Crystal-Structure Analyses: X-ray diffraction data for both compounds were collected at room temperature with an Enraf Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). Crystal data and details about structure refinements are given in Table 3. Empirical absorption corrections (ψ scans) were applied. The structures were solved by direct methods[21] and heavy-atom procedures.[22] In the structure of **1**, both acetate anions are distributed over two positions related by the twofold symmetry axis. The two images of the anion in bridging position [atoms O(1)−C(8)] overlap substantially (therefore they cannot exceed the population parameter value 0.5), whereas those of the other anion [O(3)−C(10)] lie apart and may not be mutually exclus-

Synthesis and Crystal Structure of $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$, a Dinuclear Complex with Te_2^{2-}, $TeBr^-$, and $TeBr_2$ Ligands

Johannes Beck*[a] and Klaus Müller-Buschbaum[a]

Keywords: Rhenium / Tellurium / Bromine compounds / Dinuclear rhenium complex / Crystal structure

The reaction of $ReBr_4$, Te and $TeBr_4$ in $SiBr_4$ as solvent in a sealed glass ampoule at 150 °C yields black crystals of $Re_2Te_6Br_{10}$. As the X-ray crystal structure determination shows [monoclinic, $P2_1$, $Z = 2$, $a = 1127.5(1)$, $b = 861.85(9)$, $c = 1231.0(2)$pm, $\beta = 105.47(9)°$], the structure consists of discrete dinuclear complexes. A Re–Re dumb-bell with d(Re–Re) = 279.9 pm is coordinated by a μ-Te_2 group and two μ-TeBr groups. Additionally, each Re atom is coordinated to two terminal bromine atoms and a $TeBr_2$ ligand leading to the formula $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$. $Re_2Te_6Br_{10}$ is one of only a few compounds known in the ternary system Re/Te/Br.

Introduction

In lower oxidation states rhenium is known to form dinuclear complexes with multiple Re−Re bonds as well as a large variety of clusters.[1] Among the rhenium chalcogenide halides hexanuclear octahedral cluster compounds are predominant,[2] but trinuclear triangular clusters like $Re_3E_7X_7$ (E = S, Se; X = Cl, Br)[3−5] and tetranuclear clusters like $Re_4S_4Te_4$[6] or $[Re_4(\mu_3\text{-}Te)_4(TeBr_2)_4Br_8]$ with a Re_4Te_4 heterocubane core[7] are known, too.

In the ternary system Re/Te/Br only very few compounds are known so far. Two examples of hexanuclear clusters were reported, $[Re_6Te_8(TeBr_2)_6]Br_2$[8], $Re_6Te_4Br_{10}$,[9] and the above-mentioned tetranuclear complex $[Re_4(\mu_3\text{-}Te)_4(TeBr_2)_4Br_8]$. Recently, we discovered that $ReCl_4$, Te and $TeCl_4$ yield $Te_8[ReCl_6]$.[10] We extended our synthetic attempts to the reactions of $ReBr_4$ with elemental chalcogen and its tetrabromides. Here we report the synthesis and crystal structure of a new dinuclear complex containing unusual ligands.

Results and Discussion

Synthesis

The reaction of $ReCl_4$, Te and $TeCl_4$ leads to $Te_8[ReCl_6]$ and is carried out in a sealed, evacuated ampoule at 230°C under the conditions of the chemical vapor transport.[10] All attempts to obtain polycation-containing compounds starting from $ReBr_4$, Te and $TeBr_4$ failed. The only crystalline material which could be identified was Re_3Br_9.[11][12] The use of $SiBr_4$ as solvent allowed a moderate reaction temperature of 150°C and proved to be successful for the synthesis of a ternary compound. Within two weeks black cuboid crystals of $Re_2Te_6Br_{10}$ were deposited from the solution besides silvery crystals of tellurium.

$$4\ ReBr_4 + 11\ Te + TeBr_4 \xrightarrow{SiBr_4} 2\ Re_2Te_6Br_{10}$$

An excess of tellurium was found to be necessary for the formation of the ternary phase. In other solvents like $SnBr_4$ or S_2Br_2, $Re_2Te_6Br_{10}$ was not obtainable.

Crystal Structure

The crystal structure is built of discrete molecular complexes with the formula $Re_2Te_6Br_{10}$ (Figure 1). Central unit is an Re−Re dumb-bell coordinated by a Te_2 group and two TeBr groups, bridging both Re atoms. Additionally, each Re atom has two terminal Br ligands. The coordination sphere is completed by two $TeBr_2$ molecules, bound to each Re atom. The Re−Re distance is 279.9(2) pm which represents a weak bond. In Re^{III} halides containing an Re_3 triangle with a formal Re−Re double bond, distances between 245 and 250 pm are observed.[11][13] However, the Re−Re distance in $Re_2Te_6Br_{10}$ is in good agreement with $[Re_4Te_4(TeBr_2)_4Br_8]$, for which 277.4 pm and 283.1 pm were found.[7] The angles Re−Te−Re are all in the range from 61.9 to 64.2° and thus notably acute. In the complex $[(\mu\text{-}Te)\{Cp^*Re(CO)_2\}_2]$, which contains a comparable Re−Te−Re unit, this angle is 71.8° and the Re−Re distance 314 pm.[14] Apparently, steric hindrance and the requirements for orbital overlap in the Re−Te−Re units are limiting factors for the Re−Re distances. All Re−Te bonds in $Re_2Te_6Br_{10}$ are in the narrow range from 261.7(2) to 273.5(2) pm. The Te(3)−Te(4) distance in the Te_2 group is 268.7(4) pm, slightly shorter than a Te−Te single bond of 275 pm, but comparable to other compounds containing Te_2 groups, e.g. $Nb_2Te_2X_6$ (X = Br, I) with 267.0 and 268.5 pm.[15] The distance Te(2)−Te(5) is 324.9(3) pm, indicating only a very weak interaction and the absence of a second Te_2 group. Two Br atoms are bound to Te(2) and Te(5) with Te−Br distances of 260.9(4) and 264.5(5) pm. Thus, $Re_2Te_6Br_{10}$ contains two TeBr groups, a type of ligand

which so far has been only observed in $Mo_4Te_7Br_8$, and as the analogous TeCl groups in $Mo_4Te_7Cl_8$.[16]

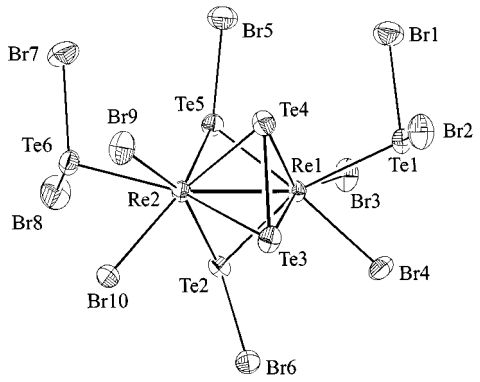

Figure 1. The structure of the molecular complex $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$; thermal ellipsoids are drawn at a 50% probability level[27]

$TeBr_2$ is unstable in the solid state,[17] but can be stabilized by coordination, which was already shown in the structures of $[Re_4(\mu_3\text{-}Te)_4(TeBr_2)_4Br_8]$[7] and $[Re_6Te_8(TeBr_2)_6]Br_2$.[8] With mean Te−Br bond lengths of 252.6 pm and Br−Te−Br angles of 96.7° the conformation of the coordinated $TeBr_2$ molecules in the structure of $Re_2Te_6Br_{10}$ is quite similar to that in the gas phase (251 pm and 98°).[18]

Together with the two terminal Br ligands each Re atom is sevenfold coordinated in a piano-stool fashion. The bonding in the complex can be rationalized by an ionic formula. Counting the terminal bromine ligands as Br^-, the Te_2 groups as Te_2^{2-}, the TeBr groups as $TeBr^-$ and thus analogous to a hypochlorite ion, and the $TeBr_2$ ligands as neutral molecules, one obtains the ionic formula $[(Re^{4+})_2(Br^-)_4(Te_2^{2-})(TeBr^-)_2(TeBr_2)_2]$. This formula is consistent with the assumption of a bonding Re−Re interaction. The presence of Re^{4+} has also been suggested for the heterocubane cluster $[Re_4Te_4(TeBr_2)_4Br_8]$. The mean Re−Br bond lengths between the central atom and the terminal bromide ligands generally are very sensitive to changes in the oxidation state of the central atom. Figure 2 shows the arrangement of the molecules in the unit cell.

Molybdenum and tungsten form a class of dinuclear chalcohalide complexes of the general formula $M_2E_6X_{10}$ (M = Mo, W; E = S, Se, Te; X = Cl, Br).[19][20] Although the formula is analogous to $Re_2Te_6Br_{10}$, these complexes are not isostructural. Mo and W compounds contain two E_2^{2-} groups, three terminal halide ligands for each metal atom and two EX_2 molecules connected with the metal atoms through the chalcogen atoms, but no TeX^- groups. Therefore, the ionic formula is $[(M^{5+})_2(X^-)_6(E_2^{2-})_2(EX_2)_2]$. The significant difference between this family of complexes and $Re_2Te_6Br_{10}$ lies in the function of two halide ligands. In the Mo and W complexes they act as terminal ligands bound to the metal atoms resulting in a coordination number of eight for Mo/W, while in $Re_2Te_6Br_{10}$ they are bound to the Te atoms of a "former" Te_2 group with the consequence of loss of the Te−Te bond and the formation of the unusual $TeBr^-$ ligands.

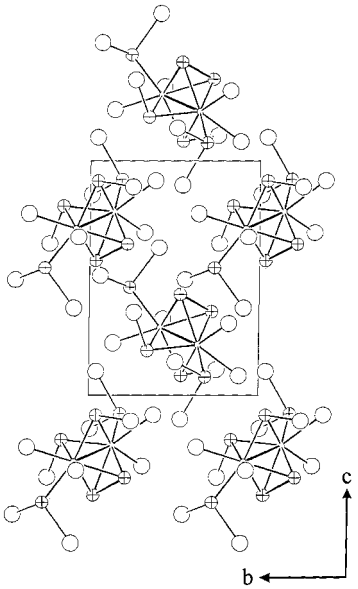

Figure 2. The unit cell of $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$ in a view along the *a* axis showing the noncentrosymmetry of the structure; rhenium atoms are shown as small, bromine atoms as large white circles, tellurium atoms as cross-hatched circles

Experimental Section

General: Tellurium (Alfa Chemicals) was sublimed before use, $TeBr_4$ was prepared from the elements,[21] using bromine (Riedel-

de Haën) dried with P_4O_{10}. BBr_3 (Riedel-de Haën) was used as received, $ReCl_5$ prepared from the elements, using Re (Riedel-de Haën), purified with H_2 at 1000°C, and chlorine gas dried with H_2SO_4. $ReBr_4$ was prepared from $ReCl_5$ and BBr_3.[22] $SiBr_4$ (Aldrich) was distilled prior to use. All compounds were handled in an argon glovebox or by standard vacuum techniques.

Synthesis of $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$: The reaction of $ReBr_4$, Te and $TeBr_4$ was carried out in an evacuated glass ampoule of 14 mm diameter and 13 cm length. The ampoule was loaded with 250 mg of the solid starting materials in a glovebox, $SiBr_4$ was added under a flow of argon. The molar ratio of all starting materials was $ReBr_4/Te/TeBr_4/SiBr_4$ = 2:13:1:40. The solids showed only little solubility in the solvent. Within 14 d black crystals of $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$ were formed at 150°C. Yields were generally low and no increase was observed on prolonged heating or at higher temperatures. The solvent was decanted and the crystals were dried in vacuo. Crystals of $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$ are weakly moisture-sensitive. They decompose in moist air within several hours under evolution of HBr.

Crystal Structure Determination: Crystals of $[Re_2Br_4(Te_2)(TeBr)_2(TeBr_2)_2]$ were sealed in glass capillaries under argon. The crystal finally chosen for the data collection had dimensions of 0.32 × 0.24 × 0.06 mm. Preliminary precession photographs showed a systematic twinning of all crystals examined with a twofold axis along the diagonal of the reciprocal $a-c$ plane as the twin element. The crystal system was determined to be monoclinic with the Laue group $2/m$. The systematic extinction $0k0$ only present for $k = 2n$ led to the spacegroups $P2_1/m$ and $P2_1$ of which the noncentrosymmetric group was confirmed by the structure analysis. Data were collected with a STOE Image Plate diffractometer using graphite monochromized radiation. The reflections of the two individuals were indexed separately with the aid of the programm RECIPE.[23] Overlapping reflex intensities were excluded from the data sets. A structure model was obtained by direct methods[24] and refined against F^2 by full-matrix least squares with anisotropic displacement parameters for all atoms and both sets of data.[25] A numerical absorption correction was applied,[26] although this is principially problematic for twinned crystals. Crystallographic data and details on the structure analysis are given in Table 1, selected distances and angles in Table 2. Further crystal structure data have been deposited at the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, Germany. Inquiries should be accompanied by the depository number CSD-410190.

Metallocenes of Nb and Ta with η^2-Se_2H, SeH, and Se Ligands – Crystal Structures of $[Cp'_2Ta(SeH)H_2]$ and $[Cp'_2Ta(=Se)H{\cdot}W(CO)_5]$ ($Cp' = tBuC_5H_4$)

Keywords: Metallocenes / Hydroselenide ligands / Selenium / Se coordination chemistry

The reactions of $[Cp^{\#}_2NbBH_4]$ (**1**) [$Cp^{\#} = C_5Me_5$ (Cp^*) or C_5Me_4Et] and $[Cp'_2TaH_3]$ ($Cp' = tBuC_5H_4$) with elemental selenium give complexes of the general composition $[Cp_2MSe_2H]$. These exist in three isomeric forms, **A–C**, depending on the metal and the chalcogen. $[Cp^{\#}_2NbSe_2H]$ (**2**) incorporates the novel η^2-Se_2H ligand (**C**), which is labile when exposed to light. Solutions of **2**(Cp^*) can be converted into $[Cp^*_2NbSe_2H]$ (**3**), which exists in two isomeric forms **A** or **B**, along with $[Cp^*_2NbSe_3H]$ (**4**) and $[Cp^*_2NbO_2H]$ (**5**). $[Cp'_2Ta(\eta^2\text{-}Se_2)H]$ (**6**) is the only isomer found for the Ta system. Se abstraction by means of $P(OEt)_3$ gives $[Cp'_2Ta(=Se)H]$ (**7**). Complex **7** can be reduced with Na/Hg and subsequently hydrolysed to give $[Cp'_2Ta(SeH)H_2]$ (**8**), which has also been observed during the formation of **6**. Coordination of $[W(CO)_5THF]$ at the Se lone pair of **7** affords the heterobimetallic complex **9**. All compounds have been characterized by means of ^1H- and, in some cases, ^{77}Se-NMR spectroscopy. Products **8** and **9** have also been subjected to X-ray diffraction analysis.

Introduction

Metallocenes of the early transition metals are excellent reagents for the stabilization of chalcogenido ligands.[1] However, only a few comparative studies have been carried out, in which the coordination behavior of various chalcogens has been studied at a specific transition metal.[2] Compounds of the class $[Cp_2MX_2H]$ (Cp = any substituted cyclopentadienyl) are predominant in Nb and Ta chalcogen chemistry. They occur as isomers **A**−**C**, where the form adopted depends on the combination of substituted cyclopentadienyl ligands [$Cp' = tBuC_5H_4$; $Cp^{\#} = C_5Me_5$ (Cp^*) or C_5Me_4Et] with the appropriate metals (M = Nb, Ta) and chalcogens (X = S, Se, Te). Examples existing as isomeric form **A** are $[Cp^{\#}_2NbS_2H]$,[3] $[Cp'_2TaS_2H]$,[3] and $[Cp^*_2TaX_2H]$ (X = S,[4] Se,[5] Te[6]). The chemistry of this isomeric form is characterized by the nucleophilic behavior of the free electron pairs of the dichalcogenido ligands, which can ultimately lead to the formation of polymetallic compounds.[7] Another feature is the photolytic rupture of its X−X bond, giving isomers of type **B** (M = Nb, Ta: X = S;[8] M = Ta: X = Se[5]). Only one example (M = Nb: X = Te) corresponding to isomer form **C** has been reported, which involves a chiral X atom: $[Cp^{\#}_2Nb(\eta^2\text{-}Te_2H)]$ serves as a reagent for the transfer of Te^0[9] or Te^{2-} ligands[10] to other organometallic complexes.

Whereas peralkylated tantalocene compounds of type **A** are well established for X = S, Se, and Te, the corresponding niobocene selenides are not known. Therefore, we decided to investigate the reactions of $[Cp^{\#}_2NbBH_4]$ and of $[Cp'_2TaH_3]$ with elemental selenium. The latter was employed because sulfido compounds containing the Cp'_2Ta fragment exhibit striking relationships in their chemical behavior when compared to sulfido compounds involving the $Cp^{\#}_2Nb$ fragment.[11]

Scheme 1. Isomeric forms of Cp_2MX_2H (M = Nb, Ta; X = S, Se, Te)

Results

The $Cp^{\#}_2Nb$/Se System

Reaction of $[Cp^{\#}_2NbBH_4]$ **1** with 2.3 equivalents of red selenium in the dark at ambient temperature gives the green compounds **2** in 85−89% yields (Equation 1). The reaction of **1** with grey Se requires a temperature of at least 40°C. FD mass spectra and elemental analyses of the products indicate their composition to be $[Cp^{\#}_2NbSe_2H]$. The ^1H-NMR spectra of compounds **2** invariably exhibit a high-field resonance at $\delta = -0.90$, surrounded by ^{77}Se satellites. ^{77}Se-NMR spectra feature resonances at $\delta = -210$ and 230, respectively, the latter exhibiting a $^{77}Se-^1H$ coupling of 34 Hz. The absence of a highly deshielded resonance rules out the presence of double-bonded Se.[5][12] The ^1H-NMR spectrum of $[(C_5Me_4Et)_2Nb(Se_2H)]$ (Figure 1) features a

multiplet attributable to the CH_2 protons. A similar NMR pattern has been observed for $[(C_5Me_4Et)_2Nb(\eta^2\text{-}Te_2H)]$, the structure of which has been determined by X-ray crystallography.[9] On this basis, compounds **2** are assigned the isomeric form **C**.

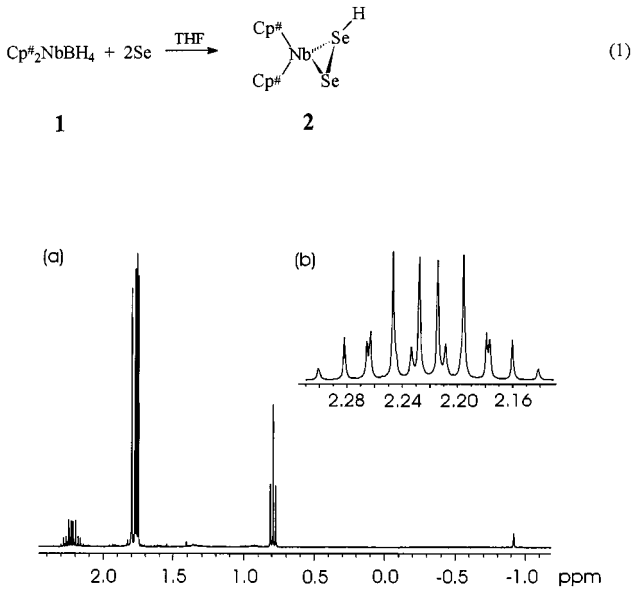

Figure 1. ^{1}H-NMR spectrum (400 MHz, C_6D_6) of $[(C_5Me_4Et)_2Nb(\eta^2\text{-}Se_2H)]$ (Figure 1a) and CH_2 resonances of the C_5Me_4Et ligands (· 5; Figure 1b)

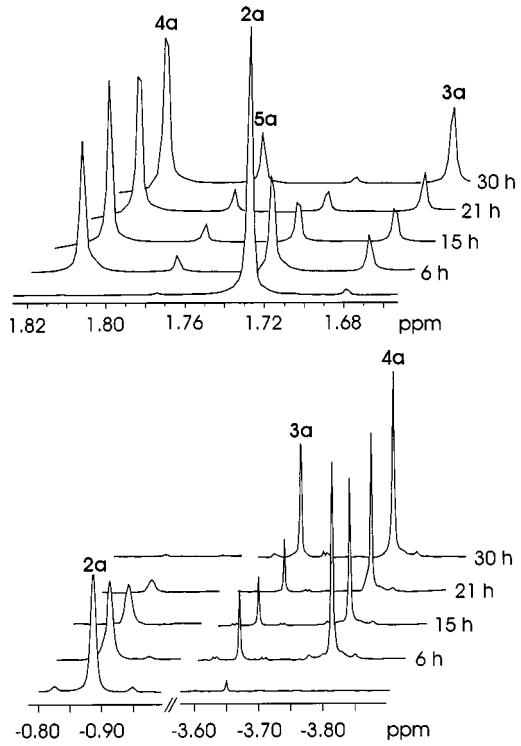
The green solutions of **2** slowly become orange when exposed to light. This process was studied by ^{1}H-NMR spectroscopy in the case of **2**(Cp*) in C_6D_6 solution. The signals at $\delta = 1.73$ (CH_3) and $\delta = -0.89$ (SeH) disappear as new signals develop (Figure 2), the latter being attributable to the compounds $[Cp^*_2NbSe_2H]$ (**3**), $[Cp^*_2NbSe_3H]$ (**4**), and $[Cp^*_2NbO_2H]$ (**5**) (Equation 2). The products were identified, after partial chromatographic separation, on the basis of their mass-spectrometric and ^{1}H-NMR-spectroscopic data, following irradiation of a solution of **2**(Cp*) on a preparative scale. Separation into discrete compounds could not be achieved, and consequently there is some scatter in the C,H elemental analysis data for **3** and **4**. In the ^{1}H-NMR spectrum of **3**, the "hydride" resonance is flanked by two pairs of ^{77}Se satellites (Figure 2b). A structural assignment to one of the two isomers **A** or **B** (Scheme 1) is not yet possible because the low solubility of **3** does not allow a ^{77}Se-NMR spectrum of sufficient quality to be recorded. IR spectra are of little use in assigning the isomeric form as the only significant absorptions are those of the ν(C−H) vibrations of the $Cp^{\#}$ rings. Irradiation of the C_5Me_4Et derivative of **2** proceeds in a similar manner, but separation into discrete complexes proved even more difficult, thus preventing clear assignments of signals in the NMR spectra. Although an unambiguous assignment of the structures of **3** and **4** is not yet possible, further support for the proposed isomeric forms is provided by the thermolysis of $[Cp^*_2NbS_2H]$. Here, isomer **A** is converted to isomer **B** in the formation of $[Cp^*_2NbS_3H]$, and both structures have been confirmed by X-ray studies.[3][8]



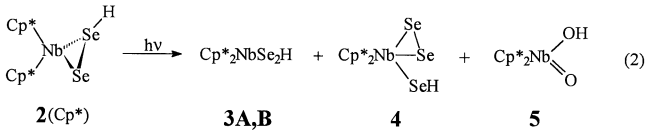


Figure 2. ^{1}H-NMR investigation of the isomerization of $[Cp^*_2Nb(\eta^2\text{-}Se_2H)]$ [**2**(Cp*)] during irradiation (400 MHz, C_6D_6); methyl resonances of the Cp* ligands of **2**(Cp*), $[Cp^*_2NbSe_2H]$ (**3**), $[Cp^*_2Nb(Se_2)SeH]$ (**4**), and $[Cp^*_2Nb(O)OH]$ (**5**) (see text; Figure 2a); high-field region (· 20; Figure 2b)

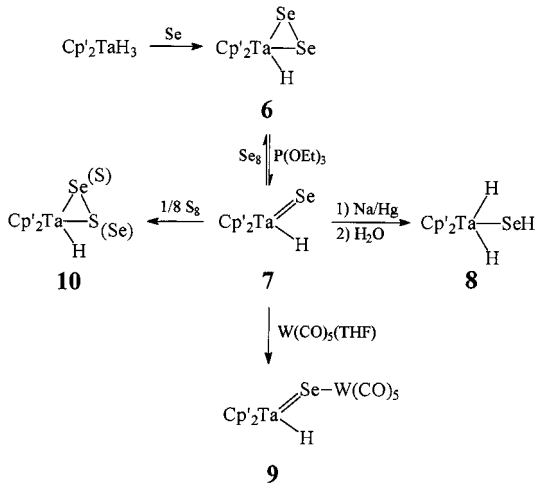
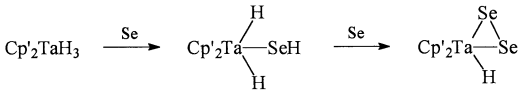
The formation of **5** may be rationalized in terms of the substitution of selenide ligands by traces of oxygen. In a control experiment, a solution of **2**(Cp*) produced bright-yellow $[Cp^*_2NbO_2H]$ (**5**) along with red selenium when exposed to air. Complex **5** belongs to the class of oxoniobocenes of the type $[Cp^*_2Nb(=O)R]$ (R = H, Cl, OCH_3, etc.).[13]



(2)

The Cp'_2Ta/Se System

Stirring of a toluene solution of $[Cp'_2TaH_3]$ with an excess of grey selenium (12 h, 25°C) leads to the formation of the red complex $[Cp'_2TaSe_2H]$ (**6**) (Scheme 2). The isomeric form **A** can be proposed on the basis of spectroscopic data. The IR spectrum of **6** shows an absorption at 1710 cm^{-1} characteristic of ν(Ta−H), and the ^{1}H-NMR spectrum exhibits a singlet at $\delta = 1.11$ for the TaH proton and a set of four resonances ($\delta = 3.81$, 4.21, 4.34, and 6.15) due to the cyclopentadienyl protons. Two resonances ($\delta = -251$ and −571) are observed for the two non-equivalent chalcogen atoms in the ^{77}Se-NMR spectrum. In contrast to the anal-



ogous $[Cp^*_2Ta(\eta^2\text{-}Se_2)H]$,[5] no $^{77}Se-^1H$ coupling is observed.

Treatment of a toluene solution of **6** with triethyl phosphite (4 h, reflux) leads to formation of the monoselenido complex $[Cp'_2Ta(=Se)H]$ (**7**). The ^{77}Se-NMR spectrum of **7** exhibits a deshielded signal at $\delta = 2303$, which is typical for doubly bonded Se.[5][12] The signal at $\delta = 7.52$ in the ^{1}H-NMR spectrum, attributable to the TaH group, is suggestive of a protic rather than a hydridic nature of the hydrogen ligand.[14] $[Cp'_2Ta(\eta^2\text{-}Se_2)H]$ (**6**) is regenerated upon addition of an excess of Se_8 to solutions of **7** (Scheme 2).

Scheme 2

Like the related tantalocene sulfide,[14][15] the Ta=Se bond in **7** can be expected to exhibit an interesting reaction potential. Thus, when a pale-blue THF solution of **7** is treated with sodium amalgam and then with a few drops of water, rapid decolouration of the reaction mixture occurs, from which the white complex **8** can subsequently be isolated. Analytical data for **8** are consistent with the composition $[Cp'_2TaSeH_3]$. In this context, it is of interest that the FD mass spectrum of **8** features the parent ion peak, whereas that of its precursor **7** shows only the peak of **6**, which is richer in Se. The ^{1}H-NMR spectrum of **8** exhibits two multiplets at $\delta = 4.91$ and $\delta = 4.37$ for the Cp protons, and a singlet at $\delta = 1.29$ for the *t*Bu group. This is in accord with the presence of two equivalent cyclopentadienyl rings. The "hydride" resonances appear as a doublet at $\delta = 2.43$ and a triplet at $\delta = -4.86$ (ratio 2:1). The ^{77}Se-NMR spectrum shows a triplet at $\delta = -570$ with $^2J(^{77}Se-^1H) = 23$ Hz. The same coupling is found for the doublet, whereas the aforementioned high-field triplet does not exhibit any SeH coupling, even upon irradiation of the doublet. The high-field resonance disappears in D_2O as $[Cp'_2Ta(SeD)H_2]$ is formed. As in the case of the related $[Cp'_2Ta(SD)H_2]$, which shows a similar spectrum,[16] no evidence for Ta–D bond formation could be detected. This is in contrast to the exchange process hydrochalcogenido vs. hydrido ligands observed by Bergman et al. in the case of $[Cp^*_2Ti(SH)H]$.[17] Complex **8** is also observed in the course of formation of **6**, so that it may be considered as the first relatively stable intermediate product in the activation of elemental selenium by $[Cp'_2TaH_3]$ (Equation 3).

8 **6** (3)

In order to gain further insight into the structure of **8**, a single-crystal X-ray analysis was carried out. This revealed the typical bent metallocene structure (Figure 3), with the Se atom located in the plane defined by the centers of the Cp ligands and the Ta atom. The final difference Fourier map exhibits several positive peaks close (< 1.5 Å) to the Ta and Se atoms. However, none of them could be refined as a bona fide hydrogen atom. Thus, even though we were unable to locate the hydrogen atoms, the overall metallocene geometry[18] of **8**, together with a long Ta–Se bond of 2.646(1) Å {some 0.3 Å longer than the Ta=Se bond in $[Cp^*_2Ta(=Se)H]$[5]}, are clearly indicative of the presence of a hydroselenide ligand. Complex **8** is one of the few examples containing this ligand.[5][19]

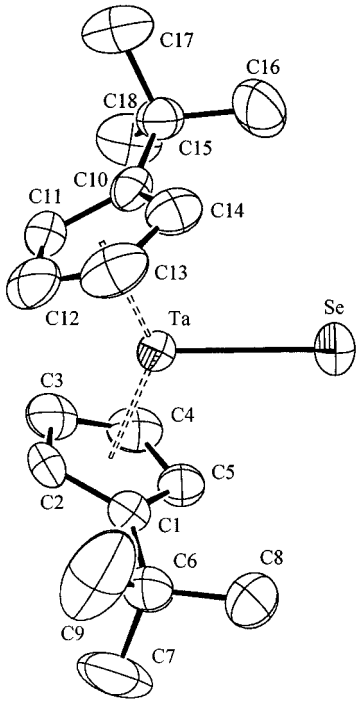


Figure 3. Molecular structure (ORTEP drawing at 50% probability level) of $[Cp'_2TaH_2SeH]$ (**8**); selected bond lengths [A] and angles [°]: Ta–Se 2.646(1), Ta–Cp1 2.09, Ta–Cp2 2.08 (Cp1 and Cp2 are the centers of the rings C1–C5 and C10–C14, respectively); Cp1–Ta–Cp2 136.9; the H atoms attached to Ta and Se could not be localized

The selenido complex **7** reacts with $[W(CO)_5(THF)]$ to afford the brown, heterobimetallic compound **9** in 65% yield (Scheme 2). This complex has been characterized by both spectroscopic and crystallographic measurements. The IR spectrum of **9** exhibits the typical absorption pattern for the coordinated $W(CO)_5$ moiety and the ^{1}H-NMR spectrum features one signal for the *t*Bu protons. The molecular

structure of **9** is shown in Figure 4. It may be classified as being of the pseudotetrahedral metallocene-type,[18] with the Se atom located 0.86 Å from the central Cp−Ta−Cp plane (cf. the "in-plane" position of Se in the structure of **8**). The Ta−Se distance [2.422(2) Å] is only slightly longer than that of other Ta=Se bonds.[5][20] The orientation of the $W(CO)_5$ group towards one of the Cp rings in the solid state should be of no relevance in solution. As in the related $[Cp'_2Ta(S)H \cdot W(CO)_5]$, a low barrier to rotation about the metal−selenium bond may be expected.[15]

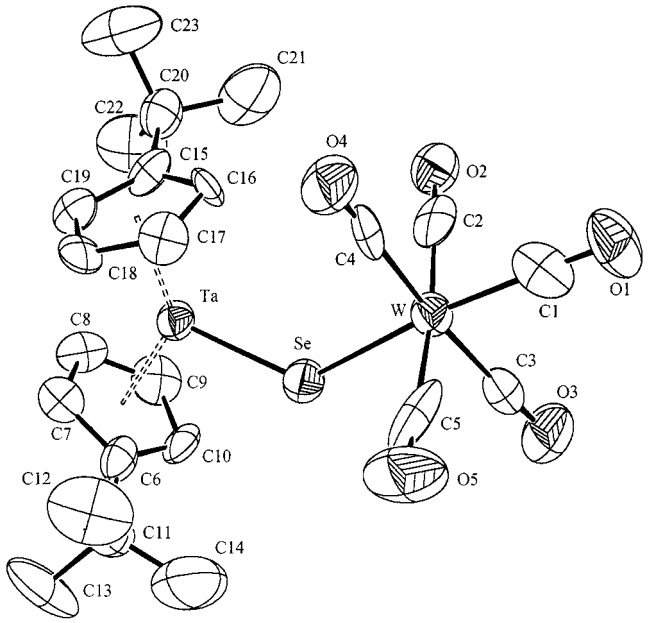

Figure 4. Molecular structure (ORTEP drawing at 50% probability level) of $[Cp'_2TaSeH{\cdot}W(CO)_5]$ (**9**); selected bond lengths [Å] and angles [°]: Ta−Se 2.422(4), Ta−Cp1 2.09, Ta−Cp2 2.09 (Cp1 and Cp2 are the centers of the rings C6−C10 and C15−C19, respectively), W−Se 2.672(2); Ta−Se−W 130.92(8), Cp1−Ta−Cp2 134.8; the H atom attached to Ta could not be localized

Another aspect of the reactivity of **7** is illustrated by its behavior towards S_8. When a toluene solution of **7** is treated with an excess of elemental sulfur, there is an immediate colour change from blue to dark-brown. After chromatographic work-up, a brown band is obtained, which consists mainly of the mixed complex $[Cp'_2Ta(SeS)H]$ (**10**), as established by mass spectrometry. The ^{1}H-NMR spectrum shows the presence of two isomers, arising from different orientations of the (η^2-SeS) ligands, besides ca. 10% of $[Cp'_2Ta(\eta^2\text{-}S_2)H]$.[3] Unfortunately, full chromatographic separation could not be achieved, precluding the analytical characterization of these isomers. However, dechalcogenation of the mixture with $P(OEt)_3$ appears to be chemoselective, since it affords exclusively $[Cp'_2Ta(=S)H]$[3] along with $Se=P(OEt)_3$. The same reactivity is observed in the cross-reaction when $[Cp'_2Ta(=S)H]$ is exposed to an excess of Se_8.

Conclusions

Transition metal complexes with hydroselenido ligands are still rare. In this paper, we have reported the facile syntheses of two different ligand types containing Se−H bonds. The results show that $Cp^{\#}{}_2Nb$ fragments play a particular role in the activation of elemental selenium as opposed to other chalcogens. Like its Te congener $[Cp^{\#}{}_2Nb(Te_2H)]$, which has already been successfully employed in the synthesis of telluride clusters,[9][10] the novel hydroselenido ligand in **2** merits attention as a potential source of reactive Se. On the other hand, the ligand arrangements in complexes **3** and **4** show similarities to niobocene−sulfide chemistry. The Se coordination chemistry induced by the Cp'_2Ta fragment closely resembles that observed for the systems Cp'_2Ta/S_8 and Cp^*_2Ta/X (X = Se, Te). The crucial difference is the stabilization of the dihydrido−hydroselenido complex **8** as an intermediate product during activation of elemental selenium. Another complex typical of tantalocene−selenium chemistry is **7**, for which a series of novel reactions have been described.

Experimental Section

General: All procedures were carried out under N_2 using dry solvents. − Elemental analyses (C,H) were performed at the Mikroanalytisches Laboratorium, Universität Regensburg. − IR spectra were obtained with a Perkin−Elmer 580 B instrument. − Molecular masses were determined by field desorption (FD) mass spectrometry (toluene solutions) using a Finnigan MAT 95 instrument. − ^{1}H- and ^{77}Se-NMR (standard: external Me_2Se) spectra were recorded with Bruker AC 200, WM 250, and WM 400 instruments. − $[(C_5Me_5)_2NbBH_4]$,[21] $[(C_5Me_4Et)_2NbBH_4]$,[22] and $[Cp'_2TaH_3]$[23] were prepared according to literature procedures. − ***Note:*** Work should be carried out in a well-ventilated fume hood because of the possible evolution of H_2Se.

Preparation of $[Cp^{\#}{}_2NbSe_2H]$ (2): It was essential that all operations were carried out in the absence of light. A mixture of 1.50 mmol of **1**, 373 mg (4.7 mmol) of red amorphous selenium,[24] and 70 mL of THF was stirred for 20 h at room temperature. After evaporation of the solvent, chromatography of the residue on SiO_2 (column 25 cm, Ø 5 cm) gave upon elution with toluene a green band containing $[Cp^{\#}{}_2NbSe_2H]$ (**2**) in 85−89% yield. − **2**: $C_{20}H_{31}NbSe_2$ (522.3): calcd. C 45.99, H 5.98; found C 45.71, H 6.01. − Mol. mass 519.1 (FD-MS, ^{78}Se). − ^{1}H NMR (400 MHz, C_6D_6): δ = 1.72 (s, 30 H, CH_3), −0.90 [s, 1 H, SeH, ^1J(H−Se) = 33.9 Hz]. − ^{77}Se NMR (76 MHz, C_6D_6): δ = 236.7 [d, 1 Se, ^1J(Se−H) = 34 Hz], −209.0 (s, 1 Se). − $C_{22}H_{35}NbSe_2$ (550.3): calcd. C 48.01, H 6.41; found C 48.00, H 6.40. − Mol. mass 547.0 (FD-MS, ^{78}Se). − ^{1}H NMR (400 MHz, C_6D_6): δ = 1.74 (s, 6 H, CH_3), 1.76 (s, 6 H, CH_3), 1.77 (s, 6 H, CH_3), 1.78 (s, 6 H, CH_3), 0.86 (t, 6 H, CH_3), 2.22 (m, 4 H, CH_2), −0.92 [s, 1 H, SeH, ^1J(H−Se) = 34.4 Hz]. − ^{77}Se NMR (76 MHz, C_6D_6): δ = 223.2 [d, 1 Se, ^1J(Se−H) = 33.6 Hz], −217.4 (s, 1 Se).

Irradiation of $[Cp^*_2NbSe_2H]$ [2(Cp*)]: A green solution of 1.5 g (2.87 mmol) of **2**(Cp*) in 150 mL of toluene was stirred for 7 d at room temperature and exposed to daylight. During this time the colour slowly changed to brown-orange. After evaporation of the solvent, the brown residue was dissolved in 20 mL of toluene and then chromatographed on SiO_2 (column 25 cm, Ø 5 cm). Elution with toluene/pentane (2:1) gave a broad yellow band containing 80 mg of product. Further elution with toluene/pentane (3:1) gave two very broad bands containing 420 and 850 mg, respectively. On the basis of mass-spectrometric and ^{1}H-NMR investigations, the

first band was found to consist of 68% [Cp*$_2$NbSe$_2$H] (**3**), 8% [Cp*$_2$NbSe$_3$H] (**4**), and 13% [Cp*$_2$NbO$_2$H] (**5**). The second band was shown to contain these compounds in a ratio of 21:68:9, while the third band consisted almost exclusively of **5**, which exhibited the same properties as an independently prepared sample (see below). − **3**: $C_{20}H_{31}NbSe_2$ (522.3): Mol. mass 519.1 (FD-MS, ^{78}Se). − ^{1}H NMR (400 MHz, C_6D_6): δ = 1.67 (s, 30 H, CH_3), −3.67 [s, 1 H, J(H−Se) = 20.9, 25.5 Hz]. − **4**: $C_{20}H_{31}NbSe_3$ (601.3): Mol. mass 598.1 (FD-MS, ^{78}Se). − ^{1}H NMR (400 MHz, C_6D_6): δ = 1.82 (s, 30 H, CH_3), −3.84 [s, 1 H, SeH, ^1J(H−Se) = 21.2 Hz].

Reaction of [Cp*$_2$NbSe$_2$H] [2(Cp*)] with Air: A solution of 300 mg (0.575 mmol) of **2**(Cp*) in 100 mL of THF was stirred for 12 h in the dark in an open flask. After filtration of the precipitated amorphous selenium, the solvent was evaporated from the yellow filtrate to give 200 mg (88% yield) of a pale-yellow powder. Recrystallization from toluene/pentane (1:2) gave analytically pure **5**. − **5**: $C_{20}H_{31}NbO_2$ (396.0): calcd. C 60.61, H 7.83; found C 60.12, H 7.71. − Mol. mass 396.0 (FD-MS). − IR (KBr): $\tilde{\nu}$ = 3470 cm^{-1} m [ν(OH)], 843 cm^{-1} s [ν(Nb=O)]. − ^{1}H NMR (250 MHz, C_6D_6): δ = 1.77 (s, 30 H, CH_3), 2.11 (s, 1 H, OH).

Synthesis of [Cp′$_2$TaSe$_2$H] (6): A mixture of 100 mg (0.23 mmol) of [Cp′$_2$TaH$_3$], 100 mg (1.26 mmol) of grey selenium, and 10 mL of toluene was stirred for 18 h at 25°C (when red selenium was used, the reaction was complete within 3 h). The solvent was subsequently removed in vacuo and the dark residue was purified by chromatography on SiO_2 (column 12 cm, Ø 2.5 cm). Elution with toluene/THF gave a red band containing 67 mg (49% yield) of **6**. Recrystallization from toluene/pentane gave red crystals. − **6**: $C_{18}H_{27}TaSe_2$ (582.3): calcd. C 37.13, H 4.67; found C 36.84, H 4.77. − Mol. mass 580.0 (FD-MS, ^{78}Se). − IR (CsI): $\tilde{\nu}$ = 1710 cm^{-1} w [ν(Ta−H)]. − ^{1}H NMR (200 MHz, C_6D_6): δ = 1.11 (s, 1 H, TaH), 1.23 (s, 18 H, CH_3), 3.81 (m, 2 H, C_5H_4R), 4.21 (m, 2 H, C_5H_4R), 4.34 (m, 2 H, C_5H_4R), 6.15 (m, 2 H, C_5H_4R). − {^{1}H}^{77}Se NMR (95 MHz, C_6D_6): δ = −251, −571.

Synthesis of [Cp′$_2$TaSeH] (7): A solution of 90 mg (0.15 mmol) of **6** and 0.5 mL (excess) of P(OEt)$_3$ in 12 mL of toluene was refluxed for 4 h. After cooling, the solvent was removed under reduced pressure and the residual solid was washed with pentane. After drying in vacuo, 55 mg (70% yield) of crude **7** was obtained as a blue solid. Recrystallization from toluene/pentane gave an analytically pure sample, the FD-MS spectrum of which showed exclusively the more Se-rich peak of the precursor **6**. − **7**: $C_{18}H_{27}TaSe$ (503.3): calcd. C 42.95, H 5.41; found C 42.69, H 5.47. − IR (CsI): $\tilde{\nu}$ = 1862 cm^{-1} w [ν(Ta−H)]. − ^{1}H NMR (200 MHz, C_6D_6): δ = 1.29 (s, 18 H, CH_3), 4.76 (m, 2 H, C_5H_4R), 5.10 (m, 2 H, C_5H_4R), 5.42 (m, 2 H, C_5H_4R), 5.82 (m, 2 H, C_5H_4R), 7.52 (s, 1 H, TaH). − {^{1}H}^{77}Se NMR (95 MHz, C_6D_6): δ = 2303.

Synthesis of [Cp′$_2$Ta(H)$_2$SeH] (8): A solution of 70 mg (0.14 mmol) of **7** in 8 mL of THF was stirred with excess sodium amalgam for 20 min and then 3−4 drops of water were added. After decantation of the organic layer and washing of the amalgam residue with THF, the solvent was evaporated to leave crude **8** as a white solid (53 mg, 75% yield). Recrystallization from toluene/pentane gave white needles. − **8**: $C_{18}H_{29}TaSe$ (505.3): calcd. C 42.78, H 5.78; found C 42.83, H 5.71. − Mol. mass 504.2 (FD-MS, ^{78}Se). − ^{1}H NMR (200 MHz, C_6D_6): δ = −4.86 [t, 1 H, SeH, ^3J(H−H) = 8.3 Hz], 1.29 (s, 18 H, CH_3), 2.43 [d, 2 H, TaH, ^3J(H−H) = 8.3 Hz, ^2J(Se−H) = 22.6 Hz], 4.37 (m, 4 H, C_5H_4R), 4.91 (m, 4 H, C_5H_4R) [^1J(Se−H) not observed]. − {^{1}H}^{77}Se NMR (95 MHz, C_6D_6): δ = −570 [t, 1 Se, ^2J(Se−H) = 23 Hz].

Synthesis of [Cp′$_2$TaSeH · W(CO)$_5$] (9): A mixture of 90 mg (0.18 mmol) of **7**, 0.22 mmol of [W(CO)$_5$(THF)], and 15 mL of THF was stirred at room temperature for 30 min. After evaporation of the solvent, the residue was chromatographed on SiO_2 (column 10 cm, Ø 2.5 cm). Eluting with toluene, a red-brown band was obtained, which was found to contain 100 mg (65% yield) of **9**. Recrystallization from toluene/pentane gave dark-brown crystals. − **9**: $C_{23}H_{27}O_5SeTaW$ (827.2): calcd. C 33.40, H 3.29; found C 33.77, H 3.27. − Mol. mass 828 (FD-MS; calcd. 828.0 for $C_{23}H_{27}TaO_5{}^{78}Se^{184}W$). − IR (THF): $\tilde{\nu}$ = 2061 s, 1928 s, 1918 sh, 1894 m cm^{-1} [ν(CO)]. − ^{1}H NMR (200 MHz, C_6D_6): δ = 1.06 (s, 18 H, CH_3), 4.32 (m, 2 H, C_5H_4R), 4.81 (m, 2 H, C_5H_4R), 5.43 (m, 2 H, C_5H_4R), 5.81 (m, 2 H, C_5H_4R), 7.36 (s, 1 H, TaH).

Synthesis of [Cp′$_2$TaSeSH] (10): To a solution of 60 mg (0.12 mmol) of **7** in 10 mL of toluene, 5 equiv. of sulfur were added. The mixture was stirred for 5 min. The solvent was then evaporated and the residual brown solid was chromatographed on SiO_2 (column 10 cm, Ø 2.5 cm). Eluting with toluene/THF (9:1), a brown band was obtained, which was found to contain **10** as a mixture of two isomers and an inseparable small amount (15%) of [Cp′$_2$TaS$_2$H] (overall yield 65%). − **10**: $C_{18}H_{27}TaSSe$ (536.1): Mol. mass 536.1 (FD-MS). − ^{1}H NMR (200 MHz, C_6D_6): Major isomer (60%): δ = 1.23 (s, 18 H, CH_3), 2.28 (s, 1 H, TaH), 3.86 (m, 2 H, C_5H_4R), 4.37 (m, 2 H, C_5H_4R), 4.43 (m, 2 H, C_5H_4R), 5.91 (m, 2 H, C_5H_4R). − Minor isomer (40%): δ = 1.24 (s, 18 H, CH_3), 1.52 (s, 1 H, TaH), 3.92 (m, 2 H, C_5H_4R), 4.37 (m, 4 H, C_5H_4R), 6.15 (m, 2 H, C_5H_4R).

X-ray Structure Determinations[25] of Complexes 8 and 9. − [Cp′$_2$Ta(H)$_2$SeH] (8): Yellow prisms (0.4 × 0.3 × 0.2 mm), monoclinic $P2_1/n$ (no. 14); cell: a = 8.036(1), b = 18.255(2), c = 12.666(2) Å, β = 97.77(1)°; V = 1840.9 Å^3, Z = 4; $d_{calcd.}$ = 1.823 gcm^{-3}; absorption correction (ψ scan): 73.64/99.86. Synthesis and X-ray Structure Determination of *tert*-Butylhydrazinium Azide and *N,N,N*-Trimethylhydrazinium Azide

Tassilo Habereder,[a][+] Anton Hammerl,[a] Gerhard Holl,[b] Thomas M. Klapötke,*[a] Jörg Knizek,[a][+] and Heinrich Nöth[a][+]

Keywords: Azides / Hydrazinium azide / Hydrazine / Nitrogen compounds

tert-Butylhydrazinium azide $[t\mathrm{BuNH_2NH_2}]^+[\mathrm{N_3}]^-$ (**1**) was prepared in a high yield reaction from *tert*-butylhydrazine and HN_3. *N,N,N*-Trimethylhydrazinium azide $[NH_2N(CH_3)_3]^+[N_3]^-$ (**2**) was prepared from the reaction of silver azide with *N,N,N*-trimethylhydraziniumiodide. Both were characterized by X-ray structural analysis, IR, Raman, and multinuclear (^{1}H, ^{13}C, ^{14}N) NMR spectroscopy.

Introduction

Hydrazinium azide, first reported by Curtius in 1891,[1a] is a powerful explosive that produces only nitrogen, hydrogen, and ammonia after explosion.[1b]

During the last 8 years, significant advances have been made in the area of inorganic azides, as indicated by the number of recent reviews covering various aspects of the subject.[2a–c] In contrast to the chemistry of many hydrazinium salts, which has been extensively explored in the last 30 years,[3][4] detailed studies into the chemistry of ionic hydrazinium azides have only recently come to fruition.[5a,b] We have recently become interested in the preparation of hydrazinium azides and their possible application as high-energy-density materials (*HEDM*) for military use.[6][7] The low melting point and the high volatility of hydrazine azide prevent its use. In order to increase the melting point and to decrease the volatility, organic substituents were attached to hydrazine. The first attempt in this direction was the synthesis of *N,N*-dimethylhydrazinium azide,[8] which proved to be more volatile than hydrazinium azide. The goal for the current research was to find a hydrazinium azide derivative that has a higher melting point and is less volatile than hydrazinium azide.

Results and Discussion

Anhydrous *tert*-butylhydrazine reacts at 0°C with a solution of hydrazoic acid in ether to form *tert*-butylhydrazinium azide **1** (Equation 1). Hydrazoic acid must be used in excess to prevent the formation of an adduct of **1** with *tert*-butylhydrazine.

$$t\mathrm{BuNHNH_2} + \mathrm{HN_3} \xrightarrow{\mathrm{Et_2O}} [t\mathrm{BuNH_2NH_2}]^+[\mathrm{N_3}]^- \quad (1)$$

The vibrational spectra show the characteristic absorptions of an ionic azide at 2037 cm^{-1} (ν_{as}, IR) and 1340 cm^{-1} (ν_s, Raman). The ^{1}H-NMR spectrum contains a broad signal at $\delta = 7.26$, which is characteristic for a hydrazinium ion. The ^{14}N-NMR spectrum shows two signals at $\delta = -134$ and -277, corresponding to the terminal azide nitrogen atom and the the central azide nitrogen atom respectively. No ^{14}N-NMR resonance was detected for the hydrazinium ion. This effect is observed with other ammonia and hydrazine compounds.[9]

Crystals of **1** are orthorhombic with space group P_{bcm} and $Z = 4$ molecules in the unit cell. The bond lengths and angles of the *tert*-butylhydrazinium ion, as indicated in Figure 1, are in accordance with the bond lengths and angles of known compounds.[10][11] The N–C bond length is in compliance with the literature data for this kind of molecule. The bond length is with 1.52 Å slightly longer than the N–C bond length of primary carbon atoms due to the bulky substituent. The bond length and angles of the azide ion are also in agreement with the literature data.[12] As can be seen in Figure 1, the azide anions are linked to the hydrazinium ions through hydrogen bonding between the terminal azide nitrogens and both nitrogen atoms of the *tert*-butylhydrazinium ion. In total there are four hydrogen bonds per azide anion (two per terminalazide nitrogen). One terminal azide nitrogen is connected through each of ist to hydrogen bonds to the protonated nitrogen atom of the hydrazinium ion. These two bonds have a length of 1.91 Å. The other terminal azide nitrogen is analogously connected to the non-protonated nitrogen of the *tert*-butylhydrazinium ion. These two bonds are longer, with a length of 2.25 Å.

This results in a highly symmetric crystal structure. The azide ions form layers, which are sandwiched between two different layers of hydrazinium ions.

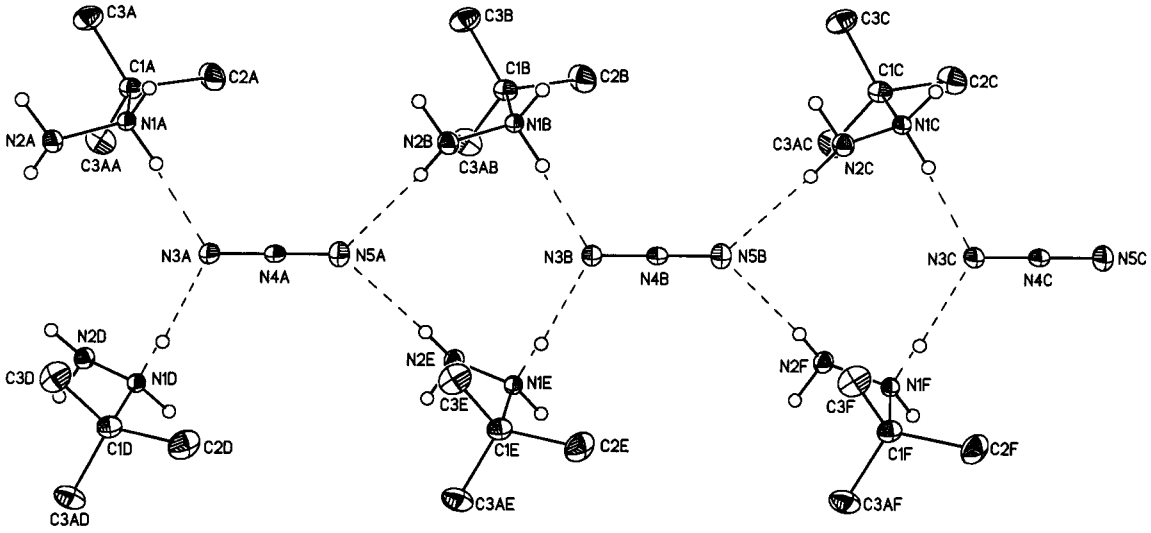

Figure 1. Molecular structure and hydrogen bonds of **1** as ORTEP plot (thermal ellipsoids represent 25% probability); selected bond lengths [Å] and angles [°] of **1**: N(1)−N(2) 1.441(2), N(1)−C(1) 1.522(2), C(1)−C(3/3A) 1.514(2), C(1)−C(2) 1.529(2), N(2)−N(1)−C(1) 107.9(7), N(1)−C(1)−C(2) 104.14(1), C(3/3A)−C(1)−N(1) 108.44(8), C(3/3A)−C(1)−C(2) 111.57(9), N(5)−N(4)−N(3) 180.0.

Synthesis of 2

N,N,N-Trimethylhydrazinium azide **2** is prepared via an ion exchange reaction with silver azide in aqueus solution. After removal of byproducts and water, **2** crystallizes from methanol.

$$[(CH_3)_3NNH_2]^+[I]^- + AgN_3 \xrightarrow[-\ AgI]{H_2O} [(CH_3)_3NNH_2]^+[N_3]^- \quad (2)$$

As mentioned for **1**, the vibrational spectra show the typical azide absorptions at 2055 cm^{-1} (ν_{as}, IR) and 1327 cm^{-1} (ν_s, Raman). The region around 3200 cm^{-1}, where NH vibrations typically occur, is different from *N,N,N*-trimethylhydrazinium iodide. Otherwise the vibrational spectra, ^{1}H-NMR and ^{13}C-NMR spectra are in agreement with the iodide.[13] The ^{14}N-NMR spectrum shows two signals for the azide ion at $\delta = -133$ (*N*N*N*) and −278 (N*N*N). The two signals of the hydrazinium ion give a very broad signal at $\delta = -306$. The compound has a melting point of 174°C and is not volatile. **2** is also very hygroscopic.

Crystal Structure of 2

Bond lengths and angles of **2** are similar to *N,N,N*-trimethylhydrazinium chloride.[14] The major difference is in the structure of the hydrogen bonds between the hydrazinium and the azide ions, explaining the different NH-vibrational bands in the vibrational spectra. The azide ion has four hydrogen bonds to adjacent hydrazinium ions. Each terminal azide nitrogen atom has two short hydrogen bonds to two hydrazinium ions of two different layers (2.20 Å and 2.17 Å). Another hydrazinium ion has two very long

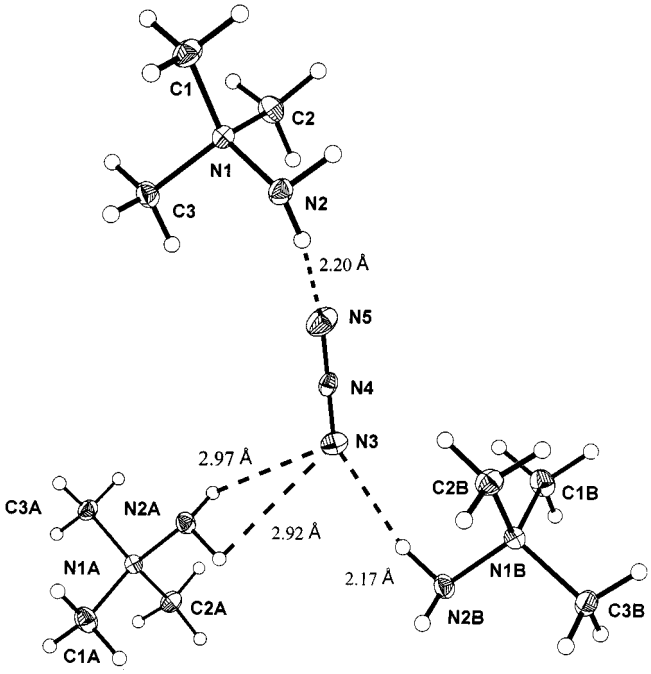

Figure 2. Molecular structure and atom numbering scheme of **2** as ORTEP plot (thermal ellipsoids represent 25% probability); selected bond lengths [Å] and angles [°] of **2**: N(1)−N(2) 1.459(1), N(1)−C(1) 1.489(2), N(1)−C(2) 1.497(2), N(1)−C(3) 1.493(2), N(3)−N(4) 1.180(2), N(4)−N(5) 1.163(2), N(2)−N(1)−C(1) 107.16(9), N(2)−N(1)−C(2) 109.4(1), N(2)−N(1)−C(3) 107.14(9), C(1)−N(1)−C(3) 109.8(1), C(1)−N(1)−C(2) 110.2(1), C(3)−N(1)−C(2) 109.4(1), N(5)−N(4)−N(3) 179.9(1).

hydrogen bonds of 2.92 Å and 2.97 Å to the terminal azide nitrogen atom that has the shorter bond length of 2.17 Å.

Tetraethylphosphonium azide lacks hydrogen bonds.[15] Therefore, there are only alternating layers of phosphonium and azide ions. In **2** there are also alternating layers of hydrazinium and azide ions. In contrast to tetraethylphos-

phonium azide the layer of the hydrazinium ions is ordered due to the hydrogen bonds.

Conclusion

The volatility of hydrazine azide can be reduced by attaching organic substituents to the hydrazine. The melting point of such substituted hydrazinium azides also rises. **1** and **2** have very symmetric crystal structures. In both compounds, hydrogen bridges are an important factor. Substance **2** is very hygroscopic, preventing its use for commercial purposes. Substance **1** does not show hygroscopicity, but has yet to be tested for its explosive properties

Experimental Section

General Remarks: ***CAUTION:*** Silver azide, hydrazoic acid, and compounds **1** and **2** are explosives. Safety equipment like leather gloves, face-shield, and ear plugs is recommended. The synthesis of **1** was carried out using standard schlenk-line techniques under dry nitrogen. Diethyl ether was purified by destillation over Na/benzophenone, methanol by destillation over Na. The destillates were stored under nitrogen. − *tert*-Butylhydrazine was prepared by the reaction of potassium hydroxide with *tert*-buylhydrazine dihydrochloride (Aldrich), *N,N,N*-Trimethylhydrazinium iodide was prepared by literature methods.[15] − NMR: Jeol EX 400 (^{1}H (400 MHz), ^{13}C (100 MHz): chemical shifts refer to $\delta_{TMS} = 0.00$; ^{14}N (28.6 MHz): external standard CH_3NO_2). − IR: Nicolet 520 FT-IR (as KBr pellets). − Raman: Perkin−Elmer FTIR-2000 spektrometer (Nd-Yag Laser: 1064 nm, Laser power: 100 mW, scattering angle: 90°). − CHN analysis: Elementar Vario EL analysator. − Melting points: Büchi B450.

***tert*-Butylhydrazinium Azide (1):** 45 mL of a 2 M solution of hydrazoic acid in ether were slowly added to 4.0 g (55 mmol) of anhydrous *tert*-butylhydrazine. A white precipitate was isolated and purified by sublimation at 10^{-3} Torr. Recrystallization from methanol yielded colorless prisms. Yield: 5.3 g (90%); m.p. 137°C. − IR (cm^{-1}): $\tilde{\nu}$ = 3428 w, 3319 m, 3194 w, 2981 w, 2828 vw, 2784 vw, 2696 vw, 2696 vw, 2506 w, 2037 s (ν_{as} N_3^-), 1605 m, 1490 w, 1469w, 1455 w, 1398 m, 1378 m, 1337 w, 1288 vw, 1254 vw, 1200 vw, 1121 m, 1031 w, 947 w, 924 w, 840 w, 728 w, 651 w and 639 vw (ν and δN_3^-), 619 vw, 518 w, 467 w, 356 w, 325 w. − Raman (cm^{-1}): $\tilde{\nu}$ = 3321 w, 3213 w, 2986 m, 2928 m, 2748 vw,2503 vw, 1509 vw, 1494 vw, 1460 w, 1340 s(ν_s N_3^-), 1289 w, 1223 w, 1120 w, 941.0 vw, 924 vw, 851 vw, 735 m, 652 vw, 517 m, 474 w, 365 w, 241 vw, 115 s. − ^{1}H NMR ([D6]DMSO): δ = 1.15 (s, 9 H, CH_3), 7.26 (s, 4 H, NH). − ^{13}C NMR ([D_6]DMSO): δ = 23.9 (CH_3), 57.4 (C quat.). − ^{14}N NMR ([D_6]DMSO): δ = −134 (*N*NN), −277 (N*N*N). − $C_4H_{13}N_5$ (131.18): calcd. ***N,N,N*-Trimethylhydrazinium Azide (2):** Silver azide was prepared by adding a solution of 7.94 g (53.3 mmol) of silver nitrate in 50 mL of water to a solution of 3.46 g (53.3 mmol) of sodium azide in 50 mL of water. Silver azide was filtered off and washed with water. The wet product was introduced to a solution of 4.12 g (20.3 mmol) *N,N,N*-trimethylhydrazinium iodide. Yellow silver iodide precipitated immediately. The reaction mixture was stirred over night, silver iodide was filtered off, and the water removed under vacuum. The crude product was washed with CH_2Cl_2 and recrystallized from methanol yielding 1.96 g (81%) of colorless needles. m.p. 174°C. − IR (cm^{-1}): $\tilde{\nu}$ = 3409 vw, 3358 m, 3316 vw, 3287 m, 3213 m, 3113 m, 2946 w, 2849 w, 2055 s, (ν_{as} N_3^-), 1632 s, 1485 s, 1467 m, 1450 w, 1397 m, 1292 m, 1159 m, 1068 w, 954 s, 922 m, 749 m, 504 m, 459 m. − Raman (cm^{-1}): $\tilde{\nu}$ = 3268 vw, 3140 w, 3034 m, 2952 m, 2876 vw, 1465 m, 1399 vw, 1327 s (ν_s N_3^-), 1246 m, 944 w, 913 w, 749 m, 465 w, 390 vw, 106 s. − ^{1}H NMR ([D_6]DMSO): δ = 3.25 (s, 9 H, CH_3), 6.21 (s, 2 H, NH). − ^{13}C NMR ([D_6]DMSO): δ = 57.1 (CH_3). − ^{14}N NMR ([D_6]DMSO): δ = −133 (*N*NN), −278 (N*N*N), −306 ($H_2NN(CH_3)_3$). − $C_3H_{11}N_5$ (117.15): calcd. C 30.76, H 9.46, N 59.78; found C 29.64, H 8.85, N 57.81.

Crystal Structure Determinations: Crystals of each compound were mounted on a glass fibre with a small amount of perflourether oil. Data was collected at 193 K on a Siemens P4 diffractometer, equipped with a Siemens CCD area detector with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). The structure was solved by direct methods (SHELXL 93 and 97).

Tri- and Tetranuclear Mixed-Metal Clusters Containing Alkyne Ligands: Synthesis and Structure of $[Ru_3Ir(CO)_{11}(RCCR')]^-$, $[Ru_2Ir(CO)_9(RCCR')]^-$, and $[HRu_2Ir(CO)_9(RCCR')]$

Vincent Ferrand,[a] Georg Süss-Fink,*[a] Antonia Neels,[a] and Helen Stoeckli-Evans[a]

Keywords: Cluster compounds / Ruthenium / Iridium / Alkynes / Butterfly structures

The tetrahedral cluster anion $[Ru_3Ir(CO)_{13}]^-$ (**1**) reacts with internal alkynes RC≡CR′ to afford the alkyne derivatives $[Ru_3Ir(CO)_{11}(RCCR')]^-$ (**2**: R = R′ = Ph; **3**: R = R′ = Et; **4**: R = Ph; R′ = Me; **5**: R = R′ = Me) which have a butterfly arrangement of the Ru_3Ir skeleton in which the alkyne is coordinated in a μ_4-η^2 fashion. Under CO pressure they undergo fragmentation to give the trinuclear cluster anions $[Ru_2Ir(CO)_9(RCCR')]^-$ (**6**: R = R′ = Ph; **7**: R = R′ = Et; **8**: R = Ph; R′ = Me; **9**: R = R′ = Me), in which the alkyne ligand is coordinated in a μ_3-η^2 parallel fashion. Protonation of these trinuclear anions leads to the formation of the corresponding neutral hydrido clusters $[HRu_2Ir(CO)_9(RC{\equiv}CR')]$ (**10**: R = R′ = Ph; **11**: R = R′ = Et; **12**: R = Ph; R′ = Me; **13**: R = R′ = Me). The protonation of the butterfly anions **2** and **3**, however, gives rise to the formation of the neutral tetrahedral clusters $[HRu_3Ir(CO)_{11}(RCCR')]$ (**14**: R = R′ = Ph and **15**: R = R′ = Et), respectively. The analogous clusters $[HRu_3Ir(CO)_{11}(PhCCCH_3)]$ (**16**) and $[HRu_3Ir(CO)_{11}(CH_3CCCH_3)]$ (**17**) are only accessible from the reaction of the neutral cluster $[HRu_3Ir(CO)_{13}]$ with the corresponding alkynes. The complexes **2**, **4**, **5**, **6**, **10**, **12** and **15** are characterised by X-ray structure analysis.

Introduction

The chemistry of mixed-metal clusters of transition metals has been studied in great detail in recent years,[1][2] stimulated by their possible catalytic potential and the combination of different metals in the same complex.[3a,3b] The mixed-metal cluster $Pt_3Ru_6(CO)_{20}(\mu_3\text{-}PhC_2Ph)(\mu_3\text{-}H)(\mu\text{-}H)$ has been shown by R. D. Adams et al. to be an very active catalyst for the hydrogenation of alkynes[3c−3e]. Tetranuclear clusters with the butterfly structure[4][5] have received much attention, due to their intermediary position between tetrahedral and square-planar clusters. They have been also considered as a model for chemisorption of small molecules,[6] and they have been studied as intermediates in homogeneous catalytic processes.[4,7,8] Both, metal atoms and ligands can vary widely in butterfly-type clusters, which determines, on the one hand, the structural properties of the butterfly framework and, on the other hand, the chemistry of the coordinated ligands.[4]

In a recent publication,[8] we have described the reactivity of the neutral tetrahedral cluster $[HRu_3Ir(CO)_{13}]$[9] towards alkynes and its catalytic potential in hydrogenation reactions. We now report the reaction of its precursor, the cluster anion $[Ru_3Ir(CO)_{13}]^-$[9] with internal alkynes, which affords anionic alkyne clusters of the type $[Ru_3Ir(CO)_{11}(RCCR')]^-$, and we also report on the reactivity of the latter anions towards CO and H^+.

Results and Discussion

Synthesis of the Cluster Anions $[Ru_3Ir(CO)_{11}(RCCR')]^-$ (2−5)

The thermal reaction of the tetrahedral cluster anion $[Ru_3Ir(CO)_{13}]^-$ (**1**) with the internal alkynes diphenylacetylene, 3-hexyne, 1-phenyl-1-propyne, or 2-butyne yields, at 90 °C in CH_2Cl_2 solution (pressure Schlenk tube), the alkyne derivatives $[Ru_3Ir(CO)_{11}(RCCR')]^-$ (**2**: R = R′ = Ph; **3**: R = R′ = Et; **4**: R = Ph; R′ = Me; **5**: R = R′ = Me) (Scheme 1). These anions can be isolated as the bis(triphenylphosphoranylidene)ammonium salts from a mixture of diethyl ether and hexane (**2**, **4**, and **5**), or from a mixture of ethanol and pentane (**3**). Complexes **2**, **4**, and **5** gave suitable crystals for X-ray structure analysis.

The infrared spectra of all the compounds display the same absorption pattern in the ν_{co} region, indicating the presence of terminal as well as bridging CO ligands (Table 1). The ^{1}H-NMR spectra of **2**−**5** are complicated by the multiplets of the $[N(PPh_3)_2]^+$ cation; for **2** and **4**, the resonances of the phenyl protons of the alkyne ligands overlap with the signals of the cation. In the case of **4** (containing an unsymmetrical alkyne ligand), only one singlet at δ = 2.82 is observed for the methyl group, indicating the presence of only one isomer. In the case of **3** and **5** (containing a symmetrical alkyne ligand), the two alkyl substituents on the alkyne are nonequivalent, suggesting the alkyne ligand to be coordinated in a nonsymmetrical fashion to the Ru_3Ir framework (Table 1). This is confirmed by the X-ray structure analysis of the bis(triphenylphosphoranylidene)ammonium salts of **2**, **4**, and **5**.

Molecular Structures of $[Ru_3Ir(CO)_{11}(RCCR')]^-$ (2, 4, and 5)

Suitable crystals of **2**, **4**, and **5** {$[N(PPh_3)_2]^+$ salts} were grown at room temperature from a mixture of diethyl ether and hexane. The molecular structures of the anions **2**, **4**, and **5** are depicted in Figures 1, 2, and 3, respectively. Selected bond lengths and angles of complexes **2**, **4**, and **5** are summarized in Tables 2, 3, and 4, respectively. The crystal structures consist of discrete $[N(PPh_3)_2]^+$ cations and $[Ru_3Ir(CO)_{11}(RCCR')]^-$ anions showing normal intermolecular contacts between the atoms of the ions. The cluster anions **2**, **4**, and **5** have the same overall structure: The four metal atoms form a butterfly skeleton where the iridium atom occupies a hinge position, whereas in the known cobalt analogue $[Ru_3Co(CO)_{11}(PhCCPh)]^-$,[10] obtained by reaction of $[Ru_3Co(CO)_{13}]^-$ with diphenylacetylene, the cobalt atom occupies a wingtip position. In other mixed-metal clusters anions with the butterfly core structure, such as $[Ru_3M(CO)_{10}Cp(CH_3CCCH_3)]^-$ (M = W, Mo)[11] and $[Co_3Ru(CO)_{10}(PhCCPh)]^-$,[12a] the single metal atom M always occupies a hinge position as found in **2**, **4**, and **5**.

All metal−metal distances in **2**, **4**, and **5** are different (Tables 2, 3, 4), but in the expected range for Ru−Ru and Ru−Ir single bonds.[4,8,9] In the three clusters, the coordination of the eleven carbonyl ligands is the same: While nine carbonyl groups are terminal, one CO ligand [C(6)O(6) in **2**, C(20)O(20) in **4**, C(10)O(10) in **5**] is bridging the Ir−Ru(3) edge, one CO ligand [C(10)O(10) in **2**, C(14)O(14) in **4**, C(15)O(15) in **5**] being coordinated to Ru(2) is semi-

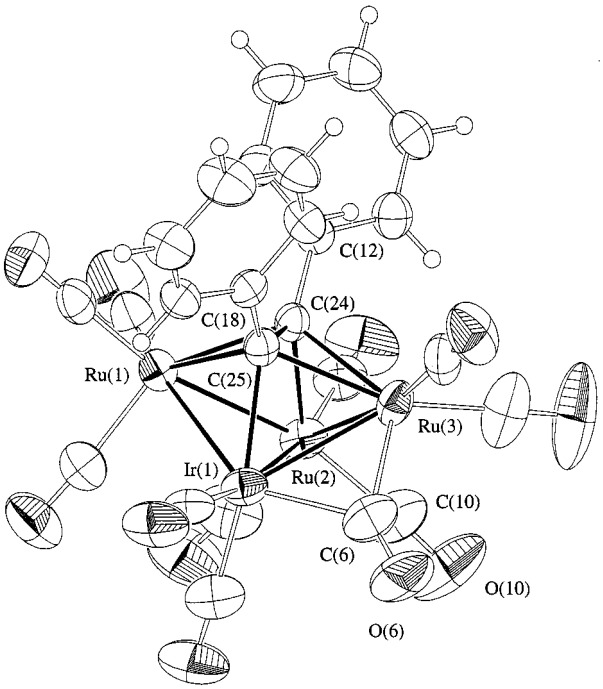

Figure 1. ORTEP plot of $[IrRu_3(CO)_{11}(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)]^-$ (anion **2**); thermal ellipsoids are drawn at 50% of propability

bridging to Ru(3) as indicated by the distances carbon−Ru(2) [**2**: C(10)−Ru(2) = 1.903(7) Å; **4**: C(14)−Ru(2) = 1.896(3) Å; **5**: C(15)−Ru(2) = 1.903(6) Å] and the carbon−Ru(3) [**2**: C(10)−Ru(3) = 2.8893(3) Å; **4**:

[a] Recorded in ether (**2**−**5**), CH_2Cl_2 (**6**−**9**, **14**−**17**), hexane (**10**−**12**, **13**). − [b] Measured in $CDCl_3$ solution at 294 K at 200 MHz (**2**, **4**−**6**, **9**, **10**, **12**−**15**, **17**). − [c] Measured in $CDCl_3$ solution at 294 K at 400 MHz (**3**, **7**, **8**, **11**, **16**). − [d] Measured in $CDCl_3$ solution at 215 K at 400 MHz (**7**, **8**).

C(14)−Ru(3) = 2.8115(3) Å; **5**: C(15)−Ru(3) = 2.8613(7) Å]. The angles C(10)−Ru(2)−Ru(3) = 73.7(2)° (**2**), C(14)−Ru(2)−Ru(3) = 71.86(10)° (**4**), C(15)−Ru(2)−Ru(3) = 73.00(19)° (**5**) are found to be similar to the angle observed in the cluster anion $[FeRu_3(CO)_{12}NO]^-$ [13] for a semibridging CO group.[14] These findings are comfirmed by the infrared spectra of **2**−**5** which exhibit a ν_{co} absorption around 1920 cm^{-1}.

The alkyne ligand in **2**, **4**, and **5** is coordinated to the Ru_3Ir metal core in a μ_4-η^2 fashion. One of the carbon atoms is σ-bonded to Ir, whereas the second one is σ-bonded to Ru(2), both carbon atoms being π-bonded to Ru(1) and Ru(3). This observation is confirmed by the ^1H-NMR spectra of **3** and **5** which display two different chemical shifts for the two ethyl or methyl substituents, respectively. The carbon−carbon bond is closer to Ru(1) than to Ru(3) in the three clusters, the torsion angle between the carbon−carbon backbone and the Ir(1)−Ru(2) edge is close to 0° [**2**: 0.0°(18); **4**: −0.04(11); **5**: 0.3°(2)] indicating that these two bonds are almost parallel.

With an electron count of 60e, **2**, **4**, and **5** are electron-deficient, since an M_4 butterfly cluster consistent with the noble-gas rule would require 62 electrons. However, considering **2**, **4**, and **5** as octahedral Ru_3IrC_2 clusters, an electron count of 60e is consistent with Wade's rules which predict a *closo* structure.[15]

Synthesis of $[Ru_2Ir(CO)_9(RCCR')]^-$ (6−9)

The cluster anions $[Ru_3Ir(CO)_{11}(RCCR')]^-$ (**2**: R = R′ = Ph; **3**: R = R′ = Et; **4**: R = Ph; R′ = Me; **5**: R = R′ = Me) undergo fragmentation of the metal core under CO pressure (2 bar) at 90 °C to give the trinuclear alkyne cluster anions $[Ru_2Ir(CO)_{11}(RCCR')]^-$ (Scheme 1). They can be isolated as the bis(triphenylphosphoranylidene)ammonium salts from a mixture of CH_2Cl_2 and diethyl ether (**6**) or from ethanol and pentane (**7**−**9**). The loss of metal fragments from a cluster has already been observed;[16][17] for example the cluster anion $[RuCo_3(CO)_{10}(\mu_4\text{-}\eta^2\text{-}C_2Ph_2)]^-$ can release a "Co(CO)" fragment to give the trinuclear complex $[RuCo_2(CO)_9(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)]$ in which the alkyne adopts a parallel coordination.[12][18]

The infrared spectra of **6**−**9** exhibit in the carbonyl region absorptions of only terminal CO ligands (Table 1). The room-temperature ^1H-NMR spectrum of **8** reveals, in addition to the signals of the $[N(PPh_3)_2]^+$ cation, two singlets for the methyl group of the MeCCPh ligand in a ratio of

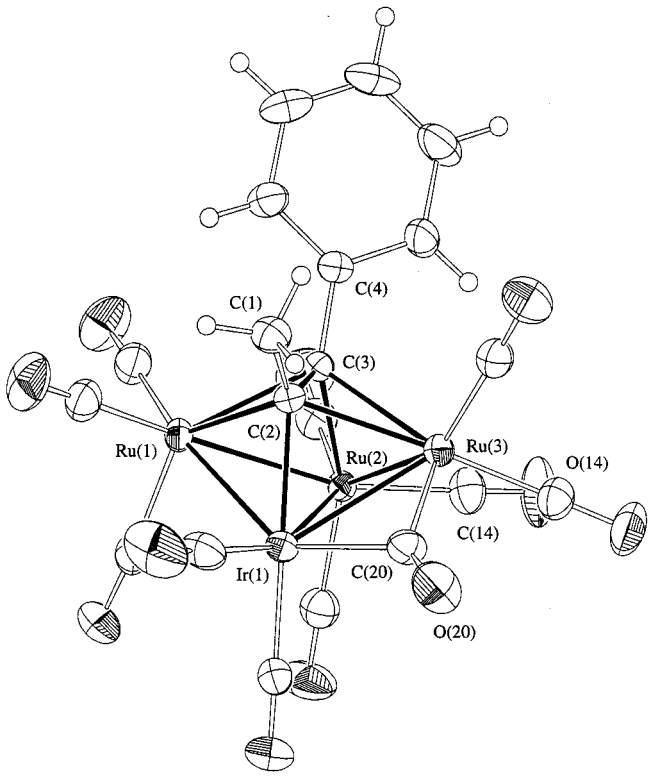

Figure 2. ORTEP plot of $[IrRu_3(CO)_{11}(\mu_4\text{-}\eta^2\text{-}PhCCMe)]^-$ (anion **4**); thermal ellipsoids are drawn at 50% of propability

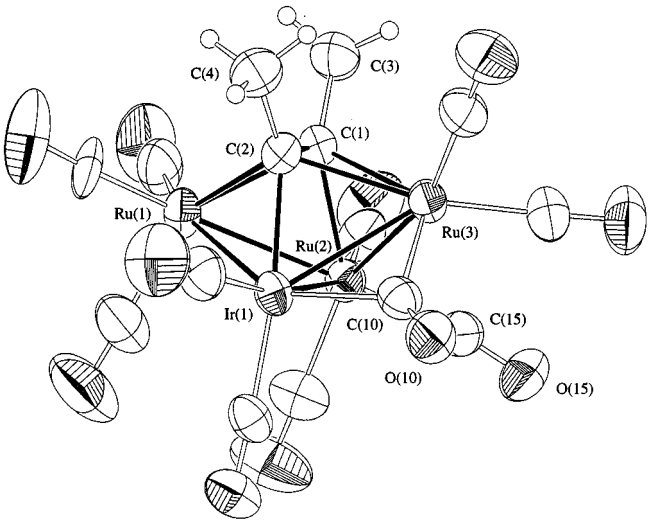

Figure 3. ORTEP plot of $[IrRu_3(CO)_{11}(\mu_4\text{-}\eta^2\text{-}C_2Me_2)]^-$ (anion **5**); thermal ellipsoids are drawn at 50% of propability

45:55. This ratio does not change down to −58 °C ($CDCl_3$), suggesting the presence of two isomers.[19−22] In the case of $[Ru_2Ir(CO)_9(MeCCMe)]^-$ (**9**), two singlets for the methyl substituents are observed in a ratio of 1:1, because the chemical environment of each CCH_3 moiety is different. The spectrum of $[Ru_2Ir(CO)_9(EtCCEt)]^-$ (**7**) is more complicated, presenting a temperature dependence of the signals of the ethyl substituents: At room temperature, four broad signals for the hydrogen atoms of the methylene groups are observed, resulting in four well-resolved multiplets at −58 °C, in a ratio of 1:1:1:1. In a selective decoupling experiment by irradiating at the resonances of the methyl proton, the four methylene multiplets resolve into four doublets with a coupling constant of 13 Hz, showing the protons of each methylene group to be diastereotopic (Table 1).[20,22a,22c,23a]

Molecular Structure of $[Ru_2Ir(CO)_9(PhCCPh)]^-$(6)

The molecular structure of **6** was confirmed by a single-crystal X-ray structure analysis of the bis(triphenylphosphoranylidene)ammonium salt. Suitable crystals were obtained by slow diffusion of diethyl ether into a concentrated dichloromethane solution at room temperature. The molecular structure of the anion is depicted in Figure 4. Selected bond lengths and angles are presented in Table 5. The crystal structure consists of discrete $[N(PPh_3)_2]^+$ cations and

$[Ru_2Ir(CO)_9(PhCCPh)]^-$ anions showing normal intermolecular contacts between the atoms of the ions. The ruthenium and iridium atoms of the cluster anion form a closed triangle in which all the metal−metal distances are different but within the range of Ru−Ru and Ir−Ru single bonds (Table 5). Each metal atom is bonded to three terminal CO groups.

Table 5. Selected bond lengths [Å], bond angles [°], and torsion angles [°] for the anion **6**; estimated standard deviations in parentheses

Ir(1)−Ru(1)	2.7120(8)	Ru(2)−C(1)	2.096(8)
Ir(1)−Ru(2)	2.7952(10)	Ru(2)−C(1)	2.096(8)
Ir(1)−C(2)	2.117(8)	C(1)−C(2)	1.363(11)
Ru(1)−Ru(2)	2.7084(11)	C(1)−C(2)−C(3)	125.4(7)
Ru(1)−C(1)	2.260(8)	C(2)−C(1)−C(9)	123.5(7)
Ru(1)−C(2)	2.246(8)	C(9)−C(1)−C(2)−C(3)	−9.8(13)

The alkyne ligand is coordinated in a classical μ_3-η^2 fashion over the metal triangle[18] as observed in $[Co_2Ru(CO)_9(C_2Ph_2)]$[12] The C(1)−C(2) backbone is almost parallel to the Ir(1)−Ru(2) edge [C(2)−Ir(1)−Ru(2)−C(1) 1.2(3)°]. The carbon atoms C(1) and C(2) are σ-coordinated to Ir(1) and Ru(2), respectively, and are both π-bonded to Ru(1).

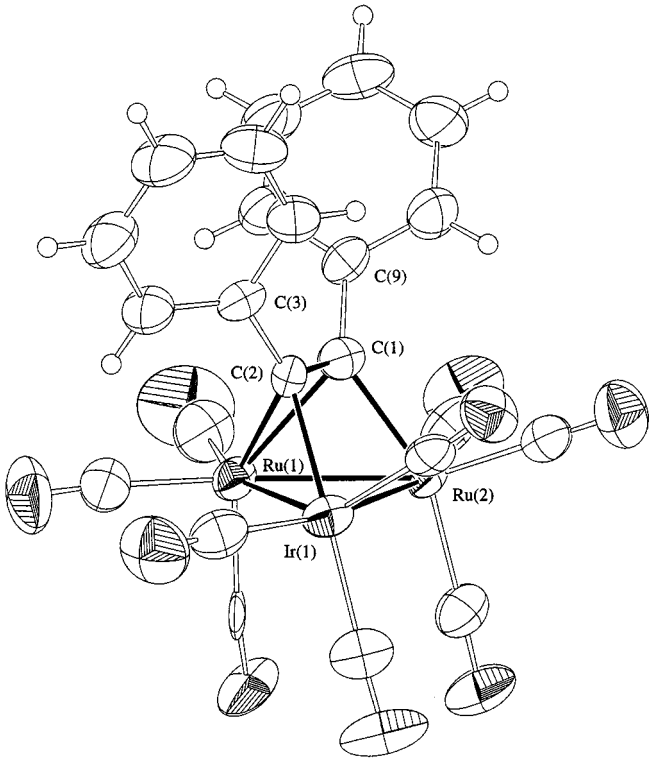

Figure 4. ORTEP plot of $[IrRu_2(CO)_9(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)]^-$ (anion **6**); thermal ellipsoids are drawn at 50% of propability

The carbon−carbon bond is shorter in **6** [C(1)−C(2) 1.363(11) Å] than in **2** [C(24)−C(25) 1.443(6) Å]. This is due to the coordination of the alkyne to only three metal atoms in **6** with respect to **2** where it is coordinated to four metal atoms. The carbon−carbon bond length in **6** [C(1)−C(2) 1.363(11) Å] compares well with that in $[Co_2Ru(CO)_9(C_2Ph_2)]$ (C−C 1.370(3) Å)[12] and related complexes in which the C−C bond length varies from 1.33 to 1.47 Å.[18] Clusters **6**−**9** have the expected electron count of 48e for trinuclear clusters which obey the noble gas rule.

Synthesis of $[HRu_2Ir(CO)_9(RCCR')]$ (10−13)

The reaction of the anions $[Ru_2Ir(CO)_9(RCCR')]^-$ (**6**−**9**) with an excess of $HBF_4 \cdot OEt_2$ at room temperature leads to the formation of the neutral hydrido clusters $[HRu_2Ir(CO)_9(RCCR')]$ (**10**: R = R′ = Ph; **11**: R = R′ = Et; **12**: R = Ph; R′ = Me; **13**: R = R′ = Me), which can be isolated by chromatographic methods and recrystallized from hexane at −18 °C (Scheme 1).

The infrared spectra of **10**−**13** display an almost identical ν_{co} absorption pattern in the region of terminal carbonyl ligands (Table 1). The ^{1}H-NMR spectra of **10**−**13** indicate, in addition to the signals of the alkyne substituents, the resonance of a bridging hydrido ligand at around δ = −15 (Table 1). In all cases, only one isomer is observed. For $[HRu_2Ir(CO)_9(EtCCEt)]$ (**11**) and $[HRu_2Ir(CO)_9(MeCCMe)]$ (**13**), the two ethyl or methyl groups are found to be nonequivalent.

Molecular Structure of $[HRu_2Ir(CO)_9(RCCR')]$ (10, 12)

Suitable crystals of $[HRu_2Ir(CO)_9(PhCCPh)]$ (**10**) and $[HRu_2Ir(CO)_9(PhCCMe)]$ (**12**) have been obtained from a concentrated hexane solution at −18 °C. The molecular structure of **10** is depicted in Figure 5 and that of **12** in Figure 6. Selected bond lengths and angles are presented in Tables 6 and 7. The crystal-structure analysis of **10** reveals two independent molecules per asymmetric unit of the unit cell, which have the same constitution, but differ slightly in bond lengths and angles.

The two clusters **10** and **12** have the same overall structure, showing the same carbonyl and alkyne coordination. The three metal atoms form a closed triangle. Each metal atom is bonded to three terminal CO groups. In both complexes the longer Ru(1)−Ru(2) distance [**10**: 2.7965(10); **12**: 2.7943(7) Å] suggests the presence of the hydrido bridge across this edge.

The alkyne ligand is coordinated in a μ_3-η^2 fashion over the Ru_2Ir framework as also found in cluster **6**. All carbon−carbon and carbon−metal distances compare well with those in other $M_3(\mu_3\text{-}\eta^2\text{-}RCCR')$ complexes.[18] The neutral complexes $[HRu_2Ir(CO)_9(RCCR')]$ (**10**−**13**) have, as the anions **6**−**9**, the expected electron count of 48e.

Reaction of $[Ru_3Ir(CO)_{11}(RCCR')]^-$ with $HBF_4 \cdot OEt_2$

Protonation of the anions $[Ru_3Ir(CO)_{11}(RCCR')]^-$ gives different results depending on the nature of the coordinated alkyne ligand. For R = R′ = Ph (**14**) or R = R′ = Et (**15**), the neutral hydrido complexes $[HRu_3Ir(CO)_{11}(PhCCPh)]$

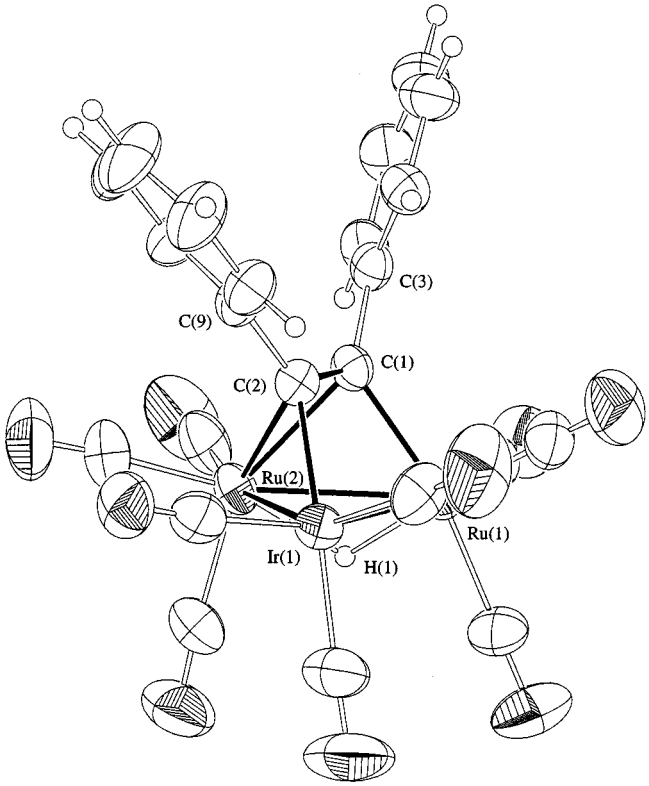

Figure 5. ORTEP plot of $[HIrRu_2(CO)_9(\mu_3\text{-}\eta^2\text{-}C_2Ph_2)]$ **10**; thermal ellipsoids are drawn at 50% of propability

(**14**) and $[HRu_3Ir(CO)_{11}(EtCCEt)]$ (**15**) are formed (Scheme 2). When R or R′ is a methyl group, the reaction does not afford the neutral hydrido complex, but leads to an unidentified green decomposition product. The expected clusters $[HRu_3Ir(CO)_{11}(PhCCMe)]$ (**16**) and $[HRu_3Ir(CO)_{11}$-(MeCCMe)] (**17**) are, however, accessible from the reaction of the neutral hydrido cluster $[HRu_3Ir(CO)_{13}]$ with the corresponding alkyne (Scheme 2). Clusters **14** and **17** have already been reported[8] and they are included here for the sake of completeness.

The infrared spectra of **14**−**17** display in the ν_{co} region the same absorption pattern: Five bands are assigned to terminal CO ligands and one absorption around 1840 cm^{-1} corresponds to a bridging CO group (Table 1). In the ^{1}H-NMR spectra of **14**−**17**, the hydrido ligand resonates as a singlet around $\delta = -19$. In **15** the ethyl substituents of the alkyne ligand are found to be equivalent, but the two hydrogen atoms of the methylene groups are diastereotopic (Table 1). The molecular structure of **15** is confirmed by a single-crystal X-ray structure analysis.

Molecular Structure of $[HRu_3Ir(CO)_{11}(EtCCEt)]$ (15)

Suitable crystals of **15** were grown at −18 °C in hexane. The molecular structure of **15** is depicted in Figure 7. Selected bond lengths and angles of **15** are listed in Table 8. The complex **15** has the same overall structure as found in **14** and **17**,[8] showing the same carbonyl, alkyne and hydride coordination pattern.

Scheme 2. Synthetic routes to clusters **14**−**17**

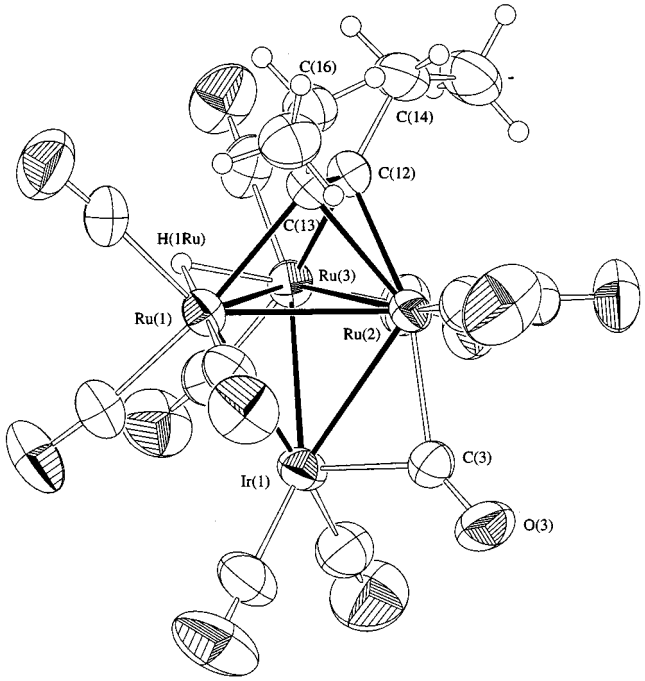

Figure 7. ORTEP plot of $[HIrRu_3(CO)_{11}(\mu_3\text{-}\eta^2\text{-}C_2Et_2)]$ **15**; thermal ellipsoids are drawn at 50% of propability

The four metal atoms form a tetrahedron in which the Ru−Ir distances vary from 2.7228(11) to 2.7833(8) Å and the Ru−Ru distances from 2.7981(10) to 2.8514(9) Å, in accordance with metal−metal single bonds.[8] The cluster **15** presents, as expected for a tetrahedral arrangement, an electron count of 60 e. The short distance Ru(2)−Ir [2.7228(11) Å] is due to the bridging carbonyl ligand over this edge. The base of the tetrahedron is composed of three ruthenium atoms. The longer Ru(1)−Ru(3) distance [2.8514(9) Å] suggests the presence of the hydrido bridge across this edge. Two of the three ruthenium atoms are bonded to three terminal CO groups, whereas Ru(2) and Ir are bonded to two terminal CO groups and share the bridging CO ligand. The alkyne is coordinated in a μ_3-η^2-bonding mode over the Ru_3 face of the tetrahedron. Due to the coordination of the alkyne group to the metal core, the carbon−carbon bond is lengthened [C(12)−C(13) 1.395(11) Å], but is in the range observed in **14**, **17**,[8] and other clusters such as $HCpWOs_3[\mu_3\text{-}\eta^2\text{-}C_2(Tol)_2]$.[24][25]

Conclusions

The Ru_3Ir framework shows a great fexibility with respect to the coordination of alkyne ligands: The tetrahedral metal skeleton in $[Ru_3Ir(CO)_{13}]^-$ (**1**) opens up upon coordination of an alkyne ligand to give a butterfly framework in $[Ru_3Ir(CO)_{11}(RCCR)]^-$ (**2**−**5**). Protonation of the butterfly clusters **2** and **3** leads, with closure of the Ru−Ru bond, back to a tetrahedral metal skeleton in the neutral clusters $[HRu_3Ir(CO)_{11}(RCCR')]$ (**14**−**15**). The second important

feature is the fragmentation of the tetranuclear anions in $[Ru_3Ir(CO)_{11}(RCCR)]^-$ (**2**−**5**) under CO pressure to give the trinuclear anions $[Ru_2Ir(CO)_9(RCCR)]^-$ (**6**−**9**). In a comparison of the 3-hexyne complexes, it is interesting to note that in the case of **3** and **11**, the two protons of the two different CH_2 groups of the 3-hexyne ligand are equivalent, whereas in **7** and **15** they are nonequivalent (diastereotopic). In the case of the tetranuclear cluster $[Ru_3Ir(CO)_{11}(EtCCEt)]^-$ (**3**) the averaging of the methylene protons may be explained by a carbonyl fluxionality involving the bridging and semi-bridging carbonyl ligands which could brigde equally well to both wingtip ruthenium atoms. In the case of the trinuclear cluster $[HRu_2Ir(CO)_9(EtCCEt)]$ (**11**), the μ_3-alkyne ligand itself might be fluxional on the trinuclear metal core, as observed in $[H_2Ru_3(CO)_9(EtCCEt)]$,[22a] $[Co_2Ru(CO)_9(EtCCEt)]$,[19] $[FeCo_2(CO)_9(EtCCEt)]$,[21] $[CpNiCoM(CO)_6(EtCCEt)]$ (M = Fe, Ru, Os),[23a] $[H_2Os_3(CO)_9(C_9H_6)]$.[23b]

Experimental Section

General: All reactions were carried out under pure nitrogen with standard Schlenk techniques. Solvents were destilled with appropriate drying agents, deoxygenated, and nitrogen-saturated prior to use.[26] − Preparative thin-layer chromatography was performed using 20 cm × 20 cm plates coated with Fluka silica gel G. The starting complexes $[Ru_3Ir(CO)_{13}]^-$ and $[HRu_3Ir(CO)_{13}]$ were prepared according to a published method.[9] − Diphenylacetylene was purchased from Fluka; 3-hexyne, 1-phenyl-1-propyne, and 2-butyne were purchased from Aldrich and used as recieved. − NMR spectra were recorded with a Varian Gemini 200 BB or a Bruker AMX 400 spectrometer, using the resonance of the residual protons of the deuterated solvents as reference. − Infrared spectra were recorded with a Perkin−Elmer 1720X FT IR spectrometer. − Micro-analyses were carried out by the Mikroelementaranalytisches Laboratorium of the ETH Zürich, Switzerland.

Preparations

$[N(PPh_3)_2][Ru_3Ir(CO)_{11}(RCCR')]$ (Anions 2−5): A solution of $[N(PPh_3)_2][Ru_3Ir(CO)_{13}]$ (anion **1**) (100 mg, $7.15\bullet10^{-2}$ mmol) in CH_2Cl_2 (30 mL) was stirred with an excess of RC≡CR′ (**2**: 38 mg, $21.46\bullet10^{-2}$ mmol; **3**: 24 μL, $21.46\bullet10^{-2}$ mmol; **4**: 27 μL, $21.46\bullet10^{-2}$ mmol; **5**: 17 μL, $21.46\bullet10^{-2}$ mmol) at 90 °C in a pressure Schlenk tube. During the reaction the pressure was released once. The reaction was followed by infrared spectroscopy; after 2.5 h, the IR spectrum in the ν_{CO} region indicated the complete desappearance of the starting complex **1**. Then the solvent was evaporated and the red-orange oil was washed three times with 10 mL of hexane to remove the excess of the unreacted alkyne. The residue was dissolved in 20 mL of Et_2O, and the solution was filtered. Dark-red air-stable crystals of the $[N(PPh_3)_2]^+$ salts of **2**, **4**, **5** were obtained by slow evaporation (room temperature) of a diethyl ether/hexane solution. The crystals were dried in vacuo. − **2**: Yield 92 mg (85%). − $C_{61}H_{40}IrNO_{11}P_2Ru_3$ (1520.36): calcd. C 48.19, H 2.65, N 0.92; found C 48.32, H 2.58, N 0.93. − **4**: Yield 83 mg (80%). − $C_{56}H_{38}O_{11}NP_2Ru_3Ir$ (1458.28): calcd. C 46.12, H 2.63, N 0.96, found C 45.94, H 2.37, N 1.00. − **5**: Yield 75 mg (75%). − $C_{51}H_{36}O_{11}NP_2Ru_3Ir$ (1396.22): calcd. C 43.87, H 2.60, N 1.00; found C 43.77, H 2.45, N 1.01. − For **3**, a different method of crystallisation was used. The filtered diethyl ether solution containing **3** was concentrated to dryness, the residue was dissolved in 10 mL of ethanol, followed by the dropwise addition of pentane until the solution became cloudy. Then the solution was cooled to −18 °C for a few days giving the $[N(PPh_3)_2]^+$ salt of **3** as dark-violet needles. The crystals were dried in vacuo. − **3**: Yield 76 mg (75%). − $C_{53}H_{40}IrNO_{11}P_2Ru_3 \bullet H_2O$ (1424.28): calcd. C 44.13, H 2.93, N 0.97; found C 43.96, H 2.76, N 1.02.

$[N(PPh_3)_2][Ru_2Ir(CO)_9(PhCCPh)]$ (Anion 6): A solution containing $[N(PPh_3)_2]$ $[Ru_3Ir(CO)_{11}(PhCCPh)]$ (anion **2**), prepared from 0.0715 mmol of **1** as described above, in Et_2O (20 mL) was placed in a pressure Schlenk tube and stirred at room temperature for 20 h under a pressure of 2 bar of CO. The colour changed from red-orange to wine-red, then to orange with precipitation of the $[N(PPh_3)_2]^+$ salt of **6** as a yellow powder. The precipitate was filtered off, washed with Et_2O (3 × 10 mL) and crystallised at room temperature by slow diffusion of Et_2O into a CH_2Cl_2 solution. The yellow crystals were dried in vacuo. **6**: Yield (with respect to **1**): 73 mg (75%). − $C_{59}H_{40}IrNO_9P_2Ru_2$ (1363.27): calcd. C 51.98, H 2.99, N 1.03; found C 51.68, H 2.99, N 1.04.

$[N(PPh_3)_2][Ru_2Ir(CO)_9(RCCR')]$ (Anions 7, 8, 9): A solution containing $[N(PPh_3)_2][Ru_3Ir(CO)_{11}(RCCR')]$ (**3**: R = R′ = Et; **4**: R = Ph; R′ = Me; **5**: R = R′ = Me), prepared from 0.0715 mmol of **1** as described above, in CH_2Cl_2 (25ml) was placed in a pressure Schlenk tube and stirred at 90 °C for 45 min under a pressure of 2 bar of CO. The colour changed, from red-orange to wine-red, then to orange. After removal of the solvent, the orange residue was washed with hexane (3 × 10 ml) to remove $Ru_3(CO)_{12}$ formed during the reaction. The remaining orange oil was dried and dissolved in 5−10 mL of ethanol, followed by the addition of pentane until the solution became cloudy. In the case of **8** no pentane was added. Then the solution was cooled to −18 °C for a few days which gave the $[N(PPh_3)_2]^+$ salt of **7** as yellow-orange crystals and the $[N(PPh_3)_2]^+$ salts of **8** and **9** precipitated as a yellow-brown powder. The solids were dried in vacuo. − **7**: Yield (with respect to **1**): 51 mg (56%). − $C_{51}H_{40}IrNO_9P_2Ru_2 \bullet 2.5\ H_2O$ (1267.19): calcd. C 46.65, H 3.42, N 1.06; found C 46.42, H 3.02, N 1.11. − **8**: Yield (with respect to **1**): 56 mg (60%). − $C_{54}H_{38}IrNO_9P_2Ru_2$ (1301.20): calcd. C 49.85, H 2.94, N 1.08; found C 49.66, H 3.16, N 1.16. − **9**: Yield (with respect to **1**): 49 mg (55%). − $C_{49}H_{36}IrNO_9P_2Ru_2$ (1239.13): calcd. C 47.50, H 2.93, N 1.13; found C 47.24, H 3.13, N 1.19.

$[HRu_2Ir(CO)_9(RCCR')]$ (10−13): To a solution of $[N(PPh_3)_2]$-$[Ru_2Ir(CO)_9(RCCR')]$ (anions **6**: R = R′ = Ph; **7**: R = R′ = Et; **8**: R = Ph; R′ = Me; **9**: R = R′ = Me) (0.0370 mmol) in CH_2Cl_2 (30 mL) a slight excess of $HBF_4 \bullet OEt_2$ (54%, 60 μL) was added under stirring. After 30 min, the solvent was evaporated, and the residue was dissolved in the minimum quantity of CH_2Cl_2. The solution was separated by thin-layer chromatography with a mixture of CH_2Cl_2 and hexane (1:6) as eluent. The yellow band containing the product was extracted with CH_2Cl_2, followed by concentration to dryness. The resulting yellow oil was dissolved in hexane and cooled to −18 °C to give yellow crystals of **10**−**13**. The crystals were dried in vacuo. − **10**: Yield 21 mg (68%). − $C_{23}H_{11}IrO_9Ru_2$ (825.69): calcd. C 33.46, H 1.34; found C 33.48, H 1.32. − **11**: Yield 18 mg (66%). − $C_{15}H_{11}IrO_9Ru_2$ (729.61): calcd. C 24.69, H 1.52; found C 24.51, H 1.54. − **12**: Yield 17 mg (60%). − $C_{18}H_9IrO_9Ru_2$ (763.62): calcd. C 28.31, H 1.19; found C 28.40, H 1.24. − **13**: Yield 16 mg (62%). − $C_{13}H_7IrO_9Ru_2$ (701.55): calcd. C 22.26, H 1.01; found C 22.12, H 1.04.

$[HRu_3Ir(CO)_{11}(RCCR')]$ (14−15): To a solution of $[N(PPh_3)_2]$-$[Ru_3Ir(CO)_{11}(RCCR')]$ (**2**: R = R′ = Ph; **3**: R = R′ = Et), prepared from 0.0715 mmol of $[N(PPh_3)_2]$**1** as described above, in 20 mL of Et_2O was added a slight excess of $HBF_4 \bullet OEt_2$ (54%,

60 μL). After 30 min at room temperature, the white precipitate was filtered off, washed twice with 10 mL of Et_2O and then discarded. The solution was concentrated, the residue dissolved in CH_2Cl_2 (2 mL) and submitted to thin-layer chromatography (silica gel, CH_2Cl_2/hexane, 1:3). The product was extracted from the orange main band with CH_2Cl_2 and crystallised from hexane at

−18 °C. The orange air-stable crystals were dried in vacuo. − **14**: Yield (starting from **1**) 36 mg (51%). − **15**: Yield (starting from **1**) 29 mg (45%) − $C_{17}H_{11}IrO_{11}Ru_3$ (886.69): calcd. C 23.02, H 1.25; found C 23.21, H 1.30.

[$HRu_3Ir(CO)_{11}$(PhCCMe)] (16): A solution of [$HRu_3Ir(CO)_{13}$][9] (83 mg, 0.096 mmol) and PhC≡CMe (18 μL, 0.145 mmol) in hexane (30 mL) was stirred at 80−85 °C in a pressure Schlenk tube. During the reaction, the pressure was released once. After 1 h, the solution changed colour from red to orange. After removal of the solvent, the dark orange residue was dissolved in 5 ml of CH_2Cl_2 and submitted to thin-layer chromatography (silica gel, CH_2Cl_2/hexane, 1:3). From the orange main band, **16** was extracted with CH_2Cl_2 and crystallised from hexane at −18 °C. The orange air-stable crystals were dried in vacuo. − **16**: Yield 27 mg (31%) − $C_{20}H_9IrO_{11}Ru_3$ (920.71): calcd. C 26.09, H 0.99; found, C 26.02, H 0.99.

X-ray Structure Analyses: Single crystals of **2**, **4**, **5, 6**, **10**, **12**, and **15** were obtained as described under Preparations. Selected crystallographic data for the complexes are summarised in Tables 9 and 10, and selected bond lengths and bond angles are listed in Tables 2−8. Single-crystal X-ray diffraction data of the $[N(PPh_3)_2]^+$ salts of **2** and **4** were collected at room temperature and −50 °C, respectively with a Stoe Imaging Plate Diffractometer System (Stoe & Cie, 1995) equipped with a one-circle goniometer and a graphite monochromator. 200 exposures (3 min per exposure) were obtained at an image-plate distance of 70 mm with $0° < \phi < 200°$ and with the crystal oscillating through 1° in φ. The $[N(PPh_3)_2]^+$ salts of **5** and **6** and complexes **10**, **12**, and **15** were measured at room temperature with a Stoe-Siemens AED2 four-circle diffractometer using Mo-K_α graphite-monochromated radiation (λ = 0.71073 Å; ω-2θ scans). The structures of the $[N(PPh_3)_2]^+$ salts of **2**, **4**, **5**, **6**, and that of complex **15** were solved by direct methods, whereas those of **10** and **12** were solved by Patterson methods using the program SHELXS-97.[27] All the structures were refined by full-matrix least squares on F^2 with SHELXL-97.[28] The salt $[N(PPh_3)_2]$**2** crystallises with a quarter of a disordered molecule of hexane. The five carbon atoms C62A, C62B, C63A, C63B, and C64 were refined isotropically using the SHELXL-97 default parameters. In compounds $[N(PPh_3)_2]$**5** and $[N(PPh_3)_2]$**6** one of the carbonyl ligands is found to be disordered and has been split into C6A-O6A and C6B-O6B (anion **5**), C21A-O21A and C21B-O21B (anion **6**), respectively, with an occupancy of a half for each atom. The position of the hydride ligands in **10**, **12**, and **15** were located from Fourier difference maps and refined isotropically, while the remaining hydrogen atoms of the methyl, ethyl or phenyl substituents were included in calculated positions and treated as riding atoms with SHELXL-97 default parameters. For $[N(PPh_3)_2]$**4**, an empirical absorption correction was applied using DIFABS[29] and for $[N(PPh_3)_2]$**5**, $[N(PPh_3)_2]$**6**, **10** **12**, **15** it was based on ψ scans.[30] The Figures were drawn with ORTEP[31] (thermal ellipsoids, 50% probability level). Complete tables of bond lengths and angles and lists of thermal parameters have been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk], on quoting the deposition numbers CCDC-111752−111758.

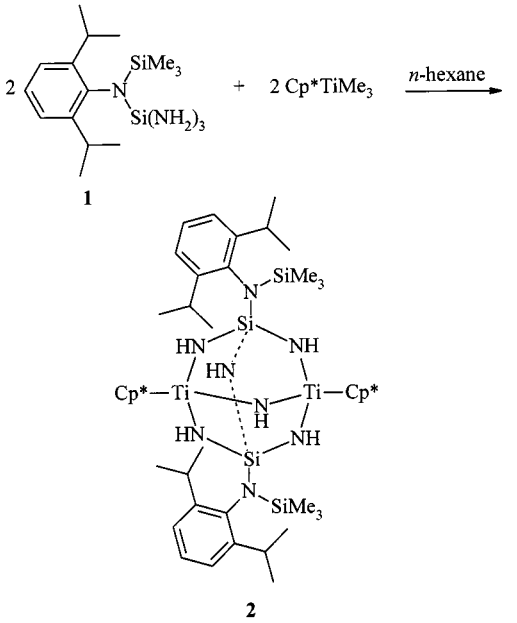
Dedicated to Professor John P. Fackler on the occasion of his 65th birthday



Keywords: Germanium / Nitrogen / Silicon / Titanium

The reaction of $dippNSiMe_3Si(NH_2)_3$ (**1**) (dipp = 2,6-$iPr_2C_6H_3$) with Cp^*TiMe_3 ($Cp^* = C_5Me_5$) and Me_3SnCl yields the new heterocyclic adamantane $(dippNSiMe_3Si)_2(Cp^*Ti)_2(NH)_6$ (**2**) containing the $Si_2Ti_2(NH)_6$ core and the silicon–nitrogen six-membered ring compound $[dippNSiMe_3Si(NH_2)NH]_3$ (**4**). $[dippNSiMe_3Ge(NH_2)_2]_2NH$ (**5**) reacts with $AlMe_3$ to give the germanium–nitrogen six-membered ring compound $[dippNSiMe_3Ge(NH_2)NH]_3$ (**6**). The compounds **2**, **4** and **6** have been structurally characterized by single-crystal X-ray structural analysis.

Introduction

Beyond the investigation of silanetriols as building blocks for new catalysts, the reactions of the isoelectronic triaminosilanes with organometallic precursors are of broad interest for materials research.[1][2] In 1995 we described the reaction of $dippNSiMe_3Si(NH_2)_3$ (**1**) with Cp^*TiMe_3 to yield a silicon−nitrogen−titanium four-membered ring system. Furthermore, we reported on the reaction of **1** and Me_3SnCl forming a compound with a monosubstituted nitrogen−tin bond. Moreover, in 1997 we published reactions of triaminosilanes with alumazene and $AlMe_3$. The reaction with alumazene forms a compound with an adamantane-like core.[3−5] Consequently, in 1998 we synthesized and published the first germanium compound containing more than one terminal amino group.[6]

Herein, we describe the reactions of $dippNSiMe_3Si(NH_2)_3$ with Cp^*TiMe_3 and Me_3SnCl under more drastic conditions and the reaction of $[dippNSiMe_3Ge(NH_2)_2]_2NH$ (**5**) with $AlMe_3$.

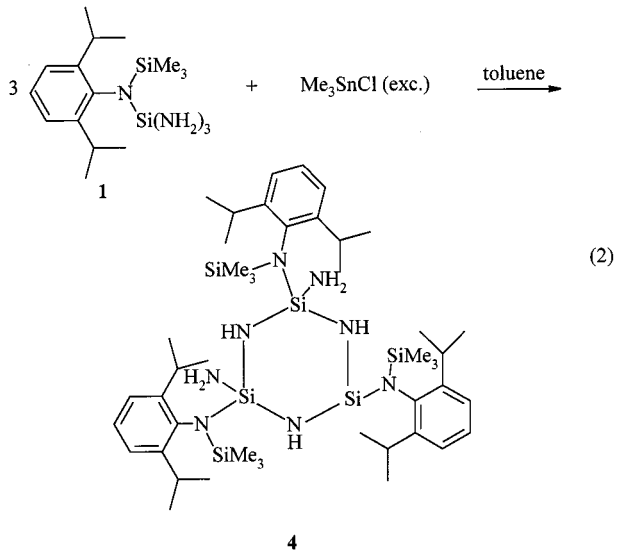
Scheme 1. Synthesis of compound **2**

Results and Discussion

Synthesis and Spectra

$dippNSiMe_3Si(NH_2)_3$ (**1**), prepared from $dippNSiMe_3SiCl_3$ and ammonia, reacts with Cp^*TiMe_3 in *n*-hexane under reflux with evolution of methane gas (Scheme 1) to give $(dippNSiMe_3Si)_2(Cp^*Ti)_2(NH)_6$ (**2**).

Compound **2** was characterized by mass spectrometry, NMR-spectral studies and by single-crystal X-ray diffraction. The proton-NMR spectrum of **2** shows a multiplet (δ = 7.19) due to the aromatic protons of the dipp-ligand. Resonances at δ = 4.05, 3.70 and 1.25 can be attributed to the methylene and methyl protons of the *i*Pr group, respectively. The signal of the methyl protons of the Cp* ligand appear as a singlet (δ = 1.91). The signal of the N−H protons is found at δ = 0.67, and the signals of the methyl protons of the $SiMe_3$ groups are observed at δ = 0.27 and 0.21. Thus, it is clear that the two $SiMe_3$ groups are in slightly different environments, and in solution the rigid structure is maintained.



The mass spectrum of the compound shows the molecular ion peak $[M^+]$ at *m*/*z* 1009 and a signal at *m*/*z* 994 due to the fragment $[M^+ - CH_3]$.

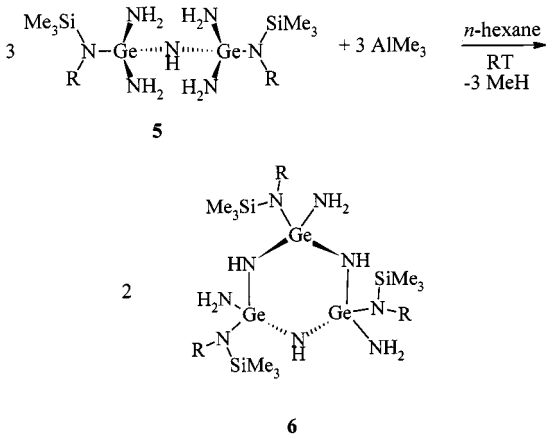
Recently, we reported that compound **1** reacts with Me_3SnCl under smooth conditions to yield the monosubstituted derivative $dippNSiMe_3Si(NH_2)_2NHSnMe_3$ (**3**).[3] However, we were interested to obtain the fully substituted compound $dippNSiMe_3Si(NHSnMe_3)_3$.

Therefore we treated **1** with Me_3SnCl in toluene under reflux for 6 h and subsequent workup afforded compound $[dippNSiMe_3Si(NH_2)NH]_3$ (**4**) instead (Scheme 2).

(2)



Scheme 2. Synthesis of compound **4**

Compound **4** was characterized by elemental analysis, NMR spectroscopy, mass spectrometry, and by single-crystal X-ray diffraction. The proton-NMR spectrum of **4** shows a multiplet (δ = 7.10) due to the aromatic protons of the dipp ligand. Resonances at δ = 3.67 and 1.31 can be attributed to the methylene and methyl protons of the *i*Pr group, respectively. The signals of N−H protons and unreacted NH_2 protons are found at δ = 0.65 and 0.75, and the signals of the methyl protons of the $SiMe_3$ groups are observed at δ = 0.12, 0.10 and 0.06.

The IR spectrum of **4** shows three absorptions ($\tilde{\nu}$ = 3401, 3486 and 3152 cm^{-1}), which are due to the N−H stretching frequencies. The mass spectrum of **4** exhibits an intense peak at *m/z* 906 [$M^+ - NH_2$].

The reaction to give compound **4** can be described as an "acid-catalyzed" condensation reaction. The intermediate **3** we had previously isolated and characterized is a product of the reaction of an amino group that functions as a Lewis base and the tin atom of Me_3SnCl as a Lewis acid. Finally, the cleavage of tin−chlorine and N−H bond takes place yielding HCl.[3] The condensation reaction occurred three times under evolution of ammonia. Due to steric reasons only the molecule containing the six-membered ring is formed.

$[dippNSiMe_3Ge(NH_2)_2]_2NH$ (**5**), prepared from $dippNSiMe_3GeBr_3$ and ammonia, reacts with $AlMe_3$ in *n*-hexane at room temperature with evolution of methane gas (Scheme 3) to yield $[dippNSiMe_3Ge(NH_2)NH]_3$ (**6**). So far we were not able to characterize any other by-products.

(3)

Scheme 3. Synthesis of compound **6**; R = dipp

Compound **6** was characterized by elemental analysis, NMR spectroscopy, mass spectrometry, and single-crystal X-ray diffraction analysis. The proton-NMR spectrum of **6** exhibits a multiplet (δ = 7.04) due to the aromatic protons of the dipp ligands. Resonances at δ = 3.60, 1.25 and 1.20 can be attributed to the methylene and methyl groups of the *i*Pr group, respectively. The signals of the N−H protons are found at δ = 0.70 and 0.65. The integration ratio of the intensities of the two N−H resonances is 1:2. We assign the signal at δ = 0.70 to the protons of the bridging N−H group. In the silicon-NMR spectrum we observed one signal (δ = 4.8) associated with the $SiMe_3$ group.

The IR spectrum of **6** shows three bands ($\tilde{\nu}$ = 3309, 3386, 3619 cm^{-1}) due the N−H stretching frequencies. The mass spectrum of **6** exhibits an intense peak at *m/z* 1040 [M^+ − Me].

X-ray Structures of 2, 4 and 6

The structure of compound **2** was determined by single-crystal X-ray structural analysis. Compound **2** crystallizes in the space group $P2_1/n$. The structure can be described as a distorted heterocyclic adamantane (Figure 1). The centroid distance of Ti−Cp* is 206 pm and the angles involving this distance are in the range of 116 to 119°. The dipp ligands and Cp* ligands are in staggered positions.

The titanium−nitrogen bond lengths are in the range of 189.9−196.4 pm and are comparable to those of the Ti−N_2−Si four-membered ring, and the average Si−N bond length (171.9−175 pm) is comparable to that in **1** (169−172 pm).[3]

The N−Ti−N angles (99.7−101.0°) are somewhat smaller than the tetrahedral bond angles, but the N−Si−N bond angles (106.1−109.9°) are in the range of a regular tetrahedron.

The central unit of the structure of **4** can be described as a six-membered ring consisting of alternating silicon and nitrogen atoms (Figure 2).

Ti(1)−N(6)−Ti(2)	122.0(2)		

Compound **4** crystallizes in the space group $P-1$. The silicon−nitrogen bond lengths within the ring are of nearly equal size (170 pm), and they are comparable to those in the starting material dippNSiMe$_3$Si(NH$_2$)$_3$ (average 171 pm). The bond angles N−Si−N (in the range of 102.63−104.46°) and Si−N−Si (in the range of 131.53−134.79°) are part of a distorted six-membered ring.

The atoms Si(1, 2, 3) and N(1, 3) are forming a plane while N(2) is out of the plane (61.57 pm), giving an envelope conformation.

The central unit of the structure of compound **6** is analogous to that of **4** (Figure 3).

Compound **6** crystallizes in the space group $P-1$. The Ge−N bond lengths in the ring are in the range of 181.9−182.8 pm. They are comparable to those described by George et al. in the six-membered ring of [(*t*BuS)$_2$Ge(NH)]$_3$.[7] The N−Ge−N bond angles are nearly 104° and the Ge−N−Ge angles (in the range of 124.8−127.6°) are part of a distorted (GeN)$_3$ six-membered ring system.

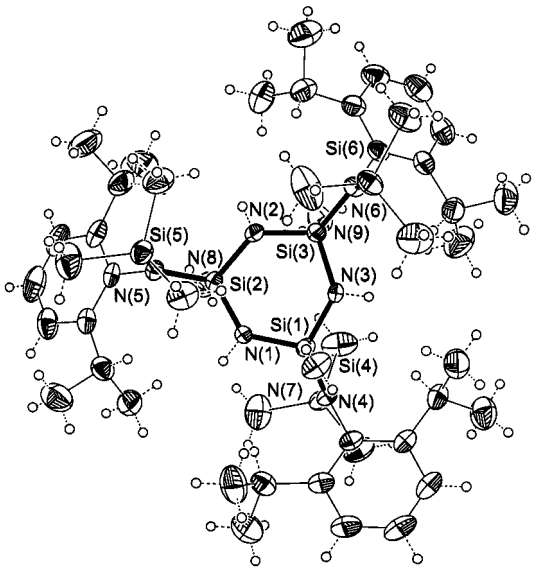

Figure 2. Crystal structure of **4**

Table 2. Selected bond lengths [pm] and angles [°] of compound **4**

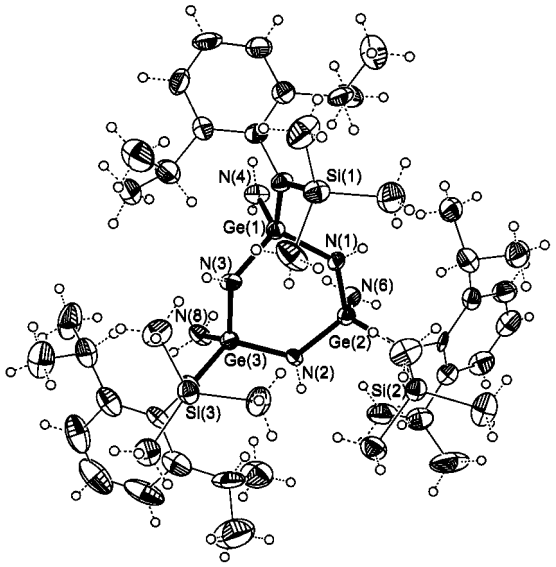

Figure 3. Crystal structure of **6**

The atoms Ge(1, 2) and N(2, 3) are forming a plane while Ge(3) and N(1) are out of the plane (19.2 and −19.2 pm), giving a chair conformation.

Conclusion

In summary, we have shown that silicon and germanium compounds containing terminal NH$_2$ groups are interesting

starting materials for preparing new inorganic ring systems with functional groups. A marked difference in reactivity has been observed while Cp*$TiMe_3$ yields the $Si_2Ti_2(NH)_6$ adamantane core, the main-group reagents Me_3SnCl and $AlMe_3$ lead to six-membered $(SiN)_3$ and $(GeN)_3$ condensation products.

Experimental Section

General: Due to the water and air sensitivity of the compounds, oxygen and moisture were excluded during all procedures. ^{1}H-NMR data were recorded with a Bruker AM 200 FT NMR spectrometer, IR data were recorded with a BIO RAD Digilab FTS 7 spectrometer and mass data with a Finnigan MAT 95 and a Varian MAT CH5 spectrometer. Elemental analyses were performed by the analytical laboratory of the institute. The starting materials dippNSiMe_3Si$(NH_2)_3$ and Cp*$TiMe_3$ were prepared by literature methods.[3][8] Me_3SnCl and dippNH_2 were commercially available.

Synthesis of 2: To a solution of 0.46 g (2 mmol) of Cp*$TiMe_3$, in *n*-hexane (8 ml), was added dropwise a solution of 0.65 g (2 mmol) of **1**, dissolved in 6 mL of *n*-hexane, at room temperature while stirring. The reaction mixture was warmed up to 69°C until the gas evolution ceased (3 h). The solvent was removed in vacuo and recrystallization of **2** from *n*-hexane (5 mL) afforded single crystals of **2**; yield 0.8 g (79%) (m.p. 260°C). −$C_{50}H_{88}N_8Si_4Ti_2$ (1008.71): calcd. C 61.39, H 9.38; found C 61.81, H 9.48. − IR (Nujol): $\tilde{\nu}$ = 3365 cm^{-1}, 3409, 3481 (N−H). − ^{1}H NMR (200 MHz, C_6D_6): δ = 0.21 [s, 9 H, Si(CH_3)$_3$], 0.27 [s, 9 H, Si(CH_3)$_3$], 0.67 (s, 6 H, NH), 1.25 [m, 24 H, CH(CH_3)$_2$], 1.91 (s, 30 H, CH_3, Cp*), 3.70 [sept, 2 H, CH(CH$_3$)$_2$], 4.05 [sept, 2 H, CH(CH$_3$)$_2$], 7.19 (m, 6 H, aromatic H). − ^{29}Si NMR (49 MHz, C_6D_6): δ = −38.7 (*Si*NH), 3.1 (*Si*Me_3). − MS (EI); *m*/*z* (%): 1009 (100) [M$^+$].

Synthesis of 4: 0.65 g (2 mmol) of **1** and 1.19 g (6 mmol) of Me_3SnCl were dissolved in 20 mL of toluene. Then the reaction mixture was warmed up to 111°C for 6 h. Removal of solvent and Me_3SnCl in vacuo afforded a white solid and recrystallization of the crude product from *n*-hexane (3 mL) gave colorless single crystals of **4**; yield 0.48 g (78%) (m.p. 260°C). − $C_{45}H_{87}N_9Si_6$ (922.07): calcd. N 13.68, Si 18.28; found N 12.65, Si 18.14. − IR (Nujol): $\tilde{\nu}$ = 3401 cm^{-1}, 3486, 3152 (N−H). − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.06 [s, 9 H Si(CH_3)$_3$], 0.10 [s, 9 H Si(CH_3)$_3$], 0.12 [s, 9 H Si(CH_3)$_3$], 0.65 [s, 3 H, Si(NH)NH$_2$], 0.75 [s, 6 H, Si(NH)NH_2], 1.31 [m, 36 H, CH(CH_3)$_2$], 3.67 [m, 6 H, CH(CH$_3$)$_2$], 7.10 (m, 9 H, aromatic H). − ^{29}Si NMR (49 MHz, $CDCl_3$): δ −43.1 [*Si*(NH)NH$_2$], −41.4 [*Si*(NH)NH$_2$], −39.8 [*Si*(NH)NH$_2$], 4.2 (*Si*Me_3), 4.7 (*Si*Me_3), 5.3 (*Si*Me_3). − MS (EI); *m*/*z* (%): 906 (80) [M$^+$ − NH$_2$], 905 (100) [M$^+$ − NH$_2$ − H].

Synthesis of 6: To a solution of 0.62 g (2 mmol) of **5** in *n*-hexane (10 mL) was added dropwise 0.53 mL of a solution of $AlMe_3$ in *n*-hexane (1.6 M) at room temperature. After 2 h, the evolution of methane ceased. Subsequently, the solvent was removed in vacuo and the colorless solid recrystallized from *n*-hexane/trichloromethane (1:1) to give single crystals of **6**; yield 0.6 g (67%) (m.p. 177°C). − $C_{45}H_{87}Ge_3N_9Si_3$ (1055.64): calcd. H 8.24, Ge 20.63; found H 7.94, Ge 19.63. − IR (KBr): $\tilde{\nu}$ = 3309 cm^{-1}, 3386, 3619 (N−H). − ^{1}H NMR (200 MHz, C_6D_6): δ = 0.21 [s, 27 H, Si(CH_3)$_3$], 0.65 [s, 6 H, Ge(NH_2)NH], 0.70 [s, 3 H, Ge(NH$_2$)NH], 1.20 [d, 18 H, CH(CH_3)$_2$], 1.25 [d, 18 H, CH(CH_3)$_2$], 3.60 [sept, 6 H, CH(CH$_3$)$_2$], 7.04 (m, 9 H, aromatic H). − ^{29}Si NMR (49 MHz, C_6D_6): δ = 4.8 (*Si*Me_3). − MS (EI); *m*/*z* (%): 73 (90) [$SiMe_3$], 1040 (100) [M$^+$ − Me].

Crystal Structure Determination of Compounds 2, 4 and 6: Data collection and processing: Intensity data were collected using the ω-2θ scan method at 153(2) K for **2**, 193(2) K for **4** and 150(2) K for **6** with a Siemens AED2 four-circle diffractometer using graphite-monochromated Mo-K_α radiation (λ = 71.073 pm) and according to the Learnt-Profile Method.[9] Of the 11865 reflections measured of compound **2** (3.51° ≤ θ ≤ 22.56°) 8424 were unique (merging R = 0.0468), of the 12450 reflections measured of compound **4** (3.51° ≤ θ ≤ 22.55°) 7708 were unique (merging R = 0.0238) and of the 16520 reflections measured of compound **6** (3.52° ≤ θ ≤ 25.04°) 11734 were unique (merging R = 0.1137). All of the reflections were used in the refinement. − X-ray crystallographic study: The structures were solved by direct methods (SHELXS-90)[9] and refined against F^2 by means of the full-matrix least-squares technique using SHELXL 93 and SHELXL 97.[10][11] The weighting schemes were $w^{-1} = \sigma^2(F_o^2) + (0.080 \cdot P)^2 + 18.55 \cdot P$ for **2**, $w^{-1} = \sigma^2(F_o^2) + (0.040 \cdot P)^2 + 1.95 \cdot P$ for **4** and $w^{-1} = \sigma^2(F_o^2) + (0.20 \cdot P)^2 + 0 \cdot P$ for **6** with $P = (F_o^2 + 2F_c^2)/3$ were applied in the final cycles of refinement. The converged residuals were $R1$ = 0.0791 for reflections with $I > 2\sigma(I)$, and $wR2$ = 0.1798 for all data of **2**, the converged residuals were $R1$ = 0.0791 for reflections with $I > 2\sigma(I)$, and $wR2$ = 0.0.0909 for all data of **4** and the converged residuals were $R1$ = 0.1066 for reflections with $I > 2\sigma(I)$, and $wR2$ = 0.2625 for all data of **6**. A final Fourier difference map showed the largest peak and hole 904 and −520 e nm^{-3} for **2**, 331 and −358 e nm^{-3} for **4** and 218.3 and 142.2 e nm^{-3} for **6**. All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were located in positions riding on the corresponding C atoms.

Synthesis of $(RSn)_4X_6$ Adamantanes (X = O, S, Se) in Liquid Ammonia and in the Two-Phase System Liquid Ammonia/THF

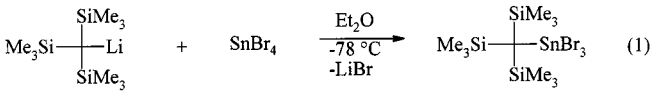
Karsten Wraage,[a] Thomas Pape,[a] Regine Herbst-Irmer,[a] Mathias Noltemeyer,[a] Hans-G. Schmidt,[a] and Herbert W. Roesky*[a]

Dedicated to Professor Dietmar Seyferth on the occasion of his 70th birthday

Keywords: Adamantane / Liquid ammonia / Oxygen / Sulfur and selenium / Tin

The reactions of $trisSnBr_3$ (**1**) [tris = $(Me_3Si)_3C$] and nBuSnCl$_3$ with Na_2X (X = O, S, Se) yield the heterocyclic adamantanes **2**–**6**. The reaction of **1** with Na_2O is carried out in liquid ammonia under normal pressure at –78 °C to give $(trisSn)_4O_6$ (**2**). However, the reaction of **1** with Na_2S and Na_2Se under pressure at room temperature results in the formation of $(trisSn)_4S_6$ (**3**) and $(trisSn)_4Se_6$ (**4**). nBuSnCl$_3$ reacts with Na_2S and Na_2Se in liquid ammonia at –33 °C under normal pressure to give $(n\text{BuSn})_4S_6$ (**5**) and $(n\text{BuSn})_4Se_6$ (**6**), respectively.

Introduction



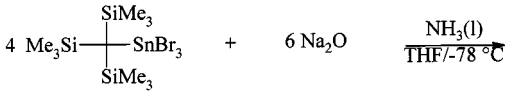
Compounds of the type $(RE)_4X_6$ (E = Si, Ge, Sn; X = S, Se) with an adamantane or a double-decker structure have been reported.[1–3] Unno et al. described the synthesis of $(RE)_4X_6$ compounds (E = Si and Ge; X = S and Se), with a double-decker structure, which afforded the corresponding adamantane upon heating.[1] Another contribution by Berwe and Haas dealt with the reaction of $RSnCl_3$ with $Na_2S \cdot 9\,H_2O$ and $Me_3SiSSiMe_3$, where a heterocyclic adamantane $(RSn)_4S_6$ was reported to be the major product.[2]

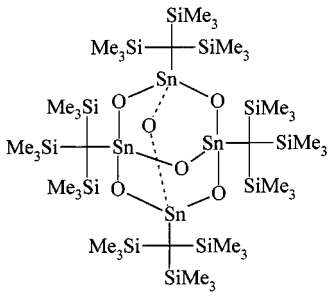
Herein the synthesis of the hitherto unknown $trisSnBr_3$ (**1**) [tris = $(Me_3Si)_3C$] and a general method for the preparation of $(RSn)_4X_6$ [R = tris; X = O (**2**), S (**3**), Se (**4**); R = nBu; X = S (**5**), Se (**6**)] are reported.

Results and Discussion

Synthesis and Spectra

$trisSnBr_3$ (**1**) is easily obtained by the treatment of tin tetrabromide with tris(trimethylsilyl)methyllithium in diethyl ether (Equation 1).[4] Compound **1** is a colorless, sublimable crystalline solid, whereas n-butyltin trichloride is a liquid.



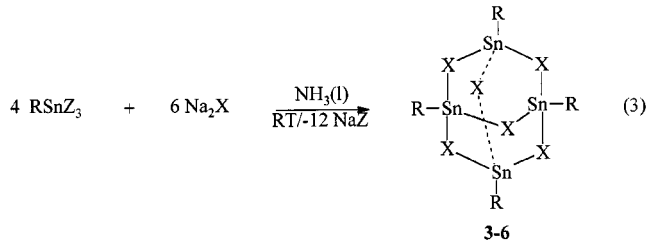


(1)

1

Compound **1** was characterized by mass spectrometry and NMR-spectral studies. The ^{1}H-NMR spectrum of **1** gives a singlet at δ = 0.32 for the protons of the methyl groups of the tris ligand, and ^{119}Sn- and ^{29}Si-NMR spectra also show singlets (at δ = −237.4 and 1.8, respectively). The mass spectrum exhibits a peak at m/z 575 [M^+ − Me]. The spectral data and elemental analysis confirm the composition of the compound to be $C_{10}H_{27}Br_3Si_3Sn$ (**1**).

Compound **1** reacts with Na_2X (X = O, S, Se) in liquid ammonia to give $(RSn)_4X_6$ [R = tris; X = O (**2**), S (**3**), Se (**4**)]. While Na_2O reacts with **1** at − 78 °C under normal pressure in liquid ammonia, Na_2S and Na_2Se, generated in situ in liquid ammonia at −78 °C, react under pressure in liquid ammonia (Equations 2 and 3). The formation of Na_2S and Na_2Se in situ is indicated by a color change of the reaction medium from blue to yellow and red, respectively.



(2)

2

The proton-NMR spectrum of $(trisSn)_4O_6$ (**2**) shows four singlets (δ = 0.13, 0.24, 0.28, 0.51), as does the ^{29}Si-NMR spectrum (δ = −1.0, −0.42, −0.27, −0.17), which indicates that the tris groups are not equivalent. However, the four tin atoms are equivalent and the compound gives only one ^{119}Sn resonance (δ = 94.3). The mass spectrum exhibits the molecular ion peak at m/z (%) 1496 (100) [M^+].

R = tris, *n*-Bu Z = Cl, Br X = S, Se

Compounds $(trisSn)_4S_6$ (**3**) and $(trisSn)_4Se_6$ (**4**) were characterized by elemental analysis, multinuclear NMR spectra and mass spectrometry. Unlike in the case of **2**, the ^{1}H-NMR spectra of both compounds **3** and **4** show singlets at $\delta = 0.22$ and 0.20, respectively. Similarly, the ^{29}Si-NMR spectra of **3** and **4** give singlets at $\delta = 4.5$. This indicates that in both compounds the tris ligands are equivalent, unlike in the case of **2**. The ^{119}Sn-NMR spectrum of **3** shows a singlet ($\delta = 72.8$) which is downfield shifted compared to that of **1** ($\delta = -237.4$) due to the formation of the heterocyclic adamantane. It should be pointed out that ^{119}Sn- and ^{77}Se-NMR spectra could not be recorded in the case of **4** due to its instability in solution. Compound **4** decomposed with the formation of selenium. The same behavior was observed for the corresponding tellurium derivative.

The mass spectrum of **3** exhibits two intense peaks (*m*/*z* 1594 [M^+], 1579 [$M^+ - CH_3$]). However, no molecular ion peak [M^+] could be observed for compound **4**, instead a peak at *m*/*z* (%) 1645 (100) [M^+ − tris] was observed.

Similar to **1**, *n*BuSnCl$_3$ reacts with Na_2S and Na_2Se in liquid ammonia at refluxing temp. (−33°C) to give $(n\text{BuSn})_4S_6$ (**5**) and $(n\text{BuSn})_4Se_6$ (**6**), respectively.

Compounds **5** and **6** were characterized by elemental analysis, mass spectrometry and multinuclear NMR-spectral studies. The ^{1}H-NMR spectra of **5** and **6** give a typical spectral pattern due to the *n*butyl group. The ^{119}Sn-NMR spectra of **5** and **6** show singlets at $\delta = 144$ and −22, respectively. This difference in resonances is due to the difference in electronegativities of S and Se. The ^{77}Se-NMR spectrum of **6** exhibits a singlet at $\delta = -169.9$. Thus, the NMR-spectral studies agree well with the proposed adamantane structure. The mass spectrum of **5** shows a peak at *m*/*z* (%) 839 (70) [M^+ − *n*-butyl]. **6** is characterized in the gas phase by two peaks: first the molecular ion peak at *m*/*z* (%) 1177 (20) and second the fragment at *m*/*z* (%) 1120 (90) [M^+ − *n*-butyl].

In all cases we were unable to detect the coupling constants of ^{117}Sn/^{119}Sn, ^{119}Sn/^{77}Se and ^{119}Sn/^{29}Si.

X-ray Structures of 2 and 3

The structure of **2** (see Figure 1) shows a highly symmetric, regular adamantane core (point group *T*) consisting of tin and oxygen atoms. This geometry is defined by a threefold axis through the Sn−C bond and three equivalent twofold axes through two opposite O atoms, so that only 1/12 of the whole molecule exists in the asymmetric unit. Due to this symmetry, each of the Sn atoms shows a distorted tetrahedral geometry with three equivalent bridging oxygen atoms and a terminal tris(trimethylsilyl)methyl group heading away from the core. All Sn−O bond lengths are equal [196.8(1) pm], as well as the Sn−C bond lengths [213.4(3) pm] and the corresponding bond angles [O−Sn−O 103.8(1)°, O−Sn−C 114.7(1)°]. Two solvent molecules of benzene exist close to the special position 1/4, 1/4, 0 and appear to rotate freely.

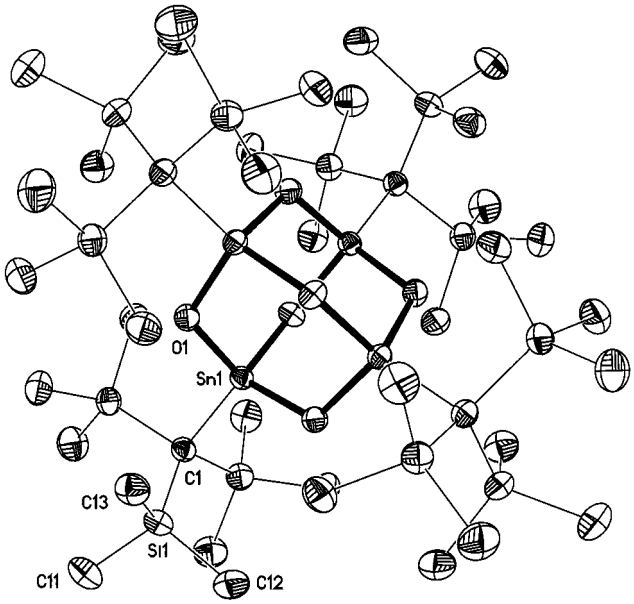

Figure 1. Crystal structure of **2**

3 (see Figure 2) is isomorphous with **2** but the O atoms are replaced by S. This substitution leads to longer bonds in the adamantane core [Sn−S 240.8(3) pm] and a longer Sn−C bond [223(2) pm] in **3**, causing the terminal tris(trimethylsilyl)methyl group to be disordered. Because of this

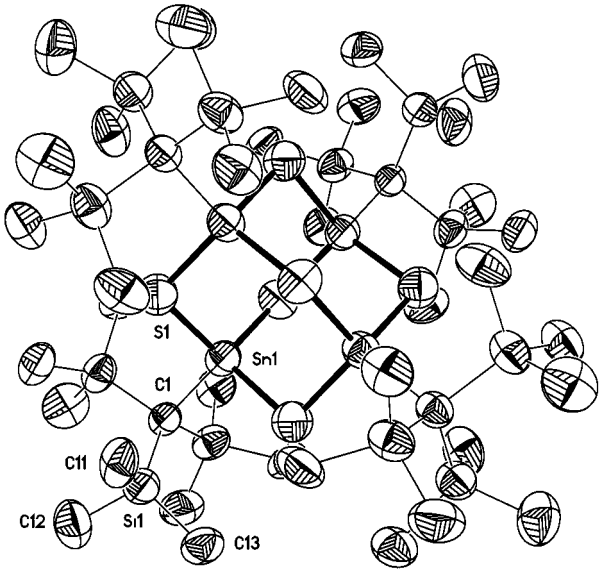

Figure 2. Crystal structure of **3**

disorder a mirror plane is added to the symmetry of the data, the space group is *Fd*−3*m* instead of *Fd*−3 as in **2**.

Conclusion

In summary, we have shown that tin adamantanes containing the chalcogens oxygen, sulfur and selenium are easily accessible using liquid ammonia as a reaction media. The structure of $(trisSn)_4O_6$ has been shown to have the most regular adamantane core of this series

Experimental Section

General: All reactions were carried out under dry nitrogen using Schlenk techniques and a drybox. Solvents were dried and distilled under nitrogen prior to use. − ^{1}H NMR (200 MHz): Bruker AM 200. − ^{29}Si NMR (49.7 MHz), ^{119}Sn NMR (93.3 MHz), ^{77}Se NMR (47.7 MHz): Bruker AC 250 NMR, tetramethylsilane, tetramethyltin and dimethylselenium, respectively, as external standards. − MS: Bruker AM 200 MS, Bruker MSL 400 MS . − M.p.: Bühler SPA-1. − The starting materials trisLi[4] and Na_2X (X = S, Se)[5] were prepared by literature methods. Tin tetrabromide and *n*-butyltin trichloride were commercially available.

Synthesis of 1: A solution of $(trisLi)_2 \cdot 4$ THF (4.4 g, 5.7 mmol, dissolved in 40 mL of diethyl ether) was added dropwise to a solution of $SnBr_4$ (5.0 g, 11.4 mmol, dissolved in 30 mL of diethyl ether) at −78°C while stirring. The reaction mixture was allowed to warm up to room temp., and the residue was dissolved in 50 mL of *n*-hexane and the precipitate of lithium bromide filtered off. 50% of the solvent was removed in vacuo. Recrystallization of the crude product at −30°C afforded 6.0 g (89%) of a colorless crystalline solid (sublimation at 155°C). − ^{1}H NMR (200 MHz, C_6D_6): δ = 0.32 {s, 27 H, $C[Si(CH_3)_3]_3$}. − ^{29}Si NMR (49.7 MHz, C_6D_6): δ = 1.8 [$C(SiMe_3)_3$]. − ^{119}Sn NMR (93.3 MHz, C_6D_6): δ = −237.4 ($trisSnBr_3$). − MS (EI); *m*/*z* (%): 575 (100) [M^+ − Me].

Synthesis of 2: Na_2O (0.093 g, 1.5 mmol) was suspended in 30 g of liquid ammonia at −78°C. **1** (0.59 g, 1 mmol) was dissolved in 20 mL of THF and added dropwise to the suspension of Na_2O while stirring. The reaction mixture was cooled at −78°C for 6 h and then warmed up slowly to room temp. THF was removed in vacuo. The remaining solid was dissolved in 50 mL of *n*-hexane, the precipitate of sodium bromide filtered off and the filtrate concentrated in vacuo. The residue was a white solid (0.28 g, 80%). Recrystallization from benzene resulted in colorless single crystals (m.p. > 250°C). − $C_{40}H_{108}Si_{12}Sn_4O_6$ (1398.38): calcd. C 32.11, H 7.71; found C 31.9, H 7.7. − ^{1}H NMR (200 MHz, C_6D_6): δ = 0.13 {s, 27 H, $C[Si(CH_3)_3]_3$}, 0.24 {s, 27 H, $C[Si(CH_3)_3]_3$}, 0.28 {s, 27 H, $C[Si(CH_3)_3]_3$}, 0.51 {s, 27 H, $C[Si(CH_3)_3]_3$}. − ^{29}Si NMR (49.7 MHz, C_6D_6): δ = −1.0 ($SiMe_3$), −0.42 ($SiMe_3$), −0.27 ($SiMe_3$), −0.17 ($SiMe_3$). − ^{119}Sn NMR (93.3 MHz, C_6D_6): δ = 94.3 (Sn_{ad}) (ad = adamantane). − MS (EI); *m*/*z* (%): 1496 (100) [M^+], 1481 (75) [M^+ − Me].

Synthesis of 3: Sulfur (0.096 g, 3 mmol) was suspended in liquid ammonia in a glass autoclave at −78°C. Sodium (0.138 g, 6 mmol) was added to the suspension while stirring. The stirring was continued until the color changed from blue to yellow. Solid **1** (1.18 g, 2 mmol) was added to the stirred suspension of sodium sulfide, and the glass autoclave was closed. The reaction mixture was allowed to warm up to room temp. After 25 min, the color of the reaction mixture changed from yellow to green. After 24 h, the autoclave was opened and the liquid ammonia vaporized. Subsequently, the residue was dissolved in 20 mL of toluene, the sodium bromide filtered off and the filtrate concentrated in vacuo. Recrystallization from benzene afforded 0.6 g (75%) of yellow crystals (decomp. 168°C). − $C_{40}H_{108}S_6Si_{12}Sn_4$ (1593.56): calcd. C 30.15, H 6.78, S 12.07, Si 21.15; found C 31.3, H 7.1, S 11.8., Si 21.3. − ^{1}H NMR (200 MHz, C_6D_6): δ = 0.22 {s, 108 H, 4 $C[Si(CH_3)_3]_3$}. − ^{29}Si NMR (49.7 MHz, C_6D_6): δ = 4.5 ($SiMe_3$). − ^{119}Sn NMR(93.3 MHz, C_6D_6): δ = 72.8 (Sn_{ad}). − MS (EI); *m*/*z* (%): 1579 (100) [M^+ − Me], 1594 (45) [M^+].

Syntheses of 4: Compound **4** was synthesized in an analogous manner to that of **3**. The reaction and isolation afforded 0.38 g (81%) of a yellow/red powder (decomp. 195−205°C). − $C_{40}H_{108}Se_6Si_{12}Sn_4$ (1874.92): calcd. C 25.62, H 5.81; found C 26.0, H 5.7. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.20 {s, 108 H, $C[Si(CH_3)_3]_3$}. − ^{29}Si NMR (49.7 MHz, $CDCl_3$): δ = 4.5 ($SiMe_3$). − MS (EI); *m*/*z* (%): 1645 (100) [M^+ − tris].

Synthesis of 5: Sulfur (0.144 g, 4.5 mmol) was suspended in 40 g of liquid ammonia in a 100-mL Schlenk flask at −78°C. Sodium (0.207 g, 9 mmol) was slowly added to this mixture. The reaction mixture was stirred until it became yellow. nBuSnCl_3 (0.847 g, 3 mmol) was then added to the suspension which was then allowed to warm up to −33°C and refluxed in liquid ammonia for 2 h. The liquid ammonia vaporized overnight. The residue was dissolved in 20 mL of *n*-hexane, the precipitate of sodium chloride filtered off and the filtrate concentrated in vacuo, yielding 0.3 g (45%) of a yellow powder (decomp. 130°C). − $C_{16}H_{36}S_6Sn_4$ (895.7): calcd. C 21.46, H 4.05, S 21.48; found C 20.9, H 4.2, S 22.3. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.85−0.95 (t, 12 H, CH_3CH_2-$CH_2CH_2Sn_{ad}$), 1.35−1.50 (m, 8 H, $CH_3CH_2CH_2CH_2Sn_{ad}$), 1.70−1.80 (m, 16 H, $CH_3CH_2CH_2CH_2Sn_{ad}$). − ^{119}Sn NMR (93.3 MHz, $CDCl_3$): δ = 144 (Sn_{ad}). − MS (EI); *m*/*z* (%): 839 (70) [M^+ − nBu], 655 (100) [M^+ − nBu − Sn − 2 S].

Synthesis of 6: Selenium (0.355 g, 4.5 mmol) was suspended in 40 g of liquid ammonia in a 100-mL Schlenk flask at −78°C. Sodium (0.207 g, 9 mmol) was added slowly to this mixture while stirring, until the solution became red. Finally, *n*-butyltin trichloride (0.847 g, 3 mmol) was added. After warming up to −33°C, the mixture was refluxed for 5 h. The liquid ammonia was vaporized overnight. The residue was dissolved in 20 mL of *n*-hexane, the precipitated sodium chloride filtered off and the solvent removed in vacuo to yield 0.6 g (68%) of a yellow powder (decomp. 118°C). − $C_{16}H_{36}Se_6Sn_4$ (1177.06): calcd. Sn 40.34; found Sn 40.5. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.90−1.00 (t, 12 H, 4 CH_3-$CH_2CH_2CH_2Sn_{ad}$), 1.35−1.55 (sext, 8 H, 4 $CH_3CH_2CH_2CH_2Sn_{ad}$), 1.65−1.80 (quint, 8 H, 4 $CH_3CH_2CH_2CH_2Sn_{ad}$), 1.90−1.98 (t, 8 H, 4 $CH_3CH_2CH_2CH_2Sn_{ad}$). − ^{119}Sn NMR (93 MHz, $CDCl_3$): δ = −22 (Sn_{ad}). − ^{77}Se NMR (47 MHz, $CDCl_3$): δ = −165.5 (Sn_{ad}-$Se_{1.5ad}$). − MS (EI); *m*/*z* (%): 1120.4 (90) [M^+ − nBu], 1177 (20) [M^+].

X-ray Crystallographic Study:[6] Crystals were grown by cooling a saturated solution of benzene (**2**) or benzene/trichloromethane (**3**) to 8°C and then mounted on a glass fiber in a rapidly cooled perfluoro polyether.[7] − Crystal data for **2**: $C_{40}H_{108}O_6Si_{12}Sn_4$ + 3 C_6H_6, M = 1731.43, space group *Fd*−3, a = 2541.2(3) pm, V = 16.41(10) nm^3, Z = 8, $\rho_{calcd.}$ = 1.402 g cm^{-3}, data collection: Stoe-Siemens-Huber four-circle diffractometer, coupled to a Siemens CCD area detector, graphite-monochromated Mo-K_α radiation, crystal size 0.5 × 0.4 × 0.4 mm, all measurements at 133(2) K, φ- and ω-collecting mode, 4.5° ≤ 2θ ≤ 59.5°, 92370 reflections measured, 1940 unique (R_{int} = 0.0270), 1795 with $I > 2\sigma(I)$, 1.419 mm^{-1} absorption coefficient, semi-empirical absorption correction from

equivalents (0.5373−0.6007 transmission factors). Data/restraints/parameters: 1940/181/124, final $R1 = 0.0265$ for $I > 2\sigma(I)$ and $wR2 = 0.0635$ for all data $\{R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$, $w^{-1} = \sigma^2(F_o)^2 + (0.0180{\cdot}P)^2 + 79.5121{\cdot}P$, $P = [F_o^2 + 2F_c^2]/3\}$, largest peak and hole in final diff. map = 642 and −745 e nm^{-3}. − Crystal data for **3**: $C_{40}H_{108}S_6Si_{12}Sn_4 + 1.57\ C_6H_6 + 0.43\ CHCl_3$, $M = 1767.39$, space group $Fd{-}3m$, $a = 2554.1(3)$ pm, $V = 16.66(10)$ nm^3, $Z = 8$, $\rho_{calcd.} = 1.409$ g cm^{-3}, data collection: Stoe-Siemens-AED2 four-circle diffractometer, graphite-monochromated Mo-K_α radiation, crystal size 0.5 × 0.4 × 0.4 mm, all measurements at 150(2) K, learnt-profile method, $7.8° \le 2\theta \le 49.3°$, 6642 reflections measured, 713 unique ($R_{int} = 0.1007$), 544 with $I > 2\sigma(I)$, data/restraints/parameters: 713/33/76, final $R1 = 0.0673$ for $I > 2\sigma(I)$ and $wR2 = 0.2304$ for all data, $w^{-1} = \sigma^2(F_o)^2 + (0.1268{\cdot}P)^2 + 304.6513{\cdot}P$, largest peak and hole in final diff. map = 1260 and −1049 e nm^{-3}. − Structural analysis and refinement: Both structures (see Tables 1 and 2) were solved by direct methods using SHELXS-97[8] and refined against F^2 on all data by full-matrix least squares with SHELXL-97.[9] All non-hydrogen atoms except those of the solvent molecules were refined anisotropically. Hydrogen atom positions were calculated from idealized geometries and refined using a riding model. In **2** solvent benzene molecules close to the special position 1/4, 1/4, 0 could not be resolved properly, and were refined using strong restraints on geometry and displacement parameters. Special position constraints were suppressed. In **3** the electron density for the solvent showed an even more disordered site than in **2** so that the solvent molecules were refined as a rigid benzene molecule and a strongly restrained trichloromethane molecule. The two molecules share the same position, the sum of their occupation factors is 1. Since this model does not describe the true situation very well the difference electron density is comparitively high. The severe disorder in structure **3** leads to a significantly worse refinement compared to structure **2**.

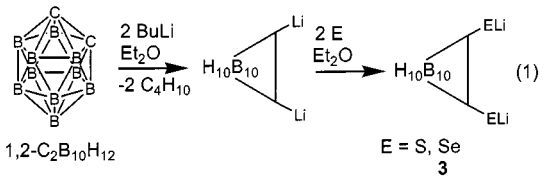
The NMR-Spectroscopic and X-ray Crystal-Structural Characterization of Two Cp*Ir Halfsandwich Complexes Containing the 1,2-Dicarba-*closo*-dodecaborane-1,2-diselenolato Ligand

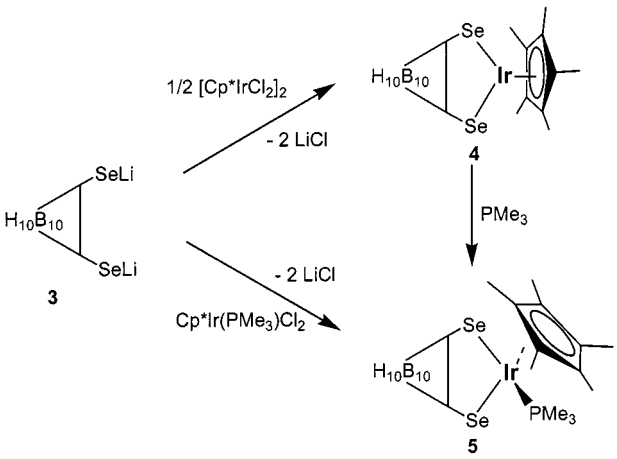
Max Herberhold,*[a] Guo-Xin Jin,[b] Hong Yan,[a] Wolfgang Milius,[a] and Bernd Wrackmeyer*[a]

Keywords: Iridium / Selenium / Diselenolenes / Carboranes / X-ray crystal structure analysis / NMR spectroscopy



The reaction of $[Cp^*IrCl_2]_2$ with dilithium 1,2-*ortho*-carborane-1,2-diselenolate **3** leads to the green 16-electron diselenolene complex $[Cp^*Ir\{Se_2C_2(B_{10}H_{10})\}]$ (**4**) which takes up two-electron ligands such as trimethylphosphane to give the 18-electron diselenolate derivative $[Cp^*Ir(PMe_3)\{Se_2C_2(B_{10}H_{10})\}]$ (**5**). The molecular structures of **4** and **5** were determined by X-ray crystal structure analysis. The ^{77}Se-nuclear shielding in **4** is lower by almost 500 ppm relative to that in **5**.

The bonding in metallacyclic 16-electron dithiolene complexes of type **1** is a matter of debate.[1] In this context, we have recently reported[2] the X-ray crystal structure analysis of the 1,2-bis(methoxycarbonyl)dithiolene complex **2** in which **M** is the (pentamethylcyclopentadienyl)iridium moiety (Cp*Ir). In order to obtain further structural and spectroscopic information, we have now combined the Cp*Ir half-sandwich fragment with the *ortho*-carboranediselenolate ligand $[H_{10}B_{10}C_2Se_2]^{2-}$ (**3**). Direct structural evidence is expected to correlate in particular with the ^{77}Se-NMR data.



1 **2**

Although complexes containing the *ortho*-carboranedithiolate ligand chelated to Mo,[3] Re,[3] Co,[4] Ni,[4] Pd,[3] Pt,[5] and Au[6] have been prepared starting from the dithiol $H_{10}B_{10}C_2(SH)_2$, the analogous or related diselenolate compounds have not been described. We prepared both *ortho*-carboranedithiolate and -diselenolate complexes from the dilithium dichalcogenates $H_{10}B_{10}C_2(ELi)_2$ [E = S, Se (**3**)] which were obtained in situ by insertion of either sulfur or selenium (1:2) into the dilithiated *ortho*-carborane intermediate (Equation 1).

As shown in Scheme 1, the dilithium *o*-carboranediselenolate **3** reacts with $[(Cp^*IrCl_2)_2]$ to give the green diselenolene complex **4**, and with $[Cp^*IrCl_2(PMe_3)]$ the yellow diselenolate complex **5**. Compound **4** takes up two-electron ligands L such as L = CO, CN*t*Bu, phosphanes and pyridines. However, attempts to remove PMe_3 from **5** using sulfur were not successful.

Scheme 1

The molecular structures of both **4** and **5** in the crystal were determined by X-ray crystal structure analyses (Figures 1 and 2). The molecule of **4** corresponds to point group symmetry C_{2v} with two perpendicular mirror planes. Addition of PMe_3 to form the 18-electron complex **5** leads to

C_s symmetry with only one mirror plane left. The iridadiselenolene heterocycle in **4** (which is coplanar with the centers of both the Cp* ring and the *ortho*-dicarbadodecaborane cluster) is bent in **5** with a dihedral angle at the Se···Se vector of 156.1°. Apparently, the ligand L = PMe_3 destroys the pseudoaromatic $IrSe_2C_2$ system in **4**. This is particularly evident from the fact that on going from **4** to **5**, the C(1)−C(2) bond length increases [from 161.2(9) to 165.0(10) pm], the Ir−Se bond lengths grow significantly [from 237.0 (av.) to 247.0 (av.) pm], while the Se−Ir−Se angle decreases [from 93.65(3) to 90.2(1)°]. Compared to **4**, the trimethylphosphane adduct **5** is an ordinary diselenolate chelate complex.

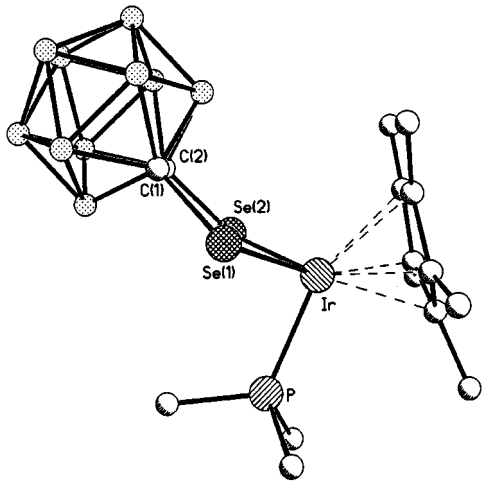

Figure 2. Molecular structure of [Cp*Ir($Se_2C_2B_{10}H_{10}$)(PMe_3)] (**5**); selected bond lengths [pm] and angles [°]: Ir−Se(1) 247.3(1), Ir−Se(2) 246.6(2), Ir−P 227.3(2), Se(1)−C(1) 194.9(6), Se(2)−C(2) 195.2(6), C(1)−C(2) 165.0(10), Ir−Z(Cp*) 188.7. Se(1)−Ir−Se(2) 90.2(1), Se(1)−Ir−P 89.1(1), Se(2)−Ir−P 89.1(1), Ir−Se(1)−C(1) 103.1(2), Ir−Se(2)−C(1) 103.9(2), Se(1)−C(1)−C(2) 119.0(4), Se(2)−C(2)−C(1) 117.6(4); dihedral angle Se(1)IrSe(2)/Se(1)C(1)C(2)Se(2) 156.1°

The ^{1}H-, ^{11}B-, ^{13}C-, ^{31}P-, and ^{77}Se-NMR data (Table 1) of **4** and **5** in solution are in complete agreement with their solid-state structures. In the case of **4**, the C_{2v} symmetry requires four ^{11}B-NMR signals in the intensity ratio of 2:4:2:2, as observed in the 180.5-MHz ^{11}B-NMR spectrum, whereas the C_s symmetry of **5** should give rise to seven ^{11}B-NMR signals in the ratio of 1:1:2:2:1:1:2, of which six are observed. The range of the δ^{11}B-NMR data is similar to that of other 1,2-substituted derivatives of 1,2-$C_2B_{10}H_{12}$.[7] There is only one ^{13}C(carborane) signal each for **4** and **5**, as expected, the one of **4** being shifted by 6.8 ppm to lower field relative to that of **5**. The structural changes between **4** and **5** are most strikingly reflected by the ^{77}Se-nuclear deshielding of almost 500 ppm in the 16-electron complex **4** relative to the 18-electron complex **5**. Such a deshielding is typical of ^{77}Se nuclei becoming part of a heteroaromatic system.[8] This effect can be traced to magnetic field induced mixing of electronic ground and energetically low-lying excited states present in such heterocycles. The complexes **4** and **5** are the first examples to compare the influence of electronic structure on ^{77}Se-nuclear shielding in closely related transition metal diselenolene complexes. A similar comparison has been carried out between titanocene diselenolene metallacycles (also 16-electron complexes) and non-cyclic derivatives.[9] However, in these cases the metallacycles are non-planar and the differences in ^{77}Se-nuclear shielding are rather small.

Experimental Section

The starting complexes [{Cp*$IrCl_2$}$_2$][10] and [Cp*Ir(PMe_3)Cl_2][11] were prepared according to established procedures; the *ortho*-carborane 1,2-$C_2B_{10}H_{12}$ is commercially available. − NMR measurements: Bruker ARX 250 and DRX 500 spectrometers; chemical shifts are given relative to $CHCl_3/CDCl_3$ (δ^1H = 7.24; δ^{13}C = 77.0), external Et_2O-BF_3 [δ^{11}B = 0 for Ξ(^{11}B) = 32.083971 MHz], external 85% aqueous H_3PO_4 [δ^{31}P = 0 for Ξ(^{31}P) = 40.480747 MHz], external Me_2Se [δ^{77}Se = 0 for Ξ(^{77}Se) = 19.071523 MHz]. − Mass spectra: VARIAN MAT CH7, EI MS (70 eV), direct inlet. − IR spectra: Perkin−Elmer 983 G.

Dilithium 1,2-Dicarba-*closo*-dodecaborane-1,2-diselenolate (3): A solution of 1,2-$C_2B_{10}H_{12}$ (0.29 g; 2 mmol) in Et_2O (40 mL) was lithiated by addition of 2.75 mL of 1.6 M butyllithium (4.4 mmol) in hexane. Addition of selenium (0.32 g; 4 mmol) gave a yellow solution of $H_{10}B_{10}C_2(SeLi)_2$ (**3**) in quantitative yield.

Pentamethylcyclopentadienyl-(1,2-dicarba-*closo*-dodecaborane-1,2-diselenolato)iridium ([Cp*Ir{$Se_2C_2(B_{10}H_{10})$}], 4): A solution of **3** (1 mmol) in Et_2O (60 mL) was added to a solution of [{Cp*$IrCl_2$}$_2$] (0.40 g; 0.5 mmol) in THF (60 mL). The colour of the Et_2O/THF solution changed gradually from red to dark green. After 24 h of stirring at ambient temperature, the solvents were evaporated under reduced pressure and the residue chromatographed on silica. Elution with CH_2Cl_2/hexane (5:1) gave a dark green zone which contained 0.57 g (91%) of **4**. Dark green prismatic crystals were grown from CH_2Cl_2/hexane/THF solvent mixtures. − IR (CsI): $\tilde{\nu}$ = 2586 cm^{-1}, ν(B−H). − EI MS (70 eV); *m/z* (%): 628 (100) [M^+], 484 (38) [$M^+ - C_2B_{10}H_{12}$], 143 (100) [$C_2B_{10}H_{11}^+$].

(1,2-Dicarba-*closo*-dodecaborane-1,2-diselenolato)(pentamethylcyclopentadienyl)(trimethylphosphane)iridium ([Cp*Ir{Se_2C_2-($B_{10}H_{10}$)}(PMe_3)], 5): Trimethylphosphane (0.10 g, 1.32 mmol) was added to the green solution of **4** (0.30 g; 0.48 mmol) in CH_2Cl_2

Spin State and Ligand Dissociation in [$CpCoL_2$] Complexes (L = PH_3, $H_2C{=}CH_2$): A Computational Study

Rinaldo Poli*[a] and Kevin M. Smith[a]

Keywords: Cobalt / Density functional calculations / Electronic structure / Ligand effects / Spin state

The relative energies of [CpCoL] compounds (L = PH_3, $H_2C{=}CH_2$) were calculated at the DFT/B3LYP level of theory. The triplet spin state was found to be favored over the singlet by between 33.0 and 21.0 kcal mol^{-1} for both fixed and optimized geometries. The basis set size was found to be important for the energy calculations, particularly when the energetics of ligand dissociation was examined. The role of the triplet spin state in facilitating the ligand dissociation process is discussed.

Introduction

The role of spin-state changes in the reactivity of [$CpCoL_2$] species remains under dispute. Several kinetic, spectroscopic, and theoretical studies have investigated this issue. Bergman et. al. examined the mechanism of phosphane substitution in [$CpCo(PPh_3)_2$] in order to determine whether interconversion between singlet and triplet species resulted in an activation barrier for the dissociative pathway. The first step in the ligand-replacement reaction was found to be the rapid, reversible formation of [$CpCo(PPh_3)$].[1] Extended Hückel molecular orbital theory calculations by Hofmann and Padmanabhan suggested that, although linear d^8 [CpML] compounds are symmetry-required to have a triplet ground spin state, a "bent" geometry for [$CpCo(PPh_3)$] (i.e. Cp−Co−P angle < 180°) might allow the substitution reaction to proceed via the singlet spin surface, thereby accounting for the observed lack of a "spin-flip barrier".[2] Later studies by Bergman, Moore, and co-workers demonstrated that photogenerated [CpCo(CO)] and [Cp*Co(CO)] did not form adducts with alkanes or noble gases, although these unsaturated species did react very rapidly with CO.[3] Using a variety of computational techniques including density functional theory (DFT), Siegbahn calculated that [CpCo(CO)] possesses a triplet ground spin state, and attributed the difference in reactivity of the 16-electron species with alkanes and CO to the varying ability of the incoming ligand to induce triplet-to-singlet spin crossover.[4] In contrast, Brookhart et. al. have recently reported C−H activation reactions of [Cp*Co(η^2-$H_2C{=}CHSiMe_3$)$_2$] that proceed by oxidative addition of benzene or aldehydes to unsaturated [Cp*Co(η^2-$H_2C{=}CHSiMe_3$)].[5]

As part of an ongoing investigation of spin state and reactivity,[6] we have recently used DFT techniques to examine how ligands can affect the relative energy of the singlet and triplet states (ΔE_{S-T}) of 16-electron [CpM(NO)]-containing complexes of Cr, Mo, and W.[7] Ultrafast IR studies have implicated triplet [$CpMn(CO)_2$] in the photolysis of [$CpMn(CO)_3$] in Et_3SiH.[8] Spin-state changes have also been proposed to play a critical role in the reactivity of cytochrome P450.[9] The computational study described in this paper was performed to address the following questions: (1) What is the ground spin state of *bent* [CpCoL] species (L = PH_3, $H_2C{=}CH_2$)? (2) Is ΔE_{S-T} substantially altered for [CpCoL] species by variation of L? (3) Can the observed C−H bond-activation reactivity of [Cp*Co(η^2-$H_2C{=}CHSiMe_3$)] be attributed to a difference in ground spin state compared to triplet [CpCo(CO)]?

Results and Discussion

Calculated Geometries and Energies

The saturated [$CpCoL_2$] (L = PH_3, $H_2C{=}CH_2$) complexes were studied with DFT using the three-parameter form of the Becke, Lee, Yang, and Parr functional (B3LYP)[10] and two basis sets, following the methodology recently developed by Siegbahn and co-workers.[11] The geometries were optimized without constraints (C_1 symmetry) with the LanL2DZ basis set;[12] the structural parameters for both complexes are listed in Table 1. Since energy calculations are more sensitive to basis set size than geometry optimizations,[13] the energies of the LanL2DZ structures were also calculated with the larger 6-311+G(2d,2p) basis set.

The bond lengths obtained for the optimized $[CpCoL_2]$ geometries are marginally longer than those reported for the solid-state molecular structures of $[CpCo(PEt_3)_2]$[14b] and $[Cp^*Co(\eta^2\text{-}H_2C{=}CHSiMe_3)_2]$.[5c] For instance, the average calculated Co−C(Cp) bond lengths are 0.09 Å longer than those found experimentally, and the theoretical Co−L(average) distances are 0.015 Å and 0.035 Å longer than those found in the corresponding X-ray molecular structures for the phosphane and alkene complexes, respectively. The alkene orientation of $[CpCo(\eta^2\text{-}H_2C{=}CH_2)_2]$ corresponds to the alignment observed experimentally, namely parallel with the Cp plane.[5] The calculated alkene C−C bond lengths in $[CpCo(\eta^2\text{-}H_2C{=}CH_2)_2]$ (1.417 and 1.414 Å) are almost identical to those reported for $[Cp^*Co(\eta^2\text{-}H_2C{=}CHSiMe_3)_2]$ (1.414 and 1.404 Å). The slight distortions in C−C bond lengths in the Cp ligand also correspond well with those previously discussed for related $[CpCoL_2]$ derivatives.[14]

As noted in the introduction, Hofmann and Padmanabhan have previously suggested that ligand dissociation from d^8 $[CpML_2]$ complexes may remain on the singlet spin hypersurface if the unsaturated [CpML] intermediate adopts a bent geometry.[2] To test this hypothesis, the energies of bent [CpCoL] compounds were calculated in both singlet and triplet spin states, using the optimized $[CpCoL_2]$ geometries with one L group removed and leaving the other structural parameters unchanged. For both $[CpCo(PH_3)]$ and $[CpCo(\eta^2\text{-}H_2C{=}CH_2)]$ in this bent conformation (Cp−Co−L < 132°), the triplet state is greatly favored over the singlet. The value of ΔE_{S-T} decreases only slightly when the larger basis set is employed, from −31.0 to −28.1 kcal mol^{-1} for the phosphane system and from −25.9 to −23.9 kcal mol^{-1} for the alkene system. Overall, only a minor difference in ΔE_{S-T} is observed upon changing the L group in [CpCoL].

Analogous results are obtained when the [CpCoL] geometries are optimized using B3LYP/LanL2DZ. Optimized triplet $[CpCo(PH_3)]$ was found to be 33.0 kcal mol^{-1} more stable using the LanL2DZ basis set, and 27.1 kcal mol^{-1} more stable at the B3LYP/6-311+G(2p,2d) level. For the alkene system, triplet $[CpCo(\eta^2\text{-}H_2C{=}CH_2)]$ was calculated to be 26.5 kcal mol^{-1} more stable than the singlet at the B3LYP/LanL2DZ level, and 21.0 kcal mol^{-1} more stable using the larger basis set. By comparison, Siegbahn's B3LYP calculation of [CpCo(CO)] gave a ΔE_{S-T} value of −27.8 kcal mol^{-1}, which falls between the results obtained here for the phosphane and alkene derivatives.[4] The structural parameters of the B3LYP/LanL2DZ optimized [CpCoL] geometries are listed in Table 2, and the relative energies are illustrated in Figure 1.

An indication of the energetics of the ligand dissociation process can be attained by comparing the energy of $[CpCoL_2]$ complexes with the sum of the energies of optimized [CpCoL] and the free L ligand, as shown in Table 3. For these relative energies, the difference between the values obtained with the two different basis sets is pronounced. In fact, at the B3LYP/LanL2DZ level, $[CpCo(PH_3)_2]$ is calculated to be 4.3 kcal mol^{-1} less stable than triplet $[CpCo(PH_3)]$ and free PH_3, contrary to experimental observations. This erroneous result is presumably due to the previously observed correlation between basis set size and bond strength.[4] Thus, while the relative energies calculated with the small basis set are skewed in favor of the dissociated species, employing the larger 6-311+G(2d,2p) basis set results in the saturated complex being 7.3 kcal mol^{-1} more stable, in accord with experimental studies of the $[CpCo(PPh_3)_2]$ system.[1]

Table 2. Optimized geometries for $[CpCo(PH_3)]$ and $[CpCo(C_2H_4)]$[a]

Parameter[b]	$[CpCo(PH_3)]$	$[CpCo(C_2H_4)]$
CNT−Co	1.782 (1.881)	1.793 (1.958)
Co−X	2.241 (2.325)	1.851 (1.932)
CNT−Co−X	140.92 (140.43)	148.32 (149.09)

[a] Singlet bond lengths in Å and angles in °, with triplet parameters indicated in parentheses. − [b] CNT = center of gravity of the Cp ring, X = P for $[CpCo(PH_3)_2]$ or center of C−C bond for $[CpCo(C_2H_4)_2]$.

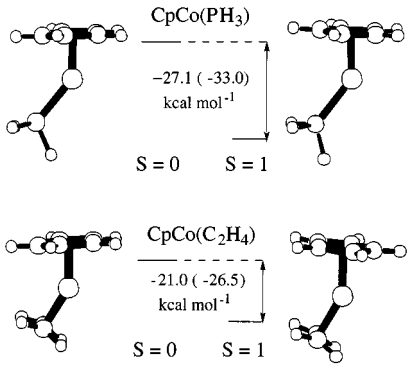

Figure 1. Relative energies of singlet and triplet $[CpCo(PH_3)]$ and $[CpCo(C_2H_4)]$; ΔE_{S-T} calculated at the B3LYP/6-311+G(2d,2p) level of theory, with B3LYP/LanL2DZ values indicated in parentheses

Table 3. Relative energies of $[CpCoL_2]$ and [CpCoL] + L[a]

	$[CpCo(PH_3)]$	$[CpCo(C_2H_4)]$
Singlet	−34.4 (−28.8)	−24.6 (−25.1)
Triplet	−7.3 (+4.3)	−3.6 (+1.4)

[a] ΔE (in kcal mol^{-1}) calculated at the B3LYP/6-311+G(2d,2p) level of theory, with B3LYP/LanL2DZ values indicated in parentheses.

Implications for Reactivity

It has been previously proposed that the lack of a high activation barrier for ligand exchange reactions in d^8 $[CpML_2]$ compounds might be due to the bent geometry of

unsaturated [CpML] species, which allows the singlet spin state to be maintained thoughout the dissociative substitution process.[15] Although extended Hückel molecular orbital calculations did not permit the relative energies of the singlet and triplet [CpML] species to be ascertained, Hofmann and co-workers recognized that this possibility was more likely for Rh and Ir than for Co.[2] Our results at the DFT/B3LYP level indicate that even in the bent conformation, the triplet spin state is considerably lower in energy for [$CpCo(PH_3)$] and [$CpCo(\eta^2\text{-}H_2C{=}CH_2)$] than the corresponding singlet electronic configuration.

It should be observed that the crossover from the singlet to the triplet surface upon phosphane dissociation from [$CpCo(PPh_3)_2$] will in fact lower the enthalpic barrier to the phosphane exchange process if the crossing point is located below the singlet [$CpCo(PPh_3)$] species. A change in spin state would only translate into an entropic contribution to the activation free energy. Thus, the facile phosphane exchange process observed for [$CpCo(PPh_3)_2$] is in fact quite nicely rationalized by the large energetic stabilization of the [$CpCo(PPh_3)$] intermediate upon changing the spin state, accompanied by a low-energy crossing point and lack of a "spin-flip barrier".[16]

Differences in ground spin state between [CpCo(CO)] and the heavier Rh and Ir congeners were utilized by Siegbahn to explain the experimentally observed differences in alkane binding and C−H bond activation reactivity of these species.[4] With this precedent, it seemed conceivable that the H/D exchange reactivity with C_6D_6 and the aldehyde C−H activation reactions observed by Brookhart and co-workers might be attributable to a low-lying or ground singlet spin state for [$Cp^*Co(\eta^2\text{-}H_2C{=}CHSiMe_3)$] intermediates.[5] Although the present study indicates that ΔE_{S-T} is *slightly* more favorable for the singlet alkene species than for the analogous phosphane system, the triplet state is still the ground state by over 20 kcal mol^{-1} for [$CpCo(\eta^2\text{-}H_2C{=}CH_2)$]. However, it has previously been shown that photogenerated [CpCo(CO)] *does* form a solvated complex with benzene[17] and forms alkene adducts at diffusion-limited rates.[17][18] Therefore, it is possible that the discrepancy in reactivity between [$Cp^*Co(CO)$] and [$Cp^*Co(\eta^2\text{-}H_2C{=}CHSiMe_3)$] is due to substrate effects; i.e. that the aromatic C_6D_6 solvent or the C=O bond of the aldehyde may help to facilitate the spin state change from triplet to singlet in the 16-electron alkene intermediate, whereas alkanes do not induce this process for [$Cp^*Co(CO)$]. MP2 calculations have indicated that a similar difference in the ability of the incoming ligand to induce spin-crossover was responsible for the experimentally observed variation between the rate of addition of CO and N_2 to triplet $Cp^*MoCl(PMe_3)_2$.[19]

Conclusion

The triplet spin state is calculated to be much more stable than the singlet state for [CpCoL] species, even in "bent" structures derived directly from the saturated [$CpCoL_2$] precursors. Varying the ligand in [CpCoL] exerts only a minor influence on the energy difference between singlet and triplet species: our present results for the PH_3 and $H_2C{=}CH_2$ systems lie on either side of the ΔE_{S-T} value obtained by Siegbahn for the CO complex. The C−H bond activation reactions reported for [$Cp^*Co(\eta^2\text{-}H_2C{=}CHSiMe_3)$] may thus be attributable to substrate effects rather than to a difference in ground spin state of the unsaturated intermediate. The comparatively high energy of the singlet [CpCoL] complexes suggest that the ligand dissociation process from [$CpCoL_2$] may be facilitated by spin crossover to the lower energy triplet species. Although the ΔE_{S-T} values are relatively basis-set-independent, the energies of the [CpCoL] species relative to the saturated [$CpCoL_2$] complexes shows a marked dependence on the size of the basis set used.

Experimental Section

General Remarks: All calculations were performed with GAUSSIAN 94[20] using an SGI Origin 200 workstation. The geometries of the [$CpCoL_2$] and [CpCoL] species and the free L ligands were optimized using B3LYP,[10] a DFT type of calculation, employing the LanL2DZ basis set. The LanL2DZ basis set includes both Dunning and Hay's D95 sets for H and C and the core potential sets of Hay and Wadt for the heavy atoms.[12] Electrons outside the core were all those for H and C, the 3s and 3p electrons for P, and the 3s, 3p, 3d, and 4s electrons for Co. All geometries were optimized at the B3LYP/LanL2DZ level without constraints, with the exception of triplet $CpCo(PH_3)$, which failed to achieve geometric convergence despite several attempts from various initial geometries. At the suggestion of a reviewer, the complex was optimized with imposed C_s symmetry starting from both possible orientations of the Cp ligand. Convergence was attained in both cases, and the configuration with the unique C−H group opposite to the P was found to be slightly less stable than the other conformation, with an energy difference of less than 0.1 kcal mol^{-1}. The fixed, bent [CpCoL] geometries were obtained from the [$CpCoL_2$] structures by removing one L ligand and keeping all other parameters unchanged. The B3LYP energy calculations were performed separately with both the LanL2DZ basis set and the larger 6-311+G(2d,2p) basis set, which has two sets of polarization functions on all atoms including two f sets on Co, and also diffuse functions.[11]

The mean value of the first-order electronic wavefunction, which is not an exact eigenstate of S^2 for unrestricted calculations on the triplet systems, was considered suitable for unambiguous identification of the spin state. Spin contamination was carefully monitored and the value of $<S^2>$ for the unrestricted B3LYP (UB3LYP) calculations on the triplet [CpCoL] species using the 6-311+G(2d,2p) basis set (LanL2DZ results shown in parentheses) [L = bent PH_3, 2.0261 (2.0228); optimized PH_3, 2.0234 (2.0205); bent $H_2C{=}CH_2$, 2.0499 (2.0463); optimized $H_2C{=}CH_2$, 2.0531 (2.0484)] indicated minor spin contamination. The energies shown in the Results and Discussion section correspond to UB3LYP calculations for the triplet [CpCoL] compounds, and to restricted B3LYP calculations for the singlet [CpCoL] and [$CpCoL_2$] complexes.[21]

Synthesis, Structure and Properties of a Mixed Mononuclear/Dinuclear Iron(II) Spin-Crossover Compound with the Ligand 4-(*p*-Tolyl)-1,2,4-triazole

Jeroen J. A. Kolnaar,[a] Martine I. de Heer,[a] Huub Kooijman,[b] Anthony L. Spek,[b] Georg Schmitt,[c] Vadim Ksenofontov,[c] Philipp Gütlich,[c] Jaap G. Haasnoot,*[a] and Jan Reedijk[a]

Keywords: Iron(II) / Spin crossover / Pentanuclear assembly / Triazole ligand / Structure elucidation

A new iron(II) compound with the formula $[Fe_2(L)_5(NCS)_4]_2$-$[Fe(L)_2(NCS)_2(H_2O)_2]$ (**I**) [where L = 4-(*p*-tolyl)-1,2,4-triazole] has been synthesized and subjected to X-ray structure determination. Compound **I** crystallizes in the triclinic space group *P*–1 (no. 2) with a = 14.5785(11), b = 16.1253(11), c = 16.1963(8) Å, α = 80.930(5), β = 85.796(5), γ = 78.132(6)°, V = 3676.2(4) Å^3. The structure refinement converged to $wR2$ = 0.172, R_F = 0.084. The structure was found to consist of two types of iron-containing structural units, a mononuclear unit and a dinuclear one. The mononuclear unit has a crystallographic inversion centre, and is coordinated by two *N*CS anions, two triazole N1 nitrogen atoms, and two water molecules, each hydrogen-bonded to one of the two dinuclear units. The dinuclear units consist of two iron(II) ions bridged by three triazole ligands in a 1,2-fashion. The coordination spheres of both iron ions are completed by two *N*CS anions and one monodentate triazole ligand. The monodentate triazole ligands are connected through the non-coordinating N atom to the mononuclear iron unit by hydrogen bonds from its coordinated water molecule. Magnetic susceptibility measurements indicate a spin transition (ST) only for the iron ions in the dinuclear units, centred at around $T_{1/2}$ = 111 K. The transition takes place within a relatively narrow T range. The mononuclear iron ion remains in the high-spin (HS) state even at very low temperature, yielding a ratio of 4:1 for the ST and HS iron ions. Temperature-dependent Mössbauer spectroscopy confirms these results.

Introduction

In the research on iron(II) compounds with a spin transition[1] (hereafter abbreviated as ST), the compounds with 4-substituted 1,2,4-triazoles have a special place. The variety of structural types and the physical properties of these compounds have been a topic of research for over 15 years. The structures characterized to date vary from mononuclear to trinuclear compounds with two triple bridges,[2–4] but one-, two-, and three-dimensional polynuclear compounds have also been found with various bridging triazole ligands.[5–7] Here, we focus on the linear structures obtained with 4-R-1,2,4-triazoles.

The variety of structural and physical properties leads to questions about the influences of variables such as the ligand substituents, the nature of the anion, and the metal-to-ligand ratio on the transition temperature, the form of the transition curve and the structure.[7] The substituents used to date have included primary and secondary alkyl and (substituted) phenyl groups.

The anions used in earlier research have varied from coordinating, e.g. NCS^- and $NCSe^-$, to non-coordinating, e.g. BF_4^-, ClO_4^- and triflate.[2–4] The effect of non-coordinating anions on the structure of the resulting compounds is usually restricted to effects related to hydrogen bonding. In an earlier paper, it was stated that the influence of non-coordinated anions is much more pronounced than the influence of the substituent used, although steric effects of the substituent can play an important role in the ST behaviour.[4] The effect of coordinating anions on the structure of divalent transition metal compounds with 1,2,4-triazole ligands is to block coordination sites. Therefore, coordinated anions limit the number of coordinated triazoles to four per metal core. For 1,2,4-triazoles having only two possible coordination sites, this leads to dinuclear units either with three bridging triazoles and one monodentate triazole per metal core,[8] or with NCS anions linking the dinuclear unit, yielding a polynuclear structure.[9] Because of this more pronounced influence on the structure, the influence on the ST behaviour can be expected to be rather large as well. It is, however, difficult to compare the influence of coordinated anions to the influence of non-coordinated anions, because of the difference in structural properties.

We now wish to report a new triazole compound, in which the mononuclear moiety shows no ST, whereas the dinuclear part shows a clear ST. The ligand used in this study is 4-(*p*-tolyl)-1,2,4-triazole, which has not previously been used in this context.

Results and Discussion

Structural Description of I

The structure was found to consist of two types of iron-containing structural units, i.e. a mononuclear unit (Figure 1) on a crystallographic inversion centre, hydrogen-bonded by two coordinated water molecules to two dinuclear units (Figures 2 and 3).

The mononuclear unit situated on a crystallographic inversion centre consists of an Fe^{II} ion, coordinated by two thiocyanate nitrogen atoms (N65) at a distance of 2.094(10) Å, two monodentate tolyl-triazole N1 atoms at 2.194(9) Å, and two water oxygen atoms (O1) at 2.185(9) Å, in an octahedral environment. The NCS anion is non-linear with the N65−C65−S5 angle 173.7(12)°; the angle of coordination to iron Fe3−N65−C65 is also non-linear being 168.8(10)°. An iron(II) centre with this chromophore of relatively weak ligand field strength can be expected to be in a high-spin (HS) state without an ST. The Fe−ligand distances are consistent with an HS state at room temperature.

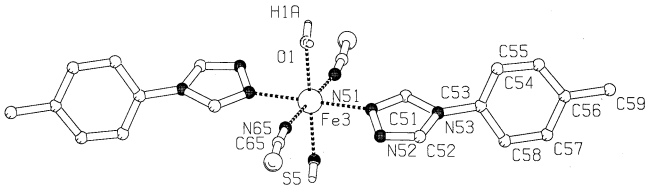

Figure 1. Structure of the mononuclear unit $Fe(L)_2(H_2O)_2(NCS)_2$ in **I**; non-water H atoms are omitted for clarity

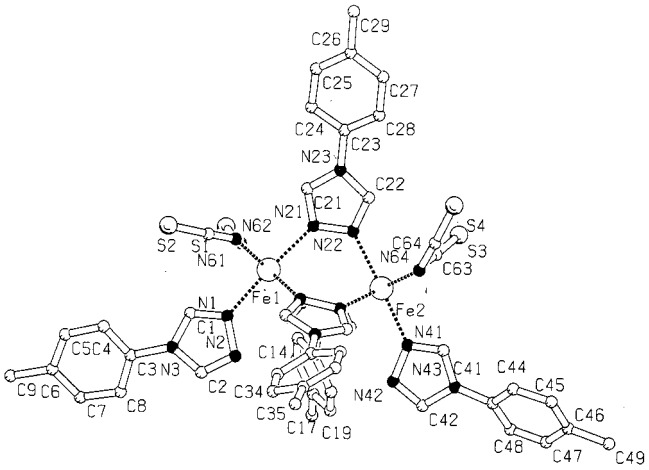

Figure 2. Structure of the dinuclear unit $[Fe_2(L)_5(NCS)_4]$ in **I**; H atoms are omitted for clarity

The unit cell also contains two dinuclear units. Both units consist of two iron ions linked by three 1,2-triazole bridges with Fe−N distances ranging from 2.151(8) Å to 2.223(8) Å, typical for an HS iron ion bound by triazole. The coordination spheres of both iron ions are completed by two thiocyanate N atoms at 2.092(9) to 2.188(9) Å, and a monodentate tolyl-triazole ligand at 2.152(8) and 2.173(8) Å, yielding a distorted octahedral N6 chromophore, which is known to produce ST compounds.

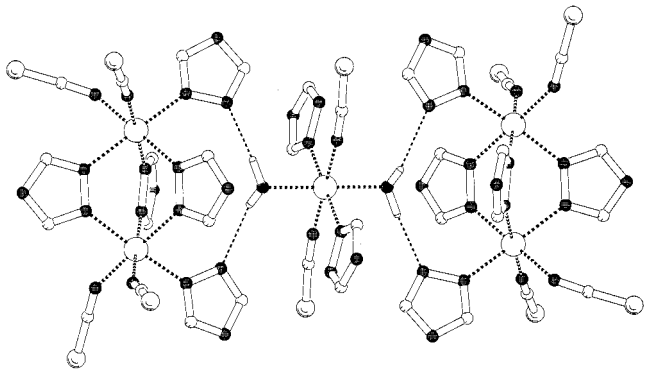

Figure 3. Pentanuclear assembly $[Fe_2(L)_5(NCS)_4]_2[Fe(L)_2(NCS)_2(H_2O)_2]$ (**I**), non-water H atoms and tolyl C atoms are omitted for clarity

Dinuclear units with this structure, M_2(1,2,4-triazole)$_5$(NCS)$_4$ (with M = divalent first-row transition metal ion), are known from the literature.[8][10] However, in these structures the monodentate triazoles are coordinated *trans* with respect to the metal−metal axis rather than *cis*, as is observed in the present structure. The *cis* configuration is clearly stabilized by a hydrogen-bonding network, which involves the water molecules coordinated by the mononuclear iron core. These water molecules form hydrogen bonds to the non-coordinated N atoms of the monodentate triazoles from the dinuclear unit (Table 1). The overall structure can thus be described as a pentanuclear unit, consisting of two dinuclear units linked by a mononuclear unit.

The overall structure contains four iron ions that might exhibit a temperature-induced ST, and one iron ion which is expected to be in an HS state at all temperatures.

Magnetic Measurements

At 290 K, χT was found to be 3.6 cm^3 K mol^{-1}, indicating all iron ions to be present in the HS state, as would be expected from the structure determination. On lowering the temperature, this value decreased only slightly, e.g. to 3.5 cm^3 K mol^{-1} at 150 K. On lowering the temperature still further, the sample showed a sharp drop in magnetization in the temperature range from 130 to 90 K. The $T_{1/2}$ was estimated to be 111 K. At 80 K, χT was found to be 0.7 cm^3 K mol^{-1} per iron ion, in agreement with one of the five iron ions being in an HS state and the other 4 being in low-spin (LS) state at low temperatures. This is in good agreement with the observed structure. Thus, a quantitative spin-state conversion $^5T_2 \rightarrow {}^1A_1$ occurs in 80% of all the iron(II) ions. This is shown clearly in Figure 4, where the fraction of HS molecules, derived from the magnetic measurements, is plotted as a function of temperature, $\gamma_{HS}(T)$. The conversion curves merge into a plateau at $\gamma_{HS} = 0.2$ at low temperatures, reflecting the expected 20% fraction of the iron ions, i.e. those localized in the centre of the pentanuclear assembly, that remain in the HS state at all temperatures. The compound did not show any variation of behaviour on cooling or heating, which is also apparent from

Table 1. Hydrogen bond geometries for **I**

	D···A [Å]	D−H [Å]	H···A [Å]	D−H···A [°]
O(1)−H(1A)···N(2) [1 − *x*,1 − *y*,−*z*]	3.031(13)	0.72(12)	2.36(13)	157(13)
O(1)−H(1B)···N(42) [1 − *x*,1 − *y*,−*z*]	3.128(13)	0.99(11)	2.15(11)	172(9)

Figure 4, where the transition curves for the cooling and heating directions are identical. No hysteresis is observed within the limits of experimental error.

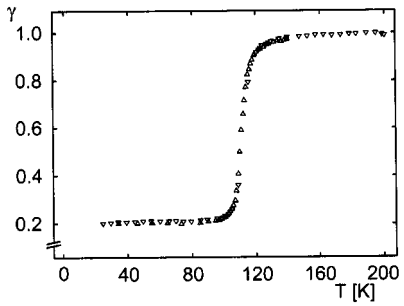

Figure 4. Molar fraction of the iron(II) HS molecules, γ_{HS}, in compound **I** as function of temperature; the conversion curves in cooling direction (▽) and heating direction (Δ) match perfectly

Mössbauer Spectroscopy

Mössbauer spectra of **I** were obtained in a temperature range between 80 K and 293 K. Figure 5 shows a selection of spectra recorded between 80 K and 200 K. At temperatures below $T_{1/2}$, the spectrum observed is indicative of two types of iron cores; at 80 K one core is in an LS state, as indicated by the apparent strong singlet absorption. The central core is in an HS state, yielding the doublet absorption (outer two signals) typical for an HS iron(II) complex denoted as HS^c. The ratio of the two states is 1 HS for every 4 LS cores, as one would expect from both the structural and magnetic data. Accordingly, one would expect a 1:4 intensity ratio (ratio of area fractions) of the LS and HS resonances in the low-temperature Mössbauer spectra. Inspecting the data of the relative area *A* (%) for the respective signals in Table 2, however, one notices that the HS area fraction at 80 K, for instance, is about 10% smaller than the expected value to match the 1:4 ratio. This discrepancy is due to the fact that the Lamb−Mössbauer factor of the LS state[11−13] differs from the HS state. The data collected in Table 2 are the results of the fitting procedure that included the thickness correction for the Mössbauer absorber.

The spectra obtained from the ST region show a clear transition from the LS state to two additional HS states; the new HS states HS1 and HS2 relate to the four iron(II) ions in the two dinuclear fragments. They are best fitted by two doublets with the same intensity and slightly different quadrupole splitting (see Table 2). This behaviour might be explained by the difference in the coordination spheres of the iron ions in the two dinuclear units. The intensity increase of the new HS quadrupole doublets is in line with the disappearance of the LS state. No change is observed in the central HS quadrupole doublet HS^c other than a normal temperature-dependent change in the splitting energy arising from the known temperature dependence of the valence electron contribution on the electric field gradient. At 200 K and above, broadened Mössbauer spectra were observed, which could satisfactorily be deconvoluted into three iron(II) HS doublets with intensity ratios of 2:2:1 at all temperatures as expected from the crystal structure. As an example, the spectrum measured at 200 K is depicted in Figure 6, together with the calculated subspectra of the three HS doublets derived from the fitting procedure.

Conclusion

The work described herein represents an important new example of the versatility of the 4-substituted 1,2,4-triazole ligand system. The new type of structural assembly is of interest from several points of view. Though the subunits of the assembly, especially the dinuclear unit, are not uncommon, and the hydrogen bonding through a non-coordinated triazole N atom has been described previously,[8] the re-

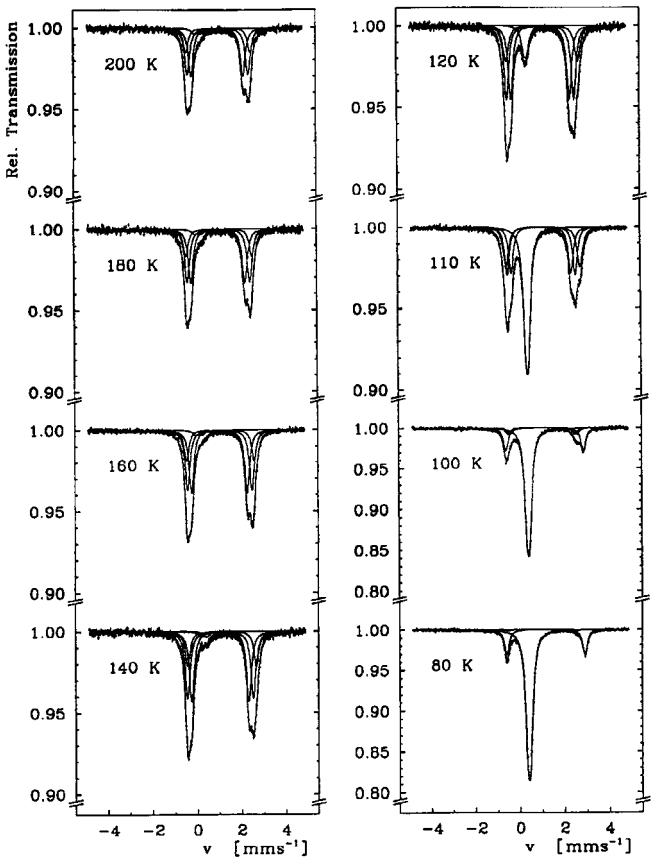

Figure 5. Selected Mössbauer spectra of compound **I** as function of temperature

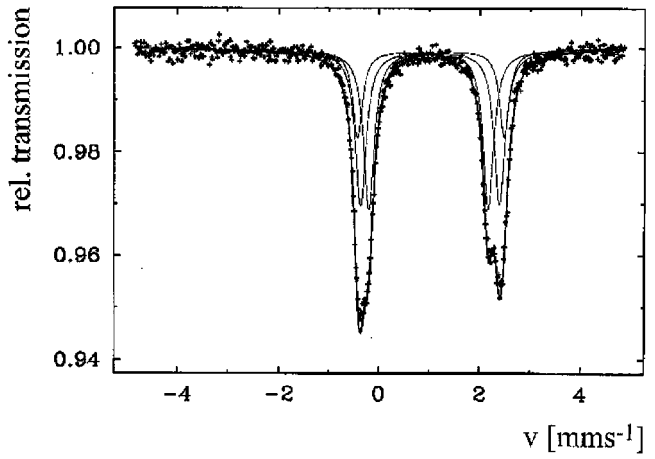

Figure 6. Mössbauer spectrum of compound **I** measured at 200 K; the broadened doublet is composed of three iron(II) HS doublets with intensity ratios of 2:2:1; the two with equal intensity relate to the four iron ions in the dinuclear units; the doublet with lowest intensity but largest splitting energy arises from the central iron(II) ion, which remains in the HS state at all temperatures

sulting species is a quite unique pentanuclear assembly, with two dinuclear units hydrogen-bonded to a mononuclear unit. The iron ion in the bridging, mononuclear unit remains in an HS state throughout the temperature range from 20 to 300 K, and does not show any variation in its Mössbauer spectra other than the normal temperature-dependent variation. On the other hand, a spin transition is observed, which is attributed to the iron ions in the dinuclear units. The Mössbauer spectra show two doublets for the iron ions with a spin transition; the slight differences in the splitting energy might be explained by the slight differences in the coordination spheres of these iron ions. This difference is mainly due to a difference in the metal−ligand bond lengths in the dinuclear unit. Though the iron ions seem to be slightly different, this has no observable influence on the spin transition temperature ($T_{1/2}$), as this is observed at a sharp T of 111 K.

Experimental Section

Preparation of I: The ligand 4-(*p*-tolyl)-1,2,4-triazole (L) was prepared according to a modified literature procedure.[14] $[Fe_2(L)_5(NCS)_4]_2[Fe(L)_2(NCS)_2(H_2O)_2]\ H_2O$ (**I**) was synthesized by adding a solution of 2.5 mmol of L in 25 mL of hot water to a solution of 1 mmol of FeCl2·2H2O and 2 mmol of NH_4NCS in 25 mL of hot water. Crystals appeared upon slow cooling to room temperature; single crystals suitable for X-ray diffraction structure determination were collected from this solution. − $C_{118}H_{114}Fe_5N_{46}O_3S_{10}$ (2824.5): calcd. C 50.18, H 4.07, N 22.81, S 11.35, Fe 9.89; found C 50.21, H 4.05, N 22.93, S 10.72, Fe 9.10.

Crystal Structure Determination of I: A block-shaped crystal of approximate dimensions 0.2 × 0.3 × 0.3 mm, suitable for X-ray structure determination, was sealed in a Lindemann glass capillary and transferred to an Enraf-Nonius CAD4-T diffractometer on a rotating anode. Accurate unit cell parameters and an orientation matrix were obtained from a least-squares fitting of the setting angles of 25 well-centred reflections (SET 4[15]) in the range 8.42° < θ < 15.11°. The unit cell parameters were checked for the presence of higher lattice symmetry.[16] Crystal data and details of the data collection are presented in Table 1. Data were collected at ambient temperature in ω/2 scan mode, with scan angle Δω = 0.82 + 0.35 tan θ°. Total data of 10732 reflections were collected, 10102 of which were independent. Data were corrected for L_P effects and for 1% instability in the three periodically measured reference reflections (2 0 4, 4 2 0, −3 1 2) during 37 h of X-ray exposure time, but not for absorption. The structure was solved by automated Patterson methods and subsequent difference Fourier techniques (DIRDIF-92[17]). Refinement on F^2 was carried out using full-matrix least-squares techniques (SHELXL-93[18]); no observance criterion was applied during refinement. Hydrogen atoms, except the water hydrogen atoms [H(1A) and H(1B)], were included in the refinement in calculated positions, riding on their carrier atoms. The coordinates of the water hydrogen atoms were allowed to refine freely. The methyl hydrogen atoms were refined as a rigid group, allowing for rotation about the C−C bond. At this stage of the refinement, a difference Fourier map revealed a number of residual density peaks (approx. height 1.5 e Å^{-3}) in a channel running parallel to the *b* axis and located at $x = 1/2$, $z = 0$, with a volume of 491.9 Å^3. No discrete solvent model could be refined. The BYPASS procedure,[19] as implemented in the program PLATON,[20] was used to take this electron density into account. A total number of 123 electrons was found in the channel, which is probably occupied by water. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in the refinement with fixed isotropic thermal parameters related to the value of the equivalent isotropic displacement parameter of the carrier atom by a factor of 1.5 for the methyl and water hydrogen

atoms, and of 1.2 for the aromatic hydrogen atoms. Convergence was reached at $wR2 = 0.172$, $w^{-1} = \sigma^2(F^2) + (0.0574P)^2$, where $P = [\mathrm{Max}(F_o^2,0) + 2F_c^2]/3$, $R_F = 0.084$ for 3501 $F_o > 4\,\sigma\,(F_o)$, $S = 0.84$ for 829 parameters. The residual density was in the range -0.48 to 0.42 e Å^{-3}. The relatively high R values and the rather high U_1/U_3 ratios for some atoms are related to the weak scattering that is most probably a consequence of the disorder in the solvent-filled channels. Selected bond lengths and angles are given in Table 4. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for Crystallography.[21] Geometrical calculations and illustrations were performed with PLATON. All calculations were performed with a DEC5000 cluster. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no CCDC-100926. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Magnetic Properties: The magnetic susceptibility of **I** was measured over the temperature range 4.2–300 K with a fully automated Manics DSM-8 susceptometer equipped with a TBT continuous-flow cryostat and a Drusch EAF 16 NC electromagnet, operating at ca. 1.4 T, and over the temperature range 20–200 K with a FONER-type magnometer (PAR 155) equipped with a Cryovac continuous-flow cryostat and a Bruker electromagnet, operating at 1 T. Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.

Mössbauer Spectra: These were measured with a ^{57}Co(Rh) source using a constant acceleration spectrometer in a cryostat with exchange gas. The obtained spectra of polycrystalline samples were fitted with Lorentzian-shaped lines using a non-linear iterative minimization routine (MOSFUN).

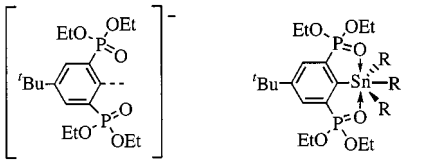
Intramolecular Donor-Assisted Cyclization of Organotin Compounds

Michael Mehring,[a] Christian Löw,[a] Markus Schürmann,[a] and Klaus Jurkschat*[a]

Dedicated to Professor Bernt Krebs on the occasion of his 60th birthday

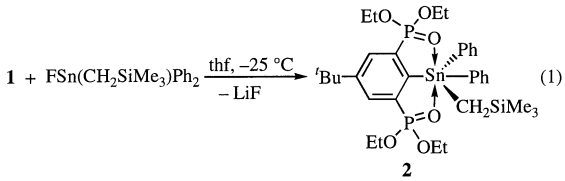


Keywords: Tin / Phosphorus / Intramolecular coordination / O ligands / Heterocycles

New intramolecularly coordinated organotin compounds containing the monoanionic O,C,O-coordinating ligand {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2\}^-$ have been synthesized by substitution reactions starting from organotin halides. In view of the enhanced reactivity of the intramolecularly coordinated compounds {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2\}SnR_2R'$ (**2**, R = Ph, R′ = CH_2SiMe_3; **3**, R = R′ = Ph; **6**, R = R′ = Cl), cationic tin species are suggested to occur as intermediates in the formation of the heterocyclic compounds [1(Sn),3(P)-$Ph_2SnOP(O)(OEt)$-5-*tert*-Bu-7-$P(O)(OEt)_2]C_6H_2$ (**8**), [1(Sn),3(P)-$Ph(Me_3SiCH_2)SnOP(O)(OEt)$-5-*tert*-Bu-7-$P(O)(OEt)_2]$-$C_6H_2$ (**15**), and {[1(Sn),3(P)-$Cl_2SnOP(O)(OEt)$-5-*tert*-Bu-7-$P(O)(OEt)]C_6H_2\}_2$ (**16**). The latter compounds are formed by intramolecular cyclizations of pentacoordinate cationic tin species under elimination of ethyl halide. Furthermore, the synthesis of [1(Sn),3(P)-$Ph_2SnOP(O)(OH)$-5-*tert*-Bu-7-$P(O)$-$(OH)_2]C_6H_2$ (**13**) is described. Reaction of **8** with an excess of Me_3SiBr leads to the unexpected formation of {2-$[P(O)(OEt)(OSiMe_3)]$-4-*tert*-Bu-6-$[P(O)(OEt)_2]C_6H_2\}SnPhBr_2$ (**9**) as a result of an O–Sn bond cleavage initiated by Me_3SiBr and subsequent reaction of the intermediate with further Me_3SiBr under Sn–C bond cleavage. The high donor capacity and the rigidity of the new ligand {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2\}^-$ are demonstrated by X-ray diffraction analyses of the tetraorganotin compound **2** and the monoorganotin trichloride **6**. Furthermore, the molecular structures of the 2,3,1-oxaphosphastannoles **8** and **16** are discussed.

Introduction

Penta- and hexacoordinate compounds of the heavier group 14 elements Sn[1] and Si[2] have been extensively studied during the last few decades. The great interest in inter- and intramolecularly coordinated silicon and tin compounds stems from their enhanced reactivity,[1a-d][2a-c][3] their stereochemical non-rigidity,[1a][1c][2a-c][2k][4] and their biological activity.[5] In particular, the use of ligands with intramolecular donor sites has led to the stabilization of highly reactive compounds such as silylenes[6] and stannylenes,[7] as well as organosilicon-[8] and organotin cations.[9] We have recently reported the novel anionic O,C,O-coordinating ligand $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}^-$ (**A**) and have demonstrated its potential in the synthesis of intramolecularly coordinated organotin[1b] and organosilicon[2p] compounds of type **B**. The rigidity of the ligand frame of **A**, coupled with the high donor capacity of its P=O groups, make this compound an eminent pincer ligand for the stabilization of cationic as well as of low-valent group 14 organoelement compounds.



In this paper, we describe our attempts to synthesize organotin cations starting from intramolecularly coordinated organotin compounds of type **B**. However, as a result of an unexpected intramolecular donor-assisted cyclization reaction, we obtained pentacoordinate 2,3,1-benzoxaphosphastannole derivatives rather than the corresponding tin cations. Furthermore, a new intramolecularly stabilized tin(II) compound, the synthesis and reactivity of which will be described in detail in a forthcoming paper, is shown to serve as a precursor in the synthesis of a novel hexacoordinate monoorganotin trichloride. The latter can also be converted into a 2,3,1-benzoxaphosphastannole.

Results and Discussion

Intramolecularly Coordinated Organotin Compounds

The intramolecularly coordinated tetraorganotin compound $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}SnPh_2(CH_2SiMe_3)$ (**2**) has been prepared in moderate yield by the reaction of $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}Li$ (**1**) with $FSnPh_2(CH_2SiMe_3)$[10] (eq. 1).

The structurally related tetraorganotin compound of type **B** {4-*tert*-Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}SnPh$_3$ (**3**), as well as the hexacoordinate diorganotin compound of type **B** {4-*tert*-Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}SnPhCl$_2$ (**4**) were prepared as described previously.[1b] The monoorganotin trichloride {4-*tert*-Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}SnCl$_3$ (**6**) was synthesized by a simple redox process between $SnCl_4$ and the heteroleptic stannylene {4-*tert*-Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}-SnCl (**5**)[11] (eq. 2). It is worth noting that the homoleptic stannylene $(C_5Me_5)_2Sn$ undergoes a similar redox reaction with $SnCl_4$ to give $(C_5Me_5)_2SnCl_2$ and $SnCl_2$.[12]

5 **6** (2)

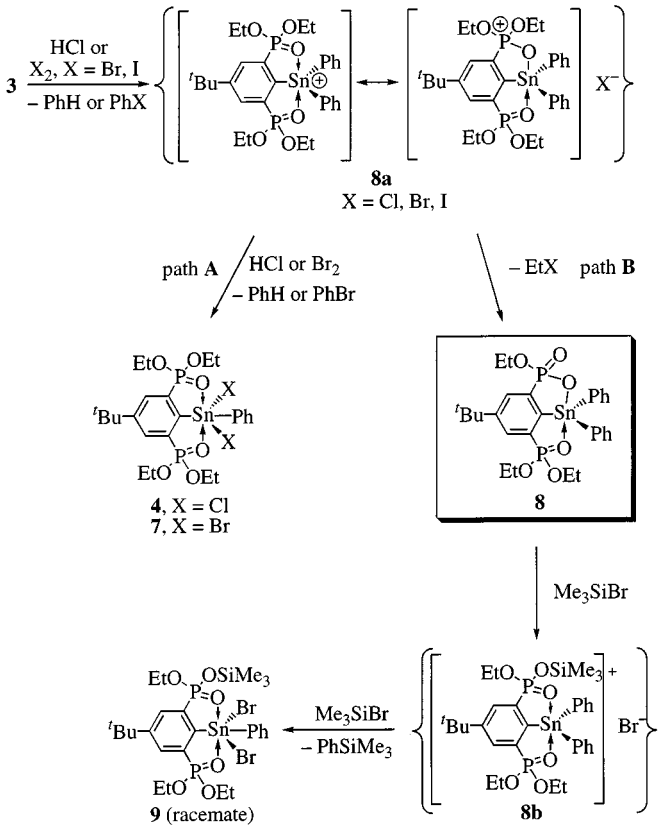
Selected NMR data for **2**−**6** are listed in Table 1. The ^{119}Sn- and ^{31}P-NMR spectra show that weak O−Sn contacts are present in **2** and **3**, whereas strong intramolecular coordination is observed in the halogen-containing compounds **4** and **6**. In comparison with tetracoordinate $Ph_3SnCH_2SiMe_3$ [$\delta(^{119}Sn) = -88.6$],[13a] the ^{119}Sn-NMR data of **2** [$\delta(^{119}Sn) = -127.5$, $J(^{119}Sn-^{31}P) = 38$ Hz] indicate a coordination number greater than four at the tin atom.[13b] Moreover, the ^{31}P-NMR chemical shift of **2** [$\delta(^{31}P) = 23.0$, $J(^{31}P-^{119}Sn) = 37$ Hz] is shifted to higher frequency than that of the phosphonate precursor 5-*tert*-Bu-1,3-[P(O)(OEt)$_2$]$_2$C$_6$H$_3$ [$\delta(^{31}P) = 18.2$].[1b] These data indicate the tin atom in **2** to be [4+2]-coordinated, in solution as well as in the solid state, by four carbons and two weak O−Sn interactions, as has previously been reported for the tetraorganotin compound **3** and its silicon analogue.[1b,2p] The formal exchange of the phenyl groups in **3** by chlorine leads to a tin center of higher Lewis acidity and thus to a remarkably stronger O−Sn interaction, as shown by the ^{119}Sn-NMR chemical shifts of the dichlorotin derivative **4** [$\delta(^{119}Sn) = -424.8$, $J(^{119}Sn-^{31}P) = 91$ Hz] and the trichlorotin derivative **6** [$\delta(^{119}Sn) = -528.8$, $J(^{119}Sn-^{31}P) = 281$ Hz]. Although some intramolecularly coordinated monoorganotin trichlorides have been characterized by X-ray crystallography,[14] to the best of our knowledge there have not been any reports of hexacoordinate monoorganotin trichlorides containing a pincer ligand. The heptacoordinate tris(2,6-dimethoxyphenyl)methyltin trichloride,[14f] the molecular structure of which is best described as a tricapped tetrahedron, shows a ^{119}Sn-NMR chemical shift of $\delta(^{119}Sn) = -344$, i.e at a significantly higher frequency than that of the O,C,O-coordinated compound **6** [$\delta(^{119}Sn) = -528.8$]. This difference in the chemical shifts highlights the high donor capacity of the new O,C,O-coordinating ligand in **6** and suggests that the O−Sn interaction in the latter is stronger than that in tris(2,6-dimethoxyphenyl)methyltin trichloride.[14f]

Intramolecularly Coordinated Organotin Heterocycles

Previously, we reported the syntheses of {4-*tert*-Bu-2,6-[P(O)(OEt)$_2$]$_2$C$_6$H$_2$}SnPhX$_2$ (**4**, X = Cl; **7**, X = Br) by reaction of **3** with two molar equivalents of HCl and bromine, respectively. The ^{119}Sn-NMR spectra of the crude reaction mixtures showed, besides the signals at $\delta(^{119}Sn) = -442.8$ and $\delta(^{119}Sn) = -432.3$ attributable to the major products **4** and **7**, respectively, one signal of low intensity (5%) at about $\delta(^{119}Sn) = -224$. This minor signal could be attributed to compound **8** (Scheme 1), which is formed as a by-product. Surprisingly, attempted synthesis of the corresponding diorganotin diiodide (X = I) by reaction of **3** with two molar equivalents of iodine was unsuccessful. Instead, compound **3** reacts with one molar equivalent of iodine to give the novel intramolecularly coordinated 2,3,1-benzoxaphosphastannole **8** in high yield. The preparation and characterization of a similar class of heterocyclic compounds has been reported previously; starting from R$_2$Sn(H)(CH$_2$)$_2$P(H)Ph (R = alkyl) and sulfur, 1-thio-1,2,5-thiaphosphastannolanes were produced.[15a,b] Compound **8** is obtained as a colorless, crystalline solid and is readily soluble in common organic solvents such as CH_2Cl_2, $CHCl_3$, Et_2O, and thf.

The ^{119}Sn-NMR spectrum of **8** shows an ABB′-type resonance at $\delta(^{119}Sn) = -224$ [$J(^{119}Sn-^{31}P) = 19$, 23 Hz]. In the ^{31}P-NMR spectrum, two signals with equal integrals are observed at $\delta(^{31}P) = 17.3$ ($W_{1/2} = 20$ Hz) and $\delta(^{31}P) = 28.6$ [$J(^{31}P-^{119}Sn) = 19$ Hz], which are characteristic of a non-coordinating P(O)(OR)$_2$ moiety and a strongly coordinating P(O)(OR)$_2$ group, respectively.[1b][15c,d] Furthermore, both the ^{1}H- and the ^{13}C-NMR spectra confirm the presence of three distinct ethoxy groups in the molecule.

The formation of the 2,3,1-benzoxaphosphastannole **8** can be formally rationalized as shown in Scheme 1. In a first step, the triphenyltin derivative **3** reacts with one molar equivalent of HCl or X$_2$ (X = Br, I) to give the intermediate cation **8a**, which is best described by the two resonance structures shown in Scheme 1. The existence of donor-stabilized triorganotin cations is well established[15e-t] and recently we succeeded in isolating and fully characterizing {4-*tert*-Bu-2,6-[P(O)(O*iso*-Pr)$_2$]$_2$C$_6$H$_2$}SnPh$_2^+$ PF$_6^-$,[15u] a related derivative of **8a**.



