The zero-field spectrum of $[Fe_2^{III}(bbpo^{ox1})Cl_4]^-$ displays a broad doublet ($\Gamma = 0.82\ mm{\cdot}s^{-1}$, not shown) that could be fitted with two slightly different quadrupole doublets of two non-equivalent ferric sites. The isomer shift and quadrupole splitting parameters of both doublets are similar and are nearly identical to those observed for the dianion (see above). This implies that the one-electron oxidation of **2** is a ligand-centered process. No indication for the presence of Fe^{IV} has been found.

It is interesting and instructive that the applied-field spectra of the monoanion (Figure 10) are significantly more complex than the spectra recorded for the symmetrical dinuclear complex **2** (Figure 4). The magnetic spectra of the monoanion display very broad signals over a large velocity range of ca. $10\ mm{\cdot}s^{-1}$ whereas the analogous spectra of **2** cover only ca. $3\ mm{\cdot}s^{-1}$. The latter were simulated with a single high-spin ferric site, which is definitely not possible for the spectra of the monoanion. Here, the two ferric ions are nonequivalent. We have used the spin coupling Scheme outlined above (and shown in Scheme 3) for the monoanion of **2** where the $S_t = {}^1/_2$ ground state is attained by a strong coupling between one high-spin ferric ion and a ligand π-radical, yielding a fictitious local S* = 2 spin state and, in addition, a weak coupling of this state with the second high-spin ferric ion.

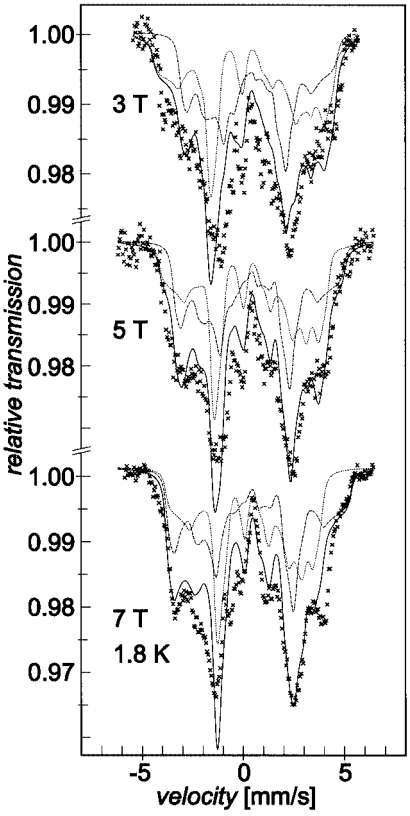

Figure 10. Applied-field Mössbauer spectra of electrochemically generated monoanion of **2** after removal of the solvent CH_2Cl_2 under reduced pressure; simulation parameters are given in Table 3; experimental data are corrected for residual non-oxidized compound **2** by subtracting 10% of the species shown in Figure 4

The same electronic Hamiltonian [Equation (1)] was applied as for the EPR interpretation of oxidized **2**, and the ZFS parameters were taken from the EPR results. Isomer shift, quadrupole splitting, asymmetry parameter and (isotropic) *A* constant of the ferric site could be taken from the data of the diferric starting complex **2**, whereas those of the oxidized S* = 2 site were independently optimized. The results are summarized in Table 3. The experimental *A* value obtained for S* = 2 was converted into a local value for Fe^{III}, $S = {}^5/_2$ by using $A_{Fe} = {}^6/_7\ A_{S^*=2}$.

