C_6D_6): δ = 53.3 (s). – $C_{25}H_{39}IOP_2Ru$ (645.5): calcd. C 46.52, H 6.09; found C 46.13, H 5.67.

14. Preparation of [$Ru(CH{=}CH_2)Cl(CO)(Pi Pr_2Ph)_2$] (12): A slow stream of acetylene was passed through a suspension of 129 mg (0.23 mmol) of **1** in 15 mL of pentane until a change of color from yellow to red occurred. After the suspension was stirred for 30 min at room temperature, a red solid precipitated which was filtered, washed with pentane and dried in vacuo; yield 119 mg (90%); m.p.

124 °C (dec.). – IR (KBr): $\tilde{\nu}$ = 1923 cm^{-1} (CO). – $^1H\{^{31}P\}$NMR (200 MHz, $CDCl_3$): δ = 8.15 [dd, *J*(HH) = 14.0 Hz, *J*(HH) = 6.0 Hz, 1 H, C*H*=CH_2], 7.81 (m, 4 H, C_6H_5), 7.38 (m, 6 H, C_6H_5), 5.22 [d, *J*(HH) = 6.0 Hz, 1 H, one H of =CH_2], 4.89 [d, *J*(HH) = 14.0 Hz, 1 H, one H of =CH_2], 3.24, 2.87 (both m, 2 H each, PC*H*CH_3), 1.26 [d, *J*(HH) = 7.0 Hz, 6 H, PCHC*H*$_3$], 1.16 [d, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 1.08 [d, *J*(HH) = 7.2 Hz, 6 H, PCHC*H*$_3$], 1.01 [d, *J*(HH) = 6.8 Hz, 6 H, PCHC*H*$_3$]. – ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 200.7 [t, *J*(PC) = 12 Hz, CO], 152.5 [t, *J*(PC) = 10 Hz, *C*H=CH_2], 133.9, 127.0 (both vt, *N* = 13 and 8 Hz, *ortho*-C and *meta*-C of C_6H_5), 129.6 (s, *para*-C of C_6H_5), 129.6 (vt, *N* = 33 Hz, *ipso*-C of C_6H_5), 120.5 (s, CH=*C*H_2), 23.7, 22.4 (both vt, *N* = 23 and 21 Hz, P*C*HCH$_3$), 20.7, 18.9, 18.3, 17.4 (all s, PCH*C*H$_3$). – ^{31}P NMR (81.0 MHz, $CDCl_3$): δ = 35.6 (s). – $C_{27}H_{41}ClORuP_2$ (580.1): calcd. C 55.90, H 7.12; found C 55.60, H 7.12.

15. Preparation of [Ru(CH=CHPh)Cl(CO)(P*i*Pr$_2$Ph)$_2$] (13): A suspension of 100 mg (0.18 mmol) of **1** in 10 mL of hexane was treated with 19 μL (0.18 mmol) of phenylacetylene and stirred for 1 h at room temperature. A violet solid precipitated which was filtered, washed three times with pentane, and dried in vacuo; yield 74 mg (62%); m.p. 148 °C (dec.). – IR (KBr): $\tilde{\nu}$ = 1916 cm^{-1} (CO). – $^1H\{^{31}P\}$ NMR (400 MHz, CD_2Cl_2): δ = 8.83 [d, *J*(HH) = 13.4 Hz, 1 H, C*H*=CHPh], 7.78 (m, 4 H, C_6H_5), 7.44 (m, 6 H, C_6H_5), 7.25 (m, 4 H, C_6H_5), 7.06 (m, 1 H, C_6H_5), 6.15 [d, *J*(HH) = 13.4 Hz, 1 H, CH=C*H*Ph], 3.27, 2.94 (both m, 2 H each, PC*H*CH_3), 1.33 [d, *J*(HH) = 7.0 Hz, 6 H, PCHC*H*$_3$], 1.27 [d, *J*(HH) = 7.1 Hz, 6 H, PCHC*H*$_3$], 1.16 [d, *J*(HH) = 7.0 Hz, 6 H, PCHC*H*$_3$], 1.04 [d, *J*(HH) = 7.0 Hz, 6 H, PCHC*H*$_3$]. – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 35.0 (s). – $C_{33}H_{45}ClORuP_2$ (656.2): calcd. C 60.40, H 6.91, Ru 15.40; found C 60.15, H 6.98, Ru 15.34.

Determination of the X-ray Crystal Structure of 7:[20] Single crystals were grown upon cooling of a saturated solution of **7** in toluene from 25 °C to −20 °C. Crystal data (from 5000 reflections, 1.95° < Θ < 26.20°): triclinic; space group *P*-1 (No. 2); *a* = 12.237(3), *b* = 14.039(6), *c* = 15.697(4) Å, α = 85.96(4), β = 76.94(3), γ = 70.33(4)°; *V* = 2474(1) Å^3, *Z* = 2; $d_{calc.}$ = 1.258 gcm^{-3}; μ(Mo-K_α) = 0.555 mm^{-1}; crystal size 0.2 × 0.2 × 0.1 mm; IPDS (STOE), Mo-K_α radiation (0.71073 Å), graphite monochromator; *T* = 173(2) K; φ-scans, max. 2θ = 52.40°; 18792 reflections measured, 9434 independent ($R_{int.}$ = 0.0557), 7477 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz and polarization effects. The structure was solved by the Patterson method (SHELXS-86).[21] Atomic coordinates and the anisotropic thermal parameters of non-hydrogen atoms were refined by full-matrix least squares on F^2 (SHELXL-93).[22] The positions of all hydrogen atoms except of H1 were calculated according to ideal geometry and refined by using the riding method. The position of H1 was located in a final difference Fourier synthesis and refined isotropically without restraints. The asymmetric unit includes one and a half molecules of toluene which were refined anisotropically with restraints. The half molecule was located on the inversion center of the space group. The other molecule of toluene was found disordered and two positions were refined with occupancy factors of 0.646 and 0.354. Conventional $R = 0.0339$ [for 7477 reflections with $I > 2\sigma(I)$], and weighted $wR_2 = 0.0953$ for all 9434 located reflections; reflection/parameter ratio 17.31; residual electron density +0.505/−0.916 eÅ^{-3}.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347) and the Fonds der Chemischen Industrie. We are grateful to the latter in particular for a Kekulé scholarship (to W. S.). Moreover, we thank C. Eichhorn for commited collaboration during an advanced study course. We also thank Dr. W. Buchner and Mrs. M.-L. Schäfer for NMR measurements, Mrs. R. Schedl and Mr. C. P. Kneis for performing the elemental analyses and DTA measurements. Generous support by the BASF AG and the Degussa AG (gifts of chemicals) is also gratefully acknowledged.

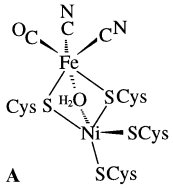
Transition Metal Complexes with Sulfur Ligands, 138[+]

Synthesis, Structures, and Reactions of Sulfur-Rich Nickel and Platinum Complexes with [MS_3] and [MNS_2] Cores

Dieter Sellmann,*[a] Daniel Häußinger,[a] and Frank W. Heinemann[a]



Dedicated to Professor Wolf Peter Fehlhammer on the occasion of his 60th birthday

Keywords: Nickel complexes / Platinum complexes / S ligands / C–S cleavage / Hydride complexes

Nickel and platinum complexes with tridentate ligands, having [S_3] or [NS_2] donor sets were investigated in order to model active sites of enzymes such as hydrogenases or CO dehydrogenases. Starting from diphenyl sulfide, a preparative synthesis was developed for 'S_3'-H_2 ['S_3'-H_2 = bis(2-mercaptophenyl) sulfide]. Reactions of 'S_3'-H_2 or anionic '$S_3'^{2-}$ with nickel and platinum precursors resulted in the formation of binuclear [Ni('S_3')]$_2$ (**1**) and trinuclear [Pt('S_3')]$_3$ (**5**). Complex **1** was cleaved by PMe_3 or CN^- to give the mononuclear complexes [Ni('S_3')(PMe_3)] (**2**) and NMe_4[Ni('S_3')(CN)] (**3**). Attempts to coordinate hydride to the [Ni('S_3')] fragment led to C–S bond cleavage of the ligand and formation of $(NMe_4)_2$[{Ni(μ-SC_6H_5)($S_2C_6H_4$)}$_2$] (**4**). Oxidative addition of Li['S_3'-H] to [Pt(PPh_3)$_4$] afforded the platinum hydride complexes Li[Pt(H)('S_3')] and Li[Pt(H)(PPh_3)('S_3')] which, however, could not be separated from each other and yielded [Pt('S_3')(PPh_3)] (**6**) when treated with MeOH. In order to investigate electronic effects of the donor set, the 'S_3' ligand was modified by alkylation of one thiol group to give 'RS_3'-H derivatives (R = Me, Et, Cy) and by replacing a mercaptophenyl unit by an amine in 'Et_2NS_2'-H ['Et_2NS_2'-H = *N*,*N*-diethyl-2-(2-mercaptothiophenyl)ethylamine]. Reactions of Ni^{II} or Ni^0 compounds with these ligands in a 1:1 ratio yielded the 1:2 complexes [Ni('MeS_3')$_2$] (**7**), [Ni('EtS_3')$_2$] (**9**) and [Ni('CyS_3')$_2$] (**10**), with '$RS_3'^-$ acting as bidentate ligands only. Complex **7** reversibly reacted with PMe_3 to form *cis*-[Ni(PMe_3)$_2$('MeS_3')$_2$] (**8**), exhibiting monodentate 'MeS_3' ligands. [Ni('Et_2HNS_2')$_2$]Br_2 (**11**) reacted reversibly with bases to presumably give octahedral [Ni('Et_2NS_2')$_2$]. Complexes **7**, **9** and **10** also did not yield any [Ni('RS_3')(H)] hydride complex when treated with hydride sources. Oxidative addition of 'CyS_3'-H to [Pt(PPh_3)$_4$] yielded the hydride complexes [Pt(H)('CyS_3')] and [Pt(H)(PPh_3)('CyS_3')] which, however, formed an inseparable mixture and underwent C–S bond cleavage when heated, affording [Pt(*o*-$S_2C_6H_4$)(PPh_3)$_2$]. The molecular structures of **1**, **2**, **3**, **5**, **6**, **7**, and **11** were determined by X-ray crystallography, revealing butterfly-like shapes for the [MS_3L] cores of the complexes.

Introduction

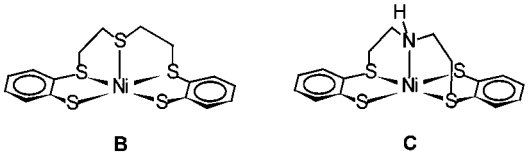
The current interest in nickel thiolate and thioether complexes to a large extent results from the nickel–sulfur moieties that constitute the active centers of enzymes such as hydrogenases[1] or CO dehydrogenases.[2] For example, the X-ray structure analysis of hydrogenase from *D. gigas* has shown that the active site contains nickel surrounded by four cysteine thiolate donors, two of which form bridges to a [Fe(CO)(CN)$_2$] moiety (**A**).[3]

A

The search for hydrogenase model compounds has resulted in a considerable number of new ligands and complexes.[4] However, complexes which model structural *and* functional features of the enzyme centers have remained very rare. These features comprise sulfur coordination of the nickel center *and* catalysis of reactions according to Equations 1a and/or 1b.

$$2\,H^+ + 2\,e^- \rightleftharpoons H_2 \qquad (1a)$$

$$H_2 + D_2O \rightleftharpoons HD + HDO \qquad (1b)$$



Reaction according to Equation 1b requires the heterolytic cleavage of H_2 into H^+ and H^- ions. When this reaction takes place at the nickel–sulfur site of hydrogenases, nickel–sulfur hydride complexes are likely intermediates. Isolable complexes of this type are extremely rare in spite of the large number of nickel hydride complexes carrying phosphane or carbon coligands. Holm et al. reported five-coordinate complexes of the type [Ni(H)-{$N(C_2H_4SR)_3$}]$^+$,[5] and we have obtained four-coordinate [Ni(H)(PMe_3)($S_2C_6H_4$)]$^-$.[6] However, these complexes proved to be extremely moisture-sensitive and could not yet be shown to catalyze the H_2/D^+ exchange according to Equation 1b. Other nickel complexes, e.g., [Ni('S_5')][7] (**B**) or

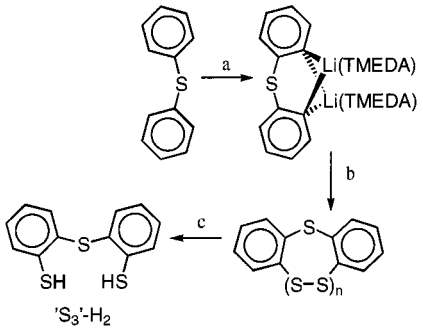
[Ni('N_HS_4')]$_2$[8] (**C**) readily underwent unwanted S−C(alkyl) cleavage reactions when investigated for the coordination of additional hydride ligands from hydride sources such as $LiAlH_4$, $LiBEt_3H$, or $NaBH_4$.[9]

These unwanted C−S cleavages, leading to destruction of the nickel−sulfur cores, drew our attention to the 'S_3'-H_2 ligand and its 'RS_3'-H and 'Et_2NS_2'-H derivatives.



S−C(aryl) bonds are usually more stable than S−C(alkyl) bonds toward reductive S−C cleavage.[10] Furthermore, [Ni('S_3')] fragments formed from Ni^{II} salts and 'S_3'$^{2-}$ were anticipated to provide a readily accessible vacant site for hydride addition. Potential [Ni(H)('S_3')]$^-$ adducts directly compare with [Ni(H)(PMe_3)($S_2C_6H_4$)]$^-$ when the phosphane is exchanged for an isoelectronic thioether ligand. 'S_3'-H_2 is related to the recently described ligands MeN(*o*-$C_6H_4SH)_2$,[11] PhP(*o*-$C_6H_4SH)_2$,[12] PhP($C_2H_4SH)_2$,[13] and P(*o*-$C_6H_4SH)_3$,[14] which also give nickel complexes.

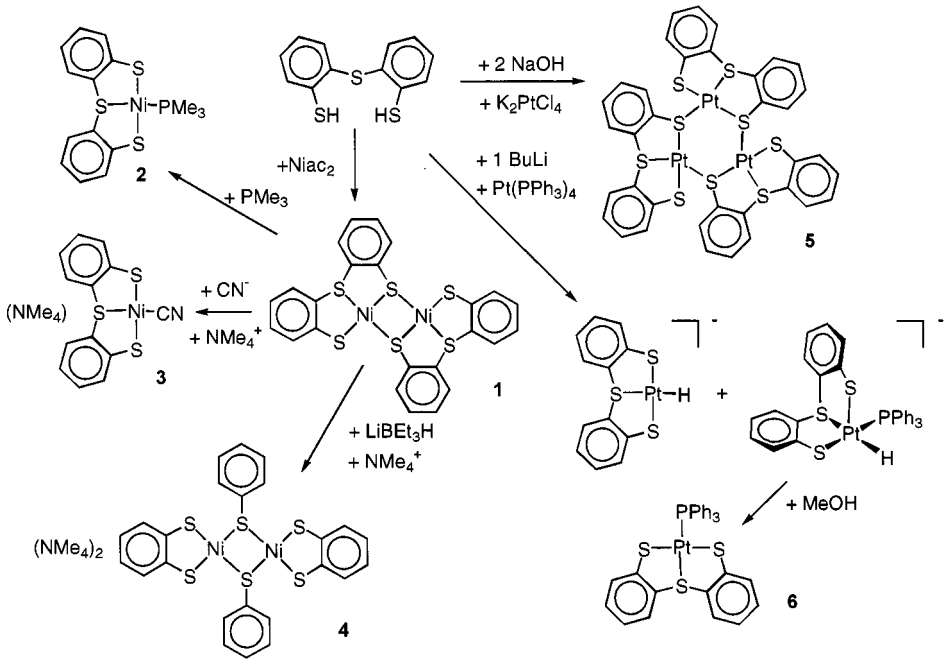
The first synthesis of 'S_3'-H_2, resulting in milligram yields after chromatography, has been reported by Block et al.[15] Therefore, the first goal of our investigations was to find a different approach to this ligand in order to make 'S_3'-H_2 available in preparative gram amounts. Attempts to coordinate 'S_3'$^{2-}$ and biologically relevant coligands such as H^-, H_2, S^{2-}, or CN^- to nickel(II) gave results that prompted us to extend our studies to platinum(II) complexes and the 'S_3' ligand derivatives 'RS_3'-H (R = Me, Et, Cy) and 'Et_2NS_2'-H.

Results and Discussion

Synthesis of 'S_3'-H_2

The target ligand 'S_3'-H_2 formed in a four-step one-pot reaction according to Scheme 1.

Scheme 1. Synthesis of 'S_3'-H_2



Twofold *ortho*-lithiation of diphenyl sulfide [$S(C_6H_5)_2$] with *n*BuLi in hexanes/TMEDA (tetramethylethylenediamine) at room temperature yielded [{Li(TMEDA)}$_2$S($C_6H_4)_2$] (step a), which has recently been characterized by Kranz et al.[16] Subsequent addition of 1.5 equivalents of elemental sulfur (3/8 S_8) gave a mixture of polysulfides in which the lithiated *ortho*-C atoms are bridged by S-chains (step b). Reduction of the S−S bonds was achieved with an excess of $LiAlH_4$ in THF at elevated temperature (70°C). Final acidification with concentrated hydrochloric acid, extraction and recrystallization from boiling THF/hexanes yielded 'S_3'-H_2 as white microcrystals (step c). By this method, 'S_3'-H_2 could be obtained in amounts of up to 10 g, which totaled ca. 20% yield from $S(C_6H_5)_2$.

Further experiments showed that step b of Scheme 1 is crucial for the overall yield. In this step, species such as thianthrene $C_{12}H_8S_2$ whose reduction cannot yield 'S_3'-H_2, are also formed. Addition of EtBr to the mixture resulting from step a yielded bis(2-ethylphenyl) sulfide in 91% yield, demonstrating that the *ortho*-lithiation of diphenyl sulfide had occurred in nearly quantitative yield. Isolation of the extremely moisture-sensitive [{Li(TMEDA)}$_2$S($C_6H_4)_2$] and its subsequent reaction with elemental sulfur did not improve the overall yield. Treatment of the [{Li(TMEDA)}$_2$S($C_6H_4)_2$] solution with S_2Cl_2 resulted only in traces of 'S_3'-H_2.

Nickel(II) and Platinum(II) Complexes of 'S_3'$^{2-}$

Scheme 2 summarizes complexes and their reactions. The reaction of 'S_3'-H_2 with $Ni(ac)_2{\cdot}4H_2O$ yielded brown-black microcrystals of analytically pure [Ni('S_3')]$_2$ (**1**). Complex **1** is air stable, diamagnetic and so sparingly soluble even in hot DMF or DMSO that no meaningful NMR spectra could be recorded. Recrystallization from hot DMF (175°C) in a sealed ampoule yielded single crystals, whose X-ray crystal structure analysis revealed the dinuclear structure of **1**. The nickel centers exhibit a tetrahedrally distorted planar coordination by four sulfur donors. The fourth coordination site in each [Ni('S_3')] fragment is blocked by a thiolate bridge.

In order to investigate the accessibility of this fourth coordination site, suspensions of [Ni('S_3')]$_2$ (**1**) were treated with nucleophiles such as PMe_3, KCN, Li_2S, and N_2H_4 in mixtures of THF/MeOH, THF/MeOH/H_2O, or MeOH/H_2O, which warranted sufficient solubility of the nucleophiles. Although [Ni('S_3')]$_2$ (**1**) is practically insoluble in these solvent mixtures, in all cases rapid reactions occurred. The resulting PMe_3 and KCN reaction products could be fully characterized. Orange [Ni(PMe_3)('S_3')] (**2**), which was obtained in nearly quantitative yield, is diamagnetic, soluble in common organic solvents except pentane or MeOH, and air-stable for longer periods of time. NMR spectra and X-ray structure determination proved that [Ni(PMe_3)('S_3')] is mononuclear in solution and in solid state. The reaction of [Ni('S_3')]$_2$ (**1**) with KCN in MeOH/H_2O rapidly afforded a yellow solution from which, upon addition of NMe_4Cl,

Scheme 2. Synthesis and reactions of nickel(II) and platinum(II) 'S_3'$^{2-}$ complexes

brown NMe_4[Ni(CN)('S_3')] (**3**) precipitated. Complex **3** too, is diamagnetic and was shown to contain a four-coordinate Ni center by X-ray structure analysis.

The reactions of [Ni('S_3')]$_2$ (**1**) with N_2H_4 or Li_2S/NMe_4Cl yielded products whose elemental analyses, IR and NMR spectra indicated the formation of [Ni(N_2H_4)('S_3')] and $(NMe_4)_2$[μ-S{Ni('S_3')}$_2$], respectively. These species, however, could not be obtained in pure form.

Numerous attempts to cleave [Ni('S_3')]$_2$ (**1**) in an analogous way with hydrides, in order to obtain a [Ni(H)('S_3')]$^-$ species, remained unsuccessful. When [Ni('S_3')]$_2$ (**1**) was treated with $LiBEt_3H$ in THF at various temperatures (−90 to −30 °C) or with $NaBH_4$ in MeOH at room temperature, rapid reactions occurred yielding dark-yellow to brown solutions. Addition of NMe_4Cl in MeOH precipitated red-brown microcrystals whose elemental analyses and spectroscopic data were compatible with the dinuclear complex $(NMe_4)_2$[Ni(SC_6H_5)($S_2C_6H_4$)]$_2$ (**4**). Complex **4** is diamagnetic and soluble in DMF or DMSO. The ^{1}H- and ^{13}C-NMR spectra of **4** revealed that the 'S_3' ligand of **1** had been cleaved into thiophenolate and 1,2-benzenedithiolate ligands. The ESI mass spectrum of **4** showed a peak at *m*/*z* = 306.9 which was assigned to the dinuclear anion of **4** (calculated for $^{12}C_{24}{}^1H_{18}{}^{58}Ni_2{}^{32}S_6$: *m*/*z* = 306.922). The formation of **4** was corroborated by its independent synthesis from Ni^{2+}, $LiSC_6H_5$, $Li_2S_2C_6H_4$, and NMe_4Cl, yielding the identical compound. C−S bond cleavage in the 'S_3' ligand was also observed when mononuclear [Ni(PMe_3)('S_3')] (**2**) was treated with $LiBEt_3H$ or $NaBH_4$. [Ni('S_3')]$_2$ (**1**) did not react with molecular hydrogen at standard pressure or with equimolar amounts of hydrochloric acid. Excess hydrochloric acid hydrolyzed **1** to give $NiCl_2$ and free 'S_3'-H_2.

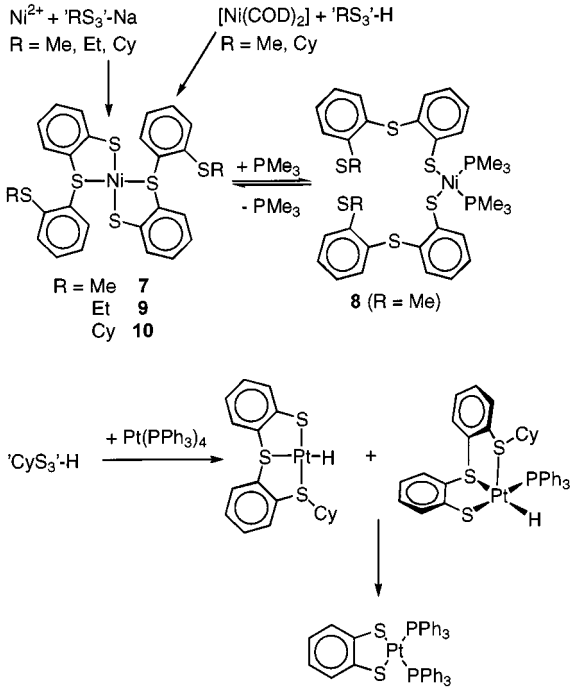
The synthesis of 'S_3'-H_2 demonstrates that 'S_3'$^{2-}$ is stable for longer periods of time in the presence of $LiAlH_4$ at elevated temperatures. Therefore the C−S bond cleavage by hydride reagents in nickel-coordinated 'S_3'$^{2-}$ is remarkable. It indicates a considerable activation of either the 'S_3' ligand or the hydrides by coordination to nickel(II). Following the tenet of coordination chemistry that the heavier homologues are frequently more stable, we also investigated reactions of 'S_3'-H_2 with platinum(II).

The reaction between K_2PtCl_4 and Na_2-'S_3' in H_2O yielded red [Pt('S_3')]$_3$ (**5**) besides other products. Its trinuclear structure was elucidated by X-ray diffraction. [Pt('S_3')]$_3$ (**5**) could also be obtained from [$PtCl_2$(COD)] and 'S_3'-H_2 in THF.[17] [Pt('S_3')]$_3$ (**5**) is air-stable and slightly more soluble than [Ni('S_3')]$_2$ (**1**), not only in DMF and DMSO, but also in THF and CH_2Cl_2. Treatment of [Pt'S_3']$_3$ (**5**) in THF with $LiBEt_3H$ at room temperature yielded yellow solutions. The ^{1}H-NMR spectra of these solutions indicated that the [Pt('S_3')] fragments had remained intact, but they showed no signals which could be assigned to a [Pt(H)('S_3')]$^-$ species. The viability of such a species, however, could be demonstrated when 'S_3'-H_2 was monodeprotonated with one equivalent of *n*BuLi and the resulting Li['S_3'-H] subsequently reacted with [Pt(PPh_3)$_4$]. By oxidative addition of the remaining SH moiety of Li['S_3'-H] to the Pt^0 center, a mixture of two hydride complexes resulted. They could be isolated in solid state, identified by their ^{1}H-NMR hydride resonances and coupling constants as Li[Pt(H)(PPh_3)('S_3')] [δ(PtH) = −10.65] and Li[Pt(H)('S_3')] [δ(PtH) = −15.72]. The Pt−H bonds were also indicated by the IR spectra showing ν(Pt−H) bands at 2109 cm^{-1} in KBr and 2127 cm^{-1} in dioxane. However these two complexes could not be separated because they exhibit practically identical solubilities. Attempts to separate the two complexes by fractional crystallization from THF/MeOH yielded only very few single orange crystals

of the hydride-free [Pt(PPh_3)('S_3')] (**6**), whose structure was determined by X-ray crystallography.

Synthesis of 'RS_3'-H Ligands (R = Me, Et, Cy) and 'RS_3' Nickel(II) and Platinum(II) Complexes

The 'RS_3'-H ligands were synthesized in order to investigate the influence of different donor sets (thioether vs. thiolate), charge (neutral vs. anionic), and sterical requirements (small vs. large R substituents) on the stability of potential nickel and platinum hydride complexes with S_3 donor sets. Selective monoalkylation of dithiols having equivalent thiol functions is not trivial,[18] and this also became apparent in the 'RS_3'-H synthesis. Alkylation of [Ni('S_3')] complexes was considered the most promising method, because previous alkylations of $[Ni(S_2C_6H_4)_2]^{2-}$ complexes had selectively yielded the monoalkylated 1,2-benzenedithiol derivatives, 1,2-C_6H_4(SH)(SR), in straightforward reactions.[19]



In contrast to these reactions, the alkylation of [Ni('S_3')]$_2$ (**1**) or [Ni(PMe_3)('S_3')] (**2**) with R_3OBF_4 (R = Me, Et) yielded mixtures of complexes that contained not only the monoalkylated target ligand 'RS_3'$^-$ but to a minor extent also dialkylated 'R_2S_3' species as well as the non-alkylated 'S_3'$^{2-}$ starting ligand. However, acidic hydrolysis of the complexes with aqueous HCl and subsequent purification of the resulting mixture of 'RS_3'-H, 'R_2S_3', and 'S_3'-H_2 species by repeated alkaline and acidic extractions yielded 'MeS_3'-H and 'EtS_3'-H in sufficient purity to be unambiguously identified by ^{1}H-NMR spectroscopy and used for the synthesis of complexes.

Alkylation of [Ni('S_3')] complexes by cyclohexyl bromide or tosylate proved impossible, probably due to steric hindrance. The "direct" alkylation of the monolithium salt Li['S_3'-H] with cyclohexyl bromide under drastic conditions (DMF, 125°C, 6 h) and acidic workup gave a mixture of 'CyS_3'-H, 'Cy_2S_3', and 'S_3'-H_2. Repeated extractions of this mixture, similar to those described above, yielded the 'CyS_3'-H target ligand in sufficient purity for identification and synthesis of complexes.

The ligating properties of the 'RS_3'$^-$ and 'S_3'$^{2-}$ ligands towards Ni^{II} differed more than expected. In all structurally characterized complexes, the 'RS_3' ligands acted as bidentate or even monodentate ligands only (Scheme 3).

The 1:1 reaction between Ni^{II} salts and Na['MeS_3'] gave the 1:2 complex [Ni('MeS_3')$_2$] (**7**). The identical complex was obtained in the attempt to coordinate 'MeS_3'-H to [Ni(1,5-cyclooctadiene)$_2$] in a 1:1 oxidative addition reaction. [Ni('MeS_3')$_2$] (**7**) is almost insoluble in all common solvents, but could be characterized by X-ray diffraction.

In an attempt to remove one 'MeS_3' ligand from [Ni('MeS_3')$_2$] (**7**) with PMe_3 in order to achieve a tridentate coordination of the remaining 'MeS_3', an excess of PMe_3 was required to achieve a reaction. However, this reaction did not yield the target complex [Ni(PMe_3)('MeS_3')] but [Ni(PMe_3)$_2$('MeS_3')$_2$] (**8**). The structure of **8** was concluded from elemental analysis and the ^{1}H-NMR spectrum showing one PMe_3 doublet and one set of eight aromatic signals for the

Scheme 3. Synthesis and reactions of nickel and platinum 'RS_3'$^-$ complexes

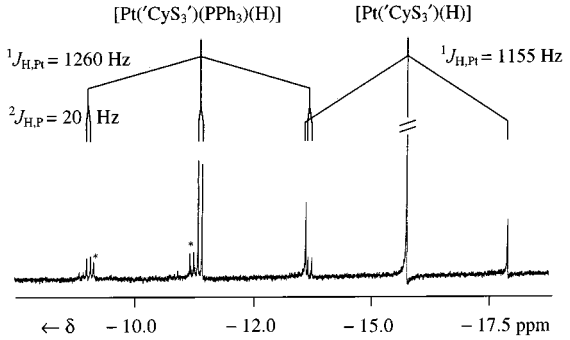
'MeS_3' ligand. One of the aromatic signals is split into a doublet of pseudotriplets by a long-range coupling to ^{31}P ($^5J_{H,P}$ = 2.6 Hz). This clearly indicates the postulated *cis* isomer of **8**, as strong coupling over five bonds can only take place along a W-shaped backbone, where the phosphane ligand is *trans* to the thiolate. The PMe_3 addition is reversible. Attempts to crystallize **8** from a $CDCl_3$ solution yielded PMe_3-free [Ni('MeS_3')$_2$] (**7**) in the course of three weeks.

'EtS_3'$^-$ was anticipated to give more soluble complexes. Indeed, [Ni('EtS_3')$_2$] (**9**), resulting from the 1:1 reaction between Ni^{II} salts and 'EtS_3'$^{2-}$, proved sufficiently soluble for recording ^{1}H-NMR spectra. They show only one set of 'EtS_3' signals indicating that [Ni('EtS_3')$_2$] (**9**) is structurally analogous to [Ni('MeS_3')$_2$] (**7**).

'CyS_3'$^-$ yielded complexes that were even more soluble. However, also with 'CyS_3'$^-$ only the 1:2 complex [Ni('CyS_3')$_2$] (**10**) could be obtained. It likewise resulted from Ni^{II} salts and 'CyS_3'-H, and oxidative addition reactions of 'CyS_3'-H with [Ni($CO)_4$], [Ni(phen)$_2$], or [Ni(PMe_3)$_4$]. Intermediate nickel hydride species such as [Ni(H)('CyS_3')] could not be detected.

Metal hydride species were observed with platinum, but again only as inseparable mixtures of at least two complexes. The oxidative addition of 'CyS_3'-H to [Pt(PPh_3)$_4$] gave a mixture of [Pt(H)('CyS_3')] and [Pt(H)(PPh_3)('CyS_3')], which were identified by their ^{1}H-NMR hydride signals at δ = −15.74 [$^1J(^{195}Pt-H)$ = 1155 Hz] and δ = −11.38 [$^1J(^{195}Pt-H)$ = 1260 Hz], respectively (Figure 1). The hy-

dride signals of [Pt(H)(PPh_3)('CyS_3')] are split into doublets by coupling to ^{31}P [^2J(H,P) = 20 Hz].



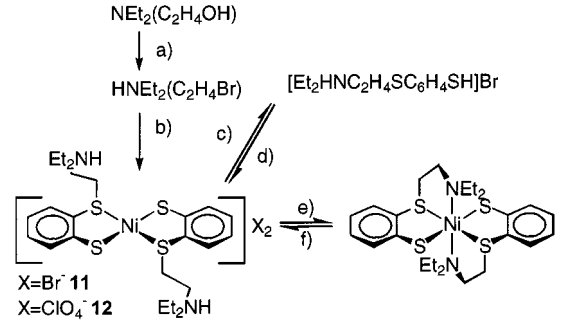


Figure 1. High-field region of the ^{1}H-NMR spectrum (270 MHz, [D_8]THF) of a mixture of [Pt('S_3')(PPh_3)(H)] and [Pt('S_3')(H)] (* denotes impurities)

Heating the mixtures in order to remove the PPh_3 ligand from [Pt(H)(PPh_3)('CyS_3')] resulted in C–S cleavage of the CyS_3 ligand, loss of the hydride ligands and formation of [$Pt(PPh_3)_2(S_2C_6H_4)$], which was characterized by elemental analysis and ^{1}H-NMR spectroscopy.

Synthesis and Reactions of [Ni('Et_2HNS_2')$_2$]$^{2+}$

In order to investigate the influence of amine vs. thioether donors, the tridentate amine–thioether–thiol ligand 'Et_2NS_2'-H was synthesized (Scheme 4).

Scheme 4. Synthesis and reactions of [Ni('Et_2HNS_2')$_2$]$^{2+}$: a) + PBr_3/HBr; b) + [$Ni(S_2C_6H_4)_2$]$^{2-}$; c) + HBr; d) + $Ni(ClO_4)_2 \cdot 6H_2O$; + *n*BuLi; f) + H_2O

Bromination of [$NEt_2(C_2H_4OH)$] with PBr_3 yielded $NEt_2(C_2H_4Br)$ as the ammonium salt [$NHEt_2(C_2H_4Br)$]Br. Subsequent treatment of the benzenedithiolate complex [$Ni(S_2C_6H_4)_2$]$^{2-}$ with [$NHEt_2(C_2H_4Br)$]Br gave [Ni('Et_2HNS_2')$_2$]Br_2 (**11**), which could be hydrolyzed with aqueous HBr to yield the ammonium bromide derivative ['Et_2HNS_2'-H]Br. Twofold deprotonation of ['Et_2HNS_2'-H]Br and reaction with either 0.5 or 1 equivalent of $Ni(ClO_4)_2 \cdot 6H_2O$ in both cases yielded the 1:2 complex [Ni('Et_2HNS_2')$_2$]$(ClO_4)_2$ (**12**). The reaction of [Ni('Et_2HNS_2')$_2$]$(ClO_4)_2$ suspensions in THF with 2 equivalents of strong bases such as BuLi or $LiBEt_3H$ reversibly gave dark-red solutions. They presumably contain [Ni('Et_2NS_2')$_2$] with six-coordinate Ni centers. However, a 1:1 complex containing [Ni('Et_2NS_2')] fragments could not be obtained.

X-ray Structure Determinations

X-ray structural characterizations allowed for the determination of the molecular structure of a considerable number of complexes and to confirm conclusions drawn from spectroscopic data. Figure 2 shows the molecular structures of [Ni('S_3')]$_2$ (**1**), [Ni(PMe_3)('S_3')] (**2**), NMe_4[Ni('S_3')CN)]·$0.5CH_2Cl_2$ (**3**·$0.5CH_2Cl_2$), [Ni('MeS_3')$_2$] (**7**), [Pt('S_3')(PPh_3)] (**6**), [Pt('S_3')]$_3$·2THF·MeOH, (**5**·2THF·MeOH), and [Ni('Et_2HNS_2')$_2$]Br_2 (**11**). Table 1 lists selected distances and angles.

All compounds consist of discrete molecules or ions. The solvate molecules do not interact with the metal complexes. [Ni('S_3')]$_2$ (**1**), [Ni('MeS_3')$_2$] (**7**), and [Ni('Et_2HNS_2')$_2$]Br_2 (**11**) exhibit crystallographically required inversion symmetry. In all complexes, the metal centers are four-coordinate, adopting distorted planar configurations. [Ni('S_3')]$_2$ (**1**), [Ni(PMe_3)('S_3')] (**2**), and [Ni(CN)('S_3')]$^-$ (**3**) exhibit a distinct tetrahedral distortion, whereas the platinum coordination of [Pt('S_3')]$_3$ (**5**) and [Pt(PPh_3)('S_3')] (**6**) is close to ideal square-planar.

The distances and angles are in the usual range found in diamagnetic nickel(II) and platinum(II) thioether–thiolate complexes. It is worth noting, however, that the Ni–S(thioether) distances of [Ni('S_3')]$_2$ (**1**) [210.3(3) pm], [Ni(PMe_3)('S_3')] (**2**) [213.8(2) pm], and [Ni(CN)('S_3')]$^-$ (**3**) [212.4(1) pm] are short and smaller than the respective Ni–S(thiolate) distances. Ni–S(thioether) distances in comparable complexes are usually in the range of ca. 217–218 pm,[20] and Ni–S distances in nickel thioether–thiolate complexes frequently do not differ at all.[21] If they differ, the Ni–S(thioether) distances are longer than the Ni–S(thiolate) distances.[22] It is remarkable that even in [Ni(PMe_3)('S_3')] (**2**) and [Ni(CN)('S_3')]$^-$ (**3**), the Ni–S(thioether) distances are short despite of the coordination *trans* to PMe_3 or CN^-, respectively, which are ligands known to have a strong *trans* influence.[23] The same holds true for the platinum complex [Pt('S_3')(PPh_3)] (**6**).[24] The short M–S(thioether) distances can be rationalized by the topology and rigidity of the 'S_3' ligand leading to rigid annellated five-membered [MSCCS] rings that force the thioether donors close to the metal centers. The rigidity of the 'S_3' ligand and sp^3 hybridization of the thioether donor further lead to the particular geometry of the [M('S_3')] fragments. They all exhibit a butterfly-like shape as illustrated by Figure 3.

In [Ni('S_3')]$_2$ (**1**), two such fragments are bridged by thiolate donors. The resulting four-membered [Ni_2S_2] ring is folded along the [S–S] axis such that the Ni(1)–Ni(1a) distance is 273.2(4) pm, and the molecule adopts a bowl-like shape (Figure 4).

A comparable Ni–Ni distance is found in [$Ni(SC_2H_4SC_2H_4S)]_2$ (273.9 pm).[25] These distances are significantly longer than Ni–Ni distances in nickel metal (249.2 pm)[26] and complexes such as [$Ni_8S(t$BuS$)_9$] (244.4 and 247.1 pm),[27] [$Ni(PhC(O)S)_2]_2$ (249 pm)[28] or [Ni(1,3-diphenyltriazenido)$_4]_2$ (238 pm),[29] for which Ni–Ni bonds

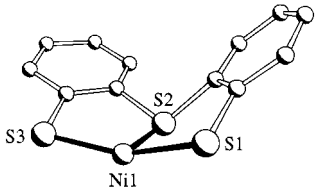

Figure 3. [Ni('S_3')] fragment in [Ni(PMe_3)('S_3')] (**2**)

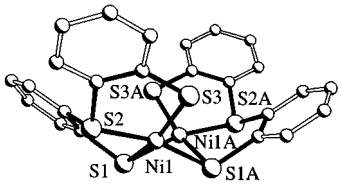

Figure 4. Lateral view of [Ni('S_3')]$_2$ (**1**)

are discussed. However, even Ni−Ni distances of 276.3(3) pm[30] and 279.5(3) pm[31] have been assumed to indicate weak Ni−Ni interactions. The trinuclear [Pt('S_3')]$_3$ (**5**) exhibits a cyclohexane-like [PtS_3]$_3$ six-membered ring with chair conformation. The Pt−S−Pt thiolate bridges are nearly symmetrical. Related structures are found in [$Pd(SC_2H_4SC_2H_4S)$]$_3$,[25b] [Ni('μ-$S_2C_3Me_2$')$_3$],[32] and [Ni('tBuS$_4$')]$_3$.[33]

The structures of [Ni('MeS_3')$_2$] (**7**) and [Ni('Et_2HNS_2')$_2$]Br_2 (**11**) unambiguously show that the potentially tridentate ligands only serve as bidentate ligands. The S(1) and S(1a) thioether donors of [Ni('MeS_3')$_2$] (**7**) occupy approximately apical positions in a distorted octahedron, but the Ni−S(1) and Ni−S(1a) distances [333.8(3) pm] are significantly larger than the sum of the van der Waals radii (310 pm)[26] and exclude Ni−S bonding interactions.

Conclusion

The objective of this work was to find nickel−sulfur ligand complexes that are stable towards reductive C−S cleavage and offer vacant sites for the coordination of hydrogenase-relevant small molecules. To achieve this goal, syntheses of 'S_3'-H_2, 'RS_3'-H (R=Me, Et, Cy), and 'Et_2NS_2'-H have been developed. X-ray structure analyses of the resulting nickel(II) and platinum(II) complexes have established the structural basis for reactivity studies.

Nickel(II) coordination by 'S_3'$^{2-}$ gave binuclear [Ni('S_3')]$_2$ (**1**) and platinum(II) formed trinuclear [Pt('S_3')]$_3$ (**5**). The [Ni('S_3')] fragment is robust and yielded stable [Ni(L)('S_3')] adducts with coligands such as PMe_3 and CN^-. In this respect, the [Ni('S_3')] fragment contrasts with other nickel thioether−thiolate complexes in which the ligands are decoordinated by cyanide.[34] The [Ni('S_3')] fragment probably also adds hydride. However, nickel-coordinated 'S_3'$^{2-}$ is unstable towards hydride reagents such as $LiAlH_4$ or $LiBEt_3H$. They cleaved the 'S_3'$^{2-}$ ligand into thiophenolate and 1,2-benzenedithiolate that formed [{Ni(SC_6H_5)($S_2C_6H_4$)}$_2$]$^{2-}$. This putatively indicates that in the reaction between [Ni('S_3')] fragments and hydride sources, highly reactive [Ni(H)('S_3')]$^-$ species form because 'S_3'$^{2-}$ in the free state is stable towards $LiAlH_4$, even under vigorous reaction conditions. While no [M(H)('S_3')]$^-$ species with M = Ni could be identified, a [Pt(H)('S_3')]$^-$ complex was detected by ^{1}H-NMR spectroscopy and isolated in the solid state. However, it could not be separated from [Pt(H)(PPh_3)('S_3')]$^-$ complexes which were formed concomitantly. Modification of 'S_3'$^{2-}$ by alkylating one thiolate donor gave the new ligands 'RS_3'-H with R = Me, Et, Cy. When coordinated to nickel(II), these ligands act as bidentate ligands only. Under all applied conditions, exclusively 1:2 complexes of the general formula [Ni('RS_3')$_2$] resulted, in which the RS-thioether donors do not coordinate.

[Ni('RS_3')] hydride complexes could not be detected. In contrast, when [Pt(PPh_3)$_4$] was treated with 'CyS_3'-H, ^{1}H-NMR spectroscopy revealed the formation of [Pt(H)('CyS_3')]. The concomitant formation of the equally highly soluble [Pt(H)(PPh_3)('CyS_3')] prevented the isolation in pure form. Additionally, the platinum-bonded hydride appears to be still highly reactive, because at elevated temperatures 'CyS_3' cleavage and formation of [Pt(PPh_3)$_2$($S_2C_6H_4$)] took place.

Modification of the 'RS_3'-H ligands by exchanging the RSC_6H_4 entity for $NEt_2(C_2H_4)$ gave the new ligand 'Et_2NS_2'$^-$. It formed the 1:2 nickel complex [Ni('Et_2HNS_2')$_2$]Br_2 (**11**) in which the two amine N atoms are protonated.

In conclusion, the tridentate sulfur ligand 'S_3'$^{2-}$ forms nickel(II) and platinum(II) complexes whose [M('S_3')] fragments coordinate coligands such as PR_3, CN^-, and H^-. The resulting [M(H)('S_3')]$^-$ species were detectable with platinum(II). The alkylated derivatives 'RS_3' preferably act as bidentate ligands and give the 1:2 complexes [Ni('RS_3')$_2$]. Current studies are probing the interaction of molecular hydrogen with the new complexes.

Experimental Section

General Methods: Unless otherwise noted, all reactions and operations were carried out under nitrogen at room temperature using standard Schlenk techniques. Solvents were dried and distilled before use. As far as possible, reactions were monitored by IR or NMR spectroscopy. − Spectra were recorded with the following instruments: IR (KBr pellets or CaF_2 cuvettes, solvent bands were compensated): Zeiss IMR 25 and Perkin−Elmer 983. − NMR: Jeol JNM-GX 270 and Jeol JNM-EX 270; with the residual protiosolvent signal used as reference for ^{1}H-NMR spectra. $^{13}C\{^1H\}$-NMR spectra were referenced using the solvent peaks, $^{31}P\{^1H\}$-NMR spectra were referenced externally. Chemical shifts are quoted on the δ scale (downfield shifts are positive) related to tetramethylsilane (^{1}H, ^{13}C) or 85% H_3PO_4 (^{31}P). Spectra were recorded at room temperature unless stated otherwise. ^{1}H: 270.0 MHz, $^{13}C\{^1H\}$; 67.8 MHz, $^{31}P\{^1H\}$: 109.4 MHz. − Mass spectra: Varian MAT 212 spectrometer and Jeol M.Station 700. − Elemental analyses: Carlo Erba EA 1106 or 1108 analyzer. − $S(C_6H_5)_2$ and *n*BuLi (2.5 M in hexanes) were purchased from Aldrich. 'S_2'-H_2,[35] [Pt(PPh_3)$_4$],[36] [Pt(PEt_3)$_4$],[37] and [$PtCl_2$(COD)][38] were prepared by literature methods.

'S_3'-H_2: At room temperature, TMEDA (38 mL, 253 mmol), a solution of *n*BuLi in hexanes (2.5 M, 100 mL, 250 mmol) and diphenyl sulfide (20 mL, 118 mmol) were successively added to 200 mL of hexanes. The solution was stirred for 24 h, in the course of which a beige solid precipitated. Under vigorous stirring elemental sulfur (10.8 g, 337 mmol) was added, the resulting yellow suspension was stirred for another 48 h, and concentrated to dryness. The yellow residue was dissolved in THF (200 mL) and $LiAlH_4$ (10.0 g, 264 mmol) was added in small portions. ***Caution:*** *A vigorous reaction takes place and the reaction suspension starts foaming up.* Subsequently, the reddish suspension was heated at reflux for 5 h, in the course of which the color turned to light yellow green. The resulting mixture was cautiously added in small portions to a mixture of crushed ice (400 g) and concentrated hydrochloric acid (200 mL). ***Caution:*** *A vigorous evolution of* H_2 and H_2S occurs, and this reaction must be carried out in a well-ventilated hood. After the vigorous reaction had ceased, a further 50 mL of concentrated HCl was added, and the resulting suspension was extracted with of CH_2Cl_2 (3 × 200 mL). The combined organic phases were washed with dilute aqueous HCl, dried with Na_2SO_4, and concentrated to dryness. The reddish yellow waxy residue was digested with Et_2O (ca. 200 mL) until an ivory solid resulted. It was separated, recrystallized from hot THF/hexanes to give brilliant white 'S_3'-H_2. Yield: 6.5 g [22% from $S(C_6H_5)_2$]. − $C_{12}H_{10}S_3$ (250.41): calcd. C 57.56, H 4.03, S 38.42; found C 57.74, H 4.06, S 38.72. − MS (FD, CCl_4); *m/z*: 250 [M$^+$]. − ^{1}H NMR ($CDCl_3$): δ = 7.45−7.35 (m, 2 H, C_6H_4), 7.25−7.0 (m, 6 H, C_6H_4), 4.10 (s, 2 H, SH). − ^{1}H NMR (C_6D_6): δ = 7.01 (m, 2 H, H6-C_6H_4), 6.96 (m, 2 H, H3-C_6H_4), 6.68 (m, 2 H, H4-C_6H_4), 6.63 (m, 2 H, H5-C_6H_4), 3.81 (m, 2 H, SH).

– $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 135.6, 132.9, 130.8, 128.9, 127.2 (C_6H_4). – $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 135.7 (C2-C_6H_4), 132.8 (C1-C_6H_4), 132.5 (C6-C_6H_4), 130.2 (C3-C_6H_4), 128.2 (C4-C_6H_4), 126.5 (C5-C_6H_4). – IR (KBr): $\tilde{\nu}$ = 3052, 2555, 1565, 1445, 1426, 1259, 1035, 745 cm^{-1}.

[Ni('S_3')]$_2$ (1): 'S_3'-H_2 (2.450 g, 9.78 mmol) in THF (30 mL) was added dropwise to a solution of $Ni(ac)_2{\cdot}4H_2O$ (2.435 g, 9.78 mmol) in MeOH (50 mL). A brown precipitate formed which was separated, washed with MeOH (50 mL) and recrystallized from boiling DMF to give black microcrystals of **1**. Yield: 2.73 g (91%). – $C_{24}H_{16}Ni_2S_6$ (614.17): calcd. C 46.94, H 2.63, S 31.33; found C 46.81, H 2.56, S 30.83. – IR (KBr): $\tilde{\nu}$ = 3050, 1561, 1443, 1425, 1093, 759, 747, 740, 729 cm^{-1}.

[Ni('S_3')(PMe_3)] (2): PMe_3 (370 mg, 4.86 mmol) was added to a brown suspension of [Ni('S_3')]$_2$ (**1**) (1.065 g, 1.73 mmol) in THF (5 mL) and a dark brown solution formed. Addition of MeOH (40 mL) precipitated orange microcrystals that were separated, washed with MeOH (40 mL) and dried. Yield: 1.25 g (94%). – $C_{15}H_{17}NiPS_3$ (383.16): calcd. C 47.02, H 4.47, S 25.11; found C 47.11, H 4.46, S 24.57. – ^1H NMR (C_6D_6): δ = 7.55 (d, 2 H, H6-C_6H_4), 7.28 (d, 2 H, H3-C_6H_4), 6.82 (m 2 H, H5-C_6H_4), 6.65 (m, 2 H, H4-C_6H_4), 0.93 [d, $^2J_{H,P}$ = 10.9 Hz, 9 H, $P(CH_3)_3$]. – $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ = 152.5 (d, $^3J_{P,C}$ = 14.0 Hz, C_6H_4) 133.3, 130.5, 129.4, 128.3, 123.5 (C_6H_4), 14.9 [d, $^1J_{P,C}$ = 30.6 Hz, $P(CH_3)_3$]. – $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 153.6 (d, *trans*-$^3J_{P,C}$ = 14.1 Hz, C1-C_6H_4), 133.3 (d, *cis*-$^3J_{P,C}$ = 2.0 Hz, C2-C_6H_4), 130.1 (d, $^4J_{P,C}$ = 1.7 Hz, C6-C_6H_4), 128.7 (s, C5-C_6H_4), 128.1 (d, $^4J_{P,C}$ = 1.2 Hz, C3-C_6H_4), 122.6 (s, C4-C_6H_4), 13.5 [d, $^1J_{P,C}$ = 30.6 Hz, $P(CH_3)_3$]. – $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ = –9.2 [$P(CH_3)_3$]. – IR (KBr): $\tilde{\nu}$ = 3040, 2960, 1564, 1444, 1425, 1096, 950, 735 cm^{-1}.

(NMe_4)[Ni('S_3')(CN)] (3): A solution of KCN (141.5 mg, 2.17 mmol) in a mixture of MeOH (10 mL) and H_2O (1 mL) was added dropwise to a brown suspension of [Ni('S_3')]$_2$ (**1**) (650 mg, 1.06 mmol) in THF (10 mL). The resulting yellow green solution was concentrated to dryness, and the remaining solid was redissolved in MeOH (20 mL) and H_2O (1 mL). The solution was filtered, combined with NMe_4Cl (220 mg, 2.0 mmol) in MeOH (2 mL), and layered with Et_2O (20 mL). Brown crystals precipitated, which were separated after 7 d, washed with Et_2O and dried in vacuo. Yield: 520 mg (60%).– $C_{17}H_{20}N_2NiS_3$ (407.26) calcd. C 50.14, H 4.95, N 6.88; found C 45.58, H 4.36, N 5.98. – ^1H NMR ([D_6]acetone/$CDCl_3$): δ = 7.36 (d, 2 H, C_6H_4), 7.03 (d, 2 H, C_6H_4), 6.78 (m, 2 H, C_6H_4), 6.68 (m, 2 H, C_6H_4), 2.92 [12 H, s, $N(CH_3)_4$]. – IR (KBr): $\tilde{\nu}$ = 3050, 3026, 2110, 1569, 1482, 1441, 1431, 948, 733 cm^{-1}.

(NMe_4)$_2$[{Ni(SC_6H_5)($S_2C_6H_4$)}$_2$] (4). – a) From [Ni('S_3')]$_2$ and $LiBEt_3H$: At –90°C, $LiBEt_3H$ (3 mL of a 1 M THF solution, 3 mmol) was added to a brown suspension of [Ni('S_3')]$_2$ (**1**) (615 mg, 1.0 mmol) in THF (15 mL). When the temperature was slowly raised to –30°C, a yellow–green solution formed. It was layered with a cold solution of NMe_4Cl (0.329 g, 3.0 mmol) in MeOH (15 mL) and kept at –30°C for 3 d. Red-brown microcrystals precipitated which were separated, washed with MeOH, and dried in vacuo. Yield: 340 mg (45%). – **b) From Ni(ac)$_2$·4H$_2$O, $SC_6H_5^-$, and *o*-$S_2C_6H_4^{2-}$:** A solution of thiophenol (1.10 g, 10 mmol) and LiOMe (380 mg, 10 mmol) in MeOH (10 mL) was added to $Ni(ac)_2{\cdot}4H_2O$ (2.48 g, 10 mmol) in MeOH (40 mL). A red-brown suspension resulted, which was combined with a solution of *o*-$C_6H_4(SH)_2$ (1.42 g, 10 mmol) and LiOMe (760 mg, 20 mmol) in MeOH (20 mL), stirred for 2 h and concentrated to dryness. Addition of DMF (40 mL) to the residue and heating the suspension to 100°C for 2 h gave a clear brown solution, which was reduced in volume to 10 mL. Addition of Me_4NCl (1.095 g, 10 mmol) in MeOH (50 mL) at room temperature precipitated red-brown microcrystals which were separated, washed with MeOH (45 mL) and Et_2O (20 mL), and dried in vacuo. Yield: 3.06 g (80%). – $C_{32}H_{42}N_2Ni_2S_6$ (764.51): calcd. C 50.28, H 5.54, N 3.66, S 25.16; found C 47.16, H 5.38, N 3.23, S 23.42. – MS (ESI, MeOH) ([$^{12}C_{24}{}^1H_{18}{}^{58}Ni_2{}^{32}S_6$]$^{2-}$); *m/z*: calcd. 306.922; found 306.9. – ^1H NMR ([D_6]DMSO): δ = 8.22 (m, 4 H, C_6H_5), 7.05 (m, 6 H, C_6H_5), 6.80 (m, 4 H, C_6H_4), 6.40 (m, 4 H, C_6H_4), 3.07 [s, 24 H, $N(CH_3)_4$]. – $^{13}C\{^1H\}$ NMR ([D_6]DMSO): δ = 150.0, 139.8, 134.8, 126.8, 125.5, 124.3, 118.7 (C_6H_5, C_6H_4), 54.35 [t, $^1J_{C,N}$ = 4.2 Hz, $N(CH_3)_4$]. – IR (KBr): $\tilde{\nu}$ = 3045, 3007, 1571, 1542, 1479, 1433, 1282, 1233, 1101, 1021, 948, 743, 692, 665 cm^{-1}.

[Pt('S_3')]$_3$ (5). – a) From K_2PtCl_4 and 'S_3'-H_2: A solution of K_2PtCl_4 (1.06 g, 2.55 mmol) in H_2O (20 mL) was combined with a solution of 'S_3'-H_2 (640 mg, 2.55 mmol) in aqueous NaOH (51 mL of a 0.1 M solution, 5.1 mmol). A yellow suspension resulted which was stirred at 50°C for 2 h. The yellow solid was separated, washed with H_2O (40 mL), dried at 50°C, and extracted with THF (20 mL). The red THF extracts were filtered and layered with MeOH to give yellow-red crystals of [Pt('S_3')]3·2THF·MeOH. – ^1H NMR ([D_8]THF): δ = 7.95–6.40 (m, C_6H_4). – **b) From [$PtCl_2$(COD)] and 'S_3'-H_2:**[17] Solid 'S_3'-H_2 (865 mg, 3.46 mmol) was added to a solution of [$PtCl_2$(COD)] (1.293 g, 3.46 mmol) in THF (20 mL) and the resulting solution was stirred for 12 h. A yellow precipitate formed which was isolated, washed with THF (10 mL) and dried in vacuo. Yield: 1.24 g (81%). – $C_{36}H_{24}S_9Pt_3$ (1330.44): calcd. C 32.50, H 1.82; found C 32.54, H 1.95.

Li[Pt('S_3')(H)], Li[Pt('S_3')(H)(PPh_3)], and [Pt('S_3')(PPh_3)] (6): *n*BuLi (0.4 mL of a 2.5 M solution in hexanes, 1.0 mmol) was added to a solution of 'S_3'-H_2 (250 mg, 1.0 mmol) in THF (10 mL), and a pale yellow solution resulted, which was added dropwise to a suspension of [$Pt(PPh_3)_4$] (1.24 g, 1.0 mmol) in THF (30 mL). A yellow-orange solution resulted and was stirred for 1 h at 70°C and concentrated to dryness. The orange residue was extracted with warm hexanes (120 mL) in several portions and the remaining pale yellow powder was isolated and dried in vacuo. It was characterized by ^1H-NMR spectroscopy to be a mixture of Li[Pt('S_3')(H)], Li[Pt('S_3')(H)(PPh_3)] and some remaining PPh_3. – ^1H NMR ([D_8]THF): δ = 7.93–6.62 (m, C_6H_4/C_6H_5), –10.65 {d + dd, $^1J_{H,Pt}$ = 1274 Hz, $^2J_{H,P}$ = 21 Hz, Pt*H* in Li[Pt('S_3')(*H*)(PPh_3)]}, –15.72 {s + d, $^1J_{H,Pt}$ = 1242 Hz, Pt*H* in Li[Pt('S_3')(*H*)]}. – IR (KBr): $\tilde{\nu}$ = 2109 cm^{-1} (ν_{PtH}); (*p*-dioxane): $\tilde{\nu}$ = 2127 cm^{-1} (ν_{PtH}).

'MeS_3'-H: At –90°C, solid [Ni('S_3')(PMe_3)] (270 mg, 0.71 mmol) was added to a suspension of Me_3OBF_4 (105 mg, 0.71 mmol) in CH_2Cl_2 (15 mL). The suspension was warmed to room temperature and stirred for 4 h to give a yellow-brown solution. Addition of Et_2O (20 mL) precipitated a yellow-green powder that was separated, washed with little Et_2O and redissolved in CH_2Cl_2 (15 mL) to give a yellow-green solution. Addition of half-concentrated hydrochloric acid (20 mL) resulted in decoloration of the CH_2Cl_2 phase. The organic layer was separated and the aqueous phase was extracted with CH_2Cl_2 (15 mL). The combined CH_2Cl_2 extracts were dried with Na_2SO_4 and concentrated to give an oily pale yellow residue. It was dissolved in Et_2O (20 mL) and the resulting solution was extracted with aqueous NaOH (10%, 20 mL). The aqueous phase was separated, washed with Et_2O (10 mL), acidified with aqueous HCl, and extracted with CH_2Cl_2 (30 mL) in several portions. The combined CH_2Cl_2 layers were dried with Na_2SO_4 and concentrated to give 'MeS_3'-H as a colorless oil, which was identified by NMR spectroscopy. Yield: 60 mg (32%). – ^1H NMR ($CDCl_3$): δ = 7.50–6.95 (m, 8 H, C_6H_4), 4.26 (s, 1 H, SH), 2.54

(s, 3 H, CH_3). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 140.2, 136.9, 134.1, 134.0, 132.6, 131.3, 130.3, 129.1, 128.4, 127.2, 126.9, 126.5 (C_6H_4), 16.8 (CH_3).

NBu_4'EtS_3': $Et_3O{\cdot}BF_4$ (743 mg, 3.91 mmol) in CH_2Cl_2 (5 mL) was added to a stirred brown suspension of [Ni('S_3')]$_2$ (1.20 g, 1.96 mmol) in CH_2Cl_2 (50 mL). In the course of 16 h, a brown solution resulted to which concentrated aqueous HCl (40 mL) was added. After stirring for another 2 h, the CH_2Cl_2 phase had turned colorless. The CH_2Cl_2 phase was separated and the remaining aqueous phase was extracted with CH_2Cl_2 (20 mL). The combined CH_2Cl_2 extracts were concentrated to give a colorless oil, which was dissolved in MeOH (20 mL) and combined with 5 mL of a 1 M MeOH solution of Bu_4NOH (5 mmol). Et_2O (100 mL) was added and the resulting solution cooled to −78°C. Colorless microcrystals precipitated, which were separated at −78°C after 1 d, washed with Et_2O (−78°C) and dried. Yield: 1.20 g (59%).− ^1H NMR ([D$_4$]MeOH): δ = 7.47−7.26 (m, 4 H, C_6H_4), 7.11 (m, 1H, C_6H_4), 6.70 (m, 1H, C_6H_4), 6.56 (m, 1H, C_6H_4), 6.32 (m, 1H, C_6H_4), 3.22 (t, 8 H, NCH_2), 2.92 (q, 2 H, SCH_2), 1.64 (m, 8 H, NCH_2CH_2), 1.39 (m, 8 H, $NCH_2CH_2CH_2$), 1.28 (t, 3 H, SCH_2CH_3), 0.99 (t, 12 H, $NCH_2CH_2CH_2CH_3$). − $^{13}C\{^1H\}$ NMR ([D$_4$]MeOH): δ = 148.5, 144.0, 140.3, 136.9, 135.8, 135.1, 129.5, 127.8, 126.5, 126.2, 125.0, 121.9 (C_6H_4), 59.5 (t, $^1J_{C,N}$ = 5.3 Hz, NCH_2), 27.1 (SCH_2), 24.9 (NCH_2CH_2), 20.8 ($NCH_2CH_2CH_2$), 14.2 (SCH_2CH_3), 14.0 ($NCH_2CH_2CH_2CH_3$).

'EtS_3'-H: [Ni('EtS_3')$_2$] (**9**) (280 mg, 0.46 mmol) was suspended in CH_2Cl_2 (20 mL), concentrated HCl (20 mL) was added and the mixture was stirred for 2 h. The CH_2Cl_2 phase was separated and the aqueous phase was extracted with CH_2Cl_2. The combined organic layers were dried with Na_2SO_4 and concentrated to yield 'EtS_3'-H as a colorless oil. Yield: 230 mg (90%). − MS (FD, CH_2Cl_2); *m*/*z*: 278 [M^+]. − ^1H NMR (CD_2Cl_2): δ = 7.47−7.03 (m, 7 H, C_6H_4), 6.88 (d, 1 H, C_6H_4), 4.28 (s, 1 H, SH), 3.02 (q, 2 H, SCH_2), 1.35 (t, 3 H, SCH_2CH_3).

'CyS_3'-H: At −30°C, 'S_3'-H_2 (5.90 g, 23.6 mmol) in THF (25 mL) was combined with *n*BuLi (10 mL of 2.5 M in hexanes, 25 mmol), and the resulting solution was concentrated to dryness at room temperature. The light yellow residue was dissolved in DMF (50 mL), combined with cyclohexyl bromide (8.00 g, 49.1 mmol) and heated to 125°C for 6 h. All volatile materials were removed at 110°C in vacuo (1 mbar), the remaining oil was dissolved in CH_2Cl_2 (30 mL) and half-concentrated HCl (50 mL) was added. The CH_2Cl_2 phase was separated, and the aqueous phase was extracted with CH_2Cl_2 (60 mL). The combined CH_2Cl_2 phases were washed with dilute aqueous HCl (5 mL), dried with Na_2SO_4, and concentrated. The remaining oil was redissolved in Et_2O (40 mL) and hexanes (10 mL) and filtered. Aqueous NaOH (50 mL, 10%) was added to the filtrate, the mixture was agitated vigorously in a separating funnel and subsequently allowed to separate. In the course of ca. 30 min three phases formed of which the thin middle one displayed a pale red color. This phase was carefully separated, acidified with half-concentrated HCl and extracted with CH_2Cl_2 (60 mL). The CH_2Cl_2 extracts were washed with dilute aqueous HCl (10 mL), dried with Na_2SO_4, and concentrated at 60°C (0.1 mbar). The remaining oil of 'CyS_3'-H was identified by NMR spectroscopy. Yield: 3.27 g (42%). − ^1H NMR ($CDCl_3$): δ = 7.55−7.01 (m, 7 H, C_6H_4), 6.67 (d, 1 H, C_6H_4), 4.33 (s, 1 H, SH), 3.27 [m, 1 H, $SCH(CH_2)_5$], 2.13 [1.15 (m, 10 H, $SCH(CH_2)_5$]. − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 140.0, 139.2, 136.3, 133.7, 133.0, 130.1, 129.5, 129.2, 127.8, 127.1, 126.1, 126.0 (C_6H_4), 46.7 [$SCH(CH_2)_5$], 33.2, 26.0, 25.7 [$SCH(CH_2)_5$].

[Ni('MeS_3')$_2$] (7): 'MeS_3'-H (210 mg, 0.80 mmol) in THF (10 mL) was treated with NaOMe (0.8 mL of a 1 M solution in MeOH, 0.80 mmol) and combined with $NiBr_2{\cdot}3H_2O$ (270 mg, 1.0 mmol) in MeOH (10 mL). A red solution resulted from which an orange to ochreous solid precipitated that was separated after 1 d, washed with MeOH (30 mL), and dried. Yield: 210 mg (90%). − $C_{26}H_{22}NiS_6$ (585.56): calcd. C 53.33, H 3.79; found C 52.18, H 3.86. − IR (KBr): $\tilde{\nu}$ = 3047, 2963, 2924, 1564, 1442, 1423, 1097, 750 cm^{-1}.

[Ni('MeS_3')$_2$(PMe_3)$_2$] (8): PMe_3 (70 mg, 0.92 mmol) was added to a suspension of Ni('MeS_3')$_2$] (**7**) (60 mg, 0.10 mmol) in THF (5 mL), and a deep red solution resulted. Addition of MeOH (8 mL) precipitated an orange solid that was separated, washed with MeOH (5 mL) and Et_2O (15 mL), and dried. Yield: 55 mg (75%). − $C_{32}H_{40}NiP_2S_6$ (737.72): calcd. C 52.10, H 5.47, S 26.08; found C 51.99, H 5.41, S 25.64. − ^1H NMR ($CDCl_3$): δ = 7.80 (d, 2 H, C_6H_4), 7.39 (d, 2 H, C_6H_4), 7.28 (pseudo-t, 2 H, C_6H_4), 7.18 (d, 2 H, C_6H_4), 7.04 (pseudo-t, 2 H, C_6H_4), 6.88 (d pseudo-t, 2 H, $^5J_{H,P}$ = 2.6 Hz, C_6H_4), 6.82−6,69 (m, 4 H, C_6H_4), 2.38 (s, 6 H, CH_3), 1.27 [d, 18 H, $^2J_{H,P}$ = 5 Hz, $P(CH_3)_3$].

[Ni('EtS_3')$_2$] (9): $NiCl_2{\cdot}6H_2O$ (200 mg, 0.85 mmol) in MeOH (5 mL) was added to a stirred solution of NBu_4'EtS_3' (440 mg, 0.85 mmol) in MeOH (10 mL). An orange-brown precipitate formed that was separated after 2 h, washed with MeOH (15 mL) and recrystallized from hot DMF. Yield: 460 mg (88%). − $C_{28}H_{26}NiS_6$ (613.61): calcd. C 54.81, H 4.27, S 31.35; found C 54.51, H 4.29, S 30.18. − ^1H NMR (C_6D_6): δ = 7.92 (m, 2 H, C_6H_4), 7.41 (m, 2 H, C_6H_4), 6.94−6.78 (m, 6 H, C_6H_4), 6.68−6.57 (m, 4 H, C_6H_4), 6.38 (m, 2 H, C_6H_4), 2.57 (q, 4 H, CH_2), 0.99 (t, 6 H, CH_3). − IR (KBr): $\tilde{\nu}$ = 3049, 2965, 2924, 1566, 1444, 1424, 1261, 1246, 1100, 756, 738 cm^{-1}.

[Ni('CyS_3')$_2$] (10): Ni(ac)$_2{\cdot}4H_2O$ (250 mg, 1.0 mmol) in MeOH (10 mL) was added to 'CyS_3'-H (175 mg, 0.53 mmol) in THF (10 mL), yielding a red solution. This solution was reduced in volume to 5 mL, and MeOH (20 mL) was added. An orange-brown solid precipitated which was separated, washed with MeOH (30 mL) and dried. Yield: 170 mg (90%). − $C_{36}H_{38}NiS_6$ (721.80): calcd. C 59.91, H 5.31, S 26.65; found C 60.00, H 5.22, S 26.38. − MS (FD, CH_2Cl_2); *m*/*z*: 720 [M^+]. − ^1H NMR ($CDCl_3$): δ = 7.99−6.69 (m, 8 H, C_6H_4), 3.35 [m, 1 H,$SCH(CH_2)_5$], 2.16−1.08 [m, 10 H, $SCH(CH_2)_5$]. − IR (KBr): $\tilde{\nu}$ = 3048, 2927, 2850, 1565, 1443, 1424, 1099, 745 cm^{-1}.

[Pt(H)('CyS_3')] and [Pt(H)('CyS_3')(PPh_3)]: A solution of 'CyS_3'-H (335 mg, 1.0 mmol) in THF (10 mL) was added to a suspension of [Pt(PPh_3)$_4$] (1.25 g, 1.0 mmol) in THF (30 mL). The yellow suspension was stirred for 20 min upon which an orange solution resulted, which was heated to reflux for 1 h. After allowing to come to room temperature, MeOH (20 mL) was added to precipitate a pale yellow solid. This product was separated and extracted several times with hot hexanes (120 mL). The remaining pale yellow powder was dried in vacuo and was characterized by means of NMR spectroscopy to consist of a mixture of [Pt('CyS_3')(H)], [Pt('CyS_3')(H)(PPh_3)] and PPh_3. − ^1H NMR ([D$_8$]THF): δ = 7.98−6.43 (m, C_6H_4/C_6H_5), 3.15−3.09 [m, $SCH(CH_2)_5$], 2.05−0.97 [m, $SCH(CH_2)_5$], −11.38 {d + dd, $^1J_{H,Pt}$ = 1260 Hz, $^2J_{H,P}$ = 20 Hz, PtH in [Pt('CyS_3')(H)(PPh_3)]}, −15.74 {s + d, $^1J_{H,Pt}$ = 1155 Hz, Pt*H* in [Pt('CyS_3')(H)]}. − $^{31}P\{^1H\}$ NMR ([D$_8$]THF): δ = 23.5 {s + d, $^1J_{P,Pt}$ = 3260 Hz, *P*Ph_3 in [Pt('CyS_3')(H)(PPh_3)]}. − IR (KBr): $\tilde{\nu}$ = 2110 cm^{-1} (ν_{PtH}); (THF): $\tilde{\nu}$ = 2117 cm^{-1} (ν_{PtH}).

[Pt(PPh_3)$_2$($S_2C_6H_4$)]: A solution of 'CyS_3'-H (330 mg, 1.0 mmol) in toluene (5 mL) was combined with a suspension of [Pt(PPh_3)$_4$] (1.240 g, 1.0 mmol) in toluene (25 mL). The resulting orange suspension was heated to 80°C (10 min) and then to 100°C to give a clear yellow-orange solution. After 30 min at 100°C, yellow microc-

rystals of $[Pt(PPh_3)_2(S_2C_6H_4)]$ precipitated, which were isolated at room temperature, washed with toluene (15 mL) and pentanes (15 mL), and dried in vacuo. − $C_{42}H_{34}P_2PtS_2$ (859.90): calcd. C 58.67, H 3.99, S 7.46; found C 58.77, H 4.04, S 7.38. − ^{1}H NMR (CD_2Cl_2): δ = 7.70−7.10 (m, 32 H, C_6H_4, C_6H_5), 6.68 (m, 2 H, C_6H_4).

[$Et_2HNC_2H_4Br$]Br: At 0°C, $Et_2NC_2H_4OH$ (45.1 g, 385 mmol) was cautiously combined with aqueous HBr (100 mL, 47%, 884 mmol) and PBr_3 (86.4 g, 320 mmol). The mixture was sealed in a thick-walled glass ampoule and heated to 140°C for 11 h. From the resulting brown product, all volatile components were removed in vacuo, the residue was redissolved in boiling EtOH (150 mL) and allowed to cool to room temperature. Upon addition of Et_2O (200 mL), colorless microcrystals precipitated, which were separated, washed with Et_2O (100 mL), and dried. Yield: 79.9 g (80%). − $C_6H_{15}Br_2N$ (261.01): calcd. C 27.61, H 5.79, N 5.37; found C 27.20, H 5.99, N 4.88.− ^{1}H NMR ([D$_4$]MeOH): δ = 4.78 (s, 1 H, NH), 3.72 (m, 2 H, NC_2H_4Br), 3.56 (m, 2 H, NC_2H_4Br), 3.25 [q, 4 H, $N(CH_2CH_3)_2$], 1.28 [t, 6 H, $N(CH_2CH_3)_2$]. − ^{13}C{^{1}H} NMR ([D$_4$]MeOH): δ = 54.0 (NCH_2CH_2Br), 48.9 [$N(CH_2CH_3)_2$], 24.4 [$N(CH_2CH_2)Br$], 9.1 [$N(CH_2CH_3)_2$].

[Ni(‘Et_2HNS_2’)$_2$](ClO$_4$)$_2$ (12): ***Caution:*** *Although we did not face any difficulties, the use of perchlorates in the presence of organic material may cause explosions and perchlorates must be treated accordingly (protective shields).* A stirred solution of *o*-$C_6H_4(SH)_2$ (3.685 g, 25.9 mmol) in MeOH (30 mL) was deprotonated with NaOMe (2.81 g, 51.8 mmol) and added to a solution of $Ni(ClO_4)_2{\cdot}6H_2O$ (4.74 g, 13.0 mmol) in MeOH (65 mL). To the resulting brown-yellow solution of $[Ni(S_2C_6H_4)_2]^{2-}$, a solution of $[Et_2HNC_2H_4Br]Br$ (6.76 g, 25.9 mmol) in MeOH (50 mL) was added dropwise within 20 min. The resulting solution was stirred for 24 h at room temperature, subsequently heated at reflux for 4 h, and then allowed to cool to room temperature again. A yellow-red precipitate formed which was separated, washed with MeOH (40 mL) and dried in vacuo for 3 d. Yield: 6.7 g (70%). − $C_{24}H_{38}Cl_2N_2NiO_8S_4$ (740.45): calcd. C 38.93, H 5.17, N 3.78, S 17.32; found C 39.58, H 5.41, N 3.83, S 17.26. − ^{1}H NMR ([D$_4$]MeOH): δ = 7.62 (m, 1 H, C_6H_4), 7.44 (m, 1 H, C_6H_4), 7.26 (m, 1 H, C_6H_4), 7.13 (m, 1 H, C_6H_4), 4.88 (s, NH), 3.71 (br., 2 H, NC_2H_4S), 3.57 (br., 2 H, NC_2H_4S), 3.24 (q, 4 H, NCH_2CH_3), 1.19 (t, 6 H, NCH_2CH_3). − IR (KBr): $\tilde{\nu}$ = 3053, 2971, 2933, 2656, 2470, 1566, 1447, 1419, 1261, 1244, 1097, 741, 624 cm^{-1}.

[‘Et_2HNS_2’-H]Br: [Ni(‘Et_2HNS_2’)$_2$](ClO$_4$)$_2$ (**12**) (500 mg, 0.675 mmol) in $CHCl_3$ (20 mL) was treated with concentrated aqueous HBr (20 mL, 47%, 175 mmol) and stirred vigorously for 2 h. The resulting light-yellow $CHCl_3$ phase was separated, dried with Na_2SO_4 and concentrated to dryness, yielding a white solid of [‘Et_2HNS_2’-H]Br that was identified by NMR spectroscopy. Yield: 270 mg (62%). − ^{1}H NMR ($CDCl_3$): δ = 10.90 (s, 1 H, br., NH), 8.02−6.21 (m, 4 H, C_6H_4), 4.59 (s, 1 H, SH), 4.00−3.19 (m, 8 H, NC_2H_4S, NCH_2CH_3), 1.63 (t, 6 H, NCH_2CH_3).

X-ray Structure Analysis of [Ni(‘S_3’)]$_2$ (1), [Ni(‘S_3’)(PMe$_3$)] (2), NMe$_4$[Ni(‘S_3’)(CN)]·0.5CH_2Cl_2 (3·0.5CH_2Cl_2), [Ni(‘MeS_3’)$_2$] (7), [Ni(‘Et_2HNS_2’)$_2$]Br_2 (11), [Pt(‘S_3’)]$_3$·2THF·MeOH (5·2THF·MeOH) and [Pt(‘S_3’)(PPh$_3$)] (6): Black cubes of [Ni(‘S_3’)]$_2$ (**1**) were obtained by solvothermal crystallization. A suspension of **1** (80 mg) in DMF (2 mL) was sealed in a thick-walled glass ampoule, heated to 175°C for 10 h by means of an electric furnace and slowly cooled to room temperature at a rate of 1°C·h^{-1}. Black prisms of [Ni(‘S_3’)(PMe$_3$)] (**2**) crystallized from a saturated THF solution that was layered with MeOH. Red-black columns of NMe$_4$[Ni(‘S_3’)(CN)]·0.5CH_2Cl_2 (**3**·0.5CH_2Cl_2) were grown from a saturated 1:1 THF/MeOH solution that was layered with Et_2O. In the course of 20 d, red prisms of [Ni(‘MeS_3’)$_2$] (**7**) grew from a $CDCl_3$ solution of [Ni(‘MeS_3’)$_2$(PMe$_3$)$_2$] which had been used for NMR measurements. [Ni(‘Et_2HNS_2’)$_2$]Br_2 (**11**) crystallized as yellow platelets upon cooling of a hot MeOH solution of [Ni(‘Et_2HNS_2’)$_2$](ClO$_4$)$_2$ (**12**) and LiBr to room temperature. Yellow-red plates of [Pt(‘S_3’)]3·2THF·MeOH (**5**·2THF·MeOH) were grown from a THF solution that was layered with MeOH. Orange columns of [Pt(‘S_3’)(PPh$_3$)] (**6**) resulted from a mixture of Li[Pt(‘S_3’)(H)] and Li[Pt(‘S_3’)(H)(PPh$_3$)] in THF that had been layered with MeOH. Suitable single crystals were sealed in glass capillaries under N_2. Data was collected at 293 K (**1**, **3**·0.5CH_2Cl_2, **6**) or 200 K (**2**, **5**·2THF·MeOH, **7**, **11**) with a Siemens P4 diffractometer using Mo-K_α radiation (λ = 71.073 pm), a graphite

Table 2. Selected crystallographic data of [Ni(‘S_3’)]$_2$ (**1**), [Ni(‘S_3’)(PMe$_3$)] (**2**), NMe$_4$[Ni(‘S_3’)(CN)]·0.5CH_2Cl_2 (**3**·0.5CH_2Cl_2), [Ni(‘MeS_3’)$_2$] (**7**), [Ni(‘Et_2HNS_2’)$_2$]Br_2 (**11**), [Pt(‘S_3’)]3·2THF·MeOH (**5**·2THF·MeOH) and [Pt(‘S_3’)(PPh$_3$)] (**6**)

monochromator and ω-scan technique (scan speed 3.0−30° min^{-1}). Due to the experimental setup, ψ-scan absorption correction was not possible, therefore absorption effects have been corrected using ΔF^2 methods (XABS2)[39] in the case of **2**, **5**·2THF·MeOH, **6**, **7**, and **11**. Structures were solved by direct methods (SHELXTL). Full-matrix least-squares refinements on F^2 were carried out with SHELXTL 5.03.[40] Non-hydrogen atoms were refined isotropically. The hydrogen atoms of **1**, **2**, **3**·0.5CH_2Cl_2, **6**, **7**, and **11** were located in Fourier synthesis difference maps. The hydrogen atoms in [Pt('S_3')]3·2THF·MeOH (**5**·2THF·MeOH) were geometrically positioned. For all hydrogen atoms both the positional parameters and a common isotropic displacement parameter were restricted during refinement. In the case of **2**, the absolute structure has been established by refinement of the Flack parameter[41] [$x = -0.02(2)$]. Table 2 contains selected crystallographic data.[42]

Acknowledgments

Support of these investigations by the Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie is gratefully acknowledged. We wish to thank Dr. M. Moll for the recording of numerous NMR spectra and Mr. W. Donaubauer for technical assistance in the X-ray diffraction studies.

Molybdenum(VI) Bisimidoaryl Phenoxide and Alkoxide Complexes: Molecular Structures of $[Mo(NAr)_2(OCMe_2\text{-}2\text{-}py)(CH_2SiMe_3)]$ and $[\{Mo(NAr)_2Me(OMe)\}_2]$

Jim A. M. Brandts,[a] Jaap Boersma,[a] Anthony L. Spek,[b][+] and Gerard van Koten*[a]

Keywords: Molybdenum / Bisimidoaryl / Alkoxide and phenoxide ligands / Intramolecular coordination / Imido complexes / Chelates

The synthesis and characterisation is reported of new, five-coordinate molybdenum(VI) bisimidoaryl complexes $[Mo(NAr)_2(O\text{-}N)(R)]$ [Ar = $C_6H_3(iPr)_2$-2,6; *O-N* = 2-pyridyldiphenylmethoxide (**a**), 2-pyridyldimethylmethoxide (**b**), 8-quinolinolate (**c**); R = Cl, Me, CH_2SiMe_3] and the corresponding bisalkoxide (**a**, **b**) and bisphenolate [**c**, **d** = $(OC_6H_4CH_2NMe_2\text{-}2)^-$] Mo^{VI} bisimidoaryl complexes $[Mo(NAr)_2(O\text{-}N)_2]$. These complexes can be formed by simple alcoholysis reactions between $[Mo(NAr)_2Cl_2(DME)]$ and the appropriate alcohol in the presence of Et_3N. The remaining chloride can be replaced by a methyl or trimethylsilylmethyl group by transmetallation with MeMgCl or $LiCH_2SiMe_3$. The solid state structure of $[Mo(NAr)_2(OCMe_2\text{-}2\text{-}py)(CH_2SiMe_3)]$ (**5**) has been determined by single-crystal X-ray analysis. A similar synthetic procedure was used to synthesise and characterise $[\{Mo(NAr)_2Me(OMe)\}_2]$ (**7**). The two methoxide ligands bridge between the two molybdenum(VI) nuclei. Compounds in which the ligand can form six-membered chelate rings {like $[Mo(NAr)_2(OC_6H_4CH_2NMe_2\text{-}2)_2]$ (**9**) and analogues} are usually difficult to obtain in a pure form and yields are typically low.

Introduction

Alkoxide and phenoxide ligands play an important role in catalysts developed for classical olefin metathesis polymerisation. The stability, reactivity and selectivity of the catalysts is often determined by the nature of the ancillary alkoxide or phenoxide ligands, as reported by Schrock,[1] Grubbs,[2] Basset[3] and others for $[WCl_{6-x}(OAr)_x]$ (x = 0−4, 6) or $[WOCl_{4-n}(OAr)_n]$ (n = 0−4) catalysts.[4] Van der Schaaf et al. have shown that the use of intramolecularly coordinating alkoxide and phenoxide ligands in tungsten(VI) alkylidene complexes yields complexes with special properties.[5] Enhanced stability, high ring-opening metathesis polymerisation (ROMP) activity (turnover frequency < 1/h at 20°C; > 20000/h at 70°C) and selectivity, and unexpected so-called "latent" behaviour were found.[6] Analogous compounds based on molybdenum as the active metal centre are desirable because molybdenum catalysts appear to tolerate functionalities to a greater degree than the corresponding tungsten catalysts.[7] Therefore, we have prepared and characterised a series of molybdenum(VI) bisimidoaryl phenoxide and alkoxide complexes containing a potentially intramolecularly coordinating amine. The ligands we used, depicted in Figure 1, are all monoanionic, potentially *O,N*-chelating ligands, i.e. $[OCPh_2\text{-}2\text{-pyridyl}]^-$ (**a**),[6][8] $[OCMe_2\text{-}2\text{-pyridyl}]^-$ (**b**),[6] 8-oxyquinolinate (**c**)[6] and $[OC_6H_4CH_2NMe_2\text{-}2]^-$ (**d**).[5]

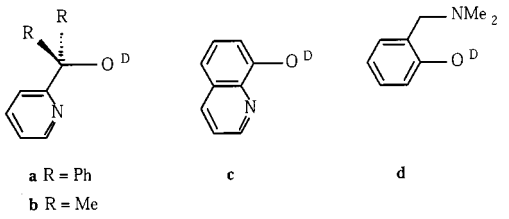

Figure 1. Selected alkoxide and phenoxide ligands with potentially *ortho*-chelating amine donors

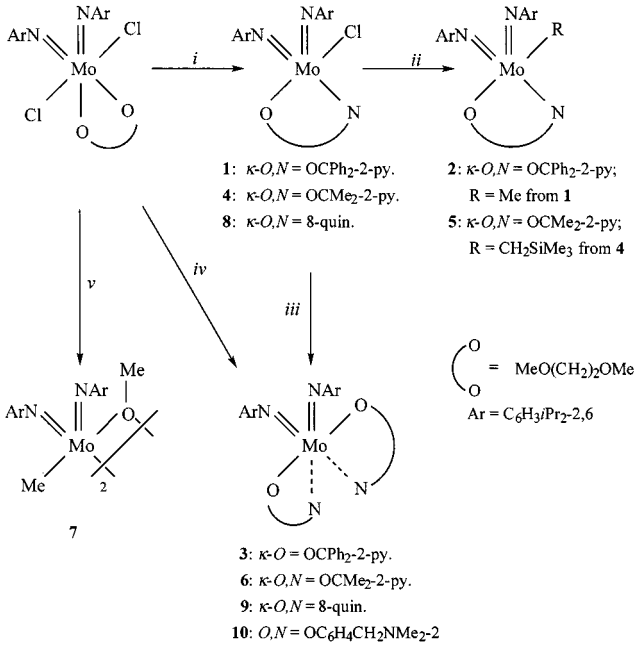
At this point we have focused on the synthesis of Mo^{VI} compounds with the general formula $[Mo(NAr)_2(O\text{-}N)(R)]$ (*O-N* = **a**, **b**, **c** or **d**; R = Cl, Me, CH_2SiMe_3; Ar = 2,6-diisopropylphenyl) and the corresponding bisalkoxide (**a**, **b**) and bisphenolate (**c**, **d**) Mo^{VI} complexes $[Mo(NAr)_2(O\text{-}N)_2]$.

Results



Synthesis of Complexes 1−6

Direct alcoholysis of $[Mo(NAr)_2Cl_2(DME)]$ with $[HOCPh_2\text{-}2\text{-py}]$ in the presence of Et_3N afforded the mono(2-pyridyldiphenylmethoxide) molybdenum(VI) complex $[Mo(NAr)_2(OCPh_2\text{-}2\text{-py})Cl]$ (**1**) in almost quantitative yield. The analogous methylated compound $[Mo(NAr)_2(OCPh_2\text{-}2\text{-py})(Me)]$ (**2**) was obtained by reaction of **1** with MeMgCl. The corresponding bis(2-pyridyldiphenylmethoxide) molybdenum(VI) complex $[Mo(NAr)_2(OCPh_2\text{-}2\text{-py})_2]$ (**3**) was made by either treating **1** with one equivalent of

[LiOCPh$_2$-2-py] or by reaction of [Mo(NAr)$_2$Cl$_2$(DME)] with two equivalents of [LiOCPh$_2$-2-py] (see Scheme 1).

Scheme 1: *i*: The appropriate alcohol, Et_3N, $-Et_3NHCl$, −1,2 dimethoxyethane, Et_2O, > 95% yield; *ii*: **2**: MeMgCl, $-MgCl_2$, THF, 92% yield; **5**: $LiCH_2SiMe_3$, Et_2O, −LiCl, 80% yield; *iii* and *iv*: by reaction of lithium phenolates or alcoholysis, see experimental section; *v*: MeOH, Et_3N, $-Et_3NHCl$, MeMgCl, $-MgCl_2$, yield: 68% yield

All these compounds are intensely coloured, e.g. dark red (**1**), orange (**2**) and red/purple (**3**). The solid complexes **1** and **2** are moisture-sensitive but can be handled in air for short periods of time (less than 1 min.) without any noticeable decomposition. Compound **3** is stable in air even at high temperatures (> 200°C). The compounds containing the 2-pyridyldimethylmethoxide ligand [OCMe$_2$-2-py]$^-$ **(b)** (**4**: Cl, **5**: CH_2SiMe_3 and **6**: [OCMe$_2$-2-py]$^-$) can be made in a similar manner (see Scheme 1). NMR spectroscopy and elemental analysis confirmed their composition.

NMR-Spectroscopic Analysis

The ^{1}H NMR spectra of **1**−**6** (C_6D_6) show a septet and two doublet resonances for the *i*Pr *ortho* substituents of the NAr ligands. In the $^{13}C\{^1H\}$ NMR spectra these *i*Pr groups appear as three separate resonances indicating that all four *i*Pr groups are equivalent but that the CMe_2 moieties are diastereotopic. The R-substituents of the *O,N*-ligand (**a**: R = Ph; **b**: R = Me) of **1**, **2**, **4** and **5** show only one set of resonaces and are equivalent over the whole temperature range (220 K − 330 K) studied. These results indicate the presence of a molecular symmetry plane in the complexes, which renders both R-substituents in the *O,N*-ligands equivalent on the NMR time scale, but gives no further information about the actual coordination mode of the *O,N*-ligand. This can only be rationalised either by a structure in which the prochiral OC[1] and py-N centres are found in an apparent molecular symmetry plane in the case of Mo−N coordination, or when the *O,N*-ligand is monodentate O-bonding and the free pyridine substituent undergoes rapid rotation around the O−CR_2 bond.

The chemical shift difference ($\Delta\delta$)[9] between the hydrogen *ortho* to the pyridyl nitrogen in the complexes and that in the free parent ligand suggests that the pyridyl group coordinates intramolecularly in complexes **1** ($\Delta\delta$ = 1.35), **2** ($\Delta\delta$ = 0.59), **4** ($\Delta\delta$ = 1.19) and **5** ($\Delta\delta$ = 0.70). This implies that the apparent molecular symmetry plane in solution arises from fluxional processes involving alternating reversible N−Mo bond breaking and formation, and monodentate O-bonding. Finally, as compounds **1**, **2**, **4** and **5** have similar features in their NMR spectra it can be assumed that these compounds have the same structural characteristics.

The ^{1}H and $^{13}C\{^1H\}$ NMR spectra of compound **3** and **6** (C_6D_6) show two sets of resonances for the R-substituents in the OCR_2 (**3**: R = Ph; **6**: R = Me) moieties of the methoxide ligands. These R-substituents are diastereotopic because only one set of pyridyl carbons appears in the ^{13}C NMR spectrum. The very small chemical shift difference value of py-H^6 in **3** ($\Delta\delta$ = −0.11) suggests the absence of Mo−N bonding, making it a four-coordinate species. This is probably forced by the presence of sterically demanding phenyl substituents. In contrast, the corresponding chemical shift difference in **6** ($\Delta\delta$ = 0.79) does suggest an intramolecular coordination between Mo and N. In this particular case, coordination of the nitrogen atoms in both methoxide ligands would lead to a hexacoordinate molybdenum species in which the two imidoaryl ligands are likely to adopt a *cis* conformation to maximise d-orbital overlap between the π-electrons of the imido ligands and the empty d-orbitals.[10] For the same reason the pyridyl-N-donor ligands will be positioned *trans* with respect to each imidoaryl ligand. This would give hexacoordinate diimidoaryl molybdenum(VI) compounds, with a ligand array similar to that present in the solid-state structure of the analogous dioxo molybdenum(VI) compound found by Schultz et al.[8c]

Solid-State Structure of [Mo(NAr)$_2$(OCMe$_2$-2-py)(CH_2SiMe_3)] (5)

To get further insight into the molecular geometry of this series of molybdenum(VI) compounds, a single crystal X-ray structure determination of **5** was carried out and its molecular structure, with the adopted numbering scheme, is depicted in Figure 2. Selected bond lengths and angles are given in Table 1.

In compound **5** the ligands form a distorted trigonal bipyrimidal geometry around the Mo^{VI} centre (43.7% along the Berry pseudorotation coordinate from trigonal bipyramid to square pyramid) in which the N3-bonded imido ligand and N1 occupy the apical positions. The metal lies in the basal plane defined by O1, N2 and the C_{ipso} (C9) of the neosilyl (= CH_2SiMe_3) group. The *O,N*-ligand is didentate

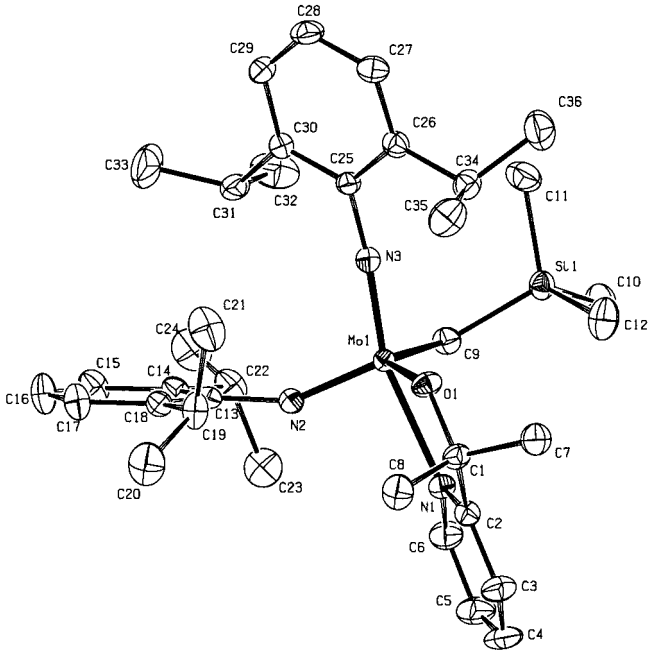

Figure 2. ORTEP drawing (50% probability atomic displacement ellipsoids) of **5**; hydrogen atoms have been omitted for clarity

chelating in the solid state with a Mo1−N1 bond length of 2.346(2) Å, typical for sp^2-nitrogen to molybdenum coordination[8c] and comparable to those found in corresponding tungsten complexes.[6][11] The metal-carbon bond length [Mo1−C9, 2.156(2) Å] observed for compound **5** is rather large (this bond in other molybdenum alkyl complexes lies in the range 2.08−2.20 Å).[12] The bond angle Mo1−C9−Si1 is larger than expected for a sp^3 carbon although similar bond angles have also been found in analogous *O,N*-ligand-containing tungsten neosilyl compounds.[6] No agostic interactions of the α-hydrogens were found (NMR, X-ray).

Table 1. Selected intramolecular distances [Å] and angles [°] of **5**[a]

Bond lengths [Å]		Bond angles [°]	
Mo1−O1	1.9504(19)	Mo1−O1−C1	128.96(13)
Mo1−N1	2.346(2)	Mo1−C9−Si1	116.82(11)
Mo1−N2	1.7686(18)	Mo1−N2−C13	152.52(15)
Mo1−N3	1.7529(19)	Mo1−N3−C25	172.95(18)
Mo1−C9	2.156(2)		
C9−Si1	1.864(2)		
O1−C1	1.406(3)		

[a] The estimated standard deviations of the last significant digits are shown in parentheses.

Formation of [{Mo(NAr)$_2$Me(OMe)}$_2$] (7)

In one attempt to synthesise the methylated derivative [Mo(NAr)$_2$(OCMe$_2$-2-py)(Me)] by reaction of compound **4** with a small excess of MeMgCl in THF, orange crystals of an unknown product (**7**) were obtained. NMR spectroscopy and elemental analysis pointed to the formation of a molybdenum compound containing one methyl, one methoxide and two imidoaryl ligands. However, compound **7** could not be synthesised again by the original synthetic route (**4** + MeMgCl in THF), not even in the presence of deliberately added air, water or methanol. Since the formation of a molybdenum compound such as **7** was unexpected and could not easily be rationalised, a single-crystal X-ray

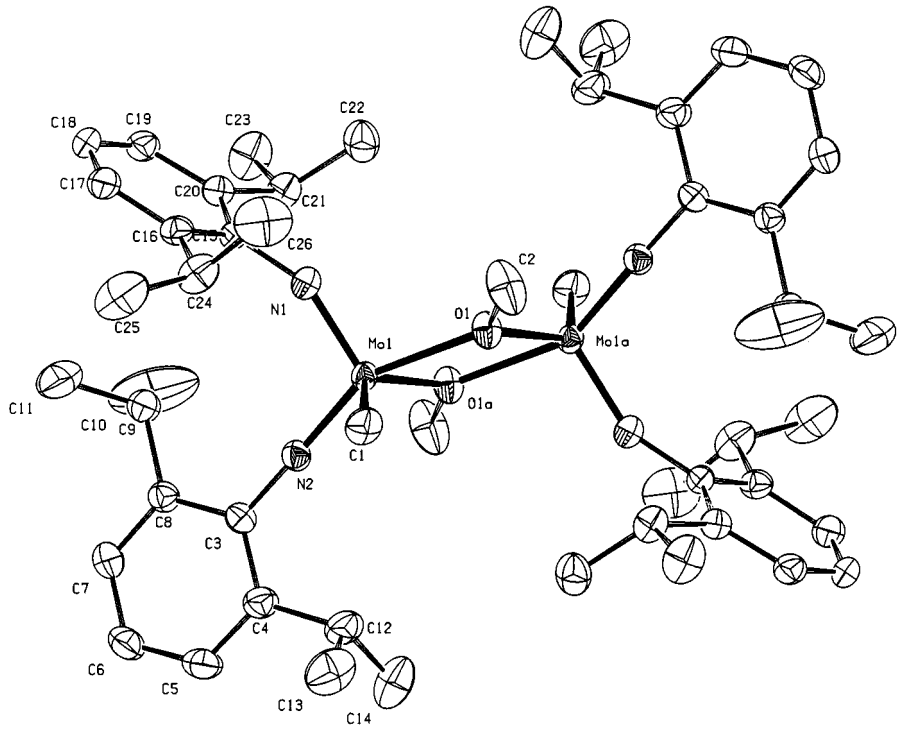

Figure 3. ORTEP drawing (50% probability atomic displacement ellipsoids) of **7**; hydrogen atoms have been omitted for clarity

analysis was carried out. The molecular structure of the orange compound, with the adopted numbering scheme, is depicted in Figure 3 and selected bond lengths and angles are given in Table 2.

Table 2. Selected geometrical details of **7**[a]

Bond lengths [Å]		Bond angles [°]	
Mo1−C1	2.161(4)	Mo1−O1−Mo1a	111.16(9)
Mo1−O1	2.157(2)	O1−Mo1−O1a	68.84(8)
Mo1−N1	1.757(3)	Mo1−N1−C15	153.7(2)
Mo1−N2	1.756(3)	Mo1−N2−C3	177.4(2)
N1−C15	1.388(4)		
N2−C3	1.383((4)		
O1−C2	1.421(5)		

[a] The estimated standard deviations of the last significant digits are shown in parentheses.

The solid state structure shows a dimeric compound in which each molybdenum nucleus indeed contains two imidoaryl ligands, one methyl group and one bridging methoxide ligand: [{Mo(NAr)$_2$Me(OMe)}$_2$] (**7**). Compound **7** has an inversion point positioned at the crossing of the virtual lines Mo1−Mo1a and O1−O1a. Each molybdenum centre has a distorted square-pyramidal coordination sphere (67.9% along the Berry-pseudorotation coordinate from trigonal bipyramid to square pyramid) in which the N1-bonded imido ligand occupies the apical position. The basal plane of the square pyramid is defined by N2, C1, O1 and O1a. Both molybdenum nuclei contain one bent [153.7(2)°] and one almost linear [177.4(2)°] imidoaryl ligand. The formation of bridging alkoxide or phenoxide ligands between two molybdenum (or tungsten) nuclei has previously been reported.[13]

Now that compound **7** had been fully analysed and characterised, a different synthetic route was developed using direct alcoholysis of [Mo(NAr)$_2$Cl$_2$(DME)] with MeOH (in presence of Et$_3$N) and subsequent reaction with MeMgCl. Compound **7** is thermally stable up to 185°C before decomposition takes place and decomposes in air within a few hours. It is soluble in most polar solvents (including CH_2Cl_2 and $CHCl_3$) but is only slightly soluble in benzene and toluene and does not dissolve in pentane or hexanes.

Synthesis and Characterisation of Complexes 8−10

The molybdenum bisimidoaryl phenoxide complexes containing the 8-quinolinolato ligand **c** (**8** and **9**) and the (dimethylamino)methyl phenoxide ligand **d** (**10**) were also synthesised by alcoholysis (see Scheme 1). The ^{1}H NMR spectra of **8** ($\Delta\delta$ = 1.20) and **9** ($\Delta\delta$ = 0.21)[14] suggest the presence of intramolecular coordination between Mo and the quinolinate nitrogen. The ^{1}H NMR spectroscopic data of **10** did not indicate the presence of such a Mo−N coordination since the H^6 proton is not shifted relative to that of the free parent 2-(dimethylamino)methyl phenol. Attempts to alkylate **8** by transmetallation reactions were unsuccessful as mixtures of the desired product and Li-**c** or ClMg-**c** that could not be separated were obtained. Apparently ligand exchange reactions do occur. Compounds in which the ligand can form six-membered chelate rings (like **10** and analogues) are usually difficult to obtain pure (also by transmetallation reactions using the sodium or lithium phenolates) and yields are typically low. Possibly, the formation of six-membered instead of five-membered chelate rings is thermodynamically less favoured.

Reactivity of the Complexes

Molybdenum(VI) complexes such as [Mo(NAr)$_2$(C$_6$H$_4$(CH$_2$NMe$_2$)-2)(Me)] react with *n*BuLi and, in the presence of dimethoxyethane (DME), the corresponding [Li(DME)$_2$Mo(NAr)$_2${C$_6$H$_4$(CH$_2$NMe$_2$)-2}(Me)(*n*Bu)] can be isolated.[15] This lithium molybdate(VI) compound can be thermally activated to give a mixture of paramagnetic Mo^V compounds, [Mo(NAr)$_2${C$_6$H$_4$(CH$_2$NMe$_2$)-2}(Me)] and [Mo(NAr)$_2${C$_6$H$_4$(CH$_2$NMe$_2$)-2}(*n*Bu)]. Small amounts of 1-butene were also detected as a result of β-H elimination reactions. This mixture becomes ROMP-active after dry air is bubbled through the solution. A tentative explanation for this is that dioxygen insertion into a Mo − C bond[16] may facilitate ligand-exchange reactions and alkylidene formation after α-H elimination.

According to their composition and structural features it is unlikely that complexes **1−10** as such can be active as ring-opening metathesis polymerisation (ROMP) catalysts. However, the reaction of compounds **2** and **5** with *n*BuLi gave products that show high ROMP activity with norbornene without activation with dry air. Analysis of these reaction products showed the presence of several Mo^V and Mo^{VI} complexes and [LiOCR$_2$-2-py] (R = Ph **2** and R = Me **5**) as a result of ligand exchange reactions. These unavoidable exchange reactions hamper the isolation of the active molybdenum alkylidene species although high molecular weight polynorbornene was found ($M_n = 1 \times 10^6$ g/mol, 90% *cis* double bonds, PDI = 2.5)

Experimental Section

General: Syntheses were carried out with standard Schlenk techniques under dry, oxygen-free nitrogen. Toluene, benzene, hexane, and pentane were carefully dried and distilled from sodium benzophenone-ketyl prior to use. CH_2Cl_2 was distilled from CaH_2. − NMR Spectra (^{1}H and ^{13}C{^{1}H}) were recorded on Bruker AC200 and Bruker AC300 spectrometers, with chemical shifts referenced to Me$_4$Si. − Elemental analyses were carried out by Dornis und Kolbe, Mikroanalytisches Laboratorium, Mülheim a.d. Ruhr, Germany. − [Mo(NAr)$_2$Cl$_2$(DME)],[17] HOCPh$_2$-2-pyridyl,[6] [LiOCPh$_2$-2-pyridyl],[6] HOCMe$_2$-2-pyridyl,[6] [LiOCMe$_2$-2-pyridyl],[6] LiCH$_2$SiMe$_3$,[18] and 2-[(dimethylamino)methyl]phenol[5] were prepared according to literature procedures.

[Mo(NAr)$_2$(OCPh$_2$-2-py-*κ*-*O,N*)Cl] (1): To a solution of [Mo(NAr)$_2$Cl$_2$(DME)] (2.34 g, 3.85 mmol) in Et$_2$O/benzene (80 mL in a 1:1 ratio) was added Et$_3$N (0.6 mL, 4.3 mmol) and a solution of HOCPh$_2$-2-pyridyl (1.00 g, 3.85 mmol) in Et$_2$O (20 mL) at ambient temperature. After stirring for 2 h, an off-white precipitate was re-

moved by centrifugation. The solid was washed with Et_2O (2 × 40 mL) and the Et_2O washings were combined with the mother liquor. All volatiles were removed in vacuo leaving a red crystalline solid (2.85 g, 100%) which was pure according to NMR spectroscopy and elemental analysis. − M.p.: 168°C − ^{1}H NMR: δ = 9.53 (d, 1, py-H^6), 7.37 (dd, 4, Ph-H), 7.05 (m, 10, ArH), 6.95 (m, 3, ArH) 6.77 (m, 1, py-H) 6.54 (m, 1, py-H), 3.87 (sept, 4, C*H*Me$_2$), 1.24 (d, 12, CH*Me*$_2$), 1.09 (d, 12, CH*Me*$_2$). − ^{13}C NMR: δ = 167.7 (py-C^2), 155.0 (C*ipso* NAr), 149.5, 146.6 (Ar-C), 144.0 (C*para* NAr), 138.1, 128.8, 128.6, 128.3, 126.9, 124.8, 123.1, 122.8 (Ar-C), 95.9 (OC), 28.7 (*C*HMe$_2$), 24.1 (CH*Me*$_2$), 23.3 (CH*Me*$_2$). − $C_{42}H_{48}ClMoN_3O$ (742.26): C 67.96, H 6.52, N 5.66; found C 67.90, H 6.58, N 5.61.

[Mo(NAr)$_2$(OCPh$_2$-2-py-κ-O,N)(Me)] (2): To a solution of **1** (0.44 g, 0.59 mmol) in THF (40 mL) was added 200 μl of a 3 M THF solution of MeMgCl (0.6 mmol). The reaction mixture was allowed to stir overnight. After 18 h all volatiles were removed in vacuo (3 h, 60°C). The remaining red solid was extracted with pentane (2 × 40 mL). The precipitate was removed by centrifugation, the pentane layers were collected, concentrated (30 mL), and stored at −30°C. After one week orange crystals (0.39 g, 0.54 mmol, 92% yield) were isolated that were pure according to NMR spectroscopy and elemental analysis. M.p.: 152°C − ^{1}H NMR: δ = 8.77 (d, 1, py-H^6), 7.47 (m, 4, Ph-H), 7.05 (m, 13, Ar-H), 6.75 (m, 1, py-H) 6.39 (m, 1, py-H), 3.84 (sept, 4, C*H*Me$_2$), 1.67 (s, 3, Mo−Me), 1.21 (d, 12, CH*Me*$_2$), 1.09 (d, 12, CH*Me*$_2$). − ^{13}C NMR: δ = 169.2 (py-C^2), 154.2 (C*ipso* NAr), 149.2, 148.0, 142.9, 137.7, 128.3, 128.1, 127.6, 125.3, 124.7, 123.0, 122.6 (Ar-C), 95.4 (OC), 28.6 (*C*HMe$_2$), 25.3 (Mo−Me), 24.5 (CH*Me*$_2$), 23.5 (CH*Me*$_2$). − $C_{43}H_{51}MoN_3O$ (721.84): C 71.55, H 7.12, N 5.82; found C 71.64, H 7.08, N 5.76.

[Mo(NAr)$_2$(OCPh$_2$-2-py-κ-O)$_2$] (3): To a solution of **1** (0.99 g, 1.34 mmol) in THF (60 mL) was added [Li−OCPh$_2$-2-pyridyl] (0.36 g, 1.34 mmol) as a solid. The reaction mixture was warmed to 50°C. After stirring two hours all volatiles were removed in vacuo (3 h, 60°C). The remaining red solid was extracted with CH_2Cl_2 (3 × 30 mL). The precipitate was removed by centrifugation, the CH_2Cl_2 layers were collected and concentrated to a volume of 10 mL. The remaining suspension was washed with pentane (3 × 20 mL), and the remaining solid dried in vacuo leaving a purple/red, air-stable product (1.23 g, 1.27 mmol, 95% yield). M.p.: > 200°C − ^{1}H NMR: δ = 8.07 (d, 2, py-H^6), 7.86 (d, 4, Ph-H), 7.47 (dd, 2, py-H), 7.26 (m, 4, Ph-H) 7.14−6.83 (m, 18, ArH), 6.58 (m, 2, py-H), 5.86 (m, 2, py-H), 4.31 (sept, 4, C*H*Me$_2$), 1.32 (d, 12, CH*Me*$_2$), 0.96 (d, 12, CH*Me*$_2$). − ^{13}C NMR: d = 164.9 (py-C^2), 155.0 (C*ipso* NAr), 151.3, 149.6, 149.2 (2 x), 141.6, 135.9, 129.6, 128.7, 127.9, 127.6, 127.1, 123.0, 122.9, 122.8, 121.5 (Ar-C), 94.1 (OC), 27.8 (*C*HMe$_2$), 24.9 (CH*Me*$_2$). − $C_{60}H_{62}MoN_4O_2$ (967.12): C 74.52, H 6.46, N 5.79; found C 74.38, H 6.43, N 5.72.

[Mo(NAr)$_2$(OCMe$_2$-2-py-κ-O,N)Cl] (4): An analogous method to that described for the synthesis of **1** was used. The synthesis was typically done on a 4 mmol scale using HOCMe$_2$-2-pyridyl. Yields are quantitative. M.p.: 177°C. − ^{1}H NMR: δ = 9.44 (d, 1, py-H^6), 7.06−6.92 (m, 7, Ar-H), 6.55 (m, 2, py-H), 4.08 (sept, 4, C*H*Me$_2$), 1.47 (s, 6, CMe$_2$), 1.28 (d, 12, CH*Me*$_2$), 1.20 (d, 12, CH*Me*$_2$). − ^{13}C NMR: δ = 171.4 (py-C^2), 154.8 (C*ipso* NAr), 149.2, 143.8, 139.1, 126.7, 122.8 (2 x), 120.1 (Ar-C), 86.4 (O*C*Me$_2$), 30.6 (OC*Me*$_2$), 28.6 (*C*HMe$_2$), 25.1 (CH*Me*$_2$), 23.4 (CH*Me*$_2$). − $C_{31}H_{44}ClMoN_3O$ (606.11): C 61.43, H 7.32, N 6.93; found C 61.49, H 7.29, N 6.82.

[Mo(NAr)$_2$(OCMe$_2$-2-py-κ-O,N)(CH$_2$SiMe$_3$)] (5): To a solution of **3** (0.75 g, 1.24 mmol) in Et_2O (60 mL) was added a solution of LiCH$_2$SiMe$_3$ (0.12 g, 1.24 mmol) in Et_2O (20 mL) at −78°C. The reaction mixture was warmed to room temperature (0.5 h). After two hours the white precipitate was removed by centrifugation and the Et_2O layer was collected and concentrated (10 mL). The orange crystals were collected and dried in vacuo (0.65 g, 0.99 mmol, 80% yield). The crystalline material was pure according to NMR spectroscopy and elemental analysis. M.p.: 154°C. − ^{1}H NMR: δ = 8.95 (dd, 1, py-H^6), 7.07 (m, 7, Ar-H), 7.66 (m, 1, py-H), 6.56 (m, 1, py-H), 4.08 (sept, 4, C*H*Me$_2$), 1.71 (s, 2, Mo−CH$_2$Si), 1.57 (s, 6, OCMe$_2$), 1.32 (d, 12, CH*Me*$_2$), 1.21 (d, 12, CH*Me*$_2$). − ^{13}C NMR: δ = 172.1 (py-C^2), 154.6 (C*ipso* NAr, broad), 148.0, 142.9 (broad), 138.2, 124.8, 122.7, 122.5, 120.4 (Ar-C), 85.0 (O*C*Me$_2$), 32.4 (MoCH$_2$Si), 31.7 (OCMe$_2$), 28.3 (*C*HMe$_2$), 25.3 (CH*Me*$_2$), 23.2 (CH*Me*$_2$), 2.1 (SiMe$_3$). − $C_{36}H_{55}MoN_3OSi$ (669.88): C 64.55, H 8.28, N 6.27; found C 64.68, H 8.35, N 6.27.

[Mo(NAr)$_2$(OCMe$_2$-2-py-κ-O,N)$_2$] (6): An analogous method to that described for the synthesis of **3** was used but **4** was the starting material. The synthesis was typically done on a 2 mmol scale with HOCMe$_2$-2-pyridyl. Yield 91%. M.p.: >200°C. − ^{1}H NMR: δ = 9.04 (m, 2, py-H^6), 7.04 (m, 4, Ar-H), 6.88 (m, 4, Ar-H), 6.55 (m, 4, py-H), 4.35 (sept, 4, C*H*Me$_2$), 1.81 (s, 6, OCMe$_2$), 1.57 (s, 6, OCMe$_2$), 1.42 (d, 12, CH*Me*$_2$), 1.12 (d, 12, CH*Me*$_2$). − ^{13}C NMR: δ = 170.5 (py-C^2), 155.3 (C*ipso* NAr), 146.8, 142.3, 137.6, 123.2, 123.0, 121.5, 119.6 (Ar C), 83.0 (O*C*Me$_2$), 31.7 (OC*Me*$_2$), 27.5 (CH*Me*$_2$), 25.4 (OC*Me*$_2$), 24.3 (CH*Me*$_2$), 24.3 (*C*HMe$_2$). − $C_{38}H_{54}MoN_4O_2$ (694.82): C 65.69, H 7.83, N 8.06; found C 65.58, H 7.86, N 7.95.

[{Mo(NAr)$_2$Me(OMe)}$_2$] (7): To a solution of [Mo(NAr)$_2$Cl$_2$(DME)] (1.45 g, 2.38 mmol) in Et_2O (50 mL) was added Et_3N (0.5 mL, 3.6 mmol) and MeOH (96 μL, 2.38 mmol). After 1 h the precipitate that had formed was removed by centrifugation and the upper layer was collected. All volatiles were removed in vacuo from this upper layer and the remaining solid was dissolved in THF (40 mL). To the solution 0.79 mL of a 3 M THF solution of MeMgCl (2.38 mmol) was added at ambient temperature. After 2 h stirring all volatiles were removed *in vacuo* (3 h, 60°C) and the remaining solids were washed with pentane (2 × 20 mL). The remaining solid was isolated and recrystallised from Et_2O (60 mL). At −30°C red crystals could be isolated after 5 days (0.80 g, 68% yield, 1.62 mmol). M.p. with decomposition.: 185°C. − ^{1}H NMR: δ = 7.07−6.94 (m, 6, Ar-H), 4.36 (s, 3, Mo−CH$_3$), 3.84 (sept, 4, C*H*Me$_2$), 1.44 (s, 3, Mo−CH$_3$), 1.25 (d, 12, CH*Me*$_2$), 1.19 (d, 12, CH*Me*$_2$). − ^{13}C NMR: δ = 152.6 (C*ipso* NAr), 144.3, 126.7, 122.8 (Ar C), 67.7 (Mo−Me) 28.8 (*C*HMe$_2$), 25.5 (Mo−Me), 24.2 (CH*Me*$_2$), 23.7 (CH*Me*$_2$). − [(C$_{26}$H$_{40}$MoN$_2$O)$_2$] (985.12): C 63.40, H 8.19, N 5.69; found C 63.25, H 8.13, N 5.63.

[Mo(NAr)$_2$(8-quin-κ-O,N)Cl] (8): An analogous method to that described for the synthesis of **1** was used. The synthesis was typically done on a 2 mmol scale with 8-quinolinol. Yield: 96%. M.p.: 194°C. − ^{1}H NMR: δ = 9.52 (d, 1, H^1-quin), 7.40 (dd, 1, H-quin), 7.22 (m, 8, Ar-H), 6.82 (dd, 1, H-quin) 6.60 (m, 1, quin-H), 4.03 (sept, 4, C*H*Me$_2$), 1.24 (d, 12, CH*Me*$_2$), 1.10 (d, 12, CH*Me*$_2$). − ^{13}C NMR: δ = 163.2 (C*ipso* quin), 154.4 (C*ipso* NAr), 149.4, 144.9 142.1, 139.1, 129.8, 127.9, 122.7, 122.0, 115.9, 114.6 (Ar C), 28.9 (*C*HMe$_2$), 24.2 (CH*Me*$_2$), 23.8 (CH*Me*$_2$). − $C_{33}H_{40}ClMoN_3O$ (626.10): C 63.31, H 6.44, N 6.71; found C 63.59, H 6.35, N 6.78.

[Mo(NAr)$_2$(8-quin-κ-O,N)$_2$] (9): To a solution of [Mo(NAr)$_2$Cl$_2$(DME)] (1.87 g, 3.08 mmol) in benzene (80 mL) was added Et_3N (1 mL, 7.2 mmol) and a solution of 8-quinolinol (0.89 g, 6.16 mmol) in Et_2O (20 mL) at ambient temperature. After stirring for 18 h, all volatiles were removed in vacuo and the remaining solid was extracted with pentane (5 × 40 mL). The precipitate was removed by centrifugation and the pentane layers were collected

and concentrated leaving a red crystalline solid (2.85 g, 100%) which was pure according to NMR spectroscopy and elemental analysis. NMR spectroscopy and elemental analysis showed the presence of one pentane solvent molecule per molybdenum atom in the crystals. M.p.: 182°C. – ^{1}H NMR: δ = 8.60 (d, 2, quin H[7]), 7.40–6.76 (m, 14, Ar-H), 6.23 (m, 2, quin H), 4.02 (sept, 4, C*H*Me$_2$), 1.35 (d, 12, CH*Me*$_2$), 0.97 (d, 12, CH*Me*$_2$). – ^{13}C NMR: δ = 164.3 (C*ipso* quin), 154.8 (C*ipso* NAr), 145.0, 141.7, 140.9, 137.4, 130.2, 129.9, 124.1, 122.5, 121.7, 114.8, 114.2 (Ar C), 28.5 (*C*HMe$_2$), 24.3 (CH*Me*$_2$), 24.0(CH*Me*$_2$). – $C_{47}H_{58}MoN_4O_2$ (806.95): C 69.96, H 7.25, N 6.94; found C 69.85, H 7.12, N 6.79.

[Mo(NAr)$_2$(OC$_6$H$_4$CH$_2$NMe$_2$-2)$_2$] (10): An analogous method to that described for the synthesis of **8** was used. The synthesis was typically done on a 4 mmol scale with two equivalents of 2-(dimethylamino)methyl phenol and an excess of Et$_3$N. The product was collected as a dark-red crystalline material from a concentrated pentane solution. Yield 28%. M.p.: 108°C. – ^{1}H NMR: δ = 7.17 (m, 4, Ar-H), 6.92 (m, 6, Ar-H), 6.84 (m, 4, ArH), 3.92 (sept, 4, C*H*Me$_2$), 3.74 (CH$_2$), 2.36 (N(CH$_3$)$_2$, 1.11 (d, 24, CH*Me*$_2$). – ^{13}C NMR: δ = 164.0 (C *ipso* OAr), 154.0 (C*ipso* NAr), 143.5, 130.1, 128.8, 126.2, 125.2, 123.0, 120.1, 119.8 (Ar C), 63.8 (CH$_2$), 47.5 (N(CH$_3$)$_2$, 28.0 (*C*HMe$_2$), 24.5 (CH*Me*$_2$). – $C_{42}H_{58}MoN_4O_2$ (746.89): C 67.54, H 7.83, N 7.50; found C 67.68, H 7.79, N 7.42.

Structure Determination and Refinement of 5 and 7: X-ray data were collected on an Enraf–Nonius CAD4T rotating anode diffractometer for a transparent, red/orange (**5**) or red (**7**) crystal glued on top of a glass fibre with inert fluorinated oil. The unit-cell parameters were checked for the presence of higher lattice symmetry. Data were corrected for Lorentz polarisation effects. An empirical absorption correction was applied (PLATON/DELABS).[19] The structures were solved by direct methods and subsequent difference Fourier techniques (SHELXS86).[20] Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL93)[21] using no observance criterion. Hydrogen atoms were included on calculated positions, riding on their carrier atoms. All non-hydrogen atoms were refined with anisotropic atomic displacement parameters. All hydrogen atoms were refined with a fixed isotropic atomic displacement parameter related to the value of the equivalent isotropic atomic displacement parameter of their carrier atom. Weights were optimised in the final refinement cycles. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for Crystallography.[22] Geometrical calculations and illustrations were performed with PLATON.[19] All calculations were performed on a DECstation 5000 cluster. Crystal data and numerical details of the structure determinations and refinements are collected in Table 3. Selected geometrical details of the structures of **5** and **7** are listed in Tables 1 and 2, respectively. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-106132 (structure **5**) and CCDC-106134 (structure **7**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat). + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Dedicated to Professor Dr. Manfred Meisel on the occasion of his 60th birthday

Keywords: Crystal structure / Solution structure / Homodinuclear lanthanide complexes / Lanthanides / Macrocyclic ligands / Polyamine polycarboxylic acid

The solid-state structures of the four homodinuclear chelate complexes, $[Na_2(Y_2OHEC)(H_2O)_2] \cdot 7\ H_2O \cdot C_2H_5OH$ (**1**), $[Na_2(Gd_2OHEC)(H_2O)_2] \cdot 12\ H_2O$ (**2**), $[Na_2(Eu_2OHEC)(H_2O)_2] \cdot 11\ H_2O$ (**3**), and $[Cs_2(La_2OHEC)(H_2O)_2] \cdot 14\ H_2O$ (**4**) (H_8OHEC = 1,4,7,10,14,17,20,23-octaazacyclohexacosane-1,4,7,10,14,17,20,23-octaacetic acid), were determined by X-ray crystal structure analysis. Each lanthanide(III) ion is ninefold coordinated by eight donor atoms of the ligand system and the oxygen atom of one water molecule. The structures are compared with those of DOTA- and TETA-coordinated complexes and the conformation of the OHEC ligand system with that of the parent amine and its dinuclear copper complex. NMR investigations of the diamagnetic complex **1** indicate a very similar environment of the lanthanide cations in solution and in the solid state. Low-temperature and variable-temperature ^{1}H-NMR measurements prove the existence of two isomers of **1** (3.5:1 ratio) which undergo conformational processes. The rate constants of these processes were deduced from a complete line shape analysis and were used to determine the activation parameters.

Introduction

Lanthanide complexes with macrocyclic polyamine polycarboxylate ligand systems have been the subject of many investigations[1] because they are promising substances for biomedical applications in the field of radioimmunotherapy[2] and can be used as contrast-enhancing agents in magnetic resonance imaging.[3] The best investigated compounds of this class are the mononuclear lanthanide(III) chelates of the macrocyclic ligand DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetate) and of ligands based on the DOTA skeleton.[4,5] The solid state X-ray structures of DOTA complexes of Ln^{III} (Ln= Y,[4d] La,[4f] Eu,[4a] Gd,[4b,c] and Lu[4e]) show the metal ions in a mono-capped square-antiprismatic coordination sphere. The high rigidity of the DOTA complexes allowed the estimation of conformational and coordination equilibria in aqueous solution by NMR spectroscopy.[4e,6]

In contrast, only a few binuclear lanthanide(III) complexes with macrocyclic polyamine ligands are known, e.g. Eu^{III}, Gd^{III}, and Tb^{III} complexes of a branched hexaazacyclododecane ligand containing six 2,2′-bipyridine pendants units,[7] Gd^{III} complexes of DOTA derivatives in which the two metal ions are located between two ligand molecules forming a dimeric unit,[5d] and the complex $[BO\{Gd(DO3A)(H_2O)\}_2]$ in which the two DO3A rings {$BO(DO3A)_2$ = 2,11-dihydroxy-4,9-dioxa-1,12-bis[1,4,7,10-tetraaza-4,7,10-tris(carboxymethyl)cyclododecyl]dodecane} are connected by a dihydroxydioxadodecane chain.[8]

Recently we reported the successful synthesis of two new hexadecadentate macrocyclic polyamine polycarboxylic ligands H_8OTEC (1,4,7,10,13,16,19,22-octaazacyclotetracosane-1,4,7,10,13,16,19,22-octaacetic acid) and H_8OHEC (1,4,7,10,14,17,20,23-octaazacyclohexacosane-1,4,7,10,14,17,20,23-octaacetic acid) and of some of their mono- and dinuclear lanthanide(III) chelate complexes,[9] among them the binuclear OHEC complexes of Y, Gd, and Eu. The acid/base properties of these ligands were characterised by potentiometry and NMR titration techniques.[10]

In this paper we present the crystal structures of the homodinuclear complexes of yttrium(III), gadolinium(III), europium(III), and lanthanum(III) with the ligand H_8OHEC as well as the solution structure and the dynamics of the diamagnetic Y^{III} complex.

Results and Discussion

Synthesis

The homodinuclear lanthanide(III) complexes were synthesised by treating H_8OHEC with the lanthanide oxides Ln_2O_3 (Ln = Eu,[9] Gd,[9] La) in refluxing water. Freshly prepared $Y(OH)_3$[9] was used for the synthesis of the yttrium complex instead of Y_2O_3, because of the faster reaction in that case. The colourless and highly water-soluble complexes were characterised by means of FAB-MS.

$$2\ Y(OH)_3 + H_8OHEC + 2\ NaOH \rightarrow Na_2[Y_2(OHEC)(H_2O)_2] + 6\ H_2O$$
1

$$Ln_2O_3 + H_8OHEC + 2\ MOH \rightarrow M_2[Ln_2(OHEC)(H_2O)_2] + 3\ H_2O$$
2 (Ln/M = Gd/Na),
3 (Ln/M = Eu/Na),
4 (Ln/M = La/Cs)

As known from the synthesis of the DOTA and modified DOTA lanthanide(III) complexes,[6a,11,12] the formation of the compounds **1** to **4** is also slow. A pH value of 8.5 and heating of the aqueous solutions to reflux are essential reaction conditions for the entrance of the lanthanide ions into the tetraaza coordination pockets of the OHEC ligand, which otherwise would be blocked by protonation of the strongly basic ring nitrogens. This is supported by the protonation scheme of H_8OHEC established by potentiometric titration and pH-dependent $^1H/^{13}C$ NMR titration [the four highest protonation constants were assigned to the ring nitrogens: log K = 11.07, 10.21, 9.58, and 8.54 (298 K, 0.1 M KCl)].[10] In neutral or acidic solution, the lanthanide ions are coordinated only weakly to the outer sphere of the cyclic ligand[13] and free lanthanide ions can be detected electrochemically,[14] by ^{89}Y-NMR,[9] and by reaction with xylenol orange.

Molecular Structures

The molecular structures of the complexes **1** to **4** were determined by single crystal X-ray diffraction. Suitable single crystals were obtained from saturated aqueous solutions of the pure complexes either by slow diffusion of ethanol into the solution of **1** or by slow evaporation of the solutions of **2**, **3**, or **4**. The composition of the crystals correspond to the formulas $[Na_2(Y_2OHEC)(H_2O)_2] \cdot C_2H_5OH \cdot 7\ H_2O$ (**1**), $[Na_2(Gd_2OHEC)(H_2O)_2] \cdot 12\ H_2O$ (**2**), $[Na_2(Eu_2OHEC)(H_2O)_2] \cdot 11\ H_2O$ (**3**) or $[Cs_2(La_2OHEC)(H_2O)_2] \cdot 14\ H_2O$ (**4**). All four complexes crystallise in the monoclinic space group $P2_1/n$. The crystal data, the data collection and the refinement parameters are listed in Table 4 (see Experimental Section).

Although only the Gd^{III} complex **2** and the Eu^{III} complex **3** are isostructural, the conformation of the macrocyclic OHEC unit as well as the coordination geometry around the metal ions are the same for all four structures. Figures 1a and 1b show the solid conformation of **1** in two different views for better understanding, Figure 1c shows the conformation in $[Na(YDOTA)(H_2O)]$ to visualise the differences of the acetate and the amine coordination in complexes of lanthanide metals with DOTA and OHEC. Due to the different ionic radii of the metals, the structures differ in the positions of the lanthanide ions with respect to the mean plane of the cyclic ligand. Whereas in the Y^{III} and La^{III} complexes **1** and **4** the inversion centre of the space group P $2_1/n$ corresponds to the centre of gravity of the molecule resulting in a centrosymmetric geometry, the two halves of the molecules **2** and **3** containing the Gd^{III} and Eu^{III} ions are only almost equal to each other.

Coordination Geometry of the Lanthanide Ions

As demonstrated for **1** in Figure 1, the two lanthanide ions of each complex are completely encapsulated by the macrocyclic ligand. Each lanthanide ion is coordinated by the four nitrogen and four carboxylic oxygen atoms belonging to one half of the overall hexadecadentate ligand. The ninth coordination site of each lanthanide ion is occupied by the oxygen atom of a water molecule. However, the resulting coordination geometry corresponds neither to a monocapped square antiprism, nor to a tricapped trigonal prism, the two coordination polyhedrons representing the most common geometries of nine-coordinate complexes.[15] It can be best described in terms of an irregular polyhedron built up by a trigonal plane and a monocapped pentagonal plane (Figure 2). Three oxygen atoms and two nitrogen atoms of the ligand form the pentagonal plane [the maximum deviation of the atoms from this plane is observed in **2** (22 pm)], which is capped by the oxygen atom of a water molecule. The donor atoms remaining from this half of the ligand, one carboxylic oxygen and two nitrogen atoms, form the trigonal plane. The lanthanide ion is sandwiched between these two planes with a shorter distance to the centre of the capped pentagonal plane (for Gd^{III} in **2** the distance from the pentagonal plane is 46 pm, that from the trigonal plane is 195 pm). In all complexes, the capping oxygen atom of the water molecule and the lanthanide ion lie on an axis passing through the centres of both planes.

In contrast to the DOTA-like lanthanide complexes, in which all acetate groups are situated on one side of the ring adopting a four-bladed propeller-like conformation (see Figure 1c), three of the four carboxylic groups of the OHEC ligand coordinate each lanthanide(III) ion from one side of the ligand ring and the fourth from the opposite side (see Figure 1b).

A least-square plane of the macrocycle formed from the propylene chains and the four adjacent N atoms was calculated for all four complexes. The displacement of the lanthanides from this plane increases with increasing ionic radius of the lanthanide. For the La^{III} complex **4**, the least-squares equation for this plane, defined by the atoms C7, C8, C9, N4, and N1 and the corresponding symmetry-equivalent atoms, corresponds to $-9.5290x + 8.9063y + 3.1741z - 1.5870 = 0$. The maximum deviation of the carbon atoms from this plane is −38.41 pm, that of the nitrogen atoms −19.76 pm. The La^{III} ions are found ±37.47 pm centrosymmetrically above and below this mean plane. The displacement of the other lanthanide atoms from the corresponding ring mean planes is ±33.06 pm for Y^{III} in **1**, +36.53 pm and −31.76 pm for Gd^{III} in **2** and +35.20 pm and −32.30 pm for Eu^{III} in **3**.

Like the metal ions, the metal-coordinating water molecules are situated centrosymmetrically (**1**, **4**) or nearly centrosymmetrically (**2**, **3**) above and below the mean ring planes with Ln−O(water) distances in the range of the Ln−O(acetate) distances (Table 1). The $Gd^{III}-OH_2$ contacts are similar to those found for mononuclear complexes.[4b,c;5a,e]

The minimum and maximum bond angles and interatomic distances of the OHEC ligand (Table 1) agree quite well with those found for TETA (1,4,8,11-tetraazacyclotetradecane-1,4,8,11-tetraacetate)[4g] and DOTA poly-

aza polycarboxylic complexes.[4] Moreover, the Ln−N and Ln−O contacts are within the range of the values reported for mononuclear structures.[4] The differences between the maximum and minimum interatomic distances are greatest for Ln−O in **1** and for Ln−N in **3**, whereas the smallest differences are found for **4**, but altogether, all these differences are much smaller than those reported for the ion $[Eu(DOTA)(H_2O)]^-$, the complex with the greatest distortions within the series of DOTA lanthanide complexes.[4a]

Conformation of the Ligand

The overall conformation of the OHEC macrocycle in the diyttrium complex **1** is shown in Figure 3, together with the qualitative torsion angles. To accommodate two large lanthanide(III) ions within the ring a centrosymmetric biangular conformation, label {13 13} by Dale,[16] with two genuine corners is adopted, which allows all eight nitrogen atoms to direct their lone electron pair efficiently to the lanthanide ions. The fourfold repetition of *anti* torsion angles in the propylene chains expands the ring. This conformation was found to be essentially the same in all four complexes (for torsion angles of the macrocycle in the dilanthanide(III) OHEC complexes see Supporting Information).

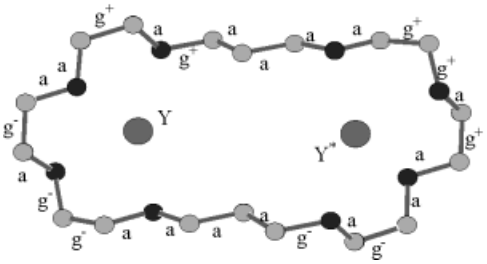

Figure 3. Conformation of the OHEC-ligand in **1**, with corresponding qualitative torsion angles

Surprisingly, the uncomplexed macrocycle of the parent compound OHEC-amine (1,4,7,10,14,17,20,23-octaazacyclohexacosane)[9] shows a highly ordered conformation ruled by a hydrogen-bonding pattern. Its solid state structure reveals a centrosymmetric quadrangular {10 3 10 3} conformation, established by both intramolecular and intermolecular three-centre and two-centre NH···N interactions, thus preventing the enclosure of water molecules into the crystal. This conformation represents a preorganised state for small transition metal ions. In fact, the OHEC-

amine ligand of the dinuclear Cu^{II} complex [Cu_2(OHEC-amine)(SO_4)$_2$][9] adopts in the solid state a very similar {5 5 3 5 5 3} conformation (for torsion angles of the macrocycle in the OHEC-amine ligand and in [Cu_2(OHEC-amine)(SO_4)$_2$] see Supporting Information).

Packing Pattern

All four complexes are wrapped in a water matrix. Besides the water molecules coordinated to the metal ions, the complexes **2** to **4** contain 12, 11, or 14 additional water molecules, respectively. In **1**, the position of one water molecule is occupied to 50% by ethanol, with identical positions of the oxygen atoms.

The crystal of **1** is built up from infinite one-dimensional chains of $[Y_2(OHEC)(H_2O)_2]^{2-}$ units, arranged parallel to the *a* axis and linked by a network of $Na^+\cdots O$ contacts, involving the sodium cation, the carboxylate oxygen atoms and the water molecules associated with the cation. In **2** and **3** the chain runs along the *c* axis. The molecular units of **4** are held together by caesium ions and water molecules forming an infinite chain parallel to the *a* axis. In all structures there is an additional three-dimensional framework built up by hydrogen bonds between water molecules and carboxylic oxygen atoms.

NMR Investigations of the Diamagnetic $[Y_2(OHEC)]^{2-}$ Complex

The lanthanide metals in the oxidation state Ln^{3+} are known to form stable but highly fluxional chelates with a variety of ligands.[6d] Their complexes with DOTA or with modified DOTA ligands together with a number of other O- or N-donor polydentate ligands[17] are among the very few examples exhibiting the same structure in the solid state as in solution. They form highly symmetric and extremely rigid structures, since the DOTA 12-membered tetraazacycle prefers to adopt a square {3 3 3 3} geometry offering a high degree of preorganisation.[6a] This is also valid for lanthanide(III) complexes of TETA, in which the cyclic ligand shows a biangular {7 7} conformation.[4g,18]

Also the large macrocyclic ligand H_8OHEC surprisingly forms a dinuclear yttrium(III) complex that is rigid on the NMR time scale. This fact gives the possibility of gaining some insight into the coordination characteristics and the solution structure of the complexes described here, and also to investigate whether conformational isomers possibly slowly equilibrate.

Temperature-dependent solution NMR studies of the diamagnetic dinuclear lanthanum(III) OHEC complex were unrevealing. The ^{1}H-NMR spectra in D_2O at 300 and 600 MHz showed a series of broad overlapping resonances characteristic of fluxional behaviour. A ^{1}H-NMR spectrum at 600 MHz of $[(La_2(OHEC)]^{2-}$ is shown as Supporting Information.

Figure 4 presents the experimental and the simulated ^{1}H-NMR spectra of $[Y_2(OHEC)]^{2-}$ at 278 K. Starting from the

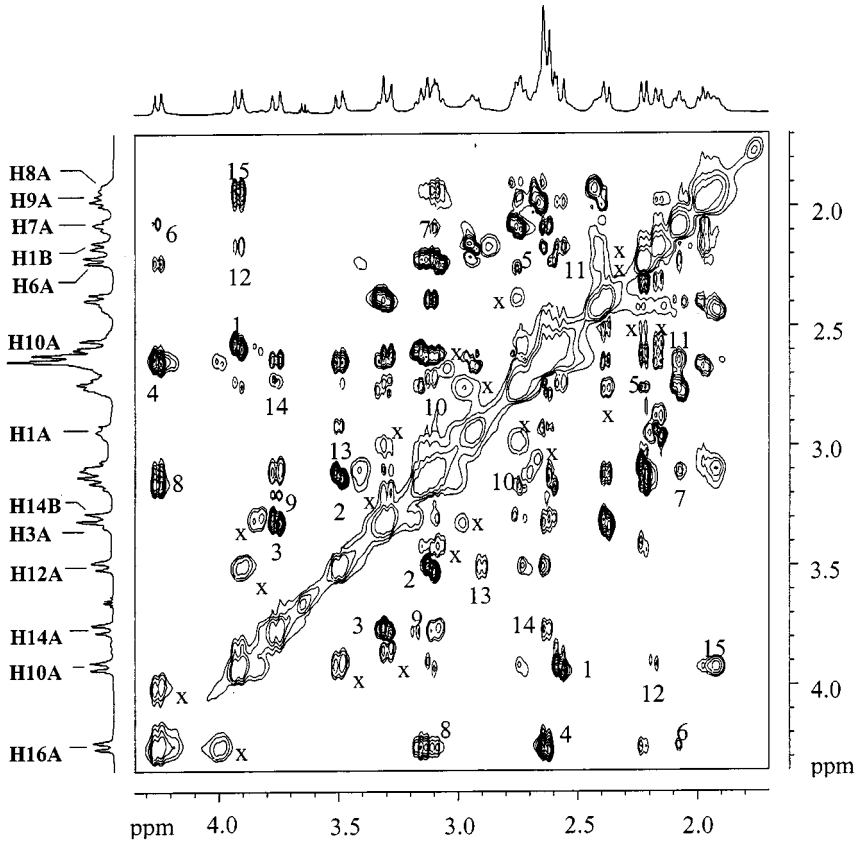

Figure 5. ROESY spectrum of $[Y_2(OHEC)]^{2-}$ at 278 K, mixing time 80 ms; the designation of the peaks is according to Table 3, column 4; exchange peaks are labelled with "x"

methylene proton H16A the step by step assignment was carried out with the HMQC and HMBC spectra and the cross peaks of the ROESY spectra. The ^{1}H- and ^{13}C chemical shift values are listed in Table 2 according to the designation in the solid-state structure.

Two features of these spectra are of particular interest. First, according to the centrosymmetric geometry of the complex in the solid state only half of the carbon and proton signals should appear in the NMR spectra. This is exactly the case for $[Y_2(OHEC)]^{2-}$, the solid-state geometry of which accounts for 26 proton and 17 carbon resonances, which all are observed in the spectra.

The second important feature of the ^{1}H-NMR spectrum (Figure 4) is the fact that the experimental spectrum clearly shows a few low intensity peaks indicating that at least two isomers (3.5:1 ratio) are present in aqueous solution. The minor isomer shows the signal number of an unsymmetric molecule, since temperature increase causes coalescence of each of the signals of the major conformation with two signals of the minor conformation. This loss of centrosymmetry may be caused by independent dynamic processes occurring in the two halves of the originally centrosymmetric molecule. Unfortunately, the NMR data do not allow an unambiguous assignment of the geometry of this minor isomer present in solution.

In order to determine the solution structure of $[Y_2(OHEC)]^{2-}$ a quantitative analysis of the ROESY spectra (Figure 5) measured at different mixing times was carried out. The intensity of the ROE signals was determined by measuring the volume of the ROESY cross peaks. On the basis of the X-ray crystal structure determination, the occurrence of non-sequential ROEs should be limited owing to the relatively large diameter of the complexed ligand. Hence, ROE information was only obtained from geminal

Table 3. Comparison of proton-proton distances derived from crystal structure and ROESY spectra

protons and protons in close neighbourhood. Table 3 lists distances derived from the crystal structure and quantitative ROE measurements. The good agreement of the distance information obtained by these two different methods allows a strong resemblance to be claimed between solid and solution structure. The level of convergence of the structures was quantified by root mean square (rms) deviations calculated as the average of all possible pairwise comparisons, giving 50 ± 5 pm for comparisons based on all heavy atoms.

The low-temperature ROESY spectrum in Figure 5 proves the existence of an exchange process between major and minor conformation by the observation of exchange peaks, designated with "x", of protons undergoing mutual chemical exchange. All NMR signals of the major isomer show two exchange peaks at low temperatures.

For the methylene proton 16A of the acetate side arm, which is little disturbed by signal overlapping, variable-temperature ^{1}H-NMR spectra have been recorded and simulated (Figure 6). At 278 K the proton shows a doublet with an intensity of 78% for the major isomer, and two further doublets at higher field each with 11% of intensity for the minor isomer. With increasing temperature broadening and coalescence of the three signals occurs, followed by a sharpening to one doublet around 365 K. The band shapes of the depicted spectra were calculated for a two-site exchange. The kinetic parameters were deduced from the Arrhenius plot (E_A = 51.3 ± 2 kJ/mol) and the Eyring plot ($\Delta H^{\#}$ = 49 ± 2 kJ/mol). The free energy of activation $\Delta G^{\#}$ at 300 K was calculated from the Eyring equation to be 65.0 ± 3 kJ/mol.

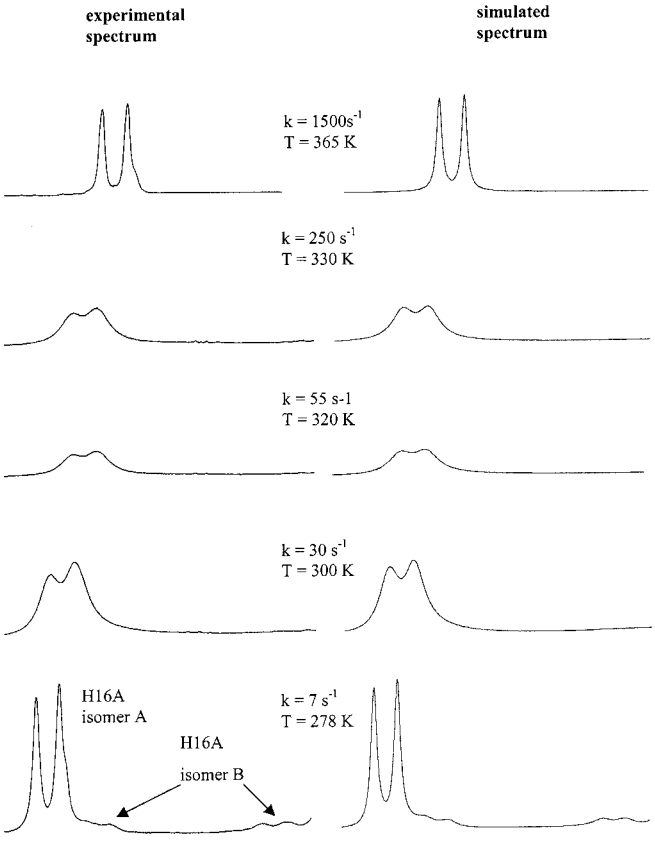

Figure 6. Selected experimental (on the left) and calculated (on the right) ^{1}H-NMR spectra of $[Y_2(OHEC)]^{2-}$ (CH_2 acetate region, proton H16A exchanging between two conformational environments) at different temperatures showing the derived rate constants

By comparison with the solution dynamics of the DOTA lanthanide complexes, two different types of motion should be possible within the $[Y_2(OHEC)]^{2-}$ moiety, one involving the rotation of the acetate arms and the other corresponding to a conformational inversion of the macrocyclic ring. Both processes potentially lead to an interchange between conformational isomers.[6] Although the DOTA and TETA complexes have totally different geometries the similar activation parameters of $[Y_2(OHEC)]^{2-}$ suggest a turning round of acetate groups without releasing the coordinative bonds.[6a,6d,4e,18]

Experimental Section

General Remarks: Materials: All reagents were purchased from Merck or Aldrich and were used without further purification. The ligand H_8OHEC as well as its yttrium(III) and lanthanide(III) complexes (Ln = Gd, Eu) were prepared by the published method.[9] − Elemental analyses and FAB mass spectra confirmed the composition of the compounds. The elemental analyses were recalculated for anhydrous compounds. The complexes contain at least two molecules of water per molecule of complex, dependent of the duration of the drying procedure. − Elemental analysis: Perkin−Elmer 2400 Series CHNS/O Analyzer. − MS: Double-focusing ZAB instrument, VG company (FAB).

H_8OHEC: M.p: 230−235°C. − $C_{34}H_{60}N_8O_{16}$ (836.41): calcd. C 48.80, H 7.23, N 13.39; found C 49.01, H 7.44, N 13.43%. − FAB^+MS (magic bullet/H_2O) *m/e*: 837 $[M + H]^+$, 859 $[M + Na]^+$, 875 $[M + K]^+$. Na^+ and K^+ are from impurities of the water used.

$Na_2[Y_2(OHEC)]$ (1): Dec. > 300°C. − $C_{34}H_{52}N_8Na_2O_{16}Y_2$ (1052.46): calcd. C 38.79, H 4.98, N 10.64; found C 38.60, H 4.69, N 10.38%.

$Na_2[Gd_2(OHEC)]$ (2): Dec. > 300°C. − $C_{34}H_{52}Gd_2N_8Na_2O_{16}$ (1189.25): calcd. C 34.34, H 4.41, N 9.42; found C 34.60, H 4.41, N 9.08%. − FAB^+MS of the complex (thioglycerine/methanol/H_2O) *m/e*: 1185−1196 $[M + H]^+$.

$Na_2[Eu_2(OHEC)]$ (3): Dec. > 300°C. − $C_{34}H_{52}Eu_2N_8Na_2O_{16}$ (1180.17): calcd. C 34.57, H 4.44, N 9.49; found C 34.83, H 4.53, N 10.00%. − FAB^+MS (thioglycerine/methanol/H_2O) *m/e*: 1177−1183 $[M + H]^+$.

$Cs_2[La_2(OHEC)]$ (4): The complex was prepared by treating 0.5 g (0.62 mmol) of H_8OHEC and 404.0 mg (1.24 mmol) of La_2O_3 suspended in 40 mL of distilled water. The mixture was refluxed for 24 h to obtain a clear solution. After cooling to room temperature and adjustment of the pH to 8.5 with 0.1 M Cs_2CO_3, the solution was refluxed for another 2 h and then filtered to remove traces of precipitated $La(OH)_3$. After removal of the solvent, the residue was recrystallised from water/ethanol. The separated colourless crystals were dried in vacuo at 80°C. Yield 76%. − $C_{34}H_{52}Cs_2La_2N_8O_{16}$ (1371.97): calcd. C 29.75, H 3.81, N 8.16; found C 29.53, H 4.01, N 8.08%. − FAB^+MS (thioglycerine/methanol/H_2O) *m/e*: 1394.5−1397.5 $[M + Na]^+$, 1128.8 $[M - 2\,Cs+Na]^-$.

X-ray Crystallographic Study: Suitable crystals of **1** were obtained by slow diffusion of ethanol into a concentrated aqueous solution of the recrystallised diyttrium complex. Suitable crystals of **2**, **3**,

and **4** were obtained by slow evaporation of a concentrated aqueous solution of the recrystallised dilanthanide complexes.

The single crystals of compounds **1**, **2**, and **4** were measured on the STOE Ipds one circle diffractometer supplied with an imaging plate area detector at 200 K in nitrogen atmosphere. Intensity correction for Lorentz and polarisation effects and in the case of **1** and **2** also for absorption (Difabs-related)[19] was applied.

A crystal of the compound **3** was measured on a STOE Stadi-4 four circle diffractometer at room temperature in air. Intensity data were corrected for Lorentz, polarisation and absorption (ψ-scan technique).[20]

Structures were solved by direct methods[21] and refined by full-matrix least squares against F^2[22] supported by STOE Xstep software. The thermal motion of all non-hydrogen atoms was treated anisotropically, that of hydrogen atoms isotropically and tied 1.2 times higher than the corresponding attached atom.

In the structure of **1** the positions of all H-atoms of the OHEC unit and six H-positions of water molecules were found in difference electron density maps (difmaps) and successfully refined in least-squares refinement. The H-atoms at the partially occupied water and ethanol sites could not be localised.

For the refinement of **2**, **3**, and **4** the hydrogen atoms of the OHEC units were calculated in their idealised positions and allowed to ride on their attached atoms during the least squares cycles.

In structure **2** two of fourteen water positions have site occupation factors of only 0.8 and 0.5. All H atoms at fully occupied water sites were found in difmaps and their positions could be refined by least squares.

In structure **3**, where either two of fourteen water sites are not fully occupied (0.67 and 0.33 in part, respectively), all H atoms of fully occupied water sites were localised in difmaps, but had to be fixed in the following least squares cycles.

In the crystal structure of **4** all seven water sites are completely occupied, but nevertheless only ten of fourteen water hydrogens could be found in difmaps (obviously the data set of **4** was of poor quality; even the application of difabs failed!). Consequently, all hydrogen atoms had to be restrained or fixed for least-squares refinement.

Further details of the crystal-structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein- Leopoldshafen, Germany, on quoting the depository numbers CSD-410446 for **1**, CSD-410447 for **2**, CSD-410444 for **3**, and CSD-410445 for **4**.

NMR: Samples for NMR spectroscopy were prepared by dissolving 50 mg of the complex in 0.75 mL of D_2O in a 5-mm sample tube (Wilmad). NMR spectra were acquired at 600 MHz on a Bruker AMX 600 spectrometer. 2D spectra (DQF-COSY, ROESY, TOCSY, HSQC, and HMBC) were recorded at 278 K with a spec-

tral width of 7200 Hz for protons and 33000 Hz for ^{13}C. The TPPI method of acquisition was used in all cases. The signal due to residual HDO was suppressed by continuous low-power irradiation. Data matrices typically consisted of 2048 complex points in F2 for each of the 512 F1 increments, the data being zero-filled to a 2048 × 1024 complex matrix before transformation. The apodisation functions used in processing were 90° shifted sine-bell squared for all 2D experiments. 2D spectra were processed using the UXNMR program on a Silicon Graphics O2 workstation. ROESY crosspeaks were integrated by the AURELIA[23] software including offset correction according to Bull.[24] The temperature dependence of the proton resonances was determined by recording the 1D spectra at 278 to 373 K with temperature steps of 10 K. The temperature was calibrated against a 100% ethylene glycol insert sample. Rate constants were evaluated by comparing the experimental spectra with those calculated with the program DNMR-SIM.[25] The simulation of one dimensional ^{1}H-NMR spectra were performed with the Bruker Software WIN-DAISY.[26]

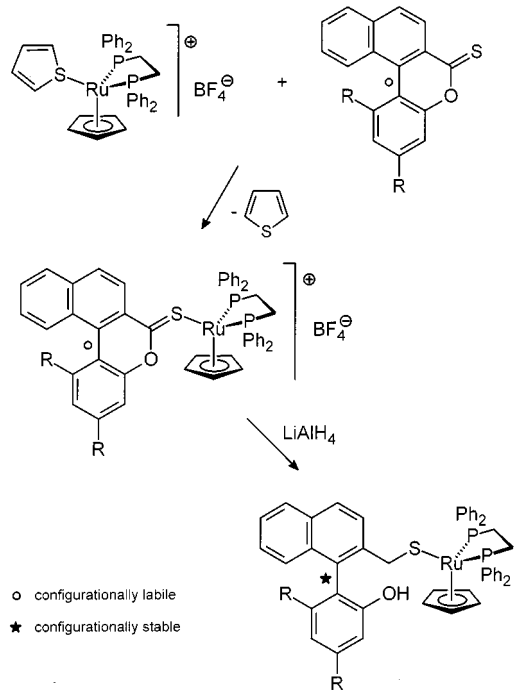
Novel Concepts in Directed Biaryl Synthesis, 68[+]
Enantioselective Organic Syntheses Using Chiral Transition Metal Complexes, 9[++]
Atropo-Diastereoselective Ring Opening of Biaryl Thionolactones Using [CpRu{(*S*,*S*)-CHIRAPHOS}]$^+$ as a Chiral Auxiliary

Wolfdieter A. Schenk,*[a] Jörg Kümmel,[a] Irene Reuther,[a] Nicolai Burzlaff,[a] Andreas Wuzik,[b] Olaf Schupp,[b] and Gerhard Bringmann*[b]



Dedicated to Professor Helmut Werner on the occasion of his 65th birthday

Keywords: Biaryls / Lactones / Nucleophilic additions / Ruthenium / S ligands

The substitution-labile thiophene complex [CpRu{(*S*,*S*)-CHIRAPHOS}(SC_4H_4)]BF_4 (**2**) [(*S*,*S*)-CHIRAPHOS = (2*S*,3*S*)-bis(diphenylphosphanyl)butane], prepared from [CpRu{(*S*,*S*)-CHIRAPHOS}Cl] (**1**), thiophene, and $AgBF_4$, reacted with the biaryl-thionolactones **3a–f** to give the corresponding S-coordinated complexes **4a–f** in high yields. The structure of **4c**, which crystallized as the pure (*S*,*S*,*P*) diastereoisomer, was determined by X-ray crystallography. Coordination of the ruthenium fragment caused an elongation of the C=S bond, a contraction of the C–O bond within the lactone ring and a flattening of that ring. Single hydride transfer with $LiBEt_3H$ converted **4a–f** into the thiolactolate complexes **5a–f** in good yields and diastereoselectivities. An X-ray structure determination of the major isomer of **5a** revealed it to be the (*S*,*S*,*S*,*P*) diastereoisomer. Protonation with NH_4PF_6 converted **5a–f** into the corresponding ring-opened thioaldehyde complexes **6a–f**. Alkylation of **5a** with methyl iodide resulted in Ru–S cleavage to give the oxothioacetal **7a** and [CpRu{(*S*,*S*)-CHIRAPHOS}I] (**8**). Full reduction of **4a–f** with $LiAlH_4$ produced the thiolate complexes **9a–f** in high yields and 6–74% *de*. Methylation at sulfur converted **9a–c** into the corresponding thioether complexes **10a–c**, which were cleaved to **8** and the free methyl thioethers **11a–c** without isomerization of the biaryl axis.

Introduction

Natural products containing a chiral, configurationally stable biaryl axis are attracting considerable attention due to their widespread pharmacological activities.[3][4] Their stereocontrolled synthesis remains a fascinating challenge. One of the most efficient synthetic pathways consists of the preparatively facile formation of a bridged, but still configurationally labile biaryl system followed by an atropo-diastereo- or atropo-enantioselective ring-opening step.[5] The necessary element of chirality may already be present in the molecule,[6] or it may be introduced either by the reagent[7] or by attaching a chiral auxiliary to the bridged biaryl substrate.[8] We have previously demonstrated that configurationally unstable biaryl thionolactones can easily be introduced as ligands into half-sandwich ruthenium complexes. Double nucleophilic addition of hydride converts the coordinated thionolactones into axially chiral racemic thiolates (Scheme 1).[9]

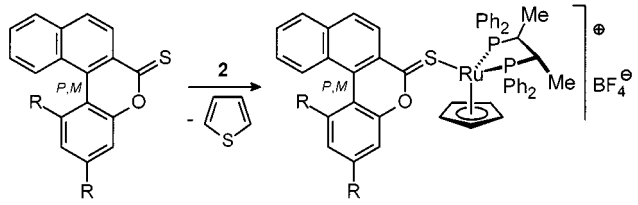
By using a similar but chiral, enantiomerically pure complex it should be possible to achieve a diastereoselective ring cleavage of the thionolactone. The coordinatively unsaturated complex fragment [CpRu{(*S*,*S*)-CHIRAPHOS}]$^+$ [(*S*,*S*)-CHIRAPHOS = (2*S*,3*S*)-bis(diphenylphosphanyl)-butane] appeared to be a promising candidate.[10] This chiral auxiliary has previously been employed by us, and with considerable success, in the diastereoselective oxidation of coordinated thioethers.[11–14]



Results

The synthesis of thionolactone complexes by ligand exchange requires a reactive starting material.[9] Thus, [CpRu{(*S*,*S*)CHIRAPHOS}Cl] (**1**) was treated with silver tetrafluoroborate in the presence of thiophene to give the enantiomerically pure thiophene complex **2** in almost quantitative yield (Equation 1).

1 **2** (95%) (1)

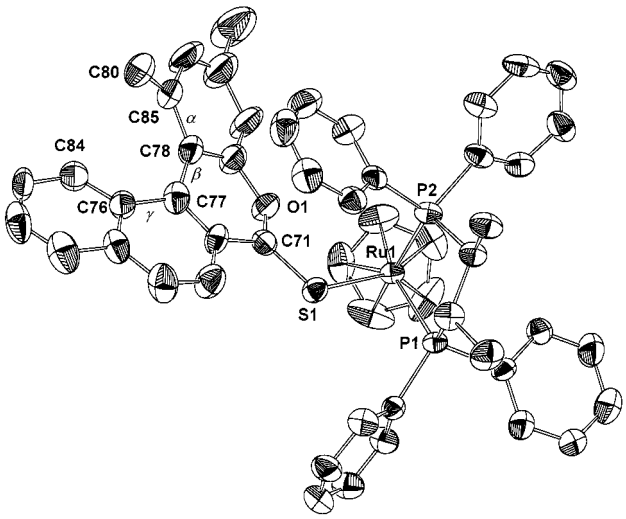
Compound **2** is a yellow, crystalline, air-sensitive material. Its ^{1}H-NMR spectrum exhibits, *inter alia*, the typical AA′XX′ pattern at δ = 5.81 and 6.83 indicating the presence of a thiophene ligand. The reaction of **2** with the thionolactones **3a**–**f** at room temperature was accompanied by an immediate color change from yellow to dark purple. The pure thionolactone complexes were readily purified by chromatography and isolated in almost quantitative yields as deep purple crystalline solids (Equation 2).

3a - f **4a - f** (91 - 96%) (2)

R	H	OMe	Me	Et	*i*-Pr	*t*-Bu
	a	**b**	**c**	**d**	**e**	**f**
de (%)		10[a]	10	14	20	6

[a] at 210 K

The ^{31}P-NMR spectra of **4a**–**f** reveal a dynamic process whose rate depends on the size of the substituent R. The limiting cases are marked by **4a** (R = H), which even at 210 K exists as a mixture of rapidly equilibrating diastereoisomers, and **4c**–**f** (R = Me, Et, *i*Pr, *t*Bu), which up to 380 K exhibit two separate sets of signals for the two diastereoisomers. With the exception of R = *t*Bu, the diastereomeric ratio increases slightly with the size of R. Compound **4b** (R = OMe) shows two sets of signals at 210 K in a 55:45 ratio (10% *ee*) which coalesce at 263 K. A standard lineshape analysis yielded an activation barrier for this process of $\Delta G^{\neq}$ = 48 kJ mol^{-1}. ^{1}H-NMR spectra of samples of **4c** and **4d**, if recorded immediately after dissolution at 253 K, gave distinctly higher diastereomeric ratios. This indicates that, for those two compounds, the epimerization of the biaryl axis has a half-life at this temperature in the range of a few minutes. In the ^{13}C-NMR spectra at 295 K the thiocarbonyl function gives rise to one (**4a, b**) or two (**4c**–**e**) signals at δ = 200, which are split into doublets of doublets due to coupling with the nonequivalent phosphorus nuclei. A single crystal of **4c** was subjected to an X-ray structure determination. Figure 1 shows a view of the cation.



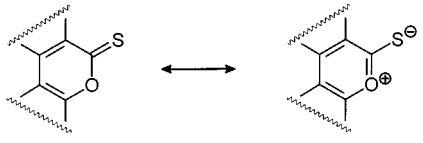


Figure 1. Structure of the Cation of [CpRu{(*S*,*S*)-CHIRAPHOS}($SC_{19}H_{14}O$)]BF_4 (**4c**) (hydrogen atoms omitted); selected bond lengths (pm) and angles (deg): Ru(1)–P(1) 227.8(2), Ru(1)–P(2) 231.2(2), Ru(1)–S(1) 233.1(2), C(71)–S(1) 165.5(8), C(71)–O(1) 134.3(10); P(1)–Ru(1)–P(2) 83.40(7), P(1)–Ru(1)–S(1) 85.42(7), P(2)–Ru(1)–S(1) 89.09(8), C(71)–S(1)–Ru(1) 114.0(3), C(71)–S(1)–Ru(1)–P(1) 169.3(5), C(71)–S(1)–Ru(1)–P(2) 86.0(5), C(80)–C(85)–C(78)–C(77) 15.2(25), C(85)–C(78)–C(77)–C(76) 27.3(23), C(78)–C(77)–C(76)–C(84) 20.0(20)

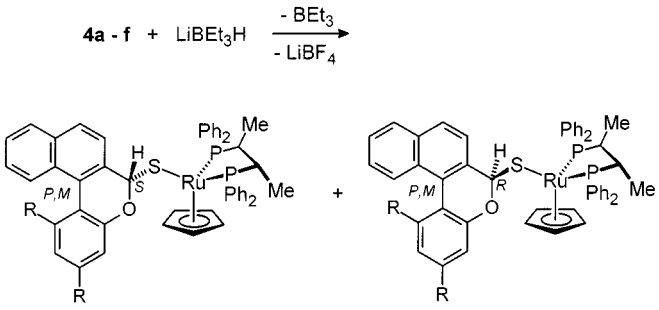
The coordination geometry around the ruthenium atom is adequately described as octahedral, in which the C_5H_5 ligand occupies three adjacent sites. All bond lengths to ruthenium are similar those in the closely related thioaldehyde complex [CpRu(dppe)(η^1-S=CHC_6H_4OMe)]PF_6.[15] The two angles S–Ru–P(1) and S–Ru–P(2) are markedly different as a result of the fixed configuration of the five-membered Ru{(*S*,*S*)-CHIRAPHOS} chelate ring. The bonding within the thionolactone ring can be described in terms of two canonical forms **A** and **B** (Scheme 2).



A **B**

Scheme 2. Resonance forms of the thionolactone ring

The coordination of a cationic metal complex at sulfur is expected to increase the contribution of the benzenoid resonance form **B** by dissipating the negative charge. Indeed, the C=S bond in the complex is 2 pm longer than in the uncoordinated thionolactone **3c**,[9] while the C(71)−O bond within the lactone ring of the complex is shorter by 1.6 pm. The two aryl moieties are helically twisted; of the two possible forms, only the *P* diastereoisomer is found in the crystal (see Figure 1). This helical distortion is a result of the steric repulsion between the *ortho* methyl group and the hydrogen atom in the 8-position of the naphthyl part. As seen in other cases,[16] the sum of the dihedral angles α [C(80)−C(85)−C(78)−C(77)], β [C(85)−C(78)−C(77)−C(76)], and γ [C(78)−C(77)−C(76)−C(84)] (Figure 1) can serve as a measure of this distortion. At 62.5°, this sum is only marginally different from the corresponding value for uncoordinated **3c** (63.6°).[9] The individual contributions to this sum, however, differ markedly; β in particular is distinctly smaller in the complex **4c** (27.3°) than in uncoordinated **3c** (33.4°). This flattening of the lactone ring, which has been observed previously for complexes of the analogous oxolactones,[8] hints at some degree of "aromatization" as expressed by the resonance form **B** (Scheme 2). The orientation of the biaryl-thionolactone ligand within the complex is another conspicuous feature of the structure of **4c**. The C=S group and the Ru−P(1) bond are nearly in the same plane, while the Ru−P(2) bond is almost perpendicular to that plane (Figure 1). As a result, one diastereomorphous half space around the thionolactone function is shielded by one of the phenyl groups of the (*S*,*S*)-CHIRAPHOS ligand, while the other half space remains exposed.

Treatment of the thionolactone complexes **4a**−**f** with $LiBEt_3H$ in THF at −70°C followed by slowly warming to 20°C was accompanied by a color change to yellow. Workup by extraction with benzene and freeze-drying gave the yellow, crystalline, slightly air-sensitive thiolactolate complexes **5a**−**f** in very good yields (Equation 3).

The room-temperature NMR spectra of these compounds indicate the presence of two (**5a**, **b**) or four (**5c**−**f**) diastereoisomers. The ^{31}P-NMR spectrum of **5b** consists of two broad signals which, upon cooling to 270 K, decoalesce into two AX spin systems due to a slowed inversion of the biaryl axis. The activation barrier could not be determined precisely but seems to be somewhat higher than that of the helimerization of **4b**. In the ^{13}C-NMR spectra the thioacetal carbon gives rise to a resonance at $\delta = 90$ with a 5 Hz coupling to only one of the phosphorus nuclei. This hints at an unsymmetrical arrangement of the thiolactolate ligand in the coordination sphere of the ruthenium atom, with one dihedral angle C−S−Ru−P close to 90° and the other close to 180°. Interestingly, for the two opposing helimers of the major diastereoisomer, the signals in the ^{1}H-NMR spectrum of the HC(S)O group are separated by up to 1.58 ppm. An inspection of the molecular structure of **5a** (see below) suggests that this may be due to differing anisotropy effects of one of the phenyl groups of the CHIRAPHOS ligand.

[a] at 220 K

(3)

An X-ray structure determination was carried out on a crystal of the major diastereoisomer of **5a**, Figure 2 shows a view of the molecule.

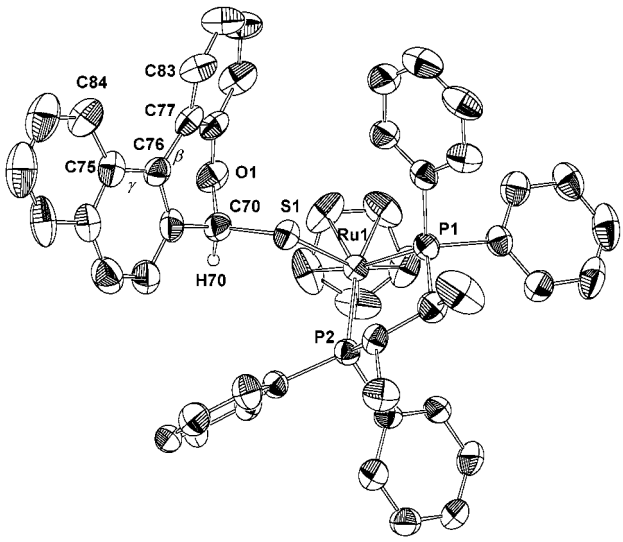

Figure 2. Structure of the Cation of [CpRu{(*S*,*S*)-CHIRAPHOS}($SC_{17}H_{11}O$)] (**5a**) [hydrogen atoms omitted, except for H(70)]; selected bond lengths (pm) and angles (deg): Ru(1)−P(1) 227.0(2), Ru(1)−P(2) 225.7(2), Ru(1)−S(1) 242.2(2), C(70)−S(1) 180.2(7), C(70)−O(1) 144.2(9); P(1)−Ru(1)−P(2) 84.41(7), P(1)−Ru(1)−S(1) 88.37(6), P(2)−Ru(1)−S(1) 81.78(6), C(70)−S(1)−Ru(1) 109.1(3), C(70)−S(1)−Ru(1)−P(1) 167.8(3), C(70)−S(1)−Ru(1)−P(2) 72.4(3). C(83)−C(77)−C(76)−C(75) 26.5(10), C(77)−C(76)−C(75)−C(84) 10.9(10)

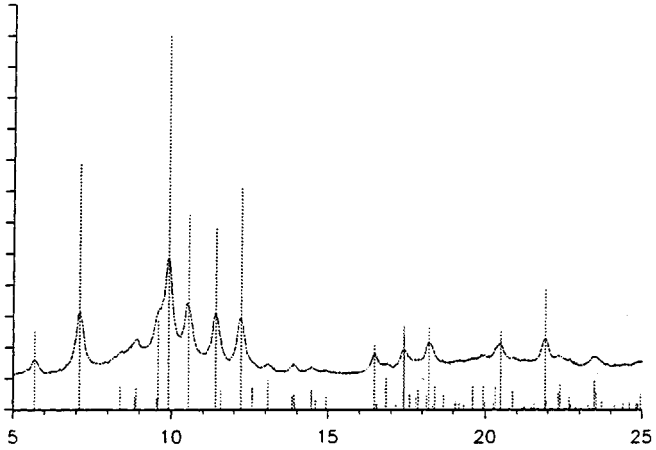
The [CpRu{(*S*,*S*)-CHIRAPHOS}] part is almost identical to that of **4c** with the exception of the orientation of one phenyl group of the chiral chelate ligand. The hydride addition has led to an increase of the Ru−S and C−S bond lengths by 9 and 15 pm, respectively. Also, the C−O bond within the former lactone ring is longer by 10 pm. The configuration at the newly formed stereocenter is *S* while the biaryl axis of the crystalline compond has a fixed *P* configuration. The dihedral angles within the biaryl system

(β = 26.5°, γ = 10.9°) still indicate a sizable distortion. These values should, however, not be compared to those of **4c** where the interaction of the *ortho* methyl substituent at the phenyl group greatly contributes to the extent of the helical distortion.[16][17] In order to prove the identity of the single crystal as the bulk material of **5a** unambiguously, a powder diffraction diagram was recorded and compared with the pattern calculated from the single crystal data, which resulted in a perfect match (Figure 3).



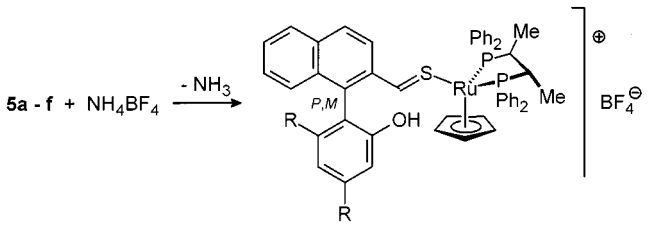


Figure 3. [CpRu{(*S*,*S*)-CHIRAPHOS}($SC_{17}H_{11}O$)] (**5a**), comparison of measured powder diffraction diagram (trace) and calculated diffraction pattern (bars)

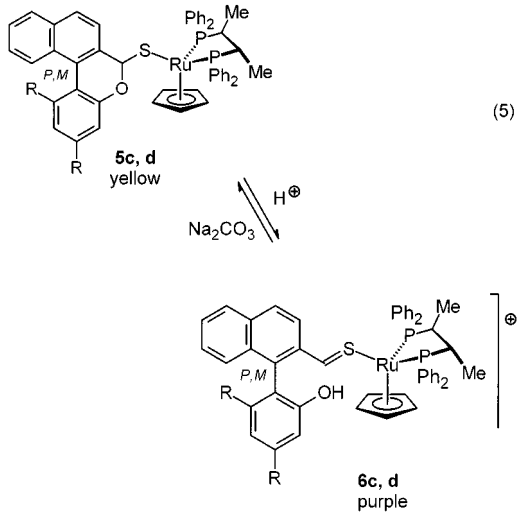
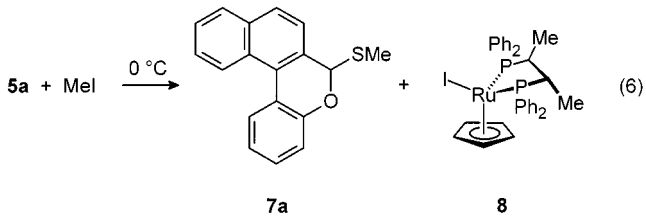


When exposed to traces of moisture or acid, solutions of the thiolactolate complexes **5a**−**f** occasionally turned deep purple, which is the characteristic color of thioaldehyde complexes.[15] Indeed, treatment of **5a**−**f** (as diastereomeric mixtures, Equation 3) with an excess of NH_4BF_4 in acetone (Equation 4) resulted in a quantitative transformation (as judged by NMR spectroscopy) into the corresponding thioaldehyde complexes **6a**−**f**.

6a - f (62 - 75%) (4)

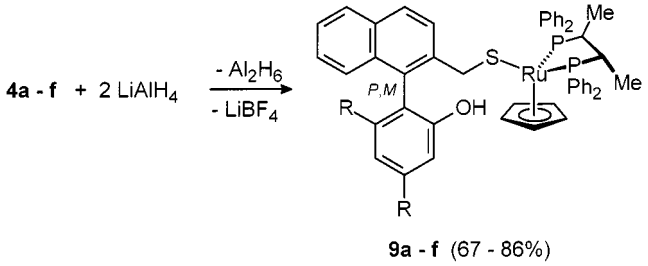
R	H	OMe	Me	Et	*i*-Pr	*t*-Bu
	a	**b**	**c**	**d**	**e**	**f**
de (%)	5	8	12	12	23	0



While **6a** was stable only in the presence of NH_4BF_4, the substituted derivatives could be isolated in good yields as deep purple crystalline solids. A similar opening of the thiolactolate could be achieved with various Lewis acids. Thus, when $LiBF_4$ was added to a solution of **5b** in acetone and the solvent removed under reduced pressure, a color change from yellow to purple was observed. According to the ^1H and ^{13}C-NMR spectra complete conversion into the thioaldehyde complex **6b** had taken place with 4% *de.* A similar result was obtained upon treatment of a solution of **5a** in THF with [$ZrCl_4(THF)_2$]. The red reaction mixture was worked up by addition of NH_4BF_4 in acetone and chromatography over silica and yielded **6a** with 20% *de.* Protonation and ring opening are reversible: Stirring suspensions of **6c** or **6d** and sodium carbonate in benzene produced clear yellow solutions, from which **5c** and **5d**, respectively, were isolated in reasonable yields (Equation 5).

(5)

As expected, **6a**−**f** were formed as mixtures of diastereoisomers in these reactions. The diastereomeric excess depends somewhat on the conditions used and increases slightly with increasing size of R; again R = *t*Bu (**6f**) is a conspicuous exception. The presence of a thioaldehyde functionality is unambiguously deduced from the characteristic low field signals in the ^1H (d = 9.7−10.3) and ^{13}C NMR (d = 210−217) spectra. The carbon resonance is split into an apparent triplet caused by roughly equal couplings to the two nonequivalent phosphorus nuclei.



In an attempt to detach the thiolactolate ligand from the metal, **5a** was treated with methyl iodide at 0°C (Equation 6).

(6)

Within a few days complete conversion into the free monothioacetal **7a** and the known iodo complex **8**[12] took place. Chromatographic separation yielded **7a** as an impure yellow oil, which was identified spectroscopically. Full re-

duction of the thionolactone complexes **4a**−**f** was achieved with an excess of $LiAlH_4$ (Equation 7).

9a - f (67 - 86%)

R	H	OMe	Me	Et	*i*-Pr	*t*-Bu

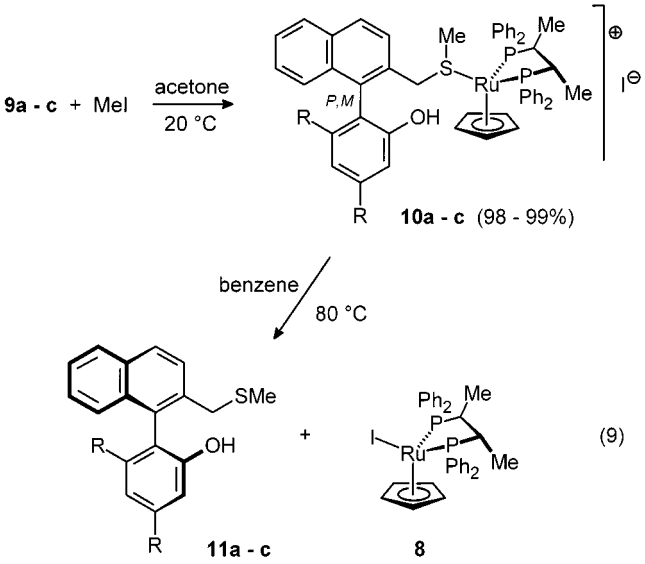
(7)

The highest diastereoselectivities were obtained by combining the reagents at −70°C, keeping the mixtures for 8 h at this temperature, and then allowing them to slowly warm to 20°C. Workup by chromatography over silica gel gave good yields of the yellow crystalline thiolate complexes **9a**−**f**. Their ^{13}C-NMR spectra show a signal at $\delta = 40$ for the benzylic carbon atom, which is split due to coupling with two nonequivalent phosphorus nuclei. The absolute values of the two coupling constants differ considerably, one of them being smaller than 1 Hz in some instances. This again hints at an unsymmetric orientation of the thiolate ligand in the coordination sphere of the ruthenium atom. The chemical shift difference of the diastereotopic benzylic protons is another noteworthy feature. It is consistently small (0.08−0.48 ppm) for the major diastereoisomer and large (0.93−1.46 ppm) for the minor one. Since chemical shift differences in these systems are mainly caused by anisotropy effects of the various aryl groups, we are confident that all major and minor isomers have the same configuration of the biaryl axis.



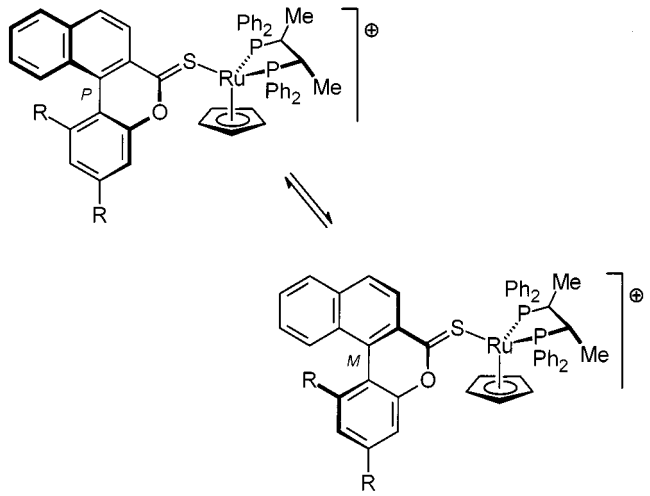
Some experiments aimed at finding ways to influence the diastereoselectivity of the ring-opening reaction were carried out. Thus, reduction of a sample of the thiolactolate **5c** (20% de) at −70°C with $LiAlH_4$ in THF gave the ring-opened thiolate complex **9c** in 61% yield and only 10% *de*. Under the same conditions, $LiBEt_3H$ was much more efficient producing **9c** in 80% yield and 50% *de*. In a similar experiment, a sample of **5a** with 86% *de* was treated at −70°C in THF with $[ZrCl_4(THF)_2]$ whereupon its color changed to red. It was kept at this temperature for 8 h to ensure complete ring opening to the thioaldehyde intermediate, and then $LiAlH_4$ was added (Equation 8).

This time, the thiolate complex **9a** was obtained with 65% yield and 18% *de* but with *opposite diastereoselectivity*, i. e. the minor diastereoisomer of Equation 7 was now the major one (hence the minus sign in Equation 8).

The demetalation of the thiolate complexes was achieved in two steps. Alkylation of **9a**−**c** with methyl iodide gave the thioether complexes **10a**−**c** in quantitative yields as light-yellow crystalline materials. The ionic nature of the

products is apparent from their insolubility in less polar media. The newly introduced methyl group gives resonances in the ^{1}H and ^{13}C-NMR spectra at $\delta = 1$ and 25, respectively. When the salts **10a**−**c** were heated in benzene a smooth ligand substitution took place, giving the iodo complex **8** and the liberated thioethers **11a**−**c** (Equation 9).

(9)

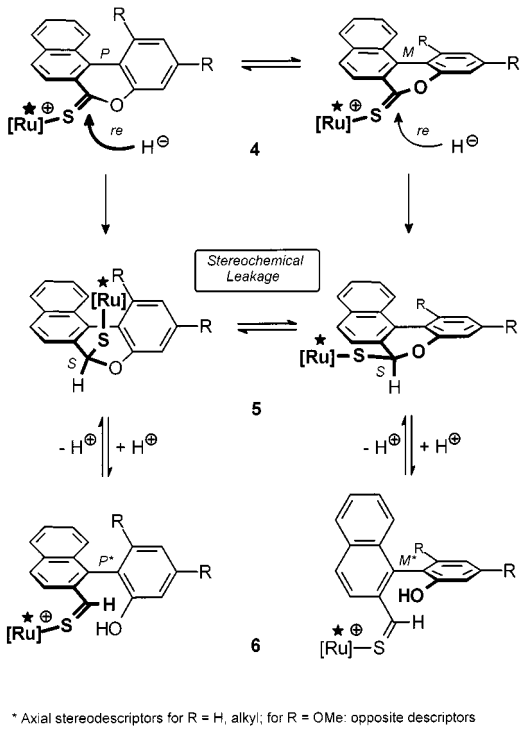


R	H	OMe	Me
	a	**b**	**c**
ee (%)	50 (*P*)	8 (*M*)	74 (*P*)

The latter were isolated after chromatography as slightly yellow oils and their enantiomeric purity checked by HPLC on a chiral phase.[18] The enantiomeric ratios of **11a**−**c** thus obtained were identical to the diastereomeric ratios of the starting complexes **9a**−**c** (Note that the change of the stereochemical descriptor for **11b** is due only to formal reasons, because of the higher priority of the MeO substituent). Finally, a comparison of the CD spectrum of **11c** with that of authentic (*M*)−**11c**[18] showed that the reaction sequence described here had yielded the *P* enantiomer.

Discussion

The work described here is part of an ongoing effort to use chiral transition metal complexes as auxiliaries for various types of enantioselective organic transformations.[19−22] Previously we have shown that double hydride addition to achiral ruthenium complexes of thionolactones leads to a smooth ring-opening reaction.[9] It was expected, therefore, that with the use of similar, but chirally modified, metal templates an atropo-diastereoselective opening of the thionolactone ring could be achieved. The required chiral thionolactone complexes **4a**−**f** are readily accessible by a ligand exchange reaction starting with the highly labile thiophene complex **2,** which in turn was obtained in excellent yield in close analogy to known syntheses.[9][23]



The structure determination of **4c** revealed some interesting aspects. First of all, the compound crystallized as a single diastereoisomer with *P* configuration at the biaryl axis, whereas in solution both diastereoisomers are of almost equal energy. In the solid state, the lactone carbon atom is perfectly shielded from the *si* side by one of the phenyl groups of the (*S*,*S*)-CHIRAPHOS ligand (Figure 1). It is thus tempting to hope that nucleophiles will add from the *re* side with high diastereoselectivity. This, however, is perhaps a too simplistic view. In solution, a dynamic equilibrium between both diastereoisomers [(*S*,*S*,*P*) and (*S*,*S*,*M*)] exists (Scheme 3), whose interconversion rate depends strongly on the size of R.

Scheme 3. Helimerization of the biaryl axis of thionolactone complexes **4a**−**e**

The limiting cases are marked by an immeasurably rapid equilibration, even at low temperature, for R = H (**4a**), and a slow interconversion in the range of several minutes for R = Me, Et, *i*Pr, *t*Bu (**4c**−**f**). This helimerization process is fundamental to an understanding of the stereoselectivity of the hydride addition, which depends on the relative rates of *re* versus *si* attack on both diastereoisomers, as well as the rate of their interconversion. An important clue to the solution structures of the thionolactone complexes comes from the observation of two fairly different ^3J(P,C) couplings of the C=S group for each of the diastereoisomers of **4b**−**f**. This indicates that the two dihedral angles C−S−Ru−P also remain unequal in solution. Furthermore, the (*S*,*S*,*M*) diastereoisomer must have a similar structure with a near coplanar arrangement of C(71), S(1), Ru(1), and P(1). This can be deduced unequivocally from the fact that, in the room temperature NMR spectra of **4a** and **4b**, the ^{13}C signal of the thionolactone group still appears as a doublet of doublets with two unequal couplings. If the inversion of the biaryl axis were accompanied by a rotation of the Ru−S bond such as to expose the *si* side for nucleophilic attack, the couplings ^3J(P,C) of the two diastereoisomers should average out and make the signal at δ = 200 appear as a triplet. The conclusion, therefore, is that for both diastereoisomers of the thionolactone complexes **4a**−**f**, *re* addition is strongly favoured over *si* addition (Equation 3). Molecular models, however, seem to indicate that the (*S*,*S*,*M*) diastereoisomers are, for steric reasons, less accessible and therefore less prone to react with any nucleophiles.

The structure determination of **5a** shows that, as expected, the (*S*,*S*,*S*) diastereoisomer is the major product. From an inspection of Figure 2 we can also see that a *P* configuration of the biaryl axis necessarily implies an axial positioning of the S−Ru unit and an equatorial one of the H substituent at the six-membered thiolactolate ring. It is unlikely that a minor change of the remote substituents R would invert the direction of the hydride addition (see above). Thus it is safe to assume that the major diastereoisomer of **5b** has the (*S*,*S*,*S*) configuration as well. For this compound the helimerization can be slowed down sufficiently to observe separate NMR signals for the (*S*,*S*,*S*,*P*) and (*S*,*S*,*S*,*M*) helimers, which at 253 K are present in a 60: 40 ratio (both helimers of the (*S*,*S*,*R*) diastereoisomer were present in too low a concentration to be assigned with certainty). The *M* helimer has the hydrogen atom in an axial position, which leads to a characteristic[24] high-field shift to δ = 3.72. These results then help to assign the relative (and absolute) configurations of the two major isomers of **5c**−**f** unambiguously. In all cases these are characterized by a large shift difference of the S(O)CH hydrogen atom, which means that the most abundant isomer has this hydrogen atom in an equatorial and the second isomer in an axial position. This implies that the two major isomers must have opposite configurations at the biaryl axis and identical configurations at the tetrahedral carbon atom. Further support for this interpretation is supplied by the stereochemical outcome of the protonation − ring opening reaction (Equation 4). The observed low diastereoselectivity clearly reflects the ratios of the two major isomers of the starting complexes **5a**−**f**. This facile ring opening is driven by the steric strain caused by the *ortho* substituent R, and produces a highly reactive thioaldehyde function which readily takes up a second hydride.[15] On the other hand, by its reversibility under basic conditions (Equation 5), the facile formation of a thioaldehyde intermediate is a serious obstacle in the attempted atropo-enantioselective ring opening reaction since it provides a "stereochemical leakage" (Scheme 4).

Scheme 4. Stereochemical leakage in the hydride addition-ring-opening sequence

As already explained for the oxo analogs[2,5,24,25] the thioaldehyde complexes *P*-**6** can cyclize back to the thiolactolate complexes *S*,*P*-**5**, equilibrate to *S*,*M*-**5**, and then burst open out of both helimeric forms of **5** to eventually give *P*- and *M*-**6**. In favourable cases, this leakage may be overcome as shown by the rapid reaction of **4c** with $LiAlH_4$, which produces **9c** with 74% *de* (Equation 7). A variation of the hydride reagent or a masking of the phenolic oxygen by addition of a strong Lewis acid (Equation 8) does indeed change the stereochemical outcome of the reduction. However, this did as yet not lead to a significant improvement, since the two configurations of the biaryl axis are already present in roughly equal amounts in the intermediates **5a**−**f**.

Conclusions

The work presented here demonstrates that transition metal complexes can be used successfully as chiral auxiliaries in the atropo-diastereoselective ring opening of configurationally unstable biaryllactones. A distinct advantage of the use of stable complexes is the possibility to isolate and structurally characterize important intermediates and thus gain detailed information on their stereochemical properties. The stereochemical leakage, however, provided by the facile helimerization and ring-opening of the thiolactolate intermediates, is still a major obstacle. Nevertheless, a further development of this strategy should be possible by combining the hydride reagent with a bulky, less reactive Lewis acid capable of discriminating between the (*S*,*S*,*S*,*P*) and (*S*,*S*,*S*,*M*) diastereoisomers of the thiolactolate intermediates **5**.

Experimental Section

All experiments were carried out in Schlenk tubes under an atmosphere of nitrogen in suitably purified solvents. Water was distilled under nitrogen immediately before use. − IR: Perkin−Elmer 283, Bruker IFS 25. − ^{1}H NMR: Bruker AMX 400, δ values relative to TMS. − ^{13}C NMR: Bruker AMX 400, δ values relative to TMS. Assignments were routinely checked by DEPT. In some cases the signals in the ^{13}C-NMR spectra for quaternary carbon atoms were too weak to be detected. − ^{31}P NMR: Bruker AMX 400, δ values relative to 85% H_3PO_4. The signals in the ^{1}H- and ^{13}C-NMR spectra of the (*S*,*S*)-CHIRAPHOS ligand are very similar for all compounds and have therefore been omitted from the lists of spectral data. − Elemental analyses: Analytical Laboratory of the Institut für Anorganische Chemie. The following starting materials were obtained as described in the literature: [CpRu{(*S*,*S*)-CHIRAPHOS}Cl] (**1**),[26] thionolactones **3a**−**f**,[9][17] $[ZrCl_4(THF)_2]$.[27] All other reagents were used as purchased.

[CpRu{(*S*,*S*)-CHIRAPHOS}(SC_4H_4)]BF_4 (2): To a solution of **1** (0.40 g, 0.64 mmol) and thiophene (0.50 g, 5.95 mmol) in dichloromethane (50 mL) was added $AgBF_4$ (0.125 g, 0.64 mmol) 0°C and the resulting mixture stirred vigorously for 30 min. The solution was then filtered over Celite, the filtrate evaporated to 2 mL, and the product precipitated by adding diethyl ether. The product thus obtained may still contain traces of silver salts but is usually pure enough for further reactions. An analytical sample was obtained by recrystallization from dichloromethane/ether. Yield 0.29 g (95%), yellow crystalline powder, m.p. 60°C (dec). − ^{1}H NMR (400 MHz, CD_2Cl_2, 20°C): δ = 4.24 (s, 5 H, C_5H_5), 5.81, 6.83 (AA′XX′-system, N = 6.1 Hz, 4 H, SC_4H_4). − ^{31}P NMR (162 MHz, CD_2Cl_2, 20°C): δ = 69.8 [d, ^2J(P,P) = 41 Hz], 81.3 [d, ^2J(P,P) = 41 Hz]. − $C_{37}H_{37}BF_4P_2RuS$ (763.6) calcd C 58.20, H 4.88; found C 57.99, H 5.16.

Synthesis of the Thionolactone Complexes 4a−f: To a solution of **2** (0.15 g, 0.20 mmol) in dichloromethane (8 mL) was added the appropriate thionolactone (0.20 mmol). The color immediately changed to deep purple. The mixture was stirred for 12 h, then evaporated to 2 mL and the product precipitated by adding diethyl ether and pentane. Further purification by chromatography over a short (10 cm) silica column with dichloromethane as an eluent, followed by crystallization from dichloromethane/pentane gave deep purple crystalline powders.

4a: Yield 179 mg (95%), m.p. 176°C (dec). − ^{1}H NMR (400 MHz, $CDCl_3$, 20°C): δ = 4.73 (s, 5 H, C_5H_5). − ^{13}C NMR (100 MHz, $CDCl_3$, 20°C): δ = 84.0 (s, C_5H_5), 199.4 [dd, ^3J(P,C) = 8 Hz, ^3J(P,C) = 5 Hz, C=S] − ^{31}P NMR (162 MHz, $CDCl_3$, 20°C): δ = 69.7 [d, ^2J(P,P) = 38 Hz], 84.1 [d, ^2J(P,P) = 38 Hz]. − $C_{50}H_{43}BF_4OP_2RuS$ (941.8) calcd. C 63.77, H 4.60; found C 62.93, H 5.02.

4b: Yield 188 mg (94%), m.p. 189°C (dec). − ^{1}H NMR (400 MHz, $CDCl_3$, 20°C): δ = 3.77 (s, 3 H, OCH_3), 3.89 (s, 3 H, OCH_3), 4.70 (s, 5 H, C_5H_5). − ^{13}C NMR (100 MHz, $CDCl_3$, 20°C): δ = 55.5 (s, OCH_3), 56.4 (s, OCH_3), 84.1 (s, C_5H_5), 199.2 [dd, ^3J(P,C) = 8 Hz, ^3J(P,C) = 5 Hz, C=S]. − ^{31}P NMR (162 MHz, $CDCl_3$, 20°C): δ = 69.6 [d, ^2J(P,P) = 37 Hz], 84.2 [d, ^2J(P,P) = 37 Hz]. − ^{31}P NMR (162 MHz, $CDCl_3$, −60°C): δ = 65.5 [d, ^2J(P,P) = 37 Hz], 69.1 [d, ^2J(P,P) = 37 Hz], 83.9 [d, ^2J(P,P) = 37 Hz], 84.2 [d, ^2J(P,P) = 37 Hz]. − $C_{52}H_{47}BF_4O_3P_2RuS$ (1001.8) calcd. C 62.34, H 4.73; found C 62.29, H 4.63.

Synthesis of the Thiolactolate Complexes 5a−f: A solution of the lactone complex (0.10 mmol) in THF (10 mL) was treated at −70°C with 0.11 mL of a 1 M solution of $LiBEt_3H$ in the same solvent. Within a few minutes the color of the solution changed from deep purple to brownish-yellow. After allowing the mixture to warm to 20°C the solvent was removed under vacuum and the residue extracted with benzene (8 mL). After filtration over Celite the mixture was evaporated to 2 mL, frozen, and the remaining benzene sublimed off under vacuum. The products were isolated as yellow crystalline powders. Compounds **5d−f** were invariably obtained contaminated with a trace of the corresponding thioaldehyde complex **6d−f**.

5a: Yield 75 mg (88%), m.p. 74°C (dec). − ^{1}H NMR (400 MHz, C_6D_6, 20°C), major diastereoisomer: δ = 4.86 (s, 5 H, C_5H_5), 5.31 [d, 1 H, ^4J(P,H) = 0.8 Hz, S(O)CH]; minor diastereoisomer: δ = 4.71 (s, 5 H, C_5H_5), 6.10 [br, 1 H, S(O)CH]. − ^{13}C NMR (100 MHz, C_6D_6, 20°C), major diastereoisomer: δ = 82.6 (s, C_5H_5), 90.7 [d, ^3J(P,C) = 7 Hz, S(O)CH]; minor diastereoisomer: δ = 83.6 (s, C_5H_5), 92.9 [br, S(O)CH]. − ^{31}P NMR (161 MHz, C_6D_6, 20°C), major diastereoisomer: δ = 77.1 [d, ^3J(P,P) = 32 Hz], 87.7 [d, ^3J(P,P) = 32 Hz]; minor diastereoisomer: δ = 74.8 [d, ^3J(P,P) = 42 Hz], 87.1 [d, ^3J(P,P) = 42 Hz]. − $C_{50}H_{44}OP_2RuS$ (856.0) calcd. Synthesis of the Thioaldehyde Complexes 6a−f: To a solution of the lactolate complex (0.10 mmol) in acetone (15 mL) was added an excess of NH_4BF_4, which caused an immediate color change to deep purple. After 1 h the product and the excess of NH_4BF_4 were precipitated by adding pentane. Compounds **6b−f** were purified by chromatography over silica gel with dichloromethane/acetone 10:1 as eluent. Compound **6a** reverted back to **5a** upon chromatography and could be separated only incompletely from the excess ammonium salt. After crystallization from dichloromethane/pentane the products were obtained as deep purple crystalline powders.

6a: Yield 100 mg (ca. 95%), contaminated with NH_4BF_4. − ^{1}H NMR (400 MHz, $CDCl_3$, 20°C), both helimers: δ = 4.48 (s, 5 H, C_5H_5), 4.58 (s, 5 H, C_5H_5), 6.92 (br, 1 H, OH), 9.77 [d, ^4J(P,H) = 1.6 Hz, 1 H, HC=S], 9.96 (br, 1 H, HC=S). − ^{13}C NMR (100 MHz, $CDCl_3$, 20°C), both helimers: δ = 85.7 (s, C_5H_5), 86.0 (s, C_5H_5), 213.3 (br, HC=S), 216.5 [t, ^3J(P,C) = 7 Hz, HC=S]. − ^{31}P NMR (161 MHz, $CDCl_3$, 20°C), both helimers: δ = 76.0 [d, ^3J(P,P) = 38 Hz], 76.2 [d, ^3J(P,P) = 37 Hz], 83.9 [d, ^3J(P,P) = 37 Hz], 84.1 [d, ^3J(P,P) = 38 Hz].

2-(Methylthio)benzonaphthopyran 7a: A solution of **5a** (50 mg, 0.06 mmol) and methyl iodide (0.5 mL, 8.03 mmol) in toluene was stored for 7 d at − 6°C. The mixture was then evaporated to dryness and the residue chromatographed over silica gel with toluene/acetone 10:1 as an eluent. The first yellow fraction contained the iodo complex **8**.[12] Compound **7a** was isolated from the second yellow band as a pale yellow oil, which was characterized spectroscopically. Yield 7 mg (45%). − ^{1}H NMR (400 MHz, $CDCl_3$, 20°C): δ = 2.21 (s, 3 H, SCH_3), 6.56 [s, 1 H, S(O)CH], 7.18 [d, ^3J(H,H) = 8.0 Hz, 1 H, aryl], 7.25 [d, ^3J(H,H) = 7.6 Hz, 1 H, aryl], 7.36 [d, ^3J(H,H) = 7.9 Hz, 1 H, aryl], 7.38 [d, ^3J(H,H) = 8.4 Hz, 1 H, aryl], 7.54 [d, ^3J(H,H) = 8.2 Hz, 1 H, aryl], 7.57 [d, ^3J(H,H) =

8.0 Hz, 1 H, aryl], 7.81 [d, ^3J(H,H) = 8.2 Hz, 1 H, aryl], 7.90 [d, ^3J(H,H) = 7.8 Hz, 1 H, aryl], 8.10 [d, ^3J(H,H) = 7.7 Hz, 1 H, aryl], 8.61 [d, ^3J(H,H) = 7.9 Hz, 1 H, aryl].

Synthesis of the Thiolate Complexes 9a−f: To a solution of the thiolactone complex (0.20 mmol) in THF (10 mL) was added $LiAlH_4$ (20 mg, 0.50 mmol) at −70°C. Within a few minutes the color of the solution changed from deep purple to yellow. After allowing the mixture to warm to 20°C the solvent was removed under vacuum and the residue extracted with benzene (8 mL). After filtration over Celite the mixture was evaporated to dryness, the residue dissolved in dichloromethane and chromatographed over silica gel. The fraction containing the yellow band was evaporated to dryness and the product crystallized from benzene/pentane and was isolated as a yellow crystalline powder.

9a: Yield 117 mg (68%), m.p. 121°C (dec). − ^{1}H NMR (400 MHz, C_6D_6, 20°C), major helimer: δ = 2.85 [d, ^2J(H,H) = 9.8 Hz, 1 H, SCH_2], 3.22 [d, ^2J(H,H) = 9.8 Hz, 1 H, SCH_2], 4.22 (s, 5 H, C_5H_5), 8.88 (s, 1 H, OH); minor helimer: δ = 1.78 [d, ^2J(H,H) = 9.9 Hz, 1 H, SCH_2], 3.01 [d, ^2J(H,H) = 9.9 Hz, 1 H, SCH_2], 4.30 (s, 5 H, C_5H_5), 9.19 (s, 1 H, OH). − ^{13}C NMR (100 MHz, C_6D_6, 20°C), major helimer: δ = 40.5 [dd, ^3J(P,C) = 6 Hz, ^3J(P,C) = 2 Hz, SCH_2], 84.6 (s, C_5H_5); minor helimer: δ = 36.8 [d, ^3J(P,C) = 5 Hz, SCH_2], 82.1 (s, C_5H_5). − ^{31}P NMR (161 MHz, C_6D_6, 20°C), major helimer: δ = 67.5 [d, ^3J(P,P) = 42 Hz], 90.5 [d, ^3J(P,P) = 42 Hz]; minor helimer: δ = 75.3 [d, ^3J(P,P) = 36 Hz], 86.1 [d, ^3J(P,P) = 36 Hz]. − $C_{50}H_{46}OP_2RuS$ (858.0) calcd. 9f: Yield 167 mg (86%). − ^{1}H NMR (400 MHz, C_6D_6, 20°C), both helimers: δ = 1.06 (s, 9 H, CH_3), 1.07 (s, 9 H, CH_3), 1.40 (s, 9 H, CH_3), 1.45 (s, 9 H, CH_3), 1.77 [d, ^2J(H,H) = 9.9 Hz, 1 H, SCH_2], 2.92 [d, ^2J(H,H) = 9.7 Hz, 1 H, SCH_2], 3.00 [d, ^2J(H,H) = 9.7 Hz, 1 H, SCH_2], 3.23 [d, ^2J(H,H) = 9.9 Hz, 1 H, SCH_2], 4.15 (s, 5 H, C_5H_5),4.24 (s, 5 H, C_5H_5). − ^{13}C NMR (100 MHz, C_6D_6, 20°C), both helimers: δ = 31.8 (s, CH_3), 31.9 (s, CH_3), 32.7 (s, CH_3), 32.9 (s, CH_3), 34.8 [s, C(*t*Bu)], 34.9 [s, C(*t*Bu)], 37.4 [s, C(*t*Bu)], 37.5 [s, C(*t*Bu)], 41.3 [dd, ^3J(P,C) = 7 Hz, ^3J(P,C) = 2 Hz, SCH_2], 83.7 (s, C_5H_5), 84.5 (s, C_5H_5). − ^{31}P NMR (161 MHz, C_6D_6, 20°C), both helimers: δ = 67.2 [d, ^3J(P,P) = 42 Hz], 76.3 [d, ^3J(P,P) = 36 Hz], 85.7 [d, ^3J(P,P) = 36 Hz], 90.0 [d, ^3J(P,P) = 42 Hz]. − $C_{58}H_{62}OP_2RuS$ (970.2) calcd. C 71.80, H 6.44, S 3.30; found C 70.08, H 6.14, S 2.98.

Hydride Reduction of 5c: To a solution of **5c** (80 mg, 0.09 mmol) in THF (5 mL) was added at −70°C an excess (0.25 mmol) of either $LiBEt_3H$ or $LiAlH_4$. After 1 h the mixture was allowed to warm to 20°C. The solvent was then removed under vacuum and the dry residue extracted with benzene. After filtration over Celite and drying under vacuum **9c** was obtained as a yellow powder. Yields and diastereoisomer ratios are given in Equation 7.

Zirconium-assisted Hydride Reduction of 5a: To a solution of **5a** (100 mg, 0.12 mmol) in THF (15 mL) was added $[ZrCl_4(THF)_2]$ (200 mg, 0.53 mmol) at −70°C whereupon the color slowly changed to purple. After 8 h at this temperature the mixture was treated with $LiAlH_4$ (20 mg, 0.50 mmol), which caused an immediate color change to yellow. A few droplets of water were added to quench the excess hydride reagent, and then the mixture was

warmed to 20°C and evaporated under vacuum. The dry residue was extracted with benzene (8 mL), filtered over Celite, and the product isolated by freeze-drying. Yield 67 mg (65%), yellow crystalline powder, identified by ^{1}H and ^{31}P NMR as a mixture of both helimers of **9a** with inverted diastereoisomer ratio.

Alkylation of the Thiolate Complexes 9a−c: To a solution of the thiolate complex (0.10 mmol) in acetone (10 mL) was added methyl iodide (0.05 mL, 0.80 mmol) at 20°C. After 10 min the mixture was evaporated to 1 mL and the product precipitated by adding diethyl ether and pentane. After repeated washings with pentane and drying under vacuum the product was isolated as a pale yellow crystalline powder.

10a: Yield 98 mg (98%), m.p. 87°C (dec). − ^{1}H NMR (400 MHz, $CDCl_3$, 20°C), major helimer: δ = 0.99 (s, 3 H, SCH_3), 4.23 (s, 5 H, C_5H_5), SCH_2 and OH signals obscured by phosphane ligand; minor helimer: δ = 4.19 (s, 5 H, C_5H_5). − ^{13}C NMR (100 MHz, $CDCl_3$, 20°C), both helimers: δ = 25.0 (s, SCH_3), 47.2 (m, br, SCH_2), 85.1 (s, C_5H_5), 85.2 (s, C_5H_5). − ^{31}P NMR (161 MHz, $CDCl_3$, 20°C), major helimer: δ = 65.9 [d, ^3J(P,P) = 39 Hz], 82.7 [d, ^3J(P,P) = 39 Hz]; minor helimer: δ = 64.9 [d, br, ^3J(P,P) = 40 Hz], 83.0 [d, ^3J(P,P) = 40 Hz]. − $C_{51}H_{49}IOP_2RuS$ (1000.0) calcd. C 61.26, H 4.94, S 3.21; found C 61.06, H 4.88, S 3.20.

10b: Yield 104 mg (98%), m.p. 91°C (dec). − ^{1}H NMR (400 MHz, $CDCl_3$, 20°C), major helimer: δ = 1.04 (s, 3 H, SCH_3), 3.39 (s, 3 H, OCH_3), 3.70 (s, 3 H, OCH_3), 4.30 (s, 5 H, C_5H_5), SCH_2 and OH signals obscured by phosphane ligand; minor helimer: δ = 1.04 (s, 3 H, SCH_3), 3.36 (s, 3 H, OCH_3), 3.68 (s, 3 H, OCH_3), 4.25 (s, 5 H, C_5H_5). − ^{13}C NMR (100 MHz, $CDCl_3$, 20°C), both helimers: δ = 24.3 (s, SCH_3), 25.1 (s, SCH_3), 46.9 (m, br, SCH_2), 47.2 (m, br, SCH_2), 55.3 (s, OCH_3), 55.7 (s, OCH_3), 85.0 (s, C_5H_5). − ^{31}P NMR (161 MHz, $CDCl_3$, 20°C), major helimer: δ = 66.2 [d, ^3J(P,P) = 40 Hz], 83.1 [d, ^3J(P,P) = 40 Hz]; minor helimer: δ = 64.9 [d, br, ^3J(P,P) = 40 Hz], 82.6 [d, ^3J(P,P) = 40 Hz]. − $C_{53}H_{53}IO_3P_2RuS$ (1060.0) calcd. C 60.06, H 5.04, S 3.02; found C 59.69, H 4.94, S 2.96.

10c: Yield 102 mg (99%), m.p. 73°C (dec). − ^{1}H NMR (400 MHz, $CDCl_3$, 20°C), both helimers: δ = 1.03 (s, 3 H, SCH_3), 1.47 (s, 3 H, CH_3), 2.18 (s, 3 H, CH_3), 4.27 (s, 5 H, C_5H_5), 4.30 (s, 5 H, C_5H_5), SCH_2 and OH signals obscured by phosphane ligand. − ^{13}C NMR (100 MHz, $CDCl_3$, 20°C), both helimers: δ = 19.7 (s, CH_3), 21.0 (s, CH_3), 25.0 (s, br, SCH_3), 47.2 (m, br, SCH_2), 84.8 (s, C_5H_5). − ^{31}P NMR (161 MHz, $CDCl_3$, 20°C), major helimer: δ = 67.0 [d, ^3J(P,P) = 40 Hz], 83.1 [d, ^3J(P,P) = 40 Hz]; minor helimer: δ = 65.5 [d, br, ^3J(P,P) = 40 Hz], 83.5 [d, ^3J(P,P) = 40 Hz]. − $C_{53}H_{53}IOP_2RuS$ (1028.0) calcd. C 61.92, H 5.20; found C 61.79, H 5.43.

Detachment of the Methyl Thioethers 11a−c: A suspension of the thioether complex (0.1 mmol) in benzene (2 mL) was heated under reflux for 12 h. The mixture was worked up as described for **7a** leaving **11a−c** as pale yellow oils which were characterized by ^{1}H NMR.

11a: − ^{1}H NMR (400 MHz, C_6D_6, 20°C): δ = 1.60 (s, 3 H, SCH_3), 3.47, 3.48 (AB system, ^2J(H,H) = 15.0 Hz, 2 H, SCH_2), 4.59 (s, 1 H, OH), 6.85−8.30 (m, 10 H, aryl).

11b: − ^{1}H NMR (400 MHz, C_6D_6, 20°C): δ = 1.71 (s, 3 H, SCH_3), 3.00 (s, 3 H, OCH_3), 3.39 (s, 3 H, OCH_3), 3.68 (s, 2 H, SCH_2), 4.78 (s, 1 H, OH), 6.22−8.31 (m, 8 H, aryl).

11c: − ^{1}H NMR (400 MHz, C_6D_6, 20°C): δ = 1.65 (s, 3 H, SCH_3), 1.78 (s, 3 H, CH_3), 2.18 (s, 3 H, CH_3), 3.50 (s, 2 H, SCH_2), 4.60 (s, 1 H, OH), 6.66−8.30 (m, 8 H, aryl).

X-ray Structure Determination of [CpRu{(*S,S*)-CHIRAPHOS}-($SC_{19}H_{14}O$)]BF_4 (4c): Black-purple crystals suitable for an X-ray structure determination were obtained by diffusion of hexane into a dichloromethane solution of **4c**. Twenty-five centered reflections from a crystal of the dimensions given in Table 1 gave a rhombohedric unit cell. Data were collected from one fourth of the reflection sphere in the range 2° < Θ < 26° (Enraf−Nonius CAD 4 diffractometer, Mo-K_α radiation, graphite monochromator, filter factor 16.4). No absorption correction was applied (minimum

transmission 97.84%). The structure was solved by Patterson methods (program SHELXS 86)[28] in the space group R3 (Nr. 146). A CH_2Cl_2 molecule was found in the asymmetric unit and refined anisotropically. H atoms were included in idealized positions, coupled to their carbon atoms. The BF_4^- anion was found distributed over three special positions, one of which was slightly disordered. Twenty restraints were introduced to preserve the geometries of BF_4 and CH_2Cl_2. Least-squares cycles of the SHELXL 93 program package[29] led to the R values given in Table 1. The five highest maxima of the final difference Fourier map were all below 0.520 e $Å^{-3}$. Further details of the structure determination may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD 408734.

X-ray Structure Determination of [CpRu{(*S,S*)-CHIRAPHOS}($SC_{17}H_{11}O$)] (5a): Clear orange crystals suitable for an X-ray structure determination grew out of a C_6D_6 solution. Twenty-five centered reflections from a crystal of the dimensions given in Table 1 gave an orthorhombic unit cell. Data were collected from one eighth of the reflection sphere in the range $2° < \Theta < 30°$ (Enraf−Nonius CAD 4 diffractometer, Mo-K_α radiation, graphite monochromator, filter factor 16.4). An empirical absorption correction based on the counts of nine reflections was applied (min. transmission 97.80%). The structure was solved by Patterson methods (program SHELXS 86)[28] in the space group $P22_12_1$ (Nr. 18). The 1.5 molecules of C_6D_6 found in the asymmetric unit were refined anisotropically. H atoms were included in idealized positions, coupled to their carbon atoms. Least-squares cycles of the SHELXL 93 program package[29] led to the R values given in Table 1. The five highest maxima of the final difference Fourier map were below 0.503 e $Å^{-3}$. Further details of the structure determination may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository number CSD 408735.

Synthesis, Structural Characterization, Electrochemistry, and Reactivities of Heptaosmium Carbonyl Clusters Bearing Thioxane Ligands – Crystal and Molecular Structures of $[Os_7(CO)_{16}\{(\mu\text{-}S(CH_2)_2OCH_2CH_2\}_2]$, $[Os_7(CO)_{17}\{(\mu\text{-}S(CH_2)_2OCH_2CH_2\}\{S(CH_2)_2OCH_2CH_2\}]$, and $[Os_7(CO)_{18}\{(\mu\text{-}S(CH_2)_2OCH_2CH_2\}]$

Kelvin Sze-Yin Leung[a] and Wing-Tak Wong*[a]

Keywords: Osmium / Cluster / Electrochemistry

Reaction of the activated heptaosmium cluster $[Os_7(CO)_{19}(MeCN)_2]$ with 1,4-thioxane in CH_2Cl_2 at ambient temperature led to the isolation of three air-stable clusters $[Os_7(CO)_{16}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S\text{–}C^\alpha)\}_2]$ (**1**), $[Os_7(CO)_{17}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S\text{–}C^\alpha)\}\{S(CH_2)_2OCH_2C^aH_2(S\text{–}C^\alpha)\}]$ (**2**) and $[Os_7(CO)_{18}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S\text{–}C^\alpha)\}]$ (**3**). The metal skeletons of these clusters are in the form of a winding helix made up of four tetrahedra sharing three common faces. From electrochemical studies, the extent of the cathodic shifts of the reduction waves of these clusters were found to differ from that of the parent cluster $[Os_7(CO)_{21}]$. Treatment of **2** with carbon monoxide produced an isomer of **3**, namely compound **4**, which has the same molecular formula as **3**, but a different ligand arrangement.

Introduction

The chemistry of heptaosmium carbonyl clusters is not well explored, probably because reliable synthetic routes are unavailable, unlike the case for the hexaosmium system.[1] Pyrolysis of $[Os_3(CO)_{12}]$ at 210°C leads to a small amount of $[Os_7(CO)_{21}]$ (< 10%) after repeated TLC purification.[2] A more rational synthesis of a heptaosmium cluster is by nucleophilic attack of a mononuclear osmium fragment at a Os_6 cluster core that contains a labile ligand such as MeCN. The heptaosmium dihydrido clusters $[H_2Os_7(CO)_{20}]$, $[H_2Os_7(CO)_{21}]$, and $[H_2Os_7(CO)_{22}]$ have been obtained by this strategy.[3] Subsequent reactions of $[H_2Os_7(CO)_{20}]$ with diphenylacetylene is reported to give $[Os_7(CO)_{15}(\mu_3\text{-}CPh)_4]$ and $[Os_7(CO)_{18}(\mu_3\text{-}CPh)_2]$.[4] A similar reaction with dimethylacetylene as the ligand afforded $[Os_7(CO)_{19}(\mu_3\text{-}\eta^2\text{-}C_2Me_2)]$.[5] Lewis and Braga have shown that treatment of the parent cluster $[Os_7(CO)_{21}]$ with trimethoxyphosphane in the presence of Me_3NO yields the red-brown cluster $[Os_7(CO)_{20}P(OMe)_3]$.[6] Hoping to develop a more accessible synthetic route for higher-nuclearity cluster systems, we previously used the preformed labile species $[Os_6(CO)_{16}(MeCN)_2]$ to synthesize a number of hexaosmium cluster derivatives bearing donor ligands.[7] We extended this approach to the heptanuclear system and prepared the title compounds and studied their reactions. Their molecular structures were determined by single-crystal X-ray crystallography.

Results and Discussion

Synthesizing a cluster derivative by nucleophilic displacement of a donor ligand with a preformed labile parent carbonyl cluster is a general and effective way to generate new clusters in low-nuclearity systems.[8] The advantage of using such a strategy is not only the mild reaction conditions needed, but also that the reaction is more selective. However, there have been only very few reports of cluster syntheses with this approach in hexa- and heptanuclear systems, such as the preparation of hexanuclear clusters from the reactions with pyridine[7a] and 7-azaindole.[7b] In this article we report the use of $[Os_7(CO)_{19}(MeCN)_2]$, which is generated from the parent cluster $[Os_7(CO)_{21}]$, to synthesize a new family of heptanuclear cluster compounds containing thioxane ligands.

Treatment of the heptanuclear carbonyl cluster $[Os_7(CO)_{21}]$ with 2 equiv. Me_3NO, in acetonitrile at −78°C, led to the formation of an activated cluster precursor $[Os_7(CO)_{19}(MeCN)_2]$. Subsequent reaction of this labile cluster with 1,4-thioxane in CH_2Cl_2, at ambient temperature for 6 h, followed by TLC purification, gave three air-stable clusters $[Os_7(CO)_{16}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}_2]$ (**1**), $[Os_7(CO)_{17}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}\{S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}]$ (**2**), and $[Os_7(CO)_{18}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}]$ (**3**) (Scheme 1). Their formulae were first established by FAB MS and ^{1}H-NMR spectroscopy, and were eventually confirmed by X-ray crystallography. All the spectroscopic data are summarized in Table 1.

The metal frameworks of clusters **1**, **2**, and **3** may be described as four fused tetrahedra sharing three common faces, or two fused bicapped trigonal bipyramids sharing a

common triangular face. This kind of Os_7 architecture differs widely from the parent cluster $[Os_7(CO)_{21}]$, which is a monocapped octahedron.[9] The compound $[Os_7(CO)_{17}(\eta^6\text{-}C_6H_6)]$[10], prepared by Lewis and co-workers, is so far the only structurally characterized homometallic example with this type of metal skeleton. Although the metal framework of some heterometallic clusters such as $[Cp_3W_3Ir_4(\mu\text{-}H)(CO)_{12}]$[11] is similar, complexes $[Fe_4(CO)_{12}\{Au(L)\}_2BH]$ (L = $AsPh_3$ or PPh_3),[12] $[Fe_3(CO)_9P\{Au(PPh_3)\}_3]$,[13] and $[Fe_4(CO)_{12}Au_2\{P(p\text{-}MeC_6H_4)_3\}_2BH]$[14] could be considered similar only if the edge-bridging, rather than face-capping, heteroatoms are regarded as one of the vertices.