Depending on the lifetime of **8a**, which is determined by the nucleophilicity of the anion X$^-$, it either reacts with a second molar equivalent of HCl or Br$_2$ to give **4** or **7**, respectively (path **A**), or else nucleophilic attack of X$^-$ (X = Cl, Br, I) at the POEt function leads to the 2,3,1-benzoxaphosphastannole **8** (path **B**). The latter reaction path is dominant when X = I, whereas path **A** dominates when X = Cl, Br.

The reaction of phosphonates with excess Me_3SiBr usually leads to complete transesterification.[16] However, reaction of the 2,3,1-benzoxaphosphastannole **8** with an excess

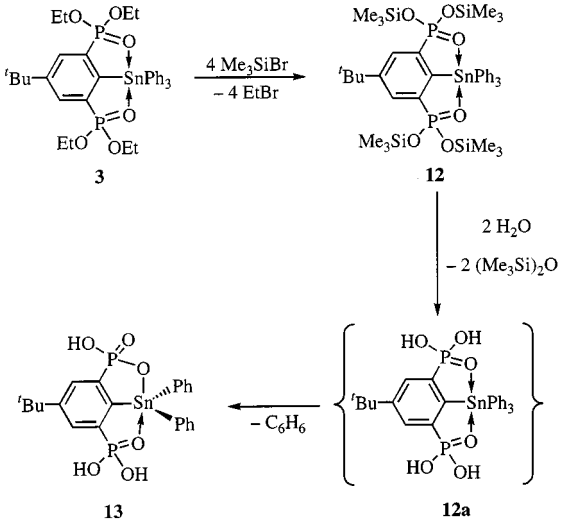
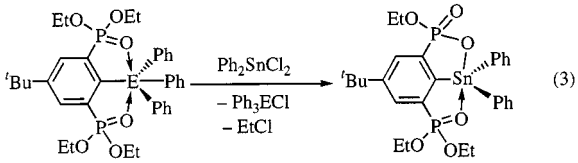


Scheme 1. Synthesis of compounds **4** and **7**–**9**

of Me_3SiBr gave the intramolecularly hexacoordinated diorganotin dibromide **9**, with only one ethoxy group being substituted by a trimethylsiloxy group (Scheme 1). This unusual reactivity is the result of an O–Sn bond cleavage in **8** by attack of Me_3SiBr, which gives the cationic tin species **8b** as an intermediate product. Subsequently, the intermediate **8b** reacts with further Me_3SiBr, which reacts here as an HBr equivalent leading to Sn–C bond cleavage, to provide the diorganotin dibromide **9**. In the ^{31}P-NMR spectrum of the crude reaction mixture, besides the signals due to **9** at $\delta(^{31}P)$ = 17.3 [$J(^{31}P-^{119}Sn)$ = 103 Hz] and $\delta(^{31}P)$ = 26.7 [$J(^{31}P-^{119}Sn)$ = 97 Hz], two minor signals (5%) with equal integrals are seen at $\delta(^{31}P)$ = 19.3 ($W_{1/2}$ = 20 Hz) and $\delta(^{31}P)$ = 29.6 ($W_{1/2}$ = 20 Hz). We tentatively attribute the latter two signals to a heterocyclic compound related to **8**, but attempts to isolate this species were unsuccessful. Evidently, the strong intramolecular O–Sn coordination in the intramolecularly coordinated cation **8b** activates the tin–carbon bonds, thereby facilitating the almost quantitative formation of the hexacoordinate diorganotin dibromide **9**. The O–Sn interactions in the reaction product **9** prevent the latter from undergoing further transesterification at the POEt function upon exposure to excess Me_3SiBr. Similar reactivity was observed when 2,4-bis(diethoxyphosphonyl)-1,5-bis(triphenylstannyl)benzene (**10**)[1b] was treated with an excess of Me_3SiBr (Scheme 2). Instead of a transesterification, substitution of phenyl by bromine was observed as a result of the strong intramolecular coordination. The reaction product, 2,4-bis(diethoxyphosphonyl)-1,5-bis(bromodiphenylstannyl)benzene (**11**) has previously been prepared by reaction of **10** with bromine and has been fully characterized.[1b] Similar reactions of Me_3SnCH_2-$CHX[P(O)(OiPr)_2]$ [X = $P(O)Ph_2$, P(O)(O*i*Pr)Ph, $P(O)(OiPr)_2$, C(O)Ph, C(O)O*i*Pr] with excess Me_3SiBr require higher temperatures, which, in turn, favour redistributions as side reactions.[16b] The intramolecularly coordinated compounds **8** and **10**, however, react even at low temperatures to give predominantly the intramolecularly coordinated organotin bromides **9** and **11**, respectively.

Scheme 2. Bromination of the intramolecularly coordinated tetraorganotin compound **10** with Me_3SiBr

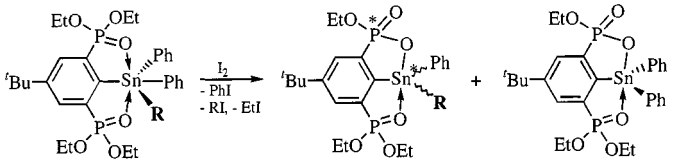


Previous investigations[1b] have shown that in the [4+2]-coordinated compound **3** the intramolecular O−Sn interactions are weaker than those in **10**. Consequently, and in contrast to the situation with **8** and **10**, the *in situ* reaction of **3** with Me_3SiBr proceeds with complete transesterification to give the silylphosphonate **12** (Scheme 3), which has been characterized by ^{31}P-, ^{29}Si-, and ^{119}Sn-NMR. The ^{119}Sn-NMR chemical shifts of the silylphosphonate **12** [$\delta(^{119}Sn) = -188.4$] and of the starting material **3** [$\delta(^{119}Sn) = -186.1$] are very similar, indicating comparable O−Sn coordination strengths in the two compounds. Subsequent reaction of **12** with water afforded the 2,3,1-benzoxaphosphastannole **13** and benzene (Scheme 3). The intermediate free acid **12a** could not be isolated. Richter and Weichmann have shown that the hydrolysis of silylphosphonates and silylphosphinates of 2,2-functionally disubstituted organotin compounds gives the corresponding stannylmethylated phosphonic and phosphinic acids, respectively, which undergo similar intramolecular cyclizations.[16b]

3 **12** **13** **12a**

Scheme 3. Transesterification and intramolecular cyclization of **3**

Recently, van Koten et al.[1d] have shown that $\{(Me_3Sn)_2$-1,4-$[C_6(CH_2NMe_2)_4$-2,3,5,6$]\}$ and $Me_3Sn[C_6H_3$-$(CH_2NMe_2)_2$-2,6] react with Me_3SnCl to give the pentacoordinate species $\{[Me_2Sn]_2$-1,4-$[C_6(CH_2NMe_2)_4$-2,3,5,6$]\}^{2+}$ $[(Me_3SnCl_2)^-]_2$ and $\{Me_2Sn[C_6H_3(CH_2NMe_2)_2$-2,6$]\}^+$ $(Me_3SnCl_2)^-$, respectively. In order to investigate whether compound **3** could be directly transformed into its cationic derivative or into the 2,3,1-benzoxaphosphastannole **8** by this method, the tetraorganotin compound **3** and Ph_2SnCl_2 were heated in refluxing toluene for 4 h. ^{119}Sn-NMR analysis of the reaction mixture showed that the heterocycle **8** was formed as the major product (eq. 3). Additional broad resonances were seen at $\delta(^{119}Sn) = -125$ (9%), −243 (24%), and −284 (28%), which were not assigned. Moreover, reaction of the intramolecularly coordinated tetraorganosilicon compound $\{4$-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2\}SiPh_3$ (**14**)[2p] with Ph_2SnCl_2, which was performed under the same reaction conditions, also gave the 2,3,1-benzoxaphosphastannole **8** as the major product (eq. 3). This result can be explained in terms of $Si-C^{aryl}$ bond cleavage and subsequent insertion of a Ph_2SnCl moiety to give the organotin cation **8a** (X = Cl), followed by intramolecular cyclization with elimination of EtCl.

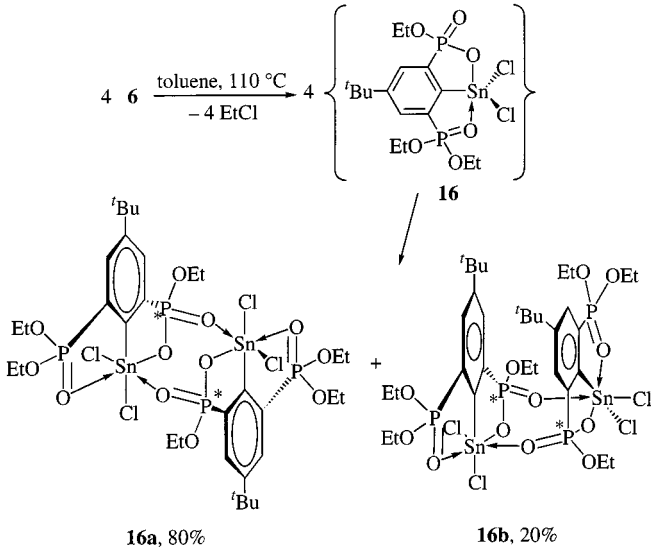


(3)

3, E = Sn
14, E = Si

8

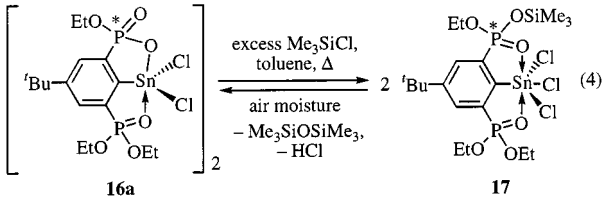
Having established that the reaction of the intramolecularly coordinated tetraorganotin compound **3** with one molar equivalent of iodine gives the 2,3,1-benzoxaphosphastannole **8**, we decided to check whether it would be possible to prepare diastereomeric 2,3,1-benzoxaphosphastannoles starting from the tetraorganotin compound **2**. Reaction of **2** with iodine (Scheme 4) gave 78% of the two diastereomers of 2,3,1-benzoxaphosphastannole **15** in a ratio of 1:0.8, together with 22% of the 2,3,1-benzoxaphosphastannole **8**, as a result of $Sn-C^{phenyl}$ and $Sn-C^{alkyl}$ bond cleavage, respectively. In contrast, reaction of triphenyl(trimethylsilylmethyl)tin with iodine resulted in exclusive cleavage of the $Sn-C^{phenyl}$ bond. Due to the intramolecular O,C,O-coordination in **2**, the Sn−C bond cleavage does not simply follow the expected order of phenyl > alkyl as is well documented for tetraorganotin compounds.[17] A similar reversed order of bond cleavage has previously been reported by Weichmann[18] and by Jousseaume[19] for related compounds.



2 **15** (2 diastereomers, 1:0.8) **8**

R = CH_2SiMe_3 78% 22%

Scheme 4. Reaction of intramolecularly coordinated **2** with iodine



The ease with which the heterocycle **8** is formed suggests that the hexacoordinate monoorganotin trichloride **6** should also undergo intramolecular cyclization to provide a dichloro-substituted 2,3,1-benzoxaphosphastannole. Indeed, this reaction occurred simply by heating **6** in refluxing toluene for several hours. As a result of intermolecular O−Sn coordination, the dichloro-substituted 2,3,1-benzoxaphosphastannole **16** formed by this reaction dimerizes to give a diastereomeric mixture of **16a** (80%) and **16b** (20%), as was apparent from the observation of four ^{31}P-NMR signals at $\delta = 11.95$ [$J(^{31}P-^{119/117}Sn) = 316/301$ Hz, $J(^{31}P-^{119/117}Sn) = 137/125$ Hz] (**16a**), $\delta = 13.12$ [$J(^{31}P-^{119/117}Sn) = 304$ Hz] (**16b**), $\delta = 25.17$ [$J(^{31}P-^{119/117}Sn) = 334/320$ Hz] (**16a**), and $\delta = 25.14$ [$J(^{31}P-^{119/117}Sn) =$

324 Hz] (**16b**), in an integral ratio of 4:1:4:1 (Scheme 5). The diastereomer **16a** could be separated by recrystallization from toluene/chloroform in 65% yield. Its molecular structure is discussed below.

Scheme 5. Intramolecular cyclization of the monoorganotin trichloride **6**

Given that the reaction of the 2,3,1-benzoxaphosphastannole **8** with Me_3SiBr led to a ring-opening, we investigated the reaction of dimeric **16a** with Me_3SiCl (eq. 4). This led to a racemic mixture of the organotin trichloride **17**. Compound **17** proved to be moisture-sensitive and after stirring for 5 days at room temperature the monosilylphosphonate had been hydrolyzed to give almost quantitatively the starting material **16a** (eq. 4) by loss of HCl and $(Me_3Si)_2O$.

This reversible transesterification of **16a** to provide **17** was investigated by ^{31}P-NMR spectroscopic analysis of a sample that had been exposed to atmospheric moisture (Figure 1). The reaction of **17** with water to give **16a** was shown to be diastereoselective; there was no indication of the presence of any **16b**.

Molecular Structures of 2, 6, 8, and 16a

The molecular structures of compounds **2**, **6**, **8**, and **16a** are shown in Figures 2–5 and relevant crystallographic parameters are listed in Table 2. Selected bond lengths and bond angles are collected in Tables 3–5.

In compound **2**, the tetrahedral geometry of the tin atom is markedly distorted and the C–Sn–C angles are found in the range between 95.1(1)° and 122.7(1)°. As has previously been reported for the tetraorganotin compound **3**[1b] and 1-Ph_3Sn-2,4,6-$(CF_3)_3C_6H_2$,[14f] the Sn(1)–C(1) bond lengths of 2.184(3) Å is longer than the Sn–C^{aryl} bond lengths Sn(1)–C(11) [2.155(3) Å] and Sn(1)–C(21) [2.161(3) Å] as a result of the steric repulsion of the rigid ligand frame. In the molecular structure of **2**, two oxygen–tin contacts of 3.108(2) Å and 2.939(2) Å are found for Sn(1)–O(1) and Sn(1)–O(2), respectively, which are significantly shorter than the sum of the van der Waals′ radii of tin and oxygen

(3.700 Å).[20] The overall coordination geometry at the tin center is thus 4+2.

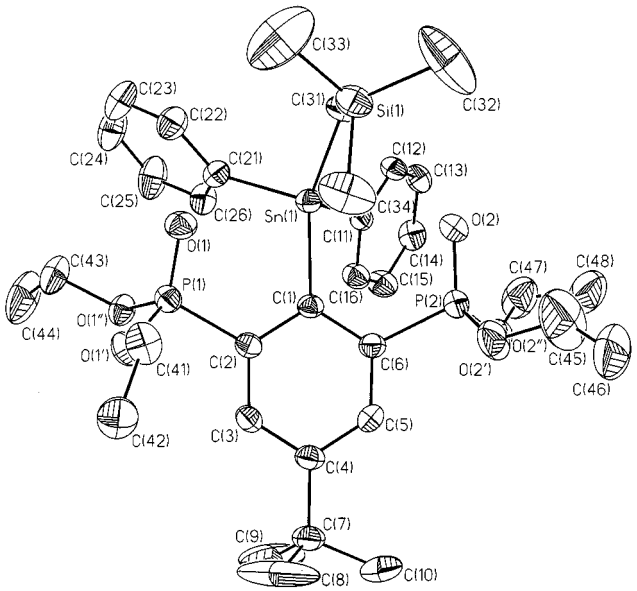

Figure 2. General view (SHELXTL-PLUS) of a molecule of **2** showing 30% probability displacement ellipsoids and the atom numbering scheme

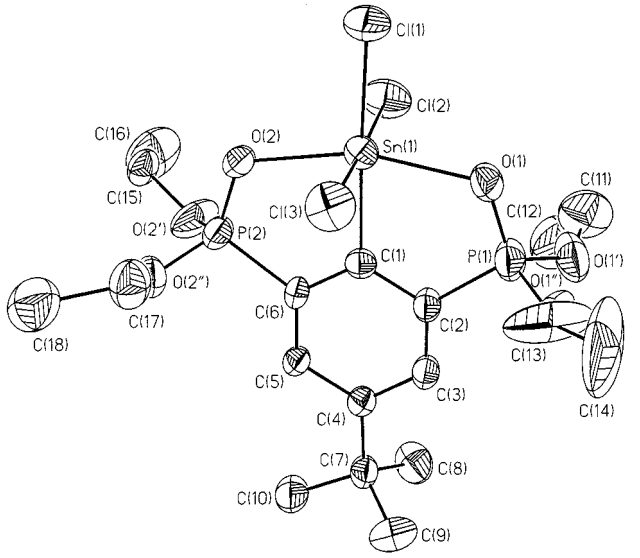

Figure 3. General view (SHELXTL-PLUS) of a molecule of **6** showing 30% probability displacement ellipsoids and the atom numbering scheme

In contrast to compound **2**, strong intramolecular O−Sn contacts are found in the monoorganotin trichloride **6**, in which the tin center adopts a distorted octahedral coordination geometry. The degree of distortion is reflected in *cis*-angles ranging from 80.4(1)° to 91.8(1)° and *trans*-angles of 177.8(1)°, 177.20(5)°, and 161.1(1)° for C(1)−Sn(1)−Cl(1), Cl(2)−Sn(1)−Cl(3), and O(1)−Sn(1)−O(2), respectively. In the previously reported {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2$-C_6H_2}$SnPhCl_2$ (**4**),[1b] the same large deviation of the O−Sn−O angle [161.1(2)°] was found as a result of the rigid ligand frame. The intramolecular bond lengths O(1)−Sn(1) and O(2)−Sn(1) amount to 2.225(3) Å and 2.221(3) Å, respectively, and thus are slightly longer than the intermolecular O−Sn interactions reported for hexacoordinate monoorganotin trichlorides such as $RSnCl_3 \cdot 2\,HMPA$ (R = Ph,[21] Et,[22] Me;[23] O−Sn 2.124−2.180 Å), $RSnCl_3 \cdot 2\,DMF$ (R = *i*Pr,[24] Me;[25] O−Sn 2.150−2.22 Å), $EtSnCl_3 \cdot 2\,Ph_3PO$ (O−Sn 2.175 Å),[22] and $(Cl_3Sn)_2CH_2 \cdot 4\,DMSO$ (O−Sn 2.109 Å).[26] In the case of the intramolecularly hexacoordinated compound $CH_3OOCCH_2CH(COOCH_3)CH_2SnCl_3$[14h] and the heptacoordinate $[2,6\text{-}(MeO)_2C_6H_4]_3CHSnCl_3$,[14f] weak O−Sn interactions of 2.460−2.640 Å have been observed, whereas in the molecular structures of $CH_2{=}CHCH_2OC(O)CH_2CH_2SnCl_3 \cdot Ph_3PO$[14e] and BuOC(O)-$CH(CH_3)CH_2SnCl_3 \cdot Ph_3PO$,[14c] weak intramolecular O−Sn interactions of 2.413 and 2.356 Å have been found, along with strongly coordinated Ph_3PO ligands with O−Sn distances of 2.188 and 2.191 Å.

It is worth noting that in spite of a substantial difference in the Lewis acidities of the monoorganotin trichloride **6** and the diorganotin dichloride **4** [O−Sn 2.203/2.278 Å],[1b] the O−Sn contacts in the two compounds are still similar, which can be attributed to the rigidity of the ligand frame in compounds of type **B**. In contrast, for intermolecularly coordinated compounds, the O−Sn interaction depends strongly on the number of chlorine atoms bonded to tin, as demonstrated by the following two pairs of complexes: $Et_2SnCl_2 \cdot 2\,Ph_3PO$ (O−Sn 2.36/2.258 Å)[27] *vs.* $EtSnCl_3 \cdot 2\,Ph_3PO$ (O−Sn 2.175 Å)[2] and $Me_2SnCl_2 \cdot 2\,HMPA$ (O−Sn 2.231 Å)[28] *vs.* $MeSnCl_3 \cdot 2\,HMPA$ (O−Sn 2.175 Å).[23] The IR spectrum of **6** is indicative of strong P=O−Sn interactions, featuring a ν(P=O) band at 1170 cm^{-1}.

The 2,3,1-benzoxaphosphastannole **8** is characterized by a slightly distorted trigonal-bipyramidal tin center, with O(1) and O(2′) occupying axial and C(1), C(11), and C(21) occupying equatorial positions. The O(1)−Sn(1)−O(2′) angle amounts to 160.2(2)°, which is very close to the O−Sn−O angle in **6**. The configuration at tin in the molecular structure of **8** can be classified as being located on the tetrahedral−trigonal bipyramidal path.[29] The position on this path is given by the difference of the sums of the equatorial and axial angles [$\Delta\Sigma(\theta)$], which amounts to 90° for the ideal trigonal bipyramid, 0° for the ideal tetrahedron, and 77.7° for compound **8**. The displacement of the tin atom from the trigonal plane defined by C(1), C(11), and C(21) amounts to 0.136 Å in the direction of O(2′). Compared with the dative O−Sn bond lengths in **6**, the dative O−Sn interaction of 2.396(4) Å in **8** is slightly longer, but is nevertheless comparable to the O−Sn bond distance found in the structurally related [2-(diphenylphosphanyl)-phenyl]dimethyltin chloride [O−Sn 2.357 Å].[30] In the crystal lattice of **8**, a polymeric chain structure is observed as a result of the incorporation of water molecules, with each water molecule linking two 2,3,1-benzoxaphosphastannoles via O(1)···H−O(3)−H···O(2′) interactions. The IR spectrum of compound **8** shows two ν(P=O) absorptions at 1172 cm^{-1} and 1242 cm^{-1}, which correspond to the P(1)−O(1) and P(2)−O(2) bond distances of 1.488(4) and

1.463(6) Å, respectively, and which unambiguously demonstrate the simultaneous presence of both a strongly coordinating and a non-coordinating phosphonyl group. The slight decrease in the ν(P=O) of the non-coordinating P=O group in comparison with a "free" arylphosphonyl group[1b] can be attributed to weak hydrogen-bonding interactions.

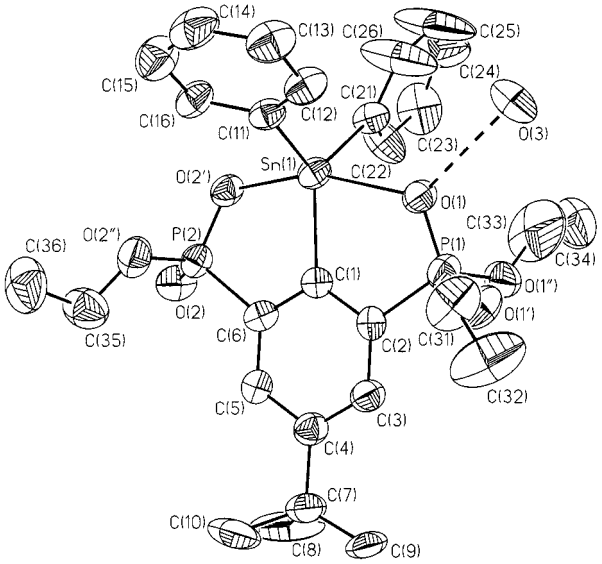

Figure 4. General view (SHELXTL-PLUS) of a molecule of **8** showing 30% probability displacement ellipsoids and the atom numbering scheme (symmetry transformations used to generate equivalent atoms: $a = -x + 0.5, -y + 0.5, -z + 0.5$)

As a result of both intermolecular and intramolecular O−Sn interactions, the tin centers in the dimeric 2,3,1-benzoxaphosphastannole **16a** adopt a distorted octahedral coordination geometry, with *cis*-angles ranging from 81.7(1)° to 97.97(7)°, and *trans*-angles of 172.8(1)°, 173.98(8)°, and 161.78(9)° for C(1)−Sn(1)−Cl(2), Cl(1)−Sn(1)−O(2a), and O(1)−Sn(1)−O(2′), respectively. In comparison with the corresponding O−Sn bond lengths in the monomeric 2,3,1-benzoxaphosphastannole **8**, the O−Sn bond lengths in **16a** are shortened. The dative bond O(1)−Sn(1) in **16a** amounts to 2.204(3) Å. The almost equal O(2′)−Sn(1) and O(2a)−Sn(1) bond lengths of 2.147(3) Å and 2.140(3) Å, respectively, are even shorter and lie in the typical range for O−Sn single bonds (2.15 Å),[31] showing that the phosphonyl group acts as a bidentate bridging ligand. Since the Lewis acidity of the tin atom in **16a** is greater than that of the tin atom in **8**, the former displays a distorted octahedral coordination as a result of dimerization. A similar control of coordination chemistry at tin has previously been reported for compounds of the type $MeXYSnCH_2C(Z)[P(O)(OiPr)_2]_2$ (X, Y = Me, Cl, Br; Z = H, Me). With X = Cl, Y = Me, and Z = H, a five-coordinate compound[15d] was observed, bearing a coordinated and a non-coordinated phosphonyl group. An increase in the Lewis acidity (X = Br, Y = Cl, Z = H)[32] led to the formation of a six-coordinate tin center, with two intramolecular O−Sn contacts. Intra- as well as intermolecular O−Sn coordination has been observed in a dimeric hexacoordinate compound by increasing the steric hindrance (X = Y = Br, Z = Me).[33]

The results of the IR spectroscopic measurements are in agreement with the X-ray data. The ν(P=O) band for the datively bonded phosphonyl group is found at 1168 cm^{-1}. Furthermore, a strong absorption at 1139 cm^{-1} can be assigned to the bidentate bridging phosphonyl group.

Conclusion

We have demonstrated the utility of the new O,C,O-coordinating ligand $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}^-$ in the synthesis of various intramolecularly coordinated organotin compounds. As a result of the high donor capacity of intramolecularly coordinating phosphonyl groups, the 2,3,1-benzoxaphosphastannole **8** and the tetraorganotin compound **10** react with Me_3SiBr under Sn−C rather than P−O bond cleavage. The high donor capacity and the rigidity of the ligand skeleton make the O,C,O-coordinating ligand $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}^-$ an eminently suitable substituent for the intramolecular donor-stabilization of highly reactive compounds.

Experimental Section

General: All manipulations were performed under an inert atmosphere of argon using standard Schlenk and vacuum line techniques. Solvents were distilled from the appropriate desiccants prior to use. Literature procedures were used to prepare $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}Li$ (**1**),[1b] $FSnPh_2(CH_2SiMe_3)$,[10] $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}SnPh_3$ (**3**),[1b] $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}SnPhCl_2$ (**4**),[1b] $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}SnCl$ (**5**),[11] $Ph_3SnCH_2SiMe_3$,[10] $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}SnPhBr_2$ (**7**),[1b] $1,5\text{-}[P(O)(OEt)_2]_2\text{-}2,4\text{-}(Ph_3Sn)_2C_6H_2$ (**10**),[1b] and $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}SiPh_3$ (**14**).[2p] − IR spectra were obtained using a Bruker FT-IR IFS 113v spectrometer. − ^{119}Sn-, ^{29}Si-, ^{13}C-, ^{1}H-, and ^{31}P-NMR spectra were recorded on Bruker DRX 400 and DPX 300 spectrometers. Chemical shifts δ are given in ppm and were referenced against Me_4Sn (^{119}Sn), Me_4Si (^{1}H, ^{13}C, ^{29}Si), and 85% H_3PO_4 (^{31}P).

{[2,6-Bis(diethoxyphosphonyl)-4-*tert*-butyl]phenyl}diphenyl(trimethylsilylmethyl)tin (2): To a solution of $FSnPh_2(CH_2SiMe_3)$ (1.66 g, 4.37 mmol) in 100 mL thf at −25°C, $\{4\text{-}tert\text{-Bu-2,6-}[P(O)(OEt)_2]_2C_6H_2\}Li$ (**1**) (1.80 g, 4.37 mmol) was added in small portions. After stirring for 20 h at room temp., the solid material formed was removed by filtration. The filtrate was concentrated to dryness in vacuo and the residue was recrystallized from ethanol to give 1.30 g (39%) of **2** as colorless crystals; m.p. 133°C. − ^{1}H NMR (400.13 MHz, C_6D_6): δ = 0.36 (s, 9 H, Me_3Si), 0.95 (t, 12 H, CH_3), 1.15 (s, 9 H, CH_3), 1.29 [s, $^{2}J(^{1}H-^{119}Sn)$ = 86 Hz, 2 H, CH_2Sn], 3.44−3.54 (complex pattern, 4 H, CH_2), 3.74−3.84 (complex pattern, 4 H, CH_2), 7.12−7.30 (complex pattern, 6 H, H^{Ph}), 8.12 [d, $^{3}J(^{1}H-^{119}Sn)$ = 49 Hz, 4 H, H^{Ph}], 8.60 (complex pattern, 2 H, H^{Ph}). − $^{13}C\{^{1}H\}$ NMR (100.63 MHz, $CDCl_3$): δ = 1.1 [s, $^{1}J(^{13}C-^{119/117}Sn)$ = 341/323 Hz, 1 C, CH_2Sn], 1.7 [s, $^{3}J(^{13}C-^{119}Sn)$ = 18 Hz, $^{1}J(^{13}C-^{29}Si)$ = 50 Hz, 3 C, Me_3Si], 15.98 [d, $^{3}J(^{13}C-^{31}P)$ = 4 Hz, 2 C, CH_3], 16.01 [d, $^{3}J(^{13}C-^{31}P)$ = 4 Hz, 2 C, CH_3], 30.9 (s, 3 C, CCH_3), 34.6 (s, 1 C, CCH_3), 61.55

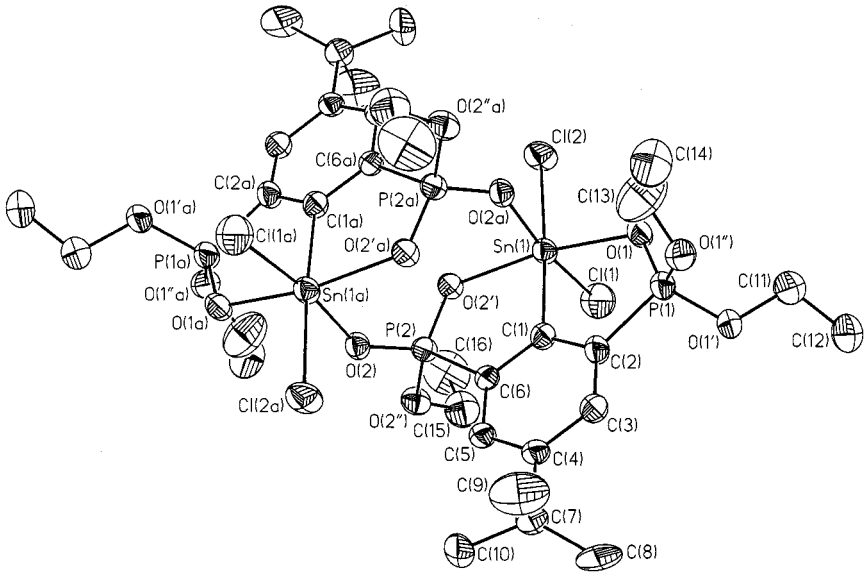

Figure 5. General view (SHELXTL-PLUS) of a molecule of **16a** showing 30% probability displacement ellipsoids and the atom numbering scheme (symmetry transformations used to generate equivalent atoms: $a = -x, -y, -z$)

[$^2J(^{13}C-^{31}P)$ = 3 Hz, 2 C, CH_2], 61.58 [$^2J(^{13}C-^{31}P)$ = 3 Hz, 2 C, CH_2], 126.9 (s, 2 C, C^{para}), 127.2 [s, $^3J(^{13}C-^{119}Sn)$ = 54 Hz, 4 C, C^{meta}], 133.1 (AA′BB′ pattern, 2 C, $C^{3,5}$), 136.9 [s, $^2J(^{13}C-^{119}Sn)$ = 36 Hz, 4 C, C^{ortho}], 137.3 [dd, $^1J(^{13}C-^{31}P)$ = 193 Hz, $^3J(^{13}C-^{31}P)$ = 20 Hz, 2 C, $C^{2,6}$], 147.5 [s, $^1J(^{13}C-^{119/117}Sn)$ = 554/530 Hz, 2 C, C^{ipso}], 150.2 [t, $^3J(^{13}C-^{31}P)$ = 13 Hz, 1 C, C^4], 153.9 [t, $^2J(^{13}C-^{31}P)$ = 23 Hz, 1 C, C^1]. – $^{119}Sn\{^1H\}$ NMR (111.91 MHz, $CDCl_3$): δ = −127.5 [t, $J(^{119}Sn-^{31}P)$ = 38 Hz]. – $^{31}P\{^1H\}$ NMR (121.49 MHz, $CDCl_3$): δ = 23.0 [$J(^{31}P-^{119}Sn)$ = 37 Hz]. – $^{29}Si\{^1H\}$ NMR (59.63 MHz, $CDCl_3$): δ = 5.0. – IR (KBr): $\tilde{\nu}$ = 1242 cm^{-1} (P=O). – $C_{34}H_{52}O_6P_2SiSn$ (765.55): calcd. C 53.34, H 6.84; found C 53.55, H 7.15.

{[2,6-Bis(diethoxyphosphonyl)-4-*tert*-butyl]phenyl}tin Trichloride (6): To a solution of {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}SnCl (**5**) (2.00 g, 3.5 mmol) in 50 mL thf at room temp., $SnCl_4(thf)_2$ (1.20 g, 3.5 mmol) was added in small portions. After stirring the reaction mixture for 2 h, the solvent was evaporated in vacuo. The residue was suspended in 40 mL chloroform and after filtration the solvent was evaporated in vacuo. This procedure was repeated three times, eventually leading to the isolation of 1.3 g (58%) of **4** as colorless crystals; m.p. > 350°C. Crystals suitable for X-ray crystallography were grown from $CDCl_3$. – ^1H NMR (400.13 MHz, $CDCl_3$): δ = 1.36 (t, 12 H, CH_3), 1.37 (s, 9 H, CH_3), 3.93–4.00 (complex pattern, 4 H, CH_2), 4.41–4.50 (complex pattern, 4 H, CH_2), 7.96 (AA′BB′ pattern, 2 H, H^{Ph}). – $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): δ = 15.5 (s, 4 C, CH_3), 30.6 (s, 3 C, CCH_3), 35.0 (s, 1 C, CCH_3), 65.4 (s, 4 C, CH_2), 123.1 [dd, $^1J(^{13}C-^{31}P)$ = 184 Hz, $^3J(^{13}C-^{31}P)$ = 17 Hz, 2 C, $C^{2,6}$], 131.2 (AA′BB′ pattern, 2 C, $C^{3,5}$), 154.4 [t, $^3J(^{13}C-^{31}P)$ = 12 Hz, 1 C, C^4], 173.1 [t, $^2J(^{13}C-^{31}P)$ = 17 Hz, 1 C, C^1]. – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −522.9 [t, $J(^{119}Sn-^{31}P)$ = 286 Hz]. – $^{31}P\{^1H\}$ NMR (161.98 MHz, $CDCl_3$): δ = 28.0 [$J(^{31}P-^{119/117}Sn)$ = 287/273 Hz]. – IR (KBr): $\tilde{\nu}$ = 1170 cm^{-1} (P=O). – $C_{18}H_{31}Cl_3O_6P_2Sn$ (630.48): calcd. C 34.29, H 4.95, Cl 16.87; found C 34.32, H 5.06, Cl 16.82.

5-*tert*-Butyl-7-diethoxyphosphonyl-3-ethoxy-3-oxo-1,1-diphenyl-2,3,1-benzoxaphosphastannole (8). – Method A: To a solution of {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}$SnPh_3$ (**3**) (254 mg, 0.34 mmol) in 8 mL CH_2Cl_2 at 0°C, 4.15 mL of a bromine solution (0.08 mol/L in CH_2Cl_2) was added dropwise. The reaction mixture was stirred for 24 h at room temp., the solvent was then removed in vacuo, and the residue was recrystallized from hexane/diethyl ether to give 203 mg (93%) of **8** as colorless crystals; m.p. 166–168°C.

Method B: To a solution of {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2$-C_6H_2}$SnPh_3$ (**3**) (232 mg, 0.31 mmol) in 5 mL CH_2Cl_2 at room temp., iodine (78 mg, 0.31 mmol) was added in small portions. The reaction mixture was stirred for 36 h at room temp., the solvent was then removed in vacuo, and the residue was recrystallized from hexane/diethyl ether to give 187 mg (89%) of **8** as colorless crystals; m.p. 167–168°C. – ^1H NMR (400.13 MHz, $CDCl_3$): δ = 1.13 (t, 3 H, CH_3), 1.25 (t, 3 H, CH_3), 1.28 (t, 3 H, CH_3), 1.34 (s, 9 H, CH_3), 3.73–4.14 (complex pattern, 6 H, CH_2), 7.34–7.37 (complex pattern, 6 H, H^{Ph}), 7.74–7.92 (complex pattern, 5 H, H^{Ph}), 8.25 (d, 1 H, H^{Ph}). – $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): δ = 15.9 [d, $^3J(^{13}C-^{31}P)$ = 6 Hz, 1 C, CH_3], 16.0 [d, $^3J(^{13}C-^{31}P)$ = 6 Hz, 1 C, CH_3], 16.6 [d, $^3J(^{13}C-^{31}P)$ = 7 Hz, 1 C, CH_3], 31.1 (s, 3 C, CCH_3), 35.2 (s, 1 C, CCH_3), 61.0 [d, $^2J(^{13}C-^{31}P)$ = 6 Hz, 1 C, CH_2], 64.0 [d, $^2J(^{13}C-^{31}P)$ = 6 Hz, 1 C, CH_2], 64.1 [d, $^2J(^{13}C-^{31}P)$ = 6 Hz, 1 C, CH_2], 128.5 [s, $^3J(^{13}C-^{119}Sn)$ = 74 Hz, 4 C, C^{meta}], 128.9/132.1 [dd/dd, $^2J(^{13}C-^{31}P)$ = 14 Hz/$^2J(^{13}C-^{31}P)$ = 12 Hz, $^4J(^{13}C-^{31}P)$ = 3 Hz/$^4J(^{13}C-^{31}P)$ = 4 Hz, 2 C, $C^{3,5}$], 129.0/140.4 [dd/dd, $^1J(^{13}C-^{31}P)$ = 184 Hz/$^1J(^{13}C-^{31}P)$ = 180 Hz, $^3J(^{13}C-^{31}P)$ = 16 Hz/$^3J(^{13}C-^{31}P)$ = 16 Hz, 2 C, $C^{2,6}$], 129.8 [s, $^3J(^{13}C-^{119}Sn)$ = 16 Hz, 1 C, C^{para}], 129.9 [s, $^4J(^{13}C-^{119}Sn)$ = 16 Hz, 1 C, $C^{para'}$], 135.7 [s, $^2J(^{13}C-^{119}Sn)$ = 51 Hz, 2 C, C^{ortho}], 136.0 [s, $^2J(^{13}C-^{119}Sn)$ = 52 Hz, 2 C, $C^{ortho'}$], 138.2 [t, $J(^{13}C-^{31}P)$ = 4 Hz, 1 C, C^{ipso}], 138.8 [t, $J(^{13}C-^{31}P)$ = 3 Hz, 1 C, $C^{ipso'}$], 153.3 [t, $^2J(^{13}C-^{31}P)$ = 18 Hz, 1 C, C^1], 154.9 [t, $^3J(^{13}C-^{31}P)$ = 12 Hz, 1 C, C^4]. – $^{119}Sn\{^1H\}$ NMR (111.91 MHz, $CDCl_3$): δ = −223.6 [dd, $J(^{119}Sn-^{31}P)$ = 19/23 Hz]. – $^{31}P\{^1H\}$ NMR (121.49 MHz, $CDCl_3$): δ = 17.3, 28.6 [$J(^{31}P-^{119}Sn)$ = 19 Hz]. – IR (KBr): $\tilde{\nu}$ = 1172, 1242 cm^{-1} (P=O). – $C_{28}H_{36}O_6P_2Sn$ (649.27): calcd. {[4-*tert*-Butyl-6-diethoxyphosphonyl-2-ethoxy(trimethylsiloxy)-phosphonyl]phenyl}phenyltin Dibromide (9): To a solution of **8** (190 mg, 0.29 mmol) in 2.5 mL CH_2Cl_2 at −30°C was added Me_3SiBr (0.15 mL, 1.16 mmol). After stirring the reaction mixture for 20 min. at room temp., the solvent was evaporated, the residue was washed three times with 2 mL hexane, and dried in vacuo to give

115 mg (49%) of **9** as a colorless solid; m.p. 133°C. – ^{1}H NMR (400.13 MHz, $CDCl_3$): δ = 0.40 (s, 9 H, $SiMe_3$), 1.28 (t, 3 H, CH_3), 1.32 (t, 3 H, CH_3), 1.33 (t, 3 H, CH_3), 1.38 (s, 9 H, CH_3), 4.13–4.54 (complex pattern, 6 H, CH_2), 7.33–7.41 (complex pattern, 3 H, H^{Ph}), 7.92 [d, $^3J(^1H-^{31}P)$ = 13 Hz, 1 H, H^{Ph}], 7.94 [d, $^3J(^1H-^{31}P)$ = 14 Hz, 1 H, H^{Ph}], 8.14 [d, $^3J(^1H-^{119}Sn)$ = 142 Hz, 2 H, H^{Ph}]. – $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): δ = 1.2 (s, 3 C, $SiMe_3$), 16.13 [d, $^3J(^{13}C-^{31}P)$ = 4 Hz, 1 C, CH_3], 16.17 [d, $^3J(^{13}C-^{31}P)$ = 4 Hz, 1 C, CH_3], 16.19 [d, $^3J(^{13}C-^{31}P)$ = 4 Hz, 1 C, CH_3], 31.2 (s, 3 C, CCH_3), 35.3 (s, 1 C, CCH_3), 65.22 [d, $^2J(^{13}C-^{31}P)$ = 4 Hz, 1 C, CH_2], 65.58 [d, $^2J(^{13}C-^{31}P)$ = 5 Hz, 1 C, CH_2], 65.67 [d, $^2J(^{13}C-^{31}P)$ = 5 Hz, 1 C, CH_2], 123.9 [dd, $^1J(^{13}C-^{31}P)$ = 183 Hz, $^3J(^{13}C-^{31}P)$ = 18 Hz, 1 C, C^2], 125.8 [dd, $^1J(^{13}C-^{31}P)$ = 191 Hz, $^3J(^{13}C-^{31}P)$ = 18 Hz, 1 C, C^6], 128.1 [s, $^3J(^{13}C-^{119/117}Sn)$ = 144/138 Hz, 2 C, C^{meta}], 129.6 [s, $^4J(^{13}C-^{119}Sn)$ = 27 Hz, 1 C, C^{para}], 131.3 [t, $J(^{13}C-^{31}P)$ = 3 Hz, 2 C, $C^{3,5}$], 133.9 [s, $^2J(^{13}C-^{119}Sn)$ = 87 Hz, 2 C, C^{ortho}], 149.4 [s, $J(^{13}C-^{31}P)$ = 5 Hz, 1 C, C^{ipso}], 153.5 [t, $^3J(^{13}C-^{31}P)$ = 13 Hz, 1 C, C^4], 172.8 [t, $^2J(^{13}C-^{31}P)$ = 18 Hz, 1 C, C^1]. – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −439.6 [t, $J(^{119}Sn-^{31}P)$ = 100 Hz]. – $^{31}P\{^1H\}$ NMR (161.98 MHz, $CDCl_3$): δ = 17.3 [$J(^{31}P-^{119/117}Sn)$ = 103/98 Hz, $^4J(^{31}P-^{31}P)$ = 7 Hz], 26.7 [$J(^{31}P-^{119/117}Sn)$ = 97/93 Hz, $^4J(^{31}P-^{31}P)$ = 7 Hz]. – IR (KBr): $\tilde{\nu}$ = 1173 cm^{-1} (P=O). – $C_{25}H_{40}Br_2O_6P_2SiSn$ (805.17): calcd. C 37.29, H 5.00; found C 36.70, H 5.20.

1,5-Bis(bromodiphenylstannyl)-2,4-bis(diethoxyphosphonyl)benzene (11): To a solution of 1,5-$[P(O)(OEt)_2]_2$-2,4-$(Ph_3Sn)_2C_6H_2$ (**10**) (139 mg, 0.13 mmol) in 2.5 mL CH_2Cl_2 at −50°C was added Me_3SiBr (0.15 mL, 1.16 mmol). The reaction mixture was allowed to warm to room temp., the solvent was evaporated in vacuo, and the residue was washed three times with 2 mL hexane to give 93 mg (67%) of **11** as colorless solid; m.p. 230–231°C (Lit. 231–233°C)[1b]. – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −180.7 (AA′XX′ pattern). – $^{31}P\{^1H\}$ NMR (161.98 MHz, $CDCl_3$): δ = 25.8 [$J(^{31}P-^{119}Sn)$ = 34 Hz, $^5J(^{31}P-^{119}Sn)$ = 15 Hz].

5-*tert*-Butyl-3-hydroxy-3-oxo-1,1-diphenyl-7-phosphono-2,3,1-benzoxaphosphastannole (13): To a solution of {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}$SnPh_3$ (**3**) (100 mg, 0.13 mmol) in 0.5 mL $CDCl_3$ at −30°C, Me_3SiBr (0.10 mL, 0.77 mmol) was added dropwise. The reaction mixture was allowed to warm to room temp., whereupon ^{119}Sn-, ^{31}P-, and ^{29}Si-NMR spectra were recorded, which indicated the formation of {4-*tert*-Bu-2,6-$[P(O)(OSiMe_3)_2]_2C_6H_2$}$SnPh_3$ (**12**) ($^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −188.4. – $^{31}P\{^1H\}$ NMR (161.98 MHz, $CDCl_3$): δ = −2.82 [$J(^{31}P-^{119}Sn)$ = 40 Hz]. – $^{29}Si\{^1H\}$ NMR (79.49 MHz, $CDCl_3$): δ = 20.1). After distilling off the solvent, the residue was redissolved in 2 mL acetone, water (0.15 mL) was added, and the solution was stirred for 2 h at room temperature. The solvent was then removed in vacuo and the residue was washed three times with 2 mL hexane to give 41 mg (57%) of **13** as a colorless solid; m.p. 280°C (dec.). – ^{1}H NMR (400.13 MHz, [D_6]-acetone): δ = 1.46 (s, 9 H, CH_3), 7.29–7.34 (complex pattern, 6 H, H^{Ph}), 7.80–8.00 (complex pattern, 4 H, H^{Ph}), 8.06–8.08 (complex pattern, 2 H, H^{Ph}). – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, [D_6]acetone): δ = −239.9 [t, $J(^{119}Sn-^{31}P)$ = 70 Hz]. – $^{31}P\{^1H\}$ NMR (161.98 MHz, [D_6]acetone): δ = 20.3, 20.4. – IR (KBr): $\tilde{\nu}$ = 1173 cm^{-1} (P=O), 3400 cm^{-1} (br, O–H). – $C_{22}H_{24}O_6P_2Sn$ (565.11): calcd. C 46.76, H 4.28; found C 46.55, H 4.65.

Reaction of {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2C_6H_2$}$SnPh_3$ (3) with Ph_2SnCl_2: To a solution of **3** (150 mg, 0.20 mmol) in 4 mL toluene was added Ph_2SnCl_2 (69 mg, 0.20 mmol) and the reaction mixture was heated under reflux for 5 h. The solvent was then removed in vacuo, the residue was redissolved in 0.5 mL $CDCl_3$ and the ^{119}Sn-NMR spectrum of this solution was recorded. – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −125, −221 [t, $J(^{119}Sn-^{31}P)$ = 19 Hz], −243 (br.), −284 (br.); integral ratio 0.6:2.6:1.6:1.9.

Reaction of {4-*tert*-Bu-2,6-$[P(O)(OEt)_2]_2$-C_6H_2}$SiPh_3$ (15) with Ph_2SnCl_2: To a solution of **14** (60 mg, 0.090 mmol) in 5 mL toluene was added Ph_2SnCl_2 (31 mg, 0.090 mmol) and the reaction mixture was heated under reflux for 24 h. The solvent was then removed in vacuo, the residue was redissolved in 0.5 mL $CDCl_3$, and the ^{119}Sn-NMR spectrum of this solution was recorded. – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −223 [t, $J(^{119}Sn-^{31}P)$ = 19 Hz], −236 (br.), −258 (br.); integral ratio 1.0:0.3:0.6.

Reaction of {[2,6-Bis(diethoxyphosphonyl)-4-*tert*-butyl]phenyl}-diphenyl(trimethylsilylmethyl)tin (2) with Iodine: To a solution of **2** (250 mg, 0.33 mmol) in 5 mL CH_2Cl_2 was added iodine (83 mg, 0.33 mmol). The reaction mixture was stirred at room temp. for 24 h, then the solvent was removed in vacuo, the residue was redissolved in 0.5 mL of $CDCl_3$, and the ^{119}Sn-NMR spectrum of this solution recorded. – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −138.3 ($W_{1/2}$ = 21 Hz), −139.2 ($W_{1/2}$ = 23 Hz), −224.1 ($W_{1/2}$ = 58 Hz); integral ratio 1:0.8:0.5.

Bis[5-*tert*-butyl-1,1-dichloro-7-diethoxyphosphonyl-3-ethoxy-3-oxo-2,3,1-benzoxaphosphastannole] (16): A solution of **6** (500 mg, 0.79 mmol) in 25 mL toluene was heated under reflux for 16 h. After removing the solid material formed by filtration, the solvent was removed in vacuo and the residue was redissolved in $CDCl_3$. The ^{31}P-NMR spectrum of this solution was recorded, which indicated formation of the two diastereomers **16a** and **16b**. – $^{31}P\{^1H\}$ NMR (161.98 MHz, toluene/D_2O-cap.): **16a**: δ = 11.95 [d, $^4J(^{31}P-^{31}P)$ = 6.8 Hz, $J(^{31}P-^{119/117}Sn)$ = 316/301 Hz, $J(^{31}P-^{119/117}Sn)$ = 137/125 Hz], 25.17 [d, $^4J(^{31}P-^{31}P)$ = 6.6 Hz, $J(^{31}P-^{119/117}Sn)$ = 334/320 Hz]. – **16b**: δ = 13.12 [d, $^4J(^{31}P-^{31}P)$ = 7.8 Hz, $J(^{31}P-^{119/117}Sn)$ = 304 Hz], 25.14 [d, $^4J(^{31}P-^{31}P)$ = 7.0 Hz, $J(^{31}P-^{119/117}Sn)$ = 324 Hz]. The $CDCl_3$ was removed in vacuo and the residue was recrystallized from toluene/$CHCl_3$ to give 290 mg (65%) of the diastereomer **16a** as colorless crystals; m.p. > 350°C. – ^{1}H NMR (400.13 MHz, $CDCl_3$): δ = 1.04 (t, 6 H, CH_3), 1.30 (t, 12 H, CH_3), 1.34 (s, 18 H, CH_3), 3.68–3.78 (complex pattern, 2 H, CH_2), 3.92–4.02 (complex pattern, 2 H, CH_2), 4.09–4.23 (complex pattern, 4 H, CH_2), 4.27–4.41 (complex pattern, 4 H, CH_2), 7.77–7.91 [d, $^3J(^1H-^{31}P)$ = 13.4 Hz, $^4J(^1H-^{119}Sn)$ = 41.8 Hz, 2 H, H^{Ph}], 8.12–8.26 [d, $^3J(^1H-^{31}P)$ = 13.6 Hz, $^4J(^1H-^{119}Sn)$ = 41.0 Hz, 2 H, H^{Ph}]. – $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): δ = 15.1 (m, 6 C, CH_3), 30.3 (s, 6 C, CCH_3), 34.6 (s, 2 C, CCH_3), 62.2 [d, $^2J(^{13}C-^{31}P)$ = 5 Hz, 2 C, CH_2], 64.5 [d, $^2J(^{13}C-^{31}P)$ = 5 Hz, 2 C, CH_2], 64.7 [d, $^2J(^{13}C-^{31}P)$ = 5 Hz, 2 C, CH_2], 122.6 [dd, $^1J(^{13}C-^{31}P)$ = 181 Hz, $^3J(^{13}C-^{31}P)$ = 16 Hz, 2 C, C^2], 128.6 [dd, $^2J(^{13}C-^{31}P)$ = 12 Hz, $^4J(^{13}C-^{31}P)$ = 3 Hz, 2 C, C^5], 129.5 [dd, $^1J(^{13}C-^{31}P)$ = 176 Hz, $^3J(^{13}C-^{31}P)$ = 16 Hz, 2 C, C^6], 132.7 [dd, $^2J(^{13}C-^{31}P)$ = 12 Hz, $^4J(^{13}C-^{31}P)$ = 3 Hz, 2 C, C^3], 154.1 [dd, $^3J(^{13}C-^{31}P)$ = 13 Hz, 2 C, C^4], 167.4 [dd, $^2J(^{13}C-^{31}P)$ = 17 Hz, $^2J(^{13}C-^{31}P)$ = 16 Hz, 2 C, C^1]. – $^{119}Sn\{^1H\}$ NMR (149.18 MHz, $CDCl_3$): δ = −547.9 [ddd, $^2J(^{119}Sn-^{31}P)$ = 139 Hz, $J(^{119}Sn-^{31}P)$ = 320 Hz, $J(^{119}Sn-^{31}P)$ = 336 Hz]. – $^{31}P\{^1H\}$ NMR (161.98 MHz, $CDCl_3$): δ = 11.9 [d, $^4J(^{31}P-^{31}P)$ = 6.6 Hz, $J(^{31}P-^{119/117}Sn)$ = 316/302 Hz, $J(^{31}P-^{119/117}Sn)$ = 137/122 Hz], 25.2 [d, $^4J(^{31}P-^{31}P)$ = 6.6 Hz, $J(^{31}P-^{119/117}Sn)$ = 335/321 Hz]. – IR (KBr): $\tilde{\nu}$ = 1168, 1139 cm^{-1} (P=O). – $C_{32}H_{52}Cl_4O_{12}P_4Sn_2$ (1131.93): calcd. C 33.96, H 4.63; found C 33.55, H 4.79.

Crystallography: Intensity data for the colorless crystals were collected on a Nonius Kappa CCD diffractometer using graphite-monochromated Mo-K_α (λ = 0.71069 Å) radiation at 293 K. The

a = $-x + 0.5, y + 0.5, -z + 0.5$.

data collection covered almost the whole sphere of reciprocal space with 360 frames by ω-rotation (Δ/ω = 1°) at two times, 10 s (**2**), 20 s (**6**, **16a**), and 75 s (**8**), per frame. The crystal-to-detector distance was 2.7 cm (**2**, **6**, **16a**) and 2.9 cm (**8**). Crystal decay was monitored by repeating the initial frames at the end of the data collection. The data were not corrected for absorption effects. On analyzing the duplicate reflections, no indication of any decay was found. The structure was solved by direct methods SHELXS-97[35] (Sheldrick, 1990) and successive difference Fourier syntheses. Refinement employed full-matrix least-squares methods SHELXL-97[36] (Sheldrick, 1997). The H atoms were placed in geometrically calculated positions and refined with common isotropic temperature factors for alkyl and aryl H atoms [C−H$^{prim.}$ 0.96 Å, C−H$^{sec.}$ 0.97 Å, C−H^{aryl} 0.93 Å; U_{iso} 0.139(3) (**2**), 0.166(5) (**6**), 0.189(9) (**9**), 0.131(5) Å^2 (**16a**)]. The occupancy (s.o.f.) of the water molecule O(3) in **8** was found to be 0.5. Disordered groups were found in **2** [OEt group C46 and C46′ (s.o.f. 0.5)], in **6** [OEt groups C11, C13, C14, C15, C17, C11′, C13′, C14′, C15′, C17′ (s.o.f. 0.5)], in **8** [*t*-Bu group C8,

2,5-Disubstituted *N,N′*-Dicyanobenzoquinonediimines (DCNQIs): Charge-Transfer Complexes and Radical-Anion Salts and Copper Salts with Ligand Alloys: Syntheses, Structures and Conductivities

Siegfried Hünig,*[a] Martina Kemmer,[a] Hubert Meixner,[a][2] Klaus Sinzger,[a][2] Hermann Wenner,[a] Thomas Bauer,[b][++] Ekkehart Tillmanns,[b][++] Franz Rudolf Lux,[c] Michael Hollstein,[c] Hans-Georg Groß,[d] Uwe Langohr,[d] Hans-Peter Werner,[d] Jost Ulrich von Schütz,[d] and Hans-Christoph Wolf[d]

Keywords: Conducting materials / Charge-transfer complexes / Radical-anion salts / Alloyed ligands / Crystal structures

The new members of the series of 2,5-disubstituted DCNQIs, **1d** (Cl/OMe), **1e** (Br/OMe), **1j** (Cl/I), **1k** (Br/I), **1l** (I/I), form conducting charge-transfer complexes with TTF (tetrathiofulvalene) which are comparable to known DCNQI/TTFs. From these DCNQIs highly conducting radical-anion salts [2-X, 5-Y-DCNQI]$_2$M (M = Li, Na, K, NH_4, Tl, Rb, Ag, Cu) can also be prepared either from the DCNQIs and MI (not AgI), on a metal wire (Ag, Cu), or by electrocrystallization (M = Tl, Ag,Cu). For better crystals a method using periodical switching between reduction and partial oxidation has been developed. With CF_3 (large, strongly electron-attracting) as the substituent in DCNQIs **1m** (OMe/CF_3) and **1n** (Me/CF_3), conducting TTF complexes remain whereas only **1n** yields an insulating copper salt. DCNQI–Cu salts with high conductivities are obtained with alloys containing two or three different DCNQIs. The temperature-dependent conductivities of DCNQI–M salts (other than copper) are similar to those of metal-like semiconductors. All new DCNQI–Cu salts are metallic [M] down to low temperatures, except [**1d** (Cl/OMe)]$_2$Cu which undergoes a sharp phase transition to an insulating state[M → I]. By variation of the ligands or their ratios in conducting alloys of DCNQI–Cu salts temperature-dependent conductivities can be tuned from M → I to M. In addition, alloying three ligands produced for the first time a radical salt with temperature-independent conductivity from 5 to 300 K. Most remarkably, alloys of the type [(2,5-Me$_2$DCNQI)$_m$] Cu/[{2,5-(CD$_3$)$_2$-DCNQI}$_n$]$_2$Cu which exhibit a sharp M → I phase transition on further cooling reenter the conducting state by an I → M transition, with changes of ca. 10^8 Scm^{-1} both ways. For the first time in the field of organic metals crystal structures of DCNQI–copper salts have been determined by X-ray powder diffraction methods and refined by Rietveld analysis. Unit cell data, coordination angles and distances of the π planes are in excellent agreement with the single-crystal X-ray data. However, bond lengths and angles of the ligands are to be less accurate. This powder method proves to be most valuable if only microcrystalline material is available.

The discovery of electrical conducting solids based on tetrathiofulvalene (TTF)[1−3] has triggered an avalanche of research for new suitable materials up to the present. The interest has been focussed both on the understanding of this unusual phenomenon and on tailoring compounds for practical applications.[4]

Although the basic requirements for conductivity of low molecular organic solids are now clear a more detailed understanding of the interplay of molecular geometry, crystal structure and conductivity (together with its temperature dependence) was hampered by the differing crystal lattices of the various materials. This situation changed with the discovery of (substituted) *N,N*-dicyanoquinoneimines (DCNQIs).[5] Especially radical-anion salts of 2,5-disubstituted DCNQIs prefer all the same space group $I4_1/a$ (or a closely related one) and therefore allow a comparison of their properties.

Thus very subtle substituent effects are translated in minor variations of the basic crystal lattice with definite changes in temperature-dependent conductivities, allowing a much more detailed understanding of this interplay.[6]

We therefore set out to explore the limit of this generalization in the papers of this series.

In a preceding paper we described a variety of new 2,5-disubstituted DCNQIs, together with their redox properties.[8] We now conclude our research activities in this field by posing the following questions arising from the already accumulated experience:

(1) Will the additional examples of 2,5-disubstituted DCNQIs presented here produce charge-transfer complexes

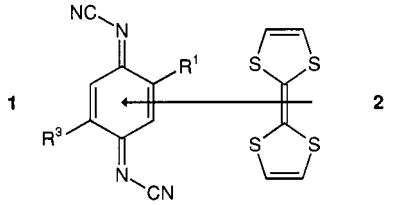
and radical-anion salts with properties similar to those already described, especially in the presence of the large and strongly electron-attracting CF_3 substituent?

(2) Can the growth of single crystals by electrocrystallization be improved by rhythmic reversal of the current flow?

(3) Which variations are tolerated for ligand alloying in DCNQI−Cu salts with two different 2,5-disubstituted DCNQIs (ratio and pattern)?

(4) Will the temperature-dependent conductivities of those alloyed copper salts mimic those of the two single copper salts or will new properties arise, especially with respect to phase transitions?



(5) Which structural data for DCNQI−Cu salts can safely be derived from powder-diffraction data refined by Rietveld analysis (so far rarely applied to organic solids) compared to single-crystal X-ray data?

The following sections concentrate mainly on answering these questions.

Charge-Transfer Complexes of DCNQIs 1a−n with TTF

As with other 2,5-disubstituted DCNQI[9] derivatives, **1a−n** immediately form black microcrystalline charge-transfer complexes on mixing their solutions in acetonitrile or dichloromethane with those of TTF (**2**). The stoichiometry in all the examples listed in Table 1 was found to be 1:1.

[a] Physical data of the DCNQIs, see ref.[9] − [b] Determined by DTA. − [c] Ref.[10] − [d] This paper.

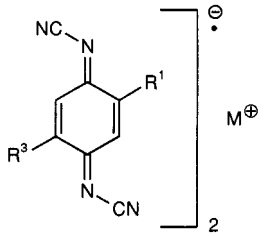
The rather high powder conductivities (10^{-1}−10^{-3} Scm^{-1}) of the new complexes correlate well with those of the complexes already reported.[9] Together with their total absorption in the infrared these data point to segregated stacks of two components. However, this arrangement is kinetically controlled since, e.g. growing single crystals of **1a·2**, **1h·2**, and **1i·2** affords insulating charge-transfer complexes with mixed stacks.[10] It is remarkable that despite the wide range of redox potentials of the DCNQIs from $E_2 = 0.15$ V of **1a** (OMe/OMe) to $E_2 = 0.63$ V of **1l** (I/I) charge-transfer complexes with TTF can be obtained, even with the same stoichiometry. However, for $E_2 = 0.83$ V, the potential of the DCNQI with R^3, $R^5 = CF_3$,[8] no charge-transfer complex with TTF could be isolated, probably due to total electron transfer to the acceptor (see ref.[11][13]). If solubilities allow, hot acetonitrile is to be preferred to dichloromethane for high-potential DCNQIs.[11−13]

In accord with $E_2 = +0.53$ V for **1m** (R^1 = OMe, R^3 = CF_3) and $E_2 = +0.55$ V for **1n** (R^1 = Me, R^3 = CF_3) both donors yield 1:1 complexes with TTF of normal conductivities. Slight deviations from the ideal 1:1 stoichiometry may either be interpreted as due to experimental errors in the combustion analysis or defective crystal growth.[13] Obviously, the rather large diameter of the CF_3 group (5.2 to 5.6 Å) does not interfere with the close packing of the π planes in the acceptor stacks, a prerequisite for conductivity. The CF_3 groups of neighbouring molecules are probably interlocked like cog wheels, similar to the acceptor itself,[8] thereby diminishing their actual size.

Radical-Anion Salts $[DCNQI]_2M$ with Monovalent Cations

Quionoid acceptors such as DCNQIs can generally be transformed into their radical-anion salts by three methods.

Preparation from Metal Iodides



The use of metal iodides as electron donors and their subsequent successful application to TCNQs has already been described by Melby.[17] Consequently, iodides have also been employed for various DNCQIs.[18] We now describe further radical-anion salts of the stoichiometry $[2\text{-X,5-Y-DCNQI}]_2M$ with M = Li, Na, K, NH_4, Rb and Cu produced by this method. Without special precautions the black salts are formed as microcrystalline powders (Table 2).

This simple and quick method is applicable to a remarkably broad variety of 2,5-substituted DCNQIs as well as to different metal ions. With one exception (**1n·**Rb) all salts display powder conductivities up to 1 to 10^{-3} Scm^{-3} from which single-crystal conductivities up to 1000^{-1} Scm^{-1} can be expected (vide infra).

Preparation from Metal Wire

DCNQI radical-anion salts of copper and silver can be most easily prepared from DCNQIs and the corresponding

metal wire in acetonitrile yielding very often single crystals of good quality.[12]

For the variety of DCNQIs described in the previous paper[8] this method has already been discussed.[14] For comparison of their conductivities with radical salts obtained by the other methods, some earlier results are also included here (Table 3).

Conductivities of these salts agree completely with those of samples prepared from metal wire and by electrocrystallization, as is to be expected from earlier results, thereby confirming the same structural features.[12]

Preparation by Electrocrystallization

The most widely used technique of electrocrystallization was also applied to a variety of DCNQIs listed in Table 4.

Table 3. Radical-anion salts $(DCNQI)_2$M(Cu, Ag) grown in acetonitrile on a metal wire in solutions of the DCNQIs **1** and $CuBr_2$ or $AgNO_3$, respectively, and their single-crystal (s) or powder (p) conductivities [S cm^{-1}]

[a] Cubes. – [b] Bushels of very thin needles. – [c] Ref.[19] – [d] Ref.[20] – [e] Microwave measurements. – [f] Current switching 70:30 s^{-1}, see this paper.

The rather low conductivities of 70 Scm^{-1} measured for $(\mathbf{1f})_2$Cu and $(\mathbf{1l})_2$Cu compared to 500 Scm^{-1} for $(\mathbf{1k})_2$Cu are probably due to the microwave techniques which had to be used for these very thin needles. Evaluations by this method are based on the exact dimensions of the sample which could not be determined in our material with sufficient accuracy.[21]

Sometimes, even electrocrystallization yields only microcrystalline material, in spite of the systematic variation of solvent, supporting electrolyte, concentration, temperature, and density of the current. In this situation, rhythmic reversal of the current flow in the electrochemical cell (see circuit diagram, Figure 13) may be helpful. This procedure is based

on the common fact that small crystals dissolve faster than large ones due to their more extended surface. From a microcrystalline material at the electrode, the smallest particles should therefore dissolve faster on reversing the current flow for a certain time. In this way, on normal current flow, new material should be deposited on the larger crystals which finally grow at the cost of the smaller ones. Indeed, single crystals of good quality were easily obtained for [2,5-$(MeO)_2$DCNQI]$_2$Cu, (**1b**)$_2$Cu and [2-I,5-(MeO)DCNQI]$_2$-Cu, (**1f**)$_2$Cu by current switching 70:30/s.

This method, disclosed here for the first time, may be advisable also for other types of electrocrystallizations.

Tables 2−4 clearly demonstrate that whenever solid DCNQI radical salts are obtained electric conductivity is

observed also. As well two large substituents of opposite electronic properties (OMe/OMe or I/I) are tolerated as two substituents strongly differing in size with equal (e.g. MeO/Me or Cl/I) or opposite electronic effects (Cl/OMe or I/Me). This great variability fortunately is connected especially with copper as gegenion (metallic conductivity[6][7]). By contrast, thallium[20] yielded a solid radical salt with **1c** (Me/Me) only. Conductivity data from crystal powder (p) are much less reliable than those obtained from single crystals (s) [cf. **1a**Cu: 0.1 Scm^{-1} (p), 700 Scm^{-1} (s)[19] vs. **1b**Cu: 0.1 Scm^{-1} (p), 80 Scm^{-1} (s)]. The accuracy of powder data suffer both from the method of measurement (compression between two electrodes) and the variable surface properties of the microcrystals.

Ligand Alloys in Copper Salts of 2,5-Disubstituted DCNQIs

As demonstrated earlier[15,16,22–27] and in this paper (vide infra), radical-anion salts of the general type [2-X,5-Y-DCNQI]$_2$Cu all crystallize in the highly symmetrical space group $I4_1/a$ in spite of the strong variation of the substituents and redox potentials of the DCNQI ligands. One group of these salts shows metallic conductivity down to low temperatures (M), whilst others possess a phase transition to an insulating state at various temperatures (M → I).

Because of the great variability in the 2,5-substituent pattern, two or even three different 2,5-disubstituted DCNQIs may form an alloy of ligands in the stacks of DCNQI−Cu salts. A study of the properties of these alloys could lead to a better understanding of the substituent dependence of electric conductivity and the temperature of phase transitions.[28]

For the preparation of the mixed DCNQI−Cu salts, a copper wire was immersed into a solution of different DCNQIs (1:1 and 10:1:1) in acetonitrile in the presence of copper(II) bromide. In this way, 26 binary and one ternary salt were isolated (Table 5).

In most cases the ratios of the components in the mixed DCNQI−Cu salts are close to those in the starting solution, namely 1:1. These ratios are calculated from the elemental analyses which are also given in Table 5. Their accuracy should not be overestimated, as can be judged from two examples where comparison with probably more precise results from neutron activation analysis (NAA) (Br, Cu, vide infra) was possible. In entry 10 the ratio 1.1:0.9 is reversed to 0.9:1.1 by NAA. Similarly in entry 21 the ratio 1.0:1.0 changes to 1.15:0.85 by NAA.

The 1:1 ratio of the two different DCNQI ligands was only expected for combinations with similar redox potentials. However, they are obviously not important for the composition of the alloys, as can be exemplified by entry 14. Although E_2 = +0.21 V of 2,5-Me_2DCNQI[30] and E_2 = +0.62 V of 2,5-Br_2DCNQI[29] differ by as much as 400 mV the copper salt contains the ligands in a ratio of 1:1, whereas a large excess of 2,5-Br_2DCNQI is to be expected. The different rates of crystal growth and solubility, which are well known from the single component salts (see Tables 3 and 4), probably outweigh the differences in reducibility. This rationalization is in line with the exceptional ratios 1.4:0.6 (entry 2), 1.8:0.2 (entry 15), and 0.5:1.5 (entry 17) where the faster growing component is the preferred one. On this basis, however, the ratio 0.6:1.4 (entry 7) should be reversed.

Electrochemical generation of DCNQI−Cu alloys was used for three different pairs of DCNQIs with varying ratios of the two acceptors. The intention was to create a series of different alloys from the same pair of DCNQIs. This was indeed possible, as can be judged from Table 6, e.g. from 2,5-Me_2DCNQI (**1c**) and 2-Br,5-MeDCNQI (**1h**) ten different mixed copper salts were obtained with ligand ratios from 1.95:0.5 to 0.10:1.9 (Table 1 of the supporting information comprises 22 entries). The ratios were again calculated from the elemental analyses. In samples which contained a bromine substituent, however, the crystals were irradiated with a neutron source and the amount of bromine and copper determined from the half life of their radioactive isotopes (NAA). The percentage of the bromine-substituted ligand can be calculated from the constant stoichiometry [DCNQI]$_2$Cu. In eleven alloys the ratio of the two ligands could be calculated in both ways. These ratios agree reasonably well, the NAA data (± 0.2%) being more reliable. The ratio of the ligands in different alloys reflects the ratio of the corresponding DCNQIs in solution but not in a linear way, as demonstrated in Figure 1.

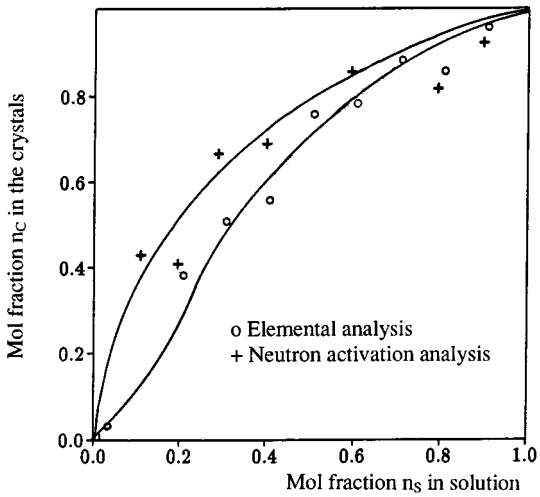

Figure 1. Correlation of the mol fractions of the products [(2,5-Me_2DCNQI)$_m$(2-Br,5-MeDCNQI)$_n$]Cu (n_C) with those of the corresponding DCNQIs in the solution for electrocrystallization (n_S)

This correlation agrees well with that of a similar investigation on the same system.[31]

The DCNQI−Cu salts generated both electrochemically and at a copper wire represent alloys with statistically distributed ligands and not crystals with domains of the two DCNQIs or even crystal mixtures of the individual salts. This conclusion can be drawn from the following results:[32] (a) Different crystals of the same mixed salt produce identical mass spectra with the same pattern; (b) in X-ray powder diagrams (vide infra) of the system [(2-Cl,5-

MeDCNQI)$_m$(2-I,-5-MeDCNQI)$_n$]$_2$Cu reflections appear which do not occur in the copper salts of the two components; the rather broad reflections, however, point to strong disorder in the crystal structure; (c) temperature-dependent single-crystal conductivities of two halves of a needle from [(2,5-Me$_2$DCNQI)$_{1.57}$(2-I,5-MeDCNQI)$_{0.43}$]Cu are identical. The existence of large domains of the two ligands is therefore improbable.

All isolated alloys have in common a total absorption between 4000 and 600 cm^{-1} indicating a high powder conductivity of > 0.2 Scm^{-1}.

Deuterated DCNQIs in Alloys of Copper Salts

In 2,5-Me$_2$DCNQI (**1c** ≡ **1c**·H$_8$) the two methyl groups can be replaced by trideuteriomethyl groups, yielding 2,5-(CD$_3$)$_2$DCNQI (**1c**·D$_6$).[3] Since (**1c**·D$_6$)$_c$Cu displays an unprecedented giant secondary isotope effect in its temperature-dependent conductivity ($\Delta\sigma = 10^8$ Scm^{-1})[29][32] the behaviour of alloys of [**1c**·H$_8$]$_2$Cu and [**1c**·D$_6$]$_2$Cu was of special interest. Mixtures of **1c**·H$_8$ and **1c**·D$_6$ in ratios from 90:10 to 10:90 (10% intervals) were therefore employed in order to grow the corresponding copper salts by electrocrystallization. Because of the extremely small differences between the two ligands the composition of the alloys {(2,5-Me$_2$DCNQI)$_m$[2,5-(CD$_3$)$_2$DCNQI]$_n$}$_2$Cu are assumed to represent the ratio of the two acceptors in solution. These alloys of DCNQI copper salts very often display a pattern of temperature-dependent conductivity which cannot be achieved by employing the corresponding salts containing only one of DCNQI ligands of the alloy (vide infra).

Temperature-Dependent Conductivity of DCNQI Radical-Anion Salts

Most valuable information can be drawn from the temperature dependence of conductivity, especially concerning semi- or metallic conduction and phase transitions. The following background has to be presented here because otherwise the very special effects observed with alloyed DCNQI copper salts could not be appreciated.

Non-Copper Salts

Silver and alkali salts of 2,5-disubstituted DCNQIs so far known have already been demonstrated to behave as "metal-like semiconductors"[35] of low dimensionality.[12,25,27,36] On cooling, the conductivity of solids of this type remains nearly constant, but finally they become insulators at very low temperatures (4-K$_f$ transition,[37] Peierls distortion[38]). The existence of an additional 2-K$_f$ transition (spin-Peierls transformation[39]) between ca. 80 and 100 K can be deduced from their high-resolution IR spectra

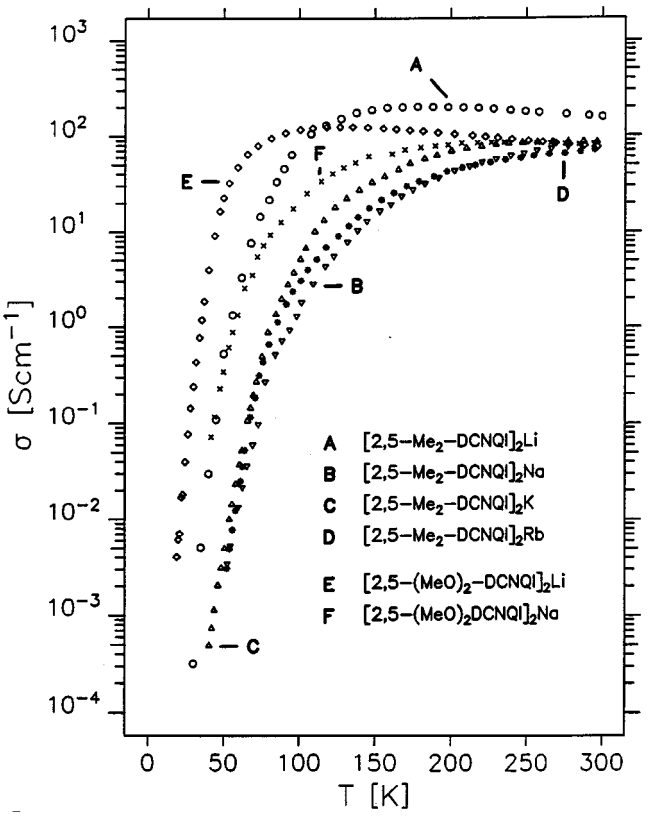

Figure 2. Temperature-dependent single-crystal conductivities of [2,5-Me$_2$DCNQI]$_2$M (M = Li, Na, K, Rb) and [2,5-(MeO)$_2$DCNQI]$_2$M (M = Li, Na)

but is not observed as a change in conductivity.[40] Figure 2 shows the temperature-dependent conductivity of various alkali metals with two sets of DCNQI ligands under identical conditions.[41]

Starting from similar conductivities (ca. 80−180 Scm^{-1}) at ambient temperature their turn to lower conductivity strongly depends on the size of the alkali ion: Rb > K > Na >> Li. In the case of [2,5-Me$_2$DCNQI]$_2$Li a slight increase in conductivity is even observed down to ca. 150 K. However, the larger and more strongly donating methoxy groups extend the range of high conductivity down to even lower temperatures. The lowest temperature for high conductivity so far observed for a non-copper DCNQI salt has been determined to be ca. 70 K for [2,5-(MeO)$_2$-DCNQI]$_2$Li.[41]

The temperature-dependent conductivity of the thallium salt [2,5-Me$_2$DCNQI]$_2$Tl has already been extensively discussed.[20] The temperature/conductivity pattern resembles that of the potassium salt in Figure 2 and that of the corresponding silver salt.[42] Although in the thallium salt the Tl−N≡C− distances are normal (sum of the van der Waals radii 309 pm) this compound is the only one (apart from the DCNQI−Cu salts) which displays a definite knight shift[43] of the $^{205}Tl^+$ ion. Therefore the s orbitals of the thallium ions must become polarized onto the DCNQI stacks.[20]

Copper Salts[6]

All DCNQI copper salts are three-dimensional metallic conductors with $\sigma = 100-1000\ Scm^{-1}$ at ambient temperature. At lower temperatures, however, they split into two groups: group M (metallic conductivity down to lowest temperatures without phase transition as shown in Figure 3), group M → I [on cooling metallic conductivity breaks down between 210 and 160 K at a sharp phase transition (Peierls transformation)[38] to an insulating state (Figure 4)]. Four-point wiring of the very thin needles of [2-I,5-MeODCNQI]$_2$Cu was not possible, although since the ESR signal is totally broadened down to 0.4 K, this salt must definitely belong to group M (Figure 3).

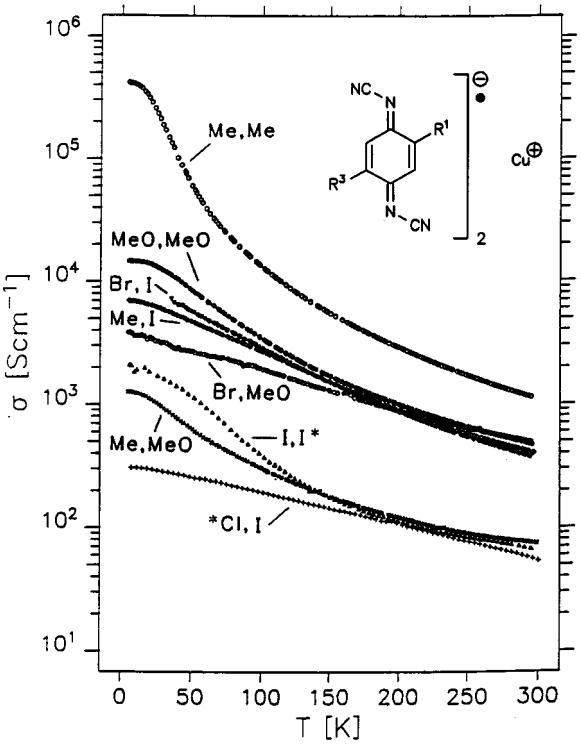

Figure 3. Temperature-dependent conductivities of DCNQI−Cu salts (group M)

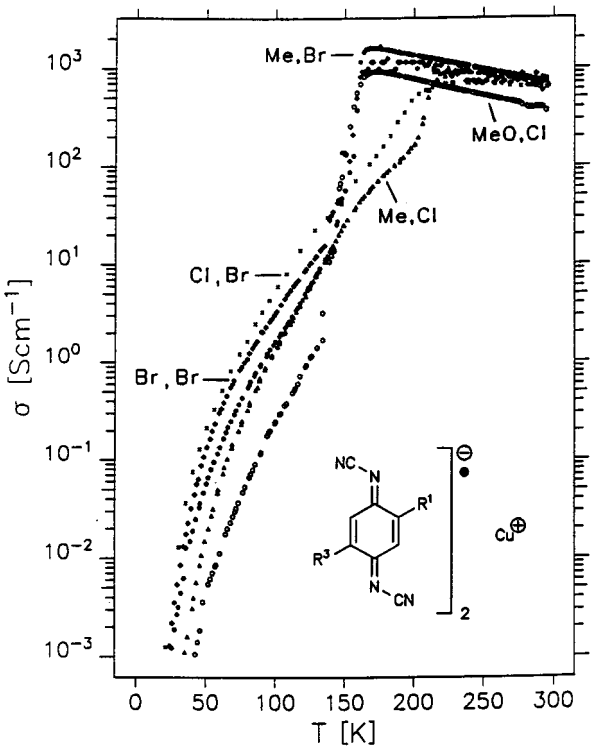
The substituent dependence of this different behaviour, as well as the substituent-dependent temperature of the phase transitions, has been thoroughly discussed.[6,8,33] [2,5-Me$_2$DCNQI]$_2$Cu displays the highest conductivity (500000 Scm^{-1}) at 0.4 K, but is a borderline case of group M; under pressure[44] or on deuteration[33,34] it switches to group M → I (vide infra).

Temperature-Dependent Conductivity of Alloys of DCNQI−Cu Salts

As already discussed, most alloys of copper salts with two or three different DCNQI ligands display high metallic conductivities (see Table 5). Compared to the situation pictured in Figures 3 and 4 conductivity/temperature correlations of the following alloys are therefore of special interest: (1) all ligands from group M; (2) one ligand group from M, the other from group M → I; (3) all ligands from group M → I at constant and varying ratios of acceptors.



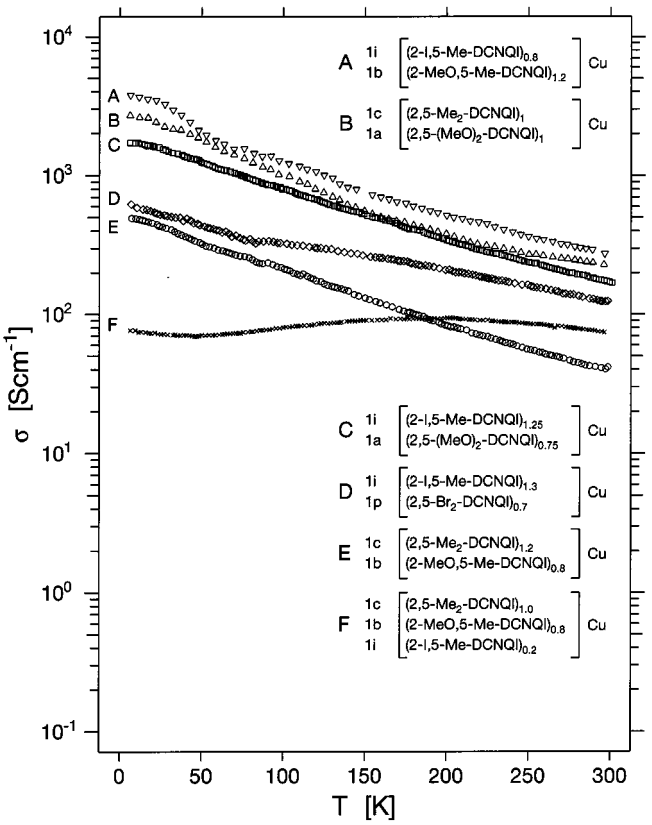


Figure 4. Temperature-dependent conductivities of DCNQI−Cu salts (group M → I)

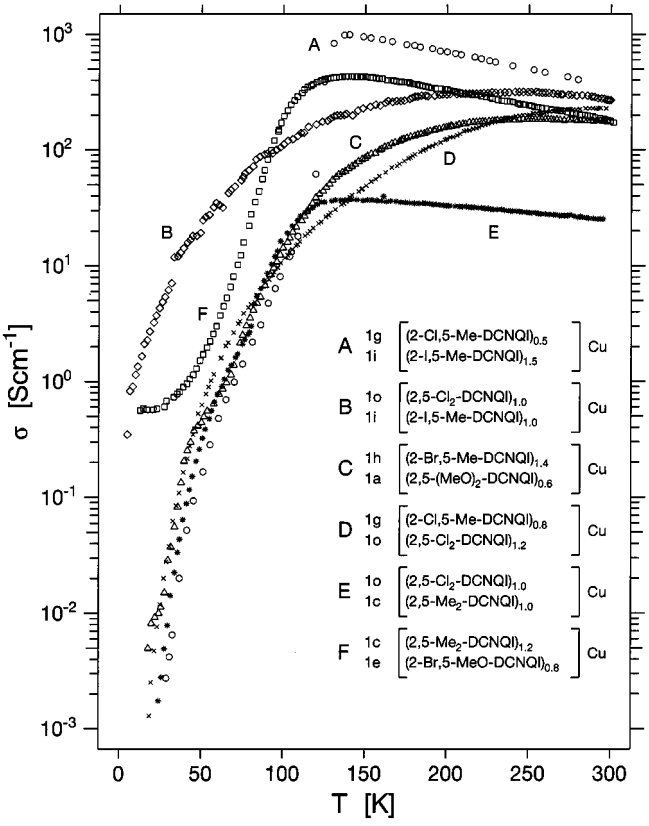

For alloys grown on a copper wire from solutions of the acceptors in acetonitrile with ratios close to 1:1 (Table 5) temperature-dependent conductivities were registered and are collected in Figures 5 and 6. In Figure 5 the similarity of the ascending slopes of curves A−E is remarkable. Curves A and C show a pattern which is expected from that of the pure DCNQI−Cu salts of Figure 3. In the case of curves B and E the strong increase in conductivity of [2,5-Me$_2$DCNQI]$_2$Cu (Figure 3) is suppressed in its alloys. Curve D represents the first case in which the M → I transition of one component ([2,5-Br$_2$DCNQI]$_2$Cu, Figure 4) is suppressed by alloying it with a group-M partner. The slight dip at ca. 80 K may reflect the suppressed M → I transition.

Another surprise comes from curve F which marks the *nearly constant conductivity over a range of 5−300 K (!)* of this ternary alloy. From the metallic behaviour of all three single components (Figure 3) an increase of conductivity as in curves A−E of Figure 5 was at least anticipated. This unprecedented behaviour demonstrates *the high potential of ligand alloying by producing temperature-independent conducting materials.*

The alloys listed in Figure 6 (except D) all belong to group M → I, albeit with strongly differing phase transitions. Curves B, C, and D resemble those for metal-like semiconductors (Figure 4). This behaviour cannot be simply connected to the fact that these alloys contain a group-M and a group-M → I ligand (A, B, C and E); only alloys

Figures 5. Temperature-dependent conductivities of alloys [2-X,5-Y-DCNQI]$_m$(2-W,5-Z-DCNQI)$_n$−Cu grown from the acceptors on a copper wire; for m and n see Table 5; group-M alloys

Figures 6. Temperature-dependent conductivities of alloys [2-X,5-Y-DCNQI]$_m$(2-W,5-Z-DCNQI)$_n$−Cu grown from the acceptors on a copper wire; for m and n see Table 5; group-M → I alloys

A and E suffer from a sharp phase transition. In addition, *the binary alloy formed from two group-M → I ligands (D) with sharp phase transitions (Figure 4) has lost this feature completely.*

The shape of curve F was not expected at all because both ligands of the alloy belong to group M (Figure 3). Obviously the borderline ligand 2,5-Me$_2$DCNQI cannot keep its group-M properties. The levelling off of curve F at < 30 K is unusual and may be connected to the reentry phenomenon of [2,5-Me$_2$DCNQI]$_2$Cu observed under pressure[28] or by alloying with its deuterated counterpart[33][34] (vide infra).

An alloy composed of the borderline group-M salt and a typical group-M → I salt, [(2,5-Me$_2$DCNQI)$_m$(2-Br,5-MeDCNQI)$_n$]$_2$Cu was also investigated (Figure 7). With the small fraction n = 0.025 (curve B) the metallic behaviour is principally retained (m = 0.975). However, the inflection between 100 and 50 K marks a phase transition which is reversed at lower temperatures ("reentrance phenomenon", vide infra). However, for n = 0.37 (curve C) at ca. 90 K a sharp M → I transition occurs typical for n = 1 (curve F, M → I at ca. 170 K) but at much lower temperatures (ca. 90 K). Interestingly, with n = 0.63 and n = 0.88 (curves D and E) this sharp phase transition disappears and a pattern is observed which resembles that of metal-like semiconductors. Independent investigations of the same alloyed DCNQI copper salt[23] are consistent with these results.

The last series of alloys studied comprised one "normal" group-M acceptor and one group-M → I acceptor [(2-I,5-MeDCNQI)$_m$(2-Br,5-MeDCNQI)$_n$]$_2$Cu (Figure 8).

In this alloy the type of metallic conductivity observed for m = 1 (n = 0, curve A) is preserved for n = 0.42 (curve B) and even for n = 0.60 (curve C) although the latter shows signs of a phase transformation. With a slightly higher concentration of the group-M → I component, n = 0.69 (curve D), a sharp phase transition occurs at ca. 110 K which keeps its pattern but moves closer to that of pure n = 1 (curve G) with n = 0.83 and n = 0.92 (curves E and F).

The rather low sensitivity of [2-I,5-MeDCNQI]$_2$Cu to doping with a second partner results from the disorder in the crystal lattice caused by the large iodine and the small methyl substituents. The bromine substituents in 2-Br,5-MeDCNQI may possibly just occupy the positions of the iodine substituent in the first ligand.

Temperature-Dependent Conductivities in Deuterated [2,5-Me$_2$DCNQI]$_2$Cu Alloys

The most remarkable effects observed for some of these alloys have already been discussed in detail.[33,45,46] For comparison with the alloys described above some features

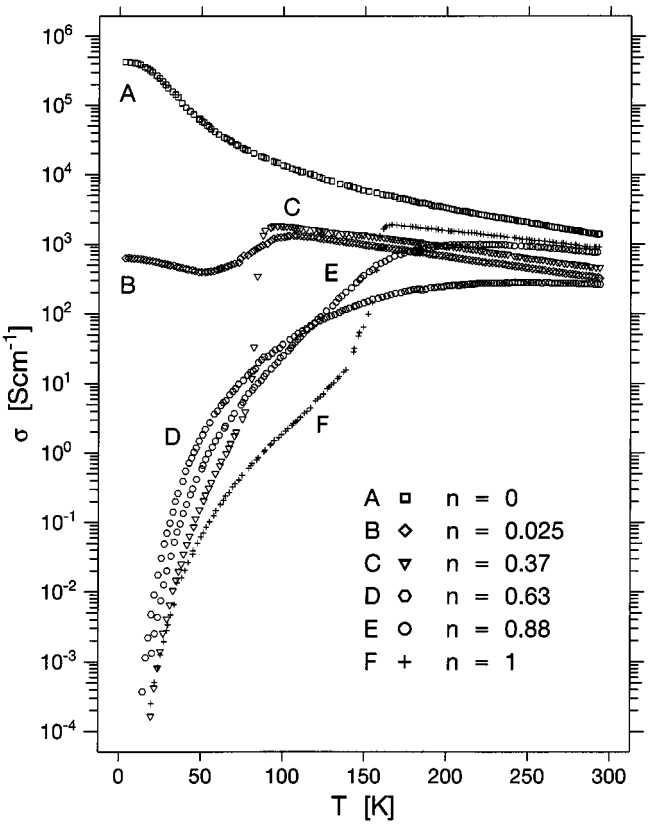

Figure 7. Temperature-dependent conductivities of alloys [(2,5-Me_2DCNQI)$_m$(2-Br,5-MeDCNQI)$_n$]$_2$Cu

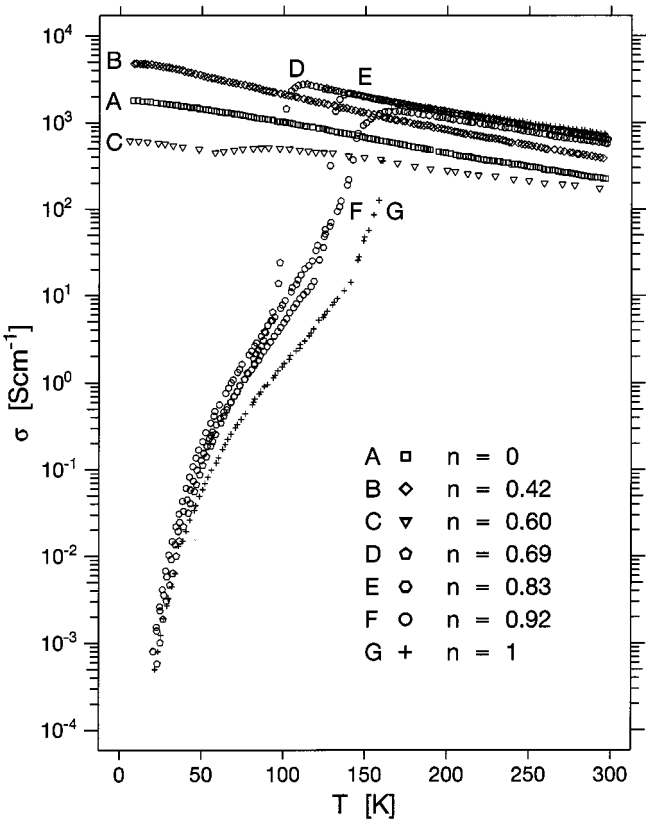

Figure 8. Temperature-dependent conductivities of alloys [(2-I,5-MeDCNQI)$_m$(2-Br,5-MeDCNQI)$_n$]Cu

of {(2,5-Me_2DCNQI)$_m$[2,5-$(CD_3)_2$DCNQI]$_n$}Cu alloys ("H_8/D_6") should be also be addressed here.

As seen in Figure 9, the metallic behaviour of "H_8" at temperatures down to 0.4 K is lost in "D_8". In this case, a sharp phase transition is observed at 73 K, where the conductivity drops by the order of 10^7-10^9.

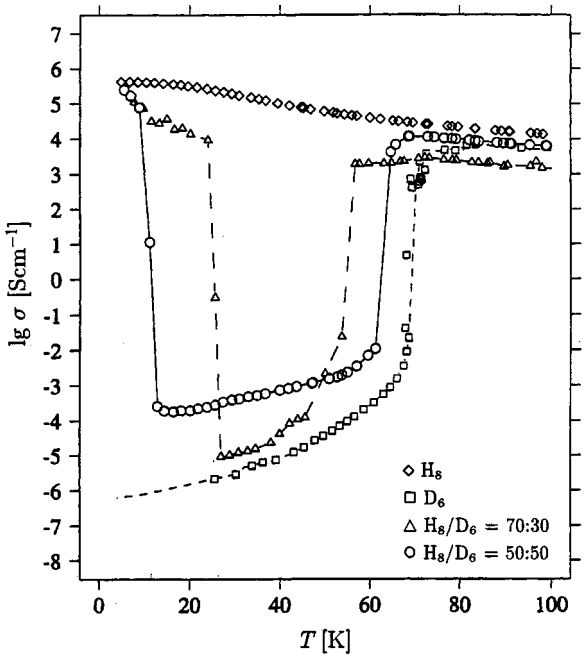

Figure 9. Temperature-dependent conductivities of [2,5-Me_2DCNQI]$_2$Cu (H_8) and [2,5-CD_3DCNQI]$_2$Cu (D_6) together with their alloys

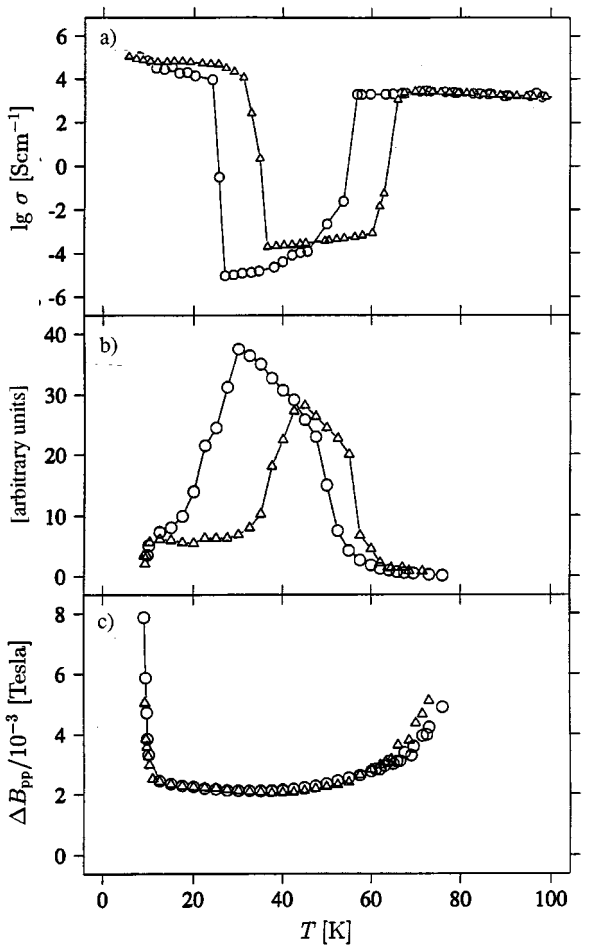
On cooling, alloys with H_8/D_6 = 70:30 and 50:50 show similar conductivities and phase transitions. However, at lower temperatures (25 K and 12 K, respectively) reentrance into the starting phase occurs with complete regeneration of the high conductivities. This process is connected to a strong hysteresis as shown for H_8/D_6 = 70:30 in Figure 10a. Using this phenomenon a very sensitive pressure/light-triggered switch can be designed.[46] Outside the highly conducting state the extremely broad ESR signal narrows sufficiently to become visible (Figure 10b and c).

All the results presented in this section clearly demonstrate that alloying DCNQI copper salts provides a powerful tool for manipulating the temperature dependence of conductivity within an unprecedented broad range.

Crystal Structures of DCNQI Metal Salts

All published structures of DCNQI salts with monovalent cations exist in the same 2:1 stoichiometry. The space group in which the salts crystallize depends entirely on the cation and not on the substituent (Scheme 1) and may be either $I4_1/a$ or the closely related space group $P4/n$ and $C2/c$ (or $I2/a$, respectively).

The structures of all radical-anion salts listed in Tables 2–4 also fit completely into this scheme. Some of these structures have already been published.



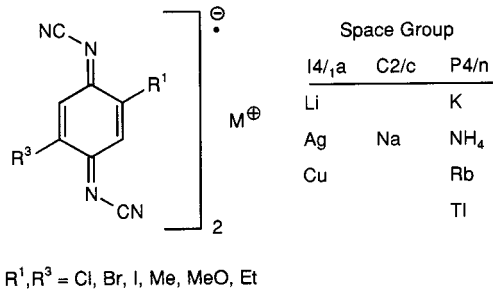


Figure 10. Alloy "H_8/D_6" = 70:30; temperature dependence of a) conductivity, b) ESR intensity, c) ESR line width; O = cooling; Δ = warming

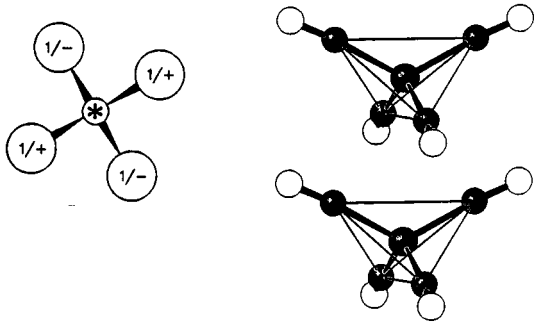
Scheme 1. Space groups for radical-anion salts [2-X,5-Y-DCNQI]$_2$M

Thallium(+1) salts resemble both silver and potassium salts. Due to the large ionic radius of this cation (K^+ = 133 pm, Tl^+ = 147 pm) the radical-anion salts (**1c**)$_2$Tl, (**1h**)$_2$Tl and (**1i**)$_2$Tl (Table 4) adopt space group *P4/n*. The special features of [2,5-Me_2DCNQI]$_2$Tl [(**1c**)$_2$Tl] have already been discussed.[20] Its structural data will be included here only for comparison with the isomophic structure of [2,5-(MeO)$_2$DCNQI]$_2$Rb[48] of the same space group and with [2-Br,5-IDCNQI]$_2$Cu[48] of type $I4_1/a$ (Scheme 2).

Scheme 2 reveals the close relationship between the two space groups. The very similar bond lengths within the DCNQI ligands are especially remarkable, in spite of their different substituent pattern in these three examples.

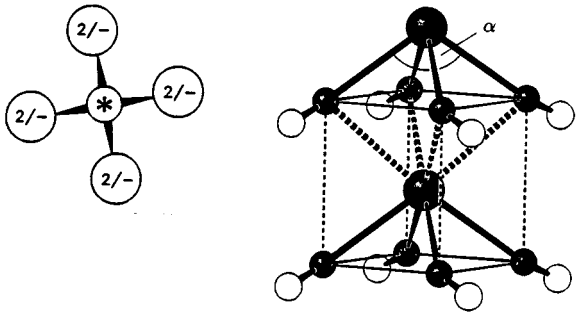
The coordination angle α = 122.5° in the *c* direction of the somewhat flattened tetrahedron in [2-Br,5-IDCNQI]$_2$Cu is below the limiting angle for phase transition and therefore guarantees metallic conductivity down to low temperatures.[33] The lengths of the four N−Cu bonds are equal (198.7 pm) whereas the cubic coordination in the rubidium− and thallium−DCNQIs involves two sets with four DCNQIs of different M−NC bond lengths (Rb: 303.3 and 310.9 ppm; Tl: 293.8 and 318.1 ppm).

The ligands are arranged in skewed stacks with the favourable "ring-over-bond" arrangement that is typical for these radical-anion salts and which provides maximum π-orbital overlap for electron transfer. As is seen in Figure 11, even the bent methoxy groups in [2,5-(MeO)$_2$DCNQI]$_2$Rb are coplanar with the π system.



A Comparison of Structural Information from X-ray Single-Crystal and Powder-Diffraction Data

Although DCQNI−metal salts can easily be prepared as microcystalline solids, suitable crystals for single-crystal X-ray analysis cannot, so far, be obtained for all salts. Structural information from X-ray powder diagrams would therefore be most welcome. In 1967, H. M. Rietveld derived a mathematical procedure for successfully refining crystal structures from neutron powder-diffraction data.[47] This method, which in the beginning was mostly employed for metal or inorganic crystals with small unit cells, has now been extended to X-ray diffraction data of not only inorganic but also organic compounds. T. Bauer[48] was one of the first to compare systematically crystal-structure refinements of organic compounds based on X-ray single-crystal and powder-diffraction data. These results are reported in this paper.



Since DCNQI radical-anion salts crystallize as isotypic compounds in space group $I4_1/a$ or related groups they represent good examples for a Rietveld treatment even though the highly ordered microcrystals can give rise to preferred orientation in the powder sample, an effect which has to be reduced by special sample preparation or corrected for during refinement. To test the reliability of this simple method, the corresponding single-crystal X-ray data of nine of these DCNQI copper salts were used as standards for comparison. Relevant parameters of single-crystal data and their deviations measured by powder diffraction are given in Table 6 (the data themselves are collected in Tables 2 and 3 of the Supporting Information).

Entries 1−5 clearly demonstrate that the cell parameters, as well as the angles around the coordination centers (Cu), and also the distances between the π planes are obtained

from powder diffraction with excellent accuracy. Compared to single-crystal data they stay well within the range of error.

However, the powder data connected to the ligand (various bond lengths and angles, entries 6−14) are much less accurate. They are still useful to picture the geometry around the ligand but not precise enough to compare the rather subtle effects of the 2,5-substituents in DCNQIs.

The same situation was found for various non copper salts (M = Li, Na, K, Rb, Tl, Ag; details see Table 4 of Supporting Information).

In Table 7 unit-cell data from powder diffraction are listed for those DCNQI radical salts where single crystals were not available. They have to be considered as highly reliable and therefore can be discussed safely like the corresponding data by single-crystal X-ray analysis.

Since further improvements in powder-diffraction techniques and evaluation of data have been already achieved in the meantime, this method is expected to gain increasing importance for organic microcrystalline solids.

Conclusions

The broad range of investigations on DCNQI derivatives presented in this paper reports on our concluding efforts in this field. Backed by the experiences gained in the last 12 years we succeeded to answer the questions from which we started in this paper in the following way.

1. In addition to the already successfully tested substituent pattern in 2-X,5-Y-DCNQIs the new substituent pairs in **1d** (Cl/OMe), **1e** (Br/OMe), **1f** (I/OMe), **1j** (Cl/I), **1k** (Br/I), **1l** (I/I) all form CT complexes with TTF ($\sigma \approx 10^{-1}-10^{-3}$ Scm^{-1}, cf. Table 1) despite the strong increase in size of the halogen substituent. Even one CF_3 group is tolerated [**1m** (OMe/CF_3); **1n** (Me/CF_3)] despite its size and strong electron attraction.

The new anion radical salts all exhibit the stoichiometry [2-X,5-Y-DCNQI]$_2$M with M = Li, Na, K, NH_4, Rb, Tl, Cu, and Ag prepared by proved methods. With respect to the CF_3 substituent only with **1n** (Me/CF_3) a copper salt deposited. Powder conductivities similar to former ones were found in the usual range ($10^{-1}-10^{-3}$ Scm^{-1}).

2. In some cases the quality of single crystals prepared by electrocrystallization could be improved by partly rhythmic reversal of the redox process. This new method may be of general importance.

3. Much effort was devoted to prepare alloyed DCNQI radical copper salts from two or three differing ligands. The ratio of the DCNQIs in solution is connected to that in the solid radical salt in a nonlinear way (Figure 1). The composition of the alloy surprisingly is hardly determined by the redox potentials of the two DCNQIs but rather by their velocity to form solid radical salts. Since their high conductivities at ambient temperature resemble those of the corresponding DCNQI copper salts with only one type of ligand, the important space group $I4_1/a$ obviously is preserved. These experiments clearly demonstrate that a wealth of alloyed DCNQI copper salts can be designed. This variation offers an approach to organic metals with rather unexpected and partly unprecedent patterns of temperature-dependent conductivity (vide infra).

4. Investigation of the temperature-dependent conductivities of various alloyed DCNQI copper salts produced rermarkable, unexpected effects. Instead of duplicating the pattern of the single components incorporated into the alloys, new patterns evolved: Metal insulation phase transitions may be induced, excluded or shifted to a different temperature range. Most remarkably even a temperature-independent conductivity between 5 and 300 K can be achieved (Figure 5). On the other hand the alloyed copper salt from 2,5-Me_2DCNQI and its deuterated counterpart

on cooling undergoes sharp phase transition with loss of conductivity of 10^7 to 10^8 Scm^{-1} which is restored at even lower temperatures (Figure 9). Because a rather broad hysteresis between heating and cooling is involved this phenomenon can be exploited for a very sensitive pressure/light-triggered switch (Figure 10).

These two extreme patterns qualify ligand alloying of DCNQI copper salts as a powerful tool for the design of highly conducting materials with a definite temperature profile.

5. Radical-anion salts of the type [2-X,5-Y-DCNQI]$_2$M with X,Y = MeO, Me, Cl, Br, I and M^+ = Li, Na, K, NH_4, Rb, C, M, Ag, Cu prefer the space group $I4_1/a$ or a closely related one. Therefore only in this type of organic metals relations between the individual electric properties and very subtle changes of the crystal lattice can be evaluated, provided single crystals for X-ray analysis are at hand. Since often only microcrystalline material is available extension to the evaluation of powder diagrams by the so-called Rietveld analysis is most welcome. This method, so far not employed to organic metals, yields excellent cell data of various DCNQI copper salts but less precise values for the geometries of the ligands.

Experimental Section

General: Melting points of the DCNQI/TTF complexes and the DCNQI radical-anion salts could not be determined with a Kofler microscope but had to be determined by differential thermoanalysis (DTA, Du Pont de Nemours Thermal Analyser TA 990). − IR spectra: Perkin Elmer 1420 and Nicolet 5 DXC FT-IR spectrometer. − Conductivities of microcrystalline solids were measured in a quartz capillary by compressing the powder with the two electrodes until the first cracks were seen. Single crystals were measured by the standard 4-point method. Solvents were purified and dried according to standard methods. Data from crystal-structure analyses: see Tables 8 and 9.

Neutron-Activation Analysis of Bromine and Copper (Table 6): The copper and bromine contents of the substances were determined by neutron-activation analysis (NAA). As reference nuclides ^{64}Cu ($t_{1/2}$ = 12.700 h) was used for copper and ^{82}Br ($t_{1/2}$ = 35.34 h) for bromine. Samples and standards were packed in quartz ampoules (Suprasil AN, Heraeus Quarzschmelze GmbH, Hanau) which had been cleaned before use. The sample mass per analysis was between 0.5 and 4 mg. Copper standard: copper(II) oxide granulated for analysis (E. Merck, Darmstadt), weighed in quantities betweeen 1.6 and 4.5 mg. Bromine standard: 50 μL of a $KBrO_3$ solution with p_{Br} = 2.664 g/l (Fixanal®, Riedel-de Haen, Seelze) was dried in a quartz ampoule (desiccator) → m_{Br} = 133.2 μg. Of the sealed ampoules, sets consisting of three samples, including a copper standard and a bromine standard were packed in aluminium foil and irradiated in the Forschungsreaktor München at xxx_{th} $Ø_{th}$ = 1.3 × 10^{13} $cm^{-2}s^{-1}$. Irradiation time = 15 min. After a waiting time (t_w) between 30 and 50 h the samples and standards were measured in the ampoules which had been cleaned outside.[50] − Counting equipment: 130-cm^3 intrinsic coaxial Ge detector, 1.9 keV resolution and 27% relative efficiency (both for the 1332.47-keV γ-line of ^{60}Co), main amplifier Silena model 7611, ADC Silena model 7423 UHS, memory buffer module Silena 7329−16K, personal computer AT/03/CO. For the evaluation of the γ spectra, emulation software mmb3 (Silena) was used. The ampoules were positioned with their axis parallel to the detector surface at a distance of 20 to 50 cm. The counting time was usually 2 h.

As a reference line for ^{64}Cu in most cases the 511-keV line was used (annihilation radiation of β^+ of ^{64}Cu). The 1345.9-keV γ-line (I_{rel} = 0.6%) was taken as the reference line if the 1368.6-keV γ-line of ^{24}Na was detected because ^{24}Na causes 511-keV radiation, too (a consequence of the pair production of the ^{24}Na γ-rays of 1368.6 keV and of 2754.1 keV). In addition, a contribution to the 511-keV line was taken into consideration by the pair ^{80m}Br (I.T.) ^{80}Br which is generated in parallel with ^{82}Br from bromine by neutron irradiation. ^{80}Br emits β^+ (2.6%). Its $t_{1/2}$ is only 17.6 min, but the $t_{1/2}$ of ^{80}Br is 4.2 h. Estimations by both calculation and measurement of bromine standards showed that after the above-mentioned t_w a contribution to the 511-keV line caused by ^{80}Br was either not detectable or negligibly small. For ^{82}Br its 776.49-keV γ-line (I_{rel} = 83%) was used as a reference.

DCNQI/TTF Complexes. − General Procedure 1 (GP1): Under nitrogen a concentrated solution of TTF in MeCN or dichloromethane (DCM) was added dropwise to a concentrated solution of the DCNQI in MeCN (20−80°C) or DCM. From the dark green to black solution the black microcrystalline charge-transfer complex separated within 1 min to 10 h. After cooling (0 to 10°C) of the mixture overnight, the solid was separated, washed with solvent and pentane and dried over silica gel (see Table 1).

2-Chloro-*N*,*N*′-dicyano-5-methoxy-1,4-benzoquinonediimine/Tetrathiafulvalene (1:1, 1d/TTF): TTF (30.4 mg, 100 μmol) in MeCN (1 mL); **1d** (22.1 mg, 100 μmol) in MeCN (3 mL, 60°). **1d**/TTF (37.0 mg, 93%), m.p. 155°C.− IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1} total absorption. − $C_{15}H_9ClN_4OS_4$ (424.7): calcd. C 42.42, H 2.14, N 13.30; found C 40.33, H 2.05, N 12.27.

2-Bromo-*N*,*N*′-dicyano-5-methoxy-1,4-benzoquinone/Tetrathiafulvalene (1:1; 1e/TTF): TTF (40.8 mg, 200 μmol) in MeCN (2 mL);

The usual ratio **1n**/CuI = 300:450 yielded a different black amorphous compound with a 7:5 stoichiometry, a distinct IR spectrum and $\sigma_p = 2 \times 10^{-7}$ Scm^{-1}, m.p. 168°C (dec.). − IR (KBr): ṽ = 2130 cm^{-1} (C≡N), 1580 (C=N). − $C_{70}H_{35}Cu_5F_{21}N_{28}$ (1984.9): calcd. C 42.36, H 1.78, N 19.76; found C 41.82, H 2.23, N 20.05.

DCNQI Radical-Anion Salts Grown on Silver or Copper Wires. − General Procedure 3 (GP3): A silver wire (diameter 0.3 mm) was flattened, polished and treated with toluene and acetonitrile. This wire was immersed 1−2 cm deep into a degassed solution of silver nitrate (100 μmol) and DCNQI **1** (100 μmol) in 8 mL of acetonitrile. After 3−10 d, the solution became colourless and from the silver wire black, shiny needles (1−20 mm) were harvested, washed with MeCN and pentane and dried over silica gel. The same procedure was followed with a copper wire (diameter = 1 mm, cleaned with 2 M HCl/3% H_2O_2, polished and treated with MeCN. The MeCN solution (10 mL) contained DCNQI **1** (100 μmol) and copper(II) bromide (100 μmol). Analytical data are collected in Table 10, and yields and conductivities in Table 3.

Table 10. Analytical data for DCNQI salts grown on a silver and copper wire

[a] Calculated (above), found (below). − [b] IR (KBr): total absorption between 4000−600 cm^{-1}.

Radical-Anion Salts (DCNQI)$_2$M by Electrocrystallization. − General Procedure 4 (GP4): Three- (C3)[51] or two- (C2) -compartment[52] cells were used with a Pt cathode (either plates, 2 cm^2 or rods, diameter = 1 mm, *l* = 5 mm, ca. 0.17 cm^2) for different current densities. Anodes were rods from platinum or glassy carbon (Fa. Sigri). Electrolysis was run at constant current in degassed acetonitrile under argon (C3 = 60 mL, C2 = 80 mL) containing *x* μmol of DCNQI **1** and *y* μmol of supporting electrolyte [A = $RbClO_4$; B = CF_3CO_2Tl; C = $Cu(CH_3CN)_4ClO_4$; D = $AgNO_3$]. The radical salts which deposited in black shiny (thin) needles were harvested before all the DCNQI had been reduced, washed with MeCN and pentane and dried (see Table 4). Periodical switching between reduction and partial oxidation was performed with a home-made apparatus (B. Brunner) according to a circuit diagram given in the Supporting Information.

(1a)$_2$Cu: 1a (130 mg, 600 μmol), C (229 mg, 700 μmol), C2; 9 μA; Pt rod (53 μA cm^{-2}), switching 7:3/s, 5°C, 264 h. (**1a**)$_2$Cu (29.0 mg, 20%), m.p. 220°C (dec.). − IR (KBr): ṽ = 4000−600 cm^{-1}, total

absorption. − $[C_{10}H_8N_4O_2]_2Cu$ (495.9): calcd. C 48.43, H 3.26, N 22.60; found C 48.44, H 3.22, N 23.05.

(1a)$_2$Rb: 1a (43.2 mg, 200 μmol), A (185 mg, 1.0 mmol), C3; 5 μA; Pt plate (2.5 μA cm^{-2}), −18°C, 117 h. (**1a**)$_2$Rb (15.2 mg, 29%), m.p. 167°C (dec.). − IR (KBr): $\tilde{\nu}$ = 2140 cm^{-1}, 2090 (C≡N). − $[C_{10}H_8N_4O_2]_2Cu$ (517.9): calcd. C 46.38, H 3.12; N 21.64; found C 46.24, H 3.14, N 21.38.

(1b)$_2$Cu: 1b (120 mg, 600 μmol), C (229 mg, 700 μmol), C3; 9 μA; Pt rod (53 μA cm^{-2}), 22°C, 97 h. (**1b**)$_2$Cu (32.0 mg, 23%), m.p. 158°C (dec.). − IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1}, total absorption. − $[C_{10}H_8N_4O]_2Cu$ (463.9): calcd. C 51.77, H 3.48, N 24.16; found C 51.61, H 3.67, N 23.81.

(1c)$_2$Tl: 1c (36.8 mg, 200 μmol), B (64 mg, 200 μmol), C2; 30 μA, Pt plate (15 μA cm^{-2}); −18°C, 72 h. (**1c**)$_2$Tl (27.1 mg, 48%), m.p. 161°C (dec.). − IR (KBr): $\tilde{\nu}$ = 2120 cm^{-1}, 2080 (C≡N). − $[C_{10}H_8N_4]_2Tl$ (572.7): calcd. C 41.93, H 2.82, N 19.57; found C 41.84, H 2.78, N 19.64.

(1d)$_2$Cu: 1d (44.1 mg, 200 μmol), C (98 mg, 300 μmol); C2; 10 μA, Pt rod (59 μA cm^{-2}); 20°C, 72 h. (**1d**)$_2$Cu (17.1 mg, 34%), m.p. 180°C (dec.). − IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1}, total absorption. − $[C_9H_5N_4ClO]_2Cu$ (504.8): calcd. C 42.82, H 2.00, N 22.20; found C 42.75, H 1.92, N 21.79.

(1e)$_2$Cu: 1e (53.0 mg, 200 μmol), C (98 mg, 300 μmol); C2; 10 μA, Pt rod (59 μA cm^{-2}); 20°C, 72 h. (**1e**)$_2$Cu (23.1 mg, 39%), m.p. 196°C (dec.). − IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1}, total absorption. − $[C_9H_5N_4BrO]_2Cu$ (563.7): calcd. C 36.41, H 1.70, N 18.88; found C 36.48, H 1.72, N 18.77.

(1f)$_2$Cu: 1f (94 mg, 300 μmol), C (195 mg, 600 μmol); C2; 9 μA, Pt rod (53 μA cm^{-2}), switching 7:3/s, 20°C, 14 d. (**1f**)$_2$Cu (10.0 mg, 8%) − IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1}, total absorption. − $C_{18}H_{10}CuI_2N_8O_2$ (687.7): calcd. C 31.44, H 1.47, N 16.29; found C 30.60, H 1.37, N 15.81.

(1h)$_2$Tl: 1h (74.4 mg, 300 μmol), B (95 mg, 300 μmol); C2; 20 μA, Pt plate (10 μA cm^{-1}), −18°C, 44 h. (**1h**)$_2$Tl (15.1 mg, 22%), m.p. 106°C (decomposition within 4 d). − IR (KBr): $\tilde{\nu}$ = 2130 cm^{-1}, 2090 (C≡N). − $[C_9H_5N_4Br]_2Tl$ (702.5): calcd. C 31.05, H 1.30, N 15.60; found C 30.77, H 1.44, N 15.95.

(1i)$_2$Tl: 1i (59.2 mg, 200 μmol), B (95 mg, 300 μmol); C2; 25 μA, Pt plate (12.5 μA cm^{-2}), −18°C, 44 h. (**1h**)$_2$Tl (15.1 mg, 22%), m.p. 111°C (dec.).− IR (KBr): $\tilde{\nu}$ = 2090 cm^{-1} (C≡N). − $[C_9H_5N_4I]_2Tl$ (976.5): calcd. C 27.14, H 1.27, N 14.07; found C 27.13, H 1.30, N 14.08.

(1j)$_2$Cu: 1j (95.0 mg, 300 μmol), C (98 mg, 300 μmol); C2; 9 μA, Pt rod (53 μA cm^{-2}), 20°C, 72 h. (**1j**)$_2$Cu (30.0 mg, 29%), m.p. 209°C (dec.).− IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1}, total absorption. − $[C_8H_2N_4ClI]_2Cu$ (696.5): calcd. C 27.59, H 0.58, N 16.09; found C 28.08, H 0.72, N 16.01.

(1k)$_2$Cu: 1k (108 mg, 300 μmol), C (147 mg, 450 μmol); C2; 9 μA, Pt rod (53 μA cm^{-2}), 20°C, 144 h. (**1h**)$_2$Cu (59.0 mg, 50%), m.p. 228°C (dec.). − IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1}, total absorption. − $[C_8H_2N_4BrI]_2Cu$ (785.4): calcd. C 24.47, H 0.51, N 14.27; found C 24.71, H 0.66, N 13.82.

(1k)$_2$Ag: 1k (36.1 mg, 100 μmol), D (34 mg, 200 μmol); C3; 10 μA, Pt plate (5 μA cm^{-2}), −25°C, 153 h. (**1k**)$_2$Ag (17.1 mg, 21%), m.p. 164°C (dec.). − IR (KBr): $\tilde{\nu}$ = 2180 cm^{-1}, 2140 (C≡N). − $[C_8H_2N_4BrI]Ag$ (829.8): calcd. C 23.16, H 0.49, N 13.51; found C 23.77, H 0.62, N 13.58.

(1l)$_2$Cu: 1l (81.6 mg, 200 μmol), C (98 mg, 300 μmol),; C2, 9 μA, Pt rod (53 μA cm^{-2}), 20°C, 135 h. (**1l**)$_2$Cu (39.0mg, 45%), m.p. 201°C (dec.). − IR (KBr): $\tilde{\nu}$ = 4000−600 cm^{-1}, total absorption. − $[C_8H_2N_4I_2]_2Cu$ (879.4): calcd. C 21.85, H 0.46, N 12.74; found C 22.01, H 0.32, N 12.51.

DCNQI Radical-Anion Copper Salts Grown from Two Different DCNQIs on a Copper Wire: Two different DCNQIs **1** (100 μmol each) and copper(II) bromide (150 μmol) were dissolved in acetonitrile (25 mL) saturated with argon. According to GP3 (vide supra) a copper wire was immersed and after 3−5 d the dark needles (1−20 mm) which had formed were harvested. All specimens showed total absorption in their IR spectra between 4000−600 cm^{-1}. For details see Table 5.

DCNQI Radical-Anion Copper Salts with different DCNQI Ligands by Electrocrystallization: Following GP4 (vide supra) a pair of DCNQIs was applied in various ratios. The harvested needles (5−20 mm long, diameter 5−15 μm) appeared similar to those grown from one DCNQI only and showed total absorption in their IR spectra between 4000−600 cm^{-1}. For details see Table 6.

Acknowledgments

Financial support by the Fonds der Chemischen Industrie, Frankfurt/Main and the BASF AG, Ludwigshafen/Rhein together with generous donations of chemicals are gratefully acknowledged.

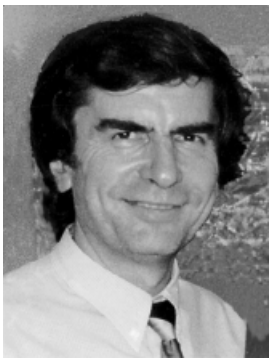
Effects of Halides and Related Ligands on Reactions of Carbonylruthenium Complexes (Ru^0–Ru^{II})

Guy Lavigne[a]

Dedicated to Herbert D. Kaesz on the ocassion of his 66th birthday

Keywords: Halides / Homogeneous catalysis / Organometallics / Ruthenium

While the primary motivation of fundamental studies on carbonylhalotriruthenium complexes was to understand the promoter effect of halides on certain ruthenium-based catalytic systems of industrial relevance, such complexes have gained significance in their own right due to their remarkable ability to provide low-activation energy pathways for the coordination of organic substrates. Limitations inherent to the fragility of these prototypes led to the design and development of a related family of more sophisticated derivatives where an aminopyridyl group serves as an alternate *hemilabile* ancillary ligand. Studies of their reactivity have revealed the possibility of achieving a number of stoichiometric or moderately catalytic "cluster-mediated" transformations of organic substrates under very mild conditions. Yet, the viability of these systems is still limited to a narrow low-energy domain. By contrast, halotriruthenium derivatives are still seen to function as catalyst precursors under the actual conditions of certain catalytic reactions where they act as sources of ruthenium(II) halide complexes that become the active components of the system. The second part of the review focuses on novel aspects of their fascinating chemistry.



Introduction

The association of carbonylruthenium complexes with halides has long been known to produce remarkably efficient catalyst precursors. Historically, Dombek and Knifton were the first to draw attention on the effects of these "magic" mixtures in two fascinating series of independent reports revealing, respectively, that *enhanced selectivity* in the syngas conversion into ethylene glycol could be achieved in the homogeneous phase with an $Ru_3(CO)_{12}$/iodide system,[1] or by ruthenium "melt" catalysis, where a bromide salt acts both as solvent and co-catalyst.[2] Two anionic species, $[Ru_3(\mu\text{-}H)(CO)_{11}]^-$ and $[Ru(CO)_3X_3]^-$, both directly generated in situ under CO/H_2, were found to be essential for optimum activity.

The CO hydrogenation leading to glycol was proposed to begin with the formation of a formyl species by *intermolecular hydride transfer* from $[Ru_3(\mu\text{-}H)(CO)_{11}]^-$ (or, more probably from $[HRu(CO)_4]^-$ generated in situ)[3] to one of the electrophilic carbonyl groups of the haloruthenium(II) complex.

At that time, however, and even though interesting model studies were done with other metals,[4] the proposed halo(hydroxyalkyl)ruthenium(II) intermediates on the way to glycol remained elusive and were even thought to be too short-lived for proper detection, which may no longer be true on the basis of recent observations (vide infra).

Guy Lavigne was born in Toulouse in 1947. He obtained his Ph.D. ("Doctorat d'Etat des Sciences") from the University of Paris VI under the supervision of Professor Yves Jeannin. In 1979, he joined the group of Professor Jean-Jacques Bonnet at the "Laboratoire de Chimie de Coordination du CNRS" (LCC). After post-doctoral studies at UCLA with Professor Herbert D. Kaesz in 1984, he returned to Toulouse at the LCC/CNRS where he was appointed Research Director in 1988. His research deals with the fundamental aspects of metal-mediated carbon–carbon bond-forming reactions and their application to homogeneous catalysis.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

These and related[5] pioneering observations paved the way to a dramatic development of research on Ru-based syngas reactions,[2b] with notable modifications including the use of different promoters such as onium chloride salts and weak acids[6] or even benzimidazoles.[7] The mixture of $[HRu_3(CO)_{11}]^-$ and $[Ru(CO)_3X_3]^-$ (X = Br or I) was later found to be active for various related reactions[8] including, in particular, the oxonation of olefins[9] and their alkoxycarbonylation.[10] Besides, Cenini and co-workers published an interesting phosgene-free process for the carbonylation of aromatic nitro compounds to carbamates, again using mixtures of $Ru_3(CO)_{12}$ and halide salts.[11]

While examining the chemical behavior of the same complexes within a much lower energy domain, Kaesz and co-workers discovered at the same time that the presence of a halide in the ligand shell of a carbonylruthenium cluster results in the regioselective incorporation of phosphane ligands[12] or organic substrates[13] under unprecedented mild conditions. A spectacular report[13] included a reaction between the halide-containing species $Ru_3(\mu\text{-H})(\mu\text{-Cl})(CO)_{10}$ and ethylene/CO mixtures (5 atm), giving the propionyl complex $Ru_3\{\mu\text{-C(O)CH}_2\text{CH}_3\}(\mu\text{-Cl})(CO)_{10}$ within minutes at 25°C (Scheme 1), thus nicely modeling a key step in olefin hydroformylation, a reaction independently found to be catalyzed by $[Ru_3(\mu\text{-H})(CO)_{11}]^-$.[14]

$Ru_3(\mu\text{-H})(\mu\text{-Cl})(CO)_{10}$

$Ru_3(\mu\text{-Cl})(\mu\text{-O=CCH}_2\text{CH}_3)(CO)_{10}$

Scheme 1. Facile activation of ethylene by a carbonylchlorohydridotriruthenium complex

In attempts to devise an anion route to the above halohydridotriruthenium derivative, Kaesz and Lavigne discovered that $Ru_3(CO)_{12}$ reacts spontaneously at 25°C with onium salts of halides or pseudohalides *in the absence of ion pairing* to give hitherto unknown adducts of the type $[Ru_3(CO)_{12-n}(X)]^-$ (n = 0−3) exhibiting remarkably *enhanced substitutional lability*.[15] These *"activated"* species primarily drew attention while appearing as the first formed intermediates on the way to Dombek's catalysts (vide supra). In fact, as explained below in the first part of this review, these and related complexes were further shown to be of specific interest as synthetic tools for a number of stoichiometric or moderately catalytic *cluster-mediated* transformations of organic substrates occurring on a laboratory scale *under very mild conditions*[16] but having no direct relevance to the applied reactions mentioned above.

A renewal of interest for ruthenium/halide systems emerged in 1989 with Keim's report[17] that carbonylruthenium chloride clusters were catalyst precursors for the hydroesterification of ethylene with methyl formate, originally disclosed by Sneeden et al.[18] The reaction was later shown by Petit and co-workers to be much more efficiently catalyzed by the multi-component Ru/iodide/DMF system.[19]

Based on what we knew at that time, carbonylhaloruthenium clusters appeared to us unlikely to survive under the reported experimental conditions. We were thus challenged to re-investigate the hydroesterification reaction with the aim of tracing the transformation of Ru_3/halide precursors toward the formation of the active species. Studies in collaboration with Kalck and co-workers led us to observe that the aforementioned anionic mononuclear carbonylruthenium(II) halide species $[Ru(CO)_3X_3]^-$ was again implied, and could even be used alone as a catalyst precursor.[20] A literature survey indicated that, in spite of the newly established implication of carbonylhaloruthenium(II) complexes as catalyst precursors in a growing number of C−C bond-forming reactions,[21] the present state of knowledge of their reactivity rests essentially on early pioneering studies.[22] Thus, a new research project was undertaken with the aim of filling the gap between the basic knowledge on these compounds and their applied reactions. The first results of our new investigation are summarized in the second part of this review.

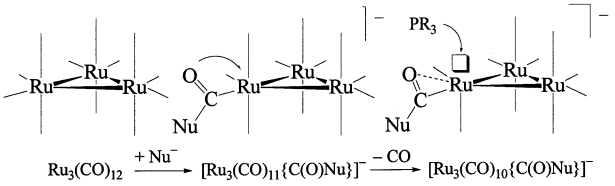
I. Chemistry of "Anion-Promoted" Ruthenium Cluster Complexes Under Mild Conditions

I.1 Catalysis of CO Displacement by Phosphanes in $Ru_3(CO)_{12}$ in the Presence of Anionic Nucleophiles

In 1984, we made the intriguing observation that addition of catalytic amounts of $[(PPh_3)_2N]Cl$ to a THF solution containing a mixture of $Ru_3(CO)_{12}$ and triphenylphosphane, results in the rapid formation of the monosubstituted derivative $Ru_3(CO)_{11}(PPh_3)$ at 25°C[15] (Equation 1).

$$Ru_3(CO)_{12} + PR_3 \xrightarrow[\text{THF, 25°C}]{\text{onium salt of Nu}^-\text{* (catalytic amounts)}} Ru_3(CO)_{11}(PR_3) + CO \quad (1)$$

(*) Nu^- = (i) CN^-, CH_3COO^-, F^-, Cl^-, Br^-, or I^-;
or, (ii) $[BHR_3]^-$ or $[HRu(CO)_4]^-$



Whereas the thermally induced substitution (ca. 2 h, 90°C) was known to give only the "thermodynamic" trisubstituted derivative $Ru_3(CO)_9(PPh_3)_3$,[23] catalysis by the salt under highly dissociating conditions (i.e. in the absence of ion pairing) appeared as a valuable means to *selectively* trap the kinetic substitution product. The system was rapidly extended to a range of nucleophilic anions [see Equation 1, catalysts type (i)] whose relative efficiencies were established on the basis of a preliminary kinetic study revealing a zero-order rate dependence on $[Ru_3(CO)_{12}]$. The effect of these ions was interpreted in terms of the enhanced substitutional lability of the methoxycarbonyl adducts $[Ru_3\{\eta^1\text{-C(O)OMe}\}(CO)_{11}]^-$ established by Ford[24] in stoichiometric reactions with phosphanes (see Equations 2−3)[25] or molecular hydrogen (sequence of Equations 2 and 4),[26] and independently applied to ^{13}CO enrichment by Darensbourg.[27]

$$Ru_3(CO)_{12} + OCH_3^- \rightarrow [Ru_3(CO)_{11}\{C(O)OCH_3\}]^- \quad (2)$$

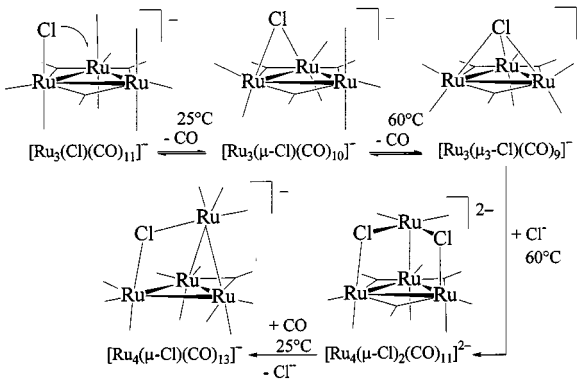
$$[Ru_3(CO)_{11}\{C(O)OCH_3\}]^- + PR_3 \rightarrow Ru_3(CO)_{11}PR_3 + CO + OCH_3^- \quad (3)$$

$$[Ru_3(CO)_{11}\{C(O)OCH_3\}]^- + H_2 \rightarrow Ru_3(\mu\text{-}H)(CO)_{11}]^- + HC(O)OCH_3 \quad (4)$$

It was suggested[15b] (Scheme 2) that CO labilization by the oxygen atom of a transient nucleophile-CO adduct "C(O)Nu" would allow the phosphane to reach the metal center. The increased basicity brought by this incoming ligand would then cause a reduction of the δ^+ character of the carbon atom, thereby facilitating the expulsion of the nucleophilic anion Nu^- and its intermolecular transfer to a neighboring cluster for the propagation of the effect.

Scheme 2. Proposed pathway for anion-promoted CO labilization (the square box denotes a vacant coordination site)

While reasoning that the simplest nucleophilic anion H^- is likely to give the same type of transient adduct $[Ru_3\{\eta^1\text{-}C(O)H\}(CO)_{11}]^-$ (or $[Ru_3\{H\}(CO)_{12}]^-$), we were able to show that catalysis of CO displacement by phosphanes into $Ru_3(CO)_{12}$ can also be efficiently carried out by *intermolecular hydride transfer*, using simple hydridic reagents like potassium tri-*sec*-butylhydroborate (K-Selectride) or $[HRu(CO)_4]^-$ as catalysts [Equation 1, catalyst type (ii)].[28] The latter procedure, exceeding the performance of the sodium benzophenone ketyl catalyst proposed earlier by Bruce,[29] is of high practical synthetic utility since "super hydrides" are found in any chemical laboratory. Significantly, the catalytic substitution can also be initiated by adding few crystals of $[PPN][Ru_3(\mu\text{-}H)(CO)_{11}]$ to a THF solution of $Ru_3(CO)_{12}$ and phosphane under CO.[28] In that case, however, an induction period is required for the latter anion to generate the actual hydride transfer agent $[Ru_3\{\eta^1\text{-}C(O)H\}(CO)_{11}]^-$ (or $[Ru_3\{H\}(CO)_{12}]^-$[30]). The mechanism proposed at that time for the formation of such adducts[28] found further support in the results of a more recent kinetic study reported by Shore,[30c] indicating that $^{13}CO/^{12}CO$ exchange in $[Ru_3(\mu\text{-}H)(CO)_{11}]^-$ is governed by competition between two parallel pathways, namely, a dissociative pathway (zero-order in anion and zero-order in CO) and an associative step (first-order in anion and first-order in CO), the latter becoming increasingly significant with increasing concentration of ^{13}CO. Thus, just like in the water gas shift reaction[30] [and also like in the hydride transfer occurring in the glycol synthesis (vide supra)], the preceding substitution reaction is governed by an associative step.



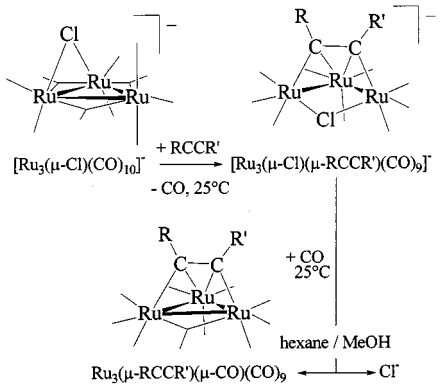
For anionic nucleophiles such as halides and pseudohalides, the nature of the initial site of attack proposed in Scheme 2 cannot be ascertained since the first formed adducts are very short-lived. Competitive nucleophilic attack at CO and at the metal center was reasonably suggested by Ford on the basis of a thorough kinetic study.[31]

I.2 Intramolecular Halide-Promoted CO Labilization and Its Application to the Controlled Activation of Unsaturated Substrates

Whereas the primary adducts discussed above are involved in the catalysis of phosphane substitution, we will now see that the subsequent anionic derivatives $[Ru_3(Cl)(CO)_{12-n}]^-$ ($n = 1-3$) are of synthetic utility when the incoming ligands are unsaturated organic substrates.

I.2.1 Equilibria within Ru_3/Halide Systems

The complete elucidation of the precise nature of these halide adducts rests on the concerted efforts of several groups.[15,20,32–35] Though Scheme 3 displays all equilibria appearing within the $Ru_3(CO)_{12}$/chloride system, the present paragraph deals only with the first three adducts $[Ru_3(Cl)(CO)_{12-n}]^-$ ($n = 1-3$), whereas further re-arrangement to tetranuclear species occurring under specific conditions will be discussed in section II.1.

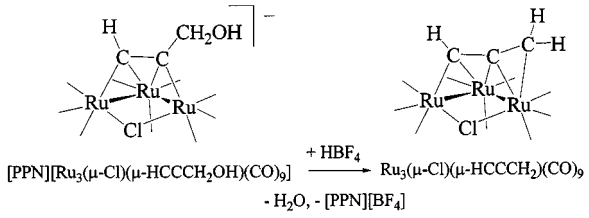


Scheme 3. Equilibria within Ru_3/halide systems

In the first observable adduct, $[Ru_3(Cl)(CO)_{11}]^-$ (readily obtained at 25°C), the halide ligand occupies an axial coordination site onto the metal triangle.[33] It then slowly labilizes one vicinal CO at 25°C while moving into an edge-bridging position to yield $[Ru_3(\mu\text{-}Cl)(CO)_{10}]^-$. Finally, it may still use one more electron pair to coordinate in a face-bridging position with concomitant CO labilization to form $[Ru_3(\mu_3\text{-}Cl)(CO)_9]^-$. However, this requires the assistance of thermal activation (60°C) and a stream of inert gas to evacuate the released CO.[34]

I.2.2 Activation of Alkynes under Ambient Conditions

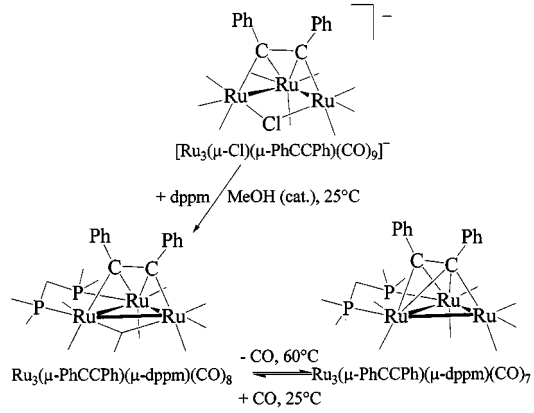
Opening of the halogen bridge in $[Ru_3(\mu\text{-}Cl)(CO)_{10}]^-$ or $[Ru_3(\mu_3\text{-}Cl)(CO)_9]^-$ provides a low-activation-energy path for the reaction of these complexes with alkynes at 25°C, giving only one species $[Ru_3(\mu\text{-}Cl)(\mu\text{-}RCCR)(CO)_9]^-$ in quantitative yield within few minutes (Scheme 4).[34][36]



The kinetics of this reaction were investigated by Basolo.[37] The halide ligand appears to be so lightly coordinated to the metal core in the latter anionic species that its displacement by a CO ligand can be readily catalyzed by a

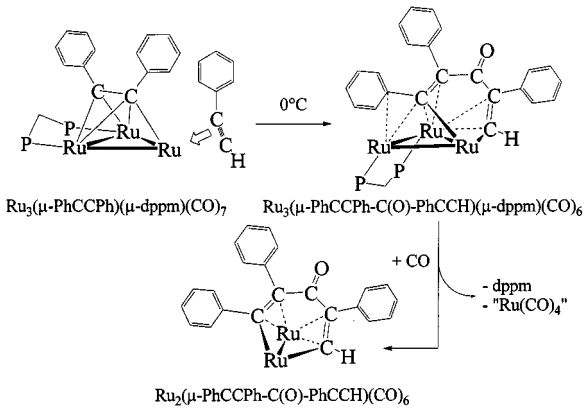
Scheme 4. Halide-promoted reaction of alkynes with $Ru_3(CO)_{12}$

protic solvent like methanol. Hence, if a biphasic hexane/methanol solvent mixture is used, the neutral complex $Ru_3(\mu\text{-RCCR})(\mu\text{-CO})(CO)_9$ transfers itself to the hexane phase, from which it can be recovered pure without chromatographic workup.[34][36] The latter complex is the kinetic product of the reaction between $Ru_3(CO)_{12}$ and alkynes, and is not observable under thermal activation.[38]



Slight modifications of the above synthetic strategy allowed the preparation of various alkyne-, alkynyl-[34][36] or allenyltriruthenium[39] complexes. For example, the new allenyl complex $Ru_3(\mu\text{-Cl})(\mu\text{-HCCCH}_2)(CO)_9$ was readily obtained within a few minutes by reaction of the anionic chlorotriruthenium complex with propargylic alcohol followed by proton-induced dehydration of the cluster-bound ligand (Scheme 5).[39]

Scheme 5. Facile dehydration of a cluster-bound alkynol

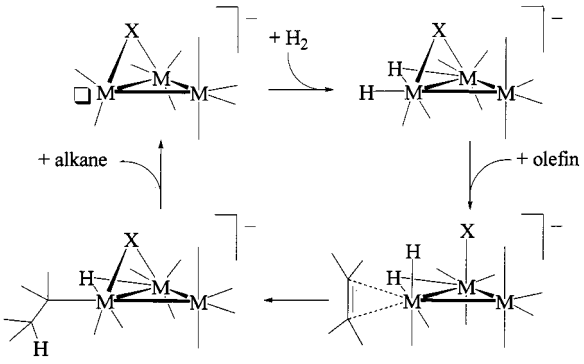


Significantly, the first and still unique prototype of unsaturated 46e$^-$-alkynetriruthenium complex, $Ru_3(\mu_3\text{-}\eta^2\text{-PhCCPh})(\mu\text{-dppm})(CO)_7$, was also prepared from the anionic alkynedecacarbonylchlorotriruthenium derivative by methanol-induced halide abstraction in the presence of dppm according to the sequence shown in Scheme 6.[40]

While the synthetic utility of the halide appeared obvious in light of the above reactions, we rapidly faced a new problem while attempting to achieve a full transformation of the "activated" alkyne directed toward the liberation of an oligomeric substrate. This is illustrated in Scheme 7.[41] We first made the encouraging observation that the cluster-bound alkyne ligand in the triruthenium complex $Ru_3(\mu\text{-PhCCPh})(\mu\text{-dppm})(CO)_7$ could be readily engaged in C−C bond formation with an incoming phenylacetylene molecule within minutes at 0°C, giving the coordinatively unsaturated "fly-over"-type complex $Ru_3[\mu\text{-PhCCPh}-C(O)-PhCCH](\mu\text{-dppm})(CO)_6$ where the dialkenyl ketone fragment

Scheme 6. Synthesis of the first prototype of an unsaturated alkyne-triruthenium cluster complex and observation of a "windshield-wiper" motion of the alkyne ligand onto the metal triangle

HC=CPh−C(O)−PhC=CPh appeared as the result of an intramolecular alkyne/CO/alkyne coupling.[41] Bearing in mind the existence of a patented process for the synthesis of hydroquinone using $Ru_3(CO)_{12}$ as a catalyst precursor,[42] we treated the newly formed derivative with CO, hoping to release a cyclic ketone or a quinone. However, this resulted in successive losses of the supporting dppm ligand and of one metal center, ending with the formation of a stable dimetallic fly-over species. It was thus becoming clear that the elimination of the free organic molecule (probable under forcing conditions, but not observed under those of our experiment) would take place only from a low-nuclearity fragment after complete degradation of the cluster (see Scheme 7, ancillary ligands omitted for clarity).



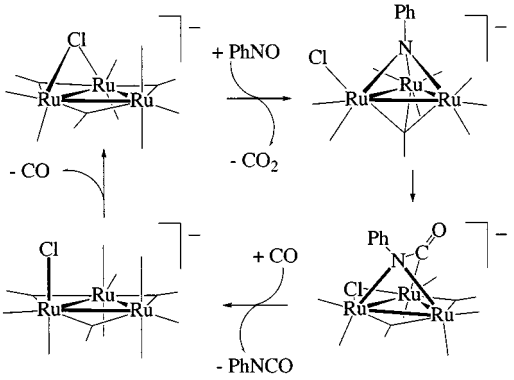
Scheme 7. Intramolecular akyne/CO/alkyne coupling

A modification of our strategy was thus required in order to observe full transformations of organic substrates on the metal core (see section I.3).

I.2.3 Activation of Olefins

In 1986, Gladfelter and co-workers reported that olefins can be readily hydrogenated at ambient temperature in the presence of the isocyanatotriruthenium cluster complex $[Ru_3(NCO)(CO)_{10}]^-$,[43] another member of the growing family of "anion-promoted" triruthenium clusters.[16] The

system was understood in terms of the ability of the pseudohalide $X^- = NCO^-$ to function reversibly as a one- or three-electron donor, thereby helping to maintain similar relative energies of the intermediates. The catalytic reaction observed with ruthenium was modeled with osmium (Scheme 8) for which the alkyl intermediate was intercepted, using succinoyl anhydride as the olefin.[44]

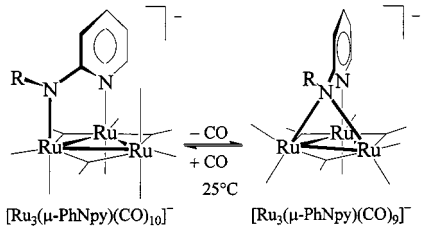


Scheme 8. Mechanism of the anion-promoted olefin hydrogenation proposed by Gladfelter and co-workers; the square box appearing in the scheme denotes a vacant coordination site on the metal center

A limitation of the system for $X^- = Cl^-$ appeared to be the facile reductive elimination of HCl from the anionic halohydrido intermediate, giving the anion $[HRu_3(CO)_{11}]^-$, a pathway related to the one shown in Equation 4.

I.2.4 Carbonylation of Nitrosobenzene

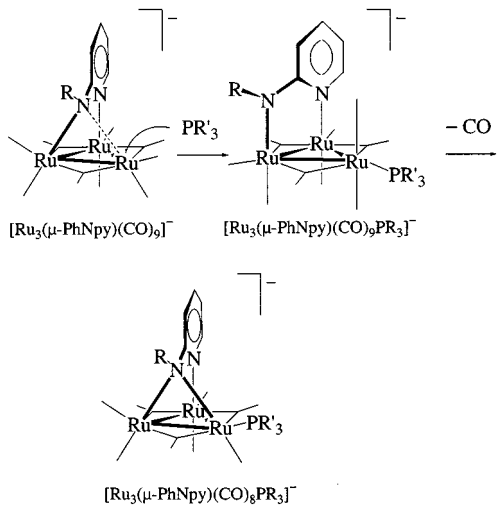
In connection with the above-mentioned discovery by Cenini et al. of a promoter effect of halides on the ruthenium-catalyzed synthesis of carbamates from aromatic nitro compounds,[11] Geoffroy and co-workers were able to show that the lightly coordinated halide in $[Ru_3(\mu\text{-}Cl)(CO)_{10}]^-$ can be engaged in bridge-opening/closing reactions assisting both the coordination of nitrosobenzene prior to NO bond cleavage and the carbonylation of the incipient nitrene intermediate to give phenyl isocyanate (Scheme 9).[45]



Scheme 9. Mechanism of the anion-promoted conversion of nitrosobenzene into isocyanate, as proposed by Geoffroy and co-workers

However, given that such a transformation occurs only under very mild conditions, there is no evidence for its value as a model for the effective carbonylation of aromatic nitro compounds, which is known to take place only under more forcing conditions.

I.3 Effects of Related Nitrogen-Based Hemilabile Ancillary Ligands

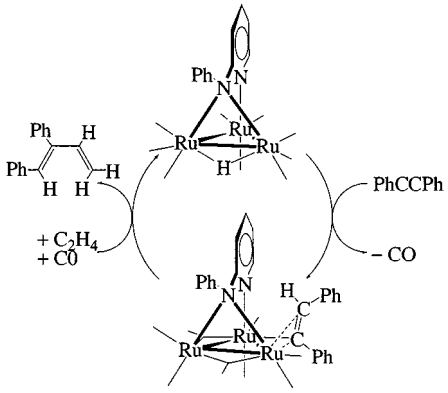


I.3.1 The Basic Concept

Since the adventitious loss of the halide from the above triruthenium species appeared as an undesirable dead end in several cases, we were led to devise a related family of "activated" cluster complexes incorporating aminopyridyl groups as alternate *hemilabile* ancillary ligands. As shown in Scheme 10, whereas the pyridyl group functions as an anchor, the amido group can adopt terminal or bridging coordination modes quite analogous to those occurring with halides (see Scheme 3).[46]

Scheme 10. Reversible CO uptake by a triruthenium cluster incorporating an aminopyridyl group as hemi-labile ancillary ligand

An advantage of aminopyridyl ligands is the possibility to tune their nucleophilicity by modifying the nature of the R group. Second-order kinetics were observed by Basolo for the reactions of anionic (aminopyridyl)triruthenium complexes with phosphanes.[47] The results were consistent with a mechanistic scheme in which nucleophilic attack by the phosphane gives an adduct bearing the amido ligand in

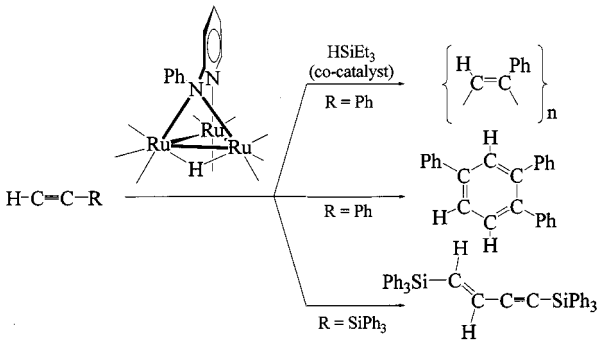


Scheme 11. Isolation of a phosphane adduct on the way to the substituted derivative

terminal position. After isomerization of such an intermediate, further reformation of the amido bridge through intramolecular nucleophilic attack with concomitant CO expulsion leads to the substituted derivative. The energy barrier for the latter step is dependent on the nucleophilicity of the amido group. Thus, whereas the intermediate adduct is trappable with R = Ph, the reaction proceeds directly to the substituted derivative when R = Me.

I.3.2 Activation of Alkynes and Vinyl-Group Transfer Reactions

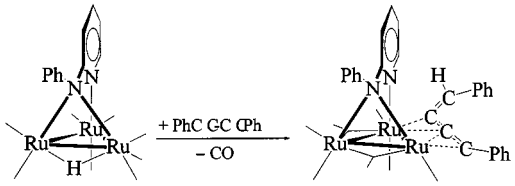
The hemilabile behavior demonstrated for the above anionic species was suggested to account for the high reactivity of the corresponding protonated complexes $Ru_3(\mu\text{-}H)(\mu\text{-}RNpy)(CO)_9$ whose reactions with phosphanes proved to be too fast, even at −40 °C, to be amenable to kinetic studies.



In 1990, we made the original observation that the anilinopyridyl complex $Ru_3(\mu\text{-}H)(\mu\text{-}PhNpy)(CO)_9$ is prone to activate alkynes selectively via the alkenyl intermediate $Ru_3(\mu\text{-}H)(\mu\text{-}PhNpy)(PhC{=}CHPh)(CO)_8$ and to promote the catalytic hydrogenation of diphenylacetylene as well as its stoichiometric hydrovinylation.[46] Whereas the kinetics and mechanism of the former reaction were subsequently investigated in detail by the group of Cabeza and Riera,[48] we became more interested in the second type of transformation which involved C−C bond formation (Scheme 12).

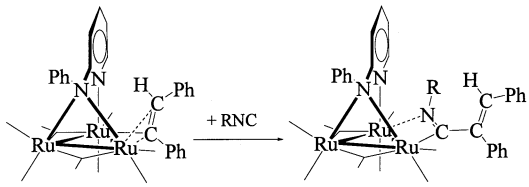
Scheme 12. Cluster-mediated hydrovinylation of diphenylacetylene

The co-dimerization leading to 1,2-diphenyl-1,3-butadiene was understood in terms of an insertion of ethylene into a ruthenium−alkenyl bond followed by β-elimination, a mechanism similar to the one established by Knox for a parallel reaction occurring at a diruthenium center.[49]



With more reactive 1-alkynes (and in the absence of alkene), multiple alkyne insertions were observed. Curiously, whereas ruthenium is not known to be an efficient alkyne polymerization catalyst, the regioselective polymerization of phenylacetylene to the *cis*-polyphenylacetylene was found to take place within few minutes at room temperature in the presence of the hydrido species $Ru_3(\mu\text{-}H)(\mu\text{-}PhNpy)(CO)_9$ and of triethylsilane (as a co-catalyst) (Scheme 13).[50] By contrast, trimerization was observed in the absence of silane.

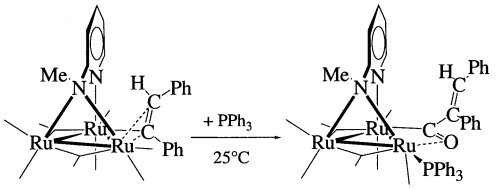
Scheme 13. Oligomerization of terminal alkynes in the presence of the (anilinopyridyl)hydridotriruthenium complex as catalyst precursor



Though polymerization of phenylacetylene under hydrosilylation conditions has been also observed in a few instances with other metals,[51] the promoter effect of the silane as a co-catalyst remains unclear.

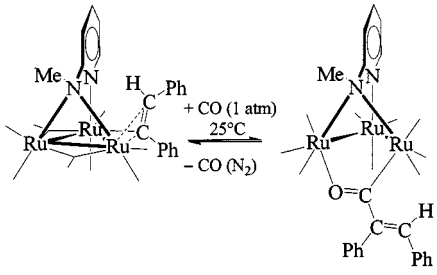
With triphenylsilylacetylene as the incoming substrate (and in the absence of silane), a rapid but poorly catalytic dimerization was observed (see Scheme 13), leading selectively to the (*E*)-1,4-bis(triphenylsilyl)but-1-en-3-yne, obtained pure as beautiful crystals appearing on the walls of the glassware. Here again, no intermediates could be detected and our approach to the mechanism had to rely on model studies. First, in order to test the mechanistic possibility of a vinylidene/acetylide coupling,[52] which should have generated a transient butenynyl intermediate,[53] we treated the hydrido complex with a preformed diyne whose insertion into the Ru−H bond was likely to give such an intermediate. Though a butenynyl complex was effectively isolated (Scheme 14),[54] it could not be regarded as a plau'sible intermediate since it was not possible to promote its reductive elimination as an enyne in the presence of an incoming alkyne.

Scheme 14. Activation of a diyne by insertion into an Ru−H bond and formation of a butenynyl ligand



Though not firmly established, the alternate possibility of an alkenyl/acetylide coupling was preferred in light of the parallel observation of a facile alkenyl-group transfer from the alkenyl complex to the α-carbon atom of an incoming isocyanide (Scheme 15).[50][54]

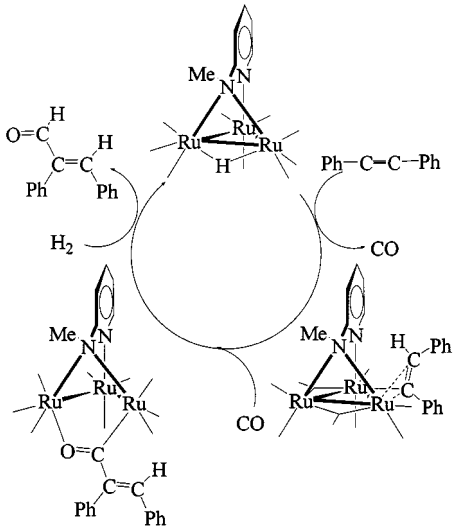
Scheme 15. Alkenyl/isocyanide coupling giving an azabutadienyl ligand



Here, the incorporation of the isocyanide ligand onto the $48e^-$ species occurs at 25°C by an associative pathway consistent with a mechanistic scheme where the transient opening of the amido bridge (or another weak bond, vide infra) assists the incorporation of the ligand, whereas its subsequent reformation triggers C−C bond formation, in exact parallel with reactions observed earlier with halides and related ancillary ligands.

With the aim of verifying the generality of such a working hypothesis, we treated our alkenyl complex with triphenylphosphane and effectively observed that the incorporation of this ligand also caused migratory CO insertion of the alkenyl group (Scheme 16).

Scheme 16. Phosphane-induced migratory CO insertion of an alkenyl group



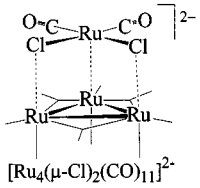
Though obtained within few minutes under very mild conditions, the resulting propenoyl complex proved to be the thermodynamic product of the reaction.[55] Evidence for the existence of a kinetic intermediate was obtained from additional experiments[55] including a preliminary kinetic study carried out by Basolo.[56] Further work indicated that, of course, CO gas itself is readily incorporated and promotes the same migratory insertion. Though the corresponding adduct is stable only under CO, we succeeded in crystallizing it under such conditions (Scheme 17).[50][55]

Scheme 17. CO-induced migratory CO insertion of an alkenyl group

Significantly, *two* carbonyl ligands were incorporated without a detectable intermediate. The fact that an open $50e^-$ cluster was obtained (rather than a closed $48e^-$ species bearing a terminal amido group) raised recurrent questions about the nature of the initial elusive adduct formed upon ligand addition to the alkenyl cluster complex. Indeed, let us remind ourselves that there are three types of weak bonds in this complex whose rupture is plausible: (i) the Ru−N bonds of the amido bridge, (ii) the π interaction between the alkenyl group and the cluster and (iii) the metal−metal bonds. Thus, hypotheses regarding the rupture of any of such bonds may be equally reasonable due to the probable similar magnitude of their respective enthalpies. However, we believe that a more realistic scheme involves *a global expansion of the structure by lengthening of several of these bonds without localized rupture*,[55] as independently demonstrated for another ligand-bridged triruthenium cluster complex.[57] Another notable feature, highlighted by the previous equilibrium, is the ease with which the propenoyl group migrates at the periphery of the cluster.

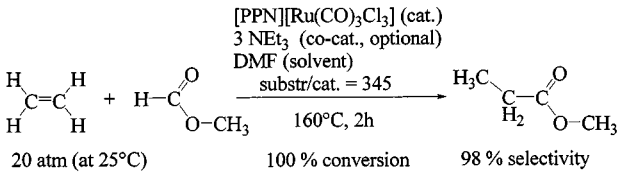
Following the isolation of the propenoyl adduct, we succeeded in releasing α-phenylcinnamaldehyde upon treatment with CO/H_2 mixtures under very mild conditions. The propenoyl complex could then be tied to a catalytic cycle for the hydroformylation of diphenylacetylene (Scheme 18).[55]

Scheme 18. Catalytic cycle for the hydroformylation of diphenylacetylene showing the isolated intermediates



Though the reaction could cycle catalytically, the viability of the system under non-optimized conditions was affected by a competitive CO insertion into the Ru−N bond of the methylaminopyridyl group, ending with the formation of an inactive carboxamido complex of lower nuclearity.

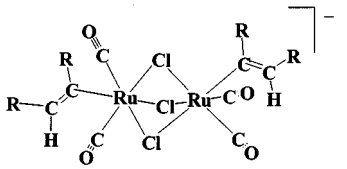
II. Aspects of the Chemistry of Carbonylhaloruthenium(II) Complexes



II.1 Evolution of $Ru_3(CO)_{12}$/Halide Mixtures under the Conditions of a Typical Hydroesterification Reaction

Studies reported in this section were undertaken in collaboration with Kalck and co-workers. Philippe Kalck was interested in the use of methyl formate as a valuable feedstock in organic synthesis. The "direct" addition of this substrate to olefins for the production of esters appeared to be a challenging reaction[58] that had been shown by Keim[17] to be catalyzed by $Ru_3(CO)_{12}$ alone or (albeit less efficiently) by the anion $[Ru_3(\mu\text{-}Cl)(CO)_{10}]^-$. A preliminary screening of the above-mentioned series of anionic triruthenium complexes incorporating halides, anilinopyridyl or alkoxypyridyl groups led us to focus on the $Ru_3(CO)_{12}$/[PPN]Cl system, which proved to be highly efficient pro-

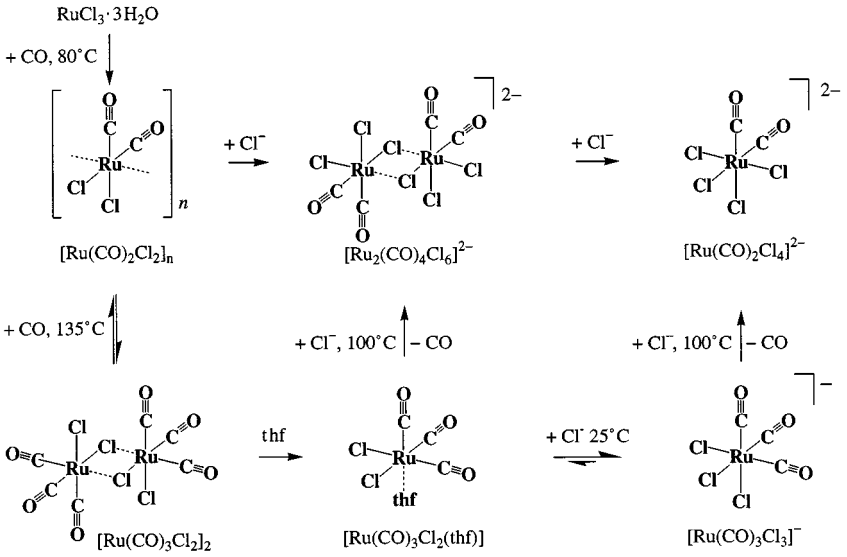
vided that an amide-type solvent like DMF was used. During the course of preliminary experiments aimed at determining the optimum Ru/Cl ratio, we noted that the $[Ru_3(\mu\text{-}Cl)(CO)_9]^-$ reacts cleanly with an excess of halide at 60°C to give the novel unsaturated dianionic species $[PPN]_2[Ru_4(\mu\text{-}Cl)_2(CO)_{11}]$ already shown in Scheme 3.[20][59] Strikingly, its structure, of an unprecedented type, gave the image of a mononuclear Ru^{II} complex "$Ru(CO)_2Cl_2$" supported on an anionic triruthenium unit "$[Ru_3(CO)_9]^{2-}$".



Intuitively, the liberation of such a fragment under catalytic conditions was thus conceivable. In fact, the above dianionic cluster species could be used alone as a catalyst precursor, just like other haloruthenium cluster complexes of the same series shown in Scheme 3. After overnight catalytic experiments, the principal species recovered in the reactor was the well-known carbido cluster $[Ru_6(C)(CO)_{16}]^{2-}$. Remembering that this inactive product had been previously detected by Dombek[1] at the end of syngas reactions using Ru/halide mixtures as catalyst precursors (vide supra), we reasoned that the active species in both systems might be the same. Then, different catalytic runs using $[PPN][HRu_3(CO)_{11}]^-$ and $[PPN][Ru(CO)_3X_3]$ (X = Cl, I) either separately, or as mixtures, led us to conclude that under the conditions of our hydroesterification reaction, the best precursor was $[PPN][Ru(CO)_3Cl_3]$ "alone".[59] It was thus appearing that the active species (still elusive) could be generated from either Ru^0 or Ru^{II} precursors. With $[PPN][Ru(CO)_3Cl_3]$, the reaction started without an induction period and proved to be very efficient (Scheme 19).

Scheme 19. Experimental conditions and performances of the catalytic hydroesterification reaction

A DMF complex $[PPN][Ru(CO)_2Cl_3(DMF)]$ appeared to be readily formed by decarbonylation of the above precursor. Interestingly, three closely related alkyl complexes $[PPN][Ru_2(\mu\text{-}Cl)_3(CO)_4RR']$ (R = Et or Me; R′ = Et or Me) were subsequently intercepted in the reactor by quenching the catalytic reaction as the system reached its optimum activity.[60] It was shown that, under the reaction conditions, the alkyl moieties were derived principally from ethylene (by insertion into an Ru−H bond) but also from the alkyl formate [by cleavage of the O−C(sp^3) bond]. Effectively, at that time, the only way to exclusively obtain the dimeric ethyl complex in a pure form proved to be the catalyzed addition of *ethyl* formate to ethylene.

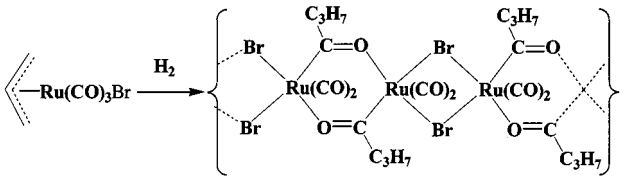


It was amazing to realize that a catalytic run performed in 1997 led to the discovery of the existence of a simple yet hitherto unknown species, some thirty years after its antecedent $[PPN][Ru(CO)_3Cl_3]$(!). Clearly, this revealed that the reactivity of carbonylchlororuthenium(II) species toward unsaturated organic substrates had not been examined in detail, or, at least needed to be revisited.

II.2 Pioneering Observations on Carbonylhaloruthenium(II) Complexes

The present state of knowledge of the chemistry of carbonylchlororuthenium(II) complexes rests on the important pioneering discoveries made in the 1960s and 1970s by several groups[22] amongst which we recognize names that have marked the development of this field: Chatt,[61] Halpern and James,[62] Bruce and Stone,[63] Braca,[64] Calderazzo,[65] Johnson and Lewis,[66] Collmann and Roper,[67] and Wilkinson.[68]

Equilibria involving the principal binary carbonylchloro derivatives are shown in Scheme 20. Chatt[61] was the first to observe that bubbling CO through a solution of $RuCl_3 \cdot 3\,H_2O$ at 85°C gives a red solution containing a structurally ill-defined polymeric complex $[Ru(CO)_2Cl_2]_n$. Prolonged treatment with CO at 120−140°C[63] gives the 16e⁻ tricarbonyl unit "$Ru(CO)_3Cl_2$", which spontaneously stabilizes itself by forming halide bridges to give $[Ru(CO)_3Cl_2]_2$.[69] Since the reverse decarbonylation is also operative at high temperature, a mixture of $[Ru(CO)_2Cl_2]_n$ and $[Ru(CO)_3Cl_2]_2$, known as the "yellow solution",[70] is generally obtained. The only way to drive the equilibrium toward the more CO-rich derivative is thus to pursue the carbonylation at room temperature.[59] As originally reported by Bruce and Stone,[63] splitting of the dimer $[Ru(CO)_3Cl_2]_2$ by a donor solvent like THF gives the nice crystalline complex $Ru(CO)_3Cl_2(thf)$ from which THF may be subsequently displaced by a halide anion to give the anionic species $[Ru(CO)_3Cl_3]^-$.

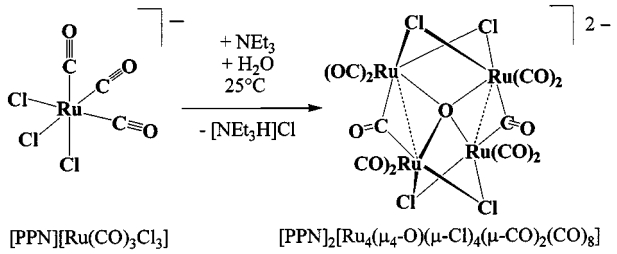


In fact, the complexes shown in Scheme 20 represent the principal possibilities to stabilize the 14e⁻ fragment "$Ru(CO)_2Cl_2$" by using all possible combinations of CO and Cl^- ligands. For a long time, these complexes were mainly regarded as intermediates for the preparation of more elaborate species.[22] For example, ruthenium chemists have long been using the above-mentioned "yellow solution" for the preparation of $Ru_3(CO)_{12}$ (by reduction with CO in the presence of zinc as a halide acceptor),[70] whereas fascinat-

Scheme 20. Interconversion between the principal known carbonylhaloruthenium(II) complexes

ing new complexes are still made nowadays by treatment of $[Ru(CO)_2Cl_2]_n$ with sophisticated phosphanes.[71]

In the early work of Pino et al.[72] we find a rare example of a carbonylhaloruthenium(II) complex bearing a hydrocarbon fragment as the only additional ligand. This is the allyl species $Ru(C_3H_5)(CO)_3Br$, prepared by oxidative addition of allyl bromide to $Ru_3(CO)_{12}$. Such a compound was shown to act as a catalyst precursor for olefin hydrogenation and isomerization,[64c] whereas its reaction with hydrogen gave a structurally ill-defined polymeric acyl species resulting from a hydrogenation of the allyl moiety followed by migratory CO insertion.[64c]

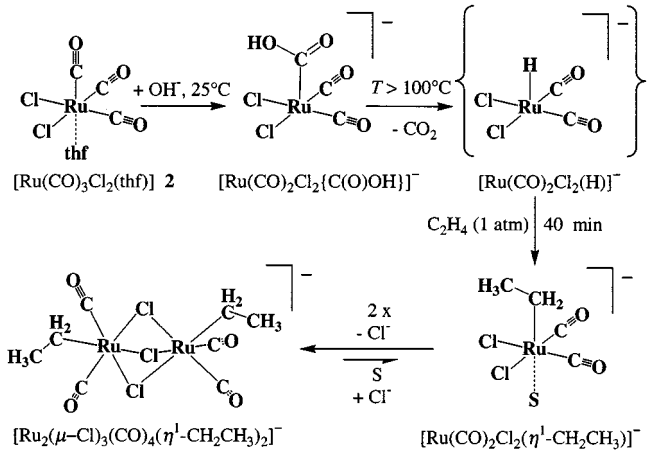


Further treatment of the latter with CO/methanol led to the stoichiometric formation of esters, thus prefigurating the possibility to achieve hydroesterification reactions.

II.3 New Findings in the Footsteps of the Pioneers

II.3.1 Facile Activation of Water

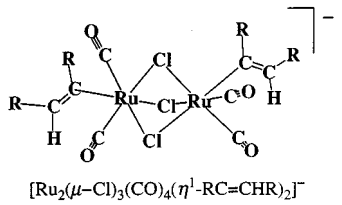
In attempts to trace the evolution of $[PPN][Ru(CO)_3Cl_3]$ under the conditions of a typical hydroesterification reaction, it was noted that treatment of this complex with triethylamine (the optional co-catalyst) resulted in *halide displacement rather than CO substitution*.[73] This provided an indication that the *neutral* fragment "$Ru(CO)_3Cl_2$" might be the reacting entity, whereas the weakly coordinated halide anion could be regarded as a lightly stabilizing ligand for the neutral unit. Furthermore, with wet triethylamine, the known[20] oxo complex $[PPN]_2[Ru_4(\mu_4\text{-}O)(\mu\text{-}Cl)_4(\mu\text{-}CO)_2(CO)_8]$ was obtained,[74] which was indicative of a facile activation of water accompanied by reductive elimination of HCl, trapped as $[NEt_3H]Cl$.



Scheme 21. Facile activation of water by a carbonylchlororuthenium(II) complex with formation of an oxoruthenium(II) species

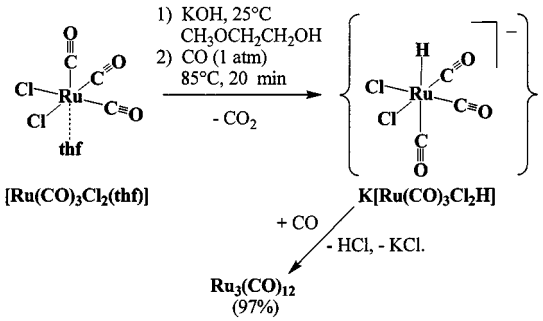
Though not fully understood, the reaction was thought to involve initial attack of OH^- ions at the carbon atom of a coordinated CO ligand.

II.3.2 A Simple Route to "Unprotected" Alkyl and Alkenyl Complexes



An obvious analogy of the preceding reaction with the basic principle of the water gas shift[24] led us to attempt the generation of a transient hydrido species by treatment of the neutral complex $[Ru(CO)_3Cl_2(thf)]$ with KOH and to examine its ability to insert olefins and, by extension, any unsaturated organic substrate. The logical sequence we envisaged (Scheme 22) effectively allowed a clean preparation of the anionic ethyl complex $[Ru_2(\mu\text{-}Cl)_3(CO)_4(CH_2CH_3)_2]^-$ in a one-pot procedure requiring no ethylene pressure.[75]

Subsequently, it was not a problem to extend the reaction to the case of alkynes and to observe in such cases a parallel

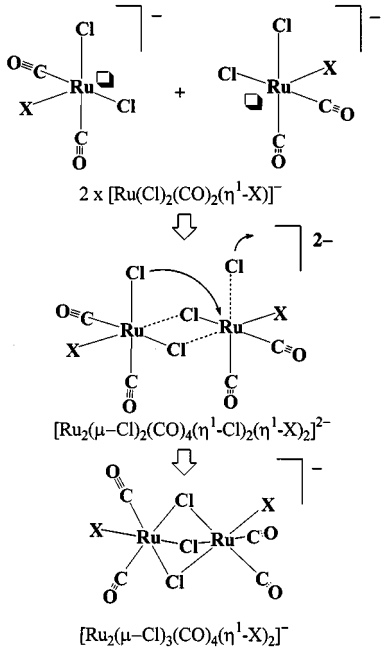


Scheme 22. Proposed mechanism for the formation of the isolated alkyl complex

cis insertion leading to the corresponding isostructural alkenyl derivative $[Ru_2(\mu\text{-}Cl)_3(CO)_4(RC{=}CHR)_2]^-$.[75]

II.3.3 Facile Interconversion $Ru^{II}-Ru^0$

A (naive) tentative attempt to intercept the transient hydrido species, generated in the preceding reaction by decarboxylation of the intermediate hydroxycarbonyl species in the presence of CO (and in the *absence* of any unsaturated substrate), led us to observe the formation of $Ru_3(CO)_{12}$ in quantitative yield(!).

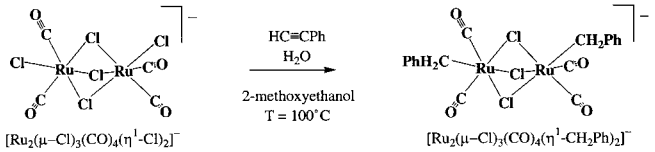


Scheme 23. A facile reduction of Ru^{II} to Ru^0

Apart from the interest in the procedure on account of its performance and of the established possibility to run the reaction directly from commercial $RuCl_3$,[75] an important extension of this finding was to establish that an extremely facile reduction of carbonylhaloruthenium(II) precursors to Ru^0 intermediates can take place by reductive elimination of HCl as soon as traces of water are present. This may have relevance to various catalytic systems involving carbonylhalo derivatives.[76]

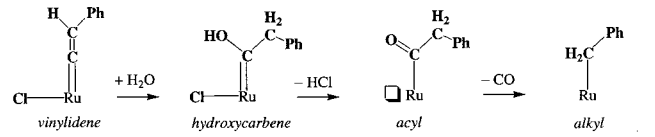
II.3.4 A New Binary Carbonylchlororuthenium(II) Species

An intriguing point in the sequence shown in Scheme 22 was the fact that dimerization of the monoanionic alkyl intermediate $[Ru(CO)_2Cl_2(\eta^1\text{-}X)]^-$ (X = R) (observable only in a donor solvent like DMF) gave a monoanionic dimer $[Ru_2(CO)_4(\mu\text{-}Cl)_3(\eta^1\text{-}X)_2]^-$ (by loss of a halide ion, see Scheme 24) rather than the expected dianionic dimer "$[Ru_2(CO)_4(\mu\text{-}Cl)_2(Cl)_2(\eta^1\text{-}X)_2]^{2-}$" (X = R), which might have been isostructural with the known "allchloro" (X = Cl) analog $[Ru_2(CO)_4(\mu\text{-}Cl)_2(Cl)_4]^{2-}$shown in Scheme 20.



Scheme 24. Aggregation of unsaturated 16-e^- haloruthenium fragments and formation of a face-sharing bi-octahedral species (FSBO); the square box appearing in the scheme denotes a vacant coordination site on the metal center

Conversely, the fact that the hypothetical allchloro anion $[Ru_2(CO)_4(\mu\text{-}Cl)_3(\eta^1Cl)_2]^-$ had never been intercepted was also intriguing. In fact, we found that such a compound does exist, and can be simply prepared by thermal decarbonylation of $[Ru(CO)_3Cl_2(thf)]$ in the presence of the appropriate amount of halide (1/2 equiv. per Ru unit).[75] It can be regarded as the simplest association of two neutral units "$Ru(CO)_2Cl_2$" that are lightly stabilized by a weakly coordinating halide.



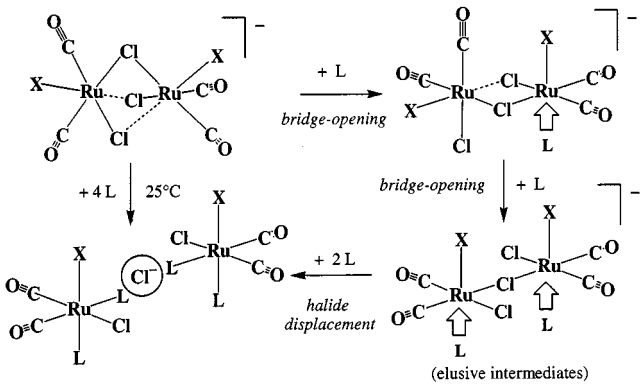
II.3.5 A Simple Route to Vinylidenes

The simple "non-hydridic" complex $[(PPh_3)_2N][Ru_2(\mu\text{-}Cl)_3(CO)_4(\eta^1\text{-}Cl)_2]$ allows the facile activation of alkynes to give *vinylidenes*.[75] To date, the latter intermediates have not yet been intercepted. Yet, we do observe *the product of their*

clean hydration involving C−C bond activation. Typically, activation of phenylacetylene gives the benzyl derivative $[Ru_2(CO)_4(\mu\text{-}Cl)_3(\eta^1\text{-}CH_2Ph)_2]^-$ (Scheme 25). The mechanism we propose for such a reaction is fully consistent with the one previously established by Bruce,[77] Bianchini[78] and Esteruelas.[79] In the present case, a transient opening of the halide bridge is believed to provide the vacant site required for alkyne activation, whereas its closure assists the final CO loss.

Proposed mechanistic pathway:

Scheme 25. Activation of the C−C triple bond of a terminal alkyne by hydration of the transient vinylidene; the square box appearing in the scheme denotes a vacant coordination site on the metal center

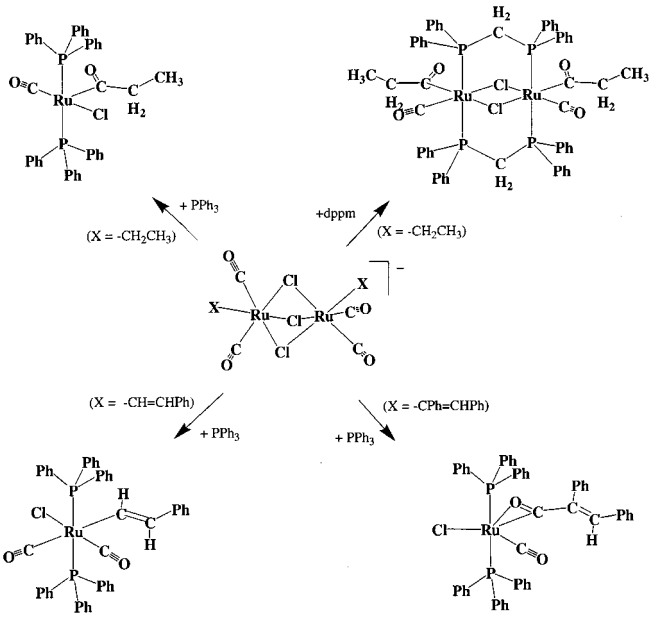


Interestingly, related ruthenium(II) halide complexes have been recently shown by Wakatsuki[80] to catalyze the hydration of alkynes to produce aldehydes and ketones. Unobserved carbenoid species have also been recently postulated as key intermediates in the construction of polycyclic ring systems from enynes involving $[Ru(CO)_3Cl_2]_2$ as a catalyst precursor.[21a]

II.3.6 Aspects of the Reactivity of FSBO (Face-Sharing Bi-Octahedral) Complexes

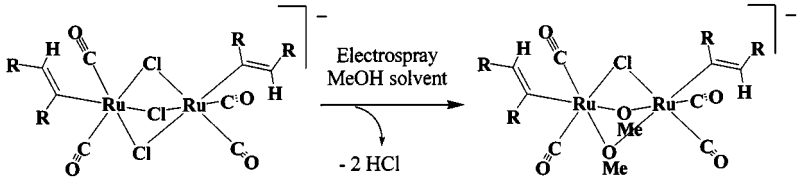
While the aggregation of carbonylhaloruthenium(II) species is understood to be a means for the unsaturated organometallic fragments to relieve their unsaturation, the reverse reaction, namely, a transient opening of halide bridges, constitutes the main pathway for substrate activation, as illustrated by the preceding reaction (Scheme 25).

A notable structural feature is that the Ru−Cl bridge bonds that are *trans* to the sigma donor (alkyl, alkenyl) are significantly longer than those *trans* to CO. This suggests the possibility of a selective opening of these bonds through a sequence (Scheme 26) that is reminiscent of the one proposed by Cotton and Poli for related FSBO species.[81]



Thus, the masked unsaturation of these aggregates also allows the facile formation of adducts with a variety of donor ligands, ultimately leading to more elaborate complexes. With L = phosphanes, a rearrangement occurs within the coordination sphere of the final mononuclear species to give the *trans*-P isomer only. If X is an alkyl group, the phosphane also induces migratory CO insertion, giving the

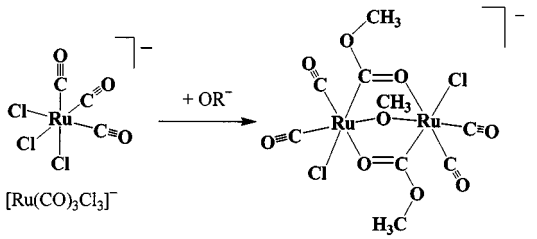
Scheme 26. General scheme for the reaction of face-sharing bi-octahedral species with nucleophiles



$16e^-$-acyl species $[Ru\{C(O)R\}(PR_3)_2(CO)Cl]$ (Scheme 27).[60]

If X is an alkenyl group, whether it migrates or not depends on the nature of the starting alkyne. As shown in Scheme 27, we have been able to obtain the alkenyl complex $[Ru(CH{=}CHPh)(PPh_3)_2(CO)_2Cl]$ from phenylacetylene, and the propenoyl complex $[Ru\{\eta^2C(O){-}PhC{=}CHPh\}(PPh_3)_2(CO)Cl]$ from diphenylacetylene, and to determine their respective structures.[82] It is noteworthy that the same complexes were originally prepared by Ros[83] from $RuH(CO)Cl(PR_3)_2$. The chemistry of these and related derivatives is currently being investigated by Werner[84a,b], Esteruelas[84] and Caulton.[85] With our procedure, retention of the dinuclear structure is possible by using a bridging ligand like bis(diphenylphosphanyl)methane, as exemplified by the facile synthesis of the dimeric acyl complex $[Ru_2(\mu\text{-}Cl)_2\{C(O)CH_2CH_3\}_2(\mu\text{-dppm})_2(CO)_2]$ (Scheme 27).[86] We are currently exploring the reactivity of the dimers $[Ru_2(\mu\text{-}Cl)_3(CO)_4(\eta^1\text{-}X)_2]$ with a variety of other ancillary ligands and substrates.

Scheme 27. Facile reactions of alkyl- and alkenylcarbonylchloro complexes with phosphanes



Another aspect of their reactivity is the facile replacement of halides by methoxide ions, which we have observed in some instances. For example, during the course of electrospray mass-spectral analyses of crystals of the dimeric alkenyl complex $[(PPh_3)_2N][Ru_2(\mu\text{-}Cl)_3(CO)_4(\eta^1\text{-}PhC{=}CHPh)_2]$ (whose structure had been ascertained by X-ray diffraction) we observed the ion $[Ru_2(\mu\text{-}Cl)(\mu\text{-}OMe)_2(CO)_4(\eta^1\text{-}PhC{=}CHPh)_2]^-$ when methanol was used as a solvent for the introduction of the samples (Scheme 28).

Scheme 28. Facile replacement of halides by methoxide ligands under the experimental conditions of electrospray mass spectrometry

We are currently exploring various possibilities to induce a systematic replacement of halides by other ancillary ligands through activation of hydrogen−element bonds, starting from compounds like thiols, imidazoles, aldehydes, etc. A full replacement of halides by methoxide ions has been reported by Süss-Fink in related methoxycarbonyl complexes.[87]

Finally we wish to conclude this section by specifying that groups other than the halides may participate in the formation of bridges between the Ru^{II} centers. Typically, in the treatment of $[PPN][Ru(CO)_3Cl_3]$ by methoxide ions, Süss-Fink isolated a complex which probably results from a transformation of the unobserved primary adduct (which we believe is $[PPN][Ru\{C(O)OMe\}(CO)_2Cl_2]$). Once again, a monoanionic aggregate (rather than a dianionic species) is obtained after loss of a halide ion. Interestingly, the new compound bears *terminal* halides and *bridging* methoxycarbonyl groups (Scheme 29).[87]

Scheme 29. Formation of methoxycarbonyl bridges rather than halide bridges in the stabilization of unsaturated carbonylhalo(methoxycarbonyl)ruthenium(II) fragments

Of course, we cannot exclude the same type of aggregation when the hydroxycarbonyl adduct we have observed (Scheme 22) is generated in a noncoordinating solvent. In that case, the whole sequence of Scheme 22 would proceed entirely through dimeric units.

Conclusion

A tantalizing observation about carbonylruthenium clusters incorporating halides or related hard bases as *hemilabile* ancillary ligands is that, in spite of their fascinating reactivity, their ability to catalyze substrate transformations with retention of the polymetallic structure is effective only under very mild conditions that are still too close to those liable to cause their degradation. An illustration of this can be found in our recent report of a *cluster-mediated* hydroformylation of diphenylacetylene.

Significantly, we now find that simple carbonylhaloruthenium(II) derivatives, easily generated from carbonylruthenium (Ru^0)/halide mixtures or by direct carbonylation of $RuCl_3$, are prone to react with olefins or alkynes in the presence of a simple source of hydride to give trappable *alkyl* or *alkenyl* complexes, whereas transient *vinylidene* species are formed from alkynes in the absence of a hydride source. These unsaturated complexes tend to relieve their unsaturation by forming aggregates whose dissociation may in turn release reactive organometallic fragments. Thus, we believe such complexes will provide realistic models for elementary transformations occurring in applied catalysis involving Ru/halide mixtures. An interplay between Ru^{II} and Ru^0 species may be expected in these multicomponent systems, due to the facile and reversible reductive elimination of HCl. Further work aimed at understanding such processes is in progress.

Acknowledgments

The author wishes to express his gratitude to all colleagues and coworkers who have made an important contribution to the research work summarized here, and, in particular, Herbert D. Kaesz, Noël Lugan, Jean-Jacques Bonnet, Philippe Kalck, Fred Basolo, Jean-Yves Saillard and Jean-François Halet. Financial support from the CNRS is also gratefully acknowledged.

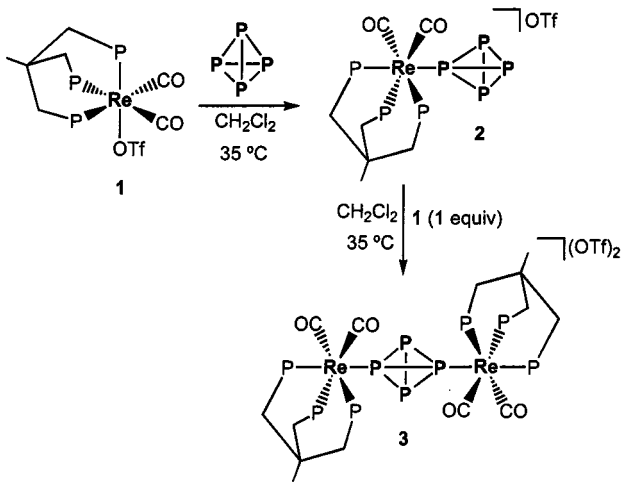
Synthesis and Characterisation of *tetrahedro*-Tetraphosphorus Complexes of Rhenium – Evidence for the First Bridging Complex of White Phosphorus

Maurizio Peruzzini,*[a] Lorenza Marvelli,[b] Antonio Romerosa,[c] Roberto Rossi,[b] Francesco Vizza,[a] and Fabrizio Zanobini[a]



Keywords: Phosphorus / Rhenium / ^{31}P-NMR spectroscopy / Tripodal polyphosphanes

Reaction of white phosphorus with [(triphos)Re(CO)$_2$(OTf)] (**1**) in dichloromethane affords the new tetraphosphorus complex [(triphos)Re(CO)$_2$(η^1-P$_4$)](OTf) (**2**) [triphos = MeC(CH$_2$PPh$_2$)$_3$; OTf = OSO$_2$CF$_3$]. Compound **2** reacts with a second equivalent of **1** to give the binuclear complex [{(triphos)Re(CO)$_2$}$_2$(μ,η^1,η^1-P$_4$)](OTf)$_2$ (**3**) in which a *tetrahedro*-P$_4$ ligand behaves as tethering unit between two [(triphos)Re(CO)$_2$]$^+$ moieties. Complexes **2** and **3** represent the first soluble metal complexes of the tetraphosphorus molecule where the P$_4$ ligand has not undergone any major modification.

The reaction of transition-metal complexes with white phosphorus has been extensively studied and has resulted in a large variety of P$_x$ ligands (x < 15) which are often unpredictable.[1] In most instance, the integrity of the P$_4$ molecule is not retained in the final complex and extensive fragmentation and aggregation processes take place.[1][2] In some cases the four atoms of the P$_4$ ligand are incorporated into the coordination polyhedron of the resulting metal complex affording derivatives containing the tetraphosphabicyclobutane[2d,3] (**I**) or the tetraphosphabutadiene[3f,4] (**II**) units. Complexes containing the *cyclo*-P$_4$ (**III**) moiety are also known.[3f,5] In contrast, there are still very few compounds featuring an intact P$_4$ molecule in the form of a simple mono-*hapto*-P$_4$ (**IV**) ligand although this coordination mode would mimic the initial interaction of white phosphorus with the metal species.

To the best of our knowledge, η^1-tetrahedral P$_4$ complexes remain limited to the [(NP$_3$)M(η^1-P$_4$)] derivatives [M = Ni, Pd; NP$_3$ = N(CH$_2$CH$_2$PPh$_2$)$_3$] described in the late 1970s by Sacconi et al.[6,9] The nickel complex was authenticated by X-ray crystallography which confirmed the presence of a tetrahedral Ni^0 complex with one coordination position taken by one of the four P atoms of an intact P$_4$ molecule.[6a] Unfortunately, these complexes are quite insoluble in common organic solvents thus *preventing any characterisation of the tetraphosphorus ligand in solution and any investigation of the reactivity of the coordinated P$_4$* molecule. Despite synthetic efforts, related complexes have not yet been described in the literature.[1] Now, in this report, we detail the synthesis and the spectroscopic characterisation of the first examples of soluble mono- and dinuclear tetraphosphorus metal complexes for which the η^1-coordination mode of the P$_4$ molecule has been confirmed by ^{31}P-NMR spectroscopy.[7]

Scheme 1. Reaction of [(triphos)Re(CO)$_2$(OTf)] with white phosphorus

Reaction of a dichloromethane solution of the weakly coordinated triflate complex [(triphos)Re(CO)$_2$(OTf)][8] (**1**) [triphos = 1,1,1-tris(diphenylphosphanylmethyl)ethane)] with a small excess of white phosphorus at ca. 35°C under nitrogen (Scheme 1), affords, after addition of ethanol/*n*-

hexane and fast concentration under nitrogen, mustard-coloured microcrystals of [(triphos)Re(CO)$_2$(η^1-P$_4$)](OTf) (**2**) in good yield. Once thus obtained, **2** is slightly air-sensitive and can be manipulated in the air and maintained at room temperature without noticeable decomposition for a few hours. When dissolved in various solvents (dichloromethane, thf, chloroform), **2** is air- and moisture-sensitive and quickly decomposes to an orange uncharacterised solid. **2** exhibits a particularly informative $^{31}P\{^1H\}$-NMR spectrum consisting of a temperature-invariant AB_2MX_3 spin system featuring strong couplings between the nuclei P_M and P_X ($^1J_{PMPX}$ = 235.7 Hz) and P_A and P_M ($^2J_{PAPM}$ = 204.7 Hz). The magnitude of the latter coupling diagnoses the *trans* disposition between one of the triphos P atoms and the unique Re-bonded P atom of the *tetrahedro*-tetraphosphorus ligand. The invariance of the ^{31}P-NMR spectrum indicates that no dynamic process is exchanging the four atoms of the P$_4$ ligand and points to the existence of a P$_4$ moiety freely rotating around the P$_A$−Re−P$_M$ axis. This causes the magnetic equivalence of the basal P atoms of the P$_4$ tetrahedron whose signal appears as a doublet at δ = −488.9 in the high-field region of the spectrum [see trace (a) in Figure 1]. Noticeably, the two sets of resonances of the P$_4$ ligand are slightly deshielded upon coordination by ca. 38.0 ppm (P$_X$) and ca. 136.4 ppm (P$_M$, δ = −390.52) when compared with the free molecule of white phosphorus (δ = −526.9). These relatively small coordination chemical shifts [Δ = δ(P$_{M/Xcoord}$) − δ(P$_{4free}$)] suggest that, upon coordination to the (triphos)rhenium moiety, only a minor perturbation of the electron density of the P$_4$ tetrahedron has occurred.

In keeping with these observations, the "distal" P$_3$-face unit of the *tetrahedro*-P$_4$ ligand is still endowed with reactivity towards unsaturated transition metal complexes and electrophiles and we envisage the generation of several new polynuclear compounds and P$_4$-functionalisation products from **2**. We are currently exploring this interesting area and preliminary tests confirm our hypothesis.

As an example, when a dichloromethane solution of **2** is treated with a small excess of **1**, coordination of a second [(triphos)Re(CO)$_2$]$^+$ moiety to the P$_4$ ligand takes place and the dinuclear complex [{(triphos)Re(CO)$_2$}$_2$(μ,η^1,η^1-P$_4$)](OTf)$_2$ (**3**) may be isolated as air-stable pale yellow microcrystals after workup (yield 90%). On the basis of the spectroscopic data, **3** is assigned a bimetallic structure where two [(triphos)Re(CO)$_2$]$^+$ fragments are held together by a tethering P$_4$ unit which behaves as a bridging μ,η^1,η^1 ligand. The formation of a dimeric compound is witnessed by the drastic modification of the high-field part of the $^{31}P\{^1H\}$-NMR spectrum which, on moving from **2** to **3**, transforms into an AA′B$_2$B′$_2$MM′X$_2$ spin system [see trace (b) in Figure 1]. Interestingly, upon coordination of the second [(triphos)Re(CO)$_2$]$^+$ unit, a more relevant downfield shift of the signals of the metallated P atoms takes place while the resonance ascribable to the uncoordinated P$_2$ atoms moves slightly downfield. To the best of our knowledge, this kind of coordination mode for a *tetrahedro*-P$_4$ molecule is unprecedented in the rich chemistry of main-group−transition-metal compounds.[1]

Investigations are continuing in our laboratories with the focus on the reactivity of the soluble P$_4$ ligand in **2** and **3**

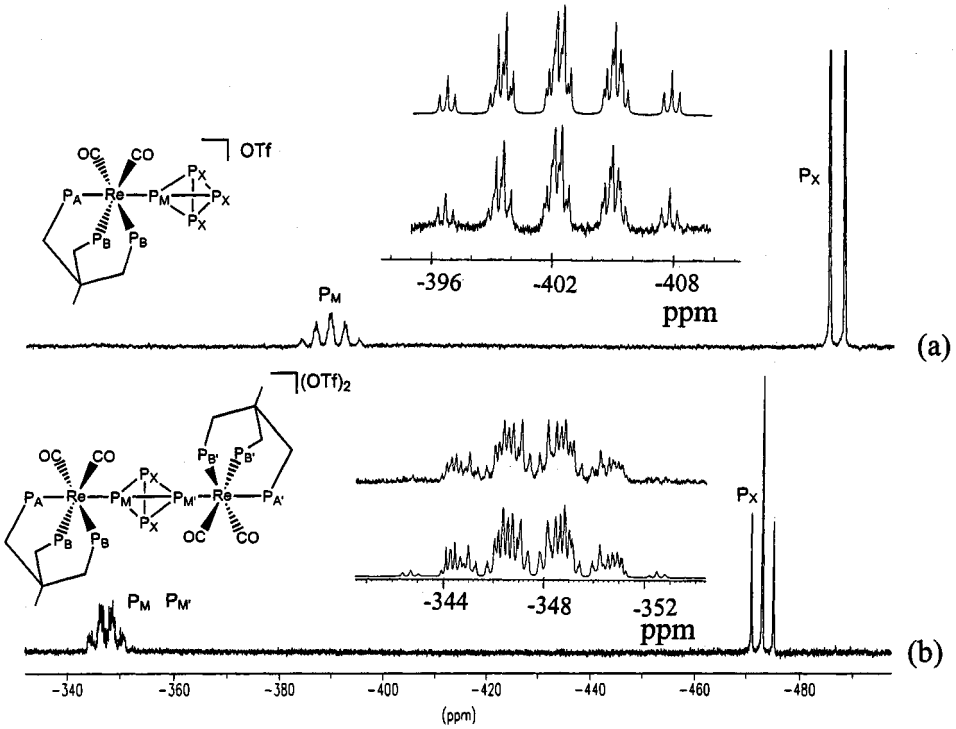

Figure 1. $^{31}P\{^1H\}$-NMR spectra of **2** (trace a) and **3** (trace b) in the high-field region (81.01 MHz, CD_2Cl_2, 298 K, 85% H_3PO_4 reference); the insets show the computed and experimental multiplets of the metallated P atom of the P$_4$ ligand in the two complexes.

as well as on the possible transferability of naked P atoms to inorganic and organic molecules.

Experimental Section

General Information: Dichloromethane was purified by distillation under nitrogen from P_2O_5. Complex **1** was prepared as described in the literature.[8] – ^{1}H- and ^{31}P{^{1}H}-NMR spectra were recorded with a Bruker AC200 or Bruker AVANCE DRX 500 spectrometers operating at 200.13 or 500.13 MHz (^{1}H) and 81.01 or 202.45 MHz (^{31}P), respectively. Peak positions are relative to tetramethylsilane (^{1}H) or 85% H_3PO_4 with downfield values taken as positive (^{31}P). The ^{31}P,^{31}P-2D COSY NMR experiments were conducted with an AVANCE DRX 500 Bruker spectrometer in the absolute magnitude mode using a 90° pulse after the incremental delay. – Elemental analyses (C, H) were performed using a Carlo Erba model 1106 elemental analyzer.

Complex 2: A dichloromethane solution (20 mL) of **1** (0.50 g, 0.49 mmol) was treated at ca. 35°C with a small excess of white phosphorus (0.08 g, 0.64 mmol) under nitrogen. Addition of ethanol/*n*-hexane (10 mL, 1:2 v/v) and concentration of the resulting solution under a brisk current of nitrogen, gave mustard-coloured microcrystals of **2** which were filtered under nitrogen and washed with ethanol (2 × 3 mL) and light petroleum ether (2 × 5 mL). Yield 76%. – IR (nujol mull): $\tilde{\nu}_{CO}$ = 1967 vs, 1912 vs; $\tilde{\nu}_{OTf}$ = 1265 s cm^{-1}. – ^{1}H NMR (CD_2Cl_2, 200.13 MHz): δ = 7.80–6.95 (30 H, m, phenyl protons), 2.70–2.40 (6 H, m, PCH_2), 1.58 (3 H, q, $^4J_{HP}$ = 2.8 Hz, CH_3). – ^{31}P{^{1}H} NMR (CD_2Cl_2, 81.01 MHz): AB_2MX_3 spin system; δ = –7.31 (1 P, dtq, $^2J_{PAPM}$ = 204.7 Hz, $^2J_{PAPB}$ = 23.7 Hz, $^3J_{PAPX}$ = 5.2 Hz, P_A), –14.59, (2 P, dd, $^2J_{PBPM}$ = 31.4 Hz, P_B), –390.52 (1 P, qdt, $^2J_{PMPX}$ = 235.7 Hz, P_M), –488.90 (3 P, dd, P_X); the assignments were confirmed by ^{31}P,^{31}P-COSY 2D-NMR spectroscopy and by computer simulation of the spectra. – FABMS; *m/z*: 867 [$M^+ - P_4$]; 839, 811 [$M^+ - P_4 - n$CO; *n* = 1–2]. – $C_{44}H_{39}F_3O_5P_7ReS$ (1139.87): calcd. C 46.36, H 3.45; found C 46.1, H 3.4.

Complex 3: Into a Schlenk flask, containing a dichloromethane solution (20 mL) of **2** (0.25 g, 0.22 mmol), a small excess of **1** (0.25 g, 0.25 mmol) was added under nitrogen as a solid in small portions. The solution was slowly heated at 35°C for 15 min and then 10 mL of an ethanol/*n*-hexane mixture (1:2 v/v) was added. Workup as described above for **2** afforded pale yellow microcrystals of **3** which were collected in the air and washed with ethanol (2 × 3 mL) and light petroleum ether (2 × 5 mL). Yield 90%. – IR (nujol mull): $\tilde{\nu}_{CO}$ = 1958 vs, 1919 vs; $\tilde{\nu}_{OTf}$ = 1267 s cm^{-1}. – ^{1}H NMR (CD_2Cl_2, 200.13 MHz): δ = 7.75–6.80 (60 H, m, phenyl protons), 2.90–2.50 (6 H, m, PCH_2), 1.72 (3 H, q, $^4J_{HP}$ = 2.9 Hz, CH_3). – ^{31}P{^{1}H} NMR (CD_2Cl_2, 81.01 MHz): δ = $AA'B_2B'_2MM'X_2$ spin system; –9.18 (2 P, m, $^2J_{PAPB}$ and $^2J_{PA'PB'}$ = 23.5 Hz, $^2J_{PAPM}$ and $^2J_{PA'PM'}$ = 201.0 Hz, $^3J_{PAPX}$ and $^3J_{PA'PX'}$ = 5.0 Hz, P_A and $P_{A'}$), –15.03 (4 P, m, $^2J_{PBPM}$ and $^2J_{PB'PM'}$ = 28.2 Hz, P_B and $P_{B'}$), –347.61 (2 P, m, $^1J_{PMPX}$ and $^1J_{PM'PX'}$ = 168.8 Hz, $^1J_{PMPM'}$ = 182.4 Hz, P_M and $P_{M'}$), –473.37 (2 P, td, P_X). – $C_{88}H_{78}F_6O_{10}P_{10}Re_2S_2$ (2155.84): calcd. C 49.03, H 3.65; found C 48.8, H 3.5.

Acknowledgments

This work was supported by the European Commission (INCO Copernicus Project ERBIC15CT960746). Thanks are expressed to Dr. José Antonio Ramirez (Valencia, Spain) and Dr. Andrea Meli (ISSECC CNR) for the simulation of the ^{31}P-NMR spectra.

Structural, Spectroscopic, Magnetic and Thermal Properties in the $[SrM(C_3H_2O_4)_2(H_2O)_5] \cdot 2\ H_2O$ (M = Mn, Fe, Co, Ni) System: Precursors of $SrMO_{3-x}$ Mixed Oxides

Keywords: Malonate / Mixed oxides / Crystal structure / Thermochemistry / Magnetic properties

The $[SrM(C_3H_2O_4)_2(H_2O)_7]$ (M = Mn, Fe, Co, Ni) compounds have been prepared and characterised by chemical analysis and X-ray diffraction. The crystal structure of $[SrCo(C_3H_2O_4)_2(H_2O)_5] \cdot 2\ H_2O$ has been solved [monoclinic, $P2_1/c$, $Z = 4$, $a = 6.880(1)$, $b = 14.360(2)$, $c = 15.800(2)$ Å. $\beta = 101.69(1)°$]. The compound exhibits a three-dimensional chain/snake structure consisting of $-CoO_6-[SrO_7]_\infty-CoO_6-$ repeating units parallel to the [0 1 1] and [0 –1 1] directions. UV/Vis data are consistent with the cations being in a high-spin octahedral symmetry. Magnetic measurements show antiferromagnetic interactions for all compounds with approximate θ values of –0.5 K, except for the cobalt compound (–24.5 K) where the decrease of the $\chi_m T$ curve can also be attributed to the spin-orbit coupling. Thermal analyses performed in air and under nitrogen show three consecutive steps: dehydration, ligand pyrolysis, and inorganic residue evolution. Thermal treatments in tubular furnaces were performed in order to obtain pure $SrMO_{3-x}$ phases. In all cases the oxides are nonstoichiometric and oxygen-deficient with structures related to that of perovskite. Lower temperatures and reaction times than those given in the literature have been used when using the ceramic method. These "soft" treatments gave rise to homogeneous particles of small grain size.

Introduction

Since the discovery of high-temperature superconducting oxides, much interest has been paid to the 3d transition metal oxides. In particular, the electronic states of the perovskite-type oxides have been extensively investigated from the standpoint of 3d band filling,[1−3] those that have transition metal ions such as Mn^{4+}, Fe^{4+}, Co^{4+}, Ni^{3+}, or Cu^{3+} in unusually high oxidation states, as well as mixed valence states, being those most studied.

The physical properties of these kinds of oxides depend greatly upon the oxidation state and the location of the cation at either tetrahedral or octahedral sites. The electronic and magnetic properties of the $SrFeO_{3-x}$ system vary a great deal with the oxidation state of the iron ions, ranging from the antiferromagnetic insulator oxide $SrFeO_{2.5}$, a brown millerite-type structure, to the antiferromagnetic metallic compound $SrFeO_3$, with cubic perovskite structure.[4] The $SrMnO_{3-x}$ phase becomes increasingly anion-deficient in air with increasing temperature.[5] For this reason the physical properties related to the crystal structures have been studied.[6] In the case of the cobalt oxides, the named cobaltites have attracted special attention due to their application as low-cost fuel-cell electrodes.[7]

In addition to the oxidation state, the physical properties also depend on either the final particle size or the preparative methods used to obtain the materials. In the last few years, "soft" chemical routes have often been employed to prepare advanced ceramic powders, as an alternative method to the conventional ceramic method. The solid solution precursor technique used for the preparation of fine oxide materials at low temperatures in this way has frequently been reported.[8] This method is quite advantageous, due to the excellent stoichiometry and low impurity content of the final phases.[9]

We are interested in the study of organometallic compounds with carboxylates, as well as their use as precursor materials for obtaining mixed oxides.[10] The chemistry of transition metal complexes involving malonate as a bridging ligand has been investigated due to a wide variety of physical properties,[11] the results concerning magnetic properties of 1D, 2D, and 3D systems being of special interest.[12]

Recently, a series of metal malonate complexes has been reported.[13] In this paper, the synthesis and characterisation of the $[SrM(C_3H_2O_4)_2(H_2O)_7]$ (M = Mn, Fe, Co, Ni) compounds is presented. Hereafter, these complexes will be denoted as SrMn, SrFe, SrCo, and SrNi, respectively. Spectroscopic and magnetic studies have been performed on these compounds. In order to obtain information concerning the formation of pure mixed oxides from the organometallic precursors, a detailed thermal study has been carried out.

Results and Discussion

The synthesis of the complexes was performed as described in the Experimental Section. Crystal structure analyses were performed for the $[SrCo(C_3H_2O_4)_2(H_2O)_7]$ complex. Crystal data and details of the structure determination are summarized in Table 1. Bond lengths and angles for non-hydrogen atoms are given in Table 2.

Table 1. Data collection and structure refinement for the $[SrCo(C_3H_2O_4)_2(H_2O)_5] \cdot 2\ H_2O$ compound

Molecular Formula	$C_6H_{18}CoO_{15}Sr$
a [Å]	6.880(1)
b [Å]	14.360(2)
c [Å]	15.800(2)
β	101.69(1)°
V [Å^3]	1528.6(4)
Z	4
Molecular mass [g]	476.75
Space group	$P2_1/c$
T [°C]	293(2)
$\rho_{obsd.}$ [g cm^{-3}]	2.07(6)
$\rho_{calcd.}$ [g cm^{-3}]	2.054
μ [mm^{-1}]	4.651
λ [Å]	0.71070
$R(F_o)$[a]	0.0427
$R_w(F_o^2)$[b]	0.0967

[a] $R_1(F_o) = [\Sigma||F_o| - |F_c||/\Sigma|F_o|]$. — [b] $wR_2(F_o^2) = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$

The asymmetric unit consists of diaquobis(malonato)cobaltate(II) anions linked to strontium ions and two water molecules of crystallization, O(6w) and O(7w) (see Figure 1). The cobalt(II) centres adopt an octahedral coordination pattern. The polyhedron is formed by the four carboxylate groups from the two malonate ions and the O(1w) and O(2w) water molecules, which are located in the axial plane. The O(1), O(5), O(3), and O(7) atoms are coplanar at average distances of 2.06 Å. The O−Co−O angles are close to 90°, in good agreement with those observed for other related compounds.[13][14] The cobalt atom is raised by 0.016(1) Å above the square plane in the direction of O(2w). The distortion around the cobalt(II) ion has been calculated by quantification of the Muetterties and Guggenberger description.[15] The value obtained, $\Delta = 0.04$, is indicative of a quite regular octahedron.

The strontium ions are surrounded by nine oxygen atoms, five of them belonging to three malonate groups, and four water molecules, O(3w), O(3w)^3, O(4w), O(5w), forming an irregular polyhedron. The average Sr−O distance is 2.67 Å. The strontium polyhedra are linked between them along the [1 0 0] direction via two different common edges, O(8)^1−O(8)^2 and O(3w)−O(3w)^3, due to the presence of an inversion centre at the middle point of these edges [at x = 0 and 1/2, for O(8)^1−O(8)^2 and O(3w)−O(3w)^3, respectively]. The Sr−O(8)−Sr and Sr−O(3w)−Sr angles are both 113.9(2)°. These $[SrO_7]_\infty$ chains, running along the [100] direction, are linked between them by corner-sharing CoO_6 distorted octahedra, where O(1) and O(7) oxygens are the common corners. These connections form new "perpendicular" chains parallel to [0 1 1] and [0 −1 1] directions

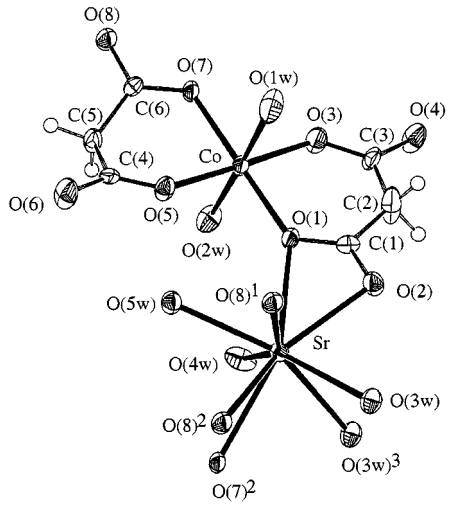

Figure 1. View of the coordination polyhedra for strontium and cobalt ions with atom numbering for the $[SrCo(C_3H_2O_4)_2(H_2O)_5] \cdot 2\ H_2O$ compound

formed by $-CoO_6-[SrO_7]_\infty-CoO_6-$ units, as can be seen in Figure 2. In these chains, the Co···Co^2 direct distance is 7.908(2) Å and the exchange distance through the O(1)−Sr−O(7)^2 atoms is 9.74 Å. In this way, the structure

could be described as a three dimensional package of strontium dimers linked through CoO_6 polyhedra. (1: $1 - x$, $y - 1/2$, $1/2 - z$; 2: x, $1/2 - y$, $1/2 + z$; 3: $-x$, $-y$, $1 - z$).

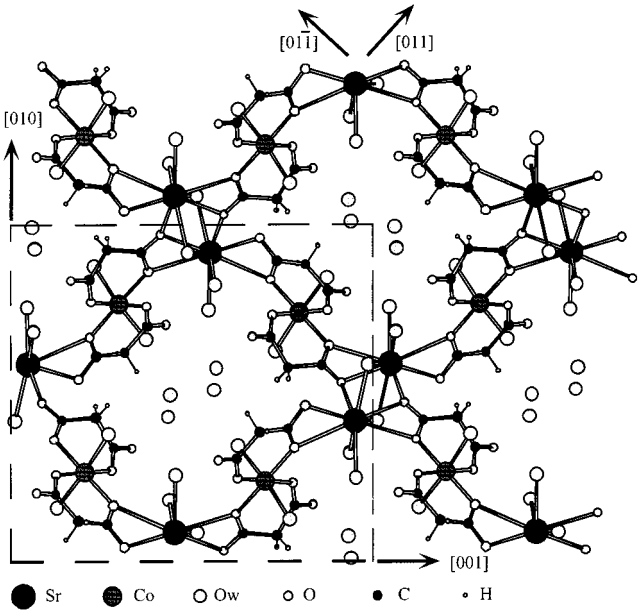

Figure 2. A perspective view of the $[SrCo(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ compound in the *bc* plane

In the malonate ligands, the dihedral angle between the planes O(5)−C(4)−O(6) and O(7)−C(6)−O(8) is 143.8(7)° and between O(4)−C(3)−O(3) and O(1)−C(1)−O(2) it is 9.4(5)°. The chelated malonate ring formed by the O(5)−C(4)−C(5)−C(6)−O(7) atoms has an envelope conformation in which only the methylene group is significantly displaced from the ring plane, while the other ring formed by the O(3)−C(3)−C(2)−C(1)−O(1) atoms is quite planar. The difference in the C(3)−C(2)−C(1), 125.2(6)° and C(4)−C(5)−C(6), 118.6(5)° angles could be explained on the basis of these linkages and the conformation of the ligands. In both malonate ions, the average C−O distances and O−C−O angles are 1.25 Å and 122.6°, respectively. All the oxygen atoms belonging to the malonate ligand are bonded to one or two metal ions, except the O(4) and O(6) atoms which are uncoordinated.

In the crystal structure, extensive hydrogen bonds involving the carboxyl groups and water molecules could be described by acceptor-donor distances of ca. 3 Å. However, the difficulty in locating the water hydrogen atoms prevents us from predicting this kind of bonding in the structure.

For the SrMn, SrFe, and SrNi phases, high-quality crystals were not obtained. X-ray diffraction patterns of the microcrystalline products were performed in the 2θ range of 5−70°. Indexation of the diffraction profile and refinement of the cell parameters were made by FULLPROF (pattern-matching analysis)[16] on the basis of the space group, $P2_1/c$, and the cell parameters found for the SrCo phase. The calculated values are given in Table 3. Taking into account these results, the four phases can be considered to be isostructural.

The IR spectra of the compounds show a strong broad absorption band in the region 3100−3600 cm^{-1}, corresponding to the stretching vibration of the hydroxy groups, ν(O−H), of the water molecules. The presence of a band at around 1580 cm^{-1} is attributed to the stretching vibration of the carbonyl group linked to the metal ions. This band appears together with the antisymmetric $\upsilon_a(COO^-)$ vibration. The bands corresponding to the symmetric $\upsilon_s(COO^-)$ vibration are localised in the 1380−1452 cm^{-1} range. The relative positions of these two bands, $\Delta = \upsilon_a(COO^-) - \upsilon_s(COO^-)$, are lower than those corresponding to the free malonic acid. This fact indicates that the coordination of the ligands to the metal ions could be through the formation of a chelate, giving rise to an electronic delocalization in the carboxylate group.[17] The presence of a shoulder at around 1700 cm^{-1} in the IR spectra could be attributed to the existence of C=O groups, which are not linked to any metal ions as was observed in the crystal structure of the SrCo compound. Nevertheless, the appearance of a broad band in this region, probably due to the presence of hydrogen bonds between the water molecules and the carboxylate groups, hampers the localization of free carboxylate groups in the IR spectra. Finally, the band observed for all compounds in the 1100−1300 cm^{-1} range corresponds to the bending vibration of the carbonyl group, δ(C=O).