It is remarkable that the quadrupole splitting and isomer shift of the ferric site with the ligand radical are slightly increased with respect to those of the starting compound or the other ferric site of oxidized **2**, whereas the local hyperfine coupling constant is significantly decreased. Similar systematic trends were indicated previously for the oxidation of iron(III) complexes with phenolate ligands.[12] The variation of the quadrupole splitting (which has no valence contribution for the $3d^5$ configuration) and the increase of the isomer shift reflect the attenuated π-donor capability of the oxidized ligand. The lower covalency of the iron−π-radical bonds for one iron site appears to be the origin of the slight increase of the iron−iron exchange coupling. The reduction of local hyperfine coupling of the ^{57}Fe nucleus at

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the "oxidized" iron site originates from covalent delocalization of radical β-spin density into the α-spin carrying metal d orbitals. The effect corresponds to spin density delocalization onto the central metal ion in radical complexes with *diamagnetic* central ions for which relative strong super hyperfine coupling with the metal nuclei is observed in the EPR spectra. Among others, oxidized compound **1** represents such an example.[1−6] The mechanism of spin delocalization corresponds to that of "*transferred*" or "*super-transferred hyperfine field*" described in solid-state applications of Mössbauer spectroscopy and magnetic materials.[13]

Conclusion

We have shown here that the tetraanion of 1,2-bis(3,5-di-*tert*-butyl-2-hydroxyphenyl)oxamide is a redox-noninnocent dinucleating ligand that reacts with 2 equiv. of $GaCl_3$ or $FeCl_3$ to form the dianionic complexes $[Ga^{III}_2(bbpo)Cl_4]^{2-}$ and $[Fe^{III}_2(bbpo)Cl_4]^{2-}$, respectively. Both dianions undergo, electrochemically, two reversible one-electron oxidations, yielding the monoanions $[M^{III}_2(bbpo^{ox1})Cl_4]^-$ (M = Ga^{III},Fe^{III}) and the neutral species $[M^{III}(bbpo^{ox2})Cl_4]^0$, respectively. The trianion $(bbpo^{ox1})^{3-}$ is a π-radical ($S = {}^1/_2$) whereas the dianion $(bbpo^{ox2})^{2-}$ is a diradical, both of which are of the *o*-iminobenzosemiquinonate type.

The three-spin system of the monoanion $[Fe^{III}_2(bbpo^{ox1})Cl_4]^-$ can be described by a ligand π-radical that couples strongly antiferromagnetically to a high-spin ferric ion, yielding a fictitious S* = 2 state, which in turn couples weakly antiferromagnetically to a second high-spin ferric ion to yield the observed $S_t = {}^1/_2$ ground state. The monoanion $[Ga^{III}_2(bbpo^{ox1})Cl_4]^-$ possesses an $S = {}^1/_2$ ground state whereas the neutral species displays, at room temperature, two uncoupled (*o*-iminobenzosemiquinonate)-gallium(III) units that couple antiferromagnetically at very low temperatures, yielding an $S_t = 0$ ground state. The spin structure provides interesting magnetic properties of long-range coupled systems with competing interactions.

Experimental Section

1,2-Bis(3,5-di-*tert*-butyl-2-hydroxoyphenyl)oxamide [H_4(bbpo)]: To an argon-purged suspension of 2-amino-4,6-di-*tert*-butylphenol[7] (4.4 g, 20 mmol) and triethylamine (2.0 g, 20 mmol) in dry diethyl ether (50 mL), oxalyl chloride (1.3 g, 10 mmol) was added dropwise at 0 °C. After stirring at 0 °C for 30 min, stirring was continued for further 2 h at 20 °C. The resultant colorless precipitate was filtered off and washed with diethyl ether. To the residue was added H_2O (20 mL) and the ligand H_4(bbpo) was filtered off and washed with H_2O until the water was free of chloride. A yellowish powder (3.0 g, 61%) was obtained which was stored under Ar; m.p. 217 °C (uncorrected). ^{1}H NMR (400 MHz, $CDCl_3$, 300 K): δ = 1.29 (s, 18 H, *tert*-butyl), 1.44 (s, 18 H, *tert*-butyl), 7.11 (m, 2 H, *p*-H), 7.28 (m, 2 H, *o*-H), 7.49 (s, 2 H, OH), 9.49 (s, 2 H, NH) ppm. ^{13}C{H} (63 MHz, $CDCl_3$, 300 K): δ = 29.8, 31.4, 34.4, 35.4, 117.7, 123.1, 124.0, 139.7, 143.3, 145.8, 157.2 ppm. MS (EI): *m*/*z* = 496. IR (KBr): $\tilde{\nu}$ = 3342 ν(N−H), 3140 ν(O−H), 1655, 1603, 1530 ν(C=O), ν(C−N) cm^{-1}. $C_{30}H_{44}N_2O_4$ (496.69): calcd. C 72.55, H 8.93, N 5.64; found C 72.8, H 8.7, N 5.4.