The molecular geometry of complex **1** and its atomic labelling scheme is depicted in Figure 1. Some selected interatomic bond lengths and angles are given in Table 2. Compound **1** crystallizes in the monoclinic space group $C2/c$ with half a molecule per asymmetric unit. All the internuclear Os−Os distances are within 2.703(9) to 2.994(4) Å which is comparable to those found in other high-nuclearity clusters. Thioxane ligands bridge the Os(1)−Os(2) and Os(1)*−Os(2)* edges of the metal skeleton. As predicted by the Effective Atomic Number (EAN) rule, there are fifteen metal−metal bonds.[15] The structure of this 96 CVE cluster can be rationalized by the condensed polyhedral approach,[16] but it is not possible to assign 18 electrons to each osmium atom. This is not uncommon for high-nuclearity system, as was suggested by Adams,[17] Kaesz,[18] and Lewis.[19]

The redox properties of cluster **1** were studied by cyclic voltammetry (CV) and controlled potential electrolysis

(CPE) at a platinum disc electrode. The parent cluster $[Os_7(CO)_{21}]$ undergoes a single, irreversible two-electron transfer step with $E_p = -0.10$ V vs Ag/AgCl, to yield the corresponding dianion $[Os_7(CO)_{20}]^{2-}$. We believe that the incorporation of a sulfur heteroatom in the cluster framework should lead to changes in redox behaviour. The cyclic voltammograms of compound **1** in acetonitrile solution contained an irreversible cathodic wave at ca. $E_p = -0.22$ V vs Ag/AgCl. Cyclic voltammetric measurements were obtained at scan rates varying from 50 mV to 10,000 mV s^{-1}, but the ΔE_p values remained virtually unchanged. This observation, together with the findings in CPE, are characteristic of an irreversible two-electron transfer process involving reduction of **1** into its corresponding dianion $[\mathbf{1}]^{2-}$. Because the thioxane groups are better σ-donors than carbonyl ligands are, coordination of such a good σ-donor in **1** would raise the LUMO energy; this in turn would make reduction more difficult, and would therefore lead to a more cathodic potential. For **1**, an additional irreversible anodic wave is located at ca. $E_p = +0.37$ V vs Ag/AgCl. It is likely that this oxidation process, which is absent in the parent cluster, is the consequence of oxidation of the thioxane ligands. Ferrocene was added as an internal reference, and its half-wave potential $E_{1/2} = +0.10$ V vs Ag/AgCl remained practically constant throughout the measurement. The electrochemical data are collected in Table 3.

2	+0.37	−0.24
4	+0.38	−0.17

[a] E_{pa} and E_{pc} are the anodic and cathodic potentials respectively.

The heptametallic cluster **2** is analogous to **1**, except that one bridging thioxane group is replaced by a terminally bonded ligand. In the solid state, both ligand forms are in the chair conformation, with all the C−C bonds staggered. A perspective drawing of cluster **2** with its atomic numbering is shown in Figure 2. Some important bond parameters are given in Table 4. Compared with their counterparts in compound **1**, all the metal−metal bond lengths are within

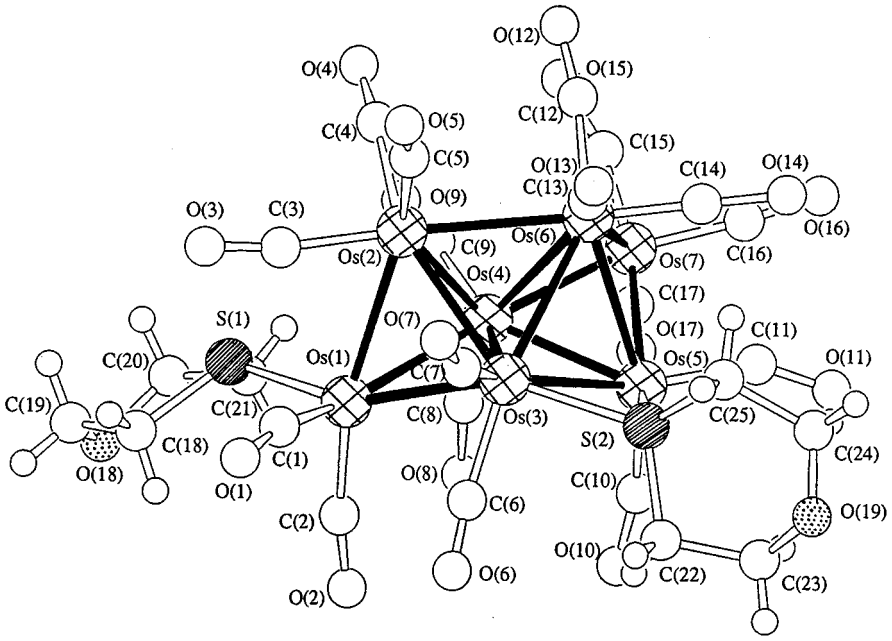

Figure 2. Molecular structure of cluster **2**

the expected ranges. The redox properties of complex **2** were also studied, and all the electrochemical data are presented in Table 3. The cyclic voltammograms of **2** are very similar to those of **1**, with one irreversible reduction wave at ca. $E_p = -0.24$ V and one irreversible oxidation peak at ca. $E_p = +0.37$ V vs Ag/AgCl. The assignment of these two

Os(4)−Os(6)	2.780(3)	Os(5)−Os(3)−S(2)	52.9(3)

peaks follow that of **1**, since **1** and **2** are structurally similar.

Carboxylation of **2** in refluxing $CHCl_3$ led to the formation of $[Os_7(CO)_{18}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}]$ (**4**) which is an isomer of **3**. Spectroscopic data of **4** (FAB MS, ^{1}H-NMR, and IR spectra) suggested that a CO molecule replaced the terminally bonded thioxane ligand. However, prolonged carboxylation of **2** did not recover the starting cluster $[Os_7(CO)_{21}]$. This contrasts with the facile replacement of both thioxane ligands observed for the analogous compound $[Os_6(CO)_{15}\{S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}]$.[20] Under similar conditions, **2** did not react with molecular hydrogen.

The metal skeleton of **3** is identical to that of **1** and **2**, with eighteen terminally bonded carbonyl groups and a thioxane ligand bridging Os(2) and Os(6). Its molecular structure is presented in Figure 3 and some selected bond parameters are given in Table 5. Interestingly, the structure can be regarded as a monocapped Os(7) atom on the hexanuclear species $[Os_6(CO)_{16}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}]$ previously reported by us.[20] The three metal−metal bonds between Os(7) and Os(4), Os(5), and Os(6) differ widely, to range from 2.678(4) to 2.866(4) Å, with a slightly tilted capping as a result. However, this is not observed for both clusters **1** and **2**. Cyclic voltammograms of cluster **3** have the same features found for **1** and **2**, with a pair of cathodic and anodic waves at ca. $E_p = -0.17$ V and $+0.38$ V vs Ag/AgCl, respectively. The reduction wave of compound **3**, however, is less cathodic than that of its disubstituted counterparts, reflecting the reduction in electron donation by a single thioxane, and hence a lower LUMO energy.

Although compounds **1**, **2**, and **3** have identical metal architectures and similar ligand dispositions, there is no evidence for their interconversion. Neither **3** nor **4** could be obtained from prolonged carboxylation of **1** in $CHCl_3$. Similarly, treating **3** with an excess of thioxane did not lead to the isolation of **4**, and vice versa. The change of the metal core in **1**, **2** and **3** from the starting osmium cluster $Os_7(CO)_{21}$ can take place in the preparation of $Os_7(CO)_{19}(MeCN)_2$. However, we have not been able to obtain the structure of $Os_7(CO)_{19}(MeCN)_2$.

Experimental Section

General: All reactions and manipulations were carried out under dry argon with standard Schlenk techniques. All solvents were purified and dried by standard methods prior to use.[21] Chemicals were purchased from Aldrich Chemicals and were used as received. Vacuum pyrolysis of $[Os_3(CO)_{12}]$ gave the heptaosmium cluster $[Os_7(CO)_{21}]$;[2] $[Os_7(CO)_{19}(MeCN)_2]$ was prepared as described below. − Infrared spectra were recorded on a Bio-Rad FTS-7 spectrometer, in 0.5 mm thick calcium fluoride solution cells. − ^{1}H NMR and ^{1}H{^{1}H} COSY spectra were recorded on a Bruker DPX-300 NMR spectrometer, in CD_2Cl_2 with reference to $SiMe_4$ (δ = 0). − Mass spectra were measured on a Finnigan MAT 95 instrument by the fast atom bombardment technique, with *m*-nitrobenzyl alcohol or α-thioglycerol as the matrix solvents. − Elemental analyses were conducted by Butterworth Laboratories, UK. − Routine separation of products in air was performed by thin-layer chromatography (TLC), on plates coated with Merck kieselgel 60 GF_{254}. − All electrochemical measurements were performed under an argon purge, to exclude oxygen, in a conventional two-compartment cell, separated by a sintered glass disc. Acetonitrile was freshly distilled and de-aerated prior to use. The supporting electrode was 0.1 M tetra-*n*-butylammonium tetrafluoroborate in MeCN. Voltammetric experiments were carried out with a Princton Applied Research (PAR) model 273A potentiostat, connected to an interfaced computer. A standard three-electrode cell consisting of an Ag/AgCl reference electrode (Bioanalytical), a platinum wire counter electrode (Aldrich), and a glassy carbon working electrode (Bioanalytical) were employed. The ferrocenium/ferrocene couple ($FeCp_2^{+/0}$) was used as internal reference.

Preparation of $[Os_7(CO)_{19}(MeCN)_2]$: The compound $[Os_7(CO)_{21}]$ (200 mg, 0.104 mmol) was dissolved in a mixture of CH_2Cl_2 (90 cm^3) and MeCN (7.2 cm^3) to give a bright orange solution. The reaction mixture was stirred at −78 °C for 30 min before dropwise addition of a Me_3NO solution (16 mg, 2 mol-equiv) in CH_2Cl_2 from a pressure-equalizing dropping funnel. After all the Me_3NO solution had been added, the reaction mixture was further stirred for 15 min before leaving it to warm up at ambient temperature. Excess Me_3NO was then filtered off and the solvent was removed in vacuo to give a bright brown solid residue. (Yield: 102 mg, 50%)

Preparation of $[Os_7(CO)_{16}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}_2]$ (1), $[Os_7(CO)_{17}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}\{S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}]$ (2), and $[Os_7(CO)_{18}\{\mu\text{-}S(CH_2)_2OCH_2C^aH_2(S-C^\alpha)\}]$ (3): The cluster $[Os_7(CO)_{19}(MeCN)_2]$ (120 mg, 0.062 mmol) was dissolved in CH_2Cl_2 (40 cm^3) and stirred while a dilute solution of 1,4-thioxane (0.57 cm^3 diluted in 10 cm^3 CH_2Cl_2) was added dropwise over 30 min at ambient conditions. After the reaction continued for a further 6 h, the solution was filtered and the volume was reduced to ca. 5 cm^3 in vacuo. The residue was subsequently purified by TLC using hexane/CH_2Cl_2 (10:20 v/v) as eluent. Three brown bands: **1** (R_f = 0.77, 20 mg, 0.010 mmol, 16%), **2** (R_f = 0.59, 45 mg, 0.022 mmol, 36%), and **3** (R_f = 0.32, 18 mg, 0.016 mmol, 27%), together with several uncharacterized, low-yield products were then eluted consecutively. Brown crystals suitable for diffraction analyses of **1** and **3** were obtained, separately, from $CHCl_3$/

toluene solutions (1:8 v/v), at room temperature, after 3 and 6 d, respectively. Compound **2** was obtained, by slow evaporation of a toluene/$CHCl_3$ solution at −10 °C for 4 d, as brown, rod-shaped crystals, as a solvate of stoichiometry **2**·C_7H_8. – **1**: $C_{24}H_{16}S_2O_{18}Os_7$: calcd. C 14.5, H 0.8, S, 3.2; found C 14.2, H 0.8, S 3.2. – **2**: $C_{25}H_{16}S_2O_{19}Os_7$: calcd. C 14.9, H 0.8, S 3.2; found C 15.0, H 0.9, S 3.2. – **3**: $C_{22}H_8SO_{19}Os_7$: calcd. C 13.6, H 0.4, S 1.7; found C 13.4, H 0.4, S 1.7.

Carboxylation and Hydrogenation of 2: Compound **2** (40 mg, 0.020 mmol) was continuously purged with a stream of carbon monoxide, in refluxing $CHCl_3$ (10 cm^3). Reaction progress was monitored by solution infrared and spot TLC over a period of 4 h. The solvent was then removed in vacuo, the residue was redissolved in a minimum amount of CH_2Cl_2 and purified by TLC, with hexane:CH_2Cl_2 (10:20 v/v) as eluent, to give compounds **4** (R_f = 0.66, 11 mg, 0.006 mmol, 29%) and unchanged **2** (R_f = 0.38, 20 mg, 0.010 mmol, 50%). The procedure described was repeated with hydrogen, but no observable changes were detected by either spot TLC or IR monitoring.

Crystallography: Single crystals, suitable for X-ray crystallography, were chosen for clusters **1** and **3.** Compound **3** was mounted on a glass fibre while **2** was mounted in a Lindermann glass capillary with epoxy resin. Diffraction data were collected at ambient temperature on a MAR research imaging plate diffractometer for exposure periods of 300, 600, and 360 s per frame for compounds **1**, **2**, and **3** respectively. All intensity data were corrected for Lorentz and polarization effects. An approximation of absorption correction by inter-image scaling was applied for all compounds. Space groups were determined for all the crystals from a Laue symmetry check, and their systematic absences, and were then confirmed by successful refinement. The structures were solved by direct method SIR92[22] and expanded by difference Fourier technique. For **1**, the solution was refined on *F* by full-matrix least-squares analysis with all atoms refined anisotropically while all the hydrogen atoms in the ligand were generated in their idealized positions (C−H 0.95 Å) and fixed throughout. However, for **2**, attempts to refine all non-hydrogen atoms anisotropically gave unreasonably high thermal parameters for the C and O atoms. Therefore, only the heavy atoms (Os and S) were included in subsequent anisotropic refinement cycles. Initial attempts to refine the toluene solvent in **2** by rigid-group constraint gave high B_{eq} values, indicating considerable disorder. It was then fixed throughout in the subsequent refinement processes to give a significant improvement. As a result of the poor quality of the diffraction data for complex **3**, only heavy atoms such as osmium and sulfur were subjected to anisotropic refinement. A summary of the crystallographic data is given in Table 6. All calculations were performed on a Silicon-Graphics computer using the program package TEXSAN.[23] Crystallographic data (excluding structure factors) for the structures reported in this paper has been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-119664 to 119666. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (int) +44-1223/336 033; E-mail: deposit@ccdc.cam.ac.uk].

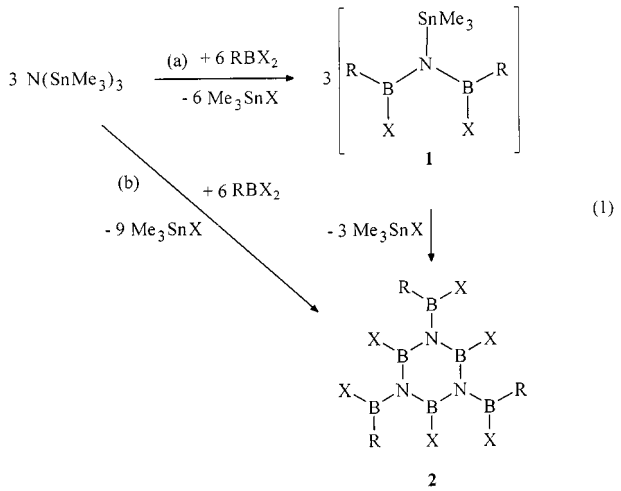
Synthesis of Boron-Halogenated Diborylamines and Diborylhydrazines by Cleavage of Stannazanes



Stefan Diemer,[a] Heinrich Nöth,*[a] and Wolfgang Storch*[a]

Keywords: Diborylamines / Diborylhydrazines / Bis(organohaloboryl)amines / Bis(organohaloboryl)hydrazines / Structure elucidation

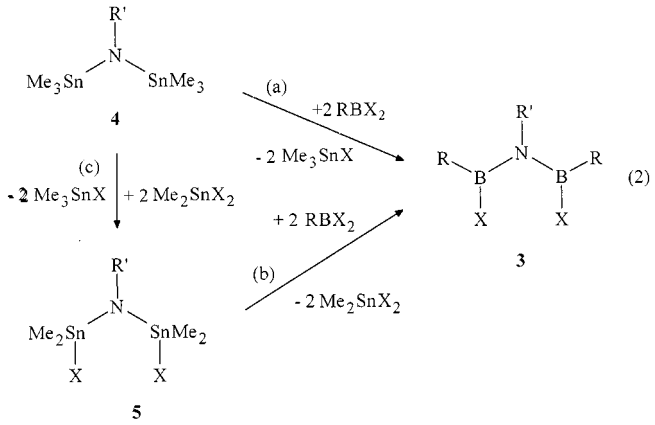
The diborylamines R′–N(BRX)$_2$ (**3**; X = Cl, Br) are obtained by stannazane cleavage of distannylorganylamines R′–N(SnMe$_3$)$_2$ (**4**) with alkyldihaloboranes RBX$_2$ in a 1:2 molar ratio. The presence of the sterically demanding substituents R and R′ also causes carbon–tin bond cleavage, resulting in low yields of **3**. However, carbon–tin bond cleavage can be suppressed by the use of bis(dimethylchlorostannyl)-organylamines **5** as the nitrogen source for the synthesis of diborylamines. This results in almost quantitative yields of the compounds **3**. Treatment of the distannylhydrazines R$_2$N–N(SnMe$_3$)$_2$ (**7**) with RBX$_2$ in a 1:2 molar ratio leads to the formation of *N*,*N*-bis(alkylhaloboryl)hydrazines **8** under mild conditions and in good yield. The molecular structures of **3** and **8** were determined by multinuclear magnetic resonance spectra in solution as well as by X-ray structure analysis in the case of **8d**. A typical structural feature of **8d** is the intramolecular BN adduct formation. Support for the constitutions of compounds **8c** comes from MS fragmentation patterns as well as from IR spectra.

Introduction

The synthetic potential of aminostannanes, distannylamines as well as tristannylamines, is due to the easy Sn−N cleavage reactions involving Lewis acids.[1] Diborylamines functionally substituted at the boron atoms of the type Me$_3$SnN(BXR)$_2$ (**1**), obtained by the reaction of (Me$_3$Sn)$_3$N with organyldihaloboranes, are labile for X = Cl, Br. The compounds decompose to borylated borazines **2** by further stannazane bond cleavage[2] according to Equation (1).

(1)

Recently, thermally stable examples of **1,** afforded by replacement of the Me$_3$Sn group by the sterically more demanding *t*Bu group, have been reported.[3] Bis(haloboryl)-amines R′−N(BRX)$_2$ (**3**) with small organyl groups R′ attached to the nitrogen atom, and bulky groups R attached to the boron atoms, are up to this date unknown. Only a few examples of asymmetrically substituted diborylamines with different alkyl groups R and X = Cl at the boron atoms have already been described.[4] Boron-functional diborylamines are, however, useful precursors for the synthesis of B-, N- and Sn-containing heterocycles.[5][6] Two different routes for the synthesis of diborylamines of type **3** have been established in recent years. One route involves the electrophilic addition of dihaloorganoboranes to iminoboranes[6] or to aminoiminoboranes.[7] The other route uses the stannazane bond cleavage of distannylamines with dihaloorganoboranes under kinetically controlled conditions. This route represents a rather convenient method for the synthesis of diborylamines of type **3,** which are not accessible by other routes.[3] Compounds **3** containing electron-withdrawing substituents R′ attached to the nitrogen atoms are hardly known. In particular this concerns *N*,*N*-diborylhydrazines containing the hydrazine moiety, obtained by formal replacement of the R′ group for the R″$_2$N group in diborylamines of type **3**.



Here we report on the synthesis of boron-halogenated diborylamines and -hydrazines by stannazane cleavage reactions and the spectroscopic properties as well as some structural features.

Bis(organylhaloboryl)organylamines

A series of diborylamines of type **3** (R′ = alkyl) have been reported using bis(trimethylstannyl)organylamines **4** as starting materials according to Equation 2a.[3] However, the synthesis of **3** with sterically more demanding groups R, for example R = *t*Bu, failed, due to the kinetically hindered approach of the organyldihaloborane to the Lewis-basic nitrogen center of **4** (see Formula 2). Therefore, cleavage of carbon−tin bonds predominates over the cleavage of the

nitrogen−tin bonds even under mild conditions. However, Sn−N cleavage is favoured again by treatment of the distannylamines $R'-N(SnMe_3)_2$ (**4**) with small organoboronhalides: For example reaction of **4** (R′ = *t*Bu) with RBX_2 compounds containing the sterically less demanding methyl group yields the diborylamine **3h**.[3] However, the Sn−N bond cleavage of **4** proceeds under mild conditions with $MeBBr_2$, and even with *i*PrBBr$_2$, yielding **3m**[8] and **3n**, in the case of R′ = Me_3Si. However, isolation of the *N*-phenyldiborylamines **3c** and **3d** failed, because they decompose rapidly to the respective borazines and organodihaloboranes (see Equation 1b) on removing the solvent from the reaction mixtures. **3f** could also not be isolated, because the stannylaminoborane, *t*BuBrB−NPh−$SnMe_3$, detected by NMR as an intermediate, decomposes more rapidly with formation of a borazine (see Equation 1) prior to a second Sn−N bond cleavage. In addition, there is a competitive reaction due to the carbon−tin bond cleavage. Obviously, the low basicity of the anilino nitrogen atom prevents the attack of another alkylboron dihalide at the N centre. However, when *N*-methyldistannylamine (**4a**) is used, the Sn−N bond cleavage is favored even when it is treated with *t*BuBBr$_2$. The product obtained is **3b** according to Equation 2a. In this case the ratio of Sn−N to Sn−C bond cleavage is 4:1, estimated on the basis of the ^{11}B-NMR spectrum of the reaction mixture. Contrary to these findings the distannylamines **4i** and **4k,** bearing sterically demanding groups R′, react even with $MeBBr_2$ quantitatively to give Me_2BBr and the bis(bromostannyl)amines **5i** and **5k,** respectively,[9] according to Equation 3.

$$\underset{\textbf{4i,4k}}{R'-N(SnMe_3)_2} \xrightarrow[-\ 2\ Me_2BBr]{+\ 2\ MeBBr_2} \underset{\textbf{5i, 5k}}{R'-N(SnMe_2Br)_2} \qquad (3)$$

Performing the same reaction with **5i**, with the sterically less demanding mesityl group as substituent R′ yields the

$$\underset{\textbf{5i}}{Mes-N(SnMe_2Br)_2} \xrightarrow[-\ 2\ Me_2SnBr_2]{+\ 2\ Me_2BBr} \underset{\textbf{3q}}{Mes-N(BMe_2)_2} \qquad (4)$$

products according to Equation 3 in the first step, but does not prevent further attack of Me_2BBr to immediately form the diborylamine **3q** at room temp. according to Equation 4.

In summary, when distannylamines, $R'-N(SnMe_3)_2$ (**4**) are used as starting materials for the synthesis of *B*-halogen-substituted diborylamines according to Equation 2a, Sn−C bond cleavage reactions can only be suppressed partially. However, almost quantitative Sn−N bond cleavage occurs when distannylamines **5** of type $RN(SnMe_2X)_2$ are treated with organoboron dihalides according to Equation 2b.

Therefore, the whole series of halogenoboron diborylamines **3a**−**3q** can be prepared using a procedure according to Equation 2b, except for **3i** and **3k**. No reaction occurs on treatment of the distannylamines **5i** and **5k** with $MeBBr_2$ even under reflux conditions for several hours. As mentioned above, the steric demands of the mesityl- and the 2,6-diisopropylphenyl group attached to the nitrogen atom of the distannazanes **5i** and **5k** prevents the attack of $RBHal_2$ at the N atom, but not at the Sn atom of the Me_3Sn moiety. Consequently, **5i** and **5k** even react with the strong Lewis acid BCl_3 with formation of the distannazanes $RN(SnMe_2Cl)_2$ by tin−carbon bond cleavage.[9]

Sterically demanding groups R attached to the boron atoms in RBX_2 also hinder the stannazane cleavage reactions, even if the distannylamine bears a sterically less demanding group R′ at the nitrogen atom. Therefore only one of the Sn−N bonds of **5a** is cleaved by treatment with an excess of $MesBCl_2$ after a period of 2 d in boiling $CHCl_3$ according to Equation 5.

Purification of the stannylaminoborane **6a** by distillation or recrystallisation failed due to slow decomposition at

$$[Me\text{-}N(SnMe_2Cl)_2]_2 \xrightarrow[-\,Me_2SnCl_2\ -\,2\,MesBCl_2]{+\,4\,MesBCl_2} 2\ Mes(Cl)B\text{—}NMe\text{—}SnMe_2Cl \qquad (5)$$

(5a)$_2$ **6a**

room temp., as indicated by ^{11}B-NMR spectroscopy. However, the presence of stannylaminoboranes **6** as intermediates en route to diborylamines is shown not only by NMR spectroscopy, but also by the reaction of the distannylamine $PhN(SnMe_2Cl)_2$ (**5d**) with $MesBCl_2$ in a 1:1 molar ratio according to Equation 6b. The stannylaminoborane **6d**, which could not be isolated, subsequently reacts with $MeBBr_2$ in a 1:1 molar ratio with the formation of the asymmetrically substituted diborylamine **3r** according to Equation 6c.

$$PhN(SnMe_3)_2 \xrightarrow[-\,2\,Me_3SnCl]{+\,2\,Me_2SnCl_2} PhN(SnMe_2Cl)_2 \qquad (6a)$$

4c **5d**

$$\mathbf{5d} \xrightarrow[-\,Me_2SnCl_2]{+\,MesBCl_2} \mathbf{6d} \qquad (6b)$$

$$\mathbf{6d} \xrightarrow[-\,Me_2SnBr_2]{+\,MeBBr_2} \mathbf{3r} \qquad (6c)$$

Surprisingly, the diborylamine **3r** can be distilled in vacuo and heated to 90°C without decomposition. In general, the synthesis of a variety of diborylamines of type **3** follows the route shown in the Equations 2c and 2b, and described step by step for **3r** (Equations. 6a–c). The derivatives **3e** and **3f**, which are also not accessible following the route according to Equation 2a, are obtained in good yield using the "one-pot reaction" described in Equations 6a–c. The progress of the reactions described by Equations 2c and 2b, leading to the formation of **3e**, has been monitored by ^{11}B-NMR as a function of time during a period of 145 h; the result is shown in Figure 1. A typical feature of this reaction is the exchange of a bromine atom of *t*BuBBr$_2$ against a chlorine atom of the distannazane **5d** in the initial step. After warming the reaction mixture from −50°C to ambient temp. over a period of 2.5 h the cleavage of the first tin–nitrogen bond of **5d** is completed with formation of the stannylaminoborane PhN(B*t*BuCl)SnMe$_2$Cl. As shown in Figure 1 even after 4 d no further reaction occurs with another equiv. of the alkylhaloborane at room temp.

However, the second Sn–N bond cleavage starts if the reaction mixture is maintained at reflux, and after 2 h the respective diborylamine **3e** is found. It can be isolated (b.p. 50°C/high vac) in good yield, decomposing to yield only trace amounts of the borazine (PhNB*t*Bu)$_3$ under these conditions. Nevertheless, the Cl/Br exchange proceeds selectively as well as quantitatively. This reaction can be used as a convenient method to introduce B–Cl bonds in functionally substituted diborylamines starting with bromoboranes.

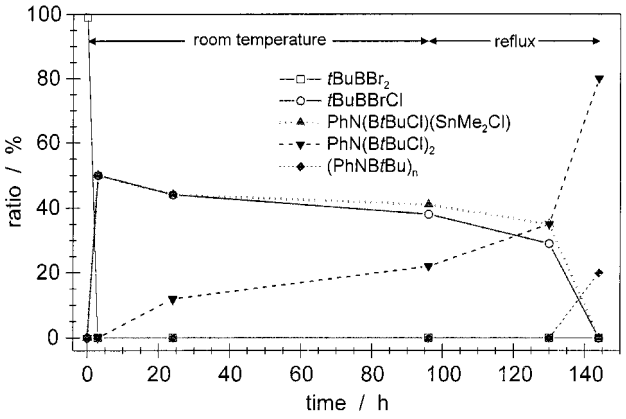

Figure 1. Reaction of $PhN(SnMe_2Cl)_2$ (**5d**) with *t*BuBBr$_2$ in a 1:2 molar ratio monitored by ^{11}B NMR over a period of 145 h

N,*N*-Bis(organylhaloboryl)-*N*′,*N*′-diorganylhydrazines

A variety of cyclic 1,1-diborylhydrazines[10] as well as few examples of noncyclic derivatives[11] are already known. Their chemical properties and structural features, for example the donor property of the diorganylamino group of the hydrazine moiety,[11b] are scarcely investigated. However, functionally boron-substituted diborylhydrazines, are hitherto unknown, although they might be attractive reagents in preparative chemistry. Moreover, they may offer information about structure and bonding, and for that reason we looked for a convenient access to this class of compounds.

The synthesis of *N*,*N*-diorganyl-*N*′,*N*′-dihaloborylhydrazines is achieved under mild conditions by allowing distannylhydrazines **7** to react with RBX_2 in a 1:2 molar ratio according to Equation 7.

$$R'_2N\text{—}N(SnMe_3)_2 \xrightarrow[-\,2\,Me_3SnX]{+\,2\,RBX_2} R'_2N\text{—}N(BRX)_2 \qquad (7)$$

Contrary to the Sn–C bond-cleavage reaction occurring with the formation of the diborylamines **3** according to Equation 2a, no such bond cleavage reaction has been observed in case of the distannylhydrazines. The basicity of the tin atoms bearing a nitrogen atom in compounds **7** is obviously high compared to the distannylamines **4**, presumably due to the α-effect of the nitrogen atom of the adjacent R_2N group.[12] Subsequently, the Sn–N bond cleavage proceeds quantitatively according to Equation 7, even in the presence of sterically demanding groups R attached to the boron atoms of RBX_2.

The treatment of the distannylhydrazines **7a** or **7b** with $MeBBr_2$ according to Equation 7 produces only a colorless solid, insoluble in polar and nonpolar solvents, after removal of the volatile components. The ^{11}B- and the ^{119}Sn-NMR spectra recorded from the reaction mixture before removal of the volatile components, however, indicate the formation of the diborylhydrazines **8a** and **8e**. In contrast, the reaction of RBX_2 with bulkier groups R = *i*Pr, *t*Bu, and Mes proceeds slowly with formation of **8b**−**d**. Surprisingly, these compounds show two ^{11}B-NMR signals pointing to the presence of tri- and tetracoordinated boron atoms (see Table 2). The remarkable structural difference between the diborylhydrazines **8** when compared to the diborylamines **3** is the formation of an intramolecular Lewis acid/base adduct, featuring a three-membered B_2N ring unit (see below). The presence of monomeric molecular units is also confirmed by a molecular-mass determination of compounds **8** in solution.

Treatment of the *N*,*N*-diphenyl-*N*′,*N*′-distannylhydrazines **7** with $MeBBr_2$ or $tBuBBr_2$ yields the corresponding diborylhydrazines, which, however, could be detected only in solution. A variety of signals are found in the ^{11}B-NMR spectrum of the reaction mixture [^{11}B NMR: (= 50.2 (**8f** uncertain), 30.3, 22.5, 2.6].[9] The isolation of **8e** and **8f** from the insoluble residue failed, presumably due to the formation of polymeric species by intermolecular B←N interaction, or adduct formation of the R_2N group of **8** with Me_3SnX. The latter can be excluded by controlling the reaction conditions, especially the concentration of the starting materials in the reaction mixture. For example, the diborylhydrazine **8d** formes an adduct only with Me_3SnCl (**8g**) when the concentration of the distannylhydrazine **7a** exceeds 0.13 mol/L in a dichloromethane solution, and the addition time of $MesBCl_2$ is shorter than 60 min (see Experimental Section). In this case the tin halide is only released from **8g** by substitution with an excess of $MesBCl_2$, forming **8h** according to Equation 8.

8g **8e** (8)

NMR Spectra

Diborylamines

Selected ^1H-, ^{11}B-, ^{13}C-, and ^{14}N-NMR data of the *B*-halogen substituted diborylamines **3** and triborylamines are listed in Table 1, and of halogenated diborylhydrazines **8** in Table 2. Both tables also contain NMR data of some other compounds for comparison. For additional data see the Experimental Section.

The shielding of the ^{11}B and ^{14}N nuclei are in accordance with a trigonal-planar environment of both atoms in the diborylamines of type **3**. They are also in agreement with the data of known diborylamines.[3][6] However, compared to aminohaloboranes, for example $Me_2N-B(Me)Cl$ (^{11}B NMR: δ = 38.5),[13] the ^{11}B nuclei of the diborylamines are deshielded by 10−15 ppm, as there is only one pair of electrons at the N atom to be shared by two boron atoms in (pp) π-bonding. Additional deshielding results from the torsion between the planes of the boron and the nitrogen atoms due to the bulky substituents R and R′ attached to these atoms. This causes an additional decrease of the (BN) π-interaction. In contrast to the ^{11}B-NMR data of asymmetrically substituted diborylamines of the type $RN(BR'X)(BR''X)$[6] with two different ^{11}B-NMR signals (see Table 1; **3p**), there is only one signal detected for the two boron nuclei in **3r**. Therefore, the degree of distortion around the BN axis of both of the boryl groups in type **3** compounds, due to sterically induced crowding, is approximately of the same order, featuring a geometry shown in Figure 2c. The structure of a "borylated aminoborane" **b** (see Figure 2) assumed for compounds of type **3p** as well as a planar diborylamine framework **a** (see Figure 2) can be excluded.

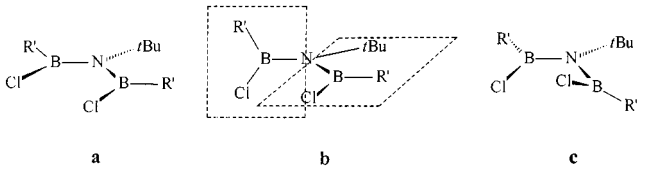

Figure 2. Alternative stereoisomers of diborylamines of type **3**

It is well known that in compounds RR′BX, the exchange of a chlorine for a bromine atom[14] results in a significant deshielding of the boron nucleus. This influence is also detected in the diborylamines of type **3**. Electron-withdrawing substituents (for example R′ = Ph) or sterically demanding groups attached to the nitrogen atom (for example R′ = $SiMe_3$, causing a larger torsion angle between the boron and nitrogen planes) also exhibit a significant downfield shift of the ^{11}B resonance. However, introduction of a third boryl group (R_2B) at the nitrogen atom leads to a larger deshielding of the boron nuclei of ca. 8 ppm, due to the π-acceptor quality of this group. **3t** (see Table 1) represents one of the rare examples of an asymmetrically substituted triborylamine.[15]

The π-acceptor function of the different boryl groups in diborylamines of type **3** is shown by the deshielding of the central nitrogen nucleus. Our NMR study confirms, that a deshielding of the nitrogen nuclei is accompanied by better shielding of the boron nuclei, owing to (BN)π interaction and vice versa. The larger sensitivity of the nitrogen nucleus to changes in (BN)π interaction is demonstrated by comparison of the $\delta^{14}N$ data for the diborylamines **3l**−**3m** as well as that of **3o**−**3n**. Replacement of a chlorine by a bromine atom leads to a significant downfield shift of about 15−16 ppm (^{14}N), as a consequence of less (BX) π-bonding in the B−Br bond. Moreover, the influence of the sterically

demanding groups R′ on the torsion angle between the nitrogen and the boron planes is demonstrated by a significant deshielding of the nitrogen nuclei as demonstrated by the compound pairs **3n/3o** (ΔN: +12 ppm) and **3m/3n** (ΔN: +11 ppm).

The ^{1}H- and ^{13}C-NMR data also are in accordance with the suggested structures, particularly the monomeric molecular geometry of the species of type **3**. The ^{13}C-NMR signals of the carbon atoms directly linked to the boron atoms can only be detected by cooling the sample between −20°C to −40°C. At ambient temp. the signals vanish due to quadrupolar relaxation of the second kind.[16] The ^{13}C resonances of carbon atoms adjacent to the boron atoms are hardly affected by changes of the shielding at the boron nuclei owing to smaller changes of the polarity of the B−C σ-bonds.

Diborylhydrazines

There is some information available about the structures of fully alkylated *N,N*-diborylhydrazines from NMR data. In particular, the nonassociated nature (^{11}B NMR: δ = 42.0) of compounds of type **A** (Scheme 1) with tricoordinated boron atoms[11] is ascertained. Replacement of both the Ph_2B groups by Me_2B groups in **A** results in only one broad ^{11}B-NMR signal at δ = 23.[17] This shift suggests a weak B−N coordinate bond and points to a fluxional behavior of the boryl groups as delineated in the sequence **C**^{1}/**D**/**C**^{2} (Scheme 1). The molecular-mass determination ascertains the presence of a monomeric unit. These data indicate an equilibrium between the intramolecular adducts **C**^{1} and **C**^{2}, with rapid migration of the Me_2N group. Therefore, only one high-field ^{11}B signal appears, according to the nonclassical constitution **D**, representing the transition state between the two resonance hybrids **C**^{1} and **C**^{2}. Asymmetrically substituted diborylhydrazines show two ^{11}B resonances (^{11}B NMR: δ = 0.7, 43.5), which point to a cyclodimeric structure of type **B**, (Scheme 1), featuring a six-membered ring.[17]

ordinated boron atom. These data are in accordance with both, a dimeric unit **B**, or with a monomeric species **C**, featuring an intramolecular adduct. Molecular-mass determination in solution and subsequently the X-ray structure determination of **8d** (see below) confirm the monomeric structure, derived from type **C**.

The tetracoordinated boron nuclei of compounds **8b−e** are better shielded than those in dimeric aminohaloboranes, for example $[EtClB-NMe_2]_2$ (^{11}B NMR: δ = 10.2), or in amineborane adducts, $Ph_2(Cl)B-NMe_3$ (^{11}B NMR: δ = 10.9),[14] or in the BN heterocycle **9** (^{11}B NMR: δ = 10.8). It is suggested that this indicates higher electron density at the boron nuclei due to the higher basicity of the hydrazine nitrogen atom of the Me_2N group compared to the aminoborane nitrogen atom. Therefore, the deformation of the bond angles in the cycloadduct, featuring a three-membered ring, have no significant influence on the shielding of the boron nuclei. The ^{11}B-NMR data of the exocyclic tricoordinated boron atoms of the diborylhydrazines are in good agreement with those of aminohaloboranes, for example *t*BuClB−NMe_2 (^{11}B NMR: δ = 40.5),[14] *t*BuClB−NHMes (^{11}B NMR: δ = 40.9),[45] indicating marked (BN) π-interaction between the exocyclic boryl group and the central nitrogen atom. A typical diborylamine ^{11}B-NMR shift of 10 ppm downfield compared to the respective aminoboranes (see above), can be measured for the diborylhydrazine **8f** (^{11}B NMR: δ = 50.2). Obviously, the weak basicity of the Ph_2N nitrogen atom, owing to the π-acceptor function of the phenyl substituents as well as their sterical demand, prevents the formation of an intramolecular adduct.

The ^{14}N-NMR data of the diborylhydrazines **8b** and **8c** confirm the proposed structures. From other derivatives no signal could be detected. Two signals are observed, one of these at high field in the range of "ammonia" nitrogen nuclei, and the other one in the range of "aminoborane" nitrogen nuclei. These values and the ^{11}B-NMR data are in good accordance with those measured for asymetrically substituted diborylamines, featuring four-membered rings with formation of an intramolecular BN adduct,[7] as depicted in **9**.

9

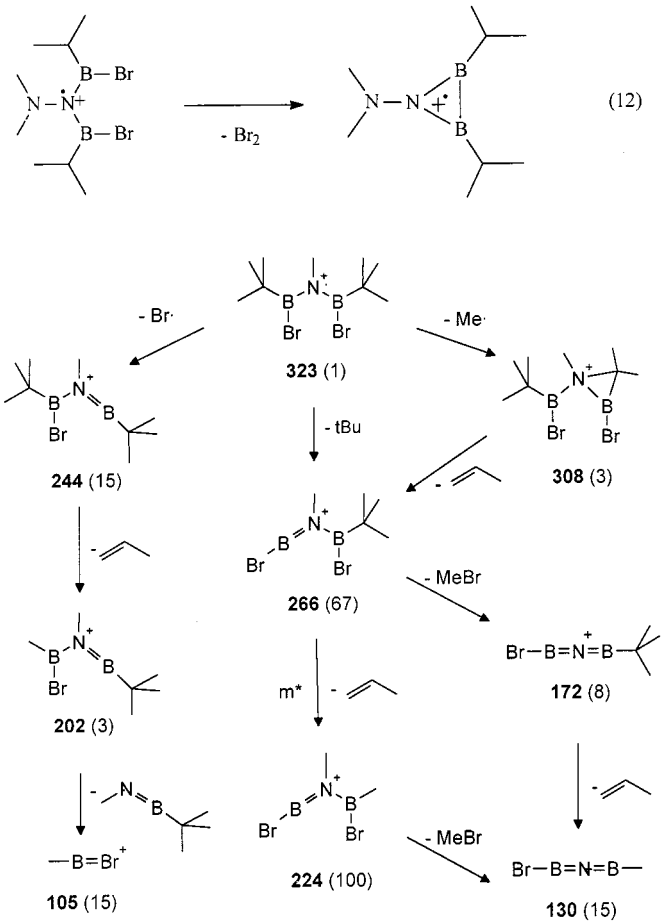
Additional information about the structural features is provided by ^{1}H- and ^{13}C-NMR data. As expected, two groups of signals for the methyl groups above and below the plane of the three-membered ring, as well as for the endo- and exocyclic organyl groups attached to the boron atoms, are observed in the NMR spectra of **8b**, **8c** and **8d**. Those of **8b** and **8d** only show a broadening of the ^{1}H- and ^{13}C-NMR signals at room temp., but the doubling of the signals of **8c** is visible even at ambient temperatures.

Mass Spectra

The diborylamines **3** as well as the diborylhydrazines **8** have been studied by mass spectrometry. Fragments with an abundance larger than 2% are listed in the Experimental Section. The fragmentations of **3b**, **3r** and **8b**, which are characteristic for both classes of compounds are summarized in Schemes 2−4. Measured isotope patterns correspond to the calculated ones.

Characteristic for the ionization by electron impact is the low intensity of the molecular ions of the species containing the B−N−B unit, which show the weak stabilization of the

positive charge of the radical cation in the molecular framework. Contrary to these findings the ionization of the diborylamine **3r** and the diborylhydrazine **8d** leads to the formation of the molecular ion as the base peak, certainly due to the better stabilization of the positive charge by delocalization into the π-system of the aromatic rings attached to the boron atoms. Therefore, these molecules show very few secondary fragments. Concerning the fragmentation pattern, the ionization proceeds preferentially at the central nitrogen atom. This is true also for the fragmentation of the diborylhydrazines, although the first ionization energy of the dimethylamino group is approximately 1 eV lower than that of the diborylamine fragment according to the photoelectron spectrum of $Me_2N-N(BMe_2)_2$.[17]



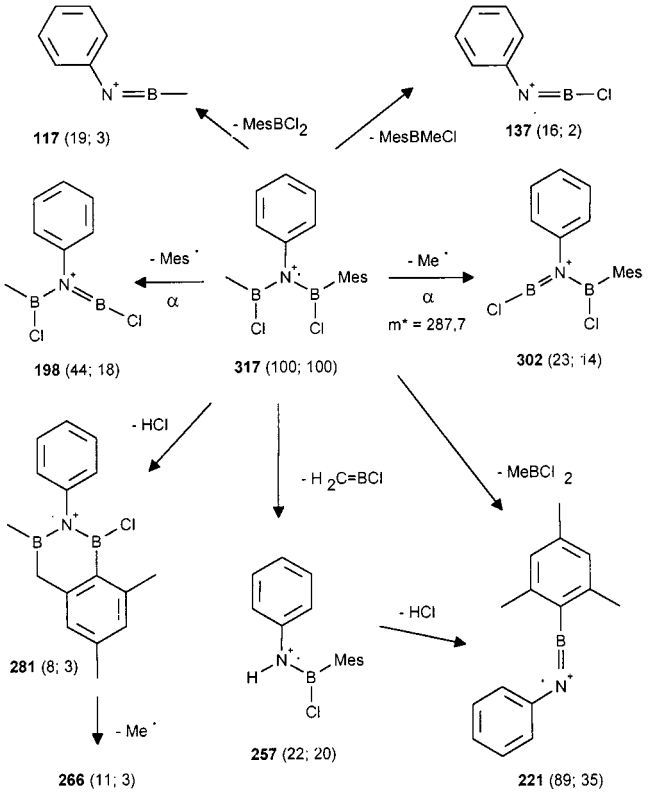
The predominant primary fragmentation is that of α-elimination, demonstrated by the appearence of nitrenium cations $Y-B=N^+R-BR'X$ (Y = alkyl, aryl, hal) in high intensity (see Scheme 2, fragment ion 244; Scheme 3, fragment ion 198). It proceeds by elimination of a substituent in α-position to the ionized centre by homolytic bond cleavage, with the sequence Mes ≈ *t*Bu > *i*Pr > Br > Cl ≈ Me. The ease of α-bond cleavage depends on the stability of the eliminated radical as well as the resulting cation. The mesityl group elimination, however, is facilitated due to the steric relief of the parent ion.

Another important primary fragmentation via neutral particles like R_2BX or RBX_2 can be detected in the mass spectra of **3r** (Scheme 2), **3e**, **8c** and **8d**, all of them showing the molecular ion as the 100% peak.

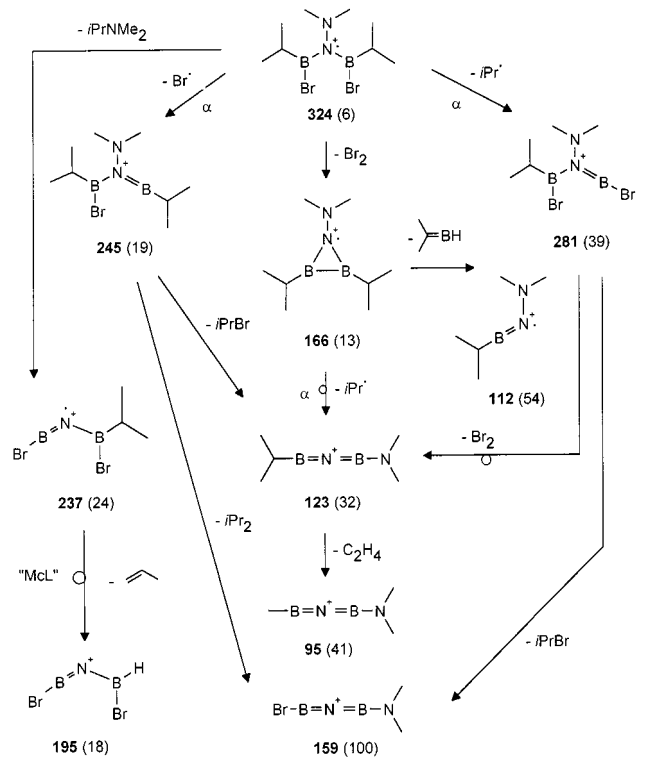
Characteristic fragments found are bis(boranediyl)iminium ions of the type $[X-B=N=B-Y]^+$; they appear at the end of a fragmentation path with remarkable intensity (Scheme 2). The appropriate ions in the mass spectra of the diborylhydrazines bear the even more stabilizing Me_2N group. Therefore, the fragment *m*/*z* 159 and 95 (Scheme 4), for example, appear as 100 and 41% peaks, respectively.

A McLafferty-type rearrangement with the elimination of propene or isobutene, denoted as "McL" in the fragmentation schemes, can be observed in the fragmentations of **3t**, **8a** and **8b** (see Schemes 2 and 4).

The mass spectra of the diborylhydrazines show no fragment ions with masses larger than the monomeric molecular units. This lends support to the formation of an intramolecular adduct as deduced from NMR data and shown in Figure **C** (Scheme 1). Therefore, all nitrenium ions with an amino group attached to the boron atom may also be drawn as a cyclic fragment ion according to the structure of type **C**. Additionally, the fragmentation patterns of the diborylhydrazines exhibit radical cations of remarkable intensity with an azadiboriridine structure. These fragments are formed by α-elimination of halogen molecules from the parent molecular cation according to Equation 12. The appearance of the azadiboriridine ring unit as a relatively stable radical cation gives rise to the assumption that the heterocycle is not only stable as a species in the exited state, but also as molecular unit in the ground state. Therefore, reactions were performed to obtain heterocycles with the hydrazine moiety, depicted in Equation12, by use of the well-known procedure of the reductive B−B bond formation.



Scheme 2. Fragmentation of the diborylamine **3b**



Molecular Structures

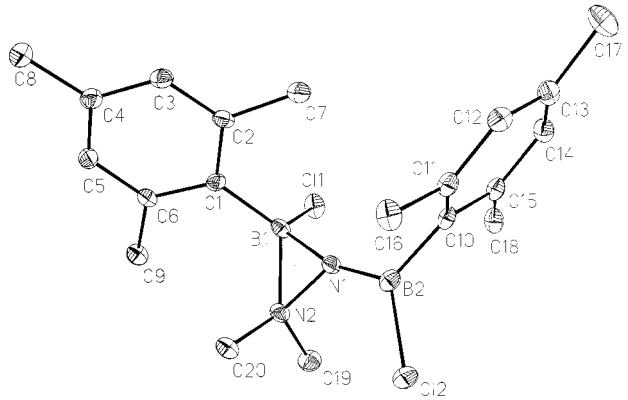
The characteristic structural features of the halogenated *N*,*N*-diborylhydrazines, found in solution, are confirmed by the molecular structure of **8d** (Figure 3), determined in the solid-state by X-ray crystallography. Selected bonding parameters are listed in the caption of Figure 3. Compound **8d** crystallizes in the orthorhombic space group $Pca2_1$, $Z = 4$, and serves as a model for the proposed intramolecular donor-acceptor complex **C** (Scheme 1). The endocyclic B1−N1 length of 1.484(5) Å is in the range of a single (sp^2-sp^2) bond length, the exocyclic B2−N1 length [1.381(5) Å] is, however, consistent with a B−N bond order of > 1.5 of a double bond. Moreover, the small torsion angle N2−N1−B2−Cl2 of 3.4° allows effective (BN) π-interaction between the exocyclic boryl group and the N1 atom of the three-membered ring. The molecular geometry of **8d** in the solid state is fully compatible with the NMR data. Thus, the structure of this compound in the solid and in solution do not differ.

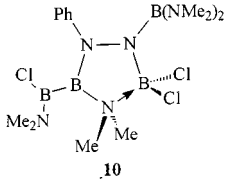
The extremely enlarged B1−N1−B2 angle of 163.3(9)° compared to the appropriate N2−N1−B2 angle of

Scheme 3. Fragmentation of the diborylamine **3r**

Scheme 4. Fragmentation of the diborylhydrazine **8b**

129.4(3)° should be noted. This asymmetrical framework can only be rationalized by a steric repulsion between the two mesityl groups. Although the bond angles in the three-membered ring are small, resulting in a weak overlap of the σ-bond orbitals, the B1−N2 length between the tetracoordinated nitrogen atom and boron atom is remarkably short. It is of the same size as that in the borylated hydrazine **10** ($d_{(BN)}$: 1.626 Å).[18] However, the respective B−N bond of the four-membered cycloadduct **11** ($d_{(BN)}$: 1.713 Å)[19] is 0.10 Å longer, probably due to the sterically more demanding tetramethylpiperidino group compared to the Me_2N group. Therefore, steric repulsion of the mesityl groups in **8d** causes the opposite effect and may be responsible for the short B1−N2 bond. As a consequence of the different hybridization of the boron atoms the B1−Cl1 bond is 0.05 Å longer than the B2−Cl2 bond.





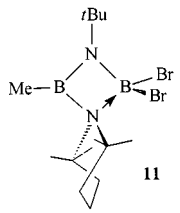


Figure 3. Molecular structure of $Me_2N-N(BMesCl)_2$) (**8d**) in ORTEP-type description; thermal ellipsoids represent a 25% probability; hydrogen atoms are not shown for the sake of clarity; selected bond lengths [Å] (esds are given in parentheses as units in the last digit): B1−N1 1.484(5), B1−N2 1.624(5), B2−N1 1.381(5), N1−N2 1.474(4), B1−Cl1 1.843(4), B2−Cl2 1.796(5), B1−C1 1.575(6), B2−C10 1.562(6), C1−C2 1.423(5), C1−C6 1.432(5), C10−C11 1.405(5), C10−C15 1.412(5); selected bond angles [°]: B1−N1−B2 163.3(9), B1−N1−N2 66.6(2), B2−N1−N2 129.4(3), N1−B2−Cl2 119.5(3), N1−B2−C10 121.8(3), C10−B2−Cl2 118.7(3), N1−B1−C1 124.0(3), N1−B1−Cl1 115.7(3); torsion angle [°]: N2−N1−B2−Cl2 3.4

Experimental Section

General: All manipulations were performed in dry nitrogen. Glassware was dried prior to use by heating in vacuo. − NMR: Bruker AC P200 (^{11}B, ^{14}N), Jeol GSX 270 (^{119}Sn) or Jeol EX 400 (^{1}H, ^{13}C) instrument; standards: TMS (internal, ^{1}H, ^{13}C), $BF_3{\cdot}OEt_2$ (external, ^{11}B), $NaNO_3$ (aqueous solution, external, ^{14}N), tetramethyltin (external, ^{119}Sn). When the coupling constant is stated as $^{n}J^{119(117)}Sn^{m}X$ = ..., (...), the value in parentheses describes the coupling of the X nucleus with the ^{117}Sn isotopomer. The notation $^{n}J(^{119/117}Sn^{m}X)$ represents the coupling of both isotopomers with X, when the coupling cannot be resolved. A questionmark after a formula or a number means assignment is uncertain. The solvent-

dependent NMR data of the alkylhalostannanes, detected in the reaction mixtures, are quoted here and compared with ref. values. If no deviation is detected, the data are not mentioned again in the procedures. – ^{1}H NMR (CH_2Cl_2): δ = 0.67 [Me_3SnCl, $^2J(^{119}Sn^1H)$ = 58.5 Hz], 0.79 [Me_3SnBr, $^2J(^{119}Sn^1H)$ = 57.8 Hz], 1.21 [Me_2SnCl_2, $^2J(^{119}Sn^1H)$ = 68.5 Hz], 1.40 [Me_2SnBr_2, $^2J(^{119}Sn^1H)$ = 65.5 Hz]. – ^{1}H NMR(ref. values in CCl_4): δ = 0.61[20] [Me_3SnCl, ^2J ($^{119}Sn^1H$) = 58.1 Hz[20]], 0.73[20] [Me_3SnBr, $^2J(^{119}Sn^1H)$ = 57.8 Hz[20]], 1.15[20] [Me_2SnCl_2, $^2J(^{119}Sn^1H)$ = 68.2 Hz[21]], 1.33[20] [Me_2SnBr_2, $^2J(^{119}Sn^1H)$ = 66.7 Hz[20]]. – ^{1}H NMR (Tol): δ = 0.27 (!)[45] (Me_3SnCl), 0.52 (!) (Me_2SnCl_2[45]), 0.52 (!) (Me_2SnBr_2[45]). – IR spectra: Nujol-Hostaflon mulls between CsI plates with a Nicolet SZDX FT-IR spectrometer, data are quoted in cm^{-1}; selected characteristic vibrations are given only. – MS: Varian CH7 instrument with electron impact ionisation at 70 eV, data are given in the sequence: *m*/*z* (%, assignment). The masses found refer to the isotopes ^{1}H, ^{12}C, ^{11}B, ^{14}N, ^{35}Cl, ^{120}Sn. – Elemental analyses: performed at the Microanalytical laboratory of the institute. When marked with * the elemental analysis by combustion suffers from a) the deviation from the calculated values due to the formation of boron carbide and boron oxide melt, and b) difficulties in handling of the samples because of spontaneous inflammability or hydrolysis. – X-ray: Siemens P4 four-circle diffractometer; Mo-K_α radiation, graphite monochromator; single crystals were mounted under argon using glass capillaries. Crystal data were determined and intensity data recorded at 213 K; program X-scan, structure solution by Patterson method and refinement using the SHELX-PLUS PC version package; final refinement was performed using the SHELX-93 programs.[22] All atoms except hydrogen atoms are described with anisotropic temp. factors, all hydrogen positions were geometrically placed [*d*(CH) = 0.96 Å] and included in the refinement by using the riding model and fixed U_i. Details of the crystal structure determination is available on request from the Cambridge Crystallographic Data Center (CCDC) on quoting the depository number CSD-112146, the names of the authors, and the journal citation.

Starting Materials: $N(SnMe_3)_3$[23] was prepared in a modified procedure[15] from $NaNH_2/NH_3/OEt_2/Me_3SnCl$, $(Me_2SnCl)_3N$,[24] Me_2SnCl_2,[25] Me–N($SnMe_3$)$_2$,[26] Ph–N($SnMe_3$)$_2$[26], Mes–N($SnMe_3$)$_2$,[9] Dipp–N($SnMe_3$)$_2$,[9] Me_3Si–N($SnMe_3$)$_2$,[27] *t*Bu–N($SnMe_2Cl$)$_2$,[9] Me_3Si–N($SnMe_2Cl$)$_2$,[9][43] Dipp–N($SnMe_2Cl$)$_2$,[9] Me_2N–N($SnMe_3$)$_2$,[28] $N_2(SnMe_3)_4$,[29] Me_2B–N($SnMe_3$)$_2$,[30] $MeBBr_2$ and Et_2BCl,[31] Me_2BBr,[32] *i*$PrBCl_2$,[33] *t*$BuBBr_2$,[34] $MesBBr_2$.[35]

General Procedure I. – Reaction of Bis(trimethylstannyl)amines with Dihaloorganylboranes RBX_2 with Sterically Less Demanding Groups R and Bis(trimethylstannyl)hydrazines with Dihaloorganylboranes: A solution of the distannylamine $RN(SnMe_3)_2$ in CH_2Cl_2 was slowly added (≥ 60 min) to a stirred solution of the dihaloorganylborane RBX_2 in CH_2Cl_2 at −65°C to −75°C. After allowing the mixture to slowly attain ambient temp., stirring was continued for 12 h at 25°C. A sample of the reaction mixture, checked by ^{1}H and ^{11}B NMR, confirmed quantitative reactions, or in some cases methylation, of the boron atoms. After removal of the solvent at 25°C/12 Torr, the most volatile component was removed either by fractional distillation of the residue using a 10-cm Vigreux column (Me_3SnBr, b.p. ca. 30°C/10^{-2} Torr or 53–55°C/12 Torr), or by sublimation (Me_3SnCl, subl.p. 25°C/10^{-3} Torr). The removal of Me_3SnCl (or Me_2SnCl_2) was completed by repeated dissolution of the residue in CH_2Cl_2, followed by removal of the solvent, and repeated sublimation. Finally, the diborylamine was obtained as the next volatile fraction.

General Procedure II. – Reactions of Bis(halodimethylstannyl)amines with Dihaloorganoboranes RBX_2 with Sterically More Demanding Groups R = *t*Bu, Mes: The bis(halodimethylstannyl)amine $RN(SnMe_2X)_2$ (X = Cl or Br), dissolved in CH_2Cl_2, was slowly added (≥ 60 min) at −60 to −50°C, whilst stirring, to a solution of the dihaloorganoborane RBX_2 in CH_2Cl_2. The mixture was then allowed to slowly attain ambient temp. and the stirring was continued for 12 h at 25°C. A sample was then checked by ^{1}H and ^{11}B NMR which confirmed an almost quantitative reaction. After stripping off the solvent at 25°C/12 Torr, the residue was dissolved in petroleum ether (ca. half of the volume of the previous solvent). The dimethyltin dihalide, which is only sparingly soluble in petroleum ether, crystallized after a period of 4–6 h at −30°C and was then removed by filtration. After removal of the solvent from the filtrate at 25°C/12 Torr the colorless residue, solidifying at ambient temp., was washed with petroleum ether (2 ×) and purified by fractional distillation in vacuo using a 10-cm Vigreux column. If the residue of the reaction mixture is a mobile oil, the Me_2SnX_2 compounds were removed by continually maintaining the product at 25°C/10^{-6} Torr. The alkylhalostannanes Me_3SnX and Me_2SnX_2 (X = Cl, Br), formed by stannazane bond cleavage according to procedure I or II, were identified by their ^{1}H-NMR spectra. Deviations and quantities are given below. The reaction proceeds with Cl/Br exchange, when X equals chlorine in $RN(SnMe_2X)_2$ and bromine in RBX_2.

Bis(bromo-*tert*-butylboryl)methylamine (3b). – Procedure I: Bis(trimethylstannyl)methylamine (**4a**) (5.40 g, 7.1 mmol), dissolved in 10 mL of CH_2Cl_2, was added to a solution of *t*$BuBBr_2$ (3.20 g, 13.9 mmol) in 20 mL of CH_2Cl_2 over 90 min. – ^{11}B NMR (reaction mixture): δ = 48.3 [**3b**, shoulder MeN($SnMe_2Br$)(BMeBr)?], 80.9 [*t*Bu(Me)BBr]; ratio: 8:2. – B.p. 35–38°C/10^{-3} Torr. – Yield: 1.0 g of **3b** (43%); colorless crystals. – M.p. ca. 30°C. – ^{1}H- and ^{11}B-NMR data correspond to another sample of **3b**, prepared according to procedure II (see below).

Attempt to Prepare Bis(bromomethylboryl)phenylamine (3c) from 4c and $MeBBr_2$ (Molar Ratio 1:2). – Procedure I: $PhN(SnMe_3)_2$ (**4c**) (5.40 g, 12.8 mmol), dissolved in 20 mL of CH_2Cl_2, was added over 30 min to a solution of $MeBBr_2$ (4.80 g, 25.9 mmol) in 20 mL of CH_2Cl_2. – ^{11}B NMR (reaction mixture): δ = 51.5 [$PhN(BBrMe)_2$ (**3c**)], 78.7 (Me_2BBr), 62.1 ($MeBBr_2$), 39.8 [$PhN(SnMe_3)(BMeBr)$], 32.3 ($Ph–N=B–Me)_3$; ratio: 10.5:1.5:0.6:1.5:0.7; after 16 h stirring: 12.5:1.5:0:0:0.6 [NMR data of **3c**: ^{1}H NMR: δ = 1.2 (s, 6 H, B*Me*), 6.9–7.5 (m, 5 H, C_6H_5); ^{11}B NMR: δ = 51.0]. During removal of the volatile components at 25°C/13 Torr the ^{11}B-NMR signal of **3c** became weaker and disappeared after the residue was kept at room temp. for 1 d (^{11}B NMR: δ = 62.1, 32.3).

Attempt to Prepare Bis(chlorophenylboryl)phenylamine (3d) by Reaction of 4c with $PhBCl_2$ (Molar Ratio 1:2). – Procedure I: $PhN(SnMe_3)_2$ (**4c**) (4.70 g, 11.3 mmol), dissolved in 25 mL of CH_2Cl_2, was added dropwise over 30 min to a solution of $PhBCl_2$ (3.50 g, 22.2 mmol) in 15 mL of CH_2Cl_2. – ^{11}B NMR (ca. 17 h stirring): δ = 55.0 ($PhBCl_2$), 47 [Ph–N($BPhCl)_2$ (**3d**)], 37.2 [Ph–N(BPhCl)($SnMe_3$)?], signal ratio: 1:0.1:1, after 12 d the ratio had changed to 0.5:9.1:0.4. The solvent and most of the Me_3SnCl was removed at 25°C/12 Torr. – ^{1}H NMR (residue, CH_2Cl_2): δ = 0.65 (Me_3SnCl), 7.30–7.68 (m, C_6H_5, **3d**). – ^{11}B NMR (residue, CH_2Cl_2): d = 46.9 (**3d**). – While Me_3SnCl was sublimed from the residue at ambient temp./10^{-3} Torr, the diborylamine **3d** decomposed slowly with formation of $(Ph–N=B–Ph)_3$ and $PhBCl_2$, the latter two were also detectable in the cold trap (^{11}B NMR: δ = 34 and 55). The borazine $(Ph–N=B–Ph)_3$,[36] separated from a petroleum ether solution of the residue and kept at room temp. for 2 d (0.52 g, 26%), was recrystallized from decane (15 mL), m.p.

124°C. – ^{1}H NMR ($CDCl_3$): δ = 6.71–6.87 (m, 5 H, C_6H_5), 6.91–7.49 (5 H, C_6H_5). – ^{11}B NMR (CH_2Cl_2): δ = 34.2. – MS: 537 (100, M^+), 460 (17, M^+ – Ph), 383 (5.2, M^+ – 2 Ph), 358 [39, $(Ph–N{\equiv}B–Ph)_2^+$], 230 (12, 460^{2+}), 179 (80, $Ph–N{\equiv}B–Ph^+$). – IR: $\tilde{\nu}$ = 3074 cm^{-1} (w), 3055 (w), 3026 (w), 3011 (w), 1599 (m), 1492 (m), 1438 (m), 1384 (s, ν(BN); for comparison ν(BN) = 1368 cm^{-1}[37]), 1369 (vs), 696 (s). – $C_{36}H_{30}B_3N_3$ (537.1)*: calcd. C 80.51, H 5.63, N 7.82; found C 72.18, H 5.65, N 5.91.

Reaction of Bis(trimethylstannyl)phenylamine (4c) with *t*BuBBr$_2$ (Molar Ratio 1:2), Attempt to Prepare Bis(bromo-*tert*-butylboryl)-phenylamine (3f), NMR-Scale reaction. – Procedure I:. A solution of *t*BuBBr$_2$ (0.37 g, 1.6 mmol), dissolved in 2 mL of CH_2Cl_2, was added dropwise to a solution of bis(trimethylstannyl)phenylamine (**4c**) (0.33 g, 0.8 mmol) in 1 mL of CH_2Cl_2 within 15 min at −78°C. – ^{11}B NMR (mixture after a period of ca. 3 d stirring at ambient temp.): δ = 80.5 [*t*Bu(Me)BBr], 66.2 (*t*BuBBr$_2$), 43.1 [PhN(B*t*BuBr)(SnMe$_3$)], signal ratio: 3:4:2. – ^{1}H NMR: δ = 7.1 (PhN), 1.14 (*t*BuBBr$_2$), 1.03 [*t*Bu(Me)BBr], 0.96 [N(B*t*BuBr)], 0.74 (Me_3SnBr), 0.53 ($NSnMe_3$).

Attempt to Prepare Bis(bromomethylboryl)-2,6-diisopropylphenylamine (3k) from 4k and MeBBr$_2$ (Molar Ratio 1:2), NMR-Scale reaction. – Procedure I: A solution of Dipp-N(SnMe$_3$)$_2$ (**4k**) (0.28 g, 0.56 mmol), dissolved in 1 mL of CH_2Cl_2, was added dropwise to a solution of $MeBBr_2$ (0.21 g, 1.1 mmol) in 1 mL of CH_2Cl_2 over a period of 30 min at −78°C. – ^{11}B NMR (mixture after ca. 1 d stirring at ambient temp.): δ = 79.1 (Me_2BBr). – ^{1}H NMR: δ = 0.79 [Sn*Me*$_2$Br, Dipp-N(SnMe$_2$Br)$_2$ (**5k**)], 1.05 (*Me*$_2$BBr), 1.15 (*Me*$_2$CH, **5k**), 3.64 (Me_2CH). – d^{1}H- and d^{11}B-NMR data correspond to an authentic sample of **5k**, prepared according to ref.[9] After 14 d stirring at room temp., no intensity change of the NMR signals in the reaction mixture was detected.

Bis(dimethylboryl)mesitylamine (3q). – Procedure II: MesN(SnMe$_3$)$_2$ (**4i**) (10.70 g, 23.5 mmol), dissolved in 25 mL of CH_2Cl_2, was added to a solution of $MeBBr_2$ (9.15 g, 49.3 mmol) in 10 mL of CH_2Cl_2 within 1 h at −50°C. – ^{1}H NMR (reaction mixture, CH_2Cl_2): δ = 0.78 [N(Sn*Me*$_2$Br)$_2$ of **5i**, ^2J (^{119}Sn^{1}H) = 63.0]. – ^{119}Sn NMR: δ = 77.8 [^2J(^{119}Sn^{117}Sn) = 135 Hz (**5i**)]. – ^{11}B NMR: δ = 78.5 ($h_{1/2}$ = 325 Hz, Me_2BBr). – After 2 d stirring at room temp. and a workup according to procedure II, the distillation yielded 4.1 g of **3q** (81%), b.p. ca. 50°C/10^{-6} Torr, as a colorless liquid. – ^{1}H NMR ($CDCl_3$): δ = 0.43 (s, br., 12 H, B*Me*$_2$), 1.93 (s, 6 H, *o*-*Me*–Ph), 2.25 (s, 3 H, *p*-*Me*–Ph), 6.85 (s, 2 H, $C_6H_2Me_3$). – ^{13}C NMR: δ = 10.38 (br., BMe_2), 19.03 (*o*-*Me*–Ph), 20.84 (*p*-*Me*–Ph), 128.79 (*m*-C), 132.59 (*o*-C), 133.62 (*p*-C), 146.48 (*i*-C). – ^{11}B NMR: δ = 58.1 ($h_{1/2}$ = 229 Hz). – ^{14}N NMR: δ = −210 ($h_{1/2}$ = 371 Hz). – MS: 215 (52, M·$^+$), 200 (100, M^+ – Me, m*), 185 (6, M^+ – C_2H_5), 160 (31, M^+ – H_2C=BMe), etc. – IR [nujol/hostaflone]: $\tilde{\nu}$ = 1314 cm^{-1} [s, $\nu_{as}(B_2N)$,[39] 1251 [s, $\nu_s(B_2N)_s$?], 1263 [s, ν(CN)?], 1000 [w, ν_{as}(BC)], 900 [w, $\nu_s(CB_2)$]. – $C_{13}H_{23}B_2N$ (215.0): calcd. C 72.64, H 10.79, N 6.52; found C 72.29, H 10.78, N 6.41. – Filtration of the residue, insoluble in petroleum ether, yielded Me_2SnBr_2 (14.6 g, 96%). – ^{1}H NMR (CH_2Cl_2: δ = 1.42 [*Me*$_2$SnBr$_2$, ^2J(^{119}Sn^{1}H = 65.5].[23]

Bis(bromomethylboryl)trimethylsilylamine (3m).[38] **– Procedure I:** A solution of $MeBBr_2$ (13.6 g, 73.1 mmol) in 40 mL of CH_2Cl_2 was added dropwise to **4l** (15.2 g, 36.5 mmol), dissolved in 50 mL of CH_2Cl_2, over 60 min at −75°C. – ^{1}H NMR (ambient temp.): δ = 0.35 (Me_3Si), 0.74 (Me_3SnBr), 1.09 (MeB). – ^{11}B NMR: δ = 49.8. – Yield: 6 g of **3m** (55%), b.p. 71–75°C/13 Torr, colorless liquid. – ^{1}H NMR: δ = 0.35 (Me_3Si), 1.1 (MeB). – ^{11}B NMR: δ = 49.5. – ^{14}N NMR: δ = −220. Consistent with the ref. values.[38]

Bis(bromoisopropylboryl)trimethylsilylamine (3n). – Procedure I: Bis(trimethylstannyl)trimethylsilylamine (**4l**) (22.8 g, 55 mmol), dissolved in 60 mL of CH_2Cl_2, was added over 60 min at ca. −78°C, to a solution of *i*PrBBr$_2$ (23.8 g, 111 mmol) in 50 mL of CH_2Cl_2. – ^{11}B NMR (mixture at ambient temp.): δ = 52.2 (**3n**). – Yield: 15.6 g of **3n** (80%) as a colorless liquid, b.p. 59–65°C/5·10^{-2} Torr. – ^{1}H NMR ($CDCl_3$): δ = 0.33 (s, 9 H, Me_3Si), 1.05 [d, 12 H, BCH*Me*$_2$, ^3J(^{1}H^{1}H) = 5.9 Hz], 1.33 (m, 2 H, BC*H*Me$_2$). – ^{13}C NMR: δ = 1.89 [$SiMe_3$, ^1J(^{29}Si^{13}C) = 59 Hz], 19.12 (BCH*Me*$_2$), 25.8 (br., B*C*HMe$_2$). – ^{11}B NMR: δ = 52.2 ($h_{1/2}$: 321 Hz). – ^{14}N NMR: δ = −230 ($h_{1/2}$: 109 Hz). – ^{29}Si NMR: δ = 5.6. – MS: 355 (12, M^+), 340 (18, M^+ – Me), 276 (65, M^+ – Br), etc. – $C_9H_{23}B_2Br_2NSi$ (354.8): calcd. C 30.47, H 6.53, N 3.95; found C 30.66, H 6.66, N 3.89.

Bis(*tert*-butylchloroboryl)trimethylsilylamine (3o).[6a] **– Procedure II:** To a solution of *t*BuBBr$_2$ (30.6 g, 135 mmol) in 90 mL of CH_2Cl_2 was added bis(chlorodimethylstannyl)trimethylsilylamine (**5l**) (30.6 g, 67.2 mmol), dissolved in 50 mL of CH_2Cl_2, within 60 min at ca. −78°C. – ^{11}B NMR (mixture at ambient temp): δ = 54.2 (**3o**). – Yield: 13.6 g of **3o** (69%) as a colorless liquid, b.p. 65–66°C/10^{-1} Torr (or 45–49°C/5·10^{-3} Torr). – ^{1}H NMR ($CDCl_3$): δ = 0.39 (s, 9 H, Me_3Si), 1.02 (s, 18 H, BC*Me*$_3$). – ^{13}C NMR: δ = 4.41 [$SiMe_3$, ^1J(^{29}Si^{13}C) = 59.5 Hz], 28.87 (BC*Me*$_3$), 34.31(B*C*Me$_3$). – ^{11}B NMR: δ = 53.82 ($h_{1/2}$: 218 Hz). – ^{14}N NMR: δ = −246 ($h_{1/2}$: 271 Hz). – ^{29}Si NMR (C_6D_6): δ = 7.56. – MS: 293 (22, M^+), 278 (19, M^+ – Me), 258 (11, M^+ – Cl), etc. – $C_9H_{23}B_2Cl_2NSi$ (294.0): calcd. C 44.95, H 9.26, N 4.76; found C 45.12, H 9.18, N 4.86.

Bis(*tert*-butylchloroboryl)methylamine (3a). – Procedure II: [MeN(SnMe$_2$Cl)$_2$]$_2$ [(**5a**)$_2$] (11.8 g, 14.9 mmol), dissolved in 70 mL of CH_2Cl_2, was added to a solution of *t*BuBBr$_2$ (13.8 g, 59.6 mmol) in 80 mL of CH_2Cl_2 within 2.5 h at −60 to −50°C. A precipitate formed which redissolved. After removal of $Me_2SnBrCl$ [15 g, 95%,^{1}H NMR(CH_2Cl_2): δ = 1.32; ^{119}Sn NMR: δ = 114.1] by crystallization and removal of the solvent at 25°C/12 Torr, compound **3a** (4.1 g, 58%) was obtained by distillation at 29–30°C/10^{-6} Torr as a colorless liquid. – ^{1}H NMR ($CDCl_3$): δ = 1.08 (s, 18 H, BC*Me*$_3$), 2.90 (s, 3 H, *Me*N). – ^{13}C NMR: δ = 25 (br., B*C*Me$_3$), 28.31 (BC*Me*$_3$), 33.16 (N*Me*). – ^{11}B NMR: δ = 50.0 ($h_{1/2}$ = 147 Hz). – ^{14}N NMR: δ = −268 ($h_{1/2}$ = 178 Hz). – MS: 235 (< 1, M^+), 220 (3, M^+ – Me), 200 (3, M^+ – Cl), 178 (49, M^+ – *t*Bu), 162 (6, 178^+ – CH_4, or 220^+ – *t*BuH), 158 (< 1, 200^+ – H_2C=CHMe), 142 (3, 158^+ – CH_4), 136 (100, 178^+ – H_2C=CHMe), 61 (10, 136^+ – MeNBCl). – IR: $\tilde{\nu}$ = 1362 cm^{-1} [vr, $\nu_{as}(B_2N)$[39]], 1283 [s, ν(CN)], 1215 [s, $\nu_s(B_2N)$], 1072 [ν(BC)], 908 [vr, ν(BCl)]. – $C_9H_{21}B_2Cl_2N$ (235.8): calcd. C 45.84, H 8.98, N 94; found C 45.31, H 8.42, N 5.59.

Bis(bromo-*tert*-butylboryl)methylamine (3b). – Procedure II: [MeN(SnMe$_2$Br)$_2$]$_2$ [(**5b**)$_2$] (5.8 g, 6.0 mmol) was added to a solution of *t*BuBBr$_2$ (5.4 g, 23.8 mmol) in 20 mL of CH_2Cl_2, dissolved in 70 mL of CH_2Cl_2, over 1.5 h at −55 to −50°C; a violent reaction with temporary formation of a solid occurred. **3b** (2.50 g, 64%) was obtained by condensation at 25–28°C/10^{-6} Torr into a cooled trap (−78°C); colorless crystals (m.p. ca. 30°C). – ^{1}H NMR ($CDCl_3$): δ = 1.09 (s, 18 H, BC*Me*$_3$), 2.88 (s, 3 H *Me*N). – ^{13}C NMR: δ = 26 (br., B*C*Me$_3$), 28.48 (BC*Me*$_3$), 33.95 (N*Me*). – ^{11}B NMR: δ = 48.0 ($h_{1/2}$ = 174 Hz). – ^{14}N NMR: δ = −259 ($h_{1/2} \approx$ 197 Hz). – MS: 323 (ca. 1, M·$^+$), 308 (3, M^+ – Me), 266 (67, M^+ – *t*Bu), 250 (2, 308^+ – *t*BuH), 244 (15, M^+ – Br), 224 (100, 266^+ – H_2C=CHMe), 202 (3, 244^+ – H_2C=CHMe), 186 (9, 202^+ – CH_4), 172 (8, *t*BuBNBBr$^+$), 160 (14, 202^+ – H_2C=CHMe), 130 (15, MeBNBBr$^+$), 105 (15, $MeBBr^+$), 92 (3, 186^+ – MeBr); – IR: $\tilde{\nu}$ =

1365 [s, $\nu_{as}(B_2N)$[39]] 1277 [m, ν(CN)], 1210 [s, $\nu_s(B_2N)$], 1068 [m, ν(BC)], 883 [vr, ν(BBr)]. − $C_9H_{21}B_2Br_2N$ (324.7): calcd. C 33.29, H 6.52, N 4.31; found C 33.05, H 6.83, N 4.97.

***tert*-Butylbis(chloro-*tert*-butylboryl)amine (3g).**[6] **− Procedure II:** **t**BuN$(SnMe_2Cl)_2$ (**5a**) (3.50 g, 8.0 mmol), dissolved in 10 mL of CH_2Cl_2, was added to a solution of *t*BuBBr_2 (3.60 g, 16 mmol) in 10 mL of CH_2Cl_2 over 0.5 h at −30°C. Yield: 2.16 g of **3g** (97%), as a colorless liquid, b.p. 42°C/10^{-2} Torr. − ^{1}H NMR ($CDCl_3$): δ = 1.11 (s, 18 H, BC*Me*$_3$), 1.28 (s, 9 H, NC*Me*$_3$). − ^{13}C NMR: δ = 27 (br., B*C*Me$_3$), 30.32 (BC*Me*$_3$), 33.24 (NC*Me*$_3$), 55.1 (N*C*Me$_3$). − ^{11}B NMR: δ = 45.5 ($h_{1/2}$ = 179 Hz). − ^{14}N NMR: δ = −226 ($h_{1/2} \approx$ 215 Hz). − MS: 275 (ca. 1, $M^{\cdot+}$), 260 (7, M^+ − Me), 240 (3, M^+ − Cl), 218 (33, M^+ − *t*Bu), 176 (100, 218^+ − H_2C=CHMe), 61 (12, MeBCl). − IR: $\tilde{\nu}$ = 1344 cm^{-1} [s, $\nu_{as}(B_2N)$], 1269 [s, ν(CN)], 1190 [s, $\nu_s(B_2N)$], 1108 [m, ν(BC)], 903 [s, ν(BCl)]. − $C_{12}H_{27}B_2Cl_2N$ (277.9): calcd. C 51.87, H 9.79, N 5.04; found C 52.90, H 10.10, N 5.39.

Bis(bromomethylboryl)-*tert*-butylamine (3h).[3] **− Procedure I:** **t**BuN$(SnMe_3)_2$ (**4g**) (26.8 g, 67.2 mmol) dissolved in 25 mL of CH_2Cl_2 was added dropwise to a solution of $MeBBr_2$ (25.0 g, 135 mmol) in 25 mL of CH_2Cl_2 at −78°C. Yield: 16.1 g of **3h** (85%), as a colorless liquid, b.p. 35°C/10^{-1} Torr. − ^{1}H NMR($CDCl_3$): δ = 1.18 (s, 6 H, B*Me*), 1.44 (s, 9 H, NC*Me*$_3$). − ^{11}B NMR: δ = 47.5 ($h_{1/2}$ = 190 Hz). − ^{14}N NMR: δ = −212, ($h_{1/2} \approx$ 230 Hz). − $C_6H_{15}B_2Br_2N$ (282.6): calcd. C 25.50, H 5.35, B 7.65, Br 56.54, N 4.96; found C 24.44, H 5.23, B 7.38, Br 55.28, N 4.70. − The NMR data are identical with ref. values.[3]

Attempt to Prepare Bis(chloromesitylboryl)methylamine (3t) from Bis(bromodimethylstannyl)methylamine (5b)$_2$ and MesBCl$_2$ (Molar Ratio 1:4): A suspension of (**5b**)$_2$ (2.6 g, 2.7 mmol) in 50 mL of CH_2Cl_2 was added to a solution of $MesBCl_2$ (2.15 g, 10.7 mmol) in 30 mL of CH_2Cl_2 within 1.25 h at −78°C. NMR data of the mixture after 7 d stirring at ambient temp. indicated the formation of the intermediate stannylaminoborane {^{11}B NMR (CH_2Cl_2): δ = 38.3 [Me−N(BMesCl) ($SnMe_2Br$) (?)], 60.4 [$MesBCl_2$, ref.: 61.4 (C_6D_6);[40] 61.1 (CD_2Cl_2)[40]]}. After keeping for 24 h in boiling CH_2Cl_2 and an additional 20 h in boiling $CHCl_3$, no change of signal intensities could be detected in an NMR sample of the reaction mixture. $Me_2Sn(Cl)Br$ (^{1}H NMR: δ = 1.32; ^{119}Sn NMR: δ = 114.1) was removed by crystallization from petroleum ether and the solvent at 25°C/12 Torr. Fractional distillation of the residue gave: (i) $MesBCl_2$ (0.24 g, ca. 85%), b.p. 50°C/10^{-5} Torr [^{11}B NMR (CH_2Cl_2): δ = 60.4]; (ii) 0.66 g of a highly viscous liquid, b.p. 80°C/10^{-5} Torr; ^{11}B NMR (CH_2Cl_2/$CDCl_3$): δ = 37.8; ^{1}H NMR: δ = 1.29 [$SnMe_2$, $^2J(^{117(119)}Sn^1H)$ = 65.2 (68.4) Hz], 2.25 (*o*,*p*-*Me*$_3C_6H_2$−B), 6.81 (*m*-H, Mes); ^{14}N NMR: δ = −282 ($h_{1/2}$ = 473 Hz); (iii) residue: yellow solid. − ^{11}B NMR (CH_2Cl_2): δ = 38.8, 47 (sh, ?). The purification by crystallization from CH_2Cl_2, toluene, or petroleum ether failed according to ^{1}H- and ^{11}B-NMR data.

Bis(*tert*-butylchloroboryl)phenylamine (3e):[45] A suspension of Me_2SnCl_2 (10.1 g, 46.1 mmol) in 40 mL of CH_2Cl_2 was treated with $PhN(SnMe_3)_2$ (**4c**), dissolved in 30 mL of CH_2Cl_2, while stirring at room temp. This mixture was added dropwise, while stirring, to *t*B$uBBr_2$ (10.5 g, 46.0 mmol), dissolved in 50 mL of CH_2Cl_2, within 1.5 h at −50°C. After allowing the reaction mixture to attain ambient temp. within 1.5 h, the progress of the reaction was controlled by NMR (see Figure 1) during a period of 96 h stirring at room temp. followed by a period of 48 h under reflux. ^{1}H- and ^{11}B-NMR data of the mixture as a function of time, given in the sequence time [h]; d^{11}B NMR [ppm], ratio [%]; d^{1}H NMR [ppm]: Measurement 1: 0; 67.5 (*t*B$uBBr_2$); 100; 0.63 (Me_3SnCl), 0.78 ($PhN(SnMe_2Cl)_2$). Measurement 2: ca. 3; 40.4 [PhN(B*t*BuCl)$SnMe_2Cl$], 50; 63.5 (*t*BuBClBr), 50; 0.72 (Me_3SnBr), 0.78 [$PhN(SnMe_2Cl)_2$], 1.33 ($Me_2SnClBr$); [^{1}H-NMR signal of Me_3SnCl and $PhN(SnMe_2Br)_2$ disappeared]. Measurement 3: 24; 42.1 [PhN(B*t*BuCl)$SnMe_2Cl$], 44; 50.4 [PhN(B*t*BuCl)$_2$], 12; 64.0 (*t*BuBClBr), 44; 0.72 (Me_3SnBr), 1.34 ($Me_2SnClBr$), (^{1}H-NMR signal of **4c** vanished completely). Measurement 4: 96; 41.2 [PhN(B*t*BuCl)$SnMe_2Cl$], 41; 49.9 [PhN(B*t*BuCl)$_2$], 22; 64.0 (*t*BuBClBr), 38; 0.73 (Me_3SnBr), 1.35 ($Me_2SnClBr$). Measurement 5: 96 (25°C) + 34 (reflux); 43.3 [PhN(B*t*BuCl)$SnMe_2Cl$], 35; 50.0 [PhN(B*t*BuCl)$_2$], 35; 63.7 (*t*BuBClBr), 29. Measurement 6: 96 (25°C) + 48 (reflux); 50.1 [PhN(B*t*BuCl)$_2$], ca. 80; 38.9 [$(PhNBtBu)_n$?], ca. 20. − After the solvent was removed at 25°C/12 Torr and Me_3SnBr as well as $Me_2SnClBr$ (d^{1}H = 1.35) was condensed into a trap at −78°C, fractional distillation of the residue yielded 3.8 g (55%) of **3e** as a colorless liquid; b.p. 48−51°C/10^{-5} Torr. − ^{1}H NMR ($CDCl_3$): δ = 1.01 (s, 18 H, BC*Me*$_3$), 7.32 (m, 5 H, C_6H_5). − d^{13}C: 26 (br., B*C*Me$_3$, detected after Gauß transformation only), 28.65 (BC*Me*$_3$), 127.03 (*p*-C), 29.02 (*o*-C), 129.02 (*m*-C), 141.47 (*i*-C). − ^{11}B NMR: δ = 50.6 ($h_{1/2}$ = 253 Hz). − ^{14}N NMR: δ = −234 ($h_{1/2}$ = 506 Hz). − MS [% (70 eV, 15 eV), assignment]: 236 (11, 7, M^+ − *t*Bu), 194 (69, 89, M^+ − *t*BuBCl), 180 (18, 16, 236^+ − C_4H_8), 152 (14, 11, 194^+ − C_3H_6). 143 (2, 7, $PhN{\equiv}BC_3H_5^+$), 138 (100, 100, 194^+ − C_4H_8), 137 (40, M^+ − tBu_2BCl), 103 (22, 14, $PhN{\equiv}BH^+$), 77 (40, 2, Ph^+). − IR: $\tilde{\nu}$ = 1365 cm^{-1} [s, $\nu_{as}(B_2N)$[42]], 1278 [s, ν(CN)], 1197 [s, $\nu_s(B_2N)$], 1104 [s, ν(BC)], 907 [s, ν(BCl)]. − $C_{14}H_{23}B_2Cl_2N$ (297.9): calcd. C 56.45, H 7.78, N 4.70; found C 54.08, H 7.52, N 4.60.

Bis(bromo-*tert*-butylboryl)phenylamine (3f): A suspension of Me_2SnBr_2 (16.10 g, 52.1 mmol) in 40 mL of CH_2Cl_2 was treated with $PhN(SnMe_3)_2$ (**4c**) (10.90 g, 26.0 mmol), dissolved in 40 mL of CH_2Cl_2, while stirring at room temp. This reaction mixture was added dropwise, while stirring, to *t*B$uBBr_2$ (11.9 g, 52.1 mmol), dissolved in 40 mL of CH_2Cl_2, within 130 min at −68 to −40°C. After allowing the reaction mixture to attain ambient temp., the solvent was removed at 25°C/12 Torr, Me_3SnBr as well as Me_2SnBr_2 was condensed into a trap at −78°C over a period of 4 d, the fractional distillation of the viscous residue yielded 7.0 g (69%) of **3f** as colorless liquid, b.p. 69−77°C/10^{-5} Torr. − ^{1}H NMR ($CDCl_3$): δ = 0.98 (s, 18 H, BC*Me*$_3$), 7.30 (m, 5 H, C_6H_5). − ^{13}C NMR: δ = 27 (br., B*C*Me$_3$, detected after Gauß transformation only), 29.24 (BC*Me*$_3$), 127.7 (*p*-C), 129.34 (*o*-C), 129.38 (*m*-C), 141.93 (*i*-C). − ^{11}B NMR: δ = 49.3 ($h_{1/2}$ = 300 Hz). − ^{14}N NMR: δ = −228 ($h_{1/2}$ = 488 Hz). − MS: *m*/*z* [% (70 eV, 15 eV), assignment]: 385 (< 1, 3, M^+), 328 (32, 66, M^+ − *t*Bu), 305 (12, 29, M^+ − HBr), 286 (17, 13, 328^+ − C_3H_6),. 263 (12, 29, 305^+ − C_3H_6), 248 (39, 46, 305^+ − *t*Bu), 239 (26, 61, 385^+ − C_4H_8BBr), 183 (100, 100, 239^+ − H_2C=CMe_2), 168 (10, 2, 248^+ − HBr), 128 (17, 0, PhBNBMe), 103 (18, 1, $PhN{\equiv}BH^+$). − IR: $\tilde{\nu}$ = 1359 [s, $\nu_{as}(B_2N)$[42]], 1270 [s, ν(CN)], 1191 [s, $\nu_s(B_2N)$], 1097 [s, ν(BC)], 884 [vr, ν(BBr)]. − $C_{14}H_{23}B_2Br_2N$ (386.8): calcd. C 43.48, H 5.99, N 3.62; found C 44.02, H 5.99, N 3.77.

Attempt to Prepare Bis(chloromesitylboryl)phenylamine (3u) from Bis(chlorodimethylstannyl)phenylamine (5d) and MesBCl$_2$ (Molar Ratio 1:2): A suspension of Me_2SnCl_2 (5.8 g, 26.4 mmol) in 20 mL of CH_2Cl_2 was treated with $PhN(SnMe_3)_2$ (**4c**) (5.54 g, 13.2 mmol), dissolved in 20 mL of CH_2Cl_2, while stirring at room temp. This mixture was added dropwise to a stirred solution of $MesBCl_2$ (5.31 g, 26.4 mmol) in 30 mL of CH_2Cl_2 over 110 min at −68 to −40°C. After the reaction mixture had attained ambient temp., it was kept for 2 d at reflux {^{11}B NMR (CH_2Cl_2): δ = 38.9 [PhN(BMesCl)$SnMe_2Cl$], 59.8 ($MesBCl_2$), ratio: ca. 1:1. − ^{1}H NMR: δ = 1.26 ($SnMe_2Cl$), 1.22 (Me_2SnCl_2), 0.66 (Me_3SnCl), ratio: 1:1:2}. After removal of the solvent at 25°C/12 Torr, the residue

was dissolved in 70 mL of toluene and kept at reflux for another 7 h. No change of signal intensities could be detected in the NMR spectra. After another 7 h at reflux, the solution contained a 1:2 mixture of the diborylamine **3u** (^{11}B NMR: δ = 48.1), the stannylaminoborane (^{11}B NMR: δ = 38.5) and (PhN≡BMes)$_2$ (^{11}B NMR: δ = 40), presumed as the decomposition product. The separation of these products either by fractional crystallization or by fractional sublimation failed. − ^{1}H NMR [CH_2Cl_2, enriched PhN(BMesCl)SnMe$_2$Cl]: δ = 1.29 [s, 6 H, Sn*Me*$_2$Cl, $^2J(^{117(119)}Sn^1H)$ = 66.5 (69) Hz], 2.29 (s, 3 H, *p*-Me), 2.42 (s, 3 H, *o*-Me), 2.93 (s, 3 H, *o*-Me), 5.58−7.30 (m, 7 H, C_6H_x of Ph and Mes). − ^{11}B NMR: δ = 39.5 ($h_{1/2}$ = 406 Hz).

Attempt to Prepare Bis(chloromethylboryl)mesitylamine (3v) from 4i and BCl_3 (Molar Ratio 1:2): BCl_3 (3.5 g, 30 mmol) was condensed into a solution of MesN(SnMe$_3$)$_2$ (**4i**) (7.0 g, 15 mmol) in 40 mL of CH_2Cl_2, cooled to −50°C. After allowing the solution to attain ambient temp., it was stirred for 17 h at room temp. [^{11}B NMR: δ = 61.4 (MeBCl$_2$), 75.9 (Me$_2$BCl), ratio: 10:0.5]. The ^{1}H- and ^{119}Sn-NMR spectra indicated the quantitative formation of MesN(SnMe$_2$Cl)$_2$ (**5i**); the signals are identical with those of an authentic sample of **5i**[9]. Although the reaction mixture was kept under reflux for additional 9 h using a dry ice condensor there was no indication (^{11}B-NMR control) of a further reaction.

(*tert*-Butylchloroboryl)mesitylamine by Reaction of (Bromodimethylstannyl)(*tert*-butylchloroboryl)mesitylamine with H_2O (Molar Ratio 1:1): After purification of **5i**, obtained according to the procedure (for **3v**) described above, by removal of the volatile components at 25°C/12 Torr and dissolution of the residue in 30 mL of toluene, it was treated dropwise while stirring with a solution of *t*BuBBr$_2$ (6.8 g, 30 mmol) in 15 mL of toluene at −60 to −50°C. NMR data of the reaction mixture after allowing to attain ambient temp. − ^{11}B NMR: δ = 66.1 (*t*BuBBr$_2$), 64.6 (*t*BuBBrCl), 62.5 *t*BuBCl$_2$. − The NMR control after additional 36 h under reflux indicated the formation of ca. 50% of MesN(B*t*BuCl)SnMe$_2$Br (^{11}B NMR: δ = 42.8). After hydrolysis with H_2O (30 µL, 1.7 mmol) and keeping the reaction mixture under reflux for72 h, the solvents were removed in vacuo and MesNHB*t*BuCl (1.5 g, 42%) was sublimed at 43−45°C/10^{-6} Torr as colorless crystals, subl. p. 42°C. − NMR data of MesNHB*t*BuCl in $CDCl_3$: ^{1}H NMR: δ = 1.13 (s, 9 H, BC*Me*$_3$), 2.18 (s, 6 H, *o*-Me), 2.29 (s, 3 H, *p*-Me), 5.44 (m, 1 H, N*H*), 6.91 (s, 2 H, *m*-H). − ^{13}C NMR: δ = 18.52 (*o*-Me), 20.90 (*p*-Me), 27.72 (BC*Me*$_3$), 128.70 (*m*-C), 134.49 (*o*-C), 135.49 (*p*-C), 135.57 (*i*-C). − ^{11}B NMR: δ = 40.9 ($h_{1/2}$ = 267 Hz). − ^{14}N NMR: δ = −270 ($h_{1/2}$ = 590 Hz). − MS: 237 (100, M$^+$), 222 (11, M$^+$ − Me), 181 (49, M$^+$ − C_4H_8, m*), 180 (55, M$^+$ − *t*Bu), 179 (100, M$^+$ − *t*BuH or 181$^+$ − H_2, MesNBCl), 145 (16, MesNBH). − IR: $\tilde{\nu}$ = 3356 cm^{-1} (s, NH), 3040 (w), 3020 (w), 3026 (w), 2942 (vs), 2863 (s), 1608 (m), 1489 (s). 1459 (s), 1442 (s), 1400 (m), 1377 (s), 1359 (s), 1280 (m, vs BN), 1250 (s), 961 (vs, νBCl), 854 (s), 651 (s), 603 (s). − $C_{13}H_{21}BClN$ (237.6)*: calcd. C 65.72, H 8.91, N 5.90; found C 64.94, H 9.13, N 5.69.

Bromomethylboryl(chloromethylboryl)(trimethylsilyl)amine (3p): Me$_3$SiN(SnMe$_2$Cl)$_2$ (**5l**) (5.2 g, 11.4 mmol), dissolved in 70 mL of CH_2Cl_2, was added dropwise to a solution of MeBBr$_2$ (4.25 g, 22.9 mmol) in 15 mL of CH_2Cl_2 within 1.5 h at −55 to −50°C. The workup was according to Procedure I; the distillation of the residue yielded **3p** (1.55 g, 65%) at 59−61°C/12 Torr as a colorless liquid. − ^{1}H NMR ($CDCl_3$): δ = 0.30 (s, 9 H, Si*Me*$_3$), 0.89 (br. s, 6 H, B*Me*X). − ^{13}C NMR: δ = 1.80 [q, $^1J(^{13}C^1H)$ = 119.4 Hz, Si*Me*$_3$], 12 [q, v. br., $^1J(^{13}C^1H)$ = 120 Hz, B*Me*Cl]. − ^{11}B NMR: δ = 50.3 ($h_{1/2}$ = 128 Hz). − ^{14}N NMR: δ = −234 ($h_{1/2}$ = 84 Hz). − ^{29}Si NMR: δ = 6.46 (recorded at 218 K). − $C_5H_{15}B_2BrClNSi$ (253.0)*: calcd. C 23.72, H 5.98, N 5.53; found C 22.98, H 5.77, N 5.01; C/H/N ratio: calcd. 5:15:1; found 5.31:15.9:1.

Bis(*tert*-butylchloroboryl)(dimethylboryl)amine (3t).[9] − Procedure II: a) A solution of *t*BuBBr$_2$ (10.85 g, 47.4 mmol) in 50 mL of CH_2Cl_2 was added dropwise to Me$_2$BN(SnMe$_2$Cl)$_2$ (10.0 g, 23.6 mmol), dissolved in 50 mL of CH_2Cl_2, within 90 min at −70°C. The distillation yielded **3t** (2.20 g, 40%), b.p. 28−38°C/10^{-6} Torr, as a colorless liquid. The NMR data are identical with those of an authentic sample of **3t** described below. − $C_{10}H_{24}B_3Cl_2N$ (261.65)*: calcd. C 45.91, H 9.25, Cl 27.10, N 5.35; found C 48.55, H 9.20, Cl 26.70, N 5.28.

b) Me$_2$BBr (5.6 g, 46.1 mmol), dissolved in 25 mL of CH_2Cl_2, was added dropwise to a solution of N(SnMe$_3$)$_3$ (23.30 g, 46.1 mmol) in 35 mL of CH_2Cl_2 while stirring for 2 h at −78 to −60°C. After allowing the mixture to attain ambient temp. and 1 h of stirring at room temp., the ^{1}H- and ^{11}B-NMR spectra recorded from a sample of the reaction mixture indicated quantitative formation of Me$_2$BN(SnMe$_3$)$_2$ (**4r**) and Me$_3$SnBr. − ^{1}H NMR (CH_2Cl_2): δ = 0.30 [s, 18 H, Sn*Me*$_3$, **4r**, $^2J(^{117(119)}Sn^1H)$ = 53 (56) Hz], 0.33 (s, 6 H, B*Me*$_2$), 0.76 (9 H, *Me*$_3$SnBr). − ^{11}B NMR: δ = 52.4 ($h_{1/2}$ = 157 Hz); ref.:[3][42] ^{1}H NMR: δ = 0.26 [s, 18 H, Sn*Me*$_3$, **4r**, $^2J(^{119}Sn^1H)$ = 55 Hz], 0.30 (s, 6 H, B*Me*$_2$). − ^{11}B NMR: δ = 53.4 ($h_{1/2}$ = 230 Hz). − This mixture was added dropwise over 45 min to a solution of Me$_2$SnCl$_2$ (20.3 g, 92.2 mmol) in 150 mL of CH_2Cl_2 at room temp. The quantitative formation of Me$_2$BN(SnMe$_2$Cl)$_2$ (**5r**) and Me$_3$SnCl was checked by NMR (CH_2Cl_2). − ^{1}H NMR: δ = 0.45 (s, 6 H, B*Me*$_2$), 0.64 (18 H, *Me*$_3$SnCl), 0.76 (9 H, *Me*$_3$SnBr), 0.93 [s, 12 H, Sn*Me*$_2$Cl, $^2J(^{117(119)}$ Sn^1 H) = 63(66) Hz]. − ^{11}B NMR: δ = 53.6 ($h_{1/2}$ = 224 Hz). − After removal of ca. 130 mL of CH_2Cl_2, the reaction mixture was added dropwise over 90 min to a solution of *t*BuBBr$_2$ (20.91 g, 91.8 mmol) in 50 mL of CH_2Cl_2 at −78°C. After allowing it to attain ambient temp., 4 d stirring at room temp., removal of the solvent at 25°C/12 Torr and the major part of the volatile components (Me$_3$SnCl, Me$_3$SnBr) at 25°C/10^{-3} Torr, Me$_2$SnBr$_2$ was separated from the solid residue by crystallization at −30°C from 50 mL of petroleum ether according to procedure II. After removal of the solvent of the filtrate at 0°C/12 Torr and sublimation of small amounts of alkylhalostannanes at 0°C/10^{-3} Torr, distillation yielded Me$_2$BN(B*t*BuCl)$_2$ (**3w**) [6.04 g, 50% based on N(SnMe$_3$)$_3$] as colorless liquid, extremly sensitive to moisture and oxygen, b.p. 43−45°C/10^{-3} Torr. − ^{1}H NMR ($CDCl_3$): δ = 0.71 (s, 6 H, B*Me*$_2$), 1.06 (s, 18 H, BC*Me*$_3$Cl). − ^{13}C NMR: δ = 12 (br., B*C*Me$_3$Cl), 14 (br., B*Me*$_2$), 28.51 (BC*Me*$_3$Cl). − ^{11}B NMR ($CDCl_3$): δ = 56.6 (2 B, *Bt*BuCl, $h_{1/2}$ = 291 Hz), 62.6 (1 B, B*Me*$_2$, $h_{1/2}$ = 276 Hz). − ^{14}N NMR: δ = −206 ($h_{1/2}$ = 179 Hz). − MS: *m/z* [% (70 eV), assignment]: 261 (1, M$^+$), 246 (2, M$^+$ − Me), 226 (1, M$^+$ − Cl), 162 (59, 204$^+$ − Me$_2$BH), 150 (40, 226$^+$ − Me$_2$BCl: *t*BuBNB*t*Bu), 148 (39, 204$^+$ − BMe$_3$), 128 (34, 204$^+$ − ClBMe$_2$), 122 (29, 204$^+$ − H$_2$C=B*t*Bu), 108 (81, 246$^+$ − *t*BuBCl$_2$: *t*BuBNBMe), 86 (87, 204$^+$ − *t*BuMeBCl), 66 (100, MeBNBMe). − IR: $\tilde{\nu}$ = 1313 cm^{-1} [s, ν_{as}(B$_3$N)], 1216 [s, ν_s(B$_3$N)], 946 [s, ν(BCl)], further frequences not assigned. − $C_{10}H_{24}B_3Cl_2N$ (261.7): calcd. C 45.91, H 9.25, N 5.35; found C 45.86, H 9.48, N 5.68.

(Chloromesitylboryl)(chloromethylboryl)phenylamine (3r): A solution of Me$_2$SnCl$_2$ (6.6 g, 30.0 mmol) in 30 mL of CH_2Cl_2 was treated with PhN(SnMe$_3$)$_2$ (**4c**) (6.31 g, 15.0 mmol), dissolved in 20 mL of CH_2Cl_2, and the mixture was then added dropwise over 90 min at −50°C, while stirring, to MesBCl$_2$ (3.0 g, 15.0 mmol), dissolved in 20 mL of CH_2Cl_2. − NMR data (after 16 h,CH_2Cl_2): ^{11}B NMR: δ = 38.5 [PhN(BMesCl)SnMe$_2$Cl (**6b**)]. − ^{1}H NMR: δ = 1.28 (SnMe$_2$Cl), 1.24 (Me$_2$SnCl$_2$), 0.69 (Me$_3$SnCl), ratio: 1:1:2.

– After cooling the reaction mixture to −50°C again, a solution of $MeBBr_2$ (2.8 g, 15.0 mmol) in 30 mL of CH_2Cl_2 was added over a period of 90 min. After 2 d stirring at room temp., the solvent was removed at 25°C/12 Torr and the organotin halides (Me_3SnCl, Me_2SnCl_2, $Me_2SnClBr$) at 25°C/10^{-6} Torr. Traces of $Me_2SnClBr$ were sublimed at 25−55°C/10^{-6} Torr and the diborylamine **3r** (1.53 g, 32%) distilled at 87−88°C/10^{-6} Torr solidifying to colorless crystals. – ^{1}H NMR ($CDCl_3$): δ = 0.88 (br. s, 3 H, B*Me*), 2.66 (s, 3 H, *p*-Me), 2.75 (s, 6 H, *o*-Me), 7.21 (s, 2 H, *m*-H, Mes), 7.44 (m, 2 H, *m*-H, Ph), 7.67 (m, 1 H, *p*-H, Ph), 7.77 (m, 2 H, *o*-H, Ph). – ^{13}C NMR: δ = 10 (br., B*Me*), 21.22 (*p*-Me), 21.89 (*o*-Me), 119.60 (*p*-C, Ph), 126.39 (*o*-C, Mes), 127.67 (*o*-C, Ph), 127.83 (*m*-C, Mes), 128.95 (*m*-C, Ph), 136.78 (*p*-C, Mes), 137 (v br., *i*-C, B-*Mes*), 146.54 (*i*-C, N−*Ph*). – ^{11}B NMR: δ = 50.2 (assym., shoulder at ca. 50, *B*Me and *B*Mes, $h_{1/2}$ = 572 Hz). – MS: *m*/*z* [% (70 eV, 20 eV), assignment]: 317 (100, 100, M^+), 302 (23, 14, M^+ − Me, m* = 287.7), 281 (8, 3, M^+ − HCl), 266 (11, 3, 281^+ − Me), 257 (22, 20, M^+ − H_2C=BCl), 221 (89, 35, M^+ − $MesBCl_2$: MesBNPh), 198 (44, 16, M^+ − Mes), 137 [16, 2, M^+ − Mes(Me)BCl], 117 (19, 3, M^+ − $MesBCl_2$). – IR: ṽ = 1368 [vr, $(B_2N)_{as}$], 1289 (s, CN), 1261 (s, CN), 1203 [s, $(B_2N)_s$], 1113 (m, BC), 1029 (m, BC), 956 (m, BCl), 878 (s, BCl). – $C_{16}H_{19}B_2Cl_2N$ (317.86)*: calcd. C 60.46, H 6.03, N 4.10; found C 61.64, H 6.33, N 4.60.

Reaction of 1,1-Dimethyl-2,2-bis(trimethylstannyl)hydrazine (7a) with $MeBBr_2$ (Molar Ratio 1:2). – Attempt to prepare 1,1-Dimethyl-2,2-bis(bromomethylboryl)hydrazine (**8a**). – Procedure I: **7a** (4.9 g, 12.8 mmol), dissolved in 15 mL of CH_2Cl_2, was added dropwise within 80 min to a solution of $MeBBr_2$ (4.6 g, 25 mmol) in 5 mL of CH_2Cl_2 at −70 to −40°C. – NMR data (after 16 h stirring at ambient temp.): ^{1}H NMR: δ = 0.76 (Me_3SnBr). – ^{11}B NMR: δ = 45 [$MeBrB(Me_3Sn)NNMe_2$?], 37, 18 (ratio: ca. 1:1:10), additional signals of very low intensity at δ = 9, −1, −4, −25. No evidence for the formation of $Me_2N-N(BMeBr)_2$ (**8a**) was detected by NMR. – After removal of the volatile components at 25°C/13 Torr and distillation of Me_3SnBr (5 g, 83%) at 25−55°C/10^{-2} Torr, a yellow/brown, viscous residue remained, which was fairly insoluble in petroleum ether and benzene. No pure product could be isolated by crystallization, neither from these solvents nor from CH_2Cl_2.

2,2-Bis(bromoisopropylboryl)-1,1-dimethylhydrazine (8b). – Procedure I: 7a (4.90 g, 12.8 mmol), dissolved in 15 mL of CH_2Cl_2, was added dropwise within 150 min to a solution of *i*$PrBBr_2$ (7.90 g, 36.8 mmol) in 40 mL of CH_2Cl_2 at −78 to −70°C. The workup was carried out after 20 h of stirring at room temp. After removal of the solvent (25°C/13 Torr) and Me_3SnBr (34°C/10^{-3} Torr), the distillation of the remaining oil yielded 2.46 g of **8b** (41%) as colorless, viscous liquid, b.p. 82−86°C/10^{-3} Torr. Redistillation at 40−41°C/10^{-5} Torr yielded 1.4 g of pure **8b** (23%) and a residue. – ^{11}B NMR ($CDCl_3$): d = 36.6 [$(Me_2NN{\equiv}BiPr)_3$?]. – **8b** is spontaneously inflammable in contact with air and turns dark brown when stored at room temp. – ^{1}H NMR ($CDCl_3$): δ = 0.97 (m, not resolved, 14 H, *iPr*B), 3.09 (s, br., not resolved, 6 H, Me_2N). – ^{13}C NMR: δ = 13 (br., B*C*HMe_2), 19.36 (br., BCH*Me*$_2$), 46.84 (br., N*Me*$_2$). – d^{11}B: 2.1 (B_{endo}, 1 B, $h_{1/2}$ = 265 Hz), 38.9 (1 B, B_{exo}, $h_{1/2}$ = 433 Hz). – ^{14}N NMR: δ = −276 (1 N, *N*B_2, $h_{1/2} \approx$ 625 Hz), −305 (*N*Me_2, 1 N, $h_{1/2} \approx$ 625 Hz); $h_{1/2}$ is a crude estimate. – MS: 324 (6, M^+), 281 (39, M^+ &NDASH; *i*Pr), 245 (19, M^+ − Br), 237 (24, M^+ &NDASH; *i*$PrNMe_2$), 195 (18, 237 − H_2C=CH−CH_3), 166 (13, M^+ − Br_2), 159 (100, $BrBNBNMe_2^+$), 130 (17, $BrBNBMe^+$), 123 (32, 166^+ − *i*Pr_2), 116 (14, $BrBNBH^+$), 112 (54, *i*$PrBNNMe_2$), 95 (41, $MeBNBNMe_2^+$). – IR (selected vibrations): ṽ = 1362 cm^{-1} [s, $\nu_{as}(B_2N)$, for comparison (BN) = 1368 cm^{-1}[42]] 1308 [m, ν(CN)], 1197 [m, $\nu_s(B_2N)$], 1058 [s, ν(BC)], 819 (s) and 743 [s, ν(BBr)], 658 [s, ν(N→B)]. – $C_8H_{20}B_2Br_2N_2$ (325.7)*: calcd. C 29.50, H 6.19, N 8.60; found C 32.35, H 6.69, N 9.48; C/H(N ratio calcd. 8:20:2; found 8:19.7:2.

2,2-Bis(bromo-*tert*-butylboryl)-1,1-dimethylhydrazine (8c). – Procedure I: 7a (15.60 g, 40.4 mmol), dissolved in 60 mL of CH_2Cl_2, was added within 3 h to a solution of *t*$BuBBr_2$ (18.40 g, 80.7 mmol) in 50 mL of CH_2Cl_2 at −78°C. After 17 h stirring at room temp., removal of the solvent and Me_3SnBr, the liquid residue was purified twice by distillation. Yield: 8.4 g of **8c** (58%) as a colorless, viscous liquid, b.p. 63−66°C/10^{-5} Torr. The liquid is spontaneously inflammable in contact with air and moisture. In a second experiment **8c** crystallized after distillation, m.p. 36−41°C. – ^{1}H NMR ($CDCl_3$): δ = 1.01 (s, 18 H, *tBu*B_{endo}), 1.04 (s, 18 H, *tBu*B_{exo}), 3.13 (s, 3 H, *Me*$_A$Me$_B$N), 3.27 (s, 3 H, Me$_A$*Me*$_B$N). – ^{13}C NMR: δ = 27.99 (B_{exo}C*Me*$_3$), 30.15 (B_{endo}C*Me*$_3$), 46.57 (N*Me*$_A$Me$_B$), 51.06 (NMe$_A$*Me*$_B$). – ^{11}B NMR: δ 2.0 (1 B, B_{endo}, $h_{1/2}$ = 96 Hz), 40.3 (1 B, B_{exo}, $h_{1/2}$ = 193 Hz) (for B*C*Me$_3$ signal not found). – ^{14}N NMR: δ = −263 (1 N, *N*B_2, $h_{1/2} \approx$ 499 Hz), −328 (1 N, *N*Me_2, $h_{1/2} \approx$ 403 Hz). – MS (70 eV, 20 eV): 352 (2, 6, M^+), 337 (5, 2, M^+ − Me), 295 (56, 100, M^+ − *t*Bu), 273 (38, 48, M^+ − Br), 239 (100, 78, 295^+ − H_2C=CMe_2), 217 (26, 8, 273^+ − H_2C=CMe_2), 194 (8, M^+ − Br_2), 179 (6, 194^+ − Me), 175 (14, 217^+ − H_2C=CH−CH_3), 159 (78, 273^+ − *t*Bu−*t*Bu), 137 (19, *t*$BuBNBNMe_2^+$), 130 (38, $BrBNBMe^+$), 126, (30, 54, *t*$BuBNNMe_2^+$), 116 (74, $BrBNBH^+$), 111 (22, *t*$BuBNNMe^+$), 95 (28, $MeBNBNMe_2^+$), 66 (21, $MeBNBMe^+$). – IR: ṽ = 1361 cm^{-1} [s, $\nu_{as}(B_2N)$], 1265 [s, ν(CN)], 1201 [s, $\nu_s(B_2N)$], 1058 [s, ν(BC)], 851 (s) and 764 [s, ν(BBr)], 651 [s, (N→B)]. – $C_{10}H_{24}B_2Br_2N_2$ (353.76)*: calcd. C 33.95, H 6.84, N 7.92; found C 35.25, H 7.31, N 8.74; C/H(N ratio calcd. 10:24:2; found 9.7:23.2:2.0; mol. mass: found 358.9 (cryoscopically in cyclohexane).

2,2-Bis(chloromesitylboryl)-1,1-dimethylhydrazine (8d). – Procedure I: a) **7a** (1.7 g, 4.4 mmol), dissolved in 20 mL of CH_2Cl_2, was added within 1 h to a solution of $MesBCl_2$ (1.8 g, 9.1 mmol) in 15 mL of CH_2Cl_2 at −70 to −60°C. The work up was carried out after 20 h of stirring at room temp. ^{1}H- and ^{11}B-NMR spectra of the reaction mixture gave no evidence for the formation of the adduct **8d**. After removal of the solvents and sublimation of Me_3SnCl, the residue of crude **8d** was purified by crystallization from CH_2Cl_2. Yield: 0.97 g of **8d** (57%) as a colorless powder, m.p. 136°C, decomp. Single crystals suitable for X-ray structure determination were obtained by recrystallization from CH_2Cl_2 at −18°C. – ^{1}H NMR ($CDCl_3$): δ = 2.23 (m, 18 H, *o*-Me−Ph, *p*-Me−Ph), 3.12 (br. s, 6 H, N*Me*$_2$), 6.78 (br. s, 4 H, *m*-H−Ph). – d^{13}C: 21.13 (*p*-Me−Ph), 29.69 (*o*-Me−Ph), 45.83 (N*Me*$_2$), 126.9 ($C_6H_2Me_3$), 127.6 ($C_6H_2Me_3$), 127.7 (br.), 138 (br, *i*-C_A), 139.5 (br.), 140 (br., *i*-C_B). – ^{11}B NMR: δ = 0.7 (1 B, B_{endo}, $h_{1/2}$ = 482 Hz), 38.6 (1 B, B_{exo}, $h_{1/2}$ = 573 Hz). – MS: 388 (100, M·$^+$), 373 (1, M^+ − Me), 353 (23, M^+ − Cl), 345 (15, M^+ − H_2C=NMe), 344 (20, 345^+ − H), 343 (21, 345^+ − H_2), 318 (8, $M^{+\cdot}$ − 2 Cl), 309 (10, 344^+ − HCl), 274 (16, $MesBNBMes^+$), 269 (75, M^+ − Mes), 225 (35, M^+ − $MesNMe_2$), 224 (39, 225^+ − H), 223 (18, M^+ − ClBMes), 190, (27, $MesBNBCl^+$), 189 (14, 225^+ − HCl), 188 (77, $MesBNNMe_2^+$), 187 (15, 223^+ − HCl), 144 (24, 344^+ − $MesBCl_2$); – IR: ṽ = 1357 cm^{-1} [s, $\nu_{as}(B_2N)$], 1260 [s, ν(CN)], 1225 [s, $\nu_s(B_2N)$], 1050 [s, ν(BC)], 932 (s) and 859 [s, ν(BBr)], 664 [s, (N→B)]. – $C_{20}H_{28}B_2Cl_2N_2$ (389.0)*: calcd. C 61.76, H 7.26, N 7.20; found C 59.69, H 7.58, N 7.36; mol. mass: found 377 (cryoscopically in cyclohexane). – X-ray structure analysis data of **8d**: Formula $C_{20}H_{28}B_2Cl_2N_2$; M_r = 388.96; colourless prism; size 0.3 × 0.2 × 0.1 mm, orthorhombic; space group *Pca*2(1), *a* = 12. 3263(1), *b* = 12.6905(2), *c* = 13.7050(1) Å, *V* = 2143.83(4) Å^3, *Z* = 4, $\rho_{calcd.}$ = 1.205 g cm^{-3}; μ(Mo-K_α) = 0.309 mm^{-1}, *F*(000) = 824. – Data

collection: 11736 reflections in $-15 \le h \le 15$, $-16 \le k \le 9$, $-16 \le l \le 16$, measured in the range $4.60° \le 2\theta \le 58.22°$; 3751 independent reflections; $R_{int} = 0.0492$, 2456 reflections with $F_o > 4\sigma(F_o)$, semi-empirical absorption correction, 243 variables, $R = 0.0376$, $wR^2 = 0.0845$, largest difference peak: 0.178 e/Å^3.

b) A solution of $MesBCl_2$ (2.5 g, 12.5 mmol) in 15 mL of CH_2Cl_2 was added to a solution of **7a** (2.5 g, 6.4 mmol) in 15 mL of CH_2Cl_2 over a period of 60 min at −70 to −60°C. NMR data after a period of 16 h stirring at ambient temp.: ^{1}H NMR: δ = 0.67 [s, 9 H, Me_3SnCl, $^2J(^{117(119)}Sn^1H)$ = 56.2 (58.6) Hz], 0.69 [s, 9 H, Me_3SnCl, $^2J(^{117(119)}Sn^1H)$ = 55.2 (57.6) Hz, $^3J(^{117(119)}Sn^1H)$ = 35.2 (38.6) Hz?], 2.31 [s, br., 6 H, NMe_2, $^3J(^{117(119)}Sn^1H)$ = 36.8 Hz], 2.57 (s, 6 H, *p*-Me−Ph), 2.93 (s, 12 H, *o*-Me), 6.81 (br. s, 4 H, *m*-H−Ph). − ^{11}B NMR: δ = 39.6 ($h_{1/2}$ = 393 Hz). − The workup was according to Procedure I after a period of 17 h. The residue, obtained after removal of the volatile components at 25 to 40°C/12−10^{-5} Torr, was dissolved in CH_2Cl_2 and checked by ^{1}H- and ^{11}B-NMR spectroscopy. The spectra are identical with those of the reaction mixture, but the signal of the noncoordinated Me_3SnCl had disappeared. The latter was detected in the trap. The ^{1}H-NMR signal for Me_3SnCl, forming an adduct with **8d**, was found at δ = 0.70 [$^2J(^{117(119)}Sn^1H)$ = 57.6 Hz]. − Sn−N bond-cleavage experiment: The NMR sample of the residue, dissolved in 5 mL of CH_2Cl_2, was checked by NMR after addition of a drop of $MesBCl_2$: ^{11}B NMR: δ = 39.1 [assignment: $Me_2N-N(BMesCl)_2 \cdot Me_3SnCl$], −0.7 [$Me_2N-N(BMesCl)_2 \cdot MesBCl_2$], ratio: 3:2. − ^{1}H NMR: δ = 0.72 and 0.74 (Me_3SnCl·coordinated and Me_3SnCl in solution). With additional $MesBCl_2$ the signal at δ = 39.1 (^{11}B NMR) lost intensity and the signal at δ = −0.7 gained intensity; the excess of $MesBCl_2$ led to the following NMR data of the reaction mixture: ^{11}B NMR: δ = 59.5 ($MesBCl_2$), 36.6 and −0.9 [assignment: $Me_2N-N(BMesCl)_2 \cdot MesBCl_2$]. − ^{1}H NMR: δ = 0.81 [sharp signal,·dissolved Me_3SnCl, $^2J(^{117(119)}Sn^1H)$ = 56.6 (59.1)]. A mixture of unidentifiable products resulted when keeping the residue at room temp. for a few hours or by heating in vacuo up to 100°C/10^{-5} Torr in order to remove Me_3SnCl coordinated to the Me_2N group.

Attempt to Prepare 2,2-Bis(bromomethylboryl)-1,1-diphenylhydrazine (8e) by Reaction of 7b with $MeBBr_2$ (Molar Ratio 1:2): 7b (5.34 g, 10.5 mmol), dissolved in 15 mL of CH_2Cl_2, was added over 60 min to a solution of $MeBBr_2$ (4.6 g, 24.8 mmol) in 15 mL of CH_2Cl_2 at −75 to −65°C. NMR data after 16 h stirring at ambient temp.: ^{1}H NMR: δ = 0.77 [s, 9 H, Me_3SnBr]. − ^{11}B NMR: δ = 34.5 [$(Ph_2NN{=}BMe)_3$?], 40.0/−2.4 [signal ratio: ca. 1:1, **8e** (intramolecular BN adduct formation?)], 48.9 [$Ph_2N-N(BMeBr)_2$ (**8e**) noncyclic compound?]. − The workup was carried out according to Procedure I after 17 h of stirring. The residue obtained after removal of the volatile components was dissolved in CH_2Cl_2 and checked by ^{1}H- and ^{11}B-NMR spectroscopy. The predominant signal among others in the ^{11}B-NMR spectrum was that at δ = 34.5 [$(Ph_2NN{=}BMe)_3$?]; after 12 h, additional signals (δ = 28.8, 31.9) could be detected in the solution. Attempts to separate the products failed even by fractional recrystallization from toluene at various temperatures. The only volatile compound obtained was Me_3SnBr.

Acknowledgments

We gratefully acknowledge the support of this research by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Chemetall GmbH. We also thank Mrs. C. Neumann for support of the synthetic work, Mrs. D. Ewald for recording the mass spectra and Mr. T. Seifert for the X-ray structure determination.

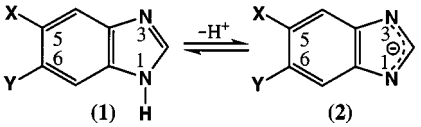
On the Metal-Ion-Coordinating Properties of the Benzimidazolate Residue in Aqueous Solution – Extent of Acidification of Benzimidazole-(N3)H Sites by (N1)-Coordinated Divalent Metal Ions

Larisa E. Kapinos[a] and Helmut Sigel*[a]



Keywords: Acidity constants / Benzimidazolate complexes / Imidazole-type ligands / Metal ion complexes / Nitrobenzimidazoles / Stability constants

The stability constants of the 1:1 complexes formed between Mg^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+} or Cd^{2+} (= M^{2+}) and the anionic 5(6)-nitrobenzimidazolate [= $(NBI–H)^-$] or 5,6-dinitrobenzimidazolate [= $(DNBI–H)^-$] were determined by potentiometric pH titrations in aqueous solution (25 °C; I = 0.5 M, $NaNO_3$). The acidity constants for the deprotonation of the (N1)H sites in neutral NBI and DNBI (= L) were measured by the same method. The comparison of the stability constants determined for the $M(L–H)^+$ complexes with those calculated from log K^M_{ML} versus pK^H_{HL} straight-line plots, which were established recently for neutral benzimidazole-type ligands, reveals that the stabilities of the $M(L–H)^+$ complexes are significantly enhanced, as one might have expected due to the negative charge present on the ligands. Of course, the electron-withdrawing properties of (N3)-bound metal ions facilitate the release of the proton from the (N1)H site in the $M(NBI)^{2+}$ and $M(DNBI)^{2+}$ complexes, if compared to the situation in the free ligands. The effect of a metal ion bound to a benzimidazolate or imidazolate residue on the coordination tendency toward a further metal ion (giving rise to an imidazolate bridge) was estimated.

1. Introduction

Benzimidazole (1,3-dideazapurine) and its derivatives show biological activity[1–6] and are often employed in drug design.[1][2] For example, nitrobenzimidazoles act as substrates for the two-electron reduction catalyzed by DT-diaphorase,[3] and 5,6-dinitrobenzimidazole and related compounds are substrates for purine nucleoside phosphorylase which allows the synthesis of nucleoside analogues.[4] Other nitrobenzimidazoles are studied for their analgesic and anti-inflammatory activity[5] as well as for their antiproliferative and antiviral activity.[6] Since benzimidazole derivatives act biologically often via their nucleoside[4] and nucleotide[1] analogues, the metal-ion-binding properties of the benzimidazole residue are of general interest because such reactions usually also involve metal ions.[7–9]

In our attempts[10] to increase the understanding of the metal-ion-binding dichotomy[11] of the adenine residue, we have recently correlated[12] the acid-base and metal-ion-binding properties of a series of benzimidazoles by constructing log K^M_{ML} versus pK^H_{HL} plots which result for a given metal ion in a straight line (see Section 2.2). In this study[12] we had included 5(6)-nitrobenzimidazole (NBI) and 5,6-dinitrobenzimidazole (DNBI) because they release the proton from their monoprotonated forms, $H(NBI)^+$ and $H(DNBI)^+$, with a low pK_a, i.e. p$K^H_{H(NBI)}$ = 3.61 and p$K^H_{H(DNBI)}$ = 1.72,[12] which allowed us to extend the indicated correlation far into the acidic pH range. Considering that the deprotonation of monoprotonated benzimidazole, $H(BI)^+$, occurs with p$K^H_{H(BI)}$ = 5.63[12] and the formation of the corresponding anion $(BI–H)^-$ with pK^H_{BI} = 12.8,[13] which means that the two pK_a values are separated by $\Delta pK_a \approx 7$,[13] one may expect that the pK_a values of NBI and DNBI differ by about the same extent, and thus, the formation of their anions is expected to occur in the pK_a range of about 8.5 to 10.5. The acid-base equilibrium for their neutral and anionic forms is depicted in Figure 1.

DNBI: X = Y = NO_2 **(DNBI–H)$^-$**

NBI: X = NO_2; Y = H **(NBI–H)$^-$**

Figure 1. Chemical structures of 5(6)-nitrobenzimidazole (NBI) and 5,6-dinitrobenzimidazole (DNBI) in their neutral (**1**) and anionic forms (**2**)

A pK_a range of 8.5 to 10.5 is easily accessible for potentiometric pH titrations and therefore also suitable for the determination of stability constants. Surprisingly, no systematic study focussing on the stability of metal ion complexes in aqueous solution appears to have been carried out[14–16] for benzimidazolate or imidazolate and related ligands, even though the latter is well known to occur as a bridging residue between two metal ions in Cu,Zn superoxide dismutase[17][18] and also in a number of (low-molecular-weight) complexes studied in solution[19–21] and in the solid state;[21][22] actually quite a number of complexes formed with deprotonated imidazole derivatives and a variety of metal ions have been isolated and their properties studied (e.g.[21–23]). Interestingly, already about 60 years ago the formation of an imidazolate complex was suggested

to occur with ferrihemoglobin[24] and the possibility to deprotonate the pyrrole nitrogen in imidazole complexes has been confirmed in the years thereafter.[25] However, with the deficit indicated above in mind we endeavored now to measure the stability constants of the complexes formed between Mg^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+}, or Cd^{2+} (M^{2+}) and 5(6)-nitrobenzimidazolate or 5,6-dinitrobenzimidazolate (Figure 1).

2. Results and Discussion

2.1. Definition of Equilibria and Results

Benzimidazole and its derivatives (L) can accept one proton at N3 to give the monoprotonated species HL^+ which gives rise to the deprotonation reaction according to Equilibrium 1a.

$$HL^+ \rightleftharpoons H^+ + L \quad (1a)$$

$$K^H_{HL} = [H^+][L]/[HL^+] \quad (1b)$$

The corresponding acidity constants for $H(NBI)^+$ and $H(DNBI)^+$ have recently been determined: $pK^H_{H(NBI)} = 3.61 \pm 0.02$ and $pK^H_{H(DNBI)} = 1.72 \pm 0.06$.[12] However, as indicated already in Section 1, one expects that the proton present at N1 in the neutral form of NBI and DNBI (Figure 1) can also be ionized according to Equilibrium 2.

$$L \rightleftharpoons (L-H)^- + H^+ \quad (2a)$$

$$K^H_L = [(L-H)^-][H^+]/[L] \quad (2b)$$

Indeed, the experiments carried out now (25°C; $I = 0.5$ M,[26] $NaNO_3$) prove this to be correct; the corresponding acidity constants are $pK^H_{NBI} = 10.58 \pm 0.03$ and $pK^H_{DNBI} = 8.92 \pm 0.03$. The present acidity constant for the deprotonation of NBI is in fair accord with earlier spectrophotometric determinations which gave $pK^H_{NBI} = 10.69$ (25°C)[27] and 10.86 (25°C; $I = 0.1$ M)[13] as well as potentiometric titrations which resulted in $pK^H_{NBI} = 10.31$ (25°C)[28][29] and 11.2.[28][30]

$$\Delta pK_a = pK^H_L - pK^H_{HL} \quad (3)$$

The difference defined in Equation 3 for the NBI and DNBI systems equals $\Delta pK_{a/NBI} = (10.58 \pm 0.03) - (3.61 \pm 0.02) = 6.97 \pm 0.04$ and $\Delta pK_{a/DNBI} = (8.92 \pm 0.03) - (1.72 \pm 0.06) = 7.20 \pm 0.07$. Hence, the acidity constants of the Equilibria 1a and 2a can be determined independently for both ligands because the buffer regions are not overlapping. The ΔpK_a values of about 7 agree with previous observations made for benzimidazole derivatives.[13]

Both, the neutral species L and the deprotonated species $(L-H)^-$ may form complexes with metal ions (M^{2+}) according to Equilibria 4a and 5a.

$$M^{2+} + L \rightleftharpoons ML^{2+} \quad (4a)$$

$$K^M_{ML} = [ML^{2+}]/([M^{2+}][L]) \quad (4b)$$

$$M^{2+} + (L-H)^- \rightleftharpoons M(L-H)^+ \quad (5a)$$

$$K^M_{M(L-H)} = [M(L-H)^+]/([M^{2+}][(L-H)^-]) \quad (5b)$$

The stability constants for the $M(NBI)^{2+}$ complexes have recently been determined by potentiometric pH titrations and those for the $M(DNBI)^{2+}$ complexes by spectrophotometry.[12] These previous results, which are listed in column 2 of Table 1, have been taken into account in the evaluations of the potentiometric pH titrations which were carried out now to determine the stability constants of the $M(NBI-H)^+$ and $M(DNBI-H)^+$ complexes (Equation 5). The corresponding results are given in column 3 of Table 1. No values for the complexes with Cu^{2+} and Zn^{2+} could be determined because of their strong tendency to form hydroxo species.

Equilibria 4a and 5a are connected via Equilibrium 6a and the corresponding acidity constant can be calculated according to Equation 7.

$$ML^{2+} \rightleftharpoons M(L-H)^+ + H^+ \quad (6a)$$

$$K^H_{ML} = [M(L-H)^+][H^+]/[ML^{2+}] \quad (6b)$$

$$pK^H_{ML} = pK^H_L + \log K^M_{ML} - \log K^M_{M(L-H)} \quad (7)$$

These acidity constants are listed in column 4 of Table 1. They allow to quantify the effect of a (N3)-bound metal ion on the deprotonation of the (N1)H site by defining the difference between the two relevant acidity constants according to Equation 8.

$$\Delta pK_{a/ML} = pK^H_L - pK^H_{ML} \quad (8)$$

These differences are given in column 5 of Table 1; they are of the order observed previously for imidazole complexes.[25] Since the error limits for the $\Delta pK_{a/ML}$ values are relatively large, no conclusions can be drawn for the $M(NBI)^{2+}$ and $M(DNBI)^{2+}$ complexes of Mg^{2+}, Mn^{2+} and Ni^{2+} regarding any possible differences in the acidification. However, for Co^{2+} and Cd^{2+} the acidification is clearly more pronounced in the $M(NBI)^{2+}$ complexes. This means that, relatively speaking, the deprotonation at the (N1)H site leads to a more significant stability increase in the case of the NBI complexes compared to the DNBI ones. This conclusion will also be confirmed below (see the final paragraph in Section 2.2).

2.2. Metal-Ion-Binding Properties of the Benzimidazolate Residue

To which extent does the deprotonation of the (N1)H site (see Figure 1) affect the stability of the complexes? An answer to this question may be obtained by applying the recently constructed $\log K^M_{ML}$ versus pK^H_{HL} plots, where L represents a series of benzimidazole-type ligands.[12] Three examples are shown in Figure 2 and the pertinent parameters which define the straight lines are listed in Table 2 for those metal ions considered in the present study.

Table 1. Logarithms of the stability constants of the ML^{2+} (Equation 4) and $M(L-H)^{+}$ complexes (Equation 5), together with the negative logarithms of the acidity constants (Equations 6 and 7) of the corresponding ML^{2+} complexes, where L = NBI or DNBI, as determined by potentiometric pH titrations in aqueous solution at 25°C and I = 0.5 M ($NaNO_3$)[a–c]

M^{2+}	log K^{M}_{ML}	log $K^{M}_{(ML-H)}$	pK^{H}_{ML}	$\Delta pK_{a/ML}$[d]

[a] Acidity constants: p$K^{H}_{H(NBI)}$ = 3.61 ± 0.02 (Equation 1; from ref.[12]), pK^{H}_{NBI} = 10.58 ± 0.03 (Equation 2); p$K^{H}_{H(DNBI)}$ = 1.72 ± 0.06 (Equation 1; from ref.[12])[f], pK^{H}_{DNBI} = 8.92 ± 0.03 (Equation 2). – [b] The error limits given are *three times* the standard error of the mean value or the sum of the probable systematic errors, whichever is larger. The error limits of the derived data (in the present case for columns 4 and 5) were calculated according to the error propagation after Gauss. Regarding the reasons why in some instances the errors are rather large, the Experimental Section should be consulted. – [c] The values in the second column are taken from ref.[12] – [d] See Equation 8 in Section 2.1. – [e] These values were experimentally not accessible (see ref.[12]); they were calculated with the straight-line equations defined in Table 2 and the micro acidity constant p$k_{ma/H(DNBI)}$ = 2.02 which follows from p$K^{H}_{H(DNBI)}$ = 1.72; see ref.[12] – [f] These values were measured by spectrophotometry (see ref.[12]).

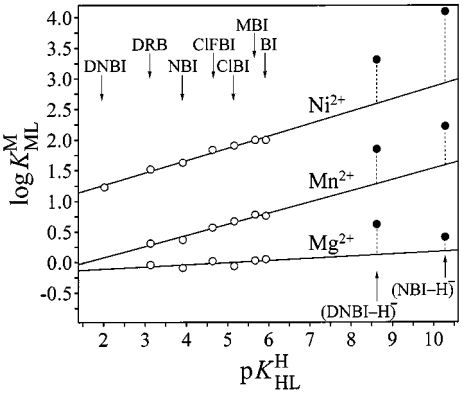

Figure 2. Evidence for an increased stability of several M^{2+} 1:1 complexes of 5,6-dinitrobenzimidazolate, $(DNBI-H)^{-}$, and 5(6)-nitrobenzimidazolate, $(NBI-H)^{-}$, (•) (see structure **2** in Figure 1), based on log K^{M}_{ML} versus pK^{H}_{HL} plots for the 1:1 complexes of Mg^{2+}, Mn^{2+} and Ni^{2+} with the following neutral benzimidazole-type ligands (o): 5,6-dinitrobenzimidazole (DNBI; see **1** in Figure 1), 5,6-dichloro-1-(β-D-ribofuranosyl)benzimidazole (DRB), 5(6)-nitrobenzimidazole (NBI; see **1** in Figure 1), 6-chloro-5-fluorobenzimidazole (ClFBI), 5(6)-chlorobenzimidazole (ClBI), 1-methylbenzimidazole (MBI) and benzimidazole (BI) (from left to right). The corresponding equilibrium constants are taken from ref.[12]; note, where appropriate the micro acidity constants (pk_{am}) were applied (for details see ref.[12]); the parameters for the least-squares lines drawn through these data sets are given in Table 2; the vertical broken lines emphasize the stability differences to the corresponding reference lines (Equation 11); these differences are listed in column 4 of Table 3; the data pairs for the $M(DNBI-H)^{+}$ and $M(NBI-H)^{+}$ complexes are from Table 1 and Equations 9 and 10; all plotted equilibrium constants refer to aqueous solutions at 25°C and I = 0.5 M ($NaNO_3$).

Table 2. Straight-line correlations for M^{2+}-benzimidazole-type complex stabilities and benzimidazole group basicities,[a,b] for aqueous solutions at 25°C and I = 0.5 M ($NaNO_3$)

M^{2+}	m	b	SD
Mg^{2+}	0.035 ± 0.020	−0.179 ± 0.095	0.051
Mn^{2+}	0.182 ± 0.017	−0.287 ± 0.081	0.045
Co^{2+}	0.186 ± 0.011	0.513 ± 0.048	0.042
Ni^{2+}	0.201 ± 0.011	0.860 ± 0.052	0.042
Cd^{2+}	0.293 ± 0.011	0.385 ± 0.050	0.039

[a] The slopes (m) and intercepts (b) for the straight baselines from plots of log K^{M}_{ML} versus pK^{H}_{HL} were calculated[12] from equilibrium constants involving the seven (or six in the case of Mg^{2+} and Mn^{2+}) sterically unhindered ligands (L) which are named in Figure 2 (see also ref.[12]). The fourth column lists *three times* the standard deviations (SD) resulting from the differences between the experimental and calculated values for the seven (or six) ligand systems. – [b] The above data for m, b and SD are abstracted from Tables 3 and 4 in ref.[12] Straight-line equation: $y = mx + b$, where x represents the pK_a value of any monoprotonated benzimidazole-type ligand and y the calculated stability constant (log K) of the corresponding ML complex; the errors given with m and b correspond to one standard deviation (1 σ). The listed SD values (3 σ; column 4) are considered as reasonable error limits for any stability constant calculation in the pK_a range 2–6; for the error limits outside of this range see Section 2.2.

For a comparison of the stability constants determined now with these straight lines, the acid-base properties of NBI and DNBI need to be considered in detail: Once the corresponding anion $(L-H)^{-}$ has formed, there are two equal ways for the formation of the neutral species L (Figure 1). Consequently, the benzimidazolate derivatives appear to be more basic than they actually are. This means, micro acidity constants as defined in Equations 9 and 10 for DNBI and NBI, in which this statistical effect is considered, need to be used in any kind of acid-base comparisons.

$$pk_{ma/DNBI} = pK^{H}_{DNBI} - 0.3 = (8.92 \pm 0.03) - 0.3 = 8.62 \pm 0.03 \quad (9)$$

$$pk_{ma/NBI} = pK^{H}_{NBI} - 0.3 = (10.58 \pm 0.03) - 0.3 = 10.28 \pm 0.03 \quad (10)$$

It may be added that this reasoning is also valid (see section 2.2 of ref.[12]) for 5(6)-nitrobenzimidazole which has non-equivalent substituents at C5 and C6 (Figure 1).

Table 3. Comparison of the logarithms of the stability constants of $M(NBI-H)^+$ and $M(DNBI-H)^+$ complexes (Equation 5) as determined by potentiometric pH titrations (exptl.)[a] in aqueous solution at 25°C and I = 0.5 M ($NaNO_3$) with the calculated (calcd.) stability constants based on the basicity[b] of the benzimidazolate nitrogen atoms and the reference-line equations of Table 2.

M^{2+}	log $K^M_{M(L-H)}$ exptl.[a]	log $K^M_{M(L-H)}$ calcd.[b]	log Δ[c]
5(6)-Nitrobenzimidazolate, $(NBI-H)^-$			
Mg^{2+}	0.41 ± 0.10	0.18 ± 0.27	0.23 ± 0.29
Mn^{2+}	2.22 ± 0.14	1.58 ± 0.23	0.64 ± 0.27
Co^{2+}	3.67 ± 0.17	2.43 ± 0.21	1.24 ± 0.27
Ni^{2+}	4.1 ± 0.4	2.93 ± 0.22	1.2 ± 0.5
Cd^{2+}	4.63 ± 0.16	3.40 ± 0.22	1.23 ± 0.27
5,6-Dinitrobenzimidazolate, $(DNBI-H)^-$			
Mg^{2+}	0.62 ± 0.08	0.12 ± 0.16	0.50 ± 0.18
Mn^{2+}	1.85 ± 0.04	1.28 ± 0.14	0.57 ± 0.15
Co^{2+}	2.73 ± 0.06	2.12 ± 0.12	0.61 ± 0.13
Ni^{2+}	3.31 ± 0.16	2.59 ± 0.14	0.72 ± 0.21
Cd^{2+}	3.34 ± 0.17	2.91 ± 0.13	0.43 ± 0.21

[a] These values are from column 3 in Table 2. – [b] Calculated with the micro acidity constants $pk_{ma/NBI}$ = 10.28 and $pk_{ma/DNBI}$ = 8.62 (see Equations 9 and 10 and text in Section 2.2) and the straight-line equations given in Table 2. These error limits are estimates; see ref.[31] – [c] The error limits for these differences were calculated according to the error propagation after Gauss.

Application of the micro acidity constants of Equations 9 and 10 and of the stability constants of the $M(NBI-H)^+$ and $M(DNBI-H)^+$ complexes leads to the solid data points seen in Figure 2. Their vertical distances to the corresponding reference lines defined for neutral benzimidazole complexes reflect the effect of the negative charge of the benzimidazolates. This stability increase is defined by Equation 11, where log $K^M_{M(L\text{-}H)expt1}$ represents the experimentally measured stability constant and log $K^M_{M(L\text{-}H)calcd}$ the one calculated with the micro acidity constants (Equations 9 and 10) and the straight-line parameters of Table 2. The corresponding results are summarized in Table 3.[31]

$$\log \Delta = \log K^M_{M(L-H)expt1} - \log K^M_{M(L-H)calcd} \quad (11)$$

The stability enhancements log Δ (Equation 11), listed in column 4 of Table 3, indicate that the $M(NBI-H)^+$ and $M(DNBI-H)^+$ complexes are by about 0.2 to 1.2 log units more stable than complexes formed with neutral benzimidazoles of the same pK_a range. Comparison of these log Δ values reveals that in the case of Mg^{2+}, Mn^{2+} and Ni^{2+} the error limits are too large for meaningful conclusions, whereas for the complexes with Co^{2+} and Cd^{2+} it is certain that the stability enhancement for $(NBI-H)^-$ is more pronounced than that for $(DNBI-H)^-$ (see Table 3). Hence, one may conclude that the slopes of log $K^M_{M(L-H)}$ versus pK^H_L plots are somewhat larger than those of log K^M_{ML} versus pK^H_{HL} seen in Figure 2. Based on the stability enhancements observed for the $M(DNBI-H)^+$ complexes, which have relatively low error limits (Table 3, column 4), it appears that the extent of the stability enhancement is relatively independent of the metal ion considered.

3. Conclusions

The present study reveals that a metal ion bound to N3 of a benzimidazole residue acidifies the proton at the (N1)H site by about 0.5 to 3 pK_a units depending on the metal ion considered. The resulting benzimidazolate complexes are more stable than those formed with the corresponding neutral benzimidazoles. Clearly, it is safe to assume that this also holds for imidazole and imidazolate complexes.

How do two metal ions bound to the same imidazolate or benzimidazolate residue affect each other, as, e.g., in Cu,Zn superoxide dismutase[17][18] where an imidazolate residue bridges the two metal ions? Our results show, ignoring the one for $Mg(NBI-H)^+$ (Table 3), that the creation of a negative charge (−1) on the ligand leads on average to a stability enhancement of about 0.5−1.2 log units for the binding of the first metal ion at one of the nitrogens. Thus, in a first approximation one may assume that binding of the second metal ion at the other nitrogen atom is inhibited due to charge repulsion of the now positively (+1) charged liganding unit by approximately the same extent. Hence, an estimation of the stability constant, log $K^M_{M_2(L-H)}$, for $M_2(L-H)^{3+}$ complexes is obtained by subtracting from the stability constants, log K^M_{ML}, valid for the ML^{2+} complexes (Table 1)[12] the mentioned 0.5−1.2 log units. This then means that the stabilities of the $M(L-H)^+$ and $M_2(L-H)^{3+}$ complexes differ overall by about 1 to 2.4 log units. This conclusion also explains why under our experimental conditions no $M_2(L-H)^{3+}$ complexes were observed.

Experimental Section

1. Materials, Apparatus, and Definitions: The same reagents, experimental equipment and computers for the calculation procedures were used as previously.[12] The acidity constants determined are so-called practical, mixed or Brønsted constants.[26] Their negative logarithms given for aqueous solution at I = 0.5 M ($NaNO_3$) and 25 °C may be converted into the corresponding concentration constants by subtracting 0.03 from the pK_a values listed in the tables.[26] The ionic product of water (K_w) does not enter into the calculations because the differences in NaOH consumption between solutions with and without ligand (see below) are evaluated. The stability constants presented are, as usual, concentration constants.

2. Determination of Equilibrium Constants: The acidity constants $K^H_{H(NBI)}$ (see also ref.[12]) and K^H_{NBI} of NBI were determined by titrating 25 mL of 7.2 mM HNO_3 (I = 0.5 M, $NaNO_3$; 25 °C) in the presence and absence of 2.5 mM 5(6)-nitrobenzimidazole with 3 mL of 0.1 M NaOH. In the calculations of the two pK_a values for this ligand (L) the species H^+, HL^+, L and $(L-H)^-$ were considered.[12] Since the solubility of 5,6-dinitrobenzimidazole is low, more diluted solutions had to be used in this case, i.e., the acidity constant K^H_{DNBI} of DNBI was measured by titrating 25 mL of 0.15 mM HNO_3 (I = 0.5 M, $NaNO_3$) in the presence and absence of 0.24 mM DNBI with 1 mL of 0.01 M NaOH and calculated by taking into account the species H^+, L and $(L-H)^-$.[12] The final results for the acidity constants K^H_L of NBI and DNBI are the averages of 34 and 21 pairs of titrations, respectively.

The stability constants $K^{M}_{M(L-H)}$ of the $M(NBI-H)^+$ and $M(DNBI-H)^+$ complexes were determined under the same conditions as the acidity constants, but $NaNO_3$ was partly or fully replaced by $M(NO_3)_2$ (I = 0.5 M; 25 °C). For the systems with NBI the following concentrations of $M(NO_3)_2$ were employed: 0.1667 M (M^{2+}/L = 67:1 for Mg^{2+} and Mn^{2+}), 0.0417 M (M^{2+}/L = 17:1 for Co^{2+} and Ni^{2+}), 0.0333 M (M^{2+}/L = 13:1 for Cd^{2+}), 0.0208 M (M^{2+}/L = 8:1 for Ni^{2+} and Cd^{2+}), and 0.0104 M (M^{2+}/L = 4:1 for Ni^{2+}). Similarly, in the case of DNBI the following $M(NO_3)_2$ concentrations were used: 0.1667 M (M^{2+}/L = 695:1 for Mg^{2+} and Mn^{2+}), 0.0833 M (M^{2+}/L = 347:1 for Mn^{2+}), 0.0208 M (M^{2+}/L = 87:1 for Co^{2+} and Ni^{2+}), 0.0167 M (M^{2+}/L = 70:1 for Co^{2+}), 0.0104 M (M^{2+}/L = 43:1 for Co^{2+}), 0.00667 M (M^{2+}/L = 28:1 for Ni^{2+} and Cd^{2+}), and 0.00333 M (M^{2+}/L = 14:1 for Ni^{2+} and Cd^{2+}). The stability constants $K^{M}_{M(L-H)}$ of the $M(NBI-H)^+$ and $M(DNBI-H)^+$ complexes were calculated by taking into account the equilibrium constants determined previously for the HL^+ and ML^{2+} species[12] and by considering now the species H^+, HL^+, L, $(L-H)^-$, M^{2+}, ML^{2+}, and $M(L-H)^+$ and by collecting the data from the titration pairs every 0.1 pH unit. The pH range from a formation degree of the complexes of about 2% to the beginning of the hydrolysis of $M(aq)^{2+}$, which was evident from the titrations without ligand, was used for the evaluations. The formation degree for the $M(DNBI-H)^+$ complexes reached approximately 20−45%, depending on the metal ion, which is satisfying. However, the $M(NBI-H)^+$ complexes formed only to about 5−14% and with Mg^{2+} even only 3.5% could be reached under the experimental conditions. This results in somewhat larger final error limits for the $M(NBI-H)^+$ complexes (see Table 1, vide supra). However, the results showed no dependence on the excess of M^{2+} used in the experiments; i.e., there was no indication for the formation of $M_2(L-H)^{3+}$ complexes. The final results given for the stability constants $K^{M}_{M(L-H)}$ are always the averages from at least four independent pairs of titrations.

[31] The error limits of the calculated stability constants given in column 4 of Table 2 apply to the pK_a range 2−6, yet the data points for the $M(NBI-H)^+$ and $M(DNBI-H)^+$ complexes (Figure 2) are located at considerably higher pK_a values. Therefore, the error limits for the values calculated (calcd.) now were estimated in the following way: The error limits given with the intercepts b in column 3 of Table 2 reflect the error for a calculation based on $pK^{H}_{HL} = 0$; since the last experimental point of the straight line for Mg^{2+} (see Figure 2) is about three pK_a units away from the intercept at $pK^{H}_{HL} = 0$, for each pK_a unit the error limit of b (column 3 in Table 2) divided by 3 results. Considering that $pk_{ma/NBI} = 10.28$ is about 4.3 pK_a units larger than the last experimental point of the straight lines (Figure 2) the

mentioned value needs to be multiplied by 4.3 giving ±(0.095 : 3) × 4.3 = ±0.136 as the error limit for the calculated stability constant of the $Mg(NBI-H)^+$ complex. To be on the safe side, this value is further multiplied by 2 to give the error limit of ±0.27 which is listed in column 3 of Table 3. For the $Mn(NBI-H)^+$ complex exactly the same procedure applies. For Ni^{2+} (see Figure 2), Co^{2+} and Cd^{2+},[12] for which the last experimental point is only about two pK_a units away from the intercept, $pK^H_{HL} = 0$, the analogous calculation gives, e.g., for $Ni(NBI-H)^+$ the error limit ±(0.052 : 2) × 4.3 × 2 = ±0.22, which appears in column 3 of Table 3, and for $Ni(DNBI-H)^+$ ±(0.052 : 2) × 2.6 × 2 = ±0.14. All the other error limits given in column 3 of Table 3 were calculated correspondingly.

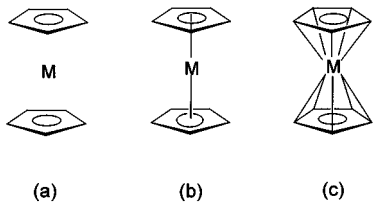
A Simple New Structural Force Field for the Computation of Linear Metallocenes

Peter Comba*[a] and Thomas Gyr[a]



Keywords: Molecular mechanics / Metallocenes / Ferrocene / Points on a sphere / Rotation barrier

A new structural force field for metallocenes is presented, which involves harmonic bonding potentials from the metal center to each of the carbon atoms, no angular potentials around the metal ion, inter-ligand 1,3-non-bonded interactions, and transferable parameters for the ligand backbones. The model has been parameterized for ferrocene, ruthenocene, and osmocene derivatives and the force field has been validated with relevant structures from the CSD files (Fe: 34, Ru: 10, Os: 2). The conformational space [rotation of the Cp (cyclopentadienyl) rings] has been searched with a cartesian stochastic search routine and energy barriers have been computed by scanning the pseudo-torsional angles involving the centroids of the two Cp rings. The computed energy barriers are smaller than those determined experimentally, but the predicted increase in transition energy upon substitution of the Cp rings is in agreement with experiment and the torsional angles for the minimum structures are computed accurately. It is suggested that the underestimated barrier height is due to the neglect of solvation.

Introduction

Molecular mechanics is well established in organic chemistry,[1][2] force-field calculations are becoming increasingly important in biochemistry,[2−5] and there is an increasing number of well-balanced force fields enabling accurate prediction of the structures and properties of transition-metal coordination compounds.[6−8] However, there are still relatively few reports concerning force fields for organometallic compounds.[6][7] One of the reasons for this is that the connectivity and type of bonding is often rather ambiguous, especially for fluxional systems. For metallocenes, for example, the very manner in which these systems are drawn highlights the problem (Scheme 1). It should be borne in mind that, in general, the basis of molecular mechanics is not to use realistic bonding models.[6] However, the computed structures and, in favorable cases, some thermodynamic parameters (isomer distributions, dynamics) and vibrational spectroscopic parameters should reproduce the experimental data.[6] Thus, any of the models represented in Scheme 1 might be used, irrespective of the fact whether any particular metallocene has more ionic or more covalent bonding character, provided that the parameterization allows a reasonable modeling of structural parameters (metal−Cp ring distance, metal−carbon distance, angle between the Cp planes, torsional angle and barrier, i.e. eclipsed or staggered conformation, and the corresponding activation energy for the interconversion). In addition, it should be easy to extend the model to other classes of organometallic compounds, such as cyclopentadienyl−metal compounds with various other donors, transition-metal compounds with other classes of ligands such as benzene or allyl groups, and cyclopentadienyl−main-group element compounds.

The molecular mechanics approaches for dealing with metallocenes used to date[9−21] can be classified according to the structural plots depicted in Scheme 1: (a) purely electrostatic models, i.e. no covalent bonds (no harmonic but electrostatic and/or van der Waals potentials) between the Cp rings and the metal center;[11][16] (b) models in which the metal center is connected to dummy atoms at the centers of the Cp rings;[9−13,15,21] (c) models with covalent bonds between the metal center and either three carbon atoms per Cp ring[21] or each of the carbon atoms (10-coordinate metal center).[19][20]

Scheme 1

The most appealing approach reported to date involves interactionless dummy atoms, where the forces on the dummy atoms at the centroid of the five-membered rings are distributed among the Cp carbon atoms to avoid strain on the Cp rings.[12] This model allowed accurate computation of the structures and vibrational spectra of linear metallocene compounds.[12] The only obvious disadvantage is that this method needs a specific algorithm, which is not generally available in commercial programs. As yet, it has only been used for linear metallocenes and has not been extended to other similar problems such as the computation of metal−allyl compounds.

We now present a new structural force field for linear metallocenes (M = Fe, Ru, Os), which involves bonding of

[a] Nomenclature: Cp = cyclopentadienyl, substructures in brackets in front of a Cp ring are substituents of the corresponding Cp; substructures between the two Cp rings are bridges; symmetrical bridges are only numbered at one Cp; Me = methylene, Et = ethylene, Prop = propylene, Bu = butylene, *t*Bu = *tert*-butylene, Pent = pentenyl, Cyh = cyclohexyl, Cyp = *n*, *n* + 1 propyl attached to a Cp ring.

all carbon atoms to the metal center (10-coordinate metal atom for MCp_2) and the replacement of valence angle terms around the metal center by inter-ligand 1,3-non-bonded interactions (modified points-on-a-sphere approach). Thus, the Cp rings are free to rotate about the centroid−metal−centroid axis without any need for defining dummy atoms, and there is no restriction in terms of a tilt between the two Cp planes. This approach is in agreement with simple MO considerations, i.e. the system is electronically degenerate with respect to the C_5 axis, which is also apparent from experiment. The points-on-a-sphere molecular mechanics model has been widely used for transition-metal coordination compounds[6,8,22,23] and is implemented in most commercially available programs. The only modification to generally available programs is the exclusion of 1,3-non-bonded interactions between covalently linked carbon atoms (intra-ligand 1,3-interactions), which has been simple to include in our software and force field. A similar but not identical approach to metallocene modeling has recently been developed for cyclopentadienyl−early transition-metal systems.[24]

Experimental Structural Data

The structural data considered in this study included selected X-ray-structural analyses of MCp_2 compounds with M = Fe, Ru, Os, where Cp_2 are two cyclopentadienyl rings or substituted Cp rings or where the two rings are bridged (substituents or bridges incorporating heteroatoms such as sulfur or silicon were not considered). The relevant structures (46 data sets; 34 Fe, 10 Ru, 2 Os), separated into simple and strapped sandwich compounds, are presented in Table 1.

Structural Parameters

The structural parameters considered here (average metal−carbon distance *b*; average distance *d* of the metal ion from the Cp planes; tilt angle α, torsional angle δ) are shown in Figure 1. The experimentally observed and computed parameters are given in Table 2 (the full set of structural data, experimental and computed, of all structures is available as Supporting Information). Note that, for some compounds, various experimental data sets are available. This is particularly true in the case of ferrocene, for which various polymorphic modifications are known and intermolecular interactions, polymorphism, disorder, gas-phase structures, and dynamics have been discussed extensively.[25−28] The fact that the computed and experimentally determined activation energies for the Cp ring rotations of the non-strapped metallocenes are generally small (see be-

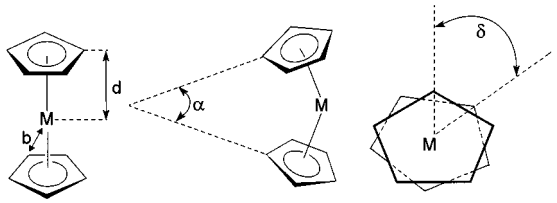

Figure 1. Definition of the structural parameters [torsion angle δ has the periodicity (360/5°), except for unsymmetrically substituted Cp rings; staggered: δ = 36°; eclipsed: δ = 0°]

Table 2. Averages of observed and computed structural parameters of metallocenes[a]

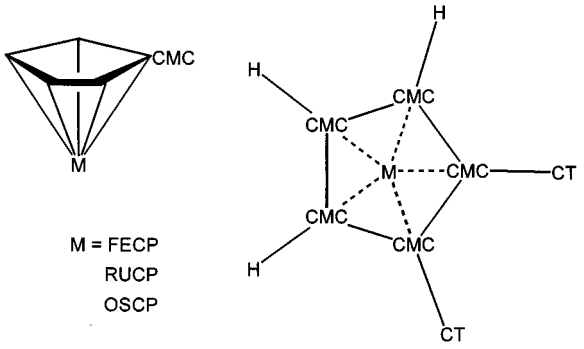

Figure 2. Definition of atom types used in Table 3

low) indicates that an arbitrary selection of test structures is acceptable.

The MOMEC program and force field were used for the calculations.[22] Parameters not previously published[23] are given in Table 3 (the atom-type labels are defined in Figure 2; starting values for the parameters were taken from vibrational spectroscopic data and/or from other force fields[6][12] and refined by fitting to the set of test structures). The conformational space was searched with a cartesian stochastic search routine ("random kick" Monte Carlo method), which has recently been implemented in MOMEC and validated for a series of (amine)cobalt(III) compounds.[29]

[a] All other parameters have been published previously.[23] − [b] For atom-type labels, see Figure 2. − [c] 1 dyn = 10 $^{-5}$ N.

The average observed and computed metal−carbon distances *b* are 2.10 Å and 2.10 Å for iron, 2.18 Å and 2.18 Å for ruthenium, and 2.11 Å and 2.18 Å for osmium (for osmium only two data sets were available, one of which related to a low-temperature structure). A similar degree of accuracy in the computations of the distances *d* of the metal center from the Cp planes is found, and the observed error in the tilt angle α is generally less than 3° and at most 7°. This is especially remarkable for the asymmetrically bridged compounds. The torsional angles δ are, in general, also predicted accurately (to within less than ±10°). Structures with larger differences between the computed and observed torsional angles have freely rotating Cp ligands (non-strapped) and crystal structures with staggered Cp rings. Plots of strain energy along the rotational coordinate indicate that structures similar to that observed are local minima (see below). Details concerning the quality of the computed structures are given in Table 4; full details are available as Supporting Information.

Cp Ring Rotation

Scanning of the strain energy along the rotational mode of the Cp rings is simple in models that use dummy atoms at the centroids of the Cp rings. We use constraints on plane-twist functions (angle between two planes; one of the planes is defined by three carbon atoms of a Cp ring, the other by the metal center and one carbon atom of each of the two Cp rings; from each of the constrained plane-twist angles the corresponding torsional angle δ is calculated). It is possible to apply a force on this rotation to increase the barrier for the Cp ring rotation. However, there does not seem to be an electronic reason for such a potential. The difference between the observed and computed energy barriers might be due to a reorganization of the solvent sheath, which is not considered explicitly in our calculations.[6] The computed energy barriers are mainly due to changes in van der Waals contacts, and it has been suggested previously that this is probably the most important effect.[6][12] It should be borne in mind, however, that our aim was to derive a structural force field for ferrocene, ruthenocene, osmocene and derivatives. Thus, the computation along the ring rotation mode is used here to evaluate local minima and not for the accurate determination of rotational barriers.

As expected, the computed energy barriers (Table 5) are generally underestimated, but the increasing barrier height upon substitution [cf. $Fe(Cp)_2$, $Fe(Me_5Cp)_2$] is of the expected order. A plot of the strain energy along the Me_5Cp rotation for the latter structure indicates that there is a concerted rotation of the methyl groups, which is shown in Figure 3. Here, the structural plots help to visualize the con-

[a] Conformational arrangement is indicated in brackets, where *e* = eclipsed, *s* = staggered. – [b] Minima determined by rotating one Cp ring in one direction using a plane-twist function (no force, i.e. $k_\delta = 0.0$); energy scan increment: 1°. – [c] Values obtained by electron diffraction in the gas phase. At low temperature, X-ray and neutron diffraction data indicate that the rings are staggered by about 10°.[66]

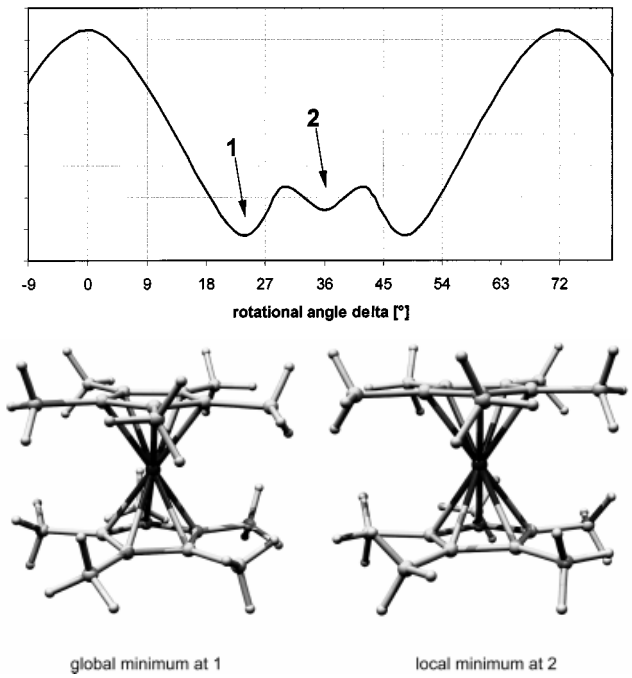

Figure 3. Rotational energy plot of $Fe(Me_5Cp_2)$ (grid: 1 kJ/mol)

certed rotations. The global energy minimum of $Fe(Me_5Cp)_2$ ($\delta = 22.2°$) is in excellent agreement with that computed using an alternative approach ($\delta = 23.7°$).[12] Thus, structural features, including those of the ring rotation, are well reproduced by our new force field, while dynamic properties are not. The approach used here allows the application of a force on the ring rotation; published data relating to other force fields suggest that this might lead to realistic energy barriers when the corresponding force constant is metal-ion-dependent.[12]

In conclusion, we have been able to demonstrate that the simple points-on-a-sphere model leads to an accurate structural force field for linear metallocenes, and that this approach may be extended to a range of other organometallic systems.

Supporting Information

Detailed structural data (comparison of experimentally observed and computed structural parameters) are available: Table S1 (supplementary to Table 2) gives the complete set of carbon-to-metal bond lengths *b* [see Figure 1; the metal center is atom number 1, C(2)–C(6) are carbon atoms of ring 1, and C(7)–C(11) are carbon atoms of ring 2] and rotational angles δ (the values given in parentheses after the rotational angles are RMS deviations of the carbon atoms from the best plane of each Cp ring). Table S2 (sup-

plementary to Table 5) lists the rotational energy barriers for all metallocene compounds discussed in Table 5.

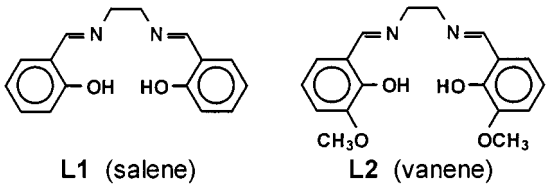
Cyanide-Bridged Arrays of 2, 3 and 4 Metal Atoms Based on Salene–Iron Complexes – Syntheses, Structures and Metal–Metal Interactions

Andreas Geiß[a] and Heinrich Vahrenkamp*[a]

Dedicated to Professor Wolf-Peter Fehlhammer on the occasion of his 60th birthday



Keywords: Iron complexes / Salene ligands / Cyanide bridging / Electron transfer / Metal–metal interactions

Salene–Fe^{III} complexes of the types LFeCl and $[LFe(CN)_2]^-$ were treated with organometallic reagents to introduce the cyanide-linked units $(CO)_5Cr$, $(CO)_5Mo$, $(CO)_5W$, $Cp(CO)_2Fe$, Cp(dppe)Fe, and $Cp(PPh_3)_2Ru$. IR spectra and structure determinations revealed that all resulting complexes contained M–CN units with N coordination to the salene–Fe units. They were either dinuclear M–CN–Fe(salene), trinuclear M–CN–Fe(salene)–NC–M, or tetranuclear M–CN–Fe(salene)–Fe(salene)–NC–M species. Cyclic voltammetry showed that there are significant electronic interactions between the two outer organometallic units in the trinuclear complexes. UV/Vis spectra indicated a metal–metal charge transfer from the outer Cp(dppe)Fe groups to the central Fe^{III}. The magnetic moments at room temperature of the tri- and tetranuclear complexes are slightly lower than those calculated for isolated high-spin Fe^{III} species.

In the previous papers of this series[1][2] and in a feature article[3] we have outlined our interest in complexes containing cyanide-bridged arrays of redox-active transition metal ions. Our aim is to elucidate the factors determining the extent of electronic interactions between remote metal centers in such arrays. Our preparative approach consists of constructing the arrays from cyanometal complexes L_nM-CN and complexes $L_nM'-X$ containing labile ligands X. This approach allows a wide variation of L, M and X, as well as of the geometrical relation between two cyanide bridges at a central metal ion (*cis*, *trans*, tetrahedral, etc.), and of the orientations of the cyanide bridges (cyanide vs. isocyanide). The techniques used to assess the metal–metal interactions include IR spectroscopy, cyclic voltammetry, preparative redox chemistry, magnetic measurements and NIR spectroscopy. Our main contribution to this area is the design and variation of suitable new compounds, the investigation of which extends the work of previous researchers in the field.[3]

So far we have gained basic knowledge by studying dinuclear M–CN–M′ complexes and then applied this knowledge to include symmetrical trinuclear complexes of the types $M(CN-M')_2$ or $M(NC-M')_2$.[2,4,5] One important finding from these studies is that, as expected, a linear array of M–CN units allows for much better remote interactions than bent arrays. This was verified by finding an interaction between the terminal metal ions in a tetranuclear complex that was obtained accidentally.[6] Accordingly, we focused our preparative efforts on building blocks that only allow a *trans* arrangement of cyanide bridges at a connecting metal center. In essence this means the use of disc-like L_nM units with planar tetradentate ligands L_n as building blocks, as already applied some years ago by Hanack for the synthesis of electrically conducting [(Pc)M–CN] polymers (Pc = phthalocyanine).[7]

For the present investigation we chose salene ligands to ensure square-planar metal coordination of the central metal ions. The advantage of these ligands is their easy accessibility and variability, as well as the fact that they are good coligands for both square-pyramidal L^4M-X and octahedral $X-ML^4-Y$ complexes.[8] Our aim was to construct linear multinuclear arrays by using cyanide for X and Y. This paper describes our results obtained with salene–iron units. Iron was chosen as the central metal because of its redox properties. The tetradentate ligands were either salene itself (**L1**) or its bis(methoxy)-substituted variant vanene (**L2**) (Scheme 1).

L1 (salene) **L2** (vanene)

Scheme 1

Preparations

The starting iron complexes with salene ligands were **1a**,**b**, and **2a**,**b**.[9] We expected the former to lead to CN-bridged arrays with (salene)Fe–N coordination and the latter to maintain their (salene)Fe–C coordination upon attachment of other metals to the cyanide ligands.

(**L1**)Fe–Cl **1a**	K[(**L1**)Fe(CN)$_2$] **2a**
(**L2**)Fe–Cl **1b**	K[(**L2**)Fe(CN)$_2$] **2b**

Complexes **1** were treated with the monofunctional cyanometal complexes **3**−**8** with the aim of replacing the halide by the cyanometal "ligands" and possibly attaching a second cyanometal unit to form trinuclear species.

$Cp(CO)_2Fe-CN$ **3**

$Na[(CO)_5Cr-CN]$ **6**

$Cp(dppe)Fe-CN$ **4**

$Na[(CO)_5Mo-CN]$ **7**

$Cp(PPh_3)_2Ru-CN$ **5**

$Na[(CO)_5W-CN]$ **8**

Conversely, complexes **2** were reacted with the monofunctional species **9**−**11**, which are the sources of the cationic electrophiles $Cp(L_2)M$ to be attached at the N terminus of the cyanide ligands.

$[Cp(CO)_2Fe(THF)]PF_6$ **9**

$[Cp(dppe)Fe(CH_3CN)]Br$ **10**

$Cp(PPh_3)_2Ru-Cl$ **11**

All 1:1 combinations between complexes **1** and reagents **4**−**8** in methanol led to products with an Fe/M ratio of 1:1. In only one case, however, was such a product isolated as a simple dinuclear complex: The two most volumious partners, **1b** and **5**, yielded **12**, whose constitution was confirmed by a structure determination of its PF_6^- salt.

$[(H_2O)(\mathbf{L2})Fe-NC-Ru(PPh_3)_2Cp]^+$ **12**

In all other cases the 1:1 products were found to be associated with dimeric entities, i.e. tetranuclear complexes, in the solid state. This was ascertained by structure determinations of **[13a]**$(PF_6)_2$ and **[13a]**$(BPh_4)_2$ and deduced from the spectral similarities and solubility properties for the other complexes. This behavior corresponds to that of **1a**, which is also dimeric in the solid state but probably monomeric in polar solvents.[9][10] Complexes **13**−**17** were isolated and, of these, the ionic ones (**13**, **14**) could be crystallized as ClO_4^-, PF_6^-, SbF_6^- or BPh_4^- salts upon addition of the corresponding counterions.

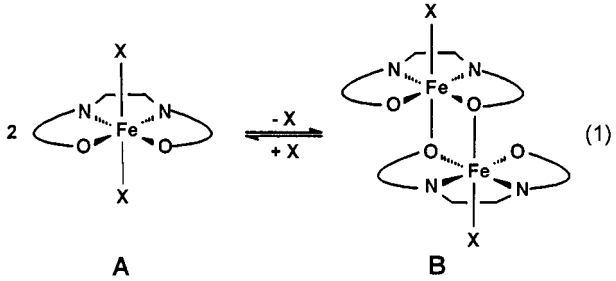
$[(\mathbf{L})Fe-NC-Fe(dppe)Cp]_2^{2+}$ **13a**: L = **L1**; **13b**: L = **L2**

$[(\mathbf{L1})Fe-NC-Ru(PPh_3)_2Cp]_2^{2+}$ **14**

$[(\mathbf{L1})Fe-NC-M(CO)_5]_2$ **15**: M = Cr; **16**: M = Mo; **17**: M = W

Some of the tetranuclear dimers **13**−**17** were also precipitated from solutions containing two equivalents of the cyanometal reagents per equivalent of starting complex **1**. By adjusting the reaction conditions, however, the expected trinuclear complexes with two cyanometal "ligands" could be isolated. Starting from **1a** and **1b** these were **18a**, **18b**, **20a**, **21**, **22**, and **23**. Of these, the cationic compounds (**18**, **20**) could again be precipitated with one or several of the four anions named above, while the anionic ones (**21**−**23**) were precipitated as PPh_4^+ salts. Their trinuclear nature was ascertained by a structure determination of **[20a]**PF_6.

$(\mathbf{L})Fe\{NC-Fe(CO)_2Cp\}_2]^+$ **18a**: L = **L1**; **18b**: L = **L2**



$[(\mathbf{L})Fe\{NC-Fe(dppe)_2Cp\}_2]^+$ **19a**: L = **L1**; **19b**: L = **L2**

$[(\mathbf{L})Fe\{NC-Ru(PPh_3)_2Cp\}_2]^+$ **20a**: L = **L1**; **20b**: L = **L2**

$[(\mathbf{L})Fe\{NC-M(CO)_5\}_2]^-$ **21**: M = Cr; **22**: M = Mo; **23**: M = W

Attempts to obtain complexes like **13**−**21** with an inverted orientation of the bridging cyanide ligands by using **2a** and **2b** as starting materials were unsuccessful. Invariably the Fe^{III}-attached cyanide ligands of **2a** and **2b** were turned around upon attachment of the other organometallic units. Thus **18a**, **19a**, and **20a** were obtained as PF_6^- salts from **2a**, and **9**, **10**, or **11**. Likewise, **19b** and **20b** resulted, though not in a pure form, from **2b** and **10** or **11**.

The formation of the isolated complexes can be understood from the solution behavior of the simple salene−Fe^{III} complexes.[8−11] It is known that **1a** and **1b**, which are molecular dimers in the solid state, are solvated and probably ionized in solution, being engaged in a monomer-dimer equilibrium as shown in Equation 1. This equilibrium should depend on the solvent, on other donor ligands, on the anions present, and on the solubility of the various species. The monomer **A**, with X = CH_3OH, would represent the simplest species in methanol solutions of **1a** or **1b**. For X = CN^- complex **A** would be the intact starting material **2a** or **2b**. Partial replacement of the labile ligands X from **A** or **B** could change the total charge of the solution species and hence their solubility or their preference in the equilibrium.

(1)

Of the isolated complexes, the 1:1 species **13**−**17** show their dimeric nature by their lower solubility compared to the 1:2 species **18**−**23**, which for **13** and **14** also corresponds to a dipositive charge of the complex cations. Steric effects are evident from the fact that the most voluminous cyanometal "ligand" **5** does not want to form a 1:2 complex (**20b**) starting from (**L2**)FeCl, but rather the unique 1:1 complex **12**. Likewise, the least voluminous cyanometal "ligand" **3** could not be incorporated into a 1:1 complex, but easily formed the 1:2 complexes **18a** and **18b**. Electronic effects can also be invoked to explain the lower tendency for the formation of **20b** in comparison to **20a**: The vanene ligand (**L2**) is more electron-rich than the salene ligand (**L1**), and hence the Fe^{III} ion coordinated by it is less prone to bind a sixth donor. The low binding tendency of all (**L1**)Fe−X or (**L2**)Fe−X complexes for a sixth donor ligand also provides

an explanation for the inversion of the cyanide attachment to the Fe^{III} center in **2a** and **2b** upon complexation to the incoming organometallic units. This feature allows the liberation of CN^- in solution, which also makes the crystallization of dimeric (salene)Fe−CN possible.[12]

Structures

One representative example of each structural type was subjected to X-ray analysis. In the case of **13a** the complex salts with either PF_6^- or BPh_4^- as counterions differed so much in their ν(CN) IR data (see below) that it seemed worthwhile to explain this phenomenon in terms of their structures.

Compound [**12**]SbF_6 (see Figure 1) is the only species in this report that is dinuclear in the solid state and that bears a ligand other than cyanide or salene on the central Fe^{III} ion. The coordination geometries in **12** [distorted octahedral at Fe^{III}, piano stool at Ru] are normal. The salene ligand **L2** defines a square-planar environment of the iron center to a good approximation and can itself be described by the "stepped" conformation.[8][11] The Fe−O(water) distance of 2.18 Å is significantly longer than the Fe−O(salene) distances (av. 1.89 Å), while the Fe−N(cyanide) distance (2.05 Å) is a little shorter than the Fe−N(salene) distances (av. 2.08 Å).

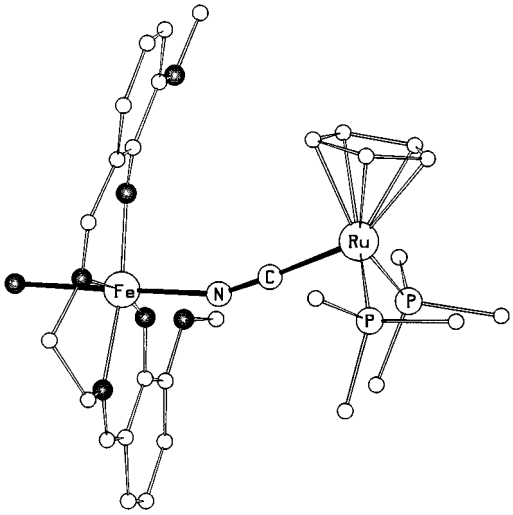


Figure 1. Structure of complex **12** in [**12**]SbF_6; Selected bond lengths [Å] and angles [°]: Fe−O(salene) 1.885(7) and 1.902(7), Fe−N(salene) 2.083(9) and 2.076(9), Fe−O(H_2O) 2.184(6), Fe−N(CN) 2.046(8), C−N(CN) 1.13(1), Ru−C(CN) 1.973(10); Fe−N−C(CN) 160.1(9), R−C−N(CN) 176.4(9)

The bridging cyanide ligand in **12** shows typical features. Its π-acceptor terminus, the C atom, is naturally bound to the electron-rich ruthenium atom as it is the better π donor. This is reflected by the Ru−C distance, which is shorter than the Fe−N distance on the other side. Likewise, the Ru−C−N angle (176°) is much closer to linearity than the Fe−N−C angle (160°). These two indicators of the π-bonding abilities of the C and N atoms of the cyanide ligand, as well as of the metal centers attached to them, have been found to be of good diagnostic value.[1−3]

The two complex salts derived from **13a**, containing PF_6^- and BPh_4^- as counterions, were both found to have the dimeric units of **13a** in the solid state. The structure determination of [**13a**]$(PF_6)_2$ resulted in an unsatisfactory *R* value of 0.119, and only the structure of [**13a**]$(BPh_4)_2$ is discussed in detail here (see Figure 2). The dimer **13a** is centrosymmetrical in both compounds. As usual for such salene complex dimers,[8][11] one each of the salene oxygen atoms is used to bridge the two monomer units resulting in a central Fe_2O_2 square, and the salene ligands once again have the "stepped" conformation.

The bonding characteristics of the bridging cyanide ligands compare closely with those in **12**, both in terms of metal−cyanide bond lengths and of the angles at C and N. There is ample precedence for bridging cyanide coordinated to the iron center at the C and N terminus,[1][2] including Prussian Blue.[13] The Fe′−C distance in **13a** compares well with other Fe−C distances in Cp(dppe)Fe−CN derivatives, but the Fe−N distance in **13a** is larger than other such distances in complexes of low-valent iron. It is, however, comparable to the Fe^{III}−N distance in Prussian Blue.

The two major differences between the shapes of the dimeric units **13a** in [**13a**]$(BPh_4)_2$ and [**13a**]$(PF_6)_2$ lie in the bending of the Fe−CN−Fe bridge and the relative orientation of the Fe(salene) units with respect to the Fe(dppe)Cp units. The latter in [**13a**]$(PF_6)_2$ are rotated by about 30° around the Fe−CN−Fe′ line compared to [**13a**]$(BPh_4)_2$. More significant is the difference in the Fe−N−C angles, which are 152° in [**13a**]$(BPh_4)_2$ and 178° in [**13a**]$(PF_6)_2$. The voluminous tetraphenylborate counterions seem to cause severe bending of the "soft" Fe−N−C angles, which in turn is the reason for the lowering of ν(CN) in [**13a**]$(BPh_4)_2$ (see below).

Compound [**20a**]PF_6 has an approximately linear Ru−CN−Fe−NC−Ru arrangement in the solid state (see Figure 3). Its general features can be compared with those of [**12**]SbF_6: The central Fe^{III} ion has a roughly octahedral coordination, its "stepped" salene ligand comprises a roughly square-planar FeO_2N_2 arrangement, and the attachment of the $Cp(PPh_3)_2Ru$−CN "ligands" is similar. The second $Cp(PPh_3)_2Ru$−CN unit in [**20a**]PF_6 occupies the position of the water ligand in [**12**]SbF_6 but is not symmetry-related to the first one.

The attachment of two cyanometal units to the (salene)-Fe^{III} center leads to different bonding characteristics of the bridging cyanide ligands in **20**. Compared to **12** the central Fe−N bonds are 0.05 Å longer, which may point to a *trans* effect, while the Ru−C(cyanide) bond lengths in both complexes are virtually identical. The bending of the Fe−N−C(cyanide) angles in **20** is less pronounced than in **12**, while the bending of the Ru−C−N(cyanide) angles is more pronounced. However, since all four angles Fe−N−C and Ru−C−N are bent in the same direction, the total deviation of the Fe−N−C−Ru sequences from linearity (18−24°) is the same in both complexes. Indeed, in **20** all

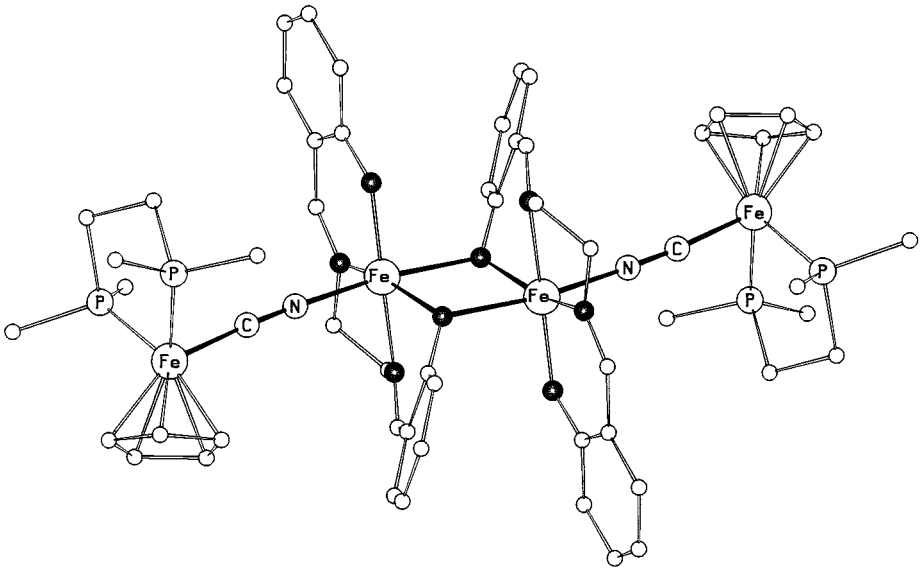

Figure 2. Structure of complex **13a** in [**13a**]$(BPh_4)_2$; selected bond lengths [Å] and angles [°]: Fe−O(unbridged) 1.876(4), Fe−O(bridge) 1.991(4), Fe−O′(bridge) 2.117(4), Fe−N(salene) 2.091(5) and 2.123(5), Fe−N(CN) 2.017(5), C−N(CN) 1.161(7), Fe′−C(CN) 1.817(7), Fe− − −Fe(across bridge) 4.835(2); O−Fe−O(bridge) 78.4(2), Fe−O−Fe(bridge) 101.6(2), Fe−N−C(cyanide) 151.5(5), Fe′−C−N(cyanide) 178.2(6)

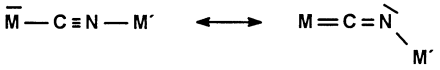
Figure 3. atoms of the Ru−CN−Fe−NC−Ru sequence lie approximately in one plane.

IR Data

The ν(CO) data of the complexes with carbonyl ligands are listed in the Experimental Section. The ν(CN) values are given in Table 1 for the solid state and for solutions.

Based on the accumulated experience with oligonuclear complexes of the cyanometal "ligands" **3**−**8**[1,2,4,5] and on the cross-comparison of the data in Table 1, several unambiguous conclusions can be drawn about the structure and bonding in the complexes described here. The simplest of these can be derived from the observation that, with few exceptions (**18a**,**b**), the ν(CN) values are lower in the bridged complexes than in the free metallocyanides **3**−**8**. This means that the kinematic effect [constraint of CN motion by double attachment, i.e. raising of ν(CN)] is outweighed by an electronic effect. The latter consists in the electron withdrawal at the N terminus of the CN by the electron-poor Fe^{III} center, which in turn causes enhanced π-backdonation from the electron-rich organometallic units at the C terminus into the π* orbitals of the C−N bond, and hence a weakening of this bond. Proof for this is found in the ν(CO) values of the "ligands" **3**, **6**, **7**, and **8**, which are raised upon formation of the oligonuclear complexes.



The data for the dimeric 1:1 complexes **13a**, **13b** and **14** indicate that the amount of π-backdonation seems to depend on structural details. The solid-state IR spectra of these complexes show a marked dependence of ν(CN) upon the counterion present. This is most evident for **13a**, which experiences a decrease of 20 cm^{-1} in ν(CN) on going from the smallest (ClO_4^-) to the largest counterion (BPh_4^-). As seen from the structure determinations (see above) this

[a] Terminal organometallic unit. − [b] C: dichloromethane, M: methanol.

corresponds to an increased bending of the C−N−Fe^{III} linkage at the nitrogen atom. In accord with similar observations for Fe−CN−Cu systems[14] a simplistic explanation for this may be proposed by formulating an angle-dependent variation between a C−N double bond and a C−N triple bond according to the resonance formula in Scheme 2.

Scheme 2

Complexes **13** and **14** also show significantly different ν(CN) values in the solid state and in solution, and their solution IR data are not dependent on the counterions present. While their tetranuclear nature in the solid state was proved by the structure determinations, this indicates that in solution they are dinuclear, i.e. monomeric. This is in accord with the electrochemical data (see below). It is also supported by the fact that **12**, the only monomeric complex of this type, shows the same ν(CN) values in the solid state and in solution and for both counterions. Unlike **13** and **14**, the uncharged 1:1 complexes **15**−**17** show the same ν(CN) values in the solid state and in solution and, furthermore, in solution their ν(CN) values are virtually identical to those of the free metallocyanides **6**−**8**. In the absence of further indicators (no structures, no good electrochemical data) it cannot be concluded whether they are tetrameric in both the solid state and in solution or dissociate to yield the free metallocyanides in solution.

The ν(CN) data of the trinuclear complexes **19** and **20** are characteristically different from those of their (in solution) dinuclear counterparts **13** and **14**: For the trinuclear systems the ν(CN) values are 40−45 cm^{-1} higher and come close to those of the free metallocyanides **4** and **5**. This demonstrates reduced π-backdonation from the terminal metals to the cyanide ligands, corresponding with the fact that in the trinuclear systems two L_nM−CN "ligands" satisfy the acceptor properties of the central (salene)Fe^{III} units. The validity of this argument is supported by two further observations: Firstly the monomeric dinuclear complex **12** shows its CN band 30 cm^{-1} higher than its water-free counterpart **14**, secondly the dimeric and tetranuclear complexes **13** and **14** show ν(CN) values that are close to those of their trinuclear analogs **19** and **20**. In all these species with clearly octahedral coordination of the central Fe^{III}, the ν(CN) values are high, while for **13** and **14** in solution they are low. A consistent interpretation thus requires that **13a**, **13b** and **14** are five-coordinate in solution, i.e. have only one donor ligand for Fe^{III} in addition to the salene ligand.

Electrochemistry

All new complexes were subjected to cyclic voltammetry in dichloromethane solution. As previously observed, it was found that the species with carbonyl ligands (**15**−**18**, **21**−**23**) do not yield reversible redox waves and lead to electrode coating. All other compounds, however, showed a reversible multistep redox behavior that allowed a consistent interpretation of their electronic nature and of their metal−metal interactions. The corresponding data are listed in Table 2.

Table 2. Cyclic-voltammetry data

	L_nM'[b]	red. Fe^{III}	ox(1) L_nM	ox(2) L_nM
4	Cp(dppe)Fe		0.48	
5	$Cp(PPh_3)_2Ru$		0.79	
[**12**]SbF_6	$Cp(PPh_3)_2Ru$	−0.30	1.08	
[**13a**]PF_6	Cp(dppe)Fe	−0.34	0.86	
[**13b**]PF_6	Cp(dppe)Fe	−0.31	0.82	
[**14**]PF_6	$Cp(PPh_3)_2Ru$	−0.32	1.12	
[**19a**]PF_6	Cp(dppe)Fe	−0.35	0.46	0.86
[**20a**]PF_6	$Cp(PPh_3)_2Ru$	−0.39	0.89	1.12[c]

[a] In dichloromethane, scan speed 100 mV/s, potentials in V vs. Ag/AgCl. − [b] Terminal organometallic unit. − [c] Irreversible.

In all oligonuclear complexes the reduction of the central Fe^{III} ion occurs within the very narrow potential range of −0.32 to −0.39 V. This points to a very good balance of electron acceptance by the central iron and electron donation by its one or two axial ligands. As an example, the water molecule and the Ru−CN ligand in **12** have about the same effect as the single Ru−CN ligand in **14**. This implies that the Ru−CN ligand in **14** must donate more

electron density than that in **12**, which is clearly evident from the IR data and, to a lesser extent, also from the redox potentials of the Ru−CN units in **12** and **14**. The inherent implication that the 1:1 complexes **13** and **14** are monomeric, i.e. dinuclear, in solution is borne out by the simplicity of their cyclic voltammograms, which for the corresponding tetranuclear complexes should show at least one more redox wave due to the stepwise reduction of the two closely spaced, i.e. strongly interacting, central Fe^{III} centers.

The increase of the redox potentials of the cyanometal "ligands" **4** and **5** upon single coordination to the (salene)-Fe^{III} unit amounts to 0.3−0.4 V. This is somewhat larger than observed previously for related dinuclear complexes,[1,2,4,5] and corresponds to the considerable withdrawal of electron density through π-backdonation as diagnosed above from the IR data. In this respect the pair of complexes **13a/13b** provides an internal test for the mutual effects of the shift of electron density between the two redox centers across the cyanide bridge. In **13a** the (salene)Fe^{III} unit is more difficult to reduce (i.e. more electron-rich) and, in addition, the Cp(dppe)Fe unit is more difficult to oxidize (i.e. more electron-poor) than their counterparts in **13b**.

In the trinuclear complexes **19a** and **20a** the Fe^{III} centers are slightly more difficult to reduce than in the dinuclear complexes, corresponding to their higher electron density due to the presence of two cyanometal donors. On the other hand, the first oxidative waves appear at significantly lower potentials than in the dinuclear complexes. This agrees again with the observations from the IR data, which indicate a significantly smaller π-backdonation from the outer organometallic units in **19a** and **20a**. Figure 4 shows the two voltammograms.

The most important feature of the trinuclear complexes **19a** and **20a** is the occurrence of two well-separated oxidative waves in their voltammograms. These must represent the stepwise oxidation of the two outer organometallic units. At first glance the two oxidation potentials in both cases are conspicuously close to those of the dinuclear complexes (**13a**, **14**) plus the two free metallocyanides (**4**, **5**), leading to the suspicion that **19a** and **20a** dissociate into these components in solution. However, these components should be detectable in the IR spectra and (for **4** and **5**) by NMR, which was not the case. Thus, the large separation of the redox waves must be taken as being real and as an indication of a strong electronic interaction between the two outer organometallic units which are ca. 10 Å apart. The extent of this interaction, as measured by the potential separation, is unusually large when compared to that in related trinuclear $(M'-CN)_2M$ complexes investigated by other researchers[15−17] and ourselves.[2][4]

It seemed feasible that the isolation of the mono-oxidized species [**19a**]X_2 or [**20a**]X_2 should be possible after chemical oxidation or controlled potential electrolysis. These species would be valuable for probing the long-range metal−metal interactions by optically induced MMCT as described in the following section. However, various attempts to generate these species chemically or electrolytically, or even to spectroscopically prove their existence in solution, met with failure.

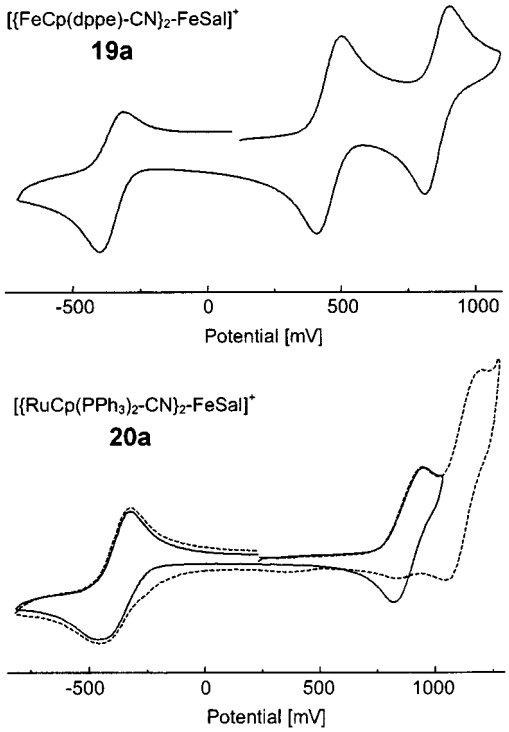

Figure 4. Cyclic voltammograms of **19a** and **20a** (for details see Table 2); for **20a** the solid line corresponds to a scan range of −0.80 to +1.05 V, the dashed line to a scan range of −0.80 to +1.35 V

Metal−Metal Charge Transfer

The phenomenon of optically induced metal−metal charge transfer (MMCT) finds its popular representation in the name Prussian Blue (generally accepted for a class of compounds of approximate composition $M^IFe^{II}Fe^{III}(CN)_6 \cdot x\ H_2O$, corresponding to an MMCT absorption at 680 nm. The practical relevance of this has led to many investigations of the optical properties of coordination compounds containing cyanide-bridged metal centers.[3] Few of those, however, reproduce the electronic situation in Prussian Blue, which contains Fe^{III} as a d^5 high-spin species attached to the N terminus and Fe^{II} as a d^6 low-spin species attached to the C terminus of the cyanide bridge. All complexes described here have just this configuration and thus are simple low-molecular representatives of Prussian Blue.

The optical properties of the complexes yield partial justification for this statement. Table 3 lists the UV/Vis absorption of the analytically pure compounds (except **15**−**17**, which are insoluble in dichloromethane). It is evident that the spectra are dominated by the LMCT absorptions in the visible range, of which those due to the (salene)Fe^{III} units are 5 to 10 times as intense as those due to the organometallic units. For the di- and trinuclear complexes containing carbonyl ligands on the organometallic units (**18**, **21**−**23**) there are no further spectral features, leading to the conclusion that a possible MMCT from the outer metal centers

to the central Fe^{III} is too high in energy to be discernable from the LMCT, in accord with the high redox potentials of these outer organometallic groups.

Table 3. UV/Vis data {in dichloromethane, $\lambda_{max}(\varepsilon_{max})$ [nm(M^{-1} cm^{-1})]}

[**23**]PPh_4	$(CO)_5W$	440(3100), 491(3600)	

[a] Terminal organometallic unit.

At first glance this also seems to be the case for the ruthenium-containing complexes **12**, **14**, and **20a**. However, their absorption intensities for the LMCT are higher and their spectral traces extend by about 100 nm further into the visible range than those of the aforementioned complexes. This situation is represented in Figure 5. It can be interpreted by a hidden MMCT absorption at ca. 550 nm. Again, the high redox potentials of the Ru centers in these complexes can serve as an explanation for the high MMCT energies.

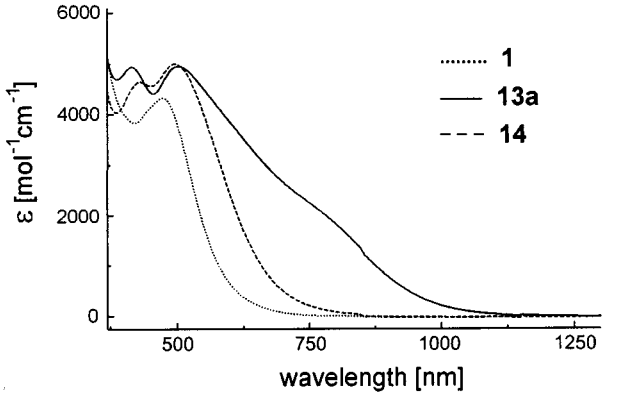

Figure 5. Superposition of the UV/Vis spectra of the reference compound **1a** and its dinuclear $Fe^{III}-NC-Fe^{II}$ and $Fe^{III}-NC-Ru^{II}$ derivatives **13a** and **14** (in CH_2Cl_2)

Only for the di- and trinuclear complexes containing Cp(dppe)Fe as the organometallic unit with the lowest redox potential on the terminal positions (**13a**, **13b**, **19a**) are the MMCT absorptions visible as shoulders in the spectra, cf. Figure 5. Compound **13b** shows the MMCT transition of lowest energy, which can be explained by the observations, mentioned above, that in **13b** both the Fe^{III} center is easier to reduce and the Fe^{II} center easier to oxidize than their counterparts in **13a**. The observation that the trinuclear complex **19a** shows an MMCT of higher energy than its dinuclear counterpart **13a**, despite the lower first redox potential of its Cp(dppe)Fe unit, cannot be explained by the simple arguments used here. It serves, however, as additional proof that **19a** does not dissociate into **13a** and **4** in solution, as suspected above. Altogether the MMCT energies of these three complexes come close enough to that of Prussian Blue to allow the statement that they represent a viable model of its high-spin-$Fe^{III}-NC-$low-spin-Fe^{II} arrangement.

The MMCT transitions observed here correspond to electronic interactions between neighboring metal centers, and in the trinuclear complexes the intramolecular redox process transfers an electron from the terminal metal centers to the central Fe^{III}. Thus, the ability of the tri- and tetranuclear species for long-range metal−metal interactions has not been exploited. This poses the challenge of either obtaining the elusive one-electron oxidation products of **19** or **20** or preparing unsymmetrical (i.e. heterotrimetallic) trinuclear complexes.

Magnetism

All new complexes contain several unpaired electrons located on the salene-bound high-spin Fe^{III} centers. Their magnetic moments were determined at room temperature by the Gouy method in order to find out how the basic magnetic properties of (salene)Fe^{III} complexes are modified by the attachment of the cyanometal "ligands" and to possibly detect new magnetic interactions. The measured values of χ_{mol} were corrected for the diamagnetic contributions,[18] and from the resulting values $c^{corr}{}_{mol}$ the magnetic moments μ_{eff} were calculated using the formula $\mu_{eff} = 2.828(\chi^{corr}{}_{mol} \cdot T)^{1/2}$. The corresponding data are listed in Table 4.

Table 4. Magnetic data at room temperature

	χ_{mol} [10^{-2} $cm^{-3}mol^{-1}$]	$\chi^{corr}mol$ [10^{-2} $cm^{-3}mol^{-1}$]	μ_{eff} [μ_B]

[**23**]PPh_4	1.225	1.298	5.51

It is known that the Fe^{III} ion in salene complexes can be low-spin [e.g. (salene)$Fe(CN)_2$] or high-spin [e.g. (salene)-Fe(imidazole)$_2$][20] and that the dimeric (salene)Fe−X complexes represented by **B** show antiferromagnetic coupling between the two high-spin Fe^{III} ions, amounting, for instance, to $J = -8\ cm^{-1}$ for our reference complex **1a**.[19] Thus, there existed the possibility that the cyanometal "ligands" employed here would induce low-spin behavior or stronger magnetic coupling within the $Fe_2(salene)_2$ cores, as we have observed before for $[Fe_4S_4]^{2+}$ cores ligated by cyanometal units.[21]

As Table 4 shows, all magnetic moments are lower than the spin-only value of 5.92 μ_B for high-spin d^5. For the trinuclear 1:2 complexes this cannot be explained by antiferromagnetic coupling. It is possibly an expression of spin crossover, i. e. the presence of small amounts of low-spin species. Such an equilibrium of high-spin and low-spin Fe^{III} complexes was deduced for [(**L2**)Fe(imidazole)$_2$]BPh_4.[20] Irrespective of this it is evident that the cyanometal "ligands" are not strong enough to induce a real low-spin situation.

The lowering of the magnetic moments for the 1:1 complexes points to antiferromagnetic coupling within the $Fe_2(salene)_2$ units with the same order of magnitude as previously observed for the (salene)Fe−X dimers.[9,12,19,20] Thereby it is another indication that all complexes **13**−**17** exist as tetranuclear dimers in the solid state with structures comparable to that of **13a**. Complex **12**, which has a typically higher magnetic moment close to that of the spin-only value, underlines this, being the only monomeric 1:1 complex in the solid state due to its aqua ligand. Thus a consistent qualitative description of the magnetic properties can be achieved with the room temperature data, while a more detailed description would require low-temperature measurements.

Conclusions

The combination of (salene)Fe^{III} fragments with cyanometal units has yielded three types of arrangements: dinuclear 1:1 complexes, dimers thereof as tetranuclear 2:2 complexes, and linear trinuclear 1:2 complexes. The constitution of the tetranuclear species, which exist only in the solid state, was confirmed by a structure determination, by the IR data and the magnetic measurements. Their existence as dinuclear species in solution was deduced from the electrochemical and IR data and by reference to the structure determination of a related complex. The identity of the trinuclear species in the solid state and in solution was ascertained by the electrochemical, spectroscopic and magnetic measurements, again in combination with a crystal structure analysis.

The electronic interactions between the metal atoms across the cyanide bridges were evaluated by cyclic voltammetry and UV/Vis spectroscopy. The electrochemical measurements revealed a strong interaction between the terminal metal atoms in the linear trinuclear M−CN−Fe−NC−M arrays, the electronic spectra showed an optically induced metal−metal charge transfer from the terminal M^{II} centers to the (salene)Fe^{III} center. The electronic situation and the energy of the MMCT make the complex [(salene)Fe^{III}−NC−Fe^{II}(dppe)Cp]$^+$ (**13**) the simplest molecular analog of Prussian Blue.

In comparison to the di- and trinuclear systems previously reported by us, which were mostly organometallic complexes,[1,2,4] the compounds described here show four characteristic features: (1) They have a compositional (and structural) variability that can only partly be controlled by the synthetic approach. (2) They are labile with respect to the orientation of the CN bridge, resulting in the accessibility of only one of the two orientational isomers. (3) They show an unusually large separation of the two redox waves for the two outer, chemically equivalent, M′ units, indicating a strong electronic interaction between them. (4) They are paramagnetic and of high spin, opening the possibility to study magnetic interactions.

Experimental Section

The general working conditions, the synthesis of the organometallic reagents and the details of the measurement procedures are listed in ref.[1] Complexes **1a**, **1b**, **2a** and **2b** were prepared according to ref.[9] Magnetic susceptibilities were measured with an MSB Auto Balance, which was calibrated with $K_3[Fe(CN)_6]$. Analytical data for the new complexes are given in Table 5.

[12]PF_6: 0.500 g (1.20 mmol) of **1b** and 0.858 g (1.20 mmol) of **5** in 50 mL of methanol were heated to 50°C for 2 h and then filtered hot. After addition of 0.195 g (1.20 mmol) of NH_4PF_6, the mixture was stirred at 50°C for 30 min and again filtered hot. The filtrate was kept in an open beaker until about half of the solvent had evaporated. The precipitate was filtered off, washed with ether and dried in a stream of nitrogen to yield 487 mg (30%) of [**12**]PF_6 as black crystals, m.p. 230°C (dec.).

[12]SbF_6: This compound was obtained in the same way from 0.500 g (1.20 mmol) of **1b**, 0.858 g (1.20 mmol) of **5** and 0.310 g (1.20 mmol) of $NaSbF_6$. Yield 504 mg (31%) of [**12**]SbF_6 as black crystals, m.p. 230°C (dec.).

[13a]ClO_4: 104 mg (0.29 mmol) of **1a** and 159 mg (0.29 mmol) of **4** in 50 mL of methanol were stirred at 50°C for 2 h, filtered hot, treated with 31 mg (0.29 mmol) of $LiClO_4$, stirred at 50°C for 30 min and filtered hot. Slow cooling to room temperature (12 h) led to the precipitation of 126 mg (45%) of [**13a**]ClO_4 as black crystals, m.p. 220°C (dec.), which were washed with ether and dried in a stream of nitrogen.

[13a]PF_6: This compound was obtained in the same way from 204 mg (0.57 mmol) of **1a**, 311 mg (0.57 mmol) of **4** and 93 mg (0.57 mmol) of NH_4PF_6. Yield 192 mg (33%) of [**13a**]PF_6, black crystals, m.p. 220°C (dec.).

[13a]BPh_4: This compound was obtained in the same way from 212 mg (0.59 mmol) of **1a**, 324 mg (0.59 mmol) of **4** and 203 mg (0.59 mmol) of $NaBPh_4$. Yield 312 mg (44%) of [**13a**]BPh_4, black crystals, m.p. 180°C (dec.).

[13a]SbF_6: This compound was obtained in the same way from 195 mg (0.55 mmol) of **1a**, 298 mg (0.55 mmol) of **4** and 141 mg (0.55 mmol) of $NaSbF_6$. Yield 235 mg (39%) of [**13a**]SbF_6, black crystals, m.p. 225°C (dec.).

[13b]PF_6: This compound was prepared in the same way as [**12**]PF_6 from 152 mg (0.36 mmol) of **1b**, 199 mg (0.36 mmol) of **4** and 59 mg (0.36 mmol) of NH_4PF_6 in 70 mL of methanol. Yield 103 mg (26%) of [**13b**]PF_6 as black crystals, m.p. 200°C (dec.).

[13b]SbF_6: This compound was prepared in the same way as described above, from 107 mg (0.26 mmol) of **1b**, 140 mg (0.26 mmol) of **4** and 66 mg (0.26 mmol) of $NaSbF_6$. Yield 89 mg (30%) of [**13b**]SbF_6 as black crystals, m.p. 190°C (dec.).

[14]ClO_4: This compound was prepared in the same way as [**12**]PF_6, from 113 mg (0.32 mmol) of **1a**, 226 mg (0.32 mmol) of **5** and 34 mg (0.32 mmol) of $LiClO_4$. Yield 153 mg (42%) of [**14**]ClO_4, black crystals, m.p. 230°C (dec.).

[14]PF_6: This compound was prepared in the same way as described above, from 154 mg (0.43 mmol) of **1a**, 309 mg (0.43 mmol) of **5** and 35 mg (0.43 mmol) of NH_4PF_6. Yield 253 mg (50%) of [**14**]PF_6, black crystals, m.p. 240°C (dec.).

[14]SbF_6: This compound was prepared in the same way as described above, from 207 mg (0.58 mmol) of **1a**, 415 mg (0.58 mmol) of **5** and 150 mg (0.58 mmol) of $NaSbF_6$. Yield 279 mg (38%) of [**14**]SbF_6, black crystals, m.p. 240°C (dec.).

[14]BPh_4: This compound was prepared in the same way as described above, from 100 mg (0.28 mmol) of **1a**, 200 mg (0.28 mmol) of **5** and 96 mg (0.28 mmol) of $NaBPh_4$. Yield 178 mg (47%) of [**14**]BPh_4, black crystals, m.p. 200°C (dec.).

15: 200 mg (0.56 mmol) of **1a** and 135 mg (0.58 mmol) of **6** in 100 mL of methanol were stirred at 50°C for 2 h. After cooling to room temperature, the mixture was filtered. The precipitate was washed 3 times with 20 mL of cold methanol and then with 20 mL of ether and dried in vacuo, leaving 123 mg (41%) of **15** as a blue-purple powder, m.p. 130°C. − IR (CH_3OH): $\tilde{\nu}$(CO) = 1907 cm^{-1} m, 1934 s, 2053 m.

16: This compound was prepared in the same way as described above, from 296 mg (0.83 mmol) of **1a** and 236 mg (0.83 mmol) of **7**. Yield 164 mg (34%) of **16** as a purple powder, m.p. 140°C. − IR (CH_3OH): $\tilde{\nu}$(CO) = 1910 cm^{-1} m, 1937 s, 2058 m.

17: This compound was prepared in the same way as described above, from 303 mg (0.85 mmol) of **1a** and 316 mg (0.85 mmol) of **8**. Yield 206 mg (36%) of **17** as a red-brown powder, m.p. 145°C. − IR (CH_3OH): $\tilde{\nu}$(CO) = 1902 cm^{-1} m, 1929 s, 2058 m.

[18a]PF_6 from 1a: 149 mg (0.42 mmol) of **1a** and 169 mg (0.83 mmol) of **3** were stirred in 50 mL of methanol at 50°C for 2 h. After a hot filtration, 68 mg (0.42 mmol) of NH_4PF_6 was added and the mixture stirred at 50°C for 30 min. After filtration, the solvent was removed in vacuo, the residue taken up in 30 mL of dichloromethane, the solution filtered and then layered with 60 mL of petroleum ether (b.p. 60−70°C). 161 mg (44%) of [**18a**]PF_6 was separated as brown crystals, m.p. 180°C (dec.), which were filtered off, washed with 20 mL of petroleum ether and dried in a stream of nitrogen. − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2024 cm^{-1} s, 2065 s.

[18a]ClO_4: This compound was prepared in the same way as described above, from 101 mg (0.28 mmol) of **1a**, 115 mg (0.57 mmol) of **3** and 30 mg (0.28 mmol) of $LiClO_4$. Yield 122 mg (52%) of [**18a**]ClO_4, brown crystals, m.p. 180°C (dec.). − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2024 cm^{-1} s, 2065 s.

[18a]SbF_6: This compound was prepared in the same way as described above, from 150 mg (0.42 mmol) of **1a**, 170 mg (0.84 mmol) of **3** and 109 mg (0.42 mmol) of $NaSbF_6$. Yield 167 mg (41%) of [**18a**]SbF_6, brown crystals, m.p. 180°C (dec.). − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2024 cm^{-1} s, 2065 s.

[18a]BPh_4: This compound was prepared in the same way as described above, from 175 mg (0.49 mmol) of **1a**, 199 mg (0.98 mmol) of **3** and 167 mg (0.49 mmol) of $NaBPh_4$. Yield 219 mg (43%) of [**18a**]BPh_4, brown powder, m.p. 165°C (dec.). − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2024 cm^{-1} s, 2065 s.

[18a]PF_6 from 2a: 230 mg (0.56 mmol) of **2a** and 41 mg (1.12 mmol) of **9** in 50 mL of methanol were stirred at room temp. for 12 h. 92 mg (0.56 mmol) of NH_4PF_6 was added, the mixture stirred for another 5 h and then filtered. The filtrate was concentrated to dryness, the residue taken up in 20 mL of dichloromethane, the solution filtered and the filtrate layered with 60 mL of petroleum ether (b.p. 60−70°C). The resulting precipitate consisted of **3** and

[**18a**]PF_6. After three crystallizations from dichloromethane/petroleum ether (1:3), 134 mg (55%) of pure [**18a**]PF_6 was obtained.

[18b]SbF_6 from 1b: This compound was prepared in the same way as described above for [**18a**]PF_6, from 155 mg (0.37 mmol) of **1b**, 151 mg (0.74 mmol) of **3** and 96 mg (0.37 mmol) of $NaSbF_6$. Yield 116 mg (27%) of [**18b**]$SbF_6 \cdot 1.5\ CH_2Cl_2$ as a dark brown powder with m.p. 180°C (dec.). − IR (CH_2Cl_2): $\tilde{\nu}$(CO) = 2014 cm^{-1} s, 2060 s.

[18b]SbF_6 from 2b: This compound was prepared in the same way as described above for [**18a**]PF_6, from 235 mg (0.50 mmol) of **2b**, 396 mg (1.01 mmol) of **9** and 130 mg (0.50 mmol) of $NaSbF_6$. Yield 125 mg (43%) of [**18b**]$SbF_6 \cdot 1.5\ CH_2Cl_2$.

[19a]PF_6: This compound was prepared in the same way as described above for [**18a**]PF_6, from 115 mg (0.28 mmol) of **2a**, 358 mg (0.56 mmol) of **10** and 46 mg (0.28 mmol) of NH_4PF_6. Yield 74 mg (33%) of [**19a**]$PF_6 \cdot 2\ CH_3OH$ as black crystals with m.p. 180°C (dec.).

[19b]SbF_6: This compound was prepared in the same way as described above for [**18a**]PF_6, from 225 mg (0.48 mmol) of **2b**, 614 mg (0.96 mmol) of **10** and 124 mg (0.48 mmol) of $NaSbF_6$. The recrystallization procedure yielded 50 mg (15%) of [**19b**]SbF_6 as a black powder that contained ca. 10% of impurities.

[20a]PF_6 from 1a: This compound was prepared in the same way as described above for [**12**]PF_6, from 100 mg (0.28 mmol) of **1a**, 401 mg (0.56 mmol) of **5** and 46 mg (0.28 mmol) of NH_4PF_6. Yield 84 mg (15%) of [**20a**]$PF_6 \cdot 1.5\ CH_3OH$ as black crystals of m.p. 190°C (dec.).

[20a]SbF_6: This compound was prepared in the same way as described above, from 150 mg (0.42 mmol) of **1a**, 601 mg (0.84 mmol) of **5** and 109 mg (0.42 mmol) of $NaSbF_6$. Yield 125 mg (15%) of [**20a**]$SbF_6 \cdot 1.5\ CH_3OH$, black crystals, m.p. 190°C (dec.).

[20a]PF_6 from 2a: 230 mg (0.56 mmol) of **2a** and 813 mg (1.12 mmol) of **11** in 50 mL of methanol were stirred at room temp. for 12 h. 92 mg (0.56 mmol) of NH_4PF_6 was added and the mixture stirred for another 5 h. After filtration, the filtrate was kept in a refrigerator, which led to the precipitation of a small amount of [**14**]PF_6. Slow concentration of the remaining solution yielded 135 mg (25%) of [**20a**]$PF_6 \cdot 1.5\ CH_3OH$, which was filtered off, washed with 20 mL of ether and dried in a stream of nitrogen.

[20b]SbF_6: This compound was prepared in the same way as described above for [**18a**]PF_6, from 225 mg (0.48 mmol) of **2b**, 696 mg (0.96 mmol) of **11** and 124 mg (0.48 mmol) of $NaSbF_6$. Yield 75 mg (14%) of crude [**20b**]SbF_6 as a black powder that contained ca. 15% of impurities.

[21]PPh_4: 200 mg (0.56 mmol) of **1a**, 271 mg (1.13 mmol) of **6** and 50 mL of methanol were stirred at 50°C for 2 h. After cooling to room temperature, the precipitate of **15** was filtered off. The filtrate was treated with 211 mg (0.56 mmol) of PPh_4Cl and stirred for 30 min at 50°C. After filtration, the solution was concentrated to dryness, the residue taken up in 20 mL of dichloromethane and layered with 50 mL of petroleum ether (b.p. 60−70°C). Within a few days, 135 mg (22%) of [**21**]PPh_4 had precipitated as dark purple needles, m.p. 135°C (dec.), which were filtered off, washed with 20 mL of petroleum ether and dried in a stream of nitrogen. − IR (CH_3OH): $\tilde{\nu}$(CO) = 1905 cm^{-1} m, 1935 s, 2058 m.

[22]PPh_4: This compound was prepared in the same way as described above for [**21**]PPh_4, from 200 mg (0.56 mmol) of **1a**, 319 mg (1.12 mmol) of **7** and 210 mg (0.56 mmol) of PPh_4Cl. Yield 175 mg (26%) of [**12**]PPh_4, red-brown needles, m.p. 150°C (dec.). − IR (CH_3OH): $\tilde{\nu}$(CO) = 1910 cm^{-1} m, 1938 s, 2059 m.

[23]PPh_4: This compound was prepared in the same way as described above for [**21**]PPh_4, from 200 mg (0.56 mmol) of **1a**, 417 mg (1.12 mmol) of **8** and 210 mg (0.56 mmol) of PPh_4Cl. Yield 163 mg (21%) of [**23**]PPh_4, brown powder, m.p. 140°C (dec.). − IR (CH_3OH): $\tilde{\nu}$(CO) = 1904 cm^{-1} m, 1930 s, 2057 m.

Structure Determinations:[22] The crystals were obtained directly from the reaction solutions. Diffraction data were recorded at room

temperature using the ω/2θ technique with a Nonius CAD4 diffractometer fitted with a molybdenum tube (K, $\lambda = 0.7107$ Å) and a graphite monochromator. Empirical absorption corrections based on ψ scans were applied. The structures were solved with direct methods and refined anisotropically with the SHELX program suite.[23] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.2 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]\}^{1/2}$. Drawings were produced with SCHAKAL.[24] Table 6 lists the crystallographic data.

Kinetics and Mechanism of the Outer-Sphere Oxidation of Horse-Heart Cytochrome *c* by an Anionic Chromium(v) Complex – Kinetic Evidence for Precursor Formation and a Late Electron-Transfer Transition State

Manuela Körner[a] and Rudi van Eldik*[a]

Keywords: Cytochrome *c* / Chromium(v) / Saturation kinetics / Separation of K and k_{ET} / Volume profile / Kinetics

The irreversible outer-sphere electron-transfer reaction between *trans*-bis(2-ethyl-2-hydroxybutanoato(2–))oxochromate(v) and cytochrome c^{II} was investigated as a function of pH, concentration, temperature and pressure. The plot of the observed pseudo-first order rate constant as a function of the Cr^{V} concentration shows a clear trend towards saturation at higher Cr^{V} concentrations, from which the precursor formation constant and the electron-transfer rate constant could be separated (K = 37 ± 5 M^{-1} and k_{ET} = 1510 ± 180 s^{-1} at pH 4.8 and 279 K). In the low Cr^{V} concentration range the second-order electron-transfer rate contants were measured as a function of temperature (ΔH^{+} = 20.9 ± 0.6 kJ mol^{-1}; ΔS^{+} = –79.9 ± 2.1 J K^{-1} mol^{-1}; ΔG^{+} (279 K) = 43.2 kJ mol^{-1}). High-pressure experiments were performed at two different pH values. The kinetic (stopped-flow) and thermodynamic (electrochemical) measurements as a function of pressure enabled the construction of a volume profile for the system at 279 K. The activation volumes for the redox process are –9.2 ± 0.2 (pH 5.0) and –11.1 ± 0.8 cm^3 mol^{-1} (pH 4.7), and the overall reaction volumes were estimated to be –7 ± 2 (pH 5.0) and –10 ± 2 cm^3 mol^{-1} (pH 4.7) . The transition state of the redox reaction lies to a large extent on the product side and can be described as "late". The results are discussed in comparison to earlier measurements using cobalt and ruthenium complexes as reaction partners for cytochrome *c*.