Reflectance spectra were recorded for the $[SrM(C_3H_2O_4)_2(H_2O)_7]$ (M = Fe, Co, Ni) compounds. For the nickel phase the bands that appear at frequencies $\tilde{\nu}_1$ = 8930, $\tilde{\nu}_2$ = 13513 and $\tilde{\nu}_3$ = 26315 cm^{-1} have been assigned to the three allowed transitions $^3A_{2g} \rightarrow {}^3T_{2g}$, $^3T_{1g}$ (F) and $^3T_{1g}$(P). The spin-forbidden transitions $^3A_{2g} \rightarrow {}^1E_g$ and $^1T_{2g}$ were also observed $\tilde{\nu}_4$ = 15570 and $\tilde{\nu}_5$ = 21500 cm^{-1}, respectively. The Dq and Racah parameters, calculated by fitting the experimental frequencies to an energy level diagram for octahedral d^8 systems are: Dq = 893 cm^{-1}, B = 957 cm^{-1} and C = 4264 cm^{-1}, values usually found for octahedrally coordinated Ni^{II} compounds.[18] In the case of the $[SrCo(C_3H_2O_4)_2(H_2O)_7]$ compound, the positions of the bands are in the range usually found for Co^{II} ions in octahedral geometries, $\tilde{\nu}_1$ = 8550, $\tilde{\nu}_2$ = 16670 and $\tilde{\nu}_3$ = 20200 cm^{-1} which have been assigned to the $^4T_{1g} \rightarrow {}^4T_{2g}(F)$, $^4A_{2g}$ (F) and $^4T_{1g}(P)$ transitions. The Dq = 966 cm^{-1} and B = 851 cm^{-1} values confirm the octahedral geometry. For the

iron compound the band corresponding to the $^5T_{2g} \rightarrow {}^5E_g$ transition is split into two, due to the Jahn−Teller distortion of the ^5E_g energy level. From the position of these bands, 11235 and 6875 cm^{-1}, a value of $(8/3)d\sigma = 4360$ cm^{-1} was calculated. This fact is indicative of the presence of a slight distortion around the metal ion in this compound.

The X-band EPR spectra of polycrystalline samples of the $[SrM(C_3H_2O_4)_2(H_2O)_7]$ (M = Mn, Co) compounds have been performed in the temperature range 4.2−300 K. The spectra at 4 K are shown in Figure 3. In the case of the manganese phase broad and isotropic signals appear at room temp., and these signals are narrower at low temperatures. The corresponding g_{iso} parameter at 4 K has a value of 2.00, in good accordance with that corresponding to the Mn^{II} ions in octahedral geometry. The spectrum of the cobalt phase shows the strong anisotropy of the g factor. The signal presents a very broad linewidth due to the spin-orbit coupling which hampers the determination of good g values for this compound.

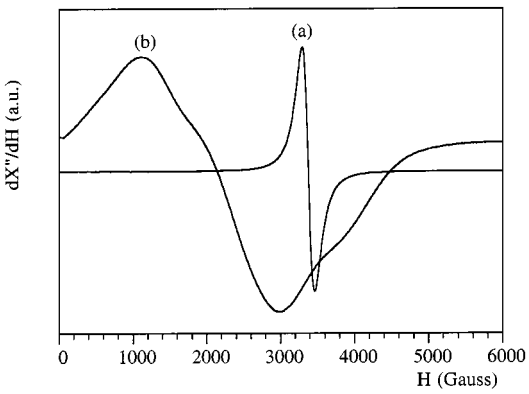

Figure 3. Powdered X-band ESR spectra for the $[SrM(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ compounds at 4 K (a) M = Mn, (b) M = Co

Susceptibility magnetic measurements of the $[SrM(C_3H_2O_4)_2(H_2O)_7]$ (M = Mn, Co, Fe, Ni) compounds were carried out in the temperature range of 1.8−300 K. A similar magnetic behaviour was observed for the SrFe, SrNi, and SrMn phases. The $\chi_m{}^{-1}$ and $\chi_m T$ vs T curves for the Mn^{II} compound is represented in Figure 4a. The $\chi_m{}^{-1}$ vs T curves for these compounds show a Curie−Weiss behaviour in the range 5−300 K with negative intercepts of −0.68 K (SrFe), −0.36 K (SrNi), and −1.8 K (SrMn). These negative θ values and the overall appearance of the $\chi_m T$ vs T curves are indicative of the presence of antiferromagnetic interactions. The values for the Curie constants are 3.65, 1.18, and 4.36 cm^3 K/mol, respectively. The $\chi_m T$ products are practically temperature-independent for $T >$ 50 K, reaching values of 2.45 (SrFe), 1.12 (SrNi), 3.7 (SrMn) cm^3 K/mol when cooling from this temperature to 4.2 K. Taking into account the crystallographic description, the magnetic behaviour could be described on the basis of either a Heisenberg square-planar system or a 3D network. Nevertheless, in all cases the best least-squares fit leads to J/k values less than 1 K.

For the SrCo compound the high-temperature data ($T >$ 60 K) were also fitted to a Curie−Weiss law with θ = −24.5 K and $Cm = 3.77$ cm^3 $Kmol^{-1}$ of metal ion (Figure 4b). The continuous decrease in the $\chi_m T$ curve must be ascribed to the antiferromagnetic exchange interactions, together with the effect of the spin-orbit coupling ($\lambda = -170$ cm^{-1} for the free Co^{2+} ion),[19] which leads to an effective spin $S = 1/2$ for the system at low temperatures ($T <$ 30 K). This effect is qualitatively similar to those of the antiferromagnetic interactions, making difficult to distinguish between the contributions of these two effects on the whole magnetic behaviour of this compound.

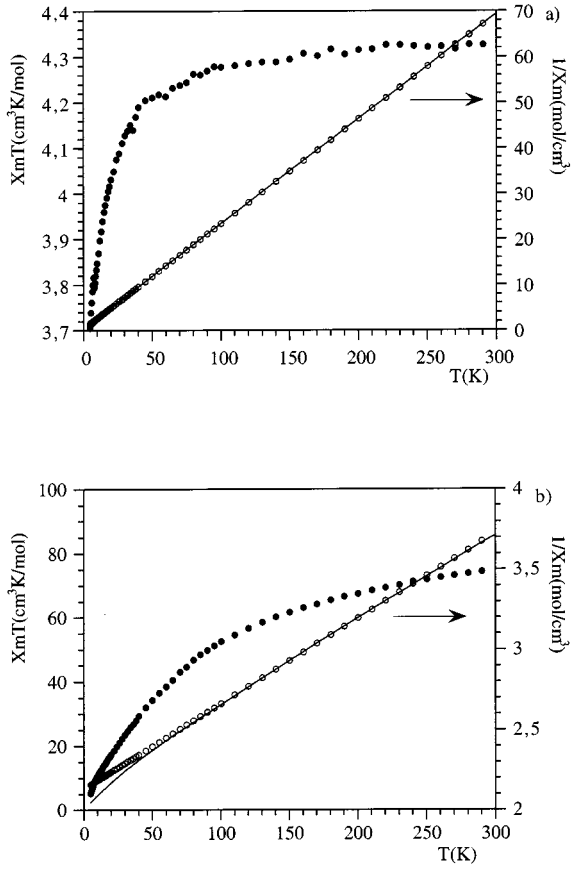

Figure 4. Thermal variations of the magnetic susceptibility ($\chi_m{}^{-1}$) and ($\chi_m T$) for $[SrM(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ compounds a) M = Mn, b) M = Co

Thermal treatments in air and under nitrogen were performed for all compounds. The TG curves are shown in Figure 5. The decomposition steps can be explained as three consecutive processes: namely dehydration, ligand pyrolysis, and evolution of the inorganic residue. The dehydration process occurs in the 70−190°C range, and it is in good accordance with the loss of the seven water molecules present in the complexes. This process seems to take place in only one step, except for the SrNi compound. However, this fact does not allow the presence of different water molecules to be deduced, as was previously observed from the structural data. After a period of stability, ligand pyrolysis occurs at around 350°C. As can be expected, and considering the nature of the cations coordinated to the malonate

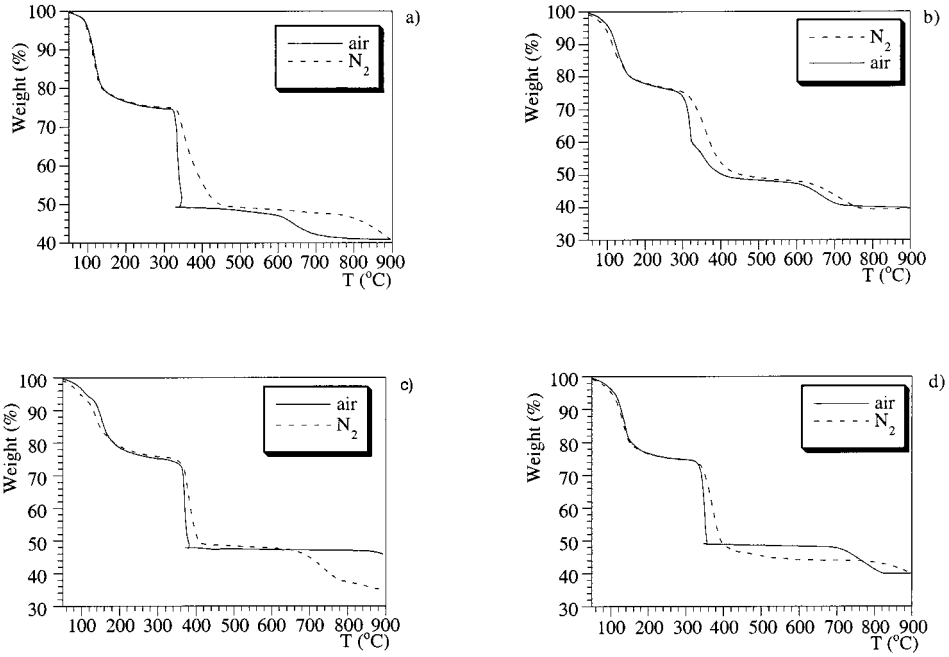

Figure 5. TGA curves for the $[SrM(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ compounds, a) M = Mn, b) M = Fe, c) M = Ni, d) M = Co, in air (−) and under nitrogen (- - -)

ligand,[20] the weight loss is in good accordance with the formation of the products obtained from its decarboxylation, such as the corresponding transition metal oxide and $SrCO_3$. This fact can be attributed to the very high stability of the alkaline-earth metal carbonates. This step remains stable until temperatures above 650°C, when carbonates undergo decomposition to yield mixed oxides. In fact, it is in this process where some differences have been observed between the treatments in air and under nitrogen. The formation of mixed oxides is obviously favoured in air. In this way, the $SrMnO_{3-x}$, $SrCoO_{2.52}$, and $SrFeO_{3-x}$ oxides have been identified by X-ray diffraction as pure phases.[21] However, in the case of the nickel compound, the final residue is formed by the mixture of NiO and $SrCO_3$. The decomposition processes under nitrogen gave rise to a mixture of phases (carbonates, metal oxides, mixed oxides) in all compounds.

In order to improve the above results and to obtain more information about the mixed oxides, thermal treatments in tubular furnaces were performed in air and under nitrogen. In this case, the malonate precursors were fired at 400°C for 12 h. to remove the organic part, followed by treatments at higher temperatures. The resulting products were characterised by IR, X-ray powder diffraction (Figure 6) and differential thermal analysis (DTA).

The metallic ions exhibit mixed valence state in all compounds obtained. In order to propose a chemical formula for all the oxides the oxidation states for the different cations have been determined by a titration method. The samples were dissolved under nitrogen in a solution of HCl, which reacts with metals in the formal +3 and +4 oxidation state. The evolving gas is collected in a solution of KI and after that, titrated with thiosulfate.[22]

The thermal decomposition of the manganese organometallic precursor at 650°C for 10 h gave rise to the non-stoichiometric $SrMnO_{3-x}$ oxide.[23] This product exhibits a dark brown color. The results of the titration analysis are consistent with the formula $SrMnO_{2.95}$. The X-ray diffraction pattern of this phase has been indexed on the basis of an orthorhombic cell with parameters a = 9.437(3), b = 5.453(2) and c = 9.083(4) Å (Figure 6). It is important to note the difference observed between this oxide and that reported in the literature which was obtained from the ceramic method. This latter compound is stoichiometric and crystallises in the hexagonal system. The presence of mixed valence Mn^{3+}/Mn^{4+}, together with a distortion to an orthorhombic symmetry, appears at temperatures above 1035°C. This fact can be due to the creation of oxygen vacancies in the compound.[24] The cell parameters of this non-stoichiometric oxide are similar to those given for $SrMnO_{2.95}$ which was obtained by using the organometallic method. Taking into account these results, and with the aim of confirming the presence of a mixed valence in the last phase, we performed further IR and ESR experiments. The IR spectrum shows two broad bands at around 600 cm^{-1} and 400cm^{-1} (Figure 7a), which could be assigned to the ν_3 stretching vibration corresponding to the $Mn^{3+}-O$ and $Mn^{4+}-O$ bonds, respectively, as usually appears in perovskites with mixed valences.[25] The split of the bands is indicative of a lowering in the symmetry of the manganese environment, probably due to the presence of oxygen vacancies in the surrounding of these ions.

The ESR spectra of this oxide at different temperatures are given in Figure 8a. As can be observed, an isotropic signal appears at room temp. with an ΔHpp value of 960 G. The intensity of the signal decreases with decreasing

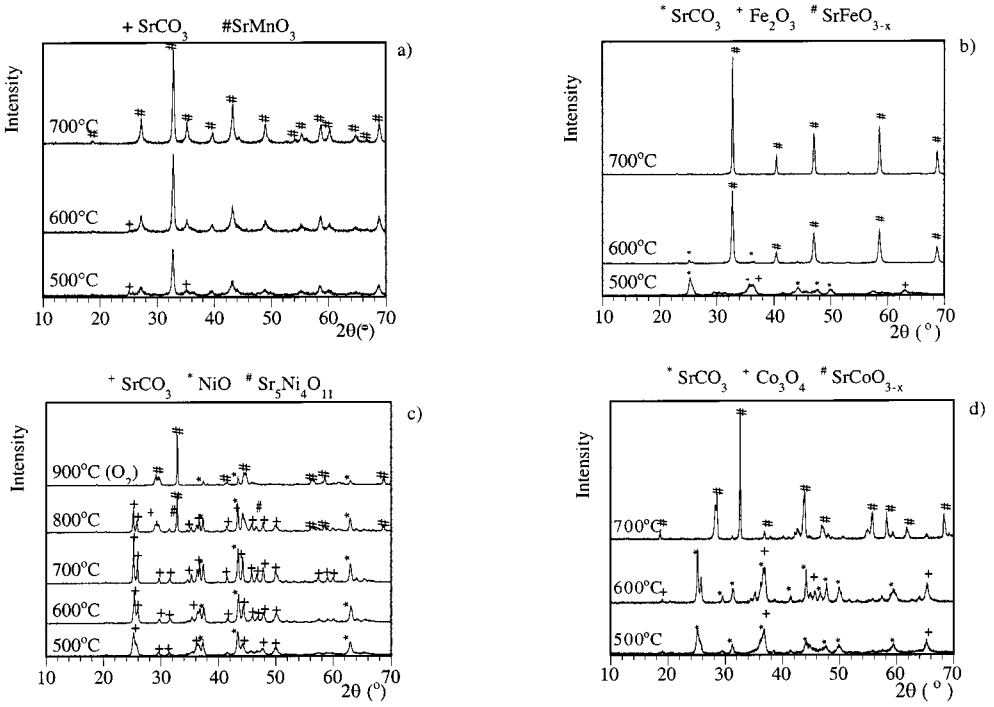

Figure 6. X-ray diffraction patterns of the phases obtained at different temperatures from the $[SrM(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ precursors, a) M = Mn, b) M = Fe, c) M = Ni, d) M = Co

temp., being undetectable at temperatures less than 250 K. These results are characteristic of compounds with antiferromagnetic interactions. Taking into account that the ESR spectra of Mn^{4+} ions show a very broad signal, the results obtained for this phase can be explained as due to the presence of a small amount of Mn^{3+} ions in the compound. These results are in good agreement with those obtained from chemical analyses.

From the decomposition of the $[SrFe(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ phase, the $SrFeO_{2.86}$ oxide[26] was obtained at 650°C for 10 h. The oxygen content was deduced from titration. The X-ray diffraction pattern (Figure 6) has been indexed on the basis of a tetragonal unit cell, *P*4*mm*, with parameters $a = 3.853(4)$ and $c = 3.861(2)$ Å. In order to observe the presence of non-stoichiometry in this phase, ATD measurements under argon were carried out up to 1100°C. An endothermic peak was observed at around 620°C, which would correspond to the reduction of the phase giving rise to the $SrFeO_{2.5}$ stoichiometric oxide. When cooling this sample to room temp. an ordered brown millerite-like structure is obtained. This ordered phase undergoes a reversible transition to the disordered cubic structure at 840°C. These results are in good agreement with those given in the literature for this phase.[27] In order to study the presence of a mixed valence state for the transition metal, IR spectra and ESR measurements in the $SrFeO_{2.86}$ oxide were carried out. As can be seen in the IR spectrum (Figure 7b), no absorption band was observed in the range 600−400 cm^{-1}, as would be expected for a perovskite with mixed valence Fe^{3+}/Fe^{4+}. This result can be explained on the basis of a short range hopping between the Fe^{3+}/Fe^{4+} positions.[27] The ESR spectrum shows an isotropic signal with a *g* value of 2.006 (Figure 8b). This result, together with the value of 620 G for the linewidth, confirms the presence of mixed valence Fe^{3+}/Fe^{4+} in this phase.

The decomposition of the $[SrNi(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ precursor at low temperatures (500−700°C) yielded a mixture of $SrCO_3$ and NiO. The $Sr_5Ni_4O_{11}$ mixed oxide was obtained only after thermal treatments up to 800°C;[28] however, the presence of NiO appears as an impurity phase in the final product (Figure 6). Further attempts to oxidise the total amount of Ni^{II} were unsuccessful.

Thermal treatments of the $[SrCo(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ compound at 700°C for 10 h., gave rise to the formation of the $SrCoO_{2.56}$ phase. Several days at 1100°C were necessary to obtain the mixed oxide from the ceramic method.[29] The X-ray diffraction pattern of the $SrCoO_{2.56}$ phase shows the presence of peaks related to the 2H-Perovskite-type structure. However, not all the diffraction peaks were indexed with this kind of structure. The diffraction patterns do not undergo any significant changes when the compounds are obtained from different thermal treatments under both oxygen and nitrogen. The chemical analysis indicates the presence of a small amount of Co^{IV} in the sample. In order to corroborate this result, further spectroscopic and magnetic measurements were carried out. The IR spectrum shows the characteristic bands at 600 and 400 cm^{-1} (see Figure 7c), corresponding to the ν_3 stretching vibration of $Co^{3+}-O$ and $Co^{4+}-O$ bonds, respectively. Magnetic measurements on this $SrCoO_{2.56}$ oxide were carried out in the temperature range of 1.8−300 K. The thermal evolution of the $\chi_m T$ and χ_m^{-1} is shown in Figure 9.

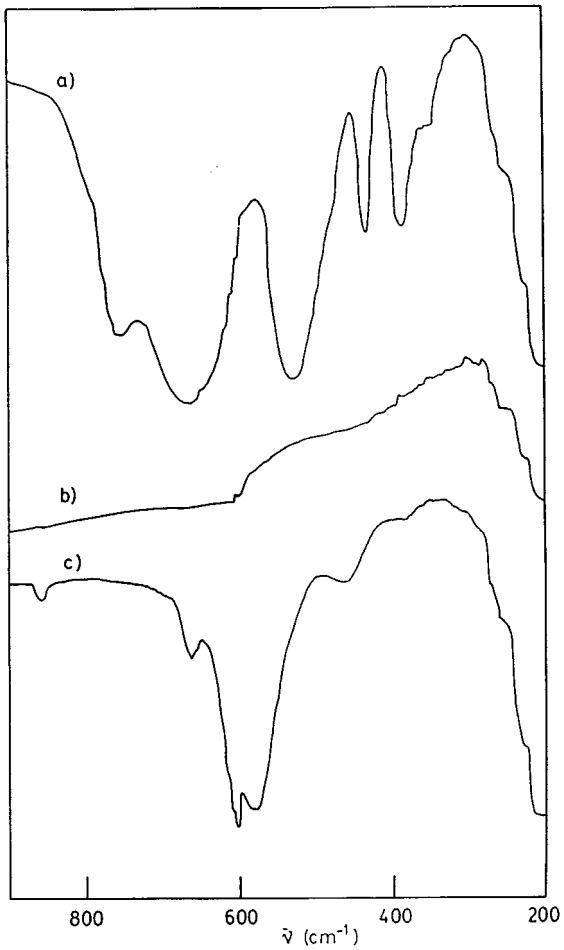

Figure 7. IR spectra of the a) $SrMnO_{2.95}$ b) $SrFeO_{2.86}$, and c) $SrCoO_{2.55}$ oxides

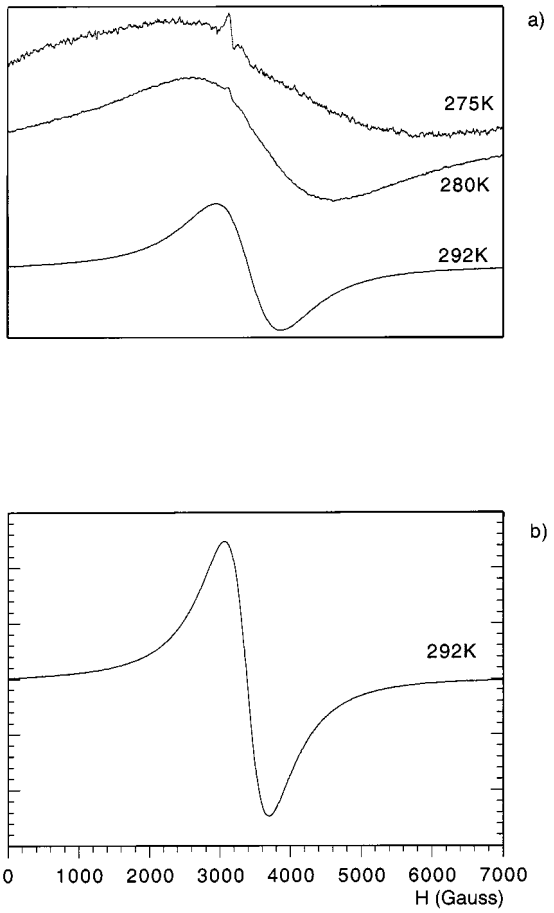

Figure 8. X-band ESR spectra for the a) $SrMnO_{2.95}$ and b) $SrFeO_{2.86}$ phases

The continual decrease observed in the $\chi_m T$ vs T curve is indicative of the presence of an antiferromagnetic ordering, with a Neel temperature value at around 25 K. It is to note an increase of the $\chi_m{}^{-1}$ values at low temperatures, which can be explained as due to the presence of a small amount of Co^{IV}, hampering the total compensation of the Co^{III} spin moments.

A scanning electron microscopic photograph of one of the oxide pellets is shown in Figure 10. In all cases, powders consisting of small homogeneous particles were observed, due to the use of soft synthesis methods. The $SrFeO_{2.86}$ oxide was obtained at the lowest temp., 650°C, and particles with a very small size (diameter less than 0.3 μm) have been favoured.

The more the temperature increases, the higher the size of the grains. Furthermore, particles with a prismatic form have been observed for the $SrCoO_{2.55}$ compound.

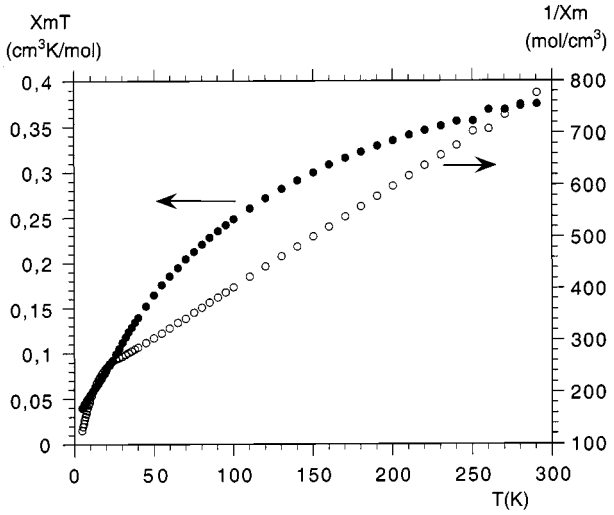

Figure 9. Thermal variation of the χ^{-1} and $\chi_m T$ product for the $SrCoO_{2.55}$ compound

Conclusions

With the aim of obtaining $SrMO_{3-x}$ oxides using soft synthesis routes, four isostructural complexes with the formula $[SrM(C_3H_2O_4)_2(H_2O)_7]$ (M = Mn, Fe, Co, Ni) have been synthesised and characterised. The structure of $[SrCo(C_3H_2O_4)_2(H_2O)_5] \cdot 2\,H_2O$ consists of a 3D network of metal ions coordinated by malonate ligand bridges. The cobalt(II) centres adopt an octahedral coordination while the strontium ions are surrounded by nine oxygen atoms. Magnetic measurements indicate the presence of weak anti-

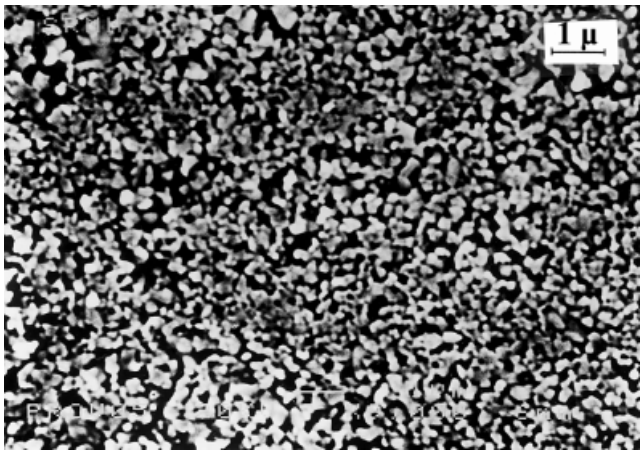

Figure 10. SEM photograph of the $SrMnO_{2.95}$ oxide

ferromagnetic interactions in all compounds. For the cobalt compound, the effect of a spin-orbit coupling must also be considered when discussing the magnetic behaviour. The decomposition steps of the metallo-organic phases, as well as the temperatures in which the evolution of the inorganic residue occurs, were deduced from the TGA studies. This information was utilised in order to perform the thermal treatments, in tubular furnaces, with the aim of obtaining mixed oxides. Depending on the reaction conditions (temperature, reaction time, atmosphere employed, etc.) control of the stoichiometry of these mixed oxides has been achieved. In this way, the oxides with stoichiometry $SrFeO_{2.86}$, $SrCoO_{2.56}$, and $SrMnO_{2.95}$ were synthesised at 600, 700, and 650°C, respectively. The appearance of Co^{IV} in $SrCoO_{2.56}$ and the presence of Mn^{III} in the $SrMnO_{2.95}$ phase is of note. This last oxide was obtained as a stoichiometric phase when synthesised using ceramic methods. The use of soft synthesis methods have also afforded homogeneous and small size particles of oxides, which have been visualised by scanning electron microscopy. In conclusion, it has been shown that from a metallo-organic precursor non-stoichiometric mixed oxides have been obtained at much lower temperatures and reaction times than those employed using the ceramic method

Experimental Section

General: IR: Mattson FTIR 1000 spectrophotometer between 400−4000 cm^{-1}, KBr disks. − Diffuse reflectance spectra: Cary 2415 spectrometer in the range 5000−45000 cm^{-1}, room temp. − Thermogravimetric measurements: Perkin−Elmer System-7 DSC-TGA, crucibles containing 20 mg of sample were heated at 5°/min under dry nitrogen and in air. − DTA: Setaran atd 92 equipment under argon. − Powder X-ray diffraction: Philips X-PERT diffractometer with Cu-$K_{\alpha 1}$ radiation, data were collected by scanning in the range 5° < 2θ < 120° with increments of 0.02°(2θ). − Magnetic susceptibilities and field dependences of magnetization (up to 7 Tesla): Quantum Design MPMS-7 Squid magnetometer, temperature range 1.8−300 K. − ESR: Bruker ESP300 spectrometer, equipped with a standard Oxford low-temperature device operating at X and Q bands, magnetic field was measured with a Bruker bnm 200 gaussmeter, and the frequency was determined with a Hewlett−Packard 5352B microwave frequency counter. Nickel(II) chloride, iron(II) chloride, sodium carbonate, and malonic acid were purchased from Aldrich Co. Strontium chloride was purchased from Merck and cobalt(II) and manganese(II) chlorides from Fluka. All of them were used without further purification.

Preparation of the Compounds: The corresponding chloride of the transition metal (3.0 mmol) was added to an aq. solution of 6.0 mmol (0.624 g) of malonic acid, neutralized with sodium carbonate. The reaction mixture was stirred without heating for about 1 h, and then an equimolar amount of strontium chloride added. The addition of ethanol (3 mL) afforded polycrystalline powders of all phases. In the case of the iron compound a closed system with nitrogen was employed. For the cobalt compound, pale pink crystals in the form of needles were collected after leaving the remaining solution for some days. The compounds were washed with water and acetone, and dried over P_2O_5. The crystals were of good quality for X-ray single-crystal studies. Attempts to obtain single crystals for the other compounds have been unsuccessful. Elemental analysis, together with Inductively Coupled Plasma measurements, were carried out in order to determine the C, H, and metal contents. − $C_6H_{18}MnO_{15}Sr$ (472.75): calcd. C 15.24, H 3.84, Mn 11.62, Sr 18.54; found C 14.94, H 3.21, Mn 11.51, Sr 17.91. − $C_6H_{18}FeO_{15}Sr$ (473.65): calcd. C 15.22, H 3.83, Fe 11.79, Sr 18.50; found C 14.93, H 3.52, Fe 11.52, Sr 19.00. − $C_6H_{18}CoO_{15}Sr$ (476.75): calcd. C 15.12, H 3.81, Co 12.36, Sr 18.38; found C 15.34, H 3.49, Co 12.11, Sr 18.47. − $C_6H_{18}NiO_{15}Sr$ (476.51): calcd. C 15.12, H 3.81, Ni 12.32, Sr 18.39; found C 15.40, H 3.59, Ni 12.86, Sr 17.62.

X-ray Crystal.Structural Determination of $[SrCo(C_3H_2O_4)_2(H_2O)_7]$: Pale pink crystals of $C_6H_{18}SrCoO_{15}$ were sealed in a glass capillary and used for data collection. Preliminary cell dimensions were calculated by Weissenberg photographs. Diffraction experiments were performed with a crystal of dimensions 0.6 × 0.1 × 0.05 mm using an Enraf-Nonius CAD4 automatic diffractometer with graphite-monochromatized Mo-K_α radiation (λ = 0.7107 Å) and the ω-scan technique. Orientation matrix and lattice parameters were determined by least-squares refinement of the diffraction data from 25 machine-centred high-angle reflections in the range 10° < 2θ < 26°. Intensities and angular positions of two standard reflections were measured every 2 h, and these showed neither decrease nor misalignment during data collection. The observed systematic extinctions were consistent with the space group $P2_1/c$. Lorentz and polarization corrections and an empirical absorption correction using XABS2 program were applied to the data.[30] The structure was solved by Patterson interpretation using the program Shelxs86.[31] It was then refined by full-matrix methods based on F^2, using Shelx93.[32] Non-hydrogen atomic scattering factors were taken from International Tables for X-ray Crystallography[33] and anisotropic thermal parameters were assigned. Difference Fourier synthesis did not allow the location of H atoms. Therefore, the hydrogen atoms of the malonate groups were calculated and isotropic thermal parameters were assigned. The final difference Fourier map showed no peaks higher than 0.70 or lower than −0.83 e $Å^{-3}$. The geometric calculations were performed with Parst[34] and Bondla[35] and molecular illustration were drawn with Platon94[36] and Atoms.[37] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-106908. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Cobalt Complexes with 1,3-Bis(trimethylsilyl)cyclopentadienyl and Substituent-Free P_n Ligands

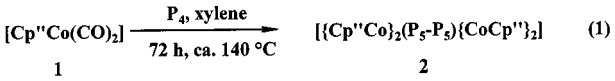
Otto J. Scherer,*[a] Thomas Völmecke,[a] and Gotthelf Wolmershäuser[a][+]

Keywords: Phosphorus / P_n / $C_5H_3(SiMe_3)_2$ ligands / Cobalt / Coordination chemistry / Crystallography

The thermal or photochemical reaction of $[Cp''Co(CO)_2]$ (**1**) [Cp'' = $C_5H_3(SiMe_3)_2$-1,3] with white phosphorus (P_4) gives $[\{Cp''Co\}_2(P_5–P_5)\{CoCp''\}_2]$ (**2**) and $[\{Cp''Co\}_3P_4(\mu\text{-}CO)]$ (**3**) as well as $[\{Cp''Co\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}P_2)_2]$ (**4**). Cobalt complexes **2**, **3**, and **4** have been characterized by an X-ray crystal-structure determination.

Introduction

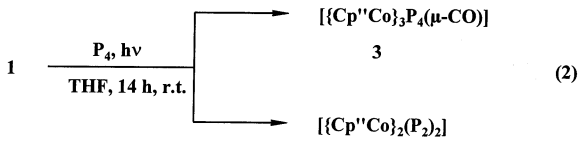
In the chemistry of transition-metal complexes with substituent-free ("naked") P_n ligands the choice of the additional Cp^R ligands plays an important role.[1] Illustrative examples are the reactions of $[\{Cp^R(OC)_2Fe\}_2](Fe–Fe)$ with white phosphorus (P_4).



Starting with $Cp^R = C_5H_5$ the cothermolysis gives the tetranuclear cluster $[\{CpFe\}_4(P_2)_2]$ with a triangulated dodecahedral Fe_4P_4 skeleton.[2] In the case of $Cp^R = C_5H_2tBu_3$-1,2,4 the complex $[\{Cp^R(OC)_2Fe\}_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}P_4)]$, a molecule with a P_4 butterfly framework was synthesized.[3] Finally, the use of $Cp^R = C_5Me_5$ gave for the first time $[Cp^*Fe(\eta^5\text{-}P_5)]$, a sandwich complex with a *cyclo*-P_5^- ligand, the all-phosphorus analogue of the cyclopentadienide ion $C_5H_5^-$.[4]

The photochemical route, realized for $Cp^R = C_5H_4Me$ or $C_5H_3tBu_2$-1,3 (Cp''), affords $[Cp^R{}_4Fe_4(CO)_6P_8]$ with an open-edged P_8 cuneane geometry[5] and all five members of the series $[Cp''{}_2Fe_2P_4(CO)_{4-n}]$ (n = 0–4) with different P_4 ligands.[6]

The experiences of the last decade have shown that especially highly alkylated Cp^R ligands are very useful in the coordinative stabilization of different P_n ligands. Interestingly, to the best of our knowledge, until now transition-metal complexes with trimethylsilyl-substituted Cp^R ligands are unknown as starting materials in P_n chemistry.



Thermal and Photochemical Reaction of $[Cp''Co(CO)_2]$ [1, Cp'' = $C_5H_3(SiMe_3)_2$-1,3] with White Phosphorus (P_4)

According to Equation 1 the cothermolysis of $[Cp''Co(CO)_2]$ (**1**) and P_4 (Co/P ≈ 1:7) affords exclusively the tetranuclear cobalt complex **2** with a P_{10} ligand in the unusually high yield of 87%.

Cp'' = $C_5H_3(SiMe_3)_2$-1,3

For a stoichiometry of Co/P ≈ 1:2 the photochemical alternative gives 30 % of **3** and 10 % of **4** (Equation 2) besides traces of **2**.

Cp'' = $C_5H_3(SiMe_3)_2$-1,3

The air-sensitive olive-green (**2**), dark-red (**3**), or black-purple (**4**) complexes are sparingly to well soluble in *n*-hexane and dissolve readily in toluene or dichloromethane.

NMR- and IR-Spectroscopic Investigations

The ^{1}H-, ^{31}P-NMR data of the complexes **2**, **3**, and **4** as well as $\tilde{\nu}$(CO) of **3** are compiled in Table 1.

The ^{1}H-NMR spectrum of **2** (measured at 340 K) affords 11 signals with relative integrals 2:2:2:2:2:1:1:18:18:18:18 in agreement with a local symmetric environment for each Cp'' ligand. In the ^{31}P-NMR spectrum of **2** (340 K) the P_{10} skeleton (Figure 1) consists of an ABCC′DD′EE′FF′ spin system. A comparison of the $^1J(P_AP_B)$ coupling constants of the P_2 bridge in **2** (−205 Hz) and **5** (−95 Hz)[7] suggests deviation of the lone pairs in the "bridge" P1–P1′ from an antiperiplanar position for complex **2**.

The Schakal plot shows that each $C_5H_3(SiMe_3)_2$-1,3 ligand of **2** is locked between two adjacent ligands.

Comparing the spectroscopic data of **3** and **7**[8] the following discrepancies were found: In contrast to the "remarkable high-field shift" discussed for **7**[8] (δ = −398.6) for the P atom surrounded by three cobalt atoms, a value of δ = 487.8 (Table 1) was measured for **3**. A redetermination of the ^{31}P-NMR spectrum of **7** gives instead of the

[+] Crystal-structure analyses.

[{Cp''Rh}$_2$(P$_5$-P$_5$){RhCp''}$_2$]

6

Cp'' = $C_5H_3Bu^t_2$-1,3

reported[8] δ = −398.6 the expected low-field shift (δ = 413.8). The other ^{31}P-NMR signals (**7**: δ = 227.5, 9.9) are in agreement with the published data.[8] Going from **7** to **3** all ^{31}P-NMR signals are shifted down-field in the bis(trimethylsilyl)cyclopentadienyl derivative **3** (cf. Table 1).

[{Cp''Co}$_3$P$_4$(μ-CO)]

7

Cp'' = $C_5H_3Bu^t_2$-1,3

The redetermination of $\tilde{\nu}$(CO) in **7** gives 1793 cm^{-1} instead of the published 1934 cm^{-1}.[8] This value is in accordance with 1808 cm^{-1} measured for **3**. Both bands are in the region expected for a μ-CO ligand (cf. Figure 5).

X-ray Crystal-Structure Determinations of the Complexes 2, 3, and 4

Compound 2

The most interesting structural aspect of complex **2** is its Co_4P_{10} skeleton (Figure 2).

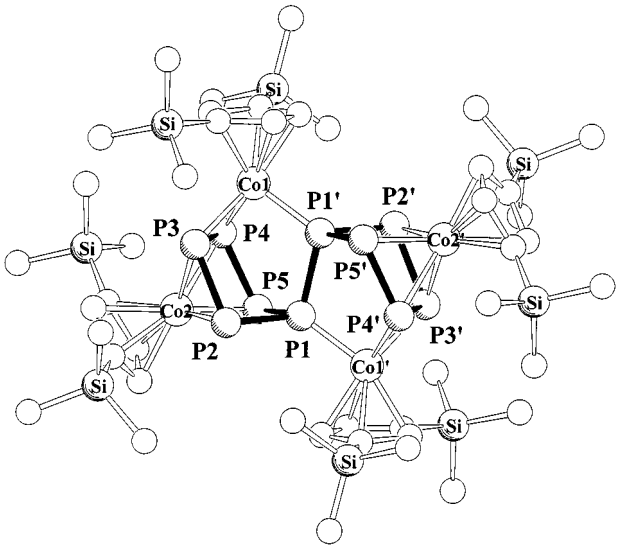

Figure 2. Selected bond lengths [Å] and angles [°]: P1−P1′ 2.1793(18), P2−P1 2.1948(14), P2−P3 2.1573(14), P3−P4 2.4743(15), P4−P5 2.1573(14), P5−P1 2.1985(14), Co1−P1′ 2.1311(11), Co1−P3 2.2405(11), Co1−P4 2.2446(11), Co2−P2 2.3108(12), Co2−P5 2.3196(12), Co2−P3 2.3355(11), Co2−P4 2.3753(11), Co1−Cp′′(centr.) 1.72, Co2−Cp′′(centr.) 1.72; P1′−Co1−P3 93.95(4), P1′−Co1−P4 93.44(4), P3−Co1−P4 66.96(4), Co1−P1′−P1 111.43(6), P2−P1−P1′ 100.11(7), P2−P1−P5 90.82(5), P5−P1−P1′ 101.18(6)

The P_{10} framework can be derived formally from the P_{10} dihydrofulvalene **A** (Figure 3) where the two 4π systems bind to Co2(2′) giving 18e⁻ per cobalt atom. This electron count can also be obtained for Co1(1′) taking into account the lone pair on P1(1′) and the bond(s) P3(3′)−P4(4′) (2.47 Å, Figure 2) which is reasonably close to the longest known 2c2e⁻-P−P bonds. For the side-on coordinated white phosphorus (P_4) in $[(Ph_3P)_2Rh(Cl)(\eta^2\text{-}P_4)]$ this edge is elongated from 2.21 Å (P_4 itself) to 2.46 Å.[9] Interestingly, for the analogous Rh_4P_{10} compound **6** a distinctly longer P···P bond (open edged) of 2.62 Å was found.[10] All the other P−P bond lengths of the P_{10} ligand in the complexes **2** and **6** are comparable [two shorter P2−P3, P4−P5: 2.16/2.15 Å (**2**/**6**); two longer: 2.20/2.19 Å (**2**/**6**)].

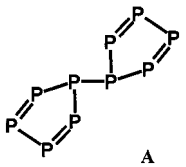

Figure 3. Hypothetic P_{10} dihydrofulvalem

Alternatively, the Co_4P_{10} framework of **2** can also be derived from Li_3P_7 (Figure 4, **B**), a well-known molecule in polyphosphide chemistry.[11]

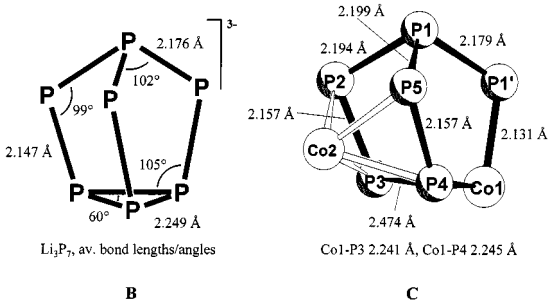

Figure 4. Comparison of P_7^{3-} with the Co_2P_6 cage of **2**

Formally, **C** (Figure 4) can be derived from **B** by replacing one basal P atom by the Co1Cp′′ fragment and capping the four-electron donor P2,3,4,5 unit by the Co2Cp′′ unit. Electron count and *d*(P1′−Co1) are in favour of a multiple-bond character.

The connection of two Co_2P_6 subunits **C** with a common edge (P1−P1′) formally gives the Co_4P_{10} skeleton of compound **2** (Figure 2). The biggest difference in bond lengths between **B** and **C** occurs, as one would expect, in the basal triangle P3,P4,Co1 (P3−P4 2.47 Å).

A further interesting parallel is realized with complexes **8**,[12] synthesized by Eichhorn's group.

$$[(\eta^4\text{-}P_7)\{M(CO)_3\}]^{3-},\quad M = Cr, Mo, W$$

8

Its carbonylation affords $[(\eta^2\text{-}P_7)W(CO)_4]^{3-}$ (**9**) where the norbornadiene-type geometry of the P_7 ligand in **8** has changed to the nortricyclane-like structure of **9** ($\eta^4 \rightarrow \eta^2$-$P_7$).[12b]

The polycyclic P_{10} core of the paramagnetic complex $[\{Cp(CO)_2Cr\}_5P_{10}]$ (**10**) consists of a P_7 norbornane with a P_2 bridge and a terminal P atom.[13]

Compound 3

Bond lengths and angles of the trinuclear cobalt complex **3** (Figure 5) differ only slightly from the values of the analogous complex **7** with $C_5H_3tBu_2$-1,3 ligands.[8]

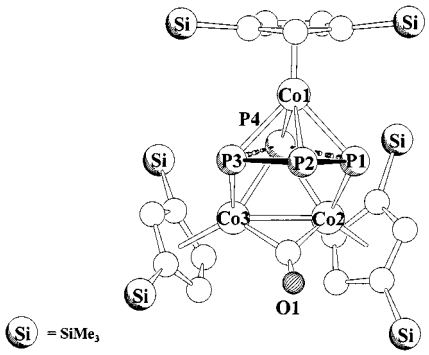

Figure 5. Selected bond lengths [Å] and angles [°]: P1−P2 2.1609(10), P2−P3 2.1585(9), P3···P4 2.5237(9), P4···P1 2.4879(8), Co2−Co3 2.4485(5), Co1−P1 2.3099(6), Co1−P2 2.2706(7), Co1−P3 2.3207(7), Co1−P4 2.2711(7), Co2−P1 2.2714(7), Co2−P4 2.2483(6), Co3−P3 2.2787(7), Co3−P4 2.2290(7), Co1−Cp′′(centr.) 1.73, Co2−Cp′′(centr.) 1.75, Co3−Cp′′(centr.) 1.74, P1−P4−P3 78.93(3), P2−P1−P4 93.02(3), P2−P3−P4 92.09(3), P3−P2−P1 95.03(4), Co2−P4−Co3 66.30(2)

A small kite-like distortion of a *cyclo*-P_4 ligand was realized for the first time in $[\{Cp^*(OC)_2Nb\}(\eta^4\text{-}P_4)]$ (**11**), Cp′′ = $C_5H_3tBu_2$-1,3.[14] Interestingly, a much stronger distortion was found for **3** and **7**. For both complexes the P···P bonds to P4 coordinating to three $CoCp^R$ fragments are distinctly longer [average of **3**: 2.50; **7**: 2.503(2) Å]. EHT calculations on **7** are in agreement with a weak P···P bonding[8] {c.f. the 2c1e⁻ P···P bond length of 2.634(3) Å in the P_4 rectangle of the diradical $[R_2N-CP_2]_2^{\bullet\bullet}$ (R = *i*Pr)[15]}.

In contrast to the planar P_4 ligand of **7** the P4 atom in **3** lies 0.34 Å above the P1,P2,P3 plane (Figure 5). The missing mirror plane in compound **3** leads to small differences in bond lengths and angles relative to those in **7** (the mean values of both compounds are nearly identical).

According to the electron-counting rules[16] of Wade and Mingos complex **3** belongs to an *arachno* cluster with (*n* + 3) = 10 SEPs (skeleton electron pairs). Its framework can formally be derived from a *closo* tricapped trigonal prism by successive elimination of two vertices.

Compound 4

The bond lengths and angles of complex **4** (Figure 6) are very similar to those of the X-ray-crystallographically characterized derivatives $[\{Cp^*Co\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}P_2)_2]$ (**12**)[17] and $[\{Cp'''Co\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}P_2)]$ (**13**) (Cp′′′ = $C_5H_2tBu_3$-1,2,4).[18]

For the side-on coordinated 4e⁻ donor P_2, which is isoelectronic and isolobal with acetylene (|P≡P| ⟶

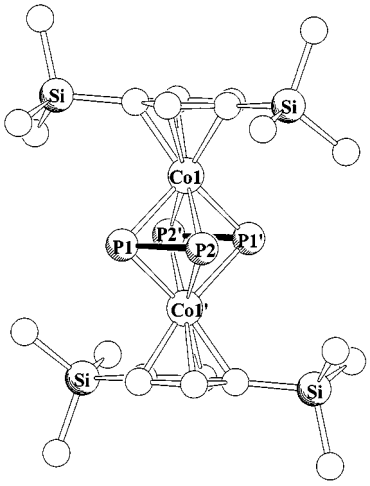

Figure 6. Selected bond lengths [Å] and angles [°]: P1−P2 2.0538(15), P1···P2′ 2.7131(14), Co1−P1 2.3069(10), Co1−P1′ 2.3162(10), Co1−P2 2.3050(10), Co1−P2′ 2.3164(10), Co1−Cp′′-(centr.) 1.70, Co1···Co1′ 3.127; P1−P2−P1′ 90.04(4), P2−P1−P2′ 89.96(4)

HC≡CH), *d*(P−P) lies in the range of 2.054 (**4**), 2.053 (**12**), and 2.052 Å (**13**) which is typical for P−P double bonds.[1] The long P···P edges of the rectangular $(P_2)_2$ ligands have nonbonding distances of 2.713, 2.705 (mean value), and 2.663 Å, *d*(Co−P) ranges from 2.311 to 2.305 and 2.308 Å, respectively. Such small differences also exist for Co···Co (3.127, Figure 6) (**12**: 3.102; **13**: 3.164 Å). For all three complexes the least-squares plane defined by the two μ-η^2:η^2-P_2 units and the planes of the two Cp^R rings differ only slightly (2°, 1°, and 2°) from a parallel arrangement.

Experimental Section

All experiments were carried out under argon in anhydrous solvents. − NMR: Bruker AMX 400, ^{1}H NMR (400.13 MHz), ^{31}P NMR (161.98 MHz). − The ^{31}P-NMR spectra of **2** was simulated with PERCH.[20] IR spectra were recorded with an FT-IR spectrometer Perkin−Elmer 16 PC. − UV irradiation: 150-W Hg high-pressure lamp, TQ 150, Heraeus Quarzlampen GmbH, Hanau. − [Cp′′Co(CO)$_2$] (**1**) [Cp′′ = $C_5H_3(SiMe_3)_2$] was synthesized from [$Co_2(CO)_8$] and Cp′′H in analogy to ref.[19]

Cothermolysis of [Cp′′Co(CO)$_2$] (1) and White Phosphorus (P_4): 1.72 g (5.3 mmol) of **1** and 1.2 g (9.7 mmol) of P_4 were heated to reflux in 50 mL of xylene for 72 h. After evaporation of the solvent under oil-pump vacuum (0 → 35°C), the residue was dissolved in ca. 20 mL of dichloromethane, and ca. 5 g of neutral Al_2O_3 (activity grade II) was added. The solvent was evaporated under oil-pump vacuum from the mixture until the residue was free-flowing. It was placed on top of a column (2 × 15 cm) filled with neutral Al_2O_3 and petroleum ether. A mixture of petroleum ether/diethyl ether (40:1) eluted [{Cp′′Co}$_2$(P_5−P_5){CoCp′′}$_2$] (**2**); yield 1.7 g (87 %) of olive-green crystals. − $C_{50}H_{98}Co_4P_{10}Si_8$ (1469.4): calcd. C 40.86, H 6.72; found C 40.34; H 6.77.

Cophotolysis of 1 and P_4: 1.13 g (3.5 mmol) of **1** and 0.19 g (1.5 mmol) of P_4 were irradiated (150-W Hg high-pressure lamp) for 14 h in 100 mL tetrahydrofuran until the ν̃(CO) bands of **1** had disappeared and a new one at 1808 cm^{-1} had emerged. Column chromatography as described for complex **2** gave with the same mixture of solvents as first fraction 115 mg (10 %) of purple [{Cp′′Co}$_2$(P_2)$_2$] (**4**) followed by 330 mg (30 %) of red-brown [{Cp′′Co}$_3$$P_4$(CO)] (**3**). − **3**: $C_{34}H_{63}Co_3OP_4Si_6$ (957.1): calcd. C 42.66, H 6.63; found C 40.05, H 6.65. − **4**: $C_{22}H_{42}Co_2P_4Si_4$ (660.7): calcd. C 39.99, H 6.41; found C 27.19 (incomplete combustion), H 5.87.

Vinylidene Transition-Metal Complexes, 50[+] Carbynehydrido- and Vinylidenehydridoosmium Complexes with $Os(PCy_3)_2$ as a Molecular Unit

Helmut Werner,*[a] Stefan Jung,[a] Birgit Weberndörfer,[a] and Justin Wolf[a]

Dedicated to Professor Christoph Elschenbroich on the occasion of his 60th birthday

Keywords: Osmium / Alkynes / Carbyne complexes / Hydrido complexes / Vinylidene complexes

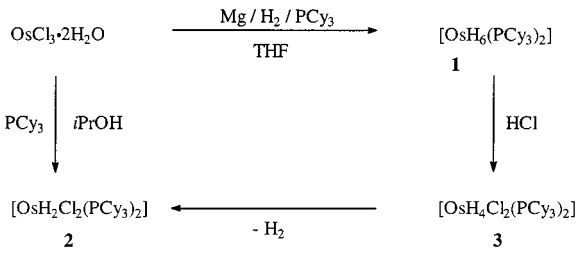
The reaction of $OsCl_3 \cdot 2H_2O$ with PCy_3 leads under reducing conditions either to $[OsH_6(PCy_3)_2]$ (**1**) or $[OsH_2Cl_2(PCy_3)_2]$ (**2**). Treatment of **2** with terminal alkynes HC≡CR (R = Ph, $SiMe_3$) affords the carbynehydrido complexes $[OsHCl_2(\equiv CCH_2R)(PCy_3)_2]$ (**4**, **5**), of which **5** (R = $SiMe_3$) is easily converted with traces of water into $[OsHCl_2(\equiv CCH_3)(PCy_3)_2]$ (**6**). Compound **4** (R = Ph) reacts with NaOMe to yield the vinylidenehydridoosmium(II) complex $[OsHCl(=C=CHPh)(PCy_3)_2]$ (**7**) which upon treatment with HBF_4/OEt_2 gives the five-coordinate cationic species $[OsHCl(\equiv CCH_2Ph)(PCy_3)_2]BF_4$ (**8**). The reaction of $[OsH_3Cl(PCy_3)_2]$ (**9**) with $HC\equiv CC(CH_3)_2Cl$ affords a mixture of $[OsHCl_2(\equiv CCH{=}CMe_2)(PCy_3)_2]$ (**10**) and $[OsCl_2(H_2)(=CHCH{=}CMe_2)(PCy_3)_2]$ (**11**). Compound **11** is quite labile and by elimination of H_2 gives **10**. The molecular structure of **10** has been determined by X-ray crystallography.

In the course of our continuous studies on the synthesis and reactivity of vinylidenemetal complexes with d^6- and d^8-metal centers,[1] we recently reported that the reaction of the ruthenium(IV) compound $[RuH_2Cl_2(P\textit{i}Pr_3)_2]$ with terminal alkynes HC≡CR led, depending on the conditions, to the formation not only of the expected vinylidene complexes $[RuCl_2(=C=CHR)(P\textit{i}Pr_3)_2]$ but also of the related carbene derivatives $[RuCl_2(=CHCH_2R)(P\textit{i}Pr_3)_2]$.[2] Since compounds of this type, in particular with PCy_3 instead of $P\textit{i}Pr_3$ as P-donor ligand, proved to be excellent catalysts for olefin metathesis (including RCM and ROMP),[3] we became interested in studying the formation of carbene complexes $[RuCl_2(=CHCH_2R)(PR'_3)_2]$ from Ru-containing precursors and HC≡CR in more detail. As a consequence we developed a convenient and very efficient one-pot synthesis of compounds $[RuCl_2(=CHCH_2R)(PCy_3)_2]$ (R = H, Ph) from ruthenium trichloride, PCy_3, Mg, H_2, water, and terminal alkynes as starting materials.[4] The principal advantage of this method is that it avoids expensive precursors such as $[RuCl_2(PPh_3)_3]$,[5] $[Ru(\eta^4\text{-}C_8H_{12})(\eta^6\text{-}C_8H_{10})]$,[6] or $[RuH_2(H_2)_2(PCy_3)_2]$,[7] and uses alkynes instead of cyclopropenes, diazoalkanes, vinyl chlorides, or propargylic chlorides as carbene sources.

The aim of the present work was to find out whether the osmium counterparts to the Grubbs-type carbeneruthenium complexes are equally accessible and if so, what their catalytic activity is. Here we report that the preparative routes which for ruthenium give the five-coordinate compounds $[RuCl_2(=CHR)(PCy_3)_2]$ afford the isomeric carbynehydrido complexes $[OsHCl_2(\equiv CR)(PCy_3)_2]$ in good yields in the case of osmium. While these six-coordinate compounds are quite stable and inert towards olefins, the five-coordinate cationic complex $[OsHCl(\equiv CCH_2Ph)(PCy_3)_2]BF_4$ is catalytically active and catalyzes the ring-opening metathesis polymerization (ROMP) of cyclopentene.

Results and Discussion

Dihydrido- and Polyhydridoosmium Complexes



Under the conditions under which $RuCl_3 \cdot 3\,H_2O$ is converted into the hydrido(dihydrogen) complex $[RuHCl(H_2)(PCy_3)_2]$,[4] the reaction of $OsCl_3 \cdot 2\,H_2O$ with activated Mg and PCy_3 under H_2 takes a different course. After the suspension in THF was stirred for 4 h at 65°C, a mixture of products was formed in which, besides two unknown compounds, the dihydridoosmium(IV) complex **2** (Scheme 1) could be identified by ^{1}H- and ^{31}P-NMR spectroscopy. The trihydrido derivative $[OsH_3Cl(PCy_3)_2]$, the generation of which was anticipated in analogy to that of $[RuHCl(H_2)(PCy_3)_2]$, could not be detected. If the reaction mixture formed from $OsCl_3 \cdot 2\,H_2O$ was continuously stirred under H_2 at 85°C for 19 h, an off-white solid precipitated from which upon extraction with CH_2Cl_2 the hexahydrido complex $[OsH_6(PCy_3)_2]$ (**1**) was isolated. The preparation of this compound was previously reported by Halpern et al.[8] who treated $(NH_4)_2[OsCl_6]$ with PCy_3 and $NaBH_4$ in the presence of ethanol. The new synthetic route described here is more efficient and has the advantage of

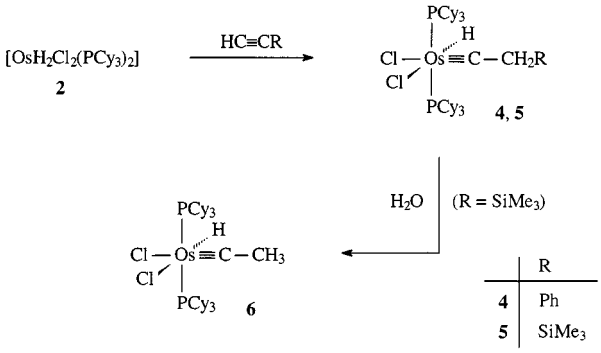
the starting material $OsCl_3 \cdot 2\,H_2O$ instead of the more expensive $(NH_4)_2[OsCl_6]$.



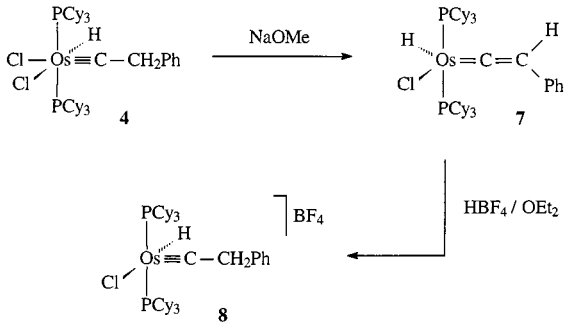
Scheme 1

The above-mentioned dihydridoosmium(IV) complex $[OsH_2Cl_2(PCy_3)_2]$ (**2**) is accessible from $OsCl_3 \cdot 2\,H_2O$ and PCy_3 in 2-propanol under reflux conditions. The same procedure had already been applied in our laboratory to afford the related species $[OsH_2Cl_2(L)_2]$ with L = P*i*Pr$_3$ and P*t*Bu$_2$Me, which represented the first examples of hexacoordinate osmium(IV) dihydrides.[9] Compound **2** was also obtained in almost quantitative yield on treatment of **1** with gaseous HCl in hexane. The most typical spectroscopic features of **2** (which is a red-brown, moderately air-sensitive solid) is the singlet for the two phosphane ligands in the ^{31}P-NMR spectrum at $\delta = 33.6$ and the triplet for the OsH_2 protons in the ^{1}H-NMR spectrum at $\delta = -15.68$. Based on the analogy of these spectroscopic data to those of $[OsH_2Cl_2(P\mathit{i}Pr_3)_2]$, we assume that the structure of **2** is similar to that of the bis(triisopropylphosphane) derivative, which is best described as a square antiprism with two missing vertexes.[9]

The reaction of **1** with hydrogen chloride deserves a special comment. If a slow stream of HCl is passed through a suspension of **1** in hexane, almost instantaneously a flocculent white precipitate is formed which, after the reaction mixture is stirred for 10−15 min, is converted into the red-brown compound **2**. When the treatment of the starting material with HCl is stopped after ca. 30 s and the flocculent precipitate separated from the solution, we observed that the color of the off-white solid changed to brown. The ^{31}P-NMR spectrum of the freshly isolated intermediate displayed, besides the signals of **1** and **2** at $\delta = 45.0$ and 33.6, a third singlet at $\delta = 13.1$, which we tentatively assign to the dichlorotetrahydridoosmium(VI) complex **3** (Scheme 1). The ^{1}H-NMR spectrum of the crude product supports this proposal since it shows in the high-field region a signal at $\delta = -10.16$ which due to P-H coupling is split into a triplet. Recently, Berke et al. reported the preparation of the corresponding triisopropylphosphane derivative $[OsH_4Cl_2(P\mathit{i}Pr_3)_2]$, the ^{1}H-NMR spectrum of which displays a resonance at $\delta = -10.55$ with a ^2J(PH) coupling constant of 10.1 Hz.[10] We note that even if the ^{1}H-NMR spectrum of the intermediate is measured in CD_2Cl_2 at −78°C, a slow evolution of gas (H_2) takes place accompanied by the conversion of compound **3** to the more stable dichlorodihydridoosmium(IV) complex **2**.

Carbyne- and Vinylideneosmium Complexes

We recently reported that the ruthenium counterpart of compound **2** with the composition $[RuH_2Cl_2(PCy_3)_2]$, which was prepared by Chaudret et al. from $[RuH_2(H_2)_2(PCy_3)_2]$ and aqueous HCl in ether[11] and independently by us from $[RuHCl(H_2)(PCy_3)_2]$,[12] reacts with phenylacetylene to give the five-coordinate vinylidene complex $[RuCl_2(=C=CHPh)(PCy_3)_2]$.[12] In contrast, treatment of **2** with three equivalents of HC≡CPh in hexane at 60°C affords instead of $[OsCl_2(=C=CHPh)(PCy_3)_2]$ the six-coordinate carbynehydrido compound **4** in 63% yield of isolated product. The analogous reaction of **2** with HC≡CSiMe$_3$ leads to a mixture of two products **5** and **6**, of which the first is by far the most dominant species (Scheme 2). The ^{31}P-NMR spectrum of the freshly isolated yellow solid displays a rather strong singlet at $\delta = 11.2$ and a weaker resonance at $\delta = 10.8$, which we assign to compounds **5** and **6**, respectively. In the hydride region of the ^{1}H-NMR spectrum of the mixture of **5** and **6** two triplets appear, the chemical shifts and the P-H coupling constants of which are only slightly different. Compound **5** containing the CH_2SiMe_3-substituted carbyne is completely converted into **6** upon addition of two drops of H_2O to a solution in CD_2Cl_2. Therefore, we assume that the small quantities of the carbyne complex **6** formed in the reaction of **2** with HC≡CSiMe$_3$ in hexane originate from traces of water in the reaction system. Besides the hydride resonance in the ^{1}H-NMR spectrum, a characteristic spectroscopic feature for **5** and **6** is the signal of the carbyne carbon atom in the ^{13}C-NMR spectrum which appears at $\delta = 267.6$ (**5**) and 265.5 (**6**), respectively. The corresponding resonance for **4** is observed at $\delta = 265.8$.

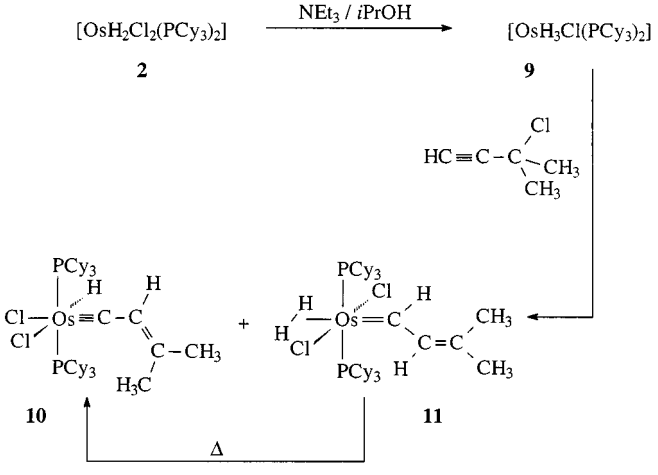


Scheme 2

With regard to the mechanism of formation of **4** and **5**, we assume that the starting material **2**, containing a metal center with a 16-electron configuration, generates in the initial step of the reaction a 1:1 adduct with the alkyne. It is conceivable that this seven-coordinate species is in equilibrium with the (dihydrogen)osmium(II) compound $[OsCl_2(H_2)(HC{\equiv}CR)(PCy_3)_2]$, which could first rearrange to the isomeric vinylidene derivative $[OsCl_2(H_2)(=C=CHR)(PCy_3)_2]$ and finally by intramolecular hydrogen transfer to $[OsHCl_2(\equiv CCH_2R)(PCy_3)_2]$. A similar reaction scheme has been proposed by Esteruelas and Oro et al.,

who prepared analogous carbynehydridoosmium complexes with two triisopropylphosphane ligands from $[OsH_2Cl_2(PiPr_3)_2]$ and HC≡CR.[13] A different synthetic route leading to $[OsHCl_2(\equiv CCH_2R)(PiPr_3)_2]$ was most recently reported by Caulton and co-workers, who used instead of 1-alkynes the corresponding alkenes CH_2=CHR as starting materials.[14] There is ample precedence for this water-assisted conversion of **5** into **6**, as we[15] as well as others[13a,16] observed that upon treatment of various low-valent transition-metal compounds with silylated alkynes or diynes in the presence of traces of H_2O or HX, metal complexes with C−H instead of C−SiR_3 bonds are formed.

The six-coordinate carbynehydrido complex **4** reacts with NaOMe in THF to give the five-coordinate vinylidenehydridoosmium(II) compound **7** in 87% isolated yield. The related bis(triisopropylphosphane) complex had been prepared on a similar route.[13b] The ^{1}H-NMR spectrum of **7** (which is a deep green, moderately air-sensitive solid) exhibits in the high-field region a triplet at δ = −16.38 which is typical for species of this type.[12][13] The presence of the vinylidene ligand is indicated by the ^{13}C-NMR resonances at δ = 282.8 and 107.3, which are assigned to the α- and β-carbon atoms of the Os=C=CHR chain. Since the ^{31}P-NMR spectrum of **7** displays a singlet at δ = 26.6, we assume, in agreement with theoretical studies by Eisenstein, Caulton et al.[17], that for the five-coordinate hydridovinylidene compound a distorted trigonal-bipyramidal geometry is most likely.



Scheme 3

The reactivity of compound **7** resembles that of the ruthenium counterpart $[RuHCl(=C=CH_2)(PCy_3)_2]$.[18] If HBF_4 is used as the substrate, the attack of the proton does not occur at the metal but at the β-carbon atom of the Os=C=CHPh unit and thus converts the vinylidene into a carbyne ligand (Scheme 3). In contrast to $[RuHCl(\equiv CCH_3)(OEt_2)(PCy_3)_2]BF_4$, which is rather labile and decomposes in CH_2Cl_2 at room temperature within 20−30 min,[18] the osmium complex **8** is considerably more stable. In the solid state, it can be stored under argon at 25°C for days, and in solution (CD_2Cl_2) at −18°C it does not decompose within 24 h.

The elemental analysis as well as the ^{1}H-NMR spectrum confirm that in **8**, unlike in $[RuHCl(\equiv CCH_3)(S)(PCy_3)_2]^+$ (S = OEt_2, OH_2)[18] and $[OsHCl(\equiv CCH_2Ph)(OH_2)(PiPr_3)_2]^+$,[13b] the open coordination site is not occupied by a solvent molecule. By taking the molecular structure of compound **10** (see below) and of the cationic carbyne complex $[OsH\{\equiv CCH=C(CH_3)_2\}(\kappa^2\text{-}O_2CCH_3)(PiPr_3)_2]^+$ into consideration,[19] we assume that in **8** the coordination around the metal center corresponds to that of a square pyramid with the carbyne moiety in the apical position. In agreement with this proposal, the ^{1}H-NMR spectrum of **8** displays a resonance for the hydrido ligand at δ = −8.75 and the ^{13}C-NMR spectrum exhibits a signal for the carbyne carbon atom at δ = 279.6, the latter of which is split into a triplet due to P-C coupling. For the related bis(triisopropylphosphane) complex $[OsHCl(\equiv CCH_2Ph)(PiPr_3)_2]^+$, which was most recently isolated by Spivak and Caulton with $[\{3,5\text{-}(CF_3)_2C_6H_3\}_4B]^-$ as the anion, the chemical shifts for the hydride and the carbyne carbon resonances are δ = −9.84 and 282.6, respectively.[20]

The synthesis of neutral six-coordinate carbynehydridoosmium(II) compounds is also possible by using propargylic chlorides instead of 1-alkynes such as HC≡CPh or $HC\equiv CSiMe_3$ as substrates. In this case, the starting material **2** was first converted into $[OsH_3Cl(PCy_3)_2]$ (**9**), which was obtained from **2** and 2-propanol in the presence of NEt_3 as a brown-yellow air-sensitive solid in almost quantitative yield (Scheme 4). The counterparts of **9** with $PiPr_3$ and $PtBu_2Me$ as phosphane ligands were recently prepared along a similar route.[17][21] Each of the three compounds of the general composition $[OsH_3Cl(PR_3)_2]$ is fluxional in solution. The ^{1}H-NMR spectrum of **9** (in CD_2Cl_2) displays a broad singlet at δ = −19.22 at 25°C, which upon cooling the solution to 0°C is split into a triplet. Below −23°C, a new broadening of the hydride signal is observed which, however, is not resolved even at −60°C. Caulton and coworkers reported that the spectrum of $[OsH_3Cl(PiPr_3)_2]$ shows AB_2 patterns in the hydride region below −80°C.[21a]

Scheme 4

The reaction of **9** with 3-chloro-3-methylbut-1-yne in dichloromethane at −40°C gives a mixture of two products. The more labile component is the carbene(dihydrogen) derivative **11** (see Scheme 4), which could not be separated from the mixture and was therefore characterized by ^{1}H-

and ^{13}C-NMR spectroscopy. Compound **11** reacts upon warming to 25°C to afford the carbynehydrido complex **10**, which was isolated as a pale brownish solid in 53% yield. The most typical spectroscopic features in the ^{1}H-NMR spectrum for **10** are, besides the resonances for the hydrido ligand and the carbyne carbon atom, the signals for the =CH proton at δ = 4.39 and for the inequivalent =CMe_2 methyl protons at δ = 2.01 and 1.50. The resonances for the =CH and =*C*Me_2 carbon nuclei appear in the ^{13}C-NMR spectrum at δ = 135.9 and 162.1.

The result of the X-ray crystal structure analysis of **10** is shown in Figure 1. The coordination geometry around the osmium center can be described as a distorted octahedron with the two phosphane ligands in the apical positions. The carbyne unit is disposed *trans* to one of the two chlorides. Both the C1−Os−Cl2 and P1−Os−P2 axes are slightly bent, the bond angle P1−Os−P2 [167.95(3)°] in **10** being somewhat larger than in the non-hydride-containing derivative [$OsCl_2$(≡CCH=CPh_2)(κ^1-*P*-*i*$Pr_2PCH_2CO_2Me$)-{κ^2-*P*,*O*-*i*$Pr_2PCH_2C(O)O$}] [165.0(1)°], which was recently prepared in our laboratory.[22] The Os−C1 distance in **10** [1.715(4) Å] is nearly identical to that in the above-mentioned carbyne complex [1.72(1) Å][22] as well as in the triisopropylphosphane derivative [$OsHCl_2$(≡CCH_2Ph)-(P*i*Pr_3)$_2$] [1.711(4) Å].[13a] There is, however, a significant difference between the Os−C bond length in **10** and in [OsCl(≡CC_6H_4Me-4)(CO)(PPh_3)$_2$] [1.78(2) Å][23] which could be explained by the different oxidation state and coordination number of the two compounds. The C1−C2 and C2−C3 bond lengths in **10** are in the expected range and this is true also for the Os−P distances.

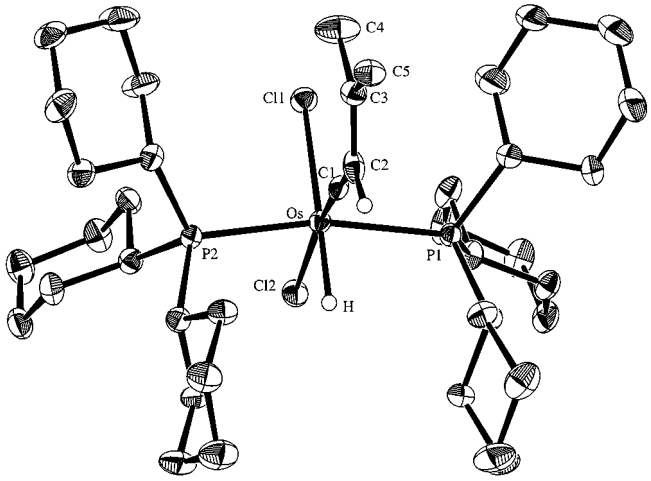


Figure 1. Molecular structure (ORTEP plot) of **10**;[a] the carbon atoms of the cyclohexyl rings are reduced in size for clarity; selected bond lengths [Å] and angles [°]: Os−C1 1.715(4), Os−P1 2.417(1), Os−P2 2.422(1), Os−Cl1 2.515(1), Os−Cl2 2.488(1), C1−C2 1.434(5), C2−C3 1.364(5), C3−C4 1.480(6), C3−C5 1.490(5); P1−Os−P2 167.95(3), P1−Os−C1 90.9(1), P1−Os−Cl1 95.42(3), P1−Os−Cl2 88.24(3), P2−Os−C1 91.0(1), P2−Os−Cl1 95.87(3), P2−Os−Cl2 87.76(3), C1−Os−Cl1 101.0(1), C1−Os−Cl2 170.0(1), Cl1−Os−Cl2 89.02(4), Os−C1−C2 174.4(3), C1−C2−C3 120.6(4), C2−C3−C4 124.1(4), C2−C3−C5 119.5(3), C4−C3−C5 116.3(3)

Catalytic Studies

It was recently found in our laboratory[18] that the cationic carbynehydridoruthenium complexes [RuHCl-(≡CCH_3)(S)(PCy_3)$_2$]BF_4 (S = OEt_2, OH_2) are highly efficient catalysts for olefin metathesis. They are not only more active than the Grubbs compound [$RuCl_2$(=CHPh)(PCy_3)$_2$] in the ring-opening metathesis polymerization (ROMP) of cyclooctene but, even more remarkably, they also catalyze the cross-olefin metathesis of cyclopentene with methyl acrylate. By this novel route, a homologous series of multiply unsaturated esters is formed. For the neutral carbyneruthenium complexes [RuCl(≡CR)(CO)-(PPh_3)$_2$], prepared by Roper et al.,[24] a similar catalytic activity is unkown.[25]

According to these results, it is not surprising that under standard conditions[5e] neither **4** nor **10** is catalytically active in ROMP of cyclopentene. However, the cationic species **8** reacts rather smoothly in CH_2Cl_2 with this olefin. After 24 h at room temperature, a highly viscous material was generated from which, after it was dissolved in $CHCl_3$ and the solution poured into methanol, a white powder could be obtained in about 40% yield. The comparison of the ^{1}H- and ^{13}C-NMR data of the polymer with those reported in the literature[25] revealed that 77% of the double bonds are *trans*-configured. The turnover frequency was determined as 154.2 h^{-1} at 25°C. To the best of our knowledge, compound **8** is the first well-defined osmium complex which catalyzes ROMP of cyclopentene.[25] We note that $OsCl_3 \cdot x\ H_2O$, an adduct of osmium chloride and cycloocta-1,5-diene,[26] and also OsO_4[25] were found to be catalytically active in olefin metathesis but as far as we know not in ROMP of cyclopentene.

Experimental Section

All operations were carried out under argon with Schlenk techniques. The alkynes and PCy_3 were commercial products from Strem and ABCR. − NMR: Bruker AC 200 and AMX 400 [vt = virtual triplet; $N = {}^1J(PC) + {}^3J(PC)$]. − Melting points determined by DTA.

1. Preparation of [$OsH_6(PCy_3)_2$] (1): To a slurry of 0.5 g (20.6 mmol) of magnesium turnings, which were activated with 0.50 mL of 1,2-$C_2H_4Cl_2$, in 25 mL of THF was added stepwise 2.23 g (7.80 mmol) of PCy_3 and 557 mg (1.70 mmol) of $OsCl_3 \cdot 2\ H_2O$. The reaction mixture was heated under vigorous stirring under H_2 (1 bar) for 90 min at 65°C and then for 19 h at 85°C. After the mixture was cooled to room temperature, the solution was separated from the solid (mainly Mg) and the solvent was removed in vacuo. The residue was dissolved in 30 mL of CH_2Cl_2 and 10 mL of H_2O. The organic layer was separated, concentrated to dryness in vacuo, and the residue washed twice with 15-mL portions of 2-propanol and dried. The remaining white solid was identified as **1** by comparison of the ^{1}H- and ^{31}P-NMR data with those reported in the literature;[8] yield 742 mg (58%).

2. Preparation of [$OsH_2Cl_2(PCy_3)_2$] (2): a) A suspension of 611 mg (1.87 mmol) of $OsCl_3 \cdot 2\ H_2O$ in 2 mL of 2-propanol was treated with a solution of 2.76 g (9.85 mmol) of PCy_3 in 20 mL of 2-propanol and then heated for 24 h under reflux. After the reaction mix-

ture was cooled to room temperature, a red-brown solid precipitated. The solid was separated from the mother liquor, washed twice with 10-mL portions of methanol (0°C), twice with 10-mL portions of ether (0°C) and dried in vacuo; yield 1.21 g (79%). – **b)** A slow stream of dry HCl was passed through a suspension of 86 mg (0.11 mmol) of **1** in 8 mL of hexane for 30 s at room temperature. A dark brown solution was formed from which, after it had been stirred for 10 min, a red-brown solid precipitated. The mother liquor was separated and the residue was washed with 5 mL of hexane and dried; yield 90 mg (96%); m.p. 94°C. – ^{1}H NMR (400 MHz, C_6D_6): δ = 2.28–1.15 (m, 66 H, C_6H_{11}), –15.68 [t, *J*(PH) = 35.1 Hz, 2 H, OsH_2]. – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 39.9 [d, *J*(PC) = 30.5 Hz, *ipso*-C of C_6H_{11}], 30.0 (s, *m*-C of C_6H_{11}), 27.8 [d, *J*(PC) = 10.2 Hz, *o*-C of C_6H_{11}], 26.9 (s, *p*-C of C_6H_{11}). – ^{31}P NMR (162.0 MHz, C_6D_6): δ = 33.6 (s). – $C_{36}H_{68}Cl_2OsP_2$ (824.0): calcd. C 52.48, H 8.32; found C 52.26, H 8.24.

3. Preparation of [$OsHCl_2$(≡CCH_2Ph)(PCy_3)$_2$] (4): A suspension of 393 mg (0.48 mmol) of **2** in 18 mL of hexane was treated with 156 μL (1.42 mmol) of phenylacetylene and stirred for 24 h at 60°C. A pale brownish solid precipitated. After the reaction mixture was cooled to room temperature, the mother liquor was separated, the solid residue was washed twice with 5-mL portions of hexane and dried; yield 282 mg (63%); m.p. 129°C. – ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 7.45–7.25 (m, 5 H, C_6H_5), 2.61 (s, 2 H, CH_2Ph), 2.33–1.04 (m, 66 H, C_6H_{11}), –6.64 [t, *J*(PH) = 16.8 Hz, 1 H, OsH]. – ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 265.8 [t, *J*(PC) = 11.5 Hz, Os≡C], 129.5, 129.1, 128.8, 128.1 (all s, C_6H_5), 56.9 (s, *C*H_2Ph), 36.8 (br. s, *ipso*-C of C_6H_{11}), 29.9, 29.4 (both s, *m*-C of C_6H_{11}), 27.9 (br. s, *o*-C of C_6H_{11}), 27.0 (s, *p*-C of C_6H_{11}). – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 8.8 [s, *J*(OsP) = 169.6 Hz]. – $C_{44}H_{74}Cl_2OsP_2$ (926.1): calcd. C 57.06, H 8.05; found C 56.58, H 7.97.

4. Preparation of [$OsHCl_2$(≡CCH_2SiMe_3)(PCy_3)$_2$] (5): A suspension of 307 mg (0.37 mmol) of **2** in 15 mL of hexane was treated with 156 μL (1.10 mmol) of HC≡$CSiMe_3$ and stirred for 6 h at 60°C. A yellow solid precipitated which was isolated as described for **4**; yield 178 mg. The NMR spectra of the isolated product indicated that besides **5** also small amounts of **6** were already formed. Typical data for **5**: ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 0.06 (s, $SiMe_3$), –7.64 [t, *J*(PH) = 17.6 Hz, OsH]. – ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 267.6 (br. s, Os≡C), 30.5 (s, CH_2). – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 11.2 (s).

5. Preparation of [$OsHCl_2$(≡CCH_3)(PCy_3)$_2$] (6): A suspension of 220 mg (0.27 mmol) of **2** in 15 mL of hexane was treated with 112 μL (0.79 mmol) of HC≡$CSiMe_3$ and a few drops of water and then stirred for 24 h at 60°C. A pale brownish solid precipitated, which was isolated as described for **4**; yield 136 mg (60%); m.p. 152°C. – ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 2.40–1.30 (m, 66 H, C_6H_{11}), 0.94 (s, 3 H, CH_3), –7.31 [t, *J*(PH) = 16.8 Hz, 1 H, OsH]. – ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 265.5 [t, *J*(PC) = 11.5 Hz, Os≡C], 38.6 (s, CH_3), 35.7 (br. s, *ipso*-C of C_6H_{11}), 29.9, 29.5 (both s, *m*-C of C_6H_{11}), 28.1, 27.9 (both vt, *N* = 10.2 Hz, *o*-C of C_6H_{11}), 27.1 (s, *p*-C of C_6H_{11}). – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 10.8 [s, *J*(OsP) = 167.9 Hz]. – $C_{38}H_{70}Cl_2OsP_2$ (850.0): calcd. C 53.69, H 8.30; found C 53.62, H 8.38.

6. Preparation of [OsHCl(=C=CHPh)(PCy_3)$_2$] (7): A suspension of 208 mg (0.23 mmol) of **4** in 35 mL of THF was treated with 14.6 mg (0.27 mmol) of NaOMe and stirred for 2 h at room temperature. After the solvent was removed, the residue was extracted with 20 mL of toluene. The extract was concentrated to dryness in vacuo, and the remaining green solid was washed with small quantities of toluene and pentane (both 0°C) and dried; yield 163 mg (87%); m.p. 131°C. – ^{1}H NMR (400 MHz, C_6D_6): δ = 7.56–6.78 (m, 5 H, C_6H_5), 2.66 (br. s, 1 H, =C*H*Ph), 2.21–1.18 (m, 66 H, C_6H_{11}), –16.38 [t, *J*(PH) = 13.0 Hz, 1 H, OsH]. – ^{13}C NMR (100.6 MHz, C_6D_6): δ = 284.1 [t, *J*(PC) = 9.5 Hz, Os=C], 128.3, 128.1, 123.4, 122.8 (all s, C_6H_5), 108.6 (s, Os=C=*C*), 36.1 (vt, *N* = 22.9 Hz, *ipso*-C of C_6H_{11}), 30.9, 30.6 (both s, *m*-C of C_6H_{11}), 28.1, 27.9 (both vt, *N* = 10.2 Hz, *o*-C of C_6H_{11}), 26.9 (s, *p*-C of C_6H_{11}). – ^{31}P NMR (162.0 MHz, C_6D_6): δ = 26.6 [s, *J*(OsP) = 181.4 Hz]. – $C_{44}H_{73}ClOsP_2$ (889.7): calcd. C 59.40, H 8.27; found C 59.07, H 7.87.

7. Preparation of [OsHCl(≡CCH_2Ph)(PCy_3)$_2$]BF_4 (8): A solution of 244 mg (0.27 mmol) of **7** in 40 mL of toluene was treated dropwise with 2 mL of a 1.4 M solution (2.8 mmol) of HBF_4 in ether. A rapid change of color from deep green to brown-yellow took place. After the reaction mixture had been stirred for 10 min at room temperatuere, a pale brownish solid precipitated which was separated from the mother liquor, washed twice with 8-mL portions of toluene and dried; yield 112 mg (43%); m.p. 134°C (dec.). – ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 7.36–7.05 (m, 5 H, C_6H_5), 3.01 (s, 2 H, CH_2), 2.39–1.17 (m, 66 H, C_6H_{11}), –8.75 (br. s, 1 H, OsH). – ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 279.6 [t, *J*(PC) = 10.8 Hz, Os≡C], 130.1, 129.2, 129.0, (all s, C_6H_5), 57.1 (s, CH_2), 36.3 (vt, *N* = 25.4 Hz, *ipso*-C of C_6H_{11}), 30.6, 30.1 (both s, *m*-C of C_6H_{11}), 27.6, 27.4 (both vt, *N* = 10.2 Hz, *o*-C of C_6H_{11}), 26.3 (s, *p*-C of C_6H_{11}). – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 46.3 (br. s). – $C_{44}H_{74}BClF_4OsP_2$ (977.5): calcd. C 54.07, H 7.63; found C 53.61, H 7.77.

8. Preparation of [OsH_3Cl(PCy_3)$_2$] (9): A suspension of 89 mg (0.11 mmol) of **2** in 5 mL of 2-propanol was treated with 38 μL (0.27 mmol) of NEt_3 and stirred for 2 h at room temperature. A change of color from red-brown to brown-yellow occurred. The solvent was removed in vacuo and the residue was dissolved in 10 mL of benzene. The solution was filtered and the filtrate was concentrated to dryness in vacuo. The remaining brown-yellow solid was repeatedly washed with methanol and dried; yield 75 mg (86%); m.p. 40°C (dec.). – ^{1}H NMR (400 MHz, C_6D_6, 25°C): δ = 2.31–1.15 (m, 66 H, C_6H_{11}), –19.22 (br. s, 3 H, OsH_3). – ^{1}H NMR (200 MHz, CD_2Cl_2, 0°C): δ = 2.10–1.21 (m, 66 H, C_6H_{11}), –19.74 [t, *J*(PH) = 11.5 Hz, 3 H, OsH_3]. – ^{13}C NMR (100.6 MHz, C_6D_6, 25°C): δ = 37.4 (vt, *N* = 23.4 Hz, *ipso*-C of C_6H_{11}), 31.0 (s, *m*-C of C_6H_{11}), 28.0 (vt, *N* = 10.2 Hz, *o*-C of C_6H_{11}), 27.0 (s, *p*-C of C_6H_{11}). – ^{31}P NMR (162.0 MHz, C_6D_6, 25°C): δ = 41.8 (s). – ^{31}P NMR (81.0 MHz, CD_2Cl_2, 0°C): δ = 41.8 (s). – $C_{36}H_{69}ClOsP_2$ (789.5): calcd. C 54.77, H 8.81; found C 55.22, H 8.64.

9. Reaction of Compound 9 with 3-Chloro-3-methylbut-1-yne: A solution of 57 mg (0.07 mmol) of **9** in 0.5 mL of CD_2Cl_2 was treated at –40°C in an NMR tube with 8.5 μL (0.18 mmol) of HC≡$CC(CH_3)_2Cl$. The NMR spectra of the solution indicated the formation of a mixture of **10** and **11** which could not be separated by fractional crystallization. Therefore, the more labile component **11** was characterized by NMR spectroscopy. Typical data for **11**: ^{1}H NMR (400 MHz, CD_2Cl_2, –70°C): δ = 16.88 [d, *J*(HH) = 12.7 Hz, 1 H, Os=CH], 7.03 [d, *J*(HH) = 12.7 Hz, 1 H, C*H*=CMe_2], 2.95–0.77 (m, 72 H, C_6H_{11} and CH_3], –7.52 [br. s, 2 H, $Os(H_2)$]. – ^{13}C NMR (100.6 MHz, CD_2Cl_2, –70°C): δ = 254.9 (br. s, Os=C). – ^{31}P NMR (162.0 MHz, CD_2Cl_2, –70°C): δ = –1.1 (br. s). – ^{31}P NMR (81.0 MHz, CD_2Cl_2, –40°C): δ = 1.2 (s).

10. Preparation of [$OsHCl_2$(≡CCH=CMe_2)(PCy_3)$_2$] (10): The solution, obtained from **9** and HC≡$CC(CH_3)_2Cl$ as described above, was stirred after warming for 1 h at room temperature. The solvent was removed, the remaining pale brownish solid was washed with

2 mL of hexane and dried; yield 34 mg (53%); m.p. 122°C. – ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 4.39 (s, 1 H, C*H*=CMe$_2$), 2.36–1.15 (m, 66 H, C_6H_{11}), 2.01 (s, 3 H, $CH_{3\ trans}$ to =CH), 1.50 (s, 3 H, $CH_{3\ cis}$ to =CH), −7.17 [t, *J*(PH) = 17.6 Hz, 1 H, OsH]. – ^{13}C NMR (100.6 MHz, CD_2Cl_2): δ = 256.0 [t, *J*(PC) = 11.4 Hz, Os≡C], 162.1 (s, =*C*Me$_2$), 135.9 (s, =CH), 36.5 (br. vt, *N* = 11.4 Hz, *ipso*-C of C_6H_{11}), 29.6, 29.3 (both s, *m*-C of C_6H_{11}), 28.2, 28.0 (both vt, *N* = 5.1 Hz, *o*-C of C_6H_{11}), 27.1 (s, *p*-C of C_6H_{11}), 26.4, 23.6 (both s, CH_3). – ^{31}P NMR (162.0 MHz, CD_2Cl_2): δ = 8.2 [s, *J*(OsP) = 169.6 Hz]. – $C_{41}H_{74}Cl_2OsP_2$ (890.1): calcd. C 55.33, H 8.38; found C 55.16, H 8.16.

11. ROMP of Cyclopentene with Compound 8 as Catalyst: A solution of 30 mg (0.03 mmol) of **8** in 1 mL of CH_2Cl_2 was treated with 10 mL (0.11 mol) of cyclopentene and stirred for 24 h at room temperature. The highly viscous reaction mixture was dissolved in 40 mL of $CHCl_3$ and the solution was poured into 100 mL of methanol. The white material was filtered and, after it was dried in vacuo, characterized by ^{1}H- and ^{13}C-NMR spectroscopy. The comparison of the NMR data with those reported in the literature[25] revealed a *trans*/*cis* ratio of the configuration at the double bonds of 77:23; yield 4.19 g.

12. Determination of the X-ray Crystal Structure of 10:[27] Single crystals of **10** were grown from CH_2Cl_2. Crystal data (from 5000 reflections, 4.26° < Θ < 54.06°): monoclinic; space group *I*2/*a* (No. 15); *a* = 25.655(5), *b* = 9.527(2), *c* = 39.988(8) Å, β = 107.26(3)°; *V* = 9333(3) Å^3; *Z* = 8; $d_{calcd.}$ = 1.448 gcm^{-3}; μ(Mo-K_α) = 3.115 mm^{-1}; crystal size 0.13 × 0.12 × 0.10 mm; STOE (IPDS), Mo-K_α radiation (0.71073 Å), graphite monochromator; *T* = 173(2) K; ψ-scans, max. 2Θ = 54.06°; 82743 reflections measured, 10147 independent ($R_{int.}$ = 0.0303), 7230 with $I > 2\sigma(I)$. Intensity data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SHELXS-86).[28] Atomic coordinates and the anisotropic thermal parameters of non-hydrogen atoms were refined by full-matrix least squares on F^2 (SHELXL-93).[29] The positions of all hydrogen atoms, except of metal-bound H, were calculated according to ideal geometry and refined by using the riding method. The position of H could be located in a final difference Fourier synthesis and was refined with fixed U_{eq}. The asymmetric unit includes one and a half molecules of CH_2Cl_2 which were refined anisotropically. Two alternative positions for CH_2Cl_2 consisting of C91, Cl5, and Cl6 were found and refined with the occupancy factors 0.54:0.46 with restraints. Conventional *R* = 0.0313 [for 7230 reflections with $I > 2\sigma(I)$], and weighted wR_2 = 0.0682 for all 10137 located reflections; reflection/parameter ratio 21.12; residual electron density +2.401/−1.213 eÅ^{-3}.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347) and the Fonds der Chemischen Industrie. We thank Dr. W. Buchner and Mrs. M.-L. Schäfer for NMR spectra, and Mrs. R. Schedl and Mr. C. P. Kneis for elemental analyses and DTA measurements. Generous support by the BASF AG and the Degussa AG (gifts of chemicals) is also gratefully acknowledged.

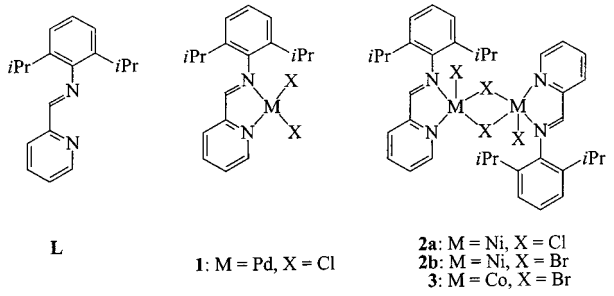
Synthesis and X-ray Structures of New Mononuclear and Dinuclear Diimine Complexes of Late Transition Metals

Timo V. Laine,*[a] Martti Klinga,[a] and Markku Leskelä[a]



Keywords: Nickel / Palladium / Cobalt / N ligands / Crystal structures

Synthesis of new palladium(II) (**1**), nickel(II) (**2a** and **2b**), and cobalt(II) (**3**) complexes bearing the unsymmetrical, bidentate nitrogen ligand 2,6-bis(1-methylethyl)-*N*-(2-pyridinylmethylene)phenylamine (**L**) is described. The solid-state structures of **1**, **2a**, and **2b** have been determined by single-crystal X-ray diffraction. The Pd^{II} compound exists in the monomeric form whereas the nickel complexes were observed as centrosymmetric dimers with slightly distorted square-pyramidal coordination sphere around each nickel center.

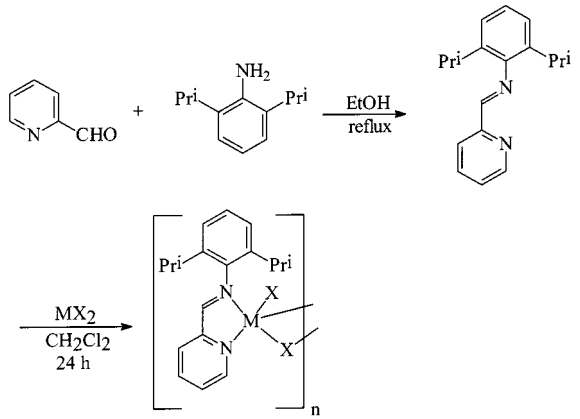
Introduction

During the past 15 years extensive research effort from academic and industrial laboratories has been devoted to the development of transition-metal-catalyzed polymerization processes.[1] As a result the polyolefin industry has since the early 1990s had the option to transfer from mixture-type systems of the classical Ziegler−Natta technology to more sophisticated single-site catalysts, such as group-4 metallocenes,[2] in which well-defined active centers and catalyst structures enable tailoring of polymer properties by modifying the catalyst precursor itself.[3] Some signs of the next prospective catalyst generation are already emerging:[1] The disclosure by the group of Brookhart in 1995 that they produced high molecular weight polyethylene for the first time with late transition metal complexes[4] has revived the investigation of late transition metal compounds as potential catalyst precursors.[5] Prior reports of the use of group-10 metals exist,[6] but these systems suffer from the highly competitive chain-termination step and produce only short-chain oligomers of up to 40 carbon atoms.[7] Therefore, very little utilization had been found for such systems leaving the nickel-catalyzed oligomerization of ethylene in the Shell Higher Olefin Process (SHOP)[8] as the sole industrial-scale application. This disadvantage was, however, overcome by the use of nickel(II) and palladium(II) complexes bearing sterically demanding 1,4-diazabutadiene ligands,[4] in which bulky aryl groups of the ligand protect the active center by blocking the axial coordination sites thus enhancing chain growth and disfavoring termination processes.[9] Depending on the ligand substitution pattern and process parameters these catalysts can produce a wide variety of products ranging from linear high-density material to highly branched, amorphous polyethylene[4,10] or even short-chain oligomers.[11] Also different types of ethylene copolymers incorporating polar comonomers, such as alkyl acrylates, can be manufactured.[12] Due to the demonstrated versatility and industrial potential[13] a comprehensive patent application covering the syntheses of numerous diazabutadiene-type transition-metal compounds and their use as polymerization catalysts has been filed.[14]

According to recent reports the group of applicable catalyst precursor metals is extending rapidly to cover other, more scarcely utilized transition metals as well. In addition to group-10 metal compounds[4,10,15] some five-coordinate iron(II) and cobalt(II) complexes bearing triimine-type ligands have demonstrated suitability as active ethylene polymerization catalysts after activation with alkylaluminum compounds.[16] Also the first examples of homogeneous chromium(III) catalysts have been published recently.[17] Reported studies, however, have mainly involved symmetrical ligands with two electronically or sterically equivalent imine nitrogen atoms.[5] In this article we present the synthesis and characterization of novel group-9 and -10 metal complexes containing the unsymmetrical, bidentate ligand 2,6-bis(1-methylethyl)-*N*-(2-pyridinylmethylene)phenylamine (**L**).

Scheme 1

Results and Discussion



Synthetic Aspects

The ligand **L** is prepared by a facile one-step condensation of 2-pyridinecarboxaldehyde and 2,6-bis(1-methylethyl)phenylamine, as shown in Scheme 2, yielding pale yellow, crystalline material after purification and recrystalliza-

tion from pentane. Due to the limited solubility of anhydrous late transition metal halides in organic solvents only in the case of cobalt the subsequent complex formation step could be performed by a direct reaction of the ligand with the metal halide. Otherwise, solvent-adduct-based precursor compounds were needed (the adduct was 1,2-dimethoxyethane and 1,5-cyclooctadiene for nickel and palladium, respectively). Complexation products were isolated as yellow (**1**), orange (**2a**), orange-red (**2b**), or deep brown (**3**) powders in good yields (70−96%). All compounds gave satisfactory distribution patterns in elemental analysis.

1: M = Pd; X = Cl; n = 1
2a: M = Ni, X = Cl; n = 2
2b: M = Ni, X = Br; n = 2
3: M = Co, X = Br; n = 2

Scheme 2. Synthesis of compounds **1**−**3**

Analysis of the palladium compound **1** by ^{1}H-NMR spectroscopy reveals certain changes in chemical shifts. First of all, the sharp doublet signal from the isopropyl methyl groups of the free ligand at $\delta = 1.17$ has been split into two smaller doublets at $\delta = 1.03$ and $\delta = 1.43$ after complexation. This may be explained by the blocking effect of the chloride ions attached to the palladium center. While in the free ligand the aryl group can rotate unobstructed around the carbon−nitrogen bond, the chloride positioned *cis* to the imine nitrogen atom restricts this movement and subjects the inner methyl groups to some degree of deshielding resulting in the observed separation of peaks. Another distinctive consequence of complex formation is the movement of certain signals in the spectrum. Protons situated in the *ortho* and *para* positions in the aromatic ring systems as well as the proton of the imine carbon atom are especially affected with chemical shifts transferred downfield by 0.30−0.51 ppm. Measurements of the ^{1}H-NMR spectra for the nickel and cobalt complexes (**2a**, **2b**, and **3**) failed apparently as a result from the interfering effect caused by the associated metal center.

Treating the nickel compounds with methylaluminoxane (MAO) provides quite effective catalysts for ethylene polymerization, while the cobalt complex shows nearly negligible activity. In nickel-catalyzed reactions the activities and polymer molecular weights depend on the polymerization temperature: Lowering the temperature to 0 °C leads to an increase in molecular weights by an order of magnitude at the expense of declining catalytic activity.[18] The MAO-activated palladium compound could not be utilized for the polymerization of ethylene but it proved to be highly active with cyclic monomers, such as norbornene.[19] In order to take full advantage of the potential provided by these systems our current work is concentrating on the effects of different ligand substitution patterns on the polymerization behavior of these compounds.

X-ray Crystallography

Crystallization from acetone (for **1**) or a mixture of acetone and pentane (2:1 for **2a**, 1:1 for **2b**) yielded deep orange crystals suitable for structural analysis. The crystal data, together with the data collection and structure refinement parameters are presented in Table 2. Selected bond lengths and angles are given in Table 1. In each compound the solid-state structures are stabilized only by van der Waals forces between the molecules.

The palladium compound **1** crystallizes in the monomeric form with two chlorine atoms (Cl1 and Cl2) and two nitrogen atoms (N1 and N8) of the bidentate ligand forming the expected square-planar coordination sphere around the palladium center (see Figure 1). The palladium atom is situated exactly in the coordination plane N1−N8−Cl2−Cl1 (0.029 Å above the calculated plane) as the average off-plane deviation is 0.053 Å. The narrow N1−Pd−N8 angle 80.08(11)° resulting from the relatively small bite size of the ligand, however, distorts the square structure in a similar fashion as observed in other pyridylimine[20] or bipyridine[21,22] complexes of palladium, but without any coordination plane distortion out of the ligand plane.[22a] In fact, the significant bond lengths and angles in complex **1** resemble the ones reported for the structure of the C_2-symmetric dichloro(2,2′-bipyridine)palladium(II),[21] which indicates electronic similarity of the two nitrogen coordination sites. The variation between the ligand nitrogen atoms, therefore, originates from the difference in steric environment of the two binding sites: The phenyl ring of the imino side arm adopts a position almost perpendicular to the metal coordination plane with the phenyl−coordination plane angle 86.84(8)° and, thus, shields the metal center from one side.

The nickel complexes **2a** and **2b**, in turn, crystallize as centrosymmetric dimers in which each nickel atom is coordinated to two ligand nitrogen atoms (N1 and N8) as two bridging halogen atoms (Cl1 and Cl1a in **2a**, Br1 and Br1a in **2b**) connect the two metal centers. A terminal halide ion (Cl2 and Br2 in **2a** and **2b**, respectively) completes the square-pyramidal coordination sphere. The intramolecular nickel−nickel distance of the chloro complex **2a** is slightly shorter [3.475(1) Å] than recently reported for other nitrogen-ligand-containing nickel(II) dimers,[23c] which is also reflected in a sharper Ni−Cl−Ni angle. Dimeric structures are commonly known for dichloronickel(II) complexes of this type,[23] while similar bipyridine-based dibromonickel-

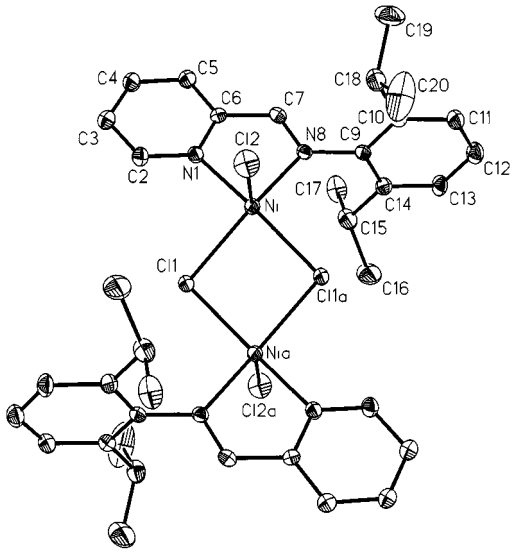

Figure 2. Molecular structure of compound **2a** with the labeling scheme

(II) compounds may exhibit monomeric complexes if additional steric bulk is introduced.[23a]

As with complex **1** also in the case of the nickel analogs the narrow nitrogen−nickel−nitrogen angle [79.37(9)° in **2a** and 79.9(4)° in **2b**] slightly deforms the basal square structure. The effect from dimerization contributes to further structural distortion leading to unequal nickel−nitrogen and nickel−halogen bond lengths: The shorter nickel−halogen bond of the bridge (Ni−Cl1 and Ni−Br1) corresponds to a similarly shorter Ni−N bond (the bond to the imino nitrogen atom N8) situated in the *trans* position. The axial chlorine atom Cl2 or bromine atom Br2, however, has the shortest bond length of all three nickel−halogen bonds.

Another common structural feature between the palladium and nickel complexes is the lack of double-bond delocalization in all three compounds. Relative to other bonds in the imino bridge [values ranging from 1.423(14) to 1.463(4) Å] the C=N double bond (C7−N8) is still the shortest [1.279(4), 1.278(3), and 1.282(14) Å for **1**, **2a**, and **2b**, respectively] even after complexation.

Besides in coordination geometry the nickel compounds differ from their palladium analog in the nature of the coordination plane. In **1** the coordination plane exhibits only slight puckering while more severe puckering was observed in the nickel compounds with average deviations of 0.119 Å for **2a** and 0.071 Å for **2b**, although the calculated value of **2b** is quite close to the average deviation in the palladium complex **1**. Also the palladium atom, as described earlier, is situated in the middle of the coordination plane whereas in the nickel complexes the metal center is elevated from the plane by 0.475(1) and 0.456(4) Å in **2a** and **2b**, respectively.

Analysis of the cobalt coordination sphere in compound **3** revealed a dimeric structure in which one terminal and two bridging bromine atoms as well as two ligand nitrogen

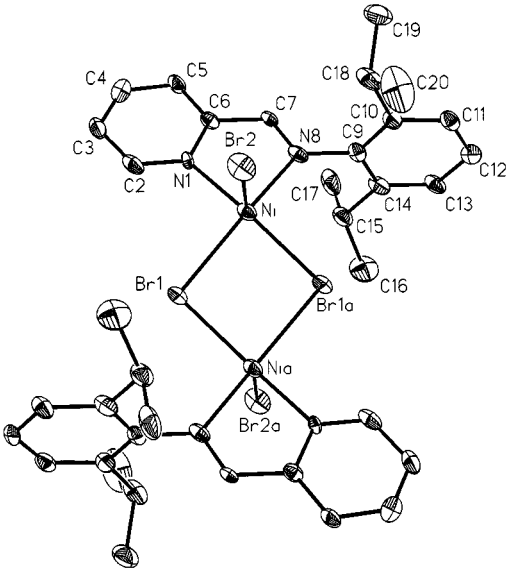

Figure 3. Molecular structure of complex **2b**

atoms create square-based pyramids around each five-coordinate metal center.[24]

Experimental Section

General: All complex preparations were performed under argon with standard Schlenk techniques. Acetone was dried by storing under argon with $CaSO_4$ granules, other solvents by refluxing with a drying agent (P_2O_5 for dichloromethane and sodium/benzophenone for the non-halogenated solvents) and distillation under argon. Dichloro(1,5-cyclooctadiene)palladium(II)[25] [(COD)$PdCl_2$] as well as dichloro(1,2-dimethoxyethane)nickel(II) [(DME)$NiCl_2$] and dibromo(1,2-dimethoxyethane)nickel(II) [(DME)$NiBr_2$][26] were prepared according to the literature. Anhydrous $CoBr_2$ (Aldrich, 99%), 2-pyridinecarboxaldehyde (Merck, 98%), and 2,6-bis(1-methylethyl)phenylamine (Aldrich, 90%) were used as received. − ^{1}H NMR: Varian Gemini 200 spectrometer (200 MHz); $CDCl_3$ or [D_6]acetone as solvent, TMS as internal standard. − EI MS: Finnigen SSQ 7000 spectrometer (70 eV); direct inlet probe. − Elemental analyses were carried out at the University of Ulm, Germany, except for the bromine content determination of complex **3**, which was performed by gravimetric analysis at the University of Helsinki.

2,6-Bis(1-methylethyl)-*N*-(2-pyridinylmethylene)phenylamine (L): The ligand was synthesized by modifying the literature procedure[27] reported for the analogous 2,6-dimethyl compound. Ethanol (100 mL), 2,6-bis(1-methylethyl)phenylamine (15.76 g, 80.0 mmol), and 2-pyridinecarboxaldehyde (8.57 g, 80.0 mmol) were combined and refluxed for 20 min. The solvent was removed and the residue was vacuum-distilled followed by chromatography on basic alumina with pentane/ethyl acetate (3:1) as eluent. Recrystallization from pentane yielded pale yellow crystals, 14.36 g (67%). − ^{1}H NMR ($CDCl_3$): δ = 1.17 (d, 12 H, H_{Me}), 2.97 (m, 2 H, C*H*Me_2), 7.16 (m, 3 H, H_{arom}), 7.42 (m, 1 H, $H_{pyridine,5}$), 7.86 (t, 1 H, $H_{pyridine,4}$), 8.27 (d, 1 H, $H_{pyridine,3}$), 8.31 (s, 1 H, C*H*=N), 8.73 (d, 1 H, $H_{pyridine,6}$). − $C_{18}H_{22}N_2$ (266.39): calcd. C 81.16, H 8.32, N 10.52; found C 81.01, H 8.37, N 10.39.

Dichloro[2,6-bis(1-methylethyl)-*N*-(2-pyridinylmethylene)-phenylamine]palladium(II) (1): The ligand **L** (0.76 g, 2.87 mmol) was dissolved in 10 mL of dichloromethane and added to a solution of [(COD)$PdCl_2$] (0.80 g, 2.80 mmol in 40 mL of CH_2Cl_2). Stirring was continued for 24 h at ambient temperature at which time precipitation occurred. The precipitated yellow powder was collected by filtration, washed with diethyl ether (2 × 20 mL) and dried in vacuo; yield 1.07 g (96%). − ^{1}H NMR ([D_6]acetone): δ = 1.03 (d, 6 H, H_{Me}), 1.43 (d, 6 H, H_{Me}), 3.27 (m, 2 H, C*H*Me_2), 7.12 (m, 3 H, H_{arom}), 7.93 (m, 1 H, $H_{pyridine,5}$), 8.22 (d, 1 H, $H_{pyridine,3}$), 8.36 (t, 1 H, $H_{pyridine,4}$), 8.69 (s, 1 H, C*H*=N), 9.18 (d, 1 H, $H_{pyridine,6}$). − $C_{18}H_{22}Cl_2PdN_2$ (443.71): calcd. C 48.73, H 5.00, N 6.31; found C 48.29, H 5.05, N 6.19.

Di-μ-chlorodichlorobis[2,6-bis(1-methylethyl)-*N*-(2-pyridinylmethylene)phenylamine]dinickel(II) (2a): To a suspension of [(DME)$NiCl_2$] (1.86 g, 8.45 mmol) in 40 mL of dichloromethane was added the yellow ligand solution (2.34 g, 8.77 mmol in 15 mL of CH_2Cl_2). After stirring the brown reaction mixture for 24 h at room temperature, the solvent was evaporated and the resulting solid material was washed with pentane (3 × 20 mL) and dried in vacuo yielding complex **2a** as orange powder, 2.65 g (79%). − $C_{36}H_{44}Cl_4N_4Ni_2$ (791.97): calcd. C 54.60, H 5.60, N 7.07; found C 54.61, H 5.94, N 6.68.

Di-μ-bromodibromobis[2,6-bis(1-methylethyl)-*N*-(2-pyridinylmethylene)phenylamine]dinickel(II) (2b): Analogously to the preparation of **2a**, complex **2b** was prepared from [(DME)$NiBr_2$] (0.40 g, 1.30 mmol) and **L** (0.36 g, 4.89 mmol) in CH_2Cl_2. The orange-red powder was collected by filtration, washed with pentane (3 × 10 mL) and vacuum-dried; yield 0.44 g (70%). − $C_{36}H_{44}Br_4N_4Ni_2$ (969.77): calcd. C 44.59, H 4.57, N 5.78; found C 44.10, H 4.59, N 5.68.

Di-μ-bromodibromobis[2,6-bis(1-methylethyl)-*N*-(2-pyridinylmethylene)phenylamine]dicobalt(II) (3): Anhydrous $CoBr_2$ (0.55 g, 2.52 mmol) was dissolved in 10 mL of acetone and combined with the ligand solution (0.68 g, 2.55 mmol in 10 mL of acetone). The resulting green-brown solution was stirred for 24 h at room temperature. After solvent evaporation, the residue was washed with hexane (3 × 10 mL) and vacuum-dried. The complex was obtained as brown powder, 1.02 g (83%). − EI MS (70 eV); *m*/*z*: 483, 485, 487 [1/2 M^+]; 404, 406 [1/2 M^+ − Br]; 323 [1/2 M^+ − 2 Br]. − $C_{36}H_{44}Br_4Co_2N_4$ (970.25): calcd. C 44.57, H 4.57, Br 32.94, N 5.77; found C 44.54, H 4.75, Br 32.61, N 5.62.

Crystal-Structure Determinations: The crystals were mounted to a glass fiber with the oil drop method.[28] Crystal data obtained with the ω−2θ scan mode were collected on an automated four-circle Rigaku AFC-7S diffractometer using graphite-monochromatized Mo-K_α radiation (λ = 0.71073 Å) at 193 K. Three standard reflections were monitored after every 200 intensity scans. The intensities were corrected for Lorentz and polarization effects. For all compounds ψ-scans were used for absorption correction.[29] Data sets were compressed to reflection files with TEXSAN Single Crystal Structure Analysis Software.[30] The structures were solved with SHELXTL PC 4.1 program package[31] using direct methods while further refinement with full-matrix least squares on F^2 was carried out with SHELXL-93[32] (for **2a**) or SHELXL-97[33] (for **1** and **2b**). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced in calculated positions (riding model) with 1.2 times the displacement factors of the host carbon atoms. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-103369 (for **1**), -103368 (for **2a**), and -103370 (for **2b**). Copies of the data can be obtained on application to CCDC, 12 Union

Synthesis, Structural Characteristics and Biological Activities of Complexes of Zn^{II}, Cd^{II}, Hg^{II}, Pd^{II}, and Pt^{II} with 2-Acetylpyridine 4-Methylthiosemicarbazone

Elena Bermejo,[a] Rosa Carballo,[b] Alfonso Castiñeiras,*[a] Ricardo Domínguez,[a] Anthony E. Liberta,[d] Cäcilia Maichle-Mössmer,[c] Michelle M. Salberg,[d] and Douglas X. West[d]

Keywords: 2-Acetylpyridine 4-methylthiosemicarbazone / Palladium / Platinum / Group-12 metal(II) complexes

Reaction of 2-acetylpyridine 4-methylthiosemicarbazone (H4ML) with halides of zinc(II), cadmium(II), and mercury(II) afforded complexes of the form $[M(H4ML)X_2]$ [M = Zn^{II} (**1**–**3**), Cd^{II} (**4**–**6**) or Hg^{II} (**7**–**9**); X = Cl, Br, or I]. Reaction of H4ML with K_2PdCl_4 and K_2PtCl_4 gave compounds of the form [M(4ML)Cl] [M = Pd^{II} (**10**) or Pt^{II} (**11**)]. In all the new compounds, which were characterized by elemental analyses, conductance measurements, and electronic, IR and ^{1}H- and ^{13}C-NMR spectroscopy, and by ^{113}Cd-, ^{195}Pt-, or ^{199}Hg-NMR spectroscopy when relevant, the ligand is N,N,S-tridentate, coordinating to the metal centre through its pyridine and azomethine nitrogen atoms and its thiocarbonyl sulfur atom, as was confirmed by X-ray diffraction studies in the cases of **4** · 2 DMSO, **5** · 2 DMSO, **6** · 2 DMSO, **7** · 2 DMSO, **10**, and **11**. In in-vitro assays, only $[Zn(H4ML)Cl_2]$ and $[Zn(H4ML)Br_2]$ showed some sign of antifungal activity against *Aspergillus niger* or *Paecilomyces variotii*.

Introduction

It has been known for some time that thiosemicarbazones have a wide range of actual or potential medical applications as antiviral,[1] antitumoral,[2] antimalarial,[3] antifungal,[4] and antibacterial[5] agents. Their mechanism of action is still controversial in many respects, but it is known that heterocyclic thiosemicarbazones act by inhibiting ribonucleotide reductase, a key enzyme in the biosynthesis of DNA precursors.[6] This effect is probably due to the thiosemicarbazone's binding to the metallic centre of the enzyme as an N,N,S-tridentate ligand, and interest in the coordination chemistry of these compounds has grown accordingly. Most work in this area has concerned coordination to transition metals;[7−13] nontransition metals have received relatively little attention.[14−16] In this article we describe the synthesis, structural characteristics and antifungal activity of complexes of zinc(II), cadmium(II), mercury(II), palladium(II), and platinum(II) with a heterocyclic thiosemicarbazone derived from 2-acetylpyridine 4-methylthiosemicarbazone (H4ML).

Results and Discussion

The condensation of 2-acetylpyridine with 4-methylthiosemicarbazide affords 2-acetylpyridine 4-methylthiosemicarbazone (H4ML). H4ML is a powerful ligand able to form coordination compounds of the types $[M(H4ML)X_2]$ (M = Zn^{II}, Cd^{II}, or Hg^{II} and X = Cl, Br, or I) and [M(4ML)X] (M = Pd^{II} or Pt^{II}, X = Cl). The ligand and its complexes are stable in air. The complexes are pale yellow or orange solids that are moderately soluble in common organic solvents. Their molar conductance values of 6.27−13.97 ohm^{-1} cm^2 mol^{-1} in DMF solution indicate nonelectrolytic behaviour. Their melting points and analytical data are listed in Table 1.

Molecular Structures

Figure 1 shows that in the solid state H4ML adopts an (*E*) conformation (for the nomenclature of the conformations of thiosemicarbazones derived from 2-formyl- and 2-acetylpyridine, see refs.[17][18]). This places the C(5)−N bond of the pyridine ring *trans* to the azomethine bond. Selected bond lengths and bond angles of H4ML are listed in Table 2. The N−N distance, 1.381(4) Å, is similar to those found in related thiosemicarbazones.[19] In particular, it is shorter than the accepted length of single N−N bonds (1.44 Å) which is compatible with the notion that charge delocalization extends throughout the molecule, affecting the thiosemicarbazone chain as well as the ring. Likewise, as in other thiosemicarbazones,[20] the partial double-bond nature of the C−S bond is shown by a length [1.675(4) Å] between those of single and double bonds (1.82 and 1.56 Å, respectively)[21] and partial double bonding is similarly

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434−1948/99/0606−0965 $ 17.50+.50/0

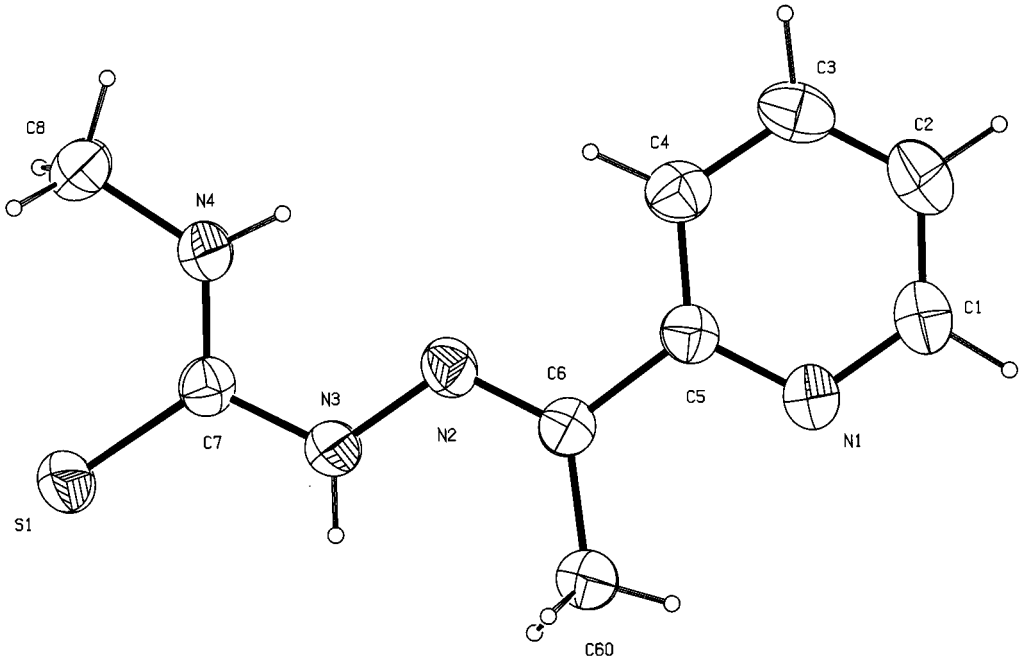

Figure 1. Molecular structure of H4ML and numbering scheme

shown by the lengths of C(7)−N(3), C(7)−N(4) and, in particular, the azomethine bond [length 1.284(4) Å]. There is an intramolecular hydrogen bond between the terminal thioamide hydrogen atom and the azomethine nitrogen atom [N(4)−H(40)−N(2): 1.02(5), 2.17(4), 2.68(3) Å, 105(3)°].

The $[M(H4ML)X_2]$ complexes for which crystals suitable for X-ray diffraction were obtained are **4** · 2 DMSO, **5** · 2 DMSO, **6** · 2 DMSO, and **7** · 2 DMSO; selected bond lengths and bond angles of the ligand in these complexes are listed in Table 2 and those involving the metal atom in Table 3. Figures 2−5 show the molecular structures. The crystals of all these compounds include two molecules of DMSO per molecule of complex, and **5** · 2 DMSO, **6** · 2 DMSO, and **7** · 2 DMSO are mutually isotypic.[22] In all these complexes H4ML is a neutral N,N,S-tridentate ligand, coordinating through its pyridine and azomethine nitrogen atoms and its thiocarbonyl sulfur atom to a metal atom whose coordination number is made up to five by bonds with the two halogen atoms. The values of 0.05−0.11 obtained for τ[23](Table 4) show that, in spite of the large deviations of both α and β from 180°, the coordination

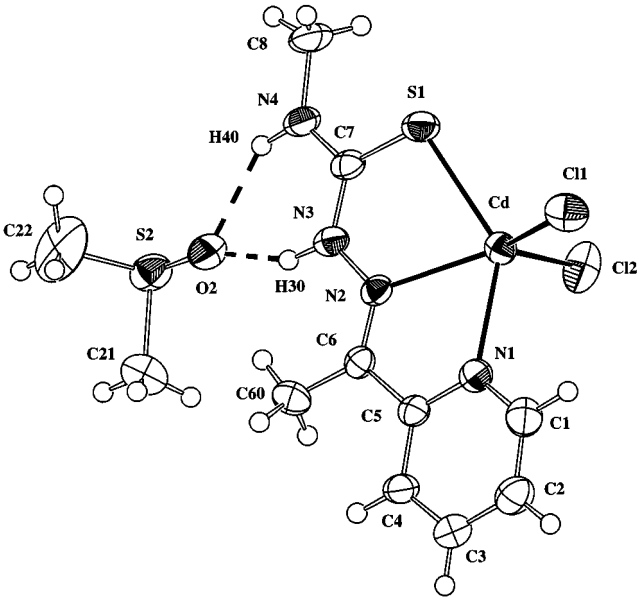

Figure 3. Molecular structure of the cadmium complex **4** · 2 DMSO, showing the hydrogen bonding

polyhedron around the metal atom is in all cases more nearly a tetragonal pyramid with halogen X(2) at its apex than a trigonal bipyramid; distorsion towards a trigonal bipyramid with N(2) and X(1) at its poles increases with the size of the halogen and with the size of the metal. The Cd−S distances (Table 3) are within the usual range for cadmium coordinated to thiocarbonyl[16][24] or thiolato[25] sulfur atoms. The distances between the cadmium atom and the pyridine and azomethine nitrogen atoms are also unexceptional,[16][24] but it may be noted that the Cd−N(azomethine) bond is in all three cases the weaker, whereas the reverse is the case in **10** and **11** (see below) and in $[Cd(HL')Cl_2] \cdot H_2O$ (HL′ = pyridine-2-carbaldehyde thiosemicarbazone).[16] In **7** · 2 DMSO the Hg−S, Hg−N(pyridine), and Hg−Cl distances are all similar to those found in other complexes of mercury(II) halides with ligands coordinating through carbonyl sulfur and pyridine nitrogen atoms,[26][27] but the Hg−N(azomethine) bond, longer than Hg−S, is very weak.

In the isotypic compounds **10** and **11** (Figures 6 and 7), in which the ligand is deprotonated, the metal centre again coordinates to the pyridine and azomethine nitrogen atoms and the thiolato sulfur atom, but has just one halogen ligand. The four donor atoms are almost coplanar, and the metal atom itself lies just 0.01 Å from the least-squares plane through the four, but distorsion of the plane tetragon appears in the S−M−N(1) and N(2)−M−Cl angles [165.7(2)° and 178.4(2)° respectively in **10**, 166.0(5)° and 177.4(5)° in **11**]. Comparison of the M−N(1) and M−N(2) distances [2.051(4) versus 1.950(3) Å in the Pd complex, 2.029(14) versus 1.969(16) Å in the Pt complex] shows that the bond with the azomethine nitrogen atom is the stronger, doubtless due to the greater basicity of this nitrogen atom and, possibly, the *trans* effect. The M−S and M−Cl distances are similar to those found in other complexes in which Pd and Pt coordinate to S[13][28] or Cl.[29] The delocalization of the charge originated by deprotonation at N(3) is apparent upon comparison of the thiosemicarbazone bond lengths in the complexes and the free ligand (Table 2): In the complexes N(3)−C(7) is shorter and C(7)−S is longer than in free H4ML, showing that, as in similar complexes,[18] bond order is increased in the former

case and decreased in the latter. The stability of the complex is no doubt increased by the rigidity of the planar tricyclic system formed by the pyridine ring and the two five-membered chelation rings.

Electronic Spectra

The electronic spectra of the palladium(II) and platinum(II) complexes were recorded in DMF/MeCN solutions. The positions of the absorption bands were not significantly different from those observed in the solid-state diffuse-reflectance spectra indicating that these complexes underwent no electronic or geometric changes upon dissolution.

The absorption bands of the Pd^{II} complex, with maxima at $\tilde{\nu}$ = 21,692, 24,096, and 27,100 cm^{-1}, may be assigned to spin-allowed *d-d* transitions corresponding to the one-electron transitions $^1A_{1g} \rightarrow {}^1A_{2g}$, $^1A_{1g} \rightarrow {}^1B_{1g}$ and $^1A_{1g} \rightarrow {}^1E_g$. Similarly, the Pt^{II} complex displayed an absorption spectrum with maxima at $\tilde{\nu}$ = 22,124, 25,126−25,707, and 26,882 cm^{-1} attributed to these same transitions. These wavenumbers are comparable to those observed previously

for square-planar palladium and platinum complexes involving similar donor atoms. In the UV region, the strong absorptions above 28,000 cm^{-1} may be charge-transfer bands[30] or intraligand bands.

Infrared Spectra

The chief IR bands of free H4ML[31] and the complexes are listed and assigned in the Supporting Information. Most of the ligand bands shift to higher frequencies upon complexation. In particular, the shifts in ν(C=N) and ν(N−N) are evidence of coordination through the azomethine nitrogen atom[32][33], while coordination through the pyridine nitrogen atom is shown by the shift to higher frequencies of the ν(CN) + ν(CC) (1539 cm^{-1}), α(CCC) (626 cm^{-1}), and φ(CC) (403 cm^{-1}) ring vibrations.[34] The shifts to lower frequencies of ν(CS) at 833 cm^{-1} in the free ligand[31] and, in the Zn, Cd, and Hg complexes, ν(NH), are the result of coordination through the thiocarbonyl sulfur atom[35] and the nitrogen atom bound to N(3).[36] The spectra of the Pd and Pt complexes, in which the ligand is deprotonated, show only one strong band instead of two in the ν(NH) region. Deprotonation results in the frequency of this remaining band increasing (rather than decreasing, as it does in the Zn, Cd, and Hg complexes), and enhances the shifts of other bands affected by complexation. In particular, the shift of about 160 cm^{-1} in ν(CS), as against about 120 cm^{-1} in the Zn, Cd, and Hg compounds, shows the ligand to be closer to a thiolato form in the Pd and Pt compounds than in the others.

In the 500−100 cm^{-1} region, the one or two strong bands whose frequencies increase in the order I complex < Br complex < Cl complex for a given metal and in the order Hg complex < Cd complex < Zn complex for a given halogen (Table 5) are attributed to metal-halogen stretching vibrations, in keeping with which the resulting values of ν(M−Br)/ν(M−Cl) (av. 0.70) and ν(M−I)/ν(M−Cl) (av. 0.63) (see Supporting Information) are similar to previously reported values.[26,27,37] The less intense band observed in the range 300−280 cm^{-1} in the Zn, Cd, and Hg compounds and around 360 cm^{-1} in the Pd and Pt compounds is attributable to ν(M−S), and those appearing in the ranges 350−330 and 330−310 cm^{-1} or at 500 and 490 cm^{-1} to ν(M−N) vibrations.[38] In the Pd and Pt compounds this latter pair are very close together; in the others it is probably the higher frequency band that corresponds to the pyridine nitrogen atom, the M−N(1) distances being slightly shorter than the M−N(2) distances in the crystals of **7** · 2 DMSO and all the Cd complexes.

^{1}H-NMR Spectra

The ^{1}H-NMR signals of H4ML and the complexes are listed in the Supporting Information. The nonappearance of the N(3)H signal (at δ = 10.34 in the free ligand), in the spectra of **10** and **11** shows that in these complexes the ligand remains deprotonated in DMSO solution. The deshielding of N(4)H in these compounds is probably due to withdrawal of charge from N(4) as the result of an increase in charge delocalization upon complexation through the thiocarbonyl sulfur atom; the shielding of the N(4) methyl protons is attributable to the same mechanism. The H(1) signal shifts upfield in the Pd complex because coordination

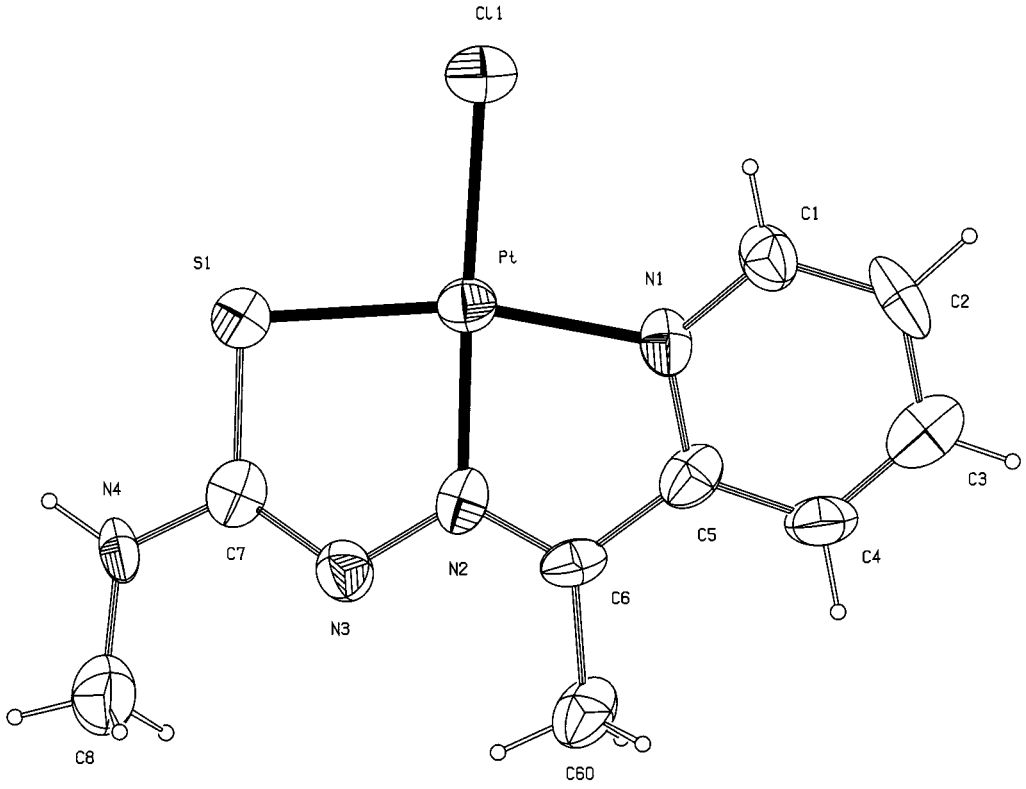

Figure 8. Molecular structure of the platinum complex **11**

through the pyridine nitrogen atom prevents H(1) from being deshielded, as it is in the free ligand, as the result of the anisotropy of the C(6)=N(2) bond and the proximity of the nitrogen atom with sp^2 hybridization.[39] In the Pt complex, on the other hand, the H(1) signal shifts downfield (as in the complex of Pt^{II} with 1-phenyl-2-formylpyridine thiosemicarbazone[40]), possibly due to the replacement of the chloride ion *trans* to the azomethine nitrogen atom by a DMSO molecule. In the $[M(H4ML)X_2]$ complexes the persistence of the N(3)H signal shows that this proton is retained in DMSO solution. The downfield shifts of the N(3)H and N(4)H signals, which increase in the order Cd < Zn < Hg, are attributable to coordination through the azomethine nitrogen atom and thiocarbonyl sulfur atom, respectively, and/or to the formation of hydrogen bonds between N(3)H [and to a much lesser extent N(4)H] and DMSO.

^{13}C-NMR Spectra

The ^{13}C-NMR signals of H4ML and all the complexes except **4**, for which we were unable to obtain a spectrum of adequate quality, are listed in the Supporting Information. The deshielding of C(7) and C(8) in the [M(4ML)Cl] complexes is attributable to a combination of the inductive effect of the metal and the move towards the thiol form induced by complexation. The simultaneous shift of the C(6) signal to higher field and that of C(60) to lower field is in consonance with coordination through the azomethine nitrogen atom in these compounds, whereas coordination through the pyridine nitrogen atom is pointed to by the behaviour of the pyridine carbon signals [shielding of the *ortho*-carbon atoms C(1) and C(5), deshielding of the others], which is qualitatively similar to their behaviour in the pyridinium ion[41] and in the protonated form of other thiosemicarbazones derived from 2-acetylpyridine.[40] In the $[M(H4ML)X_2]$ complexes C(8) (δ = 31.27) is deshielded (except in **1** and **2**) but C(7) (δ = 179.24) is shielded (although **1** is again an exception); the greatest shielding is shown in the complexes of the "*soft*" metal Hg. The other carbon signals exhibit more or less the same pattern in $[M(H4ML)X_2]$ as in [M(4ML)Cl], although the pyridine carbon shifts are generally less marked.

^{113}Cd-, ^{195}Pt and ^{199}Hg-NMR Spectra

The ^{113}Cd-NMR spectra of the Cd compounds show a single signal at δ = 363.7, 345.7, or 279.8 for the Cl, Br, and I derivatives, respectively. The nuclide is thus less shielded than in the corresponding halide CdX_2 in DMSO,[42] especially in the case of the Cl derivative. The progressive increase in shielding upon replacement of Cl by Br and of Br by I is in keeping with the decreasing electronegativity of the halogen, and the observed chemical shifts are within what may be expected for pentacoordinate halide complexes.[43]

Of the mercury compounds, only **7** was sufficiently soluble for ^{199}Hg-NMR spectroscopy. The spectrum obtained exhibits a single signal at δ = −1092.4, which is compatible with pentacoordination to the extent that it shows the nu-

Table 5. Diameters [mm] of growth inhibition zones in in-vitro antifungal activity assays (6.0 indicates no inhibition)

clide to be more shielded than is usual in tetrahedral complexes of the form HgL_2Cl_2.[44]

The Pt^{II} complex give rise to single, relatively sharp ^{195}Pt resonance at $\delta = -3092$. This supports the idea that the coordination mode of of the platinum(II) complex in solution is similar to that observed in the solid state; there is probably no exchange of the Cl^- ion for another donor.[40]

Biological Results

H4ML and the complexes were assayed in vitro for antifungal activity against the pathogens *Aspergillus niger* and *Paecilomyces variotii* (for previous data for H4ML see ref.[45]). Table 5 lists the results obtained with the compounds that at some concentration inhibited fungal growth, together with those obtained with the currently prescribed drug nystatin. Only the zinc complexes displayed some activity: At a concentration of 600 μg·mL^{-1} **1** inhibited *A. niger* rather more than either H4ML or nystatin, and at a concentration of 1000 μg·mL^{-1} both **1** and **2** inhibited *P. variotii*, though considerably less than nystatin did.

Experimental Section

General: All commercial reagents were Aldrich, Merck, or Ventron reagent-grade products. – Elemental analysis was performed with a Carlo Erba 1108 analyser. – Melting points were determined with a Büchi apparatus. – Infrared spectra were recorded with a Mattson Instruments Cygnus 100 FTIR spectrometer using KBr discs for spectra run from 4000 to 400 cm^{-1} and polyethylene-sandwiched Nujol mulls for the range 500–100 cm^{-1}. – UV/Vis spectra and reflectance spectra were recorded with a Shimadzu UV-3101PC spectrophotometer. – ^{1}H- and ^{13}C-NMR spectra were run with a Bruker WM-300 using DMSO as internal reference; chemical shifts are referred to TMS. ^{113}Cd-, ^{195}Pt-, and ^{199}Hg-NMR spectra were run with a Bruker WM-250 using DMSO solutions of about 10^{-2} M, and are referred to 0.1 M $Cd(ClO_4)_2$, H_2PtCl_6, and $HgMe_2$, respectively.

2-Acetylpyridine 4-Methylthiosemicarbazone (H4ML): H4ML was synthesized using the general procedure by Klayman et al.[3][46] for condensation of amines with aldehydes or ketones. To an aqueous solution of 4-methylthiosemicarbazide heated to 60 °C was slowly added a solution of an equimolecular amount of 2-acetylpyridine in ethanol. The reaction mixture was refluxed for 2 h, and upon cooling afforded a whitish crystalline solid which was filtered off and recrystallized from warm ethanol. After storage at low temperature, the remaining recrystallization solution afforded crystals suitable for study by X-ray diffraction. Yield 98%, m.p. 176 °C. – $C_9H_{12}N_4S$ (208): calcd. C 51.8, , H 5.8, N 27.0; found C 51.8, H 6.2, N 26.7.

Preparation of the Complexes: Complexes of the form $[M(H4ML)X_2]$ (M = Zn^{II}, Cd^{II}, Hg^{II}; X = Cl, Br, I) (**1**–**9**) were obtained by treating H4ML with the corresponding metal salts in a 1:1 molar ratio in ethanol. After prolonged stirring (about 1 week) at room temperature, the reaction mixture afforded solids (generally microcrystalline) that were filtered off, washed with ethanol, and vacuum-dried. In the cases of the cadmium complexes and $[Hg(H4ML)Cl_2]$ it was possible to obtain single crystals by redissolving the solids in DMSO and slowly evaporating the sol-

vent. − For [Pd(4ML)Cl] and [Pt(4ML)Cl] (**10** and **11**) the metal salts were dissolved in water and the reaction mixture was refluxed for 1 h. Evaporation of the solvent from the filtered reaction mixture at room temperature gave monocrystals suitable for study by X-ray diffraction.

X-ray Crystallography: Crystals of H4ML, **4**−**7**, **10**, and **11** suitable for X-ray diffraction were mounted on glass fibres and transferred to an Enraf Nonius CAD4 diffractometer. Accurate unit-cell parameters and an orientation matrix were determined by least-squares refinement of the setting angles of a set of well-centred reflections (SET4)[47] in the θ range 6.1−11.7 (H4ML), 9.0−13.0 (**4**), 4.6−12.0 (**5**), 5.7−13.2 (**6**), 7.3−14.9 (**7**), 6.1−13.3 (**10**), and 4.9−13.0° (**11**). Reduced cell calculations did not indicate higher lattice symmetry.[48] Crystal data and details of the data collection and refinement are given in Table 6. Data were corrected for Lp effects and for observed linear decay of the reference reflections. An empirical absorption correction (DIFABS)[49] was applied for all compounds. The structures were solved by automated Patterson or direct methods and subsequent difference Fourier techniques (SHELX86)[50] and refined on F (SDP/VAX)[51] or F^2 (SHELXL97).[52] Hydrogen atoms were included in the refinement in calculated positions riding on their carrier atoms. In two structures, a DMSO molecule proved to be disordered and a disorder model consisting of two (**4**) or three (**5**) alternative sites was included in the refinement; the occupation factors for **4** were 0.75 [S(31)] and 0.25 [S(32)] and for **5** were 0.40, [S(31)], 0.40, [S(32)], and 0.20 [S(33)]. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography.[53] Geometrical calculations and illustrations were performed or generated with the SHELXL97,[52] ZORTEP,[54] and PLATON98[55] packages. Crystallographic data for the structures reported in this paper (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-106651 and -106653 to -106658. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

$EuPdIn_2$, $YbPdIn_2$, and $YbAuIn_2$: Syntheses, Structures, and Properties of New Intermetallic Compounds with Ordered Re_3B-Type Structure

Yaroslav V. Galadzhun,[a] Rolf-Dieter Hoffmann,[a] Gunter Kotzyba,[a] Bernd Künnen,[a] and Rainer Pöttgen*[a]

Keywords: Europium / Ytterbium / Indium / Intermetallic compounds / Ferromagnetism

The new compounds $EuPdIn_2$ (**1**), $YbPdIn_2$ (**2**), and $YbAuIn_2$ (**3**) have been synthesized by high-frequency melting of the elements in sealed tantalum tubes and subsequent annealing at about 900 K. Their crystal structures have been determined by single-crystal X-ray diffraction techniques. Compounds **1**, **2**, and **3** crystallize with the $MgCuAl_2$-type structure (space group *Cmcm*), a ternary ordered version of the Re_3B type. Structural elements in these compounds are transition metal centered trigonal prisms made up of the rare earth and indium atoms. The transition metal (T) and indium atoms form a three-dimensionally infinite $[TIn_2]$ polyanionic network in which the large rare earth metal atoms occupy one-dimensional pentagonal tubes. A semiempirical band structure calculation on **1** reveals a non-vanishing density-of-states (DOS) at the Fermi level. The strongest bonding interactions are found for the In–In and Pd–In contacts; the Eu–Pd and Eu–In interactions are much weaker. Magnetic investigations indicate divalent character of the ytterbium atoms in **2**, showing negative susceptibilities below room temperature. Compound **1** exhibits Curie–Weiss behavior above 50 K with an experimental magnetic moment of 7.8(1) μ_B, thus indicating divalent europium. Ferromagnetic ordering was observed at T_C = 14.5(5) K, with a saturation moment of 6.8(1) μ_B/Eu at 5.5 T and 4 K, as determined from magnetization measurements. Compounds **1** and **2** are found to be metallic conductors.

Introduction

The ternary systems rare earth (RE)/transition metal (T)/indium have been extensively studied in the course of phase analytical investigations and crystal structure determinations.[1][2] The structures of a multitude of ternary compounds of this type are governed by two- or three-dimensionally infinite polyanions made up of the transition metal and indium atoms. The rare earth metal atoms, as the most electropositive component, are located within cavities or channels of the $[T_xIn_y]$ networks.

Investigations to date have mainly been focused on compounds with trivalent rare earth metal atoms, whereas relatively little information is available on compounds with alkaline earth metals, europium, or ytterbium as the electropositive component. A reason for this is most certainly the more complicated synthesis conditions required for the latter systems.

Most of the compounds $RE_xT_yIn_z$ with trivalent rare earth metals are easily accessible by means of arc-melting of the elemental components. However, due to the low boiling temperatures of the alkaline earth metals, europium, and ytterbium, such a synthetic approach employing arc-melting techniques would invariably result in large weight losses due to evaporation of these volatile metals. We have now succeeded in overcoming these experimental difficulties by modifying the synthesis conditions: (i) alkaline earth compounds such as CaAuIn[3] can be prepared in a quantitative manner by reacting the elements in glassy carbon crucibles in a novel, water-cooled sample chamber in a high-frequency furnace[3]; (ii) compounds with europium and ytterbium as the electropositive component are best prepared by high-frequency melting of the elements in sealed tantalum containers in a water-cooled quartz glass apparatus. The latter technique was first employed in syntheses of the stannides YbPtSn and $Yb_2Pt_3Sn_5$.[4] We have now extended these syntheses to indium compounds and have succeeded in preparing the new compounds $EuPdIn_2$, $YbPdIn_2$, and $YbAuIn_2$ reported herein. The present paper also deals with structure determinations and an analysis of the chemical bonding in these systems, as well as a detailed investigation of their physical properties.

Results and Discussion

Crystal Structures and Chemical Bonding of $EuPdIn_2$, $YbPdIn_2$, and $YbAuIn_2$

The new intermetallic compounds **1**, **2**, and **3** each adopt the $MgCuAl_2$-type structure,[5] a ternary ordered version of the Re_3B type.[6] As a representative example, a projection of the $EuPdIn_2$ structure is presented in Figure 1. From a geometrical point of view, the indium and europium atoms in **1** form slightly distorted trigonal prisms (every other prism is shifted by half the translation period *a*), and these prisms have palladium atoms at their centers.

The Pd−In distances (Table 1) of 277 and 284 pm in **1** agree well with the sum of Pauling single bond radii of 278 pm.[7] Similar distances have also been observed in the distorted tetrahedral [PdIn] polyanion in equiatomic EuPdIn (282 and 283 pm).[8] Due to the twofold higher indium con-

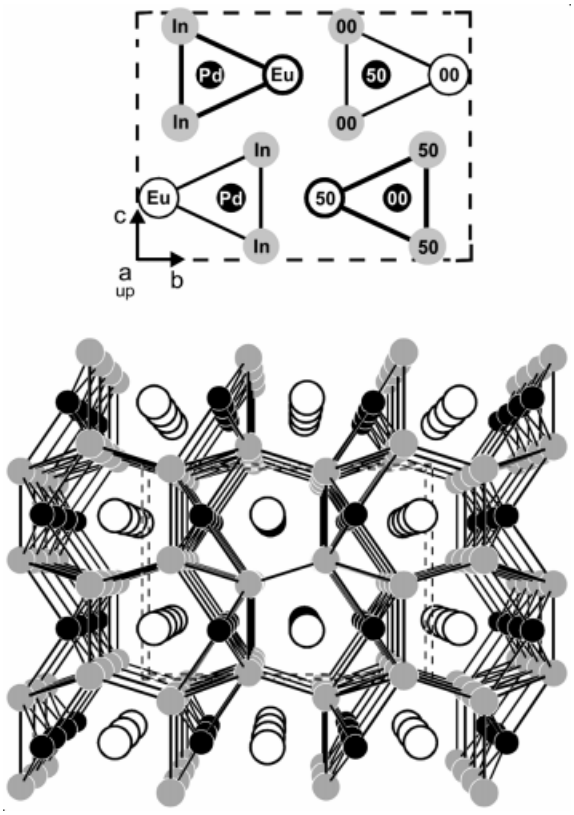

Figure 1. Projection (upper part) of the crystal structure of $EuPdIn_2$ onto the *yz* plane, emphasizing the topological arrangement of palladium-centered trigonal prisms made up of europium and indium atoms (black filled, open, and grey filled circles, respectively). The height of the atoms is given in the upper part in hundredths. In the lower part, a perspective view of the same orientation is depicted, showing an outline of the polyanionic network of palladium and indium atoms

tent, **1** has a higher degree of linkage of indium atoms, four contacts at 308 (1×) and 324 pm (3×), as compared to EuPdIn, which has one contact at 326 pm. The indium atoms together with the palladium atoms form a three-dimensionally infinite $[PdIn_2]$ polyanion, in which the europium atoms occupy distorted pentagonal channels as outlined in Figure 1. Nevertheless, there are still quite short Eu−Pd (297 and 323 pm) and Eu−In (341 pm) contacts, indicating a weak linkage of the europium atoms to the pentagonal channels. This rough assessment of the chemical bonding in **1**, made by considering only the interatomic distances, is nicely supported by the results of an extended Hückel calculation, which is discussed in detail below.

The density-of-states (DOS) for **1** is presented in Figure 2. In the DOS, the palladium contribution extends mainly from −10 eV to −8 eV, while the indium contributions extend over the whole valence region. The non-vanishing DOS at the Fermi level is in agreement with the metallic behavior discussed below. A Mulliken population analysis reveals the net charges Eu: +1.78, Pd: −1.16, In: −0.31, with the palladium atoms as the most electronegative component of **1**, in good agreement with Pearsons′ absolute electronegativities[9] of 4.45 and 3.10 eV for palladium and indium, respectively. Unfortunately, no value for the absolute electronegativity of europium is listed by Pearson.[9] Since europium exhibits chemical behavior similar to that of the alkaline earth metals calcium (χ = 2.2 eV) and strontium (χ = 2.0 eV), we assume a comparably low χ value for this rare earth element.

Table 1. Interatomic distances (pm) in the structures of $EuPdIn_2$, $YbPdIn_2$, and $YbAuIn_2$; all distances of the first coordination sphere are listed; standard deviations are all 0.2 pm or less

	$EuPdIn_2$			$YbPdIn_2$			$YbAuIn_2$

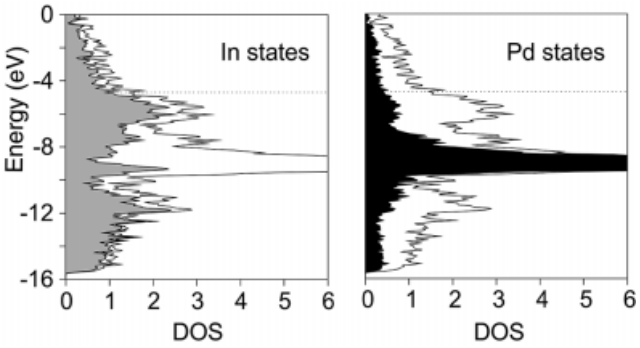

Figure 2. Density-of-states (DOS) for $EuPdIn_2$ with the indium and palladium contributions emphasized in grey and black, respectively; the Fermi level E_F is drawn as a dotted line

The In−In distances in **1** are all shorter than in the tetragonal body-centered structure of elemental indium (a = 325.2 pm, c = 494.7 pm[10]), where each indium atom has four nearest neighbors at 325.2 pm and eight further neighbors at 337.7 pm. The strong bonding character of the In−In contacts in **1** is reflected by the highest overlap population (OP) of +0.522 (Figure 3). The close Pd−In contacts (277−284 pm) also show a significant overlap population of +0.390.

In contrast, the Eu−Pd (OP +0.022) and Eu−In (OP +0.039) overlap populations are much smaller, in agreement with our description in terms of a polyanionic $[PdIn_2]$ network. Bonding between the palladium and indium atoms within the network is much stronger than the interactions of the europium atoms in the distorted pentagonal

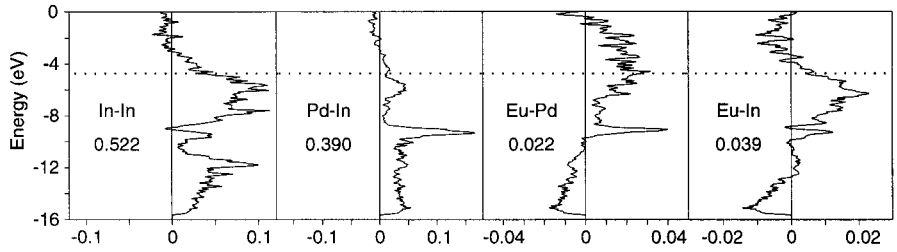

Figure 3. Chemical bonding from semiempirical crystal orbital overlap populations (COOP) for various bonding contributions in $EuPdIn_2$; the numbers represent the integrated values of the overlap population per bond, integrated up to the Fermi level (dotted line)

channels with the network. Chemical bonding in isotypic **2** and **3** is most likely analogous to that in **1**, with the palladium and gold atoms carrying most of the negative charge.

Magnetic Properties

The magnetic susceptibility of **2** as a function of temperature is plotted in Figure 4. Over the whole temperature range investigated the susceptibility of **2** is negative and has a value of $-6.2(2)\cdot10^{-9}$ m^3/mol at room temperature. At first sight, these findings appear to suggest diamagnetism. This, however, would seem to be at variance with the metallic behavior discussed below. In fact, the core diamagnetism of **2** dominates compared to the much weaker Pauli contribution of the conduction electrons, thus resulting in slightly negative susceptibilities. Similar magnetic behavior has recently been observed for the indium-rich binary compounds TIn_3 (T = Co, Ru, Rh, Ir)[11][12] and the isotypic calcium compounds $CaTIn_2$ (T = Pd, Pt, Au).[13] A reasonable correction for the core diamagnetism, however, is difficult to perform, since no reliable increments for ytterbium, palladium, and indium are available in the literature. Rough estimates for the diamagnetic contributions in TIn_3 (T = Co, Rh, Ir) and $CaAuIn_2$ are reported in ref.[12] and ref.[13]

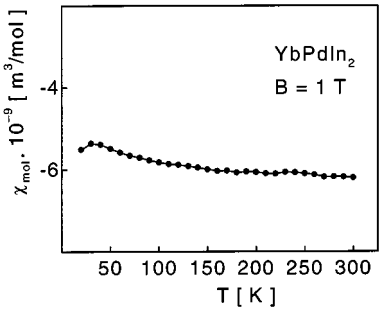

Figure 4. Temperature dependence of the magnetic susceptibility of **2**, measured at a magnetic flux density of 1 T

Compound **1** shows Curie−Weiss behavior above 50 K (Figure 5). An evaluation of the data above 50 K resulted in an experimental magnetic moment of 7.8(1) μ_B/Eu and a paramagnetic Curie temperature of $\theta = 22(1)$ K. Ferromagnetic ordering of the europium atoms was detected at low temperatures (Figure 6). The precise Curie temperature of $T_C = 14.5(5)$ K was determined from the derivative $d\chi/dT$ of a kink-point measurement (inset of Figure 6) at a magnetic flux density of 0.002 T. The derivative additionally revealed a further feature at 12.5(2) K, probably due to a very small impurity of EuPdIn,[8] which has a Néel temperature of 13.0 K.[8][14] Nevertheless, our Guinier powder pattern revealed a single-phase material. The magnetization curve at 50 K (Figure 7) was linear, as expected for a paramagnet. At 4 K, we observed a strong increase of the magnetization, even at very low field strengths. The magnetization curve tends to saturation at just 1 T and shows only a small hysteresis with negligible coercitivity and remanent magnetization. On the basis of these features, **1** can clearly be classified as a soft ferromagnet. At the highest obtainable magnetic field of 5.5 T, the saturation magnetization amounts to $\mu_{SM(exp)} = 6.8(1)$ μ_B/Eu, in good agreement with the maximum possible value of $\mu_{SM(calcd)} = 7.0$ μ_B/Eu, indicating an almost fully parallel spin alignment.

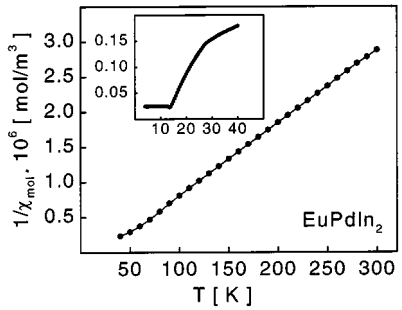

Figure 5. Temperature dependence of the reciprocal susceptibility of **1** determined at a magnetic flux density of 2 T; the low-temperature behaviour is shown in the inset

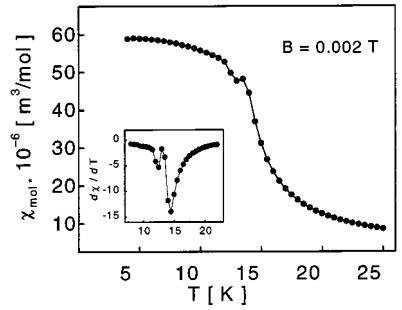

Figure 6. Low-temperature susceptibility (field-cooling mode) of **1** at 0.002 T (kink-point measurement). The inset shows the derivative $d\chi/dT$, which has a sharp peak at $T_C = 14.5(2)$ K. The second anomaly at 12.5(5) K is most likely due to a minor impurity of metamagnetic EuPdIn, which becomes magnetically ordered at 13.0 K[8][14]

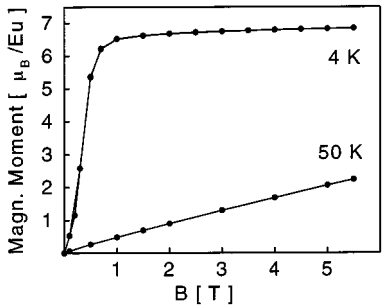

Figure 7. Magnetic moment vs. external magnetic flux density, B_{ext}, of **1** at 50 and 4 K

Electrical Conductivity

The temperature dependences of the specific resistivities of **1** and **2** are plotted in Figure 8. The specific resistivities of both compounds decrease with decreasing temperature, as is of course typical for metallic conduction. At room temperature, the values amount to 34 ± 5 μΩcm for **1** and 27 ± 5 μΩcm for **2**, indicating that both compounds are relatively good metallic conductors. The large margins of error account for the different values obtained with a series of samples. At about 4 K, the specific resistivities of **1** and **2** fall to 68% and 59% of their room temperature values, respectively. While no anomaly can be detected in the temperature dependence of ρ in the case of **2**, a very small drop is seen for **1** at the Curie temperature. This most likely results from a freezing of spin-disorder scattering below T_C.

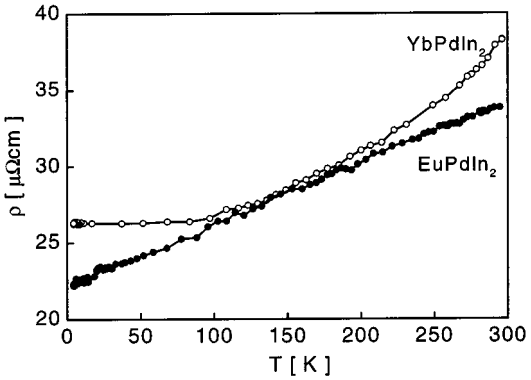

Figure 8. Temperature dependence of the specific resistivities of **1** and **2**

Experimental Section

Syntheses: Starting materials were europium ingots (Johnson Matthey), ytterbium rods (Kelpin), palladium powder (Degussa), gold wire (Degussa, ∅ 1 mm), and indium "teardrops" (Johnson Matthey), all with stated purities in excess of 99.9%. The moisture-sensitive ingots of europium and ytterbium were stored in vacuo prior to carrying out the reactions. The elemental components were mixed in the ideal 1:1:2 atomic ratio and sealed in tantalum tubes under an argon pressure of about 800 mbar. The argon was purified by passage over silica gel, molecular sieves, and titanium sponge (900 K). The tantalum tubes were then annealed in a novel, water-cooled sample chamber[4] in a high-frequency furnace (Kontron, Roto-Melt). In a first step, the tubes were heated with the maximum power output of the high-frequency generator. The occurrence of the strongly exothermic reactions was evident from a heat flash that lasted for about two seconds. The annealing temperature was then lowered to about 1000−1100 K for one minute and then raised to the maximum possible once more. Subsequently, the tubes were annealed for 30 min at about 800−900 K. The reactions resulted in polycrystalline products, which could easily be separated from the tantalum tubes. No tantalum contamination could be detected by EDX analyses. While **1** and **2** were obtained as single-phase products, **3** was accompanied by very small amounts of YbAuIn[15] (Fe_2P type) and elemental indium. Products **1**, **2**, and **3** are grey in compact form, while single crystals are silvery with a metallic lustre. Powders and compact pieces of these intermetallic compounds are stable in air; no deterioration was observed over a period of several weeks.

X-ray Investigations: Guinier powder patterns of all samples were recorded with Cu-$K_{\alpha 1}$ radiation using α-quartz (a = 491.30 pm, c = 540.46 pm) as an internal standard. The indexing of the patterns was facilitated by comparison of the observed patterns with calculated ones,[16] taking the atomic positions from the structure refinements. Single-crystal intensity data were collected at room temperature using a four-circle diffractometer (Enraf-Nonius, CAD4) with graphite-monochromated Mo-K_α radiation (λ = 71.073 pm) and a scintillation counter with pulse height discrimination. The scans were taken in the ω−2θ mode. Absorption corrections were applied on the basis of Ψ-scan data. Single crystals of **1**, **2**, and **3** were isolated from the samples by mechanical fragmentation. Buerger precession photographs of the three compounds (reciprocal layers *hk*0 and 0*kl*) showed C-centered orthorhombic lattices with symmetry *mmm*. The systematic extinctions (*hkl* only observed for $h + k = 2n$; 0*kl* only with $k = 2n$) led to the space groups *Cmcm* (No. 63) and $Cmc2_1$ (No. 36), of which the centrosymmetric group was found to be the correct one during the structure refinements. All relevant crystallographic data and experimental details are listed in Table 2.

The starting atomic parameters were obtained by direct methods using an automatic interpretation as implemented in SHELXS-86.[17] The structures were subsequently refined with anisotropic displacement parameters for all atoms using SHELXL-97 (full-matrix least-squares on F^2).[18] Final difference Fourier syntheses were flat and revealed no significant residual peaks. The results of the refinements are summarized in Table 2. Atomic coordinates and interatomic distances are listed in Tables 3 and 1, respectively. Further details of the crystal structure determinations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), by quoting the registry numbers CSD-410438 ($EuPdIn_2$), CSD-410437 ($YbPdIn_2$), and CSD-410436 ($YbAuIn_2$).

Electronic Structure Calculations: Semiempirical band structure calculations were based on an extended Hückel Hamiltonian,[19][20] where off-site Hamiltonian matrix elements were evaluated according to the weighted Wolfsberg−Helmholz formula,[21] minimizing counter-intuitive orbital mixing. The extended Hückel parameters used for the calculations were taken from refs.[22][23] (ξ orbital exponents in parentheses): Eu 6s −4.663 eV (1.345) and Eu 6p −3.403 eV (1.231); Pd 5s −9.224 eV (1.658), Pd 5p −3.279 eV (1.182), and Pd 4d −8.985 eV, ξ_1 = 3.746, c_1 = 0.815, ξ_2 = 1.501, c_2 = 0.338; In 5s −10.79 eV (2.02) and In 6p −5.35 eV (1.47). The eigenvalue problem was solved in reciprocal space at 144 k points within the irreducible wedge of the Brillouin zone by using the YAEHMOP code.[24]

Table 2. Crystal data, details of the data collections, and structure refinements of $EuPdIn_2$ (**1**), $YbPdIn_2$ (**2**), and $YbAuIn_2$ (**3**) (all with space group *Cmcm* and $Z = 4$)

Physical Measurements

Magnetic Data: The magnetic susceptibilities of polycrystalline pieces of **1** and **2** were determined with an MPMS SQUID magnetometer (Quantum Design, Inc.) in the temperature range 4.2−300 K, with magnetic flux densities of up to 5.5 T.

Electrical Conductivity: The specific resistivities of **1** and **2** were measured on small irregular shaped blocks using a conventional four-probe technique over the temperature range 4.2−300 K. Cooling and heating curves were identical within the error limits and were reproducible for different samples.

Acknowledgments

We thank Prof. Wolfgang Jeitschko for his interest and support of this work. We are also indebted to Dipl.-Ing. Ute C. Rodewald for the single-crystal data collections, to Klaus Wagner for the EDX analyses, and to Dr. Wolfgang Gerhartz (Degussa AG) for generous gifts of palladium powder and gold wire. Ya. V. G. is indebted to the DAAD for a research stipend. This work was financially supported by the Deutsche Forschungsgemeinschaft (Po573/1-2) and the Fonds der Chemischen Industrie.

A Molecular Mechanics Force Field for Alkylcobaloximes, a Model of Vitamin B_{12} Coenzyme – Implications of Steric and Electronic Factors in the Co–C Bond Cleavage

Silvano Geremia,[a] Mario Calligaris,[a] and Lucio Randaccio*[a]

Keywords: Cobaloximes / Vitamin B_{12} / Semiempirical calculations / Force field / Conformation analysis / Cone angles / Crystal structure

Molecular mechanics force field constants have been derived for alkylcobaloximes, (alkyl)Co(DH)$_2$L (DH = monoanion of dimethylglyoxime and L = planar N-donor ligand), implementing the AMBER force field. Atomic charges have been calculated by the semiempirical ZINDO/1 method. Stretching and bending constants have been calculated by the Badger and Halgren equations, with the introduction of simple functions for the description of the electronic influence of the axial ligands on the coordination geometry. 26 parameters have been optimized, by the Simplex method, to fit 4523 bond lengths and angles of 52 alkylcobaloxime accurate crystal structures. In spite of the oversimplification of the adopted method for the description of the electronic effects, this approach provides a good description of the metal coordination geometries. The root-mean-square deviations of the calculated bond lengths and angles from the experimental values average to 0.023 Å and 1.4°, respectively. The molecular mechanics results are discussed in terms of the steric properties of the axial ligands and correlated with their calculated cone angles. The force field has been used to analyse some conformational features of these compounds, such as the influence of the rotation of the axial ligands on their coordination geometry. The calculated energy for the Co–N rotational barrier agrees well with the experimetal ones derived from dynamic and saturation ^{1}H-NMR spectroscopy in (alkyl)Co(DH)$_2$(2-NH$_2$-py). In order to have more experimental data for this analysis, the crystal structures of two new cobaloximes, (CH$_2$Cl)Co(DH)$_2$L with L = py, **1**, and 1-Me-Im, **2**) have been determined. The results of a conformational analysis on ribosyl-imidazole derivatives, taken as a suitable vitamin B_{12} coenzyme model, suggest that the 1-Me-imidazole-like ligands have a significantly greater rotation freedom with respect to the benzimidazole-like ones, but cause similar stretchings of the Co–C bond, and a significantly less stretching of the Co–N one. Implications for the recent findings on the binding mode of the coenzyme B_{12} in the enzyme active site are discussed.

Introduction

For many years, simple organometallic octahedral Co^{III} complexes have been proposed as vitamin B_{12} coenzyme models and a great amount of work on these systems has been performed in solution and in the solid state. Such extensive studies have provided a foundation for understanding the behaviour of the more complex vitamin B_{12} system.[1] The structurally accurate characterization of numerous complexes, RCo(chel)L, with several alkyl groups, R, and neutral Lewis bases, L, with chel = (DH)$_2$ (cobaloximes), (DO)(DOH)pn (Costa model), salen, saloph,[2] has supplied an enormous amount of data,[1b,1c,3] which has allowed in-depth analysis of the variations in geometry of the R−Co−L fragment, on the basis of the electronic and steric properties of the R and L groups[4] as well as rationalization of the relationships between solution behaviour and structure.[4−6]

It was deduced that, irrespective of the identity of the L and chel ligands (including corrin), the influence of R on the geometry of the R−Co−L fragment is evidenced by a lengthening of the Co−L bond by up to 0.15 Å as the σ-donating ability of R increases (electronic *trans* influence) and by a lengthening of the Co−C bond by up to 0.20 Å as the bulk (steric *cis* influence) and the σ-donating ability of R increase.[4b] Recently, a statistical analysis,[4b] based on the Principal Component Analysis (PCA), of the variation with R of several experimental properties of alkylcobaloximes has suggested that the geometry of the axial fragment may be described fairly well by introducing three parameters, t_1, t_2, and t_3. Parameters t_1 and t_2 reflect the electronic and steric properties of R, respectively, whereas t_3 is related to the Co−CH$_2$−X angular deformation. It was found that the Co−C distances are a linear combination of the three parameters, whereas the axial Co−N distance is a linear function of only t_1.[4b]

The influence of the bulk of L on the Co−L (steric *cis* influence) and on the Co−C (steric *trans* influence) distances has been structurally detected,[7] the latter being particularly pronounced when R has a large bulk.[8] Analogously, the Co−C bond dissociation energies (BDE) decrease with the increase in bulk of the phosphane in the two series RCo(DH)$_2$PR$_3$ when R = CH(Me)Ph and CH$_2$Ph.[9] Structural evidence of the electronic influence of L on the Co−C bond is not so apparent.[10] On the other hand, Halpern has found that the Co−C BDE increases with the increase of the p*K*a of 4-substituted pyridines in the series

[CH(Me)Ph]Co(DH)$_2$(4-X-py).[11] However, a large deviation from the BDE trend was detected when L = 2-NH$_2$-py,[12a] due to the steric interaction of 2-NH$_2$-py with the equatorial moiety, which induces a lengthening of the axial Co−N bond by about 0.1 Å with respect to the analogous py derivative.[12b] The Co−L bond is significantly influenced by the nature of chel (*cis* influence), while the Co−C bond is essentially unaffected,[1c] although, very recently, it has been reported that the Co−C bonds in (DO)(DOH)pn complexes are slightly longer (0.01−0.03 Å) than in cobaloximes.[6] Finally, it has been observed that the geometry of the Co(DH)$_2$ moiety is not affected by the nature of the axial ligands.[1b,1c]

All these studies have given qualitative evidence of many properties of the Co coordination sphere in cobaloximes, which in many respects parallel those apparent in the vitamin B$_{12}$ system.[1][13] Thus, as illustrated above, many chemical properties of cobaloximes and cobalamins, which are related to the metal coordination, involve steric influences. The first step in the catalytic cycle of the B$_{12}$-dependent isomerases is believed to be the homolytic cleavage of the Co−C bond and steric effects, acting in several ways, have been suggested to be responsible of the Co−C bond labilization.[13][14] The task of quantifying steric interactions is not a simple one, although arguments invoking steric effects are intuitively appealing. Questions such as this should, in principle, be amenable to investigation by molecular mechanics (MM) methods, which have been proved to be a useful approach to investigate the structure and reactivity of coordination compounds.[15−17] The combined application of X-ray crystallography and MM methods to the study of structural and conformational properties of metallo-organic systems represents a useful approach, and development and parametrization of suitable force fields are receiving increasing attention.[18−21] Many reports which give force fields for Co^{III} compounds with N-donor ligands are available.[16] However, only recently have force field parameters for cobalamins been proposed, based on the structures of six derivatives,[19a] and for cobaloximes, on the basis of a large number of structures.[19b] The last force field parameters for the Co−C bond and the Co−C−C angle have been transferred to the cobalamins, showing that the previously reached conclusions[19a] remained essentially unchanged.[19b] However, all these force fields, which we can call "conventional", do not take into account the influence of electronic effects (e.g. *trans* influence) on the molecular geometry. An attempt to face this problem has been proposed by Rappé et al.,[19c] with the introduction of empirical fractional bond orders, in their Universal Force Field (UFF). However, this correction is introduced a posteriori to improve the agreement between the calculated and the experimental distances. This approach does not allow reproduction of the observed continuous variation of the axial bond lengths when the bulk and the σ-donating ability of the axial ligands are varied, as it occurs in RCo(DH)$_2$L.[22][23]

Recently, a new method for the optimization of force-field parameters, fitting experimental bond lengths and angles, and using empirical functions for the calculation of stretching and bending constants, has been described.[24] The present paper describes the derivation of force-field parameters for alkylcobaloximes, applying the above method, implemented with the introduction of a specific function, based on a fundamental parameter, which is assumed to take into account a priori the influence of the electronic factors on the coordination bond lengths and angles. Such an "unconventional" force field should permit the quantification of the intramolecular steric interactions contributing to the conformational properties. This should also allow a clear distinction of the origin (steric or electronic) of the observed structural deformations induced by the change of the axial ligands, such as the axial bond elongation, the orientation of the axial ligands with respect to the equatorial one and deformations in the equatorial moiety. In fact, there are many questions still open which are directly linked with the problem of the Co−C labilization.

The force-field parameters have been optimized to reproduce the X-ray structures of the 52 alkylcobaloximes, containing planar N-donor ligands, listed in Table 1. These include two new cobaloximes, (CH$_2$Cl)Co(DH)$_2$L, with L = py (**1**) and 1-MeIm (**2**), whose crystal structure have been determined in order to obtain further experimental data useful for the study of the influence of the orientation of L upon the Co−C and Co−N bond lengths. Finally, the biochemical implications of the MM calculations in the vitamin B$_{12}$ coenzyme model are discussed.

Results and Discussion

Methods

The AMBER force field[25] has been selected, in view of its successful application to other coordination compounds,[17][24] and the possibility of extension to the vitamin B$_{12}$ system. As known, in AMBER, the molecular strain energy, E, is given by the sum of deformation terms for bond lengths (d), bond angles (θ), and dihedral angles (ψ) (including improper torsion angles which model out-of-plane displacements), together with the van der Waals and electrostatic contributions:

$$E = \Sigma_b k^d(d - d^\circ)^2 + \Sigma_a k^\theta(\theta - \theta^\circ)^2 + \Sigma_d\{V_n/2[1 + \cos(n\psi - \psi_o)]\} + \Sigma_{ij}(a_{ij}/r_{ij}^{12} - b_{ij}/r_{ij}^{6} + q_iq_j/Dr_{ij})$$

with $a_{ij} = (\varepsilon_i\varepsilon_j)^{1/2}\ (r_i^* + r_j^*)^{12}$ and $b_{ij} = 2(\varepsilon_i\varepsilon_j)^{1/2}(r_i^* + r_j^*)^6$, where r^* and ε are the van der Waals radii and the energy well depth, respectively, for two atoms of the same type, q is the atomic charge and D the dielectric constant.

Although the oxime bridge hydrogen atoms are found either symmetrically positioned between the oxygen atoms or bonded to one oxygen atom, we have assumed that the bridge hydrogen atoms are fixed to lie on the median of the O···O segment (Figure 1). The H atom is bonded to both O atoms in order to avoid large tetrahedral distortions of

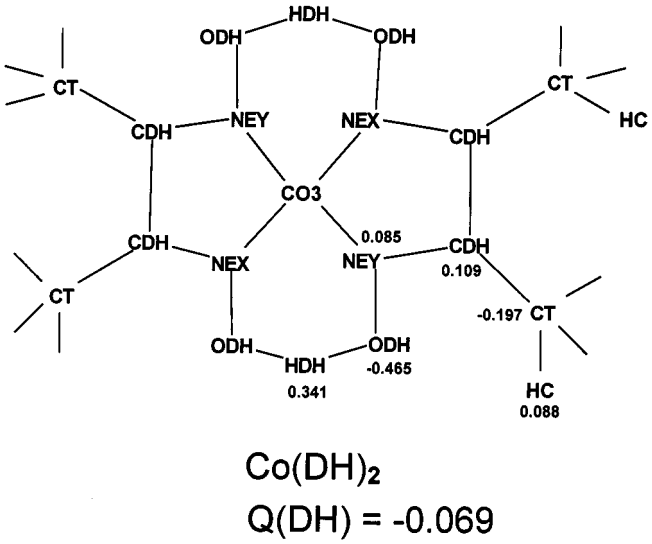

Figure 1. Atom types and charges for the equatorial $Co(DH)_2$ moiety

the equatorial moiety. Atom types are given in Figures 1 and the Supporting Information.

Energy calculations have been performed with a Pentium-200 PC, using the HYPERCHEM 4.5 molecular modeling package.[26] The Polak–Ribiere version of the conjugate gradient method was used in all energy minimizations, until the convergence criterion of 0.001 kcal mol^{-1} $Å^{-1}$ was reached.

As previously reported,[24] the potential constants for all $i-j$ bonds were calculated from Badger's rule,[27] $k^d_{ij} = [(A_{ij} - D_{ij})/(d^\circ_{ij} - D_{ij})]^3$, using the parameters proposed by Herschbach and Laurie;[28] while potential constants for the $i-j-k$ bond angles were calculated from the Halgren's equation:[29] $k^\theta_{ijk} = 1.75\ Z_iC_jZ_k\ (d_{ij} + d_{ik})^{-1}\ (\theta^\circ_{ijk})^{-2}$ $\exp[-2(d_{ij} - d_{jk})^2/(d_{ij} + d_{ik})^2]$. This approach allows automatic variation of the stretching and bending constants as a function of the reference bond lengths (d°_{ij}) and angles (θ°_{ijk}). For cobalt, two different C values (*cis* and *trans* bonds) and one Z value were assumed. Force-field constants, reported in Table 2, were optimized by an iterative procedure, in which the sum of the squares of the differences (Δ) between observed and calculated values were reduced upon variation of the parameters.[30] The observables are the bond lengths and angles of 52 accurate (crystallographic R index < 0.08) crystal structures of alkylcobaloximes (Table 1). Weights were assigned to the experimental data on the basis of the average estimated errors, $w = 1/\sigma^2$. Since several of the starting structures were taken from CSD (version 1997), where individual errors for bond lengths and angles are not reported, these were evaluated for each structure from the average differences among chemically equivalent parameters of the $Co(DH)_2$ moiety, $\bar{\sigma}$. In order to take into account the different accuracy in the atom location, related to the different electron density, the $\bar{\sigma}$ values were weighted on the basis of the atomic numbers Z, according to the equation $\sigma_w = [\Sigma(\bar{\sigma} \cdot Z \cdot n)]/\Sigma n$, where Z is the sum of atomic numbers of the atoms involved in the bond length or angle and n is the number of chemically equivalent parameters. In this calculation summations were extended over the different types of bond lengths or bond angles. The two σ_w values, for distances and angles, respectively, were used to calculate individual estimated errors as $\sigma = \sigma_w/Z$. The σ values obtained by this procedure well agree with the available experimental values, therefore providing a useful way to evaluate σ values for CSD data.

As for the previously reported Ru–sulfoxide complexes,[24] the optimization procedure was performed by adopting the Simplex method, in view of the non-linear nature of the equations and the facility of introducing restraints in the minimization.[31] Convergence was controlled by a goodness-of-fit (GOF) parameter defined as $[\Sigma w\Delta^2/(n_{obs} - n_p)]^{1/2}$, where n_{obs} = number of observables and n_p = number of parameters. Convergence was reached when the absolute relative difference between the lowest and the highest GOF values was less than 0.0001. During the preliminary refinement a marked discrepancy between the observed and calculated axial Co–N distance was found for the 2-NH_2-py derivative, together with relatively high differences between the axial Co–N–C bond angles. Change of the aminic group hydrogen atom type from H to H1 yielded a remarkable improvement, so that H1 was taken as the atom type for hydrogen atoms attached to nitrogen atoms. Torsional barriers around C–C and C–N bonds were calcu-

lated as in AMBER.[25] Barriers around coordination bonds were not considered.[32]

The observed bond lengths and, particularly, the coordination bond angles can be slightly modified by packing effects, which can force the molecule into a strained conformation. In order to simulate crystal packing effects, the torsional angles around single bonds and involving non-H atoms were constrained by a 16 kcal mol^{-1} energy barrier in the energy minimization to maintain the crystal structure conformation.

For the electrostatic contribution, atomic charges were calculated by the semi-empirical ZINDO/1 method, included in HYPERCHEM 4.5.[26] Charges of chemically equivalent atoms were averaged over the same ligands. The cobalt atom charges assured the electroneutrality of the complexes. Atom types and charges for the $Co(DH)_2$ moiety are shown in Figure 1, while for the R and L groups they are given in the Supporting Information, together with total charges, Q. The *vacuum* value (D = 1) was initially assumed for the dielectric constant. However, this value was refined since the inclusion of the dielectric constant in the optimization process ensures the proper scaling of the electrostatic contribution. The final value of 7.8 is consistent with the fact that we are considering solid-state and not gas-phase structures.

Since the Co−C and Co−N axial bonds are significantly influenced by the electronic nature of R,[1][4] the force-field parameter optimization procedure was carried out in two steps. In the first step, electronic effects were neglected, therby producing approximate parameters for the functions involving the equatorial ligand atoms, together with "average" d° values for the axial Co−C and Co−N bonds. At convergence (d°_{Co-C} = 1.964, d°_{Co-N} = 2.007 Å), the goodness of fit was quite reasonable: GOF = 3.48 for 4523 observables and 24 variables. However, as expected, the differences between observed and calculated Co−C and Co−N axial distances were rather high (see Table 3). In fact, in this step (constant d° values for Co−C and Co−N distances) the calculated axial distances can only reflect the steric contribution and not the electronic one. Thus, the differences (δ) between the calculated and observed axial distances should be related to the σ-donating ability of the R group. As a measure of the latter, the total electrostatic charge of R, Q, was taken. The validity of this choice is supported by the fairly good linear relationship (r = 0.91, n = 21) between Q and the available values of EP, which have previously been shown to provide an experimental measure of the electron-donating ability of R.[4a] In fact, the δ values for the Co−C and Co−N distances correlate well with Q, the correlation coefficients being 0.83 and 0.94, respectively.

Table 3. Average differences, <Δ>, between observed and calculated bond lengths [Å] and angles [°], together with rms values and number of observations, n, after the first and second step of the force field parameter optimization process; X, Y, Z represent generic non-metal atoms

Distances	n	first step <Δ>	rms	second step <Δ>	rms
Co−N equatorial	208	0.004	0.010	0.004	0.009
Co−N axial	52	−0.014	0.028	0.008	0.016
Co−C axial	52	−0.016	0.032	−0.003	0.020
X−Y equatorial	728	−0.009	0.017	−0.008	0.017
X−Y axial	592	−0.016	0.031	−0.016	0.031
All distances	1632	−0.010	0.024	−0.009	0.023
Angles					
Co−N−X equatorial	416	−0.1	0.6	−0.1	0.6
Co−C(N)−X axial	177	0.1	1.8	−0.1	1.8
X−Co−Y	780	−0.2	1.4	−0.2	1.3
All angles	2891	−0.1	1.4	−0.1	1.4

In order to take into account the different electronic effect of the R groups on the Co−C and Co−N axial distances,[1][4] in the second optimization step, the d° values of the Co−C and Co−N bonds were assumed to be a linear function of Q, according to Equations 1 and 2.

$$d^\circ_{Co-C} = a_{Co-C} + b_{Co-C}Q \quad (1)$$

$$d^\circ_{Co-N} = a_{Co-N} + b_{Co-N}Q \quad (2)$$

The coefficients of Equations 1 and 2 were optimized, together with all the other force-field parameters. At convergence, the GOF value reduced to 3.30 for n_{obs} = 4523 and n_p = 26.

Final values of the refined parameters are reported in Table 2, together with the calculated stretching and bending

constants. All force-field constants are reported in the Supporting Information.

The potential energy for the isolated molecules ($D = 7.8$) were explored using local Excel© Macro functions, which allow the minimization of the strain energy as the conformation of the molecule is varied through rotation around the axial Co−N bond, ψ. The torsional angle was varied in 5° steps from −180° to 180°, introducing a constraint of 1000 kcal mol^{-1}. The zero value of ψ was taken at the point where the plane of L bisects the oxime bridge. The minimum energy conformer was finally minimized using a convergence gradient of 0.001 kcal mol^{-1} $Å^{-1}$.

Cone angles for the axial ligands were calculated according to the Immirzi′s algorithm,[33] as modified in ref.[21], using the atom coordinates of the 52 energy minimized structures. The van der Waals radii used for the ligand atoms were those given by Bondi,[34] assigning a zero value to the metal-coordinated atoms. The solid cone angle Ω and the corresponding Tolman′s angle Θ were calculated at distances corresponding to the Co−C and Co−N d° values of Equations 1 and 2 and averaged for each axial ligand. The Ω and Θ values are given in Table 4 together with the d°(R) and d°(L) values.

X-ray Diffraction Analysis of Compounds 1 and 2

The ORTEP drawings with the atom numbering scheme for **1** and **2** are given in Figures 2 and 3, respectively. The schemes apply to both the crystallographically independent molecules A and B. The molecules A and B of **1** are very similar, while in **2** they display different orientations of both the axial groups with respect to the equatorial ligand, which cause a slight, but significant, difference in the Co−N axial distance and in the Co−C−Cl bond angles. In **1** the torsional angles around the Co−N(py) bond (ψ) and the Co−C bond (φ) are 4° and 74° in A, and 3° and 72° in B, respectively. On the other hand, in **2** the corresponding angles are 49° and −47° in A, and 38° and −105° in B.

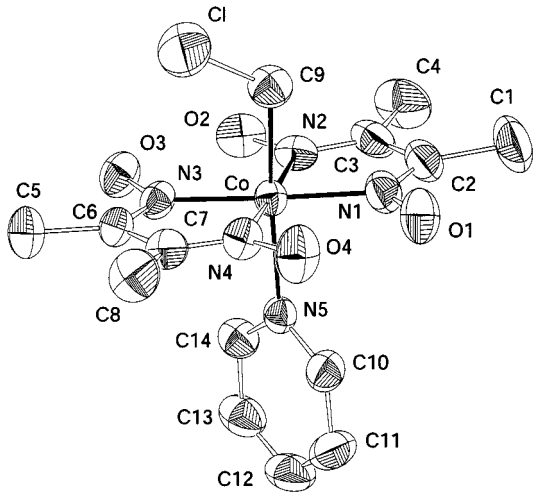

Figure 2. ORTEP drawing (50% thermal ellipsoids) of **1** together with he atom numbering scheme

It is of interest to compare the 1-Me-Im orientation in A and B with those found in other derivatives with R = Me, CH_2CH_2CN, and adamantyl. In the last derivative, the 1-Me-Im plane nearly bisects the oxime bridge ($\psi \approx 0°$), whereas in the others it approximately crosses the equatorial five-membered rings ($\psi \approx 90°$).[1c] This comparison indicates that there is significant conformational freedom for rotation around the Co−N(1-Me-Im) bond when R has a relatively small bulk. Conversely, the rotation is hindered in the case of very bulky R groups such as adamantyl, which imposes the bending of the equatorial moiety towards the *trans* N ligand and, consequently, forces the latter into the orientation with $\psi \approx 0°$. Such confor-

mational freedom is typical of Im and 1-Me-Im ligands, since in all the structurally characterized alkylcobaloximes containing planar N ligands − such as 1,5,6-Me_3-Bzm, 1,2-Me_2-Im and py − only the orientation with $\psi \approx 0°$ is found, regardless of the bulk of the R group.[1c]

Validation of the Force Field

The consistency of the force field can be evaluated from the average values of the differences (<Δ>) between observed and calculated bond lengths and angles and their root-mean-square deviations, rms = $[(\Sigma\Delta^2)/n]^{1/2}$. Deviation from zero of the average values gives a measure of the asymmetry of the Δ distribution or indicates the presence of systematic errors, while rms gives a measure of the spread of the Δ values and hence of the fit between calculated and experimental structures. The agreement between observed and calculated values appears to be quite satisfactory, especially after the second optimization step, as shown in Table 3. Inspection of Table 3 reveals a marked reduction of both the <Δ> and rms values after the second parameter optimization step only for the axial Co−C and Co−N distances, while for the other bond lengths and angles no significant improvement in <Δ> and rms values is apparent. In fact, only the axial distances are strongly affected by electronic factors, which are not taken into account in the model used in the first step. This improvement supports the assumption that the electronic factors, introduced in the second optimization step, are related to the overall charge Q of the alkyl group according to Equations 1 and 2. The axial Co−C and Co−N distances are fairly well reproduced, as shown in Figure 4, where the observed values are plotted against those calculated for the 52 cobaloximes.

In order to evidence the improvement on the axial distances derived from the introduction of the electronic factor, the experimental values are compared in Table 5 with those calculated after the first and the second step, for the

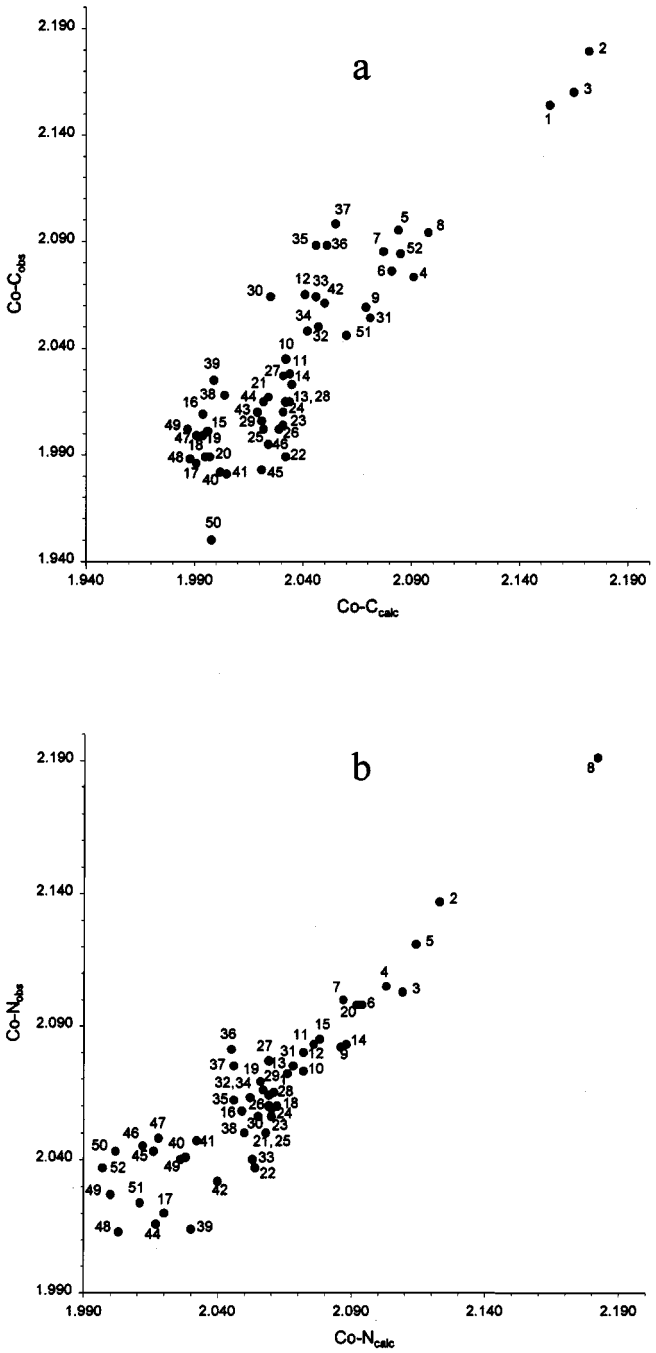

Figure 4. Plot of the observed vs. calculated Co−C (a) and Co−N (b) axial distances

series $RCo(DH)_2$(1,2-Me_2Im), having R with significantly different bulk and σ-donating ability and a relatively bulky N-donor ligand. It is also apparent that the introduction of the electronic factor well reproduces the shortening of both the Co−C and Co−N bonds when R is an electron-withdrawing group such as CCl_2CN, in agreement with the PCA results.[4b]

The geometry of the Co−R grouping is characterized by experimental Co−C(sp^3)−X angles which span a rather wide range, from 113.7° to 130.3°, and increase with the increasing of the bulk of X. This variation is well repro-

	Co−N	2.121	2.114	2.103

duced by the present force field, with just a few exceptions (see below). However, the differences between observed and calculated values appear quite acceptable if we consider that experimental values may be affected by several errors. For example, diffraction data quality (crystal quality), thermal motion effects or local static disorder, and residual packing and electronic effects.[25] In fact, for only two out of the nine $(NCCH_2CH_2)Co(DH)_2L$ derivatives considered are large differences between the observed and calculated Co−C−C angle detected when L = py[4a] (6.5°) and 1-MeIm[35] (11.2°), whereas for the other derivatives the differences do not exceed 1.9°. The two structures were accurately refined to $R = 0.042$,[4a,35] but inspection of atomic parameters shows that the thermal B factors of the C-β atom in both cases are anomalously high (by about a factor of three) relative to those of the other atoms, indicating a significant statistical occupancy disorder of that atom. Finally, the largest disagreement in the axial bond lengths is observed in the complexes containing COOMe and halogens bonded to the C-α atom (Figure 4).

Besides the general agreement between the observed and calculated structures, the validity of the present force field is further illustrated by its ability to reproduce the angular deformations around the metal center (Table 3), even using the same unstrained values of 90° or 180° for metal coordination angles. In particular, the experimental values for the equatorial N−Co−N angles average to 98.7° on the side of the oxime bridge and to 81.3° on the other side. The calculated values average to 98.5° and 81.5°, respectively. Furthermore, the remarkable angular deformations of the two Co−N(sp^2)−C angles for the coordinated lopsided ligands 1,5,6-Me_3-Bzm, 1,2-Me_2-Im, 2-NH_2-py, and 6-Cl-purine are very well reproduced, even using the same unstrained value for all the Co−N−C angles (122.0°). In fact, in these derivatives, the experimental values of the two angles differ significantly, with average values of 133.5/120.7°, 133.4/121.6°, 129.7/115.6°, and 125.9/120.6°, respectively, whereas the corresponding calculated values are 132.9/121.8°, 131.5/122.8°, 125.5/117.2°, and 125.2/120.2°.

Finally, it is of interest to compare the results of this force field for $(CN)(CH_2CN)CHCo(DH)_2$(1,5,6-Me_3Bzm) with those obtained by UFF[19c] for the same structure (Table 6). The Δ differences between observed and calculated values are similar for the Co−C distance, while the Co−N bond length, which undergoes a strong *trans* influence, is much better reproduced by the present force field.

Table 6. Differences, Δ [Å], between observed and calculated Co−C, Co−N(ax), and Co−N(eq) bond lengths for $(EtO_2C)_2$-(Me)$CCH_2Co(DH)_2$(py), obtained after the first and second step of the present force field parameter optimization process and after UFF calculations

Δ	step 1	step 2	UFF
Co−C	−0.027	−0.017	−0.023

Co−N(eq)	0.002	0.006	−0.043

[a] Assumed bond order, 1/2.

Cone Angles

According to the proposed model, the difference, δ, between the observed Co−L and Co−R axial distances and the corresponding $d°$(Co−R) and $d°$(Co−L) values should give the lengthening due to steric effects. Therefore, the δ values were expected to correlate with the bulkiness of the axial ligands, as measured by their cone angles. In fact, as shown in Figure 5, fairly good linear relationships are found, supporting the hypothesis that the steric and electronic contribution to the bond length can be considered approximately additive.

Conformational Analysis

For $MeCo(DH)_2L$ derivatives (L = Im, py, 1,5,6-Me_3-Bzm, 1,2-Me_2-Im, 6-Cl-purine, and 2-NH_2-py) the variation of the strain energy with ψ, scaled to its minimum value, is shown in Figure 6a in the range from −180° to +180°. All the curves have similar shapes with the lowest minimum at ψ = 0° and a rather broad, but structured, higher energy region around ψ = 90° ± 32°, which is particularly apparent for lopsided ligands. The latter region is characterized by two maxima and one minimum in between, with small energy differences (< 1.5 kcal mol^{-1}), for all the ligands, except 2-NH_2-py, where three maxima and two minima are observed (Figure 6a). However, the rotational energy barrier, E_{rot}, significantly increases from L = Im ($E_{rot} \approx 2$ kcal mol^{-1}), to L = py, 1,2-Im, 1,5,6-Me_3-Bzm ($E_{rot} \approx 4$ kcal mol^{-1}) up to L = 2-NH_2-py ($E_{rot} \approx 10$ kcal mol^{-1}). The variation in the axial Co−N distance with ψ, given in Figure 6b, follows a similar trend, showing that the shortest distances occur at ψ = 0° and the longest ones around ψ = 90°, for all the L ligands, with differences, Δd, which increase from L = Im ($\Delta d = 0.02$ Å), to L = 2-NH_2-py ($\Delta d = 0.05$ Å).

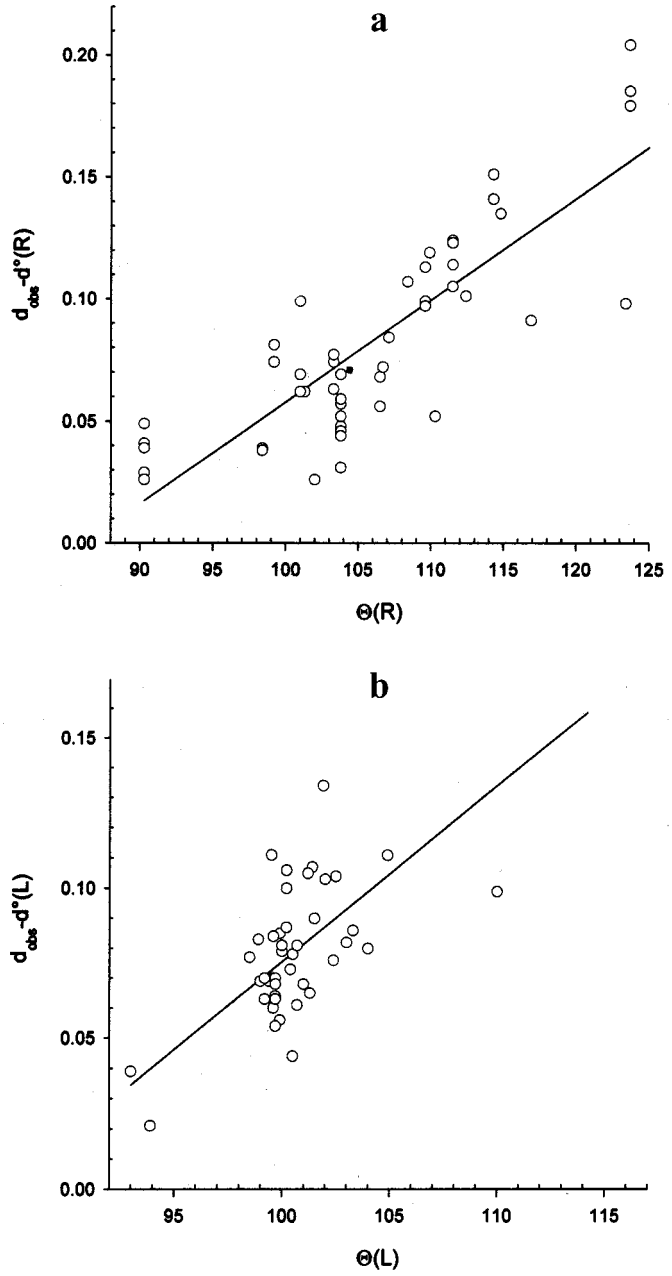

Figure 5. Plot of the differences $d(\text{obs})_{\text{Co-R}} - d°(\text{R})$ (a) and $d(\text{obs})_{\text{Co-L}} - d°(\text{L})$ (b) vs. Tolman's cone angles Θ(R) and Θ(L), respectively

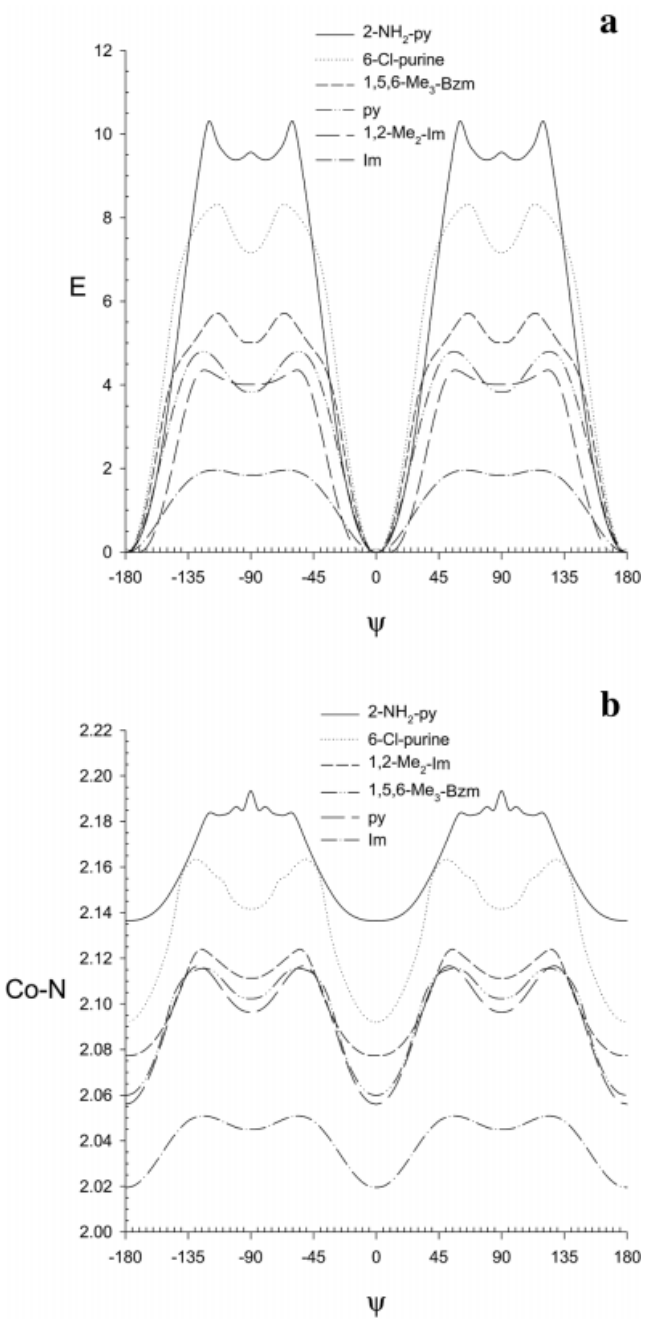

Figure 6. Plot of the strain energy (a) and of the Co−N axial distance (b) vs. ψ for different L ligands

Axial Co−N Distances

The fairly linear trend between the $d°$(Co−N) values and the experimental axial distances in complexes with the same L ligand suggests that these distances are essentially influenced by the σ-donating ability of the R groups. However, the present calculations indicate that the bulk (Figure 5b) and the orientation (Figure 6b) of the planar L ligand influence the axial Co−L bond length, as previously suggested.[1b] Since in the present model the electronic influence of R on the Co−L distance is taken into account by $d°$(Co−L), the difference between the experimental values and $d°$, δ(Co−L) = d(Co−L) − $d°$(Co−L), should represent the contribution to the distance ascribable to the bulk and orientation effects. Within this assumption, δ(Co−L) should correlate with the calculated cone angles of the L ligands, Θ(L), having the same orientation. In fact, a good correlation is found, as shown in Figure 5b for all the cobaloximes in which the L orientation nearly corresponds to $\psi \approx 0°$, i.e. in all the examined cobaloximes, with the exclusion of most of those having L = 1-Me-Im or Im. The vertical spread in Figure 5b could be related to the steric *trans* influence on the Co−L bond due to the R groups, which are able to induce an appreciable bending of the equatorial moiety towards L, displacing the latter and

lengthening the *trans* Co−L bond.[7] Thus, when L = 1,5,6-Me_3-Bzm, δ(Co−N) is 0.061 Å for R = Me and 0.111 Å for R = adamantyl, and the bending angles between the two DH units are 4.7° and −6.1°, respectively (the negative sign indicates bending towards L). The energy profiles, reported in Figure 6a for the different L ligands, clearly show that the rotation around the Co−N axial bond is significantly less hindered when L = Im, where the rotational barrier is about 2 kcal mol^{-1}, while this increases to 4 and 10 kcal mol^{-1} going from py to 2-NH_2-py. This is the reason why only for cobaloximes containing the Im (or 1-Me-Im) ligand are different orientations of L observed in the crystal, as evidenced above in the section Description and Discussion of the Structures. In fact, in $RCo(DH)_2$(1-Me-Im), ψ = 66° when R = Me, ψ = 67° when R = CH_2CH_2CN, and ψ = 38 and 49° when R = CH_2Cl. It is very likely that in these structures crystal forces are strong enough to stabilize different orientations, overwhelming the rotation energy barriers. Conversely, with the other L ligands having higher torsional barriers only the orientation with ψ ≈ 0° is found in the solid state.[1b] Inspection of Figure 6b, in which the trend of the Co−N distance vs. ψ is shown, indicates also that the lengthening of the latter distance increases significantly for the same non-zero ψ value in the order Im ≈ 1-Me-Im < py ≈ 1,5,6-Me_3Bzm ≈ 1,2-Me-Im < 6-Cl-purine < 2-NH_2-py. Finally, it is worthwhile noting that for L = 2-NH_2-py, the barrier height between ψ = 0° and ψ = 90° is about 10 kcal mol^{-1}, a value very close to the activation energies (9.2−13.1 kcal mol^{-1}) for rotation about the axial Co−N bond as derived from dynamic and saturation ^{1}H-NMR spectroscopy for the $RCo(DH)_2$(2-NH_2-py) complexes [R = *i*Pr, Et, neopentyl, CH_2Br, $CH_2C(Me)(CO_2Et)_2$, CH_2CN, and CH_2NO_2].[36] The two limit orientations, ψ = 0° and ψ = 90°, are generally distinguished as A and B, respectively.[1c,6,23] These observations lead to the suggestion that the L orientation is principally determined by steric factors (crystal packing forces in 1-Me-Im derivatives, and intramolecular forces in the other L-containing derivatives) more than to electronic ones.[1c,3a,36]

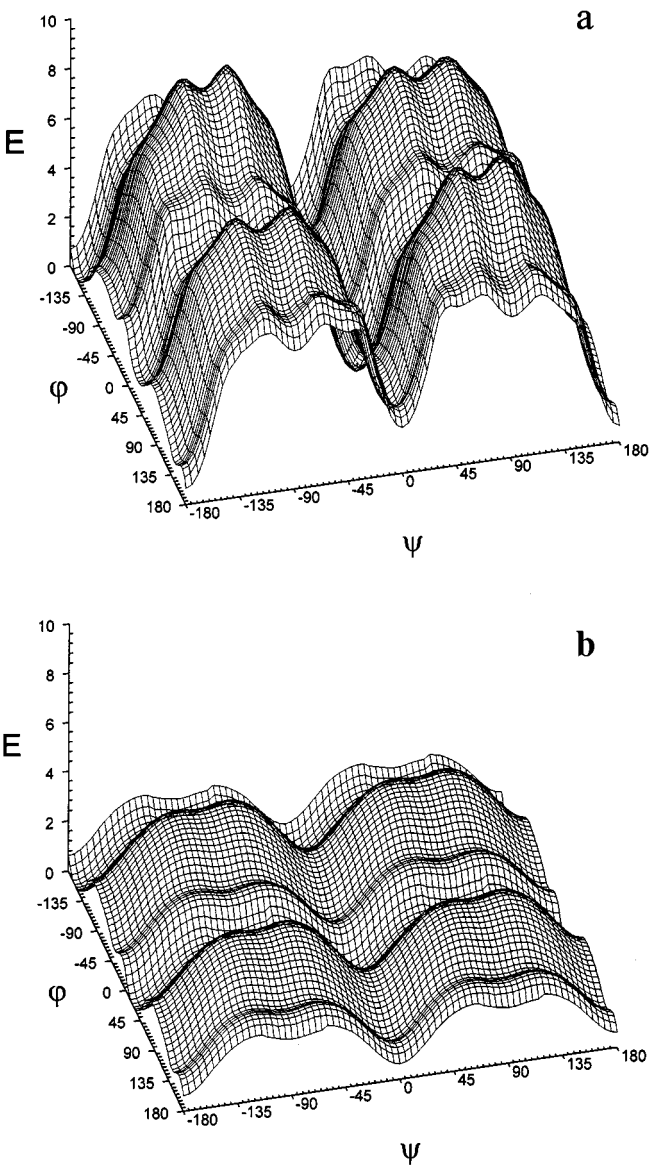

Figure 7. Plot of the strain energy vs. ψ for (ribosyl)$Co(DH)_2$(1,5,6-Me_3-Bzm) (a) and (ribosyl)$Co(DH)_2$(Im) (b)

Axial Co−C Distances

Unlike the Co−N distances, the experimental Co−C distances do not correlate with the $d°$(Co−C) values and, therefore, are significantly influenced by both the bulk (steric *cis* influence) and the σ-donating ability (electronic *trans* influence) of the R groups.[7] Therefore, the difference, δ(Co−R) between the experimental Co−R distances and $d°$(Co−R), is a measure of the contribution of the steric strain to the distance due to the bulk of R, and should correlate with the calculated cone angles of R, Θ(R). In fact, a good linear relationship is shown in Figure 5a. However, the vertical spread suggests some influence of the bulk of the *trans* N ligand on the Co−R bond, particularly when R is a bulky ligand, although some other secondary effects influencing the Co−C distance should be taken into account particularly for lopsided R ligands (vide infra). Thus, the calculated Co−adamantyl distances are 2.161 (exp. 2.154) Å and 2.182 (exp. 2.179) Å when L is 1-Me-Im and 1,3,5-Me_3-Bzm, respectively. A more enhanced effect (steric *trans* influence) was observed in adamantylcobaloximes for larger variations in the bulk of L.[8] In fact, Co−adamantyl distances of 2.129(3) and 2.217(7) Å were found when L = H_2O and PPh_2Et, respectively, whereas for the Me analogues the Co−Me distances were 1.990(5) and 2.026(6) Å, respectively. These results agree with the previous PCA analysis, where the Co−C distances are a linear combination of the three parameters, t_1, t_2, and t_3, whereas the axial Co−N distance is a linear function of only t_1.[4b] However, since the t_3 parameter is not easily functionalized, it has not been included in the force field and so the Co−C distance cannot be reproduced well as the Co−N one (Table 3).

Biological Implication

The recent X-ray crystal structure determination of the coenzyme B_{12} dependent methylmalonyl-CoA mutase[37] has promoted several studies about the benzimidazole base-off, protein histidine base-on forms of adenosylcobalamin (adoCbl).[38] In order to make a contribution to the investigation of the role of the cobalt-bound axial bases, we have carried out a conformational analysis on (ribosyl)-$Co(DH)_2L$ complexes with ribosyl = 5-deoxy-β-D-ribofuranos-5-yl and L = 1,5,6-Me_3-Bzm and Im, which are assumed to be acceptable models for the adenosyl base-on benzimidazole and adenosyl base-on histidine species. This allows the study of the geometrical variations induced in the axial fragment upon rotation around the Co−N(ψ) and Co−C(φ) bonds. The three-dimensional plot of the strain energy as a function of ψ and φ for L = 1,5,6-Me_3-Bzm is given in Figure 7a. As expected, it is characterized by steep high potential barriers (ca. 10 kcal mol^{-1}) at $\psi \approx 90°$ and 270°, over the minima at $\psi \approx 0°$ and 180°, indicating that the benzimidazole base is restricted by intramolecular forces to an orientation nearly bisecting the oxime bridges. The energy variation with φ is smoother, with a barrier of about 2−3 kcal mol^{-1}. The corresponding plot for L = Im is given in Figure 7b. It is similar to that of Figure 7a, but characterized by significantly lower energy barriers, in spite of the axial Co−N distances, which are on average shorter than those in the benzimidazole case (Table 7). The geometrical parameters of the N−Co−CH_2X fragment, at the highest and lowest energies, are compared in Table 7. This comparison indicates that the conformational strain causes a similar lengthening of the Co−C bonds in the two compounds, but a more marked increase of the Co−N bond length in the benzimidazole derivative. This situation should be even more enhanced when the equatorial ligand is corrin, whose "sentinel" side groups hinder more strongly the rotation around the Co−N axial bond. Thus, it can be concluded that histidine-like bases can rotate about the Co−N bond much more freely than benzimidazole-like ligands, but still significantly stretch the axial Co−N and Co−C bonds. This leads to the suggestion that histidine-like bases can bind to Co more easily than benzimidazole at ψ values which would require axial bond stretchings (vide infra), possibly because of geometrical protein−coenzyme binding demands. These stretchings would contribute both electronically[1a,39] and sterically[1b,1c] to enhance the Co−C homolysis, specially after the entrance of the substrate in the active site. It is kown that the enhancement of the homolysis rate of about 13 orders of magnitude for adoCbl in the enzyme with respect to the free coenzyme is for 5−6 orders of magnitude attributed to the substrate entrance in the active site.[40] Inspection of the structural results in the methylmalonyl-coenzymeA mutase[37] reveals that in addition to the long Co−N(histidine) bond of 2.50 Å, the angles Co−N−C are 130° and 116°. Although of low accuracy, these data indicate that the protein conformation requirements impose on the "symmetric" histidine imidazole an asymmetric coordination to Co (as in lopsided ligands) with a lengthening of the Co−N bond. The possible consequences upon the Co−C bond stability may be derived from earlier structural and BDE results, obtained for cobaloximes. In fact, comparison of the structures of *i*PrCo$(DH)_2$Py and *i*PrCo$(DH)_2$(2-NH_2-py) reveals an abnormally long axial bond of 2.194(4) Å in the latter compared with that of 2.094(2) Å for the py analogue, associated with a strong asymmetry in the Co−N−C angles, which are 115.7(3) and 129.7(4)° (on the side of NH_2).[12b] These angles are essentially equal and close to 120° in the py derivative. However, only a slight increase of 0.01 Å is observed in the Co−*i*Pr distance in the 2-NH_2-py complex. Correspondingly, Halpern et al.[12a] have found that the homolytic Co−C BDE in [Ph(Me)CH]Co$(DH)_2$L is of 17 and 20 kcalmol^{-1} for L = 2-NH_2-py and py, respectively. An opposite trend should be expected from the lower p*K*a of the latter ligand (5.2 vs 6.7). If these findings in models, possibly more enhanced, apply to the coenzyme in the active site, it may be concluded that histidine-like ligands are, both sterically and electronically, more suitable than benzimidazole-like ones to respond to the changes induced on the Co coordination geometry favouring homolysis. The fact that substitution of benzimidazole by imidazole gives more thermal Co−C bond heterolysis in cobinamides[38], a cobalamin-like system, does not contrast with such a hypothesis, since the steric requirements for hystidine-like ligands, due to the binding to the protein, are not fulfilled in the free cobinamide. In fact, The two Co−N−C angles are essentially equal to 127° in Co-β-cyanoimidazolylcobamide, but, as well known, they are significantly different in CNCbl (123.3° and 133.0°).[41] On the other hand, FT Raman spectroscopy measurements in methylcorrinoids[42] showed that the Co−Me stretching frequency (about 505 cm^{-1}) was only minimally affected by replacement of the benzymidazole by the imidazole moiety. However, these results are obtaind in the isolated cobalamin, in which the imidazole is symmetrically coordinated, in contrast to the asymmetric coordination of the hystidine within the enzyme.[37]

Table 7. Coordination bond lengths [Å] and angles [°] for the minimum and maximum energy conformers, of (ribosyl)$Co(DH)_2$L, with L = Im (ΔE = 4.1 kcal mol^{-1}) and 1,5,6-Me_3-Bzm (ΔE = 9.4 kcal mol^{-1})

	L = Im	L = 1,5,6-Me_3-Bzm		
	minimum	maximum	minimum	maximum

allic complexes which takes into account, in a simple but general way, the electronic *trans* influence.

The present results show that, even if the correlation between the electronic and steric properties of the axial ligands[4b,43] is neglected, the metal coordination geometry in cobaloximes is well reproduced. The force field could be also applied to the more complex cobalamins, as well as to other vitamin B_{12} coenzyme models, when MM calculations are used to gain insight into the factors affecting the Co−C cleavage. The present calculations suggest that a change from conformation A to B, stretches essentially the Co−N bond. Since the lengthening of this bond decreases the BDE of the *trans* Co−C bond[12a] it can be inferred that the Co−C bond is weaker in conformation B. This is supported by near-IR FT-Raman measurements which indicate that in methyl derivatives of similar vitamin B_{12} models, the Co−Me stretching frequencies (504−506 cm^{-1}) are higher by about 6 cm^{-1} in complexes having an orientation close to A.[44]

Finally, the conformational analysis, based on the proposed force field, allows the rationalization of the different structural behaviour of the imidazole- and benzimidazole-like ligands in cobaloximes.

Experimental Section

X-ray Diffraction: Compound **1**: $C_{14}H_{21}ClCoN_5O_4$, M = 417.74, triclinic, space group $P\bar{1}$, a = 10.569(5) Å, b = 13.114(9) Å, c = 15.032(7) Å, α = 108.34(3)°, β = 108.01(2)°, γ = 96.23(3)°, V = 1831(4) Å^3, Z = 4, D_c = 1.516 g/cm^3, μ(Mo-K_α) = 1.11 mm^{-1}, final R, wR, and S are 0.047, 0.048, and 1.52 for 452 parameters and 4187 unique observed reflections with $I > 3\sigma(I)$. − Compound **2**: $C_{13}H_{22}ClCoN_6O_4$, M = 420.74, triclinic, space group $P\bar{1}$, a = 8.840(1) Å, b = 14.629(2) Å, c = 14.865(2) Å, α = 75.04(1)°, β = 83.14(1)°, γ = 76.58(1)°, V = 1802.9(5) Å^3, Z = 4, D_c = 1.550 g/cm^3, μ(Mo-K_α) = 1.13 mm^{-1}, final R, wR, and S are 0.034, 0.035, and 1.11 for 452 parameters and 4811 unique observed reflections with $I > 3\sigma(I)$. Data were collected at 293 K using an Enraf Nonius CAD4 single-crystal diffractometer with the Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by the heavy-atom method. Refinement was carried out by full-matrix least squares of F^2 using the Molen package. Crystallographic data (excluding structure factors) reported in this paper have been deposited at the Cambridge Crystallographic Data Centre and allocated the deposition numbers CCDC-109437 and -109438. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1IZ (Fax: + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Characterization of a Nonheme Mononuclear Peroxoiron(III) Intermediate by UV/Vis and EPR Spectroscopy and Mass Spectrometry

Ariane Jalila Simaan,[a] Frédéric Banse,[a] Pierre Mialane,[a] Alain Boussac,[b] Sun Un,[b] Taraneh Kargar-Grisel,[c] Guy Bouchoux,[c] and Jean-Jacques Girerd*[a]

Keywords: Peroxo complexes / Iron / Nonheme iron / Iron / EPR spectroscopy / Mass spectrometry / UV/Vis spectroscopy

Some nonheme hydroperoxoiron(III) species have been recently characterized by several groups. The reported examples were obtained by adding H_2O_2 in excess to an Fe^{II} complex with a neutral polypyridine ligand. We show here that on deprotonation, the purple low-spin hydroperoxoiron(III) complex $[L^5Fe^{III}OOH]^{2+}$ [L^5 = *N*-methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine] gives a blue high-spin species which we characterized as the η^2-peroxoiron(III) species $[L^5Fe^{III}O_2]^+$. It seems that with such an auxiliary ligand, the hydroperoxo group is acidic in contrast with its basicity when it is coordinated to a heme group.