[N(*n*Bu)$_4$]$_2$[Ga^{III}_2(bbpo)Cl$_4$] (1): To an argon-purged suspension of the ligand H_4(bbpo) (0.50 g, 1.0 mmol) in dry CH_3OH (20 mL), was added NaOH (2 mL, 1.0 M in CH_3OH). An argon-purged solution of $GaCl_3$ (0.36 g, 2.0 mmol), dissolved in 2−3 mL of CH_3OH was added and upon continuous stirring at 20 °C a yellow precipitate formed. The mixture was then heated to reflux under Ar and [N(*n*Bu)$_4$]Cl (0.56 g, 2.0 mmol) was added. After heating to reflux for a further 4 h, a yellow, microcrystalline precipitate of **1** was obtained. Yield 0.66 g (55%). Recrystallization from CH_3OH solution by diethyl ether diffusion yielded single crystals of **1** suitable for X-ray analysis. $C_{62}H_{112}Cl_4Ga_2N_4O_4$ (1258.85): calcd. C 59.16, H 8.97, Cl 11.27, Ga 11.08, N 4.45; found C 60.0, H 8.7, Cl 11.1, Ga 11.3, N 4.6. MS (ESI-neg. ion): *m*/*z* = 737.1 $\{[Ga_2(bbpo)Cl_3]\}^-$. ^{1}H NMR (250 MHz, [D_4]MeOD, 300 K): δ = 1.02 [t, 24 H, CH_3(TBA)], 1.29 (s, 18 H, *tert*-butyl), 1.40 [m, 16 H, CH_2(TBA)], 1.47 (s, 18 H, *tert*-butyl), 1.65 [m, 16 H, CH_2(TBA)], 3.23 [t, 16 H, CH_2(TBA)], 7.13 (d, ^4J = 2.3 Hz, 2 H), 8.04 (d, ^4J = 2.4 Hz, 2 H) ppm.

[N(*n*Bu)$_4$]$_2$[Fe^{III}_2(bbpo)Cl$_4$] (2): This iron-containing complex was prepared in the same fashion as described above for the synthesis of **1** but using $FeCl_3$ instead of $GaCl_3$. The green microcrystalline product was recrystallized from CH_3OH by diethyl ether diffusion, yielding single crystals of **2** suitable for X-ray crystallography. $C_{62}H_{112}Cl_4Fe_2N_4O_4$ (1231.10): calcd. C 60.49, H 9.17, Cl 11.52, Fe 9.07, N 4.55; found C 60.5, H 9.1, Cl 11.4, Fe 9.1, N 4.6. MS (ESI-neg. ion): *m*/*z* = 709.1.

X-ray Crystallographic Data Collection and Refinement of the Structures: A yellow single crystal of **1** and a black crystal of **2** were coated with perfluoropolyether, picked up with a glass fiber and mounted in the nitrogen cold stream of the diffractometer. Intensity data were collected at 100 K using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The final cell constants were obtained from a least-squares fit of a subset of several thousand strong reflections. Data collection was performed by taking frames at 1.0° (Nonius Kappa-CCD) in ω. Crystallographic data of the compounds are listed in Table 1. The Siemens ShelXTL software package was used for solution, refinement and artwork of the structure.[14,15] The structures were readily solved by direct methods and difference Fourier techniques. All non-hydrogen atoms and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. Split-atom models with restrained C−C distances using the SADI option in SHELX97 were introduced in both structures to account for their disorder by rotation. CCDC-191601 (**1**) and -191602 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physical Measurements: Electronic spectra of complexes and spectra of the spectroelectrochemical measurements were recorded with an HP 8452A diode array spectrophotometer (range: 190−1100 nm). Cyclic and square-wave voltammograms and coulometric experiments were performed with an EG&G potentiostat/galvanostat. Temperature-dependent (2−298 K) magnetization data were recorded with a SQUID magnetometer (MPMS Quantum design) in an external magnetic field of 1 T. The experimental susceptibility data were corrected for underlying diamagnetism by use of tabulated Pascal's constants. X-band EPR spectra were re-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corded with a Bruker ESP 300 spectrometer. Zero- and applied-field Mössbauer spectra were recorded using the equipment described in ref.[16]; programs used for fitting routines have also been described.