Introduction

Cytochrome *c* typically undergoes outer-sphere electron-transfer reactions with metal complexes such as $Co(phen)_3^{2+/3-}$, $Co(terpy)_2^{2+/3+}$, or $Ru(NH_3)_5py^{2+/3+}$ (phen = 1,10-phenanthroline; terpy = 2,2′:6′,2′′-terpyridine).[1–3] This type of mechanism includes the formation of an outer-sphere precursor complex as a result of electrostatic interactions (Equation 1), a subsequent rate-determining electron-transfer step k_{ET} (Equation 2), and the dissociation of the successor complex to the final redox products (Equation 3).

Under pseudo-first-order conditions, i.e. at least a 10-fold excess of one of the reactants (viz. Red), and under the condition that the reaction proceeds to completion, this general mechanism leads to the rate law given by Equation 4.

For most systems K[Red] << 1, since the reactants are of similar charge, such that K is very small. Under these circumstances, the measured second-order rate constants represent $K \cdot k_{ET}$. If K[Red] >> 1, then the observed rate constants become independent of the [Red] at high concentrations of Red and the limiting rate constant k_{ET} is reached. In the case of highly negatively charged $Fe(CN)_6^{4-/3-}$ ions, saturation kinetics for the reaction with cytochrome were reported.[4] However, in later work it was demonstrated that the interpretation of the observed saturation kinetics was complicated by the fact that the reaction is reversible.[5] This led to a significant intercept in the plots of k_{obs} versus concentration, such that the saturation in k_{obs} at high concentrations could not be observed anymore.

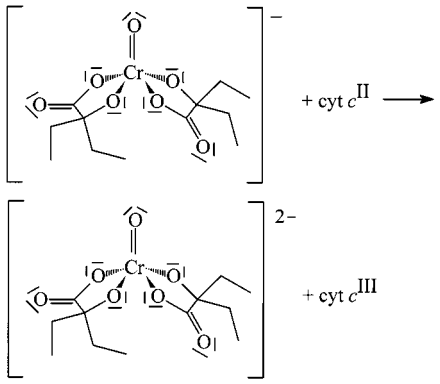
$$Ox + Red \underset{}{\overset{K}{\rightleftharpoons}} Ox/Red \quad (1)$$

$$Ox/Red \xrightarrow{k_{ET}} Ox^{-}/Red^{+} \quad (2)$$

$$Ox^{-}/Red^{+} \overset{K_{Diss}}{\rightleftharpoons} Ox^{-} + Red^{+} \quad (3)$$

$$k_{obs} = \frac{K \cdot k_{ET}[Red]}{1 + K[Red]} \quad (4)$$

In principle, it should be possible to tune the extent of precursor formation by selecting reactants of high and opposite charge. This has been attempted in a number of cases,[5–7] but to our knowledge real rate saturation has only been found in studies of the reduction of cytochrome *c* by chromous ion and dithionite.[8][9] In all other cases, the observed second-order rate constant for the outer-sphere mechanism represents the product $K \cdot k_{ET}$, and values of K and k_{ET} can only be separated by using a theoretical approach. With the aid of the Fuoss Equation,[10][11] a precursor formation constant of 3 M^{-1} for the reaction of cytochrome *c* with positively charged metal complexes such as $Ru(NH_3)_5py^{2+/3+}$, and a value of 200 M^{-1} for the reaction with $Fe(CN)_6^{4-/3-}$ was calculated.



In our earlier work we have studied the outer-sphere electron-transfer reactions between cytochrome *c* and complexes of the type $Ru(NH_3)_5X^{2+/3+}$ (X = ammonia, pyridine, 4-ethyl-pyridine, isonicotinamide and 3,5-lutidine), as well as a series of chelated Co(II/III) diimine complexes.[12–14] In these systems precursor formation was so weak that K and k_{ET} could not be separated kinetically.

However, the driving force of these reactions was so low that the kinetics of these redox reactions could be studied in both directions. This enabled us to construct volume profiles from high-pressure kinetic and thermodynamic data for the reversible electron-transfer processes, from which information on the location of the transition state in terms of volume changes along the reaction coordinate could be obtained. The volume profiles turned out to be highly symmetrical with the transition state located approximately halfway between the reactant and product states. The overall volume changes could be shown to be mainly due to intrinsic and solvational volume changes on the redox partner of cytochrome *c*, since cytochrome *c* itself undergoes almost no volume change during the electron-transfer process.[15]

In the present study we have selected an anionic Cr(v) complex, *trans*-bis(2-ethyl-2-hydroxybutanoato(2−))oxochromate(v), as the redox partner for cytochrome *c*. This complex has several negatively charged donor centers that could interact in a specific way with the positive charges on the surface of cytochrome *c* in order to enhance precursor formation. In solution, Cr^{V} species are often intermediates in Cr^{vi} oxidations of organic and biological substrates, e.g. they react rapidly with DNA. There is evidence for implicating Cr^{V} species as carcinogens in biosystems featering interactions of ribonucleotides with added chromate.[16−19] The isolation of relatively stable Cr^{V} complexes enabled detailed studies into the structures and chemistry of Cr(v).[20−23] Cr^{IV} has an even more rare oxidation state. In aqueous media alkoxo and porphyrinato complexes of Cr^{IV} are generally unstable, while diperoxo triamines $[Cr^{IV}(O_2)_2(NR_3)_3]$ are stable in water for several hours in acidic media.[24−26] To stabilize the complex used in this study in aqueous solution, the ligand 2-ethyl-2-hydroxybutyric acid was used in excess.[27] The overall redox reaction is given in Scheme 1.

Scheme 1. Reaction between *trans*-bis(2-ethyl-2-hydroxybutanoato(2−))oxochromate(V) and horse heart cytochrome c^{II}

Higher-valent metallo-oxoporphyrins of iron, manganese and chromium are essential for understanding the mechanisms of enzymatic pathways, e.g. dealing with the oxidation of metalloporphyrins by hydroperoxides in aqueous solution, and with the alkene epoxidation by higher-valent metallo-oxoporphyrins.[28] The driving force for studying metalloporphyrin-catalyzed reactions is to develop synthetic species which are able to reproduce and mimick the different heme enzyme-mediated reactions like oxygenation, oxidation, oxidative chlorination, and dismutation.[29] The result of ligand-exchange chemistry in water[30][31] and with quinic acid in methanol[32] showed that 2-hydroxy acids are preferred strongly to 1,2-diols for binding to Cr^{V}. Since 2-hydroxy acids, such as citrate and lactate, are present in cells, they may bind to the Cr^{V} that is produced intracellularly by reduction of carcinogenic Cr^{VI}. They even may show preference for binding to Cr^{V}, with respect to 1,2-diol ligands, such as ascorbate, sugars and their derivatives. The biologically relevant analogues to *trans*-bis(2-ethyl-2-hydroxybutanoato(2−))oxochromate(v) are likely to be one type of the Cr^{V} species present in the cells that are transformed genetically by exposure to Cr^{VI}. This justifies the need to study the reactions of well-characterized model 2-hydroxy acid complexes with DNA.[18][20]

Indeed the outer-sphere interaction of the redox partners turned out to be significant and could be accounted for theoretically. In addition, the volume profile constructed for the electron-transfer process clearly reveals a nonsymmetrical nature with respect to the location of the transition state, from which it can be concluded that the process is characterized by a "late" (product-like) transition state. This can be accounted for in terms of the effective precursor complex-formation found for the present system, as compared to the absence of such precursor formation in the case of the ruthenium and cobalt complexes studied before.[12−14]

Results

Kinetic Studies

The redox reaction was studied under pseudo-first order conditions. The cytochrome concentration was throughout 0.025 mM and the chromium complex in at least a 10-fold excess. A typical absorbance-time trace is shown in Figure 1.

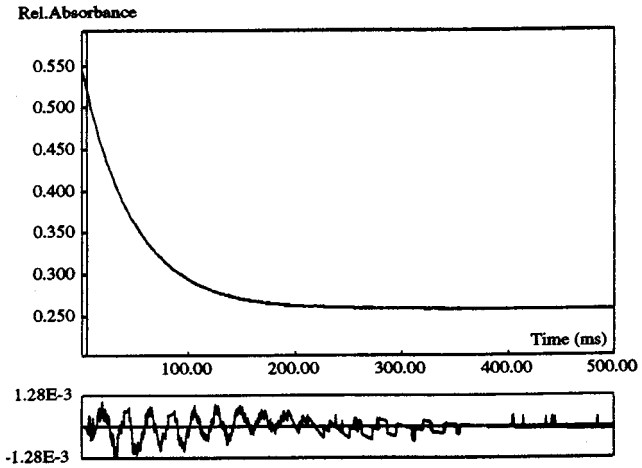

Figure 1. Typical absorbance-time trace fitted with one-exponential decay (k_{obs} = 20.9 ± 0.009 s^{-1}) for [Cr^{V}] = 0.30 mM, pH = 4.8, [L] = 0.0054 M, T = 15°C, λ = 550 nm

Aqueous acetate buffer solutions in the pH range 3.9 to 5.2 were used for the pH-dependence study reported in

Table 1. Between pH 4.6 and 5.0 the rate remains constant, whereas at pH 4.3 the reaction is accelerated by a factor of 1.5. The concentration dependence (Figure 2) was investigated at pH 4.8, and up to a 400-fold excess of Cr^V was used. In order to guarantee the stability of the chromium complex an excess of free ligand was added to the reaction medium. The free ligand concentration was increased even more in another experiment (Figure 2) to check whether there might be some aquation of the chromium complex accompanied by direct binding to cytochrome. These measured points did not differ at all from the former experiments and therefore an inner-sphere mechanism can be excluded.

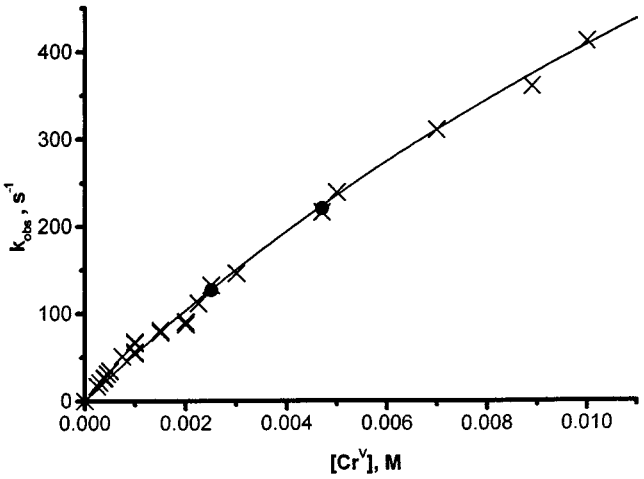

Figure 2. Observed pseudo-first-order rate constant as a function of chromium complex concentration; (×) measured data, except for the one-fold weighted point (0; 0); conditions: pH 4.8; [HAc] = 0.12 M, [KAc] = 0.20 M, [L] = 0.0054 M, $[LiNO_3]_{max}$ = 0.40 M, I = 0.6 M; 15°C; curve results from the best fit based on the kinetic saturation model, Equation 4; influence of increased free ligand concentration on the rate constant was checked (•) (personal suggestion by P. A. Lay to ensure an outer sphere mechanism and to exclude possible direct binding of the chromium complex to cytochrome); conditions: pH 4.8; [HAc] = 0.12 M, [KAc] = 0.20 M, [L] = 0.10 M, $[LiNO_3]_{max}$ = 0.30 M, I = 0.6 M; 15°C

The observed rate constants clearly show a trend toward saturation at higher Cr^V concentrations. A nonlinear least-square fit of the data according to Equation (4) resulted in $K = 37 \pm 5\ M^{-1}$ and $k_{ET} = 1510 \pm 170\ s^{-1}$ at 288 K. The temperature dependence of the reaction was studied at very low Cr^V concentration, i.e. where a linear correlation between k_{obs} and Cr^V concentration exists. The Eyring plot for the second-order rate constants is given in Figure 3, and the calculated activation parameters are $\Delta H^{\neq} = 20.9 \pm 0.1$ kJ mol^{-1} and $\Delta S^{\neq} = -79.9 \pm 0.2$ J K^{-1} mol^{-1}. All ambient pressure measurements were performed in acetate buffer mostly at pH 4.8.

Measurements at elevated pressure (up to 150 MPa) were performed at two pH values, above and below pH 4.8, in order to check the possible influence of a shift to lower pH values at higher pressure caused by an increase in the dissociation constant of acetic acid with increasing pressure.[45] As a result the pH is not constant during a pressure run. The plots of $\ln k_{obs}$ versus pressure are shown in Figure 4, from which it follows that $\Delta V^{\neq} = -9.2 \pm 0.6$ and -11.1 ± 0.8 cm^3 mol^{-1} at 279 K and pH 5.0 and 4.7, respectively. The more negative number at the lower pH is consistent with our observation mentioned above that the reaction is accelerated in more acidic solutions, as a result of the increased acid strength of the buffer at elevated pressures.

Cytochrome $c^{II/III}$ exhibits a much smaller pressure dependence, and a reaction volume of $+5$ cm^3 mol^{-1} was estimated.[15] Therefore, the observed volume of activation mainly results from volume changes on the chromium complex when it changes its overall charge from -1 to -2 during the reduction by cytochrome c^{II}. This is also demonstrated by the significantly negative activation entropy, which is in line with a significant increase in electrostriction during the electron-transfer process.

Electrochemical Studies

pressures up to 165 MPa, experiments with CV and DPV were performed. Both techniques are in general comp-

lementary, but DPV showed more reproducible data in the present case.[46,47,48] Figure 5 reports the recorded DPVs as a function of pressure.

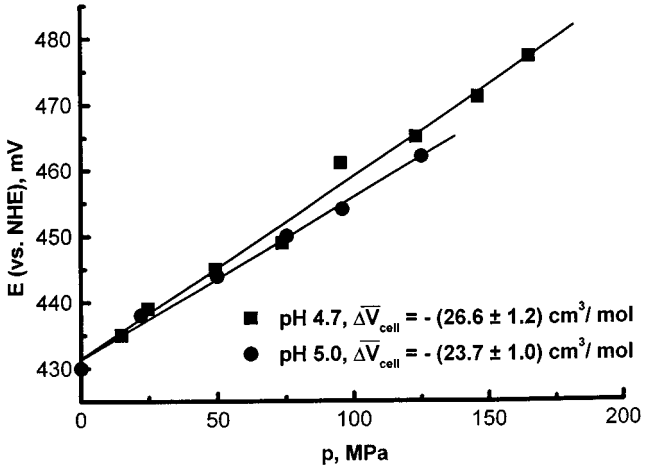

Figure 6. Plot of the redox potential for the $Cr^{V/IV}$ system at pH 5.0 and 4.7 as a function of pressure

The change in redox potential with increasing pressure is moderate, as expected for an overall charge increase from −1 to −2. The volume change associated with the overall cell reaction was estimated from the plot of the measured redox potential as a function of pressure (Figure 6). The measured $E_{1/2}$ value for the redox couple at ambient pressure is in good agreement with data reported by other authors.[49−51] The reaction volume associated with the $Cr^{V/IV}$ redox couple can now be calculated from the cell reaction volume by substracting the volume contribution of the reference electrode $Ag/AgNO_3$ which was shown to be −11.9 ± 0.5 $cm^3\ mol^{-1}$.[52] The resulting reaction volumes are −11.8 ± 0.5 (pH 5.0) and −14.7 ± 0.7 $cm^3\ mol^{-1}$ (pH 4.7), and reflect the overall volume changes arising from the reduction of Cr^V to Cr^{IV}, as well as that caused by a change in the overall charge from −1 to −2. The solvational effects in terms of a significant increase in electrostriction obviously overrule the intrinsic volume changes in order to account for the overall negative reaction volumes.

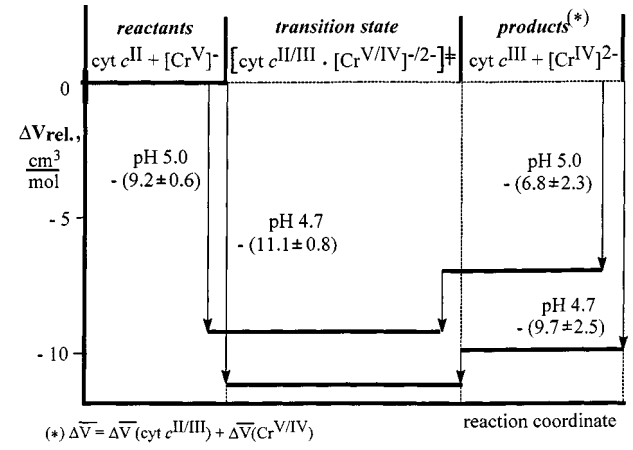

Figure 7. Volume profile for the irreversible reaction of cytochrome c^{II} with *trans*-bis(2-ethyl-2-hydroxybutanoato(2−))oxochromate(V)

The employed complex $[O{=}Cr^V(Lig)_2]^-$ was crystallographically characterized as a five-coordinate oxo compound with a distorted trigonal-bipyramidal geometry.[53] At pH 2.5 to 4.0 in the presence of ligand and buffer, Cr^{IV} solutions suffer perceptible loss within a few minutes due to disproportionation, $2Cr^{IV} \rightarrow Cr^{III} + Cr^V$, and reduction by the parent ligand, $2Cr^{IV}\ Et_2C(OH)COO^- \rightarrow 2Cr^{III} + Et_2C{=}O + CO_2 + H^+$.[25][38] Electrochemical studies have shown that major structural rearrangement follows the electron-transfer process in the Cr^{IV}/Cr^{III} system, but not in the Cr^V/Cr^{IV} couple.[51] The suggestion that a third ligand will enter the coordination sphere at the vacant site on Cr^V was disgarded later on.[35] The formation of six-coordinate forms is much less likely for complexes with the more bulky ligands. The Cr^V complex has a distorted trigonal-bipyramidal geometry, whereas the Cr^{IV} complexes are likely to remain as five-coordinate oxo complexes, like their Cr^V/Cr^V analogues. There is no evidence for Cr^V complexes containing three chelate ligands and such complexes are not expected to form for steric reasons. The redox potential for $Cr^{IV/III}$ is more positive, which means that it is a stronger oxidizing agent than $Cr^{V/IV}$. The quasi-reversible one-electron redox process (corresponding to $Cr^V + e^- \rightleftharpoons Cr^{IV}$) can only be observed at the electrode surface because there is a lack of conversion of Cr^{IV} to Cr^{III} due to an extremely slow electrokinetic process for the reduction of the Cr^{IV} intermediates.[24] Cr^{IV} exists mainly in the form of bis-chelated complexes. The stability of Cr^{IV} complexes exhibits a bell-shaped pH dependence. The region of maximum stability and the corresponding half-life ($[Cr^{IV}]_0$ = 0.1 mM; 25°C) is 30 min at pH ≈ 3. Half-lives were determined from the absorbance changes at 550 nm, where the absorbances of Cr^{III} and Cr^V complexes were negligible in comparison with that of Cr^{IV}.[25] The important difference in the chemical properties of Cr^{IV} and Cr^V is that 2-hydroxy carboxylates are much poorer ligands for Cr^{IV} than for Cr^V. This is probably the result of the lower acidity of the ROH groups bound to Cr^{IV}. Thus, the ROH groups remain largely protonated at pH 2 to 4, whereas those of the corresponding Cr^V complexes are fully deprotonated under these conditions.[25]

Saturation Kinetics

In order to account for the experimentally observed rate constants as a function of the Cr^V concentration, the Fuoss theory was applied.[10] The reaction conditions are water as solvent at 279 K and 0.6 M ionic strength. Even at high ionic strength, the acetate shows no specific binding ability for cytochrome.[74] This should be the same for the ligand, which is added in excess in order to stabilize the complex and is very similar in structure. In addition, the number of protein-bound nitrates, two in the reduced and one in the oxidized form, is independent of the anion concentration.[74] The adopted permittivity leads to a reciprocal Debye-Hückel radius of 2.52 nm.[54] There are three possible positions for negative charges on the Cr^V complex,

viz. the oxo group, the ring carboxylate oxygen, and the carboxylate oxygen, which are all exposed to solvent water. The ring hydroxo group is sterically hindered by the bulky ethyl groups. For the evaluation of the contact radius for the chromium complex, the X-ray structure and different van der Waals radii for oxygen are available.[55,56−58] The contact radius for cytochrome *c* was estimated to be 1.66 nm.[59] A combination of these values result in a contact distance in the range between 1.82 and 2.21 nm. The outer-sphere preequilibrium constant *K* and the associated rate constant k_{ET} were now calculated by varying the possible ionic charge on the cytochrome center. Since the chromium reactant carries an overall charge of −1, and the enzyme has a net charge of +6.5,[59] the product of the ionic charges can adapt theoretical values between −1 and −6.5, depending on to what extent charge is neutralized by the presence of counter ions and local charge effects influence the electron-transfer process. Both *K* and k_{ET} increase more on increasing the contact radius of the chromium complex than on changing the effective ionic charge. On the basis of a 75% agreement between the values calculated with the Fuoss Equation and those obtained in the kinetic measurements, the product of the ionic charges should be at least 1.5 for Cr...C=O, 6.5 for Cr−O and 7.0 for Cr=O. However, the following aspects should also be considered: electrostatic interactions in the precursor complex are assigned to a larger extent to charge localized at the haem crevice than to the sum of all charges;[60][61] lysine 13, 72, 86 and Histidin 33 (at pH values below its pK_a of 6.4) show kinetic relevance for anionic redox partners and a local charge of +3 to +4 on the cytochrome surface was estimated from kinetic measurements as a function of ionic strength.[62−66] Based on this information, conclusions can be reached with respect to the three possible contact radii. The most probable position for charge localization on the chromium complex is the Cr...C=O group, which is more likely than the Cr−O group and in turn much better than the Cr=O position. This is in agreement with some classical explanations.[67] In summary, the results from the kinetic studies are consistent with predictions on the basis of the Fuoss postulations.

The thermal and pressure activation parameters were determined at low Cr^{V} concentrations due to the time resolution of the kinetic equipment, with the result that the observed second-order rate constant is a composite function and represents $K{\cdot}k_{ET}$. The observed entropy and volume of activation are both significantly negative and indicate a highly-structured transition state. More mechanistic insight can be gained from an analysis of the volume profile for the overall process.

Volume Profile

The molar volume change associated with the redox couple cytochrome $c^{II/III}$ was estimated to be +(5.0 ± 0.8) cm^3 mol^{-1}.[15] This value indicates that there is a slight increase in the partial molar volume of cytochrome c^{II} during the oxidation process, even though the overall charge increases from +6.5 to +7.5, which is expected to cause a solvational volume collapse due to an increase in electrostriction. A number of reports in the literature report a more compact structure for the reduced protein as compared to cytochrome c^{III}.[59,68−71] However, the increase in the size of the protein results in the partial accommodation of water molecules from the bulk in the protein framework. A small overall volume increase is therefore obtained.[65] It is assumed that the volume change on cytochrome *c* is the same at pH 5 and 7. Cytochrome does not show any pH dependence in this pH range; deviations only occur at pH ≥ 8.0.[6,12,73] In order to calculate the overall reaction volume, the contribution arising from the $Cr^{V/IV}$ complex has to be added (see Figure 7). We found that a significant volume collapse accompanies this reduction process (see electrochemical studies).

Detailed electrochemical measurements as a function of pressure resulted in a good correlation between the volume changes associated with changes in electrostriction and the change in the overall charge on the complex.[52] As a useful working rule the electrostrictive volume changes by ca. 4 cm^3 mol^{-1} per unit difference in the square of the charge on the oxidized and reduced forms of the complex. In the present case this difference is 3, from which an electrostritive volume collapse of ca. 12 cm^3 mol^{-1} can be predicted. By way of comparison, the experimental values reported for the couples $Fe(phen)(CN)_4^{1-/2-}$ and $Fe(bpy)(CN)_4^{1-/2-}$ are −13.6 and −13.8 cm^3 mol^{-1}, respectively.[52] From this it follows that the solvational volume changes due to a significant increase in electrostriction, represent the major contribution toward the overall negative reaction volumes found in this study. The oxidation of cytochrome c^{II} by the Cr^{v} oxo species is therefore associated with a moderate overall volume decrease of −7 and −10 cm^3 mol^{-1} (see Figure 7). The location of the transition state can be described as "late" in terms of the overall volume change and is close to the product state. This can at present only be related to the efficient precursor formation occurring in the system.

In contrast, the investigated $Co^{III/II}$ and $Ru^{III/II}$ systems referred to in the Introduction show no kinetic evidence for precursor formation and exhibit very similar volume changes for both the forward and reverse electron-transfer reactions.[12−14] The ruthenium complexes exhibit negligible intrinsic volume changes and therefore mainly solvational effects account for the observed volume changes.[12] In the case of the $Co^{III/II}$ systems, there is a volume increase due to a decrease in solvent electrostriction and an intrinsic contribution.[14] Both these systems involve large volume changes, and the transition state lies almost exactly halfway between the partial molar volumes of the reactants and products in the reported volume profiles. This means that the reorganisation in the transition state is very similar for both the forward and back reactions in the reversible electron-transfer process in the absence of significant precursor formation. The nonsymmetrical nature of the volume profile found in the present study must therefore be related to

the effective formation of a precursor species. A similar situation was recently encountered in the volume profiles for a series of intramolecular electron-transfer reactions of ruthenated cytochrome *c* sytems.[72] In that case different possible explanations for the nonsymmetric appearance of the volume profiles were presented. It is our objective in future work to search for redox systems involving cytochrome *c* that will exhibit an even more efficient precursor formation in order to be able to determine a volume profile for the electron-transfer reaction within the precursor species, i.e. under conditions of saturation kinetics where electron transfer is the rate determining step, something that was not possible in the present study.

Conclusions

The outer-sphere electron-transfer reaction between horse-heart cytochrome *c* and anionic trans-bis(2-ethyl-2-hydroxybutanoato(2−))oxochromate showed a clear trend towards rate saturation, which is rather unusual for cytochrome and its interaction with small reaction partners. The precursor formation constant and the electron-transfer rate constant could be separated kinetically. In order to account for the experimentally observed rate constants as a function of the Cr^V concentration, the Fuoss theory was applied. It revealed additional information that the contact between both reactants occurs most probable with the solvent exposed carboxylate oxygen on chromium. Measured activation and reaction volumes at two pH values enabled the construction of a volume profile for the reaction which differs significantly from the symmetric volume profiles reported for outer-sphere electron-transfer reactions of cobalt and ruthenium complexes. Information regarding the location of the reaction coordinate could be obtained.

Experimental Section

Methods: UV/vis spectra were recorded on either a Hewlett−Packard HP8452 or a Shimadzu UV-2101PC spectrophotometer. − IR spectra were measured in KBr disks on a Mattson Polaris 10410R FT-IR spectrometer. − A Bruker ESP 300E X-band spectrometer operating at about 9.5 GHz was used for recording EPR spectra of solutions contained in a quartz flat cell. EPR spectrometer settings were as follows: central field, 3480 G; sweep width, 100 G; microwave power, 10.1 mW; modulation frequency, 100 kHz; modulation amplitude, 0.974 G; receiver gain, 1.25×10^3; conversion time, 20.48 ms; time constant, 10.24 ms; number of scans, 1; temperature 298 K. − The pH of the solutions was measured on a Metrohm 716 DMS Titrino pH-meter. The kinetic traces for the reduction of cytochrome *c* were recorded at 550 nm. The reactions at ambient pressure were followed using an Applied Photophysics SX-18 MV stopped-flow instruments (Leatherhead, UK), to which an online data acquisition system was connected. The kinetic traces, consisting of 1000 points per trace, were collected, stored and fitted on an Acorn 5000 computer using Applied Photophysics software (Leatherhead, UK). In order to observe the progress of the overall reaction, time resolved spectra were recorded on an Applied Photophysics SX-18 MV stopped-flow instrument (Leatherhead, UK) equipped with a J&M TIDAS 16−500 diode array detector (Aalen, Germany). A homemade high-pressure stopped-flow system was used for the high pressure kinetic measurements.[39][40] The kinetic traces consisting of 1000 points per trace, were collected and stored on an IBM-compatible computer using Biologic (Claix, France) software. The rate constants were calculated using the OLIS KINFIT program (Olis, Bogart, Georgia, USA). All Instruments were thermostated to ± 0.1 °C. The kinetic traces showed exellent first-order behavior over 5 half-lives. − In general, all solutions were prepared under nitrogen to avoid complications with dissolved oxygen. All test solutions were protected from light to avoid photoinduced decomposition.[41] The freshly prepared solutions were transferred into the stopped-flow unit using gastight Optima Graf Fortuna glass syringes (Roth). All experiments were performed in acetate buffer of different pH values. − Electrochemical measurements were performed with an EG&G Princeton Applied Research 263 System; the data were stored and fitted using Model 270/250 Research Electrochemistry Software 4.00. For electrochemical measurements at elevated pressure, a homemade, high-pressure cell similar to that described in the literature[42] and thermostated to ± 0.1 °C, was employed. Prior to use, the glassy carbon electrode surface was polished with an aqueous suspension of 3 micron followed by 1 micron alumina (Alfa) on a polishing cloth, followed by rinsing with distilled water and further cleaning with a dry tissue. The Pt plate auxiliary electrode was cleaned in 5 M aqueous HNO_3, rinsed with distilled water and dried with a tissue. The reference electrode consisted of a Ag wire in 0.01 M $AgNO_3$ and 1.0 M KNO_3 solution. The chromium solutions were filled into the electrochemical cell under nitrogen. Nitrogen was passed through the solution for another few minutes to assure that oxygen is absent. The potassium hexacyanoferrate couple was used as external standard. All Differential Pulse Voltammetric (DPV) measurements were performed under the following conditions: pulse height 25 mV, pulse weight 50 ms, scan rate 2 (pH 5.0) and 4 mV s^{-1} (pH 4.7). Voltammograms were scanned in the negative direction. For all analyses and plots, Excel[43] and Origin[44] software was used except when otherwyise stated.

Caution: Cr^V complexes are mutagenic, cleave DNA rapidly *in vitro*, and are potentially carcinogenic.[18][33] Contact with skin and inhalation must be avoided.

Reagents: Horse-heart cytochrome *c* (type VI, Sigma) was purified and reduced as reported before.[13] The concentrations of the cytochrome solutions were determined by UV/vis spectroscopy. Sodium bis(2-ethyl-2-hydroxybutanoato(2−))oxochromate(V) was synthesized following the method of Krumpolc and Rocek and was recrystallized from acetone-chloroform.[34][35] − Anal. calcd for $C_{12}H_{22}CrNaO_8$: C 39.03; H 6.01; found: C 39.58; H 6.44). − The IR spectra shows $\tilde{\nu}$(Cr=O) (cm^{-1}) = 996 (ref. 998, 1000) and $\tilde{\nu}$(C=O) = 1677 (s) (ref. 1660, 1683).[20,36,37] In the UV/vis range the complex exhibited a maximum at 510 nm with an extinction coefficient of 165 M^1 cm^{-1} in aqueous solution, which is in agreement with literature data.[34][35] The X-band EPR spectra of the sample (ca. 0.002 M) in buffer solution of pH 5.0 shows a single main peak g = 1.984 (^{52}Cr, $I = 0$) with four small lines due to the hyperfine coupling with ^{53}Cr ($I = {}^3/_2$, 9.54% natural abundance; hyperfine coupling constant 18.3 Gauss).[20,35,38] − The following chemicals were used in the preparation of the reaction solutions: 2-ethyl-2-hydroxybutyric acid (99%), potassium acetate (KAc) and acetic acid (HAc) (Aldrich), and lithium nitrate (Fluka). All commercial reagents were of analytical grade and were used without further purification. Solutions of Cr^V were prepared by dissolving the synthesized sodium salt of the complex in the buffer solutions under nitrogen directly before use.

Acknowledgments

Preparation, Characterization, and Properties of Various Novel Ionic Derivatives of Pentacarbonyltungsten

Wolfram Palitzsch,[a] Christian Beyer,[a] Uwe Böhme,*[a] Ben Rittmeister,[a] and Gerhard Roewer[a]

Keywords: Tungsten / Carbonyl complexes / Undecamethylcyclohexasilyl / Transition metal silicon compounds / Anions / Tungsten silicide / Silicon

The complexes $[Li(DIME)_2][W(CO)_5L]$ [L = OCN **2**, NCS **3a**, PPh_2 **4**, $SiMe_2Ph$ **8**, $N(SiMe_3)_2$ **9**, CH_2Ph **10**, Si_6Me_{11} **11**; DIME = diethylene glycol dimethyl ether] have been prepared by reaction of $[Li(DIME)_2][W(CO)_5I]$ (**1**) with KOCN, KSCN, $NaPPh_2$, $LiSiMe_2Ph$, $LiN(SiMe_3)_2$, $PhCH_2MgCl$, and KSi_6Me_{11}, respectively. Photochemical ligand substitution in $W(CO)_6$ has been used as an alternative method for the preparation of pentacarbonyl tungstates; $[K(DIME)_2][W(CO)_5NCS]$ (**3b**), $[Na(DIME)_2][W(CO)_5N_3]$ (**5**), $[Li(DIME)_2][W_2(CO)_{10}(\mu\text{-}H)]$ (**6**), and $[K(DIME)_2][W_2(CO)_{10}(\mu\text{-}CN)]$ (**7**) were synthesized in this manner. The molecular structure of $[Li(DIME)_2][W(CO)_5Si_6Me_{11}]$ (**11**) has been determined by X-ray diffraction analysis. The spectral and chemical properties of **2–11** are discussed. Pyrolysis of **11** leads to tungsten silicide and tungsten carbide.

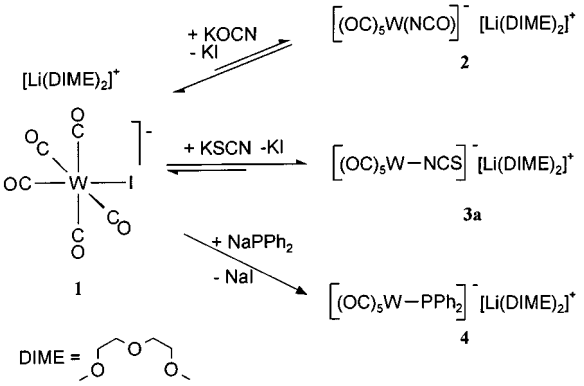
Introduction

For a long time, chemists have been interested in $[M^0(CO)_5X]^-$ anions of the Group VIA elements.[1] The fact that they could easily be prepared from $M(CO)_6$ and $R_4N^+X^-$[2] and their role as starting materials in the synthesis of derivatives of the relevant transition metals attracted considerable attention. In 1963, Abel and co-workers reported the synthesis of pentacarbonylhalometallate anions.[2] They were able to isolate $R_4N^+[M(CO)_5X]^-$ species from reactions of tetraalkylammonium halides with metal hexacarbonyls, but the products were characterized only by infrared spectroscopy. The authors indicated that the goal of isolating and purifying these compounds was frustrated by decomposition. In a recent communication, we described a cation design that should offer improved thermal stability.[3]

Because transition metal silicon compounds are useful precursors for metal silicides, the design of suitable compounds fulfilling this role is very important.[4] The chemistry of ionic transition metal silyl derivatives remains largely unexplored. Only a few compounds of this type derived from monosilanes have been reported.[5]

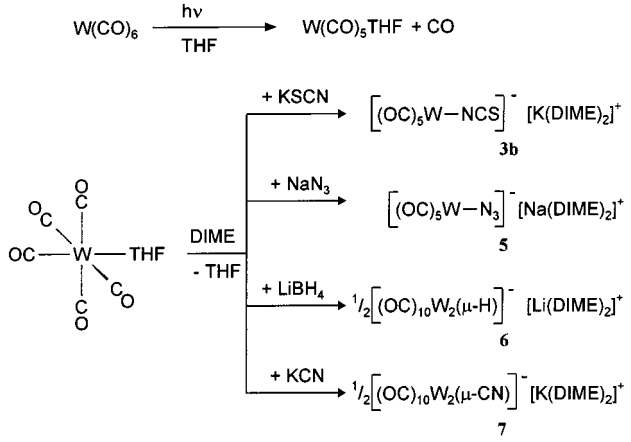
In our laboratory, compounds of the type $[Li(DIME)_2][M(CO)_5I]$ [M = W (**1**), Mo] have been synthesized with a modification of the method described by Abel and co-workers. It is very easy to substitute the iodine while retaining the d^6-character of the tungsten, and hence the $[W(CO)_5I]^-$ anion represents an interesting and versatile building block. Silyllithium or Grignard reagents react with complexes such as the $[W(CO)_5I]^-$ anion. In the present work, we describe the preparation and properties of new compounds including pseudohalide derivatives in order to further development in this field.

Accordingly, we decided to introduce the Si_6Me_{11} group into this anionic complex of tungsten. Some transition metal compounds of undecamethylcyclohexasilane have been described in the last few years,[6] but as far as we are aware, only one X-ray structure analysis of a cyclohexasilyl transition metal compound has hitherto been published.[7] We report herein on the synthesis and characterization of $[Li(DIME)_2][W(CO)_5Si_6Me_{11}]$ (**11**), for which single-crystal structural data could be obtained.



Among the transition metal silicides, those of tungsten offer excellent oxidation resistance. Consequently, they are being considered as potential high-temperature structural materials, capable of operating well beyond the stable temperature limits possible with superalloys. WSi_2 has a high melting temperature of 2165°C.[8] The fabrication and characterization of W−Si−C phases is a challenge in materials science. It would be very desirable if such high-temperature resistant materials could be prepared from potential precursors such as **11**.

Results and Discussion



The iodide complex **1** was chosen as the starting compound for the synthesis of further $[W(CO)_5L]^-$ anions. It was generated by the reaction of $W(CO)_6$ with anhydrous lithium iodide diethyl ether complex ($LiI \cdot OEt_2$) in DIME (diethylene glycol dimethyl ether). Complex **1** reacts with a variety of reagents under substitution of the iodide by the incoming nucleophile (see Schemes 1 and 3). Reactions with potassium cyanate and potassium thiocyanate were performed in DME at room temperature. However, these reactions provide the pseudohalide pentacarbonyltungstates **2** and **3a** only as mixtures with the starting material **1**.

Scheme 1. Substitution of iodide by pseudohalide ions

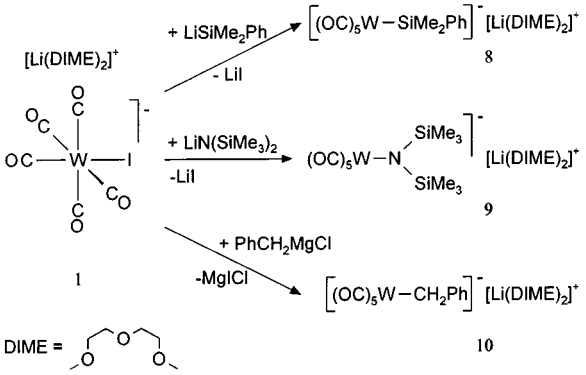
Scheme 2. Anionic derivatives starting from $W(CO)_5THF$

The infrared spectra of **2** and **3a** feature four bands in the carbonyl stretching region.[9] While only three infrared bands are to be expected for rigorous C_{4v} symmetry, the rather weak band at 1960 cm^{-1} in **3a** can be assigned to the formally infrared inactive B_1 mode.[10] The characteristic modes of the pseudohalides are found at 2245 cm^{-1} (ν_{NCO} in **2**) and 2090 cm^{-1} (ν_{NCS} in **3a**). All attempts to separate **2** and **3a** from the starting compound **1** by recrystallization were unsuccessful. As the product mixture contained **1** as the major and **2** as the minor component, we were unable to obtain a full spectroscopic characterization of **2**. Specifically, it could not be established whether the cyanate ion is coordinated through nitrogen or oxygen at the tungsten atom.

Reaction of **1** with sodium diphenylphosphide in THF/dioxane yielded a red oil, the NMR and IR spectroscopic data of which were consistent with the formula $[Li(DIME)_2][W(CO)_5PPh_2]$. The infrared spectrum features four bands attributable to the $W(CO)_5$ fragment at 2045, 1964, 1936, and 1880 cm^{-1}. In the ^{13}C-NMR spectrum, the signals of the CO carbon atoms are split into doublets due to coupling with the phosphorus atom bound to the $W(CO)_5$ fragment.

The reaction of the tungsten pentacarbonyl THF adduct with pseudohalides represents an alternative route for preparing substitution products of the type $[(OC)_5W{-}X]^-$ (see Scheme 2). Donor adducts of $W(CO)_5$ have been used previously as reactive intermediates.[11] It is easy to prepare $W(CO)_5THF$ from $W(CO)_6$ by photochemical ligand substitution in THF solution.

Reaction of $W(CO)_5THF$ with KSCN in DIME yields **3b** as a yellow microcrystalline powder. The ^{13}C-NMR spectrum features one signal due to the thiocyanate carbon atom at $\delta = 135.1$ and three signals due to the DIME ligand coordinated at the potassium ion. The signals of the CO carbon atoms are found at $\delta = 197.6$ and 201.6, with an intensity ratio of 1:4. The $^1J(^{13}C,^{183}W)$ coupling constant, which is well resolved in the spectrum of this compound, has a value of 129.2 Hz. The spectroscopic data of compound **3b** correspond well with the data of $[NEt_4][W(CO)_5NCS]$, which was described by Buchner and Schenk.[12] The infrared spectrum of **3b** features four bands in the carbonyl stretching region and one characteristic band for the stretching mode of the NCS ligand as described above. Generally, the thiocyanate ion is able to coordinate to metals through either the nitrogen or the sulfur atom. The high frequency ν_{CN} band indicates that in this case the thiocyanate is coordinated to the tungsten through the nitrogen atom.[13] As mentioned above, the product **3a** formed by nucleophilic substitution of iodide by SCN^- was found to be contaminated with the starting compound **1**; however, the product of the photochemical reaction sequence was free from impurities.

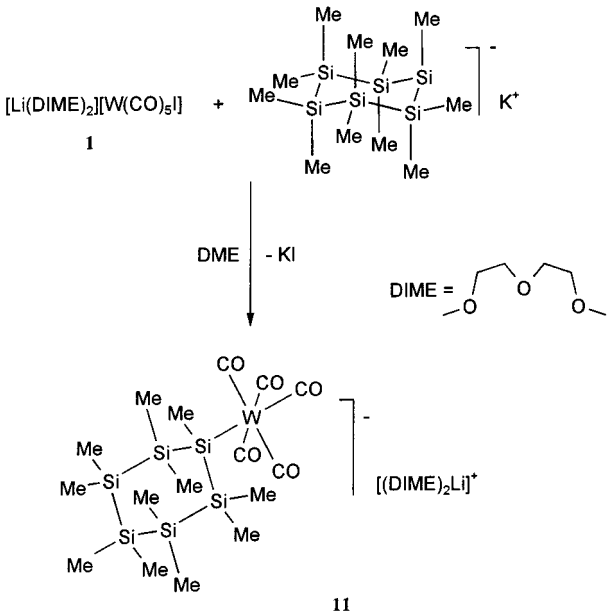


Reaction of potassium selenocyanate (KSeCN) with $W(CO)_5THF$ in DIME failed to give the desired product $[K(DIME)_2][W(CO)_5NCSe]$ in all cases, even at low temperatures. Instead, a finely divided black precipitate was formed, which was identified as elemental selenium by flame photometry and its melting point (215−217°C).

Sodium azide decomposes in solution if it is exposed to strong light. Therefore, the synthesis of $[Na(DIME)_2][W(CO)_5N_3]$ **5** was performed in a two-step sequence. The $W(CO)_5THF$ adduct was prepared photochemically as above. The solution of $W(CO)_5THF$ thus formed was then added dropwise to a solution of sodium azide protected from bright light. The product **5** was found to be air- and light-sensitive and was characterized by its ^{13}C-NMR and IR spectra. The ^{13}C-NMR spectrum features the characteristic 1:4 peak intensity ratio due to the CO carbon atoms at low field, as well as additional signals due to the DIME ligand (for details, see the Experimental Section). Four IR bands are seen in the carbonyl stretching region. One additional weak band at 2080 cm^{-1} can be assigned to the asymmetric stretching mode of the azide group. To assess the stability of compound **5** in solution, the NMR sample was stored for one week at room temperature. When an NMR spectrum was recorded after this period, the ^{13}C-NMR signals of the $[W(CO)_5N_3]^-$ ion could no longer be detected. New signals were seen, which corresponded to $W(CO)_6$ and $[W(CO)_5NCO]^-$. The mechanism of decomposition of $[W(CO)_5N_3]^-$ might be analogous to the Curtius rearrangement.[14] Reactions of metal carbonyls with N_3^- have been studied extensively.[15]

Because the tetrahydroborate ion is isoelectronic with the fluoride, hydroxide, amide, and methyl ions, we were also interested in carrying out reactions of $W(CO)_5THF$ with lithium tetrahydroborate. The ^{13}C-NMR data of **6** reveal the presence of a $W(CO)_5$ unit, since two signals for carbonyl carbon atoms are seen, with an intensity ratio of 1:4. One signal at $\delta = -12.55$ is seen in the ^1H-NMR spectrum of **6**. It is split into a triplet due to coupling with two tungsten atoms [$^1J(^1H,^{183}W) = 42.0$ Hz]. The chemical shift and coupling constant of this proton are characteristic features of such μ-hydrogen-bridged ditungsten complexes. A few examples have been described previously, which showed very similar chemical shifts and coupling constants as those found for **6**.[16] In addition, we observed signals due to a BH_4-containing side-product in the NMR spectra of **6**, which are most probably attributable to a small amount of $[Li(DIME)_2][W(CO)_4(\mu^2\text{-}BH_4)]$. It was not possible to remove this impurity by recrystallization.

Reaction of $W(CO)_5THF$ with potassium cyanide in THF in the presence of DIME yielded a yellow microcrystalline powder. The ^{13}C-NMR spectrum of this substance reveals the presence of two different $W(CO)_5$ units, since two sets of carbonyl carbon atom signals with an intensity ratio of 1:4 are seen. This pattern is suggestive of the formation of a dimeric CN-bridged complex. The carbon atom signal of the CN group is found at $\delta = 152.5$. Five bands are seen in the carbonyl stretching region of the IR spectrum (see Experimental Section). There is probably a superposition of the absorptions of the two different $W(CO)_5$ fragments. The stretching mode of the cyanide group is observed at 2124 cm^{-1}. Comparable compounds, such as the bridged complex $[PPN][W_2(CO)_{10}(\mu\text{-}CN)]$ and $[NEt_4][W(CO)_5CN]$, show absorptions at 2121 cm^{-1} and 2104 cm^{-1}, respectively.[17] The high wavenumber shift of the ν_{CN} mode, together with the aforementioned NMR data, lead us to the conclusion that the bridged complex $[K(DIME)_2][(OC)_5W(\mu\text{-}CN)W(CO)_5]$ **7** was formed in this reaction.



Reaction of $[Li(DIME)_2][W(CO)_5I]$ (**1**) with 1 molar equivalent of lithium bis(trimethylsilyl)amide $Li[N(SiMe_3)_2]$ in tetrahydrofuran gave $[Li(DIME)_2][W(CO)_5N(SiMe_3)_2]$ (**9**). Treatment of **1** with the Grignard reagent $PhCH_2MgCl$ in diethyl ether solution afforded complex **10** (Scheme 3). Complex **8** was prepared by adding a solution of $[Li(DIME)_2][W(CO)_5I]$ (**1**) in DME to an excess of $LiSiMe_2Ph$.

Scheme 3. Syntheses of compounds **8**–**10** by nucleophilic substitution

Complexes **8**, **9**, and **10** were isolated and purified by extraction with pentane. Subsequent recrystallization from dichloromethane gave yellowish solids. Compounds **8**–**11** can be safely dried in vacuo at room temperature without loss of the DIME ligands. Complex **9** proved to be more air-sensitive than compounds **8**, **10**, and **11**. The IR spectra of compounds **8**, **9**, and **10** exhibit three ν_{CO} bands ($2A_1$ and E). These stretching modes are in agreement with data found for the corresponding neutral $M(CO)_5X$ species.[18] The ^1H-NMR spectra are indicative of the presence of the DIME ligand (3 signals) and also feature characteristic signals for the substituents at the tungsten atom: $\delta = 7.54$ (m, SiPh), 0.58 ($SiMe_2$) for **8**; $\delta = 0.0$ ($SiMe_3$) for **9**; $\delta = 7.26$ (m, Ph), 1.25 (CH_2) for **10**. The ^{13}C-NMR data of **9** and **10** confirm the presence of the DIME ligand (3 signals) and of the substituents at the tungsten atom (see Experimental Section). The ^{29}Si-NMR peak of **8** at $\delta = -6.13$ gives evidence that one silicon atom is present.

Undecamethylcyclohexasilyl potassium (KSi_6Me_{11}) is well-established as a useful reagent for the synthesis of a variety of transition metal silyl complexes. $[Li(DIME)_2][W(CO)_5Si_6Me_{11}]$ (**11**) was prepared according to Scheme 4. The reaction of one equivalent of $[Li(DIME)_2][W(CO)_5I]$ with KSi_6Me_{11} in DME at ambient temperature resulted in the novel substance $[Li(DIME)_2][W(CO)_5Si_6Me_{11}]$ (**11**).

Scheme 4. Synthesis of compound **11**

The cyclohexasilyl derivative **11** was found to be more stable than complexes **8**–**10**. In the solid state, **11** is prone to very slow decomposition in air. It decomposes thermally between 160 and 250°C (TG). It is quite soluble in protic solvents, for example, wet methanol, with no evidence of decomposition in solution detectable in the NMR spectrum. Recrystallization from dichloromethane/pentane at −20°C gave analytically pure yellow crystals of **11** suitable for an X-ray crystallographic study. The structure was solved and refined in space group $P2_1/n$. **11** crystallizes in discrete ionic pairs; the structure of the cation is shown in

Figure 1. The lithium atom is coordinated by two DIME molecules in a distorted octahedral coordination geometry. The tridentate ether molecules chelate the lithium atom with meridional coordination. The Li−O bond lengths in **11** of 2.009 to 2.285 Å are in the same range as the Li−O distances reported for **1**.[3] The structures of these cations are isotypic.

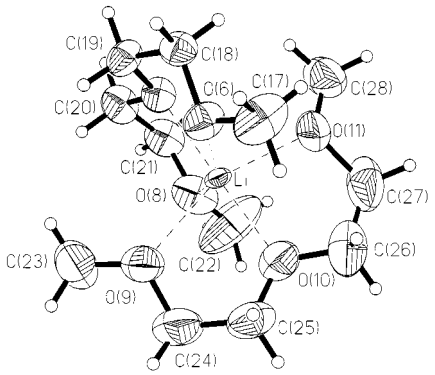


Figure 1. Structure of the $[Li(DIME)_2]^+$ cation in **11**

The structure of the undecamethylcyclohexasilylpentacarbonyltungsten anion is shown in Figure 2. The $[W(CO)_5Si_6Me_{11}]^-$ anion has approximately C_{4v} symmetry with a W−Si bond length of 2.670(2) Å, which is slightly longer than the corresponding distance of 2.614(2) Å in $[PPN][W(CO)_5SiMe_3]$.[19] The tungsten atom resides in an almost regular octahedron with $CO_{eq}-W-CO_{eq}$ angles very close to 90° and a $CO_{ax}-W-Si_{ax}$ angle of 175.3(2)°. The W−C distances for the four equatorial CO ligands range from 2.011 to 2.044 Å, while the W−C bond to the axial CO ligand measures only 1.966(6) Å. This is possibly a reflection of a greater π-back-bonding to the CO ligand situated *trans* to the silyl group. Two of the four equatorial CO′s are bent towards the Si_6Me_{11} ligand, resulting in Si(1)−W−C(4) and Si(1)−W−C(5) angles of 84.6(2) and 80.2(2)°, respectively. The cyclohexasilyl ligand adopts a chair conformation with the $W(CO)_5$ group in an equatorial position.

Crystallographic data and data collection parameters are listed in Table 3. Salient bond lengths and angles are listed in Table 1.

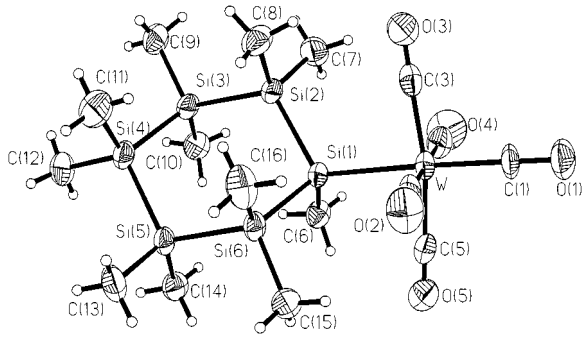

Figure 2. Structure of the $[W(CO)_5Si_6Me_{11}]^-$ anion in **11**

In the infrared spectrum of **11**, four metal carbonyl bands at 2020 (w), 1915 (m), 1890 (s), and 1860 (m) cm^{-1} are observed, which are characteristic of a metal pentacarbonyl anion.[2] The IR bands can be assigned to the three IR-active fundamental vibrations ($2A_1 + E$) expected for a C_{4v} metal pentacarbonyl species and to the B_1 vibration, although this is IR inactive for rigorous C_{4v} geometry. This assessment is in agreement with those for the corresponding $M(CO)_5X$ species by Casey.[9a] The ^{1}H-NMR signals of the DIME ligands are observed at δ = 3.40 (s, CH_3) and δ = 3.56 and 3.65 (m, CH_2CH_2). The ^{1}H-NMR resonances for the methyl groups bonded to the silicon appear in the typical range with δ values near to zero (see Table 2).

Table 2. ^{1}H-, ^{13}C-, and ^{29}Si-NMR data of compound **11**[a]

δ^{1}H DIME	Me−Si	δ^{13}C DIME	CO	Si−Me	δ^{29}Si
3.65, 3.56 (CH_2), 3.40 (CH_3)	0.49, 0.22, 0.15, 0.14, 0.11, 0.10	70.75, 69.30 (CH_2), 59.31 (CH_3)	212.16, 207.67	−2.14, −3.18, −3.79, −4.19, −4.85, −5.95, −6.79	−75.7, −42.0, −40.7, −30.7

[a] Recorded in $CDCl_3$ at 25°C; data in ppm are relative to Me_4Si at δ = 0.0.

The fact that six signals are observed indicates that the silicon ring adopts a chair conformation. Single-crystal structure analysis confirms this assumption. The ^{29}Si-NMR spectrum of compound **11** features four resonances for the *cyclo*-silyl ligand bonded at the metal atom (Table 2). The ^{29}Si-NMR chemical shifts for the anion $[W(CO)_5Si_6Me_{11}]^-$ move progressively to higher field relative to the shifts for the analogous $[Mo(CO)_5Si_6Me_{11}]$,[7] which is the expected trend for complexes of this type.[20] The ^{13}C-NMR data of **11** are in agreement with the proposed structure (Table 2).

Pyrolysis of $[Li(DIME)_2][W(CO)_5Si_6Me_{11}]$ (11)

Thermogravimetry (TG) and differential thermal analysis (DTA) were performed using a MOM Budapest Derivato-

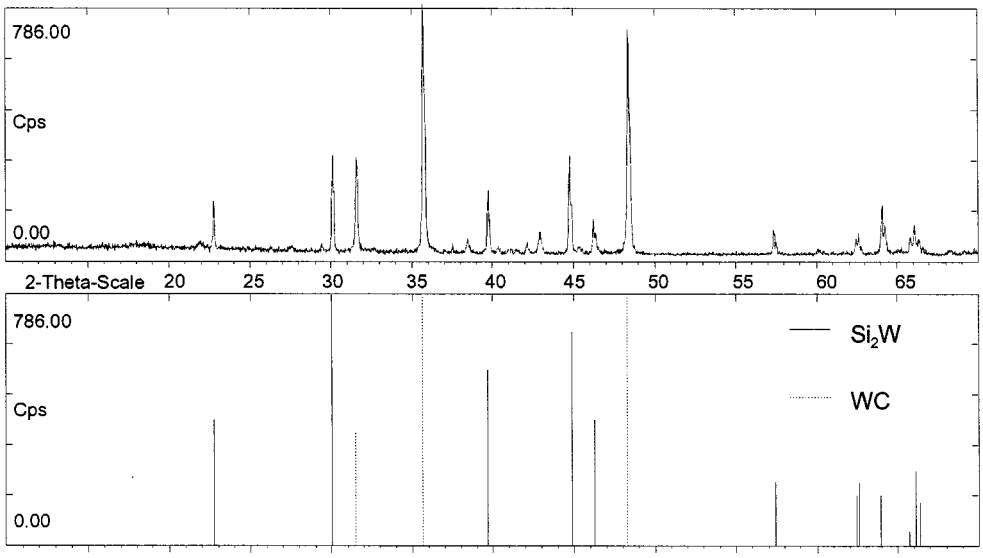

Figure 3. Comparison of the XRD pattern of the pyrolyzed sample of $[Li(DIME)_2][W(CO)_5Si_6Me_{11}]$ (**11**) (top) with powder diffraction files: 11−0195 WSi_2, 25−1047 WC (bottom)

graph. An atmosphere of Ar (at a flow rate of 200 mL/min^{-1}) and a corund open pan were used for the experiment. A sample of **11** was heated at a rate of 5 °C min^{-1} up to 1400°C. Decomposition started at 160°C and reached a maximum rate at 230°C. The mass lost amounted to 29% of the sample mass at 250°C, which corresponds to the loss of 2 DIME molecules per formula unit. The following substances could be detected by GC analysis: CO at 400−1000°C, CH_4 at 500−800°C, and H_2 < 1200°C. X-ray analysis after the pyrolysis indicated that the product was mainly a mixture of WSi_2 and WC (Figure 3).

Conclusions

In conclusion, $[Li(DIME)_2][W(CO)_5I]$ (**1**) reacts readily with nucleophilic reagents such as alkyls and organoamides, -phosphides, and -silyls. The preferred site of reactivity is the W−I bond. Thus, it is evident that **1** is a highly useful reagent for preparing a wide variety of $W(CO)_5$ derivatives. Reaction of **1** with pseudohalides leads to mixtures of starting material and product. This is probably due to the weak nucleophilicity of the pseudohalides. Therefore, the salt elimination route is not suitable for preparing pure pseudohalide−pentacarbonyltungstate derivatives. However, it is possible to obtain these derivatives by using the photochemical reaction sequence via $W(CO)_5THF$. The X-ray crystal structure of **11** confirms that the cyclohexasilyl ring is bound to the tungsten. The production of pure tungsten silicide is a challenging task with potential applications in materials science; thus it is noteworthy that thermolysis of **11** produces WSi_2 together with WC. Further investigations concerning the synthesis and thermal decomposition pathways of metal−silicon compounds are currently under way.

Experimental Section

All preparative work and sample handling was carried out under Ar with dry glassware and in dry solvents. Diethylene glycol dimethyl ether (DIME) was repeatedly distilled from freshly cut Na until effervescence was no longer observed. It was distilled once more and then stored in a sealed flask in a drybox prior to use. Starting materials $W(CO)_6$ and $Li[N(SiMe_3)_2]$ were purchased from Fluka Chemie AG. $W(CO)_6$ was vacuum-sublimed prior to use. All alkaline pseudohalides were dried in vacuo for 4 h prior to use. The syntheses of $PhCH_2MgCl$,[21] $LiSiMe_2Ph$,[22] and KSi_6Me_{11}[23] were carried out according to established procedures.

NMR spectra were recorded on a Bruker MSL 200 spectrometer. − Elemental analyses were performed on a CHN-O-Rapid (Heraeus). The carbon values recorded were systematically lower due to carbide formation. − Infrared spectra were recorded on a Specord 75 IR instrument in the range 4000 to 400 cm^{-1} for samples pressed into a KBr disc. − X-ray powder diffraction patterns were obtained using a Siemens D5000 diffractometer with Cu-K_α radiation.

Synthesis of $[Li(DIME)_2][W(CO)_5I]$ (1): A sample of $W(CO)_6$ (5.0 g, 0.014 mol) was added to a solution of $LiI{\cdot}Et_2O$ (3.0 g, ≈ 0.014 mol) in diethylene glycol dimethyl ether (20 mL). The mixture was heated at 80°C for 2 days, during which it became bright yellow. IR monitoring showed the formation of a species with a ν(CO) pattern typical for $[W(CO)_5L]$ species: $\tilde{\nu}$ = 1950, 1915, 1850 cm^{-1}. The solvent was removed in vacuo to leave a yellow residue. This was redissolved in dichloromethane and then treated with *n*-pentane to give yellow crystals of **1** (isolated yield 93.7%). − ^{1}H NMR ($CDCl_3$/TMS): δ = 3.75, 3.64, 3.45 (DIME). − ^{13}C NMR ($CDCl_3$/TMS): δ = 202.62, 197.18 (CO), 70.58, 69.37, 59.54 (DIME). − $C_{17}H_{28}ILiO_{11}W$ (697.8): calcd. C 21.88, H 3.02; found C 21.74, H 3.10.

Synthesis of $[Li(DIME)_2][W(CO)_5NCO]$ (2) and $[Li(DIME)_2][W(CO)_5NCS]$ (3a): $[Li(DIME)_2][W(CO)_5I]$ (**1**) (0.003 mol) and an equimolar amount of KOCN or KSCN, respectively, were suspended in DME and the mixture was stirred for 24 h at room tem-

perature. The solvent was then evaporated in vacuo, and the remaining solid was washed with *n*-pentane and taken up in dichloromethane. The resulting suspension was filtered to remove insoluble alkaline halides. Addition of *n*-pentane to the clear solution and cooling to 5°C led to the deposition of **3a** as a yellow solid. – ^{1}H NMR ($CDCl_3$/TMS): δ = 3.74, 3.63, 3.46 (DIME). – ^{13}C NMR ($CDCl_3$/TMS): δ = 201.4 (CO_{ax}), 197.6 (CO_{eq}), 135.4 (NCS), 70.7, 69.3 (DIME). – IR (KBr): ν_{CO} = 2060 (w), 1960 (w, sh), 1910 (s), 1860 (m) cm^{-1}; ν_{NCS} = 2090 (w) cm^{-1}. The spectra of **3a** prepared by this method show additional signals attributable to **1**.

Synthesis of [K(DIME)$_2$][W(CO)$_5$NCS] (3b): $W(CO)_5THF$ was prepared immediately prior to use by irradiating a solution of $W(CO)_6$ (2.5 g, 0.0071 mol) in dry THF (concentration about 0.1 mol/L) under Ar for 4 h with a high-pressure Hg lamp (160 W).[24] Meanwhile, a solution of potassium thiocyanate (0.69 g, 0.0071 mol) in DIME (15 mL) was prepared. The synthesized tungsten pentacarbonyl THF adduct was then added to this solution over a period of 10 min. The resulting mixture was stirred for 24 h at room temperature. The solvent and excess $W(CO)_6$ were then removed in vacuo. Pentane was added, the product was isolated by filtration, washed with *n*-pentane, and dried in vacuo to afford **3b** as a yellow microcrystalline powder. – ^{1}H NMR ($CDCl_3$/TMS): δ = 3.66, 3.59, 3.42 (DIME). – ^{13}C NMR ($CDCl_3$/TMS): δ = 201.6 (CO_{ax}), 197.6 [$^1J(^{13}C,^{183}W)$ = 129.2 Hz (CO_{eq})], 135.1 (NCS), 71.5, 69.9, 59.0 (DIME). – IR (KBr): ν_{CO} = 2066 (w), 1975 (w, sh), 1918 (s), 1864 (m) cm^{-1}; ν_{NCS} = 2093 (w) cm^{-1}.

Synthesis of [Li(DIME)$_2$][W(CO)$_5$PPh$_2$] (4): [Na(dioxane)$_n$][PPh_2] was prepared according to the method of Issleib.[25] [Li(DIME)$_2$][W(CO)$_5$I] (2.54 g, 0.0035 mol) was dissolved in THF (40 mL) and a solution of [Na(dioxane)$_n$][PPh_2] (ca. 0.01 mol) in THF/dioxane (23 mL) was added at −76°C. The resulting mixture was stirred for a period of 10 h, during which the colour changed from yellow/orange to red. DIME (20 mL) was then added to the reaction mixture. The resulting suspension was filtered and the solvents were evaporated in vacuo. All attempts at crystallization led only to a clear red oil **4**. – ^{1}H NMR ($CDCl_3$/TMS): δ = 7.73, 7.23, 7.04 (Ph), 3.75, 1.86 (THF), 3.72, 3.62, 3.44 (DIME). – ^{13}C NMR ($CDCl_3$/TMS): δ = 204.7 [$^2J(^{13}C,^{31}P)$ = 12.9 Hz (CO_{ax})], 201.2 [$^1J(^{13}C,^{183}W)$ = 123.9 Hz (CO_{eq})], 151.2 [$^1J(^{13}C,^{31}P)$ = 12.3 Hz (C_{ipso})], 133.4 [$^2J(^{13}C,^{31}P)$ = 10.9 Hz (C_{ortho})], 126.8 [$^3J(^{13}C,^{31}P)$ = 7.7 Hz (C_{meta})], 125.5 (C_{para}), 71.0, 69.7, 59.4 (DIME), 68.0, 25.6 (THF). – IR (THF): ν_{CO} = 2045 (w), 1964 (w, sh), 1936 (s), 1880 (m) cm^{-1}.

Synthesis of [Na(DIME)$_2$][W(CO)$_5$N$_3$] (5): $W(CO)_5THF$ was prepared as described above. Sodium azide (0.46 g, 0.0071 mol) was dissolved in methanol (60 mL) and THF (80 mL) and then DIME (20 mL) was added to the solution. The tungsten pentacarbonyl THF adduct was added dropwise to this mixture with stirring. After stirring for 10 h, the solvents were evaporated in vacuo and excess *n*-pentane was added to the yellow residue. The resulting yellow solid was collected by filtration and washed with *n*-pentane. The solid residue was redissolved in THF, the resulting solution was filtered, and *n*-pentane was added to the filtrate to crystallize the product. The product was found to be sensitive to light and air. It decomposes in CH_2Cl_2 and $CHCl_3$. In solution, the product converts into $W(CO)_6$ and [Na(DIME)$_2$][W(CO)$_5$NCO]. – ^{1}H NMR (CD_3OD/TMS): δ = 3.62, 3.54, 3.36 (DIME). – ^{13}C NMR (CD_3OD/TMS): δ = 203.4 (CO_{ax} N_3), 199.8 [$^1J(^{13}C,^{183}W)$ = 129.3 Hz (CO_{eq} N_3)], 202.2 (CO_{ax} OCN), 199.4 (CO_{eq} OCN), 192.4 [$W(CO)_6$], 72.9, 71.3, 59.1 (DIME). – IR (THF): ν_{CO} = 2040 (w), 1965 (s), 1910 (s), 1865 (m) cm^{-1}, ν_{N3} = 2080 (w) cm^{-1}; ν_{OCN} = 2245 (w) cm^{-1}.

Synthesis of [Li(DIME)$_2$][W$_2$(CO)$_{10}$(μ-H)] (6): $W(CO)_5THF$ was prepared as described above. $LiBH_4$ (0.185 g, 0.0085 mol) was dissolved in a mixture of THF (60 mL) and DIME (20 mL). The tungsten pentacarbonyl THF adduct was added dropwise to the $LiBH_4$ solution over a period of 15 min. at 0°C and the reaction mixture was stirred for 8 h. After evaporation of the solvent, the residue was redissolved in THF, the resulting solution was filtered, and *n*-pentane was added to the filtrate. The clear solution was cooled to −20°C to crystallize the product. – ^{1}H NMR (CD_3CN/TMS): δ = 3.61, 3.52, 3.35 (DIME), −12.55 [$^1J(^1H,^{183}W)$ = 42.0 Hz (WH)]. – ^{13}C NMR (CD_3CN/TMS): δ = 202.0 (CO_{ax}), 199.7 [$^1J(^{13}C,^{183}W)$ = 124.2 Hz (CO_{eq})], 71.7, 70.2, 59.1 (DIME); impurities: $LiBH_4$: ^{1}H NMR (CD_3CN/TMS): δ = −0.46 [quadruplet, $^1J(^1H,^{11}B)$ = 83.2 Hz]. – ^{11}B NMR ($CD_3CN/BF_3{\cdot}Et_2O$): δ = −39.43; [Li(DIME)$_2$][W(CO)$_4$(μ^2-BH_4)]: ^{1}H NMR (CD_3CN/TMS): δ = −11.84 (weak). – ^{13}C NMR (CD_3CN/TMS): δ = 201.4, 200.8 (CO, weak). – IR (KBr): ν_{CO} = 2071 (w), 2041 (m), 2014 (w), 1966 (m, sh), 1936 (s), 1873 (s, br), 1839 (m), 1802 (w, sh) cm^{-1}; ν_{BH} = 2246 (s, br) cm^{-1}.

Synthesis of [K(DIME)$_2$][W$_2$(CO)$_{10}$(μ-CN)] (7): $W(CO)_5THF$ was prepared as described above. Potassium cyanide (0.55 g, 0.0085 mol) was dissolved in a mixture of THF (40 mL) and DIME (20 mL). The tungsten pentacarbonyl THF adduct was then added dropwise to the potassium cyanide solution over a period of 15 min. at 0°C. The resulting mixture was stirred for 4 h and then the remaining traces of KCN were filtered off. The solvent was removed under reduced pressure, *n*-pentane was added to the residue, and the precipitate was collected by filtration. The green-yellow solid was taken up in THF and filtered, and the collected solid was washed with *n*-pentane and dried in vacuo to afford a yellow microcrystalline powder **7**. The product was found to be sensitive to light and air. – ^{1}H NMR ($CDCl_3$/TMS): δ = 3.65, 3.59, 3.42 (DIME). – ^{13}C NMR ($CDCl_3$/TMS): δ = 202.3 (CO_{ax} NC), 197.9 [$^1J(^{13}C,^{183}W)$ = 129.0 Hz (CO_{eq} NC)], 200.2 (CO_{ax} CN), 196.9 [$^1J(^{13}C,^{183}W)$ = 125.0 Hz (CO_{eq} CN)], 152.5 (CN), 71.5, 70.0, 59.0 (DIME). – IR (THF): ν_{CO} = 2057 (w), 1971 (sh), 1934 (s), 1900 (m), 1880 (m); ν_{CN} = 2124 (w). – UV/vis (EtOH): λ_{max} (ε/l·mol^{-1}·cm^{-1}) = 230 (80870), 248 (54515), 338 (3947), 362 (4021), 384 (2740) nm.

Synthesis of [Li(DIME)$_2$][W(CO)$_5$SiMe$_2$Ph] (8): A solution of **1** (0.005 mol, 3.49 g) in DME (20 mL) was added slowly, over a period of 4 h, to an excess of $LiSiMe_2Ph$ (0.006 mol) in THF. The mixture was stirred for further 3 h and then the solvents were removed in vacuo. The remaining orange solid was redissolved in dichloromethane (20 mL) and this solution was filtered. Pentane (50 mL) was added to the clear yellow filtrate and complex **8** crystallized on cooling. The mother liquor was removed by means of a cannula. The residue was washed with pentane, dried in a stream of argon, and then at oil-pump vacuum to afford 2.8 g (79%) of **8** as a yellow solid. – ^{1}H NMR ($CDCl_3$/TMS): δ = 7.54 (SiPh), 3.68, 3.59, 3.43 (DIME), 0.58 ($SiMe_2$). – ^{29}Si NMR (dichloromethane/D_2O): δ = −6.13. – IR ($CHCl_3$): ν_{CO} = 1925, 1887, 1815 cm^{-1}. – $C_{25}H_{39}LiO_{11}SiW$ (706.1): calcd. C 42.52, H 5.51; found C 41.86, H 5.53.

Synthesis of [Li(DIME)$_2$][W(CO)$_5$N(SiMe$_2$)$_2$] (9): A solution of **1** (0.005 mol, 3.49 g) in THF was cooled to −76°C, whereupon 5 mL (0.005 mol) of a 1 M solution of Li[$N(SiMe_3)_2$] in THF was added. The mixture was stirred for 2 h while being allowed to warm to room temperature. After evaporation of the solvent, the residue was redissolved in DME (20 mL) and the resulting solution was filtered. Pentane was added to the clear yellow solution to start the crystalli-

zation. After cooling, the yield of **9** was 1.4 g (38.3%). The product was recrystallized from dichloromethane/pentane to afford an orange solid. – ^{1}H NMR ($CDCl_3$): δ = 3.71, 3.60, 3.40 (DIME), 0.00 ($SiMe_3$). – ^{13}C NMR ($CDCl_3$): δ = 205.67, 197.04 (CO), 70.43, 69.19, 59.45 (DIME), 2.39 ($SiMe_3$). – IR ($CDCl_3$): ν_{CO} = 1928, 1874, 1855 cm^{-1}. – $C_{19}H_{46}LiO_{11}Si_2W$ (731.32): calcd. C 31.20, H 6.28; found C 30.76, H 6.22.

Synthesis of [Li(DIME)$_2$][W(CO)$_5$CH$_2$Ph] (10): $PhCH_2MgCl$ (0.005 mol, 12.8 mL of a 0.4 M Grignard solution) was treated with a solution of 0.005 mol (3.49 g) of **1** in DME (20 mL) and the resulting mixture was stirred for 2 h at room temperature. Subsequent evaporation of the solvents left a yellow solid, which was taken up in dichloromethane (30 mL) under cooling. This mixture was then filtered and the filtrate was concentrated to dryness to afford 1.7 g (51.4%) of **10**. – ^{1}H NMR ($CDCl_3$/TMS): δ = 7.26 (Ph), 3.74, 3.64, 3.44 (DIME), 1.25 (CH_2). – ^{13}C NMR ($CDCl_3$/TMS): δ = 138.78, 130.68, 128.73, 126.48 (Ph), 70.85, 69.58, 59.49 (DIME), 45.58 (CH_2). – IR ($CDCl_3$): ν_{CO} = 1934, 1916, 1885 cm^{-1}. – $C_{24}H_{35}LiO_{11}W$ (662.04): calcd. C 43.54, H 5.28; found C 43.45, H 5.24.

Synthesis of [Li(DIME)$_2$][W(CO)$_5$Si$_6$Me$_{11}$] (11): KSi_6Me_{11} was prepared from *cyclo*-Si_6Me_{12} (2.6 g, 0.007 mol) and $KOC(CH_3)_3$ (0.78 g, 0.007 mol) in DME (10 mL) and then added dropwise at room temperature over a period of 15 min. to a stirred solution of **1** (5.08 g, 0.007 mol) in DME (20 mL). After stirring the mixture at room temperature for 12 h, the solvent was removed under reduced pressure. Then, a mixture of *n*-pentane/dichloromethane (1:1, 20 mL) was added to the residue and the precipitate was filtered off. The filtrate was concentrated to dryness under reduced pressure and *n*-pentane (20 mL) was added to the residue to produce a slightly yellow suspension. An orange oil separated from the mixture after addition of approximately 10 drops of dichloromethane. Yellow crystals of **11** deposited from the oil after 1 d at −20°C. Yield: 4.82 g (74%). The NMR data are shown in Table 2. – IR (nujol): ν_{CO} = 2020 (w), 1915 (m), 1890 (s), 1860 (m). – $C_{28}H_{61}LiO_{11}Si_6W$: calcd. C 36.04, H 6.58; found C 35.91, H 6.74.

Experimental Procedure for X-ray Crystallography: A suitable single crystal of **11** was mounted on a glass fibre under paraffin oil and transferred to the diffractometer. Diffraction measurements were made on an Enraf−Nonius CAD-4 diffractometer at −83°C using graphite-monochromated Cu-K_α radiation (λ = 1.5418 Å) with ω−2θ scans. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 with anisotropic thermal parameters. Hydrogen atoms were placed in calculated positions and allowed to ride on their corresponding carbon atoms. An empirical absorption correction was performed on the basis of ψ scans. Crystallographic data and the results of the refinements are summarized in Table 3. Full crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100623. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mono- and 1,1′-Disubstituted Aza Ferrocenyl Compounds: Evidence for an Original Electroactive Fluorescent Species

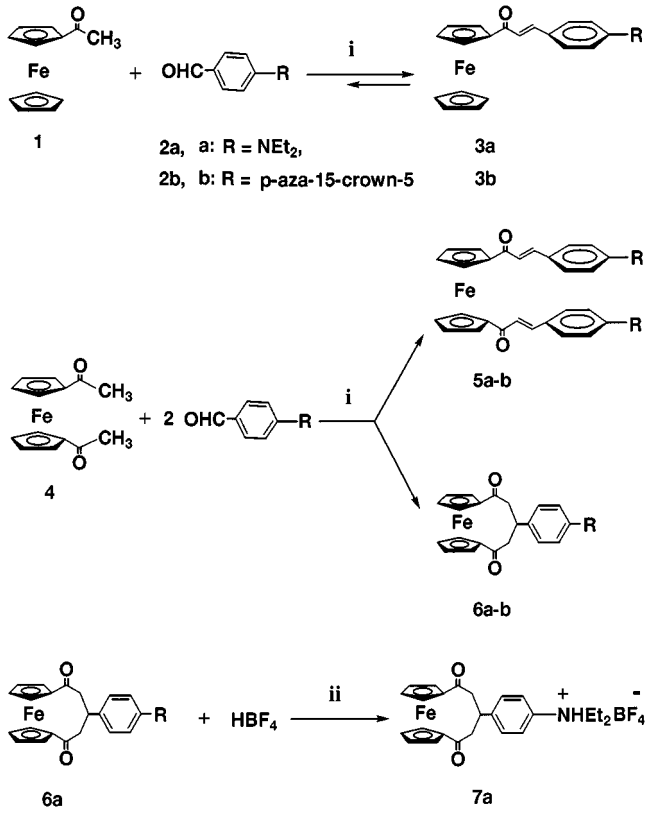
Béatrice Delavaux-Nicot*[a] and Suzanne Fery-Forgues[b]

Keywords: Ferrocenyl ligands / Electrochemistry / Fluorescence / Azaalkyl compounds / Crown compounds

New azaalkyl or azacrown ferrocenyl compounds containing a C_5H_4COCC- linkage are accessible from mono- or diacetylferrocene upon treatment with the appropriate aldehydes ($CHOC_6H_4$-*p*-R, R = NEt_2, N-aza-15-crown-5). Preliminary results concerning the electrochemical behaviour of complexes $[(C_5H_5)Fe(C_5H_4COCH{=}CHC_6H_4NEt_2)]$ (**3a**), $[Fe(C_5H_4COCH{=}CHC_6H_4NEt_2)_2]$ (**5a**), the novel ferrocenophane $[Fe(C_5H_4COCH_2)_2CHC_6H_4NEt_2]$ (**6a**) and its protonated species $[Fe(C_5H_4COCH_2)_2CHC_6H_4NHEt_2][BF_4]$ (**7a**), are reported. The ferrocenyl ligand **5a** is a rare example of a molecule which is both electroactive and fluorescent.

Introduction

The design of ferrocene-based ion sensors constitutes an area of active research,[1] especially for property-directed synthesis.[2] Of special interest are novel functionalised molecules which are able to change an easily measurable physical property by coordination or interaction with a target molecule. Among these new molecules are redox-functionalised receptors which are able to display a shift of the redox potential upon addition of particular substrates, and we have recently been involved in the synthesis of electroactive ferrocenyl receptors for the electrochemical recognition of cations and anions.[3] Studies concerning ion recognition by fluorescent sensors are also well documented and offer a wide range of applications.[4] Despite the development of these two areas, to the best of our knowledge, few examples of fluorescent ferrocenyl ion sensors have been described[5] probably because ferrocene derivatives are known to be efficient fluorescence quenchers.[6] It is noteworthy that Beer et al. have developed two particularly interesting polymetallic [Ru-Fe] systems where anion binding induces a luminescence revival.[5] In the compounds described by Beer et al.[5], luminescence arises from organometallic ruthenium(II) and osmium(II) bipyridyl moieties and the ferrocene residue acts as a quencher. As a complementary part of our research, a *purely organic* fluorescent ion sensor subunit containing an R-aza complexing moiety (−COCH=CHC_6H_4-*p*-R, R = NEt_2 or aza-15-crown-5)[7] was combined with a redox ferrocenyl fragment to give rise to a new type of ion-sensing device. This choice was mainly made for the following reasons: i) It has recently been shown for a dibenzylideneacetone containing these aza fragments that the photophysical properties of the fluorescent group can be modified upon complexation of the nitrogen atom.[7] ii) Redox active ionophores based on covalently linked crown ether-metallocene systems have received much attention in recent years and give a good selective electrochemical response to the presence of a guest cation.[8] It is worth noting that in our simple ligands, the ferrocenyl moiety is involved in the conjugated π system, and a physical response for ion recognition either by electrochemistry and/or by fluorescence methods can be expected.



In this paper we report the characterization of novel electroactive ferrocenyl ligands presenting a rare C_5H_4COCC linkage[9] (Scheme 1) and preliminary results concerning the physical properties of the original fluorescent electroactive molecule $[Fe(C_5H_4COCH{=}CHC_6H_4NEt_2)_2]$ (**5a**).

Results and discussion

In order to test the efficiency of the synthesis of easily isolable products presenting the desired properties, a reaction was performed between the monosubstituted ferrocenyl compound $[(C_5H_5)Fe(C_5H_4COCH_3)]$ (**1**) and *p*-diethylaminobenzaldehyde (**2a**) or crown aldehyde [N-(4-formylphenyl)aza-15-crown-5] (**2b**) in basic solution (1:1 ethanol/10% aqueous NaOH). With **2a**, the expected compound $[(C_5H_5)Fe(C_5H_4COCH{=}CHC_6H_4NEt_2)]$ (**3a**) formed in 40% yield (by NMR spectroscopy), after stirring for 6 hours. It was isolated as a red powder after purification and identified by DCI-NH_3 mass spectroscopy ($[M + H]^+$ = 388). The ^1H NMR spectroscopic data were consistent with a *trans* geometry of the ethylenic protons ($^3J_{H-H}$ = 15.4 Hz)[10a] and our spectroscopic assignment was in agreement with the literature data for related compounds.[11][12] The isolated yield of **3a** was not improved under different experimental conditions, probably because of a reverse aldol condensation. The compound $[(C_5H_5)Fe(C_5H_4COCH{=}CHC_6H_4$-*p*-aza-15-crown-5)] (**3b**) was obtained, after 31 h of reaction with **2b**, in 50% yield (by NMR spectroscopy) and characterized after isolation as a red oil.

Scheme 1. *Reagents and conditions*: i) 1:1 ethanol/10% aqueous NaOH, room temp; ii) CH_3CN, 20°C.

An identical procedure was carried out to obtain the disubstituted ferrocenyl derivative [Fe(C_5H_4COCH=$CHC_6H_4NEt_2)_2$] (**5a**). The analogous compound [Fe(C_5H_4-$COCH$=$CHC_6H_4NMe_2)_2$][13] has been proposed in the literature for photographic use though no characterization or yield have yet been reported. Two equivalents of **2a** were reacted with one equivalent of [Fe($C_5H_4COCH_3)_2$] (**4**) to give, after stirring for 4 h at 20°C, a mixture (50%, NMR) of compound **5a** and the ferrocenophane [Fe(C_5H_4-$COCH_2)_2CHC_6H_4NEt_2$] (**6a**) in a 2/3 ratio. A two-step chromatography workup allowed the separation of pure **5a** as a light-sensitive powder and **6a** as an orange powder with 7% and 9% yield, respectively. Attempts to improve the synthesis of **5a**, as reported in the patent in ref.,[12] or in excess of **2a** according to another published procedure,[14a] failed. The yield of ferrocenophane **6a** was increased (40%) by stirring the reagents for 18 hours (4 equivalents of aldehyde) and performing several diffusions in a toluene/pentane mixture of the red fraction obtained after simple chromatography on alumina. According to the literature, **6a** can be formed either by an aldol condensation in a 1/1 stoichiometry followed by an intramolecular Michael addition[14] or by a reverse aldol condensation in basic medium starting from **5a**.[15] This explains why **6a** is the major compound in solution.

For the disubstituted compound **5a**, DCI-NH_3 mass spectroscopy showed a $[M + H]^+$ molecular peak at the expected value of 589. The IR spectrum exhibited a $\tilde{\nu}$(C=O) vibration at 1644 cm^{-1}, this low value being due to the conjugation of the CO group in the molecule.[10b] The proposed structure was first deduced from NMR spectroscopic data, which revealed high symmetry. The protons of the CH groups, as for the monosubstituted compound **3a**, are in *trans* positions. In the $^{13}C\{^1H\}$-NMR spectrum, a singlet observed at $\delta = 192.4$ in $CDCl_3$ was attributed to the CO groups. 2D NMR experiments were carried out and clearly verified our assignments.

In the case of **6a**, the number and the multiplicity of the signals observed for the cyclopentadienyl protons in the ^1H-NMR spectrum showed the asymmetry of the molecule. In the $^{13}C\{^1H\}$-NMR spectrum a lone singlet was detected for the CO groups ($\delta = 199.5$, $CDCl_3$). Analysis of the ^1H-^{13}C HMBC spectra supported the existence of a bridge linkage between the Cp ring, in which the CO carbon atoms are strongly coupled to the H atom of the CH group and to each proton of the CH_2 groups. The bridge between the Cp rings may force them out of coplanarity and staggers them by less than 36°. It probably also pushes the CO groups out of the Cp ring planes and in the same direction.[16] Selective decoupling ^1H-NMR experiments (400 MHz, 223 K, $CDCl_3$) indicated that the CH_2 protons of the ferrocenophane chain are diastereotopic (at 293 K, a broad singlet at $\delta = 2.50$ and a triplet at $\delta = 2.90$ were detected for both CH_2 groups). X-ray structures of [5]-ferrocenophane are not common but it has been previously reported that the ferrocenophane molecules have conformational mobility in solution: the Cp rings can undergo small torsional vibrations with respect to each other around the axis passing through the center of the rings and the iron atom.[17]

The analogous reaction of **4** with the crown aldehyde **2b** produced, after stirring for 17 h, [Fe(C_5H_4COCH=CHC_6H_4-*p*-aza-15-crown-5)$_2$] (**5b**) and [Fe(C_5H_4-$COCH_2)_2CHC_6H_4$-*p*-aza-15-crown-5)] (**6b**) in a 3:7 ratio. These compounds were identified by DCI-NH_3 mass spectroscopy ($[M + H]^+ = 881$ and 576, respectively). The NMR spectroscopic data of a pure sample of **6b** were very similar to those obtained for **6a** when considering the same basic cyclic structure for both compounds. 2D NMR experiments allowed a clear assignment of the ^{13}C-NMR chemical shifts, in particular for the carbons of the Cp and crown rings whose signals appeared in the same region of the spectra.

Compound **6a** was protonated to provide useful data concerning the analysis of its electrochemical behaviour. When treated with one equivalent of $HBF_4 \cdot Et_2O$ in CH_3CN, **6a** afforded [Fe($C_5H_4COCH_2)_2CHC_6H_4$-$NHEt_2$][BF_4] (**7a**) (95% NMR, MS (FAB): 430 [M − $BF_4]^+$). The ^1H-^1H COSY NMR spectrum clearly confirmed the nature of the protonation site (nitrogen): a correlation between the NH^+ proton[3e] (broad singlet, $\delta = 8.60$) and the NCH_2 protons (complex multiplet, $\delta = 3.65$) was observed (CD_3CN, 300 MHz).

The electrochemical behaviour of compounds **3a**, **5a** and **6a** (R = NEt_2) was investigated. For compounds **3a** and **5a** two redox waves were observed by cyclic voltammetry (CV). The oxidation peak potentials (Epa) of the amine moieties (0.88 V and 0.78 V vs SCE for **3a** and **5a**, respectively) are

in the expected range of values.[18] It is to be noted that $CH_3COCH{=}CHC_6H_4NEt_2$ (**8**) was oxidized at Epa = 0.74 V in CH_2Cl_2. For the Fe(II)/Fe(III) couple, the Epa values, 0.65 V and 1.15 V for **3a** and **5a**, respectively, depend on the number of CO substituents, which are strong electron-withdrawing groups.[11b] This was confirmed by the data obtained for **1** and **4** under the same experimental conditions. Stepwise addition of $HBF_4{\cdot}Et_2O$ to a solution of compound **3a** in CH_3CN resulted in a clear evolution of the ferrocene wave from $E_{1/2}$ = 0.61 to 0.67 V, associated with the disappearance of the second wave (Figure 1, top). The solution turned pink and the new species were oxidized (Fe^{III}) and recovered by electrolysis at 0.75 and 0.30 V, respectively, although some decomposition occurred.

The electrochemical oxidation of compound **6a** resulted in the observation of quasi-reversible redox waves of equal intensity at 0.77 and 0.99 V (Epa vs SCE), assigned to the amine and ferrocene parts, respectively (Figure 1, bottom). This was verified by a two-step electrolysis at controlled potential (0.90 and 1.10 V, respectively), coupled with cyclic and linear voltammetry measurements. The stepwise addition of 1 equivalent of $HBF_4{\cdot}Et_2O$ in CH_3CN to compound **6a** induced the disappearance of the first wave, whereas there was no effect on the second. Moreover, the new species formed had the same electrochemical characteristics and behaviour towards electrochemical oxidation (at 1V) as compound **7a** under the same conditions.

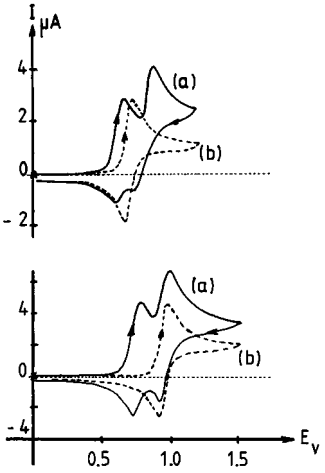

Figure 1. Cyclic voltammograms of (a) **3a**, (b) **3a** + 1 equiv. of $HBF_4{\cdot}Et_2O$ (top); cyclic voltammograms of (a) **6a**, (b) **6a** + 1 equiv. of $HBF_4{\cdot}Et_2O$, at 0.1 V s^{-1} in CH_3CN (bottom); experimental conditions: Pt electrode (1 mm) in 0.1 mol L^{-1} solution of Bu_4NPF_6 in CH_3CN, complex concentration 10^{-3} M

It has been shown that in a molecule with a saturated spacer such as **6a**, the protonation of the nitrogen atom may induce an anodic shift of the oxidation potential of the Fe^{II}/Fe^{III} couple.[3e,19] However, the nitrogen-iron distance is too long in **6a** for such an effect to be detected.[19] Interposition of a conjugated spacer between the ionophore and the ferrocene unit produces a noticeably different electrochemical response towards H^+ addition for **3a**. Electronic communication becomes possible through the spacer between the redox center and the protonated site, inducing an anodic shift of $\Delta E_{1/2}$ = 60 mV for this couple. This property is of real importance and suggests that molecules such as **3a**,**b** and **5a**,**b** could be electrochemical cation sensors.

The spectroscopic properties of compounds **3a** and **5a** were investigated in CH_3CN. The absorption spectra of these compounds (Figure 2) can be interpreted in accordance with the literature data.[6b,20] The broad low-intensity band located above 460 nm and well visible in the case of **3a** can be assigned to the d-d transition of iron in ferrocene. The intense band at 408 nm for **3a** and 416 nm for **5a** can similarly be attributed to charge transfer (CT) between the donor amino group and the acceptor carbonyl group. This band was strongly red-shifted with respect to the CT band of chalcone **8** (λ_{abs} = 382 nm in CH_3CN), which is in agreement with the extension of the conjugated system. The absorption spectrum of crown compounds **3b** and **5b** is similar in shape to that of **3a** and **5a**, respectively. Molar absorption coefficients were also found to be very close (for example ε_{404} = 28 600 and 30 000 L mol^{-1} cm^{-1} for **3a** and **3b**, respectively). The absorption spectrum of **6a** in CH_2Cl_2 displays a strong absorption band peaking around 264 nm and two weak bands between 300 and 360 nm, the latter two being assigned to the ferrocenyl moiety. It was checked that the protonated compound **7a** did not exhibit the long wavelength absorption band characteristic of the ferrocenium ion.

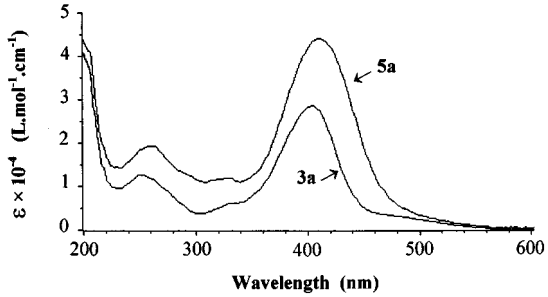

Figure 2. Absorption spectra of **3a** and **5a** in CH_3CN, ε = molar absorption coefficient

Very weak emission could be expected for compounds **3a** and **5a**, since ferrocenyl residues are known to quench luminescence. Indeed, when excited at the absorption band maximum, **3a** displays a very weak ($\Phi = 1 \times 10^{-4}$) fluorescence signal around 560 nm at room temperature. In contrast, an intense unresolved emission band was observed for compound **5a** (Figure 3). Absorption or excitation spectra of compound **5a** were similar. The quantum yield reached 7.7×10^{-2}, i.e. around ten times higher than that of **8** and only two times lower than that of diaminodibenzylidenacetone (**9**) in the same solvent.[7] This shows that in **5a** the ferrocenyl moiety, far from acting as a simple fluorescence quencher, behaves essentially as an auxochrome. Compound **5a** was studied in different solvents (Table 1). A strong positive solvatochromic effect was observed both in the absorption and emission spectra, which is also reminiscent of the behaviour of **9**.[21] This trend was accompanied by a drastic increase of the fluorescence quantum yield in polar media, which generally indicates the in-

volvement of an emissive intramolecular CT in the excited state.

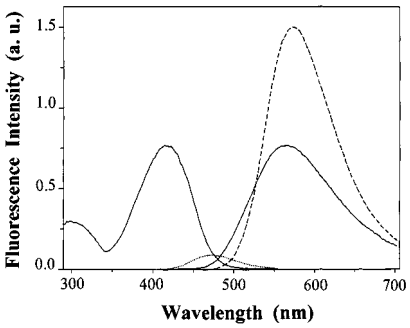

Figure 3. Excitation (λ_{em} = 560 nm) and emission (λ_{ex} = 416 nm) spectra of **5a** in CH_3CN (full line); emission spectra of **8** (λ_{ex} = 382 nm, dotted line) and **9** (λ_{ex} = 444 nm, broken line); the emission spectra are normalized according to the fluorescence quantum yield

Table 1. Spectroscopic data for **5a** in different solvents: absorption wavelength (λ_{abs}), emission wavelength (λ_{em}), fluorescence quantum yield (Φ_F) and Lippert polarity parameter (Δ_f)

Solvent	λ_{abs} (nm)	λ_{em} (nm)	Φ_F[a]	Δ_f
Cyclohexane	386	–	$<10^{-4}$	−0.001
Toluene	404	487	1.3×10^{-3}	0.013
Dioxane	404	495	4.3×10^{-3}	0.021
Ethyl acetate	404	516	1.4×10^{-2}	0.202
Tetrahydrofuran	412	523	2.1×10^{-2}	0.210
Acetone	410	541	2.4×10^{-2}	0.287
Acetonitrile	416	560	7.7×10^{-2}	0.306

[a] $\lambda_{ex} = \lambda_{abs}$.

Preliminary studies showed that crown compound **5b** was also fluorescent and could therefore find interesting applications as a fluoroionophore.

Conclusion

These results clearly indicate that new electroactive and fluorescent species containing only ferrocene as a metallic moiety can be obtained. Work is in progress to understand the electrochemical and unusual photophysical properties of **5a−b** better, and to test their potential ability for cation recognition by both techniques.

Experimental Section

Physical Methods: NMR, electrochemical and photophysical measurements were made as previously reported.[3e,7] The fluorescence spectra were corrected. The fluorescence quantum yield was determined relative to coumarin 6 in ethanol as the standard (Φ_F = 0.78).[22] Fast atom bombardment (FAB^+) or desorption chemical ionization (DCI) mass spectrometry were performed on a Nermag R 10 at the Service Commun de Spectrométrie de Masse de l'Université Paul Sabatier et du CNRS, Toulouse.

Complex 3b: To 20 mL of a basic solution (1:1 ethanol/10% aqueous NaOH) was added dropwise a mixture of 1 equiv. of **1** (315 mg, 1.38 mmol) and 1.1 equiv. of **2b** (490 mg, 1.52 mmol) dissolved in 10 mL ethanol. The light-protected mixture was stirred for 31 h at room temperature and the solvent evaporated to dryness. The organic phase was extracted with dichloromethane. The solution was filtered with a cannula under nitrogen, the solvent was evaporated off and the residue washed with pentane. The product was purified by column chromatography on alumina (eluent: pentane/CH_2Cl_2) and collected as a red fraction. After evaporation of the solvent, the product was washed with pentane and dried under vacuum for several hours to afford a red oil (240 mg, 33% yield). – ^{1}H NMR (300 MHz, $CDCl_3$, 293 K): δ = 3.67 (m, 16 H), 3.80 (m, 4 H) (CH_2 Crown), 4.22 (s, 5 H, C_5H_5), 4.56, 4.92 (each t, J_{HH} = 1.9 Hz, 4 H, C_5H_4), 6.70 (*CH*−CN), 7.55 (*CH*−CH−CN) (each d, J_{HH} = 8.9 Hz, 4 H, C_6H_4), 6.96 (CH=*CH*−CO), 7.76 (*CH*=CH−CO) (each d, J_{HH} = 15.5 Hz, 2 H). – ^{13}C{^{1}H} NMR (75.47 MHz, $CDCl_3$, 293 K): δ = 53.13, 68.69, 70.49, 70.66, 71.75 (s, CH_2 Crown), 69.99, 72.65, 81.69 (C_5H_4), 70.41 (C_5H_5), 111.93 (*CH*−CN), 123.08 (C_{ipso}−C=C), 130.65 (*CH*−CH−CN), 149.69 (C_{ipso}−N) (C_6H_4), 118.30 (CH=*CH*−CO), 141.92 (*CH*=CH−CO), 193.46 (CO), each s. MS (FAB); *m*/*z*: 533 $[M]^+$. – $C_{29}H_{35}FeNO_5$: calcd. C 65.27, H 6.62, N 2.63; found C 64.95, H 6.41, N 2.64.

Complex 5a and 6a: A mixture of 1 equiv. of **4** (400 mg, 1.48 mmol) and 2 equiv. of **2a** (524 mg, 2.96 mmol) in 20 mL ethanol was added dropwise to 20 mL of a basic solution (1:1 ethanol/10% aqueous NaOH). After stirring for 4 h at 20°C, the organic phase was extracted with dichloromethane, the solution filtered and the solvent evaporated to dryness. After column chromatography on alumina (eluent: CH_2Cl_2 then THF) a red fraction was collected and protected from light. Compounds **5a** and **6a** were separated by thin layer chromatography on silica gel (eluent: ethyl acetate/toluene: 1:2.5) in the dark. The products were rapidly extracted with acetone. Compound **5a** (red band) was purified by diethyl ether extraction and washing with pentane, and dried under vacuum to afford a red powder (61 mg, 7% yield). Compound **6a** (orange band) was washed with pentane, dried under vacuum and obtained as an orange powder (57 mg, 9% yield). Complex **5a**. – ^{1}H NMR (400 MHz, $CDCl_3$, 293 K): δ = 1.20 (t, J_{HH} = 7.1 Hz, 12 H, CH_3), 3.41 (q, J_{HH} = 7.1 Hz, 8 H, CH_2N), 4.53, 4.91 (each t, J_{HH} = 1.9 Hz, 8 H, C_5H_4), 6.62 (*CH*−CN), 7.51 (*CH*−CH−CN) (each d, J_{HH} = 8.9 Hz, 8 H, C_6H_4), 6.90 (CH=*CH*−CO), 7.75 (*CH*=CH−CO) (each d, J_{HH} = 15.4 Hz, 4 H). – ^{13}C{^{1}H} NMR (100.62 MHz, $CDCl_3$, 293 K): δ = 12.59 (CH_3), 44.47 (CH_2N), 70.99, 74.03, 82.47 (C_5H_4), 111.16 (*CH*−CN), 121.69 (C_{ipso}−C=C), 130.65 (*CH*−CH−CN), 149.37 (C_{ipso}−N) (C_6H_4), 116.87 (CH=*CH*−CO), 142.70 (*CH*=CH−CO), 192.38 (CO), each s. – MS (DCI): 589 $[M + H]^+$. – $C_{36}H_{40}N_2O_2Fe$: calcd. C 73.45, H 6.85, N 4.76; found C 73.07, H 6.97, N 4.64. Complex **6a.** – NMR: See text, close to **6b** (vide infra). MS (DCI): 430 $[M + H]^+$. – $C_{25}H_{27}FeNO_2$: calcd. C 69.91, H 6.34, N 3.26; found C 69.72, H 6.20, N 3.11.

Selected data for **6b:** ^{1}H NMR (400 MHz, $CDCl_3$, 223 K): δ = 2.41 (br d, J_{HH} = 12.0 Hz, 2 H, CH_2CO), 2.87 (br t, J_{HH} = 12.5 Hz, 2 H, CH_2CO), 3.66 (m, 20 H, CH_2 Crown), 4.25 (br t, J_{HH} = 11.5 Hz, 1 H, CH), 4.63, 4.66, 4.87, 4.91 (each br s, 8 H, C_5H_4), 6.61 (*CH*−CN), 7.21 (*CH*−CH−CN) (each d, J_{HH} = 8.5 Hz, 4 H, C_6H_4). – ^{13}C{^{1}H} NMR, (100.62 MHz, $CDCl_3$, 223 K): δ = 45.39 (CH), 46.61 (CH_2), 52.75, 67.84, 69.88, 71.57 (CH_2, crown), 68.84, 72.47, 74.25, 75.05, 81.81 (C_5H_4), 110.70 (*CH*−CN), 127.74 (*CH*−CH−CN), 131.64 (C_{ipso}−CH), 145.58 (C_{ipso}−N) (C_6H_4), 199.44 (CO), each s.

Selected data for **7a:** ^{1}H NMR (300 MHz, CD_3CN, 293 K): δ = 1.08 (t, J_{HH} = 7.1 Hz, 6 H, CH_3), 2.29 (m, 2 H, CH_2CO), 3.09 (br

t, J_{HH} = 12.4 Hz, 2 H, CH_2CO), 3.65 (m, 4 H, CH_2N), 4.15 (br t, J_{HH} = 11.4 Hz, 1 H, CH), 4.65, 5.07 (m, 8 H, C_5H_4), 7.46 (CH−CN), 7.65 (*CH*−CH−CN) (each d, J_{HH} = 8.6 Hz, 4 H, C_6H_4), 8.60 (br s, 1 H, NH). − $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$, 223 K): δ = 10.03 (CH_3), 46.14 (*CH*$_2$,CO, CH), 54.62 (CH_2N), 68.79, 72.83, 74.44, 74.94, 82.61 (C_5H_4), 122.87 (*CH*−CN), 129.60 (*CH*−CH−CN), 135.47 (C_{ipso}−N) 148.89 (C_{ipso}−CH) (C_6H_4), 179.78 (CO), each s.

Mono(cyclooctatetraenyl)samarium Complexes: the Return of the Normally "Inaccessible" Bis(trimethylsilyl)amido Derivative

M. Visseaux,*[a] A. Dormond,[a] and D. Barbier-Baudry[a]

Keywords: Samarium / Early organolanthanides / Bis(trimethylsilyl)amido / Cyclooctatetraenyl / Lanthanides

The complexes [(COT)Ln{N(SiMe$_3$)$_2$}(THF)] (Ln = late lanthanide metal) are readily accessible but, until now, the samarium analogue has proved elusive. The latter can be formed in solution but is easily desolvated during the isolation process, leading to a highly associated complex which is only soluble in coordinating solvents or in the presence of ancillary ligands.

Introduction

There is now a growing interest in the cyclooctatetraenyl derivatives of the metals of groups 3 and 4. As an alternative to traditional cyclopentadienyl chemistry, this ligand provides original structural features,[1a,1b] and, due to their potential for olefin[2] and lactone polymerization,[3] cyclooctatetraenyl complexes are often protected by patents. Our research has recently turned towards diene polymerization catalysed by early lanthanide metal complexes[4] and we envisaged the use of monocyclooctatetraenyl derivatives as possible starting materials for convenient catalyst precursors. During our first investigations into lanthanide chemistry, we had observed the formation of [(COT)Sm{N(SiMe$_3$)$_2$}(THF)], (COT = C_8H_8) in polar (deuterated THF) and nonpolar (deuterated benzene) solvents.[5] Therefore we were surprised when it was reported that the amido complexes [(COT)Ln{N(SiMe$_3$)$_2$}(THF)] could only be isolated for yttrium and the late lanthanide metals.[6a] For samarium, this compound could not be isolated, an unusual inverse half-sandwich complex being formed instead.[6b] Because [(COT)Sm{N(SiMe$_3$)$_2$}(THF)] could provide a good precursor for catalytically active cationic cyclooctatetraenyl species (see ref.[7] for recent results in this field), we decided to look again at the reaction of Na[N(SiMe$_3$)$_2$] with [(COT)SmCl(THF)]$_2$. In this communication we report new data leading to a better understanding of these apparently contradictory data.

Results and Discussion

All syntheses were first performed in an NMR tube and then scaled up. In a typical reaction, [(COT)SmCl(THF)]$_2$, **1** and NaN(SiMe$_3$)$_2$ were mixed in a 1/1 molar ratio in an NMR tube and C_6D_6 was added. The violet complex **1** is not soluble in benzene but, after vigorously stirring for a short time, a purple solution and a grey-brown precipitate were obtained. A set of signals clearly indicative of the presence of a mono(bistrimethylsilyl)amido complex was observed {δ = 9.17 (8 H, COT), and −2.37 [18 H, N(SiMe$_3$)$_2$]}.

Because the same compound had previously been obtained by mixing the reactants in deuterated THF and then changing the solvent for deuterated benzene,[8] the bulk synthesis of [(COT)Sm{N(SiMe$_3$)$_2$}(THF)], **2**, was performed in THF with 1/1 stoichiometric amounts of the reactants. After 16 hours stirring at room temperature, the solvent was removed and the crude product extracted with toluene. The reddish solution was slowly concentrated leaving a small crop of deep red crystals (unsuitable for X-ray analysis) and a mother liquor which, after separation of the crystals, was evaporated to dryness. Both fractions were analysed by NMR spectroscopy. The crystals were insoluble in benzene: when C_6D_6 was added to a sample of ca 5−6 mg, after smooth heating and ultrasonic stirring, a pale orange solution was obtained and a brown precipitate deposited. NMR spectroscopic analysis of the solution showed virtually only one component − the known complex Sm[N(SiMe$_3$)$_2$]$_3$ (δ = −1.57 ppm).[9] The NMR tube was then connected to a vacuum line, degassed and THF added. The precipitate immediately dissolved giving a pink-purple solution and only the signals previously observed for **2** were present.

The red solid which was obtained from the mother liquor was found, by elemental analysis, to correspond to the partially desolvated complex [(COT)Sm{N(SiMe$_3$)$_2$}(THF)$_{0.5}$]. It was only sparingly soluble in deuterated benzene and, as well as a reddish precipitate, a pale purple solution of **2** was obtained {δ (C_6D_6) = 9.19 (8 H, COT), 5.95 (4 H, THF), 2.17 (4 H, THF), −2.37 [18 H, N(SiMe$_3$)$_2$]}.

A sample of analytically pure unsolvated [(COT)SmN(SiMe$_3$)$_2$]$_n$ **3**, was obtained (see experimental) by the slow evaporation of a toluene solution of **2**. The IR spectrum confirmed the absence of coordinated THF[10a,b] (no absorption in the range 1010 − 1030 cm^{-1}), and the presence of the COT^{2-} ligand (C−H bending at 719, 869 cm^{-1}).[10b,11]

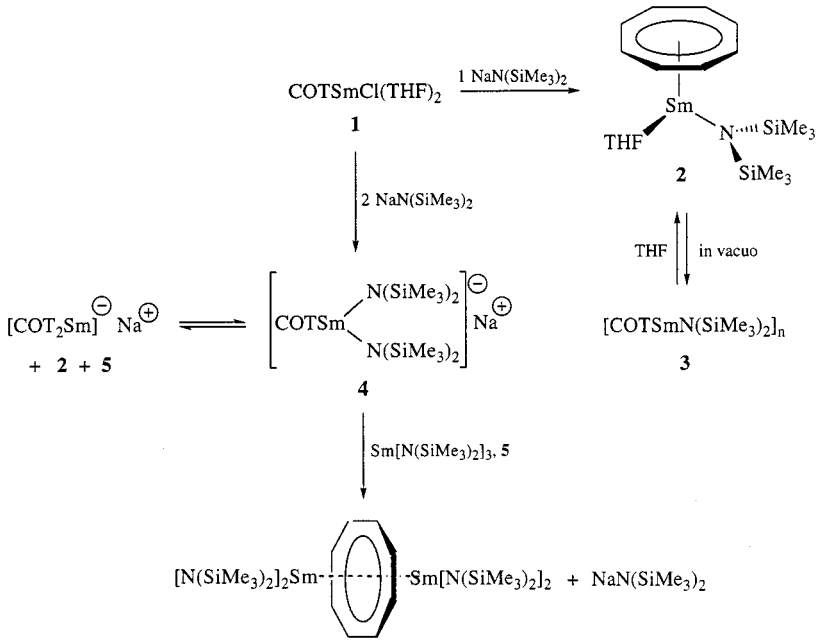
Crystals of **2** could be obtained at low temperature, as thin foliated plates, during the concentration of a THF solution but they rapidly redissolved when the temperature was raised. Simultaneously, a colour change from pink to red, corresponding to the desolvation, was observed.

By using a nearly 1:2 molar ratio of **1** and Na[N(-$SiMe_3)_2$], the formation of an anionic compound, [(COT)Sm{$N(SiMe_3)_2$}$_2$Na], **4**, was observed. This anionic complex is soluble in benzene and can be extracted with pentane. An analogous anionic compound containing two sterically demanding ligands, [(COT)Ln{$CH(SiMe_3)_2$}$_2$-$Li(THF)_2$], has also been described as being soluble in hexane.[12]

Complex **4** was not formed alone: in the benzene solution, the presence of **2** (30%) and $Sm[N(SiMe_3)_2]_3$ **(5)** (15%) was also observed {percentages estimated by integration of the (COT) and $N(SiMe_3)_2$ signals in the ^1H NMR spectrum}. In deuterated THF as solvent, the composition of the mixture was different − the presence of the less soluble [$(COT)_2$SmNa], (δ = 13.21)[10b] (10%), was also observed. The mixture contained **4** as major component (65%) and **2** (25%). The solvent was removed in vacuo and the remaining traces of coordinated solvent were eliminated by three cycles of toluene condensation and evaporation. The residue was extracted with pentane, the pentane solution transferred to another tube and pentane removed in vacuo. After addition of C_6D_6, the NMR spectrum was recorded. Signals corresponding to the half-sandwich complex[6b] were observed (10%), as well as those of **2** (25%), **4** (45%) and **5** (20%). After addition of THF, the signals of the half-sandwich complex decreased and disappeared within 12 hours.



In summary, we could observe the formation of the expected [(COT)Sm{$N(SiMe_3)_2$}(THF)] **(2)** when performing the reaction without an excess of amido reagent. This complex was easily desolvated, leading to an insoluble, highly associated compound [(COT)Sm{$N(SiMe_3)_2$}]$_n$ **(3)** isolated as deep red microcrystals, whose IR data are very close to those of unsolvated uranium and thorium analogues.[13] After addition of the required quantity of THF the soluble complex **2** is recovered. For the desolvated complex **3**, the saturation of the coordination sphere of the samarium ought to be completed by bridging $N(SiMe_3)_2$ groups, as commonly observed for main group derivatives,[14] or more seldom for transition metal organometallic complexes.[15] The previously described half-sandwich complex [{$N(SiMe_3)_2$}$_2$Sm(COT)Sm{$N(SiMe_3)_2$}$_2$] can be obtained with a 1:2.6 molar ratio of the reactants.[6b] We could also observe the formation of this compound, in a lower yield, with a 1:2 molar ratio of the reactants. It was not stable in the presence of THF. Conproportionation-disproportionation reactions have been observed in the uranium series between an associated monocyclooctatretraenyl complex and an unsolvated homoleptic borohydride (Scheme 1).[16]

$$[(C_8H_8)U(BH_4)_2]_n + U(BH_4)_4 \longrightarrow (BH_4)_3U(C_8H_8)U(BH_4)_3$$

$$(BH_4)_3U(C_8H_8)U(BH_4)_3 \xrightarrow{THF} [(C_8H_8)U(BH_4)_2](THF) + U(BH_4)_4(THF)_2$$

Scheme 1

Nevertheless, in the samarium series, by mixing **3** and $Sm[N(SiMe_3)_2]_3$ no such reaction occurred. It was consequently postulated that the formation of the half sandwich could occur in the alkane phase, from **4** and **5**, with elimination of $Na[N(SiMe_3)_2]$ (Scheme 2). In fact, after heating a (deuterated) benzene solution containing **4** and **5**, the half-sandwich complex was found to be the major component of the mixture.

Scheme 2. Formation of cyclooctatetraenylsilylamido derivatives

Conclusions

These experiments emphasize the great importance of the ionic strength or the polarity of the reaction medium for organolanthanide syntheses, dominated by the exchange ligand reactions. They also show the interest of using paramagnetic lanthanides for these studies: even for an element inducing a relatively small paramagnetic shift, the NMR spectra allow us to observe the different equilibria established in neutral or polar media.

Experimental Section

General: All experiments were performed with rigorous exclusion of oxygen and moisture, using a JACOMEX glovebox and vacuum line techniques. Solvents were stored over sodium-benzophenone and vacuum-transferred to reaction vessels. Deuterated solvents were distilled over Na/K alloy. NMR spectra were recorded on a Bruker AC 200 spectrometer (297 K). IR spectra were recorded in nujol mulls with a Bruker IFS/66V Spectrometer. Elemental analyses were performed with a Fisons EA 1108 CHONS apparatus. $[(COT)SmCl(THF)]_2$ **1** was prepared as previously described[10b] but with solid $K_2(COT)$ as reagent.[13] $Na[N(SiMe_3)_2]$ was purchased from Aldrich and used without further purification.

$[(COT)SmN(SiMe_3)_2(THF)]$ (2): *NMR scale*: $[(COT)SmCl(THF)]_2$ (8 mg) and $Na[N(SiMe_3)_2]$ (3 mg) were placed in an NMR tube, 0.5 mL of C_6D_6 was added and the mixture was stirred by sonication until the two solids dissolved. A purple solution of **2** and a grey-brown precipitate were obtained. *Bulk synthesis*: $[(COT)SmCl(THF)]_2$ (280 mg), and $Na[N(SiMe_3)_2]$ (118 mg), were placed in a flask connected to the vacuum line and THF (20 mL) was added by condensation. After 4 hours stirring the deep violet solution became purple. The solvent was then removed and toluene added. After filtration, the solution was condensed and red crystals deposited. They were separated, washed with toluene and dried. NMR(C_6D_6): soluble after addition of THF, exhibiting the set of signals for **2**.The mother liquor was transferred into another flask and the solvent removed in vacuo, giving a dark red solid. – ^{1}H NMR(C_6D_6), only partially soluble, signals of **2**: δ (C_6D_6) = 9.19 (8 H, COT), 5.95 (4 H, THF), 2.17 (4 H, THF), −2.37 [18 H, $N(SiMe_3)_2$]. – $C_{14}H_{26}NSi_2Sm(THF)_{0.5}$ (451): calcd. C 42.61, H 6.70, N 3.11; found C 42.84, H 6.31, N 3.08.

$[(COT)Sm[N(SiMe_3)_2]_n$ (3): $[(COT)SmCl(THF)]_2$ **1** (240 mg) and $Na[N(SiMe_3)_2]$ (101 mg) were placed in a flask connected to the vacuum line and THF (20 mL) was added by condensation. After 20 minutes stirring at ambient temperature, the mixture was heated at reflux for 5 minutes to give a deep purple solution, with some remaining violet crystals of **1** and a greyish precipitate. The volatiles were then removed in vacuo and toluene(20 mL) was added. After stirring for a short time, the mixture was allowed to stand overnight to allow the precipitation of the sodium salt and other insolubles. After filtration the solution was very slowly evaporated to dryness, at ambient temperature, leaving **3** as deep red microcrystals. Yield ca 65%. – IR (nujol): $\tilde{\nu}$ = 1254 (s) cm^{-1}, 1241(s), 986 (vs), 869 (s), 840 (s), 822 (s), 770 (m), 719 (s), 663 (m). – $C_{14}H_{26}NSi_2Sm$ (414.9): calcd. C 40.53, H 6.32, N 3.38; found C 40.37, H 6.17, N 3.39. No melting point was observed up to 210 °C. A slow decomposition occurred, shown by the formation of a colourless solid.

Formation of Adducts

THF Adduct: In the glove box 6 mg of **3** were introduced into an NMR tube and C_6D_6 added. No colour developed in solution after vigorous shaking. The solvent was frozen, the tube connected to the vacuum line, evacuated, and then THF was added at ambient temperature. The purple colour of **2** appeared on melting of the solvent and no precipitate was observed.

Nitrile Adduct: 6 mg of **3** were introduced into an NMR tube and C_6D_6 added. After addition of 7 mg (3 eq) of 2,4,6,trimethylbenzonitrile an orange solution was obtained. – ^{1}H NMR: δ = 9.13 (8 H, COT), −2.24 {(18 H, $N(SiMe_3)_2$}, 6.32, 2.31 and 1.78 (nitrile).

$(COT)Sm[N(SiMe_3)_2]_2Na$ (4) and Half-Sandwich Complex: In an NMR tube were placed 8 mg of **1** and 7 mg of $NaN(SiMe_3)_2$. C_6D_6 (0.5 mL) was added and after a few minutes of gentle heating, the ^{1}H NMR spectrum of the resulting orange solution was recorded. – ^{1}H NMR (C_6D_6) **4**: δ = 8.47 (8 H, COT), 3.75 (4 H, THF), 1.48 (4 H, THF), −1.56 [36 H, $N(SiMe_3)_2$] (the integration of the $N(SiMe_3)_2$ signal indicated the presence of overlapped **5**); **2**: δ = 9.19 (8 H, COT) −2.41 [18 H, $N(SiMe_3)_2$]; δ = 9.25 (8 H) and −2.23 (72 H) (traces < 3%), tentatively attributed to the half-sandwich complex The latter signals disappeared after 12 h. After changing the solvent, **4**: δ (C_4D_8O) = 8.63 (8 H) −1.75 (36 H); **2**: δ = 9.57 (8 H) −1.21(18 H); δ = 13.2 $(COT)_2SmNa$. – The tube was then pumped dry, toluene added by condensation and then removed, and pentane (1 mL) added. After stirring for five minutes and decanting, the pentane solution was transferred into another tube, the volatiles were evacuated and C_6D_6 was added: δ(C_6D_6) = 9.27 (4 H, COT), −2.24 [36 H, $N(SiMe_3)_2$], half-sandwich complex; **2**: δ = 9.06 (8 H, COT) −2.50 [18 H, $N(SiMe_3)_2$]; **4**: δ = 8.35 (8 H) and −1.64 [36 H, $N(SiMe_3)_2$]; **5**: δ = −1.56. After addition of a tenfold excess of THF, an NMR spectrum was immediately recorded. The intensities of the signals of **2** and of the half-sandwich complex had significantly decreased (by 50%). C_6D_6 was added to the pentane-insoluble residue, which was sparingly soluble in benzene. The NMR spectrum was identical to the earlier one except that **2** was present only in trace amounts (<1%). – **3** (8 mg), **5** (8 mg) and 0.5 mL of C_6D_6 were added to an NMR tube. The tube was vigorously stirred then subjected to sonication. Only **5** was present in the solution. After addition of $NaN(SiMe_3)_2$, **3** disappeared and the solution was found to contain **4** and **5**. After a few minutes of gentle heating, the ^{1}H NMR spectrum of the orange solution was recorded. Compounds **4**, **5** and the half-sandwich complex (27, 17 and 56%, respectively) were present.

The Hexahydro-*closo*-hexaborate Dianion $[B_6H_6]^{2-}$ and Its Derivatives

Wilhelm Preetz*[a] and Gerhard Peters[a]

Keywords: Hexahydro-*closo*-hexaborate / Syntheses / Protonation / Non-rigidity / Substitution reactions / Derivatives / Kinetics / Degradation and expansion products / Crystal structure data /NMR data / IR and Raman data / Normal coordinate analyses / ESR and electrochemical data / Ab initio results

$[B_6H_6]^{2-}$ as the smallest known hydro-*closo*-borate is only moderately stable, and therefore its reaction chemistry remained unexplored for quite a long time. Since the mid 1980s some progress has been made in this field, and a considerable number of derivatives has been prepared. The provided structural and spectroscopic data together with the results of more sophisticated theoretical investigations by high level ab initio methods are a good basis for a systematic review on this class of compounds, and may encourage further synthetic and theoretical work. This is the aim of the present article giving a comprehensive survey up to the beginning of 1999.

Introduction

The story of the polyhedral *closo*-borates is characterized as an interplay of theoretical and synthetic progress. Based on theoretical studies of the valence structures of boron hydrides the existence of closed-shell hydro-*closo*-borate anions of the type $[B_nH_n]^{2-}$, $n = 5-12$, had been predicted in 1954.[1−3] Even some years later, in 1959 and 1960 salts of the exceptionally stable species $[B_{10}H_{10}]^{2-}$ [4] and $[B_{12}H_{12}]^{2-}$ [5] could be synthesized. The until now smallest known member of this series $[B_6H_6]^{2-}$, which is merely moderately stable, evaded preparation until 1964[6] − a decade after its prediction.

While for $[B_{10}H_{10}]^{2-}$ and $[B_{12}H_{12}]^{2-}$ an extensive derivative chemistry had been established very soon after their discovery,[7][8] for $[B_6H_6]^{2-}$ until 1984 the unique descendant remained $[B_6Br_6]^{2-}$, which only has been mentioned in a footnote.[9] The reason for this hiatus may lie in the initially complicated synthesis using the dangerous diborane, the small yield, and the instability of $[B_6H_6]^{2-}$ in acidic media. Therefore, a more vigorous study of its reaction chemistry was difficult, and demanded better synthetic routes to

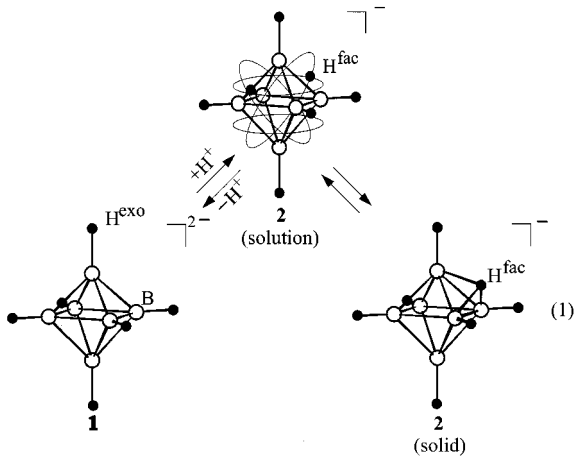
Wilhelm Preetz, born in 1934, received his Ph.D. degree in 1963 under supervision of Professor Dr. E. Blasius at the Technical University of Berlin. After his habilitation at the University of Saarland, Saarbrücken, he became Full Professor of Inorganic Chemistry at the Christian-Albrechts-University of Kiel in 1971. His main fields of research are the preparation, separation, structural, and spectroscopic characterization of octahedral mixed-ligand complexes with investigations on the trans effect and trans influence, of transition metal complexes and clusters with multiple metal−metal bonds, and since 1980 of closo-borate clusters, especially the chemistry of the little investigated $[B_6H_6]^{2-}$.



Gerhard Peters studied chemistry at the Christian-Albrechts-University of Kiel. He joined the group of Prof. Dr. W. Preetz with a thesis on thiocyanato linkage isomers of osmium and on new complexes of Re and Tc with multiple metal−metal bonds, and received his Ph.D. in 1982. Currently, he is engaged in multinuclear high-resolution NMR spectroscopy on solutions and solids at the Department of Inorganic Chemistry of the Christian-Albrechts-University of Kiel. Besides, he is an instructor for advanced students and an adviser of scientific co-workers in the fields of inorganic chemistry, radiochemistry and electrochemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

its preparation. Stimulated by our findings in the fields of classical octahedral mixed-ligand complexes of the transition metals and of the hexanuclear clusters of Mo, W, Nb, and Ta[10] with respect to the interrelation between symmetry and structural and spectroscopic properties, the octahedral B_6 cage with its terminally bonded or *exopolyhedral* substituents seemed to be a worthwhile investigation object, in order to study these interrelations in this field, too.

In this review we report on the parent compound $[B_6H_6]^{2-}$ (**1**) and its derivatives resulting by replacement of the *exopolyhedral* H atoms against inorganic and organic substituents. The cluster anion is a regular octahedral cage of 6 B atoms surrounded by a larger octahedron of 6 radially disposed *exopolyhedral* H atoms. Special attention is drawn to the property of $[B_6H_6]^{2-}$ to react as a Brønsted base, and to attach an additional proton H^{fac} giving $[B_6H_6H^{fac}]^-$ (**2**). In solution in a nonrigid structure H^{fac} fluctuates across the octahedron′s surface via the edges, and in the solid state it is fixed above one of the octahedron′s facets, as is shown in Equation 1.

(1)

The protolysis equilibrium in Equation 1 is exemplary, and it will be of crucial importance for the chemistry of the *closo*-hexaborates and their substitution processes. Furthermore, $[B_6H_6]^{2-}$ is discussed as a ligand in metal complexes, and some reactions modifying the B_6 core are included, while the carbaboranes are excluded. The literature for the title subject is covered up to the beginning of 1999.

The structures of most of the compounds have been solved by single-crystal X-ray structure analyses, and, in general, ^{11}B-NMR spectroscopy is used for the characterization of the derivatives, accompanied by the respective hetero-nucleus NMR spectroscopy in case of suitable substituent nuclei such as ^{1}H, ^{13}C, ^{19}F, ^{29}Si, ^{77}Se, ^{113}Cd, and ^{199}Hg. Further, the vibrational spectra, IR and Raman, have been measured and for sure assignment accompanied by normal coordinate analyses.

The influence of the different substituents on the kinetics, the molecular parameters and the spectral properties is discussed in detail. In some special cases ab initio calculations have been performed to obtain insight into the electronic and molecular structures, and to affirm the assignment of spectral data by frequency analysis and by calculated NMR chemical shifts.

Whenever possible, the pK_a values of the protolysis equilibria determined by potentiometric titration are reported, and for redox active species electrochemical data are added. UV/Vis and ESR spectroscopy have been applied to the colored radical anions obtained by oxidation processes.

Syntheses, Structure, and Properties of $[B_6H_6]^{2-}$

Starting with commercially available materials diborane is generated in a first step as formulated in Equation 2.

$$3\ NaBH_4 + 4\ BF_3 \cdot O(C_2H_5)_2 \xrightarrow{20\ °C,\ Diglyme} 2\ B_2H_6\uparrow + 3\ NaBF_4 + 4\ (C_2H_5)_2O \quad (2)$$

B_2H_6 is passed through a diglyme solution of tetrahydroborate, and octahydrotriborate $[B_3H_8]^-$ is formed as an intermediate product according to Equation 3.

$$B_2H_6 + NaBH_4 \xrightarrow{90\ °C,\ Diglyme} Na[B_3H_8] + H_2\uparrow \quad (3)$$

On boiling, the colorless reaction mixture turns to yellow, and in parallel reactions the following clusters are produced as given in Equations 4−6.

$$2\ Na[B_3H_8] \xrightarrow{162\ °C,\ Diglyme} Na_2[B_6H_6] + 5\ H_2\uparrow \quad (4)$$

$$4\ Na[B_3H_8] \xrightarrow{162\ °C,\ Diglyme} Na_2[B_{10}H_{10}] + 2\ NaBH_4 + 7\ H_2\uparrow \quad (5)$$

$$5\ Na[B_3H_8] \xrightarrow{162\ °C,\ Diglyme} Na_2[B_{12}H_{12}] + 3\ NaBH_4 + 8\ H_2\uparrow \quad (6)$$

The ratio of $[B_6H_6]^{2-}/[B_{10}H_{10}]^{2-}/[B_{12}H_{12}]^{2-}$ is 2:1:15, and the total amount of $[B_6H_6]^{2-}$ is 5% at most. In a recently published one-pot synthesis[11] the liberation of large and dangerous amounts of B_2H_6 is avoided, and yield of $[B_6H_6]^{2-}$ is raised to 25%. Boron trifluoride−diethyl ether is treated in diglyme at 100° C with an excess of tetrahydroborate according to Equation 7 to give $Na[B_3H_8]$,[12] which is transformed by subsequent refluxing for 36 h into a mixture of the *closo*-borate clusters.[11]

$$5\ NaBH_4 + 4\ BF_3 \cdot O(C_2H_5)_2 \xrightarrow{100\ °C,\ Diglyme} 2\ Na[B_3H_8] + 2\ H_2\uparrow + 3\ NaBF_4 + 4\ (C_2H_5)_2O \quad (7)$$

Fortunately, from the always resulting product mixtures of all synthetic routes a crude separation of $[B_6H_6]^{2-}$ from $[B_{10}H_{10}]^{2-}$ and $[B_{12}H_{12}]^{2-}$ is possible on the basis of the protolysis equilibrium of $[B_6H_6]^{2-}$ and the pH dependence of the solubility of the tetra-*n*-butylammonium $[nBu_4N]^+$ salts in water.[13][14] While $[B_{10}H_{10}]^{2-}$ and $[B_{12}H_{12}]^{2-}$ are precipitated in basic media, $[B_6H_6]^{2-}$ remains in solution, from which after separation and following cautious acidification $[nBu_4N][B_6H_6H^{fac}]$ is obtained as a scarcely soluble compound. Dissolution in dichloromethane and addition of an aliquot amount of $[nBu_4N]OH$ yields the deprotonated $[nBu_4N]_2[B_6H_6]$, which in aqueous solution is converted into the scarcely soluble Cs salt according to Equation 8.

$$[n\mathrm{Bu_4N}]_2[B_6H_6] + 2\ CsOH \rightarrow Cs_2[B_6H_6]\downarrow + 2\ [n\mathrm{Bu_4N}]OH \quad (8)$$

Protonation to the well-soluble $Cs[B_6H_6H^{fac}]$ is accomplished by addition of an aliquot amount of hydrochloric acid.

As another synthetic route, however with small yields only, the reaction of iodine with tetrahydroborate may be mentioned as described by Equation 9.[15–17]

$$6\ NaBH_4 + 2\ I_2 \rightarrow Na_2[B_6H_6] + 4\ NaI + 9\ H_2\uparrow \quad (9)$$

As in the preceding reactions the intermediate formation of $[B_3H_8]^-$ as formulated in Equations 3 and 7 is decisive, and also in the solid small amounts of $[B_6H_6]^{2-}$ are produced from salts of $[B_3H_8]^-$ on tempering them above 200° C.[18] Anhydrous $Na_2[B_6H_6]$ is conveniently prepared by reaction of $Na[B(C_5H_6)_4]$ and $[n\mathrm{Bu_4N}]_2[B_6H_6]$ in methanol.[19]

$[B_6H_6]^{2-}$ (**1**) has a regular octahedral cage of 6 B atoms surrounded by a larger octahedron of 6 radially disposed *exopolyhedral* H atoms. This octahedral structure of $[B_6H_6]^{2-}$ had been postulated already in 1954,[1][3] and could be confirmed for the solid state by X-ray structure analyses on the $[Me_4N]^+$,[20] K^+ and Cs^+ salts,[21] and for the solution state by NMR spectroscopy.[22][23] The B–B and B–H distances are 169, 172.1, 172.2 pm and 111, 107, 109 pm, respectively. On polycrystalline $Cs_2[B_6H_6]$ a solid-state ^{11}B-, ^{133}Cs-, and ^{1}H-NMR study at 1.88 T has been performed revealing fine structure due to ^{11}B-^{1}H and ^{10}B-^{1}H quadrupolar and dipolar interactions, which has allowed the calculation of the B–H distance to 119 pm. The accuracy of the determination of distances by NMR spectroscopy, X-ray, and neutron diffraction has been discussed.[24]

As the Brønsted base $[B_6H_6]^{2-}$ has a pK_a value of 7 the protonated form $[B_6H_6H^{fac}]^-$ (**2**) is present already in weak acidic solutions.[14] The localization of H^{fac} above one of the facets of the octahedron in a face-capped structure had been predicted on the basis of theoretical calculations,[25–29] and was confirmed by X-ray analyses on $[Ph_4P][B_6H_6H^{fac}]$, $[Ni(bipy)_3][B_6H_6H^{fac}]_2$, and $[Ni(phen)_3][B_6H_6H^{fac}]_2$.[30] The observed decomposition of $[B_6H_6H^{fac}]^-$ in stronger acidic media is explained by the instability of the twofold protonated species, the hypothetical *closo*-borane $[B_6H_8]$, which should better be written as $[B_6H_6(H^{fac})_2]$. This also follows from theoretical investigations, and corresponds to experimental results on $[H_2Os_6(CO)_{18}]$.[25,28,31,32]

A more profound understanding of the Brønsted base behavior of $[B_6H_6]^{2-}$ is provided by calculations of the electron density. An instructive idea is given by the electron localization function (ELF)[33][34] of the three-center, two-electron (3c2e) bonds of the B_3 faces. The maxima of electron density are centered above the eight faces resulting in the geometrical arrangement of a cube, the dual polyhedron to the octahedron. For this reason the faces of the octahedron are the favored regions for the addition of H^{fac} or the attack of other electrophilic reactants, and because of their Lewis basicity they can act as donating centers to Lewis acidic metal ions.

In principle, ^{1}H-NMR solution spectroscopy as the quick method of choice allows the reliable identification of H^{fac}, and provides slightly solvent- and cation-dependent high-field signals with unresolved ^{11}B couplings at $\delta(^1H) = -5.6$ for H^{fac}, while the signal of the *exopolyhedral* protons is a quadruplet with the typical pattern due to quadrupolar coupling to ^{11}B ($I = 3/2$) at $\delta(^1H) = 1.2$. The ^{1}H-coupled ^{11}B spectra of both $[B_6H_6]^{2-}$ and $[B_6H_6H^{fac}]^-$ show markedly solvent- and cation-dependent single doublets, each, with coupling constants $^1J(^{11}B,^1H^{exo}) = 140-150$ Hz. Table 1 gives an overview of the solvent and cation dependence.

In solutions of both $[B_6H_6]^{2-}$ and $[B_6H_6H^{fac}]^-$ the 6 B core atoms as well as the 6 terminal H atoms are chemically and magnetically equivalent at room temperature, and therefore H^{fac} must fluctuate across all faces with the same residence time. The migration is intramolecular, and takes place chiefly via the edges across the surface of the octahedron with a migration barrier in the order of 10 kcal·mol^{-1}.[22] This way is favored energetically in comparison to that across the vertices by 21 kcal·mol^{-1}.[36] From studies on different salts a cation–anion interaction must be taken into consideration,[22][36] and from relaxation considerations with respect to quadrupolar coupling and electric field gradient interactions $^1J(^{11}B,^1H^{fac})$ scalar coupling constants of 13 and 16 Hz for $[n\mathrm{Bu_4N}][B_6H_6H^{fac}]$ and $[Ni(bipy)_3][B_6H_6H^{fac}]_2$ in acetone have been derived, respectively.[22] Only after cooling of solutions containing $[B_6H_6H^{fac}]^-$ below the coalescence temperature the ^{11}B resonance is split into two signals with $\delta(^{11}B)$ shifted downfield for the uncapped facet and upfield for the facet capped by H^{fac} [22] (see Table 1). The coalescence points have been determined to 196 K at 1.88 T for $[Ni(bipy)_3][B_6H_6H^{fac}]_2$ in acetone[22] and to 227 K at 9.35 T for $[Ph_4As][B_6H_6H^{fac}]$ in CD_2Cl_2.[35] Because of the great interest in the fluxional behavior of the additional proton H^{fac} different calculations with regard to the barrier of movement across the octahedron facets have been done. From the temperature dependence of the ^{11}B-NMR spectra of $[n\mathrm{Bu_4N}][B_6H_6H^{fac}]$ and $[Ni(bipy)_3][B_6H_6H^{fac}]_2$ in acetone values of 10 and 11.5 kcal·mol^{-1} have been determined,[22] which are in good agreement with theoretical investigations resulting in 10.4 kcal·mol^{-1} with an SCF/DEHD approach,[36] 12.1 kcal·mol^{-1} at the MP2/6-31G* level,[37] and in 8.3 kcal·mol^{-1} at the B3LYP/6-311+G** level.[38] This low energetic barrier is attributed to the three-dimensional aromaticity[39][40] of *closo*-borates, which may be described as the tendency of the molecule anions to realize equal electronic conditions at all boron atoms by a "cluster current". In several theoretical studies the migration barrier of H^{fac} in $[B_6H_6H^{fac}]^-$ has been compared to those in $[B_{10}H_{10}H^{fac}]^-$ [41] and $[B_7H_7H^{fac}]^-$, $[B_9H_9H^{fac}]^-$, $[B_{12}H_{12}H^{fac}]^-$.[38,42–44] The cluster bond enthalpies have been calculated for $[B_nH_n]^{2-}$, $n = 6, 8-10$.[45]

$[B_6H_6]^{2-}$ can be deuteriated completely by treatment with D_2O.[46] Kinetic investigations have shown, that the reaction rate is proportional to the ratio of the protonated form, so that the deuteriation proceeds very fast in neutral or acidic media, while in basic media it runs not at all or very

Table 1. Chemical shifts $\delta(^1H)$ and $\delta(^{11}B)$ [ppm] and coupling constants $^1J(^1H,^{11}B)$ [Hz] of $[B_6H_6]^{2-}$ (a) and $[B_6H_6H^{fac}]^-$ (b) in different solvents, at different temperatures and with different cations and of $[B_6D_6D^{fac}]^-$ (c)

slow.[14] Although the movement of H^{fac} across the octahedral surface proceeds from face to face via the edges and not via the corners, the decisive step is the intramolecular exchange of H^{fac} or D^{fac} respectively against one of the terminally bonded H atoms. The activation energy of this process has been determined to be 18 kcal·mol^{-1}.[14]

As $[B_6H_6]^{2-}$ may serve as a paradigm of the class of doubly octahedral structured systems, its vibrational spectra have been examined and interpreted repeatedly.[47−49] The octahedral structure of $[B_6H_6]^{2-}$, which has been proven by X-ray structure analysis and by NMR spectroscopy, is clearly derived from the vibrational spectra, too. For a 12-atomic *homoleptic* molecule $[B_6X_6]^{2-}$ with point group O_h the normal modes of vibration transform as given by Equation 10.

$$\Gamma_{\tilde{\nu}} = 2\,A_{1g} + 2\,E_g + T_{1g} + 3\,T_{1u} + 2\,T_{2g} + 2\,T_{2u} \quad (10)$$

For systems with a center of symmetry the rule of mutual exclusion is valid, and according to the group-theoretical selection rules the vibrations with symmetries A_{1g}, E_g, and T_{2g} are Raman-active, those with symmetry T_{1u} are IR-active and those with T_{1g} and T_{2u} are inactive. The B_6 cage and the X_6 octahedra, put into each other, perform coherent vibrations, which are subdivided in two groups[50]:

1. Vibrations with equidirectional movement of the two spheres (in phase) transform as given in Equation 11.

$$\Gamma_{\text{in phase}} = A_{1g} + E_g + T_{1u} + T_{2g} + T_{2u} \quad (11)$$

2. Vibrations with a counter-directional movement of the two spheres (anti phase) transform as given in Equation 12.

$$\Gamma_{\text{anti phase}} = A_{1g} + E_g + T_{1g} + 2T_{1u} + T_{2g} + T_{2u} \quad (12)$$

The normal vibrations are presented in Figure 1. The highest spectral resolution on the parent compound has been achieved by measurement at low temperature.[51] As the isotopic ratio of boron at natural abundance is 80.22% ^{11}B and 19.78% ^{10}B, $[B_6H_6]^{2-}$ is in fact an isotopomeric series $[^{11}B_n{}^{10}B_{(6-n)}H_6]^{2-}$, $n = 0-6$, and this is observed in the 10 K Raman spectra with very sharp lines for the respective isotopomers having a half-width of 1.5 cm^{-1}, only. An unambiguous assignment of the normal vibrations has become possible by measurement of the final members $[^{11}B_6H_6]^{2-}$ (96% ^{11}B) and $[^{10}B_6H_6]^{2-}$ (92% ^{10}B), which have been prepared in high isotopic enrichment.[52] The Raman-active cage vibrations $\tilde{\nu}_1$, $\tilde{\nu}_2$, and $\tilde{\nu}_3$ are shifting with increasing n in steps of 7 cm^{-1} to lower frequencies. From the fine-structure of the signals even the geometrical isomers of the isotopomers, existing for $n = 2$, 3, and 4, are recognizable. Normal coordinate analysis has been carried out on the basis of a modified valence force field with the Wilson GF matrix method utilizing a set of 6 force constants (Table 2), and an excellent adaptation of the computed values to the observed frequencies has been achieved (Table 3).[50] This is true also for the deuteriated compounds $Cs_2[^{11}B_6D_6]$ and $Cs_2[^{10}B_6D_6]$.[50] Due to the markedly different masses of the boron isotopes ^{10}B and ^{11}B the isotopic effect on the degeneracy is observed.[53] Only for the pure final members of the series with $n = 0$ and $n = 6$ O_h point symmetry is valid. For the members with $n = 1-5$ symmetry is descending to D_{4h}, C_{4v}, C_{3v}, and C_{2v}, with the result that normal vibrations derived from the degenerate modes with symmetry T and E become less or nondegenerate, and the corresponding lines are split. By restriction of the rule of mutual exclusion certain lines of the IR spectrum are recognizable with weak intensity also in the Raman spectrum.[50] Calculations of the potential energy distribution (PED) show that $\tilde{\nu}_1$ and $\tilde{\nu}_3$ with PED values of 98% are nearly genuine modes of the B_6 core, while the same is right for the B−H fundamentals $\tilde{\nu}_2$ and $\tilde{\nu}_4$. The other vibrations exhibit with 10% and 90%, respectively, pronounced couplings between the core modes and the boron-substituent

modes.[50] The influence of protonation has been studied by vibrational spectroscopy on the pair $Cs_2[B_6H_6]$ and $Cs[B_6H_6H^{fac}]$.[14] The symmetric and antisymmetric vibrations of H^{fac} against the B_3 facet could not be observed, but have been calculated to lie in the range of 1800 and 1280 cm^{-1}, respectively.[54] A characteristic shift of B−H stretching modes by about 100 cm^{-1} to higher frequencies is observed on protonation, viz. the Raman lines at 2414 and 2460 cm^{-1} to 2522 and 2574 cm^{-1}, and the broad IR band at 2432 cm^{-1} to 2518−2545 cm^{-1}. In the range of the skeletal vibrations beyond 1100 cm^{-1} many additional bands are exhibited for the protonated compound if compared to the deprotonated one.[14] These observed higher B−H frequencies of the protonated cluster in comparison to the deprotonated could be verified by ab initio frequency analyses.[54]

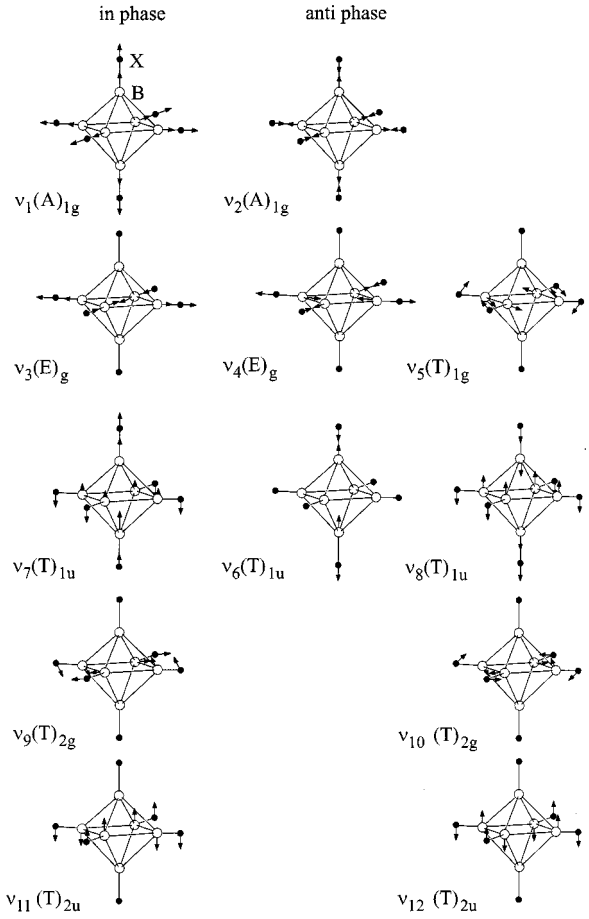

Figure 1. In-phase and anti-phase normal vibrations of a $[B_6X_6]^{2-}$ molecule

Concerning the fluxional behavior of H^{fac} the monosubstitution products of $[B_6H_6]^{2-}$ are particularly interesting, because as a consequence of substitution the octahedron is built up from two energetically different square pyramids: an upper one topped by the substituted boron atom, which is called the *ipso* boron atom, and a lower one topped by the *antipodal* boron atom. Accordingly, protonation may happen either in the *antipodal* or the *ipso* sphere (see Figure 2), and this may be influenced by the nature of the substituent. Therefore, systematic efforts have been made in preparing and characterizing such $[B_6H_5H^{fac}X]^-/[B_6H_5H^{fac}R]^-$ species. Details on this subject will be discussed in the derivatives section beyond.

Derivatives

Halogeno Substituents

The derivative chemistry of $[B_6H_6]^{2-}$ started in 1984 with the syntheses of the hexahalo-*closo*-hexaborates $[B_6X_6]^{2-}$, X = Cl, Br, and I,[55], and their characterization by ^{11}B-NMR[56] and vibrational spectroscopy.[57] They are formed in a series of substitution steps by reaction of $[B_6H_6]^{2-}$ with the free halogens in strong basic aqueous solution according to Equation 13.

$$[B_6H_6]^{2-} + n\,X_2 + n\,OH^- \rightarrow [B_6H_{(6-n)}X_n]^{2-} + n\,X^- + n\,H_2O \quad (n = 1-6) \qquad (13)$$

The pH dependence of the reaction of $[B_6H_6]^{2-}$ with iodine in aqueous solution has been studied by potentiometry showing an almost instantaneous stoichiometric course without gas evolution.[58] The partially halogenated derivatives are obtained as intermediates by moderate application of the halogens,[59] or better by reaction with the *N*-halosuccinimides NXS, X = Cl, Br, and I.[60] However, mixtures with several components always result. As the rate of halogenation is very fast for the first steps, the mono- and the disubstituted products are accessible in small yields only, while the 3- to 5-fold substituted species are produced in

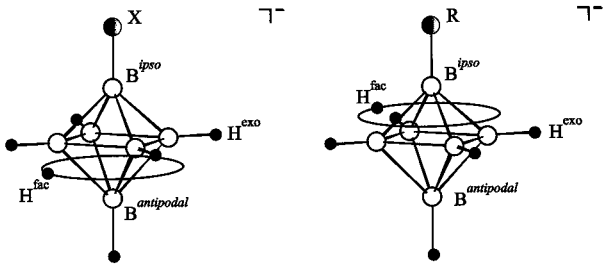

Figure 2. Fluctuation of H^{fac} in monosubstituted $[B_6H_5H^{fac}X]^-$ and$[B_6H_5H^{fac}R]^-$

high concentrations. For the isolation of pure compounds on a preparative scale ion exchange column chromatography with diethylaminoethylcellulose as a stationary phase and molar aqueous salt solutions as mobile phases has proven a well-tried method.[59−61] The rate of elution decreases strongly in the series Cl > Br > I, and additionally with increasing degree of halogenation. While the differences in mobility for higher halogenated compounds are more than 100%, those within the pairs of geometrical isomers are merely 5−15%. Therefore, their separation is very difficult, and can be overcome only by repeated ion exchange procedures with careful work up of the separated front and final sections of the corresponding chromatographic zones.

The tendency towards formation of the *cis*/*fac* isomers decreases within the series Cl, Br, I, and with increasing degree of halogenation. While in the Cl and Br series for n = 2, 3, and 4 the pairs of geometrical isomers are formed in different ratios, in the I series the pure *trans* and *mer* isomers are found exclusively. As a result *trans*-$[B_6H_4I_2]^{2-}$, *mer*-$[B_6H_3I_3]^{2-}$, and *trans*-$[B_6H_2I_4]^{2-}$ are prepared in a stereomeric pure form very easily and with highest yields.[59] Unlike compounds with a low degree of halogenation the tetra-, penta-, and hexahalohydro-*closo*-hexaborates are stable against dilute mineral acids for reasonably long times. With respect to Equation 1 only the monohalo derivatives can be protonated without difficulties, and a crystal structure of $[Ph_4P][B_6H_5H^{fac}I]$ may serve as an example.[62] Utilizing a glass electrode for potentiometric titration with 0.1 N NaOH the pk_a values have been determined for the acid-base pairs $[B_6H_5H^{fac}X]^-/[B_6H_5X]^{2-}$ to be 5.35, 5.00, and 4.65 for X = Cl, Br, and I, respectively.[14] Because of their decomposition in stronger acidic media the protonation of the dihalo derivatives and even more of the compounds with higher degree of halogenation is no longer measurable by titration. The pk_a values are < 2.5, decreasing with increasing degree of halogenation. On the protonated monosubstituted derivatives $[B_6H_5H^{fac}X]^-$ and $[B_6H_5H^{fac}R]^-$, X = Cl, Br, I, SCN, R = CH_3, C_2H_5, n-C_3H_7, n-C_4H_9,

n-C_8H_{17}, variable-temperature ^{11}B-NMR studies have been performed, and revealed the migration of H^{fac} to occur in the *ipso* sphere of the B_6 octahedron for the alkyl derivatives and in the *antipodal* sphere in case of the halogens and SCN in these series[63] (see Figure 2).

Studies on the deuteriation of the halohydro-*closo*-hexaborates have shown that the H/D exchange rate decreases in agreement with their increasing basic character in the series Cl > Br > I, and in particular with increasing degree of halogenation. Accordingly, the H/D exchange must occur via the protonated forms. Since protonation is strongly impeded with increasing degree of substitution, and further is limited by decomposition on increasing acidification, the iodo-*closo*-hexaborates with 3 or more I substituents cannot be deuteriated. Thus, to obtain the species $[B_6D_nI_{(6-n)}]^{2-}$ ($n = 1-3$) iodination of $[B_6D_6]^{2-}$ is the exclusive synthetic route.[14]

A special feature of the kinetics of deuteriation is that the H atoms are exchanged at different rates with respect to the geometrical arrangement of the substituents. For example, the H atoms in *antipodal* position to the halogen substituents in $[B_6ClH_5]^{2-}$ and $[B_6Cl_3H_3]^{2-}$ are exchanged at about the 100-fold rate in comparison to the other *exopolyhedral* H atoms. This *antipodal effect*[64] may be regarded as an analogue to the *trans effect* of the coordination compounds.[10] An impressive example of the *antipodal influence* is discussed below on the series of mixed hexahalo-*closo*-hexaborates.

The preparation of the bis-*heteroleptic* halo derivatives $[B_6X_nY_{(6-n)}]^{2-}$ ($n = 1-5$, X ≠ Y = Cl, Br, I) is achieved by reaction of the pure partially halogenated $[B_6H_nY_{(6-n)}]^{2-}$ with the corresponding halogen or *N*-halosuccinimide in aqueous basic solution.[60][65] However, in each case successive halogenation is only possible with the respective heavier halogen, in other words: in a synthetic route the more electronegative substituent must be introduced at first, and then the less electronegative substituent as the second. The reaction Equations 14a−14c are valid.

$$[B_6Cl_nH_{(6-n)}]^{2-} + (6-n)\ Br_2 \rightarrow [B_6Cl_nBr_{(6-n)}]^{2-} + (6-n)\ HBr\ (n = 1-5) \quad (14a)$$

$$[B_6Cl_nH_{(6-n)}]^{2-} + (6-n)\ I_2 \rightarrow [B_6Cl_nI_{(6-n)}]^{2-} + (6-n)\ HI\ (n = 1-5) \quad (14b)$$

$$[B_6Br_nH_{(6-n)}]^{2-} + (6-n)\ I_2 \rightarrow [B_6Br_nI_{(6-n)}]^{2-} + (6-n)\ HI\ (n = 1-5) \quad (14c)$$

The course of substitution in these series cannot be influenced by any changes in the reaction conditions, and it is impossible to unlink halogen atoms attached to the B_6 cluster, at least, if the B_6 core has to be retained. Therefore, the possibility of chlorinating or brominating some readily available partially iodinated geometric isomers in order to synthesize the respective chloro- or bromohydro-*closo*-hexaborates from the iodohydro-*closo*-hexaborates is ruled out.

On treatment of dichloromethane solutions of the hexahalo-*closo*-hexaborates with Br_2, $(SCN)_2$, BrF_3, or $K[BrF_4]$ intense colors can be observed due to the formation of the radical anions $[B_6X_6]^{\bullet-}$. The half-wave potentials $E_{1/2}$ were determined by cyclic voltammetry to be 0.58, 0.77, and 0.88 V for X = Cl, Br, I, respectively.[66][67] In case of the partially halogenated compounds $E_{1/2}$ is shifted to less positive potentials without exception, for example to 0.28 V for *fac*- and *mer*-$[B_6Cl_3H_3]^{2-}$, 0.29 V for $[B_6BrH_5]^{2-}$, and 0.19 V for $[B_6H_5I]^{2-}$. The parent compound $[B_6H_6]^{2-}$ is oxidized at a half-wave potential $E_{1/2} = 0.86$ V, however, under the experimental conditions (CH_3CN, $[nBu_4N]ClO_4$, Pt working electrode, Pt auxiliary electrode vs. Ag/AgCl/LiCl sat. in EtOH) the electrochemical process is irreversible.[66] For $Cs_2[B_6H_6]$ in water at a Pt electrode vs. saturated calomel electrode a value of −0.3 V has been reported.[68] On the preparative scale chemical oxidation with Ce^{IV} according to Equation 15 is suitable.

$$[nBu_4N]_2[B_6X_6] + [NH_4]_2[Ce(NO_3)_6] \rightarrow [nBu_4N][B_6X_6] + [nBu_4N]NO_3 + 2\ [NH_4]NO_3 + Ce(NO_3)_3\ (X = Cl, Br, I) \quad (15)$$

In this way deep blue $[B_6I_6]^{\bullet-}$, orange $[B_6Br_6]^{\bullet-}$and yellowish-green $[B_6Cl_6]^{\bullet-}$ are generated. The X-ray structures of the $[nBu_4N]^+$ and the bis(triphenylphosphanyl)imminium $[Ph_3P{=}N{=}PPh_3]^+$ salts have been solved.[66][67] Because of the paramagnetism ^{11}B-NMR spectra could not be recorded. The characteristic transitions in the UV/Vis spectra with extinction coefficients in the order of 1000−6000 $cm^2 \cdot mol^{-1}$ are shifted systematically to lower energies in the series Cl, Br, I. The radical anions and some mixed congeners of the type $[B_6X_nY_{(6-n)}]^{\bullet-}$ (X ≠ Y = Cl, Br, I), dissolved in dichloromethane, exhibit intense ESR signals in the X-band spectra, which in some cases are observable only on frozen solutions down to 4 K. The expected hyperfine couplings due to the isotopes ^{11}B and ^{10}B could not be resolved. A strongly increasing *g* anisotropy on replacing Cl by Br and especially by I with $g_1 = 2.04$, $g_2 = 1.66$, $g_3 = 1.15$ is interpreted by increasing participation of the halide orbitals in the singly occupied molecular orbitals (SOMOs) of the clusters.[69] The 10 K IR and Raman spectra of $[B_6X_6]^{2-}$, like the parent compound $[B_6H_6]^{2-}$, exhibit patterns of sharp lines reflecting the isotopomeric series $[^{10}B_n{}^{11}B_{(6-n)}X_6]^{2-}$ (X = Cl, Br, I, H; $n = 0-6$). Using the molecular parameters of X-ray structure analyses the vibrations of $[B_6X_6]^{2-}$ and the radical anions $[B_6X_6]^{\bullet-}$ have been assigned by normal coordinate analyses.[70][71] With sets of 8 force constants (Table 2) a good agreement of observed and calculated frequencies has been achieved (Table 3).

On the chemical shifts $\delta(^{11}B)$ of the series of mixed hexahalo-*closo*-hexaborates $[B_6X_nY_{(6-n)}]^{2-}$ (X ≠ Y =Cl, Br, I; $n = 5-2$) a linear regression analysis has been performed. Depending on the geometric position of the substituents in symmetric X−B···B−X and Y−B···B−Y and asymmetric X−B···B−Y arrangements of the cluster anions and their mutual influences on the electron density at the substituted ^{11}B nuclei the *antipodal influence* AI has been calculated as the difference between the ^{11}B shifts of the corresponding asymmetric and the symmetric arrangements for a given *n* according to Equation 16a.

$$AI = \delta(^{11}B)_{asym} - \delta(^{11}B)_{sym} \quad (16a)$$

The *antipodal shift constant* ASC[10] of a series is obtained as the difference of the *antipodal influences* of two successive compounds according to Equation 16b. The results are given in Table 4.

$$ASC = AI_{(n+1)} - AI_{(n)} \quad (16b)$$

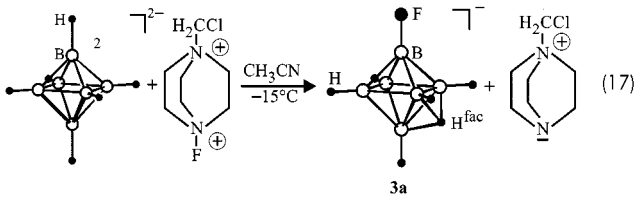

Table 4. *Antipodal Influence* AI [ppm] and *Antipodal Shift Constants* ASC [ppm] of the series *closo*-$[B_6X_nY_{(6-n)}]^{2-}$ (X ≠ Y = Cl, Br, I; n = 5−2), derived from the chemical shifts δ(^{11}B) [ppm] for symmetric X−B···B−X or Y−B···B−Y and asymmetric X−B···B−Y arrangements

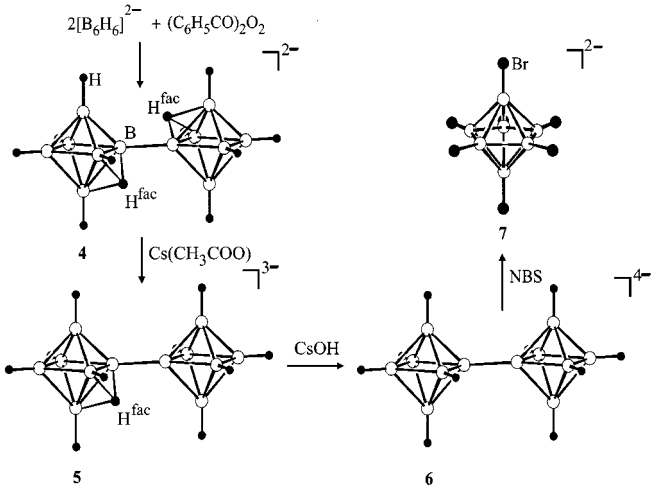
[a] The respective ^{11}B nuclei under consideration are bonded to the substituents typed with bold letters.

The synthesis of the up to now unique fluoro compounds $[B_6FH_5H^{fac}]^-$ and $[B_6FH_5]^{2-}$ has succeeded only recently. Various experiments with the common fluorination agents had failed because of their acidic character or their too strong oxidation power. However, the desired fluorination product is formed with XeF_2 in dichloromethane at −60° C, even if yield is very low. Decisive progress was made with the commercially available 1-(chloromethyl)-4-fluoro-1,4-diazabicyclo[2.2.2]octane bis(tetrafluoroborate) (abbr.: F-TEDA-$[BF_4]_2$),[72] which has tailor-made properties for this application, and thus enables synthesis of $[B_6FH_5H^{fac}]^-$ (**3a**) (see Figure 3) in 50% yield according to Equation 17. This synthesis concept has successfully applied to prepare fluorine derivatives of $[B_{10}H_{10}]^{2-}$ [73][74] and $[B_{12}H_{12}]^{2-}$.[72]

$[n\mathrm{Bu}_4N][B_6FH_5H^{fac}]$, dissolved in dichloromethane, is deprotonated by $[n\mathrm{Bu}_4N]OH$, and upon addition of cesium acetate $Cs_2[B_6FH_5]$ is precipitated. The ^{19}F resonances are observed as typical quadrupolar coupled quadruplets due to I = 3/2 of ^{11}B with δ(^{19}F) = −212.8, $^1J(^{19}F,^{11}B)$ = 63 Hz and δ = −209.5 for the protonated and deprotonated compound, respectively.[72] $^1J(^{11}B,^{19}F)$ coupling is not resolved in the ^{11}B spectra, but is attained from the ^{19}F spectra in the order of 60 Hz. The X-ray structure determination on single crystals of $K_2[B_6FH_5]$ failed because of the orientation disorder of the nearly spherical cluster anions in the unit cell. Therefore, the structural parameters of *closo*-$[B_6FH_5]^{2-}$ have been derived from ab initio calculations on the basis of C_{4v} symmetry at the MP2/6-31G* level revealing B−F and B−B bond lengths of 143.4 and 172.5−173.9 pm, respectively. The results of the ab initio frequency analysis correspond with the assignments and values obtained from normal coordinate analysis, and a good agreement of observed and calculated frequencies is achieved. The valence force constants are $f_d(BB) = 1.92\cdot10^2$ and $f_d(BF) = 5.25\cdot10^2$ N·m^{-1}.[75]



(17)

In resemblance to the iodination reactions (Equations 14b and 14c) $[B_6FH_5]^-$, prepared according to Equation 17, reacts with I_2 in aqueous solution at pH = 9 to give $[B_6FI_5]^{2-}$ {δ(^{11}B) = +3.8 (*ipso*), −30.1 (equatorial), −33.3 (*antipodal*); δ(^{19}F) = −247.6, $^1J(^{19}F,^{11}B)$ = 54 Hz} as described by Equation 18.[76]

$$[B_6FH_5]^{2-} + 5\ I_2 \rightarrow [B_6FI_5]^{2-} + 5\ HI \quad (18)$$

In contrast to the perhalogenated *closo*-hexaborates oxidation of $[B_6H_6]^{2-}$ takes a surprising course. In dichloromethane with dibenzoyl peroxide two cluster units are joined by a σ bond with a B−B distance of 170 pm to the novel *conjuncto*-cluster $[H^{fac}H_5B_6-B_6H_5H^{fac}]^{2-}$ (**4**). The deprotonation of the dianion proceeds in two steps, first with cesium acetate to the trivalent $[H^{fac}H_5B_6-B_6H_5]^{3-}$ (**5**) with pK_a = 9.6, and secondly with CsOH to $Cs_4[H_5B_6-B_6H_5]^{4-}$ (**6**).[77] By single-crystal structure analysis of $[Ph_4P]_2[H^{fac}H_5B_6-B_6H_5H^{fac}]$ the H^{fac} atoms could not be refined, but their location above the *ipso* spheres is clearly indicated by a 6% expansion of the respective faces adjacent to the B−B bridge. Based on averaged crystallographic data and adopting idealized D_{4h} symmetry a normal coordinate analysis has been performed. With a set of eleven force constants [e.g. $f_d(BB)_{conjuncto} = 2.9\cdot10^2$ and $f_d(BB)_{cage} = 1.6\cdot10^2$ N·m^{-1}] a very good agreement of observed and calculated frequencies has been achieved.[77] Even more surprising oxidation of **6** with *N*-bromosuccinimide at pH > 9 takes place under expansion of the octahedral core, and heptabromo-*closo*-heptaborate $[B_7Br_7]^{2-}$ (**7**)[78] as the first structurally secured derivative of the parent heptahydro-*closo*-heptaborate $[B_7H_7]^{2-}$ [68][79] is obtained. A single-crystal structure determination has succeeded on its $[(C_5H_5N)_2CH_2]^{2+}$ salt revealing the pen-

tagonal-bipyramidal arrangement of 7 boron atoms.[78] An illustration of these reactions is presented by Scheme 1.

Scheme 1. Oxidation of $[B_6H_6]^{2-}$

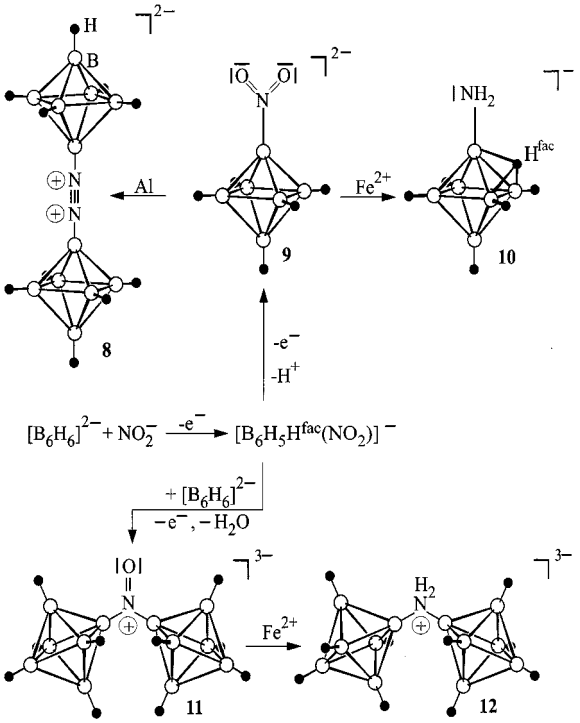
Pseudohalo and Chalcogeno Substituents

During reaction of $[B_6H_6]^{2-}$ with the pseudohalogens $(SCN)_2$ or $(SeCN)_2$ in dichloromethane the protonated compounds $[B_6H_5H^{fac}(SCN)]^-$ and $[B_6H_5H^{fac}(SeCN)]^-$ are formed, respectively,[80][81] which can be precipitated on addition of an ethanol solution of cesium acetate as the deprotonated salts $Cs_2[B_6H_5(SCN)]$ and $Cs_2[B_6H_5(SeCN)]$. A crystal structure of $Cs_2[B_6H_5(SCN)]$ with a B−S−C angle of 99.8° clearly indicates S bonding of the thiocyanate.[82] Reaction of $[B_6H_5(SCN)]^{2-}$ with Na in liquid NH_3 yields $[B_6H_5S]^{3-}$, while the analogous Se compound $[B_6H_5Se]^{3-}$ is prepared from $[B_6H_5(SeCN)]^{2-}$ already by treatment with CsOH in dichloromethane/methanol, indicating the less stability of the SeCN group. On $[Ph_4P][B_6H_5H^{fac}(SH)]$ a crystal structure determination has been performed.[83] The protonation of $[B_6H_5S]^{3-}$ is especially interesting, because the following compounds are to be assumed: $[B_6H_5H^{fac}S]^{2-}$, $[B_6H_5(SH)]^{2-}$, $[B_6H_5H^{fac}(SH)]^-$, and $[B_6H_5(SH_2)]^-$. $[B_6H_6(H^{fac})_2S]^-$, $[B_6H_5H^{fac}(SH)_2]$, and $[B_6H_6(H^{fac})_2(SH)]$ are not very likely because of their too strong acidity. Up to now the protolysis equilibria according to Eqations 19a, 19b have been established.[83]

$$[B_6H_5S]^{3-} + H^+ \rightleftharpoons [B_6H_5H^{fac}S]^{2-} \quad (19a)$$

$$[B_6H_5H^{fac}S]^{2-} + H^+ \rightleftharpoons [B_6H_5H^{fac}(SH)]^- \quad (19b)$$

The expected reaction to completely substituted derivatives in analogy to Equation 13 with an excess of $(SCN)_2$ or $(SeCN)_2$ in the presence of a base has been proven to be false.[84] Virtually, the cluster is degraded, and beside the long-known $[B(NCS)_4]^-$ [85] as a main product the novel compound $[B_2(NCS)_6]^{2-}$ is formed.[86] NCS stands for *N*-bonded thiocyanate, while SCN has the meaning of *S*-bonded thiocyanate. In contrast to the well-known boron trihalides this boron tripseudohalide is dimerized. By X-ray structure analysis on the $[Ph_3P{=}N{=}PPh_3]^+$ salt the B−B bond length has been determined to be 173 pm. An extensive vibrational spectroscopic study including ^{10}B and ^{11}B isotopic labeling accompanied by normal coordinate analysis has been performed resulting in the remarkably high force constant $f_d(BB) = 3.62{\cdot}10^2\ N{\cdot}m^{-1}$.[86] As an interesting feature *N*-bonding has been clearly confirmed by X-ray structure determination for these compounds in contrast to the *closo* clusters, where *S*-bonding prevails without exceptions up to now. The same is found in case of the SeCN compounds $[BH_n(NCSe)_{(4-n)}]^-$ ($n = 0-4$),[87] which has been proven by crystal structures on $[BH(NCSe)_3]^-$ and $[B_3H_7(NCSe)]^-$ [88] in comparison to $[B_6H_5(SeCN)]^{2-}$.[81] Here ^{77}Se-NMR spectroscopy is a valuable tool to distinguish the bonding mode of the selenocyanate: Signals of *N*-bonded substituents are found in the high-field region around $\delta(^{77}Se) = -300$, while *Se*-bonded species resonate in the downfield region between $\delta = 0$ and -100, viz. at $\delta = -72.8$ for $[B_6H_5(SeCN)]^{2-}$, at $\delta = -68.2$ for $[B_{10}H_9(SeCN)]^{2-}$, and even more deshielded at $\delta = -22.6$ for $[B_{12}H_{11}(SeCN)]^{2-}$.[81] During reaction of $[B_6H_6]^{2-}$ with cyanogen $(CN)_2$, which is generated from KCN and $CuSO_4$ in aqueous basic medium, the cyano derivatives $[B_6(CN)H_5]^{2-}$ and *cis*-$[B_6(CN)_2H_4]^{2-}$ are formed, and confirmed by X-ray structure determination.[89]



N-Bonded Substituents

On irradiation of an aqueous alkaline solution of $[B_6H_6]^{2-}$ and nitrite ions with a mercury vapor lamp the color turns to intense blue. From this solution a blue and a yellow product have been isolated by ion exchange chromatography on diethylaminoethylcellulose. On the basis of spectroscopic data these compounds have been assigned erroneously.[90] Both species are also obtainable, however in very low yields, from $[nBu_4N]_2[B_6H_6]$ in acetonitrile by addition of isopentyl nitrite. The highest yields of 8% for both of the compounds are attained during electrolysis of a dichloromethane solution containing $[nBu_4N][B_6H_6H^{fac}]$, $[nBu_4N]NO_2$, and 8-diazabicyclo[5.4.0]undec-7-ene (abbr.: DBU) as a base at a platinum electrode in the separated anodic room of an electrolysis cell with a carbon cathode. The single-crystal X-ray analysis revealed, that the yellow compound is the mononitro derivative $[B_6H_5(NO_2)]^{2-}$ (**9**),[91] and the blue compound is the dimeric bridged species $[H_5B_6-(NO)-B_6H_5]^{3-}$ (**11**).[92] *Caution! Both compounds are stable as Cs salts, however, they explode if only are touched. By anodic oxidation of* $[B_6H_5(NO_2)]^{2-}$*, the yellow, highly explosive cis-*$[B_6H_4(NO_2)_2]^{2-}$ *has become feasible.*[93] The mononitro compound $[B_6H_5(NO_2)]^{2-}$ (**9**) is reduced with Fe^{2+} in aqueous alkaline solution to the amine derivative $[B_6H_5H^{fac}(NH_2)]^-$ (**10**) analogous to aniline. Although H^{fac} could not be refined by X-ray structure analysis, it is likely positioned between a B_3 facet and the free electron pair of the NH_2 group.[94] If aluminum is used as a reducing agent in place of Fe^{2+}, the reduction process is ceased at the state of zero-valent nitrogen, and two cluster

units are bridged by a triply bonded dinitrogen molecule according to Equation 20.

$$2\,[B_6H_5(NO_2)]^{2-} + 2\,Al + 4\,H_2O \rightarrow [H_5B_6{-}N{\equiv}N{-}B_6H_5]^{2-} + 2\,[Al(OH)_4]^- \quad (20)$$

The X-ray structure analysis of μ-dinitrogenbis(pentahydro-*closo*-hexaborate) (**8**) succeeded on single crystals of the tetraphenylarsonium $[Ph_4As]^+$ salt.[95] In the same way as for $[B_6H_5(NO_2)]^{2-}$ reduction with Fe^{2+} in alkaline solution is applicable to $[H_5B_6{-}(NO){-}B_6H_5]^{3-}$ (**11**), and yields the amido-bridged derivative $[H_5B_6{-}(NH_2){-}B_6H_5]^{3-}$ (**12**).[96] According to its Brønsted base character two protons are added in neutral aqueous solution to give $[H^{fac}H_5B_6{-}(NH_2){-}B_6H_5H^{fac}]^-$, and the X-ray structure has been solved, however without refinement of H^{fac}.[96] The reactions and connections between the derivatives with N-substituents are shown in Scheme 2. Furthermore *cis*-$[B_6(CN)H_4(NO_2)]^{2-}$ and *cis*-$[(CN)H_4B_6{-}(NO){-}B_6H_4(CN)]^{3-}$ have been prepared and structurally characterized.[97] A highly interesting arrangement of B_6 in a cyclic structure has been found for hexakis(diethylamino)-*cyclo*-hexaborane $[B_6\{N(C_2H_5)_2\}_6]$,[98] however, the claimed interconversion of the *cyclo* structure to the octahedral structure could not be verified by X-ray structure determination.

Scheme 2. Derivatives of $[B_6H_6]^{2-}$ with N substituents

Organic Substituents

As already discussed in detail *closo*-$[B_6H_6]^{2-}$ is a Brønsted base with a pk_a value of 7.0. This fact will be of crucial importance during the following substitution reactions, because all protonated *closo*-hexaborates are inaccessible to substitution. This subject has already been discussed in the sections on the halogens and *pseudo*-halogens, and the same is true for the alkylation reactions. It is also the reason for the quite different alkylation conditions observed for the *closo*-borates. While the higher members $[B_{10}H_{10}]^{2-}$ and $[B_{12}H_{12}]^{2-}$ react under acidic conditions,[99] $[B_6H_6]^{2-}$ demands at least neutral solutions for the first substitution step and strong basic media for subsequent substitutions. In this way *mono*-, *di*-, and *tri*-alkyl-*closo*-hexaborates have been synthesized utilizing alkyl halides as alkylation agents.[100][101] On principle, all organic solvents must be dried accurately prior to use in order to maintain $[B_6H_6]^{2-}$ really in its deprotonated state.

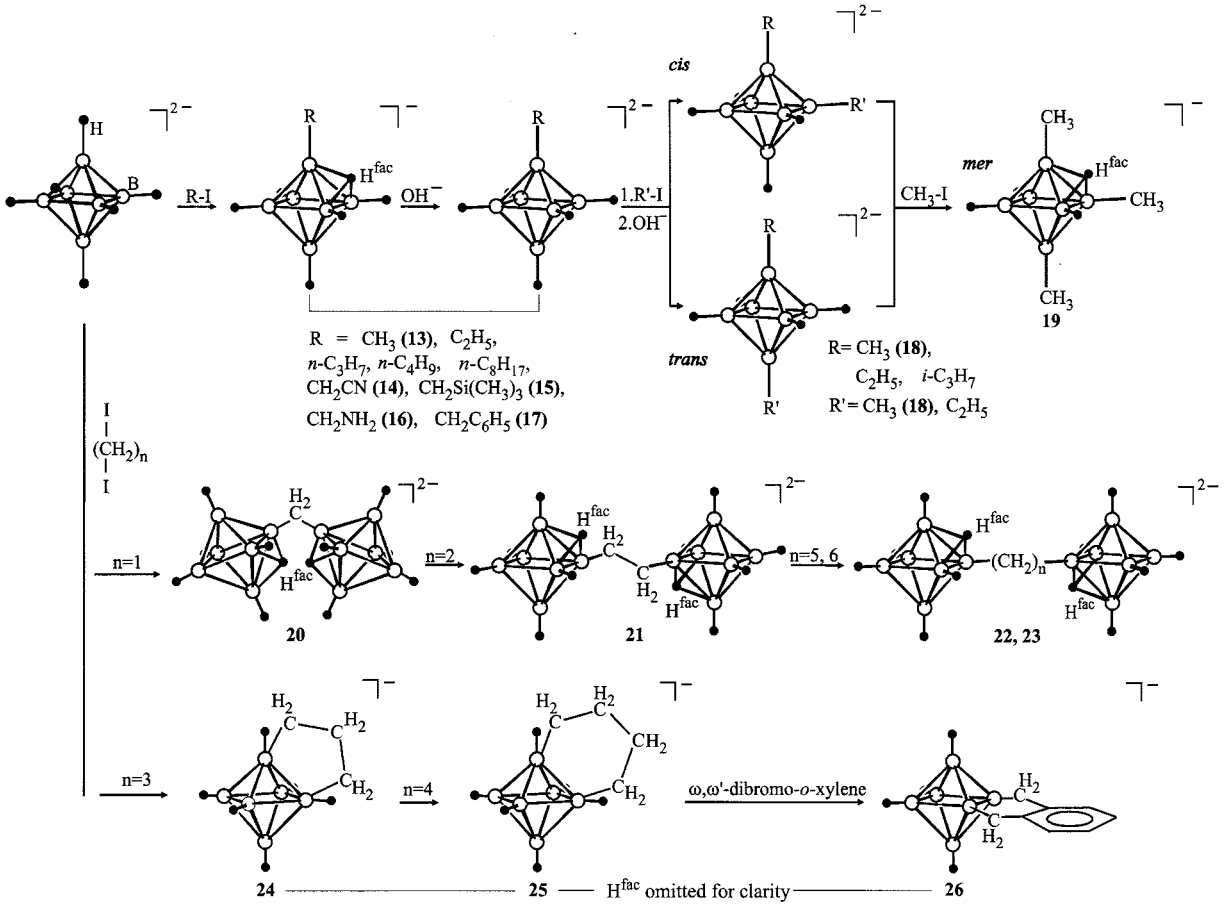
For introduction of alkyl substituents $[n\mathrm{Bu}_4\mathrm{N}]_2[B_6H_6]$ is dissolved in dichloromethane or acetonitrile and treated with alkyl halides.[101] According to common organic concepts the alkyl carbon atom attached to the halogen atom is more positive through the −I effect of the halogen according to $R{-}C^{\delta+}{-}X^{\delta-}$, and an electrophilic attack on the region of maximum electron density above the octahedron facets is to be assumed. The resulting transitory state with a four-center, two-electron (4c2e) $C^{\delta+}{-}B_3$ interaction is stabilized by displacement of an *exopolyhedral* H atom from a vertex onto a facet of the B_6 cluster giving a more favorable 4c2e $H^{fac}{-}B_3$ bond and a common 2c2e B−C σ-bond under liberation of the respective halide ion. The course of alkylation reactions is exemplified by Equation 21.

$$[n\mathrm{Bu}_4\mathrm{N}]_2[B_6H_6] + RX \rightarrow [n\mathrm{Bu}_4\mathrm{N}][B_6H_5H^{fac}R] + [n\mathrm{Bu}_4\mathrm{N}]X\ (R = CH_3, C_2H_5, n\text{-}C_3H_7, n\text{-}C_4H_9, n\text{-}C_8H_{17}) \quad (21)$$

Alkyl iodides have proven as the most suitable agents, but as reactivity generally decreases with increasing chain length, *n*-octyl iodide, for example, must be applied in large excess and at 80° C to obtain $[B_6(n\text{-}C_8H_{17})H_5H^{fac}]^-$.[80] In the series of alkyl derivatives the Brønsted base character increases with increasing chain length, as is demonstrated by the pk_a values: 8.85 for CH_3, 9.50 for C_2H_5, 9.55 for *n*-C_3H_7 and 9.60 for both *n*-C_4H_9 and *n*-C_8H_{17}.[80] Deprotonation and precipitation as Cs salts is accomplished by addition of CsOH, dissolved in ethanol, to the dichloromethane solutions of $[n\mathrm{Bu}_4\mathrm{N}][B_6H_5H^{fac}R]$ as given by Equation 22.

$$[n\mathrm{Bu}_4\mathrm{N}][B_6H_5H^{fac}R] + 2\,CsOH \rightarrow Cs_2[B_6H_5R] + [n\mathrm{Bu}_4\mathrm{N}]OH + H_2O \quad (22)$$

The Cs salts are soluble in water, but show markedly basic reactions due to protolysis according to Equation 23.



$$[B_6H_5R]^{2-} + H_2O \rightleftharpoons [B_6H_5H^{fac}R]^- + OH^- \quad (23)$$

As to be seen from Equation 21 the formation of the protonated compounds is unavoidable, and reaction is stopped at the monosubstituted state. For further substitution well-considered deprotonation procedures are required, which may be exemplified in the following substitution series: The $[Ph_4As]^+$ salt of the protonated com-

pound of choice is suspended in strong basic aqueous solution. In this way colorless $[Ph_4As][B_6H_5H^{fac}R]$ (**13**–**17**) is transformed to yellow $[Ph_4As]_2[B_6H_5R]$. The isolated deprotonated monoalkyl derivative is treated with the neat alkyl iodide of choice, whereupon the solid is decolorized. The colorless product $[Ph_4As][B_6H_4H^{fac}RR']$ (**18**) is dissolved in acetonitrile, and on addition of CsOH in 2-propanol *cis*- and *trans*-$Cs_2[B_6H_4RR']$ are obtained (R = CH_3, C_2H_5, *i*-C_3H_7; R′ = CH_3, C_2H_5).[102] With the up to now highest degree of alkylation the threefold methylated compound *mer*-$[B_6(CH_3)_3H_3H^{fac}]^-$ (**19**) has been synthesized, which refuses deprotonation, and thus further substitution. It is prepared from *cis*- or *trans*-$[Ph_4As]_2[B_6(CH_3)_2H_4]$ (**18**), which is obtained in the manner described above, on digestion with CH_3I (see Scheme 3, 1st row).

up from two protonated cluster anions bridged by methylene or a methylene chain. $[H^{fac}H_5B_6-(CH_2)-B_6H_5H^{fac}]^-$ (**20**) has a bent structure and two ionizable protons with pk_{a1} = 6.0 and pk_{a2} = 10.9[107]. For $[H^{fac}H_5B_6-(CH_2)_2-B_6H_5H^{fac}]^-$ (**21**)[108] only a single pk_a value = 10.9 has been found, and the same applies to the μ-pentamethylene (**22**) and μ-hexamethylene (**23**) derivatives with pk_a = 8.8 and pk_a = 9.1,[109] respectively. (see Scheme 3, 2nd row).

Interestingly, alkylation with 1,3-diiodopropane or 1,4-diiodobutane prefers an intramolecular route, and the two boron atoms of an edge of the octahedron are substituted resulting in *ansa*-like species with five- or six-membered anellated rings, respectively.[100] Both compounds are isolated in their protonated form $[B_6(-CH_2-CH_2-$

Scheme 3. Alkylation of $[B_6H_6]^{2-}$

Additionally, the derivatives $[B_6(CH_2CN)H_5H^{fac}]^-$ (**14**) pk_a = 5.85,[103] $[B_6\{CH_2-Si(CH_3)_3\}H_5H^{fac}]^-$ (**15**), $\delta(^{29}Si)$ = 2.25,[104] $[B_6(CH_2NH_2)H_5H^{fac}]^-$ (**16**),[105] and $[B_6\{CH_2(C_6H_5)\}H_5H^{fac}]^-$ (**17**)[106] are to be mentioned for the sake of completeness, which have been synthesized from $[nBu_4N]_2[B_6H_6]$ by reaction with chloroacetonitrile, trimethyliodomethylsilane, *N*-(chloromethyl)phthalimide, and benzyl bromide, respectively.

By reaction of $[B_6H_6]^{2-}$ with ω,ω′-diiodoalkanes $I-(CH_2)_n-I$ (*n* = 1, 2, 5, and 6) dicluster anions $[H^{fac}H_5B_6-(CH_2)_n-B_6H_5H^{fac}]^-$ are formed, which are built $H_2C-)H_4H^{fac}]^-$ (**24**) and $[B_6(-CH_2-CH_2-CH_2-H_2C-)H_4H^{fac}]^-$ (**25**) (see Scheme 3, 3rd row). Although H^{fac} could not be refined during X-ray structure analysis, its location is clearly indicated by markedly expanded B_3 facets.[100] Another six-membered anellated ring system featuring the interesting connection of a two- and a three-dimensional aromatic system is provided by *cis*-$[B_6(o$-xylene$)H_4H^{fac}]^-$ (**26**, see Scheme 3, 3rd row), which is obtained with ω,ω′-dibromo-*ortho*-xylene as alkylating agent. Structures have been solved of single crystals of the tetraphenylphosphonium $[Ph_4P]^+$ salt and the $[nBu_4N]^+$ salt.

Refinement of H^{fac} failed in the former case, but succeeded in the latter with $B-H^{fac}$ distances ranging from 111 pm to 148 pm and an expansion of the corresponding B_3 facet by about 7%.[110] A selection of the essentials of alkylation reactions is given by Scheme 3.

Very recently, the first aryl derivative the $[B_6(p\text{-}C_6H_4-NO_2)H_5H^{fac}]^-$ has been obtained by reaction of $[B_6H_6]^{2-}$ with *para*-bromonitrobenzene in acetonitrile and isolated in its deprotonated form as the red salt $Cs_2[B_6(p\text{-}C_6H_4-NO_2)H_5H^{fac}]$. After complete chlorination with *N*-chlorosuccinimide an X-ray structure determination succeeded on single crystals of $[(C_5H_5N)_2CH_2][B_6(p\text{-}C_6H_4-NO_2)Cl_5]$.[111] The reduction of $[B_6(p\text{-}C_6H_4-NO_2)H_5H^{fac}]^-$ with Fe^{II}, Al, and Raney-Ni in the presence of N_2H_4 results in a deep blue compound, which in all probability is the diazo compound $[H_5B_6-C_6H_4-N{\equiv}N-C_6H_4-B_6H_5]^{2-}$, as derived from ^{11}B- and ^{14}N-NMR data.[112]

Additionally, the following explosive alkylnitro derivatives have been synthesized and characterized by X-ray structure determination: *cis*-$[B_6(CH_3)H_4(NO_2)]^{2-}$, *fac*- and *mer*-$[B_6(CH_3)H_3(NO_2)_2]^{2-}$,[113] and *cis*-$[B_6(C_2H_5)H_4(NO_2)]^{2-}$.[114] From the structural data is to be seen, that the B_6 cage is expanded in direction towards the substituents in case of alkyl,[101][102] while it is compressed in case of cyano,[89] nitro,[91] and halo[62][115] substituents with shortening of the cage B···B diagonal distances in the order of 5−10%.

In an effort to obtain more insight into the influence of the localization of H^{fac}, and to calculate the energetic barrier of movement of H^{fac}, ab initio calculations have been performed with the GAUSSIAN 94[116] program. Structure optimization has been done according to standard methods on HF/6-31G*-basis, and the hyper face minimum has been confirmed by analytical frequency analysis.[117] The refinement of geometry and the calculation of the total energies is performed on MP2/6-31G* level assuming C_{4v} symmetry for $[B_6FH_5]^{2-}$ (**3**) and $[B_6(CH_3)H_5]^{2-}$ (**13**) and their respective protonated derivatives both for localization of H^{fac} above an *antipodal* facet (**3a** and **13a**) and an *ipso* facet (**3b** and **13b**) (see Figure 3). Similar to $[B_6H_6]^{2-}$ an energy of approx. 450 kcal·mol^{-1} is gained by protonation. This corresponds to the property of the monosubstituted derivatives to act as Brønsted bases. The relative energetic differences between *ipso* and *antipodal* protonation are indeed small, however, they are in agreement with the results of the ^{11}B-NMR investigations.[54] The fluorine compound is more stable by about 1 kcal·mol^{-1} in case of *antipodal* protonation (**3a**) as compared to *ipso* protonation (**3b**). For the methyl compound the opposite behavior is observed, and an even smaller gain in stability of merely 0.06 kcal·mol^{-1} results with *ipso* protonation (**13c**) in comparison to *antipodal* protonation (**13a**). However, the *ipso* localization of H^{fac} (**13b**) is affirmed by NMR investigations[54] and X-ray structure analysis.[101]

Between H^{fac} and the H atoms of the methyl group in $[B_6H_5H^{fac}(CH_3)]^-$ distances of 258, 279, and 320 pm have been obtained from X-ray structure. As a consequence an

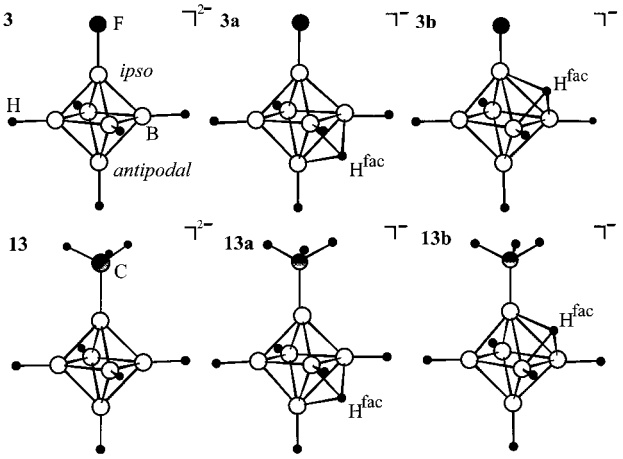


Figure 3. Localization of H^{fac} in monosubstituted $[B_6H_6]^{2-}$

assumed nuclear Overhauser interaction could be proven by 2D-^{1}H-NOESY NMR spectroscopy. This may be the reason for the decreased tendency of $[B_6H_5H^{fac}(CH_3)]^-$ with $pK_a = 8.85$[80] to dissociate in comparison to $[B_6H_6H^{fac}]^-$ with $pK_a = 7$[14] and $[B_6H_5H^{fac}F]^-$ with $pK_a = 5$.[72] Further, the obtained structure parameters served as a basis for calculation of the NMR shifts making use of the RHF/GIAO method[118] with an Ahlrichs tzp basis set.[119] In order to eliminate the solvent influence on the chemical shift referencing was done by use of signals of the respective deprotonated parent compounds in the same solvent as secondary standards. The ^{1}H-, ^{11}B-, ^{13}C-, and ^{19}F-NMR shifts have been calculated and found in good agreement with experimental data.[120] Furthermore, former results of vibrational spectroscopic assignments and the results of normal coordinate analyses could be verified by the ab initio frequency analyses. In good agreement with the experimental data[14] the ab initio calculations result in shifts of the terminal B−H valence modes by about 100 to 200 cm^{-1} to higher frequencies for the protonated cluster anions. This is consistent with the calculated shortening of the B−H distances. An effect of the protonation is also observed on the vibrational frequencies of polyatomic substituents. Accordingly, the C−H valence vibration of $[B_6(CH_3)H_5H^{fac}]^-$ is shifted to higher energy by about 150 cm^{-1} in comparison to $[B_6(CH_3)H_5]^{2-}$.[54] The symmetric and antisymmetric vibration of H^{fac} against the B_3 facet have not been observed, but are calculated to 1820 and 1295 cm^{-1} for *antipodal*-localized H^{fac}, and to 1791 and 1275 cm^{-1} for *ipso*-localized H^{fac}, respectively.[54]

The chemical shift of the nonequivalent ^{11}B nuclei in monosubstituted derivatives of $[B_6H_6]^{2-}$ and the mutual influence of substitution on the *ipso* and the *antipodal* B atoms depends on the electronegativity, the polarizability, and the spin orbit coupling of that atom bound to the cluster. While the signals of the equatorial B atoms are found nearly uninfluenced around $\delta = -15$, the resonances of the *ipso*- and *antipodal*-B are shifted increasingly with decreasing electronegativity or with increasing polarizability and spin orbit coupling, namely to high field for the *ipso*-B and

downfield for the *antipodal*-B. These qualitative trends are visualized by Figure 4.

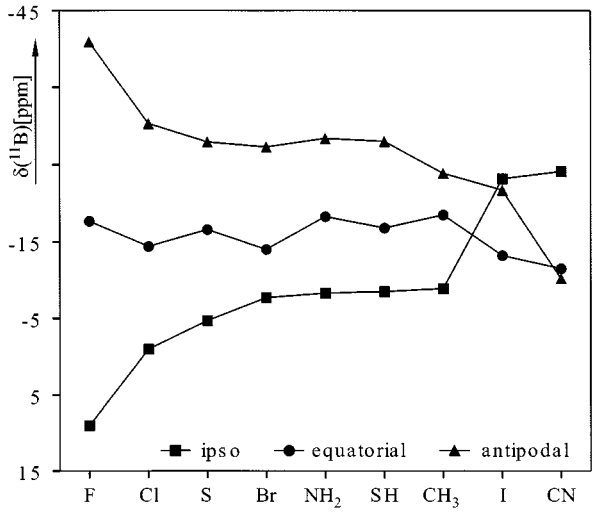

Figure 4. ^{11}B-NMR shifts of monosubstituted derivatives $[B_6H_6]^{2-}$

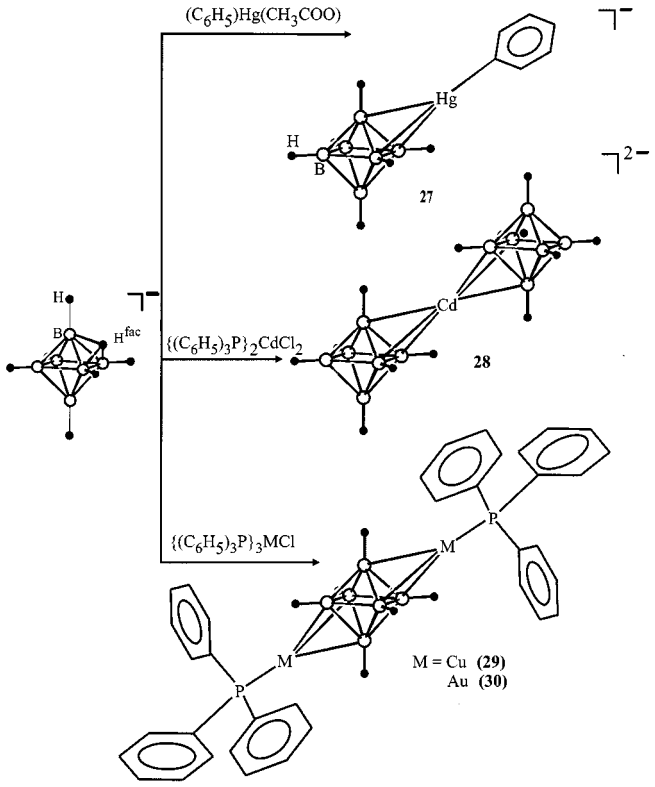
$[B_6H_6]^{2-}$ as a Ligand in Metal Complexes

In contrast to the higher *closo*-borates only a few metal derivatives are known for *closo*-$[B_6H_6]^{2-}$. By reaction of the nucleophilic nickelocene with $[B_6H_6]^{2-}$ two electrons are donated to the boron cluster, reducing it to the hypothetical $[B_6H_6]^{4-}$,[11] and induce cage opening. By elimination of a cyclopentadienyl ligand from Ni and oxidative addition of the borate moiety Ni atoms are built into the boron core, and under expansion of the octahedron the *closo*-metallaborates $[(\eta^5\text{-}C_5H_5)NiB_6H_6]^-$ [11][121] and $[(\eta^5\text{-}C_5H_5)_3Ni_3B_6H_6]^-$ [122] are formed, which correspond to the parent *closo*-borates $[B_7H_7]^{2-}$ [68][79] and $[B_9H_9]^{2-}$.[123] In contrast to the reaction of nickelocene with $[B_6H_6]^{2-}$ from cobaltocene and $[B_6H_6H^{fac}]^-$ the molecule compound $[(\eta^5\text{-}C_5H_5)Co(\eta^5\text{-}C_5H_4)B_6H_5H^{fac}]$ is formed with a normal σ(B−C) bond from one of the cyclopentadienyl groups C atoms to a vertex of the B_6 cluster having a bond length of 157.5 pm.[124]



In accordance with the high electron density above the octahedral B_3 facets $[B_6H_6]^{2-}$ can act as a Lewis base and coordinate in a 4c2e bond to the metal atom of a complex. In this way $[(C_6H_5)Hg(\eta^3\text{-}B_6H_6)]^-$ (**27**) was synthesized from phenylmercury acetate, and its structure was solved on the $[Ph_4P]^+$ salt with B−Hg distances from 240 to 243 pm indicating the localization above one facet, the edges of which are markedly elongated to 183 pm.[125] In CD_2Cl_2 at 263 K a singlet has been recorded with $\delta(^{199}Hg) = -74$ vs. $Hg_2(NO_3)_2$ saturated in D_2O. However, the *hapticity* of $[B_6H_6]^{2-}$ must not be inevitably three, but may be two. This has been found in [(2,2′-bipyridine)Pb($\eta^{2,3}$-B_6H_6)], in which $[B_6H_6]^{2-}$ is coordinated via an η^2-B_2 edge as well as via an η^3-B_3 facet,[126] although considerable long Pb−B_3 distances of about 280 pm resulted for the η^3 coordination.

Two η^3-$[B_6H_6]^{2-}$ ligands, which are symmetrically arranged with distances of 218 pm from the Cd^{2+} center to the B_3 planes, are found in $[Cd(\eta^3\text{-}B_6H_6)_2]^{2-}$ (**28**),[127] which has been prepared from $[B_6H_6]^{2-}$ and $[\{(C_6H_5)_3P\}_2CdCl_2]$. The ^{113}Cd resonance of **28** in CD_2Cl_2 is found in the low-field region at $\delta(^{113}Cd) = 117$ vs. 3 M $Cd(NO_3)_2$ in D_2O at $\delta = -692.1$. From a view on the structure the term of a Cd^{2+} sandwich complex with the two B_6 clusters as three-dimensional aromatic systems seems to be justified.

During the reactions of $[\{(C_6H_5)_3P\}_3MCl]$, M = Cu and Au, with $[B_6H_6]^{2-}$ the binuclear complexes $[\{(C_6H_5)_3P\}_2M_2(\mu\text{-bis-}\eta^3\text{-}B_6H_6)]$ (**29**, **30**) are formed, containing $[B_6H_6]^{2-}$ as a bridging ligand in a bis(tri-*hapto*) mode of two opposite B_3 facets.[128] The metal centers in **29** and **30** are found in remarkably short distances of about 210 pm above the B_3 planes. The Au compound **30** has been obtained in two polymorphous forms in dependence of the crystallization conditions. While from dichloromethane solutions on slow diffusion of methylbutane, isopentane, or petroleum ether large cubic crystals (form A, space group *Pa*3bar) are precipitated, the same procedure with diethyl ether or *n*-pentane yields needles (form B, space group *Pccn*).[129] The coordinating B_3 facets are markedly expanded in both cases, viz. by 6% in A and 8% in B. However, packing in the elementary cells is different. The molecules in A are stacked loosely against one another, whereas in form B compact infinite stacking is to be seen. Therefore, the difference of about 40% in the calculated densities ρ(A) = 1.326 and ρ(B) = 1.885 g·cm^{-3} (B) is surprising. In analogy to the reactions of Cu and Au $[\{(C_6H_5)_3P\}_3AgCl]$ forms with $[B_6H_6]^{2-}$ in a first step $[\{(C_6H_5)_3P\}_2Ag_2\{\mu\text{-bis}(\eta^3\text{-}B_6H_6)\}]$. However, this complex is very instable, and due to the lack of suitable single crystals structural proof by X-ray analysis has not yet been done. The ^{11}B-NMR spectra agree with those of the respective Cu and Au complexes. During decomposition of the initial product metallic silver is precipitated, and from the remnants a dichloromethane adduct of *hypho*-decahydrohexaborane $[\{(C_6H_5)_3P\}_2B_6H_{10}] \cdot CH_2Cl_2$ could be crystallized, and its structure could be solved.[130] This is the first documented example for the opening of a *closo*-B_6 cluster to a *hypho*-hexaborane. An illustration of the versatile ligating capabilities of $[B_6H_6]^{2-}$ is given in Scheme 4.

Concluding Remarks

Systematically synthesized derivatives of the hexahydro-*closo*-hexaborate $[B_6H_6]^{2-}$ with classical inorganic and organic substituents were characterized structurally and spectroscopically. In this way, a better insight into the chemical and physical properties of this class of compounds was gained, and strong mutual support of the ab initio results and the experimental data could be achieved. As a central point of the reaction chemistry the protolysis behavior and its special importance during substitution reactions was discussed. The localization of the additional proton H^{fac}, bound in the solid state above one of the facets of the octa-

Scheme 4. $[B_6H_6]^{2-}$ as a tri-*hapto* ligand in metal complexes

hedron via a 4c2e bond, could be refined in several X-ray structures. In the solution state clear evidence of H^{fac} was given by ^{1}H-NMR spectroscopy. The dynamic behavior due to the fluctuation of H^{fac} across the octahedron facets in the parent compound $[B_6H_6H^{fac}]^-$ and the $[B_6H_5H^{fac}X]^-$ species was elucidated by variable-temperature ^{11}B-NMR spectroscopy and determination of the coalescence points. The interrelations between symmetry, electronic and geometrical structure, and spectroscopic properties could be demonstrated by the monosubstituted derivatives as instructive examples for the energetic difference between the *ipso* and the *antipodal* sphere arising through substitution. The effect of this imbalance depends on the nature of the substituent. This has been proven by single-crystal X-ray structure determinations and different NMR-spectroscopic techniques, and has been affirmed by ab initio calculations with the GAUSSIAN 94 program on the MP2/6-31G* level resulting in a consistent discussion of the experimental and theoretical data with strong mutual support. From the empirical data the following facts could be manifested:

- $pK_a < 7$ for X = halogen, pseudohalogen or NO_2, $pK_a > 7$ for X = alkyl
- In solid salts and in solution below the coalescence temperature H^{fac} is fixed above one of the *antipodal* facets in the case of halogen and pseudohalogen substituents, while it resides above one of the *ipso* facets in the case of alkyl substituents. The B_3 facets capped by H^{fac} are generally expanded by 5−8%.
- On substitution the octahedral B_6 cage is deformed with changes of the diagonal cage B···B distances up to 5−10%. It is compressed in direction towards the substituents in the case of halogen, pseudohalogen or N-substituents and expanded in direction towards substituents in the case of alkyl.
- The synthesis of bis(heteroleptic) derivatives $[B_6X_nY_{(6-n)}]^{2-}$ ($n = 1-5$, X ≠ Y = Cl, Br, I) requires that in a synthetic route the more electronegative substituent must be introduced at first, and then the less electronegative substituent as the second.
- During repeated substitution further substituents are directed in *trans*/*mer* position by I^- and in *cis* positions by NO_2^- and CN^-.
- A systematic *antipodal* influence within the complete series of persubstituted mixed halo-*closo*-hexaborates $[B_6Cl_nBr_{(6-n)}]^{2-}$, $[B_6Cl_nI_{(6-n)}]^{2-}$, and $[B_6Br_nI_{(6-n)}]^{2-}$ ($n = 1-5$) has been found, and therefrom for each series a characteristic *antipodal* shift constant (ASC) has been derived.

Besides this subsumption of the results of systematic synthetic work, which is already a good justification to pursue derivative chemistry, some reactions of the *closo*-B_6 parent compound have led unintentionally into new directions: Under formation of a B−B bond the *conjuncto* compounds $[H^{fac}H_5B_6-B_6H_5H^{fac}]^{2-}$ and $[H_5B_6-B_6H_5]^{4-}$ were formed, and therefrom by expansion the first structurally characterized *closo*-heptaborate $[B_7Br_7]^{2-}$ was established. Another new field of research is the introduction of $[B_6H_6]^{2-}$ as a ligand in coordination compounds, bound in an η^3 fashion to metal centers like Pb^{2+}, Cd^{2+}, Hg^+, Cu^+, Ag^+, and Au^+. For the first time opening to a *hypho*-borane of a ligated $[B_6H_6]^{2-}$ to Ag^+, the decahydrohexaborane B_6H_{10}, has been realized. Last, but not least the planned expansion of the octahedral cage by metal atoms to form hydro-*closo*-metallaborates with some examples of Ni is in its beginning, and promises interesting new pathways.

Formation and Structural Characterisation of an Unusual Cyclic Hexameric Oxotitanium Complex

Tim Kemmitt,*[a] Najeh I. Al-Salim,[a] and Graeme J. Gainsford[a]

Keywords: Titanium / Amino alcohols / Metal alkoxide / Oxo alkoxide / Metallacycles

$Ti_6O_6(MDEA)_6 \cdot 2CH_2Cl_2$ (MDEA = *N*-methyldiethoxoamine) was obtained by the controlled hydrolysis of the $Ti(MDEA)_2$ complex and analysed by X-ray diffraction. The compound consists of a ring of six [TiO_5N] octahedra, edge bridged by μ_2-oxide and a μ_2-alkoxide arm of the aminoalkoxide ligand.

Introduction

Modification of metal alkoxides is a common technique in the formation of sol-gel materials, and is used to control the hydrolysis rate and condensation pathways of the oxo-alkoxide fragments. The modification involves the introduction of bi- or multidentate anionic ligands, such that the reactivity of the resulting compound is lower than the parent alkoxide thus allowing size control of the primarily formed oxo-particles. Examples of titanium oxo-complexes include oxo-alkoxides,[1−5] β-diketonates,[6−8] carboxylates,[9−15] and related complexes.[16−22] These exhibit a rich variation in structural types characterised by different coordination modes of the ligands, variations in linkages of the coordination polyhedra, degree of hydrolysis, and coordination number of the central atom. The titanium oxo-alkoxides exhibit degrees of condensation {defined as z/x for $[Ti_xO_z](OR)_{4x-2z}$} from 0.33 to 1.33,[3] while the degree of condensation accessible to the titanium carboxylates and other derivatives is more limited due to the increased coordination requirement of the modifying ligands. Mixed-metal complexes have been reported which further extend the range of structural features available.[23,24]

The coordination number for titanium is commonly 6, although ligand constraints have resulted in complexes with coordination numbers of 5[8,25−27] and 7.[25,26,28,29] Di- and polynuclear titanium complexes are generally characterised by vertex- and edge-sharing polyhedra, although a diolato-alkoxide containing a rare face-sharing linkage was recently reported.[25]

Amino alcohols have been applied as modifiers, and have been demonstrated to exhibit favourable properties for application in titanium sol-gel chemistry[30,31] and MOCVD.[32] Several derivatives of triethanolamine have been reported,[26,27,29,33−35] two of which contain oxo- linkages,[26,34] but crystalline derivatives of other amino alcohols are rare[28,36] and none of these are oxo-complexes.

Results and Discussion

We have isolated a crystalline derivative of *N*-methyldiethanolamine (MDEA), of composition $Ti_6O_6(MDEA)_6 \cdot 2CH_2Cl_2$. This compound was obtained by the hydrolysis and condensation of $Ti(MDEA)_2$ **(2)** prepared from the reaction of $Ti(OPr)_4$ with two equivalents of $MDEAH_2$. It is difficult to be definitive about the sequence of substitution and hydrolysis reactions occurring, but it seems necessary to first form the bis MDEA complex from $Ti(OPr)_4$, which can then be carefully hydrolysed to form **1**. Although **1** contains a single equivalent of MDEA per titanium, we have been unsuccessful in our attempts to prepare and isolate this product using this reactant ratio. The hexameric oxo complex **1** is much more hydrolytically stable than the parent bis complex which is highly hydrophilic. Crystals of **1** retained their integrity for several hours in the open air, degrading only due to the loss of dichloromethane molecules of crystallisation. This also occurred if the crystals were stored in sealed containers in the absence of dichloromethane vapour. In contrast, crystals of **2** became soft and waxy almost immediately on exposure to atmospheric moisture. The preparation and isolation of **2** will be reported later in a full paper, together with data on other related complexes.

Compound **1** consists of a ring of six [TiO_5N] edge-linked octahedra (Figure 1). This contrasts with titanium oxo-carboxylates which include a high proportion of corner-shared octahedra. Each titanium is coordinated to a single MDEA ligand incorporating one terminal alkoxide, one μ_2-bridging alkoxide, and one terminal amine (Figure 2). The six μ_2-oxide bridges are located on the inside edge of the ring, alternating above and below the plane of the ring. The methylamine groups similarly appear on alternating faces of the ring, but are located on the outside edge of the ring. Each of these methyl groups is involved in a C−H···O interaction with the terminal alkoxide oxygen of an adjacent diethoxomethylamino group {C(25)−H(25A)···O(14), H···O = 233 pm}. Two molecules of dichloromethane are co-crystallised with each macrocycle, and are located one on each face of the ring, with their

hydrogen atoms pointing towards the plane of the ring and their chlorine atoms pointing away from the ring. Significant hydrogen bonding occurs between these dichloromethane protons and the closest μ_2-oxide bridges {C(120)−H(12C)···O(10), H···O = 229 pm, C···H···O = 154°}. The total assembly is pseudo-centrosymmetric.

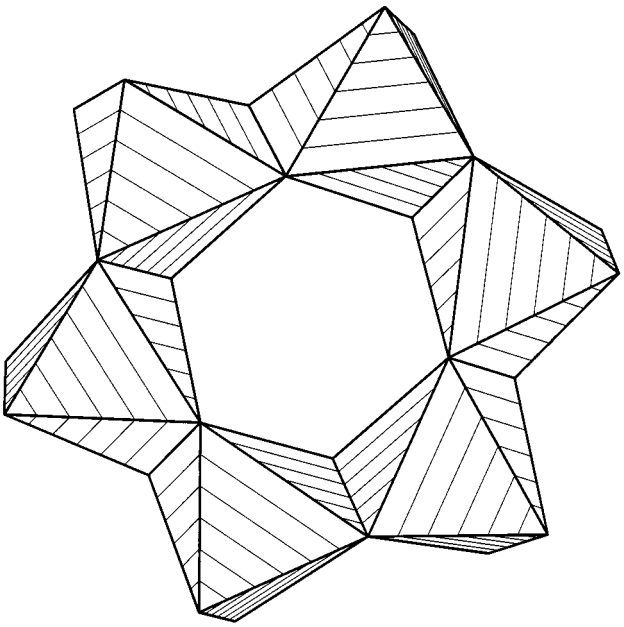

Figure 1. Molecular geometry of the coordination polyhedra in $[Ti_6(\mu_2\text{-}O_6)(\mu_2\text{-}OCH_2CH_2NCH_3{\cdot}CH_2CH_2O)_6{\cdot}2CH_2Cl_2$

The narrow bite angles (74, 76 and 79°) made by the coordinated MDEA, and the long Ti−N bond (av. = 235 pm), result in a coordination geometry around titanium that is extremely distorted from an ideal octahedron. The Ti−O bond lengths of the oxo bridges alternate long and short around the ring, with the shorter distances (av. = 175.7 pm) being *trans* to the long Ti−N bonds, and the longer distances (av. = 196.3 pm) being *trans* to the shorter terminal alkoxy arm of the MDEA.

The MDEA ligand coordinated to Ti(6) exhibits conformational disorder. Conformational rigidity may be preserved in the other MDEA ligands by the proximity of the dichloromethane to the ligands coordinated to Ti(1), Ti(2), Ti(4) and Ti(5). The MDEA coordinated to Ti(3) {which is pseudosymmetrically related to Ti(6)} is also held in one conformation by hydrogen bonding with a molecule of dichloromethane {C(31)−H(31A)···Cl(2), H···Cl = 270 pm} and weak intermolecular hydrogen bonding with a bridging oxygen from an adjacent macrocycle {C(32)−H(32B)···O(24), H···O = 258 pm}.

The macrocycle hole size, measured between opposite oxygens (less 140 pm for oxygen van der Waals radii), is 451, 447 and 480 pm for O(10)···O(40), O(30)···O(60) and O(20)···O(50) respectively. Related six- and eight-membered "coronate" complexes of Fe have been prepared with MDEA and triethanolamine ligands.[37] Bridging in these complexes is solely via the μ_2-alkoxo groups of the amino alcohols as the complexes do not include oxo ligands.

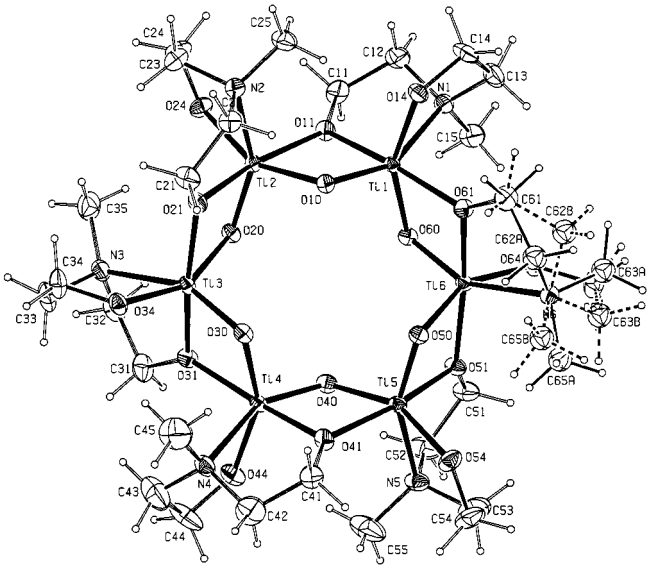

Figure 2. X-ray crystal structure of the hexameric assembly **1** (ORTEP drawing) showing the conformational disorder in the ligand attached to Ti(6)

Experimental Section

Hexakis[titanium(μ_2-oxo)(*N*-methyldiethoxoamine)] (1): A sample of $Ti(MDEA)_2$ (0.1 g) was dissolved in dry dichloromethane (5.0 mL). A layer of moist diethyl ether (10 cm^3) was carefully added and left to diffuse slowly into the the dichloromethane solution over 4 days. The crystalline product precipitated from solution, and X-ray quality crystals were removed from the side of the flask. Yield 0.06 g.

X-ray Crystallographic Study:[38] $C_{32}H_{70}{\cdot}Cl_4N_6O_{18}Ti_6$, Fw = 1256.14. Monoclinic, space group $P\ 2_1/c$, a = 1101.63(2), b = 2238.60(5), c = 2108.43(5) pm, β = 100.203(1)°, V = 5117.4(2)·10^6 pm^3, d_{calc} = 1.63 $Mg{\cdot}m^{-3}$ for Z = 4, μ = 1.171 mm^{-1}, λ(Mo-K_α) = 71.073 pm, T = 158 K. A tabular crystal 0.80 × 0.50 × 0.40 mm was cut from a larger block immersed in mounting oil and rapidly mounted under a nitrogen stream on a Siemens P4 SMART diffractometer with a Siemens CCD area detector. The data collection nominally covered a hemisphere of reciprocal space, by a combination of two sets of exposures (14322 reflections). Each exposure took 15 s, the first at 0.3° intervals over a total of 52.8° in ω; the second covered 360° in ϕ (the mounting axis). Crystal decay was monitored by repeating the initial 10 frames at the end of the data collection and analyzing the duplicate reflections. The data (θ = 2.62 to 26.08°) were corrected for Lorentz and polarization factors and crystal decay (SAINT) and an empirical absorption correction (SADABS) was applied giving 7184 unique data.

The structure was solved by direct methods (SHELXS-97)[38] and successive difference-Fourier syntheses. Refinement was by full matrix least-squares based on wF_o^2 using $w = 1/[\sigma^2(F_o^2) + (0.0635*P)^2 + 0.34*P]$ where $P = (F_o^2 + 2F_c^2)/3$ and F_o and F_c are the observed and calculated structure factor amplitudes from SHELXL-97.[39] The disorder found for the ligand bound to Ti(6) was modelled using two conformations which refined to occupancies of 0.680(4) and 0.320(4) (see Figure 2). All hydrogen atoms were refined as riding atoms with isotropic thermal parameters set at 1.2 times the atom to which they were bound. All other atoms were refined with anisotropic thermal parameters. Refinement converged at R_1 = 0.0454, [for 5723 reflections with $I > 2\sigma(I)$], 588 parameters, wR_2 = 0.1320; final GOF = 1.008. The final difference map

showed no peak larger than 1.047 eA^{-3} and no hole larger than -0.604 eA^{-3}, and these were < 120 pm from Ti and C atoms.[40]

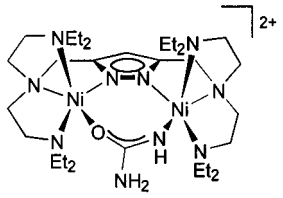
Novel μ_3-Coordination of Urea at a Nickel(II) Site: Structure, Reactivity and Ferromagnetic Superexchange

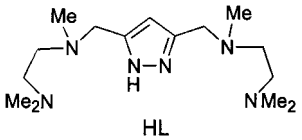


Franc Meyer,*[a] Matthias Konrad,[a] and Elisabeth Kaifer[a]

Keywords: Urea / Nickel / Coordination modes / Cooperative effects / Magnetic properties

A tetranuclear mixed-spin nickel(II) complex featuring two urea molecules in an unprecedented μ_3-κN:κN′:κO coordination mode has been structurally characterized. The two central high-spin nickel(II) ions exhibit ferromagnetic coupling (J = +3.4 cm^{-1}) mediated by the NH_2–C–O linkages of the bridging urea. In solution the temperature dependence of the UV/Vis optical absorption and of the magnetic moment indicate that, upon cooling, additional solvent molecules bind to the terminal low-spin metal ions and a concomitant spin change occurs. In the solid state the coordinated urea ligands can be thermally degraded to cyanate within the grip of the multimetallic nickel(II) site.

The coordination and conversion of urea at transition metal complexes,[1] in particular at dinuclear nickel(II) systems,[2−5] has received considerable attention in recent years. The main incentive for this arises from the endeavor to understand and mimic the unique properties of the natural metalloenzyme urease, which contains two cooperating nickel(II) ions within its active site, and which achieves at least a 10^{14}-fold rate enhancement for the biological hydrolysis of urea.[6][7] According to the initially proposed mechanism[8] of urease activity, the urea substrate is activated by O-coordination to one nickel(II) ion in conjunction with extensive hydrogen bonding within the active site pocket, and is attacked by a nucleophilic hydroxide bound to the adjacent second metal ion. Subsequent structural findings for both native and inhibited urease, however, together with structure-based molecular modeling of the catalytic mechanism, led to the alternative suggestion of a bridging coordination mode of both urea and hydroxide at the bimetallic core.[9] The most recent reactivity studies of urea derivatives coordinated to mononuclear metal centers have indicated that a cyanate NCO intermediate might be involved in the urease mechanism.[10] Evidently, the precise details of urea binding within the enzyme active site, as well as the key steps of its catalytic conversion, are still far from being fully understood.