Several nonheme hydroperoxoiron(III) complexes have been recently prepared[1−6] as models of "Activated Bleomycin" which was demonstrated to contain an $Fe^{III}OOH$ unit.[7] A hydroperoxoiron(III) intermediate has also been postulated as an active oxidant in a cytochrome P450 mutant[8][9] and in heme oxygenase.[10] A peroxo intermediate has been detected by Benson et al.[11] and Vaz et al.[12] in cytochrome P450 mutants in which the protonation of the distal oxygen atom of the peroxo group is inhibited. Peroxoiron(III) species have been observed several times in heme models,[13−15] but only once in a nonheme model system.[16] In these models an η^2-coordination mode was suggested based on spectroscopic studies.

Scheme 1

We show here that, by deprotonation of the hydroperoxoiron(III) species, prepared with the pentadentate ligand L^5 [*N*-methyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)ethane-1,2-diamine],[3][6] a peroxoiron(III) species is obtained. EPR spectroscopy suggests a side-on coordination mode for the peroxo group.

The synthesis and spectroscopic characteristics of $[L^5Fe^{II}Cl]PF_6$ have been reported by Bernal et al.[3] In MeOH, an excess of H_2O_2 (100 equiv.) leads to the purple species $[L^5Fe^{III}OOH]^{2+}$.[3][6] It exhibits a UV/Vis spectrum with an intense band at λ_{max} = 537 nm (ε = 1000 $M^{-1}\cdot cm^{-1}$) and an EPR spectrum typical for a low-spin Fe^{III} species (g_2 = 2.19, g_2 = 2.12, g_3 = 1.95). We have synthesized the analogous $[L^5Fe^{II}Cl]Cl$ complex and observed the same intermediate in the presence of H_2O_2 which we have also detected by mass spectrometry at *m*/*z* 218.[6]

Upon adding a base to a purple methanol solution of $[L^5Fe^{III}OOH]^{2+}$, a blue color appeared and was stable for about 15 minutes at room temperature. Figure 1 shows the UV/Vis spectra recorded at 0 °C before and after addition of 5 equiv. (based on Fe) of triethylamine. The band at 537 nm disappeared and a new band appeared at 740 nm (ε = 500 $M^{-1}\cdot cm^{-1}$). This blue species has also been obtained with other bases (NaOH, 2,6-dimethylpyridine). Depending on the pK_a, different amounts of base were needed to complete the reaction. To obtain the maximum absorbance of the band at 740 nm, 3 equiv. of NaOH, 5 equiv. of NEt_3 or 50 equiv. of 2,6-dimethylpyridine were necessary. Because of its steric hindrance 2,6-dimethylpyridine cannot coordinate to the iron center, confirming that the blue adduct is obtained by deprotonation of $[L^5Fe^{III}OOH]^{2+}$.

The same blue species has also been characterized at 10 K by EPR spectroscopy as shown in Figure 2. Spectra recorded at various temperatures ranging from 4 K to 30 K are typical for high-spin Fe^{III}. The analysis of the set of spectra led to the conclusion that two different species were present. One of them has an E/D = 0.29 with the resonances at g = 9.3 and g = 4.3 arising from the lower and middle Kramers doublet of a nearly rhombic complex.[17] The other has an E/D = 0.08 with the resonances at g = 7.5 and 5.9 arising from the upper Kramers doublet and the middle one with $D < 0$.[18] The decrease in intensity of

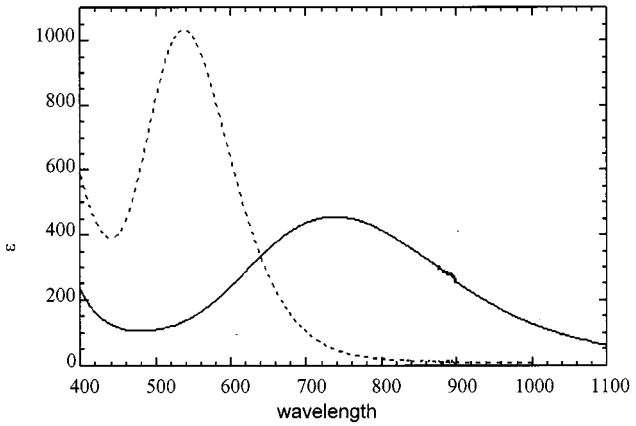

Figure 1. UV/Vis spectra at 0°C of $[L^5Fe^{III}OOH]^{2+}$ (1 mM in MeOH, 100 equiv. of H_2O_2) before (- - -) and after addition of 5 equiv. of NEt_3 (−); the bands at 537 nm and 740 nm are attributed to LMCT transitions respectively in $[L^5Fe^{III}OOH]^{2+}$ and $[L^5Fe^{III}O_2]^+$; ε in $M^{-1}\cdot cm^{-1}$, wavelength in nm

the UV/Vis band at 740 nm was followed at room temperature as a function of time while EPR spectra were recorded at 10 K on several aliquots sampled at known times and quickly frozen in liquid nitrogen. During the course of the experiment, the resonances at $g = 7.5$ and $g = 5.9$ decreased in intensity while that at $g = 4.3$ increased. The $E/D = 0.08$ species corresponds to the blue intermediate and that at $E/D = 0.29$ to a Fe^{III} degradation product.

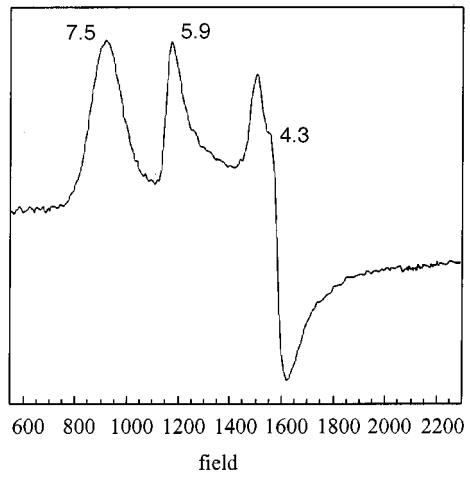

Figure 2. EPR spectrum of $[L^5Fe^{III}OOH]^{2+}$ + 5 NEt_3 recorded at 10 K; the resonances at $\delta = 7.5$ and 5.9 are attributed to the quasi-axial high-spin $[L^5Fe^{III}O_2]^+$ species and the resonances at $\delta \approx 4.3$ to a rhombic high-spin Fe^{III} degradation product; field in gauss

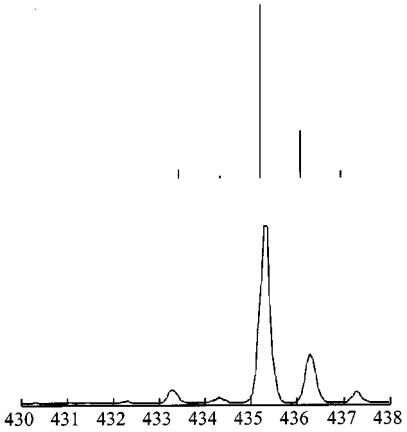
Electrospray ionization mass spectra of methanol solutions of [L5FeCl]Cl treated with H_2O_2 and either NaOH or triethylamine were identical. Both spectra exhibit a peak at *m/z* 435 (Figure 3) which can be attributed to $[L^5Fe^{III}O_2]^+$. This assignment is supported by the theoretical isotopic pattern shown in Figure 3 and corroborates the fact that the hydroperoxoiron group is acidic enough to yield a per-



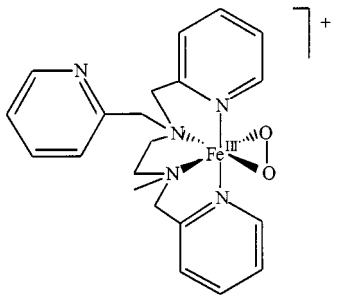


Figure 3. Electrospray-ionization mass-spectroscopic features (*m/z* values) of $[L^5Fe^{III}O_2]^+$ at *m/z* 435; theoretical isotope patterns are represented by bars above the peak cluster

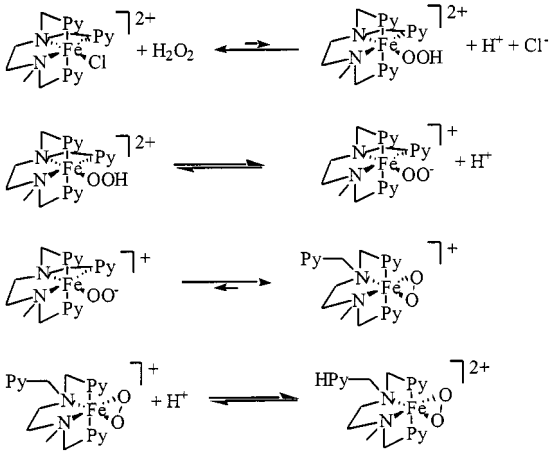
oxoiron species in the presence of a base. We propose that the blue species is the high-spin Fe^{III} species $[L^5Fe^{III}O_2]^+$.

By analogy with $[L^5Fe^{III}OOH]^{2+}$, one expects an η^1-peroxo complex $[L^5Fe^{III}O_2]^+$, in which L^5 is pentacoordinated, to be low spin. The blue species must thus contain a peroxo group linked in an η^2-mode. Moreover the EPR spectrum of $[L^5Fe^{III}O_2]^+$ is very similar to those of two high-spin iron(III) species with two *cis*-chloro groups: $[(bispicMe_2en)Fe^{III}Cl_2]^+$[19][20] and $[(bispicBz_2en)Fe^{III}Cl_2]^+$.[21] We thus suggest that $[L^5Fe^{III}O_2]^+$ has the structure represented in Scheme 2.



Scheme 2

In this complex, the pentadentate ligand L^5 acts as a tetradentate one as already reported by Nivorozhkin et al.[22] for $[L^5ClFe^{III}OFe^{III}ClL^5]^{2+}$. Raman spectroscopy experiments have been performed to observe a peroxidic vibrational signal but the adduct appeared to degrade when irradiated as already described for a similar compound.[2]

The deprotonation of $[L^5Fe^{III}OOH]^{2+}$ has also been studied with a smaller amount of base ($NEt_3/Fe < 5$ or $NaOH/Fe < 3$) by UV/Vis spectroscopy at 2 °C. Under these experimental conditions, the blue species was not formed quantitatively, and moreover it disappeared slowly while the $[L^5Fe^{III}OOH]^{2+}$ species reappeared, but without attaining its original concentration. This slow and incomplete reappearance of $[L^5Fe^{III}OOH]^{2+}$ was attributed to a slow increase in proton concentration due to the sluggish formation of $Fe^{III}-O-Fe^{III}$ decomposition products fol-

lowing the condensation reaction according to Equation 1. The experimental observations reported here can be summarized by the reactions shown in Scheme 3.

$$2\ Fe^{III}(OH_2) \rightarrow Fe^{III}-O-Fe^{III} + H_2O + 2\ H^+ \quad (1)$$

Scheme 3

During the first step, a chloro group of $[L^5Fe^{III}Cl]^{2+}$ is replaced by a hydroperoxo group. As this reaction needs an excess of H_2O_2, the reverse reaction is assumed to be predominant. The second step is the acid-base equilibrium between $[L^5Fe^{III}OOH]^{2+}$ and its deprotonated η^1-form. The next reaction leads to the blue $[L^5Fe^{III}O_2]^+$ adduct after coordination of the peroxo group in an η^2-fashion and decoordination of a pyridine group. This reaction must be rapid and favorable since we did not detect a low-spin species such as η^1-$[L^5Fe^{III}O_2]^+$. The protonation of the pendant pyridine moiety is certainly possible. However, this cannot compete since pyridine is a weak base.

In conclusion, our study reports the formation and spectroscopic characterization of a new nonheme mononuclear iron(III) complex with an η^2-peroxo and a nonoxygenated ligand. In the model presented here, as in other examples of artificial peroxoiron(III) units, the η^2-coordination mode is found, which must correspond to a profound trend for this unit. Proteins as cytochrome P450 may stabilize the intrinsically unstable η^1-coordination either by hydrogen bonding with amino acid groups in the distal side or, as proposed recently by Selke and Valentine,[23] by the axial cysteine ligand that may act as a switch that opens the side-on bound peroxo. Our study shows also that the deprotonation of the hydroperoxoiron(III) is thermodynamically easy and may be easier than with heme or bleomycin systems since we are able to produce the peroxo species in the presence of water while the peroxo species of cytochrome P450, for example, is protonated by a water molecule.[24] The acidity or basicity of the hydroperoxo group must be a function of the auxiliary ligand: Negatively charged ligands like hemes must favor basicity and neutral ligands acidity. It is clear that the enhancement of basicity in the case of hemes is crucial for the subsequent formation of the active ferryl species.

Experimental Section

General: All manipulations were carried out by using standard Schlenk techniques. Starting materials were purchased from Acros. Solvents were purchased from Merck and were used without further purification. − UV/Vis: Varian Cary 5E equipped with a temperature controller was used. − MS: Quattro II (Micromass, Manchester, UK) triple quadrupole electrospray mass spectrometer. Typical optimized values for the source parameters were: capillary 2.94 kV, counterelectrode 0.4 kV, source temperature 80 °C, RF lens 0.7 V, skimmer lens offset 5 V, cone voltage 25 V. − EPR: X-band Bruker ER 200 E and 300 spectrometers were used. Low-temperature experiments were performed using an Oxford Instruments continuous-flow liquid-helium cryostat and a temperature-control system. − Syntheses of L^5 and $[L^5FeCl]PF_6$: The ligand and the complex were prepared as described in the literature.[3]

Synthesis of the Complex $[L^5FeCl]Cl$: A solution of 200 mg (1 mmol) of $FeCl_2 \cdot 4\ H_2O$ in 10 mL of THF was added to a solution of L^5 (1 mmol) in 10 mL of THF. A yellow powder precipitated and was collected by filtration (yield 50%). − ESI MS; *m/z*: 438 ($[L^5FeCl]^+$). − $C_{21}H_{25}Cl_2FeN_5 \cdot 2.5\ H_2O$ (519.2): calcd. C 48.58, H 5.82, N 13.49; found C 48.67, H 5.16, N 12.93. − UV/Vis: $\lambda_{max} = 385$ nm ($\varepsilon = 1750\ м^{-1} \cdot cm^{-1}$).

Syntheses and Crystal Structures of $(Pr_4N)_2Re_4Q_4(CH_3CONH)_2Cl_8$ (Q = S, Se) – Conversion of Solvent CH_3CN into the Acetamido Ligand

Yuri V. Mironov[a][+]

Keywords: Rhenium / Clusters / Solid-state structures

The first two Re_4 chalcogenide halide clusters $(Pr_4N)_2Re_4Q_4(CH_3CONH)_2Cl_8$ (Q = S, Se) with ionic molecular structures have been synthesized by treatment of neutral molecular clusters $Re_4Q_4Cl_8(TeCl_2)_4$ (Q = S, Se) with Pr_4NCl in refluxing CH_3CN. During the reaction acetonitrile solvent molecules are converted into acetamido ligands, coordinated as dinucleating ligands to Re–Re bonds.

Introduction

Rhenium chalcogenide halide cluster compounds have been studied extensively in recent years, the majority of which contain Re_6 octahedra.[1−4] Recently, the first examples of Re_4 tetrahedra chalcogenide halide clusters of general formula $Re_4Q_4X_8(TeX_2)_4$ with Q = S, Se, Te and X = Cl, Br[5,6] have been prepared. These are neutral molecular compounds that are insoluble in organic solvents and water.

Here we describe two new Re_4 chalcogenide halide clusters with ionic structures $(Pr_4N)_2Re_4Q_4(CH_3CONH)_2Cl_8$ (Q = S, Se). The only known ionic examples of this class of compound are $[Re_4S_4(\mu\text{-}S_3)_6]^{4-}$[7,8] and $[Re_4Q_4(CN)_{12}]^{4-}$[9−11]. We have now successfully extended this work to allow the isolation of the first clusters with terminal chloride ligands. To our surprise the characterised compounds also included bridging acetamido ligands, which are presumably formed by reaction of CH_3CN solvent molecules with H_2O in the metal coordination sphere.

Results

Treatment of molecular clusters $Re_4Q_4Cl_8(TeCl_2)_4$ (Q = S, Se) with Pr_4NCl in refluxing CH_3CN leads to formation of the soluble ionic complexes $(Pr_4N)_2Re_4Q_4(CH_3CONH)_2Cl_8$ (Q = S, Se).

During the reaction acetonitrile solvent molecules are converted into acetamido $(CH_3CONH)^-$ ligands, coordinated as bridging ligands to Re−Re bonds. In total we observe an exchange of four $TeCl_2$ neutral ligands by two acetamido ligands $(CH_3CONH)^-$.

The structures of both compounds $(Pr_4N)_2Re_4S_4(CH_3CONH)_2Cl_8$ (**1**) and $(Pr_4N)_2Re_4Se_4(CH_3CONH)_2Cl_8$ (**2**) were determined by single-crystal X-ray analysis. The view of the cluster anion **2** is shown in Figure 1. Compounds **1** and **2** are isostructural and possess crystallographic $\bar{3}$ symmetry. Each contains an Re_4Q_4 cubane-like core formed from a nearly regular Re_4 tetrahedron with two slightly shorter Re−Re distances, resulting from the coordination of acetamido ligands to these bonds. Distances are similar [2.656(1) (**1**) and 2.695(1) Å (**2**)] for these acetamido-bridged Re−Re bonds and in the ranges 2.754(2)−2.760(1) (**1**) and 2.813(2)−2.821(1) Å (**2**) for the remaining Re−Re bonds. Each Re atom is further ligated by two terminal chloro ligands [Re−Cl distances are in range 2.395(5)−2.413(5) for **1** and 2.419(6)−2.438(6) Å for **2**] and by an oxygen or nitrogen atom of a bridging acetamido ligand, with Re−O and Re−N distances of 2.13(1) and 2.12(2) Å in **1** and 2.14(1) and 2.10(2) Å in **2**.

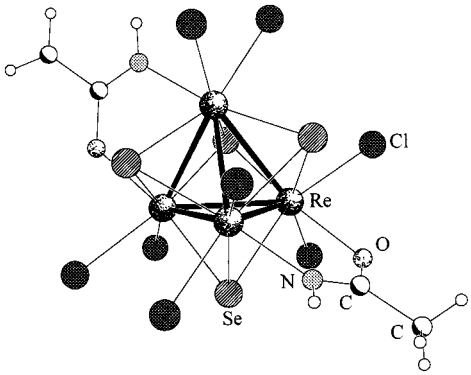

Figure 1. Structure of $[Re_4Q_4(CH_3CONH)_2Cl_8]^{2+}$ [Q = S (**1**), Se (**2**)] cation; selected bond lengths [Å] and angles [°]: **1**: Re1−Re2 2.656(1), Re1−Re1a 2.754(2), Re1−Re2a 2.760(1), Re−S in range 2.301(4)−2.340(5), Re1−O 2.128(12), Re1−N 2.122(15), Re2−Re1−Re1a 61.33(2), Re2−Re1−Re2a 61.10(3), Re1a−Re1−Re2a 57.58(2), Re1−Re2−Re2a 61.32(3), Re1−Re2−Re1a 61.10(3), Re2a−Re2−Re1a 57.57(2), C−O−Re1 122.2(12), C−N−Re2 123.5(13) N−C−O 125(2); **2**: Re1−Re2 2.695(1), Re1−Re1a 2.813(2), Re1−Re2a 2.821(1), Re−Se in range 2.419(2)−2.452(2), Re1−O 2.138(14), Re1−N 2.095(17), Re2−Re1−Re1a 61.57(3), Re2−Re1−Re2a 61.29(4), Re1a−Re1−Re2a 57.16(3), Re1−Re2−Re2a 61.56(3), Re1−Re2−Re1a 61.28(3), Re2a−Re2−Re1a 57.15(3), C−O−Re1 121(2), C−N−Re2 125(2) N−C−O 126(2)

An interesting feature of these syntheses is the conversion of the solvent molecules (CH_3CN) into acetamido ligands. Conversion of acetonitrile into acetamide in the metal coordination sphere is well known for Pt complexes and takes

place in alkaline solution.[12,13] A similar conversion into the one discussed in the present work has recently been described for the reaction of K_2PtCl_6 with *cyclo*-$(CH_3AsO)_n$ in a sealed tube at 100 °C, with further coordination taking place to a Pt−As bond.[14] In the present work, formation of the acetamido ligand has been observed at a lower temperature and normal pressure.

In the title compounds the C−O and C−N distances of 1.27(2) and 1.29(2) Å in the (CH_3CONH) units of **1** and 1.32(3) and 1.26(3) Å (**2**) are close to each other and similar to the values found for Pt complexes.[14] The determination of the positions of O and N atoms was made by comparison of the corresponding isotropic temperature factors and by the localisation of an H atom at the appropriate site for an amide nitrogen atom in a difference Fourier synthesis. The mechanism of formation of the acetamido ligands may be proposed to involve initial N coordination of a solvent CH_3CN molecule to an Re atom to afford the intermediate compound $(Pr_4N)_2Re_4Q_4(CH_3CN)_2Cl_{10}$. Subsequent nucleophilic attack on the C atom of the C≡N bond by an oxygen atom of water followed by deprotonation (giving HCl) and coordination of this O atom to the neighbouring Re atom, generates **1** and **2**. The formation of these clusters is not observed when the reactions are performed in carefully dried CH_3CN under argon.

The presence of the acetamido ligands in **1** and **2** is confirmed by spectroscopic studies. In the IR spectra of these two complexes the N−H stretching vibrations occur at 3384 (**1**) and 3381 cm^{-1} (**2**) as very sharp lines. Two bands at 1542 and 1521 (**1**) and 1540 and 1517 cm^{-1} (**2**) correspond to C=O vibrations of acetamido ligands. In ^{1}H-NMR spectra δ(NH) = 7.23 (**1**) and 7.07 (**2**); δ(CH_3) = 2.39 (**1**) and 2.47 (**2**). The resonances exhibit an integral ratio of 1:3.

Experimental Section

All manipulations were performed in air. $Re_4Q_4Te_4Cl_{16}$ (Q = S, Se) were obtained as described before.[5] − ^{1}H NMR: Bruker AM 400 FT-NMR. − FTIR: Perkin−Elmer 1760X. − Elemental analyses: Elemental Analyser system Vario E1.

$(Pr_4N)_2Re_4S_4(CH_3CONH)_2Cl_8$ (1): $Re_4S_4Te_4Cl_{16}$ (195 mg, 0.1 mmol) was refluxed in 20 mL of CH_3CN with Pr_4NCl (222 mg, 1 mmol) for 1 h. The final solution was filtered and the filtrate concentrated in air at room temperature. The solid product was then redissolved in 5 mL of CH_3CN, and recrystallised from the system CH_3CN/toluene to afford brown-red crystals of **1** which were filtered, washed with methanol and ether, and then dried. Yield 90 mg (55%). − $C_{28}H_{64}Cl_8N_4O_2Re_4S_4$ (1645.47): calcd. C 20.4, H 3.9, N 3.4, S 7.8; found C 20.1, H 3.9, N 3.3, S 7.6. − IR (KBr): $\tilde{\nu}$ = 3390 (m), 2969 (m), 2878 (w), 1541 (m), 1522 (m), 1460 (s), 1195 (m), 1034 (w), 970 (m), 751 (w), 704 (m), 670 (m), 588 (w). − ^{1}H NMR (CD_3CN): δ = 0.921−0.96 (m, CH_3), 1.60−1.70 (m, CH_2), 3.03−3.07 (m, CH_2) (Pr_4N); δ = 2.39 (CH_3), 7.23 (NH) (CH_3CONH).

$(Pr_4N)_2Re_4Se_4(CH_3CONH)_2Cl_8$ (2): 120 mg (66%) of **2** was obtained from $Re_4Se_4Te_4Cl_{16}$ (214 mg, 0.1 mmol) and Pr_4NCl (222 mg, 1 mmol) as described for **1**. − $C_{28}H_{64}Cl_8N_4O_2Re_4Se_4$ (1833.07): calcd. C 18.4, H 3.5, N 3.1; found C 18.3, H 3.6, N 3.1. − FAB MS; *m/z* (%): 1652 (20) $[M - (Pr_4N)]^-$, 1463 (20) $[M - 2\,(Pr_4N)]^-$, 732 (10) $[M - 2\,(Pr_4N)]^{2-}$, 1428 (100) $[M - 2\,(Pr_4N) - Cl]^-$, 1389 (50) $[M - 2\,(Pr_4N) - 2\,Cl]^-$, 1289 (26) $[M - 2\,(Pr_4N) - 5\,Cl]^-$, 1253 (32) $[M - 2\,(Pr_4N) - 6\,Cl]^-$, 1219 (37) $[M - 2\,(Pr_4N) - 7\,Cl]^-$. − IR (KBr): $\tilde{\nu}$ = 3385 (m), 2967 (m), 2876 (w), 1539 (m), 1517 (m), 1456(s), 1186 (m), 1037 (w), 968 (m), 750 (w), 700 (m), 668 (m), 586 (w). − ^{1}H NMR (CD_3CN): δ = 0.91−0.95 (m, CH_3), 1.59−1.69 (m, CH_2), 3.02−3.06 (m, CH_2) (Pr_4N); δ = 2.48 (CH_3), 7.07 (NH) (CH_3CONH).

X-ray Structural Analyses: Siemens P4 difractometer, graphite monochromator, Mo-K_α radiation (λ = 0.71073 Å), SHELXS-86[15] for structure solution by direct methods and SHELXL-93[16] for refinement by full-matrix least squares. Semi-empirical absorption corrections were applied to the intensity data by use of ψ scans. Hydrogen atoms were included at calculated position.[17]

1: $(Pr_4N)_2Re_4S_4(CH_3CONH)_2Cl_8$, M = 1645.47, trigonal, space group $P3_221$, $a = b$ = 12.670(3), c = 26.09(1) Å, V = 3627(2) Å^3, Z = 3, $D_{calcd.}$ = 2.260 g cm^{-3}, μ = 10.63 mm^{-1}. Novel Chiral Pyridine *N*-Oxide Ligands and Their Application in the Enantioselective Catalytic Reduction of Ketones and the Addition of Diethylzinc to Aldehydes

Volker Derdau,[a] Sabine Laschat,*[a] Eike Hupe,[a] Wilfried A. König,[b] Ina Dix,[a] and Peter G. Jones[c]

Keywords: Pyridine *N*-oxide / Pyridine / Asymmetric catalysis / Amino acids / Amino alcohols

Starting from picolinic acids **3** and **4**, the amino acid-derived 2-aminoacylpyridine *N*-oxides **1a**,**c**–**e** and 2,6-bis(aminoacyl)pyridine *N*-oxides **2b**–**e** can be prepared in two steps by the coupling of picolinic acid *N*-oxides **5** and **6** under Appel conditions with the corresponding L-amino acid ester or (1*R*,2*S*)-norephedrine. Compounds **1** and **2** were used as chiral ligands in two different asymmetric catalyses. In the catalytic addition of diethylzinc to benzaldehyde **11**, low enantioselectivities (2–29% *ee*) were obtained regardless of the amino acid moiety. However, the corresponding 2,6-bis(aminoacyl)pyridines **7** and **8** led to increased *ee* values (55% *ee*). In the catalytic reduction of ketones **9a**–**c** to alcohols **10a**–**c** low enantioselectivities were observed for alanine-, valine-, and leucine-derived *N*-oxides **1a**,**c** and **2b**,**c**. An increase of selectivity was observed for bis-methionine ligand **2d** (32–38% *ee*) relative to that of mono-methionine ligand **1d** (7–16% *ee*). However, mono-norephedrine ligand **1e** (≤ 64% *ee*) and the corresponding bis-norephedrine ligand **2e** (≤ 51% *ee*) displayed the highest selectivities. The influence of the *N*-oxide moiety on the enantioselectivity was demonstrated by the observation that 2,6-bis(aminoacyl)pyridines **7** and **8** gave much lower selectivities than the corresponding pyridine *N*-oxides **2d** and **e**.

Chiral pyridines and especially 2,6-diacylpyridines have been used extensively as ligands in asymmetric catalysis.[1][2] It was also found that metallomicelles containing diacylpyridine moieties show a prominent catalytic ability to mimic hydrolytic metallo enzymes.[3] In contrast, pyridine *N*-oxides have been used mainly in achiral form for rate enhancement of transition metal catalyzed processes.[4] They were employed only in few cases as ligands,[5] e.g. for the thione−thiol rearrangement[6] or as chiral NMR solvating agents.[7] This is surprising for several reasons. First, the amine *N*-oxide acts as a strong electron donor, which provides a suitable electronic environment for a central metal ion.[8] Second, attachment of chiral substituents to the pyridine *N*-oxide is easily achieved with a 2,6-diacylpyridine precursor and a chiral amine. Because of the wide variety of chiral amines derived from natural products, it should therefore be possible to tune the stereochemical environment of the ligand as desired. In particular, 2,6-bis(aminoacyl)pyridine *N*-oxides might even be used for asymmetric transformations as chiral ligands in the absence of any metal ion, because of their marked ability to form hydrogen bonds.[9] Therefore we decided to prepare mono- and disubstituted pyridine *N*-oxides **1**and **2** (Scheme 1). For evaluation of the enantioselectivity of the ligands **1** and **2** two different asymmetric catalyses were chosen, viz. the catalytic reduction of ketones with $BH_3 \bullet SMe_2$[10] and the addition of diethylzinc to aldehydes.[11] In order to enhance the chelating abilities and hopefully the enantioselectivity, chiral amines derived from amino acids bearing additional donor groups X were employed, because previous work by O′Neil et al. has shown that amine *N*-oxides derived from tertiary amines could be successfully used for the enantioselective reduction of ketones.[12] The authors reported increased selectivities for those amine *N*-oxides bearing donor groups such as hydroxy or pyridine. The following manuscript describes the synthesis of the novel ligands **1** and **2** and their application in asymmetric catalysis.

Scheme 1

Two different synthetic approaches towards pyridine *N*-oxides **1** and **2** are conceivable. Starting from picolinic acids **3** and **4**, either the amides may be formed first followed by subsequent oxidation, or alternatively **3** and **4** are oxidized to the corresponding *N*-oxides **5** and **6** and then coupled with chiral amines to give **1** and **2** (Scheme 2). Preliminary

experiments showed that oxidation of aminoacylpyridines proceeded rather sluggishly even under forcing conditions. This was particularly true for the disubstituted derivative, presumably as a result of the steric hindrance of the carbonyl oxygens around the pyridine nitrogen. A similar observation was recently reported by Sharpless when he attempted to prepare methyl picolinate *N*-oxide with bis(trimethylsilyl)peroxide in the presence of catalytic amounts of perrhenic acid.[13]

We therefore turned our attention to the second strategy. Following a procedure by Profft and Steinke,[14] 2-picolinic acid **3** was converted into the corresponding potassium carboxylate, which was further oxidized with hydrogen peroxide in HOAc to give *N*-oxide **5** in 79% yield. Analogous reaction of 2,6-dipicolinic acid **4** gave *N*-oxide **6** in 76% yield.[15] Unfortunately, facile racemization of the amino acids prevented the use of acid chlorides for amide formation. In addition, application of milder coupling agents such as *N,N'*-dicyclohexylcarbodiimide[16] gave only low conversions to **1** and **2**. Next, we tried a method of Hruby[17] employing bromotrichloromethane/triphenylphosphane for activation of the carboxylic acids **5** and **6**, which gave the desired amides **1** and **2** upon addition of a chiral amine in moderate yields. The following amines were used: *L*-alanine ethyl ester, L-valine methyl ester, L-leucine methyl ester, L-methionine methyl ester, and (1*R*,2*S*)-norephedrine.

In case of the bis-methionine pyridine *N*-oxide **2d**, an X-ray crystal structure could be obtained, which is shown in Figure 1.[18] In the solid state compound **2d** displays exact C_2 symmetry, whereby the amino acid moieties are oriented in such a way that the *N*-oxide is stabilized via two intramolecular hydrogen bonds. The absolute configuration was confirmed on the basis of anomalous scattering by sulfur.

For comparison, the corresponding 2,6-bis(aminoacyl)-pyridines **7** and **8** were prepared by converting **4** to the 2,6-diacyl chloride and subsequent treatment with methionine methyl ester or norephedrine,[2b] respectively (Scheme 3).

Chiral pyridine *N*-oxides **1** and **2** and pyridines **7** and **8** were used as ligands in the catalytic reduction of ketones **9a**–**c** with $BH_3 \cdot SMe_2$ (Scheme 5).[19] In a typical experiment 5 mol-% of ligand **1**, **2**, **7**, or **8** were sufficient to achieve complete conversion of **9** within 5 min.[20] After workup the corresponding alcohols **10** were obtained in 97–99% yield. Concerning the reduction of acetophenone **9a** and propiophenone **9b**, the results in Table 1 show that both mono- and disubstituted pyridine *N*-oxides **1a**,**c** and **2b**,**c** derived from alkyl-substituted amino acids such as alanine, leucine or valine gave only low enantioselectivities (7–17% *ee*). This outcome is in good agreement with previous results by Grundon et al.[21]. The authors observed 17–20% *ee* for the reduction of **9a** with amino acid ester borane complexes derived from leucine, phenylalanine, or valine. In contrast, ligands derived from methionine or norephedrine displayed a different behavior. Whereas the monosubstituted ligands **1d**,**e** again resulted in low *ee* values (7–21% *ee*), a significant increase of the enantioselectivity was observed for the corresponding disubstituted ligands **2d**,**e** (31–38% *ee*). When methionine- and norephedrine-derived diacylpyridines **7** and **8** were used for the reduction of acetophenone **9a** instead of the corresponding *N*-oxides **2d**,**e** the enantioselectivity dropped to 4 and 14% *ee*, respectively. This clearly demonstrates the influence of the *N*-oxide moiety. Using 2-chloroacetophenone **9c** gave slightly increased enantioselectivities over those of the other ketones **9a**,**b**. Again bis-methionine ligand **2d** produced a much higher enantiomeric excess (37% *ee*) than monomethionine ligand **1d** (16% *ee*). The only exceptions to the general trend were the norephedrine-derived ligands **1e**, **2e**. Contrary to the previously mentioned cases, mono-norephedrine ligand **1e** gave alcohol **10c** in 64% *ee*, compared to 51% *ee* for the disubstituted ligand **2e**. As shown in Scheme 4, the major enantiomers of the product alcohols **10a**–**c** have the same absolute configuration. It should be noted however that, because of the priority rules of the CIP system, alcohols **10a**,**b** are (*R*) configured, whereas alcohol

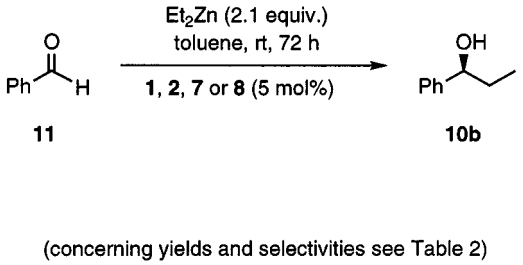
Scheme 3

10c is (*S*) configured. O′Neil reported 68 and 96% *ee* for alcohols (*R*)-**10a** and (*S*)-**10c**, respectively, when using chiral prolinol *N*-oxides.[12] In his ligands the presence of a tertiary alcohol and a pyridyl moiety seemed to be essential for achieving high enantioselectivities.

Scheme 4



Next, pyridine *N*-oxides **1** and **2** were tested in the asymmetric addition of diethylzinc to aldehydes (Scheme 5). According to a procedure by Chelucci[22] *N*-oxides **1** and **2** were treated with diethylzinc at 0° C, followed by addition of benzaldehyde **11**. After 72 h at room temperature the mixture was worked up to give 1-phenylpropanol **10b** in moderate to high yields depending on the ligand (Table 2). Higher yields were generally observed with disubstituted ligands **2b**−**e**. Both mono- and disubstituted ligands **1a**,**c** and

11	99	14	---	---	---	---

[a] Reaction conditions: **9** (1 equiv.), $BH_3 \cdot SMe_2$ (1 equiv.), ligand **1**, **2**, **7**, or **8** (0.05 equiv.), THF, reflux, 5 min. Yields refer to isolated product. − [b] Enantiomeric excesses were determined by capillary GC of the crude products using a chiral stationary phase. Depending on the substituent R, the major enantiomer of **10** has the following absolute configuration: (*R*)-**10a** (R = Me), (*R*)-**10b** (R = Et), (*S*)-**10c** (R = CH_2Cl). For details see Experimental Section.

2b,**c** derived from alanine, valine, or leucine gave only low enantioselectivities (7−16% *ee*). An increase of selectivity and yield was discovered for bis-methionine ligand **2d** (92%, 29% *ee*) relative to that of mono-methionine ligand **1d** (37%, 2% *ee*). Surprisingly low selectivities were obtained for the norephedrine ligands (**1e**: 9% *ee*, **2e**: 8% *ee*). However, much higher enantioselectivities of **10b** could be accomplished by using 2,6-bis(aminoacyl)pyridines **7** and **8** (55 and 56% *ee*, respectively). Except for the reaction catalyzed by *N*-oxide **2e**, the absolute configuration of the major enantiomer of **10b** was assigned (*S*).

Scheme 5

From these results several conclusions can be drawn. It seems reasonable to assume that concerning the enantioselective reduction of ketones **9** proceeds by in situ complexation of boron by the oxygen atom of the *N*-oxide.[23] This stabilization is enhanced by the presence of additional donor groups such as thiomethyl (**1d**, **2d**) or hydroxy (**1e**, **2e**).[24] Thus a boronate species with a stereochemically defined environment is formed, which coordinates the prochiral ketone, so that attack of the hydride occurs preferentially from the *Si*-face (for **12a**,**b**) or *Re*-face (for **12c**). In particular, bis-methionine *N*-oxide **2d** and norephedrine *N*-oxides **1e** and **2e** are superior to the corresponding 2,6-bis(aminoacyl)pyridines **7** and **8** and seem to be good candidates for designing further novel ligands for the catalytic

Table 2. Yields and enantiomeric excesses of 1-phenylpropanol **10b** (R = Et) via addition of diethylzinc to benzaldehyde **11** in the presence of chiral ligands **1**, **2**, **7**, or **8**[a,b]

asymmetric reduction of ketones. Work towards this end is currently in progress. In contrast, 2,6-bis(aminoacyl)pyridine ligands **7** and **8** are much better suited to the diethylzinc addition than the corresponding pyridine *N*-oxides **1** and **2**. This reaction is probably highly dependent on the presence of a β-amino alcohol function in the catalytic species in order to achieve high enantioselectivities

Experimental Section

General: All reactions were carried out under nitrogen with standard Schlenk techniques. Solvents were dried and deoxygenated by standard procedures. − Analytical TLC was performed on precoated Merck Si 254 F plates (0.25 mm thickness) and the products were visualized by UV detection. Flash chromatography[25] was carried out with Merck silica gel 60 (230−400 mesh). − NMR spectra: Bruker AC 200 P (^{1}H: 200 MHz, ^{13}C: 50 MHz), Bruker AM 400 (^{1}H: 400 MHz, ^{13}C: 100 MHz). Multiplets in ^{13}C-NMR spectra were assigned with the aid of DEPT experiments. − Optical rotations (1-dm cells, 1-mL capacity, room temp.): Perkin−Elmer Model 241 polarimeter. − Melting points: Rheometric Scientific DSC SP, heating and cooling rate: 10 K min^{-1}. − IR: Nicolet 5DXC FT-IR spectrometer. − MS: Finnigan Model MAT 8430 (EI). − For determination of enantiomeric excesses of **10a**,**b** a Carlo Erba Instruments GC (column 1) coupled with a Carlo Erba Instruments GC (column 2) was used. Column 1: Macherey−Nagel DD-wax capillary column (ID 0.25 mm, length 30 m), column 2: Macherey−Nagel Hydrodex β-3P capillary column (ID 0.25 mm, length 25 m). For determination of enantiomeric excesses of **10c** a GC with heptakis(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrine as chiral stationary phase (50% in polysiloxane OV 1701, w/w, column length 10 m)[26] was used. − (1′*R*,2′*S*)-2,6-Bis[2-(1-hydroxy-1-phenyl)propylaminocarbonyl]-pyridine (**8**) was prepared according to ref.[2b] The absolute configuration was determined by comparison with authentic samples.

Picolinic Acid *N*-Oxide (5): To an ice-cooled solution of picolinic acid **3** (25.0 g, 0.20 mol) in MeOH (140 mL) was added KOH (11.4 g, 0.20 mol). The solvent was removed in vacuo and the remaining solid was dissolved in HOAc (120 mL). Then H_2O_2 (24 mL, 30% aqueous solution) was added and the mixture was heated at 80°C for 3 h. Additional H_2O_2 (20 mL, 30% aqueous solution) was added and the mixture was stirred at 90°C for 24 h. After removal of the solvent in vacuo, the residue was dissolved in H_2O (10 mL) and the pH adjusted to 1 by addition of conc. HCl. The precipitate was filtered and washed with ice-cold H_2O (100 mL) to give 21.9 g (0.16 mol, 79%) of a colorless solid: mp. 162°C. − ^{1}H NMR (200 MHz, NaOD): δ = 7.45 (d, *J* = 6.1 Hz, 1 H, 6-H), 6.93 (dd, *J* = 7.0/8.2 Hz, 1 H, 5-H), 6.69−6.65 (m, 2 H, 4-H, 3-H). − ^{13}C NMR (50 MHz, NaOD): δ = 168.1 (CO), 147.6 (C-2), 139.6 (C-6), 132.4, 126.5, 124.4 (C-3, C-4, C-5). − MS (EI) *m*/*z* (%): 139 (42) [M$^+$], 95 (67), 78 (100), 63 (8), 51 (23). $C_6H_5NO_3$ (139.11): calcd. C 51.80, H 3.62, N 10.07; found C 51.68, H 3.76, N 10.08.

Dipicolinic Acid *N*-Oxide (6): Following the procedure described for **5** but using dipicolinic acid **4** (16.7 g, 0.10 mol) 13.9 g (76.0 mmol, 76%) of a colorless solid were obtained: mp. 171°C. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 14.67−14.59 (br, 2 H, COOH), 8.74 (d, *J* = 8.0 Hz, 2 H, 3-H), 7.99 (t, *J* = 8.0 Hz, 1 H, 4-H). − ^{13}C NMR (100 MHz, $CDCl_3$): δ = 158.3 (COOH), 138.2 (C-2), 133.7 (C-3), 132.5 (C-4). − MS (EI) *m*/*z* (%): 183 (22) [M$^+$], 139 (100), 122 (78), 106 (18), 94 (30), 78 (41), 63 (8), 51 (34). − $C_7H_5NO_5$ (183.02): calcd. C 45.91, H 2.75, N 7.65; found C 46.02, H 2.94, N 7.53.

General Procedure for the Preparation of Pyridine *N*-Oxides (1, 2): To a solution of triphenylphosphane (1.05 g, 4.00 mmol), picolinic acid *N*-oxides **5** or **6** (4.00 mmol), and bromotrichloromethane (0.79 g, 4.00 mmol) in THF (20 mL) was added amine (8.00 mmol in case of **5** or 16.0 mmol in case of **6**), and the resulting mixture was refluxed for 16 h. After cooling to room temperature, the precipitate was removed by filtration. The solvent was removed in vacuo and the crude product was purified by flash chromatography.

(2′*S*)-2-[(1-Ethoxycarbonyl)ethylaminocarbonyl]pyridine *N*-Oxide (1a): Flash chromatography on SiO_2 (hexanes/$CHCl_3$/2-propanol, 8:3:1) gave 560 mg (2.35 mmol, 59%) of a yellow oil; $[\alpha]_D^{22}$ = 0.3 (*c* = 1.00, $CHCl_3$). − IR (KBr): ṽ = 1740 cm^{-1}, 1669, 1530. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 11.71 (d, *J* = 5.4 Hz, 1 H, NH), 8.40 (dd, *J* = 2.5/7.9 Hz, 1 H, 3-H), 8.27 (dd, *J* = 1.0/6.4 Hz, 1 H, 6-H), 7.46 (ddd, *J* = 1.0/6.4/7.4 Hz, 1 H, 4-H), 7.42 (ddd, *J* = 2.5/7.9/7.4 Hz, 1 H, 5-H), 4.77 (dd, *J* = 5.4/7.2 Hz, 1 H, 2′-H), 4.25 (q, *J* = 7.3 Hz, 2 H, OCH_2CH_3), 1.55 (d, *J* = 7.2 Hz, 3 H, 3′-H), 1.30 (t, *J* = 7.3 Hz, 3 H, OCH_2CH_3). − ^{13}C NMR (100 MHz, $CDCl_3$): δ = 172.0 (COO), 159.2 (CONH), 140.5 (C-6), 140.3 (C-2), 128.8 (C-3), 127.4 (C-5), 126.9 (C-4), 61.4 (OCH_2CH_3), 48.8 (C-2′), 18.0 (OCH_2CH_3), 14.0 (C-3′). − MS (EI) *m*/*z* (%): 239 (100) [M$^+$ + 1], 223 (11), 165 (32), 160 (5), 141 (6), 122 (6). − $C_{11}H_{14}N_2O_4$ (238.24): calcd. (2′*S*)-2,6-Bis[(1-methoxycarbonyl-3-thiomethyl)propylaminocarbonyl]pyridine (8): A mixture of dipicolinic acid **4** (140 mg, 0.75 mmol) and thionyl chloride (8.15 g, 5 mL, 70.0 mmol) was refluxed for 2 h. After removal of the remaining thionyl chloride in vacuo, the residue was dissolved in CH_2Cl_2 (5 mL) and added dropwise to an ice-cooled solution of L-methionine methyl ester (262 mg, 1.60 mmol) in CH_2Cl_2 (5 mL). The mixture was stirred for 3 h at room temperature and then hydrolyzed with 1 N NaOH (10 mL). The layers were separated and the aqueous layer was extracted with CH_2Cl_2 (2× 20 mL). After drying the combined organic layers with $MgSO_4$ and evaporating the solvent in vacuo, the crude product was purified by flash chromatography on SiO_2 (ether) to give 230 mg (0.50 mmol, 67%) of a yellow oil; $[\alpha]_D^{22}$ = −8.0 (*c* = 1.00, $CHCl_3$). − IR (film): $\tilde{\nu}$ = 1744 cm^{-1},1679, 1526. − ^1H NMR (400 MHz, $CDCl_3$): δ = 8.62 (d, *J* = 7.9 Hz, 2 H, NH), 8.36 (d, *J* = 7.9 Hz, 2 H, 3-H), 8.06 (t, *J* = 7.9 Hz, 1 H, 4-H), 4.97 (ddd, *J* = 7.9/7.4/5.4 Hz, 1 H, 2′-H), 3.80 (s, 6 H, OCH_3), 2.67 (t, *J* = 7.4 Hz, 2 H, 4′-H), 2.34−2.29 (m, 1 H, 3′-H_a), 2.25−2.18 (m, 1 H, 3′-H_b), 2.14 (s, 6 H, SCH_3). − ^{13}C NMR (100 MHz, $CDCl_3$): δ = 172.0 (COO), 163.2 (CONH), 148.2 (C-2), 139.0 (C-4), 125.3 (C-3), 52.6 (OCH_3), 51.9 (C-2′), 31.1, 30.2

(C-3′, C-4′), 15.4 (SCH_3). − MS (EI) *m/z* (%): 457 (26) [M^+], 398 (20), 383 (100), 351 (24), 328 (21), 268 (45), 252 (12), 220 (13), 194 (25), 162 (26), 134 (10), 124 (11), 106 (17), 78 (13), 61 (31). − $C_{19}H_{27}N_3O_6S_2$: calcd. 457.1341, found 457.1335 (MS).

General Procedure for the Reduction of Ketones (9a−c) to Alcohols (10a−c): To a solution of pyridine *N*-oxide **1**, **2** or pyridine **7**, **8** (0.05 mmol) in THF (5 mL) was added $BH_3 \bullet SMe_2$ (0.5 mL, 0.10 mmol of a 2 M solution in THF) and the resulting mixture was refluxed for 5 min. Then ketone **9** (1.00 mmol) in THF (1.0 mL) was added dropwise and the mixture was refluxed for 5 min.[20] After cooling to room temperature the mixture was hydrolyzed by addition of H_2O (3 mL) and the aqueous layer was extracted with CH_2Cl_2 (3× 30 mL). The combined organic layers were dried with $MgSO_4$, evaporated in vacuo and the crude products **10a**,**b** and **10c** were analyzed by capillary GC-GC and capillary GC respectively, using chiral stationary phases.

1-Phenylethanol (10a): Temperature program: 170°C isothermal for 3 min, then with 5°C min^{-1} up to 200°C (column 1), 100°C isothermal for 20 min, then with 1°C min^{-1} up to 160°C (column 2). *(R)-Isomer:* R_t = 15.25 min. *(S)-Isomer:* R_t = 15.88 min.

1-Phenylpropanol (10b): Temperature program: 170°C isothermal for 3 min, then with 5°C min^{-1} up to 200°C (column 1), 100°C isothermal for 5 min, then with 1°C min^{-1} up to 160°C (column 2). *(R)-Isomer:* R_t = 24.55 min. *(S)-Isomer:* R_t = 25.19 min.

2-Chloro-1-phenylethanol (10c): Temperature: 100°C isothermal. *(S)-Isomer:* R_t = 9.18 min. *(R)-Isomer:* R_t = 11.25 min.

General Procedure for the Addition of Diethylzinc to Benzaldehyde (11): Diethylzinc (2.2 mL, 2.20 mmol of a 1 M solution in hexane) was added dropwise over 5 min at 0°C to a solution of pyridine *N*-oxide **1** or **2** (0.05 mmol) and the resulting mixture was stirred for 20 min at room temperature and then cooled to 0°C. Then benzaldehyde **11** (106 mg, 1.00 mmol) was added dropwise and the mixture was stirred for 72 h at room temperature. After hydrolysis with H_2SO_4 (5 mL, 10% aqueous solution), the mixture was extracted with Et_2O (3× 30 mL), washed with sat. $NaHCO_3$ (30 mL), and dried with $MgSO_4$. After removal of the solvent in vacuo the crude product **10b** was analyzed by capillary GC using chiral stationary phases as described above.

Thermochemical Study of Reduction and Oxidation Reactions of Molybdovanadophosphoric Heteropolyacids in Aqueous Solutions

E. G. Zhizhina,*[a] V. F. Odyakov,[a] and K. I. Matveev[a]

Keywords: Heteropolyacids / Molybdovanadophosphates / Hydrazine hydrate / Reduction / Oxidations / Thermochemistry

Differential enthalpies of reduction, $-\Delta_r H_{4j}$, have been found at 343 K for 0.2 m aqueous heteropolyacids $H_{3+x}PV_xMo_{12-x}O_{40}$ (HPA-x, where $1 \le x \le 6$) and their salts by hydrazine hydrate (HH). The $-\Delta_r H_{4j}$ values depend on x and m, where $m = [V^{IV}]/[\text{HPA-x}]$. At $m \approx 0$, the initial $-\Delta_r H_{4j}$ value is 436 ± 14 kJ mol^{-1} HH for all HPA-x. For HPA-x with $3 \le x \le 6$, the curves $-\Delta_r H_{4j} = f(m_j)$ have maxima associated with formation and reduction of the outer-sphere cation $V^{V}V^{IV}O_3^{3+}$. A similar maximum is observed on reduction of 0.1 M VO_2ClO_4 in 4 m $HClO_4$. No maxima are observed for the reduction of HPA-1, HPA-2, and salts of HPA-3. For HPA-3 salts, $-\Delta_r H_{4j} = f(m_j)$ depends primarily on the pH of the salt solution, rather than on the nature of the cation. Reduction and oxidation of HPA-x and their salts are reversible reactions. In HPA-x solutions, VO_2^+ in the outer sphere is reduced first, and V^V in the inner coordination sphere of the heteropoly anion is reduced next. Differential enthalpies for the oxidation of the reduced HPA-x by dioxygen ($-\Delta_r H_{2j}$) have been calculated. The sequence of the oxidation of different V^{IV} forms in the reduced H_mHPA-x solutions is the reverse of that for the reduction of the V^V forms in the initial HPA-x solutions.

Introduction

The aqueous solutions of heteropolyacids $H_{3+x}PV_xMo_{12-x}O_{40}$ (HPA-x, $1 \le x \le 6$) of the Keggin structure and their acidic salts with cations such as $M_bH_{3+x-bz}PV_xMo_{12-x}O_{40}$ (where z is the cation charge and b is the number of cation atoms), are widely used as homogeneous oxidation catalysts, for example, in reactions[1][2] such as the oxidation of ethylene to acetaldehyde,[3] C_3-C_8 olefins to ketones,[4][5] CO to CO_2,[6] and H_2S to sulfur.[7] Substituted phenols and hydroxynaphthalenes are selectively oxidized in the presence of these catalysts to *p*-quinones.[8][9] The compounds HPA-x are very promising catalysts for oxidation of many other substrates.

In oxidation catalysis, the ability of HPA-x to perform reversible reductions[10][11] is used. Thus, the oxidation of substrates (Su) by reaction according to Equation 1 is followed by the reduction of HPA-x to H_mHPA-x, where H_mHPA-x = $H_{3+x+m}PV_m^{IV}V_{x-m}^{V}Mo_{12-x}O_{40}$ [where m is the number of vanadium(IV) atoms]. The reduced forms, H_mHPA-x, are oxidized further by dioxygen (reaction according to Equation 2) regenerating the initial HPA-x forms. Thus, reduction and oxidation of HPA-x/H_mHPA-x correspond to the valence transition $V^V \rightarrow V^{IV}$ and back. The substrate oxidation is, therefore, a combined catalytic process.

$$\text{Su} + H_2O + {}^2/_m\ \text{HPA-}x \rightarrow \text{SuO} + {}^2/_m\ H_m\text{HPA-}x \quad (1)$$

$${}^4/_m\ H_m\text{HPA-}x + O_2 \rightarrow {}^4/_m\ \text{HPA-}x + 2\ H_2O \quad (2)$$

$$2\ \text{Su} + O_2 \xrightarrow{\text{HPA-}x} 2\ \text{SuO} \quad (3)$$

It is very important to exclude any direct contact between the oxidized substrate and dioxygen, as the latter can form explosive mixtures with gaseous substrates (e.g. C_2H_4). This precaution is also necessary if dioxygen initiates some side reactions. In this case, stages (1) and (2) must be performed in separate reactors.[12]

It is necessary to know the heat effects and enthalpies of each stage, such as $\Delta_r H_1 = -q_1/n_{Su}$ and $\Delta_r H_2 = -q_2/n_{O_2}$ where n is the number of moles and the heats, q and q_2 are the enthalpies of reactions (1) and (2), $\Delta_r H_1$ and $\Delta_r H_2$, respectively.

The enthalpy of reaction (3) is readily found as the difference between standard (tabled) enthalpies of the product and the substrate formation (SuO and Su): $\Delta_r H_3 = \Delta_f H_{SuO} - \Delta_f H_{Su}$. However, the enthalpies of stages (1) and (2) are still unknown, since there is no reliable information in the literature on the enthalpies of HPA-x reduction and oxidation.

Reaction (2) is common for oxidation processes of type (3). However, direct measurements of its heat effects are hindered, because its rate changes by three powers of ten.[13] To calculate the heat effects of reactions (1) and (2), the difference of enthalpies $\Delta_f H_{H_mHPA\text{-}x} - \Delta_f H_{HPA\text{-}x}$ must be known; this difference can be found experimentally using a model reaction. The most reliable and accurate data for $\Delta_r H_2$ were obtained indirectly by measuring the heats of reaction for the oxidation of hydrazine hydrate (HH) by heteropolyacid to release gaseous N_2,[14] that is, heats q_4 of reaction (4).

$$N_2H_4 \cdot H_2O + {}^4/_m\ \text{HPA-}x \rightarrow N_2 \uparrow + {}^4/_m H_m\text{HPA-}x + H_2O \quad (4)$$

If $\Delta_r H_4$ for reaction (4) and $\Delta_r H_5$ for reaction (5) are known, one can readily calculate $\Delta_r H_2$ by Equation (6).

$$N_2H_4 \cdot H_2O + O_2 \rightarrow N_2 + 3\ H_2O \quad (5)$$

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434–1948/99/0606–1009 $ 17.50+.50/0

$$\Delta_r H_2 = \Delta_r H_5 - \Delta_r H_4 \quad (6)$$

The enthalpies of reactions (1) and (2) for various HPA-x compounds are also significant for steering of catalytic activity of HPA-x ions in these reactions.

The initial (oxidized) forms of HPA-x dissociate reversibly eliminating cation VO_2^+ by reaction (7) due to the acidity of HPA-x itself.[15][16] In turn, the reduced H_mHPA-x forms ($m = x$) eliminate the cation VO^{2+} even more easily by reaction (8),[17][18] resulting in an increase of pH in the course of reduction of HPA-x solutions.[9]

$$(13-x)PV_xMo_{12-x}O_{40}^{(3+x)-} + 27\ H^+ \overset{K_{ox}}{\rightleftharpoons} (12-x)PV_{x-1}Mo_{13-x}O_{40}^{(2+x)-} + 12\ VO_2^+ + H_3PO_4 + 12\ H_2O \quad (7)$$

$$(13-m)PV^{IV}{}_mMo_{12-m}O_{40}^{(3+2m)-} + 51\ H^+ \overset{K_{rel}}{\rightleftharpoons} (12-m)PV^{IV}{}_{m-1}Mo_{13-m}O_{40}^{(1+2m)-} + 12\ VO^{2+} + H_3PO_4 + 24\ H_2O \quad (8)$$

Therefore, the enthalpies $\Delta_r H_1$,and $\Delta_r H_4$ depend on $m = [V^{IV}]/[HPA\text{-}x]$, which is the degree of HPA-x reduction.[17] They also depend on the solvent nature which influences the degree of HPA-x or H_mHPA-x dissociation in reactions (7) and (8).

The only thermochemical study of reaction (4)[14] was performed using HPA-x solutions with a high concentration of SO_4^{2-} anions, which essentially affected the results. The SO_4^{2-} anion forms complexes with both VO_2^+[19] and VO^{2+}.[20][21] Enthalpies of formation for the sulfate complexes are different, and they depend differently on solution pH. In turn, the pH of HPA-x solutions depends on the degree of HPA-x reduction (see Figure 5 in ref.[9]). These features enhance the complexity of the composition of HPA-x solutions,[14] and somehow affect the enthalpy values. In addition, some heat losses caused by scattering were not taken into account,[14] because the heats were measured at room temperature (299 K), when reaction (4) proceeded very slowly (up to 80 min).

Results and Discussion

Here and later, we use index j for the interpolated values of m_j and $\Delta_r H_{4j}$. The same values without an index refer to the reference data.

Reduction of VO_2ClO_4 Solutions by Hydrazine Hydrate

Solutions of VO_2ClO_4 (0.1 M) in $HClO_4$ have a simple composition. They are reduced by hydrazine hydrate (HH) by reaction (9).

$$4\ VO_2^+\ (aq.) + N_2H_4\ (aq.) + 4\ H^+\ (aq.) \rightarrow 4\ VO^{2+}\ (aq.) + N_2\uparrow + 4\ H_2O \quad (9)$$

The calculation of the enthalpy for reaction (9) from the enthalpies of formation $\Delta_f H$ for each component (data from ref.[22]) gives: $-\Delta_r H_9 = 524.8$ kJ mol^{-1} HH. However, experimental $-\Delta_r H_{9j}$ values were often not constant, and changed with α_j, where $\alpha = [VO^{2+}]/([VO^{2+}] + [VO_2^+])$ is the fraction of vanadium reduced to VO^{2+} (aq.) (Figure 1).

When $[HClO_4] = 1$ M, $-\Delta_r H_9$ does not depend on α and is equal to 435 ± 6 kJ mol^{-1} HH (Figure 1, curve 1). When $[HClO_4] = 4$ M, there is a sharp maximum $-\Delta_r H_{9j} = f(\alpha_j)$ (Figure 1, curve 2), which reaches ca. 660 kJ mol^{-1} HH at $[VO_2^+] \approx [VO^{2+}]$. We attribute this maximum to formation of a cation with mixed valences of vanadium by reaction (10).

$$VO_2^+(aq.) + VO^{2+}(aq.) \rightleftharpoons V^VV^{IV}O_3^{3+}\ (aq.) \quad (10)$$

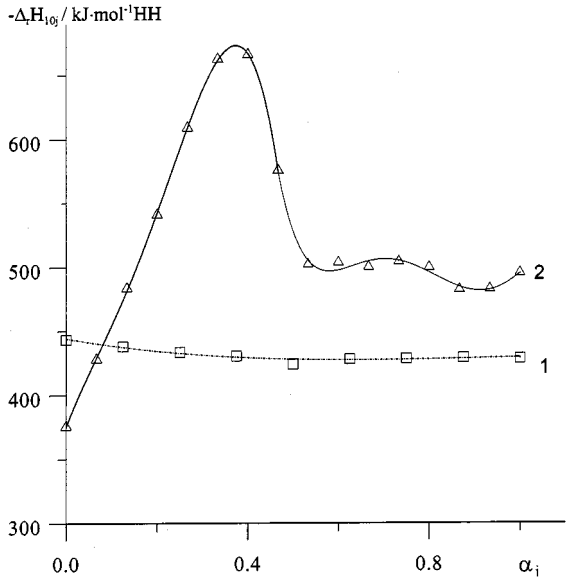

Figure 1. Differential enthalpies for reaction (9) vs. fraction of vanadium reduced to VO^{2+} (aq.) for 0.1 M solutions of VO_2ClO_4: 1: $[HClO_4] = 1$ M; 2: $[HClO_4] = 4$ M

The formation of such a cation was also observed by spectrophotometry in ≥ 3 M H_2SO_4 or $HClO_4$,[23][24] but not in 1 M $HClO_4$.[24] The composition of this cation with mixed valences of vanadium is likely to be $V^V{}_2V^{IV}O_4^{6+}$ rather than $V^VV^{IV}O_3^{3+}$.[23][24] Such a composition is more consistent with the influence of acidity on $V^V{}_2V^{IV}O_4^{6+}$ formation, and the position of the maximum in curve 2 (Figure 1).

$$2\ VO_2^+\ (aq.) + VO^{2+}\ (aq.) + 2\ H^+ \rightleftharpoons V^V{}_2\ V^{IV}O_4^{6+}\ (aq.) + H_2O \quad (10a)$$

Reduction of Aqueous $H_{3+x}PV_xMo_{12-x}O_{40}$ Solutions by Hydrazine Hydrate

For $x = 1$, ^{31}P- and ^{51}V-NMR spectra of HPA-1 solution show the presence of only one heteropoly anion $PVMo_{11}O_{40}^{4-}$.[25] For $x > 1$, these spectra show that solutions of average composition $PV_xMo_{12-x}O_{40}^{(3+x)-}$ actually contain the complex equilibrium mixtures of different indi-

vidual heteropoly anions $PV_yMo_{12-y}O_{40}^{(3+y)-}$, where $y = x, x \pm 1, x \pm 2$, etc.,[25][26] including their isomers.[27] These solutions also contain equilibrium concentrations of VO_2^+ cation, and $H_zPO_4^{(3-z)-}$ anions.[21] The heat evolution coincided at times with the nitrogen liberation. The absence of any heat effects after complete dinitrogen liberation indicates that the equilibration between different heteropoly anions is faster than any interaction of these anions with HH.

The cations VO_2^+ in HPA-x solutions are considered to exist as outer-sphere complexes with $PV_yMo_{12-y}O_{40}^{(3+y)-}$ anions (see below). According to ^{51}V-NMR spectroscopy,[28] an outer-sphere complex of VO_2^+ and HPA-2 is formed from HPA-2 and $Na_6V_{10}O_{28}$ in a of solution water + acetic acid. Thus, reduction of HPA-x solutions in reaction (4) is more complicated than that of VO_2^+ (aq.) in reaction (9).

The relationships $-\Delta_rH_{4j} = f(m_j)$ for reduction of different HPA-x or their salts depend on the number x. On reduction of HPA-1 and HPA-2, $-\Delta_rH_{4j}$ values decrease gradually with an increase of m_j (Figure 2, curves 1 and 2). This decrease is especially sharp when m_j is close to x. The initial $-\Delta_rH_{4j}$ values (at $m_j \leq 0.5$) are 431 ± 11, and 440 ± 14 kJ mol^{-1} HH for HPA-1 and HPA-2, respectively. Note that these values are very close to $-\Delta_rH_{9j} = 435 \pm 6$ kJ mol^{-1} HH for reduction of 0.1 M VO_2ClO_4 in 1 M $HClO_4$. At $m_j > x$, HPA-1 reduces further, indicating a valence transition of Mo^{VI} to Mo^{V} (see Figure 2, curve 1) . Such an over-reduction of HPA-1 was also observed by potentiometry.[18][29]

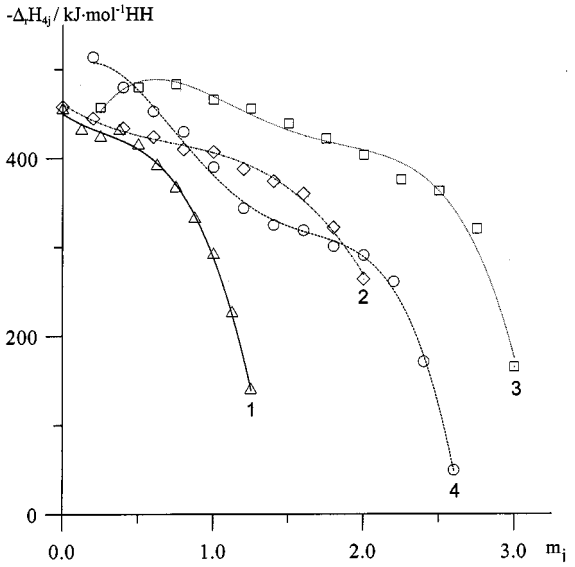

Figure 2. Differential enthalpies for reaction (4) vs. degree of reduction of various HPA-x and salts of HPA-3 in 0.2 M aqueous solutions: 1: $H_4PVMo_{11}O_{40}$; 2: $H_5PV_2Mo_{10}O_{40}$; 3: $H_6PV_3Mo_9O_{40}$; 4: $MgH_4PV_3Mo_9O_{40}$, $Na_2H_4PV_3Mo_9O_{40}$, and $K_2H_4PV_3Mo_9O_{40}$

For HPA-x with $x \geq 3$, the relationships $-\Delta_rH_{4j} = f(m_j)$ have a maximum (Figures 2 and 3), when $-\Delta_rH_{4j}$ values increase slightly at first (as m_j values are low) and then decrease. The higher the value of x (the number of vanadium atoms in HPA-x), the greater the shift of maximum $-\Delta_rH_{4j}$ to the region of high m_j values. Thus, the maximum occurs at $m_j \approx 0.65$ for HPA-3 (Figure 2, curve 3), and at $m_j \approx 1.2$ for HPA-4 and HPA-6 (Figure 3). For the latter solutions, there is a region of m_j after the maximum of $-\Delta_rH_{4j}$, where $-\Delta_rH_{4j}$ values practically do not change and reach 300 ± 7 kJ mol^{-1} HH. This region with a roughly constant $-\Delta_rH_{4j}$ occurs at ca. $2.5 \leq m_j \leq 3.5$, and ca. $3 \leq m_j \leq 5.8$ for HPA-4, and HPA-6, respectively.

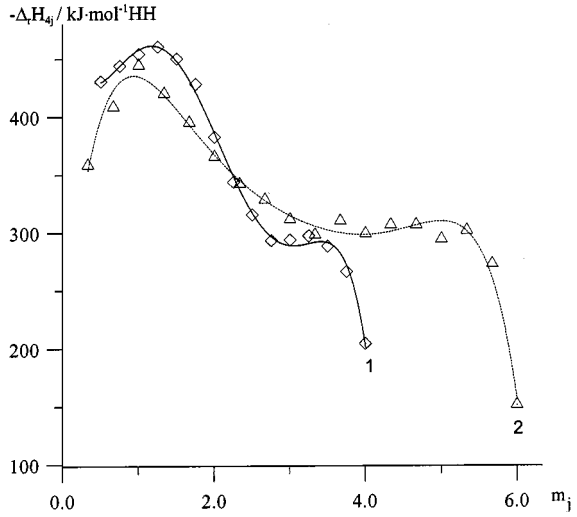

Figure 3. Differential enthalpies for reaction (4) vs. degree of reduction of HPA-x in 0.2 M aqueous solutions: 1: $H_7PV_4Mo_8O_{40}$; 2: $H_9PV_6Mo_6O_{40}$

For HPA-x solutions regenerated with dioxygen or H_2O_2, $-\Delta_rH_{4j} = f(m_j)$ relationships agree with those for fresh HPA-x solutions. Therefore, the composition and properties of HPA-x solutions are completely reversible.

For 0.2 M solutions of salts $M^I{}_2H_4PMo_9V_3O_{40}$ with cation $M^I = Na^+$, K^+, or 1/2 Mg^{2+}, the relationships $-\Delta_rH_{4j} = f(m_j)$ do not depend on the cation nature (Figure 2, curve 4). The $-\Delta_rH_{4j}$ values for these salts are lower than for HPA-3 itself (Figure 2, curve 3). This difference is associated with higher values of $pH_j = \varphi(m_j)$ for HPA-3 salts as compared with HPA-3 itself. Thus, the pH_0 of 0.2 M HPA-3 is ca. 0.4, whereas the pH_0 of each 0.2 M twice-substituted salt of HPA-3 is ca. 0.6.

Table 1. Dependence of m_j and Δ_rH_{4j} on the pH_j value for 0.2 M solutions of HPA-3 and its magnesium salt; index a refers to the acid, index s refers to the salt

0.2 M solution	pH_j	Interpolated values m_{ja} or m_{js}	$-\Delta_rH_{4j}$ [kJ mol^{-1} HH]
$H_6PMo_9V_3O_{40}$	0.8	1.65	429
$MgH_4PMo_9V_3O_{40}$		0.75	435
$H_6PMo_9V_3O_{40}$	1.0	2.14	391
$MgH_4PMo_9V_3O_{40}$		1.06	381

As m increases, the pH values of different HPA-x or their salts solutions increase too.[9] That is, $pH = \varphi(m)$. We chose m_{ja} values for HPA-3 itself, and m_{js} values for HPA-3 salts

in order to obtain the same pH_j values for their solutions (see Table 1). It is proved that $-\Delta_r H_{4j}$ values are very similar, when pH_j are identical. Thus, relationships $-\Delta_r H_{4j} = f(m_j)$ for HPA-x salts depend primarily on the pH of HPA-x salt solution rather than on the nature of cation M.

For partially reduced 0.2 M solutions of HPA-x, the pH values are limited within $0.4 \leq pH \leq 1.5$.[9] At these pH values, cation VO_2^+ (aq.) is readily hydrolyzed to acid $H_2V_{12}O_{31}\cdot xH_2O$,[30] whose solubility is 0.047 g at V L^{-1} in 0.2 M $HClO_4$.[31] According to ^{51}V-NMR spectroscopy, the equilibrium concentration of VO_2^+ is about 0.1 M, 0.16 M, and 0.4 M in 0.2 M solution of HPA-3, HPA-4, and HPA-6, respectively.[26] Such a concentration is much higher than the equilibrium concentration of VO_2^+ in the absence of heteropoly anions and other complexing agents. Therefore, VO_2^+ is not free in HPA-x solutions. It evidently forms outer-sphere complexes with heteropoly anions. Thus, the solvated large heteropoly anion (> 1.3 nm in size[32]) is considered as an acidic particle with weakly bound less acidic cations VO_2^+ and VO^{2+}. (Their sizes do not exceed 0.3 nm.[33])

Reaction (10) between cations VO_2^+ and VO^{2+} can proceed either in 4 M $HClO_4$ or likely in the outer coordination sphere of HPA-x with $3 \leq x \leq 6$. This follows from the similarity of the position of the maxima in curves $-\Delta_r H_{9j} = f(\alpha_j)$ (Figure 1), and $-\Delta_r H_{4j} = f(m_j)$ (Figures 2 and 3). However, the maxima in curves $-\Delta_r H_{4j} = f(m_j)$ are less sharp than in curve $-\Delta_r H_{9j} = f(\alpha_j)$. It seems that the enthalpy of reaction (10) in the outer coordination sphere of the heteropoly anion is probably less than in $HClO_4$ solution.

For 0.2 M HPA-1, HPA-2, and salts of HPA-3 solutions, there are no maxima in the $-\Delta_r H_{4j} = f(m_j)$ curves. This is associated with a low equilibrium concentration of VO_2^+ in these solutions. The ^{51}V-NMR spectra indicate that the VO_2^+ concentration is zero, < 0.01 M, and about 0.1 M in 0.2 M solution of HPA-1, HPA-2, and HPA-3, respectively.[26] The equilibrium concentration of VO_2^+ in solutions of HPA-x salts decreases with increasing pH.[34] Therefore, it is lower for solutions of HPA-3 salts than for those of HPA-3 itself. This explains the absence of maximum $-\Delta_r H_{4j} = f(m_j)$ on the reduction of HPA-3 salts solutions.

Values of $-\Delta_r H_4$ for solutions of VO_2HSO_4 and HPA-x in sulfate medium were found per 1 mole of HPA-x.[14] We recalculated them per 1 mole of HH, and found that they ranged from 679 to 879 kJ mol^{-1} HH. Rather high values of $-\Delta_r H_4$ for sulfate medium probably indicate, that complexes of SO_4^{2-} with VO^{2+}[20][21] are much stronger than with VO_2^+.[19]

The run of curves $-\Delta_r H_{4j} = f(m_j)$ for $H_{3+x}PV_xMo_{12-x}O_{40}$ solutions shows a definite sequence of reduction of different forms of vanadium(V) in these solutions. At lower m_j, the outer-sphere cation VO_2^+ is likely to be reduced first ($-\Delta_r H_{4j}$ = 431 ± 14 kJ mol^{-1} HH). For HPA-2, this quasi-free cation is reduced at $m_j \leq 0.5$. Note that the normal oxidation potential of VO_2^+ (aq.)/VO^{2+} (aq.) couple (1.00 V[22]) is higher than that of molybdovanadophosphates (from 0.68 to 0.715 V[29]). For HPA-x with $3 \leq x \leq 6$, it is reduced in the region of initial and maximal values of $-\Delta_r H_{4j}$. Vanadium(V) in the structure (inner sphere) of heteropoly anions $PV_yMo_{12-y}O_{40}^{(3+y)-}$ is reduced next. In this case, there is a region of curves $-\Delta_r H_{4j} = f(m_j)$ with a relatively small inclination (for HPA-2 and HPA-3) or relatively constant $-\Delta_r H_{4j}$ = 300 ± 7 kJ mol^{-1} HH (for HPA-4 and HPA-6). Figure 3 illustrates that this region has a longer length for HPA-6 than for HPA-4. We assume that the $H_{3+x+m}PV^{IV}{}_mV^V{}_{x-m}Mo_{12-x}O_{40}$ formed dissociates to eliminate vanadium(IV) as a quasi-free cation VO^{2+} [see Equation (8)]. Thus, the concentration of VO^{2+} in the outer sphere of heteropoly anions becomes higher than the initial concentration of VO_2^+ in the same sphere. (For HPA-2 solutions, this is also shown in ref.[35]) At the last stage, when m_j values are rather close to x, $-\Delta_r H_{4j}$ drops. In this stage, vanadium(V) in the structure of heteropoly anion is reduced without elimination of the cation VO^{2+}.

Oxidation of $H_{3+x+m}PV^{IV}{}_mV^V{}_{x-m}Mo_{12-x}O_{40}$ Solutions by Dioxygen

The calculated relationships $-\Delta_r H_{2j} = f(m_j)$ for oxidation of 0.2 M solutions of $H_{3+x+m}PV^{IV}{}_mV^V{}_{x-m}Mo_{12-x}O_{40}$ (H_mHPA-x) by dioxygen are shown in Figure 4. It follows from Equation (6) that changes in $-\Delta_r H_{2j}$ are always contrary to changes in $-\Delta_r H_{4j}$. For lower H_mHPA-x (x = 1, 2), the values of $-\Delta_r H_{2j}$ gradually decrease with decreasing m_j. For H_mHPA-x with $3 \leq x \leq 6$, they go through a minimum. For H_mHPA-x with x = 4 or 6, there is a region with relatively constant $-\Delta_r H_{2j}$ values (306 ± 7 kJ mol^{-1} O_2) at a rather high m_j (Figure 4). This region for oxidation of H_mHPA-x is similar to that for reduction of HPA-x (see Figure 3).

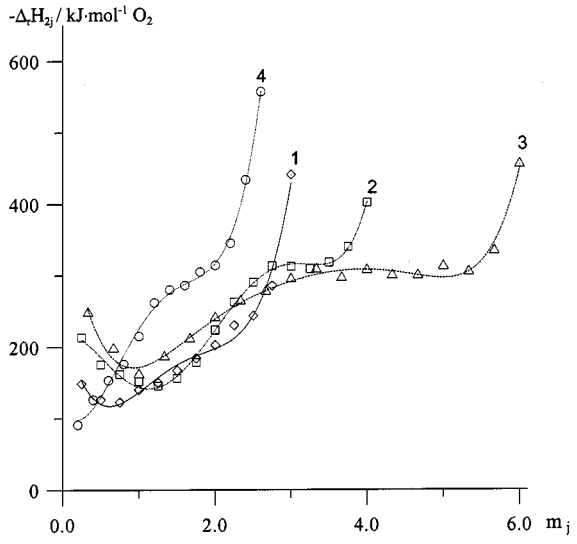

Figure 4. Differential enthalpies for reaction (2) vs. degree of reduction of HPA-x in 0.2 M aqueous solutions: 1: $H_{6+m}PV^{IV}{}_mV^V{}_{3-m}Mo_9O_{40}$; 2: $H_{7+m}PV^{IV}{}_mV^V{}_{4-m}Mo_8O_{40}$; 3: $H_{9+m}PV^{IV}{}_mV^V{}_{6-m}Mo_6O_{40}$; 4: $MgH_{5+m}PV^{IV}{}_mV^V{}_{4-m}Mo_8O_{40}$, $Na_2H_{5+m}PV^{IV}{}_mV^V{}_{4-m}Mo_8O_{40}$, and $K_2H_{5+m}PV^{IV}{}_mV^V{}_{4-m}Mo_8O_{40}$

We found earlier that the rates of reaction (2) decreased with decreasing m_j.[13] This means that changes in $-\Delta_r H_{2j}$ follow the changes in the rates of reaction (2).

The sequence of oxidation of different vanadium (IV) forms in $H_{3+x+m}PV^{IV}{}_mV^V{}_{x-m}Mo_{12-x}O_{40}$ solutions is evidently the reverse of the sequence of reduction of different vanadium (V) forms in $H_{3+x}PV_xMo_{12-x}O_{40}$ solutions. At the highest values of m_j, vanadium(IV) in the structure of anions $PV^{IV}{}_mV^V{}_{y-m}Mo_{12-y}O_{40}{}^{(3+x+m)-}$ is oxidized with high enthalpies $-\Delta_r H_{2j}$, which gradually decrease. Subsequently, at the middle values of m_j, the outer-sphere VO^{2+}, weakly bound with heteropoly anion $H_mHPA\text{-}x$, is oxidized to vanadium(V) which enters the structure of the heteropoly anion. (Outer-sphere complexes of the cation VO^{2+} with heteropoly anions are likely to be formed, for example, in dehydration of hydrated VO^{2+} salts of $H_4SiW_{12}O_{40}$ or $H_3PMo_{12}O_{40}$ at 423 to 523 K.[36]) Such regions are observed for HPA-x with $2 \leq x \leq 6$. At the lowest m_j, the outer sphere VO^{2+} is oxidized to $VO_2{}^+$ with the lowest $-\Delta_r H_{2j}$ values (from 120 to 180 kJ mol^{-1} O_2) remaining in the outer sphere. Cations $VO_2{}^+$ and VO^{2+} in the outer sphere of the heteropoly anion can probably interact reversibly with each other to yield mixed valence cations.

Thus, the thermochemical study of the $H_{3+x}PV_xMo_{12-x}O_{40}$ reduction and the $H_{3+x+m}PV^{IV}{}_mV^V{}_{x-m}Mo_{12-x}O_{40}$ oxidation in aqueous solutions proves that the composition of heteropoly anions changes reversibly in the course of reactions (1) and (2).[11] In these conversions, the cations $VO_2{}^+$ and VO^{2+} participate and can also interact in the outer coordination sphere of the heteropoly anion.

Experimental Section

We used HPA-x solutions containing no foreign anions which could act as complexing agents. Reaction (4) was carried out at 343 ± 0.1 K for 5 to 15 min. Under these conditions, the effect of uncontrolled factors on measuring data was minimal.

For preparing 0.2 M aqueous solutions of $H_{3+x}PV_xMo_{12-x}O_{40}$ (HPA-x, $1 \leq x \leq 6$), the reaction of H_3PO_4 and MoO_3 with an aqueous solution of $H_6V_{10}O_{28}$ was used.[26] The initial pH value of the HPA-x solutions (hereafter designated as pH_0) ranged from 0.35 to 0.4. For preparing 0.2 M solutions of HPA-3 salts of $M^I{}_2H_4PMo_9V_3O_{40}$ composition, metal carbonates were dissolved in the 0.2 M solution of HPA-3. Values of the pH of prepared solutions (HPA-x and their salts) were measured using a digital ionometer I-130.

For preparing 0.1 M solutions of VO_2ClO_4 in $HClO_4$, V_2O_5 was dissolved in cold 5% H_2O_2;[37] the solutions of the peroxyvanadium compounds produced were decomposed to yield O_2 and $H_6V_{10}O_{28}$,[37] which was transformed to VO_2ClO_4 using the calculated amount of $HClO_4$. An analogous 0.2 M solution of VO_2ClO_4 in 1 M $HClO_4$ could not be prepared either by our method or by the direct dissolution of V_2O_5 in $HClO_4$.[38] Hydrazine hydrate (of analytical grade purity) was used as a ca. 10 M aqueous solution, whose precise concentration was determined by iodometry.[39]

Our experiments were carried out in a thermostated Thiane-Calvet glass reactor-calorimeter[40] (150 mL in volume), equipped with a stirrer. The reactor was adapted to studies of liquid-phase reactions. The high sensitivity of the calorimeter was provided by two sensors (thermocouple batteries) connected towards each other. The sensors measured the temperature difference between the inner reactor part and the outer thermostated water and the sensor signals were then magnified and registered by an integrator. The heat released in the reactor was proportional to the temperature difference and the duration of heat liberation, recorded by the integrator. The gas space of the reactor was connected to a thermostated burette for measuring the volume of released dinitrogen. The proportionality coefficient K between the released heat q_{4i} and a number of heat pulses k_i on the integrator was found by a current calibration of the reactor-calorimeter. One pulse of the integrator corresponded to 0.0335 J. The average error of the q_{4i} measurements was within ± 2%. The volume of dinitrogen released, V_{gi}, was recalculated to the number of moles n_{gi}.

Each solution under study (HPA-x or VO_2ClO_4) was tested in 3−5 runs in dinitrogen, q_{4i} and V_{gi} being measured. During a run, 7−12 small portions of HH solution (thoroughly agitated) were injected through a rubber membrane into the reactor, containing 100 mL of the solution being under study. This permitted a stepwise increase of m_i, allowing calculation of differential enthalpies $-\Delta_r H_{4i}$ per mole of HH, which depend on the instantaneous m_i. We used fresh solutions of HPA-x as well as those reoxidized by dioxygen or H_2O_2. Since the heat of dilution of ca. 10 M HH solution is below 8.6 kJ mol^{-1},[41] it does not exceed the errors of our measurements and we therefore did not take it into account.

All heat effects were observed only in the course of dinitrogen liberation. The number of moles of released nitrogen, n_{gi}, was equal to that of introduced HH with an accuracy of ± 1%. This proves that vanadium(V) in the HPA-x solution was reduced stoichiometrically by Equation (4a), and any side conversions of HH did not occur.

$$4\,[V^V]_{HPA\text{-}x} + N_2H_4{\cdot}H_2O \rightarrow 4\,[V^{IV}]_{H_mHPA\text{-}x} + 4\,H^+ + H_2O + N_2\uparrow \quad (4a)$$

When the reactor contained $n_L = C_LV_L$ moles of HPA-x, the degree of reduction of HPA-x increased to $m_i = m_{i-1} + 4\,n_{gi}/n_L$ after the ith injection of HH. The measured differential heats, $q_{4i} = K{\cdot}k_i$ were related to the average degree of HPA-x reduction $m_i = 0.5\,(m_{i-1} + m_i)$. The enthalpy of reaction (4a) was calculated in all cases for 1 mole of dinitrogen (HH, respectively): $\Delta_r H_{4i} = -q_{4i}/n_{gi}$.

The sum of reactions (4) and (2) corresponds to reaction (5). At 343 K, the enthalpy of this reaction, $\Delta_r H_5$, was calculated from the standard formation enthalpies of H_2O and $N_2H_4{\cdot}H_2O$,[22] and is approximately equal to 606 kJ·mol^{-1} (Equation 11).

$$\Delta_r H_2 = -606 - \Delta_r H_4 \quad (11)$$

The m_i and corresponding $\Delta_r H_{4i}$ and $\Delta_r H_{2i}$ values were calculated using a special computer program. To interpolate $\Delta_r H_{4i} \rightarrow \Delta_r H_{4j}$ and $\Delta_r H_{2i} \rightarrow \Delta_r H_{2j}$, we used the standard programs for uniformly distributed m_j, followed by averaging for several runs. The interpolation errors were below ± 2.5%. The total error for $\Delta_r H_{4j}$ and $\Delta_r H_{2j}$ did not exceed ± 4.5%.

Acknowledgments

The authors thank Dr. Yu. D. Pankratiev for assistance in experiments, and Dr. R. I. Maksimovskaya for a discussion about the composition of HPA-x solutions.

Synthesis and ^{1}H-, ^{15}N-, ^{31}P-, ^{183}W-Multinuclear Magnetic Resonance Study of the Cyclotriphosphazenes $[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2]$ and $[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4]$ and Their $W(CO)_5$ Complexes (dobp = 2,2′-dioxybiphenyl)

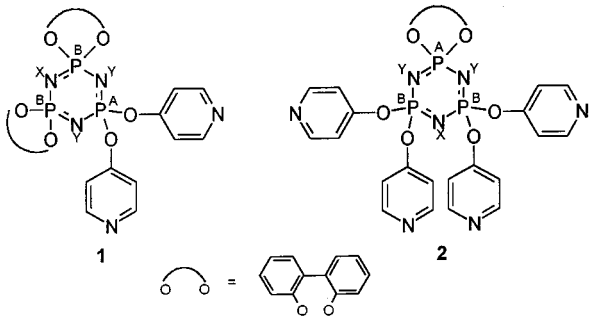
Keywords: Cyclotriphosphazenes / Oxypyridine / Carbonyltungsten compounds / NMR spectroscopy / Heterocycles



The reactions of $[N_3P_3(dobp)_2Cl_2]$ and $[N_3P_3(dobp)Cl_4]$ with a mixture of HOC_5H_4N-4 and K_2CO_3 in acetone give the cyclotriphosphazenes $[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2]$ and $[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4]$, respectively. These compounds react with $[W(MeOH)(CO)_5]$ in methanol to give mixtures of the polymetallic complexes $[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2\{W(CO)_5\}_x]$ (x = 1, 2) and $[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4\{W(CO)_5\}_x]$ (x = 1–4), which are unstable in solution, slowly undergoing loss of the pentacarbonyl moiety. A complete characterization by multinuclear ^{1}H, ^{15}N, ^{31}P, ^{183}W magnetic resonance has revealed that the complexation of the N atom of one 4-oxypyridine ligand by the $W(CO)_5$ fragment has a measurable effect on other parts of the phosphazene molecule very far away from the coordination site. The changes observed in $\delta^{183}W$ have been used to identify the components in mixtures of compounds incorporating different numbers of tungsten atoms in the molecule. The characterization of less sensitive nuclei has been accomplished by means of indirect detection methods.

Introduction

Polyphosphazenes bearing aryloxy side groups are materials with interesting properties. For example, they exhibit fire-retardant properties,[1] have high refractive indices,[2] and might find application in non-linear optics,[3] as ferroelectric materials,[4] as liquid crystals,[5] or as photoactive materials.[6] In all applications, their properties depend on the substituents linked to the aryloxy rings. One way of modifying the phenoxy moiety would be the introduction of a nitrogen atom into the ring. The resulting polymers would then contain pyridine side groups with N-donor sites available for metal complexation,[7] opening new possibilities for modifying their properties. The key aspect of this chemistry can be envisaged as being the incorporation of transition metals into the structure of the polymer.

At a macromolecular level, the evaluation of structural effects induced by the side groups bonded to phosphorus is difficult. However, a reasonable starting point would be to focus on small model compounds suitable for NMR-spectroscopic characterization. This strategy is well documented with cyclotriphosphazenes as model molecules,[8] although the number of cyclotriphosphazenes complexed to transition metals through the side groups remains relatively few.[9][10] Recently, we reported the synthesis of several carbonylmanganese complexes of cyclic phosphazenes bearing either nitrile or pyridine ligands.[11] In principle, the incorporated transition metal atom might have constituted a probe for assessing structural and bonding effects of the coordination, in view of the high sensitivity of such nuclei to subtle electronic and steric effects in the molecule.[12] However, ^{55}Mn is a quadrupolar nucleus (I = 5/2) with a medium-sized quadrupole moment ($Q = 0.55 \times 10^{-28}$ m^2). Consequently, very broad signals can be expected,[13] which would be useless for the measurement of small changes in the nuclear shielding. On the contrary, ^{183}W would give the characteristic sharp signals of a spin 1/2 nucleus, albeit with the difficulty presented by its low sensitivity. Fortunately, this drawback can easily be overcome through the use of indirect detection methods.[14] In fact, ^{183}W is one of the most extensively studied transition metal nuclei.[12a,15]

In this article, we describe the multinuclear magnetic resonance characterization of the cyclotriphosphazenes **1** and **2** (Scheme 1), as well as that of their pentacarbonyltungsten complexes **3**–**11**, formed by adding variable amounts of the labile complex $[W(MeOH)(CO)_5]$ in methanolic solution. The study extends to the nuclei ^{1}H, ^{15}N, ^{31}P, and ^{183}W.

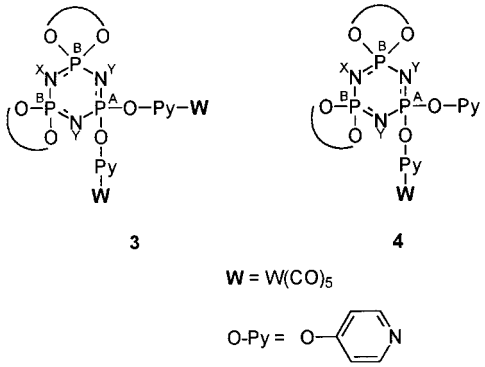
Results



The phosphazenes bearing oxypyridine groups $[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2]$ (**1**) and $[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4]$ (**2**) were prepared from the corresponding chlorophosphazenes and HOC_5H_4N-4 with K_2CO_3 in acetone, following the general method published previously.[16]

The NMR spectra of **1** and **2** are relatively simple and the relevant ^1H, ^{31}P, and ^{15}N data are collected in Table 1. For the discussion below we will focus on the protons *ortho* to the nitrogen atom of the pyridine ring (hereafter denoted H^o), since these are subject to the largest shielding modifications upon coordination of tungsten. Their signals appear at $\delta = 8.65$ and $\delta = 8.55$ in compounds **1** and **2**, respectively {cf. $\delta H^o = 7.68$ in 4-hydroxypyridine and $\delta H^o = 8.5$ in $[N_3P_3(OC_5H_4N\text{-}4)_6]$[11]}.

The ^{15}N chemical shifts of **1** and **2** lie within the expected range for nitrogen atoms incorporated into cyclotriphosphazene[17][18] or pyridine rings.[19] The nitrogen atoms of the phosphazene could be straightforwardly identified through their correlations in the 2D $^{31}P,^{15}N\{^1H\}$-HMQC spectra. The phosphorus nucleus labelled A shows a cross-peak with only one nitrogen atom, while that labelled B correlates with the two heterotopic nitrogen nuclei of the ring. The $^1J(^{31}P,^{15}N)$ coupling constants were measured from the ^{15}N satellites in the ^{31}P-NMR spectra obtained by performing the $^{31}P,^{15}N\{^1H\}$-HMQC pulse sequence in the 1D mode.

Addition of phosphazene **1** to a solution of two equivalents of $[W(MeOH)(CO)_5]$ in methanol resulted in a mixture of the bi- and monometallic complexes $[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2\{W(CO)_5\}_x]$, $x = 2$ (**3**), $x = 1$ (**4**) (Scheme 2), containing a slightly variable amount of unreacted **1**, depending on the isolation procedure used. Increasing the amount of the pentacarbonyltungsten reagent gave mixtures richer in **3**, but a very large excess had to be used in order to generate exclusively this bimetallic complex. Moreover, the ^1H- and ^{31}P-NMR spectra showed that the latter, as well as the mixtures, continuously lose $W(CO)_5$ in solution (ca. 8% per month), a process which is much slower in the solid state as monitored by NMR measurements on freshly prepared samples from different stocks of tungsten complexes. By monitoring the relative intensities of the signals of the *ortho* protons of the three species, it could be concluded that the step from **3** to **4** is slightly faster than that from **4** to **1**. The assignment of the signals to the complexes **4** and **3** was based on the variation of their intensities with the $W(CO)_5$ content in the mixtures.

Taking compound **1** as a reference, coordination at one of the pyridine rings in compound **4** leads to a deshielding of 0.16 ppm of the protons *ortho* to the nitrogen atom. This shift increases to 0.20 ppm in **3**, where both pyridine rings are coordinated to tungsten (Table 1). The signal due to the *ortho* protons of the uncoordinated pyridine of **4** is practically unaffected. A similar trend is observed in the ^{31}P-NMR signals: P_A is deshielded by 0.06 ppm in **4** and by 0.09 ppm in **3**. Interestingly, P_B seems to be more sensitive to the coordination to $W(CO)_5$ than P_A and is shifted to lower δ values rather than being deshielded: $\Delta\delta(P_B) = -0.55$ and -1.01 ppm for **4** and **3**, respectively. Substituent effects in excess of 1 ppm on phosphorus shielding transmitted through phenoxy groups have previously been observed for aryl phosphates.[20]

Scheme 2. Tungsten complexes of cyclotriphosphazene **1**

The successive coordination of pyridine substituents to tungsten also has a measurable effect on the nitrogen atom of the phosphazene ring: N_Y is deshielded by 0.6 ppm in **4** and by 1.5 ppm in **3**. Unfortunately, the intensity of the N_X signal is too low to allow its discernment above the noise. Obviously, the largest $\delta^{15}N$ variation is observed for the pyridine nitrogen atom, which is shielded by about 75 ppm upon coordination to the tungsten atom. The 5.5 ppm shielding shown by the ^{15}N of the free pyridine in **4** is, however, also noteworthy. Similar substituent effects have previously been reported for fluorinated monophosphazenes.[21]

Considering the high sensitivity of transition metal nuclei to very small electronic modifications in their environment, the shielding effect in the present case should also be detectable on the tungsten atom. Indeed, in the $^1H,^{183}W$-HMQC correlation spectrum, the chemical shift of **3** is deshielded by 4 ppm compared to that of **4**, which represents a relatively large shift for an interaction between two apparently distant groups (Table 1).

The spectra of the mixtures of **3** and **4** obtained in various independent experiments showed the presence of small amounts (not reproducible, but never exceeding 5 mol-%) of another species **5** with $\delta^{183}W = -2728$. However, all attempts to characterize this contaminant were unsuccessful.

Like **1**, the phosphazene **2** reacted with $[W(MeOH)(CO)_5]$ in methanol to give mixtures of the polymetallic complexes $[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4\{W(CO)_5\}_x]$, $x = 4$ (**6**), $x = 3$ (**7**), $x = 2$ (**8**, **9**, **10**), $x = 1$ (**11**) (Scheme 3). Thus, upon addition of 4.4 equivalents of the pentacarbonyltungsten reagent to **2**, two major products **6** and **7** (> 97%) were formed in a relative ratio of 85:15, as measured from the integrals of H_{meta} in the ^1H-NMR spectrum. For the mixture, the spectral region corresponding to the H^o protons ($\delta = 8.5-9.0$, Figure 1) features only one intense multiplet at $\delta = 8.85$ attributable to **6**, while at least three signals at $\delta = 8.65$, 8.76 and 8.82 of equal relative intensity

are observed for **7**. The excess of $[W(MeOH)(CO)_5]$ used implies that **6** must be the tetracoordinated $W(CO)_5$ complex of **2**, and consequently **7** must be its tricoordinated tungsten derivative. Furthermore, on the basis of a statistical distribution of tungsten on the pyridine nitrogen atoms of **2**, the two additional multiplets at δ = 8.59 and δ = 8.63 of very low intensity (< 3%) may be assigned to the corresponding bimetallic complexes **8**−**10**. Considering the low intensity of the dicoordinated complexes, the monometallic species **11** would not be detectable. The assignment of the ^{31}P-NMR spectra of compounds **7**−**10** was accomplished through titration experiments using different ratios of **2**/$[W(MeOH)(CO)_5]$ (1:1; 1:2; 1:3; 1:4.4). The spectra are summarized in Table 1. As expected, the increase in the tungsten content has a shielding effect on each of the phosphorus nuclei in the phosphazene ring (cf. **4** and **3**). However, the ^{31}P nucleus bonded to the biphenoxy substituent again shows the greatest upfield shift. Due to the similarity of **9** and **10**, there is some overlapping of their ^{31}P signals. Significantly, the ^{31}P nuclei in compound **8** are seen to be deshielded compared to those in **9** and **10**.

Compound **7** contains four different pyridine rings. However, only three signals with an intensity ratio of 1:1:1 are observed for the H^o protons. The fourth multiplet is overlapped by the signal of the H^o protons of **6**, as revealed by the integrals of the multiplet at δ = 8.85 and of the signal due to the *meta* protons of the pyridine rings. This overlap indicates that both types of protons are found in the same environment. By comparison with the H^o signals of **3** and **4**, the most deshielded protons of **7** can be assigned as H^o(A) (Scheme 3), while the most shielded multiplet of **7** should be attributable to H^o of the pyridine molecule not coordinated to tungsten H^o(D). The assignment of H^o(B) and H^o(C) poses some difficulties because the nuclear shielding of these protons will be determined by a combination of the electronic effects induced by the coordination of the nitrogen atom to $W(CO)_5$ and the diamagnetic anisotropy of the neighbouring rings, the latter depending on the orientation of the interacting groups (cf., for example, the crystal structure of the hexasubstituted phosphazene $[N_3P_3(OC_5H_4N\text{-}4)_6]$, where one of the three 4-oxypyridines

Scheme 3. Tungsten complexes of cyclotriphosphazene **2**

on one side of the N_3P_3 plane is oriented almost perpendicular to the other two).

These difficulties could be overcome by analysing the ^{183}W-NMR data obtained from the ^{1}H,^{183}W-HMQC correlation spectrum of the mixture of **6** and **7**. This spectrum featurs seven signals, which are labelled **I**−**VII** in Figure 2: $\delta^{183}W$ = −2696 (**I**), −2699 (**II**, **III**), −2700 (**IV**), −2701 (**V**), −2703 (**VI**, **VII**). The ^{183}W chemical shift variations observed between **3** and **4** suggest that $\delta^{183}W$ values are not subject to neighbouring anisotropy effects, but are deter-

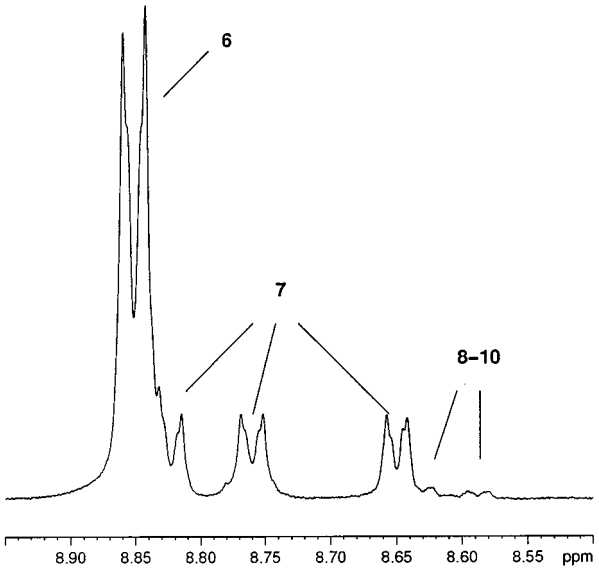

Figure 1. H^o region of the ^{1}H-NMR spectrum of a mixture of **2** with excess [W(MeOH)(CO)$_5$]

mined by the number of W(CO)$_5$ moieties coordinated to the substituents on a given phosphorus atom: the greater the number, the larger the ^{183}W chemical shift. Accordingly, the cross-peak **I** in the ^{1}H,^{183}W-HMQC spectrum of **6** and **7** can be assigned to the tungsten signal of **6**. Following the same reasoning, the two cross-peaks at $\delta^{183}W = -2699$ with the protons at $\delta = 8.85$ and 8.76 (**II**, **III**) can be ascribed to the long-range coupling of H^o(A) and H^o(B) of **7** with W_A and W_B, respectively. Since H^o(A) has been previously assigned to the multiplet at $\delta = 8.85$, it follows that H^o(B) resonates at $\delta = 8.76$. By a process of elimination, H^o(C) must be responsible for the multiplet at $\delta = 8.82$, which correlates with the most shielded ^{183}W of **7** at $\delta = -2701$ (**V**) [i.e. the tungsten bonded to the moiety with the lower W(CO)$_5$ content]. Additionally, the signal at $\delta = 8.65$ can be confirmed as being due to H^o(D), in view of the lack of any correlation with the tungsten atom. The shielding differences between H^o(B) and H^o(C) can be ascribed to differences in the diamagnetic anisotropy effect produced by the adjacent rings on the same side of the phosphazene plane. Upon rotation of the pyridine rings, H^o(B) would temporarily be oriented in a perpendicular arrangement in relation to an unperturbed pyridine and therefore would experience the full shielding effect of the ring current induced by its six π electrons. On the other hand, H^o(C) would, under these circumstances, experience a smaller ring current effect as these protons would be faced by a pyridine coordinated to tungsten, part of the electronic density of which will be involved in bonding to the transition metal.

Cross-peaks **IV**, **VI**, and **VII** in the $^{1\,H,183}$W-HMQC spectrum may be attributed to correlations with the H^o protons in the three possible dicoordinated W(CO)$_5$ complexes **8**–**10**. Applying the same assignment criteria as discussed for **7**, it can be concluded that the most deshielded signal **IV** arises from the two equivalent ^{183}W nuclei of **8**, "pendant" from the same phosphorus atom. The corresponding

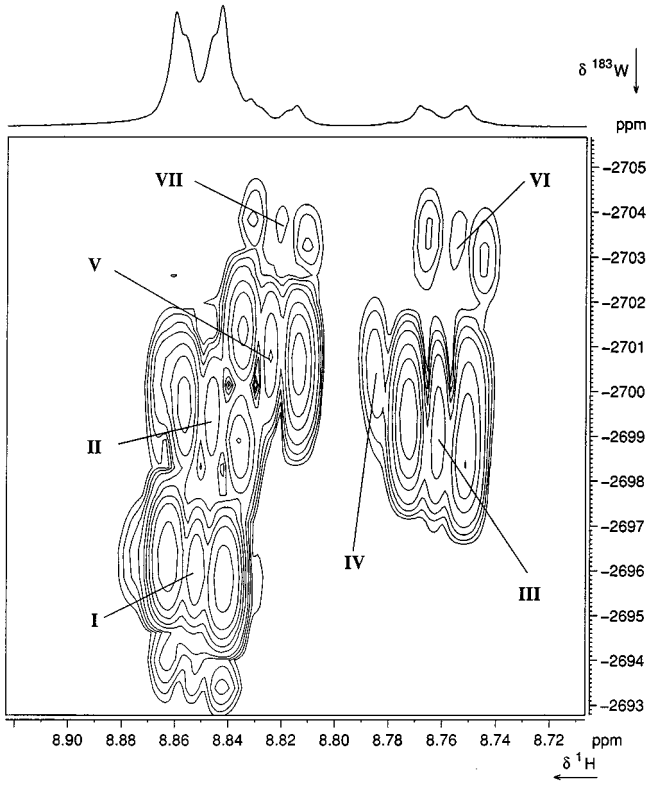

Figure 2. ^{1}H,^{183}W HMQC of a mixture of **2** and [W(MeOH)(CO)$_5$] in a ratio of 1:4.4

H^o protons appear at $\delta = 8.78$ and this signal is partially overlapped by that of H^o(B) of **7**. The two remaining cross-peaks **VI** and **VII** originate from tungsten nuclei bonded to pyridine substituents on different phosphorus atoms. Focusing on the H^o protons of the pyridine ring coordinated to W(CO)$_5$, it can be concluded that the neighbourhood, and therefore the diamagnetic anisotropic effect, of these protons in **9** is very similar to that of H^o(B) in **7**, while the analogous protons in **10** resemble H^o(C) in **7**. On the basis of these observations, the ^{1}H signals at $\delta = 8.76$ and 8.82 can be assigned to **9** and **10**, respectively. Finally, the signals at $\delta = 8.59$ and 8.63 can be assigned to two of the three types of H^o protons of the pyridines not bonded to the metal center. The unobserved third signal is most probably overlapped by the multiplet at $\delta = 8.76$ due to the proton H^o(D) of **7**.

To our surprise, the ^{1}H,^{15}N-HMQC spectrum was much less informative. The signal-to-noise ratio achieved was rather poor and only the H^o protons of the pyridines coordinated to the metal center in **6** and **7** showed correlations with ^{15}N. The data obtained are collected in Table 1. Once the identity of the H^o protons had been established, the assignment of the corresponding ^{15}N signals was trivial. Significantly, the ^{15}N chemical shifts vary in the same way as the δ^{183}W values and by a similar order of magnitude (see Table 1). On the other hand, the solubility of the complexes proved to be too low to allow measurement of ^{15}N data for the nitrogen atoms of the cyclotriphosphazene through phosphorus detection.

The above assignments are supported by the NMR data obtained by performing the reaction in a 1:3 ratio. The ^1H spectrum shows a strong overlap between multiplets in the region corresponding to the H^o protons. The high intensity of the signal at $\delta = 8.75$ indicates that it is attributable to the monometallic species **11**. The ^{31}P spectrum features a large number of lines of different intensity arising from the AB_2-like multiplets produced by the various components of the mixture.

On the contrary, the $^1H,^{183}W$-HMQC spectrum of the mixture is much easier to interpret and supports the assignments given above (Figure 3). Now, the signals of W_A in **7** and of the tungsten atom in **8** are slightly shifted to higher field ($\Delta\delta \approx 0.5$ ppm). However, the important point is that a new correlation is observed between a ^1H multiplet at $\delta = 8.75$ and a tungsten signal at $\delta = -2706$, which must correspond to the monometallic complex **11**. This confirms that $\delta^{183}W$ in the series of complexes studied here decreases on decreasing the amount of $W(CO)_5$ in the molecule.

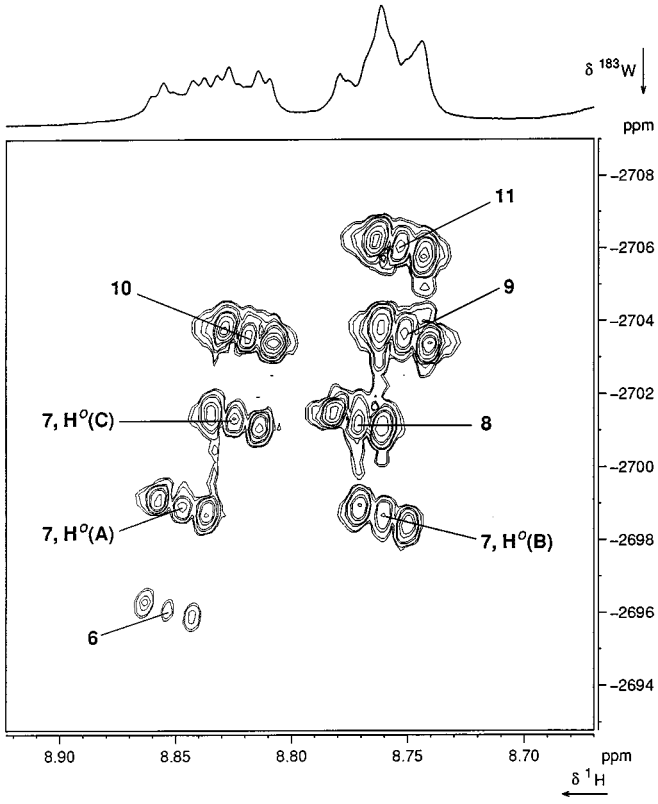

Figure 3. $^1H,^{183}W$ HMQC of a mixture of **2** and $[W(MeOH)(CO)_5]$ in a ratio of 1:3

Conclusions

The multinuclear magnetic resonance study performed on the two model cyclotriphosphazenes and their $W(CO)_5$ complexes has revealed that complexation can be monitored through several nuclei of the molecule. The δ^1H variations can be explained in terms of a mixture of charge polarization and anisotropic effects, which are difficult to predict. Moreover, the ^1H-NMR spectra of the polymetallic complexes show strongly overlapped signals, which render this nucleus of low diagnostic value for identification purposes. However, the high sensitivity of transition metal nuclei to small electronic changes in their coordination spheres has allowed the use of ^{183}W NMR in assigning all the components of the complex mixtures of compounds incorporating different amounts of tungsten, as well as positional isomers, with ^{183}W chemical shift differences in the range of 1−4 ppm. $\delta^{183}W$ values have been found to decrease on increasing the number of tungsten atoms in the molecule, and screening of the ^{15}N nuclei of the pyridine rings bonded to the metal center has revealed the same trend.

Experimental Section

General: All reactions were carried out under dry nitrogen. K_2CO_3 was dried at 140°C prior to use. The acetone used as solvent was predistilled from $KMnO_4$, and distilled twice from anhydrous $CaSO_4$. Methanol was distilled from CaH_2. Petroleum ether refers to the fraction boiling in the range 60−65°C. Hexachlorocyclotriphosphazene $[N_3P_3Cl_6]$ (Fluka) was purified by recrystallization from hot petroleum ether and dried in vacuo. The starting phosphazenes $[N_3P_3(dobp)Cl_4]$ and $[N_3P_3(dobp)_2Cl_2]$ were prepared as described elsewhere.[22] The complex $[W(MeOH)(CO)_5]$ was obtained as described in the literature.[23] − Elemental analyses: Perkin−Elmer 2400. − IR: Perkin−Elmer FT 1720-X, Paragon 1000 (KBr pellets). − NMR: Bruker AMX 400; spectra were referenced to tetramethylsilane for ^1H, neat $MeNO_2$ for ^{15}N, 85% H_3PO_4 for ^{31}P, and Na_2WO_4 for ^{183}W. The spectral parameters for the $^{31}P,^{15}N\{^1H\}$-HMQC[17] and $^1H,^{183}W$-HMQC[24] experiments have been described previously. Linear prediction of the 2D spectra using standard Bruker software was employed. Samples were prepared in $CDCl_3$ and the spectra were measured at 303 K. In view of the very small shifts in δ that we aimed to detect, experiments were performed several times with different samples in order to minimize systematic errors arising from concentration and temperature variations.

$[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2]$ (1): A mixture of $[N_3P_3(dobp)_2Cl_2]$ (0.304 g, 0.53 mmol), HOC_5H_4N-4 (0.122 g, 1.28 mmol) and K_2CO_3 (2.0 g, 14.5 mmol) in acetone (50 mL) was refluxed for 3 h. The volatiles were then removed in vacuo and the residual solid was washed with water (3 × 80 mL) and extracted with CH_2Cl_2 (3 × 50 mL). The organic phase was dried over anhydrous Na_2SO_4, filtered, and the solvent was evaporated in vacuo. The product was recrystallized from CH_2Cl_2/petroleum ether to give **1** as a very pale yellow crystalline solid. Yield 0.25 g (67%). − $C_{42}H_{24}N_5O_6P_3$ (786.9): calcd. C 59.1, H 3.50, N 10.1; found C 58.4, H 3.60, N 9.82.

$[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4]$ (2): A mixture of $[N_3P_3(dobp)Cl_4]$ (0.461 g, 1 mmol), HOC_5H_4N-4 (0.456 g, 4.8 mmol) and K_2CO_3 (2.0 g, 14.5 mmol) in acetone (50 mL) was refluxed for 6 h. The volatiles were then removed in vacuo and the residual solid was washed with water (3 × 80 mL) and extracted with CH_2Cl_2 (3 × 50 mL). The organic phase was dried with anhydrous Na_2SO_4, filtered, and the solvent was evaporated in vacuo. The product was recrystallized from CH_2Cl_2/petroleum ether to give **2** as a very pale yellow crystalline solid. Yield 0.52 g (75%). − $C_{36}H_{24}N_7O_6P_3$ (742.9): calcd. C 55.3, H 3.48, N 14.1; found C 55.0, H 3.35, N 13.9.

Preparation of the Mixture of Complexes $[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2\{W(CO)_5\}_x]$, $x = 1$ (4), $x = 2$ (3): A water-cooled solution of $[W(CO)_6]$ (0.104 g, 0.296 mmol) in methanol (18 mL) was ir-

radiated with UV light until the disappearance of the IR band at 1977 cm^{-1} (ca. 1 h). The resulting orange solution (IR bands at 2075 w, 1932 s, and 1887 m, br. cm^{-1}) was then added to a solution of the phosphazene $[N_3P_3(dobp)_2(OC_5H_4N\text{-}4)_2]$ (**1**) (0.100 g, 0.145 mmol) in CH_2Cl_2 (20 mL) and the mixture was stirred at room temperature until the disappearance of the IR band at 1887 cm^{-1} (ca. 4 h). The volatiles were then removed in vacuo and the residue was washed with petroleum ether (2 × 30 mL) to leave a yellow solid. Yield 0.12 g. Variation of the proportions of the carbonyltungsten and the phosphazene resulted in mixtures of different composition. − IR (KBr pellet): $\tilde{\nu}$ = 2072 w cm^{-1}, 1975 w, 1918 s, br. (CO).

Preparation of the Mixture of Complexes $[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4\{W(CO)_5\}_x]$, x = 1 (11), x = 2 (8, 9, 10), x = 3 (7), x = 4 (6): A water-cooled solution of $[W(CO)_6]$ (0.208 g, 0.591 mmol) in methanol (24 mL) was irradiated with UV light until the disappearance of the IR band at 1977 cm^{-1} (ca. 1 h). The resulting orange solution (IR bands at 2075 w, 1932 s, and 1887 m, br. cm^{-1}) was then added to a solution of the phosphazene $[N_3P_3(dobp)(OC_5H_4N\text{-}4)_4]$ (**2**) (0.092 g, 0.133 mmol) in CH_2Cl_2 (24 mL) and the mixture was stirred at room temperature until the disappearance of the IR band at 1887 cm^{-1} (ca. 13 h). The volatiles were then removed in vacuo and the residue was washed with petroleum ether (2 × 30 mL) to leave a yellow-brown solid. Yield 0.10 g. Variation of the proportions of the carbonyltungsten and the phosphazene resulted in mixtures of different composition. − IR (KBr pellet): $\tilde{\nu}$ = 2073 w cm^{-1}, 1975 sh, 1910 s, br. (CO).

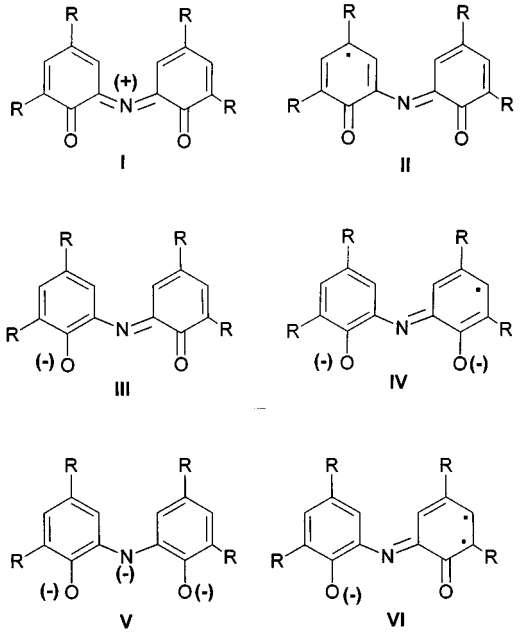
Syntheses and Characterization by NMR Spectroscopy and X-ray Diffraction of Complexes Derived from Metals of Groups 2 and 13 and the Ligand Bis(3,5-di-*tert*-butyl-1-hydroxy-2-phenyl)amine

Carlos Camacho-Camacho,[a] Gabriel Merino,[b] Francisco Javier Martínez-Martínez,[c] Heinrich Nöth,[d] and Rosalinda Contreras*[b]

Keywords: Alkaline earth metals / Group-13 metals / Coordination chemistry / Bis(3,5-di-*tert*-butyl-1-hydroxy-2-phenyl)amine ligand / Nonacoordinated strontium compound

Reaction of 3,5-di-*tert*-butylcatechol and aqueous ammonia with boron, aluminum, gallium, or strontium chloride, or with calcium or barium acetate produce, under oxidizing conditions, neutral complexes of stoichiometric formulae ML (M = BCl), ML_2, [M = Al (**2**), Ga (**3**), Ca (**4**), and Ba (**5**)], and ML_3H [M = Sr (**6**)] [L = different oxidation states of bis(3,5-di-*tert*-butyl-1-hydroxy-2-phenyl)amine]. The structures of **1** and **4**–**6** were established by ^1H- and ^{13}C-NMR spectroscopy and of **2**, **3**, and **6** by X-ray diffraction. The coordination compound ClBL (**1**) was obtained by transmetallation of ZnL_2 with BCl_3. It is a tetracyclic compound with tetracoordinated boron and nitrogen atoms, the ligand being in the reduced form, bis(hydroxyphenyl)amine. The paramagnetic complexes **2** and **3** crystallized in the triclinic system and are hexacoordinated with two orthogonal planar ligands bonded to the metal atoms. The ligands appear in two different oxidation states: one as the monoanion and another as a radical dianion. Based on their X-ray diffraction molecular structures, it is deduced that both ligands have similar structures, confirming electronic delocalization and fast interconversion of their oxidation states. Ca and Ba complexes are diamagnetic and hexacoordinated, both ligands being monoanions The strontium complex crystallized in the monoclinic system, the metal atom is nonacoordinated, having two ligands as monoanions, and a third one is a neutral protonated diquinone. Its structure is a distorted helix with three paddles in a C_3 geometry and its unexpected diamagnetic behaviour is due to the presence of a reduced protonated ligand.

Introduction



We are interested in developing the heterocyclic chemistry of main-group elements and bis(hydroxyphenyl)amines.[1−7] These heterocycles are particularly stable and are suitable models for structural and spectroscopic investigation. The preparation of some organometallic heterocycles bearing a bis(hydroxyphenyl)amine ligand has already been reported.[2,6,8−10] A relevant property of the bis(hydroxyphenyl)amine molecules is that they allow the stabilisation of uncommon species such as some which contain pentacoordinated phosphorus atoms.[1,2,4]

The template synthesis with 3,5-di-*tert*-butylcatechol and metals in the presence of ammonia lead to metallic hexacoordinated complexes bearing two ligands formed by the condensation of two catechol molecules to one nitrogen atom.[11] The complexes have two planar, tridentate ligands. The analogous transition-metal complexes of general formula ML_2 have been the subject of extensive research work[11−19] and several X-ray diffraction structures have been reported.[12−18] Theoretically, several different stable oxidation states could exist for this ligand, ranging in charge from 0 to −3 (Scheme 1). It is surprising that only the monoanion (**III**) and the radical dianion (**IV**) have been found in the previously reported complexes. The oxidation state of the ligand depends on the nature of the metals: With metals in oxidation state II both ligands appear as monoanion (**III**), while for metals in oxidation state III one ligand is a monoanion (**III**) and the other is a radical dianion (**IV**), and in metals in oxidation state IV both are radical dianions (**IV**).

The reports in the literature have focused on complexes formed with two different oxidation forms of the ligand, **III** and **IV**. Detailed magnetic and electrochemical studies of these compounds have been performed.[11−21] The magnetic studies indicate that there is a strong ferromagnetic coupling between the ligands through the empty metal orbitals. It was proposed that they are valence tautomers with an intramolecular electronic tautomeric equilibrium due to electronic transfer between the ligand and the metal.[21] In addition, it was found by electrochemical studies that the complexes can suffer one-electron oxidation or one-electron reduction, both processes occurring at the ligand-based orbitals.[20]

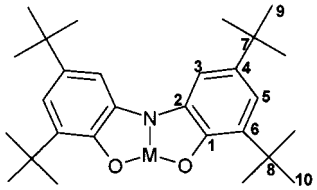
Scheme 1. Oxidation states of the bis(3,5-di-*tert*-butyl-1-hydroxy-2-phenyl)amine ligand



The versatile behaviour of this ligand guarantees the interest of further studies on these compounds. Relatively little effort has been directed toward synthesising and studying the reactivity of the bis(hydroxyphenyl)amines and main-group and alkaline-earth metals. Therefore we have investigated the complexes derived from bis(3,5-di-*tert*-butyl-1-hydroxy-2-phenyl)amine and boron (**1**), aluminium (**2**), gallium (**3**), calcium (**4**), barium (**5**), and strontium (**6**). During the preparation of this manuscript the synthesis and a magnetic investigation for the aluminium derivative has been reported;[21] the crystal structure for this compound is presented in this study.

Results and Discussion

Compound **1** has been synthesized by BCl_3 transmetallation of ZnL_2. Complexes **2**–**6** have been prepared directly by reaction of 3,5-di-*tert*-butylcatechol and the metallic chloride or acetate in the presence of ammonia. All are dark solids.

Compounds **1** and **4**–**6** are diamagnetic and their ^{1}H-NMR spectra are similar (Table 1). The ^{13}C-NMR spectra of the complexes **1** and **4**–**6** (Table 2) show six resonances in the aromatic domain indicating that the phenyl rings in each complex are equivalent. The chemical shift of atom C-1 in compound **1** is $\delta = 153.9$, characteristic of a phenoxy group. In contrast, the chemical shift for this atom in compounds **4**–**6** ($\delta = 176-180$) is consistent with quinone character. The chemical shift for the ^{11}B-NMR resonance ($\delta = +14.9$) of compound **1** indicates that the boron atom is tetrahedral and coordinated to the nitrogen atom. ^{1}H- and ^{13}C-NMR data, the mass spectrum and the elemental analysis indicate that the boron atom is bonded to one chlorine atom and to one reduced ligand **V**. Its structure is depicted in Scheme 2.

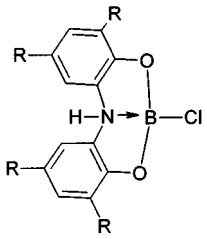


Table 1. ^{1}H-NMR chemical shift data of complexes **1** and **4**–**6** (in C_6D_6); the numbering of the atoms is shown in the figure

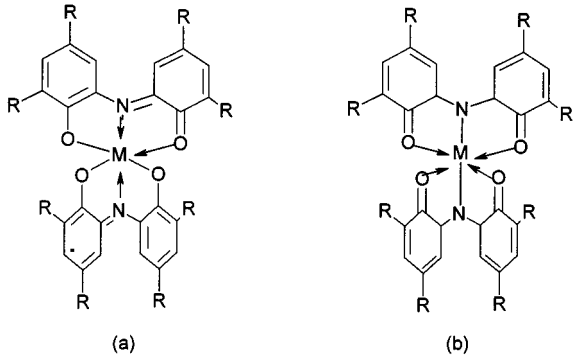
Compound	3-H	5-H	9-H (*t*Bu)	10-H (*t*Bu)
1	7.21	6.95	1.34	1.28
4	7.05	6.89	1.20	1.08
5	7.08	6.91	1.22	1.11
6	7.26	6.75	1.37	1.24

Table 2. ^{13}C-NMR chemical-shift data of complexes **1**, and **4**–**6** (in C_6D_6)



Compound	C-1	C-2	C-3	C-4	C-5
1	153.9	130.9	116.3	140.6	123.5
4	176.8	142.7	117.4	144.3	130.7
5	176.0	142.8	117.5	144.4	130.7

6	142.8	34.7	29.4	34.1	28.7

Scheme 2. Proposed structure for compound **1**

Complexes **2** and **3** were found to crystallize from CH_2Cl_2/ethanol. Crystals of **2** and **3** are triclinic, space group $P-1$. Selected bond length and angles are listed in Table 3 and the molecular structures are depicted in Figures 1–3. The neutral complexes **2** and **3** show oxygen atoms occupying the equatorial sites of an octahedron, with two tridentate ligands, the four cycles of each ligand lying almost in the same plane. The MO_4N_2 coordination spheres show only slight distortions in bond angles at the equatorial atoms. Thus, angles for compound **2** are O2–Al–O4 91.0(2), O2–Al–O3 91.5(2), O1–Al–O4 92.3(2), O1–Al–O3 89.6(2)°, and those for compound **3** are O1–Ga–O4 92.7(1), O1–Ga–O3 91.5(1), O2–Ga–O4 89.8(1), O2–Ga–O3 91.52(14)°, while the angles between the atoms N–M–O show deviations from ideal octahedral geometry (Tables 3, 4). The nitrogen atoms are in *trans* po-

sitions [N1−Al−N2 176.8(3) and N1−Ga−N2 176.7(1)°]. The M−O bond lengths are identical, for compound **2** the average Al−O bond length is 1.877(5) Å and for compound **3** the average Ga−O bond length is 1.959(3) Å, similar to the Ga−O bonds reported for other hexacoordinated gallium compound [1.96(1) Å].[8] The Al−N and Ga−N bond lengths differ slightly [Al−N1 1.982(5), Al−N2 1.976(5), Ga−N1 2.014(3), Ga−N2 2.025(3) Å]. It is proposed[21] that the Al and Co^{III} compounds are formed by the bonding of two ligands in two different oxidation states, ligand **III** and ligand **IV** (Schemes 1 and 3). The C−O bond lengths in **2** and **3** are similar (1.29 Å) and indicate a double-bond character; the C−N bond lengths are also similar and their lengths are in between a double and a single bond (1.35 Å). The pattern of carbon−carbon bond lengths in **2** and **3** shows that the bonds C3−C4 and C5−C6 are consistently shorter than the other C−C bonds. We could not distinguish, based on bond lengths, two different structures of the ligands that could be attributed to different oxidation states. This could mean that the ligands become similar by the electronic delocalization and fast interconversion of the oxidation states between them as has been proposed for other compounds.[21]

Scheme 3. (a) Proposed structure for compounds **2** and **3**; (b) proposed structure for compounds **4** and **5**

From the NMR data and elemental analysis, it is deduced that compounds **4** and **5** derived from calcium and barium are bonded to two monoanionic ligands **III** in a hexacoordinated array analogous to that of aluminium and gallium complexes.

Compound **6** crystallizes from CH_2Cl_2/ethanol monoclinic in space group $P2(1)/c$, and its X-ray structure is shown in Figures 3−4. The complex presents a new coordination behaviour because three ligands are bonded to a metal centre, resulting in a nonacoordinate strontium atom. The nine bond lengths between the strontium and the ligands are normal coordination bonds with Sr−O bonds varying from 2.47 to 2.71 Å, whereas the Sr−N bonds vary from 2.67 to 2.77 Å. The strontium bond lengths are in accord with another nonacoordinated compound [strontium bis(thiocyanate)−hexaethylene glycol].[22] The structure of the molecule can be best described as a helix of three paddles of distorted C_3 geometry. If the different oxidation states of the ligand are considered the compound must be formed by two ligands in the monoanion oxidation state

a hydrogen atom sitting between the oxygen atoms O4 and O5 was discovered (bond lengths: O4−H 1.341 Å, O5−H 1.148 Å, bond angle O4−H−O5 174.1°) and the position of this hydrogen atom was freely refined (x, y, z; H_{iso} = 0.0897). Thus, the third ligand was in fact a new reduced neutral form of the ligand (Scheme 4). In each ligand, the four carbon and nitrogen atoms are found in a plane. If only these atoms are considered the structure resembles a helix formed with three bidentate chelates in a hexacoordinated array (Figure 4). If the oxygen atoms are examined, they lie slightly out of the plane for each ligand and they are folded in a *trans* orientation. Examination of the bond lengths shows that the two ligands bonded to the hydrogen atom are similar with one short C−O bond length (1.23−1.26 Å) and a longer C−O one (1.33 Å, Table 5). The other ligand has two short C−O bonds (1.26 Å). The point group of **6** is not perfectly C_3 because of the presence of the hydrogen atom, the bond lengths of the atoms bonded to the strontium atom are different. The presence of the hydrogen bonding between atoms O4 and O5 makes the angle O4−Sr−O5 narrower [54.6(1)°] than the other two similar angles O2−Sr−O3 [90.03(1)°] and O6−Sr−O1 [87.7(1)°]. One of the ligands presents shorter distances [Sr−O1 2.475(2), Sr−O2 2.476(2) Å] than the other two [Sr−O3 2.569(2), Sr−O4 2.686(2) Å and Sr−O5 2.719(2), Sr−O6 2.575(2) Å]. The aromatic rings in each ligand are twisted due to the steric effect of the *tert*-butyl groups and the helical structure.

Scheme 4. Proposed structure for compound **6**

Conclusions

The X-ray diffraction of complexes of Al and Ga show that they are isostructural and that the ligands in these compounds also have similar structures, confirming the electronic delocalization and fast interconversion of the oxidation state of the ligands (**III** → **IV**). Hexacoordinated complexes are also proposed for the diamagnetic complexes of Ba and Ca. The strontium compound is the first example with a nonacoordinated metal atom for the complexes with bis(3,5-di-*tert*-butyl-1-hydroxy-2-phenyl)amine as ligand. The compound has three tridentate ligands in a distorted helix of three paddles, with a geometry close to C_3. The diamagnetic behaviour results from the presence of a new

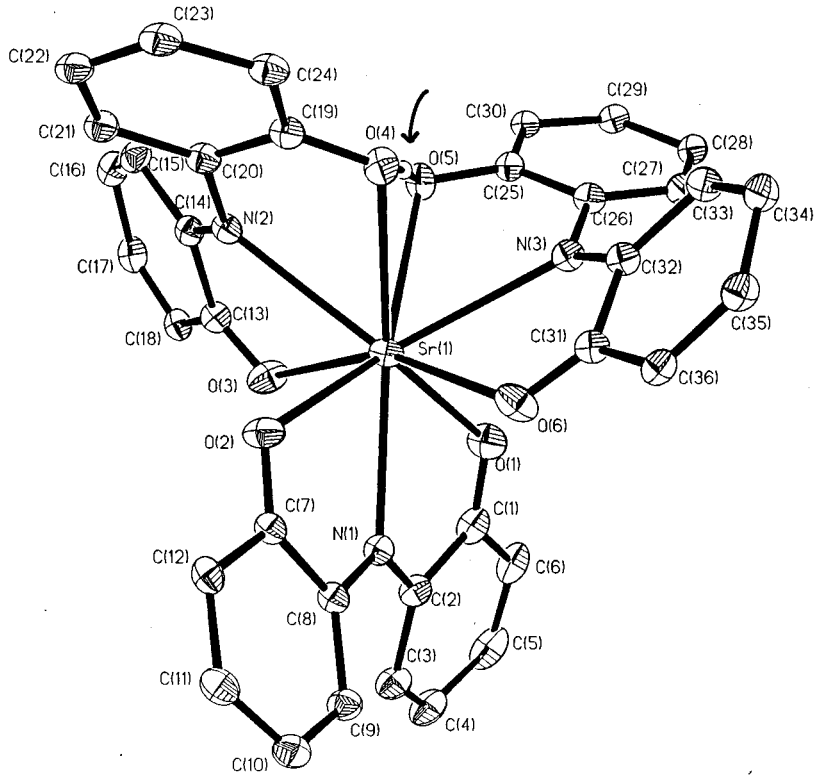

Figure 3. Molecular structure of $C_{84}H_{120}SrN_3O_6$ (**6**); the *tert*-butyl groups are not shown and the arrow marks the position of the hydrogen atom bonded to O4 and O5; thermal ellipsoids represent a 25% probability

oxidation state of the ligand that transforms the neutral radical oxidation state **II** (Scheme 1) into a diamagnetic neutral one.

Experimental Section

General Remarks: All solvents were freshly distilled and dried before use according to established procedures. − Melting points were measured with a Gallenkamp apparatus and are uncorrected. − The IR spectra were taken in KBr discs using a Perkin Elmer 16F PC IR spectrometer. − All the NMR spectra were obtained on a JEOL GXS-270 and JEOL-400 spectrometers in $CDCl_3$ solution. ^1H- and ^{13}C-NMR spectra were measured with TMS as the internal reference. − Elemental analyses were performed with a Fisons Instrument EA 1108 elemental analyzer CHNS-O. − Mass spectra were obtained with a Hewlett-Packard HP 5989A. − The X-ray

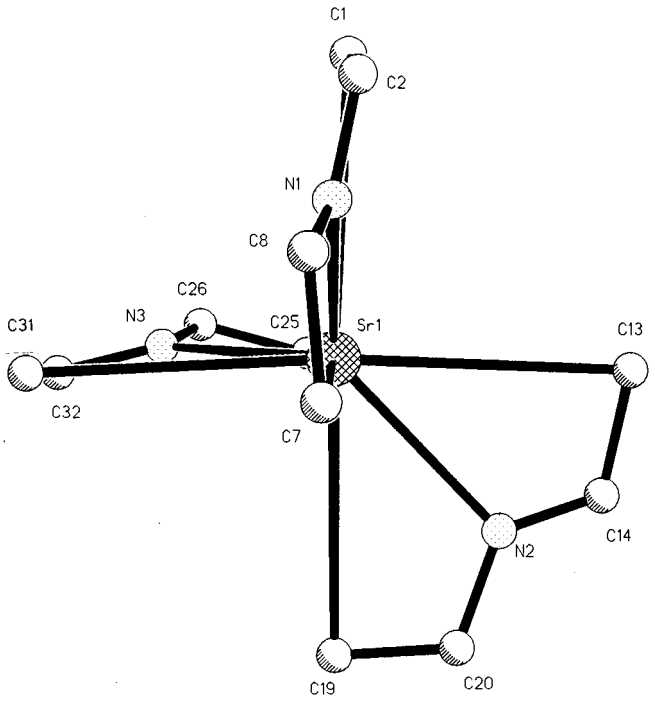

Figure 4. The core structure of the strontium complex **6** showing a helix of three paddles, the four carbon and nitrogen atoms being coplanar

diffraction studies of the gallium and aluminium compounds were performed with an Enraf-Nonius CAD4 diffractometer [λ(Mo-K_α) = 0.71073 Å, monochromator: graphite, T = 293(2) K, ω−2θ scan]. Cell parameters were determined by least-squares refinement of diffractometer angles for 24 automatically centred reflections. The X-ray diffraction study of the strontium compound **6** was performed with a Siemens P4 instrument equipped with a CCD area detector and a low-temperature device LTP2. The unit cell was determined from the data for 75 frames and data collection was performed in the hemisphere mode with Δφ = 0−3°, 10 s/frame exposures. Data reduction used the program SAINT. The structures were solved by direct methods (SHELXL-86). The experimental parameters are listed in Table 6. Atom H of compound **6** was found in the difference Fourier and refined freely including U_i. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-114655 to -114657. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[Bis(3,5-di-*tert*-butyl-2-hydroxy-2-phenyl)amine]boron Chloride (1): A solution of 0.50 g (0.54 mmol) of Zn[3,5-di-*tert*-butyl-1,2-quinone (3,5-di-*tert*-butyl-2-hydroxy-1-phenyl)imine]$_2$[11] in 20 mL of dry benzene was treated dropwise at room temperature and under vigorous stirring with BCl3·DMS (96 mg, 0.54 mmol). Additional stirring for 5 h afforded a suspension. The $ZnCl_2$ formed was filtered and the solvents were removed at reduced pressure to leave a violet powder. The powder was washed with hexane to obtain 0.156 g of **1** (63%). − ^{11}B NMR: δ = +14.9. − IR (KBr): $\tilde{\nu}$ = 2960 cm^{-1}, 1458, 1420, 1364, 1202, 1036, 876, 670 and 474. − MS; *m*/*z*: 469 [M$^+$] (calcd. 469). − $C_{28}H_{41}BClNO_2$ (469.81): calcd. Steric Promotion of Aromatic C–H Bond Activation in Primary Benzylamines

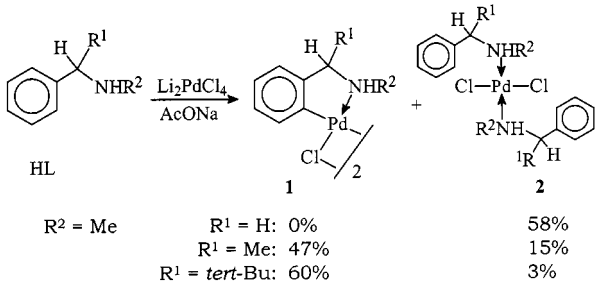
Valery V. Dunina,*[a] Lyudmila G. Kuz'mina,[b] Marina Yu. Kazakova,[a] Ol'ga N. Gorunova,[a] Yury K. Grishin,[a] and Elena I. Kazakova[c]

Keywords: Palladium / Primary benzylamines / NMR spectroscopy / Structure elucidation / Conformation analysis

ortho-Palladation of a sterically crowded primary benzylamine, α-phenylneopentylamine, was accomplished in a moderate yield of 50% in the reaction with the weakest of palladation agents (Li_2PdCl_4) under very mild conditions, due to a steric promotion of an aromatic C–H bond activation. The structure of dimer **1a** thus formed and the palladacycle conformation were established on the basis of ^{1}H-NMR spectroscopy of its mononuclear derivatives with [D_5]pyridine (**3a**) and triphenylphosphane (**4a**), and an X-ray investigation of the latter.



Introduction

Widening the scope of direct intramolecular palladation reactions is of great importance for further development of regioselective palladium-mediated organic synthesis.[1][2] In particular, cyclometallated derivatives of primary amines seem to be especially promising synthons for the heterocyclization processes based on a combined use of the C−Pd and N−H bond reactivities.[3−5] However, after initial unsuccessful attempts with the use of tetrachloropalladate,[6] the direct *ortho*-palladation reactions of these substrates proved to be elusive.

Several recent findings have made an important contribution towards a solution to this problem: (i) the use of palladation agents of higher electrophilicity; and (ii) the realization of the necessity for creating a coordination vacancy at a metal centre. The first point includes a substitution of palladium acetate for commonly used tetrachloropalladate salts.[7−11] The second goal may be simply achieved by keeping the palladium/ligand ratio equal to 1:1. It results in the formation of binuclear coordination complexes as reaction intermediates capable of dissociating easily to form two unsaturated tricoordinated species of high reactivity.[8][10] At this stage, a polar solvent may facilitate the dissociative formation of the coordination vacancy that is required for a subsequent C−H bond activation. In principle, all these problems may be solved simultaneously by utilizing the methodology involving a halide abstraction from the intermediate bis(amine) complexes [$Pd(HL)_2Hal_2$] by the action of soluble Ag^+ salts.[12][13]

Despite numerous publications dealing with the direct cyclopalladation of primary benzylamines, the possibility of steric promotion of this process still remains unexplored. The pioneer work of Lewis and co-workers[14] cannot be considered as conclusive enough because this publication does not contain any spectral evidence that the isolated (triphenylmethylamine)palladium complexes have a cyclopalladated structure.

Our investigation of the direct *ortho*-palladation of secondary arylalkylamines[15−19] has revealed a phenomenon of a remarkable steric facilitation of this process. The reaction of Li_2PdCl_4 with a series of *N*-methylbenzylamines was found to be dependent on the volume of substituent R^1 (R^1 = H, Me, *t*Bu) in the α-benzylic position.

Scheme 1. Steric promotion of aromatic C−H bond activation in secondary benzylamines

Thus, the reaction with α-nonsubstituted *N*-methylbenzylamine stops at the stage of the simple coordination complex of type **2**;[15] α-Me-substituted amine forms *ortho*-palladated dimer of type **1** only in refluxing methanol in moderate yield of 47%.[15] In contrast, α-*t*Bu-substituted analogue undergoes the cyclopalladation reactions even at room temperature in excellent yield of 86%.[18][20] Moreover, activation of sp^3 C−H bond (26%) becomes possible in the case of the latter sterically crowded benzylamine in competition with sp^2 C−H bond activation (60%) to give two possible regioisomers in a ca. 1:3 ratio.[20]

These findings gave an impetus for studying a similar steric effect in the C−H bond activation of primary benzylamines. The role of solvents, particularly acetone, in these processes is also of interest. Another task is the inves-

tigation of conformational features of the five-membered palladacycles containing a primary amino group using ^{1}H-NMR and X-ray studies. These characteristics seem to be especially important for utilization of the new kind of palladacycles in the processes of chiral recognition (for example, see ref.[21]).

Results and Discussion

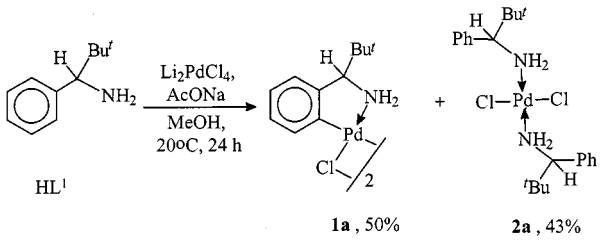
Cyclopalladation Reactions

To estimate the role of steric effects in the processes of the intramolecular C−H bond activation in primary benzylamines, we have chosen α-phenylneopentylamine (HL^1) bearing a bulky *tert*-butyl group in the α-benzylic position as the most suitable ligand. In accordance with recent information regarding the cyclometalation mechanisms,[22−24] the equimolar ligand/Pd ratio was kept under all conditions to facilitate the formation of the free coordination vacancy after the first stage of the ligand-to-palladium *N*-coordination.

Firstly, a study of the HL^1 *ortho*-palladation was carried out using palladium(II) acetate, one of the most efficient reagents due to its high electrophilicity.

Conditions for 1) and yields: benzene, r.t., 24h - 43%
acetone, 50°C, 50h - 68%
MeOH, 50°C, 1.5 h - 68%
MeOH, r.t., 24h - 71%

Scheme 2. Influence of conditions on the *ortho*-palladation of the primary amine HL^1 with palladium(II) acetate



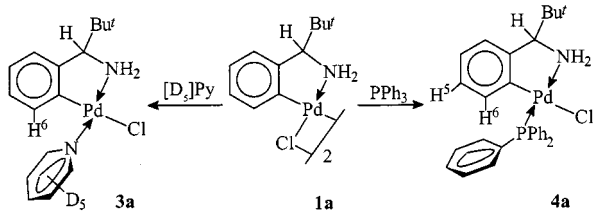
The reaction performed in benzene at room temperature afforded (after standard AcO^-/Cl^- metathesis and chromatographic purification) the desired dimeric chloro-bridged *ortho*-palladated complex **1a** in a 43% yield. In comparison, the α-methyl-substituted μ-bromo analogue was obtained previously under similar conditions in a yield of only 17% after one day, or in the same yield (43%) after three days.[9] Both enantiomers of the corresponding μ-chloro dimer were prepared by Fuchita in higher yields of 57−63% by means of a two-step procedure (including the isolation of the intermediate μ-acetato dimer) only after heating at 50°C for a long period of time.[11]

The yield of dimeric complex **1a** was increased to 68% by carrying out the same reaction in acetone at higher temperature (50°C); however, this procedure requires ca. 50 hours of heating. The best results were achieved when the reaction was performed in methanol; dimer **1a** was isolated in a yield of nearly 70% after heating for 1.5 hours at 50°C or after stirring for 24 hours at room temperature. In comparison, the formation of the α-Me-substituted analogue in a 50−70% yield required heating at 60°C for four hours.[21]

The results obtained in this series of *ortho*-palladation reactions with palladium(II) acetate make it evident that polar solvents have some advantages over the non-polar ones. It may be a consequence of their strong solvating effect that assists in the generation of the reactive three-coordinate intermediate of the [(HL)Pd(OAc)$_2$(Solv)]-type[8] required for subsequent C−H bond activation. Solvent basicity may also be important at the stage of C−H bond activation.[24]

The first successes in the palladation of primary benzylamines were achieved with the use of acetone as solvent.[8,11,13] Such a choice seems to be a rather strange one when the possibility of a metal-assisted interaction between the carbonyl and NH_2 groups is considered. Precedents for the C=N bond formation[25] and cleavage[26−28] at the palladium matrix are known. These transformations may allow the reaction to go through *ortho*-palladation of the more reactive short-lived ketimine intermediate. This route may result in the facilitation of the whole process. However, contrary to expectations, the use of acetone as solvent in the palladation of the amine HL^1 did not provide any advantages over the use of methanol; moreover, in this case, more vigorous conditions or increased reaction times are required. This observation allowed for the exclusion of the *ortho*-palladation route via intermediate ketimine ligand formation (at least for HL^1).

The results obtained when using the weak palladation agent Li_2PdCl_4 may be considered as the most convincing evidence for the steric promotion of the C−H bond activation: dimer **1a** was isolated in a 50% yield in the reaction performed in MeOH in the presence of sodium acetate excess at room temperature.



Scheme 3. *ortho*-Palladation of primary amine HL^1 using tetrachloropalladate

Under these conditions a simple coordination complex *trans*-[Pd(HL^1)$_2$Cl$_2$] (**2a**) was isolated in a yield of ca. 43% (based on the ligand) as a side product. Its 1:2 stoichiometry differs from the starting Pd/HL^1 ratio of 1:1 and may be explained by a partial Pd^{II} reduction. Under the same conditions, primary α-methylbenzylamine forms only a coordination compound of type **2**, which tends to decompose at increased temperatures.[15] The formation of complex **2a** occurs without any diastereoselectivity: a mixture of nearly equal amounts of (*R**,*R**)- and (*S*,*R*)-diastereomers was isolated in the reaction of racemic HL^1 with Li_2PdCl_4. One of these diastereomers may be separated by crystallization.

We believe that two main factors determine the easier *ortho*-palladation of the sterically hindered ligands (includ-

ing amine HL^1): (i) a large effective volume of the ligand must increase an internal energy of the intermediate binuclear coordination compounds due to a set of unfavourable non-bonding interactions,[29] thus stimulating an intermediate dissociation to form reactive three-coordinate species; (ii) the same steric effect must result in a weakening of the Pd−N bond in the coordination intermediate,[30] to make the palladium(II) centre more electrophilic. Both effects essentially facilitate the C−H bond activation.

For the subsequent spectral and structural investigations of the new dimeric complex **1a**, its mononuclear derivative with [D_5]pyridine (**3a**) was generated in situ, and an adduct with PPh_3 (**4a**) was prepared by a standard μ-chloro bridge cleavage.

Scheme 4. Mononuclear derivatives of the *ortho*-palladated primary amine HL^1

The identity of the samples of dimer **1a** prepared under all afore-mentioned conditions was confirmed by their melting points, TLC of complex **1a** and the ^{1}H-NMR spectra of its mononuclear derivatives **3a** and **4a**.

Structure of Complexes 1a−4a in Solution

The *ortho*-palladated structure of complexes **1a**, **3a** and **4a** was confirmed by the IR and ^{1}H-NMR spectra (Table 1) using a comparison with the spectral data for simple coordination compound **2a**. An assignment of their ^{1}H-NMR spectra was based on homonuclear spin-spin decoupling experiments and NOE differential spectroscopy.[31]

The IR spectrum of dimer **1a** contains a single intense absorption of the aromatic C−H bonds out-of-plane deformation at 740 cm^{-1}[18,19,32,33] compared to two bands found in the IR spectra of the free starting amine HL^1 and coordination complex **2a** (720, 785 and 705, 750 cm^{-1}, respectively). The ^{1}H-NMR spectra of mononuclear adducts **3a** and **4a** reveal only four well-resolved single-proton resonances of the *ortho*-phenylene group in the aromatic field (δ = 6.0−7.0), compared to two complicated multiplets of *ortho* (δ = 7.00, 4 H) and *meta* and *para* protons (δ = 7.27, 6 H) further downfield in the case of coordination complex **2a**.

The nine-proton singlet of the *t*Bu group (δ = 1.23−1.30 for adducts **3a** and **4a**) unambiguously supports the suggestion that the palladation site is the *ortho*-position of benzylamine Ph ring. Both the diastereotopic nonequivalence (Δδ = 0.3−2.7 ppm) and the coordination shift values (Δδ = 1.7−4.5 ppm) observed for the two NH_2 protons in the complexes **2a**−**4a** confirm the *Pd*-coordination of the primary amino group. Thus, the η^1-*N*-coordination of the HL^1 ligand in complex **2a** and η^2-*C*,*N*-binding of the $(L^1)^-$ ligand in adducts **3a**, **4a** and also in starting dimer **1a** are evident enough.

The assignment of the signals of the aromatic palladacycle protons is important not only for the confirmation of the *ortho*-palladated structure and the geometric configuration of these and related complexes, but also for the utilization of the palladacycle as an internal reference in the estimation of the stereochemistry of *Pd*-bonded chiral ligands.[34−39]

Unfortunately, most publications devoted to the *ortho*-palladation of primary benzylamines either disregard any

assignments of the aromatic protons[9,13,21] or do so only in part.[11] Moreover, several attempts to assign these signals for phosphane adducts[8][10] gave a result which strongly disagreed with the usual trends reported for the related derivatives of secondary[7,18,19,40,41] and tertiary [33,42−44] benzylamines. This disagreement includes three points: (i) the most downfield signal was assigned to the H^6 proton (nearest to the metallation site); (ii) as a result, the long-range constant $^5J_{HP}$ of a very high value was ascribed to the H^3 proton that is far remote from the ^{31}P nucleus; (iii) at the same time, the corresponding constant for the H^6 proton is lacking despite its proximity to the ^{31}P nucleus being closer than the sum of their van der Waals radii of 3.0 Å[45] (for example, 2.78 Å was found by the X-ray study of a related complex[46]).

Such a large discrepancy between the spectral characteristics of palladacycles for derivatives of primary benzylamines on the one hand, and those of secondary and tertiary amines on the other, forced us to provide unambiguous support for our version of assignment on the basis of the NOE differential spectra of the phosphane adduct **4a**.

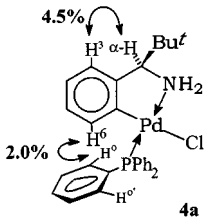

Figure 1. Selected $^1H\{^1H\}$ NOEs for the phosphane adduct **4a** in $CDCl_3$

The irradiation of the low-field H^3 proton of the palladated phenylene ring (δ = 7.00 for the **4a** in $CDCl_3$) results in an enhancement of ca. 4.5% of the signal for the α-benzylic methine proton nearest to H^3 (see Figure 1); when the *ortho*-protons of the PPh groups were irradiated (δ = 7.73, identified on the basis of the constant value of $^3J_{HP}$ = 11.1 Hz) the only observed interligand response was that of the H^6 proton (δ = 6.39, ca. 2%). Hence, a downfield position of the H^3 signal and an upfield location of the H^6 resonance of the palladated phenylene group are evident.

Thus, in the ^1H-NMR spectra of the arylphosphane adducts of *ortho*-palladated primary benzylamines, the sequence of the signals of the phenylene H^6-H^3 protons remains the same as in the case of their analogues derived from secondary and tertiary amines, namely, from high field (H^6) to low field (H^3). This tendency, as well as the detection of the J_{HP} constant for the H^6 proton, may be used for the reliable estimation of the geometric configuration and for the solution of stereochemical problems by means of NOE technique (cf. ref.[39,47,48]) using palladacycles as an internal reference.

A *trans*(C,Cl) geometry of the mononuclear derivatives of dimer **1a** seems to be evident enough from the high field position of the signals of the H^6 proton (**3a**) or the H^6 and H^5 protons (**4a**) of the palladated phenylene moiety, caused by the influence of anisotropy of the pyridine or *P*-phenyl rings, respectively. The large high-field value of the H^6 resonance in the ^1H-NMR spectrum of adduct **3a** (δ = 6.04) may be considered as an indication of the nearly orthogonal mutual arrangement of the pyridine and palladated phenylene rings.[49]

In the case of phosphane derivative **4a**, the signal of the H^6 proton appears at δ = 6.39, with the constant J_{HP} = 6.0 Hz, which is in close agreement with the values previously reported for related derivatives of primary aralkylamines (J_{HP} = 5.5−6.4 Hz).[50][51] For the more distant aromatic H^5 proton, this value decreases to J_{HP} = 0.5 Hz; it can only be detected by means of an NMR-spectrum simulation.

The conformation of the palladacycle formed by primary benzylamine HL^1 could be estimated by means of the analysis of the $HC^{\alpha}-NH$, $HC^{\alpha}-^{31}P$ and $HN-^{31}P$ spin-spin coupling constants. A strong dependence of the efficiency of the interaction between the protons of palladacycle and the ^{31}P nucleus of *Pd*-bonded phosphane ligands on the extent of their planarity may be expected from general considerations.[52][53]

A distinction in the assignments of two NH protons (NH^{eq} and NH^{ax}) is not a simple problem. In most reported ^1H-NMR spectra of *ortho*-palladated primary aralkylamines, these resonances were described as broad multiplets[8,13,21,51] or broad singlets[9][11] without their assignments. In the spectrum of pyridine adduct **3a** recorded in $CDCl_3$, the diastereotopic NH_2 proton signals appear as a broad apparent singlet (Δν > 20 Hz) and a broad doublet at δ = 5.89 and 3.14, respectively, with a typical geminal coupling constant of $^2J_{NH\text{-}NH} \approx 11$ Hz (cf. ref.[51,54,55]).

Homonuclear decoupling of adduct **3a** showed that a broad downfield signal at δ = 5.89 originates from the NH proton interacting with the α-methine proton ($^3J_{HCNH}$ = 5.7 Hz). In the case of phosphane adduct **4a**, the signals of NH protons are additionally complicated due to their spin-spin coupling with the ^{31}P nucleus. In the ^1H-NMR spectrum of **4a** measured in a $[D_6]$acetone/$CDCl_3$ mixture, two NH proton signals appear as a broad multiplet at δ = 5.19 ($^3J_{HNP}$ = 4.0 Hz, $^3J_{HCNH}$ = 6.0 Hz) and a doublet at δ = 3.58 ($^3J_{HNP} \leq 1.0$ Hz) with a geminal coupling constant of $^2J_{HNH}$ = 10.6 Hz.

Under these conditions, the α-methine proton of **4a** appears as a doublet of doublets at δ = 4.13 with the $^3J_{HCNH}$ and $^4J_{HCP}$ constants of 6.0 and 7.0 Hz, respectively. Both of these constants seem to be extremely useful for conformational analysis. The dependence of ^1H-^{31}P spin-spin coupling on the position of the α-CH proton (*pseudo*-axial or *pseudo*-equatorial) becomes evident from the spectral pattern for α-nonsubstituted palladacycles. Only one of the diastereotopic protons of the α-CH_2 group in phosphane adducts of *ortho*-palladated secondary[7][19] and tertiary benzylamines[56] shows a coupling with the ^{31}P nucleus ($^4J_{HCP}$ = 2.0−4.2). The average constant value of $^4J_{HCP}$ = 2.8 Hz reported for the two equivalent (on NMR time scale) α-benzylic protons in the more flexible α,*N*-nonsubstituted palladacycles,[50] may be used as a middle point for the conformation estimates. The $^4J_{HCP}$ = 6−8 Hz reported

for the strictly planar aldimine palladacycles may serve as the upper boundary point.[21][57]

The values of the $^4J_{HCP}$ constant for the α-methine proton ranging within 6.5−7.0 Hz in the ^{1}H-NMR spectra of complex **4a** are close to the above-mentioned upper limit. It may serve as an indication of its *pseudo*-equatorial position which is in agreement with the prediction of a *pseudo*-axial position of a bulky α-*t*Bu group. A comparison of these characteristics with those for the related derivatives of secondary[18][41] and tertiary α-*tert*-butylbenzylamines[44] ($^4J_{HCP}$ = 5.4−6.1 Hz) allows for a suggestion that a steric interaction between the α-*t*Bu substituent and the aromatic H^3 proton is the main factor controlling the palladacycle conformation. The role of the *N*-substituents seems not to be very significant in this case, in contrast with the assumption made previously.[58][59]

Unfortunately, no information could be found regarding the $^4J_{HCP}$ constant for the α-methine proton of related α-Me-substituted palladacycles based on primary arylalkylamines; usually this signal was described as a multiplet,[8][13] or a broad multiplet.[9][21] If the signal of the α-methine proton for the *ortho*-palladated derivative of primary α-(1-naphthyl)ethylamine is really a pure quadruplet as was reported,[51] the value of this constant must be equal to zero. Hence, the palladacycle must adopt the conformation with the α-Me group in an equatorial position, which contradicts the data ($^4J_{HCP}$ = 5.8-6.3 Hz) reported for related derivatives of the corresponding tertiary amine containing η^1-*P*-bonded phosphane ligands.[60−63]

A valuable additional source of stereochemical information is the HN−C^{α}H coupling. Newman projections along the N−C^{α}H bond for two possible conformations of the palladacycle, λ(*S*) and δ(*S*) (Figure 2), were constructed with regard to the real values of the torsion angles taken from the X-ray study of adduct **4a** (see the next section).

λ(*S*) δ(*S*)

Figure 2. Newman projections of (*S*)-palladacycle along the N−C(α) bond for two possible conformations, λ(*S*) and δ(*S*)

The most important dihedral angles between the C^α−H and the *pseudo*-axial and *pseudo*-equatorial N−H bonds for the λ(*S*) conformation are equal to ca. 31° and −88°, respectively, in the crystal of **4a**. As a result, an observable $^3J_{HCNH}$ constant can be predicted only for one of the two NH protons, namely NH^{ax}, if the same λ(*S*) conformation remains in solution. This particular situation takes place in the case of adducts **3a** and **4a**: $^3J_{HCNH}$ = 5.6−6.0 Hz was found for only one downfield resonance of the NH proton.

In contrast, in the case of the hypothetical δ(*S*) conformation of the palladacycle, the dihedral angles between the C^α−H and axial and equatorial N−H bonds should be nearly equal to one another from the point of view of the Carplus−Conroy equation[64] (ca. −30° and −150°, respectively). Hence, nearly equal values of the $^3J_{HCNH}$ constant are expected for both of the NH protons of the primary amino group. Moreover, the C^α−H bond in this conformation should be oriented nearly orthogonally to the mean coordination plane, and the $^4J_{HCP}$ constant for this proton should be approximately zero (cf. ref.[52,53,65]).

All these arguments allow for the exclusion of the δ(*S*) conformation of palladacycle in **3a** and **4a** from the consideration. It should be noted that the opposite (and incorrect) conclusion can be made from the analysis of "classic" Newman projections constructed without regard for the palladacycle flattening (with all dihedral angles equal to 60°): nearly equal $^3J_{HCNH}$ constant values have to be predicted for both NH protons in the λ(*S*) conformation and different values only for the δ(*S*) skew-envelope. The difference in the predicted values of the $^3J_{HCNH}$ constant may serve as a basis of the reliable criteria for identification of the axial and equatorial NH protons in the palladacycles derived from primary and secondary benzylamines.

As additional support for the axial position of the *t*Bu group in the palladacycle of λ(*S*) or δ(*R*) conformation, the downfield shift of its signal compared to the free ligand HL^1 should be mentioned (Δδ = 0.4−0.5 ppm for the complexes **3a** and **4a**). Commonly, such an effect is considered as a consequence of the metal anisotropy influence.[66][67] In the case of **3a** and **4a** complexes, the actual shift calculated for one proton must be essentially higher (Δδ up to 4 ppm) if one keeps in mind that each of the nine protons of the *t*Bu group spends nearly one ninth of all time in the proximity to the metal centre. Such a high shift may serve as an indirect indication for a weak *t*Bu···Pd agostic interaction.[66−69]

All these data support our statement that the palladacycles of dimer **1a** and its mononuclear derivatives **3a** and **4a** exist in solutions predominantly in the λ(*S*) or δ(*R*) conformation with the equatorial α-CH proton and the axial *t*Bu group. This result is important for further practical use of this new chiral matrix, because the conformational rigidity of palladacycles enhances their ability for chiral recognition.[36,52,53,63,70,71]

The relation between the $^3J_{HNP}$ constants for the two N−H protons of the primary amino group is difficult to predict. Taking into account the similar dihedral angles H^{ax}−N−Pd−P and H^{eq}−N−Pd−P, found for adduct **4a** in the crystal (110.7° and −130.9°, respectively), it is conceivable to suggest that both NH protons may reveal a spin-spin coupling with the ^{31}P nucleus. A little more efficient interaction may be expected for the *pseudo*-equatorial NH proton. However, the ^{1}H-NMR spectrum of **4a** reveals the reverse relation, namely, $^3J_{HNP}$ = 4.0−5.0 and 1.0−3.1 Hz for the NH^{ax} and NH^{eq} protons, respectively. Examples of equal[37,38,62,72] and substantially different[36,60,62,73] values of the $^4J_{HP}$ constant for NMe groups may be found among the spectra of phosphane complexes with the *ortho*-palladated *N*,*N*-dimethyl-α-(1-naphthyl)ethylamine, despite a high conformational stability of this palladacycle. This ob-

servation made the J_{HP} values for NH_2 and NMe_2 groups less suitable for the conformation analysis.

The structure of coordination complex **2a** can shed some light on the nature of the steric promotion of *ortho*-palladation reactions. Its ^{1}H-NMR spectrum indicates a restricted rotameric mobility of η^1-*N*-coordinated ligand HL[1]. A large difference between $^3J_{HCNH}$ constant values for two NH protons (11.2 and 3.1 Hz) pointed to the φ^3 or φ^5 conformation of *Pd*-bonded amine, with *transoid* orientation of one of the NH protons relative to the α-methine one. For the alternative φ^1 rotamer, nearly equal and low values of $^3J_{HCNH}$ constant may be predicted[64] from the Newman projections (Figure 3).

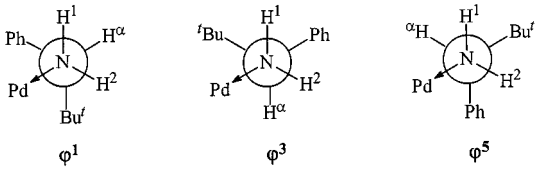

Figure 3. Newman projections of *Pd*-coordinated (*S*)-α-phenylneopentylamine along the N−C(α) bond for three main rotamers, φ^1, φ^3 and φ^5

The absence of deshielding effects (caused by the metal anisotropy[66−69]) for the *t*Bu protons in the spectra of complex **2a** (δ = 0.83 is close to δ = 0.91 for the free ligand HL[1]) allows for the differentiation between φ^3 and φ^5 rotameric forms in favour of the latter, where the *t*Bu group is far remote from the palladium centre.

Therefore, at the stage of monodentate *N*-coordination, the bulky HL[1] ligand adopts predominantly the φ^5 conformation with the Ph ring disposed in proximity to the metal centre (cf. ref.[74][75]). This conformation seems to be the most suitable starting state for the subsequent *ortho*-palladation. In contrast, monodentate *N*-coordination of the related α-Me-substituted primary benzylamine in the framework of binuclear μ-acetato coordination complex occurs in the φ^3 conformation with remote *transoid* position of the Ph ring with respect to the palladium centre.[10] Such a difference in the starting rotameric states of *N*-coordinated α-*t*Bu- and α-Me-substituted primary benzylamines may contribute to some extent to the steric promotion of the C−H bond activation in the former instance.

X-ray Structure Investigation of Phosphane Derivative 4a

Suitable crystals of triphenylphosphane adduct **4a** were grown from a dichloromethane/acetonitrile mixture. The molecular structure of the complex is presented in Figures 4 and 5; selected bond lengths and angles are given in Tables 2 and 3, respectively.

Only two other triphenylphosphane adducts of *ortho*-palladated primary benzylamines have been previously characterized structurally, namely, that of the α-Me-substituted analogue (*R*)-**4b**[13] and of the 2-phenylglycine methyl ester derivative (*R*)-**4c**.[11] The related derivative of 2-phenylethylamine containing a six-membered palladacycle was also studied by X-ray diffraction.[10]

4a (and, therefore, that of starting dimer **1a**) is supported. The complex has a *trans*(C,Cl) geometry, expected from the spectral data. The Pd−C and Pd−N bond lengths [2.006(4) and 2.087(4) Å, respectively] are similar to those reported for other derivatives of primary benzylamines (2.019 and 2.092−2.089 Å for **4b** and **4c**, respectively).[10,11,13] The shorter value of the Pd−N bond in the structures of complexes **4a−c**, compared to that reported for the related derivatives of tertiary benzylamines [for example, 2.19(1) Å for *N*-isopropyl-*N*,α-dimethylbenzylamine analogue[46]] may serve as reliable evidence in favour of a tighter coordination of the primary amino group with the palladium centre.

The palladium atom in complexes **4a** and **4b** has nearly square-planar coordination with a slight tetrahedral distortion: the dihedral angles between the planes (CPdN) and (PPdHal) fall within the range 2.7−7.8°.

The palladacycle conformation in adduct **4a** may be described as a distorted envelope with the nitrogen atom displaced from the plane ($PdC^1C^6C^7$) of the remaining four atoms by −0.5999 Å as compared to −0.5113 and 0.399 Å for **4b** and **4c**, respectively. As a measure of a palladacycle twisting, the value of the dihedral angle between the phenylene ring of the benzylaminate ligand (C_6H_4) and the mean coordination plane (PdC^1HalNP) may be used. The values equal to 20.0 and 15.5° for **4a** and **4b**, respectively, indicate a more puckered conformation of the α-*t*Bu-substituted palladacycle.

The stereochemistry of palladacycle conformation is in agreement with the ^{1}H-NMR data in solutions, namely, λ for the (*S*), and δ for the (*R*) enantiomer. The bulky α-*t*Bu substituent assumes a position close to the axial one and the α-methine proton is arranged nearly equatorially: C^7-C^8 and C^7-H^{7a} bonds form angles of 168.4° (an adjacent angle 11.6°) and 66.9°, respectively, with the normal to the mean coordination plane.

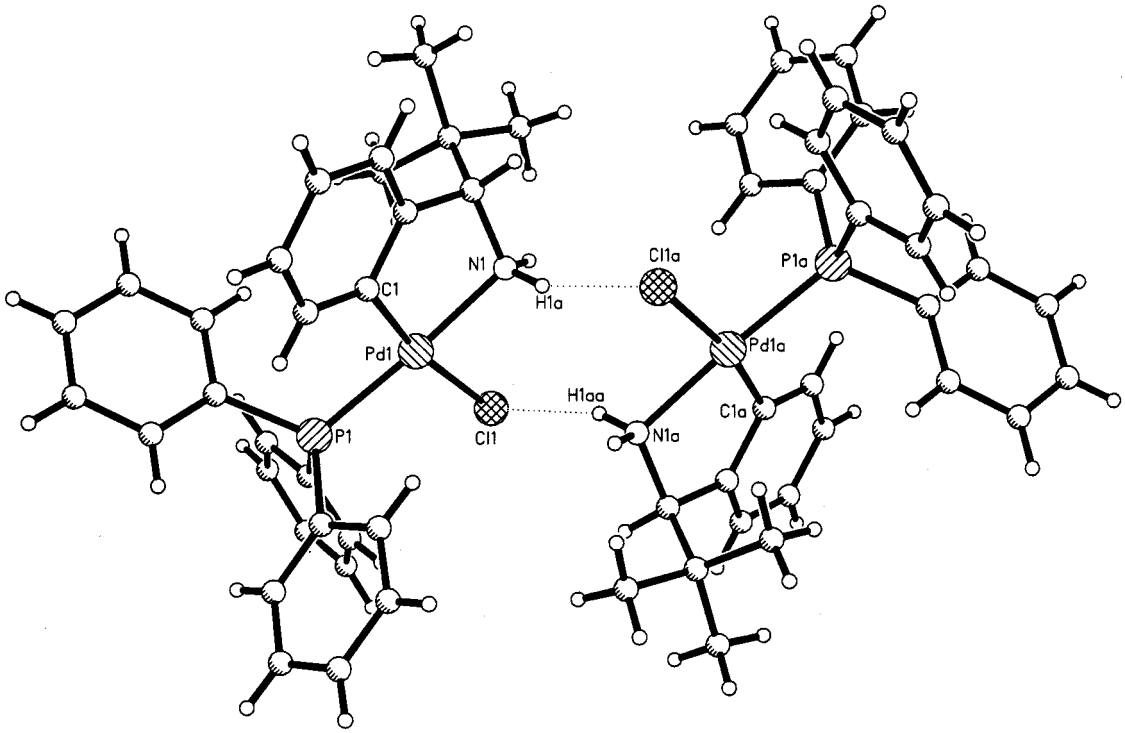

Figure 5. The mutual arrangement of two H-bonded (N−H···Cl) centrosymmetrically related enantiomers of phosphane adduct **4a** in the crystal

It is probable that a weak agostic interaction between one of the Me groups of the *t*Bu substituent with the palladium centre contributes to some extent to a stabilization of this conformation: the $H^{10b}\cdots Pd$ distance is 2.802 Å, which is less than the sum of the van der Waals radii for these atoms (3.1 Å[45]). It is noteworthy that similar secondary interactions were previously observed in the structures of *ortho*-palladated derivatives of α-*tert*-butyl-*N*,*N*-dimethylbenzylamine, namely, of a dimer (2.91−2.92 Å[76]) and its mononuclear derivative with pyridine (2.74−2.85 Å[20]).

The presence of the primary amino group in the palladacycle of **4a** results in a specific packing of molecules in the crystal, based on the hydrogen bonds of the type N−H···Cl (see Figure 5). Two enantiomers of the racemic complex are bonded in a centrosymmetric dimer by means of two rather strong hydrogen bonds, with the $NH^{1a}\cdots Cl^{1a}$ distances being equal to 2.416 Å, which is essentially less than the sum of the van der Waals radii for these atoms (3.3 Å[45]). The similar NH···Br hydrogen bonds (2.46 Å) were also found in the structure of α-Me-substituted analogue **4b**.[13]

In the crystal, the solvate acetonitrile is bonded with the coordinated chlorine atom by means of a hydrogen bond involving a methyl hydrogen atom (see Figure 4): The $CH^{2''f}\cdots Cl^{1}$ distance of 2.672 Å is also less than the sum of the van der Waals radii for these atoms (3.3 Å[45]).

Conclusions

The possibility of a steric promotion of the aromatic C−H bond activation in primary benzylamines bearing only one bulky α-substituent was shown. *ortho*-Palladation of α-phenylneopentylamine may be achieved under very mild conditions, using Li_2PdCl_4 in methanol at room temperature.

To the best of our knowledge, this work is the first presentation of the completely interpreted ^{1}H-NMR spectra of *ortho*-palladated primary benzylamine. It allows for establishing that the palladacycle formed adopts the λ(*S*) or δ(*R*) conformation with an axially oriented α-*t*Bu group both in the crystal and in solution. It seems reasonable to propose that such stereochemistry is dictated by unfavourable interactions between a bulky equatorial α-substituent and the neighbouring phenylene proton in alternative δ(*S*) or λ(*R*) conformations. The conformational stability of a new palladacycle shows a promising utility in a homochiral state as a matrix for the diverse processes of chiral recognition.

Experimental Section

General: ^{1}H- and ^{31}P-NMR spectra were recorded with a Varian VXR-400 spectrometer operating at the frequencies 400 and 161.9 MHz for ^{1}H and ^{31}P nuclei, respectively. The measurements were carried out at ambient temperature in $CDCl_3$ solutions (unless otherwise indicated). The proton chemical shifts are reported in parts per million relative to TMS as internal standard; the ^{31}P chemical shifts are given relative to H_3PO_4 as an external reference. The assignment of signals was performed on the basis of homonuclear decoupling, NOE experiments and spectral simulation. − IR spectra were recorded with a UR-250 spectrometer.

Solvents: Acetonitrile was distilled under argon from P_2O_5 and then from K_2CO_3; benzene, hexane and ether were dried with the appropriate drying agents and then distilled under argon from Na; anhydrous MeOH was prepared by distillation from MgOMe; dichloromethane was passed through a short Al_2O_3 column and distilled under argon; CCl_4 was refluxed in the presence of P_2O_5 and distilled; acetone of highest purity, and [D_1]chloroform (from Aldrich) were used as received; [D_5]pyridine was dried with 4-Å molecular sieves and distilled from KOH.

Reagents: Sodium acetate trihydrate was dehydrated by heating at 400°C; triphenylphosphane was purified by twofold recrystallization from a benzene/hexane mixture; hydroxylamine hydrochloride was used as received; lithium tetrachloropalladate was prepared according to a published procedure[6] and carefully dried in vacuo (3 Torr) over P_2O_5; palladium(II) acetate was purchased from Aldrich and used as received.

Starting Compounds: *tert*-Butyl phenyl ketone oxime was prepared by heating of pivalophenone[77] (12.80 g, 79 mmol) with hydroxylamine hydrochloride (6.05 g, 87 mmol) in the presence of $AcONa\cdot 3H_2O$ (11.8 g, 87 mmol) in aqueous methanol according to a published procedure;[78] after recrystallization from EtOH, the oxime was isolated in an 88% yield (17.93 g); m.p. 163−164°C. − ^{1}H NMR ($CDCl_3$): δ = 1.15 (s, 9 H, *t*Bu), 7.12 (dd, $^3J_{HH}$ = 7.9 Hz, $^4J_{HH}$ = 1.5 Hz, 2 H, *ortho-H* of Ph group), 7.33−7.45 (m, 3 H, *meta-H* and *para-H* of Ph group), 9.25 (br. s, 1 H, O*H*).

Racemic α-*tert*-Butylbenzylamine (HL^1) was prepared by reduction of *tert*-butyl phenyl ketone oxime (16.68 g, 0.094 mmol) under conditions previously described[79] in a yield of 72% (11.06 g, 0.068 mmol); b.p. 108−109°C/18 Torr; ^{1}H NMR ($CDCl_3$): δ = 0.91 (s, 9 H, *t*Bu), 1.40 (br. s, 2 H, NH_2), 3.69 (s, 1 H, α-C*H*), 7.21−7.32 (m, 5 H, Ph).

Synthesis of Cyclopalladated Compounds: All reactions were performed under argon in anhydrous solvents. Reactions were monitored by means of TLC on Silufol plates using an ether/heptane (5:1) mixture as eluent (unless otherwise indicated). In the case of μ-acetato complex formation, its conversion into the μ-chloro analogue by AcO^-/Cl^- metathesis (by treatment of a test probe of reaction mixture with LiCl solution in MeOH) was undertaken before spotting on the TLC plate. Dimeric complexes obtained were purified (unless otherwise indicated) using flash chromatography on a "dry" column[80][81] (Silpearl, *d* = 2.5 cm, *h* = 3.5 cm) with the eluents' polarity increasing (ether/heptane mixtures in the ratios from 1:10 up to 10:1 and then pure ether).

Di-μ-chlorobis[2-{1-amino-2,2-dimethylpropyl}phenyl-*C*,*N*]-dipalladium (II) (1a)

1. *ortho*-Palladation with Palladium(II) Acetate: i) Palladium acetate (0.206 g, 0.918 mmol) was added to racemic α-*tert*-butylbenzylamine HL^1 (0.150 g, 0.919 mmol) in methanol (5 mL) and the reaction mixture was stirred for 24 h at room temp. A solution of lithium chloride (0.190 g, 4.48 mmol) in methanol (3 mL) was added and the mixture was stirred for 2 h and then filtered. The residue was washed with methanol, combined with the mother liquor, concentrated in vacuo, and redissolved in dichloromethane (10 mL). The solution formed was washed with water to remove inorganic components, dried with sodium sulfate and concentrated to a volume of 2−3 mL. Flash column chromatography gave the coordination complex **2a** (from the first fraction) as a pale yellow microcrystalline solid in a yield of 19% (0.0443 g, 0.088 mmol) after

recrystallization from a dichloromethane/hexane mixture. From the second fraction, the μ-Cl dimer **1a** was isolated as a lime-yellow amorphous powder in a yield of 70% (0.195 g, 0.321 mmol) after precipitation from benzene by hexane.

For dimer **1a**: m.p. 217−219°C (dec). − R_f = 0.54. − IR (nujol): $\tilde{\nu}$ = 3213, 3308 cm^{-1} [ν(NH_2)]; 740 cm^{-1} [δ(CH_{ar})]. − ^{1}H NMR ($CDCl_3$, isomeric mixture): δ = 1.14 (br. s, 9 H, *t*Bu), 2.87 and 4.03 (br. s, 2 H, N*H*$_2$), 3.62 and 3.66 (s, 1 H, α-C*H*), 6.72 (br. s, 1 H, C_6H_4), 6.89 (m, 2 H, C_6H_4), 7.19 (br. s, 1 H, C_6H_4). − $C_{22}H_{32}Cl_2N_2Pd_2$ (608.26): calcd. C 43.44, H 5.30, N 4.23; found C 43.85, H 5.29, N 4.61.

For coordination complex **2a**: m.p. 171−173°C, R_f = 0.92.

ii) The same reaction of palladium acetate (0.225 g, 1.00 mmol) and amine HL[1] (0.163 g, 1.0 mmol) conducted in methanol (5 mL) at 50°C required 1.5 h for completion. After the treatment of the reaction mixture as described above [i)] it afforded the dimer **1a** in a 68% yield (0.207 g, 0.340 mmol); m.p. 217−219°C (dec), R_f = 0.54 (ether/heptane, 5:1); R_f = 0.44 (benzene/acetone, 7:1). − $C_{22}H_{32}Cl_2N_2Pd_2$: calcd. C 43.44, H 5.30, N 4.23; found C 43.40, H 5.35, N 4.27. − Under these conditions the coordination complex **2a** was formed in trace quantities.

iii) In a similar way, the reaction of palladium acetate (0.281 g, 1.25 mmol) and amine HL[1] (0.204 g, 1.25 mmol) was performed in acetone (10 mL). After heating at 50°C for 50 h and treatment of the reaction mixture as described above [i)], dimer **1a** was isolated in a yield of 68% (0.258 g, 0.424 mmol); m.p. 219−221°C (dec), R_f = 0.54.

iv) The interaction of palladium acetate (0.212 g, 0.944 mmol) and ligand HL[1] (0.154 g, 0.943 mmol) in benzene (7 mL) at room temp. afforded, after the stirring for 24 h and the treatment of reaction mixture as described above [i)] the dimer **1a** in a 43% yield (0.123 g, 0.202 mmol); m.p. 217−219°C (dec), R_f = 0.54. Under these conditions the coordination complex **2a** was isolated in a 41% yield (0.097 g, 0.193 mmol): m.p. 172−173°C, R_f = 0.92.

2. *ortho*-Palladation with Lithium Tetrachloropalladate(II): Racemic α-*tert*-butylbenzylamine (0.150 g, 0.919 mmol) in methanol (20 mL) was added to a mixture of lithium tetrachloropalladate (0.255 g, 0.973 mmol) and excess of sodium acetate (0.232 g, 2.83 mmol) in methanol (20 mL). The reaction mixture was stirred at room temp. for 23 h; after overnight storage, it was filtered and the residue was washed with methanol and then dichloromethane. The combined organic solutions were concentrated in vacuo and redissolved in dichloromethane (10 mL). Chromatographic separation using a dry column (Silpearl, d = 2.5 cm, h = 5 cm, ether/hexane from 1:10 up to 10:1 and then pure ether) and recrystallization as described above [i)] gave dimer **1a** as a limon−yellow amorphous powder in a yield of 50% (0.140 g, 0.230 mmol) from the second fraction. The mixture of diastereomeric coordination complexes (*R*,*R*)*/(*R*,*S*)-**2a** in an approximately 1:1 ratio (^{1}H-NMR data) was isolated from the first fraction in a 43% yield based on the ligand (0.100 g, 0.198 mmol); one of diastereomers was separated from this mixture by recrystallization from benzene/hexane and then from dichloromethane/hexane in a yield of 12% (0.0286 g, 0.057 mmol) as a pale yellow microcrystalline solid.

For **1a**: m.p. 217−219°C (dec), R_f = 0.54. − $C_{22}H_{32}Cl_2N_2Pd_2$ (608.26): calcd. C 43.44, H 5.30, N 4.23; found C 43.51, H 5.55, N 4.36.

For (*R*,*R*)*-**2a**: m.p. 171−173°C, R_f = 0.92. − IR (nujol): $\tilde{\nu}$ = 3310, 3230 cm^{-1} [br., ν(NH_2)], 750, 790 [δ(CH_{ar})]; (CCl_4): $\tilde{\nu}$ = 3310, 3233 cm^{-1} [br., ν(NH_2)]. − For ^{1}H-NMR data of the individual diastereomer **2a** see Table 1. − $C_{22}H_{34}Cl_2N_2Pd$ (503.85): calcd. C 52.44, H 6.80, N 5.56; found C 52.73, H 6.73, N 5.76.

^{1}H NMR of mixture of diastereomers (*R*,*R*)*/(*R*,*S*)-**2a** ($CDCl_3$): δ = 0.81 (s, 18 H, *t*Bu), 0.82 (s, 18 H, *t*Bu), 3.15 (br. t, 2 H, N*H*), 3.19 (br. t, 2 H, N*H*), 3.67 (br. m, 4 H, N*H*), 3.74 (m, 4 H, α-C*H*), 7.04 (m, 8 H, *ortho*-*H* of Ph groups), 7.26 (m, 12 H, *meta*- and *para*-*H* of Ph groups).

[2-{1-Amino-2,2-dimethylpropyl}phenyl-*C*,*N*]chloro([D$_5$pyridine)]-palladium(II) (3a) was generated in situ by the addition of 2−3 drops of [D_5]pyridine to a solution of dimer **1a** in $CDCl_3$ in an NMR tube. For ^{1}H-NMR data of complex **3a** see Table 1.

[2-{1-Amino-2,2-dimethylpropyl}phenyl-*C*,*N*]chloro(triphenylphosphane)palladium (II) (4a) was prepared by treatment of dimeric complex **1a** (0.100 g, 0.164 mmol) with triphenylphosphane (0.086 g, 0.33 mmol) in benzene (15 mL). The reaction mixture was stirred for 40 min at room temp. and concentrated to dryness. Recrystallization from dichloromethane/hexane and then from dichloromethane/acetonitrile afforded the mononuclear adduct **4a** in

Table 4. Crystal data, data collection, structure solution and refinement parameters for [2-(1-amino-2,2-dimethylpropyl)phenyl-*C*,*N*]chloro(triphenylphosphane)palladium(II)·MeCN solvate **4a**

X-ray Crystallography for Complex 4a: Details of the X-ray experiment are given in Table 5. The experimental data were collected with an ENRAF Nonius CAD4 diffractometer using graphite-monochomatized Mo-K_α radiation. Experimental reflections were corrected for Lorentz and polarization effects. The hydrogen atoms were found from a difference Fourier synthesis and included in the refinement using the "riding model" with B_{iso} equal to $1.5B_{eq}$ of the parent atom. The structure was refined in the anisotropic approximation for the non-hydrogen atoms. A solvent molecule of acetonitrile was found during the structure solution, which forms a hydrogen bond with the coordinated chloride ligand of the main complex. The structure was solved and refined using the SHELXS-86[82] and SHELXL-93[83] software. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-104570. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Reactivity of Bis(phospholyl)neodymium(III) and -samarium(III) Chlorides and Alkyl Derivatives

François Nief,*[a] Philippe Riant,[a] Louis Ricard,[a] Pascale Desmurs,[b] and Denise Baudry-Barbier[b]

Keywords: Organolanthanide / Neodymium / Samarium / Phospholyl / Hydrides / Lanthanides

The reaction of 2,3,4,5-tetramethylphospholylpotassium [C_4Me_4PK] with [$LnCl_3(THF)_x$] (Ln = Nd, Sm) in a 2:1 ratio gave unsolvated ate complexes of the formula [$(C_4Me_4P)_2LnCl_2K$]. Crystallisation of the samarium complex from ether afforded a polymeric ether solvate: {[(η^5-C_4Me_4P)Sm(μ_3-Cl)$_2$(μ:η^5,η^1-C_4Me_4P)K(Et_2O)]$_\infty$}, which was characterised by X-ray crystallography. Reaction of [$(C_4Me_4P)_2LnCl_2K$] with [$LiCH(SiMe_3)_2$] in toluene gave the alkyl complexes [$(C_4Me_4P)_2LnCH(SiMe_3)_2$]; these complexes were most efficiently prepared from [$LnCl_3(THF)_x$], [KC_4Me_4P] and [$LiCH(SiMe_3)_2$] in a one-pot procedure. Reaction of [$(C_4Me_4P)_2LnCH(SiMe_3)_2$] with molecular hydrogen gave [$(C_4Me_4P)_2NdH$], when Ln = Nd, whereas, when Ln = Sm, reduction occurred and the already known [$(C_4Me_4P)_2Sm$] was isolated instead.

Introduction

Bis(cyclopentadienyl) and substituted bis(cyclopentadienyl) complexes of trivalent lanthanides are interesting because of their structural and mechanistic properties, and also for their catalytic potential.[1] Modification of the parent cyclopentadienyl ligands has been achieved by the introduction of various types of substituents, e.g. those with bulky,[2] chiral and/or bridging properties.[3] A heterocyclopentadienyl ligand such as the 2,3,4,5-tetramethylphospholyl ligand (C_4Me_4P) has been used successfully as an alternative to the cyclopentadienyl ligand in organolanthanide and organoactinide chemistry.[1a] The C_4Me_4P ligand is interesting because it can be considered as relatively bulky, with steric properties resembling that of the ubiquitous C_5Me_5 ligand (in fact very close to that of the tetramethylcyclopentadienyl ligand[4]), while it is much less electron-rich than polyalkylated cyclopentadienyl ligands, and its electronic properties are similar to those of the unsubstituted Cp ring.[5] The authors have described previously (in a communication) the interaction of the C_4Me_4P ligand with the halides of yttrium and lutetium and the synthesis of the ate complexes [$(C_4Me_4P)_2LnCl_2Li(solv.)_2$],[6] and wish to extend these results to the synthesis of bis(tetramethylphospholyl) complexes of samarium and neodymium, because of the more interesting potential of bis(cyclopentadienyl) complexes of the larger Nd^{III} and Sm^{III} ions in catalysis. While catalytic tests on the title compounds are underway, this paper reports on the synthetic part of the work concerning the synthesis of bis(tetramethylphospholyl)neodymium and -samarium chlorides and alkyl derivatives, and the synthesis of a bis(phospholyl)neodymium hydride.

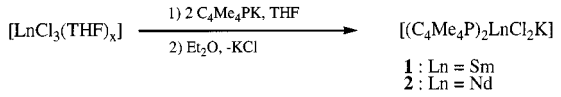
Results



Synthesis of [$(C_4Me_4P)_2SmCl_2K$] (1) and [$(C_4Me_4P)_2NdCl_2K$] (2)

The preparation of [$(C_4Me_4P)_2LnCl_2Li(solv.)_2$] involved the reaction of anhydrous [YCl_3] or [$LuCl_3$] with two equiv. of [C_4Me_4PLi] prepared in situ. Due to the previous development of the use of the potassium salt [C_4Me_4PK],[7] which can be isolated and purified by recrystallization, the reaction of two equiv. of [C_4Me_4PK] with one equiv. of anhydrous [$SmCl_3$] or [$NdCl_3$] in THF was tried initially. No reaction was found to occur even after refluxing overnight: No colour change took place, and examination of the reaction mixture by ^{31}P NMR only showed the [C_4Me_4PK] resonance.

However, when THF-solvated [$LnCl_3(THF)_x$] was substituted for anhydrous [$LnCl_3$], the reaction with two equiv. of [C_4Me_4PK] started immediately (at room temp.), as indicated by a colour change to orange (Ln = Sm) or blue (Ln = Nd), and was completed within 1 h. After evaporation of the solvent, extraction of the residue with ether and drying under vacuum, light orange (Ln = Sm) or light blue (Ln = Nd) powders were obtained in fair to good yield. These products were assigned the formulas of unsolvated ate complexes [$(C_4Me_4P)_2SmCl_2K$] (**1**) and [$(C_4Me_4P)_2NdCl_2K$] (**2**), respectively, on the following grounds: (a) ^{31}P- and ^1H-NMR spectra of the isolated products displayed coordination shifts of the methyl and phosphorus resonances indicating that coordination of the C_4Me_4P ligand around Nd and Sm had indeed occurred, (b) only very small traces of ether or THF were present according to the ^1H-NMR spectra of either the Nd or Sm

complexes in [D$_8$]THF, (c) elemental analyses were not compatible with the possibility of neutral complexes such as {[(C$_4$Me$_4$P)$_2$LnCl]$_x$} but were in agreement with the formulae given above for **1** and **2** (Scheme 1).

Scheme 1. Synthesis of the complexes **1** and **2**

[LaCl$_3$(THF)$_x$] also reacted with [C$_4$Me$_4$PK] but the isolated product, presumably [(C$_4$Me$_4$P)$_2$LaCl$_2$K], was obtained in very low yield because the ether extraction procedure worked poorly for the very insoluble La compound.

Crystal Structure of {[(η^5-C$_4$Me$_4$P)Sm(μ_3-Cl)$_2$(μ:η^5,η^1-C$_4$Me$_4$P)K(Et$_2$O)]$_\infty$} (3)

In order to gain more insight into the structure of the aforementioned ate complexes X-ray analysis of the crystal structure was carried out. Recrystallization of **1** from diethyl ether gave crystals that were suitable for X-ray analysis. It appears that **1** picked up one diethyl ether molecule in the process, which ended up coordinated to the potassium ion in the crystal, and that the analyzed structure was that of **3**: {[(η^5-C$_4$Me$_4$P)Sm(μ_3-Cl)$_2$(μ:η^5,η^1-C$_4$Me$_4$P)K(Et$_2$O)]$_\infty$}. X-ray details are listed in Table 1, selected bond lengths and angles are collected in Table 2 while ORTEP plots of the asymmetric unit of **3** and of four such repeating units are shown in Figures 1 and 2, respectively. The structure of **3** closely resembles that of [{(η^5-C$_5$Me$_5$)$_2$Ce(μ_3-Cl)$_2$K(THF)}$_\infty$] previously described by Evans:[8] In both cases it is the triply bridging chlorine atoms (between the Ln and K atoms) that are responsible for the polymeric chain that links the organolanthanide residues. However, there are two differences between the structures of **3** and of Evans' cerium complex: (a) in Evans' complex, which is noncentrosymmetric, the (C$_5$Me$_5$)$_2$CeCl$_2$K(THF) unit repeats itself by a glide plane along the axis of the polymeric chain, whereas in **3**, which is centrosymmetric, the (C$_4$Me$_4$P)$_2$SmCl$_2$K(Et$_2$O) units are related by inversion centres on the axis of the chain; (b) in **3** the potassium atom is six-coordinate because of additional bonding with the phosphorus lone pair on one of the C$_4$Me$_4$P ligands.

Bond lengths and angles of **3** are listed in Table 2. The Sm−Cl bonds (2.66 and 2.67 Å) are unusually short for a triply bridging chlorine atom bonded to Sm (usually 2.76−2.92 Å).[9] Interestingly, Evans had also noted short Ce−Cl bonds for the triply bridging chlorine atoms in {[(η^5-C$_5$Me$_5$)$_2$Ce(μ_3-Cl)$_2$K(THF)]$_\infty$}. The Sm−P bonds are similar to that of other phospholylsamarium(III) complexes.[10] The K−P2 distance is within the recorded bond length-limits (towards the high end, however),[11] denoting K−P electrostatic interaction. The K−O bond length is significantly longer (0.1 Å) than in other K−OEt$_2$ solvates.[12]

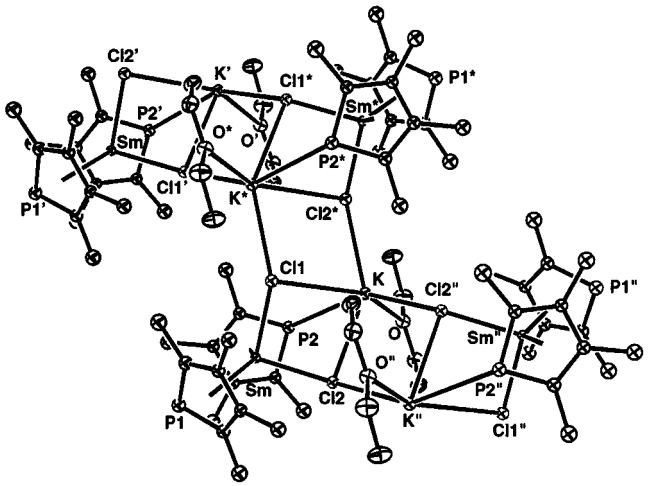
Synthesis of [(C$_4$Me$_4$P)$_2$SmCH(SiMe$_3$)$_2$] (4) and [(C$_4$Me$_4$P)$_2$NdCH(SiMe$_3$)$_2$] (5)

Alkyl compounds of organolanthanides are the precursors of organolanthanide hydrides by hydrogenolysis of the lanthanide−carbon σ-bond. [Bis(trimethylsilyl)methyl]lan-



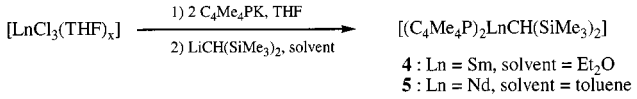


Figure 2. ORTEP plot of **3** (four repeating units); ellipsoids are scaled to enclose 50% of the electronic density

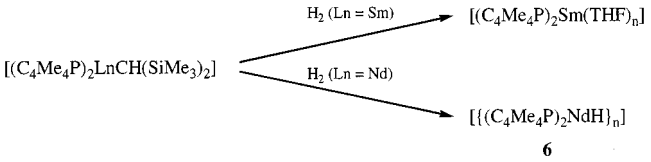
thanide complexes are often used because they are usually hydrocarbon-soluble unsolvated compounds that can be straightforwardly obtained by reaction of organolanthanide halides with $[LiCH(SiMe_3)_2]$.[2g,2i] Initially, small-scale experiments established that reaction of **1** and **2** with $[LiCH(SiMe_3)_2]$ did produce the desired alkyl complexes $[(C_4Me_4P)_2SmCH(SiMe_3)_2]$ (**4**) and $[(C_4Me_4P)_2NdCH(SiMe_3)_2]$ (**5**). However, the overall yields were not especially good and we found that **4** and **5** were best prepared by a one-pot reaction: The crude products from the reaction of $[LnCl_3(THF)_x]$ with $[C_4Me_4PK]$ reacted smoothly with $[LiCH(SiMe_3)_2]$ to give **4** and **5** in fair to good yields. The main advantage was in avoiding the long extraction procedure necessary to isolate pure **1** and **2** (Scheme 2).

Scheme 2. One-pot synthesis of alkyl complexes **4** and **5**

$[(C_4Me_4P)_2LaCH(SiMe_3)_2]$ was also obtained by the same procedure, but the yields were very low and inconsistent. The NMR properties of **4** and **5** are similar to that of their C_5Me_5 analogues:[2g] The steric bulk of the $(C_4Me_4P)_2Ln$ moiety impedes free rotation of the alkyl ligand around the Ln−C σ-bond so that the two C_4Me_4P rings are anisochronous. Thus, **4** and **5** each show four proton signals for the α-, β-, α′- and β′-methyl groups and two phosphorus resonances.



Reaction of $[(C_4Me_4P)_2LnCH(SiMe_3)_2]$ with H_2 (Ln = Sm, Nd) and the Synthesis of $[\{(C_4Me_4P)_2NdH\}_n]$ (6)

Exposure of a benzene solution of **4** to dihydrogen resulted in the formation of a dark black product which gradually separated from solution. ^1H NMR of the reaction mixture indicated the presence of bis(trimethylsilyl)-methane. The black product was characterised as $[(C_4Me_4P)_2Sm(THF)_n]$ on the basis of the known high-field position of its ^{31}P resonance in THF solution (δ = −540).[13] Thus, presumably hydrogenolysis of the Sm−C bond occurred, but the hydride $[(C_4Me_4P)_2SmH]$ is unstable and decomposes by disproportionation into $[(C_4Me_4P)_2Sm]$ and H_2.

Hydrogenolysis of **5** under 1 atm of dihydrogen was then attempted in C_6D_6 (NMR experiment) and in pentane (preparative experiment). In the NMR experiment, formation of bis(trimethylsilyl)methane was evident from the ^1H-NMR data of the yellow solution while new resonances (α- and β-methyl groups on the C_4Me_4P ligand) appeared at δ = +17.8 and δ = −17.8; the phosphorus resonance was shifted to δ = 551. Exposure of this reaction mixture to THF vapour caused a colour change to green and a shift in the phosphorus resonance to δ = 377.

In the preparative experiment, a yellow precipitate was isolated, having an elemental analysis compatible with the composition $(C_4Me_4P)_2NdH$. However, this precipitate was sparingly soluble in C_6D_6, and the proton spectrum was complex; exposition of the NMR tube to THF vapour resulted in complete dissolution into a green solution and the appearance of a phosphorus resonance at δ = 377. The yellow precipitate was also soluble in C_4D_8O ($[D_8]$THF) and the proton spectrum displayed resonances at δ = 11.7 and δ = 1.14.

These experiments were interpreted as follows: In the NMR-tube experiment, the new peaks at δ = +17.8 and −17.8 (^1H) and 551 (^{31}P) are attributed to $\{[(C_4Me_4P)_2NdH]_n\}$ (**6**); upon exposure to THF vapour, a shift in the ^{31}P-NMR spectrum and colour change to green are presumably due to the formation of $[(C_4Me_4P)_2NdH(THF)]$. In the preparative experiment **6** was also formed. After precipitation from pentane, it was obtained in a sparingly soluble oligomeric form which converted into $[(C_4Me_4P)_2NdH(THF)]$ upon exposure to THF. The proton spectrum in C_4D_8O shows the resonances of the α- and β-methyl groupss of the C_4Me_4P ligand in $[(C_4Me_4P)_2NdH([D_8]THF)]$ (Scheme 3).

Scheme 3. Reaction of the alkyl complexes **4** and **5** with dihydrogen

Discussion

The reaction of $[C_4Me_4PK]$ with early lanthanide chlorides gives ate complexes containing the $[(C_4Me_4P)_2LnCl_2K]$ unit. The crystal structures of **3** $\{[(\eta^5\text{-}C_5Me_4P)_2Sm(\mu_3\text{-}Cl)_2K(Et_2O)]_\infty\}$ and of its analog $\{[(\eta^5\text{-}C_5Me_5)_2Ce(\mu_3\text{-}Cl)_2K(THF)]_\infty\}$ are closely related to one another. However, the vacuum-dried ate complexes $[(C_4Me_4P)_2LnCl_2K]$ isolated with the phospholyl ligand are

desolvated, in contrast with those isolated with the C_5Me_5 ligand; the neutral complex $\{[(C_5Me_5)_2CeCl]_n\}$ was obtained upon heating $[(C_5Me_5)_2CeCl_2K(THF)]$ under vacuum.[8] It is to be noted that the K−O(ether) bond in **3** is one of the longest recorded; a weakness of the K−O bond might thus account for the ease of desolvation in the case of the bis-(phospholyl) ate complexes.

The one-pot reaction leading to **4** and **5** gives yields comparable to those obtained for the methods used in the preparation of other [bis(trimethylsilyl)methyl]lanthanide complexes, e.g. the analog $[(C_5Me_5)_2LnCH(SiMe_3)_2]$. Like these analogs, the alkyl complexes **4** and **5** are unsolvated, pentane-soluble crystalline powders. Whereas $[(C_5Me_5)_2SmCH(SiMe_3)_2]$ gives the hydride $\{[(C_5Me_5)_2SmH]_2\}$ in the presence of dihydrogen, the reaction of **4** with dihydrogen is different because in this case $[(C_4Me_4P)_2Sm]$ was isolated. The reduction of alkylsamarium(III) to Sm^{II} in the presence of H_2 is unprecedented. It is known in actinide chemistry that the uranium(IV) dihydride $[(C_5Me_5)_2UH_2]$ is unstable and disproportionates into the uranium(III) hydride $\{[(C_5Me_5)_2UH]_n\}$ and H_2, whereas $[(C_5Me_5)_2ThH_2]$ is stable.[14] Likewise, it has been reported that $[(C_4Me_4P)_2UH_2]$ was not detected when $[(C_4Me_4P)_2UR_2]$ (R = CH_3, CH_2SiMe_3) was exposed to dihydrogen; $[(C_4Me_4P)_3U]$ was obtained under these conditions.[15] Although the mechanistic pathway for the reduction to Sm^{II} is unknown, a samarium(III) hydride might be less stabilised with respect to reduction by the relatively poor π-donating C_4Me_4P ligand than by the electron-rich C_5Me_5 ligand.

Similarly to $[(C_5Me_5)_2NdCH(SiMe_3)_2]$, the reaction of **5** with dihydrogen gives the hydride $\{[(C_4Me_4P)_2NdH]_n\}$ (**6**). However, when isolated in pentane, this compound is in a sparingly soluble oligomeric form.

Experimental Section

General: All isolated compounds are air- and moisture-sensitive and were handled in rigourously inert-atmosphere conditions, on a vacuum line, or under argon in a glovebox (Braun Labmaster 130) with H_2O, O_2 < 1 ppm. $[C_4Me_4PK]$[7] was recrystallised from DME/THF. $[LiCH(SiMe_3)_2]$[16] was purified by extraction and crystallisation from hexane. Anhydrous lanthanide trichlorides were used as received from the suppliers and transformed into $[LnCl_3(THF)_x]$[17] according to known procedures. All solvents were dried by vacuum transfer from sodium/benzophenone. − NMR: 200 MHz for ^1H and 80 MHz for ^{31}P. − Elemental analyses: CHN analyser at the Université de Dijon.

General Procedure for the Synthesis of $[(C_4Me_4P)_2LnCl_2K]$: In a glovebox, a mixture of $[LnCl_3(THF)_x]$ (1 equiv.) and $[C_4Me_4PK]$ (2 equiv.) was placed in a vessel fitted to a swivel Schlenk filter. The filter assembly was then taken out of the glovebox, attached to a vacuum line through a vacuum PTFE stopcock and evacuated. THF (20 mL) was then transferred in vacuo onto the solids and the assembly was isolated from the vacuum by closing the stopcock.. The reaction mixture immediately became orange (Ln = Sm) or blue (Ln = Nd). After stirring at room temp. for 1 h, the solution was concentrated to dryness and diethyl ether (20 mL) was transferred in vacuo onto the residue. The filter assembly was then rotated and the solid residue continuously extracted on the frit with warm diethyl ether by placing the receiving flask in a water bath at about 40°C, whereupon the product precipitated from the diethyl ether solution. The extraction usually took 1−2 d (Ln = Sm) and 4−5 d (Ln = Nd). The swivel filter was then rotated back into its original position and the product filtered, rinsed with cold diethyl ether and dried under vacuum overnight. The filter assembly was then returned to the glovebox and the product collected and weighed.

Isolation of $[(C_4Me_4P)_2SmCl_2K]$ (1): 340 mg (0.63 mmol, 63%) of **1** was isolated from $[SmCl_3(THF)_3]$ (474 mg, 1 mmol) and $[C_4Me_4PK]$ (356 mg, 2 mmol). − ^1H NMR ($[D_8]$THF): δ = 0.87 (s, 12 H), 1.98 (s, 12 H). − ^{31}P NMR: δ = 49.7. − $C_{16}H_{24}Cl_2KP_2Sm$ (538.68): calcd. C 35.68, H 4.49; found C 34.81, H 4.49.

Isolation of $[(C_4Me_4P)_2NdCl_2K]$ (2): 0.680 g (1.28 mmol, 57%) of **2** was isolated from $[NdCl_3(THF)_{1.5}]$ (800 mg, 2.23 mmol) and $[C_4Me_4PK]$ (0.800 g, 4.49 mmol). − ^1H NMR ($[D_8]$THF):δ = 0.66 (s, 12 H), 13.03 (s, 12 H). − ^{31}P NMR: δ = 459. − $C_{16}H_{24}Cl_2KNdP_2$ (532.56): calcd. C 36.09, H 4.54; found C 35.74, H 4.65.

Synthesis of $[(C_4Me_4P)_2SmCH(SiMe_3)_2]$ (4) (One-Pot Procedure): THF (20 mL) was condensed onto a mixture of $SmCl_3(THF)_3$ (474 mg, 1 mmol) and $[C_4Me_4PK]$ (356 mg, 2 mmol). After 1 h at room temp., the solvent was evaporated to dryness in vacuo. Solid $[LiCH(SiMe_3)_2]$ (166 mg, 1 mmol) was added to the residue and 20 mL of diethyl ether condensed onto the mixture. After 2.5 h, the reddish/brown reaction mixture was concentrated to dryness and extracted into 20 mL of hexane. The reaction mixture was concentrated to a small volume whereupon a precipitate appeared, which was filtered and rinsed with cold hexane, leaving **4** as an orange/brown powder (310 mg, 0.53 mmol, 53%) that was recrystallised from hexane. − ^1H NMR (C_6D_6): δ = −4.46 (s, 18 H), −3.02 (s, 6 H), −2.60 (s, 6 H), 2.70 (s, 6 H), 3.11 (s, 6 H), 20.31 (s, 1 H). − ^{31}PNMR: δ = 43.4 (s), 46.7 (s). − $C_{23}H_{43}P_2Si_2Sm$ (588.07): calcd. C 46.98, H 7.37; found C 46.32, H 7.68.

Synthesis of $[(C_4Me_4P)_2NdCH(SiMe_3)_2]$ (5) (One-Pot Procedure): THF (20 mL) was condensed onto a mixture of $[NdCl_3(THF)_{1.5}]$ (490 mg, 1.37 mmol) and $[C_4Me_4PK]$ (490 mg, 2.75 mmol). After 1 h at room temp., the solvent was evaporated to dryness in vacuo. Solid $[LiCH(SiMe_3)_2]$ (0.225 g, 1.35 mmol) was added to the residue and 20 mL of toluene was condensed onto the mixture. After 2.5 h, the green reaction mixture was concentrated to dryness and extracted into 20 mL of pentane. The reaction mixture was concentrated to a small volume whereupon a precipitate appeared, which was filtered and rinsed with cold pentane, leaving **5** as a forest-green powder (0.530 g, 0.91 mmol, 67%) that was recrystallised in pentane. − ^1H NMR (C_6D_6): δ = −11.71 (s, 18 H), −10.55 (s, 6 H), −8.01 (s, 6 H), 12.96 (s, 6 H), 13.34 (s, 6 H), 91.52 (br. s, 1 H). − ^{31}P NMR: δ = 456 (s), 501 (s). − $C_{23}H_{43}NdP_2Si_2$ (581.95): calcd. C 47.47, H 7.45; found C 47.11, H 7.40.

Reaction of $[(C_4Me_4P)_2SmCH(SiMe_3)_2]$ (4) with H_2: Dihydrogen gas was admitted to a solution of **4** (5 mg) in C_6D_6 at 0°C. The reaction mixture immediately turned dark brown and a black precipitate appeared. While $CH_2(SiMe_3)_2$ was present in the C_6D_6 solution, a ^{31}P-NMR spectrum of the black precipitate in THF showed a signal at δ = −540, characteristic of $[(C_4Me_4P)_2Sm(THF)_x]$.

Reaction of $[(C_4Me_4P)_2NdCH(SiMe_3)_2]$ (4) with H_2 (NMR Scale): An NMR tube containing a solution of $[(C_4Me_4P)_2NdCH(SiMe_3)_2]$ (6 mg, 0.01 mmol) in C_6D_6 (0.5 mL) was exposed to 1 atm of dihydrogen gas. An immediate colour change from green to yellow was

observed, $CH_2(SiMe_3)_2$ was detected in the solution, and new signals appeared that were attributed to $\{[(C_4Me_4P)_2NdH]_n\}$ (**6**). – ^{1}H NMR: δ = −17.8 (s, 12 H), 17.8 (s, 12 H); H−Nd signal was not detected. – ^{31}P NMR: δ = 551. – Exposure of the tube to THF vapour caused a colour change to green and a shift in the ^{31}P spectrum to δ = 347.

Synthesis of $[\{(C_4Me_4P)_2NdH\}_n]$ (6): Dihydrogen gas was admitted to a solution of **5** (80 mg, 0.14 mmol) in pentane at 0°C. The reaction mixture turned yellow and a precipitate appeared. This precipitate was filtered, rinsed with pentane and **6** was isolated as a yellow powder (50 mg, 0.12 mmol, 85%). – NMR (C_6D_6): no interpretable spectrum (see text). – ^{31}P NMR (THF):δ = 377. – $C_{16}H_{25}NdP_2$ (423.56): calcd. C 45.37, H 5.95; found C 45.40, H 5.70.

X-ray Crystallographic Study of 3: Crystals of **3**, $C_{20}H_{33}Cl_2KOP_2Sm$ (611.79), were grown at room temp. from a diethyl ether solution of the compound. Data were collected with an Enraf-Nonius CAD4 diffractometer. The compound crystallised in the centrosymmetric space group $P2_1/n$ (no. 14). The crystal structure was solved by direct methods (SIR) and refined using the Enraf-Nonius MOLEN software package. Anisotropic temperature factors were assigned to all non-hydrogen atoms, while hydrogen atoms were included as fixed contributions to the structure factor. A non-Poisson weighting scheme was applied with a *p* factor equal to 0.06. The final agreement factors were $R = 0.039$, $R_w = 0.047$, G.O.F. = 1.01. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-106502. Copies of the data can be obtained free of charge on application to CCDC, 12 Union road, Cambridge CB2 1EZ [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Catalytic Formation of Carbon–Carbon Bonds by Activation of Carbon–Hydrogen Bonds

Yannick Guari,[a] Sylviane Sabo-Etienne,[a] and Bruno Chaudret*[a]

Keywords: Homogeneous catalysis / C–H activation / Carbon–carbon coupling

The direct functionalization of C–H bonds by formation of a C–C bond is an interesting and important alternative to coupling reactions involving halide derivatives. These reactions are complex but during the past few years a number of new systems have been developed which display promising scope. This microreview will briefly mention the different mechanisms leading to C–H activation and describe the new systems leading to the catalytic formation of carbon–carbon bonds.

Introduction

Much research has been devoted during the past 20 years to the activation of the carbon−hydrogen bond,[1] whether it concerns intermolecular (Equations 1−3)[1a−1k] or intramolecular (cyclometallation, Equation 4) activation.[1l−1q] The first process is of special interest for the functionalisation of hydrocarbons, whereas the second one is of importance for the synthesis of fine chemicals where the production of by-products is minimized. A great deal of knowledge has been gained on the process of C−H bond activation and three main mechanisms identified, namely oxidative addition,[2] σ-bond metathesis,[3] and electrophilic

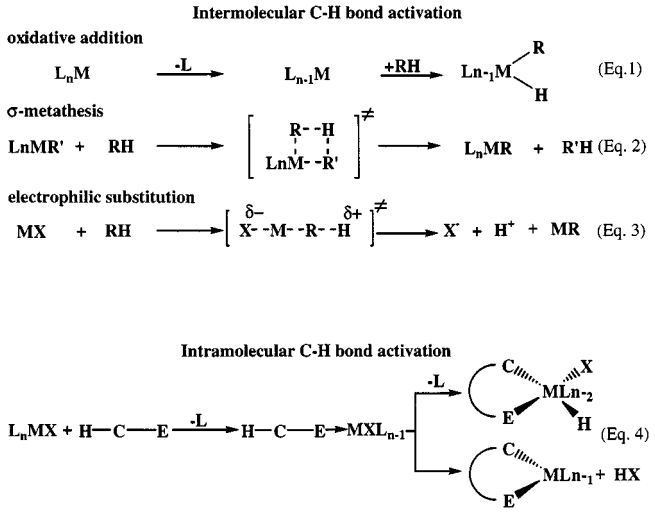
Yannick Guari (left, top) was born in Castelnaudary, France, in 1971. He studied chemistry at the Université Paul Sabatier in Toulouse, France, where he graduated. He then joined the group of Bruno Chaudret to work in the field of dihydrogen complexes and received his doctoral degree in 1998. He is now a postdoctoral fellow at the Universiteit van Amsterdam, The Netherlands, with Prof. Piet W. N. M. van Leeuwen. His current interest concerns palladium-catalysed carbon−nitrogen bond formation.

Sylviane Sabo-Etienne (right) was born in 1956 in Tarbes (France). She studied at the Université Paul Sabatier, Toulouse, and obtained her "Thèse de Troisième Cycle" in 1980 working under the supervision of Prof. Danièle Gervais. She then entered the CNRS in 1980 and obtained her "Doctorat d'Etat" in 1984. In 1985 she went to the Université de Bretagne Occidentale in Brest, to work with Prof. Hervé des Abbayes. After a year working with Prof. Maurice Brookhart (Chapel Hill, USA) she returned to the Laboratoire de Chimie de Coordination where she is currently "Directrice de Recherche". Her research interests concern the chemistry and spectroscopic properties of polyhydride, dihydrogen, silane, and more generally σ-bond complexes, with particular focus on catalytic applications.



Bruno Chaudret (left bottom) was born in 1953 in Ferolles (France). He received his degree from the "Ecole Nationale Supérieure de Chimie de Paris" in 1975, his Ph.D. from Imperial College of Science and Technology, London, working under the direction of Prof. Sir Geoffrey Wilkinson in 1977 and his "Doctorat d'Etat" from the Université Paul Sabatier, Toulouse, working under the direction of Prof. René Poilblanc in 1979. He entered the CNRS in 1977 and was promoted to the position of "Directeur de Recherche" in 1988. His research interests concern the chemistry and spectroscopic properties of polyhydride, dihydrogen and more generally σ-bond complexes and their application in catalysis and for C−H activation as well as the synthesis, chemistry, and physical properties of nanoparticles of metals, alloys, and oxides.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

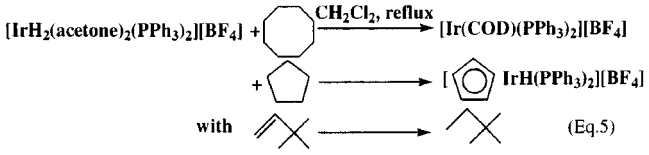
substitution,[4] all of which have been substantiated by stoichiometric studies.

However, despite this intense research activity, the number of catalytic processes including C−H bond activation as an elementary step have remained limited. This microreview will focus on the catalytic activation of cabon−hydrogen bonds leading to the formation of new carbon−carbon bonds. This will omit some very promising systems, such as that involving Pt(bipym) complexes recently described by Periana et al.[5] We will also omit the MERCAT process developed by Crabtree et al.[6] This is probably the most powerful system used to date to create new carbon−carbon and carbon−heteroatom bonds from alkanes, but it involves a mechanism based on electron transfer, and has recently been reviewed by Crabtree.



After the activation of a carbon−hydrogen bond, a new metal−carbon bond is generated. The new species has several possible pathways to react further: i) reductive elimination of an alkane in the case of an oxidative addition process; ii) β-elimination of the alkyl group to give an alkene; iii) insertion of small molecules into the metal−carbon bond leading to new functionalities. The first process is non-productive, we will consider only the latter two processes in the following review, and include the dehydrogenation processes as they formally generate a new carbon−carbon bond.

1. Alkane Dehydrogenation

With a Hydrogen Acceptor

Hydrocarbon dehydrogenation has been known in heterogeneous catalysis since 1937;[7] however, only recently have homogeneous systems been developed.

Alkane dehydrogenation could, in principle, be performed by good hydrogenation catalysts but this reaction is energetically unfavourable ($\Delta H \approx 30$ kcal·mol^{-1}). In order to circumvent this problem, Crabtree has employed a hydrogen acceptor, 3,3-dimethylbut-1-ene (*tert*-butylethylene), which is bulky enough to coordinate weakly to the transition metal centre, and which also shows a high enthalpy of hydrogenation. By using $[IrH_2(acetone)_2(PPh_3)_2][BF_4]$,[8] only stoichiometric reactions were observed (Equation 5).

However, catalytic dehydrogenation of cyclooctane to cyclooctene was achieved at 150°C using $IrH_2(CF_3CO_2)$-$[P(p\text{-}F-C_6H_4)_3]_2$ with a total turnover number of 16.[9] A similar system was developed by Felkin, Ephritikhine, and Baudry with polyhydrides such as $ReH_7(PR_3)_2$, $IrH_5(PR_3)_2$, and $RuH_4(PR_3)_3$ as catalysts.[10] At 150°C turnover numbers reaching 70 were obtained for the best systems.

The reaction path is proposed to involve a mechanism which is the reverse to that of alkene hydrogenation,[11] and which also involves highly coordinatively unsaturated intermediates (see Figure 1).[10]

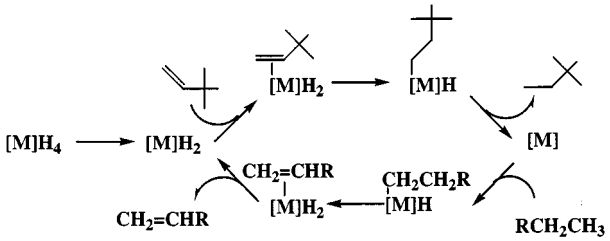


Figure 1. Proposed catalytic cycle for the dehydrogenation of saturated hydrocarbons

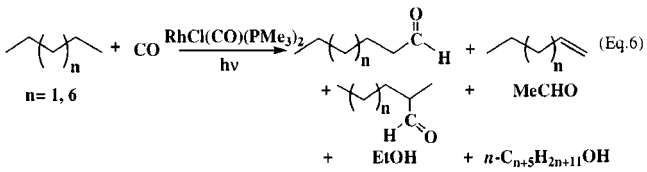
The first significant improvement was brought about by Goldman who performed the dehydrogenation reaction with $RhCl(CO)(PMe_3)_2$ as a catalyst and under a dihydrogen pressure of 69 bars. This system allows very high turnover numbers (1000) to be reached under mild conditions (60°C), but the problem is the necessary consumption of 6−8 mol of norbornene (used as hydrogen acceptor) per mol of dehydrogenated hydrocarbon. A number of linear and cyclic alkanes could be dehydrogenated in this way.[12]

More recently, Jensen et al. found that the complex $IrH_2[C_6H_3(CH_2PtBu_2)_2\text{-}2,6]$ (very stable even at high temperatures) could dehydrogenate cyclooctane to cyclooctene at 200°C in the presence of *tert*-butylethylene with a turnover frequency of 12 min^{-1}.[13] The thermal stability of this compound results from the use of the "pincer" ligand $C_6H_3(CH_2PtBu_2)_2\text{-}2,6$. Furthermore this system is able to dehydrogenate ethylbenzene or ethylcyclohexane to styrene, tetrahydrofuran to dihydrofuran,[14] cyclohexane to cyclohexene and benzene and decalin to octahydronaphthalene, tetrahydronaphthalene, and eventually naphthalene.[15] These reactions are slower than the dehydrogenation of cyclooctane. It is, however, remarkable that the formation of arenes does not poison the system.