Self-Assembly of Five Cadmium(II) Coordination Polymers from 4,4′-Diaminodiphenylmethane

Junhua Luo,[a] Maochun Hong,*[a] Ruihu Wang,[a] Rong Cao,[a] Qian Shi,[a] and Jiabao Weng[a]

Keywords: Cadmium / Coordination polymers / Self-assembly / N ligands

Five cadmium(II) coordination polymers formed from dadpm (dadpm = 4,4′-diaminodiphenylmethane), namely, $[Cd(dadpm)(I)_2]_n$ (**1**), $[\{Cd(dadpm)_2(Cl)\}(dca)]_n$ (**2**) [dca = dicyanamide anion, $N(CN)_2^-$], $[\{Cd(dadpm)_2(Br)\}(dca)]_n$ (**3**), $[Cd(dadpm)(SCN)_2]_n$ (**4**) and $[Cd(dadpm)(dca)_2]_n$ (**5**) have been synthesized and characterized by NMR, IR, and fluorescence spectroscopy as well as TG analysis. The ligand dadpm in **1** bridges the metal centers to form a zigzag chain where the halide anion I^- acts as a terminal ligand. Weak Cd···I interactions between adjacent chains extend the zigzag chains into a wave-like layer. Complexes **2** and **3** are isomorphous, the metal centers are bridged by dadpm to generate a double-stranded chain containing the metallacycles of $[Cd_2(dadpm)_2]$, and the halide anions (Cl^- in **2** and Br^- in **3**) link adjacent chains into 2D layer structures in a *trans* mode. Dicyanamide anions in the two complexes lie between the layers as supported anions and link the adjacent layers into 3D structures through hydrogen bonds. In complex **4**, the metal centers are bonded by the thiocyanate anions to form double-stranded chains, which are linked by dadpm in different orientations resulting in a cross-linked 3D structure. In **5**, dicyanamide anions connect the cadmium(II) centers to form a $[Cd(dca)_2]_n$ 2D layer, which contains 24-membered ring units $[Cd_4(\mu_{1,1}\text{-dca-}N,N)_4]$. The dadpm ligand links the adjacent layers into an α-Po-like 3D network structure.

Introduction

In the research of supramolecular chemistry, much interest has recently been focused on the crystal engineering of coordination frameworks because of their intriguing architectures, fascinating topologies, intertwining phenomena, and potential application in functional materials.[1] Self-assembly based on molecules has emerged as an attractive approach to the fabrication of these new materials, and considerable effort has been made towards the supramolecular networks assembled by covalent and hydrogen bonds or other molecular interactions.[2] The family of metallacyclic nanostructures assembled from transition metal junctions and bridging ligands is now a well-established group of coordination polymers,[3] and the diversity of such coordination nanostructures makes them remarkable examples in the growing library of self-assembled entities.[4] Although many topologically promising architectures have been constructed from building blocks containing nitrogen donors,[5] such as 4,4′-bipyridine,[6] pyrazine,[7] bis(4-pyridyl)ethane,[8] 1,4-bis(4-pyridyl)benzene,[9] 2,4,6-tri(pyridyl)-1,3,5-triazine[10] and 4,4′-azobis(pyridine),[11] few coordination polymers based on bifunctional neutral ligands containing aromatic NH_2 donors are documented. The involvement of oligoaniline in the assembly of supramolecular chemistry is limited because of its instability, as it is easily oxidized in an aqueous solution and/or in air. Although the aromatic diamine ligand dadpm has a poorer donor ability than the corresponding pyridyl-type ligands used before, it can still coordinate to transitional metal ions by one NH_2 group to act as a terminal ligand as in $[Cu_2(C_2H_4N_2O_2)(dadpm)_2(Br)_2]$ [$C_2H_4N_2O_2$ = bis(2-aminoethyl)oxamidato][12a] or two NH_2 groups to act as a bridging ligand as in $\{[Cu(dadpm)(C_3H_4O_4)Cl]Cl\}_2$ ($C_3H_4O_4$ = malonic acid)[12b] and $[Cu_2(dadpm)_2(PyCH_2NHCOCONHCH_2Py)]\cdot 2NO_3\cdot 6H_2O$.[12c] The ligand dadpm may be utilized as a building block for the construction of novel organic/inorganic hybrid materials. In this paper, we report on the self-assembly reactions of dadpm and cadmium(II) halides in the presence of dca^- or SCN^- ions, and the structural characterizations of five coordination polymers, $[Cd(dadpm)(I)_2]_n$ (**1**), $[\{Cd(dadpm)_2(Cl)\}(dca)]_n$ (**2**), $[\{Cd(dadpm)_2(Br)\}(dca)]_n$ (**3**), $[Cd(dadpm)(SCN)_2]_n$ (**4**) and $[Cd(dadpm)(dca)_2]_n$ (**5**).