This situation, therefore, stimulates the synthesis and investigation of small nickel(II) coordination compounds in order to elucidate possible coordination modes of urea − also in a more general sense − and to probe their relevance to the metal-assisted hydrolytic degradation of this fundamental and ubiquitous substrate at multimetallic sites. Whereas several dinickel(II) complexes with η^1(O)-coordinated urea have hitherto been prepared and studied,[3][4] only recently have we reported the pyrazolate-based complex **1** which represents the first structurally characterized example of a μ_2-κN:κO bridging coordination mode of (deprotonated urea at a dinickel(II) site (Scheme 1).[5]

1

Scheme 1. Urea-bridged dinickel(II) complex **1**[5]

This system enabled a thermal decomposition of the substrate within the tight grip of the bimetallic pincer to yield a N,O-bridging cyanate, but no substantial activation towards hydrolytic degradation (tested by attempting ethanolytic cleavage to yield ethyl carbamate) could be observed. We considered the absence of any additional docking site for the alcohol nucleophile as one likely reason for the lack of hydrolytic reactivity of **1**, in accordance with the idea of a requisite activation of both the urea substrate and the nucleophile at the bimetallic core. To avoid this drawback, we have now employed a different dinucleating ligand matrix L (Scheme 2),[11] which bears fewer N-donors within the chelating side arms attached to the heterocycle, and which was thus expected to provide accessible coordination sites at both metal centers.

HL

Scheme 2. Ligand HL employed in this work[11]

Treatment of HL with two equivalents of base and [Ni(H$_2$O)$_6$](ClO$_4$)$_2$ in the presence of an excess of urea affords the red compound **2**, which is moderately soluble in polar solvents such as a mixture of methanol/acetone (1:1). Its mass spectrum shows signals corresponding to

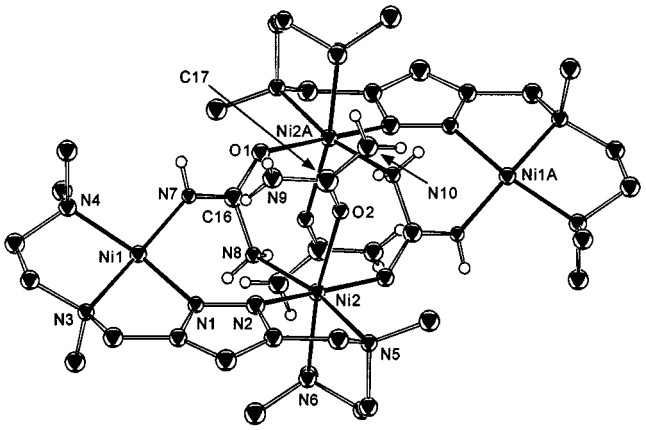
$[LNi_2(OCN_2H_3)]^+$ and $[LNi_2(OCN_2H_3)(ClO_4)]^+$, confirming the formation of a dinickel(II) complex containing deprotonated urea. The presence of the latter is further corroborated by strong IR absorptions at 1636 cm^{-1} [$\tilde{\nu}$(C=O)] as well as in the range 3100−3460 cm^{-1} [$\tilde{\nu}$(N−H)]. Small crystals of **2** could be obtained by layering a solution in methanol/acetone (1:1) with Et_2O, and an X-ray crystallographic analysis was performed (Figure 1).[12]



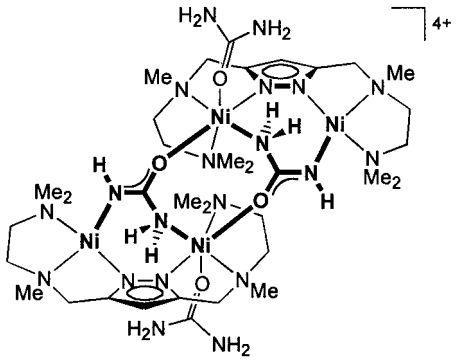


Figure 1. Molecular Structure of the cation of **2**; for clarity most of the hydrogen atoms have been omitted; selected atom distances (Å) and angles (°): Ni1−N1 1.886(3), Ni1−N3 1.897(4), Ni1−N4 1.975(3), Ni1−N7 1.897(4), Ni2−O1A 2.070(3), Ni2−O2 2.151(3), Ni2−N2 2.014(4), Ni2−N5 2.143(4), Ni2−N6 2.176(4), Ni2−N8 2.108(4), N1−N2 1.372(5), O1−C16 1.254(5), N7−C16 1.311(6), N8−C16 1.427(5), O2−C17 1.249(5), N9−C17 1.339(6), N10−C17 1.357(6), Ni1···Ni2 4.232, Ni2···Ni2A 4.349; O1−C16−N7 125.7(4), O1−C16−N8 117.8(4), N7−C16−N8 116.5(4), O2−C17−N9 123.6(5), O2−C17−N10 120.5(4), N9−C17−N10 115.9(4)

The solid-state structure of **2** reveals that pyrazolate-based bimetallic moieties containing urea as secondary bridging units have indeed been formed. Unexpectedly however, two of these moieties are found to be linked by an unprecedented μ_3-κN:κN′:κO coordination of the urea substrate. The central feature of the tetranuclear framework is an eight-membered ring system which is composed of two nickel atoms spanned by two N,O-bound urea molecules (Scheme 3), and which is situated on a crystallographic center of symmetry. The remaining deprotonated urea NH-groups are coordinated to the additional outer nickel centers.

An unambiguous distinction between the O, NH, and NH_2 donors of the μ_3-bridging, planar urea ligand (sum of angles around C16: 360.0°) is primarily based on the characteristic order of bond lengths *d*(C16−O1) = 1.254(4) Å, *d*[C16−N7(NH)] = 1.311(6) Å and *d*[C16−N8(NH_2)] = 1.427(5) Å, where the two C−N bonds are significantly shortened or lengthened, respectively, in comparison to the C−N bonds of purely η^1(O)-bound urea [1.339(6)/1.357(6) Å, see below]. Further corroboration stems from the assignment of the N-bound H atoms which were located in the difference fourier map and refined. Thus the sum of bond

Scheme 3. Schematic structure of the cation of **2**; the central core featuring the μ_3-bridging urea is set off in bold

angles around the trigonal-planar amide−N7 amounts to 359.4°, while the angles around the tetrahedral amine center N8 are found in the expected range of 105−114°.

A further urea molecule is η^1(O)-bound to the central Ni2 and Ni2A ions, thereby completing their distorted octahedral (OC-6) coordination spheres. In contrast, the outer Ni1 and Ni1A atoms are nested in square-planar (SP-4) environments, which can be attributed to the stronger σ-donor capacity of the anionic NH(amide) donor compared to the neutral NH_2(amine) and O donor sites of the μ_3-bridging urea ligand. The predicted low-spin d^8-configuration for such SP-4 nickel(II) ions is confirmed by magnetic measurements performed on powdered samples of solid **2**, which are in accordance with the presence of a mixed-spin complex having only two paramagnetic high-spin d^8 centers per tetranuclear complex (μ_{eff} = 3.21 μ_B at 288 K per paramagnetic Ni^{II}).

Upon cooling a solution of **2** in methanol/acetone (1:1) a color change from red to greenish-blue is observed. Following this process by UV/Vis spectroscopy (Figure 2) confirms the gradual disappearance of the major optical absorption of **2** at λ_{max} = 480 nm and a slight shift and rise of the low intensity absorption bands at around 380 and 625 nm.

These changes suggest an increase in coordination number of the SP-4 nickel ions and the formation of five- or even six-coordinate metal centers caused by the additional binding of extra solvent molecules at lower temperatures. However, the absence of any isosbestic points is indicative of a more complex process which is possibly due to a sequential coordination of the solvent ligands to the two terminal metal ions in **2**, or to a concurrent break-up of the tetranuclear system into bimetallic entities. The solution magnetic moment (determined by the Evans method)[15] rises from 3.5(±0.1) μ_B at 303 K to 4.1(±0.1) μ_B at 223 K per pyrazolate-based bimetallic unit (Figure 3), where the maximum value is close to the spin-only value expected for two high-spin nickel(II) ions (the slight decrease of μ_{eff} at even lower temperatures might be due to antiferromagnetic coupling within the pyrazolate-based bimetallic units). This corroborates the assumed transformation of the low-spin

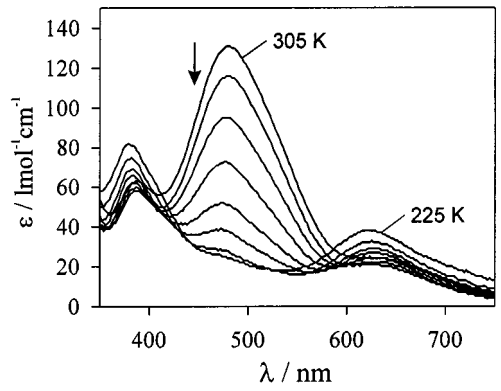

Figure 2. Temperature dependence of the UV/Vis spectrum of **2**; spectra at 225 K and in the range 245−305 K (steps of 10 K) are shown

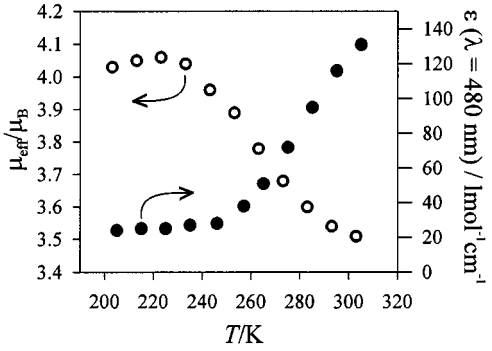

Figure 3. Temperature dependence of the molar optical absorption at 480 nm for **2** (solid circles) and of the solution magnetic moment per pyrazolate-based bimetallic fragment of **2** (open circles)

SP-4 nickel(II) ions to five- or six-coordinate high-spin nickel(II) centers upon cooling.

The temperature dependence of both the UV/Vis data as well as of the solution magnetic moment (Figure 3) reveals that conversion of the greenish-blue species to the red complex **2** is still incomplete at temperatures up to 305 K. It is pivotal in the present context, that activation of a potential nucleophile by coordination to the terminal nickel(II) ions is apparently feasible in **2**; this is assumed to be required for a subsequent nucleophilic attack on either the bridging urea or on the η^1(O)-bound urea substrate at the proximate central site. Still, the activity of **2** for the ethanolysis of urea (determined by a method described previously[3d]) is low, amounting to a conversion of only 1.2 equivalents of the substrate after five days refluxing in ethanol. It appears reasonable to ascribe this to the anionic character of the deprotonated μ_3-urea ligand, which obviously prevents it from being susceptible to nucleophilic attack. On the other hand, heating of solid **2** to elevated temperatures (140°C) causes conversion of coordinated urea to cyanate, as evidenced by the gradual appearance of the characteristic IR absorption for the ν_{asym}(NCO) stretch[5b] at 2193 cm^{-1} and a dominant mass spectrometric signal at m/z = 552 corresponding to $[LNi_2(NCO)(ClO_4)]^+$. This finding again shows that urea can be thermally degraded to cyanate within the clamp of an appropriate arrangement of nickel(II) ions.[3c,5]

The magnetic properties of powdered samples of solid **2** have been studied over the temperature range 4.8−288 K, as major structural changes of the tetranuclear framework (as observed in solution) are not expected to occur in the solid state. Data for the magnetic susceptibility and μ_{eff} are depicted in Figure 4. The rise of μ_{eff} with decreasing temperature − reaching a maximum of 3.69 μ_B per pyrazolate-based dinickel(II) entity at 7.0 K − is indicative of ferromagnetic coupling between the two central OC-6 metal centers.

At even lower temperatures the magnetic moment tends to drop, which is probably due to zero-field splitting effects or additional intermolecular antiferromagnetic interactions. The experimental data were simulated by a modified expression based on the isotropic Heisenberg model ($\boldsymbol{H} = -2J \times \boldsymbol{S}_1 \times \boldsymbol{S}_2$ with $S_1 = S_2 = 1$) {Equation (1)} where p is the molar fraction of paramagnetic impurities and θ is a Weiss constant that was included to describe phenomenologically the decrease of $\mu_{eff}(T)$ at low temperatures.[16] The best fit parameters obtained are g = 2.25, J = +3.4 cm^{-1}, $p < 0.01$ and θ = −0.62 [$R = \Sigma(\chi^{calc} - \chi^{obs})^2/\Sigma(\chi^{obs})^2 = 6.0 \times 10^{-5}$].

Considering the large separation of the two high-spin nickel(II) ions in **2** (4.349 Å), the surprising ferromagnetic exchange interaction is expected to be ligand-mediated and is evidently transmitted by a σ-bond pathway. These combined abilities of deprotonated urea to (i) mediate ferromagnetic superexchange and (ii) to bind three metal ions in a bridging fashion, make this component a promising candidate for the design of higher-dimensional coordination networks with interesting magnetic properties. Insight into the geometric requirements and the underlying mechanisms of the exchange coupling will be the subject of future studies.

In conclusion, we have shown that urea can simultaneously bind to three different metal ions, and that it can be thermally degraded to cyanate within such grip of a multimetallic nickel(II) site. Furthermore, urea is able to bring

$$\chi_m = (1-p)\{[Ng^2\mu_B{}^2/k(T-\theta)][2\exp(2J/kT) + 10\exp(6J/kT)]/[1 + 3\exp(2J/kT) + 5\exp(6J/kT)]\} + 2p(2Ng^2\mu_B{}^2/3kT) + 2N_\alpha \quad (1)$$

about ferromagnetic exchange coupling in the novel μ_3-κN:κN′:κO-coordination mode. These findings should offer new perspectives with respect to the use of the simple urea molecule as a building block for extended coordination networks, as well as with respect to the metal-mediated activation and transformation of this ubiquitous substrate.

Experimental Section

Caution! Although no problems were encountered in this work, transition metal perchlorate complexes are potentially explosive and should be handled with proper precautions.

Complex 2: A solution of the ligand HL[11] (0.25 g, 0.84 mmol) in thf (20 mL) and MeOH (1 mL) was treated with two equivalents of *n*BuLi (2.5 M in hexane) at 0°C and stirred for 5 min. $[Ni(H_2O)_6](ClO_4)_2$ (0.62 g, 1.69 mmol) and additional MeOH (20 mL) were then added and the red solution stirred at room temperature for 1 h. After the addition of urea (0.15 g, 2.50 mmol) stirring was continued for a further 2 h. All volatile material was then removed under reduced pressure and the residue taken up in MeOH/acetone (1:1, 60 mL) and layered with Et_2O. Red crystalline material of the product **2**·2(acetone) gradually formed (0.51 g, 0.32 mmol, 77%). − IR (KBr): $\tilde{\nu}$ = 3456 (s), 3346 (s), 3115 (m), 2915 (w), 1689 (m, $C{=}O_{acetone}$), 1636 (vs), 1571(m), 1463 (s), 1096 (vs) cm^{-1}. − $C_{34}H_{76}Cl_4N_{20}Ni_4O_{20}$·2(acetone) (1577.84): calcd C 30.45, H 5.62, N 17.75; found C 30.08, H 5.63, N 17.37.

Synthesis and Structure of the First Fullerene Complex of Titanium $Cp_2Ti(\eta^2\text{-}C_{60})$

V. V. Burlakov,[a] A. V. Usatov,[a] K. A. Lyssenko,[a] M. Yu. Antipin,[a] Yu. N. Novikov,[a] and V. B. Shur*[a]

Keywords: Fullerenes / Titanium / Complexes / X-ray analysis

The first fullerene complex of titanium $Cp_2Ti(\eta^2\text{-}C_{60})$ has been synthesized by reaction of the bis(trimethylsilyl)-acetylene complex of titanocene $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ with an equimolar amount of fullerene-60 in toluene at room temperature under argon. An X-ray diffraction study of the complex has shown that it has the structure of a titanacyclopropane derivative.

Recent studies have revealed the ability of fullerenes to form complexes with transition metal compounds.[1,2] The majority of studies in this exciting area have been conducted on C_{60} for which a large number of complexes with different transition metals have been prepared and structurally characterized. Among fullerene complexes, the least studied ones are those of the Group IVB metals. Thus, for zirconium, the only available data on complexation with fullerenes concern the work on the hydrozirconation of C_{60} with Cp_2ZrHCl.[3,4] For titanium and hafnium, no fullerene complexes have previously been described.

In the present communication, we wish to report on the synthesis and structure of the first fullerene complex of titanium $Cp_2Ti(\eta^2\text{-}C_{60})$ **(1)**, which is readily obtained from the reaction of the bis(trimethylsilyl)acetylene complex of titanocene $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ with an equimolar amount of fullerene-60 in toluene at room temperature under argon.

The isolated complex is a black crystalline solid which is poorly soluble in aromatic hydrocarbons. According to elemental analysis and X-ray diffraction data (see below), crystals of the complex contain one molecule of toluene per molecule of **1**. The molecular structure of $\mathbf{1}\cdot C_6H_5CH_3$ is shown in Figure 1. Selected bond lengths and angles for $\mathbf{1}\cdot C_6H_5CH_3$ are given in Table 1. The complex is a bis(η^5-cyclopentadienyl)titanium derivative in which the $(\eta^5\text{-}C_5H_5)_2Ti$ unit is bound to the olefinic C(1)−C(2) bond at the 6:6 ring junction of the fullerene core in an η^2-fashion. Such a mode of bonding is typical of fullerene complexes with transition metal compounds.

The coordination to titanium results in a significant elongation of the fullerene C(1)−C(2) bond. The length of this bond in **1** is 1.507(6) Å which is considerably greater than the corresponding C−C distance in free C_{60} (1.38 Å)[1] and is close to the values characteristic of the endocyclic C−C single bonds of cyclopropane [1.510(2) Å][7] and its heteroanalogues [e. g. 1.484(3) Å in thiirane,[8,9] 1.502(5) Å in phosphirane[8,10]]. Thus, complex **1** has the structure of a titanacyclopropane derivative.

A similar η^2-coordination of the olefin molecule with a titanium atom has been found in the previously described ethylene complex of permethyltitanocene $Cp^*_2Ti(\eta^2\text{-}C_2H_4)$.[8] However, the length of the coordinated C−C bond of the olefin ligand in this complex [1.438(5) Å] is noticeably smaller than that in complex **1**.

The influence of the complexation to titanium on the geometry of the C_{60} moiety is manifested not only in the elongation of the C(1)−C(2) bond but also in the lengthening of the other C−C bonds formed by the C(1) and C(2) atoms. As can be seen from Table 1, the C(1)−C(6), C(1)−C(9), C(2)−C(3) and C(2)−C(12) bond lengths in the molecule of **1** span the range of 1.478(6)−1.492(6) Å (av. 1.486 Å) while the average C−C distance at the other 5:6 ring junctions is 1.467 Å (1.45 Å in free fullerene[1]). The average C−C bond length at the 6:6 ring junctions in complex **1** [excluding the C(1)−C(2) bond] is 1.393 Å which is close to that in free C_{60} (1.38 Å[1]). Due to coordination by the Cp_2Ti unit, the C(1) and C(2) atoms of the fullerene ligand deviate from the planes of the corresponding 5- and 6-membered rings (by ca. 0.19 Å), as a result of which these rings acquire an envelope and a flattened sofa conformation, respectively. The other 5- and 6-membered cycles in the C_{60} moiety are planar within 0.005 Å. The distortion of the fullerene core in **1** can also be demonstrated by the comparison of its "radii" in different directions. Thus, the distances from the centroid of the C_{60} ligand[11] to the C(1) and C(2) atoms bonded to titanium are 3.75 Å whereas the corresponding average distance to the other carbon atoms of C_{60} is significantly shorter (3.540 Å).

The geometry of the bent sandwich in **1** is not exceptional. The planes of the $\eta^5\text{-}C_5H_5$ rings form a dihedral angle of 48.2°. The titanium atom and the coordinated C(1)−C(2) bond of the fullerene are located in the bisector plane of this dihedral angle. The distance from the titanium to the centroids of the $\eta^5\text{-}C_5H_5$ ligands is 2.06 Å. The Ti(1)−C(1) and Ti(1)−C(2) bond lengths are virtually identical [2.304(4) and 2.295(5) Å]. The Ti(1)−C(1)−C(2)

[a] Cp(1) and Cp(2) are the centroids of Cp rings C(61)−C(65) and C(66)−C(70), respectively.

and Ti(1)−C(2)−C(1) bond angles are 70.5(2) and 71.2(2)°, respectively. The mutual orientation of the η^5-C_5H_5 rings closely corresponds to a staggered conformation. The average C−C bond length in the η^5-C_5H_5 groups is 1.386 Å.

Analysis of the atomic anisotropic displacement parameters of **1** was performed using the THMA-11 program.[12] The agreement between the experimental U_{ij} values and those calculated from the rigid-body LTS model[13] is characterized by a high value of the R_u factor (0.25), while the same value calculated in the segmented-rigid approximation for the (η^2-C_{60})Ti moiety was found to be rather low (0.095). Thus, the metallofullerene fragment in **1** can be correctly analyzed in terms of the LTS approximation and the high value of R_u for the whole molecule is probably caused by the significant libration motion of the η^5-C_5H_5 ligands. Analysis of the rigid-body LTS tensors for the (η^2-C_{60})Ti unit revealed that its libration motion is highly anisotropic. The eigenvalues of the libration tensor (L) are 17.3, 6.0 and 4.8 deg^2 and its maximum eigenvalue (L_1) is observed along the axis with the minimum moment of inertia, which coincides with the C_2 symmetry axis of the molecule. Taking into account that the L_1 value is rather low we can conclude that the barrier of the rotation for the C_{60} moiety in the crystal structure of **1**·$C_6H_5CH_3$ is high.

The crystal packing of **1** can be described as corrugated layers parallel to the *bc* crystallographic plane with the solvate toluene molecules between the layers. The shortest distance between the centroids of the C_{60} cores within the layers is 9.816 Å, while the corresponding distance between the layers is 10.29 Å. It is noteworthy that the distance within the layers is considerably shorter than in the crystal structure of free fullerene-60 (10.02 Å)[14] and the Van der Waal's radius of C_{60} (10.18 Å).[15]

Experimental Section

Experiments were carried out under argon with careful exclusion of air and moisture. Toluene was purified in the usual manner and freshly distilled before use over sodium under an atmosphere of

argon. The starting acetylene complex $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ was prepared by the method described in refs.[5,6]

Synthesis of $Cp_2Ti(\eta^2\text{-}C_{60})$ (1): Fullerene-60 (0.101 g, 0.14 mmol) was dissolved in 50 mL of toluene and to the resulting violet solution was added a solution of $Cp_2Ti(\eta^2\text{-}Me_3SiC_2SiMe_3)$ (0.055 g, 0.16 mmol) in toluene (5 mL). The reaction mixture was filtered and then kept overnight at room temperature under argon. During the course of the reaction, the colour of the mixture turned dark brown/green and within 24 h black crystals of $\mathbf{1}\cdot C_6H_5CH_3$ were precipitated. The solution was decanted, the crystals were washed with a small amount of toluene and dried at 20°C in a stream of argon. The yield of $\mathbf{1}\cdot C_6H_5CH_3$ was 0.04 g (29%). – $C_{77}H_{18}Ti$ (990.81): calcd. C 93.34, H 1.83; found C 93.34, H 1.75.

X-ray Structure Determination of 1: Crystals of $\mathbf{1}\cdot C_6H_5CH_3$ are monoclinic, space group $P2_1/c$, a = 15.951(5) Å, b = 13.678(4) Å, c = 19.313(6) Å, β = 108.11(2)°, V = 4005(2) Å^3, $d_{calc.}$ = 1.643 g·cm^{-3}, Z = 4. Intensities of 6329 reflections (R_{int} = 0.0174) were measured at 150 K on a Siemens P3 automated diffractometer using Mo-K_α radiation (λ = 0.71073 Å, balanced filter, $\theta - 2\theta$ scan, $\theta \leq 24°$). The structure was solved by direct methods and refined by full-matrix least squares against F^2 in the anisotropic (H-atoms isotropic) approximation. All hydrogen atoms were located from the electron density difference synthesis and were included in the refinement using the rigid motion model. The refinement converged to wR_2 = 0.2254 and GOF = 1.115 for 6329 independent reflections {R_1 = 0.0757 was calculated against F for 4699 observed reflections with $I > 2\sigma(I)$}. The number of refined parameters was 706. The final difference electron density map showed a maximum of 0.368 and a minimum of −0.642 eÅ^{-3}. All calculations were performed using SHELXTL PLUS 5.0 on an IBM PC/AT. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary no. CCDC-127616. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

1D- and 2D-Coordination Polymers from Self-Complementary Building Blocks: Co-Crystallization of (*P*)- and (*M*)-Single-Stranded Diastereoisomers

Rolf W. Saalfrank,*[a] Harald Maid,[a] Frank Hampel,[a] and Karl Peters[b]

Dedicated to Prof. Dr. W.-P. Fehlhammer on the occasion of his 60th birthday

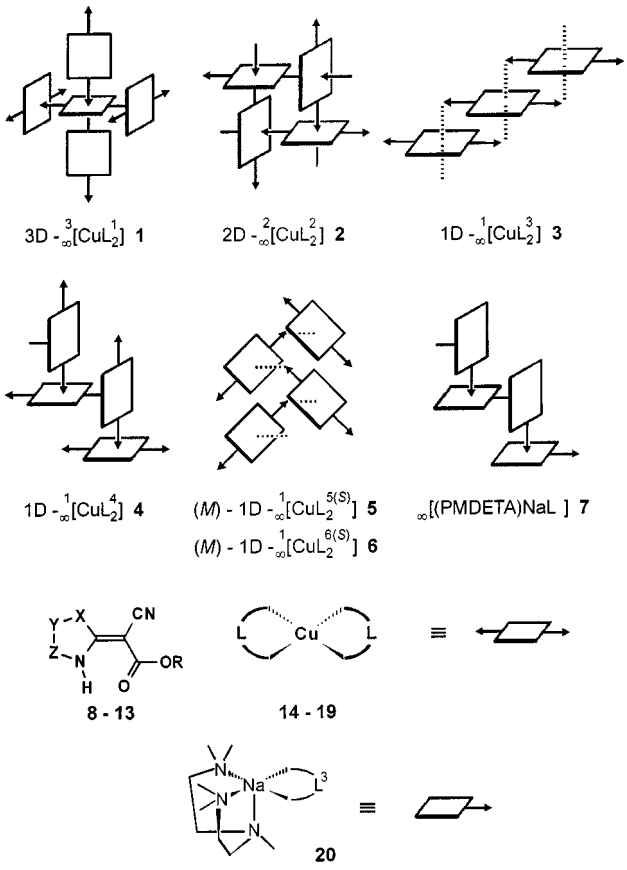
Keywords: Coordination polymers / Helical structures / Copper / Self-assembly / Supramolecular chemistry

Reaction of methanolic copper(II) acetate solution with oxazolidine **21** (HL^7) led to the formation of the one-dimensional coordination polymer 1D-$^1_\infty[CuL^7_2]$ **23**. On the contrary, reaction of copper(II) acetate in methanol with pyrrolidine **24** (HL^8) yielded the two-dimensional coordination polymer 2D-$^2_\infty[CuL^8_2]$ **26**. A common feature of **23** and **26** are the C_{2h}-symmetric coordinatively unsaturated building blocks **22** and **25**. In 1D-$^1_\infty[CuL^7_2]$ **23**, the cyano groups are linked to copper in a *side-on* fashion and the monomers **22** are oriented parallel to one another, whereas in 2D-$^2_\infty[CuL^8_2]$ **26** the cyano groups are bound to copper in the *end-on* mode and the monomers **25** are oriented at an angle of 117° to one another. In both 1D-**23** and 2D-**26**, copper has a distorted octahedral coordination sphere. On the other hand, reaction of methanolic copper(II) acetate solution with enantiomerically pure (5*S*)-pyrrolidine **27** ($HL^{9(S)}$) led to the formation of the diastereomeric helical strands (*M*)-/(*P*)-1D-$^1_\infty[CuL^{9(S)}_2]$ **29**. (*M*)- and (*P*)-**29** are present in pairs in the infinite unit cell. In helical 1D-**29**, copper is tetragonal-pyramidally coordinated and the C_2-symmetric monomers **28** ($CuL^{9(S)}_2$) are linked through only one cyano group. Moreover, it has been shown that the reaction of chiral racemic pyrrolidine **30** ($HL^{10(R,S)}$) with copper(II) acetate via the intermediate C_i-symmetric building blocks **31** ($CuL^{10(R)}L^{10(S)}$) furnishes one-dimensional 1D-$^1_\infty[CuL^{10(R)}$-$L^{10(S)}]$ **32**. Single-crystal X-ray diffraction analyses of the supramolecular species **23**, **26**, **29**, and **32** unequivocally establish the structures of these coordination polymers.

Introduction

With the growing understanding of supramolecular chemistry,[1] it might ultimately become feasible to routinely design and control solid-state architectures and therefore function.[2] Increasingly, solid structures are being invented and created rather than discovered. Realisation of such macromolecular targets requires the ability to assemble small supramolecular units that can be further aggregated in a controlled fashion. In order to construct such assemblies, we have developed coordinatively unsaturated building blocks of copper(II) and iron(II) with two additional ligating sites that do not interfere with the monomer assembly process but facilitate controlled aggregation.

We have recently shown that reaction of methanolic copper(II) acetate solution with tetrazole **8** (HL^1) leads to the formation of the three-dimensional coordination polymer 3D-$^3_\infty[CuL^1_2]$ **1**,[3] whereas under exactly the same conditions pyrrolidine **9** (HL^2) forms the two-dimensional coordination polymer 2D-$^2_\infty[CuL^2_2]$ **2**.[4] A prerequisite for the formation of 3D-**1** and 2D-**2** is the intermediate generation of the coordinatively unsaturated copper(II) building blocks **14** ($L = L^1$) and **15** ($L = L^2$). The monomers **14** and **15** are bidentate and coordinate through the two cyano groups. This leads to *perpendicular* linking of the monomers and to coordinative saturation at the copper(II) centers of **14** and **15** with formation of the corresponding three- and two-dimensional coordination polymers **1** and **2**. Thus, during the crystallization of the polymers **1** and **2**, the role of the building blocks **14** and **15** is twofold. They react both as metals and as ligands.[5] The exact structures of **1** and **2** were established by single-crystal X-ray analyses. In both polymers, the coordination sphere about the copper(II) atoms is a slightly distorted tetragonal bipyramid.



Unexpectedly, reaction of methanolic copper(II) acetate solution with tetrazole **10** (HL^3) furnished the coordination polymer 1D-$^1_\infty[CuL^2_2]$ **3**. In the case of **3**, a *parallel* rather than a *perpendicular* orientation of the building blocks **16** ($L = L^3$) leads to one-dimensionality.[6] A one-dimensional zigzag coordination polymer 1D-$^1_\infty[CuL^4_2]$ **4** was also obtained starting from benzoxazolidine **11** (HL^4). The reduced dimensionality of **4** allows **17** ($L = L^4$) to coordinate to copper(II) through one cyano group only.[7]

In contrast to the C_{2h}-symmetric monomers **14**–**17**, the C_2-symmetric building block (*S*,*S*)-**18** ($L = L^{5(S)}$), generated from (*S*)-methoxycarbonylpyrrolidine **12** ($HL^{5(S)}$), is sterically shielded at one side and thus couples only through

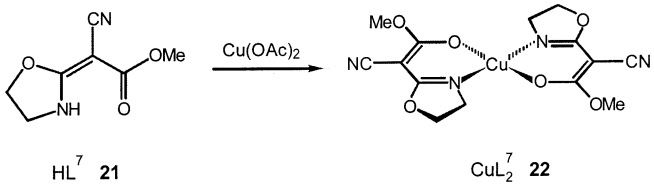
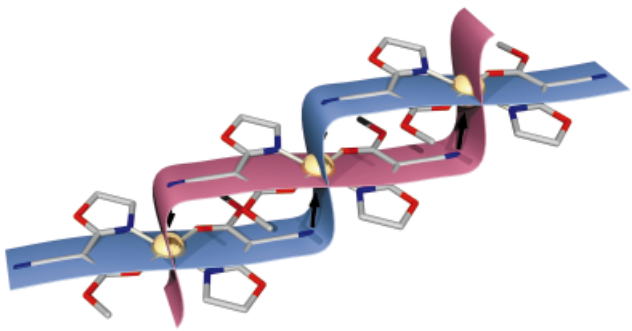
one cyano group. This leads to the helical one-dimensional coordination polymer 1D-$^{1}_{\infty}$[$CuL^{5(S)}_{2}$] **5**. According to the X-ray diffraction analysis, the crystal is composed of two almost identical helix strands, (*P*)-1D-$^{1}_{\infty}$[$CuL^{5(S)}_{2}$] **5** and (*M*)-1D-$^{1}_{\infty}$[$CuL^{5(S)}_{2}$] **5**,[8] which generate pairs of diastereoisomers.[9] It is noteworthy that the stereogenic centers in (*S*,*S*)-**18** do not lead to asymmetric induction. Racemic mixtures of single-stranded coordination polymers with (*P*)- and (*M*)-helicity were also obtained with achiral ligands and copper(I).[10]

To date, only a few examples of chiral, non-racemic helical coordination polymers have been reported, where the chirality is induced by a stereogenic center.[11][12] For example, reaction of a methanolic solution of enantiomerically pure oxazolidines **13** ($HL^{6(R/S)}$) with copper(II) acetate and crystallization from chloroform afforded single-crystals suitable for X-ray diffraction analysis. This analysis showed the crystals to be composed of identical, palindromic one-dimensional strands (*P*)-1D-$^{1}_{\infty}$[$CuL^{6(R)}_{2}$] **6** and (*M*)-1D-$^{1}_{\infty}$[$CuL^{6(R)}_{2}$] **6**.[8][13] Each cylindrical strand is formed by a set of C_2-symmetric copper(II) building blocks (*R*,*R*)-**19** (L = $L^{6(R)}$) and (*S*,*S*)-**19** (L = $L^{6(S)}$).

Regardless of steric considerations, by using a Group 1 metal, the zigzag one-dimensional coordination polymer 1D-$^{1}_{\infty}$[(PMDETA)NaL^{3}] **7** was formed. The polymer **7** is generated from the coordinatively unsaturated building block [(PMDETA)NaL^{3}] **20**.[14]



We report here on the synthesis of the one-dimensional coordination polymers 1D-$^{1}_{\infty}$[CuL^{7}_{2}] **23** and 1D-$^{1}_{\infty}$[$CuL^{10(R)}$-$L^{10(S)}$] **32**, the two-dimensional coordination polymer 2D-$^{2}_{\infty}$[CuL^{8}_{2}] **26**, and the helical coordination polymer strands (*P*)-/(*M*)-1D-$^{1}_{\infty}$[$CuL^{9(S)}_{2}$] **29**, which generate pairs of diastereoisomers in the infinite unit cell.[15]



Results and Discussion

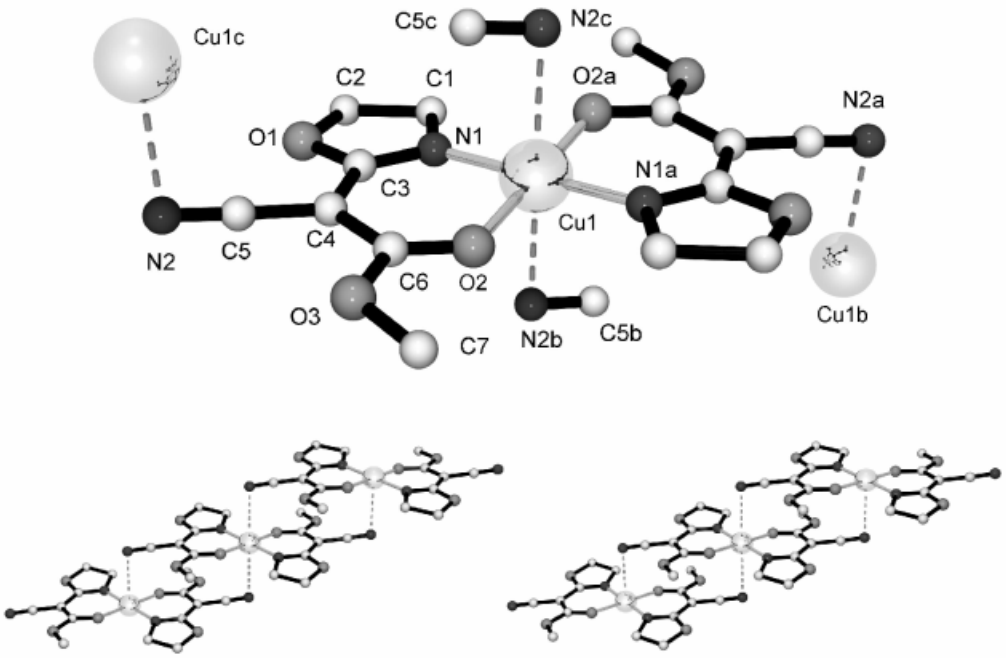
One-Dimensional Coordination Polymer 1D-$^{1}_{\infty}$[CuL^{7}_{2}] (23)

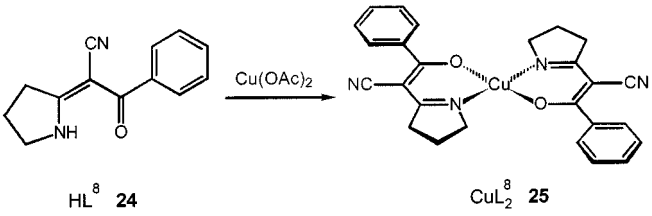
Reaction of a solution of NH-acidic oxazolidine **21** (HL^{7})[16][17] with copper(II) acetate in methanol yielded dark-green microcrystals.

HL^{7} **21** CuL^{7}_{2} **22**

1D - $^{1}_{\infty}$[CuL^{7}_{2}] **23**

On the basis of elemental analysis data and an X-ray diffraction study, the product was identified as the one-dimensional coordination polymer 1D-$^{1}_{\infty}$[CuL^{7}_{2}] **23**. The construc-





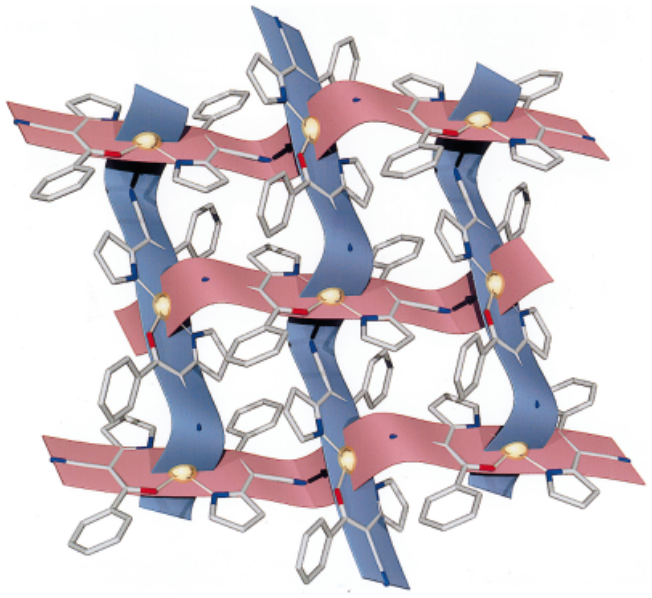


Figure 1. Top: structure of monomeric unit **22** of one-dimensional coordination polymer 1D-$^{1}_{\infty}$[CuL$^{7}_{2}$] **23** showing atomic numbering; H atoms omitted for clarity; bottom: stereoview of **23** in the infinite unit cell

tion of **23** becomes clear if one assumes the formation and linkage of the self-complementary building blocks **22** (Cu L$^{7}_{2}$). Intermediate **22** is coordinatively unsaturated and is also bis-monodentate with respect to the two CN groups. Specifically, the C_{2h}-symmetric monomers **22** are aligned parallel to one another. The equatorial cyano groups are coupled to copper in a *side-on* fashion with a Cu(1c)−N(2)−C(5) angle of 99.84° (Figure 1). The d^{9}-Cu^{II} ions are six-fold coordinated and are located in the center of a square-planar bipyramid. The Cu(1c)−N(2) distance amounts to 291.0 pm.

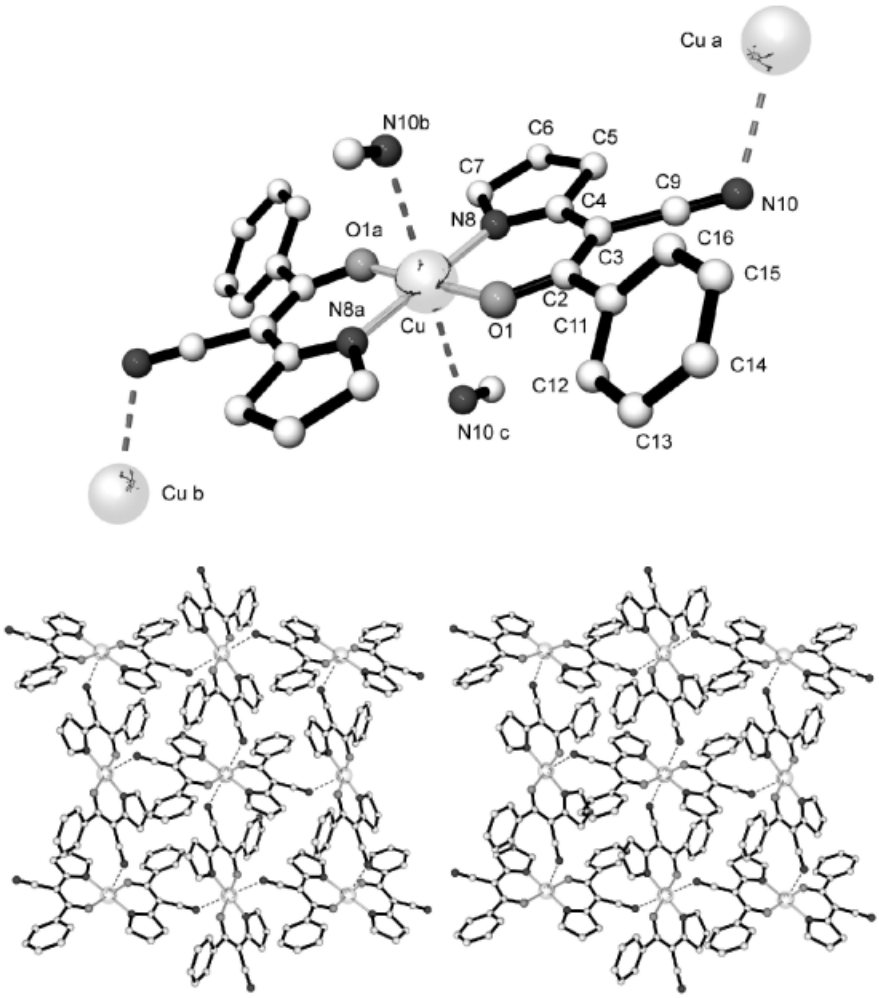
HL^{8} **24** CuL$^{8}_{2}$ **25**

2D -$^{2}_{\infty}$[CuL$^{8}_{2}$] **26**

Two-Dimensional Coordination Polymer 2D-$^{2}_{\infty}$[CuL$^{8}_{2}$] (26)

In order to study the effect of the ligands on the dimensionality of the coordination polymers, we treated a methanolic solution of pyrrolidine **24** (HL^{8})[16][18] with copper(II) acetate and isolated a green precipitate, which dissolved most readily in coordinating solvents. According to the microanalytical data and a single-crystal X-ray diffraction analysis, the two-dimensional coordination polymer 2D-$^{2}_{\infty}$[CuL$^{8}_{2}$] **26** was formed.

Polymer **26** is generated from the coordinatively unsaturated C_{2h}-symmetric building blocks **25** (CuL$^{8}_{2}$) along the two cyano groups. This leads to coordinative saturation at the copper(II) centers through distorted tetragonal bipyramids (Figure 2). The Cu(a)−N(10) distance measures 277.1 pm. The cyano groups of monomer **25** are bound to copper with a Cu(a)−N(10)−C(9) angle of 117.0°. The Cu−Cu distances amount to 759.9 pm (coplanar) and 992.3 pm (interplanar).



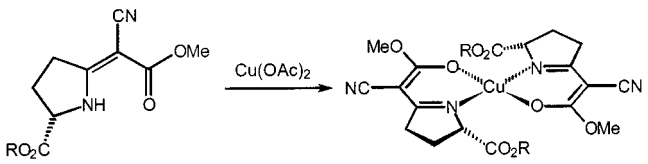


Figure 2. Top: structure of monomeric unit **25** of two-dimensional coordination polymer 2D-$^{2}_{\infty}$[CuL^{8}_{2}] **26** showing atomic numbering; H atoms omitted for clarity; bottom: stereoview of **26** in the infinite unit cell

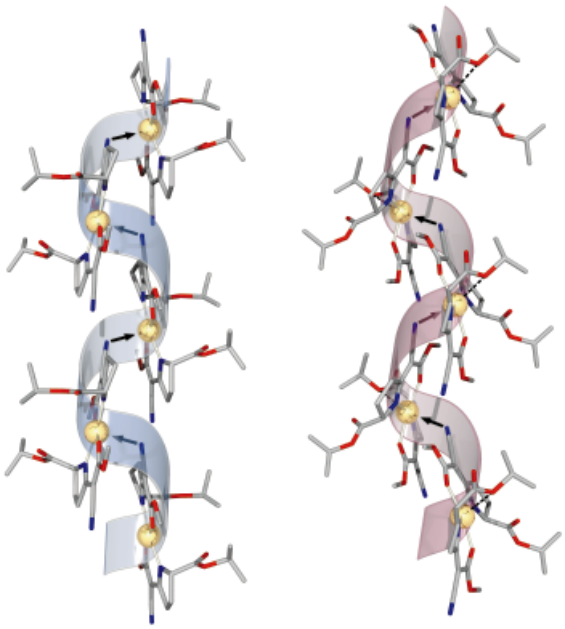


Helical Strands (M)-/(P)-1D-$^{1}_{\infty}$[$CuL^{9(S)}_{2}$] (29)

Reaction of a methanolic copper(II) acetate solution and (*S*)-isopropyloxycarbonylpyrrolidine **27** ($HL^{9(S)}$)[16] in the presence of triethylamine furnished light-green needles. According to the stoichiometric composition and an X-ray crystal structure analysis, the product obtained consisted of the helical coordination polymer (*M*)-/(*P*)-1D-$^{1}_{\infty}$[$CuL^{9(S)}_{2}$] **29**.[19]

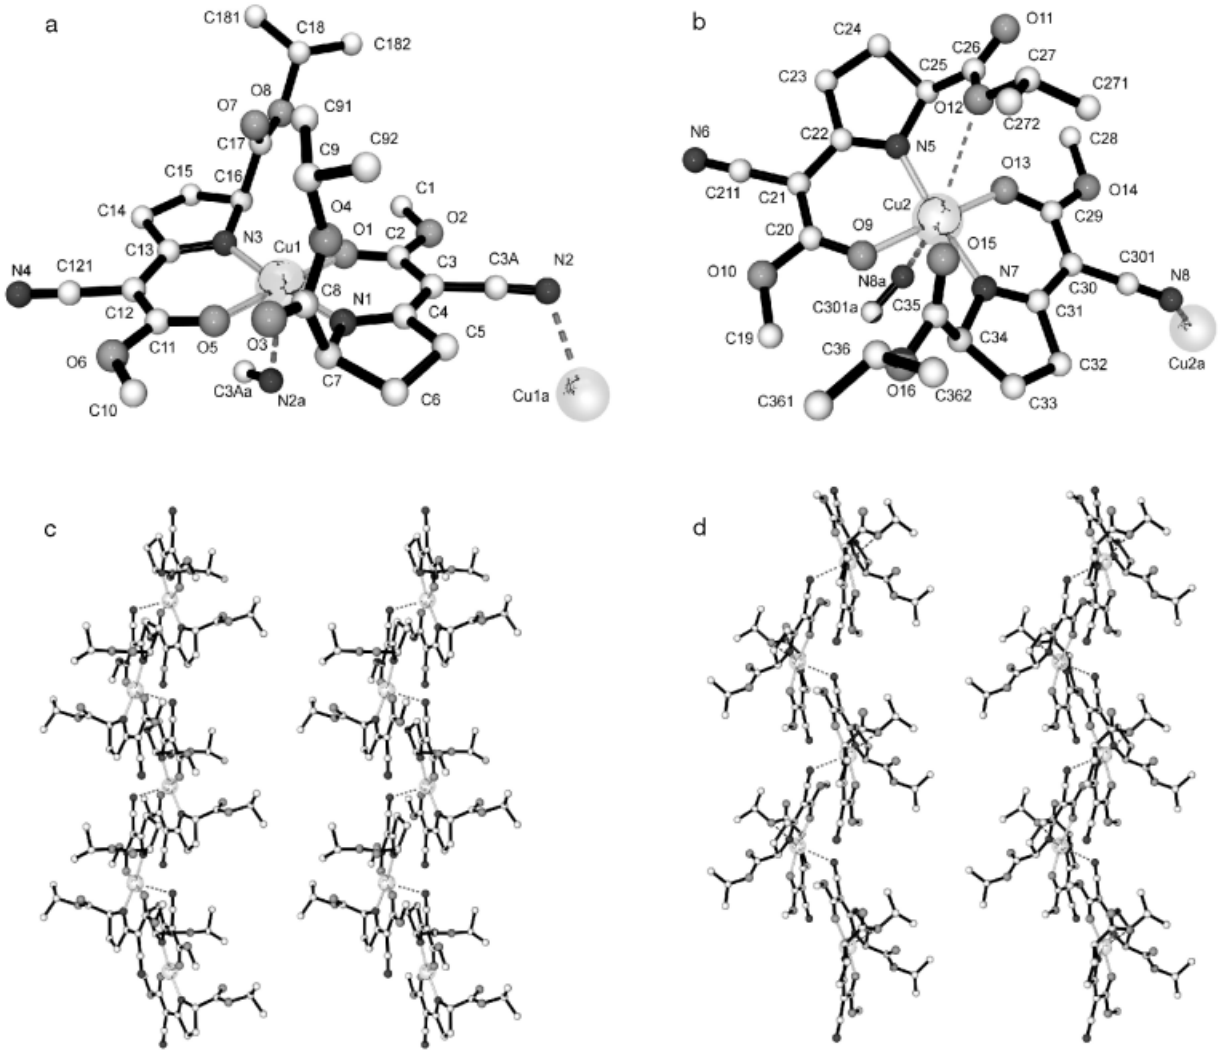
The formation of the one-dimensional coordination polymer **29** can be rationalized if one assumes the intermediate generation of the coordinatively unsaturated C_2-symmetric building block [$CuL^{9(S)}_{2}$] **28**, which is sterically shielded at one side by two isopropyloxycarbonyl groups. Therefore, in

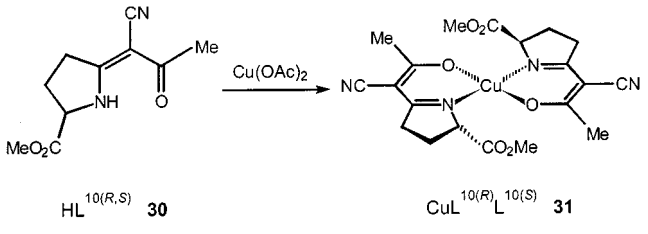
$HL^{9(S)}$ **27** R = $CHMe_2$ $CuL^{9(S)}_{2}$ **28**

(*M*)-/(*P*) -1D-$^{1}_{\infty}$[$CuL^{9(S)}_{2}$] **29**

contrast to 1D-$^{1}_{\infty}$[CuL$^{7}_{2}$] **23**, where copper displays tetragonal-bipyramidal coordination, attack of **28** through only one cyano group is possible. This leads to tetragonal-pyramidal coordination at the copper(II) centers with formation of **29**. The infinite unit cell is composed of helix strands made up of pairs of the diastereoisomers (*M*)-/(*P*)-1D-$^{1}_{\infty}$[CuL$^{9(S)}_{2}$] **29**.

It is noteworthy that the stereogenic centers of the chiral C_2-symmetric monomers [CuL$^{9(S)}_{2}$] **28** did not induce asymmetry in favour of either an (*M*)- or a (*P*)-helix. Each strand is composed of a set of identical monomeric building blocks **28**, which differ considerably in their bond lengths and angles. The available structural data for the monomeric units (*M*)-**28** [Figure 3 (a)] and (*P*)-**28** [Figure 3 (b)] reveal that each of the Cu atoms of the helical diastereoisomers (*M*)-**29** [Figure 3 (c)] and (*P*)-**29** [Figure 3 (d)] is linked through the nitrogen atom of only one neighbouring cyano group of the monomers. The central Cu atoms in (*M*)-**29** and (*P*)-**29** are almost tetragonal-pyramidally coordinated, with the planes of the two ligands L$^{9(S)}$ (HL$^{9(S)}$ = **27**) twisted with respect to one another to form angles of 7.97° and 13.64° [torsion angles: angles between the perpendiculars of the planes O(1)−Cu(1)−N(1), O(5)−Cu(1)−N(3), and O(9)−Cu(1)−N(5), O(13)−Cu(1)−N(7), respectively]. The distances Cu(1)−N(2a) and Cu(2)−N(8a) are 259.3 pm in (*M*)-**29** and 265.3 pm in (*P*)-**29**. The bond angles C(3Aa)−N(2a)−Cu(1) and C(301a)−N(8a)−Cu(2) are found to be 114.0° in (*M*)-**29** and 127.4° in (*P*)-**29**, respectively. The main difference between (*M*)-**28** and (*P*)-**28** is the short distance of 301.8 pm between Cu(2) and O(12) in (*P*)-**28**.





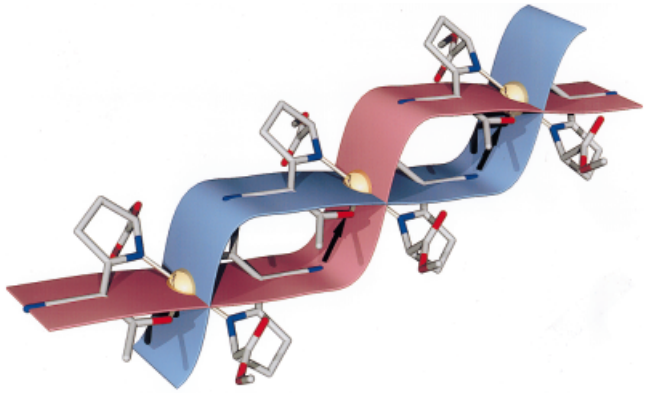


Figure 3. Top: structure of the monomeric units (*M*)-**28** (a) and (*P*)-**28** (b) showing atomic numbering of the helical diastereoisomers (*M*)-/(*P*)-1D-$^{1}_{\infty}$[CuL$^{9(S)}_{2}$] **29**; H atoms omitted for clarity; bottom: stereoview of **29** in the infinite unit cell (c) (*M*)-**29**, (d) (*P*)-**29**

One-Dimensional Coordination Polymer 1D-$^{1}_{\infty}$[CuL$^{10(R)}$L$^{10(S)}$] (32)

In contrast to enantiomerically pure pyrrolidine **27** (HL$^{9(S)}$), which led via the C_2-symmetric intermediate **28** to the helical strands (*M*)-/(*P*)-1D-$^{1}_{\infty}$[CuL$^{9(S)}_2$] **29**, reaction of a methanolic solution of NH-acidic, chiral, racemic pyrrolidine **30** (HL$^{10(R,S)}$) with copper(II) acetate afforded the C_i-symmetric coordinatively unsaturated building block (CuL$^{10(R)}$L$^{10(S)}$) **31**. Dipole−cation interaction between the CN groups and the copper(II) centers of the key intermediates **31** yielded the one-dimensional coordination polymer 1D-$^{1}_{\infty}$[CuL$^{10(R)}$L$^{10(S)}$] **32**.

HL$^{10(R,S)}$ **30** CuL$^{10(R)}$L$^{10(S)}$ **31**

1D -$^{1}_{\infty}$[CuL$^{10(R)}$L$^{10(S)}$] **32**

The monomers **31** are aligned parallel to one another and the equatorial cyano groups of **31** are directed towards the copper in a *side-on* fashion with a Cu(1a)−N(2)−C(4) angle of 111.6° (Figure 4). The d^9-Cu(II) ions are six-fold coordinated and are located in the center of a square plane. The Cu(1)−N(2b) distance of 354.6 pm in **32** is rather long compared with that of 291.0 pm in **23** (Figure 1).

Conclusions

The high degree of symmetry of the coordination polymers obtained through spontaneous organization of the self-complementary building blocks **22** and **25** (C_{2h}), **28** (C_2), and **31** (C_i) is surprising. However, we are far from being able to foresee structures such as the one-dimensional coordination polymers 1D-$^{1}_{\infty}$[CuL$^{7}_2$] **23** and 1D-$^{1}_{\infty}$[CuL$^{10(R)}$L$^{10(S)}$] **32**, the two-dimensional sheets 2D-$^{2}_{\infty}$[CuL$^{8}_2$] **26**, or the helical strands (*M*)-/(*P*)-1D-$^{1}_{\infty}$[CuL$^{9(S)}_2$] **29**, which generate pairs of diastereoisomers in the infinite unit cell. The present study on the use of self-complementary building blocks for the construction of coordination polymers suggests that more experimental endeavour is necessary in order to be able to predict the dimensionality of these potential materials.

Experimental Section

Materials and Methods: All common reagents and solvents were purchased from commercial suppliers and were used without further purification unless otherwise indicated. − Melting points were determined on a Wagner−Munz apparatus and are uncorrected. − Infrared spectra were recorded on a Beckman Acculab or on a Perkin−Elmer 1420 ratio recording infrared spectrophotometer. − ^{1}H- and ^{13}C-NMR spectra were recorded on a JEOL JNM-GX-400 spectrometer at 400 and 100.5 MHz, respectively. The carbon atoms were assigned with the aid of the DEPT technique. All chemical shifts are based on the δ scale, referenced to TMS as an internal standard. − Mass spectra were recorded on a Varian MAT311 A (EIMS) or on a micromass ZabSpec (ion-desorption from a *m*-nitrobenzyl alcohol matrix: 8 keV, caesium atoms FAB-MS).

General Procedure for the Synthesis of the Vinylogous Amide Ligands 21, 24, 27, and 30:[16] A stirred mixture of a cyclic imino ether and the corresponding β-oxo nitrile (for quantitative proportions, refer to specific cases) was heated for 24 h at 100°C. Ethanol, formed during the reaction, was distilled off (in a stream of nitrogen in the case of **27** and **30**). The hot reaction mixture was then filtered, cooled to 20°C, and the excess starting materials were recovered by distillation under reduced pressure. The brownish crude product was washed with cold methanol. Colourless crystals were obtained from methanol.

Methyl (*E*)-2-Cyano-2-(oxazolidine-2-ylidene)acetate (21): Prepared from 4,5-dihydro-2-ethyloxyoxazole[16] (4.6 g, 40 mmol) and methyl cyanoacetate (15.8 g, 160 mmol). Yield: 4.2 g (62%); m.p. 144°C. − ^{1}H NMR (400 MHz, $CDCl_3$/[D$_6$]DMSO, 5:1, 25°C): δ = 3.75 (s, 3 H, CH_3), 3.93 [t, ^3J(H,H) = 8.3 Hz, 2 H, $C_{(4)}H_2$], 4.72 [t, ^3J(H,H) = 8.3 Hz, 2 H, $C_{(5)}H_2$], 8.72 (br. s, 1 H, NH). − ^{13}C NMR (100.5 MHz, $CDCl_3$/[D$_6$]DMSO, 5:1, 25°C): δ = 43.67 ($C_{(4)}$), 51.56 (CH_3), 55.92 (=*C*−CN), 69.50 ($C_{(5)}$), 116.67 (CN), 168.34, 172.07 (C=O or $C_{(2)}$). − IR ($CHBr_3$): $\tilde{\nu}$ = 3320 (NH), 2940 (CH), 2200 (C≡N), 1670 (C=O), 1590 cm^{-1} (C=C). − MS (70 eV, EI): *m*/*z* (%): 168 [M$^+$] (30).

(*Z*)-2-Cyano-2-(pyrrolidine-2-ylidene)-1-phenylethanone (24):[18] Prepared from 5-ethyloxy-3,4-dihydro-2*H*-pyrrole[16] (4.1 g, 36 mmol) and benzoylacetonitrile (1.3 g, 9 mmol). Yield: 1.7 g (89%); m.p. 145°C. − ^{1}H NMR (400 MHz, $CDCl_3$, 25°C): δ = 2.09 (br. q, 2 H, $C_{(4)}H_2$), 3.02 (br. t, 2 H, $C_{(3)}H_2$), 3.72 (br. t, 2 H, $C_{(5)}H_2$), 7.40−7.49 (m, 3 H, Ar $C_{(3,4,5)}$H), 7.79−7.87 (m, 2 H, Ar $C_{(2,6)}$H), 10.89 (br. s, 1 H, NH). − ^{13}C NMR (100.5 MHz, $CDCl_3$, 25°C): δ = 20.23 ($C_{(4)}$), 34.13 ($C_{(3)}$), 49.80 ($C_{(5)}$), 77.63 (=*C*−CN), 121.00 (C≡N), 127.78, 128.09 (Ar $C_{(3,4,5)}$), 131.25 (Ar $C_{(2,6)}$), 138.91 (Ar $C_{(1)}$), 176.03 ($C_{(2)}$), 190.88 (C=O). − IR (KBr): $\tilde{\nu}$ = 3280 (NH), 3030 (CH), 2190 (C≡N), 1620 (C=O), 1585, 1490 cm^{-1} (C=C). − MS (70 eV, EI): *m*/*z* (%): 212 [M$^+$] (50).

Methyl (*Z*)-2-Cyano-2-[(2*S*)-2-isopropyloxycarbonylpyrrolidine-5-ylidene]acetate (27): Prepared from (2*S*)-5-ethyloxy-2-isopropyloxycarbonyl-3,4-dihydro-2*H*-pyrrole (15 g, 75 mmol) and methyl cyanoacetate (30 g, 300 mmol). Yield: 15.6 g (82%); m.p. 130°C. − ^{1}H NMR (400 MHz, $CDCl_3$, 25°C): δ = 1.28, 1.29 [d, ^3J(H,H) = 6.0 Hz, 3 H, CH_3], 2.18−2.27 (m, 1 H, $C_{(3)}H_A$), 2.43−2.52 (m, 1 H, $C_{(3)}H_B$), 2.93−3.08 (m, 2 H, $C_{(4)}H_2$), 3.77 (s, 3 H, OCH_3), 4.54 [dd, ^3J(H,H) = 8.8 Hz, ^3J(H,H) = 5.5 Hz, 1 H, $C_{(2)}$H], 5.07 [sept., ^3J(H,H) = 6.1 Hz, 1 H, CH], 9.16 (br. s, 1 H, NH). − ^{13}C NMR (100.5 MHz, $CDCl_3$, 25°C): δ = 21.81 (2 CH_3), 25.44 ($C_{(3)}$), 32.60 ($C_{(4)}$), 51.77 (OCH_3), 62.60 ($C_{(2)}$), 68.83 (=*C*−CN), 70.15 (OCH), 118.27 (C≡N), 167.93, 170.01, 173.63 (2 C=O or $C_{(5)}$). − IR ($CHBr_3$): $\tilde{\nu}$ = 3332 (NH), 2980, 2950 (CH), 2207 (C≡N), 1736, 1677 (C=O), 1592 cm^{-1} (C=C). − MS (70 eV, EI): *m*/*z* (%): 252 [M$^+$] (12).

(*Z*)-1-Cyano-1-(2-methoxycarbonylpyrrolidine-5-ylidene)propan-2-one (30): Prepared from β-oxobutyronitrile[20] (7.1 g, 86 mmol) and (2*S*)-5-ethyloxy-2-methoxycarbonyl-3,4-dihydro-2*H*-pyrrole (29.6 g, 173 mmol). Yield: 2.8 g (16%); m.p. 117°C. − ^{1}H NMR (400 MHz, $CDCl_3$, 25°C): δ = 2.22−2.32 (m, 1 H, $C_{(3)}H_A$), 2.41−2.51 (m, 1 H, $C_{(3)}H_B$), 2.33 (s, 3 H, CH_3), 2.94−3.10 (m, 2 H, $C_{(4)}H_2$), 3.78 (s, 3 H, OCH_3), 4.63 [dd, ^3J(H,H) = 8.9 Hz, ^3J(H,H) = 5.3 Hz, 1 H, CH], 10.61 (br. s, 1 H, NH). − ^{13}C NMR (100.5 MHz, $CDCl_3$, 25°C): δ = 24.60 ($C_{(3)}$), 27.80 (CH_3), 32.59 ($C_{(4)}$), 52.87 (OCH_3), 62.53 ($C_{(2)}$), 80.09 (=*C*−CN), 119.79 (C≡N), 170.38, 173.32 (O−C=O or $C_{(5)}$), 195.12 (C=O). − IR ($CHBr_3$): $\tilde{\nu}$ = 3230 (NH), 2990, 2940 (CH), 2180 (C≡N), 1750, 1640 (C=O), 1580 cm^{-1} (C=C). − MS (70 eV, EI): *m*/*z* (%): 208 [M$^+$] (28).

General Procedure for the Synthesis of the Coordination Polymers 23 and 26: A solution of vinylogous amide ligand **21** (336 mg, 2 mmol) or **24** (442 mg, 2 mmol) in 40 mL methanol was added to a stirred solution of 1 mmol copper(II) acetate monohydrate in 50 mL methanol. After 1 h, the analytically pure precipitate was filtered off, dried in vacuo (oil pump), and crystallized.

1D-$^1_\infty$[CuL$^7_2$] (23): Yield: 397 mg (100%) as dark-green crystals from chloroform/diethyl ether; m.p. > 250 °C. − IR ($CHBr_3$): $\tilde{\nu}$ = 2960 (CH), 2190 (C≡N), 1625 (C=N), 1535 cm^{-1} (C=C). − MS (FAB): *m*/*z* (%): 628 [$Cu_2L_3^+$] (17), 460 [$Cu_2L_2^+$] (16), 398 [CuL_2^+] (11).

1D-$^1_\infty$[CuL$^8_2$] (26): Yield: 422 mg (97%) as turquoise-green crystals from chloroform/diethyl ether; m.p. > 250°C (dec.). − IR ($CHBr_3$): $\tilde{\nu}$ = 2940, 2870 (CH), 2190 (C≡N), 1590 (C=N), 1490, 1480 (C=C). − MS (70 eV, EI): *m*/*z* (%): 485 [CuL_2^+] (56).

General Procedure for the Synthesis of the Coordination Polymers 29 and 32: A solution of vinylogous amide ligand **27** (336 mg, 2 mmol) or **30** (442 mg, 2 mmol) in 40 mL methanol was added to a stirred solution of copper(II) acetate monohydrate (200 mg, 1 mmol) in 50 mL methanol. Triethylamine (0.27 mL, 2 mmol) was then added and after 15 min the solvent was removed in vacuo. The residue was dissolved in 100 mL chloroform and the resulting solution was washed with water (3 × 50 mL) and dried with magnesium sulfate. The solvent was then removed and the product was crystallized. In the case of coordination polymer **29** it proved important to carry out all reaction steps at room temperature and to adhere strictly to the reaction time in order to prevent partial racemization.

(*P*)-/(*M*)-1D-$^1_\infty$[CuL$^{9(S)}_2$] (29): Yield: 380 mg (67%) as light-green crystals from chloroform/diethyl ether; m.p. 213°C (dec.). − IR ($CHBr_3$): $\tilde{\nu}$ = 2980, 2880 (CH), 2200 (C≡N), 1730, (C=O), 1605 (C=N), 1510 cm^{-1} (C=C). − MS (FAB): *m*/*z* (%): 1510 [$Cu_4L_5^+$] (1), 1258 [$Cu_4L_4^+$] (25), 1195 [$Cu_3L_4^+$] (68), 944 [$Cu_3L_3^+$] (44), 881 [$Cu_2L_3^+$] (47), 630 [$Cu_2L_2^+$] (17), 566 [CuL_2^+] (100).

1D-$^1_\infty$[CuL$^{10(R)}$L$^{10(S)}$] (32): Yield: 233 mg (49%) as dark-green crystals from chloroform/diethyl ether; m.p. 209°C (dec.). − IR ($CHBr_3$): $\tilde{\nu}$ = 2990, 2920 (CH), 2190 (C≡N), 1740 (C=O), 1590 (C=N), 1480 cm^{-1} (C=C). − MS (FAB): *m*/*z* (%): 1019 [$Cu_3L_4^+$] (6), 957 [$Cu_2L_4^+$] (0.3), 812 [$Cu_3L_3^+$] (1), 749 [$Cu_2L_3^+$] (15), 540 [$Cu_2L_2^+$] (6), 478 [CuL_2^+] (100).

Crystal Structure Determination of Compound 23: $C_{14}H_{14}CuN_4O_6$, M_r = 397.83, monoclinic space group $P2_1/n$, a = 674.53(8) pm, b = 898.31(24) pm, c = 1312.53(10) pm, β = 96.182(8)°, V = 0.7907(2) nm^3, Z = 2, ρ_{calcd} = 1.671 Mgm^{-3}, F(000) = 406, λ =

71.073 pm, T = 293(2) K, μ(Mo-K_α) = 1.422 mm^{-1}, crystal dimensions 0.40×0.040×0.30 mm, 5.5° ≤ 2Θ ≤ 52.6°; 1671 measured reflections, of which 1603 were independent (R_{int} = 0.0221) and were employed in the structure refinement (116 parameters, 0 restraints). The R values are $R1 = \Sigma |F_o - F_c|/|F_o|$ = 0.0306 [$I > 2\sigma(I)$] and $wR2 = [\Sigma W(F_o^2 - F_c^2)/\Sigma wF_o^4]^{1/2}$ = 0.0897 (all data); residual electron density (peak/hole): 391/−415 e/nm^3.

Crystal Structure Determination of Compound 26: $C_{26}H_{22}CuN_4O_2$, M_r = 486.05, monoclinic space group $P2_1/a$, a = 1054.0(2) pm, b = 1094.8(1) pm, c = 992.2(2) pm, β = 102.57(1)°, V = 1.1176(3) nm^3, Z = 2, ρ_{calcd} = 1.444 Mg m^{-3}, λ = 71.073 pm, μ(Mo-K_α) = 1.01 mm^{-1}, crystal dimensions 0.5×0.55×0.1 mm, θ range: 1.75° to 27.5°; 2563 measured reflections, of which 2316 were independent; data/parameter ratio 12.50. The final reliability indices based on 1888 reflections with $F > 3\sigma(F)$ were R = 0.039 and wR = 0.037 using the weighting scheme $w = 1/\sigma^2(F)$; min./max. residual electron density: 370/460 e/nm^3.

Crystal Structure Determination of Compound 29: $C_{24}H_{30}CuN_4O_8$, M_r = 566.06, monoclinic space group $P2_1$, a = 1241.2(3) pm, b = 1181.6(2) pm, c = 1905.7(4) pm, β = 105.28(3)°, V = 2.6962(9) nm^3, Z = 4, ρ_{calcd} = 1.394 Mg m^{-3}, F(000) = 1180, λ = 71.073 pm, T = 293(2) K, μ(Mo-K_α) = 0.862 mm^{-1}, crystal dimensions 0.50×0.30×0.20 mm, 5.6° ≤ 2Θ ≤ 49.2°; 7900 measured reflections, of which 4791 were independent (R_{int} = 0.0406) and were employed in the structure refinement (667 parameters, 1 restraint). The R values are $R1$ = 0.0369 [$I > 2\sigma(I)$] and $wR2$ = 0.1039 (all data); residual electron density (peak/hole): 300/−424 e/nm^3.

Crystal Structure Determination of Compound 32: $C_{20}H_{22}CuN_4O_6$, M_r = 477.96, triclinic, space group $P\bar{1}$; a = 767.00(5) pm, b = 871.04(11) pm, c = 858.66(6) pm, α = 108.142(7)°, β = 94.301(6)°, γ = 103.008(8)°, V = 0.52459(8) nm^3, Z = 1, ρ_{calcd} = 1.513 Mg m^{-3}, F(000) = 247, λ = 71.073 pm, T = 293(2) K, μ(Mo-K_α) = 1.086 mm^{-1}, crystal dimensions 0.30×0.30×0.10 mm, 5.1° ≤ 2Θ ≤ 48.1°; 1775 measured reflections, of which 1636 were independent (R_{int} = 0.0234) and were employed in the structure refinement (143 parameters, 0 restraints). The R values are $R1$ = 0.0373 [$I > 2\sigma(I)$] and $wR2$ = 0.1084 (all data); residual electron density (peak/hole): 643/−655 e/nm^3. − Crystallographic data for **23**, **29** and **32** were collected on Nonius CAD-MACH3 diffractometers equipped with graphite-monochromated Mo-K_α radiation by use of θ and ω scans. The structures were solved by direct methods (SHELX-86) and refined by full-matrix least-squares treatment against F^2 using the SHELXL-93 program system.[22] All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were fixed in ideal positions (riding model) and were included without refinement and with fixed isotropic U. − Crystallographic data for **26** were collected on a Siemens R3m/V diffractometer equipped with graphite-monochromated Mo-K_α radiation using the Wyckoff-scan technique. The structure was solved by direct phase determination and refined by full-matrix least-squares treatment using the SHELXTL-PLUS program system. The positions of the hydrogen atoms were included as a riding model without refinement and with fixed isotropic U. − Two-dimensional 2D-$^2_\infty$[CuL_2^{12}] **33** and 2D-$^2_\infty$[CuL_2^{12}] **34** were also obtained with ethyl (*Z*)-2-cyano-2-(pyrrolidine-2-ylidene)acetate (HL^{11}) and (*E*)-2-cyano-2-(oxazolidine-2-ylidene)-1-phenylethanone (HL^{12}). − Crystallographic data (excluding structure factors) for all structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-111706 (**23**), CCDC-111831 (**26**), CCDC-111702 (**29**), CCDC-111703 (**32**), CCDC-111704 (**33**), and CCDC-111705 (**34**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) +44 (0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

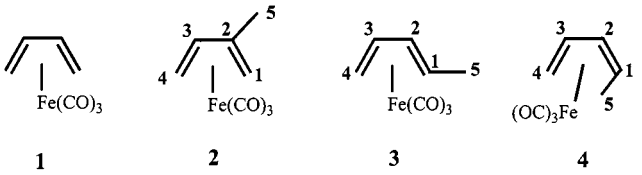
Structural and Energetical Characterization of the Methylbutadiene–$Fe(CO)_3$ Isomers and Related Reactive Intermediates with Quantum Chemical Methods

Anja Pfletschinger,[a] Hans-Günther Schmalz,*[a] and Wolfram Koch*[a][+]



Keywords: Density functional calculations / 1,3-Diene–$Fe(CO)_3$ / Conformational analysis / Iron / Organometallic chemistry / Reactive intermediates

A theoretical investigation of isoprene–$Fe(CO)_3$ (**2**), (*E*)-1,3-pentadiene–$Fe(CO)_3$ (**3**), (*Z*)-1,3-pentadiene–$Fe(CO)_3$ (**4**), and reactive intermediates derived from these complexes was undertaken, employing the HF/DFT hybrid functional Becke3LYP, and the results are presented. Special emphasis is placed on cationic, anionic, and radical intermediates formally derived by abstraction of a hydride, a proton, or a hydrogen atom from the methyl group of the parent complexes. The geometry, energy, and electronic situation of the calculated species are discussed in the context of experimental facts. This leads to a better mechanistic understanding of the chemistry of acyclic butadiene–$Fe(CO)_3$ complexes, provides insights into structural details of the intermediates involved, and allows the evaluation of possible resonance formulae. The calculation of transition states of isomerization (or racemization) processes even permits a quantitative description of energy profiles. In this way, the configurational stability of relevant cationic, anionic and radical intermediates can be estimated.

Introduction

Acyclic 1,3-diene−$Fe(CO)_3$ complexes are well established as valuable intermediates in organic synthesis.[1] Besides the use of the $Fe(CO)_3$ fragment as a protecting group for the 1,3-diene unit, many synthetic applications are based on transformations that exploit the ability of the $Fe(CO)_3$ unit to stabilize positive[2] or negative[3] charge in a position adjacent to the complexed diene. Due to the steric bulk of the metal fragment, many reactions of such complexes additionally proceed with a high level of stereocontrol.[4]

While crystal structures of the parent η^4-butadiene−$Fe(CO)_3$ complex **1** and quite a large number of other neutral 1,3-diene−$Fe(CO)_3$ complexes are available,[5] very little is definitely known about the structure of the anionic and cationic intermediates.[6] In order to develop a deeper understanding of these systems and to improve the predictability of the chemistry of acyclic butadiene−$Fe(CO)_3$ complexes, it would be highly desirable to obtain information about structural and energetical details of reactive intermediates involved in this chemistry. As a follow-up to our previous theoretical investigation employing density functional theory of cationic, anionic, and radical reactive intermediates derived from toluene−$Cr(CO)_3$,[7] we provide in this paper a detailed and comprehensive picture of the computed structural and energetical features of η^4-methylbutadiene−$Fe(CO)_3$ isomers **2**, **3**, and **4**, as well as the corresponding cationic, anionic, and even radical species of type $(C_5H_7)Fe(CO)_3^{+/-/\bullet}$ derived from **2**, **3**, and **4** by formal abstraction of a proton, a hydride, or an H radical from the methyl group.

Computational Details

In the work described in this paper we used the same computational strategy that we successfully applied in our previous work on reactive intermediates derived from η^6-toluene−$Cr(CO)_3$.[7] Therefore, a brief description of the computational strategy will suffice at this point. For further details the reader is referred to ref.[7] All calculations were carried out using the popular Becke3LYP hybrid density functional.[8] An all electron basis set, described by Wachters,[9] was extended by a set of f-functions for the iron atom and was applied while the standard D95* split valence basis set was chosen for C, H, and O. All calculations were performed employing Gaussian94[10] as implemented on our own IBM RS/6000 workstations and the CRAY J90 computer of the Konrad-Zuse-Zentrum für Informationstechnik Berlin. The electron density was analyzed through the *Natural Bond Orbital* (NBO) scheme introduced by Weinhold and co-workers.[11] The harmonic frequencies were calculated for all molecules considered in order to identify

stationary points as minima or transition states and to estimate the zero point energies (ZPE) for which all energies are corrected. The calculations of the radical complexes all resulted in the expected S^2 value of 0.75 for a doublet.

Results and Discussion

The Neutral $C_5H_8-Fe(CO)_3$ Complexes

We began our study with the neutral complexes **2**, **3**, and **4**, which are shown in Figure 1. These three neutral isomers serve as reference systems for the investigation of the related cationic, anionic, and radical intermediates discussed below. The complexes **3** and **4** can be considered as configurational isomers, which formally can be converted into each other by a simple rotation around the C1−C2 bond. The theoretically predicted structures of complexes **2**, **3**, and **4** are depicted in Figure 1.[12]

The neutral isoprene tricarbonyl iron complex **2** shows a regular arrangement of the η^4-diene ligand with a slightly shorter internal C2−C3 bond (1.423 Å) compared to the C1−C2 and the C3−C4 bonds (1.436 Å and 1.434 Å, respectively). The iron atom is positioned symmetrically below the plane of the butadiene fragment and the $Fe(CO)_3$-tripod assumes a conformation with one CO pointing towards the open side of the diene ligand. As in the case of previous theoretical studies on **1**,[13] the structure calculated for **2** is in good general accordance with X-ray crystal structures[5] of such complexes and with a microwave structure for **1**.[14] The barrier for the rotation of the $Fe(CO)_3$ moiety in **2** was computed to be 11.1 kcal mol^{-1}, which is considerably closer to the experimentally determined barrier (10.6 kcal mol^{-1}) than values from previous calculations.[15] It is interesting to note that this barrier is significantly higher than, for instance, that of the metal fragment in the neutral toluene $Cr(CO)_3$ complex, which amounts to only 0.8 kcal mol^{-1}.[7] In the rotational transition state **2′** (Figure 2), the C2−C3 bond is now *longer* than the bond lengths of the terminal C−C bonds by 0.017 Å. The calculation of the harmonic vibrational frequencies confirms that structure **2′** is indeed the transition state of the $Fe(CO)_3$ rotation and is characterized by an imaginary frequency of 82.4 cm^{-1}, connected to the expected transition mode.

In the other two isomers, **3** and **4** (Figure 1), the iron is also η^4 bonded to the organic ligand with Fe−C bond lengths of about 2.0 Å. The structures show that the methyl substituents do not visibly disturb the preferred geometry of the parent η^4-butadiene−$Fe(CO)_3$ substructure. Compound **3** is energetically more stable than its stereoisomer **4** by 8.9 kcal mol^{-1}. In all three complexes the $C-CH_3$ bond appears as a normal σ-bond with a typical bond length between 1.51 and 1.53 Å.

A view of the NBO analysis (see Figure 1) reveals a negative partial charge on the iron atom (≈ −0.32 |e|) in all three neutral complexes. The CO groups have positive charges of +0.125 |e| to +0.155 |e| (sum of the partial

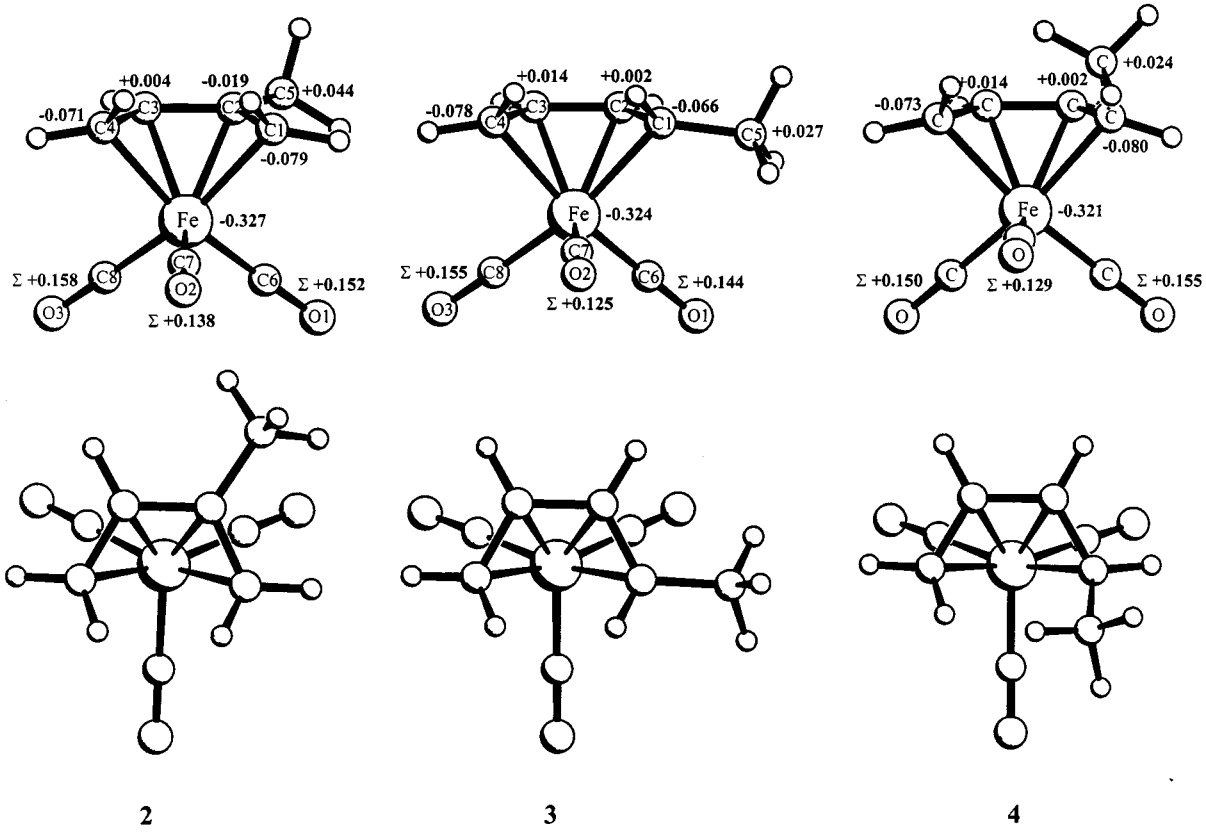

Figure 1. Ground-state structures of the neutral methylbutadiene complexes **2**, **3** and **4**; the charges of the hydrogen atoms are summed into the carbon atoms

Scheme 2. Mesomeric structure of the cationic intermediates derived from the isoprene−$Fe(CO)_3$ complex **2**

charges of C and O). In all cases the CO group, which is pointing towards the open side of the butadiene ligand, carries the smallest positive charge. Therefore, the $Fe(CO)_3$ unit, which is characterized by total charges of at least +0.1 |e|, cannot be regarded as an electron-withdrawing group, in contrast to the metal fragment in arene−$Cr(CO)_3$ complexes,[7] where the $Cr(CO)_3$ moiety was negatively charged. Compared to C1 and C4, the inner carbon atoms (C2 and C3) have a slightly more positive partial charge. This is in accord with the experimental observation that under kinetic control the attack of nucleophiles occurs regioselectively at the inner carbon atoms.[16]

The geometrical parameters of the neutral complexes **2**, **3**, and **4** serve as a good indicator for the intepretation of the data obtained for the cationic, anionic and radical intermediates (see Table 1). The total energies and the zero point corrections for all calculated structures are collected in Table 2.

The Cationic C_5H_7−$Fe(CO)_3$ Complexes

Transformations of 1,3-diene−$Fe(CO)_3$ derivatives involving metal-stabilized cationic intermediates have been known for many years and have gained particular importance in organic syntheses.[1,2,17] Although some of the cationic intermediates have been characterized by spectroscopic methods,[18] data concerning structural and energetic features of these intermediates are very rare. At this point, modern theoretical methods open an ideal complementary avenue for obtaining far reaching insights into structural, energetical and, finally, mechanistic details of such species.

We commenced our investigation by first characterizing the cationic C_5H_7−$Fe(CO)_3^+$ complexes **5** and **6**, which were formally generated by abstraction of a hydride from the methyl group of the isoprene complex **2** (Scheme 2).

Our calculations suggest that only two minimum structures can be distinguished and these differ in the hapticity of the metal coordination. In the energetically most stable structure the metal coordinates to the ligand in an η^5 mode. This structure, which obeys the 18-valence electron (VE) rule, may be represented by the three mesomeric forms **5a**, **5b** and **5c** depicted in Scheme 2. The second structure, a formal 16 VE species that is energetically less favored by 7.4 kcal mol^{-1}, is perfectly described by formula **6**. In contrast to a previous picture based on a Frontier Orbital Analysis,[19] it is not possible to treat the two structures **5a** and **5b** as separate species. The calculated structures of species **5** and **6** are depicted in Figure 3 while the theoretically predicted bond lengths are collected in Table 1.

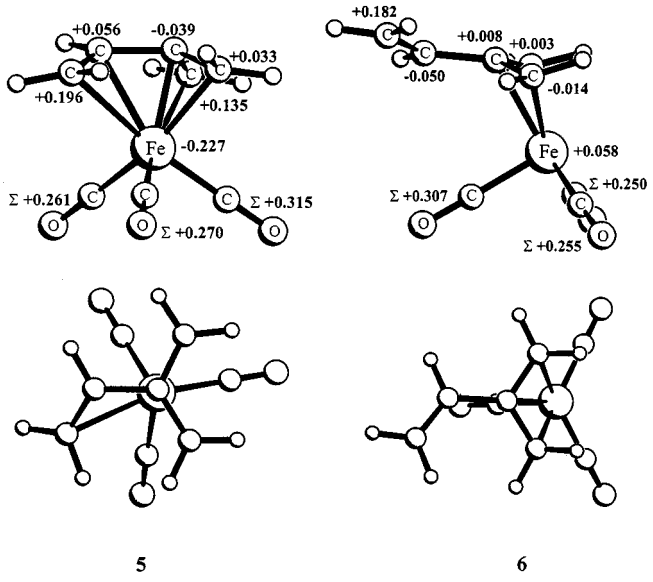

Figure 3. Structures of the two cationic complexes **5** and **6**

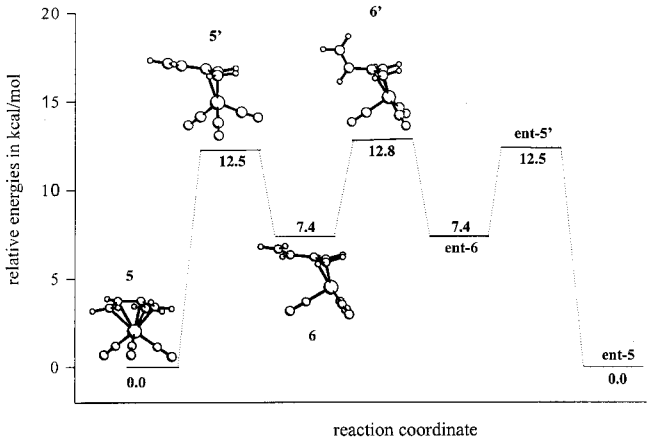
Compared to the neutral complex **2**, in structure **5** the iron tricarbonyl tripod has moved more closely to C2. This leads to a trimethylenemethane−$Fe(CO)_3$-type substructure involving the carbon atoms C1, C2, C3, and C5. As a result, the bond between Fe and C2 is shortened to 1.991 Å from 2.107 Å in **2** while C1, C3, and C4 have similar bond lengths to the iron (2.145, 2.197, and 2.266 Å, respectively). Whereas about 50% of the positive charge is localized on the metal carbonyl unit, in the organic ligand positive partial charges are mainly found at C4 (+0.196 |e|) and C5 (+0.135 |e|), a situation that is in accord with the mesomeric structures **5a** and **5b**. Taken together, all three meso-

meric structures seem to contribute, but **5c** is probably the best formal representation of the calculated structure. In the η^3-isomer **6** the iron is bonded to C1, C2, and C5. This structure can be considered as a cationic η^3-allyl−$Fe(CO)_3$ complex bearing a vinyl side-chain. Two features of this structure are especially remarkable: Firstly, about 80% of the positive charge is now transferred to the iron carbonyl moiety. Secondly, the most electron deficient carbon atom is C4 (+0.182 |e|), which has no interaction with the $Fe(CO)_3$ group. It is further worth noting that the preferred conformation of the $Fe(CO)_3$ tripod has changed from fully staggered in **5** to eclipsed in **6** (Figure 3). Because the C2−C3 bond (1.48 Å) in **6** is a single bond, rotation around this bond should be possible. This would lead to a racemization of the planar chiral structure (**6** → *ent*-**6**). Calculation of the transition state of this process resulted in a barrier of $\Delta H^{\#} = 5.4$ kcal mol^{-1}. As **6** is energetically only 7.4 kcal mol^{-1} above **5**, the overall energy barrier for the racemization of the η^5 structure **5** amounts to 12.8 kcal mol^{-1}. This translates into a half life for **5** of ca. 10^{-3} s at 0°C and of ca. 14 s at −78°C.[20] The energy profile of the racemization of **5** is depicted in Figure 4.



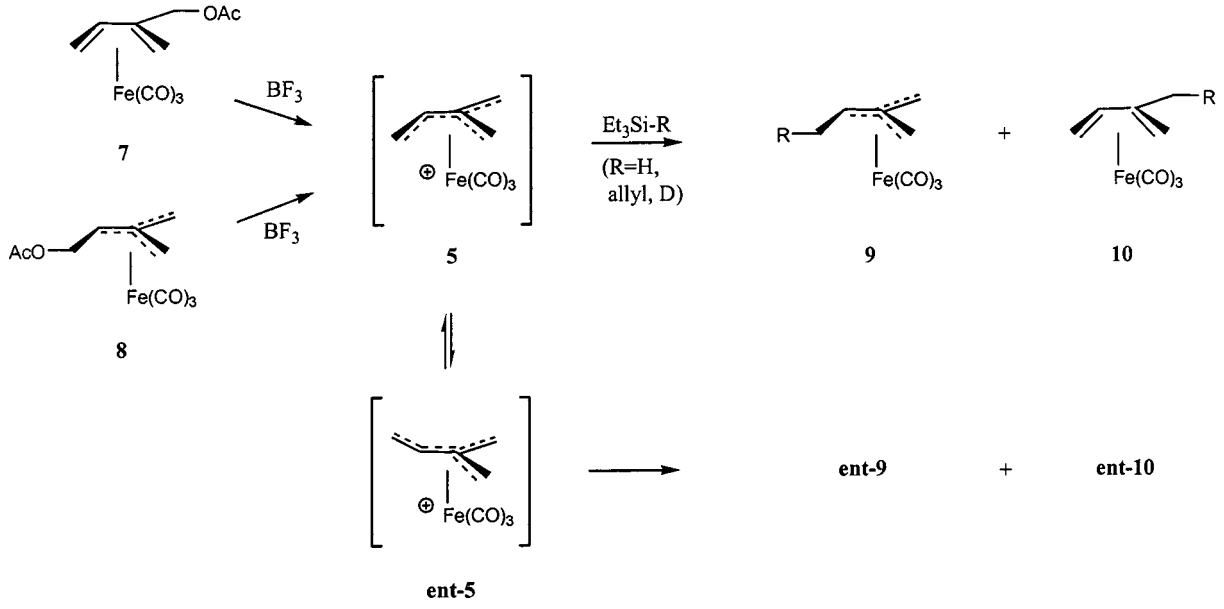


Figure 4. Energy profile of the racemization of **5** to *ent*-**5**

These results are in very good agreement with the qualitative picture that was derived by Gerlach,[21] Donaldson,[22] and Franck-Neumann[23] from experimental studies. These authors had shown that the intermediate cations **5**, generated from precursors **7** or **8** in the presence of Lewis acids, undergo reaction with (soft) nucleophiles to afford mixtures of products **9** and **10** (Scheme 3). The predominant formation of trimethylenemethane complexes **9** under kinetically-controlled conditions shows that the nucleophilic attack occurs preferentially at C4. This regioselectivity correlates nicely with the calculated partial charges in the intermediate **5** (Figure 3). The rather low barrier of racemization discussed above is also in good agreement with the experimental fact that a high degree of stereospecificity (retention of absolute stereochemical information) is only achieved when the reactions are performed at low temperatures (−78°C).[21]

The chemistry discussed above is often complicated by facile proton-catalyzed isomerization of **9** to **10**.[19−21] It was therefore interesting to calculate the relative energies of these two species (for R = H). The calculated structure (Figure 5) of the parent methyl-substituted trimethylenemethane (TMM)[24] complex **9** (R = H) reveals the expected coordination mode of the iron fragment to the ligand. This structure is in excellent agreement with X-ray crystal structures of TMM−$Fe(CO)_3$ derivatives. The maximum deviation of the bond lengths amounts to 0.03 Å and, in particular, the distances between iron and the TMM ligand are very well represented with deviations less than 0.02 Å.[25] In order to achieve a stronger coordination to the metal, the central carbon atom (C2) of the ligand is no longer planar but significantly pyramidalized ("umbrella-like").

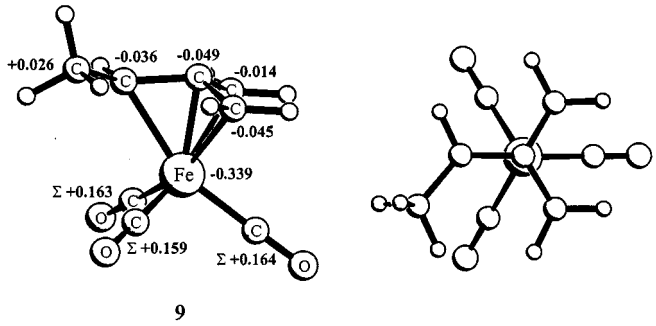
The $Fe(CO)_3$ tripod prefers the fully staggered conformation. Compared to **10** (R = H; i.e. **2**), the isomer **9** (R = H) is less stable by 4.5 kcal mol^{-1}. This explains the almost complete disappearance of **9** in the equilibrium.



Another important point is the configurational stability of the intermediates of type **5** during S_N1-type transformations at C5 in the case of substituted substrates, which proceed with retention of configuration (Scheme 4).[21] This is reflected by our quantum chemical calculations, which predict a very high barrier of 44.2 kcal mol^{-1} for the rotation around the C2–C5 bond in the parent model compound **5**. In the transition structure **5ts** the positive charge is mostly localized at C5 and cannot be stabilized by interaction with the iron atom due to the orthogonal orientation of the formally empty p-orbital and the correspondingly vanishing overlap of C5 with potential donor orbitals from the metal.

Scheme 4. Retention of configuration in S_N1 transformations

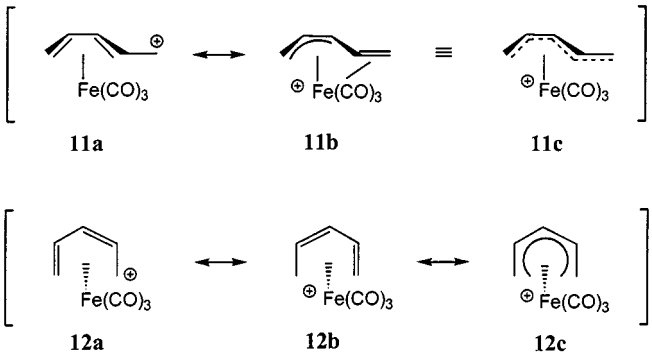
Figure 5. Structure of the neutral trimethylenemethane complex **9**



Because of this lack of interaction between the iron and the positive center C5, the transition structure **5ts** contains an almost undistorted diene−$Fe(CO)_3$ unit.

5ts

Figure 6. Transition state (**5ts**) for the rotation of the $C5H_2$ group around the bond between C2 and C5

A second system, namely the cationic pentadienyl $Fe(CO)_3$ complexes, was also investigated. These species (**11** and **12**) formally result from abstraction of a hydride ion (H^-) from the methyl group of the neutral diene−$Fe(CO)_3$ complexes **3** and **4**, respectively (Scheme 5). Possible representations of the two configurational isomers **11** and **12** are shown in Scheme 5.

Scheme 5. Mesomeric forms of the cationic intermediates **11** and **12**

Our computational investigation of **11** and **12** led to the two minimum structures shown in Figure 7.[12] The calculated geometry of **11** indicates an η^4 coordination mode with an additional attractive interaction between Fe and C5. This becomes evident in a strong bending of C5 towards the metal. The clear double bond character of the C1−C5 bond (1.37 Å) emphasizes the contribution of the mesomeric form **11b**. About 50% of the positive charge is transferred to the $Fe(CO)_3$ group as expressed by formulae **11b** and **11c**. On the other hand, structure **11a** mirrors the charge distribution of the ligand. As expected, the calculated structure of complex **12** exhibits C_s symmetry with the organic ligand forming a totally delocalized π-system. The C−C bond lengths in the pentadienyl ligand are all in the same range of ca. 1.4 Å, which fits well with the experimental data of an X-ray diffraction analysis of [(2,4-dimethylpentadienyl)$Fe(CO)_3$]BF_4.[6] The $Fe(CO)_3$ tripod interacts with the pentadienyl ligand in an η^5-manner, which is also in full agreement with NMR spectroscopic results.[18a] All carbon atoms of the ligand in **12** have a similar, slightly positive, partial charge. Structure **12** is computed to be more stable than **11** by 9.2 kcal mol^{-1}.

The facile (reversible) isomerization of intermediates of type **11** to the more stable horseshoe isomers of type **12** is a well established experimental fact that has often been exploited in selective synthesis.[26] In this case an experimental value for the barrier of isomerization was available[27] and we therefore considered this system as being an ideal touchstone for the accuracy of our computational methodology. The isomerization of **11** to **12** can formally be regarded as a rotation around the C2−C3 bond. Our calculations predict an activation energy for this process, connected with the transition structure **13**, of 11.0 kcal mol^{-1} above that of **11**. In Figure 8 the energy profile for this process is displayed. The experimental value of 13 kcal mol^{-1} found by Sorensen et al. for the barrier of isomeriz-

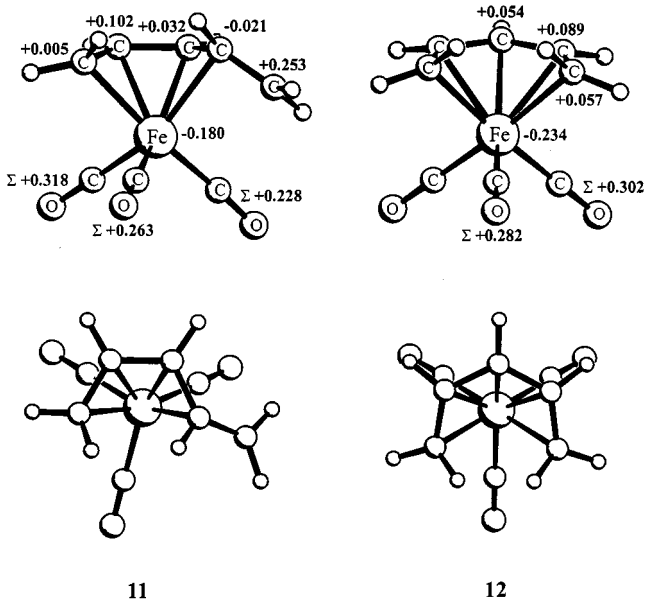


Figure 7. Structures of the cationic pentadienyl−Fe(CO)$_3$ complexes **11** and **12**

ation is therefore in very good agreement with the computed barrier.[27]

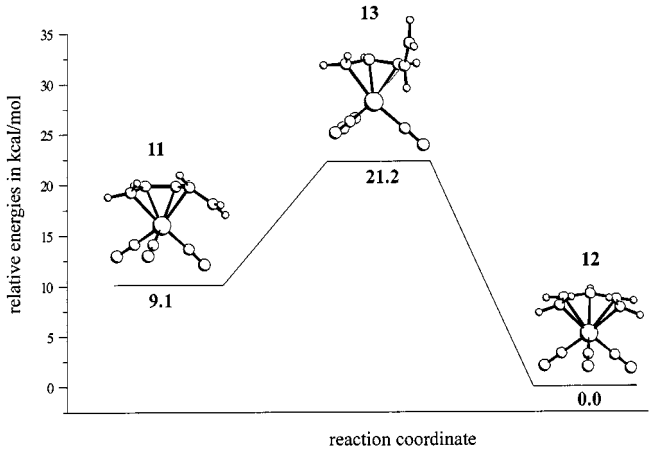

Figure 8. Energy profile for the isomerization of complexes **11** and **12**

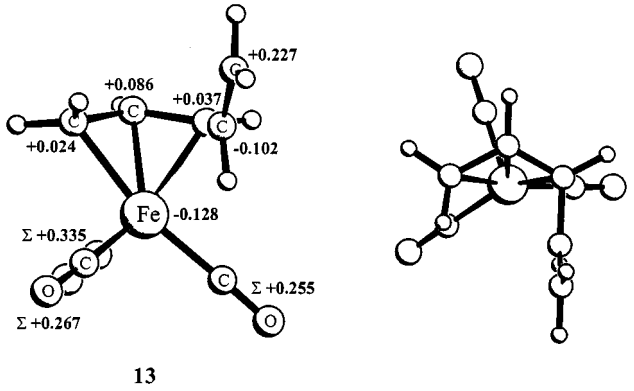
Analysis of the transition state structure **13** clearly shows only an η^3 coordination of the iron fragment to the ligand. This structure is a 16 VE cationic η^3 allyl complex in which the vinyl substituent is turned to the opposite side of the metal fragment by about 90° around the C2−C3 bond. It is interesting to note that all our attempts failed to locate the transition state structure for this rotation in the neutral complexes **3** and **4**. The reason for the much higher rotational barrier for the interconversion of these isomers is probably that any η^3 bonded intermediate (transition state) would correspond to a disfavored zwitterionic or diradical species.



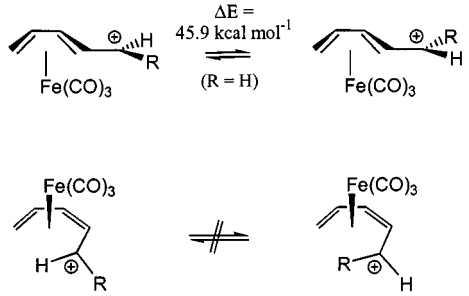


Figure 9. Structure of the transition state **13**, which is passed during the isomerization process shown in Figure 8

From the point of view of the synthetic chemist it is highly useful that S_N1-type reactions in the allylic position (at C5) of 1,3-pentadiene−Fe(CO)$_3$ complexes proceed with virtually complete retention of configuration.[28] We were interested to see if our calculations could quantify the obvious configurational stability of the cationic intermediates. In the case of the pentadienyl cation **11** we were able to determine a rotational barrier of 45.9 kcal mol^{-1} (Scheme 6). The corresponding transition structure **11ts** is depicted in Figure 10. In contrast, the transition state for the corresponding isomerization of **12** could not be localized. This indicates a very strong stabilization of the U-shaped pentadienyl cation by η^5-coordination to the metal. Therefore, the energy barrier for the rotation of a terminal CH_2 group in **12** should be extremely high and isomerization is not likely to take place.

Scheme 6. Rotation of the C5H$_2$ group around the bond between C1 and C2 of the cationic complexes **11** and **12**

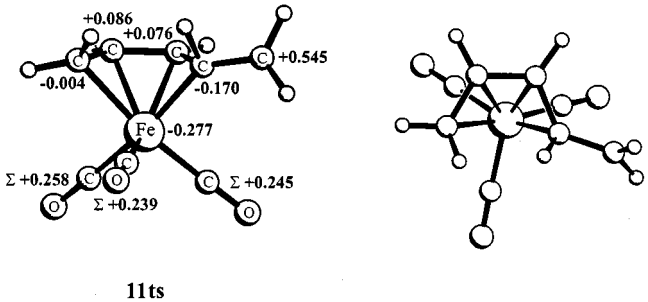

Figure 10. Transition structure **11ts** for the rotation of the C5H$_2$ group around the bond between C1 and C2 of the cationic complex **11**

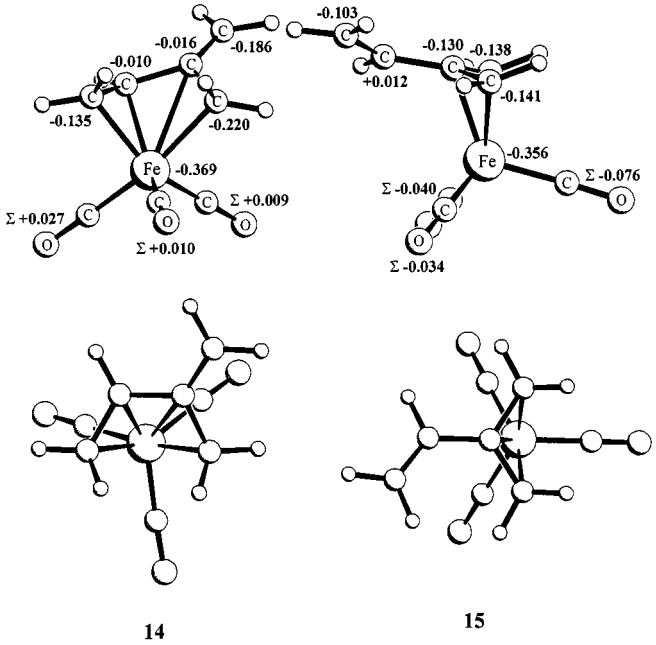
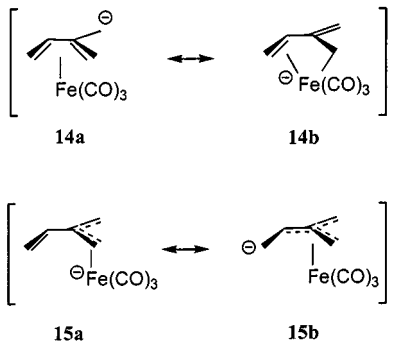
The Anionic $C_5H_7-Fe(CO)_3$ Complexes

Compared to the cationic complexes discussed above, very little has been reported about the corresponding anionic iron complexes. While a few reactions involving such intermediates have been described,[3] virtually nothing is known about their geometry and electronic structures.

Firstly, we will present our results concerning the anionic system arising from proton abstraction from the methyl group of the isoprene complex **2**. The calculations revealed the two minimum structures **14** and **15** depicted in Figure 11. Both species formally count 18 VE and may be represented by two resonance formulae according to Scheme 7.





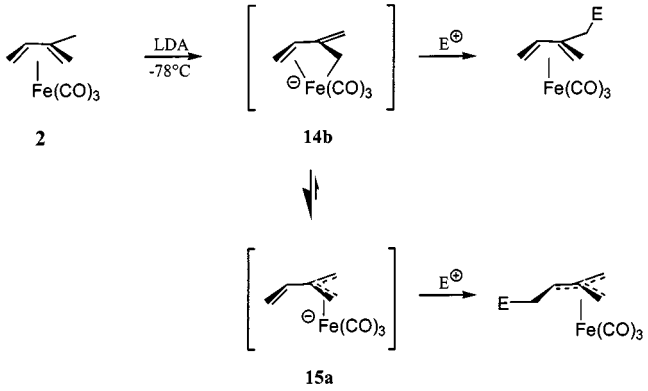


Figure 11. Structures of the anionic complexes **14** and **15**

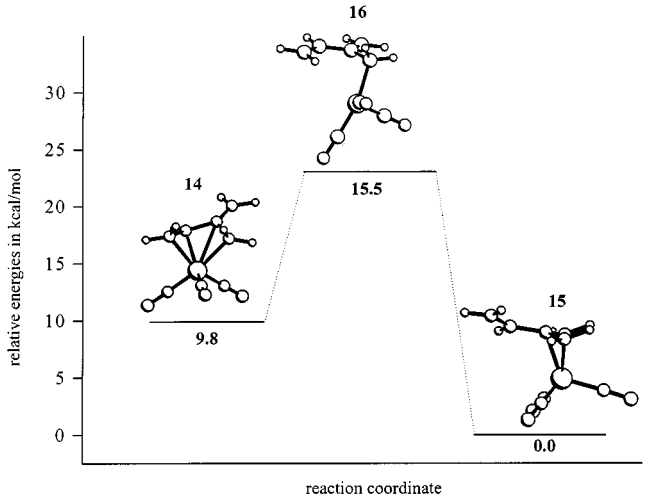
Scheme 7. Mesomeric forms of the anionic complexes **14** and **15** derived from the isoprene−$Fe(CO)_3$ complex **2**

In structure **14** the deprotonated center (C5) has no contact with the iron. The C2−C5 bond has clear double bond character (bond length 1.36 Å) and is bent away to the opposite side of the $Fe(CO)_3$ moiety. The short Fe−C1 distance (2.12 Å) and a negative partial charge of −0.323 |e| of the $Fe(CO)_3$ fragment also indicate that **14b** is a better representation of this species than **14a**. In contrast to **14**, in the isomeric species **15** there is a strong interaction between the iron and C5. In fact, **15** is best regarded as a vinyl-substituted η^3-allyl complex as expressed by formula **15a**. Here the iron tricarbonyl group takes over 50% of the negative charge. It is interesting to note that this isomer is more stable than **14** by 9.2 kcal mol^{-1}. It is clear that the anionic intermediate prefers an η^3-allyl coordination mode (**15**) where more negative charge can be transferred to the metal fragment than in the mixed π/σ bonding in **14**. This is in accordance with the experimental observation that species **14**, which is initially formed through deprotonation of **2** at low temperatures, rearranges to a more stable isomer (**15**) on warming. While **14** gives 2-substituted butadiene−$Fe(CO)_3$ derivatives on reaction with electrophiles, **15** gives rise to TMM-type products (Scheme 8).[3a]

One should note that this situation is contrary to the one found for the cationic complexes **5** and **6**, where structure **5** is energetically more favored. However, this can easily be understood in terms of the 18-electron rule.

Scheme 8. Deprotonation reaction of the isoprene−$Fe(CO)_3$ complex **2** involving the anionic intermediates **14** and **15**, respectively

In order to gain a better understanding of this chemistry, the transition state for the interconversion of **14** to **15** was calculated. The relative energy of the resulting transition structure **16** was found to lie 15.4 kcal mol^{-1} above **14** and 24.6 kcal mol^{-1} above **15**. The energy profile for this process is shown in Figure 12.



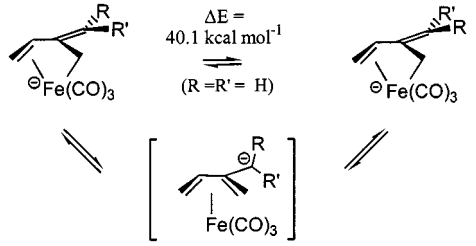


Figure 12. Energy profile for the isomerization of **14** and **15**

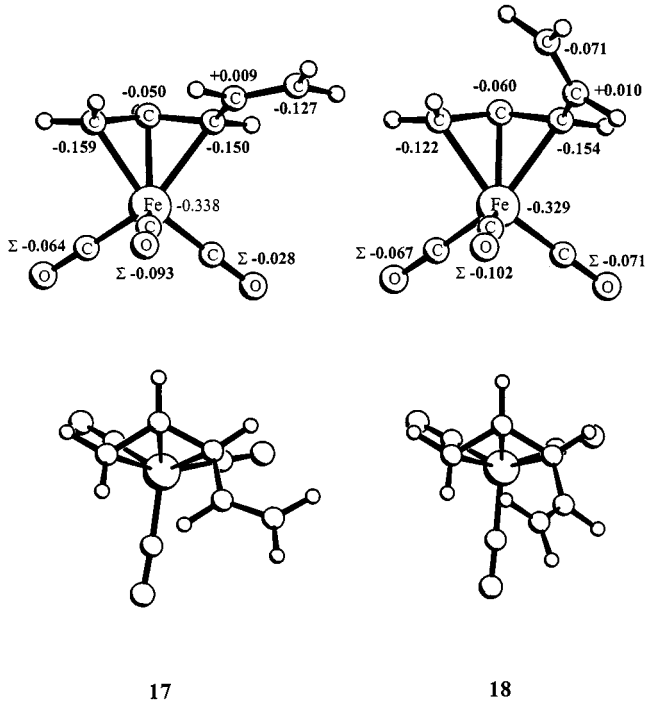
We further addressed the question as to whether a deprotonation/alkylation sequence at C5 of 5-substituted derivatives of **2** would proceed with stereochemical retention or not. In order to estimate the configurational stability of the corresponding intermediates, the barrier for the rotation around the C2−C5 bond in **14** was computed. A value of 40.1 kcal mol^{-1} was obtained and this shows that no isomerization should occur under common reaction conditions (Scheme 9). The high rotational barrier results from the fact that in the transition state the negative partial charge is not delocalized and is mainly located at C5 (−0.64 |e|) while the butadiene−$Fe(CO)_3$ substructure remains almost undisturbed.

Scheme 9. Rotation of the $C5H_2$ group around the bond between C2 and C5 of the anionic complex **14**

Very little has been reported about the generation and reactivity of the anionic pentadienyl $Fe(CO)_3$ complexes **17** and **18**.[29] Therefore, it is particularly interesting to look at the results of the optimized structures of these species (Figure 13).



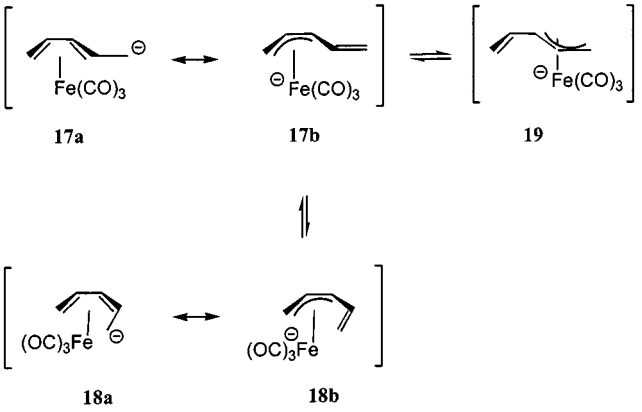


Figure 13. Structures of the anionic complexes **17** and **18**

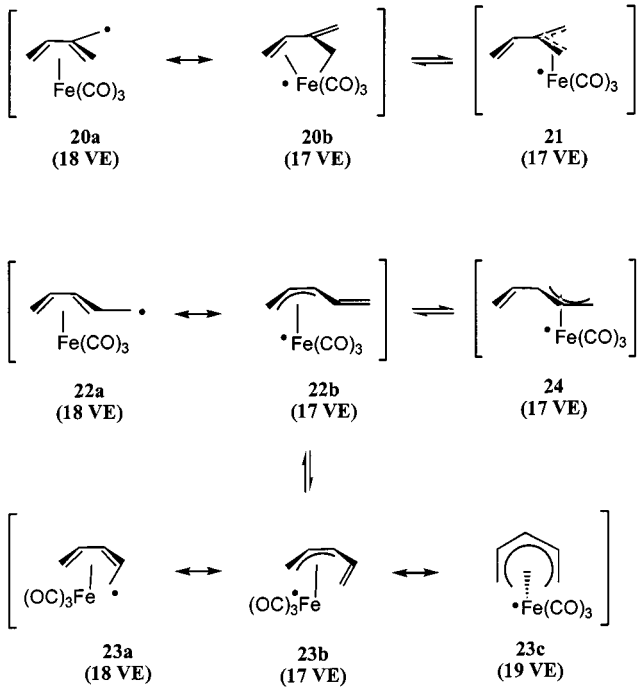
In both isomers, **17** and **18**, the bond between C1 and C5 is characterized as a double bond with bond lengths of 1.356 Å and 1.354 Å, respectively. The iron is η^3-bonded to the pentadienyl ligand and the C_3H_4−$Fe(CO)_3$ substructure has a local mirror symmetry with one CO group, the iron atom and C3 lying in the mirror plane. The three carbon atoms C2, C3, and C4 assume a delocalized π-allyl system with C−C bond lengths of 1.43 Å. The two anionic complexes **17** and **18** can be considered as being conformers by rotation around the C1−C2 single bond. It is important to note that **17** is more stable than the sterically congested isomer **18** by 5.6 kcal mol^{-1}. These results can be described in terms of the mesomeric structures depicted in Scheme 10.

Scheme 10. Mesomeric forms of the anionic pentadienyl−$Fe(CO)_3$ complexes **17** and **18**



In accordance with the structural features discussed above, formulae **17b** and **18b** are unambiguously the better representations of these anionic intermediates. This becomes especially apparent by looking at the geometrical details (η^3 bonding mode) and the electron density distribution that is characterized by accumulating more than one half of the negative charge at the $Fe(CO)_3$ group. It should be briefly mentioned that the configurational stability at the deprotonated center in **17** is very high ($\Delta E^{\ddagger} = 52.9$ kcal mol^{-1}) due to similar reasons as in the case of **14**. We also investigated the isomer **19**, a species that could possibly arise from **17** by haptotropic rearrangement of the metal fragment (Scheme 10). It was found that **19** is disfavored energetically by 3.7 kcal mol^{-1} compared to **17**. This suggests that, if anyone were to succeed in selectively deprotonating **3** at C5, the products of a subsequent reaction with an electrophile will be governed by the reactivity of the (most stable) anionic intermediate **17**. From the theoretical point of view there is no reason why this kind of transformation should not be feasible.

The Radical C_5H_7−$Fe(CO)_3$ Complex

To the best of our knowledge, very few radical reactions of butadiene $Fe(CO)_3$ complexes have ever been described.[30] Therefore, the investigation of possible radical intermediates with theoretical methods could help to evaluate potential preparative opportunities.

We will begin with a discussion of the radical complex **20**, which is formally derived by abstracting a hydrogen

atom ($H^{\bullet}$) from the isoprene complex **2**. It is of interest to assess whether the unpaired electron is mainly located at C5 or delocalized to the $Fe(CO)_3$ moiety, corresponding to the mesomeric formulae **20a** and **20b**, respectively (Scheme 11). The calculated structure of this species (Figure 14) indicates that one third of the spin density is located at the iron and two thirds at C5. Regarding the geometry (the iron shows an η^4 bonding mode to the butadiene) as well as the fact that the main part of the spin density is located at C5, the mesomeric structure **20a** seems to be the better representation of this complex. On the other hand, the bond between C2 and C5 is shortened (1.407 Å) and part of the spin density is located at Fe, indicating a contribution of **20b** and suggesting an energetical barrier for the rotation around the C2−C5 bond. Indeed, a barrier of 11.3 kcal mol^{-1} was determined for this process.

Scheme 11. Mesomeric forms of the radical intermediates **20**−**24**

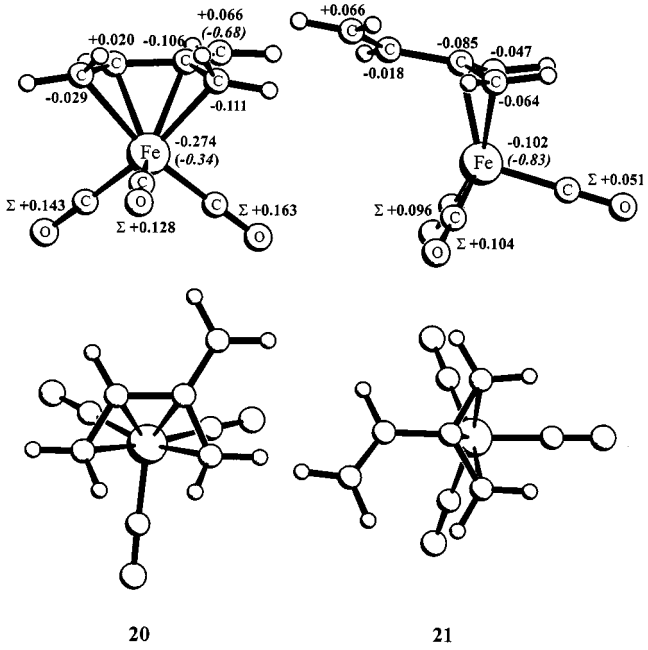


Figure 14. Structures of the radical complexes **20** and **21** formally derived by abstraction of a hydrogen atom from the neutral isoprene−$Fe(CO)_3$ complex **2**

Calculation of the isomeric structure **21** (Scheme 11) revealed that this isomer is energetically favored by 11.6 kcal mol^{-1} in comparison with **20**. In isomer **21** more than 80% of the spin density is localized at the iron center. Thus, it is not unlikely that trimethylenemethane derivatives with a substituent at C4 will be formed in reactions of such intermediates. The energetical difference between **20** and **21** is about 2 kcal mol^{-1} larger than that between the corresponding anionic complexes **14** and **15**, and it is therefore not improbable that a rapid isomerization of **20** to the more stable intermediate **21** will occur.

Finally, the radical pentadienyl complexes **22** and **23**, formally derived from **3** and **4**, respectively, will be discussed. These two species both show an η^3 bonding mode of the metal to the organic ligand (Figure 15) and a geometry akin to that of the anionic pentadienyl complexes **17** and **18**. In both complexes (**22** and **23**) the spin density is almost completely localized at the iron atom (−0.83 |e| and −0.86 |e|, respectively). Therefore, the mesomeric formulae **22b** and **23b** (Scheme 11) perfectly describe the calculated structures. These species can thus be considered as conformers. The calculations revealed an energetical difference of 7.7 kcal mol^{-1} with **22** being the more stable conformer. The interconversion of **22** and **23** by rotation of the vinyl group can easily take place as it is associated with only a small barrier (11.7 kcal mol^{-1} from **22** to **23** and 4.0 kcal mol^{-1} from **23** to **22**). For complex **22** another isomer (**24**) must be considered that, according to our calculations, is energetically 6.4 kcal mol^{-1} disfavored in comparison with **22**. One can expect that the haptotropic isomerization of **22** to **24** should easily take place. It is interesting to note that all these open shell systems prefer a 17 VE configuration at the iron. The (formal) 18 VE structures **22a/23a** and especially the (η^5) 19 VE structure **23c**[30b] do not describe these complexes well.

These results nicely reflect the experimental observation that radicals of type **22/23** react with CBr_4 at the iron to form η^3-allyl−$Fe(CO)_3Br$ complexes.[30b] On the other hand, the small contribution of the mesomeric formulae **22a/23a** provides some spin density at C5, which explains the formation of C5−C5 dimers.[30b,c] Calculation of the transition state for the rotation of the $C5H_2$ group in **22** predicts an energy barrier of 28.6 kcal mol^{-1} for this process. Although this barrier is not as high as in the corresponding cationic or anionic complexes (**11** and **17**, respectively), the configurational stability at C5 should be sufficiently high to allow stereospecific transformations in the case of C5-substituted derivatives.

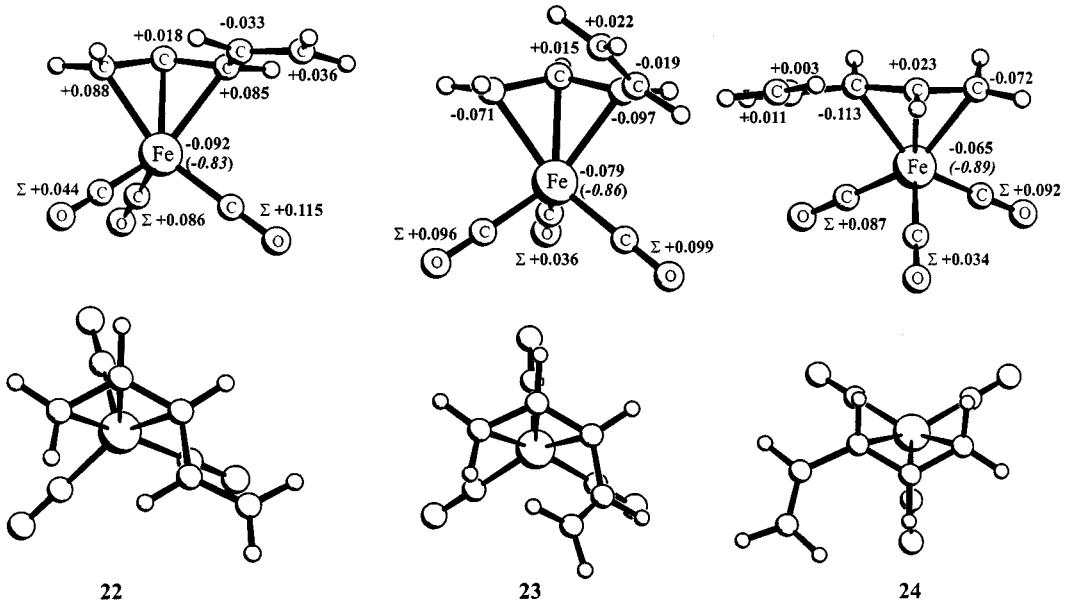

Figure 15. Structures of the radical complexes **22**, **23** and **24** formally derived by abstraction of an hydrogen atom from the neutral pentadiene−Fe(CO)$_3$ complexes **3** and **4**, respectively

Conclusions

The quantum chemical investigation of acyclic 1,3-diene−Fe(CO)$_3$ complexes and their cationic, anionic, and radical intermediates with density functional methods gives a very clear and precise picture of the structures and the reactivity of such species. The high accuracy of the calculations becomes obvious in the few cases where the comparison with experimental data is possible. The calculated structures are used as a reliable basis for the evaluation of possible resonance formulae and for the subtle interpretation of the electronic and conformational situation in the various intermediates. Furthermore, the calculation of energy barriers even permits the rationalization of dynamic phenomena such as isomerization (and racemization) processes. In particular, the calculations predict a pronounced configurational stability of the different intermediates, challenging experimental exploitation. All in all, our computational study provides new insights into the chemistry of acylic 1,3-diene−Fe(CO)$_3$ complexes and experimental facts now appear in a much more lucid light.

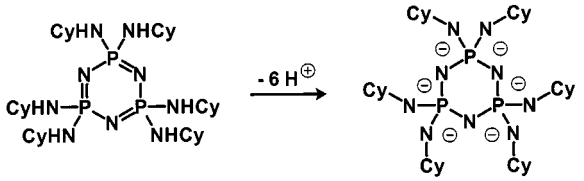
Organometallic Complexes of Multianionic Phosphazenates

Gavin T. Lawson,[a] Chacko Jacob,[a] and Alexander Steiner*[a]



Keywords: Phosphazenes / Phosphazenates / Aluminium / Zinc / Multianionic ligands

The amino-substituted phosphazene $P_3N_3(NHCy)_6$ **1** reacts as a multiprotic acid undergoing full deprotonation in the presence of Me_3Al and Et_2Zn, respectively, which results in the formation of multinuclear metal phosphazenates: Trimethyl aluminium deprotonates **1** with evolution of six equivalents of methane to give the pentanuclear organoaluminium complex $[(thfMeAl)(Me_2Al)_4\{P_3N_3(NCy)_6\}]$ **2**. Diethylzinc deprotonates **1** yielding the hexanuclear zinc complex $[(EtZn)_6\{P_3N_3(NCy)_6\}]$ **3**. The higher homologue $P_4N_4(NHCy)_8$ **4** reacts with diethylzinc undergoing sixfold deprotonation giving the hexanuclear complex $[(EtZn)_6\{P_4N_4(NHCy)_2(NCy)_6\}]$ **5**, where two NH functions remain protonated. All three metal complexes **2**, **3** and **5** are soluble in aprotic organic solvents. The highly charged phosphazenate ligands contain three and four PN_4 tetrahedra which are fused in a corner-sharing manner forming P_3N_3 and P_4N_4 ring structures, respectively. These are isoelectronic with *meta*-silicate anions, but in addition equiped with organic groups at terminally arranged N atoms. Both phosphazenate ligands contain various coordination sites and show a high flexibility of their central P–N ring conformation toward the complexed organometallic framework.

Introduction

Metal complexes of multianionic ligand systems (X^{n-}, $n \geq 4$), which are soluble in aprotic organic solvents, are very rare, due to the high polarity of their salt-like structures. Deprotonated calixarenes[1] and porphyrinogens[2] as well as two examples of carbanionic derivatives[3][4] are among the few systems reported so far. Nevertheless, multianionic ligands of high solubility in aprotic organic solvents such as hydrocarbons or aliphatic ethers promise interesting applications in organometallic chemistry, in particular they facilitate multinuclear metal arrangements.

Recently we have shown that cyclic phosphazenes, which are substituted with primary amino groups, can act as multiprotic acids in the presence of strong organometallic bases yielding multianionic phosphazenates, a novel class of highly charged ligand systems (Scheme 1).[5] *n*-Butyllithium deprotonates $P_3N_3\{N(H)Cy\}_6$ (**1**) six times generating the dimeric complex $[(thf)_4Li_{12}\{P_3N_3(NCy)_6\}_2]$ (**1a**).[5a]

Scheme 1. Multiple deprotonation leading to the phosphazenate hexaanion $[P_3N_3(NCy)_6]^{6-}$

Although **1a** contains two phosphazenate hexaanions $[P_3N_3(NCy)_6]^{6-}$ and twelve lithium cations, it is soluble in hydrocarbons. In fact, $[P_3N_3(NCy)_6]^{6-}$ is the most highly charged anion reported so far, which forms an alkaline metal complex of high solubility in hydrocarbon solvents. Lithium cations are tightly bonded via N atoms to the central P_3N_9 core in **1a**. The peripherally arranged organic groups cover the complex with a lipophilic surface and provide solubility in nonpolar solvents. The central P_3N_3 ring in **1a** is puckered. In contrast, planar ring conformations are usually observed in neutral cyclotriphosphazenes.[6] P−N bond lengths are similar throughout the P_3N_9 core, whereas ring P−N bonds in neutral amino-substituted phosphazenes are usually considerably shorter than P−N bonds involving amino substituents, due to different bond order. Thus it can be assumed that in phosphazenates such as **1a** the negative charge is spread more or less equally over all nitrogen atoms. This is also indicated by the coordination behaviour of $[P_3N_3(NCy)_6]^{6-}$, where all N atoms are involved in coordination to metal centers. Phosphazenate anions are electronically related to silicate anions, which are well-known anionic frameworks in solid-state chemistry. The central P_3N_9 core in $[P_3N_3(NCy)_6]^{6-}$ is isoelectronic to the trimeric *meta*-silicate ion $[Si_3O_9]^{6-}$. In addition it is equiped with organic groups providing solubility in nonpolar media and thus facilitating organometallic chemistry in solution. In particular the generation of multinuclear metal complexes looks very promising due to the number of possible coordination sites and the formally multianionic nature of the ligands. In this paper we present our investigations regarding the coordination behaviour of phosphazenates in multinuclear organometallic complexes of aluminium and zinc.

Results and Discussion

We have treated $P_3N_3(NHCy)_6$ (**1**) with trimethylaluminium or diethylzinc. Both reactions were carried out in refluxing toluene and organometallic reagents were applied

in excess (1.2 equiv. per deprotonation step) to ensure high metalation grades. Gas evolution was observed in all cases and clear reaction solutions were obtained. Evaporation of the solvent gave colourless microcrystalline solids, which are thermally stable and show no sign of decomposition below 200°C. However, all obtained metal complexes are air and moisture sensitive and require handling in an inert gas atmosphere.

[(thfMeAl)(Me$_2$Al)$_4${P$_3$N$_3$(NCy)$_6$}] (2)

Complete deprotonation of **1** occurs in the presence of excess Me_3Al in toluene. The crude product of the reaction of **1** with Me_3Al was crystallised from a mixture of THF/n-hexane. X-ray structure analysis reveals the formation of the pentanuclear aluminium complex [(thfMeAl)(Me$_2$Al)$_4$-{P$_3$N$_3$(NCy)$_6$}] (**2**) (Figure 1).

$$\underset{\mathbf{1}}{P_3N_3(NHCy)_6} + 5\,Me_3Al \rightarrow \underset{\mathbf{2}}{[(thfMeAl)(Me_2Al)_4\{P_3N_3(NCy)_6\}]} + 6\,CH_4 \quad (1)$$

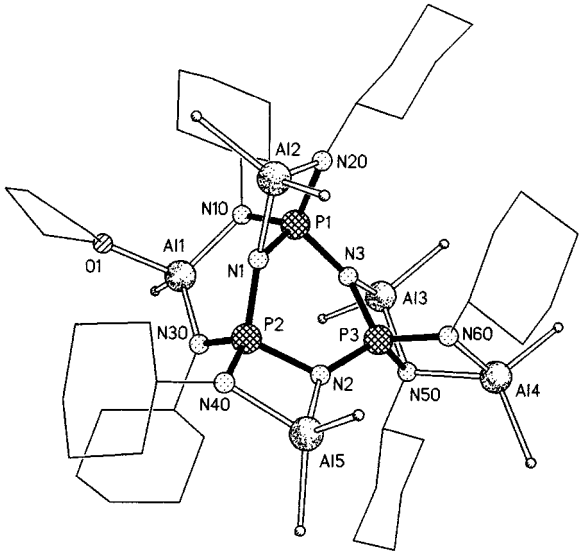

Figure 1. Crystal structure of **2**

Complex **2** contains four Me_2Al units and one MeAl unit which is further coordinated by one thf molecule. All five Al atoms have tetrahedral environments and are accommodated in bidentate chelating coordination sites at the centrally arranged phosphazenate core. Al atoms of Me_2Al units are coordinated by N−P−N chelates and thus part of four-membered Al−N−P−N ring systems, whereas the aluminium atom of the thfMeAl unit is part of a six-membered Al−N−P−N−P−N ring system. Al−N bond lengths to Me_2Al units are slightly longer (av. 1.95 Å) than Al−N lengths to the monomethyl-substituted Al atom (av. 1.86 Å) reflecting the relatively strong Al−N-bonds between the ligand and the formally dicationic MeAl unit. The N−Al−N angle at the AlMe unit is considerably wider [109.4(3)°] than at the Me_2Al units [av. 77.0(3)°] (see Table 1). All nitrogen atoms of the phosphazenate core are involved in coordination towards metal centers. Altogether

the ligand shows three different coordination pattern in **2**, which are the bidentate chelates **A**, **B** and **C** referring to Scheme 2. Similar coordination pattern have been observed in other aluminium complexes containing P−N ligands, but in contrast to the pentanuclear complex **2**, they exclusively accommodate only one or two metal centers.[7]

The six-membered P−N ring system of the phosphazenate core shows a distorted boat conformation. As already observed in the structure of **1a** there is no marked distinction between terminal and ring P−N-bond lengths in **2** (see Table 1), with the exception of the rather long bond between P-3 and N-50 which is coordinating to two aluminium atoms. The P−N-stretching frequency of the phosphazenate ring in **2** (1079 cm^{-1}) is red-shifted compared to corresponding bands in IR spectra of neutral amino-substituted phosphazenes (1200 cm^{-1})[6] indicating a decrease in bond order between ring atoms from the neutral to the metalated species as well as strong interactions between metal centers and ligand N atoms.

Three signals are present in the ^{31}P NMR spectrum of **2** due to the three nonequivalent phosphorus atoms, thus dynamic behaviour at room temperature can be excluded. As expected each ^{31}P signal shows a dd pattern. However coupling constants differ markedly between ^{31}P nuclei. Whereas two coupling constants are relatively large (J = 12.4 and 16.3 Hz, respectively), the third one amounts only to 2.5 Hz, indicating low electronic interactions across one P−N−P unit within the P_3N_3 ring. The ^{1}H spectrum of **2** is rather complex, due to nonequivalent substituents. Me_2Al protons appear between $\delta = -0.1$ and $-\delta = 0.4$, whereas the protons of the MeAl unit show a chemical shift of $\delta = 0.61$.

[(EtZn)$_6${P$_3$N$_3$(NCy)$_6$}] (3)

Treatment of **1** with excess Et_2Zn in toluene leads to complete deprotonation of the hexaprotic phosphazene precur-

sor, which results in the formation of the hexanuclear zinc complex $[(EtZn)_6\{P_3N_3(NCy)_6\}]$ (**3**) (Figure 2).

$$\underset{\mathbf{1}}{P_3N_3(NHCy)_6} + 6\,Et_2Zn \rightarrow \underset{\mathbf{3}}{[(EtZn)_6\{P_3N_3(NCy)_6\}]} + 6\,C_2H_6 \quad (2)$$

Six metal atoms occupy bi- and tridentate coordination sites in **3** encapsulating the centrally arranged multidentate ligand. Four ethylzinc moieties are accommodated in tripodal sites, two of type **D** (Zn-2, Zn-3) and two of type **E** (Zn-1, Zn-4), resulting in a cage structure comprising the phosphazenate ring atoms, the four terminal N atoms N-10, N-20, N-40, N-60 and the aforementioned four Zn atoms. The other two ethylzinc units (Zn-5, Zn-6) are chelated in the bidentate fashion **B**. All nitrogen functions are involved in coordination toward metal atoms. Zn−N distances vary widely and depend mainly on coordination numbers of participating atoms. These correspond to those found in zinc phosphazene complexes containing related coordination sites.[8] The shortest distances are observed between the tri-coordinate zinc atoms and the terminally arranged N atoms [av. 1.90 Å]. Distances of Zn-5 and Zn-6 to the ring−N-functions are considerably longer [av. 2.31 Å]. Within tripodal sites of the cage each zinc atom has two shorter [av. 2.12 Å] and one longer Zn−N-bond [av. 2.43 Å]. An interesting feature of **3** is the substantial involvement of N_{ring} atoms in coordination toward metal centers. Each one interacts with two zinc atoms, resulting in a distorted tetrahedral environment at N-2 (av. Zn−N−Zn 99°) and in an almost linear Zn−N−Zn arrangement at N1 and N3 (av. 157°). P−N lengths of ring- and terminally located P−N-bonds in **3** are in the same range [av. 1.64 Å] indicating equal charge distribution over all N-functions (see Table 2). The six-membered phosphazenate ring system in **3** adopts a *twist* conformation.

NMR-spectra of **3** are in correspondence with the crystal structure (Table 4). ^{31}P NMR of **3** shows a triplet (P-1) and a doublet (P-2/P-3) in the intensity ratio 1:2 reflecting the molecular C_2-symmetry of **3**, where P-1 and N-2 are located on a noncrystallographic C_2-axis. The ^1H NMR shows two distinct environments for zinc-bonded ethyl groups, which can be assigned to bidentate and tripodal coordination sites, respectively. The very strong P−N-stretch band appears at 1055 cm^{-1} and is, as in **2**, markedly red-shifted compared to corresponding bands of neutral phosphazenes.

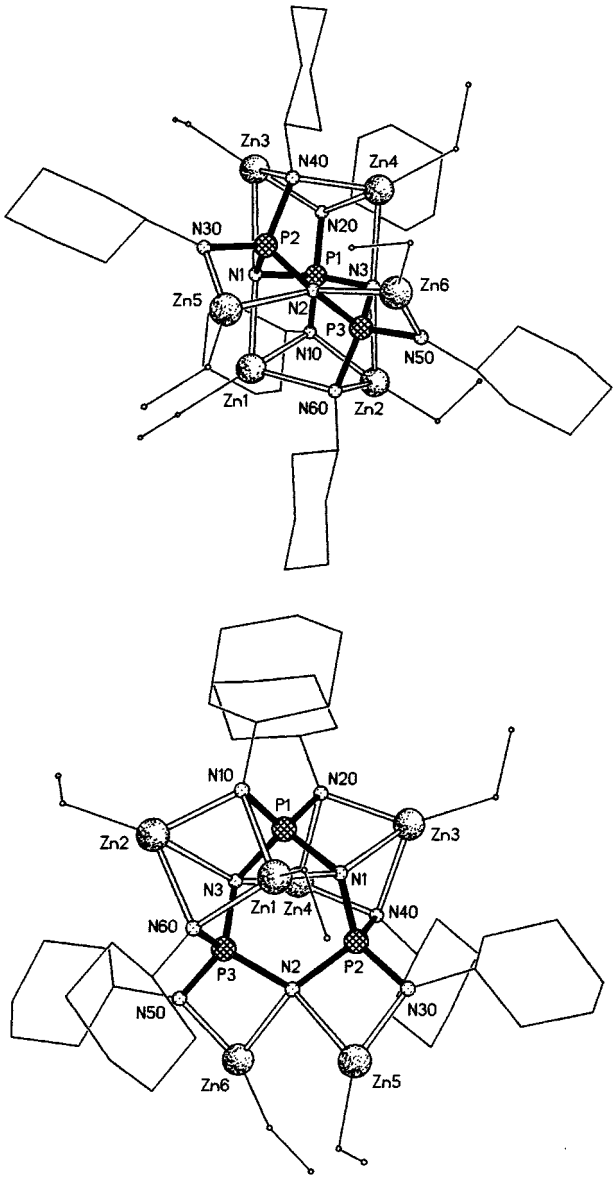

Figure 2. Crystal structure of **3** showing two views from different angles. Only one of two independent complexes in the asymmetric is shown

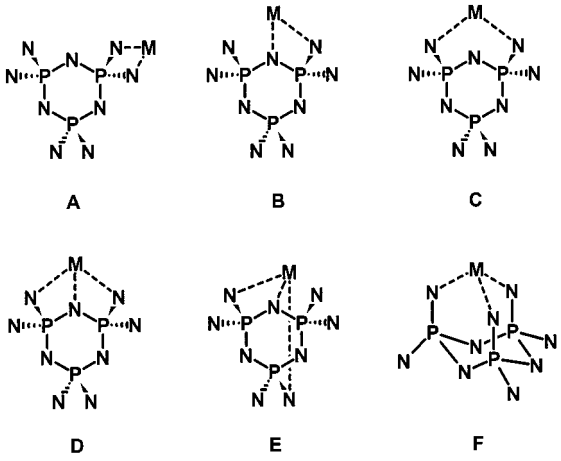
Coordination Pattern of the Hexaanionic Ligand System $[P_3N_3(NCy)_6]^{6-}$



Scheme 2 illustrates the coordination modes which we have observed so far in complexes containing the hexaanionic ligand system $[P_3N_3(NCy)_6]^{6-}$. Both terminal and ring N atoms can take part in coordination to metal centers via bidentate (**A**, **B** and **C**) as well tripodal sites (**D**, **E** and **F**). Exclusively bidentate coordination sites of type **A**, **B** and **C** are present in the aluminium complex **2**, resulting in four (**A** and **B**) and six-membered (**C**) metallo heterocycles. Ethylzinc moieties in **3**, occupy in addition to the bidentate site **B**, tripodal sites of type **D** and **E**. Another tripodal coordination mode, which involves exclusively terminal N atoms of one ligand face resulting in a hetero-adamantane cage (**F**), has been observed in the lithium complex **1a**.[5a]

Six-membered phosphazenate ring systems in **2** and **3** are puckered as in the lithium complex **1a**, which is in contrast to the usually planar arrangement of six-membered rings in neutral cyclotriphosphazenes.[6] This reflects the high flexibility of the phosphazenate backbone in the presence of cooordinated metal centers. The complexed metal array determines the conformation of the central P_3N_3 ring, resulting in a *chair* conformation in the presence of lithium cations in **1a**, a *boat* conformation in the organo aluminium complex **2** and a *twist* conformation in the organozinc derivative **3**.

Scheme 2. Coordination pattern of the hexaanionic ligand system $[P_3N_3(NCy)_6]^{6-}$

$[(EtZn)_6\{P_4N_4(N(H)Cy)_2(NCy)_6\}]$ (5)

Having studied the coordination behaviour of the six-membered ring phosphazenate $[P_3N_3(NCy)_6]^{6-}$ in the presence of various metal environments we were interested what type of coordination modes its higher homologue $[P_4N_4(NCy)_8]^{8-}$ might adopt. So far we have succeeded in determining the structure of the product gained from the reaction of $P_4N_4(NHCy)_8$ (**4**) with diethylzinc: Although an excess of Et_2Zn has been used only six of the eight NH functions in **4** have been deprotonated, even after refluxing the reaction mixture for 12 h in toluene. The hexanuclear zinc complex **5** has been isolated which contains the hexaanionic ligand system $[P_4N_4(NHCy)_2(NCy)_6]^{6-}$ (Figure 3)

$$\underset{\mathbf{4}}{P_4N_4(NHCy)_8} + 6\,Et_2Zn \rightarrow \underset{\mathbf{5}}{[(EtZn)_6\{P_4N_4(NHCy)_2(NCy_6\}]} + 6\,C_2H_6 \quad (3)$$

The structure of **5** is closely related to that of **3**: The six zinc atoms occupy bi- and tridentate coordination sites around the centrally arranged multidentate ligand. Four EtZn units are accommodated in tripodal sites (Zn-1, Zn-2, Zn-3 and Zn-4), resulting in cage structure assembled of phosphazenate ring atoms, four terminal N-functions and the four Zn atoms. Zn-5 and Zn-6 are chelated in bidentate ligand sites. The complex exhibits noncrystallographic C_2-symmetry. Structural parameters involving metal centers correspond largely to those observed in **3** (see Table 3) and coordination modes around the P_4N_{12} core of **5** resemble types **B**, **D** and **E** of the P_3N_9 core (Scheme 2). It is worth mentioning that both complexes **3** and **5** are the only ones which have been structurally characterised so far, where one single ligand accommodates such a large number of Zn atoms.

Two N functions in **5** remain protonated, even if excess of the strong organozinc base is used. This is also indicated by the appearance of a weak N−H-band at 3400cm^{-1} in the IR spectrum of **5**. The incomplete deprotonation of **4** in the presence of Et_2Zn can be rationalised by the increased number of sterically demanding cyclohexyl groups covering the surface of the complexes (from six in **3** to eight in **5**), which is accompanied by only modest expansion of the ligand core. With the exception of the two protonated N atoms, all nitrogen-functions are involved in coordination toward metal-centers. The P_4N_4 ring is puckered and has a similar conformation to that in the tetraanionic ligand system $[N_4\{P(Ph)(NCy)\}_4]^{4-}$.[5b]

Two signals in the ^{31}P NMR of **5** reveal two pairs of chemically equivalent phosphorus nuclei: P-1 and P-3 are carrying exclusively deprotonated substituents, whereas both P-2 and P-4 are bonded to one deprotonated and one protonated nitrogen atom. Surprisingly both ^{31}P NMR signals in **5** exist of doublets, where one would anticipate a set of two triplets in case the four ^{31}P nuclei act as a A_2B_2-system. Temperature dependent measurements (−80°C to 40°C) indicate no sign of fluctuation within the complexes. The $^3J_{P-P}$ coupling constants across two P−N−P units located opposite to each other in the P_4N_4 ring might be too small to be observed. A similar observation was made in **2**, where one P−N−P unit gave a considerably lower coupling constant as the other two P−N−P units. The ^1H NMR spectrum resembles that of **3**. There are two distinct sets of signals for zinc-bonded ethyl groups, which can be assigned to tripodal and bidentate coordination sites, respectively. However, evidence for both protonated NH groups cannot be drawn from the ^1H NMR spectrum, due to overlap of the NH-signal with the complex pattern of cyclohexyl groups.

Conclusion

Organometallic complexes of multianionic phosphazenates have been generated by deprotonation reactions of

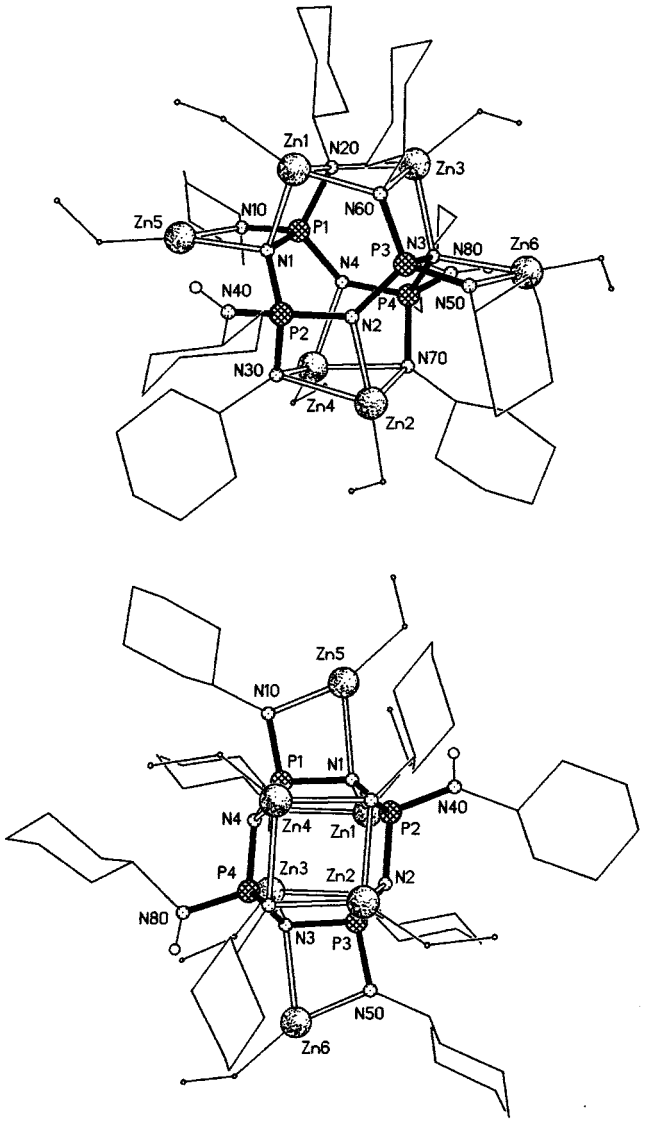

Figure 3. Crystal structure of **5** showing two views from different angles

amino-substituted phosphazenes with strong organometallic bases. The high charge of these new ligands facilitates the accommodation of a large number of metal cations per ligand molecule. The lipophilic character of these systems provides synthetic applications in aprotic organic solvents. We are focussing on transition metal complexes and extending our investigations to polymeric derivatives based on polyphosphazenates. Metal complexes of polyphosphazenates promise novel hybrid materials with unusual electronic or magnetic properties depending on the accommodated metal species. The organic substituent determines the appearance and flexibility of the material (e.g. films, fibres, glasses). Small molecular derivatives, such as the cyclic phosphazenates presented in this paper, can act as useful model compounds mimicking the microscopic behaviour of the corresponding polymer.

Experimental Section

General Remarks: All manipulations were performed under dry nitrogen atmosphere in standard Schlenk-glassware or in a glove box. − Solvents were dried over sodium (toluene) and potassium (hexane, THF), respectively. − Precursors **1** and **4** were prepared according to literature methods.[9] Organometallic reagents were applied as standard solutions: Me_3Al, 2.0 M in hexane (Aldrich); Et_2Zn, 1.0 M in hexane (Aldrich). − FT-IR spectra were recorded on a Perkin−Elmer Paragon 1000 spectrometer in nujol between CsI plates. − NMR spectra were recorded on a Bruker AMX 400 spectrometer.

Preparation of [(thfMeAl)(Me$_2$Al)$_4${P$_3$N$_3$(NCy)$_6$}] (2): Me_3Al (5 mL of a 2.0 M solution in hexane, 10 mmol) was added to a solution of **1** (1 g, 1.38 mmol) in toluene (20 mL). The reaction mixture was refluxed for 1 h, then stirred for 30 min at room temperature and subsequently filtered through Celite. The solvent was evaporated and the residue recrystallised from of THF/hexane solution. After storage at room temperature for several days, colourless crystals of the solvate **2**·THF·hexane were obtained. Lattice solvent could be removed in vacuum. Yield of lattice solvent free product: 1.07 g, 1.01 mmol (73%). − ^{1}H NMR (400 MHz, $CDCl_3$, 25°C, TMS): δ = −0.4 to −0.1 [b, 24 H, $(CH_3)_2$Al], 0.61 (b, 3 H, CH_3Al), 1.40 (m, 4 H, thf), 1.5−2.4 [m, 60 H, CH(CH_2)$_5$], 2.56 (m, 4 H, thf), 3.42 [m, 6 H, CH(CH_2)$_5$]. − ^{31}P NMR (162 MHz, $CDCl_3$, 25°C, 85% H_3PO_4): δ = 9.55 (dd, $^2J_{P-P}$ = 2.5, 16.3 Hz), 12.5 (dd, $^2J_{P-P}$ = 12.4, 16.3 Hz), 16.4 (dd, $^2J_{P-P}$ = 2.5, 12.4 Hz). − IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 1413, 1293, 1260, 1216, 1190, 1124, 1079 (vs, P−N stretch), 1029, 956, 890. 849, 816, 630. − $C_{49}H_{101}Al_5N_9OP_3$ (1060.23): calcd. C 55.51, H 9.60, N 11.89; found C 54.89, H 9.51, N 11.64.

Preparation of [(EtZn)$_6${P$_3$N$_3$(NCy)$_6$}] (3): Et_2Zn (10 mL of a 1.0 M solution in hexane, 10 mmol) was added to a solution of **1** (1 g, 1.38 mmol) in toluene (20 mL). The reaction mixture was refluxed

Preparation of [(EtZn)$_6${P$_4$N$_4$(N(H)Cy)$_2$(NCy)$_6$}] (5): Et_2Zn (10 mL of a 1.0 M solution in hexane, 10 mmol) was added to a solution of **4** (1 g, 1.04 mmol) in toluene (20 mL). The reaction mixture was refluxed for 1 h, then stirred for 30 min at room temperature and subsequently filtered through Celite. The solvent was evaporated and the residue recrystallised from of thf/hexane solution. After storage at room temperature for several days, colourless crystals of the solvate **5**·hexane were obtained. Lattice solvent could be removed in vacuum. Yield of solvent free product: 0.84 g, 0.55 mmol (53%). − ^{1}H NMR (400 MHz, $CDCl_3$, 25°C, TMS): δ = 0.21 (q, 4 H, CH_3CH_2Zn), 0.28 (q, 8 H, CH_3CH_2Zn), 0.50 (t, 6 H, CH_3CH_2Zn), 0.93 (t, 12 H, CH_3CH_2Zn), 1.1−2.2 [m, 80 H, $CH(CH_2)_5$], 3.04 [m, 8 H, $CH(CH_2)_5$]. − ^{31}P NMR (162 MHz, $CDCl_3$, 25°C, 85% H_3PO_4): δ = 21.3 (d, $^2J_{P-P}$ = 10 Hz), 26.4 (d, $^2J_{P-P}$ = 10 Hz). − IR (Nujol): $\tilde{\nu}$ [cm^{-1}] = 3400 (w, N−H stretch), 1579, 1261, 1071 (vs, P−N stretch), 1021, 930, 887, 798, 666; $C_{60}H_{120}N_{12}P_4Zn_6$ (1525.87): calcd. C 47.23, H 7.93, N 11.02; found C 46.84, H 7.94, N 10.78.

X-ray Structure Determination of 2, 3 and 5: Crystal data were recorded on a Rigaku-AFC6S diffractometer, Mo-K_α radiation (λ = 0.71073 Å), T = 153 K, $2\theta_{max.}$ = 45°, 2θ/ω-scan mode, absorption corrections based on ψ-scans, structures were solved by direct methods and refined by full-matrix least squares against F^2 using all data.[10] The asymmetric unit of the crystal structure of **3** contains two crystallographically independent complexes. Crystals of **2** and **5** crystallise as solvates: Asymmetric unit content: **2**·THF·hexane, **3** and **5**·hexane, respectively. Lattice solvents in both structures are disordered as well as part of ethyl groups in **3** and **5** and cyclohexyl groups in **5**. Disordered groups were split on two positions and refined using geometrical restraints. All nonhydrogen groups were refined anisotropically with the exception of lattice solvent molecules, C and N positions in **3** and disordered C positions in **5**, which were refined isotropically. H positions were fixed geometrically. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-118485 (**2**), CCDC-118486 (**3**) and CCDC-118487 (**5**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: (internat.) + 44-1223/336−033; E-mail: deposit@ccdc.cam.ac.uk

Hydrido(carbene), Hydrido(diazoalkane), Aqua(carbene), and Vinyl(carbene) Complexes of Osmium(II)

Helmut Werner,*[a] Wolfram Stüer,[a] Justin Wolf,[a] Matthias Laubender,[a] Birgit Weberndörfer,[a] Regine Herbst-Irmer,[b] and Christopher Lehmann[b]

Dedicated to Professor Alberto Ceccon on the occasion of his 65th birthday

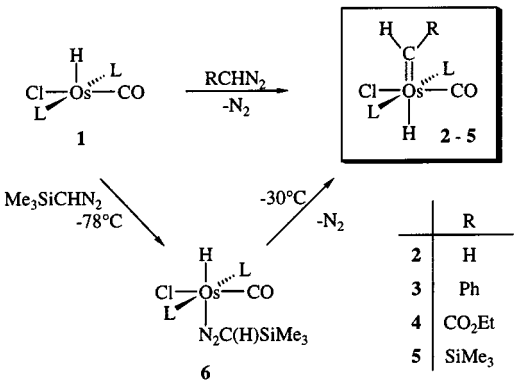
Keywords: Osmium / Carbene complexes / Hydrido complexes / Diazoalkane complexes / Vinyl complexes

The five-coordinate compound [OsHCl(CO)(P*i*Pr$_3$)$_2$] (**1**) reacts with CH_2N_2 and other diazoalkanes $RCHN_2$ (R = Ph, CO_2Et, $SiMe_3$) in ether or toluene at 25 °C to give instead of the expected insertion products [Os(CH_2R)Cl(CO)(P*i*Pr$_3$)$_2$] the isomeric hydrido(carbene)osmium(II) complexes [OsHCl(=CHR)(CO)(P*i*Pr$_3$)$_2$] (**2–5**) in excellent yields. With Me_3SiCHN_2 as the substrate, the 1:1 adduct [OsHCl(N_2CHSiMe_3)(CO)(P*i*Pr$_3$)$_2$] (**6**) was detected at low temperature as an intermediate. The reactions of **1** with Ph_2CN_2 and $Cl_4C_5N_2$ afford the hydrido(diazoalkane)compounds [OsHCl(N_2CR_2)(CO)(P*i*Pr$_3$)$_2$] (**7**, **8**), which are quite stable and do not eliminate N_2 to give the corresponding hydrido(carbene)metal derivatives. Treatment of **3** (R = Ph) with either HCl or HBF_4/H_2O leads to the cleavage of the Os-H bond and results in the formation of [$OsCl_2$(=CHPh)(CO)(P*i*Pr$_3$)$_2$] (**10**) and [OsCl(=CHPh)(OH_2)(CO)(P*i*Pr$_3$)$_2$]BF_4 (**11**), respectively. The vinyl compound [OsCl(CH=CHPh)(CO)(P*i*Pr$_3$)$_2$] (**12**) behaves similarly to **1** and affords the carbene complex [OsCl(CH=CHPh)(=CHPh)(CO)(P*i*Pr$_3$)$_2$] (**13**) upon treatment with $PhCHN_2$. Compound **13** rearranges in solution at room temperature to give the π-allyl complex [Os(η^3-PhCHCHCHPh)Cl(CO)(P*i*Pr$_3$)$_2$] (**14**) as the dominating species. The crystal and molecular structures of **4**, **5**, **10**, and **11** have been determined by X-ray crystallography.

After we found that the four- and five-coordinate iridium complexes containing [IrCl(P*i*Pr$_3$)$_2$] as a building block offer a rich chemistry, including various routes to C−H activation,[1] we started a search for related osmium compounds with a 14- or 16-electron configuration at the metal center. Attempts to prepare either [$OsCl_2$(P*i*Pr$_3$)$_2$] or [$OsCl_2$(P*i*Pr$_3$)$_3$] by treatment of $OsCl_3 \cdot 3\,H_2O$ with triisopropylphosphane in methanol led instead to the five-coordinate hydrido(carbonyl) compound [OsHCl(CO)(P*i*Pr$_3$)$_2$] (**1**) supposedly with a square-pyramidal configuration.[2] This compound reacts with a variety of small molecules such as H_2, O_2, CO, CH_2=CHCN, and acetone to give 1:1 adducts in which the entering ligand occupies the free coordination site *trans* to hydride.[2][3] However, when we used terminal alkynes HC≡CR as the substrate we observed that compound **1** does not produce the expected six-coordinate hydrido(alkyne) complexes [OsHCl(CO)(η^2-HC≡CR)(P*i*Pr$_3$)$_2$] but gives the five-coordinate vinylosmium(II) derivates [OsCl(CH=CHR)(CO)(P*i*Pr$_3$)$_2$] in excellent yields.[4]

This unexpected insertion prompted us to study also the reactivity of **1** towards CH_2N_2 and other diazoalkanes with the hope that on this route, via OsH(CHR) species as intermediates, coordinatively unsaturated alkyl(carbonyl)osmium(II) compounds could be formed. From previous studies in our laboratory we knew that, by using [OsH(η^2-BH_4)(CO)(P*i*Pr$_3$)$_2$] as the starting material, alkylosmium(II) complexes of the general composition [OsH(CH_2R)(CO)$_2$-(P*i*Pr$_3$)$_2$] are accessible but due to the 18-electron configuration of the metal center these compounds are quite inert.[5] After Roper reported that the reaction of diazomethane with [OsCl(*o*-Tol)(CO)(PPh_3)$_2$] gave the η^2-acyl compound [OsCl{η^2-C(O)*o*-Tol}(=CH_2)(PPh_3)$_2$] by migration of the aryl ligand to CO,[6] it seemed also conceivable that from **1** and CH_2N_2 even a formylosmium species [OsCl{η^2-C(O)H}(=CH_2)(P*i*Pr$_3$)$_2$] could be obtained.

In this paper we describe the preparation of a series of hydrido(carbene)osmium(II) complexes from CH_2N_2 and $RCHN_2$ as the carbene source, the spectroscopic characterization of a labile OsH(N_2CHR) intermediate as well as the isolation of stable hydrido(diazoalkane) compounds with Ph_2CN_2 and $N_2C_5Cl_4$ as ligands, the reactivity of the hydrido(carbene)metal derivatives toward Broensted acids, and the synthesis of a vinyl(carbene)osmium compound that rearranges to an isomeric η^3-allyl complex by C−C coupling. Parts of these studies have already been communicated.[7]



Results and Dicussion

The reaction of the starting material **1** with a freshly prepared solution of diazomethane in ether proceeds quite rapidly at room temperature and furnishes, after removal of the solvent, the hydrido(carbene) complex **2** in almost quantitative yield (Scheme 1). The fact, that compound **2** and not the isomeric methyl derivate [OsCl(CH_3)(CO)(P-*i*Pr$_3$)$_2$] is formed, is confirmed by the ^{1}H-NMR spectrum

which displays besides the signals for the two phosphane ligands a triplet of triplets for the OsH proton at high field (δ −4.48) and two broadened singlets for the $OsCH_2$ protons at low field (δ 17.90 and 16.88). The ^{13}C-NMR spectrum of **2** exhibits resonances at δ = 285.0 and 182.0, which are assigned to the $OsCH_2$ and OsCO carbon atoms, respectively.

Scheme 1. L = P*i*Pr$_3$

Substituted diazomethanes such as $PhCHN_2$, EtO_2CCHN_2 and Me_3SiCHN_2 behave similarly to CH_2N_2 and react with the hydrido compound **1** to produce the corresponding carbene complexes **3**−**5** in excellent yields. The reaction of **1** with Me_3SiCHN_2 is relatively slow and needs ca. 15 h for completion at room temperature. We found that the octahedral compound $[OsHCl(CO)(PPh_3)_3]$[8] equally reacts with CH_2N_2 and $PhCHN_2$ quite smoothly but in this case the diazoalkane is converted into N_2 and the respective olefin without changing the composition of the osmium(II) derivative.

The new hydrido(carbene) complexes **3**−**5** are orange to yellow microcrystalline solids which are only moderately air-sensitive and which, in contrast to **2**, can be stored under argon at room temperature for weeks. The $OsCH_2$ compound **2** is more labile and, particularly in solution, decomposes slowly to give a mixture of products among which ethene was detected. The most characteristic features of the spectroscopic data of **3**−**5** are the hydride resonances at δ −4.5 to −5.6 in the ^1H NMR and the signal of the carbene carbon atom at δ 267−327 in the ^{13}C-NMR spectra. It should be emphasized that the signal of the OsH proton of compounds **2**−**5** experiences a significant downfield shift by ca. 27 ppm compared to the starting material **1**, which presumably is due to the strong influence of the carbene ligand *trans* to the hydride. The IR spectra of **2**−**5** (in KBr) exhibit a strong ν(CO) bond at ca. 1880−1940 cm^{-1} as well as a weaker absorption at ca. 1830−1865 cm^{-1}, which is assigned to the Os−H stretching frequency.

The molecular structures of **4** and **5** are shown in Figures 1 and 2. In both cases, the coordination geometry arround the metal center is distorted octahedral with the two phosphanes, the CO and the chloride, and the hydride and the carbene ligand occupying *trans* positions. The most noteworthy detail is the strong bending of the P−Os−P axis [144.88(2)° for **4** and 141.38(4)° for **5**] toward the (not exactly localized) position of the hydride ligand. This bending is much more pronounced than in *cis*,*cis*,*trans*-$[OsH(CH_3)(CO)_2(PiPr_3)_2]$ [165.6(1)°][5] and in the five-coordinate compound $[OsCl(CH{=}CHPh)(CO)(PiPr_3)_2]$ (**12**, see below) where the P−Os−P angle is 167.4(1)°.[4] The Os−C(carbene) distances in **4** and **5** are in the range of that of other carbene(chloro)osmium(II) complexes such as $[OsCl(=CH_2)(NO)(PPh_3)_2]$ [1.92(1) Å] and $[OsCl(=CF_2)(NO)(PPh_3)_2]$ [1.967(4) Å] containing NO as an additional ligand.[9]

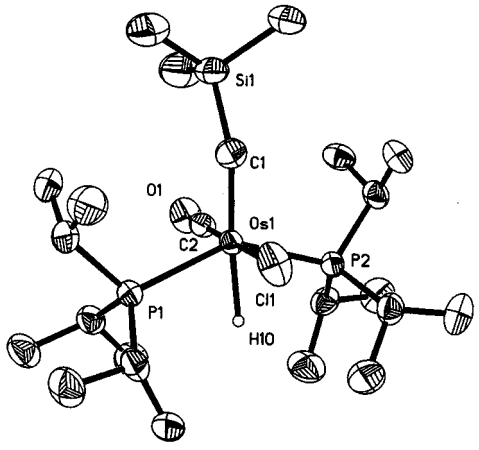

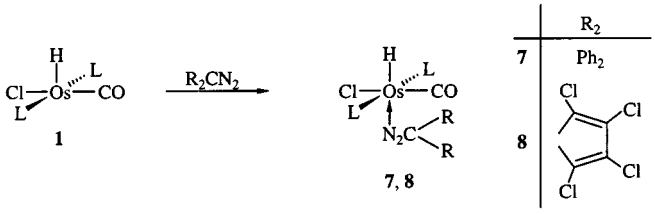

Figure 2. Molecular structure of **5**; the metal-bonded hydrogen is not exactly located, the other hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Os−Cl 2.514(1), Os−P1 2.403(1), Os−P2 2.396(1), Os−C1 1.965(5), Os−C2 1.830(5), O1−C2 1.166(5), C1−Si 1.878(5); P1−Os−P2 141.38(4), P1−Os−Cl 89.88(4), P1−Os−C1 110.4(2), P1−Os−C2 90.4(1), P2−Os−Cl 89.93(4), P2−Os−C1 107.8(2), P2−Os−C2 91.5(2), Cl−Os−C1 82.1(2), Cl−Os−C2 177.3(1), C1−Os−C2 95.3(2), Os−C1−Si 144.9(3), Os−C2−O 179.4(4)

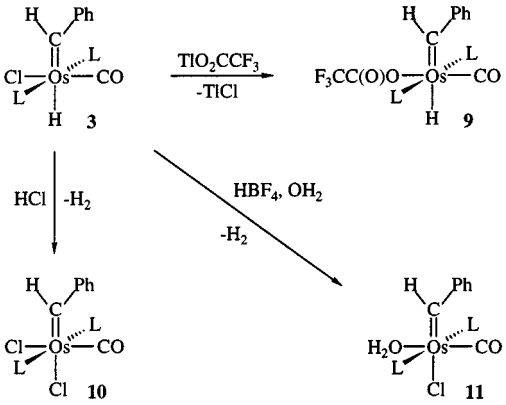

Following the observation that compound **1** reacts much more slowly with Me_3SiCHN_2 than with the other diazoalkanes, attempts were made to detect or even isolate an $Os(N_2CHR)$ species as an intermediate. Therefore, we carried out the reaction of **1** with Me_3SiCHN_2 in toluene at −78°C and found that under these conditions a product is formed that is stable at −78°C for several days. Evaporation of the solvent led to a slow evolution of gas (N_2) and to partial formation of the hydrido(carbene) complex **5**. This compound is formed nearly quantitatively upon warming the toluene solution to ca. −20°C. The ^{1}H-NMR spectrum of the low-temperature product **6** displays a hydride signal at δ = −13.70 (broadened singlet) and a resonance for the Me_3SiCHN_2 proton at δ = 2.80. Owing to these data, we assume that the intermediate is an $OsH(N_2CH\text{-}SiMe_3)$ derivative in which the trimethylsilyldiazomethane occupies the coordination position *trans* to hydride (see Scheme 1). The ^{13}C-NMR spectrum of **6** exhibits a signal for the $N_2CHSiMe_3$ carbon atom at δ = 33.4 and the IR spectrum, apart from the ν(CO) bond at 1890 cm^{-1}, an absorption at 1933 cm^{-1} which can be assigned either to the Os-H or the N≡N stretching frequency.

If compound **1** is not treated with CH_2N_2 or a monosubstituted derivative $RCHN_2$ but with Ph_2CN_2 or $Cl_4C_5N_2$ in toluene (see Scheme 2), a reaction takes place which is not accompanied by the evolution of gas. After removal of the solvent, off-white or light brown solids are isolated which in agreement with the elemental analyses are the hydrido(diazoalkane)osmium complexes **7** and **8**. At room temperature under argon, the compounds are stable for weeks and in solution even on warming to 40°C do not eliminate N_2 to give the corresponding hydrido(carbene) derivatives $[OsHCl(=CPh_2)(CO)(P\textit{i}Pr_3)_2]$ and $[OsHCl(=C_5Cl_4)(CO)(P\textit{i}Pr_3)_2]$, respectively. While the ^{1}H-NMR spectrum of **8** displays the hydride resonance at δ = −7.06 as a triplet with ^2J(P,H) = 22 Hz, the corresponding Os−H signal of **7** appears at δ = −11.44 as a broad singlet at room temperature. However, upon cooling the solution of **7** in $CDCl_3$ to −10°C the broadening disappears and a sharp triplet is observed. Since the pattern of the phosphane resonances of **7** does not change at different temperatures, we assume that the broadening of the hydride signal at 25°C is due to the mobility of the diphenyldiazomethane ligand which could coordinate either via the terminal nitrogen atom or via the N=N bond.[10][11] Based on the IR data of **7**, it is difficult to decide whether an $Os(\eta^1\text{-}N_2CPh_2)$ or an $Os(\eta^2\text{-}N_2CPh_2)$ bonding mode exists.

Scheme 2. L = P*i*Pr$_3$

The hydrido(carbene) complexes **3**−**5** are thermally as well as photochemically rather inert and do not react either in the absence or in the presence of Lewis bases such as CO or CN*t*Bu to afford the corresponding five- or six-coordinate alkylosmium(II) derivatives by migratory insertion. Some other reactions aimed to displace one of the anionic ligands of compound **3** are illustrated in Scheme 3. Treatment of a solution of **3** in toluene with an equimolar amount of TlO_2CCF_3 led to the formation of the related trifluoroacetato compound **9** which is isolated as an orange, almost air-stable solid in 89% yield. A comparison of the IR data of **9** with those of other carboxylato transition-metal complexes[12] indicates that the $CF_3CO_2^-$ ligand of **9** is coordinated in a κ^1- and not in a κ^2-fashion. It should be mentioned that compound **9** like the related chloro derivative **3** does not react upon warming to 60°C in benzene to give the corresponding isomer $[Os(CH_2Ph)(O_2CCF_3)(CO)(P\textit{i}Pr_3)_2]$.

Scheme 3. L = P*i*Pr$_3$

While the reaction of **2** with a solution of HCl in toluene yields a mixture of products, among which the dihydrogen adduct $[OsCl_2(H_2)(CO)(P\textit{i}Pr_3)_2]$ could be observed by ^{1}H- and ^{31}P-NMR spectroscopy,[13] the single component **10** is obtained on treatment of **3** with HCl in toluene. The isolated yield of the dark red, air-stable solid is 98%. The ^{1}H- and ^{13}C-NMR spectra of **10** both exhibit a low-field signal for the Os*CH* proton at δ = 19.04 and the Os*C*H carbon atom at δ = 278.0, respectively, and therefore confirm that a derivative of **3** still containing the carbene ligand is formed.

The structural proposal for **10** has been substantiated by X-ray crystallography. There are two independent molecules **A** and **B** in the asymmetric unit which slightly differ in the conformation of the phosphane ligands with respect to the carbene unit. As shown in Figure 3 for molecule **A**, the osmium center of compound **10** is octahedrally coordinated with the two chloro ligands in *cis* and the two triisopropylphosphanes in *trans* disposition. In contrast to the hydrido(carbene) complexes **4** and **5**, the axis P−Os−P of **10** is much less bent, the bond angle P−Os−P being 167.5(2)° for **A** and 166.3(2)° for **B**, respectively. While the Os−CO distances of **4**, **5** and **10** are almost the same, the bond length Os−C(carbene) of **10** is slightly shorter than that of

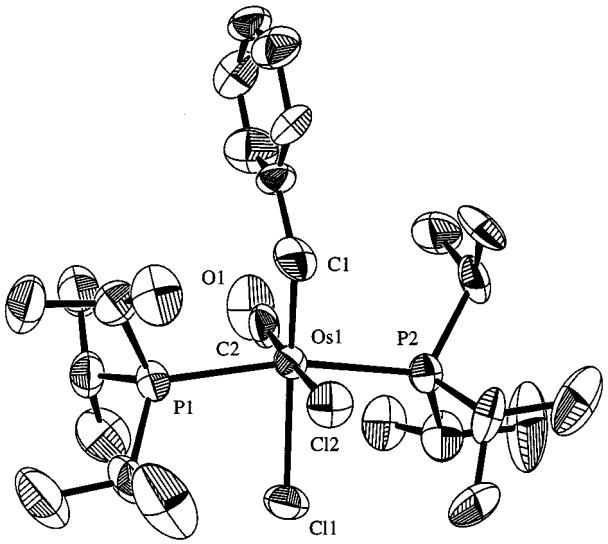

Figure 3. Molecular structure of **10**; there are two independent molecules **A** and **B** in the asymetric unit; hydrogen atoms apart from H1 are omitted for clarity; selected bond lengths [A] and angles [°]: Molecule **A**: Os1−Cl1 2.484(4), Os1−Cl2 2.487(5), Os1−P1 2.469(5), Os1−P2 2.466(5), Os1−C1 1.95(2), Os1−C2 1.85(2), C1−C50 1.46(2), O1−C2 1.13(2); P1−Os1−P2 167.5(2), P1−Os1−Cl1 84.6(2), P1−Os1−Cl2 90.7(2), P1−Os1−C1 93.3(5), P1−Os1−C2 91.3(5), P2−Os1−Cl1 82.9(2), P2−Os1−Cl2 90.7(2), P2−Os1−C1 99.0(5), P2−Os1−C2 89.9(5), Cl1−Os1−Cl2 86.8(2), Cl1−Os1−C1 169.3(2), Cl1−Os1−C2 95.9(6), Cl2−Os1−C1 82.7(6), Cl2−Os1−C2 176.8(2), C1−Os1−C2 94.6(8), Os1−C1−C50 139(2), Os1−C2−O1 176(2), Molecule **B**: Os2−Cl3 2.489(5), Os2−Cl4 2.478(4), Os2−P3 2.466(5); Os2−P4 2.476(5), Os2−C3 1.89(2), Os2−C4 1.83(2), C3−C60 1.49(2), O3−C4 1.16(2); P3−Os2−P4 166.3(2), P3−Os2−Cl3 82.1(2), P3−Os2−Cl4 88.8(2), P3−Os2−C3 98.0(5), P3−Os2−C4 89.6(6), P4−Os2−Cl3 84.2(2), P4−Os2−Cl4 90.3(2), P4−Os2−C3 95.5(5), P4−Os2−C4 91.7(6), Cl3−Os2−Cl4 88.1(2), Cl3−Os2−C3 171.4(5), Cl3−Os2−C4 93.5(6), Cl4−Os2−C3 93.5(6), Cl4−Os2−C4 177.5(5), C3−Os2−C4 95.0(8), Os2−C3−C60 142(1), Os2−C4−O2 179(2)

5. The distance Os−C1 in molecule **A** is nearly identical with the Os−C(carbene) bond length in the related bis(triphenylphosphane)osmium(II) derivative *cis,cis,trans*-$[OsCl_2(=CHPh)(CO)(PPh_3)_2]$ [1.94(1) Å],[14] whereas the distance Os−C3 in molecule **B** [1.89(2) Å] corresponds precisely to the Os−C(carbene) distance of *cis,cis,trans*-$[OsCl_2(=CHCH_2Ph)(CO)(P\mathit{i}Pr_3)_2]$ [1.887(9) Å].[13] There is no difference in the Os−Cl bond lengths in **10** (in neither **A** nor **B**), indicating that the *trans* influences of the carbonyl and carbene ligands are virtually the same. We note in this context that the formation of **10** from **3** and HCl is uncommon insofar as analogous reactions of carbeneosmium(II) and -ruthenium(II) compounds with Broensted acids mainly proceed by attack of the proton at the carbene carbon atom to give alkylmetal derivatives.[9,14,15]

Similarly to the reaction of **3** with HCl, treatment of the starting material **3** with HBF_4 in the presence of water leads to the cleavage of the Os−H bond and affords the cationic aqua(carbene) complex **11** in 68% isolated yield. Instead of HBF_4, the carbenium salt $[CPh_3]BF_4$ can also be used as the electrophilic substrate. The composition of **11** (which is an orange, slightly air-sensitive solid) has been confirmed both by elemental analysis and conductivity measurements. The presence of the coordinated water molecule is clearly indicated in the IR spectrum by the strong ν(OH) bond at 3373 cm^{-1}. The ^{1}H-NMR spectrum of **11** (in CD_2Cl_2) is temperature-dependent. While at 290 K and slightly below (see Figure 4) the resonance for the OH_2 protons cannot be observed, at 266 K a relative broad signal appears which sharpens at 243 K to a singlet. This change of pattern is accompanied by a distinct separation of two resonances in the region between δ = 8.0−8.8 which are assigned to the *ortho*-hydrogen atoms of the phenyl ring. Brookhart[16] and Grubbs[17] both reported about similar observations in the case of cationic carbeneiron and -ruthenium complexes and attributed the observed effects to the interaction between the phenyl substituent and the positively charged carbene carbon atom. For **11** an analogous explanation could also be reasonable, in particular since in the ^{1}H-NMR spectrum of the related, but neutral, precursor **3** even at 213 K only one broadened resonance for the *ortho*-CH protons of the phenyl ring appears. We note that an aqua(carbene)osmium-

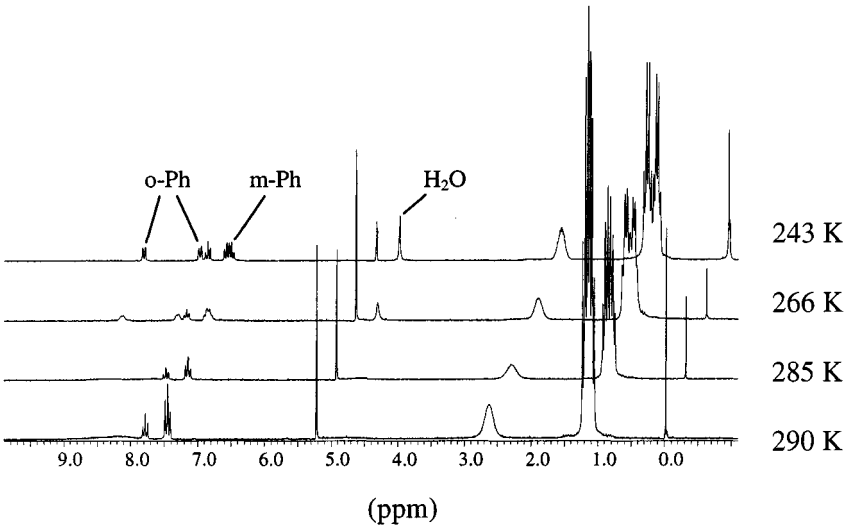

Figure 4. ^{1}H-NMR spectra of compound **11** in CD_2Cl_2 at different temperatures

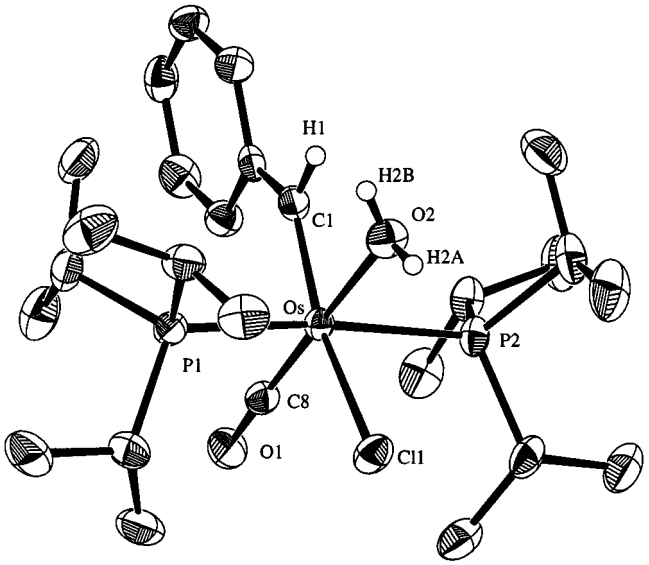

Figure 5. Molecular structure of the cation of **11**; hydrogen atoms apart from H1, H2A, and H2B are omitted for clarity; selected bond lengths [Å] and angles [°]: Os−P1 2.476(2), Os−P2 2.477(2), Os−Cl1 2.477(2), Os−C1 1.915(7), Os−C8 1.823(7), Os−O2 2.182(5), C1−C2 1.449(9), C8−O1 1.159(8); P1−Os−P2 172.90(6), P1−Os−Cl1 85.42(6), P1−Os−C1 95.3(2), P1−Os−C8 89.5(2), P1−Os−O2 89.9(2), P2−Os−Cl1 87.49(6), P2−Os−C1 91.6(2), P2−Os−C8 91.1(2), P2−Os−O2 89.3(2), Cl1−Os−C1 165.3(2), Cl1−Os−C8 98.0(2), Cl1−Os−O2 80.5(2), C1−Os−C8 96.7(3), C1−Os−O2 84.9(3), C8−Os−O2 178.4(2), Os−C8−O1 177.3(6), Os−C1−C2 140.9(5)

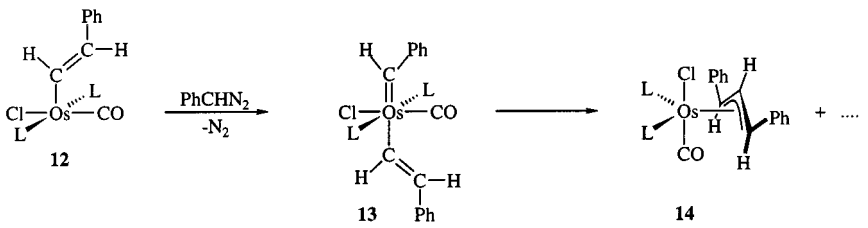

(II) compound similar to **11** with the composition $[OsCl(=CHCH=CH_2)(H_2O)(CO)(P\mathit{i}Pr_3)_2]BF_4$ has been described by Esteruelas et al. but due to the lability of this species neither NMR-spectroscopic nor structural data have been reported.[18]

The molecular structure of the cation of **11** is shown in Figure 5. Although in analogy to the other carbeneosmium(II) complexes **4**, **5**, and **10** the coordination geometry around the metal center is not perfectly octahedral, the bending of the three main axes P1−Os−P2, C8−Os−O2, and C1−Os−Cl1 is less pronounced than in the related neutral compounds with an Os−CHPh bond. The most noteworthy structural feature is that in contrast to **4**, **5**, and **10** the chloro ligand in **11** is mutually *cis* and not *trans* to the CO group. The conclusion is that in the course of the reaction of **3** with HBF_4/H_2O a rearrangement of the ligand sphere occurs. The bond length Os−C1 in **11** is slightly shorter than in the hydrido(carbene) derivatives **4** and **5**, but corresponds almost exactly to the average of the metal−carbene distances found for molecules **A** and **B** in the dichloro complex **10**.

The five-coordinate vinylosmium(II) compound **12**, which (as mentioned above) was prepared from **1** and phenylacetylene,[4] also reacts with $PhCHN_2$ to give the expected six-coordinate carbene complex **13** in 82% yield (Scheme 4). Attempts to prepare **13** on an alternative route failed because in contrast to **1** the hydrido(carbene) derivative **3** does not react with PhC≡CH by insertion of the alkyne into the Os−H bond. The ^{1}H- and ^{31}P-NMR spectra of **13** in ($CDCl_3$) reveal that in solution two isomeric species in the ratio of 2:1 are present which probably differ in the orientation of the carbene unit to the vinyl ligand. Although due to the preliminary results of an X-ray structure analysis of **13**[19] there is no doubt that in the crystal the CHPh and the CH=CHPh groups are *trans* to each other, we cannot exclude that in solution a mixture of both the *cis* and the *trans* isomer exists. With regard to the stereochemistry of the OsCH=CHPh moiety, the large H−H coupling of ca. 19 Hz between the vinyl protons indicates that the metal and the phenyl group are *trans*-disposed.

In benzene or toluene, the carbene(vinyl)osmium(II) derivative **13** is somewhat labile and rearranges slowly to a product which probably is the π-allyl complex **14**. The same reaction in chloroform leads to a mixture of at least two compounds which could not be separated by fractional crystallization or chromatographic techniques. Attempts to obtain **14** in analytically pure form also failed since during column chromatography of a solution of **14** in benzene decomposition occurred. The most typical features of the ^{1}H-NMR spectrum of **14** are the sharp triplet at δ = 6.09 for the central CH proton of the allyl moiety and the doublet of doublet resonance at δ = 4.14 (with the relative intensity of 2 H) which is assigned to the two equivalent terminal protons of the PhCHCHCHPh group. The relatively large H−H coupling constant (11.6 Hz) for these two signals indicate that the terminal protons are in *anti* position. A related compound to **14** with the composition $[OsH(\eta^3\text{-}C_3H_5)(CO)(P\mathit{i}Pr_3)_2]$ exists and has been prepared in our laboratory from **1** and C_3H_5MgBr.[20]

With regard to the mechanism of formation of **14** from compound **13** we note that in rhodium and ruthenium chemistry work by Maitlis and us has already demonstrated that coupling between a vinyl group and a carbene ligand in the coordination sphere of a transition-metal occurs leading to an allyl unit.[21][22] Moreover, Hill and co-work-

Scheme 4. L = P*i*Pr$_3$

ers recently reported that the five-coordinate vinyl complex $[Ru(CH=CH_2)Cl(CO)(PPh_3)_2]$ reacts with excess diazomethane to afford the corresponding π-allyl species $[RuCl(\eta^3\text{-}C_3H_5)(CO)(PPh_3)_2]$ via a carbeneruthenium compound as an observed intermediate.[23]

Conclusion

The work presented in this paper has shown that treatment of the five-coordinate starting material **1** with CH_2N_2 and substituted diazoalkanes $RCHN_2$ does not lead to the insertion of the respective carbene into the Os−H bond and, therefore, does not afford the alkylosmium(II) complexes $[Os(CH_2R)Cl(CO)(P\textit{i}Pr_3)_2]$. Instead, the isomeric hydrido(carbene) derivatives **2−5** are formed in excellent yields. The X-ray crystal structure analyses of two representatives **4** and **5** have confirmed that in the hydrido(carbene)osmium(II) compounds the hydride and the carbene ligand are in *trans* disposition. The same stereochemistry has been found for the related ruthenium(II) complexes $[RuHCl(=CHR)(CO)(P\textit{i}Pr_2Ph)_2]$ where R is H or Ph.[24] Recently, Caulton and co-workers reported that the reaction of $[MHCl(CO)(P\textit{t}Bu_2Me)_2]$ (M = Os, Ru) with diazomethane yields at low temperature also the corresponding hydrido(methylidene) derivatives $[MHCl(=CH_2)(CO)(P\textit{t}Bu_2Me)_2]$ which, however, isomerize at 25°C or below to $[M(CH_3)Cl(CO)(P\textit{t}Bu_2Me)_2]$.[25] In agreement with our studies, these authors equally observed that the osmium complex **2** decomposes unselectively to a mixture of products among which **1** and ethene could be detected. Caulton et al. assume that the remarkable ligand dependence ($P\textit{t}Bu_2Me$ vs. $P\textit{i}Pr_3$) is attributed to the fact that the $MH(=CH_2)$ to $M(CH_3)$ isomerization of the six-coordinate compounds require phosphane dissociation and that the smaller $P\textit{i}Pr_3$ (compared to $P\textit{t}Bu_2Me$) fails to dissociate at a rate competitive with alternative decomposition reactions.[25] Recent ab initio MP2 calculations by Eisenstein et al.[26] are in agreement with these results. The theoretical work also reveals that for $[OsHCl(=CH_2)(CO)(P\textit{i}Pr_3)_2]$ the isomer, in which H and CH_2 are mutually *cis*, is more stable than that in which these ligands are mutually *trans*.[26] Therefore, the final conclusion is that the isolated hydrido(carbene) complex **2** and probably also the analogous derivatives **3−5** are kinetically protected by a high barrier for site exchange which seems to be a prerequisite for an insertion reaction

Experimental Section

All operations were carried out under argon using Schlenk techniques. The starting materials **1**[2] and **12**[4] were prepared as described in the literature. − NMR: Bruker AC 200 and AMX 400 [dvt = doublet of virtual triplets; $N = {}^3J(PH) + {}^5J(PH)$ or ${}^2J(PC) + {}^4J(PC)$, respectively]. − Melting points determined by DTA.

1. Preparation of $[OsHCl(=CH_2)(CO)(P\textit{i}Pr_3)_2]$ (2): A suspension of 84 mg (0.15 mmol) of **1** in 10 mL of diethyl ether was treated at room temperature with 0.80 mL of a freshly prepared 0.3 M solution of diazomethane in OEt_2. An evolution of gas (N_2) occurred. After the reaction mixture was stirred for 2 min, the solvent was removed and the yellow microcrystalline solid dried in vacuo; yield 86 mg (99%); m.p. 95°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1910 cm^{-1} (CO), 1857 (OsH). − ^1H NMR (400 MHz, C_6D_6): δ = 17.90, 16.88 (both br s, 1 H each, $OsCH_2$), 2.46 (m, 6 H, $PCHCH_3$), 1.10 [dvt, N = 14.4, ${}^3J(H,H)$ = 7.2 Hz, 18 H, $PCHCH_3$], 1.02 [dvt, N = 14.6, ${}^3J(H,H)$ = 7.2 Hz, 18 H, $PCHCH_3$], −4.48 [tt, ${}^2J(P,H)$ = 30, ${}^3J(H,H)$ = 2 Hz, 1 H, OsH]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 285.0 (br s, $Os=CH_2$), 182.0 [t, ${}^2J(P,C)$ = 8.0 Hz, CO], 25.0 (vt, N = 28.6 Hz, $PCHCH_3$), 19.1, 18.5 (both s, $PCHCH_3$). − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 56.5 [s, ${}^1J(^{187}Os,^{31}P)$ = 168 Hz]. − $C_{20}H_{45}ClOOsP_2$ (589.2): calcd. C 40.77, H 7.70; found C 40.50, H 8.01.

2. Preparation of $[OsHCl(=CHPh)(CO)(P\textit{i}Pr_3)_2]$ (3): A solution of 200 mg (0.35 mmol) of **1** in 10 mL of toluene was treated dropwise with 0.30 mL of a 1.4 M solution of $PhCHN_2$ in hexane at room temperature. An evolution of gas (N_2) occurred which was accompanied by a change of color from orange to dark yellow and finally to red (indicating excess of $PhCHN_2$). After the reaction mixture was stirred for 30 min, it was worked up as described for **2**. Orange crystals; yield 230 mg (99%); m.p. 117°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1878 cm^{-1} (CO), 1830 (OsH). − ^1H NMR (400 MHz, $CDCl_3$): δ = 17.45 (m, 1 H, Os=CH), 8.20 (m, 2 H, C_6H_5), 7.51 (m, 1 H, C_6H_5), 7.29 (m, 2 H, C_6H_5), 2.61 (m, 6 H, $PCHCH_3$), 1.10 [dvt, N = 14.0, ${}^3J(H,H)$ = 6.8 Hz, 36 H, $PCHCH_3$)], −4.50 [dt, ${}^2J(P,H)$ = 29.5, ${}^3J(H,H)$ = 4.5 Hz, 1 H, OsH]. − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 296.8 (br s, Os=*C*HPh), 183.4 [t, ${}^2J(P,C)$ = 8.0 Hz, CO], 157.2 (s, *i*-C_6H_5), 132.1, 129.8, 129.6 (all s, C_6H_5), 25.9 (vt, N = 27.8 Hz, $PCHCH_3$), 18.8, 18.7 (both s, $PCHCH_3$). − ^{31}P NMR (162.0 MHz, $CDCl_3$): δ = 47.9 [s, ${}^1J(^{187}Os,^{31}P)$ = 168 Hz]. − $C_{26}H_{49}ClOOsP_2$ (665.3): calcd. C 46.94, H 7.42; found C 47.34, H 7.42.

3. Preparation of $[OsHCl(=CHCO_2Et)(CO)(P\textit{i}Pr_3)_2]$ (4): A solution of 105 mg (0.18 mmol) of **1** in 5 mL of toluene was treated with 0.04 mL of N_2CHCO_2Et at room temperature. An evolution of gas (N_2) occurred which was accompanied by a change of color from orange to dark brown. After the reaction mixture was stirred for 30 min, the solvent was removed in vacuo and the residue was extracted with a mixture of 10 mL of hexane and 0.5 mL of toluene. The extract was filtered and the filtrate was concentrated in vacuo to give an orange solid; yield 98 mg (81%); m.p. 133°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1923 cm^{-1} (CO), 1863 (OsH), 1650 (CO_2Et). − ^1H NMR (400 MHz, C_6D_6): δ = 17.22 [dt, ${}^3J(H,H)$ = ${}^3J(P,H)$ = 3.0 Hz, 1 H, Os=CH]; 4.23 [q, ${}^3J(H,H)$ = 7.5 Hz, 2 H, CH_2CH_3], 2.60 (m, 6 H, $PCHCH_3$), 1.17 [t, ${}^3J(H,H)$ = 7.5 Hz, 3 H, CH_2CH_3], 1.14, 1.06 [both dvt, N = 14.7, ${}^3J(H,H)$ = 7.5 Hz, 18 H each, $PCHCH_3$], −4.95 [dt, ${}^3J(H,H)$ = 3.0, ${}^2J(P,H)$ = 31.6 Hz, 1 H, OsH]. − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 267.7 (br s, Os=*C*HCO_2Et), 181.5 [t, ${}^3J(P,C)$ = 2.5 Hz, *C*O_2Et], 179.3 [t, ${}^2J(P,C)$ = 8.9 Hz, CO], 59.6 (s, *C*H_2CH_3), 29.9 (vt, N = 28.8 Hz, $PCHCH_3$), 18.7 (s, $PCHCH_3$), 14.4 (s, CH_2CH_3). − ^{31}P NMR (81.0 MHz, $CDCl_3$): δ = 56.6 [s, ${}^1J(^{187}Os,^{31}P)$ = 165 Hz]. − $C_{23}H_{49}ClO_3OsP_2$ (661.3): calcd. C 41.78, H 4.79; found C 41.51, H 7.19.

4. Preparation of $[OsHCl(=CHSiMe_3)(CO)(P\textit{i}Pr_3)_2]$ (5): A solution of 100 mg (0.17 mmol) of **1** in 5 mL of toluene was treated with 0.15 mL of a 2.0 M solution of Me_3SiCHN_2 in hexane and stirred for 15 h at room temperature. The solvent was evaporated in vacuo, the remaining yellow microcrystalline solid washed twice with 2 mL of hexane and dried in vacuo; yield 91 mg (79%); m.p. 132°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1938 cm^{-1} (CO). − ^1H NMR (200 MHz, $CDCl_3$): δ = 19.85 [dt, ${}^3J(P,H)$ = ${}^3J(H,H)$ = 2 Hz, 1 H, Os=C*H*$SiMe_3$], 2.53 (m, 6 H, $PCHCH_3$) 1.20 [dvt, N = 14.2, ${}^3J(H,H)$ = 7.2 Hz,

18 H, PCHCH_3], 1.08 [dvt, N = 14.7, ^3J(H,H) = 7.3 Hz, 18 H, PCHCH_3], 0.16 (s, 9 H, $SiCH_3$), −5.62 [dt, ^2J(P,H) = 28.6, ^3J(H,H) = 2 Hz, 1 H, OsH]. − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 327.3 (s, Os=*C*HSiMe$_3$), 182.6 [t, ^2J(P,C) = 8.0 Hz, CO], 25.2 (vt, N = 28.6 Hz, P*C*HCH$_3$), 19.2, 18.8 (both s, PCH*C*H$_3$), 0.5 (s, $SiCH_3$). − ^{31}P NMR (162.0 MHz, $CDCl_3$): δ = 56.5 [s, J(^{187}Os,^{31}P) = 170 Hz]. − $C_{23}H_{53}ClOOsP_2Si$ (661.4): calcd.C 41.77, H 8.08; found C 41.32, H 8.26.

5. Generation of [OsHCl(N$_2$CHSiMe$_3$)(CO)(P*i*Pr$_3$)$_2$] (6): A solution of 35 mg (0.06 mmol) of **1** in 5 mL of toluene was treated at −78°C with 0.05 mL of a 2.0 M solution of Me_3SiCHN_2 in hexane. An instant change of color from orange to light yellow occurred which is not accompanied by an evolution of gas. Attempts to isolate the product by low-temperature evaporation of the solvent led always to a mixture of **5** and **6**. Spectroscopic data for **6**: IR (KBr): $\tilde{\nu}$ = 1890 cm^{-1} (CO), 1933 (OsH or N_2). − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.80 (s, 1 H, Me$_3$SiC*H*N$_2$), 2.62 (m, 6 H, PC*H*CH$_3$), 1.26 [dvt, N = 13.2, ^3J(H,H) = 6.7 Hz, 18 H, PCHCH_3], 1.23 [dvt, N = 13.6, ^3J(H,H) = 7.0 Hz, 18 H, PCHCH_3], 0.13 (s, 9 H, $SiCH_3$), −13.70 (br s, 1 H, OsH). − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 178.8 [t, ^2J(P,C) = 8.3 Hz, CO], 33.4 (s, Me$_3$Si*C*HN$_2$), 24.5 (vt, N = 26.0 Hz, P*C*HCH$_3$), 19.2, 19.0 (both s, PCH*C*H$_3$), 0.3 (s, $SiCH_3$). − ^{31}P NMR (162.0 MHz, $CDCl_3$): δ = 28.3 [s, J(^{187}Os,^{31}P) = 176 Hz].

6. Preparation of [OsHCl(N$_2$CPh$_2$)(CO)(P*i*Pr$_3$)$_2$] (7): A solution of 51.0 mg (0.09 mmol) of **1** in 2 mL of toluene was treated dropwise at room temperature with a solution of 18.1 mg (0.09 mmol) of Ph_2CN_2 in 5 mL of toluene. After the reaction mixture was stirred for 2 min, the solvent was removed in vacuo and the residue washed twice with 3 mL of hexane. An off-white solid was obtained which was dried in vacuo; yield 51 mg (75%); m.p. 69°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1890 cm^{-1} (CO), 1952 (OsH or N_2). − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.32 (m, 8 H, C_6H_5), 7.15 (m, 2 H, C_6H_5), 2.60 (m, 6 H, PC*H*CH$_3$), 1.22 [dvt, N = 13.7, ^3J(H,H) = 6.6 Hz, 18 H, PCHCH_3], 1.15 [dvt, N = 13.8, ^3J(H,H) = 6.8 Hz, 18 H, PCHCH_3], -11.44 (br s, 1 H, OsH). − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 179.2 [t, ^2J(P,C) = 9.1 Hz, CO], 129.2, 128.6, 127.7, 126.5 (all s, C_6H_5), 24.6 (vt, N = 25.8 Hz, P*C*HCH$_3$), 19.4, 19.3 (both s, PCH*C*H$_3$), signal of Ph_2CN_2 not observed. − ^{31}P NMR (162.0 MHz, $CDCl_3$): δ = 28.0 [s, J(^{187}Os,^{31}P) = 180 Hz]. − $C_{32}H_{53}ClN_2OOsP_2$ (769.4): calcd. C 49.95, H 6.94, N 3.64; found C 49.66, H 6.78, N 3.55.

7. Preparation of [OsHCl(N$_2$C$_5$Cl$_4$)(CO)(P*i*Pr$_3$)$_2$] (8): This compound was prepared analogously as described for **7**, using 50.0 mg (0.09 mmol) of **1** and 23.8 mg (0.10 mmol) of $N_2C_5Cl_4$ as starting materials. Light brown solid; yield 53 mg (75%); m.p. 73°C (dec.). − IR (hexane): $\tilde{\nu}$ = 1904 cm^{-1} (CO), 1941 (OsH or N_2). − ^{1}H NMR (400 MHz, C_6D_6): δ = 2.55 (m, 6 H, PC*H*CH$_3$), 1.15−1.08 (br m, 36 H, PCH*C*H$_3$), −7.06 [t, ^2J(P,H) = 22 Hz, 1 H, OsH]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 177.3 [t, ^2J(P,C) = 7.8 Hz, CO], 113.3, 108.0 (both s, CCl), 82.2 (br s, N_2C), 24.9 (vt, N = 27.4 Hz, P*C*HCH$_3$), 19.9, 19.0 (both s, PCH*C*H$_3$). − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 26.3 [s, J(^{187}Os,^{31}P) = 170 Hz]. − $C_{24}H_{43}Cl_5N_2OOsP_2$ (805.1): calcd. C 35.81, H 5.38, N 3.48; found C 35.37, H 5.62, N 3.36.

8. Preparation of [OsH(O$_2$CCF$_3$)(=CHPh)(CO)(P*i*Pr$_3$)$_2$] (9): A solution of 120 mg (0.18 mmol) of **3** in 10 mL of toluene was treated with 58 mg (0.18 mmol) of CF_3CO_2Tl and stirred for 15 h at room temperature. A white solid (TlCl) slowly precipitated. The solution was filtered, the filtrate was concentrated in vacuo and the remaining orange solid dried; yield 121 mg (89%); m.p. 106°C (dec.). − IR (KBr): $\tilde{\nu}$ = 1885 cm^{-1} (CO), 1680 (OCO asym), 1425 (OCO sym). − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 17.16 [m, d after ^{31}P decoupling, ^3J(H,H) = 4.4 Hz, 1 H, Os=C*H*Ph], 8.15 (m, 2 H, C_6H_5), 7.54 (m, 1 H; C_6H_5), 7.35 (m, 2 H, C_6H_5), 2.43 (m, 6 H, PC*H*CH$_3$), 1.15 [dvt, N = 14.0, ^3J(H,H) = 7.0 Hz, 18 H, PCHCH_3], 1.12 [dvt, N = 13.6, ^3J(H,H) = 6.8 Hz, 18 H, PCHCH_3], −2.93 [dt, ^2J(P,H) = 29.7, ^3J(H,H) = 4.4 Hz, 1 H, OsH]. − ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 295.5 (s, Os=*C*HPh), 185.4 [t, ^2J(P,C) = 9.0 Hz, CO], 160.5 [q, ^2J(C,F) = 36 Hz, O$_2$*C*CF$_3$], 156.6 (s, *i*-C_6H_5), 132.5, 130.4, 129.6 (all s, C_6H_5), 115.1 [q, ^1J(C,F) = 293 Hz, O$_2$C*C*F$_3$], 26.4 (br vt, P*C*HCH$_3$], 18.9, 18.8 (both s, PCH*C*H$_3$). − ^{31}P NMR (162.0 MHz, $CDCl_3$): δ = 53.0 [s, J(^{187}Os,^{31}P) = 170 Hz]. − ^{19}F NMR (188.0 MHz, CD_2Cl_2): δ = −75.0 (s). − $C_{28}H_{49}F_3O_3OsP_2$ (742.3): calcd. C 45.27, H 6.65; found C 45.04, H 6.32.

9. Preparation of [OsCl$_2$(=CHPh)(CO)(P*i*Pr$_3$)$_2$] (10): A solution of 100 mg (0.15 mmol) of **3** in 5 mL of toluene was treated with 1.80 mL of a ca. 1.0 M solution of HCl in toluene. A rapid change of color from orange to red occurred which was accompanied by the evolution of gas (H_2). The solvent was removed, the red air-stable solid was washed twice with 5 mL of pentane and dried; yield 102 mg (98%); m.p. 155°C. − IR (KBr): $\tilde{\nu}$ = 1915 cm^{-1} (CO). − ^{1}H NMR (400 MHz, C_6D_6): δ = 19.04 (s, 1 H, Os=C*H*Ph), 8.28 (br s, 2 H, C_6H_5), 7.07 (m, 3 H, C_6H_5), 2.72 (m, 6 H, PC*H*CH$_3$), 1.25 [dvt, N = 14.0, ^3J(H,H) = 7.0 Hz, 18 H, PCHCH_3], 1.08 [dvt, N = 13.6, ^3J(H,H) = 6.8 Hz, 18 H, PCHCH_3]. − ^{13}C NMR (100.6 MHz, C_6D_6): δ = 278.0 (s, Os=*C*HPh), 181.0 [t, ^2J(P,C) = 7.6 Hz, CO], 157.2 (s, *i*-C_6H_5), 132.9, 132.0, 130.3 (all s, C_6H_5), 25.6 (vt, N = 28.8 Hz, P*C*HCH$_3$), 20.1, 19.4 (both s, PCH*C*H$_3$). − ^{31}P NMR (162.0 MHz, C_6D_6): δ = 9.3 [s, J(^{187}Os,^{31}P) = 154 Hz]. − $C_{26}H_{48}Cl_2OOsP_2$ (699.8): calcd. C 44.63, H 6.91; found C 44.35, H 6.67.

10. Preparation of [OsCl(=CHPh)(CO)(H$_2$O)(P*i*Pr$_3$)$_2$]BF$_4$ (11): a) A solution of 234 mg (0.35 mmol) of **3** in 5 mL of benzene was treated with 1.0 mL of a 48% solution of HBF_4 in water (7.65 mmol) and vigorously stirred for 3 min at room temperature. The aqueous phase was separated and washed four times with 5 mL of benzene each. The organic phase and the benzene washings were combined, and the solution was concentrated to ca. 10 mL in vacuo. Upon standing for 3 h, an orange solid precipitated which was seperated from the mother liquor. The solid was then dissolved in 10 mL of ether and the solution stored for 10 h at −20°C. Orange-yellow crystals were formed which were filtered, washed twice with 2 mL of ether (0°C) and dried; yield 184 mg (68%). − b) A solution of 60 mg (0.09 mmol) of **3** in 5 mL of toluene was treated with 30 mg (0.09 mmol) of $[CPh_3]BF_4$ and stirred for 15 h at room temperature. The solvent was removed, the orange-yellow solid washed four times with 3 mL of hexane each and dried; yield 44 mg (64%); m.p. 109°C (dec.). − Λ = 65 cm$^2\Omega^{-1}$mol^{-1} (in CH_3NO_2). − IR (KBr): $\tilde{\nu}$ = 3375 cm^{-1} (OH), 1936 (CO). − ^{1}H NMR (200 MHz, CD_2Cl_2, −30°C): δ = 17.18 (s, 1 H, Os=C*H*Ph), 8.80, 7.97, 7.85 (all m, 1 H each, C_6H_5), 7.53 (m, 2 H, C_6H_5), 4.98 (s, 2 H, H_2O), 2.55 (m, 6 H, PC*H*CH$_3$), 1.26 [dvt, N = 14.7, ^3J(H,H) = 7.3 Hz, 18 H, PCHCH_3], 1.11 [dvt, N = 13.7, ^3J(H,H) = 6.9 Hz, 18 H, PCHCH_3]. − ^{13}C NMR (50.3 MHz, CD_2Cl_2, −30°C): δ = 274.2 [t, ^2J(P,C) ca. 15 Hz, Os=*C*HPh], 181.2 [t, ^2J(P,C) ca. 9 Hz, CO], 134.8, 134.6, 132.5, 130.7, 130.6 (all s, C_6H_5), 24.1 (vt, N = 25.5 Hz, P*C*HCH$_3$), 19.2, 18.0 (both s, PCH*C*H$_3$). − ^{19}F NMR (188.0 MHz, CD_2Cl_2, −30°C): δ = −148.7 (s). − ^{31}P NMR (81.0 MHz, CD_2Cl_2, −30°C): δ = 19.6 (s). − $C_{26}H_{51}BClF_4O_2OsP_2$ (770.1): calcd. C 40.55, H 6.68; found C 41.01, H 6.97.

11. Preparation of [Os(CH=CHPh)Cl(=CHPh)(CO)(P*i*Pr$_3$)$_2$] (13): A suspension of 112 mg (0.17 mmol) of **12** in 5 mL of hexane was

treated dropwise with 0.30 mL of a 1.4 M solution of $PhCHN_2$ in hexane at room temperature. A red solution was formed from which after stirring for 20 min a red solid precipitated. The mother liquor was decanted, the remaining red solid was washed three times with 3 mL of hexane (0°C) and dried; yield 104 mg (82%); m.p. 68°C (dec.). – IR (C_6H_6): $\tilde{\nu}$ = 1890 cm^{-1} (CO). – ^1H NMR (400 MHz, C_6D_6): δ = 19.08 (s, 1 H, Os=C*H*Ph), 9.92 [d, ^3J(H,H) = 19.0 Hz, 1 H, CH=C*H*Ph], 8.42, 7.59 (both br s, 2 H each, C_6H_5), 7.38 [dt, ^3J(H,H) = 19.0, ^3J(P,H) ≈ 2 Hz, 1 H, C*H*=CHPh], 7.27, 7.04 (both m, 3 H each, C_6H_5), 2.49 (m, 6 H, PC*H*CH_3), 1.14 [dvt, *N* = 14.0, ^3J(H,H) = 7.1 Hz, 18 H, PCHC*H*$_3$], 1.10 [dvt, *N* = 13.6, ^3J(H,H) = 6.8 Hz, 18 H, PCHC*H*$_3$]. – ^1H NMR (400 MHz, $CDCl_3$), isomer **A**: δ = 19.31 (s, 1 H, Os=C*H*Ph), 9.15 [d, ^3J(H,H) = 18.7 Hz, 1 H, CH=C*H*Ph], 8.35, 7.59 (both m, 2 H each, C_6H_5), 7.26 (m, C_6H_5), 6.99 (m, 1 H, C*H*=CHPh), 2.49 (m, 6 H, PC*H*CH_3), 1.11 [dvt, *N* = 14.0, ^3J(H,H) = 7.1 Hz, 36 H, PCHC*H*$_3$]; isomer **B**: δ = 18.66 (s, 1 H, Os=C*H*Ph), 9.38 [d, ^3J(H,H) = 18.9 Hz, 1 H, CH=C*H*Ph], 8.27, 7.59 (both m, 2 H each, C_6H_5), 7.26 (m, C_6H_5), 6.90 [d, ^3J(H,H) = 18.9 Hz, 1 H, C*H*=CHPh], 2.49 (m, 6 H, PC*H*CH_3), 0.99 [dvt, *N* = 14.0, ^3J(H,H) = 7.1 Hz, 36 H, PCHC*H*$_3$]. – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 302.8 (m, Os=*C*HPh), 184.6 [t, ^2J(P,C) = 9 Hz, CO], 158.3 (s, *i*-C_6H_5), 147.4 [t, ^2J(P,C) = 6 Hz, *C*H=CHPh], 142.5 [t, ^2J(P,C) = 3 Hz, CH=*C*HPh], 133.4, 131.5, 130.2, 125.6, 125.5, 125.4 (all s, C_6H_5), 27.0 (vt, *N* = 28 Hz, P*C*HCH_3), 19.9, 19.7 (both s, PCH*C*H$_3$). – ^{31}P NMR (162.0 MHz, C_6D_6): δ = 2.1 [s, J(^{187}Os,^{31}P) = 154 Hz]. – ^{31}P NMR (162.0 MHz, $CDCl_3$), isomer **A**: δ = 3.5 (s); isomer **B**: δ = 2.6 (s). – $C_{34}H_{56}ClOOsP_2$ (768.5): calcd. C 53.14, H 7.35; found C 52.73, H 7.16.

12. Generation of [OsCl(η^3-PhCHCHCHPh)(CO)(P*i*Pr$_3$)$_2$] (14): A solution of 80 mg (0.10 mmol) of **13** in 2 mL of benzene was stirred for 24 h at room temperature. After the solvent was evaporated, a red oil was obtained. The ^1H-NMR spectrum of this material revealed that apart from small amounts of **13** and some unidentified by-products the dominating species (ca. 90%) is compound **14**. Attempts to seperate the by-products from the wanted complex **14** by fractional crystallisation or chromatographic techniques failed. Characteristic NMR data for **14**: ^1H NMR (400 MHz, C_6D_6): δ = 7.63 (br s, 4 H, C_6H_5), 7.20 (m, 6 H, C_6H_5), 6.09 [t, ^3J(H,H) = 11.6 Hz, 1 H, PhCHC*H*CHPh], 4.14 [dd, ^3J(H,H) = 11.6, ^2J(P,H) = 4.8 Hz, 2 H, PhC*H*CHC*H*Ph], 2.47 (m, 6 H, PC*H*CH_3), 1.40, 1.31 (both br m, 36 H, PCHC*H*$_3$). – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 180.8 [t, ^2J(P,C) = 10.0 Hz, CO), 96.8 (br s, Ph*C*HCH*C*HPh), 67.0 (br s, PhCH*C*HCHPh), 31.0 (br s, PCH*C*H$_3$), 21.1 (br s, PCH*C*H$_3$), signals of phenyl carbon atoms are very broad and could not be exactly assigned. – ^{31}P NMR (162.0 MHz, C_6D_6): δ = −8.5 (br s).

13. Determination of the X-ray Crystal Structures of Compounds 4, 5, 10, and 11: Single crystals of **4** and **10** were obtained from toluene/hexane at −20°C, crystals of **5** from hexane at −20°C, and crystals of **11** from benzene/ether at −20°C. Data of **4** and **5** were collected on a Stoe–Siemens–Huber diffractometer with CCD area detector, those of **10** and **11** on an Enraf–Nonius CAD4 diffractometer using monochromated $Mo_{K\alpha}$ radiation (λ = 0.71073 Å). Intensity data were corrected for LP effects. Multi-scan absorption correction was applied for **4** and **5** and a semi-empirical absorption correction was applied for **10** and **11**. The structures of **4**, **10**, and **11** were solved by direct methods and the structure of **5** by Patterson and Fourier methods..[27] All non-hydrogen atoms were refined anisotropically by full-matrix least squares on F^2,[28] and a riding model was employed in the refinement of the hydrogen atom positions. The hydrogen atoms H19 and H20 of **4** and H10 of **5** were refined freely; H1 of **5** was refined with a distance restraint and by setting the displacement parameter to 120% of the equivalent isotropic U value of C1; H1, H2A, and H2B of **11** were refinded by setting the displacement parameter to 120% of the equivalent isotropic U value of C1 and O2. Two independent molecules (**A** and **B**) of **10** were found in the asymmetric unit. In Figure 3 only molecule **A** is shown. Table 1 contains crystallographic data of the whole asymmetric unit (the chemical formula belongs to one molecule). In the asymmetric unit of **11,** one benzene molecule and two half benzene molecules were found and refined anisotropically with restraints. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-128215 (**4**), -128216 (**5**), -128217 (**10**), and -128218 (**11**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: internat. + 44-1223/336–033; E-mail: deposit@ccdc.cam.ac.uk).

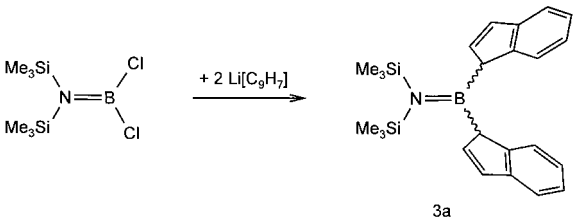
Synthesis and Structure of [1]Borametallocenophanes of Titanium, Zirconium, and Hafnium

Holger Braunschweig,*[a] Carsten von Koblinski,[a] Maliya Mamuti,[a] Ulli Englert,[a] and Ruimin Wang[a]

Keywords: Boron / Titanium / Zirconium / Hafnium / Metallocenophanes / Metallocenophanes

Various [1]borametallocenophane complexes of all the group IV metals were obtained in high yield by a very efficient multistep, one-pot synthesis. By this method not only the biscyclopentadienyl and diindenyl complexes [{$R_2NB(\eta^5$-$C_5H_4)_2$}MCl_2] (M = Zr, R = Me, $SiMe_3$, **4a**, **b**; M = Hf, R = $SiMe_3$, **5**) and [{$(Me_3Si_2)NB(\eta^5$-$C_9H_6)_2$}MCl_2] (M = Ti, **6**; M = Zr, **7**) were obtained, but also complexes with two different η^5-coordinated ligands such as [{$i Pr_2NB(\eta^5$-$C_5H_4)(\eta^5$-$C_9H_6)$}MCl_2] (M = Zr, **8**; M = Hf, **9**). Some of compounds **4–9** were chosen to investigate their catalytic properties with respect to Ziegler-Natta-type polymerisation of olefins, and proved to be highly efficient for the preparation of polyethylene.