Without a Hydrogen Acceptor

Whilst the interest of these systems is not in doubt, the presence of hydrogen acceptors make them unpractical. Therefore, several authors have looked for photocatalytic systems which avoid the use of hydrogen acceptors. Crabtree has shown that $IrH_2(CF_3CO_2)(PCy_3)_2$ is able to dehydrogenate cyclooctane to cyclooctene under UV irradiation with a turnover number of 7 at 25°C.[9] In this system, dehydrogenation of linear alkanes leads to a mixture of alkenes. Catalytic dehydrogenation of hexane, heptane, and octane has been carried out by Saito[16] using $RhCl(CO)(PR_3)_2$ (R = Me, Et, Ph), and Tanaka[17] using $RhCl(CO)(PMe_3)_2$. The reactions of Saito are carried out between 60 and 92°C and display a moderate variation in rate as a function of temperature, but no such variation as a function of the nature of the alkane substrate. The activity of the catalyst decreases in the order $PMe_3 > PEt_3 > PPh_3$. Tanaka's experiments were carried out under photolytic conditions and concern hexane as well as cycloalkanes such as cyclohexane and cyclooctane. In the case of hexane, 155 turnovers were obtained after 27 h, leading to (*E*)-/(*Z*)-2-hexene.

In all cases, the mechanism is proposed to involve β-elimination from an alkyl hydrido complex produced by oxidative addition of alkane to a coordinatively unsaturated species.



The best system was again found in 1997 by Goldman and Jensen, and involves the dehydrogenation of cyclodecane at 201°C under refluxing conditions leading to 360 turnovers after 24 h. The system is much less active for dehydrogenation of cyclooctane in a sealed tube at 200°C, thus suggesting the need for reflux.[18]

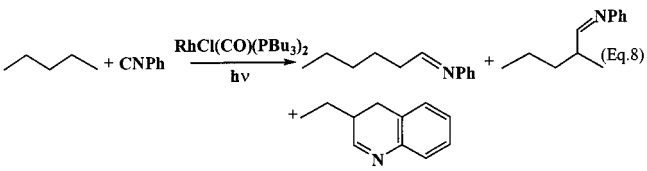
2. Formation of Carbon−Carbon Bonds

2.1 Insertion of Carbon Monoxide

The insertion of carbon monoxide into a carbon−hydrogen bond being thermodynamically unfavourable, all processes are photoassisted. Eisenberg was the first to show that square-planar iridium and rhodium complexes are able to catalytically insert carbon monoxide into a C−H bond of benzene when exposed to light (λ > 366 nm).[19] The complexes used were IrH(CO)(dppe), IrBr(CO)(dppe), $IrCl(CO)(PPh_3)_2$, and $RhCl(CO)(PPh_3)_2$ which gave rise to 2 catalytic cycles. A kinetic study carried out in the latter case shows that initial rates increase under reduced CO pressures, whereas larger turnover numbers were obtained under a high CO pressure.[19]

A similar but more efficient system was developed by Tanaka al. Using $RhCl(CO)(PMe_3)_2$, it was possible to catalytically carbonylate benzene itself or benzene monosubstituted by methyl, methoxy, chloro, or cyano groups with efficiencies reaching that of 65 turnovers.[20] This system can be extended to the carbonylation of saturated hydrocarbons. In this case, products of both carbonylation and dehydrogenation are obtained, those involving the initial activation of the terminal methyl groups being the most abundant (Equation 6).[20b,21]

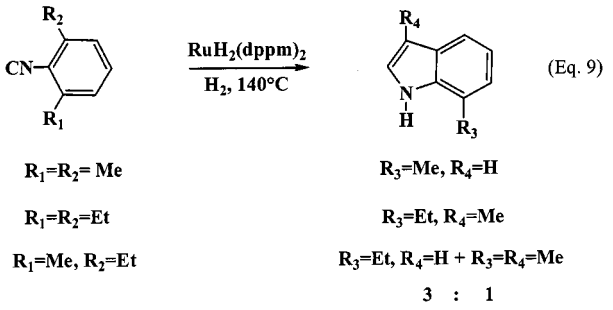
The mechanism of this reaction was studied at wavelengths shorter than 320 nm by Goldman et al.[22] Under these conditions, the authors propose that the first step is the oxidative addition of a benzene C−H bond to a photoexcited catalyst, and not photoextrusion of a ligand (CO or PR_3). Field et al. have prepared $RhHCl(Ph)(CO)(PMe_3)_2$ (2 isomers: *cis*-HCl and *trans*-HCl) by irradiation of $RhCl(CO)(PMe_3)_2$ in a benzene/tetrahydrofuran mixture at low temperatures in the absence of added CO.[23] Kinetic activation parameters (ΔH^{+} and ΔS^{+}) for the interconversion of both isomers are in agreement with those obtained by Goldman, and strongly suggest the intermediacy of a photoactive intermediate such as $RhHCl(Ph)(CO)(PMe_3)_2$ in benzene photocarbonylation. Finally, Eisenberg has also shown that d^8-ruthenium complexes accomodating carbonyl and phosphane ligands are also active for the photocarbonylation of benzene.[24]



Sen and co-workers have studied electrophilic systems for the functionalization of alkanes.[1r] Whereas most systems concern the oxidation of alkanes, the reaction of $RhCl_3 \cdot 3\,H_2O$ with methane, dioxygen, and carbon monoxide in a mixture of C_3F_7COOH, $(CF_3)_2CHOH$, and D_2O produces methanol and acetic acid at 80°C with high efficiency. The proposed mechanism involves insertion of CO into a rhodium−methyl bond.[4k,4l] This direct formation of acetic acid is a promising method of activating methane.

2.2 Isocyanide Insertion

Insertion reactions of isocyanide groups (RNC, R = Ph, Me, *t*Bu, *p*-tolyl), a ligand formally similar to the carbonyl ligand, into a C−H bond of benzene have been carried out by Tanaka et al. using $RhCl(CO)(PMe_3)_2$. The reaction needs to be photoassisted and leads mainly to aldimines (Equation 7).[25]



In the case of linear alkanes, $RhCl(CO)(PBu_3)_2$ was used and the reaction was found to be only stoichiometric (Equation 8).

A similar reaction had been previously described by Jones et al. who showed that isocyanide insertion into the C−H bond of benzene could be catalysed at room temp. by $Fe(CNR)_3(PMe_3)_2$ (R = Me, *t*Bu, CH_2CMe, Ph, 2,6-xylyl) under UV light.[26] This reaction does not work for alkanes such as pentane or cyclohexane. The same reaction is possible using $RhCl(CNR')(PR_3)_2$ (R = Me, Et, *i*Pr and R′ = neopentyl, 2,6-xylyl, Me) as a catalyst, leading to 7.7 turnovers after 16 h in the best case (R = *i*Pr et R′ = neopentyl) but again no insertion of isocyanides into the C−H bond of alkanes was observed using this system.[27]

$RuH(naphthyl)(dmpe)_2$,[28] the first complex to be shown to activate C−H bonds of aryl and activated aliphatic C−H bonds, was reinvestigated by Jones for the synthesis of indoles from bulky isocyanides. 2,6-Xylyl isocyanide reacts at 60°C with $RuH(naphthyl)(dmpe)_2$ for 24 h in toluene to give *trans*-$RuH[2\text{-}(7\text{-methylindole})](dmpe)_2$ which isomerizes at 100°C to *cis*-$RuH[2\text{-}(7\text{-methylindole})](dmpe)_2$. The latter eliminates 7-methylindole at 140°C under 0.66 bar H_2 to yield $RuH_2(dmpe)_2$. The mechanism involves initial intramolecular C−H activation of a methyl substituent of the xylyl group attached to the isocyanide moiety. Using $RuH_2(dmpe)_2$, 3.6 turnovers could be obtained at 140°C (Equation 9).

2.3 Alkene and Alkyne Insertion into Unsupported Carbon−Hydrogen Bonds

The insertion of alkynes into C−H bonds of benzene, *n*-hexane, cyclohexane, or diethyl ether can be achieved with $RhCl(CO)(PMe_3)_2$ in the presence of UV light. However, the reaction is less efficient than carbon monoxide or isocyanide insertion, and only 6 turnovers were obtained in the best case.[29] In addition to insertion products, the reaction in the case of benzene leads to dimers and trimers of acetylenes as well as biphenyl. The latter product, and other biaryls, can be obtained directly from the photolysis of arenes in the presence of $RhCl(CO)(PMe_3)_2$.[30] Cyclohexane, *n*-hexane, and diethyl ether react in the same way with phenylacetylene to give the corresponding α-substituted styrenes with a good regioselectivity but in low yield (from 19%/Rh for cyclohexane to 77%/Rh for *n*-hexane) and with the formation of several by-products.[29]

Some thermal systems involving insertion of unsaturated molecules into C−H bonds of benzene have been known for a long time. Thus, Hong et al. have shown that insertion of alkynes (RC≡CR′; R = Ph, Me, R′ = Ph; R = R′ = *p*-MeC_6H_4),[31] heterocumulenes,[32] aryl isocyanates (RN=C=O; R = Ph, *p*-MeC_6H_4, *p*-ClC_6H_4, α-$C_{10}H_7$),[32] ethylene,[33] monosubstituted ethylene (CH_2=CHCOR; R = OMe, OH, NMe_2, NMePh, Me),[34] disubstituted ethylene (RCH=CHR′; R = Me, Ph, CO_2Me, R′ = CO_2Me;[34] CH_2=CRR′; R = Me, R′ = CO_2Me)[34] and cyclic alkenes[34] into the C−H bonds of benzene, arenes (PhR; R = Me, OMe, F; Figure 2) or furans ($C_4H_3R''O$; R″ = H, Me, $MeCO_2$, MeCO, CHO; Figure 3) could be achieved at 220°C with $Rh_4(CO)_{12}$ as catalyst and under a pressure of CO. A maximum turnover number of 360 was obtained in the case of the addition of CH_2=$CHCO_2Me$ to benzene under 29 bars of CO. The reaction is favoured by the presence of electron-withdrawing substituents leading the authors to propose initial attack of a nucleophilic low-valent rhodium cluster onto the substrate C−H bond, followed by C−H bond cleavage and alkyne or isocyanate insertion. The CO pressure would be necessary to regenerate the active catalytic species. In some cases, secondary products can be formed, such as indenones in the case of the reaction between acetylenes and benzene, which result from CO insertion.

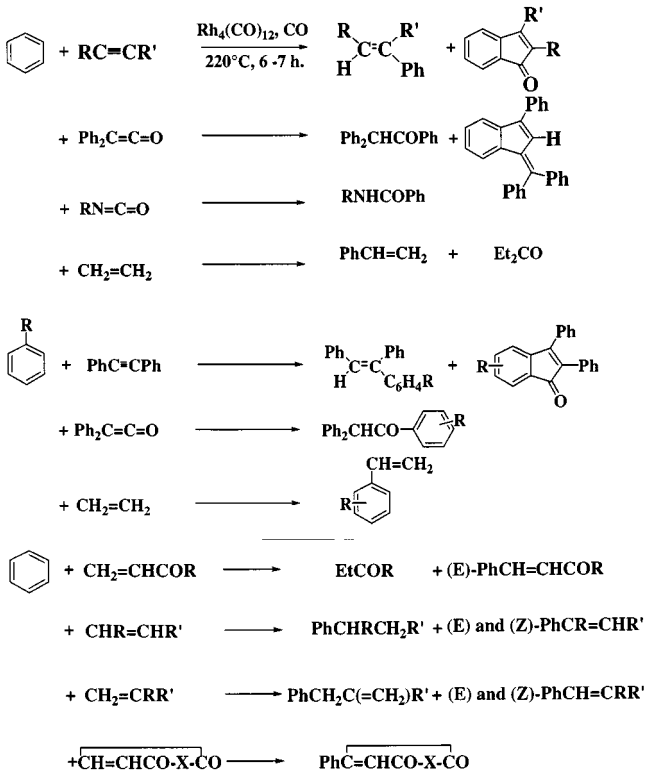


Figure 2. Carbon−carbon bond formation between arenes and unsaturated hydrocarbons catalysed by $Rh_4(CO)_{12}$

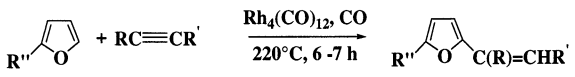

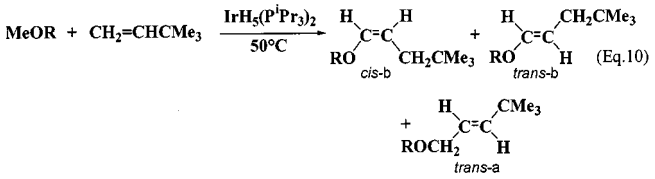

Figure 3. Carbon−carbon bond formation between furan and unsaturated hydrocarbons catalysed by $Rh_4(CO)_{12}$

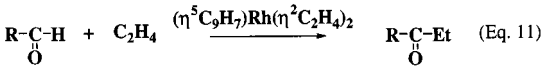
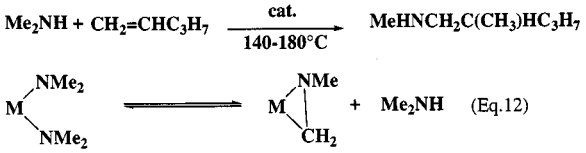


An interesting coupling reaction between a C−H bond of methyl ethers (MeOR; R = CH_2CH_2OMe, C_6H_{11},

$C_6H_{10}Me$) and 3,3-dimethylbut-1-ene has been reported by Lin, Ma, and Lu with $IrH_5(PiPr_3)_2$ as the catalyst.[35] The reaction produces olefins and enol esters with a maximum turnover number of 12 after 24 h at 50°C (Equation 10).

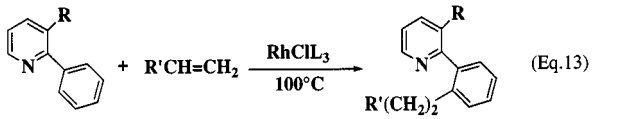
The mechanism of this reaction involves the formation of an unsaturated 14-electron intermediate, similar to that proposed by Felkin et al. for alkane dehydrogenation, which is able to insert into the activated C−H bond of the methyl ether. The absence of β-hydrogen allows the coupling reaction to occur. This reaction is followed by a rapid isomerisation of the olefin formed.

Finally, the coupling reaction between aldehydes and olefins involves the activation of a particular C−H bond. Milstein et al. have shown that $[(\eta^5C_9H_7)Rh(\eta^2C_2H_4)_2]$ catalyses the insertion of ethylene at 100°C under 69 bars into the C−H bond of aldehydes RC(O)H (R = Ph, *p*-$CF_3C_6H_4$, *p*-MeC_6H_4) with a turnover frequency of 4 h^{-1}(Equation 11).[36]



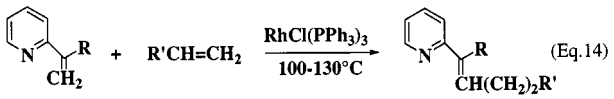
The reaction presumably proceeds by initial activation of the aldehyde C−H bond, as in the decarbonylation reactions of aldehydes catalysed by numerous transition metal complexes. It is, however, interesting to note that no decarbonylation product has been observed in this case.

2.4 Alkene and Alkyne Insertion into Potentially Chelating Systems

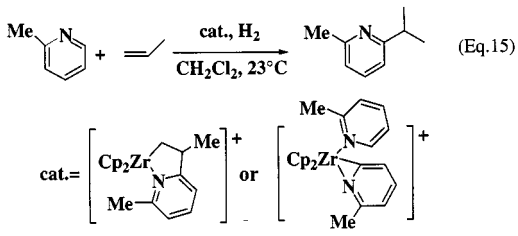


It has been shown in section 2.3 that most systems involving direct C−C coupling through C−H activation were relatively inefficient. It is, however, known from literature on organometallics that the activation of a C−H bond linked to a functional group (phosphane, amine, ketone, ...), thus maintaining it in close proximity to a metal centre, is much easier. This led several authors to investigate the functionalization of cyclometallated hydrocarbons. Lewis and Smith[37] have described the insertion of ethylene into the ruthenium−carbon bond of an *ortho*-metallated phosphite group. However, catalytic reactions were developed for systems containing a nitrogen or oxygen donor group as chelating assistant of the insertion reaction into the C−H bond.

Nitrogen Donor Chelating Assistants



A catalytic amination reaction of olefines has been described by Nugent et al.[38] which does not involve, as expected, the formation of a C−N bond, but the formation of a C−C bond. The catalysts are amido transition metal complexes. The proposed mechanism involves the intermediacy of a metallacycle and the insertion of the olefin into the M−C bond (Equation 12).



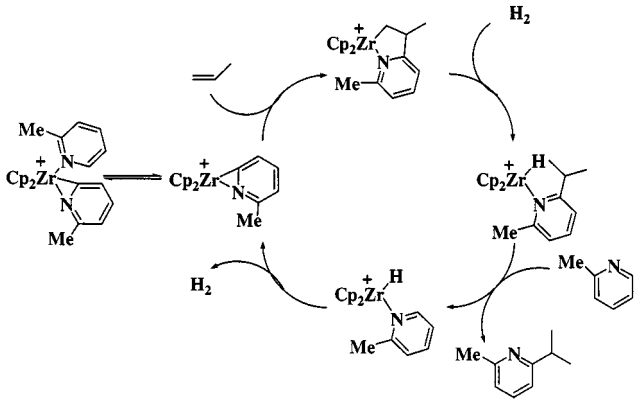
Recently, Lim, Kim, and Bang have described the catalytic alkylation of the phenyl ring of 2-phenylpyridine and 3-methyl-2-phenylpyridine in the *ortho* position relative to pyridine. Several olefins were used, namely R′CH=CH_2 [R′ = $Me(CH_2)_2$, $Me(CH_2)_3$, $Me(CH_2)_5$, $Me_3C(CH_2)_2$, $Si(OEt)_3$, $Si(OMe)_3$], in the presence of the catalyst $RhCl(PPh_3)_3$ leading at 100°C to 10 turnovers in 22 h for the best system (Equation 13).[39]

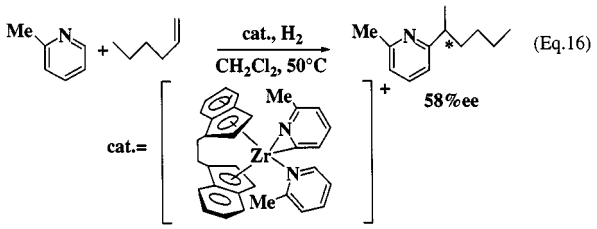
The intermediacy of an *ortho*-metallated hydridorhodium complex has been postulated. The reaction has been extended to carbon−carbon coupling reactions of substituted 2-vinylpyridines *o*-RC(=CH_2)−C_6H_4N (R = Me, Ph) with the olefins R′CH=CH_2 previously mentioned.[40] This reaction leads to 10 turnovers at 100−130°C (in the best case) in the presence of the same rhodium catalyst (Equation 14).

More unexpectedly, chelating assistance by the pyridine nitrogen atom is also involved in the functionalisation of *ortho* C−H bonds in pyridine. Jordan et al. have first described the alkylation of pyridines in *ortho* position relative to the nitrogen atom. The reaction occurs under H_2 at 23°C in the presence of cationic zirconium complexes, leading to up to 40 turnovers (Equation 15).[41]

The mechanism involves the initial formation of $[Cp_2Zr(\eta^2\text{-6-methylpyrid-2-yl})(THF)]^+$ from $[Cp_2ZrMe(THF)]^+$ through a σ-bond metathesis process. In this system intermediates were isolated and demonstrated to be ac-

tive in the catalytic coupling of 2-methylpyridine with propene (see Figure 4).





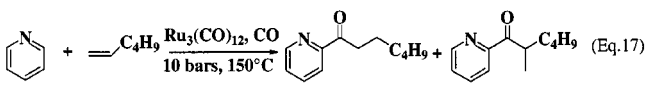


Figure 4. Reaction mechanism of coupling between 2-methylpyridine and propene catalysed by zirconium complexes

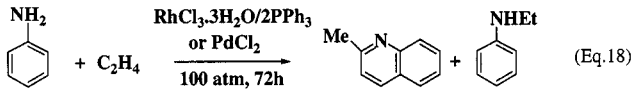
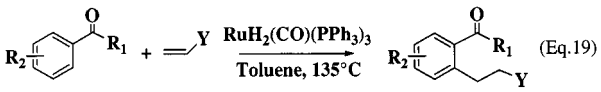
Recently, this reaction was extended to the regio- and stereoselective insertion of olefins into a methylpyridine C−H bond using chiral catalysts such as [$^{ch}Cp_2Zr(\eta^2$-pyrid-2-yl)]$^+$ [$^{ch}Cp_2$ = ethylenebis(indenyl) (EBI) or ethylenebis-(tetrahydroindenyl) (EBTHI)].[42] The catalytic activity of the chiral complexes is 10 times lower, but at 50°C, in the presence of H_2, [(*S*,*S*)-(EBTHI)Zr(η^2-6-methylpyrid-2-yl)(2-methylpyridine)]$^+$, generated in situ from (*S*,*S*)(EBTHI)$ZrMe_2$, [$HNBu_3$][BPh_4], and 2-methylpyridine, catalyses the addition of 1-hexene to 2-methylpyridine to give (*R*)-2-methyl-6-(2-hexyl)pyridine with a 58% enantiomeric excess (Equation 16).



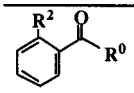
Moore et al. have shown that it is possible to insert two different molecules, namely carbon monoxide and olefins (R′CH=CH_2; R′ = H, C_4H_9, $C_{18}H_{37}$, Me_3C), into the C−H bond of pyridine in the *ortho* position relative to the nitrogen atom.[43] The reaction occurs at 150°C, under 10 bars of CO and leads to a turnover frequency of up to 300 h^{-1} when using 3,3-dimethyl-1-butene. The reaction can be extended to quinolines and to the use of cyclic alkenes but does not work for tri- and tetrasubstituted olefines. The authors present evidence for the implication of a trinuclear catalyst based on kinetic data and the absence of reactivity of photolytically generated mononuclear species (Equation 17).

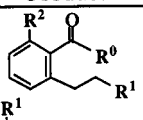


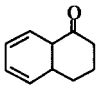
A very similar system was used by Murai for the acylation of substituted imidazoles. The reaction is carried out under relatively harsh conditions (160°C, 20 bars of CO) and leads to a limited yield of coupling products; up to 23 turnovers in the best case.[44]

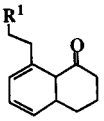
Finally, during attempts to catalyse olefin amination, Diamonds and co-workers observed a new cyclization reaction leading to the formation of 2-methylquinoline. The reaction conditions are severe (200°C, 101 bars, 72 h) and the yields modest (30 turnovers for the formation of *N*-ethylaniline and 10 turnovers for 2-methylquinoline), but this reaction represents the first catalytic synthesis of heterocycles and is thought to involve intermediate species containing *ortho*-metallated aniline (Equation 18).[45]

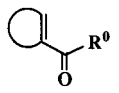
Oxygen Donor Chelating Assistants

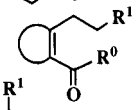


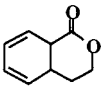


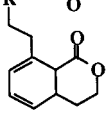


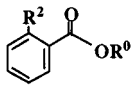


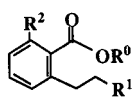


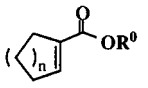


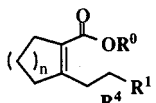


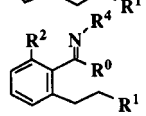












Perhaps the most interesting and promising system for the functionalization of aromatic hydrocarbons in α-position relative to a functional group has been described by Murai and co-workers.[46−48] Initially, Murai (1993) described the alkylation of aromatic ketones using ruthenium catalysts, namely $RuH_2(CO)(PPh_3)_3$ (the most efficient example), $Ru(H)_2(PPh_3)_4$, $Ru(CO)_2(PPh_3)_3$, and $Ru(CO)_3(PPh_3)_2$.[46−48] The reaction was carried out in vigourously refluxing toluene, a temperature of 135°C being indicated by the authors, and led to ca. 50 turnovers of coupling product in the best case (Equation 19).

The scope of the reaction has proven to be fairly general. Thus, similar alkylation reactions were observed for acylbenzene derivatives,[46−48] α-tetralones,[49] α,β-enones,[50] lactones,[51] aromatic and heteroaromatic esters,[51] cyclic esters,[52] and aromatic imines[52] using substituted olefins[46−48,50−52] and alkynes.[49] Table 1 summarizes some of the reactions studied by Murai′s group. This system has since then been extended by Weber et al. to the copolymerization of acetophenone with α,ω-dienes[53] as well as to the modification of unsaturated polymers,[54] whereas Woodgate used this system for alkylating hydroxyacetophenone and extended it to the functionalization of aromatic diterpenoids.[55]

The mechanism proposed by Murai involves the formation of a 16-electron ruthenium(0) intermediate produced by hydrogenation of the incoming olefin. The formation of triethoxyethylsilane (0.036 mmol) has been observed when $RuH_2(CO)(PPh_3)_3$ (0.04 mmol) was treated with 3 equiv. of triethoxyvinylsilane at 135°C for 1 min. The ruthenium complex was not identified. Addition of acetophenone (0.08 mmol), at 135°C and within 1 min, leads to the coupling product. An *ortho*-metallated intermediate, "RuH[*o*-C_6H_4−C(O)R]", is proposed (see Figure 5). Similar com-

plexes have been known since their first preparation by Cole-Hamilton and Wilkinson.[56] Hydrogen migration and carbon−carbon coupling would lead to the organic product and regenerate the active species [Ru].[46−52]

Trost et al. have studied the coupling of olefins with α-unsaturated esters catalysed by $RuH_2(CO)(PPh_3)_3$.[57] The catalytic activity is similar to that observed by Murai and the reaction is inhibited by the presence of a CO pressure or when carried out in a closed system, hence suggesting the need for CO to be eliminated for the reaction to proceed. The authors propose an active species "$RuS(PPh_3)_3$" stabilized by interaction with the solvent S.[57]

Weber et al. have recently mentioned the isolation of $[Ru\{MeC(O)C_6H_4CH=CH_2\}(CO)(PPh_3)_2]$ through the reaction of *o*-acetylstyrene with $[RuH_2(CO)(PPh_3)_3]$ in the presence of styrene at 120°C.[58] Such a complex could be a model for a late intermediate in the catalytic alkylation cycle and catalyses the copolymerisation of acetophenone and 1,3-divinyltetramethyldisiloxane.

More recently, Murai et al. have extended their study to the intramolecular asymetric coupling of substituted 1-(2-pyridyl)-1,5-dienes (Equations 20 and 21) or substituted 1-(1-methyl-2-imidazolyl)-1,5-dienes using a different catalytic system: $[RhCl(COE)_2]_2$ in the presence of alkyl (*R*)-1-[(*S*)-2-(diphenylphosphanyl)ferrocenyl] ether {alkyl = Me [(*R*)-(*S*)-PPFOMe], Et}.[59] The reaction proceeds at 25°C giving rise to 2 turnovers after 20 h and an enantiomeric excess of 78%. Up to 15 turnovers can be obtained at 120°C within 1 h but the enantiomeric excess decreases to 71%.

In our group, we have recently prepared a series of hydrido dihydrogen complexes containing *ortho*-metallated ligands (see Figure 6). For example, the reaction of 2-phenylpyridine leads to a new complex displaying interesting spectroscopic properties.[60a] These complexes are reminiscent of the intermediates proposed by Murai. This led us to attempt the same reaction with acetophenone and benzophenone. Hydrido dihydrogen complexes containing *ortho*-metallated aromatic ketones can thus be synthesized. These complexes further react with CO to give carbonyl hydrido complexes corresponding to precursors in Murai's cycle. The bis(dihydrogen) complex $[Ru(H)_2(H_2)_2(PCy_3)_2]$[60b] and the complexes containing *ortho*-metallated aromatic ketones were tested as catalysts for Murai's reaction in order to validate the catalytic cycle and define the role of CO. The reactions were carried out at room temp. in the presence of ethylene (20 bars). A catalytic reaction was observed when using $[RuH_2(H_2)_2(PCy_3)_2]$ or $[RuH(H_2)[OC(R)C_6H_4]-(PCy_3)_2]$ (R = Me, Ph) leading to the alkylation of the phenyl group in the *ortho* position of the ketone substituent. 10 turnovers are obtained under these conditions for the alkylation of acetophenone after 20 h, and 20 turnovers in the alkylation of benzophenone (see Figure 7). In the latter case, the reaction produces almost exclusively the dialkylated product. However, when using the carbonyl hydrido complexes $[RuH(CO)\{OC(R)C_6H_4\}(PCy_3)_2]$ (R = Me, Ph) no reaction was observed, even upon heating the solution. This suggests that the need for a high temperature in Murai's reaction is due to the necessity to eliminate CO from the coordination sphere of the ruthenium centre.

Conclusion

In conclusion, in this microreview we have briefly presented some of the latest results concerning the functionalization of C−H bonds through the formation of C−C bonds. If the alkane dehydrogenation is still difficult and requires harsh conditions, the catalytic insertion of alkenes into aromatic C−H bonds seems to be one of the most promising reactions regarding synthetic applications, especially if these reactions can be carried out under mild conditions (at room temperature for example). The development of such reactions would then avoid the by-products of conventional routes, salts in particular, and this research could therefore lead to new "environmentally friendly" processes.

Cycloisomerization of Alkynols at Transition Metal Templates

Bernd Weyershausen[a] and Karl Heinz Dötz*[a]

Keywords: Alkynols / Isomerizations / Oxacycloalkylidene complexes / Vinylidene complexes / Transition metal templates

The metal-assisted cycloisomerization of ω-alkynols to oxacycloalkylidene complexes is reviewed. A variety of low-valent coordinatively unsaturated transition metal templates from group 6 to 10 mediate the cyclization of ω-butynols, -pentynols, and -hexynols to give the corresponding oxacycloalkylidene complexes. In some cases kinetic hydroxyalkylvinylidene complex intermediates can be isolated and characterized.

Introduction

Carbene ligands coordinated to a transition metal center play an important role in both stoichiometric reactions directed towards organic synthesis,[1] and in catalytic processes such as olefin metathesis.[2] Recently, stable nucleophilic carbenes have received a great deal of attention.[3] Their ligand properties resemble those of the well-established phosphane ligands; thus, they may serve as "spectator" ligands in transition metal complexes, which have been successfully applied to olefin metathesis,[4] hydroformylation, and Heck-type reactions.[5] Electrophilic carbenes can be stabilized by coordination to low-valent transition metals; this type of complexes, developed by E. O. Fischer in the 1960s and 1970s,[6] has been increasingly used in stoichiometric C−C bond formation. They undergo ligand-centered reactions which are assisted by a carbonylmetal electron-acceptor fragment; moreover, the metal fragment may serve as a template which activates unsaturated ligands for cycloaddition reactions.[1c,1e,7]

This review deals with the cycloisomerization of alkynols at coordinatively unsaturated transition metal templates of group 6 to 10 metals affording cyclic electrophilic carbene complexes. Although the most versatile route to acyclic Fischer-type carbene complexes is still based on the two-step addition of a nucleophile and an electrophile across the C−O bond in carbonylmetal compounds,[8] the most

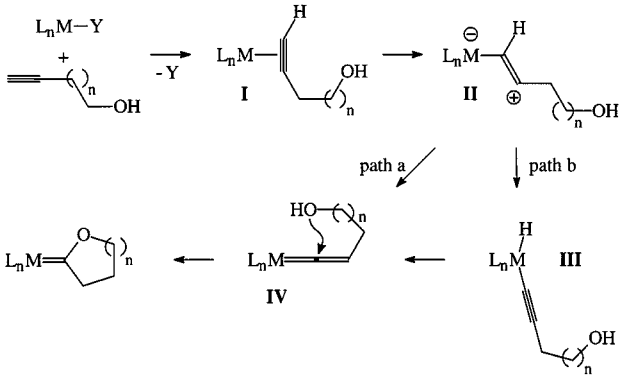
Bernd Weyershausen studied chemistry at the University of Bonn. After the diploma thesis with Prof. J. Barluenga at the University of Oviedo (Spain) he started his Ph. D. thesis under the supervision of Prof. K. H. Dötz at the University of Bonn and received his Ph. D. degree there in 1998. Currently, he is working as a postdoctoral fellow in the group of Prof. K. C. Nicolaou at The Scripps Research Institute in La Jolla (USA) supported by a Feodor Lynen Fellowship.



Karl Heinz Dötz was born in 1943 and began his chemical education at the Technical University of Munich where he received his Ph. D. with Professor E. O. Fischer. He then moved towards the borderline between Inorganic and Organic Chemistry, focussed during his habilitation on the organic chemistry of metal carbenes which he applied to novel metal-assisted cycloaddition patterns. In 1986 he became Professor of Organometallic Chemistry at the University of Marburg. In 1992 he was lucky to choose among a few offers, and finally joined the University of Bonn where he was appointed Professor of Organic Chemistry and Co-Director of the Kekulé Institute. He holds visiting appointments in Princeton and Paris, and is a recipient of the Victor Grignard−Georg Wittig Lectureship. His research interests concentrate on organometallic template reactions, stereoselective synthesis, asymmetric catalysis and on carbohydrate chemistry.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

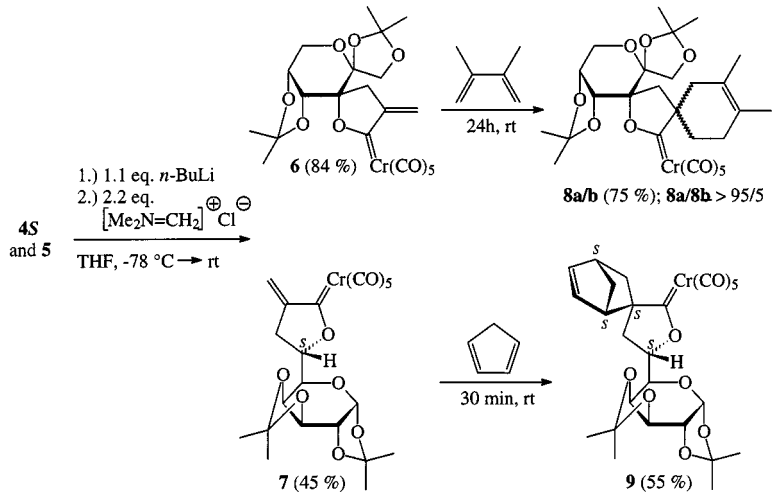
common approach to cyclic Fischer-type carbene complexes is the metal-assisted cyclization of alkynols at low-valent metal templates.[9] Heteroatom-containing cyclic carbene transition metal complexes have also been prepared via ω-haloacyl-,[10] carbamoyl-, alkoxycarbonyl-, or imidometal intermediates,[11] and through the ring opening of epoxides by deprotonated Fischer-type carbene complexes followed by elimination of lithium methoxide upon intramolecular cyclization of the γ-lithium alkoxide substituted complex intermediate.[12] Even direct activation of tetrahydrofuran and other cyclic ethers by $TpIr^{III}$ complexes[13] has been observed with formation of Fischer-type carbene derivatives.[14] Another route is based on the addition of alcohol nucleophiles to vinylidene species accessible from the isomerization of terminal alkynes at a late transition metal center. This strategy, initiated by Chisholm and Clark,[15] has been extended to alkynols which have been treated with a series of group 6 to 10 metals. The formation of the cyclic carbene ligands from ω-alkynols can be rationalized in terms of a vinylidene complex intermediate **IV** which undergoes an intramolecular nucleophilic attack of the hydroxy function at the α-carbon atom of the vinylidene complex (Scheme 1). Experiments using a series of different metal systems have demonstrated that vinylidene complexes can be generated from terminal alkynes by 1,2-hydride migration.[16] These reactions are supposed to involve an initial η^2-alkyne complex **I** which rearranges to its η^1 isomer **II**. The 1,2-hydride shift may occur either directly to the β-carbon atom (path a) or by oxidative addition to a σ-alkynyl(hydrido) species **III** (path b). Whereas calculations favour a direct hydrogen transfer,[17] the oxidative addition pathway is established by experimental evidence.[18]

Scheme 1. Mechanism of the cycloisomerisation of ω-alkynols at metal templates



actions.[1c,1e,7] Recently, the authors have started a program aimed at the synthesis of carbohydrate-functionalized oxacycloalkylidene complexes[20] in order to exploit the chiral information provided by the carbohydrate moiety in stereoselective reactions, and to evaluate their potential in the synthesis of natural products and biologically active compounds. As the cycloisomerization of alkynols at coordinatively unsaturated group 6 metals[9] is the most common approach to oxacyclocarbene complexes, interest is focused on the preparation of carbohydrate-derived alkynols and their cyclization at a solvent-stabilized pentacarbonylchromium or -tungsten template. In general, butynols are easily accessible by addition of propargylic organometals to carbonyl compounds.[21] In this case, however, the reagent of choice turned out to be allenylmagnesium bromide[22] which at low temperature undergoes clean γ-addition to the carbonyl functionality of carbohydrate-based aldehydes and ketones to give the desired butynols in yields up to 90%. Carbohydrate-derived aldehydes afford mixtures of diastereomeric butynols, whereas the allenylmagnesium bromide adds with complete diastereoselectivity to carbohydrate-derived ketones. As the diasteromeric butynols are difficult to separate using chromatographic techniques, they were treated as a mixture of diastereomers with pentacarbonyl(tetrahydrofuran)chromium(0) or -tungsten(0) generated by UV irradiation of the corresponding hexacarbonylmetal in tetrahydrofuran at −10°C. The separation of the resulting mixtures of diastereomeric carbene complexes was readily achieved by column chromatography and afforded pure diastereomers of various acyclic[23] and spirocyclic[24] carbohydrate-functionalized 2-oxacyclopentylidene complexes; some examples are shown in Scheme 2.

(Oxacycloalkylidene)chromium, -molybdenum, and -tungsten Complexes

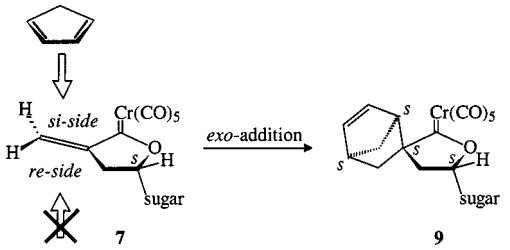
Cyclic Fischer-type metal carbene complexes are valuable tools in organic synthesis.[1] Carbene complexes with group 6 metals are especially synthetically useful reagents, and their synthetic potential is based on both the pronounced α-CH acidity[19] within the alkyl side chain, and on either metal-centered or carbene ligand-centered cycloaddition re-

Scheme 2. Synthesis of carbohydrate-functionalized 2-oxacyclopentylidene complexes

Scheme 3. Diastereoselective Diels–Alder reaction with α-*exo*-methylene-functionalized 2-oxacyclopentylidene complexes

The absolute configuration of the major diastereomers **1*S*** and **2*S*** has been determined by single-crystal X-ray analysis to be (3*S*,4′*R*).[25] In the case of the complex **4** the absolute configuration at C-3 of the minor diastereomer has been determined by single-crystal X-ray analysis of the Diels–Alder product **9** (Scheme 3) to be (3*S*).[26] In general the cycloisomerization of butynols at a tungsten template requires shorter reaction times and gives higher yields of the corresponding carbene complex, indicating that the tungsten template is more reactive than the chromium analogue. Following the procedure reported by Maiorana et al.[27] the carbohydrate-functionalized 2-oxacyclopentylidene complexes could be converted into their α-*exo*-methylene derivatives which serve as potent dienophiles in diastereoselective Diels–Alder reactions (Scheme 3).[20,25,26]

In contrast to the Diels–Alder reaction with 2,3-dimethylbutadiene, the stereoselective addition of cyclopentadiene to the α-*exo*-methylene double bond of complex **7** requires a differentiation not only between *si*- and *re*-side attack, but also between *exo* and *endo* addition. If we take into consideration the absolute stereochemistry at C-3 of complex **7** the diene is expected to add to the α-*exo*-methylene double bond from the top face (*si* side) due to the sterical hindrance of the bottom face (*re* side) caused by the carbohydrate moiety. A single-crystal X-ray analysis of **9** revealed that, due to the steric requirements of the bulky pentacarbonylchromium fragment resulting from the fixed *s-cis* conformation of the (vinylcarbene)metal dienophile **7**, the stereochemical outcome is in accord with an *exo* approach of the diene to the sterically less hindered face (*si* side) of the dienophile (Figure 1).[26][28]



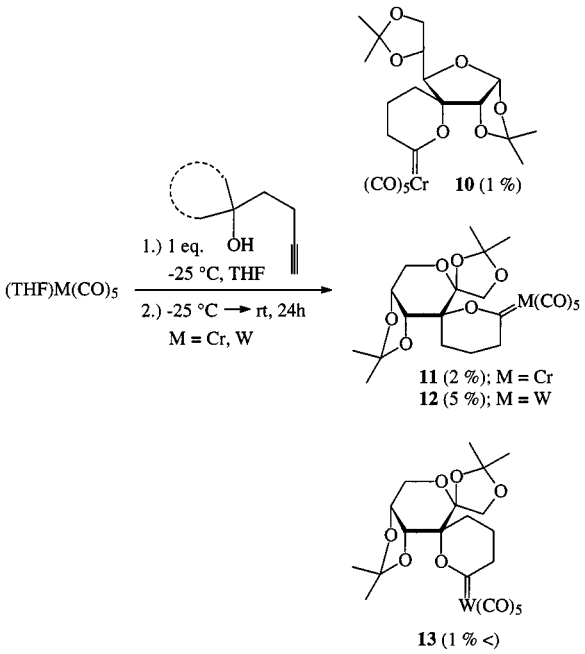


Figure 1. Stereopreference for the addition of the diene to the α-*exo*-methylene double bond

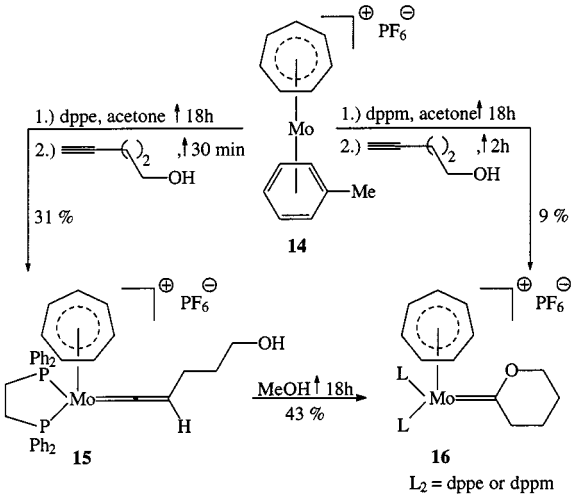
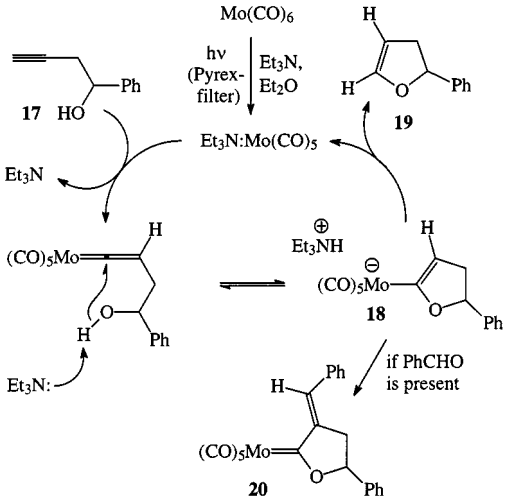


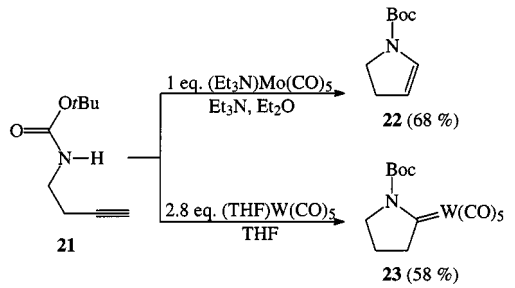
In order to evaluate the potential of this methodology for the synthesis of spirocyclic carbohydrate-derived 2-oxacyclohexylidene complexes the metal-assisted cycloisomerization of suitable carbohydrate-based ω-pentynol precursors was addressed.[29] (Scheme 4). Although in general the cycloisomerization of ω-pentynols gives lower yields compared with the cyclization of ω-butynols, the yields obtained for complexes **10**–**13** were below expectations. This

Scheme 4. Carbohydrate-derived spirocyclic 2-oxacyclohexylidene complexes



outcome might be rationalized in terms of a slower intramolecular nucleophilic attack of the ω-pentynol hydroxy group at the α-carbon atom of the vinylidene complex inter-

mediate, as a result of a higher flexibility of the hydroxyalkyl substituent combined with a lower thermal stability of the vinylidene complex intermediate. It is noteworthy that in contrast to the reaction of the psicose-based butynol with pentacarbonyl(tetrahydrofuran)chromium(0) affording the complex **5**, the analogous reaction with the psicose-based pentynol resulted in neither isolation of the desired 2-oxacyclohexylidene complex nor in its in situ identification by IR spectroscopy. The more reactive tungsten template allowed the formation of the psicose-derived spirocyclic oxacycloalkylidene complex **13**, as monitored spectroscopically by IR as a decrease in the intensity of the $A_1{}^1$ band of pentacarbonyl(tetrahydrofuran)tungsten(0) at 2074 cm^{-1} along with an increased intensity of the $A_1{}^1$ band of 2-oxacyclohexylidene complex **13** at 2068 cm^{-1}; after 24 h, a small amount of **13** was isolated by column chromatography. Attempts to heat the reaction mixture up to 40°C did not improve the yield, but resulted in decomposition of the solvent-stabilized tungsten template without formation of **13**. So far, there are only a few examples of 2-oxacyclohexylidene group 6 metal complexes which have been prepared by cycloisomerization of the corresponding pentynol.[30][31] The successful isolation and characterization of the hydroxyalkylvinylidene complex **15** suggest that the length and the flexibility of the alkyl chain of the vinylidene complex intermediate as well as the ligands[32] coordinated to the metal template play an important role in the subsequent cyclization[29] (Scheme 5).

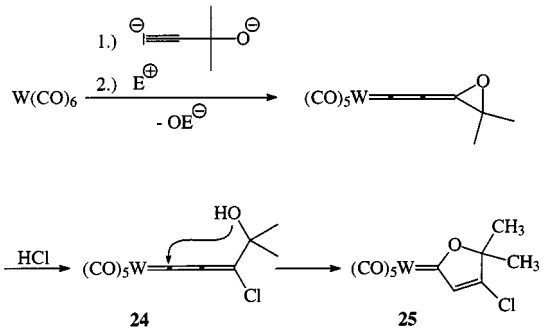


Scheme 5. Isolation and subsequent cyclization of the hydroxyvinylidene intermediate **14**

It has been previously suggested that the formation of oxacycloalkylidene complexes from ω-alkynols proceeds by intramolecular cyclization of a hydroxyalkylvinylidene intermediates.[9b,24c,33] The molybdenum sandwich **14** is able to cycloisomerize ω-pentynol in the presence of DPPM to give the oxacyclohexylidene complex **16** in poor yield.[34] If DPPM is replaced by DPPE the hydroxyalkylvinylidene complex **15** was isolated, which could be converted into **16** in refluxing methanol for 18 h. McDonald et al. reported on a modestly catalytic cycloisomerization of ω-butynols[35] to 2,3-dihydrofurans, and of epoxyalkynes[36] to furans. The pentacarbonylmolybdenum template required for these transformations is best generated by photolysis of hexacarbonylmolybdenum in a mixture of diethyl ether and triethylamine. The mechanism proposed for the cycloisomerization of alkynol **17** to 2,3-dihydrofuran **19** (89% optimized yield using 26 mol-% hexacarbonylmolybdenum) is shown in Scheme 6.

Scheme 6. Proposed mechanism for the catalytic alkynol cycloisomerization

The role of the carbenemolybdenum anion **18** as an intermediate in the catalytic cycle was supported by isolation of the apparent aldol condensation−dehydration[12b,37] product **20**, obtained from the reaction of **17** with $(Et_3N)Mo(CO)_5$ in the presence of benzaldehyde. The metal-promoted cycloisomerization methodology has also been extended to *N*-protected alkynylamines and 2-alkynylanilines.[38] For example, the reaction of *N*-BOC-aminobutyne **21** with 1 equiv. of $(Et_3N)Mo(CO)_5$ in a mixture of triethylamine and diethyl ether as solvent afforded a yield of 68% of 2,3-dihydropyrrole **22**; similarly, azacycloalkylidene complex **23** was formed in a yield of 58% upon the reaction of **21** with 2.8 equiv. of pentacarbonyl(tetrahydrofuran)tungsten(0) (Scheme 7).

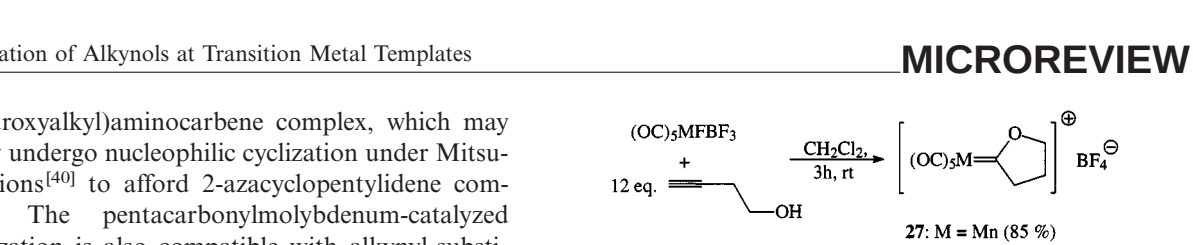


Scheme 7. Cycloisomerization of alkynylamide **21**

This route provides a complementary access to azacycloalkylidene complexes. Their synthesis, so far, has been reported from γ-lactams requiring $K_2[M(CO)_5]$ as a troublesome organometal nucleophile,[39] or from 2-oxacyclopentylidene complexes by aminolysis to give an open-

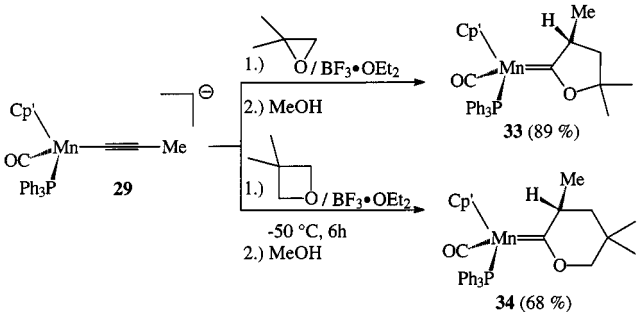
chain (γ-hydroxyalkyl)aminocarbene complex, which may subsequently undergo nucleophilic cyclization under Mitsunobu conditions[40] to afford 2-azacyclopentylidene complexes.[23][41] The pentacarbonylmolybdenum-catalyzed cycloisomerization is also compatible with alkynyl-substituted carbon nucleophiles such as diethyl 2-(3-butyn-1-yl)-malonate, giving the corresponding cyclopentene derivatives.[42]

Whereas great attention has been paid to 2-oxacycloalkylidene complexes bearing a saturated carbon skeleton, less effort has focused on their endocyclic α,β-unsaturated analogues. The first example of this type of compound was prepared by Berke et al.[43] who studied the reaction of 1,1-dimethylpropynolate with hexacarbonyltungsten. Deoxygenation and subsequent hydrochlorination of the acyltungstate have been suggested in order to generate a hydroxyallenylidene intermediate **24**, which undergoes cyclization to give the 2-oxacyclopentenylidene complex **25** (Scheme 8). Subsequently, complementary routes to endocyclic α,β-unsaturated oxacycloalkylidene complexes have been reported,[37b,44] including classic elimination reactions[12d] or addition of alkyl radicals, generated from epoxides and $(Cp_2TiCl)_2$, to alkynylalkoxycarbene complexes.[31a]



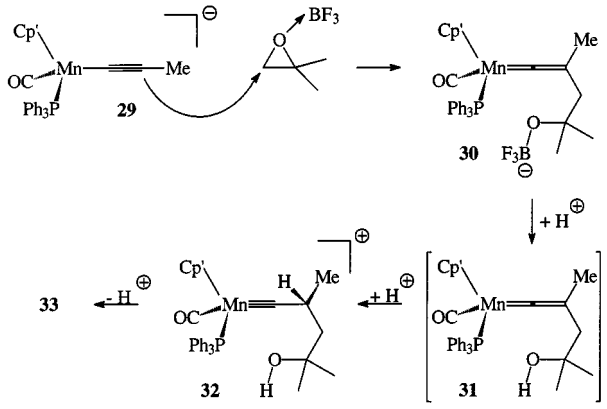
Scheme 8. Synthesis of 2-oxacyclopentenylidene complex **25**

The alkynol cycloisomerization at group 6 metal templates has been successfully applied to the synthesis of natural products and bioactive compounds[30c,30e,45] such as stavudin (d4T)[46] or (±)-andirolactone.[47]



(Oxacycloalkylidene)manganese and -rhenium Complexes

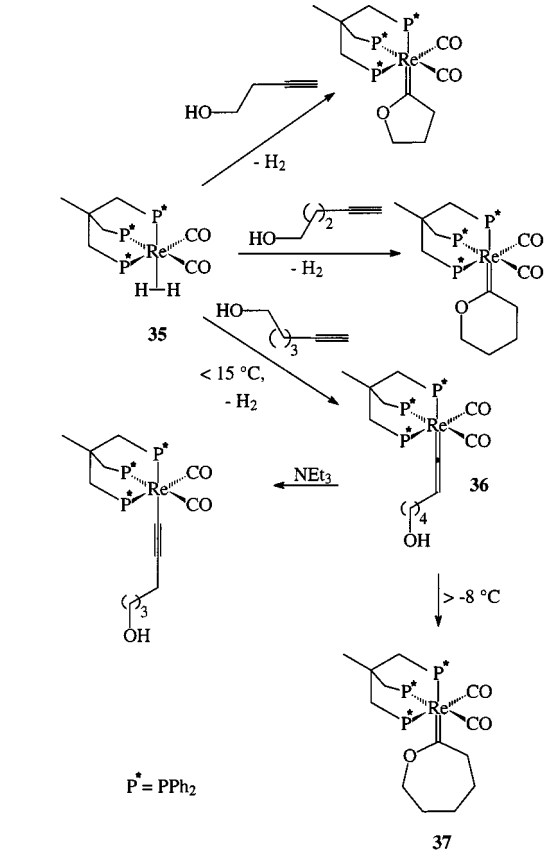
Based on the isoelectronic relation of pentacarbonyl compounds of group 6 and cationic pentacarbonyl compounds of group 7 metal templates, Beck and co-workers[48] extended the alkynol cycloisomerization to cations $[(OC)_5M]^+$ (M = Mn, Re) stabilized by the weakly coordinating tetrafluoroborate ligand. $(OC)_5MFBF_3$ complexes (M = Mn, Re) react with excess 3-butyn-1-ol in dichloromethane to give excellent yields of the cationic 2-oxacyclopentylidene complexes **27** and **28** (Scheme 9).



Chiral oxacycloalkylidene complexes can be obtained by ring expansion of oxiranes and oxetanes by the highly nucleophilic anionic alkynyl complex $[(\eta^5\text{-}C_5H_4Me)(OC)(Ph_3P)MnC{\equiv}CMe]^-$ (**29**).[49] Activation of the strained 2,2-dimethyloxirane and 3,3-dimethyloxetane by boron trifluoride–diethyl ether allows for the addition of the organometallic alkynyl nucleophile to afford, after protonation with methanol, the chiral (oxacycloalkylidene)-manganese complexes **33** and **34** in good to very good yields (Scheme 10). The NMR data of the oxycylopentylidene complex **33** indicated the formation of a single pair (*RR*/*SS* or *RS*/*SR*) of diastereomers, implying that the configuration at the metal center efficiently controls the configuration at the chiral ring-carbon atom of the cyclic carbene ligand. Single-crystal X-ray analysis established an (*RS*/*SR*) configuration, placing the methyl substituent and the bulky triphenylphosphane ligand on opposite sides of the (oxacyclopentylidene)metal fragment, as anticipated on the basis of steric arguments. The mechanism proposed for the formation of **33** is shown in Scheme 11.

Scheme 9. Cationic 2-oxacyclopentylidene complexes of manganese and rhenium

Scheme 10. Synthesis of the chiral (oxacycloalkylidene)manganese complexes



Scheme 11. Proposed mechanism for the formation of **33**

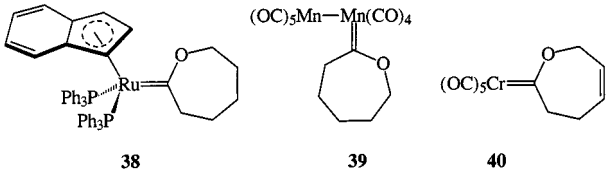
The first step likely involves a Lewis acid assisted ring opening of the epoxide by the nucleophilic attack of **29** to form the anionic vinylidene complex **30**, which represents

another variety of hydroxyalkylvinylidene intermediates, as previously proposed for the cycloisomerization of alkynols at coordinatively unsaturated metal templates. The complex **30** eluded isolation, but its formation was supported by monitoring the reaction by IR; after 10 min, IR absorption bands appeared in the regions characteristic of similar vinylidene complexes prepared by Geoffroy and co-workers[49] [$\tilde{\nu}_{CO}$ = 1886 cm^{-1}, $\tilde{\nu}_{C=C}$ = 1636 cm^{-1}]. Based on the observation of a carbonyl IR absorption band at 1998 cm^{-1}, indicative of a carbynemanganese cation[49][50] and detected in solution after the addition of methanol, the authors favour a stepwise double protonation of **30**, at the oxygen and the β-carbon atoms to form the cationic carbyne complex **32**, over a direct cyclization of the hydroxyalkylvinylidene intermediate **31**. Finally, the hydroxy group is supposed to add to the carbyne carbon atom with concomitant deprotonation to give **33**. It should be noted that the formation of oxacyclopentylidene complex **33** also occurs slowly and with lower yield in the absence of the Lewis acid, whereas for the ring expansion of 3,3-dimethyloxetane the presence of $F_3B \cdot OEt_2$ is crucial.

The mechanism of the oxacycloalkylidene formation was addressed in a very recent comparative study on the reaction of a comparable rhenium template $[\{MeC(CH_2PPh_2)_3\}Re(CO)_2]^+$[51] with a series of ω-alkynols bearing different numbers of CH_2 spacers between the alkynyl and hydroxy functionalities. Previous experiments revealed that the intramolecular addition of the hydroxy group to the α-carbon atom of the hydroxyalkylvinylidene complex is disfavoured with increasing length of the alkyl chain separating the alkynyl and hydroxy moieties.[29,32,49] Consequently, the activation of 5-hexyn-1-ol at a coordinatively unsaturated metal template results in the formation of stable hydroxybutylvinylidene complexes[52] rather than that of the corresponding 2-oxacycloheptylidene isomer. For instance, Bianchini and co-workers succeeded in the interception and charactization of the kinetic (hydroxybutylvinylidene)rhenium intermediate **36**, which they could further convert into the thermodynamically more stable 2-oxacycloheptylidene complex **37** (Scheme 12).[51]

NMR monitoring of the reaction of the dihydrogen complex **35** with a series of ω-alkynols in the temperature range from −50°C to 20°C established the vinylidenerhenium complex **36** as an intermediate in the cycloisomerization of 5-hexyn-1-ol to the thermodynamically stable 2-oxacycloheptylidene complex **37**. In contrast, no homologous intermediate could be detected in the reactions with ω-butynol and ω-pentynol. The hydroxybutylvinylidene complex **36** is stable in solution below −10°C, which allows its unambiguous characterization in solution and its isolation in the solid state. However, it is slowly converted into the 2-oxacycloheptylidene isomer **37** at increasing temperature, and the conversion is fast at room temp. Fischer-type carbene complexes bearing a 2-oxacycloheptylidene ligand are extremely rare compounds. To the best of the authors knowledge, only one other example of the activation of ω-hexynol at a transition metal template, leading to the 2-oxacycloheptylidene complex **38** (Figure 2), has been mentioned in the literature as a footnote without further details.[53] Two other examples of 2-oxacycloheptylidene complexes have been described. The dinuclear dimanganese complex **39** was prepared by reaction of the pentacarbonylmetalate $K[Mn(CO)_5]$ with α,ω-bistriflatopentane,[54] whilst the γ,δ-unsaturated (2-oxacycloheptylidene)chromium complex **40** was synthesized by ring-closure metathesis of the [allyloxy(butenyl)carbene]metal precursor (Figure 2).[55]

Scheme 12. Reaction of $[(triphos)Re(CO)_2]^+$ template with ω-alkynols



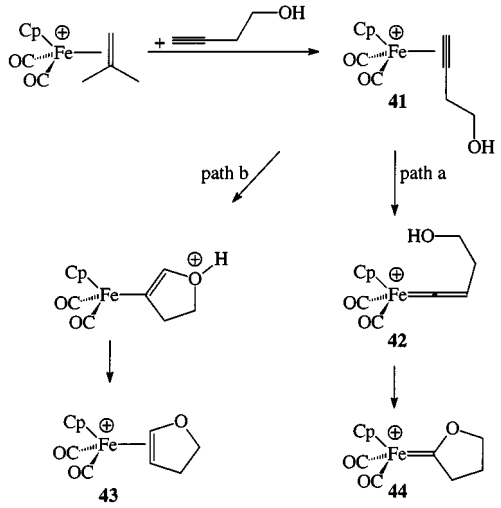


Figure 2. Oxacyclohept(en)ylidene complexes

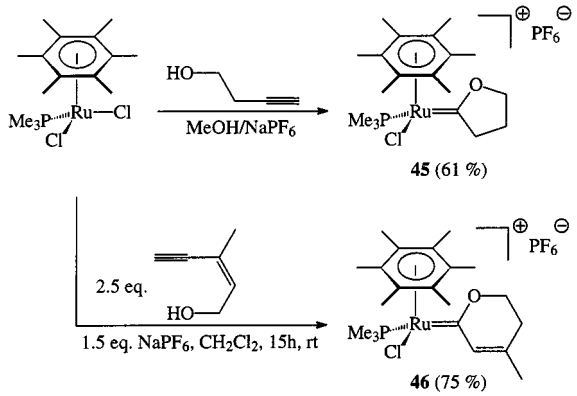
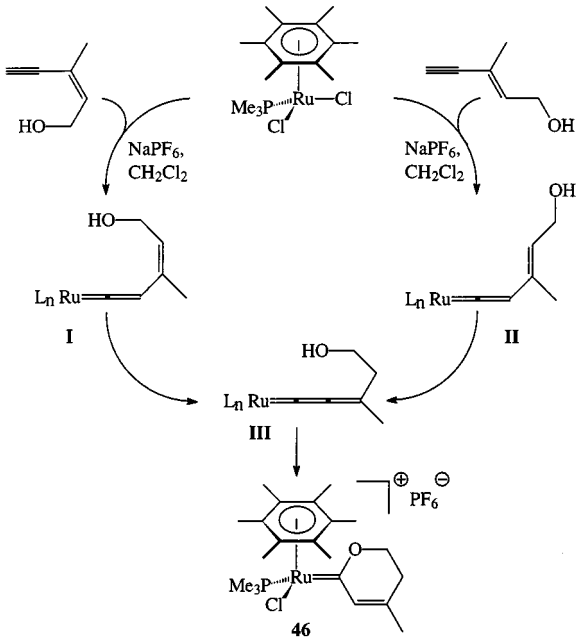
(Oxacycloalkylidene)iron, -ruthenium, and -osmium Complexes

The reaction of 3-butyn-1-ol with the dicarbonyl(η^5-cyclopentadienyl)iron cation led to a 1:1 mixture of two compounds which, after careful separation by fractional crystallization, were identified as η^2-2,3-dihydrofuran complex **43** and 2-oxacyclopentylidene complex **44** (Scheme

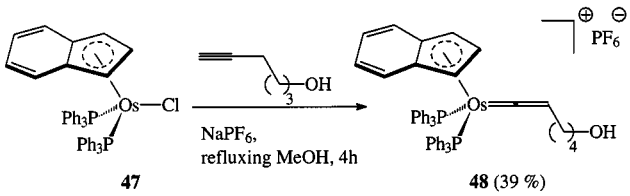


13).[56] Interestingly, the anticipated η^2-alkyne complex intermediate **41** does not only rearrange to the vinylidene complex **42** (path a) as expected, but is also able to undergo direct nucleophilic attack of the hydroxy function at C-4 of the coordinated 3-butyn-1-ol (path b) leading to an η^1-2,3-dihydrofuran-4-yl complex intermediate, which finally undergoes a σ,π rearrangement to give **43**. A chiral metal analogue of **44**, the carbonyl(η^5-cyclopentadienyl)(2-oxacyclopentylidene)(triphenylphosphane)iron(II) cation, was applied to the stereoselective synthesis of 2,2-dialkylbutyrolactones.[57]



Scheme 13. Competitive pathways for the reaction of 3-butyn-1-ol with $[Cp(OC)_2Fe]^+$

Chiral (oxacycloalkylidene)ruthenium complexes such as **45** are accessible from hexamethylbenzene(trimethylphosphane)ruthenium(II) dichloride and 3-butyn-1-ol (Scheme 14).[58] An extension of the cycloisomerization strategy from simple ω-alkynols to enynols resulted in the synthesis of α,β-unsaturated 2-oxacyclohexylidene complexes,[59] e.g. **46** (Scheme 14).[60] Remarkably, both the (*Z*)- and (*E*)-enynol isomer are activated by the ruthenium template to afford the same α,β-unsaturated 2-oxacyclohexenylidene complex **46**. Obviously, the cycloisomerization does not result from an intramolecular nucleophilic attack of the hydroxy group at the α-carbon atom of vinylidene complex **II** (Scheme 15). Previous results[61] rather suggest the subsequent formation of an allenylidene intermediate **III**[62] involving a 1,3-H migration from the β-carbon atom of **II** to C-4. Thus, the stereochemical information present in the enynol precursor is lost, and the activation of both (*Z*) and (*E*) isomers is expected to lead to the same allenylidene intermediate **III** which, upon intramolecular addition of the hydroxy group to the α-carbon atom, finally produces the α,β-unsaturated cyclic carbene complex **46**. Other (2-oxacyclopentylidene)ruthenium(II) complexes have also been described in the literature.[63]



The electron-rich osmium template, provided by (η^5-indenyl)bis(triphenylphosphane)osmium(II) chloride (**47**), also effects the activation of ω-alkynols to metal-coordinated vinylidene compounds.[52b] Whereas ω-butynol and ω-pentynol undergo in situ cycloisomerization to give cycloalkylidene complexes,[64] the activation of ω-hexynol stops at the hydroxybutylvinylidene complex stage **48** (Scheme 16). The stability of **48** reflects the typical increased stability of osmium derivatives compared with their ruthenium analogues,[52b] as demonstrated for the cycloisomerization of ω-hexynol with the ruthenium analogue of **47**.

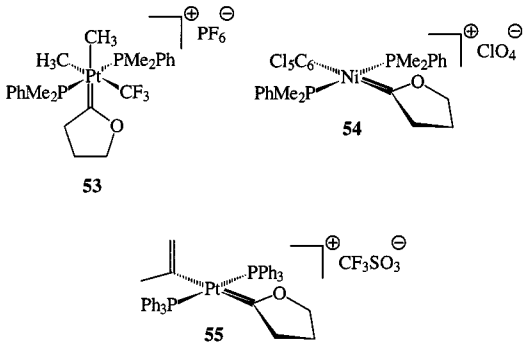
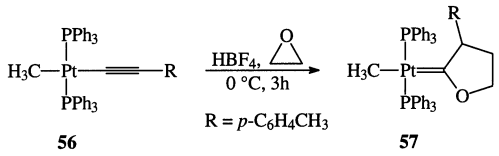
Oxacycloalkylidene Complexes of Group 9 and 10 Metals



Octahedral (oxacycloalkylidene)iridium(III) complexes were among the first examples of alkynol cycloisomerization products.[65] More recently, the excellent leaving-group properties of triflate ligands have been exploited in the synthesis of square planar (2-oxacyclopentylidene)rhodium and -iridium(II) complexes.[66] The cycloisomerization of alkynols is compatible with the presence of additional metal−carbon σ-bonds. Activation of 3-butyn-1-ol at room temperature by the iridacycle **49** afforded the oxacyclopentylidene complex **50** which represents the first isolable example of a metallacyclic carbene complex (Scheme 17).[67] The metallacyclic template **51**, bearing two labile leaving group type ligands, undergoes a high-yield double cycloisomerization to give the bis(oxacyclopentylidene) complex **52**, which is remarkably stable towards carbene dimerization.[68] The crucial role of the metal template is evident from the comparison of the iridacyclopentadiene **49** with a similar rhodium analogue. The rhodacyclopentadiene did not induce the cycloisomerization of 3-butyn-1-ol; instead, alkyne insertion into the metallacyclic rhodium−carbon bond occurred, followed by reductive elimination to give an aromatic six-membered ring.[67b,69]

Scheme 17. Metallacycle−carbene and −bis(carbene) complexes



The cationic platinum(IV) complex **53**[15c] was the first example of a carbene ligand coordinated to a metal center in an oxidation state higher than two. Other (oxacycloalkylidene)nickel[70] and -platinum[65][71] complexes, such as **54** and **55**, bearing a metal(II) center have been synthesized by cycloisomerization of 3-butyn-1-ol (Scheme 18).

A complementary route to (2-oxacyclopentylidene)platinum complexes is based on the ring opening of oxiranes by alkynylplatinum(II) complexes assisted by HBF_4 (Scheme 19).[72] Two possible mechanisms, both of which so far lack experimental support, have been suggested for this reaction: The first involves protonation of the alkynyl complex **56**, generating a reactive vinylidene intermediate which may undergo nucleophilic addition of the oxirane oxygen atom at the α-carbon atom. Oxirane opening and subsequent re-

Scheme 18. (Oxacycloalkylidene)nickel and -platinum complexes

cyclization afford the oxacycloalkylidene complex **57**. The second proposal relies on initial protonation of the oxirane followed by β-carbon atom attack of the alkynyl complex **56**, to give a reactive hydroxyethylvinyl intermediate. Final intramolecular cyclization results in the formation of the (oxacycloalklidene)metal complex.

Scheme 19. (Oxacyclopentylidene)platinum complex **57** by ring opening of oxirane

Conclusions

The cycloisomerization of 1,ω-alkynols at transition metal templates provides a general and straightforward approach to oxacycloalkylidene complexes. Recently, this methodology has been successfully extended to alkynylamines and alkynyl-substituted carbon nucleophiles leading to azacycloalkylidene complexes and 2,3-dihydropyrroles, respectively, as well as cyclopentenes. In some cases, hydroxyalkylvinylidene complex intermediates could be intercepted and characterized, supporting the mechanism suggested earlier. In particular, oxacycloalkylidene complexes of group 6 metals have been developed to provide valuable reagents in organic synthesis. The multifunctionality of Fischer-type oxacycloalkylidene complexes may be exploited in subsequent addition reactions of nucleophiles,[23] as well as in metal-[44f,73] or ligand-centered[25,28,44g] cycloaddition reactions aiming at targets both in organometallic and organic chemistry.

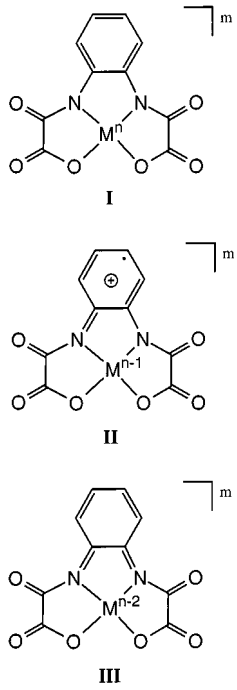
A Square-Planar Dinickel(II) Complex with a Noninnocent Dinucleating Oxamate Ligand: Evidence for a Ligand Radical Species

Ally Aukauloo,*[a] Xavier Ottenwaelder,[a] Rafael Ruiz,[a][+] Sandrine Poussereau,[a] Yu Pei,[a] Yves Journaux,*[a] Paul Fleurat,[b] Francois Volatron,[b] Beatriz Cervera,[c] M. Carmen Muñoz[d]

Keywords: Amides / Nickel / Polynuclear complexes / Radicals / Redox chemistry

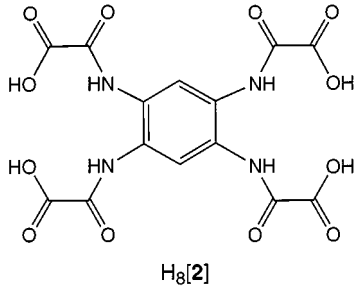
The new bimetallic nickel(II) compound $(PPh_4)_4[Ni_2(\mathbf{2})]\cdot 6H_2O$ (**3**), where H_8[**2**] stands for *N*,*N*′,*N*″,*N*‴-1,2,4,5-benzenetetrayltetrakis(oxamic acid), has been synthesized and its crystal structure determined by single-crystal X-ray diffraction. The structure of **3** consists of $[Ni_2(\eta^4{:}\eta^4\text{-}\mathbf{2})]^{4-}$ anions, tetraphenylphosphonium cations, and water molecules. Facile one-electron oxidation of the square-planar diamagnetic dinickel(II) complex $[Ni_2(\eta^4{:}\eta^4\text{-}\mathbf{2})]^{4-}$ generates the metallo-radical species $[Ni_2(\eta^4{:}\eta^4\text{-}\mathbf{2}^{\cdot+})]^{3-}$ with characteristic *intra*-ligand π-cation radical transitions in the visible region (475–550 nm) as well as a typical quasi-isotropic EPR signal at $g \approx 2.0$.

Interest in the chemistry of metal coordination compounds with organic ligands of a radical nature (radical ligands) is rapidly increasing in several areas ranging from bioinorganic chemistry to solid-state physics.[1][2] Radical ligand complexes are currently being studied as biomimetic catalysts, because experimental evidence is accumulating about the involvement of organic radical species in the active sites of diverse metalloproteins.[3][4] Likewise, mixed materials incorporating organic radicals coordinated to metal ions have been extensively investigated with the aim of generating molecular-based magnets.[5][6] The development of these new classes of compounds relies on the firm understanding of factors that influence the ligand′s innocence or noninnocence in describing of the electronic structure of metal complexes. This plays a pivotal role in the coordination chemistry field in connection with the formal oxidation state assignment of the metal centre and, particularly, in high-valent transition metal complexes where the coordinated ligand contains an extended delocalized system.[7]



Recently, we have shown that substituted oxamato ligands like H_4[**1**],[8] the parent acid of the tetraanionic polychelating ligand *N*,*N*′-1,2-phenylenebis(oxamate), can stabilize unusual high oxidation states of first-row transition metal ions, ranging from manganese to copper.[8–11] We have found that the resulting square-planar four-coordinated copper(II) and nickel(II) complexes, $[M(\mathbf{1})]^{2-}$, oxidise at relatively low potentials, i.e. 0.41 and 0.60 V vs. SCE, respectively[10][11] (CH_3CN, 25 °C, 0.1 mol·dm^{-3} NBu_4PF_6). For the nickel complex, however, a second electron can be removed but at a higher potential (1.10 V vs. SCE). Since this particular ligand H_4[**1**] contains a benzenediamido-N unit with potential π-noninnocent character, these oxidation processes may involve the metal ion as well as the ligand. Thus, the electronic distribution in a given oxidised complex can be described by any one of the three redox isomers depicted in Scheme 1, for which the formal oxidation states of the metal centre are different (resonance forms **I** to **III**). Our observations clearly indicate that, at least the one-electron-oxidised species, $[M(\mathbf{1})]^{-}$ (M = Cu, Ni), are genuine copper(III) and nickel(III) complexes of form **I**.[10][11] Metal-radical ligand species (form **II**) can be ruled out as might be expected on the basis of the strong σ field of the tetradentate planar ligand (high σ-donor capacity of the amido-N group[12–15]).

Hence, in the scope of our continuous research in this field we have extended our studies to the related ligand H_8[**2**], the parent acid of the ligand *N*,*N*′,*N*″,*N*‴-1,2,4,5-benzenetetrayltetrakis(oxamate) (Scheme 2). Potentially, this dinucleating ligand possesses a noninnocent character, as its mononucleating counterpart, because the benzenetetraamido-N fragment is also a putative oxidation site.[16] We report herein the synthesis, general physical and structural characterisation together with the electrochemical properties of the tetraphenylphosphonium salt of the dinickel(II) complex of formula $(PPh_4)_4[Ni_2(\mathbf{2})]\cdot 6\,H_2O$ (**3**), as well as a preliminary ab initio theoretical study of its electronic structure.



The ^{1}H-NMR spectrum of **3** shows a sharp singlet corresponding to the two magnetically equivalent phenylene protons of the ligand at δ = 8.35, along with the signals from the aromatic protons of the PPh_4^+ cations located in the region δ = 7.7–8.0. The sharpness of these NMR peaks, as well as the small shift of 0.50 ppm for the benzene proton

Scheme 1. Resonance structures of the metal complexes with the noninnocent *N*,*N*′-1,2-phenylenebis(oxamato) ligand

Scheme 2. *N*,*N*′,*N*′′,*N*′′′-1,2,4,5-Benzenetetrayltetrakis(oxamic acid)

signal relative to that of the free ligand Et_4H_4[**2**] (δ = 7.85) are indicative of a diamagnetic nickel(II) complex. That is to say, the Ni^{II} ion is in a square-planar coordination geometry (low-spin d^8-electronic configuration for Ni^{II}). This spectroscopic observation was further confirmed by a single-crystal X-ray structure analysis.

The structure of **3** includes centrosymmetric dinuclear nickel(II) complex anions, $[Ni_2(\mathbf{2})]^{4-}$ (Figure 1), tetraphenylphosphonium cations and water molecules of crystallisation. As expected, the coordination environment of each nickel atom is essentially square-planar, formed by two deprotonated amide-N and two carboxylate-O atoms of the bis-tetradentate chelating ligand [largest deviations from the plane of the four donor atoms are 0.002(1) Å with the metal ion 0.018(1) Å out of the mean basal plane]. The average Ni−N and Ni−O bond lengths (1.82 and 1.89 Å, respectively) are identical to those found for the monomeric nickel(II) complex $(PPh_4)_2$[Ni(**1**)],[11] but significantly shorter than those of the copper(II) complex, $(PPh_4)_2$[Cu(**1**)] (1.91 and 1.95 Å, respectively).[10b] The entire ligand skeleton is nearly planar [maximum deviation from the mean molecular plane of 0.264(2) Å for O(5)] (Figure 1, top). All the bond lengths are identical, within the 3σ criterion, to those of the related mononucleating ligand in the isostructural complexes $(PPh_4)_2$[Cu(**1**)][10b] and $(PPh_4)_2$[Ni(**1**)].[11] The observed C−C *intra*-ring benzene distances in **3** are almost equivalent and are intermediate between those of single and double bonds (average 1.40 Å), whereas the C−N bond lengths between the benzene ring and the amide nitrogen atoms are characteristic of single bonds (average 1.42 Å), thereby reflecting complete π delocalisation mainly within the benzene ring.

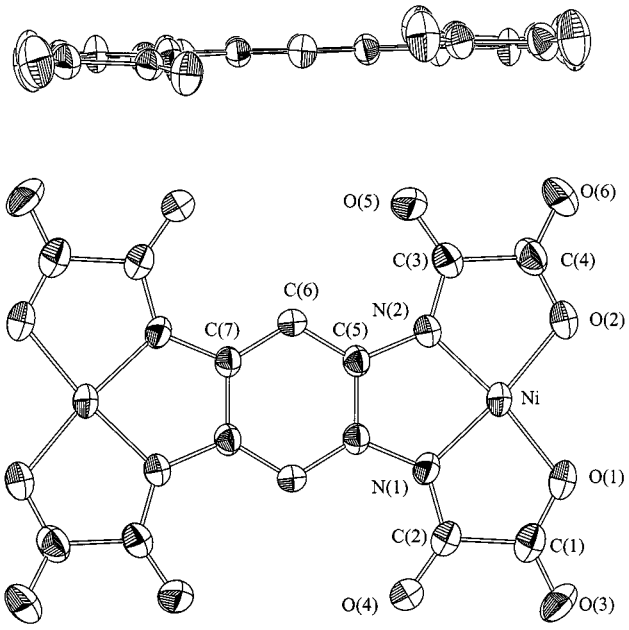

Figure 1. Perspective views of the anionic dinuclear unit of **3** with the atom-numbering scheme; thermal ellipsoids are drawn at the 30% probability level (hydrogen atoms have been omitted for clarity); selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Ni−N(1) 1.822(2), Ni−N(2) 1.823(2), Ni−O(1) 1.879(2), Ni−O(2) 1.889(2); N(1)−Ni−N(2) 86.36(10), N(1)−Ni−O(1) 86.76(10), N(1)−Ni−O(2) 172.74(10), N(2)−Ni−O(1) 173.06(10), N(2)−Ni−O(2) 86.47(10), O(1)−Ni−O(2) 100.39(10)

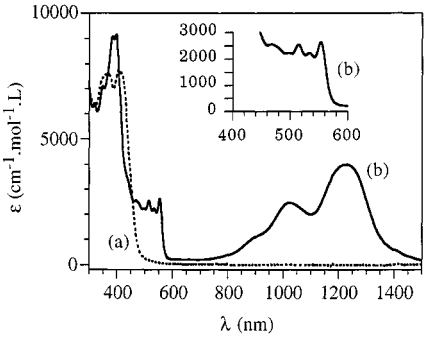
The cyclic voltammogram of **3** in dry acetonitrile shows two well-separated one-electron reversible oxidation waves at the remarkably low potentials of 0.05 and 0.40 V vs. SCE (25 °C, 0.1 mol·dm^{-3} NBu_4PF_6). The one-electron nature of both waves was confirmed by coulometric measurements. A comparison of the potentials of the $[Ni_2(\mathbf{2})]^{3-/4-}$ and $[Ni_2(\mathbf{2})]^{2-/3-}$ redox couples with that of $[Ni(\mathbf{1})]^{-/2-}$ (0.60 V vs. SCE), where both ligands have the same set of donor atoms, reveals that both oxidised dinuclear complexes $[Ni_2(\mathbf{2})]^{3-}$ and $[Ni_2(\mathbf{2})]^{2-}$ are much more easily accessible than the corresponding mononuclear complex $[Ni(\mathbf{1})]^{-}$. A survey on the kinetic stability of the oxidised species obtained after bulk electrolysis of **3** in dry acetonitrile (−40 °C, 0.2 mol·dm^{-3} NBu_4PF_6, 0.24 and 0.60 V vs. SCE, respectively), indicates that the complex $[Ni_2(\mathbf{2})]^{3-}$ is stable over several days under nitrogen at room temperature. However, the doubly oxidised species, $[Ni_2(\mathbf{2})]^{2-}$, rapidly de-

composes under these same conditions, being stable only on the time-scale of the cyclic voltammetry measurement. Preliminary electrochemical studies by combined UV/Vis and EPR techniques have been carried out in order to determine the nature of the chemically stable one-electron-oxidised species of **3**.

The electronic absorption spectrum of the orange complex **3** in acetonitrile [Figure 2, curve (a)] consists of two intense asymmetric bands in the UV region centred at 425 and 370 nm, corresponding to the π-π* *intra*-ligand charge transfer. A third, less intense band appears in the visible region at 560 nm, which corresponds to a d−d transition of a low-spin d^8-Ni^{II} ion.[17] The most remarkable feature of the spectrum of the electrochemically generated red complex $[Ni_2(\mathbf{2})]^{3-}$ is the appearance of new absorption bands on the high- and low-energy side of the visible region [Figure 2, curve (b)]. The first group of transitions are formed by two rather sharp and intense bands located at 555 and 515 nm, along with additional bands at 540 (sh), 500 (sh), and 475 nm. All these bands, which are not present in the spectrum of the nickel(III) complex $[Ni(\mathbf{1})]^-$, are similar in both shape and intensities to those observed for the "Wurster′s Blue" salts containing the 1,4-bis(dimethylamino)-benzene radical cation.[16] The absorption intensities and energies of these bands are dependent on the substitution pattern on the benzene ring. This observation can therefore be assigned to a ligand-centred one-electron oxidation process of **3** rather than the nickel centre. Accordingly, the second group of bands in the Vis/NIR region comprising one broad, intense band at 1230 nm with two distinct shoulders at 1030 and 900 nm probably originates from metal-to-ligand charge-transfer (MLCT) transitions. The presence of this rather low-energy MLCT transition on the spectrum of $[Ni_2(\mathbf{2})]^{3-}$ at 1230 nm (8130 cm^{-1}) indicates that there is a relatively small energy separation between the ground and excited states (corresponding to the two opposed situations where the locus of oxidation is the ligand and the metal ion, respectively). Consequently, a small portion of mixing can occur between both electronic states.



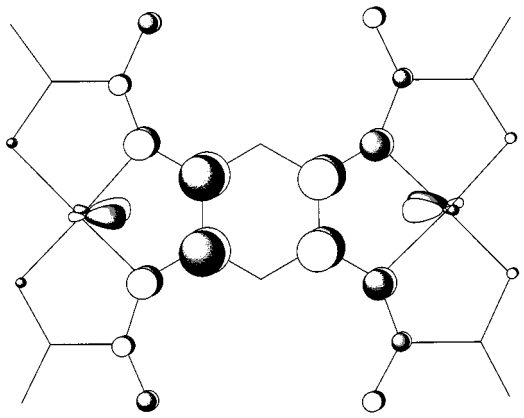


Figure 2. Electronic absorption spectra in acetonitrile solution of the dinickel(II) complex $[Ni_2(\mathbf{2})]^{4-}$ (a) and the electrochemically generated complex $[Ni_2(\mathbf{2})]^{3-}$(b)

Theoretical calculations have been performed on both dinuclear ($[Ni_2(\mathbf{2})]^{4-}$) and mononuclear ($[Ni(\mathbf{1})]^{2-}$) species at the DFT-B3LYP level with the Gaussian 94 package.[18−20] Preliminary calculations have been carried out on unsubstituted, 1,2-diamido- and 1,2,4,5-tetraamidobenzene molecules. The HOMO is of π-type in both cases and rises in energy from −6.7 (benzene) to −6.0 (diamide) and to −5.6 eV (tetraamide). These calculations indicate, as expected, that the π-donating ability of the ligand is enhanced with the number of amide substituents.

The electronic structure of $Na_4[Ni_2(\mathbf{2})]$[19] shows that the HOMO is essentially located on the organic moiety of the complex. Coefficients of the d orbital are small (about 0.03) whereas those of the p orbitals on the ligand atoms are considerably larger (0.10−0.16). The HOMO is strongly polarised on the benzene ring and results from the antibonding combination of the tetraamidobenzene HOMO with the d_{xz} of the nickel atoms as illustrated in Scheme 3. Due to the high energy of the ligand orbital, the contribution from the metallic moiety in this combination is very weak. Similar calculations on the mononickel complex $Na_2[Ni(\mathbf{1})]$ give rather different results and show that the three highest molecular orbitals are mainly of d character.

Scheme 3. Shape of the HOMO of $[Ni_2(\mathbf{2})]^{4-}$ moiety

The EPR spectrum at 4.4 K of the electrochemically generated complex $[Ni_2(\mathbf{2})]^{3-}$ exhibits an almost unique and narrow resonance band *g* close to 2.0 having a linewidth of only 50 G [Figure 3, curve (a)], typical of an isotropic radical species. This observation further supports the hypothesis of ligand rather than metal oxidation. Once again, this is in clear contrast with the observed EPR spectrum of the nickel(III) complex $[Ni(\mathbf{1})]^-$, where a nearly axial signal with apparent *g* at 2.230 and 2.006 is observed [Figure 3, curve (b)]. In that case, the large anisotropy and the average *g* value of 2.155 for $[Ni(\mathbf{1})]^-$ unambiguously indicate that the oxidation is located on the metal centre. Moreover, the fact that $g_\perp > g_{||} \approx 2.0$ clearly establishes a d_{z^2}-electronic ground-state configuration for the Ni^{III} ion.[14b,15b] However, the situation for $[Ni_2(\mathbf{2})]^{3-}$ is somewhat more complicated; actually, the EPR signal is slightly anisotropic with $g_1 = 2.037$, $g_2 = 2.012$ and $g_3 = 1.998$. The result can primarily be interpreted as an $Ni^{II}{}_2$ complex containing a ligand-based π-cation radical; this feeble anisotropy observed on the EPR signal being due to the partial delocalisation of the unpaired electron onto the d_π-type orbitals of the nickel centres.

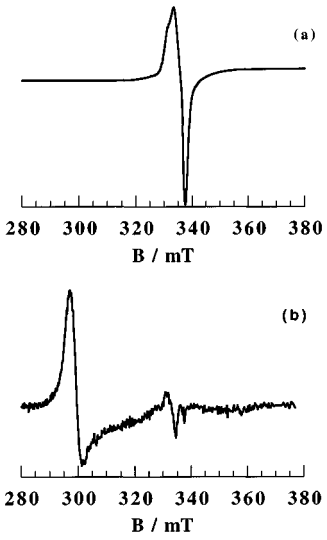

Figure 3. X-band EPR spectrum in frozen acetonitrile solution of the electrochemically generated complex $[Ni_2(\mathbf{2})]^{3-}$ (a) compared to that of complex $[Ni(\mathbf{1})]^{-}$ (b) at 4.4 K

In summary, compound **3** represents an interesting example of radical-ligand bimetallic complex precursor when oxidised to the π-cation radical species. In one, we have shown that the dinucleating ligand provides a ready locus of oxidation due to its larger π-electron donor properties than those of the mononucleating ligand analogue. Secondly, it also shifts the oxidation potentials of the metal ions to values beyond those of the aromatic π system because of its smaller σ-electron donor properties,[17] thus precluding metal oxidation. Substitution of diamagnetic nickel(II) ions by paramagnetic ones, such as copper(II), is a promising strategy to electrochemically control the magnetic exchange coupling in dimetallic complexes.[21] On the other hand, it may always be expected that these dinickel and dicopper complexes readily bind additional paramagnetic ions to the terminal carbonyl oxygen atoms giving oxamato-bridged polymetallic compounds, as is the case for the mononuclear analogues.

Experimental Section

Synthesis of H_8[2]: The proligand H_8[**2**] resulted from the condensation of 1,2,4,5-tetraaminobenzene and ethyl oxalyl chloride in *N*,*N*-dimethylformamide under inert atmosphere, and it was isolated as its tetraethyl ester derivative Et_4H_4[**2**]: To a solution of 1,2,4,5-tetraaminobenzene tetrahydrochloride (2.84 g, 10 mmol) in DMF (250 mL) was added ethyldiisopropylamine (14 mL, 80 mmol). This solution was then added dropwise, by using a dropping funnel, to ethyl oxalyl chloride (4.7 mL, 40 mmol). The resulting mixture was stirred for 1.5 h at 50°C and the solvent removed in a rotatory evaporator. The remaining oil was dissolved in a minimum amount of methanol and treated with diethyl ether to give a white solid, which was collected by filtration and dried under vacuum (3.76 g, 70%). − ^{1}H NMR ([D$_6$]DMSO): δ = 1.29 (t, 12 H, CH_3), 4.24 (q, 8 H, CH_2O), 7.82 (s, 2 H, *p*-H of $C_6H_2N_4$), 10.45 (s, 4 H, NH). − IR (KBr): $\tilde{\nu}$ = 3280 cm^{-1} (NH), 1770, 1743, and 1702 cm^{-1} (C=O). − $C_{22}H_{26}N_4O_{12}$ (538): calcd. C 49.07, H 4.87, N 10.40; found C 49.24, H 5.26, N 10.21.

Synthesis of 3: The sodium salt of the dinickel(II) complex was obtained by reaction of the tetraethyl ester Et_4H_4[**2**] with Ni^{2+} in basic aqueous media: To a suspension of Et_4H_4[**2**] (1.1 g, 2.0 mmol) in water (50 mL) was added an aqueous solution (10 mL) of NaOH (0.68 g, 17 mmol). After stirring for 15 min at room temperature until complete dissolution, an aqueous solution (25 mL) of $Ni(NO_3)_2 \cdot 6\,H_2O$ (1.16 g, 4.0 mmol) was added dropwise. The orange solid that formed was collected by filtration, washed with ethanol and air-dried (90%). Then, the tetraphenylphosphonium salt of complex **3** was obtained by metathesis of the sodium salt through the intermediacy of the silver salt: To a suspension of $Na_4[Ni_2(\mathbf{2})]$ (0.95 g, 1.5 mmol) in water (100 mL) was added an excess of $AgNO_3$ (1.36 g, 8 mmol). After 30 min of stirring, the orange solid was collected by filtration, washed with water and ethanol, and air-dried (1.3 g, 90%). To a suspension of $Ag_4[Ni_2(\mathbf{2})]$ (0.97 g, 1 mmol) in water (25 mL) was added a solution of PPh_4Cl (1.5 g, 4 mmol), dissolved in a minimum amount of water (10 mL). A white precipitate of AgCl formed and was removed by filtration after 15 min of stirring. Well-shaped large crystals of **3** suitable for X-ray diffraction were obtained from slow concentration of the mother liquor. − ^{1}H NMR ([D$_6$]DMSO): δ = 8.35 (s, 2 H, *p*-H of $C_6H_2N_4$), 7.71−8.10 (m, 80 H, C_6H_5 of PPh_4^+). − IR (KBr): $\tilde{\nu}$ = 1661 and 1617 cm^{-1} (C=O). − $C_{110}H_{82}Ni_2P_4N_4O_{12} \cdot 6\,H_2O$ (2001): calcd. C 65.96, H 4.70, N 2.80; found C 65.90, H 4.64, N 2.88.

X-ray Crystallographic Study of 3:[23] Crystal data: $C_{55}H_{47}NiP_2N_2O_9$, *FW* = 1000.6, triclinic, space group *P*−1, *a* = 13.558(1) Å, *b* = 13.799(2) Å, *c* = 14.604(1) Å, α = 78.43(1)°, β = 73.01(1)°, γ = 67.33(1)°, *V* = 2399.1(5) Å^3, *d* = 1.385 g cm^{-3}, *Z* = 2. − Data collection: Enraf-Nonius CAD-4 diffractometer, Mo-K_α radiation, λ = 0.71073 Å, graphite monochromator, 293 K, ω-2θ, Lorentz and polarization effects and absorption correction, μ = 0.532 mm^{-1}, 2.0° ≤ θ ≤ 22.5°, crystal size 0.1 × 0.1 × 0.1 mm. 6280 unique reflections, and 6259 assumed as observed with $I > 2\sigma(I)$. − Structural analysis and refinement: standard Patterson methods with subsequent full-matrix least-squares method refinement on F^2, SHELX93.[24] The hydrogen atoms were located from a difference synthesis and refined with an overall isotropic thermal parameter. Refinement of 811 variables with anisotropic thermal parameters for all nonhydrogen atoms gave R = 0.035 and R_w = 0.079 with S = 1.029.

[17] The electronic absorption spectrum of the nickel(II) complex $(PPh_4)_2$[Ni(**1**)] in acetonitrile shows a similar pattern to that of **3**, consisting of an intense band in the UV region located at 350 nm and a less intense band in the visible region at 420 nm. The significant red shift observed in the visible d−d absorption maximum of the orange dinickel complex $[Ni_2(\mathbf{2})]^{4-}$ related to the yellow nickel complex $[Ni(\mathbf{1})]^{2-}$, in spite of the presence of the same chromophor NiN_2O_2, clearly indicates the weaker ligand field associated with the ligand $[\mathbf{2}]^{8-}$ than with $[\mathbf{1}]^{4-}$. Likewise, the *intra*-ligand UV bands in the spectrum of $[Ni_2(\mathbf{2})]^{4-}$ corresponding to intraligand π-π* transitions within the aromatic benzene ring are also red-shifted with respect to the analogous band in $[Ni(\mathbf{1})]^{2-}$. The higher aromaticity of the 1,2,4,5-tetrasubstituted benzene ring of $[\mathbf{2}]^{8-}$ than of the 1,2,-disubstituted benzene ring of $[\mathbf{1}]^{4-}$ is presumably responsible for this bathochromic effect. These differences in the spectroscopic properties between the dinuclear nickel(II) complex and the mononuclear analogue already announce their dramatically different electrochemical behaviour.

In the calculations, the metal ions and the ligand have been explicitly taken into account. The PPh_4^+ counterions have been replaced by Na^+ cations and are located at the phosphorus site of PPh_4^+ cations. Furthermore, the geometry used has been taken from the one determined by X-ray crystallography. We have used the 6-31G* basis set for the ligands atoms. The nickel basis set is that determined by Wachters supplemented with f-polarization function. The sodium cations have been taken as point charges (no vacant orbital on the atom), the core electrons being described by an effective core potential. This procedure, which explicitly takes into account a repulsion potential, avoids too strong orbital polarizations towards the point charges.

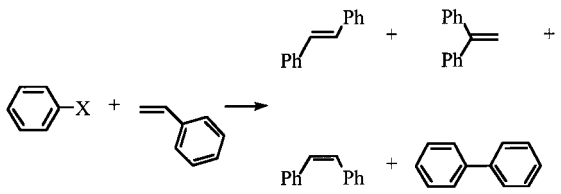
Fast Palladium Catalyzed Arylation of Alkenes Using Bulky Monodentate Phosphorus Ligands

Gino P. F. van Strijdonck,[a] Maarten D. K. Boele,[a] Paul C. J. Kamer,[a] Johannes G. de Vries,*[b] and Piet W. N. M. van Leeuwen*[a]



Keywords: C–C coupling / Homogeneous catalysis / Kinetics / Palladium / Phosphorus amidite

Complex **1b** shows an unprecedented high activity in the Heck reaction. Kinetic studies show that in this system not the oxidative addition but the alkene coordination/migratory insertion is the rate determining step.

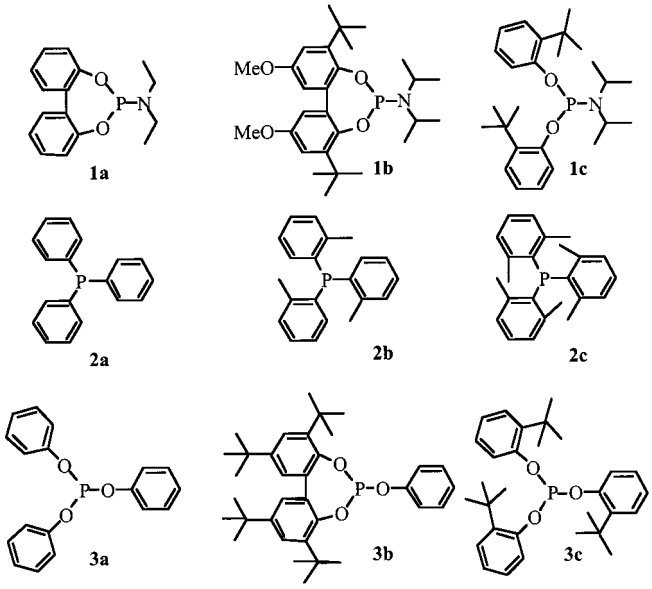
The palladium-catalyzed arylation of alkenes, also known as the Heck reaction, has proven to be a versatile method for the formation of carbon−carbon bonds.[1] The Heck reaction is compatible with a broad range of substituents, but it also suffers from severe drawbacks which often preclude industrial use.[2] Even though some progress has been reported towards catalyst performance,[3] there is still a need for better catalysts.

Ligand effects[4] have been studied extensively for many metal catalyzed reactions. In the Heck reaction mainly phosphanes have been used. In a limited amount of papers the use of 1,10-phenanthroline derivatives has been reported[5] and recently phosphites were used.[6] Pfaltz and co-workers have reported on the use of mixed phosphane oxazoline ligands in an enantioselective Heck reaction.[7] Phosphorus amidites form a unique class of ligands, which have proven their usefulness in catalysis.[8] Their electronic properties are in between those of phosphanes and phosphites. As part of our studies on ligand effects, we decided to study the effect of phosphorus amidites and phosphites in the Heck reaction.

As a model reaction to study the effect of electronic and steric properties of the ligands on the Heck reaction we have chosen the reaction of iodobenzene with styrene in acetonitrile and triethylamine as a base.

Scheme 1. Heck reaction of styrene with phenyl halides

The use of 1 mol-% of $Pd(dba)_2$ and 2 equivalents of phosphorus amidite **1b** (80°C) resulted in the very fast formation of mainly *trans*-stilbene, the Heck product (Scheme 1). In a series of ligands with approximately the same steric bulk the order of activity was found to be: phosphorus amidites (**1**) > phosphites (**3**) > phosphanes (**2**). Within a series of phosphorus amidite ligands with increasing steric bulk, ligand **1b** gave the fastest catalysis. In the phosphane and phosphite series a similar trend was observed, viz. **b** > **a** > **c** (see Table 1). When more equivalents of ligands are used, the activity drops, except for **1b**. Addition of more equivalents of this ligand does not affect the activity. Using the more bulky ligands **c**, relatively more of the *cis* product and less *trans*-stilbene was found with increasing L/Pd ratio.



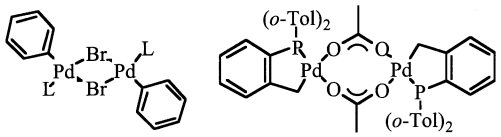


Figure 1. Monodentate ligands

The use of $Pd(dba)_2$ without an additional ligand resulted in a low conversion and the formation of palladium black. The same was observed using $Pd(OAc)_2$ without additional ligand.

Recently, Beller and co-workers reported on cyclometallated palladium complexes as efficient catalysts for Heck

[a] Conditions: see Experimental Section. – [b] Based on iodobenzene, measured after 45 minutes. – [c] Less than 1% biphenyl was formed.

Phosphorus amidite **1b** gave the most active catalyst. To obtain further details of the catalytic cycle, we performed a kinetic study. To avoid interference of equilibria between the pre-catalyst and the intermediates involved in the catalytic cycle[9], we prepared compound **4b** and compared its catalytic behavior with that of tris(*o*-tolyl)phosphane-coordinated complex **4a** in the reaction of iodobenzene with styrene. Osmometric molecular mass determination in dichloromethane showed that compound **4b** exists as a dimer. A broad signal at $\delta = 118.3$ in the ^{31}P-NMR spectrum is indicative of a fast equilibrium between the *cis* and the *trans* isomers[10]. After cooling the solution to 240 K we observed two sharp peaks at $\delta = 119.8$ and 117.5 in a 4:3 ratio. The major product is probably the *trans* product. In acetonitrile, only one sharp singlet was observed at $\delta = 122.3$ in a temperature range of 255–335 K.

The rate of the reaction between iodobenzene and styrene catalyzed by palladium complexes **4** was independent of the concentration of iodobenzene (0.10–2.0 M) and the concentration of triethylamine (0.16–2.5 M). Figure 3 shows a linear dependence of the initial turn over frequency (TOF_{ini}) on the styrene concentration (0–4.0 M). The reaction rate increases linearly with the square root of the palladium concentration (0–4.0 mM; see Figure 4). Using palladium concentrations below 4.0 mM and conversions up to 70% no formation of palladium black was observed.

The rate of the Heck reaction shows a large dependence on the solvent and the alkene used. In acetonitrile, the reaction of iodobenzene with styrene (1 M), catalyzed with 0.125 mol-% complex **4b** (0.25% Pd) gave 50% conversion after 2 h. In DMF, the conversion after 2 h. was 75%. In *N*-methyl pyrrolidinone (NMP) the reaction was even faster: within 45 minutes the reaction was completed. Reaction of iodobenzene with *n*-butylacrylate, in NMP at 80°C with 0.125 mol-% complex **4b**, was completed within 6 minutes. This reaction was more than 99% selective towards the *trans* coupled product. With this system we do not only have an extremely fast but also a stable catalyst and a very high turn-over number (> 500 000) has been obtained.

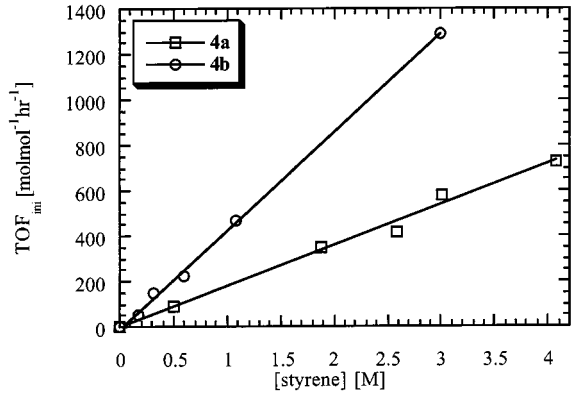

Figure 3. Plot of TOF_{ini} versus [styrene] for the reaction of iodobenzene with styrene in CH_3CN at 65°C catalyzed with complexes **4** (TOF_{ini} is the amount of products formed per mol Pd per hour after 5 min)

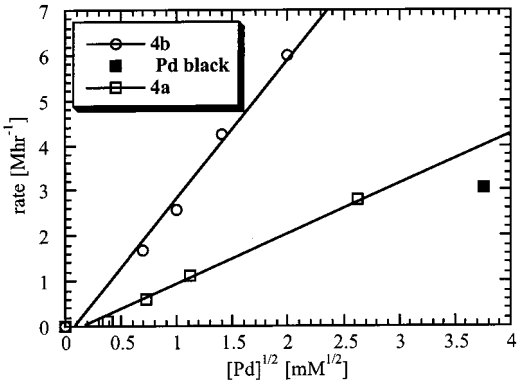

Figure 4. Plot of the rate versus $[Pd]^{1/2}$ for the reaction of iodobenzene with styrene in CH_3CN at 65°C catalyzed with complexes **4** (rate = *d*[products]/*d*t, measured after 5 min)

The unique kinetic observations are rationalized in terms of the catalytic cycle shown in Figure 5. In this cycle oxidative addition of an aryl halide to [PdL] gives a Pd^{II} compound which is in fast equilibrium with its dimer. The monomer forms a complex with the alkene. Next, the migratory insertion of this alkene takes place. After β-hydrogen elimination and reductive elimination of HX, the intermediate palladium(0) species with one ligand per palladium is obtained again.

Studies on phosphapalladacycles in the Heck reaction[3f,11] suggest that a monophosphane palladium(0) species, [R_3P-Pd], is a crucial intermediate of the cycle. This species is presumed to undergo fast oxidative addition of aryl halides followed by a dimerization giving the known compound **4a**.[10] Molecular weight determinations indicated that also complex **4b** exists as a dimer.

After alkene coordination and subsequent insertion of the alkene, the reaction is assumed to follow the widely accepted[12] pathway shown in Figure 5.

This proposed cycle is consistent with the kinetic data. Kinetic studies on the use of diphosphane ligands in the palladium catalyzed reaction of iodobenzene with styrene showed that the oxidative addition is one of the slower steps of the catalytic cycle. Since in the case of the bulky monodentate ligands the rate is independent of the concentration of iodobenzene the oxidative addition is not the turn over limiting step in these systems. This is quite surprising since phosphorus amidites render palladium less electron rich than phosphanes. The reaction rate is linearly dependent on the square root of the palladium concentration and first order in styrene concentration. This means that in this system either the alkene complexation or the migratory insertion must be the turn over limiting step. This step proceeds faster for complex **4b** than for complex **4a**.[13]

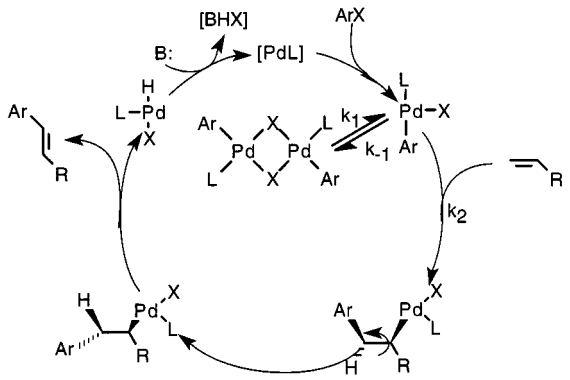

Figure 5. Postulated catalytic cycle for the Heck reaction; if we assume that $k_{-1} >> k_1 >> k_2$[alkene], then the rate = $k_2K^{1/2}$[alkene][Pd]$^{1/2}$; $K = k_1/k_{-1}$

The subtle combination of electronic and steric properties of ligand **1b** results in a highly active catalyst for the Heck reaction. The ligand is sufficiently bulky to provide complexes having a Pd:P ratio of 1:1. A bulkier ligand, however, retards the reaction. The relatively small phosphorus amidite **1a** forms a palladium compound with two ligands under the reaction conditions as can be concluded from the NMR data.[14] This also decreases the activity of the catalyst.

In summary, the use of a bulky phosphorus amidite as ligand in the palladium-catalyzed arylation of alkenes resulted in an extremely active catalyst system. From kinetic studies we conclude that, under the reaction conditions employed, not the oxidative addition, but the coordination or insertion of the alkene is the rate-determining step in this reaction. Further exploration of the scope of the reaction and the implications of the unprecedented kinetics are in progress.

Experimental Section

The ligands were prepared as described in the literature.[8a][15]

Complex **4a** was prepared as described by Hartwig.[11b] Complex **4b** was prepared in an analogous way in 81% yield. – $C_{68}H_{94}Br_2N_2O_4Pd_2$: calcd. C 54.38, H 6.31, N 1.86; found C 54.86, H 6.38, N 1.69. – $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, 25°C, H_3PO_4): δ = 118.3 (s). – ^1H NMR (300 MHz, $CDCl_3$, 25°C, TMS): δ = 1.23 (s, 12 H, CH_3), 1.25 (s, 12 H, CH_3), 1.41 (s, 36 H, *t*Bu), 3.81 (s, 12 H, CH_3O), 4.45 (m, 4 H, CH), 6.62 (m, 10 H, ArH), 6.81 (m, 4 H, ArH), 6.94 (m, 4 H, ArH). – $^{13}C\{^1H\}$ NMR (78 MHz, $CDCl_3$, 25°C, TMS): δ = 25.0 (CH_3), 31.7 (*t*Bu), 35.6 (C), 49.9 [d, ^2J(C,P) = 18 Hz, CH], 50.0 (CH), 55.4 (CH_3O), 113.2 (ArH), 114.5 (ArH), 117.1 (Ar), 122.7 (ArH), 126.7 (ArH), 131.3 (Ar), 135.2 (ArH), 141.9 (Ar), 143.0 [d, ^2J(C,P) = 14 Hz, Ar], 155 (Ar).

Catalysis with in situ Prepared Catalysts: Under a dinitrogen atmosphere, a Schlenk vessel, fitted with a septum, was charged with $Pd(dba)_2$ (26.1 mg, 0.05 mmol) and ligand (0.1 mmol). Subsequently, 5 mL of freshly distilled acetonitrile (CaH_2), 250 μL of decane (1.28 mmol) as internal standard, 550 μL of iodobenzene (4.9 mmol) and 650 μL of styrene (5.5 mmol) were injected. The Schlenk vessel was heated to 80°C and 750 mL of triethylamine (5.4 mmol) was added. The reactions were monitored by gas chromatography (DB1 column).

Kinetic Studies: Under a dinitrogen atmosphere, a Schlenk vessel, fitted with a septum, was charged with complex **4**. Subsequently, freshly distilled acetonitrile (to a total volume of 10 mL), 500 μL of decane (2.56 mmol) as internal standard, iodobenzene, and styrene were injected. The Schlenk vessel was heated to 65°C and triethylamine was added (t = 0). The reactions were monitored by gas chromatography (DB1 column).

Catalysis with Complex 4a: Under a dinitrogen atmosphere, a Schlenk vessel, fitted with a septum, was charged with complex **4a** (9.4 mg, 0.00625 mmol). Subsequently, 5 mL of freshly distilled solvent, 250 μL of decane (1.28 mmol) as internal standard, 550 μL of iodobenzene (4.9 mmol) and alkene (5.5 mmol) were injected. The Schlenk vessel was heated to 80°C and 750 mL of triethylamine (5.4 mmol) was added. The reactions were monitored by gas chromatography (DB1 column).

How the Organic Moiety Drives the Coordination Chemistry of Metal Phosphonates: The First Enantiomerically Pure Zinc Phosphonate

Florence Fredoueil,[a] Michel Evain,[b] Martine Bujoli-Doeuff,[b] and Bruno Bujoli*[a]

Keywords: Zinc / Phosphonate complexes / Chirality / P ligands

The first enantiomerically pure metallophosphonate, (*R*)-$Zn[O_3PCH_2P(O)(CH_3)(C_6H_5)]\cdot H_2O$ has been prepared. The layered arrangement in this compound is drastically different from that observed in the racemic series; this observation gives clear evidence of the critical role played by the organic moiety that fully drives the coordination chemistry of phosphonic acids with transition metals.

Metal phosphonate chemistry is undergoing rapid expansion, with applications in various areas such as ion exchange, catalysis, sensors, proton conductors, magnetism, or photochemically active materials.[1] Furthermore, an attractive feature is their potential for supramolecular assembly, provided that the structure of the phosphonate framework can be finely tuned by the suitable design of the RPO_3H_2 phosphonic acid precursor. For that purpose, it is essential to know, for a given metal, the role played by the organic moiety R attached to the phosphorus atom [via its shape, its rigidity, and the number and nature of its functional groups], on the structure and dimensionality of the resulting metal phosphonates. In this context, we have recently reported the coordination chemistry of phosphonic acids bearing functionalities of various bulks, showing that a control of the dimensionality of zinc phosphonates could be achieved.[2] Another aspect that has never been studied is the possibility to get enantiomerically pure phosphonate networks using chiral precursors. In this paper, we report the synthesis and structural characterization of the first enantiomerically pure metal phosphonate: (*R*)-$Zn[O_3PCH_2P(O)(CH_3)(C_6H_5)]\cdot H_2O$ (compound **A**), based on mixed phosphonic acid−phosphane oxide chiral building blocks.

The phosphonic acid $H_2O_3PCH_2P(O)(CH_3)(C_6H_5)$ racemate was prepared as previously described[2c] and the optical resolution was performed using quinine to give a 1:1 complex [quinine:$H_2O_3PCH_2P(O)(CH_3)(C_6H_5)\cdot 2\,H_2O$] in 81% yield (based on one of the enantiomer). The complex was treated with two equivalents of aqueous sodium hydroxide, and after extraction with dichloromethane to remove quinine, the pure enantiomeric (*R*)-form of the acid was quantitatively recovered by evaporation of the aqueous phase ($[\alpha]_D^{20} = -18$ (*c* = 1.0 in 1 M HCl)); reaction with zinc nitrate in water, under neutral-pH conditions, then yielded compound **A** in 85% yield. To ensure that all the crystals of the preparation corresponded to the same enantiomeric form, the specific rotation of compound **A** (after dissolution in 1 M HCl) was measured and found to be identical to that of the isolated resolved phosphonic acid precursor.

The structure consists of layers (*ab* plane; Figure 1) in which the zinc atoms are tetrahedrally coordinated with three oxygen atoms from the phosphonate groups [Zn−O: 1.891(6)−1.918(7) Å] and one oxygen atom from the phosphane oxide moiety [Zn−O: 1.993(5) Å]. In each layer, the zinc atoms are arranged in 12-membered rings, constructed by corner-sharing of alternating ZnO_4 and PO_3C tetrahedra. The phenyl groups are oriented toward the interlayer space, with a basal spacing (*c*/2 = 12.65 Å) shorter than the usual 15−16 Å value observed for layered metal phenylphosphonates, due to a close-packing of the sheets caused by the interdigitation of the aromatic rings from neighbouring slabs (Figure 2). The lattice water molecules are present

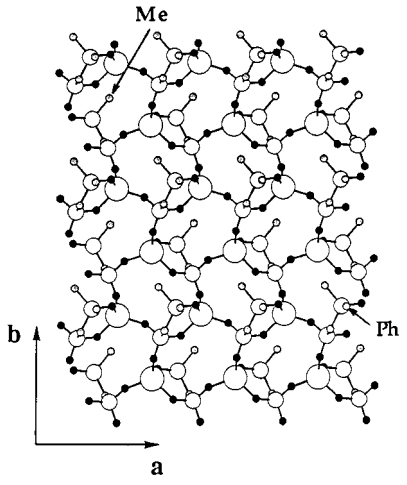

Figure 1. Schematic representation of a (*R*)-[$Zn(O_3PCH_2P(O)(CH_3)(C_6H_5)]\cdot H_2O$ layer viewed down the *c* axis. The water molecule O(5) and the carbon atoms that are not directly bonded to the phosphorus atoms have been omitted for clarity (Me = methyl, Ph = phenyl)

between the layers, presumably weakly hydrogen-bonded to phosphonate oxygen atoms [dO(H_2O)−O(phosphonate) = 3.06(1), 3.17(1), and 3.34(1) Å], thus explaining the low temperature (55°C) at which the dehydration takes place.

One important feature of this compound is the configuration of the phosphorus atom of the phosphane oxide that was unambiguously determined to be (*R*) (see Figure 2). Moreover, in a previous study, we had prepared from the phosphonic acid racemic precursor, in similar pH conditions, a layered zinc phosphonate (**B**) of composition $Zn[O_3PCH_2P(O)(CH_3)(C_6H_5)] \cdot 0.67\ H_2O$, in which the phosphane oxide is similarly bonded to zinc. It is important to note that the metal−PO_3 arrangement within the layers in this latter product (Figure 3) is different from that described for **A**; for example we can notice the presence of 16-membered rings forming at their junction smaller rings (see detail in Figure 3), in which the $O_3PCH_2P(O)(CH_3)(C_6H_5)$ units are arranged in pairs of opposite configurations, leading to a racemic zinc phosphonate. This observation clearly demonstrates that the inorganic framework has to adapt itself even to the presence of chiral atoms on the organic backbone, according to its racemic or optically pure character.

In summary, this study nicely gives an additional evidence for the critical role played by the organic moiety that fully drives the coordination chemistry of phosphonic acids with transition metals. Furthermore, when the chiral organic precursor is enatiomerically pure, no racemization occurs during the preparation of the corresponding metal phosphonate, leading to an enantiomerically pure product.

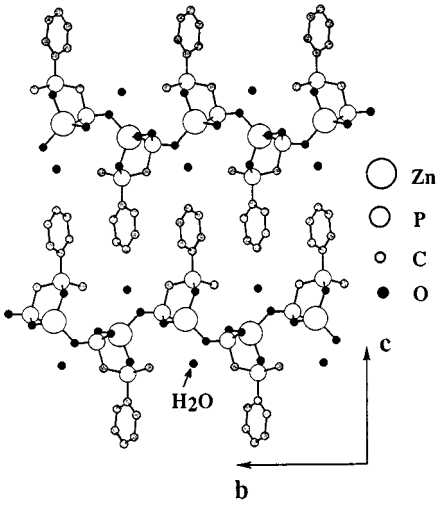

Figure 2. Schematic representation of (*R*)-$Zn[O_3PCH_2P(O)(CH_3)(C_6H_5)] \cdot H_2O$ (**A**) as seen perpendicular to the *a* axis; the (*R*)-configuration of the phosphorus atom of the phosphane oxide is clearly apparent

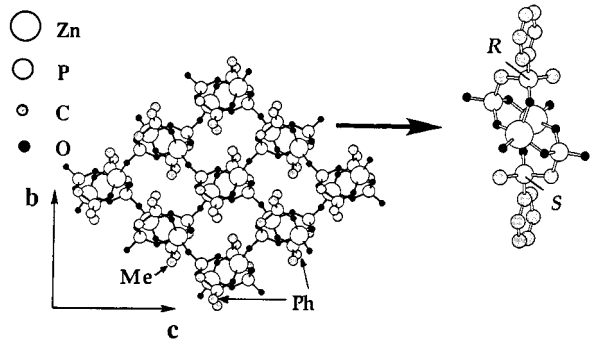

Figure 3. Schematic representation of a (*R*/*S*)-$Zn[O_3PCH_2P(O)(CH_3)(C_6H_5)] \cdot 0.67\ H_2O$ (**B**) layer as seen perpendicular to the *a* axis, according to ref.[2c] The water molecule O(5) and the carbon atoms that are not directly bonded to the phosphorus atoms have been omitted for clarity (Me = methyl, Ph = phenyl). A detail of the structure showing the pairs of $O_3PCH_2P(O)(CH_3)(C_6H_5)$ blocks of opposite configuration (*R*) and (*S*) is given.

Experimental Section

Synthesis of (*R*)-$Zn[O_3PCH_2P(O)(CH_3)(C_6H_5)] \cdot H_2O$ (A): A solution of 500 mg of racemic $H_2O_3PCH_2P(O)(CH_3)(C_6H_5)$ [2.13 mmol] in 30 mL of hot ethanol was added to a solution of 1.039 g of quinine [3.2 mmol] in 15 mL of ethanol. The mixture was allowed to stand for 5 days at room temperature, after which the crystals that gradually appeared were isolated by filtration, corresponding to a 1:1 dihydrate complex (81% yield. Elemental analysis: found: P 9.97, C 56.29, H 6.76, N 4.72; calcd. for $C_{28}P_2O_8N_2H_{40}$: P 10.42, C 56.56, H 6.78, N 4.71. $[\alpha]_D^{20} = -153$ (c = 1.0 in 1 M HCl). The complex (150 mg) was then suspended in 45 mL of water; 2 equivalents of sodium hydroxide were then added and the mixture was stirred for 1 hour. The reaction medium was then extracted 2 times with dichloromethane, allowing to recover quinine in the organic phase. The pure enantiomeric (*R*)-form of the acid was then quantitatively recovered by evaporation of the aqueous phase ($[\alpha]_D^{20} = -18$ (c = 1.0 in 1 M HCl)). The same result was obtained using cinchonidine as the resolving agent. Then a mixture of zinc nitrate (0.3 mmol) and the resolved phosphonic acid described above (0.2 mmol) in 20 mL water was placed in the PTFE cell of an autoclave, that was sealed and kept at 110°C in a drying oven for 3 days. Compound **A** was obtained as white crystals, used for the X-ray structure determination, in 85% yield.

Structure Determination: Data were collected from a single crystal (0.2 × 0.04 × 0.006 mm) on an STOE image plate system (ω scan, $\sin(\theta)/\lambda \leq 0.57$) and a Nonius CAD-4F diffractometer (ω/2θ scan, $\sin(\theta)/\lambda \leq 0.68$) at room temperature. After the usual Lorentz-polarization and decay (< 2%) corrections, the 8233 reflections from the IPDS and the 4234 reflections from the CAD4 were merged based upon the intensities of 218 common reflections with $I/\sigma(I) > 10$. Since the data set was consistent with the $P2_12_12_1$ space group, the reflections were then averaged according to the point group 222 (internal (*R*) value of 7.5%). Data processing and structure refinements were carried out with the JANA98 program.[3] Direct methods (using SHELXTL V5.0 package)[4] revealed the positions of all Zn and P and some C and O atoms. Subsequent full-matrix, least-squares refinements on *F* followed by difference Fourier syntheses revealed the position of the remaining O and C atoms. All hydrogen atoms were refined, but those of the water molecule were placed at their theoretical positions. The CH_3 group was refined as a rigid body. The refinement of the zinc, phosphorus, oxygen, and carbon atoms with independent anisotropic displacement parameters (ADP) converged with $R/wR = 0.0309/0.0312$ for 1071 independent reflections with $I/\sigma(I) > 3$ and 148 parameters. The hydrogen ADPs were restrained to those of the atom the hydrogen atom was attached to.

Crystal data: $ZnP_2O_4C_8H_{10} \cdot H_2O$; orthorhombic $P2_12_12_1$; a = 5.5378(11), b = 8.4143(12), c = 25.270(8) Å, V = 1177.5(5) Å^3

from the centering of 25 high angle reflections (CAD4) and monochromated Mo-K-$L_{2,3}$ radiation; $Z = 4$; $M = 315.5$; $\rho_{calcd.} = 1.779\ g.cm^{-3}$; $\mu = 23.5\ cm^{-1}$; residual electron density [−0.49, +0.39] e/Å^3. The absolute configuration was determined by refining the inversion twin ratio. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-112086. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (+44) 1223/ 336-033; E-mail: deposit@ccdc.cam.ac.uk].

Formation of Anionic $PdX_3(PPh_3)^-$ Complexes by Reaction of Halide Ions with $PdX_2(PPh_3)_2$

Christian Amatore,*[a] Anny Jutand,*[a] and Loïc Mottier[a]

Keywords: Palladium / Anionic complexes / Phosphane substitution

Halide ions react with $PdX_2(PPh_3)_2$ (X = Cl, Br, I) complexes in an equilibrated reaction in which the phosphane ligand is substituted by the halide X^- to form anionic complexes $PdX_3(PPh_3)^-$ in THF and DMF. The equilibrium constants have been determined by cyclic voltammetry.

Introduction

It has been established that halide ions are good ligands for palladium(0) complexes.[1−3] The best way to investigate the effect of halide ions on the structure and reactivity of palladium(0) complexes in oxidative addition with aryl halides[2−5] was to generate them by electrochemical reduction of $PdX_2(PPh_3)_2$ in the presence of various amounts of halides X^- (X = Cl,[2][3] Br,[3] I[3]) in THF. However, during the course of these reactions, it was observed that the reduction peak of $PdX_2(PPh_3)_2$ was affected by the presence of added X^- so that its usual single bielectronic reduction peak became split into two peaks whose relative currents depended on the halide concentration: the higher the concentration of X^-, the higher the second reduction peak current relative to the first one.[2][3] This phenomenon was first discarded and tentatively interpreted as the formation of an intermediate palladium(I) complex by reduction of the palladium(II) complex. Its stabilization by halide ions as an anionic 18-electron dimer e.g. $[Pd^I(PPh_3)_2X_2]_2^{2-}$ would indeed make it less easily reduced than $Pd^{II}X_2(PPh_3)_2$, thus giving rise to the second reduction peak.[2][3]

However, careful investigation of this reaction led us now to reconsider our first tentative hypothesis and to establish that reactions of halides X^- with $PdX_2(PPh_3)_2$ result in substitution of one phosphane ligand with formation of an anionic $PdX_3(PPh_3)^-$ species; this palladium(II) complex is more difficult to reduce. In other words, the two peaks represent the reduction of two different palladium(II) complexes.[6]

Results and Discussion

Evidence of the Formation of $PdX_3(PPh_3)^-$ Complexes by Reaction of X^- and $PdX_2(PPh_3)_2$ by ^{31}P-NMR Spectroscopy in THF and DMF

The ^{31}P-NMR spectra of $PdCl_2(PPh_3)_2$ (3 mmol dm^{-3}) in THF exhibited a single signal at δ = 23.80. Two new signals appeared in the presence of 120 equivalents of nBu_4NCl (Figure 1): one signal at δ = −5.27 characteristic of the phosphane PPh_3 and a second one at δ = 27.42 assigned to the anionic species $PdCl_3(PPh_3)^-$ by comparison with an authentic sample of $[PdCl_3(PPh_3)^-, nBu_4N^+]$.[7]

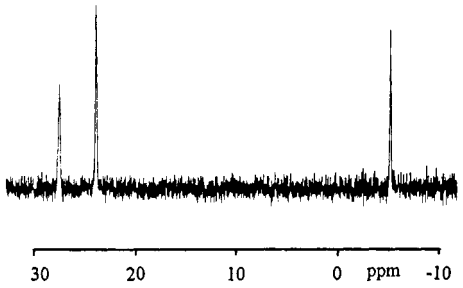

Figure 1. ^{31}P-NMR spectrum (162 MHz) of a solution of $PdCl_2(PPh_3)_2$ (3 mmol·dm^{-3}) and nBu_4NCl (360 mmol dm^{-3}) in 3 mL of THF and 0.2 mL of [D_6]acetone with H_3PO_4 as an external reference

The signal of $PdCl_2(PPh_3)_2$ was still present even in the presence of a large excess of chloride ions suggesting that Cl^- substituted one phosphane from $PdCl_2(PPh_3)_2$ through an equilibrated reaction (Equation 1).

$$Pd^{II}Cl_2(PPh_3)_2 + Cl^- \rightleftharpoons Pd^{II}Cl_3(PPh_3)^- + PPh_3 \quad (1)$$

The dynamic of this equilibrium is relatively slow compared to the time-scale of the NMR experiment since three distinct narrow signals were observed for $PdCl_2(PPh_3)_2$, $PdCl_3(PPh_3)^-$, and PPh_3 (Figure 1). Similar equilibria have been observed using ^{31}P-NMR spectroscopy by treating nBu_4NBr with $PdBr_2(PPh_3)_2$ and nBu_4NI with $PdI_2(PPh_3)_2$ in THF (Equation 2, Table 1).

$$Pd^{II}X_2(PPh_3)_2 + X^- \rightleftharpoons Pd^{II}X_3(PPh_3)^- + PPh_3 \qquad K_X \quad (2)$$

X = Cl, Br, I

In DMF, in the absence of any added halide ions, the ^{31}P-NMR spectra of $PdCl_2(PPh_3)_2$ exhibited three signals. The major signal at δ = 24.4 is assigned to $PdCl_2(PPh_3)_2$. The two other minor (10%) but of same magnitude signals are assigned to PPh_3 (δ = −5.54) and to the dimer

[a]162 MHz versus H_3PO_4 as external standard. − [b] Volt versus SCE at a gold disk electrode at 0.2 V s^{-1} at 25 °C.

$Pd_2Cl_4(PPh_3)_2$ (δ = 33.54) by comparison with authentic samples.[9] These results suggest that the equilibrium according to Equation 3[10] operates in DMF and not in THF and is frozen on the time-scale of ^{31}P-NMR spectroscopy.

$$2\ PdCl_2(PPh_3)_2 \rightleftharpoons Pd_2Cl_4(PPh_3)_2 + 2\ PPh_3 \quad (3)$$

In DMF, the ^{31}P-NMR spectra of $PdBr_2(PPh_3)_2$ also exhibited three signals. However, the signal at δ = 25.47, assigned to the dimer $Pd_2Br_4(PPh_3)_2$, was detected at traces level compared to that of $PdBr_2(PPh_3)_2$ at δ = 22.86. A solution of $PdI_2(PPh_3)_2$ exhibited a single signal at δ = 13.40 in DMF suggesting that the dimer $Pd_2I_4(PPh_3)_2$ was not formed.

Determination of the Equilibrium Constant K_X by Cyclic Voltammetry in THF and DMF

As recalled in the introduction, progressive addition of nBu_4NCl to a solution of $PdCl_2(PPh_3)_2$ (1.5 mmol·dm^{-3} in THF containing nBu_4NBF_4 0.3 mol·dm^{-3}) provoked a split of its bielectronic reduction peak R_1 at $E^p = -1.04$ V versus SCE into two reduction peaks, R_1 and R_2 at $E^p = -1.25$ V versus SCE (Figure 2a).[2][3]

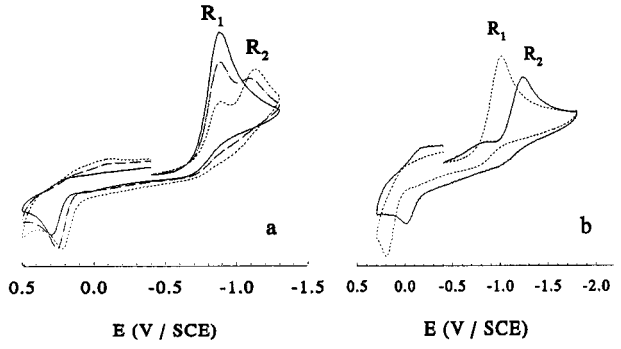

Figure 2. Cyclic voltammetry performed in THF (containing nBu_4NBF_4, 0.3 mol·dm^{-3}) at a steady gold disk electrode (i.d. = 0.5 mm) with a scan rate of 2 V s^{-1}, at 25 °C: (a) $PdCl_2(PPh_3)_2$ (1.5 mmol·dm^{-3}) in the presence of 0 (——), 14 (− − −), 85 (····) equivalents of nBu_4NCl; (b) [$PdCl_3(PPh_3)^-$, nBu_4N^+] (0.8 mmol·dm^{-3}): alone (——); in the presence of 10 equivalents of PPh_3 (····)

From the ^{31}P-NMR investigation reported above, it can be inferred that the second reduction peak is not relevant to the reduction of intermediate palladium(I) complexes as earlier proposed[2][3] but to the reduction of the anionic divalent complex $Pd^{II}Cl_3(PPh_3)^-$. This assumption has been confirmed by the cyclic voltammetry of an authentic sample of [$PdCl_3(PPh_3)^-$, nBu_4N^+][7] performed in THF which exhibited the unique reduction peak R_2 (Figure 2b). Moreover, when 10 equivalents of PPh_3 were added to $PdCl_3(PPh_3)^-$, the reduction peak R_2 of $PdCl_3(PPh_3)^-$ disappeared and was replaced by the reduction peak R_1 of $PdCl_2(PPh_3)_2$ (Figure 2b), evidencing the backward reaction of equilibrium 2 (X = Cl).

$$\underset{R_1}{PdX_2(PPh_3)_2} + X^- \rightleftharpoons \underset{R_2}{PdX_3(PPh_3)^-} + PPh_3 \quad (2)$$

The formation of anionic species was also observed by performing cyclic voltammetry on mixtures of nBu_4NBr and $PdBr_2(PPh_3)_2$, as well as on mixtures of nBu_4NI and $PdI_2(PPh_3)_2$ in THF. The reduction peak potentials of the neutral and anionic complexes are collected in Table 1.

From ^{31}P-NMR spectroscopy, the equilibrium according to Equation 2 was found to be slow compared to the time-scale of the NMR experiment. In cyclic voltammetry, the reduction of $PdX_2(PPh_3)_2$ at R_1 is governed by a CE mechanism.[11] If the equilibrium according to Equation 2 is fast compared to the time-scale of the cyclic voltammetry, reduction of $PdX_2(PPh_3)_2$ at R_1 should result in a shift of the equilibrium to its left-hand side by the continuous consumption of $PdX_2(PPh_3)_2$ due to its reduction in the diffusion layer. A dynamic concentration should be measured which becomes larger as the scan rate is reduced. If not, thermodynamic equilibrium concentrations can be determined. The ratio $r = i/i_0$ [i: reduction peak current at R_1 of $PdCl_2(PPh_3)_2$ in the presence of 100 equivalents of nBu_4NCl; i_0: same current but in the absence of added nBu_4NCl] was then plotted versus the logarithm of the scan rate (Figure 3a).

This ratio clearly does not depend on the scan rate which means that within the time-scale of the cyclic voltammetry investigated here ($0.2 < v < 20$ V s^{-1}), equilibrium 2 is frozen, so that the thermodynamic concentration of $PdCl_2(PPh_3)_2$ in the equilibrium can be determined by the ratio $r = i/i_0 = [PdCl_2(PPh_3)_2]_{equil}/[PdCl_2(PPh_3)_2]_0$. This allows the determination of the equilibrium constant K_{Cl}. In the present case, the dynamics of equilibrium 2 are not accessible because it would require scan rates much lower than 0.2 V s^{-1}, which could not be used since diffusion processes would be contaminated by convection.

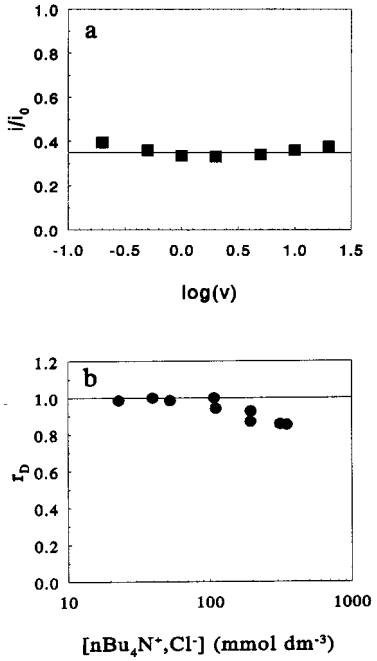

Figure 3. (a) Variation of the ratio $r = i/i_0$ versus the logarithm of the scan rate (v in $V{\cdot}s^{-1}$); i: reduction peak current at R_1 of $PdCl_2(PPh_3)_2$, 1.5 $mmol{\cdot}dm^{-3}$ in THF (containing nBu_4NBF_4, 0.3 $mol{\cdot}dm^{-3}$) in the presence of 100 equivalents of nBu_4NCl; i_0: same current but in the absence of added nBu_4NCl at 20 °C; the reduction peak currents were measured at steady gold disk electrodes (i.d. = 0.5 mm for $v < 5$ $V{\cdot}s^{-1}$ and i.d. = 0.125 mm for $v > 5$ $V{\cdot}s^{-1}$); (b) variation of the ratio $r_D = i/i_0$ versus the logarithm of the concentration of nBu_4NCl; i: reduction peak current at R_1 of $PdCl_2(PPh_3)_2$, 1.5 $mmol{\cdot}dm^{-3}$ in THF (containing nBu_4NBF_4, 0.3 $mol{\cdot}dm^{-3}$) in the presence of n equivalents of nBu_4NCl and 10 equivalents of PPh_3; i_0: same current but in the absence of added nBu_4NCl; the reduction peak currents were measured at a steady gold disk electrode (i.d. = 0.5 mm) with a scan rate of 0.2 $V{\cdot}s^{-1}$ at 20 °C

$$PdX_2(PPh_3)_2 + X^- \rightleftharpoons PdX_3(PPh_3)^- + PPh_3 \quad K_X \qquad (2)$$

at t = 0	C_0	nC_0	0	0
at equil.	rC_0	$(n-1+r)C_0 \approx nC_0$	$C_0(1-r)$	$C_0(1-r)$

$$K_X = \frac{[PdX_3L^-][L]}{[PdX_2L_2][X^-]} = \frac{(1-r)^2}{n\times r} \quad \text{where } n = [X^-]_0/[PdX_2(PPh_3)_2]_0$$

From this expression one obtains

$$r^2 - 2r(1 + nK_X/2) + 1 = 0$$

so that

$$r = 1 + nK_X/2 - \{(nK_X/2)^2 + nK_X\}^{1/2} \qquad (4)$$

The ratio $r = i/i_0$ was measured for various amounts of X^- [n equivalents/Pd^{II}] at a given scan rate. Plotting the experimental value of r versus log n at a given rate constant and comparison with the theoretical curve should allow the determination of K_X. However, this calculation is based on the fact that the reduction peak current i at R_1 is proportional to the concentration of the species $PdX_2(PPh_3)_2$ which is in fact true if the diffusion coefficient D of $PdX_2(PPh_3)_2$ ($i \propto D^{1/2}$)[12] does not vary with the experimental conditions i.e. when the concentration of nBu_4NX and consequently the ionic strength increases. This has been checked by performing cyclic voltammetry of $PdX_2(PPh_3)_2$ for X = Cl, Br, I, in the presence of various amounts of nBu_4NX but with a large excess of PPh_3 (10 equivalents), so that the equilibrium according to Equation 2 was completely shifted to its left-hand side and consequently only the reduction peak R_1 of $PdX_2(PPh_3)_2$ was observed. Under these conditions, the reduction peak current i of $PdX_2(PPh_3)_2$, at a constant scan rate, was found to vary with the concentration of nBu_4NX (X = Cl, Br). This is illustrated in Figure 3b where the ratio $r_D = i/i_0$ [i: reduction peak current at R_1 of $PdCl_2(PPh_3)_2$ in the presence of n equivalents of nBu_4NCl and 10 equivalents of PPh_3; i_0: same current but in the absence of added nBu_4NCl] was plotted versus log [nBu_4NCl]. The ratio r_D differs from unity at high chloride concentrations. This suggests that the diffusion coefficient of $PdCl_2(PPh_3)_2$ is not constant but decreases upon increasing the concentration of chloride ions because of the higher and higher viscosity of the solution. Consequently, the equilibrium constant K_X was determined as explained above but by plotting the ratio $i/(i_0 \times r_D)$ instead of i/i_0 versus log n (Figure 4). The values of the equilibrium constant K_X (X = Cl, Br, I) are collected in Table 2.

Table 2. Equilibrium constant K_X for the equilibrium $PdX_2(PPh_3)_2 + X^- \rightleftharpoons PdX_3(PPh_3)^- + PPh_3$, with nBu_4N^+ as the countercation at 25 °C

X		Cl	Br	I
$10^{+3}K_X$	THF	10 (±1)	0.9 (±0.1)	1.7 (±0.3)
$10^{+3}K_X$	DMF	2 (±1)	n.d.	n.d.

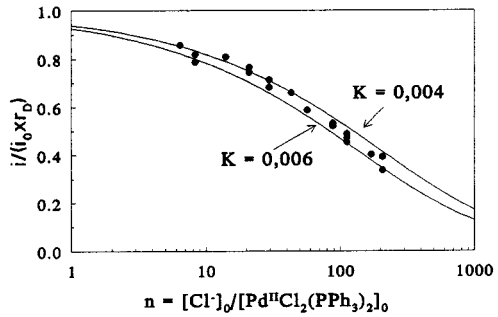

Figure 4. Determination of the equilibrium constant K_{Cl} (see Equations 2 and 4) in THF at 20 °C; plot of $i/(i_0 \times r_D)$ versus the logarithm of n (equivalents of nBu_4NCl); i: reduction peak current at R_1 of $PdCl_2(PPh_3)_2$, 1.5 $mmol{\cdot}dm^{-3}$ in THF (containing nBu_4NBF_4, 0.3 $mol{\cdot}dm^{-3}$) in the presence of various amounts of nBu_4NCl; i_0: same current but in the absence of added nBu_4NCl; the reduction peak currents were measured at a steady gold disk electrode (i.d. = 0.5 mm) with a scan rate of 0.2 $V{\cdot}s^{-1}$; for the definition of r_D see caption of Figure 3b; the solid lines are the theoretical predictions according to Equation 4

The equilibrium constant K_{Cl} has been determined at different temperatures in THF. The equilibrium according to Equation 2 favors production of the anionic species at higher temperatures. The Arrhenius plot of $\ln K_{Cl}$ versus $1/T$ (Figure 5) allows the determination of the activation par-

ameters from the slope and intercept, so that $\Delta H^0 = 20$ kJ mol^{-1} and $\Delta S^0 = -20$ J K^{-1}.

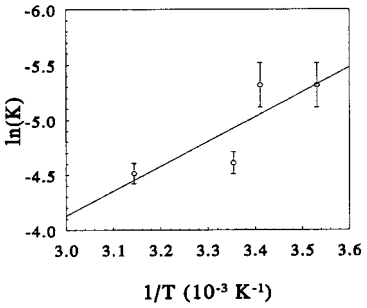

Figure 5. Arrhenius plot for the equilibrium $PdCl_2(PPh_3)_2 + Cl^- \rightleftharpoons PdCl_3(PPh_3)^- + PPh_3$ (with nBu$_4$N as counter-cation) in THF containing nBu$_4$NBF$_4$ (0.3 mol·dm^{-3}); variation of ln K_{Cl} versus $1/T$

The small value of ΔS^0 is indicative of a reaction in which there is no variation of the numbers of species in solution.

Miscellaneous Reactions

All reactions investigated above concern the substitution of the phosphane ligand by the same halide X^- as those present in $PdX_2(PPh_3)_2$. Reactions are more complicated when different halides are considered. For example: when 30 equivalents of nBu$_4$NI were added to a solution of $PdCl_2(PPh_3)_2$ (2.4 mmol·dm^{-3}) in THF, PPh_3 was detected in the ^{31}P-NMR spectrum as a narrow signal indicative of the substitution of the phosphane ligand by one iodide ion which generates anionic species: $PdCl_2I(PPh_3)^-$.

$$PdCl_2(PPh_3)_2 + I^- \rightarrow PdCl_2I(PPh_3)^- + PPh_3 \quad (5)$$

However, this complex could not be characterized since an unresolved broad signal was present at $\delta = 17.5$ suggesting that scrambling reactions occurred by equilibria such as in Equation 6 and/or 7.

$$PdCl_2I(PPh_3)^- + PPh_3 \rightleftharpoons PdICl(PPh_3)_2 + Cl^- \quad (6)$$

$$PdCl_2(PPh_3)_2 + I^- \rightleftharpoons PdICl(PPh_3)_2 + Cl^- \quad (7)$$

Under these conditions, several neutral or anionic complexes may be formed: $PdICl(PPh_3)_2$, $PdI_2(PPh_3)_2$, $PdCl_2I(PPh_3)^-$, $PdClI_2(PPh_3)^-$, $PdI_3(PPh_3)^-$ involved in different and simultaneous equilibria, responsible for the unresolved broad signal observed in the ^{31}P-NMR spectrum.

Discussion and Conclusion

Halide ions can substitute a phosphane ligand in $PdX_2(PPh_3)_2$ complexes to afford anionic species $PdX_3(PPh_3)^-$ by an equilibrium. Similar anionic $NiCl_3(PR_3)^-$ (R = isopropyl) complexes have been reported to be formed by phosphane substitution[13] while $PtCl_3(PR_3)^-$ complexes are usually synthesized by allowing chloride ions to react with phosphane-deficient dimeric complexes, $Pt_2Cl_4(PR_3)_2$.[14] However, $PdX_2(PPh_3)_2$ remains the more stable complex in THF and DMF for moderate halide ion concentrations. The phosphane substitution is easier for chloride ions which reveals the higher nucleophilic affinity of Cl^- for the palladium(II) center than that of Br^- or I^-. This can be understood as an interaction between "hard" Lewis acids and bases. The substitution of the phosphane by the chloride is more efficient in THF than in DMF probably due to the lower capacity of THF relative to DMF to solvate chloride ions compared to the larger anionic species PdX_3L^-.

Conversely, we have reported that the affinity of Cl^- for palladium(0) centers is less than that of Br^- or I^- which can be rationalized as an interaction between "soft" centers.[3] Those results evidence the ability of halide ions to coordinate both palladium(0) and palladium(II) complexes and thus probably to influence further reactions involving such complexes. We have already reported the consequences of the ligation of palladium(0) complexes by halide[3–5] or acetate ions[5][15] on the mechanism of palladium-catalyzed reactions. Although palladium(II) dihalide complexes are less involved as promoters of catalytic reactions than palladium(0) complexes, arylpalladium(II) halide complexes are postulated to be crucial intermediates in palladium(0)-catalyzed reactions involving aryl halides. Reactions of halide ions X'^- with $ArPdX(PPh_3)_2$ complexes do not result in a substitution of one phosphane ligand but rather substitution of the halide X^- to form neutral $ArPdX'(PPh_3)_2$ complexes.[16] In fact, we have established that $ArPdX(PPh_3)_2$ complexes are not reactive intermediates in cross-coupling[3][5] or Heck[5][15] reactions and the effect of chloride or acetate anions on the course of these reactions is to produce new anionic or neutral complexes such as $ArPdX(Cl)(PPh_3)_2^-$, $ArPdX(OAc)(PPh_3)_2^-$, $ArPd(OAc)(PPh_3)_2$ where the two phosphane ligands remain attached to the palladium(II) center

Experimental Section

General: ^{31}P-NMR spectra were recorded with a Bruker W 400 spectrometer (162 MHz) with H_3PO_4 as an external reference. Cyclic voltammetry was performed with a home-made potentiostat and a waveform generator Tacussel GSTP4 or EGG. The cyclic voltammograms were recorded with a Nicolet 301 oscilloscope.

Chemicals: DMF was distilled from calcium hydride under vacuum and kept under argon. Commercial nBu$_4$NCl, nBu$_4$NBr, nBu$_4$NI (Acros) were used after crystallisation. They were melted and dried under vacuum. $PdCl_2(PPh_3)_2$, $PdBr_2(PPh_3)_2$, $PdI_2(PPh_3)_2$, was prepared according to described procedures.[17]

Electrochemical Set Up and Electrochemical Procedure for Cyclic Voltammetry: Experiments were carried out in a three-electrode cell connected to a Schlenk line. The counter electrode was a platinum wire of ca. 1 cm^2 apparent surface area; the reference was a saturated calomel electrode (Tacussel) separated from the solution by a bridge filled with 3 mL of THF or DMF containing nBu$_4$NBF$_4$ (0.3 mol·dm^{-3}).

General Procedure: 12 mL of THF or DMF containing nBu$_4$NBF$_4$ (0.3 mol·dm^{-3}) was poured into the cell followed by $PdCl_2(PPh_3)_2$

(16.8 mg, 0.024 mmol) and various amounts of nBu$_4$NCl. Cyclic voltammetry was performed at steady gold disk electrodes with various scan rates.

Structural Studies of Novel Siloxysilsesquioxanes

Norbert Auner,*[a] Burkhard Ziemer,[b] Bernhard Herrschaft,[a] Wolfgang Ziche,[c] Peter John,[c] and Johann Weis[c]

Dedicated to Prof. Dr. Peter Jutzi on the occasion of his 60th birthday

Keywords: Silsesquioxanes / MALDI-TOF / DSC / Structure elucidations / Thermochemistry / Mass spectrometry

Five silsesquioxanes $(RSiO_{3/2})_{2n}$ with R = siloxy and n = 4, 5 have been investigated by X-ray crystallography, MALDI-TOF mass spectrometry, and differential scanning calorimetry (DSC).

Silicon and silicon-containing compounds have found widespread use in modern technology; this field includes purely inorganic materials (e.g. for electronics) as well as organosilicon polymers.[1] Especially interesting are globular oligosilsesquioxanes $(RSiO_{3/2})_{2n}$ (n = 3, 4, 5, ...), also called spherosiloxanes due to their shape,[2] in which the Si−O core is trigonal-prismatic (n = 3), cubic (n = 4), or pentagonal-prismatic (n = 5). These are widely used in fields ranging from optical fibres to cosmetics.[3−5] Generally, silsesquioxanes may be best described as an interface between the purely inorganic silicates and carbosilanes composed of a rigid silicate core and chemically useful peripheral organic functionalities. Thus, silsesquioxanes serve as precursors for novel organosilicon polymers,[6] organolithiated macromolecular materials,[7][8] and porous hybrid inorganic-organic materials.[9] By virtue of the fact that they are both rigid and polyfunctional, they serve as suitable cores for the formation of three-dimensional dendrimers[10] and liquid crystals.[11] Furthermore, they are useful as templates for the preparation of polymeric and ceramic materials by sol-gel techniques.[12] Their derivatization with organometallic functionalities leads to precursors for catalyst preparation (e.g. cobalt carbide nanoparticles in a silicaceous matrix[13]) or to materials that are useful in electrochemical devices.[14]

The hydrido species $(HSiO_{3/2})_{2n}$ may be employed for the deposition of SiO_2 films in material technology,[15][16] and is widely used as a starting compound for the synthesis of substituted silsesquioxanes.[12][17] The silsesquioxanes also serve as model compounds for the study and understanding of the properties of zeolites and silicates.[18] While crystal structures have been reported for hydrido siloxanes[19] and organosilsesquioxanes,[20] not much is known about siloxy-functionalized silsesquioxanes (or silyl silicates),[21−25] although the pioneering work of Lentz[26] and Hoebbel[27] dates back to the 1960s.

In this paper, we report the crystal structures of five basic siloxysilsesquioxanes (R = $OSiMe_3$, $OSiMe_2H$, $OSiMe_2Vi$ for n = 4, and R = $OSiMe_3$, $OSiMe_2H$ for n = 5). Discrepancies between the structures obtained and the results of ^{29}Si-MAS-NMR studies are clarified by investigation of the thermal behaviour of the cage compounds by DSC. Their suitability as siloxane mass standards for MALDI-TOF mass spectrometry is tested. The siloxysilsesquioxane $[(M_3Q)DQ]_8$, **6** [R = $OSiMe_2(OSiMe_3)$, n = 4], for which no crystal structure could be obtained, was also included in this part of the study.

Molecular Structures

The common structural feature of the present eight-membered cyclic compounds $Si_8O_{20}R_8$ is a heterocubane anion in which the silicon atoms are placed at the corners of a cube, each one bearing a terminal oxygen atom. Twofold bridging oxygen atoms are positioned at each edge of the cube, leading to the coordination formula $[(SiO_{1/1}O_{3/2})^{1-}]_8 = [Si_8O_{20}]^{8-}$ for the core. Eight silyl groups, specifically $SiMe_3$ in **1** $[M_8Q_8]$, $SiMe_2H$ in **2** $[M^H{}_8Q_8]$, and $SiMe_2Vi$ in **3** $[M^V{}_8Q_8]$, are attached to the terminal oxygen atoms, resulting in electrically neutral molecules. Relative to the $[Si_8O_{20}]^{8-}$ anion in Ekanite, $ThKCaNa[Si_8O_{20}]$[28], the Si−O distances in compounds **1**−**3** are slightly longer and the bond angles at the bridging oxygen atoms have slightly smaller values. This clearly stems from the coordinative requirements in Ekanite, which are essentially dominated by the geometrical constraints imposed by the cations. In **1**−**3**, these are replaced by bulky SiR_3 substituents with a comparably high steric demand, hence the molecular units are no longer linked together by electrostatic cation interactions, but only by weak dispersion interactions caused by the relatively non-polar silyl groups.

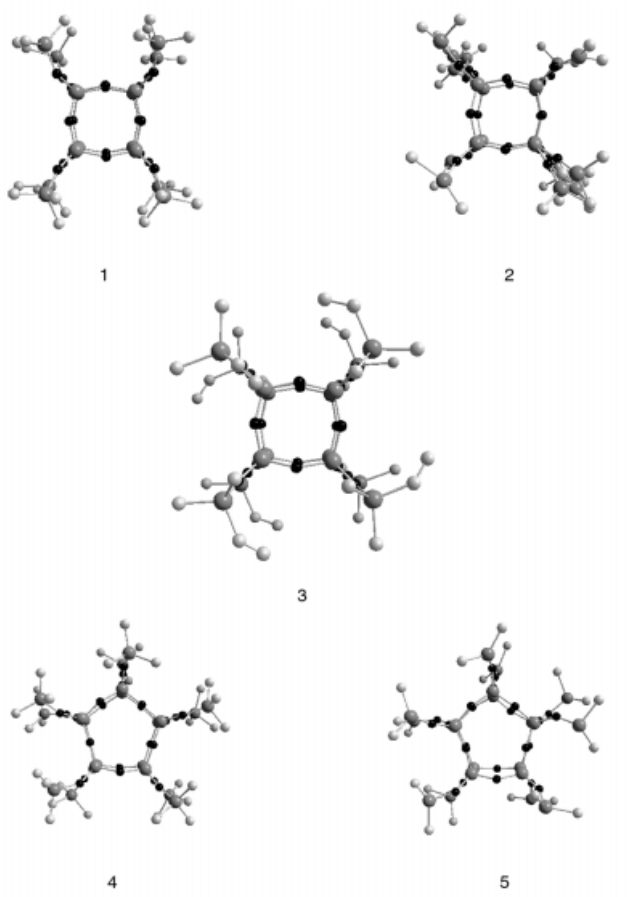

Figure 1. Molecular structures of compounds **1**−**5**

The molecular core of the silsesquioxanes $Si_{10}O_{25}R_{10}$, derived from $[Si_{10}O_{25}]^{10-}$ anions, formally results from the insertion of an $[O(SiO_{1/2}O_{1/1})_2]^{2-} = [Si_2O_5]^{2-}$ unit into a pseudo-cubic $[Si_8O_{20}]^{8-}$ anion, leading to a pentagonal-prismatic anion $[(SiO_{1/1}O_{3/2})^{1-}]_{10} = [Si_{10}O_{25}]^{10-}$. Isolated anions of this type have not been observed in the solid state, but they do occur as building blocks in zeolites (pentasil units in ZSM-5 and ZSM-11)[29]. The novel cyclic silicates $Si_{10}O_{25}R_{10}$ (**4**, R = $SiMe_3$, $M_{10}Q_{10}$; **5**, R = $SiMe_2H$, $M^H{}_{10}Q_{10}$) may be regarded as model compounds of the anions $[Si_{10}O_{25}]^{10-}$ characterized as their silyl-substituted molecular entities. The geometrical features are similar to those discussed for $Si_8O_{20}R_8$. The molecular structures of

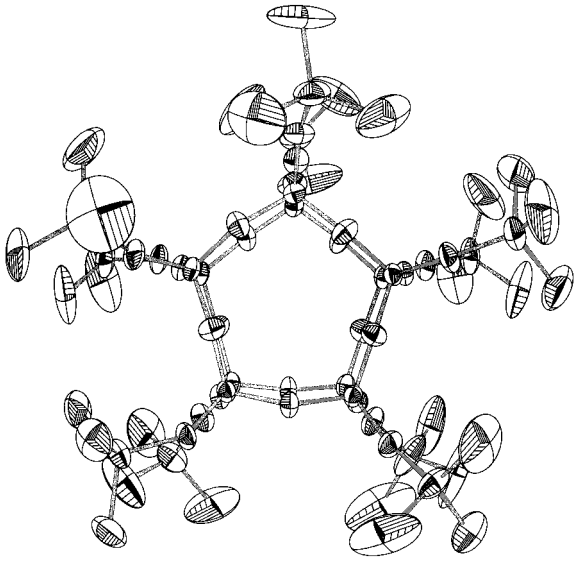

Figure 2. Molecular structure of **4** showing 15% probability atomic displacement ellipsoids

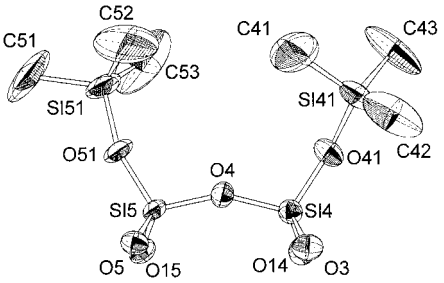

Figure 3. Part of the molecular structure in **5** showing 30% probability atomic displacement ellipsoids

the silsesquioxanes **1**−**5** have been determined by single-crystal X-ray diffraction and are shown in Figure 1.

Results and Discussion

As can be seen from Table 1, no unusual interatomic distances or bond angles were detected.[30] As expected, the accuracies of the Si−O and Si−C bond-length determinations are higher for the low-temperature structure analysis and decrease considerably on going from the inner to

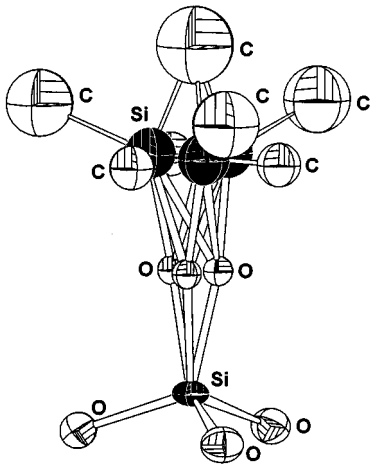

Figure 5. Superposition structure of **2** about the threefold axis; detail of disordered $OSiMe_3$ groups: "ice-cream cone motif"

the outer sphere within each molecule. This disorder may be explained either in terms of an intense thermal motion of the atoms at room temperature, which is frozen on cooling, or, alternatively, by considering closely neighbouring but slightly different atom positions partially occupied by almost fixed atoms at low temperature.

As mentioned above, these experimental findings may be attributed to a decrease in the rigidity of the core owing to the replacement of metal cations, or in this particular case – following the syntheses of silsesquioxanes **1**–**5** given in the Experimental Section – of ammonium cations $[NR_4]^+$ ($R = CH_3$, C_4H_9), by organosilyl groups. All five structures are characterized by unusually large anisotropic displacement parameters. Figure 2 shows the ellipsoids for **4**, which

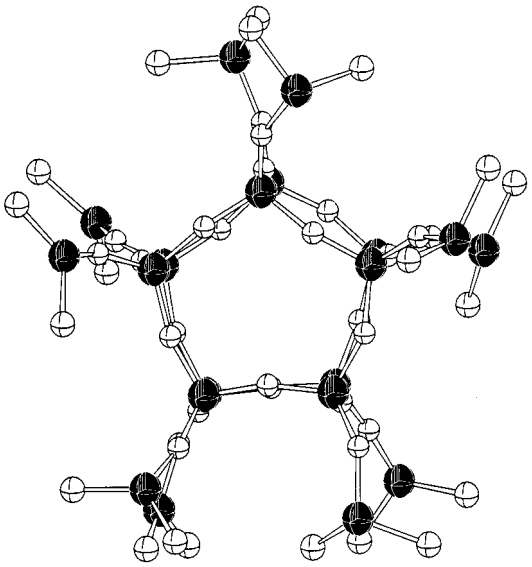

Figure 6. Model structure of **5** with twenty crystallographically independent silicon sites at 200 K

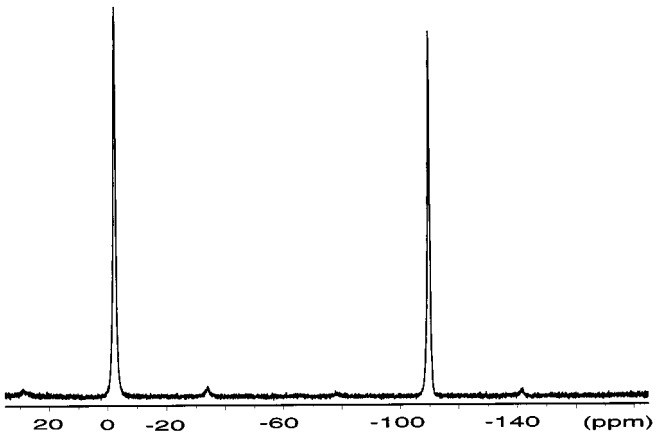

Figure 7. ^{29}Si-MAS-NMR spectrum (spinning rate 2000 Hz) of **5** at 293 K, showing two signals for two sets of ten magnetically equivalent silicon atoms

are seen to increase markedly on going from the inner to the outer part of the molecule.

Unusually large anisotropic displacement parameters U_{ij} with $U_3/U_1 > 10$ were found for two peripheral C atoms in **1**, for thirteen C atoms in **4**, and for two C atoms and two ligand Si atoms in **5**. Figure 3 shows a detail of a part of **5** containing one such ligand (Si51, C51, and C52). However, the same figure reveals that the neighbouring ligand (Si41, C41, and C42) does not exhibit unusually large anisotropic displacement parameters.

This indicates atom site disorder, which is individually different for the various ligands and, therefore, cannot be a consequence of a rigid body motion of the whole molecule.

The $OSiMe_3$ groups in **1** are found to be disordered (Figure 4); this may explain why other researchers did not succeed in determining an accurate molecular structure.[21]

The highest degree of disorder in all the crystal structures reported in this paper was observed for compound **2**. Here, a split-atom model had to be introduced in order to permit refinement of the atomic positions of all the ligands. Figure 5 shows the superposition structure of **2** about the threefold axis, with each atom site one-third occupied for reasons of symmetry. The ligands at the other corners of the cube are also strongly disordered, but are not subject to any symmetry constraints.

Inspection of the data in Table 2 reveals that **1** and **4** have significantly lower densities than the other silsesquioxanes **2**, **3**, and **5**. In contrast to the other compounds, **1** and **4** have exclusively methyl groups as their outer ligands, which may be a reason for their loose crystal packings.

From the crystal-structure analysis of **5**, it can be seen that at temperatures as low as 200 K (measuring temperature) the whole molecule can be regarded as an asymmetrical unit, with ten crystallographically independent silicon sites making up the core subunit (Figure 6). Notably, in the solid-state ^{29}Si-MAS-NMR spectrum (Figure 7) of the

[a] Weight loss in open-pan measurements due to sublimation of the compound; measurement up to 300 °C with a 10 °C min^{-1} heating rate.

sample, only two rather than twenty signals appear at ambient temperature, one for the siloxy groups and one upfield-shifted signal for the carbosiloxy groups, indicating the magnetic equivalence of the individual silicon atoms within the two sets of silicon sites.[31]

A better ordering and relative orientation of the silsesquioxanes is achieved by the introduction of vinyl groups into the peripheral silyl substituents at the Si−O core, as exemplified by the crystal structure analysis of **3**. A stereo plot illustrates the interlocking of the vinyl groups (Figure 8).

The findings of (i) the disorder in **1** and **2**, and (ii) the discrepancy between the results of the ^{29}Si-MAS-NMR-spectrometric investigations and of the X-ray analysis of **5** prompted us to measure the DSC curves of the siloxysilsesquioxanes. The results are summarized in Table 3.

Compound **5** shows low-temperature phase transitions (Figure 9). Thus, the differences between the ^{29}Si-MAS-

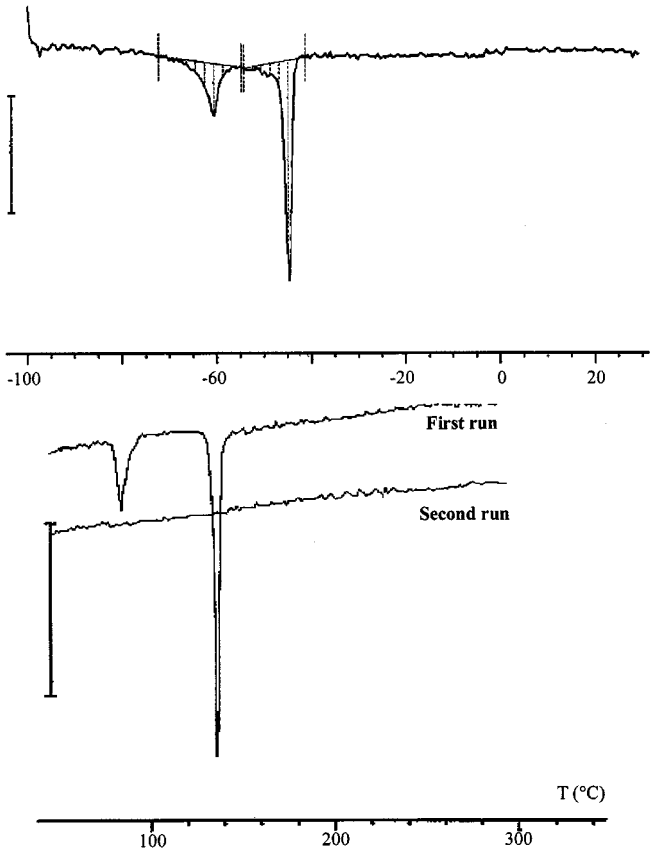

Figure 9. DSC traces of **5** from −100°C to 30°C (vertical bar 0.1 Wg^{-1}; 2°C min^{-1}) and from 30°C to 300°C (top trace; 10°C min^{-1}), repetition with same sample (bottom trace; vertical bar 0.2 Wg^{-1})

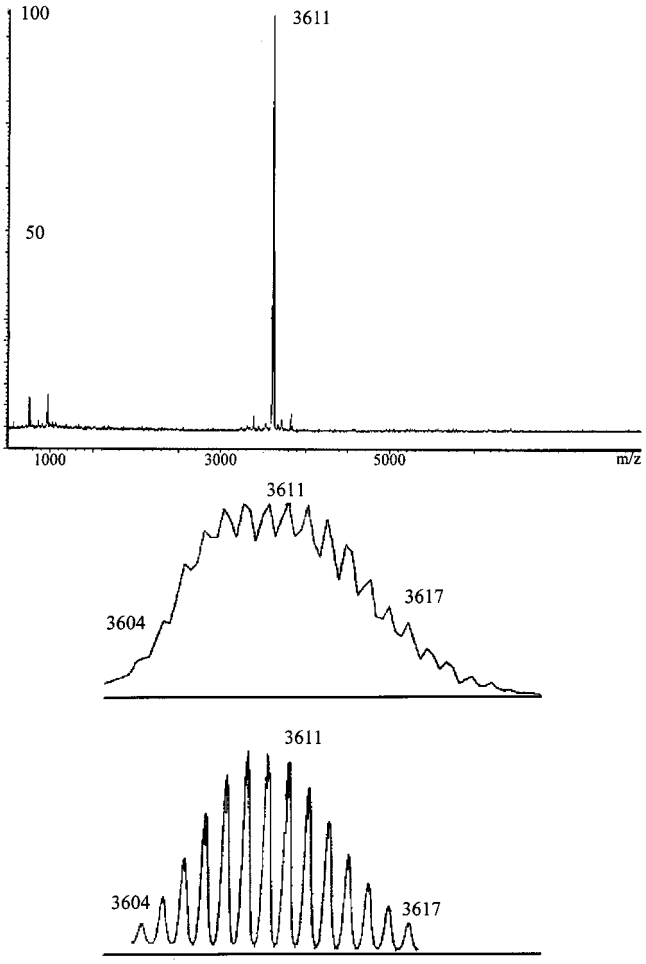

Figure 10. MALDI-TOF mass spectrum of $[(M_3Q)DQ]_8$ (**6**) at *m/z* = 3611; insert shows measured and calculated spectrum from *m/z* = 3604 to 3620

NMR results and the X-ray crystallography analysis are understandable: While at low temperatures a highly asymmetric modification is stable, at room temperature a much more symmetric arrangement is energetically favoured. Another interesting feature is the low melting point of **5**, which is more than 100°C lower than those of the other studied silsesquioxanes.

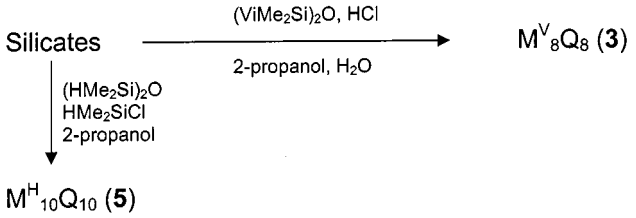
Silsesquioxanes bearing peripheral reactive groups undergo reaction when heated. In particular, **5** reacts completely to form an amorphous glass, which no longer shows any prominent peaks in a subsequent DSC run. ^{29}Si-NMR studies on a sample heated to 220°C under exclusion of air for 4 h show the formation of $HSiO_{3/2}$ and $Me_2SiO_{2/2}$ groups.

X-ray powder-diffraction experiments were utilized to investigate the nature of two-phase transitions in **1** and **5**.

The diffraction pattern of **1** breaks down at 200°C. This temperature is in good accord with the phase transition at 199°C detected by DSC. Simultaneously, **1** begins to decompose and/or to sublime. This behaviour may be explained in terms of the well-known Hedvall effect.[32] The diffraction pattern of **5** changes at 80°C (upwards) and reversibly at 40°C (downwards). The high-temperature modification obtained shows a sharp diffraction pattern on the Guinier photograph, but despite this it could not be indexed for a unit-cell determination. A single crystal of **5** heated to 90°C on a STOE IPDS diffractometer crumbled to a powder, indicating that no topotactic relationship exists between the low- and high-temperature modification.

In addition to structural investigations, compounds **1**−**5** were also characterized by mass-spectrometric methods. Simultaneously, the applicability of the siloxysilsequioxanes as mass standards for **M**atrix-**A**ssisted **L**aser **D**esorption **I**onisation/**T**ime **o**f **F**light (MALDI-TOF) mass spectrometry was investigated (Table 4). Despite the expected high stabilities of the siloxanes, fragmentation and reaction with matrix components was found in some cases. **1** and **2** were found to be contaminated by Q_6M_6[33]; the H-siloxanes reacted with the acidic matrix and showed quite extensive decomposition and fragmentation under the experimental conditions. The excellent result for **3** is not surprising in view of the well-known coordination of carbon−carbon multiple bonds to silver ions. Quite astonishing, however, is the clean spectrum of **6** (Figure 10).[34]

Experimental Section



General: Compounds **1**−**6** were prepared according to known literature procedures[35] by treating freshly precipitated silicic acid

Table 4. Results of MALDI-TOF mass spectrometry

Compound	Fragmentation[a]	Molecular ion[a]
1 Q_8M_8	771 (85%): Q_6M_6 − Me_3Si; 1165 (100%): Q_8M_8 − $SiMe_2CH_2$	1237 (77%)
2 $M^H{}_8Q_8$	1253 (100%): $M^H{}_8Q_8$ − H + O-octyl; 3 others below 20%, "noise" ca. 5%	1125 (37%)

[a] Ag^+ adducts.

with tetramethylammonium hydroxide to form the cyclic octasilicate $[(NMe_4)^+]_8[Si_8O_{20}]$. From the condensation reaction of $Si(OEt)_4$ with tetrabutylammonium hydroxide/H_2O, the decasilicates were obtained. Subsequent treatment of these silicates with mixtures of the corresponding disiloxanes and chlorosilanes or HCl in 2-propanol solution, furnished the octasiloxy- or decasiloxy-substituted silsesquioxanes **1**−**6** in good yields. The representative syntheses of compounds **3** and **5** are depicted in Scheme 1.

Scheme 1. Syntheses of siloxysilsesquioxanes

The crystalline products thus obtained were recrystallized from CH_2Cl_2/CH_3CN (1:1) by slow evaporation of the solvents at 25°C. Purities were checked by ^{1}H-, ^{13}C-, and ^{29}Si-NMR spectroscopy in $CDCl_3$ solution.

MALDI-TOF: 10 mg of the sample was dissolved in 1 mL of THF. The matrix solution was made up from 10 mg of 2-nitrophenyl octyl ether in 1 mL of acetone, to which 10 μL of 0.1% trifluoroacetic acid had been added. To assist the ionization, a 0.01 M solution of silver trifluoroacetate in acetone was used. The thin-layer technique was used for sample preparation: 0.5-μL aliquots of the matrix, silver salt, and sample solutions were successively applied. The spectra thus showed the silver adducts. External calibration was carried out with a peptide mixture (substance P and insulin). The mass accuracy was ±1 Da; the masses were rounded to integral numbers.

DSC and TGA measurements were carried out using a Netzsch STA 429 apparatus.

IR and Raman spectra correspond to literature data.[36] Vibrations due to the siloxane framework are assigned as follows (vibrations of organic functional groups are omitted). − IR: 1252−1257 cm^{-1} (s, δ_s Si−CH_3), 1074−1098 (vs, ν_{as} Si−O−Si), 755, 844, 868 (s, δ_s Me−Si−O in **1**, **4**, and **6**), 772, 838 (s, δ_s Me−Si−O in **2** and **5**), 621 (m), 559−522 (several s, ν_s Si−O−Si), 901 (s, δ O−Si−H in **2** and **5**). − Raman: Strongest bands at 2902−2912 cm^{-1} (vs, ν CH_3) and 2963−2971 (s, ν CH_3), and at 608−652 (vs, ν_s Si−O−Si); other bands: 1410−1412 (w, δ C−H), 692 (w, ν_s Si−O−Si), several below 420 (w to m, δ O−Si−O); 3057, 1597, 1274, 786 attributable to −CH=CH_2 in **3**; 474 (ν_s Si−O−Si) in **6**.

Crystal-Structure Determination: Single crystals of compounds **1** and **4** were examined with a four-circle diffractometer (STOE; STADI4) at room temperature in air. Single crystals of compounds **2**, **3**, and **5** were examined with a one-circle diffractometer equipped with an imaging plate area detector (STOE; IPDS) at 200 K under nitrogen. Intensity data were corrected for Lorentz and polarization effects and in the case of **4** an absorption correction had to be applied (ψ-scan technique[37]) since a crystal of rather anisotropic habit was used for the data collection. The structures were solved by direct methods[38] and refined by full-matrix least-squares techniques against F^2.[39] The thermal motion of all non-hydrogen atoms, better described in terms of atomic displacement parameters (adp′s) in the present structures, was treated anisotropically. All hydrogen atoms were calculated in idealized positions and allowed to ride on their corresponding carbon atoms. Their isotropic thermal parameters were set at 1.2 times that of the adjacent C atom. Crystallographic data (excluding structure factors) for the crystal structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101329. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. High-temperature X-ray diffraction on powders of **1** and **5**, representing structure types M_8Q_8 and $M_{10}Q_{10}$, respectively, were carried out with a Nonius Guinier-Lenné camera. The powders were prepared on a platinum gauze and heated to temperatures below their melting points in air or under nitrogen.

Silaheterocycles, 35[+]

Carbon=Carbon Hydrogenation of Silicon-Functionalized Silaheterocycles

Norbert Auner,*[a] Hans-Uwe Steinberger,[b] and Bernhard Herrschaft[a]

Dedicated to Prof. Dr. Drs. h.c. Hans Bock on the occasion of his 70th birthday

Keywords: Silanorbornenes / Silanorbornanes / Silicon-functionalized olefins / Silacyclobutanes / Hydrogenations / Heterocycles

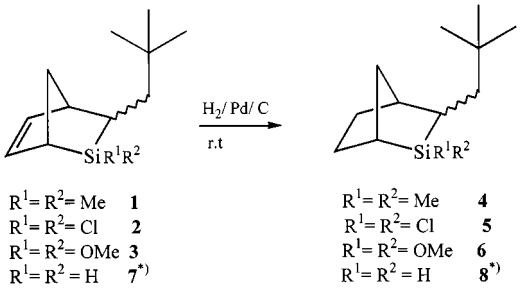
Catalytic hydrogenation of olefins containing functionalized silicon groups affords the saturated products in good yields. Chloro and alkoxy substituents at the silicon atom remain unaffected and, in the case of heterocyclic compounds, the cyclic or bicyclic moieties remain intact. The 2-silanorbornanes **4**, **5**, and **6** were synthesized from the corresponding 2-silanorbornenes **1**, **2**, and **3**, and organosilanes **13** and **14** possessing the cyclopentyl group, were prepared from the cyclopentenyl-substituted precursors **10** and **12**. The 3-vinyl-substituted silacyclobutanes **15**, **17**, and **18** were also hydrogenated in a simple apparatus with diethyl ether or THF as solvent, and Pd/C as a recoverable catalyst system. A basic organosilicon compound, trichloro(vinyl)silane, is hydrogenated in a nearly quantitative yield to form the saturated trichloro(ethyl)silane; this emphasizes the general applicability of this method.

Introduction

Vinylsilanes are of great importance in organosilicon chemistry both for academic research and industrial applications.[2] This class of compounds[3] is available by large-scale processes (such as the cleveage of disilanes by vinylic chlorides,[4] the hydrosilylation of conjugated dienes or acetylenic derivatives,[5] and the thermal condensation of chlorohydridosilanes with vinylic chlorides[6]) and it′s members are commonly used as starting materials for the production of silicon-based polymers, the hydrosilylation reaction being widely used to crosslink silicon and carbon moieties.[2] Particularly in polymerization reactions, the defunctionalization of vinyl groups, directly attached to silicon centers or bound to carbon atoms in the polymeric backbone, is of importance in controlling the molecular mass or in preventing polymerization taking place. In this respect the hydrogenation of the vinylic unit could be a valuable method, but the reaction has to be very selective, forming the corresponding saturated derivatives in high yield, even in the presence of other functional groups, such as chlorine or alkoxy, at the silicon atom. In general, the direct synthesis of chloro(ethyl)silanes results in a complex mixture of differently substituted products with low yields.[7] Using catalysts for the hydrogenation of vinylsilanes the application is restricted to nonhalogenated derivatives, since the catalyst (e.g. Adam′s platinum or Raney′s nickel[8]) can affect the chlorine function or can be deactivated. Only Dunogues has reported on an efficient method using nickel chloride/triethylsilane as a catalyst,[9] but this method does not seem very practical for large-scale syntheses.[10] This paper reports on a synthetic route to transform unsaturated carbon−carbon moieties of organosilicon compounds into their corresponding saturated derivatives by use of Pd/C as a catalyst for a heterogeneous catalytic hydrogenation. This combination is well known to be cheap, easily available, and most effective in organic chemistry.[11] For these very basic studies we synthesized a series of silyl-functionalized silaheterocycles as model compounds containing both endo- or exocyclic vinyl subunits.[12] Carrying out the hydrogenation reactions, the chloro and alkoxy functionalities at the silicon atom and the cyclic carbon skeletons are preserved.

Results and Discussion

The hydrogenation of carbon−carbon doubly bonded moieties is technologically a very important reaction[13] and requires the activation of molecular hydrogen and/or the unsaturated substrates by catalysts.[14] Heterogeneous hydrogenation uses Ni, Pd, Pt, and Rh metals supported on activated carbon, silica, aluminium oxides, and barium sulfate as catalysts.[15]



For the hydrogenation of a series of silaheterocycles Pd/C was used as a catalyst at room temperature in ether or THF as solvent. Starting from the 2-silanorbornenes **1**, and **2** (which were synthesized by the reaction of chlorodimethyl-(vinyl)silane,[16] trichloro(vinyl)silane,[17] and *tert*-butyllithium in the presence of cyclopentadiene) and from **3**, which

is easily available from **2** by a substitution reaction,[18] the corresponding 2-silanorbornanes are accessible in a yield of about 90% (after distillation) (see Scheme 1). The products were fully characterized by NMR and MS methods. In order to facilitate the NMR-spectroscopic assignments a semipreparative gas-chromatographic separation of the *exo*/*endo* diastereoisomers **4** was carried out (see Experimental Section).

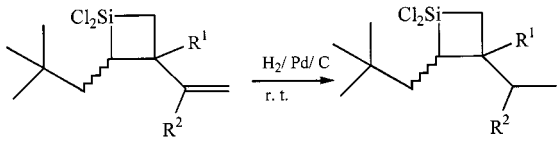
Scheme 1. Synthesis of silanorbornanes from silanorbornenes; *) formation of polymeric products from hydrosilylation

Surprisingly, hydrogenation of the *Si*-dihydro-substituted silanorbornene (**7**), which is available from **2** and $LiAlH_4$,[17] failed. Instead hydrosilylation took place, giving polymeric products, which have not been characterized in detail. Alternatively, the parent dihydro-substituted silanorbornane **8** can be synthesized from **5** by the use of $LiAlH_4$ as a reducing agent.

The hydrogenation reactions described in Scheme 1 provide another route for the synthesis of 2-silanorbornane skeletons: These bicyclic compounds are also available from both, the intramolecular hydrosilylation reaction of cyclopentenyl-substituted silanes $C_5H_7CH(HSiR_2)CH_2tBu$[18] and the reaction of the latter with catalytic amounts of trityl tetrakis(pentafluorophenyl)borate via the intermediacy of a silanorbornyl cation.[19][20] Furthermore, a carbon-functionalized 2-silanorbornane is easily available from silanorbornene **2** by the addition of hydrogen chloride to the carbon−carbon double bond.[18]

In contrast to compound **2**, the 2-silanorbornenes **1** and **3** do not add hydrogen chloride, but an allylic cleavage gives the cyclopentenyl-substituted chloro(organo)silanes **9**, and **11**.[18] The organo-substituted derivatives **10** and **12** were synthesized by the reactions of the chlorosilane precursors **9** and **11**, respectively, with fluorenyllithium and a 1-naphthyl Grignard reagent (see Scheme 2). After recrystallisation of **10** from ether/pentane (1:5), suitable single crystals were obtained for X-ray crystal analysis.



R= Me **9**

R= OMe, R^3= 1- naphthyl **12, 14**

Scheme 2. Synthesis of cyclopentane-substituted organosilanes

Notably, the hydrogenation of the cyclopentenyl derivatives **10** and **12** gives the corresponding cyclopentane-substituted compounds **13** and **14** in high yields (**13**: 88%; **14**: 82%).

In order to prove the utility of the hydrogenation reaction for exocyclic vinyl groups, 1,1-dichloro-3-vinyl-1-silacyclobutanes **15**, **17**, and **18** were chosen as model compounds. These compounds are easily prepared by the reaction of trichloro(vinyl)silane, Li*t*Bu, and isoprene (**17**, **18** isomeric mixture) or 2,3-dimethylbutadiene (**15**).[21] The corresponding 3-ethyl-substituted derivatives **16**, and an isomeric product mixture of **19** and **20** were exclusively obtained from the catalyst-supported reaction at room temperature and were isolated in high yields (ca 75%) after distillation. The four-membered ring moieties remain stable and the same is true for the dichlorosilyl functionality (see Scheme 3).

Scheme 3. Synthesis of 3-ethyl-substituted silacyclobutanes from vinyl-substituted precursors

Molecular Structure of 10

The crude slightly yellow crystalline organosilane **10** was recrystallized from an *n*-pentane/ether (5:1) mixture; a single crystal was used for X-ray diffraction analysis. In the solid state **10** forms a 1:1 inclusion compound with acetaldehyde, which was obviously introduced by an impurity within the solvents used for recrystallization (see Figure 2). No exceptionally short intermolecular distances indicating the presence of strong intermolecular interactions between silane **10** and the solvent molecule are observed. The packing of the silane and the disordered solvent molecules in the crystal structure is as close as possible and no further potentially solvent accessible cavities are left. The silicon atom is tetrahedrally surrounded by four carbon atoms of two methyl groups, the 5-fluorenyl, and the (3-cyclopentenyl)-3,3-dimethylbutyl substituent. Although sterically demanding ligands are present in the molecule, the bond angle C14−Si−C15 (113.26°) beween the methyl groups is the largest one at the silicon center. The mean distance $Si-C_{Me}$ is slightly shorter (187 pm) than the $Si-C_{fluorenyl}$ and the $Si-C_{butyl}$ bond length (191 pm) (see Figure 1). The fluorenyl ligand is mutually planar within the accuracy achieved and the observed range for the C−C bond lengths is characteristic for aromatic hydrocarbons in the solid state. The cyclopentenyl substituent adopts an envelope conformation with a carbon−carbon bond length of 130.4 pm. Due to the packing in the crystal structure the orientation of the *tert*-butyl group is ideally staggered with respect to

the C22−C23 bond (torsion angles: 61.8°, 63.3°, and 179.8°).

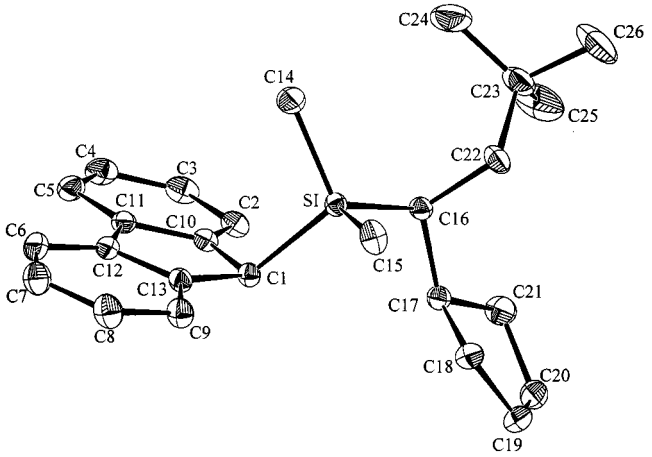

Figure 1. DIAMOND[22] drawing (30% envelopes) of 3-(3-cyclopentenyl)-2-fluorenyl-2,5,5-trimethyl-2-silahexane (**10**): Si−C1 191.41(14) pm, Si−C14 186.74(16), Si−C15 187.82(19), Si−C16 190.25(14); C14−Si−C15 106.85(9)°, C14−Si−C16 113.28(7), C15−Si−C16 111.16(7), C14−Si−C1 107.05(7), C15−Si−C1 109.78(7), C16−Si−C1 108.60(6)

Conclusion

The Pd/C-catalyzed hydrogenation of endo- and exocyclic carbon−carbon doubly bonded moieties occurs under mild conditions, e.g. one atmosphere of hydrogen pressure and at room temperature, in nearly quantitative yields. Functional groups at the silicon atom, e.g. chlorine, alkoxy, or aryl substituents are preserved, as well as the mono- or bicyclic carbosilane skeletons. No side products can be detected, the yields for the hydrogenated compounds given in Table 1 in the Experimental Section are those after distillation.

To prove the whole range of applicability and to show the limitations of the discussed synthetic method, an industrially (economically) important chloro(vinyl)silane was used as a starting compound for hydrogenation: Within 24 h trichloro(vinyl)silane was completely converted into the corresponding ethylsilane, $Cl_3SiCH_2CH_3$. From this finding we conclude that the reaction may be widely used for the synthesis of chloro(ethyl)silanes from their vinyl-substituted precursors. However, the method does not work when the C=C bond is strongly shielded by sterically demanding substituents. Thus, treating 1,1-dichloro-2,3-diphenyl-4-neopentyl-1-silacyclobutene,[23] under comparable conditions, no hydrogenation occurs to form a silacyclobutane; the silacyclobutene is completely recovered from the reaction mixture. Further studies to expand this method using different vinylsilanes and a variety of functional groups at the silicon atom are currently being carried out in our laboratories.

Experimental Section

General Remarks: All manipulations were performed under purified argon using standard Schlenk techniques. Solvents were dried by refluxing under nitrogen with the appropriate drying agent and were distilled prior before use. $CDCl_3$ was dried with molecular sieves, while [D_6]benzene was dried with potassium/sodium and distilled prior to NMR sample preparation. − NMR spectra: Bruker AM 300 (^{29}Si), DPX 300 (^{1}H, ^{13}C) and AMX 600 (^{1}H, ^{13}C), ^{1}H- and ^{13}C-NMR chemical shifts (δ) were internally referenced [δ(C*H*Cl_3) = 7.24, δ(*C*DCl_3) = 77.00, δ(C_6D_5*H*) = 7.15, δ(C_6D_6) = 128.00], ^{29}Si-NMR shifts were externally referenced to TMS. − GC/MS: Chrompack CP 9000 (capillary column CP-SIL/5CB-MS, diameter 0.25 mm, 12.5 m length) coupled with a Finnigan MAT Ion Trap Detector 800 (electron impact, space current 3000 μA, ionisation energy 70 eV, ion-source temperature 250°C), for chemical ionisation methanol was used. − Elemental analyses: Microanalytical Laboratory of the Department of Chemistry, Humboldt-University, Berlin. Trichloro(vinyl)- and chlorodimethyl(vinyl)-silane were distilled from sodium carbonate prior before use. *tert*-Butyllithium was used as a 1.7 M solution in pentane. All other chemicals were used as purchased by Aldrich and Fluka.

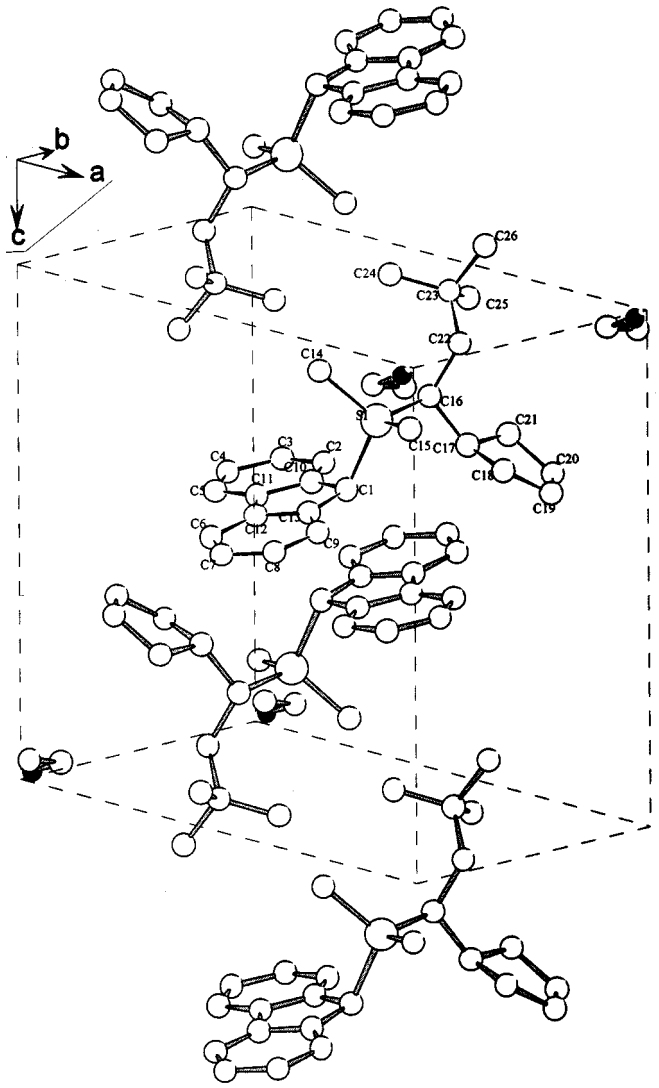

Figure 2. DIAMOND[22] representation of the crystal structure viewed along [100] showing the inclusion of acetaldehyde molecules

Hydrogenation Apparatus: A suitable reaction flask was connected to a set of two dropping funnels by a small glass tube. The two dropping funnels themselves were connected with a flexible tube

Table 1. Preparative details of the hydrogenation reactions

and filled with silicone oil as sealing fluid. Then the oil in the first dropping funnel was displaced by hydrogen. The volume was marked before the tap of the reaction flask was opened. During the hydrogenation reaction the amount of hydrogen consumed was monitored as change in volume. For a sketch of the hydrogenation apparatus described see ref.[24]

General Reaction Procedure: The carbon−carbon unsaturated silaheterocycles or the vinylsilanes were placed in the reaction flask of the hydrogenation apparatus described and dissolved in THF or diethyl ether. 250 mg of Pd/C (10% on activated carbon) were added. Then the reaction mixture was stirred and allowed to react with hydrogen for 16 h. The volume of gas consumed indicated the end of the reaction. The catalyst Pd/C was filtered off, the solvent removed under reduced pressure, and the products distilled for purification at 10^{-2} mbar (Table 1).

For a semipreparative gas-chromatographic separation of the *exo*-/*endo*-3-neopentyl diastereomers **4** a packed column (10% OV 101 on 80−100 mesh Chromosorb W, HO, DMCS) was used in a Chromatron gas chromatograph. The column temperature was 110°C (isotherm) and the flow rate was set to 3.6 L H_2/h. A heat conductivity cell (Chromatron) was used for detection. The purity of the separation had been checked with a capillary gas chromatogaph and was detected to be 98.5% (2,2-dimethyl-*exo*-3-neopentyl-2-silabicyclo[2.2.1]silaheptane) and 98.7% (2,2-dimethyl-*endo*-3-neopentyl-2-silabicyclo[2.2.1]silaheptane). For the assignment of the NMR-chemical shifts of the silanorbornanes **4**−**6** and **8** the atoms are numbered as shown by the formula in Scheme 4.

Scheme 4. Numbering scheme for **4**−**6** and **8**

2,2-Dimethyl-*exo*-3-neopentyl-2-silabicyclo[2.2.1]silaheptane (*exo*-4): ^{1}H NMR (600 MHz, $CDCl_3$): δ = 0.07 (s, 3 H, $SiCH_{3\ endo}$), 0.13 (s, 3 H, $SiCH_{3\ exo}$), 0.45 (m, 1 H, 3-H), 0.95 [s, 9 H, $C(CH_3)_3$], 1.21 (dddd, $^2J_{5x/5e}$ = 12.2 Hz, $^3J_{5x/6e}$ = 6.0 Hz, $^3J_{5x/6x}$ = 8.3 Hz, $^4J_{5x/7s}$ = 1.8 Hz, 1 H, 5x-H), 1.25 (dd, $^2J_{HH}$ = 13.8 Hz, $^3J_{HH}$ = 4.6 Hz, 1 H, CH_aH_btBu), 1.26 (m, 1 H, 1-H), 1.47 (dddd, $^2J_{7a/7s}$ = 10.8 Hz, $^3J_{7a/1}$ = 2.8 Hz, $^3J_{7a/4}$ = 2.8 Hz, $^4J_{7a/3}$ = 2.9 Hz, 1 H, 7a-H), 1.50 (dd, $^2J_{HH}$ = 13.8 Hz, $^3J_{HH}$ = 6.8 Hz, 1 H, CH_aH_btBu), 1.60 (d, br., $^2J_{HH}$ = 10.8 Hz, 1 H, 7s-H), 1.63 (m, 1 H, 6x-H), 1.68 (dddd, $^2J_{6e/6x}$ = 12.0 Hz, $^3J_{6e/1}$ = 5.9 Hz, $^3J_{6e/5e}$ = 12.0 Hz, $^3J_{6e/5x}$ = 6.0 Hz, 1 H, 6e-H), 1.78 (dddd, $^2J_{5e/5x}$ = 12.2 Hz, $^3J_{5e/6e}$ = 12.0 Hz, $^3J_{5e/6x}$/$^3J_{5e/4}$ = 6.0, 4.0 Hz, 1 H, 5e-H), 2.15 (s, br., 1 H, 4-H). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 47.11 (C-4), 46.28 (C-8), 36.36 (C-7), 31.51 (C-9), 31.53 (C-5), 23.85 (C-6), 29.76 (C-10), 29.35 (C-1), 24.23 C-3), −4.21 [$SiCH_3$ (*exo*)], −4.35 [$SiCH_3$ (*endo*)]. − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = 10.20. − MS (70 eV); *m*/*z* (%): 210 (0) [M^+], 153 (74.73) [$M^+ - t$Bu], 125 (98.91), 59 (100), 57 (33.15) [tBu$^+$].

Synthesis of *exolendo*-3-Neopentyl-2-silabicyclo[2.2.1]silaheptane (*exolendo*-8): 1.61 g (42.34 mmol) of $LiAlH_4$ and 80 mL of diethyl ether were placed in a flask. The suspension was cooled to 0°C and 5.32 g (21.17 mmol) of **5** added dropwise. The reaction mixture was heated under reflux for 5 h. The solvent was removed by evaporation in vacuo. The product was then extracted with 60 mL of *n*-pentane, excess lithium alanate filtered off, and washed with pentane (2 × 10−15 mL). After removing the solvent, the mixture was distilled at 10^{-2} mbar to give 3.40 g of **8** (88%). The product is a colourless, viscous liquid; b.p. 67°C/10^{-2} mbar.

***exo*-8:** ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.77 (m, 1 H, 3-H), 0.90 (s, 9 H, CH_2tBu), 1.15 (m, 1 H, 5x-H), 1.57 (m, 1 H, 1-H), 1.41 (m, 1 H, 7a-H), 1.41 (dd, $^2J_{HH}$ = 13.9 Hz, $^3J_{HH}$ = 3.7 Hz, 1 H, CH_aH_btBu), 1.45 (m, 1 H, 6x-H), 1.46 (dd, $^2J_{HH}$ = 13.9 Hz, $^3J_{HH}$ = 5.5 Hz, 1 H, CH_aH_btBu), 1.49 (m, 1 H, 7s-H), 1.64 (m, 1 H, 6e-H), 1.65 (m, 1 H, 5e-H), 2.16 (s, br., 4-H), 3.36 [dm, $^2J_{HH}$ = 11.9 Hz, 1 H, SiH (*exo*)], 3.78 [dm, $^2J_{HH}$ = 11.9 Hz, 1 H, SiH (*endo*)]. − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 49.02 (C-8), 45.44 (C-4), 35.88 (C-7), 31.87 (C-9), 31.11 (C-5), 29.77 (C-10), 24.74 (C-6), 24.32 (C-1), 20.98 (C-3). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = −10.23 ($^1J_{SiH}$ = 203 Hz). − MS (70 eV); *m/z* (%): 181 (3.16) [M^+ − H], 125 (38.14) [$M^+ - t$Bu], 97 (100), 57 (23.00) [tBu$^+$].

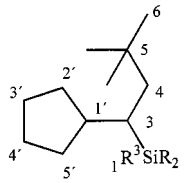
Synthesis of 3-(3-Cyclopentenyl)-2-fluorenyl-2,5,5-trimethyl-2-silahexane (10): Fluorenyllithium was synthesized by the dropwise addition of 7.8 mL *n*BuLi (1.7 M in hexane) to a solution of 2.12 g (12.77 mmol) of fluorene in 40 mL of *n*-pentane and 10 mL of diethyl ether at 0°C. The yellow precipitate was stirred vigorously for 1 h and then 2.12 g (12.77 mmol) of **9** was added slowly. After stirring for 1 h, the solution was filtered off from LiCl. The solvent was removed in vacuo and **10** was isolated as a crude (slightly yellow) crystalline solid. After recrystallisation from pentane/ether (5:1), a white solid was obtained [yield: 3.01 g (63%)]; m.p. 57°C. For the assignment of the NMR chemical shifts in **10** the atoms are numbered as expressed by the formula in Scheme 5. − ^{1}H NMR ($CDCl_3$): δ = −0.12 (s, 3 H, $SiCH_3$); 0.07 (s, 3 H, $SiCH_3$); 0.96 (s, 9 H, CH_2tBu), 1.21−1.52 (m, 3 H, CH_2tBu and C*H*−Si), 2.24−2.38 [m, 2 H, CH_2 (cyclopentenyl)], 2.42−2.58 [m, 2 H, CH_2 (cyclopentenyl)], 2.77 [m, 1 H, CH (cyclopentenyl)], 4.11 [s, br., 1 H, aliphatic CH group (fluorenyl)], 5.82 (s, br., 2 H, 2 CH olefin.), 7.43−7.46 (m, 4 H, 4 aromatic CH groups), 7.68 (m, 2 H, aromat.), 7.96 (m, 2 H, aromat.). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 130.78 (C-3′), 130.78 (C-4′), 41.90 (C-1′), 41.25 (C-4), 40.71 [C-7′′ (fluorenyl)], 38.29, 38.21 (C-2′/C-5′), 31.67 (C-5), 30.53 (C-6), 23.11 (C-3), −3.01, 3.01 (C-1/$SiCH_3$). − **10** has 12 diastereotopic aromatic carbon atoms, their ^{13}C-chemical shifts are: δ = 146.26, 146.01, 140.84, 140.79 (4 C_q, fluorenyl), 126.06 (CH intensity 2), 125.40 (CH intensity 2), 120.06 (CH intensity 2), 124.33, 124.26 (in total 8 aromatic CH groups). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = 8.27. − MS(CI); *m/z* (%): 375 (0) [(M + 1)$^+$], 358 (31.00) [$M^+ - CH_4$], 209 (100) [$M^+ - C_{13}H_9$ (fluorenyl)], 165 (22.54) [$C_{13}H_9^+$ (fluorenyl)], 194 (8.19) [$M^+ - CH_3 - C_{13}H_9$], 223 (27.26) [$SiMe_2$fluorenyl$^+$]. − $C_{26}H_{34}Si$ (374.644): calcd. C 83.36, H 9.15; found C 80.94, H 10.25.

Scheme 5. Numbering scheme of **10** and **12**

X-ray Structure Determination of 10: The single crystal was mounted on the glass fibre tip, glued with silicone grease (Wacker AG, FRG), and transfered to the goniometer. The crystal was cooled to 180 K (Oxford Cryo Stream, UK) for all subsequent manipulations. The data collection was performed by means of a four-circle diffractometer (Stoe Stadi4, Darmstadt, FRG) equipped with a fine focus sealed X-ray tube (Mo-K_α radiation, 50 kV, 35 mA), a graphite monochromator and an eulerian cradle. The initial lattice constants were determined by indexing 16 accurately centered, independant reflections (15° < 2Θ < 25°). The initial orientation matrix was refined by centering 32 strong reflections measured at large angles in 2Θ (35° < 2Θ < 45°). To obtain accurately scaled raw intensities, the intensity data collection (3° < 2Θ < 60°) was monitored by the repeated (every 12 h) measurement of three medium strong control reflections taken from the strong reflection set found. 7403 reflections were collected and corrected for Lorentz and polarisation effects. To refine the lattice constants 13 large angle reflections (45° < 2Θ < 49°) were recentered to estimate the final lattice constants. The atom form factors[25] were implemented in the used program system. The crystal structure was solved by Direct Methods (SHELXS86).[26] After two cycles of difference



Fourier syntheses and subsequent full-matrix least-squares refinement (SHELXL93)[27] the structure model was complete. All non-hydrogen atoms were assigned as anisotropic, no absortion or extinction correction was done. 20 reflections seemed to be disturbed by a strong extinction and were therefore excluded from the refinement calculations. Hydrogen atoms were calculated in their ideal positions and allowed to ride on their pivot atom. Further details of the crystal structure analysis are given in Table 2. Crystallographic data (excluding structural factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-103265. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

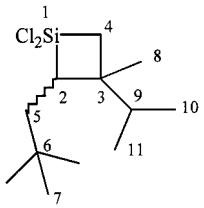
Largest diff. peak and hole [eÅ^{-3}]	0.725 and −0.578

Synthesis of 2-(3-Cyclopentenyl)-1,1-dimethoxy-4,4-dimethyl-1-naphthyl-1-silapentane (12): 570 mg (13.10 mmol, 30% excess) of magnesium and 150 mL of diethyl ether were placed into a 250-mL 3-necked flask with a dropping funnel and a reflux condenser. 4.94 mL (13.10 mmol, 30% excess) of 1-bromonaphthalene was added dropwise. The mixture was refluxed for 3 h. After cooling to room temperature, 3.04 g (10.08 mmol) of **11** was slowly added. The reaction mixture was then refluxed for 2 h. The solvent was removed in vacuo, the residue dissolved in 50 mL of pentane, and the magnesium salts were filtered off and extracted with pentane (2 × 15 mL). After removing the solvent, **12** (2.30 g) was isolated as a slightly yellow viscous oil (57%). For the assignment of the NMR chemical shifts the atoms are numbered as expressed by the formula in Scheme 5. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.03 (s, 9 H, CH_2tBu), 1.07−1.25 (m, 1 H, CHSi), 1.58 (dd, $^2J_{HH}$ = 14.1 Hz, $^3J_{HH}$ = 5.1 Hz, 1 H, CH_aH$_b$tBu), 2.10 (dd, $^2J_{HH}$ = 14.1 Hz, $^3J_{HH}$ = 4.9 Hz, 1 H, CH$_a$$H_b$tBu), 2.40−2.46 [m, 2 H, CH_2 (cyclopentenyl)], 2.52−2.57 [m, 2 H, CH_2 (cyclopentenyl)], 2.74−2.84 [m, 1 H, CH (cyclopentenyl)], 3.81 (s, 3 H, $SiOCH_3$), 3.82 (s, 3 H, $SiOCH_3$), 5.78−5.80 (m, 2 H, 2 CH olefin.), 7.61−7.73 (m, 3 H, aromat.), 7.97−8.05 (m, 2 H, aromat.), 8.18−8.25 (d, $^3J_{HH}$ = 6.8 Hz, 1 H, aromat.), 8.61 (d, $^3J_{HH}$ = 8.4 Hz, 1 H, aromat.). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 130.71 (C-3′), 130.64 (C-4′), 51.37 ($SiOCH_3$), 51.02 ($SiOCH_3$), 40.41 (C-1′), 40.28 (C-3), 38.29 (C-2′), 37.86 (C-5′), 30.66 (C-4), 30.11 (C-5), 25.98 (C-2). − **12** contains 10 diastereotopic aromatic carbon atoms, their ^{13}C chemical shifts are: 137.37, 133.27, 132.49 (3 C_q); 136.30, 130.81, 129.12, 128.28, 126.27, 125.62, 125.29 (7 CH aromatic). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = −18.61. − MS (70 eV); *m/z* (%): 368 (2.65) [M^+], 337 (7.63) [$M^+ - OCH_3$], 241 (100) [$M^+ - C_{10}H_7$ (naphthyl)], 217 (18.80) [$Si(OCH_3)_2$naphthyl$^+$], 67 (6.25) [$C_5H_7^+$], 57 (26.16) [tBu$^+$]. − $C_{23}H_{32}SiO_2$ (368.59): calcd. C 74.95, H 8.75; found C 74.78, H 8.69.

3-Cyclopentyl-2-fluorenyl-2,5,5-trimethyl-2-silahexane (13): For the assignment of the NMR chemial shifts in **13** the atoms are numbered as expressed by the formula in Scheme 6. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = −0.42 (s, 3 H, $SiCH_3$), −0.06 (s, 3 H, $SiCH_3$), 0.80 (s, 9 H, CH_2tBu), 0.84−0.86 (m, 2 H), 1.10−1.33 (m, 5 H), 1.37−1.75 (m, 4 H), 1.97−2.03 [m, 1 H, CH (cyclopentyl)], 4.02 (s, 1 H, fluorenyl−CH), 7.27−7.35 (m, 4 H, aromatic), 7.54 (dm, J_{HH} = 6.8 Hz, 2 H, aromatic), 7.84 (dm, J_{HH} = 7.8 Hz, 2 H, aromatic). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 43.98 (fluorenyl−CH), 41.64 (C-1′), 40.83 (C-4), 32.60, 31.14 (C-2′/C-5′), 31.49 (C-5), 29.73 (C-6), 25.10, 24.48 (C-3′/C-4′), 21.89 (C-3), −3.26 ($SiCH_3$), −3.74 ($SiCH_3$). − Aromatic ^{13}C shifts: 146.16, 145.96, 140.70, 140.63 (4 C_q), 125.89 (intensity 2), 125.17 (intensity 2), 124.22, 124.17, 119.83 (intensity 2) (in total 8 CH aromatic). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = 8.43. − MS (70 eV); *m/z* (%): 376 (0) [M^+], 211 (26.05) [$M^+ - C_{13}H_9$ (fluorenyl)], 165 (33.33) [$C_{13}H_9^+$ (fluorenyl)], 73 (100), 67 (12.01) [$C_5H_7^+$], 59 (61.00), 57 (56.01) [tBu$^+$]. − $C_{26}H_{36}Si$ (376.66): calcd. C 82.91, H 9.63; found C 83.07, H 9.72.



Scheme 6. Numbering scheme of **13** and **14**

2-Cyclopentyl-1,1-dimethoxy-4,4-dimethyl-1-naphthylsilapentane (14): For the assignment of the NMR chemial shifts in **14** the atoms are numbered as expressed by the formula in Scheme 6. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.94 (s, 9 H, CH_2tBu), 1.02−1.08 (m, 1 H, CHSi), 1.28−1.68 (m, 6 H), 1.82−1.83 [m, 2 H, CH_2 (cyclopentyl)], 2.01−2.29 [m, 3 H, CH_2 and CH (cyclopentyl)], 3.73 (s, 3 H, $SiOCH_3$), 3.75 (s, 3 H, $SiOCH_3$), 7.49−7.66 (m, 3 H, aromat.), 7.87−7.95 (2 H, aromat.), 8.14−8.16 (d, $^3J_{HH}$ = 7.4 Hz, 1 H, aromat.), 8.55 (d, $^3J_{HH}$ = 8.1 Hz, 1 H, aromat.). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 50.73 ($SiOCH_3$), 50.31 ($SiOCH_3$), 42.82 (C-1′), 40.07 (C-3), 32.37, 31.17 (C-2′/C-5′), 31.53 (C-4), 29.49 (C-5), 25.00, 24.99 (C-3′/C-4′), 24.99 (C-2). − Aromatic ^{13}C shifts: 136.97, 133.13, 132.21 (3 C_q aromatic), 135.74, 130.26, 128.58, 127.74, 125.89, 125.08, 124.75 (in total 7 aromatic CH groups). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = −21.71. − MS (CI); *m/z* (%): 371 (1.81) [(M + 1)$^+$], 339 (75.81) [$M^+ - OCH_3$], 243 (100) [$M^+ - C_{10}H_7$ (naphthyl)], 128 (12.24) [$C_{10}H_8^+$], 57 (22.22) [tBu$^+$]. − $C_{23}H_{34}SiO_2$ (370.61): calcd. C 74.54, H 9.25; found C 74.39, H 9.13.

(*E*)-1,1-Dichloro-3-isopropyl-3-methyl-2-neopentyl-1-silacyclobutane (*E*-16): For the assignment of the NMR chemical shifts in **16** the atoms are numbered as expressed by the formula in Scheme 7. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.86−0.90 (m, 6 H, 10-H and 11-H), 0.91 [s, 9 H, C(CH_3)$_3$], 0.99 (s, 3 H, 8-H), 1.33 (dd, $^2J_{HH}$ =

13.2 Hz, $^3J_{HH}$ = 2.6 Hz, 1 H, CH_aH$_b$*t*Bu), 1.54 (m, 1 H, 4-H), 1.60 (dd, $^2J_{HH}$ = 13.2 Hz, $^3J_{HH}$ = 12.8 Hz, 1 H, CH$_a$$H_b$*t*Bu), 1.64 (m, 1 H, 9-H), 1.76 (m, 1 H, 4-H), 1.96 (dd, $^3J_{HH}$ = 12.8 Hz, $^3J_{HH}$ = 2.6 Hz, 1 H, 2-H). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 46.37 (C-2), 42.60 (C-6), 40.87 (C-3), 40.40 (C-9), 38.50 (C-4), 30.53 (C-10), 29.51 (C-11), 28.73 (C-4), 17.77 (C-7), 17.95 (C-8). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = 19.65.

Scheme 7. Numbering scheme of **16**, **19**, and **20**

(*Z*)-1,1-Dichloro-3-isopropyl-3-methyl-2-neopentyl-1-silacyclobutane (*Z*-16): ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.86−0.90 (m, 6 H, 10-H and 11-H), 0.90 [s, 9 H, C(CH_3)$_3$], 1.18 (s, 3 H, 8-H), 1.34 (m, 1 H, 9-H), 1.46 (dd, $^2J_{HH}$ = 13.6 Hz, $^3J_{HH}$ = 2.3 Hz, 1 H, CH_aH$_b$*t*Bu), 1.57 (m, 1 H, 4-H), 1.61(dd, $^2J_{HH}$ = 13.6 Hz, $^3J_{HH}$ = 12.6 Hz, 1 H, CH$_a$$H_b$*t*Bu), 1.88 (m, 1 H, 2-H), 2.14 (m, 1 H, 4-H). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 49.53 (C-2), 41.43 (C-3), 38.23 (C-9), 36.26 (C-4), 32.92 (C-6), 30.60 (C-10), 29.45 (C-11), 27.40 (C-5), 18.86 (C-8), 18.70 (C-7). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = 19.35. − MS (70 eV) of (***E*/*Z*)-16**; *m*/*z* (%): 266 (4.65), 268 (3.37), 270 (0.71) [M^+] (isotopic pattern $SiCl_2$), 251 (1.17), 253 (1.27) [$M^+ - CH_3$] (isotopic pattern $SiCl_2$), 235 (0.56) [M^+ − Cl], 209 (9.35)/211 (7.34) [M^+ − *t*Bu] (isotopic pattern $SiCl_2$). − $C_{12}H_{24}Cl_2Si$ (267.32): calcd. C 53.92, H 9.05, Cl 26.53; found C 53.95, H 10.29, Cl 26.04.

(*E*)-1,1-Dichloro-3-ethyl-3-methyl-2-neopentyl-1-silacyclobutane (*E*-19): Numbering of atoms in *E*-**19** see Scheme 7, 11 = H. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.84−0.89 (m, 3 H, 10-H), 0.91 [s, 9 H, C(CH_3)$_3$], 1.16 (s, 3 H, 8-H), 1.24 (dd, $^2J_{HH}$ = 13.2 Hz, $^3J_{HH}$ = 3.0 Hz, 1 H, CH_aH$_b$*t*Bu), 1.46 (m, 1 H, 9-H), 1.55 (m, 1 H, 4-H), 1.59 (m, 1 H, 9-H), 1.66 (dd, $^2J_{HH}$ = 13.2 Hz, $^3J_{HH}$ = 12.1 Hz, 1 H, CH$_a$$H_b$*t*Bu), 1.92 (m, 1 H, 4-H), 1.94 (dd, $^3J_{HH}$ = 12.1 Hz, $^3J_{HH}$ = 3.0 Hz, 1 H, 2-H). − ^{13}C NMR (75.40 MHz, $CDCl_3$): δ = 50.65 (C-2), 39.64 (C-8), 38.48 (C-3), 38.33 (C-4), 30.22 (C-9), 29.53 (C-10), 28.86 (C-5), 28.82 (C-6), 8.41 (C-7). − ^{29}Si NMR (59.25 MHz, $CDCl_3$): δ = 18.88.

Gold(I) Complexes with Amine Ligands, 4[+]

The Role of N–H···Cl Hydrogen Bonds in Gold(I) Complexes with Aliphatic Amine Ligands

Birte Ahrens,[a] Peter G. Jones,*[a] and Axel K. Fischer[b]

Keywords: Amines / Aurophilicity / Gold / Hydrogen bonds

Various gold(I) complexes of aliphatic amines have been prepared by the reaction of chloro(tetrahydrothiophene)-gold(I) with the respective amines. The stability of these complexes can be attributed partly to the formation of hydrogen bonds involving the N–H functions, and partly to aurophilic interactions. Analysis of these secondary contacts suggests an inverse correlation between lengths of aurophilic interactions and hydrogen bonds.

Introduction

Amine complexes of gold(I) have been little studied and are generally regarded as relatively unstable; this has been rationalized in terms of incompatibility of the soft metal centre with the hard nitrogen donor. Exceptions are furnished by complexes also involving a phosphane or similar ligand as a stabilising influence.[1] From previous studies of systems with solely amine or halide ligands only three structure types are known: (i) $[L_2Au^+][AuCl_2^-]$ (e.g. L = pyridine, 3-methylpyridine),[2][3] (ii) $[L_2Au^+]Cl^-$ (e.g. L = 4-hydroxymethyl-1,5-dimethylimidazole),[4] (iii) [LAuCl] (e.g. L = 2-methylpyridine, piperidine).[3][5] For the imine L = diphenylmethanimine, structures of type (i) and (iii) are known.[6] Type (ii) is also represented by the ammine complex $[(NH_3)_2Au^+]Br^-$.[7]

We have begun a more systematic study of gold(I) complexes with aliphatic amine ligands, generally bearing an N−H function, and have recently reported the structure of $[(pyrrolidine)_4Au_3Cl_3]$,[8] where structure types (ii) and (iii) were present in the same crystal.

Stabilising influences in gold(I) complexes tend to be provided by formally non-bonding Au···Au contacts (aurophilic interactions);[9] the role of hydrogen bonds is of course limited to those systems where suitable functional groups are available, but they have been shown to stabilise e.g. iminegold(I) complexes.[10] In $[(pyrrolidine)_4Au_3Cl_3]$ the Au···Au contacts were long and thus presumably weak [3.2041(7), 3.5834(4) Å],[8] whereas hydrogen bonds were more significant [N···Cl 3.179(6), 3.284(6) Å]. In [(piperidine)AuCl][5] similar Au···Au contacts were observed [Au···Au 3.301(5) Å], but hydrogen bonding was not commented upon, although it is in fact present in the form of bifurcated three-centre hydrogen bonds (Figure 1; N···Cl 3.346, 3.358 Å).