Introduction



In the course of our investigations on both strained[1a,1b] and unstrained[2a,2b] [1]borametallocenophanes, we recently reported the first [1]boratitanocenophanes, which were obtained in high yields from a convenient one-pot synthesis. Metallocenophanes of group IV elements are of special interest due to their remarkable qualities as highly active Ziegler-Natta-type catalysts for olefin polymerisation.[3] Such catalytic processes could be accelerated by a bridging Lewis acidic centre such as boron.[4] Structurally authenticated boron-bridged metallocenophanes of group IV metals are restricted to a very few examples, including [{$(Me_2S)PhB(\eta^5$-$C_5H_4)_2$}$ZrCl_2$] (**1**) which has a four-coordinate boron atom in the bridge.[5] During the preparation of this paper, further zirconium complexes with three- and four-coordinate boron atoms [{$i Pr_2NB(\eta^5$-$C_5H_4)_2$}$ZrCl_2$] (**2a**), [{$i Pr_2NB(\eta^5$-$C_9H_6)_2$}$ZrCl_2$] (**2b**), [{(L)$PhB(\eta^5$-$C_9H_6)_2$}$ZrCl_2$] (L = PMe_3, thf, OEt_2; **2c**), obtained by an analogous method to that described for the synthesis of [{$(Me_3Si)_2NB(\eta^5$-$C_5H_4)_2$}$TiCl_2$],[2a,2b] were reported by Ashe and Reetz.[6a,6b]

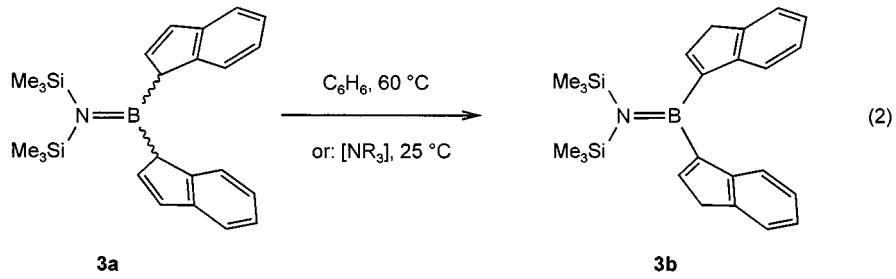
In the present paper we report on the synthesis, structure and catalytic properties of several [1]borametallocenophanes of Ti, Zr, and Hf, which were obtained by convenient reactions in high yields.

Results and Discussion

Synthesis and Structure of $(Me_3Si)_2NB(C_9H_7)_2$ (3a, b)

As already reported for $(Me_3Si)_2NB(C_5H_5)_2$[2a] the corresponding diindenylborane $(Me_3Si)_2NB(C_9H_7)_2$ (**3a**) is obtained in almost quantitative yields as a colourless solid from the reaction of $(Me_3Si)_2NBCl_2$ with $Li[C_9H_7]$ according to Equation 1.

(1)



3a

The 1-indenyl isomer **3a**, in which boron is bound to a saturated carbon atom and thus adopts an allylic position, represents the kinetically controlled product of this reaction. A quantitative rearrangement yielding the thermodynamically more stable vinylic isomer **3b** is achieved by either heating **3a** for 2 h to 60°C in benzene or by treating **3a** with catalytic amounts of NEt_3 in benzene at room temperature (Equation 2). The spectroscopic data of **3a, b**, such as the distinct low-field shift in the ^{11}B NMR spectrum for the allylic isomer with respect to the vinylic isomer [δ = 57.6 (**3a**) and 50.6 (**3b**)], resemble those of corresponding diindenyl(organyl)boranes,[6b] diorganyl(indenyl)boranes[7a,b] and 1,2-diindenyldiboranes(4),[8] which were reported very recently to undergo the same type of rearrangement. Compound **3a**, with two stereocentres, is expected to form a mixture of a C_2-symmetrical *rac* and a C_S-symmetrical *meso* isomer. The presence of both isomers is evident from the double set of signals in the ^{13}C NMR spectra.

Single crystals of **3b** suitable for an X-ray structure analysis were obtained from hexane at −30°C. The compound crystallises in the monoclinic space group *C*2/*c* and the molecule adopts almost C_2 symmetry in the solid state (Figure 1). Both the boron and nitrogen atoms are in a trigonal-planar environment, and due to the steric demand of the bulky Me_3Si groups, the Si1−N−Si2 plane is twisted with respect to the C11−B−C21 plane. The corresponding torsion angles are −51.28° (Si1−N−B−C21) and −50.73° (Si2−N−B−C11). Hence, together with an extended B−N

bond length of 144.3(5) pm a less effective backbonding from nitrogen to boron can be assumed. Both B−C and C−C bond lengths are in the expected range and resemble the data known for the corresponding 1,2-diindenyldiborane(4) derivative.[8]

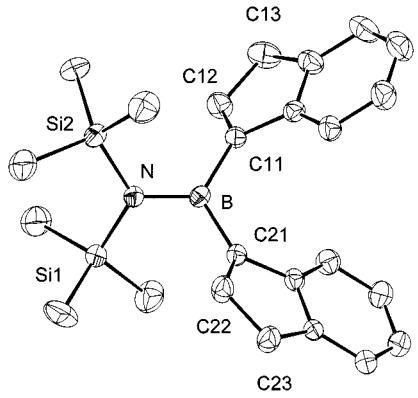

Figure 1. Structure of **3b** in the crystal (ellipsoids at 30% probability); selected distances (pm) and angles (°): B−N 144.3(5), B−C11 157.5(5), C11−C12 133.8(6), C12−C13 150.3(5); Si1−N−B 118.3(3); N−B−C11 120.1(4), C11−B−C21 118.9(3)

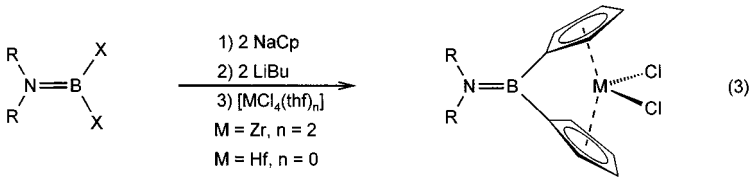


Synthesis and Structure of the [1]Borametallocenophanes

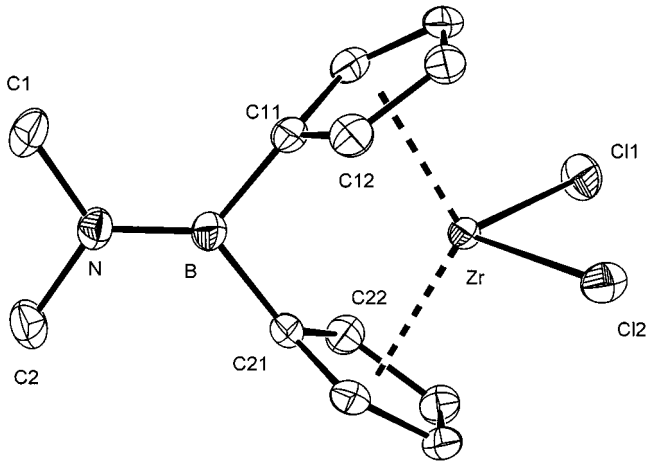
In analogy to the synthesis of [{$(SiMe_3)_2NB(\eta^5$-$C_5H_4)_2$}$TiCl_2$][2a,2b] the [1]borametallocenophanes [{$R_2NB(\eta^5$-$C_5H_4)_2$}MCl_2] (M = Zr, R = Me, $SiMe_3$, **4a**, **b**; M = Hf, R = $SiMe_3$, **5**) were obtained in three-step, one-pot syntheses according to Equation 3.[2b] In the case of **4a** the dibromoborane Me_2NBBr_2 served as starting material, whereas **4b** and **5** were obtained from the dichloro derivative $(Me_3Si)_2NBCl_2$. Although being sterically rather demanding, the latter aminodihaloborane is known to undergo substitutions of both chloride ligands more easily than the much smaller Me_2NBCl_2.[9a,9b] This is due to the electron-withdrawing effect of the silyl ligands, which enhances the electrophilicity of the boron centre. All products were isolated as yellow crystalline solids in high yields (**4a,** 91%; **4b,** 96%; **5,** 85%). These zirconium and hafnium complexes are readily soluble in CH_2Cl_2 and proved to be more stable towards decomposition in solution than the corresponding titanium derivative [{$(SiMe_3)_2NB(\eta^5$-$C_5H_4)_2$}-$TiCl_2$].[2a]

The structure of **4a**, **b** and **5** in solution was derived from multinuclear NMR spectra, showing the expected two pseudo triplets in the ^{1}H NMR spectra for the AA′BB′ spin system of the cyclopentadienyl protons at δ = 5.28, 6.62 (**4a**), 5.16, 6.61 (**4b**), and 5.54, 6.68 (**5**). The resonances in the ^{11}B NMR spectrum of **4b** and **5** at about δ = 47 resemble the signal of the uncoordinated ligand[2a] and show the expected low-field shift with respect to the signal of the dimethylamino derivative **4a** at δ = 38.7.

Suitable single crystals of **4a** were obtained by recrystallisation from a 70:30 mixture of CH_2Cl_2 and Et_2O at −30°C. The compound crystallises in the space group $P2_1/n$, and the molecule exhibits a slight deviation from the C_{2v} symmetry, which was assumed from its structure in solution (Figure 2). The B−N distance was found to be 138.4(4) pm, thus indicating a B−N double bond. As expected the two cyclopentadienyl ligands adopt an eclipsed orientation, and the geometry of **4a** is very similar to that of [{$(SiMe_3)_2NB(\eta^5$-$C_5H_4)_2$}$TiCl_2$],[2a] and to the corresponding zirconium complex [{iPr$_2$NB(η^5-$C_5H_4)_2$}$ZrCl_2$] (**2a**), the structure of which was described very recently.[6a]

The boron-bridged diindenyl complexes [{(Me_3Si_2)-$NB(\eta^5$-$C_9H_6)_2$}MCl_2] (M = Ti, **6**; M = Zr, **7**) were obtained according to the procedures described in Equations 4a and 4b. $(Me_3Si_2)NBCl_2$ was treated with two equivalents of Li[C_9H_7] in hexane, LiCl was removed by filtration, and after addition of Et_2O, the filtrate was treated with two equivalents of BuLi. The obtained slurry was subsequently reacted with [$TiCl_3(thf)_3$] or [$ZrCl_4(thf)_2$] at low tempera-

4a, b; M = Zr, R = Me, X = Br; R = Me_3Si, X = Cl
5; M = Hf, R = Me_3Si, X = Cl



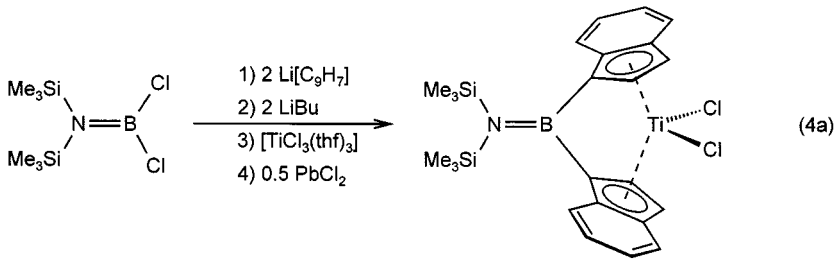


Figure 2. Structure of **4a** in the crystal (ellipsoids at 30% probability); selected distances (pm) and angles (°): Zr−Cl1 242.92(8), Zr−Cl2 245.79(9), B−N 138.4(4); Cl1−Zr−Cl2 100.87(3), C11−B−C21 105.9(3), C11−B−N 127.5(3), C21−B−N 126.5(3)

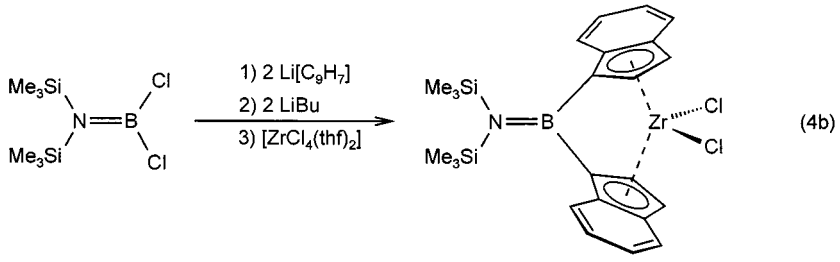
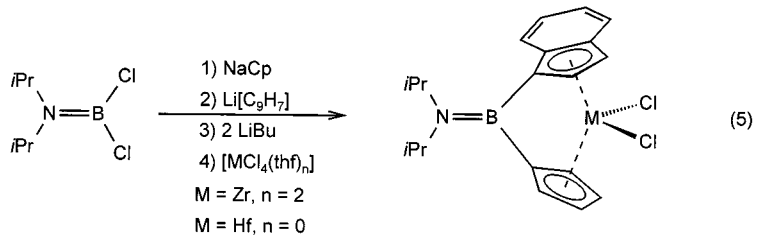
tures. In the case of the titanium complex **6** the intermediate Ti^{III} species was oxidised with $PbCl_2$.[10] The two complexes were isolated as dark red or orange crystalline materials, respectively, in yields of 71% (**6**) and 82% (**7**) and their constitutions in solution deduced from multinuclear NMR spectra. Although the general formation of a mixture of both *rac* (C_2 symmetry) and *meso* (C_s symmetry) isomers was reported for related element-bridged diindenyl complexes,[6a,6b,11] single sets of signals in the ^{13}C NMR spectra of **6** and **7** reveal the presence of only one isomer in our case. After reaction of **7** with two equivalents of LiMe, the corresponding complex $[\{(Me_3Si_2)NB(\eta^5\text{-}C_9H_6)_2\}ZrMe_2]$ was obtained,[12] and a single resonance for both metal-coordinated methyl groups in the NMR spectra indicates the presence of the *rac* isomer. This is further demonstrated by the formation of predominantly isotactic polypropylene (M.p. 116°C, triad ratio mm/mr/rr = 86:7:7 determined by ^{13}C NMR spectroscopy[13]) from **7** as a catalyst for the polymerisation of propene.

The preparation of [1]borametallocenophanes by the present method can be extended to the corresponding boron-bridged complexes with two different η^5-coordinated ligands, which have not previously been reported. This is demonstrated by the synthesis of $[\{i Pr_2NB(\eta^5\text{-}C_5H_4)(\eta^5\text{-}C_9H_6)\}MCl_2]$ (M = Zr, **8**; M = Hf, **9**) according to Equation 5. Stepwise treatment of iPr_2NBCl_2 with $Na[C_5H_5]$ and $Li[C_9H_7]$, subsequent reaction with two equivalents of BuLi, and addition of $[MCl_4(thf)_n]$ (M = Zr, n = 2; M = Hf, n = 0) afforded the mixed [1]borametallocenophanes **8**, **9** in 82% and 74% yield, respectively, as orange, crystalline solids. The spectroscopic data of both compounds, such as the ^{11}B NMR signals at about δ = 40, together with the expected patterns for η^5-cyclopentadienyl and η^5-indenyl ligands in the ^1H and ^{13}C NMR spectra prove their constitution in solution. A restricted rotation with respect to the boron−nitrogen double bond is indicated by double sets of signals for the isopropyl groups in both the ^1H and ^{13}C NMR spectra.



Conclusion

The synthetic method described in this paper and previously reported for $[\{(Me_3Si)_2NB(\eta^5\text{-}C_5H_4)_2\}TiCl_2]$ provides a convenient and general route to group IV [1]borametallocenophanes showing either η^5-cyclopentadienyl or η^5-indenyl ligands such as $[\{R_2NB(\eta^5\text{-}C_5H_4)_2\}MCl_2]$ (M = Zr, R = Me, $SiMe_3$, **4a**, **b**; M = Hf, R = $SiMe_3$, **5**) and $[\{(Me_3Si_2)NB(\eta^5\text{-}C_9H_6)_2\}MCl_2]$ (M = Ti, **6**; M = Zr, **7**). The novel complexes $[\{iPr_2NB(\eta^5\text{-}C_5H_4)(\eta^5\text{-}C_9H_6)\}MCl_2]$



(4a)

6

(4b)

7

8; M = Zr
9; M = Hf

(M = Zr, **8**; M = Hf, **9**) showing two different η^5-coordinated ligands are obtained in a similar manner. Further studies will focus on the catalytic properties of these [1]Borametallocenophanes. Preliminary investigations have already shown them to be highly efficient catalysts for the Ziegler-Natta-type polymerisation of olefins, showing, for example, activities of 5258 kg PE·mol[catalyst]$^{-1}$h^{-1} (**6**) and 8905 kg PE·mol[catalyst]$^{-1}$h^{-1} (**4a**)

Experimental Section

All manipulations were carried out under a dry nitrogen atmosphere with common Schlenk techniques. Solvents and reagents were dried by standard procedures, distilled, and stored under nitrogen over molecular sieves. $(Me_3Si)_2NBCl_2$,[14] iPr_2NBCl_2,[15] $Na[C_5H_5]$,[16] $[ZrCl_4(thf)_2]$,[17] $[TiCl_3(thf)_3]$[17] and Me_2NBBr_2[18] were obtained according to literature procedures. NMR: Varian Unity 500 at 499.843 MHz (^{1}H, internal standard TMS), 150.364 MHz (^{11}B, BF3·OEt2 in C_6D_6 as external standard), 125.639 MHz (^{13}C{^{1}H}, APT, internal standard TMS); all NMR spectra were recorded in CD_2Cl_2 as solvent unless otherwise stated. Mass spectra were recorded on a Finnigan MAT 95 (70 eV) and elemental analyses (C, H, N) were obtained from a Carlo−Erba elemental analyzer, model 1106.

$(Me_3Si)_2NB(1\text{-}C_9H_7)_2$ (3a): $Li[C_9H_7]$ (7.38 g, 60.41 mmol) was suspended in 100 mL hexane, and a solution of $(Me_3Si)_2NBCl_2$ (7.31 g, 30.20 mmol) in 20 mL hexane was added at 0°C. The yellow suspension was allowed to warm to ambient temperature and stirred for 2 h. All volatiles were removed in high vacuum, and the remaining solid was extracted with 50 mL of hexane. After filtration **3a** was obtained as a white crystalline solid by cooling to −30°C (11.64 g, 96%). − ^{1}H NMR (C_6D_6): δ = 0.24 (s, 18 H, $SiMe_3$), 3.61 (m, 2 H, B−CH_{ind}), 6.06−7.43 (m, 12 H, CH_{ind}) − ^{11}B NMR: δ = 57.6 (s). − ^{13}C NMR: δ = 3.75 (isomer 1), 4.83 (isomer 2) ($SiMe_3$), 54.8 (br, B−C_{ind}), 120.8 (1), 121.0 (2), 123.6 (1), 123.9 (2), 124.8 (1), 125.4 (2), 125.9 (1), 126.4 (2), 131.3 (1), 131.9 (2), 135.0 (1), 136.3 (2) (CH_{ind}), 144.1 (1), 144.3 (2), 146.3 (1), 146.7 (2) (C_{ind}). − MS; *m/z* (%): 401 (90) [M$^+$], 386 (25) [M$^+$ − Me], 286 (40) [M$^+$ − ind]. − $C_{24}H_{32}BNSi_2$ (401.51): calcd. $(Me_3Si)_2NB(3\text{-}C_9H_7)_2$ (3b): Compound **3b** was quantitatively obtained by a) refluxing a solution of **3a** (2.00 g, 4.98 mmol) in 50 mL benzene for 3 h, or by b) treatment of **3a** (1.50 g, 3.74 mmol) with a catalytic amount of NEt_3 (0.1 mL) in 40 mL benzene for 2 h at ambient temperature. Suitable single crystals of **3b** were obtained by recrystallisation from hexane at −30°C. − ^{1}H NMR (C_6D_6): δ = 0.23 (s, 18 H, $SiMe_3$), 3.22 (m, 4 H, CH_{2ind}), 6.70−7.29 (m, 10 H, CH_{ind}) − ^{11}B NMR: δ = 50.6 (s). − ^{13}C NMR: δ = 4.66 ($SiMe_3$), 40.18 (CH_{2ind}), 122.97, 123.78, 124.74, 126.42, 128.29, 142.70, 144.29 (C_{ind}).

[{$Me_2NB(\eta^5\text{-}C_5H_4)_2$}$ZrCl_2$] (4a): $Na[C_5H_5]$ (1.69 g, 19.20 mmol) was suspended in 40 mL hexane and a solution of Me_2NBBr_2 (2.05 g, 9.55 mmol) in 10 mL hexane was added dropwise at 0°C. After warming to ambient temperature, the yellow suspension was stirred for 2 h. NaBr was removed by filtration, and the residue was washed with 15 mL of diethyl ether. The filtrate was cooled to 0°C and 13.00 mL (20.80 mmol) of 1.6 M BuLi in hexane was slowly added . A white precipitate was formed immediately, the suspension was allowed to come to ambient temperature and stirred for 16 h. The yellow suspension was cooled to −70°C and $[ZrCl_4(thf)_2]$ (3.62 g, 9.60 mmol) and 15 mL of diethyl ether was added. After warming to ambient temperature and stirring for an additional 2 h, the yellow suspension was filtered. The filtrate was stored overnight at −30°C to yield **4a** as a yellow, crystalline solid (3.02 g, 91%). − ^{1}H NMR ([D$_8$]toluene): δ = 2.49 (s, 6 H, NMe_2), 5.28 (m, 4 H, C_5H_4), 6.62 (m, 4 H, C_5H_4). − ^{11}B NMR: δ = 38.7 (s). − ^{13}C NMR: δ = 39.43 (NMe_2), 111.58, 125.69 (C_5H_4), 137.52 (C_{ipso}). − MS; *m/z* (%): 345 (60) [M$^+$], 330 (5) [M$^+$ − Me], 301 (20) [M$^+$ − NMe_2]. − $C_{12}H_{14}BCl_2NZr$ (345.19): calcd. X-ray Structure Determination of 3b: $C_{24}H_{32}BNSi_2$; formula mass 401.51 g·mol^{-1}, monoclinic spacegroup *C*2/*c* (No. 15); *a* = 33.283(6), *b* = 7.069(2), *c* = 23.734(5) Å, β = 120.08(3)°, *V* = 4832(5) Å^3, *Z* = 8, ρ_{calcd} = 1.10 g·cm^{-3}, μL_{in} = 1.38 mm^{-1}. ENRAF-Nonius CAD4 diffractometer; CuK_α-radiation (λ = 1.54184 Å); graphite monochromator. Data collection at 293 K on a colourless crystal of about 0.44 × 0.22 × 0.16 mm^3 using ω scans in the diffraction range 3 < 2Θ < 65° yielded 8368 reflections. The data were corrected for Lorentz and polarization effects, and a numerical absorption correction by Gaussian integration[19] (min. trans. 0.669, max. trans. 0.817) was applied. After merging symmetry-equivalent data 4159 unique reflections remained for structure solution by direct methods[20] and subsequent Fourier difference syntheses. Least-squares refinement on structure factors[21] was performed with anisotropic displacement parameters for all non-hydrogen atoms and hydrogen atoms in calculated positions {C−H = 0.98 Å, U_{iso}(H) = 1.3 U_{eq}(C)}. Convergence was obtained for 253 variables, 2382 unique observations with $I > 1.0\,\sigma(I)$ and R = 0.064, R_w = 0.069, GOF = 1.145. A final difference Fourier map showed fluctuations of less than 0.65 eÅ^{-3}.

X-ray Structure Determination of 4a: $C_{12}H_{14}BCl_2NZr$; formula mass 345.19 g·mol^{-1}, monoclinic spacegroup $P2_1/n$ (No. 14); *a* = 11.532(3), *b* = 10.099(4), *c* = 12.179(4) Å, β = 104.70(2)°, *V* = 1372(1) Å^3, *Z* = 4, ρ_{calcd} = 1.67 g·cm^{-3}, μL_{in} = 2.67 mm^{-1}. ENRAF-Nonius CAD4 diffractometer; AgK_α-radiation (λ = 0.56087 Å); graphite monochromator. Data collection at 293 K on a colourless rod of about 0.40 × 0.20 × 0.15 mm^3 using ω−2Θ scans in the diffraction range 1 < Θ < 24° resulted in 9114 reflections. The data were corrected for Lorentz and polarization effects. After merging symmetry-equivalent data 4368 unique reflections remained for structure solution by direct methods;[20] the structure model was completed by Fourier difference syntheses. Least-squares refinement on structure factors[21] was performed with anisotropic displacement parameters for all non-hydrogen atoms and hydrogen atoms in calculated positions {C−H = 0.98 Å, U_{iso}(H) = 1.3 U_{eq}(C)}. Convergence was obtained for 168 variables, 3408 observed data with $I > 1.0\,\sigma(I)$ and R = 0.041, R_w = 0.039, GOF = 0.964. A final difference Fourier map showed fluctuations of less than 0.96 eÅ^{-3}.

Crystallographic data (excluding structure factors) for the structures) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-127944 (**3b**) and CCDC-127945 (**4a**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) +1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

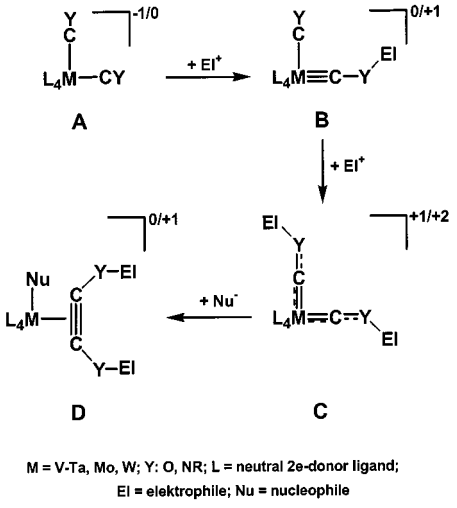
Intramolecular Carbyne–Isocyanide Coupling to an Alkyne Ligand at a d^4 Tungsten Center



Alexander C. Filippou,*[a] Bernhard Lungwitz[a] and Gabriele Kociok-Köhn[a]

Keywords: Carbyne complexes / Carbene complexes / Alkyne complexes / C_1 building blocks / C–C coupling

Oxidative decarbonylation of $Cp^*(CO)_2W{\equiv}CNEt_2$ (**1**) with $PhICl_2$ affords the aminocarbyne complex *cis*-$Cp^*(Cl)_2(CO)W{\equiv}CNEt_2$ (**2**), which reacts with *t*BuNC to give the CO substitution product *cis*-$Cp^*(Cl)_2(t\text{BuNC})W{\equiv}CNEt_2$ (**3**) ($Cp^* = C_5Me_5$). Complex **3** undergoes a carbyne–isocyanide coupling reaction with HCl to yield the alkyne complex $Cp^*(Cl)_3W[\eta^2\text{-}t\text{Bu(H)NC}{\equiv}CNEt_2]$ (**4**). In comparison, the reaction of *cis*-$Cp^*(Cl)_2[P(OMe)_3]W{\equiv}CNEt_2$ (**5**) with HCl affords the 16e carbene complex $Cp^*(Cl)_3W{=}C(H)NEt_2$ (**6**) after elimination of $P(OMe)_3$. Complex **5** was obtained from the CO ligand-exchange reaction of **2** with $P(OMe)_3$. Treatment of **6** with *t*BuNC yields the cationic 18e carbene complex $[Cp^*(Cl)_2(t\text{BuNC})_2W{=}C(H)NEt_2]Cl$ (**7**). The mechanism of the C–C coupling reaction of **3** to give **4** is discussed and the crystal structures of **4** and **6** are described.

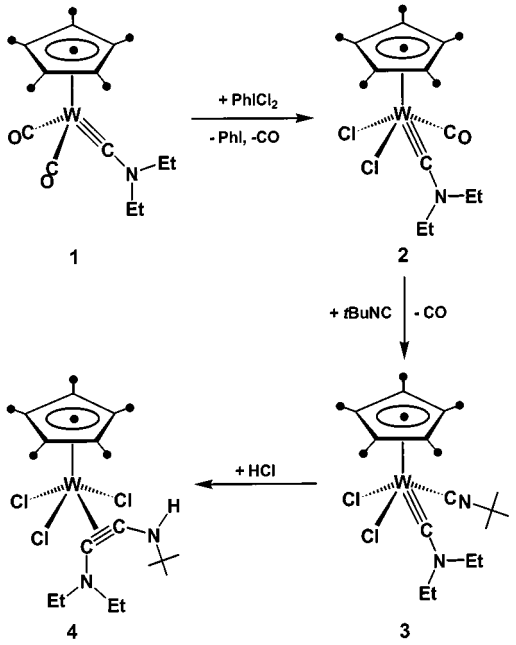
Introduction

The transition-metal-mediated conversion of carbon monoxide and related C_1 building blocks to organic compounds is a major goal in organometallic chemistry.[1] In this context a class of metal-centered C−C bond-forming reactions involving the coupling of two carbonyl or isocyanide ligands to an alkyne unit has attracted the attention of several research groups (Scheme 1).[2]

Scheme 1. Mechanism of the carbonyl/isocyanide coupling reactions of Group V and VI transition metal complexes; first ionic charge: M = V−Ta, second ionic charge: M = Mo, W

In the first two steps of these reactions successive addition of an electrophile occurs to the O/N atom of the carbonyl/isocyanide ligand leading initially to the carbyne complex **B** and then to the bis-carbyne complex **C**.[3] In the last step a carbyne−carbyne coupling reaction of **C** affords the alkyne complex **D** (Scheme 1).[3g,3k−3m,3o−3q] The carbonyl or isocyanide ligands in **A** and **B** are activated for an electrophilic addition at the heteroatom. This activation occurs upon coordination of these ligands to an octahedral, "electron-rich" d^6 metal center, which is known to form strong metal−carbon triple bonds.[3,4] It was therefore interesting to elucidate whether such ligand-coupling reactions could also occur at transition-metal centers with a different d electron configuration. This has prompted us to carry out the following work reporting on the intramolecular coupling of a carbyne with an isocyanide ligand at a d^4 tungsten center.

Results and Discussion



Starting material for the reactions described below was the W^{II} aminocarbyne complex **2**,[4] which was prepared upon oxidative decarbonylation of **1**[5] with one equivalent of $PhICl_2$ in dichloromethane and isolated as a violet solid in 88% yield (Scheme 2). Complex **2** is readily soluble in CH_2Cl_2 and THF, poorly soluble in Et_2O, insoluble in pentane and decomposes upon heating at 176°C.

Treatment of **2** with *t*BuNC in refluxing toluene yielded the CO substitution product **3**. Complex **3** was isolated in 76% yield as a rose-colored, thermally stable solid, which melts at 105°C (Scheme 2). **3** undergoes a selective and fast carbyne−isocyanide coupling reaction with HCl in diethyl ether to afford the violet W^{IV} alkyne complex **4** in 92% yield (Scheme 2). Complex **4** is thermally stable in the solid state and decomposes upon heating at 157°C.

Complexes **2**−**4** were fully characterized (see Experimental Section). The IR spectra of **2** and **3** in CH_2Cl_2 show an intense absorption for the $\nu(C_{carbyne}{\equiv}N)$ stretching vibration at $\tilde{\nu}$ = 1600 and 1571 cm^{-1}, which indicates the strong π conjugation of the amino group with the tungsten−carbon triple bond.[5] The ^1H- and $^{13}C\{^1H\}$-NMR

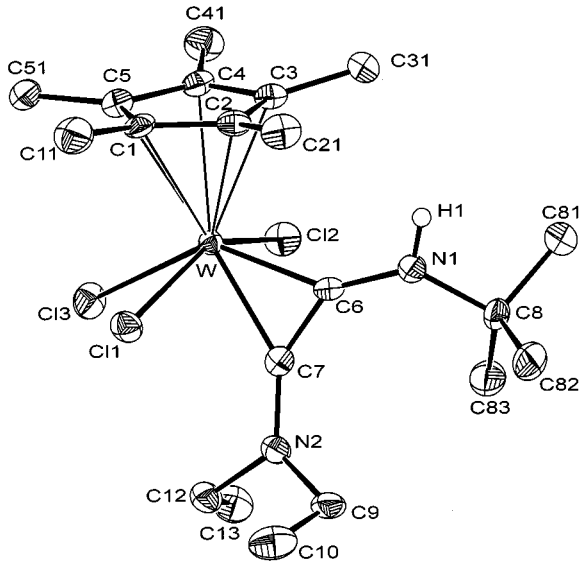
Scheme 2. Syntheses of the complexes **2**, **3** and **4**

spectra of **2** and **3** at 293 K display one set of resonances for the methyl and methylene protons of the aminocarbyne ligand indicating a fast rotation of the diethylamino group around the $C_{carbyne}-N$ bond. The methylene protons of each ethyl group are diastereotopic because of the C_1 symmetry of **2** and **3**. However, they are isochronous by accident and give rise to one quadruplet resonance in the ^{1}H-NMR spectra of **2** and **3** at 293 K. Variable-temperature ^{1}H-NMR spectra (300 MHz) of **2** in CD_2Cl_2 show this complex to be fluxional due to hindered rotation of the amino group about the $C_{carbyne}-N$ bond. The free energy of activation, $\Delta G^{\neq}(T_c)$, for the site exchange of the ethyl groups was calculated at the coalescence temperature T_c of the methyl proton resonances (T_c = 191 K, 300 MHz) to be 39.8 kJ mol^{-1}. The activation barrier is smaller than that of *cis*-Cp(Cl)$_2$(CO)W≡CN*i*Pr$_2$ [$\Delta G^{\neq}$ = 50.5 kJ mol^{-1}] and *cis*-Cp*(Cl)$_2$(CO)W≡CN*i*Pr$_2$ [$\Delta G^{\neq}$ = 47.4 kJ mol^{-1}], but similar to that of *cis*-Cp*(Br)$_2$(CO)W≡CNEt$_2$ [$\Delta G^{\neq}$ = 39.6 kJ mol^{-1}].[5c,6] Further support for the structures of **2** and **3** was given by the ^{13}C{^{1}H}-NMR spectra, which display a carbyne−carbon resonance at low field (**2**: δ = 310.0; **3**: δ = 306.4). This resonance is accompanied by tungsten satellites due to coupling with the ^{183}W nucleus. The ^1J(W,C) coupling constant of 210.0 (**2**) and 223.3 Hz (**3**) is typical of 18e W^{II} aminocarbyne complexes.[4,5c] In comparison, two low-field resonances are observed in the ^{13}C{^{1}H}-NMR spectrum of **4** (δ = 218.5, 219.3) indicating the presence of a 4e-donor alkyne ligand.[3c,3g,3k,7] Furthermore, an intense absorption band is observed in the IR spectrum of **4** in CH_2Cl_2 at 1667 cm^{-1}, which can be assigned to the ν(N=C=C=N) stretching vibration of the diaminoacetylene ligand and suggests an extensive delocalization of the amino-nitrogen lone-pair electrons in the alkyne ligand.[3c,3g,3k] Further evidence for this was given by the NMR spectra of **4** revealing a "frozen" rotation of the diethylamino group about the $C_{alkyne}-N$ bond (see Experimental Section) and the single-crystal X-ray diffraction study of **4**, which shows rather short $C_{alkyne}-N$ bonds [1.301(5) and 1.347(5) Å] and $W-C_{alkyne}$ bonds [2.008(4) and 2.043(4) Å], a long $(C-C)_{alkyne}$ bond of 1.366(6) Å and planar amino groups (Figure 1).[3g,3k,7] Planarity of the amino groups is indicated by the sum of bond angles at the atoms N1 and N2 of 359.3 and 354.6°, respectively. Other features of the molecular structure of **4** are the near orthogonality of the alkyne-ligand plane defined by the atoms W,C6,C7 and the Cp* ring plane (dihedral angle = 80.9°), as well as the *trans* position of the *t*Bu substituent.[8]



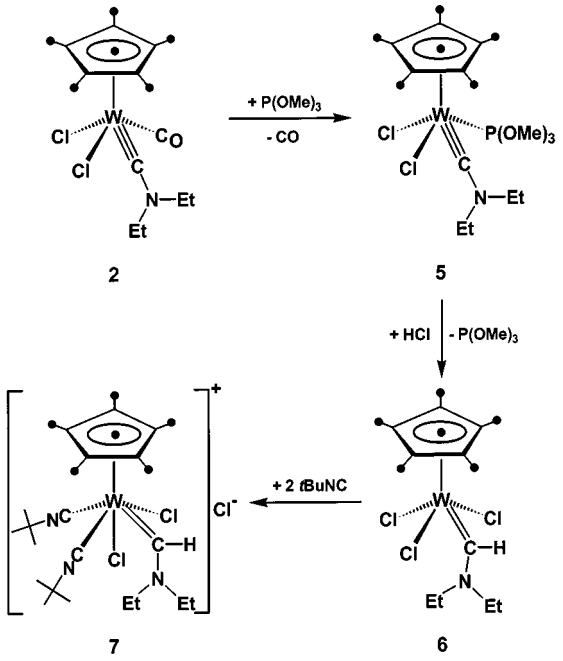


Figure 1. ZORTEP plot of the molecular structure of **4** with the thermal ellipsoids drawn at the 50% probability level; hydrogen atoms are omitted for clarity reasons except that bonded to the nitrogen atom N1; selected bond lengths [Å] and angles [°]: W−C6 2.008(4), W−C7 2.043(4), W−Cl1 2.4457(13), W−Cl2 2.4817(12), W−Cl3 2.4477(12), C6−C7 1.366(6), C6−N1 1.347(5), C7−N2 1.301(5), W−C_g 2.089, (C_g denotes the center of gravity of the Cp* ring), Cl1−W−Cl2 149.04(4), Cl1−W−Cl3 80.92(4), Cl2−W−Cl3 79.21(4), N1−C6−C7 140.5(4), N2−C7−C6 142.4(4), C6−W−C7 39.4(2), W−C6−N1 147.4(3), W−C7−N2 146.8(3), C6−N1−C8 129.4(4), C7−N2−C9 123.5(4), C7−N2−C12 119.5(4), C9−N2−C12 116.3(4)

We were interested to elucidate the mechanism of the acid-promoted carbyne−isocyanide coupling reaction of **3** (Scheme 2) and therefore prepared the aminocarbyne complex **5** from **2** and P(OMe)$_3$ by thermal CO ligand exchange in THF (Scheme 3).

Complex **5** was isolated after purification by column chromatography on silanized silica as an orange solid in 77% yield. It is readily soluble in CH_2Cl_2 and THF, sparingly soluble in Et_2O and decomposes upon heating at 98°C. Treatment of **5** with one equivalent of HCl afforded, after elimination of P(OMe)$_3$, the 16e tungsten(IV) aminocarbene complex **6** as a red, water-sensitive solid in 64% yield (Scheme 3).[4] Complex **6** is very soluble in CH_2Cl_2, sparingly soluble in Et_2O and decomposes upon heating at 135°C.

Scheme 3. Syntheses of the complexes **5**, **6** and **7**

The reaction of complex **6** with *t*BuNC was studied. Addition of the isocyanide to the Lewis acidic tungsten center of **6** would be expected to give the 18e carbene complex $Cp^*(Cl)_3(tBuNC)W{=}C(H)NEt_2$, which would rearrange to afford the alkyne complex **4**, if addition of HCl to the tungsten–carbon triple bond of **3** is the first step of the carbyne–isocyanide coupling reaction of **3** to give **4** (Scheme 2). However, treatment of **6** with *t*BuNC in CH_2Cl_2 afforded the cationic 18e tungsten(IV) aminocarbene complex **7** selectively,[4] which was isolated as a yellow solid in 82% yield (Scheme 3). The outcome of this reaction was independent of the molar ratio of the reactants, half of the starting material **6** being converted into **7**, when only one equivalent of *t*BuNC was used. These results suggest that carbene complex intermediates are not formed during the reaction of **3** with HCl.[3f,3p,9] Instead of this, they indicate a reaction pathway involving protonation of **3** at the isocyanide nitrogen atom followed by spontaneous carbyne–carbyne ligand coupling to afford the alkyne complex **4**. This suggestion is supported by earlier work showing that the 2e-oxidation of W^{II} bis(aminocarbyne) complexes is accompanied by C–C coupling of the carbyne ligands.[3g]

Complexes **5**–**7** were also fully characterized (Experimental Section). The IR spectrum of the aminocarbyne complex **5** in CH_2Cl_2 displays an intense absorption for the $\nu(C_{carbyne}{\equiv}N)$ stretching vibration at 1547 cm^{-1}. This absorption appears at lower wavenumbers than that of **2** and **3** indicating stronger metal–carbyne back bonding.[5] The ^{1}H-NMR spectrum of **5** at 293 K shows one triplet resonance for the methyl protons and two doublets of quadruplets for the diastereotopic methylene protons of the aminocarbyne ligand due to fast rotation of the diethylamino group about the $C_{carbyne}$–N bond and the presence of only the C_1-symmetric *cis* stereoisomer in solution.[5c] The

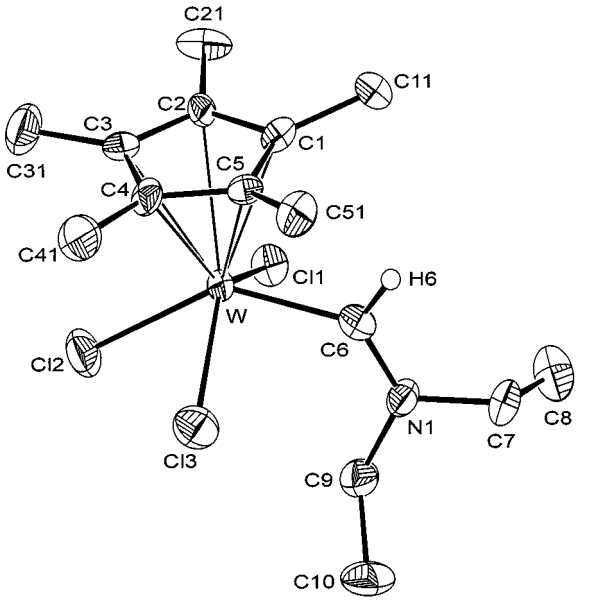

Figure 2. ZORTEP plot of the molecular structure of **6** with the thermal ellipsoids drawn at the 50% probability level; hydrogen atoms are omitted for clarity reasons except that bonded to the carbon atom C6; selected bond lengths [Å] and angles [°]: W–C6 2.065(7), W–Cl1 2.413(2), W–Cl2 2.418(2), W–Cl3 2.382(2), W–C_g 1.979 (C_g denotes the center of gravity of the Cp* ring), C6–N1 1.300(9), Cl1–W–Cl2 81.93(7), Cl1–W–Cl3 133.49(7), Cl2–W–Cl3 81.08(8), Cl1–W–C6 81.8(2), Cl2–W–C6 138.5(3), Cl3–W–C6 83.0(2), W–C6–N1 129.2(6), C6–N1–C7 120.6(7), C6–N1–C9 123.2(6), C7–N1–C9 116.1(6)

$^{13}C\{^1H\}$ spectrum of **5** diplays a doublet resonance for the carbyne–carbon nucleus at $\delta = 306.5$ [^2J(P,C) = 37.8 Hz]. The aminocarbene complexes **6** and **7** are distinguished by an IR absorption band of medium intensity at 1508 and 1579 cm^{-1}, which is assigned to the $\nu(C_{carbene}{\equiv}N)$ stretching vibration. The position of this band indicates the strong π interaction of the amino group with the metal–carbon double bond. This is supported by the temperature-dependent ^{1}H-NMR spectra of **6** (400 MHz) in the range of 233–293 K revealing a hindered rotation of the diethylamino group about the $C_{carbene}$–N bond. The free energy of activation for the site exchange of the inequivalent ethyl groups was found to be 57.3 kJ mol^{-1}. Furthermore, the ^{1}H-NMR spectrum of **7** (400 MHz) in CD_2Cl_2 at 293 K displays two sets of resonances for the methyl and methylene groups indicating that rotation of the diethylamino group around the $C_{carbene}$–N bond is slow on the NMR time scale. The ^{1}H-NMR spectra of **6** and **7** show a singlet resonance at low field (**6**: $\delta = 10.56$; $\delta = 9.95$) for the proton bound to the carbene carbon atom. Accordingly, the carbene carbon resonances of **6** and **7** at $\delta = 248.7$ and 230.9 are split into doublets in the proton-coupled ^{13}C-NMR spectra. The ^1J(C,H) coupling constant of the 16e complex **6** is, at 140.1 Hz, of similar magnitude to that of the 18e complex **7** (144.2 Hz) and excludes any agostic interaction of the C–H bond with the metal center in **6**.[9,10] This is verified by the solid-state structure of **6** showing a W–$C_{carbene}$–N bond angle [W–C6–N1 = 129.2(6)°] in the range found for nondistorted carbene ligands (Figure

2).[10,11] The W−$C_{Carbene}$ bond of 2.065(7) Å is shorter than that of structurally related W^{II} aminocarbene complexes {e.g. [*cis*-Cp*$(CO)_2$(Cl)W=C(H)NEt_2]: W−C = 2.141(3) Å} due to the smaller covalent radius of tungsten(IV). The short $C_{carbene}$−N bond of 1.300(9) Å reflects the double-bond character of this bond in full agreement with the spectroscopic data of **6**. The plane of the aminocarbene ligand passing through the atoms W, C6, and N1 is almost perpendicular to the Cp* ring plane (dihedral angle between the best planes = 88.5°).

Conclusion

The carbyne−isocyanide coupling reaction of *cis*-Cp*$(Cl)_2$(*t*BuNC)W≡$CNEt_2$ (**3**) with HCl to give the alkyne complex Cp*$(Cl)_3$W[η^2-*t*Bu(H)NC≡$CNEt_2$] (**4**) shows that electrophilic activation of C_1 ligands related to carbon monoxide, is also possible at a metal center in high oxidation state and induces C−C bond formation. In comparison, the aminocarbyne complex *cis*-Cp*$(Cl)_2$[$P(OMe)_3$]W≡$CNEt_2$ (**5**) adds HCl to the metal−carbon triple bond to afford the 16e aminocarbene complex Cp*$(Cl)_3$W=C(H)NEt_2 (**6**) after elimination of $P(OMe)_3$. The reaction of **6** with *t*BuNC to give the 18e carbene complex [Cp*$(Cl)_2$(*t*BuNC)W=C(H)NEt_2]Cl (**7**) suggests that electrophilic activation of **3** occurs upon protonation of the isocyanide ligand at the nitrogen atom.

Experimental Section

General: Standard inert-atmosphere techniques were used for all syntheses and sample manipulations. The solvents were dried by standard methods (pentane with CaH_2, diethyl ether, THF and toluene with Na/benzophenone, CH_2Cl_2 with P_2O_5 and Na/Pb alloy) and distilled under argon prior to use. Column chromatography was carried out on a silanized silica support (Merck 7719; 0063−0.200 mm) as the stationary phase in a thermostated column of 15-cm length and 2-cm diameter. The silanized silica was dried in vacuo at 150°C prior to use. Complex **1**,[5b] $PhICl_2$,[12] and *t*BuNC[13] were prepared according to literature procedures. $P(OMe)_3$ was distilled under argon prior to use. All other chemicals were commercially available. − Elemental analyses were obtained from the Central Analytical Group of the Department of Chemistry of the Humboldt-Universität zu Berlin and the Microanalytical Laboratory of the Institute of Inorganic Chemistry of the Technische Universität München. − Solution IR spectra were recorded on a Bruker IFS-55 spectrometer using a NaCl cell. ^{1}H-, $^{13}C\{^1H\}$-, and $^{31}P\{^1H\}$-NMR spectra were recorded on a Bruker AM-300 or a Jeol GX-400 spectrometer in dry, deoxygenated [D_2]dichloromethane. The ^{1}H- and $^{13}C\{^1H\}$-NMR spectra were calibrated against the internal residual proton and natural-abundance ^{13}C resonances of the deuterated solvent ([D_2]dichloromethane, δ_H = 5.32 and δ_C = 53.8) and the $^{31}P\{^1H\}$-NMR spectra against an external 85% H_3PO_4 aqueous solution. − Mass spectra were obtained with a Hewlett−Packard 5995A or a Varian MAT 311 A spectrometer; *m*/*z* values are given relative to the ^{184}W and ^{35}Cl isotopes. − Melting points were determined using a Büchi 530 melting point apparatus and are not corrected. The samples were sealed under argon in capillary tubes and heated with a rate of 1 K min^{-1}. − IR spectra of the heated samples were recorded and compared with those of authentic samples to determine whether the compounds had decomposed.

***cis*-Cp*$(Cl)_2(CO)$W≡$CNEt_2$ (2):** A solution of **1** (0.46 g, 1.00 mmol) in 20 mL of CH_2Cl_2 was cooled to −78°C and treated with a solution of freshly prepared $PhICl_2$ (0.275 g, 1.00 mmol) in 10 mL of CH_2Cl_2. The reaction mixture was allowed to warm to room temperature and stirred for 2 h. Evolution of gas was observed and the color of the solution changed from intense yellow to violet. The complete conversion of **1** to **2** was confirmed by IR spectroscopy in the region of 2200−1500 cm^{-1}. The purple solution was concentrated in vacuo to a few milliliters and a diethyl ether/pentane mixture (1:1) was added to precipitate complex **2**. The supernatant solution was discarded and the residue was washed twice with 10 mL of a diethyl ether/pentane mixture (1:1) and dried in vacuo. Yield 0.44 g (88%), violet, microcrystalline solid, m.p. 176°C (decomp.). − IR (CH_2Cl_2): $\tilde{\nu}$ = 1986 cm^{-1}, vs [ν(CO)], 1600 s [$\nu(C_{carbyne}\cdots N)$]. − ^{1}H NMR (400 MHz, CD_2Cl_2, 293 K): δ = 1.32 [t, ^3J(H,H) = 7.3 Hz, 6 H, $N(CH_2CH_3)_2$], 2.05 (s, 15 H, C_5Me_5), 3.50 [q, ^3J(H,H) = 7.3 Hz, 4 H, $N(CH_2CH_3)_2$]. − $^{13}C\{^1H\}$ NMR: (100.6 MHz, CD_2Cl_2, 293 K): δ = 11.8 (C_5Me_5), 14.9 [$N(CH_2CH_3)_2$], 50.6 [$N(CH_2CH_3)_2$], 109.3 (C_5Me_5), 228.2 [CO, ^1J(W,C) = 135.6 Hz], 310.0 [W≡C, ^1J(W,C) = 210.0 Hz]. − EI-MS (70 eV): *m*/*z* = 473 [M^+ − CO], 444 [M^+ − CO − Et], 389 [M^+ − CO − Et − EtNC]. − $C_{16}H_{25}Cl_2NOW$ (502.14): calcd. C 38.27, H 5.02, Cl 14.12, N 2.79, O 3.19, W 36.61; found C 38.17, H 4.85, Cl 14.52, N 3.05, O 3.75, W 36.99%.

***cis*-Cp*$(Cl)_2$(*t*BuNC)W≡$CNEt_2$ (3):** A suspension of **2** (1.02 g, 2.03 mmol) in 50 mL of toluene was treated at ambient temperature with *t*BuNC (0.253 mL, 2.23 mmol) and then refluxed for 2 h. The color of the solution changed from violet to bright-red. An IR spectrum of the solution was recorded to confirm the complete conversion of **2** to **3**. The solution was then evaporated to dryness, the residue dissolved in a minimum amount of CH_2Cl_2 and the solution treated at −78°C with 10 mL of diethyl ether and 20 mL of pentane to precipitate complex **3**. This procedure was repeated once to afford **3** as a rose-colored, microcrystalline solid. − Yield 0.86 g (76%), m.p. 105°C. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2135 cm^{-1}, vs [ν(*t*BuN≡C)], 1571 s [$\nu(C_{carbyne}\cdots N)$]. IR (toluene): $\tilde{\nu}$ = 2129 cm^{-1}, vs [ν(*t*BuN≡C)], 1577 s [$\nu(C_{carbyne}\cdots N)$]. − ^{1}H NMR (300 MHz, CD_2Cl_2, 293 K): δ = 1.29 [t, ^3J(H,H) = 7.2 Hz, 6 H, $N(CH_2CH_3)_2$], 1.56 (s, 9 H, Me_3C), 1.98 (s, 15 H, C_5Me_5), 3.46 [q, ^3J(H,H) = 7.2 Hz, 4 H, $N(CH_2CH_3)_2$]. − $^{13}C\{^1H\}$ NMR: (75.5 MHz, CD_2Cl_2, 293 K): δ = 11.9 (C_5Me_5), 15.4 [$N(CH_2CH_3)_2$], 31.2 (Me_3C), 49.5 [$N(CH_2CH_3)_2$], 58.5 (Me_3C), 107.2 (C_5Me_5), 166.7 (Me_3CNC), 306.4 [W≡C, ^1J(W,C) = 223.3 Hz]. − $C_{20}H_{34}Cl_2N_2W$ (557.26): calcd. [Cp*(Cl)₂(*t*BuNC)₂W=C(H)NEt₂]Cl (7): A solution of **6** (0.125 g, 0.24 mmol) in 10 mL of CH_2Cl_2 was treated at room temperature with *t*BuNC (0.058 mL, 0.51 mmol). The color of the solution changed from red over green to orange. After 1 h stirring at room temperature the solution was evaporated to dryness, the residue dissolved in a minimum amount of THF and the product precipitated by addition of diethyl ether. Yield 0.136 g (82%), yellow solid, m.p. 102°C. − IR (CH_2Cl_2): $\tilde{\nu}$ = 2188 cm^{-1}, s, 2132 m [ν(*t*BuN≡C)], 1579 w [$\nu(C_{carbene}{\cdots}N)$]. − ^{1}H NMR (300 MHz, CD_2Cl_2, 293 K): δ = 1.32 [t, 3 H, ^3J(H,H) = 7.3 Hz, CH_2CH_3], 1.40 [t, ^3J(H,H) = 7.3 Hz, 3 H, CH_2CH_3], 1.56 (s, 18 H, 2 × CMe_3), 2.13 (s, 15 H, C_5Me_5), 3.84 (q, ^3J(H,H) = 7.3 Hz, 2 H, CH_2CH_3), 4.15 (m, 2H, CH_2CH_3), 9.95 (s, 1H, W=C*H*). − ^{13}C NMR (75.5 MHz, CD_2Cl_2, 293 K): 11.8 (C_5Me_5), 14.2 (CH_2CH_3), 14.5 (CH_2CH_3), 30.4 (CMe_3), 30.9 (CMe_3), 53.6 (CH_2CH_3), 58.4 (CH_2CH_3), 59.0 (CMe_3), 59.9 (CMe_3), 103.7 (C_5Me_5), 146.4 (*t*BuN*C*), 154.6 (*t*BuN*C*), 230.9 [W=*C*, ^1J(W,C) = 84.4 Hz; ^1J(C,H) = 144.2 Hz]. − $C_{25}H_{44}Cl_3N_3W$ (676.85): calcd. C 44.36, H 6.55, Cl 15.71, N 6.21; found C 44.40, H 6.61, Cl 15.59, N 5.83%.

X-ray Crystal-Structure Determination of 4 and 6: Data collection for **4** was performed on a CAD4-Enraf−Nonius and for **6** on a STOE STADI4 four-circle diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). After data reduction and LP correction the structures were solved with Patterson Methods (SHELXS-86)[14] and subsequent difference-Fourier synthesis (SHELXL-93).[15] Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-93). Non-hydrogen atoms were refined anisotropically, the atoms H1 in **4** and H6 in **6** were refined isotropically. All other hydrogen atoms were calculated using a riding model. Geometrical calculations were performed with PLATON[16] and illustrations with ZORTEP.[17]

Single crystals of **4** were obtained upon diffusion of diethyl ether into a solution of **4** in CH_2Cl_2 at −30°C; $C_{20}H_{35}Cl_3N_2W$ (593.70); crystal dimensions 0.6 × 0.3 × 0.2 mm; orthorhombic, space group $P2_12_12_1$ (Nr. 19), *a* = 9.460(2), *b* = 13.868(4), *c* = 17.056(3) Å, *V* = 2237.7(9) $Å^3$, *Z* = 4, $\rho_{calcd.}$ = 1.762 g cm^{-3}; *T* = 166 K, μ = 5.327 mm^{-1}, *F*(000) = 1176, ω-2Θ scan, 4° ≤ 2Θ ≤ 50°; 2321 total reflections, 2168 unique and 2161 with $I > 2\sigma(I)$, which were used for refinement; empirical absorption correction DIFABS (min. 0.876, max. 1.112);[18] residual electron density, min/max −0.359/0.389 e$Å^{-3}$; refinement of the 239 parameters resulted in R_1 = 0.0142, $wR_2(F^2)$ = 0.0312, GOF = 1.088.

Single crystals of **6** were obtained upon diffusion of diethyl ether into a solution of **6** in CH_2Cl_2 at −30°C; $C_{15}H_{26}Cl_3NW$ (510.57); crystal dimensions 0.5 × 0.4 × 0.3 mm; orthorhombic, space group *Pbca* (Nr. 61), *a* = 12.551(9), *b* = 15.487(10), *c* = 18.663(2) Å, *V* = 3628(4) $Å^3$, *Z* = 8, $\rho_{calcd.}$ = 1.870 g cm^{-3}; *T* = 190 K, μ = 6.553 mm^{-1}, *F*(000) = 1984, ω−2Θ −scan, 4° ≤ 2Θ ≤ 50°; 1984 total reflections, 1754 unique and 1745 with $I > 2\sigma(I)$, which were used for refinement; empirical absorption correction DIFABS (min. 0.906, max. 1.337); residual electron density, min/max −0.722/0.609 e$Å^{-3}$; refinement of the 185 parameters resulted in R_1 = 0.0269, $wR_2(F^2)$ = 0.0586, GOF = 1.134.[19]

Keywords: Macrocycles / Photochemistry / Fluorescence spectroscopy / Coordination chemistry / Zinc

The macrocyclic ligands **L2** and **L3**, containing a triethylenetetraamine and a tetraethylenepentaamine moiety linked to the methyl groups of 2,9-dimethyl-1,10-phenanthroline, bind H^+ and Zn^{2+} ions giving rise to modulation of the fluorescence emission intensity. The equilibrium constants and the enthalpy changes for ligand protonation were determined by means of pH-metric and microcalorimetric methods in 0.1 M Me_4NCl solutions at 298.1±0.1 K. Also the stability constants of the Zn^{2+} complexes were determined under the same experimental conditions. **L2** forms only mononuclear complexes, while **L3** also forms dizinc(II) species. The phenanthroline group has fluorescence emission properties, but interaction with the lone pairs of benzylic nitrogen atoms produces an efficient quenching of the emission. Such a quenching effect can be avoided by deactivation of the benzylic nitrogen atoms by means of protonation or Zn^{2+} complexation. Hence, **L2** and **L3** behave as chemosensor for H^+ and Zn^{2+}, the photochemical properties of the ligands being modulated by the formation of different protonated and complexed species. In the case of **L3**, the fluorescence emission is also controlled by the metal to ligand molar ratio, because of the formation of an emissive binuclear complex.

Introduction

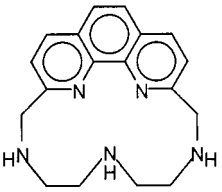
One of the most attractive methods to detect the presence of a chemical species in solution lies in the use of fluorescent receptors whose fluorescence emission is sensitive to the binding of the target substrate.[1−9] Either enhancement or quenching of the fluorescence emission signals can be observed upon substrate coordination, and can be used to quantify the receptor−substrate interaction.

Such *chemosensors*, namely molecules capable of binding substrates and at the same time signaling their presence, contain binding and signaling functions. Phenanthroline, for instance, is characterised by an intense fluorescence emission and contains two amine groups, which can act as binding sites for H^+ and metal cations, producing important modifications of the emission properties.[10] For this reason phenanthroline has attracted a great deal of interest in the last year for the preparation of efficient chemosensors. Nevertheless, this chelating ligand does not form stable complexes with a large number of metal cations and consequently its applicability as chemosensor is strongly reduced.

A convenient approach to prepare efficient chemosensors for metal cations consists in the association of the fluorescence emission properties of phenanthroline with the high stability conferred to metal complexes by macrocyclic ligands. For this purpose, we have synthesised the three macrocyclic ligands **L1**−**L3** containing a phenanthroline moiety and a polyaminic chain of increasing length and increasing number of nitrogen donor atoms.

In recent studies,[11−13] macrocyclic polyamines with similar structures but containing *p*-phenylene spacers instead of phenanthroline, have been used as chemosensors for binding H^+ and metal ions in solution. These ligands exhibit pH dependence of the fluorescence emission at room temperature, showing an increase in emission with increasing ligand protonation, and chelation enhancement of fluorescence (CHEF effect) in the presence of Zn^{2+}.

In the present paper we report the results of a thermodynamic and photochemical study of the binding of H^+ and Zn^{2+} cations by the phenanthroline derivatives **L1**−**L3**, showing that the insertion of different aromatic spacers in cyclic polyamines produces chemosensors characterised by significantly different photochemical properties. The results obtained with **L1** were published in a previous paper.[14]



Results and Discussion

Ligand Proton Transfer Properties

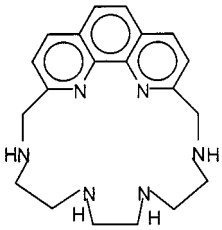


Table 1 lists the thermodynamic parameters (log*K*, $\Delta H°$, $T\Delta S°$) experimentally determined for the protonation reactions involving **L1**−**L3**. These data follow the trend found for the analogous polyazamacrocycles containing only secondary amine groups, characterised by decreasing protonation constants with increasing protonation degree, and largely favourable ($\Delta H° < 0$) enthalpic contributions to li-

L2

L3

gand protonation.[15] In particular the enthalpy changes found in each protonation step are significantly higher than the analogous values reported for the protonation of 2,9-dimethyl-1,10-phenanthroline (20 kJ mol^{-1}),[16] which can be considered the most appropriate reference compounds for the phenanthroline moiety of **L1**−**L3**, suggesting that such a moiety is not directly involved in the protonation processes, despite the fact they should be at least capable of assisting protonation of the secondary amine groups by means of hydrogen bonding, as observed in the crystal structure of the $[H_3\mathbf{L1}]Br{\cdot}H_2O$ salt.[14] The distribution of the protonated species formed at the different pH values by **L2** and **L3** is shown in Figure 1.

In order to ascertain the role played by the phenanthroline nitrogen atoms in the protonation of the present ligands, we have investigated the microscopic protonation sequence of **L1**−**L3** by recording their ^{1}H- and ^{13}C-NMR spectra in aqueous solutions at various pH values. All the assignments were made on the basis of ^{1}H-^{1}H homonuclear and ^{1}H-^{13}C heteronuclear correlation experiments at the different pH values studied. The results obtained for **L1** were presented in a recent report.[14] Accordingly, it was shown that the first proton binding of **L1** involved the central amine group of the ligand, while the second protonation produced a reorganisation of the proton distribution with localisation of the two H^+ ions on the benzylic nitrogens, and all three secondary amine groups are protonated in $[H_3\mathbf{L1}]^{3+}$.

Table 1. Thermodynamic parameters for the protonation of **L1**, **L2** and **L3** in 0.1 M Me_4NCl at 298.1 K[a,b]

[a] Values in parentheses are standard deviations in the last significant figure. − [b] Values for **L1** are taken from ref.[14]

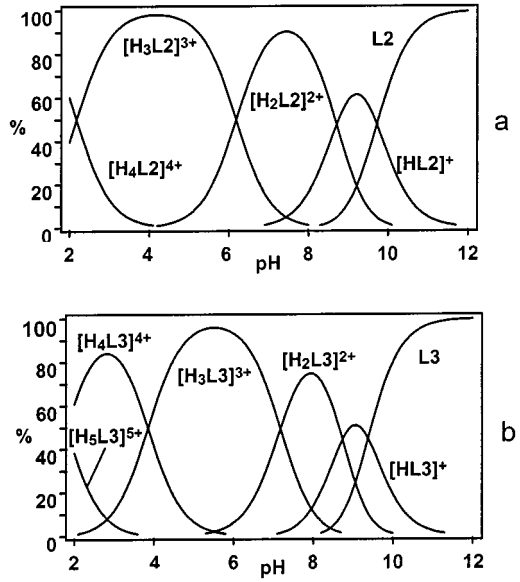

Figure 1. Distribution diagrams of the protonated species formed by **L2** and **L3** as a function of pH ([L] = 1×10^{-3} M, 0.1 M Me_4NCl, 298.1 K)

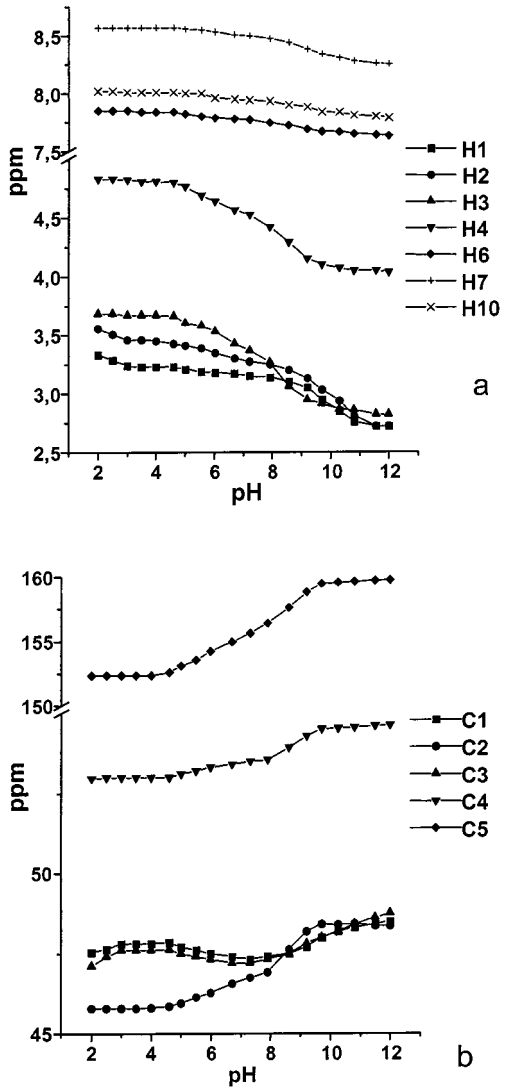
Figure 2a shows the ^{1}H-NMR spectra recorded at various pH values and Figure 2b reports ^{13}C-NMR chemical shifts of **L2** as a function of the pH value. The ^{13}C-NMR spectrum of **L2** at pH = 12.0, where the unprotonated amine predominates in solution (Figure 1), exhibited four peaks for the aliphatic carbons C1−C4, and six peaks for

the aromatic carbon atoms C5−C10. The ^{1}H-NMR spectrum of **L2** at this pH value showed a singlet at δ = 2.72 (integrating for four protons and assigned to the hydrogen atoms of the ethylenic chain H1), a multiplet at δ = 2.82 (eight protons, the hydrogen atom H2 and H3) and a singlet at δ = 4.03 (4 protons, H4). Also evident were a singlet at δ = 7.42 and two doublets at δ = 7.49 and δ = 8.04 for the aromatic protons H10, H6 and H7, respectively. These spectral features indicate a time-averaged C_{2v} symmetry. This symmetry is preserved throughout all the pH range investigated.



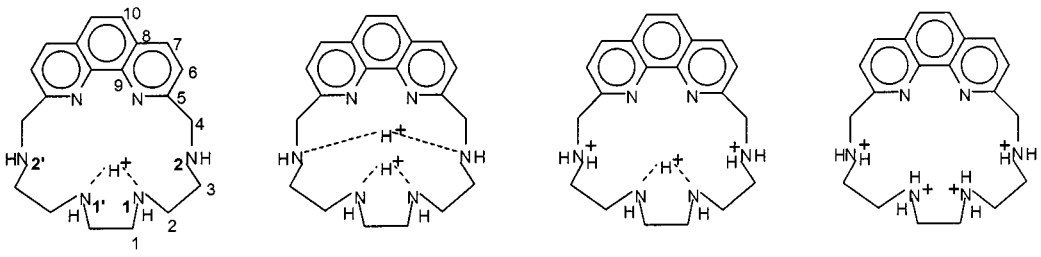


Figure 2. pH dependence of ^{1}H-NMR (a) and ^{13}C-NMR (b) chemical shifts of significant **L2** signals; for the sake of simplicity, the remaining ^{13}C-NMR signals are not reported since they do not shift significantly over the considered pH range 12−2: C6: δ = 124.3−124.4; C7: δ = 138.8−140.4; C8: δ = 128.8−130.2; C9: δ = 144.9−145.1; C10: δ = 127.0−128.3

In the pH range 11−9, where the first proton binds to the ligand (Figure 1), the signal of the hydrogen atoms H1 and H2 in the α-position with respect to N1 exhibits a downfield shift, while the other signals do not shift appreciably. This suggests that the first protonation step involves the nitrogen atoms N1 and N1′ (Scheme 1). This hypothesis is confirmed by the ^{13}C-NMR spectra recorded in the same pH range which show that the resonances of the carbon atoms C3 and C1, in the β-position with respect to N1 and N1′, respectively, shift upfield (Figure 2b), in good agreement with the β-shift reported for the protonation of polyamines.[15] This higher proton affinity of the nitrogen atoms N1 and N1′ in comparison with N2 and N2′ can be ascribed to the inductive effects of the heteroaromatic moiety on the adjacent N2 and N2′ amine groups.

In the pH range 9−7, the macrocycle binds a second proton, giving the $[H_2\mathbf{L2}]^{2+}$ species (Figure 1). The formation of this diprotonated form markedly affects the pattern of the ^{1}H- and ^{13}C-NMR spectra. In particular, the signals of H3 and H4 show a remarkable downfield shift (Figure 2a). On the other hand, the signals of H1 and H2 do not shift appreciably in this pH range. Considering the ^{13}C-NMR spectra (Figure 2b), the resonances of C2 and C5 in the β-position with respect to N2 exhibit a marked upfield shift. It is noteworthy that the β-shifts observed for signals of aromatic carbon atoms are more pronounced than those for aliphatic ones.[15] The same effect will be observed for **L3**. These spectral features indicate that the second protonation step takes place on the benzylic nitrogen atoms N2 and N2′, as shown in Scheme 1. As can be seen in Figure 1, **L2** is mainly in its triprotonated form in the pH range 6−2. The formation of the triprotonated species is accompanied by a marked downfield shift of the signals of H3 and H4 in the ^{1}H-NMR spectra, and by an upfield displacement of the resonances of C2 and C5 in the ^{13}C-NMR spectra. These observations indicate that the third protonation step occurs once again on the benzylic nitrogen atoms N2 and N2′. Therefore in the $[H_3\mathbf{L2}]^{3+}$ species both the benzylic nitrogen atoms are protonated and a proton is shared between the N1 and N1′ nitrogen atoms. The fourth protonation step takes place on the N2 and N2′ amine groups, as evidenced by the downfield shift of the signals of H1 and H2 at pH < 3.

It is interesting to note that the signals of the aromatic protons H7 and H10 undergo a small, but significant, downfield shift from alkaline to acidic pH. A similar, although less evident behaviour of the ^{1}H-NMR signals of aromatic protons was observed for **L1**,[14] and ascribed to the involvement of phenanthroline nitrogen atoms in stabilising the protonated forms by means of hydrogen bonding and/or partial delocalisation of the acidic protons, which are expected to increase with decreasing pH value. The same explanation applies for **L2**.

L3 shows a similar protonation mechanism. In this case, the macrocycle also presents a time-averaged C_{2v} symmetry in aqueous solution, throughout all the pH ranges investigated. Figures 3a and 3b show the ^{1}H- and ^{13}C-NMR spectra, respectively, recorded at various pH values. In the pH range 10−8, where the first two protons bind to the ligand (Figure 1), the signals of the hydrogen H1 in the α-position with respect to N1, as well as those of H2 and H3, in the α-position with respect to N2, exhibit a downfield shift,

$[HL2]^{+}$ $[H_2L2]^{2+}$ $[H_3L2]^{3+}$ $[H_4L2]^{4+}$

Scheme 1

while the other signals do not shift appreciably, indicating that the first two protonation steps involve the nitrogen atoms N1, N2 and N2′ (Scheme 2). This hypothesis is confirmed by the ^{13}C-NMR spectrum recorded in the same pH range, which shows that the resonances of the carbon atom C2, in the β-position with respect to N1, as well as the signals of C1 and C4, in the β-position with respect to N2, shift upfield (Figure 3).

In the pH range 8−5, the macrocycle binds a third proton, giving the $[H_3\mathbf{L3}]^{3+}$ species (Figure 1). The most significant effect in the ^{1}H-NMR spectrum is the remarkable downfield shift of the signal of H5 (Figure 3a). Considering the ^{13}C-NMR spectrum (Figure 3b), the resonance of C2 in the β-position with respect to N1, as well as the signals of C3 and C6, in the β-position with respect to N3 exhibit a marked upfield shift. On the contrary, the signals of C1 and C4, in the β-position with respect to N2, shift downfield. These spectral features indicate that in the $[H_3\mathbf{L3}]^{3+}$ species the acidic protons are located on the N1, N3 and N3′ nitrogen atoms. Since the protons occupy alternate positions, separated by either the aromatic moiety or the unprotonated N2 and N2′ amine groups, such a disposition would mean a minimum in electrostatic repulsion, resulting in a stabilisation of the $[H_3\mathbf{L3}]^{3+}$ species, which is prevalent in aqueous solution in a wide pH range (pH = 7.5−4). At pH < 5, the macrocycle binds a fourth proton. As shown in Figure 3b, in the pH range 5−2, a remarkable upfield shift of the signals of the carbon atoms C4 and C1in the β-position with respect to N2 is observed. On the contrary, the resonance of C2 shifts downfield. These data indicate that in the $[H_4\mathbf{L3}]^{4+}$ species, the four acidic protons are positioned on the N2, N2′, N3 and N3′ nitrogen atoms.

On the other hand, in the case of **L3**, the signals of the aromatic protons (H7, H8, H10) in the ^{1}H-NMR spectrum shift downfield on lowering the solution pH. Such a shift, although more pronounced than for **L2**, is rather modest when compared to the shifts experienced by the aliphatic protons, but is indicative, as observed for **L1** and **L2**, of some involvement of phenanthroline nitrogen atoms in stabilising the protonated forms by means of hydrogen bonding and/or partial delocalisation of the acidic protons. As shown below, such modest involvement of phenanthroline nitrogen−proton binding contributes significantly to the luminescent behaviour of these ligands.

Actually, the fluorescence emission is very sensitive to the protonation state of these molecules. The shape and the position of the fluorescence emission spectra of **L2** and **L3** are identical to those of phenanthroline but, as previously observed for **L1**,[14] the intensity of the emission increases with decreasing pH, decreasing again in very acidic solutions (Figure 4). The position of the spectra are maintained over all the pH ranges. In other words, for these types of macrocyclic polyamines, protonation increases the emission intensity, but the fully protonated species are not the most emissive forms, as otherwise observed for polyazacyclophanes.[11−13] As a matter of fact, the decrease in intensity of fluorescence emission in very acidic solution coincides with the formation of the $[H_4\mathbf{L2}]^{4+}$ and $[H_5\mathbf{L3}]^{5+}$.

This quenching effect found at low pH values is more marked for **L3** than for **L2** (Figure 4), while it is less evident for **L1**. To explain these features, we must consider that quenching of fluorescence emission in these molecules can be achieved by: i) interaction of the phenanthroline nitrogen atoms with positively charged species, such as H^+, leading to a relative stabilisation of the weak emissive $n\pi^*\rightarrow$gs state in comparison with the strong emissive $\pi\pi^*\rightarrow$gs one; as already found for **L1**,[14][17] this interaction can explain the quenching observed at very acidic pH values; ii) electron-transfer processes from the lone pairs of the amine groups to the excited state of phenanthroline, a phenomenon that can account for the quenching owing to the deprotonation of polyamines. In the case of **L1**, it was suggested that the amine groups responsible for type-ii quenching are the benzylic ones. This hypothesis is confirmed by the pH dependence of the fluorescence emission of **L2** and **L3**. As can be seen in Figure 4, where the intensity of the emission is superimposed on the species distribution diagram of the protonated species formed as a function of pH, the most emissive species are $[H_3\mathbf{L2}]^{3+}$, $[H_3\mathbf{L3}]^{3+}$ and $[H_4\mathbf{L3}]^{4+}$, in agreement with the NMR-spectroscopic results indicating that the benzylic nitrogen atoms are protonated in these species. However, in the fully protonated forms the benzylic

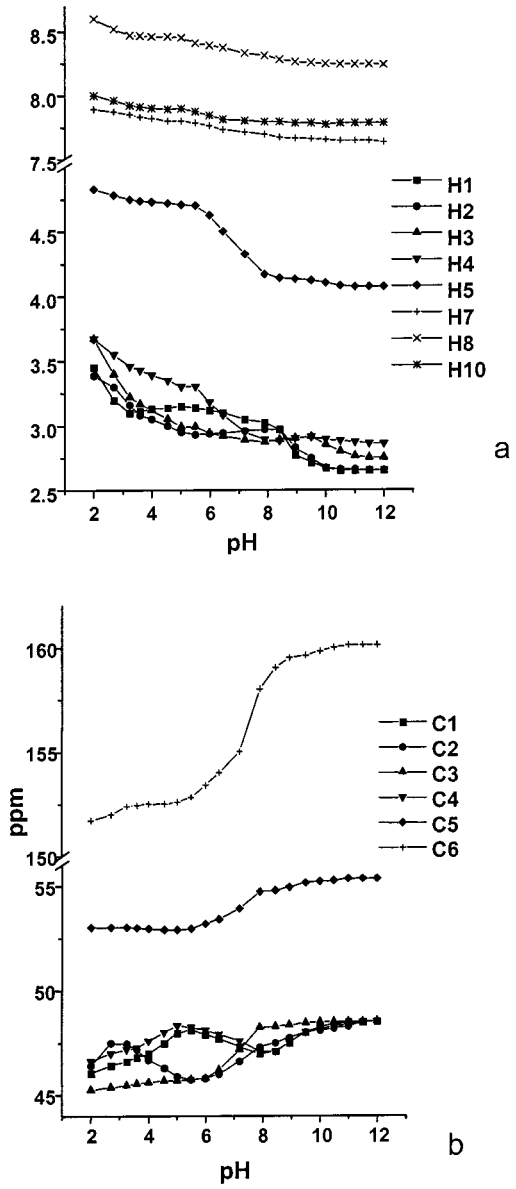

Figure 3. pH dependence of ^{1}H-NMR (a) and ^{13}C-NMR (b) chemical shifts of significant **L3** signals; for the sake of simplicity, the remaining ^{13}C-NMR signals are not reported since they do not shift significantly over the considered pH range 12−2: C7: δ = 124.6−124.3; C8: δ = 138.9−140.2; C9: δ = 128.8−130.2; C10: δ = 145.1−145.1; C11: δ = 127.2−128.4

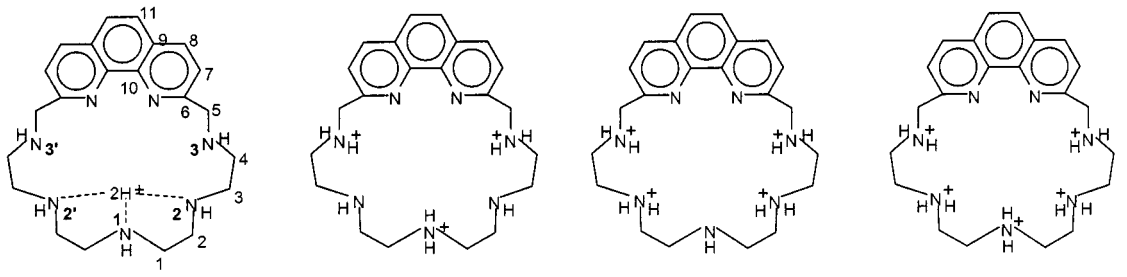
nitrogen atoms are also protonated, but the increasing involvement of the phenanthroline nitrogen atoms in stabilising the protonated forms by means of hydrogen bonding and/or delocalisation of H^+ ions quench the fluorescence emission. This quenching effect (type i) increases in the order **L1** < **L2** < **L3** along with the overall number of H^+ ions binding the receptors. Such behaviour is also in accordance with the shifts observed in the absorption spectra; as already observed for **L1**, by increasing the pH value, a red shift is observed, except for very acidic solutions where the opposite effect occurs. Similar two-valley one-peak profiles of the fluorescence intensity were recently observed for the protonated species of acyclic amines containing pyridyl and anthracene frangments.[4a]

Zn^{2+} Complexation in Solution



The stability constants of the complexes formed by **L2** and **L3** with Zn^{2+} are listed in Table 2, together with the analogous data[14] previously reported for **L1**, while the distribution diagrams of the complexes formed as a function of the pH value for equimolar concentrations (1×10^{-3} M) of ligands and metal ion are shown in Figure 5. From these data it is evident that increasing the dimensions of the ligand from **L1** to **L3** by inserting additional amine groups gives rise to: i) decreasing stability of the $[ZnL]^{2+}$ complex; ii) increasing ability to form protonated complexes; and iii) formation of binuclear complexes.

Comparison of the stability constant of $[Zn\mathbf{L1}]^{2+}$ with the stability constant of the analogous complex with the pentaazamacrocycle 1,4,7,10,13-pentaazacyclopentadecane suggested[14] that the lower stability of the **L1** complex could be explained by considering that some donor atoms of the **L1** complex are not involved, or are weakly involved, in the coordination to the metal ion. This suggestion was supported by the crystal structure of the $[Zn\mathbf{L1}H_2O]^{2+}$ complex which showed the metal ion in a distorted tetrahedral coordination environment defined by the phenanthroline nitrogen atoms, the central aliphatic nitrogen atom and a water molecule, the two benzylic nitrogen atoms interacting weakly at a large distance (ca. 2.5Å).[14]

The decreasing stability trend observed for the $[ZnL]^{2+}$ complexes with **L1**−**L3** indicates that the presence of a larger number of donor atoms does not enhance the binding ability of such ligands toward Zn^{II}, suggesting that the number of donor atoms participating in the coordination does not parallel the increasing number of donors in the ligands. Hence, a larger number of donors not involved in the coordination determines the formation of larger, less stable chelate rings, which reduce the complex stability. On the other hand, an increasing number of uncoordinated amine groups favours the formation of protonated complex species, as actually observed, and allows the complex of the larger ligand **L3** to have enough free donor atoms to bind a further metal ion.

Notwithstanding that, **L3** does not exhibit a marked tendency to bind the second metal ion, as revealed by the value of the relevant equilibrium constant {$\log K = 4.39(6)$ for $[ZnL]^{2+} + Zn^{2+} = [Zn_2L]^{4+}$; Table 2} and displayed in Figure 5b by the low percentage of $[Zn_2\mathbf{L3}]^{4+}$ (maximum 15%) formed in the presence of equimolar concentrations (1×10^{-3} M) of ligands and metal ion. The three ligands also seem to have different characteristics in the formation of hydroxylated complexes (Table 2), but positive conclusions on this aspect cannot be drawn, considering the restricted pH range (2.5−8) in which it was possible to study complexation with **L3** (see Experimental Section).

Information concerning the donor atoms involved in the coordination to Zn^{2+} are furnished by the emission properties of these complexes. Figure 6 displays the fluorescence emission behaviour of the Zn^{2+}/**L2** system in the pH range 2−8; the emission curve in this Figure is superimposed on the species distribution diagram of the system. The emis-

sion in the pH range in which no complex formation occurs (pH = 2–3.5) is determined by the emission properties of the free ligand protonated species previously described. Taking into account such emission properties of the ligand protonated species, the emission curve in Figure 6 can be fitted, considering all uncomplexed and complexed species, showing that the $[ZnH\mathbf{L2}]^{3+}$ complex is an emissive species, the quantum yield being slightly lower than for $[H_3\mathbf{L2}]^{3+}$, while $[Zn\mathbf{L2}]^{2+}$ determines a quenching effect. The same characteristic was observed for $[Zn\mathbf{L1}]^{2+}$.[14] In that case it was verified that the quenching effect is independent of the coordination of the phenanthroline nitrogen atoms to Zn^{2+}, but it is determined by electron transfer from the lone pairs of the benzylic amine groups to the excited state of phenantroline. Hence, quenching of the fluorescence emission can be prevented by "neutralisation" of the lone pairs of the benzylic nitrogen atoms, which can be attained by both protonation, as discussed above, and Zn^{2+} complexation. Tak-

ing into account these considerations, we deduce that in the not-emissive $[ZnL2]^{2+}$ species the benzylic nitrogens are not involved, or not fully involved, in metal ion coordination, while in the emissive $[ZnHL2]^{3+}$ complex these nitrogen atoms are involved in the binding of H^+ and Zn^{2+}.

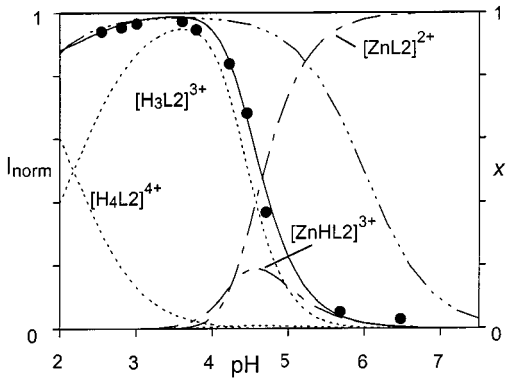

Figure 6. Fluorescence emission profile (•) of the system **L2**/Zn^{2+} as a function of pH and molar fractions of the species formed in the examined solution ([L] = $[Zn^{2+}]$ = 2×10^{-5} M, 0.1 M Me_4NCl, 298.1 K); the dotted-dashed line is the fluorescence profile in the absence of a metal ion

Similar considerations can be used to explain the fluorescence emission properties of the Zn^{2+}/**L3** system (Figure 7). In this case, the formation of both mono- and binuclear complexes must be considered. Spectrofluorimetric measurements performed with a solution containing Zn^{2+} and **L3** in 1:1 and 2:1 molar ratios, at different pH values, showed that $[ZnH_2L3]^{4+}$ and $[Zn_2L3]^{4+}$ are emissive species, the second one being significantly less efficient. Fitting of the fluorescence emission curves in Figure 7 was achieved taking into account the contributions deriving from the protonated forms of **L3** determined in the absence of a metal ion. The nonemissive character of the $[ZnL3]^{2+}$ complex reveals that, as already observed for the analogous complexes with **L1** and **L2**, the benzylic nitrogen atoms of the ligand are not involved, or at most are partially involved, in the coordination, in agreement with the conclusion previously drawn on the basis of the equilibrium data. In this case, even protonation of the complex leading to the $[ZnHL3]^{3+}$ species does not deactivate the quenching properties of the benzylic nitrogen atoms, and fluorescence emission is observed only when the diprotonated complex $[ZnH_2L3]^{4+}$ is formed. The quantum yield of this species is almost identical to that found for $[H_3L3]^{3+}$ in which the benzylic nitrogen atoms are protonated. On the other hand, the quantum yield of the binuclear complex $[Zn_2L3]^{4+}$ is about fivefold lower, indicating that the deactivation of the benzylic nitrogen atoms determined by the two metal ions is not complete. Considering the particular reluctance of benzylic nitrogen atoms to participate in the formation of mononuclear complexes, resulting from the molecular rigidity around the phenanthroline moiety, we can also expect that in the formation of the binuclear $[Zn_2L3]^{4+}$ species, the ligand suffers serious strain preventing the full involvement of benzylic nitrogen lone pairs in coordination.

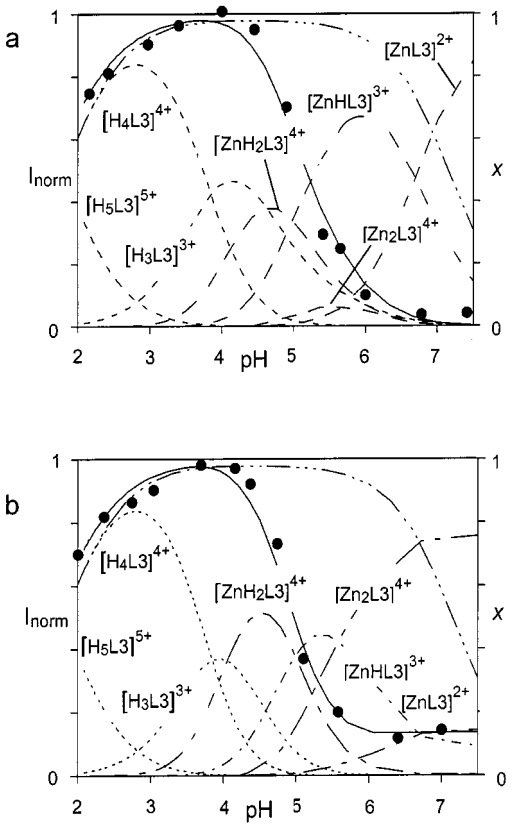

Figure 7. Fluorescence emission profile (•) of the system **L3**/Zn^{2+} as a function of pH and molar fractions of the species formed in the examined solutions; a: [L] = $[Zn^{2+}]$ = 2×10^{-5} M; b: [L] = 2×10^{-5} M, $[Zn^{2+}]$ = 4×10^{-5} M; 0.1 M Me_4NCl, 298.1 K; the dotted-dashed line is the fluorescence profile in absence of metal ion

Conclusion

Insertion of the large and rigid phenanthroline unit into macrocyclic structures leads to strained ligands, such as **L1**−**L3**, in which the simultaneous coordination of all donor atoms to a single metal ion is precluded. In the case of **L1**−**L3**, the benzylic nitrogen atoms in close proximity to the phenanthroline unit are not involved in the coordination to the metal ion in the $[ZnL]^{2+}$ complexes, independently of the number of donor atoms and ligand size.

The phenanthroline groups have fluorescence emission properties, but interaction with the lone pairs of benzylic nitrogen atoms produces an efficient quenching of the emission. To avoid such a quenching effect, the benzylic nitrogen atoms can be deactivated by protonation or Zn^{2+} complexation. Hence, **L1**−**L3** behave as chemosensors for H^+ and Zn^{2+}, the emissive properties of the ligands being modulated by the formation of different protonated and complexed species. The ability of Zn^{2+} to form nonemissive species (chelation enhancement of quenching, CHEQ) is a peculiarity of these ligands. The opposite effect (chelation enhancement of fluorescence, CHEF) is commonly ob-

served[11−13] with other families of polyamine ligands. In the case of the larger **L3** ligand, the fluorescence emission is also controlled by the molar metal-to-ligand ratio, because of the formation of the emissive $[Zn_2\mathbf{L3}]^{4+}$ species.

Experimental Section

General Procedures and Materials: Ligands **L1**−**L3** were synthesised as reported[18] and used in the form of their hydrobromic salts. All pH-metric measurements (pH = −log [H^+]) employed for the determination of ligand protonation constants and Zn^{2+} complexation constants were carried out in 0.1 M Me_4NCl solutions at 298.1±0.1 K, by using the equipment and the methodology that has been already described.[19] The combined Ingold 405 S7/120 electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free NaOH solutions and determining the equivalent point by Gran's method[20] which allows one to determine the standard potential $E°$ and the ionic product of water [pK_w = 13.83(1) at 298.1±0.1 K in 0.1 M Me_4NCl]. At least three measurements (about 100 data points each) were performed for each system in the pH ranges 2.5−10.5 (2.5−8 for Zn^{2+}/**L3** owing to precipitation occurring at higher pH values). In all experiments the ligand concentration [L] was about 1×10^{-3} M, while in the complexation experiments, the Zn^{2+} concentration was varied in the range 0.8[L] < [Zn^{2+}] < 1.5[L]. The computer program HYPERQUAD[21] was used to calculate both protonation and complexation constants from emf data. The enthalpies of ligand protonation were determined in 0.1 M Me_4NCl solution by means of an automated system composed of a Thermometric AB thermal activity monitor (model 2277) equipped with a perfusion-titration device and a Hamilton Pump (model Microlab M) coupled with a 0.250-mL gas-tight Hamilton syringe (model 1750 LT). The measuring vessel was housed in a 25-L water thermostat which was maintained at the chosen temperature within $\pm2\times10^{-4}$ K. The microcalorimeter was checked by determining the enthalpy of reaction of strong base (NaOH) with strong acid (HCl) solutions. The value obtained, −13.55(5) kcal mol^{-1} was in agreement with the literature value.[16] − In a typical experiment, an Me_4NOH solution (0.1 M, addition volumes 15 μL) was added to acidic solutions of the ligands (5×10^{-3} M, 1.5 mL). − Corrections for the heats of dilution were applied. The corresponding enthalpies of reaction were determined from the calorimetric data by means of the AAAL program.[22] At least three titrations (about 120 data points) were performed for each system. − 200.0-MHz ^{1}H- and 50.32-MHz ^{13}C-NMR spectra in D_2O solutions at different pH values were recorded at 298 K with a Bruker AC-200 spectrometer. In ^{1}H-NMR spectra, peak positions are reported relative to HOD at δ = 4.75. Dioxane was used as reference standard in ^{13}C-NMR spectra (δ = 67.4). ^{1}H-^{1}H and ^{1}H-^{13}C 2D correlation experiments were performed to assign the signals. Small amounts of 0.01 M NaOD or DCl solutions were added to a solution of the ligand to adjust the pD value. The pH value was calculated from the measured pD values using the following relationship:[23] pH = pD − 0.40. Spectrophotometric and spectrofluorimetric titrations were performed in 0.1 M Me_4NCl solutions at 298.1±0.1 K with a Perkin−Elmer Lambda-6 spectrophotometer and with a SPEX F111 Fluorolog spectrofluorimeter, respectively. The sample-pH values, measured by means of a Metrohm 713 pH-meter, were adjusted by appropriate additions of $HClO_4$ and NaOH solutions.

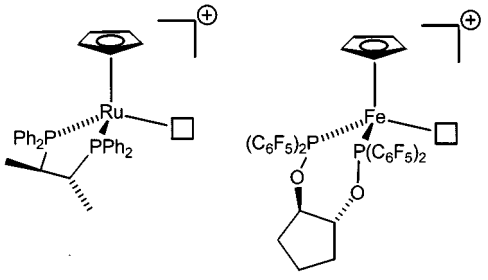
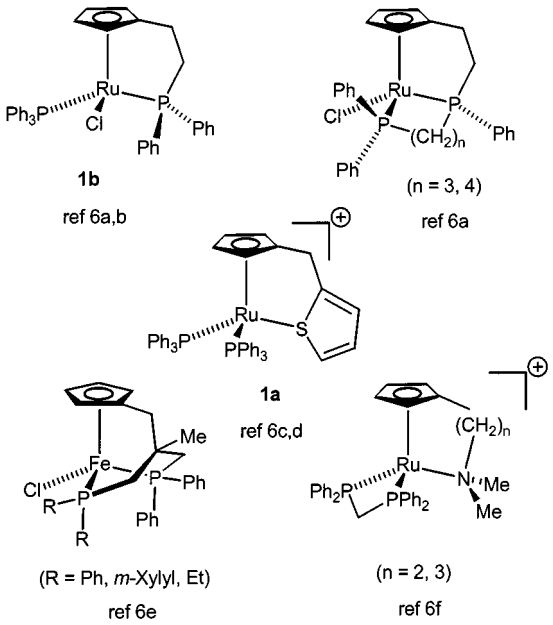
Synthesis and Properties of Chiral Ruthenium Complexes Containing *O*-, *S*- and *P*-Functionalized Cp-Ligands

Adolphus A. H. van der Zeijden,*[a] Jhonny Jimenez,[a] Chris Mattheis,[a] Christoph Wagner,[b] and Kurt Merzweiler[b]



Keywords: Ruthenium / Chirality / Cyclopentadienyl complexes / Kinetics / Asymmetric catalysis

Novel, functionalized, chiral Cp-ligands with S- and P-donor atoms were designed. Together with known analogues containing ether side-chains they were complexed to ruthenium for use as chiral Lewis-acid catalysts. In the ether complexes [RuCl(η^5-$C_5H_4CH_2CH_2OR$)(PPh_3)$_2$] {R = Me, (1*S*)-isobornyl, (1*R*)-menthyl, (1*R*)-fenchyl} the Cp-ligand is only η^5-coordinated; all attempts to provoke a bidentate, Cp/O coordination were unsuccessful. The sulfide complex [Ru{η^5:η^1-$C_5H_4CH_2CH_2S$[(1*R*)-neomenthyl]}(PPh_3)$_2$][OTf] contains a bidentate Cp/S-coordinated ligand, but it is unstable. The stable phosphane complex [RuCl(η^5:η^1-$C_5H_4CH_2CH$(Me)-PPh_2)(PPh_3)] exists as a 77:23 mixture of diastereomers containing a strongly bidentate Cp/P ligand. The diastereomers interchange, with Ru–Cl bond cleavage as the rate-determining step.

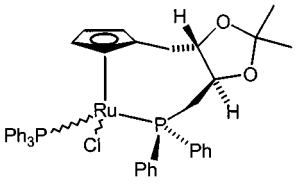


Introduction

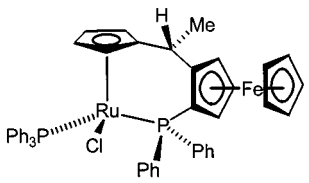
The use of chiral Lewis acids in organic transformations is mainly confined to derivatives of the elements aluminium, boron, and titanium.[1] The use of other transition metals is very limited mainly because of their reduced Lewis acidity.[2] However, with a proper choice of ligands (notably π-acceptor ligands like NO and CO) and a positive charge, complexes can be obtained with quite high Lewis-acidities {e.g. $Cp(CO)_2Fe^+$}.[3] Moreover, the use of transition metals offers a greater choice of ligands, and therefore more possibilities for (chiral) modifications, than the classical main group and d^0-metal complexes. Last but not least, transition metal Lewis acids are generally much less sensitive to water. The 16-electron half-sandwich complexes of type $CpM(L)_2^+$ (M = Fe, Ru; L = CO, phosphane) have been thoroughly studied as Lewis-acid catalysts especially for the Diels–Alder reaction.[3c,f] Chiral modifications have been synthesized using bidentate diphosphane ligands.[4]

We pursue another strategy, in that we connect a Cp-ring with a chiral functional group capable of intramolecular coordination.[5] Examples of group 8 metal complexes containing Cp-ligands with phosphorous (**1b**), sulfur (**1a**) and amine side-chains are known.[6]

ref 4a ref 4b



Until recently, only two examples of enantiopure systems were known.[7a,b]



A very recent paper by Trost describes the design of a whole range of chiral, functionalized Cp-ligands as well as the synthesis of their ruthenium derivatives.[7c] In an extension of this work we present our efforts on the synthesis and use of chiral ruthenium complexes using the known ether ligands $C_5H_5CH_2CH_2OR$ {R = Me (**2a**), isobornyl (**2b**), menthyl (**2c**), fenchyl (**2d**)},[5c,d] the newly developed

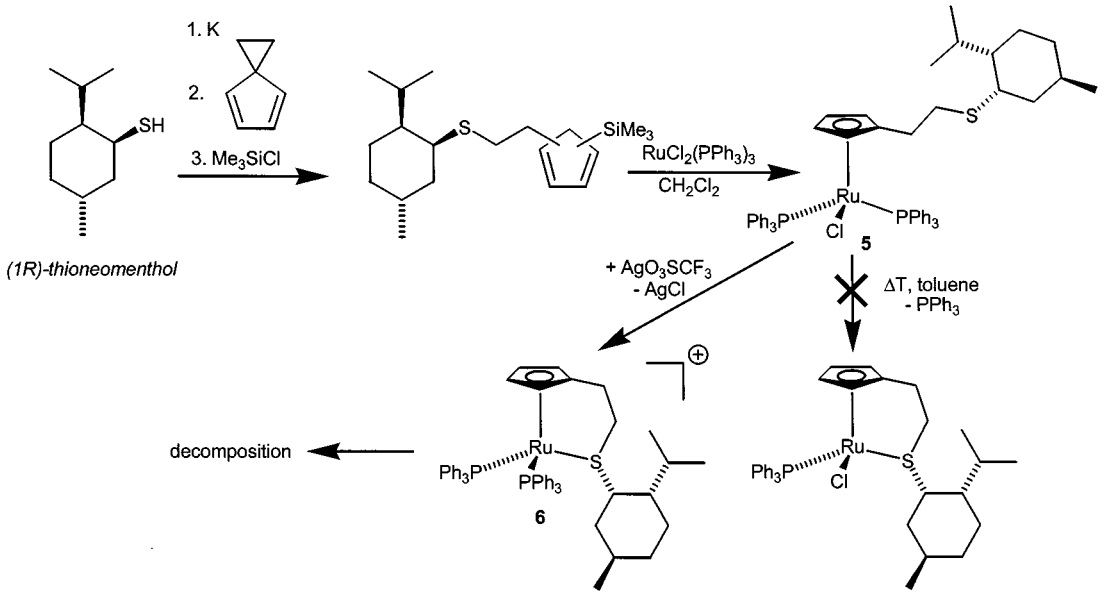
chiral sulfur ligand $C_5H_5CH_2CH_2S$[(*1R*)-neomenthyl] and the phosphorous ligand *(S)*-$C_5H_5CH_2CH(Me)PPh_2$. Special interest is also focused on the stereochemical rigidity of the ruthenium center.

Results and Discussion

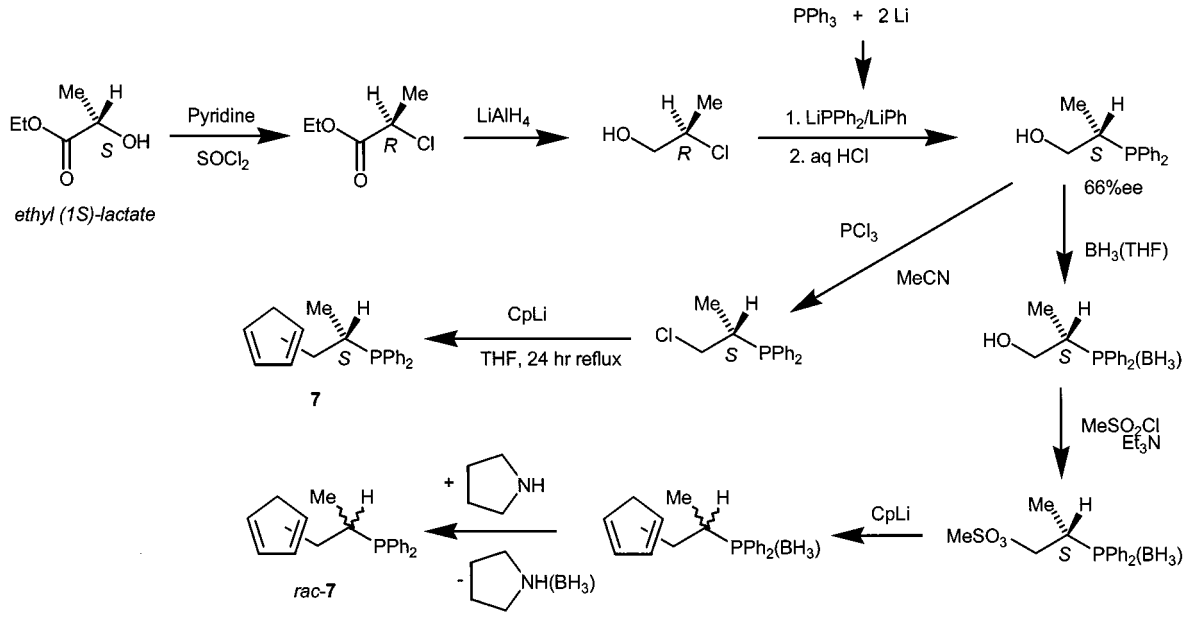
According to the procedure of Kauffmann the ether ligands $C_5H_5CH_2CH_2OR$ {R = Me (**2a**), (1*S*)-isobornyl (**2b**)} were reacted with $RuCl_2(PPh_3)_3$ (Scheme 1),[6a] affording $[RuCl(\eta^5\text{-}C_5H_4CH_2CH_2OR)(PPh_3)_2]$ (**3a**, **3b**) in moderate yield. Much better yields were obtained when using the Me_3Si-derivative of the Cp-ligand affording **3a** (R = Me), **3c** {R = (1*R*)-menthyl} and **3d** {R = (1*R*)-fenchyl}. The complexes were characterized by their elementary analyses and their ^1H, ^{31}P and ^{13}C NMR spectra (see supplementary material).



Coordination of the ether-moiety should be revealed by low-field shifts in the ^1H and ^{13}C NMR spectra of the CH_2OCH moieties,[5d] and this is not the case.[9] Moreover, *O*-coordination in the isobornyl derivative **3b** is expected to result in ether cleavage with formation of camphene, and this is also not observed.[5d] The problem is not steric in nature, since the small, achiral methyl ether ligand in **3a** and **4a** doesn't coordinate either. There is obviously a reluctance of the "hard" ether moieties to coordinate to the 'soft' ruthenium center. We therefore concentrated further efforts on the design of Cp-ligands with the "soft" donor atoms sulfur and phosphorous.

A new Cp-ligand with a chiral sulfide side-chain was prepared as outlined in Scheme 2. Its synthesis is based on a method developed by Kauffmann involving a nucleophilic ring-opening reaction of spiro[2.4]hepta-4,6-diene.[10a,b] The potassium salt of (1*R*)-neomenthanethiol[10c,d] was used as the nucleophile. The resulting potassium cyclopentadienide was directly converted into the trimethylsilyl derivative and reacted with $RuCl_2(PPh_3)_3$ affording $[RuCl\{\eta^5\text{-}C_5H_4CH_2CH_2S[(1R)\text{-neomenthyl}]\}\{PPh_3)_2]$ (**5**) in good yield. The chiral ruthenium complex was characterized by its elemental analysis and ^1H, ^{13}C and ^{31}P NMR spectra. As for the ether analogues **3**, the side-chain is not coordinated to the ruthenium center. In this case also prolonged heating in toluene does not result in substitution of one of

Scheme 1. Ruthenium chemistry of the ether-derived Cp ligands



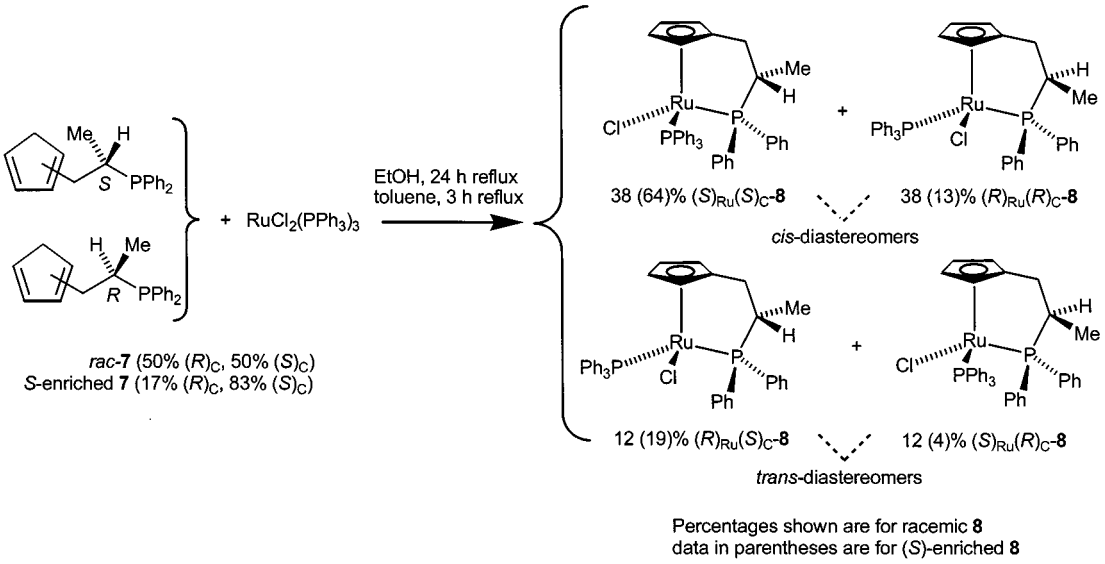
The analytical data indicate that the ether handle in **3** is not coordinated. Prolonged heating of **3** in toluene does not result in expulsion of one of the coordinated PPh_3 ligands (Scheme 1) and subsequent coordination of the ether handle. In another attempt to coordinate the ether handles, and in view of the existence of $[CpRu(PPh_3)_2(THF)][PF_6]$[8], the triflate complexes **4a–c** were synthesized (Scheme 2). the phosphane ligands by the sulfide moiety. Reaction of **5** with AgOTf yields the triflate complex $[Ru\{\eta^5\text{:}\eta^1\text{-}C_5H_4CH_2CH_2S[(1R)\text{-neomenthyl}]\}\{PPh_3)_2][OTf]$ **6**. In contrast to the ether homologues **4**, there is clear evidence for intramolecular coordination of the sulfide side-chain in **6**, and a cationic structure similar to **1a** is proposed.[6c] In comparison to the signals of **5**, low-field shifts are observed

Scheme 2. Synthesis of a chiral sulfur-based Cp ligand and its ruthenium complexes

for the nuclei of the SCH_2-moiety in **6** (^{1}H NMR: from 2.5−2.7 to 3.6−3.9 ppm. ^{13}C NMR: from 31.8 to 53.9 ppm). There is also a smaller low-field shift in the ^{13}C NMR spectrum for the adjacent SCH moiety from 46.5 to 49.9 ppm, whereas the signal shifts to *high*-field in the ^{1}H NMR spectrum (from 3.14 to 2.53 ppm). This contrasting observation may be due to the proximity of the phenyl rings of the PPh_3 ligands causing ring-current shielding. Further evidence for intramolecular coordination of the sulfide moiety comes from the ^{31}P NMR spectrum of **6**, in which the proximity of the chiral neomenthyl moiety causes a clear diastereotopic splitting of the signals of the two PPh_3 ligands ($^2J_{PP}$ = 36 Hz). Unfortunately, complex **6** is unstable and decomposes within a few hours at room temperature, possibly by S−C bond scission. We were therefore unable to use **5** or **6** as an asymmetric Lewis acid catalyst, and therefore concentrated our further efforts on the design of chiral phosphorous ligands.

A novel chiral Cp/phosphane ligand *(S)*-$C_5H_5CH_2CH(Me)PPh_2$ (**7**) was synthesized by the pathway outlined in Scheme 3. The starting material, (*S*)-ethyl lactate, was first converted into (*R*)-$HOCH_2CH(Me)Cl$ according to the literature.[11] The reaction with a mixture of Ph_2PLi and PhLi (prepared in situ from PPh_3 and lithium), after the method developed by Pringle,[12] afforded (*S*)-$HOCH_2CH(Me)PPh_2$ in excellent yield.[13][14] The crude material had an *ee* of 60% by optical rotation {the actual *ee* was 66% (*S*/R = 83:17), vide supra}. As the reaction

Scheme 3. Synthesis of a chiral lactic acid based Cp/phosphane ligand



pathway involves two S_N2 reactions (Scheme 3), at least one of them apparently did not proceed with complete inversion at the stereogenic carbon center.

The conversion of the hydroxy functionality into a leaving group (in order to react it with CpLi) without oxidation of the phosphane is quite difficult.[15] Therefore, the phosphane moiety was protected through coordination with borane.[15] The alcohol could then be converted into the mesylate ester. Subsequent reaction with CpLi {curiously, CpNa mainly results in elimination and formation of $H_3BP(allyl)Ph_2$} and decomplexation of borane with pyrrolidine affords $C_5H_5CH_2CH(Me)PPh_2$ (**7**). However, this substance is a racemate, which we discovered after its complexation with ruthenium (vide infra). Racemization probably occurred during the reaction with CpLi by (reversible) deprotonation of the stereogenic carbon which is activated by complexation of BH_3.[16]

Fortunately, we found a method to chlorinate (*S*)-$HOCH_2CH(Me)PPh_2$ without oxidation of the phosphane. The reagent of choice was PCl_3 and, in the presence of excess Et_3NHCl and using acetonitrile as a solvent, (*S*)-$ClCH_2CH(Me)PPh_2$ is obtained in 60−70% yield. The reaction with CpLi afforded **7** in moderate yield, but with 66% *ee*. Reaction of *rac*-**7** or *S*-enriched **7** with $RuCl_2(PPh_3)_3$ according to Kauffmann's method,[6a] afforded $[RuCl\{\eta^5:\eta^1\text{-}C_5H_4CH_2CH(Me)PPh_2\}(PPh_3)]$ (**8**) in low yield {8% based on (*S*)-$HOCH_2CH(Me)PPh_2$, Scheme 4} after isolation by chromatography.

whereas the minor set contains the $(S)_{Ru}(R)_C/(R)_{Ru}(S)_C$ enantiomers (*trans*-diastereomer). Discrimination and assignment was based on an X-ray crystal structure determination of the latter (vide infra). The $(S)_C$ enantiomerically-enriched material contains a total of 83% (64 + 19) $(S)_C$ diastereomers (see Scheme 4). The minor *trans*-diastereomer is much more soluble than the major *cis*-diastereomer, and therefore the former can be selectively extracted and crystallized out of a saturated diethyl ether solution within a few days (interconversion of diastereomers is slow in this solvent, vide infra). Curiously, *rac, trans*-**8** crystallizes in both a monoclinic and a triclinic space group. The X-ray structure determinations show that both unit cells contain enantiomeric pairs of the *trans*-diastereomer (Figure 1). The geometrical data (Tables 3−4) are very similar and also closely resemble those of **1b**.[6b] Minor differences between the three crystal structures are found in the puckering of the chelate ring and in the orientation of some of the phenyl groups, especially those of C(31)−C(36) and C(41)−C(46) of the PPh_3 ligand.

The conformation of the chelate ring of solid **8** is largely maintained in solution (Figure 2). The methyl group in the ring is fixed in an *anti* position with respect to the Cp-ring. Consequently, in the CH_2-moiety one of the hydrogens is in an *anti*-position with respect to the PPh_2-group and the other is *gauche*. This is clearly seen from the $^3J_{HP}$ coupling constants of 48.9 and 8.7 Hz, respectively, for the major *cis*-diastereomer of **8**. The minor *trans*-diastereomer has a simi-

Scheme 4. Ruthenium complexes with ligand **7**

The orange compound was characterized by elementary analysis, mass spectrometry, and ^1H, ^{13}C and ^{31}P NMR spectroscopy (Table 1 and 2). The NMR spectroscopic data are very similar to those of the achiral analogue **1b**, and are in agreement with a bidentate coordination of the Cp/phosphorous ligand. The ruthenium center is chiral, and therefore **8** is composed of two sets of diastereomers in about 77:23 ratio. The major set contains the $(R)_{Ru}(R)_C/(S)_{Ru}(S)_C$ pair of enantiomers (*cis*-diastereomer),[21] lar *anti*-coupling of 45.8 Hz and a *gauche*-coupling of 2.8 Hz.

Another spectroscopic feature of **8** is the extreme upfield chemical shift in the ^1H NMR spectrum of one of the Cp hydrogens (2.35 ppm for the *cis*-diastereomer and 2.98 ppm for the *trans*-diastereomer in $CDCl_3$). This phenomenon has also been observed for **1b** (2.45 ppm) and was ascribed to shielding by one of the phenyl rings of the PPh_3 ligand.[6b] The chemical shifts of the nuclei of the Cp-ring of

cis- and *trans*-**8** could be assigned with help of COSY and $^1H,^{13}C$-HETCOR experiments (see *supplementary material*).

Reaction of **1b** (as a pair of enantiomers) with $AgBF_4$ in the presence of (*R*)-$H_2NCH(Me)Ph$ yields the cationic complex $[Ru(\eta^5:\eta^1\text{-}C_5H_4CH_2CH_2PPh_2)(PPh_3)\{(R)\text{-}H_2NCH(Me)Ph)\}][BF_4]$ as a 50:50 mixture of diastereomers.[6b] A similar reaction conducted with *rac*-**8** (using AgO_3SCF_3 and (*S*)-$H_2NCH(Me)Ph$) affords the salt $\{RuCl[\eta^5:\eta^1\text{-}C_5H_4CH_2CH(Me)PPh_2](PPh_3)[(S)\text{-}H_2NCH(Me)Ph)]\}(O_3SCF_3)$ (**9**) as a mixture of four diastereomers in the ratio of 38:38:12:12 (Scheme 5). The reaction is assumed to proceed with retention of configuration at the metal, as is usual for substitutions on $CpML_2X$ systems.[17] If the same reaction is conducted with $(S)_C$-enriched **8**, the four diastereomers of **9** are obtained in a 64:13:19:4 ratio. Identification of the diastereomers by NMR spectroscopy (Table 5) was possible due to differences in the intensity of the signals. It was assumed that the starting compound (*S*)-$HOCH_2CH(Me)PPh_2$ {having an estimated (*S*)-enrichment of 60% by optical rotation}, did not change its configuration during the synthesis of **7**−**9**. Therefore, from the pair of diastereomers with $(S)_{Ru}(S)_C$ and $(R)_{Ru}(R)_C$ configuration (64 + 13%), the major diastereomer (64%) has configuration $(S)_{Ru}(S)_C$ and the minor one (13%) has $(R)_{Ru}(R)_C$. Consequently, the diastereomer with 19% abundance has configuration $(R)_{Ru}(S)_C$, and that with 4% abundance has $(S)_{Ru}(R)_C$. Finally, the enantiopurity of $(S)_C$-enriched **8** and of the starting compound (*S*)-$HOCH_2CH(Me)PPh_2$ is now more accurately determined as being 66% (64 + 19−13−4). The product mixture of **9** is unstable. Some of the $(S)_{Ru}$ isomers are converted into the $(R)_{Ru}$ isomers within a few days in solution, thereby maintaining the ratio of the $(S)_C$ and $(R)_C$ isomers (83:17). Longer standing times lead to decomposition of the reaction mixture.

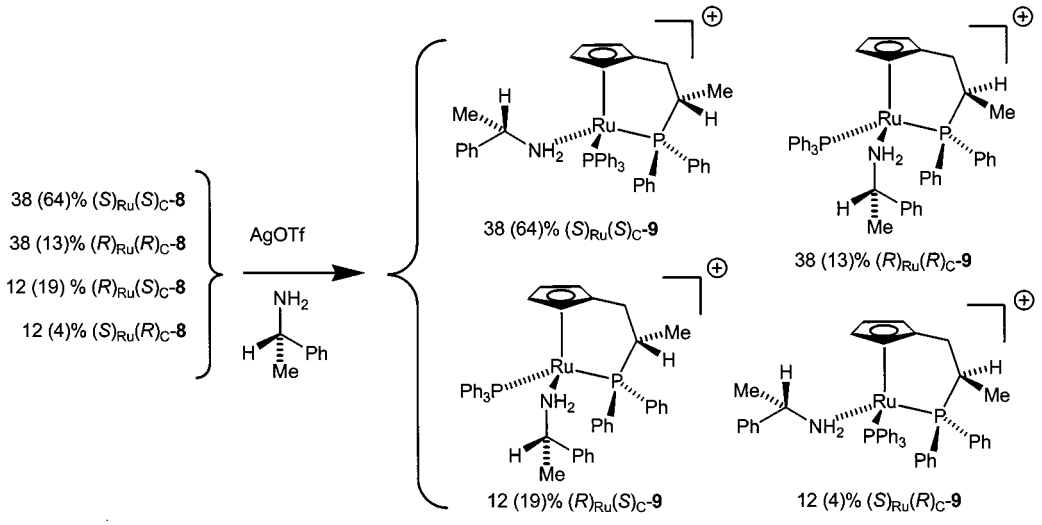
The presumable reaction product of $(S)_C$-enriched **8** with AgOTf, $[Ru(\eta^5{:}\eta^1\text{-}C_5H_4CH_2CH(Me)PPh_2)(PPh_3)][OTf]$ (**10**), is a poor Lewis acid, since for instance it does not catalyse the Diels−Alder reaction between cyclopentadiene and methacrolein. In agreement with this is the fact that the related complex $[RuCp(S,S\text{-chiraphos})(C_2H_4)]^+$ doesn't catalyse this reaction either.[2b] NMR spectra of **10** only show broad signals that are not very diagnostic. Without adding a Lewis base, **10** is unstable and fully decomposes within a few hours at room temperature, presumably by reaction with the solvent. The immediate reaction with Lewis bases like (S)-$H_2NCH(Me)Ph$ (vide supra) appears to be stereoselective, with retention of configuration at ruthenium. The reaction of a freshly prepared solution of **10** with Cl^- (as Et_3NHCl) after 10 min affords **8** with the original diastereomer ratio of 77:23.

It was found that the diastereomers of **8** exchange in solution. When crystals of the *trans*-diastereomer are dissolved, one observes the gradual formation of the *cis*-diastereomer until an equilibrium is reached having the original 77:23 ratio (Figure 3). The ruthenium diphosphane complex $[RuCl(\eta^5\text{-}Cp)\{(R)\text{-}Ph_2PCH(Me)CH_2PPh_2\}]$ shows similar

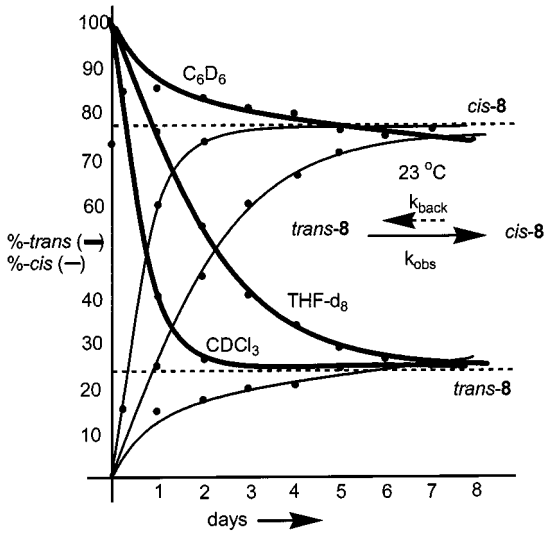


8, *cis*- diastereomer (77%) **8**, *trans*- diastereomer (23%)

Figure 2. Selected ^{1}H NMR data of **8**; the $^2J_{HH}$ coupling of 13.7 Hz in *trans*-**8** is averaged from the measured data (13.5, 13.8 Hz)

behaviour although exchange between the two diastereomers takes several days in chlorobenzene.[18] It was found that the rate of the isomerisation is very solvent-dependent, consistent with dissociation of Cl^- being the rate-determining step (pathway A in Scheme 6) and not decomplexation of the PPh_3 ligand (pathway B in Scheme 6). It also suggests that interconversion of the *cis*- and *trans*-diastereomers of the intermediate cations $[Ru]^+$ is faster than Ru−Cl bond dissociation. It was further found that the presence of extra PPh_3 did not slow down the reaction rate of the *trans-cis* interconversion of **8** in $CDCl_3$, confirming that phosphane dissociation does not trigger the conversion (Figure 4). Despite this, dissociation of PPh_3 in **8** probably does occur. In the related compound $[RuCl(\eta^5\text{-Cp})(PPh_3)_2]$ dissociation of PPh_3 occurs with a rate constant of 5×10^{-6} s^{-1} (thf, 21°C), which is of the same magnitude as chloride dissociation in **8** (4.8×10^{-6} s^{-1}, thf, 23°C).[19] If phosphane dissociation in **8** occurs with a similar rate, then this means that the interconversion of the *cis*- and *trans*- isomers (i.e. site exchange of the chloride) of the intermediate $[RuCl(\eta^5{:}\eta^1\text{-}C_5H_4CH_2CH(Me)PPh_2)]$ is very slow.

In another experiment the *trans-cis* interconversion of **8** was monitored in $CDCl_3$ in the presence of Et_3NHCl (Figure 4). It was expected that when Ru−Cl dissociation is rate-determining for the conversion, then adding Cl^- should slow down the conversion. Actually, the presence of



Scheme 5. Preparation of the amine complex **9** as a mixture of 4 diastereomers

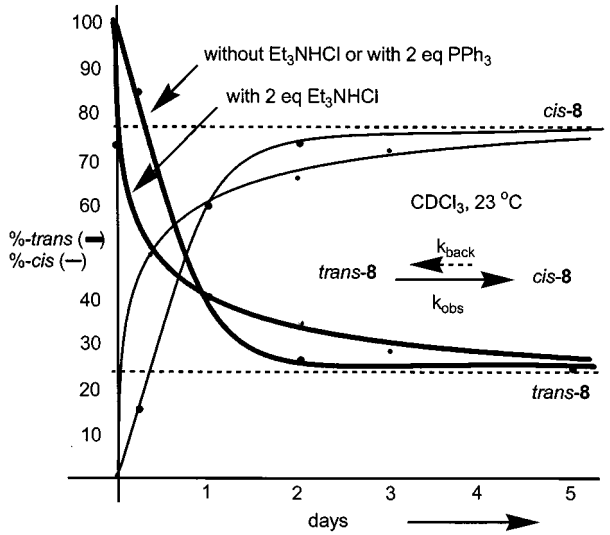

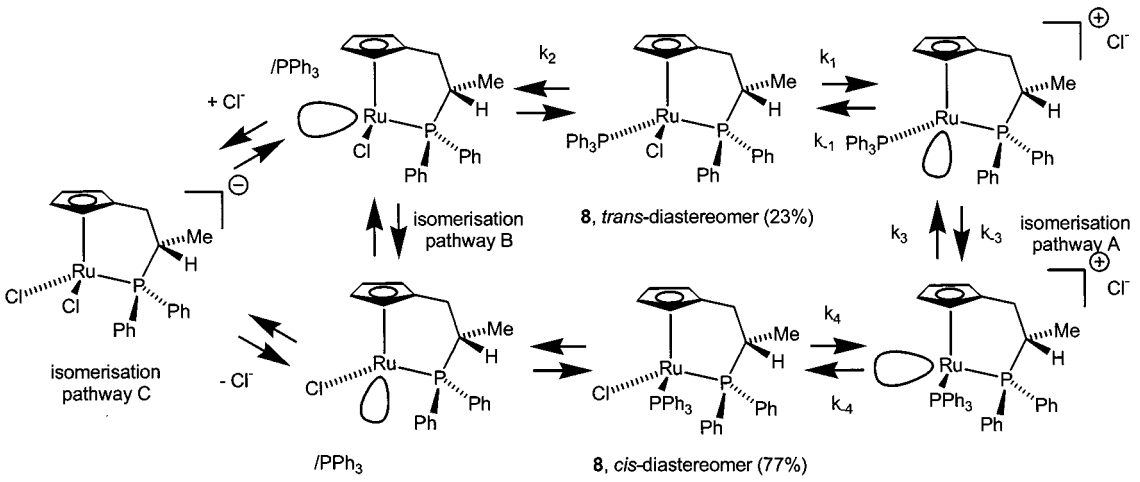

Figure 4. Equilibration of the *trans*- and *cis*-diastereomers of **8** in $CDCl_3$ in the presence of either PPh_3 or Et_3NHCl

other diastereotopic site. This, however, would imply that $Ru-PPh_3$ dissociation becomes rate-determining, and that this dissociation is in fact faster than Ru−Cl dissociation.

In order to study the relative reactivity of *cis*- and *trans*-**8** in more detail we investigated the substitution reactions of **8** with NaBr or NaI. This reaction results in quantitative formation of [RuBr{η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$}(PPh_3)] (**11**) or [RuI{η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$}(PPh_3)] (**12**) (see Tables 1 and 2). The reaction was monitored by NMR spec-

Scheme 6. Interconversion of the *trans* and *cis* diastereomers of **8**

Et_3NHCl *enhances* the rate. One reason might be that the slowing down due to the presence of extra Cl^- is counterbalanced by the enhanced polarity of the solvent (a salt effect). It is also possible that Et_3NH^+ labilizes the Ru−Cl bond by forming a hydrogen bond. Another explanation is that a third mechanism is operative for the conversion (pathway C in Scheme 6): after dissociation of PPh_3 from **8** the intermediate [RuCl(η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$] is trapped by Cl^- forming the anion [$RuCl_2$(η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$]$^-$ which than loses Cl^- from the troscopy in $CDCl_3$ (Figure 5 and 6). After the reaction was complete, the *cis*/*trans* ratio of **11** and **12** is about the same as in **8**. The presence of 3 equivalents of PPh_3 during the reaction with NaI does not change the reaction profile so that, again, $Ru-PPh_3$ dissociation is not expected to play a role in these substitution reactions. The rate of reaction of **8** is about the same for both substitutions, and is also of a similar magnitude as the *cis*/*trans* conversion of **8**. Although the reactions are heterogenic, it again suggests that Cl^- dissociation is the rate-determining step. For both substi-

tutions the minor *trans*-diastereomer of **8** reacts about three times as fast as the *cis*-diastereomer. This is also in agreement with the rate constants for Cl^- dissociation in *cis*- and *trans*-**8** (Figure 3). As the *cis*-diastereomer has about three times the abundance of the *trans*-isomer, at the beginning of the reaction the *cis*- and *trans*-diastereomers of the cation $[Ru]^+$ should have about equal abundance. As a result, a relatively large proportion of the *trans*-diastereomers of **11** and **12** is formed (Figure 5 and 6). For the reaction with NaI the amount of *trans*-**12** after 2 days is even larger (42%) than the initial amount of *trans*-**8** (23%). This is probably due to the fact that, as *trans*-**8** reacts and disappears about three times faster than *cis*-**8**, the *cis*/*trans* equilibrium of **8** is out of balance and *cis*-$[Ru]^+$ will convert into *trans*-$[Ru]^+$. Then, after both *cis*- and *trans*-**8** have been consumed, the *cis*/*trans* ratio of **12** changes until equilibrium has been reached after about a week. From the profile in Figure 6 it is estimated that I^- dissociation in *trans*- and *cis*-**12** in $CDCl_3$ is about three times as slow ($k_1 = 4.3 \times 10^{-6}$, $k_{-1} = 1.5 \times 10^{-6}$ s^{-1}) as Cl^- dissociation in **8** (see Figure 3). This "peaking" of the abundance of the *trans*-diastereomer is not observed during the reaction of **8** with NaBr. We think that exchange between the *cis*/*trans* diastereomers in **11** is faster than for **12**, and that equilibrium is reached before **8** has completely reacted.

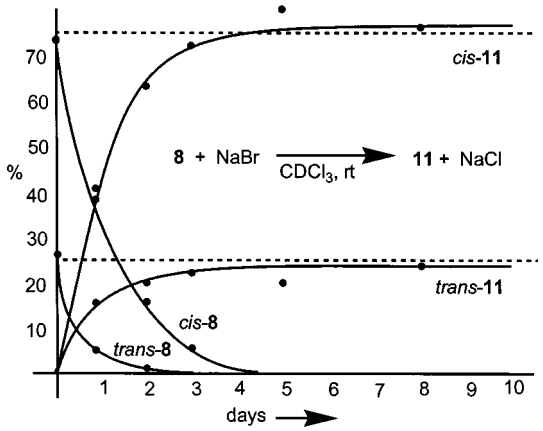

Figure 5. Reaction of **8** with NaBr in $CDCl_3$

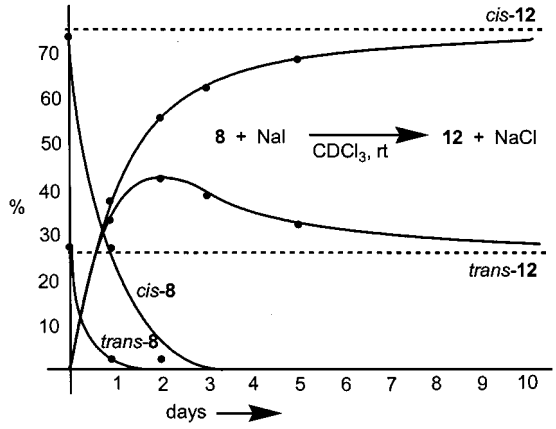

Figure 6. Reaction of **8** with NaI in $CDCl_3$

Conclusions

The experiments presented above confirm that the *cis*- and *trans*-diastereomers of the Cp/phosphane complex **8** (and **11**, **12**) exchange through Cl^- dissociation with intermediate formation of the cations *cis*- and *trans*-**[Ru]**$^+$. The rate of Cl^- dissociation in *trans*-**8** is about 3 times as large as in *cis*-**8**. Furthermore, the cations **[Ru]**$^+$ are too electron rich to develop significant Lewis acidity for asymmetric catalysis. Further modifications of the functionalized Cp-ligands should lead to the formation of only one diastereomer upon coordination, as in the ferrocene-based Cp/phosphane ligand designed by Hidai, mentioned earlier.[7b] Thus, the presence of two, possibly counteracting, diastereotopic sites on the catalyst is not very promising for obtaining high enantioselectivity. Another solution might be the separation of the diastereomers. However, this is only meaningful when the ruthenium complexes are configurationally stable at the metal center. The situation may be improved by using π-acceptor ligands which at the same time would increase the Lewis acidity. In future work, we will concentrate on other coordination environments and transition metals to avoid the diastereomer problem.

Experimental Section

General: All manipulations were carried out under an atmosphere of argon using Schlenk techniques. Solvents were dried and degassed by conventional procedures prior to use. − ^1H and ^{13}C NMR: Varian Gemini 300. − The ^1H and ^{13}C NMR spectra were measured in $CDCl_3$ unless stated otherwise ($CHCl_3$: $\delta_H = 7.24$; $CDCl_3$: $\delta_C = 77.0$) − Mass spectra: AMD Intectra 402, EI-MS, 70 eV; only the primary signal of a mixture of isotopes is given. − Combustion analyses (C,H): CHNS-932 LECO analyzer. The Cp/ether ligands were prepared according to ref.[5c] and their Me_3Si-derivatives according to ref.[5d]

[RuCl{η^5-$C_5H_4CH_2CH_2O$[(1*R*)-fenchyl]}$(PPh_3)_2$] (3d): A suspension of $RuCl_2(PPh_3)_3$ (2.00 g, 2.1 mmol) and {C_5H_4-(CH_2CH_2Ofenchyl)($SiMe_3$)} (1.1 g, 3.5 mmol) in 100 mL of toluene was refluxed for 5 h. After cooling to room temperature the mixture was concentrated and chromatographed (Fluka: silica gel 60, toluene/THF, 9:1). Concentration of the extracts afforded a yellow-orange air stable powder that was washed once with a little pentane. Yield: 1.60 g (1.92 mmol, 91%). − $C_{53}H_{55}ClOP_2Ru$ (906.5): calcd. C 70.2, H 6.1; found C 68.9, H 6.5. − (EI) MS for **3d**, and also for **3a**−**c**, do not show fragments for M; main fragments are due to PPh_3 (262, 183, 108, 78); a fragment with low abundance was recognized as the metallocene Cp'_2Ru (for **3d**: *m*/*z* = 592), obviously a result of rearrangement.

[RuCl{η^5-$C_5H_4CH_2CH_2O$[(1*R*)-menthyl]}{$PPh_3)_2$] (3c): As for **3d**. Yield: 95%. − $C_{53}H_{57}ClOP_2Ru$ (908.5): calcd. C 70.0, H 6.3; found C 70.0, H 5.8.

[RuCl[η^5-$C_5H_4CH_2CH_2OMe$](PPh$_3$)$_2$] (3a). − Method 1: A suspension of $RuCl_2(PPh_3)_3$ (1.0 g, 1.1 mmol) and 0.3 $C_5H_5CH_2CH_2OMe$ (0.3 g, 2.5 mmol) in degassed ethanol was refluxed overnight under argon. The solvent was then replaced by toluene and the mixture heated to reflux for a few hours. Concentration and chromatograpy (Fluka: silica gel 60, toluene/THF, 15:1) afforded a yellow-orange powder (0.4 g, 45%). − **Method 2:** As for **3d**. Yield: 90%. − $C_{44}H_{41}ClOP_2Ru$ (784.3): calcd. C 67.4, H 5.3; found C 67.1, H 5.4.

[RuCl{η^5-$C_5H_4CH_2CH_2O$[(1*S*)-isobornyl]}$(PPh_3)_2$]: As for **3a**, method 1. Yield: 40%. $C_{53}H_{55}ClOP_2Ru$ (906.5): calcd. C 70.2, H 6.1; found C 68.4, H 5.9.

[Ru(O_3SCF_3){η^5-$C_5H_4CH_2CH_2OR$}$(PPh_3)_2$] {R = Me (4a), isobornyl (4b) or menthyl (4c)}: In a typical experiment 0.10 g of **3** was reacted with a slight excess of AgO_3SCF_3 in 10 mL of CH_2Cl_2. After stirring for 10 min at room temperature the solution was filtered over Celite, and evaporated to dryness. The triflates were unstable in solution, and were therefore characterized by their ^{1}H, ^{13}C, and ^{31}P NMR spectra measured immediately after their preparation.

C_5H_4{CH_2CH_2S[(1*R*)-neomenthyl]}($SiMe_3$): A solution of (*S*)-(+)-neomenthanethiol[10b,c] (8.6 g, 50 mmol) in 50 mL of THF was stirred in the presence of excess potassium metal at room temperature overnight. The solution of the resulting potassium thiolate was decanted and spiro[2.4]hepta-4,6-diene[10d] (4.6 g, 50 mmol) was added at 0°C. After stirring for 5 h at 45°C, the reaction mixture was cooled to −78°C and 6 mL (excess) of $ClSiMe_3$ was added. After stirring for 2 h, solvent was evaporated and the residue extracted with a mixture of water and pentane. The pentane extracts were collected, dried over Na_2SO_4, filtered and evaporated to dryness affording the oily title compound in quantitative yield and high purity. − $C_{20}H_{36}SSi$ (336.7): calcd. C 71.4, H 10.8, S 9.5; found C 70.5, H 10.3, S 9.1.

[RuCl{η^5-$C_5H_4CH_2CH_2S$[(1*R*)-neomenthyl]}$(PPh_3)_2$] (5): A mixture of $RuCl_2(PPh_3)_3$ (4.79 g, 5.0 mmol) and C_5H_4{CH_2CH_2S[(1*R*)-neomenthyl]}($SiMe_3$) (1.68 g, 5.0 mmol) in CH_2Cl_2 was stirred overnight at room temperature. The solvent was then evaporated and the residue washed once with pentane. The orange product was isolated by exhaustive extraction with diethyl ether. Yield: 2.96 g (64%). − $C_{53}H_{57}ClP_2RuS$ (924.6): calcd. C 68.9, H 6.2, S 3.5; found C 67.6, H 6.6, S 3.3. − ^{1}H NMR: δ = 0.85, 0.87, 0.91 (all d, 3 × 3 H, neomenthyl), 2.5−2.7 (m, 4 H, CCH_2CH_2S), 3.14 (1 H, SC*H*), 3.27, 3.31, 3.99, 4.01 (C_5H_4). − ^{13}C NMR: δ = 20.9, 21.1, 22.2 ($C_{7,9,10}$), 25.9 (CCH_2), 26.3 (C_8), 27.3 (C_5), 29.9 (C_1), 31.8 (SCH_2), 35.4 (C_6), 40.7 (C_2), 46.5 (C_3), 48.9 (C_4), 76.4, 76.9, 80.0(br), 80.3(br) (C_5H_4).^{31}P NMR: δ = 40.0.

[Ru(O_3SCF_3){η^5-$C_5H_4CH_2CH_2S$[(1*R*)-neomenthyl]}$(PPh_3)_2$] (6): A solution of **6** was generated from **5** as described for **4**. Complex **6** decomposes within a few hours at room temperature in $CDCl_3$ and was therefore only characterized by NMR spectroscopy. Selected NMR spectroscopic data: ^{1}H NMR: δ = 0.61, 0.88, 0.98 (all d, 3 × 3 H, neomenthyl), 2.17, 2.44 (m, 2 × 1 H, CCH_2), 2.53 (1 H, SC*H*), 3.59, 3.97 (m, 2 × 1 H, SCH_2), 4.04, 4.19, 4.50, 4.55 (C_5H_4). − ^{13}C NMR: δ = 20.4, 21.2, 23.7 ($C_{7,9,10}$), 23.9 (CCH_2), 26.4 (C_5), 28.6, 29.1 ($C_{1,8}$), 31.8 (C_6), 36.6 (C_2), 47.2 (C_4), 49.9 (C_3), 53.9 (SCH_2), 76.0, 76.8, 79.8, 82.7 (C_5H_4). − ^{31}P NMR: δ = 33.1 (d, *J* = 36 Hz), 42.8 (d, *J* = 36 Hz).

(*S*)-$HOCH_2CH(Me)PPh_2$: A solution of Ph_2PLi and PhLi was prepared by reacting PPh_3 (29.95 g, 114 mmol) and lithium shavings (3.0 g, 430 mmol) in 200 mL of THF at room temperature overnight. The bright orange solution was then filtered and cooled to −70°C upon which *(R)*-$HOCH_2CH(Me)Cl$ (9.9 g, 105 mmol) was added. The solution was slowly raised to room temperature and stirred overnight. The resulting colorless solution was evaporated to dryness. Water and 100 mL of CH_2Cl_2 were added (in air), and 3 M HCl was added until the mixture was just neutral (ca 40 mL). The organic layer was separated, dried over Na_2SO_4 and evaporated to dryness affording 27.2 g (100%) of a very viscous colorless oil. Except for some trace amounts of $Ph_2P(O)H$, this material was virtually pure. − $C_{15}H_{17}OP$ (244.3): calcd. C 73.8, H 7.0; found C 72.7, H 7.0. − $[\alpha]_D$ (*c* = 3.2, CH_2Cl_2) +4.5° (*ee* ≈ 60%; *S*/*R* ≈ 80:20). Actually, the optical purity is 66% as was found after complexation to ruthenium (vide infra). − ^{1}H NMR: δ = 1.09 (dd, $^3J_{HH}$ = 6.9 Hz, $^3J_{HP}$ = 13.9 Hz, 3 H, CH_3), 2.61 (m, 1 H, C*H*CH_3), 3.54 (ddd, $^2J_{HH}$ = 10.9 Hz, $^3J_{HH}$ = 7.6 Hz, $^3J_{HP}$ = 7.6 Hz, 1 H, OCH_2), 3.70 (ddd, $^2J_{HH}$ = 10.9 Hz, $^3J_{HH}$ = 4.6 Hz, $^3J_{HP}$ = 8.9 Hz, 1 H, OCH_2), 7.32 (m, 6 H, Ph), 7.50 (m, 4 H, Ph). − ^{13}C NMR ($CDCl_3$): δ = 13.71 (d, $^2J_{CP}$ = 13.1 Hz, *C*H_3), 33.64 (s, *C*CH_3), 65.16 (d, $^2J_{CP}$ = 19.8 Hz, O*C*H_2), 128.7, 129.6, 133.7 (m, Ph). − ^{31}P NMR: δ = −9.2.

[RuCl{η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$}(PPh_3)] (racemic) (8): To a solution of (*S*)-$HOCH_2CH(Me)PPh_2$ (22.4 g, 92 mmol) was added 100 mL of a 1 M solution of BH_3 in THF at −30°C. After stirring for 1 h at room temperature the solvent was removed affording crude (*S*)-$HOCH_2CH(Me)PPh_2(BH_3)$ as a very viscous colorlous oil (23.3 g, ≈ 100%). − ^{1}H NMR: δ = 1.15 (dd, $^3J_{HH}$ = 7.0 Hz, $^3J_{HP}$ = 15.7 Hz, 3 H, CH_3), 2.82 (m, 1 H, C*H*CH_3), 3.6−3.8 (m, 2 H, OCH_2), 7.42 (m, 6 H, Ph), 7.73 (m, 4 H, Ph). − ^{13}C NMR ($CDCl_3$): δ = 11.88 (sbr, *C*H_3), 31.61 (d, $^1J_{CP}$ = 34.9 Hz, *C*CH_3), 63.17 (d, $^2J_{CP}$ = 6.6 Hz, O*C*H_2), 128.7, 131.3, 132.5 (m, Ph). − ^{31}P NMR: δ = 19.8. − A solution of the borane-adduct (6.85 g, 26.6 mmol) and Et_3N (6.0 mL, 43 mmol) in 80 mL of CH_2Cl_2 was cooled to −30°C upon which $MeSO_2Cl$ (3.0 mL, 39 mmol) was added. The thick suspension was stirred for a few hours at room temperature. Addition of water resulted in the formation of two clear layers. The CH_2Cl_2 layer was washed with water several times, then separated, dried over Na_2SO_4 and evaporated to dryness affording 8.77 g (26.1 mmol, ca 98%) of (*S*)-$MeSO_3CH_2CH(Me)PPh_3(BH_3)$ as a light-brown viscous oil. − ^{1}H NMR: δ = 1.20 (dd, $^3J_{HH}$ = 6.9 Hz, $^3J_{HP}$ = 15.4 Hz, 3 H, CCH_3), 2.84 (s, 3 H, SCH_3), 3.10 (m, 1 H, C*H*CH_3), 4.21 (ddd, $^2J_{HH}$ = 10.2 Hz, $^3J_{HH}$ = 6.8 Hz, $^3J_{HP}$ = 9.6 Hz, 1 H, OCH_2), 4.35 (ddd, $^2J_{HH}$ = 10.2 Hz, $^3J_{HH}$ = 4.7 Hz, $^3J_{HP}$ = 6.6 Hz, 1 H, OCH_2), 7.46 (m, 6 H, Ph), 7.65−7.85 (m, 4 H, Ph). − ^{13}C NMR ($CDCl_3$): δ = 11.79 (sbr, *C*H_3), 29.50 (d, $^1J_{CP}$ = 34.9 Hz, *C*CH_3), 37.26 (s, S*C*H_3), 70.24 (d, $^2J_{CP}$ = 11.8 Hz, O*C*H_2), 129.0, 131.7, 132.4 (m, Ph). − ^{31}P NMR: δ = 20.0. − A solution of CpLi was generated by adding 26 mL of a 1.61 M solution of *n*BuLi (42 mmol) in hexane to a solution of 3.5 mL (42 mmol) of freshly cracked CpH in 60 mL of THF with ice-cooling. Then, the above mentioned mesylate (26.1 mmol) was added at −20°C and the dark brown reaction mixture was stirred overnight at room temperature. Solvents were removed and the residue was extracted into CH_2Cl_2. Filtration and removal of solvent afforded 7.91 g of a dark brown oil, mainly containing (*S*)-$C_5H_5CH_2CH(Me)PPh_2(BH_3)$ as a mixture of two regioisomers. − ^{1}H NMR: δ = 1.06 (dd, $^3J_{HH}$ = 7.0 Hz, $^3J_{HP}$ = 16.4 Hz, 3 H, CH_3), 2.3−3.0 {m, C*H*CH_3, CCH_2, Cp(aliphatic), 5 H}, 6.01 (s), 6.17 (s), 6.23 (d, *J* = 5.4 Hz), 6.31−6.40 {m, Cp(olefinic), 3H in total}, 7.41 (m, 6 H, Ph), 7.74 (m, 4 H, Ph). − ^{13}C NMR: δ = 13.23/13.33 (sbr, *C*H_3), 28.03 (d, $^1J_{CP}$ = 36.0 Hz)/28.70 (d, $^1J_{CP}$ = 35.6 Hz, *C*CH_3), 30.56 (d, $^2J_{CP}$ = 3.7 Hz)/31.41 (d, $^2J_{CP}$ = 4.1 Hz, *C*H_2CP), 41.09/42.91 {Cp(aliphatic)}, 133.60/134.03 {Cp(olefinic CH)}, 143.58 (d, $^3J_{CP}$ = 13.6 Hz)/145.63 {d, $^3J_{CP}$ = 14.2 Hz, Cp(olefinic)}, other Cp signals hidden by Ph signals, 128.4 (m), 130.8 (m), 132.2 (m, all Ph). − ^{31}P NMR: δ = 24.8. − This oil was dissolved in 30 mL of degassed pyrrolidine and heated at 70−80°C for 30 min. After removal of solvent the residue was extracted with warm pentane (ca 150 mL in total), and filtered over Celite. Removal of solvent afforded 3.95 g (ca 13 mmol) of (*S*)-$C_5H_5CH_2CH(Me)PPh_2$ as a yellow oil. This material could not be distilled without decomposition and was therefore used without further purification. − ^{1}H NMR: δ = 0.99 (dd, $^3J_{HH}$ = 6.8 Hz, $^3J_{HP}$ = 15.0 Hz, 3 H, CH_3), 2.0−2.9 (m, C*H*CH_3, CCH_2, 3 H), 2.94 {s, Cp(aliphatic), 2 H}, 6.02 (s), 6.18 (s), 6.25 (d, *J* = 4.2 Hz),

6.40 {s, Cp(olefinic), 3H in total}, 7.32 (m, 6 H, Ph), 7.51 (m, 4 H, Ph). – ^{13}C NMR: δ = 16.16 (d, $^2J_{CP}$ = 16.3 Hz)/16.28 (d, $^2J_{CP}$ = 16.4 Hz, *C*H$_3$), 29.87 (d, $^2J_{CP}$ = 10.3 Hz)/30.67 (d, $^2J_{CP}$ = 10.3 Hz, *C*H$_2$CP), 33.59 (d, $^1J_{CP}$ = 19.0 Hz)/34.49 (d, $^1J_{CP}$ = 19.3 Hz, *C*CH$_3$), 41.26/43.48 {Cp(aliphatic)}, other Cp signals hidden by Ph signals, 128.3 (m), 128.7 (m), 133.6 (m, all Ph). – ^{31}P NMR: δ = −0.4. – A suspension of $RuCl_2(PPh_3)_3$ (3.1 g, 3.2 mmol) and 1.83 g of the above oil in 50 mL of degassed ethanol was refluxed overnight. Then, ethanol was replaced by toluene and the mixture was heated to reflux for another few hours. Workup by chromatography (see above) afforded 0.68 g {1.0 mmol, 8% based on $HOCH_2CH(Me)PPh_3$} of racemic [RuCl{η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$}(PPh_3)] as a 77:23 mixture of diastereomers (NMR) as an orange powder. – $C_{38}H_{35}ClP_2Ru$ (689.6): calcd. C 66.1, H 5.1; found C 64.3, H 5.3. – MS; *m*/*z*(%): 690 (30) [M$^+$], 428 (100) [M$^+$ – PPh_3], 393 (100), [M$^+$ – Cl – PPh_3], 315 (5) [M$^+$ – Cl – PPh_3 – Ph].

Determination of the Enantiopurity of [RuCl{η^5:η^1-C_5H_4-$CH_2CH(Me)PPh_2$}(PPh_3)]. Formation of {Ru[η^5:η^1-$C_5H_4CH_2CH$-$(Me)PPh_2$][(***S*****)-H$_2$**NCH(Me)Ph](PPh_3)}{O_3SCF_3} (9): A solution of **8** (0.10 g, 0.14 mmol) in 2.0 mL of dry $CDCl_3$ was treated with AgO_3SCF_3 (0.04 g, 0.16 mmol) and (*S*)-$H_2NCH(Me)Ph$ (0.12 g, 1 mmol). After stirring for 30 min the silver salts were removed by filtration and the resulting yellow-green solution was analyzed by NMR spectroscopy. The salt **9** is present as a 38:38:12:12 mixture of isomers and is therefore completely racemic.

[RuCl{η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$}(PPh_3)] (*S* enriched) (8): A mixture of (*S*)-$HOCH_2CH(Me)PPh_2$ (*S*/R ≈ 80:20, see above, 6.0 g, 24.7 mmol) and Et_3NHCl (6.3 g, 46 mmol) in 150 mL of degassed acetonitrile was cooled to −30°C, upon which PCl_3 (4.0 mL, 46 mmol) was added. The resulting bright yellow suspension was stirred for 2 days at 50−60°C. Solvent was removed in vacuo and CH_2Cl_2 and degassed water were added. The CH_2Cl_2 layer was washed with water, filtered and dried over $CaCl_2$. Filtration and removal of solvent afforded 6.24 g of an oily substance mainly containing (*S*)-$ClCH_2CH(Me)PPh_2$ (up to 30% of $Ph_2P(O)H$ may be present due to the partial formation of Ph_2PCl during the chlorination procedure and subsequent hydrolysis). – ^{1}H NMR: δ = 1.18 (dd, $^3J_{HH}$ = 6.8 Hz, $^3J_{HP}$ = 14.6 Hz, 3 H, C*H*$_3$), 2.69 (m, 1 H, C*H*CH$_3$), 3.32 (ddd, $^2J_{HH}$ = 10.4 Hz, $^3J_{HH}$ = 3.1 Hz, $^3J_{HP}$ = 10.4 Hz, 1 H, OC*H*$_2$), 3.68 (ddd, $^2J_{HH}$ = 10.4 Hz, $^3J_{HH}$ = 4.6 Hz, $^3J_{HP}$ = 8.9 Hz, 1 H, OC*H*$_2$), 7.32 (m, 6 H, Ph), 7.50 (m, 4 H, Ph). – ^{13}C NMR ($CDCl_3$): δ = 15.09 (d, $^2J_{CP}$ = 16.2 Hz, *C*H$_3$), 33.72 (d, $^1J_{CP}$ = 13.8 Hz, *C*CH$_3$), 49.07 (d, $^2J_{CP}$ = 26.9 Hz, O*C*H$_2$), 128.8, 130.6, 132.5 (m, Ph). – ^{31}P NMR: δ = −5.1. – This oil was added to a solution of CpLi generated from mixing 21 mL of a 1.61 M solution of *n*BuLi (34 mmol) in hexane and a solution of 3.0 mL (36 mmol) of CpH in 50 mL of THF. This mixture was refluxed for 2 days. Then, 1 mL of water was added and the mixture was evaporated to dyness. Extraction with pentane afforded 2.17 g (ca 7 mmol) of (*S*)-$C_5H_5CH_2CH(Me)PPh_2$ as a yellow oil. Reaction with $RuCl_2(PPh_3)_3$ (3.3 g, 3.4 mmol) and workup as described above afforded 1.17 g of **8** {1.7 mmol, 8% based on $HOCH_2CH(Me)PPh_2$}. The reaction with AgO_3SCF_3 and (*S*)-$H_2NCH(Me)Ph$ (vide supra) afforded a 64:13:19:4 mixture of isomers of **9** and therefore the enantiomeric excess of the Cp-Ligand was 66% (64 + 19−13−4; *S*/*R* = 83:17) which is an agreement with the estimated enantiopurity of the starting product $HOCH_2CH(Me)PPh_2$ of 60% (vide supra).

X-ray Structure Determination of *rac*, *trans*-8: Orange crystals suitable for an X-ray diffraction study were grown within a few days from a saturated ether solution at room temperature. There were two crystal forms. Crystallographic and experimental details are summarized in Table 3. No absorption corrections were made. The structures were solved by direct methods (SHELXS-86)[20a] and refined by full-matrix least squares against F^2 (SHELXL-97).[20b] All non-hydrogen atoms were refined anisotropically, hydrogen atoms isotropically. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-117007 (triclinic *rac, trans*-**8**) and 117006 (monoclinic *rac, trans*-**8**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ {fax: (internat.) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk}.

Reaction of Racemic 8 with NaBr: A solution of **8** (0.08 g, 0.12 mmol) in 1.0 mL of dry $CDCl_3$ was treated with NaBr (0.10 g, 1.0 mmol) of and stirred at room temperature. The reaction was monitored by NMR spectroscopy. After 1 week the reaction was complete. The solution was filtered and evaporated to dryness affording orange-brown RuBr[η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$](PPh_3) (**11**) as a 76:24 mixture of diastereomers. MS; *m*/*z*(%): 736 (20) [M$^+$], 474 (90) [M$^+$ – PPh_3], 393 (100), [M$^+$ – Br – PPh_3], 315 (5) [M$^+$ – Br – PPh_3 – Ph].

Reaction of Racemic 8 with NaI: The reaction with NaI was performed analogously. The reaction was complete after about 2 weeks. The brown RuI[η^5:η^1-$C_5H_4CH_2CH(Me)PPh_2$](PPh_3) (**12**) was obtained as a 73:27 mixture of diastereomers. MS; *m*/*z*(%): 782 (20) [M$^+$], 520 (100) [M$^+$ – PPh_3], 393 (95), [M$^+$ – I – PPh_3], 315 (5) [M$^+$ – I – PPh_3 – Ph]. Neither the rate of the reaction nor the product formation was changed when the reaction was conducted in the presence of 3 equiv. of added PPh_3 per Ru (NMR monitoring).

Catalysis. Diels−Alder reaction: To a solution of *S*-enriched **8** (0.08 g, 13 μmol) in 10 mL of CH_2Cl_2 was added an excess of AgO_3SCF_3 (0.18 g). After stirring for 10 min the resulting red-brown suspension was filtered over Celite and cooled to −60°C. Then, *i*Pr_2NEt (9 μL, 50 μmol), cyclopentadiene (1.8 mL, 22 mmol) and methacrolein (1.0 mL, 12.2 mmol) were added. The clear yellow solution was stirred at −4°C. Samples were taken regularly over a period of a few days. They were quenched by flash chromatography over silica gel. Volatiles were removed in vacuo (without heating) and the residue was analyzed by ^{1}H NMR spectroscopy. The Diels−Alder product 2-formyl-2-methyl-bicyclo[2.2.1]hept-5-ene could not be found;[5b] instead the gradual formation of dicyclopentadiene was observed.

Supporting Information: ^{1}H, ^{13}C and ^{31}P NMR spectroscopic data for **3** and **4**. A drawing of the assignment of the ^{1}H and ^{13}C NMR spectroscopic data of **8**.

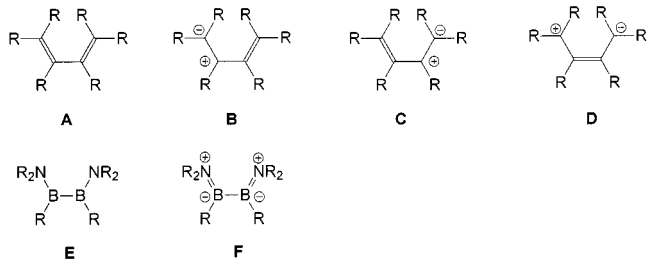
Contribution to the Chemistry of Boron, 245[+] A Boron–Boron Double Bond in the Dianions of Tetra(amino)diborates

Heinrich Nöth,*[a] Jörg Knizek,[a] and Werner Ponikwar[a]



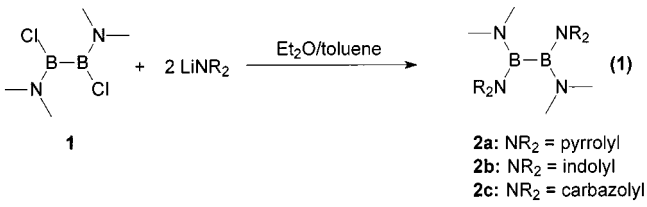
Dedicated to Prof. Dr. Wolfgang Steglich on the occasion of his 65th birthday

Keywords: Diboron compounds / B–B double bond / Dilithium tetra(amino)diborates(2–) / Structure elucidation

A series of mixed tetraaminodiborane(4) compounds bearing pyrrolyl, indolyl, and carbazolyl substituents besides dimethylamino groups has been prepared and subjected to reduction with elemental Li in the presence of diethyl ether. Tetraaminodiborates(2–) are formed, which feature a boron–boron double bond. The diborate anion acts as a double bidentate ligand coordinating pairwise through two of its nitrogen atoms to an Li center, which is tricoordinated by one O and the two N atoms. The new diborates are isoelectronic with tetraaminoethylenes and are expected to be electron-transfer reagents.

Introduction

One of the foremost principles in inorganic and metalorganic chemistry is that of isoelectronic or isolobal systems.[2] One of the systems where this concept first came to prominence was that of boron−nitrogen compounds since the BN atom pair is isoelectronic and isolobal with a pair of carbon atoms. The consequences of isoelectronic systems have been delineated in two classical papers by Wiberg,[3] in which physical properties and structural relationships for pairs of isoelectronic compounds were correlated. As the amount of structural information and our knowledge of the reactivity of boron−nitrogen compounds progressed, it became apparent that fundamental differences exist due to the more polar electron distribution in BN systems compared to that in CC systems. For instance, although the bis(amino)diboranes $R_2N(R)B-B(R)NR_2$[4] are isoelectronic with the 1,3-butadienes $R_2C=(R)C-C(R)=CR_2$, the bonding in the latter is best described by the canonical formulae **A** to **D**, while formulae **E** and **F** describe the bonding situation in the diborane(4) derivative.



Typical for the diborane(4) derivative is the absence of a double-bond contribution to the boron−boron core, and this is reflected not only in the bond lengths (1.74 Å), but also in the fact that the two $(R_2N)RB$ units adopt interplanar angles between 60 and 90°, depending on the nature of the substituents.[4,5,6]

The majority of tetraaminodiboranes(4), $(R_2N)_4B_2$, are obtained by dehalogenation of bis(amino)boron halides $(R_2N)_2BHal$.[7][8] Yields of the resulting diborane species range from >70% to <1% in very unfavorable cases depending on conditions as well as on experimental skills. Dehalogenation by sodium metal is often the method of choice compared to the use of Na/K alloy, even though longer reaction times are required. One of the possible reasons for the low yields may be a further reaction of the $B_2(NR_2)_4$ formed with excess metal. We report here on this perspective.

Tetraaminodiboranes(4)

For the present study, a number of new tetraaminodiboranes(4) **2a**−**2c** were prepared by allowing bis(dimethylamino)diboron(4) dichloride **1**[9] to react with lithio amides as shown in Equation 1.

The results of X-ray crystal structure determinations of **2a** and **2b** are depicted in Figures 1 and 2 (see also Table 1). The BN bonds to the dimethylamino groups measure 1.390(3) and 1.396(2) Å, respectively. They form interplanar angles with the $B_2(N_A)_2$ plane (the subscript A indicates the amino N atoms) of just 4° and 9° and thus can be considered as being almost coplanar. This allows the formation of strong BN_A π-bonds with a bond order close to 2, as

reflected in the short BN_A bond lengths. In contrast, the BN_H bonds (the subscript H indicates the heterocyclic N atoms) to the indolyl and pyrrolyl ligands are much longer, with an average length of 1.48 Å. The torsion angles between the indolyl and pyrrolyl rings and the BN_AN_H units are 32° and 35°, respectively, which would still allow for a non-negligible BN_H π-interaction. On the other hand, both heterocyclic groups are electronegative substituents, which tend to avoid π-bonding through their N_H atoms. Considering its NMR data, the same holds for compound **2c**.

The dihedral angles N3−B2−B1−N4 and N2−B2−B1−N1 are 75° and 72° in **2a** and 59° and 55° in **2b**. Thus, the twisting about the B−B bond is larger in **2a** than in **2b**, which is remarkable considering the greater steric requirement of the indolyl group. Finally, the boron−boron bond lengths amount to 1.716(2) Å in **2a** and 1.723(4) Å in **2b**, which are appropriate values for B−B single bonds.[10] Therefore, the structural parameters are consistent with a significant contribution from formulae **E** and **F** to the ground states of these molecules.

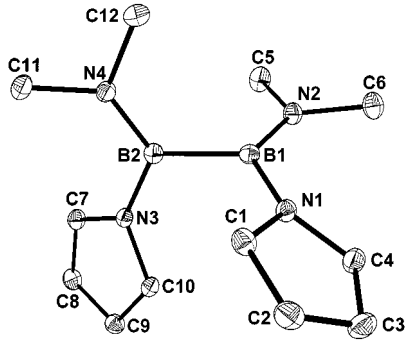

Figure 1. Molecular structure of the diborane(4) **2a** in the crystal; thermal ellipsoids are shown at a 25% probability level

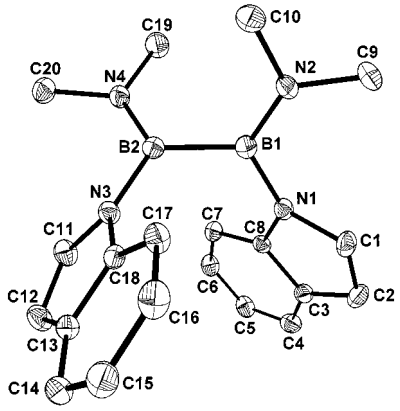

Figure 2. Molecular structure of the diborane(4) **2b** in the crystal; thermal ellipsoids are shown at a 25% probability level

Reduction to Tetraaminodiborates(2−)

Treating solutions of the $B_2(NR_2)_4$ compounds **2a**−**2c** with elemental Li (in finely dispersed form) in toluene leads to a very slow reaction of the metal. The reaction is accompanied by a slight color change of the solution and eventually the ^{11}B-NMR signal disappears, indicating that an insoluble boron-containing precipitate is formed. By carrying out these reactions of **2a** and **2c** in diethyl ether/toluene, yellow and red solutions are formed, respectively. However, for the reduction of **2b**, neat diethyl ether is required as the solvent; in this case the solution turns orange. These reactions proceed according to Equation 2.

From the red solutions of the reduced $B_2(NR_2)_4$ compounds **2a**−**2c**, yellow crystals of **3a**, orange crystals of **3b**, and red crystals of **3c** were isolated. All were found to be extremely air- and moisture-sensitive.[19] Preliminary studies of their chemical behaviour have demonstrated that they can be considered as strong reducing agents. This will be reported in a separate paper.

NMR Spectra

The shielding at the boron atoms of the tetraaminodiboranes(4) (δ^{11}B = 37.0 for **2a**; 36.7 for **2b**; 37.9 for **2c**) corresponds to that found for $B_2(NMe_2)_4$ (δ^{11}B = 36.6) or $B_2(NMe_2)_2Cl_2$ (δ^{11}B = 37.5). Two signals for the NMe_2 groups, both in the ^{1}H- and the ^{13}C-NMR spectra, are indicative of hindered rotation about the B−NMe_2 bond. Considering the ^{1}H-NMR data, the shift differences between these two signals are 0.12 ppm for **2a**, 0.18 ppm for **2b**, and 0.04 ppm for **2c**. The small difference found for **2c** may indicate a greater twisting of the NMe_2 groups in relation to the N_2BB planes, while for **2a** and **2b** the twisting does not exceed 10°.

On anion formation, the boron centers become more shielded by 4.0−9.6 ppm. While the NMR signals for the NMe_2 groups are slightly upfield shifted in **3a** and **3b**, a deshielding of 0.1 ppm is observed for **3c**. These observations are in accord with the trend in the ^{11}B shieldings shown by compounds $Ph(Me_2N)B-B(NMe_2)Ph$[14] and $[Ph(Me_2N)B=B(NMe_2)Ph](LiOEt_2)_2$,[14] where δ^{11}B changes from 49.3 to 33. Since in the anions **3** the amino groups are almost perpendicularly oriented in relation to the B_2N_4 plane, all effects of B−N π-bonding can be neglected and the increased shielding, as well as the decrease in the line width, indicates higher electron density at the boron atoms. This is of course due to the strong B−B π-bonding, which also has the effect that the two BN_2 planes tend to become mutually planar, in contrast to the 57−70° torsion angle found in the neutral compounds. Moreover, the much simpler ^{1}H- and ^{13}C-NMR spectra of the "anions" **3a**−**3c** compared to those of **2a**−**2c** suggest a higher symmetry for the anions (see X-ray structure analysis).

X-ray Structure Analysis

The molecular structures of the dilithium tetraaminodiborates are depicted in Figures 3−5. The structural parameters of the compounds **2a**, **2b**, **3a**−**3c** are summarized in Table 1.

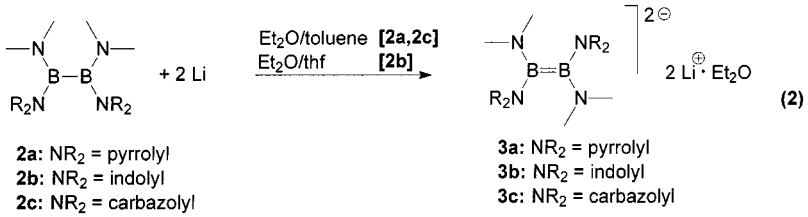

Table 1. Selected bonding parameters; bond lengths in Å, bond angles, and angles between planes in degrees

[a] The molecule is centrosymmetric, therefore B2 corresponds with the symmetry-equivalent atom B1A. – [b] Of the two independent molecules of **3b** in the asymmetric unit, one is centrosymmetric (related data given as B1N1N2), while the other is non-centrosymmetric. The core of the molecule has been labelled B2N3N4 and B4N5N6. In the columns, B1 refers to B3, B2 to B4, etc. – [c] There are two independent centrosymmetric molecules in the asymmetric unit. The first molecule is labelled B1N1N2/B1AN1AN2A, the second B2N3N4/B2BN3BN4BA.

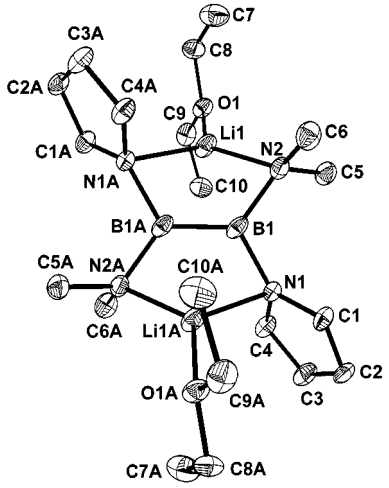

Figure 3. Molecular structure of the diborate **3a** in the crystal; thermal ellipsoids are shown at a 25% probability level

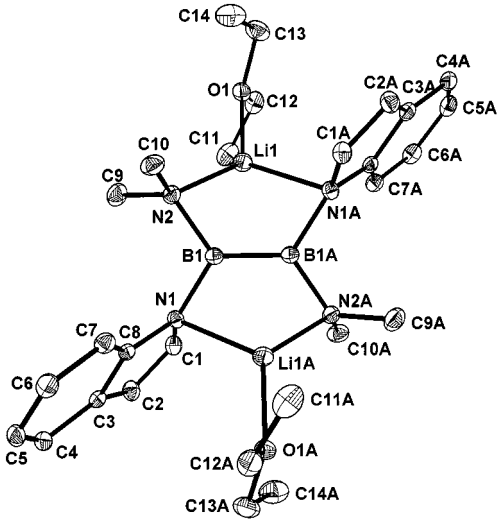

Figure 4. Molecular structure of the diborate **3b** in the crystal; thermal ellipsoids are shown at a 25% probability level

There are two independent molecules in the asymmetric unit for compounds **3b** and **3c**. One of the two molecules of **3b** lies on a crystallographic inversion center, and this also holds true for compound **3a**.

In contrast to the neutral diborane(4) compounds **2**, a planar B_2N_4 moiety is present in the anions of **3**. More importantly, the B−B bond lengths are 0.12 Å shorter than those in the corresponding tetraaminodiboranes. This, as well as the planarity of the B_2N_4 skeleton, gives an excellent indication for the presence of B=B double bonds.

Another structural feature to be noted is that the Me_2N groups are perpendicularly arranged in relation to the B_2N_4 planes, their N atoms being pyramidal, with an average BN_A distance of 1.54 Å. BN_A π-bonding is therefore absent. Moreover, the BN_H bond lengths to the *N*-heterocycles are longer: 1.564(6) Å in **3a**, on average 1.56 Å in **3b**, and 1.562(6) Å and 1.572(6) Å in **3c**, respectively. The rings themselves are twisted in relation to the B_2N_4 plane by 64°,

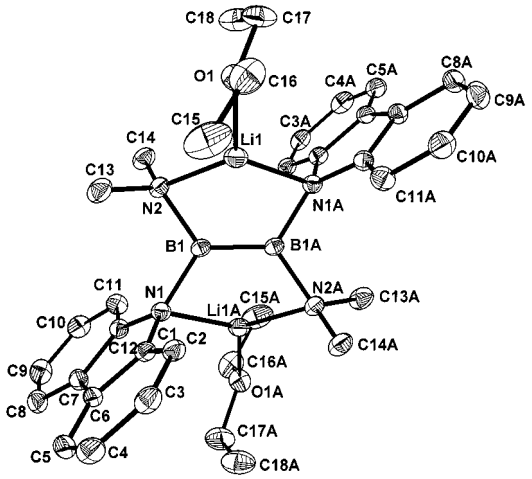

Figure 5. Molecular structure of the diborate **3c** in the crystal; thermal ellipsoids are shown at a 25% probability level

67°, and 74°; BN_H π-bonding can, therefore, also be excluded.[11]

However, the orientation of the amino groups is essential for the coordination of the lithium cations, which are surrounded in a trigonal-pyramidal geometry by two nitrogen atoms and an oxygen atom of an ether molecule. Thus, the tetraaminodiborate(4) unit acts as a bis-bidentate ligand. We assume that this feature of the molecular structure of the diborate can be considered as one reason for the ease of reduction of the tetraaminodiborane to the diborate. The LiN atom distances lie in the range 1.98 Å to 2.25 Å, and compare well with those found in many other LiN compounds.[12][13] Rather wide N−Li−N bond angles are responsible for the comparatively short Li−B distances (2.3−2.2 Å). An even more important reason for the ease of reduction of the tetraaminodiboranes to diborates seems to be that the starting material must bear an aromatic substituent. Considering literature data and our own investigations, there would seem to be no known reductions of diboranes(4) where there is not at least one aromatic ring system connected to the B_2 moiety.[14][15] This leads to the supposition that, in the mechanism of these reactions, the aromatic substituent may act as the primary electron acceptor.

MO Calculations

In order to support the experimental results and to obtain information on the bonding situation and the possibilities of delocalization of the B−B π-bond, geometry optimized MO calculations,[16] including an NBO analysis,[17] were performed on the model compound $(H_2OLi)_2(Me_2N)_2B_2(NC_4H_4)_2$ **4**. Figure 6 shows the geometry of the calculated compound. Some results are summarized in Table 2.

The NBO analysis shows that the B−B σ-bonding orbital and a B−B π orbital are strongly occupied, with each boron $2p_z$ orbital holding 0.9404 e. These orbitals are perpendicular to the B_2N_4 plane and therefore represent a typically

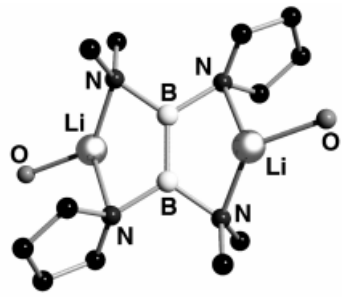

Figure 6. Calculated structure of **4**, Becke 3LYP/6-31G* optimized, NIMAG 0; H atoms have been omitted for clarity

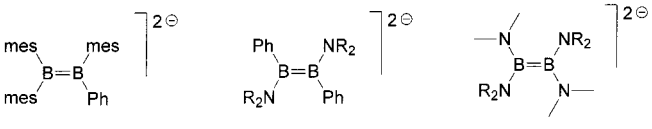

Table 2. Geometrical data for model compound **4** based on Becke 3LYP/6-31G* calculations compared with experimental data for compounds **3a**−**3c**

	Theor. $d_{(E-E)}$ [pm]	Exp. $d_{(E-E)}$ [pm]	Theor. ϕ [°]	Exp. ϕ [°]

$B-NMe_2$	154	154	69	62−67

localized π-bond. The "second-order pertubation analysis" shows that there is no significant donor−acceptor interaction of the B−B π-bond with orbitals of other atoms. Delocalization of the π-electron density through the BN bonds can therefore be excluded.

Discussion

The first two-electron reduction of a diboron(4) compound was discovered by Power et al. in 1992 using tris(mesityl)phenyldiborane(4) as the diborane(4) source.[15] Shortly afterwards, the reduction of 1,2-bis(dimethylamino)-1,2-diphenyldiborane(4) by lithium in the presence of diethyl ether gave access to the dianion $[Ph(Me_2N)B=B(NMe_2)Ph]^{2-}$.[14] Dianions of the type $[R_2N(Me_2N)B=B(NMe_2)NR_2]^{2-}$ (R_2N = pyrrolyl, indolyl, carbazolyl) now complete a series of tetraaminodiborates(4). Proceeding along this series from the dianion **4a** through **4b** to **4c**, one notes that the differences in the chemical shifts $\delta^{11}B$ become increasingly smaller.

4a **4b** **4c**

For the tetraaryldiborate(4) dianion $\Delta\delta^{11}B$ is 74.3 ppm, for the bis(dimethylamino)bis(phenyl)diborate(4) $\Delta\delta^{11}B$ is 16.3 ppm, while for the tetraaminodiborates(4) described here $\Delta\delta^{11}B$ is only 9.0−9.6 ppm. This is due to the increasing B−N π-bonding effects on the shielding of the B atoms in the neutral diboranes, as demonstrated by the short Me_2N bonds in compounds **2a** and **2b**, which are coplanar

with the N_2BB plane. Therefore, the gain in electron density at the boron atoms in the dianions is largest in compound **4a**, because there is little if any B−C π-bonding in the starting material [it should be noted that the boron atoms in $tBu_3(Me_3Si)B_2$ are even more strongly deshielded; $\delta^{11}B$ = 120], and is obviously smallest in $(R_2N)(Me_2N)B-B(NMe_2)(NR_2)$, which bears four amino groups.

On the other hand, the decrease in the B−B bond lengths on reduction is largest for the tetraaminodiboron moiety (ca. 0.12 Å), while for **4a** Δd(B−B) is 0.08 Å and for **4b** it is 0.07 Å. This cannot be exclusively attributed to the fact that the B−B bond lengths are shorter in $mes_2B-BmesPh$ [1.71(1) Å][15] and $Ph(Me_2N)B-B(NMe_2)Ph$ [1.714(4) Å][14] as compared to those in the new tetraaminodiboranes [1.718(2) Å, 1.723(4) Å]. One reason for the greater contraction of the B−B bond lengths in compounds **3** may lie in the fact that the dianion acts as a chelating ligand forming two five-membered heterocycles with the Li atoms. The lone pairs of the Li-coordinating N atoms are all orientated towards the Li atoms, which precludes delocalization of the boron π-electrons.

While there is normally an atom distance difference of 0.2 Å if a single-bonded system becomes doubly bonded (e.g. the C−C bonds in ethane and ethene, respectively), the B−B bond length difference is smaller. This is to be expected because in the diborate dianions the boron atoms do not change their coordination number and remain sp^2 hybridized. In addition, the two-electron reduction imparts to the boron atom a charge of −0.94 e, which should result in a repulsion between the two boron atoms and hence a counteractive effect on the B=B double bond length. However, the planarity of the B_2N_4 units in the new diborates(4), in addition to all the other discussed geometrical and electronic features and the results of the MO calculations, provide strong evidence for the presence of a truly localized B=B double bond.

Based on the present result, one might envisage that even the simplest tetraaminodiborane(4), $B_2(NMe_2)_4$, might be reducible by lithium. However, experiments carried out in analogy to those described here did not produce a $B_2(NMe_2)_4^{2-}$ anion. Therefore, we suggest that an "aromatic" moiety must be present to allow the electron transfer from lithium (metal) to boron [of the diborane(4)].

Experimental Section

General: All experimental manipulations were conducted under anhydrous conditions employing Schlenk techniques using argon as a protecting blanket. Solvents were dried by conventional methods. Boron-containing starting materials were prepared by literature methods.[7][8] − NMR: Jeol 270 and 400 spectrometers [standards: TMS (^1H, ^{13}C), external $BF_3{\cdot}OEt_2$ (^{11}B)]. − X-ray structure determination: Siemens P4 with CCD area detector, Mo-K_α radiation, graphite monochromator, LT device.

Bis(dimethylamino)bis(pyrrolyl)diborane(4) (2a): To a vigorously stirred suspension of pyrrolyllithium (2.35 g, 29 mmol) in toluene (40 mL) at −78°C was added a solution of dichlorobis(dimethylamino)diborane(4) (2.35 g, 13 mmol) in toluene (15 mL). The suspension was allowed to warm to ambient temperature and stirring was continued for a further 23 h. Then, THF (0.25 mL) was added and, after stirring for an additional 1 h, the insoluble material was removed by centrifugation (15 min at 15000 rpm). The solid was washed with toluene (10 mL). All volatiles were then removed from the solution in vacuo. A greenish colored oil remained, which solidified within a few minutes. Pure **2a** was obtained by sublimation (90°C/9·10^{-3} Torr) in large colorless prisms.[18] Yield: 2.54 g of **2a** (81%), m.p. 48−51°C. − ^{11}B NMR (64 MHz, C_6D_6): δ = 37.0 [$h_{1/2}$ = 320 Hz, $B_2(NMe_2)_2(pyrrolyl)_2$]. − ^1H NMR (270 MHz, C_6D_6): δ = 6.93 (dd, 4 H, $H^{1,4}$), 6.49 (dd, 4 H, $H^{2,3}$), 2.56 [s, 6 H, $N(CH_3)_2$], 2.44 [s, 6 H, $N(CH_3)_2$]. − ^{13}C NMR (68 MHz, C_6D_6): δ = 124.6 (pyrrolyl $C^{1,4}$), 111.6 (pyrrolyl $C^{2,3}$), 42.6 [$N(CH_3)_2$], 39.3 [$N(CH_3)_2$]. − $C_{12}H_{20}B_2N_4$ (241.94): calcd. C 59.57, H 8.33, N 23.16; found C 59.12, H 8.35, N 22.29.

Bis(dimethylamino)bis(indolyl)diborane(4) (2b): Prepared in analogy to **2a** from indolyllithium (7.39 g, 60.0 mmol) in toluene (60 mL) and $B_2(NMe_2)_2Cl_2$ (5.42 g, 30.0 mmol) in toluene (25 mL) with stirring for 18 h. Addition of THF (1 mL), reducing the volume of the solution by ca. 50% and storage for 4 days at −20°C gave crystalline **2b**.[18] Yield: 8.80 g of **2b** (89%), m.p. 63−67°C. − ^{11}B NMR (64 MHz, C_6D_6): δ = 36.7 [$h_{1/2}$ = 400 Hz, $B_2(NMe_2)_2(indolyl)_2$]. − ^1H NMR (400 MHz, C_6D_6): δ = 7.72 (dd, 2 H, H^4), 7.49 (dd, 2 H, H^7), 7.19 (dd, 2 H, H^6), 7.12 (dd, 2 H, H^5), 7.03 (d, 2 H, $^3J_{HH}$ = 2.7 Hz, H^1), 6.67 (d, 2 H, $^3J_{HH}$ = 2.7 Hz, H^2), 2.45 [s, 6 H, $N(CH_3)_2$], 2.27 [s, 6 H, $N(CH_3)_2$]. − ^{13}C NMR (100 MHz, C_6D_6): δ = 139.8 (indolyl C^8), 131.4 (indolyl C^3), 129.5 (indolyl C^1), 122.2 (indolyl C^5), 120.9 (indolyl C^4), 120.7 (indolyl C^6), 113.1 (indolyl C^7), 106.0 (indolyl C^2), 41.2 [$N(CH_3)_2$], 39.9 [$N(CH_3)_2$]. − $C_{20}H_{24}B_2N_4$ (342.05): calcd. C 70.23, H 7.09, N 16.38; found C 69.84, H 7.06, N 16.26.

Bis(carbazolyl)bis(dimethylamino)diborane(4) (2c): Prepared in analogy to **2a** from carbazolyllithium (1.60 g, 9.2 mmol) in toluene (40 mL) and $B_2(NMe_2)_2Cl_2$ (0.83 g, 4.6 mmol) in toluene (20 mL) with stirring for 18 h. THF (0.3 mL) was added, all volatiles were removed from the solution, and then the residue (2.92 g) was dissolved in hot toluene (60 mL). Removal of some insoluble material and cooling to −20°C afforded small crystals. Yield: 1.95 g of **2c** (95%), m.p. 113−117°C. − ^{11}B NMR (64 MHz, toluene): δ = 37.9 [$h_{1/2}$ = 780 Hz, $B_2(NMe_2)_2(Cbz)_2$]. − ^1H NMR (400 MHz, C_6D_6): δ = 8.01 (d, 4 H, $^3J_{HH}$ = 7.8 Hz, $H^{6,9}$), 7.35 (d, 4 H, $^3J_{HH}$ = 8.3 Hz, $H^{3,12}$), 7.29 (ps. t, 4 H, $^3J_{HH}$ = 7.6 Hz, $H^{4,11}$), 7.17 (ps. t, 4 H, $^3J_{HH}$ = 7.3 Hz, $H^{5,10}$), 2.70 [s, 6 H, $N(CH_3)_2$], 2.66 [s, 6 H, $N(CH_3)_2$]. − ^{13}C NMR (100 MHz, C_6D_6): δ = 142.2 (Cbz $C^{7,8}$), 125.6 (Cbz $C^{2,13}$), 125.5 (Cbz $C^{4,11}$), 119.9 (Cbz $C^{6,9}$), 112.6 (Cbz $C^{3,12}$), 41.3 [$N(CH_3)_2$], 41.2 [$N(CH_3)_2$]. − $C_{28}H_{28}B_2N_4$ (442.18): calcd. C 76.06, H 6.38, N 12.67; found C 75.74, H 6.82, N 12.60.

Dilithium Bis(dimethylamino)bis(pyrrolyl)diborate(4) (3a): A suspension of Li powder (40 mg, 13 mmol) in diethyl ether (20 mL) was cooled to −78°C. A solution of **2a** (1.54 g, 6.4 mmol) in toluene (20 mL) was then added under stirring and the suspension was allowed to warm to ambient temperature. After 18 h, the solution was yellow-green in color. The excess Li was then removed and the solution was concentrated in vacuo to a volume of ca. 30 mL. Cooling to −20°C for ca. 12 h led to the deposition of light-yellow crystals.[18] Yield: 1.89 g of **3a** · 2 EtO_2 (73%). **3a** was found to decompose rapidly at 73°C, and within 10 d at ambient temperature. − ^{11}B NMR (64 MHz, C_6D_6): δ = 27.4 [$h_{1/2}$ = 140 Hz, $Li_2B_2(NMe_2)_2(pyrrolyl)_2$]. − ^1H NMR (270 MHz, C_6D_6): δ = 7.13 (m, 4 H, $H^{2,3}$), 7.02 (dd, 4 H, $H^{1,4}$), 3.26 [q, 8 H, ^3J(H,H) = 3.8 Hz, $(OCH_2CH_3)_2$], 2.10 [s, 12 H, $N(CH_3)_2$], 1.10 [t, 12 H, ^3J(H,H) =

3.8 Hz, $(OCH_2CH_3)_2$]. – ^{13}C NMR (68 MHz, C_6D_6): δ = 124.2 (pyrrolyl $C^{1,4}$), 111.7 (pyrrolyl $C^{2,3}$), 65.9 [$(OCH_2CH_3)_2$], 39.5 [$N(CH_3)_2$], 15.5 [$(OCH_2CH_3)_2$].

Dilithium Bis(dimethylamino)bis(indolyl)diborate(4) (3b): Prepared in analogy to **3a** from Li (50 mg, 7.2 mmol) in diethyl ether (15 mL) and **2b** (1.37 g, 4.0 mmol) in diethyl ether (25 mL). Following the addition of **2b** to the Li suspension, an orange-coloured solid separated at −10°C. It was isolated and redissolved in THF (15 mL), then the excess Li was removed by filtration. On leaving the solution to stand overnight at 4°C, orange crystals separated.[18] Yield: 1.73 g (86%). **3b** was found to decompose within 1 d at ambient temperature and within 3 d at 4°C. – ^{11}B NMR (64 MHz, C_6D_6): δ = 27.9 [$h_{1/2}$ = 130 Hz, $Li_2B_2(NMe_2)_2(indolyl)_2$]. – ^{1}H NMR (400 MHz, [D_8]toluene): δ = 8.28 (br. d, 2 H, H^1), 8.02 (br. d, 2 H, H^2), 7.76 (m, 2 H, H^4), 7.44 (m, 2 H, H^7), 7.20 (m, 4 H, $H^{5,6}$), 3.25 [q, 8 H, ^3J(H,H) = 3.8 Hz, $(OCH_2CH_3)_2$], 2.21 [s, 12 H, $N(CH_3)_2$], 1.10 [t, 12 H, ^3J(H,H) = 3.8 Hz, $(OCH_2CH_3)_2$]. – ^{13}C NMR (100 MHz, [D_8]toluene): δ = 140.7 (indolyl C^8), 137.8 (indolyl C^1), 134.8 (indolyl C^3), 122.4 (indolyl C^5), 121.2 (indolyl C^4), 120.1 (indolyl C^6), 113.8 (indolyl C^7), 110.4 (indolyl C^2), 65.9 [$(OCH_2CH_3)_2$], 41.5 [$N(CH_3)_2$], 15.2 [$(OCH_2CH_3)_2$].

Dilithium Bis(dimethylamino)bis(carbazolyl)diborate(4) (3c): To a stirred suspension of Li powder (50 mg, 7.2 mmol) in diethyl ether (20 mL) at 0°C was added a warm solution of **2c** (640 mg, 1.5 mmol) in toluene (25 mL). The solution rapidly turned reddish brown. After stirring for 3 days, the excess Li was removed by filtration and washed with diethyl ether (20 mL). The combined filtrate and washings were then kept at 4°C until some red-brown crystals separated.[18] – ^{11}B NMR (64 MHz, toluene/Et_2O): δ = 28.9 ($h_{1/2}$ = 200 Hz). – ^{1}H NMR (270 MHz, C_6D_6): δ = 7.73 (m, 8 H, H_{arom}), 7.21 (m, 8 H, H_{arom}), 3.14 [q, ^3J(H,H) = 7.0 Hz, $(OCH_2CH_3)_2$], 2.96 [s, 12 H, $N(CH_3)_2$], 1.02 [t, ^3J(H,H) = 7.0 Hz, $(OCH_2CH_3)_2$]. – ^{13}C NMR (68 MHz, C_6D_6): δ = 144.3 (Cbz $C^{7,8}$), 129.1 (Cbz $C^{2,13}$), 126.1 (Cbz $C^{4,11}$), 120.1 (Cbz $C^{6,9}$), 119.5 (Cbz $C^{5,10}$), 116.2 (Cbz $C^{3,12}$), 67.2 [$(OCH_2CH_3)_2$], 43.2 [$N(CH_3)_2$], 15.8 [$(OCH_2CH_3)_2$].

X-ray Structure Determinations: Crystals were covered with perfluoropolyether oil at −40°C and suitable specimens were selected and mounted on a glass fibre. Cell dimensions were determined from the reflections on 15 frames each at four different χ and ψ settings by changing ψ by 0.3° per frame at 193 K. Data collection was performed in the hemisphere mode of the SMART program at 193 K by collecting a total of 1300 frames. Data reduction was performed using the program SAINT; no absorption correction was applied. The structures were solved by direct methods (SHELXTL-97). Non-hydrogen atoms were refined anisotropically (SHELX-97) and hydrogens were placed in calculated positions by applying a riding model. Crystallographic data and selected data relating to the data collection and refinement are summarized in Table 3.

Acknowledgments

We thank the Fonds der Chemischen Industrie, Chemetall AG, and the Leibniz Rechenzentrum München for support, and Mr. P. Mayer and Mr. W. Linscheid for recording the many spectra.

[19] The stabilities of the tetraaminodiborates(4) **3** decrease rapidly if a stronger donor than diethyl ether is used for coordination of the lithium atoms. Thus, the preparation of the THF-coordinated dilithium tetraaminodiborate(4) **3a** by reduction of the corresponding tetraaminodiborane(4) **2a** in THF or via ligand exchange leads to the desired THF-coordinated dianionic species, which decomposes rapidly above −30°C. In the presence of crown ether ligands, however, the decomposition temperature decreases to less than −78°C. On the other hand, the lithium atoms are not necessary for the stability of all the diborate species: substitution of the NMe_2 groups in the diborane(4) **2a** with mesityl groups leads to the compound mes(pyrrolyl)BB(pyrrolyl)mes **2d**. By reduction of **2d** with lithium in diethyl ether or THF, dilithium tetraaminodiborates(4) can be obtained, which are stable at room temperature. These and other results will be reported shortly.

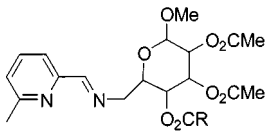
[Pd(N,N-chelate)(olefin)] Complexes Containing Chiral Nitrogen Chelates Based on Carbohydrates – Enantioselectivity of Olefin Coordination

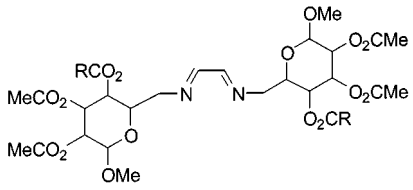
Maria L. Ferrara,[a] Federico Giordano,[a] Ida Orabona,[a] Achille Panunzi,[b] and Francesco Ruffo*[a]

Dedicated to Prof. Fausto Calderazzo on the occasion of his 70th birthday



Keywords: Palladium / Bidentate nitrogen ligands / Carbohydrates / Alkenes / Enantioselectivity

Chiral N,N-chelates of formula 6-Me-pyridine–2-CH=N–R (**1**) and R–N=CH–CH=N–R (**2**) (R = 6-deoxy-α-D-glucoside or 6-deoxy-α-D-mannoside residue) and their palladium(0) complexes [Pd(N,N-chelate)(olefin)] (**I**) were prepared. Symmetrical type **2** ligands induced higher enantioselectivity in the coordination of prochiral olefins. The ability of a type **1** chelate to promote a stereoselective process was also assessed, i.e. dimethylfumarate inserted into the Pd–Me bond formed upon methylation of a type **I** complex with 50% ee. Finally, a water-soluble Pd^0 complex was also prepared by deprotecting the alcoholic functions on the sugar residue, and its molecular structure determined through X-ray diffractometry.



Introduction

An important challenge that chemical sciences must meet in the forthcoming third millenium is that of making available chiral products by means of environmentally friendly processes. Organometallic chemistry may be able to fulfill this demand,[1] since metal-assisted enantioselective syntheses can often reduce the consumption of resources. To date, the best results have been achieved by using phosphanes as chiral auxiliaries of active transition metals.[2] However, nitrogen ligands are attracting increasing interest.[3] Aiming to contribute to this growing field of research, we investigated the feasibility of using new chiral N,N-chelates based on carbohydrates[4] (Figure 1), with the assumptions that (i) these natural products can be a convenient source of chiral auxiliaries, and (ii) both a lypophylic and a hydrophilic form of the ligands can be available depending on whether or not the alcoholic functions are protected. In the latter case the environmental and economic benefits of using the ligands in aqueos media would be added.

In a previous report[5] we described type **1** and **2** ligands derived from α-D-mannose, and their alkene−Pt^0 complexes. A preliminarly investigation of the ability of the ligands to induce stereoselective coordination of prochiral olefins yielded encouraging results. Therefore, our studies have been extended to the synthesis of related chelates based on α-D-glucose. Olefin−Pd^0 species containing nitrogen ligands are currently receiving a lot of attention,[6] so [Pd(N,N-chelate)(olefin)] complexes **I** were prepared. In this paper we describe the synthesis of the ligands, and the preparation and the solution behaviour of the complexes. The ability of the chelates to induce enantioselective coordination of prochiral olefins is also discussed. Furthermore, the ability of one chelate to promote a stereoselective stoichiometric process is assessed, i.e. insertion of dimethylfumarate into the Pd−Me bond formed upon oxidative addition of Me_3OBF_4 to a complex of type **I**. Finally, preparation of a water-soluble compound of type **I** by deprotecting the alcoholic functions on the sugar residue is reported, along with its structure as determined through X-ray crystallography.

Results and Discussion

Synthesis and Characterization of the Ligands

The synthesis of the N,N-chelates is depicted in Scheme 1. The compounds are identified by a number followed by a capital letter, which indicates the sugar (M = mannose or G = glucose), and by the specification of the R substituent (Me or Ph). The symmetry of ligands of type **1** and **2** is C_1 and C_2, respectively. For both types three different derivatives were obtained. Among derivatives of type **1**, **1G-Ph** and **1M-Ph** differ by the nature of the carbohydrate (respectively glucose and mannose), substituents being equal. **1G-Me** and **1G-Ph** are both based on glucose, while the R substituent in position 4 is different. Analogous considerations hold true for ligands of type **2**.

Scheme 1

Known procedures allowed the synthesis of methyl-2,3,4-tri-*O*-acetyl-6-azido-6-deoxy-α-D-glucoside (**3G-Me**),[7] methyl-2,3-di-*O*-acetyl-4-*O*-benzoyl-6-azido-6-deoxy-α-D-glucoside (**3G-Ph**),[8][9] methyl-2,3-di-*O*-acetyl-4-*O*-benzoyl-6-azido-6-deoxy-α-D-mannoside (**3M-Ph**)[9] by starting from the corresponding commercial methyl-α-D-piranosides. Reaction of these azides with $PMePh_2$ afforded the iminophosphoranes **4**,[10] which were converted in situ into type **1** or type **2** ligands by condensation with, respectively, 6-methyl-2-pyridinecarboxaldehyde or glyoxal. The ligands were obtained in pure form as white powders by column chromatography. Their characterization was performed through NMR spectroscopy, elemental analysis and optical activity measurements (see Experimental Section).

Synthesis of [Pd(N,N-chelate)(olefin)] Complexes (I)

It is known[11] that the metal−alkene bond can be described in terms of a σ donation from the filled alkene π orbital to an empty metal orbital, and a π back donation from a filled metal orbital to the empty π* orbital of the alkene. The latter contribution plays a prominent role in Pd^0- and Pt^0-olefin complexes, and, for this reason, their stability increases as the electron-acceptor properties of the alkene grow.[6a,6d,6e]

In the presence of good donor ligands,[6e,12] such as type **1** or **2** diimines, a satisfactory electronic balance within the complex is met only if the alkene is able to withdraw effectively electron density from the metal centre through π back donation. Hence, stable type **I** complexes could be obtained only with olefins bearing good electron-acceptor substituents. Dimethylfumarate (dmf), fumarodinitrile (fdn), and maleic anhydride (ma) were effectively used. The synthesis of the complexes was performed by reacting $[Pd(dba)_2]$[13] (dba = dibenzylideneacetone) with the chelate and the olefin in dry toluene (Equation 1). The products were obtained in pure form after column chromatography as yellow to orange microcrystalline powders.

$$[Pd(dba)_2] + \text{N,N-chelate} + \text{olefin} \rightarrow \mathbf{I} + 2\ \text{dba} \quad (1)$$

Alternatively, fdn or ma derivatives could be synthetized by substituting dmf in **I** according to Equation 2.

$$[Pd(\text{N,N-chelate})(\text{dmf})] + \text{ma} \rightarrow [Pd(\text{N,N-chelate})(\text{ma})] + \text{dmf} \quad (2)$$

Only with ligands **1** was it possible to obtain dmf complexes of type **I** in acceptable yields, while in the presence of chelates **2** dmf complexes displayed little stability. These results probably reflect the electronic features of both the alkenes and the N,N-chelates. Actually, fdn and ma show similar electron-withdrawing abilities, both more pronounced than that displayed by dmf.[6d,14] Furthermore, according to previous studies,[12] ligands **2** are expected to be better σ donors than ligands **1** where one nitrogen atom belongs to a pyridine ring. Therefore, it seems reasonable that the above-mentioned good electronic balance within the complex can be achieved only in the presence of fdn or ma.

Type **I** complexes can be handled in air and were stored for long time at 233 K without appreciable decomposition.

They were fairly soluble in chlorinated solvents or toluene, but were poorly soluble in ether and insoluble in hexane. Complexes of type **1** ligands were stable in solution, while a slow decomposition process (days to completion) leading to Pd, N,N-chelate and free olefin was monitored for type **I** complexes containing ligands **2**.

NMR Spectroscopy

Large high-field shift [$\Delta\delta(^1H) \geqslant 3$ ppm, $\Delta\delta(^{13}C) \geqslant 90$ ppm] of both olefin protons and carbons was observed in the NMR spectra (Tables 1 and 2) according to a remarkable π back donation contribution to the Pd−alkene bond. As expected, the shift[15] was more pronounced for maleic anhydride and fumarodinitrile, which display the better electron-acceptor properties.

NMR spectra also allowed information to be gained on the solution behaviour of species of type **I**. Previous studies[6d,6e] disclosed that [Pd(N,N-chelate)(olefin)] complexes can be involved in dynamic processes in solution, i.e. olefin dissociation/association and olefin rotation around the metal−alkene axis. The rate of both processes decreases as the bulkiness of the N,N-ligand and/or the electron-accepting properties of the alkene grow.

For a given complex of type **I** the number of possible isomers and their symmetry depend on the geometry of both the alkene and the N,N-chelate. Prochiral olefins (dmf or fdn, C_{2h} symmetry) can afford two diastereomers depending on whether the alkene coordinates *re* or *si*. They can interconvert by dissociation of the alkene and its reassociation (with the opposite enantioface) to Pd. Spectra recorded at 298 K displayed separated signals for the diastereomers, which indicates that their interconversion, and hence olefin dissociation, is slow[16] at room temperature. At 328 K the spectra showed little difference with respect to those recorded at room temperature, but for variation of the olefin patterns due to the increased rate of alkene rotation. However, when an excess of olefin was added, the signals broadened even at room temperature. Two exceptions were [Pd(**2G-Me**)(fdn)], for which it was necessary to raise the temperature in order to observe broad olefin signals, and [Pd(**1G-Me**)(dmf)], whose spectrum at 328 K displayed averaged signals for the diastereomers even in the absence of free dmf. This spectral evidence indicates that the rate of alkene dissociation−reassociation is increased by the presence of free unsaturated ligand, according to an associative mechanism.[6d,6e]

The two halves of dmf or fdn in each one of the diastereomers containing either **1M-Ph** or **1G-Me** appeared not to be equivalent at 298 K, i.e. olefin protons gave rise to doublets or AB quartets and/or the corresponding carbons resonated separately. This result indicates that at room temperature olefin rotation is also slow, since a fast rotation would exchange the two halves of the unsaturated ligand. As expected, olefin resonances broadened in the spectra at 328 K, due to a fastened olefin rotation.

On the other hand, the room-temperature NMR spectra of [Pd(**1G-Ph**)(fdn)] showed a symmetrical olefin in one of the two diastereomers. This suggests that olefin rotation may or may not be hindered, according to which enantioface is coordinated. At 328 K olefin rotation also becomes

fast in the more stereochemically rigid isomer. A similar situation holds true for [Pd(**1G-Ph**)(dmf)].

No information concerning olefin rotation was available from NMR spectra of dmf or fdn derivatives containing ligands of type **2**. Actually, since the complexes display C_2 symmetry, all the nuclei related by the twofold axis are expected to be equivalent.

Maleic anhydride (C_{2v} symmetry) affords complex [Pd(**1M-Ph**)(ma)] in two isomeric forms, which can interconvert by either olefin rotation or dissociation/reassociation of the alkene. Since the isomers are separately observed in both spectra, it can be inferred that both motions are hindered at room temperature. At 328 K the proton spectrum consists of a unique broad pattern due to fast interconversion of the diastereomers. Conversely, complex [Pd(**2M-Ph**)(ma)] exists as a unique isomer. Both ^{1}H- and ^{13}C-NMR spectra show an unsymmetrical olefin, thus demonstrating that dissociation/reassociation of the alkene is slow at 298 K. Also the rotation of the alkene is hindered at room temperature, as suggested by the nonequivalence of the two halves of the N,N-ligand in the carbon spectrum. On raising the temperature to 328 K olefin rotation becomes fast, as suggested by the presence of a symmetric and sharp proton pattern for the N,N-chelate.

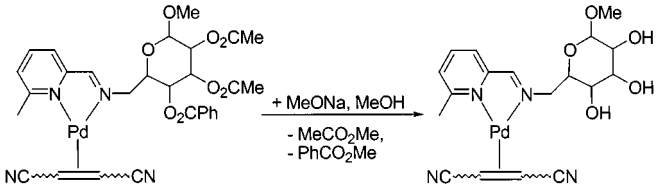
Enantioselectivity of Olefin Coordination

As mentioned above, the coordination of prochiral olefins to the [Pd(N,N-chelate)] moiety gives rise to two diastereomers according to which enanantioface is bound to the metal centre. Fresh solutions of complexes of type **I** displayed the presence of both diastereomers, whose ratio could be measured by integrating suitable peaks (Table 3). The ratio was neither affected by prolonged standing in solution nor by the presence of free olefin, which merely increased the rate of interconversion of the diastereomers (see above). These observations indicate that equilibrium is reached within a few seconds from dissolution of the samples. Analogous platinum compounds[5] require several minutes before equilibrium is attained.

Table 3. Diastereomeric equilibrium composition[a] for complexes of type **I** with prochiral olefins

Complex	Composition
[Pd(**1M-Ph**)(dmf)]	55:45
[Pd(**1M-Ph**)(fdn)]	55:45
[Pd(**1G-Ph**)(dmf)]	55:45
[Pd(**1G-Ph**)(fdn)]	55:45
[Pd(**1G-Me**)(dmf)]	55:45
[Pd(**1G-Me**)(fdn)]	85:15
[Pd(**2M-Ph**)(fdn)]	70:30
[Pd(**2G-Ph**)(fdn)]	75:25
[Pd(**2G-Me**)(fdn)]	97:3
[Pd(**1M***)(fdn)][b]	55:45

[a] In $CDCl_3$ at 298 K. – [b] In D_2O at 298 K.



An inspection of Table 3 reveals that the most relevant result concerning enantioselectivity was obtained in the case of [Pd(**2G-Me**)(fdn)]. The ratio between the diastereomers was estimated to be 97:3, indicating a strong preference for the coordination of one enantioface. Discrimination was also observed for the same olefin in the presence of either **2G-Ph** or **2M-Ph**, although to a lesser extent, affording diastereomeric ratios of 75:25 and 70:30, respectively. These results reveal that changing the 4-substituent on the glucoside residue (**2G-Me** vs **2G-Ph**) plays a more important role

than variation of the carbohydrate residue itself (**2G-Ph** vs **2M-Ph**). Among ligands **1**, only **1G-Me** competes with the symmetrical chelates, giving rise to a diastereomeric ratio of 85:15 in the presence of fdn. Conversely, the other ligands of type **1** induce little preference for one enantioface of dmf or fdn. It is also noteworthy that the values of diastereomeric excesses reported in Table 3 are very close to those measured for corresponding Pt^0 complexes containing the same ligands,[5][17] as observed for other related M^0 compounds.[6e,18]

These findings indicate that type **2** ligands prompt more effectively enantioselective coordination of *trans*-olefins. It is also observed that **1G-Me** and **2G-Me**, both based on a glucoside having acetyl groups as substituents, display the better discriminating properties within the corresponding class. However, the complexity of the ligands in terms of both steric and electronic features does not allow an easy rationalization of the factors which determine these results.

Synthesis and X-ray Structure of the Water-Soluble Complex [Pd(1M*)(fdn)]

Water-soluble Pd^0 complexes have recently attracted attention due to their possible use as catalysts in aqueous media.[19] During this work we successfully attempted the synthesis of a water-soluble type **I** complex by deprotecting the alcoholic functions in the sugar residue of the ligand. Treatment of [Pd(**1M-Ph**)(fdn)] with a catalytic amount of sodium methoxide in methanol resulted in quantitative hydrolysis of the ester groups of the carbohydrate residue (Scheme 2).

Scheme 2

The corresponding product [Pd(**1M***)(fdn)] could be isolated in high yield by adding diethyl ether to the reaction mixture. The most prominent feature of the complex is its solubility in both lypophilic (e.g. chloroform) and hydrophylic (e.g. water or methanol) solvents. Analogous to its parent derivative, the complex exists in solution as an equilibrium mixture of two diastereomers in 55:45 ratio.

The X-ray solid-state structure of the complex was determined. Crystallization from methanol/diethyl ether yielded

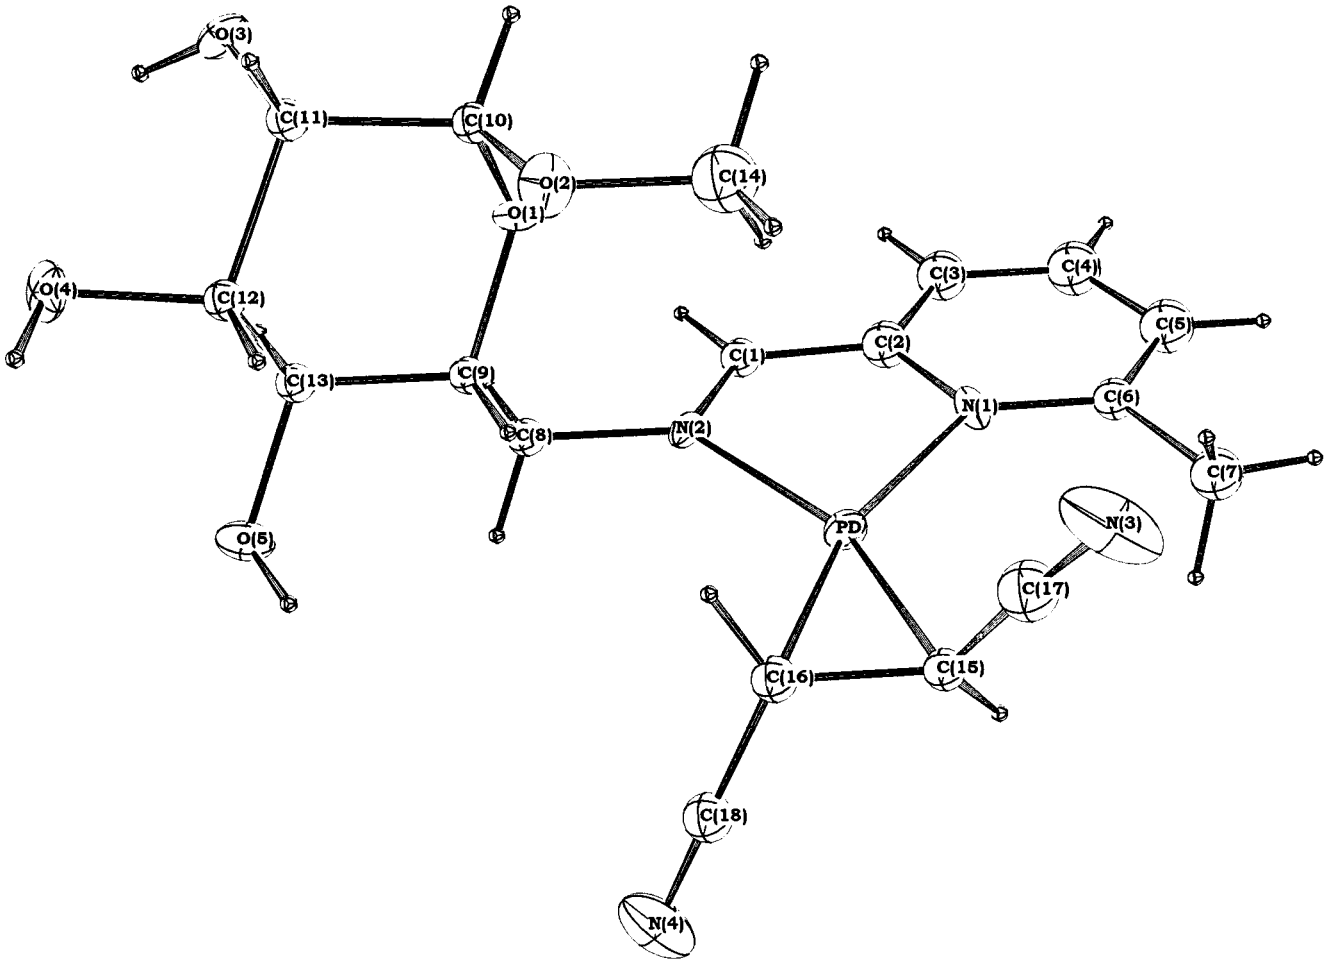


Figure 2. ORTEP view of [Pd(**1M***)fdn] showing the atom labelling scheme

single crystals only for one of the two diastereomers. An ORTEP drawing of this molecule with the atom labelling scheme is shown in Figure 2. Relevant geometric parameters are given in Table 4.

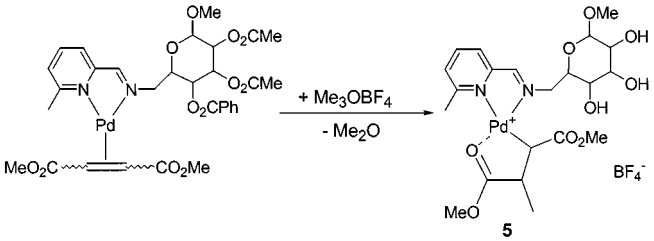
[a] ESDs in parentheses.



As expected[6e] for zerovalent [Pd(N,N-chelate)(olefin)] complexes the coordination geometry at Pd is trigonal planar. The coordination plane includes the pyridine ring. In fact, the atoms Pd, N(1), N(2), C(15), C(16), C(1), C(2), C(3), C(4), C(5), C(6), C(7), C(8) are coplanar within 0.06(2) Å. The sugar residue adopts the expected chair conformation and its mean plane is almost orthogonal to the coordination plane. As a consequence of the chemical non-equivalence, the bond lengths Pd−N(1) [2.17(1) Å] and Pd−N(2) [2.11(1) Å] are slightly, but significantly, different, and lie at the extremes of the range commonly found in Pd/α-diimine complexes,[6a,6c,6e] the shorter bond being adjacent to the double bond C(1)−N(2). The bite angle N(1)−Pd−N(2) [77.5(5)°] is very close to that found for most bidentate nitrogen ligands.[6c,6e] The olefin is bound to the metal in a regular arrangement. The two Pd−C bond lengths are equal, within the experimental error [average value 2.045(20) Å], and compare well with the values found in Pd complexes of α-diimines with electron-poor olefins.[6c,6e] The lengthening of the olefinic bond [C(15)−C(16) 1.46(3) Å], and the large out-of-plane displacements of the cyano groups [the torsion angle C(17)−C(15)−C(16)−C(18) being 145(2)°] compared with the value of 1.34 Å for the free alkene provide clear evidence of a rehybridization towards sp^3 of the olefinic carbon atoms upon coordination, in keeping with the substantial π back donation from the metal (see above).

Addition of Me_3OBF_4 to [Pd(1G-Ph)(dmf)]

Use in catalysis of type **I** complexes seems plausible.[6f] As organic processes promoted by Pd^0 species often involve oxidative addition to Pd^{II} and/or (stereoselective) insertion of unsaturated substrates into Pd^{II}−alkyl bonds, a preliminarly investigation of the feasibility of stoichiometric reactions of this kind in the coordination environment provided by a chelate of type **1** was made.

We previously reported[20] that [Pd(1,10-phen)(dmf)] reacts with Me_3OBF_4 affording the cyclometallated Pd^{II} product [Pd{CH(CO_2Me)CHMe(CO^aOMe)}(1,10-phen)-(*Pd*−O^a)]BF_4. The process proceeds in two steps, i.e. (i) oxidative addition of the oxonium salt to the Pd^0 complex affording the Pd^{II}−Me bond, and (ii) olefin insertion with attainment of a stereogenic carbon atom bound to Pd.

The analogous reaction was performed on [Pd(**1G-Ph**)(dmf)] (Scheme 3). The process was monitored through NMR spectroscopy and was complete within 24 hours at room temperature affording **5**. The *trans* arrangement of the carbonyl group with respect to the *N*-imino atom was assigned, taking into account the well-established geometry of a closely related Pt^{II} species.[5] The presence of two diastereomers in 75:25 ratio indicates that the reaction had occurred with significant stereoselectivity.

Scheme 3

Conclusion

This work demonstrated the reasonable feasibility of synthesising chiral diimino ligands based on carbohydrates. Results of preliminary investigations into their ability in inducing enantioselective processes were promising results, with Pd^0 complexes with prochiral olefins being prepared

stereoselectively and achievement of a stoichiometric asymmetric insertion process. A rare example of a chiral Pd^0 water-soluble complex was also provided by deprotecting the alcoholic groups of the carbohydrate residue in one ligand, and its structure determined through X-ray diffractometry.

Experimental Section

General: NMR spectra were recorded with a 250-MHz spectrometer (Bruker Model AC-250). The solvents were $CDCl_3$ [$CHCl_3$ (δ = 7.26) and $CDCl_3$ (δ = 77.0) as standards for ^1H and ^{13}C spectra, respectively] and CD_3NO_2 [CD_2HNO_2 (δ = 4.33) and $^{13}CD_2HNO_2$ (d = 62.9) as standards for ^1H and ^{13}C spectra, respectively]. Optical activity measurements were performed with a Perkin−Elmer Polarimeter (Model 141). The following abbreviations are used for describing NMR multiplicities: d, doublet; dd, double doublet; dt, double triplet; m, multiplet; no attribute, singlet; t, triplet. − Compounds **3G-Me**,[7] methyl-2,3-di-*O*-acetyl-4-*O*-benzoyl-6-bromo-6-deoxy-α-D-glucoside,[8] **1M-Ph**,[5] **2M-Ph**[5] and $[Pd(dba)_2]$[13] were prepared according to published methods. Toluene was distilled from sodium, dichloromethane from calcium hydride, and methanol from magnesium immediately before use. − Elemental analysis for the new compounds are collected in Table 5.

3G-Ph: The compound was prepared in 80% yield as described for **3M-Ph**[9] by starting from methyl-2,3-di-*O*-acetyl-4-*O*-benzoyl-6-bromo-6-deoxy-α-D-glucoside.[8] − ^1H-NMR resonances (in $CDCl_3$, at 250 MHz): δ = 7.97 (d, 2 H), 7.57 (t, 1 H), 7.45 (t, 2 H), 5.68 (t, 1 H), 5.22 (t, 1 H), 5.02 (d, 1 H), 4.95 (dd, 1 H), 4.08 (m, 1 H), 3.48 (3 H, OMe), 3.40 (m, 2 H), 2.09 (3 H, $MeCO_2$), 1.89 (3 H, $MeCO_2$). − Selected ^{13}C-NMR resonances (in $CDCl_3$, at 62.9 MHz): δ = 96.7 (1 C, C1 of glucoside), 70.9, 70.2, 69. 4, 68.9 (4 C, C2−C5 of glucoside), 55.6 (1 C, OMe), 51.1 (1 C, NCH_2), 20.7 (1 C, *Me*CO_2), 20.6 (1 C, *Me*CO_2).

1G-Ph, 1G-Me, 2G-Ph, and 2G-Me: To a stirred solution of $PPhMe_2$ (0.14 g, 1.0 mmol) in 5 mL of dry dichloromethane kept in an ice bath was added dropwise a solution of the appropriate azide **3** (1.0 mmol) in 5 mL of dry dichloromethane. After the addition was complete, the ice bath was removed and formation of nitrogen was observed. Progression of the reaction was monitored by TLC analysis on silica of the reacting mixture with ethyl acetate/petroleum ether, 1:1. The reaction affording the corresponding imino-phosphorane **4** was complete within 3 hours. In the case of **1G-Ph** and **1G-Me** the solvent was removed under vacuum and the residue was dissolved in 5 mL of dry toluene containing 4-Å molecular sieves. To the solution was added 6-methyl-2-pyridinecarboxaldehyde (0.12 g, 1.0 mmol), and after 1 h of stirring at 363 K the solvent was removed under vacuum. In the case of **2G-Ph** and **2G-Me**, after formation of **4** was complete, glyoxal (40% w/w in water, 0.5 mmol) was added to the dichloromethane solution, followed by sodium sulphate. After 15 minutes the reaction mixture was filtered and the solvent removed under vacuum. In all cases, the crude reaction products were filtered through a column of Florisil (15 × 1.5 cm) with ethyl acetate/petroleum ether, 1:1 to give the products as white glassy solids (yield: 60−70%). − Selected ^1H-NMR resonances (in $CDCl_3$, at 250 MHz): **1G-Ph**: δ = 8.32 (1 H, CH=N), 5.75 (t, 1 H), 5.35 (t, 1 H), 5.00 (m, 1 H), 4.93 (1 H), 4.29 (m, 1 H), 3.90 (d, 1 H), 3.75 (dd, 1 H), 3.36 (3 H, OMe), 2.55 (3 H, Me-py), 2.07 (3 H, $MeCO_2$), 1.90 (3 H, $MeCO_2$); **1G-Me**: δ = 8.32 (1 H, CH=N), 5.50 (m, 1 H), 5.10 (t, 1 H), 4.88 (m, 2 H), 4.15 (m, 1 H), 3.84 (d, 1 H), 3.66 (dd, 1 H), 3.33 (3 H, OMe), 2.56 (3 H, Me-py), 2.05 (3 H, $MeCO_2$), 2.02 (3 H, $MeCO_2$), 2.00 (3 H, $MeCO_2$); **2G-Ph**: δ = 7.78 (2 H, CH=N), 5.70 (t, 2 H), 5.27 (t, 2 H), 4.95 (m, 4 H), 4.23 (m, 2 H), 3.77 (dd, 2 H), 3.59 (dd, 2 H), 3.40 (6 H, OMe), 2.08 (6 H, $MeCO_2$), 1.89 (6 H, $MeCO_2$); **2G-Me**: δ = 7.88 (2 H, CH=N), 5.47 (t, 2 H), 5.05 (t, 2 H), 4.87 (m, 4 H), 4.08 (m, 2 H), 3.75 (dd, 2 H), 3.57 (dd, 2 H), 3.35 (6 H, OMe), 2.05 (6 H, $MeCO_2$), 2.01 (6 H, $MeCO_2$), 1.98 (6 H, $MeCO_2$). − Selected ^{13}C-NMR resonances (in $CDCl_3$, at 62.9 MHz): **1G-Ph**: δ = 164.8 (1 C, CH=N), 96.4 (1 C, C1 of glucoside), 71.1, 71.0, 70.0 and 68.4 (4 C, C2-C5 of glucoside), 61.2 (1 C, NCH_2), 55.1 (1 C, OMe), 24.2 (1 C, *Me*-py), 20.7 (1 C, *Me*CO_2), 20.6 (1 C, *Me*CO_2); **1G-Me**: δ = 164.9 (1 C, CH=N), 96.4 (1 C, C1 of glucoside), 71.0, 70.4 and 68.1 (4 C, C2-C5 of glucoside), 60.9 (1 C, NCH_2), 55.1 (1 C, OMe), 24.1 (1 C, *Me*-py), 20.7 (3 C, *Me*CO_2); **2G-Ph**: δ = 164.2 (2 C, CH=N), 96.6 (2 C, C1 of glucosides), 71.1, 70.9, 69.9, 68.3 (8C, C2-C5 of glucosides), 61.2 (2 C, NCH_2), 55.3 (2 C, OMe), 20.8 (2 C, *Me*CO_2), 20.6 (2 C, *Me*CO_2); **2G-Me**: δ = 164.3 (2 C, CH=N), 96.5 (2 C, C1 of glucosides), 70.9, 70.3, 67.9 (8C, C2-C5 of glucosides), 60.8 (2 C, NCH_2), 55.2 (2 C, OMe), 20.7 (6 C, *Me*CO_2). − $[\alpha]_D^{25}$ (0.050 M in dichloromethane): **1G-Ph**: +100; **1G-Me**: +100; **2G-Ph**: +85; **2G-Me**: +110.

[Pd(N,N-chelate)(olefin)]: To a suspension of $[Pd(dba)_2]$ (0.58 g, 1.0 mmol) in 5 mL of dry toluene were added the N,N-chelate (1.5 mmol) and the olefin (1.5 mmol). After 1 h of stirring (12 h when olefin = dmf) the solvent was removed under vacuum from the resulting mixture. The residue was separated by chromatography on silica gel with dichloromethane (to remove dba) and then

with dichloromethane/methanol, 40:1. The solvents were removed under vacuum from the collected yellow-orange fractions affording the product as a yellow microcrystalline solid (yield: 75−85%). Alternatively, fdn or ma complexes could be prepared by starting from the corresponding dmf complexes, according to the following example: To a solution of [Pd(**1M-Ph**)(dmf)] (0.074 g, 0.10 mmol) in 1 mL of dichloromethane was added fumarodinitrile (0.012 g, 0.15 mmol). The resulting solution was chromatographed as described above affording pure [Pd(**1M-Ph**)(fdn)] (yield 80−85%).

[Pd(1M*)(fdn)]: To a stirred solution of [Pd(**1M-Ph**)(fdn)] (0.067 g, 0.10 mmol) in 2.5 mL of dry methanol was added a catalytic amount of sodium methoxide in the same solvent. After 30 min of reaction, separation of the yellow product was observed. After a further 16 h of stirring, the precipitation of the product was enhanced by addtion of diethyl ether. The complex was separated, washed with diethyl ether (3 × 3 mL) and dried under vacuum (0.040 g, yield: 83%).

Addition of Me_3OBF_4 to [Pd(1G-Ph)(dmf)] with Formation of 5: A solution of the complex (0.022 g, 0.030 mmol) in 0.5 mL of deuterionitromethane was added to solid Me_3OBF_4 (0.005 g, 0.033 mmol). The resulting solution was transferred into an NMR tube and spectra were recorded until no more chemical changes were detected. − Selected ^{1}H-NMR resonances (in CD_3NO_2, at 250 MHz): **5** (diastereomer, 75%): δ = 8.41 (1 H, CH=N), 4.09 (3 H, OMe), 3.50 (3 H, OMe), 3.40 (3 H, OMe), 2.70 (3 H, *Me*-py), 1.07 (d, 3 H, CH*Me*); (diastereomer, 25%): 8.42 (1 H, CH=N), 4.10 (3 H, OMe), 2.62 (3 H, *Me*-py), 1.00 (d, 3 H, CH*Me*).

X-ray Crystal-Structure Determination of [Pd(1M*)(fdn)]: Crystals suitable for X-ray analysis were grown from methanol/diethyl ether. The crystal, collection, and refinement data are presented in Table 6. Data collection was performed at room temperature with an Enraf−Nonius MACH3 diffractometer with graphite-monochromated Mo-K_α radiation using the ω/θ scan technique. The unit-cell parameters and orientation matrix were obtained from a least-squares fitting of the setting values of 25 strong reflections in the range $13° \leq \theta \leq 14°$. Three monitoring reflections, measured every 500, showed no intensity decrease. Corrections for Lorentz-polarization effects were applied but not for absorption. The structure was solved by routinary application of Patterson and Fourier techniques. Refinement on *F* was carried out by full-matrix least squares minimizing the quantity $\Sigma w(\Delta F)^2$ with $w^{-1} = [\sigma^2(F_o) + (0.02F_o)^2 + 1]$, where σ is derived from counting statistics. Owing to the insufficient number of observed reflections of high values of θ, the final refinement was carried out with anisotropic thermal parameters for Pd, O and N, and isotropic for C and the non-hydrogen atoms of the solvent molecule MeOH. H atoms at calculated positions were added as riding atoms with isotropic thermal parameters 1.3 times larger than that of the carrier atoms. The H atoms of the solvent molecule were neglected. The final Fourier difference map was within ±0.6 e/Å^3. All calculations were performed with the Enraf−Nonius (SDP) set of programs.[21] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no CCDC-133171. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physicochemical Characterization of MS-325, a New Gadolinium Complex, by Multinuclear Relaxometry[+]

Robert N. Muller,*[a] Bernd Radüchel,[b] Sophie Laurent,[a] Johannes Platzek,[b] Corinne Piérart,[a] Peter Mareski,[b] and Luce Vander Elst[a]

Keywords: MS-325 / Angiography / MRI contrast agent / NMR spectroscopy / Interaction with HSA / Gadolimium

The physicochemical characterization of MS-325 [trisodium {4-(*R*)-[(4,4-diphenylcyclohexyl)phosphanooxymethyl]-3,6,9-triaza-3,6,9-tris(methoxycarbonyl)undecanedioato}gadolinium-(III)], a new derivative of Gd-DTPA {Magnevist®: dimeglumin [{3,6,9-triaza3,6,9-tris(methoxycarbonyl)undecanedioato}gadolinium(III)], presented as a potentially useful angiographic contrast agent, was carried out in various media. Water solution, protein-containing solution, phosphorylated metabolites solution, and Zn^{2+}-containing solution were investigated using different NMR techniques such as water ^{1}H nuclear magnetic relaxation rates, water ^{17}O transverse relaxation rates, and ^{31}P longitudinal relaxation rates of phosphorylated metabolites. The proton relaxivity of MS-325 in water was found to be higher than that of the parent compound Gd-DTPA; this can be attributed to the longer rotational correlation time (τ_R) of the hydrated complex, and possibly to an apparently shorter mean distance (r) between the protons of the coordinated water molecule and the gadolinium ion. The kinetic and thermodynamic stability of MS-325 in solutions containing phosphorylated metabolites (ATP, phosphocreatine and inorganic phosphate) were measured by ^{31}P relaxation rate analysis and found to be higher than for Gd-DTPA. Similarly, the Zn^{2+} transmetallation process studied by proton relaxometry is slower than for the same reference compound. Finally, an analysis of the noncovalent binding of MS-325 to serum proteins by proton relaxometry showed that MS-325 interacts with human serum albumin (HSA) and that the association constant of this interaction is equal to 6100 ± 2130 M^{-1}. A peak relaxivity of approx. 50 $s^{-1}mM^{-1}$ was determined at 25 MHz for the protein-bound paramagnetic complex. This value is lower than the maximal relaxivity predicted for a paramagnetic center totally immobilized at the surface of the protein.

Introduction

Small gadolinium complexes, which can interact with high molecular weight molecules through covalent or noncovalent bonds, are potential intravascular Magnetic Resonance Imaging (MRI) contrast agents. A noncovalent binding to endogenous proteins can exist in vivo; this results in a reduced extravasation of the paramagnetic complex, and therefore in a subsequent increase of its persistence in blood, but does not preclude a fairly rapid and selective renal excretion. On the other hand, binding to macromolecules decreases the molecular mobility and thus enhances the relaxivity of the paramagnetic center, i.e. its ability to increase the relaxation rate of the protons of water molecules. Contrast agents that are likely to interact with serum proteins, are therefore attracting a great deal of interest.

MS-325 [trisodium {4-(*R*)-[(4,4-diphenylcyclohexyl)phosphonooxymethyl]-3,6,9-triaza-3,6,9-tris(methoxycarbonyl)-undecanedioato}gadolinium(III)] (Figure 1) is a new MRI contrast agent which has been reported to exhibit a remarkable affinity for serum proteins.[1][2] This derivative of Gd-DTPA [Magnevist®: dimeglumin {3,6,9-triaza-3,6,9-tris-(methoxycarbonyl)undecanedioato}gadolinium(III)] has a diphenylcyclohexyl group attached to one of the ethylene bridges of the backbone by means of a phosphodiester linkage.[1][2] The presence of this substituent is responsible for the noncovalent binding to plasma proteins which, as expected, leads to a reduction in the rate of molecular tumbling and, consequently, to an enhanced efficacy as a relaxing agent in blood.[1] In addition, the interaction with blood macromolecules produces a marked increase in the plasma half-life relative to hydrophilic contrast agents such as Gd-DTPA, the parent compound, or Gd-DOTA {Dotarem®: meglumin [1,4,7,10-tetrakis(methoxycarbonyl)-1,4,7,10-tetraazacyclododecane]gadolinium(III)}.[3] MS-325 has been shown to provide very good and persistent enhancement of blood vessels on MRI angiographic evaluations.[3–8]

So far, few physicochemical data are available concerning a comprehensive description and understanding of the properties of this molecule. The aim of this work is to extend the in vitro physicochemical characterization of MS-325 by quantitatively evaluating and interpreting: 1) the proton relaxivity (r_1) in water at various magnetic fields and temperatures; 2) the exchange time of the coordinated water molecule (τ_M) estimated through the analysis of the temperature-dependence of the ^{17}O transverse relaxation rate of water in MS-325 aqueous solution; 3) the rotational correlation time (τ_R) calculated from ^{2}H longitudinal relaxation rate of the deuterated ligand complexed to lantha-

num, a diamagnetic lanthanide ion; 4) the noncovalent interaction with human serum albumin studied by proton and deuterium relaxometry; 5) the transmetallation by Zn^{2+} ions using proton relaxometry; and 6) the kinetic and thermodynamic stability of the gadolinium complex in solutions containing phosphorylated metabolites which are potential competitors for the complexation of the lanthanide ions {ATP, phosphocreatine (PCr), and inorganic phosphate (Pi)}. This study will be carried out through the evolution of the ^{31}P longitudinal relaxation rates.

Considering the clinical context of this kind of study, most of the data are reported at 310 K, the physiological body temperature, as well as at the standard temperature of 298 K.

Results and Discussion

Water Solution

The residence time of water molecules in the first coordination sphere of the complex (τ_M) was obtained from the analysis of the temperature-dependence of the ^{17}O transverse relaxation rate of water in MS-325 solution. This procedure allows for the determination of: i) the hyperfine coupling constant ($A/\hbar$) between the ^{17}O nucleus and the electron spin; ii) the parameters defining the rate of exchange of the coordinated water molecule {enthalpy ($\Delta H^{\neq}$) and entropy ($\Delta S^{\neq}$) of activation}; and iii) the parameters related to the electronic relaxation time [the correlation time of the modulation of the zero-field splitting τ_V, the activation energy for this process E_V, and B which depends on the trace of the square of the zero-field splitting tensor (Δ^2) and on the electron spin S ($B = \Delta^2\{4S(S + 1) - 3\}/25$)].[9][10]

The theoretical fitting of the reduced transverse relaxation rates ($1/T_2^r = [H_2O]/\{[\text{Gd-complex}] \cdot T_2^P\}$) obtained over a temperature range extending from 276 to 351 K (Figure 2) gives a τ_M^{298} value of 195 ± 32 ns similar to that of 200 ± 51 ns reported for another C-substituted Gd-DTPA derivative (*S*)-Gd-EOB-DTPA [disodium {4-(*S*)-3,6,9-tris(methoxycarbonyl)-4-(4-ethoxybenzyl)-3,6,9-triazaundecanedioato}gadolinium(III)].[9] These τ_M values are however shorter than those observed for Gd-DTPA (τ_M^{298} = 331 ± 60 ns,[11] 303 ns[12]). In our fitting, the number of coordinated water molecules (q) was assumed to be equal to 1 as in Gd-DTPA and (*S*)-Gd-EOB-DTPA complexes. The other parameters of the fitting are given in Table 1.

Table 1. Parameters obtained from the fitting of the reduced transverse relaxation rate of oxygen-17 in MS-325 solution ([MS-325] = 12.5 mM)

	MS-325	Gd-DTPA[a]	(*S*) Gd-EOB-DTPA[b]
τ_M^{298} [ns]	195±32	331±60	200±51 (201)
τ_V^{298} [ps]	18.7 ±0.9	12.3±0.3	15.3±1.94 (2.4)
B [10^{20} s^{-2}]	5.22 ±0.24	2.60±0.30	2.51±0.28 (0.49)
E_V [kJ/mol]	6.4±2.7	4.5±4.2	7.1±5.9 (12.0)
$A/\hbar$ [10^6 rad s^{-1}]	−4.1±0.06	−3.41±0.11	−4.07±0.45 (−4.24)
$\Delta H^{\neq}$ [kJ/mol]	51.3 ±0.3	51.5±0.3	53.5±0.3 (54.3)
$\Delta S^{\neq}$ [J/mol K]	55.8±0.4	52.1±0.6	63.0±12.9 (65.7)

[a] From ref.[11] – [b] the values reported in this table were obtained by improving the fitting of the data of ref.[9]; the values in parentheses are from ref.[9]

The proton relaxivity (r_1), defined as the increase of the solvent relaxation rate induced by 1 mmol·l^{-1} of the paramagnetic complex, is the sum of two contributions arising from short-distance interactions (innersphere mechanism) and from longer-distance interactions (outersphere mechanism). The influence of τ_M on proton relaxivity is well understood. When this exchange time is short relative to the relaxation time of the protons of the coordinated water molecules, the overall proton relaxivity is enhanced by a temperature decrease. On the contrary, when the exchange time is long, the global relaxivity is levelled off or even decreased by a reduction of the temperature. This latter behavior has been observed for bisamide derivatives of Gd-DTPA.[11,13–15] The τ_M values found for MS-325 by ^{17}O-NMR spectroscopy over the temperature range explored are characteristic of a nonlimiting exchange. This is con-

firmed by the increase of the relaxivities when the temperature is decreased (Figure 3).

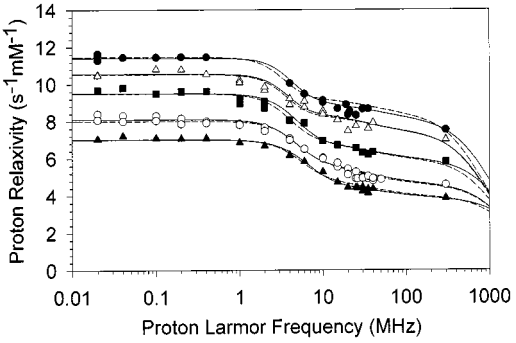

Figure 3. ^{1}H NMRD relaxivity profiles of MS-325 in water at different temperatures ([MS-325] = 1 mM): 278 K: closed circles, 288 K: open triangles, 298 K: closed squares, 310 K: open circles, 318 K: closed triangles. The lines correspond to the theoretical fittings of the data points (solid lines: r = 0.295 nm, dashed lines: r = 0.31 nm)

As compared to Gd-DTPA,[9][16] the proton relaxivity of MS-325 at 310 K is higher over the whole proton Larmor frequency range and, in this respect, behaves like that of (*S*)-Gd-EOB-DTPA. For this last compound, the increased relaxivity was mainly attributed to a shorter mean distance of interaction between the protons of the coordinated water molecule and the gadolinium ion (0.281 nm for (*S*)-Gd-EOB-DTPA and 0.31 nm for Gd-DTPA).[9]

The fittings of the proton Nuclear Magnetic Relaxation Dispersion (NMRD) profiles were performed as described in the experimental section according to the classical paramagnetic relaxation formalisms.[17−19] The following strategy was adopted: after subtraction of the diamagnetic relaxation rate of the solvent, the outersphere and the innersphere contributions were simultaneously fitted after attribution of fixed or calculated values to the various parameters. The relative diffusion constant D was fixed to the diffusion constant of water,[20] d, the distance of closest approach for the outer sphere contribution was set at 0.36 nm,[14][21] τ_M values were those obtained by ^{17}O NMR, and q, the number of water molecules in the first coordination sphere of Gd^{3+}, was given a value of one. The parameters describing the electronic relaxation times, τ_V and τ_{SO} (the electronic relaxation time at zero field), were optimized for the outersphere and the innersphere contributions simultaneously. It is well-known that parallel and accurate determination of both τ_R, the rotational correlation time of the hydrated complex, and r, the distance between the protons of the coordinated water molecules and the gadolinium ion, can be ambiguous, unless independent information about τ_R and/or r is available. For instance, good fits of the 310 K experimental data can be achieved with pairs of values of r and τ_R ranging from 0.285 to 0.31 nm for the former and from 68 to 110 ps for the latter (Table 2).

Assuming that τ_R can be estimated by the Stokes−Einstein law and that the molecular volume is roughly proportional to the molecular weight, the τ_R of MS-325 should be approximately 1.6 times larger than that of Gd-DTPA.

Table 2. Values of τ_R obtained from the fitting of the proton NMRD profiles at 310 K using different r values

r [nm]	τ_R [ps]
0.285	68
0.290	76
0.295	84
0.3	91
0.31	110

At 310 K, τ_R values of MS-325 should thus be around 90−95 ps and correspond to a distance r of 0.3 nm. If (*S*)-Gd-EOB-DTPA is taken as a reference, τ_R should be around 80−85 ps at 310 K and r should be 0.295 nm. The τ_R value obtained by the analysis of the deuterium longitudinal relaxation rate of the deuterated ligand complexed to the diamagnetic La^{3+} ion is however markedly longer (τ_R = 117±12 ps at 310 K) and corresponds to a distance of 0.31 nm. Two values of r (0.295 and 0.31 nm) were thus used for the fittings performed at 278, 288, 298, 310, and 318 K (Figure 3 and Table 3).

As for other C-substituted derivatives of Gd-DTPA,[9,11,21] the proton relaxivity enhancement observed for MS-325, as compared to the unsubstituted Gd-DTPA, can thus be related to a longer rotational correlation time τ_R and possibly to a shorter apparent H−Gd distance r.

Solutions Containing Phosphorylated Metabolites

In an earlier study, adenosine triphosphate (ATP) was shown to efficiently compete with open-chain chelates for the complexation of gadolinium ions.[22] This metabolite thus appears to be a good probe to assess the kinetics as well as the thermodynamic stability of the complex. The decrease of the T_1 of the phosphorus nuclei of ATP in solutions containing Gd-DTPA has indeed been reported to result from the formation of a complex between ATP and Gd^{3+} whose characteristics have been described elsewhere.[23] The same protocol was applied to MS-325 in ATP-containing solutions and the results were compared to those previously obtained for Gd-DTPA[22] and (*S*)-Gd-EOB-DTPA[9] (Figure 4).

Immediately after addition of the gadolinium complex, ^{31}P relaxation rates increase and reach a plateau after a delay which depends on the structure of the Gd complex. The equilibrium value of the P-31 relaxation rates is reached more quickly for Gd-DTPA (ca. 30 min) than for (*S*)-Gd-EOB-DTPA (ca. 6 h) or for MS-325 (ca. 24 h). The kinetic stability of MS-325 is thus increased as compared to (*S*)-Gd-EOB-DTPA which itself is more stable than Gd-DTPA. The thermodynamic stability was then tested at equilibrium on solutions containing various amounts of contrast agents. The measurements were performed after the steady state was reached for each solution (24 h, 8 h and 1 h after mixing the phosphorylated metabolite solution and MS-325, (*S*)-Gd-EOB-DTPA and Gd-DTPA, respectively) (Figure 5).

Table 3. Values of τ_R, τ_{SO}, τ_V, and τ_M obtained from the fitting of the proton NMRD profiles at different temperatures (d = 0.36 nm)

T [K]	D [10^{-5} cm^{2}s^{-1}]	τ_{so} [ps][a]	τ_v [ps][a]	τ_R [ps][a]	τ_M [ns][b]
278	1.42	91 or 110	30 or 39	165 or 241	930
288	1.96	86 or 101	30 or 38	140 or 189	415
298	2.62	78 or 101	22 or 33	110 or 142	195
310	3.5	72 or 93	18 or 32	84 or 108	83
318	4.1	66 or 83	13 or 25	69 or 92	50

[a] The first values correspond to the results of the fitting performed with r set to 0.295 nm, the second ones correspond to r = 0.31 nm. – [b] These values were obtained from ^{17}O NMR spectroscopy and fixed during the proton NMRD fitting.

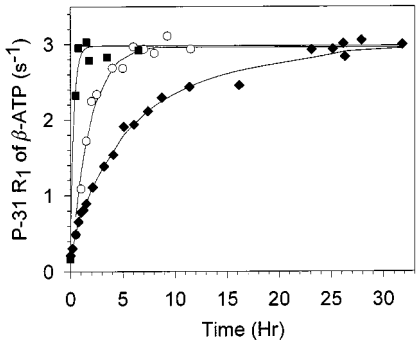

Figure 4. ^{31}P longitudinal relaxation rates of β-ATP peak in a buffered solution (Krebs–Henseleit, pH = 7.2 to 7.4) containing 20 mM of ATP, PCr, and Pi and 0.124 mM of MS-325 (closed diamonds), (*S*)-Gd-EOB-DTPA (open circles) or Gd-DTPA (closed squares) as a function of the time elapsed after addition of the contrast agent

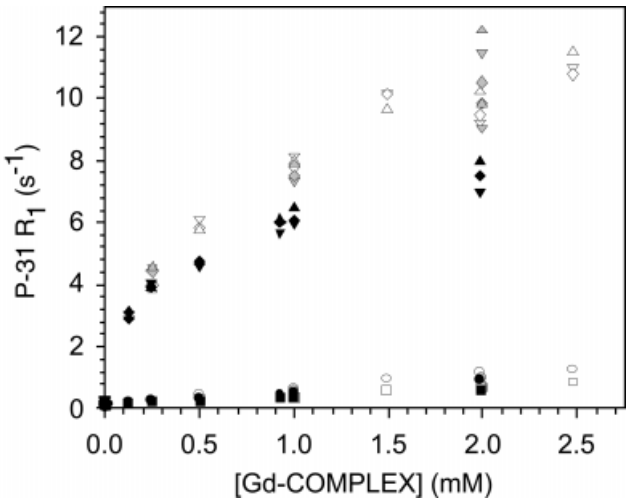

Figure 5. ^{31}P longitudinal relaxation rates of ATP, PCr, and Pi peaks in a buffered solution (Krebs-Henseleit, pH = 7.2 to 7.4) containing 20 mM of ATP, PCr, and Pi and increasing amounts of MS-325, (*S*)-Gd-EOB-DTPA or Gd-DTPA; the measurements were performed at the equilibrium of the reaction between the Gd complex and phosphorylated metabolites (24 h, 8 h or 1 h, respectively after mixing of the phosphorylated metabolites and the complex); MS-325 (black closed symbols), (*S*)-Gd-EOB-DTPA (open symbols), Gd-DTPA (gray closed symbols), Pi (circles), PCr (squares), α-ATP (reversed triangles), β-ATP (diamonds), γ-ATP (triangles)

The slightly lower P-31 relaxation rate enhancements obtained with MS-325 indicate that the concentration of the complex formed between Gd and ATP is lower. Consequently, the thermodynamic stability of MS-325 appears to be high as compared to Gd-DTPA or (*S*)-Gd-EOB-DTPA.

Transmetallation by Zn^{2+} Ions

Transmetallation of the complex by Zn^{2+} results in the release of gadolinium ions in solutions. In the presence of phosphate ions, with which they form an insoluble phosphate complex, these released lanthanide ions precipitate and no longer contribute to the proton paramagnetic relaxation rate of the solution. Consequently, the water proton relaxation rate decreases during the transmetallation process and its evolution can be used to quantitatively monitor the evolution of the system. In identical experimental conditions (B_0 = 0.47 T, T = 310 K, 2.5 mM of gadolinium complex, 2.5 mM of Zn^{2+} ions and phosphate buffer pH 7) no significant change of the paramagnetic relaxation rate was noticed for the macrocyclic gadolinium complexes Gd-DOTA and Gd-HPDO3A [{10-(2-hydroxypropyl)-1,4,7-tris(methoxycarbonyl)-1,4,7,10-tetraazacyclododecane}-gadolinium(III)] (Figure 6). This observation is in good agreement with the well-known very high kinetic and thermodynamic stabilities of these complexes.[24][25] On the contrary, R_1^P decreased to about 50% of its initial value for Gd-DTPA after 5000 minutes, showing that a significant transmetallation takes place for this open-chain gadolinium complex (Figure 6). Comparatively, the results obtained

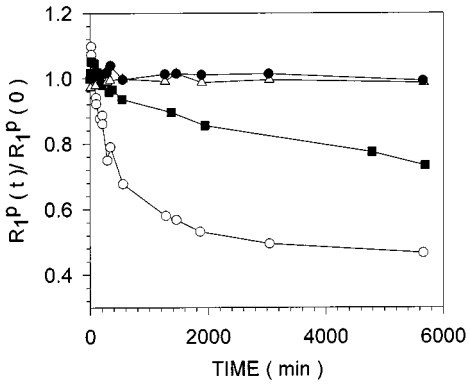

Figure 6. Time evolution of the normalized water proton paramagnetic relaxation rate (T = 310 K, ν_o = 20 MHz) in solution containing 2.5 mM of gadolinium complex and 2.5 mM of Zn^{2+} (MS-325: closed squares, Gd-DTPA: open circles, Gd-HPDO3A: closed circles, Gd-DOTA: open triangles)

with MS-325 indicate a relatively slower and limited evolution of the proton paramagnetic longitudinal relaxation rate (about 75% of its initial value after 5000 minutes).

These results demonstrate that MS-325 is more stable towards transmetallation by Zn^{II} than Gd-DTPA.

Serum and Other Protein-Containing Solutions

The high "apparent" proton relaxivity of MS-325 in serum has been related to its binding to serum proteins as studied by ultrafiltration methods.[3][6] Binding to macromolecules results in a significant τ_R increase which in turn usually induces a hump in the high field part of the ^1H NMRD profile. The NMRD profiles recorded in a reconstituted lyophylized serum (Kontrollogen) or in human serum albumin (HSA) are characteristic of such interactions with macromolecules (Figure 7).

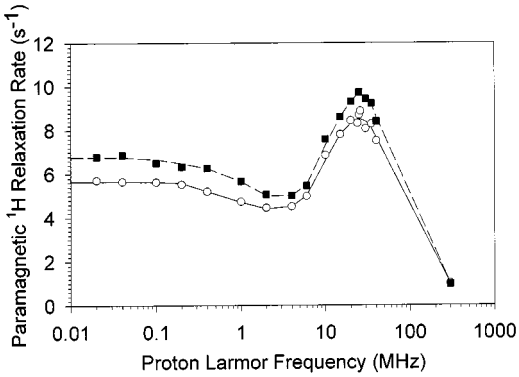

Figure 7. Proton paramagnetic relaxation rate of solutions containing 0.25 mM of MS-325 and 4% of HSA (open circles) or serum Kontrollogen (closed squares) at 310 K

The non-linear increase of the proton paramagnetic relaxation rate measured at 20 MHz on solutions containing 4% of HSA ([HSA] = $p°$ = 0.6 mM) and various concentrations of MS-325 ($s°$ = 0−2.08 mM) (Figure 8) agrees with a strong binding. At this magnetic field, the paramagnetic relaxation rate of a solution containing 1 mM of MS-325 and 4% of HSA is 4.6 times larger than in pure water.

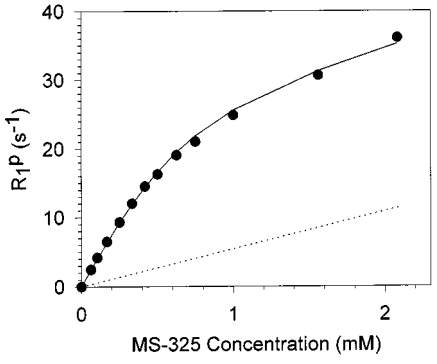

Figure 8. Proton longitudinal paramagnetic relaxation rate in solutions containing 4% of HSA and increasing amounts of MS-325 (closed circles) (ν_o = 20 MHz, T = 310 K); the plain line corresponds to the fitting of the data and the dashed line represents R_1^P in a water solution free of albumin

The "apparent" relaxivity calculated for each MS-325 concentration decreases from about 40 $s^{-1}mM^{-1}$ at low concentrations to 17 $s^{-1}mM^{-1}$ for the maximum concentration of 2.08 mM. Fitting of the data according to Equation 1 provides, on the one hand, an estimation of the association constant (Ka) characterizing the interaction between HSA and MS-325 and, on the other hand, a value of the relaxivity of the noncovalently bound complex (r_1^c). The relaxivity of the free contrast agent is r_1^f. The fitted Ka and r_1^c values are 6100±2130 M^{-1} and 48.9±3.5 $s^{-1}mM^{-1}$, respectively [the number of equivalent and independent interaction sites (N) was set to 1]. Consequently, in solutions containing 4% of HSA and less than 0.3 mM of MS-325, more than 70% of MS-325 interacts with the protein. These results are in good agreement with the ultrafiltration data of Lauffer et al. who reported that the association constant of the strongest site(s) is in the order of 10^4 M^{-1}.[6]

In the experimental conditions of the NMRD study (Figure 7, 0.25 mm of MS-325 and 4% of HSA), 0.18 mM of MS-325 are bound to the protein. The proton paramagnetic relaxation rate profiles (Figure 7) thus represent the combined contributions of the free and the bound Gd complex. Knowing the proton NMRD profile of the free MS-325 as well as the concentration of free and bound Gd complex obtained from the equilibrium study (see above), the proton NMRD profile of the HSA-MS-325 complex can be calculated (Figure 9).

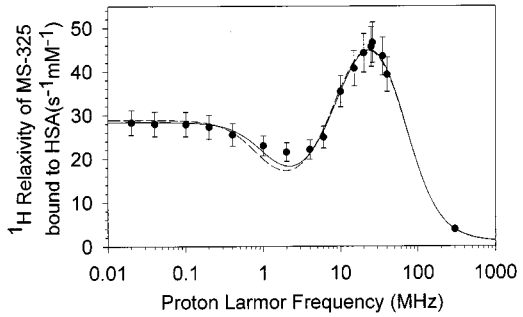

Figure 9. Calculated theoretical ^1H NMRD profile of the complex HSA-MS-325 at 310 K (closed circles) and its fittings (plain line: r = 0.295 nm, dashed line: r = 0.31 nm)

The fitting of this profile was then performed using the equations usually adopted for the description of small gadolinium complexes in aqueous solutions for the two distances r used previously (see Experimental Section). These equations, however, are known to be unappropriate to describe the low field range of the profile for slow-rotating systems, especially regarding the electron spin system.[26] Depending on the distance r used for the fittings, the values of τ_V and τ_{SO} are 38 or 41 ps and 287 or 351 ps. These values are thus recognized as inaccurate but the values of τ_R (3.3 or 4.4 ns), which are mainly determined from the high field range, are acceptable. In separate experiments run on the deuterated lanthanum analog of MS-325, the increase of the deuterium linewidths measured in solutions containing 4% of HSA and decreasing concentrations of the complex was analyzed as described in reference 9. The fitted value of K_a and R_2 of the complex (R_2^c) were 5590

M^{-1} and 1210 s^{-1} respectively. This R_2^c value corresponds to a τ_R of the order of 6 to 7 ns. All these values of τ_R are lower than the value of 14 ns calculated for HSA at 310 K using Stokes's law.[27] This difference indicates that the mobility of the paramagnetic center is higher than expected for a complex fully immobilized on the surface of the protein and agrees with the picture of the ligand interacting with the protein through the [(4,4-diphenylcyclohexyl)phosphonooxymethyl] chain and leaving some mobility freedom to the rest of the bound molecule. The longer τ_M obtained by the fitting (171 or 252 ns as compared to 83±13 ns in aqueous solution free of protein) might result from interactions at the surface of the protein, although this hypothesis seems to be contradicted by the previous discussion about molecular mobility.

In serum Kontrollogen, the paramagnetic relaxation rates are slightly higher than in albumin solution (Figure 7). For other paramagnetic complexes like Gd-DTPA, Gd-DOTA, or Gd-HPDO3A which do not interact with blood macromolecules, 10 to 25% higher water proton relaxation rates were also observed in serum as compared to HSA solutions (unpublished data). This can be explained by the higher viscosity of serum as compared to a 4% HSA solution (at 310 K, the viscosity of serum Kontrollogen is equal to 1.18 cp as compared to 0.84 cp for a 4% HSA solution). From the above, it is thus clear that the increase of the paramagnetic relaxation rate in serum mostly results from the noncovalent interaction of MS-325 with albumin. These results are in good agreement with the high performance liquid chromatography experiments of Lauffer et al.[6]

Conclusion

The multinuclear magnetic resonance approach used in this work shows that, compared to its parent compound Gd-DTPA, MS-325 exhibits a higher proton relaxivity which can be attributed to a slower tumbling resulting from a higher molecular weight and possibly to an apparently shorter mean distance between the hydrogen atoms of the water molecules and the gadolinium ions. The exchange time of the coordinated water molecule τ_M does not limit the proton relaxivity as demonstrated by the ^{17}O and proton relaxometric studies performed between 278 to 318 K.

In solutions containing ATP, a partial decomplexation of MS-325 occurs but the rate and the extent of this process are smaller than for the parent compound. The kinetic and the thermodynamic stabilities of this C-substituted derivative are thus increased. Similarly, the transmetallation process by Zn^{2+} ions is reduced as compared to Gd-DTPA. These results confirm a previously reported hypothesis regarding the favorable role of C-substitution.[9]

The proton relaxometric study of the noncovalent interaction with serum proteins, and more particularly with HSA, shows that the association constant characterizing the equilibrium between HSA and MS-325 is about 6100±2130 M^{-1} for a number of interaction sites equal to 1. As shown by the parameters calculated from the ^1H and ^2H relaxometry data, the paramagnetic center of the noncovalently bound complex is not fully immobilized at the surface of the protein and consequently does not develop the maximum relaxivity allowed by the rate of the water exchange. If the paramagnetic complex would experience the rotational correlation time of albumin (τ_R = 14 ns[27]), its relaxivity calculated with the parameters reported above should be maximal around 20−25 MHz and reach 59 $s^{-1}mM^{-1}$.

Experimental Section

General: MS-325 was synthesized as described by McMurry et al.[2] and Sajiki et al.[28] − Gd-DTPA (Magnevist®) was provided by Schering AG (Berlin, Germany), Gd-DOTA (Dotarem®) by Guerbet (Aulnay-sous-Bois, France), Gd-HPDO3A (ProHance®) by Bracco (Milano, Italy), and (*S*)-Gd-EOB-DTPA (Eovist®) by Schering AG (Berlin, Germany). D_2O (99.9%) was obtained from Aldrich (Bornem, Belgium), serum (Kontrollogen L) from Behring (Marburg, Germany), and nondefatted human albumin (fraction V) from Sigma (Bornem, Belgium). ATP disodium salt (Janssen Chimica, Geel, Belgium), phosphocreatine disodium salt (Sigma, Bornem, Belgium), Na_2HPO_4 (Merck, Overijse, Belgium), and NaN_3 (Aldrich, Bornem, Belgium) were used for ^{31}P NMR measurements. Phosphate buffer pH 7 (Merck, Overijse, Belgium) and $ZnCl_2$ (Fluka, Bornem, Belgium) were used for the transmetallation studies. − The lanthanum complex was synthesized by reaction of La_2O_3 with the ligand in water and was precipitated by addition of acetone. Deuteration of the lanthanum complex at the α position of the carboxylic groups was performed by the procedure described by Wheeler and Legg:[29] 200 mg of lanthanum complex were dissolved in 20 mL of D_2O, the pD was adjusted to 10.6 by addition of K_2CO_3 and the mixture was heated at reflux with stirring for 24 h. The pD was then adjusted to 7 with concentrated hydrochloric acid, the solution was evaporated to a final volume of 10 mL and the solid KCl was removed by filtration. Acetone was added to induce precipitation of the deuterated compound, which was isolated by filtration, dissolved in 10 mL of H_2O, dialyzed, and isolated after lyophilization. The deuteration was confirmed by ^1H-NMR spectroscopy. The sodium and potassium contents were controlled by ion-selective electrodes. The final product was labelled with 10 deuterium atoms and contained 2 Na^+ and 1 K^+ counterions. − ^1H NMR (D_2O): La-complex: δ = 7.5−7.15 (10 H); 4.3−1.7 (29 H); La-deuterated complex: δ = 7.5−7.15 (10 H); 4.3−1.7 (19 H)

NMR Spectroscopy: Proton Nuclear Magnetic Relaxation Dispersion (NMRD) profiles were recorded on a Field Cycling Relaxometer (Field Cycling Systems, Oradell, New Jersey, USA) working between 0.24 mT and 1.2 T. The samples (0.6 mL) were contained in 10 mm o.d. tubes. Proton relaxation rates were also measured at 0.47 T on a Minispec PC-20 (Bruker, Karlsruhe, Germany). The temperature was controlled by a perchlorinated liquid flow. T_1 shorter than 50 ms were measured on this system using a specially-designed pulse sequence to overcome the limitations of the standard Minispec microprocessor. The data points were then fitted with a three-parameter minimization routine. The additional relaxation rates at 7.05 T were obtained on a Bruker AMX-300 (Bruker, Karlsruhe, Germany) spectrometer. − ^1H NMRD curves were fitted according to the theoretical innersphere model described by Solomon[17] and Bloembergen[18] and to the outersphere contribution described by Freed.[19] Calculations were performed with previously described software.[30][31] − The proton data ob-

$$R_1^{p\,obs} = 1000 \times \left\{ \left(r_1^{f} \times s^\circ \right) + \frac{1}{2}\left(r_1^{c} - r_1^{f} \right) \left(\left(N \times p^\circ \right) + s^\circ + Ka^{-1} - \sqrt{\left(\left(N \times p^\circ \right) + s^\circ + Ka^{-1} \right)^2 - 4 \times N \times s^\circ \times p^\circ} \right) \right\} \quad (1)$$

tained in HSA solution were fitted using Equation 1,[32] where *Ka* is the association constant, p° is the protein concentration, s° is the concentration of the paramagnetic complex, *N* is the number of independent interaction sites, and r_1^c and r_1^f are the relaxivities of the complex HSA-contrast agent and of the free contrast agent, respectively.

^{31}P-NMR T_1 measurements were performed on 2 mL samples contained in 10 mm o.d. tubes on a Bruker MSL-200-15 spectrometer (Bruker, Karlsruhe, Germany) fitted with a broadband probe. The temperature was regulated by air or nitrogen flow controlled by a BVT 1000 unit. The solutions contained 20 mM of ATP, phosphocreatine (PCr) and inorganic phosphate (Pi) dissolved in Krebs Henseleit buffer (pH = 7.2−7.4) with 2 mM of NaN_3 added to prevent degradation of ATP and PCr by bacteria. The 90° and 180° pulse lengths were 7 μs and 14 μs, respectively. − Transmetallation by Zn^{II} ions was evaluated by the decrease of the water proton longitudinal relaxation rate at 310 K and 20 MHz (Bruker Minispec PC 20) of buffered solutions (pH 7, phosphate buffer) containing 2.5 mM of the gadolinium complex and 2.5 mM of Zn^{II}. − ^{17}O- and ^{2}H-NMR spectra were recorded on 2 mL samples (10 mm o.d. tubes) on a Bruker AMX-300 spectrometer (Bruker, Karlsruhe, Germany) using a broadband probe and a Bruker BVT-2000 unit for temperature control. ^{17}O transverse relaxation times of distilled water (pH = 6.5) were measured using a CPMG sequence and a subsequent two-parameter fit of the data points. The 90° and 180° pulse lengths were 25 μs and 50 μs, respectively. ^{17}O T_2 of water in MS-325 solution ([MS-325] = 12.5 mM, pH = 6.0−7.0) was obtained from linewidth measurement. Checks were performed so that for this paramagnetic solution, the T_2 obtained from linewidth measurement and from CPMG sequence were similar. All ^{17}O spectra were proton decoupled. The concentration of MS-325 was 12.5 mM. The analysis of the ^{17}O and ^{2}H data is described elsewhere.[9] − All T_1 measurements at 4.7 T and 7.05 T (^{1}H, ^{2}H, ^{31}P) were performed with the inversion recovery or fast inversion recovery Fourier transform technique and a subsequent three-parameter fit of the peak heights.

The Interpretation of the Terminal ν(CO) Spectra of Some Tetranuclear Carbonyl Clusters

Sidney F. A. Kettle,*[a] Eliano Diana,[b] Enrico Boccaleri,[b] and Pier Luigi Stanghellini*[c]

Keywords: Cluster compounds / Vibrational spectroscopy / Spherical harmonics / Carbonyl complexes

The recently suggested spherical (SHM) and tensor (THM) harmonic models are applied to the interpretation of the terminal ν(CO) spectra of twenty six tetrahedral transition metal clusters containing between four and twelve terminal carbonyl groups. Although the SHM is perhaps the more generally relevant, there are species for which the THM is appropriate as a first approximation. The distinction between the two appears to be associated with a disruption of the band structure of the cluster either by the introduction of heterometal atoms or by the presence of a group – acetate ester, halide or hydride – presumably acting as an electronegative substituent.

Introduction

In a recent communication we explored the application of a novel, spherical harmonic, model (SHM) to the interpretation of the terminal ν(CO) vibrational spectra of transition metal cluster carbonyls.[1] The model, which in its simplest form ignores the cluster structure and geometry, was found to be of general applicability. It is the only extant model which successfully explains how a large, low-symmetry molecule with a large number of terminal CO groups can show only a single peak in the solution infrared. The model in its simplest form carries out a spherical harmonic expansion of the ν(CO) modes, considering the CO groups as radially attached to the spherical cluster surface. The spherical harmonic analysis of the vibrational problem shows that, of the harmonic subtended (S + P + D + F +....), only the P mode is infrared active and only the S and D modes are Raman active. So the simple model predicts two Raman bands, noncoincident with the single infrared. When the model is extended to take account of the molecular symmetry, splitting of the single degenerate feature is expected, together with intensity transfer between the spherical harmonic descendants of the same symmetry. More complex spectra can arise, yet there are very few clusters containing a three-dimensional array of metal atoms for which the SHM fails to give a convincing spectral interpretation.[2]

A limited group of clusters, all with a tetrahedral metal core, was found to exhibit a different spectral pattern. This pattern was susceptible to interpretation by a tensor harmonic formalism (the tensor harmonic model, THM), which requires the introduction of strong tangential (to the surface of the sphere) dipolar-active modes. This model predicts several strong and well-separated peaks. This point is illustrated in Figure 1, where we give the expected qualitative diagrammatic spectra for C_{3v} tetranuclear clusters with nine terminal CO groups (the most common structure − vide infra), following the SHM or THM, respectively.

The two models can be related to the recently proposed "metal cluster selection rule",[3] which is a cluster-equivalent to the well-known "surface selection rule" of metals.[4] A dipole moment change in an adsorbed molecule (or in a CO bonded to a cluster) induces an image dipole moment change in the metal bulk (or in the metal cluster). The dipole moment changes perpendicular to the metal surface reinforce and those parallel to it cancel, leading to the rule "only dipole moment changes perpendicular to the surface are spectrally dipole active". The clusters following the SHM are able to sustain image dipole and so behave as metals. The clusters following the THM are not able to do this and so approximate to insulators.

Some tetrahedral clusters required the SHM for the interpretation of their spectra and others the THM. Those that required the latter model were those in which the metal atoms were separated by electronegative bridging ligands.[5] The interpretation placed on this observation is that the presence of these ligands gave clusters which lacked the transition-dipole induced metallic conductivity. However, it was recognised that the matter was not so simple: "...it can be a delicate matter. So, although a sulfur bridged Re_4 species is [one that follows the THM] the reported data indicate that corresponding iron compound [does not]".[2] Related to this is the fact that it appears to be the case that it is only for tetrahedral species that the duality of model applicability occurs with such clarity. In that the tetrahedron is the simplest of all three-dimensional arrangements of metal atoms, this itself is perhaps not too surprising − the larger the metal cluster the more applicable the SHM, or so it seems.

Given the "delicate" nature of the choice of applicability of the SHM or the THM to tetrahedral clusters we felt the matter worthy of a more detailed study. All the evidence indicates that, in reality, there is continuity between the SHM and the THM, an aspect which, as the above dis-

cussion shows, seems particularly important for tetrahedral clusters. What of tetrahedral clusters which have no electronegative bridge atoms? Is there evidence that they may show at least putative THM behaviour? The present work is devoted to a study of this question and does so by a review of the infrared and, wherever data are available, the Raman spectra of some tetrahedral transition metal cluster carbonyls.

Results

Table 1 details the tetrahedral metal carbonyl clusters that we have reviewed. They were selected from those references that include figures which show the infrared spectra and do not merely give frequency data.

The Raman spectra were recorded by us whenever possible. It is convenient to start by a study of the spectra of

[a] The numbers refer to the number and to the arrangement of the terminal CO′s, irrespective of the presence of bridging CO′s, other ligands or different metal atoms; **1**: (9 CO′s), $[M(CO)_3][M(CO)_2]_3$; **2**: (8 CO′s), $[M(CO)_3][M(CO)_2]_2[M(CO)]$ (**2e** is $[M(CO)_2]_4$); **3**: (7 CO′s), $[M(CO)_3][M(CO)_2][M(CO)]_2$; **4**: (10 CO′s), $[M(CO)_3]_3[M(CO)]$; **5**: (12 CO′s), $[M(CO)_3]_4$; **6**: (4 CO′s), $[M(CO)]_4$. – [b] The symmetry relates to the terminal CO groups and to the whole molecule, respectively. – [c] Applicable as a first approximation.

three structurally closely related species, **1a, 1b** and **1c**, all of C_{3v} symmetry, symmetry shared, of course, by the arrangement of the terminal CO groups. The group-theoretically predicted features are $3A_1 + 3E$, all modes being both infrared and Raman active. Their infrared and Raman spectra are shown in Figures 2, 3 and 4.

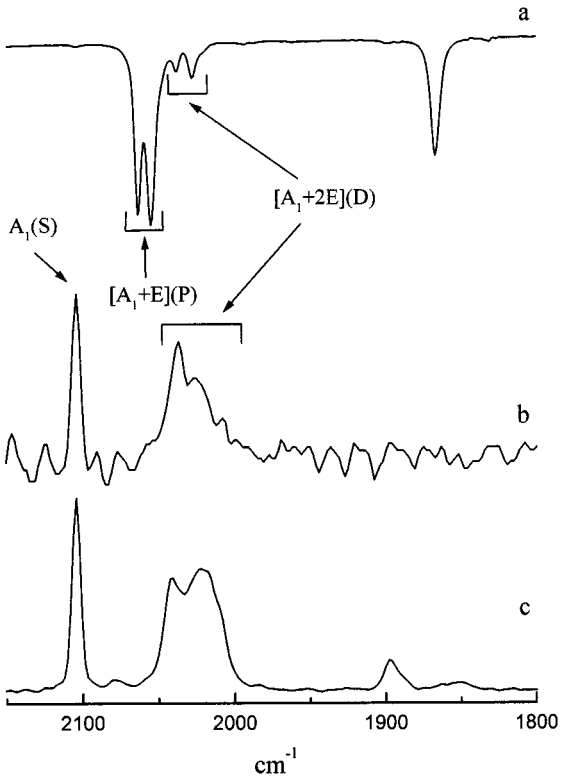

Figure 2. Solution infrared (a) and Raman (b: solution; c: crystals) spectra in the CO stretching region; complex: $Co_4(CO)_{12}$ (**1a**); solvents: (a) *n*-hexane, (b) CCl_4.

In these figures we also give the Raman spectra of crystalline samples; comparison of these with those from solutions gives confidence that the Raman spectrum of a crystalline compound, where this is the only one available, is not far removed from that of the dissolved species. All species show a high frequency A_1 mode, strong in the Raman spectrum and weak but coincident in the infrared spectrum; we shall have little to say concerning this mode beyond noting that it is the S mode of the SHM.

The complex $Co_4(CO)_{12}$ provides a good starting point for the study of the other modes because its spectra conform to the SHM predictions rather well. Consider the infrared spectrum, with two intense peaks, one approximately twice the intensity of the other, separated by ca. 8 cm^{-1}. Assignment as an $A_1 + E$ splitting of the P mode of the SHM by the molecular C_{3v} symmetry is clear. Equally clear is that very little mixing occurs between functions originating in the P and D harmonics; the $2E + A_1$ peaks at lower frequency, D in origin, are relatively weak in the infrared. The absence of any significant Raman intensity at the positions of the two strong infrared peaks is in accordance with the occurrence of little mixing. Conversely, the Raman D-originating peaks are split into a strong Raman peak, corre-

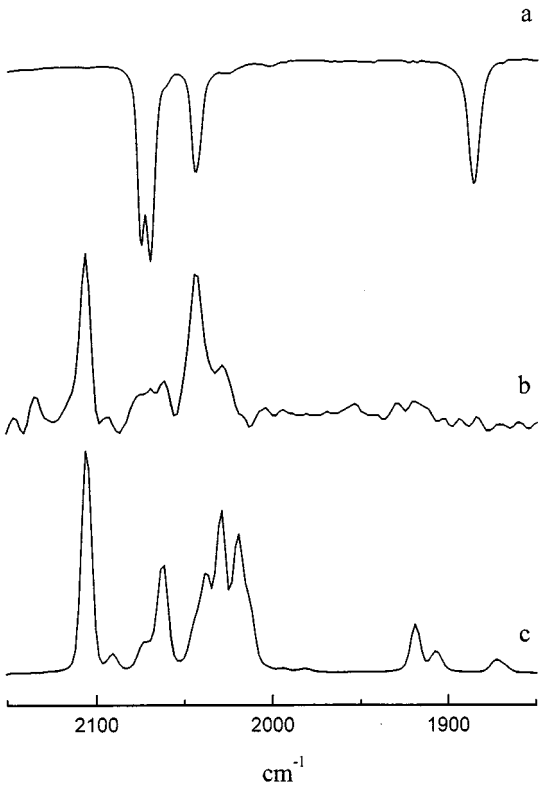

Figure 3. (see Figure 2); complex: $Rh_4(CO)_{12}$ (**1b**); solvents: (a) *n*-hexane, (b) CCl_4.

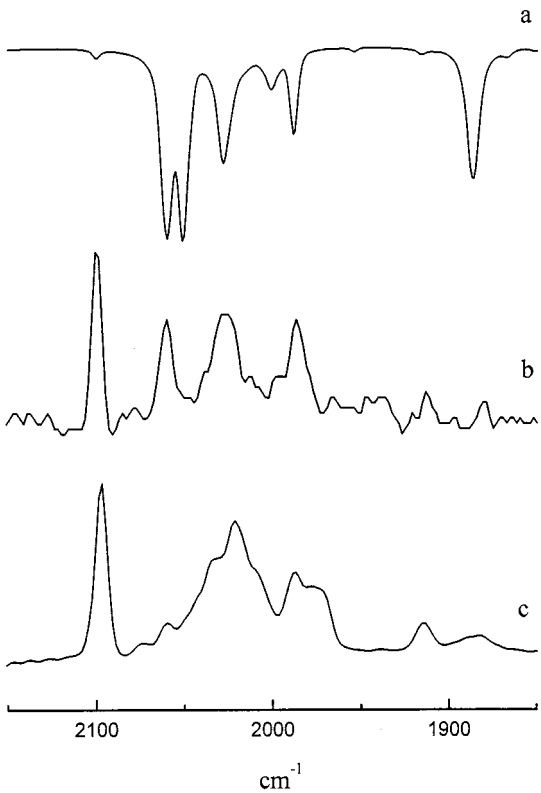

Figure 4. (see Figure 2); complex: $Co_3FeH(CO)_{12}$ (**1c**); solvents: (a) *n*-hexane, (b) CCl_4.

sponding to a weak infrared band, and a medium-broad peak largely coincident with another weak infrared absorption. There is another very weak and broad infrared peak at longest wavelength. As we shall see, a consistent pattern emerges if it is the lower frequency E modes which are most effective at stealing infrared intensity from the higher E mode. The Raman intensities, therefore, suggest that the assignment of these three infrared peaks is E, E and A_1 in that order, rather than E, A_1, E as previously suggested on the basis of the infrared spectrum alone.[4] The general explanation of the spectra seems clear, as is the conclusion arising from them: the SHM provides a convincing interpretation of the vibrational spectra. With this interpretation established, that of **1b** is also clear; it is basically the same. However, there is one significant difference: although the splitting of the individual spherical harmonics is less, the mixing between P and D functions is greater. The evidence for this assertion is that in the infrared the higher of the two E (D) is (relatively) stronger than in the cobalt species. Conversely, and as required by the SHM, the Raman E (P) is (relatively) stronger than in **1a** (the solid state spectra help to remove any ambiguity on this point). The spectra of **1c**, although significantly different, are related to the pattern set by **1a** and **1b**. However, the splitting of the (infrared active) P mode seems reversed. The E mode infrared intensity is distributed amongst all of the infrared-active E modes so that the E (P) is now weakened such that it is of about the same intensity as the A_1 (P), a considerable intensity having been transferred to both of the E (D) s, this transfer serving to identify them. The A_1/E (P) interchange is indicated by the infrared-Raman coincidence, which for this species occurs for the higher frequency P-derived mode (cf. **1b**). The infrared intensities indicate clearly that the zeroth-order SHM functions are significantly mixed in this species. The Raman is in complete agreement with this, the correspondences being just those expected. However, the reversed pattern of splitting in the P mode of the SHM (and, probably, changes in the D mode splitting too, vide infra), show that the substitution of a Co by FeH has had a significant disruptive effect and induced a significant move towards THM behaviour. A limiting THM behaviour would be characterised by an A_1 (S) and [A_1 + E](P) splitting of the radial modes and a [A_1 + 2E] splitting of the tangential modes. In particular, the tangential modes will have significant infrared intensity, a feature that serves to characterise the THM; it is to be noted that a P mode splitting occurs in both the SHM and the THM, although it seems to be larger in the latter.

In summary, through the series **1a**−**c** we see a progression from almost pure SHM behaviour through to something that shows characteristics which surely indicate a transition to something closer to the THM limit. For this reason we do not regard the evident E, A_1, E splitting of the lower infrared set in **1c** as requiring the same pattern for **1a**.

The effect of metal-atom substitution in tetrahedral clusters can be further explored in the complex **1d**. It has a (solid state) Raman spectrum which very closely resembles that of **1b** and which surely must be interpreted similarly (Figure 5).

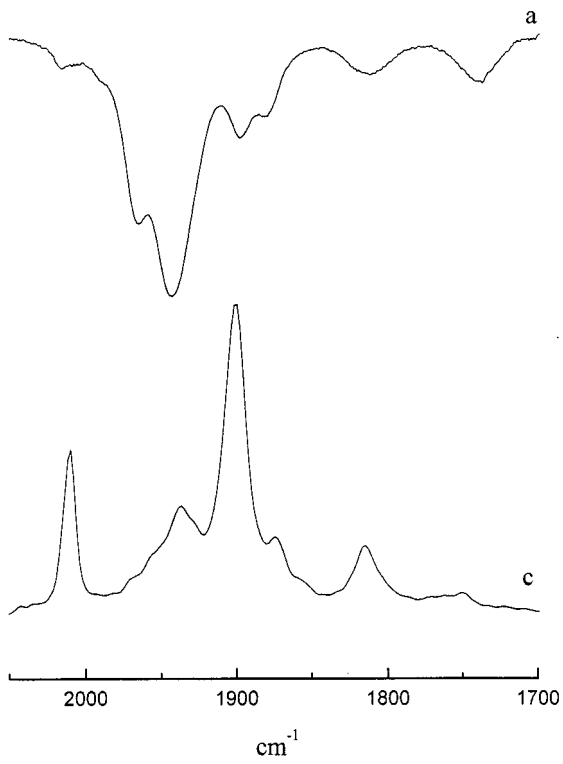

Figure 5. (see Figure 2); complex: $[Fe_3RhH(CO)_{12}]^{2-}$ (**1d**); solvents: (a) CH_3CN.

The intermolecular CO coupling (factor group effects) in anionic metal carbonyl clusters is minimised by the dilution effect caused by the presence of a large counterion. This is relevant to complex **1d** which has C_s symmetry, as the rhodium atom lies in the basal triangle.[7] Notwithstanding its lower symmetry and the presence of a "hetero" metal atom, the similarity of its spectra with those of **1b** is remarkable. As we have pointed out, such an indifference to metal atom heterogeneity is not unusual in clusters and the fact that the indifference is implicit within the SHM has been claimed[2] as a strength of the model. Other complexes sustain this assessment. Consider the pair **1e** and **1f**, whose spectra have already been reported.[8] The similarity of the spectra of **1e** with those of the C_{3v} complexes is clearly evident. The spectra of **1f** suffer from the poor quality of the Raman spectrum and of the broadness of the infrared; however, the patterns seem similar and so too, presumably, are the explanations. Moreover, the complex **1g**, structurally derived from **1e** with an $AuPPh_3$ unit bridging the basal $FeIr_2$ triangle,[8] does not show any significant changes in the spectra (Figure 6) − the splitting of the P and D modes is simply more evident.

Finally, we have considered seven other species, **1h**−**1n**. Like all of the molecules considered so far, they have nine terminal CO groups and C_s symmetry. Immediately evident is the overall similarity between comparable spectra, both

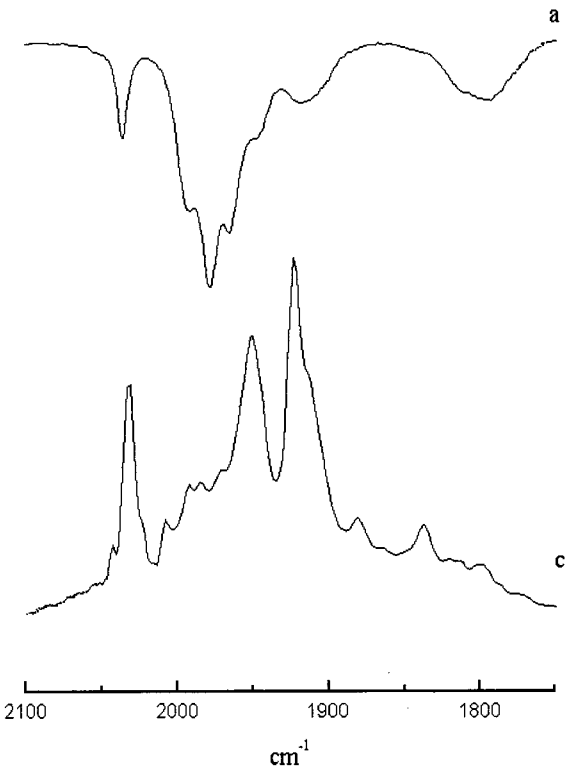

Figure 6. (see Figure 2); complex: $[Fe_2Ir_2(CO)_{12}AuPPh_3]^-$ (**1g**); solvents: (a) CH_2Cl_2.

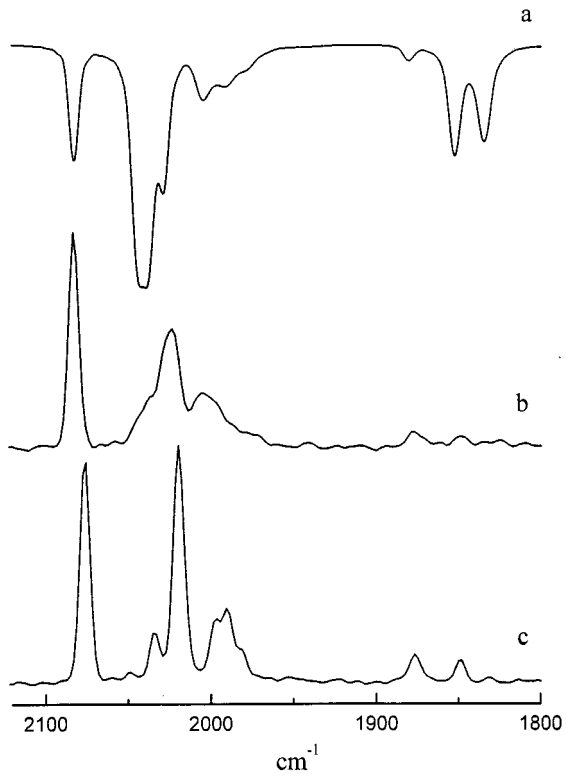

Figure 7. (see Figure 2); complex: $Co_4(CO)_{11}PPh_3$ (**2a**); solvents: (a) CCl_4, (b) CCl_4.

between these species and those of Figures 2−6, notwithstanding the fact that two of these species contain H as a bridging ligand and that one has a M_4, two a MM'_3 and the other four a $M_2M'_2$ core. It is clear that the general pattern established for the first three molecules, of C_{3v} symmetry, is applicable to others of C_s. This is helpful because the low symmetry of the latter means that group theory, unaided, offers few insights.

Figure 7 shows the ir and Raman spectra of **2a**, a species derived from **1a** by substitution of a basal CO by a phosphane.[14] Consequently, it has eight terminal carbonyl groups with the structural form $M(CO)_3[M(CO)_2]_2M(CO)$. Like the molecules **1d−1n**, the molecular symmetry is C_s, but whereas for these latter the idealised CO group arrangements are all C_{3v}, this arrangement now has only C_s symmetry. Despite this change, and that of the number of terminal CO ligands, the spectra of Figure 7 are qualitatively very similar to those of Figures 2−6; the S + P + D pattern is clearly recognisable. The only change that seems evident is that the highest frequency, totally symmetric, A′ mode has an increased infrared activity. This is not surprising in view of the reduction in CO group symmetry. The literature reports a set of $[M_4(CO)_{11}COOR]^-$ (M = Co, Rh, Ir) complexes,[15−17] all having the same number and arrangement of the CO groups. Raman spectra are not available but the infrared spectra exhibit a behaviour very close to that just discussed. A general comment which may be made at this point is that, as Table 1 shows, neither metal atom nor terminal carbonyl symmetries have any apparent influence on the spectral behaviour observed.

The compounds **2b−2d** are very interesting in that they all contain a single acetate-derived substituent. As a first approximation, the second and third row transition element examples conform to the THM whilst the first row example lies somewhere between the two extremes. Whilst they conform to the pattern that the introduction of electronegative substituents leads to near THM behaviour, they provide the first examples in which the presence of a single electronegative substituent is sufficient to bring about this transition. The compound **2e**, with a single iodide anion, is borderline, as are a number of other species with H as a ligand. It should be recognised that the species which have been the subject of the present paragraph serve to remove a possible ambiguity concerning the THM. This concerns the matter of Mν(CO)−M′ν(CO) coupling. In that it does not invoke the (additional) coupling via an induced-dipole mechanism of the SHM, could it be that the THM is only appropriate to species in which Mν(CO)−M′ν(CO), or perhaps just $[M\nu(CO)_n]-[M'\nu(CO)_m]$, (with no constraints on M, M′, n or m as long as they refer to different units) coupling is negligible? The present series seem to make it quite clear that the existence of coupling is entirely consistent with the applicability of the THM.

The final set which we review is a series of four tetranuclear species (**3a−d**) containing just seven terminal carbonyl groups. They comprise one M_4, one M_3M' and two $M_2M'_2$ compounds. Their infrared spectra, again of variable quality, are illustrated in the Figures of the relevant papers (Table 1). Yet again, the general impression is one of similarity with the other spectra given in this paper. The essen-

tial indifference of the spectra to the number of terminal carbonyl groups is an indicator of the applicability of a common model and this seems to be that of a borderline between the SHM and THM, with a bias towards the latter.

Finally, we group together three more complexes with different numbers of CO groups and different symmetries. The anion **4a**, of C_3 symmetry but now with ten terminal CO groups has recently bee reported. The carbonyl groups in this complex are arranged as $[M(CO)][M(CO)_3]_3$.[19] In this discussion, this is grouped with the well-known $Ir_4(CO)_{12}$ (**5a**) and $[Rh_4(CO)_{12}]^-$ (**6a**) complexes, with $[M(CO)_3]_4$ and $[M(CO)]_4$ carbonyl arrangements, respectively. What is remarkable is the fact that their infrared spectra differ very little from each other and are even simpler than those reported in Figures 1 and 2, despite the considerable difference in number of terminal CO groups in, and different symmetries of, the relevant molecules. The SHM is applicable to all of them, explaining the spectral observations.

Discussion

The most evident conclusion to be drawn from the spectra discussed above is that they are all related and show little sensitivity to the detailed molecular geometry or, indeed, to the number of terminal carbonyl groups in the molecule. The formal charge on the carbonyl species affects the mean frequency of the band pattern but not its general characteristics. As a starting point, the SHM is clearly appropriate. However, as we suspected when the present work commenced, there seem to be some species that show at least some aspects of a move towards the applicability of the THM. Although we recognise that distinctions are arbitrary − there can be conflicting indications − we incline to the view that when the (commonly observed) splitting of the P mode is less than, say, 10 cm^{-1}, then the SHM is applicable. This applicability is also manifest in the fact that whilst there is infrared intensity in the Raman-active D modes and Raman intensity in the infrared-active P modes, this transfer is less than in the species about to be discussed. When the splitting of the P mode features is greater than, say, 25 cm^{-1}, there is a significant movement towards the applicability of the THM (although the limiting characteristics of this model are rarely encountered). Another indicator of the move towards THM behaviour is an increase in infrared-Raman intensity transfer. So, clusters **1a**, **1b**, **1h**, **1j**, **1k**, **1m**, **2a**, **4a**, **5a** and **6a** show SHM-type behaviour whilst clusters **1d**, **1e**, **1f**, **1g**, **2b**, **2d** and **3c** show a significant move towards THM-type behaviour. Others, **1c**, **1i**, **1l**, **1n**, **2c**, **2e**, **3a**, **3b** and **3d** are rather borderline, emphasising the existence of continuity between the SHM and THM. To further explore this point, we can go back to Figure 1.

The pattern can be reinterpreted in terms of the basic model behind the SHM/THM distinction. Pure SHM has been interpreted as the metal cluster core behaving as a perfect conductor; it can sustain an image dipole, presumably because of a dipole-induced mixing with low-lying excited states. Conversely, pure THM behaviour is associated with the cluster behaving like a perfect insulator. So, the data that we have presented above indicate that the Co_4 cluster is more "metallic" than is the Rh_4. Further, the replacement of a Co by an FeH in the Co_3Fe unit is sufficient to disrupt the band pattern of Co_4 and to give a much less metallic unit. At the present it only seems possible to make such comments post hoc. We have previously commented on the fact that, very often, replacement of a metal atom with a quite different one in a cluster has little, if any, effect on the vibrational spectra. Given the discussion at the beginning of this paper, we would expect that any metal-atom substitutional effect would be particularly evident for tetrahedral clusters and this expectation seem justified, although it does not mean that all tetrahedral mixed-metal species conform to the THM.

In the present work we have reviewed the terminal ν(CO) vibrational spectra of some twenty six tetrahedral cluster carbonyls. The details of the reviews have decreased throughout the paper, for two reasons. First, the spectral similarities observed means that there would otherwise have been much repetition. Second, for many of the later species either no Raman data were available or only relatively poor quality spectra. For the examples discussed at the beginning of the paper, good quality Raman data provided important corroborative evidence for conclusions reached from the infrared. Nonetheless, the general conclusion to be reached is clear. Tetrahedral cluster carbonyls seem to show sensitivity to the molecular composition greater than that revealed for comparable species of a higher nuclearity in a recent survey. In retrospect, this is not a surprising conclusion since the "cluster selection rule" that seems to control cluster spectral activities is related to the surface selection rule of metal surfaces. Tetrahedral clusters are those clusters most removed from the surface of bulk metal. Not surprisingly, therefore, some of the tetrahedral clusters reviewed in the present work seem to show a significant tendency to exhibit vibrational spectroscopic characteristics indicative of a move towards the THM. That the presence of electronegative ligands can make the THM that which is applicable is therefore entirely consistent. Overall, this suggests that other examples of THM applicability will only be found in low-nuclearity clusters.

Conclusions

In the present paper we have addressed the problem of the relative applicability of the SHM and the THM to the terminal ν(CO) vibrations of tetrahedral transition metal carbonyl clusters. For the species, which we surveyed − which were as broadly based as the data available in the literature would allow − they were found to be roughly equally applicable. This pattern explains a confusion apparent in the literature, that there are some tetrahedral species for which the available data are such as to make a normal coordinate analysis possible and others for which the data are not. The former are those that follow the THM. Over-

all, the pattern revealed is one that strongly supports the interpretation of the SHM in terms of a cluster selection rule, akin to the surface selection rule. Substitution of a metal atom of a homometallic cluster by a different metal or the addition of a highly electronegative group or atom to a molecule both have the effect of making the THM more applicable. Equally, they will have the effect of disrupting, at least to some extent, the band structure associated with the metal atoms in the cluster. This connection between band-structure disruption and THM applicability is just that expected on the basis of the cluster selection rule. This conclusion leads to a useful prediction, that THM behaviour should become increasingly rare as the cluster size increases and, as our recent survey has shown, this seems to be the case. In the other direction, there are trimetallic clusters (and, indeed, a whole family of clusters in which all of the metal atoms are located in the same plane) but these clearly merit a separate discussion concerning the applicability of the SHM and THM (vibrations located in the molecular plane may well behave rather differently from displacements perpendicular to it)

Experimental Section

$Co_4(CO)_{12}$[23] (**1a**), $Co_3FeH(CO)_{12}$[24] (**1c**) and $Co_4(CO)_{11}PPh_3$[14] (**2a**) were prepared as previously reported. $Rh_4(CO)_{12}$ (**1b**) was purchased from Sigma Aldrich and used after recrystallisation from *n*-hexane under CO. $[Fe_3RhH(CO)_{12}]^{2-}$ (**1d**) and $[Fe_2Ir_2(CO)_{12}AuPPh_3]^-$ (**1g**) were kindly donated by Professor R. Dalla Pergola, University of Milan.

IR spectra were recorded on a Bruker Equinox 55 FT-IR spectrophotometer at a resolution of 2 cm^{-1} in *n*-hexane for neutral complexes, and in CH_2Cl_2 for anionic systems, both in a NaCl cell. Raman spectra were recorded on a Bruker RFS 100 spectrophotometer equipped with an Nd^{3+}:YAG laser and Ge-diode detector at a resolution of 4 cm^{-1}. Measurements on crystalline samples were performed in capillary vials sealed under inert gas. Due to the risk of heating and decomposition, low laser powers (10−30 mW) were used and several scan-packets (of 50−100 scans each), interleaved by a recovery time and then averaged, were made. Solution spectra were recorded in CCl_4, a solvent that proved to have a very low background in the carbonyl stretching spectral region. Solutions were prepared by stirring the sample in a flask under a nitrogen flow and then filtering off the insoluble excess (highly concentrated solutions are required). Solutions were put into a quartz cuvette, which was sealed under inert gas. Laser powers of about 200 mW and about 3000 scans were used.

Mononuclear palladium carbene complexes **2a–c** and **3** derived from 1,1′-methylenebis(4-alkyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene) have been obtained by the reaction of 1,1′-methylenebis(4-alkyl-1,2,4-triazolium) diiodides **1a–d** with palladium acetate under mild conditions. The mononuclear complexes **2a–c** have been transformed into their corresponding *trans*-binuclear complexes **4a–c**. All compounds were characterized by spectroscopic techniques and the dynamic behavior of **2a–c** and **4a–c** has been studied. The X-ray structures of **2a** and **4c** are reported.

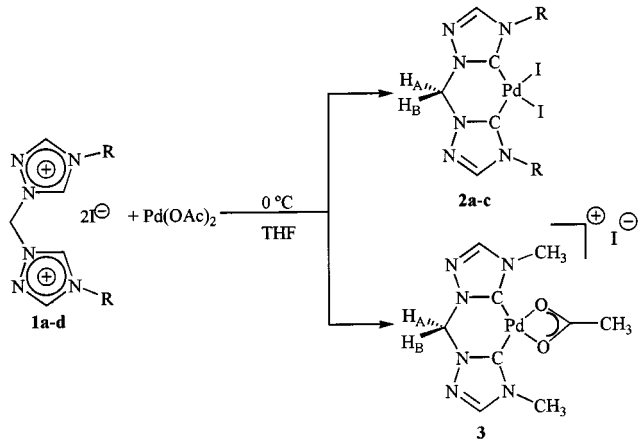
Introduction

A large number of palladium(II) complexes with bidentate ligands (L−L) are known, with this kind of ligand acting predominantly as a chelate to form mononuclear *cis*-[PdX_2(L−L)] complexes. Although some examples of chelate complexes with a *trans*-configuration are known, they are rare; normally, bidentate ligands act as bridges when they form palladium(II) complexes with a *trans*-configuration, but there are relatively few examples of *trans*-binuclear palladium(II) complexes (*trans*-[PdX_2(μ-L−L)]$_2$).[1,2]

In recent years, heterocyclic carbenes have generated a great deal of interest and a large number of reports covering theoretical aspects,[3] synthetic approaches,[4] coordination[4b,4c,4e,5] and catalytic[5g,5k,6] applications have been published. Imidazole and imidazoline rings with different substitution patterns have been extensively studied, several free carbenes and a great number of complexes derived from 2,3-dihydro-1*H*-imidazole-2-ylidene have been obtained.[4] However, carbenes based on the 1,2,4-triazole ring, where an additional nitrogen atom is present in the ring, have received little attention. As far as we know 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene is the only example of a free carbene isolated.[7] Several rhodium,[6c,6e] and *cis*- and *trans*-palladium[8] complexes derived from 4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene have been prepared, a tungsten compound, with a similar structure to the chelate carbene complex, derived from 1,1′-methylenebis(4-methyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene)[9] and 1,1′-methylenebis(4-methyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene)-1,1′-methylenebis(3-methyl-4,5-dihydro-1*H*-imidazole-5-ylidene)palladium(II) diiodide[5q] have also been reported.

In this paper we report the preparation of mononuclear palladium(II) complexes derived from 1,1′-methylenebis(4-methyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene) (mbmdty), 1,1′-methylenebis(4-isopropyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene) (mbidty), 1,1′-methylenebis(4-butyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene) (mbbdty) and 1,1′-methylenebis(4-octyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene) (mbodty), and their transformation into the corresponding *trans*-binuclear complexes.

Results and Discussion



Synthesis of [PdI_2(mbidty)] (2a), [PdI_2(mbbdty)] (2b) and [PdI_2(mbodty)] (2c)

Carbene complexes were prepared by a modification of the palladium(II) acetate route reported by Herrmann for the synthesis of similar compounds.[5g,6a] The reaction of the 1,1′-methylenebis(4-alkyl-1,2,4-triazolium) diiodides[10] (**1a−c**) with palladium(II) acetate in THF at 0°C led exclusively to the mononuclear species **2a−c**, as outlined in Scheme 1. The acidity of the H5 protons of the 1,2,4-triazole ring is higher than that of the H2 imidazole protons. This fact permits very mild reaction conditions in comparison with the usual procedures described for the synthesis of imidazole carbene complexes.[5g,6a]

Compounds **2a−c** present the same patterns in the ^{1}H- and ^{13}C{^{1}H} NMR spectra in [D_6]DMSO, except for the signals of the alkyl substituents. At room temperature an

Scheme 1. Summary of reactions leading to the preparation of **2a**−**c** and **3**

AB system was observed for the two methylene bridge protons (H_A and H_B) at about 6.53 and 6.95 ppm. Their coupling constants are in agreement with a geminal coupling. This assignment has been confirmed by NOE difference and HETCOR experiments; NOE intensities of 26% (**2a**), 13% (**2b**), and 14% (**2c**) between the methylene bridge protons have been observed and, in addition, HETCOR experiments show a correlation between each of the signals of the AB system in the ^{1}H NMR spectrum with only one signal in the $^{13}C\{^1H\}$ NMR spectrum (δ = 66.6, 66.7 and 66.7, respectively).

Each compound (**2a**−**c**) showed only one set of signals in the ^{1}H- and $^{13}C\{^1H\}$ NMR spectra for the alkyl substituents (the assignment was confirmed by HETCOR and NOE experiments).[12] These results indicate the equivalence of the alkyl groups, which is in agreement with a symmetric structure. However, in the ^{1}H NMR spectra two doublets of triplets were observed for **2b** and **2c** − one for each proton of N4−CH_2 (δ = 4.18 and 4.80 for **2b** and δ = 4.18 and 4.78 for **2c**) − due to a vicinal coupling (J = 7.1 Hz for both compounds) and a geminal coupling (J = 13.4 Hz for **2b** and 13.6 Hz for **2c**), which show the nonequivalence of the these two protons. In the ^{1}H NMR spectrum the isopropyl groups (**2a**) showed two doublets (δ = 1.33 and 1.53) for the CH_3 protons, which indicates that the methyl groups are nonequivalent, although these nonequivalent methyl groups are from the same isopropyl group because only one signal (δ = 5.41, sep) was observed for N4−CH, which indicates that the two isopropyl groups are equivalent. The equivalence of the isopropyl groups and the nonequivalence of the methyl groups was confirmed by $^{13}C\{^1H\}$ NMR spectroscopy, in which only one signal for N4−CH (δ = 52.7) and two signals for CH_3 (δ = 21.0 and 23.4) were observed.

The patterns in the ^{1}H- and $^{13}C\{^1H\}$ NMR spectra for compounds **2a**−**c** indicate that the two triazole rings are equivalent. We observed only one signal at lower field for H3 in the ^{1}H NMR spectrum (δ = 9.12, **2a**; 8.92, **2b**; 8.90, **2c**), which integrated for two protons, one for each heterocycle. In the $^{13}C\{^1H\}$ NMR spectra of all three compounds two signals appeared at lower field, one for C3 at 142.3 ppm (**2a**), 144.7 ppm (**2b**) or 144.8 ppm (**2c**) and the other for C5 at 166.7 ppm (**2a**), 166.3 ppm (**2b**) or 166.3 ppm (**2c**). The chemical shifts of C5 are in agreement with a coordinated heterocyclic carbenic carbon.[8b] This assignment has also been confirmed by HETCOR experiments.

The NMR spectroscopic and microanalytical data are in accordance with a 1,1′-methylenebis(4-alkyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene) system, although it is not possible to distinguish between mononuclear or binuclear palladium(II) complexes. The FAB-MS for compounds **2a**−**c** showed a peak at an *m*/*z* value double that expected for the mononuclear complexes. Nevertheless, by CI-MS with direct sample introduction the appropriate molecular peak for the mononuclear species was observed. This behavior may be explained by the formation of dimmeric species in solution, a phenomenon that has been observed previously in other systems.[11]

On the basis of the spectroscopic data a square-planar structure for palladium is proposed. Two coordination sites are occupied by two carbenes forming a rigid six-membered metallacyclic structure with a boat-conformation, and the other two coordination sites are occupied by the two iodine atoms (Figure 1). In our complexes the alkyl groups probably create sufficient steric hindrance to prevent boat-to-boat inversion.

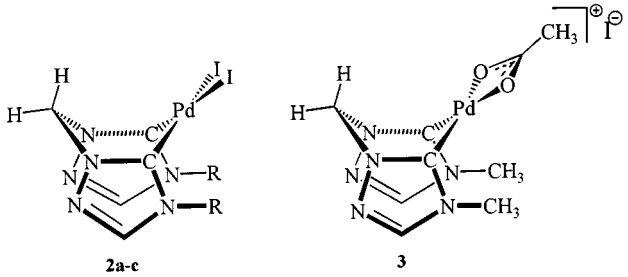

Figure 1. Proposed structures for **2a**−**c** and **3**

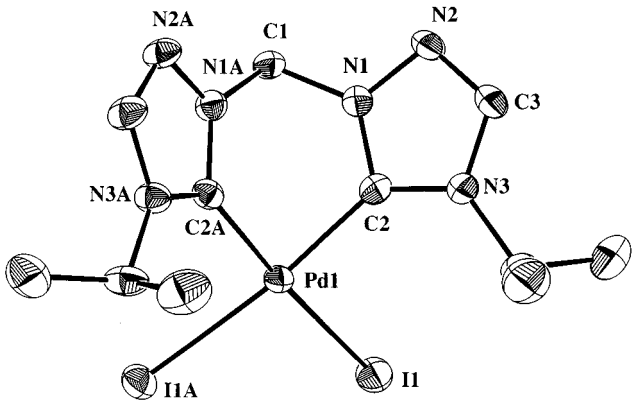
In order to confirm this proposal an X-ray crystal structure determination for **2a** was carried out. The solid state structure of this compound is shown in Figure 2. Compound **2a** is mononuclear in the solid state. The coordination sphere of the palladium atom shows a square planar geometry with the two iodide atoms in *cis*-positions.

Synthesis of [Pd(OAc)(mbmdty)]I (3)

Reaction of 1,1′-methylenebis(4-methyl-1,2,4-triazolium) diiodide[12] (**1d**) with palladium(II) acetate under the same conditions as for compounds **2a**−**c** (THF, 0°C) yielded an unexpected carbenic species, **3**, as shown in Scheme 1. This cationic palladium(II) dicarbene complex was characterized by IR, ^{1}H- and $^{13}C\{^1H\}$ NMR spectroscopy and mass spectrometry. The IR spectrum showed characteristic bands at 1408 and 1540 cm^{-1}, which correspond to $\nu_s(CO_2^-)$ and $\nu_a(CO_2^-)$, respectively. The ^{1}H NMR signals for the two



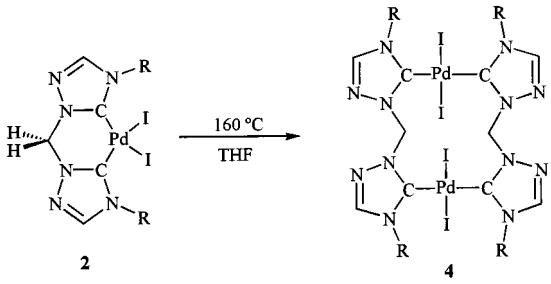


Figure 2. Solid state structure of **2a**; hydrogen atoms and a non-coordinated THF molecule are omitted for clarity; selected bond lengths [pm] and angles [°]: Pd1−C2 1.996(4), Pd1−I1 2.634(1); C2−Pd1−C2A 84.3(2), I1−Pd1−I1A 90.7(1), C2−Pd1−I1 92.2(1), C2−Pd1−I1A 173.2(1).

protons of the methylene bridge form an AB system with signals at 6.94 and 7.56 ppm, with a geminal coupling constant of 14.6 Hz. Moreover, H3 appears as a singlet at 8.95 ppm and we observed two other high-field singlets: one at 3.89 ppm for N4−CH_3 and the other at 1.87 ppm for the methyl group of the acetate. The $^{13}C\{^1H\}$ NMR spectrum showed three signals at lower field: 147.0, 152.0 and 181.7 ppm for C3, the carbenic carbon and COO, respectively. The carbon of the methylene bridge was observed as one signal at 65.0 ppm and two signals appeared at higher field: one at 23.6 ppm for the methyl of the acetate group and the other at 35.8 ppm for N4−CH_3.

CI-MS with direct sample introduction and FAB-MS of compound **3** showed mass peaks corresponding to the mononuclear complex (*m*/*z*: 343 D, $[M - I]^+$; 411 D, $[M - OAc]^+$) but with very low intensity. However, electrospray-MS showed these peaks with intensity of 100% and 66%, respectively. In a similar way to complexes **2a**−**c**, all spectroscopic data obtained for **3** are consistent with a rigid six-membered metallacyclic structure in the boat conformation, as shown in Figure 1.

Synthesis of $[PdI_2(\mu\text{-mbidty})]_2$ (4a), $[PdI_2(\mu\text{-mbbdty})]_2$ (4b) and $[PdI_2(\mu\text{-mbodty})]_2$ (4c)

Heating the carbene complexes **2a**−**c** in THF at 160°C in a Fisher−Porter bottle gave the new *trans*-binuclear palladium(II) species **4a**−**c** as the only products (Scheme 2). Compounds **4** show similar patterns in the ^1H- and $^{13}C\{^1H\}$ NMR spectra ([D_6]DMSO), except for the typical signals of the alkyl substituents. The NMR spectra of **4** were found to be different to those of the mononuclear complexes **2**: The ^1H NMR spectrum shows a very broad singlet at about 7.10 ppm (**4a**), 7.30 ppm (**4b** and **4c**) for the methylene bridges, a broad singlet due to N4−CH_2 for **4b** (δ = 4.40−4.60) and **4c** (δ = 4.30−4.50), and only one doublet (δ = 1.55) for all the methyl groups of the isopropyl units (**4a**). These facts indicate that the structure of the binuclear complexes **4a**−**c** is nonrigid and symmetrical at room temperature. This assignment is in agreement with the $^{13}C\{^1H\}$ NMR spectra, with one signal for the methylene bridges at δ = 67.0 (**4a**); 67.2 (**4b**); 67.3 (**4c**), one signal for N4−CH_2 (δ = 48.8, **4b**; 49.1, **4c**) and one signal for the CH_3 of the isopropyl groups (δ = 25.1, **4a**). The other signals in the ^1H- and $^{13}C\{^1H\}$ NMR spectra are typical for alkyl substituents.[12] In the ^1H NMR spectra only one signal appeared at low field (δ = 9.26, 9.03 and 9.02 for **4a**−**c**, respectively) for H3 of the heterocyclic rings, and these were correlated with only one signal in the $^{13}C\{^1H\}$ NMR spectra (δ = 143.5, **4a**; 145.7, **4b**; 145.8, **4c**). In the $^{13}C\{^1H\}$ NMR spectra we observed one signal of low intensity at lower field, corresponding to the carbenic carbon C5 (δ = 172.0, **4a**; 171.3, **4b**; 171.5, **4c**). This evidence corroborates the symmetrical structure indicated above.

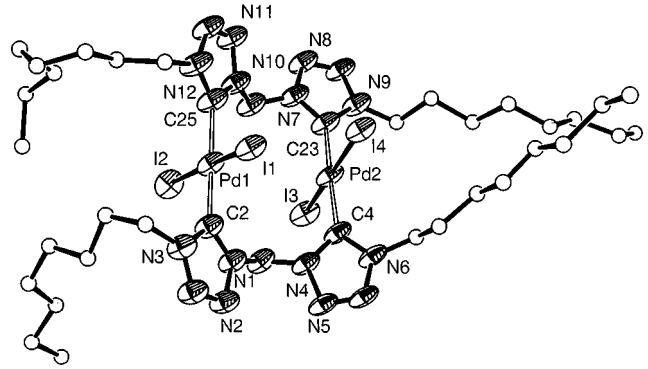
a: R = Isopropyl, **b**: R = Butyl, **c**: R = Octyl

Scheme 2. Summary of reactions leading to the preparation of **4a**−**c**

In a similar way to compounds **2a**−**c**, both the spectroscopic and microanalytical data are in agreement with the structure of the 1,1′-methylenebis(4-alkyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene) system. However, these compounds could have either a mono- or binuclear structure. CI-MS with direct sample introduction, and FAB-MS, for compounds **4a**−**c** showed, without doubt, peaks corresponding to binuclear compounds.[12]

In order to ascertain whether the complexes exist in the *cis*- or *trans*-configuration in the solid state an X-ray crystal structure determination for **4c** was carried out. The solid state structure (Figure 3) shows a binuclear structure in which two dicarbene ligands act as a bridge between two palladium atoms with a *trans*-square planar geometry about the metal centers.

When the mononuclear compounds were transformed into the binuclear complexes a change in their configuration was observed; while the former showed a *cis*-configuration the latter presented a *trans*-configuration. This is reminiscent of the *cis*/*trans* isomerization observed by Herrmann for diiodobis(1,4-dimethyl-4,5-dihydro-1*H*-1,2,4-triazole-5-ylidene)-palladium(II),[8b] in which the rearrangement took place without dissociation of the ligand. However, our results are not consistent with this model because it is not possible to prepare *trans*-chelate complexes with our biscarbenes. − they should act as bridges to form complexes with a *trans*-configuration and, therefore, dissociation of the ligand is necessary.



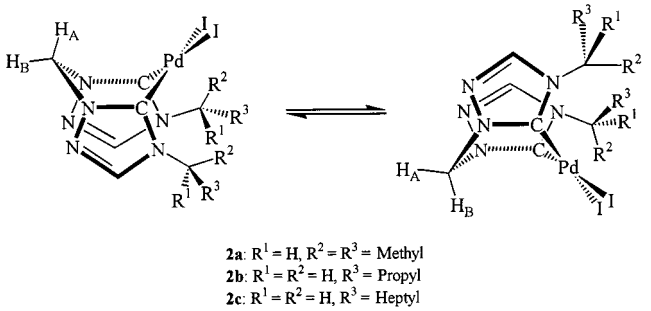


Figure 3. Solid state structure of **4c**; for clarity, the hydrogen atoms and a toluene molecule are omitted, and the octyl substituents are presented in a ball and stick style; selected bond lengths [pm] and angles [°]: Pd1−C2 1.970(17), Pd1−C25 2.018(17), Pd1−I1 2.619(2), Pd1−I2 2.600(2), Pd2−C4 2.017(16), Pd2−C23 1.973(16), Pd2−I3 2.595(2), Pd2−I4 2.599(2); C2−Pd1−C25 177.3(8), I1−Pd1−I2 174.2(1), C2−Pd1−I2 90.0(7), C25−Pd1−I2 92.2(7), C2−Pd1−I1 85.5(7), C25−Pd1−I1 92.3(7), C4−Pd2−C23 176.4(8), I3−Pd2−I4 173.9(1), C23−Pd2−I3 87.5(7), C4−Pd2−I3 90.9(6), C23−Pd2−I4 87.3(7), C4−Pd2−I4 94.1(6)

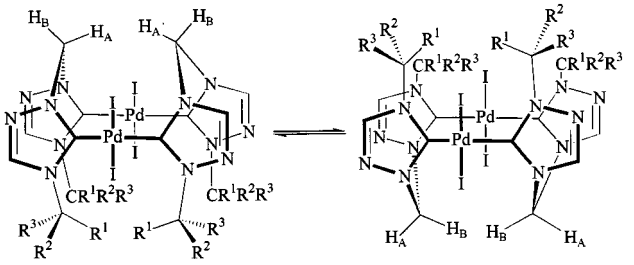
Scheme 3. Boat-to-boat inversion of **2a**−**c**

Study of the Dynamic Behavior of the Mononuclear and Binuclear Complexes

We have mentioned above that the structures of the mononuclear complexes **2a**−**c** are rigid at room temperature. However, when solutions of these compounds were heated some dynamic behavior was observed. The signals in the ^{1}H NMR spectra of the methylene bridge, N4-methylene for **2b** and **2c,** and methyl (isopropyl) groups for **2a** were observed during the dynamic study. When the ^{1}H NMR spectra of **2a**−**c** were recorded at high temperature, the AB systems corresponding to the diastereotopic protons of the methylene bridges coalesce. This indicates that boat-to-boat inversion takes place at high temperature as shown in Scheme 3.



In addition, at high temperature the two doublets due to the methyl protons of the isopropyl groups (**2a**) coalesce, becoming a doublet, and the doublet of triplets due to N4−CH_2 (**2b** and **2c**) also coalesce, to give a triplet. Coalescence temperatures and free energy values[13] ($\Delta G^{\neq}$) are summarized in Table 1.

The similar free energy values obtained for each compound for the methylene bridge protons and from the substituent (N4−R) indicate that the rigid structure exhibited by the mononuclear compounds is responsible for the nonequivalence of the methylene bridge protons, the methylene protons bonded to N4 (**2b** and **2c**), and the methyl groups of the isopropyl substituents (**2a**). Therefore boat-to-boat inversion must be responsible for the equivalence of these sets of protons at higher temperatures.

The binuclear compounds **4a**−**c** also showed a dynamic behavior. In the ^{1}H NMR spectra ([D_8]THF) the methylene bridge protons give rise to a very broad singlet at room temperature which becomes sharper at high temperature and resolves into an AB system at low temperature. This is in agreement with a structure that shows a boat-to-boat-like inversion at room temperature, as outlined in Scheme 4; this inversion could be stopped at low temperature. Moreover, the broad singlet for the N4−CH_2 group of **4b** and **4c** (δ = 4.50 and 4.40, respectively) appeared as two broad signals at low temperature (two doublets of triplets were expected, but broad signals were observed probably due to a loss of resolution in the NMR apparatus at this temperature). In addition, an AB system appeared for the N4−CH_2 group in **4b** and **4c** upon irradiation, at low temperature, at the frequencies of the methylene protons in the 2-position of the chain (N4$CH_2C\mathit{H}_2$) for butyl (**4b**, δ = 2.13) and octyl (**4c**, δ = 2.15) substituents. On the other hand, it was not possible to study the dynamic behavior of **4a** by studying the methyl groups due to the fact that the two doublets expected at low temperature were not observed, again probably because of a loss of resolution in the

Table 1. Coalescence temperatures and free energy values[13] ($\Delta G^{\neq}$)

	AB System		N4−CH_2 or N4−CH_3	
Compound	Coalesc. T (K)	$\Delta G^{\neq}$ (kcal/mol)	Coalesc. T (K)	$\Delta G^{\neq}$ (kcal/mol)

4c	293	12.78	273	12.42

2a: R^1 = H, R^2 = R^3 = Methyl
2b: R^1 = R^2 = H, R^3 = Propyl
2c: R^1 = R^2 = H, R^3 = Heptyl

Scheme 4. Conformational inversion of **4a**−**c**

NMR apparatus. Coalescence temperatures and free energy values[13] ($\Delta G^{\neq}$) are summarized in Table 1.

We can draw similar conclusions for the binuclear compounds **4a**−**c**. Free energy values indicate that the rigid structure at low temperature is responsible for the nonequivalence of the methylene bridge protons, the nonequivalence of the methylene protons bonded to N4 (**4b** and **4c**), and therefore the inversion at room temperature makes them equivalent.

Experimental Section

General considerations: All operations were performed under an inert atmosphere using standard vacuum line techniques. Solvents were purified by distillation from appropriate drying reagents before use. Melting points were determined in capillary tubes on a Gallenkamp apparatus and are uncorrected. Elemental analyses were performed on a Perkin−Elmer 2400 CHN microanalyzer. IR spectra were recorded (in the region between 4000 and 200 cm^{-1}) on a Perkin−Elmer PE 883 IR spectrophotometer in KBr. NMR spectra were recorded on a Varian Unity 300. Chemical shifts are expressed in parts per million (δ) relative to TMS as internal standard in [D_6]DMSO. FAB-MS were recorded on a VG Autospect instrument using *m*-nitrobenzylalcohol as matrix. CI-MS were recorded on a NERNAG R10−10H instrument in NH_3 or CH_4. The 1,1′-Methylenebis(4-alkyl-1,2,4-triazolium) diiodides (**1a**−**c**) were prepared as previously reported.[10]

Preparation of 1,1′-methylenebis(4-methyl-1,2,4-triazolium) diiodide (1d): A mixture of 1,1′-methylenebis(1,2,4-triazole)[10] (100 mg, 0.67 mmol) and an excess of methyl iodide (15 mL) was stirred and heated at 130°C for 10 h in a 50 mL Fisher−Porter bottle. After cooling, the suspended solid was isolated by filtration, washed with ethyl acetate and recrystallized from ethanol. Yield: 87%; m.p. 211−213°C (decomposition). − ^{1}H NMR: δ = 3.97 (s, 6 H, CH_3), 7.17 (s, 2 H, CH_2), 9.29 (s, 2 H) and 10.39 (s, 2 H) (H3 and H5). − ^{13}C{1H} NMR: δ = 34.6 (CH_3), 62.2 (CH_2), 145.5, 146.4 (C3 and C5). − $C_7H_{12}I_2N_6$ (434.02): calcd C 19.37, H 2.79, N 19.36; found C 18.95, H 3.09, N 19.41.

General Procedure for Preparation of Mononuclear Complexes (2a−c, 3): A suspension of the corresponding 1,1′-methylenebis(4-alkyl-1,2,4-triazolium) diiodide (**1a**−**d**) (0.44 mmol) and palladium acetate (89.7 mg, 0.40 mmol) in THF (250 mL) in an 1 L Schlenk tube was stirred at 0°C for between 4 and 48 h. The crude mixture was filtered and the solvent was evaporated under vacuum. Pure products were isolated as indicated in each case.

Preparation of [PdI_2(mbidty)] (2a): The general procedure for mononuclear complexes was followed. Reaction time was 24 h. The pure product was obtained as a yellow solid after washing with chloroform. Yield: 97%; m.p. 318−320°C (decomposition). − ^{1}H NMR: δ = 1.33 (d, *J* = 6.7 Hz, 6 H, CH_3), 1.53 (d, *J* = 6.7 Hz, 6 H, CH_3), 5.41 (sep, *J* = 6.7 Hz, 2 H, C*H*Me_2), 6.50 and 6.92 (AB system, *J* = 13.9 Hz, 2 H, NCH_2N), 9.12 (s, 2 H, H3). − ^{13}C{^{1}H} NMR: δ = 21.0 (CH_3), 23.4 (CH_3), 52.7 (*C*HMe_2), 66.6 (NCH_2N), 142.3 (C3), 166.7 (C5). − MS (FAB$^+$); *m*/*z* (%): 467 (37) [M + 1 − HI]$^+$, 594 (10) [M]$^+$, 701 (5) [2M − Pd − 3I]$^+$, 1060 (8) [2M − HI]$^+$. − MS (CI, NH_3); *m*/*z* (%): 251 (100) [M + 1 + NH_4 − Pd − 2HI]$^+$, 467 (18) [M + 1 − HI]$^+$, 484 (8) [M + NH_4 − HI]$^+$, 612 (44) [M + NH_4]$^+$. − $C_{11}H_{18}I_2N_6Pd$ (594.53): calcd C 22.22, H 3.05, N 14.14; found C 22.21, H 3.03, N 13.86.

Preparation of [PdI_2(mbbdty)] (2b): The general procedure for mononuclear complexes was followed. Reaction time was 4 h. The pure product was obtained as an orange solid after recrystallization from dichloromethane/diethyl ether. Yield: 95%; m.p. 295−297°C (decomposition). − ^{1}H NMR: δ = 0.87 (t, *J* = 7.3 Hz, 6 H, CH_3), 1.20 (sxt, *J* = 7.3 Hz, 4 H, $NCH_2CH_2CH_2CH_3$), 1.79 (m, *J* = 6.9 Hz, 4 H, $NCH_2CH_2CH_2CH_3$), 4.18 (dt, *J* = 13.4 Hz, *J* = 7.1 Hz, 2 H, one H from each $NCH_2CH_2CH_2CH_3$), 4.80 (dt, *J* = 13.4 Hz, *J* = 7.1 Hz, 2 H, one H from each $NCH_2CH_2CH_2CH_3$), 6.55 and 6.96 (AB system, *J* = 14.0 Hz, 2 H, NCH_2N), 8.92 (s, 2 H, H3). − ^{13}C{^{1}H} NMR: δ = 13.3 (CH_3), 18.7 ($NCH_2CH_2CH_2CH_3$), 31.8 ($NCH_2CH_2CH_2CH_3$), 48.9 ($NCH_2CH_2CH_2CH_3$), 66.7 (NCH_2N), 144.7 (C3), 166.3 (C5). − MS (FAB$^+$); *m*/*z* (%): 495 (100) [M + 1 − HI]$^+$, 621 (15) [M − 1]$^+$, 757 (11) [2M − Pd − 3I]$^+$, 1118 (40) [2M + 2 − HI]$^+$. − MS (CI, NH_3); *m*/*z* (%): 278 (11) [M + NH_4 − Pd − 2HI]$^+$, 512 (3) [M + NH_4 − HI]$^+$, 640 (100) [M + NH_4]$^+$. − $C_{13}H_{22}I_2N_6Pd$ (622.59): calcd C 25.08, H 3.56, N 13.50; found C 24.67, H 3.44, N 13.54.

Preparation of [PdI_2(mbodty)] (2c): The general procedure for mononuclear complexes was followed. Reaction time was 4 h. The pure product was obtained as an orange solid after recrystallization from diethyl ether and washing with cold diethyl ether. Yield: 100%; m.p. 304−306°C (decomposition). − ^{1}H NMR: δ = 0.84 (t, *J* = 6.6 Hz, 6 H, CH_3), 1.12−1.34 [m, 20 H, $NCH_2CH_2(CH_2)_5CH_3$], 1.70−1.92 [m, 4 H, $NCH_2CH_2(CH_2)_5CH_3$], 4.18 [dt, *J* = 13.6 Hz, *J* = 7.1 Hz, 2 H, one H from each $NCH_2CH_2(CH_2)_5CH_3$], 4.78 [dt, *J* = 13.6 Hz, *J* = 7.1 Hz, 2 H, one H from each $NCH_2CH_2(CH_2)_5CH_3$], 6.53 and 6.95 (AB system, *J* = 14.0 Hz, 2 H, NCH_2N), 8.90 (s, 2 H, H3). − ^{13}C{^{1}H} NMR: δ = 13.9 (CH_3), 22.0, 25.6, 28.4, 28.5, 29.9, 31.2 [$NCH_2(CH_2)_6CH_3$], 49.2 [$NCH_2(CH_2)_6CH_3$], 66.7 (NCH_2N), 144.8 (C3), 166.3 (C5). − MS (FAB$^+$); *m*/*z* (%): 607 (100) [M + 1 − HI]$^+$, 735 (15) [M + 1]$^+$, 981 (59) [2M − Pd − 3I]$^+$, 1342 (93) [2M + 2 − HI]$^+$, 1470 (18) [2M + 2]$^+$. − MS (CI, NH_3); *m*/*z* (%): 607 (2) [M + 1 − HI]$^+$, 626 (3) [M + 2 + NH_4 − HI]$^+$, 734 (2) [M]$^+$, 752 (100) [M + NH_4]$^+$. − $C_{21}H_{38}I_2N_6Pd$ (734.80): calcd C 34.33, H 5.21, N 11.44; found C 33.97, H 5.37, N 11.74.

Preparation of [Pd(OAc)(mbmdty)]I (3): The general procedure for mononuclear complexes was followed. Reaction time was 48 h. The crude mixture was extracted with dichloromethane and was filtered, the solvent was evaporated under vacuum and an oil was obtained. The product was isolated as a brown solid after washing with cold chloroform and crystallized together with one molecule of palladium(II) iodide. Yield: 45%; m.p. 309−311°C. − IR: $\tilde{\nu}$ = 1408 cm^{-1} (ν_s CO_2^-), 1540 cm^{-1} (ν_a CO_2^-). − ^{1}H NMR: δ = 1.87 (s, 3 H, CH_3COO), 3.89 (s, 6 H, NCH_3), 6.94 and 7.56 (AB system, *J* = 14.6 Hz, 2 H, NCH_2N), 8.95 (s, 2 H, H3). − ^{13}C{^{1}H} NMR:

δ = 23.6 (CH_3COO), 35.8 (NCH_3), 65.0 (NCH_2N), 147.0 (C3), 152.0 (C5), 181.7 (CH_3COO). − MS (FAB^+); *m/z* (%): 343 (18) [M − I]$^+$, 411 (5) [M − OAc]$^+$. − MS (CI, CH_4); *m/z* (%): 343 (5) [M − I]$^+$, 411 (10) [M − OAc]$^+$. − MS (Electrospray); *m/z* (%): 284 (17) [M − I − OAc]$^+$, 343 (100) [M − I]$^+$, 411 (66) [M − OAc]$^+$. − $C_9H_{13}IN_6O_2Pd{\cdot}PdI_2$ (470.57): calcd C 13.01, H 1.58, N 10.12; found C 13.31, H 1.43, N 10.19.

General Procedure for the Preparation of Binuclear Complexes (4a−c): A THF (15 mL) solution of the mononuclear complex (**2a−c**) (0.20 mmol) was stirred and heated at 160°C in a 50 mL Fisher−Porter bottle for between 24 and 72 h. After cooling, the solution was filtered and solvent was evaporated under vacuum to give an oil. Pure products were isolated as indicated in each case.

Preparation of $[PdI_2(\mu\text{-mbidty})]_2$ (4a): The general procedure for binuclear complexes was followed. The reaction time was 24 h. The crude material was extracted with dichloromethane, filtered, the solvent was evaporated under vacuum and an oil was obtained. The pure product was isolated as a yellow solid after washing with diethyl ether. Yield: 90%; m.p. 321−323°C (decomposition). − ^{1}H NMR: δ = 1.55 (d, *J* = 6.8 Hz, 24 H, CH_3), 5.31 (sep, *J* = 6.8 Hz, 4 H, NC*H*Me_2), 6.60−7.60 (br s, 4 H, NCH_2N), 9.26 (s, 4 H, H3). − ^{13}C{^{1}H} NMR: δ = 25.1 (CH_3), 52.6 (*C*HMe_2), 67.0 (NCH_2N), 143.5 (C3), 172.0 (C5). − MS (FAB^+); *m/z* (%): 809 (25) [M + 1−3I]$^+$, 935 (24) [M-2I]$^+$, 1063 (68) [M + 1−I]$^+$, 1191 (10) [M + 2]$^+$. − MS (CI, NH_3); *m/z* (%): 706 (100) [M + 4 − Pd − 3I]$^+$, 1063 (28) [M + 1 − I]$^+$. − $C_{22}H_{36}I_4N_{12}Pd_2$ (1189.06): calcd C 22.22, H 3.05, N 14.14; found C 22.52, H 3.38, N 14.03.

Preparation of $[PdI_2(\mu\text{-mbbdty})]_2$ (4b): The general procedure for binuclear complexes was followed. The reaction was complete after 24 h. The pure product was isolated as a yellow solid after washing with cold dichloromethane. Yield: 100%; m.p. 302−304°C (decomposition). − ^{1}H NMR: δ = 0.91 (t, *J* = 7.2 Hz, 12 H, CH_3), 1.30 (sxt, *J* = 7.4 Hz, 8 H, $NCH_2CH_2CH_2CH_3$), 2.02 (qui, *J* = 7.4 Hz, 8 H, $NCH_2CH_2CH_2CH_3$), 4.40−4.60 (br s, 8 H, $NCH_2CH_2CH_2CH_3$), 6.80−7.80 (br s, 4 H, NCH_2N), 9.03 (s, 4 H, H3). − ^{13}C{^{1}H} NMR: δ = 13.3 (CH_3), 19.0 ($NCH_2CH_2CH_2CH_3$), 31.1 ($NCH_2CH_2CH_2CH_3$), 48.8 ($NCH_2CH_2CH_2CH_3$), 67.2 (NCH_2N), 145.7 (C3), 171.3 (C5). − MS (FAB^+); *m/z* (%): 367 (13) [(M/2) − 1 − 2I]$^+$, 867 (11) [M + 3 − 3I]$^+$, 992 (18) [M + 1 − 2I]$^+$, 1119 (100) [M + 1 − I]$^+$. − MS (CI, NH_3); *m/z* (%): 1119 (100) [M + 1 − I]$^+$, 1264 (4) [M + 1 + NH_4]$^+$. − $C_{26}H_{44}I_4N_{12}Pd_2$ (1245.17): calcd C 25.08, H 3.56, N 13.50; found C 25.43, H 3.42, N 13.30.

Preparation of $[PdI_2(\mu\text{-mbodty})]_2$ (4c): The general procedure for binuclear complexes was followed. Reaction time was 72 h. The crude material was extracted with dichloromethane, the solvent was evaporated under vacuum and an oil was obtained. The pure product was isolated as a yellow solid after crystallization from cold diethyl ether. Yield: 90%; m.p. 268−270°C. − ^{1}H NMR: δ = 0.83 (t, *J* = 6.3 Hz, 12 H, CH_3), 1.10−1.30 [m, 40 H, $NCH_2CH_2(CH_2)_5CH_3$], 1.90−2.10 [br s, 8 H, NCH_2CH_2-$(CH_2)_5CH_3$], 4.30−4.50 [br s, 8 H, $NCH_2CH_2(CH_2)_5CH_3$], 6.80−7.80 (br s, 4 H, NCH_2N), 9.02 (s, 4 H, H3). − ^{13}C{^{1}H} NMR: δ = 13.9 (CH_3), 22.0, 26.0, 28.6, 29.3, 31.2 [$NCH_2(CH_2)_6CH_3$], 49.1 [$NCH_2(CH_2)_6CH_3$], 67.3 (NCH_2N), 145.8 (C3), 171.5 (C5). − MS (FAB^+); *m/z* (%): 477 (73) [(M/2)-3−2I]$^+$, 981 (20) [M − 1 − Pd − 3I]$^+$, 1089 (29) [M + 1 − 3I]$^+$, 1215 (8) [M − 2I]$^+$, 1343 (100) [M + 1 − I]$^+$, 1469 (6) [M]$^+$. − MS (CI, CH_4); *m/z* (%): 608 (100) [(M/2) − I]$^+$, 735 (16) [(M/2) + 1]$^+$, 1344 (7) [M + 2 − I]$^+$, 1470 (1) [M + 1]$^+$. − $C_{42}H_{76}I_4N_{12}Pd_2$ (1469.60): calcd C 34.33, H 5.21, N 11.44; found C 34.20, H 5.61, N 11.69.

X-ray Crystal Structure Determination for 2a: $C_{15}H_{26}I_2N_6OPd$, M = 666.62, orthorhombic, Pnma, *a* = 14.347(2) Å, *b* = 13.029(1) Å, *c* = 11.482(2) Å, *V* = 2146.3(5) Å^3, *Z* = 4, ρ_c 2.063 Mg m^{-3}, *F(000)* = 1272, λ = 0.71073 Å, T = 173(2) K, μ (Mo Kα) = 3.757 mm^{-1}, crystal size 0.7 × 0.6 × 0.5 mm, 2.84° < &*Theta;* < 24.28°, 16230 reflections (1778 independent, R_{int} = 0.0394) were collected at low temperatures using an oil-coated shock-cooled crystal[14] on a STOE-IPDS diffractometer. A numerical absorption correction was employed and the min./max. transmissions are 0.4539 and 0.5424. The structure was solved by direct methods (SHELXS-97)[15] and 144 parameters using 13 restraints were refined using the least-squares method on F^2.[16] Largest electron density residue: 0.558 e Å^{-3}, R_1 [for $F>2\sigma(F)$] = 0.025 and wR_2 = 0.060 (all data) with $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$. A mirror plane leads to the disorder of a noncoordinated molecule of THF, which is refined anisotropically by ignoring the symmetry (PART-1) using ADP and distance restraints.

X-ray Crystal Structure Determination for 4c: $C_{49}H_{80}I_4N_{12}Pd_2$, M = 1557.65, monoclinic, I2/a, *a* = 17.410(3) Å, *b* = 18.417(3) Å, *c* = 38.870(9) Å, β = 93.74(2)°, *V* = 12437(4) Å^3, *Z* = 8, ρ_c = 1.664 Mg m^{-3}, *F(000)* = 6096, λ = 0.71073 Å, T = 173(2) K, μ(Mo-K_α) = 2.604 mm^{-1}, crystal size 0.2 × 0.2 × 0.02 mm, 1.88° < θ < 21.26°, 50565 reflections (6913 independent, R_{int} = 0.2406) were collected at low temperatures using an oil-coated shock-cooled crystal[14] on a STOE-IPDS diffractometer. The structure was solved by direct methods (SHELXS-97)[15] and 607 parameters using 640 restraints were refined using the least-squares method on F^2.[16] Largest electron density residue: 2.142 e Å^{-3}, R_1 [for $F>2\sigma(F)$] = 0.101 and wR_2 = 0.285 (all data) with $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{0.5}$. The high freedom of movement of the octyl substituents combined with the poor quality and small size of the crystals led to some problems with the refinement of **4c**. An absorption correction was not possible. The heart of the molecule is very clear and easy to refine, but it is very difficult to localize the positions of the carbon atoms of the chains. For this reason the values of *R*, R_1 and wR_2 are poor.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-117654 (**2a**) and CCDC-117655 (**4c**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

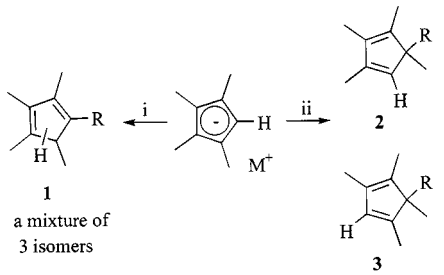
A Novel Route to the 5-[2-(Diphenylphosphanyl)ethyl]-1,2,3,4-tetramethylcyclopentadienyl Ligand – Synthesis and Crystal Structure of $[\eta^5:\eta^1\text{-}C_5(CH_3)_4CH_2CH_2PPh_2]ZrCl_3\cdot THF$

Dmitrii P. Krut'ko,*[a] Maxim V. Borzov,[a] Eduard N. Veksler,[a] Roman S. Kirsanov,[a] and Andrei V. Churakov[b]



Keywords: Phosphanylethyl-functionalized cyclopentadienyl ligands / Intramolecular coordination / Spiro compounds / Zirconium

The five-step synthesis of the first transition metal complex with the $C_5(CH_3)_4CH_2CH_2PPh_2$ ligand $[\eta^5:\eta^1\text{-}C_5(CH_3)_4CH_2CH_2PPh_2]ZrCl_3\cdot THF$ (**11**), starting from the known compound [2-(dimethylamino)ethyl]tetramethylcyclopentadiene (**4**) via 4,5,6,7-tetramethylspiro[2,4]hepta-4,6-diene (**7**), is reported. Lithium cyclopentadienide $LiC_5(CH_3)_4CH_2CH_2PPh_2$ (**9**), silylated cyclopentadiene $(CH_3)_3SiC_5(CH_3)_4CH_2CH_2PPh_2$ (**10**) and cyclopentadiene $HC_5(CH_3)_4CH_2CH_2PPh_2$ (**12**) were isolated and characterised as pure substances. The crystal structure of the zirconium complex **11** was established by X-ray diffraction analysis.

Introduction

Despite the attractiveness of [2-(diorganophosphanyl)ethyl]tetramethylcyclopentadienes as novel prospective ligands for organometallic synthesis, these side-chain-functionalized cyclopentadienes are relatively unavailable and complexes derived from them are still unknown. Direct alkylation of 1,2,3,4-tetramethylcyclopentadienides with alkyl halides or alkyl toluenesulfonates seems to be of little use in the preparation of 5-alkyl-1,2,3,4-tetramethylcyclopentadienes (**1**), and the question of the regioselectivity of this reaction remains unclear. Both the products of 5-alkylation (**1**)[1][2] and those of 1- and 2-alkylation (**2** and **3**, *gem*-dialkyl-subsituted cyclopentadienes)[3][4] were reported to dominate in the resultant mixtures of alkyltetramethylcyclopentadienes (see Scheme 1).

Nowadays, the synthesis of cyclopentadienes **1** is usually performed by treating 2,3,4,5-tetramethylcyclopenten-2-one with various Grignard or organolithium reagents, followed by dehydration.[5] Unfortunately, this approach is not applicable for the 2-heteroatom-functionalized ethyltetramethylcyclopentadienes **1** ($R = CH_2CH_2ER'_n$; $ER'_n = OR'$, SR', PR'_2, NR'_2, etc.) due to the known instability of 2-heteroatom-functionalized alkylmagnesium or lithium compounds.[6] To overcome this difficulty, preparation procedures for $HC_5(CH_3)_4CH_2CH_2ER'_n$ involving double *sec*-butenylation of esters of 2-heteroatom-substituted propanoic acids $R''O(O)CCH_2CH_2ER'_n$ [$ER'_n = OCH_3$,[3][7] $N(CH_3)_2$,[3] SCH_3[8]], followed by dehydration and cyclization, were developed and shown to give good results. However, synthesis of tetramethyl(2-phosphanylethyl)cyclopentadienes by this latter method has not been reported.

route i dominates:

R-X = $ClCH_2CH_2$-OTs, $M^+ = Li^+$, THF, -10 - 0 °C (ref.[1])

R-X = $ClCH_2CH_2$-Br, $M^+ = K^+$, ether, r.t. (ref.[2])

route ii dominates:

R-X = $ClCH_2CH_2$-OTs, $M^+ = Li^+$, THF, -10 - 0 °C (refs.[3][4])

R-X = $(CH_3)_2NCH_2CH_2$-Cl, $M^+ = K^+$, THF, reflux (ref.[3])

Scheme 1. Direct alkylation of the tetramethylcyclopentadienide

Fortunately, the known cyclopropane ring cleavage reaction of spiro[2,4]hepta-4,6-diene with lithium dialkyl- or diarylphosphides[9] was recently shown for the novel 4,5,6,7-tetramethylspiro[2,4]hepta-4,6-diene (**7**),[2][4] and provided a straightforward route to $LiC_5(CH_3)_4CH_2CH_2PR_2$ (R = alkyl, aryl). In this way, the spiroheptadiene **7** could be, in principle, considered as a key compound in the synthesis of a variety of transition metal complexes derived from tetramethyl(2-phosphanylethyl)cyclopentadienes. However, the availability of the spirane **7** seemed to be rather doubtful. In this paper a convenient preparation procedure for **7**, and synthesis of the first example of a transition metal complex derived from the $C_5(CH_3)_4CH_2CH_2PPh_2$ ligand, are presented.

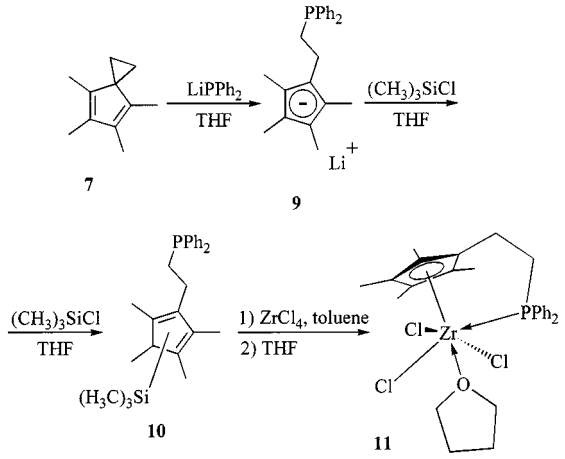
Results and Discussion

The Synthesis of Tetramethylspiroheptadiene 7

5-[2-(Dimethylamino)ethyl]-1,2,3,4-tetramethylcyclopentadiene (**4**) is a well-known and widely used ligand in organometallic chemistry.[10] However, it can also serve as a convenient synthetic precursor of the tetramethylspiroheptadiene **7**. Thus, quaternation of the amine **4** with iodomethane, followed by treatment of the ammonium salt **5** with *n*-butyllithium, leads to the spirane **7** in a good overall yield (see Scheme 2). The isolated product **7** is obtained as an orange/pale yellow liquid (m.p. −7°C). The coloration of **7** is caused by small amounts (ca. 1%) of 1,2,3,4,6-pentamethylfulvene (**8**),[11] which are detectable by ^{1}H-NMR spectroscopy. Probably, the fulvene **8** is formed from the traces of tetramethyl(vinyl)cyclopentadiene which can be expected in the reaction mixture as the "normal" product of a destruction of the quaternary ammonium salt **5** with strong bases.

Scheme 2. Synthesis of the tetramethylspiroheptadiene **7**

The quaternary ammonium salt **5** was isolated as a white crystalline powder with > 95% purity (NMR-spectroscopy data). The dominant identifiable impurity is CH_2=$CHC(O)C(CH_3)$=$CH(CH_3)$. Supposedly, this admixture is formed from $(H_3C)_2NCH_2CH_2C(O)C(CH_3)$=$CH(CH_3)$ which is a typical pollutant of the starting aminoethylcyclopentadiene **4**. It is worth mentioning here that in contrast to the majority of quaternary ammonium iodides, the compound **5** is rather sensitive to air, especially when in a solution, and prolonged operations with it should be carried out either in a dry oxygen-free inert atmosphere or in vacuo.

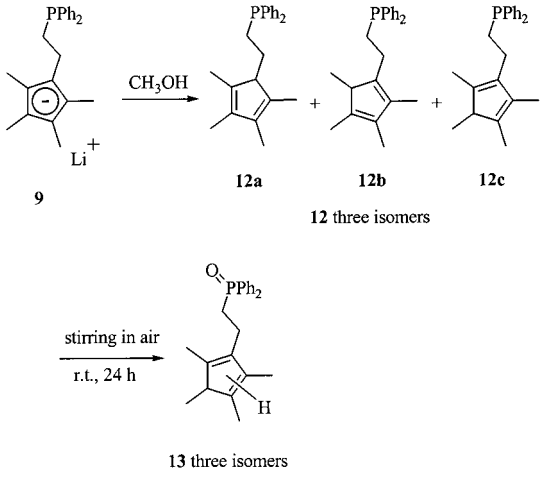


In general, ammonium salts are not typical synthetic precursors of cyclopropanes. In instances where examples of such quaternary salts producing cyclopropanes on treatement with strong bases are known,[12] there are hydrogen atoms at the γ-position to the ammonium group, which possess distinct C−H acidity. Following on from such work,[12] the formation of spiroheptadiene **7** from **5** might be supposed to proceed in at least two steps: deprotonation of cyclopentadiene **5** and the subsequent elimination of $N(CH_3)_3$ (see Scheme 2). In fact in practice, on adding *n*BuLi to a suspension of **5** in THF at −50°C and gradual warming the mixture up to −20°C, the consistency of the initial slurry changes and the precipitate becomes more voluminous. Vigorous evolution of $N(CH_3)_3$ begins only at temperatures exceeding 40−50°C, and to complete the reaction, which is indicated by the dissappearance of the solid phase and no further evolution of $N(CH_3)_3$, it is necessary to heat the reaction mixture under reflux for at least 30 min.

To clarify the reaction pathway, the stepwise conversion of the salt **5** into the spiroheptadiene **7** was attempted. It was found that the reaction of the ammonium salt **5** with *n*BuLi leads first to a solid product **6**, a snow-white powder which is extremely sensitive to air and moisture. Characterisation of the intermediate **6** by means of NMR spectroscopy proved impossible. When attempting to record the ^{1}H-NMR spectrum only signals attributable to the spirane **7** and $N(CH_3)_3$ [NMR (30°C, [D$_8$]THF): δ_H = 2.11 (s), δ_C = 47.94 (s), molar ratio 1:1] were observed; indicative of the thermal instability of **6** in the solvating medium. Moreover, compound **6** is thermally unstable, not only in the presence of THF, but also when dry, and decomposes at a detectable rate when stored at −18°C (evacuated vessel). Thermolysis of dry **6** in vacuo (1.3×10^{-3} mbar) leads to the spirane **7**, $N(CH_3)_3$ (both trapped at −196°C) and LiI (residue) in a molar ratio 1:1:1. Despite the difficulties of characterising **6** by the usual techniques, the authors believe, however, that this deprotonation product possesses the structure suggested in Scheme 2.

Preparation of $LiC_5(CH_3)_4CH_2CH_2PPh_2$ (9) and $[\eta^5{:}\eta^1\text{-}C_5(CH_3)_4CH_2CH_2PPh_2]ZrCl_3\cdot THF$ (11)

The complete synthesis of $[\eta^5{:}\eta^1\text{-}C_5(CH_3)_4CH_2CH_2PPh_2]ZrCl_3\cdot$THF (**11**) is presented in Scheme 3. The three-membered ring cleavage reaction for the spirane **7** with $LiPPh_2$ was performed as described previously,[4] but the excess of $LiPPh_2$ employed was decreased. In comparison with the considerably exothermic reaction of spiro[2,4]heptadiene-4,6 with $LiPPh_2$, which proceeds vigorously even at 10−15°C, in the case of **7** heating at 80−100°C for at least 8 h was required. It is suggested that this is a result of a lower thermodynamic preference for the formation of the pentaalkylcyclopentadienide anion compared to that of the monoalkylcyclopentadienide anion. The elevated temperature required also complicates the reaction due to the process of THF ring cleavage with phosphides,[13] and makes it necessary to apply a considerable excess of $LiPPh_2$.



In its pure state the lithium salt **9** is a white crystalline powder, which is extremely sensitive to air and moisture. It is moderately soluble in THF at room or lower temperature. However, the solubility of **9** grows rapidly within the range 80−100°C (sealed vessel), and on cooling a stable supersaturated solution is formed. Previously, we observed that in contrast to the practically insoluble $LiC_5(CH_3)_5$ or $LiC_5(CH_3)_4H$, lithium cyclopentadienides $LiC_5(CH_3)_4CH_2CH_2ECH_3$ (E = O[7], S[8]) and $LiC_5H_4CH_2CH_2PPh_2$,[14]

Scheme 3. Synthesis of the halfsandwich complex **11**

with *n*-donor heteroatom functionalities in side chains, exhibit very good solublities in THF. Thus, from this viewpoint, the cyclopentadienide **9** presents an intermediate case. In the ^{1}H-, ^{13}C{^{1}H}- and ^{31}P{^{1}H}-NMR spectra of **9** ([D$_8$]THF, 30°C) the signals are broadened, probably due to the inter- and/or intramolecular processes of coordination of Li^+ to PPh_2 groups. At the same time no signals due to [H$_8$]THF are present and, thus, one can conclude that the lithium salt **9** contains no solvated THF in the solid state. Taking all these facts into account, it is supposed that in the solid state **9** possesses a "multidecker polymer" structure, which is characteristic for C_5H_5Li,[15] while in a THF solution the cyclopentadienide **9** exists as mono-, or at least oligomeric, species with PPh_2 groups coordinated to Li^+.

As mentioned above, the preparation of $HC_5(CH_3)_4CH_2CH_2PPh_2$ (**12**) was reported previously by other workers.[1] In order to compare the present results with those given in this previous work dry cyclopentadienide **9** was quenched with methanol and the ligand of interest isolated in its C−H form, **12**, as a viscous pale yellow oil sensitive to air (see Scheme 4).

Scheme 4. Preparation and oxidation of the [2-diphenylphosphanyl)-ethylcyclopentadiene **12**

The assignment of the signals in the NMR spectra was performed on the basis of homo- and heteronuclear correlation spectroscopy experiments and coupled ^{13}C spectra. The assignment of the signals to each of the isomers was additionally confirmed by homonuclear NOE experiments (difference spectra), with the relative intensities of the signals also taken into account. As was expected, it was found that **12** is a mixture of three (not two, as reported in ref.[1]) isomers, **12a−c**, in a molar ratio of 1:1.4:1.7, which is close to that observed previously for the three analogous isomers of $HC_5(CH_3)_4CH_2CH_2SCH_3$ (molar ratio ca. 3:4:5).[8] It must be noted here that, in general, the ^{1}H-, ^{31}P{^{1}H}-, and especially ^{13}C{^{1}H}-NMR data for **12** in C_6D_6 solution presented in this work are in poor agreement with that reported by J. Szymoniak et al. for **12** in the same solvent.[1]

When a pentane solution of **12** is exposed to air, the precipitation of the corresponding phosphane oxides, **13a−c** (white amorphous powder), begins after several minutes. However, to complete the oxidation it is neccesary to stir the pentane solution for at least 24 h in air {NMR-spectroscopy monitoring of the reaction mixture; δ_P = 30.0 [s, (**13b**)], 30.1 [s, (**13c**)], 31.7 [s, (**13a**)]}.

In the ^{1}H- and ^{13}C-NMR spectra the isomers **12a−c**, **5a−c**[16] and the previously reported $HC_5(CH_3)_4CH_2CH_2SCH_3$[8] exhibit some significant common features which are worth mentioning here. In both these cases the side-chain protons H^6 and H^7 in the symmetric **a** isomers are markedly shielded (up to 0.5−0.6 ppm) with respect to the same protons in the **b** and **c** isomers. A similar high-field shift (up to 4−8 ppm) is also observed for the signals of C^7 in the **a** isomers. In contrast, the C^6 carbon atoms in the **a** isomers are deshielded (up to ca. 2 ppm) relative to the C^6 carbon atoms in the **b** and **c** isomers. These particularities of the ^{1}H- and ^{13}C{^{1}H}-NMR spectra also seem to be characteristic of a broad variety of 2-heteroatom-functionalized ethyltetramethylcyclopentadienes $HC_5(CH_3)_4CH_2CH_2X$ (X = O, S, N, P heteroatom functionality).

Lithium pentaalkylcyclopentadienides are the most usual and widely used direct precursors of the corresponding cyclpentadienyltrihalozirconium compounds. Undoubtedly, if treated with $ZrCl_4$ in either ether or toluene, the lithium salt **9** would give the desired half-sandwich **11**. However, in this work it was preferred to introduce an additional step and prepare the complex **11** via the intermediate trimethylsilyl-substituted cyclopentadiene **10**.

Cyclopentadienyltrimethylsilanes can be considered as one of the most convenient precursors of the monocyclopentadienyl trihalides of the Group IV metals $C_5H_5MCl_3$ (M = Ti, Zr and Hf).[17] Not long ago this method proved to be useful in the preparation of their ring-permethylated analogues, $C_5(CH_3)_5MCl_3$ (M = Ti, Zr and Hf).[18] In comparison with the route via lithium cyclopentadienides, application of silylated cyclopentadienes affords a number of advantages arising from the fact that the presence of LiCl as a co-product is initially excluded. It is known that LiCl can interact with the target half-sandwiches and form stable ionic products.[19] This complicates the isolation procedure,

and in some cases high-vacuum sublimation is necessary for the final purification of a metal complex.[7,8,20]

Treatment of **9** with $(CH_3)_3SiCl$ in THF followed by removal of the solvent and high-vacuum distillation gives the silane **10** as an air-sensitive pale yellow viscous oil, in an almost quantitative yield. It is an interesting fact that in contrast to the reaction between $(CH_3)_3SnCl$ and $C_5(CH_3)_5Li$ silylation of **9** does not proceed in ether, even at elevated temperatures (80−90°C, 7 h), and the initial cyclopentadienide **9** can be regenerated quantitatively. As expected, the broadened exchange signals in the ^1H- and $^{31}P\{^1H\}$-NMR spectra of **10** indicate that it exists as an equilibrium mixture of three isomers [isomeric with respect to the position of the $(CH_3)_3Si$ group].

The zirconium complex **11** was obtained in a similar fashion to its ring nonmethylated analogue [η^5:η^1-$C_5H_4CH_2CH_2PPh_2$]$ZrCl_3$·THF (**14**),[14] and isolated as an adduct with one molecule of THF (well-formed pale yellow crystals moderately sensitive to air and moisture). The half-sandwich compound **11** was characterised by elemental analysis, mass spectrometry, ^1H-, $^{13}C\{^1H\}$- and $^{31}P\{^1H\}$-NMR spectroscopy and X-ray diffraction analysis (see below). In the NMR spectra, apart from the evident changes caused by replacement of CH_3 groups for hydrogen atoms, the parameters of **11** and **14** are rather similar. The ^{31}P shift of the PPh_2 group in CD_2Cl_2 for the compound **11** (δ_P = 5.8) indicates that in a solution this group remains coordinated to the metal centre [compare with δ_P = 6.1 for **14** (in CD_2Cl_2)[14] and $\delta_P \approx -14$ for non-coordinated PPh_2 groups of (η^5-$C_5H_4CH_2CH_2PPh_2$)(η^5-C_5H_5)$ZrCl_2$[14] and compounds **9**, **10** and **12**].[21]

It is also notable that intramolecular coordination of the PPh_2 group to the Zr centre inverts the order of the absolute $^1J_{C-P}$ and $^2J_{C-P}$ values in the $Ph_2PCH_2CH_2$ fragment. Thus, both for **11** and **14** direct $|^1J_{C-P}|$ exceeds geminal $|^2J_{C-P}|$, while for all other previously studied compounds possessing the non-coordinated $Ph_2PCH_2CH_2$ moiety $|^1J_{C-P}| < |^2J_{C-P}|$.[14]

X-ray Crystal Structure Analysis of the Complex 11

The crystal structure of **11** is shown in Figure 1. The central Zr atom possesses a distorted octahedral coordination, if one assumes that the cyclopentadienyl ligand occupies one coordination site. The cyclopentadienyl ring and the THF molecule lie in the apical positions while the phosphanyl group and three chlorine atoms occupy equatorial positions. The deviation of the Zr atom from the equatorial plane towards the cyclopentadienyl ligand is 0.53 Å. Analysis of the Cambridge Structural Database (Release: April 1998)[22] shows that the Zr−Cl distances [2.4619(10)−2.4921(8) Å] in **11** are within the range of normal values for terminal Zr^{IV}−Cl bonds in monocyclopentadienyl complexes (2.385−2.561 Å). The Zr−P bond [2.8906(11) Å] is significantly longer than was found for both crystalline modifications of the closely related complex **14** [2.8474(5)−2.8729(11) Å].[14] The latter fact can be explained by the influence of the electron-donating effect of four methyl groups at the cyclopentadienyl ring. The Zr−O(THF) bond [2.419(2) Å] in the structure of **11** is also much longer than was observed for the same apical bonds in $(C_5H_4R)ZrCl_3$·2THF [R = H, 2.393(3) Å; R = Me, 2.377(2) Å],[23] and in both modifications of **14** [2.350(3)−2.3613(12) Å].[14]

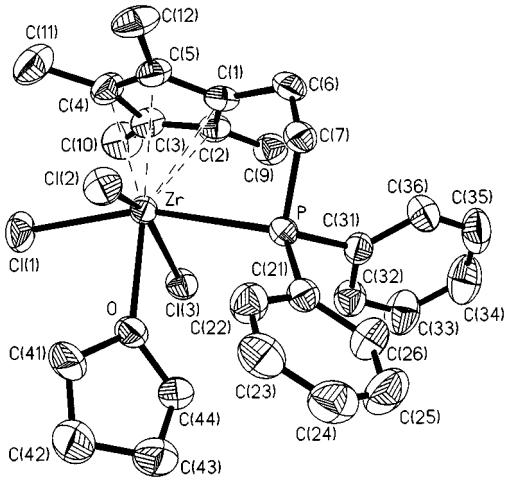


Figure 1. Molecular structure of complex **11**; displacement ellipsoids are shown at 50% probability level; hydrogen atoms are omitted for clarity; selected bond lengths [Å] and angles [°]: Zr−O 2.419(2), Zr−Cl(1) 2.4619(10), Zr−Cl(2) 2.4647(9), Zr−Cl(3) 2.4921(8), Zr−P 2.8906(11), Zr−PL, 2.256(1), P−C(31) 1.828(3), P−C(7) 1.829(3), P−C(21) 1.835(3); O−Zr−Cl(1) 81.72(5), O−Zr−Cl(2) 76.64(5), O−Zr−Cl(3) 76.76(5), Cl(1)−Zr−Cl(2) 89.69(3), Cl(1)−Zr−Cl(3) 90.06(3), Cl(2)−Zr−Cl(3) 153.15(3), O−Zr−P 77.30(5), Cl(1)−Zr−P 158.55(3), Cl(2)−Zr−P 81.23(3), Cl(3)−Zr−P 89.45(3), C(31)−P−C(7) 104.62(14), C(31)−P−C(21) 102.52(12), C(7)−P−C(21) 104.29(13), C(7)−P−Zr 98.59(11), C(21)−P−Zr 123.59(9), C(31)−P−Zr 120.43(9), C(1)−C(6)−C(7) 113.6(2), C(6)−C(7)−P 108.9(2); PL means the least-squares plane of the cyclopentadienyl ring

The cyclopentadienyl ring C(1) through C(5) is planar to within 0.009 Å. All four methyl substituents deviate slightly from the least-squares plane of the ring in the direction opposite to the Zr atom (0.111−0.241 Å). The maximum deviation was found for C(12), which is probably caused by the short intramolecular contact with the Cl(2) atom (3.116 Å).

The coordination environment of the phosphorus atom represents a distorted tetrahedron with approximately equal C−P−C angles [102.52(12)−104.62(14)°]. However, the exocyclic C(Ph)−P−Zr angles [120.43(9)° and 123.59(9)°] are much larger than the endocyclic C(7)−P−Zr angle [98.59(11)°]. Thus, the (Zr−)C(1)−C(6)−C(7)−P−Zr pseudo-metallacycle is significantly strained.

Conclusion

It is evident, that the zirconium half-sandwich **11** may be considered as only the first "model" example of a transition metal complex derived from tetramethyl(2-phosphanylethyl)cyclopentadienyl ligands. Moreover, the authors are convinced that the availability of the key tetramethylspiroheptadiene **7** by the method reported herein opens a facile pathway to a broad variety of transition metal complexes,

not only with the $C_5(CH_3)_4CH_2CH_2PR_2$ ligands but also, probably, with their 2-arsanylethyl analogues.

Experimental Section

General Remarks: All procedures were performed using either conventional glassware in dry oxygen-free argon or in sealed evacuated glass vessels. The solvents employed (and their perdeuterated analogues) were dried with, and distilled from, conventional agents {namely: diethyl ether and THF (sodium benzophenone ketyl); toluene, heptane and pentane (Na/K alloy); CH_2Cl_2 (P_2O_5 and then CaH_2); acetonitrile (a minimal amount of P_2O_5)]; CD_3CN [stirred with and distilled from CaH_2 via a high-vacuum line (1.3×10^{-3} mbar) at 0−10°C]}. When performing procedures in evacuated vessels, the degassed solvents were stored in evacuated reservoirs over the corresponding drying agent, and then transferred via a high-vacuum line directly into reaction vessels by trapping with liq. N_2. Iodomethane (Fluka) was distilled from CaH_2; chlorotrimethylsilane (Fluka) was refluxed with and distilled from aluminium powder (high-vacuum line); diphenylphosphane and zirconium tetrachloride (Fluka) were used without additional purification. $(CH_3)_2NCH_2CH_2C_5(CH_3)_5H$ (**4**) was prepared according to the modified procedure.[3] Thus, for the dehydration and cyclization of $[(CH_3)_2NCH_2CH_2]C(OH)[(CH_3)CH{=}CH(CH_3)]_2$ anhydrous TsOH and DME were used instead of $TsOH{\cdot}H_2O$ and diethyl ether. Lithium diphenylphosphide was obtained by the reaction of Ph_2PH with *n*-butyllithium in pentane, washed with the same solvent on a glass filter and dried in vacuo. − ^1H, ^{13}C, and $^{31}P\{^1H\}$ NMR: Varian VXR-400 spectrometer at 400, 100, and 162 MHz, respectively, internal reference standards CD_3CN (δ_H = 1.93 and δ_C = 1.3), $CDCl_3$(δ_H = 7.24 and δ_C = 77.0), C_6D_6 (δ_H = 7.15 and δ_C = 128.0), CD_2Cl_2 (δ_H = 5.32 and δ_C = 53.8), [D_8]THF (δ_H = 1.73 and δ_C = 25.3), external reference 85% H_3PO_4 ($^{31}P\{^1H\}$). − Elemental analyses: Carlo−Erba automated analyser. − Mass spectra: Kratos-MS-890 and Varian MAT CH7a Fa spectrometers.

Ammonium Salt 5: 25 mL (57.11 g, 402.4 mmol) of CH_3I was added dropwise, at a rate sufficient to maintain gentle reflux, to a stirred solution of cyclopentadiene **4** (38.90 g, 201.2 mmol) in 100 mL of CH_3CN. The reaction mixture was stirred under reflux for an additional 1 h and left overnight at room temp. The crystalline precipitate was filtered off, washed on a glass filter with an ice-cold mixture of CH_3CN/Et_2O (1:1, 2 × 20 mL) and with ether (3 × 20 mL) and dried in vacuo. The mother liquor and washings were combined, concentrated to ca. 50 mL and cooled to −18°C. The precipitated crystals were separated and washed as described above. The mother liquor and washings were worked up once more to give an additional portion of the product. The total amount of quaternary ammonium salt **5** was 47.30 g (70%). Decomposition at ca. 120°C without melting. − ^1H NMR (30°C, CD_3CN): δ = 0.98, 1.00 (each d, $^3J_{HH}$ = 7.6 Hz, $CHC\mathit{H}_3$), 1.69, 1.74, 1.75, 1.78, 1.80, 1.81, 1.86 (each br. s, CCH_3), 2.12 (m, $CHC\mathit{H}_2CH_2N$), 2.54 (m, $C\mathit{H}CH_3$, $CC\mathit{H}_2CH_2N$), 2.66 (m, $C\mathit{H}CH_3$, $CHCH_2C\mathit{H}_2N$), 2.80 (m, $C\mathit{H}CH_2CH_2N$, $CC\mathit{H}_2CH_2N$), 3.04, 3.17, 3.20 (each s, NCH_3), 3.25, 3.43 (each m, $CCH_2C\mathit{H}_2N$). − ^{13}C NMR (30°C, CD_3CN): δ = 10.96, 11.23, 11.56, 11.68, 11.81, 11.97 (each q, $^1J_{CH}$ = 125 Hz, $C\mathit{C}H_3$), 14.19, 14.34 (each q, $^1J_{CH}$ = 126 Hz, $CH\mathit{C}H_3$), 20.35, 20.79 (each t, $^1J_{CH}$ = 129 Hz, $C\mathit{C}H_2CH_2N$), 20.93 (t, $^1J_{CH}$ = 129 Hz, $CH\mathit{C}H_2CH_2N$), 50.17, 52.51 (each d, $^1J_{CH}$ = 123 Hz, $\mathit{C}HCH_3$), 53.51 (d, $^1J_{CH}$ = 123 Hz, $\mathit{C}HCH_2CH_2N$), 53.68 (br. q, $^1J_{CH}$ = 143 Hz, NCH_3), 62.84 (t, $^1J_{CH}$ = 144 Hz, $CHCH_2\mathit{C}H_2N$), 65.71, 66.20 (each t, $^1J_{CH}$ = 144 Hz, $CCH_2\mathit{C}H_2N$), 132.46, 132.96, 133.96, 134.69, 135.23, 138.10, 139.41, 140.02, 140.89, 143.55 (each s, $\mathit{C}CH_3$, $\mathit{C}CH_2CH_2N$). − EI MS (250°C, 70 eV); *m/z* (%): 149 (8) $[HC_5(CH_3)_4CH_2CH_2^+]$, 148 (55) $[HC_5(CH_3)_4CH{=}CH_2^+]$, 147 (8) $[C_7H_3(CH_3)_4^+]$, 142 (5) $[CH_3I^+]$, 134 (5) $[(CH_3)_4C_5{=}CH_2^+]$, 133 (100) $[C_7H_4(CH_3)_3^+]$, 128 (12) $[HI^+]$, 127 (10) $[I^+]$, 119 (21) $[C_7H_5(CH_3)_2^+]$, 105 (41) $[C_7H_6(CH_3)^+]$, 91 (42) $[C_7H_7^+]$, 59 (27) $[(CH_3)_3N^+]$, 58 (61) $[(CH_3)_2N{=}CH_2^+]$. − Compound **5** presents a material of > 95% purity (^1H-NMR data). The dominant admixture is $CH_2{=}CHC(O)C(CH_3){=}CH(CH_3)$. − ^1H NMR (30°C, CD_3CN): δ = 1.41 (dq, 3 H, $^3J_{HH}$ = 6.8 Hz, $^4J_{HH}$ = 1.6 Hz, $=CHC\mathit{H}_3$), 1.77 [quint, 3 H, $^4J_{HH}$ = $^5J_{HH}$ = 1.6 Hz, $=C(CH_3)-$], 5.21 (dd, 1 H, $^2J_{HH}$ = 1.6 Hz, $^3J_{HH}$ = 11.0 Hz, *cis*-$CH_2{=}$), 5.35 (dd, 1 H, $^2J_{HH}$ = 1.6 Hz, $^3J_{HH}$ = 17.1 Hz, *trans*-$CH_2{=}$), 5.43 (qq, 1 H, $^3J_{HH}$ = 6.8 Hz, $^4J_{HH}$ = 1.6 Hz, $=C\mathit{H}CH_3$), 6.87 (dd, 1 H, $^3J_{HH}$ = 17.1 Hz, $^3J_{HH}$ = 11.0 Hz, $C\mathit{H}{=}CH_2$).

4,5,6,7-Tetramethylspiro[2,4]hepta-4,6-diene (7): 57 mL of a 2.16 M hexane solution of *n*-butyllithium (124.0 mmol) was added to a stirred suspension of the ammonium salt **5** (41.53 g, 123.9 mmol) in 250 mL of THF at −60°C. The reaction mixture was allowed to warm gradually to room temp. under continued stirring. Scarlet coloration of the solution appeared and deepened while the white precipitate became more voluminous (ca. −20°C). The mixture was then heated for 30 min under reflux. Vigorous evolution of $N(CH_3)_3$ began at 40−50°C. The colour of the solution changed slowly from dark scarlet to pale orange and the precipitate dissolved. The resultant solution was cooled down to 0°C and poured into an approximately equal volume of ice-cold water. The organic layer was separated, the aqueous layer extracted with Et_2O (3 × 50 mL) and the combined extracts dried with $MgSO_4$. On removing the solvents in a rotary evaporator the product was isolated by distillation as a yellow oil moderately sensitive to air, b.p. 47−48°C at 1.5 mbar. M.p. −7°C. Yield 15.57 g (85%). Compound **7** exhibited a pronounced tendency to undergo polymerisation and was stored at −18°C. − ^1H NMR (30°C, $CDCl_3$): δ = 1.23 (s, 4 H, CH_2), 1.64 (s, 6 H, CH_3), 1.94 (s, 6 H, CH_3). − ^{13}C NMR (30°C, $CDCl_3$): δ = 8.76 (q, $^1J_{CH}$ = 125 Hz, CH_3), 11.21 (t, $^1J_{CH}$ = 164 Hz, CH_2), 11.53 (q, $^1J_{CH}$ = 125 Hz, CH_3), 37.44 (s, C-3), 133.99, 134.39 (each s, $\mathit{C}CH_3$). − EI MS (25°C, 70 eV); *m/z* (%): 148 $[M]^+$ (3), 147 $[C_7H_3(CH_3)_4]^+$ (100), 133 $[C_7H_4(CH_3)_3]^+$ (33), 119 $[C_7H_5(CH_3)_2]^+$ (11), 105 $[C_7H_6(CH_3)]^+$ (10), 91 $[C_7H_7]^+$ (16), 28 $[C_2H_4]^+$ (15). − $C_{11}H_{16}$ (148.25): calcd. C 89.12, H 10.88; found C 88.73, H 11.11.

Deprotonation Product 6:[24] 0.33 mL of a 2.18 M solution of *n*BuLi in hexane (0.72 mmol) was added to a stirred suspension of **5** (0.23 g, 0.69 mmol) in 20 mL of THF at −60°C, and the reaction mixture allowed to warm up to ca. 0°C. The voluminous snow-white precipitate was separated by filtration, washed rapidly on a glass filter with THF (3 × 5 mL) and dried in vacuo to give 0.22 g of **6** as an extremely air- and moisture-sensitive powder. The product was not stable thermally and decomposed noticeably even when stored in an evacuated vessel at −18°C (and considerably faster when stored under THF).

Thermolysis of Deprotonation Product 6:[24] A small portion (41.5 mg, 0.12 mmol) of **6** was placed into a glass tube connected via a liq. N_2 cooled trap to a high-vacuum line. The tube was heated for 20 min at 80°C and then for 20 min at 120°C. The pale yellow liquid (24.0 mg) in the trap presented an equimolar mixture of $N(CH_3)_3$ (0.12 mmol) and spirane **7** (0.12 mmol) (^1H-NMR data). The pale yellow solid residue in the tube (16.5 mg) was found to be LiI (0.12 mmol).

Lithium Cyclopentadienide (9):[24] Solutions of spiroheptadiene **7** (2.46 g, 16.6 mmol) and lithium diphenylphosphide (4.00 g, 22.6 mmol) in THF (total volume 75 mL) were mixed at room

temp. and heated at 90−100°C for 10 h. The solvent was removed by distillation from a hot water bath and the residual brown/red oil allowed to cool down to room temp. In 1 d formation of a white precipitate began. After introducing 15 mL of THF and stirring at room temp. for 5 h, the precipitate was filtered off, washed with 10 mL of cold THF and then with 15 mL of ether. On drying in vacuo 4.50 g (80%) of **9** was obtained as a white powder which was extremely sensitive to air and moisture. − ^{1}H NMR (30°C, [D$_8$]THF): δ = 1.70 (br., 12 H, CH_3), 1.99 (br., 2 H, CH_2P), 2.32 (br., 2 H, CH_2CH_2P), 7.26 (m, 6 H, *meta*-, *para*-C_6H_5), 7.41 (m, 4 H, *ortho*-C_6H_5). − ^{13}C{^{1}H} NMR (30°C, [D$_8$]THF): δ = 11.1 (br. s, CH_3), 23.4 (br. d, $^2J_{CP}$ = 18 Hz, CH_2CH_2P), 32.2 (br. d, $^1J_{CP}$ = 14 Hz, CH_2P), 105.9, 106.7 (each br. s, CCH_3), 112.5 (br. d, $^3J_{CP}$ = 14 Hz, CCH_2CH_2P), 128.65 (s, *para*-C_6H_5), 128.82 (d, $^3J_{CP}$ = 6.0 Hz, *meta*-C_6H_5), 133.61 (d, $^2J_{CP}$ = 18.0 Hz, *ortho*-C_6H_5), 141.2 (br. d, $^1J_{CP}$ = 15 Hz, *ipso*-C_6H_5). − ^{31}P{^{1}H} NMR (30°C [D$_8$]THF): δ = −14.6 (br.).

(2-Diphenylphosphanylethyl)tetramethylcyclopentadiene (Mixture of Isomers) (12):[24] 10 mL of dry degassed methanol [from over $Mg(OCH_3)_2$] was condensed via a high-vacuum line directly onto 0.67 g (1.97 mmol) of lithium cyclopentadienide **9** by trapping with liq. N_2 and the mixture allowed to warm up to room temp. On trapping methanol with liq. N_2 product **12** was isolated by distillation in vacuo as a pale yellow viscous oil (0.65 g, 99%). − ^{1}H NMR (30°C, C_6D_6): δ = 0.90 [d, $^3J_{HH}$ = 7.6 Hz, $CHCH_3$ (**12c**)], 0.95 [d, $^3J_{HH}$ = 7.6 Hz, $CHCH_3$ (**12b**)], 1.65, 1.68, 1.71, 1.76, 1.78 (each br. s, CCH_3), 1.68 [obscured m, CH_2P (**12a**)], 1.85 [m, CH_2CH_2P (**12a**)], 2.06−2.19 [m, CH_2P (**12b**, **12c**)], 2.37 [m, CH (**12b**)], 2.42 [m, CH_2CH_2P (**12b**, **12c**)], 2.52 [m, CH (**12a**)], 2.57 [m, CH (**12c**)], 7.01−7.13 (m, *meta*-, *para*-C_6H_5), 7.40−7.50 (m, *ortho*-C_6H_5). − ^{13}C NMR (30°C, C_6D_6): δ = 11.17, 11.20, 11.27, 11.31, 11.76, 11.80, 11.85 (each q, $^1J_{CH}$ = 126 Hz, CCH_3), 14.16 [q, $^1J_{CH}$ = 128 Hz, $CHCH_3$ (**12c**)], 14.25 [q, $^1J_{CH}$ = 128 Hz, $CHCH_3$ (**12b**)], 21.86 [dt, $^1J_{CH}$ = 128 Hz, $^1J_{CP}$ = 11.8 Hz, CH_2P (**12a**)], 22.61 [dt, $^1J_{CH}$ = 128 Hz, $^2J_{CP}$ = 18.4 Hz, CH_2CH_2P (**12b**)], 22.92 [dt, $^1J_{CH}$ = 128 Hz, $^2J_{CP}$ = 17.7 Hz, CH_2CH_2P (**12c**)], 24.10 [dt, $^1J_{CH}$ = 128 Hz, $^2J_{CP}$ = 19.7 Hz, CH_2CH_2P (**12a**)], 29.20 [dt, $^1J_{CH}$ = 128 Hz, $^1J_{CP}$ = 14.7 Hz, CH_2P (**12b**)], 29.91 [dt, $^1J_{CH}$ = 128 Hz, $^1J_{CP}$ = 14.3 Hz, CH_2P (**12c**)], 49.41 [d, $^1J_{CH}$ = 123 Hz, CH (**12c**)], 51.76 [d, $^1J_{CH}$ = 123 Hz, CH (**12b**)], 56.86 [dd, $^1J_{CH}$ = 123 Hz, $^3J_{CP}$ = 13.4 Hz, CH (**12a**)], 128.60 [dm, $^1J_{CH}$ = 158 Hz, *meta*-, *para*-C_6H_5], 133.17 [dm, $^1J_{CH}$ = 158 Hz, *ortho*-C_6H_5], 133.58, 134.22, 134.54, 135.02, 136.42, 138.21, 138.25, 138.26 (each s, CCH_3), 139.46 [d, $^3J_{CP}$ = 12.5 Hz, CCH_2CH_2P (**12b**)], 139.79 [d, $^1J_{CP}$ = 14.6 Hz, *ipso*-C_6H_5], 139.83 [d, $^1J_{CP}$ = 14.0 Hz, *ipso*-C_6H_5], 139.94 (d, $^1J_{CP}$ = 14.7 Hz, *ipso*-C_6H_5), 142.46 [d, $^3J_{CP}$ = 12.3 Hz, CCH_2CH_2P (**12c**)]. − ^{31}P{^{1}H} NMR (30°C, C_6D_6): δ = −14.4 [s, (**12c**)], −13.9 [s, (**12b**)], −12.6 [s, (**12a**)]. − ^{1}H NMR (30°C, CD_2Cl_2): δ = 1.00 [d, $^3J_{HH}$ = 7.6 Hz, $CHCH_3$ (**12c**)], 1.04 [d, $^3J_{HH}$ = 7.6 Hz, $CHCH_3$ (**12b**)], 1.56 [m, CH_2P (**12a**)], 1.74, 1.78, 1.82, 1.84, 1.86, 1.87 (each br. s, CCH_3), 1.84 [obscured m, CH_2CH_2P (**12a**)], 2.14−2.31 [m, CH_2P (**12b**, **12c**)], 2.37 [m, CH_2CH_2P (**12b**, **12c**)], 2.50 [m, CH (**12b**)], 2.71 [m, CH (**12a**, **12c**)], 7.34−7.45 (m, *meta*-, *para*-C_6H_5), 7.49−7.54 (m, *ortho*-C_6H_5). − EI MS (250°C, 70 eV); *m*/*z* (%): 334 (88) [M$^+$], 319 (85) [M$^+$ − CH_3], 306 (69) [M$^+$ − CH_3−CH_3], 291 (25) [M$^+$ − CH_3−CH_3−CH_3], 199 (100) [$(C_6H_5)_2PCH_2^+$], 121 (99) [M$^+$ − $(C_6H_5)_2PCH_2CH_2$]. − $C_{23}H_{27}P$ (334.45): calcd. Zirconium Complex 11:[24] A suspension of 1.28 g (5.49 mmol) of $ZrCl_4$ in 10 mL of toluene and a solution of 2.23 g (5.48 mmol) of silane **10** in 30 mL of the same solvent were mixed at room temp. and the reaction mixture heated at 90−100°C under vigorous stirring for 3 h. On cooling down to room temp., the reaction mixture consisted of a bright yellow solution and a small amount of a brown viscous oil. The solution was decanted and the oil extracted with hot toluene (2 × 5 mL). Removal of all of the volatile components from the combined extracts gave 2.54 g (87%) of crude THF-free **11** as a viscous lemon yellow oil. Addition of 10 mL of THF led to complete dissolution of crude **11**. In less than 1 min fast crystallization began. On removing approximately one-half of the initial amount of THF the mixture was kept overnight. The crystalline product **11** was filtered off, washed on a filter with ether (2 × 5 mL) and dried in vacuo. Yield 1.11 g (34%). The product decomposed at 143°C with foaming (elimination of THF). Single crystals suitable for X-ray analysis were obtained by crystallization from hot THF. − ^{1}H NMR (30°C, CD_2Cl_2): δ = 1.75 (m, 4 H, CH_2CH_2O in THF), 1.98, 2.18 (each s, 6 H, CH_3), 2.97 (dt, 2 H, $^3J_{HH}$ = 7.0 Hz, $^3J_{HP}$ = 21.0 Hz, CH_2CH_2P), 3.09 (q, 2 H, $^3J_{HH}$ = 7.0 Hz, $^2J_{HP}$ = 7.0 Hz, CH_2P), 3.77 (m, 4 H, CH_2O in THF), 7.40 (m, 6 H, *meta*-, *para*-C_6H_5), 7.70 (m, 4 H, *ortho*-C_6H_5). − ^{13}C NMR (30°C, CD_2Cl_2): δ = 13.24, 13.41 (each q, $^1J_{CH}$ = 127 Hz, CH_3), 21.18 (dt, $^1J_{CH}$ = 131 Hz, $^2J_{CP}$ = 11.0 Hz, CH_2CH_2P), 25.77 (t, $^1J_{CH}$ = 133 Hz, CH_2CH_2O in THF), 29.84 (dt, $^1J_{CH}$ = 134 Hz, $^1J_{CP}$ = 21.4 Hz, CH_2P), 69.10 (t, $^1J_{CH}$ = 145 Hz, CH_2O in THF), 128.32, 128.38 (each s, CCH_3), 129.53 (dd, $^1J_{CH}$ = 160 Hz, $^3J_{CP}$ = 8.4 Hz, *meta*-C_6H_5), 130.60 (d, $^1J_{CH}$ = 160 Hz, *para*-C_6H_5), 132.64 (d, $^1J_{CP}$ = 27.5 Hz, *ipso*-C_6H_5), 132.69 (dd, $^1J_{CH}$ = 160 Hz, $^2J_{CP}$ = 9.5 Hz, *ortho*-C_6H_5), 134.06 (d, $^3J_{CP}$ = 4.0 Hz, CCH_2CH_2P). − ^{31}P{^{1}H} NMR (30°C, CD_2Cl_2): δ = 5.8 (s). − EI MS (250°C, 70 eV); *m*/*z* (%): 528 (13) [M$^+$ − THF], 513 (1) [M$^+$ − THF−CH_3], 493 (3) [M$^+$ − THF−Cl], 333 (23) [M$^+$ − THF−$ZrCl_3$], 308 (6) [M$^+$ −THF−$(C_6H_5)_2PCl$], 199 (100) [$(C_6H_5)_2PCH_2^+$], 185 (90) [$(C_6H_5)_2P^+$], 147 (14) [$C_7H_3(CH_3)_4^+$], 133 (24) [$C_7H_4(CH_3)_3^+$], 121 (48) [$C_9H_{13}^+$], 108 (59) [$C_8H_{12}^+$], 91 (21) [$C_7H_7^+$]. − $C_{27}H_{34}Cl_3OPZr$ (603.12): calcd. X-ray Crystallographic Study of Complex 11:[25] Crystal data: $C_{27}H_{34}Cl_3OPZr$, M = 603.12, monoclinic, a = 8.336(2), b = 33.943(10), c = 9.863(3) Å, β = 101.90(2)°, V = 2730.8(13) Å^3, space group $P2_1/c$, Z = 4, D_c = 1.467 g/cm^3, F(000) = 1240, μ(Mo-K_α) = 0.773 mm^{-1}. Data collection, structure solution and refinement. A crystal of approximate dimensions 0.4 × 0.3 × 0.3 was used for data collection. A total of 6093 reflections (4470 unique, R_{int} = 0.0244) were measured with an Enraf−Nonius CAD4 diffractometer (graphite-monochromatized Mo-K_α radiation, λ =

0.71073 Å) at room temp. Data was collected in the range $2.19° < \theta < 24.99°$ ($-9 \le h \le 9$, $-40 \le k \le 40$, $0 \le l \le 11$) using the ω scan mode. The structure was solved by direct methods[26] and refined by full-matrix least squares on F^2[27] with anisotropic thermal parameters for all non-hydrogen atoms. All H atoms were placed in calculated positions. Both coordinates and isotropic thermal parameters for H atoms at side-chain carbon atoms C(6) and C(7) and at Ph groups were refined. All other hydrogen atoms were refined using a riding model (U_{iso} were taken as $1.5 \times U_{eq}$ of parent C atoms). The methyl group at C(2) was found to be rotationally disordered over two positions with equal occupancies. The weighting scheme was $w^{-1} = \sigma^2(F^2) + (0.0483P)^2 + 0.5400P$, where $P = (2F_c^2 + F_o^2)/3$. The final residuals were: $R_1 = 0.0285$, $wR_2 = 0.0750$ for 3543 reflections with $I > 2\sigma(I)$ and 0.0463, 0.0802 for all data and 359 parameters. Goof: 1.086, maximum shift/e.s.d.: 0.001, maximum $\Delta\rho = 0.638$ e × Å^{-3}.

Self-Assembly of Pyrazolyl Based Ligands and Silver Cation into Metallamacrocycles and Tubular Coordination Networks

Marielle Loï,[a] Mir Wais Hosseini,*[a] Abdelaziz Jouaiti,[a] André De Cian,[b] and Jean Fischer[b]

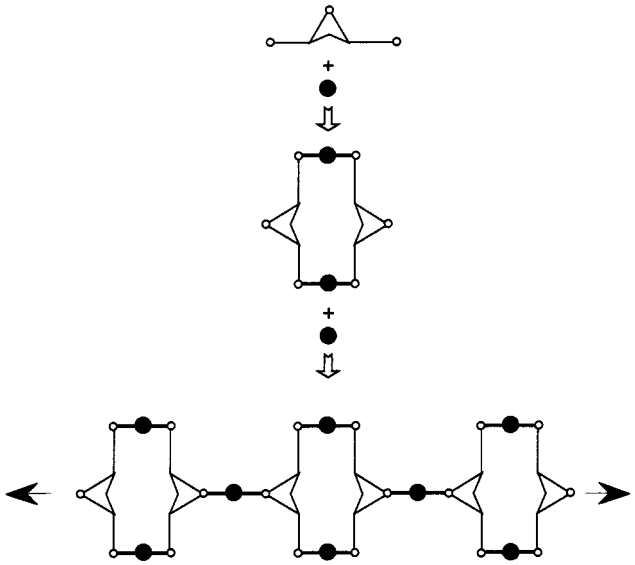
Keywords: Pyrazole / Silver / Metallacycles / Macrocycles / Self-assembly

The 2,6-bis(pyrazolyl)pyrazine ligand **1** forms a 2,2-metallamacrocycle **3**, composed of two ligands and two cations, in the presence of the Ag^+ cation. In the crystalline phase, the 1,3,5-tris(pyrazolyl)benzene ligand **2** leads to an infinite metallatubular network in the presence of the Ag^+ cation, composed of the 2,2-metallamacrocycle **4**, which is formed from two molecules of **2** and two cations. This infinite network is formed by double interconnection of consecutive metallamacrocycles through binding of Ag^+ centers by the free pyrazolyl moieties.

For the last decade, much attention has been focused on the formation of metallamacrocycles,[1] and many bis-monodentate ligands such as 4,4′-bipyridine, pyrimidine, bipyrazine, 4,7-phenanthroline or bis-pyridines interconnected by rigid or flexible spacers have been shown to form a variety of metallamacrocycles.[2] Recently, we have reported the formation of silver and palladium 2,2-metallamacrocycles using ligands based on two *p*-dialkylaminopyridine units connected by aliphatic chains of variable length.[3]

A further development in this area could be the formation, using self-assembly processes, of coordination molecular networks based on the interconnection of metallamacrocycles by coordination bonds. As schematically represented in Figure 1, one can design tridentate ligands in which two coordination sites are positioned in such a manner that, in the presence of divalent metal cations, they form 2,2-metallacycles composed of two metals and two ligands; the remaining coordination site would then serve as a connecting center allowing binding to another divalent metal cation and the formation of infinite 1-D networks. This strategy has been demonstrated by using terpyridine ligands bearing a thioether group.[4]

In order to investigate this possibility, ligand **1** was designed, synthesized and structurally characterized in the crystalline phase by X-ray diffraction on a single crystal. Indeed, ligand **1**, based on a pyrazine moiety bearing two pyrazolyl groups at the 2 and 6 positions, may fulfil the above criteria if the two pyrazolyl units and the N4 nitrogen atom of the pyrazine unit participate in the binding of linearly coordinated metal centers. However, **1** can also act either as a tridentate chelating ligand if the N1 nitrogen atom of the pyrazine ring was acting as coordination site in conjunction with the two pyrazolyl groups, or as a tetradentate ligand if, in addition to the two pyrazolyl moieties, both nitrogen atoms of the pyrazine ring were participating in the bonding of metal centers.



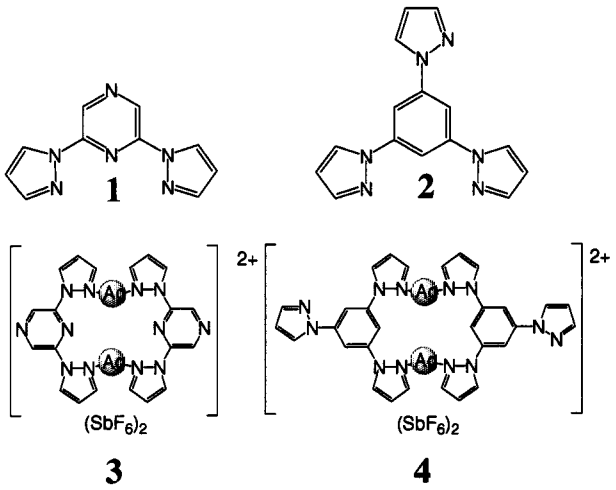


Figure 1. Schematic representation of an infinite coordination network based on interconnection of 2,2-metallamacrocycles by bridging metal centers

Ligand **1** was prepared in 77% yield upon coupling the sodium salt of pyrazole with 2,6-dichloropyrazine in DMF. The pyridine analogue of **1** and its Ru(II)[5] and Cu(II)[6] complexes have previously been reported. The solid state structure of **1** (Figure 2) was determined by an X-ray diffraction study which revealed the following features. In the solid state, the free ligand **1** possesses a plane of symmetry and adopts an almost planar conformation with an N1−N2−C5−N3 dihedral angle of 171.6°. Both the N1 and N1′ atoms are in a trans configuration with respect to N3. Whereas the C5−N2 bond length is 1.4000 Å, the C5−N3 bond is much shorter (1.324 Å), as expected; the N1−N2 bond length is 1.362 Å.

In an attempt to form infinite 1-D networks based on the interconnection of metallamacrocycles, the binding of the

Ag^+ cation by the ligand **1** was investigated. The Ag^+ cation was selected because, firstly, it forms kinetically labile complexes with nitrogen-containing ligands and, secondly, it may adopt a linear coordination geometry. Indeed, we have previously obtained a silver 2,2-metallamacrocycle in which the Ag^+ cation is linearly coordinated to two nitrogen atoms.[3] However, other types of coordination geometry, in particular trigonal or tetrahedral, are commonly observed. In this case, infinite 1-D linear[7] or helical[8] silver coordination networks in which the cation acts as a tetrahedrally connecting center, were obtained.

Upon reacting equimolar amounts of ligand **1** and $AgSbF_6$in $CHCl_3$/EtOH (1:3) at room temperature, the binuclear silver metallamacrocycle **3** was obtained in 70% yield (Scheme 1). The structure of **3** was investigated by an X-ray diffraction study (Table 1) on a single crystal (see Figure 3). The crystal is exclusively composed of discrete 2,2-metallamacrocycles **3** and SbF_6^- anions; the cationic part is a binuclear silver complex composed of two ligands and two Ag^+ cations forming a 2,2-metallamacrocycle. The latter is formed by the bridging of two pyrazolyl moieties of the ligand by two silver atoms, implying that **1** behaves as a bidentate unit. For ligand **1**, the pyrazolyl and the pyrazine units are tilted by −21.6°. The two ligands are not coplanar but twisted, thus leading to a rather short Ag−Ag distance of 2.911 Å. Both silver cations are almost linearly coordinated (N−Ag−N angle of 178.2°) to two pyrazolyl nitrogen atoms with a N−Ag distance of 2.160 Å. The SbF_6^- anions are neither disordered nor in specific interactions with the cationic units. The formation of such a metallamacrocycle is not unprecedented, analogous structures were obtained from Cu^I and benzimidazole-based ligands,[9] and bis-pyridine and Ag^I.[10] Attempts to generate the desired infinite coordination network by increasing the Ag^+/**1** stoichiometry and by varying the crystallization conditions have so far been unsuccessful.

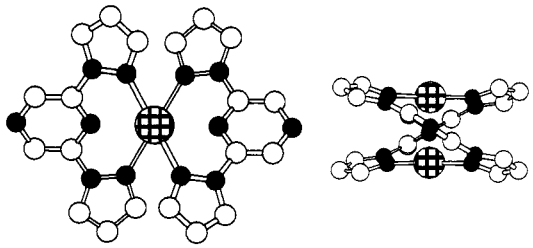

Figure 3. X-ray structure of the metallamacrocycle **3** {projection along the Ag-Ag axis (left) and lateral view (right)} obtained under self-assembly conditions between **1** and the Ag^+ cation (Table 1); hydrogen atoms and anions omitted for clarity; for bond lengths and angles see text

Tubular structures are interesting architectures, in particular with respect to their ability to transport ions or molecules. In principle, such structures may be obtained either from nonreversible covalent bonds, or other types of reversible interactions such as H-bonding or stacking processes. It has been shown that tubular systems may be formed by 1-D chains adopting a helical structure, as observed for polypeptides in natural systems,[11][12] or for helical coordination polymers;[8][13] by interconnection of ring modules as, for example, for cyclic peptides;[11][12] by stacks of cyclic units in the liquid crystalline phase;[14] by poly-[15] or oligomeric[16] structures bearing ring systems; or by rolling up 2-D sheets such as graphite leading to carbon nanotubes.[17] Following the above strategy for the formation of 1-D coordination networks based on the interconnection of metallamacrocyclic units, we reasoned that, by an appropriate choice of ligands, it should be possible to generate tubular coordination networks using the self-assembly strategy based on the formation of reversible coordination bonds. Indeed, the appropriate interconnection of metallamacrocycles may lead to a variety of tubular systems. An example of such an architecture, based on the mutual interconnection of metallamacrocycles, is schematically represented in Figure 4. The formation of such a structure requires a ligand and metal-cation pair allowing the reversible formation of metallamacrocycles and their mutual interconnection (Figure 4). This strategy was demonstrated using terpyridine ligands bearing a thioether group.[9]

We believed that the tridentate ligand **2** composed of three pyrazolyl moieties located in the 1, 3 and 5 positions of a benzene ring might be an interesting unit for the formation of a metallatubular 1-D coordination network. Compound **2**[18] and its 1,3,5-triazine[19] and 1,3,5-(pyrazolyl-1-methyl)[20] analogues have previously been reported. With

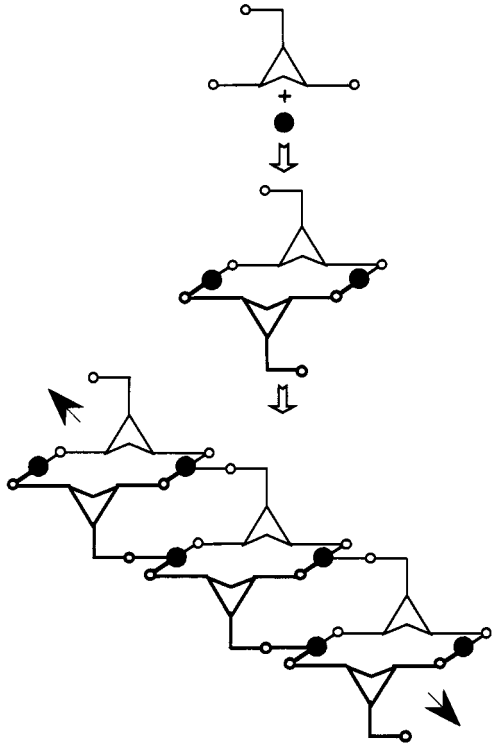

Figure 4. Schematic representation of an infinite coordination tubular network based on mutual interconnection through coordination bonds of consecutive 2,2-metallamacrocycles

respect to the bridging metallic center, the above mentioned strategy requires a tricoordinated metal adopting a T-type coordination geometry. Again, we believed that the Ag^+ cation was the best candidate.

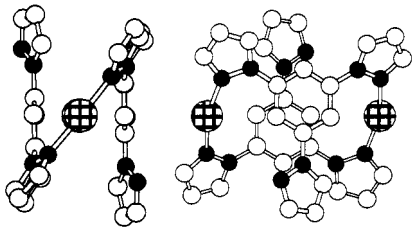

Figure 5. The X-ray structure of the metallamacrocycle **4** composed of **2** and the Ag^+ cation (Table 1). Projection along the Ag-Ag axis (left) and lateral view (right). H atoms and anions are not presented for clarity. For bond lengths and angles see text

Upon slow diffusion in the dark and at room temp. of a solution of **2** in $CHCl_3$ into an EtOH solution of $AgSbF_6$, colorless crystals were obtained after three days which were studied by X-ray diffraction (Table 1). The crystal (Figures 5 and 6), consisting exclusively of ligand **2**, Ag^+ cations and SbF_6^- anions, is composed of parallel cationic metallatubular coordination networks and the SbF_6^- anion. The formation of the tubular structure results from the mutual bridging of the binuclear silver 2,2-metallamacrocycles **4**, (Scheme 1), composed of two Ag^+ cations and two ligands **2** and analogous to the metallamacrocycle **3** obtained with ligand **1**. For the formation of the metallamacrocyclic unit **4** (Figure 5) within each of the two tridentate ligands **2**, two out of three pyrazolyl units are bridged by two Ag^+ cations, the remaining two pyrazolyl units, located at each end of the cyclic structure and pointing in opposite directions with respect to the plane defined by the metallamacrocycle, serve to interconnect consecutive cyclic units (Figure 6). Dealing

with the ligand **2**, the three pyrazolyl moieties are tilted by −41.2°, 32.4° and 23.0° with respect to the phenyl ring, respectively. For the metallamacrocycle **4**, the N−Ag and Ag−Ag distances are 2.150 Å, 2.154 Å and 7.785 Å, respectively. As stated above, the metallamacrocycles are mutually and doubly interconnected (Figure 6) by the third pyrazolyl on each ligand **2** with a rather long N−Ag distance of 2.620 Å; thus the overall coordination geometry around the Ag^+ cation may be described as severely distorted trigonal (T-type) with N−Ag−N angles of 162.4°, 99.0° and 98.6°. As in the case of **3** mentioned above, the SbF_6^- anions were neither disordered nor in specific interactions with the cationic units. Although in terms of topology the network formed may be described as tubular, due to the size of the metallamacrocyclic unit, the internal space within each tubular network is exceedingly small.

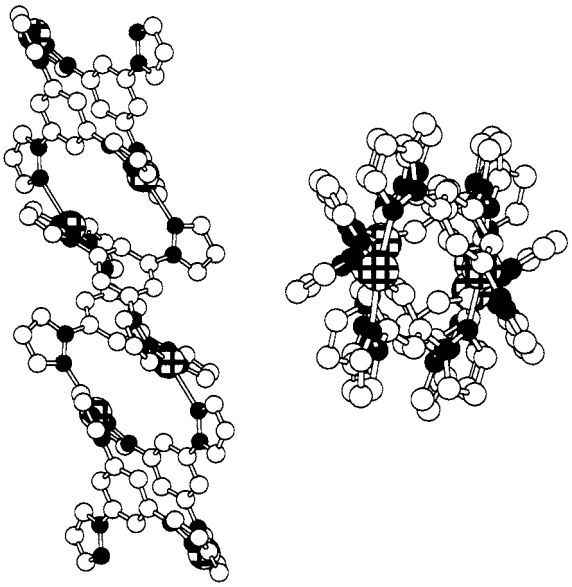

Figure 6. A portion of the X-ray structure showing the formation of the metallatube {parallel (left) and perpendicular (right) views} between the tridentate ligand **2** and Ag^+ cations; hydrogen atoms and anions omitted for clarity

In conclusion, from ligand **1**, bearing two pyrazolyl units, and the Ag^+ cation, both in solution and in the solid state, the formation of a binuclear silver 2,2-metallamacrocycle was achieved and its solid structure was elucidated by X-ray diffraction on a single crystal. With the Ag^+ cation and ligand **2** containing three pyrazolyl, units, the formation of a 1-D tubular coordination network was observed in the solid state by X-ray diffraction on a single crystal. The tubular coordination network results from the mutual interconnection of metallamacrocycles through N−Ag coordination bonds. Due to the size of the metallamacrocyclic unit, the internal size of the tubular architecture obtained was exceedingly small, thus precluding any possible application in terms of its use as a channel. However, increasing the size of the metallamacrocycle by using larger ligands such as 1,3,5-tris(phenylpyrazol)ylbenzene, one might be able to generate tubular networks with sufficient internal space. This type of architecture, due to its cationic nature, may be of interest for the transport of anions, which remains a challenge. Work along these lines is currently in progress

Experimental Section

Synthesis of Ligand 1: To a suspension of pyrazole (274 mg, 4 mmol) in DMF (35 mL) was added NaH (168 mg, 4.22 mmol) and the mixture stirred under argon at 50°C for 20 minutes. To this suspension was added 2,6-dichloropyrazine (300 mg, 2 mmol) and the resulting yellow mixture was heated to 90°C under argon and stirred for a further 12 hours before it was allowed to cool to room temperature. Upon pouring the suspension into cold water, the desired compound **1** was obtained in 77% yield (330 mg) as a white solid which was filtered and further washed with water. m.p. 180−181°C. − ^{1}H NMR (300 MHz, 25°C, [D$_6$]acetone): δ = 6.66 (dd, *J* = 1.3, 2.7 Hz, 2 H, pyrazole), 7.89 (d, *J* = 1.5 Hz, 2 H, pyrazol), 8.84 (d, *J* = 1.5 Hz, 2 H, pyrazole), 9.14 (s, 2 H, pyrazine). − ^{13}C NMR (75.46 MHz, 25°C, $CDCl_3$): δ = 108.8, 127.3, 131.5, 143.3, 144.8. − UV (25°C, $CHCl_3$) λ_{max} (ε mol^{-1}lcm^{-1}): 270 (18400), 327 (29200) nm. − FAB$^{+\ m/z}$ (%) = 212.1 (100%).

Synthesis of the Binuclear Silver Complex 3: Stirring an equimolar mixture of **1** and $AgSbF_6$ (0.23 mmol) in $CHCl_3$/EtOH (1:3) for 5 hours at room temperature in the dark under argon, gave the binuclear silver complex **3** in 80% yield as a white powder which was filtered, washed with CH_2Cl_2 and EtOH and dried. m.p. 240°C (decomposition). − ^{1}H NMR (300 MHz, 25°C, [D$_6$]acetone): δ = 6.83 (dd, *J* = 2.0, 2.7 Hz, 2 H, pyrazole), 7.87 (d, *J* = 1.9 Hz, 2 H, pyrazole), 8.96 (d, *J* = 3.0 Hz, 2 H, pyrazole), 9.40 (s, 2 H, pyrazine). − ^{13}C NMR (75.46 MHz, 25°C, $CDCl_3$): δ = 111.1, 131.2, 134.1, 143.8, 145.2. − FAB$^{+\ m/z}$ (%) = 874.9 (100%, **3**-SbF_6).

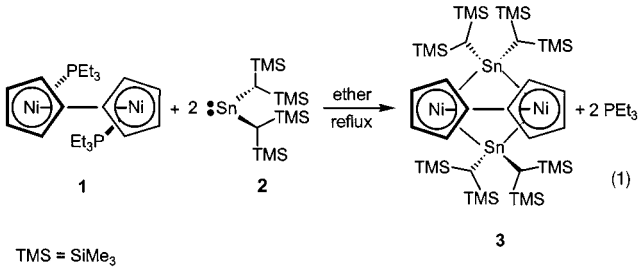
Keywords: Cluster / Nickel / Tin / Bimetallic complexes / Electrochemistry

Addition of stannylene $[\{(SiMe_3)_2CH\}_2Sn\mathbf{:}]$ (**2**) to the unbridged homobimetallic Ni–Ni bond of $[\{PEt_3Ni(\eta^5\text{-}Cp)\}_2]$ (**1**) gives the heterobimetallic, tetranuclear compound $[\{\{(SiMe_3)_2CH\}_2Sn–Ni(\eta^5\text{-}Cp)\}_2]$ (**3**) with a butterfly arrangement and leaves the Ni–Ni bond of **1** intact. Elimination of both PEt_3 ligands from the starting material **1** is observed, probably due to steric restraints. Compound **3** is formally related to the hypothetical *closo*-borane $B_4H_4^{2-}$. The Ni–Ni bond in **3** is only slightly elongated [2.454(3) Å] when compared to the starting material **1** [2.41(1) Å]. Compound **3** displays a butterfly arrangement with a hinge angle of 62.5°. An alternative route to **3** is by a direct reaction between nickelocene (**5**) and Lappert's stannylene $[\{(SiMe_3)_2CH\}_2Sn\mathbf{:}]$ in 63% yield. Treating **3** with water results in the cleavage of an Ni–Sn bond and subsequent opening of the cluster cage of **3** to form the trinuclear compound $[(\eta^5\text{-}Cp)Ni\{Sn(CH(SiMe_3)_2\}_2OH]$ (**6**) having an Sn–OH–Sn bridge. The hydroxy proton in **6** can be exchanged by deuterium within a few minutes, as determined by ^{1}H-NMR spectroscopy, giving the monodeuterio product, $[D_1]$-**6**. Compound **6** is reactive towards acetonitrile, leading to cleavage of one Ni–Sn bond, elimination of one $[\{(SiMe_3)_2CH\}_2Sn\mathbf{:}]$ unit, and formation of the organotin hydroxo complex $[\{(SiMe_3)_2CH\}_2(OH)Sn–Ni(\eta^5\text{-}Cp)(CH_3CN)]$ (**7**). In this complex, acetonitrile is coordinated to Ni via its σ lone pair, bearing the OH ligand in a terminal bonding mode to tin.

Introduction

Unbridged transition metal bonds (M−M) exhibit a high reactivity towards insertion and addition reactions of metal ligand fragments, especially when the M−M bond is polarized.[1] For complexes containing homo-metallic M−M bonds as in L_xM-ML_x-type dimers, usually little or no electronic polarization effects are available to enhance the reactivity of the particular M−M bond. Drastic reaction conditions are therefore often necessary to enhance the reactivity of these M−M bonds towards insertion or addition reactions. A unique way to activate homometallic M−M bonds and to increase their reactivity towards further reaction is to sterically overcrowd the ligand periphery L at each L_xM fragment. This results in a substantial weakening of M−M bonding, an increased reactivity, and consequently an easy homolytic scission of the M−M bond in such complexes.

We are interested in the reactivity of the dimer $[\{(\eta^5\text{-}Cp)Ni(PEt_3)\}_2]$ (**1**) containing an unbridged Ni−Ni bond.[2] Although the M−M bond in **1** is in the usual range for an Ni−Ni single bond and shows no significant elongation, **1** displays an unusually high reactivity with respect to a scission of its unbridged Ni−Ni bond.[2][3] This is a result of the sterically crowded situation at both Ni atoms of **1**, as revealed by X-ray crystallography and by ^{1}H-NMR spectroscopy in solution.[2] Rotation of the PEt_3 ligand around the Ni−Ni bond vector is restricted, even in solution, due to steric hindrance. This sterically encumbered ligand situation in **1** gives rise to cleavage of the Ni−Ni bond and insertion of a variety of low-valent main-group-element compounds.[2][3] For example, group-14 chloride $SnCl_2$, displaying carbenoid character, inserts into the Ni−Ni bond of **1** giving $[\{(\eta^5\text{-}Cp)Ni(PEt_3)\}_2SnCl_2]$. Subsequent dehalogention leads to the stannio(IV) monochloride complex $[\{(\eta^5\text{-}Cp)Ni(PEt_3)\}_3SnCl]$.[2] In our work reported here, we set out to find new synthetic entries into Ni/Sn organometallics by direct insertion routes into the M−M bond of **1**. Such Ni/Sn organometallics might be valuable single-source target compounds in MOCVD processes for the preparation of Ni/Sn intermetallics, which recently gained interest with respect to the nature of intermetallic phases like NiSn and Ni_3Sn_2.[4] Further interest is in their use as single-source precursors in bimetallic silica-supported catalysts based on a combination of Ni−Sn, Pd−Sn and Pt−Sn, which up to now are only accessible from a mixture of Sn and M (M = Ni, Pd, Pt) molecular precursors.[5a] Such bimetallics have potential in CO oxidation reactions.[5a] In addition, Ni/Sn intermetallics have proven their catalytic properties as cyclohexane dehydrogenation catalyst.[5b]



A number of transition metal complexes of stannanediyls $\mathbf{:}SnR_2$ are known so far, and have proven their versatility for coordination of transition metals.[6] We have choosen Lappert's bis{bis(trimethylsilylmethyl)tin} $[\{\{(SiMe_3)_2CH\}_2Sn\}_2]$ (**2**),[7] as candidate for introducing an organic

SnR_2 group into transition metal compounds under mild conditions. We have recently shown that addition of elemental Se and Te towards the unbridged Co−Sn bond of $[\{(SiMe_3)_2CH\}_2Sn-Co(\eta^2\text{-ethene})(\eta^5\text{-Cp})]$, derived from reaction of **2** with $[(Cp)Co(ethene)_2]$, leads to unique ternary Co/Sn/E organometallics.[8]

We describe here, our studies on the reactivity of Lappert's bis(stannanediyl) **2** towards the Ni−Ni bond of **1**, leading to the formation of a bimetallic Ni−Sn complex **3** with a *closo* cage structure; **3** is formed by the addition of subvalent SnR_2 fragments to the Ni−Ni bond of **1**. The electrochemistry of **3** and of its cage-opened product **6** is reported. In addition, the reactivity of **1** towards cage opening with water as a nucleophile and subsequent further reactivity of this product with acetonitrile is studied.

Results and Discussion

Reaction of $[\{(\eta^5\text{-Cp})Ni(PEt_3)\}_2]$ (1) with $[\{\{(SiMe_3)_2CH\}_2Sn\}_2]$ (2)

Over the course of several days, **1** does not react with **2** at ambient temperature in diethyl ether. However, reflux conditions in diethyl ether for 12 h led to a color change of the initially deep green reaction solution to brown. Workup by crystallization (from ether) gave brown-green crystals of **3** in 50% yield (Equation 1).

According to ^1H and ^{13}C NMR, **3** is diamagnetic and does not contain any signals corresponding to the PEt_3 ligands originally present in the starting complex **1**. This result is confirmed by mass-spectrometric studies which show the molecular peak of **3** at m/z = 1122, with a correct isotropic pattern corresponding to the composition Ni_2Sn_2 (Figure 1). Figure 1 clearly indicates that **3** is thermally robust, propably leaving the Ni_2Sn_2 metal core intact upon vaporization. This is of significance for further MOCVD applications of this compound.

Definitive proof of the spectroscopic data, especially the loss of the PEt_3 ligand came from a single-crystal X-ray investigation, which showed **3** to be indeed a dinickel complex (Figure 2).[9] Two $\{CH(SiMe_3)\}_2Sn$ fragments bridge two 15e-$\{(\eta^5\text{-Cp})Ni\}$ fragments, resulting in a tetrameric Ni_2Sn_2 metal core. The metal atoms show a butterfly arrangement with a hinge angle of 62.5(4)°. The two tin atoms display a distorted tetrahedral geometry with significantly compressed bond angles $\{Si(CH_3)_3\}_2HC-Sn-CH\{Si(CH_3)_3\}_2$, e.g. C6−Sn−C7 102.9(2)°. A characteristic feature of the structure of **3** is the Ni−Ni bond, which is only slightly elongated when compared to the Ni−Ni bond in the starting material **1**. [2.41(1) Å[2] vs. 2.454(3) Å]. Obviously, the steric repulsion upon addition of two **:**SnR_2 stannylene fragments to the Ni−Ni bond has only a minor impact on the geometry of **3**. The Ni−Sn bond length is well in accord with the Ni−Sn bond in $[(\eta^5\text{-Cp})Ni)\{(\mu\text{-}\eta^1\text{:}\eta^1\text{-}$

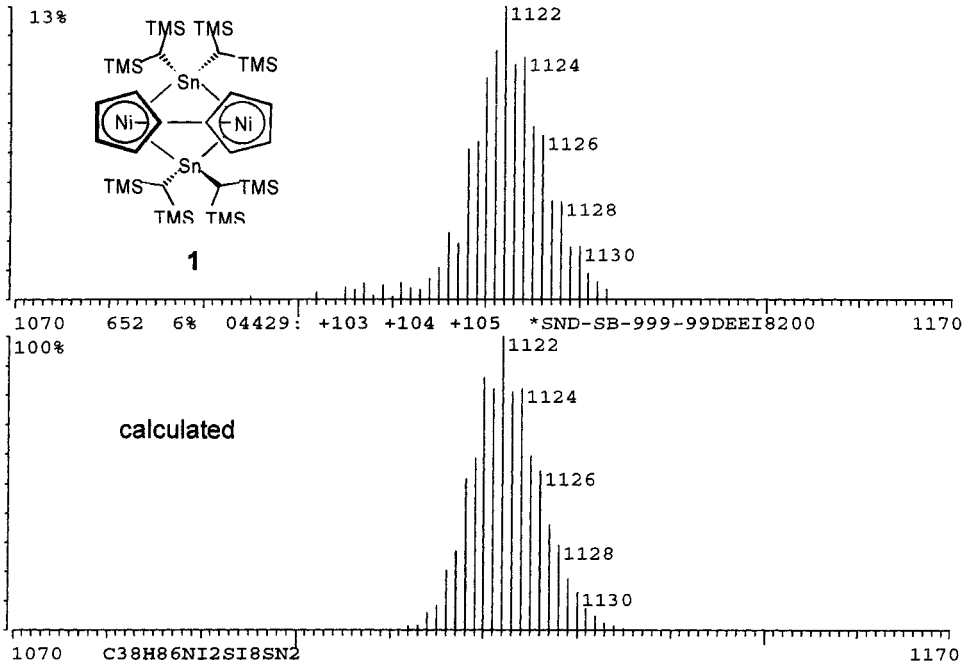

Figure 1. Top: experimental isotopic pattern of the molecular ion peak of **3**; bottom: calculated isotopic pattern for the molecular ion of composition $C_{38}H_{86}Ni_2Si_8Sn_2$

Cp){Sn(*N*(*t*Bu))$_2$SiMe$_3$}$_2$}] (**4**)[12] (Figure 3), containing a somewhat similar {(η^5-Cp)Ni−SnR$_3$} unit with a tetracoordinated Sn atom. The distance between the two tin atoms in **3** is 3.72 Å.

ether, under reflux conditions, to give brown crystals of **3** in 65% (Equation 2).

In contrast to Equation 1, formation of **3** here proceeds by addition of two electronically unsaturated 15e-{CpNi}

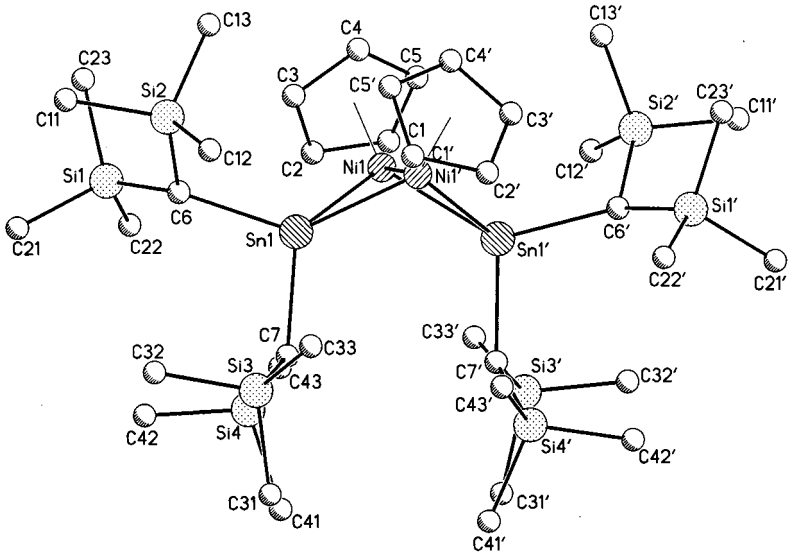

Figure 2. Molecular structure of **3** in the solid state; selected bond lengths [Å] and angles [°]: Sn−Ni 2.502, Ni−Ni 2.454, Sn−C7 2.208(6), Sn−C6 2.230(6), Ni−X1A (1B) 1.74; C6−Sn−C7 102.9(2), Ni−Sn−Ni′ 58.7(1), Sn−Ni−Sn′ 96.2(1)

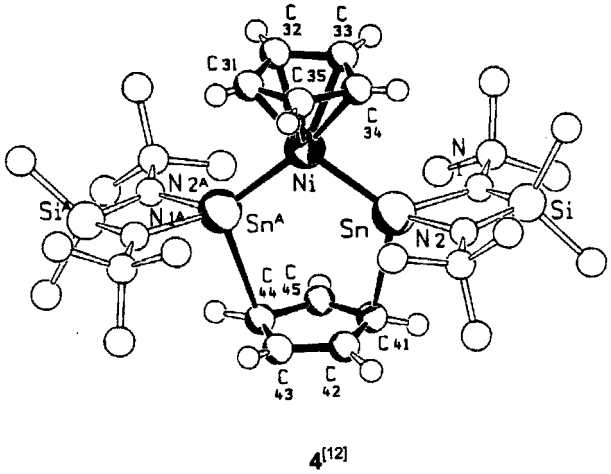

Figure 3. Molecular structure of **4** (reproduced from ref.[12] with permission)

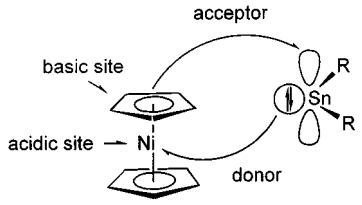

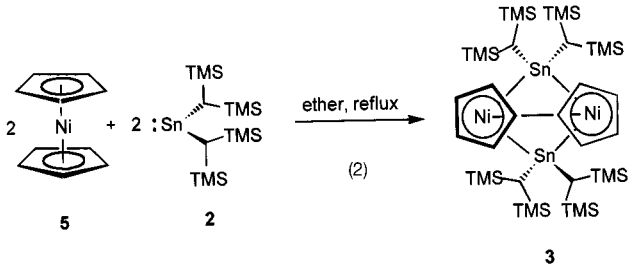

Figure 4. Different reaction sites of nickelocene with an amphiphilic Lewis acid/base stannylene ligand :SnR$_2$

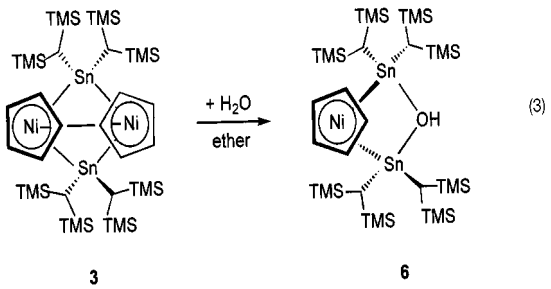

Equation 1 represents a rare case of addition of stannylene fragments SnR$_2$ towards an unbridged M−M bond.[13][14] For electron bookkeeping sake, **3** formally represents a hetero-*closo* structure according to Wade's rules.[15] Taking into account that **3** does not contain any PEt$_3$ ligands (originally present in the starting material **1**), finding a direct synthesis to **3** was challenging. Stannylenes :SnR$_2$ are either able to react as donor or acceptor molecules due to their carbenoid character and the electron-accepting empty π orbitals on tin. Electron-rich metallocenes like nickelocene (**5**) offer either acidic metal sites or basic ligand sites, at which substitution chemistry may proceed (Figure 4). We therefore found that **5** reacts with **2** in fragments, generated thermally from nickelocene, to give the tetranuclear Ni$_2$Sn$_2$ cluster **3**. Veith and Stahl reported a similar reaction of nickelocene with the N-donor-substituted, but more basic, stannylene [Sn(N*t*Bu)$_2$SiMe$_2$}] to yield **4**.[12] Consequently, this reaction resulted in an attack of this stannylene at the acidic Ni center and formal insertion of a stannanediyl fragment into the nickelocene sandwich structure. Obviously, the bis(silyl)stannylene [:Sn{CH(SiMe$_3$)$_2$}$_2$] (**2**) is basic enough to follow this reaction pathway.

With respect to the reactivity of **3**, we observed that if a mixture of **1** and **2** (Equation1) containing **3** is not directly

crystallized from the initial reaction mixture, but still further purified by column chromatography (SiO_2, pentane), aside from **3**, a second compound **6** can be isolated in varying yields. The yield of **6** depends on the chromatography time and age of the stationary SiO_2 phase used. Older charges of SiO_2 containing higher water contents, consequently gave higher yields of **6**. Compound **6** was characterized by spectroscopic data (NMR, MS, and IR). In the mass spectrum, the molecular base-peak for **6** is found at $m/z = 1016$, showing a characteristic Sn/Ni atom isotopic ratio of 2:1 and an initial mass loss of $m/z = [1016 - 17]$, owing to the loss of an OH unit. The OH grouping shows up in the IR spectrum with a sharp OH stretching absorption at $\tilde{\nu} = 3623\ cm^{-1}$.

The ^{1}H-NMR spectrum of **6** gives a characteristic broad OH proton resonance at $\delta = 1.46$ with a $^{119}J_{Sn-H}$ coupling of 12 Hz, which characterizes the Sn−OH−Sn bridge in **6**. Unambigous proof of this assignment and the existence of such a bridging μ-OH ligand came from a deuterium exchange experiment.

Addition of N_2-saturated D_2O to a freshly prepared NMR sample of **3** in N_2-saturated C_6D_6 resulted in a substantial broadening of the initially very sharp OH signal after 5 min contact time, and complete disappearance of the OH proton resonance signal after 30 min, indicating the formation of **5**[OD] by H/D exchange. The remaining proton signals in the ^{1}H-NMR spectrum broaden significantly but do not change their chemical shifts and relative intensity ratios.

To prove the assumption that **6** is not a direct reaction product of **1** and **2**, but is indeed formed by reaction of **3** with water, which must then be responsible for the Ni−Sn bond cleavage of the *closo* cluster **3**, a direct reaction of **3** with H_2O was conducted (Equation 3).

Stirring of an ethereal solution of **3** with a fourfold excess of N_2-saturated H_2O resulted in a color change from brown to red-brown within a few minutes. Workup furnished **6** as brown crystals in 63% yield. All spectroscopic data of **6** obtained by this independent route are in accord with the material obtained by chromatography of **3** on wet SiO_2 as described before. As a result of these experiments it is obvious that **3** is prone to the opening of the butterfly structure by oxidative addition of water. We found that **6** is also formed in a one-pot reaction by addition of excess water to a reaction mixture of **5** and **2** under reflux conditions, followed by subsequent crystallization of the crude material from ether.

A preliminary X-ray crystallographic study of **6** confirms the connectivity of the heavy-atom skeleton containing Sn and Ni, as well as the complete silicon/carbon framework. However, the μ-OH bridge could not be unambigously pinpointed due to the poor crystal quality of **6** obtained so far.[16]

Electrochemistry of 3 and 6

Figure 5 shows the cyclic voltammetric profiles exhibited by complexes **3** and **6** in dichloromethane solution. The dinickel complex **3** displays a rather complicated oxidation pathway (Figure 5, upper trace), in which only the first anodic step exhibits features of transient chemical reversibility (Figure 5, lower trace left). In contrast, the mononickel complex **6** undergoes a single oxidation process, chemically reversible in character on the cyclic voltammetric timescale (Figure 5, right trace).

Controlled potential coulometry ($E_w = +0.5$ V) showed that the oxidation of **6** involves the removal of one electron/molecule. The solution resulting from exhaustive oxidation

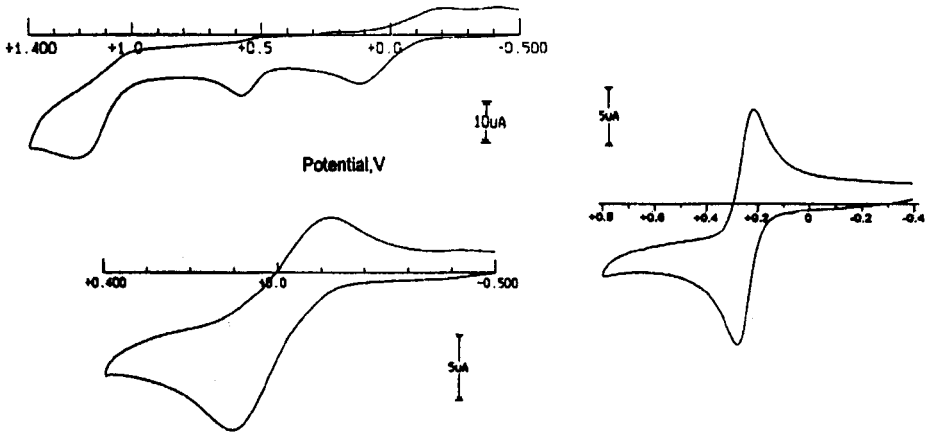

Figure 5. Cyclic voltammetric responses recorded at a platinum electrode in CH_2Cl_2 solutions containing $[Bu_4N][PF_6]$ (0.2 mol dm^{-3}) and **3** (9×10^{-4} mol dm^{-3}) (upper and lower left trace) or **6** (7×10^{-4} mol dm^{-3}) (right trace)

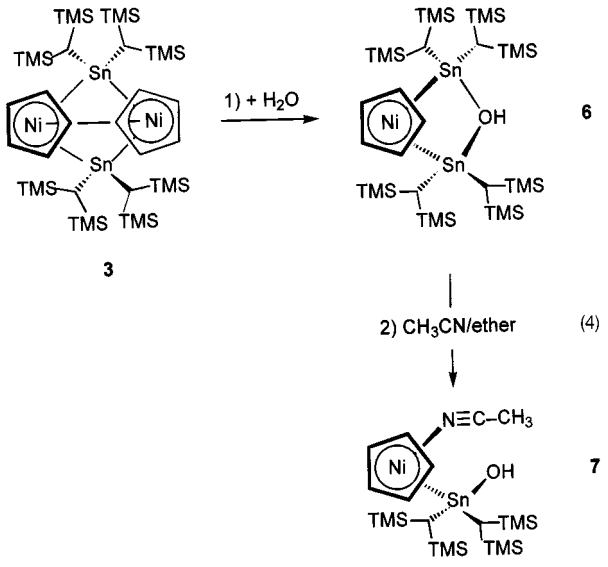

exhibits a cyclic voltammetric profile quite complementary to the original one, thus testifying the chemical reversibility of the redox change **6/6**$^+$ ($E^{\circ\prime}$ = +0.25 V) also during the long times of macroelectrolysis.

The analysis of the cyclic voltammograms of **6** with the scan rate varying from 0.02 Vs^{-1} to 1.00 Vs^{-1} indicates that the anodic step is substantially reversible also from the electrochemical viewpoint, in that the peak-to-peak separation, particularly at slow scan rates, deviates slightly from the theoretical value of 60 mV.[17] For instance, at 0.05 Vs^{-1} it is equal to 70 mV, quite paralleling the value we obtain for the one-electron oxidation of ferrocene under the same experimental conditions ($E^{\circ\prime}$ = +0.38 V). In this picture, the electrochemical reversibility suggests that no significant structural reorganization should accompany the electron removal from **6**.

As far as complex **3** is concerned, we limited our study to the first, partially reversible anodic step (at 0.05 Vs^{-1}, i_{pc}/i_{pa} = 0.7; $E^{\circ\prime}$ = −0.01 V). Controlled potential coulometry (E_w = +0.2 V), even if affected by severe electrode-poisoning phenomena which required repeated cleaning of the electrode surface, seems to involve one electron/molecule. It is important to take into account that after completion of electrolysis a number of new waves appear, which testify the occurrence of framework-destroying processes, but none of this was attributable to the **6/6**$^+$ system. This means that the redox-induced cleavage of the cage of **3**, in spite of the unavoidable presence of traces of water in solution, follows a path different from that illustrated in Equation 3.

Reactivity of 6 Towards CH_3CN

The Sn−OH−Sn bridge in **6** is reactive, and can be opened by a nucleophilic attack, e.g. by acetonitrile. Addition of a large excess of CH_3CN to an ethereal solution of **6** results in a color change from brown-red to blood-red. Prolonged cooling (weeks) of this solution eventually results in brick-red rectangular-shaped crystals of **7** containing a terminal *Ni*-bonded {Sn{CH(TMS)$_2$}$_2$}OH ligand, and a CH_3CN ligand according to spectral data (see Experimental Section) (Equation 4). The OH stretching frequency of **7** at $\tilde{\nu}$ = 3624 cm^{-1} is well in accord with the one observed for **6**.

The molecular structure of **7** in the solid state was determined by X-ray crystallography[9] and displays a two-legged piano-stool geometry at the Ni center (Figure 6), with a trigonal planar structure at Ni as its most prominent feature. The tin atom is coordinated in a strongly distorted tetrahedral environment. The Sn−O bond length [2.017(2) Å] points towards an Sn=O π-bond contribution as it is discussed for [{SnR$_2$(OH)}$_2$(μ-O)] containing a μ-Sn−O−Sn bridge, and two terminal Sn−OH groups [2.032(5) Å].[18] In contrast to **7**, organotin hydroxides often have a bridging OH as in **6** or [Sn(μ-OH)(phenyl)$_3$]$_\infty$.[19] Besides [{SnR$_2$(OH)}$_2$(μ-O)],[18] tris(tropolone)tin hydroxide[20] and [{CH(SiMe$_3$)$_2$}$_2$Sn(H)(OH)],[21] **7** represents another rare case of a compound having a terminal OH functionality.

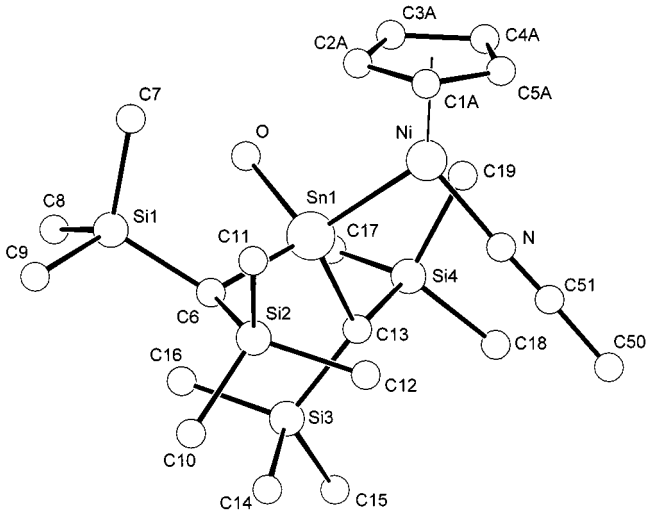

Figure 6. Molecular structure of **7** in the solid state; selected bond lengths [Å] and angles [°]: Ni−Sn 2.472(1), Ni−N 1.829(3), Sn−C13 2.209(3), Sn−C6 2.203(3), Sn−O 2.017, N−C51 1.138(5); C13−Sn−C6 109.3, O−Sn−Ni 109.6(1), C13−Sn−O 102.0(1), O−Sn−C6 102.5(2), C13−Sn−Ni 112.0(2), C6−Sn−Ni 119.6(1), N−Ni−Sn 93.7(1)

Conclusion

Bulky SnR_2 fragments are able to add to the Ni−Ni bond of **2**, forming the tetranuclear Ni_2Sn_2 cluster **3** with a *closo* cage structure. However, steric demands require that both PEt_3 ligands are eliminated in this addition/elimination-type reaction. A novel feature in this complex is the bulky R_2Sn-bridged Ni−Ni bond which is without precedent so far. Compound **3** displays reactivity towards cage opening with H_2O, leading to the trinuclear μ-OH bridged complex **6**. SnR_2 elimination and cleavage of the μ-OH bridge in **3** can be achieved by reaction with acetonitrile. The free coordination site generated by this cleavage is occupied by a σ-donor N→Ni dative bond of the CH_3CN

ligand to the Ni atom. The fact that **3** can be obtained in high yield under mild conditions and is prone to cage opening of its Ni_2Sn_2 skeleton offers some useful features for further studies. It can be envisaged that addition of various nucleophiles other than H_2O are also able to open a synthetic useful pathway into new Ni−Sn organometallics by the cage-opening reaction route of **3**.

The 1:1 Ni/Sn stoichiometry of **3**, as well as its promising evaporation characterictics (10^{-2} Torr/100°C, without decomposition) make **3** an outstanding candidate as single-source precursor to intermetallic nanostructured binary Ni/Sn phases[4][22] by MOCVD techniques. Very recently we have shown that the presence of the bulky mixed hydrocarbyl/organosilyl ligand $\{CH(SiMe_3)_2\}$ in volatile organo-bimetallic main-group complexes is in no way detrimental towards a succesful MOCVD application of organometallic complexes containing this ligand.[23]

Experimental Section

General: All reactions were carried out under dry nitrogen with standard Schlenk techniques. Compounds **1** and **2** were prepared according to published procedures.[2][6] − Microanalyses were performed by the microanalytical laboratory of the Chemistry Department of the University−GH Essen. − All solvents were dried appropriately and were stored under nitrogen. − The NMR spectra were recorded with a Bruker AC 300 spectrometer (300 MHz for ^1H, 75 MHz for ^{13}C) and referenced against the remaining protons of the deuterated solvent. NMR samples were prepared by vacuum transfer of solvents onto the appropriate amount of solid sample, followed by flame sealing of the NMR tube. − MS spectra were recorded with a MAT 8200 instrument using standard conditions (EI, 70 eV) and the fractional sublimation technique for compound inlet. − Materials and apparatus for electrochemistry and coupled EPR spectroscopy have been described elsewhere.[24] − Either a BAS 100 A or a BAS 100 W were used in cyclic voltammetric measurements. The potential values reported refer to the saturated calomel electrode (SCE).

Synthesis of $[\{(SiMe_3)_2CH\}_2Sn-Ni(\eta^5\text{-}Cp)\}_2]$ (3)

A: By Reaction of 1 and 2: To a solution of 700 mg (1.44 mmol) of **1**, dissolved in 100 mL of diethyl ether, was added 1.26 g (1.44 mmol) of dimeric stannanediyl $[\{Sn\{CH(SiMe_3)_2\}_2\}_2]$ (**2**). This solution was refluxed for 24 h resulting in a color change from green-brown to brown. After removal of all volatiles in vacuum, the remaining solid was dissolved in pentane and this solution was filtered. Crystallization at −30°C during the course of several days gave brown crystals of **3** (0.73 mmol, 51%). − MS (EI, 70 eV, T_{vap} = 140°C); *m/z* (%): 1122 (40) [M^+], 963 (30), [M^+ − $CH(SiMe_3)_2$], 685 (15) [M^+ − $Sn\{CH(SiMe_3)_2\}_2$]. − ^1H NMR ([D_6]benzene): δ = 5.30 (s, Cp, 10 H), 2.46 (s, CH, 4 H), 0.32 [s, ^1J(Si,H) = 6.0 Hz, $SiMe_3$, 72 H]. − $\{^1H\}^{13}C$ NMR ([D_6]benzene): δ = 89.12 (s, Cp), 7.91 (s, CH), 5.95 (s, $SiMe_3$) − $C_{38}H_{86}Ni_2Si_8Sn_2$ (1122.58): calcd. C 40.64, H 7.70; found C 40.90, H 7.65.

B: By Reaction of 4 and 2: To a solution of **4** (1.0 g, 5.30 mmol), dissolved in 150 mL of ether, was added 2.32 (2.65 mmol) of $[\{Sn\{CH(SiMe_3)_2\}_2\}_2]$ (**2**). This solution was refluxed for 3 d. Evaporation of all volatiles in vacuum and recrystallisation of the crude residue from pentane gave 1.94 g (1.73 mmol, 64%) of brown crystals of **3**.

Synthesis of $[(\eta^5\text{-}Cp)Ni(\mu\text{-}OH)\{Sn(CH(Si(CH_3)_3)_2)_2\}_2]$ (6): A fourfold excess of N_2-saturated H_2O was added a solution of **3** in diethyl ether {prepared from 0.571 mmol of $[\{Sn\{CH(SiMe_3)_2\}_2\}_2]$ (**2**) and 1.14 mmol of **4**}. After stirring the initial brown solution for about 5 min, a color change to bright red was observed. Additional stirring for 2 h, followed by vacuum removal of all volatiles and recrystallization of the crude residue from diethyl ether at −30°C, gave 368 mg (0.363 mmol, 64%) of **6**. − MS (EI, 70 eV, T_{vap} = 130°C); *m/z* (%): 1016 (20) [M^+], 999 (10) [M^+ − OH] 857(30), [M^+ − $CH(SiMe_3)_2$], 697(100), [M^+ − $[CH(SiMe_3)_2]_2$]. − IR (KBr): $\tilde{\nu}$ = 3623 cm^{-1} (s) (OH), 2949 (s), 2898 (s), 1402 (s), 1250 (s), 839 (br.), 784 (br.) (all tms), 1348 (s), 1315 (s), 1294 (s), 1139 (s), 959 (s) [all Cp]. − ^1H NMR ([D_6]benzene): δ = 5.23(s, Cp, 5 H), 1.46 [br. s, $^2J(^{119}Sn,H)$ = 12 Hz, OH, 1 H], 0.67 (s, CH, 4 H), 0.42 (s, $SiMe_3$, 36 H), 0.24 (s, $SiMe_3$, 36 H). − $\{^1H\}^{13}C$ NMR ([D_6]benzene): δ = 88.4 [s, $^2J(^{119}Sn,C)$ = 19 Hz, Cp], 20.66 (s, CH), 5.17 [s, ^3J(Sn,C) = 15 Hz, $SiMe_3$], 4.29 [s, $^3J(^{119}Sn,C)$ = 15 Hz, $SiMe_3$]. − $C_{33}H_{82}NiOSi_8Sn_2$ (1015.79): calcd. C 39.00, H 8.14, found C 39.06, H 8.15.

Synthesis of $[(\eta^5\text{-}Cp)(CH_3CN)Ni-Sn(OH)\{CH(Si(CH_3)_3)_2\}_2]$ (7): A fourfold excess of N_2-saturated H_2O was added to a solution of **3** in 50 mL of diethyl ether {prepared from 0.571 mmol of $[\{Sn\{CH(SiMe_3)_2\}_2\}_2]$ (**2**) and 1.14 mmol of **4**}. After stirring of the initial brown solution for about 5 min, a color change to bright red was observed. After additional stirring for 2 h, 25 mL of ether was removed under vacuum and replaced by 20 mL of acetonitrile. This solution was filtered and stored for two weeks at −20°C whereupon 730 mg (0.72 mmol, 79%) of brick-red crystals of **7** could be isolated, co-crystallized with 220 mg (0.25 mmol) of **1**. These two compounds were then separated mechanically. − ^1H NMR ([D_6]benzene): δ = 5.29 (s, Cp, 5 H), 1.48 (br. s, *J* = 24 Hz, OH, 1 H), 0.78 (s, C−CH_3, 3 H), 0.43 (s, $SiMe_3$, 36 H). − $\{^1H\}^{13}C$ NMR ([D_6]benzene): δ = 94.48 (s, C_{Sp}), 88.58 [s, Cp, ^2J(Sn,C) = 14.3 Hz], 20.88 [s, CH, $^1J(^{119}Sn,C)$ = 117 Hz, ^1J(Si,C) = 39.0 Hz], 5.36 [s, $SiMe_3$, ^3J(Sn,C) = 16 Hz]. − IR (KBr): $\tilde{\nu}$ = 3624 cm^{-1} (OH), 3220, 2271, 1371 (CH_3CN), 2947, 2923, 2894, 1249, 1015, 841, 663, 608, 521 (all tms), 3088, 2961, 2835, 1400, 1346, 1292, 1242, 1108, 779 (all Cp).

Acknowledgments

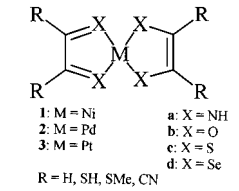
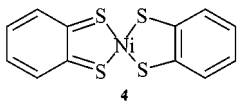
Density Functional Derived Structures and Molecular Properties of Nickel Dithiolenes and Related Complexes

Christa Lauterbach[a] and Jürgen Fabian*[a]

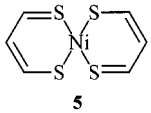


Keywords: Metal dichalcogenolene / Density functional calculations / Cyclic π-electron delocalization / Nickel



The molecular and electronic structure of the planar nickel dithiolene (**1c**, R = H) and of related complexes derived from nickel dithiolene by replacement of Ni by Pd (palladium dithiolene, **2c**, R = H) or by Pt (platinum dithiolene, **3c**, R = H), or by replacement of S by NH (nickel diiminolene, **1a**, R = H), O (nickel dioxylene, **1b**, R = H) or Se (nickel diselenolene, **1d**, R = H), were studied by density functional theory using the B3LYP functional and the valence triple-zeta basis set 6-311+G* for all atoms except Pd and Pt. For the latter atoms the quasirelativistic effective core potentials of the Stuttgart group were employed. The molecular structure of nickel dithiolene (**1c**, R = H) is satisfactorily reproduced by DFT calculations. The geometry of the corresponding platinum complexes **3a–3d** is more sensitive to relativistic effects, resulting in the contraction of the X–Pt bonds. As shown with the metal dithiolenes, the two ligands are structurally related to mononegative ions of open shell structure. The C–C bond lengths of the complexes are close to those of aromatic and chain-type polymethine structures (about 1.4 Å). The nickel dithiolene (**1c**, R = H) and related complexes have D_{2h} symmetry and are 14 π-electron systems with 10 π-electrons at the ligands and 4 π-electrons at the metal center. The natural population analysis has confirmed that metal M^{++} does accept electrons from the ligands but to a lesser extent than expected. The empty d-orbitals of M^{++} are only partly occupied in the molecular ground state. The positive charge of the metal decreases in the order Ni > Pd > Pt. The ^{1}H chemical shifts and the nucleus-independent chemical shifts (NICSs) of the ring moieties calculated by GIAO-DFT display a pronounced electron delocalization. In agreement with the calculated C–C bond lengths the ^{1}H chemical shifts and the NICS values show a marked bond delocalization. The NICS values show a change of the aromatic delocalization in the order Ni > Pd < Pt and NH > O < S < Se. The wave numbers of the IR spectra of the complexes calculated by DFT are grouped in separate frequency regions. The very intense absorption of **1c** (R = H) in the visible region of the spectrum is surprisingly well reproduced by ab initio single-only configuration interaction calculations. While the color band of the palladium complex is predicted to be red-shifted relative to the nickel complex, a blue shift is calculated on passing from the palladium to the platinum complex. The blue shift is, in part, due to the relativistic contraction of bond lengths in the Pt complexes.