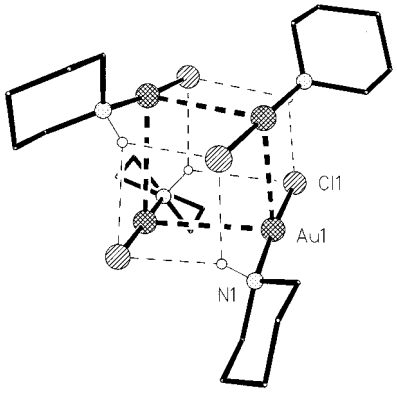

Figure 1. Chloro(piperidine)gold(I),[5] monomeric units related by a $\bar{4}$ axis; only the asymmetric unit is numbered; atom radii are arbitrary; dashed lines represent hydrogen bonds (thin) and aurophilic interactions (thick); carbon-bound hydrogen atoms are omitted for clarity

Here we report the synthesis of gold(I) complexes with the amine ligands piperidine {the complexes [(piperidine)AuCl], $[(piperidine)_2Au^+]Cl^-$, and $[(piperidine)_2Au^+]PF_6^-$ had been previously synthesised by us},[5] 2,2,6,6-tetramethylpiperidine, 4-methylpiperidine, morpholine, piperazine, pyrrolidine, diethylamine, dicyclohexylamine, cyclohexylamine, benzylamine, 1-phenylethylamine, and 3-iodobenzylamine; all complexes were obtained from (tht)AuCl (tht = tetrahydrothiophene) and the corresponding amine. With pyrrolidine, morpholine, cyclohexylamine, and benzylamine, complexes of empirical formula L_2AuCl were obtained; with the other ligands complexes of empirical formula LAuCl. For L = piperidine formerly only crystals of the loosely associated tetramer $(LAuCl)_4$ were obtained;[5] in contrast, we have only been able to obtain crystals of the ionic type $[L_2Au^+]Cl^-$. For L = pyrrolidine, we have now shown that the previously reported $L_4Au_3Cl_3$[8] is a by-product; the main product is $[L_2Au^+]Cl^-$.

No evidence was found for an ionic nature of the complexes in solution: all complexes behave as non-conductors

in acetone solution (Λ_c < 25 cm^2 Ω^{-1} mol^{-1}; c.f. Λ_c = 140 cm^2 Ω^{-1} mol^{-1} in the case of 1:1 electrolytes such as PPN^+Cl^-), implying that for all aminegold(I) complexes the molecular structure LAuCl is the more stable in solution. Even complexes L_2AuCl were essentially non-conducting, implying some equilibrium involving the uncharged species [LAuCl] in solution.

We have crystallographically characterised complexes of empirical formula LAuCl (L = 2,2,6,6-tetramethylpiperidine: **1**; dicyclohexylamine: **2**), both molecular in nature, and L_2AuCl (L = piperidine: **3**; pyrrolidine: **4**; and cyclohexylamine: **5**). For the latter complexes the ionic structure type (i), $[L_2Au^+]Cl^-$, was found for all three structures. Because no structure is known of a molecular aminegold(I) complex with empirical formula L_2AuX (i.e. where gold would be three-coordinate, with two amine ligands L), we assume an ionic composition for all aminegold(I) complexes of this empirical formula.

Because both types of structure, [LAuCl] and $[L_2Au^+]Cl^-$, have been observed for L = piperidine, it might be concluded that the energetic difference between both types cannot be large. Similar conclusions were drawn from the reactions of (tht)AuCl with methylpyridines,[3] and from ab initio calculations for various spatial associations of complexes with formula $[L_2Au^+][AuCl_2^-]$.[11]

Treatment of the new gold(I) complexes [LAuCl] (L = dicyclohexylamine) or $[L_2Au^+]Cl^-$ (L = piperidine or cyclohexylamine) with $AgSbF_6$ and excess L led in all cases to ionic complexes $[L_2Au^+]SbF_6^-$ (**13**, **14**, and **15**). Complex **13** was crystallographically characterised.

In all the new complexes hydrogen bonding is important in the solid state (Table 1), and for the ionic compounds appears more important than aurophilic interactions (see below). All complexes are less stable in solution than in the solid state. This could be attributed to a change in hydrogen bonding in solution, where the N−H protons are involved in hydrogen bonds to solvent molecules (in ^{1}H-NMR experiments broad signals for the N−H protons were observed, but no variation for the chemical shift). The low solubility of complexes with NH_2 functional groups could also be attributed to hydrogen bonding.

Molecular Structures

We have reported the structure of **2** in a preliminary communication.[12] The structure of **1** (Figure 2) is similar to that of **2** (Figure 3). Both complexes crystallise as loose molecular dimers $(LAuCl)_2$ and display ring motifs. In **1** and **2** only one crystallographically independent hydrogen bond is present, and therefore the ring motifs can be described by the graph set[13] $N_1 = R_2^2(8)$ at unitary level.

The dimers in **1** and **2** have inversion symmetry, making the N−Au−Cl axes antiparallel. Additionally, the molecule of **1** has crystallographic mirror symmetry, with N, Au, Cl, and C3 in the mirror plane. The gold atom in **1** is linearly coordinated [N−Au−Cl 177.21(9)°]. The Au−N and Au−Cl bond lengths of 2.088(3) and 2.2693(10) Å are

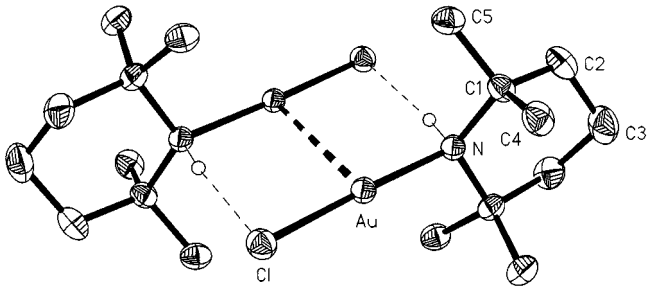

Figure 2. Chloro(2,2,6,6-tetramethylpiperidine)gold(I), **1**, monomeric units related by inversion symmetry; only the asymmetric unit is numbered; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds (thin) and aurophilic interactions (thick); carbon-bound hydrogen atoms are omitted for clarity

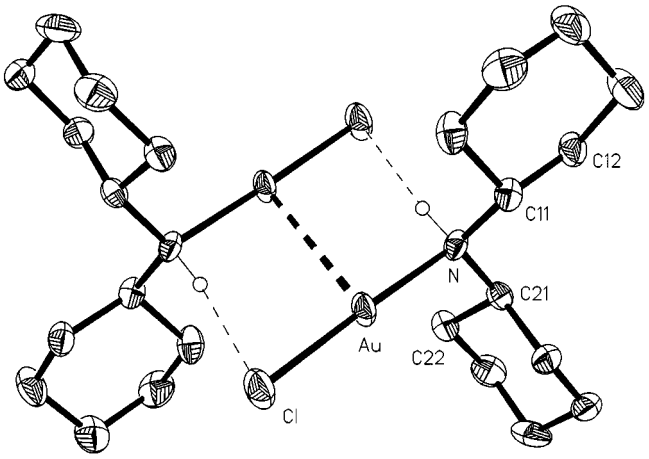

Figure 3. Chloro(dicyclohexylamine)gold(I), **2**, monomeric units related by inversion symmetry; only the asymmetric unit is numbered; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds (thin) and aurophilic interactions (thick); carbon-bound hydrogen atoms are omitted for clarity

longer than those in (piperidine)AuCl [2.068(18), 2.256(8) Å][5] but similar to those in **2** [2.077(7), 2.266(2) Å]. The dimers of **1** display aurophilic interaction and hydrogen bonding [Table 1; Au···Au 3.2792(4), N···Cl 3.417(3) Å], comparable to those in **2** [3.2676(14), 3.391(8) Å] and (piperidine)AuCl [3.301(5), 3.346 and 3.580 Å].[5]

Ionic Structures

We have reported the structure of **3** in a preliminary communication.[12] In **3** two crystallographically independent hydrogen bonds are involved in the ring motif (Table 1, Figure 4), which can be described by the graph set $N_2 = R_4^2(12)$ at binary level. In **3** the gold atom is linearly coordinated [N1−Au−N2 179.0(3)°]. The N−Au bond lengths of 2.050(6) and 2.055(6) Å are similar to those of 2.068(18) in (piperidine)AuCl.[5] Thus it can be assumed that the *trans* influence of amine and chloro groups is similar.

The hydrogen bonds (Table 1) in the ionic compound **3** are shorter [N···Cl 3.108(6), 3.122(7) Å] and the Au···Au distance in **3** of 4.085(2) Å is remarkably longer than in

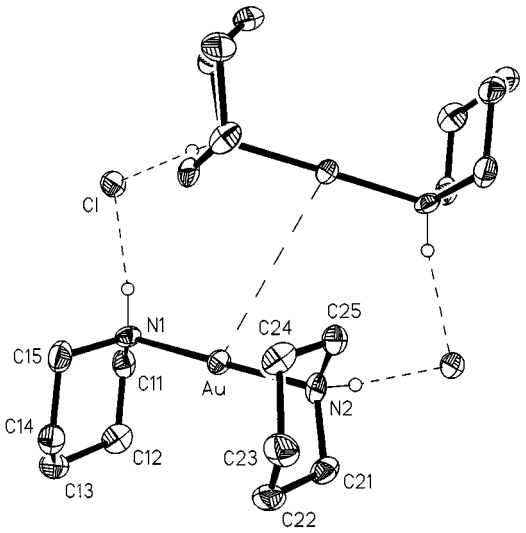

Figure 4. Bis(piperidine)gold(I) chloride, **3**, monomeric units related by a twofold axis; only the asymmetric unit is numbered; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds and aurophilic interactions; carbon-bound hydrogen atoms are omitted for clarity

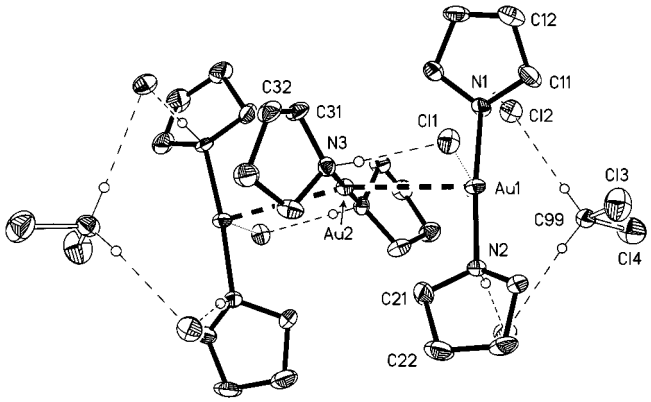

Figure 5. Bis(pyrrolidine)gold(I) chloride (dichloromethane solvate), **4**; only the asymmetric unit is numbered; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds (thin) and aurophilic interactions (thick), dotted lines Au···Cl interactions; carbon-bound hydrogen atoms are omitted for clarity

(piperidine)AuCl,[5] **1** and **2**. Gold−gold distances within the range of 2.50 to 4.00 Å have been considered as aurophilic interactions.[14] Thus the gold-gold interaction in **3** must be extremely weak.

Compounds **4** and **5** both crystallise as dichloromethane solvates $[(L_2AuCl)_3 \cdot (CH_2Cl_2)_2]$ with chain and layer structures. In **4** the L_2Au^+ cations (with L = pyrrolidine) form trimers about a twofold axis, with Au2 on this axis and Cl1 on an inversion centre (Figure 5). Both gold atoms of the asymmetric unit are linearly coordinated [N−Au−N 175.0(3), 179.6(4)°]. The Au−N bond lengths Au1−N1 of 2.055(7), Au1−N2 of 2.052(6), and Au2−N3 of 2.052(5) Å are slightly longer than those in $(pyrrolidine)_4Au_3Cl_3$ of 2.042(6) and 2.048(6) Å.[8] The gold atoms of the trimers in **4** display aurophilic interactions [Au1···Au2 3.2790(7) Å]. The N−Au−N axes within these dimers are nearly perpendicular to each other, with torsion angles of 87.3(3) and −93.2(3)° (N1−Au1···Au2−N3, N2−Au1···Au2−N3, respectively). The hydrogen atom at N3 is involved in a hydrogen bond to Cl1 [N3···Cl1 3.311(5) Å; Table 1]. This hydrogen bond connects the trimers to form chains parallel to (0 0 1) [descriptor $C_2^1(6)$; Figure 6], which are additionally stabilised by short Au···Cl contacts [Au1···Cl1 3.176(1) Å]. The hydrogen atoms at N1 and N2 are involved in hydrogen bonds to Cl2 [N1···Cl2 3.149(7), N2···Cl2′ 3186(7) Å; Table 1]. These hydrogen bonds connect the chains to form layers perpendicular to (0 0 1), with descriptor $C_2^1(6)$ at binary level (Figure 7). The dichloromethane molecules lie within these layers. They show non-conventional hydrogen bonding to the chloride anion Cl2 [C···Cl 3.625 Å (mean)]. One of the chlorine atoms of the dichloromethane molecules is involved in a weak contact to one of the gold atoms [Au1···Cl3 3.635(3) Å], the other chlorine atom displays a Cl···Cl contact to the symmetry-equivalent atom of the next dichloromethane moiety [Cl4···Cl4′ 3.547(5) Å; operator $1 - x, 1 - y, -z$]. The secondary contacts of the dichloromethane molecules result in a honeycomb-like pattern within the layers perpendicular to (0 0 1) (Figure 7). These contacts presumably have a stabilising influence on

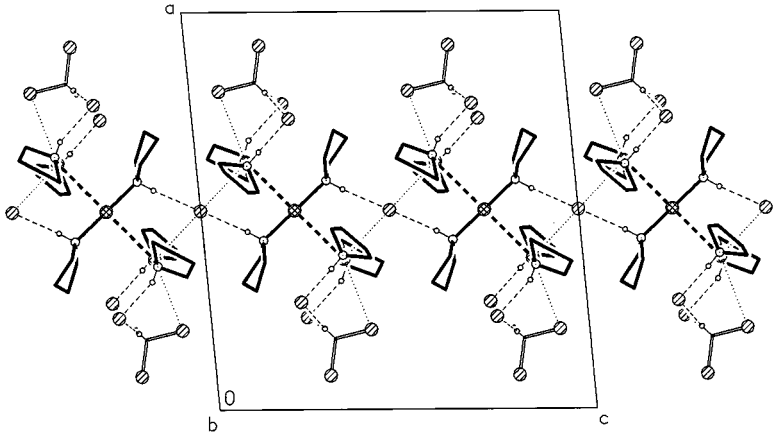

Figure 6. Bis(pyrrolidine)gold(I) chloride (dichloromethane solvate), **4**, chain structure parallel to (0 0 1); atom radii are arbitrary; dashed lines represent hydrogen bonds (thin) and aurophilic interactions (thick), dotted lines Au···Cl interactions; carbon-bound hydrogen atoms, except for CH_2Cl_2, are omitted for clarity

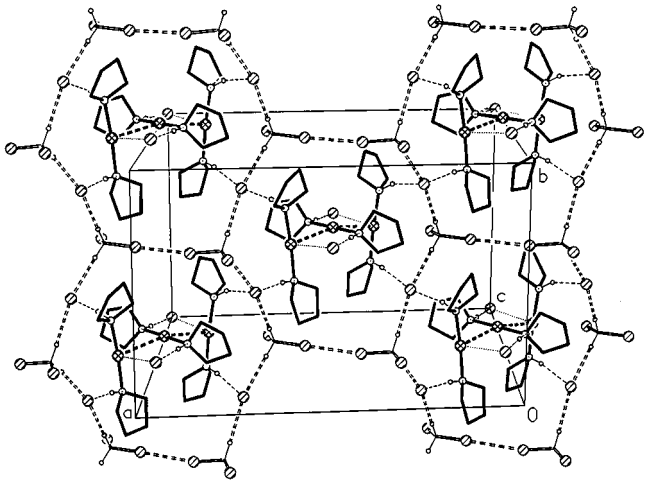

Figure 7. Bis(pyrrolidine)gold(I) chloride (dichloromethane solvate), **4**, layer structure perpendicular to (0 0 1); atom radii are arbitrary; dashed lines represent hydrogen bonds (thin) and aurophilic interactions (thick), dotted lines Au···Cl^- interactions; Au···dichloromethane interactions are not shown; double dashed lines represent secondary interactions of the dichloromethane molecules; carbon-bound hydrogen atoms, except for CH_2Cl_2, are omitted for clarity.

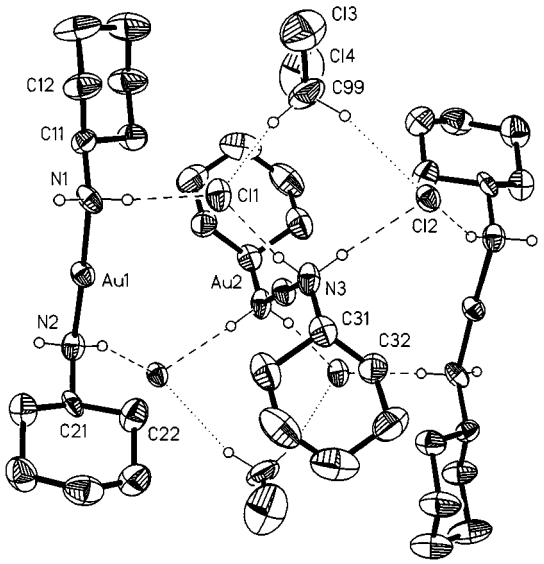

Figure 8. Bis(cyclohexylamine)gold(I) chloride (dichloromethane solvate), **5**, asymmetric unit with numbering scheme; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent N−H hydrogen bonds, dotted lines C−H hydrogen bonds; carbon-bound hydrogen atoms, except for CH_2Cl_2, are omitted for clarity

the structure, in addition to that of the N−H···Cl hydrogen bonds discussed above.

In **5** the L_2Au^+ cations (with L = cyclohexylamine) also form trimeric units (Figure 8), here with inversion symmetry (Au2 and Cl2 lie on inversion centres). The gold atoms are linearly coordinated [N1−Au1−N2 177.6(4), N3−Au2−N3′ 180° (by symmetry)]. The Au−N bond lengths Au1−N1 of 2.036(9), Au1−N2 of 2.047(9) and Au2−N3 of 2.051(8) Å are similar to those in (pyrrolidine)$_4Au_3Cl_3$ or **2** [2.042(6)−2.055(7) Å].[8] No aurophilic interactions are observed, the shortest Au···Au distance being 4.740(1) Å. The cations are connected to form layers parallel to the *xy* plane via N−H···Cl hydrogen bonds (Figure 9, Table 1), with N···Cl contacts between 3.230(9) and 3.343(9) Å, resulting in a pattern of ring motifs. These rings are associated with descriptors from graph sets at higher levels: $R_4^2(8)$ (binary and ternary), $R_4^2(12)$ (ternary). Every dichloromethane molecule is involved in two non-conventional hydrogen bonds [C99···Cl1 3.576(15), C99···Cl2 3.641(13) Å]. Cl1 is the acceptor atom for one, Cl2 (because of the inversion centre) for two of these hydrogen bonds. The dichloromethane molecules are thus positioned alternately above and below the layer (Figure 8).

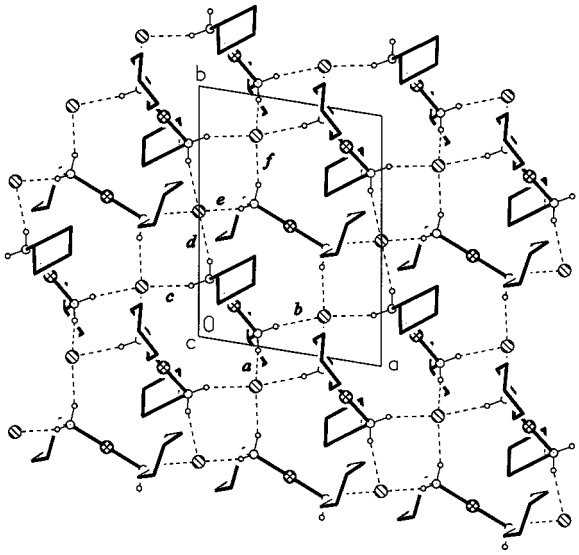

Figure 9. Bis(cyclohexylamine)gold(I) chloride (dichloromethane solvate), **5**, layer structure; atom radii are arbitrary; dashed lines represent hydrogen bonds (Table 1); dichloromethane molecules and carbon-bound hydrogen atoms are omitted for clarity

Anion Exchange

By preparing the compound bis(dicyclohexylamine)-gold(I) hexafluoroantimonate, **13** (Figure 10), it was shown that it is possible to obtain L_2Au^+ cations even with this bulky ligand.

The gold atom in **13** is linearly coordinated [N1−Au−N2 179.1(2)°]. The Au−N bond lengths of 2.085(6) and 2.069(6) Å are similar to those in **2** [2.077(7) Å], consistent with our previous observation on *trans* influences (see above). The hydrogen atoms of the amine groups are involved in long hydrogen bonds to fluorine atoms of two hexafluoroantimonate anions [N···F 2.975(8), 3.268(9) Å; Table 1], thereby forming chains [graph set $N_2 = C_2^2(8)$].

Conclusions

Many complexes of gold(I) with aliphatic amines are stable, in contrast to the generally held view based on the

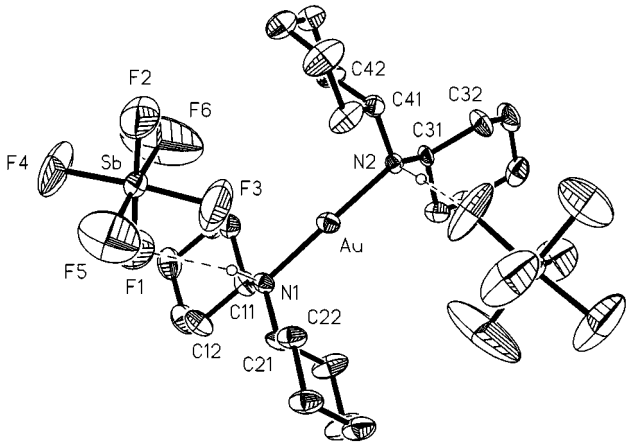

Figure 10. Bis(cyclohexylamine)gold(I) hexafluoroantimonate, **13**, asymmetric unit with numbering scheme; thermal ellipsoids are shown with 50% probability; hydrogen radii are arbitrary; dashed lines represent hydrogen bonds

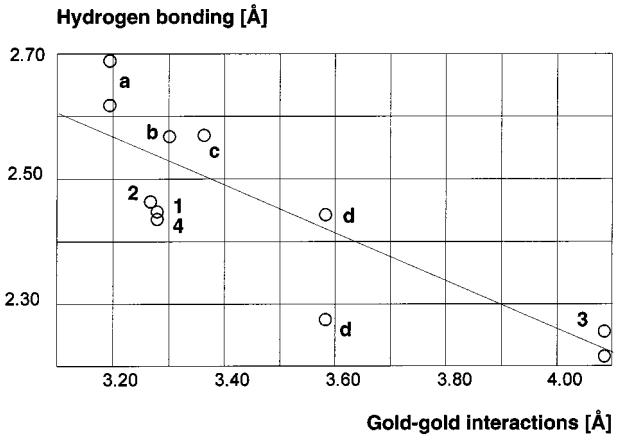

Figure 11. Plot of hydrogen bonding against aurophilic interactions for aminegold(I) complexes; the correlation coefficient is −0.842; a: $[(Ph_2C{=}NH)_2Au^+][AuCl_2^-]$;[6] b: [(piperidine)AuCl];[5] c: $[(Ph_2C{=}NH)AuCl]$;[6] d: $[(pyrrolidine)_4Au_3Cl_3]$[8]

incompatibility of hard ligands with soft metal centres. The stability results in part from the formation of hydrogen bonds involving the N−H functions. In ionic complexes of empirical formula L_2AuCl, hydrogen bonds appear to be more important than in complexes of empirical formula LAuCl; this may be attributable to the positive charge of the gold moiety in the former. Aurophilic interactions appear to have greater influence in complexes of empirical formula LAuCl. By combining data for similar structures (obtained from a search in the CSD database)[15] with our results, we found a tendency that shorter hydrogen bonds are accompanied by longer aurophilic interactions and vice versa (Figure 11). In the complexes with L = pyrrolidine ($L_4Au_3Cl_3$,[8] **4**) hydrogen bonds and aurophilic interactions appear to be necessary to stabilise the complexes, which, surprisingly for complexes with charged gold moieties, display short aurophilic interactions.

Previous difficulties in preparing aminegold(I) complexes may have been caused by (i) the insolubility of many products, (ii) the tendency to form mixtures of complexes (e.g. for pyrrolidine) and/or by-products such as amine hydrochlorides or hemihydrochlorides[16] or (iii) the use of unsuitable amines (e.g. tertiary amines, where we could not obtain stable complexes, presumably because of the lack of hydrogen bonding).

Anions with more functional groups for hydrogen bonding (e.g. disulfonylamine anions) are expected to render a stabilising contribution to aminegold(I) complexes. It may

Experimental Section

General: NMR spectra were measured with a Bruker AC 200 spectrometer in $CDCl_3$ solution with TMS as internal standard (if not otherwise stated). Frequencies: 200.1 MHz (^{1}H), 50.3 MHz (^{13}C). − Mass spectra were recorded with a Finnigan MAT 8430. − Conductivities were measured with a WTW LF 530 (LTA 1 electrode) conductometer. − All reactions were carried out with exclusion of light at room temperature. − All aminegold(I) complexes with liquid amines were prepared as follows: (tht)AuCl (tht = tetrahydrothiophene) (160 mg, 0.5 mmol) was dissolved in neat amine (5 mL). The solution was stirred for 1 h with exclusion of light at room temperature; a white precipitate formed. Light petroleum ether was added and after cooling for 1 h at −18 °C the precipitate was filtered off and recrystallised from dichloromethane/light petroleum ether. Except for **5** (see below) crystals were obtained by diffusion of light petroleum ether into dichloromethane solution. − All complexes with SbF_6^- anions were prepared as follows: [LAuCl] or [L_2Au^+]Cl^- (0.5 mmol) was dissolved in a solution of 5 mL of dichloromethane and 1 mL of amine (L) and $AgSbF_6$ (344 mg, 1 mmol) was added. The suspension was stirred for 1 h with exclusion of light at room temperature. The AgCl precipitate was filtered off through a layer of $MgSO_4$. Light petroleum ether was added to the solution and after cooling overnight at −18 °C colourless, light-sensitive crystals were obtained.

Chloro(2,2,6,6-tetramethypiperidine)gold(I) (1): Yield 53%, dec. >122 °C. − ^{1}H NMR: δ = 1.44 (s, 6 H, CH_3), 1.48 (m, 2 H, β-CH_2), 1.57 (s, 6 H, CH_3), 1.65 (m, 2 H, γ-CH_2), 1.76 (m, 2 H, β-CH_2), 4.6 (br., NH). − ^{13}C NMR: δ = 17.12, (γ-CH_2), 28.14, (CH_3), 37.26, (β-CH_2), 59.27 (α-CH_2) (classified by C-H correlation). − EI MS; *m/z* (%): 126 (100) [M − CH_3 − AuCl], 141 (2) [M − AuCl]. − Conductivity: Λ_c = 8 cm^2 Ω $^{-1}$ mol^{-1}. − $C_9H_{19}AuClN$ (373.68): calcd. C 28.93, H 5.12, N 3.75; found C 28.85, H 5.08, N 3.51.

Chloro(dicyclohexylamine)gold(I) (2): Yield 75%, dec. > 114 °C. − ^{1}H NMR: δ = 1.26−1.84 (16 H, CH_2), 2.12, 2.40 [m, 4 H, 2-, 2′-CH_2 (eq.)], 2.99 (m, 2 H, CH). − ^{13}C NMR: δ = 25.05 (3-C), 35.50 (4-C), 34.82 (2-C), 58.73 (1-C). − EI MS; *m/z* (%): 181 (16) [M − Au − Cl]. − $C_{12}H_{23}AuClN$ (413.74): calcd. C 34.84, H 5.60, N 3.39; found C 34.86, H 5.55, N 3.34.

Bis(piperidine)gold(I) Chloride (3): Yield 91%, dec. > 86 °C. − ^{1}H NMR: δ = 1.73 (m, 4 H, β-CH_2), 3.25 (m, 4 H, α-CH_2). − ^{13}C NMR: δ = 23.41 (β-CH_2), 26.52 (γ-CH_2), 53.50 (α-CH_2). − EI MS; *m/z* (%): 84 (100) [M − Au − Cl − H]. − Conductivity: Λ_c = 24 cm^2 Ω^{-1} mol^{-1}. − $C_{10}H_{22}AuClN_2$ (402.72): calcd. C 29.82, H 5.51, N 6.96; found C 29.34, H 5.35, N 7.06.

Bis(pyrrolidine)gold(I) Chloride (4): Yield 85%, dec. at room temperature. − ^{1}H NMR: δ = 1.90 (br., 4 H, β-CH_2); 3.00 (br., 2 H), 3.54 (br., 2 H) (α-CH_2). − ^{13}C NMR: δ = 23.62 (β-CH_2); 52.54 (α-CH_2). − FAB MS (pos.); *m/z* (%): 72 (100) [K − $C_4H_8NAu]^+$. − $C_8H_{18}AuClN_2 \cdot 0.67\ CH_2Cl_2$ (431.20): calcd. C 24.15, H 4.52, N 6.50; found C 23.95, H 4.67, N 7.05; the elemental analysis is affected by co-crystallised dichloromethane, which could not be removed even after prolonged pumping. − (Pyrrolidine)$_4Au_3Cl_3$[8] was obtained as a by-product of this reaction.

Bis(cyclohexylamine)gold(I) Chloride (5): Crystals were obtained by diffusion of cyclohexylamine into a solution of (tht)AuCl in dichloromethane. Yield 75%, dec. > 114 °C. − ^{1}H NMR: δ = 1.16 (m, 12 H, CH_2, ax.); 1.77 (m, 10 H, CH_2, eq.); 2.62 (m, 2 H, CH); 4.5 (br., NH_2). − ^{13}C NMR: δ = 26.95 (3-C); 31.06 (4-C); 35.54 (2-C); 55.69 (1-C). − EI MS; *m/z* (%): 99 (19) [M − $C_6H_{13}NAuCl$]. − $C_{12}H_{26}AuClN_2$ (430.77): calcd. C 33.46, H 6.08, N 6.50; found C 33.57, H 6.07, N 6.52.

Chloro(4-methylpiperidine)gold(I) (6): Yield 55%, dec. > 67 °C. − ^{1}H NMR: δ = 0.87 (d, 3 H, CH_3), 0.93 (d, 3 H, CH_3), 1.28 (m, 1 H, β-CH_2), 1.45 (br., 1 H, γ-CH), 1.63 (m, 1 H, γ-CH), 1.67 (m, 3 H, β-CH_2), 3.01 (m, 2 H, α-CH_2), 3.36 (m, 1 H, α-CH_2), 3.52 (m, 1 H, α-CH_2), 5.5 (br., NH) (classified by C-H correlation). − ^{13}C NMR: δ = 21.60, 21.65 (CH_3); 29.93, 30.14 (γ-CH); 34.17, 35.26 (β-CH_2); 52.28, 53.72 (α-CH_2) [doubling of signals is due to two conformers (*cis* and *trans*)]. − EI MS; *m/z* (%): 98 (100) [M − AuCl − H]. − Conductivity: Λ_c = 21 cm^2 Ω^{-1} mol^{-1}. − $C_6H_{13}AuClN$ (331.60): calcd. C 21.73, H 3.95, N 4.22; found C 23.99, H 4.27, N 4.34.

Bis(morpholine)gold(I) Chloride (7): Yield 76%, dec. > 72 °C. This compound was not stable enough to obtain NMR spectra. − EI MS; *m/z* (%): 87 (100) [M − $C_4H_9NOAuCl$]. − Conductivity: Λ_c = 22 cm^2 Ω^{-1} mol^{-1}. − $C_8H_{18}AuClN_2O_2$ (406.66): calcd. C 23.63, H 4.46, N 6.89; found C 23.41, H 4.42, N 7.49.

Chloro(piperazine)gold(I) (8): (tht)AuCl (160 mg, 0.5 mmol) was dissolved in a solution of piperazine in ethanol (10 mL, 50% excess of piperazine). The suspension was stirred for 1 h with exclusion of light at room temperature. Diethyl ether was added and after cooling for 1 h at −18 °C the white precipitate was filtered off and recrystallised from dichloromethane/light petroleum ether. Yield 75%, dec. > 109 °C. − ^{1}H NMR: δ = 2.94 (m, 8 H, CH_2). − EI MS; *m/z* (%): 86 (66) [M − AuCl]. − $C_4H_{10}AuClN_2$ (318.56): calcd. C 15.08, H 3.16, N 8.79; found C 15.54, H 3.28, N 8.94. − This compound was not soluble enough to obtain crystals.

Chloro(diethylamine)gold(I) (9): Yield 95%, dec. at room temperature. − ^{1}H NMR: δ = 1.39 (br., 6 H, CH_3), 3.02 (br., 4 H, CH_2), 4.9 (br., NH). − EI MS; *m/z* (%): 73 (34) [M − AuCl]. − $C_4H_{11}AuClN$ (305.56): calcd. C 15.72, H 3.63, N 4.58; found C 15.68, H 3.69, N 4.63. − This compound was not stable enough to obtain crystals.

Bis(benzylamine)gold(I) Chloride (10): Yield 82%, dec. > 149 °C. This compound was not soluble enough for NMR measurements.

− EI MS; *m/z* (%): 107 (65) [M − C_7H_9NAuCl]. − $C_{14}H_{18}AuClN_2$ (446.73): calcd. C 37.64, H 4.06, N 6.27; found C 37.91, H 4.05, N 6.33. − This compound was not soluble enough to obtain crystals.

Chloro(1-phenylethylamine)gold(I) (11): Yield 46%, dec. > 123°C. − ^{1}H NMR: δ = 1.38, 1.41 (s, 3 H, CH_3), 4.12 (dd, 1 H, CH), 7.35 (m, 2 H, Ph). − EI MS; *m/z* (%): 106 (100) [M − CH_3 − AuCl], 121 (2) [M − AuCl]). − $C_8H_{11}AuClN$ (353.60): calcd. C 27.17, H 3.14, N 3.96; found C 27.36, H 3.09, N 3.77. − This compound was not soluble enough to obtain crystals.

Chloro(3-iodobenzylamine)gold(I) (12): Yield 49%, dec. > 119°C. − ^{1}H NMR ([D_6]DMSO): δ = 3.96 (m, 2 H, CH_2), 7.18 (m, 1 H, *m*-Ph), 7.44 (m, 1 H, *p*-Ph), 7.67 (m, 1 H, o^6-Ph), 7.84 (m, 1 H, o^2-Ph), 5.8 (br., NH_2). − EI MS; *m/z* (%): 106 (100) [M − I − AuCl]), 233 (32) [M − AuCl]). − $C_7H_8AuClNI$ (465.47): calcd. C 18.06, H 1.73, N 3.01, Cl 7.62; found C 17.74, H 1.68, N 2.87, Cl 7.64. − This compound was not soluble enough to obtain crystals.

Bis(dicyclohexylamine)gold(I) Hexafluoroantimonate (13): Yield 59%, dec. > 112°C. − ^{1}H NMR ([D_6]acetone): δ = 1.07−2.98 (40 H, CH_2); 3.25 (m, 4 H, CH); 5.3 (br., NH). − FAB MS (pos.); *m/z* (%): 559 (100) $[K]^+$. − $C_{24}H_{46}AuF_6N_2Sb$ (795.35): calcd. C 36.24, H 5.83, N 3.52; found C 36.12, H 5.82, N 3.44.

Bis(piperidine)gold(I) Hexafluoroantimonate (14): Yield 30%, dec. > 173°C. − ^{1}H NMR: δ = 1.75 (m, 6 H, β-, γ-CH_2), 3.24 (m, 4 H, α-CH_2), 4.4 (br., NH). − FAB MS (pos.); *m/z* (%): 86 (18) [K − $C_5H_{10}NAu]^+$, 282 (2) [K − $C_5H_{11}N]^+$, 367 (100) $[K]^+$. − $C_{10}H_{22}AuF_6N_2Sb$ (603.01): calcd. C 19.92, H 3.68, N 4.65; found C 19.81, H 3.70, N 4.59.

Bis(cyclohexylamine)gold(I) Hexafluoroantimonate (15): Yield 23%, dec. > 74°C. − ^{1}H NMR ([D_6]acetone): δ = 1.16−2.28 (20 H, CH_2), 3.81 (m, 2 H, CH), 5.5 (br., NH). − FAB MS (pos.); *m/z* (%): 100 (100) [K − $C_6H_{12}NAu]^+$, 395 (42) $[K]^+$. − $C_{12}H_{26}AuF_6N_2Sb \cdot 0.5\ C_6H_{13}N$ (680.65): calcd. C 26.47, H 4.81, N 5.14; found C 27.72, H 5.39, N 5.10; the elemental analysis is affected by co-crystallised excess cyclohexylamine, which could not be removed even after prolonged pumping.

X-ray Structure Determinations: Crystal data: Table 2. − Data collection and reduction: The crystals were mounted in inert oil on a glass fibre. Data were measured using Mo-K_α radiation (λ = 0.71073 Å) with a Stoe STADI4 (**3**, **13**), Siemens P4 diffractometer (**2**, **4**, **5**) or a Siemens Smart area detector (**1**), each fitted with an LT-2 low-temperature attachment. Semi-empirical absorption corrections were based on psi-scans (XEMP) (**2**, **3**, **4**, **5**, **13**) or on multiple scans (SADABS) (**1**). Structures were solved by direct (**2**, **3**) or Patterson (**1**, **4**, **5**, **13**) methods and subjected to full-matrix least-squares refinement on F^2 (program SHELXL-97).[17] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included using a riding model except for those bonded to nitrogen atoms in **1**, **2**, **3** and **4**, which were refined "freely", in **1**, **2** and **4** with restrained N−H bond lengths. − Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre under the numbers CCDC-440/051 (**2**, **3**),[12] CCDC-113728 (**1**), CCDC-113729 (**4**), CCDC-113730 (**5**) and CCDC-113731 (**13**). Group-4 Metallocene Cation Complexes of Oligopeptides: Reaction of $[Cp_2ZrCH_3(THF)^+BPh_4^-]$ with Boc-Protected Di- and Tripeptide Esters

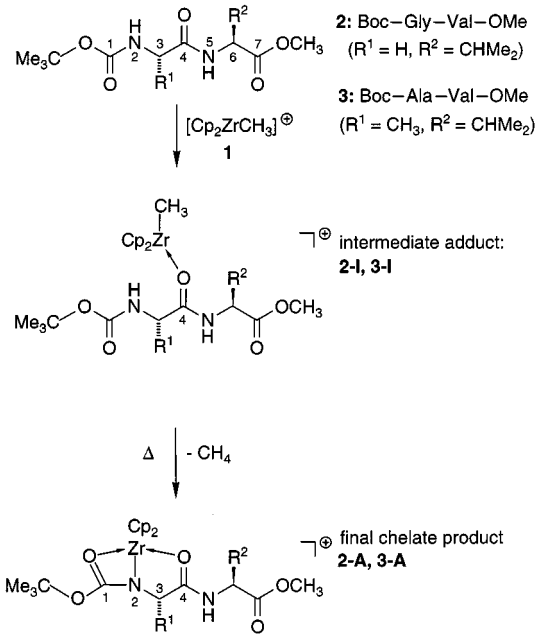
Jörg Wonnemann,[a] Markus Oberhoff,[a] Gerhard Erker,*[a] Roland Fröhlich,[a] and Klaus Bergander[a]

Keywords: Bioorganometallic chemistry / Zirconocene complexes / Metallocene cations / Group-4 metallocene peptide complexes

The dipeptide derivatives Boc-Gly-Val-OMe (**2**) and Boc-Ala-Val-OMe (**3**) selectively add the methylzirconocene cation **1** to the carbonyl oxygen atom of the *N*-terminal amino acid residue (κ-C^4=O coordination) upon treatment with $[Cp_2ZrCH_3(THF)^+BPh_4^-]$ in dichloromethane at low temperature (< 0 °C) to generate the complexes **2-I** and **3-I**, respectively. Above 0 °C methane is eliminated to give the stable chelate peptide metallocene cation complexes **2-A** and **3-A**, respectively, both featuring a combined C^1=O/N2/C^4=O coordination to the zirconium center. Complex **3-A** was characterized by X-ray diffraction. The analogous tripeptide derivatives Boc-Gly-Val-Val-OMe (**6**), Boc-Ala-Ala-Val-OMe (**7**), Boc-Ala-Val-Val-OMe (**8**), and Boc-Val-Val-Gly-OMe (**9**) all form analogous κ-C^4=O $Cp_2ZrCH_3^+$ cation adducts (**6–9**)-**I** under kinetic control and after subsequent loss of CH_4 C^1=O/N2/C^4=O chelate complexes (**6–9**)-**A** under thermodynamic control, both involving selective bonding of the organometallic cation to the terminal amino acid residue of the respective peptide derivatives. Thermolysis of the primary adduct **7-I** (> 0 °C) resulted in methane elimination and formation of a mixture of the isomers **7-B** and **7-A** (isolated in a 3:4 ratio). According to the detailed NMR analysis **7-A** shows the favored chelate coordination at the *N*-terminus involving C^1=O/N2/C^4=O bonding, whereas the cation complex **7-B** exhibits a similar chelate structure at the internal Ala moiety, characterized by C^4=O/N5/C^7=O coordination to the zirconium center. Similarly, methane liberation from **8-I** and **9-I** gave mixtures of the respective cationic chelate complex isomers **8-A/8-C** (2:3) and **9-A/9-C** (1:1), respectively. The (**8**,**9**)-**A** isomers have the zirconium ion bonded at the *N*-terminus, whereas (**8**,**9**)-**C** exhibit the Cp_2Zr^+ unit at the *C*-terminus of the peptide chain, involving the ester carbonyl group in forming the chelate framework (C^7=O/N8/C^{10}=O coordination). The (**6–9**)-**A** isomers are thermodynamically favored. The cation complexes **7-B**, **8-C**, **9-C** rearrange to the **A**-type isomers upon prolonged standing at temperatures > 0 °C in dichloromethane solution.

Introduction

Principles and many details of the important interaction of metal ion systems with typical biomolecules have been recognized due to a large number of investigations in the field of bioinorganic chemistry. Bioorganometallic chemistry is a much less mature discipline.[1] It tries to combine favorably the characteristic features of typical biomolecules, such as amino acids, oligopeptides, heterocyclic nucleobases, oligonucleotides etc., with those of organometallic building blocks in order to generate e.g. new reagents for organic synthesis or precursors of novel active and selective catalyst systems, but also to study the response of the "natural" bio-related systems to interactions with rather "unnatural" organometallic metal/ligand combinations and arrangements.[2] A major problem in bioorganometallic chemistry is to find suitable conditions that allow to combine the usually rather hydrophilic biomolecules with the in part extremely hydrophobic world of many organometallic systems and to keep their mutual adducts and reaction products stable. It is very likely that many useful applications will follow once this has been achieved for a sufficient number of bioorganometallic systems.[3]



The methylzirconocene cation ($[Cp_2ZrCH_3^+]$, **1**) is a sensitive, very electrophilic organometallic fragment that has found important use in homogeneous metallocene Ziegler catalysis.[4] We have used this species as a typical model system to investigate the modes of interaction of a very reactive, extremely hydrophobic organometallic building block derived from an oxophilic transition metal from the left side of the periodic table with peptide derivatives, as typical examples of biomolecule-related substrates. This has led to the disclosure of interesting coordination behavior and subsequent reactions of this metallocene-derived reagent with such multifunctional and polar substrates. A series of typical examples is described in this article.

Results and Discussion

As the organometallic starting material the ligand-stabilized $[Cp_2ZrCH_3(THF)^+BPh_4^-]$ methylzirconocene cation **1a** was used in this study.[4a] The coordinated tetrahydrofuran is readily exchanged for other donor ligands under very mild conditions. The cation complex **1a** was treated with a variety of *N*-*tert*-butoxycarbonyl-(i.e. Boc-)protected oligopeptide esters. Here the outcome of the reactions with two

selected dipeptide and a series of four tripeptide methyl esters will be described.[5]

The reaction of **1a** with the dipeptide ester Boc-Gly-Val-OMe (**2**) shall serve as an example to illustrate a typical reaction series. Upon mixing the two components in a 1:1 stoichiometry at −15°C in [D_2]dichloromethane an instantaneous reaction was observed by NMR to take place. THF is liberated from "Jordan's cation" ([$Cp_2ZrCH_3(THF)^+$]) and the reactive $Cp_2ZrCH_3^+$ cation takes up a dipeptide ester as a ligand. A combination of various NMR techniques (for details see the Experimental Section) has allowed for a complete spectroscopic characterization of this rapidly formed primary product as the [$Cp_2Zr(CH_3)$(Boc-Gly-Val-OMe)$^+$] coordination complex **2-I** (see Scheme 1). As it is evident from the compilation of the ^{1}H- and ^{13}C-NMR data (Tables 1 and 2), compound **2-I** still contains all the intact components of both the subunits [Cp_2Zr-CH_3^+] (**1**) and Boc-Gly-Val-OMe (**2**): The zirconium-bonded [Zr]-CH_3 group is still there and both NH functionalities are intact. From the ^{13}C-NMR comparison between **2** and **2-I** (see Table 2) it is deduced that complex formation has apparently occurred by coordination of the glycine-derived amido carbonyl group to the zirconium center. The pronounced shifting of the respective O=C^4 ^{13}C-NMR resonance from δ = 170.1 to δ = 179.1 strongly indicates the newly formed (Gly)amido−Zr bond as the essential structural feature of the primary [(Boc-Gly-Val-OMe)·**1**] adduct. All the other ^{13}C-NMR resonances are essentially unaffected.

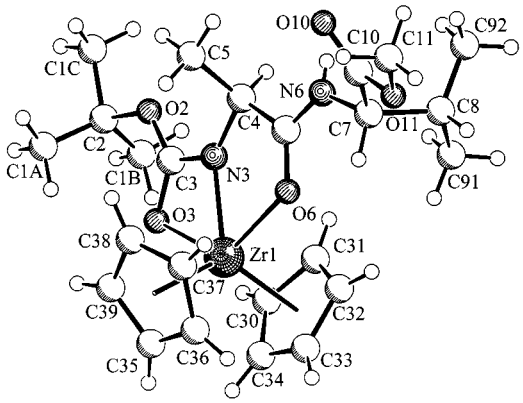
Complex **2-I** is a reactive intermediate. At temperatures above 0°C it reacts further. Methane is formed[6] and the final product **2-A** is obtained. The stable complex **2-A** was synthesized by treatment of **1a** with Boc-Gly-Val-OMe in dichloromethane (0°C to room temperature for a few hours) on a preparative scale and isolated in 96% yield. Both the ^{1}H- and the ^{13}C-NMR spectra show that the [Zr]-CH_3 group is no longer present. It has been utilized for selectively abstracting the N*H* proton[6b] of the Gly part of the peptide ligand systems. Consequently, the former 2-H resonance of the peptide chain is not observed in the ^{1}H-NMR spectrum of the product **2-A** (see Table 1 and Scheme 1). The pronounced shift of the amido O=C^4 ^{13}C-NMR resonance to a larger δ value for **2-A** relative to the free peptide ligand **2** (Δδ = +9.0 ppm) strongly indicates the coordination of this amido group to the zirconium center.[7]

A more detailed picture of the coordination behavior of the mono-deprotonated peptide ligand to the remaining Cp_2Zr unit in the cation complex **2-A** is hard to obtain from the NMR-spectroscopic analysis alone, but − as we will see later − can be derived quite confidently in a combination of the spectroscopic features with the result of an X-ray crystal structure analysis.

We had recently characterized a related (peptide)zirconocene tetraphenylborate salt by X-ray diffraction.[3b] The complex **5** was prepared by treatment of **1a** with the isocyanate **4** of the dipeptide H-Val-Val-OMe.[8] The Zr−CH_3 group had added to the heterocumulene to form the cationic bis-chelate complex **5**. It was shown by X-ray diffraction that the zirconium center was bonded to the *N*-terminal Val-nitrogen atom and to the oxygen atoms of both adjacent C=O groups, i.e. the *N*-acetyl carbonyl group and the C=O group of the *N*-terminal Val moiety (see Scheme 2).

Scheme 2. Formation and structural parameters of **5**

Treatment of Boc-Ala-Val-OMe (**3**) with **1a** at low temperature (−15°C) in CD_2Cl_2 gave the adduct **3-I** (see Scheme 1 and Tables 1 and 2). The NMR analysis also indicates the selective coordination of the $Cp_2ZrCH_3^+$ cation to the amido carbonyl group of the *N*-terminal amino acid building block (i.e. formation of $C^4{=}O{-}$[Zr] of the Ala moiety). Warming to room temperature again leads to a rapid reaction that results in (Ala)N^2-H deprotonation with liberation of methane and the selective formation of the cationic chelate complex **3-A**. Diffusion of pentane vapor into a solution in bromobenzene gave single crystals of **3-A** for an X-ray crystal structure analysis. This structure suffers from the presence of a small nonidentified molecule (probably water). Therefore, we will not discuss the structure in detail. But the X-ray analysis is of a sufficient quality to characterize the overall structural arrangement of **3-A** as being of the same type as **5**. Thus, complex **3-A** is again of a bis-chelate type and exhibits a metallabicyclic central framework around the zirconium center. In this, the amido carbonyl group of the *N*-terminal Ala unit strongly coordinates to the zirconium ion − this was already deduced from the strong deshielding effect[3b] in the ^{13}C-NMR spectrum (C4 coordination shift **3** → **3-A** $\Delta\delta = +10$ ppm, see Table 2). In addition, the *N*-Boc carbonyl group also coordinates strongly to the zirconium ion (see Figure 1). This feature did not show up in the ^{13}C-NMR analysis, which is probably due to a compensation effect (the $C^1{=}O$ bond becomes weaker upon coordination, but at the same time the C1=N2 bond becomes stronger). But a close inspection of the ^{13}C-NMR data (see Table 2) shows that the chelate coordination (i.e. the transformation of **3-I** → **3-A**) results in a pronounced and characteristic shift of the Boc-*C*Me_3 ^{13}C-NMR resonance to larger δ values ($\Delta\delta = +4.7$ ppm for **3-A**, +5.4 for **2-A**). We thus conclude, that the thermodynamically favored final products **2-A** and **3-A** are both characterized by a doubly chelating coordination of the Boc−amido unit and the internal amido moiety of the *N*-terminal amino acid building block of the dipeptide derivatives as depicted in Scheme 1. This follows from the combined NMR/X-ray analysis. This typical coordination mode does not lead to any significant shifting of the $C^1{=}O$ ^{13}C-NMR signal, but can readily be recognized by the resulting pronounced ^{13}C-NMR coordination shifts of the Boc-*C*Me_3 and the $C^4{=}O$ resonances.



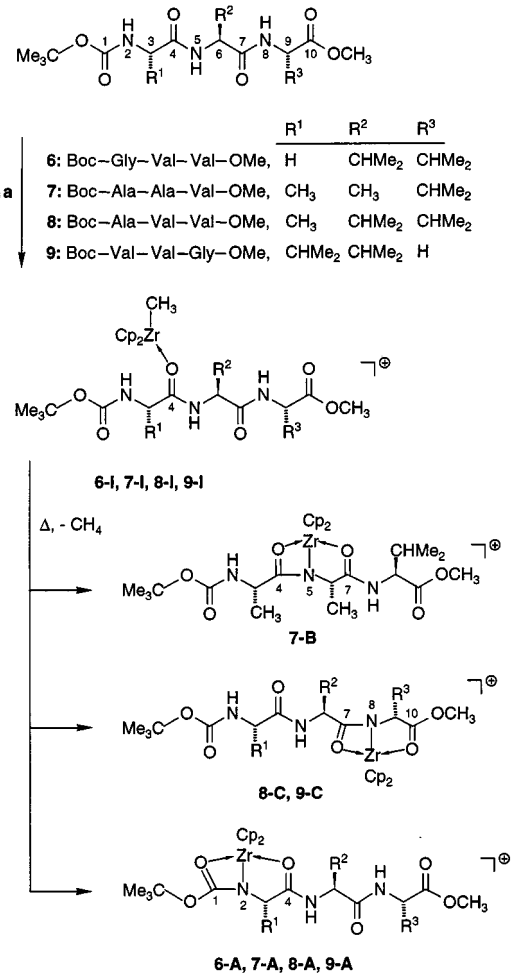


Figure 1. A view of the molecular structure of the product **3-A** (cation only, with unsystematical atom numbering scheme) as determined by X-ray diffraction

We next treated "Jordan's cation" (**1a**) with the tripeptide derivative Boc-Gly-Val-Val-OMe (**6**).[9] There is a clean and selective adduct formation observed at −15°C in [D_2]dichloromethane. The product contains the intact $Cp_2Zr{-}CH_3^+$ unit coordinated to the tripeptide framework. This is evident from the observation of the NMR signals of a pair of diastereotopic Cp ligands at the zirconium center and the presence of a [Zr]$-CH_3$ group. From the characteristic coordination shift of the carbonyl carbon atom C4 in the ^{13}C-NMR spectrum ($\Delta\delta = +7.8$ ppm) attachment of the methylzirconocene cation to the $C^4{=}O$ amido carbonyl group of the *N*-terminal Gly moiety of **6** is indicated. Since there are no other significant NMR changes we must assume that the **1a** + **6** reaction has resulted in a simple adduct formation to give the cationic complex **6-I** (see Scheme 3, with BPh_4^- anion).

Warming of the intermediate **6-I** above 0°C again leads to methane evolution. In this case also a single thermodynamically favored product (**6-A**) is obtained, that was also prepared and isolated on a preparative scale. The ^{1}H-NMR spectrum (see Table 3) shows that the N*H* proton of the Gly section of the tripeptide has been abstracted by the [Zr]$-CH_3$ group to give methane. The adjacent amido carbonyl group ($C^4{=}O$) is involved in the chelate complex formation. This is evident by the shifting of the ^{13}C-NMR signals of carbon atoms C4 ($\Delta\delta = +7.7$ ppm) and C3 ($\Delta\delta = +6.2$ ppm) for the **6** → **6-A** transformation. Again, we must assume that the $C^1{=}O$ amido carbonyl group adjacent to the directly bonded nitrogen atom N2 is involved and used for constructing the typical second chelate "arm" of the overall metallabicyclic framework. This is evident from the characteristic shifting of the *C*Me_3 ^{13}C NMR signal of the Boc group ($\Delta\delta = +5.9$ ppm), whereas the corresponding C1 resonance remains completely unaffected from the **6** → **6-A** transformation, probably due to the typical compensation effect discussed above and in the literature.[3b] Thus, treatment of the tripeptide derivative **6** with $Cp_2ZrCH_3^+$

from **1a** leads to a selective kinetically controlled adduct formation at the *N*-terminal Gly amido group followed by thermally induced methane elimination to give a single cationic metallocene/peptide chelate complex (**6-A**) where the zirconium center is bonded to the C^1=O, N2, and C^4=O groups (see Scheme 3).

The reaction between Boc-Ala-Ala-Val-OMe (**7**) with **1a** is slightly more complicated. At low temperature, the adduct [Boc-Ala-Ala-Val-OMe · $ZrCp_2CH_3^+$] (**7-I**) is formed selectively. Unfortunately, this is the only case where we

were not able to locate two of the ^{13}C-NMR carbonyl resonances, but from the overall spectral characteristics it is quite obvious that again the typical Zr coordination to the amide oxygen atom of the *N*-terminal amino acid residue (here: Ala) has taken place (see Tables 3 and 4).

Raising the temperature again results in consumption of the reactive intermediate **7-I** with formation of CH_4. However, in this case a mixture of two bis-chelate complexes is obtained. These were formed in a ratio of **7-B**/**7-A** ≈ 3:4 under the specific conditions used for their synthesis on a preparative scale (see the Experimental Section for details). Complex **7-A** exhibits the typical spectroscopic features (see Tables 3 and 4) that identifies it as an example of the *N*-terminal chelate peptide/zirconocene cation complex type. Analogously, as in the "**A**-type" cation examples discussed above, the double framework is formed by attaching the C^1=O/N2/C^4=O subunits to the central Cp_2Zr moiety.

Complex **7-B** is of a similar type, only that the C^4=O/N5/C^7=O groups are here involved in the coordination to the zirconium center. The ^{1}H-NMR spectra show that in this case it is the 5-H amido hydrogen atom that is lost upon thermally induced methane formation. In addition, pronounced ^{13}C-NMR shift differences have resulted in the **7** → **7-B** transformation at the carbonyl carbon atoms C4 (Δδ = +7.7 ppm) and C7 (Δδ = +6.6 ppm) as well as the adjacent Ala-*C*HMe carbon atom C6 (Δδ = +8.2 ppm).

The *N*-terminal chelate cation complex **7-A** seems to be the thermodynamically favored product. During ca. two weeks at 0°C in CD_2Cl_2 the by-product **7-B** has almost completely disappeared and has been transformed into the more stable peptide–group-4 metallocene cation system **7-A**.

A similar situation was found when the peptide derivatives Boc-Ala-Val-Val-OMe (**8**) or Boc-Val-Val-Gly-OMe (**9**) were treated with **1a**. In each case a single $Cp_2ZrCH_3^+$ adduct was formed at low temperature (–15°C). Coordination at the C^4=O carbonyl oxygen atom of the *N*-terminal amino acid moiety was evident from the NMR analysis (see Tables 5 and 6). The thus formed primary product **8-I** eliminated methane at temperatures > 0°C to form a mixture of the new cationic chelate complex **8-C** (see Scheme 3) in addition to **8-A** (obtained in a 2:3 ratio on a preparative scale). In the case of **8-C** the C^7=O/N8 amido

group of the *C*-terminal Val moiety and C^{10}=O of the terminal ester group have formed the chelate coordination to the zirconium center [^{13}C-NMR shift differences of the **8** → **8-C** transformation: Δδ = +8.9 ppm (C7), +7.3 (C10), +8.1 (C9)].

Similarly, the selectively formed addition product **9-I** (C^4=O coordinated to zirconium, see Scheme 3 and Tables 5 and 6) is transformed to a ca. 1:1 mixture of **9-C** and **9-A** upon heating (with loss of CH_4). Again the product **9-C** exhibits C^7=O/N8/C^{10}=O chelate coordination to zirconium [Δδ = +7.5 ppm (C7), +10.4 (C10)] whereas complex **9-A** is again characterized by the presence of the *N*-terminal C^1=O/N2/C^4=O chelate. Both the complexes **8-C** and **9-C** do not represent the most stable structures on their respective hypersurfaces. They both convert completely to their thermodynamically favored isomers **8-A** and **9-A**, respectively, upon standing for prolonged time at temperatures > 0°C.

We conclude that complexes between the electrophilic methylzirconocene cation and *N*- and *C*-protected di- and tripeptides can readily be generated. In the series investigated these are formed with a very high selectivity – in all the cases characterized here the [$Cp_2ZrCH_3^+$] attachment takes place exclusively at the amido carbonyl oxygen function of the *N*-terminal amino acid moiety, i.e. adjacent to the Boc-protective group. We assume that this position is sterically the least shielded, and that the regioselective formation of the adduct complexes (**2**, **3**, **6**–**9**)-**I** under kinetic control is probably governed by steric effects. Very stable chelate complexes (**2**, **3**, **6**–**9**)-**A** are obtained from these intermediates by thermally induced methane elimination. Overall, an analogous regiochemical preference for the *N*-terminal amino acid coordination (here with involvement of the C^1=O group of the Boc-protective group) is observed for this product formation under thermodynamic control. Other regioisomers (**7-B**, **8-C**, **9-C**) that have been observed on the way to these final chelate products may again be less favored because of steric interference. For this series of peptide derivative/$Cp_2ZrCH_3^+$ reactions we have shown that a group-4 metal complex fragment can rather readily and even selectively be attached to peptide frameworks. The resulting complexes are rather stable and they can be prepared on a preparative scale. This might open new ways to use peptide derivatives as stereochemically active and well-defined ligand systems in less protected early transition metal complexes that may have an interesting potential especially in asymmetric catalysis. Such developments are actively being pursued in our laboratory.

Experimental Section

General Remarks: Reactions involving organometallic compounds were carried out under argon in a glove box or using Schlenk type glassware. Solvents (including deuterated solvents) were dried and distilled under argon prior to use. – NMR experiments were performed on a Varian Unity Plus 600 spectrometer at 258 K (^{1}H: 600 MHz, ^{13}C: 150 MHz). Assignments in ^{1}H- and ^{13}C-NMR spectra were confirmed by GCOSY, 1D-TOCSY, GHSQC, and GHMBC experiments.[10] Atom numbering as given in Schemes 1 and 3. – IR spectra were acquired with a Nicolet 5 DXC Fourier transform IR spectrometer. – Melting points were obtained by differential scanning calorimetry (DSC 2010, TA Instruments), elemental analyses were determined with a Foss-Heraeus CHN-Rapid elemental analyzer. – The organometallic reagent [$Cp_2ZrCH_3(THF)^+BPh_4^-$] (**1a**),[4a] the oligopeptides and Boc-protected di- and tripeptide esters were prepared according to literature procedures.[9][11]

General Procedures. – Preparation of Protected Dipeptide Esters (A): A typical run was as follows: To a stirred and ice-cooled solution of the Boc-protected amino acid (20 mmol) in chloroform (30 mL) dicyclohexylcarbodiimide (4.13 g, 20 mmol) was added. After 30 min, the mixture was combined with a mixture of the amino acid methyl ester hydrochloride (20 mmol) and triethylamine (2.02 g, 2.72 mL, 20 mmol) in chloroform (30 mL). The combined phases were stirred in an ice bath for 3 h and then kept overnight; then a few drops of acetic acid were added. The mixture was stirred for 15 min and filtered. The filtrate was washed successively with water, a 10 % citric acid solution, a 5 % sodium hydrogen carbonate solution, and water. The solution was dried with magnesium sulfate; solvent was then removed in vacuo. Separation from remaining dicyclohexyl urea was achieved by solving the dipeptide ester product in ethyl acetate and filtering off the insoluble urea. The ethyl acetate was removed in vacuo to yield the analytically pure dipeptide derivative as a white solid.

Preparation of Protected Tripeptide Esters (B): A typical run was as follows: To an ice-cooled solution of the *C*-deprotected Boc-dipeptide (10 mmol) in chloroform (20 mL) hydroxybenztriazol

(1.54 g, 10 mmol) and dicyclohexylcarbodiimide (2.06 g, 10 mmol) were added. After 30 min, the mixture was combined with a mixture of the amino acid methyl ester hydrochloride (10 mmol) and triethylamine (1.01 g, 1.39 mL, 10 mmol) in chloroform (30 mL). The combined phases were stirred in an ice bath for 3 h and then kept overnight. A few drops of acetic acid were added. The mixture was then stirred for 15 min and filtered. The filtrate was washed successively with water, a 10% citric acid solution, a 5% sodium hydrogen carbonate solution, and water. The solution was dried with magnesium sulfate and solvent was then removed in vacuo. Separation from remaining dicyclohexyl urea was done by dissolving the dipeptide in ethyl acetate and filtering off the insoluble urea. Further purification was by chromatography on a silica-gel column using an ethyl acetate/petroleum ether/ether solvent mixture as eluent.

Preparation of the Metal Peptide Complexes (C): A solution of the protected dipeptide or tripeptide ester (2.0 mmol) in dichloromethane (5 mL) was combined with a solution of Jordan′s cation (2.0 mmol) in dichloromethane (10 mL) at 0 °C. The mixture was stirred for 3 h and then warmed to room temperature. The solvent was removed in vacuo, the residue washed with toluene and pentane to yield the analytically pure metal peptide complex as a white solid.

Preparation of the Metal Peptide Complexes (NMR Experiment) (D): A solution of the protected dipeptide or tripeptide ester (63.8 μmol) in [D_2]dichloromethane (0.4 mL) was combined with a solution of Jordan′s cation (63.8 μmol) in [D_2]dichloromethane (0.4 mL) at −15°C.

Preparation of Boc-Gly-Val-OMe (2): *N-tert*-Butoxycarbonylglycine (3.50 g, 20.0 mmol) and valine methyl ester hydrochloride (3.35 g, 20 mmol) were treated according to procedure A to yield the dipeptide Boc-Gly-Val-OMe (5.25 g, 91%) as an oil. − IR (KBr): $\tilde{\nu}$ = 3326 (s, NH), 2971 (m), 2932 (m), 2878 (w), 1744 (m), 1683 (s), 1664 (vs), 1525 (s), 1366 (w), 1169 (m), 864 (m), 737 (w) cm^{-1}. − ^{1}H NMR (CD_2Cl_2, 599.8 MHz): δ = 7.16 (br., 1 H, 5-H), 5.86 (br., 1 H, 2-H), 4.46 (dd, ^3J = 9.0 Hz, ^3J = 5.2 Hz, 1 H, 6-H), 3.78 (m, 2 H, 3- and 3′-H), 3.69 (s, 3 H, 7-OCH_3), 2.17 [m, 1 H, 6-CH(CH_3)$_2$], 1.40 [s, 9 H, 1-OC(CH_3)$_3$], 0.88 and 0.84 [2 d, 2 ^3J = 7.4 Hz, 2× 3 H, 6-CH(CH_3)$_2$]. − ^{13}C NMR (CD_2Cl_2, 150.8 MHz): δ = 172.7 (C-7), 170.1 (C-4), 156.2 (C-1), 79.9 [1-OC(CH_3)$_3$], 57.0 (C-6), 52.5 (7-OCH_3), 44.1 (C-3), 31.3 [6-CH(CH_3)$_2$], 28.1 [1-OC(CH$_3$)$_3$], 19.0 and 17.6 [6-CH(CH$_3$)$_2$].

Reaction of Boc-Gly-Val-OMe (2) with [$Cp_2ZrCH_3(THF)^+BPh_4^-$] (1a). − Formation of 2-I: Boc-Gly-Val-OMe (18.4 mg, 63.8 μmol) and **1a** (40.0 mg, 63.8 μmol) were treated according to procedure D to generate **2-I**. − ^{1}H NMR (CD_2Cl_2, 599.8 MHz): δ = 7.69 (br., 1 H, 2-H), 7.45 (br., 1 H, 5-H), 6.24 and 6.20 (2 s, 2 × 5 H, Cp- and Cp′-H), 4.35 (br., 1 H, 6-H), 3.80 (s, 3 H, 7-OCH_3), 3.63 (m, 2 H, 3- and 3′-H), 2.10 [m, 1 H, 6-CH(CH_3)$_3$], 1.43 [s, 9 H, 1-OC(CH_3)$_3$], 0.87 and 0.84 [2 d, 2 ^3J = 6.7 Hz, 2 × 3 H, 6-CH(CH_3)$_2$], 0.48 (s, 1 H, Zr-CH_3), [BPh_4]$^-$: 7.45 (m, 8 H, *o*-H), 7.10 (m, 8 H, *m*-H), 6.93 (m, 4 H, *p*-H); THF: δ = 3.72 (m, 4 H, α-H), 1.81 (m, 4 H, β-H). − ^{13}C NMR (CD_2Cl_2, 150.8 MHz): δ = 179.1 (C-4), 168.4 (C-7), 155.3 (C-1), 113.2 and 113.1 (Cp C and Cp′ C), 81.1 [1-OC(CH_3)$_3$], 58.4 (C-6), 53.0 (7-OCH_3), 44.1 (C-3), 33.0 (Zr-CH$_3$), 31.0 [6-CH(CH_3)$_2$], 27.4 [1-OC(CH$_3$)$_3$], 18.1 and 16.8 [6-CH(CH$_3$)$_2$]; [BPh_4]$^-$: δ = 163.8 (q, $^1J_{CB}$ = 49 Hz, *i-C*), 135.3 (*o*-C), 125.7 (*m*-C), 121.7 (*p*-C); THF: δ = 67.9 (α-C), 25.2 (β-C).

Reaction of 2 with 1a. − Formation of 2-A: Boc-Gly-Val-OMe (**2**, 0.58 g, 2.0 mmol) and **1a** (1.25 g, 2 mmol) were treated according to procedure C to yield the metal peptide complex **2-A** (1.59 g, 96 %) as a white solid; m.p. 51 °C (decomp). − $[\alpha]_D$ = −25 (*c* = 0.10, CH_2Cl_2). − $C_{47}H_{53}BN_2O_5Zr$ (828.0): calcd. Rhodium-Catalyzed Amination of Vinylpyridines: Hydroamination versus Oxidative Amination

Matthias Beller,*[a,b] Harald Trauthwein,[b] Martin Eichberger,[†] Claudia Breindl,[b] and Thomas E. Müller[b]

Keywords: Coordination chemistry / Rhodium / Aminations / Hydroaminations / Oxidative aminations / Vinylpyridines

Cationic rhodium complexes catalyze the amination of 2- and 4-vinylpyridine with secondary amines. Depending on the substrate and the reaction conditions either oxidative amination to yield the corresponding enamines **1a−8a** or hydroamination to give 2-aminoethylpyridines **1b−8b** occurs. In all cases products with anti-Markovnikov regioselectivity are obtained. For mechanistic studies novel cationic complexes of rhodium(I)-containing cyclooctadiene and vinylpyridine **12** as well as complexes containing cyclooctadiene, vinylpyridine, and morpholine **13** were prepared and characterized by NMR spectroscopy and X-ray diffraction analysis.

Introduction

The construction of carbon−nitrogen bonds by using transition metal catalysts, especially for the synthesis of amines, has become an area of intensive research. Catalytic aminations of olefins[2] to selectively give primary, secondary, or tertiary amines are particularly interesting because of the atom efficiency of the process and the availability of feedstocks. One of the few examples is the newly developed intermolecular oxidative amination of aromatic olefins to give enamines.[3] Interestingly, this reaction yields the anti-Markovnikov products in a highly selective manner (Scheme 1).

Ar = aryl; R' = aryl, alkyl

Scheme 1. Anti-Markovnikov oxidative amination of styrene

This amination process allows the conversion of simple monoamines, such as piperidine and diethylamine, into the corresponding ω-enamines in good yields by employing cationic (phosphane)rhodium complexes as catalysts. An additional equivalent of the aromatic olefin is concurrently reduced to ethylbenzene. For the first time the transition-metal-catalyzed hydroamination of styrene is possible in an anti-Markovnikov manner with amines, such as morpholine, that contain a hemilabile second coordination site.[1]

In connection with mechanistic studies to understand the features that control whether hydroamination or oxidative amination of olefins occurs, we became interested in the reaction of vinylpyridines. Additional interest in these reactions results from the fact that 2-(2′-aminoethyl)pyridines are used as building blocks for pharmaceuticals and fine chemicals for hydrometallurgy.[4]

In contrast to styrene, 2- and 4-vinylpyridine are Michael systems, i.e. the double bond is in conjugation with an electron-withdrawing group. This activation favors the anti-Markovnikov hydroamination of 2- and 4-vinylpyridine. However, in contrast to acrylamide or acrylnitrile, which react quantitatively with amines without a catalyst even under mild conditions, 2- and 4-vinylpyridine react only sluggishly without a catalyst due to the weaker electron-withdrawing effect of the pyridine ring.

The hydroamination of vinylpyridines was first reported in the late 1940s.[5] Typically, the hydroamination of vinylpyridines is catalyzed by either acid or base.[6] For example, Matusko et al. obtained good results with vinylpyridines by employing a mixture of methanol and acetic acid.[7] However, some amines, like pyrrolidine, are not basic enough to react under these conditions. Successful amination of 2-vinylpyridine occurs when the reaction is performed with the addition of catalytic sodium metal in order to generate the more nucleophilic amide.[8] Surprisingly, the use of transition metal catalysts in the amination of vinylpyridines is rare.[9]

In this report we present for the first time various amination reactions of 2- and 4-vinylpyridines using cationic rhodium catalysts. Depending on the reaction conditions, varying amounts of hydroamination and oxidative amination products are obtained. In order to understand the mechanistic background, new cationic rhodium complexes that contain 2-vinylpyridine as a ligand have been isolated and characterized by X-ray crystallography. These complexes are shown to be important intermediates in the catalytic hydroamination of vinylpyridines.

Results and Discussion

Catalytic Amination of 2- and 4-Vinylpyridine

Cationic (phosphane)rhodium complexes such as $[Rh(cod)_2]BF_4/2\ PPh_3$ are the only known class of active transition metal catalysts for the intermolecular anti-Markovnikov amination and hydroamination of styrenes.[2] In order to investigate how these catalysts effect the amination of a more activated olefin the reaction of 2-vinylpyridine with piperidine was chosen for initial studies (Scheme 2). Under the typical reaction conditions of the oxidative amination of styrene (THF reflux, 2.5 mol-% $[Rh(cod)_2]BF_4$/ 2 PPh_3, 20 h) three products are obtained. The major product, *N*-[2-(2′-pyridyl)ethyl]piperidine (**2b**), resulting from a hydroamination reaction, was isolated in 53% yield. Also, for the first time an intermolecular oxidative amination of 2-vinylpyridine was achieved giving *N*-[2-(2′-pyridyl)ethenyl]piperidine (**2a**) in 47% yield. A second equivalent of 2-vinylpyridine is concurrently reduced to 2-ethylpyridine, which was isolated in 42% yield. All yields are based on piperidine.

Scheme 2. Rhodium-catalyzed amination of 2-vinylpyridine

As expected, all amination reactions occur exclusively with anti-Markovnikov regioselectivity. This is explained by the strong polarization of the vinyl group by the pyridine ring. When the reaction is performed under identical conditions without a catalyst the hydroamination product *N*-[2-(2′-pyridyl)ethyl]piperidine is obtained in only 3% yield. Hence, both the hydroamination and the oxidative amination are catalyzed by the cationic rhodium catalyst.

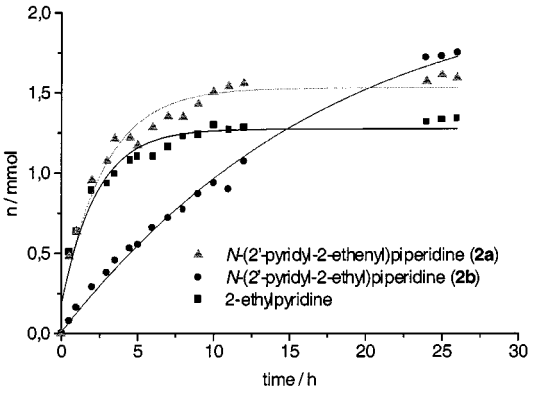

Figure 1. Time/concentration diagram for the reaction of 2-vinylpyridine and piperidine

In a further catalysis experiment the reaction of piperidine with 2-vinylpyridine to form the different amination products was followed with time. As depicted in Figure 1 it is evident that enamine and ethylpyridine are formed mainly during the first hours. After about 10 h, no further enamine formation is observed. In contrast, only a small amount of aminoalkylpyridine is formed at the beginning of the reaction, but the rate of its formation remains nearly constant until all piperidine is consumed. Similar to the oxidative amination of styrene, the enamine formation is probably catalyzed by cationic rhodium species that contain monodentate phosphane ligands. During the course of the reaction the rhodium catalyst is deactivated, either by loss of its cationic character or by the formation of chelate complexes with the products behaving as bidentate ligands. Independent of the oxidative amination process, the formation of the alkylamine proceeds by a different mechanism. In order to gain further insight into the different reaction pathways and to evaluate the critical reaction parameters for both oxidative amination and hydroamination we varied the catalyst system and the reaction conditions (Table 1).

The oxidative amination proceeds best with THF as the solvent (entries 1, 6). The catalyst is also active in toluene, although the formation of alkylamine is increased (entry 2). The dipolar aprotic solvent dimethylacetamide (DMAC) completely inhibits the enamine formation and lowers the yield of alkylamine (entry 3). By reducing the amount of catalyst from 2.5 mol-% to 1 mol-% (entry 1 vs. 4) it is shown that the oxidative amination is more sensitive than the hydroamination to the concentration of the cationic catalyst. This is a good indication that the hydroamination reaction is catalyzed by various rhodium species, while the oxidative amination is catalyzed by a discrete cationic (phosphane)rhodium complex. Further support for this assumption comes from the fact that the presence of phosphane is a prerequisite for enamine formation (entry 5). In the presence of $[Rh(cod)_2]BF_4$ without triphenylphosphane, only hydroamination occurs to give *N*-[2-(2′-pyridyl)ethyl]-piperidine (**2b**) in high yields (97%). By lowering the ratio of vinylpyridine to piperidine to 2:1 the oxidative amination becomes the major reaction pathway and *N*-[2-(2′-pyridyl)ethenyl]piperidine (**2a**) is isolated in 82% yield (entry 6). The different influence of the olefin/amine ratio on the oxidative amination of styrenes and 2-vinylpyridines can be explained by the different coordination ability of styrene and 2-vinylpyridine. 2-Vinylpyridine is able to coordinate to the rhodium center through the pyridine-nitrogen atom, which is not possible for styrene. The coordination of the nitrogen atom of pyridine activates the olefinic bond in 2-vinylpyridine for a nucleophilic attack of the amine, which enhances hydroamination but has no effect on the oxidative amination. In contrast, we assume that the oxidative amination proceeds by an amine-activation mechanism. A lower concentration of 2-vinylpyridine would favor the coordination of the amine to the rhodium center, which facilitates N−H activation.

In order to investigate the influence of pK_a, steric and electronic parameters of the amines on the amination reaction, we tested different aliphatic amines R_2NH, such as piperazines, which have an additional functional group (Table 2).

Table 1. Rhodium-catalyzed reaction of 2-vinylpyridine and piperidine[a]

Entry	Olefin/Amine	Catalyst (mol-%)	Solvent, reaction time	Amine product (%)	Enamine (%)	Ethylpyridine (%)	Amine product/Enamine
1	4:1	$[Rh(cod)_2]BF_4$/2 PPh_3 (2.5)	THF, reflux, 20 h	53	47	42	1.1

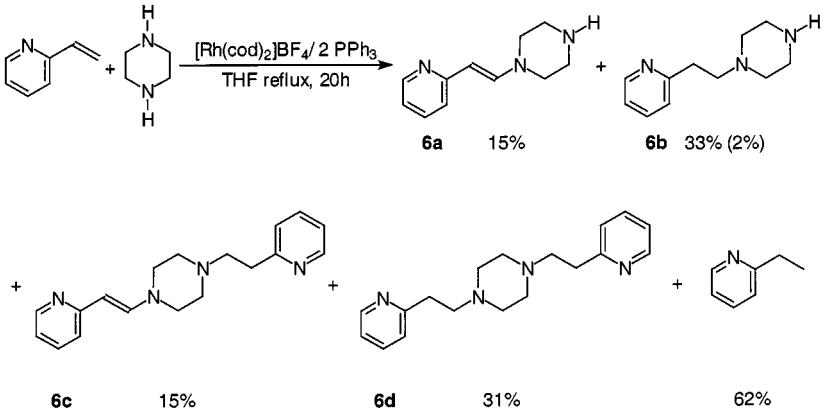
[a] 2-Vinylpyridine/amine = 4:1, 2.5 mol-% $[Rh(cod)_2]BF_4$/2 PPh_3 referred to amine, THF reflux, 20 h. The yield was determined by GC with hexadecane as internal standard and is referred to amine. – [b] The results of the uncatalyzed reaction under the same conditions as the rhodium-catalyzed reaction are shown in parentheses. – [c] The reaction of piperazine is shown in Scheme 3.



The reactions were performed in refluxing THF for 20 h. In all cases only the 2-(2′-aminoethyl)pyridine derivatives were detected as hydroamination products due to the polarization of the double bond. The yields, which were obtained without a catalyst, are given in brackets. Apart from thiomorpholine the amines reacted only to a slight extent (< 10%) without a catalyst. Also, no oxidative amination was observed, i.e. neither the corresponding enamine nor ethylpyridine was formed. Comparing the ring size of the amine applied (pyrrolidine, piperidine, and hexahydroazepine) it is evident that the yield of the oxidative amination product decreases with increased ring size of the amine, with pyrrolidine providing the highest yield in enamine. Bifunctional amines predominantly led to hydroamination reactions. It is likely that the conformation favored by the chelating effect infers the β-H-elimination step that is required for oxidative amination. Interestingly, enamine formation was observed to some extent with all three piperazine derivatives. This is in contrast to the rhodium-catalyzed amination of styrene and piperazine derivatives. In the latter reaction chelating amines inhibit the reaction, which is caused by the formation of insoluble (piperazine)rhodium complexes.[10] Thus, we assume that the amination of 2-vinylpyridine proceeds by activation of the 2-vinylpyridine.

Piperazine, which has two reactive N–H groups, leads to the formation of five different products (Scheme 3). Apart from 2-ethylpyridine, mono- and dialkylated piperazines **6a–d** were obtained in a ratio of 2.2:1:2.1:1.

The ratio of hydroamination products **6b** and **6d** to enamines **6a** and **6c** is approximately 2:1. Surprisingly, no product with two enamine groups was detected. Hence, it is assumed that the dialkylated products are formed mainly by a consecutive reaction of *N*-[2-(2′-pyridyl)ethyl]piperazine. This might be due to the better coordination ability of *N*-[2-(2′-pyridyl)ethyl]piperazine (**6b**) in comparison to *N*-[2-(2′-pyridyl)ethenyl]piperazine (**6a**).

In addition to aliphatic amines, we tested aromatic amines (aniline, pyrrole) as well as amides (acetamide) in the rhodium-catalyzed amination of 2-vinylpyridines. Unfortunately, these substrates did not react in either a hydroamination or in an oxidative reaction. We explain this behavior as being due to the lower pK_a value of these substrates compared to that of 2-vinylpyridine [pK_a(pyridine) = 5.2]. Due to the lower nucleophilicity, hydroamination does not occur even after activation of vinylpyridine. Oxidative amination is not observed because the formation of (amine)rhodium complexes is unfavorable. Hence, N–H activation by the rhodium center is not possible.

Next, we studied the reaction of 4-vinylpyridine with three amines (Table 3). None of the amines reacted with 4-vinylpyridine in the absence of a rhodium catalyst. In the presence of the catalyst system $[Rh(cod)_2]BF_4$/2 PPh_3 all

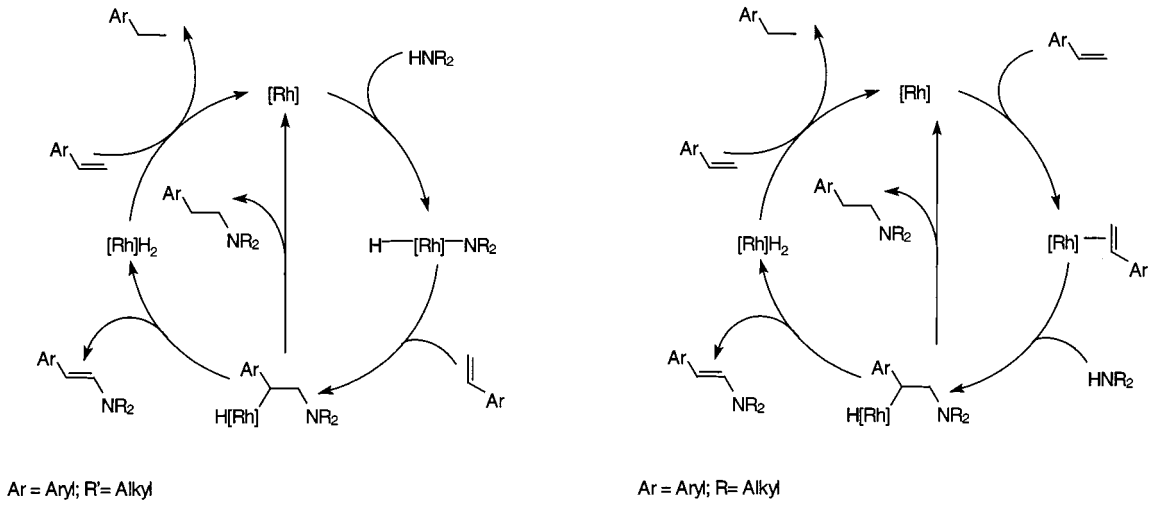
Scheme 3. Reaction of 2-vinylpyridine and piperazine; the yields obtained without catalyst are given in parentheses

Table 3. Rhodium-catalyzed amination of 4-vinylpyridine with aliphatic amines[a]

Entry	Amine	Enamine (%)	Pyridylamine (%)	Ethylpyridine (%)
1	Piperidine	< 1	57 [**9**]	< 1
2	Hexahydroazepine	< 1	21 [**10**]	< 1
3	Morpholine	< 1	54 [**11**]	< 1

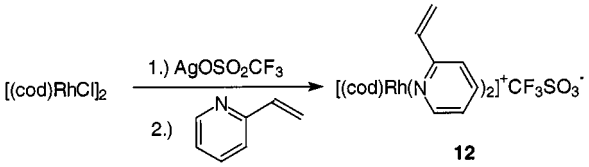
[a] 4-Vinylpyridine/amine = 4:1, 2.5 mol-% $[Rh(cod)_2]BF_4$/2 PPh_3 referred to amine, THF reflux, 20 h. The yield is referred to amine and was determined by GC with hexadecane as internal standard.

amines employed gave only the terminal hydroamination products **9**, **10**, **11**. Oxidative amination was not observed. It is evident that for oxidative amination to occur both the nitrogen atom of the pyridine ring and the vinyl group have to be in steric proximity to the rhodium center.



Mechanistic Studies − Cationic Rhodium Complexes with 2-Vinylpyridine as Ligand

Amination of olefins can take place either by activation of the olefin or by activation of the amine N−H bond.[11] In general, non-functionalized olefins become susceptible towards nucleophiles upon complexation to an electrophilic metal center. Addition of a nucleophile to the metal-bound olefin and protolysis yields the corresponding product and the catalyst. Alternatively, β-hydride elimination results in the formation of imines or enamines. It is important to note that catalytic activation of olefins in the presence of amines is difficult to achieve due to the strong binding of amines to electrophilic metal centers. One possible amine activation pathway involves oxidative addition of an amine to an unsaturated metal center in a low oxidation state. The resulting amido hydrido complex may insert an olefin into the metal−nitrogen bond yielding an aminoalkyl hydrido complex. Subsequent reductive elimination of the amine produced regenerates the catalyst. Alternatively, β-hydride elimination can take place to give enamines and dihydridometal complexes.



In contrast to other olefins, vinylpyridines can be activated by cationic rhodium complexes either by coordination of the double bond, the heteroaromatic ring or by coordination of the nitrogen atom. As suggested above, the mode of coordination of the vinylpyridine is of fundamental importance for explaining the various results obtained in the amination of 2- and 4-vinylpyridine. Therefore, we investigated the coordination chemistry of cationic rhodium complexes with amines and 2-vinylpyridine as ligands.

In contrast to the organometallic chemistry of cationic rhodium complexes with secondary amines that has been described recently,[10] rhodium complexes with 2-vinylpyridine as a ligand have not been studied in detail. Denise and Pannetier described the synthesis of $[Rh(cod)(2\text{-vinylpyridine})_2]PF_6$ by treatment of $[Rh(cod)Cl]_2$ with 2-vinylpyridine and $NaPF_6$.[12] However, no detailed characterization by NMR and X-ray studies of this complex has been performed. Therefore, we synthesized $[Rh(cod)(2\text{-vinylpyridine})_2]OSO_2CF_3$ (**12**) by combining $[Rh(cod)Cl]_2$ and $AgOSO_2CF_3$ followed by addition of 2-vinylpyridine.

At room temperature the ^{1}H-NMR spectrum (Figure 2) of **12** shows several broad resonances indicating fluxionality in the molecule. The signals at $\delta = 8.9$ and 8.7 are assigned to 6-H in the pyridine ring and the internal proton of the olefin, respectively. The other signals in the olefinic and aromatic region of the ^{1}H-NMR spectrum are sharper and are ascribed to 4-H ($\delta = 7.66$), 3-H ($\delta = 7.55$), and 5-H ($\delta = 7.32$). The terminal olefinic protons of the vinyl group show resonances at $\delta = 6.05$. Clearly, the protons that are adjacent to the rhodium center have broader signals compared to the protons that are further away from the metal center. The resonances of both the olefinic protons at $\delta = 4.0$ and the two sets of aliphatic protons of the cod ligand at $\delta = 2.7$ and 2.0 are very broad at room temperature, which is most likely caused by free rotation of the 2-vinylpyridine. Upon cooling **12** to −60°C the broad signals in the ^{1}H-NMR spectrum sharpen to give clearly distinguishable signals. It is interesting to note that the resonances of the olefins show a vicinal and geminal coupling of $J = 11$

Scheme 4. Catalytic cycles for the amination of aromatic olefins by (a) amine activation and (b) olefin activation

Scheme 5. Synthesis of the cationic complex [Rh(cod)(2-vinylpyridine)$_2$]CF_3SO_3 (**12**)

and 17 Hz, respectively. The signals of the cod protons, which appear as three sharp pseudo-doublets, can be used as a probe for the conformation of **12**. Due to steric reasons, both vinyl groups should be opposite to each other.

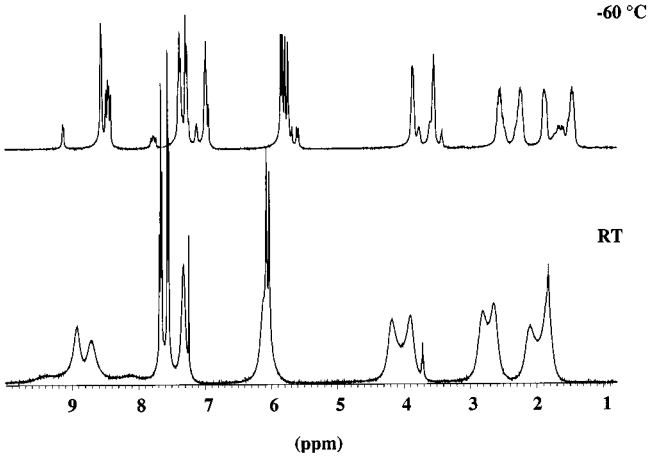


Figure 2. ^{1}H-NMR spectrum of [Rh(cod)(2-vinylpyridine)$_2$]CF_3SO_3 at room temperature and at −60°C in $CDCl_3$

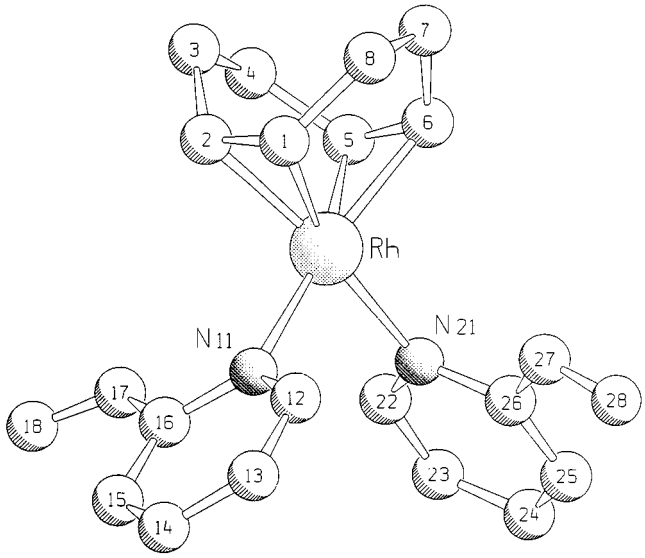
The ^{13}C-NMR spectrum supports this conformational analysis. At room temperature the resonances of the olefinic carbon atoms of the cod ligand are very broad. However, at −60°C two doublets appear, due to the Rh-C coupling ($J_{Rh\text{-}C}$ = 12.6 and 11.7 Hz). This confirms that the olefinic carbon atoms are not identical. Also, there is no interaction between the vinyl group of the 2-vinylpyridine and the rhodium center, as no Rh-C coupling was detected here.

In both the ^{1}H-NMR and the ^{13}C-NMR spectra a second set of patterns (5% intensity) appears upon lowering the temperature. We tentatively ascribe this minor pattern to a rhodium species with pyridine rings, where both vinylic groups are pointing in the same direction.



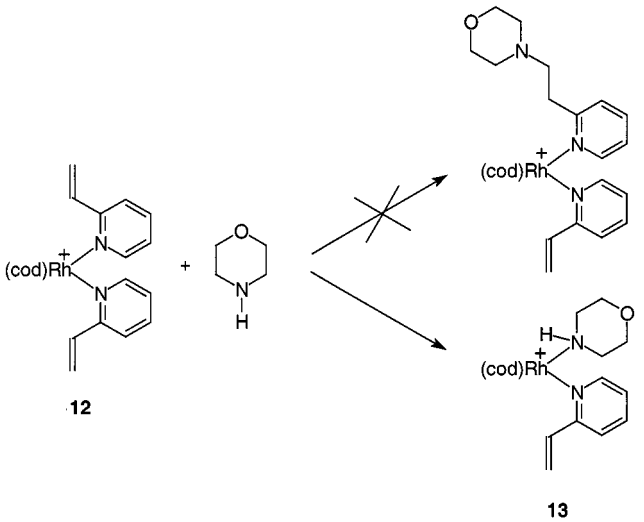


Figure 3. The molecular structure of [Rh(cod)(2-vinylpyridine)$_2$]$^+$

Crystals of **12** were obtained by slowly adding diethyl ether to a dichloromethane solution of **12**. The X-ray analysis (Table 4) is in agreement with the conformation discussed on the basis of the NMR studies. The rhodium center is in an approximately square-planar coordination sphere. The lengths of the rhodium−amine bonds [Rh−N11 = 2.129(2) Å and Rh−N21 = 2.118(3) Å] and the distances from rhodium to the centers X1 and X2 of the cod double bonds C1−C2 and C5−C6 (Rh−X1 = 2.019 Å, Rh−X2 = 2.018 Å) are within the typical range. The angles X1−Rh−X2 (87.6°) and N11−Rh−N21 [89.2(1)°] are close to right angles. The coordination sphere is distorted tetraedric. Associated distances from a mean plane contain-

ing the rhodium atom are X1 +0.057 Å, X2 −0.061 Å, N21 +0.053 Å and N11 −0.057 Å. The 2-vinylpyridine ligands are arranged perpendicular to the coordination plane (82.1°, 89.2°), so that both ring systems are also perpendicular to each other (88.2°). The vinylic groups are on opposite sides of the coordination plane and are slightly twisted against the parent aromatic ring (5.9° and 13.6° for the vinyl group defined by C16, C17, C18 and C26, C27, C28, respectively). There is no coordinative interaction of the vinylic group in the two 2-vinylpyridine ligands with the rhodium center. This is confirmed by a shorter vinylic double bond [C17−C18 = 1.303(6) Å, C27−C28 = 1.308(6) Å] compared to the double bonds in the cod ligand [C1−C2 = 1.385(5) Å, C5−C6 = 1.386(6) Å].

Scheme 6. Reaction of [Rh(cod)(2-vinylpyridine)$_2$]CF_3SO_3 (**12**) with morpholine

Cationic rhodium complexes containing an amine as well as a 2-vinylpyridine ligand are likely intermediates in the catalytic cycle of the amination of 2-vinylpyridine. In order to gain more insight into this system we studied the stoichiometric reaction of [Rh(cod)(2-vinylpyridine)$_2$]CF_3SO_3 (**12**) with 2 equivalents of morpholine. The reaction led to [Rh(cod)(morpholine)(2-vinylpyridine)]CF_3SO_3 (**13**), which was formed in 84% yield (Scheme 6). This is confirmed by mass spectrometry and elemental analysis as well as by IR spectroscopy, where a strong N−H frequency at 3215 cm^{-1} is observed. Interestingly, there is no indication for an attack of the amine on the activated vinyl group of the 2-vinylpyridine.

The ease of formation of the (morpholine)(2-vinylpyridine)rhodium complexes suggests that these complexes are precursors for the intermediates in the catalytic cycle.

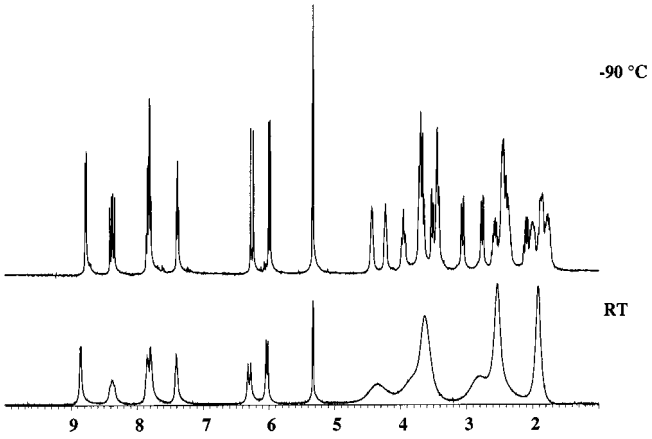

Figure 4. ^{1}H-NMR spectrum of [Rh(cod)(morpholine)(2-vinylpyridine)]CF_3SO_3 (**13**) at room temperature and at −90°C in CD_2Cl_2

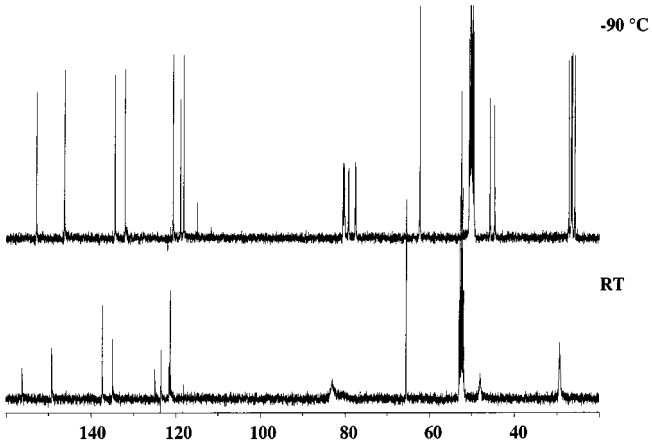

Figure 5. ^{13}C-NMR spectrum of [Rh(cod)(morpholine)(2-vinylpyridine)]CF_3SO_3 (**13**) at room temperature and −90°C in $CDCl_3$

The ^{1}H- and ^{13}C-NMR spectra of [Rh(cod)(morpholine)(2-vinylpyridine)]CF_3SO_3 (**13**) are depicted in Figures 4 and 5, respectively. The signals in the ^{1}H-NMR spectrum at room temperature are broad, especially in the aliphatic region. ^{1}H-NMR analysis at −90°C shows sharper signals, which indicates the existence of a preferential conformation. The splitting of the resonances reveals interesting details about the preferred low-temperature conformation. The multiplets at δ = 3.67 and 3.43 are assigned to the olefinic cod protons as well as the protons of the morpholine protons adjacent to the oxygen atom. There is also a splitting of the resonance of the methylene group of the morpholine ligand adjacent to the nitrogen atom with signals observed at δ = 3.05 and 2.75.

The ^{13}C-NMR spectrum shows similar behavior. The olefinic and the aliphatic cod resonances are very broad at room temperature, but at −90°C the broad olefinic signal at δ = 82.9 is split into four doublets, while the broad aliphatic signal at δ = 29.3 is split into four singlets. Information about the conformation of the morpholine ligand can be obtained from the ^{13}C-NMR spectrum at −90°C. The signal of the methylene group adjacent to the oxygen atom is a singlet, whereas the resonance of the methylene group adjacent to the nitrogen atom is a doublet. The latter methylene groups seem to be influenced by the 2-vinylpyridine ring, whereas the methylene groups adjacent to the oxygen atom in the morpholine ligand are too far away from the pyridine ring for the resonance to be split. Complex **13** was also characterised by X-ray crystallography. The molecular structure of **13** is shown in Figure 6 and selected bond lengths and angles are summarized in Table 5.

The rhodium center is coordinated in a square-planar fashion with the bond lengths Rh−N11 = 2.155(2) Å and Rh−N21 = 2.129(3) Å, as expected for cationic amine−-rhodium bonds.[10] The bond lengths from rhodium to the centers X1 and X2 of the two double bonds C1−C2 and C5−C6 associated with the cod ligand are 2.023 Å and 2.007 Å, respectively. Each ligand around the rhodium center is arranged nearly perpendicular to the two neighbors with X1−Rh−X2 = 87.4°, X2−Rh−N11 = 91.3°, N11−Rh−N21 = 91.3(1)° and N21−Rh−X1 = 89.9°. There is a slight pyramidal distortion, which can be seen by positive distances for each of the coordinating atoms from a plane through the rhodium center (X1 +0.022 Å, X2 +0.075 Å, N11 +0.027 Å and N21 +0.073 Å). The 2-vinylpyridine is arranged nearly perpendicular (87.8°) to the coordination plane. The vinyl group is twisted by 1.7° against the aromatic ring of the 2-vinylpyridine. The double bond of the vinyl group is significantly shorter than the double bonds of the cod ligand [C27−C28 = 1.310(6) Å vs. C1−C2 = 1.360(5) Å, C5−C6 = 1.360(6) Å]. This is in agreement with an elongation of the C1−C2 and C5−C6 bonds caused by their coordination to the rhodium center. There is no coordinative interaction of the rhodium center with the vinyl group in 2-vinylpyridine. The proton of the amine forms a hydrogen bond with the tosylate [H11···O1 = 2.27 Å, N11−H11 = 0.83(2) Å, N11−H11···O1 = 160.3°] and there is a C−H···O hydrogen bond between the aromatic ring and the oxygen atom of the morpholine ligand in a neighboring molecule (H24···O14 = 2.33 Å, C24−H24 = 0.93 Å, C24−H24···O14 = 159.0°).[13]

Table 6. Examples for complexes containing vinylpyridine as ligand; the lengths of the vinylic C−C bond, its distance from the metal center and the twist of the vinyl group against the pyridine ring are given

$[Os_3(\mu\text{-H})_2(CO)_9(\mu_3\text{-C-vpy})]$	1.39(2)	n. b.	28.2	[24d]

X = center of the vinylic C−C bond, vpy = 2-vinylpyridine, n. b. = non bonded.

The X-ray structures of complexes **12** and **13** reveal that in the solid state there is no binding interaction of the rhodium center with the vinyl group in 2-vinylpyridine. The consequence of this are relatively short C−C bond lengths in the vinyl groups, a fact that is in agreement with other late transition metal complexes containing the 2-vinylpyridine ligand (Table 6). The dimeric $[Cu_2(\mu\text{-vpy})_2(vpy)_2](ClO_4)_2$ (vpy = 2-vinylpyridine) incorporates two copper

centers bridged by two vinylpyridine molecules with each of the copper atoms coordinating one further vinylpyridine molecule in a monodentate fashion through the nitrogen atom. The C−C bonds of the two vinyl groups coordinated to the copper center [1.368(17) Å, 1.358(16) Å] are slightly longer compared to non-coordinated vinyl groups [1.307(23) Å, 1.319(23) Å]. Similar vinylic C−C bond lengths are observed in the complexes $[Cu(vpy)Cl]_\infty$ and $[Ni(PPh_3)(vpy)]_2$ [1.380(7) Å, 1.378(7) and 1.414(5) Å, 1.433(5) Å, respectively], which contain the vinylpyridine in a bridging fashion, whereas the vinylpyridine ligand in the complex $[Cu(vpy)I]_\infty$ is bound only through the nitrogen atom that is associated with a shorter vinylic C−C bond [1.29(2) Å]. Other examples are the complexes $[Os_3(\mu\text{-}H)_2(CO)_9(\mu\text{-}CH\text{-}\eta^2\text{-}vpy)]$ and $[Os_3(\mu\text{-}H)_2(CO)_9(\mu_3\text{-}C\text{-}vpy)]$. In these complexes the nitrogen atom of the vinylpyridine moiety is bound to a methylidyne and methylidene bridge connecting three or two osmium atoms, respectively. The vinyl group in the former complex is coordinated to the metal center, whereas it is not coordinated in the second complex. This is associated with slightly longer C−C bond lengths in the first complex [1.43(2) Å] compared to the latter complex [1.39(2) Å].

The comparison with these data confirms that in **12** and **13** there is no binding interaction of the rhodium center with the vinyl group in 2-vinylpyridine. Hence, the activation of 2-vinylpyridine in the presence of cationic rhodium complexes towards hydroamination most likely proceeds by a coordination of the rhodium center to the pyridine nitrogen atom, which leads to a decrease in the electron density of the vinyl group. Clearly, oxidative amination that takes place in the presence of additional phosphane ligands must take place by a different mechanism. Unfortunately, all efforts to isolate or characterize an (amine)(phosphane)(vinylpyridine)rhodium complex turned out to be unsuccessful. Further work in this direction is in progress.

Conclusion

For the first time the oxidative amination of 2-vinylpyridine is described. In the presence of cationic (phosphane)rhodium complexes both oxidative amination as well as hydroamination occurs to yield products with anti-Markovnikov regiochemistry. Interestingly, the ratio of enamine to alkylamine is strongly influenced by the solvent, the phosphane and the ratio of olefin to amine. It is assumed that the hydroamination is initiated by an activation of the 2-vinylpyridine through coordination of the pyridine nitrogen atom to the rhodium center. In contrast, oxidative amination proceeds by a different mechanism. While cyclic amines that do not contain additional heteroatoms give good yields of the corresponding enamines, hydroamination dominates in the case of bidentate amines such as morpholine. Hydroamination of 4-vinylpyridine is achieved under surprisingly mild conditions.

A possible intermediate for the catalyst formation, $[Rh(cod)(2\text{-vinylpyridine})_2]CF_3SO_3$ (**12**) was synthesized and completely characterized. **12** reacts selectively with morpholine to give $[Rh(cod)(morpholine)(2\text{-vinylpyridine})]CF_3SO_3$ (**13**), which is a likely intermediate in the catalytic cycle.

Experimental Section

Materials and Methods: All reactions of air- and/or water-sensitive compounds were performed using standard high-vacuum or Schlenk techniques. All solvents were dried and distilled prior to use according to standard procedures. Amines were distilled from CaH_2, silver salts and other chemicals were purchased from Fluka or Aldrich and used as received. $[Rh(cod)Cl]_2$[14] and $[Rh(cod)_2]BF_4$[15] were prepared as described in the appropriate reference.

Physical and Analytical Methods: ^{1}H- and ^{13}C-NMR spectra were recorded with a Bruker AT 360 and referenced in ppm relative to tetramethylsilane. − Infrared spectra were obtained with a Perkin−Elmer 1600 spectrometer. − Mass-spectrometric analysis was performed with a Finnigan MAT 311A by the Fast Atom Bombardment (FAB) method. − Elemental analyses were performed by the Microanalytical Laboratory of the Technische Universität München. − GC analyses were conducted with a Hewlett−Packard 6890 instrument using an HP-1 capillary column. Yields were determined against hexadecane as an internal standard. GC/MS analyses were conducted with a Hewlett-Packard 5890 with 70-eV electron impact ionization (detector: HP 5970 B).

Reaction of 2-Vinylpyridine with Pyrrolidine: 45 mg of $[Rh(cod)_2]BF_4$ (0.11 mmol) and 58 mg of PPh_3 (0.22 mmol) were mixed in 10 mL of THF. Subsequently, 0.37 mL of pyrrolidine (4.40 mmol) and 1.90 mL of 2-vinylpyridine (17.6 mmol) were added at room temperature. The reaction was heated to reflux for 20 h before being cooled to room temperature. The yield of (*E*)-*N*-[2-(2-pyridyl)ethenyl]pyrrolidine (**1a**) was determined by gas chromatography with hexadecane as an internal standard. − In order to isolate a more stable derivative of (*E*)-*N*-[2-(2-pyridyl)ethenyl]-pyrrolidine (**1a**) , 0.5 g of Pd/C (5%) was added to the crude reaction and the mixture was stirred for 48 h under H_2 at a pressure of 1 atm. After filtration, the solvent was removed by evaporation. The residue was dissolved in 20 mL of dichloromethane and extracted three times with 5% HCl. The combined aqueous phases were neutralized by adding NaOH until pH = 9 was reached and the product was extracted three times with dichloromethane. The combined organic layers were dried with $MgSO_4$ and the solvent was distilled off. *N*-[2-(2-Pyridyl)ethyl]pyrrolidine (**1b**) was obtained after column chromatography (chloroform/methanol, 50:1) in 75% yield.

Reaction of 4-Vinylpyridine with Morpholine: In a procedure analogous to the synthesis of **1**, 0.38 mL of morpholine (4.40 mmol) and 1.90 mL of 4-vinylpyridine (17.6 mmol) in 10 mL of THF were treated in the presence of 45 mg of $[Rh(cod)_2]BF_4$ (0.11 mmol) and 58 mg of PPh_3 (0.22 mmol).

***N*-[2-(4-Pyridyl)ethyl]morpholine (11):** GC yield: 54%; isolated yield: 44% (37 mg). – ^{1}H NMR (360 MHz, 25°C, $CDCl_3$): δ = 8.28 [d, ^3J(H,H) = 4.5 Hz, 2 H, *H*-2], 7.01 [d, ^3J(H,H) = 4.5 Hz, 2 H, 3-H], 3.60 [t, ^3J(H,H) = 4.4 Hz, 4 H, CH_2−O], 2.67 (m, 2 H, Py−CH_2−CH_2), 2.51 (m, 2 H, Py−CH_2), 2.40 [t, ^3J(H,H) = 4.4 Hz, 4 H, CH_2N]. – ^{13}C{^{1}H} NMR (91 MHz, 25°C, $CDCl_3$): δ = 149.5 (C-2), 149.1 (C-4), 124.0 (C-3), 66.7 (*C*−O), 59.1 (Py−C−*C*), 53.4 (*C*−N), 32.4 (Py−*C*). – MS; *m*/*z*: 192 [M − H^+], 132, 106 [C_5H_4N−$C_2H_4^+$], 100 [CH_2=N$(CH_2)_4O^+$].

[(1,2,5,6-η)-1,5-Cyclooctadiene]bis[*N*-(2-vinylpyridine)]rhodium(I) Tetrafluoroborate (12): 100 mg of $[Rh(cod)Cl]_2$ (0.20 mmol) and 80 mg of $AgBF_4$ (0.41 mmol) were dissolved in 2 mL of THF and the solution was stirred for 10 min. After filtering off the AgCl precipitate, the orange solution was cooled to 0°C and 94 mg of 2-vinylpyridine (0.90 mmol) was added. After stirring the reaction mixture for several minutes, a yellow precipitate was obtained. After filtration, the crude product was washed three times with 1 mL of THF and three times with pentane. Drying in vacuo furnished 154 mg of **12** (76%). – ^{1}H NMR (400 MHz, $CDCl_3$, 20°C): δ = 8.92 (s, br., 1 H, 6-H), 8.71 (s, br., 1 H, *H*-7), 7.66 [t, ^3J(H,H) = 7.9 Hz, 1 H, 4-H], 7.55 [d, ^3J(H,H) = 7.9 Hz, 1 H, 3-H], 7.32 (s, 1 H, 5-H), 6.05 [d, br., ^3J(H,H) = 17.6 Hz, 2 H, *H*-8], 4.17 [s, br., 2 H, C*H* (cod)], 3.90 [s, br., 2 H, C*H* (cod)], 2.81 [s, br., 2 H, CH_2 (cod)], 2.64 [s, br., 2 H, CH_2 (cod)], 2.10 [s, br., 2 H, CH_2 (cod)], 1.84 [s, br., 2 H, CH_2 (cod)]. – ^{13}C NMR (100 MHz, $CDCl_3$, 20°C): δ = 157.1 (C-2), 151.0 (C-6), 138.2 (C-8), 135.7 (C-4), 124.4 (C-5), 123.0 (C-7), 121.8 (C-3), 85.4 [*C*H (cod)], 83.9 [C*H* (cod)], 31.5 [CH_2 (cod)], 29.6 [CH_2 (cod)]. – At −60°C, in both the ^{1}H-NMR and the ^{13}C-NMR spectra, a second set of weak resonances (w) appears, which has only 1/10 of the intensity of the main one (ss): ^{1}H NMR (400 MHz, $CDCl_3$, −60°C): δ = 9.43 (w, m, 1 H), 8.92 [ss, d, ^3J(H,H) = 4.4 Hz, 1 H, 6-H], 8.74 [ss, dd, ^3J(H,H) = 11.0 Hz, ^3J(H,H) = 17.0 Hz, 1 H, *H*-7], 8.08 [w, dd, ^3J(H,H) = 11.0 Hz, ^3J(H,H) = 17.0 Hz], 7.66 [ss, t, ^3J(H,H) = 7.9 Hz, 1 H, 4-H], 7.55 [ss, d, ^3J(H,H) = 8.0 Hz, 1 H, 3-H], 7.42 (w, m, 1 H), 7.28 (ss, m, 1 H, 5-H), 6.09 [ss, dd, br., ^3J(H,H) = 17.6 Hz, ^3J(H,H) = 11.0 Hz, 2 H, *H*-8], 6.00 (w, m, 1 H), 5.89 [w, d, ^3J(H,H) = 11.0 Hz], 4.16 [ss, m, 2 H, C*H* (cod)], 4.06 (w, s, 1 H), 3.93 (w, s, 1 H), 3.83 [ss, m, 2 H, C*H* (cod)], 2.84 [ss, m, 2 H, CH_2 (cod)], 2.64 [ss, m, br., 2 H, CH_2 (cod)], 2.17 [ss, m, 2 H, CH_2 (cod)], 1.97 (w, m, 1 H), 1.82 (w, m, 1 H), 1.84 [ss, br., 2 H, CH_2 (cod)]. – ^{13}C NMR (100 MHz, $CDCl_3$, −60°C): δ = 157.1 (ss, C-2), 156.0 (w, C-2), 151.1 (ss, C-6), 150.6 (w, C-6), 138.4 (ss, C-8), 138.1 (w, C-8), 136.5 (w, C-4), 135.6 (ss, C-4), 124.7 (w, C-5), 124.5 (ss, C-5), 123.5 (ss, C-7), 122.3 (w, C-7), 122.0 (ss, C-3), 121.6 (w, C-3), 88.2 [w, d, ^1J(C,Rh) = 11.7 Hz, *C*H (cod)], 85.2 [ss, d, ^1J(C,Rh) = 11.7 Hz, *C*H (cod)], 84.9 [ss, d, ^1J(C,Rh) = 11.7 Hz, C*H* (cod)], 81.2 [w, d, ^1J(C,Rh) = 11.7 Hz, C*H* (cod)], 32.1 [ss, CH_2 (cod)], 30.6 [w, CH_2 (cod)], 30.4 [w, CH_2 (cod)], 29.1 [ss, CH_2 (cod)]. – $C_{22}H_{26}BF_4N_2Rh$ (508.17): calcd. C 52.0, H 5.2, N 5.5; found C 51.8, H 5.3, N 5.4.

Crystal Data and Structure Refinement of 12: Crystals were grown by slow diffusion of Et_2O into a solution of [Rh(cod)(2-vinylpyridine)$_2$]CF_3SO_3 in CH_2Cl_2. A yellow crystal of dimensions 0.35 × 0.30 × 0.17 mm was mounted by the Lindeman technique. Cell constants were determined by least-squares refinement of 5000 reflections in the intervall 16.8° < 2Θ < 49.8° with the program

CELL.[16] Crystal data: monoclinic $P2_1/n$; a = 11.3081(7) Å, b = 17.0699(6) Å, c = 12.2946(7) Å, β = 90.911(6)°; V = 2372.9(2) Å^3; formula unit = $C_{23}H_{26}F_3N_2O_3RhS$ with Z = 4; FW = 570.43; F(000) = 1160; μ(Mo-K_α) = 8.59 cm^{-1}; λ(Mo-K_α) = 0.71069 Å; $\rho_{calcd.}$ = 1.597 g cm^{-3}. Preliminary examination and data collection were carried out with an imaging-plate diffraction system (IPDS; STOE & Cie) equipped with a rotating anode (NONIUS FR591; 50 kV; 80 mA) and graphite monochromator. The data were collected at 293(2) K with an exposure time of 5.0 min per image (rotation scan modus from φ = 0.0° to 300° with Δφ = 1°). 24641 reflections were collected (2.05° < Θ < 24.6°). Final full-matrix least-squares refinement (on F^2) based on 3760 unique reflections of which 3753 were used converged with 452 variable parameters and 15 restraints. Non-hydrogen atoms were refined anisotropically, hydrogen atoms were refined isotropically with U(H) = 1.2 U_{eq}(parent atom). $R1$ = 0.0300, for $F^2 > 2\ \sigma(F^2)$; $wR2$ = 0.0770;[17] Goof(F^2) = 0.953; $\Delta\rho_{max}$ = 0.56, $\Delta\rho_{min}$ = −0.42 e$^-$ Å^{-3}. The data analysis and the drawing were made using the programs STRUX-V,[18] SIR-92,[19] SHELXL-93,[20] and SCHAKAL-97.[21]

[(1,2,5,6-η)-1,5-Cyclooctadiene](*N*-morpholine)[*N*-(2-vinylpyridine)]-rhodium(I) Trifluoromethylsulfonate (13): 100 mg of [Rh(cod)(2-vinylpyridine)$_2$]CF_3SO_3 (0.18 mmol) was dissolved in 1 mL of THF. 16 mg of morpholine was added to the yellow solution. Immediately a yellow precipitate was obtained, which was filtered off and washed three times with 1 mL of THF and 1 mL of pentane. After drying in vacuo, 83 mg (84%) of **13** was obtained. − ^{1}H NMR (400 MHz, CD_2Cl_2, 20°C): δ = 8.85 (s, 1 H, 6-H), 8.38 (s, br., 1 H, *H*-7), 7.48 [d, ^3J(H,H) = 6.5 Hz, 1 H, 4-H], 7.80 (s, 1 H, 3-H), 7.41 (s, 1 H, 5-H), 6.29 [d, ^3J(H,H) = 17.0 Hz, 1 H, *H*-8 (*trans*)], 6.03 [d, ^3J(H,H) = 11.0 Hz, 1 H, *H*-8 (*cis*)], 4.34 [s, br., 2 H, C*H* (cod)], 3.63 [s, br., 7 H, C*H* (cod), N−*H*, CH_2−O], 2.79 (s, br., 2 H, N−CH_2), 2.53 [s, br., 6 H, CH_2 (cod), N−CH_2], 1.9 [s, br., 4 H, CH_2 (cod)]. − ^{13}C NMR (100 MHz, $CDCl_3$, 20°C): δ = 156.2 (C-2), 149.2 (C-6), 137.3 (C-8), 134.9 (C-4), 124.9 (C-5), 123.5 (C-7), 121.3 (C-3), 82.9 [C*H* (cod)], 65.5 (*C*−O), 48.0 (*C*−N), 29.3 [CH_2 (cod)]. − IR (KBr): $\tilde{\nu}$ = 3215 cm^{-1} s, 2941 m, 2987 m, 1601 m, 1480 s, 1444 m, 1272 ss, 1263 ss, 1249 ss, 1153 ss, 1029 ss, 880 s. − MS; (FAB) *m/z*: 316 [M$^+$ − morpholine]. − $C_{19}H_{28}BF_4N_2ORh$ (552.41): calcd. C 44.9, H 5.2, N 4.8; found C 44.9, H 4.7, N 5.2.

Crystal Data and Structure Refinement of 13: Crystals were grown by slow diffusion of Et_2O into a solution of [Rh(cod)(morpholine)(2-vinylpyridine)]CF_3SO_3 in CH_2Cl_2. A yellow crystal of dimensions 0.25 × 0.27 × 0.1 mm was mounted by the Lindeman technique. Cell constants were determined by least-squares refinement of 1998 reflections in the intervall 27.3° < 2Θ < 51.7° with the program CELL. Crystal data: triclinic $P-1$; a = 9.7085(2), b = 10.7786(2), c = 12.6294(2) Å, α = 76.3538(14)°, β = 72.1748(14)°, γ = 65.7518(11)°; V = 1137.86(4) Å^3; empirical formula $C_{20}H_{28}F_3N_2O_4RhS$, Z = 2; FW = 552.41; F(000) = 564; μ(Mo-K_α) = 8.95 cm^{-1}; λ(Mo-K_α) = 0.71073 Å; $\rho_{calcd.}$ = 1.612 g cm^{-3}. Preliminary examination and data collection were carried out with a Kappa-CCD equipped with a rotating anode (NONIUS FR591; 50 kV; 80 mA) and graphite monochromator. The data were collected at 293(2) K with an exposure time of 20 s per image (detector−image 30 mm, rotation-scan modus from φ = 0.0° to 360° with Δφ = 1°). 15058 reflections were collected (4.60° < Θ < 26.35°). Final full-matrix least-squares refinement (on F^2) based on 3917 unique reflections converged with 367 variable parameters and 28 restraints. Non-hydrogen atoms were refined anisotropically, hydrogen atoms were refined isotropically with U(H) = 1.2 U_{eq}(parent atom) using a riding model. The R factor is slightly increased due to disorder in the cod ligand (C4 and C7), the 2-vinylpyridine and the tosylate. $R1$ = 0.0281, for $F^2 > 2\ \sigma(F^2)$; $wR2$ = 0.0701;[17] Goof(F^2) = 1.035; $\Delta\rho_{max}$ = 0.40, $\Delta\rho_{min}$ = −0.50 e$^-$ Å^{-3}. The data analysis and the drawing were made using the programs STRUX-V,[18] SIR-92,[19] SHELXL-93,[20] and SCHAKAL-97.[21]

Acknowledgments

We thank Dr. E. Herdtweck and Dr. W. Scherer (TU München) for performing the X-ray analyses. Prof. B. Hanson (Virginia Tech) is thanked for helpful comments on this manuscript. H. T. thanks the Fonds der Chemischen Industrie for a fellowship and T. E. M. for a Liebig-Stipendium. Financial support (Be 1931−3/1) from the Deutsche Forschungsgemeinschaft (DFG) and loans of precious metals by the Degussa AG and the Hoechst AG are gratefully acknowledged.

Derivative Chemistry of $[Ru_2(\mu\text{-bdt})(CO)_6]$, a Binuclear Ruthenium(I) Carbonyl Complex Containing a Bridging Benzene-1,2-dithiolate Ligand

Javier A. Cabeza,*[a] M. Angeles Martínez-García,[a] Víctor Riera,[a] Diego Ardura,[b] Santiago García-Granda,[b] and Juan F. Van der Maelen[b]

Keywords: Ruthenium / Thiolate ligands / Dithiolate ligands / Substitution reactions / Electrophilic additions

The known dithiolate-bridged ruthenium(I) complex $[Ru_2(\mu\text{-bdt})(CO)_6]$ (**1**) (bdt = benzene-1,2-dithiolate) has been prepared in fair yield (55%) by the sequential treatment of $RuCl_3{\cdot}nH_2O$ with carbon monoxide, benzene-1,2-dithiol and zinc in a one-pot reaction. Complex **1** reacts readily with monodentate phosphanes to give, stepwise, the penta- and tetracarbonyl derivatives $[Ru_2(\mu\text{-bdt})(CO)_{6-n}(PR_3)_n]$ (n = 1, 2; R = Ph, Cy, *i*Pr). However, the reaction of **1** with one equivalent of bis(diphenylphosphanyl)methane (dppm) affords a mixture of complex **1** and the disubstituted derivative $[Ru_2(\mu\text{-bdt})(CO)_4(\eta^1\text{-dppm})_2]$, in which the dppm ligands are monodentate. This mixture is subsequently transformed into a polymeric material of formula $[\{Ru_2(\mu\text{-bdt})(CO)_4\}(\mu\text{-dppm})]_n$, which consists of binuclear $\{Ru_2(\mu\text{-bdt})(CO)_4\}$ units linked to each other by bridging dppm ligands. The use of two equivalents of dppm leads to $[Ru_2(\mu\text{-bdt})(CO)_4(\eta^1\text{-dppm})_2]$ in quantitative yield. The X-ray diffraction structure of $[Ru_2(\mu\text{-bdt})(CO)_4(P\textit{i}Pr_3)_2]$ (**3c**) confirms that the phosphane ligands are located in axial positions, *cis* to both sulfur atoms, and that the Ru–Ru distance is short [2.6753(7) Å]. A comparative study of the reactivity of complexes **1** and **3c** with the electrophiles H^+, $[Au(PPh_3)]^+$, and $HgCl_2$ has allowed the isolation of the derivatives $[Ru_2(\mu\text{-H})(\mu\text{-bdt})(CO)_{6-n}(P\textit{i}Pr_3)_n][BF_4]$ (n = 0, 2), $[Ru_2Au(\mu\text{-bdt})(CO)_{6-n}(P\textit{i}Pr_3)_n(PPh_3)][BF_4]$ (n = 0, 2) and $[Ru_2HgCl_2(\mu\text{-bdt})(CO)_{6-n}(P\textit{i}Pr_3)_n]$ (n = 0, 2), respectively.

Introduction

Over the past few years, several authors have reported general high-yield routes to binuclear ruthenium(I) tetracarbonyl complexes containing two bridging alkyl- or arylthiolate ligands of the type $[Ru_2(\mu\text{-SR})_2(CO)_4(PR_3)_2]$[1–4]. However, the closely related hexacarbonyl compounds $[Ru_2(\mu\text{-SR})_2(CO)_6]$, although known for many years, have so far been prepared in low yields[5–11], their derivative chemistry being virtually unexplored.

We now report a new synthesis of the hexacarbonyl complex $[Ru_2(\mu\text{-bdt})(CO)_6]$ (**1**) (bdt = benzene-1,2-dithiolate), starting from readily accessible starting materials ($RuCl_3 \cdot n\ H_2O$, benzene-1,2-dithiol, carbon monoxide, and zinc), in a fair yield (50–60%), following a simple one-pot reaction which can be carried out on milligram or gram scales.

Such a convenient synthetic procedure, in addition to the fact that the doubly bridging attachment of the bdt ligand to the metal atoms in complex **1** rules out the complication of having *syn* and *anti* isomers, which do exist in bis(monothiolate)-bridged complexes[4], makes complex **1** an excellent candidate for reactivity studies. We report herein its reactivity with some nucleophilic and electrophilic reagents. This type of reactivity study has not been previously reported on hexacarbonyl thiolate-bridged diruthenium(I) complexes, probably as a consequence of the lack of a convenient synthetic route to such compounds.

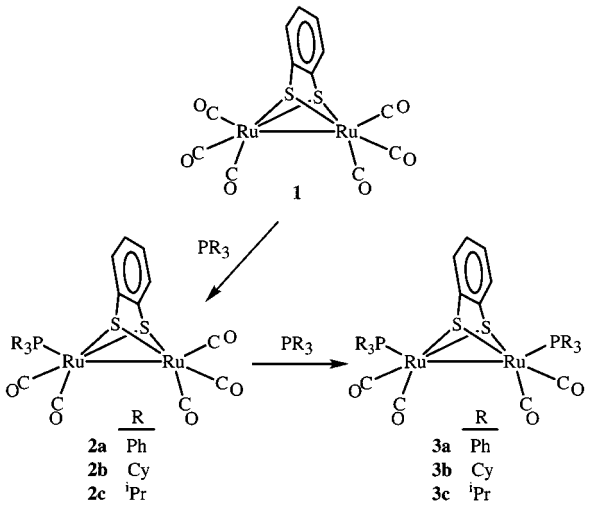
Results and Discussion

Synthesis of Complex 1

The reaction of carbon monoxide with $RuCl_3 \cdot n\ H_2O$ in 2-methoxyethanol at reflux temperature gives a yellow solution. Treatment of this solution with benzene-1,2-dithiol and granular zinc as reducing agent has allowed the isolation of the hexacarbonyl complex **1** in 55% yield. This complex has previously been prepared in lower yield (35%) by treating $[Ru_3(CO)_{12}]$ with benzene-1,2-dithiol in toluene at reflux temperature[11].



An analogous synthetic method has previously been used to prepare other complexes containing ligand-bridged $Ru(CO)_3$ units, such as $[Ru_2(\mu\text{-pz})_2(CO)_6]$ (Hpz = pyrazole)[12] and $[Ru_3(\mu\text{-}PPh_2)_3(CO)_9]Cl$[13]. It is well known that the yellow solution formed by treating $RuCl_3 \cdot n\ H_2O$ with carbon monoxide in 2-methoxy- or 2-ethoxyethanol is a useful precursor for the synthesis of mononuclear ruthenium(II) compounds[14] and for the low-pressure preparation of $[Ru_3(CO)_{12}]$[15]; however, not until recently was the colorless ruthenium(II) dimer $[Ru_2Cl_2(\mu\text{-Cl})_2(CO)_6]$ described as the major component of that yellow solution[16].

Reactions of Complex 1 with Monodentate Phosphane Ligands

Addition of one equivalent of a monodentate phosphane ligand to a room temperature THF solution of compound

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1999 1434–1948/99/0707–1133 $ 17.50+.50/0

1 led to the quantitative (IR) formation of monosubstituted derivatives of the type $[Ru_2(\mu\text{-bdt})(CO)_5(PR_3)]$ (**2a**: R = Ph; **2b**: R = Cy; **2c**: R = *i*Pr). The three compounds have very similar IR spectra in the carbonyl stretching region (Table 1), as expected for compounds having analogous structures. The structure depicted in Scheme 1 for these compounds, in which the phosphane ligand is in a position *cis* to both sulfur atoms, has been unequivocaly inferred from their ^{1}H-NMR spectra, which show the aromatic protons of the bridging bdt ligand as two multiplets corresponding to an AA′MM′ spin system; therefore, the phosphorus atom of the phosphane ligand is in a mirror plane that cuts the bdt ligand into two identical halves (C_s symmetry).

[a] Abbreviations for IR data: s = strong, m = medium, w = weak, v = very. − [b] In $CDCl_3$; abbreviations for NMR data: s = singlet, d = doublet, t = triplet, m = multiplet. − [c] In CH_2Cl_2. − [d] In Nujol mull. − [e] $J_{P\text{-}P}$ = 32.0 Hz. − [f] In acetone.

Addition of at least two equivalents of a monodentate phosphane ligand to a room temperature THF solution of compound **1** led to the immediate formation of monosubstituted derivatives. The incorporation of a second phosphane ligand into the complexes required a higher temperature (THF under reflux), leading to the compounds $[Ru_2(\mu\text{-bdt})(CO)_4(PR_3)_2]$ (**3a**: R = Ph; **3b**: R = Cy; **3c**: R = *i*Pr). The structure of C_{2v} symmetry shown in Scheme 1 for these compounds is validated by their IR [three ν(CO) absorptions] and NMR spectroscopic data (an AA′MM′ spin system accompanied by the signals corresponding to the phosphane ligand in the ^{1}H-NMR spectrum and one singlet in the ^{31}P{^{1}H}-NMR spectrum), which are compatible with the existence in the compounds of two perpendicular mirror planes.

It has been reported that the binuclear ruthenium(I) complex $[Ru_2(\mu\text{-dan})(CO)_6]$ (H_2dan = 1,8-diaminonaphthalene), which is structurally related to **1** but has an *N*-donor instead of an *S*-donor bridging ligand, undegoes a rapid substitution of two CO ligands by phosphane ligands at room temperature[17]. This has been associated with a strong *cis* labilization effect of the hard *N*-donor bridging ligand[18]. The fact that the second substitution of CO by a phosphane ligand in **1** is slow indicates that the bdt ligand is not as strong *cis* labilizer as the dan ligand, probably due to the softer character of the *S*-donor ligand.

Compounds **3a**, **3b**, and **3c** could also be prepared in fair yields (43−73%) in one-pot reactions starting from $RuCl_3 \cdot n\,H_2O$, in an analogous procedure as that described above for compound **1** but carrying out the final step in the presence of the appropriate phosphane ligand. While this work was in progress, Shiu et al. reported an alternative synthesis of compound **3a** by treating the cationic binuclear compound $[Ru_2(CO)_4(PPh_3)_2(MeCN)_4][BF_4]_2$ with benzene-1,2-dithiol in the presence of triethyl amine[3].

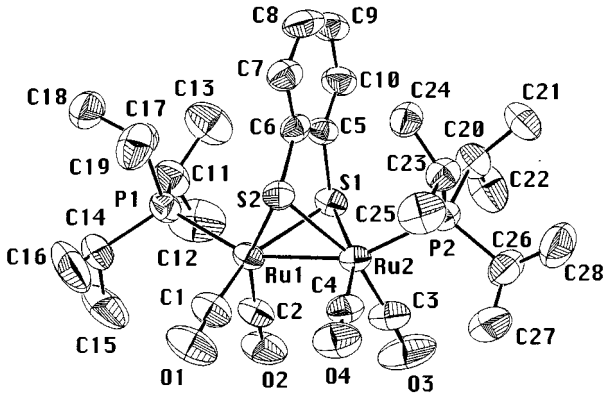

Figure 1. Molecular structure of complex **3c**. Thermal ellipsoids are drawn at 50% probability level

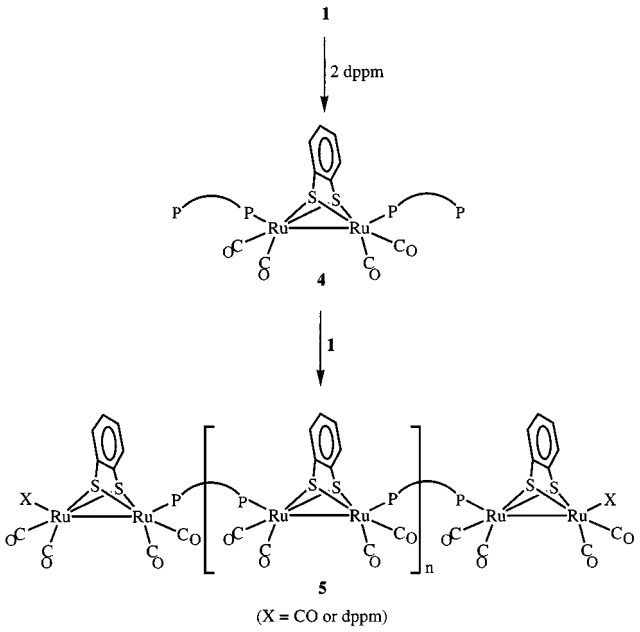
Compound **3c** has been characterized by X-ray diffraction methods (Figure 1). Relevant bond lengths and angles are given in Table 2. Overall, the structure reminds those of many other diruthenium(I) complexes containing bridging ligands[2−4,11,18,19]. The most interesting feature is that the Ru−Ru distance [2.6753(7) Å] is comparable to that found in the unsubstituted complex **1** [2.650(2) Å][11] and also to those found in related complexes containing other thiolate bridging ligands[2−4]. These data indicate that the metal−metal distance in diruthenium(I) compounds containing bridging ligands is little affected by the nature of the terminal ligands. However, such a distance is indeed affected



by the nature of the bridging ligands, since the shorter Ru−Ru distance found in the complex $[Ru_2(\mu\text{-dab})(CO)_4(PPh_3)_2]$ (H_2dab = 1,2-diaminobenzene), 2.558(1) Å[19], which is analogous to **3a** but has *N*-donor instead of *S*-donor atoms, can be associated to the smaller size of bridgehead nitrogen atom.

Table 2. Selected structural parameters in complex **3c**

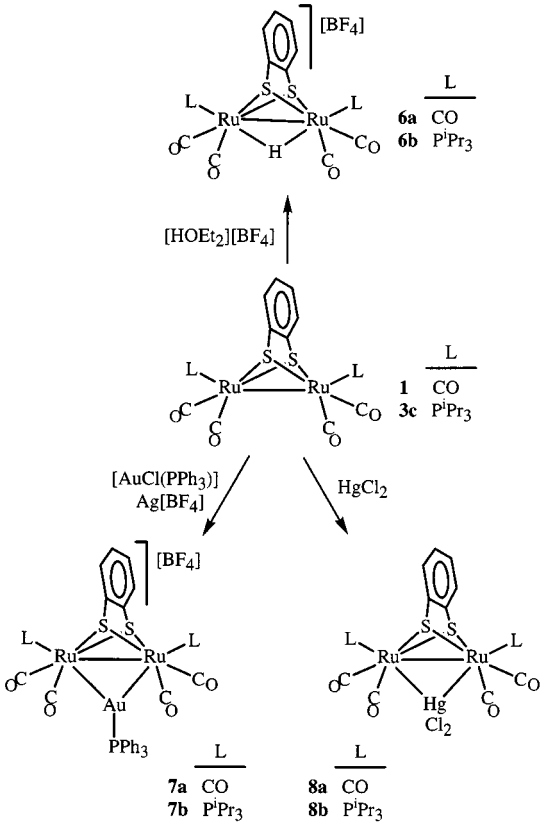
Reactions of Complex 1 with the Bidentate Ligand dppm

Treatment a THF solution of compound **1** with bis(diphenylphosphanyl)methane (dppm), in a 1:1 mol ratio, readily resulted (30 min, room temperature) in the formation of the disubstituted derivative $[Ru_2(\mu\text{-bdt})(CO)_4(\eta^1\text{-dppm})_2]$ (**4**), while half the initial amount of the starting complex **1** remained (IR identification). After stirring for 4 h, a yellow solid began to precipitate from the solution. After 3 days the precipitate was copious and the liquid phase was nearly colorless. This solid, subsequently identified as the polymer $[\{Ru_2(\mu\text{-bdt})(CO)_4\}(\mu\text{-dppm})]_n$ (**5**), is insoluble in all common solvents. Compound **4** can be prepared in high yield by treating **1** with dppm in a 1:2 mol ratio.

Scheme 2. Reactivity of complex **1** with dppm

The structure shown in Scheme 2 for complex **4** is substantiated by its analytical and spectroscopic data. In particular, its $^{31}P\{^1H\}$-NMR spectrum, which consists of two multiplets at δ = 25.7 and −24.9 (AA′XX′ spin system), indicates that the two dppm ligands are symmetry-related and that they are coordinated in a monodentate mode. The ν(CO) region of its IR spectrum is comparable to those of compounds **3a**, **3b**, and **3c** (Table 1), indicating a similar arrangement of the carbonyl ligands (C_{2v} symmetry). Analogous spectral data have previously been reported for the related diruthenium(I) complexes $[Ru_2(\mu\text{-dan})(CO)_4(\eta^1\text{-dppm})_2]$[17] and $[Ru_2(\mu\text{-MeCO}_2)_2(CO)_4(\eta^1\text{-dppm})_2]$[20], which contain *N*- and *O*-donor bridging ligands, respectively.



Due to its insolubility, compound **5** could only be characterized by microanalysis and IR spectroscopy. Nevertheless, we think that its structure is likely to be that depicted in Scheme 2, because the available data indicate that there is only one dppm ligand per $\{Ru_2(\mu\text{-bdt})(CO)_4\}$ unit (CHN microanalysis) and that the local C_{2v} symmetry of the $\{Ru_2(\mu\text{-bdt})(CO)_4\}$ unit is maintained in the polymer since three ν(CO) absorptions are observed in the IR spectrum (Table 1). It has been reported that the compounds $[\{Ru_2(\mu\text{-dan})(CO)_4\}(\mu\text{-dppm})]_n$[17] and $[\{Ru_2(\mu\text{-MeCO}_2)_2(CO)_4\}(\mu\text{-dppm})]_n$[20] also have a polymeric nature, in which the dppm ligands linking the corresponding dimetallic units. However, the iodide-bridged compound $[Ru_2(\mu\text{-I})_2(CO)_4(\mu\text{-dppm})]$ is not polymeric and the dppm ligand spans the same metal atoms as the iodide bridges[21].

Reactions of Compounds 1 and 3c with Electrophilic Reagents

The availability of both the hexacarbonyl compound **1** and the phosphane-substituted tetracarbonyl derivative **3c** allowed us to carry out a comparative study of their reactions with electrophilic reagents. Among the phosphane-substituted tetracarbonyl derivatives prepared from complex **1**, we decided to use **3c** for the reactivity studies because it contains the most basic phosphane ligand. Such a reactivity study would help us to determine whether or not the nucleophilic character of the dithiolate-bridged ruthenium(I) dimers is affected by the nature of the axial ligands. Furthermore, such a study, coupled to previous ones carried out with related complexes having *N*-donor bridging ligands[17,22,23], would also shed light on the effect that the nature of the bridging ligand has on the nucleophilic character of this class of ligand-bridged ruthenium(I) dimers.

Both compounds, **1** and **3c**, could be protonated with an excess of $[HOEt_2][BF_4]$ in dichloromethane solvent to give the cationic derivatives $[Ru_2(\mu\text{-H})(\mu\text{-bdt})(CO)_{6-n}(P\textit{i}Pr_3)_n][BF_4]$ (**6a**: $n = 0$; **6b**: $n = 2$). Compound **6a** was unstable in solution and it undergoes spontaneous deprotonation in the absence of an excess of acid, even in solvents of low basicity such as dichloromethane or chloroform, to reform the neutral precursor **1**[11]. However, the substituted derivative **6b**

is stable as far as deprotonation in solution is concerned. Curiously, it has been reported that the behavior of $[Ru_2(\mu\text{-dan})(CO)_6]$[17] and $[Ru_2(\mu\text{-dan})(CO)_4(P\textit{i}Pr_3)_2]$[22] in protonation reactions is comparable to that observed for complexes **1** and **3c**.

Scheme 3. Reactions of compounds **1** and **3c** with electrophilic reagents

Compounds **1** and **3c** reacted with $[AuCl(PPh_3)]$ in the presence of $Ag[BF_4]$ to give AgCl and the cationic trinuclear derivatives $[Ru_2Au(\mu\text{-bdt})(CO)_{6-n}(P\textit{i}Pr_3)_n(PPh_3)][BF_4]$ (**7a**: $n = 0$; **7b**: $n = 2$). In related reactions, treatment of **1** and **3c** with mercury(II) chloride resulted in the formation of the corresponding adducts $[Ru_2HgCl_2(\mu\text{-bdt})(CO)_{6-n}(P\textit{i}Pr_3)_n]$ (**8a**: $n = 0$; **8b**: $n = 2$). Their IR spectra display the ν(CO) absorptions shifted to higher wavenumbers than those of the corresponding starting materials (Table 1), confirming a decrease of electron density at the ruthenium atoms. The $^{31}P\{^1H\}$-NMR spectra of the tetracarbonyl derivatives **7b** and **8b** indicate that both compounds have equivalent $P\textit{i}Pr_3$ ligands since that of **7b** consists of an AX_2 spin system and that of **8b** is just a singlet, supporting the structures depicted in Scheme 3. It has been reported that the diamido-bridged compound $[Ru_2(\mu\text{-dan})(CO)_6]$ is not basic enough to react with the metallic electrophiles $[Au(PPh_3)]^+$ and $HgCl_2$[17]; however, they do react with the disubstituted derivative $[Ru_2(\mu\text{-dan})(CO)_4(P\textit{i}Pr_3)_2]$ to give the corresponding adducts[22][23]. The related compound $[Ru_2(\mu\text{-dab})(CO)_4(PPh_3)_2]$ also reacts with electrophilic metallic fragments to give stable adducts[24].

All these data indicate that, in ligand-bridged diruthenium(I) carbonyl complexes, the basicity of the metal atoms is greatly affected by the nature of both the terminal and the bridging ligands. It was known that compounds having terminal phosphane ligands are more basic than their unsubstituted carbonyl precursors[22][23], but the results commented above experimentally demonstrate that complexes containing thiolate bridging ligands are more basic than their amido-bridged relatives. These results have also been confirmed by simple theoretical calculations at the extended Hückel level, which have shown that (a) the HOMOs of this kind of binuclear ligand-bridged ruthenium(I) complexes are of bonding character between the metal atoms, (b) that their composition is based mainly of orbitals belonging to the metal atoms[11][25] and (c) that the positive charges beared by the metal atoms in $[Ru_2(\mu\text{-dan})(CO)_6]$ and $[Ru_2(\mu\text{-bdt})(CO)_6]$ are higher than those beared by the substituted derivatives $[Ru_2(\mu\text{-dan})(CO)_4(PH_3)_2]$ and $[Ru_2(\mu\text{-bdt})(CO)_4(PH_3)_2]$. These charges are expected to be inversely related to the basicity of the metal atoms in the complexes (the higher the charge, the less basic the metal atom), thus supporting the experimental reactivity results.

Experimental Section

General: Solvents were dried with sodium diphenyl ketyl (THF, diethyl ether, hydrocarbons), molecular sieves (2-methoxyethanol) or CaH_2 (dichloromethane) and distilled under nitrogen prior to use. − Unless otherwise stated, the reactions were carried out under nitrogen at room temperature by Schlenk-vacuum line techniques, and were routinely monitored by solution IR spectroscopy (carbonyl stretching region). − The compounds **6a**[11] and $[AuCl(PPh_3)]$[26] were prepared as described in the literature, $RuCl_3 \cdot n\,H_2O$ was purchased from Pressure Chemicals, all other reagents were purchased from Aldrich. − IR: Perkin−Elmer FT 1720-X. − NMR: Bruker AC-200 and AC−300, 23°C, $SiMe_4$ (internal, for ^1H) or 85% H_3PO_4 (external, for ^{31}P) as standards (δ = 0 ppm). − Microanalyses were obtained from the University of Oviedo Analytical Service.

One-Pot Synthesis of 1 from $RuCl_3 \cdot n\,H_2O$: Carbon monoxide was bubbled through a solution of $RuCl_3 \cdot n\,H_2O$ (500 mg, 2.054 mmol) in 2-methoxyethanol (30 mL) at reflux temperature until the color changed to pale yellow (ca. 3 h). The addition of H_2bdt (130 μL, 1.130 mmol) was followed by addition of granular zinc (ca. 1 g). Maintaining the bubbling of carbon monoxide, the mixture was stirred at reflux temperature for 2 h to give an orange precipitate. After cooling to room temperature, the mixture was poured into a beaker containing water (500 mL). The tan precipitate was filtered through a celite pad. The solid was washed with water (3× 5 mL), dried by passing air through the filter and extracted from the filter with dichloromethane. The extracts were concentrated to ca. 2 mL and the concentrate introduced into a chromatography column (2.5 × 10 cm) packed with neutral alumina (activity I) in hexane. After the column was washed with hexane, dichloromethane eluted a yellow band which afforded compound **1** as a yellow solid. − Yield: 270 mg (55%). − Its analytical and spectroscopic data matched those reported in the literature[11].

Preparation of 2a, 2b, 2c, 3a, 3b, and 3c by Reaction of Compound 1 with Monodentate Phosphane Ligands: The appropriate amount

of the corresponding phosphane ligand was added to a solution of compound **1** in THF (10 mL). After being stirred at the appropriate temperature, the solvent was removed under reduced pressure and the residue was washed with hexane (2× 2 mL) and dried under vacuum to give the product as a yellow solid.

2a: Reagents: 42 mg (0.082 mmol) of **1** and 22 mg (0.083 mmol) of PPh_3. − Reaction time: 3 h at room temperature. − Yield: 50 mg (81%). − $C_{29}H_{19}O_5PRu_2S_2$: calcd: C 46.77, H 2.57; found: C 46.54, H 2.55. − ^{1}H NMR ($CDCl_3$): δ = 7.44−7.22 (m, 15 H), 6.61 (m, 2 H), 6.24 (m, 2 H).

2b: Reagents: 80 mg (0.156 mmol) of **1**, 44 mg (0.156 mmol) of PCy_3. − Reaction time: 3 h at room temperature. − Yield: 80 mg (67%). − $C_{29}H_{37}O_5PRu_2S_2$: calcd: C 44.66, H 4.89; found: C 44.86, H 5.01. − ^{1}H NMR ($CDCl_3$): δ = 7.13 (m, 2 H), 6.60 (m, 2 H), 2.30−1.10 (m, 33 H).

2c: Reagents: 50 mg (0.098 mmol) of **1**, 18.4 μL (0.098 mmol) of P*i*Pr$_3$. − Reaction time: 10 min at room temperature. − Yield: 55 mg (78%). − $C_{20}H_{25}O_5PRu_2S_2$: calcd: C 37.38, H 3.92; found: C 37.02, H 3.94. − ^{1}H NMR ($CDCl_3$): δ = 7.11 (m, 2 H), 6.57 (m, 2 H), 2.10 (m, 3 H), 1.22 (m, 18 H).

3a: Reagents: 30 mg (0.059 mmol) of **1**, 33 mg (0.124 mmol) of PPh_3. − Reaction time: 20 min at reflux temperature. − Yield: 40 mg (70%). − $C_{46}H_{34}O_4P_2Ru_2S_2$: calcd: C 56.44, H 3.75; found: C 56.41, H 3.75. − ^{1}H NMR ($CDCl_3$): δ = 7.42−7.29 (m, 30 H), 6.06 (m, 2 H), 5.85 (m, 2 H).

3b: Reagents: 30 mg (0.059 mmol) of **1**, 33 mg (0.117 mmol) of PCy_3. − Reaction time: 40 min at reflux temperature. − Yield: 45 mg (78%). − $C_{46}H_{70}O_4P_2Ru_2S_2$: calcd: C 56.32, H 7.19; found: C 56.10, H 7.15. − ^{1}H NMR ($CDCl_3$): δ = 7.06 (m, 2 H), 6.54 (m, 2 H), 1.52−1.17 (m, 66 H).

3c: Reagents: 50 mg (0.098 mmol) of **1**, 46 μL (0.245 mmol) of P*i*Pr$_3$. − Reaction time: 25 min at reflux temperature. − Yield: 60 mg (79%). − $C_{28}H_{46}O_4P_2Ru_2S_2$: calcd: C 43.40, H 5.98; found: C 42.98, H 5.71. − ^{1}H NMR ($CDCl_3$): δ = 7.02 (m, 2 H), 6.47 (m, 2 H), 2.07 (m, 6 H), 1.22 (m, 36 H).

One-pot Synthesis of 3a, 3b, and 3c from $RuCl_3 \cdot n\,H_2O$: Carbon monoxide was bubbled through a solution of $RuCl_3 \cdot n\,H_2O$ (500 mg, 2.054 mmol) in 2-methoxyethanol (30 mL) at reflux temperature until the color changed to pale yellow (ca. 3 h). The addition of H_2bdt (130 μL, 1.130 mmol) was followed by addition of granular zinc (ca. 1 g). Maintaining the bubbling of carbon monoxide, the mixture was stirred at reflux temperature for 15 min to give an orange precipitate. After adding the appropriate amount of the corresponding phosphane ligand (2.060 mmol), the mixture was cooled to room temperature under nitrogen and was stirred for 3 h. The suspension was filtered through a celite pad. The liquid phase was discarded off and the solid was extracted from the filter with dichloromethane. The extract was evaporated to dryness and the residue was washed with diethyl ether (2 × 3 mL) to give the corresponding product as a yellow solid. − Yields: 48% (**3a**), 43% (**3b**), and 73% (**3c**).

Preparation of 4: Solid dppm (75.3 mg, 0.196 mmol) was added to a solution of complex **1** (50 mg, 0.098 mmol) in THF (25 mL). The solution was stirred for 5.5 h and the solvent was removed under reduced pressure. The residue was washed with diethyl ether (2× 2 mL) and dried under vacuum to give complex **4** as a yellow solid. − Yield 90 mg (75%). − $C_{60}H_{48}O_4P_4Ru_2S_2$: calcd: C 58.74, H 4.05; found: C 58.92, H 3.95. − ^{1}H NMR ($CDCl_3$): δ = 7.1−7.3 (m, 40 H), 6.16 (m, 4 H) 2.96 (m, 4 H).

Preparation of 5: Solid dppm (37.6 mg, 0.098 mmol) was added to a solution of complex **1** (50 mg, 0.098 mmol) in THF (25 mL). After stirring for 30 min, the IR spectrum showed a ca. 50% mixture of complexes **1** and **4**. After 4 h, a yellow solid began to precipitate. The mixture was stirred for 3 days, when the precipitate was copious and the liquid phase was nearly colorless. The liquid was decanted off and the solid was washed with THF (2 × 5 mL) and dried under vacuum. − Yield 90 mg (75%). − $C_{35}H_{26}O_4P_2Ru_2S_2$: calcd: C 50.12, H 3.12; found: C 49.38, H 3.02.

Preparation of 6b: An excess of $[HOEt_2][BF_4]$ (4 drops from a pasteur pipette) was added to a solution of complex **1** (100 mg, 0.129 mmol) in dichloromethane (10 mL). The color of the solution changed from yellow to very pale yellow. The solvent was removed under reduced pressure and the oily residue was washed with diethyl ether (3 × 2 mL) to give complex **6b** as a white powder. − Yield 89 mg (80%). − $C_{28}H_{47}BF_4O_4P_2Ru_2S_2$: calcd: C 38.98, H 5.49; found: C 38.29, H 5.78. − ^{1}H NMR (CD_2Cl_2): δ = 7.24 (m, 2 H), 6.83 (m, 2 H), 2.20 (m, 6 H), 1.3 (m, 36 H), −16.16 (t, $J_{H\text{-}P}$ = 29.5 Hz, 1 H).

Preparation of 7a and 7b: Solid $Ag[BF_4]$ was added to a THF solution (15 mL) containing $[AuCl(PPh_3)]$ and the appropriate ruthenium starting complex. A white precipitate of AgCl was immediately formed. The mixture was stirred for 30 min and the solvent was removed under reduced pressure. The residue was extracted with dichloromethane (3 × 5 mL) and the filtered solution was evaporated to dryness. The yellow solid was washed with diethyl ether (2 × 3 mL) and dried under vacuum.

7a: Reagents: 20 mg (0.039 mmol) of **1**, 19.3 mg (0.039 mmol) of $[AuCl(PPh_3)]$, 7.6 mg (0.039 mmol) of $Ag[BF_4]$. − Yield: 29 mg (73%). − $C_{30}H_{19}AuBF_4O_6Ru_2S_2$: calcd: C 35.14, H 1.87; found: C 34.89, H 1.98. − ^{1}H NMR ($CDCl_3$): δ = 7.6−7.3. (m, 17 H), 6.88 (m, 2 H).

7b: Reagents: 50 mg (0.064 mmol) of **3c**, 31.7 mg (0.064 mmol) of $[AuCl(PPh_3)]$, 13 mg (0.064 mmol) of $Ag[BF_4]$. − Yield: 60 mg (72%). − $C_{46}H_{61}AuBF_4O_4P_2Ru_2S_2$: calcd: C 42.83, H 4.77; found: C 42.91, H 4.83. − ^{1}H NMR ($CDCl_3$): δ = 7.57 (m, 15 H), 7.15 (m, 2 H), 6.78 (m, 2 H), 2.23 (m, 6 H), 1.72 (m, 36 H).

Preparation of 8a and 8b: Solid $HgCl_2$ was added to a solution of the appropriate ruthenium starting complex in THF (15 mL). The solution was stirred for 30 min to give a yellow solid (**8a**) or a yellow solution (**8b**). The solvent was removed under reduced pressure and the solid yellow residue was washed with diethyl ether (2 × 3 mL) and dried under vacuum.

8a: Reagents: 30 mg (0.059 mmol) of **1**, 16 mg (0.059 mmol) of $HgCl_2$. − Yield: 30 mg (65%). − $C_{12}H_4Cl_2HgO_6Ru_2S_2$: calcd: C 18.43, H 0.52; found: C 18.41, H 0.75. − ^{1}H NMR ([D$_6$]acetone): δ = 7.44 (m, 2 H), 6.92 (m, 2 H).

8b: Reagents: 50 mg (0.064 mmol) of **3c**, 17.5 mg (0.064 mmol) of $HgCl_2$. − Yield: 40 mg (60%). − $C_{28}H_{46}Cl_2HgO_4P_2Ru_2S_2$: calcd: C 32.14, H 4.43; found: C 31.83, H 4.36. − ^{1}H NMR ($CDCl_3$): δ = 7.19 (m, 2 H), 6.77 (m, 2 H), 2.21 (m, 6 H), 1.3 (m, 36 H).

Crystal Structure Determination of 3c: Crystal data and details of the structure determination are listed in Table 3. The unit cell dimensions were determined from the angular settings of 25 reflections with 15° < Θ < 20°. The orthorhombic space group $P2_1nb$ was determined from systematic absences and confirmed by the structure determination. The intensity was checked throughout data collection by monitoring three standard reflections every 60 min. Final drift correction factors were between 1.00 and 1.01. Profile analysis[27] was performed on all reflections. A semiempirical absorption correction was applied, using ψ scans[28] (correction factors were in the range 0.973 to 1.000). No doubly measured

reflections were obtained. Lorentz and polarization corrections were applied and data were reduced to $|F_o|^2$ values.

The structure was solved by Patterson interpretation using the program DIRDIF92[29]. An isotropic least-squares refinement, using a local version of SHELX[30], was followed by an empirical absorption correction[31] (maximum and minimum correction factors 1.547 and 0.698, respectively). Full-matrix anisotropic least-squares refinement over F^2, using the program SHELXL92[32], followed by a difference Fourier synthesis allowed the location of all the hydrogen atoms. Positional parameters and anisotropic thermal parameters of the non-hydrogen atoms were refined. All hydrogen atoms were refined isotropically, constraining the bond angles but with free distances to their parent atoms. The thermal parameter used for the aliphatic hydrogen atoms was differerent from that used for the aromatic hydrogen atoms. The function minimized was $\Sigma w(|F_o|^2 - |F_c|^2)^2$, $w = 1/[\sigma^2(F_o^2) + (0.0462{\cdot}P)^2]$, with $\sigma(F_o)$ from counting statistics and $P = (F_o^2 + 2F_c^2)/3$. Atomic scattering factors were taken from the literature[33]. The plot in Figure 1 was made with the EUCLID package[34]. Geometrical calculations were made with PARST[35]. All computations were performed on an Alpha AXP3000 workstation.

Crystallographic data (excluding structure factors) for compound **3c** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-109933. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: +44 (1223) 336033, E-mail: deposit@ccdc.cam.ac.uk, www: http://www.ccdc.cam.ac.uk].

EHMO Calculations: Theoretical MO calculations were carried out at the extended Hückel level[36], using the CACAO program[37]. The geometrical parameters used were based on X-ray diffraction data, averaging the appropriate distances and angles in order to obtain ideal C_{2v} symmetry. The orbital parameters used in the calculations were those used in previous works[11].

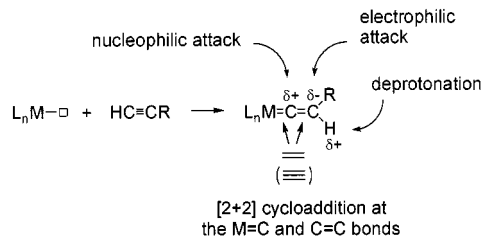
Ruthenium Tris(pyrazolyl)borate Complexes, 12[+] Cross Coupling of Acetylenes with Olefins – Formation of η^3-Butadienyl and η^2-Butadiene Complexes via a Metallacyclobutane Intermediate



Christian Slugovc,[a] Kurt Mereiter,[b] Roland Schmid,[a] and Karl Kirchner,*[a]

Keywords: C–C coupling / Metallacycles / Metallacyclobutane / Ruthenium / Tripodal ligands / Vinylidene complexes

Selective coupling of olefins and terminal acetylenes is shown to be effected in the coordination sphere of Ru^{II} by the successive intermediacy of vinylidene and ruthenacyclobutane complexes. Subsequent deprotonation of one of the β-hydrogen atoms of the latter by NaOEt yields η^3-butadienyl complexes, while in the presence of Cl^- rearrangement takes place to give neutral η^2-butadiene complexes by a β-hydrogen elimination/reductive elimination sequence. [Ru(tp)(COD)Cl] and [Ru(tp){η^3-(*P,C,C*)-$Ph_2PCH{=}CHC(Ph){=}CH_2$}Cl] were the starting materials which were treated with HC≡CR (R = Ph, C_6H_9, ferrocenyl, CH_2Ph, *n*Bu). The η^3-butadienyl complexes are nucleophilic at the enynyl carbon atom reacting readily with the electrophiles H^+ and I_2 to give the corresponding η^2-butadienyl complexes. X-ray structures of representative products are given.

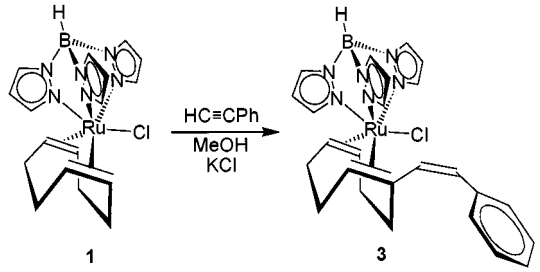
Introduction

The transition metal mediated transformation of acetylenic substrates is an important process in applied (organometallic) chemistry.[1] Particularly reactive are terminal alkynes which form, when exposed to a transition metal center, vinylidene complexes. This class of compounds exhibits a wide range of reactivity as illustrated in Scheme 1 including migratory insertions of alkyl, aryl, vinyl, alkynyl, and hydride ligands onto the electrophilic α-carbon atom of the vinylidene moiety.[2]

Scheme 1. Formation and common modes of reaction of vinylidene complexes

A rather rare example of C−C bond formation within a vinylidene complex is the cycloaddition of alkynes and olefins to the M=C bond giving metallacyclobutene and metallacyclobutane intermediates, respectively, which then polymerize through ring opening.[3] Although the underlying process is characteristic of early transition metals, we report here a facile C−C coupling reaction between olefins and terminal acetylenes proceeding via a ruthenacyclobutane[4] intermediate which finally converts into either η^3-butadienyl or η^2-butadiene complexes depending on the reaction conditions.[2c,5] In addition, we demonstrate that η^3-butadienyl complexes are nucleophilic at the enynyl carbon atom and react with electrophiles to give the corresponding functionalized η^2-butadiene complexes. A preliminary account of this work has already been published.[6]

Results and Discussion



In an attempt to prepare the cationic vinylidene complex $[Ru(tp)(COD)(=C=CHPh)]^+$ (tp = hydrido(trispyrazolyl)-borate, COD = 1,5 cyclooctadiene), [Ru(tp)(COD)Cl] (**1**) has been treated with HC≡CPh in boiling MeOH. A polar medium has been chosen to allow for better ionization of the chloride to facilitate the opening of a coordination site. We[7] and others[8] have already shown that protic solvents favor cationic vinylidene complexes. However, no such complex was formed and basically unchanged **1** was obtained, together with polymeric materials[9] and a small amount of a new complex identified as [Ru(tp){(1,2-η;5,6-η)-1-[(*Z*)-3-phenyl-1-ethenyl]cyclooctadiene}Cl] (**3**). In the presence of excess KCl (6 equiv.) the formation of polymeric compounds is largely suppressed to afford **3**, isolated in 74% yield (Scheme 2). Characterization of **3** was by a combination of elemental analysis, and ^{1}H- and $^{13}C\{^1H\}$-NMR spectroscopy. Characteristic solution ^{1}H-NMR-spectroscopic data for **3** include two doublets at δ = 6.82 and 6.58 with a coupling constant $^3J_{HH}$ = 11.7 Hz, consistent with a (*Z*) arrangement of the double bond. All other resonances are unremarkable. The structural identity of **3** was unequivocally proven by X-ray crystallography. The result is depicted in Figure 1 with selected bond lengths and angles reported in the caption. The overall structure of **3** is similar

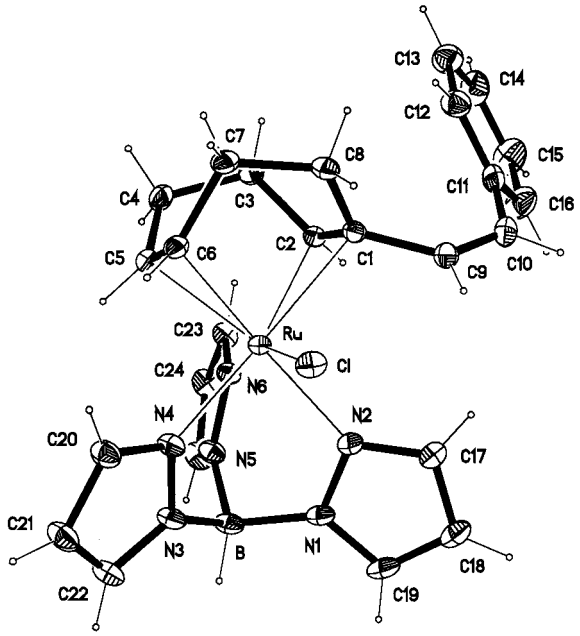
to that of Ru(tp)(COD)Br and related complexes containing the $[Ru(tp)(COD)]^+$ fragment.[10]

Scheme 2. Reaction of **1** with HC≡CPh in the presence of excess KCl



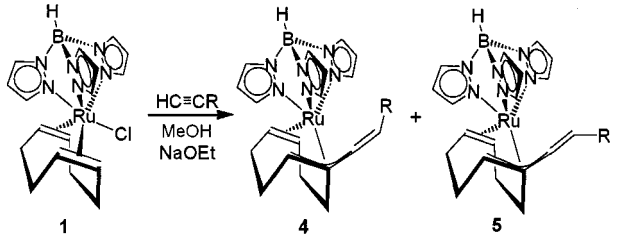


Figure 1. Structural view of **3**; selected bond lengths [Å] and angles [°]: Ru−N(2) 2.163(1), Ru−N(4) 2.121(1), Ru−N(6) 2.166(1), Ru−C(1) 2.311(2), Ru−C(2) 2.243(2), Ru−C(5) 2.226(2), Ru−C(6) 2.219(2), Ru−Cl 2.427(1), C(1)−C(2) 1.385(2), C(5)−C(6) 1.384(2), C(9)−C(10) 1.335(3); N(6)−Ru−Cl 159.9(1), N(4)−Ru−N(2) 87.3(1), N(4)−Ru−N(6) 86.2(1), N(2)−Ru−N(6) 79.7(1)

It is interesting to note that only the (*Z*) isomer is formed in which the −CH=CHPh substituent points towards the chloride ligand. Complex **3** did not undergo a further coupling reaction with HC≡CPh (to give a COD ligand containing two −CH=CHPh substituents). It is interesting that under the same reaction conditions (and even after prolonged heating and extended reaction times) internal acetylenes such as PhC≡CPh and MeOOCC≡CCOOMe did not undergo an oxidative coupling. Instead, unchanged **1** was largely recovered together with about 15% of the known hydride complex [Ru(tp)(COD)H].[11]

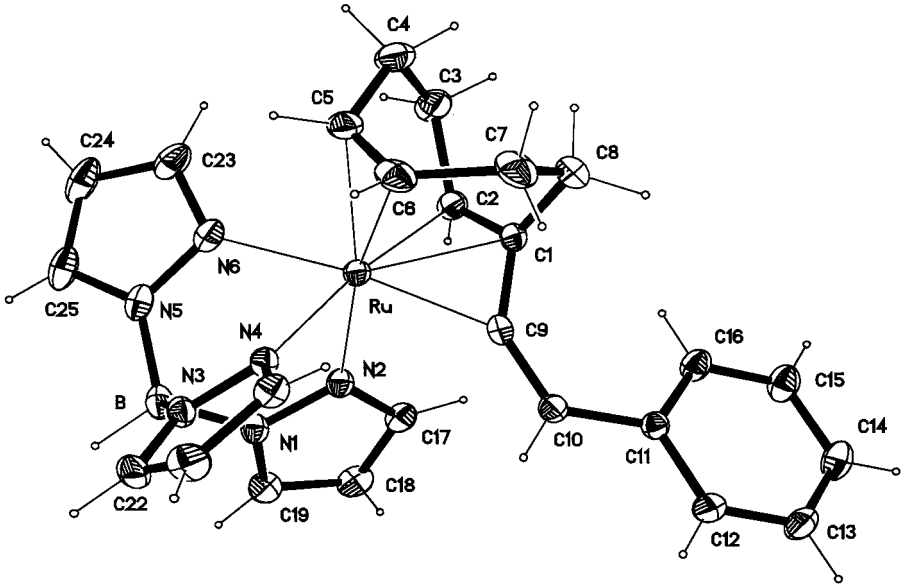
In order to establish whether [Ru(tp)(COD)H] is an intermediate on the pathway to **3**, [Ru(tp)(COD)H] (in place of **1**) was treated with HC≡CPh under otherwise the same conditions. However, no **3** but small amounts (< 20%) of the new compound η^3-butadienyl complex [Ru(tp){(5,6-η;η^3)-2-[(*E*)-2-phenyl-1-ethenylidene]-5-cyclooctenyl}] (**5a**) (vide infra) were obtained, in addition to polyacetylenes as the main products. Likewise, internal alkynes, such as PhC≡CPh do not react with **1** and [Ru(tp)(COD)H] is apparently not a precursor to **3**. Accordingly, the formation of **5a** can be interpretated that under basic conditions ([Ru(tp)(COD)H] may act as a base) a different course of reaction is followed. Treatment of Ru(tp)(COD)Cl (**1**)[10] with terminal acetylenes HC≡CR (R = Ph, C_6H_9, ferrocenyl, CH_2Ph, *n*Bu) in MeOH in the presence of NaOEt (1 equiv., 65°C, 24 h) afforded the η^3-butadienyl complexes **4a**−**e** and **5a**−**e** in high yields (Table 1). Characterization of **4** and **5** was again by elemental analysis, and ^{1}H- and $^{13}C\{^1H\}$-NMR spectroscopy. The solution ^{1}H-NMR spectra for **4** include a singlet between δ = 5.9 and 6.9 assigned to the terminal (*E*)-butadienyl proton, while in the corresponding (*Z*)-butadienyl fragment there is a slight upfield shift of the terminal proton giving rise to a signal between δ = 4.7 and 5.9. In the $^{13}C\{^1H\}$-NMR spectrum, the enynyl carbon atoms exhibit a characteristic resonance at δ = 171−181. All other resonances are unremarkable.

Table 1. Conversion and product distribution of the reaction of **1** with terminal acetylenes

			products[a]	
entry	R	% conversion[a]	% Z	% E
1	Ph	100	**4a** 98	
2	C_6H_9	100	**4b** 24	**5b** 76
3	ferrocenyl	100		**5c** 97
4	CH_2Ph	97	**4d** 94	**5d** 6
5	*n*-Bu	93	**4e** 66	**5e** 33

[a] Conversions and product distributions have been determined by ^{1}H NMR spectroscopy

It may be emphasized that **4a** appears to be the first (η^3-butadienyl)ruthenium complex with tp as a co-ligand. The molecular structure determined by X-ray crystallography is shown in Figure 2, with selected bond lengths and angles given in the caption. The most notable feature is the distorted *s-trans* structure of the butadienyl moiety. Since the two allyl carbon atoms, C(1), C(2), are noticeably further from the Ru center [Ru−C(1) = 2.153(3) Å, Ru−C(2) = 2.154(3) Å] than the enynyl carbon atom C(9) [Ru−C(9) = 2.038(3) Å], a major resonance contribution from the vinyl alkene structure is indicated. Furthermore, the relatively uniform bond lengths for the three allyl carbon atoms point to a substantial π-electron delocalization [C(1)−C(2) =



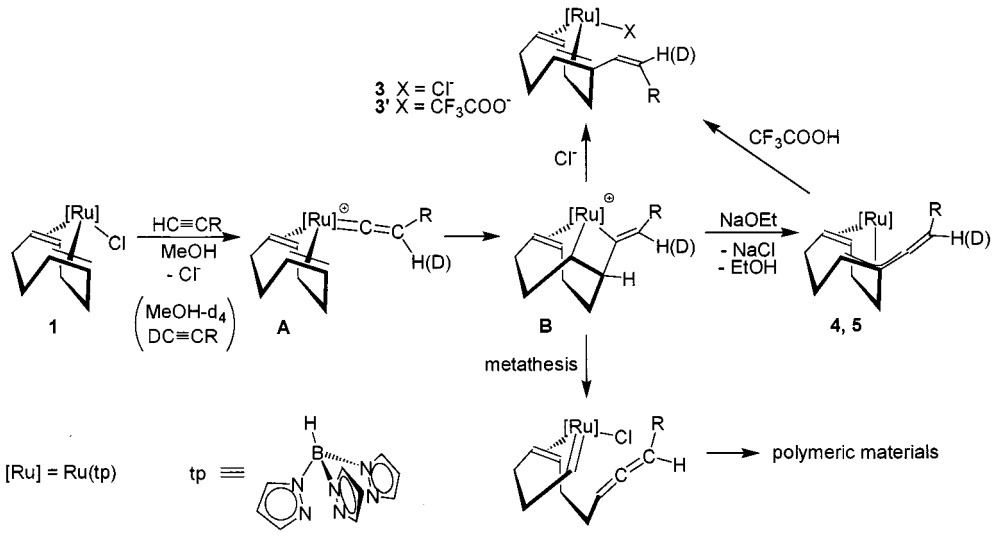


Figure 2. Structural view of **4a**; selected bond lengths [Å] and angles [°]: Ru−N(2) 2.149(2), Ru−N(4) 2.158(2), Ru−N(6) 2.223(2), Ru−C(1) 2.153(3), Ru−C(2) 2.154(3), Ru−C(9) 2.038(3), Ru−C(5) 2.184(3), Ru−C(6) 2.218(3), C(1)−C(9) 1.418(4), C(1)−C(2) 1.425(4), C(9)−C(10) 1.328(4), C(5)−C(6) 1.386(5); C(9)−Ru−N(2) 80.4(1), C(9)−Ru−C(1) 39.4(1), N(2)−Ru−C(1) 101.1(1), C(9)−Ru−C(2) 71.6(1), N(2)−Ru−C(2) 90.5(1), C(1)−Ru−C(2) 38.7(1), C(9)−Ru−N(4) 103.0(1), C(9)−Ru−N(6) 160.1(1)

1.425(4) Å, C(2)−C(9) = 1.418(4) Å].[2c,5] The Ru−N(tp) bond lengths are within the usual range.[10][12]

The reaction mechanism shown in Scheme 3 represents our final working hypothesis providing the formation of the η^2-butadiene complexes **3**, the η^3-butadienyl products **4** and **5**, and polymeric materials. For the first step, the formation of the cationic vinylidene complex **A** by a 1,2-hydrogen shift is a now well-established process.[13] Prerequisite for this process is the availiability of a vacant coordination site. In this context, it has to be noted that the chloride ligand in **1** is easily replacable by Br^- and CN^- on treatment with KBr and KCN in MeOH at elevated temperatures indicating that the Cl^- ligand is substitutionally labile under these conditions.[14] Attempts to prepare **A** by treating **1** with 1 equiv. of $AgCF_3SO_3$ and HC≡CPh in CH_2Cl_2 failed.[10] The metallacyclobutane complex **B** is subsequently formed by a [2+2] cycloaddition, followed by deprotonation of one of the β-hydrogen atoms of **B**, yielding the stable η^3-butadienyl complex. The following observations may be taken to support this mechanism. (i) The occurrence of a vinylidene intermediate could be verified by a labeling experiment. Thus, the η^3-butadienyl product **[D$_1$]4a** of the reaction of deuterium-labeled phenylacetylene DC≡CPh and **1** contain deuterium bound exclusively at the olefinic carbon atom of the butadienyl moiety (Scheme 3). On the other hand, the η^3-butadienyl complex **4a** did not incorporate deuterium to give **[D$_1$]4a** under reflux in [D$_4$]MeOH in the presence of NaOEt.

Scheme 3. Vinylidene mechanism

(ii) In the absence of base only polyacetylenes[9] were obtained with decomposition of the Ru complex to intractable materials. (iii) When in place of NaOEt an excess of KCl is added, **B** rearranges presumably by a β-hydrogen elimination/reductive elimination sequence (equivalent to a 1,2-hydrogen shift) to the neutral η^2-butadiene complex **3**. The vacant coordination site of the resulting 16-electron intermediate is occupied by the incoming chloride.

The stereochemistry of **4** and **5**, difficult to determine by NMR methods, is established on the basis of the products formed from the reaction with CF_3COOH at room temperature included in Scheme 3. In this way the corresponding olefin complexes **3′** [(*Z*) and (*E*) isomers] with the vinyl side chain are formed. Under this experimental condition no isomerization takes place and the stereochemistry of the butadienyl fragment is readily apparent from the vicinal coupling constant $^3J_{HH}$ of the vinyl moiety (about 11 and 16 Hz in case of a *cis* and *trans* arrangement, respectively). From this it is concluded that the enynyl carbon atom of η^3-butadienyl complexes is nucleophilic, which offers the possibility of further kinds of functionalization by treating them with electrophiles. In fact, **4a** reacts with I_2 to yield complex **6** in essentially quantitative yield (Scheme 4). The NMR spectra of **6** are similar to those of **3** and are not discussed here. The solid-state structure of **6** is depicted in Figure 3 with selected bond lengths and angles given in the caption. The overall structures of **6** and **3** are very similar. The three Ru−N(Tp) bond lengths show only minor variations [on average the Ru−N(tp) distance is 2.141(1) Å] and are within the range of other ruthenium(tp) complexes. The Ru−I(1) and C(9)−I(2) distances are 2.780(1) and 2.126(2) Å, respectively. Additionally, a weak intermolecular interaction between the two I(2) atoms of pairs of neighboring molecules is observed, where the I(2)···I(2) distance is found to be 3.67 Å. Despite this interaction molecular packing is not very efficient in crystalline **6** and the structure contains voids of about 40 $Å^3$ per unit cell. If an excess of I_2 is present during crystallization of **6**, a new kind of crystal, **6**·0.5 I_2, is readily formed which will be reported elsewhere.

It may be mentioned that the above reactions are not restricted to COD complexes. In similar fashion to **1**, [Ru(tp){η^3-(*P*,*C*,*C*)-$Ph_2PCH{=}CHC(Ph){=}CH_2$}Cl] (**2**) was found to react with HC≡CR (R = Ph, C_6H_9) to give the η^3-butadienyl complexes **7a**,**b** (Scheme 5). In addition to full spectroscopic and analytical characterizations of the products, the solid-state structure of **7b** was determined by X-ray crystallography. As shown in Figure 4 the coordination geometry around the ruthenium center is a distorted octahedron in which three coordination positions are occupied by the tp ligand, and the remaining three are taken by the phosphorus atom and the butadienyl fragment of the $Ph_2PCH{=}CHC(Ph)CHCCHC_6H_9$ ligand. The Ru−C(24), Ru−C(25), and Ru−C(26) bond lengths are 2.255(3), 2.110(3), and 2.077(3) Å, respectively. Similar to the other η^3-butadienyl complexes,[5] the two allyl carbon atoms, C(24), C(25), are significantly further from the Ru center than is the enynyl carbon atom C(26). The bond lengths between the two allyl and the enynyl carbon atoms are 1.419(4) and 1.445(4) Å. The C(26)−C(27) bond length is 1.341(4) Å. The Ru−N(tp) and Ru−P bond lengths are within the usual ranges.[10][12] The cyclohexene ring consisting of C(34) through C(39) has an envelope conformation with an up/down disorder of C(37a)/C(37b) and C(38a)/C(38b). Only the b-orientation [C(37b/(C(38b)] is shown in Figure 4.

Conclusion

It is shown that selective coupling of olefins and terminal acetylenes is feasible in the coordination sphere of Ru^{II}. Although in the present case there is particular assistance by

Scheme 5. Reaction of **2** with HC≡CR (R = Ph, C_6H_9)

the intramolecular mode with favorable stereochemical conditions imposed by an anchoring group, an extension to the intermolecular mode should be conceivable. The deprotonation pathway for the onward reaction of the metallacyclobutane complex has not yet been considered. The butadienyl fragment is nucleophilic at the enynyl carbon atom and is capable of reacting with electrophiles such as H^+ and I_2 to give the 1,3-diene unit. We believe this work may initiate a systematic search of coupling olefins with acetylenes into functionalized 1,3-dienes in a synthetically useful fashion

Experimental Section

General Techniques: All compounds were manipulated with standard Schlenk techniques and/or a glove box under purified argon. All chemicals were of standard reagent grade and used without further purification. The solvents were purified according to standard procedures.[15] The deuterated solvents were purchased from Aldrich and dried with 4-Å molecular sieves. For column chromatography silica gel purchased from Merck, grade 60, 70−230 mesh, 60 Å, or neutral MN aluminum oxide, purchased from Macherey−Nagel, was used. [Ru(tp)(COD)Cl] (**1**) and [Ru(tp){η^3-(*P*,*C*,*C*)-$Ph_2PCH{=}CH(Ph){=}CH_2$}Cl] (**2**) were prepared according to the literature.[7][10] − ^{1}H-, ^{13}C{^{1}H}-, and ^{31}P{^{1}H}-NMR spectra were recorded with a Bruker AC-250 spectrometer operating at 250.13, 62.86, and 101.26 MHz, respectively, and were referenced to $SiMe_4$ and to H_3PO_4 (85%). − Microanalysis were done by Microanalytical Laboratories, University of Vienna.

Synthetic Studies

Ru(tp)(η^4-1,5-cyclooctadiene)H: A suspension of **1** (100 mg, 0.22 mmol) and NaOEt (14.9 mg, 0.22 mmol) in MeOH (5 mL) was heated under reflux for 2.5 h. The reaction mixture was cooled to room temperature and the resulting yellow precipitate was collected on a glass frit, washed with MeOH (5 × 1.5 mL) and Et_2O (2 × 1 mL), and dried under vacuum. Yield: 65 mg (70%). In the absence of base the conversion is completed after about 20 h with 64% yield of isolated [Ru(tp)(η^4-1,5-cyclooctadiene)H]. The NMR spectra are in agreement with the published values.[11]

Ru(tp){(1,2-η;5,6-η)-1-[(*Z*)-2-phenylethenyl]cyclooctadiene}Cl (3): To a suspension of **1** (200 mg, 0.44 mmol) in MeOH (4 mL), KCl (200 mg, 2.68 mmol) and HC≡CPh (144 μL, 1.32 mmol) were added and heated at reflux for 20 h. The reaction mixture was then cooled to 0 °C and the resulting orange precipitate was collected on a glass frit and washed twice with methanol (1.5 mL). The crude product was redissolved in CH_2Cl_2 and insoluble materials were removed by filtration. After removal of the solvent, analytically pure product was obtained. Yield 180 mg (74%). − $C_{25}H_{28}BClN_6Ru$ (559.86): calcd. C 53.63, H 5.04, N 15.01; found C 53.64, H 5.12, N 14.88. − ^{1}H NMR ($CDCl_3$, 20 °C): δ = 8.24

Crystallographic Structure Determinations: Crystal, data collection, and refinement parameters for complexes **3**, **4a**, **6**, and **7b** are given

in Table 2. Crystals were obtained by diffusion of diethyl ether into CH_2Cl_2 solutions, except for **7b**, where crystals were grown by layering of *n*-hexane over a CH_2Cl_2 solution. All X-ray data were collected with a Siemens Smart CCD area detector diffractometer (graphite-monochromated Mo-K_α radiation, $\lambda = 0.71073$ Å, 0.3° ω-scan frames). Corrections for Lorentz and polarization effects, for crystal decay, and for absorption were applied. The structures were solved by direct or Patterson methods.[16] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were inserted in idealized positions and were refined riding with the atoms to which they were bonded. The structures were refined against F^2.[17] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-105597/105598/105599/105600. Copies of data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Applications of Photoelectron Spectroscopy to Molecular Properties, 52[+] Gas-Phase Characterization of an Unhindered Germaimine by UV-Photoelectron Spectroscopy

Séverine Foucat,[a] Thierry Pigot,[a] Geneviève Pfister-Guillouzo,*[a] Stéphane Mazières,[b] and Hélène Lavayssière[b]

Keywords: Germacyclopentene / Germaimine / Photoelectron spectroscopy / Ab initio calculations / Germanium

An unhindered germaimine has been generated and characterized by the coupling of flash vacuum pyrolysis of two different precursors with UV-photoelectron spectroscopy. The Ge=N unit exhibits two ionizations in the low-energy region, corresponding to the ejection of an electron from the nitrogen atom lone pair and from the $\pi_{Ge=N}$ orbital, respectively.

Introduction

The chemistry of low-coordinated group-14 and -15 elements of the third and fourth periods has undergone considerable development over the past 35 years. The first experimental characterizations of the C≡P triple bond[1] and of the Si=C double bond appeared in the 1960s.[2] Soon after, germanium compounds with multiple bonds were reported. These species showed greater overall kinetic instability when they were slightly sterically hindered.

The germaimines, compounds with a Ge=N double bond, were first characterized indirectly using various trapping reagents.[3] Only in the last ten years have sufficiently stable germaimines been synthesized to allow their analysis in the solid state (XR, IR) or in solution (IR, NMR).[4−7] However, there have been no reports of the characterization of germaimines in the gas phase, other than that by Lee[8] concerning $H_2Ge{=}NCF_3$. This latter exhibited a surprising stability and proved to be resistant to hydrolysis (!).

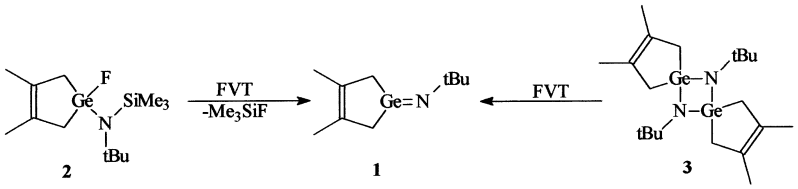
We present in this paper the first characterization of an unhindered germaimine by UV-photoelectron spectroscopy (UV-PES), specifically *N-tert*-butyl-3,4-dimethyl-1-germacyclopent-3-en-1-imine (**1**).

Results and Discussion

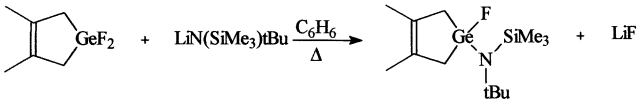
The aforementioned germaimine was generated by flash vacuum thermolysis (FVT) of the fluorogermacyclopentene **2** and the cyclodigermazane **3**, and was analyzed by photoelectron spectroscopy (UV-PES). The coupling of FVT with UV-PES has turned out to be particularly well suited for the detection of highly reactive species and has recently been used in studies of *N*-alkylated and *N*-silylated silaimines.[9][10]

The precursor **2** was synthesized by condensation of the corresponding lithiated amine with germacyclopentene difluoride. After several weeks at ambient temperature under inert atmosphere, **2** had undergone spontaneous conversion into a white crystalline solid corresponding to the cyclodigermazane **3**, which was fully characterized by MS and NMR analysis.

The photoelectron spectrum of the precursor **2** (Figure 1a) features a first well-resolved band at 8.4 eV, corresponding to the ejection of an electron from the nitrogen atom lone pair[11] and the $\pi_{C=C}$ orbital.[12] The broader signal seen at 10.3 eV is associated with ionization from the σ_{Si-C} orbitals. The latter signal shows an obvious shoulder at 9.7 eV, which corresponds to ionization from the σ_{Ge-C} orbitals. The following ionization, which is attributed to the ejection of an electron from the σ_{Ge-N} orbital, is poorly resolved (11.6 eV).



The PE spectrum of the cyclodigermazane **3** (Figure 1c) is characterized by two bands in the low-energy region, at 7.4 eV and 8.2 eV. We attribute the band at 7.4 eV to ionizations from the antibonding and bonding combinations of the nitrogen atom lone pairs. Ionizations of the antibonding and bonding $\pi_{C=C}$ orbital combinations are responsible for the broad signal at 8.2 eV. The bands above 9.0 eV correspond to the ejection of an electron from the σ_{Ge-C} and σ_{Ge-N} bonds.



The short-path thermolysis spectrum of **2** at 673 K is displayed in Figure 1b. In the low-energy region, a broad signal at 7.0 eV, and an intense band at 8.7 eV with a marked shoulder at 8.1 eV can be seen. Beyond these signals, an ionization at 10.9 eV with a shoulder at 10.3 eV, and another signal at 11.4 eV can be noted. The ionization energy at 10.9 eV corresponds to Me_3SiF, formation of which was unambiguously proven when long-path thermolysis experiments were performed (520 K). An identical spectrum (lacking the band at 10.9 eV) was obtained upon

heating the cyclic dimer **3** at the same temperature. Thus, it seems as though the same species was generated in each case, namely the germaimine **1**.

In order to verify the assigned natures of the ionizations, we have theoretically evaluated the energies of the first three ionic states of a structurally similar germaimine, **1′** (*N*-methyl rather than *N*-*tert*-butyl). These calculations were performed using the density functional method with the hybrid functional B3LYP[13] and the LANL2DZ(d) basis set.[14][15] The optimized structure of this molecule is shown in Figure 2. The calculated Ge=N bond length (1.696 Å) is in excellent agreement with both the experimental[7] and a previous theoretical value.[16]

The magnitudes and assignments of the first three vertical ionization energies are summarized in Table 1. We note that the ionization energies of the nitrogen atom lone pair and $\pi_{C=C}$ double-bond orbitals of *N*-alkylated germaimine are very close (7.78 eV and 7.71 eV). Moreover, the destabilizing effect of a *tert*-butyl group on the nitrogen atom compared to a methyl group has previously been observed for ionization from the n_N and $\pi_{Si=N}$ orbitals of dimethylsilaimines (0.5 eV and 0.9 eV, respectively).[9]

Table 1. Calculated [B3LYP/LANL2DZ(d), ΔSCF] and experimental first ionic states energies of **1** and **1′** [eV]

Ionic states	Calculated energies of **1′**	Experimental energies of **1**
$^2A'$ (n_N)	7.71	7.0
$^2A''$ ($\pi_{Ge=N}$)	7.78	7.0
$^2A''$ ($\pi_{C=C}$)	7.93	8.1

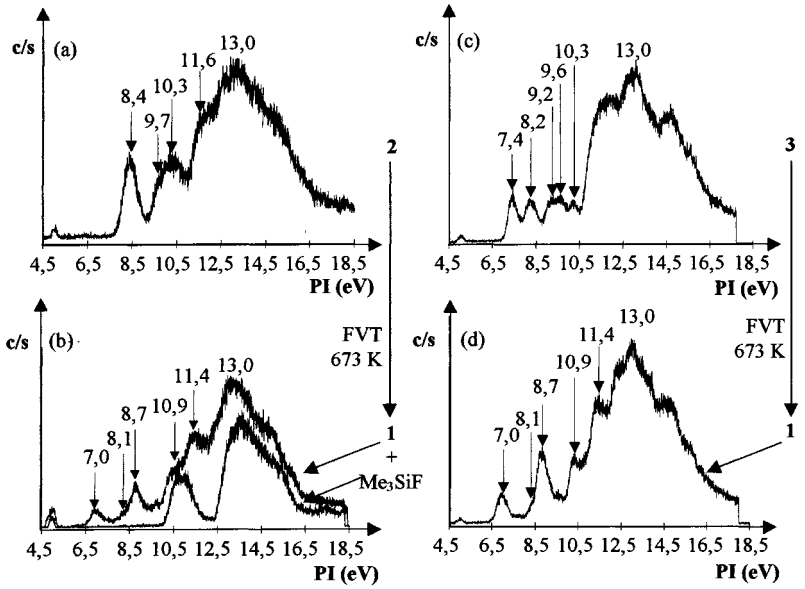

Figure 1. PE spectra of **2** at 300 K (a), at 673 K (b), of **3** at 300 K (c), and at 673 K (d)

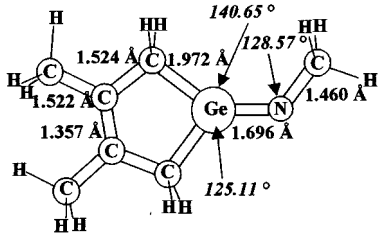

Figure 2. Geometrical parameters of the *N*-methylated germaimine **1′** [B3LYP/LANL2DZ(d)]

Thus, it seems reasonable to attribute the broad signal centered at 7.0 eV to ionizations from the nitrogen atom lone pair and $\pi_{Ge=N}$ bond, and the third ionization energy at 8.1 eV, the shoulder of the band at 8.7 eV in the PE spectrum, to the ejection of an electron from the $\pi_{C=C}$ cyclic bond (calculated at 7.93 eV). The ionizations of the antibonding and bonding combinations of the Ge−C bonds are observed at higher energies of 9.7 and 10.3 eV, respectively.[12] The intense signal at 8.7 eV is characteristic of the first ionization of 2,3-dimethylbuta-1,3-diene. Thus, at this temperature we observed the onset of the loss of 2,3-di-

methylbuta-1,3-diene, corresponding to a second decomposition process (confirmed when long-path thermolysis experiments were conducted at 673 K).

Conclusion

To the best of our knowledge, this work constitutes the first gas-phase characterization of a germaimine generated by flash vacuum thermolysis. This compound displays two characteristic ionizations in the low-energy region, corresponding to electron abstraction from the nitrogen atom lone pair and the Ge=N double bond. As in the case of silaimines, a $\pi_{Ge=N}$ orbital destabilization relative to the imines is in evidence. This stems from the kinetic instability and higher reactivity of the germaimines.

Experimental Section

Photoelectron Spectroscopy: Photoelectron spectra were recorded with a Helectros 0078 spectrometer, monitored by a microcomputer system supplemented by a digital analog converter (DAC). The spectra were built up from 2000 points and are accurate to within ±0.1 eV. They were recorded with 21.21 eV HeI radiation as the photon supply and were calibrated against the well-known helium ionization at 4.98 eV and nitrogen ionizations at 15.59 eV and 16.98 eV. Two types of pyrolysis experiments were performed, in combination with photoelectron spectroscopy. In short-path pyrolyses, the furnace was placed inside the ionization chamber of the UV spectrometer. The pressure in the ionization chamber was 10^{-5} mbar prior to introduction of the sample, and less than 10^{-4} mbar when the product was present. This first experimental procedure permitted analysis of species of short lifetime as well as their decomposition products. The second thermolysis system was external from the spectrometer. Thermolysis was performed in a vacuum device (oven pressure: 10^{-3} mbar without sample) connected to the spectrometer. In this case, only the stable species could be characterized after cryogenic distillation. Unstable compounds decompose and/or polymerize because of the considerable distance between the oven and the ionization head (around 1 m).

Synthesis of Precursors 2 and 3

1-[*tert*-Butyl(trimethylsilyl)amino]-1-fluoro-3,4-dimethyl-1-germacyclopent-3-ene (2): Germacyclopentene difluoride (6.65 g, 34.5 mmol) was added to a solution of LiN(*t*Bu)$SiMe_3$ (5.21 g, 34.5 mmol) in 20 mL of dry THF. The resulting yellow solution was stirred for 2 h at ambient temperature. Then, the THF was evaporated and pentane was added. LiF was eliminated by centrifugation and the organic layer was purified by vacuum distillation to yield 4.39 g (40%); b.p. 88°C/0.04 Torr. − MS (70 eV); *m/z*: 319 [M^+]. − ^{1}H NMR ($CDCl_3$): δ = 0.22 [s, 9 H, $Si(CH_3)_3$], 1.34 [s, 9 H, $C(CH_3)_3$], 1.74 (m, 6 H, cyclic CH_3), 1.84 (m, 2 H, cyclic CH_2), 1.92 (m, 2 H, cyclic CH_2). − ^{19}F NMR ($CDCl_3$): δ = −85.6 (m).

3: Compound **3** was obtained by spontaneous transformation of **2**. After one month under inert atmosphere, **2** was transformed into yellow crystals of **3** as Me_3SiF was given off; m.p. 174−176°C. − MS (70 eV); *m/z*: 452 [M^+]. − ^{1}H NMR ($CDCl_3$): δ = 1.15 [s, 18 H, $C(CH_3)_3$], 1.71−1.75 (m, 10 H, cyclic H).

Calculation Method: The theoretical evaluations were performed by means of an ab initio molecular orbital calculation method as implemented in the Gaussian 94 program package.[15] The geometrical parameters of neutral species were optimized by functional density theory using the B3LYP analytical function in conjunction with the LANL2DZ (D95 on H, C, N,[13] Los Alamos ECP plus DZ on Si, Ge[14]) basis set, extended with d orbitals (exponents: 0.8 for C and N; 0.202 for Ge). Ionization potentials (IPs) were evaluated at the ΔSCF level (IPs = $E_{neutral} - E_{ion}$).

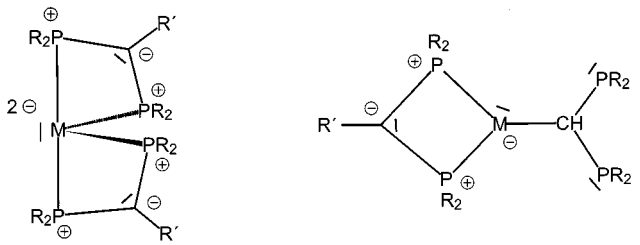
On the Bonding Properties of Diphosphanylmethanide Complexes with the Group-14 Elements Silicon, Germanium, Tin, and Lead in Their Divalent Oxidation States



Wolfgang W. Schoeller,*[a] Andreas Sundermann,[a] Markus Reiher,[a] and Alexander Rozhenko[a]

Keywords: Ab initio calculations / Chelates / Donor–acceptor systems / P ligands

The mono- and bidentate chelation of the main-group elements silicon, germanium, tin, and lead through the phosphorus atoms of the diphosphanylmethanide ligand has been studied by means of quantum chemical methods. In accord with experimental investigations, the species are found to adopt a ψ-tbp conformation of high flexibility. The various distortional modes causing the axial and equatorial positions to become equivalent have also been investigated. In addition, the bonding situations in the electronically related bis(diamino)- and the higher element homologue bis(diarsanyl)methanide ligand systems have been studied. The bonding situation in the hitherto experimentally unknown bis(diamino)methanide ligands is predicted to be similar to that in bis(amidinate) complexes. An analysis of the electron distributions (natural bond orbital population analysis) in these compounds reveals that the central main-group element is positively charged and weakly chelated by the surrounding ligands.

Introduction

Divalent silicon compounds are currently of interest due to their high potential in new synthetic routes. Archetypal compounds in this field are $(C_5Me_5)Si$ with η^5-bonded ligands (silicocene)[1] and the intramolecular donor-stabilized diphosphanylmethanide complexes **1** (M = Si).[2] For the higher element homologues with M = Ge[3] and Sn,[4] corresponding compounds have also been characterized experimentally. Besides the connectivity seen in **1**, chelation of the main-group element can also occur in three-fold coordinated compounds such as **2** (Scheme 1).

M = Si, Ge, Sn
R = phenyl
R´= SiMe3

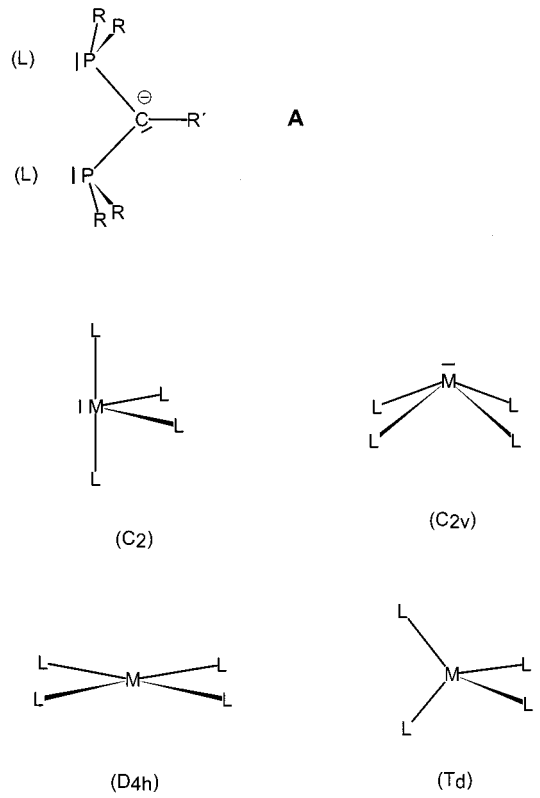
1 **2**

Scheme 1

Species of this kind are known for M = Ge, Sn, and Pb.[5] Recently, a diphosphanylmethanide complex was reported with phosphorus as the central main-group element.[6] For the Group-14 elements, chelation has been well documented in the amidinate chemistry of these species, which has been extensively investigated for tin and lead[7–10] as well as for germanium.[11] For silicon, bidentate amidinate chelation could be deduced on the basis of NMR investigations.[12] A first quantum chemical interpretation of the various structural alternatives in amidinate chemistry has recently been presented.[13]

The extremely rich chemistry in this field prompted us to investigate diphosphanylmethanide structures containing a Group-14 element (Si, Ge, Sn, Pb) as the central atom by quantum chemical methods. We report here the results of ab initio calculations on the chelated main-group elements in their divalent oxidation states, utilizing relativistic effective core potentials for the description of the higher main-group elements. In particular, we have analyzed the following aspects of the complexes: (a) bis(diphosphanyl)methanide chelation, and (b) the likelihoods of various geometrical arrangements at the central atom, i.e. trigonal-pyramidal (C_2) or planar (D_{2h}) environments. From experimental investigations it is known that these structures preferentially adopt pseudo-trigonal-bipyramidal (Ψ-tbp) geometries, which can easily be distorted. In solution, the structures undergo geometrical rearrangements that may be observed as dynamic processes by NMR spectroscopy.[4][5] All these aspects have been analyzed by means of quantum chemical calculations. Details of the quantum chemical methodology are given in the Appendix.

Results and Discussion



(a) The Ligand Field of the p-Block Elements

We begin our analysis with a discussion of some qualitative aspects. The formation of diphosphanylmethanide complexes can be considered in terms of the coordination of a

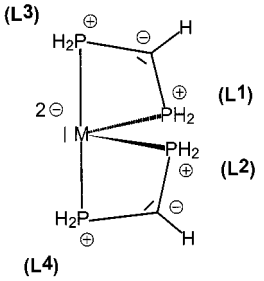
central element M (Si, Ge, Sn, etc.) in a ligand field[14] that is spanned by the diphosphanylmethanide ligands **A** (Scheme 2).



Scheme 2

The ligand **A** refers to two two-electron donors (denoted here as L). In other words, each two-electron donor is confined to a non-bonding lone pair at the (terminal) phosphorus atoms and each phosphorus atom of the diphosphanylmethanide ligand supplies two electrons to the central atom M. Various a priori possible conformations can be drawn. In each of them, the ligand exerts a ligand field[14] on the central atom. The orbital splitting for the different geometrical arrangements can be deduced from symmetry considerations, as has been shown previously for coordination of a central atom M with amidinato ligands.[13] In the C_2 and C_{2v} conformations, a non-bonding lone-pair orbital is operative at the central element M. The latter differs from the former geometry in that all M−L bonds are equivalent. It can be considered as the transition state geometry for interchange of the equatorial and axial bond positions in the dynamic rearrangement.[3] Possible planar (D_{4h}) or tetrahedral (T_d) conformations are not observed experimentally, and are thus not included in our considerations. For the corresponding amidinate complexes, the latter tetrahedral structure incorporates four strong bonds between the central atom M and the ligands, and can be assigned to a structure with a high degree of open-shell character.[13] For a more exhaustive discussion on the action of the ligand field on the orbitals of the central element M, the reader might like to refer to a recent report.[13]

(b) Bidentate Chelation

In this section, we report the numerical results obtained for the parent bis(diphosphanyl)methanide structures **B** (R = H). We first studied their equilibrium geometries with the main-group element M being varied by descending the group Si, Ge, Sn, and Pb. As ligands L^i (i = 1 to 4), the diamino- (L^i = N), diphosphanyl- (L^i = P), and diarsanylmethanide (L^i = As) components were chosen (Scheme 3). Experimentally, only the case of L^i = P is known, so our calculations make predictions for a variety of structures of experimentally unknown homologues. In all calculations we replaced the substituents at L^i and at the carbon atoms by hydrogen atoms. In the actual experimental situation the bis(diphosphanyl)methanide complexes are kinetically protected by bulky substituents (aryl, alkyl) at the chelating phosphorus atoms. Hence, our present calculations cannot account for these steric effects, but should accurately reflect the trends in bonding. The relevant equilibrium bonding parameters (bond lengths in Å, bond angles in degrees), obtained by energy optimizations of the equilibrium structures, are collected in Table 1.

Scheme 3

The most stable structure is found to be the ψ-tbp geometry, in accord with experiment. Two ligands L^1 and L^2 occupy equatorial while the other two L^3 and L^4 occupy axial positions. All of the equilibrium geometries could be ascertained by corresponding vibrational analyses. As expected, the equatorial bonds are invariably shorter than the axial ones. This is a common feature of the trigonal-bipyramid surrounding a central main-group element.[15] The actual equilibrium geometry of the ψ-tbp complex is determined by the electronegativity of the chelating axial and equatorial atoms (groups). We may discuss this for the case M = Si, L^i = N (diaminomethanide ligand), for which corresponding experimental structures are unknown. Here, the two axial bonds are equivalent in length, hence this molecule strictly adopts C_2 symmetry. On the other hand, replacement of N by P (diphosphanylmethanide ligand) makes the two axial bonds asymmetrical. The trend increases in the order (L^4/L^3, N = 1.0, P 1.35, As 1.41). However, with increasing atomic size of the central element M (Si < Ge < Sn < Pb), the asymmetry of the axial bonds becomes less marked. In fact, for M = Sn the two axial bonds in the ψ-tbp geometries are invariably symmetrical. The effects on the equatorial bonds are almost negligible so

[a] Unstable (transition state) structure, rearranges to **d**.

that these have similar lengths in all cases. We note that for M = Pb and L^i = N the corresponding structure **B** is not stable on the electronic hypersurface, but further rearranges to its isomer **d** (vide infra) without having to surmount an energy barrier.

It is of interest to inspect the population analyses (NBO) of the resulting equilibrium geometries. These are presented in Table 2.

Table 2. Wiberg bond indices and NBO charges of complexes **1**

	As	0.86	0.80	0.75	0.06	0.22
Ge	N	0.32	0.32	0.20	0.20	1.36
	P	0.77	0.77	0.40	0.40	0.39
	As	0.81	0.78	0.60	0.17	0.36
Sn	N	0.21	0.21	0.17	0.16	1.48
	P	0.66	0.66	0.37	0.37	0.64
	As	0.67	0.67	0.36	0.36	0.64
Pb	N	0.16	0.16	0.15	0.15	1.51
	P	0.63	0.63	0.34	0.34	0.73
	As	0.63	0.63	0.33	0.33	0.74

In general, the Wiberg bond indices for the axial bonds are smaller than those for the equatorial bonds. Nevertheless, for L^i = N, M = Si both the equatorial and the axial bonds are even weaker than a half bond. Replacing the ligands L^i by more electropositive elements (P, As) increases the strengths of the equatorial bonds, but makes the axial bonds more asymmetrical. As a further consequence, one axial bond becomes much stronger than the other (e.g. M = Si, L^i = P). As will be shown below by energetic considerations (vide infra), the overall energy differences resulting from the increased strength of one axial bond and the simultaneous weakening of the other are fairly small. With the higher element homologues as the central atom, M = Ge > Sn > Pb, the trend towards asymmetry of the two axial bonds is diminished.

It is notable that the axial bonds of the diphosphanylmethanide structures can easily become asymmetrical. Thus, one axial bond lengthens while the other shortens, and the energy difference between these forms and the highly symmetrical structure (C_2 symmetry) is fairly small. In order to further support this argument we have performed calculations at a higher level for the case M = Si, L^i = P. The two stationary points, with either C_2 symmetry (transition state structure) or C_1 symmetry (equilibrium structure) were taken into consideration. At the MP2 level, we obtained the following energy differences (in kJ/mol) as a function of the basis sets: (a) 6-31g** level 3.9, (b) 6-31+g** 5.1, (c) 6-311+g** 3.6. Thus, at higher computational levels our findings compare extremely well with the results obtained with the effective core potential basis sets. In other words, the more refined calculations are supportive of the present discussion. In the actual experiment, however, the structures are substituted by bulky substituents, which exert a steric hindrance. Hence, the subtle energy differences revealed by the quantum chemical theory for the unsubstituted cases can be neglected in comparison with the steric effects exerted by the substituents. The calculations also predict that the trend towards decreased symmetry should increase with decreasing positive charge at the central main-group element, e.g. for M = Si, in the order N < P < As.

We have also analyzed the extent of a bonding interaction between the negatively charged methanide carbon atoms and the central atom M. Overall, the Wiberg bond indices, i.e. the bond orders, are negligible (≤ 0.05) for the cases M = Si to Pb. Of interest is the charge at the central atom M. For L^i = N (diaminomethanide ligand) this amounts to ca. +1.3 to +1.5, while for the higher element homologues L^i = P, As it is much less (ca. +0.2 to +0.7). Such a description also holds true for the related amidinate complexes.[13] On the basis of the charge densities and the Wiberg bond indices, one can view the bonding situation in the complexes in terms of the three canonical structures **a** to **c** (Scheme 4).

In **a**, the central element M is tetravalent but additionally bears a lone pair orbital. Thus, this canonical structure formally refers to a 10-electron configuration at M. In comparison, in the canonical structure **b** the central atom M is chelated by four two-electron donating groups. In this structure, M is assigned a formal charge of +2. Finally, we may add a third canonical structure **c**. It is characterized by equatorial single bonds and two axial bonds fixed by a

Scheme 4

donor−acceptor interaction with the central atom. According to the population analyses, the various complexes can be divided into two categories: (a) In cases where the donating atoms are strongly electronegative (e.g. with the diaminomethanide ligand), the resulting compounds are best described by canonical structure **b**. In these cases, the Wiberg bond indices indicate a bond order of less than a half for the equatorial *and* axial bonds. However, the latter bonds are invariably stronger than the former ones. (b) On the other hand, in the case of L^i = P, As (diphosphanyl-, diarsanylmethanide ligands) the equatorial and, to a much lesser extent, the axial bonds become stronger. This supports the predominance of canonical structure **c** for the overall bonding description. Interestingly, for the structures with asymmetrical bonds, the shorter axial bond becomes much stronger, while the longer axial bond is weakened (e.g. M = Si, L^i = P).

Besides the ψ-tbp conformations with symmetrical (C_2 symmetry) or asymmetrical (C_1) axial bonds, we also explored structures in which the axial and equatorial bonds in the complexes were of equal length. This refers to the case of C_{2v} symmetry and represents the transition state for pseudorotation, i.e. the positional interchange of the equatorial and axial bonds. We will not present here the details of the equilibrium structures, but all geometries refer to transition states established from the corresponding vibrational analyses. They are in accordance with one imaginary vibration in these C_{2v} geometries. A summary of the energies of the ψ-tbp geometries and their corresponding C_{2v} geometries is also given in Table 3.

Table 3. Relative energies (in kJ/mol) for complexes **1**

M	L^i	$E(C_1)$	$E(C_2)$	$E(C_{2v})$
Si	N	0.0	0.0	21.9
	P	0.0	3.8	34.0
	As	0.0	6.1	41.7
Ge	N	−	0.0	15.0
	P	−	0.0	33.6
	As	0.0	0.6	38.1
Sn	N	−	0.0	6.2
	P	−	0.0	15.7
	As	−	0.0	20.0
Pb	N	−	0.0	9.6
	P	−	0.0	11.9
	As	−	0.0	15.0

The numerical data indicate that the energy differences between the two conformations are fairly small. The values decrease in the order M = Si > Ge > Sn > Pb and with increasing electronegativity of the chelating atoms, N < P < As. In the same order, canonical structure **b** comes to the fore.

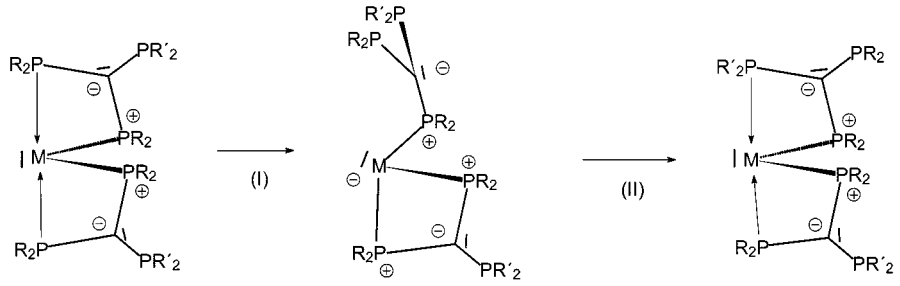
These results allow a clear-cut assignment of the various mechanisms for the dynamic rearrangement of the bis(diphosphanyl)methanides. It has been noted that these species undergo exchange of the equatorial and axial phosphorus atoms and even more facile exchange of the axial and *exo*-phosphanyl groups.[3] The mechanism for the latter process is outlined in Scheme 5.

One axial bond is readily extended, while the other is strengthened. This is followed by a facile rotation about the P−C bond (I) and subsequent ring-closure (II). Along this reaction coordinate, the phosphanyl groups undergo positional interchange. Considering the presented results, such a process is easy to understand. While one axial bond is stretched, the other is shortened and the overall energy expense for such a process is fairly small.

There is another point that needs to be considered here. It has been reported that certain bis(diphosphanyl)methanide structures undergo irreversible reaction of the ψ-tbp geometry[4] to give a structure in which one diphosphanylmethanide ligand is linked through an M−C bond (structure **d**, Scheme 6).

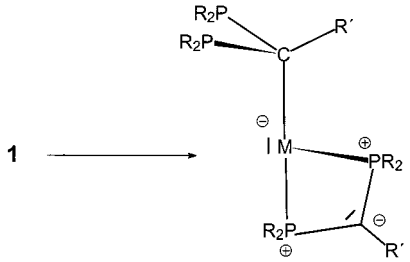
In order to gain an insight into the stability of the latter geometry, we have calculated the energy balances for various cases (different M, L^i and R′, R = H) (Table 4).

In all cases, the structures **d** are found to be more stable than the ψ-tbp structures. Furthermore, the investigations indicate that with various substituents R the energy balances between the two structures are not significantly affected. This indicates that silyl or phosphanyl groups[16] at the carbon atom in structure **d** do not exert strongly stabilizing effects on the ψ-tbp geometries.



Conclusions

The results of our investigation can be summarized as follows:



1. The bis(diphosphanyl)methanide complexes with Group-14 central elements have been studied by quantum chemical methods at an effective core potential level. They have been found to be capable of facile pseudorotation over a C_{2v} symmetrical structure. The energy barrier for the degenerate rearrangement decreases in the order Si > Ge > Sn > Pb. Rearrangement is also facilitated with increasing difference in electronegativity between the central and chelating atoms, As > P > N.

2. The structures with the diphosphanylmethanide and diarsanylmethanide ligands are best described as having equatorial single bonds and weak axial bonds, which can distort to form asymmetrical trigonal bipyramids. This explains the experimentally observed facile rearrangement of these species.

3. A "true" chelation, i.e. the formation of partial bonds between the central atom M and the ligands is observed only for the case L^i = N, i.e. the hitherto experimentally

Scheme 5

d

Scheme 6

Table 4. Energy differences (in kJ/mol) between ψ-tbp and geometries **d**

unknown diaminomethanide ligand. In this case, an extremely facile exchange of the equatorial and axial ligating atoms can be expected.

4. Structures in which one diphosphanylmethanide ligand is linked through an M−C bond are considerably lower in energy and the energy differences are found to be almost independent of the substituents R′ attached to the carbon atoms.

Experimental Section

All quantum chemical calculations were carried out at the MP2 level of theory using the Gamess set of programs.[17] The relativistically corrected effective core potential basis sets were taken from Stevens, Basch, and Krauss,[18] with a double-ζ basis set expansion for the valence space. All heavy atoms were augmented by a single set of polarization functions, as provided by Schmidt et al.[19] The energy optimizations of structures were performed at the MP2 level utilizing analytically determined nuclear coordinate gradients.[20] The force constants for the ECP(d) calculations were derived by the method of numerical differences. The population analyses at the given computational level were performed according to the Weinhold−Reed partitioning scheme.[21]

Bonding Analysis in Inorganic Transition-Metal Cubic Clusters, 5[+] $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ Species Centered and Hexacapped by Main-Group Atoms

Régis Gautier,[a] François Ogliaro,[a] Jean-François Halet,*[a] Jean-Yves Saillard,*[a] and Evert Jan Baerends[b]

Keywords: Electron count / Electronic structure / Density functional calculations / Transition metals / Cluster compounds / Interstitial element / Main-group elements

The bonding in main-group atom-centered hexacapped transition-metal cubic clusters $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ has been analyzed by means of density functional theory (DFT) calculations. Although only one example of such compounds has been characterized so far, DFT results indicate that it should be possible for other members of this family to be synthesized. As for their metal-centered parents, there are several "magic" electron numbers that are able to satisfy the closed-shell requirement for such species, depending on the nature of the metal and the capping ligands. The most probable cluster valence electron counts that imply significant M–M bonding are 120 and 122. The former value is favored when E′ is an early main-group element while the latter value is favored when E′ is a late main-group element. Owing to the high connectivity between the atoms, such a regular cubic architecture may also be observed with open-shell electron configurations, as observed for the 119-cluster-valence-electron cluster $Ni_8(\mu_8\text{-}As)(\mu_4\text{-}As)_6(PPh_3)_8$.

Introduction

Among the simplest polyhedral architectures encountered in transition-metal clusters, the M_4 tetrahedral and M_6 octahedral arrangements are by far the most common.[1–4] However, an increasing number of compounds having an M_8 cubic or distorted-cubic cluster core have been characterized in recent years.[5–10] These cubic arrays may be empty[6][7] or centered by an interstitial atom.[8–10] In previous papers, we have analysed the electronic structure of cubic empty clusters of general formula $M_8(\mu_4\text{-}E)_6L_n$ (E = main-group atom or ligand),[11] as well as metal-centered $M_8(\mu_8\text{-}M)(\mu_4\text{-}E)_6L_8$ clusters[12] and other related compounds.[13] These geometries are characterized by a large range of allowed cluster valence electron (CVE) counts, most of which correspond to open-shell configurations or small HOMO–LUMO gaps. The high atom connectivity present in these clusters considerably reduces their Jahn–Teller instability. The largest allowed CVE count generally corresponds to a magic number satisfying the closed-shell requirement for stable diamagnetic molecules.

The possibility of the existence of hexacapped transition-metal cubic clusters centered by a main-group atom has been suggested by Wheeler[14] based on extended Hückel (EH) calculations on $Ni_8(\mu_8\text{-}Te)(\mu_4\text{-}Te)_6L_8$ models, for which he predicted two favored closed-shell CVE counts, namely 110 and 126. On the other hand, the application to these species of Mingos' inclusion principle,[15] which allows prediction of closed-shell electron counts for centered clusters, leads to the values of 114 CVEs and 120 CVEs. More recently, the 119-CVE cluster $Ni_8(\mu_8\text{-}As)(\mu_4\text{-}As)_6(PPh_3)_8$ (**1a**) was synthesized and characterized in the group of D. Fenske.[16] The X-ray molecular structure of this compound (see Figure 1) has exact C_i and approximate O_h symmetries, with the following average bond lengths [Å]: Ni–Ni = 2.89; Ni–(μ_8-As) = 2.50; Ni–(μ_4-As) = 2.32; Ni–P = 2.21; (μ_8-As)···(μ_4-As) = 2.54. This prompted us to undertake a density functional theory (DFT) analysis of the electronic structure of **1a** as well as that of various model clusters of the general type $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ (E′ = main-group atom; E = main-group atom or ligand) in order to rationalize the bonding, stability and properties of these centered clusters with respect to their possible CVE counts.