Introduction



The complexes **1**−**4** (henceforth called metal diheterolenes) are 16-electron metal complexes. In the formal oxidation state of +2 they have a square-planar coordination and two planar bidentate ligand systems. In contrast to porphyrin-based complexes with a metal ion within the cyclic ligand and metallocene-type complexes with a metal ion intercalated between two planar ligands, diheterolenes contain the metal ion as a link between two planar ligands, forming a coplanar compound with five-membered conjugated rings. The metal ion is part of a delocalized π-electron system.

Nickel dithiolenes were first synthesized in the 1960s and the results of the subsequent extensive research were reviewed by Schrauzer,[1][2] Eisenberg,[3] Hoyer,[4][5] Burns[6] and Mueller-Westerhoff[7] and co-workers. Early semiempirical quantum chemical studies revealed the ground-state configuration of the parent nickel dithiolene with the highest occupied (HOMO) and lowest unoccupied molecular orbital (LUMO) of π-type character.[1][2] The lowest unoccupied molecular orbital is mainly located at the ligand. Nickel dithiolene (**1c**, R = H) is a 14 π-electron system with five π-electrons at each ligand and four π-electrons at the nickel center.[8] This complex is clearly distinguished from the bis(3-thioxopropene-1-thiolato)nickel complex **5**, which is a 16-π system with six π-electrons at each ligand.

Viewed in terms of building units of appropriate oxidation states, the dithiolene complexes are derived from M^{2+} and two dimethine radical anions that are terminated by sulfur atoms. These components constitute the neutral complex. Such a ligand system is a member of a series of vinylogous $[N + 1]\pi$ polymethines (polymethine violenes) with $N = 4$.[9] In the composite complex the spins of the radical fragments are paired. This composition of the complex may suggest some biradical character and therefore a nonclassical fragment structure. In fact, to avoid nonsymmetrical formulae, nickel dithiolenes were first represented as resonance hybrids of two Lewis−Kekulé-type structures[1][2] **A** and **B**.

Scheme 2

Complexes related to nickel dithiolene (**1c**, R = H) contain metal atoms M, such as Pd (**2**) and Pt (**3**) in place of Ni (**1**), and hetero atoms X such as NH (**a**), O (**b**) or Se (**d**) in place of S (**c**). Nickel complexes are the most extensively studied so far in this field,[1−8,10] and knowledge about the Pd[11−13] and Pt complexes[14−17] is mainly restricted to compounds with more complex ligands or to metal−metal-bonded dimers.[18][19] The nickel complexes are unique in their electronic, optical and photophysical properties. The facile and reversible electron transfer of **1c**-type complexes has been taken as a model in the study of the function of nickel-containing enzymes.[4,5,20] Nickel dithiolenes may also serve as catalysts.[4][5] These compounds form stacks in the solid state or segregated stacks with donor molecules such as tetrathiofulvalene (TTF) and TTF-type compounds and are electric semiconductors or conductors ("1D metals").[21−27] Complexes with 2-thioxo-1,3-dithiole-4,5-dithiolate and related ligands have attracted particular attention. On the other hand, nickel dithiolenes are chromophores that exhibit intense long-wavelength absorptions in the visible or in the near infrared region of the spectrum[10,12,28−32] up to wavelengths of 1400 nm and with absorption coefficients as large as 80000 $cm^2 \cdot mmol^{-1}$. Given their ability to inhibit photofading of organic dyes they were studied in optical data storage systems[12] and, more recently, as near infrared laser dyes.[10][28] Nickel dithiolenes are versatile building blocks for the design of functional supramolecular arrays and polymer systems[33] and in the search for materials for the emerging optoelectronic technology. Conducting nickel dithiolenes and crown ethers form ion channels in the solid that are potential switches.[34] Efficient second-order NLO chromophores have been recently inserted in a layer of a nickel dithiolene derivative.[27]

We are aware of only a few high-level quantum chemical calculations on metal diheterolenes. These calculations were performed on particular complexes. The parent nickel dithiolene (**1c**, R = H) was calculated by Hartree−Fock,[35−37] by post-Hartree−Fock second-order perturbation theory[38] and by density functional theory.[12] The spin densities of a substituted nickel dithiolene[20] (**1c**, R = CN) were also studied by the latter method. The INDO-type semiempirical CIS approach was used in a basic study of structure and electronic excitation of nickel dithiolene.[8] Nickel dithiolene was first studied by extended Hückel[37] and Pariser−Parr−Pople calculations.[39]

The availability today of low-cost methods for density functional theory (DFT) and of well-defined quasirelativistic effective core potentials of transition metals enables more extended series of compounds to be studied. The purpose of this study is to calculate structure and structure-property relationships of the parent complexes **1**−**3** and of compounds derived from these by substitution of R (R = SH, SMe, CN) by density functional theory (DFT). For the sake of comparison, compounds **4** and **5** were also calculated. The question has been asked as to what extent electron excitation energies are satisfactorily predicted by ab initio calculations based on DFT optimum geometries.

Computational

DFT quantum chemical calculations were carried out using the 1994 release of the GAUSSIAN suite of programs.[40] The functional used throughout this study consists of a nonlocal hybrid HF/DF exchange functional as defined by Becke's three-parameter-equation[41] in conjunction with the nonlocal Lee−Yang−Parr correlation functional[42] (B3LYP for short). In numerous recent calculations DFT provided results that are comparable with those of post-Hartree−Fock ab initio quantum chemistry. For the sake of comparison, MP2 calculations were also performed with the inner electrons kept frozen. Open-shell structures were calculated by the unrestricted Kohn−Sham method. The eigenvalues of the S^2 operator, calculated as 0.76 and 2.03 at maximum, differ only slightly from the exact values (0.75 and 2.0, respectively) thus indicating low-spin contamination. The ground-state geometries were obtained by full geometry optimization. The optimum structures were confirmed by the Hessians. The second derivatives provided the harmonic vibrational frequencies, which were not corrected in this paper for anharmonicity and additional correlation effect by scaling. The calculations were performed by the valence triple-zeta basis set 6-311G augmented by a set of polarization and a set of diffuse functions at the nonhydrogen atoms. The basis set 6-311+G* was used throughout this study. Effective core potentials (ECP) were employed for complexes with Pd and Pt but not for the majority of calculations of complexes with Ni. Central to the concept of effective core potentials is the idea that electrons of the atomic inner shells are chemically inactive and can be substituted by an effective core potential instead being treated explicitly.[43][44] Furthermore, relativistic effects can be incorporated in full-relativistic or quasi-relativistic ECPs .[43−45] Calculations of Pt- and Pd-containing complexes were performed using the beyond Hartree−

Fock quasirelativistic effective core potentials ECP28MWB and ECP60MWB, respectively, which were developed by Stoll and Preuß.[46] The valence basis set is (8s7p6d)/[6s5p3d] in these cases[46] with an additional p-type polarization function for each of the two metals.[47] Since well-known relativistic effects may play an essential role in describing structure and properties of higher row transition-metal compounds,[43−45] the nonrelativistic effective core potential ECP60MHF[48] of Pt was also used for the sake of comparison. The calculations of ^{1}H chemical shifts and of the nucleus-independent chemical shifts (NICSs) were performed by the gauge-including atomic orbital procedure, designated by GIAO-DFT. Because of computational problems in calculating NICSs of complexes containing transition metals by hybrid HF/DF functionals using GAUSSIAN 94, $\delta(^1H)$ chemical shifts and NICS values were calculated by the BLYP functional.[49] NICS values are probes for the extent of "aromatic" electron delocalization in cyclic conjugated systems. These values were defined by von Ragué-Schleyer et al.[50] as the negative values of the isotropic magnetic shieldings in ppm calculated at the center of the rings. NICS1 values refer to the location 1 Å above the center. In the NICS1 values local contributions of the σ-bonds are reduced in favor of the π-effects.[51]

Electronic transition energies were calculated at DFT optimum geometries by full single configuration interactions (CIS) at the ab initio level of theory[52] using the 6-311+G* basis set. Atomic charges were derived by Weinhold's natural population analysis (NPA) using the natural orbital (NBO) partitioning scheme.[53][54] Along these lines the electron population of the π-type orbitals was evaluated in terms of the p_π and d_π contributions of the nonhydrogen atoms.

Results and Discussion

Structure

Selected structural data of the compounds 1−5, optimized by DFT, are collected in Table 1 along with the available experimental data. Experimental parameters were determined by X-ray structure analyses. The experimental data of the Pd complex refer to a substituted Pd dithiolene with monomeric subunits. Experimental M−X bond lengths were found to be shorter in the crystal than those of gas-phase structures.[55] In addition, DFT bond lengths of second and higher row main-group elements are systematically too large.[56] C−S bond lengths, for instance, are overestimated by about 0.03 Å. Given these limitations the agreement between theory and experiment is satisfactory.

Inspection of the data collected in Table 1 shows that the bond lengths are sensitive to the nature of the metal, M, as well as to the hetero atoms, X. As one would expect, the M−S bond lengths in the series of metal dithiolenes increase on passing from Ni−S (2.178 Å) to Pd−S (2.310 Å) and Pt−S (2.314 Å). Thus, the bonds of Pd−S and Pt−S are nearly equal in length. The Pt−S bond length is overestimated if relativistic effects are neglected (ECP60MHF of Pt). The Pt−S bond is contracted by 0.09 Å on replacing the nonrelativistic by the quasirelativistic effective core po-

[a] Ref.[8] – [b] Ref.[3] – [c] Ref.[37] – [d] Experimental data from averaged bond lengths of a substituted palladium dithiolene, see ref.[12] – [e] ECP60MWB of Pt instead of the ECP60MHF.

tential. The C−C bond lengths of the Pt complexes are only slightly shortened and the C−X bonds slightly lengthened. In the series **1c**−**3c** (R = H) the C−S bond lengths are nearly constant (1.71 Å). The lengths of these bonds are practically unaffected by the choice of the effective core potentials. According to the DFT calculations, substitution of the hydrogen atoms of nickel dithiolene by CN (**1c**, R = CN) results in a slight increase in the C−S and C−C bond lengths, whereas the Ni−S bond lengths are slightly shortened. The extension of the C−S bond length is confirmed by the X-ray data. However, the extension in the bond length of the C−C bond with donor and acceptor substitution is noticeable. The bond lengths increase from 1.374 Å (H) to 1.399 Å (CN) and 1.404 Å (SMe).

The C−C bond lengths of the complexes should be an indicator of the cyclic electron delocalization. The calculated C−C bond lengths are mostly affected by the hetero atom X and are in the range between 1.36 Å (X = Se) and 1.40 Å (X = NH). The latter value corresponds to the bond lengths of benzene. According to the C−C bond lengths the degree of bond delocalization decreases in the order NH = O > S > Se. The conjugated electronic system of the complexes appears more or less delocalized. As would be expected, the C−C bond lengths of the dithiolene **4** are more benzenoid if the C−C bonds are simultaneously part of an annulated benzenoid ring. These compounds seem to be only known as anions,[57] a situation that is in contrast to the analogous nitrogen-containing hetero compounds.[58]

In the case of nickel dithiolene (**1c**, R = H) the geometrical parameters were calculated both by DFT and ab initio MP2 with the same basis set 6-311+G* for all main atoms. The most interesting bond lengths are compared in Figure 1.

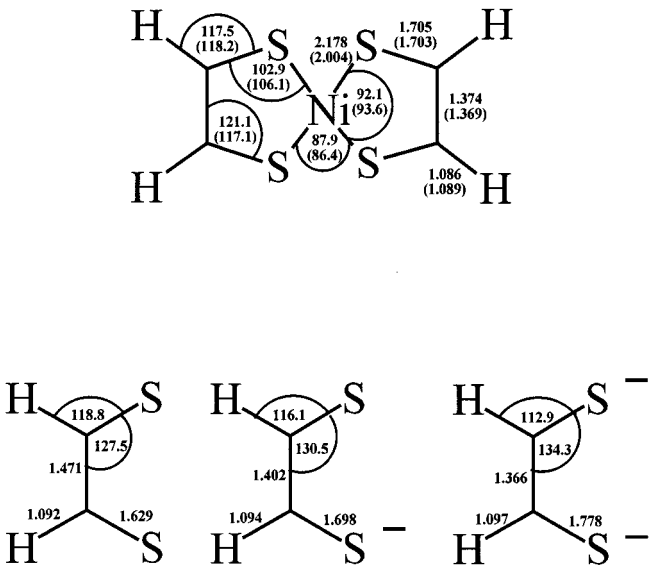

Figure 1. Comparison of selected bond lengths [Å] and bond angles [°] of nickel dithiolene (**1c**, R = H) calculated by DFT (B3LYP/6-311+G*) and by ab initio MP2/6-311+G* calculations (MP2 in parentheses) and the neutral, mononegative and dinegative ligand molecules

Except for the S−Ni bond the differences in the bond lengths calculated by the two theoretical models are remarkably small and confirm the good performance of DFT with respect to ab initio calculations. Because experimental geometries of **1c** (R = H)[3] do not refer to free molecules, the S−Ni bond length does not allow more detailed evaluation of the two methods. It should be mentioned that replacement of the all-electron treatment of Ni by the full-relativistic effective core potential ECP10MDF gives essentially the same bond lengths. The MP2 S−Ni bond length of nickel dithiolene (**1c**, R = H) reported in the literature[38] is between those found in this paper by the different theoretical models. This calculation was performed with a minimal basis set and the LANL1DZ effective core potential of Ni and S atoms.

The C−C bond lengths of the ligands in the complex differ greatly from those of the dithial and ethene-1,2-dithiolate ligand systems, which are the precursor compounds in the synthesis of the complex using reductive and oxidative conditions, respectively. However, the most closely related ligand is the sulfur-terminated dimethine radical. The C−C and C−S bond lengths of this radical are 1.402 and 1.698 Å, respectively, compared with 1.374 and 1.705 Å in the nickel dithiolene complex (see Figure 1).

Electron Distribution and Bonding

The total atomic charges and the population of π-type orbitals are determined by NBO analysis and are listed in Tables 2 and 3, respectively.

[a] Total population of π-type orbitals at the parent complexes. − [b] ECP60MWB of Pt instead of the ECP60MHF. − [c] Non-adjacent to sulfur.

tive charges alter in the order: Ni > Pd < Pt. The atomic charge of Ni in nickel dithiolene is +0.46. In other words, 1.54 electrons are transferred from the two ligands to Ni^{++}. The charge at the Ni increases to a maximum value of about +1 when S is replaced by N or O. Thus, the charge of the Ni is less than expected given the oxidation number of Ni^{II}. The negative charge at the hetero atoms, X, decrease in the order NH > O and becomes positive with S and Se. The carbon atoms adjacent to the chalcogen atoms are also negatively charged. As expected, substituents R may act as donors (SMe) or as acceptors (CN) relative to hydrogen. The effect of the CN acceptor group is characterized by the considerably reduced electron population at the hetero atoms X.

According to the NBO analysis, the occupation of the p_π orbitals of the metal center is negligibly small while the two d_π orbitals are occupied by about 3.8 electrons (see Table 3). The d_π orbital population of the carbon and the hetero atoms is less than 0.005 and, therefore, not listed in Table 3. The populations of the p_π orbitals of nickel dithiolene (**1c**, R = H) at the sulfur and carbon atoms (1.500 and 1.045, respectively) are reminiscent of those in the dimethine ligand system with values of 1.437 and 1.058, respectively. The highly delocalized π-system of the dimethine radical is essentially retained in the complex. The electron populations of the hetero atoms X shows that their donor strength in the π-system is in the order (NH, O) < (S, Se). Clearly, the more polarizable atoms are more strongly involved in the delocalization. Inspection of the electron occupation shows that the 4s and 4p orbitals of the metal center are hardly occupied. This clearly conflicts with the dsp^2-hybridisation model. According to the NBO analysis the d^8 element Ni is occupied by 9.54 electrons ($3d^{9.01}\ 4s^{0.45}\ 4p^{0.07}$) in the nickel dithiolene parent complex. The occupation of the metal 4p orbital is very low. There is an increasing doubt[59] as to whether NBO analysis provides an adequate occupation of (n + 1)p orbitals of transition metals. The occupation is considerably larger if p orbitals are enclosed in the valence shell.[60]

In agreement with Zerner et al.[8] the complex **1c** (R = H) is a 14π-electron system. According to the DFT calculations this conclusion holds for the whole series **1**−**3**. As expected, the metal complex **5** is a 16π-electron system. The electron structure of **5** differs slightly from **1c** (R = H) in the population of π-type orbitals of metal and hetero atoms and in the total amount of electrons that occupy π-type orbitals due to the presence of two more π-type orbitals at the two additional carbon atoms (see Table 3).

Spectral Properties

Because of their intense long-wavelength light absorption, nickel dithiolene and related compounds are well characterized by UV/Vis spectroscopy. For the whole series of compounds considered, one intense low energy electron transition appears in the visible or near infrared region. The calculated absorption wavelength of 623 nm (vertical transition) of nickel dithiolene (**1c**, R = H) has to be compared with the value of 719 nm measured in hexane.[8] Thus, the calculated absorption is about 100 nm in error, a deviation that corresponds to 0.27 eV in units of energy. In general, the error of CIS transition energies is larger.[61] According to CIS calculations of **1**−**3**, the color-determining π→π* ($A_g - B_{3u}$) transition is allowed and of large intensity. This finding is in agreement with previous semiempirical calculations on nickel dithiolenes.[1,2,8] The electronic transition is essentially determined by the HOMO−LUMO one-electron transition. The HOMO (b_{1u}) and LUMO (b_{2g}) are essentially localized over the two ligands (intra-ligand tran-

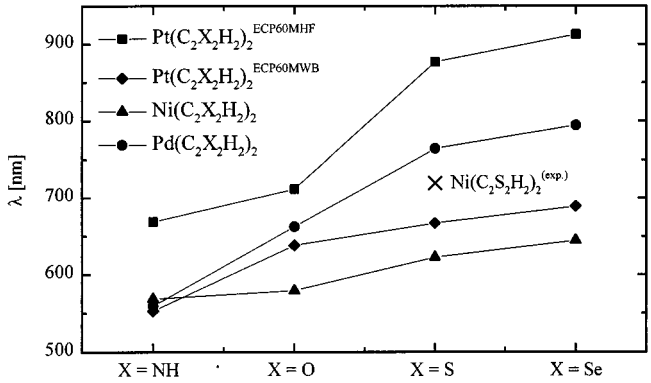

Figure 2. Absorption wavelengths [λ] of the complexes **1**−**3** (R = H) of the first intense electronic transition π→π* in the visible region of the spectrum (experimental value λ_{max} in hexane see ref.[6])

sition). A $3d_{\pi}$-type orbital of the metal ion contributes to the LUMO to a minor extent only. Due to the HF-based single-only approximation the calculated oscillator strengths are too large. In accordance with the predominant localized nature of the frontier orbitals, the ligand-to-metal CT character of the color-determining transition is small and amounts only to 0.01 electrons. As long as the nonrelativistic effective core potential of Pt was used (ECP60MHF) for the CIS calculations the absorption wavelengths of the color band λ_{max} are predicted to increase in the order Ni < Pd < Pt and NH < O < S < Se for nickel dithiolene complexes (see Figure 2 and Table 4). However, the calculated absorption wavelength of the platinum complex is lower than that of the palladium complex if the quasirelativistic ECP60MWB for Pt is taken into account (see Figure 2 and Table 4). The spectral shift is clearly due to the relativistic Pt−S bond contraction that naturally results in an increased energy gap as well as the relativistic destabilization of the LUMO, which includes $5d_{\pi}$-type orbitals.[45] This conclusion was supported by additional calculations: The CIS absorption wavelengths were calculated by using both nonrelativistic and quasirelativistic ECPs for **3c**, whose geometry was optimized without consideration of any relativistic effects. The quasirelativistically calculated absorption wavelength is nearly 100 nm blue-shifted in comparison with that calculated nonrelativistically. If the absorption energy of **3c** is calculated with quasirelativistic ECPs and with the molecular geometry optimized in the same quasirelativistic approximation, then the absorption wavelength is nearly 200 nm blue-shifted.

Thus, the absorption wavelength is predicted to increase on passing from the Ni to the Pd complexes and to decrease from the Pd to the Pt complexes.

HOMO−LUMO energy gaps calculated by RHF ab initio methods are, in general, not used to estimate electron-excitation energies and the calculated energies are much to high. This is not the case with the corresponding Kohn−Sham orbital gap (see Table 4). Encouraged by a recent study,[62] DFT energy gaps were also calculated. The results are listed in Table 4. As can be seen, both the energy differences of the Kohn−Sham frontier orbitals and the CIS excitation energies are nearly of the same order of magnitude and in the correct order: Ni < Pd ≥ Pt (see ref.[21]). Finer details, however, are not reproduced. Whereas the effect of the different metal ion is correctly calculated, the effect of the hetero atoms is at variance with the results of the CIS calculations.

It should be mentioned that the recently tested and very promising time-dependent density functional theory (TD-DFT) methods[63] predict the color band in the visible region at nearly the same absorption wavelength (656 nm) as CIS (623 nm) for nickel dithiolene (**1c**, R = H) based on

the DFT optimum geometry using the 6-311+G* basis. The TD-DFT calculation with the smaller basis set (6−31+G*) provides nearly the same absorption wavelength (655 nm) and is more economical.

Biradicaloid chromophoric ylides may have exceptional behavior in that the visible absorption features are well predicted.[64][65] Therefore, the question has been asked as to whether the complexes **1a**−**1d** may be biradicaloid as well. The biradicaloid character should be indicated by the S_0/T_1 splitting energy. The adiabatic S_0/T_1 energy gaps were therefore calculated by an energy-difference method by (U)DFT after optimization of the singlet and triplet molecules (see Figure 3). U in (U)DFT stands for unrestricted Kohn−Sham used in the calculation of the triplet molecule.

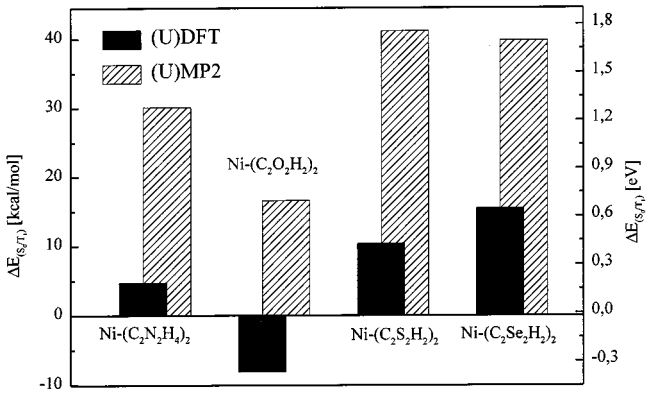

Figure 3. The adiabatic singlet/triplet (S_0/T_1) splitting energies of the complexes **1a**−**1d** (R = H) calculated by (U)DFT (B3LYP/6-311+G*) and (U)MP2 (B3LYP/6-311+G*)

Except for the oxygen-containing complex **1b** (R = H) all molecules are calculated with singlet multiplicity in the ground state. The adiabatic S_0/T_1 energy gap of nickel dithiolene (**1c**, R = H) calculated by (U)DFT is low (10.4 kcal/mol). Because (U)DFT seems to underestimate the singlet-triplet gap, the calculations were repeated on the (U)MP2 level of theory. In this approximation the energy gap amounts to 41.2 kcal/mol for nickel dithiolene. This splitting energy is clearly outside of the range of typical singlet biradicaloid organic compounds (about 25 kcal/mol[66]). In contrast to the (U)DFT calculations, (U)MP2 predicts the oxygen-containing complex **1b** (R = H) as a biradicaloid singlet molecule with an S_0/T_1 splitting energy of about 16 kcal/mol (see Figure 3).

The vibrational spectra of the parent structures **1a** (R = H), **2a** (R = H) and **3a** (R = H) have 45 normal modes, and all the other parent structures of the series **1**−**3** have 33 modes. Because of the D_{2h} symmetry the vibration belongs to 8 representations. Only vibrations due to the representations B_{1u} (out of plane), B_{2u} and B_{3u} (in plane) are allowed in the infrared spectrum and are considered in the following discussion. The calculated wave numbers are hardly dependent on the metal. The line spectra presented in relative intensity in Figure 4 are well grouped in few frequency regions.

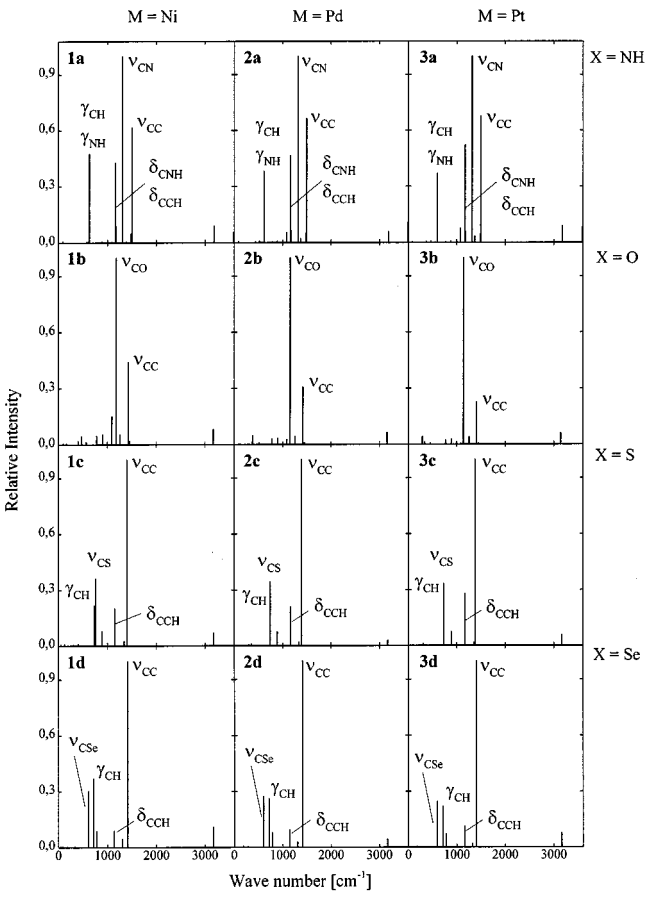

Figure 4. Line spectra of the allowed vibrations of **1**−**3** and assignments of the most intense transitions (relative intensity with respect to the most intense vibrational transitions)

As already documented in some cases, vibrations including the metal center are of small energy. The frequencies are lower than 500 cm^{-1} and of low intensity. However, the intensity of the whole spectrum seems to be greatly dependent on the hetero atoms X. The most intense IR vibrations are ν_{CN}, ν_{CO} and ν_{CC}.

The allowed vibrational frequencies of nickel dithiolene (**1c**, R = H) are compared with data of three experimental studies[67−69] in Table 5. In order to facilitate comparison of the frequencies they are classified according to the symmetry. This classification was also undertaken in two of the experimental studies.[67][68] As far as possible the assignments were given with the same descriptors. The assignments in refs.[67][68] were based on normal coordinate analyses and, in part,[67] on nickel isotope substitution.

The best agreement between the data predicted by DFT and experimental findings was reported by Schläpfer[67] et al. The assignment of the vibration for the systems reported in this paper is fully confirmed. The most intense calculated frequencies deviate by 40 cm^{-1} at maximum without scaling. Some vibrations, such as C−H, C−S and C=C, appear twice in the experimental spectrum.[67] Higher frequencies are overestimated because of the fact that anhar-

[a]Assigned by animation of the calculated vibrations (program: GAUSSIAN94, GAUSSVIEW). – [b] Ref.[67] – [c] Ref.[68] – [d] Ref.[69], no classification of the representations was given.

monicity has been neglected and insufficient consideration has been given to the electron correlation. The assignment in this study does not correspond with that of ref.[68] in the region between 700 and 800 cm^{-1} (see Table 5). The intense vibrations in the region 50 to 500 cm^{-1} found by Adams[69] et al. are also not confirmed.

The C=C frequency of the experimental and theoretical studies is remarkably low. For comparison, the IR spectrum of 2*H*-1,3-dithiole **7** was calculated. The metal of the five-membered ring is now replaced by CH_2. Whereas the C=C vibration of **7** was calculated at 1598 cm^{-1}, the C=C frequency of nickel dithiolene (**1c**, R = H) appears at 1397 cm^{-1}. The assignment of this vibration is more complicated, with the CCH bending also being involved in the vibration.

6 **7**

Scheme 3

The NMR chemical shifts may provide information regarding the electronic structure of the complexes. The paramagnetic ^{1}H chemical shift is a probe for cyclic electronic delocalization.[70] The results of the calculations are gathered in Table 6. The calculated ^{1}H chemical shifts are compared with experimental data of ref.[7] in the cases of **1c**, **2c**, **3c** and **5**. The theoretical ^{1}H chemical shifts of these compounds are slightly underestimated by our calculations compared to the experimental values.

For the sake of comparison the corresponding ^{1}H chemical shifts of 1,3-dithiolylium (δ = 8.95) (**6**) and 2*H*-1,3-dithiol (δ = 5.58) (**7**) were also calculated. Compound **6** is a prototype for a delocalized 6π-electron system with two sulfur atoms, while the bond system is fully localized in **7**. The proton shifts of the complexes **1**–**5** are strongly low-field shifted with respect to the shift in **7** and approach that of the cationic system **6**. Thus, all calculated compounds **1**–**3** seem to have a cyclic electron delocalization, which is in the order NH < O < S < Se and Ni ≈ Pd ≈ Pt.

Finally, Schleyer′s nucleus-independent chemical shifts (NICSs)[50] are considered as a probe of "aromatic" delocalization (see Table 6). NICS values of less than about δ = −3 indicate aromatic delocalization in organic compounds.[71] For nickel dithiolene the calculated NICS values are lower than δ = −8 and indicate aromatic delocalization. According to NICSs the complex **5**, with two six-membered rings, appears to be less delocalized. Electron delocalization is also supported in the five-membered rings of the annulated aromatic rings of **4**. The NICS values of the benzene rings of **4** are about δ = −6.6. The NICS values decrease in the order Ni > Pd > Pt if the Pt complexes were calcu-

Table 6. ^{1}H-NMR chemical shifts and nucleus-independent chemical shifts (NICS) [ppm] calculated by GIAO BLYP/6-311+G*, based on the B3LYP/6-311+G* optimum geometries

		X = NH	X = O	X = S[a]	X = Se

				−6.64/−8.51[f]	
	5			−1.37/−1.54	

[a] Experimental value from ref.[7] in parenthesis, measured in $CDCl_3$. − [b] ECP60MWB of Pt instead of ECP60MHF. − [c] The larger value of the ^{1}H-chemical shift belongs to the carbon atom adjacent to the sulfur atom. − [d] NICS/NICS1 of benzene: −7.7/−9.9, calculated by GIAO BLYP/6-311+G*; NICS/NICS1 of benzene: −9.7/−11.5, calculated by HF/6−31+G* (Schleyer et al.[50]). − [e] NICS/NICS1 of the five-membered ring. − [f] NICS/NICS1 of the annelated aromatic ring.

lated with the nonrelativistic effective core potential ECP60MHF. Thus, the aromatic delocalization of Pt-containing complexes appears low in this classification scheme. If relativistic effects for platinum are taken into account, the NICS values alter in the order Ni > Pd < Pt, and the Pt complexes seem to be more aromatic. NICS1 values confirm these conclusions. Less is known of specific effects of the metal on NICS values.

Conclusions

A series of iso-π-electronic metal complexes of the same topology was considered and calculated by the Hohenberg−Kohn−Sham density functional theory. Valence triple-zeta basis sets augmented by two sets of polarization functions and quasirelativistic effective core potentials for transition metals were used. As shown with nickel dithiolene, experimental bond lengths and bond angles are satisfactorily reproduced by DFT calculations. A remarkable relativistic M−X bond length contraction is calculated for platinum complexes. The calculated C−C bond lengths of all Ni, Pd and Pt complexes are in the range between 1.36 Å and 1.40 Å. The strong bond delocalization is supported by the proton chemical shift calculated by GIAO. The chemical shifts are low-field shifted with respect to protons at the double bond in a nonconjugated system. The aromatic delocalization is also supported by Schleyer′s nucleus-independent chemical shift. Ab initio CIS calculations predict satisfactorily an intense absorption in the visible region. The transition is essentially a π→π* transition between HOMO and LUMO and is mainly located at the ligand. According to CIS calculations the wavelengths of the color band λ_{max} increases in the order NH < O < S < Se and Ni < Pd > Pt. The singlet/triplet (S_0/T_1) splitting energies of the complexes **1a**−**1d** (R = H) calculated by the energy difference method by (U)DFT is relatively small. The larger values obtained by (U)MP2 are more reliable. The biradicaloid character of nickel diheterolenes suggested by the formula representation with 5 π-electrons at each ligand is therefore not supported in general, except for the oxygen-containing complex. The electrons clearly interact strongly through the metal center

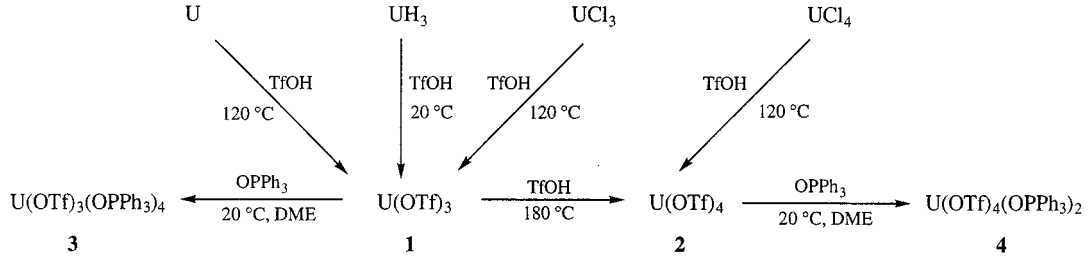
Reactions of pure triflic acid (TfOH) with UH_3 at 20 °C and with U or UCl_3 at 120 °C afforded $U(OTf)_3$ (**1**), which was transformed into $U(OTf)_4$ (**2**) by reaction with TfOH at 180 °C; **2** was also synthesized by treating UCl_4 with TfOH at 120 °C. The yields were in excess of 90%. The crystal structure of $[U(OTf)_2(OPPh_3)_4][OTf]$ (**3**) was determined, which revealed a seven-coordinate uranium(III) centre bound by monodentate and bidentate triflate ligands.

The widespread interest in metal triflates in both organic and inorganic chemistry[1] prompted us to consider the potential of such complexes of uranium. We recently reported on the first uranium(IV) triflates, $U(OTf)_4(NC_5H_5)$ (OTf = OSO_2CF_3), as well as on some organometallic derivatives. These were prepared by a novel synthetic route, namely the protonolysis of alkyl and amide precursors with pyridinium triflate.[2] Following these first results, it soon became apparent that further studies of uranium triflates would be considerably expedited if we had at our disposal sufficient quantities of the base-free complexes $U(OTf)_3$ (**1**) and $U(OTf)_4$ (**2**). Here, we present simple, large-scale syntheses of **1** and **2** from classical starting materials; Lewis base adducts of **1** and **2** have also been prepared and the crystal structure of one of the first uranium(III) triflates, $[U(OTf)_2(OPPh_3)_4][OTf]$ (**3**), has been determined.

Syntheses of the U^{III} and U^{IV} triflates are summarized in Scheme 1. **1** and **2** were prepared by treating triflic acid (TfOH) with either U, UH_3 or UCl_3 in the absence of solvent; **2** was also synthesized from UCl_4. It was essential that the acid was freshly distilled in order to achieve a clean and straightforward reaction. Treatment of UH_3 with excess TfOH at 20°C afforded **1** as an ochre powder within a few minutes, the reaction being accompanied by the vigorous evolution of dihydrogen gas. Reactions of activated uranium turnings or uranium trichloride were much slower, requiring 3 d at 120°C to reach completion. After evaporation of the excess TfOH and drying in vacuo, **1** was obtained in almost quantitative yield as a very fine green powder. Uranium(III) triflate (**1**) proved to be remarkably stable at 120°C in suspension in pure TfOH and its oxidation, signified by a colour change from ochre to pale green-blue, occurred only when the temperature was raised to 170−180°C; after 10 h, the acid was evaporated and **2** was isolated in quantitative yield. Of course, **2** could be prepared directly, without isolating **1**, by heating U, UH_3 or UCl_3 in TfOH at 180°C. To the best of our knowledge, these reactions of U or UH_3 with TfOH represent the first syntheses of metal triflates from the metal or metal hydride.[1a,3] Alternatively, compound **2** could be synthesized by reaction of TfOH with UCl_4 at 120°C; rapid HCl evolution occurred and the pale green-blue powder of **2** was recovered in 91% yield after evaporation of the excess TfOH.



Irrespective of their mode of preparation, compounds **1** and **2** were obtained in a pure state, as established from their elemental analyses. However, the samples retained a trace of triflic acid, even if they were thoroughly dried in vacuo at 150°C for several days; this was evidenced by the formation of pyridinium triflate (< 1%) upon their dissolution in pyridine. The strong Lewis acids **1** and **2** were found to be quite soluble in coordinating solvents such as pyridine and dimethoxyethane (DME), giving stable adducts. Use of tetrahydrofuran (THF) as a solvent was not practical since it was readily polymerized at ambient temperature.

Addition of stoichiometric amounts of $OPPh_3$ to solutions of **1** and **2** in DME led to the immediate formation of $U(OTf)_3(OPPh_3)_4$ (**3**) and $U(OTf)_4(OPPh_3)_2$ (**4**), which were isolated in yields of 85% as red and pale-green powders, respectively. These $OPPh_3$ adducts, as well as the pyridine adducts of **1** and **2**, were found to be soluble in THF and no polymerization of the solvent was observed.

X-ray analysis showed the crystals of **3** to be composed of discrete pairs of OTf anions and $U(OTf)_2(OPPh_3)_4$ cations; such a dissociation of OTf ligands has frequently been encountered, in particular from lanthanide triflates.[4] The structure of **3** is shown in Figure 1, together with selected bond lengths and angles. The uranium atom is surrounded by seven oxygen atoms, which form a distorted pentagonal bipyramid. The apical positions are occupied by two $OPPh_3$ ligands [O(1) and O(4)], while the equatorial positions are occupied by two $OPPh_3$ ligands [O(2) and O(3)], a bidentate triflate group [O(5) and O(6)], and a monodentate triflate group [O(8)]; the U and the five equatorial O atoms are

Scheme 1. Syntheses of the uranium triflates **1**–**4**

coplanar within ± 0.13 Å. The $OPPh_3$ ligands are arranged such that the steric interactions are minimized. The lengths of the U–O($OPPh_3$) bonds are unexceptional, with an average value of 2.36(2) Å. The U–O(8) bond length to the monodentate OTf ligand [2.446(4) Å] may be compared with those measured in $U(C_5Me_5)_2(OTf)_2(OH_2)$ [2.36(1) and 2.40(1) Å] and $U(C_5H_5)_3(OTf)(CN\mathit{t}Bu)$ [2.485(9) Å].[2] This length is longer than those of typical U–O σ bonds (2.0–2.2 Å) and is even longer than the U–O($OPPh_3$) bond lengths, confirming the weak nucleophilic character of the OTf group. More interestingly, **3** is the first structurally characterized f-block element compound containing an η^2-*O*,*O*′-bonded triflate ligand. Such examples of a bidentate triflate ligand have previously been encountered in d-transition metal complexes, but remain very rare.[5] The U–O(5) and U–O(6) lengths are 0.2 Å longer than the U–O(8) length; such a difference between the metal–oxygen bond lengths of mono- and bidentate OTf ligands has previously been observed, most notably in the titanium compound Ti(NCN)(O*i*Pr)$(OTf)_2$ [NCN = C_6H_3-$(CH_2NMe_2)_2$-2,6].[5a]

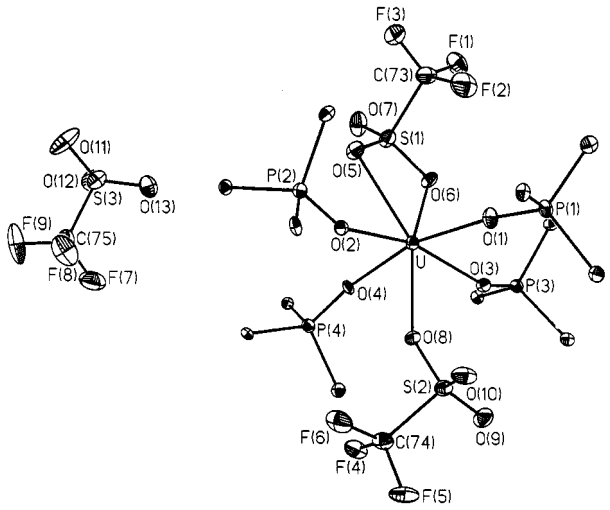

Figure 1. X-ray crystal structure of $[U(OTf)_2(OPPh_3)_4][OTf]$ (**3**) with thermal ellipsoids drawn at the 30% probability level; for the sake of clarity, only the *ipso* carbon atoms (not labelled) of the phenyl rings are represented; selected bond lengths [Å] and angles [°]: U–O(1) 2.370(4), U–O(2) 2.352(4), U–O(3) 2.389(4), U–O(4) 2.348(4), U–O(5) 2.645(5), U–O(6) 2.614(4), U–O(8) 2.446(4); O(1)–U–O(4) 166.2(2), O(3)–U–O(6) 72.45(13), O(5)–U–O(6) 53.80(14), O(2)–U–O(5) 72.88(13), O(2)–U–O(8) 77.95(14), O(3)–U–O(8) 83.12(14)

In conclusion, the new uranium triflates **1** and **2** have been synthesized by treating triflic acid with the corresponding chlorides in a classical manner, or by two novel routes from uranium metal or its hydride. The reactions were easy to perform and, by adjusting the temperature, **1** and **2** were obtained selectively in good yields. The crystal structure of **3** revealed three distinct triflate groups, one being dissociated and the other two coordinating in monodentate and bidentate ligation modes

Experimental Section

All preparations were carried out under argon (less than 2 ppm oxygen and water). Activated uranium turnings were prepared according to ref.[6] except that HgI_2 was replaced by iodine. UH_3,[7] UCl_3,[8] and UCl_4[9] were prepared by published methods. Triflic acid (99%; Aldrich) was freshly distilled prior to use.

Uranium(III) Triflate (1). – From UH_3: Triflic acid (1 mL) was added to UH_3 (250 mg, 1.04 mmol) in a 50-mL round-bottomed flask. The black powder of the hydride was rapidly transformed into an ochre powder, which was accompanied by the vigorous evolution of H_2 gas (***CAUTION!***). In order to ensure that the reaction had reached completion, the mixture was further heated at 100°C for 15 h. The excess TfOH was then distilled off and **1** was obtained as a green powder after drying in vacuo at 120°C for 24 h (687 mg, 96%). – $C_3F_9O_9S_3U$ (685): calcd. F 24.95, S 14.04; found F 24.73, S 13.85. – **From U or UCl_3:** A 200-mL flask was charged with activated uranium turnings (1050 mg, 4.41 mmol) and triflic acid (3 mL) and the mixture was heated for 3 d at 120°C. The excess TfOH was then distilled off and **1** was dried in vacuum at 120°C for 30 h (2840 mg, 94%). – $C_3F_9O_9S_3U$ (685): calcd. F 24.95, S 14.04; found F 24.80, S 14.32. – According to the same procedure, **1** was obtained in 96% yield from UCl_3 (250 mg, 0.72 mmol) and TfOH (3 mL). – $C_3F_9O_9S_3U$ (685): calcd. F 24.95, S 14.04; found F 24.68, S 13.80.

Uranium(IV) Triflate (2). – From UCl_4: A 100-mL flask was charged with UCl_4 (4.0 g, 10.5 mmol) and TfOH (8.5 mL) and the mixture was heated at 120°C. The colour of the powder rapidly turned from green to pale green-blue, which was accompanied by the evolution of HCl vapour. The HCl was pumped off to avoid a build-up of pressure (***CAUTION!***). After 10 h, the excess TfOH was distilled off and the green-blue powder **2** was dried in vacuo at 150°C for 60 h (8.0 g, 91%). – $C_4F_{12}O_{12}S_4U$ (834): calcd. F 27.32, S 15.37; found F 27.10, S 15.25, Cl < 0.1%. – **From U, UH_3 or UCl_3:** The procedure was identical to that used for the preparation of **1** except that the reaction mixture was heated at 180°C for 15 h (UH_3) or 3 d (U or UCl_3). The yields were almost quantitative and the samples were found to be analytically pure.

Tetrakis(triphenylphosphane oxide)uranium(III) Triflate (3): A mixture of **1** (250 mg, 0.36 mmol) and $OPPh_3$ (406 mg, 1.46 mmol) was dissolved in DME (30 mL). After 30 min, the red solution was

concentrated to a volume of 5 mL and diethyl ether (30 mL) was added, whereupon **3** precipitated as a red powder. The product was collected by filtration, washed with toluene, and dried in vacuo (556 mg, 85%). – $C_{75}H_{60}F_9O_{13}P_4S_3U$ (1798): calcd. C 50.09, H 3.36, S 5.35; found C 49.92, H 3.20, S 5.51.

Bis(triphenylphosphane oxide)uranium(IV) Triflate (4): A mixture of **2** (250 mg, 0.30 mmol) and $OPPh_3$ (167 mg, 0.60 mmol) was dissolved in DME (30 mL). After 30 min, the pale-green solution was concentrated to a volume of 5 mL and diethyl ether (40 mL) was added. The green oily material was transformed into a fine powder after stirring for 12 h; the green product **4** was then filtered off, washed with diethyl ether and toluene, and dried in vacuo for 12 h at 20°C (350 mg, 84%). – $C_{40}H_{30}F_{12}O_{14}P_2S_4U$ (1390): calcd. C 34.54, H 2.17, S 9.22; found C 34.71, H 2.30, S 9.08.

X-ray Crystallography of 3: Single crystals were obtained from a mixture of the DME adduct of **1** and excess $OPPh_3$ in THF/diethyl ether. A red crystal of approximate dimensions $0.18 \times 0.12 \times 0.12$ mm was selected. Diffraction data were collected with a Nonius diffractometer equipped with a CCD detector. The lattice parameters were determined from ten images recorded with 1° Φ scans and later refined on all data. The data were recorded at 123 K. A 180° Φ range was scanned in 2° increments with the crystal-to-detector distance fixed at 26 mm. Data were corrected for Lorentz polarization and absorption[10] effects. The structure was solved by the heavy-atom method and refined by full-matrix least squares on F^2 with anisotropic thermal parameters for all non-H atoms. H atoms were introduced at calculated positions and constrained to ride on their parent C atom. $C_{75}H_{60}F_9O_{13}P_4S_3U$ (1798.32), triclinic, space group $P-1$, $a = 13.694(1)$, $b = 14.734(1)$, $c = 19.420(1)$ Å, $\alpha = 92.143(4)$, $\beta = 108.393(4)$, $\gamma = 91.460(4)°$, $V = 3713(3)$ Å^3, $Z = 2$, $D_c = 1.609$ g cm^{-1}, Mo-K_α ($\lambda = 0.71073$ Å), $\mu_{Mo} = 2.441$ mm^{-1}, $F(000) = 1790$, total reflections = 19977, independent reflections = 10109 ($R_{int} = 0.076$), observed reflections [$I > 2\sigma(I)$] = 7023, $R_1 = 0.044$, $wR_2 = 0.077$. All calculations were performed with an O2 Silicon Graphics Station using the SHELXTL package.[11] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-115885. Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Hexakis(alcohol)zinc Complexes

Claas Sudbrake,[a] Bodo Müller,[a] and Heinrich Vahrenkamp*[a]

Dedicated to Professor Lawrence F. Dahl on the occasion of his 70th birthday

Keywords: Zinc complexes / Alcohol ligands / Structure and bonding

Hexakis(methanol) and hexakis(ethanol) complexes of zinc were prepared under strictly anhydrous conditions and crystallized as perchlorate or hexafluorosilicate salts in space groups of high symmetry. All their OH functions are engaged in hydrogen-bonded cation–anion networks. Their Zn–O distances correspond to those in $[Zn(H_2O)_6]^{2+}$. Their water sensitivity can be explained by a gain in entropy and by a gain in polar interactions upon replacement of alcohol by water ligands.

Hexaaqua transition-metal cations are commonplace and serve as reference points for the discussion of structures, spectra or ligand-field effects as well as being the natural starting materials in preparative coordination chemistry. In contrast, their simplest organic analogues, the hexakis(alcohol) complexes, are so uncommon that they are normally not mentioned in textbooks or even in comprehensive handbooks.[1] The reason for this is their extremely labile nature which does not allow them to be exposed to even traces of the "better" ligand water.

When it comes to synthetic usefulness this lability becomes favourable. Accordingly, hexakis(methanol) or hexakis(ethanol) complexes have been proposed as starting materials for other complexes with weakly coordinating ligands, and for this purpose a number of them have been prepared as salts of the divalent transition metals.[2][3] They were fully characterized by analyses and spectra. From their UV/Vis spectra it could be concluded that the simple alcohols have about the same position in the spectrochemical series as water. So far, only one hexakis(methanol)vanadium(II) complex[4] and two hexakis(ethanol)cobalt(II) complexes[5] have been subjected to crystal structure determinations.

Our interest in these complexes arose from our attempts at modelling the zinc enzyme alcohol dehydrogenase.[6] These studies required the investigation of zinc−alcohol, zinc−alkoxide, and zinc−aldehyde complexes. It turned out that some of the latter are accessible starting from hexakis(ethanol)zinc salts.[7] This fact, together with the limited knowledge about hexakis(alcohol)zinc complexes,[2][3] prompted us to re-investigate their chemistry and to gather information on their structures.

Preparation and Identification

The extreme sensitivity of the isolated complexes toward water required them to be handled with more than the usual precautions. In contrast, at the beginning of the preparations moisture posed no problems as the zinc reagents were the hexahydrates of the zinc salts. Their dehydration was performed with trimethyl or triethyl orthoformate in the corresponding alcohol, which produces the alcohol itself as the hydrolysis product. This procedure, which was applied by van Leeuwen for compounds **1** and **2**,[2][3] was found to be useful for all three types of hexakis(alcohol)zinc salts prepared here. Thus, from solutions of the hexahydrates of zinc perchlorate, tetrafluoroborate, and hexafluorosilicate in methanol or ethanol, after treatment with a large excess of the corresponding trialkyl orthoformate (10−20 fold), the known perchlorate **1b**, the known tetrafluoroborates **2a**, **b**, and the new hexafluorosilicates **3a**, **b** were obtained {$[(ROH)_6Zn](ClO_4)_2$: **1a**: R = Me; **1b**: R = Et; $[(ROH)_6Zn](BF_4)_2$: **2a**: R = Me; **2b**: R = Et; $[(ROH)_6Zn](SiF_6)$: **3a**: R = Me; **3b**: R = Et}. They are colourless crystalline solids. Their hygroscopicity does not allow them to persist for more than a few seconds in the normal atmosphere.

Unambiguous characterizations of **1b**, **3a** and **3b** were achieved with the structure determinations described below. NMR spectra in deuterioacetone showed that the alcohol ligands stay attached to the zinc ion in this solvent, see Table 1. The observed chemical shifts referred to those of the free alcohols in the same solvent are small, yet significant. Typical dependencies of the chemical shifts upon the nature of the counterions point to cation−anion interactions in solution. The wide spread of the OH NMR resonances indicates the presence of hydrogen bonding. The latter can also be concluded from the IR absorptions in a KBr matrix (see Table 2), which for **1** and **2** roughly resemble those in nujol mulls.[2][3] The $\tilde{\nu}$(OH) bands around

3500 cm^{-1} are quite broad and of relatively low energy. Other noticeable features in the IR spectra include the OH bending vibrations around 1630 cm^{-1} and the typical intense absorptions of the anions in the 1000−1100 cm^{-1} range for ClO_4^- and BF_4^- and around 750 cm^{-1} for SiF_6^{2-}.

Solid-State Structures

Crystals of **1b**, **3a** and **3b** were found suitable for an X-ray data collection at ca. −100 °C. All three compounds crystallize in rhombohedral or hexagonal space groups with the zinc ions located on threefold axes in positions with sixfold point symmetry. Thus, there is only one alcohol ligand each in the asymmetric unit, and one Zn−O bond length and two O−Zn−O angles define the coordination sphere. In the case of **3b** a disorder problem of both the coordinated and a co-crystallized ethanol molecule affects the precision of the molecular details which therefore are not discussed here. The general features of the complex cation of **3b**, however, are the same as those of **1b**.

Figures 1 and 2 are combined views of the complex cations, showing both the ball-and-stick and the space-filling displays. The symmetry of the complexes is close to ideally octahedral. The Zn−O bond lengths (average 2.08 Å) are virtually identical to those in the $Zn(H_2O)_6^{2+}$ cation (average 2.09 Å).[8] Hence, there is no lengthening due to steric crowding of the six alcohol molecules, and the lability of the zinc−alcohol complexes cannot be explained by a weakness of the Zn−O bonds.

While the ball-and-stick models in Figures 1 and 2 emphasize the symmetry of the complexes and their similarity to the aqua complexes, their peculiarities can better be visualized by space-filling models. Figure 1 shows that the methanol complex has an ellipsoid-like shape. The separation of hydrophilic and hydrophobic parts therein is noticeable from the orientations of the O−H bonds which

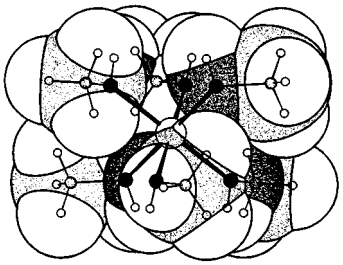

Figure 1. Cation of the methanol complex **3a**; code: Zn and H white, C light grey, O dark grey; bond lengths [Å] and angles [°]: Zn−O 2.086(1), O−C 1.430(2); O−Zn−O 180.0, 87.26(3), and 92.74(3), Zn−O−C 125.5(1)

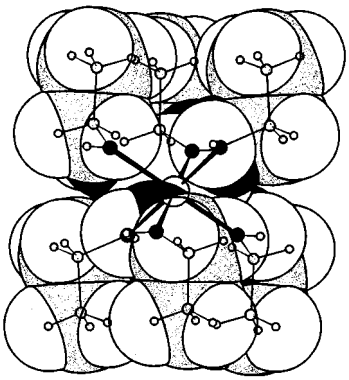

Figure 2. Cation of the ethanol complex **1b** (and similarly **3b**); code: Zn and H white, C light grey, O dark grey; bond lengths [Å] and angles [°] for **1b**: Zn−O 2.078(2), O−H 0.82(6), O−C 1.445(4), C−C 1.483(7); O−Zn−O 180.0, 86.9(1) and 93.1(1), Zn−O−C 130.2(2), O−C−C 110.9(4)

cause the O−H hydrogen atoms to occur in two groups of three on opposite sides of the ellipsoid, cf. the top center of Figure 1. Figure 2 shows that in both ethanol complexes the C−C bonds of the ethyl groups are oriented similarly and roughly parallel to the threefold crystallographic axis, arranging the ethanol ligands in two groups of three. The van der Waals contacts of the ethanol ligands are maximized in this arrangement, forming two hydrophobic islands separated from the polar center of the complex comprised of the Zn−O and O−H bonds. The resulting and characteristic barrel shape of the ethanol complex cations is also verified for the hexakis(ethanol)cobalt(II) complex.[5] It is reminiscent of the layered arrangement of the two *cis*-1,3,5-cyclohexanetriol ligands in their ZnL_2 complex.[9]

The separation of the hydrophilic and hydrophobic regions in the complexes also has the consequence that the alcoholic O−H bonds are exposed to the exterior of the cations. For instance in Figure 2 the white ball to the top right of the zinc ion represents an OH hydrogen atom. This in turn means that these quite acidic hydrogen atoms are within contact distance of the anions in the lattice, facilitating hydrogen bonding between cations and anions. It turns out that this is the case in all three compounds. Each OH group is engaged in a reasonably strong (< 2.8 Å) hydrogen bond. For **1b** this means that three oxygen atoms of each perchlorate anion are hydrogen-bonded. For **3a** and **3b** the number of fluorine atoms matches that of the OH

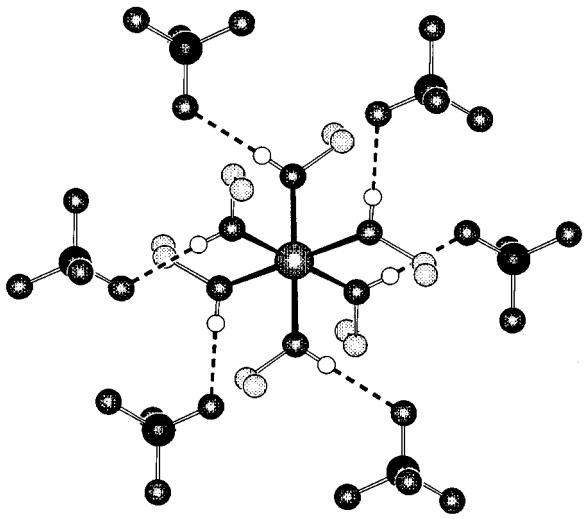

Figure 3. Hydrogen-bonded cation−anion contacts of one $Zn(EtOH)_6$ unit in **1b** (O···O = 2.79 Å)

groups implying that there are also six hydrogen-bonding interactions per SiF_6^{2-} anion. The resulting networks are different in all three cases, see Figures 3−5. Complex **3a** displays a one-dimensional array of hydrogen-bonded cations and anions with triple junctions, complex **3b** a single-layered two-dimensional array with double junctions, and complex **1b** a double-layered two-dimensional array with single junctions.

Discussion

In an alcoholic or water-free environment the hexakis(alcohol) complexes of zinc are stable as salts with noncoordinating anions. Even traces of water, however, lead to their hydrolysis. The alcohols are weaker ligands for zinc than acetone, as can be seen from the persistence of the complexes in acetone solution. They compete with aromatic al-

dehydes, as evident from the synthesis of mixed alcohol/aldehyde complexes of zinc.[7] Thus, the alcohol complexes should be valuable as starting materials for other complexes of zinc with weakly coordinating ligands.

The solid-state structures of the alcohol complexes reveal a contrast between the polar environment of the zinc ion as well as the O−H bonds and the hydrophobic nature of the alkyl groups. The former results in hydrogen-bonded cation−anion networks in which all OH functions are engaged. The latter gives rise to a typical barrel shape of the hexakis(ethanol)zinc cations.

The Zn−O bonds in the complexes are as long as the Zn−O bonds in the $Zn(H_2O)_6^{2+}$ ion which indicates that they are equally strong. Hence, the lability toward hydrolysis cannot be explained by bond-strength arguments. However, the structures of the hexakis(ethanol) complexes offer two arguments for the water sensitivity. One of them is a gain of entropy upon release of the alcohol ligands which experience a high degree of order in the complexes. The other is a gain of polar and hydrogen-bonded interactions upon replacement of alcohol by water ligands, both between cations and anions in the solid state and between complex cations or the released alcohols and the solvent molecules in aqueous solution

Experimental Section

General: General working and measuring procedures, see ref.[10]. The zinc salts were obtained commercially. The alcohols were obtained water-free and further dried with magnesium. [D_6]Acetone and petroleum ether (b.p. 50−70°C) were distilled from and kept over 4-Å molecular sieves. Nitrogen (99.999%) as inert gas was dried with BTS catalyst. Reaction vessels, gas pipes etc. were heated in vacuum before use. − Complexes **1b**, **2a**, and **2b** were prepared according to the published procedures.[2][3] The hygroscopicity of the complexes did not allow for C/H determinations.

Hexakis(methanol)zinc Hexafluorosilicate (3a): 6.00 g (19.02 mmol) of $Zn(H_2O)_6(SiF_6)$ in 25 mL of methanol was treated with 40 mL (38.8 g, 366 mmol) of trimethyl orthoformate which caused heating of the mixture and complete dissolution. After stirring for 24 h at room temp. and filtration, all volatiles were removed in vacuo. The residue was taken up in methanol and layered with petroleum ether to yield 5.80 g (76%) of **3a** which was freed from solvent by a syringe and dried in vacuo. − $C_6H_{24}F_6O_6SiZn$ (399.7): calcd. Zn 16.36; found Zn 16.23.

Hexakis(ethanol)zinc Hexafluorosilicate (3b): Like **3a** from 6.00 g (19.02 mmol) of $Zn(H_2O)_6(SiF_6)$ and 40 mL (35.6 g, 240 mmol) of triethyl orthoformate in 25 mL of ethanol with 48 h of stirring. Yield 4.20 g (46%) of **3b**. − $C_{12}H_{36}F_6O_6SiZn$ (483.9): calcd. Zn 13.51; found Zn 13.75.

Structure Determinations:[11] The crystals were obtained directly from the reaction solutions and used without drying in vacuo. They were immersed in fluorinated polyether oil and immediately placed in the nitrogen stream of the diffractometer's cooling system. Diffraction data were recorded at ca. −100°C with the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator. Empirical absorption corrections based on ψ scans were applied. The structures were solved with direct methods and refined anisotropically with the SHELX program suite.[12] Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.5 times those of their attached atoms. The OH hydrogen atom of **1b** was located and refined freely. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]\Sigma[w(F_o^2)^2]]^{1/2}$. Drawings were produced with SCHAKAL.[13] Table 3 lists the crystallographic data.

Difluorosilanethione $F_2Si{=}S$ by Flash Vacuum Thermolysis of $(F_3Si)_2S$ and by Reaction of SiS with F_2 – Matrix Studies and Ab initio Calculations

Helmut Beckers,[a] Jürgen Breidung,[b] Hans Bürger,*[a] Ralf Köppe,[c] Carsten Kötting,[d] Wolfram Sander,[d] Hansgeorg Schnöckel,[c] and Walter Thiel[b]

Keywords: Ab initio calculations / Flash pyrolysis / Matrix isolation / Silicon / Multiple bonds / IR spectroscopy

Difluorosilanethione $F_2Si{=}S$ (**1**) has been synthesized by Flash Vacuum Pyrolysis of $(F_3Si)_2S$ at ≥ 500 °C and trapped in an Ar matrix. Furthermore, **1** has been obtained by co-deposition of SiS and F_2/Ar and by pyrolysis of a matrix-isolated SiS_2–XeF_2 complex under cryogenic conditions. All six vibrational fundamentals of **1** have been observed in the matrix IR spectrum. Ab initio calculations at the MP2 and CCSD(T) levels using large basis sets have been performed. These calculations have guided the detection of **1** and the vibrational assignment. The best estimate of the structure of **1** with C_{2v} symmetry is: r(Si=S) 191.1(1) pm, r(SiF) 156.1(1) pm, ∠(FSiF) 103.3(2)°.

Our knowledge of molecular species exhibiting multiple bonds to silicon has expanded greatly over the past 20 years due to both experimental progress and improvements in theoretical methods. Above all, kinetic stabilization by bulky substituents at both sites of Si=Si,[1] Si=C,[2] and Si=Pn (Pn = N, P, As) linkages[3] has enabled the synthesis and isolation of numerous compounds that are thermally stable up to, and even above, room temperature and possess "formally" double bonded silicon atoms. However, chalcogeno derivatives $R^1R^2Si{=}Ch$, with Ch = O, S, etc., provide only the silicon site to accommodate bulky substituents, and it is not surprising that the first kinetically stabilized thioxosilane (silanethione[4]) that is stable at ambient temperature was made only recently.[5]

Monomeric silanones and silanethiones with trigonal planar geometry at silicon are kinetically unstable due to the lack of stabilization by bulky ligands. They have been frequently postulated as intermediates, mostly on the evidence of trapping experiments.[6] Only very few of these short-lived intermediates were, however, directly and unambiguously detected by spectroscopic methods, either in the gas phase, or in cryogenic matrices. Silanones $X_2Si{=}O$ with X = H,[7] F,[8] Cl,[9] and CH_3[10] have been the subject of quite a few successful experimental studies, and numerous theoretical studies have guided and confirmed experimental work.

Photolysis of matrix-isolated SiS in the presence of Cl_2[11] and HCl[12] has provided the first silanethiones, $Cl_2Si{=}S$ and Cl(H)Si=S, with trigonal Si coordination. Monomeric $(CH_3)_2Si{=}S$ (**3**), which was detected by photoelectron spectroscopy, has been generated in the gas phase by flash vacuum thermolysis (FVT) of the cyclotrimer (**4**) and of other organosilicon precursors.[13] However, attempts to synthesize the unsubstituted parent species $H_2Si{=}S$ by FVT of different precursors failed, and only the dehydrogenation product SiS has been observed.[14]

The present investigation adds to the limited list of unstabilized monomeric, four-atom silanethiones by describing $F_2Si{=}S$ (**1**). We report on the synthesis of this species by FVT of $(F_3Si)_2S$ (**2**). The unambiguous synthesis of the latter is also reported here for the first time. Alternatively, **1** can be made in analogy to $Cl_2Si{=}S$[11] by the action of F_2 on SiS under cryogenic conditions. High-level ab initio calculations, which guided the detection and support the characterization of **1** by matrix IR spectroscopy, will also be presented.

1	**2**	**3**	**4**

Experimental Results

It has been shown that at elevated temperature the cyclodimer of **3**, $[(CH_3)_2SiS]_2$ (**5**), is in equilibrium with the cyclotrimer **4**.[15] The photoelectron spectroscopic detection of **3** in the FVT of **4** proved that this equilibrium involves the monomer as an intermediate[13a] although it was not possible to trap **3** in an Ar matrix.[16]

$[(CH_3)_2SiS]_2$

5

We chose **1** as our target molecule because reactions analogous to the dehydrogenation of $H_2Si{=}S$,[14] or its isomerisation to yield the silylene HSi−SH, are unlikely to occur for **1** for thermodynamic reasons, the Si−F bond being particularly strong. It was therefore obvious to examine the thermal decomposition of $(F_2SiS)_2$ (**6**), which has been reported in the literature.[17] This promising precursor **6** was first mentioned by Gutmann et al.,[17a] who passed SiF_4

over SiS_2 at 1000°C in a quartz tube. Later, Aylett et al.[17b] claimed to have synthesized **6** by reaction of SiF_2I_2 with red HgS at room temperature.

$(F_2SiS)_2$
6

We have reexamined both reactions[18] and, although we were able to reproduce their general courses and the sparse spectroscopic data quoted, the products claimed to be **6** were in fact identified as $(F_3Si)_2O$[17a] and **2**,[17b] respectively. Our attempts to prepare **6** or other perfluorocyclosilthianes by reaction of the high temperature species SiF_2[19] with OCS or SPF_3 were unsuccessful in spite of the usefulness of OCS to transfer S onto matrix-isolated $SiCl_2$.[11]

Thermolysis of $F_3SiSSiF_3$

The thermolysis of noncyclic silthianes, which might be useful precursors for silanethiones, has not yet been investigated. We have found that in the condensed phase at room temperature **2** decomposes slowly to give SiF_4 and the trisildithiane $F_8Si_3S_2$ (**7**).[18] Upon prolonged storage at 20°C, decomposition of **2** proceeds further to yield more SiF_4 and a solid deposit. The formation of **7** can be rationalized if **1** is considered to be an intermediate (Equations 1 and 2).

$$\mathbf{2} \rightarrow \mathbf{1} + SiF_4 \quad (1)$$

$$\mathbf{2} + \mathbf{1} \rightarrow \underset{\mathbf{7}}{(F_3SiS)_2SiF_2} \quad (2)$$

In order to detect any **1**, which is presumed to be formed according to Equation 1, we pyrolyzed 0.2% **2** seeded in Ar as a carrier gas at ≥ 500°C in a quartz tube of 20 mm length and 10 mm inner diameter. The thermolysis products were condensed onto a cold window mounted at a distance of ca. 20 mm from the port of the oven. The deposit was first studied by infrared spectroscopy with a resolution of 0.5 cm^{-1} in the 400−4000 cm^{-1} region. The spectrum is displayed in Figure 1A.

Evidently the decomposition of **2** is almost quantitative. The spectrum is dominated by the very intense absorption of $^{28}SiF_4$ at 1023.3 cm^{-1}, accompanied by satellites of $^{29}SiF_4$ at 1014.4 cm^{-1} (4.7%) and of $^{30}SiF_4$ at 1006.2 cm^{-1} (3.1%). In addition there are two sharp absorptions at 995.7 and 969.1 cm^{-1} with an intensity ratio of ca. 2:1 (Figure 1A). These absorptions are assigned to a hitherto unknown product. Both the wavenumbers of these two absorptions and their relative intensities agree perfectly with the ab initio predictions for the ν_1 and ν_4 absorption bands, respectively, of $F_2Si{=}S$ (**1**), Table 3.

Although lying in the recorded spectral region, the Si=S stretching vibration ν_2, expected near 640 cm^{-1}, was not found in this particular mid-infrared experiment (Figure 1A) with its predicted intensity being only 0.4% of ν_1.

In order to gather more information on the vibrational spectrum of **1** we have also investigated the matrix in the Far-IR range. Along with bands arising from the ν_4 vibration of SiF_4 and from F_3SiSH (**8**)[18] owing to some hydrolysis or minor contamination of **2**, we eventually detected absorptions at 337, 296, and 247 cm^{-1} with relative intensities of 2.5:4.5:1 (Figure 1B). These absorptions were assigned to **1**. The intensities of these absorptions decreased uniformly on annealing the matrix to 42 K, while absorp-

Figure 1. tions of the stable products persisted. UV irradiation of 193 and 248 nm did not change the spectrum.

F_3SiSH

8

The assignment in the 200−360 cm^{-1} range is not as straightforward as in the SiF stretching region because of partial overlap with bands arising from the precursor **2** and the hydrolysis product **8**. Matrix absorptions at 354.1 cm^{-1} (**2**) and 343.1 cm^{-1} (**8**) did not disappear upon annealing the matrix; they correspond to strong gas phase absorptions at 358 and 346 cm^{-1}, respectively, and are assigned to δ_s SiF_3.[18] The corresponding asymmetric deformations observed in the gas phase at 335 and 326 cm^{-1} (**2**) and 325 cm^{-1} (**8**) are weaker and occur in the matrix spectrum at 335.6 cm^{-1} and 322 cm^{-1} (broad, Figure 1). There is a coincidence of the 335.6 cm^{-1} band with that of **1** at 336.5, hence upon annealing of the matrix the band at 337 cm^{-1} is only weakened while those at 296 and 247 cm^{-1} disappear entirely.

Comparison of the matrix spectra before and after annealing reveals a weak feature at 638 cm^{-1} (Figure 1B) that must be due to an unstable intermediate. On the basis of the ab initio calculations (Table 3; see below) we definitely assign this feature to the Si=S stretching vibration. On the other hand, new weak absorptions at 1004, 981.5, 862.2, and 858.0 cm^{-1} (ν SiF) and 561 and 557 cm^{-1} (ν SiS) appear in the annealed spectrum; these have not yet been assigned but might be due to oligomers of **1**.

Reaction of Matrix-Isolated SiS with F_2

In analogy to the synthesis of Cl_2SiS from SiS and Cl_2[11] co-condensation of SiS with F_2 and Ar promises access to **1**. IR spectra of these deposits (Figure 2) revealed, in addition to absorptions of SiS (739 cm^{-1}) and its dimer and its trimer, some red-shifted bands at 728 cm^{-1}, which are assigned to association products of molecular SiS with F_2.

Furthermore, three additional absorptions at 995.6, 969.1, and 296.5 cm^{-1} were observed that, owing to their invariant relative intensities, were assigned to the same, novel short-lived species. Of these, the two strong absorptions > 900 cm^{-1} are likely to be due to SiF stretching vibrations of tetravalent silicon bonded to two or more fluorine atoms. Respective absorptions of Si^{II} fluorides should occur at lower wavenumbers, 840−869 cm^{-1}.[21] One further band at 903 cm^{-1} (Figure 2) has not yet been assigned.

Both the wavenumbers and intensities of the three absorptions mentioned above are in perfect agreement with those that had been assigned in the pyrolysis experiment to **1** on the basis of ab initio calculations. Once again the SiS stretching vibration of **1**, predicted to be near 640 cm^{-1} with very low IR intensity and observed in the spectrum shown in Figure 1B, was too weak to be detected. In addition to the bands of **1**, SiF stretching absorptions of the stable product **8** (986.6 and 865.2 cm^{-1}) and SiF_4 (1023 and 386.7 cm^{-1}) were also observed.

In order to support the assignment of the absorptions of **1** we condensed gaseous SiS with XeF_2 and Ar and photolyzed the resulting deposit with radiation from a high pressure Hg lamp. This experiment was performed by passing Ar over crystalline XeF_2 at −40°C and co-condensing this mixture with SiS. The IR spectrum of this deposit revealed only the presence of SiS, XeF_2 and a band at 725 cm^{-1} assigned to a $SiS{-}XeF_2$ complex. After photolysis, absorptions similar to those observed with a SiS/F_2 mixture appeared and were assigned to **1**. We did not find the SiS stretching vibration of **1** in this experiment. In order to confirm our observation of this vibration (Figure 1B) we plan to study the $SiS{-}Ar/F_2$ system by Raman spectroscopy.

Ab initio Calculations

Theoretical Methods

Quantum-chemical calculations were carried out at the correlated levels of second-order Møller−Plesset perturbation theory (MP2)[22] and coupled cluster theory with single and double excitations[23] augmented by a perturbational estimate of the effects of connected triple excitations [CCSD(T)].[24] These calculations were performed with GAUSSIAN94[25] and MOLPRO94.[26][27]

The correlation-consistent polarized valence basis sets (cc-pVXZ)[28][29] were used throughout, supplemented as suggested recently[30] to take into account core polarization effects in the case of second-row atoms. Specifically, three different basis sets were employed: the first one denoted as VTZ+1 is derived from the triple-zeta cc-pVTZ basis[28][29] by adding a single set of d functions for Si and S[30] whose exponents equal the highest d exponent in the corresponding cc-pV5Z basis.[31] Analogously, the second basis (VQZ+1) is obtained from the quadruple-zeta cc-pVQZ basis set[28][29] by adding the same high-exponent d functions for Si and S.[30][31] Replacement of the cc-pVQZ functions for F and S by the corresponding augmented sets (aug-cc-pVQZ)[29][32] generates the third basis (AVQZ+1), which contains low-exponent diffuse functions to account for the electronegative character of F and S.

Spherical harmonics were used throughout. Unless stated otherwise, the fluorine 1s-like and the silicon and sulfur 1s2s2p-like core molecular orbitals were always required to remain doubly occupied (frozen core approximation). Nondynamical electron correlation is not overly important in F_2SiS, as judged from the coupled cluster T_1 diagnostic,[33][34] which is 0.013 for all three basis sets at the corresponding CCSD(T) minimum energy structures. Therefore, **1** is expected to be well described by single reference coupled cluster wavefunctions. The molecules SiS and SiF_2 were also treated (see below). The T_1 diagnostic for SiF_2 is about 0.014, i.e. similar to the value of F_2SiS, and 0.021 for SiS. Although this latter value is already critical in the sense that results from single-reference electron correlation methods limited to single and double excitations (e.g. MP2, CCSD) should be viewed with caution, CCSD(T) still performs reasonably well.[34]

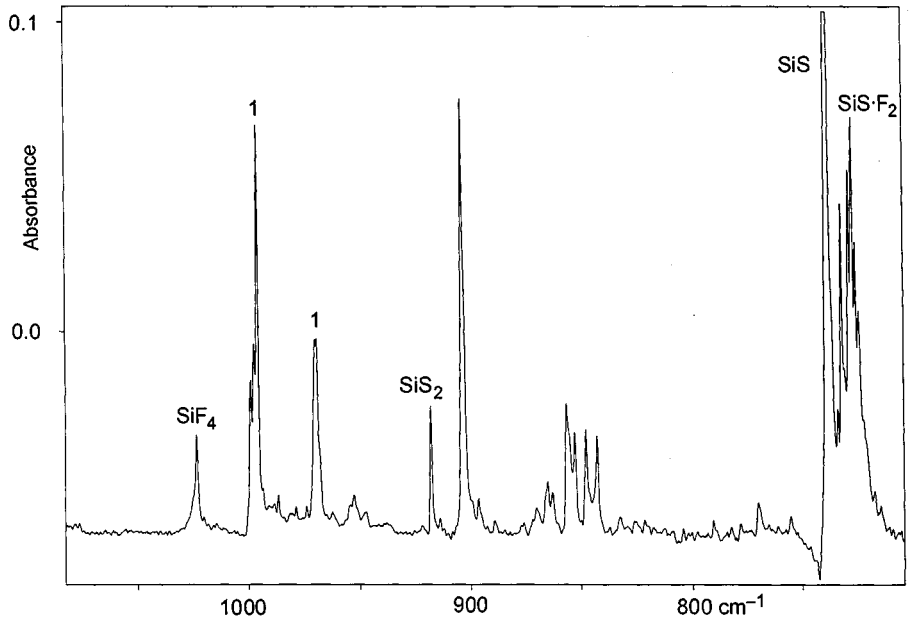

Figure 2. IR spectrum in the 700−1200 cm^{-1} range of the deposit formed by co-deposition of SiS and F_2/Ar; **1**: $F_2Si{=}S$

The molecular geometry of **1** was optimized within the constraint of C_{2v} point group symmetry. For the purpose of comparison, the molecular structures of SiS ($C_{\infty v}$) and SiF_2 (C_{2v}) were also optimized. Analytic energy gradients, as implemented in the GAUSSIAN94 program,[25] were used at the MP2 level of theory, and numerical gradients were employed at the CCSD(T) level with MOLPRO94.[26][27] The largest internal gradient components at the stationary points did not exceed $3{\cdot}10^{-5}$ au.

At the computed equilibrium geometries, harmonic force fields were evaluated either analytically in Cartesian coordinates (MP2/VTZ+1)[25] or numerically in symmetry-adapted internal coordinates from energies[26] (step sizes 0.02 Bohr for bond lengths and 1° for bond angles). The normal modes and the harmonic vibrational frequencies were obtained in the usual manner.[35][36] At the CCSD(T) level, electric dipole moments were determined as numerical derivatives of the potential energy with respect to a finite field component (0.003 au) using the MOLPRO94 program.[26]

The following symmetry coordinates were chosen to represent the quadratic CCSD(T)/VQZ+1 force field:

$S_1(a_1) = 2^{-1/2}\,(r_1 + r_2)$
$S_2(a_1) = R$
$S_3(a_1) = 6^{-1/2}\,(2\alpha - \beta_1 - \beta_2)$
$S_4(b_1) = 2^{-1/2}\,(r_1 - r_2)$
$S_5(b_1) = 2^{-1/2}\,(\beta_1 - \beta_2)$
$S_6(b_2) = \gamma$

where r_1 and r_2 are the two SiF bond lengths, R is the Si−S bond length, α is the F−Si−F bond angle, β_1 and β_2 are the two F−Si−S bond angles, and γ is the out-of-plane angle between the Si−S bond and the SiF_2 plane.

For comparison with the present experimental data, the cubic and quartic force fields of **1** are required to deduce theoretical values for the fundamental vibrational frequencies. The MP2/VTZ+1 cubic and quartic normal coordinate force constants that are not reported explicitly were determined with the use of a finite difference procedure[37] involving displacements along reduced normal coordinates (step size $\Delta q = 0.05$) and the calculation of analytic second derivatives (relative precision $\varepsilon < 10^{-7}$) at these displaced geometries. At the MP2/VTZ+1 equilibrium geometry of **1**, the Cartesian gradient components did not exceed $5{\cdot}10^{-7}$ au. The anharmonicity corrections to the harmonic vibrational wavenumbers were computed from the theoretical anharmonicity constants using standard formulas based on second-order rovibrational perturbation theory.[38][39]

Results and Discussion

Table 1 shows the computed equilibrium geometries, electric dipole moments and atomic charges from a natural population analysis[25] of F_2SiS. As expected, the enlargement of the basis set from VTZ+1 to VQZ+1 shortens the SiF bonds slightly (0.13−0.18 pm) and the SiS bond somewhat more (0.34−0.49 pm) while the FSiF bond angle increases by 0.12−0.15°. The addition of diffuse functions at F and S (AVQZ+1) leads to almost negligible changes in the structural parameters: the bond lengths increase by less than 0.1 pm and the FSiF bond angle decreases by less than 0.05°. For a given basis, CCSD(T) predicts a longer SiS bond and shorter SiF bonds than MP2, but the differences remain small (0.23−0.38 pm), and the computed bond angles are almost identical. Correlating all electrons at the CCSD(T)/VQZ+1 level shortens the SiS and SiF bonds considerably, viz. by 0.85 pm and 0.83 pm, respectively, whereas the FSiF bond angle is only slightly affected (+0.07°). The computed values for the electric dipole moment of **1** are close to 1.2 Debye (see Table 1). The present

Table 1. Computed equilibrium geometries and electric dipole moments of F_2SiS[a]

Constant	MP2 VTZ+1	VQZ+1	AVQZ+1	CCSD(T) VTZ+1	VQZ+1	VQZ+1(ae)[b]	AVQZ+1	Best estimate[c]

[a] Bond lengths in pm, bond angles in degrees, dipole moments in Debye. – [b] ae = all electrons correlated. – [c] See text. Estimated errors in parentheses. – [d] CCSD(T)/AVQZ+1 value at the best estimated molecular geometry. The dipole vector is directed from S to Si. A natural population analysis (MP2/VTZ+1)[25] revealed the following atomic charges (atomic units): Si +1.903, S −0.678, F −0.613.

best value [CCSD(T)/AVQZ+1] is believed to be accurate to about 0.1 Debye.

The calculated geometrical data of F_2SiS may be improved by taking into account the errors that appear in analogous calculations for the related molecules SiS and SiF_2, where accurate experimental equilibrium geometries are known.[40][41] For this purpose Table 2 presents computed and experimental equilibrium structures for both species. It is seen that CCSD(T)/VQZ+1 overestimates the bond lengths in SiS and SiF_2 by as much as 0.97 pm and 0.69 pm, respectively, if inner-shell contributions to the electron correlation are neglected. As in the case of **1**, taking core correlation into account [CCSD(T)/VQZ+1(ae)] leads to a considerable contraction of the bond lengths in SiS (−0.69 pm) and SiF_2 (−0.76 pm) while the bond angle in SiF_2 changes only moderately (+0.12°). Consequently, the all-electron bond lengths in SiS and SiF_2 are much closer to the experimental values than those obtained by correlating only the valence electrons (see Table 2). If the errors in the calculated bond lengths of these two molecules (with and without the frozen core approximation) are used to correct the corresponding data for the target molecule **1**, we arrive at three consistent estimates for the equilibrium distances in F_2SiS. The best estimate (see Table 1) is the average of these three individual estimates, which lie within the quoted uncertainty. Since the calculated FSiF bond angles in **1** are quite similar at all levels, we have adopted the CCSD(T)/VQZ+1 value (103.3°) as our best estimate and have assigned an error bar (0.2°) that covers all theoretical values of this angle (see Table 1).

Table 3 reports theoretical results for the fundamental vibrational wavenumbers of F_2SiS and compares them with their experimental counterparts determined in this work. The theoretical values were derived from the corresponding harmonic wavenumbers obtained at a given level, by adding the anharmonicity corrections from MP2/VTZ+1 calculations. At this level there are no complications due to anharmonic resonances, except for $\nu_2/2\nu_6$ where perturbationally and variationally determined Fermi shifts due to this cubic interaction differ by about 4 cm^{-1}. Consequently, all theoretical Fermi shifts of ν_2 (ranging from 3.5−6.4 cm^{-1}) were obtained by matrix diagonalization using harmonic wavenumbers from the given level of theory and the coupling element W_{266} = 10.2 cm^{-1} from MP2/VTZ+1. The calculated fundamental wavenumbers are quite stable with respect to the employed basis sets, i.e. the corresponding data differ at most by 5 cm^{-1}. Comparing CCSD(T) with the associated MP2 data, the differences do not exceed 9 cm^{-1} in absolute value. Generally, the calculated wavenumbers agree with experiment to within 9 cm^{-1}, with the exception of the out-of-plane vibrational mode where the differences range from 11−20 cm^{-1}. From a theoretical point of view, our best data are those from CCSD(T)/VQZ+1 where the rms deviation from experiment is 7 cm^{-1}. This agreement between theory and experiment is as good as can be expected,[34] especially when taking into account that the experimental vibrational wavenumbers have been measured in an argon matrix (15 K) and not in the gas phase. Therefore, our calculations are fully consistent with the assignment of the measured bands to F_2SiS. Further support for this assignment comes from the theoretical (MP2/VTZ+1) intensity pattern of the infrared absorptions, which is in very good agreement with the experimental relative intensities (see Table 3).

In Table 4 the CCSD(T)/VQZ+1 harmonic symmetry force constants of **1** are listed. Not surprisingly, this force field is dominated by the diagonal stretching constants F_{11} (SiF_2 sym. str.), F_{44} (SiF_2 asym. str.), and F_{22} (SiS str.). The associated potential energy distribution (PED) matrix reveals a significant coupling only between the symmetric SiF_2 (S_1) and the SiS (S_2) stretching coordinates (ν_1: 68% SiF_2, 28% SiS; ν_2: 28% SiF_2, 69% SiS), whereas the other

	3	3	0.833				

[a] CCSD(T)/VQZ+1. – [b] Units are consistent with energies in aJ, bond lengths in 100 pm, and angles in radians.

normal modes correspond to almost pure symmetry coordinates (dominant PED contributions to $\nu_3 - \nu_6$: above 95%).

Discussion

The present study establishes the existence of hitherto unknown **1** under cryogenic conditions. We have been able to synthesize **1** by FVT of **2**, by reaction of SiS with F_2 in an Ar matrix, and by photolysis of a matrix isolated $SiS{-}XeF_2$ complex. All vibrational fundamentals of **1** were observed. These fundamentals were assigned on the basis of high-level ab initio calculations.

Owing to the strong mixing of the S_1 and S_2 coordinates, the vibration with predominantly Si=S stretching character at $638\ cm^{-1}$ is much lower than those of $Cl_2Si{=}S$ ($805.6\ cm^{-1}$)[11] and Cl(H)Si=S ($775\ cm^{-1}$)[12]. In matrix-isolated Si=S this vibration lies at $739.1\ cm^{-1}$.[42] The Si=S stretching force constant of **1** obtained by quantum chemical calculations, 5.167 Ncm^{-1} (Table 4), exceeds that of $Cl_2Si{=}S$ (4.90 Ncm^{-1})[11] and Cl(H)Si=S (4.83 Ncm^{-1})[12] as well as those of SiS and SiS_2, 4.9 Ncm^{-1}.[43] The C=S stretching force constants of related CS (8.5 Ncm^{-1}), CS_2 (7.7 Ncm^{-1}) and F_2CS (6.7 Ncm^{-1})[44] vary much more.

Difluorosilanethione has the shortest SiS bond and largest SiS stretching force constant so far determined. The "best" prediction of the SiS bond length in **1**, 191.1 pm (Table 1), is significantly shorter than those of the two independent 2,4,6-$[(Me_3Si)_2CH]_3C_6H_2$[2,4,6-$(Me_2CH)_3$-C_6H_2]Si=S molecules as determined by single crystal X-ray diffraction, 194.8(4) and 195.2(4) pm.[5] It is also shorter than in SiS 192.9264(2) pm.[40] The SiS single bond length in $H_3SiSSiH_3$ is considerably longer, 213.6(2) pm.[45]

Experimental Section

Synthesis of $(F_3Si)_2S$ (2):[18] 8.6 g (39.2 mmol) of SiF_3I and 16 g (69 mmol) of HgS were sealed together in a pyrex tube with a volume of 13.3 mL and allowed to react for 7 d at room temperature. Volatile products were purified by fractionated distillation using a low temperature column to yield 0.7 g (6.7 mmol) of SiF_4, 1.7 g (7.9 mmol) of SiF_3I, 2.1 g (10.7 mmol) of **2**, and 0.5 g of less volatile products containing Si and S. The purity of **2**, b.p. −3°C, was checked by IR and ^{19}F-NMR spectroscopy.

Thermolysis of 2: Matrix isolation experiments were performed using standard techniques with an APD CSW-202 Displex closed-cycle He cryostat. Matrices were produced by deposition of Ar (Messer Griesheim, 99.9999%) at a rate of 1.5 sccm/min on a CsI window at 15−20 K. Infrared spectra were recorded with a resolution of $0.5\ cm^{-1}$ employing a Bruker IFS 66 FTIR spectrometer equipped with a KBr beam splitter and a MCT detector. The Far IR experiments were performed using polyethylene windows, a Mylar beam splitter and a DTGS detector. Irradiations were carried out with an Excimer Laser (Lambda Physics COMPex 100, ArF 193 nm, KrF 248 nm).

Reaction of Matrix-Isolated SiS with F_2 or with XeF_2: Experiments were carried out using a Leybold RGD 510 closed cycle cryostat. Matrices were condensed onto a cold copper mirror. Spectra were recorded in absorption by means of a reflection unit using a Bruker IFS 113v FTIR spectrometer. A constant flow of molecular SiS was produced by passing H_2S over solid silicon resistively heated to 1200°C in an alumina tube. Fluorine was stored and mixed with Ar in passivated stainless steel containers. Photolysis (310 nm interference filter) was performed with a high pressure Hg lamp (Osram HBO 200).

Aluminium Hydrazides: Reactions of *tert*-Butylaluminium Chlorides with Dilithium Bis(trimethylsilyl)hydrazide – Formation of Iminoalanes and their Hydrazido Adducts

Werner Uhl,*[a] Jens Molter,[a] and Rainer Koch[a]

Keywords: Aluminium / Hydrazides / Alanes / Lithium / Imino compounds

Di(*tert*-butyl)aluminium chloride reacted with dilithium bis(trimethylsilyl)hydrazide with the formation of a novel $Al_2Li_2N_4$ cage compound **1**. Its structure consists of a dimeric iminoalane $RAl(\mu N–SiMe_3)_2AlR$ (R = CMe_3), which is bridged by a dilithiumhydrazido ligand with an intact N–N bond. A heterocubane-type molecule is formed, in which two vertices are occupied by Al atoms, two by Li atoms and four by N atoms. One face of the cube is strongly distorted due to the short N–N distance of the hydrazido group. A similar compound, **3**, was formed with bis(neopentyl)aluminium chloride but it was isolated in very poor yield. The reaction of $Li_2N_2(SiMe_3)_2$ with $(Me_3C)_2AlCl$ in the presence of THF yielded an adduct **2**, in which each Li atom of the cage is additionally coordinated via Li–Cl–Al bridges to the ligand $(Me_3Al)_2Cl·THF$. The reaction of dilithium bis(trimethylsilyl)hydrazide with *tert*-butylaluminium dichloride gave, by complete cleavage of the hydrazido groups, a dimeric iminoalane $[Me_3C(THF)AlNSiMe_3]_2$ (**4**), in which each aluminium atom is coordinated to one THF molecule. Its uncoordinated, solvent-free form **5** was obtained by heating solid **4** to 150 °C in vacuo for several hours. It was identified as the tetrameric iminoalane $(Me_3CAlNSiMe_3)_4$, which does not adopt the expected heterocubane-type structure, but consists of three anellated four-membered Al_2N_2 heterocycles in a kind of ladder structure. Remarkably, the cage compound **1** could not be obtained by the reaction of an excess of lithium hydrazide with the iminoalanes **4** and **5**. All compounds **1**–**5** were characterized by crystal structure determinations.

Introduction

In contrast to boron hydrazides,[1] which form a well-established class of compounds, only a few hydrazides of the heavier group three elements aluminium to thallium are known in the literature.[2–7] Recently, such compounds have found an increased interest as they are potentially useful as precursors for the formation of ceramic materials like aluminium and gallium nitride.[4–6] Boron hydrazides are easily accessible by the reaction of boron halides with silylhydrazines and the release of chlorosilanes.[1] As recently shown by our group,[8] this method cannot be applied to the synthesis of aluminium hydrazides. Bis(trimethylsilyl)hydrazine, for instance, did not react with dialkylaluminium chlorides with the expected formation of trimethylchlorosilane, but a dismutation reaction occurred and adducts of the aluminium halides with the thermally unstable mono(trimethylsilyl)hydrazine were isolated. The few aluminium or gallium hydrazides known in the literature were obtained by four different methods: (i) the reaction of trialkyl derivatives with the N–H protons of hydrazines with the elimination of alkanes; (ii) the reaction of monolithiated hydrazides with the corresponding aluminium or gallium chlorides; (iii) the treatment of $LiAlH_4$ with hydrazines and the release of elemental hydrogen; (iv) the hydroalumination reaction of azobenzene with an arylaluminium dihydride, which gave elemental hydrogen and an iminoalane as by-products.[2–7] Recently, Nöth et al. synthesized a series of aluminium hydrazides using methods (ii) and (iii).[3] Beside the synthesis of monoaluminium derivatives, we are also very interested in the synthesis of polyaluminium or polygallium hydrazides which contain more than one aluminium or gallium atom coordinated to each N–N group, and we report here on the reaction of *tert*-butylaluminium chlorides with dilithium bis(trimethylsilyl)hydrazide.

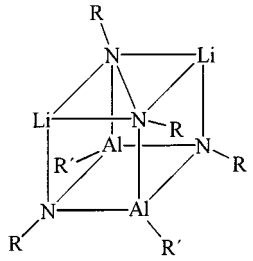
Results and Discussion



Reaction of Dilithium Bis(trimethylsilyl)hydrazide with $(Me_3C)_2AlCl$

In order to obtain a hydrazido group attached to two aluminium atoms we treated the dilithium hydrazide $Li_2N_2(SiMe_3)_2$[9] with two equivalents of di(*tert*-butyl)aluminium chloride[10] in toluene at room temperature for 36 hours. A complicated mixture of products was formed, from which one component (**1**, Equation 1) was isolated in a pure form after a three-step recrystallization from toluene/*n*-hexane in a yield of 34%. The NMR spectroscopic characterization showed that the desired dialuminiumhydrazide could not have been formed. Three singlets were observed in the ^1H-NMR spectrum with equal intensities, of which two were in the characteristic range for trimethylsilyl groups (δ = 0.38 and −0.05). The other one was assigned to a *tert*-butyl group attached to an aluminium atom (δ = 1.42). Thus, a compound must have been formed which has two chemi-

cally different $SiMe_3$ groups and one type of *tert*-butyl group. The constitution of **1** was established by an X-ray crystal structure determination.

$$2\ ClAl(CMe_3)_2 + Li_2N_2(SiMe_3)_2 \xrightarrow{-\ LiCl}$$

(1)

1 (R = $SiMe_3$; R′ = CMe_3)

The molecular structure of **1** is depicted in Figure 1. A remarkable cage compound was formed, which comprises a four-membered Al_2N_2 heterocycle with each aluminium atom further attached to one *tert*-butyl group and each nitrogen atom to a trimethylsilyl group. Each aluminium atom becomes coordinatively saturated by an interaction with one nitrogen atom of a hydrazido dianion, which bridges the iminoalane heterocycle and has an intact N−N bond. The cage is completed by two lithium atoms, each of which is coordinated by both nitrogen atoms of the hydrazido ligand and one nitrogen atom of the iminoalane moiety. Thus, the structure resembles that of a heterocubane type molecule although it is strongly distorted due to the N−N single bond across one of its faces. The Al_2N_2 heterocycle is not planar, but folded across the N−N axis by 31.2°. Owing to a coordination number of four at the aluminium atoms the Al−N bond lengths (189.2 pm on average) are longer than in some dimeric iminoalanes known from the literature with three-coordinate Al and N atoms (180 to 182 pm),[11] and also longer than the bond lengths calculated by ab-initio methods for $(HAl{-}NH)_2$.[12] A remarkably short transannular Al−Al distance of 248.5(2) pm is observed, which is shorter than in dimeric trimethylaluminium with a 2e-3c AlCAl bond (262 pm)[13] or in dialanes(4) with Al−Al single bonds (264 to 275 pm).[14] Similar short transannular distances have been observed before in other dimeric iminoalanes[11] and in many other heterocyclic main-group compounds.

This iminoalane heterocycle is bridged by a hydrazido group, where each nitrogen atom is attached to one aluminium atom. The Al−N distances (201.1 pm) are longer than those of the Al_2N_2 heterocycle and are in the typical range for dative N→Al bonds.[15] The N−N single bond length [158.9(5) pm] is longer than those usually observed in hydrazine derivatives[8][16] or in the related dimetalated hydrazide $Li_2N_2(SiMe_3)_2$,[9] which has a side-on coordination of the N−N group by both lithium atoms similar to **1**. The Li−N distances are significantly different, those to the imino nitrogen atoms and to one atom of the hydrazido group are short (198.4 pm on average), whilst the distance to the second hydrazido nitrogen is lengthened (215.5 pm).

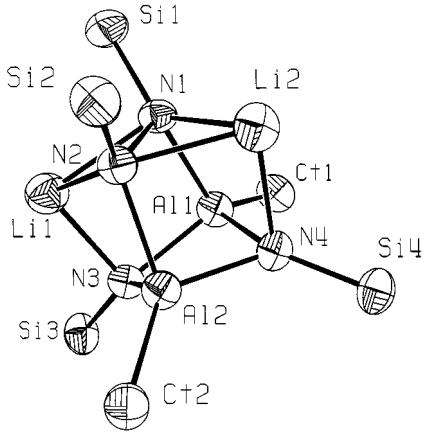

Figure 1. Molecular structure and numbering scheme of compound **1**; thermal ellipsoids are drawn at the 40% probability level (methyl groups omitted for clarity); selected bond lengths [pm] and angles [°]: Al1−N3 187.6(4), Al1−N4 191.4(4), Al2−N3 189.4(4), Al2−N4 188.3(4), N3−Si3 169.9(4), N4−Si4 168.3(4), Al1−Ct1 200.4(5), Al2−Ct2 200.9(5), Al1−N1 201.3(4), Al2−N2 200.8(4), Li1−N1 215.3(10), Li1−N2 196.8(9), Li1−N3 197.3(10), Li2−N1 197.8(9), Li2−N2 215.6(10), Li2−N4 201.8(10), N1−N2 158.9(5), N1−Si1 173.6(4), N2−Si2 174.0(4); N3−Al1−N4 93.8(2), Al1−N3−Al2 82.5(2), N3−Al2−N4 94.2(2), Al1−N4−Al2 81.8(2), Al1−N3−Li1 93.6(3), Al2−N3−Li1 86.2(3), Al1−N4−Li2 85.8(3), Al2−N4−Li2 93.7(3), N1−Al1−N3 92.6(2), N1−Al1−N4 91.3(2), N2−Al2−N3 91.2(2), N2−Al2−N4 92.3(2), N1−Li1−N2 45.1(2), N1−Li1−N3 85.8(4), N2−Li1−N3 90.1(4), N1−Li2−N2 45.0(2), N1−Li2−N4 89.3(4), N2−Li2−N4 84.5(4), Li1−N1−Li2 129.5(4), Li1−N2−Li2 129.9(4), Li1−N1−N2 61.3(3), Li1−N2−N1 73.6(3), Li2−N1−N2 73.5(3), Li2−N2−N1 61.6(3)

At first sight the Li atoms seem to be coordinatively unsaturated, with short contacts to only three nitrogen atoms, but each one also interacts with one methyl group of a trimethylsilyl substituent (Li1−C11 251.0 pm and Li2−C21 248.1 pm). Similar Li−C interactions have been observed in methyllithium[17] and in some lithium bis(trimethylsilyl)methylaluminates.[18]

We have also carried out quantum chemical calculations of the model compound $Li_2(H_3CAlNSiH_3)_2(H_3SiNNSiH_3)$ (**1a**), in which the *tert*-butyl and trimethylsiyl groups of **1** were replaced by CH_3 and SiH_3, respectively. The optimization of the molecular structure of **1a** resulted in a very good agreement between the experimental and calculated structural parameters. Some selected distances and bond angles are summarized in the Experimental Section, where it can be seen that the method chosen is suitable for the description of compound **1**. The largest deviations were observed for the Li−N separations (up to 5 pm) and for the N−N distance of the hydrazido group (151.3 pm instead of 158.9 pm), which may be partially caused by the smaller CH_3 and SiH_3 substituents employed in the calculated molecule **1a**. As clearly shown by NBO analysis, the short Al−Al distance (**1a**: 250.7 pm) must not be interpreted in terms of an Al−Al bonding interaction, and no two- or three-center interactions between the aluminium atoms can be found. The Al−Al bond order is close to zero, and no significant additional interaction between Al orbitals is observed similar to the four-membered heterocycles with short transannular E-E contacts reported previously.

Donor solvents like THF or diethyl ether had a strong influence on the course of this reaction (Equation 1). In diethyl ether no reaction was observed at all over a period of several days at room temperature, and in boiling ether decomposition occurred and only traces of the ether adduct $(Me_3C)_2AlCl{\cdot}OEt_2$ were isolated after recrystallization. Similar observations were made in THF as a solvent. Treatment of dilithium bis(trimethylsilyl)hydrazide with THF gave, after thorough evaporation of the obtained solid, a solvate which, from the integration of its ^1H NMR spectrum, contained half a molecule of THF for each formula unit of the hydrazide. The reaction of this solvate with di(*tert*-butyl)aluminium chloride in hexane gave another cage compound **2** in low yield and a complicated mixture of unknown products (Equation 2). The molecular structure of **2** in the solid state (Figure 2) can be derived from the cage of **1**, but each lithium atom is additionally coordinated via Li−Cl−Al bridges to a THF adduct of the starting chloroalane. The structural parameters of the cage are very similar to those of **1** and are not discussed here in detail. The chloro bridges are almost linear (Cl1 173.9°; Cl2 167.5°), which is in accordance with the steric shielding of the Li atom by the substituents of the cage and the high ionic character of the Li−Cl interaction. Li−Cl (240.1 pm) and Al−Cl distances (219.3 pm) are in the expected range.[19]

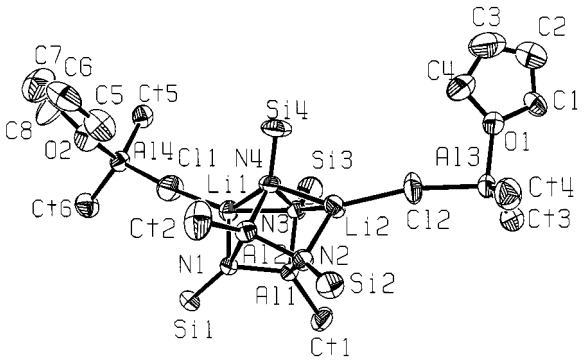

Figure 2. Molecular structure and numbering scheme of compound **2**; thermal ellipsoids are drawn at the 40% probability level (methyl groups omitted for clarity); selected bond lengths [pm] and angles [°]: Al1−N1 187.9(2), Al1−N2 188.8(3), Al2−N1 188.1(3), Al2−N2 188.5(3), N1−Si1 169.6(2), N2−Si2 168.9(2), Al1−Ct1 200.1(3), Al2−Ct2 201.7(4), Al1−N3 199.5(2), Al2−N4 200.0(3), Li1−N1 199.5(6), Li1−N3 212.4(5), Li1−N4 201.6(6), Li2−N2 198.8(5), Li2−N3 203.2(6), Li2−N4 216.4(6), N3−N4 156.1(4), N3−Si3 173.2(2), N4−Si4 172.3(3), Li1−Cl1 237.9(5), Li2−Cl2 242.2(5), Al3−Cl2 219.4(1), Al4−Cl1 219.3(1), Al3−O1 190.6(2), Al4−O2 189.3(3); N1−Al1−N2 93.5(1), Al1−N1−Al2 82.1(1), N1−Al2−N2 93.5(1), Al1−N2−Al2 81.7(1), Al1−N1−Li1 92.0(2), Al2−N1−Li1 86.8(2), Al1−N2−Li2 86.6(2), Al2−N2−Li2 93.6(2), N1−Al1−N3 92.9(1), N2−Al1−N3 92.6(1), N1−Al2−N4 92.6(1), N2−Al2−N4 92.4(1), N3−Li1−N4 44.2(1), N1−Li1−N3 85.9(2), N1−Li1−N4 88.8(2), N3−Li2−N4 43.5(1), N2−Li2−N3 88.6(2), N2−Li2−N4 84.9(2), Li1−N3−Li2 131.0(2), Li1−N4−Li2 129.5(2), Li1−N3−N4 64.3(2), Li1−N4−N3 71.6(2), Li2−N3−N4 72.7(2), Li2−N4−N3 63.7(2), Li1−Cl1−Al4 173.9(1), Li2−Cl2−Al3 167.5(1)

The reaction of dimethylaluminium chloride or di(*tert*-butyl)aluminium bromide with $Li_2N_2(SiMe_3)_2$ gave only mixtures of unknown products, from which no single component could be isolated by recrystallization. A further cage compound **3**) was obtained from the reaction with di(neopentyl)aluminium chloride, and was isolated in a very poor, but reproducible, yield of only 10% after recrystallization from diethyl ether/hexane (Equation 3). Compound **3** decomposes slowly in the reaction mixture, so that the reaction must be stopped after six hours at room temperature. The molecular structure of **3** (Figure 3) is quite similar to that of **1** and need not be discussed in detail. One of the Li atoms (Li2) is coordinated to an ether molecule. As a result the cage is slightly more distorted and the Li−N bonds to Li2 are longer (204.0 and 216.1 pm) than those to Li1 (197.5 and 210.2 pm).

$$2\ ClAl(CH_2CMe_3)_2 + Li_2N_2(SiMe_3)_2 \xrightarrow[-\ LiCl]{Et_2O} \quad (3)$$

$$Li_2(Al\text{-}CH_2CMe_3)_2(Me_3SiN\text{-}NSiMe_3)(N\text{-}SiMe_3)_2 \cdot OEt_2$$

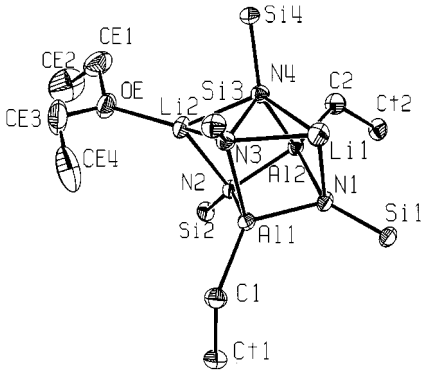
Reaction of Dilithium Bis(trimethylsilyl)hydrazide with $(Me_3C)AlCl_2$

The mechanism of the formation of the cage compounds is not well understood. We supposed that a dismutation reaction might play an important role although, in this case, the corresponding trialkylaluminium compound should be formed. However, these trialkylaluminium derivatives could not be unambiguously identified in the NMR spectra of the reaction mixtures. Nevertheless, *tert*-butylaluminium dichloride as a possible intermediate in a dismutation reaction seemed to be an appropriate starting compound for the synthesis of such derivatives in a higher yield. The imido group may be formed by a disproportionation of $[N_2(SiMe_3)_2]^{2-}$, which could yield dilithium or dialuminium trimethylsilylamide and a reactive nitrene or diimine intermediate which could be consumed by the formation of unknown secondary products.

Treatment of $Me_3C-AlCl_2$ with $Li_2N_2(SiMe_3)_2$ in an equimolar ratio without a coordinating solvent gave only decomposition products. Only with the THF solvate of the Li compound and reaction at low temperature was a pure product isolated after recrystallization in a yield of 31%. This compound was subsequently identified as the THF adduct of the corresponding dimeric iminoalane (**4**, Equation 4). Once again, the N−N bond of the hydrazido group was cleaved by the reaction with a chloroalane, and only half of the nitrogen atoms were transferred to the product. The other components of the reaction mixture, which should give more insight into the mechanism of the reaction and the fate of the missing NR groups, could neither be isolated nor identified by NMR spectroscopy. As expected, singlets of equal intensity were observed in the NMR spectra of **4** for the CMe_3 and $SiMe_3$ groups, and broad multiplets were detected for the protons of the coordinated THF molecules. The crystal structure of **4** (Figure 4) reveals two, crystallographically independent, planar Al_2N_2 heterocycles. One is



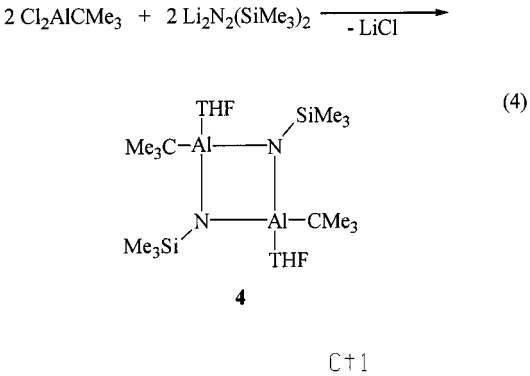


Figure 3. Molecular structure and numbering scheme of compound **3**; thermal ellipsoids are drawn at the 40% probability level (methyl groups omitted for clarity); selected bond lengths [pm] and angles [°]: Al1−N1 188.7(2), Al1−N2 187.2(2), Al2−N1 188.5(2), Al2−N2 188.9(2), N1−Si1 169.0(2), N2−Si2 169.8(2), Al1−C1 198.4(2), Al2−C2 197.9(2), Al1−N3 203.3(2), Al2−N4 200.9(2), Li1−N1 197.7(4), Li1−N3 210.2(4), Li1−N4 197.3(4), Li2−N2 203.9(4), Li2−N3 204.1(3), Li2−N4 216.1(4), N3−N4 157.1(2), N3−Si3 173.2(2), N4−Si4 174.9(2), Li2−OE 196.5(3); N1−Al1−N2 93.18(7), Al1−N1−Al2 82.46(6), N1−Al2−N2 92.67(7), Al1−N2−Al2 82.75(6), Al1−N1−Li1 91.5(1), Al2−N1−Li1 85.9(1), Al1−N2−Li2 88.4(1), Al2−N2−Li2 92.1(1), N1−Al1−N3 92.42(7), N2−Al1−N3 91.95(7), N1−Al2−N4 92.47(7), N2−Al2−N4 92.91(7), N3−Li1−N4 45.20(9), N1−Li1−N3 87.9(1), N1−Li1−N4 90.8(2), N3−Li2−N4 43.78(8), N2−Li2−N3 87.1(1), N2−Li2−N4 84.5(1), Li1−N3−Li2 129.4(2), Li1−N4−Li2 129.9(2), Li1−N3−N4 63.1(1), Li1−N4−N3 71.7(1), Li2−N3−N4 72.2(1), Li2−N4−N3 64.1(1)

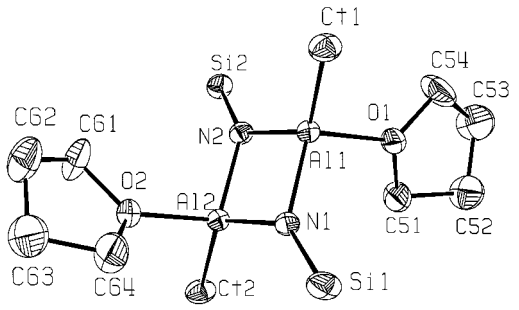
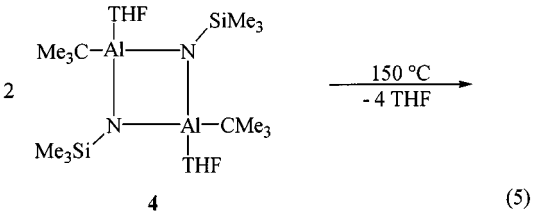
located on a crystallographic inversion center, and the other shows a maximum deviation of any atom from the plane of 1 pm. Each Al atom is further coordinated to one *tert*-butyl group and one THF molecule in a distorted tetrahedral environment, while the nitrogen atoms are attached to only one silyl group besides the aluminium atoms of the ring. The nitrogen atoms are almost ideally planar-coordinated with the sum of the angles between 359.4 and 360.0°. The heterocycles deviate slightly from an ideal square geometry and have angles of 87.3° at the nitrogen atom and 92.7° at the aluminium atom. The Al−N distances (183.4 pm on average) are shorter than in the cage compounds described above, which may be due to less steric crowding in the molecules. They are similar to the solvent free iminoalanes reported in the literature.[11] The transannular Al−Al contacts are very small (252.7 pm). As predicted by theory (see above), they do not indicate any bonding interactions between the metal atoms.

The solvent free compound **5** was obtained by heating the THF adduct to 150°C under vacuum for several hours (Equation 5). Compound **5** is almost insoluble in noncoordinating solvents like pentane or toluene and was purified by extraction with boiling toluene in a Soxhlet apparatus. Therefore, we were not able to determine its molar mass in solution by cryoscopy. Two singlets were observed in the ^{1}H NMR spectrum for the $SiMe_3$ and CMe_3 groups with equal intensity, which remained unchanged upon cooling solutions in toluene to −90°C. In the solid state, **5** reveals a unique molecular structure of a tetrameric iminoalane (Figure 5), which comprises three annelated planar four-membered heterocycles. Usually, iminoalanes give cage molecules with up to eight formula units,[20] while very large substituents give dimers or trimers with four- or six-membered heterocycles.[11] No cage compound is formed here, instead a kind of a ladder structure results with angles between the normals of the planes of 63.7°. Different Al−N bond lengths are observed. The shortest one is found between the coordinatively unsaturated atoms Al2 and N2 (180.2 pm), intermediate are the distances between the tri- and tetracoordinated atoms (188.8 pm) and the longest is the separation between the tetracoordinated atoms (Al1−N1 200.6 and Al1−N1′ 193.8 pm). The Al−Al distances are longer than described before (Al1−Al2 262.4 pm, Al1−Al1′ 278.3 pm). As expected, the N−Si bond lengths depend on the coordination number of the nitrogen atom, a short bond is observed to N2 (172.5 pm) and a longer one to N1 (177.4 pm). A similar structure has been observed in a tetraaluminium tetraoxo compound.[21]





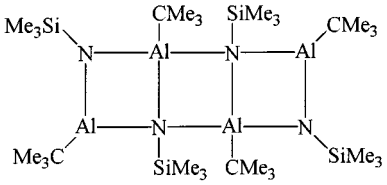


Figure 4. Molecular structure and numbering scheme of compound **4**; thermal ellipsoids are drawn at the 40% probability level (methyl groups omitted for clarity); selected bond lengths [pm] and angles [°]: Al1−N1 184.5(2), Al2−N1 183.0(2), Al1−N2 183.0(2), Al2−N2 183.8(2), Al1−O1 192.8(2), Al1−Ct1 200.5(3), Al2−O2 192.9(2), Al2−Ct2 200.5(3), N1−Si1 167.7(2), N2−Si2 168.5(2); Al1−N1−Al2 87.34(8), Al1−N2−Al2 87.51(8), N1−Al1−N2 92.45(9), N1−Al2−N2 92.67(9), Al1−N1−Si1 133.9(1), Al2−N1−Si1 138.7(1), Al1−N2−Si2 137.1(1), Al2−N2−Si2 134.8(1)

In agreement with the NMR spectroscopic data described above, the structure of **5** in solution may be quite different from that in the solid state. A dimeric iminoalane may be formed by dissociation, or a heterocubane or larger aggregate may exist as the most stable form. Remarkably, the reaction according to Equation 5 is irreversible, and treatment of **5** with a large excess of THF did not yield the THF adduct **4**. Also, the formation of the cage compound **1** was not achieved by the reaction of the solvent-free iminoalane **5** with $Li_2N_2(SiMe_3)_2$ under various conditions,

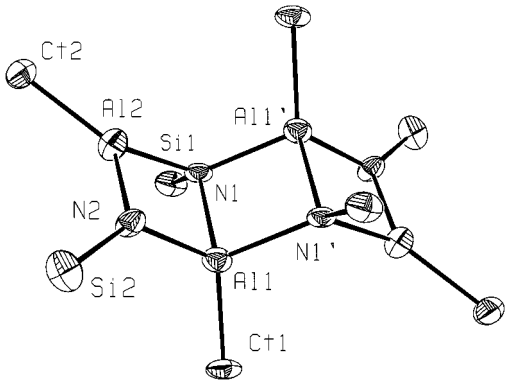

Figure 5. Molecular structure and numbering scheme of compound **5**; thermal ellipsoids are drawn at the 40% probability level (methyl groups omitted for clarity); selected bond lengths [pm] and angles [°]: Al1−N1 200.6(4), Al1−N1′ 193.8(3), Al1−N2 186.6(4), Al1−Ct1 200.8(5), Al2−N1 191.0(4), Al2−N2 180.2(4), Al2−Ct2 196.2(4), N1−Si1 177.4(4), N2−Si2 172.5(3); N1−Al1−N1′ 90.3(1), N1−Al1−N2 89.7(2), Al1−N1−Al1′ 89.7(1), Al1−N1−Al2 84.1(1), Al1′−N1−Al2 117.2(2), N1−Al2−N2 94.8(2), Al1−N2−Al2 91.3(2); Al1′ and N1′ generated by $-x + 1$, $-y$, $-z + 1$

and even the THF adduct did not react with an excess of the lithium hydrazide to form **1**. Obviously, the mechanism of the formation of such cages is very complicated and seems to be determined by several factors, which must remain unclear as long as we have no information concerning the constitution of the by-products

Experimental Section

General: All procedures were carried out under purified argon in dried solvents (THF, diethyl ether and toluene over Na/benzophenone; *n*-hexane and cyclopentane over $LiAlH_4$; pentafluorobenzene over molecular sieves). $Li_2N_2(SiMe_3)_2$,[9] di(*tert*-butyl)aluminium chloride[10] and *tert*-butyl aluminiumdichloride[18] (similar to the bromo derivative) were synthesized according to literature procedures.

Synthesis of 1: A suspension of dilithium bis(trimethylsilyl)hydrazide (0.788 g, 4.19 mmol) in 50 mL of toluene was treated at room temperature with a solution of di(*tert*-butyl)aluminium chloride (1.48 g, 8.38 mmol) in 50 mL of toluene. The mixture was stirred for 36 h, then filtered and evaporated to dryness. Colorless **1** was purified by threefold recrystallization from a toluene/hexane mixture. Yield: 0.38 g (34% based on hydrazide). − M. p. (argon, sealed capillary): 152°C (dec). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 1.42 (s, 18 H, CMe_3), 0.38 (s, 18 H, $Al_2N-SiMe_3$), −0.05 [s, 18 H, $N_2(SiMe_3)_2$]. − ^{13}C NMR (C_6D_6, 75 MHz): δ = 31.2 (CMe_3), 7.7 and 2.8 ($N-SiMe_3$), AlC not detected. − IR (CsBr, paraffin): $\tilde{\nu}$ = 1302 vw, 1252 s, 1223 w δ(CH_3), 1182 vw, 1169 vw, 1152 vw, 1063 w, 997 m, 978 m, 937 m, 889 m ν(CC), ν(NN); 837 vs, 748 s, 723 m ρ(CH_3); 658 w, 635 m, 619 w, 602 w ν(SiC), ν(SiN); 515 m, 457 w, 438 w ν(AlC), ν(AlN); 351 vw δ(SiC). − $C_{20}H_{54}Al_2Li_2N_4Si_4$ (530.9): calcd. Al 10.2; found Al 10.1. − Mol. mass: 522 (cryoscopically in benzene).

Synthesis of 2: Dilithium bis(trimethylsilyl)hydrazide (0.602 g, 3.20 mmol) was dissolved in THF. The solvent was then removed in vacuo and an NMR spectroscopic characterization showed that the adduct $Li_2N_2(SiMe_3)2{\cdot}0.5THF$ had formed. This compound was suspended in 50 mL of *n*-hexane and cooled to −30°C. A solution of di(*tert*-butyl)aluminium chloride (1.132 g, 6.41 mmol) in 50 mL of *n*-hexane was then added dropwise, and the mixture was stirred at room temperature for 16 h. After filtration and evaporation the product was purified by recrystallizing twice from *n*-hexane. Yield: 0.170 g (10% based on hydrazide). − M. p. (argon, sealed capillary): 133°C (dec). − ^{1}H NMR (C_6D_6, 133 MHz): δ = 3.61 (m, 8 H, $O-CH_2$ of THF), 1.46 (s, 18 H, CMe_3 of iminoalane), 1.19 (s, 36 H, CMe_3 of chloroalane ligand), 0.97 (m, 8 H, CH_2 of THF), 0.42 (s, 18 H, $Al_2N-SiMe_3$), 0.15 [s, br., 18 H, $N_2(SiMe_3)_2$]. − ^{13}C NMR (C_6D_6, 75 MHz): δ = 73.4 ($O-CH_2$ of THF), 31.5 (CMe_3 of iminoalane), 30.5 (CMe_3 of chloroalane), 24.6 (CH_2 of THF), 7.8 and 3.7 ($N-SiMe_3$); AlC not detected. − IR (CsBr, paraffin): $\tilde{\nu}$ = 1300 vw cm^{-1}, 1250 s δCH_3; 1182 w, 1138 vw, 1109 vw, 1040 m, 1003 m, 968 s, 934 s ν(CC), ν(CO), ν(NN); 883 m, 839 vs ρ(CH_3); 814 s ν(C_3C); 754 s, 723 w ρ(CH_3); 664 w $\nu_{as}(SiC_3)$; 638 m, 621 m, 598 m $\nu_s(SiC_3)$, ν(SiN); 546 w, 523 w, 463 w ν(AlC); 434 m, 403 m ν(AlCl); 382 vw, 361 w δ(SiC_3). − $C_{44}H_{106}Al_4Cl_2Li_2N_4O_2Si_4$ (1028.4): calcd. Al 10.5; found Al 10.3.

Synthesis of 3: A solution of dineopentylaluminium chloride (0.826 g, 4.04 mmol) in 25 mL of toluene was added at −40°C to a suspension of dilithium bis(trimethylsilyl)hydrazide (0.381 g, 2.02 mmol) in 25 mL of toluene. The mixture was allowed to warm slowly to room temperature. After stirring for 6 h LiCl was filtered off, and the solvent was removed in vacuo. The residue was recrystallized from diethyl ether/*n*-hexane. Yield: 0.130 g (10% based on hydrazide). − M. p. (argon, sealed capillary): 141°C (dec). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 3.20 (q, 4 H, $O-CH_2$), 1.43 (s, 18 H, CMe_3), 0.98 (t, 6 H, CH_3 of diethyl ether), 0.75 (s, 4 H, $Al-CH_2$), 0.43 (s, 18 H, $Al_2N-SiMe_3$), 0.11 [s, 18 H, $N_2(SiMe_3)_2$]. − ^{13}C NMR (C_6D_6, 75 MHz): δ = 65.5 ($O-CH_2$), 36.0 (CMe_3), 14.8 (CH_3 of diethyl ether), 7.4 and 4.1 ($N-SiMe_3$); AlC not detected. − IR (CsBr, paraffin): $\tilde{\nu}$ = 1304 w cm^{-1}, 1250 s δ(CH_3); 1182 w 1167 w, 1152 w, 1125 m, 1096 m, 1065 m, 1005 m, 970 m, 934 s ν(CO), ν(CC), ν(NN); 889 s, 837 vs, 756 s, 721 m ρ(CH_3); 667 m, 662 sh, 621 w, 604 w ν(SiC), ν(SiN); 563 w, 525 m, 463 m ν(AlC); 425 w ν(AlCl). − $C_{22}H_{58}Al_2Li_2N_4Si_4{\cdot}OC_4H_{10}$ (633.0): calcd. Al 8.5; found Al 8.2.

Synthesis of 4: Dilithium bis(trimethylsilyl)hydrazide (1.52 g, 8.07 mmol) was dissolved in THF and the solvent removed in vacuo to give a solid containing half a molecule of THF per formula unit of the hydrazide. This solid was treated with 50 mL of *n*-hexane and cooled to −50°C. *tert*-Butylaluminium dichloride (1.26 g, 8.07 mmol) in 50 mL of *n*-hexane was then added, and the mixture

was slowly warmed to room temperature in 8 h. Colorless crystals of **4** were obtained after filtration, evaporation and recrystallization (twice) from a mixture of hexane and toluene. Yield: 1.21 g (31%). − M. p. (argon, sealed capillary): 255°C (dec). − ^{1}H NMR (C_6D_6, 300 MHz): δ = 3.95 (m, 8 H, O−CH_2), 1.30 (s, 18 H, CMe_3), 1.23 (m, 8 H, CH_2 of THF), 0.30 ppm (s, 18 H, N−$SiMe_3$). − ^{13}C NMR (C_6D_6, 75 MHz): δ = 71.6 (O−CH_2), 31.6 (CMe_3), 25.0 (CH_2 of THF), 7.0 (N−$SiMe_3$), Al−C not detected. − IR (CsBr, paraffin): $\tilde{\nu}$ = 1298 w cm^{-1}, 1246 m, 1235 m δ(CH_3); 1181 w, 1074 m, 1017 vs, 934 w, 922 w ν(CC), ν(CO); 845 s ρ(CH_3); 822 s ν_{C3C}; 760 m, 754 m, 721 w δ(CH_3); 681 m, 658 m, 629 w ν(SiC), ν(SiN); 544 w 519 w, 492 w, 463 w, 434 m ν(AlC), ν(AlN), ν(AlO); 397 vw, 374 vw, 351 vw, 328 vw δ(C_3C), δ(SiC). − $C_{22}H_{52}Al_2N_2O_2Si_2$ (486.8): calcd. Al 11.1; found Al 11.1. − Mol. mass: 455 (cryoscopically in benzene).

Synthesis of 5: Compound **4** (1.0 g, 2.05 mmol) was heated in vacuo to 150°C for 5 h. Product **5** was extracted from the almost insoluble residue by treating with boiling toluene. It can be recrystallized from toluene. Yield: 0.25 g (36%), colorless crystals, sparingly soluble in organic solvents. − M. p. (argon, sealed capillary): >400°C. − ^{1}H NMR (C_6D_6, 300 MHz): δ = 1.31 (s, 9 H, CMe_3), 0.42 (s, 9 H, N−$SiMe_3$). − ^{13}C NMR (C_6D_6, 75 MHz): δ = 32.3 (CMe_3), 8.0 ($SiMe_3$), Al−C not detected. − IR (CsBr, paraffin): $\tilde{\nu}$ = 1312 w, 1252 vs δ(CH_3); 1167 w, 1155 w, 1086 w, 1030 w, 1003 m, 936 s ν(CC); 876 vs, 837 vs ρ(CH_3); 808 vs ν(C_3C); 754 vs, 725 s ρ(CH_3); 679 w, 621 vs ν(SiC), ν(SiN); 552 vs, 465 m ν(AlC). − $C_{28}H_{72}Al_4N_4Si_4$ (685.2): calcd. Al 15.8; found Al 15.7.

X-ray Crystal Structure Determinations: Single crystals were obtained upon cooling solutions of the compounds in hexane/toluene (**1** and **4**), hexane (**2**), hexane/diethyl ether (**3**) or toluene (**5**). Crystal data and structure refinement parameters are given in Table 1.[24] In compound **2**, the trimethylsilyl groups of Si3 and Si4 are disordered. The carbon atoms were refined with occupancy factors of 0.6 and 0.4. The THF carbon atoms C1 and C8 were refined on split positions with occupancy ratios of 0.5 to 0.5 and 0.4 to 0.6, respectively. In compound **4**, the THF molecules of the heterocycle in general position were disordered, and the atoms C11, C12, C14, C21 and C24 were refined in split positions. The molecule located on a crystallographic inversion center was completely disordered and refined in two positions with occupancy factors of 0.68 and 0.32.

Quantum Chemical Calculations: Standard ab initio molecular orbital calculations[25] were carried out with the GAUSSIAN 94 set of programs.[26] The structure of **1a** was optimized at the HF level by using the 6−31G* basis set. Population analysis was performed by employing the NBO program[27] within GAUSSIAN. Bond lengths [pm] and angles [°] of **1a** (average values, experimental values in brackets): Al−N(1,2) 201.6 (201.1), Al−N3 189.5 (188.5), Al−N4 190.2 (189.9), Li−N(3,4) 193.9 (199.6), Li−N(1,2) 198.3 and 219.3 (197.3 and 215.5), N−N 151.3 (158.9), Al−C 197.1 (200.7), N−Si(1,2) 172.8 (173.8), N−Si(3,4) 170.2 (169.1), Al···Al 250.7 (248.5), Li···Al 266.3 and 277.8 (265.9 and 282.8), Al−N−Al 82.7 (82.2), N−Al−N 93.0 (94.0), Li−N−Li 130.2 (129.7), N1−Li−N2 42.1 (45.1), Li−N−N 61.5 and 76.3 (61.5 and 73.6).

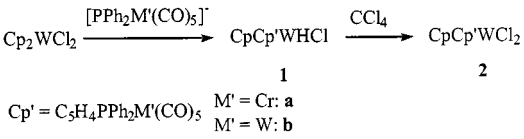
Photochemical Synthesis and Reactivity of New Chloro-Bridged Complexes with Tungstenocene (η^5-C_5H_5)(η^5-$C_5H_4PPh_2$)WClX (X = H, Cl) and Tetracarbonylmetal (Cr, W) Units

Virginie Comte,[a] Marek M. Kubicki,*[a] and Claude Moïse*[a]

Keywords: Tungsten / Sandwich complexes / Bimetallic compounds / Carbonyl complexes

Chloro-bridged bimetallic complexes (η^5-C_5H_5)[η^5-$C_5H_4PPh_2M'(CO)_4$]W(μ-Cl)X [X = Cl (**3**), X = H (**4**); M′ = Cr, W] were prepared by photochemical irradiation of (η^5-C_5H_5)[η^5-$C_5H_4PPh_2M'(CO)_5$]WClX [X = Cl (**1**), X = H (**2**); M′ = Cr, W]. The reactivity of the chloro-bridged complexes towards Lewis bases was studied; by exposure to CO or phosphanes, a facile cleavage of the chloro bridge accompanied by regio- and stereospecific coordination at M′ occurs. The X-ray structure of complex **3** (M′ = W) is reported.

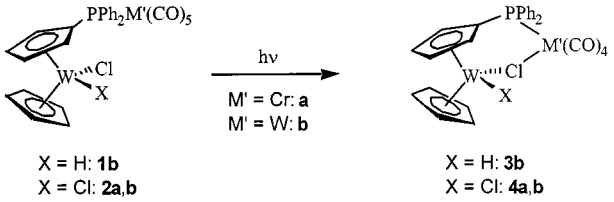
Introduction



We have recently reported that on treatment of the bent molybdocene and tungstenocene dichlorides with the metallophosphide anions $[PPh_2M'(CO)_x]^-$ (M′ = Cr, Mo, W), nucleophilic S_N2' substitution on one cyclopentadienyl Cp ring occurs.[1] This unexpected reaction offers the possibility of synthesizing various heterobimetallic systems by changing either the metal of the metallophosphide anion (M′) or that of the metallocene dichloride (M = Mo, W). Also in this field, we have observed that compounds with some interesting structures may be obtained by linking the two metallic units by an orthometallation reaction or by the formation of a hydride bridge.[2] The latter μ-H bimetallic cyclic complexes are prepared by UV irradiation of the corresponding terminal dihydrido precursors. They react with CO and phosphanes with concomitant cleavage of the hydride bridge.[3] Our ongoing interest in this area has led us to investigate the behavior of related chloro-hydrido complexes, with emphasis on the nature of the products obtained upon their photolysis. The present paper deals with the tungstenocene derivatives.

Results and Discussion

Chloro-Bridged Complexes



The two starting complexes **1** and **2** (Scheme 1) were prepared as reported previously.[2a] Thus, **1a**,**b** were prepared from Cp_2WCl_2 and $[PPh_2M'(CO)_5]^-$ (M′ = Cr, W) while the corresponding dichloro derivatives **2** were obtained by treatment of **1** with CCl_4.

UV irradiation of **1b** results in the formation of the chloro-bridged complex **3b** (Scheme 2). However, analogous

Scheme 1

treatment of the chromium derivative **1a** does not allow the isolation of defined products.

Scheme 2

Spectroscopic data for the tungsten complex are supportive of the μ-chloro structure **3b**. The CO absorption pattern is typical of an $M'(CO)_4$ fragment (four CO stretching bands), while the ^{1}H-NMR spectrum features a hydride resonance at δ = −12.3 (the signal is found at δ = −10.7 in the precursor **1b**). This suggests that the tungstenocene hydride does not interact with the $W(CO)_4$ fragment and therefore behaves as a terminal ligand. The ^{31}P resonance is shifted downfield with respect to that in **1b** (Δδ = 43 ppm). Such a deshielding may indicate some steric strain on the phosphorus atom due to the formation of the cyclic structure.[4]

Dichlorides **2** may also be transformed to chloro-bridged species by photochemical means (**4**). In contrast to compounds **1**, this reaction works for both M′ = Cr and W. The CO absorption pattern is consistent with an $M'(CO)_4$ chromophore with approximate C_{2v} symmetry. The absorptions are observed at nearly the same frequencies for **3b** and **4b** (mean values are only 5 cm^{-1} lower for **3b** than for **4b**), indicating that the substitution of the terminal H by Cl has little or no effect on the electron density within the $W(CO)_4$ fragment. It is worth noting that ν̃(CO) frequencies re-

corded for our (P)(Cl)W(CO)$_4$ units are lower than those reported for diphosphane derivatives (P)$_2$W(CO)$_4$.[5] In particular, the lowest energy B_2 band (assuming C_{2v} symmetry) is shifted by 40−50 cm^{-1}. This indicates that the chloride bridge behaves as a weaker π-acceptor than the phosphane ligand. Note, however, that the values observed for **3b** and **4b** are close to those reported for dibridged complexes Cp$_2$M(μ-PPh$_2$,H)M′(CO)$_4$ (MPPh$_2$ instead of a CpPPh$_2$ bridge),[6] but are higher than those reported for a trinuclear complex with mono-bridged bimetallic units [Cp$_2$MoH(μ-PMe$_2$)]$_2$W(CO)$_4$ (1976, 1901, 1859, and 1811 cm^{-1})[7] or for an electron-rich anion [W(CO)$_4$(PPh*i*Pr$_2$)Cl]$^-$ (1997, 1869, 1857, and 1812 cm^{-1}).[8] ^{31}P resonances for **4a** and **4b** are shifted to lower fields with respect to those of the parent compounds (Δδ = 30 ppm, M′ = Cr; Δδ = 48 ppm, M′ = W). Once again, the observed deshieldings can be attributed to steric strain on the phosphorus atom.

In order to unambiguously establish that complex **3b** contains a chloride bridge, its molecular structure was determined by X-ray diffraction analysis. Suitable crystals for this study were grown from acetone solution. The crystal structure of **3b** is built up by dinuclear organometallic molecules, in which each metal center retains its typical pseudo-tetrahedral (W2) and pseudo-octahedral (W1) geometry (Figure 1). The two metallic fragments are linked through C$_5$H$_4$PPh$_2$ and Cl bridges without direct metal−metal interaction, thus forming a formally five-membered ring. The W1−W2 separation amounts to 4.2611(8) Å (Table 1). Such a separation roughly corresponds to the metal−metal distances observed in mono-bridged one-atom μ-phosphido complexes, e.g. 4.39 Å in Cp$_2$MoH(μ-PPh$_2$)Mn(CO)$_2$Cp[9] and 4.56 Å in [Cp$_2$MoH(μ-PMe$_2$)]$_2$W(CO)$_4$,[7] but is ca. 1 Å longer than the W−W distance (3.27 Å) reported for a dibridged Cp$_2$W(μ-PPh$_2$,μ-H)W(CO)$_4$ complex containing a four-membered central ring.[6] The longest metal−metal distance (4.78 Å) in complexes with a metallocene fragment has been reported for the dibridged compound Cp$_2$Nb(μ-PPh$_2$,dmpm)Mo(CO)$_4$, which has a six-membered central ring.[10] Consequently, the size of the central bridging ring determines the metal−metal distance for complexes without a metal−metal bond.

The refined terminal hydride is found at a typical distance of 1.8(1) Å from the W2 atom. The W1−P bond length of 2.527(3) Å is of little diagnostic value as the W−P distances in W(CO)$_4$P fragments fall in a rather large range from 2.49 to 2.60 Å.[11] The most similar W−P distances are found in the pentacarbonyl compounds W(CO)$_5$PMe$_3$ (2.52 Å)[12] and W(CO)$_5$PPh$_3$ (2.54 Å),[13] the tetracarbonyl compound [W(CO)$_4$PEt$_3$]$_2$(μ-NCC$_6$H$_4$CN) (2.53 Å),[14] as well as in the tetracarbonyl anions [W(CO)$_4$(PR$_3$)X]$^-$ (X = Cl, OAc, OPh and Me) where the W−P bond lengths are close to 2.53−2.54 Å.[15] It can be noted (Table 1) that the W1^0−Cl bond [2.593(3) Å] is longer than the W2^{IV}−Cl one [2.484(3) Å], a difference which is a priori due to the different covalent radii of W^0 and W^{IV}. The tungstenocene−chloride bond length is close to that reported for Cp$_2$MoCl$_2$ (2.47 Å),[16] but is larger than the values reported for the terminal M−Cl bonds in the related [CpPPh$_2$Cr(CO)$_5$]$_2$W(H)Cl [structural model Cp$_2$W(H)Cl, W−Cl = 2.408(4) Å][3] and in *ortho*-metallated Cp[CpPPh$_2$Cr(CO)$_5$]Mo(Cl) [structural model Cp$_2$Mo(C)Cl, Mo−Cl = 2.476(2) Å].[2c] Thus, the W2−Cl bond in **3b** may be considered as remaining strong with little perturbation resulting from coordination to the second W1 atom. Consequently, the W1−Cl bond [2.593(3) Å] has to be regarded as being rather long and weak. A search of the Cambridge Structural Database for W(CO)$_4$Cl structures yielded only 8 entries. The structures of (CO)$_4$W(μ-Cl)$_3$W(CO)$_3$SnCl$_3$ (heptacoordinated W, bridging chlorides) (W−Cl = 2.52 Å, W−Cl−W = 89°)[17] and Cl(CO)$_4$WC(C$_6$H$_5$)Cr(CO)$_3$ (W−Cl = 2.48 Å),[18] as well as those of the anionic species [W(CO)$_5$Cl]$^-$ (W−Cl = 2.56 Å)[19] and [W(CO)$_4$(PMePh$_2$)Cl]$^-$ (W−Cl = 2.58 Å)[15a] are indicative of a weak W1−Cl bond.

Table 1. Selected bond lengths [Å] and angles [°] for **3b**

	Bond length [Å]		Bond angle [°]

[a] CP1 and CP2 are the centroïds of the C(5)−C(9) and C(10)−C(14) rings.

Reactions of Bridged Complexes with CO and Phosphanes

We have examined the reactivity of the two kinds of chloro-bridged compounds **3** and **4** towards CO and phosphanes, and, for a comparative study, we also carried out similar experiments with the previously reported μ-hydrido complex **5**.[2a] Addition of Lewis bases is regiospecific and occurs in all cases at the M′ metal center. Bubbling of CO through a THF solution of **3b**, **4b** or **5b** leads to the recovery of their precursors **1b**, **2b** and **6b** in high yields (Scheme 3).

Reactions of phosphanes with the chloro derivatives **3b** and **4b** proceed rapidly. With PMe$_3$ and PPhH, only the *cis* isomer is formed, whereas a *cis*/*trans* mixture (ratio 30:70) is obtained when the bulkier triphenylphosphane is used. Thus, the stereochemical course of the ring-opening reaction depends on steric hindrance to the incoming ligands (the cone angles for PMe$_3$, PPh$_2$H and PPh$_3$ are 118°, 126°

Scheme 3

and 145°, respectively).[20] Moreover, the size of the M′ metal ion also seems to play a crucial role in determining the coordination site. The tungsten derivative **3b** furnishes exclusively the *cis* isomer when treated with PMe_3, whereas we have mentioned in a previous paper[3] that its chromium analogue **5a** gives a mixture of *trans* and *cis* isomers in an 80:20 ratio. We have also observed that a longer reaction time or heating is needed in order to achieve cleavage of the hydride bridge in **5b**. The more severe conditions required indicate a greater stability of the M−H−M′ linkage (stronger H−M′ bond) in the μ-H bridged compound **5b** compared to the M−Cl−M′ linkage (weaker Cl−M′ bond). The rather long W1−Cl bond found for **3b** (vide supra) supports this idea. The kinetic nature of the *cis* stereoisomer[21] is confirmed by the isomerization that occurs upon prolonged standing in solution. Thus, the *cis* complex **7b** gives a 70:30 *trans*/*cis* mixture, for example, after 4 h in THF solution. The *cis* and *trans* assignments were made on the basis of IR and ^{31}P-NMR data. Thus, the presence of one or four CO absorptions characterizes a *trans* (D_{4h}) or a *cis* (C_{2v}) arrangement about the M′ metal center. In ^{31}P-NMR spectroscopy, both the chemical shifts and the *J* values are indicative of the mutual position of the two phosphane ligands. A *cis* configuration results in a more shielded resonance of the bridging phosphido group, together with the observation of a smaller $^2J_{pp}$ value (*cis* $^2J_{pp} = 20$ Hz vs. *trans* $^2J_{pp} = 50$ Hz).[22]

Reactions of μ-Chloro Complexes with PPh_2^-

We envisaged that the bridge-opening reaction described above might allow a chloride substitution reaction by treating the μ-chloro complexes with the anionic species $[PPh_2]^-$. The reaction did not proceed starting from the dichloro compound **4b**, but proceeded as expected from the monochloride monohydride **3b** affording the diphosphido complex **16b** together with a small amount of **8b**. Chromatographic purification led to the isolation of **16b** in pure form (Scheme 4).

3b 16b

Scheme 4

The hydride resonance for **16b** is seen as a double doublet ($^2J_{PH}$ = 18.5 Hz and $^4J_{PH}$ = 5 Hz) at δ = −10.3, while the ^{31}P-NMR spectrum displays two well-defined doublets ($^2J_{PP}$ = 20 Hz) located at δ = 38.5 and −27.2, respectively. The *J* value is indicative of the *cis* configuration (vide supra) and the shielded resonance corresponds to the nucleus of a W−P−W phosphido bridge.

We have already discussed the dependence of the ^{31}P chemical shifts in phosphido-bridged bimetallic systems on the M−P−M′ angle.[6] The chemical shift observed for **16b** can be compared with those of related phosphido-bridged complexes, in particular with those displayed by mono-bridged M(μ-P)M′ and by dibridged M(μ-P, μ-H)M′ and M(μ-P, μ-Cl)M′ structures.[23] The former are structures with relatively open M−P−M′ angles (about 125°) and the ^{31}P resonance signals lie at high field in the range δ = −60 to −65 for tungsten compounds. The latter contain a bimetallic cyclic framework with a small M−P−M′ angle value (about 80°), which results in a ^{31}P resonance deshielding by more than 100 ppm.[24] In the complex **16b**, the W−P−W linkage forms part of a pseudo five-membered ring with relatively little angle strain, which accounts for the smaller deshielding compared to those seen in four-membered M(μ-P, μ-H)M′ or M(μ-P, μ-Cl)M′ cyclic frameworks.

Conclusion

In conclusion, chloro-bridged bimetallic complexes **3** and **4** have been synthesized by photochemical irradiation. It is interesting to note that the reaction proceeds equally well when dichloro compound **1** or monochloro-monohydrido compound **2** are used. We have also shown that the chloro bridges are cleaved in a regio- and stereospecific manner when the μ-chloro complexes are exposed to two-electron donor ligands.

Experimental Section

General Comments: All reactions were carried out under purified argon. The solvents and eluents were dried by appropriate procedures and distilled under argon from sodium/benzophenone immediately prior to use. Standard Schlenk techniques and conventional glass vessels were employed. − Column chromatography was performed under argon on silica gel (70−230 mesh). − Elemental analyses were carried out with a Fisons Instruments EA 1108 CHNS-O apparatus. − Electron ionization mass spectra were recorded with a Kratos Concept 32S spectrometer. − ^{1}H- and ^{31}P-NMR spectra were recorded with a Bruker AC 200 spectrometer. Chemical shifts are quoted relative to internal TMS (^{1}H) or external H_3PO_4 (^{31}P). − IR spectra were recorded with a Nicolet 205 FT-IR spectrometer. − The complexes (η^5-C_5H_5)[η^5-C_5H_4-$PPh_2M'(CO)_5$]W(H)(Cl) (**1**), (η^5-C_5H_5)[η^5-C_5H_4-$PPh_2M'(CO)_5$]-WCl_2 (**2**), and (η^5-C_5H_5)[η^5-C_5H_4-$PPh_2M'(CO)_4$]W(H)(μ-H) (**5**) (M′ = Cr, W) were prepared according to literature procedures;[2a,3] PMe_3 and PPh_3 (Strem) were used as received. PPh_2H was prepared according to a literature method[25] and PPh_2Li was prepared from PPh_2H and butyllithium.

(η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4$]W(H)(μ-Cl) (3b): A solution of (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_5$]W(H)(Cl) (**1b**) (1.7 g, 2 mmol) in THF (100 mL) was irradiated with a Hanau TQ 150 lamp for 2 h at room temperature. The solvent was then removed in vacuo, and the residue was washed with 40 mL of pentane and chromatographed (toluene/THF, 1:1). **3b** was obtained as red crystals by recrystallization from acetone; yield 1.0 g (60%). − IR (THF): $\tilde{\nu}_{CO}$ = 2013 (m), 1901 (s), 1882 (s), 1844 (s) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = −12.35 (br., 1 H, W−H), 4.28 (m, 1 H, C_5H_4), 4.38 (m, 1 H, C_5H_4), 4.61 (m, 1 H, C_5H_4), 4.90 (s, 5 H, C_5H_5), 6.42 (m, 1 H, C_5H_4), 7.39−7.50 (m, 6 H, C_6H_5), 7.71−7.92 (m, 4 H, C_6H_5). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 55.5 (br.). − $C_{26}H_{20}ClO_4PW_2$ (830.6): calcd. C 37.60, H 2.43; found C 37.33, H 2.29.

(η^5-C_5H_5)[η^5-C_5H_4−$PPh_2M'(CO)_4$]W(Cl)(μ-Cl) (4): Complexes **4a** and **4b** were obtained according to the same procedure as described above for **3b**, except that (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2M'(CO)_5$]WCl_2 **2** (0.5 mmol) was used. The crude product was chromatographed on silanized silica (chloroform) to afford **4a** (220 mg, 60%) and **4b** (215 mg, 50%) as green crystals after recrystallization from chloroform. − (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2Cr(CO)_4$]W(Cl)(μ-Cl) (4a): IR (THF): ($\tilde{\nu}_{CO}$ = 2011 (m), 1913 (s), 1888 (s), 1854 (s) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 4.07 (m, 1 H, C_5H_4), 5.45 (s, 5 H, C_5H_5), 5.51 (m, 2 H, C_5H_4), 6.61 (m, 1 H, C_5H_4), 7.35−7.50 (m, 6 H, C_6H_5), 7.56−7.88 (m, 4 H, C_6H_5). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 82 (s). − $C_{26}H_{19}Cl_2CrO_4PW$ (733.2): calcd. C 42.59, H 2.61; found C 42.14, H 2.73. − (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4$]W(Cl)(μ-Cl) (4b): IR (THF): $\tilde{\nu}_{CO}$ = 2015 (m), 1909 (s), 1885 (s), 1849 (s) cm^{-1}. − ^{1}H NMR ($CDCl_3$): δ = 3.99 (m, 1 H, C_5H_4), 5.43 (s, 5 H, C_5H_5), 5.51 (m, 1 H, C_5H_4), 5.87 (m, 1 H, C_5H_4), 6.63 (m, 1 H, C_5H_4), 7.41−7.64 (m, 6 H, C_6H_5), 7.70−7.88 (m, 4 H, C_6H_5). − ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 62.08 (s + d, J_{WP} = 262 Hz). − $C_{26}H_{19}Cl_2O_4PW_2$ (865.02): calcd. C 36.10, H 2.21; found C 36.01, H 2.22.

Synthesis of (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_5$]W(X^1)(X^2) (X^1 = H, X^2 = H, Cl; X^1 = X^2 = Cl): At 50°C, 0.5 mmol of (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4$]W(X^1)(μ-X^2) (**3b**, **4b** or **5b**) was stirred in THF (20 mL) under carbon monoxide for 2 h. The solvent was then removed under reduced pressure, and the mono-bridged complex (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_5$]W(X_1)(X_2) (**1b**, **2b** or **6b**)[2a] was isolated.

Synthesis of (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4$(L)]W(H)(Cl) (L = PMe_3, PPh_2H, PPh_3): To a solution of **3b** (200 mg, 0.25 mmol) in THF (20 mL) was added 1 equiv. of the appropriate phosphane and the resulting mixture was stirred at room temperature for 2 h. The solvent was then removed, and the crude product was washed

with pentane (3 × 20 mL). All attempts to recrystallize the complexes resulted in their decomposition.

(η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4(PMe_3)$]W(H)(Cl) (7b): The reaction afforded purely the *cis* isomer **7b**, which was obtained as an orange powder in 60% yield (140 mg). After redissolution of this product in THF and stirring at room temperature, small amounts of the *trans* isomer could be detected. − ***cis* Isomer 7b:** IR (THF): $\tilde{\nu}_{CO}$ = 2013 (m), 1906 (s), 1892 (s), 1872 (s) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = −10.68 (s + d, $^1J_{WH}$ = 60 Hz, 1 H, W−H), 1.16 (d, $^2J_{PH}$ = 7.4 Hz, 9 H, Me), 4.19 (m, 1 H, C_5H_4), 4.58 (m, 1 H, C_5H_4), 4.79 (s, 5 H, C_5H_5), 5.09 (m, 1 H, C_5H_4), 5.75 (m, 1 H, C_5H_4), 7.29−7.43 (m, 6 H, C_6H_5), 7.53−7.62 (m, 4 H, C_6H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −41.9 (d + dd, $^2J_{PP}$ = 20 Hz, $^1J_{WP}$ = 216 Hz, PMe_3), 16.30 (d + dd, $^2J_{PP}$ = 20 Hz, $^1J_{WP}$ = 246 Hz, PPh_2). − $C_{29}H_{29}ClO_4P_2W_2$ (906.65): calcd. C 38.42, H 3.22; found C 38.86, H 3.60. − ***trans* Isomer 7b:** IR (THF): $\tilde{\nu}_{CO}$ = 1882 (s) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = −10.66 (s + d, $^1J_{WH}$ = 60 Hz, 1 H, W−H), 1.27 (d, $^2J_{PH}$ = 7.4 Hz, 9 H, PMe), 3.25 (m, 1 H, C_5H_4), 4.15 (m, 1 H, C_5H_4), 4.72 (s, 5 H, C_5H_5), 5.19 (m, 1 H, C_5H_4), 6.03 (m, 1 H, C_5H_4), 7.20−7.60 (m, 10 H, C_6H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −34.1 (d + dd, $^2J_{PP}$ = 50 Hz, $^1J_{WP}$ masked, PMe_3), 16.30 (d + dd, $^2J_{PP}$ = 50 Hz, $^1J_{WP}$ masked, PPh_2).

(η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4(PPh_2H)$]W(H)(Cl) (8b): The *cis* isomer **8b** was obtained as an orange powder in 50% yield (125 mg). (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4(PPh_3)$]WH_2 (15b): A mixture of the *cis* and *trans* isomers of **15b** (*cis*/*trans* = 30:70) was obtained after stirring for 48 h at 50°C. The isomers were invariably obtained accompanied by small amounts of the μ-hydrido complex **6b**. − ***cis*/*trans* Mixture:** IR (THF): $\tilde{\nu}_{CO}$ = 2017 (m), 1914 (s), 1889 (s), 1845 (s) cm^{-1}. − ***cis* Isomer 15b:** ^1H NMR ($CDCl_3$): δ = −12.29 (s + d, $^1J_{WH}$ = 71 Hz, 2 H, W−H), 4.03 (m, 2 H, C_5H_4), 4.39 (s, 5 H, C_5H_5), 4.96 (m, 2 H, C_5H_4), 7.26−7.82 (m, 25 H, C_6H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 12.15 (d + dd, $^2J_{PP}$ = 25 Hz, $^1J_{WP}$ masked, PPh_3), 20.10 (d + dd, $^2J_{PP}$ = 25 Hz, $^1J_{WP}$ masked, PPh_2). − ***trans* Isomer 15b:** ^1H NMR ($CDCl_3$): δ = −12.19 (s + d, $^1J_{WH}$ = 72 Hz, 2 H, W−H), 4.24 (m, 2 H, C_5H_4), 4.32 (s, 5 H, C_5H_5), 5.00 (m, 2 H, C_5H_4), 7.25−7.82 (m, 25 H, C_6H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 18.70 (d + dd, $^2J_{PP}$ = 60 Hz, $^1J_{WP}$ masked, PPh_3), 25.10 (d + dd, $^2J_{PP}$ = 60 Hz, $^1J_{WP}$ masked, PPh_2).

Synthesis of (η^5-C_5H_5)[η^5-C_5H_4−$PPh_2W(CO)_4$]W(H)(μ−PPh_2) (16b): A solution of PPh_2Li (100 mg, 0.5 mmol) in THF (5 mL) was added dropwise to a stirred solution of **3b** (400 mg, 0.5 mmol) in THF (20 mL) at −78°C. The resulting mixture was allowed to warm to room temperature and then stirred for 3 h. Removal of the solvent afforded an orange residue. NMR spectra indicated the presence of two products, namely the complexes **8b** and **16b**. The crude residue was chromatographed (toluene/THF, 1:1). The first orange band contained **8b**, while **16b** was isolated in ca. 40% yield from the second yellow band (200 mg) as a yellow powder after recrystallization from acetone. − IR (THF): $\tilde{\nu}_{CO}$ = 2004 (m), 1905 (s), 1876 (s), 1860 (s) cm^{-1}. − ^1H NMR ($CDCl_3$): δ = −10.36 (dd + ddd, $^4J_{PH}$ = 5 Hz, $^2J_{PH}$ = 18.5 Hz, $^1J_{WH}$ masked, 1 H, W−H), 4.28 (s, 5 H, C_5H_5), 4.66 (m, 1 H, C_5H_4), 5.04 (m, 1 H, C_5H_4), 5.19 (m, 1 H, C_5H_4), 5.67 (m, 1 H, C_5H_4), 7.18−7.81 (m, 20 H, C_6H_5). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = −27.2 (d + dd, $^2J_{PP}$ = 20 Hz, $^1J_{WP}$ = 211 Hz, $^1J_{WP}$ masked, μ-PPh_2), 38.5 (d + dd, $^2J_{PP}$ = 20 Hz, $^1J_{WP}$ masked, PPh_2). − MS; *m*/*z*: 979 [M^+]. − $C_{38}H_{30}O_4P_2W_2$ (980.3): calcd. C 45.13, H 2.99; found C 45.99, H 3.16.

X-ray Crystallographic Study of 3b: An orange crystal of approximate dimensions 0.35 × 0.35 × 0.10 mm was used for unit cell measurements and intensity data collection, carried out at 296 K with an Enraf−Nonius CAD4 diffractometer with Mo-K_α radiation (λ = 0.71073 Å). The pertinent crystallographic data are given in Table 2. The unit cell was determined from 25 randomly selected reflections (CAD4-EXPRESS).[26] Intensity data were reduced with PROCESS as implemented in the MolEN package[27] with neutral-atom scattering factors taken from the usual source. An empirical absorption correction (ψ scan) was applied. The structure was solved by direct methods (SHELXS-97)[28] and refined by using the SHELXL-97 library.[29] The hydride ligand was located from a difference Fourier map. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-117399. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Table 2. Crystal data and structure refinement for **3b**

Empirical formula	$C_{26}H_{20}ClO_4PW_2$
Molecular mass	830.54
T [K]	293(2)
Wavelength [Å]	0.71073
Crystal system, space group	monoclinic, $P2_1/c$
Unit cell dimensions	*a* = 16.048(3) Å, *b* = 10.148(2) Å, *c* = 15.728(2) Å, β = 102.14(1)°
V [Å^3]	2504.1(8)
Z	4
Calculated density [Mg/m^3]	2.203
Absorption coefficient [mm^{-1}]	9.381
F(000)	1552
Crystal size [mm]	0.35 × 0.35 × 0.10
Theta range for data collection [°]	2.39 to 24.97
hkl range	0/19, 0/12, −18/18
Reflections collected/unique	4836/3562
EAC, ψ scan, min./max. transm.	25.54/99.99
Refinement method	Full-matrix least squares on F^2
Data/restraints/parameters	3562/0/311
Goodness-of-fit on F^2	1.094
Final *R* indices [$I > 2\sigma(I)$]	*R*1 = 0.0426, *wR*2 = 0.1278
Largest diff. peak and hole [eÅ^{-3}]	2.850 and −2.457

The Lewis Basicity of Diaminocarbene – A Theoretical Study of Donor–Acceptor Complexes of $C(NH_2)_2$, NH_3 and CO with the Lewis Acids EF_3, ECl_3 (E = B, Al, Ga, In), TiF_4 and $TiCl_4$

Ariana Beste,[a] Oliver Krämer,[a] Anja Gerhard,[a] and Gernot Frenking*[a]

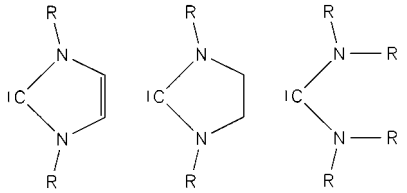
Keywords: Diaminocarbenes / Lewis basicity / Ab initio calculations / Donor–acceptor complexes

Quantum chemical calculations at the MP2 level using large valence basis sets up to TZ+2P quality have been carried out in order to predict the geometries and bond energies of the title compounds. The nature of the donor–acceptor bond has also been investigated. The calculations show clearly that diaminocarbenes are much stronger Lewis bases than amines. The complexation energies of $C(NH_2)_2$ have been calculated to be 14–27 kcal/mol higher than those of NH_3. The most strongly bonded complex is $Cl_3Al–C(NH_2)_2$, which has a theoretically predicted Al–C bond energy D_o = 59.1 kcal/mol. In all the complexes, the strength of the Lewis bases is $C(NH_2)_2 > NH_3 > CO$, but the ordering of Lewis acid strength of EX_3 depends on the coordinated Lewis base. TiF_4 and $TiCl_4$ have similar Lewis acidities as BF_3, but the titanium tetrahalides may bind one or two donor molecules with almost the same bond strength. The investigated donor–acceptor bonds have a high degree of ionic character. The largest covalent contributions are found for the diaminocarbene complexes. The covalent character of the $X_3E–CO$ bond increases on going from E = boron to the heavier Group 13 elements, while the opposite order is found for the $X_3E–NH_3$ and $X_3E–C(NH_2)_2$ bonds.

Introduction

The concept of "dative" or "semipolar" bonds between an electron-pair donor and an acceptor introduced by Lewis[1] has become very useful for understanding the structures, bond strengths, and reactivities of donor−acceptor complexes. Chemical bonding in main group chemistry is usually discussed in terms of covalent or ionic interactions and the model of donor−acceptor bonds plays only a minor role. In contrast, it is customary to consider chemical bonding in transition metal compounds as arising from closed-shell interactions between the metal M and the donor ligand D, even when formal cleavage of the M−D bond yields charged fragments M^+ and D^-. This is because coordination compounds are much more common in transition metal chemistry than in main group element chemistry. Nevertheless, it has been shown that the donor−acceptor model is a very useful device for many main group compounds as well.[2]

The strength of a donor−acceptor bond depends on the Lewis acidity and basicity of the binding partners. A given set of Lewis acids or bases can be classified in order of ascending acidity/basicity, but this order may only be valid with respect to a particular binding partner. For example, the π-donor ability of the halogens in BX_3 increases regularly on going from X = fluorine to iodine,[3] but the Lewis acid strength of BX_3 either increases or decreases on going from BF_3 to BI_3, depending on whether the donor−acceptor bond in the complex has more ionic or covalent character. This is the well-known basis of the model of hard and soft acids and bases.[4]



A Lewis base is characterized by having an energetically high-lying electron pair, which serves as the donor moiety. This can either be an atom-centered electron lone-pair, or the π-electrons of a multiple bond. Compounds that have neither lone-pair electrons nor multiple bonds[5] are usually weak Lewis bases. The strongest donor−acceptor bond of a main group complex that has been determined experimentally is that between NMe_3 and $AlCl_3$.[2] The measured dissociation energy of $Cl_3Al−NMe_3$ in the gas phase is D_o = 47.5 ± 2.0 kcal/mol.[6] Even stronger bonds have been predicted theoretically for donor−acceptor complexes of the strong Lewis acid BeO, but this has not yet been experimentally verified.[7]

It is generally the case that the Lewis basicity of lone-pair donor molecules increases on going from right to left across the periodic system of the elements. Thus, the trend in the donor strengths is Ne < FH < OH_2 < NH_3. The next member of this series would be ($^1A_1$) CH_2. Indeed, carbenes are well-known ligands in transition metal chemistry[8] and many transition metal carbene complexes have been synthesized and characterized since Fischer isolated the first example of such a species.[9] Main group carbene complexes have only been known following the isolation by Arduengo of the first stable carbene, i.e. the 1,3-bis(adamantyl) derivative of imidazol-2-ylidene **A** (Scheme 1).[10] Several complexes of substituted analogues of **A** with BH_3, BF_3, AlH_3, and other Lewis acids have since been synthesized.[11][12]

A B C

Scheme 1. Examples of diaminocarbenes that have been synthesized

The chemistry of *N*-heterocyclic carbenes has become one of the most extensively investigated areas of organic and organometallic chemistry in the last decade. Milestones were the isolation of stable saturated diaminocarbenes **B**,[13] the synthesis of stable noncyclic diaminocarbenes **C**,[14] and reports on stable heterocyclic carbenes with other neighbouring atoms such as sulfur[15][16] and oxygen.[16] The interest in metal complexes of *N*-heterocyclic carbenes increased considerably after it was reported that carbene complexes exhibit catalytic properties which might be comparable with those of phosphane complexes.[12][17] In spite of numerous experimental studies, there has been no report concerning the measurement of the bond strength of a donor−acceptor bond between a metal and an *N*-heterocyclic carbene ligand. Experimental observations indicate that the bonds are quite strong, and that the donor−acceptor bonds show mainly carbene→metal σ-donation but little carbene←metal π-back-donation.[12] This assumption is supported by two recent theoretical studies of carbene complexes with beryllium[18] and Group 11 transition metal halides (CuCl, AgCl, AuCl).[19]

The focus of the present paper is the trend in the donor strengths of Lewis bases on going from nitrogen to carbon, i.e. the difference between the donor−acceptor bond strengths of amines and *N*-heterocyclic carbenes when they are bonded to Lewis acids of main group elements or early transition metals. We have chosen the parent compounds NH_3 as the amine and $C(NH_2)_2$ as the carbene. CO has also been included in order to highlight the different donor abilities of carbon lone-pair electrons in sp- and sp^2-hybridized orbitals. The difference between the Lewis basicities of NH_3 and substituted amines is known from experimental[20] and theoretical work.[21] $C(NH_2)_2$ should be a good model for studying the donor strength of *N*-heterocyclic carbenes since substituents at nitrogen influence the carbene center only indirectly. The different donor abilities of $C(NH_2)_2$ and substituted analogues thereof is the subject of another ongoing study in our group. The chosen Lewis acids were the main group compounds EF_3, ECl_3 (E = B, Al, Ga, In) and the titanium tetrahalides TiF_4 and $TiCl_4$. We report here the equilibrium geometries and bond energies calculated at the MP2 level using polarized valence basis sets of up to TZ+2P quality. The electronic structures of the molecules were analyzed with the help of the natural bond orbital (NBO) partitioning scheme developed by Weinhold.[22] This work is part of our ongoing systematic investigation of the structures and stabilities of donor−acceptor complexes of main group and transition metal elements.[23]

Theoretical Methods

The geometry optimizations were carried out using Møller−Plesset perturbation theory terminated at second order (MP2)[24] in conjunction with our standard basis set II,[25] which has a relativistic effective core potential (ECP)[26] with a (441/2111/41) valence basis set for Ti, 6−31G(d)[27] all-electron basis sets for H, B, C, N, O, and F, and ECPs with a (31/31/1) valence basis set for the heavier main-group elements Al, Ga, In, Cl.[28] Improved energy calculations were carried out at the MP2 level using the larger basis set II+. The latter has an additional f-type polarization function at Ti (ζ = 1.506),[29] 6−311G(2d,p)[30] all-electron basis sets for H, B, C, N, O, F, Al, and Cl, and ECPs with a TZ+2P valence basis set (311/311/11)[28] for Ga and In. The harmonic vibrational frequencies and zero-point vibrational energies (*ZPE*) were calculated at the MP2/II level. All structures reported here are minima on the potential energy surface (only positive eigenvalues of the Hessian matrix). The calculations were carried out using the Gaussian-94 program package.[31]

Bond Energies and Geometries

Figure 1 shows the optimized structures and the most important geometrical parameters predicted at the MP2/II level of theory for the complexes **1a**−**10cc** comprising the Lewis acids **1**−**10** and the Lewis bases **a**−**c**. Table 1 gives the energies calculated at the MP2/II+ level using the MP2/II optimized geometries.

The calculated bond dissociation energies of the main group and transition metal complexes containing $C(NH_2)_2$ are very high, showing that the diaminocarbene ligand is a very strong Lewis base. The largest value is calculated for $Cl_3Al-C(NH_2)_2$ (**6c**) (D_e = 61.6 kcal/mol; D_o = 59.1 kcal/mol), while the lowest is predicted for $F_4Ti-C(NH_2)_2$ (**9c**) (D_e = 38.5 kcal/mol). Thus, diaminocarbenes are not only stronger Lewis bases than NH_3, but are even stronger than $N(CH_3)_3$, for which a bond dissociation energy of D_e = 50.2 kcal/mol (D_o = 47.6 kcal/mol, experimental value D_o = 47.5 ± 2 kcal/mol)[6] has been predicted at the MP2/II level for the complex $Cl_3Al-N(CH_3)_3$.[23b] It can thus be foreseen that complexes between *N*-heterocyclic carbenes and $AlCl_3$ will soon replace $Cl_3Al-N(CH_3)_3$ as the most strongly bonded donor−acceptor complexes of main group elements known experimentally.

The Lewis basicity of NH_3 is also high, but is clearly lower than that of $C(NH_2)_2$. The bond dissociation energies of the ammonia complexes are calculated to be between D_e = 44.1 kcal/mol (Cl_3Al-NH_3, **6a**) and D_e = 24.1 kcal/mol (F_4Ti-NH_3 **9a**) for complexes with one Lewis base. The second ammonia ligand in $F_4Ti(NH_3)_2$ (**9aa**) has the lowest bond energy among the NH_3 complexes (D_e = 21.6

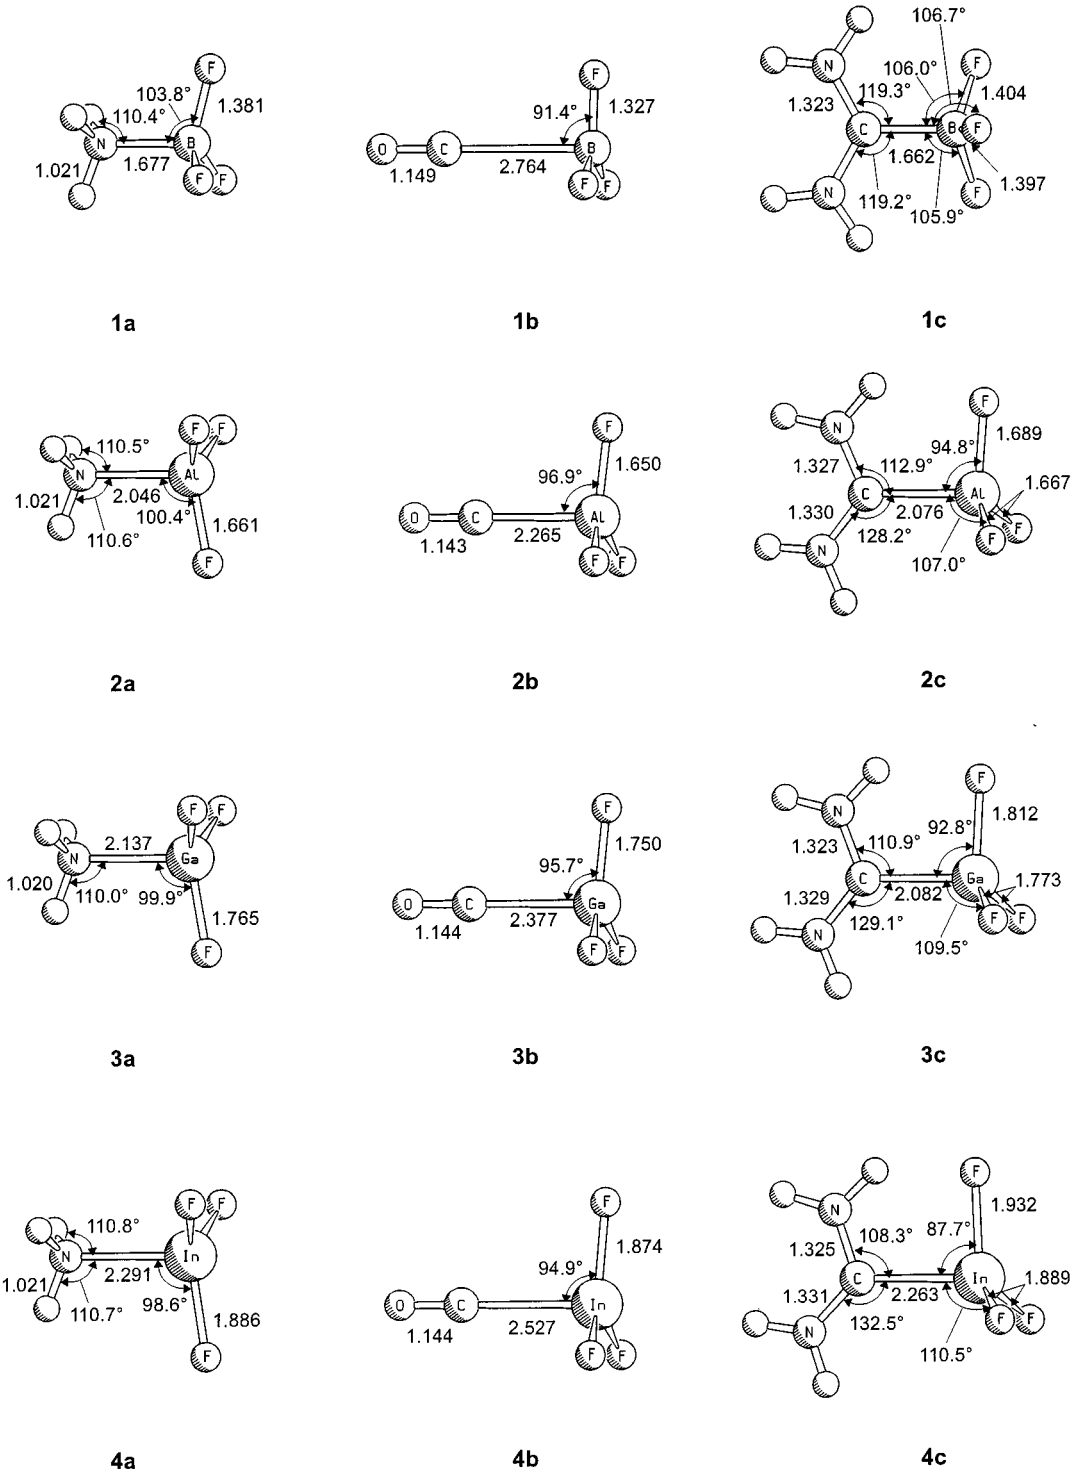

Figure 1. Optimized geometries of the complexes and fragments at the MP2/II level; bond lengths in Å, angles in degrees

kcal/mol). For all the complexes, the calculations show a clear trend in the Lewis basicities CO < NH_3 < $C(NH_2)_2$. CO is always significantly less strongly bonded (by 17−30 kcal/mol) in the complexes than NH_3, while $C(NH_2)_2$ is more strongly bonded (by 14−27 kcal/mol) than NH_3. The most strongly bonded CO complex is predicted to be F_3Al−CO (**2b**) (D_e = 15.1 kcal/mol). Note that CO forms particularly weak bonds with boron halides (D_e = 3.2 kcal/mol in **1b**, 2.3 kcal/mol in **5b**).

The calculated trends in the bond strengths of the Lewis acid adducts depend both on the nature of the Lewis base D and on the halogen atom. For the F_3E−D species, it is found that the complexes with E = Al, Ga, In, and the same ligand D have similar bond dissociation energies,

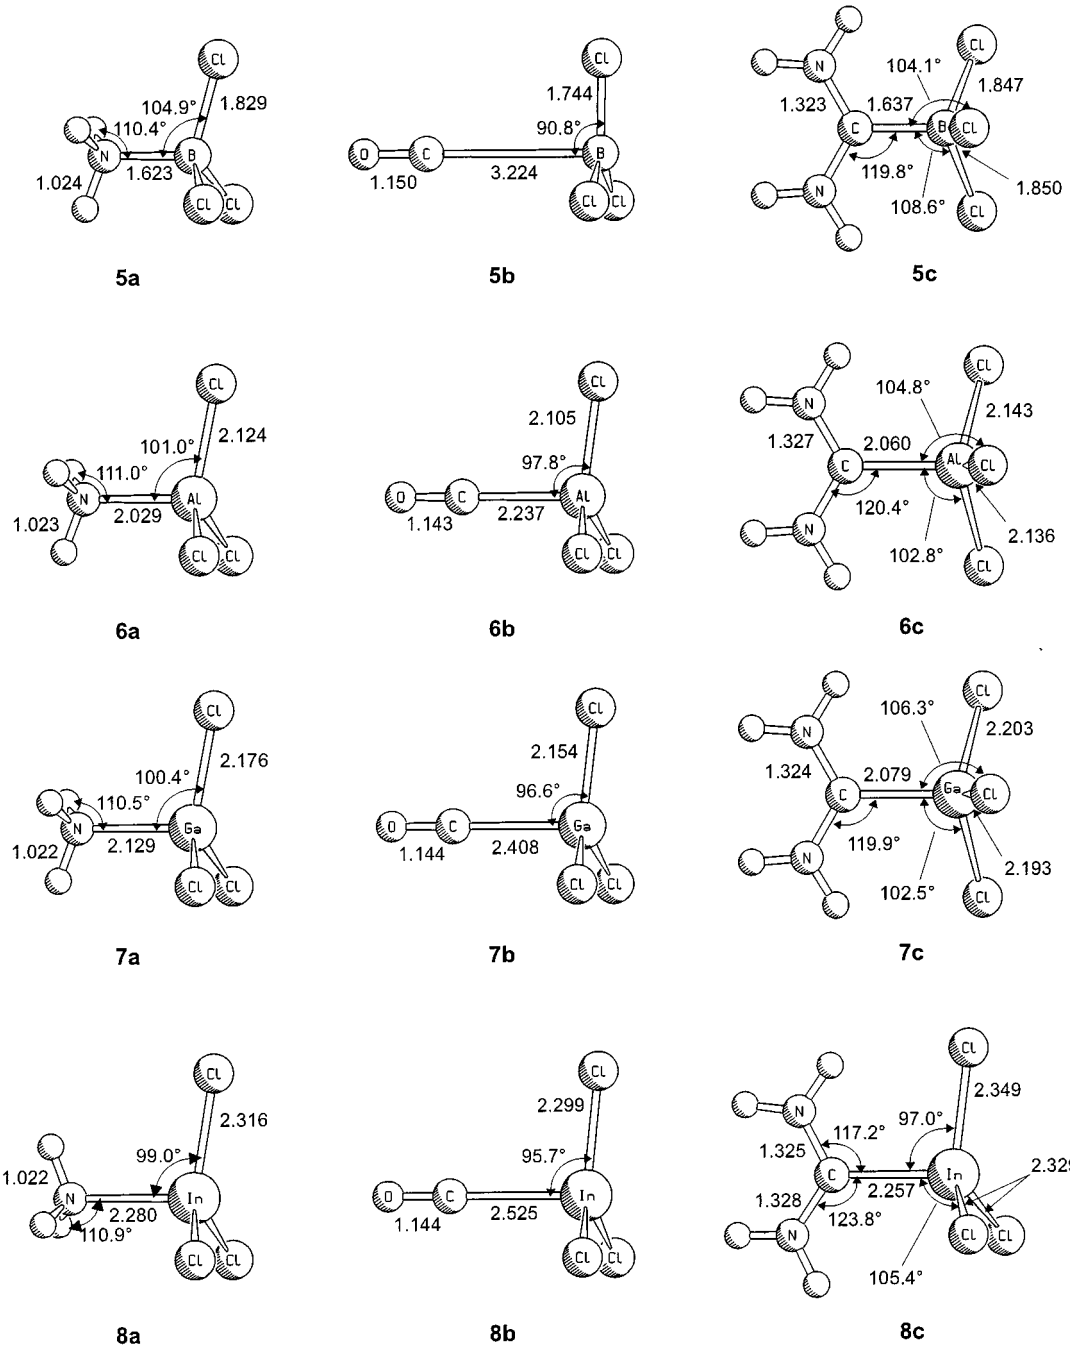

Figure 1. *(Continued)*

while the F_3B-D complexes are clearly less strongly bonded. The situation with the Cl_3E-D complexes is somewhat different. $Cl_3B-C(NH_2)_2$ (**5c**) has a higher bond dissociation energy (D_e = 59.7 kcal/mol) than the gallium complex **7c** (D_e = 57.5 kcal/mol) or the indium complex **8c** (D_e = 57.6 kcal/mol), and it is only slightly less strongly bonded than $Cl_3Al-C(NH_2)_2$ (**6c**) (D_e = 61.6 kcal/mol). NH_3, and particularly CO, form weaker bonds with BCl_3 than with the heavier analogues $AlCl_3$, $GaCl_3$, and $InCl_3$.

A comparison of the donor–acceptor bond strengths of the main group complexes with those of the transition metal compounds shows that for the three donor ligands D, TiF_4 and $TiCl_4$ have similar Lewis acidities as BF_3. The difference between the two groups of complexes is that TiF_4 and $TiCl_4$ can strongly bind *two* ligands D with almost the same bond strength, thereby yielding TiX_4D and TiX_4D_2, while main group Lewis acids show only weak affinities for binding more than one Lewis base.[2] Table 1 shows that in most cases the theoretical bond strengths of the first and second Ti–D bonds are similar. The second Ti–D bond may even be stronger than the first. For example, the energies required for dissociation of the first and second $C(NH_2)_2$ ligands from $Cl_4Ti[C(NH_2)_2]_2$ are 45.8 kcal/mol and 41.2 kcal/mol, respectively. The first and second am-

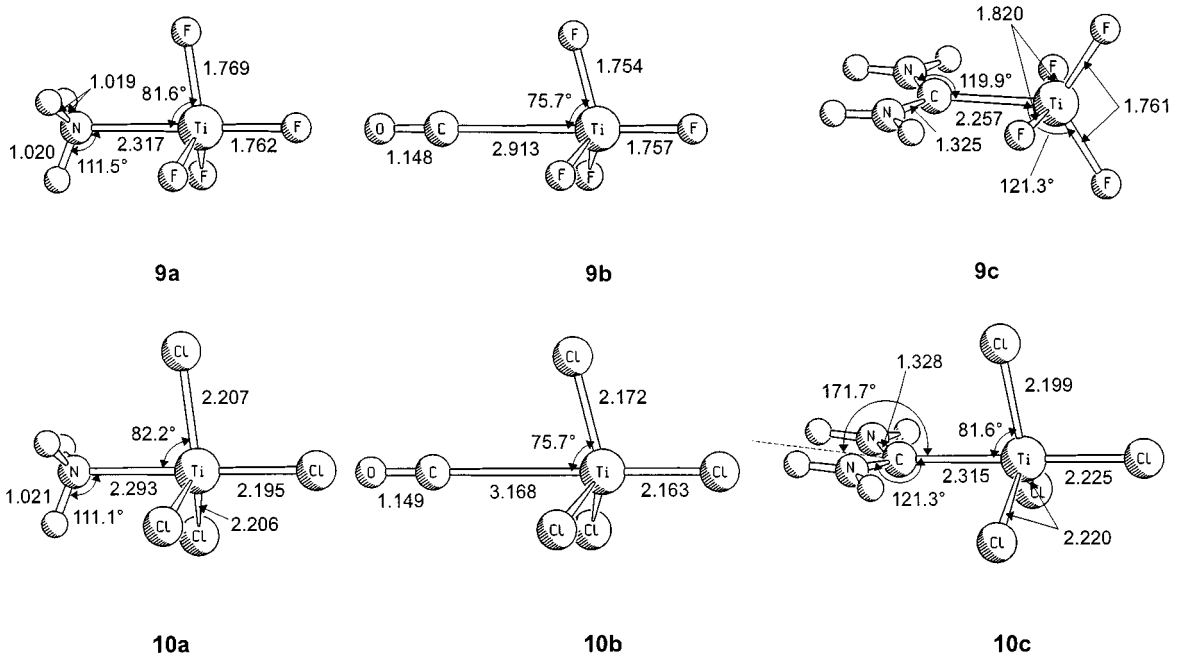

Figure 1. *(Continued)*

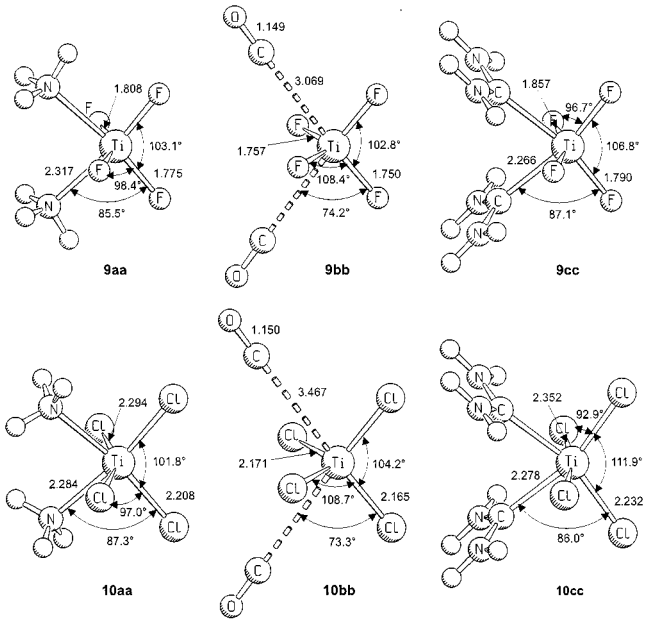

Figure 1. *(Continued)*

monia ligands of $Cl_4Ti(NH_3)_2$ are bound with similar bond strengths (D_e = 24.3 and 23.8 kcal/mol, Table 1). This is in contrast to the relative bond strengths in $OsO_4(NH_3)_2$, where the second NH_3 is clearly more weakly bound (D_e = 7.0 kcal/mol) than the first (D_e = 13.9 kcal/mol).[23b]

The theoretically predicted strong bonding of the first and second carbene ligands in $Cl_4Ti[C(NH_2)_2]_2$ is consistent with the experimental observation that the reaction of $MCl_4(THF)_2$ (M = Ti, Zr, Hf) with 1,3-dialkyl derivatives of imidazol-2-ylidene **A** may yield the respective monocarbene complex Cl_4TiD[32] or the dicarbene complex Cl_4TiD_2,[33] depending on the stoichiometry of the starting materials.

Experimental values for the bond energies are not available, but previous work on other donor−acceptor complexes carried out at the same level of theory showed that the theoretical values deviated by less than 3 kcal/mol from the experimental data.[23b] We believe the present values to have a similar degree of accuracy.

The geometries shown in Figure 1 reveal interesting aspects of the donor−acceptor interactions. We begin the discussion with the main group complexes **1a**−**8c**. It has previously been found that the B−F bond length in BF_3 becomes longer in donor−acceptor complexes F_3B−D, and that this extension of the B−F distance increases with increasing strength of the F_3B−D bond.[23b] The data in Figure 1 and Table 1 show that this also holds true for the BF_3 complexes investigated here, i.e. the B−F bond length increases in the order BF_3 < **1b** < **1a** < **1c**. The same trend is calculated for the other E−F and E−Cl bond lengths. The carbonyl complexes invariably have the shortest E−X bonds, while the longest are found for the diaminocarbene complexes. A correlation of the X_3E−D bond energies with the pyramidalization of the EX_3 moiety of **1a**−**8c** is also found. The angle D−E−X becomes larger in the order D = CO < NH_3 < $C(NH_2)_2$. Some D−E−X bond angles with D = $C(NH_2)_2$ become acute because of hydrogen bonding between one X atom and a proton of the amino group. In particular, the F_3E−$C(NH_2)_2$ complexes show an increased asymmetry about the E−C bond in the order **1c** < **2c** < **3c** < **4c**. Note the significant lengthening of the in-plane E−F

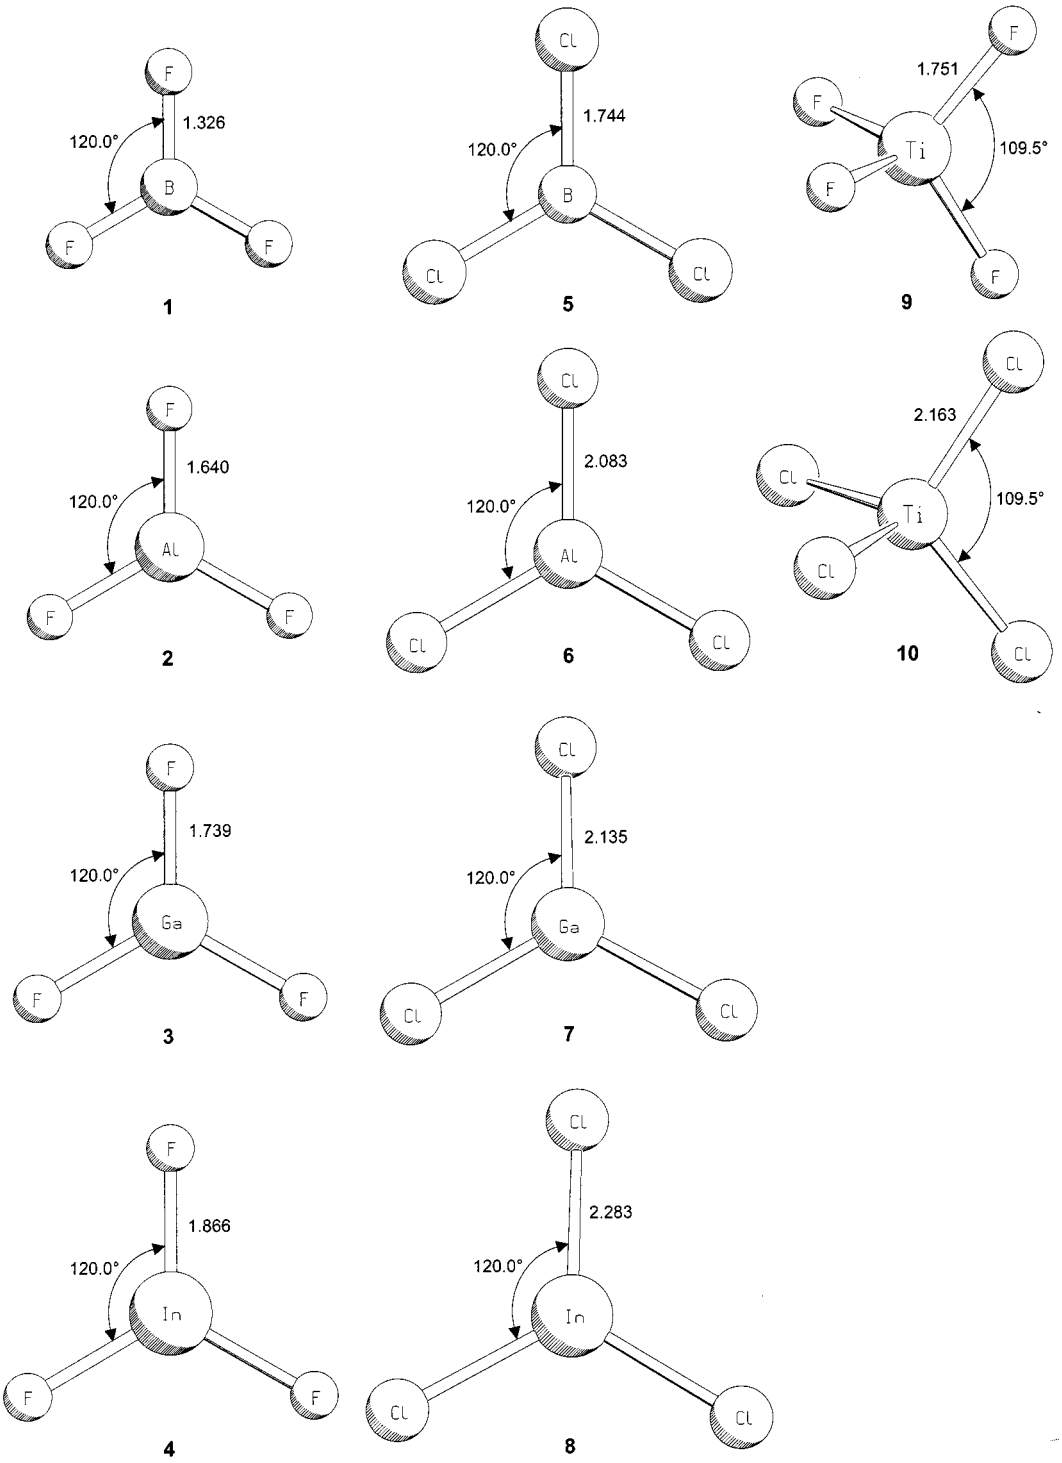

Figure 1. *(Continued)*

bond and the tilt of one amino group towards the in-plane fluorine atom in the complexes. Among the chlorine analogues, the same effect is found only for the indium complex **8c** (Figure 1).

The donor moieties in the pentacoordinated transition metal complexes X_4TiD have the ligand D *trans* to X, except in **9c**, where hydrogen bonding between fluorine and the amino group protons enforces an equatorial position of the carbene ligand. The diaminocarbene ligand in **10c** is slightly tilted from the N_2CTi plane (Figure 1). The hexacoordinated complexes X_4TiD_2 have the ligands D *cis* to one another. The *trans* forms (not shown here) are clearly higher in energy. This is in agreement with experimental evidence.[34]

We did not systematically calculate the activation barriers for rotation about the D−E bonds. However, some test cal-

culations showed that the rotational barriers appear to be very low, e.g. < 2 kcal/mol.

Analysis of the Bonding Situation

Table 2 shows the results of NBO analyses of the complexes. The data reveal some unexpected features concerning the bonding situations in the molecules.

The calculated D→EX_3 charge donations in complexes of the Group 13 elements E show a marked difference between the boron halides and the heavier analogues. The charge donation OC→BX_3 is negligible, while the charge donations H_3N→BX_3 and $(NH_2)_2C$→BX_3 are rather large. The OC→EX_3 charge donation is greater for the heavier elements E = Al, Ga, In, while the H_3N→EX_3 and $(NH_2)_2C$→EX_3 charge transfer is less than that in the boron complexes. In fact, OC→EX_3 and H_3N→EX_3 charge donations are rather similar for the heavier Group 13 elements (Table 2). The calculated charge transfers in the Group 13 complexes suggest that the covalent character of the OC−EX_3 bond becomes stronger on going from E = boron (where it is practically nil) to E = Al, Ga, In, while the covalency of the H_3N−EX_3 and $(NH_2)_2C$−EX_3 bonds decreases on going from E = boron to E = Al, Ga, In.[35] This surprising result is supported by the calculated bond orders, which are clearly higher for the OC−EX_3 bonds of the heavier Group 13 elements than for boron, while the opposite order is calculated for the H_3N−EX_3 and $(NH_2)_2C$−EX_3 bonds (Table 2). The same conclusion can be drawn from the trend in the polarities of the D−EX_3 bonds. The donor−acceptor bond orbital is invariably polarized towards the donor atom. The polarization is higher for the OC−BX_3 bond (which is a pure carbon lone pair orbital) than for the heavier OC−EX_3 analogues, while the polarizations of the H_3N−EX_3 and $(NH_2)_2C$−EX_3 bonds show the opposite trend. However, in all cases, the donor−acceptor bonds of $C(NH_2)_2$ retain the highest covalent character of the three Lewis bases. The calculated charge donation Δq(D→A), the polarization, and the bond order of the D−A bonds indicate that the covalent character increases in the order X_3B−CO < X_3B−NH_3 < X_3B−$C(NH_2)_2$, while for the other Group 13 Lewis acids the trend is X_3E−CO ≈ X_3E−NH_3 < X_3E−$C(NH_2)_2$.

The Ti−D bonds in the transition metal complexes have less covalent character than those in the Group 13 complexes. The NBO method finds a Ti−D bond orbital only for diaminocarbene complexes, while the TiX_4 complexes with CO and NH_3 as donor ligands have lone-pair orbitals at their donor atoms. The Ti−D bonds are mainly held together by the charge attraction between the large positive charge at the titanium atom and the negative charge of the lone-pair electrons. The calculated partial atomic charges do not reveal the extent of the charge interaction, which is strongly influenced by the topography of the anisotropic charge distribution.

An important feature is highlighted by the calculated hybridization at the Ti end of the X_4Ti−$C(NH_2)_2$ bonds.

Table 2. Results of the NBO analysis at the MP2/II level[a]

[a] Donor→acceptor charge donation Δq(D→A); partial atomic charges q of the donor atoms D(x) and acceptor atoms A(y); polarization of the donor−acceptor bond D(x)−A(y) in%x, hybridization of the D(x)−A(y) bond, Wiberg bond orders BO of the D(x)−A(y) bond.

Table 2 shows that the contribution from the 3d orbitals to the titanium−carbon bond is much greater than the 4s contribution. It has been suggested that the covalent bonds of the 3d elements are mainly formed by the 4s orbital and that the 3d orbitals are negligible.[36] However, the results presented here and elsewhere[37] show that this bonding model is not in agreement with quantum chemical calculations.

Finally, we would like to mention the NBO results concerning the bonding situation in the free diaminocarbene ligand. The calculations show that the formally vacant p(π) AO of the carbon atom in free $C(NH_2)_2$ is significantly populated by 0.67 e through N→C π-donation. This shows the importance of the allyl-anion-type delocalization in determining the stability of the diamino-substituted carbenes. The same conclusion was drawn from earlier theoretical studies.[38]

Summary and Conclusion

The calculations clearly show that diaminocarbene is a much stronger Lewis base than amines. This has been proven for donor−acceptor interactions with Group 13 trihalides and titanium tetrahalides, and probably holds true for complexes with other Lewis acids as well. The complexation energies of $C(NH_2)_2$ have been calculated to be 14−27 kcal/mol higher than those of NH_3. The most strongly bonded complex is $Cl_3Al-C(NH_2)_2$, which has a theoretically predicted Al−C bond energy D_o = 59.1 kcal/mol. BX_3 is clearly the weakest Lewis acid among the Group 13 trihalides. TiF_4 and $TiCl_4$ have similar Lewis acidities as BF_3, but the titanium tetrahalides may bind one or two donor molecules with almost the same bond strength. The donor−acceptor bonds have a high degree of ionic character. The greatest covalent contributions are found for the diaminocarbene complexes. The covalent character of the X_3E-CO bond becomes higher on going from E = boron to the heavier elements, while the opposite order is found for the X_3E-NH_3 and $X_3E-C(NH_2)_2$ bonds.

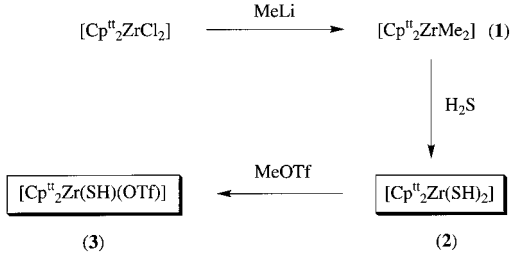
New *Early* Zirconium-Sulfido Metallaligands for *Late* Transition Metals; Synthesis and Reactivity of $[Cp^{tt}_2Zr(SH)_2]$ and $[Cp^{tt}_2Zr(SH)(OTf)]$

Marc A. F. Hernandez-Gruel,[a] Jesús J. Pérez-Torrente,[a] Miguel A. Ciriano,*[a] José A. López,[a] Fernando J. Lahoz,[a] and Luis A. Oro*[a]



Keywords: Zirconium / Metallocenes / Triflate / Hydrosulfido / Rhodium / Early-late complex

The bishydrosulfido zirconium metallocene compound $[Cp^{tt}_2Zr(SH)_2]$ (**2**) containing the bulky η^5-1,3-di-*tert*-butylcyclopentadienyl (Cp^{tt}) ligand is readily accessible from $[Cp^{tt}_2Zr(CH_3)_2]$ (**1**) upon treatment with H_2S. Reaction of **2** with methyltriflate gives the monohydrosulfido complex $[Cp^{tt}_2Zr(SH)(OSO_2CF_3)]$ (**3**) which exists as two isomers in solution, and has been characterized by X-ray diffraction methods. Complex **2** is an effective metallaligand for the controlled synthesis of new trinuclear *early-late* heterobimetallic complexes (ELHB) with a $ZrRh_2$ core such as $[Cp^{tt}_2Zr(\mu_3\text{-}S)_2\{Rh(CO)_2\}_2]$ (**4**).

Interest in *early-late* heterobimetallic complexes (ELHB) stems in part from the potential new reactivity patterns associated with the presence of two widely divergent transition metals.[1] The combination of both an electron-deficient *early* transition metal and an electron-rich *late* transition metal in a single molecule provides a bifunctional environment which should allow the cooperative activation of organic substrates in both catalytic[2] and stoichiometric reactions.[3] A useful synthetic approach for ELHB complexes involves the use of *early* transition metal complexes as metallaligands for *late* transition metal species.[4] Following this approach we have recently described the use of the titanium bishydrosulfido compound $Cp_2Ti(SH)_2$ for the construction of unusual *early-late* titanium-rhodium tetranuclear complexes and hexanuclear clusters such as $[CpTi(\mu_3\text{-}S_3)\{Rh(tfbb)\}_3]$[5] and $[\{CpTi\}_2(\mu_4\text{-}O)(\mu_3\text{-}S)_4\{Rh_4(CO)_4(PR_3)_2\}]$,[6] respectively.

As part of our general interest in this chemistry we have extended this synthetic methodology to the preparation of zirconium-rhodium ELHB complexes. Mononuclear metallocene zirconium sulfido and hydrosulfido derivatives are rare and usually undergo the loss of H_2S to give sulfido-bridged dimers.[7] Thus, we have attempted to synthesize stable mononuclear zirconium-metallocene hydrosulfido compounds suitable for the synthesis of ELHB complexes. This paper describes the synthesis of such zirconium hydrosulfido complexes containing the bulky Cp^{tt} ligand (Cp^{tt} = η^5-1,3-di-*tert*-butylcyclopentadienyl) and their use as metallaligands for the construction of heterotrinuclear Zr-Rh complexes.

The bishydrosulfido complex $[Cp^{tt}_2Zr(SH)_2]$ (**2**) is obtained in two steps starting from the corresponding metallocene dichloride (Scheme 1). Thus, reaction of $[Cp^{tt}_2ZrCl_2]$ with a slight excess of MeLi in diethyl ether at −78°C gives the dimethyl complex $[Cp^{tt}_2Zr(CH_3)_2]$ (**1**) which can be isolated as off-white crystals,[8] in 96% yield, after removal of LiCl by extraction of the product with hexane. Reaction of **1** with an excess of H_2S(g), in toluene at 95°C in a Pyrex bomb under pressure for 14 h, affords a bright yellow solution from which the complex $[Cp^{tt}_2Zr(SH)_2]$ (**2**) can be obtained as pale yellow crystals, in 87% yield, after recrystallisation from diethyl ether. The ^{1}H NMR spectrum of **2** shows the expected resonances for the protons of the two equivalent Cp^{tt} rings (C_{2v} symmetry) and a singlet at δ = 2.11 ppm for the SH groups. The complex $[Cp^{tt}_2Zr(SH)_2]$ (**2**) reacts with a threefold excess of methyltriflate (CF_3SO_3Me) in dichloromethane to give the monohydrosulfido complex $[Cp^{tt}_2Zr(SH)(OSO_2CF_3)]$ (**3**). This complex is isolated as moisture-sensitive yellow crystals in 81% yield after recrystallisation from diethyl ether.

Scheme 1. The synthesis of hydrosulfido zirconium complexes

The crystal structure of **3** consists of discrete monomers (Figure 1). The metal centre exhibits a *pseudo*-tetrahedral geometry with the sulfur atom of the hydrosulfido ligand, the oxygen of the coordinated triflate anion and the two Cp^{tt} ring centroids at the apices. The Zr−Cp^{tt} ring-centroid distances {2.237(4) and 2.239(5) Å} are identical to those observed in the related complex $[Cp^{tt}_2ZrI_2]$ (2.248 and 2.251 Å)[8a] although the Cp^{tt}−Zr−Cp^{tt} angle is slightly smaller in **3** {129.78(15)°} than in the latter compound (133.0°). The relative disposition of the Cp^{tt} rings along the G(1)···G(2) direction is staggered with a dihedral angle C(2)···G(1)···G(2)···C(15) of 52.4(5)°, thereby reducing the

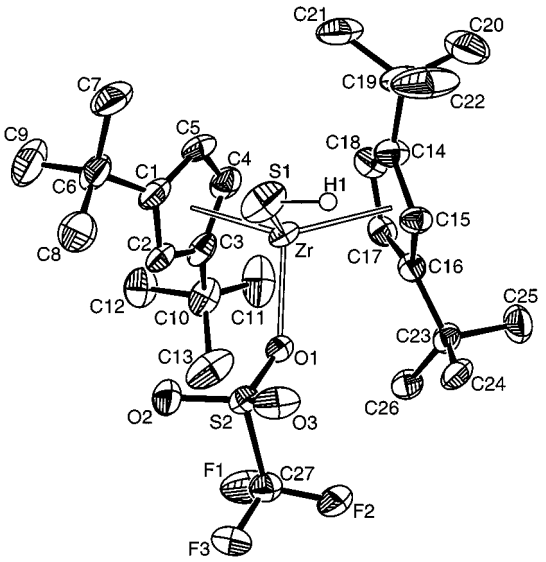
steric hindrance of the bulky *tert*-butyl substituents. The Zr−O(1) bond length {2.199(3) Å} is similar to other Zr−O(triflate) bond lengths, such as that reported in $[Cp_2Zr(OSO_2CF_3)(\mu\text{-}H)]_2$ {2.205(2) Å};[9] the rather large Zr−O(1)−S(2) angle, 136.59(15)°, compares well with the values described in other triflate complexes (range: 100−164°).[10]



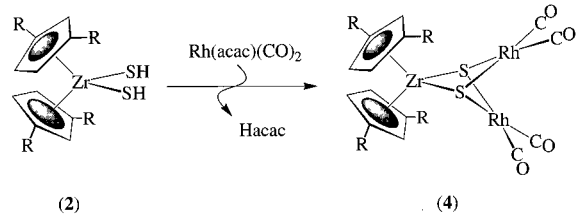


Figure 1. Molecular drawing of $[Cp^{tt}_2Zr(SH)(OSO_2CF_3)]$ (**3**) (hydrogen atoms, except H1, have been omitted for clarity); selected bond lengths [Å] and angles [°]: Zr−S(1) 2.4586(15), Zr−O(1) 2.199(3), Zr−G(1) 2.237(4), Zr−G(2) 2.239(5); S(1)−Zr−O(1) 92.61(7), S(1)−Zr−G(1) 106.74(12), S(1)−Zr−G(2) 105.99(12), O(1)−Zr−G(1) 107.69(13), O(1)−Zr−G(2) 107.74(14), G(1)−Zr−G(2) 129.78(15) [G(1) and G(2) represent the midpoints of the C(1)−C(5) and C(14)−C(18) rings, respectively]

The complex $[Cp^{tt}_2Zr(SH)(OSO_2CF_3)]$ (**3**) exists in solution as two isomers (3:1 ratio in C_6D_6, isomers **3a** and **3b**) as evidenced by ^1H, ^{19}F and ^{13}C NMR spectroscopy. These isomers do not arise from a dissociation of the triflate ligand nor from association of mononuclear complexes, since **3** is a nonconductor in dichloromethane and the molecular weight measured in chloroform is in agreement with a mononuclear formulation. Both isomers show three triplets for the protons of the two equivalent Cp^{tt} rings in the ^1H NMR spectrum in C_6D_6 in accordance with the lower symmetry of **3** compared to its precursor **2**. The main difference between **3a** and **3b** concerns the SH ligand. The major isomer **3a** possesses the structure found in the solid state, since an NOE effect (10%) is observed between the proton of SH ligand at δ = 4.04 ppm and one of the protons of the Cp^{tt} ring {the H(1)···H(C15) distance is 2.526 Å in the solid state}. The minor isomer **3b** shows an unusually low-field-shifted resonance for the proton of the hydrosulfido ligand at δ = 6.27 ppm. In addition, no NOE effect is observed between the SH group and any of the protons of the Cp^{tt} ligands. A reasonable explanation for these observations in **3b** could be the existence of an intramolecular hydrogen bonding between the SH proton and one of the unbound oxygen atoms of the triflate ligand forming a six-membered metallacycle. In fact, a rotation of the hydrosulfido ligand around the Zr−S bond in a molecular model based on the solid state structure of **3** can bring the hydrogen atom to a distance from O(3) of less than 2.55 Å. It should be noted that a similar intramolecular interaction has been observed in the solid state structure of the aquo-complex $[(CH_3)_2Au(\text{-}H_2O)(OSO_2CF_3)]$.[11] Interestingly, the related complex $[Cp^*_2Zr(OH)(OSO_2CF_3)]$ ($Cp^* = \eta^5\text{-}C_5Me_5$), obtained by reaction of $[Cp^*_2Zr(OH)Cl]$ with silver triflate, exits as a single compound in solution.[12]

Additive-deprotonation of $[Cp^{tt}_2Zr(SH)_2]$ (**2**) with appropriate rhodium complexes results in the clean formation of trinuclear d^0-d^8 ELHB compounds with a $ZrRh_2$ core. In contrast, additive-deprotonation reactions of $[Cp^{tt}_2Zr(SH)(OSO_2CF_3)]$ (**3**) are much more complex since the transfer of the sulfido ligands to the d^8 metal centres is observed. Thus, reaction of **2** with two molar equiv. of $[Rh(acac)(CO)_2]$, in diethyl ether, gives the complex $[Cp^{tt}_2Zr(\mu_3\text{-}S)_2\{Rh(CO)_2\}_2]$ (**4**) as a sparingly soluble, emerald-green microcrystalline powder in 93% yield (Scheme 2). The structure of **4** has a triangular $ZrRh_2$ core capped by two symmetrical μ_3-sulfido ligands in accordance with the high symmetry (C_{2v}) observed by NMR spectroscopy. In particular, the ^1H NMR spectrum shows only two resonances for the protons of the Cp^{tt} rings, and a unique doublet for the carbonyl ligands is observed in the $^{13}C\{^1H\}$ NMR spectrum. Reaction of **3** with one molar equiv. of $[Rh(acac)(CO)_2]$ in diethyl ether does not afford the desired *early-late* heterodinuclear complex since a ligand redistribution process takes place. The known anion[13] $[Rh_3(\mu_3\text{-}S)_2(CO)_6]^-$ and the new cation[14] $[Cp^{tt}_2Zr(acac)]^+$ are detected in the reaction mixture. Both species are formed by the transference of the sulfido ligands from zirconium to rhodium, probably through a heterobimetallic intermediate. However, the formation of the ion-pair compound $[Cp^{tt}_2Zr(acac)][Rh_3(\mu_3\text{-}S)_2(CO)_6]$[15] is not clean since the trinuclear ELHB complex **4** and free HCp^{tt} are also observed spectroscopically.

In conclusion, we have synthesized new zirconium hydrosulfido metallocenes containing the bulky Cp^{tt} ligand and shown the ability of the bishydrosulfido complex **2** to build unusual $ZrRh_2$ ELHB complexes in a controlled way. Further work concerning both the scope of this synthetic methodology and the potential reactivity of the monosulfido complex **3** is in progress.

Scheme 2. The synthesis of a trinuclear *early-late* complex with a $ZrRh_2$ core; R denotes the *tert*-butyl group

Experimental Section

General: All manipulations were performed under a dry argon atmosphere using standard Schlenk techniques. Solvents were dried

by standard methods and distilled under argon immediately prior to use. $[Cp^{tt}_2ZrCl_2]$[16] and $[Rh(acac)(CO)_2]$[17] were prepared according to reported methods. NMR spectra were recorded at 20°C on Varian Gemini 2000 (^1H: 300.08, ^{19}F: 282.33 and $^{13}C\{^1H\}$: 75.47 MHz) or Varian UNITY 300 (^1H cyclenOe experiments) spectrometers. Chemical shifts δ are reported in ppm and referenced to Me_4Si using the signal of the deuterated solvent (^1H and ^{13}C). ^{19}F chemical shifts are relative to $CFCl_3$. Coupling constants are given in Hz. IR spectra were recorded on a Nicolet 550 spectrometer. Elemental analyses were performed with a Perkin−Elmer 2400 analyzer. Conductivities were measured in ca. 5×10^{-4} M dichloromethane solutions with a Philips PW 9509 conductimeter. Molecular weights were determined with a Knauer osmometer from chloroform solutions of the complexes. Mass spectra were recorded on a VG Autospec double-focusing mass spectrometer operating in both FAB^+ and FAB^- modes. Ions were produced with the standard Cs^+ gun at ca. 30 kV, 3-nitrobenzyl alcohol (NBA) was used as matrix.

$[Cp^{tt}_2Zr(CH_3)_2]$ (1): $[Cp^{tt}_2ZrCl_2]$ (5 g, 9.68 mmol) was slurried in 100 mL of diethyl ether at −78°C and reacted with a 1.5 M diethyl ether solution of methyllithium (14 mL, 21 mmol). The reaction mixture was allowed to warm to room temperature and then stirred for a further 12 h. The mixture was again cooled to −78°C and 1 mL of methanol was added to destroy the unchanged methyllithium. Solvents were removed under vacuum and the residue was extracted with 70 mL of n-hexane and filtered over dry celite. The resulting solution was concentrated under reduced pressure to ca. 20 mL and stored at −25°C overnight to give off-white crystals. The crystals were collected by filtration and dried in vacuo. Concentration and cooling of the mother liquor gave a second crop of crystals. Overall yield: 4.4 g (96%). − ^1H NMR ($CDCl_3$): δ = 6.47 [t, ^4J(H,H) = 2.7 Hz, 2 H, H_2], 5.38 (d, ^4J(H,H) = 2.7 Hz, 4 H, H_4 and H_5), 1.21 (s, 36 H, CMe_3) (Cp^{tt}), −0.28 (s, 6 H, Zr−CH_3). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 138.6 (C_1 and C_3), 115.7 (C_2), 100.5 (C_4 and C_5), 33.4 (*C*Me$_3$), 31.4 (C*Me*$_3$) (Cp^{tt}), 31.0 (Zr−*C*H$_3$). − $C_{28}H_{48}Zr$ (475.91): calcd. C 70.67, H 10.17; found C 70.00, H 9.33.

$[Cp^{tt}_2Zr(SH)_2]$ (2): A solution of $[Cp^{tt}_2Zr(CH_3)_2]$ (**1**) (2 g, 4.202 mmol) in toluene (10 mL) was placed in a Pyrex bomb. The reaction vessel was evacuated and charged to a pressure of *ca.* 2.5 atm. with H_2S. The solution was stirred at 95°C for 14 h. The reaction vessel was depressurised and the resulting bright yellow solution flushed with argon. The volatiles were removed under reduced pressure and the residue was dissolved in 55 mL of diethyl ether. The solution was filtered and concentrated under vaccum to the point of crystallisation. Cooling of the solution to −25°C overnight gave the compound as pale yellow crystals which were collected and dried in vacuo. Concentration and cooling of the mother liquor gave a second crop of crystals. Overall yield: 1.876 g (87%). − ^1H NMR ($CDCl_3$): δ = 6.46 [t, ^4J(H,H) = 2.7 Hz, 2 H, H_2], 5.71 [d, ^4J(H,H) = 2.7 Hz, 4 H, H_4 and H_5 of Cp^{tt}], 2.11 (s, 2 H, Zr−S*H*), 1.31 (s, 36 H, C*Me*$_3$). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 140.6 (C_1 and C_3), 119.8 (C_2), 102.2 (C_4 and C_5), 33.8 (*C*Me$_3$), 31.7 (C*Me*$_3$). − MS (CH_2Cl_2, *m*/*z*,%); FAB^+: 477 (100) $[Cp^{tt}_2Zr(SH)^+]$; FAB^-: 509 (90) $[Cp^{tt}_2Zr(SH)(S)^-]$, 331 (100) $[Cp^{tt}Zr{=}S(S)^-]$. − $C_{26}H_{44}S_2Zr$ (511.98): calcd. C 61.00, H 8.66, S 12.53; found C 60.95, H 8.07, S 12.61.

$[Cp^{tt}_2Zr(SH)(OSO_2CF_3)]$ (3): A solution of $[Cp^{tt}_2Zr(SH)_2]$ (**2**) (0.2 g, 0.391 mmol) in dichloromethane (5 mL) was reacted with methyltriflate (130 μL, 1.185 mmol) to give a bright yellow solution which was stirred for 15 min at room temperature. The volatiles were removed under vacuum and the residue was extracted with 10 mL of diethyl ether. The solution was then filtered and cooled to −25°C to give yellow crystals of the complex which were isolated by filtration and dried under reduced pressure. Yield: 0.1985 g (81%). − ^1H NMR ([D$_6$]benzene); isomer **3a**: δ = 6.92, 5.83 and 5.68 [t, J(H,H) = 2.7 Hz, 2 H each, H_2, H_4 and H_5 of Cp^{tt}], 4.04 (s, 1 H, Zr−S*H*), 1.22 and 1.21 (s, 18 H each, C*Me*$_3$); isomer **3b**: δ = 6.49, 5.95 and 5.76 [t, J(H,H) = 2.7 Hz, 2 H each, H_2, H_4 and H_5 of Cp^{tt}], 6.27 (s, 1 H, Zr−S*H*) 1.21 and 1.13 (s, 18 H each, C*Me*$_3$). − ^{19}F ([D$_6$]benzene): δ = −76.1 and −76.7 (Zr−OSO_2CF_3, isomers **3a** and **3b**, respectively). − $^{13}C\{^1H\}$ NMR ([D$_6$]benzene); isomer **3a**: δ = 144.9 and 144.7 (C_1 and C_3 of Cp^{tt}), 120.0 [q, J(C,F) = 320 Hz, Zr−OSO_2CF_3], 119.1, 105.5 and 104.9 (C_2, C_4 and C_5 of Cp^{tt}), 34.2 and 33.6 (*C*Me$_3$), 31.3 and 31.1 (C*Me*$_3$); isomer **3b**: δ = 148.9 and 147.3 (C_1 and C_3 of Cp^{tt}), 120.2 [q, J(C,F) = 320 Hz, Zr−OSO_2CF_3], 111.6, 107.1 and 104.2 (C_2, C_4 and C_5 of Cp^{tt}), 33.7 and 33.5 (*C*Me$_3$), 31.0 and 30.5 (C*Me*$_3$). − MS (CH_2Cl_2, *m*/*z*,%); FAB^+: 477 (11) $[Cp^{tt}_2Zr(SH)^+]$; FAB^-: 149 (100) $[CF_3SO_3^-]$. − Molecular weight ($CHCl_3$, g mol^{-1}): 622 (calcd. 628). − Conductivity Λ_M (CH_2Cl_2, $4.97.10^{-4}$ M, Ω^{-1} cm^{2}mol^{-1}): 0.22. − $C_{27}H_{43}F_3O_3S_2Zr$ (627.98): calcd. C 51.64, H 6.90, S 10.21; found C 51.55, H 7.17, S 9.14.

$[Cp^{tt}_2Zr(\mu_3\text{-}S)_2\{Rh(CO)_2\}_2]$ (4): $[Rh(acac)(CO)_2]$ (0.504 g, 1.953 mmol) was added to a yellow solution of $[Cp^{tt}_2Zr(SH)_2]$ (**2**) (0.5 g, 0.977 mmol) in diethyl ether (20 mL). The solution immediately turned dark green and a solid crystallized out while stirring for 10 min at room temperature. Filtration of the resulting suspension gave the title compound as an emerald-green microcrystalline powder after washing with n-hexane (2×10 mL) and drying in vacuo. Yield: 0.7535 g (93%). − ^1H NMR ($CDCl_3$): δ = 6.56 [t, ^4J(H,H) = 2.6 Hz, 2 H, H_2], 6.03 [d, ^4J(H,H) = 2.6 Hz, 4 H, H_4 and H_5 of Cp^{tt}], 1.31 (s, 36 H, C*Me*$_3$). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 185.3 [d, J(C,Rh) = 73 Hz, Rh−*C*O], 148.6 (C_1 and C_3), 121.3 (C_2), 109.0 (C_4 and C_5), 34.6 (*C*Me$_3$), 32.3 (s, C*Me*$_3$). − MS (FAB^+, CH_2Cl_2, *m*/*z*,%): 826 (29) $[M^+]$, 770 (39) $[M^+ - 2CO]$, 742 (34) $[M^+ - 3CO]$, 714 (100) $[M^+ - 4CO]$, 649 (30) $[M^+ - Cp^{tt}]$, 565 (29) $[M^+ - Cp^{tt} - 3CO]$. − IR (CH_2Cl_2) $\tilde{\nu}_{(CO)}$: 2066 (s), 2041 (s), 1994 (s) cm^{-1}. − $C_{30}H_{42}O_4Rh_2S_2Zr$ (827.82): calcd. C 43.53, H 5.11, S 7.75; found C 43.60, H 5.12, S 7.82.

X-ray Structure Analysis of 3: X-ray quality crystals were obtained from a satured solution of **3** in diethyl ether at −25°C. Crystal data for **3**: $C_{27}H_{43}F_3O_3S_2Zr$, M = 627.95, monoclinic, space group $P2_1/n$, a = 12.1680(16), b = 16.594(3), c = 15.184(2) Å, β = 91.260(14)°, V = 3065.1(9) Å^3, T = 173 K, Z = 4, D_c = 1.361 g cm^{-3}, μ(Mo-K_α) = 0.538 mm^{-1}, graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data collected on a Siemens-Stoe AED-2 diffractometer. 8504 ref. collected, 5491 unique and used in the refinement. A ψ-scan absorption correction was applied (min. and max. transmission factors: 0.773, 0.862). The structure was solved by direct methods (SIR92) and refined by full-matrix least-squares on F^2 (SHELXL97). Anisotropic displacement parameters used for all non-hydrogen atoms. Hydrogens were refined riding on the corresponding atoms and included in the model in calculated positions, except that of the hydrosulfido ligand which has been located in a difference-Fourier map. Final R_1 = 0.0456 (4239 ref., $F_o > 4\sigma(F_o)$) and wR_2 = 0.1110 (all data). Crystallographic data for the reported structure have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-124105 Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

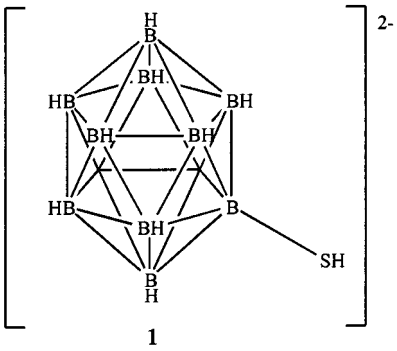
Clusters on Clusters: *closo*-Dodecaborate as a Ligand for Au_{55} Clusters

Günter Schmid,*[a] Raphaël Pugin,[a] Wolfgang Meyer-Zaika,[a] and Ulrich Simon[a]

Dedicated to Professor Gerhard Fritz on the occasion of his 80th birthday

Keywords: Gold clusters / *closo*-Dodecaborate / Conductivity / Charging energy



The exchange of PPh_3 in $Au_{55}(PPh_3)_{12}Cl_6$ by $Na_2[B_{12}H_{11}SH]$ using a phase-transfer reaction from CH_2Cl_2 to water needs 6 weeks for reaction, but finally results in the quantitative formation of $Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ (**2**). Cluster **2**, which is of considerable stability in aqueous solution, has been characterized by ^{1}H-NMR, ^{11}B-NMR, and IR spectroscopy as well as by transmission electron microscopy (TEM). The Na^+ cations can be exchanged by $(octyl)_4N^+$ making the resulting cluster **4** soluble in polar organic solvents. The electrical properties of **2** and **4** are compared with those of $Au_{55}[Ph_2PC_6H_4SO_3N(octyl)_4]_{12}Cl_6$ (**3**), the ammonium derivative of the sodium salt. Cluster **3** shows the expected increase of activation energy in the temperature range of 130–250 K owing to the increase of cluster spacing compared with the sodium derivative. However, clusters **2** and **4**, show electromigration in the electric field, caused by the huge amount of ionic charges in the ligand shell.

Introduction

Over the past decade, the effect of particle size on the electronic properties of ligand-protected metal clusters and colloids has been discussed as one of their most exciting physical properties.[1−6] Since the two-shell cluster $Au_{55}(PPh_3)_{12}Cl_6$[7] has a metal core diameter of 1.4 nm, which is of the order of characteristic length scales such as the de Broglie wavelength, the mean free path or the phase relaxation length, this cluster can be considered as a zero-dimensional quantum dot containing just a few metallic electrons.[4−6,8] Moreover, physical investigations such as impedance[4−6] or charge-transport measurements,[9] as well as scanning tunnelling spectroscopy,[10,11] have clearly indicated the existence of size effects for this cluster, where the protective ligand shell acts as a well-defined insulating barrier around the clusters. A protective ligand shell is an essential condition for control of the growth of the metal particles to prevent them from coalescence or Ostwald ripening. It is of fundamental interest to modify the nature and the thickness of this ligand shell in order to study its influence on the electronic properties. Understanding of this will allow the control of a specific size−property relationship of these solid-state nanomaterials enabling building blocks to be tailored for nanoelectronic devices.[4−6]

In the present work we report the use of disodium mercaptoundecahydro-*closo*-dodecaborate $Na_2[B_{12}H_{11}SH]$ (**1**) (BSH, see Figure 1) as a protective ligand to stabilize Au_{55} clusters for two main reasons: to elaborate new highly stable Au_{55} clusters with Au−S bonds by the use of different bulky ligands, and to follow our prospective work concerning the correlation between cluster spacing and charging energy determined by electronic intercluster tunnelling processes.

Figure 1. Formal structure of the BSH ligand

A secondary aspect concerns the use of BSH in Boron Neutron Capture Therapy (BNCT).[12] This therapy is a binary treatment modality that can selectively irradiate tumour tissues. BNCT uses drugs containing the ^{10}B isotope that are capable of preferentially accumulating in the tumour which is then irradiated with low-energy neutrons. The interactions of the ^{10}B nucleus with a thermal neutron (neutron capture) causes it to split releasing a lithium nucleus and an alpha particle, so damaging the tumour cells. $Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ (**2**), described in the following, is highly soluble in water and contains 144 boron atoms per molecule, perhaps enabling a drastic increase of the boron concentration in tumour tissues.

Results and Discussion

In a previous work[13] we described the exchange of the PPh_3 ligands in $Au_{55}(PPh_3)_{12}Cl_6$ by $Ph_2PC_6H_4SO_3Na$ in a phase-transfer reaction to give the water-soluble gold cluster $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$. More recently, owing to the lability of the triphenylphosphane coordinated to the surface gold atoms and to the well-known affinity of thiol

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434−1948/99/1111−2051 $ 17.50+.50/0

$$\underset{CH_2Cl_2}{Au_{55}(PPh_3)_{12}Cl_6} + 12\ \underset{\substack{\mathbf{1}\\ water}}{(B_{12}H_{11}SH)Na_2} \xrightarrow[r.t.,\ 6\ weeks]{} \underset{\substack{\mathbf{2}\\ water}}{Au_{55}[(B_{12}H_{11}SH)_{12}Cl_6} + \underset{CH_2Cl_2}{PPh_3} \quad (1)$$

functions to gold atoms, we reported the synthesis of a new Au_{55} cluster protected by a thiol-functionalized oligosilsesquioxane ($T_8-OSS-SH$) ligand, causing excellent solubility in nonpolar hydrocarbons, such as pentane.[14]

Combining these two methods, we have now succeeded in synthesizing a novel *closo*-borate stabilized Au_{55} cluster by a phase-transfer reaction.

The phase-transfer reaction, which in the past has allowed us to substitute PPh_3 by $Ph_2PC_6H_4SO_3Na$, took two days,[13] whereas only two hours were necessary for the synthesis of the thiol-functionalized oligosilsesquioxane gold cluster in organic solvents.[14] Two reasons may be responsible for the extraordinary long reaction time to prepare **2**. First, in contrast to $T_8-OSS-SH$ where a propyl chain separates the thiol function from the bulky oligosilsesquioxane cage, the thiol group in **2** is directly coordinated to the *closo*-borane cluster, so that all bulky protective ligands are very close to the metal core. Second, electrostatic interactions should play a decisive role. Since each *closo*-borate ligand is doubly charged, the observed rapid exchange of half of the PPh_3 molecules by six $[BSH]^{2-}$ anions generates a twelve-fold negatively charged, water-soluble gold cluster. Repulsive electrostatic forces make it progressively more difficult to add additional $[BSH]^{2-}$ ligands. This last point is supported by the ^{1}H-NMR signals and by elementary analyses after different reaction times. Actually, both show that the first six PPh_3 ligands were substituted after a couple of days, one week more being necessary for the next three ones and a further five weeks more for the three last ones. Nevertheless, the expected $Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ cluster with a total of twenty four negative charges is formed in almost quantitative yield.

After the reaction time of six weeks the $^{13}C\{^1H\}$-NMR, as well as the $^{31}P\{^1H\}$-NMR, spectra of the product do not give any signal and so indicate the absence of PPh_3. This is supported by the ^{1}H-NMR spectrum, where signals for aromatic protons cannot be detected. Elementary analyses indicate only traces of carbon. On the other hand, the presence of BSH is clearly indicated by a broad multiplet in the ^{1}H-NMR spectrum between $\delta = 0.2$ and 2.8 and by the $^{11}B\{^1H\}$-NMR spectrum showing a broad signal between $\delta = -20$ and -11 and a singlet at $\delta = -7.8$. Compared with the spectrum of free BSH the multiplicity is lost due to the coordination to a large metal cluster. The broad ^{11}B-NMR signal can be attributed to the three initial doublets of the free BSH (see Experimental Section). The singlet at $\delta = -7.8$ is caused by the B atom directly bound to the thiol function. In contrast to the corresponding singlet for free BSH ($\delta = -9.6$), it is low-field shifted owing to the coordination of the thiol group to gold. Infrared investigations resulted in bands at $\tilde{\nu} = 2500.6$ (ν B−H), 1061.7 (ν asym. B−S), 973.2 and 947.9 (δ asym. B−S), 836.5 and 723 cm^{-1} (ν B−B). The signals of $Au_{55}(PPh_3)_{12}Cl_6$ at 1584.9 and 1478.7 (ν C=C arom.), 1434.7 and 1097.9 (ν P−Ph), 1328.5, 1026.4, and 690.3 cm^{-1} (δ C−H) could not be observed.

Practical advantages of the new cluster **2** are the solubility and the improved stability. It is soluble in numerous polar solvents like acetone, ethanol, acetonitrile, or methanol, but also in water which allows us to expect possible clinical applications. Transmission electron microscopy (TEM) investigations showed exclusively 1.4 nm particles (Figure 2). Figure 3 shows a model of the relevant cluster part $[Au_{55}(B_{12}H_{11}SH)_{12}]^{24-}$.

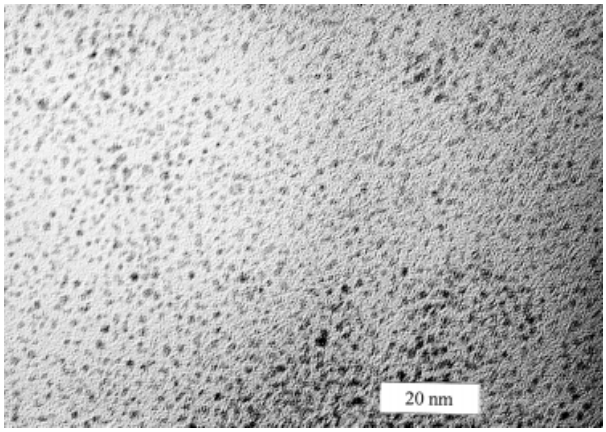

Figure 2. TEM image of $Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ clusters indicating the monodispersity

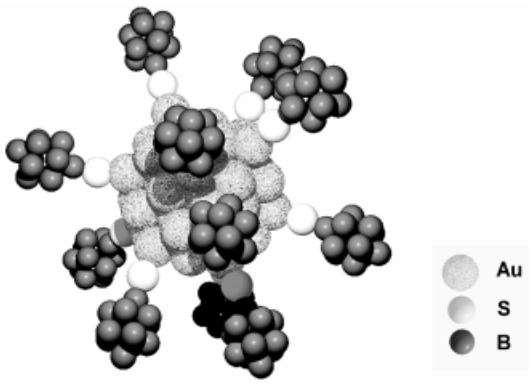

Figure 3. Computer model of the cluster part $[Au_{55}(B_{12}H_{11}SH)_{12}]^{24-}$; the H atoms are omitted

No aggregation was observed in cluster solutions over several months. Compared to the very labile $Au_{55}(PPh_3)_{12}Cl_6$, which aggregates in solution after a couple of hours, this most remarkable change allows reliable investigations not only in the solid state, but also in solutions. Thus, by UV measurements the characteristic plasmon resonance between 500−600 nm of colloids could be excluded.

The unusual stability of **2** compared with $Au_{55}(PPh_3)_{12}Cl_6$ is explained by the greater affinity of thiol func-

$$Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6 + 12\ BrN(octyl)_4 \rightarrow Au_{55}[Ph_2PC_6H_4SO_3N(octyl)_4]_{12}Cl_6 + 12\ NaBr \quad (2)$$

water — CH_2Cl_2 — **3** CH_2Cl_2 — water

$$Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6 + 24\ BrN(octyl)_4 \rightarrow Au_{55}[(B_{12}H_{11}SH)\{N(octyl)_4\}_2]_{12}Cl_6 + 24\ NaBr \quad (3)$$

water — CH_2Cl_2 — **4** CH_2Cl_2 — water

tions to bind surface gold atoms compared with phosphanes and in particular it is the repulsive electrostatic forces between the 24-fold negatively charged clusters. This is probably the main reason why coalescence between clusters is efficiently suppressed since approaches of two clusters are prevented. Similar explanations allowed us in previous works to compare the stability of $Au_{55}(PPh_3)_{12}Cl_6$ to those of the water soluble $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$.[13] Actually, although $Au_{55}(PPh_3)_{12}Cl_6$ degrades after two hours if dissolved, the water-soluble cluster stays stable in solution without significant aggregation over weeks. Comparison with cluster **2** suggests that this is probably due to the combination of strong and bulky ligands and of repulsive Coulomb forces.

To investigate the chemical properties and to see if the size of the ligand shell could still be increased, we tried to exchange Na^+ by the bulkier tetraoctylammonium cation. For comparison, this was first realized with the water-soluble cluster $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$.

This phase-transfer reaction was completed after 3 h and cluster **3** was isolated in almost quantitative yield as a dark-brown solid. The integration of the aryl and alkyl ^{1}H-NMR signals gave a 1:1 ratio of $Ph_2PC_6H_4SO_3^-$ and $[(octyl)_4N]^+$. Moreover, the elementary analyses agreed well with the expected values. Based on these promising results the corresponding phase-transfer reaction was attempted with $Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ (**2**). The reaction worked as well as that in Equation 2. Cluster **4** was obtained in good yield and was characterized by ^{1}H NMR and TEM. This cation-exchange reaction did not induce any aggregation of the particles and the size distribution of **4** was found by TEM to be as good as that of **2**.

The availability of these new compounds raised the question of how the charge-transport properties are affected by the modified ligand shell as compared to $Au_{55}(PPh_3)_{12}Cl_6$. As described earlier,[4–6,15] single-electron charging effects occur in three-dimensional dense packings of ligand-stabilized metal clusters. The charging energy, involving a thermally activated tunnelling process through the insulating ligand shell, corresponds to the activation energy E_A of the conductivity of the cluster arrangements and therefore depends on the cluster size, as well as on the cluster spacing. While the size is determined by the number of the metal atoms forming the cluster, i.e. 55 in the materials discussed here, the cluster spacing corresponds to the thickness of the ligand shell. Therefore, by modifying the thickness of the ligand shell, a correlation between cluster spacing and charging energy could be established. Actually, a charging energy of 0.15 eV was observed for $Au_{55}(PPh_3)_{12}Cl_6$, having a 0.35 nm thick ligand shell, i.e. a cluster spacing of 0.7 nm. This value increases linearly with the spatial separation of the metallic cores up to 0.26 eV for the previously described $Au_{55}(T_8{-}OSS{-}SH)_{12}Cl_6$, which corresponds to a cluster spacing of 2.8 nm.[16]

This shows that the charging energy in three-dimensional cluster arrangements can be tailored chemically by varying the cluster spacing due to incorporation of bulky ligands or by introduction of spacer molecules. In this context the electrical properties of the clusters **2**, **3**, and **4** are of considerable interest. In contrast to the materials we have examined before, it was not possible to obtain mechanically stable pellets with dense cluster packing. Therefore the clusters were dissolved and then deposited on interdigital microelectrodes (see Experimental Section). Whilst an optically homogeneous layer of **2** with an average thickness of 50–100 μm was formed, **3** and **4** remained as highly viscous films on the microelectrode structure. The temperature dependence of the conductivity was determined in a temperature range of 130–293 K.

According to earlier measurements a temperature dependence $\sigma(T) \sim (T_0/T)^\gamma$ was expected (Mott's conductivity law). At low temperature $\gamma = 1/d + 1$, where d is the dimensionality of the system, reflecting a variable-range hopping process. Going to higher temperatures up to room temperature, the charge transport is dominated by nearest neighbour hops of single electrons instead of hops of variable range, thus being simply activated with $\gamma = 1$ (Arrhenius behaviour). Here the activation energy E_A ($= k_B T_0$) is the energy to transfer one electron from an initially neutral cluster to a next neighbouring neutral cluster via the insulating ligand shell.[15][17] Thus, E_A represents the charging energy, or chemically speaking, the disproportionation energy, which is size and distance dependent.

All samples show significant conductivity at room temperature and thermally activated behaviour. No evaluable results could, however, be obtained from samples **2** and **4** due to pronounced conductance fluctuations during the measurements. This, at a first glance, might be attributed to the huge amount of ionic charges provided by the 12 two-fold negatively charged borate ligands on each cluster. This may lead to electromigration of the clusters in the electric field during the measurements, leading to a fluctuating degree of disorder in the samples. A detailed analysis of this problem will be subject of our future works.

In contrast, the measurements on cluster **3**, which has just 12 instead of 24 charges on its ligand shell, showed a reliable temperature dependence. However, neither a $\sigma(T) \approx 1/T$ nor a $\sigma(T) \approx 1/T^{1/4}$ behaviour could be observed over

the whole temperature range. As displayed in Figure 4, it seems to be possible to divide the temperature range tentatively into a high-temperature and a low-temperature part; in the low-temperature part, which ranges from 130 K up to approx. 250 K an E_A of 0.16 eV could be deduced, while

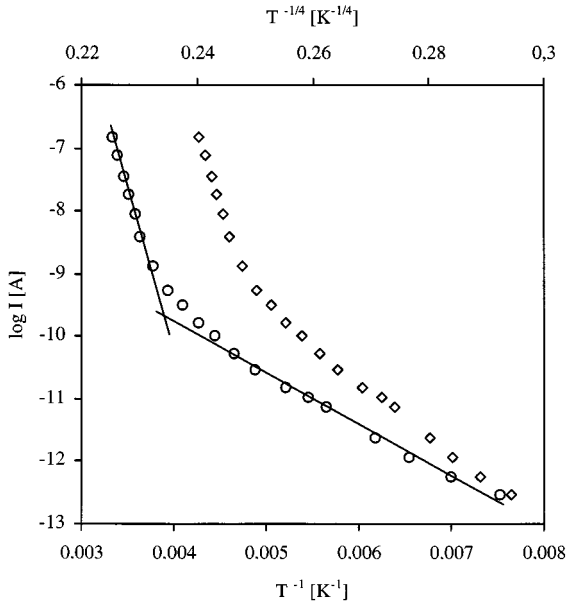

Figure 4. Temperature-dependent current I at a constant voltage U = 5 V of **3** according to the Arrhenius relation (circles) and according to Mott's conductivity law (rhombs); below 250 K E_A = 0.16 eV and above E_A = 0.95 eV

the high-temperature part above displays an E_A of 0.95 eV.

Although it is difficult to determine the exact size of the highly flexible ammonium octyl chains, a cluster spacing of 2.90 ± 0.01 nm might be derived from geometrical considerations if the alkyl chains are stretched. With respect to the previously described linear dependence of the E_A of the cluster spacing, an E_A of 0.24 ± 0.02 eV is expected, which is significantly higher than the 0.16 eV determined here. Thus it seems evident that the alkyl chains are folded and lie close to the central nitrogen atom to give an effective cluster spacing, which is comparable to that in the sodium derivative, even though Na^+ is considerably smaller than $N(octyl)_4^+$. It may also be that the ammonium ions interact strongly with the phenyl rings by hydrophobic−hydrophobic interactions, whereas the Na^+ ion in **2** occupies a position at the periphery of the ligand shell. The rapid increase of E_A above 250 K might originate from an electromigration process during the measurements resulting in disorder, with an increased cluster to cluster and an increased cluster to electrode spacing. Structural deviations from ideal arrangements induce huge effects in the electrical response, especially in the nanometre size range.[18,19,20] Keeping in mind that cluster **3** is a highly viscous liquid instead of a solid, like the Na^+ analogue, it seems to be consistent that this kind of field-induced disorder appears in the octyl ammonium form **3** and not in the Na^+ form.

Conclusions

The series of known Au_{55} clusters bearing 12 $B_{12}H_{11}SH^{2-}$ ions as ligands has been extended by the synthesis of a very special example: the cluster $Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ (**2**) and its tetraoctylammonium derivative consisting of a 24-fold negatively charged anion with 144 B atoms per molecule. This high concentration of B atoms and the very good solubility in water, accompanied by a remarkable stability, makes this cluster a promising candidate for boron neutron capture therapy. The synthesis succeeds via the exchange of PPh_3 in $Au_{55}(PPh_3)_{12}Cl_6$ by the borate, based on a phase-transfer reaction from dichloromethane to water. The bulkiness of the thiols and especially its two-fold negative charge result in a six-week reaction time. Nevertheless, the reaction is quantitative. ^{1}H- and ^{11}B-NMR spectra, elementary analyses, and transmission electron microscopy have been used to prove the composition and size of the clusters. The sodium cations can be exchanged by tetraoctylammonium making the cluster **4** oily, but also soluble in polar solvents like acetone or alcohols.

In addition to the novel clusters **2** and **4** we synthesized the cluster $Au_{55}[Ph_2PC_6H_4SO_3N(octyl)_4]_{12}Cl_6$ (**3**) to enable a comparison of its electrical properties with those of **2** and **4**. Cluster **3** consists of a twelve-fold negatively charged anion, whereas **2** and **4** have the extreme charge of −24.

The electrical properties of the new compounds **2** and **4** are significantly different from the properties of the clusters investigated previously. While cluster **3** shows an activation energy in the temperature range of 130−250 K which is comparable to the corresponding Na^+ form, above that temperature the microstructure of the samples seems to be affected by the electric field due to electromigration. The latter is also assumed to be the reason for the extraordinary behaviour of **2** and **4**. Although this is just a tentative explanation for the properties observed, it may hint to a principle limit of modifiability of the ligand shell with respect to the possible application in nanoelectronic devices, since the huge amount of ionic charges in the ligand shell seems to induce structural instabilities in the samples under test

Experimental Section

General: $(B_{12}H_{11}SH)Na_2$ (BSH) was commercially available from BORON BIOLOGICALS. As it is highly hygroscopic all reactions were performed using standard Schlenk techniques. Before use it was characterized by NMR spectroscopy: ^{1}H NMR (D_2O): δ = 0.25−1.92 (br. m, 12 H, BH and SH). ^{11}B{^{1}H} NMR (D_2O): δ = −19.55 (d, 1 B, −BH), ^1J(BH) = 125.2 Hz, −16.00 (d, 5 B, −BH), ^1J(BH) = 134.8 Hz, −14.00 (d, 5 B, −BH), ^1J(BH) = 135.0 Hz, −9.6 (s, 1 B, B−SH). − The solvents were dried and purified by standard procedures. − NMR spectra were recorded with a Bruker DPX working at 300 MHz for ^{1}H, 75.5 MHz for ^{13}C{^{1}H}, 121.5 MHz for ^{31}P{^{1}H} and 96.3 MHz for ^{11}B{^{1}H}. − Infrared spectra were recorded on a BIO-RAD FTS-175 spectrometer. − TEM images were obtained using a Philips CM 200 FEG microscope working with 200 kV accelerating voltage and to confirm the absence of colloidal particles, electronic spectra of cluster solutions

were measured on a Varian Cary-1 UV/Vis spectrometer. − Elementary analyses were carried out by the Analytical Laboratory of the Fachbereich Chemie of the University of Essen. − For electrical measurements the samples were deposited from solvent on gold interdigital microelectrodes (structural width = 10 μm) on a quartz substrate.[21,22] After drying the samples in vacuum they were kept under argon during the measurements. Current measurements were performed in a voltage range of ± 5 V using a Keithley 6517 electrometer with an integrated voltage source in a low-temperature measuring cell.

$Au_{55}(PPh_3)_{12}Cl_6$ and $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$ were synthesized according to described procedures.[7][13]

$Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ (2): To a solution of 16.7 mg (76.09 μmol) of $[(B_{12}H_{11}SH)Na_2]$ (**1**), dissolved in 125 mL of distilled water and placed in a 250-mL flask, a solution of 80 mg (5.64 μmol) of $Au_{55}(PPh_3)_{12}Cl_6$, dissolved in 60 mL of CH_2Cl_2, was added under vigorous stirring. After 4−6 days the water phase showed a dark brown colour. After a total reaction time of 6 weeks, the emulsion was placed in a separating funnel to separate the water phase carefully from the colourless organic phase and to wash it 4 times with 30 mL of CH_2Cl_2 to remove PPh_3. The solvent was removed under vacuum at room temperature. The brown product was then dissolved in 25 mL of distilled water and filtered through an ANOTOPE® filter (Merck, 20 nm porous diameter) and was precipitated by CH_2Cl_2 and separated. The filtration pad was washed with copious amounts of CH_2Cl_2 and the fine microcrystalline black powder dried overnight under vacuum. Yield: 52 mg (68%). − IR (KBr): $\tilde{\nu}$ = 2500.6 cm^{-1}, vs (ν B−H), 1061.7, m (ν asym B−S), 973.2, w and 947.9, w (δ asym B−S), 836.5, m and 723, w (ν B−B). − ^1H NMR (D_2O): δ = 0.20−2.80 (br. m, 12 H, BH and SH). $^{11}B\{^1H\}$ NMR (D_2O) (10 mm ∅ NMR tube): δ = −20 to −11 (br. m., 11B, *o*-, *m*-, *p*- BH), −7.8 (s, 1 B, B−SH). − ^{31}P- and ^{13}C-NMR signals could not be observed. $Au_{55}B_{144}Cl_6H_{144}Na_{24}S_{12}$ (13683.26 g mol^{-1}): calcd. C 0.00, H 1.05, S 2.81, Na 4.10, Au 79.17; found C 1.30, H 1.26, S 2.72, Na 5.16, Au 77.01.

$Au_{55}[Ph_2PC_6H_4SO_3N(octyl)_4]_{12}Cl_6$ (3): To a solution of 50.0 mg (3.24 μmol) of $Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6$, dissolved in 50 mL of distilled water and placed in a 200-mL flask, a solution of 21.5 mg (39.32 μmol) of $[(octyl)_4N]Br$, dissolved in 50 mL of CH_2Cl_2, was added under vigorous stirring. After 3 h the water phase was colourless whereas the organic phase was dark brown. The emulsion was placed in a separating funnel, the organic phase was carefully separated from the colourless water phase and washed 4 times with 30 mL of distilled H_2O to remove NaBr. The solvent was removed at room temperature under vacuum. The brown product was then dissolved in 20 mL of CH_2Cl_2 and filtered through an ANOTOPE® filter (Merck, 20 nm porous diameter). The solvent was evaporated under vacuum and the gold cluster **3** was precipitated by pentane and separated. The filtration pad was washed with copious amounts of pentane, the black microcrystalline powder was dried overnight under vacuum. Yield: 57 mg (85%). This cluster is slightly soluble in benzene and soluble in polar solvents like CH_2Cl_2, $CHCl_3$, acetone, or acetonitrile. − IR (KBr): $\tilde{\nu}$ = 3000−2850 cm^{-1}, s (ν C−H), 1584.7, m and 1478.5, m (ν C=C arom), 1434.8, s and 1097.9, s (ν P−Ph), 1370.0, m (δ C−H), 1328.5, w 1026.6, w and 690.4, vs (δ C−H). − ^1H NMR ($CDCl_3$): δ = 0.85 (t, 12 H, $N[(CH_2)_7CH_3]_4$), 1.26−1.62 (br, 48 H, $N[CH_2(CH_2)_6CH_3]_4$), 3.27 (br, 8 H, $N[CH_2(CH_2)_6CH_3]_4$), 7.30−8.30 (m, 14 H, $Ph_2PC_6H_4SO_3$). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 35.90 (s, $Ph_2PC_6H_4SO_3$). − $C_{600}H_{984}Au_{55}Cl_6N_{12}O_{36}P_{12}S_{12}$ (20737.3 g mol^{-1}): calcd. C 34.75, H 4.75, N 0.8, S 1.84, Na 0.00, Au 52.24; found C 34.40, H 4.78, N 0.9, S 1.44, Na 0.19, Au 50.32.

$Au_{55}[(B_{12}H_{11}SH)(N(octyl)_4)_2]_{12}Cl_6$ (4): To a solution of 40.0 mg (2.92 μmol) of $Au_{55}[(B_{12}H_{11}SH)Na_2]_{12}Cl_6$ (**2**) dissolved in 40 mL of distilled water and placed in a 200-mL flask, a solution of 40 mg (70.16 μmol) of $[(octyl)_4N]Br$, dissolved in 40 mL of CH_2Cl_2, was added under vigorous stirring. After 3 h reaction, the water phase was colourless, the organic phase presented a dark brown colour. Then, the emulsion was placed in a separating funnel, the organic phase was carefully separated from the colourless water phase and washed 4 times with 30 mL of distilled H_2O in order to remove NaBr. The solvent was removed at room temperature under vacuum. The brown product was dissolved in 20 mL of CH_2Cl_2 and filtered through an ANOTOPE® filter (Merck, 20 nm porous diameter). After removing the solvent under vacuum, **4** was precipitated by pentane but could not be isolated as a powder. A dark-brown oil was obtained which was washed several times with a few mL of pentane and dried overnight under vacuum. This cluster was slightly soluble in benzene and soluble in polar solvents like CH_2Cl_2, $CHCl_3$, acetone, or acetonitrile. − IR (KBr): $\tilde{\nu}$ = 3000−2850 cm^{-1}, s (ν C−H), 2500.0, vs (ν B−H), 1375.0, m (δ C−H), 1060.5, m (ν asym B−S), 972.1, w and 946.5, w (δ asym B−S), 836.0, m and 723, w (ν B−B). ^1H NMR ($CDCl_3$): δ = 0.10−2.25 (br, 132 H, BH and SH, $N[(CH_2)_7CH_3]_4$, $N[CH_2(CH_2)_6CH_3]_4$), 3.30 (br, 16 H, $N[CH_2(CH_2)_6CH_3]_4$). Due to its viscous nature elemental analyses could no be performed.

Sulfur Compounds, 209[+]
The Gas Phase Acidities of the Sulfanes H_2S_n (n = 1–4)

André H. Otto[a] and Ralf Steudel*[a]

Keywords: Sulfur / Sulfanes / Acidity / Ab initio MO calculations / Hyperconjugation

The gas-phase acidities ΔG_{acid}(298 K) of the sulfanes H_2S_n (n = 1–4) have been calculated by ab initio molecular orbital theory using the G2 and G2(MP2) methods, which were applied to the geometries of lowest energy. The results show that the higher sulfanes are surprisingly strong proton donors. The acidities (in kJ mol^{-1}) are as follows: H_2S (1444), H_2S_2 (1406), H_2S_3 (1370), H_2S_4 (1347). The latter three values may be compared to those of other strong Brønsted acids like gaseous HNO_2 (1396), HCl (1371), and HBr (1332). The monoanions HS_n^- exhibit an interesting bond length distribution as a consequence of the charge delocalization by hyperconjugation, which in turn may be responsible for the high acidities of the sulfanes.

Introduction

The hydrogen polysulfides or sulfanes H_2S_n ($n > 1$) form a long series of homologous chain-like molecules since the number of sulfur atoms can practically assume any value. Only the lower members with $n = 2-6$ have been prepared as pure compounds.[1] Under standard conditions they form colorless to light yellow liquids. H_2S_2, H_2S_3, and H_2S_4 can be distilled in vacuo. However, all members with n values up to 35 have been detected by ^{1}H-NMR spectroscopy in so-called crude sulfane.[2] These higher members of the series are often called polysulfanes.

For a long time these species were considered to be of academic interest only until it was suspected that H_2S_2 is present in certain "sour gases"[3] while the higher members were detected in the elemental sulfur produced from sour gas. Sour gas is a natural gas that contains substantial concentrations of H_2S (up to 50%). It is produced in large quantities, for instance, in Northern Germany, in Alberta (Canada), and in The United States. If the underground reservoir of the gas also contains elemental sulfur, the following equilibrium will be established (Equation 1).

$$H_2S\,(g.) + 1/8\ S_8\,(s.) \rightleftharpoons H_2S_2\,(l.) \qquad (1)$$

The very high pressure in the underground gas bearing deposits shifts this equilibrium to the right. Since H_2S_2 is a volatile compound, the gas seems to transport elemental sulfur when it is produced.[4] However, during production the gas is partly decompressed and cools down resulting in decomposition of any sulfanes H_2S_n with precipitation of elemental sulfur. This process sometimes causes severe plugging of pipes and valves by solid sulfur. Before such a natural gas can be used as a fuel or as a reagent in the chemical industry the H_2S must be extracted by treatment with ethanolamine or similar solvents, which on heating liberate the H_2S again. This almost pure H_2S is then oxidized by the Claus process to elemental sulfur (Equation 2).

$$H_2S + 1/2\ O_2 \rightarrow 1/n\ S_m + H_2O \qquad (2)$$

The sulfur (S_m) produced by this method is obtained in the liquid form. It consists mainly of S_8 molecules but other homocycles, like S_7, S_6, and larger rings, are also present.[5] However, since reaction (2) will never be complete the liquid sulfur produced also contains some H_2S, which is present mainly as a mixture of long-chain polysulfanes H_2S_n.[6]

$$H_2S\,(g.) + x\ S_m\,(l.) \rightleftharpoons H_2S_n\,(l.) \qquad (3)$$

Due to the high toxicity of H_2S and to the danger of explosions, both the polysulfanes and the H_2S must be removed almost quantitatively from the liquid sulfur, a goal that is achieved by purging with air.[7]

The gas phase structures of the first three members of the sulfane series are well-known from either microwave spectra (H_2S_2,[8] H_2S_3[9]) or high-level ab initio MO calculations (H_2S_4[10]). While H_2S_2 adopts a conformation of C_2 symmetry similar to that of H_2O_2, the higher members H_2S_3 and H_2S_4 exist as equilibrium mixtures of several conformational isomers of almost identical energy. All sulfane molecules are characterized by torsional angles at the S–S bonds of 90°(±10°), but these angles may be positive or negative resulting in the aforementioned conformational variety. The signs of the torsional angles define the so-called motif, which characterizes each conformational isomer. For H_2S_2 the two isomers with $\tau = \pm 90°$ are enantiomers. In the case of H_2S_3 the motif may be either + + (symmetry C_2; the enantiomer has the motif − −) or + − (identical to motif − +; both are of C_s symmetry). In the case of H_2S_4 the motif may be + + + (or − − −; these are enantiomers and of C_2 symmetry), + + − (or − − +; C_1) or +

− + (identical to − + −; C_s); these conformational isomers are shown in Figure 1.

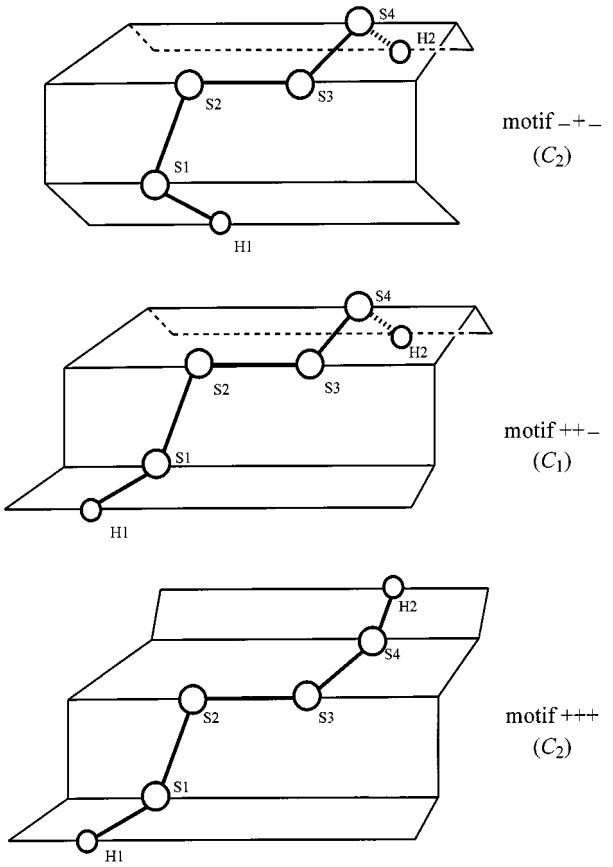

Figure 1. Conformational isomers of H_2S_4 according to a high-level ab initio MO calculation (ref.[10]); the isomer of C_1 symmetry is of lowest energy at 0 K

Hydrogen sulfide, H_2S, is a weak acid in water with pK_a values of 7 and 17 for the first and second dissociation steps (Equations 4, 5).[11]

$$H_2S + H_2O \rightleftharpoons H_3O^+ + HS^- \qquad pK_a = 7 \qquad (4)$$

$$HS^- + H_2O \rightleftharpoons H_3O^+ + S^{2-} \qquad pK_a = 17 \qquad (5)$$

The corresponding pK_a values of the higher sulfanes are not known with certainty. The only related information available comes from the investigation of aqueous polysulfide solutions, which formally contain the dianions of the polysulfanes. In 1960 Schwarzenbach and Fischer[12] titrated aqueous solutions of pure alkali polysulfides (Na_2S_n and K_2S_n with $n = 2-5$) with hydrochloric acid in a flow system and measured the pH value of the mixtures obtained. From these data they derived the following pK_a values for the first and second deprotonation reactions of H_2S_4 and H_2S_5.

		pK$_a$(1)	pK$_a$(2)
$H_2S_4 + H_2O \rightleftharpoons H_3O^+ + HS_4^-$		3.8	
$HS_4^- + H_2O \rightleftharpoons H_3O^+ + S_4^{2-}$			6.3
$H_2S_5 + H_2O \rightleftharpoons H_3O^+ + HS_5^-$		3.5	
$HS_5^- + H_2O \rightleftharpoons H_3O^+ + S_5^{2-}$			5.7

These authors assumed that their starting solutions did not contain any other anions besides HS^-, S_4^{2-}, and S_5^{2-}. Today it is known that this assumption is a crude approximation.[13][14] Therefore, the results obtained by these authors must be considered as approximate. Nevertheless, it became clear that the acidity of the H_2S_n species increases markedly with increasing number of sulfur atoms.

The gas phase acidity of sulfanes is defined as the Gibbs free energy of the dissociation reaction (Equation 6).

$$H_2S_n \rightarrow HS_n^- + H^+ \qquad (6)$$

In the vapor phase the acidity of H_2S has been determined experimentally as $\Delta G_{acid}(298\ K) = 1443 \pm 8$ kJ mol^{-1}.[15] Similar values[16] have been obtained by ab initio MO calculations.[17,18,19]

In the case of H_2S_2 the mass spectrometric investigation of the reaction of the anion HS_2^- with a number of proton donors of known acidity has resulted in a value of ΔG_{acid} of 1418±13 kJ mol^{-1} at 298 K.[20] No experimental or theoretical data are available for the gas phase acidities of H_2S_3 and H_2S_4.

We have studied the gas phase acidities of H_2S, H_2S_2, H_2S_3, and H_2S_4 by theoretical methods. Such data are of significance for studying the problem of corrosion of steel by sour gas containing these species.

Computational Methods

Ab initio molecular orbital calculations were performed at the G2[21] and G2(MP2)[22] levels of theory using the GAUSSIAN program system.[23] The G2 method essentially implies an energy calculation at the QCISD(T)/6-311+G(3df,2p) level of geometries optimized at the

MP2(full)/6-31G(d) level. Harmonic vibrational wavenumbers were obtained at the HF/6-31G(d) level and were scaled by a factor of 0.8929. The G2(MP2) method is a modified version of G2 but uses the second order Møller−Plesset perturbation theory (MP2) for the basis set extension correction instead of the fourth order (MP4). G2(MP2) is nearly as accurate as the full G2 method at a substantially reduced computational expense. The excellent performance of these methods in predicting gas phase acidities of small molecules is well established.[24]

In order to calculate the atomic charges in the anions HS_n^- ($n = 1-4$) a natural bond orbital (NBO) analysis was carried out at the MP2(fu)/6-31G(d) level of theory.

For details of the quantum chemical methods see ref.[25] All calculations were carried out on a Cray J90 or on a Linux workstation.

In order to allow for the thermal corrections to the Gibbs free energy of the proton a value of −0.010654 Hartree (−28 kJ mol^{-1}) was used.

Results and Discussion

The Gibbs free energies at 298 K of the species H_2S_n and HS_n^- for $n = 1-4$ are given in Table 1. In the case of H_2S_3 the most stable conformation with the motif + + (helical chain) was calculated. For H_2S_4 there are two entries: one for the most stable conformer (motif + + −) and one for the helical isomer of C_2 symmetry, which is slightly less stable.

The geometrical parameters of the sulfanes and of their monoanions are presented in Table 2.

The structures of the neutral sulfanes have been discussed several times by previous authors. However, the monoanions HS_n^- with more than one sulfur atom have neither been calculated nor observed before (excepting HS_2^- by mass spectrometry[20]). These species show an interesting bond length pattern in so far as the S−S bond adjacent to the S−H bond is the longest in the anion (210.8−213.6 pm) and much longer than the single bond length as calculated, for example, for H_2S_2 (206.9 pm). On the other hand, the terminal S−S bonds in HS_3^- and HS_4^- are shorter (204 pm) than the single bond while the central S−S bond in HS_4^- is of intermediate length (207.6 pm). Since the torsion angles at all S−S bonds are in the normal range of 73−100° the differing S−S bond lengths must be caused by the delocalization of the additional negative charge within the anion. An explanation is provided by the concept of hyperconjugation between the lone pair in the 3*p* orbital at an atom S(x) and the antibonding σ* molecular orbital of the bond between atoms S($x + 1$) and S($x + 2$) (Figure 2).

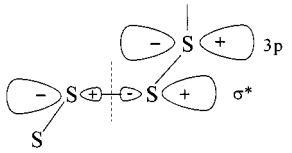

Figure 2. Interaction of the lone pair orbital of sulfur atom S(x) with the empty antibonding σ* molecular orbital of the bond between atoms S($x + 1$) and S($x + 2$) (hyperconjugation); as a consequence the bond S(x)−S($x + 1$) is strengthened while bond S($x + 1$)−S($x + 2$) is weakened

This type of interaction is well-known in sulfur chemistry.[26] It results in a π bond between atoms S(x) and S($x + 1$) (shortened bond) but in a weakening of the bond between atoms S($x + 1$) and S($x + 2$). In HS_4^- two such interactions have to be assumed since the lone pair at S(4) will be delocalized into the σ* MO between S(3) and S(2) and the lone pair at S(3) will be delocalized into the σ* MO at bond S(2)−S(1). In this way the steady increase in the S−S bond lengths from the terminal S atom towards the SH group can be understood.

Table 3. Natural charges (NBO analysis) of the atoms in the anions HS_n^- ($n = 1-4$)

n	H	S(1)	S(2)	S(3)	S(ω)
1	0.05322				−1.05322
2	0.07353	−0.30214			−0.77139
3	0.09949	−0.27652	−0.09775		−0.72522
4	0.13539	−0.23008	−0.09715	−0.07954	−0.72863

The calculated NBO atomic charges of the four anions are presented in Table 3. All sulfur atoms are negatively charged and the hydrogen atoms are always positively charged. This positive charge slightly increases with increasing number of sulfur atoms from +0.05 for HS^- through 0.07 in HS_2^- to 0.10 in HS_3^- and 0.14 in HS_4^-. The ter-

minal sulfur atom is always the most negatively charged atom but its charge decreases from −1.05 in HS^- through −0.77 in HS_2^- to −0.73 in HS_3^- and HS_4^-. The second most negatively charged atom is always the one linked to the hydrogen atom; its charge decreases from −0.30 in HS_2^- through −0.28 in HS_3^- to −0.23 in HS_4^-. The other atoms carry a charge of less than −0.1.

In the case of HS_2^- the geometry and the NBO charges were also calculated at the MP2/6-311++G(d,p) level. While the S−S bond length was calculated as 212.6 pm (0.8% longer than above) the charge of the terminal atom was practically identical (−0.766) as that calculated with the smaller basis set (−0.771).

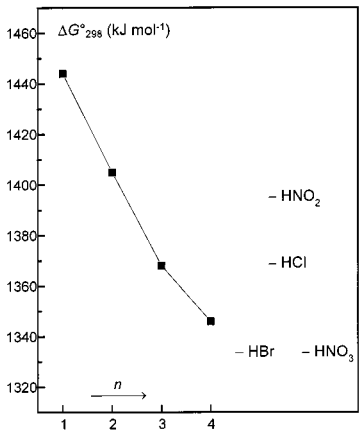

Figure 3. Dependence of the gas phase acidities of the sulfanes H_2S_n (n = 1−4) on the number of sulfur atoms (n) and comparison with the gas phase acidities of HNO_2, HCl, HBr, and HNO_3

The gas phase acidities derived from the data in Table 1 are given in Table 4 and are depicted in Figure 3.

Table 4. Gas phase acidities $\Delta G°_{298}$ [kJ mol^{-1}] of the species H_2S_n (n = 1−4) calculated by the G2(MP2) and G2 methods

System	Symmetry	G2(MP2)	G2
H_2S	C_{2v}	1446	1444
H_2S_2	C_2	1407	1405
H_2S_3	C_2	1371	1368
H_2S_4 (+ − +)	C_2	1349	1346
H_2S_4 (+ − −)	C_1	1350	1347

The acidities calculated for H_2S by the G2 and G2(MP2) methods of 1446 and 1444 kJ mol^{-1}, respectively, are in excellent agreement with the experimental value of 1443 kJ mol^{-1} quoted above. This demonstrates once more that these methods yield reliable data for sulfur compounds.

The dissociation of di-, tri-, and tetrasulfane requires much less Gibbs free energy (free enthalpy) than that of H_2S. There is a drop in ΔG_{acid}(298 K) by 40 kJ mol^{-1} from H_2S to H_2S_2 and of 37 kJ mol^{-1} from H_2S_2 to H_2S_3. Even the addition of another sulfur atom, as in H_2S_4, reduces ΔG_{acid}(298 K) by another 22 kJ mol^{-1}. In other words, the gas phase acidities of di-, tri-, and tetrasulfane are much higher than that of H_2S. The value obtained for disulfane (1406 kJ mol^{-1}) is in excellent agreement with the experimental value of 1418 ± 13 kJ mol^{-1}[20] and comparable to the gas phase acidity[27] of nitrous acid HNO_2 (1396 kJ mol^{-1}). Trisulfane (1370 kJ mol^{-1}) is as strong a proton donor as hydrogen chloride HCl (1371 kJ mol^{-1}), while the acidity of tetrasulfane (1347 kJ mol^{-1}) comes close to that of hydrogen bromide HBr (1332 kJ mol^{-1}) and of nitric acid HNO_3 (1330 kJ mol^{-1})! Since the increase in acidity from H_2S_3 to H_2S_4 is still considerable it can be assumed that H_2S_5 and H_2S_6 will be even stronger acids. A rational explanation for the increase of the acidities with increasing number of sulfur atoms can be given on the basis of the charge capacity of the HS_n fragments, which can obviously accommodate an additional electron more easily the more sulfur atoms they contain since the charge is delocalized onto all sulfur atoms, as discussed above. Therefore, the dissociation of H_2S_2 requires much less Gibbs free energy than that of H_2S and the dissociation of H_2S_3 requires less than that of H_2S_2 and so forth. Since the charge delocalization in the monoanions will also occur in aqueous solution, one would expect the acidity of the aqueous sulfanes to be much higher than that of aqueous H_2S, which is in agreement with the measurements by Schwarzenbach and Fischer.

Derivatives of the sulfanes like the sulfane oxides H−S−S−OH[28] and H−S−S(O)−S−H[29] will probably be similarly strong acids in the vapor phase. These molecules have been proposed as intermediates in the aforementioned Claus process.[29]

In the presence of water vapor the high acidity of gaseous H_2S_2, for example, will result in the formation of hydrated ion pairs like $H_3O^+(H_2O)_x \cdot HS_2^-$ as has been demonstrated in the case of other acids.[30] Since the sour gas always contains water vapor, such ion pairs will be formed and these may be the species responsible for the severe corrosion of steel pipes that has been observed in cases where the sour gas deposit contains both elemental sulfur and H_2S resulting in the formation of H_2S_2.

Structural Analyses of Borane and Chloroborane Adducts of 1,3,5-Dithiaza-, -Dioxaza-, -Thiadiaza-, and -Triazacyclohexanes and Their Rearrangement Products, Boracyclohexanes

Angelina Flores-Parra,*[a] Sonia A. Sánchez-Ruíz,[a] and Carlos Guadarrama-Pérez[a]

Keywords: Borane adducts / Triazacyclohexanes / Thiadiazacyclohexanes / Dioxazacyclohexanes / Boracyclohexanes / Rearrangements

Structural and conformational studies performed by ^{1}H-, ^{11}B-, ^{13}C-, two-dimensional, and variable-temperature NMR spectroscopy of borane and chloroborane adducts of 1,3,5-heterocyclohexanes and their rearrangement products, boracyclohexanes, are reported. *N*-Methyl derivatives gave equatorial *N*-borane adducts whereas the *N*-isopropyl derivatives produced the axial borane compounds. Rearrangement reactions of the adducts gave the first examples of chloroboracyclohexanes bearing boron and nitrogen atoms as stable stereogenic centers. $BClH_2$ and BCl_2H adducts were found to be more stable towards ring rearrangement than the corresponding *N*-BH_3 analogs.

Introduction

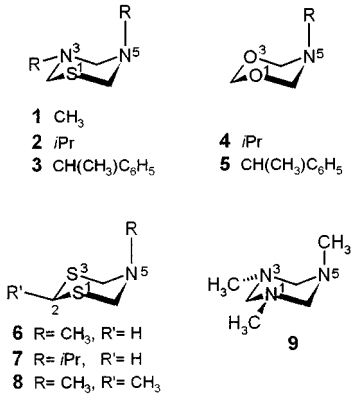
We have been systematically studying the synthesis and particularly the coordination behavior of 1,3,5-heterocyclohexanes bearing heteroatoms such as O, S, and N, which are rich in lone pairs and good ligands for Lewis acids.[1] Reactions with boron[1a,1b,1e−1f] and lithium[1g] compounds were investigated because these reagents function as coordination probes conveniently studied by NMR techniques.

Herein, we report extended studies of chloroboranes, which are more acidic reagents which could give stronger coordination bonds and more stable adducts, and of new families of heterocycles: 1,3,5-thiadiazacyclohexanes and 1,3,5-dioxazacyclohexanes. Because these heterocycles are difficult to prepare, few examples of them were known,[2] but fortunately we have recently established suitable reaction conditions for their preparation.[1h]

Results and Discussion

Herein, we present the study of the reactions of BH_3·THF and various chloroborane·DMS with the heterocycles 3,5-dialkyl-1,3,5-thiadiazacyclohexane (**1**, **2**,[1h,2] and **3**[1h]), 5-alkyl-1,3,5-dioxazacyclohexane (**4** and **5**[1h]), 5-alkyl-1,3,5-dithiazacyclohexane (**6**, **7**,[1d] and **8**[1g]), and 1,3,5-trimethyl-1,3,5-triazacyclohexane[1f] (**9**) (Figure 1).

Acid−base studies with BH_3 as the Lewis acid partner, showed that the potential basicity decreases in the order N > S > O. Therefore, we would expect mono(*N*-BX_3) derivatives to form from the reactions of **1**−**9** with BH_3 or chloroborane compounds, and that two or even three borane molecules would coordinate to heterocycles **1**−**3** and **9**. Also,



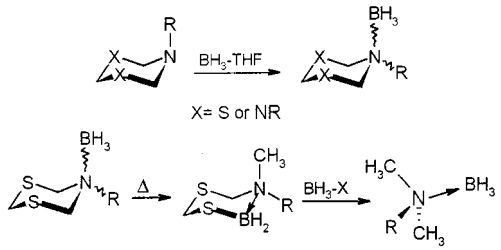


Figure 1

we were interested to find out if coordination would freeze the conformations of the heterocycles. NMR studies of heterocycles **1**−**7** and **9** showed that they are in ring- and nitrogen-conformational equilibrium at room temp. (400-MHz ^{1}H NMR), whereas compound **8** has a preferred chair conformation with the 2-methyl group in the equatorial and the *N*-methyl group in the axial position.[1g]

When heated, *N*-BH_3 adducts of 1,3,5-dithiazacyclohexanes rearrange into boracyclohexanes by exchange of boron and carbon atoms[1b] (Scheme 1). The stability of these boraheterocycles depends on the size of the *N*-alkyl group: Those with bulky groups are rapidly converted into *N*-(BH_3)-dimethylalkylamine complexes.[1b] This rearrangement was not found for 1,3,5-triazacyclohexanes. Therefore, we wanted to investigate if these rearrangements occur for other heterocyclohexanes or with the more reactive chloroboranes, if the more acidic boron atom in the resulting chloroborate allows better coordination and a more stable ring, if the chlorine atom could have a preferred position in a frozen ring and thus result, stereoselectively, in a stereogenic boron atom. In addition, we wanted to study the influence of the chlorine atom on the reactivity and NMR data and on the conformational behavior.

Scheme 1. Rearrangement of the BH_3 adducts

Borane Adducts

NMR spectroscopy showed that the equimolar reaction of thiadiazacyclohexane **1** with BH_3·THF resulted in monoadduct **10**, whereas an excess of borane led to bis(borane) **11** (Figure 2). The ^{13}C-NMR spectrum of compound **1**, at −90°C in [D_8]THF (100.53 MHz), did not indicate a preferred conformation, as the CH_3 and SCH_2N resonances were averaged, indicating that $\Delta G^{\neq}$ for the ring inversion is very low. In contrast, **10** and **11** are present in frozen conformations, because the CH_2 groups have geminal coupling patterns. Their *N*-BH_3 groups are in equatorial positions as shown by the position of the *N*-CH_3 group in the ^{13}C spectrum at δ ≈ 45;[1e] this conformation is also supported by an X-ray diffraction structure.[1i] The bis(borane) **11** is an analog of the reported compound **12**.[1f] In solution, adduct **10** is slowly transformed into **11** and the free heterocycle. ^{1}H-NMR data are summarized in Table 1.

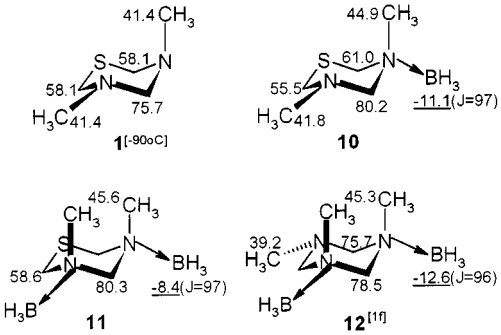

Figure 2. ^{11}B- and ^{13}C-NMR chemical shifts of **10**−**12**

The reaction of equimolar amounts of BH_3·THF and 3,5-diisopropyl-1,3,5-thiadiazacyclohexane (**2**) afforded the stable *N*-borane **13** with the two isopropyl groups in equatorial positions and the BH_3 group in the axial position (Figure 3). Compound **13** is more stable than **14**,[1b] which could be observed only at low temperature. In the presence of an excess of BH_3·THF, **13** rapidly rearranged into **31** (vide infra, Figure 8), whereas the triisopropyltriazacyclohexane **15**[1f] gave a small amount of the bisadduct **16**.[1f] The reaction of BH_3·THF with the dioxazacyclohexane **4** also yielded an *N*-borane, **17**, as shown by NMR spectroscopy at room temp. The stability of the borane adducts is shown by the order of the ease of rearrangemen: **14** > **17** > **13** > **15**.

The room-temp. NMR spectra of **13**−**17** (Figure 3) show that the ring conformation is preferentially that of a chair with the bulky isopropyl groups in equatorial positions, as shown by the ^{13}C-δ values for CH (δ ≈ 54; for the axial position δ ≈ 46).[1e] These heterocycles provide examples of axial BH_3 groups. The frozen conformation of **13** that results from BH_3 addition makes the N atoms stereogenic centers and the C−CH_3 groups diasterotopic. The signal of CH_3 groups of the isopropyl group attached to the coordinated nitrogen atom appear at δ = 15.9 and 15.7, whereas those of the ones attached to the free nitrogen atom appear at δ = 18.8 and 18.4. In the free ligand **2** the signals of all the CH_3 groups appear at δ = 20.1.

Chloroborane Adducts

We prepared the chloroborane adducts of 1,3,5-heterocyclohexanes **18**−**22** and **24**−**29**. The reaction of a commercial mixture of BH_2Cl, $BHCl_2$, and BH_3 (in the ratio 90:8:2, respectively), in DMS, with compounds **6** and **8** produced, in the same ratio, the corresponding adducts **18**−**21** (Figure 4). Upon coordination, the ring of adducts **18**−**21** adopted a preferred conformation with the *N*-methyl group in the axial position as indicated by their ^{13}C-δ values in the range δ = 37.7−40.2 (Table 2). To analyze the trends in the NMR spectra, the data of compounds **18**−**21** were compared to those of the BCl_3 (**22**) and BH_3 (**23**[1b]) adducts of **6**. In the ^{1}H as well as the ^{11}B spectra, the resonances of the CH_2 groups close to the N−B bond are systematically shifted to higher frequencies with an increasing number of chlorine atoms. The coupling constants ^1J(B−H) increase in the same order.

We found that chloroborane adducts are more stable to ring rearrangement than the corresponding *N*-BH_3 analogs, making them useful for the observation and study of coordination compounds of heterocycles with bulky groups. For example, we obtained adduct **24**, derived from 3-isopropyl-1,3,5-dioxazacyclohexane (Table 1, Figure 5). It is moderately stable and could be observed by NMR, but we were not able to detect the corresponding BCl_2H adduct. The *N*-BH_3 adducts of **3** and **5** could not be observed because they are rapidly reduced to the corresponding dimethylamineborane.

Heterocycle **1** has two N sites for borane coordination and readily formed monoadduct **25** and bis(monochloroborane) adduct **26**. Both are stable compounds with the *N*-chloroborane group in the equatorial position as the preferred conformation. In contrast, only one example of an *N*-BCl_3 adduct of a 1,3,5-thiadiazacyclohexane was prepared, **27**, which is a weak complex that decomposes on vacuum evaporation of the solvent. According to its ^{13}C-NMR spectrum, the BCl_3 adopts an axial position (Figure 5). An interesting observation was that BCl_3 adducts of the studied heterocycles are less stable than adducts with at least one B−H bond. This can be explained by the stabilization resulting from interaction between the hydrides on B and the protons on C, as discussed in the next paper.[1i]

The *N*-BH_2Cl monoadduct **28** and bisadduct **29** of 1,3,5-triazacyclohexane (**9**) were obtained. The BH_2Cl groups oc-

cupy equatorial positions and the ring is not fluxional. The ^{13}C chemical shifts of **28** and **30**[1f] were similar, and those of **29** and **12** were also similar[1f] (Figures 2, 6).

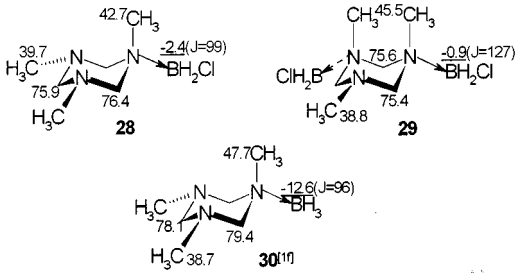

Figure 6. ^{11}B- and ^{13}C-NMR data and the preferred conformations of **28**, **29**, and **30**

1,3,5,6-Thiadiazaboracyclohexane (31)

Herein, we report the first example of a 1,3,5,6-thiadiazaboracyclohexane (**31**), quantitatively formed by reaction of 1,3,5-thiadiazacyclohexane (**2**) and an excess of BH_3·THF in $CHCl_3$ at room temp. The ^{11}B-NMR spectrum of **31** shows a triplet at $\delta = -5.3$, characteristic of an $S-BH_2\leftarrow N$ group. The ring appears nondynamic on the time scale of the ^1H-NMR spectrum at room temp (Figure 7).

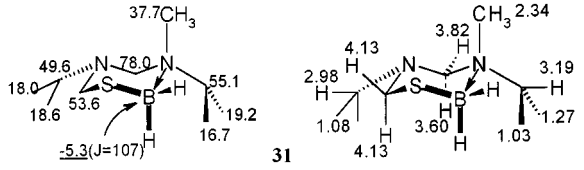

Figure 7. ^{13}C-, ^{11}B-, and ^1H-NMR chemical shifts of **31** at 25°C

1,3,5,6-Dithiazaboracyclohexanes 32−36

2-Chlorobora-1,3,5-dithiazacyclohexanes **32−36** were formed by allowing the 1,3,5-dithiazacyclohexanes **6−8** to react with excess BH_2Cl·DMS in $CHCl_3$. The resulting structures were assigned by HETCOR, COSY, and APT NMR experiments. The positions of the chlorine atoms were determined by their effects on the ^1H resonances of the neighboring protons and by comparison with the analogous BH_2 compounds. The boron atom becomes a stereogenic center and two isomers were indeed observed. At room temp. compound **32** is an equilibrium mixture of the two conformers shown in Figure 8. At −65°C, both conformers were observed in the ^{13}C- (Table 2) and ^{11}B-NMR spectra, for assignment a comparison with **37** was helpful. The conformer with the Cl atom in axial position was present in 70% abundance. At this temperature the $^1J(B-H)$ values of the two isomers differed significantly, with 161 Hz for equatorial B−H and 127 Hz for axial B−H, indicating frozen conformations.

Compound **8** with an excess of BH_2Cl produced the two diasteromers **33** and **34** in a 1:1 ratio (Figure 9). The ^1H- and ^{13}C-NMR data indicate that the chair conformation is the preferred one for both molecules at room temp., and the $C-CH_3$ group anchors the molecule. Here, the boron atom and C-2 are stereogenic centers.

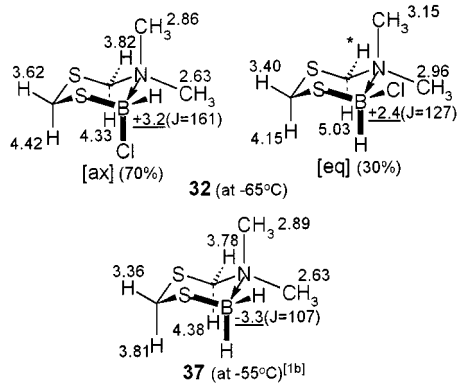

Figure 8. ^1H- and ^{11}B-NMR data of **32** and **37**

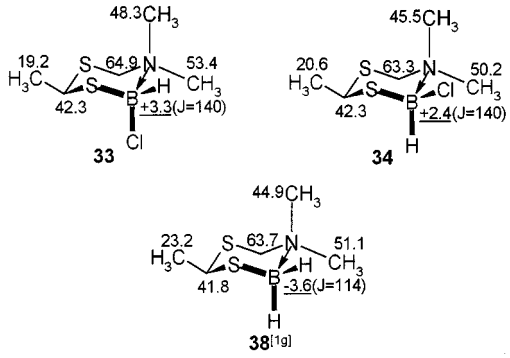

Figure 9. ^{13}C-NMR data of **33**, **34**, and **38** at 25°C

To see if a more bulky *N*-substituent will also function as an anchor for ring inversion, we treated the 1,3,5-dithiazacyclohexane **7** in equimolar amounts with the mixture of chloroboranes for 5 h at room temp. The reaction products were the cyclohexanes **35** (60%) and **36** (40%) (Figure 10). Both compounds were shown by their ^1H-NMR spectra to be nonfluxional, and their boron and nitrogen atoms are stereogenic centers. The equatorial position of the isopropyl groups was found by ^{13}C-NMR spectroscopy (CH at $\delta =$ 59.4 and 54.7 in **35** and **36**, respectively). An anomeric effect produced by the axial chlorine atom on the axial *N*-methyl group (which is deshielded) was observed for **33** and **35**.

Conclusions

The 1,3,5-heterocyclohexanes and borane or chloroborane form stable adducts which have frozen conformations as shown by the geminal coupling pattern of the CH_2 groups. The values of the coupling constants in the frozen free heterocycles vary according to the nature of the heteroatom (OCH_2O: 5.9; SCH_2S: ca. 13.3; NCH_2N: 8.0; SCH_2N: 10.5−13.5). The corresponding values in the adducts do not show systematic trends except for the triazacy-

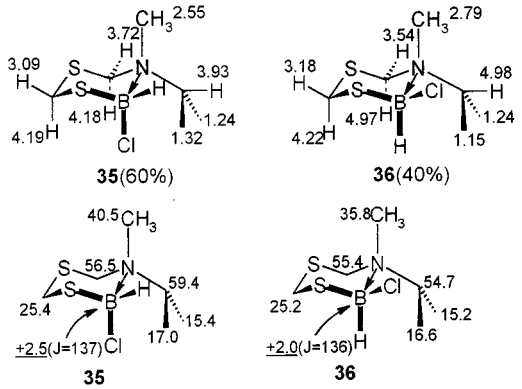

Figure 10. ^{13}C-, ^{11}B-, and ^{1}H-NMR chemical shifts of **35** and **36**

clohexanes and dithiazacyclohexanes where these values increase upon coordination [e.g., in **9** it increases from 8 Hz to 9.1 and 11.7 Hz, and in **6** (SCH_2N) it increases from 12.6 to 13.9−14.3 Hz, Table 3]. The frozen conformations are also deduced from the ^4J_w couplings between the equatorial protons, the values of which vary between 1.2 to 2.6 Hz. In **37** this coupling occurs between the equatorial C−H and B−H, with J = 2.0 Hz.

The configuration of the nitrogen atoms in borane and chloroborane adducts of triaza-, thiadiaza-, dithiaza-, and dioxazacyclohexanes is determined by the size of the *N*-substituents. The bulky isopropyl groups direct the borane units into the axial positions, while the methyl groups direct the boranes to the equatorial positions. ^1J(B−H) constants for axial BH_3 are smaller that the corresponding values for equatorial BH_3, which could be attributed to a weaker coordination of axial borane.

That the formation of adducts resulted in frozen ring conformations indicate that there is a hydride−proton interaction.[1i] This is supported by the result that BCl_3 did not give stable adducts. The use of excess borane and chloroboranes led to new boracyclohexanes. The chloroborata compounds are more stable because SBHCl is more acidic than the SBH_2 group.

Experimental Section

^{1}H-, ^{13}C-, and ^{11}B-NMR spectra were recorded with Jeol spectrometers at frequencies of 270 and 400 MHz for protons; δ values are referenced to TMS, and to $BF_3{\cdot}OEt_2$ for ^{11}B-NMR spectra. − $BH_3{\cdot}$THF was prepared as described.[3] The $BH_{3-n}Cl_n{\cdot}S(CH_3)_2$ mixture was purchased from Aldrich Co. Anhydrous solvents were prepared according to usual laboratory methods. − All reactions were carried out in inert atmosphere with oven-dried glassware. − Adducts **10**, **11, 13**, **17**−**21**, **24**−**29**, and boracyclohexanes **31**−**36** were analyzed only by variable-temperature, and two-dimensional ^{1}H-, ^{13}C-, ^{11}B-NMR spectroscopy. Our attempts to isolate them from the mixture of adducts were unsuccessful because they are unstable. Therefore, we could not perform elemental analyses. However, their structures were derived by comparison to fully characterized similar compounds.[1]

Preparation of Mono-*N*-BH_3 Adducts 10, 13, and 17. − General Procedure: To a solution of the corresponding heterocyclohexane (0.25 g) in 20 mL of dry THF, was added a solution of $BH_3{\cdot}$THF (1.2 mmol) at −78°C. The mixture was stirred for 5 min, and then the solvent was removed under vacuum leaving behind a mixture of adducts as white solids which were analyzed by NMR spectroscopy (**10**, 80%; **13**, 85% and **17**, 80%).

Preparation of 3,5-Bis(borane)-3,5-dimethyl-1,3,5-thiadiazacyclohexane (11): To a stirred solution of **1** (0.25 g, 1.9 mmol) in 20 mL of dry THF, was added a solution of $BH_3{\cdot}$THF (2.0 mmol) at 25°C. After 10 min, more $BH_3{\cdot}$THF (4.1 mmol) was added and the reaction mixture was kept for 30 min at 50°C. The solvent was then removed under vacuum to give the adduct as a white solid. Compound **11** (80%, 0.24 g) was crystallized from $CHCl_3$. m.p. 40°C. − $C_5H_{18}B_2N_2S$ (132.23): calcd. C 37.56, H 11.34, N 17.52; found C 37.51, H 11.46, N 17.36.

Preparation of *N*-$BHCl_2$ and *N*-BH_2Cl Adducts 18−21, 24−26, 28, and 29. − General Procedure: To a stirred solution of the corresponding heterocyclohexane (**1**, **5**, **6**, **8**, or **9**) (0.25 g) in 20 mL of dry $CHCl_3$, was added at −60°C a solution of 1 or 2 equiv. of $BH_{3-n}Cl_n\ SMe_2$. The reaction mixture was stirred for 5 min. The solvents were then removed under vacuum to afford the *N*-$BHCl_2$ and *N*-BH_2Cl adducts: **19** and **21** (8%); **24** (50%); **25** (95%); **26** (85%); **28** (40%), and **29** (95%). − Adduct **18** was crystallized from $CHCl_3$ and obtained in 80% yield (0.27 g). − $C_4H_{11}BClNS_2$ (183.53): calcd. C 26.18, H 6.04, Cl 34.94, N 7.63; found C 26.69,

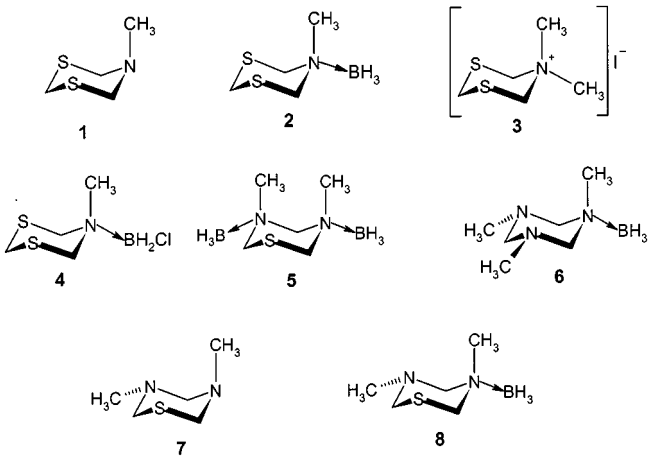
$BH^{\delta-}$–$^{\delta+}HC$ Interactions in *N*-Borane and *N*-Chloroborane Adducts Derived from 1,3,5-Heterocyclohexanes

Angelina Flores-Parra,*[a] Sonia A. Sánchez-Ruiz,[a] Carlos Guadarrama,[a] Heinrich Nöth,[b] and Rosalinda Contreras[a]



Keywords: Hydridic–protic hydrogen interactions / Amine boranes / 1,3,5-Heterocyclohexanes

The molecular structures of 5-methyl-1,3-dithia-5-azinium-cyclohexane iodide, 5-chloroborane-5-methyl-1,3-dithia-5-azacyclohexane, 3,5-bis(borane)-3,5-dimethyl-1-thia-3,5-diazacyclohexane, and 1-borane-1,3,5-trimethyl-1,3,5-triazacyclohexane were determined by X-ray diffraction studies. Interactions between hydridic and protic hydrogen atoms are present when the distances between hydridic and protic hydrogen atoms are shorter than 265 pm and angles for B–N–C bonds are smaller than 107.6(3)°. These interactions explain the conformation of the borane adducts in the solid state.

Introduction

Six-membered 1,3,5-triheterocyclohexanes bearing N and O and/or S atoms are rich in lone pairs and are therefore expected to be versatile ligands.[1] We have been systematically studying the synthesis of 1,3,5-heterocyclohexanes bearing at least one nitrogen atom[1c,1d,2] and the coordination of these heterocyclohexanes to boranes.[1a–1c,1e–1h]

The *N*-borane adduct **2**, derived from *N*-methyldithiazacyclohexane (**1**), was shown by NMR methods to have a fixed conformation at room temp. in $CDCl_3$ or [D_8]THF. Its NMR spectrum at room temp. is similar to that of the free heterocycle **1** at −65°C (270-MHz ^1H), which, at room temp., in ring-conformational equilibrium, has its CH_3 group in the axial position ($\Delta G^{\geq} = 46.0 \pm 0.8$ kJ/mol). The remarkably static behavior of **2** needs to be explained because the BH_3 and CH_3 groups are expected to behave similarly with regard to ring inversion, and **2** would therefore be expected to be a fluxional cyclohexane like its isolobal compound 5,5-dimethyldithiazoniumcyclohexane iodide (**3**). To find an explanation, the solid-state molecular structures of **1**–**6** and the conformational behavior of **1**,[1a] **2**,[1a,1b] **3**,[1g] **4**,[1h] **5**,[1h] and **6**[1f] were studied. The conformations of **2** and **4**–**6** were shown by NMR spectroscopy to be fixed at room temp. and in solution. A dipolar interaction between the hydridic B–H and protic C–H groups, previously reported for some aminoboron hydrides,[3] could explain these frozen conformations. This possibility was confirmed by the results of the structure analyses of compounds **1**–**6**. The structure of **1** has already been reported,[1c] but is important for comparison with the data of **3** and **4**.

Syntheses

Compound **3** was obtained by conventional methods from **1** and CH_3I, and was crystallized from H_2O. The 1:1 reaction of a commercial mixture of BH_2Cl, $BHCl_2$, and BH_3 in DMS (in a ratio of 90:8:2, respectively) with **1** produced the adducts in the same ratio.[1h] Compound **4** was isolated from this mixture by crystallization from $CHCl_3$ and was characterized by NMR spectroscopy. Its ^{13}C-NMR chemical-shift data indicate that the *N*-methyl group (δ = 39.2) is present in an axial position.[1h]

The N–BH_3 adduct **6** was prepared from the reaction between BH_3·THF and 1,3,5-trimethyl-1,3,5-triazacyclohexane.[1f] It was also a byproduct of the reaction of the same heterocycle with $LiBH_4$ in boiling hexane, and it was isolated by sublimation and recrystallization from the same solvent.

The reaction of 3,5-dimethyl-1-thia-3,5-diazacyclohexane (**7**) with 1 or 2 equiv. of BH_3·THF gave the monoadduct **8** and the bisadduct **5**, as deduced from their NMR spectra.[1h] In both compounds, the $N-BH_3$ groups are in the equatorial positions, as indicated by the ^{13}C-NMR chemical shifts of the $N-CH_3$ groups (close to $\delta = 45$).[1a]

Molecular Structures

The molecular structure of compound **3** is depicted in Figure 1. Crystallographic data and bonding parameters are summarized in Tables 1−2. The formation of the cation is accompanied by a shortening of the S−C bonds (on average 0.03 Å) compared with those of compound **1**. There are intermolecular S···S contacts (2.99 Å) as well as four comparatively short C−H···I contacts ranging from 3.04 to 3.28 Å.

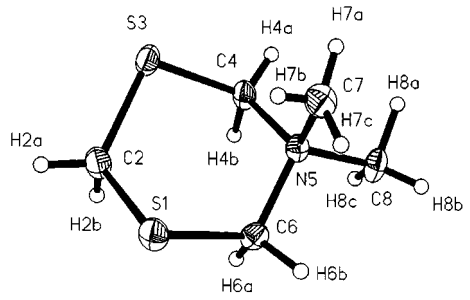

Figure 1. Molecular structure of the cation of **3**

The ring of **4** is also in the chair conformation (Figure 2). The methyl groups are in axial positions and the BH_2Cl moiety is in an equatorial position. The chlorine atom stands antiperiplanar to the methyl group. The molecular structure of **4** compared with that of the free heterocycle **1**[1d] (Table 2) has C−S bonds that are on average shorter by 0.015 Å, a consequence of the ammonium-type N atom in **4**. The BH_3 coordination changes the bond lengths in the ring: The N−C4 [1.502(5) Å], N−C6 [1.496(5) Å], and N−C7 [1.495(5) Å] bonds are expectedly longer in the adduct than in **1** [N−C4: 1.428(4); N−C6: 1.433(4); N−C7: 1.466(5) Å]. On the other hand, in the adduct, the angles C7−N5−C4 [111.0(3)°], C7−N5−C6 [111.0(3)°], and C6−N5−C4 [110.3(3)°] are closer to the angles in the free 1,3,5-dithiazacyclohexane [C7−N5−C4: 114.6(3)°; C7−N5−C6: 114.2(3)°; C6−N5−C4: 113.1(3)°], in accordance with the increased sp^3 character of the nitrogen atom. It is interesting to note the narrow angle C7−N5−B [105.4(3)°] which allows the hydridic atom to be closer to the CH hydrogen atom. Steric repulsion instead of an attractive force between the borane and the methyl group would have resulted in a wider angle.

Single crystals of **5** were obtained from a chloroform solution of **8**. The crystals were obviously formed by disproportionation of the monoborane **8** into **7** and bisborane adduct **5**. The molecular structure of **5** is shown in Figure 3, and its bonding parameters are summarized in Table 2. The C−S bond lengths in **5** match the average C−S bond

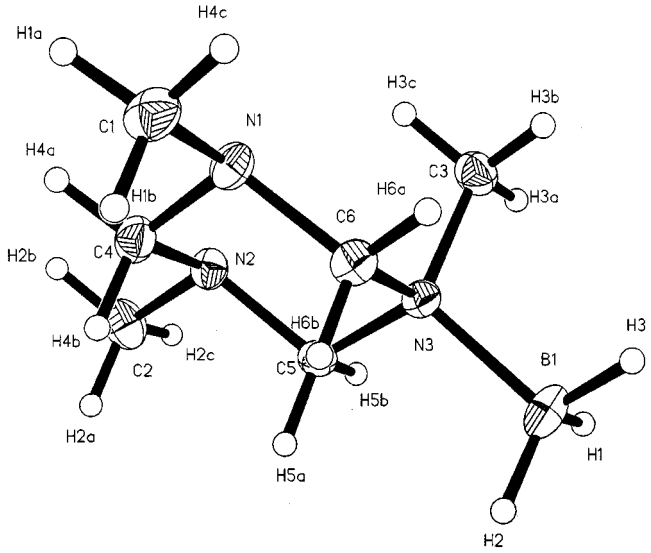
lengths of **4**, therefore the two CH_3NBH_3 units must have the same inductive effect on the C−S bond as the ammonium character of the N atom in **4**. Moreover, the N−B bond lengths in **5** are longer than the N−B bond length in **4**. We explain this by the missing inductive effect of the chlorine atom. Compound **5** shows a chair conformation (Figure 3). The two BH_3 groups are in equatorial positions and the two CH_3 groups are in axial positions; the open angles C8−N3−C4 114.6(3)° and C7−N5−C4 114.8(3)° indicate the steric compression suffered by the methyl groups.

The molecular structure of **6** is depicted in Figure 4 and its crystallographic data are presented in Tables 1−3. The heterocycle adopts a chair conformation. The angles around N1, N2, and N3 indicate sp^3 hybridization of these atoms. Two CH_3 groups and BH_3 occupy equatorial positions, and the N3−CH_3 group occupies an axial position.

Interactions between Hydridic and Protic Hydrogen Atoms

The van der Waals radius for the hydrogen atom in a methyl group is reported to be 120 pm.[3] Larger radii have been calculated (145 and 165 pm).[4] In metallic hydrides,



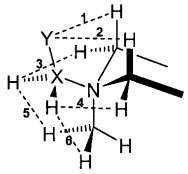


Figure 4. Molecular structure of **6**

the hydrogen ionic radii were found to range from 137 to 154 pm.[5] If an average of 145 pm is assumed, the sum of the van der Waals radii of a protic and an ionic hydridic hydrogen atom is 265 pm. Since the van der Waals radius of the C−H species is 90 pm larger than the hydrogen atomic radius one can estimate that the van der Waals radius of a hydridic hydrogen atom is 145 + 90 = 235 pm. The sum of these van der Waals radii is therefore even larger than that assumed for *r*(H) (van der Waals) + *r*(H^-).

The C−H···H−B atomic distances for **3**−**6** are summarized in Table 3. The distances that are shorter than 265 pm are considered to be the sum of the van der Waals radii, and indicate a strong stabilizing H^+-H^- interaction.[6] The distances in the *N*-methyldithiazinium iodide are all larger than 265 pm.

Hydridic and protic hydrogen atoms have been found to deform the angles of their molecular backbones.[6] $H^{\delta-}-H^{\delta+}$ interactions can therefore also be deduced from the angles between the methyl and the borane groups. For

example, B9−N5−C7 [105.0(3)°] in **4**, and B9−N5−C7 and B10−N3−C8 [107.6(3)°] in **5** are smaller than the angle C7−N5−C8 [109.0(4)°] in **3**, thus allowing the close approach of the hydridic and the protic hydrogen atoms as expected for dipolar forces. The torsional angles C5−H5A−H2−B1 (−3.1°), C6−H6B−H2−B1 (4.9°), C5−H5B−H1−B1 (2.2°), and C6−H6A−H3−B1 (−0.5°) are close to 0°, showing that the H^+-H^- interaction is almost at an optimum.

In conclusion, we propose that this kind of intramolecular H^+-H^- interaction[6] is a dominating factor in stabilizing the conformation of boron hydride adducts of azacyclohexanes. It seems to be as important as the intermolecular N−H···H−B interactions that are characteristic for amine−boranes in the solid state, which has recently been pointed out by Crabtree et al.[7]

Experimental Section

The X-ray diffraction studies of **3**−5 were performed with an Enraf−Nonius CAD4 diffractometer (Mo-K_α = 71.069 pm, monochromator: graphite, ω-2θ scan). Cell parameters were determined

by least-squares refinement of diffractometer angles for 24 automatically centered reflections. Absorption corrections were not necessary; corrections were made for Lorentz and polarization effects. Solution and refinement: direct methods (SHELXS-86) for structure solution. The SHELXL[8] software package was used for refinement and data output. All hydrogen atoms in structures were found in the difference Fourier map. Data was collected for compound **6** with a Siemens P4 instrument with a CCD area detector and a low-temperature device LTP2. The unit cell was determined from the data on 75 frames and data collection was performed in the hemisphere mode with $\Delta\varphi = 0.3°$ and 10 s/frame exposures. Data reduction used the program SAINT. The structure was solved by direct methods (SHELXL-86). Experimental parameters are listed in Table 1. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data as supplementary publications nos. CCDC-133313 (**3**), -133314 (**4**), -133315 (**5**) and -133316 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat). + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

5-Methyl-1,3,5-dithiazoniacyclohexane Iodide (3): To a solution of 5-methyl-1,3,5-dithiazacyclohexane (**1**) (1 mmol) in 20 mL of dry THF, CH_3I (1.2 mmol) was added at room temp. The mixture was stirred for 3 h; compound **3** precipitated from the solution. It was filtered and crystallized from H_2O.

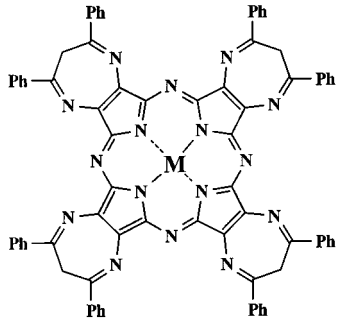
Porphyrazines with Annulated Diazepine Rings, 1 Synthesis and Characterization of Tetrakis-2,3-(5,7-diphenyl-6*H*-1,4-diazepino)porphyrazine and Its Mg^{II}, Cu^{II}, and Zn^{II} Complexes – X-ray Crystal Structure of 2,3-Dicyano-5,7-diphenyl-6*H*-1,4-diazepine

Maria Pia Donzello,[a] Claudio Ercolani,*[a] Pavel A. Stuzhin,*[b] Angiola Chiesi-Villa,[c] and Corrado Rizzoli[c]

Keywords: Porphyrazines / Diazepines / Tetrakis(diazepino)porphyrazines / Metal complexes / Macrocyclic ligands / Magnesium / Copper / Zinc

A new class of porphyrazine macrocycles carrying peripheral diazepine rings, i.e. tetrakis-2,3-(5,7-diphenyl-6*H*-1,4-diazepino)porphyrazine $[Ph_2DzPzH_2](H_2O)_4$, and its metal derivatives of formula $[Ph_2DzPzM](H_2O)_{x=2-7}$ [M = Mg^{II}-(H_2O), Cu^{II}, Zn^{II}] have been prepared and characterized. Single crystal X-ray work on the monomeric precursor 5,7-diphenyl-2,3-dicyano-6*H*-1,4-diazepine, $Ph_2(CN)_2Dz$, and NMR spectra ($CDCl_3$, $(CD_3)_2SO$) and UV/Vis spectra in solution of different media (basic, neutral, acid) of the monomer and its macrocyclic derivatives have provided information on the conformational flexibility of the diazepine ring as well as on the structural and electronic features of the entire porphyrazine skeleton.

Introduction



Tetrapyrrolic macrocycles such as porphyrins[1] and phthalocyanines (tetrabenzoporphyrazines), substituted phthalocyanines or their aza analogues,[2] object of extensive studies and practical applications for several decades, have been even more intensively investigated during the last 10−20 years. Comparatively, porphyrazines without annulated six-membered aromatic rings (commonly named also as tetraazaporphyrins), a distinct class of novel macrocycles, have been little studied, although the object of recent increasing attention.[3] Very recently, we have reported on the synthesis and characterization of new classes of porphyrazines carrying five-membered S- and Se-containing heterocycles annulated to the pyrrole rings of the central porphyrazine core, namely tetrakis-3,4-(1,2,5-thiadiazole)-[4] and tetrakis-3,4-(1,2,5-selenodiazole)porphyrazines.[5] Definitely, these new macrocycles can be seen as phthalocyanine-like systems in terms of the square-planar molecular geometry, number of π-electrons, and physical properties (low-solubility, high thermal stability, vaporizability). Nevertheless, the presence in the macrocyclic ring of N atoms and of soft atoms such as S and Se certainly determines a different electronic distribution within the skeletal ring. In addition, S and Se can play an important role in affecting the solid state interunit contacts, which are presently deepfully investigated, this probably opening promising perspectives for the new molecular materials in the field of practical applications (electrical conductivity, electrochromism, nonlinear optical properties, etc.).

We have now extended our attention to the synthesis and characterization of porphyrazine macrocycles having peripheral heptaatomic heterocyclic rings, and report here on the X-ray crystal structure of 5,7-diphenyl-2,3-dicyano-6*H*-1,4-diazepine, $Ph_2(CN)_2Dz$, and on the use of this dicyano species as a monomeric precursor for the synthesis of a new class of porphyrazine macrocycles, i.e. tetrakis-2,3-(5,7-diphenyl-6*H*-1,4-diazepino)porphyrazine, Ph_8DzPzH_2, and its complexes with Mg^{II}, Cu^{II}, and Zn^{II} (see Scheme 1). These tetrapyrrolic species, owing to the structural features of the annulated diazepine rings (see below), markedly differ from the S- and Se-porphyrazines mentioned above, and from the phthalocyanines as well, in many respects. First, they are far from being entirely planar, and, hence, the problem is faced of how the central essentially flat porphyrazine core and the peripheral non planar diazepine rings will reciprocally interfere both structurally and electronically. In addition, the presence of the eight peripheral phenyl groups contribute to infer to the new materials specific physical properties, among them solubility, which may diversify the spectrum of the possible practical applications. Special account should be taken of the fact that the physical properties of this new class of complexes can be modulated by operating appropriate substitutions, presumably possible, in the 5, 6, and 7 positions of the external diazepine rings.

Results and Discussion

First, we briefly illustrate the structure of the monomeric precursor **1**, and then report on the synthesis and characterization of the macrocycles **2**−**5**.

X-ray Crystal Structure of 5,7-Diphenyl-2,3-dicyano-6*H*-1,4-diazepine, $Ph_2(CN)_2Dz$ (1)

The crystal structure of $Ph_2(CN)_2Dz$ consists of discrete molecules and the crystal packing is determined by van der Waals interactions. Crystal data and details associated with data collection are given in Table 1. The side and front views of the molecule are given in Figure 1 (A, B). Selected bond lengths and angles are quoted in Table 2. The diazepine ring exhibits a boat conformation flattened at the stern, as indicated by the displacements of the C(6), C(2), C(3) atoms from the N(1)−N(4)−C(5)−C(7) mean plane, which are 0.837(2), 0.572(2), 0.588(2) Å, respectively. The dihedral angles formed by the C(5)−C(6)−C(7) and N(1)−C(2)−C(3)−N(4) mean planes with the N(1)−N(4)−C(5)−C(7) mean plane are 119.0 and 148.4°, respectively. The diazepine ring possesses a pseudosymmetry plane running through C(6) and the midpoint of the C(2)−C(3) bond, as indicated by the asymmetry parameter ΔC_s (C4) = 0.011(1). Considering the sequence N(1)−C(2)−C(3)−N(4)−C(5)−C(6)−C(7) the puckering parameters are as follows: q_2 = 0.830(2); q_3 = 0.308(2); Q_T = 0.886(2); φ_2 = 24.3(2); φ_3 = 128.3(4); θ_2 = 69.6(1). The N−C and C−C bond lengths within the diazepine ring appear to be intermediate between those expected for single and double bonds. In fact N(1)−C(2) and N(4)−C(5) lengths are shorter (ca. 1.36 Å) than those in a single bond, while N(1)−C(7) and N(4)−C(5) both 1.301(2) Å], and C(2)−C(3) [1.378(2) Å] are longer than those in a double bond. This indicates that π conjugation permeates the fragment C(7)−N(1)−C(2)−C(3)−N(4)−C(5) internal to the diazepine ring, despite of the fact that the latter is considerably displaced from planarity. The C(51)...C(56) and C(71)...C(76) phenyl rings, which form a dihedral angle of 75.8(1)°, are tilted with respect to the N(1)−N(4)−C(5)−C(7) mean plane by 126.7(1) and 129.0(1)°, respectively.

Unique total data [$I > 0$]	2862
Unique observed data [$I > 2(I)$]	2492
R	0.055
$wR2$	0.176
GOF	1.162

$R = \Sigma|\Delta F|/\Sigma|F_o|$ calculated on the unique observed data [$I > 2(I)$]; $wR2 = [\Sigma w|F^2|^2/w|F_o{}^2|^2]^{1/2}$ calculated on the unique total data with $I > 0$; $GOF = [\Sigma w|F^2|^2/(NO - NV)]^{1/2}$.

As can be well seen from Figure 1A, two hydrogen atoms of the $-CH_2-$ group are inequivalent: One of them is in the equatorial position while another one, being in the quasi-axial position, is located over the diazepine ring. Thus, in the solid state, **1** exists as 6*H* tautomer of type **I** (Scheme 2).

Macrocycles 2−5: Synthetic and General Aspects

Although 2,3-dicyano-6*H*-1,4-diazepines have been known for a long time[6][7] no attempt, to our knowledge, has so far been made to use them as precursors for the preparation of porphyrazines. We have attempted the template tetramerization in presence of magnesium propylate of both 5,7-dimethyl-2,3-dicyano-6*H*-1,4-diazepine, $Me_2(CN)_2Dz$, and 5,7-diphenyl-2,3-dicyano-6*H*-1,4-diazep-

[a] Atom numbering corresponds to that shown in Figure 1.

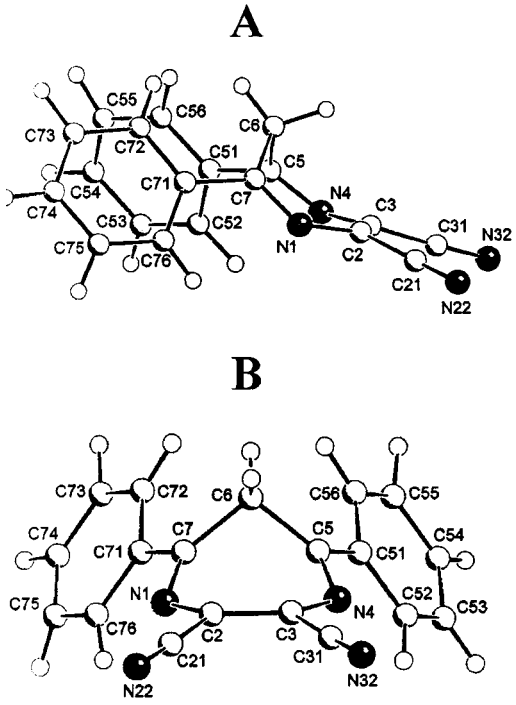

Figure 1. SCHAKAL side (A) and front-top (B) views of $Ph_2(CN)_2Dz$ (**1**)

ine [$Ph_2(CN)_2Dz$, **1**], but only with **1** cyclotetramerization takes place and the Mg^{II} complex $Ph_8DzPzMg$ (**2**) is formed in a high yield as a hydrated bluish-green material.

The Mg complex **2** can be demetallated to the metal-free macrocycle Ph_8DzPzH_2 (**3**) in boiling glacial acetic acid. The use of stronger acids such as CF_3COOH or 96% H_2SO_4 immediately determines demetallation of **2** upon dissolution even at room temperature, as can be evidenced by the UV/Vis spectra (see below). However, these strong acids cannot be used for preparative purposes; in fact, although **3** is stable in 96% H_2SO_4 for days, its precipitation by pouring the solution on ice gives an impure material with low yields, and solutions of **3** in CF_3COOH appear to be not stable enough, and, after even a rapid evaporation of the solvent, an unidentified brown product is obtained (molecular peak in the FAB spectrum at *m*/*z* 1084) instead of the green Ph_8DzPzH_2 (M^+ at 1187.5). A similar brown material, which is presently the object of further investigation, is obtained when non glacial acetic acid is used for preparation of **3** from **2**.

Refluxing of the Mg^{II} complex **2** in glacial acetic acid in the presence of excess of copper acetate results in the formation of the Cu^{II} complex $Ph_8DzPzCu$ (**4**). This latter, and the Zn^{II} complex as well, can be obtained by reaction of the metal-free macrocycle **3** with the pertinent metal acetate in dimethyl sulfoxide (DMSO). All samples of the compounds **2**−**5** were obtained as hydrated materials with slightly variable amounts of water molecules depending on the particular samples, as is evidenced by elemental analysis (C,H,N), thermogravimetric measurements, and IR spectra (see Experimental Section). These water molecules can be completely removed by mild heating under vacuum, exception made for one water molecule retained by the Mg complex. It is assumed that such a water molecule is directly and fairly strongly ligated to the metal center, as observed for several similar Mg^{II}−porphyrazines.[4,5,8]

The macrocyclic structure given in Scheme 1 for the present species is confirmed by FAB measurements (see Experimental Section), and is further supported by NMR, IR, and UV/Vis data. The presence of the peripheral 1,4-diazepine rings in this kind of macrocycles requires examination, developed below, of specific problems concerning their structural and conformational flexibility as well as chemical behaviour, since it is known that 1,4-diazepines can exist, depending on substituents, as 6*H* or 1*H* tautomers **I** and **II**, and in acid media they can be protonated forming successively monocations (diazepinium salts) **III** and dications **IV**[9] (Scheme 2).

^{1}H-NMR Spectra of $Ph_2(CN)_2Dz$ (1) and of the Zn^{II} Complex $Ph_8DzPzZn$ (5)

$Ph_2(CN)_2Dz$ (1) in Solution of $CDCl_3$ and $(CD_3)_2SO$

The ^{1}H-NMR spectrum of **1** (Figure 2, Table 3) definitely confirms that its structure in solution of a nonacidic solvent (chloroform, dimethyl sulfoxide) is similar to that found in the solid state. In fact, in addition to the multiplets of the phenyl protons in the low field region (δ = 7.93, 7.50, and 7.41 for *o*-Ph, *p*-Ph and *m*-Ph, respectively), two doublets for the $-CH_2-$ protons are observed at δ = 1.98 and 5.74 in $CDCl_3$ at 293 K (AB system, ^2J = 11.23 Hz). Such a ^{1}H-NMR pattern for **1** is fully consistent with the tautomeric structure **I** (6*H* tautomer). According to the available ^{1}H-NMR data the 6*H* tautomer **I** is also preferred for the dimethyl derivative $Me_2(CN)_2Dz$,[6] and for 5,7-disubstituted 2,3-benzo-1,4-diazepines (R_2BzDz; R = Me, Ph),[10] whilst the 1*H* tautomer **II** is present in 2,3-dihydro-1,4-diazepines.[9c]

An interesting aspect of the observed ^{1}H-NMR spectrum of **1**, worth to be discussed, is that the CH_2 protons appear,

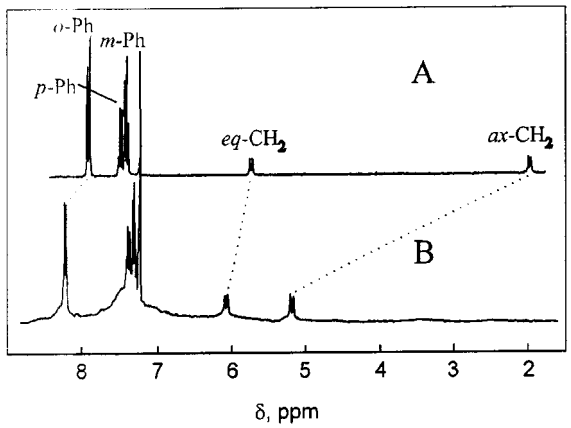

Figure 2. ^{1}H-NMR spectra of (A) $Ph_2(CN)_2Dz$ (**1**) and (B) $Ph_8DzPzZn$ (**5**) in $CDCl_3$

boiling $(CD_3)_2SO$ allowed to explore a wider range of temperatures up to 363 K. As shown in Figure 3 (spectra A−D), the two AB doublets of the CH_2 protons located at δ = 2.32 and 6.19 at 303 K (spectrum A), progressively broaden, completely disappearing at 363 K, thus giving a rough estimation of the coalescence temperature T_c. The high T_c value observed suggests that the ring inversion process for $Ph_2(CN)_2Dz$ is markedly hindered, very likely because of the presence of the two phenyl rings in the 5- and 7-positions.

As far as the position of the CH_2 signals of **1** is concerned, the quasi-axial proton (*ax*-CH_2) is shielded, being located over the plane of the C=N double bonds (Figure 1). Accordingly, the signal is found at higher field than is usual for CH_2 protons adjacent to two sp^2 carbon atoms. The substituents in the diazepine ring appear to have little influence on the resonance position of the *ax*-CH_2 proton

Table 3. Positions of the CH_2 proton signals in the ^{1}H-NMR spectra of compounds containing 1,4-diazepine rings

Compound	Solvent	δ [ppm] *ax*-CH_2	*eq*-CH_2	Splitting ^2J [Hz]	T [°C]

[a] From ref.[6] – [b] From ref.[10]

even at room temperature, as two sharp doublets (again depicted here as an AB system,[9][14] although, owing to their large inequivalence, they might alternatively be considered as an AX system). This means that the inversion of the diazepine ring in this species is slow under these conditions. A different situation is observed in the case of the dimethyl derivative $Me_2(CN)_2Dz$[6] and of 2,3-benzo-1,4-diazepines (R_2BzDz; R = Me, Ph)[10] (Table 3), since for these species the CH_2 protons give a singlet resonance peak at room temperature and only at lower temperatures the peak splits into two doublets (the coalescence temperature T_c is close to room temp. or below, Table 3). Variable temperature ^{1}H-NMR measurements for $Ph_2(CN)_2Dz$ in solution of $CDCl_3$ show that the gradual raising of the temperature from 293 K causes the broadening of the two sharp doublets of the CH_2 protons, and at 333 K two broad unsplit signals are still observed at δ = 2.01 and 5.70 for the axial and equatorial protons, respectively, although clearly the coalescence temperature is not definitely reached. The higher

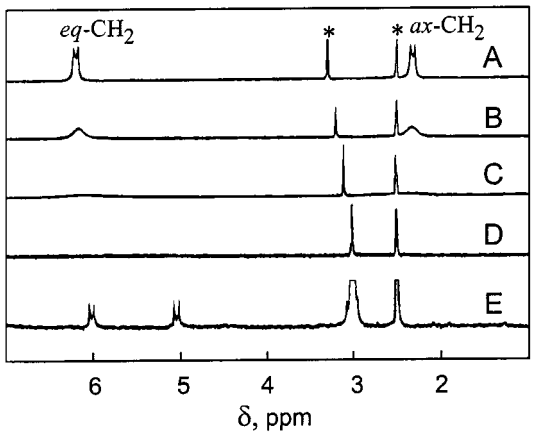

Figure 3. ^{1}H-NMR spectra of $Ph_2(CN)_2Dz$ (**1**) (A−D) and $Ph_8DzPzZn$ (**5**) (E) in $(CD_3)_2SO$ at 313 K (A), 333 K (B), 353 K (C), and 373 K (D, E); signals of nondeuterated solvent and water traces are marked with an asterisk

(Table 3). As to the equatorial proton (*eq*-CH_2), the substituents (especially in 5- and 7-positions) strongly affect the position of its resonance. In $Ph_2(CN)_2Dz$ the *eq*-CH_2 proton is deshielded by the adjacent C=N double bonds and, additionally, by the π-electron ring current of the phenyl rings. Hence, its resonance shifts downfield as compared with that of $Me_2(CN)_2Dz$.

$Ph_8DzPzZn$ (5) in Solution of $CDCl_3$, $(CD_3)_2SO$, CF_3COOH, and H_2SO_4

The ^{1}H-NMR spectrum of $Ph_8DzPzZn$ (**5**) in $CDCl_3$ shows general features similar to those of the monomeric compound $Ph_2(CN)_2Dz$ (compare A and B, Figure 2). At 293 K the phenyl protons give resonances at δ = 8.23, 7.32, and 7.37 for *o*-Ph, *m*-Ph and *p*-Ph, respectively. As to the CH_2 protons, two doublets appear at δ = 5.18 and 6.08 (^2J = 12.5 Hz), which means that in $CDCl_3$ and in $(CD_3)_2SO$ as well (Table 3), all diazepine rings of the Zn^{II} complex **5** are present in the form of the 6*H* tautomer **I**. It can be seen from Figure 2 that in going from $Ph_2(CN)_2Dz$ (**1**) to $Ph_8DzPzZn$ (**5**) a downfield shift is observed for the resonances of the *o*-Ph and CH_2 protons, due to their close position to the porphyrazine macrocycle. These downfield shifts are probably the result of combined structural and electronic effects, since annulation of the diazepine rings very likely implies an increased planarity of the C(7)−N(1)−C(2)−C(3)−N(4)−C(5) moiety, thus allowing an extension of the π-electron conjugation and this, in turn, the deshielding effect of the strong π-electron ring current of the formed porphyrazine macrocycle to which the diazepine rings are attached in this case. The unusually large downfield shift of the axial methylene proton (δ = 3.2) to the new position of δ = 5.18 is especially remarkable and indicates its proximity to the macrocycle. In fact, the distance of this axial methylene hydrogen atom from the center of the porphyrazine macrocycle (ca. 5.3 Å, as can be estimated from the MM+ geometry optimization procedure of the Hyperchem[11]), is 1.7 Å shorter than that of the equatorial hydrogen. Furthermore, such distance is comparable with that of the aromatic pyrrole protons for the Zn complex of unsubstituted porphyrazine (ca. 5.1 Å, singlet at δ = 9.4 in its ^{1}H-NMR spectrum[12]). It is remarkable that in the ^{1}H-NMR spectrum of $Ph_8DzPzZn$ in $(CD_3)_2SO$ even at 373 K (Figure 3, spectrum E) the CH_2 protons give two sharp doublets of the AB system, whilst approximately at the same temperature the monomeric precursor **1** showed coalescence. This means that annulation to the porphyrazine macrocycle very strongly reduces the conformational flexibility of the diazepine ring.

The ^{1}H-NMR spectra of $Ph_8DzPzZn$ in trifluoroacetic and sulfuric acids (Figure 4) differ from those taken in $CDCl_3$ or $(CD_3)_2SO$. This is not surprising, because it is known[9] that 1,4-diazepines exhibit strong basic properties, forming easily (e.g. in CF_3COOH) monocations **III** of diazepinium salts ($pK_{a1} \approx 9$ and 13 for 2,3-benzo- and for 2,3-dihydro-1,4-diazepines, respectively), and, under much more severe conditions (conc. H_2SO_4), diprotonated forms **IV** ($pK_{a2} \approx -1$ and −3 for 2,3-benzo- and for 2,3-dihydro-1,4-diazepines, respectively). The signals of the *m*-Ph and *p*-Ph protons are shifted downfield in CF_3COOH (δ = 8.03 and ca. 8.25, respectively) as compared to their position in the $CDCl_3$ solution. Whilst no AB doublets attributable to the CH_2 protons are observed, two singlets of equal intensity (4 H each) are found present at δ = 4.90 and 8.32.[13] These two resonances can be assigned to the −CH= and NH protons. Their position and relative intensity prove that diazepine rings of $Ph_8DzPzZn$ in the CF_3COOH solution are present in the form of the 1*H* tautomer **II**, rather than in the form of a type-**III** cation. In support of this: a) the olefinic −CH= and NH protons of the 1*H* tautomer **II** of 2,3-dihydro-5,7-dimethyl-1*H*-1,4-diazepine give, similarly, resonances of equal intensity at δ = 4.40 and 7.76 for solution in CCl_4;[9c] b) for the corresponding cation of type **III** in the case of 2,3-dihydro-5,7-diphenyl-1,4-diazepine occurring in CF_3COOH, signals of the −CH= and NH protons are observed at lower fields and have intensity ratio 1:2 [δ = 5.95 (1 H) and 8.1 (2 H)[14]]. Hence, if the tetracation $[Ph_8(DzH)PzZn]^{4+}$ with diazepine rings in form **III** were the case, the −CH= and especially NH resonances should appear at lower fields (due to the influence of the macrocyclic π-electron ring current) and have relative intensity 1:2. Transformation of the diazepine rings of $Ph_8DzPzZn$ from 6*H* tautomer **I** in neutral $CDCl_3$ solution to the 1*H* tautomer **II** in CF_3COOH occurs evidently because of the specific acid solvation of the second nitrogen atom of the diazepine rings and *meso*-nitrogen atoms of the porphyrazine macrocycle by molecules of trifluoroacetic acid. Unlike

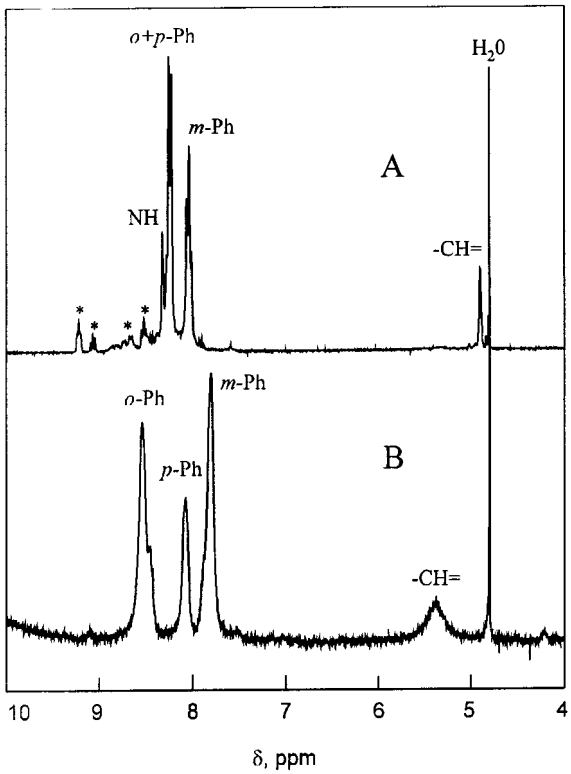

Figure 4. ^{1}H-NMR spectra of $Ph_8DzPzZn$ (**5**) in CF_3COOH (A) and in H_2SO_4 (B); signals of decomposition products are marked with an asterisk

monomeric 1,4-diazepine derivatives, protonation of the diazepine rings in the macrocyclic complex **5** with formation of the tetracation $[Ph_8(DzH)PzZn]^{4+}$ is not favourable under these conditions. Noteworthy, in the case of monomer **1**, due to two electron-withdrawing CN groups present and strongly reducing its basicity, the diazepinium salt $Ph_2(CN)_2DzH^+$ of type **III** is also not formed in CF_3COOH. Accordingly, the ^{1}H-NMR spectral pattern remains characteristic for the 6*H* tautomer **I**, although all signals, because of the acidic solvation, appear at lower fields [multiplets at δ = 8.35, 8.02, 7.87 for *o*-, *p*- and *m*-Ph and two AB doublets (^2J = 11 Hz) at δ = 2.77 and 6.51 for the axial and equatorial CH_2 protons].

The ^{1}H-NMR spectrum of the Zn^{II} complex **5** in H_2SO_4 contains nonresolved multiplets of the phenyl protons (δ = 8.54, 8.07, 7.80 for *o*-, *p*- and *m*-Ph, respectively) and one broad signal at δ = 5.39. The intensity ratio of this signal to the signals of the phenyl protons is 1:10, which allows us to assign it to the olefinic −CH= proton of the monoprotonated diazepine rings in form **III**. For a structure containing doubly protonated diazepine rings **IV** this ratio should be 1:5. Resonances of the NH protons which should be present for both possible structures **III** and **IV** have not been observed. The NH groups located close to the aromatic porphyrazine macrocycle should be strongly deshielded by its π-electron ring current and give resonances downfield with respect to their position in mono- and diprotonated 2,3-dihydro- or 2,3-dibenzo-1,4-diazepines (for 2,3-dihydro-1,4-diazepinium salts **III** δ_{NH} = 8.5−9.5[14][15] and for form **IV** of Me_2BzDz in H_2SO_4 δ_{NH} = 13.4[9c]). No signals are present in the lowfield region (δ > 12.6), where resonances of the NH protons for the structure with doubly protonated diazepine rings **IV** could be expected. Therefore, the octacationic structure $Ph_8(DzH_2)PzZn^{8+}$ can be excluded for the H_2SO_4 solution. For the tetracation $Ph_8(DzH)PzZn^{4+}$ with monoprotonated diazepine rings (form **III**), the NH resonances, expected in the region δ = 9−12, are very likely underneath the intense absorption of H_2SO_4 at δ = 9.3−12.6. In the spectrum taken in deuterated sulfuric acid, the signal of the −CH= proton is not present. This is easily explained by deuterio exchange which is facilitated by the quasi-aromatic properties of the diazepinium salt **III** and hence its reactivity in electrophylic substitution.[16][17]

Although *meso*-nitrogen atoms of the porphyrazine macrocycle can also take part in the acid-base interaction processes,[18] no signal attributable to the $^+N_{meso}$−H resonance was found either in CF_3COOH or in H_2SO_4. It is not surprising that the ^{1}H-NMR spectra provide no evidence of protonation of *meso*-nitrogen atoms. Low relative intensity and broadness (due to the rapid exchange with media) make difficult the detection of these signals, expected in the low field region (possibly nearby the OH absorption of the solvent). UV/Vis spectroscopy in some cases can provide more definite information about acid-base interaction of *meso*-nitrogen atoms.[18]

The ^{1}H-NMR spectra of the Mg^{II} complex **2** in weakly donor solvents show features strictly similar to those observed for the Zn^{II} complex [see data in Table 3 for $(CD_3)_2SO$)]. Similar spectra are also obtained for the free ligand as to the presence of the Ph and CH_2 groups, although the spectra are of poor quality because of low solubility. In strong acids such as H_2SO_4 (96%) complex **2** undergoes demetallation to the free ligand, whose spectra did not allow identification of the central NH groups.

UV/Vis Spectra

UV/Vis spectra of the macrocyclic compounds **2**−**5**, which show strong absorptions in the ranges 250−410 (Soret region) and 600−700 nm (*Q*-band region), deserve some detailed discussion.

Spectra in Basic, Neutral, and Slightly Acidic Solvents

Remarkably, the UV/Vis spectra of the metal-free ligand **3** and the metal complexes **2**, **4**, and **5** in basic, neutral and slightly acidic solvents [pyridine (Table 4), $CHCl_3$, $(CH_3)_2SO$, alcohols, acetic acid] show two well distinct bands in the *Q*-band region (see Figure 5A, B, C for the free ligand, and Figure 5F, G, H for the Cu^{II} complex), i.e. an intense sharp short-wave band with $\lambda_{max} \approx 630-640$ nm (split for the free ligand **3** because of its lower symmetry, i.e. D_{2h}) accompanied by a slightly broader less intense well separated satellite with $\lambda_{max} \approx 660-680$ nm (ca. 800−1000 cm^{-1}).

These two bands cannot be considered as two components of the split *Q*-band originating from considerable lowering of the symmetry of the molecule, since annulation of the four nonplanar diazepine rings cannot significantly disturb the overall D_{4h} symmetry of the chromophore. A split *Q*-band could alternatively originate from dimer formation caused by strong π-interaction,[19] and, indeed, such type of splitting (800−1000 cm^{-1}) has been observed for macrocyclic units brought very close to one another and firmly held together, as occurs, for instance, for the diphthalocyanine systems $(PcRh)_2$,[20] $(PcFe)_2(-C)$ and $(PcRu)_2(-C)$.[21] This is not, however, the case for the present species, for which, noteworthy, the ^{1}H-NMR spectra in $CDCl_3$ give no indication of molecular association even at high concentrations of the species. Clearly, then, the two peaks in the *Q*-band region have a different origin. We suggest that the sharp more intense band at 630−640 nm is associated with the lowest π→π* transition ("normal" *Q*-band), and the less intense long-wave band at 660−680 nm is due to the low lying n→π* transition (Q_n-band), as it is further discussed below.

The φ_n orbitals of the *meso*-nitrogen atoms of the porphyrazine macrocycle and the pyridine-type nitrogen atoms of the annulated heterocyclic rings (e.g. in tetrapyrazinoporphyrazines) have a lower energy than the HOMO, and corresponding n→π* transitions are observed in the Soret band region.[22] The lone pairs of these nitrogen atoms are located in the plane of the porphyrazine skeleton. Differently, the lone pairs of the imido nitrogen atoms in the diazepine rings of compounds **2**−**5** are not coplanar with the macrocycle forming an angle with its mean plane of about

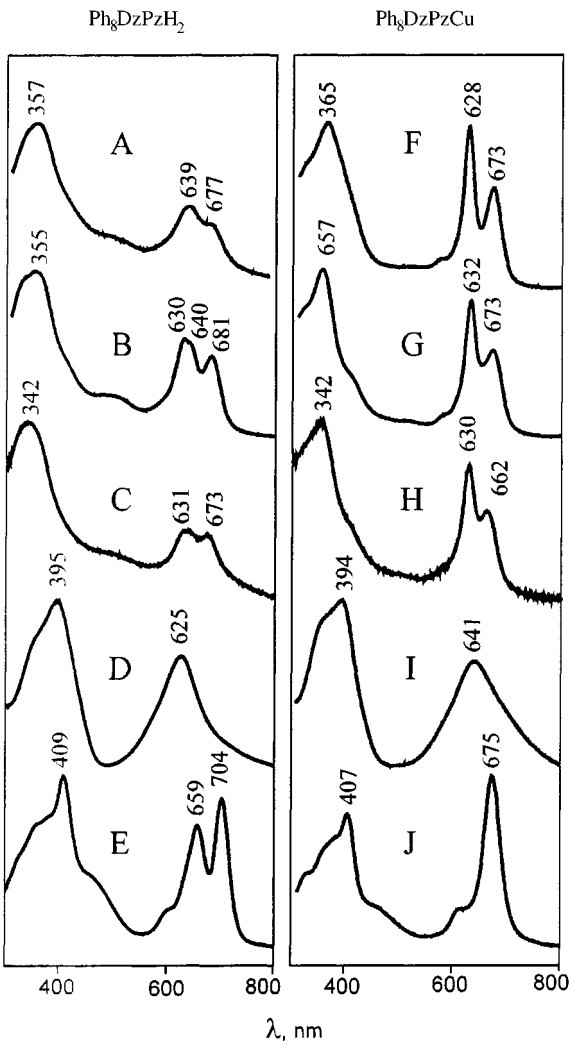

Figure 5. UV/Vis spectra of Ph_8DzPzH_2 (A−E) and $Ph_8DzPzCu$ (F−J) in pyridine (A, F), $CHCl_3$ (B, G), CH_3COOH (C, H), CF_3COOH (D, I) and H_2SO_4 (E, J)

only negligibly affected. This is clear for our species looking at Figure 5 (see spectra B and C, and also F, G, and H).

Spectra in Strong Acids (CF_3COOH, H_2SO_4)

The UV/Vis spectra in CF_3COOH (Figures 5, D and I) show a Soret band at λ_{max} = 394−401 nm, and a broad *Q*-band at λ_{max} = 625−664 nm. No distinct Q_n-band is observed. This type of spectrum is consistent with diazepine rings being present in the 1*H*-tautomeric form **II** as was concluded on the basis of the ^{1}H-NMR data. Strong acidic solvation of the diazepine imido and amino nitrogen atoms and *meso*-nitrogen atoms of the porphyrazine macrocycle is responsible for the diffuse character of the *Q*-band envelope.

The spectra of the Cu and Zn complexes **4** and **5** and of the metal-free macrocycle **3** in solution of conc. H_2SO_4 (96%) are very similar to the spectra of the corresponding unsubstituted, alkyl- or aryl-substituted, and benzo-annulated porphyrazines in neutral solvents[18][19] in that they show a single *Q*-band for complexes **4** and **5** ($\lambda_{max} \approx$ 675−690 nm), and two well-resolved Q_x and Q_y components (659 and 704 nm) for the metal-free ligand **3**. The main maximum in the Soret band envelope is considerably moved towards higher wavelengths (Figure 5, E and J). Such spectra are in full agreement with the symmetrical structure of the macrocycle containing protonated diazepine rings in form **III,** as was also suggested on the basis of the ^{1}H-NMR data. In this structure there is no lone pair on the nitrogen atoms of the diazepine rings and hence the Q_n-band is absent in the spectra. Usually at least one of the *meso*-nitrogen atoms of metalloporphyrazines is protonated in H_2SO_4, which results in a bathochromic shift of the *Q*-band and its observed splitting (in case of interaction with one, two or three *meso*-nitrogen atoms).[18] For our metal complexes, although the maximum of the *Q*-band is shifted bathochromically as compared with neutral solvents by ca. 1000 cm^{-1}, there is no splitting observed due to nonsym-

Table 4. UV/Vis data for Ph_8DzPzH_2, and its Mg^{II}, Cu^{II} and Zn^{II} derivatives in pyridine solution

Compound		λ [nm] (lg ε)					
		Soret region			Q-band region		
Ph_8DzPzH_2	**3**		339sh (4.83)	357 (4.86)	484sh	639 (4.55)	677sh (4.44)
$Ph_8DzPzMg$	**2**		351sh (5.01)	374 (5.05)	589 (4.22)	639 (5.12)	680 (4.83)
$Ph_8DzPzCu$	**4**		323sh (4.82)	365 (4.94)	577 (4.24)	628 (4.93)	673 (4.73)
$Ph_8DzPzZn$	**5**	348sh (4.96)	367 (5.02)	384sh (5.01)	585 (4.20)	637 (5.07)	678 (4.80)

35−40° (as can be estimated from the X-ray data on **1**, and MM+ geometry optimization of Ph_8DzPz^{2-}). As a result the φ_n orbitals of the diazepine imido nitrogen atoms should rise in their energy over HOMO, thus causing the corresponding n→π* electronic transition to appear as a Q_n-band in the long-wave region, as indeed it occurs. The solvatochromic effect is normally large on the peak position of the n→π* transitions, whereas the π→π* transitions are metrical protonation. Symmetrical acid-base interaction with all four *meso*-nitrogen atoms which should give a single bathochromically shifted *Q*-band (e.g. by more than 2500 cm^{-1} for metallophthalocyanines in H_2SO_4)[18] is also impossible. In fact, four positively charged diazepine rings acting as strong electron acceptors should decrease the basicity of the *meso*-nitrogen atoms as compared with unsubstituted porphyrazines in which only two *meso*-nitrogen

atoms can be protonated in H_2SO_4. Thus, in tetra(2,3-pyridino)porphyrazines only one *meso*-nitrogen atom can be protonated in addition to four pyridinium rings.[18] The observed strong bathochromic shift of the Soret band maximum allows to discard protonation of *meso*-nitrogen atoms in H_2SO_4 (and in CF_3COOH as well), because the *B*-band ($a_{2u} \rightarrow e_g$ transition), which is the strongest in the Soret envelope, should be hypsochromically shifted upon protonation.[23]

Conclusion

A new class of porphyrazine macrocycles carrying seven-membered diazepine rings annulated at the periphery of the "internal" tetrapyrrolic macrocycle is reported. This new class of complexes shows specific structural (displacement from planarity of the external diazepine rings, presence of peripherally attached phenyl rings) and UV/Vis spectral features in the *Q*-band region. Further synthetic work is presently being extended to other metal derivatives. Alternative peripheral substitution is possible on the diazepine rings and attempts are in due course for the preparation of new macrocyclic diazepine materials showing better solubility, either in donor or nondonor solvents, and original chemical and physical properties.

Experimental Section

Solvents and Chemicals: Solvents (1-propanol, $CHCl_3$, CH_3COOH, CF_3COOH, pyridine, ethyl alcohol, dimethyl sulfoxide (DMSO), ethyl acetate, acetonitrile, 96% H_2SO_4) and reagents [diaminomaleodinitrile, dibenzoylmethane, P_2O_5, Mg turnings, $Cu(OCOCH_3)_2 \cdot H_2O$, $Zn(OCOCH_3)_2 \cdot 2H_2O$] were pure chemicals (Carlo Erba, Aldrich, Merck).

Chemical Physical Measurements: IR spectra were taken with a Perkin−Elmer 783 spectrophotometer in the range 4000−200 cm^{-1} by using Nujol mulls between CsI disks or KBr pellets. − UV/Vis solution spectra were taken with a Varian Cary 5E spectrometer. − Thermogravimetric analyses were carried out with a Stanton Re Model STA-781 analyzer in N_2 (0.5 L/min). − FAB experiments were carried out with a multiple quadrupole instrument (VG quattro). − Elemental analyses (C, H, N) were provided by the "Servizio di Microanalisi" at the Dipartimento di Chimica, Università "La Sapienza" (Rome).

2,3-Dicyano-5,7-dimethyl-6*H*-1,4-diazepine, $Me_2(CN)_2Dz$: This species has been prepared from diaminomaleodinitrile and acetylacetone according to a known procedure.[6]

2,3-Dicyano-5,7-diphenyl-6*H*-1,4-diazepine, $Ph_2(CN)_2Dz$ (1): Diaminomaleodinitrile (2.4 g, 20 mmol) and dibenzoylmethane (5.0 g, 20 mmol) were condensed in absolute ethanol (80 mL) in the presence of P_2O_5 following closely the procedure reported in the literature.[7] Yield 88%. This material was used for the synthesis of the macrocyclic compounds without further purification. − $Ph_2(CN)_2Dz$ (**1**): $C_{19}H_{12}N_4$ (296.3): calcd. C 77.01, H 4.08, N 18.91; found C 76.94, H 3.88, N 18.80. − ^1H NMR ($CDCl_3$): δ = 1.98 (d, *J* = 11.27 Hz, 1 H, *ax*-CH_2), 5.74 (d, *J* = 11.18 Hz, 1 H, *eq*-CH_2), 7.41 (m, 4 H, *m*-Ph), 7.50 (m, 2 H, *p*-Ph), 7.93 (m, 4 H, *o*-Ph). − ^{13}C NMR ($CDCl_3$): δ = 39.22 (CH_2), 115.04 (CN), 123.68 ($C_{2,3}$), 129.13 (*o*-Ph), 129.82 (*m*-Ph), 133.13 (*p*-Ph), 133.40 (*ipso*-Ph), 149.20 ($C_{5,7}$).

Substituted Porphyrazinatomagnesium Pentahydrate, $[Ph_8DzPzMg(H_2O)] \cdot 4H_2O$ (2): Magnesium metal (0.54 g, 22.2 mmol) was suspended, with stirring, in propyl alcohol (25 mL) in the presence of a small amount of I_2 and the mixture was refluxed for 10 h to complete the conversion of Mg into its corresponding propylate. $Ph_2(CN)_2Dz$ (**1**) (1.5 g, 5.06 mmol) was then added and the mixture kept refluxing for further 8 h. During the reaction the gray mixture changed to dark green, and then to dark blue. At the end of the reaction, propanol was evaporated under reduced pressure and the solid material was suspended in 50% aqueous acetic acid and stirred for 3 h to dissolve the residual unchanged magnesium propylate. The dark bluish-green solid, separated by filtration, was washed with water to neutrality, then with 3 portions of methanol, and brought to constant weight in a vacuum dessicator. Yield 1.42 g (93%). The product can be recrystallized from pyridine/ethyl acetate. All samples obtained from different preparations contained variable amounts of weakly ligated water molecules (4−7). − Representative sample of formula $[Ph_8DzPzMg(H_2O)] \cdot 4H_2O$: $C_{76}H_{58}MgN_{16}O_5$ (1299.71): calcd. C 70.23, H 4.50, N 17.24; found C 69.68, H 4.68, N 16.82. − Thermogravimetric analysis revealed a featureless loss of four water molecules for this sample in the temperature range 25−200°C (found 5.76%, calculated for 4 molecules of H_2O 5.54%), whereas the fifth molecule is more strongly retained, being most likely directly ligated to the central metal. − MS (FAB); *m*/*z* (%): 1210.5 (100) $[M - 5H_2O]^+$, 1227.9 (7) $[M - 4H_2O]^+$, 2418.9 (20) $[M - 5H_2O]_2^+$. − UV/Vis (pyridine): λ_{max} (lg ε) = 351 nm sh, 374 (5.05), 589 (4.22), 639 (5.12), 680 (4.83). − IR (KBr): $\tilde{\nu}$ = 3060 cm^{-1} w, 1645 m, 1600 w, 1580 w, 1527 vs, 1498 w, 1470 w, 1448 s, 1395 w, 1320 m, 1305 w, 1277 m, 1175 s, 1120 s, 1043 m, 1027 w, 1003 w, 983 m, 952 w, 925 vw, 875 w, 840 w, 782 vw, 760 s, 740 w, 710 vs, 690 s, 420 w. − ^1H NMR [$(CD_3)_2SO$ 373 K]: δ = 5.06 (d, *J* = 12.21 Hz, 4 H, *ax*-CH_2), 5.99 (d, *J* = 11.99 Hz, 4 H, *eq*-CH_2), 7.41 (m, 16 H, *m*-Ph), 7.49 (m, 8 H, *p*-Ph), 8.13 (d, *J* = 7.92 Hz, 16 H, *o*-Ph).

Substituted Porphyrazine Tetrahydrate, $[Ph_8DzPzH_2] \cdot 4H_2O$ (3): Solvated magnesium complex **2** (310 mg, 0.24 mmol) was suspended in glacial acetic acid (15 mL) and the mixture refluxed for 16 h. After cooling, the reaction mixture was poured into water. The precipitated dark green solid formed was separated by filtration, washed with H_2O, then with acetone, and brought to constant weight in a vacuum dessicator. Yield 233 mg (77%). − $[Ph_8DzPzH_2] \cdot 4H_2O$: $C_{76}H_{58}N_{16}O_4$ (1259.40): calcd. C 72.48, H 4.64, N 17.79; found C 72.22, H 4.21, N 17.74. − MS (FAB); *m*/*z* (%): 1187.5 (100) $[M - 4H_2O]^+$. − UV/Vis (pyridine): λ_{max} (lg ε) = 339 nm sh, 357 (4.86), 490 sh, 639 (4.55), 677 (4.44). − IR (KBr): $\tilde{\nu}$ = 3298 cm^{-1} w (NH), 3060 m, 1650 m, 1600 vw, 1535 vs, 1498 w, 1480 vw, 1448 s, 1390 vw, 1320 m, 1306 vw, 1285 m, 1187 m, 1120 s, 1080 w, 1040 vw, 1025 m, 1000 w, 975 m, 945 w, 845 w, 790 w, 753 m, 688 vs, 660w, 610 vw, 415 w.

Substituted Porphyrazinatocopper Dihydrate, $[Ph_8DzPzCu] \cdot 2H_2O$ (4): A mixture of $[Ph_8DzPzH_2] \cdot 4H_2O$ (**3**) (250 mg, 0.20 mmol) and anhydrous copper acetate (463 mg, 2.55 mmol) in pyridine (10 mL) was kept refluxing for 6 h. After cooling, the solid separated by centrifugation was washed with water to remove the unchanged Cu^{II} acetate, and dried in a vacuum dessicator. Yield 111 mg (44%). − $[Ph_8DzPzCu] \cdot 2H_2O$: $C_{76}H_{52}CuN_{16}O_2$ (1284.90): calcd. C 71.04, H 4.08, Cu 4.94, N 17.44; found C 70.77, H 4.11, Cu 4.68, N 17.64. − UV/Vis (pyridine): λ_{max} (lg ε) = 323 nm sh, 365 (4.94), 577 (4.24), 628 (4.93), 674 (4.73). − IR (KBr): $\tilde{\nu}$ = 3060 w, *1645 s*, 1600 w, 1585 w, 1530 vs, 1500 m, 1485 m, 1447 s, 1410 w, 1319 m, 1304 m, 1280 m, 1188 s, 1128 vs, 1080 vw, 1050 m, 1028 m, 1000 w, 980m, 952 m, 880 w, 840 vw, 782 vw, 758 s, 737 w, 712 vs, 688 s, 652 w, 622 w, 592 vw, 558 vw, 468 w, 418 m. − Alternatively, the

Cu complex can be prepared by refluxing a mixture of the corresponding Mg^{II} complex (160 mg, 0.125 mmol) and anhydrous copper acetate (176 mg, 0.97 mmol) in glacial acetic acid (10 mL) for 5 h. Yield 83 mg (52%). − $[Ph_8DzPzCu]\cdot 4H_2O$: $C_{76}H_{56}CuN_{16}O_4$ (1320.93): calcd. C 69.11, H 4.27, Cu 4.81, N 16.97; found C 68.14, H 3.62, Cu 5.39, N 17.13.

Substituted Porphyrazinatozinc Heptahydrate, $[Ph_8DzPzZn]\cdot 7H_2O$ (5): A mixture of $[Ph_8DzPzH_2]\cdot 4H_2O$ (**3**) (274 mg, 0.22 mmol) and zinc acetate (380 mg, 1.73 mmol) in pyridine (10 mL) was refluxed for 6 h. After cooling, water (10 mL) was added, and the solid material, separated by centrifugation, was washed with water to remove the excess of the unchanged Zn^{II} salt, and dried in a vacuum dessicator. Yield 192 mg (67%). − $[Ph_8DzPzZn]\cdot 7H_2O$: $C_{76}H_{62}N_{16}ZnO_7$ (1376.80): calcd. C 66.30, H 4.54, N 16.29; found C 65.70, H 4.00, N 16.02. − MS (FAB); *m/z*: 1252 $[M - 7H_2O]^+$. − UV/Vis (pyridine): λ_{max} (lg ε) = 348 nm sh, 367 (5.02), 384 sh, 585 (4.20), 637 (5.07), 678 (4.80). − IR (KBr): $\tilde{\nu}$ = 3055 cm^{-1} w, *1645 s*, 1600 vw, 1582 vw, 1527 vs, 1498 w, 1473 w, 1447 s, 1400 w, 1320 m, 1305 w, 1278 m, 1220 vw, 1178 s, 1127 vs, 1080 vw, 1062 vw, 1043 m, 1027 w, 1002 w, 982 m, 952 w, 872 w, 842 w, 782 wv, 760 s, 748 w, 710 vs, 690 s, 652 w, 623 w, 422 m. − ^1H NMR ($CDCl_3$, 293 K): δ = 5.18 (d, *J* = 12.7 Hz, 4 H, *ax*-CH_2), 6.08 (d, *J* = 12.5 Hz, 4 H, *eq*-CH_2), 7.31 (m, 16 H, *m*-Ph), 7.39 (m, 8 H, *p*-Ph), 8.23 (d, *J* = 7.4 Hz, 16 H, *o*-Ph); [$(CD_3)_2SO$ 373 K]: δ = 5.03 (d, *J* = 12.2 Hz, 4 H, *ax*-CH_2), 5.99 (d, *J* = 12.23 Hz, 4 H, *eq*-CH_2), 7.42 (m, 16 H, *m*-Ph), 7.50 (m, 8 H, *p*-Ph), 8.13 (d, *J* = 7.33 Hz, 16 H, *o*-Ph).

X-ray Crystal Structure Determination of $Ph_2(CN)_2Dz$ (1): Single crystals of **1** were obtained as light-yellow hexagonal prisms during recrystallization of $Ph_2(CN)_2Dz$ from hot acetonitrile. A suitable colorless crystal with the approximate dimensions 0.31×0.34×0.55 mm was mounted on a glass fiber. The reduced cell was obtained with use of TRACER.[24] Data were collected at 295 K with a Siemens AED single-crystal diffractometer. For intensities and background the individual reflection profiles were analyzed.[25] The structure amplitudes were obtained after the usual Lorentz and polarization corrections[26] and the absolute scale was established by the Wilson method.[27] The crystal quality was tested by ψ scans showing that crystal absorption effects could be neglected. The function minimized during the least-square refinements was $\Sigma w(\Delta F^2)^2$. Anomalous scattering corrections were included in all structure factor calculations.[28b] Scattering factors for neutral atoms were taken from ref.[28a] for nonhydrogen atoms and from ref.[29] for H. Structure solution was based on the observed reflections [$I > 2(I)$] while the refinement was based on the unique reflections having $I > 0$. The structure was solved by the direct methods using SIR92.[30] Refinement was done by full-matrix least-squares first isotropically and then anisotropically for all non-H atoms using SHELX93.[31] The hydrogen atoms were located from a difference Fourier map and introduced in the refinements as fixed atoms contributions (U_{iso} = 0.10 $Å^2$). In the last stage of refinement the weighting scheme $w = 1/[\sigma^2(F_o^2) + (aP)^2]$ [with $P = (F_o^2 + 2F_c^2)/3$] was applied with *a* resulting in the value of 0.1001. The final difference map showed no unusual features, with no significant peaks above the general background.[32]

Crystal Structure and Dynamic Behavior of a New Class of Monocationic Organometallic Pd^{II} Compounds with Two Molecules of Bidentate Ligands: $[Pd(L–L)(N–N)(CH_2NO_2)][PF_6]$ (L–L = N–N, dppp)

Barbara Milani,*[a] Gianni Corso,[a] Ennio Zangrando,[a] Lucio Randaccio,[a] and Giovanni Mestroni[a]

Keywords: Palladium / N ligand / P ligand / Copolymerization

Two new classes of organometallic palladium(II) compounds, namely $[Pd(N–N)(CH_2NO_2)_2]$ and $[Pd(L–L)(N–N)(CH_2NO_2)][PF_6]$ [N–N = 2,2′-bipyridine, 1,10-phenanthroline and their substituted derivatives; L–L = 1,3-bis(diphenylphosphino)-propane or N–N] have been synthesized and fully characterized both in the solid state and in solution. The crystal structures of $[Pd(phen)_2(CH_2NO_2)][PF_6]$ and of $[Pd(dppp)(tmphen)(CH_2NO_2)][PF_6]$ show a square-planar coordination geometry for the palladium atom and an unexpected monodentate coordination for the N–N ligand. The behavior in solution, investigated by NMR spectroscopy, shows the presence of dynamic processes involving only the N–N molecules. This fluxional behavior is different for $[Pd(N–N)_2(CH_2NO_2)][PF_6]$ and $[Pd(dppp)(N–N)(CH_2NO_2)][PF_6]$: in the former it most likely involves the substitution of the nitrogen atom *trans* to the CH_2NO_2 moiety by the uncoordinated nitrogen atom of the other N–N ligand; in the latter it may involve the exchange of the two nitrogen atoms at the same coordination site (flipping).

Introduction

Recent developments in homogeneous catalysis show an increasing interest in the use of nitrogen-donor molecules as ancillary ligands.[1] Among the wide variety of nitrogen compounds, ligands containing sp^2-hybridized nitrogen atoms, especially when the N-atom is part of an aromatic ring, like 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen) and bis-oxazoline, have been applied to two reactions of high industrial interest: the reductive carbonylation of nitroaromatic compounds to urethanes[2–4] and the CO/olefin co- and terpolymerization reactions.[5–8]

For several years we have been studying bis(chelate) palladium(II) compounds of general formula $[Pd(N–N)_2][PF_6]_2$ (**I**) and $[Pd(dppp)(N–N)][PF_6]_2$ (**II**) {dppp = 1,3-bis(diphenylphosphino)propane; N–N = bipy, 4,4′-dimethyl-2,2′-bipyridine (dmbipy), phen, 4,7-dimethyl-1,10-phenanthroline (dmphen), 3,4,7,8-tetramethyl-1,10-phenanthroline (tmphen)}, which were found to be efficient catalyst precursors for the above-mentioned reductive carbonylation (compounds of class **I**)[9][10] and copolymerization (compounds of class **I** and **II**)[11–13] reactions. In particular, in the CO/olefin copolymerization reaction the influence of the nitrogen ligand has been investigated in detail with monocationic Pd^{II} compounds which have only one molecule of chelating ligand (N–N) bound to the metal center. The effect of N–N on the stereochemistry of the resulting polyketones was studied by Brookhart,[8] while the influence of N–N in the first and successive insertion steps of CO and alkenes in the copolymerization mechanism was reported by Elsevier and Vrieze.[14] To the best of our knowledge, we are the only group to use Pd^{II} compounds with two molecules of chelating ligand (N–N and/or P–P) as precatalysts for the CO/olefin copolymerization. In this catalytic system the second molecule of chelating ligand, N–N in both classes of complexes, plays an important role, which has been partially examined[12,13,15] although some aspects still remain unclear.

In this paper we report the synthesis and characterization, both in the solid state and in solution, of two new series of stable organometallic Pd^{II} compounds of general formula $[Pd(N–N)(CH_2NO_2)_2]$ and $[Pd(L–L)(N–N)(CH_2NO_2)][PF_6]$ (L–L = dppp, N–N) (Figure 1).

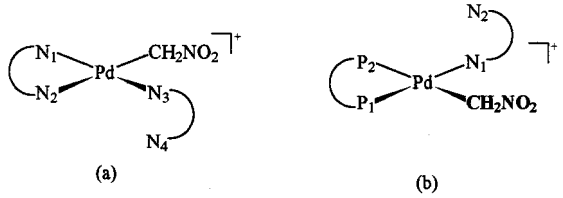

Figure 1. Schematic drawing of complexes $[Pd(N–N)_2(CH_2NO_2)][PF_6]$ and $[Pd(dppp)(N–N)(CH_2NO_2)][PF_6]$

Results and Discussion

Synthesis of the Complexes $[Pd(N–N)(CH_2NO_2)_2]$ (1–5) and $[Pd(L–L)(N–N)(CH_2NO_2)][PF_6]$ (6–11)

The synthesis of the new series of organometallic Pd^{II} compounds, $[Pd(N–N)(CH_2NO_2)_2]$, is achieved by the treatment of a methanolic suspension of the bischelated complexes $[Pd(N–N)_2][PF_6]_2$ with nitromethane in the

presence of a strong base, at room temperature. Depending on the nature of the nitrogen-donor chelating ligand the obtained solid has a different composition. When N−N is 2,2′-bipyridine, or its substituted derivatives, only $[Pd(N-N)(CH_2NO_2)_2]$ is obtained as a yellow solid (Scheme 1). On the other hand, when N−N is 1,10-phenanthroline, or its substituted derivatives, we obtain a mixture of compounds containing $[Pd(N-N)(CH_2NO_2)_2]$, as expected, and a new species formulated as $[Pd(N-N)_2(CH_2NO_2)][PF_6]$.

$$[Pd(N\text{-}N)_2][PF_6]_2 \xrightarrow[NaOH,\ MeOH]{CH_3NO_2} [Pd(N\text{-}N)(CH_2NO_2)_2] + 2NaPF_6$$

N-N = bipy and its substituted derivatives

$$[Pd(N\text{-}N)_2][CF_3COO]_2 \xrightarrow[NaOH,\ MeOH]{CH_3NO_2} [Pd(N\text{-}N)(CH_2NO_2)_2] + 2CF_3COONa$$

N-N = phen and its substituted derivatives

Scheme 1. Synthesis of complexes $[Pd(N-N)(CH_2NO_2)_2]$ (**1−5**)

The bis(nitromethyl) compounds with N−N = phen, dmphen and tmphen can easily be synthesized in high yield starting from the more soluble $[Pd(N-N)_2][CF_3COO]_2$, rather than from the corresponding hexafluorophosphate derivatives (Scheme 1).[16] The related monosubstituted derivatives $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ are obtained in pure form as orange solids starting from $[Pd(N-N)_2][PF_6]_2$ and separating the solid from the reaction mixture as soon as the colour turns from yellow to orange, followed by recrystallization of the solid (see Experimental Section). Starting from $[Pd(N-N)_2][PF_6]_2$ the formation of $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ (N−N = phen, dmphen, tmphen) was followed by recording the ^{1}H NMR spectrum of the solid isolated from the reaction mixture at different reaction times. In all cases the solid isolated after 15 min does not contain the starting material and is found to be a mixture of the monosubstituted derivative $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ and the disubstituted derivative $[Pd(N-N)(CH_2NO_2)_2]$ in different ratios depending on the nature of N−N. This ratio increases on going from phen to tmphen.

Therefore, the synthesis of the complexes $[Pd(N-N)(CH_2NO_2)_2]$ is a two-step nucleophilic substitution reaction: the first step, which is very fast, is the attack of the $CH_2NO_2^-$ with formation of the addition product $[Pd(N-N)_2(CH_2NO_2)][PF_6]$; the second step requires dissociation of one of the two chelating ligands and coordination of the second molecule of nucleophile. The second step is slower than the first one, and its rate depends on the nature of the chelating ligand, being fast for unsubstituted phen and slow for tmphen. In the case of bipy as ligand the addition product was never isolated, but the transient orange colour of the synthetic solution of the bis(nitromethyl) derivatives suggests its formation, followed by a very fast reaction to give the final product.

In the case of the mixed-ligand complexes, $[Pd(dppp)(N-N)][PF_6]_2$, the addition product $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ (**9−11**) is synthesized following two different procedures: (i) a direct reaction of $[Pd(dppp)(N-N)][PF_6]_2$ with nitromethane, as for the $[Pd(N-N)_2][PF_6]_2$ complexes (Scheme 2a); (ii) a ligand exchange reaction of one N−N molecule with a molecule of dppp starting from the complexes $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ (Scheme 2b).

$$[Pd(dppp)(N\text{-}N)][PF_6]_2 \xrightarrow[NaOH,\ MeOH]{CH_3NO_2} [Pd(dppp)(N\text{-}N)(CH_2NO_2)][PF_6] + NaPF_6 \quad (a)$$

$$[Pd(N\text{-}N)_2(CH_2NO_2)][PF_6] \xrightarrow[MeOH]{dppp} [Pd(dppp)(N\text{-}N)(CH_2NO_2)][PF_6] + N\text{-}N \quad (b)$$

Scheme 2. Synthesis of complexes $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ (**9−11**)

Characterization of Complexes $[Pd(N-N)(CH_2NO_2)_2]$ (1−5)

The solid-state infrared spectra show two strong bands, one in the range 1481−1457 cm^{-1} and the other between 1348 and 1345 cm^{-1}, which are assigned to the asymmetric and symmetric nitrogen-oxygen stretching frequency, respectively.

The characterization in solution was done by ^{1}H NMR spectroscopy in [D$_6$]DMSO (Table 1). The spectra of all the complexes show a series of signals equal to half the number of chemically equivalent groups for the nitrogen ligand protons, indicating the equivalence of the two halves of the complex. All signals are downfield-shifted with respect to those of the free ligand. The assignments were made as previously reported.[17] The signal due to the two methylenic protons of $CH_2NO_2^-$ appears as a singlet between 5.06 and 4.88 ppm, depending on the nature of N−N (Table 1).

As has already been pointed out,[17a] the signals in the ^{1}H NMR spectrum of H^{2,9} in the phenanthroline series, and

[a] In [D$_6$]DMSO at room temperature: region of aromatic and $CH_2NO_2^-$ protons. − [b] Compound **3** is not soluble in [D$_6$]DMSO at room temperature. − s = singlet, d = doublet, t = triplet, m = multiplet, dd = doublet of doublets.

of $H^{6,6'}$ in the bipyridine series, are excellent probes for the evaluation of the coordination environment of the palladium atom. Their chemical shifts and bandshape are highly sensitive to the nature of the other ligands bound to the metal and to the presence of dynamic phenomena in solution.

A comparison of the NMR spectra of bis(nitromethyl) complexes $[Pd(N-N)(CH_2NO_2)_2]$ and of monochelated carboxylato derivatives $[Pd(N-N)(CF_3COO)_2]$[17a] shows that, in the first series, the frequencies of the "probe-protons" are downfield shifted with respect to the free ligand, while in the second one they are upfield shifted (Table 2). This observation, together with a lower CIS value (CIS = coordination induced shift; $\Delta\delta$) (Table 2) for the bis(nitromethyl) derivatives with respect to that of the trifluoroacetato compounds, suggests a weaker Pd-N bond in the former, in agreement with the *trans* influence of the $CH_2NO_2^-$ fragment.

Table 2. CIS value ($\Delta\delta$)[a] for the "probe protons" in the two series of complexes $[Pd(N-N)(CF_3COO)_2]$ and $[Pd(N-N)(CH_2NO_2)_2]$

N−N	$[Pd(N-N)(CH_2NO_2)_2]$ $\Delta\delta$ (ppm)	$[Pd(N-N)(CF_3COO)_2]$ $\Delta\delta$ (ppm)
phen	0.37	−0.68
dmphen	0.43	−0.74
bipy	0.47	−0.60
dmbipy	0.44	−0.63

[a] CIS values are positive when shifted downfield with respect to free ligand and negative when shifted upfield.

Characterization of the Complexes $[Pd(L-L)(N-N)(CH_2NO_2)][PF_6]$ (6−11)

The solid-state infrared spectra show the familiar bands of the asymmetric and symmetric nitrogen-oxygen stretching frequency, together with those of the hexafluorophosphate anion.

The molecular structures of the complex cations in **6** and **11** are shown in Figures 2 and 3, respectively, and relevant geometrical parameters are reported in Table 3.

In the $[Pd(phen)_2(CH_2NO_2)]^+$ cation, **6**, the Pd atom exhibits a distorted square planar coordination geometry with one phen molecule acting as a monodentate ligand[18] and the other as a bidentate one (Figure 2), with the metal displaced out of the plane of the four donors by 0.037(2) Å towards N(2).

The chelating phen ligand and the unidentate one are planar within ±0.033(4) and ±0.077(4) Å, respectively, and their mean planes are nearly perpendicular to each other {dihedral angle of 88.91(5)°}. Because of the *trans* influence exerted by the CH_2NO_2 moiety, the Pd-N(5) distance {2.076(3) Å} is longer by 0.035 Å than the Pd-N(4) one {2.042(3) Å}. The latter distance has a value slightly longer than those of about 2.00 Å reported for $[Pd(phen)X_2]$ species,[17a] where X is a weak *trans* influencing ligand and very close to those of about 2.04 Å in the bischelating

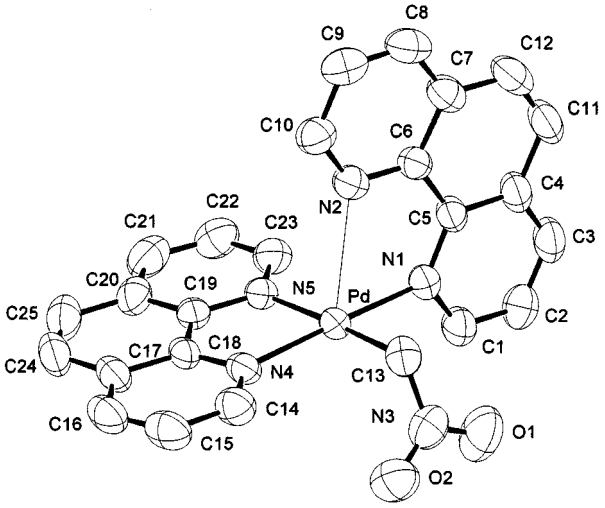

Figure 2. An ORTEP drawing (40% probability thermal ellipsoids) with atom numbering scheme of the cation of **6**

$[Pd(phen)_2]^{2+}$ cations,[17a] which suggests greater steric crowding in the cation of **6** than in $[Pd(phen)X_2]$ complexes. The monodentate phen ligand is bonded to Pd through N(1) {2.065(3) Å}, the other nitrogen being at a distance of 2.674(3) Å.

		C(10)−N(2)−Pd	133.9(5)

The CH_2NO_2 group, characterized by the Pd−C(13) distance and the N(3)−C(13)−Pd bond angle of 2.052(5) Å and 108.8(3)°, respectively, is oriented in such a way that NO_2 points to the less "crowded" side of the coordination plane (Figure 2), i.e. towards the coordinated side of the unidentate phen.

In the $[Pd(dppp)(tmphen)(CH_2NO_2)]^+$ cation, **11**, the metal shows a distorted square planar geometry with the tmphen ligand binding in a monodentate fashion through N(1), the other positions being occupied by the diphos-

phine and the CH_2NO_2 group (Figure 3). The metal ion is displaced by 0.129(3) Å out of the plane of the four donors, towards the N(2) atom of tmphen, resulting in a slightly disphenoidal distorsion[19] of the Pd, C(13), N(1), P(1) and P(2) atoms.

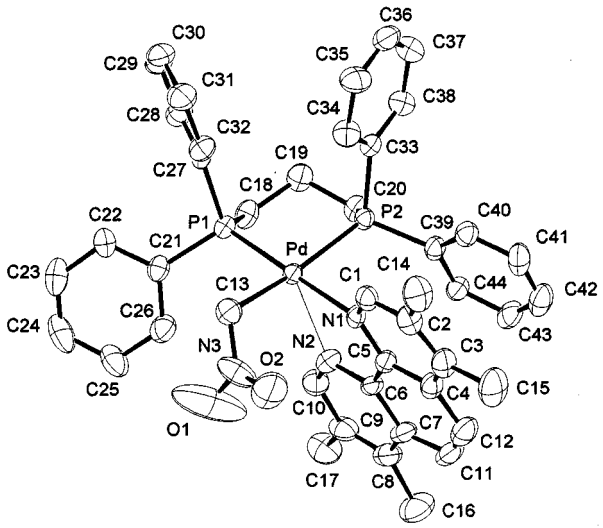

Figure 3. An ORTEP drawing (40% probability thermal ellipsoids) with atom numbering scheme of the cation of **11**

The tmphen ligand is planar within ±0.063(7) Å and makes an angle of 78.9(1)° with the mean coordination plane. It binds with a Pd−N(1) bond length of 2.104(5) Å, longer than that found in **6**, in agreement with the greater *trans* influence of P with respect to that of N. It is worthwhile to note in Figure 3 the stacking of the tmphen ligand with one of the phenyl rings at P(2). The corresponding mean planes make a dihedral angle of 11.5(1)°, with the shortest non-bonding distance N(1)···C(39) of 3.10 Å.

The Pd−P distances are significantly different {2.245(2) and 2.333(2) Å}, the longer one, Pd−P(2), reflecting the *trans* influence of the CH_2NO_2 ligand. The Pd−P(1) distance is similar to those of 2.244(1) and 2.249(2) Å detected in $[Pd(dppp)Cl_2]$[20] and does not significantly differ from the values of 2.262(3) Å found for both the phosphorus atoms in the $[Pd(dppp)(bipy)]^{2+}$ cation.[12] Likewise, steric strains are evidenced in the diphosphine ligand by the large deviations from ideality of the bond angles in the propylenic bridge {from 111.7(5) to 117.4(5)°}.

The Pd−CH_2NO_2 fragment is characterized by a Pd−C(13) distance and a N(3)−C(13)−Pd angle of 2.157(8) Å and 112.9(6)°, respectively. Comparison with the analogous fragment of the cation of **6** shows that in **11** the metal-donor distance is increased by ≈ 0.1 Å and the angle by ≈ 4°. This observation, together with the orientation of the CH_2NO_2 group (towards the uncoordinated side of tmphen), suggests that the latter undergoes more strained interactions with respect to those in the cation of **6**. However, it cannot be excluded that, at least partially, the elongation of the Pd−C(13) bond can be ascribed to the *trans* influence of the P atom as compared to that exerted in **6** by N(5).

The shorter Pd−N(2) distance in the cation of **11** {2.562(6) Å} relative to that found in **6** (2.674(3) Å) is probably due to to the greater coordinating capability of tmphen with respect to that of phen.

These structural results prompted us to indicate for Pd^{II} a strong tendency to be square planar. Very recently the closely related complex $[Pd(phen)_2(COOMe)][PF_6]$ has been reported together with its crystal structure.[21] Although the authors described the complex to be pentacoordinate, the Pd−N distance {2.637(4) Å}, rather longer than normal,[17] and the ratio of the axial/equatorial bond lengths of 1.29 are distinctive of a square planar coordination geometry rather than of a square pyramidal one, as recently reported by Vrieze et al.[18] However, the displacement of the Pd atom towards the uncoordinated nitrogen of the phen (or tmphen) base is indicative of a weak Pd−N interaction both in the present complexes and in the one mentioned above.

The chemical behavior in solution for the $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ compounds (**6-8**) was studied by ^1H NMR spectroscopy in $[D_6]$DMSO (Table 1). The spectra of $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ show, for the nitrogen ligands, four signals integrating for a quarter of the number of chemically equivalent groups, indicating the equivalence of the two ligands bound to palladium and of the two halves of each ligand. In these complexes the signal attributed to the "probe-protons" is shifted upfield with respect to the same signal in the free ligand. The singlet due to the methylenic protons of CH_2NO_2 moiety falls in the range between 4.97 and 4.87 ppm. Its chemical shift is upfield-shifted on going from phen to dmphen and to tmphen. This trend might be related to the electron-donor properties of the ligands. Moreover in the complex $[Pd(tmphen)_2(CH_2NO_2)][PF_6]$ it is possible to unambiguously distinguish the singlet due to the $H^{2,9}$ protons from that of $H^{5,6}$ on the basis of their positive NOE effect with the protons of CH_2NO_2.

For the $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ derivatives (**9-11**) in the ^1H NMR spectra (Table 4), recorded in CD_2Cl_2 at room temperature, three different groups of signals are present: that of the aromatic protons, where the resonances due to the N−N ligand are separated from those of the dppp allowing a clear assignment; that of the $CH_2NO_2^-$, and that of the protons of the propylenic bridge of dppp. The protons of the N−N ligand generate four signals of equal intensity indicating, again, the equivalence of the two halves of this ligand (Table 4a). All signals are shifted with respect to those of the free ligand and, in particular, that due to $H^{2,9}$ is downfield shifted. No signal due to free ligand is present.

The protons of coordinated 1,3-bis(diphenylphosphino)-propane give the same pattern for all complexes: three broad multiplets at high field for the propylenic bridge and four multiplets at low field for the phenyl rings (Table 4b). The number of signals, and their integration, indicates the non-equivalence of the two halves of the diphosphine ligand, as can also be seen from the X-ray structure.

10	15.25(d)	3.73(d)	21.5
11	15.03(d)	3.80(d)	21.4

[a] In Hz. − [b] Protons of groups bonded to P_1 (Figure 1b). − [c] Protons of groups bonded to P_2 (Figure 1b). − [d] ^{31}P NMR of free dppp: $\delta = -17.6$.

On the basis of the chemical shift (Table 4b), the four multiplets of the protons of the aromatic rings of dppp can be divided into two sets of two multiplets each: one set is formed by the two multiplets which are upfield shifted with respect to the signals of free dppp (hereafter referred to as the *upfield set*), and the other one by the two multiplets which are shifted downfield (the *downfield set*). The cross peaks in the COSY spectrum correlate the two multiplets inside each set and no cross peak between the *upfield set* and the *downfield* one is present. Therefore, each set is generated by protons belonging to the same phenyl group. The total integration of each set is for ten protons, accounting for two phenyl rings. The comparison of the ^1H NMR spectra of these compounds and those of the $[Pd(dppp)(N-N)][PF_6]_2$ series[12] allows us to assign the *downfield set* to the protons of the two phenyl rings bound to the phosphorus atom *trans* to the Pd−N bond (P_1 in Figure 1b). This assignment is also in agreement with the upfield shift of the resonances of the other two phenyl rings. Indeed, due to the stacking interactions observed in the X-ray structure, their protons are affected by the shielding anisotropy of the tmphen ligand. A similar situation has previously been reported by Natile et al. for the compound *trans*-$[Pt(2,9\text{-dmphen})Br(PPh_3)_2][Br]$.[22]

In the ^1H NMR spectra, the signal due to the methylenic protons of the CH_2NO_2 moiety appears as a doublet of doublets centered at 4.17 ppm (Table 4a). Its chemical shift is practically unaffected by the nature of N−N. Its fine structure is due to a $^1H-^{31}P$ coupling with the two different phosphorus atoms of dppp with coupling constants $^3J(P-H)_{cis} = 3.9$ Hz and $^3J(P-H)_{trans} = 8.8$ Hz.

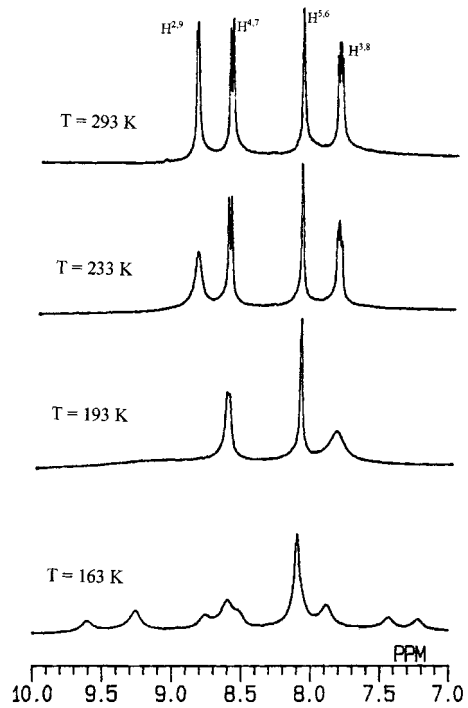
The $^{31}P\{^1H\}$ NMR spectra present, at room temperature, two sharp doublets, in agreement with the different coordination environment of the phosphorus atoms (Table 4c). The doublet at lowest frequency is attributed to the phosphorus *trans* to the organic fragment (P_2 in Figure 1b).[23] Both of them are at higher frequencies than the signal of free dppp.

Fluxional Behavior of Complexes 6−11

The most important feature in the spectra of the compounds $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ and $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ is the equivalence of the bidentate nitrogen ligand. The presence of a dynamic process has been demonstrated by recording the spectra at low temperature in CD_2Cl_2.

For the complexes $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ at room temperature all signals are sharp. The decrease of temperature causes a progressive broadening of the aromatic frequencies which is particularly evident in the case of $H^{2,9}$ signals. For these protons the signal disappears at T = 193 K. At the lowest temperature we reached, T = 163 K, at least eight signals can be detected (Figure 4). Unfortunately they are still too broad to allow a clear assignment. On the contrary, the signal due to the CH_2NO_2 protons is unaffected by the variation of temperature.

These experiments indicate that at room temperature the dynamic process, which makes the two N−N ligands equivalent, is fast on the ^1H NMR time scale. When one equivalent of the N−N ligand is added to a solution of the com-



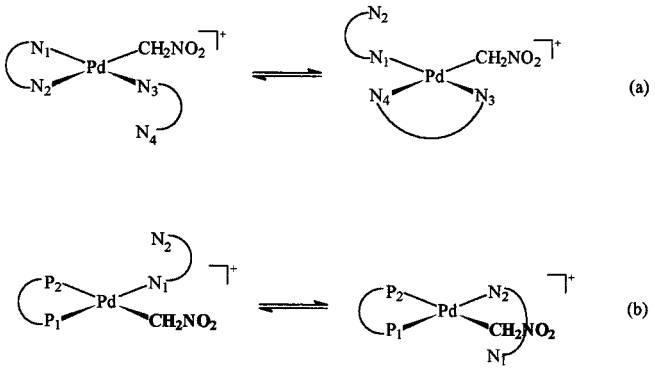


Figure 4. ^{1}H-NMR spectra of $[Pd(phen)_2(CH_2NO_2)][PF_6]$ in CD_2Cl_2: variation with temperature; region of signals of aromatic protons

plex $[Pd(N-N)_2(CH_2NO_2)][PF_6]$, the spectrum measured at room temperature, also shows slightly broadened signals due to free ligand. Therefore, the dynamic process also involves an exchange with the free ligand, which is slower than the intramolecular one. On the basis of these results, one of the possible fluxional processes is the exchange between the unbound nitrogen of the monocoordinated phen (N_4) and one of the two bound nitrogens of the chelated phen, probably the one *trans* to the CH_2NO_2 fragment (N_2) (Scheme 3a).

Scheme 3. Schematic representation of the intramolecular dynamic process of compounds **6**–**11**

For the complexes $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ the signals due to the protons of N–N are sharper than those of the dppp phenyl rings, at room temperature. However, by lowering the temperature all of them broaden. In this case, the $H^{2,9}$ signal disappears at T = 173 K. As already observed for the compounds $[Pd(N-N)_2(CH_2NO_2)][PF_6]$, the decoalescence starts at T = 163 K and again no signal assignment could be performed (Figure 5).

In the compounds $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ the signal of the CH_2NO_2 protons also broadens when lowering the temperature and at T = 163 K it is split into two signals (Figure 5).

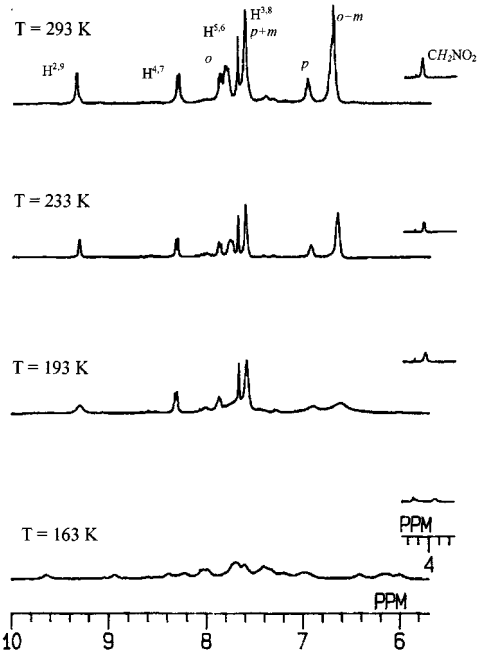

Figure 5. ^{1}H-NMR spectra of $[Pd(dppp)(phen)(CH_2NO_2)][PF_6]$ in CD_2Cl_2: variation with temperature; region of signals of aromatic protons and of CH_2NO_2 moiety

It should be noted that in the $^{31}P\{^1H\}$ NMR spectrum no variation with temperature is observed, suggesting that the two phosphorus atoms are fixed on palladium.

As already observed for the $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ compounds, after addition of one equivalent of N–N to a solution of $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ the spectrum at room temperature also exhibits the signals of free N–N ligand, indicating that the exchange between coordinated and free ligand is slow on the ^{1}H NMR time scale. Therefore, as regards the fluxional behavior of the compounds $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$, at least three intramolecular dynamic processes can be involved: (i) the movement of the dppp propylenic bridge, whose rate, at room temperature, is intermediate on the ^{1}H NMR time scale; (ii) the rotation of the phenyl rings of dppp around the P-C_{ipso} bond; (iii) the flipping of the N–N ligand, which exchanges the two nitrogen atoms (N_1 and N_2) at the same coordination site (Scheme 3b). This flipping might be responsible for the equivalence of the two phenyl rings bound to the phosphorus atom *cis* to N–N (P_2 in Figure 1b), one of which exhibits a stacking interaction in the solid state (see above). At room temperature the movements (ii) and (iii) are fast on the ^{1}H NMR time scale.

At the lowest temperature we reached, the CH_2NO_2 protons generate two different signals (Figure 5), because they

are diastereotopic as the palladium atom becomes a stereogenic center. Indeed, the pseudo-symmetry plane present for the complex at room temperature disappears at T = 163 K.

A comparison of the spectra of $[Pd(phen)_2(CH_2NO_2)][PF_6]$ and of $[Pd(dppp)(phen)(CH_2NO_2)][PF_6]$ at T = 163 K shows that the signal at lowest field (9.61 ppm and 9.64 ppm, respectively) has practically the same chemical shift, therefore it may be tentatively attributed to the proton in the *ortho* position with respect to the phen uncoordinated nitrogen atom (N_4 in Figure 1a and N_2 in Figure 1b).

Conclusion

The Pd complexes described above represent one of the first examples of monodentate phen-type ligands with no alkyl substituents at the 2 and 9 positions.

The X-ray structural characterization of these complexes strongly indicates the tendency of palladium(II) to assume a square planar coordination. This is in support of our previous studies on bischelated species where this geometry is ensured by bowing the N−N ligand,[24] and of more recent examples where one of the two molecules of N−N is forced to act as a monodentate ligand.[18][21]

A detailed NMR investigation shows the presence of different dynamic processes in solution: (i) an exchange between coordinated and free N−N ligand; (ii) an intramolecular competition of the unbound nitrogen towards a coordination site at the expense of one N atom of the chelated phen in the $[Pd(N-N)_2(CH_2NO_2)][PF_6]$ complexes; (iii) a flipping of the N−N ligand, in the $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ derivatives, that exchanges the two nitrogen atoms at the same coordination site. The rate of these dynamic processes increases on going from the first to the last one, altough a complete decoalescence could not be reached.

Experimental Section

General Remarks: The nitrogen-donor chelating ligands and dppp (Aldrich) together with the analytical grade solvents (Baker) were used without further purification for synthetic and spectroscopic purposes. IR spectra were recorded on a Perkin Elmer 983G spectrometer in KBr pellets. ^1H NMR spectra were recorded at 400 MHz on a JEOL EX 400 spectrometer operating in Fourier-transform mode, with tetramethylsilane (TMS) as internal standard. Two-dimensional homonuclear correlated spectra (COSY) were obtained with the automatic program of the instrument. ^{31}P NMR spectra were recorded at 161.86 MHz with H_3PO_4 as external reference, where positive shifts are at high frequency.

Syntheses: The compounds $[(N-N)H][PF_6]$, as well as the complexes $[Pd(N-N)_2][PF_6]_2$ and $[Pd(dppp)(N-N)][PF_6]_2$ were synthesized according to the procedures reported in the literature.[11][12] Elemental analyses (C, H, N), performed by Dr. E. Cebulec (Dipartimento di Scienze Chimiche, Trieste, Italy), were in perfect agreement with the proposed stoichiometry (Tables 5 and 6).

Compounds $[(N-N)H][CF_3COO]$: The dinitrogen ligand N−N (5.0 mmol) was dissolved in acetone (15 mL) at room temperature, and trifluoroacetic acid 99% was added (0.47 mL, N−N/CF_3COOH = 1:1.2). Concentration of the solution to approximately a third of the original volume and addition of diethyl ether (15 mL) induced precipitation of the product as a white solid. The solid was removed by filtration and dried under vacuum. Average yield: 70%.

Complexes $[Pd(N-N)_2][CF_3COO]_2$: $Pd(MeCOO)_2$ (0.9 mmol) was dissolved in acetone (10 mL) at room temperature. After 30 min, $[(N-N)H][CF_3COO]$ (2.0 mmol; Pd/$[(N-N)H][CF_3COO]$ = 1:2.2) was added as a solid to the filtered red solution. The product readily precipitated as a yellow solid. After 30 min, it was isolated by filtration, washed with cold acetone and dried under vacuum. Average yield: 75%.

Table 5. Elemental analyses for $[(N-N)H][CF_3COO]$ and $[Pd(N-N)_2][CF_3COO]_2$[a]

Compound	C	H	N
$[(phen)H][CF_3COO]$	57.1 (57.2)	3.05 (3.08)	9.55 (9.52)
$[Pd(phen)_2][CF_3COO]_2$	47.8 (48.5)	2.40 (2.33)	7.90 (8.09)
$[(dmphen)H][CF_3COO]$	59.4 (59.6)	4.02 (4.07)	8.60 (8.69)
$[Pd(dmphen)_2][CF_3COO]_2$	50.5 (51.3)	3.55 (3.60)	9.55 (9.62)
$[(tmphen)H][CF_3COO]$	60.8 (61.7)	4.98 (4.89)	7.96 (8.00)
$[Pd(tmphen)_2][CF_3COO]_2$	49.9 (50.6)	4.54 (4.68)	8.88 (8.93)

[a] Calculated values are reported in parentheses.

$[Pd(N-N)(CH_2NO_2)_2]$ (1−5): The complex $[Pd(N-N)_2][X]_2$ (X = PF_6^- for N−N = bipy and dmbipy; X = CF_3COO^- for N−N = phen, dmphen and tmphen) (0.2 mmol) was suspended in nitromethane (10 mL). A solution of NaOH 0.2 M in methanol was added (3.5 mL; Pd/OH^- = 1:4), obtaining a solution from which the product precipitated as a yellow solid. After 30 min, the solid was removed by filtration, washed with methanol and vacuum dried. Average yield: 70%.

$[Pd(N-N)_2(CH_2NO_2)][PF_6]$ (6−7): The complex $[Pd(N-N)_2][PF_6]_2$ (N−N = phen, dmphen; 0.5 mmol) was added with vigorous stirring to a solution of NaOH in methanol in the presence of nitromethane (4.2 mmol of NaOH in 20 mL CH_3OH and 1.2 mL of CH_3NO_2; Pd/OH^- = 1:8; Pd/CH_3NO_2 = 1:30). The colour of the solid rapidly turned from yellow to orange. The solid was rapidly isolated by filtration, washed with cold methanol and vacuum dried. Average yield: 70%.

Recrystallization: The solid was dissolved in a minimal amount of CH_2Cl_2. From the filtered solution the product precipitated upon addition of diethyl ether.

$[Pd(tmphen)_2(CH_2NO_2)][PF_6]$ (8): The complex $[Pd(tmphen)_2][PF_6]_2$ (0.2 mmol) was suspended in methanol (20 mL). To the suspension a solution of NaOH 0.2 M in methanol (5.0 mL; Pd/OH^- = 1:4) and nitromethane (0.6 mL) were added; the colour turned from yellow to orange. After stirring for 1 h at room temperature the solid was removed by filtration, washed with methanol and vacuum dried. Yield: 80%.

$[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]$ (9−11): The complexes $[Pd(dppp)(N-N)(CH_2NO_2)][PF_6]_2$ can be synthesized following two different procedures: the first slightly differs depending on the nature of N−N (method A), while the second is the same with all the series (method B).

Method A. − $[Pd(dppp)(phen)(CH_2NO_2)][PF_6]$ (9): A solution of NaOH (0.4 mmol; NaOH/Pd = 1.05:1) in methanol (3 mL) in the presence of nitromethane (0.2 mL) was added to a suspension of $[Pd(dppp)(phen)][PF_6]_2$ (0.4 mmol) in methanol (4 mL). The colour of the suspension immediately turned bright yellow and part of the

Table 6. Elemental analyses for the complexes **1**−**11**[a]

Complex	C	H	N
1 [Pd(phen)(CH_2NO_2)$_2$]	40.9 (41.3)	2.90 (2.97)	13.6 (13.8)
2 [Pd(dmphen)(CH_2NO_2)$_2$]	43.9 (44.2)	3.64 (3.71)	12.7 (12.9)
3 [Pd(tmphen)(CH_2NO_2)$_2$]	46.4 (46.7)	4.24 (4.35)	12.0 (12.1)
4 [Pd(bipy)(CH_2NO_2)$_2$]	37.8 (37.7)	3.13 (3.16)	14.2 (14.6)
5 [Pd(dmbipy)(CH_2NO_2)$_2$]	40.8 (40.9)	3.89 (3.93)	13.7 (13.6)
6 [Pd(phen)$_2$(CH_2NO_2)][PF_6]	43.5 (44.7)	2.56 (2.70)	10.2 (10.4)
7 [Pd(dmphen)$_2$(CH_2NO_2)][PF_6]	47.0 (47.8)	3.50 (3.60)	9.50 (9.62)
8 [Pd(tmphen)$_2$(CH_2NO_2)][PF_6]	49.9 (50.6)	4.53 (4.68)	8.86 (8.93)
9 [Pd(dppp)(phen)(CH_2NO_2)][PF_6]	52.7 (53.1)	3.90 (4.01)	4.59 (4.65)
10 [Pd(dppp)(dmphen)(CH_2NO_2)][PF_6]	53.9 (54.1)	4.33 (4.33)	4.38 (4.51)
11 [Pd(dppp)(tmphen)(CH_2NO_2)][PF_6]·CH_2Cl_2	51.8 (51.7)	4.48 (4.44)	4.05 (4.02)

[a] Calculated values are reported in parentheses.

solid was dissolved. After 1 h diethyl ether (50 mL) was added and the mixture was filtered, the solid was washed with cold methanol and vacuum dried. Yield: 85%.

[Pd(dppp)(dmphen)(CH_2NO_2)][PF_6] (10): A solution of NaOH (0.1 mmol; NaOH/Pd = 1.2:1) in methanol (1 mL) in the presence of nitromethane (50 μL) was added to a suspension of [Pd(dppp)(dmphen)][PF_6]$_2$ (0.1 mmol) in methanol (3 mL). The colour of the suspension immediately turned bright yellow and part of the solid was dissolved. Concentration to approximately half of the original volume induced more precipitation of the product as a yellow solid. The solid was removed by filtration, washed with cold methanol and dried under vacuum. Yield: 90%.

[Pd(dppp)(tmphen)(CH_2NO_2)][PF_6] (11): A solution of NaOH (0.4 mmol; NaOH/Pd = 4:1) in methanol (2.5 mL) in the presence of nitromethane (0.25 mL) was added to a suspension of [Pd(dppp)(tmphen)][PF_6]$_2$ (0.1 mmol) in methanol (1 mL). The colour of the suspension immediately turned bright yellow. After 1 min the mixture was filtered, the solid was washed with cold methanol and vacuum dried. Yield: 90%.

Recrystallization: Complex **10** (0.03 g) was recrystallized by dissolving it in methanol (10 mL), yielding a yellow solution from which the product precipitated upon addition of diethyl ether. Complex **11** was recrystallised from a minimal amount of dichloromethane. The solid precipitated upon addition of diethyl ether.

Method B: To a supension of [Pd(N−N)$_2$(CH_2NO_2)][PF_6]$_2$ (0.2 mmol) in methanol (2.5 mL) was added dppp (dppp/Pd = 1:1) together with a minimal amount of dichloromethane (0.15 mL). The mixture was stirred at room temperature for 2 h yielding a bright yellow suspension. The solid was removed by filtration, washed with cold methanol and vacuum dried. Yield: **9** 30%; **10** 70%; **11** 77%.

(tmphen)(CH_2NO_2)][PF_6] (**11**) suitable for X-ray analysis were obtained with the double-layer method by dissolving the complex in a minimal amount of acetone. Double the volume of diethyl ether was stratified on the filtered yellow solution. The crystals were obtained overnight.

Details of crystal parameters, data collection and refinements of compounds **6** and **11** are summarized in Table 7. Diffraction data were carried out at room temperature using the $\omega-2\theta$ scan technique on a CAD4 Enraf-Nonius single-crystal diffractometer equipped with graphite monochromator and Mo−K_α radiation (λ = 0.7107 Å). Three standard reflections, measured at regular intervals throughout the data collections, showed no noticeable variation in intensity for either crystal. An absorption correction based on ψ-scan method was applied to both the data sets.

The structures were solved by conventional Patterson[25] and Fourier analyses and refined on F^2 by the full-matrix anisotropic least-squares method using the SHELXL-93 package.[26] In both the crystals, a difference Fourier synthesis revealed the presence of a molecule of acetone. In compound **6** this molecule was disordered over two positions with refined site occupancies that complement to 1.0. The final cycles with the fixed contribution of hydrogen atoms, except those of the solvent molecule, converged to final $R1$ and $wR2$ factors reported in Table 3. Refined weighting schemes were $1/[\sigma^2 (Fo^2) + (0.0805P)^2 + 0.07P]$ and $1/[\sigma^2 (Fo^2) + (0.0746P)^2]$ for compound **6** and **11**, respectively, where $P = \{\text{Max}(Fo^2, 0) + 2Fc^2\}/3$. The Flack x parameter[27] of 0.01(4) is indicative of the correct absolute configuration for compound **11**. Crystallographic data (excluding structure factors) for the structures reported in this paper have deposited with the Cambridge Crystallographic Data Center as supplementary publication n. CCDC-113500/113501. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: + 44-1223/336-033; E-mail:deposit@ccdc.cam.ac.uk).

Crystallographic and Spectroscopic Characterization of Tetrakis(μ-*N*,*N*′-diarylformamidinato)dichlorodirhenium(III,III) Compounds

Judith L. Eglin,*[a] Chun Lin,[b] Tong Ren,[b] Laura Smith,[a] Richard J. Staples,[c] and David O. Wipf[a]

Keywords: Metal−metal bonds / Rhenium / Formamidinate / UV/Vis spectroscopy / Electrochemistry

Through a variation in the aryl substituents of the formamidinate ligand, a variety of dirhenium compounds has been synthesized with $[XArNC(H)NArX]^-$ where Ar is a substituted C_6H_5 or C_6H_4 aryl ring and X is *p*-MeO (**1**), H (**3**), *m*-MeO (**4**), *p*-Cl (**5**), *m*-Cl (**6**), *m*-CF_3 (**7**), *p*-CF_3 (**8**), 3,4-Cl_2 (**9**), and 3,5-Cl_2 (**10a**, **10b**). UV/Vis and NMR spectroscopy and electrochemical data for **1** and **3–10** have been obtained. X-ray crystallographic analysis of $Re_2Cl_2(\mu\text{-form})_4$ with four different diarylformamidinate ligands and one analog with two different interstitial solvents are presented; $Re_2Cl_2[(p\text{-}MeOC_6H_4)NCHN(p\text{-}MeOC_6H_4)]_4$ (**1**), $Re_2Cl_2[(m\text{-}MeOC_6H_4)NCHN(m\text{-}MeOC_6H_4)]_4 \cdot 2\ CH_2Cl_2$ (**4**), $Re_2Cl_2[(3,4\text{-}Cl_2C_6H_3)NCHN(3,4\text{-}Cl_2C_6H_3)]_4 \cdot 2\ CH_2Cl_2$ (**9**), $Re_2Cl_2[(3,5\text{-}Cl_2C_6H_3)NCHN(3,5\text{-}Cl_2C_6H_3)]_4 \cdot 4\ CH_2Cl_2$ (**10a**), and $Re_2Cl_2[(3,5\text{-}Cl_2C_6H_3)NCHN(3,5\text{-}Cl_2C_6H_3)]_4 \cdot OC_4H_8$ (**10b**).

Introduction

Amidine and amidinate ligands are adaptable ligands in the synthesis of dinuclear transition metal compounds that span the periodic table.[1] Dinuclear transition metal complexes include Ti_2,[2−4] Zr_2,[5] V_2,[6][7] Ta_2,[8−10] Cr_2,[11−13] Mo_2,[11,13−18] W_2[12], Tc_2,[19] Re_2,[20][21] Fe_2,[22−25] Ru_2,[26−32] Os_2,[33] Co_2,[25,34−37] Rh_2,[34,38−41] Ni_2,[42−44] Pd_2,[44][45] Pt_2,[46][47] Cu_2,[48] Ag_2,[48][49] In_2,[50] and Sn_2,[51] and the diversity of dinuclear complexes demonstrates the versatility of the ligand to form both metal−metal bonded and non-bonded systems. Recently, the systematic study of the tunability of the electronic and spectroscopic properties of the resultant complexes with variations in the ligand periphery has become a focus area.[14,15,26−28,43,52,53]

Redox tuning of dinuclear compounds by varying the remote substituents on the aryl ring of diarylformamidinate ligands (form) has been studied in a series of dichromium(II,II),[52] dimolybdenum(II,II),[14][15] and dinickel(II,II)[43] complexes. In the previously studied dinickel systems, metal−metal bonding is absent with a long Ni−Ni separation of 2.462(2) Å observed for $Ni_2[(3,5\text{-}Cl_2C_6H_3)NCHN(3,5\text{-}Cl_2C_6H_3)]_4$.[43] In contrast, the $Cr_2(\mu\text{-form})_4$ and $Mo_2(\mu\text{-form})_4$ systems contain metal−metal quadruple bonds, $\sigma^2\pi^4\delta^2$, with much shorter Cr−Cr and Mo−Mo mean bond lengths of 1.911 and 2.096 Å.[15][52] The study is extended to correlate structural, spectroscopic, and electrochemical properties of $Cr_2^{II,II}$, $Mo_2^{II,II}$, and $Re_2^{III,III}$ quadruply-bonded complexes with the inclusion of the $Re_2Cl_2(\mu\text{-form})_4$ series.[20,21,52] The addition of the $Re_2Cl_2(\mu\text{-form})_4$ complexes allows the comparison of compounds with axially coordinated chlorides and the relativistic effects associated with 5d orbitals to the $Cr_2(\mu\text{-form})_4$ and $Mo_2(\mu\text{-form})_4$ systems previously studied.[20,21,52] A series of dirhenium compounds of the general type $Re_2Cl_2(\mu\text{-form})_4$ has been synthesized with the ligand $[XArNC(H)NArX]^-$, where Ar is a substituted C_6H_5 or C_6H_4 ring and X is *p*-MeO (**1**), H (**3**), *m*-MeO (**4**), *p*-Cl (**5**), *m*-Cl (**6**), *m*-CF_3 (**7**), *p*-CF_3 (**8**), 3,4-Cl_2 (**9**), and 3,5-Cl_2 (**10a**, **10b**). UV/Vis, ^{1}H-NMR, and ^{13}C-NMR spectroscopy are reported for the series in addition to the structural characterization of **1**, **4**, **9**, and **10a**, **b**. A linear free energy relationship is determined from electrochemical studies of the $Re_2Cl_2(\mu\text{-form})_4$ complexes by varying the remote substituents on the aryl ring of the diarylformamidinate ligands.

Results and Discussion

Synthesis

Synthesis of compounds **1** and **3−10** with the general formula $Re_2Cl_2(\mu\text{-form})_4$ proceeds as previously described.[21] Molten reactions of $Re_2Cl_2(\mu\text{-}O_2CCH_3)_4$ with the respective substituted diarylformamidine ligands were performed using a minimum four fold excess of the ligand (Hform) at reaction temperatures between 150° to 180° for 1.5 to 18 hours. Reactions times are dependent on the melting point of the diarylformamidine ligands. A short reaction time results in incomplete ligand substitution and an elevated reaction temperature leads to thermal decomposition of the diarylformamidine ligand.

Molecular Structures

^{1}H-NMR spectra were recorded for compounds **1** and **3−10** to confirm the expected diamagnetic ground state for

all of the compounds, $\sigma^2\pi^4\delta^2$. The simplicity of the ^{1}H-NMR spectra reflects the high symmetry of the Re_2Cl_2(μ-form)$_4$ complexes and confirms both the bulk purity of the compounds and the general structure of the compounds where X-ray crystallographic data were not obtained.[21] The downfield shift of the singlet for the methine proton (−NC*H*N−) is a distinct feature in the ^{1}H-NMR spectra of the Re_2Cl_2(μ-form)$_4$ series and ^{1}H-NMR data combined with structural data for **1**, **4**, **9**, and **10a**, **b** allowed the calculation of the value of the diamagnetic anisotropy of the Re-Re bond. ^{13}C-NMR spectra were recorded for all of the compounds except **3** and **9** where the solubility of the compounds in CH_2Cl_2 is limited. As a result of poor solubility in most common solvents, the ^{13}C-NMR spectrum of **1** and **4** do not have -O*C*H$_3$ peaks tabulated due to an overlap of the methoxy carbon peak of the compound with the carbon peak of the CH_2Cl_2 solvent which dominates the spectrum.

Crystal structures have been determined for Re_2Cl_2[(*p*-MeOC$_6$H$_4$)NCHN(*p*-MeOC$_6$H$_4$)]$_4$ (**1**), Re_2Cl_2[(*m*-MeOC$_6$H$_4$)NCHN(*m*-MeOC$_6$H$_4$)]$_4$ · 2 CH_2Cl_2 (**4**), Re_2Cl_2[(3,4-Cl$_2$C$_6$H$_3$)NCHN(3,4-Cl$_2$C$_6$H$_3$)]$_4$ · 2 CH_2Cl_2 (**9**), Re_2Cl_2-[(3,5-Cl$_2$C$_6$H$_3$)NCHN(3,5-Cl$_2$C$_6$H$_3$)]$_4$ · 4 CH_2Cl_2 (**10a**), and Re_2Cl_2[(3,5-Cl$_2$C$_6$H$_3$)NCHN(3,5-Cl$_2$C$_6$H$_3$)]$_4$ · OC$_4$H$_8$ (**10b**), with **10a** and **10b** containing the same diarylformamidinate ligand with two different interstitial solvent molecules. Structures of **1**, **4**, **9**, and **10a**, **b** are shown in Figures 1−5, and reflect the D_4 geometry adopted by the dirhenium core ($Re_2N_8Cl_2$) in the molecules.

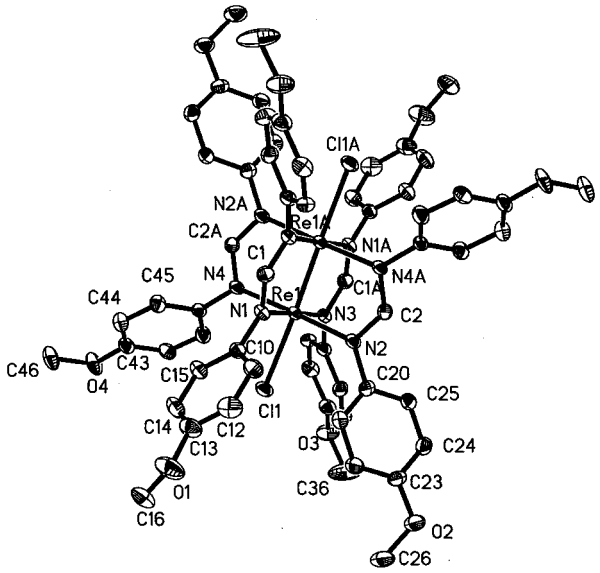

Figure 1. The ORTEP plot of compound **1**; hydrogen atoms are omitted for clarity

A comparison of the Hammett constant of the ligand versus the Re−Re and Re−Cl bond lengths of **1**, **4**, **9**, and **10a**, **b** and Re_2Cl_2[(*p*-tolylC$_6$H$_4$)NCHN(*p*-tolylC$_6$H$_4$)]$_4$ (**2**)[21] indicates the electron donating or withdrawing ability of the ligand has no substantial influence on the bond lengths or angles in the structure (Table 1). The most significant deviation in the Re−Re bond lengths within the series occurs as a result of a change in the interstitial solvent, as in the case of Re_2Cl_2[(3,5-Cl$_2$C$_6$H$_3$)NCHN(3,5-Cl$_2$C$_6$H$_3$)]$_4$ with Re−Re bond lengths of 2.2734(3) Å (4 CH_2Cl_2) and 2.2840(5) Å (OC$_4$H$_8$). More dramatic changes in the structure of the amidinate ligand result in more significant changes in the observed bond lengths and angles.[20] For Re_2Cl_2[(CH$_3$N)$_2$CPh]$_4$ with the *N,N′*-dimethylbenzamidinate ligand and Re−Re and Re−Cl bond lengths of 2.208(2) and 2.654(6) Å, the Re−Cl bond length is significantly elongated in comparison to the diarylformamidinate derivatives due to steric repulsions.[20] As observed in the Re_2Cl_2(μ-form)$_4$ series, only minor variations in the core bond lengths with changes in the substituents on the diarylformamidinate ligands occur for Cr_2(μ-form)$_4$, Mo_2(μ-form)$_4$, and Ni_2(μ-form)$_4$ complexes.[14,15,43,52,54−57]

In order to include relativistic effects of the 5d orbitals and the influence of axially coordinated chlorides in the comparison of the metal−metal bond lengths, the "formal shortness ratio" (FSR) is used to minimize changes in the bond length due to the size of the metal atoms. To determine the FSR for a bond A−B, Equation 1 is applied where D_{A-B} is the distance between the atoms, R_1^A is the radius of atom A, and R_1^B is the radius of atom B.[58] The FSR has been calculated for the Cr_2(μ-form)$_4$ [0.806], Mo_2(μ-form)$_4$ [0.809], and W_2(μ-form)$_4$ [0.839] complexes using the average M−M bond lengths for the diarylformamidinate analogs.[12,43,52,59] Using the average Re−Re bond length (2.2776 Å) in the Re_2Cl_2(μ-form)$_4$ series and a radius of 1.283 Å for the Re atom,[21][60] the FSR of the Re−Re bond [0.888] is significantly larger than the FSR for the group 6 M_2(μ-form)$_4$ series due to coulombic repulsion between the Re^{III} centers[21] and larger than the FSR for $[Re_2Cl_8]^{2-}$ [0.869] due to the presence of two axial chlorides.[58][61]

Electrochemistry

Electrochemical studies of the compounds in the Re_2Cl_2(μ-form)$_4$ series were performed in CH_2Cl_2 under nitrogen. Data were obtained at scan rates of 20, 50, 100, and 200 mV/s to determine the values of the first [$E_{1/2}^1$] and second [$E_{1/2}^2$] quasireversible one-electron reduction potentials of compounds **1**−**4** (Table 2). Prior electrochemical studies of **2**, abbreviated Re_2Cl_2(μ-DFM)$_4$,[21] were repeated in order to compare electrochemical data performed under the same experimental conditions. As shown in Scheme 1, successive reduction of Re_2Cl_2(μ-form)$_4$ produces $[Re_2Cl_2$(μ-form)$_4]^-$ and subsequently $[Re_2Cl_2$(μ-form)$_4]^{2-}$.

Table 2. Hammett constant (σ) of the remote substituents of the formamidinate ligands, $E_{1/2}^1$, and $E_{1/2}^2$ values for electrochemical studies of the Re_2Cl_2(μ-form)$_4$ compounds, **1**−**4**, with two one-electron quasireversible reductions

Compound	Hammett constant	$E_{1/2}^1$	$E_{1/2}^2$
1	−0.27	−1.41	−1.68
2	−0.17	−1.39	−1.67
3	0.00	−1.28	−1.55
4	0.12	−1.25	−1.53

A least-squares fit of the $E_{1/2}$ values versus 8σ according to Equation 2 is linear with a slope of ρ, the reactivity constant, period The Hammett constant, σ, is multiplied by eight to account for all of the remote substituents on aryl

rings of the diarylformamidinate ligands. An anodic shift of the reduction with an increase in the value of the Hammett constants for the diarylformamidinate ligands is observed for **1**−**4** for both successive one-electron reductions of the dirhenium(III,III) core. At a scan rate of 100 mV/s, the correlation coefficient of the least squares fit of the plot of 8σ versus the $E_{1/2}{}^1$ value for $Re_2Cl_2(\mu\text{-form})_4$ series is 0.990 with ρ equal to 61 mV. When the average of the quasireversible reduction potentials observed at all scan rates is used, as shown in Figure 6, the correlation coefficient of the least squares fit to 8σ versus $E_{1/2}{}^1$ decreases [0.982] with a slight decrease in ρ, 56 mV.

$$\Delta E_{1/2} = E_{1/2}(X) - E_{1/2}(H) = \rho 8\sigma_X \quad (2)$$

where X is the substituent on the formamidinate ligand and H is a hydrogen atom

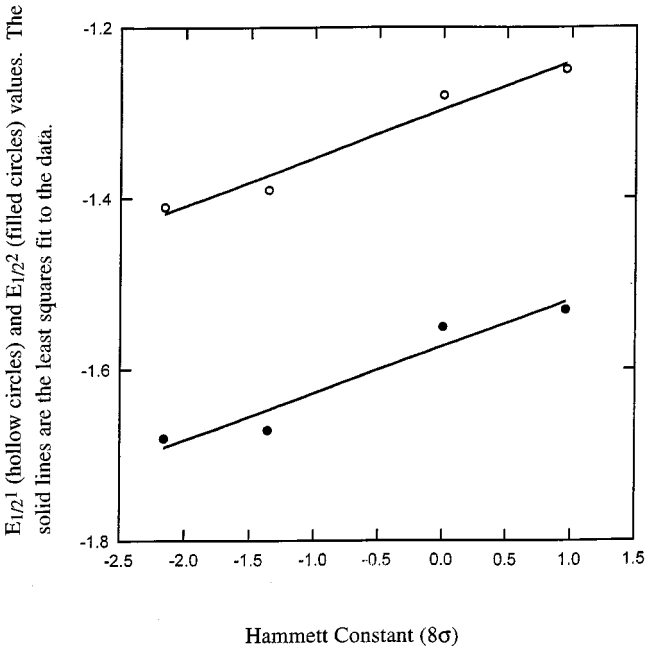

Figure 6. Dependence of $E_{1/2}{}^1$(hollow circles) and $E_{1/2}{}^2$(filled circles) values using the average of all scan rates on the Hammett constant (8σ) for the $Re_2Cl_2(\mu\text{-form})_4$ series. The circles represent the experimental data and the solid lines are the least squares fit to the data

For the $E_{1/2}{}^2$ values, correlation coefficients of the linear least squares fit of the data of 0.968 and 0.966 with ρ values of 51 mV (100 mV/s) and 55 mV (all scan rates, as shown in Figure 6) are observed. The $E_{1/2}{}^1$ values for the $Re_2Cl_2(\mu\text{-form})_4$ series varied over 160 mV and $E_{1/2}{}^2$ values over 150 mV for **1**−**4** (Table 2) and reflect the ability to use remote substituents to fine tune the electrochemical properties at a dinuclear core.[15,43,52,62] A similar trend is observed for $Re_2Cl_2(\mu\text{-}O_2CR)_4$ complexes with alkyl carboxylates. Plots of $E_{1/2}$ values versus the Taft σ* parameter, an indicator of the electron donating or withdrawing ability of the carboxylates, are linear.[62] The anodic shift of the oxidation with increasing values of the Hammett constant of the form ligand is also observed in the $Ni_2(\mu\text{-form})_4$,[43] $Cr_2(\mu\text{-form})_4$,[52] and $Mo_2(\mu\text{-form})_4$[15] series.

Studies of the $M_2(mhp)_4$ series where M_2 is Cr_2, CrMo, Mo_2, MoW, and W_2 and mhp is the 2-oxo-6-methylpyridine ion have demonstrated the first oxidation half potential correlates with the energy of the highest occupied molecular orbital as determined by photoelectron spectroscopy [PES].[63] For the series $Ni_2(\mu\text{-form})_4$ [ρ = 114 mV],[43] $Cr_2(\mu\text{-form})_4$ [ρ = 52.8 mV],[52] $Mo_2(\mu\text{-form})_4$ [ρ = 87.2 mV],[15] and $Re_2Cl_2(\mu\text{-form})_4$ [56 mV ($E_{1/2}{}^1$), 55 mV ($E_{1/2}{}^2$)], the magnitude of the value of ρ correlates to the ligand character of the orbital where the loss of the electron (oxidation) or gain of the electron (reduction) occurs. For the $Ni_2(\mu\text{-form})_4$ series with a large reactivity constant, the HOMO involved in the oxidation is the $6b_1$ orbital with 58% Ni and 42% N character.[44] A smaller reactivity constant is observed for the oxidation of the $Mo_2(\mu\text{-form})_4$ series[15] with a $2b_{2g}$ HOMO orbital with 87% Mo and 4% N character.[18]

The reactivity constants calculated for the $Re_2Cl_2(\mu\text{-form})_4$ complexes **1**−**4** are lower than either the dinickel or dimolybdenum series and similar for both reductions. Since a reduction is occurring, the orbital of interest in the determination of the value of ρ for both $E_{1/2}{}^1$ and $E_{1/2}{}^2$ is the LUMO, $6e_g$, with 91% Re and 1% N character. Very little change in the ligand character of the electrochemically active orbital is observed upon reduction to $Re_2(HNC(H)NH)_4$ with 97% Re and 2% N character for the $5e_g$ orbital.[21] The general trend observed in the $M_2(\mu\text{-form})_4$ complexes is a dependence of the reactivity constant on the ligand character of the orbital involved in either the reduction (LUMO) or oxidation (HOMO). With an increase in the ligand character of the electrochemically active orbital, the $E_{1/2}$ value is more strongly dependent on changes in the remote substituents of the ligand.

In contrast to the two one-electron reductions observed for **1**−**4**, studies of compounds **5**−**10** (Table 3) with more electron-withdrawing substituents on the diarylformamidinate ligands resulted in an irreversible two-electron reduction of the compound, as demonstrated by a ratio of peak currents of 2.48 (a ratio of 2.83 is predicted for compounds **5**−**10** versus **1**−**4** based on no change in diffusion coefficients and concentrations[64]). Two-electron reductions result when the loss of a second electron occurs more easily than the first electron due to an inversion of the reduction potentials[65] and are the result of a structural change.[65−69] For example, the electrochemistry of $[Mo_2Cp_2(CO)_4\{\mu\text{-}$

η^2:η^3-HCC−C(R1)(R2)}]$^+$ complexes is controlled by the R1 and R2 substituents as a result of changes in the energy of the LUMO orbital.[66]

To explain the change in the redox behavior of the Re_2Cl_2(μ-form)$_4$ complexes[57] with more electron-withdrawing substituents, the relative energies of the orbitals involved in the reduction were investigated. Fenske−Hall calculations performed on the Mo_2(μ-form)$_4$ series indicate the δ* orbital (LUMO) with approximately 76% metal character increases in energy by 1.18 eV upon a change in the remote substituent of the formamidinate ligand from 3,5-dichloro to *p*-MeO.[15] In contrast, the σ* orbital with approximately 87% metal character increases in energy by only 0.83 eV with the same variation in the remote substituents.[15] The Fenske−Hall calculations[15] demonstrate that, with increasing ligand character of a particular orbital, a more significant change in the orbital energy occurs with a change in the ligand substituents.

The orbitals of predominantly metal character for Re_2Cl_2(μ-DFM)$_4$ are, in order of increasing energy, $5a_{1g}$ (σ, −14.22 eV), $5e_u$ (π, −11.225 eV), $2b_{2g}$ (δ, −8.804 eV), $6e_g$ (π*, LUMO, −7.174 eV), $2b_{1u}$ (δ*, −6.912 eV), and $6a_{2u}$ (σ*, −3.295 eV). Only a −0.262 eV difference in energy is predicted between the two lowest unoccupied orbitals (π* and δ*) with Re characters of 91% and 59%, respectively.[21] Based on the trend observed in the previous studies of Mo_2(form)$_4$,[15][21] the energy of the δ* orbital decreases more rapidly than the π* orbital with an increase in the electron-withdrawing ability (σ) of the remote substituent on the aryl group of the formamidinate ligand in Re_2Cl_2(μ-form)$_4$ complexes. The energy difference between the π* and δ* orbitals diminishes or even becomes negative with increasing σ, as shown in Figure 7. As a result of the change in the orbital manifold across the series of Re_2Cl_2(μ-form)$_4$ complexes, two quasireversible one-electron reductions occur for the electron donating substituents and an irreversible two-electron reduction occurs for the electron-withdrawing substituents. Although the same general trend in reduction potentials is observed for both the one-electron quasireversible and two-electron irreversible reduction of the Re_2Cl_2(μ-form)$_4$ complexes as shown in Tables 2 and 3, a linear least squares fit of the Hammett constant versus the two-electron irreversible reduction at 100 mV [Table 3] is poor with a correlation coefficient of 0.832 and a ρ value of 44 mV. The electrochemical decomposition product is subsequently oxidized but has not been structurally or spectroscopically characterized.

Electronic Spectra

The electronic spectra of **1** and **3−10** consist of an intense peak between 386 to 418 nm. The transition at 403 nm for Re_2Cl_2[(*p*-tolylC$_6$H$_4$)NCHN(*p*-tolylC$_6$H$_4$)]$_4$[21] is assigned to the δ to δ* transition. The intense peak occurring between 386 and 418 nm in the Re_2Cl_2(μ-form)$_4$ series is assigned to the same transition with no correlation between the Hammett constants of the remote substituents and the energy of the δ to δ* transition observed.[15,54−57]

Diamagnetic Anisotropy of the Re−Re Bond

An induced field from circulating electrons results in the diamagnetic anisotropy in transition metal complexes containing metal-metal multiple bonds. In the Re_2Cl_2(μ-form)$_4$ series, the methine proton (−NC*H*N−) of the bridging diarylformamidinate ligand is affected by the induced field caused by the circulating electrons of the Re−Re quadruple bond. As a result, the methine proton is deshielded and a downfield chemical shift is observed. From the chemical shift difference of the methine proton [Δδ = δ(−NC*H*N−Re_2) − δ (−NC*H*N−Ni_2)][43] and structural parameters of these protons (r and θ) extracted from the crystallographic data, the diamagnetic anisotropy for the Re−Re bond is calculated from Equation 3 shown below.[70]

$$\Delta\delta = \frac{\Delta\chi}{4\pi}\left[\frac{1-3\cos^2\theta}{3r^3}\right]$$

The Δχ values calculated based on crystallographic and ^{1}H spectroscopic data for Re_2Cl_2(μ-form)$_4$ with the substituents *p*-MeO, *m*-MeO, 3,5-Cl_2, and 3,4-Cl_2 are 4034, 3890, 3940, and $4154\cdot10^{-36}$ m^3 molecule^{-1}, respectively or $4004\cdot10^{-36}$ m^3 molecule^{-1} on average. Since the chemical shift of the methine proton of Ni_2[(3,4-$Cl_2C_6H_3$)NCHN(3,4-$Cl_2C_6H_3$)]$_4$ is not available, the chemical shift was estimated (δ = 6.185) based on the average

change in the methine proton chemical shift upon coordination to the Ni_2 core from values of nine reported Ni_2(μ-form)$_4$ complexes and the corresponding free ligands.[43] The values are somewhat smaller than $\Delta\chi$ value of $4430 \cdot 10^{-36}$ m^3 $molecule^{-1}$ reported previously for Re_2Cl_2(μ-DFM)$_4$.[12] The correlation of the diamagnetic anisotropy to the Hammett constant of the remote substituents on the diarylformamidinate ligands for the Re_2Cl_2(μ-form)$_4$ series is extremely poor.

Conclusions

With the synthesis of a series of Re_2Cl_2(μ-form)$_4$ compounds incorporating a variety of electron donating and withdrawing remote substituents on the diarylformamidinate ligands, the comparison of structural and spectroscopic properties of M_2(μ-form)$_4$ complexes is extended to include dirhenium(III,III) compounds with axially coordinated chlorides. In the metal−metal bonded, Cr_2(μ-form)$_4$, Mo_2(μ-form)$_4$, and Re_2Cl_2(μ-form)$_4$, and non-bonded systems, Ni_2(μ-form)$_4$, which have variations in the Hammett constant of the remote substituents on the diarylformamidinate ligands, no correlation between the metal−metal bond lengths or metal−nitrogen bond lengths and σ is observed.[14,15,43,52]

The two quasireversible one-electron reductions for **1**−**4** and the two-electron irreversible reductions observed for **5**−**10** reflect the ability to tune the reduction potential over a 150 mV range (**1**−**4**) via the remote substituents on the diarylformamidinate ligand.[14,15,43,52,66] The reactivity constants of the Re_2Cl_2(μ-form)$_4$ series (**1**−**4**) are similar in magnitude to the Cr_2(μ-form)$_4$ series and significantly smaller than either the Mo_2(μ-form)$_4$ or Ni_2(μ-form)$_4$ series.[14,15,43,52] Based on systems where both electrochemical and theoretical data are available, the $E_{1/2}$ value becomes more strongly dependent on changes in the remote substituents on the diarylformamidinate ligand with increasing ligand character of the electrochemically active orbital.[15,18,21,43,44,52] Studies of a series of W_2(μ-form)$_4$ complexes with a variety of substituents on the diarylformamidinate ligands are in progress to determine the effect of the Hammett constant of the ligand substituents on the electrochemical process.

Experimental Section

Starting Materials: The starting materials $[N(n\text{-}Bu)_4]_2[Re_2Cl_8]$,[71] Re_2(μ-$O_2CCH_3)_4Cl_2$,[72] and **2**[21] were synthesized by the standard literature methods. All the diarylformamidine ligands were synthesized according to literature methods, washed under an argon atmosphere with freshly distilled hexanes, and transferred to the drybox.[15][73] The solvents ethanol (EtOH), methanol (MeOH), CH_2Cl_2, ethyl acetate, and hexanes for the synthesis of the Re_2Cl_2(μ-form)$_4$ complexes were used as received without distillation.

Preparation of the Complexes: $Re_2Cl_2[(p\text{-}MeOC_6H_4)NCHN(p\text{-}MeOC_6H_4)]_4$ (**1**). Re_2Cl_2(μ-$O_2CCH_3)_4$ (0.090 g, 0.13 mmol) was heated at 140°C with (p-$MeOC_6H_4$)NHCHN(p-$MeOC_6H_4$) (3 g, 11.7 mmol) under argon for 5 hours. EtOH (40 mL) was added to the molten reaction mixture while hot, and the mixture was vigorously stirred for 1 hour. The orange-yellow solid was collected by filtration and dried under dynamic vacuum. ^{1}H-NMR spectroscopy revealed the presence of free ligand, and the crude product was further purified by chromatography. Yield: 0.093 g (48.8%). − ^{1}H NMR: δ = 8.30 (*s*, 4 H), 6.66 (*m*, 32 H), 3.75 (*s*, 24 H). − ^{13}C NMR δ: 171.1 (*s*), 158.1 (*s*), 145.6 (*s*), 129.2 (*s*), 127.7 (*s*), 113.2 (*s*), 111.8 (*s*). − UV/Vis: λ_{max} (nm) = 278, 418.

$Re_2Cl_2[(C_6H_5)NCHN(C_6H_5)]_4$ (3): Re_2Cl_2(μ-$O_2CCH_3)_4$ (0.110 mg, 0.16 mmol) was heated at 150°C with (C_6H_5)NHCHN(C_6H_5) (2.94 g, 15.0 mmol) under argon for 8 hours. Upon completion of the reaction, the product was extracted with hot ethanol (80 mL), but a clean separation was not achieved. The filtrate and solid were combined and dried on a rotovap. Ethyl acetate (50 mL) was added and the mixture was heated to reflux and the resultant mixture was cold filtered to remove the bulk of the free ligand. The crude product was suspended in 6 mL of CH_2Cl_2 and heated to reflux. Following addition of 30 mL of ethyl acetate and an additional reflux period of 10 minutes, vigorous stirring of the reaction mixture during cooling to room temperature yielded golden flakes of **3**. The solid product was collected by filtration and dried under dynamic vacuum. Yield: 0.142 g (72.5%). − ^{1}H NMR: δ = 8.40 (*s*, 4 H), 7.13 (*d*, 16 H, ^3J = 1.6 Hz), 7.11 (*d*, 8 H), 6.76 (*dd*, 16 H). − ^{13}C NMR: δ = 152.2 (*s*), 128.4 (*s*), 127.0 (*s*). − UV/Vis: λ_{max} (nm) = 278, 396.

$Re_2Cl_2[(m\text{-}MeOC_6H_4)NCHN(m\text{-}MeOC_6H^4)]_4$ (4): Re_2Cl_2(μ-$O_2CCH_3)_4$ (0.110 g, 0.16 mmol) was heated at 140°C with (m-$MeOC_6H_4$)NHCHN(m-$MeOC_6H_4$) (3 g, 11.7 mmol) under argon overnight. Ethyl acetate (35 mL) was added to the molten reaction mixture and the solution refluxed for an hour. The orange-yellow solid was collected by filtration and dried under vacuum. Since TLC indicated incomplete purification, another 35 mL of ethyl acetate was added to the crude product and the mixture refluxed. The purified solid product was collected by filtration and dried under dynamic vacuum. Yield: 0.210 g (89.6%). − ^{1}H NMR: δ = 8.40 (*s*, 4 H), 7.12 (*t*, 8 H, ^3J = 8.0 Hz), 6.66 (*dd*, 8 H, ^3J = 8.3 Hz, ^4J = 1.9 Hz), 6.60 (*d*, 8 H, ^3J = 7.6 Hz), 6.34 (*s*, 8 H), 3.29 (*s*, 24 H). − ^{13}C NMR: δ = 171.3 (*s*), 169. 9 (*s*), 158.7 (*s*), 153.5 (*s*), 128.9 (*s*), 127.5 (*s*), 119.7 (*s*), 118.2 (*s*), 114.5 (*s*), 113.1 (*s*). − UV/Vis: λ_{max} (nm) = 286, 400.

$Re_2Cl_2[(p\text{-}ClC_6H_4)NCHN(p\text{-}ClC_6H_4)]_4$ (5): Re_2Cl_2(μ-$O_2CCH_3)_4$ (0.17 g, 0.25 mmol) was heated at 180°C with (p-ClC_6H_4)NHCHN(p-ClC_6H_4) (2.12 g, 8.0 mmol) under argon for 3 hours. The solid product was dissolved in CH_2Cl_2 and precipitated from solution with EtOH. The orange solid was collected by filtration and dried under dynamic vacuum. Yield: 0.262 g (69.9%). − ^{1}H NMR: δ = 8.32 (*s*, 4 H), 7.14 (*d*, 16 H, ^3J = 8.6 Hz), 6.63 (*d*, 16 H, ^3J = 8.7 Hz). − ^{13}C NMR: δ = 171.3 (*s*), 150.1 (*s*), 132.6 (*s*), 129.3 (*s*), 128.6 (*s*), 128.0 (*s*), 127.2 (*s*). − UV/Vis: λ_{max} (nm) = 274, 398.

$Re_2Cl_2[(m\text{-}ClC_6H_4)NCHN(m\text{-}ClC_6H_4)]_4$ (6): Re_2Cl_2(μ-$O_2CCH_3)_4$ (0.11 g, 0.16 mmol) was heated at 180°C with (m-ClC_6H_4)NHCHN(m-ClC_6H_4) (2.12 g, 8.0 mmol) under argon for 3 hours. Ethyl acetate (15 mL) was added while the molten reaction mixture was still hot. The crude solid product was collected by filtration. The residual free ligand was removed by redissolving the crude product in CH_2Cl_2 and precipitating **6** with hexanes. The orange-yellow solid was collected by filtration and dried under dynamic vacuum. Yield: 0.130 g (54.2%). − ^{1}H NMR: δ = 8.48 (*s*, 4 H), 7.12−7.21 (*m*, 16 H), 6.74 (*d*, 8 H, ^4J = 1.9 Hz), 6.73 (*s*, 8 H). − ^{13}C NMR: δ = 171.7 (*s*), 170.1 (*s*), 152.5 (*s*), 133.2 (*s*), 129.6 (*s*),

128.6 (*s*), 128.2 (*s*), 127.7 (*s*), 127.3 (*s*), 126.3 (*s*), 126.1 (*s*), 124.7 (*s*). − UV/Vis: λ_{max} (nm) = 278, 390.

$Re_2Cl_2[(m\text{-}CF_3C_6H_4)NCHN(m\text{-}CF_3C_6H_4)]_4$ (7): $Re_2Cl_2(\mu\text{-}O_2CCH_3)_4$ (0.17 g, 0.25 mmol) was heated at 156°C with (*m*-$CF_3C_6H_4$)NHCHN(*m*-$CF_3C_6H_4$) (3.1 g, 9.3 mmol) for 15 hours. EtOH (40 mL) was added to the reaction mixture while hot. The mixture stirred vigorously for 1 hour. The solid was collected by filtration, washed with 20 mL of EtOH and 10 mL of hexanes, and dried under vacuum. Yield: 0.39 g (88%). − ^{1}H NMR: δ = 8.57 (*s*, 4 H), 7.46 (*d*, 8 H, ^3J = 7.6 Hz), 7.36 (*t*, 8 H, ^3J = 7.9 Hz), 7.08 (*d*, 8 H, ^3J = 7.4 Hz), 6.85 (*s*, 8 H). − ^{13}C NMR δ: 171.3 (*s*), 151.45 (*s*), 130.12 (*s*), 128.77 (*s*), 124.83 (*s*), 123.93 (*s*). − UV/Vis: λ_{max} (nm) = 294, 386.

$Re_2Cl_2[(p\text{-}CF_3C_6H_4)NCHN(p\text{-}CF_3C_6H_4)]_4$ (8): $Re_2Cl_2(\mu\text{-}O_2CCH_3)_4$ (0.20 g, 0.30 mmol) was heated at 170°C with (*p*-$CF_3C_6H_4$)NHCHN(*p*-$CF_3C_6H_4$) (2.0 g, 6.0 mmol) for 1.5 hours. After cooling, acetone (20 mL) was added to the reaction mixture and the red-orange supernatant solution transferred from the unchanged ligand. Slow evaporation of the acetone resulted in red-orange crystals. The crystals were washed with 10 mL of hexanes, and dried under vacuum. Yield: 0.305 g (57.5%). − ^{1}H NMR: δ = 8.47 (*s*, 4 H), 7.45 (*d*, 16 H, ^3J = 3.9 Hz), 6.81 (*d*, 16 H, ^3J = 3.9 Hz). − ^{13}C NMR: δ = 171.22 (*s*), 154.38 (*s*), 129.44 (*q*, $^1J_{C-F}$ = 33.8 Hz), 127.94 (*d*, $^2J_{C-F}$ = 14.1 Hz), 126.68 (*s*), 125.51 (*s*), 122.91 (*s*), 120.21 (*s*). − UV/Vis: λ_{max} (nm) = 386.

$Re_2Cl_2[(3,4\text{-}Cl_2C_6H_3)NCHN(3,4\text{-}Cl_2C_6H_3)]_4$ (9): $Re_2Cl_2(\mu\text{-}O_2CCH_3)_4$ (0.100 g, 0.15 mmol) was heated at 170°C with (3,4-$Cl_2C_6H_3$)NHCHN(3,4-$Cl_2C_6H_3$) (2.0 g, 6.0 mmol) under dynamic vacuum for 7 hours. Ethanol (30 mL) was added to the orange-brown solid while the reaction mixture was warm. After stirring the solution overnight to dissolve excess ligand, the solution was filtered and the yellow-orange solid collected on the frit. The purified solid product was dried under dynamic vacuum. Yield: 0.132 g (49.6%). − ^{1}H NMR: δ = 8.398 (*s*, 4 H), 7.244 (*d*, 4 H, ^3J = 8.5 Hz), 6.699 (*d*, 4 H, ^4J = 2.4 Hz), 6.603 (*dd*, 4 H, ^3J = 8.5 Hz, ^4J = 2.4 Hz). − UV/Vis: λ_{max} (nm) = 282, 398.

$Re_2Cl_2[(3,5\text{-}Cl_2C_6H_3)NCHN(3,5\text{-}Cl_2C_6H_3)]_4$ (10a, 10b): $Re_2Cl_2(\mu\text{-}O_2CCH_3)_4$ (0.550 g, 0.81 mmol) was heated at 170°C with (3,5-$Cl_2C_6H_3$)NHCHN(3,5-$Cl_2C_6H_3$) (2.0 g, 6.0 mmol) under dynamic vacuum for 7 hours. The orange-brown solid was loaded on a column of chromatographic Silica Gel of 200 to 425 mesh and eluted with CH_2Cl_2. The yellow solution was collected and dried under dynamic vacuum. The addition of ethanol dissolves the excess ligand and the yellow-orange product was collected by filtration of the ethanol suspension. The purified solid product was dried under dynamic vacuum. Yield: 0.302 g (21.0%). − ^{1}H NMR: δ = 8.50 (*s*, 4 H), 7.20 (*s*, 8 H), 6.6 (*d*, H, ^4J = 1.8 Hz). − ^{13}C NMR: δ = 171.3 (*s*), 152.3 (*s*), 134.4 (*s*), 127.4 (*s*), 125.9 (*s*). − UV/Vis: λ_{max} (nm) = 278, 314, 388.

Physical Measurements: The spectroscopy, UV/Vis and ^{13}C-NMR, was performed using CH_2Cl_2 dried over P_2O_5 and freshly distilled under argon prior to use. ^{1}H-NMR spectra were recorded on either a Bruker AMX-360 NMR spectrometer or a General Electric Omega 400 MHz NMR spectrometer with chemical shifts (δ) referenced to the residual $CHCl_3$ (δ = 7.27) in the $CDCl_3$ solvent. ^{13}C-NMR spectra were recorded on a General Electric Omega 400 MHz NMR spectrometer with a 10 mm broad band probe with chemical shifts (δ) referenced to CH_2Cl_2 (δ = 54.2). 10-mm NMR tubes for ^{13}C-NMR spectra were prepared by dissolving the respective $Re_2Cl_2(\mu\text{-form})_4$ complexes in CH_2Cl_2 with a 4 mm NMR insert of either $CDCl_3$ or CD_3CD_2OD to lock. ^{13}C-NMR spectra required 4 to 24 hours of data collection to obtain reasonable signal

to noise levels. Data could not be obtained for **3** or **9** due to poor solubility of the compounds in CH_2Cl_2. The UV/Vis spectra were recorded on a Hewlett Packard model 8452 diode array spectrophotometer from 250 to 820 nm. Cyclic voltammetry measurements of compounds **1**−**10** were performed using a Solartron S1 1287 Electrochemical Interface in 0.1 M (nBu$_4$N)PF$_6$ electrolyte and 0.6 mM Re_2Cl_2(μ-form)$_4$ solutions with a 1.6-mm diameter Pt disk working electrode and a Ag wire quasi-reference electrode. The CH_2Cl_2 solutions of the respective complexes were purged for 20 minutes with nitrogen before data were recorded. The nitrogen was presaturated with CH_2Cl_2 to minimize solution evaporation. All electrode potentials are reported versus the ferrocene/ferrocenium $E_{1/2}$ value [0 V].

X-ray Crystallographic Study:[74] Crystals of **1**, **4**, **9**, and **10a**, **b** were grown by slow diffusion of CH_2Cl_2 (**1**, **4**, **9**, and **10a**) or THF (**10b**) solutions of the respective compounds with hexanes. Data were collected for **1**, **4**, **9**, and **10a**, **b** using a Siemens SMART CCD based diffractometer equipped with a LT-2 low-temperature apparatus operating at 213 K. Suitable crystals were mounted on a glass fiber using grease. Data were measured using omega scans of 0.3° per frame for 30 seconds such that a hemisphere was collected. A total of 1271 frames were collected with a final resolution of 0.75 Å (**1**, **4**, and **10a**) and 0.85 Å (**9** and **10b**). The first 50 frames were recollected at the end of data collection for each of the crystals to monitor for decay, but no decomposition during data collection was observed. Cell parameters for **1**, **4**, **9**, and **10a**, **b** were retrieved using SMART[75] software and refined using SAINT on all observed reflections. Data reductions were performed using SAINT[76] software which corrects for decay and Lorentz and polarization effects. Absorption corrections were applied using SADABS[77] supplied by George Sheldrick. The structures were solved by direct methods using the SHELXL-90[78] program and refined by least squares method on F^2, SHELXL-93,[79] incorporated in SHELXTL.PC V 5.03.[80] All non-hydrogen atoms are refined anisotropically. The positions of the hydrogen atoms were determined by difference Fourier methods and refined in **9** and **10a** and were calculated geometrically and refined as a riding model for **1**, **4**, and **10b**. One of the ligands in **9** showed a disorder of the ring to result in a disorder of two of the chloride positions with an occupany of 50% each. Although the dichloromethane solvent molecules of **4** could not be modeled successfully as disordered, the remaining electron density in the structure resides within the solvent molecule. Selected bond lengths and angles for **1**, **4**, **9**, and **10a**, **b** are listed in Table 1 and pertinent crystallographic parameters are summarized in Table 4.