Qualitative Approach

The electronic structure of an $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ compound of approximate O_h symmetry can be qualitatively analysed in a similar way to that previously described by us for the metal-centered $M_8(\mu_8\text{-}M)(\mu_4\text{-}E)_6L_8$ species,[12] i.e. resulting from the interaction of the $M_8(\mu_4\text{-}E)_6L_8$ empty cage with the interstitial atom. We have shown that, as long as there is substantial M−M bonding, a noncentered $M_8(\mu_4\text{-}E)_6L_8$ cube should present a significant HOMO−LUMO gap for the ideal 120-CVE count, separating the more or less nonbonding d-type levels (the d-band) from the significantly antibonding levels.[11] This situation satisfying the closed-shell requirement is represented in the top-middle of Figure 2. The electron configuration corresponding to the 120-CVE magic electron count of the empty cage will be written as $[116](e_g)^4$ in the following discussion.

The interstitial E′ atom has four valence orbitals of a_{1g} (s) and t_{1u} (p) symmetry. They are expected to interact mainly with some metallic counterparts in the d-manifold, which are close in energy and available for bonding. If the four E′ orbitals interact strongly, the resulting antibonding

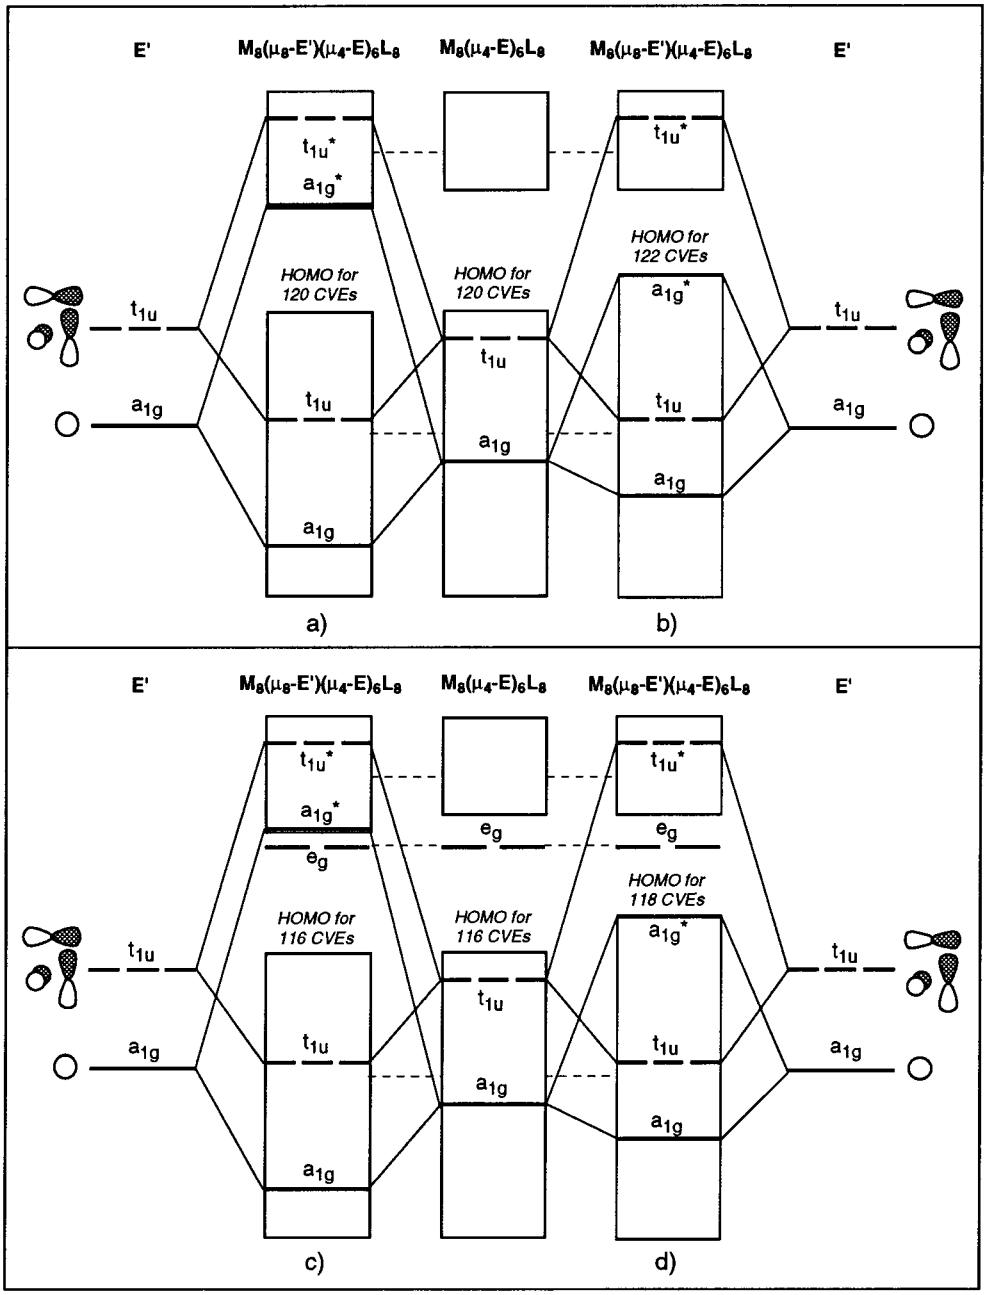

Figure 2. Qualitative MO interaction diagrams for four possible closed-shell configurations in the case of $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ species in which significant M−M bonding is present: (a) the four s (a_{1g}) and p (t_{1u}) E′ valence AOs interact strongly with the cubic host; (b) only the E′ valence p (t_{1u}) AOs interact significantly; (c) and (d) particular situation where the interactions are similar to those in (a) and (b), respectively, but the capping ligand E is a single main-group atom that tends to destabilize the highest e_g level of the d-band.

combinations will lie at high energy, leaving the same number of bonding and nonbonding levels as in the empty $M_8(\mu_4\text{-}E)_6L_8$, as shown in Figure 2a. In such a situation, the closed-shell requirement is expected to be satisfied for the same 120-CVE count as for the noncentered $M_8(\mu_4\text{-}E)_6L_8$ species, and with the same $[116](e_g)^4$ configuration.

Another closed-shell situation may occur if the E′ atom retains an s-type lone pair, as some heavy main-group atoms often do. This would correspond to a weak a_{1g} interaction, leaving at low energy the weakly antibonding a_{1g} combination. In such a case, a significant HOMO/LUMO gap is expected for the 122-CVE count, corresponding to the $[116](e_g)^4(a_{1g})^2$ configuration. This situation is shown in Figure 2b.

Finally, mention should be made of the special effect induced by the capping E ligands when they are single heavy main-group atoms. This *bare-atom-capping* effect tends to destabilize the highest e_g level of the metallic d-block, whether the cage is centered or not.[12] If this effect is moderate, open-shell configurations will be favored with partial occupation of the e_g level. On the other hand, if this effect is strong enough, the e_g orbitals will become unavailable, leading to the 116-CVE closed-shell count for the empty $M_8(\mu_4\text{-}E)_6L_8$ cluster, with the $[116](e_g)^0$ configuration, as shown in the bottom-middle of Figure 2. In the case of the centered $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ species, this would correspond to the 116- and 118-CVE possible magic numbers, depending on whether the a_{1g} interaction is strong or not, respectively. These two particular hypothetical closed-shell situations are represented in Figure 2c and d.

The 119-CVE Cluster $Ni_8(\mu_8\text{-}As)(\mu_4\text{-}As)_6(PH_3)_8$

In order to reduce computational effort, cluster **1a** was modeled by changing the PPh_3 ligands into PH_3 phosphanes. Single-point spin-polarized DFT calculations were first performed on $Ni_8(\mu_8\text{-}As)(\mu_4\text{-}As)_6(PH_3)_8$ (**1b**), with an idealized O_h geometry obtained by averaging the experimental structure of **1a** and assuming P−H distances of 1.42 Å. The ground state was found to be a doublet, with the configuration $[116](a_{1g})^2(e_g)^1$. Unfortunately, no experimental data about the magnetic properties have been reported so far for **1a** to confirm this doublet spin state. The level ordering corresponding to spin-restricted calculations is shown in Figure 3. The $5e_g$ and $6a_{1g}$ levels are close in energy and lie in the middle of a large gap separating the nonbonding levels from the antibonding ones. Clearly, the magnitude of the a_{1g} interaction as well as the magnitude of the e_g destabilizing effect due to the bare capping As atoms are both intermediate between strong and weak. The $5e_g$ and $6a_{1g}$ orbitals are plotted in Figure 4. Both are Ni−Ni bonding. The $6a_{1g}$ MO is Ni−(μ_4-As) bonding, whereas the $5e_g$ MO is antibonding along these contacts. As qualitatively predicted (Figure 2), $6a_{1g}$ is Ni−(μ_8-As) antibonding. This orbital is also (μ_8-As)···(μ_4-As) antibonding. The $6a_{1g}$ and $5e_g$ levels are situated in the middle of a large energy gap and so the closed-shell requirement for this kind of cluster should be satisfied for two different electron configurations (among the four predicted above): $[116](a_{1g})^2(e_g)^4$ (122 CVEs) and $[116](a_{1g})^0(e_g)^0$ (116 CVEs).

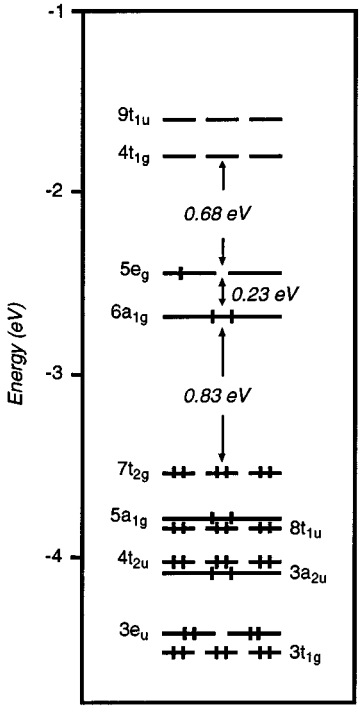

Figure 3. MO level ordering for model **1b** (spin-restricted calculations)

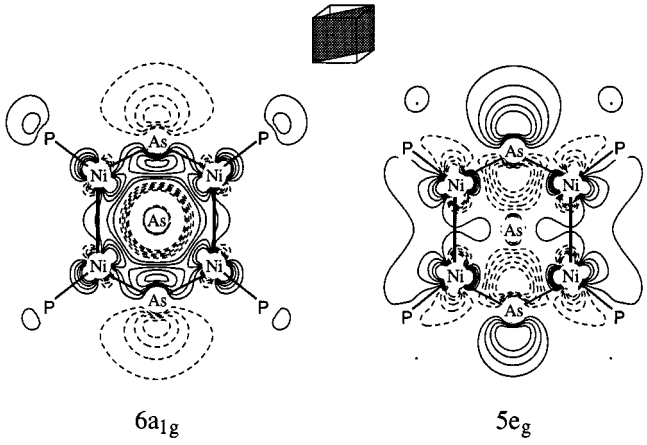

Figure 4. Contour plots of the $6a_{1g}$ and one of the $5e_g$ orbitals of **1b** in one diagonal plane (shaded) containing four Ni atoms and two capping As atoms; contour values are ±0.01, ±0.02, ±0.05, ±0.10, ±0.20, ±0.50 (e $bohr^{-3})^{1/2}$

In a further step, spin-polarized geometry optimizations of **1b** were performed for the three lowest spin states, corresponding to the $[116](a_{1g})^2(e_g)^1$, $[116](a_{1g})^1(e_g)^2$, and $[116](e_g)^3(a_{1g})^0$ configurations, still assuming O_h symmetry. The computed energies and metrical parameters are given in Table 1, together with the data corresponding to the single-point calculations on the averaged experimental structure. The three configurations lead to similar optimized P−H, Ni−(μ_4-As), and Ni−P bond lengths. The latter is in a reasonable agreement with the averaged Ni−PPh_3 exper-

imental value, while the optimized Ni−(μ_4-As) distance is somewhat longer than the averaged experimental one. The Ni−Ni and consequently the Ni−(μ_8-As) separations are found to be strongly dependent upon the electron configuration. Depopulating the $6a_{1g}$ orbital results in decreasing of the size of the cube. This can be attributed to the Ni−(μ_8-As) antibonding character of this orbital. The fact that the Ni−(μ_4-As) distance does not change with the orbital occupations is probably the result of compensating effects associated with the Ni−(μ_4-As) bonding and (μ_8-As)···(μ_4-As) antibonding characters of the a_{1g} orbital.

Other Electron Counts

Geometry optimizations were also performed on model **1b** with different electron counts: 118 CVEs (**1b**$^+$), 120 CVEs (**1b**$^-$), 116 CVEs (**1b**$^{3+}$), and 122 CVEs (**1b**$^{3-}$). The major results are given in Table 1. Again, one can see that the size of the cube strongly depends on the a_{1g} occupation. The other structural parameters primarily vary with the CVE count, almost independently from the electron configuration. It is noteworthy that an increase of the CVE count induces a shortening of the Ni−P distance and an increase of the pyramidalization of the PH_3 ligands. Adding electrons weakens the bonding within the cluster core and reinforces the Ni−PR_3 bonds through π back-bonding. As for **1b**, the three computed electron configurations of **1b**$^+$ and **1b**$^-$ are close in energy, with the lowest state corresponding to an empty $6a_{1g}$ orbital. In this situation, the bonding interaction between the interstitial As atom (considered as neutral) and its cage is maximum. Although significant, the HOMO/LUMO gaps associated with the closed-shell configurations of **1b**$^+$, **1b**$^-$, **1b**$^{3+}$, and **1b**$^{3-}$ are rather small. In order to find examples of clusters having favored CVE counts secured by larger HOMO/LUMO gaps, we have undertaken calculations on different model clusters.

[a] Open-shell configuration. − [b] Bonding energy with respect to fragmentation in individual neutral atoms. − [c] Bonding energy between the neutral interstitial As atom and its cubic host $Ni_8As_6(PH_3)_8$.

The ADF program allows the calculation of the bonding energy between two or several fragments of a molecule.[19] The bonding energy between the central As atom and its $Ni_8(\mu_4\text{-As})_6(PH_3)_8$ cage in **1b** is given in Table 1 for the three electron configurations considered. Consistent with the Ni−(μ_8-As) and (μ_4-As)−(μ_8-As) antibonding characters of the $6a_{1g}$ orbital, the bonding is stronger when this level is vacant. On the other hand, the depopulation of $6a_{1g}$ to the benefit of $5e_g$ weakens the Ni−Ni and Ni−(μ_4-As) bonding to a similar extent, since the three configurations are close in energy. They lie within a range of 0.25 eV, a value barely significant at the considered level of calculations for such a large cluster. In particular, one should note that the potential energy surface associated with the variation of the Ni−Ni and Ni−(μ_4-As) distances in the O_h symmetry was found to be rather flat. Moreover, **1b** is associated with an open-shell configuration, which may present some Jahn−Teller distortion away from the ideal O_h symmetry. As a matter of fact, the crystal structure of **1a** is of C_i symmetry in the solid state and exhibits some dispersion of the Ni−Ni and Ni−(μ_4-As) separations.[16] Geometry optimizations with lower symmetries, which could allow first-order Jahn−Teller distortion to occur, give results that are not significantly different from those of the $(a_{1g})^2(e_g)^1O_h$ configuration. We therefore conclude that the restriction to the O_h symmetry is a satisfying approximation for analysing the bonding in this type of cluster, owing to their soft flexibility with respect to Ni−Ni distance variation.

Changing the Nature of the Capping and Interstitial Ligands

The 120-CVE and 122-CVE Models $[Ni_8(\mu_8\text{-}E')(\mu_4\text{-}GeH)_6(CO)_8]^{q-}$ (E′ = Si, Ge, P, As, S, Se; $q = 0-4$)

The choice of these hypothetical models was driven by the fact that the diamagnetic 124-CVE metal-centered cluster $Ni_8(\mu_8\text{-Ni})(\mu_4\text{-GeEt})_6(CO)_8$ is known,[8a] and was calculated to present a large HOMO/LUMO gap.[12] Indeed, the presence of Ge−R groups as capping ligands allows to alleviate the destabilizing effect of the cluster e_g frontier level

caused by the μ_4-As bare atoms in **1b**$^{3+/+/-/3-}$. This is expected to particularly favor the 120-CVE and/or 122-CVE magic numbers (see Figure 2a and 2b). In the $[Ni_8(\mu_8\text{-}E')(\mu_4\text{-}GeH)_6(CO)_8]^{q-}$ models (denoted as **[2-E′]**$^{q-}$ in the following discussion), the interstitial main-group atom is varied in order to tune the magnitude of the a_{1g} interaction with respect to the electronegativity and size of E′. The reported calculations correspond to the CVE counts of 120 and 122 for E′ = Si, Ge, P, As, S, and Se. Geometry optimizations have been carried out assuming O_h symmetry. In any case, a single minimum was found on the potential energy hypersurface. The major results are given in Table 2. The computed one-electron level orderings are shown in Figure 5. As expected and in contrast to the case of **1b**, the $5e_g$ level for all the **[2-E′]**$^{q-}$ species lies deep in energy. They are not shown in Figure 5. The highest level of the band occupied for the 120-CVE count is now the $8t_{2g}$ level, which corresponds to the $7t_{2g}$ level in **1b**. In the following discussion the configuration designated above as $[116](e_g)^4$ will be alternatively written as $[110](e_g)^4(t_{2g})^6$. Most of the free anions which were calculated have occupied MOs associated with a positive energy, indicating instability with respect to electron loss. However, when a cationic environment is mimicked by positive point charges introduced in the calculations, these levels are in most of the cases significantly stabilized to negative energies. This is a quite common result for stable anionic clusters.[17] Moreover, it is clear that the hypothetical **[2-E′]**$^{q-}$ clusters should be considered as a series of models for more realistic compounds (see below).

As mentioned above for **1b**, the Ni−Ni separation is very sensitive to the a_{1g} occupation number. In the case of the 120-CVE $[110](e_g)^4(t_{2g})^6(a_{1g})^0$ configuration, this distance lies in the range 2.7−2.9 Å, whereas for the 122-CVE $[110](e_g)^4(t_{2g})^6(a_{1g})^2$ configuration it is longer by ca. 0.2 Å. This difference is smaller in the cases where E′ = S and Se because the a_{1g} level is still occupied in the corresponding 120-CVE configuration. Electron-electron repulsion is also responsible for the long Ni−Ni separations in the negatively charged **[2-E′]**$^{4-}$ (E′ = Si, Ge) and **[2-E′]**$^{3-}$ (E′ = P, As) models. Indeed, the replacement of the CO ligands by isoelectronic NO^+ units in **[2-Ge]**$^{4-}$ leads to shorter optimized Ni−Ni distances in the 122-CVE $[Ni_8(\mu_8\text{-}Ge)(\mu_4\text{-}GeH)_6(NO)_8]^{4+}$ cationic model.

The results on the **[2-E′]**$^{q-}$ series illustrate nicely the trend accompanying the variation of the nature of E′ across the periodic table. When E′ is an early main-group element, the a_{1g} interaction is strong, favoring the closed-shell 120-CVE count. Conversely, with late main-group encapsulated atoms the a_{1g} interaction is weak, favoring the closed-shell 122-CVE count. This is exemplified for the clusters **[2-Si]**$^{2-}$ and **[2-Ge]**$^{2-}$ (120 CVEs), and **[2-S]**$^{4-}$ and **[2-Se]**$^{4-}$ (122 CVEs) for which large HOMO/LUMO gaps are computed.

The 116-CVE and 118-CVE Models: $[Ni_8(\mu_8\text{-}Ge)(\mu_4\text{-}Ge)_6(CO)_8]^{4-}$ and $[Ni_8(\mu_8\text{-}Se)(\mu_4\text{-}Ge)_6(CO)_8]^{4-}$

Starting for example from **[2-Ge]**$^{2-}$ (120 CVEs) and **[2-Se]**$^{4-}$ (122 CVEs), the MO diagrams of which correspond to the general cases of Figure 2a and 2b, the formal removal of the H substituents on the Ge atoms is expected to induce a destabilization of a low-lying e_g level (see above) leading to the general cases of Figure 2c and 2d. In order to check this hypothesis, calculations were carried out on the "deprotonated" models $[Ni_8(\mu_8\text{-}Ge)(\mu_4\text{-}Ge)_6(CO)_8]^{4-}$ (116 CVEs) and $[Ni_8(\mu_8\text{-}Se)(\mu_4\text{-}Ge)_6(CO)_8]^{4-}$ (118 CVEs). They fully confirm the hypothesis illustrated in Figure 2c and 2d, with significant HOMO/LUMO gaps computed for the $[116](eg)^0$ (1.04 eV) and $[116](a_{1g})^2(eg)^0$ (0.88 eV), respectively. As for the **[2-E′]**$^{4-}$ models, the size of the cube is

[a] Bonding energy with respect to fragmentation in individual neutral atoms.

Closed-shell ground-state configurations, namely $[116](e_g)^4(a_{1g})^0$ {or $[110](e_g)^4(t_{2g})^6(a_{1g})^0$} and $[116](e_g)^4(a_{1g})^2$ {or $[110](e_g)^4(t_{2g})^6(a_{1g})^2$}, were found for all the 120-CVE and 122-CVE models, respectively, except two of them. In the case of the 120-CVE species having E′ = S and Se, the $[110](e_g)^4(a_{1g})^2(t_{2g})^4$ open-shell ground-state configuration was found. This result suggests that with the more electronegative chalcogen elements as encapsulated atoms, the a_{1g} interaction is weak, requiring its occupation even for the 120-CVE count, for which a partially depopulated t_{2g} HOMO is preferred.

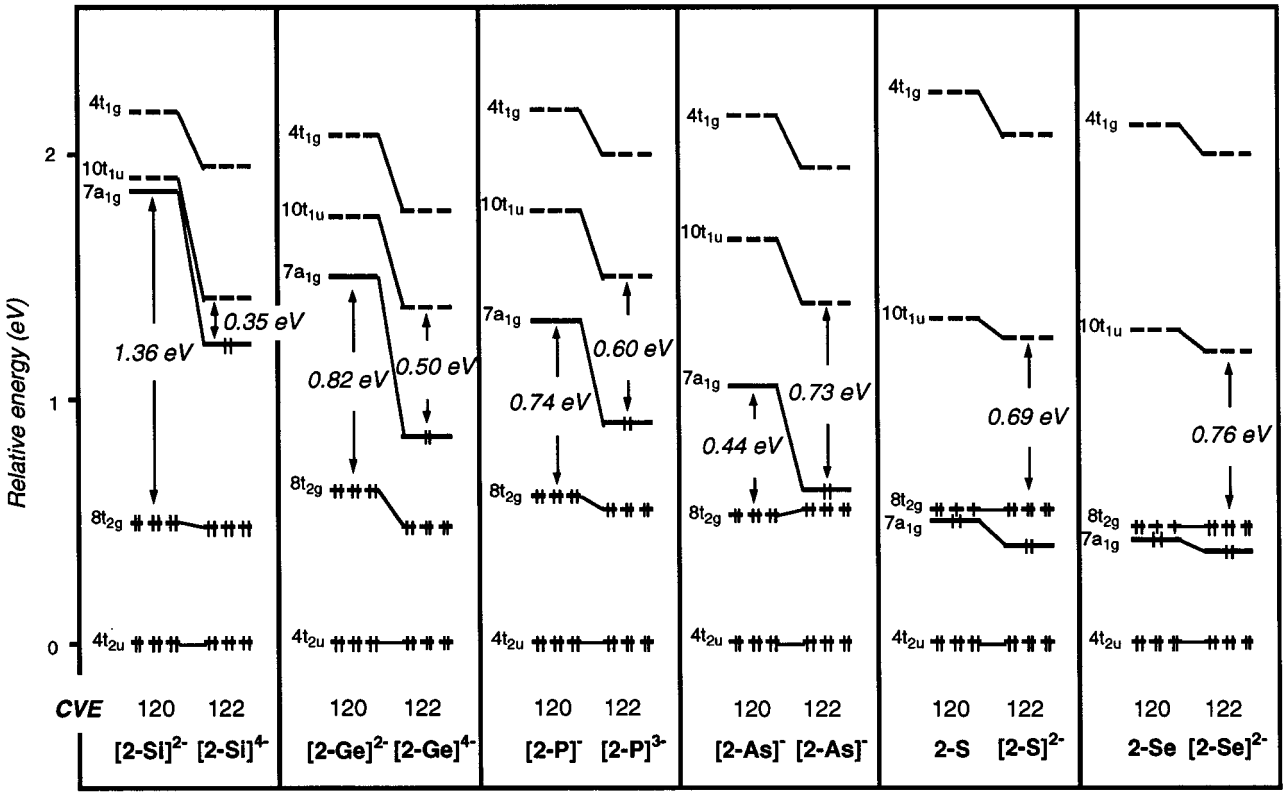

Figure 5. MO level orderings for the 120-CVE and 122-CVE cluster models **[2-E′]**$^{q-}$ (in all cases, the zero energy has been arbitrarily set to be the energy of the $4t_{2u}$ level)

rather large in these highly charged anions (Ni−Ni ca. 3.1 Å). Calculations on the isoelectronic cation $[Ni_8(\mu_8\text{-Ge})(\mu_4\text{-Ge})_6(NO)_8]^{4+}$ (116 CVEs) lead to a similar electronic configuration, with a HOMO/LUMO gap of 1.07 eV. In this latter model, the optimized Ni−Ni and Ni−(μ_4-Ge) distances are 2.79 Å and 2.42 Å, respectively.

Other Possible Electron Counts

The MO diagrams of **[2-E′]**$^{2-/4-}$ (E′ = Si, Ge) and of **[2-E′]**$^{-/3-}$ (E′ = P, As) exhibit a significant gap below the occupied $8t_{2g}$ level. This suggests that the count of 114 CVEs could be a possible closed-shell electron count for some members of the $M_8(\mu_8\text{-E}')(\mu_4\text{-E})_6L_8$ series. This is confirmed by calculations on the $[Co_8(\mu_8\text{-P})(PH)_6(CO)_8]^{3+}$ model (see Table 3), which show a significant HOMO/LUMO gap of 0.60 eV for the $[110](e_g)^4(t_{2g})^0$ ground-state configuration. The $8t_{2g}$ orbitals are mainly localized on the Co atoms (64%) with a very weak participation of the d-type polarization function of the encapsulated atom (its s and p valence orbitals do not have the proper t_{2g} symmetry). They exhibit some Co−Co and Co−(μ_4-P) antibonding character. The monoccupation of these MOs in $[Co_8(\mu_8\text{-P})(PH)_6(CO)_8]^{3+}$ tends to reinforce the corresponding bonds, as illustrated by comparing the corresponding bond lengths with their homologs in the 120-CVE **[2-P]**$^-$ cluster (see Table 2).

Table 3. Optimized geometries and corresponding bonding energies for the 114-CVE $[Co_8(\mu_8\text{-P})(\mu_4\text{-PH})_6(CO)_8]^{3+}$ and the 128-CVE $[Cu_8(\mu_8\text{-S})(\mu_4\text{-GeH})_6(CO)_8]$ species

Model compound	$[Co_8(\mu_8\text{-P})(\mu_4\text{-PH})_6(CO)_8]^{3+}$	$Cu_8(\mu_8\text{-S})(\mu_4\text{-GeH})_6(CO)_8$
CVE	114	128
M−M [Å]	2.68	2.88
M−(μ_8-E) [Å]	2.32	2.50
M−(μ_4-E′) [Å]	2.33	2.59
(μ_8-E)−(μ_4-E′) [Å]	2.69	3.04
P/Ge−H [Å]	1.44	1.60

[a] Bonding energy between the neutral interstitial E′ atom and its cubic host $M_8(\mu_4\text{-E})_6(CO)_8$.

On the other hand, the MO diagrams of **[2-E′]** and **[2-E′]**$^{2-}$ (E′ = S, Se) exhibit large $10t_{1u}/4t_{1g}$ separations, suggesting that the $[110](e_g)^4(a_{1g})^2(t_{2g})^6(t_{1u})^6$ configuration should satisfy the closed-shell requirement in the case of electron-rich metals. This is confirmed by calculations on the 128-CVE $Cu_8(\mu_8\text{-S})(GeH)_6(CO)_8$ model (see Table 3). The optimized Cu−Cu and Cu−Ge distances are long, indicating weak bonding. The $10t_{1u}$ orbitals are predominantly localized on the Cu (28%) and Ge (31%) atoms, with

a smaller S (18%) participation. Although it exhibits some Cu−S antibonding character, this level cannot be identified as being the t_{1u}* level shown in the diagrams of Figure 2. In fact, this $10t_{1u}$ level is better described as being associated with the Cu−Ge bonds.[11] Therefore, its occupation is expected to weaken these bonds (see above) or to induce a Jahn−Teller distortion of the octahedral architecture. Such a distortion is unlikely to occur, as shown by geometry optimizations carried out under the T_d and D_{4h} symmetry constraints, which provide results not significantly different from those obtained under the O_h symmetry.

One may be tempted to compare the 128-CVE face-capped $Cu_8(\mu_8\text{-}S)(GeH)_6(CO)_8$ model and a series of Cu_8 edge-capped cubic 128-CVE clusters synthesized by Fackler, Coucouvanis and co-workers[7] in which the Cu−Cu separations (2.8−2.9 Å) are similar to that optimized in $Cu_8(\mu_8\text{-}S)(GeH)_6(CO)_8$ (2.88 Å). The similarity is, in fact, fortuitous. In the edge-capped clusters the bonding can be simply described by a 2-electron/2-center bonding scheme in which the Cu atoms are 16-electron centers, with no formal Cu−Cu bonding.[5][7] Such a description does not apply at all for the highly delocalized $Cu_8(\mu_8\text{-}S)(GeH)_6(CO)_8$ system. There is also no simple relationship between this latter cluster and the recently characterized edge-capped Cu_8 clusters centered by other main-group atoms.[10]

The 122-CVE count is likely to be the upper limit of the allowed CVE range, since adding more electrons would result in the occupation of strongly antibonding levels. The lowest CVE limit is probably much lower, owing to the fact that the lowest predicted and observed (so far) values for the noncentered $M_8(\mu_4\text{-}E)_6L_8$ species are 76[11] and 99,[6] respectively.

Conclusion

Although only one example of main-group atom-centered hexacapped cubic clusters of the type $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ is known so far, namely **1a**,[16] DFT calculations that we carried out indicate that there is no reason for this kind of compound to be unstable. It is therefore very likely that other members of this family will be characterized in the future. The major challenge for their synthesis appears to be the accomplishment of the right combinations of the various M, E, E′, and L building blocks in such a way that they would fit with an allowed CVE count and a reasonable ionic charge (if any).[18]

As for their metal-centered parents,[12] there are several "magic" electron numbers susceptible to satisfy the closed-shell requirement for stable $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ molecules. The most probable electron counts are 120 and 122. The former is favored when E′ is an early main-group element while the latter is favored when E′ is a late main-group element. These two CVE counts are the corresponding values of the most commonly encountered 120-CVE number in noncentered $M_8(\mu_4\text{-}E)_6L_8$ clusters.[5][11] They imply substantial M−M bonding. In the particular case where the capping ligand E is a bare heavy main-group atom, these two closed-shell electron counts diminish to 116 and 118, respectively. In the case of stronger M−M overlap, the highest level of the d-manifold, of t_{2g} symmetry, can become unavailable, favoring the 114-CVE count. Conversely, weak M−M overlap allows the occupation of the lowest M−E antibonding level, of t_{1u} symmetry, leading to the closed-shell count of 128 CVEs. It is likely that this value constitutes the upper limit of the allowed CVE range, since adding more electrons would result in the occupation of strongly antibonding levels. As for their noncentered and metal-centered relatives, there must be a continuum within this allowed range of electron counts for $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ species.[6][8] Most of these electron counts should correspond to open-shell configurations or small HOMO/LUMO gaps associated with the absence of, or only weak, Jahn−Teller instability, as suggested by the calculations we performed on some of them. A similar stability with respect to the capped cubic architecture was found for the noncentered and metal-centered relatives.[5,11−13] The lowest limit of the allowed CVE range is probably much lower than the closed-shell 114 count, owing to the fact that the lowest predicted and (so far) observed values for the noncentered $M_8(\mu_4\text{-}E)_6L_8$ species are 76[11] and 99,[6] respectively. Assuming orbital interactions as depicted in Figure 1a, the lowest hypothetical limit is also 76 CVE. Such a value should be approached with M = Fe or earlier transition metals.

Regardless of the real limits of the allowed range of electron counts within the whole $M_8(\mu_8\text{-}E')(\mu_4\text{-}E)_6L_8$ series of compounds, its large width suggests that one particular member of this family should have by itself a significant range of allowed CVE counts, i.e. should behave as an electron reservoir and/or sink. For example, compound **1a** is a very good electron donor, owing to the ionization potential calculated for model **1b** (4.8 eV). This value is close to that of the famous 19-electron electron-reservoir $(\eta^5\text{-}C_5H_5)Fe(\eta^6\text{-}C_6Me_6)$ complex.[19] It is likely that, as for $(\eta^5\text{-}C_5H_5)Fe(\eta^6\text{-}C_6Me_6)$, the kinetic stability of **1a** is partly due to the protection of the reactive centers by bulky ligands.

Experimental Section

Density functional calculations were carried out on $Ni_8(\mu_8\text{-}As)(\mu_4\text{-}As)_6(PH_3)_8$ and related species using the Amsterdam Density Functional (ADF) program.[20] Becke exchange[21] and Perdew correlation[22] nonlocal gradient corrections were included in the local density approximation.[23][24] The geometry optimization was based on the method developed by Versluis and Ziegler.[25] The Slater-type basis was of triple-ζ quality. The Ni, Co, and Cu (1s−3p); C and O (1s); Si, P, and S (1s−2p); Ge, As, and Se (1s−3d) cores were kept frozen.[26] Single-ζ 4p polarization functions were included in the Ni, Co, and Cu valence sets, as well as a single-ζ 3d one in the C and O valence sets, a single-ζ 4d one in the Si, P, S, Ge, As, and Se valence sets and a single-ζ 2p one in the H basis set. Test calculations carried out with f polarization functions on Ni and As atoms give results similar to those carried out without f polarization functions.

Acknowledgments

Exchanges between the groups in Amsterdam and Rennes have been made possible through a European Human Capital and Mobility Network Grant (ERBCHRXCT-930156). J.-F. H. and J.-Y. S. thank the Centre de Ressources Informatiques (CRI) of Rennes and the Institut de Développement et de Ressources en Informatique Scientifique du Centre National de la Recherche Scientifique (IDRIS-CNRS) of Orsay for computing facilities. [18] Unlike for most of the empty and metal-centered capped cubic clusters,[11–13] we found that extended Hückel calculations lead to conclusions that, even at a qualitative level, strongly disagree with DFT calculations. In particular, the a_{1g} interaction (see Figure 1) is always found to be very strong at the extended Hückel level, whatever is the nature of E′. In addition, the e_g effect caused by E when it is a bare atom appears to be systematically overestimated when compared to the DFT results. As a result, most of the favored electron counts as predicted by extended Hückel theory are likely to be unrealistic.

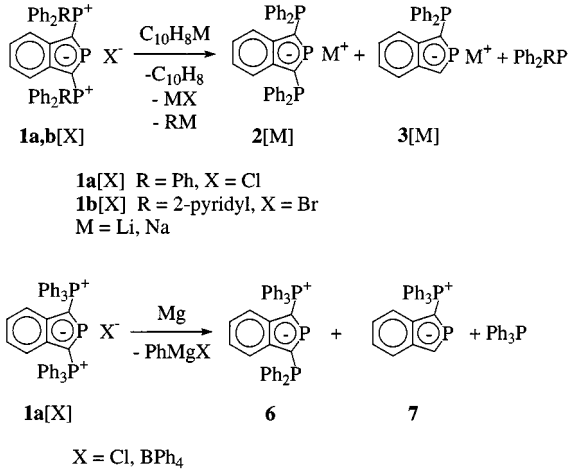
Reduction of Bis(phosphonio)isophosphindolides to Phosphane-Functionalized Benzo[*c*]phospholides

Dietrich Gudat,*[a] Volker Bajorat,[a] Stefan Häp,[a] Martin Nieger,[a] and Gisela Schröder[a]

Dedicated to Professor Dr. Edgar Niecke on the occasion of his 60th birthday

Keywords: Phosphorus heterocycles / Phospholides / Nickel complexes / Reductions / NMR spectroscopy

Bis(phosphonio)benzo[*c*]phospholides (isophosphindolides) **1a**,**b** have been found to react with magnesium or alkali metal naphthalenides $MC_{10}H_8$ (M = Li, Na, K) with reduction of one or both of the phosphonio groups. The main products are the mono- or bis(phosphanyl)-substituted heterocycles **2**, **3**, **6**, **7**, which have been characterized by in situ NMR studies and in some cases isolated. Subsequent reaction of **2** with excess $[Ni(CO)_4]$ gave the complex **4**, which has been characterized by X-ray diffractometry. Reactions of **1a** with alkali metals followed a more complicated course and gave a mixture of **2**, **3**, and the substitution product **8**, which was further reduced to the phosphanido-substituted benzo[*c*]phospholide **9**. The latter could be formed selectively by first converting **1a** into **8** by treatment with PhNa and then treating this with lithium. NMR data of the phosphane-substituted benzo[*c*]phospholides and the structural features of **4** are discussed.



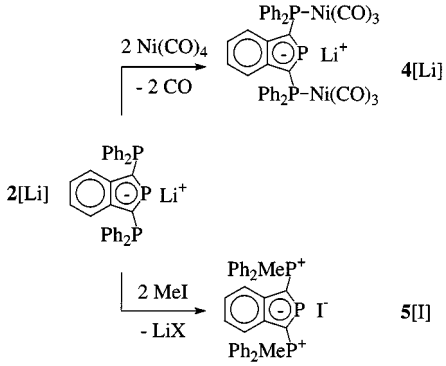
Introduction

Phospholides[1] are hetero analogues of cyclopentadienide anions and are distinguished by both high aromatic character[2] and versatile ligand properties. The phospholide moiety is not only capable of acting as a 6e π-donor ligand similar to an η^5-coordinated cyclopentadienide, but may also coordinate as a terminal 2e donor through the phosphorus lone pair, or, through a combination of σ and π coordination, as a bridging 4e or 8e ligand.[1] Whereas recent developments in the field of cyclopentadienides have been focused on derivatives bearing additional ligand groups attached either directly to the ring or on pendant side chains,[3] reports on analogous phospholide derivatives are scarce.[4][5] In view of the fact that a general route to tertiary phosphanes involves reductive cleavage of phosphonium salts,[6] we have examined the potential of reduction of bis(phosphonio)-substituted isophosphindolides incorporating a fused benzo[*c*]phospholide ring system.[7] We found that this reaction gives access to previously unknown[8] neutral and anionic benzo[*c*]phospholides bearing exocyclic phosphane functionalities.

Results

Reactions

Reactions of the bis(triphenylphosphonio)isophosphindolide salts **1a**[Cl][9] and **1b**[Br] (R = 2-pyridyl)[10] with four equivalents of lithium naphthalenide in THF were found to proceed with selective cleavage of one P−C bond in each exocyclic phosphonium moiety, thereby affording a mixture of the phosphane-substituted benzophospholide anions **2** and **3**. The by-products produced included the cleavage products C_6H_5Li or C_5H_4NLi along with triphenylphosphane or diphenylpyridylphosphane, respectively, as well as some $LiPPh_2$ arising from further reduction of the latter (Scheme 1).



Scheme 1. X = Cl, Br, BPh_4; M = Li, Na; R = Ph (**1a**), 2-pyridyl (**1b**)

The anions **2**, **3** were generated in a ratio of approximately 3:1 almost irrespective of the reaction temperature. Mixtures of similar composition were also obtained in other solvents (DME, liq. NH_3) or when sodium naphthalenide was used as the reducing agent. No further intermediates could be detected; only mixtures of **2**, **3** and unreacted starting material were produced when the reactions were performed with less than four equivalents of the metal naphthalenide.

All reaction products were identified in situ by multinuclear 1D- and 2D-NMR studies (see Experimental Section). A salt **2**[Li(THF)$_x$] was isolated in crude form (approximately 95% pure on the basis of ^{31}P- and ^{1}H-NMR data) after quenching the remaining lithiated species with a stoichiometric amount of $FeCl_2$, filtering, and precipitation of the product with diethyl ether/hexane. Attempted purification of the product by recrystallization was unsuccessful, but a crystalline derivative could be obtained after reaction of either crude **2**[Li], or the reaction mixture containing both anions **2** and **3**, with excess $Ni(CO)_4$, followed by repeated recrystallization of the formed complex **4**[Li(THF)$_4$] from THF/diethyl ether. Likewise, reaction of crude **2**[Li] with excess MeI afforded the quaternization product **5**[I], which could be isolated in pure form after recrystallization from CH_2Cl_2/THF (Scheme 2).

Scheme 2

Only one phosphonium moiety was reduced in reactions of **1a**[X] (X = Cl, BPh_4) with magnesium. As in the case of the naphthalenide reduction, two main products were formed, which were identified by ^{31}P-NMR spectroscopy as the neutral species **6** and **7** (Scheme 1; the generation of **7** was accompanied by the formation of Ph_3P). The exact reaction conditions and the product ratio varied with the specific physical state of the employed metal: The use of magnesium turnings required activation by treatment with I_2 or CCl_4 and produced some 25−50% of the cleavage product **7**; in contrast, application of a suspension of magnesium powder, freshly prepared by thermal decomposition of magnesium−anthracene,[11] resulted in shorter overall reaction times and a higher selectivity, giving up to 80% of the phosphane-substituted heterocycle **6**. Isolation and further spectroscopic characterization of this product was feasible after solvent extraction of the reaction mixture and recrystallization from toluene. The by-product **7** decomposed during the workup procedure and could not be further characterized.

A different and more complicated reaction pathway was observed when alkali metals were used instead of their naphthalenides as reducing agents. NMR-spectroscopic monitoring of the early stages of the reactions of **1a**[Cl] with Li or Na revealed, besides the presence of the anions **2**, **3** [and concomitant formation of the cleavage products C_6H_5Li(Na) and Ph_3P], the formation of the substitution product **8** (Scheme 3). The concentration of the latter decreased during the course of the reaction as a new species appeared, which was later identified as the phosphanide-substituted benzophospholide **9**[M_2] (M = Li, Na). In total, **2**, **3**, and **9** constituted approximately 90% of all the phosphorus-containing species; a higher percentage was prevented by unspecified side reactions and slow cleavage to give $MPPh_2$. Prolonged reaction times or elevated temperatures led to the decomposition of all other species, leaving the phosphanides $MPPh_2$ as the only well-defined phosphorus-containing reaction products.

Scheme 3

The formation of **8** by substitution of the cation **1a** by C_6H_5M (which was generated in the initial reduction of **1a** to give **2** and **3**) was proven by its independent synthesis from **1a**[Cl] and one equivalent of C_6H_5Na. Since a control experiment revealed that lithium reduction of an isolated sample of **2** under similar conditions did not yield any detectable amount of **9**[M_2], formation of this product can be assumed to occur exclusively through the intermediate **8**. This was confirmed by an investigation of the reaction of pure **8** with lithium under ultrasound sonification, which gave **9**[M_2] together with a small amount (10−15%) of $LiPPh_2$ as the only reaction products detectable by ^{31}P-NMR spectroscopy. Even though all attempts to isolate **9**[M_2] from any of the reaction mixtures have hitherto been unsuccessful, it could be characterized in situ by multinuclear NMR spectroscopy (see below).

NMR-Spectroscopic Investigations

The identities of the neutral and anionic benzophospholides **2**−**4**, **6**, **7**, and **9**, the benzophosphole **8**, and the cation **5** were unequivocally established from their ^{1}H-, ^{13}C-, and ^{31}P-NMR data. Substitution patterns at the fused ring system were easily assigned from the habit of the ^{31}P{^{1}H}-NMR spectra, which featured characteristic A_2X (**2**, **4**, **5**), A_2B (**8**), AMX (**6**, **9**), or AX patterns (**3**, **7**). Consequently, the ^{1}H-NMR spectra displayed ABCD (**3**, **6**, **7**, **9**) or AA′BB′ patterns (**2**, **4**, **5**, **8**) for the four protons of the benzenoid fragment of the fused ring system. In addition, the spectra of **3** and **7** also featured a resonance for the 2-H proton, showing characteristic splitting due to coupling with the two phosphorus atoms. Discrimination between phosphonio (Ph_3P−), phosphane (Ph_2P−), and phosphanido [Ph(M)P−] substituents was feasible on the basis of characteristic ^{31}P chemical shift differences (Table 1). Signals for the first two types of substituents appear in common spectral regions, while the resonance of the phosphanide group in **9** appears at much higher field than in simple diarylphosphanides [δ^{31}P = −22.5, −36 for Ph_2P(Na, Li)[12]]. The resonances of the Ph(M)P and Ph_2P

[a] Not determined. – [b] Spectral analysis as $[A]_2BX$ system gave $J_{P(B),C}/J_{P(B'),C} < 0$ and $^4J_{P(B),P(B')} = 5.5$ Hz.

fragments in **9** are further distinguished by different multiplicities in ^1H non-decoupled ^{31}P spectra, showing coupling to two or four *ortho* protons, respectively. The chemical shifts of the phospholide P atoms in **2**, **4**, **6**, and **9** are seen to be somewhat more shielded as in **1a** ($\delta^{31}P = 241.8$[9]), but significantly less shielded than in monocyclic phospholides ($\delta^{31}P = 55-142$[1b]). This trend could be confirmed by a comparison with calculated[13] $\delta^{31}P$ values of model compounds (Table 2). This revealed that the deshielding of the resonance of **1a** (as well as of **2** and **4**) compared to those of the monocyclic phospholides can be attributed to similar contributions from both the benzanellation and the influence of the phosphonio (phosphane) substituents. Inspection of the results of calculations suggests that the deshielding shows a correlation with both a continuously decreasing energy gap between the phosphorus lone pair and the lowest π* orbital, and an increasing shift of π electron density from the two-coordinate phosphorus atom to the adjacent carbon atoms, which tends to impose some "ylidic" character on the P−C bond.

Comparison of $\delta^{31}P$ values for the corresponding nuclei in the lithium and sodium salts of the anions **2**, **3**, and **9** indicates some influence of the counterion, which is less pronounced for the monoanions **2**, **3** than for **9** and suggests some degree of ionic association (contact ion pair formation) in solution. Of diagnostic relevance in the ^{13}C-NMR spectra are the signals of the ring carbon atoms adjacent to the two-coordinate phosphorus atoms: Carbon atoms bearing exocyclic phosphonio groups display similar chemical shifts and exocyclic $^1J(P,C)$ couplings as seen in **1a**, whereas those bearing phosphanyl groups exhibit lower $^1J(P,C)$ values and chemical shifts appear further downfield resembling those due to the α-carbon atoms in phospholides.[1]

Table 2. Calculated [GIAO-B3LYP/6−311+g(2d,d,p)//B3LYP/6−31+g(d,p)] ^{31}P chemical shifts of phospholides and of the parent and 1,3-disubstituted benzo[*c*]phospholides[12]

	$\delta^{31}P$
$[C_4H_4P]^-$	139.4
$[C_8H_6P]^-$ (benzo[*c*]phospholide)	200.5
$[1,3\text{-}(H_2P)_2\text{-}C_8H_4P]^-$	306.0
$[1,3\text{-}(H_3P)_2\text{-}C_8H_4P]^+$	311.5

Crystal Structure of Compound 4

The results of an X-ray crystal structure analysis of **4**[$Li(THF)_4$] revealed a salt-like composition with two independent, only slightly different pairs of $[Li(THF)_4]^+$ cations and benzophospholide anions per asymmetric unit (Figure 1). The bonding parameters in the fused ring systems of the anions do not differ significantly from those in the phosphonio-substituted cation **1a**.[14] On the other hand, the exocyclic P−C distances (1.774−1.789 Å) are longer than the corresponding bonds in **1a** (1.747−1.749 Å[14]) but shorter than the peripheral P−C(phenyl) distances (1.825−1.847 Å). The P−Ni distances in **4** are comparable with typical values in PPh_3−Ni complexes (2.225 ± 0.070 Å).[15] The remaining bond parameters display no peculiarities. On the whole, these findings suggest that electronic perturbation of the 10π system in **4** by hyperconjugation with the substituents[7] is lower than that in **1a**. In view of the rather low degree of electronic interaction between the five- and six-membered rings in a structurally characterized benzo[*b*]phospholide,[8] the anion **4** would seem to represent the first example of a benzophospholide with a unique 10π electron system having an electronic structure comparable to that found in heteronaphthalenic benzodithiaphospholium cations.[16]

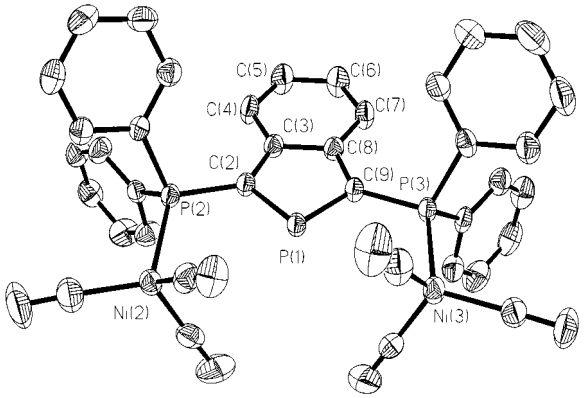

Figure 1. Representation of one of the two crystallographically independent anions in crystalline **4**[Li(THF)$_4$] (50% thermal ellipsoids); selected bond lengths [Å] and angles [°] (data of the second anion in brackets): P(1)−C(2) 1.732(4) [1.747(4)], P(1)−C(9) 1.736(4) [1.744(4)], C(2)−C(3) 1.441(5) [1.423(5)], C(2)−P(2) 1.789(4) [1.777(4)], C(3)−C(4) 1.416(5) [1.416(5)], C(3)−C(8) 1.432(5) [1.440(5)], C(4)−C(5) 1.367(5) [1.371(5)], C(5)−C(6) 1.399(6) [1.401(5)], C(6)−C(7) 1.372(5) [1.380(5)], C(7)−C(8) 1.413(5) [1.400(5)], C(8)−C(9) 1.440(5) [1.431(5)], C(9)−P(3) 1.780(4) [1.774(4)], P(2)−Ni(2) 2.241(1) [2.238(1)], P(3)−Ni(3) 2.241(1) [2.240(1)]; C(2)−P(1)−C(9) 93.0(2) [92.6(2)]

Discussion

The reported reactions of the bis(phosphonio)isophosphindolide cations **1a**, **b** conform to the general scheme of the reduction of phosphonium salts through cleavage of P−C bonds to give phosphanes and carbanions. The latter may be protonated to give the corresponding hydrocarbons during workup.[6] For the bis(phosphonium) cations studied here, the extent of the reduction appears to be controlled by the reductive power of the metal: The reaction with magnesium stops after reduction of the first phosphonium functionality, while the stronger reducing agent alkali metal/naphthalene attacks both substituents. The failure to observe the neutral species **6**, **7** as intermediates under these conditions, which would be expected if a stepwise reaction is assumed, may be attributed to kinetic factors: The second reaction step may be faster, presumably due to the low solubility of the starting material in the solvents employed.

The formation of product mixtures in the observed reactions reflects the presence of different types of P−C single bonds: Starting from the cation **1a**, cleavage of a peripheral phenyl group affords the phosphane-substituted phospholide **6** and the corresponding phenylmetal compound, both of which were observed in the reaction mixtures, while fission of a P−C(ring) bond should liberate Ph_3P and an α-deprotonated benzophospholide anion. The latter was not directly detected and is most likely quenched by abstraction of a proton (presumably from a solvent molecule) to afford the neutral compound **7**, which could be isolated in the course of the reaction with magnesium. Further reduction of **6** and **7** with alkali metals can be expected to afford a mixture of **2** and **3**, together with Ph_3P and the parent benzophospholide anion. The latter was not observed, suggesting that the second reduction step occurs either with selective P−C(phenyl) bond fission, or that this product decomposes under the reaction conditions. If one considers that the ease of reductive P−C cleavage in phosphonium salts generally parallels the ability of the leaving group to stabilize a negative charge,[6] the observed product ratio in the reduction of **1a** suggests a slightly higher charge-stabilizing capacity of a triphenylphosphoniobenzophospholide as compared to a phenyl moiety, whereas selective cleavage of pyridyl instead of phenyl groups in the reduction of **1b** suggests that the pyridyl group is superior to both.

The outcome of the reduction of **1a** with alkali metals in the absence of naphthalene is consistently explained in terms of two competing reaction channels, viz. reduction of the cation **1a** and its substitution by the formed metal phenyl to give **8**. The successful competition of the two different pathways under these conditions is again attributable to kinetic factors: the reduction proceeds at a much lower rate when solid metals are used rather than soluble metal naphthalenides, so that the slower substitution of the formed phenylmetal compound with still present starting material to give **8** may take place. Further conversion of **8** to the dimetallated species **9**[M_2] requires the reductive cleavage of phenyl groups from both the two exocyclic ylide moieties and the endocyclic phosphorus atom. Both types of reactions are known in principle. Reductive cleavage of triphenylphosphonium ylides has been reported, and even though this process is not fully understood, it is considered to follow a different mechanism than the reduction of phosphonium salts,[17] thus accounting for the different nature of the obtained product. Reductive cleavage of P−Ph bonds in phospholes has been extensively studied, in particular by Mathey and co-workers.[1] Since no further intermediates were identified, the exact mechanism of the reaction from **8** to **9** cannot be further elucidated. Nonetheless, it appears reasonable to assume reduction of one of the phosphonium moieties as the first step.

Conclusion

Our investigations have shown that bis(phosphonio)isophosphindolides can be reduced with preservation of the fused aromatic ring system to give phosphane-substituted benzo[*c*]phospholides. Despite the formation of mixtures of products, which arise from the presence of different P−C bonds in the starting materials that may possibly be cleaved, the novel phosphane-substituted benzophospholide **6** and the anionic nickel complex **4** could be isolated. Further investigations into the syntheses and reactivities of other phosphane-substituted (poly)phospholide derivatives, in particular with respect to a side-on π coordination to transition metal ions, are currently in progress.

Experimental Section

General Remarks: NMR spectra were recorded at 30°C with a Bruker AMX 300 spectrometer (300.13, 121.50, and 75.46 MHz for ^{1}H, ^{31}P, and ^{13}C). Chemical shifts are referenced to external TMS (^{1}H, ^{13}C) or 85% H_3PO_4. ^{13}C,^{31}P{^{1}H}INEPT spectra were recorded with a 5-mm triple-resonance probe head equipped with an inner

tunable coil adjusted to ^{13}C and a second coil double-tuned to ^{1}H and ^{31}P. The spectra of **3** and **6** were recorded directly from the reaction mixtures with suppression of the solvent signals by presaturation. Signal assignments were made with the aid of (semi)selective 1D $^{13}C,^{31}P\{^{1}H\}$-INEPT and 2D $^{1}H,^{1}H$-COSY/TOCSY, $^{1}H,^{13}C$-HMQC, and $^{1}H,^{31}P$-HMQC-TOCSY spectra. The atoms of the benzophospholide moiety are denoted by C-1 to C-7a and 1-H to 7-H, the carbon atoms of the phenyl groups by C_{para}, C_{meta} etc., and the designation of the phosphorus nuclei is as given in Table 1. Resonances in the ^{13}C spectra forming part of $[A]_2MY$ or $[A]_2Y$ spin systems (A, M = ^{31}P) were in some cases analyzed using the program WINDAISY; in the remaining cases the given values of ΣJ and J_M denote the sum of the couplings to the isochronous ^{31}P nuclei of the $[A]_2$ fragments and the coupling to the endocyclic phosphorus atom, respectively. − IR spectra: Nicolet Magna 550 FT-IR spectrometer.

Reduction of 1a[Cl] with Lithium Naphthalenide: A freshly prepared solution of lithium napththalenide [obtained from 180 mg (30 mmol) of Li and 3.84 g (30 mmol) of $C_{10}H_8$] in 150 mL of THF was slowly added to a stirred suspension of **1a**[Cl] (5.45 g, 7.5 mmol) in 50 mL of THF at 0 °C. Stirring was continued for 1 h. Anions **2**, **3**, Ph_3P, and PhLi were identified in situ in the dark-red mixture by multinuclear NMR analyses. A stoichiometric amount of $FeCl_2$ was then added to quench the PhLi, and the resulting mixture was stirred for a further 2 h. After addition of 10 mL of Et_2O, stirring was continued for another 30 min, then the mixture was filtered. The filtrate was concentrated in vacuo to a volume of 15 mL and 100 mL of a Et_2O/hexane (2:1) mixture was added. The resulting precipitate was collected by filtration, redissolved in a little THF, and reprecipitated with Et_2O/hexane. ^{31}P- and ^{1}H-NMR analysis revealed that the product consisted of approximately 95% **2**[Li(THF)$_x$]; yield 3.00 g (50%). The same protocol was used for the reduction of **1a**[Cl] with $C_{10}H_8Li$ and for that of **1a**,**b**[Cl] with $C_{10}H_8Na$. − **2**[Li]: ^{1}H NMR (THF): δ = 7.53 (m, 8 H, H_{ortho}), 7.45 (m, 2 H, 4-H/7-H), 7.08 (m, 8 H, H_{meta}), 7.04 (m, 4 H, H_{para}), 6.49 (m, 2 H, 5-H/6-H). − $^{13}C\{^{1}H\}$NMR (THF): δ = 145.2 (m, ΣJ = 18.2 Hz, J_M = 2.2 Hz, C_{ipso}), 144.1 (m, ΣJ = 15.1 Hz, J_M = 7.6 Hz, C-3a/C-7a), 132.9 (m, $^{3}J_{P(A),C}$ = 18.7 Hz, $^{5}J_{P(M),C}$ = 1 Hz, C_{meta}), 126.9 (m, spectral analysis gave $^{4}J_{P(A),P(A)'}$ = 1.8 Hz, $^{2}J_{P(A),C}$ = 5.5 Hz, C_{ortho}), 125.6 (s, C_{para}), 124.4 (ddd, $^{1}J_{P(M),C}$ = 51.0 Hz, $J_{P(A)/A',C}$ = 13, 10 Hz, C-1/C-3), 119.4 (m, ΣJ = 10 Hz, J_M = 6.8 Hz, C-4/C-7), 115.1 (s, C-5/C-6). − **3**[Li]: ^{1}H NMR (THF): δ = 7.58 (dd, $^{2}J_{H,P(X)}$ = 39.3 Hz, $^{4}J_{H,P(A)}$ = 2.9 Hz, 1 H, 3-H), 7.50 (m, 4 H, H_{meta}), 7.47 (m, 1 H, 4-H), 7.34 (m, 1 H, 7-H), 7.07 (m, 4 H, H_{ortho}), 7.02 (m, 2 H, H_{para}), 6.52 (m, 1 H, 6-H), 6.40 (m, 1 H, 5-H).

Reduction of 1b[Br] with Lithium Naphthalenide: The reduction of **1b**[Br] (1.94 g, 2.5 mmol) with lithium naphthalenide [obtained from 60 mg (10 mmol) of Li and 1.28 g (10 mmol) of $C_{10}H_8$] was carried out under analogous conditions as described above. Anions **2**, **3**, (2-py)Ph_2P, and (2-py)Li were identified in situ in the dark-red solution by ^{31}P- and ^{1}H-NMR analyses. No further workup of the reaction mixture was attempted.

Nickel Complex 4[Li(THF)$_4$]: A solution of 1.00 g (1.25 mmol) of crude **2**[Li(THF)$_x$] in 10 mL of THF was added dropwise with stirring to a freshly prepared solution of 1.2 mL of $Ni(CO)_4$ in 10 mL of THF. After stirring for a further 2 h, the mixture was concentrated to a volume of 5 mL, treated with 5 mL of Et_2O, and filtered. Storage of the filtrate at 2 °C for several weeks led to the deposition of a colorless precipitate, which was recrystallized once from THF to give 540 mg (40%) of complex **4**[Li(THF)$_4$], m.p. 150 °C (dec.), as colorless cubic crystals. − ^{1}H NMR ($CDCl_3$): δ = 7.56 [m, 8 H, $H_{meta}(PPh_2)$], 7.20−7.05 [m, 12 H, $H_{ortho/para}(PPh_2)$], 6.96 (m, 2 H, 4-H/7-H), 6.28 (m, 2 H, 5-H/6-H). − IR (THF): $\tilde{\nu}$ (CO) = 2056 (s), 1982 (vs), 1972 (vs) cm^{-1}.

Bis(methyldiphenylphosphonio)isophosphindolide Iodide (5[I]): A solution of 0.50 g (3.5 mmol) of methyl iodide in 5 mL of THF was added dropwise to a solution of 1.00 g (1.25 mmol) of crude **2**[Li(THF)$_x$] in 10 mL of THF. The mixture was refluxed for 10 min, allowed to cool to room temperature, and then concentrated to dryness. The residue was extracted with 10 mL of CH_2Cl_2, the extract was filtered, and the filtrate was concentrated to a volume of 5 mL. Addition of 15 mL of THF led to the deposition of 620 mg (63%) of an off-white precipitate of **5**[I], m.p. 185 °C, which was collected by filtration and dried in vacuo. − ^{1}H NMR ($CDCl_3$): δ = 7.75−7.53 (m, 20 H, C_6H_5), 7.08 (m, 2 H) and 6.93 (m, 2 H, C_6H_4), 2.77 (dd, 6 H, $^{2}J_{H,P}$ = 12.8 Hz, $^{4}J_{H,P}$ = 1.4 Hz, CH_3). − $^{13}C\{^{1}H\}$NMR (CH_2Cl_2): δ = 143.5 (m, ΣJ = 25.4 Hz, J_M = 2.2 Hz, C-3a/C-7a), 133.7 (s, C_{para}), 132.4 (m, ΣJ = 10.7 Hz, C_{ortho}), 129.4 (m, ΣJ = 13.1 Hz, C_{meta}), 122.8 (dd, $J_{P(A),C}$ = 89.0 Hz, $J_{P(X),C}$ = 2.9 Hz, C_{ipso}), 120.8 (s) and 119.8 (m) (C-4/C-7 and C-5/C-6), 109.4 (ddd, $J_{P,C}$ = 95.5, 54.3 and 14.3 Hz, C-1/C-3), 12.6 (dd, $J_{P(A),C}$ = 61.2 Hz, $J_{P(X),C}$ = 7.9 Hz, CH_3). − $C_{34}H_{30}I_2P_3$ (785.34): calcd. C 52.00, H 3.85; found C 51.5, H 3.8.

Reduction of 1a[Cl] with Magnesium: To a stirred suspension of 3.0 g (12.3 mmol) of Mg powder (freshly prepared by decomposition of $C_{14}H_{10}Mg$[11]) in 150 mL of THF was added 6.91 g (10 mmol) of **1a**[Cl]. Once the reaction had commenced, stirring was continued overnight. ^{31}P-NMR-spectroscopic assay of the dark-red mixture confirmed the formation of **6** (ca. 80%) and **7**/Ph_3P (ca. 20%). The mixture was subsequently treated with 40 mL of Et_2O, filtered, and the filtrate was concentrated in vacuo. The residue was suspended in 120 mL of DME/Et_2O (5:1), stirred for 1 h, and then filtered. The volume of the filtrate was reduced to 40 mL, and the product was precipitated by addition of 100 mL of MeOH. Recrystallization from toluene afforded 3.35 g (58%) of **6** as a yellow powder, m.p. 150 °C. − ^{1}H NMR ($CDCl_3$): δ = 7.67 (m, 1 H, 4-H), 7.60 [m, 6 H, $H_{ortho}(PPh_3)$], 7.48 [m, 4 H, $H_{ortho}(PPh_2)$], 7.35−7.45 [m, 9 H, $H_{meta/para}(PPh_3)$], 7.15−7.25 [m, 6 H, $H_{meta/para}(PPh_2)$], 6.91 (m, 1 H, 7-H), 6.85 (m, 1 H, 6-H), 6.74 (m, 1 H, 5-H). − $^{13}C\{^{1}H\}$NMR ($CDCl_3$): δ = 146.3 (ddd, $^{3}J_{P(A),C}$ = 17.2 Hz, $^{2}J_{P(M),C}$ = 15.3 Hz, $^{2}J_{P(X),C}$ = 6.5 Hz, C-7a), 144.3 (ddd, $^{2}J_{P(A),C}$ = 10.2 Hz, $^{2}J_{P(X),C}$ = 5.4 Hz, $^{3}J_{P(M),C}$ = 1.2 Hz, C-3a), 143.2 (ddd, $^{1}J_{P(X),C}$ = 53.4 Hz, $^{1}J_{P(A),C}$ = 14.1 Hz, $^{3}J_{P(M),C}$ = 11.9 Hz, C-3), 140.4 [dd, $^{1}J_{P(A),C}$ = 10.7 Hz, $^{3}J_{P(X),C}$ = 8.8 Hz, $C_{ipso}(PPh_2)$], 134.0 [dd, $^{2}J_{P(M),C}$ = 10.3 Hz, $^{4}J_{P(X),C}$ = 1.1 Hz, $C_{ortho}(PPh_3)$], 133.3 [dd, $^{3}J_{P(A),C}$ = 18.3 Hz, $^{5}J_{P(X),C}$ = 1.2 Hz, $C_{meta}(PPh_2)$], 132.9 [d, $^{4}J_{P(M),C}$ = 3.1 Hz, $C_{para}(PPh_3)$], 129.1 [d, $^{3}J_{P(M),C}$ = 12.8 Hz, $C_{meta}(PPh_3)$], 127.8 [d, $^{2}J_{P(A),C}$ = 6.9 Hz, $C_{ortho}(PPh_2)$], 127.4 [s, $C_{para}(PPh_2)$], 125.2 [dd, $^{1}J_{P(M),C}$ = 89.7 Hz, $^{3}J_{P(X),C}$ = 1.9 Hz, $C_{ipso}(PPh_3)$], 120.7 (dd, $^{3}J_{P(A),C}$ = 12.1 Hz, $^{3}J_{P(X),C}$ = 7.5 Hz, C-4), 120.0 (d, $J_{P,C}$ = 4.2 Hz, C-7), 119.4 (d, $J_{P,C}$ = 3.1 Hz, C-5), 118.3 (s, C-6), 92.8 (ddd, $^{1}J_{P(X),C}$ = 98.8 Hz, $^{1}J_{P(M),C}$ = 60.0 Hz, $^{3}J_{P(A),C}$ = 10.1 Hz, C-1). − $C_{38}H_{29}P_3$ (578.57): calcd. C 78.89, H 5.05; found C 78.0, H 4.9.

Reduction of 1a[Cl] with Lithium: To a stirred suspension of **1a**[Cl] (1.45 g, 2 mmol) in 15 mL of THF was added approximately 60 mg (10 mmol) of freshly cut lithium wire. After 30 min, ^{31}P-NMR-spectroscopic monitoring revealed, besides the presence of unreacted **1a**, the formation of **2**, **3**, Ph_3P, Ph_2PLi (from cleavage of Ph_3P), as well as of the substitution product **8**. Prolonged reaction times led to a decay of the signals due to **8**, while those due to a new product **9** intensified. Continuation of the reaction for several days, or heating, led to the disappearance of all resonances other

than that due to Ph_2PLi. Similar results were obtained when the reduction of **1a**[Cl] was performed with sodium.

Benzophosphole 8: A freshly prepared solution of phenyllithium (26.6 mmol) in 100 mL of THF was added dropwise to a suspension of **1a**[Cl] (15.7 g, 21.7 mmol) in 80 mL of THF at 0°C. The mixture was stirred for 5 h at 0°C, then treated with 20 mL of Et_2O, and filtered. The filtrate was concentrated to dryness, the residue was refluxed for 1 h with 250 mL of toluene, and the hot solution was filtered. Slow cooling of the filtrate resulted in the deposition of a crystalline precipitate, which was collected by filtration and dried in vacuo to give 14.3 g (90%) of **8** as black needles; m.p. 160°C. – ^{1}H NMR ($CDCl_3$): δ = 7.55 [m, 12 H, $H_{meta}(PPh_3)$], 7.38 [m, 6 H, $H_{para}(PPh_3)$], 7.27 [m, 12 H, $H_{ortho}(PPh_3)$], 7.21–7.15 [m, 3 H, $H_{ortho/para}(PPh)$], 6.91 [m, 2 H, $H_{meta}(PPh)$], 6.08 (m, 2 H, 5-H/6-H), 5.94 (m, 2 H, 4-H/7-H). – $^{13}C\{^1H\}$ NMR ($CDCl_3$):[18] δ = 154.6 [m, $^1J_{P(B),C}$ = 58.7 Hz, ΣJ = 2.6 Hz, $C_{ipso}(PPh)$], 148.3 (m, ΣJ = 29 Hz, $^2J_{P(B),C}$ = 0.5 Hz, C-3a/C-7a), 133.9 [m, $^2J_{P(A),C}$ = 9.6 Hz, $^4J_{P(B),C}$ = 2.0 Hz, $C_{ortho}(PPh_3)$], 130.8 [m, $^4J_{P(A),C}$ = 2.3 Hz, $C_{para}(PPh_3)$], 129.7 [m, $^1J_{P(A),C}$ = 86.7 Hz, $^3J_{P(B),C}$ = +3.1 Hz, $C_{ipso}(PPh_3)$], 128.2 [d, $^3J_{P(B),C}$ = 6.9 Hz, $C_{meta}(PPh)$], 127.8 [m, $^3J_{P(A),C}$ = 11.1 Hz, $C_{meta}(PPh_3)$], 126.4 [d, $^2J_{P(B),C}$ = 4.6 Hz, $C_{ortho}(PPh)$], 125.7 [s, $C_{para}(PPh)$], 116.6 (m, ΣJ = 1.9 Hz, C-4/C-7), 116.3 (s, C-5/C-6), 33.3 (m, $^1J_{P(A),C}$ = 119.2 Hz, $^3J_{P(A)',C}$ = −9.3 Hz, $^1J_{P(B),C}$ = 11.4 Hz, C-1/C-3). – $C_{50}H_{39}P_3$ (732.78): calcd. C 81.95, H 5.36; found C 81.0, H 5.1.

Reduction of Benzophosphole 8 with Lithium: To a solution of 1.00 g (1.37 mmol) of **8** in 25 mL of THF was added an excess of lithium powder, and the resulting mixture was allowed to react for 30 min under sonification with ultrasound. ^{1}H- and ^{31}P-NMR-spectroscopic assays confirmed the formation of **9**[Li_2] (accounting for ca. 85–90% of the phosphorus-containing material), some Ph_2PLi (ca. 10–15%), and phenyllithium. Characterization of the major product **9**[Li_2] was achieved in situ by multinuclear (^{1}H-, ^{13}C-, ^{31}P-)NMR analyses. All attempts to isolate and further purify the product were unsuccessful, invariably resulting in partial or complete decomposition. – **9**[Li_2]: ^{1}H NMR ($CDCl_3$): δ = 7.60 (m, 1 H, 6-H), 7.44 [m, 4 H, $H_{meta}(PPh_2)$], 7.38 (m, 1 H, 4-H/5-H), 7.22 (m, 1 H, 5-H/4-H), 7.13 [m, 2 H, $H_{meta}(PPh)$], 6.91 [m, 4 H, $H_{ortho}(PPh_2)$], 6.80 (m, 1 H, 7-H), 6.68 [m, 2 H, $H_{ortho}(PPh)$], 6.40 [m, 2 H, $H_{para}(PPh_2)$], 6.28 [m, 1 H, $H_{para}(PPh)$]. – $^{13}C\{^1H\}$NMR ($CDCl_3$): δ = 160.2 [dd, $^1J_{P(A),C}$ = 45.8 Hz, $^3J_{P(X),C}$ = 7.6 Hz, $C_{ipso}(PPh)$], 146.6 [dd, $^1J_{P(M),C}$ = 14.3 Hz, $^3J_{P(X),C}$ = 5.0 Hz, $C_{ipso}(PPh_2)$], 144.8 (dd, $^1J_{P(M)/A,C}$ = 15.0 Hz, $^3J_{P(X),C}$ = 7.2 Hz, C-3a/C-7a), 144.5 (dd, $^1J_{P(M)/A,C}$ = 7.5, 1 Hz, $^3J_{P(X),C}$ = 1 Hz, C-7a/C-3a), 139.2 (ddd, $^1J_{P(X),C}$ = 46.1 Hz, $^1J_{P(M),C}$ = 30.3, $^3J_{P(A),C}$ = 6.3 Hz, C-3), 133.6 [dd, $^3J_{P(M),C}$ = 18.7 Hz, $^5J_{P(X),C}$ = 1.5 Hz, $C_{meta}(PPh_2)$], 128.2 [dd, $^3J_{P(A),C}$ = 17.8 Hz, $^5J_{P(X),C}$ = 2.0 Hz, $C_{meta}(PPh)$], 126.9 [d, $^3J_{P(M),C}$ = 5.7 Hz, $C_{ortho}(PPh_2)$], 126.1 [d, $^3J_{P(M),C}$ = 5.7 Hz, $C_{ortho}(PPh)$], 120.6 (dd, $^3J_{P(A),C}$ = 7 Hz, $^3J_{P(X),C}$ = 6 Hz, C-7), 120.4 (dd, $^4J_{P(A)/M,C}$ = 4 Hz, $^4J_{P(X),C}$ = 6 Hz, C-4/C-5), 119.7 (ddd, $^4J_{P(A)/M,C}$ = 5.5, 1.7 Hz, $^4J_{P(X),C}$ = 12.0 Hz, C-5/C-4), 118.6 (dd, $^3J_{P(M),C}$ = 15.7 Hz, $^4J_{P(X),C}$ = 4.8 Hz, C-6), 116.5 [s, C_{para} (PPh_2)], 116.0 [s, $C_{para}(PPh)$], 116.0 (ddd, $^1J_{P(X),C}$ = 52 Hz, $^1J_{P(A),C}$ = 8 Hz, $^3J_{P(M),C}$ = 5 Hz).

X-ray Crystal Structure Determination of 4[Li(THF)$_4$]: $C_{38}H_{24}Ni_2O_6P_3 \cdot Li(THF)_4 \cdot Et_2O$, colorless, M_r = 1156.4; monoclinic, space group $P2_1/c$ (No. 14), a = 32.3511(7) Å, b = 13.8186(5) Å, c = 29.4593(8) Å, β = 116.262(2)°, V = 11810.3(6) Å^3, Z = 8, μ(Mo-K_α) = 0.78 mm^{-1}, T = 123(2) K, 68443 reflections measured ($2\theta_{max}$ = 50°), 19310 independent reflections used for structure solution (direct methods) and refinement (on F^2 anisotropic with SHELXL-93), 1348 parameters, 2915 restraints, H atoms as a riding model, $wR2(F^2)$ = 0.145, $R[F, I > 2\sigma(I)]$ = 0.049. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101915. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

X-ray Structures of a Phenanthroline-Strapped Porphyrin and Its Dihydrated Zinc(II) Complex: Convergent Distal Hydrogen Bonds and "CH···O" Interactions

Philippe Ochsenbein,[a] Michel Bonin,[b] Kurt Schenk,[b] Jérôme Froidevaux,[c] Jennifer Wytko,[c] Ernest Graf,[d] and Jean Weiss*[c]

Dedicated to the memory of Dr. Michael Momenteau

Keywords: Hydrogen bonds / Inclusion compounds / Solid-state structures / Porphyrinoids / Zinc

The X-ray structure of a phenanthroline-(phen-)strapped 1,10-diphenylporphyrin **1** has been resolved. From the structure obtained, it is apparent that in spite of the rigidity of the strap the porphyrin ring is only slightly distorted, and that the substituents on the phen moiety define what would seem to be a hydrophobic pocket. Metallation of the free base **1** with zinc(II) acetate yields a metallic complex (**1**)Zn with a free axial coordination site. Crystallization of the zinc complex in the presence of a hindered base (*N*-methylimidazole, denoted *N*-MeIm) in organic solvents affords single crystals of a porphyrinatozinc(II) species, in which two water molecules are surprisingly present in the encumbered (distal) pocket of the phen site. One water molecule is axially bound to the zinc(II) ion, while the other is doubly hydrogen-bonded, as an H-bond donor to the phenanthroline and as an H-bond acceptor to the axial water ligand.

Introduction

Metalloporphyrins capable of forming hydrogen bonds (H bonds) have been extensively studied due to their involvement in photosynthetic processes of higher plants, either as main pigments such as chlorophyll a, or as accessory pigments such as chlorophyll b. Zinc and magnesium porphyrins and chlorin derivatives constitute the majority of models studied to date. H-bond formation can occur either at the periphery of the tetraaza ligand or along the axis defined by the metal $4p_z$ and $4d_{z^2}$ orbitals, but in either case is associated with selective assembling processes. These assembling processes include substrate recognition[1] and axial ligand selection (e.g. CO/O_2),[2] dimer formation,[3] and anchoring to proteins and membranes.[4][5] Water molecules may play a crucial role in bridging H-bond donors and H-bond acceptors, leading to superstructures;[6] thus, H bonding may originate from a water molecule coordinated axially to a metalloporphyrin.

An example of a self-assembling process of a porphyrin derivative mediated by an axially bound water molecule, leading to a dimeric porphyrin−quinone assembly, has recently been described by Fajer.[7] This type of interaction has been envisaged for decades,[8] and analysis of several metalloporphyrin structures, including those of mono-[9] and dihydrated[10] chlorophyll, has suggested that hydrogen bonding plays an important role in the anchoring of pigments on proteins. A confirmation of the role of water in the three-dimensional structure of a peridin-chlorophyll light-harvesting complex was reported by Hofmann and Welte.[11] In this case, a histidine imidazole ring of the pigment, which is stacked with ring II of the chlorophyll, is H-bonded through a water molecule coordinated at the central Mg. Coordination of water to the central metal in pigments may also be involved in the modification and control of the redox properties of charged radical intermediate species.[12] Thus, H bonding contributes in various ways to a better control of electron transfer in natural systems,[13] and in this regard it is important that well-defined hydrated structures of metalloporphyrins are obtained. In this paper, we present the structure of a dihydrated zinc porphyrin complex, together with that of the corresponding free base.[14]

In a search for controlled architectures combining porphyrins and either metal- or H-binding sites, we have described the synthesis of a phenanthroline-(phen-)strapped porphyrin **1**.[14] The formation of copper and silver mixed-valence complexes with this heteroditopic ligand has illustrated its coordination capabilities.[15] In the course of the synthesis of a heterodinuclear zinc-copper complex of ligand **1**, we found that it was possible to crystallize the free base and the dihydrated zinc(II) complex. The X-ray structures[16] of both are described and compared herein. Moreover, the H-bond network of the two water molecules found

in the hydrophobic environment of the phenanthroline pocket in the case of the Zn^{II} porphyrin is discussed.

Results and Discussion

Crystals of the free base **1** were obtained by slow diffusion of hexane and traces of methanol into a concentrated (10^{-2} M) solution of the porphyrin in dichloromethane. The structure depicted in Figure 1 clearly shows that the tetrapyrrolic macrocycle is only slightly distorted.

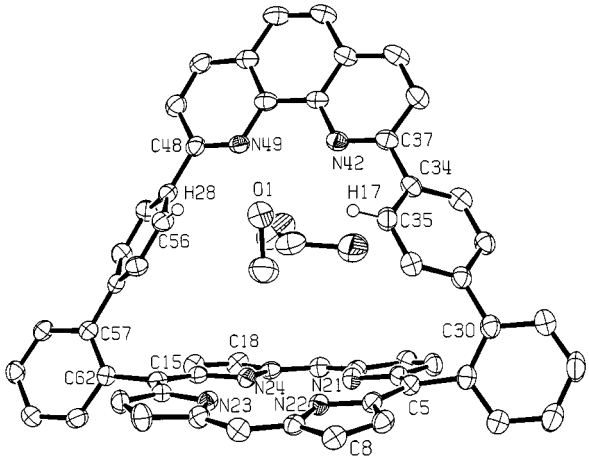

Figure 1. Crystallographic view of **1**; hydrogen atoms are omitted for the sake of clarity and only atoms discussed in the text are labelled; selected bond lengths and angles are discussed in the text

There had previously been some doubt as to the degree of planarity of the porphyrin ring, as the rate of metallation of **1** is three orders of magnitude faster than that of regular tetraphenylporphyrin (TPP).[15] The deviation from planarity shows that the conformation adopted by the (24-atom) core is saddled with respect to the orientation of the pyrrole rings and ruffled when considering the *meso* positions [maximum deviation from planarity of 0.24 Å for the *meso*-(C5) and β-carbon atoms (C8)]. The phenyl spacers between the porphyrin and phenanthroline units are tilted away from the phen plane (by 41° and 49°), which is in agreement with previously reported 2,9-diphenylphenanthroline structures.[17] The frozen orientation of the phenyl spacers is observed only in the solid state; ^{1}H-NMR data are consistent with their free rotation in solution. A tilt of the strap towards one side of the porphyrin is also seen in the crystal, while solution ^{1}H-NMR data are consistent with a mirror plane containing the phen subunit (apparent C_{2v} symmetry).[14] The cleft, or cavity, defined by the two phenyl spacers should be referred to as the distal pocket, in accordance with standard mono-*ansa*-porphyrin nomenclature. The width of this pocket is ca. 11.0 Å (C30−C57) above the porphyrin plane (between the two *meso*-phenyl groups), and ca. 6.7 Å (C37−C48) near the phenanthroline unit (between the two phenyl spacers in the 2- and 9-positions of the phen). A methanol guest molecule resides in the pocket, held in position by a set of four weak interactions. There are two hydrogen bonds to the phenanthroline nitrogen atoms, with distances of 3.19(2) Å between O1 (methanol) and N42 and 3.21(2) Å between O1 and N49. In addition, two strong "CH···O" interactions[23] are present between O1 and C35−H17 and C56−H28 with H···O distances (CHO angles) of 2.41(2) Å (147.7°) and 2.45(2) Å (139.4°), respectively. As depicted in the unit-cell view (Figure 2), intermolecular π interactions may be responsible for the bending of the phen strap. This distortion of the free base cannot be guest-induced, as might be the case for the corresponding zinc(II)-imidazole complex and for the dihydrated porphyrinatozinc(II) complex (vide infra).

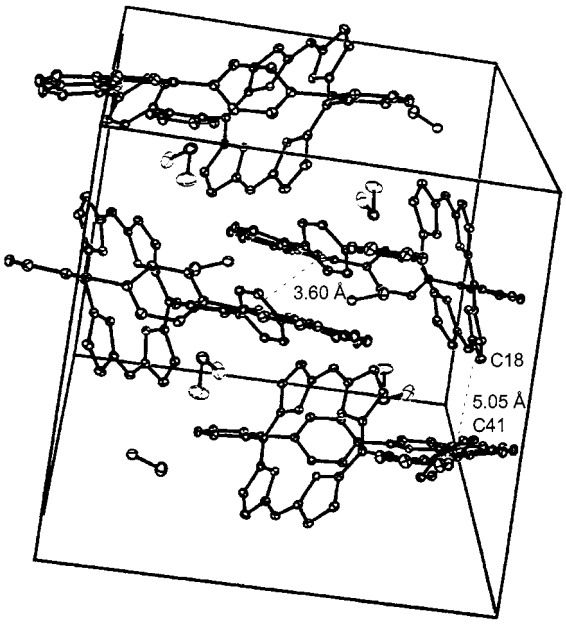

Figure 2. Packing of **1** in the unit cell; additional methanol molecules occupy free spaces defined by the head-to-tail arrangement of **1**

A π-stacking interaction at van der Waals distances is present between two phenyl spacers of neighboring molecules, with maximum and minimum interplanar distances of 3.611(4) and 3.590(4) Å for C34 and C35, respectively, from the mean plane of the neighboring phenyl spacer. As depicted in Figure 2, these two particular aromatic rings are parallel in the solid state, with a dihedral angle of 0.00(9)° and a centroid−centroid distance of 3.807(5) Å. Edge-on (or T-shaped) σ−π interactions[19] between the *meso* and β positions of one porphyrin unit and the phen nucleus of another are also observed with, for example, a minimum distance of 5.03(5) Å between C18 and C41 (see Figure 2). The structure of the free base would appear to be well-suited for the formation of mixed-valence homobinuclear complexes, as reported previously.[15] Moreover, due to the allowed bending of the phen strap, the inclusion of substrates within the cleft, already observed for monometallic species,[18] should also be possible in a bimetallic complex.

Metallation of the free base with zinc acetate in refluxing DMF afforded [(**1**)Zn(H_2O)$_2$] in 80% yield after purification by chromatography on alumina (CH_2Cl_2 + traces of pyridine).[19] Crystals of [(**1**)Zn(H_2O)$_2$] were obtained by diffusion of hexane into a dilute solution of (**1**)Zn in dichloromethane containing one equivalent of *N*-methylimidazole

(*N*-MeIm). Initially, *N*-MeIm was added to complete the coordination sphere of zinc(II) on the expected proximal side of the porphyrinatozinc(II) species, but subsequent binding studies revealed a low affinity of *N*-MeIm for the zinc complex.[18] Instead, the coordination sphere of the pentacoordinated zinc(II) cation is completed by an oxygen atom of a water molecule, as depicted in Figure 3.

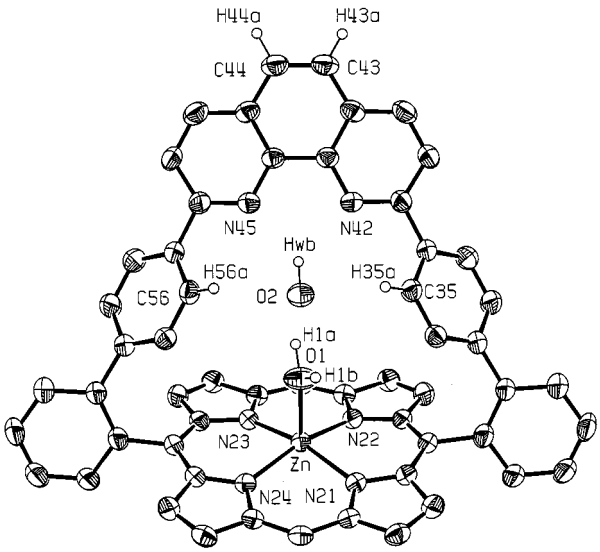

Figure 3. Front view and selected atom numbering for [(**1**)Zn(H_2O)$_2$]; only the hydrogen atoms involved in the H-bond network found by Fourier difference techniques are represented; selected bond lengths and angles are discussed in the text

The conformation of the porphyrin (24-atom) core is changed from ruffled in the solid state to domed, as would be expected for the coordination of large metal cations. This variation of conformation of the (24-atom) core does not affect the phenanthroline strap, the distance between the two *meso*-carbon atoms remaining unchanged. This confirms that no conformational restraints are imposed by the rigid phen strap. The unexpected presence of two water molecules within the distal pocket merits special comment.

The slightly domed porphyrin ring bears a resemblance to reported conformations of pentacoordinated zinc porphyrin complexes with oxygen donors occupying the fifth coordination site.[2,7,9a,9b,12,22] The coordination sphere around the zinc(II) atom is a slightly distorted tetragonal pyramid. The Zn−O1 bond [2.09(2) Å] is perpendicular to the (24-atom) core in that the N−Zn−O1 angles for N21 to N24 are 98.58(8), 98.52(8), 98.34(8), and 98.19(8)°, respectively. While the hydrogen atoms were added to the ligand using a routine treatment of the data, high resolution of the structure allowed us to establish the precise locations, by Fourier difference analysis (see Crystallographic Studies), of the two hydrogen atoms of the axially bound water molecule, as well as that remotely bound to the phenanthroline moiety. As depicted in Figure 3, the plane containing the axial water molecule is orthogonal to the phen plane and is oriented above the unsubstituted $C_{meso}-C_{meso}$ axis with an H1a−O1−H1b angle of 108(3)° and Zn−O1−H1a and Zn−O1−H1b angles of 126(2)° and 123(2)°, respectively. The O1−H1b bond length of 0.92(2) Å is slightly shorter than the O1−H1a distance [0.97(2) Å] due to the hydrogen bonding of H1a with O2. The detailed drawing of the H-bond network given in Figure 4 shows that the 1.69(2) Å distance between H1a and O2 corresponds to a strong H bond, with an oxygen−oxygen distance of 2.621(2) Å.

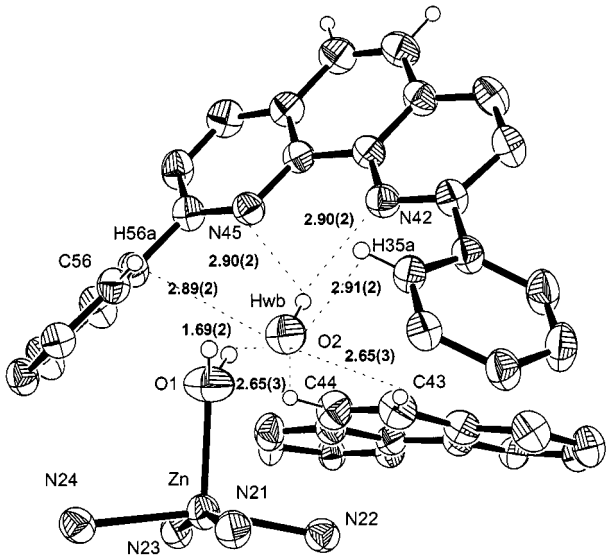

Figure 4. Crystallographic detail of the H-bond (3) and "CH···O" (4) interactions; the direct environment of the O2 water oxygen atom is represented; only the parts of the molecules involved in the binding are depicted; distances are given in Å; an additional van der Waals contact is observed between C44 and C43 and the porphyrin plane (C10) with equal distances of 3.40(2) Å

The angle of 114(2)° between H1a and the uncoordinated O2−Hwb bond, coupled with the precise location of Hwb at 2.27(3) and 2.21(3) Å from the phen nitrogen atoms N42 and N45, respectively, would seem to indicate that there is a direct interaction between H1a and the uncoordinated oxygen lone pairs, and that the second hydrogen atom of the uncoordinated water molecule is disordered in the crystal. This water molecule is fixed in the crystal by means of four "CH···O" interactions.[23] Two bonds of this type are found between the uncoordinated oxygen atom and the two top-central carbon atoms (C44 and C43) of the neighboring adjacent phenanthroline backbone, with identical H···O distances of 2.65(3) Å. The other two "CH···O" interactions are found between the aromatic *ortho* protons of the phenyl spacer and the uncoordinated oxygen atom, with shorter H···O distances of 2.89(2) and 2.91(2) Å. The three hydrogen bonds and four "CH···O" interactions are depicted in detail in Figure 4.

The packing of the metalloporphyrin in the crystal, as depicted in Figure 5, shows that additional π interactions are also present, mainly between the phenanthroline nuclei and open faces of the porphyrin rings. Each porphyrin unit resides on the phen strap of the molecule below, thereby forming Z-shaped stacks (a herringbone arrangement) of porphyrin units. The stacks are mutually interpenetrated by a partial overlap of the back of the phen moiety with the unsubstituted edge of the porphyrin ring in the next stack,

which allows the formation of the inter-stack "CH···O" interactions described above. As indicated in Figure 5, distances corresponding to strong aromatic-ring-stacking interactions, as well as edge-on interactions are observed within and between the zig-zag columns of the porphyrin units.

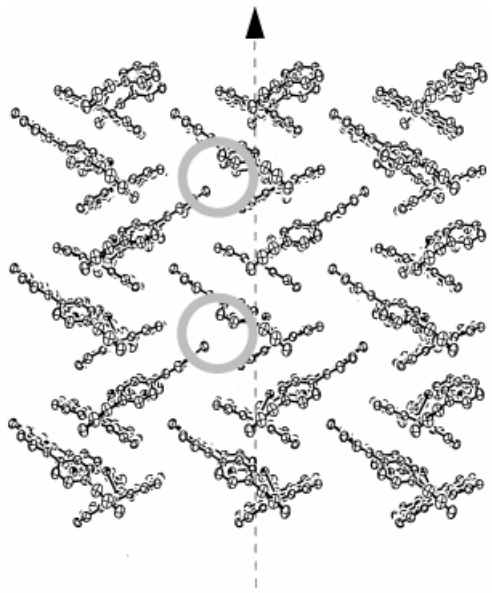

Figure 5. Packing of [(**1**)Zn(H_2O)$_2$]; the crystal consists of parallel arrangements of layers made up of zig-zag stacks (along the --- axis) of [(**1**)Zn(H_2O)$_2$] connected by "CH···O" interactions (identified by grey circles for the left stack); CH_2Cl_2 molecules are omitted for the sake of clarity

The presence of these additional intermolecular interactions certainly contributes in making the observed "CH···O" interactions quite strong (C···O distance: ca. 3.29 Å; CHO angle: ca. 124°) compared to the range of strengths previously reported in the literature.[24] Indeed, the particular nature of the C44−C43 bond in the phenanthroline defines the H44 and H43 atoms involved in the "CH···O" bond as vinylic protons rather than aromatic protons, which usually exhibit "C···O" distances in the range 3.55 to 3.65 Å,[25] with CHO angles commonly in the range 140−180°.[26]

A possible explanation for the high affinity for water shown by the hindered side of the porphyrin ligand is that the coordination of water does not induce any major conformational changes in the ligand. Indeed, the tilt of the *meso*-phenyl substituents on the porphyrin ring in the free base is very similar to that observed in the dihydrated zinc(II) complex. The measured dihedral angles between the *meso*-phenyl groups and the porphyrin plane are 67.86(6)° and 72.07(8)° in the zinc(II) complex and 66.83(10)° and 71.14(11)° in the free base. Furthermore, the dihedral angle between the phen subunit and the porphyrin core remains unchanged during the metallation/hydration process (ca. 61°). Thus, the energetic requirements for accommodating the two water molecules are minimized. Moreover, the lipophilic nature of the solvent (CH_2Cl_2) in which the crystals were grown might have been more conducive to *O* coordination of water at the zinc center than to *N* coordination of the imidazole.

Conclusion

The structure of a mono-*ansa*-porphyrin bearing a phenanthroline strap maintained at a fixed distance by means of two phenyl spacers has been resolved, as has that of the corresponding zinc(II) complex. The structure of the free base shows a relatively large cavity within the strap, with a distance of approximately 6 Å between the two coordination sites. The structure of the zinc complex obtained in the presence of *N*-MeIm does not show binding of an axial nitrogen ligand, but two water molecules are found to be present in the phenanthroline pocket. One water molecule is axially bound to the zinc atom, while the second completes the hydrogen-bond "network" to the phenanthroline nitrogen atoms. Experiments to determine the affinity of **1** for water in solution and the exchange rate of water are currently in progress, as are investigations in which the zinc ion is replaced by a magnesium ion to allow comparison of the photophysical properties of metalloporphyrin cores in the presence and absence of coordinated water.

Experimental Section

General: All solvents and reagents used were of commercial analytical grade. − Ligand **1** was prepared according to ref.[14] − ^{1}H-NMR spectra were recorded with a Bruker WP 300 MHz instrument; data were processed using WINNMR software available from Bruker, with residual non-deuteriated solvent as chemical-shift reference (CH_2Cl_2 at δ = 5.29). − UV/Vis spectra were recorded with a Hewlett-Packard HP8452A diode-array spectrophotometer (2 nm resolution).

[1(Zn)]: To a solution of the free base **1** (50 mg, $6.5\cdot10^{-5}$ mol) in 20 mL of DMF was added Zn(OAc)$_2$ (100 mg, $45.5\cdot10^{-5}$ mol) and the solution was refluxed under argon until the Soret band at 412 nm had disappeared from the UV/Vis spectra of withdrawn aliquots (ca. 4 h). The resulting mixture was then poured into water (200 mL). The pink-red precipitate was collected by filtration, washed with water, and dried by azeotropic distillation with toluene and ethanol, to afford the pure zinc(II) complex as a red solid (47 mg, $5.5\cdot10^{-5}$ mol, 85%); m.p. > 250°C. − ^{1}H NMR (300 MHz, CD_2Cl_2): δ = 10.15 (s, 2 H), 9.28 (d, *J* = 4.4 Hz, 4 H), 9.01 (d, *J* = 4.4 Hz, 2 H), 8.75 (d, *J* = 7.4 Hz, 2 H), 7.96 (d, *J* = 8.2 Hz, 2 H), 7.89 (m, 6 H), 7.49 (d, *J* = 8.2 Hz, 2 H), 7.48 (s, 2 H), 6.62 (d, *J* = 8.3 Hz, 4 H), 6.51 (d, *J* = 8.3 Hz, 4 H). − [**1**(Zn)] + CH_2Cl_2 + 3/2 H_2O: $C_{57}H_{37}Cl_2N_6O_{1.5}Zn$ (968.2): calcd. C 70.86, H 3.86, N 8.70; found C 71.06, H 4.02, N 8.72. − UV/Vis (CH_2Cl_2): λ_{max} [nm] (ε [$M^{-1}\cdot cm^{-1}$]): 284 (28000), 308 (29000), 418 (259000), 546 (11000), 578 (2000). − Positive-ion FAB MS; *m/z*: calcd. for $[M]^+ = [C_{56}H_{32}N_6Zn]^+$ 852; found 853.

X-ray Crystallographic Study:[16] Crystals of **1** were obtained by vapor diffusion of hexane into a CH_2Cl_2/MeOH (95:5) solution of the porphyrin. Crystal data for $C_{56}H_{34}N_6\cdot CH_2Cl_2\cdot CH_3OH$: M_r = 907.91, monoclinic, space group $P2_1/c$, *a* = 17.763(5), *b* = 16.800(4), *c* = 15.759(3) Å, β = 111.59(2)°, *V* = 4372(3) Å^3, *Z* = 4, $\rho_{calcd.}$ = 1.38 gcm^{-3}, μ(Cu-K_α) = 1.743 mm^{-1}. Data were collected with a Philips PW 1100/16 diffractometer using Cu-K_α

graphite-monochromated radiation (λ = 1.5418 Å) at −100°C. A dark-red crystal of dimensions 0.40 × 0.40 × 0.40 mm was used and a total of 5517 reflections were collected, $3° < \theta < 53°$ (max θ limited by cooling device). 4178 reflections with $I > 3\sigma(I)$ were used for the structure determination and refinement. The structure was solved using direct methods and refined against $|F|$. Hydrogen atoms were introduced as fixed contributors. Empirical absorption corrections, transmission factors: 0.64, 1.00. For all computations, the Nonius OpenMoleN package[20] was used. Final results: R_f = 0.052, wR (F) = 0.080, GooF on F: 1.537, maximum residual electronic density: 0.58 eÅ^{-3}. Crystals of [(**1**)Zn(H_2O)$_2$] were obtained by slow diffusion of hexane into a dichloromethane solution of (**1**)Zn containing one equivalent of *N*-methylimidazole. − Crystal structure of [(**1**)Zn(H_2O)$_2$]: $C_{57}H_{35}Cl_2N_6O_2Zn$, M_r = 972.18, red rectangular plates, monoclinic, space group *Ia*, a = 12.355(3), b = 12.658(3), c = 28.639(6) Å, β = 89.99(3)°, V = 4479(3) Å^3, Z = 4. Data were collected at room temperature with a STOE-IPDS diffractometer using Mo-K_α graphite-monochromated radiation (λ = 0.70910 Å). Structure solution and anisotropic refinement were performed with the SHELXTL package[21] using 6664 independent reflections of the 14456 reflections collected. Hydrogen atoms were geometrically positioned with all distances X−H being free to refine, except for those attached to oxygen atoms, which were located by Fourier difference techniques. Final results: R_1 = 0.0342 [$I > 2\sigma(I)$], wR_2 = 0.0865 (all data), GooF on F^2: 1.342, maximum residual density: 0.405 eÅ^{-3}.

New Chelating Nitroxide Free Radical Ligands For Heterospin-Magnetic Engineering

Kira E. Vostrikova,[a] Elie Belorizky,[b] Jacques Pécaut,[a] and Paul Rey*[a]

Keywords: Nitronyl nitroxides / Coordination chemistry / Magnetic properties / Radicals / Chelates / Chelates

Polychelating nitroxide ligands derived from *N*-methylethylenediamine and piperazine have been prepared by reactions of 2-bromomethyl nitronyl nitroxide with the corresponding polyamines. Two of these ligands have been structurally and magnetically characterized, along with some of their transition metal complexes, the magnetic properties of which are compared to those of previously reported related species. In particular, the properties of a nickel(II) derivative of a pentadentate tris(nitroxide), the ground spin-state of which is a quadruplet, are discussed in detail.

The popularity of nitroxide free radicals stems from their high stability and the well-studied, sophisticated organic chemistry.[1−3] Thus, ease of chemical modification allows the synthesis of nitroxides specially designed for use in fields as different as spin labelling[4][5] and materials chemistry.[6−9] In recent years, there has been increasing interest in the incorporation of nitroxide spin carriers into large homo-[9−11] and heterospin assemblies[6−8,12−15] of exchange-coupled species.

Coordination compounds incorporating nitroxide ligands are especially attractive since ligation through the nitroxyl oxygen atom ensures significant magnetic interactions. Moreover, overlap of magnetic orbitals of different types, d and p, may result in special situations where these orbitals are orthogonal and the interaction is ferromagnetic.[6][7] Among the various types of nitroxides, nitronyl nitroxides[16][17] have attracted special interest because of their delocalized electronic structures and their bridging properties, which have been exploited in the construction of extended structures made up of interacting organic and metallic spin carriers. The coordination chemistry of nitroxide free radicals is, however, highly dependent on the weakly basic character of ligands of this type, which precludes coordination to metal ions other than those bearing electron-withdrawing groups.[18−21] Enhancement of the Lewis acid properties of the metal center may easily be achieved, but most of the coordination sites would then be occupied by ancillary ligands and structures of high dimensionality would not be accessible, other than for high-spin polyradicals.[8] Consequently, most of the extended species described to date are one-dimensional alternating arrays of metal ions and nitroxide ligands which are ordered at low temperature.[22−24] In an attempt to circumvent this difficulty, we have investigated the coordination properties of a few nitronyl nitroxides in which the substituent bears a donor such as a nitrogen atom, which enforces the coordination of the nitroxyl oxygen atom through the chelate effect.[12,14,25] The results of these preliminary investigations have prompted us to develop a more general method, which should allow the design of paramagnetic ligands suitable for developing the field of molecular nitroxide-based magnetic coordination compounds.

We report herein on the preparation of a reactive nitroxide synthon, **1** (Figure 1), which couples with *N*-methylethylenediamine to afford tri- (**2**) and tetranitroxide (**3**) ligands, and with piperazine to give a biradical (**4**). The magnetic properties of these polychelating ligands have been investigated and two of them (**3**, **4**) have been structurally characterized. In a preliminary step, and for comparison with previously reported species, complexes of metal hexafluoroacetylacetonates **6** {**4**[$Mn(hfac)_2]_2$}, **7** {**4**[$Co(hfac)_2]_2$}, and **8** {**4**[$Ni(hfac)_2]_2$} have been prepared and their structural and magnetic properties have been investigated. Finally, we report the synthesis and magnetic behavior of a pentacoordinate nickel(II) complex, **5** {**2**[$Ni(ClO_4)_2] \cdot H_2O$}, which illustrates the potential of ligands of this type in the design of new molecular magnetic materials.

Results and Discussion

Although the yield of **1** was rather low (ca. 30%), the one-pot synthesis from the readily available 2,3-dimethyl-2,3-dinitrobutane described here affords samples of the compound from which the amino derivatives can conveniently be prepared. Synthesis of a similar synthon, the chloro compound analogous to **1**, has been described previously.[26] This chloro compound was used in the preparation of 2-(phenyloxymethyl)imidazoline-*N,N′*-dioxyl derivatives, but it is unreactive toward amines.

The synthesis of metal complexes did not present any problems; the chelating nature of these ligands ensures coordination of the nitroxyl groups to the metal center, as

observed for the Mn^{II} (**6**), Co^{II} (**7**), and Ni^{II} (**8**) derivatives of **4**, the X-ray structures of which have been determined.

Structural Studies

Since only one structure of a 2-aminomethyl derivative of a nitronyl nitroxide has been reported previously,[26] it seemed worthwhile to structurally characterize a few of these ligands.

Views of the molecular structures of $\mathbf{3}^+$ and **4** are depicted in Figures 2 and 3, respectively. In both compounds, the imidazoline *N*-oxide *N*′-oxyl fragments exhibit struc-

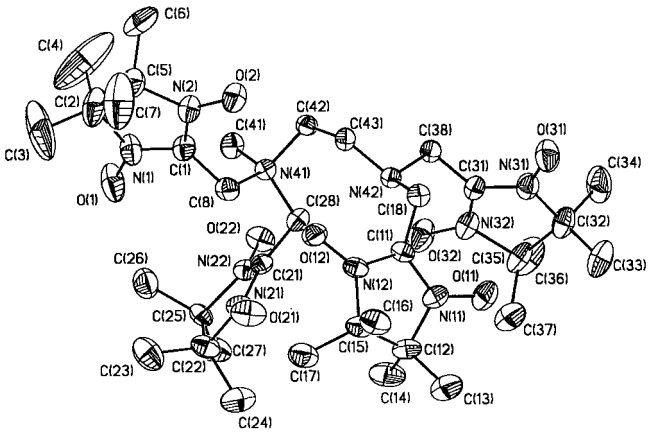

Figure 2. Molecular structure of ligand $\mathbf{3}^+$ showing the atom numbering scheme; thermal ellipsoids are drawn at a 30% probability level; selected bond lengths [Å] and angles [°]: Oi−Ni (av.) = 1.281(6), Ci1−Ci8 (av.) = 1.470(6), C8−N41 = 1.514(4), C28−N41 = 1.530(6), C18−N42 = 1.490(5), C38−N42 = 1.470(4); C1−C8−N41 = 114.3(4), C11−C18−N42 = 112.4(3), C21−C28−C41 = 112.9(3), C31−C38−N42 = 114.6(4)

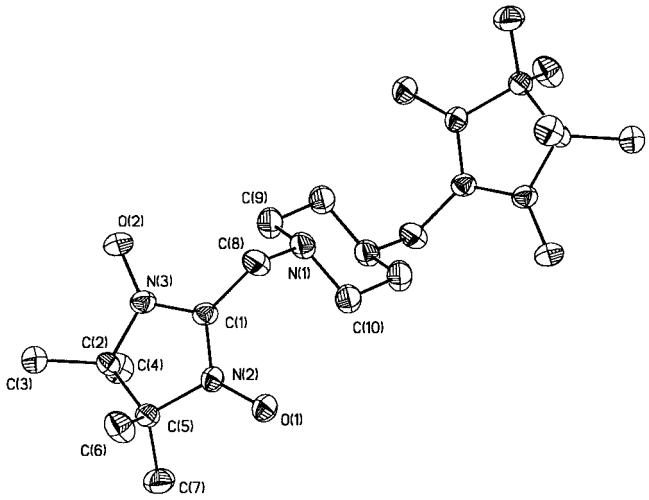

Figure 3. Molecular structure of ligand **4** showing the atom numbering scheme; thermal ellipsoids are drawn at a 30% probability level; selected bond lengths [Å] and angles [°]: N2−O1 = 1.272(4), N3−O2 = 1.285(4), C1−C8 = 1.489(5), C8−N1 = 1.461(5); C1−C8−N1 = 117.0(3)

tural features characteristic of nitronyl nitroxides,[6] such as NO bond lengths in the range 1.26−1.29 Å. Regarding the 2-aminomethyl moiety, one observes the following structural features: (i) In both ligands, the imidazoline ring is almost perpendicular to the plane defined by the sp^2-hybridized carbon atom (C1; Figure 2) and the aminomethyl group (84.6−93.5°). This can be rationalized by considering the steric requirements, since in this arrangement the oxyl groups are far removed from the organic fragment bearing the amino function. (ii) In **3**, the relative arrangement of the four imidazoline-*N*,*N*′-dioxyl groups is such that two of them are almost parallel [12.4(4)°] and each group within this pair is almost perpendicular (83−87°) to the other two. (iii) In **4**, the C1−C8−N1 plane is roughly orthogonal to

both the imidazole ring and the mean plane of the piperazine fragment. Finally, the ethylenediamino group in **3** is in a gauche conformation, while in the centrosymmetric compound **4** the six-membered piperazine ring adopts a chair form. Numerous weak intermolecular interactions involving the oxyl groups are observed, with distances larger than 5 Å.

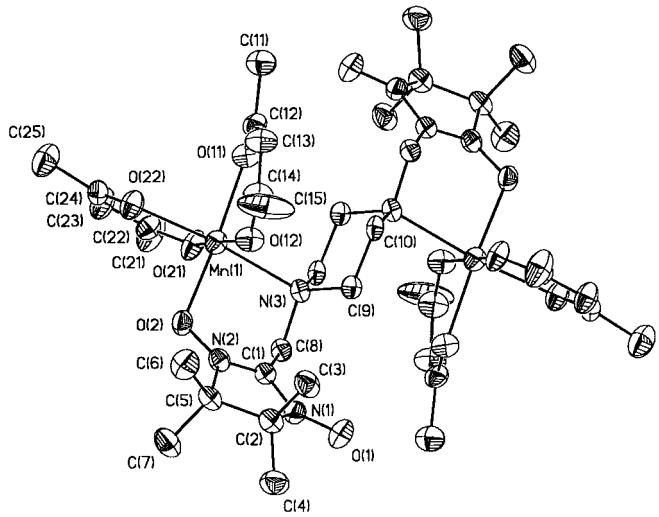

Figure 4. Molecular structure of complex **6** showing the atom numbering scheme; thermal ellipsoids are drawn at a 30% probability level; selected bond lengths [Å] and angles [°]: N1−O1 = 1.266(7), O2−N2 = 1.309(7), Mn−O2 = 2.158(5), Mn−N3 = 2.463(5); O2−Mn−N3 = 88.7(2), O2−Mn−O11 = 163.3(2), N3−Mn−O22 = 163.3(2), C1−C8−N3 = 112.0(5)

Although complex **6** {**4**[Mn(hfac)$_2$]$_2$} on the one hand, and the isostructural complexes **7** {**4**[Co(hfac)$_2$]$_2$} and **8** {**4**[Ni(hfac)$_2$]$_2$} on the other, do not crystallize in the same space group (*P*1 and *P*21/*n*, respectively), their molecular structures (Figure 4) are very similar. They are centrosymmetric species incorporating a piperazine ring in a chair conformation. The metal coordination spheres are octahedral, with that of the manganese ion being more distorted than those of the cobalt and nickel ions. It is worth noting that each metal center is chiral, but since the molecular structures are centrosymmetric the complexes exist in inactive forms. In both molecular structures, the chelate ring involving the nitroxide oxygen atom adopts a boat conformation, and the N−O distance in the coordinated nitroxyl group is larger than that in the uncoordinated one by as much as 0.03 Å. This latter feature is diagnostic of significant metal−nitroxide magnetic coupling. Furthermore, the chelate ring is distorted because, due to steric factors, the metal−nitrogen(piperazine) distance is much larger than usual [2.463(5) Å in **6** and 3.300(6) Å in **7**]. Finally, the smallest intermolecular distances are observed between symmetry-related uncoordinated oxyl groups, with distances as small as 3.41 Å in **6**. Therefore, the magnetic behavior of these metal complexes may depend not only on intramolecular metal−nitroxide couplings, but also on intermolecular nitroxide−nitroxide interactions.

Magnetic Studies

Ligands **2**−**4** exhibit similar magnetic behavior characterized by obeyance of the Curie law down to ca. 40 K, followed by a decrease of the product of the magnetic susceptibility and the temperature, indicative of antiferromagnetic interactions. In biradical **4**, the saturated piperazine moiety is not expected to mediate sizeable intramolecular interactions between the two nitroxide spin carriers. Indeed, the Bleaney−Bowers expression[27] was not able to reproduce the experimental data. However, fairly good results were obtained by considering independent spins interacting with neighboring molecules[28] [^{z}J = −2.4(3) cm^{-1}, R = 6.2·10^{-4}].[29] As mentioned above, in tetraradical **3** intra- and intermolecular contacts are of the same order of magnitude. Consequently, good agreements were obtained either by considering a four-spin system with identical intramolecular interactions being operative between the nitroxide fragments [J = −2.1(2) cm^{-1}, R = 2.4·10^{-4}] or an S = 1/2 spin interacting with an unknown number (z) of neighbors [^{z}J = −6.8(2) cm^{-1}, R = 1.7·10^{-4}]. This latter model could also be successfully applied to triradical **2** [^{z}J = −5.9(3) cm^{-1}, R = 3.5·10^{-4}], for which structural information is not available. Although the magnetic behavior of the ligands is somewhat unremarkable, the small magnitudes of the coupling constants suggest that analysis of the magnetic properties of the complexes could be performed neglecting inter-nitroxide coupling within the metal coordination sphere.

Curie behavior is observed for complex **6**. The almost constant value of χT from room temperature (6.06 cm^3·K·mol^{-1}) down to 5 K (5.97 cm^3·K·mol^{-1}) precludes any quantitative analysis of the coupling constant. This value of $\chi T \approx 6$ cm^3·K·mol^{-1} is consistent with the presence of two independent S = 2 spins, resulting from a large metal−nitroxide antiferromagnetic interaction at both complexing sites of the molecule. Indeed, the value at room temperature indicates that the magnitude of the coupling constant should be as large as −100 cm^{-1}, and that intermolecular interactions should be negligible. Such large Mn^{II}−nitroxide interactions have been reported previously, but it has been suggested that geometric constraints imposed by the chelation usually lessen the extent of magnetic interaction.[25] Indeed, if one considers that the interaction primarily originates from overlap of the π* orbital of the nitroxyl group with the metal orbital directed towards the oxyl oxygen atom, chelation would result in unfavorable local structural parameters for overlap and strong coupling. In **6**, these parameters (M−O−N angle 116.5°; angle between the M−O−N and N−C−N planes 51.4°) are similar to those observed in the related complex Mn(hfac)$_2$NIT · 2 Py (120° and 42°),[25] where the chelating donor atom is a pyridyl nitrogen atom and the Mn^{II}−nitroxide interaction has a magnitude of just −65 cm^{-1}.

Similarly, antiferromagnetic behavior is shown by the analogous nickel(II) complex **8**, for which the value of χT decreases from 2.04 to 0.91 cm^3·K·mol^{-1} over the 300−2 K temperature range and the ground spin-state is the sum of

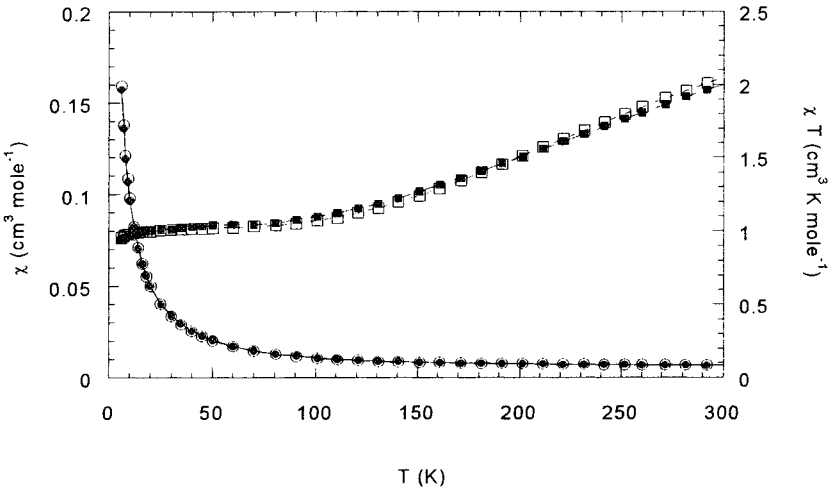

Figure 5. Magnetic behavior of complex **8** displayed as χ (full circle: experimental; open circle: calculated; see text) and χT (full square: experimental; open square: calculated)

two doublets. However, in this case the variation of χT is sufficiently large (Figure 5) to allow calculation of a reliable value of $J_{Ni-nitroxide} = -131(4)$ cm^{-1} [$g = 2.11(1)$, $R = 3.4 \cdot 10^{-4}$], which is smaller than that found for the Ni^{II} complex of the pyridyl-substituted radical (-161 cm^{-1}).[25] Structural parameters relating to magnetic orbital overlap in these two compounds are also similar. Therefore, these two examples illustrate how slight structural modifications within the metal coordination sphere can have a significant influence on the magnitude of the metal−radical magnetic interaction.

In the case of complex **7** {**4**[Co(hfac)$_2$]$_2$}, one observes a decrease in χT, which is probably the result of antiferromagnetic metal−nitroxide interactions. Owing to the significant orbital contribution to the magnetic behavior of octahedral Co^{II} species, no attempts have been made to determine a coupling constant.

The magnetic behavior of complex **5** is depicted in Figure 6. On decreasing the temperature, χT increases from 2.31 emu·K·mol^{-1} (independent spins) to 2.53 emu·K·mol^{-1} at 38 K, and then decreases to ca. 1.0 emu·K·mol^{-1} at 2 K. The presence of dominant ferromagnetic interactions is confirmed by a positive θ value of 8.6 K, as shown by the temperature dependence of $1/\chi$. Although Ni^{II}−nitroxide interactions are usually antiferromagnetic, recent reports have documented special situations where ferromagnetic couplings can be attributed to specific structural features of the coordination sphere.[30] In the present case, structural information is not available but, as shown in Figure 7, the complex may exist in two isomeric forms, namely OC-6-25 (*mer*) and OC-6-35 (*fac*). Of these, the *mer* configuration is probably more stable due to steric factors, as has been observed previously for related nickel(II) complexes of other chelating nitroxide ligands.[13]

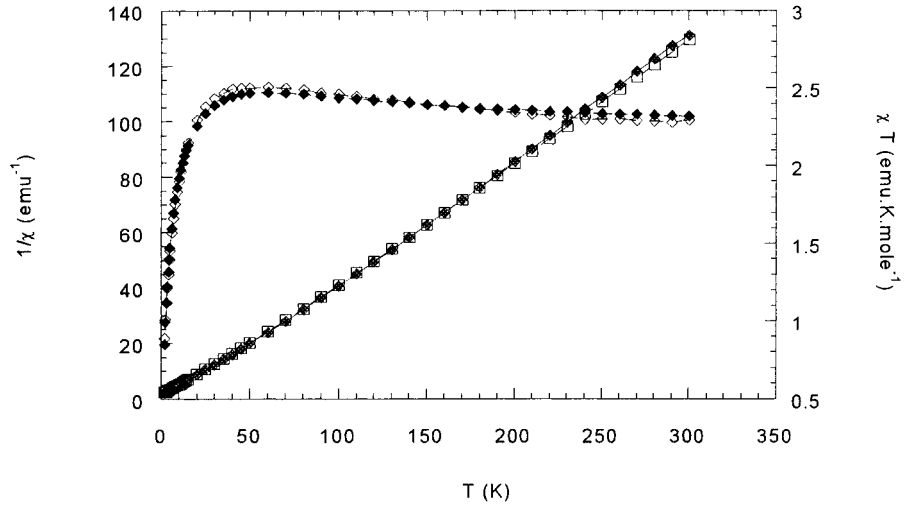

Figure 6. Temperature dependence of χT (full circle: experimental; open circle: calculated) and $1/T$ (full square: experimental; open square: calculated) for complex **5**

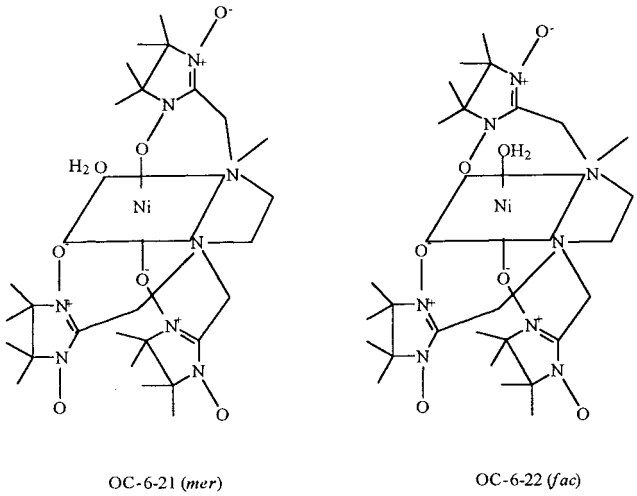

Figure 7. Sketch of the possible isomeric modifications of complex **5**; enantiomeric modifications are not represented

From a magnetic point of view, there are two different sets (axial and equatorial) of coordinated nitroxide ligands, irrespective of the configuration. Accordingly, a model including two different Ni−nitroxide coupling constants was considered, which led to the following parameters: $J_{Ni-C} = -5.3(6)$ cm^{-1}, $J_{Ni-A} = J_{Ni-B} = +12(3)$ cm^{-1}, $g = 2.13(2)$, and furthermore indicated a weak intermolecular interaction of 0.45(2) cm^{-1} ($R = 8.2 \cdot 10^{-4}$). This coupling scheme suggests that the ground spin-state of the "isolated" complex is a quadruplet. Figure 8 shows plots of the theoretical Brillouin function for $S = 3/2$ ($g = 2.13$) and the magnetization data of the complex collected at $T = 2$ K. These two curves have been extrapolated to high field using a sum of exponential functions for the experimental data. Although at low field the data deviate markedly from the calculations, one observes that at high field the experimental magnetization extrapolates to a value close to that of a quadruplet state. The discrepancy observed at low field is most likely attributable to zero-field effects, which split the ground state into two Kramer doublets.

Concluding Remarks

We have presented a general strategy for the incorporation of donor atoms in chelating positions to the oxyl group in nitronyl nitroxides. The method allows the preparation of metal−nitroxide exchange-coupled species with weakly acidic metal centers. The variety of amino-functionalized organic fragments that can be used as precursors for designing nitroxide ligands makes this strategy very attractive for magnetochemists. For example, complex **5**, which has a spin quadruplet ground state and a free coordinating position, can be used to build up high-spin clusters. Work along these lines using this $S = 3/2$ complex as a terminal building block for metal hexacyanates is currently in progress.

Experimental Section

Synthesis of 2-Bromomethyl-4,5-dihydro-4,4,5,5-tetramethyl-1-oxy-1*H*-imidazolyl 3-Oxide (1): This compound was synthesized directly from 2,3-dimethyl-2,3-dinitrobutane.[31] The precursor (10 g, 57 mmol) and ammonium chloride (5 g) were dissolved in a mixture of water (20 mL) and THF (80 mL). Subsequent reduction to the bis(hydroxylamino) derivative was performed by adding zinc powder (13 g) over a period of 1 h at 10°C. The resulting slurry was stirred for 5 h at room temperature and then filtered. The filtrate was acidified to pH = 1 with HCl and the THF was evaporated in vacuo. The remaining aqueous solution was treated with 8 mL of 2-bromoacetaldehyde dimethylacetal and the resulting mixture was stirred at 10°C for 2 d. The solution was subsequently extracted with diethyl ether and the aqueous phase was neutralized to pH = 7 with $NaHCO_3$. Then, 200 mL of dichloromethane was added, the mixture was cooled to 5°C, and oxidation was carried out by adding 7 g of sodium periodate in 50 mL of water over a period of 1 h. The organic phase was subsequently dried and concentrated in vacuo and the crude deep-red compound was chromatographed (SiO_2; diethyl ether) to afford 2.6 g (18%); m.p. 126°C (dec.). The product was found to be stable for months at −28°C, but only for a few hours at room temperature. Thus, it had to be used promptly in the subsequent reactions.

Synthesis of *N*-Methylethylenediamine Derivatives: Celite (5 g) and *N*-methylethylenediamine (100 mg, 1.35 mmol) were mixed in 30 mL of acetonitrile. A solution of 1.0 g (4.0 mmol) of bromomethyl nitronyl nitroxide in 20 mL of MeCN was then added dropwise at room temperature and stirring was continued for a further 2 h. Filtration and evaporation of the solvent from the filtrate afforded a crude mixture, which was chromatographed on alumina (Woelm, activity grade V). Compounds **2** and **3** were successively eluted. − **2**: With dichloromethane/acetonitrile, 60:40; 423 mg (72%); m.p. 145°C (dec.); $C_{27}H_{52}N_8O_6$ (585): calcd. C 55.46, H 8.96, N 19.16; found C 55.58, H 8.72, N 18.97. − Bromide **3:** With acetonitrile. **3** was dissolved in a mixture of methanol/water (1:1) containing one equiv. of sodium perchlorate. After allowing the mixture to stand for 2 d, the crystals deposited were collected by filtration; yield 158 mg (17%); m.p. 189°C (dec.); $C_{35}H_{71}ClN_{10}O_{12} \cdot 4\,H_2O$: calcd. C 45.37, H 8.05, N 15.12, Cl 3.83; found C 45.18, H 8.12, N 15.26, Cl 4.08. Crystals of this compound proved suitable for an X-ray diffraction study.

Synthesis of a Piperazine Derivative: Using the same procedure as above, starting from 1.0 g (4.0 mmol) of **1** and 172 mg of piperazine (2.0 mmol), chromatography on alumina (Woelm activity grade V, CH_2Cl_2/CH_3CN, 70:30) afforded 428 mg (50%) of **4**; m.p. 156°C; $C_{20}H_{36}N_6O_4$ (424.5): calcd. C 56.58, H 8.55, N 19.80; found C 56.78, H 8.53, N 19.92. Crystals suitable for an X-ray diffraction study were obtained by slow evaporation of the solvents from acetone/hexane solutions. Other compounds were present in small quantities, which were not characterized.

Metal Complexes

Nickel(II) 5: Ligand **2** (100 mg, 0.17 mmol) was dissolved in 8 mL of methanol. To this solution, a solution of Ni(ClO4)2·6H2O (70 mg, 0.2 mmol) in 5 mL of MeOH was added portionwise. A red powder (128 mg, 95%) was immediately precipitated, which, after drying in vacuo, gave a satisfactory analysis for $C_{27}H_{51}Cl_2N_8NiO_{15}$ (786.4): calcd. C 37.83, H 6.00, N 13.07, Ni 6.85; found C 37.59, H 5.93, N 13.12, Ni 6.94. All attempts to grow single crystals from solutions in various solvents were unsuccessful.

Manganese(II) Complex 6: Manganese(II) hexafluoroacetylacetonate dihydrate (250 mg, 0.5 mmol) was dissolved in 30 mL of boiling heptane and reflux was continued in order to obtain an anhydrous solution of the metal salt. A solution of ligand **4** (100 mg, 0.23 mmol) in 5 mL of dichloromethane was added to the solution at ca. 50°C. Precipitation occurred on cooling and acetone was added until the solid redissolved. Subsequent slow evaporation of the solvent led to well-formed crystals of complex **6** (223 mg, 33%; m.p. 188°C); $C_{40}H_{40}F_{24}Mn_2N_6O_{12}$ (1362.6): calcd. C 35.26, H 2.96, Mn 8.06, N 6.17; found C 34.98, H 3.11, Mn 7.97, N 6.04.

Cobalt(II) Complex 7 and Nickel(II) Complex 8: Crystals suitable for X-ray diffraction experiments were obtained starting from the appropriate metal salt and following the same procedure as above.

Crystal Structure Determinations: All crystals (**3**, **4**, **6**, **7**) were analyzed using a Siemens SMART CCD area detector three-circle diffractometer (Mo-K_α radiation, graphite monochromator, λ = 0.71073 Å). The cell parameters were determined from intensities detected in three batches of 15 frames with a 10-s exposure time for each. For three settings of Φ and 2Θ, 1200 narrow data frames were collected for successive increments in ω of 0.3°. A full hemisphere of data was collected for each complex. At the end of collection, the first 50 data frames were re-examined in order to check for decay during the data collection. Unique intensities with $I > 10\sigma(I)$ selected from all the data frames using the SAINT program were used to refine the cell parameters. The substantial degree of redundancy in the data allowed empirical absorption corrections to be applied using multiple measurements of equivalent reflections with the SADABS program. Space groups were derived from systematic absences and were later confirmed by the successful solutions of the structures.[32] The structures were solved by direct methods as implemented in the SHELXTL 5.05 package and all atoms were located on difference Fourier maps. Non-hydrogen atoms were refined anisotropically on F^2, while hydrogen atoms, located by calculation, were refined isotropically. For compound **4**, use of the data collected at 20°C led to a structural scheme in which the perchlorate anion was highly disordered. Attempts to collect the data at low temperature were unsuccessful owing to disintegration of the crystals. Therefore, the anion was tentatively modelled on two different chlorine locations with equal occupancies and the oxygen atoms were distributed over a sphere. Although this disorder has a significant effect on the *R* factor values, it does not hamper the chemical interpretation of the cationic part of the molecule. The nickel(II) complex **8** was found to be isostructural with the cobalt(II) analogue **7**.

Magnetic Susceptibility Measurements: Magnetic susceptibility data were collected using a Quantum Design MPMSR2 magnetometer working at a 0.5-T field strength over the 2−300 K temperature range. Squid outputs were corrected for the contribution of the sample holder and susceptibility data were corrected for the diamagnetic contribution of the constituent atoms using Pascal constants.

First Metal Complexes of Oligonitrile Ligands: Palladium(II) Complexes of *N*-Methoxycarbonyl- and *N*-Thiobenzoyl-1,3,5,7-tetraazaoctatetraenes

Nicola C. Aust,[a] Anke Beckmann,[a] Ria Deters,[a] Roland Krämer,*[a] Lothar Terfloth,[a] Sabine Warzeska,[b] and Ernst-Ulrich Würthwein*[a]

Dedicated to Professor Bernt Krebs at the occasion of his 60th birthday

Keywords: Palladium(II) complexes / Oligonitriles / N ligands / S ligands / *N*-Acylimine

Two mononuclear six-membered chelate $PdCl_2$ complexes **2a**, **b** of the two different types of tetrameric oligonitriles **1a**, **b** have been synthesized. Both contain square-planar palladium(II) with a *cis* arrangement of the chloride atoms. In complex **2a** of the ω-amino-substituted *N*-methoxycarbonyl oligonitrile **1a** the metal center is coordinated by the nitrogen atoms N1 and N3. Within the chelate ring alternating bond lengths for the C–N bonds are observed, whereas the non-complexed, more flattened part of the oligonitrile chain shows almost equal C–N bond lengths, indicating strong donor-acceptor interactions involving the terminal amino group and the N3–Pd moiety of the molecule. The complex **2b** is derived from the thiobenzoyl ligand **1b** bearing a terminal (*R*)-fenchylidene group. In **2b** the sulfur atom S1 and the nitrogen atom N2 are involved in complexation. In contrast to **2a**, strong bond-length alternation is observed in **2b** for the complexed and the non-complexed part of the ligand. From the NMR spectra of both complexes no indication for a migration of the $PdCl_2$ unit along the chain could be derived.

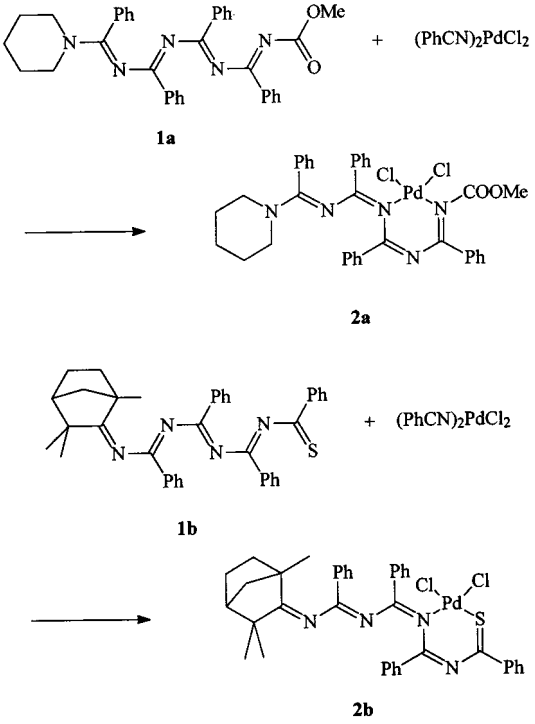
Introduction

Recently, variably substituted oligonitriles became available for the first time in monodisperse, well-defined form.[1−4] Although these substances are isoelectronic with polyacetylenes (polyenes), their structural and electronic properties are entirely different. For instance they adopt nonplanar three-dimensional structures (often helices in the crystalline state) without far-reaching conjugation. Of special interest is their behavior in complexation and redox reactions as well as their electrical conductivity[5] and the NLO properties.

In this paper we report on our investigations of the complexation ability of oligonitriles using palladium(II) as metal counterpart. Oligonitriles are expected to serve as potent polydentate ligands since each imine nitrogen atom is a potential σ donor. Furthermore, the numerous C=N bonds may give rise to π complexation. High molecular flexibility due to low barriers of rotation around the C−N single bonds is expected to facilitate complexation additionally.

Results and Discussion

Two different types of substituted oligonitrile molecules have been used, both carrying four adjacent imino bonds ("tetramers") and one additional terminal C=X functionality. Substance **1a** bears a methoxycarbonyl moiety at nitrogen atom N1 whereas **1b** is a thiobenzoyl derivative. For the formation of the complexes the ligands were dissolved in acetonitrile, and bis(benzonitrile)palladium dichloride was added. Crystallization was achieved by adding a surplus of diethyl ether, yielding metal complex **2a**, and **2b**.[6]



Both new compounds **2a** and **2b** were subjected to X-ray analysis. Both are mononuclear 1:1 complexes with a *cis*-$PdCl_2$ unit.

The methoxycarbonyl compound **1a** leads to metal complex **2a** by complexation of nitrogen atom N1 and N3 (crystallographic numbering) to Pd forming a six-membered chelate ring (Figure 1). The palladium center is tetracoordinate forming the expected square-planar geometry[7] as indicated by the sum of angles around palladium (359.88°). Coordinative bond lengths are in the typical range of $Pd^{II}-N(sp^2)$ and $Pd^{II}-Cl$ bonds. As expected for a palladium compound, coordination to nitrogen atoms is clearly preferred over complexation to oxygen atoms of the methoxycarbonyl group. The chelate ring deviates strongly from planarity leading to a twisted-boat-shaped structure. The two other nitrogen atoms N4 and N5 are not involved in complexation. This observation may be explained by

Molecular structure of **2a** (hydrogen atoms omitted for clarity); selected bond lengths [Å], bond angles [°], and torsional angles [°]: bond lengths [Å]: Pd−Cl(1) 2.282(1), Pd−Cl(2) 2.276(1), Pd−N(1) 2.041(2), Pd−N(3) 2.017(2), O(1)−C(2) 1.187(4), C(2)−N(1) 1.434(4), N(1)−C(3) 1.295(4), N(2)−C(3) 1.381(4), N(2)−C(10) 1.285(4), N(3)−C(10) 1.407(4), N(3)−C(17) 1.322(4), N(4)−C(17) 1.330(4), N(4)−C(24) 1.328(4), N(5)−C(24) 1.322(4); bond angles [°]: Cl(1)−Pd−Cl(2) 92.93(3), N(1)−Pd−N(3) 83.45(10), Cl(1)−Pd−N(1) 91.04(7), Cl(2)−Pd−N(3) 92.46(7), O(1)−C(2)−N(1) 123.4(3), C(2)−N(1)−C(3) 120.2(3), N(1)−C(3)−N(2) 120.7(3), C(3)−N(2)−C(10) 121.0(3), N(2)−C(10)−N(3) 120.6(3), C(10)−N(3)−C(17) 118.8(2), N(3)−C(17)−N(4) 118.3(3), C(17)−N(4)−C(24) 124.2(3), N(4)−C(24)−N(5) 118.1(3); torsional angles [°]: O(1)−C(2)−N(1)−C(3) −58.8, C(2)−N(1)−C(3)−N(2) 162.0, N(1)−C(3)−N(2)−C(10) 45.0, C(3)−N(2)−C(10)−N(3) 3.5, N(2)−C(10)−N(3)−C(17) 113.2, C(10)−N(3)−C(17)−N(4) 7.1, N(3)−C(17)−N(4)−C(24) −149.2, C(17)−N(4)−C(24)−N(5) −153.5, N(4)−C(24)−N(5)−C(31) −164.4

strong interactions of the two chlorine atoms to the palladium center which could not be replaced by the nitrogen functionalities.[7] In the six-membered chelate ring of **2a** alternating C=N double bonds (1.29−1.30 Å) and C−N single bonds (1.38−1.41 Å) are found. This structural feature is typical for the free oligonitriles which form nonplanar solid-state structures with alternating bond lengths.[1][2] Similarly, UV/Vis spectra of oligonitriles including **1a** do not indicate long-range conjugation in solution. Much in contrast to this, the exocyclic oligonitrile chain (N3 to N5) of **2a** bears C−N bonds with almost equal bond lengths (1.32−1.33Å). This (*Z*,*E*,*E*)-configured part of **2a** does not deviate much from planarity as the torsional angles indicate (see Figure 1). Both observations indicate a strong conjugative donor−acceptor interaction of N5 (lone pair) and Pd^{II} coordinated to N3, similar to 2-azavinamidinium-type structures.[8] Unfortunately, interpretation of the UV/Vis spectra of this chromophore is difficult due to strong UV absorptions of Pd^{II}. These favorable electronic interactions as well as steric factors based on the bulky substituents at N4 may lead to the unexpected regioselectivity of the complexation reaction which does not involve the nitrogen atoms N2, N4 or N5 which present better donor groups than the acceptor-substituted N1.

The thiobenzoyl-substituted oligonitrile **1b** also forms a six-membered chelate **2a** on reaction with $PdCl_2(PhCN)_2$, but now the sulfur atom is involved in coordination to the palladium center (Figure 2). This is not unexpected in view of the high affinity of the soft Pd^{II} ion for S ligands. Again a square planar coordination geometry of the palladium center (sum of angles 360.0°) is observed. Due to the chiral (*R*)-fenchyl group, which was introduced enantiomerically pure into the molecule, a chiral space group is required for the crystallization of the substance. However, good adaption was achieved by calculating for the monoclinic space group $P2_1/c$ whereas refinement assuming chiral space groups was unsuccessful. Large U_{iso} values of fenchyl C atoms, which were refined isotropically, and high residual electron density around the fenchyl group may in part be a consequence of the structure solution in the achiral space group. Attempts to apply a split-atom model to the fenchyl group were unsuccessful; however, it is quite likely that (*E*/*Z*) isomers with regard to the N5−C29 bond of **2b** give rise to these difficulties. The C−N bond lengths alternate strongly in the chelate ring and − in contrast to **2a** − also in the uncomplexed part of the chain. This observation supports the postulated donor−acceptor interaction in **2a**, since the imine nitrogen atom N4 and the fenchyl group in **2b** do not have the donor properties of N5 in **2a**. All C=N double bonds show (*Z*) configuration as it is often found in the structures of oligonitriles.[2]

NMR Spectra

The ^{1}H-NMR spectra of complexes **2a** and **2b** at 25 °C in $CDCl_3$ display broad and poorly resolved signals for the phenyl protons and the piperidyl and fenchyl protons,

respectively, due to dynamic properties of the complexes. However, the presence of a single, sharp CO_2CH_3 signal of **2a** at $\delta = 3.8$ (0.3 ppm downfield relative to **1a** in $CDCl_3$[2]) indicates that the N1−N3 coordination in the solid state is retained in solution since metal coordination at N1 reduces the electron density of the ester group. Alternatively, magnetic anisotropy caused by sterically hindered phenyl groups may be responsible for this chemical shift. At −50 °C the phenyl and the alkyl signals of **2a** are much sharper but the CO_2CH_3 signal is very broad. We interpret this effect by a sterically hindered, slow rotation of the ester group around the C2−N1 bond. The ^{13}C-NMR spectrum of **2a** at both 20 °C and −50 °C supports the presence of a single isomer in $CDCl_3$ solution. No indications for a migration of the $PdCl_2$ unit along the chain could be detected in the temperature range used.

Experimental Section

Materials and Methods: Compounds **1a** and **1b** were prepared as previously described.[2][3] Commercially available solvents (p.a. quality) were used without further purification. − CHN analyses were performed with a DiaCHN 240 (Perkin−Elmer). − IR spectra were recorded with a Bruker FT-IR IFS 48 spectrophotometer as KBr pellets. − UV/Vis spectra were recorded using an HP 8453 diode array spectrophotometer (Hewlett-Packard). − ^{1}H- and ^{13}C-NMR spectra were obtained using a Bruker AC 200 and Varian Unity 600 spectrometer.

$PdCl_2$ Complex of *N*-Methoxycarbonyl-2,4,6,8-tetraphenyl-8-piperidino-1,3,5,7-tetraazaoctatetraene (2a): 27 mg (0.049 mmol) of **1a**[2] was treated at room temperature with 19 mg (0.049 mmol) of $(PhCN)_2PdCl_2$ in 1 mL of acetonitrile. After stirring for 10 min, a clear, orange solution was formed, which was treated with 1 mL of diethyl ether. Later, 10 mL of diethyl ether and 10 mL of pentane were added carefully in such a way that an upper layer was formed. After 5 d, red crystals of **2a** were collected [31 mg (0.042 mmol), 21% yield]. − UV/Vis($CDCl_3$): λ_{max} [nm] (ε) = 445 (100), 375 (shd), 300 (2900). − ^{1}H NMR(600 MHz, 298 K, $CDCl_3$): δ = 1.31 (br., 4 H, CH_2), 1.52 (br., 2 H, CH_2), 3.07 (br., 4 H, NCH_2), 3.80 (s, 3 H, OCH_3), 6.35, 6.85, 7.10, 7.35, 7.54 (br., phenyl-CH), 7.55, 7.63 (t, phenyl-CH), 7.80, 7.99 (s, br., phenyl-CH), 8.25 (br., phenyl-CH). − ^{13}C NMR(150.85 MHz, 298 K, $CDCl_3$): δ = 23.72, 24.78, 26.40 (CH_2), 49.76 (NCH_2), 54.71 (OCH_3), 128.19, 128.64, 128.89, 128.98, 130.42, 130.60 (CH), 131.69, 132.51 (C_i), 132.91, 133.24 (CH), 137.68 (C_i), 157.94, 162.54, 164.85, 166.76 (CN, CO). $-C_{35}H_{33}Cl_2N_5O_2Pd \cdot Et_2O$ (807.08): calcd. C 57.71 H 4.97 N 9.09; found C 57.26 H 5.13 N 9.02.

X-ray Diffraction Analysis of $2a \cdot Et_2O$ ($C_{35}H_{33}Cl_2N_5O_2Pd \cdot Et_2O$):[9] The red single crystals were analyzed with a Siemens P3 diffractometer using Mo-K_α radiation (λ = 0.71073 Å) and a graphite monochromator at 170(2) K. Crystal system: monoclinic, space group $P2_1/n$ with cell parameters a = 10.186(2), b = 22.633(5), c = 16.221(3) Å, β = 95.73(3)°, V = 3720.9(13) Å^3, $\rho_{calcd.}$ = 1.441 g cm^{-3}, Z = 4. Crystal size: 0.38 × 0.34 × 0.15 mm. 8573 reflections were collected leading to 8118 independent and 6422 observed [$I > 2\,\sigma(I)$] reflections. Absorption coefficient μ = 0.687 mm^{-1}, no absorption correction, 452 refined parameters. Non-hydrogen atoms were refined anisotropically. H atoms were geometrically positioned (riding model). $R(F)$ = 0.0417, $wR(F^2)$ = 0.0904; residual electron density: 0.551/−1.097 e Å^{-3}. The structure was solved and refined using SHELXS-86 and SHELXL-93.[10]

$PdCl_2$ Complex of 2,4,6,8-Tetraphenyl-8-(1,3,3-trimethylbicyclo-[2.2.1]hept-2-ylidene)amino-1-thia-1,3,5,7-octatetraene (2b): 24 mg (0.042 mmol) of **1b**[3] was suspended in 1 mL of acetonitrile and treated with a solution of 18.8 mg (0.049 mmol) of $(PhCN)_2PdCl_2$ in 2 mL of acetonitrile. After stirring for 5 min, a clear, deeply red solution has formed, from which after 30 min a red, powder-like solid precipitated. The solid was separated by filtration, washed with little acetonitrile and dried in vacuo. Yield: 17 mg (0.022 mmol; 53%). − IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3058 (w), 2962−2868 (w), 1734 (m), 1585 (m), 1560 (s), 1495 (s), 1478 (s), 1450 (s), 1345 (m), 1323 (m), 1309 (m), 1285 (m), 1267 (m), 1205 (m), 766 (m), 696 (m). − $C_{38}H_{36}Cl_2N_4PdS$(758.07): calcd. C 60.20 H 4.78 N 7.39; found C 59.04 H 5.06 N 7.68.

X-ray Diffraction Analysis of 2b ($C_{38}H_{36}Cl_2N_4PdS$):[9] The red single crystals were analyzed at 170(2) K with a Siemens P3 diffractometer using Mo-K_α radiation (λ = 0.71073 Å) and a graphite monochromator. Crystal system: monoclinic, space group $P2_1/c$ (see text) with cell parameters a = 11.244(2), b = 30.714(4), c = 11.562(2) Å, β = 118.42(3)°, V = 3511.7(10) Å^3, $\rho_{calcd.}$ = 1.434 g cm^{-3}, Z = 4; crystal size 0.12 × 0.20 × 0.38 mm). 8037 reflections were collected leading to 7657 independent and 5399 observed [$I > 2\,\sigma(I)$] reflections. Adsorption coefficient μ = 0.773 mm^{-1}, no absorption correction. 379 refined parameters. Non-hydrogen atoms were refined anisotropically with exception of the fenchyl C atoms which were refined isotropically. H atoms were geometrically positioned (riding model). $R(F)$ = 0.0594, $wR(F^2)$ = 0.1625; residual electron density: 2.072/−0.887 e Å^{-3}. The structure was solved and refined using SHELXS-97 and SHELXL-97.[10]

Acknowledgments

The authors thank Prof. Dr. B. Krebs for the use of a Siemens P3 diffractometer and Dr. R. Fröhlich for his valuable help with the X-ray diffraction analyses. We gratefully acknowledge financial support by the Deutsche Forschungsgemeinschaft (SFB 424) and by the Fonds der Chemischen Industrie. R. D. thanks the Fonds der Chemischen Industrie for a Ph. D. fellowship.

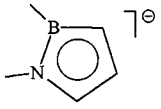
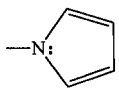
Synthesis, Structure and Reactivity of 3,4-Dihydro-2*H*-1,2,4,3-triazaboroles

Lothar Weber,*[a] Markus Schnieder,[a] Hans-Georg Stammler,[a] Beate Neumann,[a] and Wolfgang W. Schoeller[a]



Keywords: Boron / Triazaboroles / Heterocycles / Halogens / Cyanides

3,4-Dihydro-2,4-diphenyl-2*H*-1,2,4,3-triazaboroles **3a**, **3b**, and **4** were synthesized by cyclocondensation of N^1,N^3-diphenylformamidrazone (**1**) with dibromophenylborane, dibromomethylborane, and boron trichloride. 3-Chloro-3,4-dihydro-2,4-diphenyl-2*H*-1,2,4,3-triazaborole (**4**) was converted into 3,4-dihydro-2,4-diphenyl-2*H*-1,2,4,3-triazaborole (**5**) by treatment with $LiAlH_4$. The corresponding 3-cyanato and 3-cyano derivatives **6** and **7** resulted from the reaction of **4** with AgOCN and AgCN, respectively. Compound **7** was transformed into the bis(1,2,4,3-triazaborolyl)oxane **8** by silver oxide. Compounds **1–8** were characterized by elemental analyses and spectroscopic methods (^{1}H, ^{11}B, and ^{13}C NMR; IR; MS). The molecular structure of **8** was established by single-crystal X-ray diffraction analysis.



Replacing a pair of adjacent carbon atoms in the cyclopentadienide anion **I** by the isoelectronic B−N combination affords the dihydro-1,2-azaborolyl anion **II**. With pyrrol **III** and imidazole **V** the same formalism leads to 2,3-dihydro-1*H*-1,3,2-diazaboroles **IV** and 3,4-dihydro-2*H*-1,2,4,3-triazaboroles **VI**, respectively.

Whereas the chemistry of 1,2-azaborolyl anions **II** has been thoroughly studied, especially with respect to its ligating properties,[1][2] and a series of papers has dealt with 1,3,2-diazaboroles **IV**,[3][4] information on 3,4-dihydro-2*H*-1,2,4,3-triazaboroles is scarce. 3,4-Dihydro-2,3,4,5-tetraphenyl-2*H*-1,2,4,3-triazaborole was formed in 5% yield during the cothermolysis of the pyridine adduct of diphenylboron azide and 2,5-diphenyltetrazole at 210°C.[5] In a brief communication the preparation of eight 1,2,4,3-triazaboroles **VI** by cyclocondensation of amidrazones $R^2C(NHR^1)=NNHR^3$ with boronic acid derivatives R^4BX_2 (X = Cl, OMe, OEt, OH, NMe_2) was reported.[6] Similarly, four bis(1,2,4,3-triazaborole)s **VII** were obtained from $PhB(OH)_2$ or $BuB(OH)_2$ and oxamidrazones.[7] No spectroscopic details were given for **VI** and **VII**.

Bezuglaya et al. were concerned with IR,[8] mass[9], electronic absorption,[10] and X-ray photoelectron spectra,[11] as well as electrochemical studies,[12] acylation[13] and protonation reactions on 2,3,5-triaryl-1,2,4,3-triazaboroles[14] in which the aryl rings were *para*-substituted phenyl groups. Theoretical studies on the 2,3,5-triphenyl derivative as well as the UV spectra are not in accordance with heteroaromaticity.[10] Interestingly, in all the described 1,2,4,3-triazaboroles no other substitutents than phenyl (or *para*-substituted phenyl) rings and the *n*-butyl group are ligated to the boron atom.

We decided to investigate the chemistry of this ring system in more detail and from our experience with 2-halo-1,3,2-diazaboroles first envisaged the synthesis of 3-halo-1,2,4,3-triazaboroles. For synthetic and spectroscopic reasons the carbon atom of the ring should bear a hydrogen atom.

Results and Discussions

For the preparation of 3-halo-1,2,4,3-triazaboroles and derivatives thereof it was necessary to explore the experimental conditions in more detail and, moreover, provide

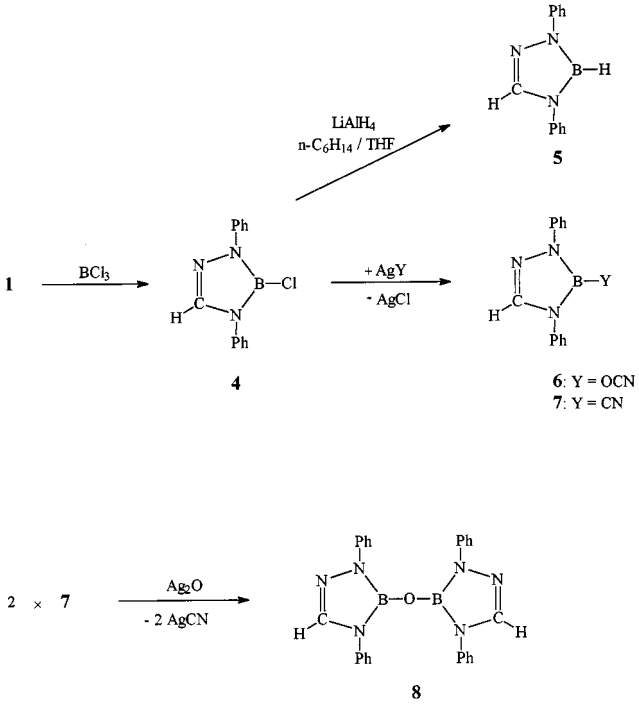
the NMR data that was lacking for some of the known species.

Combination of equimolar amounts of $PhBBr_2$ with formamidrazone **1** in toluene at 80°C for 1 h did not lead to the ring system **3a** as indicated in ref.[6] Instead the acyclic bromo(hydrazino)phenylborane derivative **2a/2a′** was obtained as a colorless crystalline solid (62% yield). Similarly, the bromo(hydrazino)methylborane derivative **2b/2b′** resulted from the reaction of **1** with $MeBBr_2$ in toluene at 80°C (52%). The air- and moisture-sensitive compounds display singlets at δ = 28.9 and 29.1 in the $^{11}B\{^1H\}$-NMR spectra. The amidine hydrogen atoms in the ^1H-NMR spectra of **2a/2a′** and **2b/2b′** give rise to singlets at δ = 8.93 and 9.03. In the $^{13}C\{^1H\}$-NMR spectrum the corresponding carbon atoms of **2a/2a′** and **2b/2b′** were observed as singlets at δ = 141.3 and 140.8. Basicly, the boryl group can be attached to the hydrazino group as indicated in **2a** and **2b** or alternatively to the anilino function as shown in **2a′** and **2b′**. No unambigious differentation between the two isomers was possible only by means of the spectroscopic data. Unfortunately, crystals of **2a/2a′** or **2b/2b′** suitable for an X-ray analysis were not available.



Cyclization of **2a/2a′** and **2b/2b′** to **3a** and **3b**, respectively, was effected by dehydrobromination with triethylamine. Alternatively the heterocycles were directly obtained by cyclocondensation of **1** with equimolar amounts of $PhBBr_2$ or $MeBBr_2$ in boiling toluene. By this method improved yields (74 and 69%) were achieved. In a control experiment the cyclization also occurred by heating a toluene solution of **2a/2a′** to 110°C.

Scheme 1

Heating a toluene solution of boron trichloride with a threefold excess of **1** at 90°C for 2.5 h led to the formation of the 3-chloro-1,2,4,3-triazaborole **4**, which was isolated as a colorless, extremely moisture-sensitive solid in 63% yield. This compound proved to be a valuable starting material for a series of other 1,2,4,3-triazaborole derivatives. Thus, formation of **3b** from **4** and an equimolar amount of methyllithium cleanly occurred in 83% yield.

Lithium aluminium hydride reduction of **4** in an *n*-hexane/THF mixture afforded the colorless crystalline 3-hydro-substituted 1,2,4,3-triazaborole **5** (84%). Treatment of **4** with equimolar amounts of silver cyanate or silver cyanide in acetonitrile in the absence of light smoothly generated the compounds **6** and **7** in 68% and 63% yield. Like **4** both products are extremely moisture-sensitive colorless solids. Their great propensity for hydrolysis is evident from impurities, revealed as bis(1,2,4,3-triazaborolyl)oxane (**8**) (δ ^{11}B = 20.5). A clean high-yield synthesis of **8** made use of the reaction of 3-cyano derivative **7** with silver oxide in acetonitrile (Scheme 2).

Scheme 2

The $^{11}B\{^1H\}$-NMR spectra of the triazaboroles described here display an increased shielding as follows: **3b** (δ = 27.8) > **3a** (26.4) > **4** (22.8) > **5** (21.5) > **8** (20.5) > **6** (17.1) > **7** (13.9). A comparable order was observed with the corresponding *N*-arylated 1,3-diazaboroles. Thus, in $PhN^a-C(Me)=C(Me)N^b(Ph)B-Me(N^a-B)$,[15] $XylN^aC(H)=C(H)-N^b(Xyl)BCl(N^a-B)$,[4a] $XylN^a-C(H)=C(H)-N^b(Xyl)BH(N^a-B)$, and $XylN^aC(H)=C(H)-N^b(Xyl)BCN(N^a-B)$ (Xyl = 2,6-$Me_2C_6H_3$) ^{11}B-NMR signals were recorded at δ = 28.0,[15] 21.1,[4a] 21.9,[4c] and 13.5[4a]. In the proton-coupled ^{11}B-NMR spectrum of **5** a doublet ($^1J_{B-H}$ = 162.5 Hz) was observed. The corresponding doublet in the diazaborole $tBuN^a-CH=CH-N^b(tBu)BH(N^a-B)$ at δ = 21.9 showed a coupling constant $^1J_{B-H}$ = 158 Hz.[4c] In the ^1H-NMR spectra of **3a,b–8** the CH protons of the heterocycle were observed as singlets at δ = 7.33–7.87. In the $^{13}C\{^1H\}$-NMR spectra the corresponding ^{13}C atoms gave rise to singlets at δ = 138.39–141.03. Interestingly, in the ^1H-NMR spectrum of **5** a broad 1:1:1:1 quadruplet at δ = 5.39 ($^1J_{B-H}$ = 158 Hz) appeared for the proton at the boron atom. In *t*BuN-

$^{a}C(H)=C(H)N^{b}(tBu)BH(N^{a}-B)$ a quadruplet at $\delta = 4.78$ ($^{1}J_{B-H} = 150$ Hz) was attributed to this proton.[4c]

The IR spectrum of **5** displayed a week, sharp band at $\tilde{\nu} = 2645$ cm^{-1} for the BH stretching vibration. A weak band at $\tilde{\nu} = 2224$ cm^{-1} in the IR spectrum of **7** was assigned to the stretching mode of the cyano group. The antisymmetric NCO vibration gave rise to a strong band at $\tilde{\nu} = 2309$ cm^{-1} in the IR spectrum of **6**. In isocyanato boranes of the type $(R_2N)_2BNCO$ intense bands for ν_{as}(NCO) were measured in the range $\tilde{\nu} = 2290 \pm 15$ cm^{-1}.[16]

X-ray Structural Analysis of 8

In the crystal, molecule **8** (Figure 1) has an overall similarity to the bent twisted structures of the bis(1,2,3-diazaborolyl)oxane **9**[4b] and tetramesityldiboroxane,[17] which display B−O−B angles of 157.1(3)° and 165.5(12)°, respectively. In **8**, however, the valence angle at the oxygen atom is more compressed [133.6(3)°]. Both BCN_3 rings in **8** are planar, enclosing an interplanar angle $\Psi = 66.0°$. Due to the bulky *tert*-butyl group in **9** the diazaborole rings in **9** are mutually orthogonal.

Figure 1. 10

11

The respective bond lengths and bond angles within both 1,2,4,3-triazaborole units of **8** are identical within experimental error. The B−N distances [av. 1.429(5) Å] fall in the range of 1.407(3) to 1.450(7) Å measured for B−N bond lengths in a series of 1,3,2-diazaboroles and indicate multiple bond character. The endocyclic bond lengths N(1)−C(1) [1.377(4) Å] and N(4)−C(14) [1.379(4) Å] are significantly shorter than the exocyclic N−C (sp^2) bonds [av. 1.421(4) Å]. Within experimental error they are comparable to the N(Ph)−C(Ph) distances in 4,5-dihydro-1,3,4-triphenyl-1*H*-1,2,4-triazole-5-ylidene (**10**) [1.391(2) Å] and 4,5-dihydro-5-methoxy-1,3,4-triphenyl-1*H*-1,2,4-triazole (**11**) [1.391(6) Å].[18] The endocyclic bonds N(3)−C(1) [1.283(4) Å] and N(6)−C(14) [1.294(4) Å] are also close to those in **10** [1.304(3) Å] and **11** [1.296(6) Å], and are thus not significantly elongated relative to the calculated C=N bond length in formaldehyde imine [1.283 Å][18] or the experimentally determined C=N bond length in formaldehyde oxime [1.276 Å].[19] The interatomic distance N(2)−N(3) in **8** [1.409(4) C] is similar to the N−N bond length in **11** [1.394(6)] C,[18] and has to be regarded as a localized single bond.

The endocyclic angles B(1)−N(2)−N(3) [109.8(3)°] and B(2)−N(5)−N(6) [110.0(3)°] in **8** are more obtuse than the endocyclic angles B(1)−N(1)−C(1) [105.1(3)°] and B(2)−N(4)−C(14) [105.1(3)°]. The latter values compare well with the corresponding angles B−N−C in **9** [105.7(3)−106.5(2)°]. The angles at the endocyclic carbon atoms in **9** [110.3(3)−110.5(3)°] are markedly compressed relative to the endocyclic angles at C(1) [115.8(3)°] and C(14) [115.8(3)°] in **8**. The angles at the dicoordinate ring nitrogen atoms N(3) and N(6) are 105.2(3) and 105.1(3)°. In conclusion, the structural parameters of **8** provided by the X-ray analysis give no support for a 6π-electron delocalization within the 1,2,4,3-triazaborole ring as claimed in ref.[6]

In order to analyze this aspect in more detail we performed quantum-chemical ab initio calculations[20] at RHF/6-31g* and density functional level (B3LYP/6-31g*)[21] on **8** and its parent compound without the phenyl groups. Corresponding Molden plots[22] of the computed equilibrium geometries are given in Figure 2.

In the parent compound the two five-membered ring units are twisted (torsion angle N−B−O−B 23.2°). The RHF and density functional calculations yield almost similar bond lengths within the ring geometries. The structure of the diborolyloxane changes markedly on the introduction of the four phenyl substituents. It adopts an equilibrium structure which is in perfect agreement with the results of the X-ray investigations (torsion angle N−B−O−B 45.0°). Consequently, the actual structure of **8** is largely determined by the steric demand of the phenyl groups. Since from the computed structure it is not clear how the π bonds are delocalized in the heterocyclic units, we performed population analyses at the given equilibrium geometries, utilizing the natural bond orbital scheme.[23] The results of these investigations will not be recorded here in detail. However, an inspection of the corresponding Wiberg bond

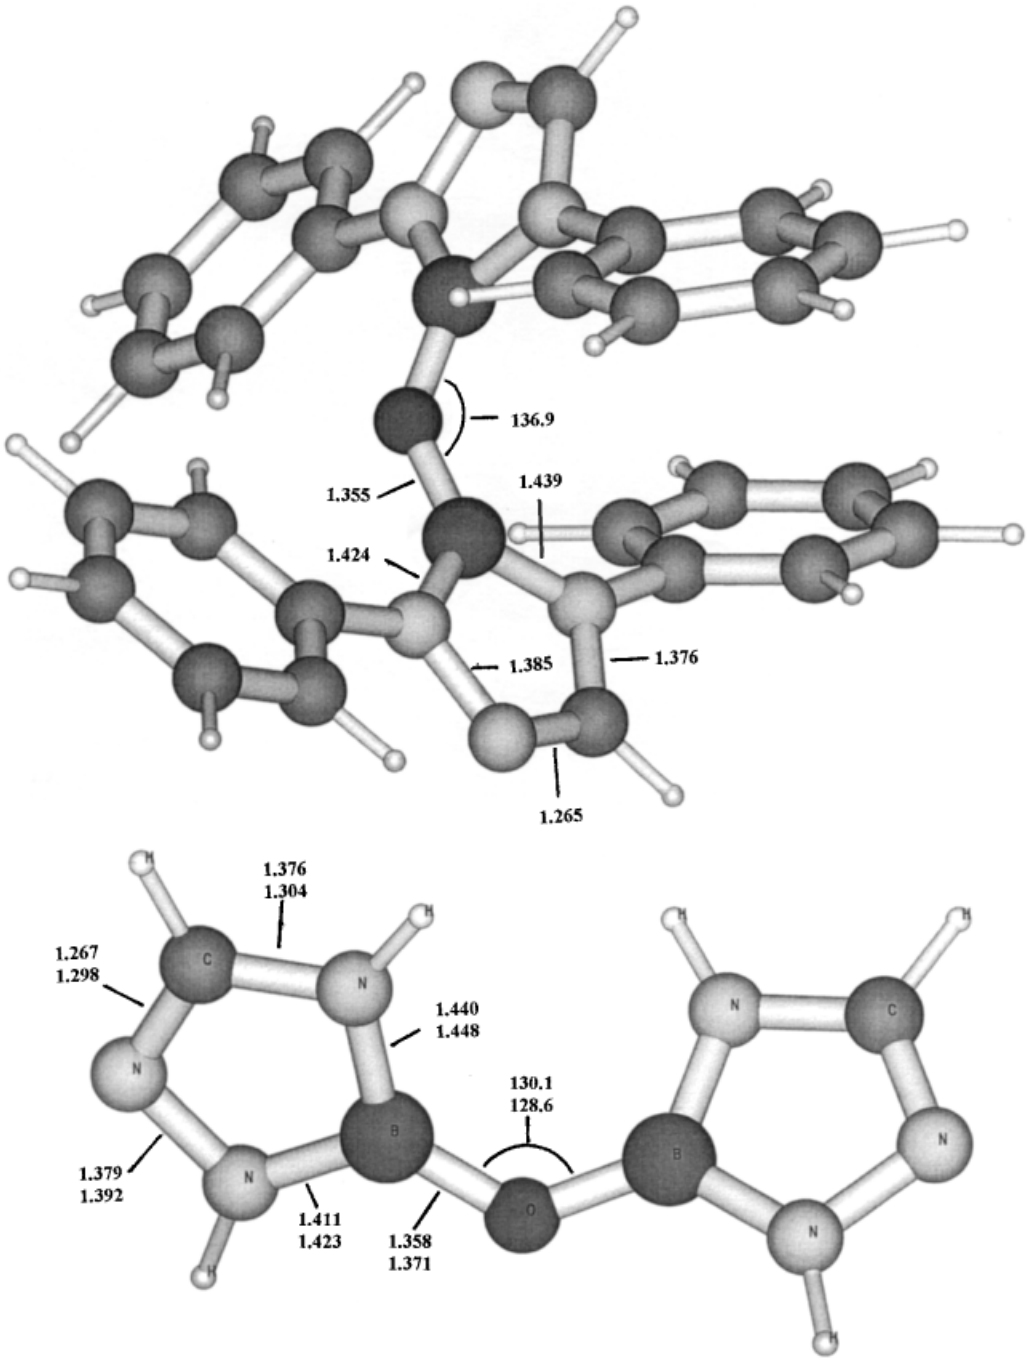

Figure 2. Computed equilibrium structures of 8 (A) and parent compound (B) (bond lengths in Å) at RHF/6-31g* (top) and B3LYP/6-31g* (bottom) level.

indices[23] indicates that the π bonds in the five-membered rings are essentially localized. In other words these results do not indicate significant π delocalization in **8**. These considerations are equally true for all computed structures and agree with the results reported in ref.[10]

Experimental Section

General: All manipulations were performed under dry argon. Solvents were rigorously dried with an appropriate drying agent and distilled before use. The following compounds were prepared as described in the literature: ethyl *N*-phenylformimidate,[24] dibromophenylborane,[25] dibromomethylborane.[25] Boron trichloride, boron tribromide, tetraphenylstannane, tetramethylstannane, lithium aluminium hydride, phenylhydrazine, silver cyanide, silver cyanate, and silver oxide were purchased commercially. − IR spectra: Bruker FT IR IFS66. − ^{1}H-, ^{11}B-, and ^{13}C-NMR spectra: Bruker AC 100 (^{1}H, 100.13 MHz) and Bruker Avance DRX 500 (^{1}H, 500.13 MHz; ^{11}B, 160.46 MHz; ^{13}C, 125.75 MHz); references: $SiMe_4$ (^{1}H, ^{13}C), $BF_3 \cdot OEt_2$ (^{11}B). − Mass spectra (EI): VG Autospec sector-field mass spectrometer (Micromass) 70 eV.

***N*^{1},*N*^{3}-Diphenylformamidrazone (1):** A mixture of ethyl *N*-phenylformimidate (10.0 g, 67.0 mmol) and phenylhydrazine (7.24 g,

67.0 mmol) in ethanol (20 mL) was stirred at 20°C for 16 h. The resulting viscous red solution was layered with *n*-pentane (50 mL) and stored overnight at −18°C. Orange crystals were collected by filtration and washed with *n*-pentane (2 × 50 mL) to afford 12.81 g (90%) of **1**. − ^{1}H NMR (CD_3OD): δ = 6.74 (t, J_{H-H} = 7.3 Hz, 1 H, C_6H_5), 6.96 (m, 3 H, C_6H_5), 7.05 (d, J_{H-H} = 8.0 Hz, 2 H, C_6H_5), 7.17 (t, J_{H-H} = 7.32 Hz, 2 H, C_6H_5), 7.28 (t, J_{H-H} = 7.6 Hz, 3 H, C_6H_5 and HC=N). − $^{13}C\{^1H\}$ NMR (CD_3OD): δ = 114.24, 116.42, 120.15, 122.95, 129.91, 130.60, 136.71, 142.17 (C-phenyl), 148.76 (HC=N). − MS/EI (70 eV); *m/z* (%): 212 (65) [M^+ + H], 119 (10) [M^+ − HNPh], 91 (100) [PhN]. − $C_{13}H_{13}N_3$ (211.24): calcd: C 73.98, H 6.18, N 19.83; found C 73.60, H 6.14, N 19.98.

PhN(H)C(H)=N−N(Ph)B(Br)Ph (2a) or PhN(BBrPh)C(H)=N−N-(H)Ph (2a′): A solution of dibromophenylborane (5.21 g, 21.0 mmol) in 30 mL of toluene was added dropwise to a chilled toluene solution (100 mL, 0°C) of **1** (4.44 g, 21.0 mmol). After warming to room temp., the mixture was heated at 80°C for 1 h. Cooling to 20°C led to the separation of an ocher precipitate. Volatile compounds were removed in vacuo, and the tan solid residue was dissolved in 200 mL of CH_2Cl_2. It was filtered and the filtrate was concentrated to 50 mL. Storing at 4°C for 16 h afforded 4.92 g (62%) of colorless crystalline **2a**. − ^{1}H NMR (CD_2Cl_2): δ = 7.26−7.51 (m, 15 H, Ph), 8.93 (s, 1 H, HC=N). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 124.87, 125.23, 128.56, 128.83, 129.13, 129.82, 130.16, 130.99, 134.44, 136.45, 136.61 (C-phenyl), 141.28 (HC=N). − $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 28.9.

PhN(H)C(H)=NN(Ph)B(Br)(Me) (2b) or PhN(BBrMe)C(H)=N−N-(H)Ph (2b′): Analogously, the combination of dibromomethylborane (3.34 g, 18.0 mmol) and 3.80 g (18.0 mmol) of **1** in 130 mL of toluene gave 4.32 g (52%) of colorless crystalline **2b**. − ^{1}H NMR (CD_2Cl_2): δ = 0.85 (s, 3 H, CH_3), 7.10−7.52 (m, 10 H, C_6H_5), 9.03 (s, 1 H, HC=N). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 123.28, 124.35, 127.91, 128.61, 129.67, 130.04, 136.42, 136.74 (C-phenyl), 140.77 (HC=N). − $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 29.1. − $C_{14}H_{15}BBrN_5$ (316.01): calcd: C 53.21, H 4.78, N 13.30; found C 53.14, H 4.89, N 13.38.

PhN^a−N=C(H)−N(Ph)BPh(*N*^{a}−*B*) (3a): A solution of 4.13 g (16.6 mmol) of dibromophenylborane in toluene (30 mL) was added dropwise at 0°C to a stirred solution of 3.52 g (16.6 mmol) of **1** in toluene (100 mL). After warming to room temp., the mixture was refluxed for 3 h. Cooling to ambient temp. was accompanied by the formation of an ocher precipitate. Solvent and all volatile components were removed at 10^{-2} Torr. The red-brown residue was dissolved in CH_2Cl_2 (100 mL) and filtered. The ocher filtrate was concentrated to 50 mL and stored for 16 h at −18°C to afford 3.65 g (74%) of colorless crystals. − ^{1}H NMR (CD_2Cl_2): δ = 7.13−7.40 (m, 15 H, C_6H_5), 7.74 (s, 1 H, HC=N). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 121.83, 124.63, 124.85, 126.56, 128.63, 129.01, 129.28, 129.58, 134.17, 139.69 (C-phenyl), 141.03 (HC=N), 143.76 (C-phenyl). − $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 26.4. − MS/EI; *m/z*: 297 (100) [M^+]. − $C_{19}H_{16}BN_3$(297.15): calcd. C 76.79, H 5.42, N 14.14; found C 74.83, H 5.35, N 12.40.

PhN^{a}N=C(H)−N(Ph)BMe(*N*^{a}−*B*) (3b). − Path 1: A solution of 2.49 g (13.4 mmol) of dibromomethylborane in 30 mL of toluene was added dropwise at 0°C to a solution of 2.83 g (13.4 mmol) of **1** in 50 mL of toluene and allowed to warm to 20°C with stirring. Then the mixture was heated at reflux for 2 h. Solvent and volatiles were removed in vacuo to yield a red-brown residue. The residue was dissolved in 20 mL of CH_2Cl_2 and filtered. The violet filtrate was stored overnight at −18°C to afford 2.16 g (69%) of colorless crystalline **3b**. − **Path 2:** A solution of triethylamine (0.55 g, 5.43 mmol) in 10 mL of toluene was added dropwise to the solution of **2b/2b′** (2.50 g, 5.43 mmol) in 30 mL of toluene at room temp. After 1 h of stirring, the mixture was concentrated to dryness and the light brown residue was extracted with 50 mL of *n*-pentane and filtered. The filtrate was concentrated to dryness to afford 0.83 g of **3b**. − **Path 3:** An *n*-hexane solution made of 0.75 mL of 1.6 M ethereal methyllithium solution (1.20 mmol) in 30 mL of *n*-hexane was added dropwise to a chilled solution (−20°C) of **4** (0.30 g, 1.17 mmol) in 150 mL of *n*-hexane. It was slowly warmed to room temp. Precipitated LiCl was removed by filtration. The filtrate was concentrated to 50 mL and stored overnight at −18°C to give 0.23 g (83%) of **3b**. − ^{1}H NMR (CD_2Cl_2): δ = 0.87 (s, 3 H, CH_3), 7.16 (t, J_{H-H} = 7.5 Hz, 1 H, *p*-C_6H_5), 7.29 (m, 2 H, C_6H_5), 7.31 (t, J_{H-H} = 7.6 Hz, 1 H, *p*-C_6H_5), 7.39 (t, J_{H-H} = 7.8 Hz, 2 H, C_6H_5), 7.46 (t, J_{H-H} = 7.8 Hz, 2 H, C_6H_5), 7.50 (d, J_{H-H} = 7.5 Hz, 2 H, C_6H_5), 7.63 (s, 1 H, CH=N). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 120.69, 123.95, 124.29, 126.33, 129.24, 129.81, 140.05 (C-phenyl), 140.46 (CH=N), 144.28 (C-phenyl). − $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 27.8. − MS/EI; *m/z* (%): 235 (100) [M^+]. − $C_{14}H_{14}BN_3$ (235.13): calcd. C 71.45, H 6.00, N 17.87; found C 71.11, H 6.01, N 17.55.

PhN^a−N=C(H)−N(Ph)BCl(*N*^{a}−*B*) (4): A chilled solution (−30°C) of boron trichloride (1.76 g, 15.0 mmol) in toluene (30 mL) was added dropwise within 2 h to a chilled suspension (−35°C) of **1** (5.44 g, 40 mL) in toluene (160 mL). The mixture was allowed to warm to room temp., and then was stirred for 2.5 h at 90°C. The resulting suspension was cooled to 20°C and filtered. The filtrate was concentrated to dryness. The residue was extracted with *n*-hexane (100 mL) during the course of 4 h. Removal of solvent from the extract yielded 2.15 g (63%) of **4** as a colorless solid. − ^{1}H NMR (CD_2Cl_2): δ = 7.22 (t, J_{H-H} = 7.5 Hz, 1 H, *p*-C_6H_5), 7.36−7.49 (m, 7 H, C_6H_5), 7.71 (d, J_{H-H} = 7.3 Hz, 2 H, *o*-C_6H_5), 7.72 (s, 1 H, HC=N). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 120.74, 123.89, 125.28, 127.15, 129.29, 129.89, 138.08 (C-phenyl), 140.53 (HC=N), 142.31 (C-phenyl). − $^{11}B\{^1H\}$ NMR (CD_2Cl_2): δ = 22.8. − MS/EI; *m/z* (%): 255 (100) [M^+]. − $C_{13}H_{11}BClN_3$ (255.07): calcd. Platination of the Exocyclic Amino Group of the Adenine Nucleobase by Pt^{II} Migration

Jorma Arpalahti*[a] and Karel D. Klika[a]

Keywords: Metal migration / NMR spectroscopy / Nucleobases / Platinum / Structure elucidation

Migration of coordinated Pt^{II} from the endocyclic N(1) site to the exocyclic nitrogen atom in 9-methyladenine occurs at high pH values. The resulting N(6)-platinated complex has been characterized by X-ray crystal structure analysis and by ^{1}H- and ^{195}Pt-NMR spectroscopy. The ^{1}H-NMR spectra show that the Pt^{II}(dien) unit at N(6) can adopt either a *syn* or an *anti* conformation with respect to the N(1) site, and that protonation of the ring nitrogen atoms N(1) and/or N(7) perturbs the *syn*/*anti* equilibrium.

The ability of Pt^{II} to form kinetically inert complexes with the base residues in DNA is crucial for the biological activity of various platinum anticancer drugs.[1][2] Although different Pt^{II} compounds show a clear preference for the guanine N(7) site followed by the adenine N(7) atom,[3] coordination to other sites cannot be excluded when assessing the active binding mode of Pt drugs. For example, the selectivity of the N(7) site most probably results from kinetic factors, since in 9-substituted purine nucleobases the Pt−N(1) bond seems to be thermodynamically more stable than the Pt−N(7) bond.[4] Because of the differing basicities of the purine nitrogen atoms, the distribution of Pt^{II} between the N(1) and N(7) sites can be affected by (de)protonation of the purine nucleobases.[3][5] When coordination to these sites is hindered, Pt^{II} binding to N(3) may be observed,[5][6] but only in very rare cases is platination of the exocyclic amino or oxo groups of 9-substituted purines observed.[5] For example, coordination of Pt^{II} to C(6)−NH_2 in adenosine and 2′-deoxyadenosine has been proposed with 4-picoline(2,2′:6,2′′-terpyridine)platinum(II), but only *after* the initial N(1) platination.[7] There are also a few reported cases of structurally characterized complexes exhibiting N(6) binding mode with other metal ions.[8] Hence, in the search for unusual Pt^{II} binding patterns we report here the preparation, X-ray crystal structure determination, and NMR-spectroscopic characterization of the model nucleobase 9-methyladenine (9-made) bearing a Pt^{II}(dien) unit (dien = diethylenetriamine) at N(6).

In general, metal-ion binding to the exocyclic amino group of the adenine moiety requires proton abstraction from the NH_2 group and it is the high pK_a value (ca. 17) of the NH_2 group which makes direct complexation at this site very difficult.[5][8] However, it is known that coordination of electrophilic Pt^{II} to the adenine N(1) and N(7) sites lowers the pK_a value of the exocyclic NH_2 group by ca. 4 log units.[5] In addition, the N(6) atom seems to be spatially quite close to Pt^{II} in N(1)-platinated adenine derivatives.[4b] These considerations prompted us to employ an indirect strategy to accomplish Pt^{II} binding to the N(6) site, i.e. via the N(1)-platinated species. Although the reaction of aquated Pt^{II}(dien) with an excess of 9-made initially gives the N(1)-bound complex as the minor species, a slow N(7) → N(1) isomerization takes place at elevated temperatures analogous to that found earlier with adenosine.[4b] The employment of [Pt(dien)(9-made-*N*1)]$(ClO_4)_2$ (**1**) as the starting material enables the facile preparation of the N(6)-platinated species, [Pt(dien)(9-made-*N*6)]$(ClO_4)_2$ (**2**), in strongly basic solution.

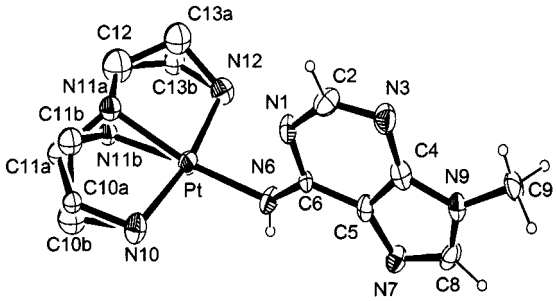

Figure 1. Structure of the cation of [Pt(dien)(9-made-*N*6)]$(ClO_4)_2$; selected interatomic distances [Å] and angles [°] with estimated deviations in parentheses: Pt−N(6) 2.010(18), Pt−N(10) 2.079(17), Pt−N(11a) 2.09(4), Pt−N(11b) 2.04(3), Pt−N(12) 2.081(18), N(6)−C(6) 1.30(3), N(6)−Pt−N(11a) 167.0(14), N(6)−Pt−N(11b) 171.5(12), N(6)−Pt−N(10) 98.8(8), N(6)−Pt−N(12) 92.8(8), N(10)−Pt−N(12) 168.3(6), C(6)−N(6)−Pt 128.9(13)

The X-ray crystal structure of **2** confirms Pt^{II} binding to the deprotonated amino group (Figure 1).[9] Comparison with **1** reveals that the N(1) → N(6) migration of Pt^{II} does not substantially change the nucleobase geometry. Since **2** was isolated at pH = 6, the nucleobase moiety of the dication is expected to bear a proton.[10] Unfortunately, unambiguous assignment of the protonation site was not forthcoming from the X-ray data. Although all the ring nitrogen atoms N(1), N(3), and N(7) display nonbonded contacts, only the N(1) site seems to act as a donor [N(1)···O(13a) 2.83(6) Å, N(1)···O(14b) 3.16(4) Å].[11] It is worth noting that the distance of 3.96 Å between N(1) and N(12) does not indicate an intramolecular H bond in *dicationic* **2**, even

though this interaction may be present in the *syn* conformer of deprotonated **2** (vide infra). These findings suggest that it is the N(1) site that bears the required proton, as was also observed in the N(6)-bound Hg^{II} complex.[8b] In fact, both dicationic **2** and the Hg^{II} complex[8b] represent a metalated form of the rare imino tautomer of the adenine nucleobase. However, the internal ring angle C(2)−N(1)−C(6) does not unambiguously verify N(1) as the protonation site[8b] since the value of 122.8(16)° found for **2** has only increased by 2.2σ[12] from that in free 9-made,[13] viz. 118.7(1)°. For comparison, in the N(6)-bound Hg^{II} complex the C(2)−N(1)−C(6) angle [126(1)°] increases by 7.3σ upon N(1) protonation.[8b]

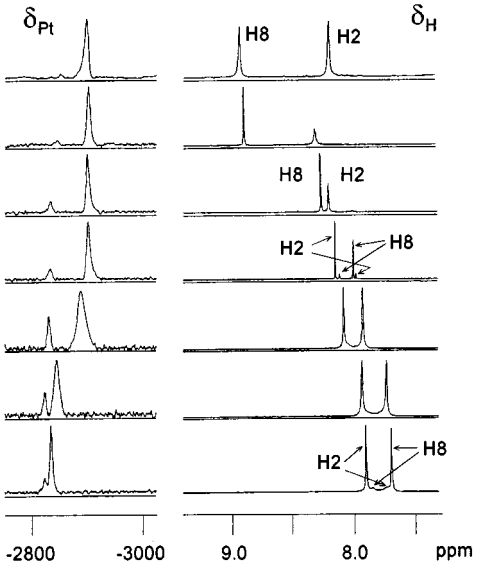

Figure 2. Sections of the ^{195}Pt- and ^{1}H-NMR spectra of **2** in D_2O/water solutions at different pH values (from bottom to top: 12.6, 8.5, 7.4, 6.0, 1.4, 0.6, ca. 0); the assignments of H(2) and H(8) are based on long-range C−H correlations (major conformer) and exchange correlations (minor conformer)

Both, ^{195}Pt- and ^{1}H-NMR spectra show pH-dependent dynamic processes for **2** (Figure 2),[14] which may be attributed predominantly to the restricted rotation about the C(6)−N(6) bond.[4b] Thus, the Pt^{II}(dien) unit may adopt either a *syn* or an *anti* orientation with respect to the N(1) site.[8b] In the deprotonated (monocationic) **2**, the major *syn* conformation is concomitant with an apparent H bond formed between dien−NH_2 and the N(1) site bearing a (partial) negative charge resulting in a stronger deshielding of H(2) relative to H(8). In the minor *anti* conformer, the reversal of the H(2) and H(8) chemical shifts may be attributed to H-bond formation between dien−NH_2 and the N(7) site. With decreasing pH value all of the ^{1}H signals shift downfield suggestive of an effect from both protonation and a shift in the conformational equilibrium. In the formation of dicationic **2**, N(1) protonation in the major species eliminates the H bonding from dien−NH_2 to N(1) and may cause a shift in the *syn* ⇌ *anti* equilibrium. As a consequence, both H(2) and H(8) are shifted downfield in the major species, the former due to protonation and the latter due to H bonding. Because two sets of aromatic protons are again detected for dicationic **2**, also with a reverse of the order of H(2) and H(8) chemical shifts in the minor conformer, there seems to be, in addition to the restricted rotation about the C(6)−N(6) bond, also a concomitant prototropic tautomeric equilibrium in effect between N(1) and N(7). The larger downfield shift of H(8) over H(2) in the minor species of the dicationic **2** suggests that in this case it is the N(7) site which is protonated with the Pt^{II}-(dien) unit in the *syn* conformation. This is implied by the comparable chemical shifts for H(2) in the monocationic, major species and in the dicationic, minor species, where in both cases H bonding can be in effect between dien−NH_2 and the N(1) site, and for H(8) in the monocationic, minor species and in the dicationic, major species where similarly in both cases H bonding can be in effect between dien−NH_2 and the N(7) site. Unfortunately, we were unable to independently confirm the proposed conformations. Further acidification down to pH < 0 results in a marked downfield shift only for H(8) suggesting that the second protonation occurs predominantly at N(7). Although the *syn* and *anti* conformers are no longer resolvable in the aromatic protons, the two species remain discernible in the ^{195}Pt-NMR spectra.

Two mechanistic explanations may be given for the adenine N(1) → N(6) isomerization, both of which require deprotonation of the C(6)−NH_2 group. First, the migration of Pt may be analogous to the Dimroth rearrangement, in which an alkyl group migrates from a heterocyclic nitrogen atom to an α-amino or α-imino group.[15] Alternatively, the imino group at C6 may directly attack Pt^{II} in the starting compound resulting in a 5-coordinate intermediate, where cleavage of the expectedly weaker Pt−N(1) bond gives the N(6)-bound species. It is worth noting that in **1** the distance between N(6) and Pt^{II} is 3.19(1) Å, very similar to that found in the corresponding adenosine complex, viz. 3.25 Å (unit A) and 3.16 Å (unit B).[4b] At this stage both explanations are feasible, although the proposed simultaneous binding of Pt to the endocyclic and exocyclic N atoms in pyrimidine complexes[16] lends support to the latter explanation. We note, however, that the bond rearrangement in the adenine moiety must still be mechanistically different from that in the pyrimidine complex, since the latter occurs in acidic solution via Pt^{IV}, while the adenine N(1) → N(6) migration proceeds in strongly basic solution without any detectable redox reaction

Experimental Section

[Pt(dien)(9-made-*N*1)](ClO$_4$)$_2$ (1): A mixture of aquated Pt^{II}(dien) {1.0 mmol, prepared by treating [PtI(dien)]I with 1.9 equiv. of $AgClO_4$[17]} and 9-made[18] (2.0 mmol) in 15 mL of water was stirred for 7 d at 75−85°C. According to HPLC analysis the initial N(1)/N(7) ratio of 2:3 increased to 2:1 during this treatment. After concentration to ca. 5 mL, the pH of the solution was adjusted to 1.5 using 1.0 M $HClO_4$. The addition of $NaClO_4$ (4 mmol) afforded 460 mg of crystalline product. Recrystallization from 0.1 M $HClO_4$ gave clear prisms of [Pt(dien)(9-made-*N*1)](ClO$_4$)$_2$ (**1**). Based on HPLC analysis, the product was analytically pure. The crystals were washed with cold water and air-dried; yield 220 mg (45% from

Pt). The N(1)-binding mode in **1** was confirmed by X-ray crystal structure analysis.[19][20]

[Pt(dien)(9-made-*N*6)](ClO$_4$)$_2$ (2): For the preparation of **2**, 71 mg (0.11 mmol) of **1** was dissolved in 5 mL of 0.1 M NaOH. The solution (pH = 12.8) was stirred for 3 h at 60−65°C after which the pH value was adjusted to 6.5 by using 1 M $HClO_4$. The solution was concentrated to ca. 0.5 mL, and left at 4°C to afford [Pt(dien)(9-made-*N*6)](ClO$_4$)$_2$ (**2**) as thick, clear plates or prisms; yield 55 mg (77%). Satisfactory elemental analysis (C, H, N) was obtained. − $C_{10}H_{20}Cl_2N_8O_8Pt$ (646.33): calcd. C 18.58, H 3.12, N 17.34; found C 18.65, H 3.18, N 17.21.

Combined Quantum Chemical and Mass Spectrometry Study of $[Ge,C,H]^+$ and Its Neutral Counterpart

Phillip Jackson,[a] Martin Diefenbach,[a] Detlef Schröder,[a] and Helmut Schwarz*[a]

Dedicated to Professor Hans Bock on the occasion of his 70th birthday

Keywords: Organogermanium ions / Mass spectrometry / *Ab initio* theory / NBO

The cation $[Ge,C,H]^+$ has been generated by the electron ionisation of trichloromethylgermane. Collisional activation experiments were used to establish a Ge–C–H connectivity in this species, for which a significant fraction of the ion population was found to survive neutralisation-reionisation mass spectrometry (NRMS) experiments. Thus, the neutral counterpart $[Ge,C,H]^0$ is stable on a microsecond timescale. Becke's 3 parameter hybrid density functional (B3LYP) was used to map the ion and neutral potential-energy surfaces, in conjunction with double-zeta and triple-zeta basis sets. The computational results obtained using the triple-zeta basis sets suggest that, for the cation, the global minimum is the high spin $^3\Sigma$ $GeCH^+$, with the first Ge–C–H excited state, $^1\Sigma$ $GeCH^+$, approximately 39 kcal mol^{-1} less stable. The lowest energy ion structure with H–Ge–C connectivity is bent ($^3A''HGeC^+$, $\angle$H–Ge–C = 126.3) and 69 kcal mol^{-1} less stable than the global minimum. For the neutral, a doublet ($^2\pi$) with Ge–C–H connectivity is predicted to be the global minimum. The classical barrier for the neutral 1,2-hydrogen shift reaction on the doublet surface is negligible (0.1 kcal mol^{-1}), while the smallest barrier for the cation is 13.0 kcal mol^{-1}, corresponding to ($^3A''$) $HGeC^+ \rightarrow$ ($^3\Sigma$) $GeCH^+$. Natural bond order analysis has been used to establish the order of the metal–carbon bond for selected states of both the neutral and the ion. Neutral and cationic isomers with Ge–C triple bonds were found to be high-energy excited states, with the metal–carbon bonds in the cation and neutral ground states of order 2.0 and 2.5, respectively. The instability of Ge–C triple bonded species is attributed to the energy required for electronic promotion in the metal in order to achieve a hybrid configuration suitable for the formation of such a bond.

Introduction

In 1991, neutral [Si,C,H] was detected by means of neutralisation-reionisation mass spectrometry (NRMS).[1] Collisional activation (CA) experiments established the connectivity in the cation precursor as Si−C−H, for which a subsequent NR recovery signal was detected. Thus, the CA and NRMS results together vindicated the predictions of ab initio calculations, which suggested that the radical $SiCH^\bullet$ was 2.6 eV more stable than the $CSiH^\bullet$ isomer, and that $SiCH^+$ is more stable than $HSiC^+$ by at least 3.0 eV.[2] In the years since 1991, a plethora of molecules whose existence has only been proposed by spectroscopists or theoreticians have been detected using this technique.[3]

Whereas the number of challenges remaining in the area of silicon chemistry are now few,[4] the chemistry of germanium is still largely unexplored. This is perhaps due to a low terrestrial abundance[5] and broad similarities in the chemistry of main-group elements as one progresses from the third to fifth rows, which enable predictions based on the behaviour of lighter or heavier congeners. It is interesting to note that there has been recent interest in the electronic structure and gas-phase chemistry of homonuclear germanium clusters.[6] Several small germanium-hydrocarbon molecules have been previously generated in the gas phase, but still very little is known of their structures. Operti et al. were able to generate $GeCH_n^+$ (n = 1−5) and some digermanium-organo cations from ion-molecule reactions between germane and methylgermane in a high pressure source,[7] although studies towards structural characterisation were not undertaken. Willett and coworkers[6c] were able to generate $GeC_2H_3^+$, $GeC_3H_5^+$, and $Ge_nCH_2^+$ (n = 1,2) via the reactions of laser ablated Ge^+, Ge_2^+ with cyclopropane. While $Ge_2CH_2^+$ was the only reaction product observed for Ge_2^+, branching for Ge^+ yielded $GeCH_2^+$ as the major product, followed by $GeC_2H_3^+$ and $GeC_3H_5^+$. Density functional theory (BLYP/6-31G*) investigations of $[Ge_2,C,H_2]^+$ suggests that the disubstituted methane isomer Ge−CH_2−Ge is more stable than the isomer with Ge−Ge−CH_2 connectivity by approximately 15 kcal mol^{-1}.[6c] Although it was established that both structures were minima on the PES, and the disubstituted methane structure is probably the ground state, it must be noted that no structures with Ge−H bonds were investigated.[8]

Concerning other small germanium molecules and ions, $[Ge,O,H]^{0/+}$ have been studied using double- and triple-zeta basis sets in conjunction with the coupled cluster theory.[9] The most stable isomer for the ion was linear and possessed Ge−O−H connectivity, whereas a bent structure, with analogous connectivity, was found to be the ground state of the neutral. Results from a kinetic study of the neutral-neutral reaction between germylene (GeH_2) and germane

(GeH_4) have appeared recently,[10] and the experimental evidence suggests the rate of the association reaction leading to Ge_2H_6 depends on collisional cooling by a third body. The structures of the triatomic halogermylenes HGeX (X = Cl, Br) have been proposed on the basis of high level ab initio calculations[11] and rovibrational bands observed in laser-induced fluorescence experiments.[12] In the last year, this technique has been employed to characterise HGeI.[13]

This paper is divided into two sections: in the first, experimental results for $[Ge,C,H]^{0/+}$ are presented. In the second section, the results of density functional calculations are discussed in relation to the ground states of $GeCH^{0/+}$ and the possible existence of $HGeC^{0/+}$ isomers. The 1,2 hydrogen shift barrier, and results from Ge−C bond order analyses of selected ion and neutral isomers are then examined. The nature of multiple bonds involving heavier main-group elements are the focus of current interest and speculation.[3e,14] According to criteria proposed by Goubeau in 1957,[15] double bonds stable towards polymerisation are achievable if the sum of the electronegativities of the bonding partners exceeds the approximate value of 5. Using the literature values for the Mulliken electronegativities[16] of Ge ($4sp^3$), 2.50, and C (2sp), 3.29,[17] the sum obviously exceeds this value, suggesting there is a good chance of forming a Ge−CH bond of order 2 or greater.

Results and Discussion

Mass Spectrometry

The CA-mass spectrum of $GeCH^+$ is presented in Figure 1. Loss of $CH^\bullet$ is the major fragmentation observed under single collision conditions (66% fragment ion current), suggesting a Ge−C−H connectivity in the ion. It is interesting to note that there is also a minor signal corresponding to GeH^+ at *m/z* 71 (5% fragment ion current), indicating that there may be small amounts of an isomer with H−Ge−C connectivity, or that post-collisional isomerisation precedes fragmentation. If the barrier for the associated 1,2-shift lies above the GeC^+ + H and GeH^+ + C dissociation asymptotes, then the CA spectrum unequivocally confirms the existence of $HGeC^+$ (see below). In contrast, there was an additional source of uncertainty regarding the assignment of the fragment at *m/z* 29 in the CA spectrum of the silicon congener,[1] due to the small but non-negligible abundance of the ^{29}Si isotope.

The NR-mass spectrum of $[Ge,C,H]^+$ yields a distinct recovery signal for the parent ion (Figure 2), thus demonstrating that [Ge,C,H] is a stable molecule on the microsecond timescale. The most intense fragment ion that results from the reduction and subsequent oxidation of $[Ge,C,H]^+$ is Ge^+, which suggests that the Ge−C bond length in the neutral is displaced from the bond length in the ion, resulting in vertical transitions to high vibrational levels. Although it appears that there is a peak of low intensity at *m/z* 71 corresponding to loss of C, the uncertainty due to the higher signal to noise ratio suggests that only a tentative assignment can be made in this instance. In summary, the precursor structure as well as the CA and the NR spectra of $[Ge,C,H]^+$ are in accord with a Ge−C−H connectivity.

Theoretical Calculations

In order to map the potential-energy surfaces (PES) of neutral and cationic $[Ge,C,H]^{0/+}$, the relative energies were investigated for various spin isomers in linear and bent geometries for the connectivities Ge−C−H and H−Ge−C. Although the various cation and neutral minima were investigated using both BS-I and BS-II, only the results obtained using BS-II are presented here. The corresponding BS-I results can be provided on request.

(i) $[Ge,C,H]^+$ Potential Energy Surface: A schematic of the cation PES is presented in Figure 3. For the sake of clarity, we have omitted high-lying excited states. In Table 2, we present the bond energies of any associated diatomics and the zero-point corrected energies required to effect various ion dissociations. Only the lowest energy asymptotes corresponding to each particular dissociation are shown.

The global minimum on the $[Ge,C,H]^+$ PES corresponds to linear $^3\Sigma$ $GeCH^+$. This state lies approximately 110 kcal mol^{-1} below the lowest energy Ge^+ + CH dissociation asymptote, and almost 82 kcal mol^{-1} below the transition structure ^{3}TS for the associated 1,2 H-shift. The lowest energy cation isomer with H−Ge−C connectivity is $^3A''$

$D^0(Ge^+-CH)$[b] = 107.7 kcal mol^{-1}
$D^0(GeC^+-H)$[c] = 104.9 kcal mol^{-1}

[a] These structures correspond to the entrance channel barriers depicted in Figure 3. − [b] Evaluated using zero point energies derived from BS-I vibrational frequencies for $^3\Sigma$ $GeCH^+$ and $^2\Pi$ CH, calculated at the BS-I optimised geometries: $^3\Sigma$ $GeCH^+$, r_e(Ge−C) = 1.919 Å; r_e(C−H) = 1.094 Å, ZPE = 9.9 kcal mol^{-1}. $^2\Pi$ CH, r_e(C−H) = 1.151 Å, ZPE = 3.9 kcal mol^{-1}. − [c] Evaluated using zero point energies derived from BS-I vibrational frequencies for $^3\Sigma$ $GeCH^+$ (see footnote 2) and $^4\Sigma$ GeC^+, calculated at the BS-I-optimised geometries: $^4\Sigma$ GeC^+, r_e(Ge−C) = 1.973 Å, ZPE = 0.9 kcal mol^{-1}.

$HGeC^+$. According to B3LYP/BS-II, the classical barrier for the 1,2 H-shift reaction on the triplet surface is 13.0 kcal mol^{-1}, which may suffice for the detection of $HGeC^+$ from suitable precursors.

Although several linear isomers of $HGeC^+$ were found as minima on the triplet surface at the B3LYP/BS-I level, all are less stable than the bent structure. Moreover, transition state searching failed to locate a barrier linking the linear and bent isomers, suggesting the linear species reside in shallow minima and should convert into bent structures with minimal activation.

From Figure 3, it is apparent that there is only one curve crossing between the singlet and triplet surfaces, and this is near the Ge^+ + CH dissociation limit. A distinctive feature of the singlet PES is the large energy required to couple the ground states of Ge^+ ($^2\Pi$) and CH ($^2\Pi$) to form $^1\Sigma$ $GeCH^+$. Although pure DFT methods are largely considered unsuitable for the calculation of van der Waals and charge-exchange complexes,[18] hybrid DFT often performs better in this regard, and because this barrier is much larger than typical rotational barriers (of the order of a few kcal mol^{-1}), it must be associated with an electron promotion

Table 2. States, total energies (E_{SCF}, Ha), bond lengths (r_e, in Å), calculated ionization energies (IE, in eV), and bond dissociation energies (D^0, in kcal mol^{-1}) of various atomic and diatomic fragments used in the calculations of bond energies and dissociation asymptotes at B3LYP/6-311++G(d,p) level of theory. Tabulated dissociation energies include zero point energy corrections calculated using the frequencies obtained with BS-I.[a]

D^0(Ge−CH) [c] = 110.8 kcal mol^{-1}
D^0(GeC−H) [c] = 94.3 kcal mol^{-1}
IE_{ad} (GeCH) = 8.00 eV

[a] A second $^2\Sigma$ GeCH minimum was located using Gaussian 94, lying 44.4 kcal mol^{-1} above the global minimum with a slightly shorter r_e(Ge−C) = 1.664 Å, than the lowest energy $^2\Sigma$ state. Analysis of the molecular orbitals and populations revealed this minimum to be an artefact (identical to the lowest $^2\Sigma$ GeCH). − [b] A second ^{2}A′ HGeC minimum was located using Gaussian 94, lying 61.1 kcal mol^{-1} above the global minimum with bond lengths r_e(Ge−C) = 1.780 Å, r_e(Ge−H) = 1.544 Å and ∠H−Ge−C = 121.3°. Analysis of the molecular orbitals and populations revealed this minimum to be an artefact (identical to the lowest ^{2}A′ HGeC). − [c] Evaluated using zero point energies derived from BS-I vibrational frequencies for $^2\Pi$ GeCH, $^2\Pi$ CH or $^3\Pi$ GeC, calculated at the BS-I-optimised geometries: $^2\Pi$ GeCH, r_e(Ge−C) = 1.798 Å; r_e(C−H) = 1.086 Å, ZPE = 7.3 kcal mol^{-1}. $^2\Pi$ CH, r_e(C−H) = 1.151 Å, ZPE = 3.9 kcal mol^{-1}. $^3\Pi$ GeC, r_e(Ge−C) = 1.844, ZPE = 1.1 kcal mol^{-1}.

in the diatomic fragment. Even though the coupling energy required is close to the calculated B3LYP first excitation energy of CH ($^4\Sigma \leftarrow {}^2\Pi$, 20.8 kcal mol^{-1}: B3LYP/BS-II), this state does not correlate with the singlet surface. Rather, it must correspond to either an $a^2\Pi$ or $^2\Sigma$ excitation.

The lowest energy minimum on the singlet surface is $^1\Sigma$ $GeCH^+$, which is ca. 71 kcal mol^{-1} below the ground state Ge^+ + CH dissociation asymptote, and almost 78 kcal mol^{-1} below ^{1}TS. No bent minima could be located, so ^{1}TS effectively connects two linear isomers. This was verified by following the reaction coordinate downhill from the saddle-point. The classical barrier to the 1,2 H-shift on the singlet surface is 20.5 kcal mol^{-1}, which is larger than the triplet barrier. In summary, we conclude that $^3\Sigma$ $GeCH^+$ is by far

the most stable $[Ge,C,H]^+$ species, whereas all other conceivable states and/or structures are much more energy demanding. These results support our assignment of a Ge−C−H ion structure derived from the fragmentation patterns in the CA and NR experiments (see above).

(ii) $[Ge,C,H]^0$ Potential Energy Surface: The neutral PES is presented in Figure 4. For further information regarding the various minima depicted or higher excited states not shown in this figure, consult Table 3. In contrast to the cation PES, the global minimum of the neutral corresponds to a *low* spin Ge−C−H isomer, $^2\Pi$ GeCH. This state lies more than 114 kcal mol^{-1} below the lowest energy $^3\Pi$ Ge + $^2\Pi$ CH dissociation asymptote, almost 43 kcal mol^{-1} below the most stable bent quadruplet state $^4A''$ GeCH, and more than 61 kcal mol^{-1} below the lowest energy structure with H−Ge−C connectivity, $^2A'$ HGeC. It is important to note that all linear structures having H−Ge−C connectivity were characterised as transition structures using BS-I. In order to unambiguously establish the instability of linear HGeC isomers towards rearrangement, vibrational analysis of $^2\Pi$ HGeC using BS-II was undertaken, which revealed this species is indeed a transition structure. It should also be noted that the PES in the vicinity of the $^2A'$ HGeC minimum is very flat, and ^{2}TSa, which links $^2\Pi$ GeCH and $^2A'$ HGeC (1,2 H-shift barrier), lies only 0.1 kcal mol^{-1} above the bent minimum. For the quadruplet PES, the classical barrier for the 1,2 H-shift reaction is 22.6 kcal mol^{-1}, and is of a similar magnitude to the singlet barrier on the cation PES. No barrier was encountered for the coupling of Ge and CH on the doublet PES.

(iii) Natural Bond Order (NBO) Analyses: A qualitative MO diagram for the linear Ge−C−H ground states of both $[Ge,C,H]^{0/+}$ is presented in Figure 5. For the $^3\Sigma$ ground state of the cation, the uncoupled electrons reside in π-bonding MOs with 18% Ge and 82% C character. Note that the next MO lower in energy than the π-bonding MOs is a σ-nonbonding MO, which is occupied by both 4s electrons of Ge. This implies that the CH unit, or more precisely C, is the source of the two π-electrons, as the remaining Ge electron is involved in formation of the Ge−C σ-bond. Thus, we deduce that the electronic configuration of Ge^+ in $^3\Sigma$ $GeCH^+$ is $4s^24p^1$, which also corresponds to the electron configuration of the $^2\Pi$ Ge^+ ground state. The NBO evaluation of the natural electron configuration of the constituent atoms yields $Ge(4s^{1.89}4p^{0.83})$ $C(2s^{1.54}2p^{2.90})$ $H(1s^{0.80})$, in agreement with empirical deductions. Moreover, the C atom is sp^3 hybridised, and the Ge^+−C σ-bond contribution from the metal is $4s^{0.08}4p^{0.92}$. The order of the Ge^+−C bond was evaluated by (i) summing the orbital populations of the σ- and π-*bonding* MOs, and subtracting from this, (ii) the sum of the populations of the Ge^+−C σ- and π-*antibonding* MOs. This result is then divided by two to yield a value of 1.99 for the Ge^+−C bond in $^3\Sigma$ $GeCH^+$. It should be noted that the derived bond order of 1.99, does

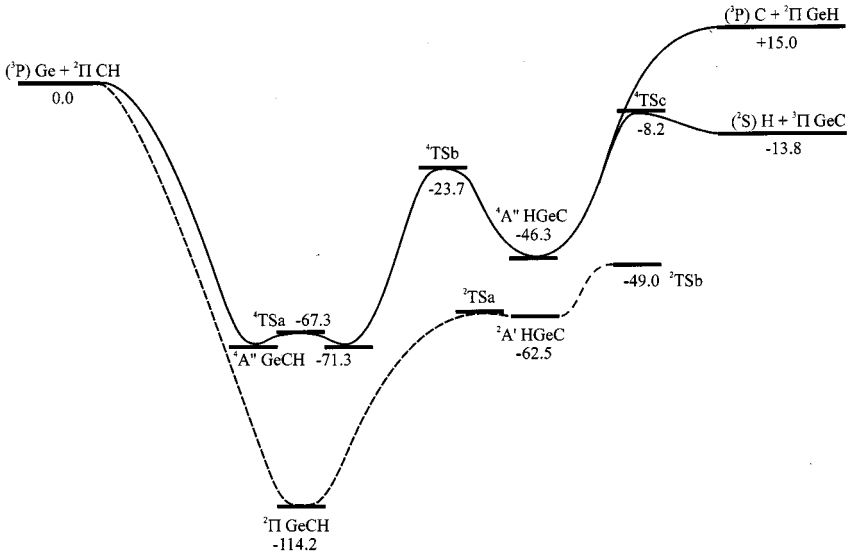

Figure 4. PES for $[Ge,C,H]^0$ from B3LYP/6-311++G(d,p) calculations; refer to Table 3 for details of particular structures, and Table 2 for details regarding asymptotes

The (quadruplet) 1,2 H-shift barrier height suggests that $HGeC^+$ isomers may be detectable in matrix isolation or other spectroscopic experiments. Unfortunately, the barrier for the bent to linear conversion of the neutral is negligible, and given the finite possibility for spin inversion, generation of long-lived HGeC appears unlikely.[3d] Finally, the isomerisation barriers on the singlet and triplet surfaces of the cation, are either lower than, or close in energy to, the lowest energy exit channels. Thus the CA results regarding the formation of H−Ge−C isomers are inconclusive, as the keV ion-neutral collisions excite the ions to dissociative vibrational levels well above the barriers associated with interconversion between GeCH and HGeC.

not imply the presence of formally paired π-electrons on both the germanium and carbon centres. The addition of an electron to one of the π-bonding MOs of $^3\Sigma$ $GeCH^+$ leads to some minor electronic and geometrical adjustments in the transition to the neutral ground state. The minor increase in Ge−C bond strength for the ground state neutral (Tables 1 and 3) is expected; however, the large decrease

in the C−H bond strength could be considered unusual. Comparison of the MO energies reveals the C−H σ-bonding MO in $^2\Pi$ GeCH is inverted with respect to the Ge−C σ-bonding MO in $^3\Sigma$ $GeCH^+$, and the population of the C−H σ-antibonding MO is much higher in $^2\Pi$ GeCH than $^3\Sigma$ $GeCH^+$. The second order energy of interaction between the σ-nonbonding MO, localised on the metal, and the C−H σ-antibonding MO in the neutral is 13.5 kcal mol^{-1} (alpha + beta sum), while the Ge 3s/C−H σ-antibonding MO interaction energy amounts to 7.7 kcal mol^{-1}. It is evident that core polarisation effects, in particular electron donation to the C−H σ-antibonding MO, has a pronounced effect on the C−H bond *strength* in the neutral, but the expected effect on the bond length is not dramatic. In fact, a slight bond contraction is observed, which is ascribed to enhanced Coulombic attraction between the C and H atoms of the neutral. The atomic charges in the neutral and cation ground states verify this point i.e. $C^{-0.85e}H^{+0.18e}$ for $^2\Pi$ GeCH, and $C^{-0.45e}H^{+0.20e}$ for $^3\Sigma$ $GeCH^+$.

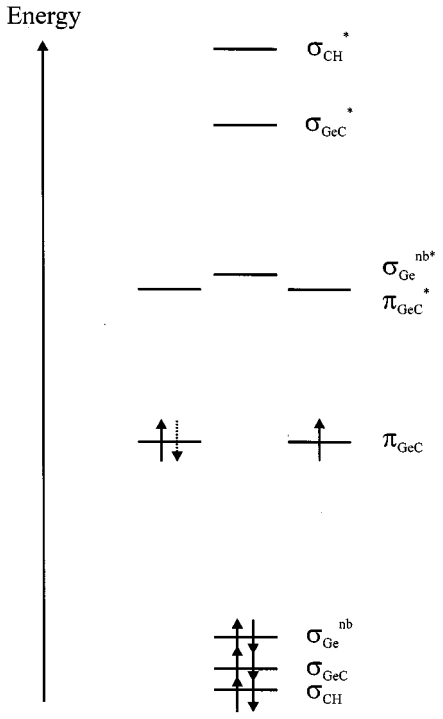

Figure 5. Qualitative MO diagram for the linear ground states of $[Ge,C,H]^{0/+}$; the dashed electron signifies the neutralisation of the cation to form the ground state configuration of the neutral

The Ge−C bond contraction upon formation of the ground state neutral (bond order 1.99) corresponds to 0.12 Å, which is significant considering the new Ge−C bond order is only 2.49, compared with 1.99 for the ground state cation. It is not surprising then that a significant signal for Ge^+ is detected in the NRMS spectrum of $GeCH^+$. For comparison, the typical bond length contraction for reduction of an alkane to an alkene is approximately 0.20 Å, and from an alkene to alkyne is 0.14 Å.[20]

The other noteworthy features of the NBO analysis of $^2\Pi$ GeCH are the extent to which the carbon atom is reduced, and the energy difference between the closed and half filled π-bonding MOs. To discuss the reduction of the carbon atom, first consider the natural electron configurations of the constituent atoms in $^2\Pi$ GeCH: $Ge(4s^{1.79}4p^{1.51})$ $C(2s^{1.44}2p^{3.41})$ $H(1s^{0.83})$. Comparison with the cation values presented above reveals the carbon atom to be sufficiently electronegative in the neutral to have gained $0.85e^-$, most of which comes from the metal. Even in the cation, the carbon atom has managed to extract 0.24 e^- from Ge. The origin of the energy splitting of the π MOs is more difficult to explain, but is probably due to closed-shell core-valence repulsions.

We have also performed NBO analyses for some of the neutral and cation excited states, and interesting aspects of the bonding and electronic features of these isomers is discussed in the following paragraphs. The first excited neutral state, $^2\Sigma$ GeCH, r_{GeC} = 1.667 Å, has a bond order of 2.99, and probably represents the best possibility of generating and observing a Lewis-type triple bond between Ge and C. Destabilisation of this isomer with respect to the ground state is due to excitation of a metal 4s electron from the σ-nonbonding orbital to the nearest π-bonding orbitals. This excitation costs 35.2 kcal mol^{-1}, ignoring additional molecular stabilisation gained by bond adjustments. The electronic configurations of the constituent atoms of this isomer are: $Ge(4s^{1.25}4p^{1.89})$ $C(2s^{1.30}2p^{3.77})$ $H(1s^{0.76})$. This suggests the electron promotion gives rise to a highly polar bonding arrangement in which a metal 4s electron is virtually transferred to the carbon atom, as confirmed by the calculated atomic charges: $Ge^{+0.85e}C^{-1.08e}H^{+0.24e}$. The first cation excited state is formed by the spin inversion of one of the two parallel-spin π-bonding electrons of the ground state isomer. Most of the inherent bonding features of this isomer are described in the NBO analysis of ground state $^3\Sigma$ $GeCH^+$, and no further discussion is warranted.

Before continuing with the relative structures of high energy excited states, it is acknowledged that at the full-CI level of theory, the particular cation configurations examined in the following paragraphs could correspond to transition structures on the potential energy hypersurface. For an understanding of the origins of Ge−C triple bond instability, a discussion of these structures cannot be overlooked.

The species with the shortest Ge−C bond lengths, and highest Ge−C bond orders, are the high energy excited states $^1\Sigma$ $GeCH^+$, r_{GeC} = 1.636 Å, and $^1\Sigma$ $HGeC^+$, r_{GeC} = 1.629 Å (see Table 2). The electronic configurations of the various constituent atoms in each isomer are: $Ge(4s^{0.94}4p^{1.50})$ $C(2s^{1.35}2p^{3.60})$ $H(1s^{0.61})$ and $H(1s^{0.83})$ $Ge(4s^{1.07}4p^{1.94})$ $C(2s^{1.30}2p^{2.87})$. It is immediately apparent that the electronic configuration of Ge in these high energy structures is approximately $4s^14p^2$, which corresponds to the excited cation state ^4P Ge^+. According to B3LYP/BS-II, the promotion energy required for hybridisation of Ge^+, in the absence of electric fields, is 6.5 eV ($^2\Pi$ $Ge^+ \rightarrow$ $^4\Pi$ Ge^+). The corresponding neutral value is 5.5 eV, whereas the promotion energy for CH (see Table 1), which for simplicity can be extracted from the $^2\Pi$ CH → $^4\Sigma$ CH excitation energy, amounts to 0.85 eV. It is clear that little, if

any, of this energy is recovered by GeC triple-bond stabilisation. Thus, it appears that the energy required to hybridise heavy group 14 congeners for triple-bond formation accounts for any relative destabilisation. The other characteristic feature of the excited states with short Ge−C bonds is the nature of the Ge−C σ bonding orbital. In the cation and neutral ground states, this orbital is a Ge($4p_z$) C($2sp_z$) hybrid, whereas the hybridisation for the excited cationic states is Ge(4s) C($2sp_z$). Moreover, this orbital has 47% Ge character in $^1\Sigma$ $GeCH^+$, 32% Ge character in $^1\Sigma$ $HGeC^+$ but only 18% Ge character in the cation ground state $^3\Sigma$ $GeCH^+$. This suggests the greater the carbon character of the Ge−C σ-bond, the greater the stability of the isomer.

Finally, it is interesting to compare the relative atomic charges of $^1\Sigma$ $GeCH^+$ and $^1\Sigma$ $HGeC^+$, which are: $Ge^{+1.58e}C^{-0.96e}H^{+0.38e}$ and $H^{+0.17e}Ge^{+1.01e}C^{-0.18e}$. On the basis of these values, it is expected that the $^1\Sigma$ $GeCH^+$ excited state would be more reactive than the $^1\Sigma$ $HGeC^+$ state, due to the much higher polarity of the Ge−C bond. Electronic reorganisation of $^1\Sigma$ $GeCH^+$ to a more stable open shell configuration would be favourable on the grounds of simple entropy arguments.

Experimental Section

For a detailed description of the experiment and the instrument used, the reader is advised to consult the recent review by Schalley et al.[21] In brief, the experiments were performed using a four-sector modified HF-ZAB AMD 604 mass spectrometer with BEBE configuration, where B and E represent magnetic and electric sectors respectively. $^{70}GeCH^+$ was generated by the 100 eV electron ionisation of trichloromethylgermane (Gelest Inc., PA, USA). The isotopomer $^{70}GeCH^+$ was selected for analysis as there are no isobaric interferences at *m*/*z* 83 due to other possibilities such as $GeCH_n$ (n = 0−3). Typical electron ionisation source conditions are as follows: source temperature 200°C; trap current 100 μA; repeller voltage 15 V; ion extraction voltage 8 kV; $m/\Delta m \geq 1500$. Collisional activation of B(1)/E(1)-mass selected $GeCH^+$ was effected in collision cells, positioned between E(1) and B(2), using He as a target gas. The collision cell pressure was maintained such that 80% of the parent ion beam was recovered after passing through this cell. This corresponds to an average of 1.1−1.2 collisions per ion.[22] CA products were recorded by scanning the second magnetic sector B(2).

NRMS experiments were performed for B(1)/E(1)-mass selected $GeCH^+$, utilising the dual collision cells between sectors E(1) and B(2). Cation neutralisation was achieved by collision with Xe at 80% transmittance, while reionisation was achieved by collision of the neutrals with O_2, again at 80% transmittance. Any ions remaining after the first collision event were deflected from the primary neutral beam using an electrode maintained at a high voltage (2 kV) positioned before the second collision cell. In order to detect a reionisation signal, the neutral species must be stable for approximately one microsecond. NRMS spectra were averaged over 100 acquisitions in order to obtain a sufficient S/N ratios, while CA spectra were averaged over 20−50 acquisitions.

The B3LYP calculations were performed using the Gaussian 94 software[23] on IBM RS/6000 computers running AIX 4.2.1. The structures of $[Ge,C,H]^+$ were investigated as follows: first, geometry optimisations were performed using the 3-parameter hybrid density functional method of Becke (B3LYP)[24] in conjunction with valence basis sets of double-zeta quality, and an effective core potential (ECP) replacing the $1s^2-3d^{10}$ electrons of Ge.[25] These basis sets are collectively referred to hereafter as BS-I. The nature of each stationary point located at this level of theory was then established via subsequent frequency analysis.

The optimised structures obtained using BS-I were then re-optimised using the all-electron 6-311G basis set of Krishnan and coworkers for C and H,[26] and the basis set of McGrath, Curtiss and coworkers for Ge.[27] The respective all-electron basis sets were supplemented with single p and d functions for Ge, one p and one d function for C, and one s and one p function for H. These basis sets are referred to as BS-II. The natural bond orbital analyses were performed at the re-optimised BS-II geometries using version 3.0 of the NBO code of Weinhold and coworkers.[28] In some instances, frequency analyses were repeated using BS-II at the optimised BS-II geometry to unambiguously establish the nature of low energy stationary points.

Acknowledgments

This research was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie. The Konrad-Zuse Zentrum, Berlin, is acknowledged for generous allocation of computer time. We would also like to thank Prof. Yitzhak Apeloig, for providing the inspiration to undertake this work during a recent visit to TU Berlin.

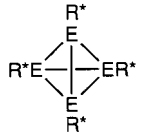
Tetrasupersilyl-tristannaallene and -tristannacyclopropene (tBu$_3$Si)$_4$Sn$_3$ – Isomers with the Shortest Sn=Sn Double Bonds to Date

Nils Wiberg,*[a] Hans-Wolfram Lerner,[a] Sham-Kumar Vasisht,[a] Susanne Wagner,[a] Konstantin Karaghiosoff,[a][+] Heinrich Nöth,[a][++] and Werner Ponikwar[a][++]

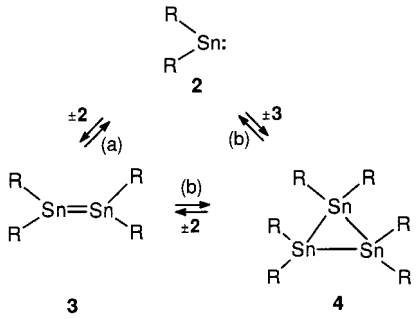


Dedicated to Professor Wolf-Peter Fehlhammer on the occasion of his 60th birthday

Keywords: Double Bonds / NMR Spectroscopy / Silicon / Tin / X-ray structure analyses

The dark blue, air- and moisture-sensitive, thermolabile tristannaallene R$^\star_2$Sn=Sn=SnR$^\star_2$ (**5**) (R* = SitBu$_3$) is prepared by reaction of Sn(OtBu)$_2$ or Sn[N(SiMe$_3$)$_2$]$_2$ with R*Na in pentane/benzene at –25°C. The dark red-brown, air-sensitive, moisture-insensitive, and thermostable cyclotristannene R$^\star_4$Sn$_3$ (**6**) with a –R*Sn=SnR*– moiety as part of a Sn$_3$ ring is obtained from the reaction of Sn(OtBu)$_2$ or Sn[N(SiMe$_3$)$_2$]$_2$ with R*Na in pentane at 25°C or from the isomerization of **5** at room temperature ($\tau_{1/2}$ = 9.8 h). According to the result of X-ray structural analyses the Sn$_3$ framework of chiral **5** is bent (156°) and the terminal Sn atoms have pyramidal surroundings. The SnSn double bonds in **5** (2.68 Å) are shorter than those found for the hitherto structurally investigated distannenes (2.77–2.91 Å). Even shorter is the double bond in **6** (2.59 Å). The unsaturated Sn atoms here have nearly planar surroundings in perfect analogy to the carbon atoms in CC double bonds. The SnSn double bond in **6** can therefore be considered as the first "true" Sn=Sn bond. The structures of **5** and **6** can be deduced also from ^{119}Sn- and ^{29}Si-NMR studies in solution.

The reaction of tin dichloride SnCl$_2$ with supersilyl sodium R*Na ("supersilyl" **R*** = tri-*tert*-butylsilyl SitBu$_3$) in tetrahydrofuran (THF) attracted our attention for two reasons:

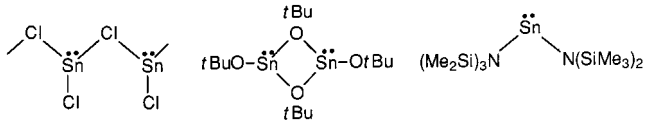


(i) By treating germanium dichloride (in form of its dioxane adduct) with an excess of supersilyl sodium in THF (molar ratio GeCl$_2$ to R*Na of 1:3) we synthesized in 1996 **1b**, the first molecular germanium compound with a Ge$_4$ tetrahedron[3]. Three years earlier we had already reported **1a**, the first molecular silicon compound with a Si$_4$ tetrahedron[4]. In continuation of our investigations we attempted the synthesis of **1c**, the first molecular tin compound bearing a Sn$_4$ tetrahedron by the analogous reaction of SnCl$_2$ with R*Na in THF.

R* = SitBu$_3$

1a : E = Si
1b : E = Ge
1c : E = Sn

(ii) The reaction of tin dichloride with the twofold molar amount of supersilyl sodium should yield in THF according to SnCl$_2$ + 2 R*Na → R*$_2$Sn + 2 NaCl the stannylene R*$_2$Sn as the first product. We hoped that it would be possible to isolate or detect the bis(supersilyl)stannylene as the monomer **2** or – less probable – as the dimer **3** or the trimer **4** at low enough temperatures [see Scheme 1, Equations (a) and (b), R = R*].



Scheme 1

In fact, a few distannenes of type **3** with organyl as well as silyl substituents R of *intermediate bulkiness* could be prepared and structurally characterized in the last years (see Table 1 and refs.[5–9]). NMR investigations reveal, however, that in solution these "bis(stannylenes)" **3** are in equilibrium with the corresponding "mono(stannylenes)" **2** and in one case[7] with the "tris(stannylene)" **4**. *Very bulky* organyl as well as silyl substituents (e.g. R = 2,4,6-tBu$_3$C$_6$H$_2$[9] and also R = R* [see below]) prevent the formation of distannenes **2** even in the solid state.

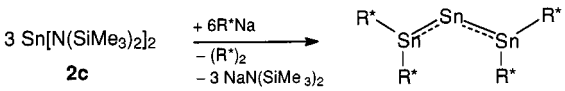
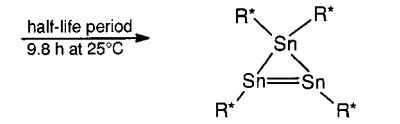
Electronegative substituents R can also stabilize the stannylenes **2**. In such cases with substituents of small, intermediate or large steric demand [e.g. R = Cl,[10] O*t*Bu,[11] or $N(SiMe_3)_2$[12]] they exist as oligomers, dimers, or monomers, respectively. In the oligomers and dimers R acts as a bridge between two tin atoms. As a consequence of the polymeric structure the dichloride **2a** is insoluble in hydrocarbons like pentane and soluble only in ethers like THF in which it forms adducts, whereas the dialkoxide **2b** and the diamide **2c** are soluble also in hydrocarbons.

2a: $(SnCl_2)_x$ **2b:** $[Sn(Ot\,Bu)_2]_2$ **2c:** $Sn[N(SiMe_3)_2]_2$



Here we first describe the reactions of the Sn^{II} compounds **2a**−**2c** with supersilyl sodium, which yield together with other products *tetrasupersilyl tristannaallene* **5** and *tetrasupersilyl tristannacyclopropene* **6** (referred to in the following as tristannaallene and cyclotristannene). The subsequent sections deal with the characterization as well as with multinuclear NMR and X-ray studies of the products **5** and **6**.

Preparation of the Tristannaallene 5 and Cyclotristannene 6



Some years ago[13] we observed that a solution of $SnCl_2$ (**2a**) in THF when added dropwise to a solution of the twofold molar amount of R*Na in THF at −78 °C followed by warming to ambient temperature gives a microcrystalline extremely air-sensitive blackish-brown *insoluble tin compound* (main product) and a dark brown solution. The latter contains a *soluble tin compound* as well as superdisilane $tBu_3Si{-}SitBu_3$.[14] We had obtained this soluble tin compound already as a product of the dehalogenation of disupersilyltin dichloride $R^*_2SnCl_2$ with sodium metal in benzene.[15] It is also formed from the reaction of $Sn(OtBu)_2$ (**2b**) or of $Sn[N(SiMe_3)_2]_2$ (**2c**) with supersilyl sodium in alkanes like pentane or heptane.

The chemical identity of the insoluble and the soluble tin compounds remained initially obscure. In a communication published recently[16] it is suggested that the insoluble tin compound probably has the tetrasupersilyl *tetrahedro* tetrastannane structure **1c**, whereas for the soluble tin compound a zwitterionic distannene structure $R^*_2Sn{\rightarrow}SnR^*_2$ was proposed. Both presumed structures are inconsistent with our results, however. According to our experience the tetrahedrane **1c** should be soluble in organic solvents and thus cannot account for the insoluble compound (cf. ref.[1]). Our analytical studies reveal that this compound must be a mixture of supersilyl, tin, and sodium containing products.[17] Chemical, NMR, and X-ray studies show the soluble tin compound to be the *cyclotristannene* **6** − a structure, which has been already reported by Sekiguchi et al. for the germanium homologue $R^*_4Ge_3$[18] and by Kira et al. for the silicon homologue $R_3R'Si_3$ ($R' = tBuMe_2Si$; $R = R'_3Si$).[19]

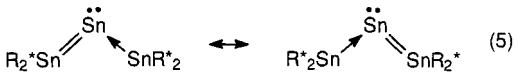
We could gain a deeper insight into the reaction pathway of Sn^{II} compounds with supersilyl sodium by studying the reaction of the diamide **2c** with donor free R*Na in pentane at low temperatures. It yields in the first stage according to Equation (1) together with superdisilane the *tristannaallene* **5** (at first we believed this product to be the expected tetrastannatetrahedrane **1c**[20]). The tristannaallene **5** rearranges at ambient temperature (25 °C), as shown by Equation (2) to the isomeric cyclotristannene **6**. This rearrangement implies the migration of one supersilyl substituent to the supersilyl free central tin atom with concomitant formation of a chemical bond between the outer tin atoms of the tristannaallene. An analogous reaction sequence is observed also for the reaction of **2b** with R*Na in pentane.

5 (1)

6 (2)

The formation of the tristannaallene **5** could proceed according to Equations (3) and (4) via the disupersilyl stannylene R^*_2Sn. The stannylene could subsequently add first one and than a second molecule R^*_2Sn with elimination of supersilyl radicals, which dimerize to give superdisilane. The intermediate formation of R^*_2Sn in pentane at −78 °C is supported by the fact that when the diamide **2c** is allowed to react with an equimolar amount of R*Na half of **2c** remains unchanged. Obviously due to steric reasons the stannylene R^*_2Sn cannot dimerize according to Equation (a) in Scheme 1, but loses, as shown by Equation (4), in the course of its "trimerization" two supersilyl groups. We have no proof for the existence of radicals $R^*_3Sn^{\bullet}_2$, which should form according to the mechanism suggested by Equation (4). We have noted, however, that in the course of the reaction of **2c** with R*Na in pentane at low temperatures the NMR signals of **2c** disappear, while a strong ESR signal appears. As the reaction proceeds further the ESR signal disappears and at the same time the NMR signals of **5** can be detected.

(3)



(4)

Characterization and Structure of the Tristannaallene 5

From a solution of **5** in 1.7 mL of pentane/0.1 mL of C_6D_6 at −25 °C, prepared from 0.7 mmol of $Sn[N(SiMe_3)_2]_2$ and 0.7 mmol of tBu_3SiNa in 0.7 mL of pentane/0.1 mL of C_6D_6 at −25 °C (cf. Experimental), dark blue crystals of **5** are formed within several days. These are sensitive to air as well as to moisture and slowly thermolyse at room temperature. Hereby, as shown in Equation (2) isomerization with formation of **6** takes place according to a first order reaction with half-life of 9.8 h at 25 °C.

The *structure* of the tristannaallene **5** results unambiguously from the $^{119}Sn\{^1H\}$- and $^{29}Si\{^1H\}$-NMR spectra, as well as from an X-ray structure analysis. In the *$^{119}Sn\{^1H\}$-NMR spectrum* (cf. Figure 1) two signals at low field (δ = 503, 2233, intensity ratio 2:1) are observed, which result from the isotopomers with ^{119}Sn in terminal and central position, respectively. The chemical shift of the terminal three-coordinate Sn atoms in **5** compares well with that of the distannene **3** with R = 2,4,6-iPr$_3$C$_6$H$_2$ (δ = 427.3[7]) − the only distannene known so far to be stable in solution at ambient temperature. In contrast, the NMR signal of the central two-coordinate Sn atom appears at much lower field in the same region where also the signals of the symmetrically and unsymmetrically substituted stannylenes **2** with $R_2 = (Me_3Si)_2C-CH_2-CH_2-C(SiMe_3)_2$ (δ = 2323[21]) as well as $[CH(SiMe_3)_2]_2$ (δ = 2328[22]) and R/R = 2,4,6-iPr$_3$C$_6$H$_2$/2,4,6-[(Me$_3$Si)$_2$CH]$_3$C$_6$H$_2$ (δ = 2208[23]) are found. This similarity suggests for the central tin atom in **5** a considerable stannylene character with a stereochemically active lone pair of electrons − a fact which is further supported by the bent Sn−Sn−Sn arrangement resulting from the X-ray structure analysis for the solid state (see below). Thus, the bonding situation in **5** is best described by the resonance formulae shown in Equation (5).

(5)

The ^{119}Sn-NMR signals of the central and terminal tin atoms are each accompanied by two pairs of satellites, which arise from the isotopomers having either one ^{119}Sn and one ^{117}Sn or two ^{119}Sn nuclei in one of the terminal positions and in the central position (Figure 1). The signal of the terminal tin atoms exhibits an additional pair of satellites, which results from the two-bond $^{119}Sn,^{117}Sn$ coupling of the isotopomer having one ^{119}Sn and one ^{117}Sn in the terminal positions. The observed value for the one-bond tin,tin coupling of 4302 Hz for $^1J(^{119}Sn,^{119}Sn)$ and 4117 Hz for $^1J(^{119}Sn,^{117}Sn)$ is considerably larger than $^1J(^{119}Sn,^{117}Sn)$ in the distannenes **3** with R = 2,4,6-iPr$_3$C$_6$H$_2$ (2930 Hz[24]) and R = CH(SiMe$_3$)$_2$ (1340 Hz, from the ^{119}Sn CPMAS spectrum[22]). This is in accord with the shorter Sn=Sn distance in **5** (2.68 Å) relative to the Sn=Sn distances reported so far for distannenes (2.76−2.94 Å; cf. Table 1). $^2J(^{119}Sn,^{117}Sn)$ is with 1679 Hz also remarkably large.[25]

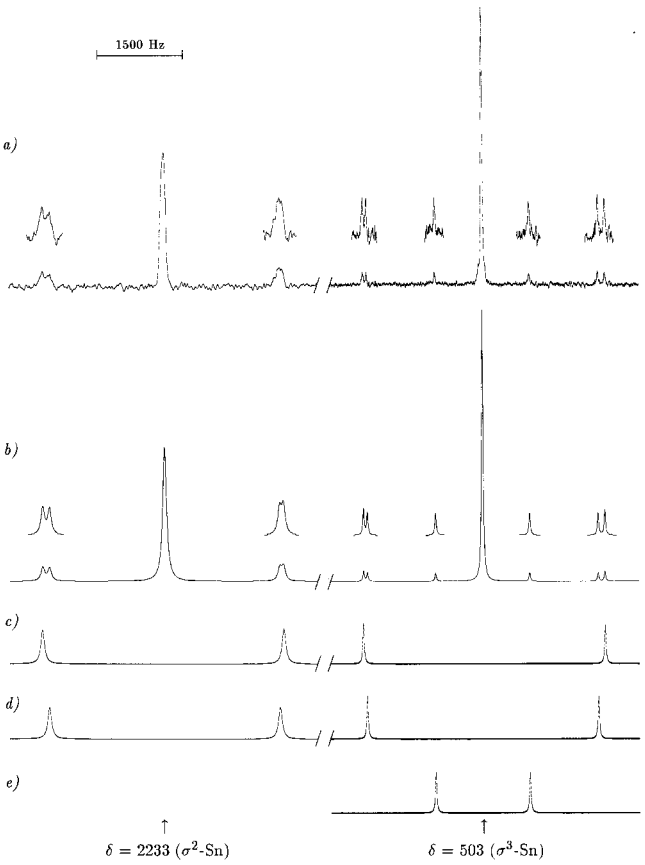


Figure 1. $^{119}Sn\{^1H\}$-NMR spectrum of the tristannaallene **5**: *a)* Observed spectrum at 100.7 MHz and −20 °C (ca. 0.1 M solution in [D$_8$]toluene, 10000 scans with 0.7 s repetition time). − *b)* Calculated total spectrum (Program DSYMPC, G. Hägele, R. Spiske, S. Goudetsidis, F. Mistry, University of Düsseldorf, **1994**), representing the sum of the spectra of all isotopomers with ^{119}Sn, and ^{119}Sn together with ^{117}Sn, weighted according to their natural abundances. The tin satellites of the low field signal originate from the superposition of the signals of the σ^2−Sn atom in the isotopomers with one additional ^{119}Sn (14.3% rel. intensity, $^1J(^{119}Sn,^{119}Sn)$ = 4302 Hz) and ^{117}Sn (12.7% rel. intensity, $^1J(^{119}Sn,^{117}Sn)$ = 4117 Hz) in the terminal positions. (cf. *c* and *d*) For the signal of the σ^3-Sn atoms the tin satellites result from the superposition of the signals of the isotopomers with one additional ^{119}Sn (7.2% rel. intensity) and ^{117}Sn (6.3% rel. intensity) in the central position, as well as ^{117}Sn (6.3% rel. int, $^2J(^{119}Sn,^{117}Sn)$ = 1679 Hz) in the other terminal position (cf. *c*, *d*, and *e*).

The *$^{29}Si\{^1H\}$-NMR spectrum* of **5** shows only one signal at δ = 77.3. It is accompanied by three pairs of satellites, arising from the isotopomers with one ^{119}Sn or ^{117}Sn nucleus in the three possible positions. From the satellites the values of 109 Hz for ^1J(Sn,Si), of 54 Hz for ^2J(Sn,Si), and of 12 Hz for ^3J(Sn,Si) can be estimated.

The dark-blue crystals of the tristannaallene, obtained from pentane/benzene at −25°C, contain according to the result of an *X-ray structure analysis* in the unit cell two independent molecules of **5**, which form an axially chiral pair of enantiomers. The structure of one of the molecules of **5**

in the unit cell is displayed in Figure 2 together with selected bond lengths and angles for both molecules **5**. Figure 3 shows Newman projections of both enantiomeric molecules **5** viewed in direction of the outer tin atoms of the Sn_3 chain together with selected fold and torsion angles.

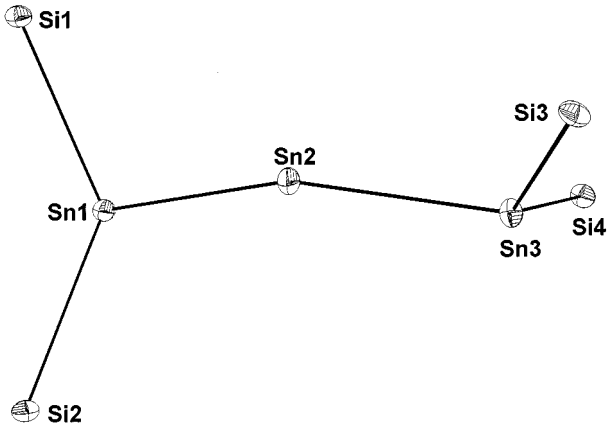

Figure 2. View of the crystal structure of one of the two enantiomers **5** in the unit cell (ORTEP, 25% thermal probability ellipsoide, tert-butyl groups omitted for clarity). Selected bond lengths [Å] and angles [°] (in brackets corresponding data of the other enantiomer **5** in the unit cell with Sn6/Sn5/Sn4/Si7/Si8/Si6/Si5 instead of Sn1/Sn2/Sn3/Si1/Si2/Si3/Si4; for folding and torsion angles see Figure 3): Sn1−Sn2 2.684 (1) [2.682(1)], Sn2−Sn3 2.675(1) [2.675(1)], Sn1−Si1 2.692(3) [2.694(3)], Sn1−Si2 2.689(3) [2.687(3)], Sn3−Si3 2.683(3) [2.701(3)], Sn3−Si4 2.696(3) [2.697(3)]. − Sn1−Sn2−Sn3 156.01(3) [155.81(3)], Si1−Sn1−Si2 134.29(9) [133.96(9)], Si1−Sn1−Sn2 100.58(7) [101.16(7)], Si2−Sn1−Sn2 109.39(7) [108.69(7)], Si3−Sn3−Si4 133.61(10) [134.38(10)], Si3−Sn3−Sn2 100.48(7) [99.94(6)], Si4−Sn3−Sn2 112.79(8) [113.01(8)].

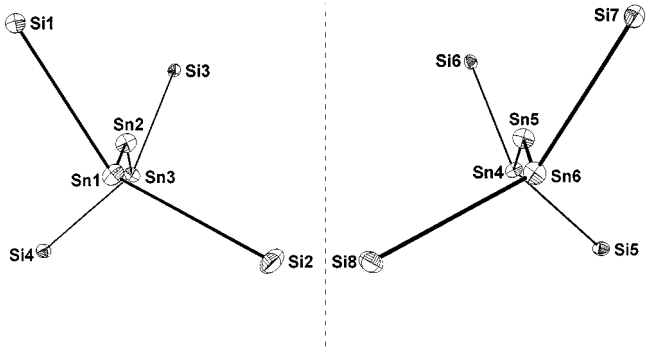

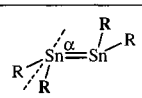

Figure 3. Newman projection of the two tristannaallene enantiomers **5** in the unit cell, viewed in direction Sn1−Sn3 and Sn6−Sn4. Folding angles [°] between the bisector b-Sn of the SiSnSi angles and the SnSn bonds as well as torsion angles [°] between the SiSn bonds of the two R^*_2Sn groups in **5** (for bond lengths and angles see Figure 2): b-Sn1/Sn1−Sn2 48.5, b-Sn3/Sn3-Sn2 43.4, b-Sn6/Sn6−Sn5 48.9, b-Sn4/Sn4−Sn5 43.3. − Si1−Sn1−Sn3−Si3 53.0, Si1−Sn1−Sn3−Si4 98.0, Si2−Sn1−Sn3−Si3 97.1, Si2−Sn1−Sn3−Si4 111.8, Si7−Sn6−Sn4−Si6 52.5, Si7−Sn6−Sn4−Si5 99.6, Si8−Sn6−Sn4−Si6 98.9, Si8−Sn6−Sn4−Si5 111.1.

The most striking feature of the structure of **5** are the short SnSn distances, for which an avarage value of 2.683 Å is found. The SnSn distances in **5** are thus shorter than all SnSn distances observed for distannenes so far

Table 1. Double bond lengths *d*(SnSn), fold angles α (cf. formula in the Table), and dihedral angles δ(**R**SnSn**R**) of distannenes **3** studied by X-ray structure analyses to date

R/R in 	*d* (SnSn)	α	δ(**R**SnSn**R**)	Ref.

Tristannaallene **5**[c]	2.68 Å	24/46°	—	present
Cyclotristannene **6**[c]	2.59 Å	< 5°		paper

[a] R'_4C_6H = 2-*t*Bu-4,5,6-Me_3C_6H. − [b] From solutions that contain 3 $(Tip_2Sn)_2$ ⇌ 2 $(Tip_2Sn)_3$ with Tip = 2,4,6-*i*$Pr_3C_6H_2$ only $(Tip_2Sn)_3$ crystallizes.[7] − [c] Mean values.

(2.77−2.91 Å; cf. Table 1), but longer than the one found for the Sn=Sn bond in **6** (2.59 Å, see below). This suggests, in accordance with the resonance formulae (5), a bond order between one and two for the SnSn bonds in **5**; in contrast, a bond order of nearly one for the "distannenes" is listed in Table 1 (cf. 2.85 Å for the Sn−Sn single bond length in **6**), as indicated by the resonance formulae

$$[R_2Sn{\rightarrow}SnR_2 \leftrightarrow R_2Sn{\leftarrow}SnR_2]. \quad (5)$$

Another interesting feature, which becomes evident from Figure 2, is − as already mentioned − the bent rather than linear Sn_3 chain in **5**. This is again in accordance with the resonance formulae (5), and consequently **5** does not represent a "real" homologue of an allene. Indeed, the observed SnSnSn bond angle of 155.9° is quite large (cf. NSnN angle in crystalline **2c**[12], 104.7°) − a consequence of the steric interactions of the supersilyl groups and perhaps also a consequence of a small participation of the lone pair of electrons at the central tin atom in the bond system of the Sn_3 fragment.

The two outer tin atoms of the Sn_3 chain in **5** have no planar surroundings, as is the case with the corresponding carbon atoms in allenes; they are located each at the top of a flat pyramid, the base of which is formed by two supersilyl groups and the inner Sn atom (sum of the angles at the outer Sn atoms on average 345.6°). The "folding angle" between the bisecting line of the SiSnSi angle and the bond axis between the outer and the central tin atoms falls with an average value of 46.0°, in the same range as the folding angles observed for distannenes (21−64°, cf. Table 1).

As a consequence of the steric pressure of the two Sn-bonded supersilyl groups the SiSnSi bond angle in the two R^*_2Sn groups of compound **5** is quite large and clearly exceeds 120° (on average 134.1°; cf. SiSnSi angle in $R^*_2SnCl_2$, 145.0°,[26] and in **6**, 131°, see below). The R^*_2Sn groups in **5** adopt − as the R_2C groups in allenes − a *gauche* configuration (cf. Figure 3). The four supersilyl groups in compound **5** occupy in close approximation the edges of a bis-

phenoid (cf. Figure 3). They cover the Sn_3 chain almost completely and prevent undesired reactions between the Sn_3 groups of different molecules. The SnSi distances (2.68−2.70 Å) are larger than the sum of the atomic radii $r_{Sn} + r_{Si}$ (1.40 + 1.17 = 2.57 Å[10]) − obviously a consequence of the mutual steric repulsion of the supersilyl groups.

Characterization and Structure of the Cyclotristannene 6

From a solution of **6** in 30 mL of *tert*-butyl methyl ether at −25 °C, prepared from 12 mmol of $Sn(OtBu)_2$ and 24 mmol of $tBu_3SiNa(THF)_2$ in 60 mL of pentane at −78 °C and 25 °C (cf. Experimental), dark red-brown crystals of **6** are formed within several days. These are sensitive to air, but stable to moisture at room temperature. As a solid, **6** decomposes at 166 °C; in benzene solution it slowly thermolyses at 100 °C with the formation of hexasupersilyl-*hexahedro*-octastannane $R^*_6Sn_8$.[17]

The *structure* of **6** − an isomere of tristannaallene **5** − with a distannene unit integrated in a Sn_3 ring is suggested by the $^{119}Sn\{^1H\}$- and the $^{29}Si\{^1H\}$-NMR spectra as well as by an X-ray structure analysis. The *$^{119}Sn\{^1H\}$-NMR spectrum* (cf. Figure 4) exhibits a signal at high field (δ = −694) together with a second signal at low field (δ = 412) with double intensity. The position of the low-field signal corresponds to that observed for the distannene **3** with R = 2,4,6-$iPr_3C_6H_2$ (δ = 427.3[7]) and for the terminal tin atoms in the tristannaallene **5** (s. above). Thus it can be unambiguously assigned to the three-coordinate tin atoms of the distannene unit in **6**. The high-field signal appears in the same region as the signals of the only cyclotristannanes **4** known so far with R = 2,6-$Et_2C_6H_3$ (δ = −416.5[6]) and with R = 2,4,6-$iPr_3C_6H_2$ (δ = −378.9[24]) and has to be assigned to the tetracoordinate tin atom in **6**.

The $^{119,117}Sn$ satellites originate from the isotopomer with two anisochronic ^{119}Sn nuclei and from the isotopomers with one ^{119}Sn and one ^{117}Sn nucleus and are clearly observable (Figure 4). The observed relative intensity of the tin satellites (22% for the low field signal and 28% for the high field signal) proves the presence of three tin atoms in the molecule and at the same time clearly excludes the zwitterionic distannene structure suggested in ref.[16]. The striking unsymmetrical arrangement of the satellites (Figure 4) is caused by the AX spectrum of the isotopomer with two anisochronous ^{119}Sn nuclei, which already slightly deviates from the first order. $^1J(^{119}Sn,^{117}Sn)$ between the two three-coordinate tin atoms of the distannene unit is 2110 Hz, almost half the coupling observed for **5** (see above), and roughly comparable to the Sn,Sn coupling constant in the distannene **3** with R = 2,4,6-$iPr_3C_6H_2$ (2930 Hz[7]). On the other hand the observed value is definitely larger than the one reported for the distannene **3** with R = $CH(SiMe_3)_2$ (1340 Hz[22]), for which an exceptionally weak Sn,Sn bond is discussed. The coupling constants $^1J(^{119}Sn,^{119}Sn)$ and $^1J(^{119}Sn,^{117}Sn)$ between the three- and the tetracoordinate

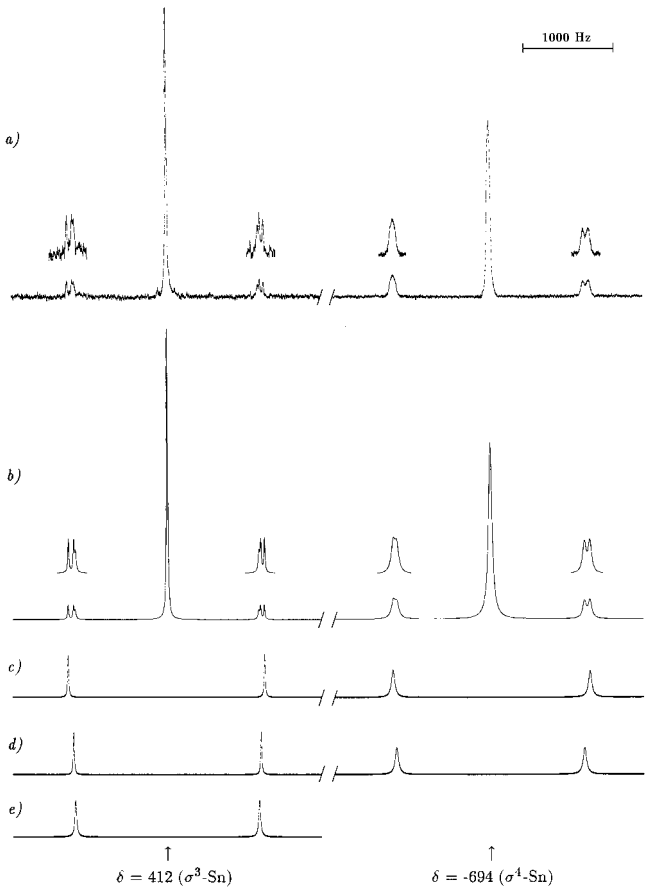

Figure 4. $^{119}Sn\{^1H\}$-NMR spectrum of the cyclotristannene **6**: *a)* Observed spectrum at 100.7 MHz (ca. 0.1 M solution in C_6D_6, 70000 scans with 0.7 s repetition time). − *b)* Calculated total spectrum (Program DSYMPC, G. Hägele, R. Spiske, S. Goudetsidis, F. Mistry, University of Düsseldorf, **1994**), resulting from the addition of the spectra of all isotopomers containing ^{119}Sn, and ^{119}Sn together with ^{117}Sn, weighted according to their natural abundances. The Sn satellites of the low-field signal originate from the superposition of signals of the σ^3-Sn atoms in the isotopomers with one additional ^{119}Sn in 3-position [7.2% rel. intensity, $^1J(^{119}Sn,^{115}Sn)$ = 2223 Hz], ^{117}Sn in 3-position (6.3% rel. intensity, $^1J(^{119}Sn,^{117}Sn)$ = 2123 Hz) and ^{117}Sn in 1(2)-position (6.3% rel. intensity, $^1J(^{119}Sn,^{117}Sn)$ = 2110 Hz) (cf. *c*, *d*, and *e*). For the high field signal the Sn satellites arise from the signals of the σ^4-Sn atom of the isotopomers with one additional ^{119}Sn (14.3% rel. intensity) and ^{117}Sn (12.7 rel. intensity) in 1(2)-position (cf. *c* and *d*).

Sn atoms in **6** of 2223 and 2123 Hz, respectively, are of the same order of magnitude as $^1J(^{119}Sn,^{117}Sn)$ in the cyclotristannanes **4** with R = 2,6-$Et_2C_6H_3$ (2285 Hz[6]) and with R = 2,4,6-$iPr_3C_6H_2$ (3017[24]).

The *$^{29}Si\{^1H\}$-NMR spectrum* of **6** shows, in accordance with the cyclotristannene structure, two signals of equal intensity at δ = 58.0 (for $Sn(SitBu_3)_2$) and at δ = 35.6 (for $SnSitBu_3$). Each of the two signals is accompanied by one pair of satellites, resulting from the isotopomers with one ^{119}Sn or ^{117}Sn directly bonded to the ^{29}Si nucleus. A $^1J(Sn,Si)$ of 81 Hz for the $SitBu_3$ groups at the distannene unit falls into the usual range. In contrast, an unusually small value[25] of $^1J(Sn,Si)$ = 12 Hz is observed for the $SitBu_3$ groups bonded to the tetracoordinate tin atom.

The dark red-brown crystals of the cyclotristannene, obtained from *tert*-butyl methyl ether at −25 °C, contain according to the result of an *X-ray structure analysis* two independent molecules **6** in the unit cell. Figure 5 shows the structure of one of the molecules **6**, as well as selected bond lengths and bond angles for both molecules. However, due to the poor quality of the crystals obtained from *t*BuOMe (no crystals could be obtained from heptane or benzene), only the positions of the Sn and Si atoms could be determined with sufficient accuracy.

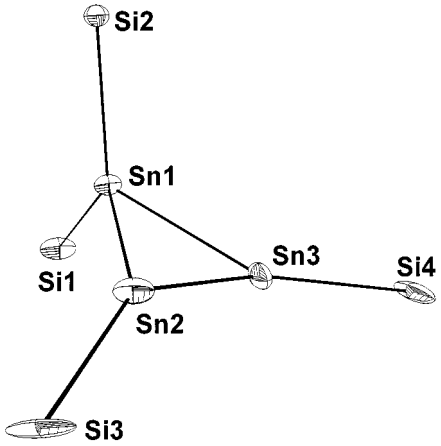

Figure 5. View of the molecular core of one of the two crystallographically independent cyclotristannene molecules **6** in the unit cell (ORTEP plot, 25% thermal probability ellipsoids, *tert*-butyl groups omitted for clarity). Selected bond lengths [A] and angles [°] (in brackets corresponding data of the second molecule **6** in the unit cell with Sn4/Sn5/Sn6 instead of Sn1/Sn2/Sn3): Sn1−Sn2 2.852(2) [2.841(3)], Sn1−Sn3 2.859(3) [2.846(2)], Sn2−Sn3 2.601(3) [2.582(4)]. − Sn2−Sn1−Sn3 54.19(7) [53.99(8)], Sn1−Sn2−Sn3 63.05(7) [63.07(8)], Sn2−Sn3−Sn1 62.76(6) [62.94(7)]. − Angle sum at Sn2/Sn3 350.8/355.8, at Sn5/Sn6 359.6/360.0.

The most striking feature in the structure of **6** is the SnSn double bond length in the Sn_3 rings, for which an average value of only 2.59 Å is found. The cyclotristannene **6** exhibits thus the shortest Sn=Sn bond of all structurally investigated distannenes so far (cf. Table 1). The Sn=Sn moiety has a nearly planar surrounding, formed by the directly attached Si atoms and by the tetracoordinate Sn atom. Thus the "distannene" **6** is the first compound with a Sn=Sn bond analogous to C=C bonds. As in the case of other analogous of the C=C bond, the length of a "true" Sn=Sn bond can be calculated as the sum of the atom radii, each reduced by 0.1 Å ($2 \times r_{Sn} - 0.2 = 2 \times 1.40 - 0.2 = 2.60$ Å[10]). The SnSn single bond lengths in the Sn_3 rings are with an average value of 2.85 Å somewhat longer than the sum of the Sn atom radii (2.80 Å).

The four supersilyl groups in compound **6** occupy roughly the edges of a tetrahedron, thus adopting a close packing. They cover the Sn_3 ring almost completely and prevent it from reacting with the Sn_3 ring of another molecule. The distances between the Si atoms and the attached unsaturated Sn atoms in **6** of 2.57−2.60 Å fall within the usual range ($r_{Sn} + r_{Si} = 1.40 + 1.17 = 2.57$ Å). On the other hand the distances of the Si atoms bonded to the saturated Sn atom in the cyclotristannene (2.72−2.76 Å) are clearly elongated as a consequence of the steric interactions between the two supersilyl groups.

Experimental Section

All experiments were carried out in flame-dried glass apparatus with the Schlenk technique under dry argon atmosphere. During all manipulations air and moisture were strictly excluded. *t*Bu_3SiNa (in pentane),[27] *t*Bu_3SiNa (in THF),[27] Sn(O*t*Bu)$_2$,[11] and Sn[N(SiMe$_3$)$_2$]$_2$[12] were prepared according to literature procedures. The solvents (pentane, benzene, tetrahydrofuran) were distilled from sodium/benzophenone immediately before use. − The NMR spectra were recorded with a JEOL GSX-270 (^{1}H/^{13}C/^{29}Si/^{119}Sn: 270.17/67.94/53.67/100.75 MHz) and a JEOL EX-400 (^{1}H/^{13}C/^{29}Si/^{119}Sn: 399.78/100.54/79.43/149.08 MHz) spectrometer. The ^{29}Si-NMR spectra were recorded with the INEPT pulse sequence using empirically optimized parameters for polarization transfer from the *t*Bu substituents. For the ^{119}Sn-NMR spectra an acquisition time of 0.3−0.4 s and a repetition rate of ca. 0.6 s were used; for 0.1 m solutions of the tin compounds typically 5000 scans were necessary to obtain spectra with satisfactory signal to noise ratio.

Formation of 5 from Sn[N(SiMe$_3$)$_2$]$_2$: A solution of 0.311 g (0.708 mmol) of Sn[N(SiMe$_3$)$_2$]$_2$ in 0.7 mL of pentane and 0.1 mL of C_6D_6 was added dropwise to 0.152 g (0.685 mmol) of solid *t*Bu_3SiNa at −196 °C. The resulting reaction mixture was warmed to −25 °C. At this temperature the reaction solution contains, according to the ^{119}Sn-NMR spectrum, **5** (see below), **6** (see below), Sn[N(SiMe$_3$)$_2$]$_2$,[12] and a still unidentified tin compound **7** bearing *t*Bu_3Si as well as Me_3Si groups and two equivalent tin atoms [integral ratio of the ^{119}Sn NMR signals of **5** (1 + 2 Sn atoms), **6** (1 + 2 Sn atoms), **7** (2 Sn atoms) = (7 + 14):(1/2 + 1):5].[28] In the ^{29}Si-NMR spectrum of the reaction solution at −25 °C in addition to **5**, **6**, Sn[N(SiMe$_3$)$_2$]$_2$, and **7**, as well as *t*Bu_3Si−Si*t*Bu_3 (δ = 35.2) and *t*Bu_3SiH (δ = 17.4) can be identified. The reaction solution was separated at −25 °C from the precipitate formed, which was then washed with pentane (1 mL). The combined pentane solutions are kept at −25 °C for several days during which time dark blue crystals of *tetrakis(tri-tert-butylsilyl)tristannaallene* (**5**) (0.040 g, 0.035 mmol, 20%) are formed. − ^{1}H NMR (C_6D_6, −25 °C, TMS internal reference (int.)): δ = 1.40 (s, 4 Si*t*Bu_3). − ^{29}Si NMR (C_6D_6, −25 °C, TMS external reference (ext.)) and ^{119}Sn NMR ($C_6D_5CD_3$, −20 °C, $SnMe_4$ ext.): Cf. general part and Figure 1. − X-ray structure analysis. Cf. Figure 2 and 3.

Formation of 5 from Sn(O*t*Bu)$_2$: In an NMR tube 0.055 g (0.207 mmol) of Sn(O*t*Bu)$_2$ and 0.046 g (0.207 mmol) of *t*Bu_3SiNa are dissolved in 0.6 mL of C_6D_6 and the solution was immediately cooled to −25 °C. The reaction mixture instantly adopts a black color. The ^{29}Si-NMR spectrum of the reaction solution shows after warming to ambient temperature the signals of *t*Bu_3Si−Si*t*Bu_3, *t*Bu_3SiH, and **5**.

Formation of 6 from Sn(O*t*Bu)$_2$: A solution of 3.179 g (12.00 mmol) of Sn(O*t*Bu)$_2$ in 20 mL of pentane was added dropwise at −78 °C to a solution of 8.799 g (24.00 mmol) of *t*Bu_3SiNa(THF)$_2$ in 60 mL of pentane. After stirring for 3 d at −78 °C and for further 2 d at ambient temperature the reaction solution contains, according to the ^{1}H-NMR spectrum, in addition to supersilane *t*Bu_3SiH (formed from the hydrolysis of *t*Bu_3SiNa) practically only *t*Bu_3Si−Si*t*Bu_3 and **6** in a molar ratio of 1.1 (in the case the formation of **6** would proceed exclusively via (1) and (2) the molar ratio should amount to 1.0). The solvent and all volatile components are removed in vacuo, the remaining brown residue was stirred with 50 mL of *n*-heptane, and the insoluble materials (mainly NaO*t*Bu and small

amounts of an insoluble tin compound) are separated by filtration. The solvent was removed from the filtrate in vacuo and the residue left dissolved in 20 mL of pentane. In the course of 2 weeks at −23 °C one part of the dissolved superdisilane crystallizes from the pentane solution and was separated by filtration. The pentane filtrate was subjected to flash chromatography on an Al_2O_3 column with *n*-heptane as mobile phase. The heptane was removed in vacuo and the residue dissolved in 30 mL of *t*BuOMe. After several days *1,2,3,3-tetrakis(tri-tert-butylsilyl)cyclotristannene* (**6**; 1.244 g, 1.080 mmol, 27%) crystallizes from this solution at −25 °C as dark red-brown rods. − ^{1}H NMR (C_6D_6, TMS int.): δ = 1.409 (s; 2 SnSi*t*Bu$_3$), 1.515 [s; Sn(Si*t*Bu$_3$)$_2$]. − ^{13}C{^{1}H} NMR ($C_6D_5CD_3$, TMS int.): δ = 29.05/34.66 (*C*Me$_3$/C*Me*$_3$ of 2 SnSi*t*Bu$_3$), 26.42/32.55 [*C*Me$_3$/C*Me*$_3$ of Sn(Si*t*Bu$_3$)$_2$]. − ^{29}Si (C_6D_6, TMS ext.) and ^{119}Sn NMR (C_6D_6, SnMe$_4$ ext.): Cf. General part and Figure 4. − X-ray structure analysis: Cf. Figure 5.

Thermolysis of 5: A solution of 0.152 g (0.306 mmol) of Sn[N(SiMe$_3$)$_2$]$_2$ in 0.6 mL of C_6D_6 was added to 0.059 g (0.265 mmol) of *t*Bu$_3$SiNa and the resulting blue reaction solution was investigated by ^{1}H and ^{29}Si NMR. Every 24 min a ^{1}H-NMR spectrum (16 scans, PD = 2.5 s) was recorded at 25 °C for a total of 27 ^{1}H-NMR spectra. Between every two ^{1}H experiments a ^{29}Si-NMR spectrum was recorded in order to control the course of the reaction. The first recorded ^{1}H-NMR spectrum showed the following signals: δ = 1.407 (**5**, rel. intensity 2.69), 1.476 and 1.378 (**6**, rel. intensity of both signals together 2.19), 1.365 (*t*Bu$_3$Si−Si*t*Bu$_3$, rel. intensity 1.67), 1.118 (*t*Bu$_3$SiH, rel. intensity 2.65), 1.343 and 0.456 (**7**, rel. intensity of both signals together 2.76), 0.274 {Sn[N(SiMe$_3$)$_2$]$_2$, rel. intensity 11.5}. The intensities of the ^{1}H-NMR signals as resulting from the evaluation of the integrals, are assumed to correspond to the relative concentrations of the single compounds in the reaction solution. To determine the reaction order ln(signal region **5** + signal region **6**/signal region **5**) was plotted against the time *t*, where signal regions **5** and **6** are the relative intensities of the ^{1}H-NMR signals of **5** and **6** (both signals of **5** as well as **6** together), respectively. The half-life of the first-order isomerization was determined to be 9.8 h at 25 °C.

X-ray Structure Determination of 5: Siemens P4 diffractometer, Mo-K_α radiation, graphite monochromator, CCD area detector, crystal dimensions 0.2 × 0.15 × 0.1 mm. The crystal was mounted in perfluoro ether oil, T = 183(2) K, $C_{48}H_{108}Si_4Sn_3$, M_r = 1153.77, deep purple prism, orthorhombic, a = 28.7513(6), b = 12.1963(2), c = 33.3574(2) Å, α = β = γ = 90°, V = 11697.1(4) Å^3, Z = 8; space group *Pca*2(1), ρ_{cacd} = 1.310 Mg m^{-3}, μ = 1.381 mm^{-1}, F(000) = 4816. *Data collection*: 2 θ from 2.44 to 58.38°, $-38 \le h \le 30$, $-15 \le k \le 15$, $-41 \le l \le 41$; of 64648 reflections 22638 were independent (R_{int} = 0.1221) and 14134 were observed [$F > 4\sigma(F)$], semiempirical absorption correction with SADABS (max./min. transmission 0.9765/0.8571), R_1 = 0.0708, wR_2 = 0.0801 [$F > 4\sigma(F)$], GOOF (F^2) = 0.989; maximum residual electron density 1.226 eÅ^{-3}. *Structure determination:* The structure was solved by direct methods (SHELXL-97). The absolute structure could not be determined. Three C atoms could only be refined with isotropic displacement parameters. The structure has not been completely refined until now.[29]

X-ray Structure Determination of 6: Siemens P4 diffractometer, Mo-K_α radiation, graphite monochromator, CCD area detector. It was extremely difficult to select a suitable crystal from the almost brown-black solution, and a large number of crystals were tested. The crystals were mounted in perfluoro ether oil, T = 183(2) K, $C_{48}H_{108}Si_4Sn_3$, M_r = 1153.77, deep red-brown plates. The best crystal 0.2 × 0.15 × 0.1 mm, gave the following monoclinic cell: a = 13.133(3), b = 29.956(6), c = 16.752(3) Å, β = 95.365(8)°, V = 6561.4 Å, Z = 4. In spite of absorption correction (SADABS), it was difficult to find an acceptable space group. For the best crystal it was space group *P*2(1). Structure solution by the heavy atom method revealed clearly the Sn_3Si_4 core of the molecule. The Sn−Si atom distances covered the range from 2.567(7) to 2.763(7) Å. Almost all *tert*-butyl groups showed rotational disorder. Therefore, the R_1 value of the "best" solution is only 17%. This is of course rather unsatisfactory; however, the data for the Sn−Sn distances are reliable if the esd′s are considered.

Chiral Phosphoramidite Ligands Based on 8-Chloroquinoline and Their Rhodium(III), Palladium(II), and Platinum(II) Complexes

Giancarlo Franciò,[a] Carmela G. Arena,[a] Felice Faraone,*[a] Claudia Graiff,[b] Maurizio Lanfranchi,[b] and Antonio Tiripicchio[b]

Keywords: Phosphoramidite / Chiral ligands / Platinum / Rhodium

The new chiral ligands 2-butyl-8-chloro-1-(4,8-di-*tert*-butyl-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a*,*c*]cyclohepten-6-yl)-1,2-dihydroquinoline (BIPHENPHOSHQUIN, **3**) and 2-butyl-8-chloro-1-(3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]-dinaphthalen-4-yl)-1,2-dihydroquinoline (BINAPHOSHQUIN, **4**; **4a**: S_aR_C, **4b**: S_aS_C) have been synthesized starting from the rigid backbone of 8-chloroquinoline. The reactions of **3** and **4** with rhodium(I), palladium(II), and platinum(II) substrates are reported. The reaction of **3** with $[Rh(CO)_2Cl]_2$ in a 2:1 molar ratio in hexane afforded a binuclear chloro-bridged rhodium(III) species by intramolecular oxidative addition of the C–Cl bond of ligand **3** across the rhodium(I) centers. The rhodium(III) complex **5**, incorporating the enantiomers S_aR_C-**3** and R_aS_C-**3**, has been fully characterized by X-ray diffractometry. Reactions of $[Pd(PhCN)_2Cl_2]$ with the ligands **3** and **4a** in 1:2 molar ratio in toluene afforded the products *cis*-$[Pd(\mathbf{3})_2Cl_2]$ (**9**) and *cis*-$[Pd(\mathbf{4a})_2Cl_2]$ (**10**). Similarly, reaction of $[Pt(COD)I_2]$ with **4a** in a 1:2 molar ratio afforded the complex *cis*-$[Pt(\mathbf{4a})_2I_2]$ (**11**). An X-ray analysis has been carried out to obtain information on the effect of the ligand **4a** on the overall structure of **11**.

Introduction

Recently, much attention has been focused on the development of chiral ligand-modified catalysts for application in asymmetric synthesis.[1] Attempts have been made to correlate structural and electronic characteristics of the coordinated ligands with the catalytic activities of the resulting metal complexes. The structural features of the ligands, such as the "natural bite angle",[2] the rigidity, and the presence of bulky substituents, drastically influence the chemo- and regioselectivity of the catalytic process.[3] Recent contributions[4] have shown that diphosphites or a mixed phosphane/phosphite containing a chiral bridging moiety are efficient ligands in the rhodium-catalyzed asymmetric hydroformylation of olefinic substrates. Several mono- and bidentate phosphane ligands have been prepared starting from molecules with rigid polyaromatic backbones.[5] Their abilities in determining unusual geometries when coordinated to a metal center are of great interest.

The present work stems from our interest in developing large chiral mono- and bidentate ligands starting from the rigid backbone of quinolines, and to study the properties of their d^8-metal complexes, particularly in homogeneous catalysis. We report here the synthesis of large chiral monodentate phosphoramidites, and of their rhodium(III), palladium(II), and platinum(II) complexes, together with the X-ray structures of some representative compounds of this series. Recently,[6] phosphoramidite ligands have been used in homogeneous catalysis. Several metal complexes incorporating ligands based on quinolines, such as 8-(dimethylphosphanyl)quinoline, 8-(dimethylarsanyl)quinoline, 8-(diphenylphosphanyl)quinoline, 8-(diphenylarsanyl)quinoline, bis(6-methylquinolin-8-yl)phenylarsane, tris(6-methylquinolin-8-yl)phenylarsane, (*R*)- and (*S*)-methylphenyl(8-quinolyl)phosphane, and (*R*)- and (*S*)-methylphenyl(8-quinolyl)-arsane, have previously been reported.[7] Application of ligands **3** and **4** in copper-catalyzed enantioselective Michael addition will soon be reported.[8]

Results and Discussion

Synthesis of the Ligands

Reaction of 8-chloroquinoline with *n*BuLi[9] in a 1:1 molar ratio in tetrahydrofuran at −78 °C involves addition of the butyl group to the carbon atom in the 2-position and lithiation of the nitrogen atom. Consequently, the ring containing the nitrogen atom loses its aromaticity and the carbon atom in the 2-position becomes a stereogenic center. Addition of an excess of neat PCl_3 to the THF solution of anion **1** affords, after removal of the unreacted PCl_3 under reduced pressure, compound **2** (Scheme 1). Subsequent treatment of a solution of **2** in toluene at 0 °C with equimolar amounts of 3,3′-di-*tert*-butyl-2,2′-dihydroxy-5,5′-dimethoxybiphenyl and NEt_3 affords the ligand 2-butyl-8-chloro-1-(4,8-di-*tert*-butyl-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a*,*c*]cyclohepten-6-yl)-1,2-dihydroquinoline (BIPHENPHOSHQUIN, **3**) (Scheme 1).

Compound **3** was also obtained by treating 4,8-di-*tert*-butyl-6-chloro-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo-

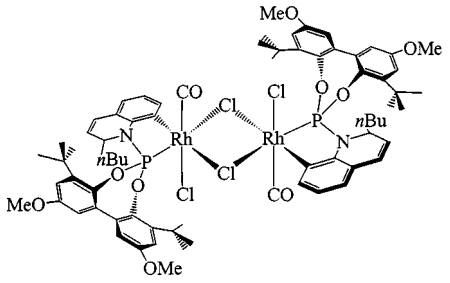

Scheme 1. (i) thf, −78°C, BuLi; (ii) thf, −78°C, PCl_3; (iii) thf, −78°C, 4,8-di-*tert*-butyl-6-chloro-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a*,*c*]cycloheptene; (iv) thf, −78°C, (*S*)-4-chloro-3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]dinaphthalene; (v) toluene, 0°C, Et_3N, 3,3′-di-*tert*-butyl-2,2′-dihydroxy-5,5′-dimethoxybiphenyl; (vi) toluene, 0°C, Et_3N, (*S*)-2,2′-dihydroxybinaphthyl

[*a*,*c*]cycloheptene with the anion **1** in THF solution. Because of the atropoisomerism of the biphenyl moiety and the presence of a stereogenic carbon atom, compound **3** may be obtained as a racemic mixture of two diastereoisomers [(S_aR_C), (R_aS_C), (S_aS_C), and (R_aR_C)]. The $^{31}P\{^1H\}$-NMR spectra in CD_2Cl_2 solution at 293 K and 193 K show a singlet at δ = 141.1 and are consistent with either the presence of only one of the two possible enantiomeric pairs, or with rapid atropoisomerization of the biphenyl moiety on the NMR time scale. In some cases, $^{31}P\{^1H\}$-NMR spectroscopy does not allow a distinction of species present in solution.[10] In the ^1H-NMR spectrum in $CDCl_3$, the *tert*-butyl groups display two different chemical shifts due to their diastereotopicity.

The ligand 2-butyl-8-chloro-1-(3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]dinaphthalen-4-yl)-1,2-dihydroquinoline (BINAPHOSHQUIN, **4**) was similarly obtained either by addition of the enantiomer (S_a)-(−)-2,2′-dihydroxy-1,1′-binaphthyl in toluene to a solution of **2** in the same solvent, or by addition of (*S*)-4-chloro-3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]dinaphthalene in THF to a solution of the anion **1** in the same solvent (Scheme 1). An improved procedure[4a] was utilized for the synthesis of (*S*)-4-chloro-3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]dinaphthalene (see Experimental Section). Compound **4** was found to be moisture-sensitive and was obtained as a mixture of the two diastereoisomers [(S_aR_C)and (S_aS_C)]. Thus, the $^{31}P\{^1H\}$-NMR spectrum in $CDCl_3$ solution shows two peaks at δ = 137.6 and 145.1, while in the ^1H-NMR spectrum two sets of signals are seen. The synthesis method had an effect on the diastereoisomer ratio. Starting from **2**, the diastereoisomers were formed in a 50:50 ratio, whereas starting from the anion **1** an excess (70:30) of the (S_aS_C) diastereoisomer was obtained. The (S_aR_C) and (S_aS_C) diastereoisomers (**4a** and **4b**, respectively) could be separated as white solids by virtue of their different solubilities in hexane and were characterized by microanalysis and spectroscopic data. By comparison with the structure of *cis*-[Pt(**4a**)$_2$I$_2$] (**11**) (see below), it can be inferred that the diastereomer exhibiting a $^{31}P\{^1H\}$-NMR resonance at δ = 137.6 has the absolute configuration (S_aR_C).

Syntheses of the Complexes

We treated the ligands **3** and **4** with rhodium(I), palladium(II), and platinum(II) precursors. Addition of a hexane solution of ligand **3** to $[Rh(CO)_2Cl]_2$ in the same solvent in a 2:1 molar ratio afforded a yellow solid, which was recrystallized from CH_2Cl_2/hexane. The air-stable product **5** proved to be non-conducting in benzene solution and its structure was fully elucidated by an X-ray analysis of crystals of its hexane solvate (see below).

5

The IR spectrum (Nujol mull) of **5** shows a ν(CO) band at 2112 cm^{-1}, consistent with an oxidative process on the starting rhodium(I) center. It is noteworthy that the ^1H-NMR spectrum in $CDCl_3$ solution features two signals with very different shifts (δ = 1.75 and 1.08) due to the *tert*-butyl groups; a slight difference in the methoxy group resonances is also observed (δ = 3.86 and 3.87). The $^{31}P\{^1H\}$-NMR spectrum in $CDCl_3$ solution shows a single resonance at δ = 127.7 (J_{RhP} = 197 Hz).

In the crystals of **5** · 2 C_6H_{14}, dimeric rhodium(III) complexes, having an imposed C_i symmetry, are present, together with disordered molecules of hexane. A view of the dimer showing the atomic numbering system is presented in Figure 1. Selected bond lengths and angles are given in Table 1. Two Cl atoms bridge the two rhodium atoms in an asymmetric manner.

The metal has an octahedral coordination sphere, involving three Cl atoms (two bridging and one terminal), a carbonyl group, and the P1 and C3 atoms of the chelating ligand, derived from oxidative addition of **3**. The five-membered Rh−P1−N1−C2−C3 chelating ring is approximately planar. The Rh−Cl2 bond length, 2.328(4) Å, is much shorter than those involving the bridging Cl1 and Cl1′ atoms, which amount to 2.454(4) and 2.536(4) Å. In accordance with the *trans* influence, the Rh−Cl1 bond length (Cl1 *trans* to P1) is shorter than the Rh−Cl1′ bond length (Cl1′

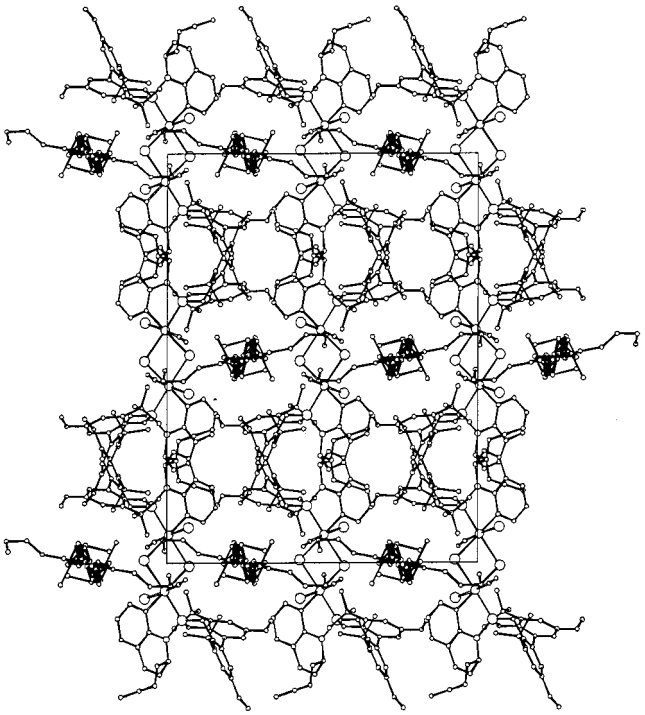
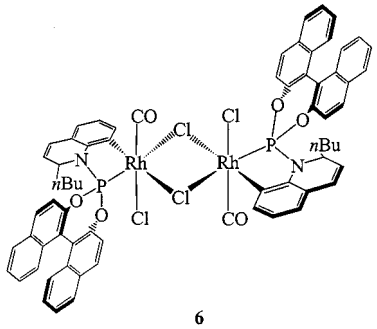
trans to C3). As a result of the chelation, the mean plane of the fragment derived from the quinoline approximately bisects the O−P−O angle. The chiral C10 atom lies out of the plane formed by the other five atoms of the ring by 0.44(2) Å. The *n*-butyl groups are situated in axial positions so as to minimize steric repulsion with the biphenyl moiety and thus determine the configuration [(S_aR_C) and (R_aS_C)] of the atropoisomeric unit in complex **5**. The torsion angle, determining the axial chirality of the ligand [τ(C11−C16−C17−C18)], is 55(2)°. The nitrogen atom shows a remarkable degree of sp^2 character.

The packing of the complexes in the crystal leads to the formation of large channels that extend along the *b* axis, into which hexane molecules can insert in a disordered fashion (Figure 2).

It seems very likely that the formation of **5** occurs via an intermediate rhodium(I) species. In this way, an intramolecular redox process, due to the addition of the C−Cl bond of the coordinated ligand **3** across the rhodium(I) center, can account for the formation of the product **5**. The breaking of the C(aromatic)−Cl bond may be induced by the rigidity and steric requirements of **3**, which fix the chlorine atom in the proximity of the metal center in the rhodium(I) intermediate.

Nozaki et al.,[4a] using phosphane/phosphite ligands derived from reaction of optically active (*R*)-2-(diphenylphosphanyl)-1,1′-binaphthalen-2′-ol with the phosphorochloridite of biphenol in the rhodium(I)-catalyzed hydroformylation of olefins, found that a single species is present in solution and they proposed that the biphenyl is fixed in an (*S*) configuration. Analogously, the phosphane/phosphite ligand prepared starting from racemic 2-diphenylphosphanyl-2′-hydroxybiphenyl by reaction with the phosphorochloridite of (*R*)-binaphthol was obtained as a 55:45 equi-





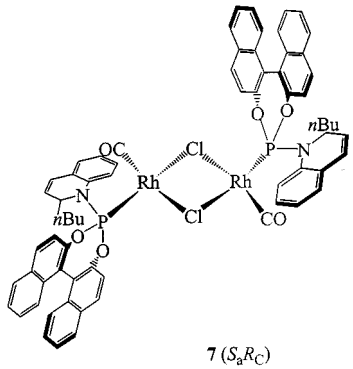


Figure 2. Projection of the structure of $\mathbf{5} \cdot 2\ C_6H_{14}$ along the *b* axis showing the channels into which the hexane molecules are inserted in a disordered manner

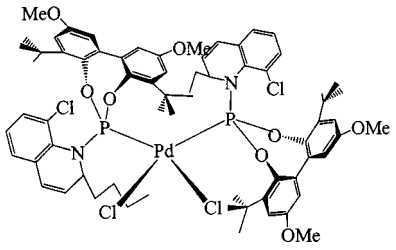
librium mixture of two diastereomers. Interconversion between the diastereomers seems to be inhibited by coordination to the rhodium(I) center and in the resulting compound the ligand adopts only one configuration.[4a] Other examples of the fixation of biphenyl rings following coordination to a metal center, using biphenol-derived bis(phosphites), have been reported in the literature.[11] Fixation of the biphenyl rings also occurs in compound **5** due to the presence of the substituents and the rigidity of the chelate quinoline ring.

The reaction of $[Rh(CO)_2Cl]_2$ with **4** proceeds differently to that with **3**. Addition of a twofold molar excess of diastereomer **4a** (S_aR_C) in hexane to a solution of $[Rh(CO)_2Cl]_2$ in the same solvent afforded a yellow solid. The IR spectrum shows ν(CO) bands at 2106 and 2012 cm^{-1}, indicating the presence of the rhodium(III) species **6** as the major product, together with the rhodium(I) species **7** (ratio 10:1.5). The $^{31}P\{^1H\}$-NMR spectrum of the mixture in $CDCl_3$ solution features a resonance at δ = 134.8 (J_{RPh} = 192 Hz) for the major product **6**, together with a resonance at δ = 135.0 (J_{RhP} = 191 Hz) of very low intensity. The similar values of the ^{31}P chemical shifts for **6** and **7** are consistent with structures in which the ligands *trans* to **4a** are the same. Assuming that **6** has a structure analogous to that of **5**, it is very likely that **7** has a binuclear structure with chloro bridges, i.e. $[Rh(CO)(\mathbf{4a})Cl]_2$. A similar intermediate, $[Rh(CO)(\mathbf{3})Cl]_2$, should be formed in the reaction of $[Rh(CO)_2Cl]_2$ with **3**. Compound **6** was obtained in an analytically pure state by several crystallizations from benzene/hexane. The ^1H-NMR spectrum of **6** in $CDCl_3$ solution shows a multiplet at δ = 5.15 and a doublet at δ = 6.28 (^3J = 10.2 Hz) due to the olefinic protons, while a multiplet at δ = 3.24 can be assigned to the proton on the stereogenic carbon atom.

6

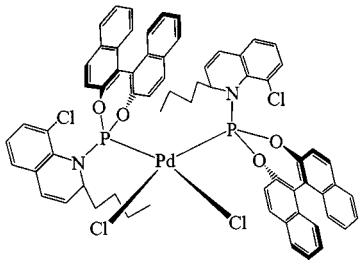
7 (S_aR_C)

8 (S_aS_C)



The reaction of $[Rh(CO)_2Cl]_2$ with **4b** in hexane gave only the rhodium(I) species, i.e. $[Rh(CO)(\mathbf{4b})Cl]_2$ (**8**) with the ν(CO) appearing at low wavenumbers. With this diastereoisomer, the intramolecular redox process of addition of the C−Cl bond across the rhodium(I) center seems to be hindered.

Binuclear chloro-bridged compounds, such as **7** and **8**, have been detected previously by NMR spectroscopy.[12] In the reactions with $[Rh(CO)_2Cl]_2$, the rigidity and steric requirements of the ligands **3**, **4a**, and **4b** might be a factor determining the nature of the reaction products. Thus, in reactions of $[Rh(CO)_2Cl]_2$ with sterically hindered ligand molecules, a CO substitution reaction might be preferred to cleavage of the chloro bridges. The C−Cl bond in haloarenes is rather inert. Unlike alkyl halides, haloarenes exhibit low reactivities toward nucleophiles.[13] The use of rhodium(I) complexes in catalytic transformations of chloroarenes is limited to a few examples of C−Cl bond hydrogenolysis.[13] Intramolecular activation of the C−Cl bonds in $[Rh(CO)(\mathbf{3})Cl]_2$, **7** and **8**, requires a proximity of the chlorine atom to the metal center. The diastereoisomers **4a** and **4b** behave differently in the intermediate, most probably because with the (S_aS_C) diastereomer **4b**, the C−Cl bond is positioned away from the rhodium(I) center.



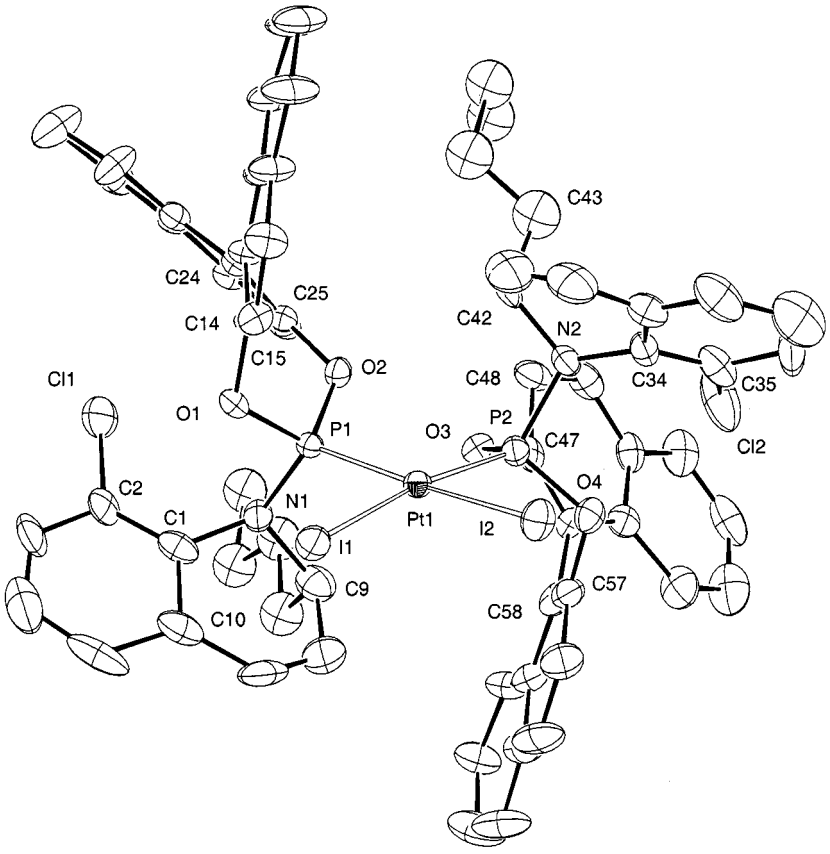
Overnight stirring of $[Pd(PhCN)_2Cl_2]$ and ligand **3** in a 1:2 molar ratio in toluene led to a bright-yellow solution. Workup of the reaction mixture furnished the product $[Pd(\mathbf{3})_2Cl_2]$ (**9**) as a yellow solid, which was found to be stable in air in the solid state and soluble in dichlorometh-

ane. In this case, in contrast to the situation in the rhodium(I) complex **5**, the ligand **3** acts as a monodentate ligand. Compound **9** was characterized by microanalysis and spectroscopic data. The $^{31}P\{^1H\}$-NMR spectrum in CD_2Cl_2 solution shows two partially overlapped singlets at $\delta = 134.1$ and $\delta = 134.2$, with an intensity ratio of ca. 1:0.7. This supports the presence of only two diastereomers, i.e. [Pd(R_C-**3**)(R_C-**3**)Cl_2] {[Pd(S_C-**3**)(S_C-**3**)Cl_2]} and [Pd(S_C-**3**)(R_C-**3**)Cl_2], assuming that the rapid atropoisomerism of the biphenyl moiety is still possible. In the ^1H-NMR spectrum in CD_2Cl_2 solution, at either 298 K or 193 K, only one set of signals is observed, hence there is no discrimination between the two diastereomers. The *tert*-butyl groups give rise to singlets with markedly different chemical shift values ($\delta = 0.95$ and 1.61), whereas only a slight difference is seen in the δ values of the methoxy groups ($\delta = 3.78$ and 3.84).

The reaction of [Pd$(PhCN)_2Cl_2$] with ligand **4a** in a 1:2 molar ratio proceeded similarly and the complex [Pd(**4a**)$_2Cl_2$] (**10**) was obtained in high yield as a yellow solid. The product was found to be stable in air in the solid state and soluble in benzene, acetone, and chlorinated solvents. Its $^{31}P\{^1H\}$-NMR spectrum in $CDCl_3$ shows a single peak at $\delta = 117.5$. In the ^1H-NMR spectrum in $CDCl_3$, the olefinic protons give rise to a double-doublet at $\delta = 4.50$ ($^3J = 5.4$ Hz, $^3J = 9.4$ Hz) and a doublet at $\delta = 6.40$ ($^3J =$ 9.4 Hz). The proton at the stereogenic center appears as a multiplet at $\delta = 3.95$. The appearance of two ν(PdCl) bands at about 335 and 300 cm^{-1} in the IR spectrum (Nujol mull) is indicative of a *cis* configuration for **9** and **10**.

9

10



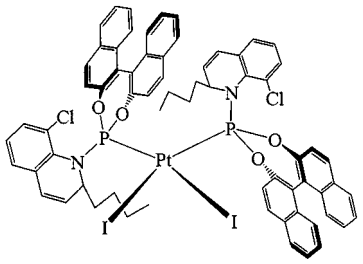


Figure 3. ORTEP view of the structure of complex **11** showing the atomic numbering scheme; thermal ellipsoids are drawn at a 30% probability level

Similarly, reaction of $[Pt(COD)I_2]$ with **4a** in a 1:2 molar ratio afforded *cis*-$[Pt(\mathbf{4a})_2Cl_2]$ (**11**) as a yellow crystalline solid. The compound was characterized by microanalysis and spectroscopic data. The effect of the coordinated ligand **4a** on the overall structure of **11** was assessed by X-ray analysis.

A view of complex **11** showing the atomic numbering system is depicted in Figure 3. Selected bond lengths and angles are given in Table 2. The Pt atom has a distorted square-planar coordination sphere involving two iodine atoms and the P atoms of two **4a** ligands.

The *cis* arrangement of these very bulky ligands leads to a remarkable distortion of the coordination geometry. The two P atoms deviate above and below the mean square plane by about 0.20(1) Å. The absolute configuration of both ligands is (S_aR_C). The two binaphthyl fragments reside on opposite sides with respect to the coordination plane, and the torsion angles determining the axial chirality [τ(C14−C23−C24−C25) and τ(C47−C56−C58−C57)] are 48(2)° and −54(2)°, respectively. In contrast to the nitrogen atoms in ligand **3** in complex **5**, the nitrogen atoms of the coordinated ligand **4a** in complex **11** show a remarkable degree of sp^3 hybridization, such that these atoms can be considered as chiral centers. In both ligands, the nitrogen atoms are of (*S*) configuration. In accordance with the observed structure, the $^{31}P\{^1H\}$-NMR spectrum shows a single resonance at δ = 94.5 (J_{PtP} = 5296 Hz), while the ^1H-NMR spectrum in $CDCl_3$ solution features a double-doublet at δ = 4.36 and a doublet at δ = 6.20 due to the vinylic protons, and a multiplet at δ = 4.05 attributable to the proton at the stereogenic center.

Surprisingly the compound $[Pt(COD)I_2]$ does not react with **3** in solution, even if an excess of the ligand is used. Most probably, the presence of OMe and *t*Bu substituents on the biphenyl ring of the ligand **3** prevents the formation of a *cis* square-planar platinum(II) complex.

Experimental Section

The compounds 3,3′-di-*tert*-butyl-2,2′-dihydroxy-5,5′-dimethoxybiphenyl and 4,8-di-*tert*-butyl-6-chloro-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a,c*]cycloheptene were prepared according to literature procedures.[5a,14] 8-Chloroquinoline was purchased from Tokyo Kasei Organic Chemicals, whereas all other reagents were purchased from Sigma/Aldrich and were used as supplied. Solvents were dried by standard procedures. All experiments were performed under purified nitrogen. − IR spectra were obtained from Nujol mulls on KBr plates using a Perkin−Elmer FT-IR 1720 spectrophotometer. − ^1H- and $^{31}P\{^1H\}$-NMR spectra were recorded with a Bruker AMX R300 instrument. ^1H-NMR spectra are referenced to internal tetramethylsilane and $^{31}P\{^1H\}$-NMR spectra to external 85% H_3PO_4; positive chemical shifts for all nuclei refer to higher frequencies. − Elemental analyses were performed by Redox s.n.c., Cologno Monzese, Milano.

2-Butyl-8-chloro-*N*-(dichlorophosphanyl)-1,2-dihydroquinoline (2): To a solution of 8-chloroquinoline (1.00 g, 6.1 mmol) in tetrahydrofuran (20 mL) at −78°C, 3.9 mL of a 1.6 M hexane solution of *n*-butyllithium was added dropwise. The reaction mixture was allowed to warm to −50°C, stirred for 1 h, then cooled to −78°C once more. Excess PCl_3 (8.37 g, 61.1 mmol) was then rapidly added to the lithium reagent. The reaction mixture was slowly allowed to warm to room temperature and then stirred for 2 h. After removal of the solvents and the excess PCl_3, the residue was extracted with toluene (40 mL). Evaporation of the solvent from the combined extracts afforded the product as a pale-yellow oil, which was used without further purification. Yield: 1.47 g (75%). − ^1H NMR

($CDCl_3$): δ = 6.94 (d, ^3J = 6.0 Hz, 1 H, Ar-H), 6.56 (m, 2 H, Ar-H), 6.05 (d, ^3J = 9.6 Hz, 1 H, CH=CH), 5.80 (dd, ^3J = 9.6 Hz, ^3J = 5.6 Hz, 1 H, CH=CH), 4.68 (m, 1 H, CH), 1.38−1.13 (m, 6 H, CH_2), 0.82 (t, ^3J = 7.2 Hz, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 160.7 (s).

(*S*)-4-Chloro-3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]dinaphthalene: A suspension of (*S*)-2,2′-dihydroxybinaphthyl (1.00 g, 3.5 mmol) and 1-methyl-2-pyrrolidone (0.001 g, 0.01 mmol) in PCl_3 (7.21 g, 52.5 mmol) was warmed to 75°C and then stirred for 5 min. After this time, a clear solution was obtained. The bulk of the excess PCl_3 was removed under reduced pressure and then the final traces were removed by azeotropic distillation with toluene (10 mL) in vacuo. A white solid corresponding to the title compound was obtained.

2-Butyl-8-chloro-1-(4,8-di-*tert*-butyl-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a*,*c*]cyclohepten-6-yl)-1,2-dihydroquinoline (3). − Method A: A solution of 3,3′-di-*tert*-butyl-2,2′-dihydroxy-5,5′-dimethoxybiphenyl (1.11 g, 3.1 mmol) and Et_3N (1.57 g, 15.5 mmol) in toluene (10 mL) was added dropwise over a period of 1 h to a solution of **2** (1.00 g, 3.1 mmol) in the same solvent (20 mL) at 0°C. The mixture was stirred at room temp. for 40 min and then the precipitate of $Et_3N \cdot HCl$ formed was removed by filtration. The toluene was evaporated from the filtrate and the residue was extracted with hexane (50 mL). Removal of the solvent from the combined extracts afforded **3** (1.69 g, 90%) as a white foam. − ^1H NMR ($CDCl_3$): δ = 7.34 (d, ^4J = 3.0 Hz, 1 H, Ar-H), 7.23 (d, ^4J = 3.0 Hz, 1 H, Ar-H), 6.89 (d, ^4J = 3.0 Hz, 1 H, Ar-H), 6.86 (d, ^4J = 3.0 Hz, 1 H, Ar-H), 6.75 (m, 3 H, Ar-H), 6.33 (d, ^3J = 9.5 Hz, 1 H, CH=CH), 5.83 (dd, ^3J = 9.5 Hz, ^3J = 5.7 Hz, 1 H, CH=CH), 4.48 (m, 1 H, CH), 3.49 (s, 3 H, OCH_3), 3.47 (s, 3 H, OCH_3), 1.83 [s, 9 H, $C(CH_3)_3$], 1.45 [s, 9 H, $C(CH_3)_3$], 1.56−1.53 (m, 2 H, CH_2), 1.24−1.12 (m, 4 H, CH_2), 0.84 (t, ^3J = 7.2 Hz, 3 H, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 141.1 (s). − $C_{35}H_{43}ClNO_4P$ (608.16): calcd. C 69.12, H 7.13, Cl 5.83, N 2.30; found C 68.85, H 7.01, Cl 5.59, N 2.15. − **Method B:** To a solution of 8-chloroquinoline (1.00 g, 6.1 mmol) in tetrahydrofuran (20 mL) cooled in an acetone/dry-ice bath, 3.9 mL of a 1.6 M hexane solution of *n*-butyllithium was added dropwise. The reaction mixture was allowed to warm to −50°C, stirred for 1 h, and cooled to −78°C once more. A precooled solution of 4,8-di-*tert*-butyl-6-chloro-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a*,*c*]cycloheptene (2.58 g, 6.1 mmol) in THF (3 mL) was then rapidly added to the lithium reagent (anion). The reaction mixture was slowly allowed to warm to room temperature and then stirred for 2 h. After removal of the THF, the residue was extracted with hexane (50 mL). Removal of the solvent from the combined extracts afforded **3** as a white foam. Yield: 2.97 g, 80%.

2-Butyl-8-chloro-1-(3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]-dinaphthalen-4-yl)-1,2-dihydroquinoline (4). Method A: In analogy to Method A for the preparation of compound **3**, compound **4** was synthesized from (*S*)-2,2′-dihydroxybinaphthyl (1.00 g, 3.5 mmol), Et_3N (1.76 g, 17.5 mmol), and **2** (1.13 g, 3.5 mmol). The ^1H- and $^{31}P\{^1H\}$-NMR spectra of the crude reaction mixture were consistent with the formation of an approximately 1:1 mixture of two diastereoisomers. Recrystallization from hexane allowed the components to be separated. The compound more soluble in hexane (0.56 g, 30%) proved to be the (S_aR_C) diastereoisomer **4a** (assignment based on X-ray studies of the corresponding diiodoplatinum complex). − ^1H NMR ($CDCl_3$): δ = 8.04−7.88 (m, 3 H, Ar-H), 7.64 (m, 1 H, Ar-H), 7.44−7.28 (m, 9 H, Ar-H), 7.23−7.03 (m, 2 H, Ar-H), 6.52 (d, ^3J = 9.5 Hz, 1 H, CH=CH), 5.74 (dd, ^3J = 9.5 Hz, ^3J = 5.6 Hz, 1 H, CH=CH), 4.35 (m, 1 H, CH), 1.48−1.20 (m, 6 H, CH_2), 0.61 (t, ^3J = 7.2 Hz, 3 H). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 137.6 (s). − $C_{33}H_{27}ClNO_2P$ (536.01): calcd. C 73.95, H 5.08, N 2.61, Cl 6.61; found C 73.75, H 5.02, N 2.71, Cl 6.45. − The compound less soluble in hexane (0.75 g, 40%) proved to be the (S_aS_C) diastereomer **4b**. − ^1H NMR ($CDCl_3$): δ = 7.96−7.89 (m, 3 H, Ar-H), 7.65 (m, 1 H, Ar-H), 7.45−7.26 (m, 9 H, Ar-H), 7.28−7.26 (m, 2 H, Ar-H), 6.36 (d, ^3J = 9.3 Hz, 1 H, CH=CH), 5.92 (dd, ^3J = 9.3 Hz, ^3J = 5.6 Hz, 1 H, CH=CH), 3.72 (m, 1 H, CH), 1.52−1.22 (m, 6 H, CH_2), 0.72 (t, ^3J = 7.2 Hz, 3 H, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 145.1 (s). − $C_{33}H_{27}ClNO_2P$ (536.01): calcd. C 73.95, H 5.08, Cl 6.61, N 2.61; found C 73.78, H 5.07, Cl 6.55, N 2.63. − **Method B:** In analogy to Method B for the preparation of compound **3**, compound **4** was synthesized from 8-chloroquinoline (0.3 g, 0.18 mmol), *n*BuLi (1.6 M in hexane, 0.56 mL), and (*S*)-4-chloro-3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]dinaphthalene (0.643 g, 0.18 mmol). In this case, the diastereomeric ratio was 70:30, with the (S_aS_C) diastereomer constituting the major product.

[Rh(CO)(P−C)Cl$_2$]$_2$ [P−C = 2-Butyl-1-(4,8-di-*tert*-butyl-2,10-dimethoxy-5,7-dioxa-6-phosphadibenzo[*a*,*c*]cyclohepten-6-yl)-1,2-dihydro-8-quinolyl] (5): A solution of **3** (0.317 g, 0.52 mmol) in hexane (15 mL) was added to a stirred solution of $[Rh(CO)_2Cl]_2$ (0.100 g, 0.26 mmol) in the same solvent (15 mL) at room temp. A yellow precipitate was deposited during the course of the addition. This solid was collected, washed with petroleum ether, and dried. Yield 0.382 g (95%). − IR (KBr, Nujol): ν(CO) = 2112 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 7.19 (d, ^4J = 2.9 Hz, 1 H, Ar-H), 6.97 (d, ^4J = 2.9 Hz, 1 H, Ar-H), 6.72 (m, 3 H, Ar-H), 6.68 (d, ^4J = 2.9 Hz, 1 H, Ar-H), 6.62 (d, ^4J = 2.9 Hz, 1 H, Ar-H), 6.19 (d, ^3J = 9.6 Hz, 1 H, CH=CH), 5.33 (br. dd, 1 H, CH=CH), 3.87 (s, 3 H, OCH_3), 3.86 (s, 3 H, OCH_3), 3.60 (br. m, 1 H, CH), 1.75 [s, 9 H, $C(CH_3)_3$], 1.08 [s, 9 H, $C(CH_3)_3$], 1.82−0.86 (m, 6 H, CH_2), 0.71 (t, ^3J = 7.3 Hz, 3 H, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 127.7 (d, J_{RhP} = 197 Hz). − $C_{36}H_{43}Cl_2NO_5PRh$ (774.53): calcd. C 55.83, H 5.60, Cl 9.15, N 1.81; found C 55.78, H 5.68, Cl 8.91, N 2.01.

[Rh(CO)(P′−C)Cl$_2$]$_2$ [P′−C = (S_aR_C)-2-Butyl-1-(3,5-dioxa-4-phosphacyclohepta[2,1-*a*;3,4-*a*′]dinaphthalen-4-yl)-1,2-dihydro-8-quinolyl] (6): A solution of **4a** (0.279 g, 0.52 mmol) in hexane was slowly added at room temp. to a stirred solution of $[Rh(CO)_2Cl]_2$ (0.100 g, 0.26 mmol) in the same solvent (15 mL) until the CO stretching bands of the reagent disappeared from the IR spectrum. A yellow precipitate was deposited during the course of the addition. This solid was collected and washed with petroleum ether. After repeated recrystallization from benzene/hexane, the pure title compound was obtained. Yield: 0.255 g (70%). − IR (KBr, Nujol): ν(CO) = 2106 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 8.08−7.36 (m, 12 H, Ar-H), 6.91−6.86 (m, 3 H, Ar-H), 6.28 (d, ^3J = 10.2 Hz, 1 H, CH=CH), 5.15 (m, 1 H, CH=CH), 3.24 (m, 1 H, CH), 1.24−0.76 (m, 6 H, CH_2), 0.54 (t, ^3J = 7.3 Hz, 3 H, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 134.8 (d, J_{RhP} = 192 Hz). − $C_{34}H_{27}Cl_2NO_3PRh$ (702.38): calcd. C 58.14, H 3.87, Cl 10.10, N 1.99; found C 58.35, H 3.93, Cl 9.89, N 2.03.

***cis*-[Pd(3)$_2$Cl$_2$] (9):** A solution of **3** (0.475 g, 0.78 mmol) in toluene (10 mL) was added to a solution of $[Pd(PhCN)_2Cl_2]$ (0.150 g, 0.39 mmol) in the same solvent (20 mL) cooled in an ice bath. The reaction mixture was then stirred overnight at room temperature. The yellow solution was subsequently concentrated to a volume of 5 mL and upon addition of 30 mL of diethyl ether a lemon-yellow solid was deposited. This solid was collected, washed with diethyl ether, and dried in vacuo. Yield: 0.489 g (90%). − IR (CsI, Nujol): ν(PdCl) = 335, 302 cm^{-1}. − ^1H NMR (CD_2Cl_2): δ = 7.62−7.54 (m, 3 H, Ar-H), 7.29 (d, ^3J = 7.4 Hz, 1 H), 7.13 (br., 1 H), 7.07

(d, ^4J = 3.0 Hz, 1 H, Ar-H), 6.86 (d, ^4J = 3.0 Hz, 1 H, Ar-H), 6.71 (d, ^4J = 3.0 Hz, 1 H, Ar-H), 6.65 (d, ^4J = 3.0 Hz, 1 H, Ar-H), 4.55 (m, 1 H, CH), 3.84 (s, 3 H, OCH_3), 3.78 (s, 3 H, OCH_3), 1.61 [s, 9 H, $C(CH_3)_3$], 1.48−1.22 (m, 6 H, CH_2), 0.95 [s, 9 H, $C(CH_3)_3$], 0.85 (t, ^3J = 7.1 Hz, 3 H, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 131.6 (s). − $C_{70}H_{86}Cl_4N_2O_8P_2Pd$ (1393.6): calcd. C 60.33, H 6.22, Cl 10.18, N 2.01; found C 60.45, H 6.28, Cl 9.96, N 2.03.

***cis*-[Pd(4a)$_2$Cl$_2$] (10):** A solution of **4a** (0.418 g, 0.78 mmol) in toluene (10 mL) was added to a stirred solution of $[Pd(PhCN)_2Cl_2]$ (0.150 g, 0.39 mmol) in the same solvent (20 mL) cooled in an ice bath. The reaction mixture was then stirred overnight at room temperature, resulting in the deposition of an orange precipitate. This was filtered off, washed with toluene (in which the product is slightly soluble), and dried. Yield: 0.195 g (40%). − IR (CsI, Nujol): ν(PdCl) = 335, 301 cm^{-1}. − ^1H NMR ($CDCl_3$): δ = 8.33 (d, ^3J = 9.2 Hz, 1 H, Ar-H), 8.08−7.98 (m, 3 H, Ar-H), 7.55−7.35 (m, 9 H, Ar-H), 6.87 (m, 1 H, Ar-H), 6.80−6.76 (m, 2 H, Ar-H), 6.40 (d, ^3J = 9.4 Hz, 1 H, CH=CH), 4.50 (dd, ^3J = 9.4 Hz, ^3J = 5.4 Hz, 1 H, CH=CH), 3.95 (m, 1 H, CH), 0.88−0.68 (m, 6 H, CH_2), 0.56 (t, ^3J = 7.2 Hz, 3 H, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 117.5 (s). − $C_{66}H_{54}Cl_4N_2O_4P_2Pd$ (1249.3): calcd. C 63.45, H 4.36, Cl 11.35, N 2.24; found C 63.35, H 4.28, Cl 11.12, N 2.15.

***cis*-[Pt(4a)I$_2$] (11):** At room temp. a solution of **4a** (0.097 g, 0.18 mmol) in toluene was added to a stirred solution of $[Pt(COD)I_2]$ (0.050 g, 0.09 mmol) in the same solvent (20 mL). After 4 h, the bright-yellow solution was concentrated to a volume of ca. 5 mL and upon addition of 30 mL of diethyl ether a light-yellow solid was deposited. This solid was collected, washed with diethyl ether, and dried in vacuo. Yield: 0.123 g (90%). Recrystallization from $CHCl_3$/hexane gave yellow single crystals suitable for X-ray diffraction analysis. − ^1H NMR ($CDCl_3$): δ = 8.49 (d, ^3J = 9.2 Hz, 1 H, Ar-H), 8.04−7.95 (m, 3 H, Ar-H), 7.51−7.31 (m, 8 H, Ar-H), 6.89 (m, 1 H, Ar-H), 6.80−6.75 (m, 2 H, Ar-H), 6.20 (d, ^3J = 9.6 Hz, 1 H, CH=CH), 4.36 (dd, ^3J = 9.6 Hz, ^3J = 5.4 Hz, 1 H, CH=CH), 4.05 (m, 1 H, CH), 0.95−0.74 (m, 6 H, CH_2), 0.51 (t, ^3J = 7.2 Hz, 3 H, CH_3). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 94.5 (J_{PtP} = 5296 Hz). − $C_{66}H_{54}Cl_2I_2N_2O_4P_2Pt$ (1520.9): calcd. C 52.12, H 3.58,, Cl 4.66, I 16.69 N 1.84; found C 52.26, H 3.60, Cl 4.76, I 16.47, N 1.89.

Crystal Structure Determination of Complexes 5 · 2 C$_6$H$_{14}$ and 11: Intensity data for **5** · 2 C_6H_{14} were collected at room temperature (22°C) with an Enraf-Nonius CAD-4 single-crystal diffractometer using graphite-monochromated Cu-K_α radiation. Intensity data for **11** were collected at room temperature (22°C) with a Philips PW 1100 single-crystal diffractometer using graphite-monochromated Mo-K_α radiation. In both cases, the θ/2θ scan technique was employed. Final unit-cell parameters were obtained from least-squares refinements using 24 (**5** · 2 C_6H_{14}) and 30 (**11**) reflections. Crystallographic and experimental details pertaining to both structures are summarized in Table 3.

Data were corrected for Lorentz and polarization effects in the usual manner. A correction for absorption was made for both complexes [maximum and minimum values for the transmission coefficients 1.000 and 0.7101 (**5** · 2 C_6H_{14}) and 1.000 and 0.3741 (**11**)].[15] Both structures were solved by Patterson and Fourier methods and refined by full-matrix least-squares procedures (based on F_o^2) with anisotropic thermal parameters in the final cycles of the refinement for all non-hydrogen atoms other than the carbon atoms of the *n*-butyl moiety and of the solvent molecules in **5** · 2 C_6H_{14}. The *n*-butyl group was found to be disordered and distributed over two positions with the first carbon atom (C1A) in common, with occupancy factors of 0.62 and 0.38, respectively. The

Table 3. Crystal data and structure refinement for **5** · 2 C_6H_{14} and **11**; $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$

hexane molecules of solvation were found to be disordered over three different positions within the channels present in the crystal structure. The hydrogen atoms (other than those of the disordered *n*-butyl group and of the hexane molecules in **5** · 2 C_6H_{14}) were placed in geometrically calculated positions and were refined riding on the corresponding carbon atoms. In the final cycles of the refinement, weighting schemes $w = 1/[\sigma^2F_o^2 + (0.1275P)^2]$ (**5** · 2 C_6H_{14}) and $w = 1/[\sigma^2F_o^2 + (0.0668P)^2]$ (**11**), where $P = (F_o^2 + 2F_c^2)/3$, were used. All calculations were carried out with the CNRDIF computers of the Centro di Studio per la Strutturistica Diffrattometrica del CNR, Parma, using the SHELXS-86 and SHELXL-92 packages of crystallographic computer programs.[16,17] Supplementary material available for both structures includes lists of atomic coordinates for the non-H atoms, of calculated coordinates for the hydrogen atoms, and of anisotropic thermal parameters. Details of the crystal structure determinations have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-110254 (**5** · 2 C_6H_{14}) and -110253 (**11**). Copies of the data can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Metal thiolates / Helical chirality / Spontaneous resolution / Disulfide / Intramolecular coordination

The synthesis and characterization of homoleptic zinc(II), cadmium(II), and mercury(II) thiolates derived from 4,4-dimethyl-2-phenyloxazoline (**1**) are described. The disulfide [Ox_2S_2 (**3**), Ox = 2-(4,4-dimethyl-2-oxazolinyl)phenyl] is prepared by the oxidation of lithium arenethiolate OxS^-Li^+ (**2**), and structurally characterized. The disulfide **3** is chiral and enantiomerically pure in the solid state. The thiolate derivatives, $M[S(Ox)]_2$ [M = Zn (**4**), or Cd (**5**)], are prepared in good yield by the metathesis reactions of MCl_2 with lithium arenethiolate **2**. The mercury complex **6** is synthesized by treating **3** with elemental mercury. The complexes are quite stable and highly soluble in common nonpolar organic solvents. X-ray diffraction results show that the zinc thiolate **4** and cadmium thiolate **5** are monomeric in the solid state. The geometry around the metal ion in these two complexes is found to be distorted tetrahedral. The zinc complex is chiral and has crystallized in two different crystalline modifications. The single crystal structures have been determined for both the crystalline modifications, a monoclinic modification (**4a**) and an orthorhombic one (**4b**). The crystal structure of **4a** shows that the complex is "helically" chiral and enantiomerically pure whereas the crystal structure of **4b** shows the modification to be racemic. The spontaneous splitting of the racemates, which is responsible for the isolation of optically active compound, indicates that there should be some solubility differences between the racemates and pure enantiomers. ^1H- and ^{13}C-NMR measurements indicate that the complex **4** retains its "helical" structure in solution.

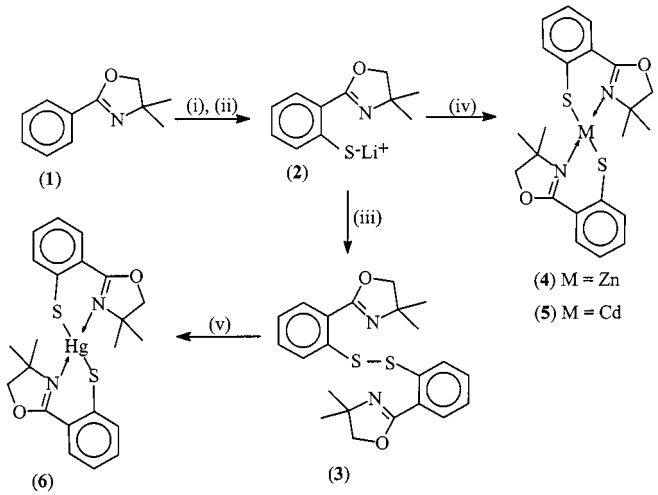
Introduction

There is considerable general interest in the bonding and unusual structures adopted by chalcogenolate complexes of the Group 12 elements.[1] Besides their importance as single-source stoichiometric precursors to Group 12−16 semiconductors,[2] the metal-chalcogen chemistry of these elements has yielded many surprising results with respect to structural features, method of preparation, and degree of aggregation.[3]

As part of our work on intramolecularly coordinated organochalcogens,[4] we have recently isolated some stable monomeric mercury selenolates using *ortho*-chelating [(dimethylamino)benzyl]- and [(dimethylamino)ethyl]ferrocenyl ligands[5] and well-characterized examples of zinc, cadmium and mercury selenolato complexes by using a more rigid 4,4-dimethyl-2-phenyloxazoline substrate.[6] Interestingly, the zinc selenolato complex derived from 4,4-dimethyl-2-phenyloxazoline was found to be chiral at room temperature and the cadmium selenolate showed chirality at low temperatures. Although the corresponding tellurolate complexes of zinc and cadmium showed chirality at low temperatures, the complexes could not be crystallized due to their instability in solution.[7] In order to investigate the effect of the chalcogen atom on the chirality in Group 12 chalcogenolates, we extended our approach to the thiolate chemistry since the high affinity of zinc ions towards thiolates and the very marked preference for ZnN_2S_2 coordination may allow the isolation of "helically" chiral metal complexes.

In this paper, we describe the use of a phenyloxazoline-derived ligand to prepare monomeric Group 12 metal thiolates including a novel "helically" chiral zinc thiolate **4** and its spontaneous resolution. Structurally characterized "mono-helical" complexes of zinc are very rare[8] and this is the first example, to the best of our knowledge, where the two optically active forms have been spontaneously resolved in a four-coordinate zinc thiolate complex. We also describe the synthesis and structure of a novel chiral disulfide stabilized by intramolecular S···N interactions. In addition, the thermal behavior of the zinc, cadmium, and mercury thiolates provided some insight into their utility as CVD precursors.

Results and Discussion



Monomeric Thiolates

Synthesis of the thiolate complexes was approached by the metathesis reaction of the lithium arenethiolate with the corresponding MCl_2 in ether according to our recently reported method for the synthesis of metal selenolates (Scheme 1).[6] The 2:1 molar reactions of **2** and anhydrous MCl_2 (M = Zn, Cd) in ether afforded the desired products in moderate yields. Attempts to synthesize the mercury thi-

olate by the reaction of **2** with $HgCl_2$ were unsuccessful. The 2:1 molar reactions of **2** and anhydrous $HgCl_2$ afforded the corresponding disulfide **3** resulting, presumably, due to the oxidation of **2** with $HgCl_2$. Recently, we have shown that pure monomeric mercury selenolate complexes could be obtained in two further steps, whereby the lithium areneselenolate was oxidized to the diselenide (which was air-stable and readily purified), followed by the oxidative addition of mercury.[5,6] Therefore, we have approached the synthesis of **6** by the reaction of **3** with elemental mercury. In contrast to the synthesis of corresponding diselenide[4f] and ditelluride,[7] the synthesis of disulfide by aerial oxidation of the lithium arenethiolate **2** was found to be difficult due to higher stability of the arenethiol produced by the addition of the lithium arenethiolate to water, and, therefore, vigorous oxidation was required to convert the thiol to disulfide. The reaction of **3** with elemental mercury then afforded, after several days of stirring at room temperature, **6** in 60% yield.

Scheme 1. Synthesis of M^{II} complexes; reagent and conditions: (i) *n*BuLi, hexane, room temp., 1 h; (ii) S powder, ether, 0°C, 2 h; (iii) O_2, H_2O; (iv) anhydrous MCl_2, 0°C, 1 h, and room temp., 18 h; (v) elemental mercury, methanol, room temp., 5 d

The significant feature of the chemistry of the entire class of complexes **4**–**6** is their excellent solubility in both nonpolar and slightly polar solvents at room temperature which is generally not a feature of metal chalcogenolate chemistry. They are, however, almost insoluble in highly polar solvents like DMSO and methanol.

Complex **4**, obtained as a yellow solid, shows some interesting features. The complex affords two types of crystals; yellow needle-shaped (**4a**, enantiomerically pure) and white plates (**4b**, racemic) crystals due to spontaneous crystallization of the enantiomers (vide infra). The complex **4** shows very good solubility in ether but the solubility is reduced for the enantiomers in the same solvent. The differences observed between **4a** and **4b** may also be ascribed to the different speed of crystallization. The crystals of **4a** were obtained from a mixture of chloroform/hexane within a day whereas the crystals of **4b** were separated from the solution after five days.

NMR-Spectroscopic Studies

In order to investigate the solution behavior of **3** and the complexes **4**–**6**, we have studied the ^{1}H- and ^{13}C-NMR spectra in $CDCl_3$. Although the crystal structure shows that **3** is chiral (vide infra), the room-temperature NMR (^{1}H, ^{13}C) spectra are not indicative of chirality. A sharp singlet for the methylene protons and another sharp singlet for the methyl protons observed in the ^{1}H-NMR spectrum of **3** at room temperature infer that the nonbonded S···N interactions are weak in the solution. The room-temperature ^{1}H-NMR spectrum of **4** contains a well-resolved AB doublet of doublets for the methylene protons and two sharp singlets for the methyl protons (Figure 1). The AB pattern for the methylene protons implies that the strong coordination of the "hard" imine nitrogen atom with the "hard" zinc(II) ion removes the erstwhile enantiotopic nature of these protons. The protons become diasteriotopic resulting in chirality of the complex. We[6] and others[8b,9] have noted a similar AB spin behavior of methylene protons in other complexes and have used it as a diagnostic probe of chirality. The inequivalence of the methylene group protons and two methyl group protons even at 55°C indicates a strong coordination of the nitrogen atom to the metal center and retention of the "helicity" even at higher temperatures. The spectra of both the crystalline modifications [yellow needles (**4a**) and white square plates (**4b**)] are identical.

The room-temperature ^{1}H-NMR spectrum of **5** consists of a sharp singlet for the methylene protons and another sharp singlet for the methyl protons. At −60°C, the methyl protons give rise to two singlets, however, the signal for the methylene protons is observed as a broad singlet (Figure 2). This is in contrast to the spectra of the corresponding cadmium selenolate[6] and cadmium tellurolate[7] where an AB doublet of doublets for the methylene protons was observed at −60°C. This indicates that the complex is probably not rigid even at −60°C. For complex **6**, the signals for the methylene and methyl protons are observed as sharp singlets. Since the exchange between "helical" and "nonhelical" arrangements is very fast, the splitting of the signals due to chirality could not be detected even at −60 °C. At this temperature only a slight broadening of the signals was observed.

From the current results and their comparison with those of corresponding selenolates[6] and tellurolates,[7] it is observed that the chemical shift values in all the complexes lie almost in the same region and there is no drastic change in the chemical shift values by changing the metal atom or changing the chalcogen atom. However, the signals due to the methyl and methylene protons are shifted upfield compared with the corresponding dichalcogenides probably due to the d^{10} configuration of the metal ions.

The ^{13}C-NMR spectra of the complexes are not very informative. The chemical shift values for the methyl and methylene carbon atoms are very close to the values observed for the disulfide. However, the ^{13}C-NMR spectrum of complex **4** gives some information about the chirality of the complex. Two signals at δ = 26.99 and 28.28 observed

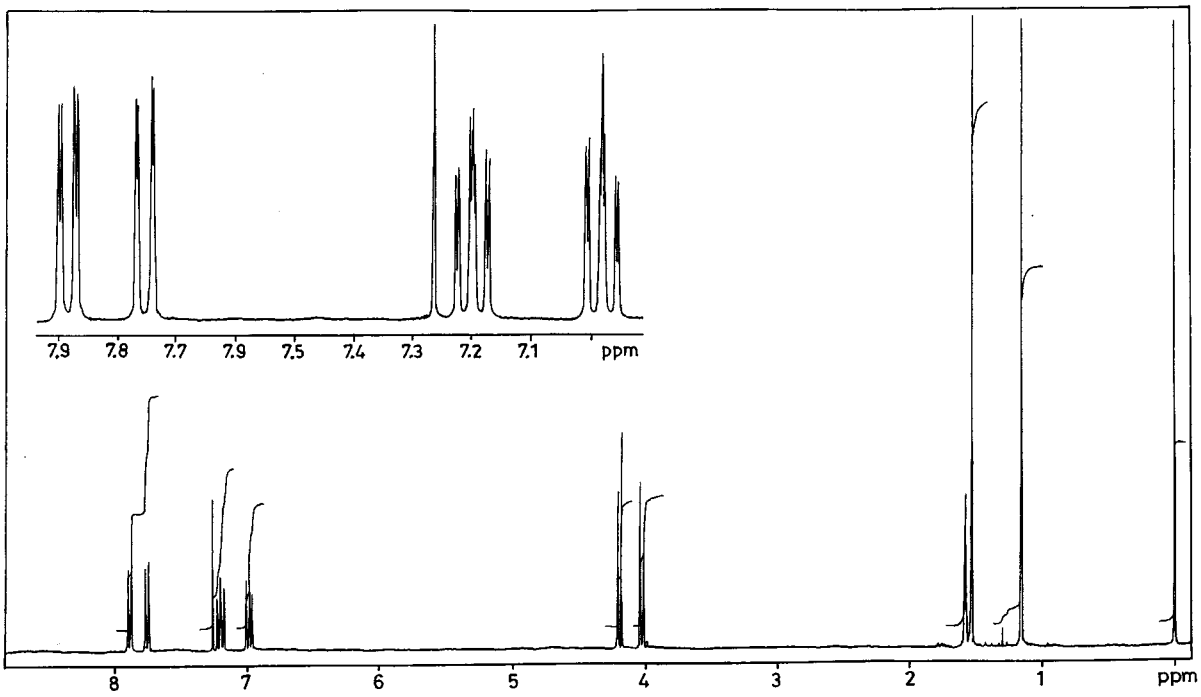

Figure 1. Room-temperature ^{1}H-NMR spectrum of **4a** ($CDCl_3$, 300 MHz)

for the methyl group carbon atoms clearly indicate that the two methyl groups present in the complex are nonequivalent.

Mass-Spectrometric Studies and Thermal Behavior

The mass spectra were recorded for complexes **4** and **5**. The mass spectra of complexes **4** and **5** are indicative of the presence of both monomeric and dimeric species in the gas phase {**4**; *m/z*: 477 [$Zn(SOx)_2^+$], 750 [$Zn_2(SOx)_3^+$]; **5**; *m/z*: 525 [$Cd(SOx)_2^+$], 844 [$Cd_2(SOx)_3^+$]}. The molecular ion peaks and the peaks due to other fragments containing S and M exhibit the expected isotope patterns.

The complexes have sharp melting points in the range 120−195°C giving clear liquids. To further know the volatility of the complexes and the decomposition pathway, TGA and DTA were recorded for all three complexes. The DTA curves of complexes **4**, **5** and **6** showed a phase transition (endothermic peak) in the range 130−200°C which corresponds to their melting. The TGA of complexes **4** and **5** showed the formation of expected metal sulfides (MS: M = Zn, Cd) at 530 and 390°C, respectively at ambient pressure. The mercury complex **6** showed complete weight loss in this temperature range probably due to the high volatility of this complex.

Molecular Structure of Compound 3

The crystal structure of **3** is shown in Figure 3 and the bond lengths and angles are given in Table 1. The interesting feature in this structure is that compound **3** crystallizes in the chiral space group $P2_12_12_1$ of the orthorhombic system. The structure is different from that of the corresponding diselenide[4f] and ditelluride[7] which are not chiral. Refinement of the Flack enantiopole parameter[10] shows that the compound has crystallized in enantiomerically pure form. Generally, the S···N interactions are expected to be weak compared with Se···N and Te···N interactions. However, in compound **3** the S···N interactions are found to be quite strong. The S(1)···N(1) and S(2)···N(2) bond lengths (2.815 and 2.787 Å) are considerably shorter than the sum of the van der Waals radii (3.35 Å) of these two atoms. In contrast to the selenium and tellurium analogues, the two S···N distances are almost equal. The S−S bond length of 2.053(1) Å is comparable to the single-bond covalent radii (2.08 Å).[11] The S(1)−C(11) and S(2)−C(21) bond lengths [1.798(3) Å and 1.790(3) Å] are also comparable to the corresponding single-bond covalent radii (1.81 Å). The angles N(1)···S(1)−S(2) and S(1)−S(2)···N(2) are 173.5° and 172.9°, respectively, indicating an almost linear arrangement of N···S−S···N atoms. The torsion angle C(11)−S(1)−S(2)−C(21) is −79.47°.

Molecular Structure of Compound 4

Complex **4** crystallizes in two different enantiomorphs (**4a** and **4b**). The structures of both crystalline modifications were determined.

Molecular Structure of Compound 4a

The structure of complex **4a** is consistent with the solution data. Interestingly, complex **4a** crystallizes in a chiral space group $P2_1$ with two molecules per unit cell. Crystals

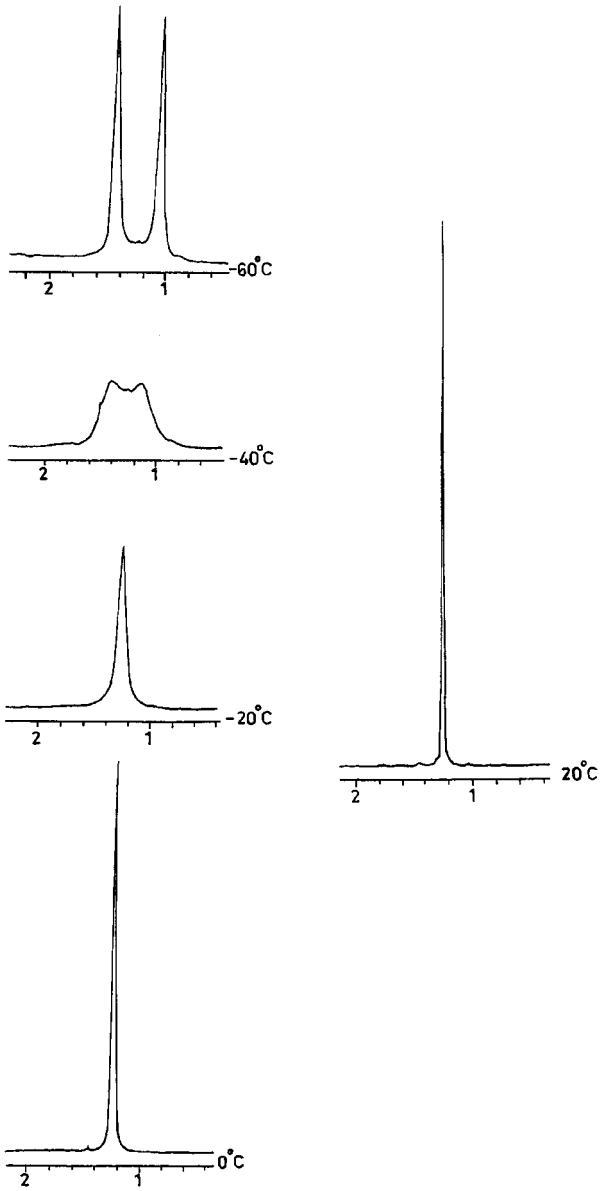

Figure 2. Variable-temperature ^{1}H-NMR ($CDCl_3$, 300 MHz) spectra (in part only) of **5**; at −60°C, the signals due to the CH_3 protons split into two singlets

of the complex **4a** belong to the monoclinic system. The ORTEP[12] view of the molecule is shown in Figure 4 and selected bond lengths and angles are given in Table 2. The structure is similar to that of the corresponding zinc selenolate complex,[6] which also crystallized in the same space group and almost with same cell parameters [the cell in **4** corresponds to $P2_1$ with a = 9.371(1), b = 11.397(1), c = 10.881(1) Å and β = 97.351(9)°; the cell in selenolate[6] corresponds to $P2_1$ with a = 9.390(1), b = 11.618(2), c = 10.882(1) Å and β = 98.245(8)°] and, therefore, the two compounds appear to be isostructural. Although, tetrahedral complexes with AB-type chelate ligands are expected to be chiral, to our knowledge, no optically pure chiral tetrahedral thiolatozinc complexes have been reported so far (generally they crystallize as racemates). Refinement of the Flack enantiopole parameter[10] led to a value of ca.

Table 1. Selected bond lengths [Å] and angles [°] for **3**

S(1)−N(1)	2.815(3)	S(2)−N(2)	2.787(3)
S(1)−C(11)	1.798(3)	S(2)−C(21)	1.790(3)
O(1)−C(17)	1.357(4)	O(1)−C(18)	1.437(6)
O(2)−C(27)	1.352(4)	O(2)−C(28)	1.438(6)
N(1)−C(17)	1.244(4)	N(1)−C(19)	1.485(4)
N(2)−C(27)	1.254(4)	N(2)−C(29)	1.492(4)
S(1)−S(2)	2.053(1)		
C(26)−C(21)−S(2)	119.4(2)	C(12)−C(11)−S(1)	121.0(2)
C(11)−S(1)−S(2)	105.6(1)	C(16)−C(11)−S(1)	119.7(2)
C(21)−S(2)−S(1)	105.5(1)	C(22)−C(21)−S(2)	121.5(2)

zero for **4a** thus confirming the enantiomeric purity of the crystals.

The complex is monomeric with the zinc atom coordinated to two nitrogen and two sulfur atoms forming a distorted tetrahedron. As a consequence of the interaction of the two chelating ligands which causes the complex to distort in a helical way, chirality is induced at the metal center. The average Zn−S bond length 2.270(1) Å is close to the Zn−S length reported for an $(N_2S_2)Zn^{II}$ Schiff base complex incorporating pyrazole [Zn−S: 2.293(1) Å][13] but slightly shorter than that reported for a chiral five-coordinate Zn^{II} complex (2.34 Å)[8a] and for $Zn(SAr)_2(imid)_2$ (2.315 Å).[14] The Zn−N bond lengths [Zn−N(1): 2.043(3); Zn−N(2): 2.036(4) Å] are very close to the Zn−N length reported for the pyrazole Schiff base complex [2.039(3) Å][13] and for $Zn(SAr)_2(imid)_2$ (2.048Å)[14] and that reported for zinc and typical N-donor ligands which normally range from 2.04 Å to 2.14 Å. However, this bond is much stronger than the Zn−N bond reported for the chiral five-coordinate Zn^{II} complex (2.21 Å).[8a] The C−S bond lengths [S(1)−C(11): 1.758(4) Å; S(2)−C(21): 1.756(5) Å] are intermediate between that of a thione (C−C=S: 1.6 Å) and that of a thiol (C−C−SH 1.8 Å)[15] which is normal for N_2S_2 Schiff base complexes.[16] The chelate bite angles of S(1)−Zn−N(1) and S(2)−Zn−N(2) are 96.16(9) and 97.18(9)°, respectively. The larger bite angle leads to relatively smaller N−Zn−N and S−Zn−S angles of 106.45(14) and 116.47(9)°, respectively.

Interestingly, in the case of the selenium analogue[6] of **4**, the N−Zn−N and Se−Zn−Se bond angles [106.6(2)° and 113.49(4)°] are close to ideal tetrahedral angles and in this case we have isolated optically pure complex whereas in the oxygen analogue, the deviation from the ideal tetrahedral

geometry is even higher [N−Zn−N: 121.13(9); O−Zn−O: 117.73(9)] and in this case no optically pure enantiomer could be isolated.[17]

Molecular Structure of Compound 4b

The colorless crystals of complex **4b** belong to the space group *Pbca* of the orthorhombic system with 8 molecules per unit cell. Surprisingly, although the crystals of **4b** exhibited optical rotation, the space group indicates the formation of racemic crystals. This indicates that **4b** is probably a mixture of optically pure and racemic forms. An ORTEP view of the structure is shown in Figure 5 and selected bond lengths and angles are given in Table 3. The geometry around the metal center is distorted tetrahedral. Although the bond lengths around the metal ion are found to be similar to that of **4a**, the bond angles show significant differences. The N(1)−Zn−N(2) [110.6(1)°] and S(1)−Zn−S(2) [118.34(6)°] angles are slightly larger than the corresponding angles observed in complex **4a**. The N(1)−Zn−S(2) [114.4(1)°] and N(2)−Zn−S(1) [117.0(1)°] bond angles are considerably smaller than the corresponding angles observed in **4a** [N(1)−Zn−S(2): 120.98(9)°; N(2)−Zn−S(1): 120.9(1)°]. The average chelate bite angle of 98.6° is larger than that of **4a** [96.67(9)°].

Molecular Structure of Compound 5

The colorless crystals of **5** belong to the space group *Pbca* of the orthorhombic system with 8 molecules per unit

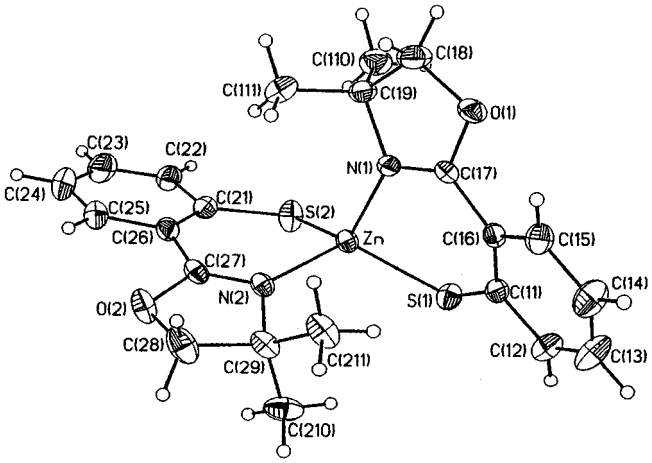

Figure 5. Crystal structure of monomeric Zn^{II} complex **4b**

cell. From the space group and the cell parameters, complex **5** can be considered as isostructural with the corresponding selenolate.[6] An ORTEP diagram of the structure is shown in Figure 6. The bond lengths and angles are given in Table 4. The geometry around the metal center is distorted tetrahedral. In contrast to other cadmium thiolates, **5** is monomer without any close intermolecular contacts. The Cd−S bond lengths [Cd(1)−S(1): 2.453(3); Cd(1)−S(2): 2.459(3) Å] are much smaller than the corresponding lengths reported for $[Cd(C_5H_4NS)_2]_n$ (2.81 Å)[18] and $[Cd(C_7H_4N_2S)_2]_n$ (2.55 Å).[18] The Cd−N bond lenghts [Cd(1)−N(1): 2.286(8); Cd(1)−N(2): 2.261(8) Å] are, however, comparable to that reported for $[Cd(C_5H_4NS)_2]_n$ (2.34 Å) and $[Cd(C_7H_4N_2S)_2]_n$ (2.28 Å). The bond angle S(1)−Cd−S(2) [139.1(1)°] and the chelate ring bite angle S−Cd−N [88.2(2)°] are much larger than that of $[Cd(C_5H_4NS)_2]_n$ in which the S−Cd−S bond angle is 103.4(3)° and the chelate bite angle is 60.80°. In contrast to the zinc complex **4**, complex **5** is not chiral which indicates that the interactions between the nitrogen atom and the cadmium ion are not strong enough to create the required distortion around the metal center.

The bond lengths and angles for the oxazoline rings in all the cases reflect certain similarities with other five-membered heterocycles containing O and N atoms such as isoxazoline[19] and oxazolo[20] compounds. The O(1)−C(17) lengths [1.357(4) Å and 1.36(1) Å] in complexes **4a** and **4b**, respectively are significantly shorter than the O(1)−C(18) bond lengths [1.442(5) Å and 1.46(1) Å], while the same is

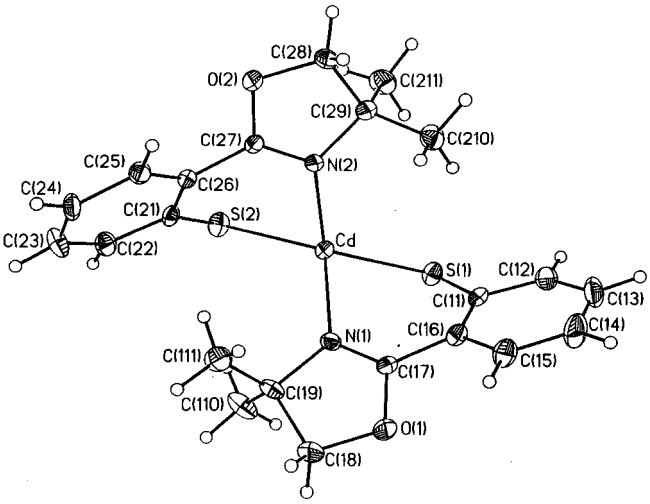

Figure 6. Crystal structure of monomeric Cd^{II} complex **5**

Table 4. Selected bond lengths [Å] and angles [°] for **5**

Cd(1)−N(1)	2.286(8)	Cd(1)−N(2)	2.261(8)

true for the N(1)−C(17) lengths [1.244(4) Å and 1.26(1) Å] with respect to the N(1)−C(19) bond lengths [1.485(4) Å and 1.51(1) Å]. This indicates a similar double-bond character in both O(1)−C(17) and N(1)−C(17). The O(1)−C(17) bond lengths are slightly shorter than the corresponding length observed for the zinc selenolate [1.362(8) Å].[6] Complex **5** also shows similar double-bond character in both O(1)−C(17) and N(1)−C(17).

Conclusion

The intramolecularly coordinating 2-(4,4-dimethyloxazolino)benzenethiolate ligand can be successfully used for the isolation of a series of monomeric four-coordinate Group 12 metal thiolate complexes, including the rare example of a "helically" chiral zinc complex. The high affinity of zinc ions towards thiolates and the strong coordination of the imine nitrogen atom to the metal center facilitate the separation of two enantiomorphs by crystallization. The AB spin behavior of methylene protons present in the oxazoline ring can be used as a diagnostic probe of chirality in the complexes. The thiolate ligand shows chirality only with the zinc ion, whereas the selenolate and tellurolate ligands show chirality with the zinc and cadmium ions. The isolation of "helically" chiral zinc complex is much more facile in the case of thiolate compared with selenolate and tellurolate. However, the chirality observed in these complexes at either room temperature or low temperatures shows the general tendency of the oxazoline ligand to form "helical" metal complexes. As expected, the stability of the Group 12 metal complexes decreases in the order S > Se > Te. In addition, the low molecularity, excellent solubility in hydrocarbon solvents, low melting points and relatively high volatility of the complexes render them of interest as single-source precursors to Group 12−16 thin-film semiconductors.

Experimental Section

General Procedures: All reactions were carried out under nitrogen or argon using standard vacuum-line techniques. Solvents were purified by standard procedures[21] and were freshly distilled prior to use. Mercury and $ZnCl_2$ were purified prior to use.[21] Commercially available $CdCl_2$ and $HgCl_2$ were used as received. − Melting points were recorded in capillary tubes and are uncorrected. − ^{1}H- and ^{13}C-NMR spectra were obtained at 300 and 75.42 MHz, respectively, in $CDCl_3$ with a Varian VXR 300S spectrometer. Chemical shifts are cited with respect to $SiMe_4$ as internal standard. − Elemental analyses were performed with a Carlo-Erba model 1106 elemental analyzer. − Fast atom bombardment (FAB) mass spectra were recorded at room temperature with a JEOL SX 102 DA-6000 mass spectrometer/data system with xenon (6 kV, 10 mV) as the bombarding gas. The acceleration voltage was 10 kV and *m*-nitrobenzyl alcohol was used as the matrix with positive-ion detection. In case of isotopic patterns the value given is for the most intense peak. − Thermal analyses were performed at atmospheric presure with a Shimadzu D30 thermal analyser under nitrogen with the heating rate of 10°C/min. − Optical rotations were measured with a JASCO Model DIP 370 digital polarimeter.

Synthesis of Ox_2S_2 (3): To a suspension of 4,4-dimethyl-2-oxazolinylphenyl lithium[6] (1.82 g, 10 mmol) in dry ether (30 mL), elemental sulfur (0.32 g, 10 mmol) was added rapidly at 0°C. After 3 h, all sulfur was consumed to give a yellow solution of **2**. To this, distilled water (10 mL) was added and complete oxidation was affected by passing oxygen through the mixture for 2 h. The resulting organic layer and the ether extracts from the aqueous layer were combined, dried with anhydrous sodium sulfate, and concentrated in vacuo to give a yellow oil. Crystallization of this from chloroform/methanol (1:1) afforded **3** as white needles. Yield: 0.8 g, (40%); m.p. 142−144°C. − $C_{22}H_{24}N_2O_2S_2$ (412.6): calcd. C 63.98, H 5.82, N 6.79; found C 63.86, H 5.42, N 5.94. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.44 (s, 12 H, CH_3), 4.12(s, 4 H, CH_2), 7.17−7.22 (m, 2 H, Ar-H), 7.26−7.35 (m, 2 H, Ar-H), 7.71−7.74 (m, 2 H, Ar-H), 7.78−7.81 (m, 2 H, Ar-H). − ^{13}C NMR ($CDCl_3$): δ = 27.97, 68.68, 78.70, 124.66, 125.81, 126.69, 128.97, 131.64, 138.51, 160.57.

Synthesis of $Zn[S(Ox)]_2$ (4): To the lithium arenethiolate (2.14 g, 10 mmol), prepared as described above, was added anhydrous $ZnCl_2$ (0.68 g, 5 mmol) and stirring was continued for 1 h at 0 °C and 18 h at room temperature. The resulting solution was filtered through Celite and concentrated to give a yellow compound. The compound was recrystallized from a chloroform/hexane (1:1) mixture to give **4**. The spontaneous resolution of the racemate was observed during the crystallization process. The crude yellow compound (1.62 g) was dissolved in chloroform (20 mL) and hexane (20 mL) was added. Evaporation of the solvent at room temperature afforded the crystals of the two enantiomorphs. Fast crystallization (in 24 h) in an open vessel resulted in pale yellow crystals (**4a**) whereas slow evaporation of the remaining solvent (in 5 d) in

a flask covered with a rubber septum with a small hole resulted in white crystals (**4b**).

4a: Yellow crystals. Yield: 1.07 g (45%); m.p. 192−194°C. − $C_{22}H_{24}N_2O_2S_2Zn$ (477.9): calcd. C 55.30, H 5.03, N 5.87; found C 54.68, H 4.82, N 5.12. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.16 (s, 6 H, CH_3), 1.38 (s, 6 H, CH_3), 4.01−4.18 (dd, 4 H, CH_2), 6.95−6.98 (m, 2 H, Ar-H), 7.00−7.22 (m, 2 H, Ar-H), 7.73−7.77 (m, 2 H, Ar-H), 7.86−7.90 (m, 2 H, Ar-H). − ^{13}C NMR ($CDCl_3$): δ = 26.99, 28.28, 68.50, 78.15, 121.97, 122.78, 131.30, 131.62, 136.54, 150.45, 167.46. − MS; *m/z* (%): 652 [$C_{33}H_{36}N_3O_3S_3Zn_2^+$], 587 [$C_{33}H_{36}N_3O_3S_3Zn^+$], 477 [$M^+$, $C_{22}H_{24}N_2O_2S_2Zn^+$], 412 [$C_{22}H_{24}N_2O_2S_2^+$], 380 [$C_{22}H_{24}N_2O_2S^+$], 206 (100) [$C_{11}H_{12}NOS^+$]. − $[\alpha]_D^{25}$ = −6.158 (*c* = 1.0, $CHCl_3$).

4b: White crystals. Yield: 0.48 g (20%). m.p. 190−192°C. − $C_{22}H_{24}N_2O_2S_2Zn$ (477.9): calcd. C 55.30, H 5.03, N 5.87; found C 55.50, H 5.02, N 5.25. − $[\alpha]_D^{25}$ = +5.080 (*c* = 1.0, $CHCl_3$). − ^{1}H- and ^{13}C-NMR chemical shifts are in full accordance with the values reported for **4a**.

Synthesis of Cd[S(Ox)]$_2$ (5): Compound **5** was prepared according to the method described for **4** using 1.82 g (10 mmol) of 4,4-dimethyl-2-oxazolinylphenyllithium,[6] 0.32 g (10 mmol) of elemental sulfur and 0.917 g (5 mmol) of anhydrous $CdCl_2$. The crude product was recrystallized from a chloroform/hexane (1:1) mixture to give white crystals of **5**. Yield: 1.36 g (52%); m.p. 186−188°C. − $C_{22}H_{24}CdN_2O_2S_2$ (524.9): calcd. C 50.34, H 4.58, N 5.34; found C 50.49, H 4.45, N 5.28. − ^{1}H NMR(300 MHz, $CDCl_3$): δ = 1.25 (s, 12 H, CH_3), 4.09(s, 4 H, CH_2), 6.97−7.02 (m, 2 H, Ar-H), 7.15−7.20 (m, 2 H, Ar-H), 7.73−7.76 (m, 2 H, Ar-H), 7.75−7.81 (m, 2 H, Ar-H). − ^{13}C NMR ($CDCl_3$): δ = 27.91, 68.18, 77.82, 122.66, 124.99, 130.77, 131.30, 137.17, 147.66, 167.11. − MS; *m/z* (%): 746 [$C_{33}H_{36}Cd_2N_3O_3S_3^+$], 524 [$M^+$, $C_{22}H_{24}CdN_2O_2S_2^+$], 380 [$C_{22}H_{24}N_2O_2S^+$], 318 [$C_{11}H_{12}CdNOS^+$], 206 (100) [$C_{11}H_{12}NOS^+$].

Synthesis of Hg[S(Ox)]$_2$ (6). − Method A: Synthesis of compound **6** was approached by the method described for **4** from 10 mmol of 4,4-dimethyl-2-oxazolinylphenyllithium,[6] 0.32 g (10 mmol) of elemental sulfur and 1.358 g (5 mmol) of anhydrous $HgCl_2$. Elemental analysis and other analytical data for the white solid obtained from the reaction indicated the formation of the disulfide **3**. The crude product was recrystallized from a chloroform/hexane (1:1) mixture. Yield: 2.12 g (60%). All analytical data are in full accordance with the values reported for **3**.

Method B: To a stirred solution of **3** (0.413 g, 1 mmol) in methanol (20 mL) was added an excess of mercury (1 g, 5 mmol) at room temperature. The reaction mixture was stirred for 5 d to give an almost colorless solution. This was filtered through a Celite-padded filter frit to remove the unchanged mercury. The filtrate was concentrated to give a colorless crystalline product (0.5 g). This was recrystallized from a chloroform/methanol (1:1) mixture to give colorless crystals of **6**. Yield: 0.37 g (60%); m.p. 122−124°C. − $C_{22}H_{24}HgN_2O_2S_2$ (612.6): calcd. C 43.12, H 3.92, N 4.52; found C 42.95, H 3.86, N 4.10. − ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.17 (s, 12 H,CH_3), 3.99 (s, 4 H, CH_2), 7.06−7.11 (m, 2 H, Ar-H), 7.24−7.28 (m, 2 H, Ar-H), 7.67−7.71 (m, 2 H, Ar-H), 7.74−7.78 (m, 2 H, Ar-H). − ^{13}C NMR ($CDCl_3$): δ = 28.05, 68.53, 77.92, 124.76, 126.87, 132.67, 133.35, 139.32, 148.93, 165.23.

Caution: Cadmium and mercury complexes are expected to be toxic and must be handled with care.

X-ray Crystallographic Studies: The diffraction measurements for compounds **3**, **4a**, **4b**, and **5** were performed at room temperature (293 K) with a Siemens R3m/V diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.7170 Å). The unit cell was determined from 25 randomly selected reflections using the automatic search index and least-squares routine. For **3**, the θ range for data collection was from 2.61 to 30.00° whereas for **4a**, **4b**, and **5** it ranged from 2.60 to 27.50°, 2.52 to 27.50° and 2.53 to 27.50°, respectively. The index range for **3** was $0 \le h \le 11$, $0 \le k \le 21$, $0 \le l \le 23$ while for **4a**, **4b**, and **5** it was $0 \le h \le 12$, $-14 \le k \le 0$, $-14 \le l \le 14$; $0 \le h \le 11$, $-26 \le k \le 0$, $0 \le l \le 30$; and $-16 \le h \le 0$, $0 \le k \le 23$, $0 \le l \le 27$, respectively. The data for **4b** and **5** were corrected for Lorentz, polarization and absorption effects. The maximum/minimum transmission values of the correction factors for compounds **4b** and **5** were 0.9471/0.5626 and 0.8588/0.5163, respectively. The data were monitored by measuring two standard reflections every 60 min of X-ray exposure time. The structures were solved by routine heavy-atom (using SHELXS 86[22]) and Fourier methods and refined by full-matrix least squares

On the Influence of the Bite Angle of Bidentate Phosphane Ligands on the Regioselectivity in Allylic Alkylation

Richard J. van Haaren,[a] Henk Oevering,[b] Betty B. Coussens,[b] Gino P. F van Strijdonck,[a] Joost N. H. Reek,[a] Paul C. J. Kamer,[a] and Piet W. N. M. van Leeuwen*[a]

Keywords: Palladium / Phosphane ligands / Bite angle / Allylic alkylation / Molecular modelling

The natural bite angle of bidentate phosphane ligands influences the isomer distribution (*syn* and *anti*) in (1-methylallyl)(bisphosphane)Pd OTf complexes. It was found (^{31}P- and ^{1}H-NMR studies) that the *syn*/*anti* ratio changes from 12 (dppp) to 1.3 (sixantphos). Molecular orbital calculations [PM3(tm) level] indicate that for ligands inducing a large bite angle, the phenyl rings of the ligand embrace the allyl moiety, thus influencing the *syn*/*anti* ratio. This bite-angle effect on the *syn*/*anti* ratio is transferred to the regioselectivity in stoichiometric allylic alkylation. Ligands inducing large bite angles direct the regioselectivity towards the formation of the branched product **2**. Catalytic alkylation of (*E*)-2-butenyl acetate showed that for ligands with a small bite angle the regioselectivity of the catalytic and stoichiometric alkylation are in good agreement. This correspondence is worse for ligands with a larger bite angle, which is rationalised in terms of the relative rates of *syn*/*anti* isomerisation and alkylation. The ligand with the largest bite angle (sixantphos) gives the most active catalytic species.

The palladium-catalysed allylic alkylation reaction receives much interest.[1–7] Most of the research in this field focuses on asymmetric induction. Less effort is put into understanding the regioselectivity found in the alkylation of nonsymmetrically substituted allyl fragments.[5,13] Åkermark[5] has shown that the cone angle of substituted phenanthrolines has a large influence on both the isomer distribution of (1-methylallyl)Pd complexes and the regioselectivity of stoichiometric alkylation. The methyl substituents on the 2,9-dimethyl-1,10-phenanthroline ligand interfere with the methyl substituent on the allyl moiety. This causes the *anti* isomer of the complex to prevail over the otherwise more stable *syn* isomer. It was shown that stoichiometric alkylation of the *syn* complex resulted in almost exclusive formation of the linear (*E*) product (**1**). The *anti* complex reacted to the branched (**2**) and the linear *cis* product (**3**) in an approximately 1:1 ratio.

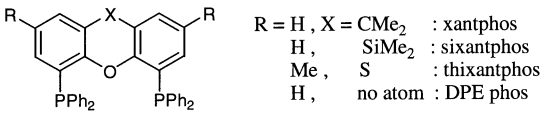

Figure 1. Generic xantphos structure

In our research group much research has been conducted concerning the effect of the natural bite angle[21] (β_n) of bidentate phosphane ligands on transition-metal-catalysed reactions.[15] This research led to the development of a new class of ligands that enforces (very) large bite angles up to 110° (the xantphos-type ligands: see Figure 1). Significant dependencies of the catalyst performance on the natural bite angle have been observed in reactions such as the rhodium-catalysed hydroformylation[8] and the nickel-catalysed hydrocyanation.[9] Recently, we communicated on the effect found in the alkylation of (*E*)-2-hexenyl acetate with sodium diethyl 2-methylmalonate.[11] Ligands with a large natural bite angle were found to direct the regioselectivity to the linear (*E*) product **1** resulting in smaller amounts of the branched product.

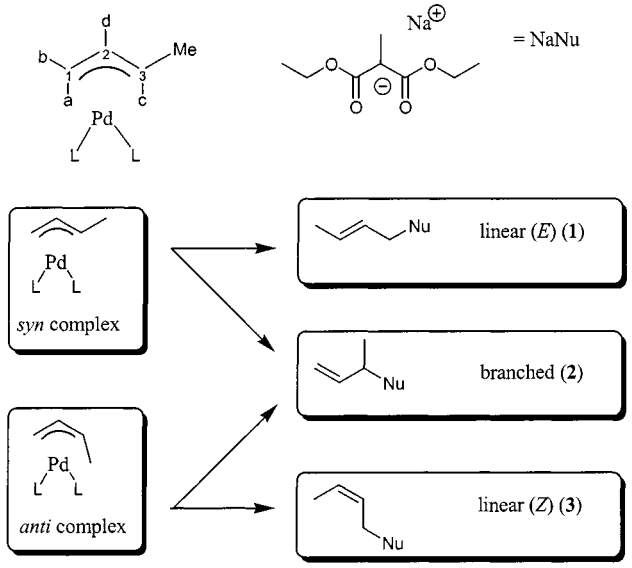

Figure 2. Numbering scheme and formation of regioisomers in the stoichiometric alkylation of (bisphosphane)(1-methylallyl)PdOTf complexes

In order to further investigate the nature of this bite angle effect, we have prepared and isolated (bisphosphane)(1-methylallyl)PdOTf complexes of several bisphosphane ligands. NMR studies (^{1}H and ^{31}P) of these compounds show that they exist as an equilibrium mixture of the *syn*

and *anti* isomers. The *syn*/*anti* ratio is dependent on the bite angle of the ligand and is significantly lower in complexes of ligands inducing larger bite angles (Table 1).

To understand the effect of the P−Pd−P angle[20] (β) on the structure of the (allyl)Pd complex, molecular orbital calculations [semiempirical PM3(tm) level] were carried out on the cationic (1-methylallyl)(bisphosphane)Pd^+ complexes. The P−Pd−P angle (β), taken from the calculated structures, varies from 85° (dppe) to 110° (sixantphos). The allyl moiety is found to be embraced by the phenyl rings of the ligand. When the bite angle is larger, the embracing becomes more pronounced. This is visualised in Figure 3.

In all the complexes studied using molecular modelling, the *syn* isomer has a lower energy than the *anti* isomer. The energy *difference* between the *syn* and *anti* isomer, however, decreases with larger bite angle. This is in agreement with the experimental data: a lower *syn*/*anti* ratio is observed when ligands inducing larger bite angles are applied (Table 1). The embracing effect in complexes of ligands inducing a *small* bite angle, however, is of minor influence. The relatively high *syn*/*anti* ratio of (dppp)(1-methylallyl)PdOTf is therefore the result of electronic rather than steric effects. This special case will be discussed in more detail elsewhere.[16]

The percentage of **3** remains almost constant along the bite angle range studied.

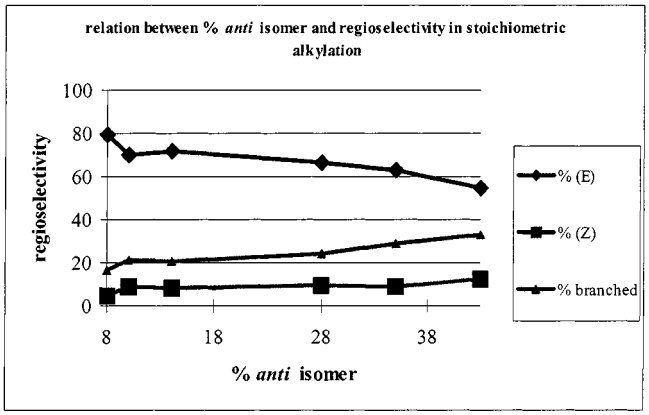

Figure 4. Relation between isomer distribution in cationic (bisphosphane)(1-methylallyl)PdOTf complexes and the regioselectivity of stoichiometric alkylation

It has been suggested[1] that in allylic alkylation reactions the structure of the allyl complex determines the (enantio)-selectivity in an early transition state. Recent developments,[4,6,12−15] however, indicate that in many cases a late transition state is more likely. In an early transition state the steric accessibility of the two carbon atoms of the allyl moiety will determine the selectivity. Due to steric hindrance between the substituent on the allyl moiety and the ligand, it will be bent out of the allyl plane, away from the palladium centre. Therefore the substituted allyl carbon atom C-3 will be less accessible for nucleophilic attack and consequently alkylation of the unsubstituted allyl carbon atom C-1 will prevail.

In a late transition state, nucleophilic attack of the malonate anion at the substituted allyl carbon atom C-3 will cause a change in the hybridisation on C-3 from sp^2 to sp^3. This causes the substituent to bend towards a phenyl ring of the ligand. A large bite angle results in an increase of the steric hindrance in this stage of the reaction (Figure 3), which hampers the formation of **2**.[11]

With a small group like a methyl substituent on the allyl moiety the steric hindrance during the nucleophilic attack is of less influence. Consequently, electronic factors may be-

Table 1. Relation between the bite angle and 1) Δ*E* (*syn*/*anti*) calculated by molecular modelling [PM3(tm) level] and obtained from experimental data (NMR), and 2) the regioselectivity in stoichiometric alkylation of the equilibrium mixtures of (bisphosphane)(1-methylallyl)PdOTf complexes

[a] β Obtained from the calculated (bisphosphane)(1-methylallyl)Pd complexes. − [b] The relative large energy difference in the calculations is most likely the result of the absence of solvent and anion.

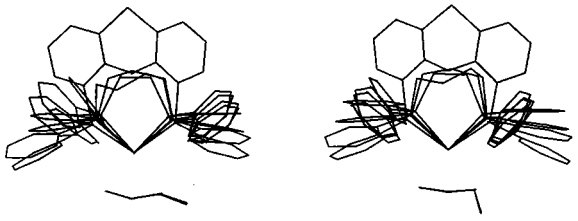

Figure 3. The embracing effect of the phenyl rings cause the substituent on the allyl moiety to bend out of the allyl plane; left = *syn*, right = *anti*

The *syn*/*anti* ratio governs the regioselectivity of the stoichiometric alkylation (Table 1, Figure 4). In (bisphosphane)(1-methylallyl)PdOTf complexes of ligands inducing a *small* bite angle the *syn* isomer largely prevails and the relative amount of the linear (*E*) product **1** is high. Going to a larger bite angle (from dppp to sixantphos), the percentage of *syn* isomer as well as the selectivity to **1** drops, whereas the selectivity to the branched product **2** increases.

come more important. This would explain the good correlation between the *syn*/*anti* ratio and the observed regioselectivity. Therefore it is concluded that in the alkylation of (bisphosphane)(1-methylallyl)PdOTf complexes the transition state of the reaction is not late. The relative importance of steric and electronic factors is dependent on the nature of the ligand and the (*syn* or *anti*) orientation of the substituents on the allyl moiety.

In addition to these stoichiometric experiments we have also carried out the *catalytic* alkylation of (*E*)-2-butenyl acetate. The catalytic experiments have been performed using the isolated (bisphosphane)(1-methylallyl)PdOTf complexes, instead of using a precursor, such as $Pd(dba)_2$, or $Pd(OAc)_2$, and the ligand. This procedure excludes an incubation step which is necessary for the formation of the catalytically active species, as well as the possibility of preequilibria by complexation of dba to Pd.[18] The retarding effect of dba is clear, if we compare the reaction rates presented in Table 2 with the reaction rates presented in a previous communication of the bite angle effect on allylic alkylation.[11] The difference in the rate of reaction is at least one order of magnitude.[16] Remarkably, the observed trend in reaction rate does not remain the same. Starting from the isolated (bisphosphane)(1-methylallyl)PdOTf complex, sixantphos is found to yield the most active catalytic species, whereas use of $Pd(dba)_2$ results in DPEphos or dppb to yield the most active catalyst.[11] Obviously, the catalytically active species is less easily formed from $Pd(dba)_2$ when a rigid ligand inducing a large bite angle is used.

In contrast to most literature procedures for allylic alkylation reactions only one equivalent of ligand per palladium atom is used. When a precursor, such as $Pd(OAc)_2$ is used, an additional equivalent of ligand might be required to reduce the Pd^{II} to the active Pd^0 species.[17] The presence of an excess of ligand will also reduce the rate of the reaction, by complexation to the Pd^0 species which is formed after alkylation. Before coordination of the substrate dissociation of the extra ligand is necessary. This can retard the overall reaction rate.

The bite-angle effect as observed in the *stoichiometric* alkylation of (bisphosphane)(1-methylallyl)PdOTf complexes is less obvious in the *catalytic* alkylation of (*E*)-2-butenyl acetate. The starting complex enters the catalytic cycle by alkylation of the starting (bisphosphane)(1-mehylallyl)-PdOTf complex. The next step involves oxidative addition of the substrate to the thus formed Pd^0 species. As the substrate configuration is mainly (*E*) (95%), initially the *syn*-(bisphosphane)(1-methylallyl)PdOAc complex is formed as the main product. This complex is cationic, so the acetate leaving group will remain as a counterion in the coordination sphere. Interaction of the counterion with the palladium centre is known to increase the rate of dynamic behaviour of the allyl moiety.[19] This results in an isomerisation of the *syn* complex to the *anti* complex and vice versa. The resulting regioselectivity of the catalytic reaction (Table 2) is dependent on the relative rates of *syn*/*anti* isomerisation and alkylation.

NMR experiments with the (bisphosphane)(1-methylallyl)PdOTf complexes used in the alkylation reactions, indicate that the *syn*/*anti* isomerisation in these complexes is slow relative to stoichiometric alkylation. The isomerisation, however, may play a significant role when acetate instead of the weakly co-ordinating triflate is the counterion, as is the case in the catalytic experiments.

The correlation between the regioselectivity in stoichiometric and catalytic alkylation is good for ligands inducing a small bite angle, such as dppe and dppp, but also for dppf (Table 1 and 2). Going to a larger bite angle, the selectivity follows a different trend as that in the stoichiometric reaction. The sixantphos ligand directs the regioselectivity towards 85% of the linear (*E*) product. This can be rationalised in terms of a fast alkylation rate, relative to isomerisation, of the complexes with ligands inducing a large bite angle.

In conclusion, we have shown that for (bisphosphane)(1-methylallyl)PdOTf complexes with ligands inducing a large bite angle the *syn*/*anti* ratio is much lower than in the corresponding complexes with ligands with a small bite angle. Molecular modelling studies indicate that this is caused by an increasing embracement of the allyl moiety by the phenyl rings of the ligand. This bite-angle effect on the *syn*/*anti* ratio can be transferred to the regioselectivity in stoichiometric allylic alkylation. Ligands inducing large bite angles direct the regioselectivity towards the formation of **2**. In the *catalytic* alkylation of (*E*)-2-butenyl acetate, however, the regioselectivity is also determined by the relative rates of *syn*/*anti* isomerisation and alkylation. The correlation between the regioselectivity found in the stoichiometric and

[a] β Obtained from the calculated (bisphosphane)(1-methylallyl)Pd complexes. – [b] t.o.f. is the initial turn over frequency, determined after 10 min of reaction time. – [c] Based on the formation of **1**, **2**, and **3**, as determined after 30 min by GC, using the internal standard method. The catalytic reactions were performed in THF (10 mL), using 0.05 mol-% of catalyst (0.00050 mmol), 1.0 mmol of substrate, and 2.0 mmol of sodium diethyl 2-methylmalonate. The reaction was monitored by GC using decane as the internal standard.

the catalytic alkylation is best for ligands inducing a small bite angle. The ligands with the largest bite angle (sixantphos) is found to result in the most active catalytic species.

Experimental Section

^{1}H- (300 MHz, TMS, $CDCl_3$) and ^{31}P-NMR spectra (121.5 MHz external 85% H_3PO_4, $CDCl_3$) were recorded with a Bruker AMX-300 spectrometer. − Elemental analyses were performed with an Elementar Vario EL (Foss Electric). − All calculations were carried out using the commercially available SPARTAN program (version 5.0.3). The geometry optimisation was performed on the semiempirical pm3(tm) level. − The product distribution was measured with an Interscience Mega2 apparatus, equipped with a DB1 column, length 30 m, inner diameter 0.32 mm, film thickness 3.0 μm, and an F.I.D detector. − All experiments were carried out using standard Schlenk techniques. All solvents were freshly distilled prior to use. − Sodium diethyl 2-methylmalonate (0.5 M in THF) was prepared from diethyl 2-methylmalonate and NaH in THF at 273 K. − The stoichiometric alkylation reactions were performed by adding an excess of sodium diethyl 2-methylmalonate (0.1 mL of a 0.5 M solution in THF) to a solution of 10 mg of the Pd complex in 1 mL of THF. Reaction was instantaneous and after 1 min, the mixture was worked up with water, filtered through silica gel, and analysed by GC. − The catalytic reactions were performed in THF (10 mL), using 0.05 mol-% of catalyst (0.00050 mmol), 1.0 mmol of substrate, and 2.0 mmol of sodium diethyl 2-methylmalonate. The reaction was monitored by taking samples from the reaction mixture which, after aqueous workup, were analysed by GC using decane as the internal standard. − The Pd complexes were prepared in CH_2Cl_2 from [(1-methylallyl)Pd(μ-Cl)]$_2$ by adding 2 equiv. of ligand and abstracting the Cl atom with AgOTf. The complexes were isolated in quantitative yield (white microcrystalline powder) as their analytically pure equilibrium mixtures and were used as such in the alkylation reaction. The syntheses of DPEphos and sixantphos have been published elsewhere.[6] Dppe, dppp, dppb, and dppf were obtained from Acros chemicals and used as received. − Analytical data of the (ligand)(1-methylallyl)-PdOTf complexes are given for their equilibrium mixtures. The NMR signals of the *syn* and *anti* isomers could easily be distinguished. The *syn*/*anti* ratio was determined by comparing the intensities of the signals of the methyl substituent on the allyl moiety. NMR data of the complexes were obtained in $CDCl_3$ (δ values).

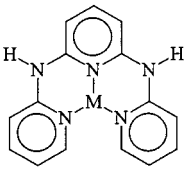
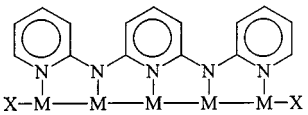
Linear Five-Centred Chromium Multiple Bonds Bridged by Four $tpda^{2-}$ Ligands [$tpda^{2-}$ = tripyridyldiamido dianion] – Synthesis and Structural Studies



Hsiao-Chi Chang,[a] Jia-Tzung Li,[a] Chih-Chieh Wang,[a] Tzu-Wei Lin,[a] Hsiao-Ching Lee,[a] Gene-Hsiang Lee,[a] and Shie-Ming Peng*[a]

Keywords: Metal string complexes / Multicentered metal–metal multiple bond / Quadruple bonds / Metal-metal interactions / Chromium

The linear pentanuclear chromium complexes $[Cr^{II}_5(\mu_5\text{-tpda})_4Cl_2]$ (**1**), $[Cr^{II}_5(\mu_5\text{-tpda})_4(NCS)_2]$ (**2**), $[Cr^{III}Cr^{II}_4(\mu_5\text{-tpda})_4F_2](BF_4)$ (**3**), and $[Cr^{III}Cr^{II}_4(\mu_5\text{-tpda})_4F(OTf)](OTf)$ (**4**), with four all-*syn* tri(α-pyridyl)diamido dianion ($tpda^{2-}$) ligands, have been prepared and structurally characterized. Compounds **1** and **2** possess a delocalized $Cr^{(II)}$–$Cr^{(II)}$–$Cr^{(II)}$–$Cr^{(II)}$–$Cr^{(II)}$ five-centred metal–metal bond of order 1.5. In both **1** and **2** two values for Cr^{II}–Cr^{II} bond lengths are found both; the outer ones connected with axial ligands are 2.284(1) and 2.285(2) Å, and the inner ones are 2.2405(8) and 2.246(1) Å, for **1** and **2,** respectively. When compound **1** reacts with 2 equiv. of $AgBF_4$ or Ag(OTf), a oxidation reaction takes place and one of the terminal chromium(II) ions is oxidized to produce $[Cr^{III}Cr^{II}_4(\mu_5\text{-tpda})_4F_2]BF_4$ (**3**) or $[Cr^{III}Cr^{II}_4(\mu_5\text{-tpda})_4F(OTf)](OTf)$ (**4**). Two short Cr–Cr distances [1.969(2) and 2.138(2) Å for **3**, 1.846(1) and 1.922(1) Å for **4**] are found, with the presence of two quadruple bonds among four adjacent Cr^{II} ions. The fifth Cr^{III} ion, which is separated from the neighboring Cr^{II} ion by 2.487(2) Å for **3** and 2.610(1) Å for **4**, is simply a square pyramidal unit with no metal–metal bonding interaction.



Introduction

The coordination chemistry of oligo-α-pyridylamino ligands[1] is an interesting topic, not only on the subject of the synthetic varieties of *all-anti* and *all-syn* complexes, but also as concerns the specific conformations and chemical properties of these complexes.[1–9]

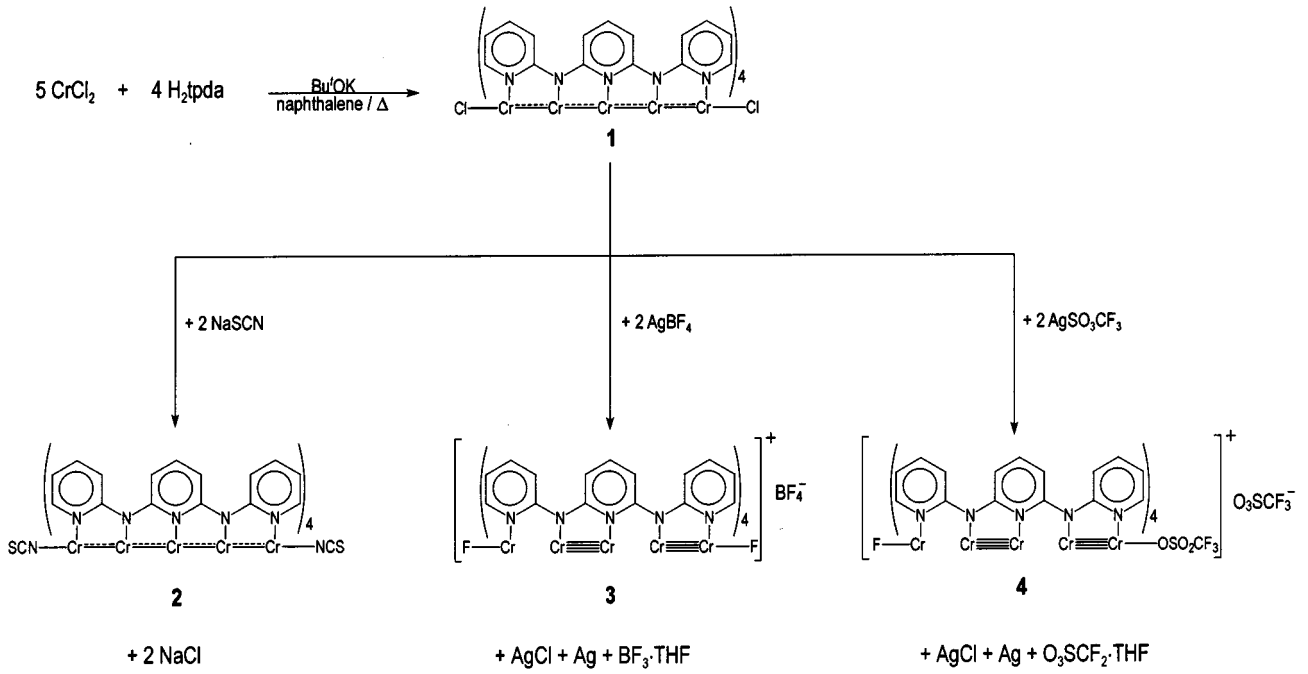
All *anti*-form

M = Fe, Co, Ni, Cu, Zn

All *syn*-form

M = Co, Ni

Previous reports on the extension of di-nuclear metal complexes[10–12] to metal string complexes supported by oligo-α-pyridylamino ligands were focused on the tri-nuclear $[M_3(dpa)_4X_2]$ (M = Cr,[2] Co,[3,4] Ni,[5] Cu,[6] Rh,[7] Ru;[7] dpa^- = dipyridylamido anion), and pentanuclear $[M_5(tpda)_4X_2]$ (M = Co, Ni; $tpda^{2-}$ = tripyridyldiamido dianion) systems.[8,9] There is good correlation between the metal–metal distance obtained from structural analysis and the bond order predicted by qualitative M. O. calculations for the tri-nuclear metal string complexes $[M_3(dpa)_4X_2]$. The M–M distances are affected by the axial ligands, and the magnetic behavior of the M^{II}_5 unit in $[Ni_5(tpda)_4X_2]$ and $[Co_5(tpda)_4X_2]$ complexes has been studied in detail. In order to achieve a complete bonding scheme for five-centred metal–metal multiple bonds, the early transition metal string complexes $[Cr_5(tpda)_4Cl_2]$ (**1**), $[Cr_5(tpda)_4(NCS)_2]$ (**2**) have been synthesized. In addition, two oxidation products of $[Cr^{III}Cr^{II}_4(tpda)_4F_2](BF_4)$ (**3**) and $[Cr^{III}Cr^{II}_4(tpda)_4F(CF_3SO_3)](CF_3SO_3)$ (**4**) are reported. The structural analyses are described and discussed in detail (see Table 5).



Results and Discussions

The synthetic procedures for compounds **1**, **2**, **3**, and **4** are summarized in Scheme 1. Compound **1** can be synthesized under nitrogen using anhydrous $CrCl_2$ and the H_2tpda ligand as the starting materials, and naphthalene as the solvent. *t*BuOK was used as a base to deprotonate the H atom on the amido group of the H_2tpda ligand. Compound **2** was synthesized via the axial ligand replacement method with the NCS^- ligand instead of the Cl^- ligand in **1**. Compounds **3** and **4** are the products of the oxidation reactions of compound **1** with **2** equiv. of $AgBF_4$ and AgOTf, respectively. The presence of the F^- ion in **3** and **4** can be explained by considering the dissociation in THF of the BF_4^- and $SO_3CF_3^-$ anion, respectively.[2a]

For compounds **1** and **2**, each structure basically consists of a linear chain of five chromium atoms bridged by four $tpda^{2-}$ ligands. The steric crowding of the β-carbon hydrogen atoms on the pyridyl rings forces the $tpda^{2-}$ ligand to

Scheme 1. Synthetic routes for compounds **1**, **2**, **3** and **4**

bind helically with the metal ion. Both are essentially isostructural with $[M_5(\mu_5\text{-tpda})_4X_2]$ (M^{II} = Co, X = Cl^-, NCS^-, N_3^-, CH_3CN and M^{II} = Ni, X = Cl^-, CN^-, NCS^-, N_3^-, CH_3CN).[8,9] Complex **1** crystallizes in the *C*2/*c* space group with the Cr(3) atom located at the crystallographic 2-fold axis. The molecular structure of **1** is shown in Figure 1. Complex **2** crystallizes in the *I*4/*m* space group with the Cr(3) atom located at the crystallographic 4/*m* symmetry, and the asymmetric unit contains only one eighth of the complex. The atomic positions of the complex **2** are averaged, because the right-turn and left-turn helical complexes are seriously disordered in the crystal. The eight nitrogen atoms from the amido group (occupancy 0.5) coordinated to chromium ions [Cr(2)], and the α-carbon atoms of the pyridyl groups have high anisotropic thermal parameters. One of the helical structures of **2** is shown in Figure 2. All of the Cr ions and two axial ligands for **1** and **2** are nearly co-linear. The five-centred Cr^{II} delocalized

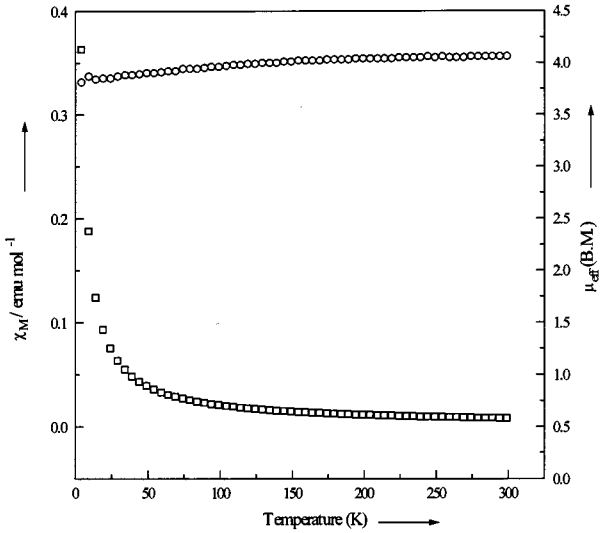
multiple bond is the focus of this study. Two types of Cr−Cr bond lengths are found in **1** and **2**. The outer ones connected to the axial ligands are 2.284(1) and 2.285(2) Å, and the inner ones are 2.2405(8) and 2.246(1) Å, for **1** and **2** respectively. Both are shorter than those found in trinuclear complexes {2.365(1) Å in $[Cr_3(dpa)_4Cl_2]$[2]} and dichromium(II) tetracarboxylate complexes {2.29−2.53 Å in $[Cr_2(O_2CR)_4X_2]$[10]}, but much longer than those in super-short dichromium(II) complexes bridged by N,N-containing ligands {e.g. 1.843(2) Å in $[Cr_2(MeNC(Ph)NMe)_4]$,[19] 1.870(3) Å in $[Cr_2(Me\text{-pyridylamido})_4]$,[20] 1.858(1) Å in $[Cr_2(PhN_3Ph)_4]$[21]}. They are also comparable with the values of 2.28 Å and 2.23 Å found in the $[Co_5(\mu_5\text{-tpda})_4X_2]$ complex, which exhibits a double bond among the $Co^{II}{}_5$ unit.[8] The qualitative molecular orbital analysis of the Cr−Cr−Cr−Cr−Cr system, according to the atomic coordinates of **1** derived from the X-ray data, is shown in Figure 3. The bonding features among the five Cr atoms are similar to those of $[Co_5(tpda)_4(NCS)_2]$ and $[Ni_5(tpda)_4(NCS)_2]$, with a linear combination of the d_{z^2} orbitals of the five Cr atoms forming five σ orbitals, the (d_{xz}, d_{yz}) of the five Cr atoms forming ten π orbitals and the ($d_{x^2-y^2}$ or d_{xy}) orbitals of the five Cr atoms forming five nonbonding orbitals.[9] A total of twenty d electrons of Cr^{II} ions fill up to n_π degenerate orbitals leading to the configuration of $\sigma_1{}^2\sigma_2{}^2\pi_1{}^4\pi_2{}^4\delta_{n1}{}^2\delta_{n2}{}^2\ \delta_{n3}{}^2\pi_{n(dxz)}{}^1\pi_{n(dyz)}{}^1$. This configuration shows that two unpaired electrons are delocalized among the $Cr^{II}-Cr^{II}-Cr^{II}-Cr^{II}-Cr^{II}$ unit and that the bond order is 1.5 for each $Cr^{II}-Cr^{II}$ bond (the δ bonds are regarded as nonbonding orbitals for the helical conformation of the $tpda^{2-}$ ligand). The temperature independent magnetic susceptibility measurement of compound **1** is shown in Figure 4 with μ = 4.0 B.M, which is consistent with the M.O. prediction. This measured magnetic value is larger than the spin-only value (μ = 2.82 B.M), and this may be due to the orbital contribution of π-nonbonding orbitals. [The magnetic moment (μ_{eff}) is 3.6 B. M. for $[Cr_3(dpa)_4Cl_2]$ which is also larger than spin-only value (2.82).] If the M−M distances in the $[M_5(\mu_5\text{-tpda})_4X_2]$ system are compared with the distances for those systems having the axial ligands Cl^- and NCS^- for different metal centers (listed in Table 1) it can be seen that, i) in the Ni case, the outer M−M distance is obviously changed from 2.385(2) Å to 2.369(2) Å when the axial ligand is changed from Cl^- to NCS^- with the Ni−Ni bond order being zero,[8,9] ii) in compounds **1** and **2**, the outer Cr−Cr distance is nearly the same [2.284(1) and 2.285(2) Å] whether the axial ligand is Cl^- or NCS^-, with the Cr−Cr bond order being 1.5. These results indicate that, in the $[M_5(\mu_5$-



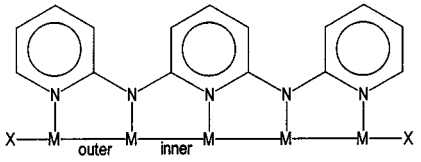


Figure 4. Magnetic measurement for compound **1**. □ indicates the observed magnetic susceptibility (χ_M) and ○ the observed effect magnetic moment (μ_{eff})

Table 1. Comparison of M−M bond length [Å] in $[M_5(tpda)_4X_2]$ complexes (M = Cr, Co, Ni; X = Cl, NCS)

Compound	Outer M−M distance	Inner M−M distance	Bond order
$[Cr_5(tpda)_4Cl_2]$ (**1**)	2.284(1)	2.2405(8)	1.5
$[Cr_5(tpda)_4(NCS)_2]$ (**2**)	2.285(2)	2.246(1)	1.5

[a] Ref.[8] and ref.[9]

tpda)$_4X_2$] system, the outer M−M distance could be affected or not affected by the axial ligands, and that the bonding strength of M−M bond is an important factor. When the M−M interaction is weak {in $[Ni_5(tpda)_4X_2]$ case}, the outer M−M distance is easily affected by the different axial ligands,[9] but the M−M distance is not influenced by the axial ligand when the metal−metal bond is strong {in the case of $[Cr_5(tpda)_4X_2]$}. However, such structural characterizations should be studied further by synthesizing more $[M_5(\mu_5\text{-tpda})_4X_2]$ complexes, with different metal center and axial ligands, and supporting the results by theoretical calculations.

Compounds **3** and **4** crystallize in $P2_1/n$ and $P2_1/c$ space groups, respectively, with both molecules residing in general positions. As for the compounds **1** and **2**, all of the Cr ions and two axial ligands are nearly co-linear and the five Cr centers are also helically wrapped by four $tpda^{2-}$ ligands. One of the terminal Cr^{II} atoms in these compounds is oxidized to Cr^{III}, connected with the axial ligand F^-, and the other terminal Cr^{II} ion is connected with the axial ligand F^- and $CF_3SO_3^-$ (**3** and **4**, respectively). The crystal structures of **3** and **4** are shown in Figures 5 and 6. Four unsym-

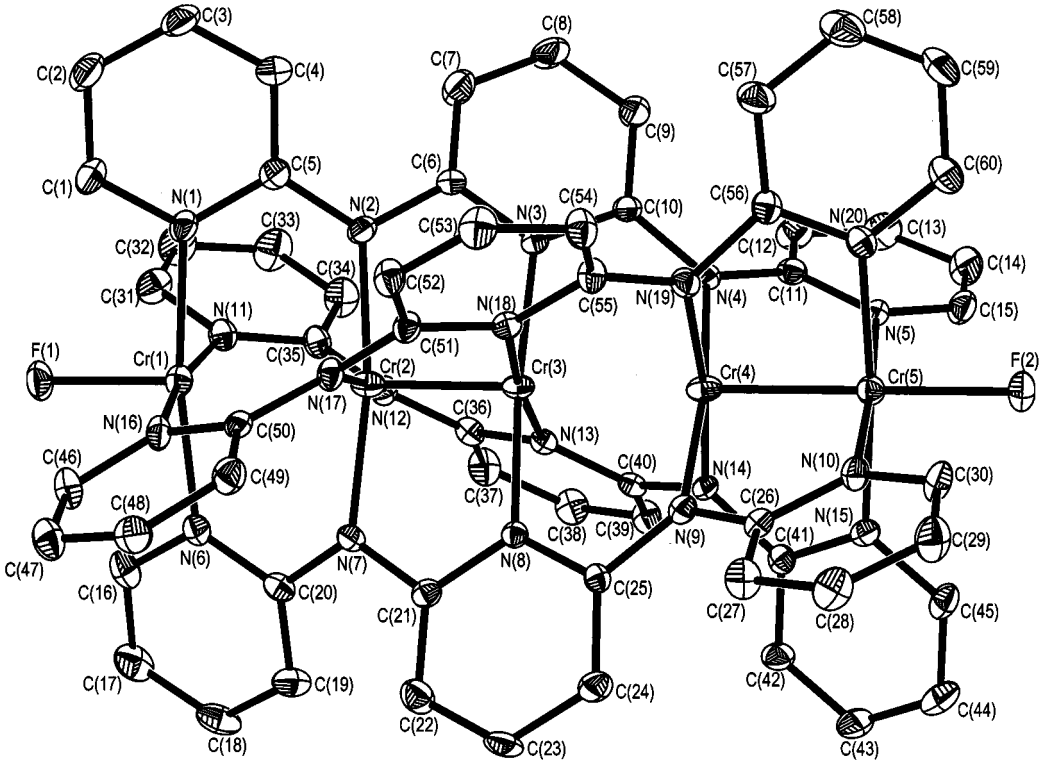

Figure 5. Crystal structure of $[Cr_5(\mu_5\text{-tpda})_4F_2]^+$ **3**. Atoms are shown as 20% vibrational thermal ellipsoids

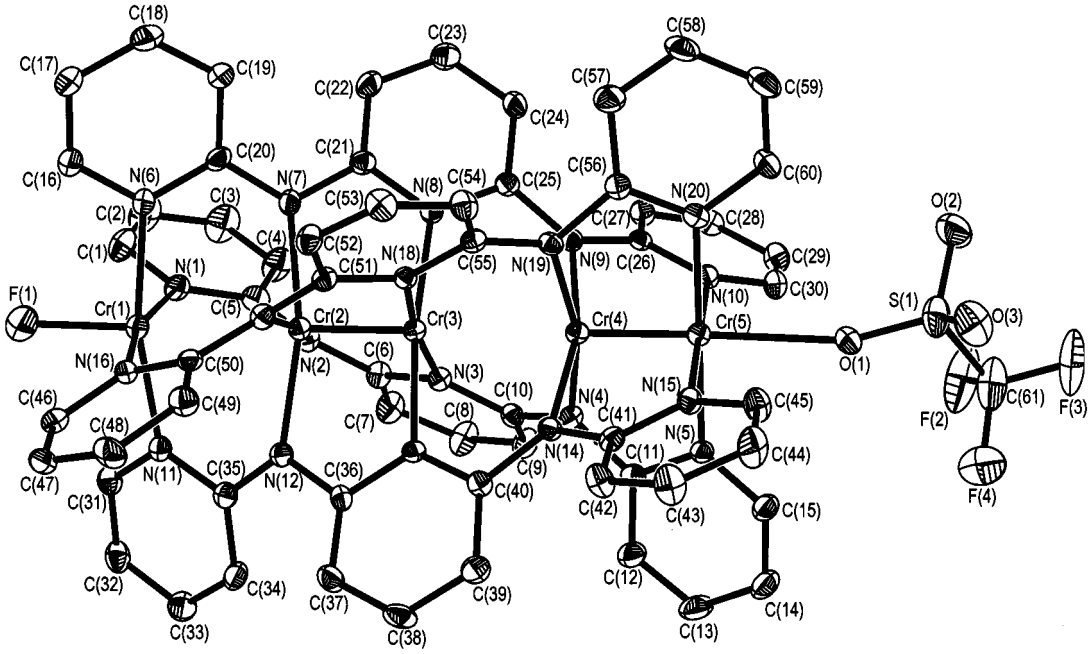

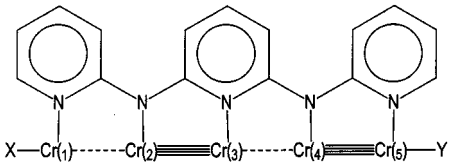

Figure 6. Crystal structure of $[Cr_5(\mu_5\text{-tpda})_4F(SO_3CF_3)]^+$ **4**. Atoms are shown as 20% vibrational thermal ellipsoids

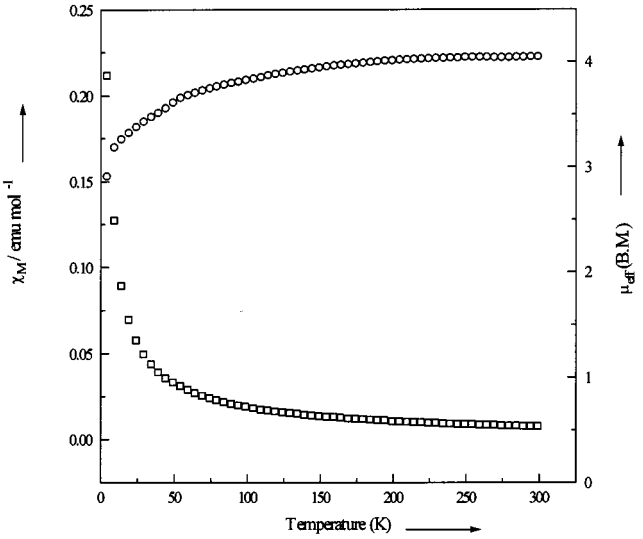
metric Cr−Cr distances listed in Table 2 are observed in both compounds. Two short Cr−Cr distances [1.969(2) and 2.138(2) Å for **3**, 1.846(1) and 1.922(1) Å for **4**] are found along with the presence of two quadruple bonds among four adjacent Cr^{II} ions. The longer distances of 1.922(1), 1.969(2), and 2.138(2) Å are comparable with those found in the dichromium(II) complexes (1.937−2.354 Å) bridged by N,N- or N,O-containing ligands (e.g. formamidinate and 2-oxopyridinates),[10] and in the trichromium(II) complexes bridged by the dpa^- ligand {1.9952(8) Å in $[Cr_3(dpa)_4Cl(BF_4)]$}.[2] The shortest distance of 1.846(1) Å is comparable with those found in the super-short dichromium(II) complexes which are bridged by N,N-containing ligands {e.g. 1.843(2) Å in $[Cr_2(MeNC(Ph)NMe)_4]$,[19] 1.870(3) Å in $[Cr_2(Me\text{-}pyridylamido)_4]$,[20] 1.858(1) Å in $[Cr_2(PhN_3Ph)_4]$[21]}. Complexes **3** and **4** are so far the only cases found in the literature where two Cr−Cr quadruple bonds co-exist in a molecule. In the dichromium(II) complex an unusually wide range of Cr−Cr bond lengths (1.828−2.541 Å) are exhibited.[10] The presence or absence of axial ligand was found to be the determining factor over the Cr−Cr bond length when considering the same bridging ligands. In complexes **3** and **4**, the influence of the axial ligand on the Cr−Cr quadruple bond is also significant (Table 2). The intermediate Cr(2)−Cr(3) bond lengths [**3**, 1.969(2) Å; **4**, 1.846(1) Å] are obviously shorter than the terminal Cr(4)−Cr(5) bond lengths [**3**, 2.138(2) Å; **4**, 1.922(1) Å] with one axial ligand (**1**, F^-; **2**, $SO_3CF_3^-$) connected to Cr(5). Meanwhile, the terminal Cr(4)−Cr(5) distance is shortened from 2.138(2) Å to 1.922(1) Å when the axial ligand connected on Cr(5) is changed from a strong σ-donating F^- ligand to a weak $CF_3SO_3^-$ ligand. The distances [Cr(3)−Cr(4)] between the two quadruple bonds are long [2.419(2) and 2.596(1) Å for **3** and **4** respectively] which can be explained by the absence of a metal−metal bonding interaction. The fifth Cr^{III} [Cr(1)] ion connected with F^-, which is separated from the neighboring Cr^{II} ion by 2.487(2) and 2.610(1) Å (**3** and **4** respectively), is simply

Table 2. Selected bond lengths [Å] for $[Cr_5(tpda)_4F_2](BF_4)$ and $[Cr_5(tpda)_4F(OTf)](OTf)$

Compound	Cr(1)−X[a]	Cr(1)−Cr(2)	Cr(2)−Cr(3)	Cr(3)−Cr(4)	Cr(4)−Cr(5)	Cr(5)−Y[a]
$[Cr_5(tpda)_4F_2](BF_4)$	1.840(4)	2.487(2)	1.969(2)	2.419(2)	2.138(2)	1.931(4)
$[Cr_5(tpda)_4F(OTf)](OTf)$	1.863(5)	2.610(1)	1.846(1)	2.596(1)	1.922(1)	2.353(5)

[a] X = F^-, Y = F^- or $SO_3CF_3^-$.



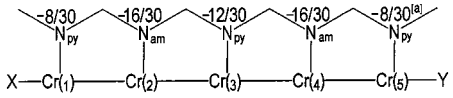


Figure 7. Magnetic measurement for compound **3**. □ indicates the observed magnetic susceptibility (χ_M) and ○ the observed effect magnetic moment (μ_{eff})

a square pyramidal $F-Cr^{III}-N_4$ unit without a metal−metal bonding interaction. The $Cr^{III}-F$ distances of 1.840(4) Å (**3**) and 1.863(5) Å (**4**) are comparable with those of 1.824(7) and 1.802(6) Å in the $[Cr_3(dpa)_4F(BF_4)](BF_4)$ complex.[2] The magnetic measurement of compound **3** is shown in Figure 7. The temperature independent magnetic moment of μ_B = 4.0 B.M. indicates that there are three unpaired electrons. These can be assigned to the $Cr^{3+}(d^3)$ species; the two quadruply bonded fragments would not be expected to contribute to the paramagnetism of the molecule.

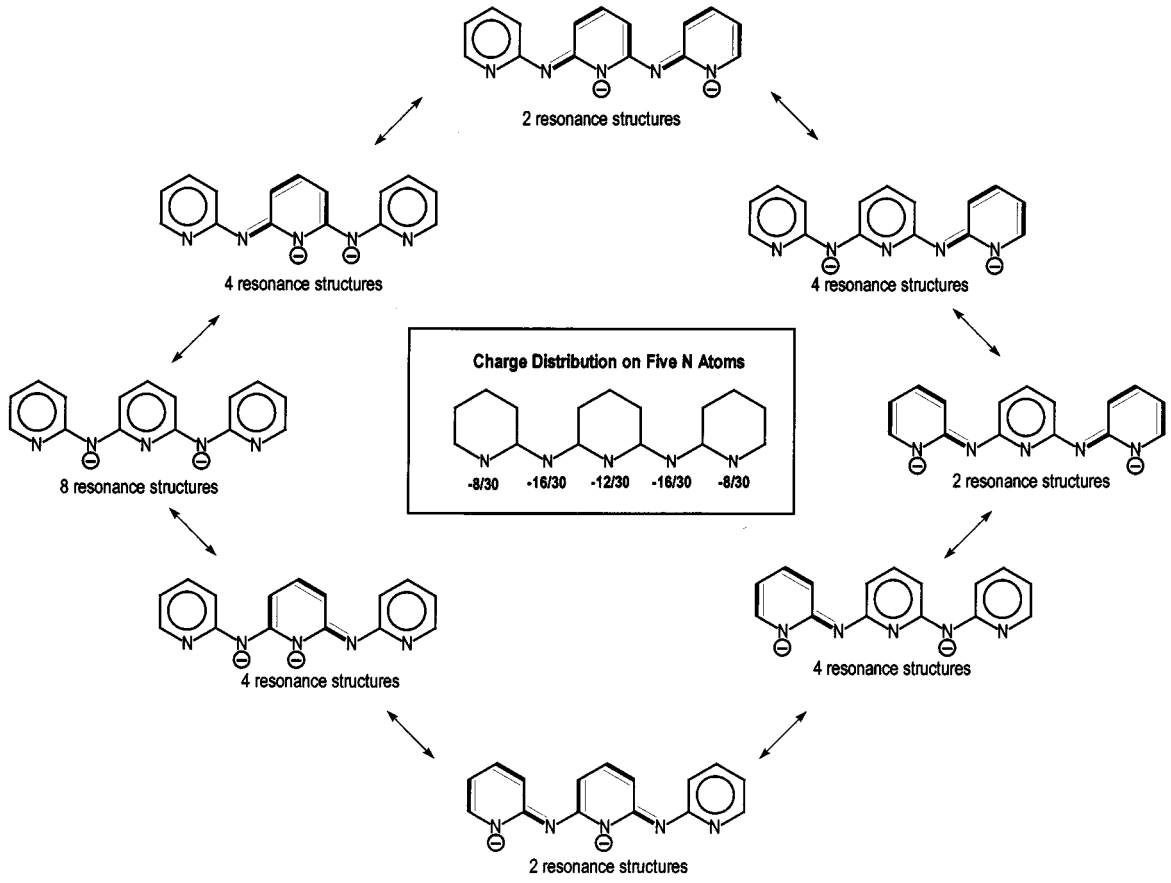

Table 3. The averaged Cr−N distances [Å] for compounds **1**, **2**, **3**, and **4**

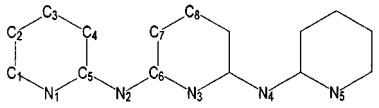
Compound	Cr(1)−N	Cr(2)−N	Cr(3)−N	Cr(4)−N	Cr(5)−N
1	2.119(3)	2.021(3)	2.050(3)	2.021(3)	2.119(3)
2	2.086(3)	2.019(5)	2.055(3)	2.019(5)	2.086(3)
3	2.070(7)	2.004(6)	2.034(6)	1.992(6)	2.079(6)
4	2.081(6)	2.014(5)	2.053(5)	2.031(5)	2.095(5)

[a] Charges on the nitrogen atoms according to 30 resonance structures.



According to the structural analyses listed in Table 3, the Cr−N distances are in the order $Cr-N_{amido}$ [Cr(2)−N] < the central $Cr-N_{py}$ [Cr(3)−N] < the terminal $Cr-N_{py}$ [Cr(1)−N] for compounds **1**, **2**, **3**, and **4**. This result could be due to the charge distribution on the $tpda^{2-}$ ligand. The resonance structures of the $tpda^{2-}$ ligand is described in Scheme 2. The probability of two negative charges distri-

Scheme 2. Resonance structures of $tpda^{2-}$ ligand

buting on the terminal N_{py}, the N_{amido}, and the central N_{py} atoms are 8:30, 16:30, and 12:30, respectively. From this negative charge distribution, the bond interaction between Cr and N atoms should be in the sequence of the Cr−N_{amido} > the central Cr−N_{py} > the terminal Cr−N_{py} bond. Such a result will reflect directly on the Cr−N distance giving the order Cr−N_{amido} < the central Cr−N_{py} < the terminal Cr−N_{py}. The Cr−N distance predicted from the resonance structures of the $tpda^{2-}$ ligand is in a good agreement with those obtained from structural analyses. No matter what the oxidation state of terminal Cr ion is (2+ or 3+), or what the axial ligand is, the averaged terminal Cr−N_{py} distances are always the longest and the averaged Cr−N_{amido} bond lengths are the shortest. This result is also found in $[Ni_5(\mu_5\text{-tpda})_4X_2]$ and $[Co_5(\mu_5\text{-tpda})_4X_2]$ complexes.[8][9] Beside the Cr−N bond lengths, the π bond orders of C−N and C−C bonds obtained from the resonance structures shown in Scheme 2 are also consistent with those observed for the $tpda^{2-}$ ligands in compounds **1**, **3**, and **4** (Table 4).

Table 4. The averaged N−C and C−C distances [Å] for compounds **1**, **3**, and **4**

Bond type	π-Bond order[a]	1	3	4
N1−C1	11/30	1.356(5)	1.357(10)	1.359(9)
N1−C5	11/30	1.363(5)	1.357(10)	1.359(9)
N2−C5	8/30	1.373(4)	1.384(10)	1.373(8)
N2−C6	6/30	1.379(5)	1.387(10)	1.385(8)

[a] π bond order was calculated according to 30 resonance structures.

Conclusions

In summary, a five-centred multiple bonding scheme has been successfully demonstrated for both late transition metal ions (M = Ni, Co)[8][9] and an early transition metal ion (M = Cr) (compounds **1** and **2**). According to the structural analyses two types of Cr−Cr−Cr−Cr−Cr unit are observed in the $[Cr_5(tpda)_4]$ fragments. One is a delocalized Cr^{II}_5 system (compounds **1** and **2**) with four nearly equal Cr−Cr distances, the other is a localized $[C^{III}\cdots C^{II}_4]$ system (compounds **3** and **4**) with four asymmetric Cr−Cr distances. Two short quadruple bonds are found. The magnetic behaviors of these two systems are in accordance with the structural analysis and qualitative theoretical predictions.

Experimental Section

Spectroscopic Measurements: IR: Nicolet Fourier-Transform IR, MAGNA-IR 500 spectrometer in the range of 500−4000 cm^{-1}, KBr discs. − UV/Vis: Hewlett Packard (HP) 8453 spectrophotometer. − Temperature dependent magnetic susceptibility: SQUID system with 10,000 Gauss external magnetic field. − Molar magnetic susceptibility: recorded every 5 K in the range of 5−300 K. The H_2tpda ligand was synthesized according to the literature.[1,8a]

Preparation and Characterization of $[Cr_5(\mu_5\text{-tpda})_4Cl_2]$ (1): Anhydrous $CrCl_2$ (0.369 g, 3 mmol), H_2tpda (0.526 g, 2 mmol) and potassium *tert*-butoxide (0.44 g, 4 mmol) were placed in an Erlenmeyer flask, and naphthalene (10 g) added under nitrogen in the glove box. The mixture was refluxed under nitrogen and heated to 180−200°C for 6 h. After the mixture had cooled, *n*-hexane was added to wash out the naphthalene. The remaining solid was extracted with CH_2Cl_2 and re-crystallized from a $CHCl_3$/ether solution. Deep brown crystals were obtained (yield: 30%). − IR (KBr): $\tilde{\nu}$ = 1602 cm^{-1}, 1578, 1547 (C=C). − MS (FAB); *m/z* (%): 1376 (7) $[M]^+$. − UV/Vis (CH_2Cl_2): λ_{max} (ε) = 283 nm ($7.56\cdot10^4$ M^{-1} cm^{-1}), 326 ($5.58\cdot10^4$ M^{-1} cm^{-1}), 390 ($4.20\cdot10^4$ M^{-1} cm^{-1}), 710 ($8.15\cdot10^3$ M^{-1} cm^{-1}). − $\mathbf{1}\cdot CHCl_3\cdot O(C_2H_5)_2$: calcd. C 49.74, H 3.53, N, 17.85; found C 49.66, H 3.66, N 17.84.

Preparation and Characterization of $[Cr_5(\mu_5\text{-tpda})_4(NCS)_2]$ (2): $[Cr_5(\mu_5\text{-tpda})_4(Cl)_2]$ (0.05 g, 0.036 mmol) was placed in an Erlenmeyer flask in THF (40 mL). The brown solution was stirred for 5 min and filtered off. NaSCN (0.06 g, 0.72 mmol) was added to the filtrate and stirring continued for 2 d. Then water (50 mL) was added to dissolve unchanged NaSCN. The solution was extracted with CH_2Cl_2 (3× 60 mL) and Na_2SO_4 added to remove water. The remaining solvent was removed by rotary evaporator and recrystallized from a CH_2Cl_2/ether solution. Deep brown crystals were obtained (yield: 30%). − IR (KBr): $\tilde{\nu}$ = 1604 cm^{-1}, 1577, 1546 (C=C), 2033 (C≡N). − MS (FAB); *m/z* (%): 1421 (1) $[M]^+$. − UV/Vis (CH_2Cl_2): λ_{max} (ε) = 288 nm ($1.19\cdot10^5$ M^{-1} cm^{-1}), 332 ($7.84\cdot10^4$ M^{-1} cm^{-1}), 392 ($7.52\cdot10^4$ M^{-1} cm^{-1}), 721 ($9.02\cdot10^3$ M^{-1} cm^{-1}). − $\mathbf{2}\cdot CH_2Cl_2\cdot 6\,H_2O$: calcd. C 46.86, H 3.62, N 19.08; found C 47.70, H 3.71, N 19.08.

Preparation and Characterization of $[Cr^{III}Cr^{II}_4(\mu_5\text{-tpda})_4F_2]BF_4$ (3): $[Cr_5(\mu_5\text{-tpda})_4(Cl)_2]$ (0.1 g, 0.072 mmol) and silver tetrafluoroborate ($AgBF_4$, 0.028 g, 0.14 mmol) were placed in a 50 mL flask containing THF (20 mL). After 1 h of stirring, the solution was filtered to remove AgCl and Ag solid, leaving a clear dark brown solution. The solution was concentrated and a brown powder obtained. The powder was recrystallized from CH_3CN/ether solution. Deep brown crystals were obtained (yield: 35%). − IR (KBr): $\tilde{\nu}$ = 1606 cm^{-1}, 1581, 1547 (C=C). − UV/Vis (CH_2Cl_2): λ_{max} (ε) = 290 nm ($9.03\cdot10^4$ M^{-1} cm^{-1}), 396 ($6.00\cdot10^4$ M^{-1} cm^{-1}), 716 ($5.38\cdot10^3$ M^{-1} cm^{-1}). − MS (FAB): *m/z* (%): 1343 (60) $[M]^+$. − $\mathbf{3}\cdot 2\,CH_2Cl_2\cdot 3\,H_2O$: calcd. C 43.07, H 3.32, N 15.95; found: C 43.27, H 3.23, N 15.95.

Preparation and Characterization of $[Cr^{III}Cr^{II}_4(\mu_5\text{-tpda})_4F(CF_3SO_3)](CF_3SO_3)$ (4): $[Cr_5(\mu_5\text{-tpda})_4(Cl)_2]$ (0.05 g, 0.036 mmol) and $AgCF_3SO_3$ (0.019 g, 0.072 mmol) were placed in 50 mL flask containing THF (20 mL). After 1 h of stirring, the solution was filtered to remove AgCl and Ag solid, leaving a clear dark brown solution. The solution was concentrated and a brown powder obtained. The powder was recrystallized from $CHCl_3$/ether solution. Deep brown crystals were obtained (yield: 30%). − IR (KBr): $\tilde{\nu}$ = 1604 cm^{-1}, 1581, 1547 (C=C). − MS (FAB); *m/z* (%): 1454 (21) $[M]^+$.

Crystal Structure Determinations: Data collection was carried out on a Siemens SMART diffractometer with a CCD detector with

Mo radiation (λ = 0.71073 Å) at room temp. A preliminary orientation matrix and unit cell parameters were determined from 3 runs of 15 frames each, each frame correspond to a 0.3° scan in 20 s, following by spot integration and least-squares refinement. For each structure, data were measured using ω scans of 0.3° per frame for 20 s until a complete hemisphere had been collected. Cell parameters were retrived using SMART[13] software and refined with SAINT on all observed reflections. Data reduction was performed with the SAINT[14] software and corrected for Lorentz and polarization effects. Absorption corrections were applied with the program SADABS.[15] The detail crystal data of compounds **1**, **2**, **3**, and **4** are listed in Table 5.

Crystal Data of 1·2 $O(C_2H_5)_2$·4 $CHCl_3$: A brown crystal of approximation dimensions 0.5 × 0.4 × 0.3 mm was mounted on a glass capillary. A total of 27034 reflections in 1650 frames were collected with a final resolution of 0.75 Å. Sadabs absorption correction (T_{min} 0.59 and T_{max} 0.72), 9601 unique reflections (2θ < 55°, R_{int} = 0.058) were used in the refinement. Full-matrix least-square refinement on F^2 converged to R_F = 0.1004 (all data), 0.0672 [$I > 2\sigma(I)$] and $R_w(F^2)$ = 0.1669 (all data), 0.1419 [$I > 2\sigma(I)$].

Crystal Data of 2: A brown crystal of approximation dimensions 0.4 × 0.2 × 0.2 mm was mounted on a glass capillary. A total of 10471 reflections in 1680 frames were collected with a final resolution of 0.75 Å. Sadabs absorption correction (T_{min} 0.58 and T_{max} 0.80), 1614 unique reflections (2θ < 52.7°, R_{int} = 0.040) were used in the refinement. Full-matrix least-square refinement on F^2 converged to R_F = 0.0696 (all data), 0.0543 [$I > 2\sigma(I)$] and $R_w(F^2)$ = 0.1729 (all data), 0.1575 [$I > 2\sigma(I)$].

Crystal Data of 3·1.5 CH_3CN·2 H_2O·THF: A brown crystal of approximation dimensions 0.4 × 0.2 × 0.1 mm was mounted on a glass capillary. A total of 42784 reflections in 1666 frames were collected with a final resolution of 0.75 Å. Sadabs absorption correction (T_{min} 0.51 and T_{max} 0.71), 11400 unique reflections (2θ < 50°, R_{int} = 0.106) were used in the refinement. Full-matrix least-square refinement on F^2 converged to R_F = 0.1448 (all data), 0.0899 [$I > 2\sigma(I)$] and $R_w(F^2)$ = 0.2462 (all data), 0.2163 [$I > 2\sigma(I)$].

Crystal Data of 4·2 $CHCl_3$: A brown crystal of approximation dimensions 0.4 × 0.1 × 0.04 mm was mounted on a glass capillary. A total of 41618 reflections in 1666 frames were collected with a final resolution of 0.75 Å. Sadabs absorption correction (T_{min} 0.65 and T_{max} 0.86), 13463 unique reflections (2θ < 50°, R_{int} = 0.089) were used in the refinement. Full-matrix least-square refinement on F^2 converged to R_F = 0.1361 (all data), 0.0758 [$I > 2\sigma(I)$] and $R_w(F^2)$ = 0.2090 (all data), 0.1750 [$I > 2\sigma(I)$].

The structures of **1**, **2**, **3**, and **4** are solved by direct methods with the SHELX-93[15] program and refined by full-matrix least-squares methods on F^2 with SHELXTL-PC V 5.03.[16] All nonhydrogen atomic positions were located in difference Fourier maps and refined anisotropically. Hydrogen atoms were placed in their geometrically generated positions.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-113116 {$[Cr_5(tpda)_4Cl_2]$}, -113117 {$[Cr_5(tpda)_4(NCS)_2]$}, -113118 {$[Cr_5(tpda)_4F_2](BF_4)$}, -113119 {$[Cr_5(tpda)_4(F)(OTf)](OTf)$}. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Molecular Orbital Calculation: A simple molecular orbital calculation namely Extended Hückel Molecular Orbital method (EHMO) was chosen to apply on such a large system for the purpose of investigating the bonding features of five-centred Cr−Cr−Cr−Cr−Cr bond qualitatively. The EHMO is performed using the program ICON.[17] The atomic coordinates are derived directly from the X-ray diffraction data of $[Cr_5(tpda)_4Cl_2]$ (**1**). The basis functions of Cl, C, N, and H are taken from the default values of the program. The basis functions for Cr is as follows:[18] $H_{ii}(4s) = -8.66$ eV, $\zeta = 1.70$; $H_{ii}(4p) = -5.24$ eV, $\zeta = 1.70$; $H_{ii}(3d) = -11.22$ eV, $\zeta_1 = 4.95$, $C_1 = 0.488$, $\zeta_2 = 1.60$, $C_2 = 0.721$.

Syntheses and Characterization of New Tertiary Phosphane Ligands Prepared from *p*-Anisyl- and *p*-Thioanisyldichlorophosphanes

Riitta H. Laitinen,*[a] Helena Riihimäki,[a] Matti Haukka,[b] Sirpa Jääskeläinen,[b] Tapani A. Pakkanen,[b] and Jouni Pursiainen[a]

Keywords: Phosphane ligands / ^{31}P-NMR spectrometry / Substituent increments / Electronic and steric properties

The syntheses and spectroscopic parameters of the new tertiary phosphane ligands (*p*-$MeOC_6H_4$)(*o*-$MeOC_6H_4$)$_2$P (**1**), (*p*-$MeOC_6H_4$)(*o*-$MeSC_6H_4$)$_2$P (**2**), (*p*-$MeSC_6H_4$)(*o*-$MeSC_6H_4$)$_2$P (**3**), (*p*-$MeSC_6H_4$)(*o*-$MeOC_6H_4$)$_2$P (**4**), (*p*-$MeOC_6H_4$)(*o*-NC_5H_4)$_2$P (**5**), and (*p*-$MeSC_6H_4$)(*o*-NC_5H_4)$_2$P (**6**) are reported. Single-crystal X-ray structures of all the compounds (**1–6**) have been determined. The dependence of the ^{31}P-NMR chemical shifts on the substituent groups of the phosphanes is discussed.

Introduction

Aromatic tertiary phosphanes, such as triphenylphosphane, are important ligands that find widespread use in homogeneous organometallic catalysts. They stabilize the low oxidation states of the metal centers and can be used to modify both the electronic and steric properties of the catalysts. The incorporation of substituents at the *ortho*-, *meta*-, or *para*-positions of the aromatic rings offers a means of tailoring the properties of the ligands. Such substituents affect both the metal−phosphorus bond lengths and the associated angles.[1]

Ways of quantifying the electronic and steric properties of phosphanes have been extensively studied since 1970. Tolman′s electronic and steric parameters (ν and θ, respectively) have formed the basis for these studies over the last 30 years.[1,2,3] The improvements in NMR techniques and molecular modelling have introduced new possibilities for delineating the properties of phosphanes.[4,5,6,7]

In the present study, we have prepared and characterized a series of new ligands derived from *p*-anisyl- and *p*-thioanisyldichlorophosphanes. The ligands have been designed with a view to modifying triphenylphosphane by introducing heteroatoms at various positions on the phenyl rings. This should allow different coordination modes in metal complexes. The electronic and steric properties of these ligands, assessed on the basis of their experimental ^{31}P-NMR shifts and crystal structures, are discussed.

Results and Discussion

Syntheses

The new mixed *ortho*/*para*-substituted tertiary phosphane ligands were prepared from *para*-substituted aryldichlorophosphanes. Friedel−Crafts reaction of phosphorus trichloride with anisole or thioanisole in the presence of aluminium chloride as catalyst furnished the desired aryldichlorophosphanes.[8] These were then allowed to react with *ortho*-substituted organolithium compounds, which were obtained by halogen−metal interchange reactions.[9] Organolithium compounds bearing anisyl-, thioanisyl-, and pyridyl groups were employed in order to modify the functionality of the new ligands. These groups induce both steric and electronic changes in the phosphane ligands. The ligands thus obtained, bearing *o*-anisyl and *o*-thioanisyl substituent groups, are potentially tridentate. However, experimental findings indicate that the *o*-thioanisyl ligands behave as bidentate ligands in metal complexes,[10] while the *o*-anisyl ligands behave mainly as monodentate ligands.[11][12] The *o*-pyridyl ligands are also potentially tridentate, but in fact form either monodentate complexes or behave as bridging ligands so as to form bimetallic coordination compounds.[13][14] The introduction of pyridyl groups can also have a modifying effect on the solubilities of phosphanes and their complexes.[15]

^{31}P-NMR Spectra

The behaviour of phosphanes as ligands is dependent on the electron-donating and -accepting properties of the phosphorus atom. The catalytic properties of phosphanes are, for example, regulated by the basicities of these ligands. ^{31}P-NMR spectrometry is an important tool for obtaining information concerning the chemical nature of the phosphorus atom. The ^{31}P-NMR chemical shifts have been shown to be dependent on the R groups of a phosphane PR_3.[16][17] Indeed, the chemical shifts of tertiary phosphane ligands can be estimated empirically (Equation 1):[16]

$$\delta = -62 + \sum_{n=1}^{3} \sigma_n^P$$

Here, σ^P values are increments that are characteristic for each substituent group. The reference value corresponds to PMe_3 ($\delta = -62$ vs. 85% H_3PO_4).

The increments (σ^P) for the various substituent groups incorporated in the new tertiary phosphane ligands reported herein can be calculated from the published ^{31}P-NMR chemical shifts (Table 1). In these ligands, all three substituent groups are similar. On using the aforementioned increments to calculate theoretical ^{31}P-NMR chemical shifts for the six new ligands prepared in this work, a relatively good agreement with the experimental values is observed (Table 2). This indicates that with information on the substituent increments at hand, the electronic properties of the phosphane can be predicted with reasonable accuracy. This helps in the targeted modification of the phosphanes towards known applications.

Table 1. Increments of substituted phenyl groups

Ligand	Empirical shift [ppm]	σ^P increment [ppm]
(o-$MeSC_6H_4$)$_3$P	−30.2[18]	10.60
(p-$MeSC_6H_4$)$_3$P	−8.3[19]	17.90
(o-$MeOC_6H_4$)$_3$P	−37.1[18], −38.5[19]	8.30, 7.83
(p-$MeOC_6H_4$)$_3$P	−10.2[19], −9.60[20]	17.27, 17.47
(o-NC_5H_4)$_3$P	−1.3[21]	20.23

Table 2. Comparison of empirical and theoretical ^{31}P-NMR shifts of the new ligands

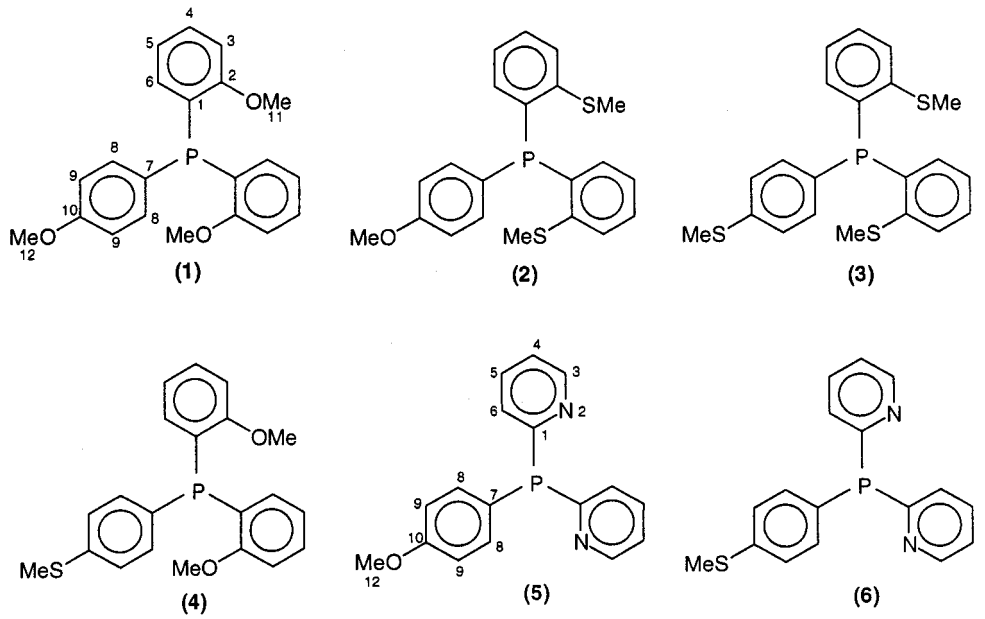
Ligand	Empirical shift [ppm]	Theoretical shift [ppm]
1	−27.7	−28.13
2	−23.1	−23.53
3	−21.1	−22.90
4	−25.9	−27.50
5	−2.3	−4.27
6	−1.6	−3.64

Tolman[2] has estimated the electron-donating properties of tertiary phosphanes by measuring the IR frequencies of the carbonyl groups in $Ni(CO)_3(PR_3)$. The frequencies obtained with various ligands were compared to that with tri-*tert*-butylphosphane, which proved to be the most basic ligand in the series. Based on the experimental results, Tolman calculated the substituent contributions (χ_i) of various attached groups. The relationship can be expressed empirically by Equation 2:

$$\nu(CO) = 2056.1 + \sum_{i=1}^{3} \chi_i \, cm^{-1}$$

Here, the frequency 2056.1 cm^{-1} is that seen with tri-*tert*-butylphosphane attached to Ni. The larger the χ_i value, the less basic the ligand.

Tolman and Allman recognized that there is no general correlation between basicity and ^{31}P-NMR chemical shifts of phosphane ligands.[3][22] However, the basicities of the corresponding phosphane oxides have been shown to be directly related to the ^{31}P-NMR chemical shifts.[23] Phosphane oxides were chosen to minimize the effect of the lone pair on phosphorus on the chemical shift, which allows the electronic effects to dominate. However, it seems that within certain chemically related groups of phosphanes, a relationship between ^{31}P-NMR shifts and basicity can be found. For example, the values for trialkylphosphanes correlate quite well: P(tBu)$_3$: ν(CO) = 2056.1 cm^{-1} vs. δ = 63; P(iPr)$_3$: ν(CO) = 2059.2 cm^{-1} vs. δ = 19.4; PEt_3: ν(CO) = 2061.7 cm^{-1} vs. $\delta = -20.0$; PMe_3: ν(CO) = 2064.1 cm^{-1} vs. $\delta = -62$.[2][3]



A similar kind of correlation, although of opposite direction, can be noted in the series of anisyl-substituted phosphane ligands. ν(CO) values of these ligands can be calculated by using the substituent contributions of o-$C_6H_4OCH_3$ (0.9 cm^{-1}) and p-$C_6H_4OCH_3$ (3.4 cm^{-1}) reported by Tolman.[2] When the experimental ^{31}P-NMR shifts are compared with these calculated ν(CO) values, a reasonably good agreement is seen: (o-$MeOC_6H_4$)$_3$P: ν(CO) = 2058.8 cm^{-1} vs. $\delta = -37.1$; (p-$MeOC_6H_4$)(o-$MeOC_6H_4$)$_2$P: ν(CO) = 2061.3 cm^{-1} vs. $\delta = -27.7$; (p-$MeOC_6H_4$)$_3$P: ν(CO) = 2066.3 cm^{-1} vs. $\delta = -10.2$.

The fairly good correlation of ν(CO) values and ^{31}P-NMR shifts in these examples suggests that ^{31}P-NMR chemical shifts give adequately reliable information concerning the basicities of closely related phosphane ligands. Therefore, the basicity order of the new ligands should be **6 > 5 > 3 > 2 > 4 > 1**. This order is also supported by the observation that electron-donating substituents increase while electron-withdrawing substituents decrease the basic strengths of the ligands.[2][24]

Molecular Structures

The X-ray crystal structures of all six ligands are essentially very similar. There are no significant differences in bond lengths or bond angles between the ligands. For example, the C−P bond lengths all fall within a range of just 0.025 Å. Similarly, the variations in the C_{arom}−O, C_{methyl}−O, C_{arom}−S, and C_{methyl}−S bond lengths are relatively small: 0.017, 0.021, 0.023, and 0.055 Å, respectively. Furthermore, the relative orientation of the MeO or MeS groups does not seem to have a systematic effect on the bond lengths. The small geometrical variations suggest that the structural impact of the *ortho* or *para* groups or the pyridyl ring on the overall form of the ligands is only minor. The X-ray crystal structures of the ligands **2** and **6** are presented in Figures 1 and 2.

The steric effects of phosphanes as ligands are often expressed in terms of the Tolman cone angles θ.[1][3] These are estimated by assuming an average M−P bond length of 2.28 Å. Substituent groups in the *para* positions of the aryl rings do not significantly influence the steric properties of the ligands. This is illustrated by the similar cone angles found for PPh_3 and (pTol)$_3$P, both $\theta = 145°$.[1] Of the ligands prepared in this work, (p-$MeOC_6H_4$)(o-NC_5H_4)$_2$P (**5**) and (p-$MeSC_6H_4$)(o-NC_5H_4)$_2$P (**6**) should therefore resemble PPh_3 from a steric point of view. The four other ligands (p-$MeOC_6H_4$)(o-$MeOC_6H_4$)$_2$P (**1**), (p-$MeOC_6H_4$)(o-

Scheme 1. Schematic structures of the reported ligands; numbering corresponds to the NMR data

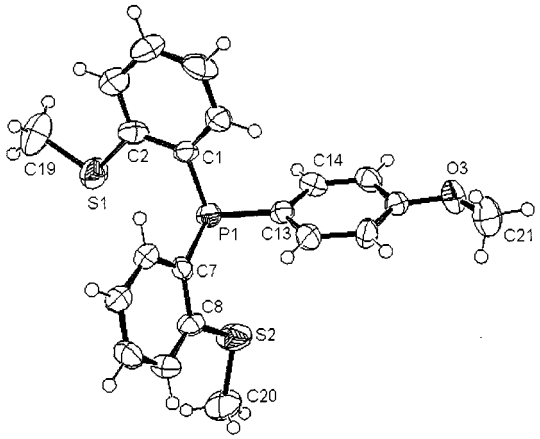


Figure 1. X-ray crystal structure of (p-$MeOC_6H_4$)(o-$MeSC_6H_4$)$_2$P (**2**)

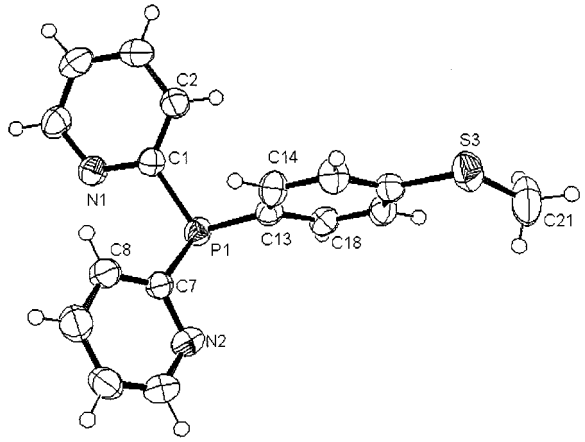

Figure 2. X-ray crystal structure of (p-$MeSC_6H_4$)(o-NC_5H_4)$_2$P (**6**)

$MeSC_6H_4$)$_2$P (**2**), (p-$MeSC_6H_4$)(o-$MeSC_6H_4$)$_2$P (**3**), and (p-$MeSC_6H_4$)(o-$MeOC_6H_4$)$_2$P (**4**) should be sterically analogous to (o-$MeOC_6H_4$)$_2$PPh and (o-$MeSC_6H_4$)$_2$PPh ligands. The steric requirements of these ligands are affected by the conformations of the o-anisyl and o-thioanisyl groups, and therefore the cone angles may not have strictly defined values. The cone angles of these ligands have not been determined

Experimental Section

The ligands were characterized mainly on the basis of ^{1}H-, ^{13}C-, and ^{31}P-NMR data. NMR spectra were recorded on Bruker AM200 and Bruker DPX400 spectrometers. ^{1}H- and ^{13}C-NMR spectra were referenced to TMS; ^{31}P-NMR spectra to 85% H_3PO_4. − Elemental analyses were carried out on a Perkin−Elmer 2400 Series II CHNS/O analyzer. − Exact mass peaks were measured on a Kratos MS-80 spectrometer. − X-ray crystal structures were determined with either an Enraf−Nonius Kappa-CCD or a Nicolet R3m diffractometer. − Commercial reagents were used without further purification. Diethyl ether was distilled from sodium/benzophenone ketyl under nitrogen prior to use. Standard Schlenk techniques were used for the syntheses.

Starting Materials: p-Anisyldichlorophosphane and p-thioanisyldichlorophosphane were prepared according to a published procedure for p-anisyldichlorophosphane.[25][26] The reaction time for the preparation of p-thioanisyldichlorophosphane was extended to 90 h. p-Anisyldichlorophosphane was collected at 98−100°C/0.3 Torr; p-thioanisyldichlorophosphane at 125−126°C/0.15 Torr.

(p-Methoxyphenyl)bis(o-methoxyphenyl)phosphane (1): o-Bromoanisole (1.0 g, 0.7 mL, 5.4 mmol) was lithiated with n-butyllithium (nBuLi) (2.2 mL, 2.5 M in hexane, 5.4 mmol) in sodium-dried diethyl ether (Et_2O) (20 mL) at 0°C. The mixture was stirred for 1 h at 0°C, and then a solution of p-anisyldichlorophosphane (0.6 g, 2.7 mmol) in Et_2O (15 mL) was added. The resulting mixture was stirred for a further 1 h at 0°C and the precipitate formed was filtered off and dried in vacuo. The product (0.5 g, 1.5 mmol, 55.1%) was recrystallized from ethanol. Single crystals suitable for X-ray crystallographic analysis were obtained by slow evaporation

of the solvents from a dichloromethane/hexane solution at −20°C. M.p. 146−149°C. − $C_{21}H_{21}O_3P$: calcd. C 71.6, H 6.0; found C 71.7, H 6.0. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.7 (s, 6 H, H^{11}), 3.8 (s, 3 H, H^{12}), 6.7 (dd, $^3J_{H-H}$ = 6.0 Hz, $^3J_{H-P}$ = 2.2 Hz, 2 H, H^6), 6.8 (m, 6 H, H^3, H^5, and H^9), 7.2 (t, $^3J_{H-H}$ = 7.6 Hz, 2 H, H^8), 7.3 (t, $^3J_{H-H}$ 7.7 Hz, 2 H, H^4). − $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ = 55.1 (s, 1 C, C^{12}), 55.6 (s, 2 C, C^{11}), 110.1 (s, 2 C, C^3), 113.9 (d, $^2J_{C-P}$ = 7.9 Hz, 2 C, C^8), 120.8 (s, 2 C, C^5), 125.7 (d, $^1J_{C-P}$ = 12.3 Hz, 2 C, C^1), 126.8 (d, $^1J_{C-P}$ = 6.9 Hz, 1 C, C^7), 130.0 (s, 2 C, C^4), 133.5 (s, 2 C, C^6), 135.6 (d, $^3J_{C-P}$ = 22.5 Hz, 2 C, C^9), 160.1 (s, 1 C, C^{10}), 161.2 (d, $^2J_{C-P}$ = 15.9 Hz, 2 C, C^2). − $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): δ = −27.7 (s).

(*p*-Methoxyphenyl)bis(*o*-thiomethylphenyl)phosphane (2): *o*-Bromothioanisole (2.0 g, 1.3 mL, 9.8 mmol) was lithiated with *n*BuLi (3.9 mL, 2.5 M in hexane, 9.8 mmol) in sodium-dried diethyl ether (20 mL) at 0°C. The mixture was stirred for 2 h at 0°C, and then a solution of *p*-anisyldichlorophosphane (1.0 g, 4.9 mmol) in Et_2O (20 mL) was added. The resulting mixture was stirred for a further 2 h at 0°C and the precipitate formed was filtered off and dried in vacuo. The product (1.1 g, 2.9 mmol, 59.2%) was recrystallized from ethanol/toluene. Single crystals suitable for X-ray crystallographic analysis were obtained by slow evaporation of the solvents from a dichloromethane/hexane solution. M.p. 155−157°C. − $C_{21}H_{21}OPS_2$: calcd. C 65.6, H 5.5, S 16.7; found C 65.5, H 5.5, S 16.3. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.4 (s, 6 H, H^{11}), 3.8 (s, 3 H, H^{12}), 6.7 (dd, $^3J_{H-H}$ = 7.5 Hz, $^3J_{H-P}$ = 3.8 Hz, 2 H, H^6), 6.9 (d, $^3J_{H-H}$ = 7.7 Hz, 2 H, H^9), 7.1 (m, 2 H, H^5), 7.2 (t, $^3J_{H-H}$ = 7.8 Hz, 2 H, H^8), 7.3 (m, 4 H, H^3 and H^4). − $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): δ = 17.3 (d, $^4J_{C-P}$ = 8.7 Hz, 2 C, C^{11}), 55.1 (s, 1 C, C^{12}), 114.4 (d, $^2J_{C-P}$ = 8.7 Hz, 2 C, C^8), 125.3 (s, 2 C, C^5), 125.9 (d, $^1J_{C-P}$ = 7.3 Hz, 1 C, C^7), 126.8 (d, $^3J_{C-P}$ = 4.4 Hz, 2 C, C^3), 129.2 (s, 2 C, C^4), 133.1 (s, 2 C, C^6), 136.1 (d, $^3J_{C-P}$ = 23.2 Hz, 2 C, C^9), 136.8 (d, $^1J_{C-P}$ = 8.7 Hz, 2 C, C^1), 143.5 (d, $^2J_{C-P}$ = 27.6 Hz, 2 C, C^2), 160.5 (s, 1 C, C^{10}). − $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): δ = −23.1 (s).

(*p*-Thiomethylphenyl)bis(*o*-thiomethylphenyl)phosphane (3): *o*-Bromothioanisole (2.0 g, 1.3 mL, 9.8 mmol) was lithiated with *n*BuLi (3.9 mL, 2.5 M in hexane, 9.8 mmol) in sodium-dried diethyl ether (30 mL) at 0°C. The mixture was stirred for 2 h at 0°C, and then a solution of *p*-thioanisyldichlorophosphane (1.1 g, 4.9 mmol) in Et_2O (20 mL) was added. The resulting mixture was stirred for a further 2 h at 0°C and the precipitate formed was filtered off and dried in vacuo. The product (0.9 g, 2.2 mmol, 45.0%) was twice recrystallized, first from ethanol/toluene and then from hexane/ethanol. Crystals were used for X-ray crystallographic analysis without further crystallization. M.p. 144°C. − $C_{21}H_{21}PS_3$: calcd. C 63.0, H 5.3, S 24.0; found C 62.9, H 5.4, S 24.0. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.4 (s, 6 H, H^{11}), 2.5 (s, 3 H, H^{12}), 6.7 (dd, $^3J_{H-H}$ = 7.3 Hz, 2 H, H^6), 7.1 (m, 2 H, H^5), 7.2 (m, 4 H, H^8 and H^9), 7.3 (m, 4 H, H^3 and H^4). − $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$): δ = 15.1 (s, 1 C, C^{12}), 17.3 (d, $^4J_{C-P}$ = 8.7 Hz, 2 C, C^{11}), 125.3 (s, 2 C, C^5), 126.1 (d, $^2J_{C-P}$ = 8.7 Hz, 2 C, C^8), 126.8 (d, $^3J_{C-P}$ = 4.4 Hz, 2 C, C^3), 129.3 (s, 2 C, C^4), 131.3 (d, $^1J_{C-P}$ = 10.2 Hz, 1 C, C^7), 133.3 (s, 2 C, C^6), 134.7 (d, $^3J_{C-P}$ = 20.3 Hz, 2 C, C^9), 136.2 (d, $^1J_{C-P}$ = 10.2, 2 C, C^1), 140.0 (s, 1 C, C^{10}), 143.7 (d, $^2J_{C-P}$ = 29.1 Hz, 2 C, C^2). − $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): δ = −21.1 (s).

(*p*-Thiomethylphenyl)bis(*o*-methoxyphenyl)phosphane (4): *o*-Bromoanisole (1.9 g, 1.2 mL, 9.8 mmol) was lithiated with *n*BuLi (3.9 mL, 2.5 M in hexane, 9.8 mmol) in sodium-dried diethyl ether (30 mL) at 0°C. The mixture was stirred for 1 h at 0°C, and then a solution of *p*-thioanisyldichlorophosphane (1.1 g, 4.9 mmol) in Et_2O (20 mL) was added. The resulting mixture was stirred for a further 2