Results and Discussion

Syntheses

During the preparation of the dadpm/Cd complexes, direct treatment of dadpm with various cadmium halides

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/ejic.200200540

failed to produce a complex, which may be ascribed to the poor coordination ability of dadpm. As the dicyanamide anion has various coordination modes,[13] and thus can provide a suitable "building block" for assembling novel inorganic/organic hybrid materials, we want to introduce this anion ligand into the Cd halide/dadpm reaction mixture as a co-ligand in order to prepare some novel dadpm−Cd complexes. Mixing of $CdX_2{\cdot}nH_2O$ (X = I, n = 0; X = Br, n = 4; X = Cl, n = 2.5) with 4,4′-diaminodiphenylmethane and sodium dicyanamide in a 1:2:1 ratio in hot aqueous solution resulted in the crystalline complexes **1**, **2** and **3** with 1D to 2D structures. As in our recent report on Cd coordination frameworks,[15] the larger radius of I^- results in the cadmium atom adopting a tetracoordinated geometry upon coordination, while with the halide ions Cl^- and Br^-, the cadmium ion adopts a six-coordinate geometry. The dca^- anion is not incorporated into complex **1**, but acts as a supported anion in both **2** and **3**. The effect of the dca^- anion in the formation of **1** is still unclear. While we changed the reaction sequence, namely, first mixing the Cd salt with the dadpm ligand, then adding the dicyanamide anion to the reaction mixture, complex **5** with an α-P_o-like 3D net structure was obtained, which is completely different from those of **1**, **2** and **3**. Using another anion ligand with a different size and shape, the SCN^- anion, complex **4** with a cross-linked 3D structure was obtained.

Description of the Structures

The X-ray analysis revealed that the cadmium atoms in complex **1** are bridged by a dadpm ligand with the occurrence of an 1D coordination polymeric chain along the *a* axis. An ORTEP view of the chain with atom labeling is shown in Figure 1 (a). Each cadmium atom is tetracoordinated by two nitrogen atoms of two dadpm ligands and two I^- anions with square-planar coordination geometry. The Cd−N(dadpm) bond length is 2.32(2) Å, and the Cd−I distance 2.794(3) Å. The Cd···Cd separation is 13.131 Å through the bridging dadpm ligand. The inter-chains are tightly packed (Cd···Cd = 4.520 Å) by the weak interaction between the Cd^{II} center and the I^- anion belonging to neighbor chains [Cd(E)−I = 3.587 Å, symmetry code: (E) x, y, 1 + z], forming a quasi-2D wave-like sheet as shown in Figure 1 (b). In the sheet structure, there are a four-membered ring and a 28-membered ring, the former contains two cadmium(II) ions and two I^- anions, and the latter two cadmium(II) ions, two I^- anions and two dadpm ligands.

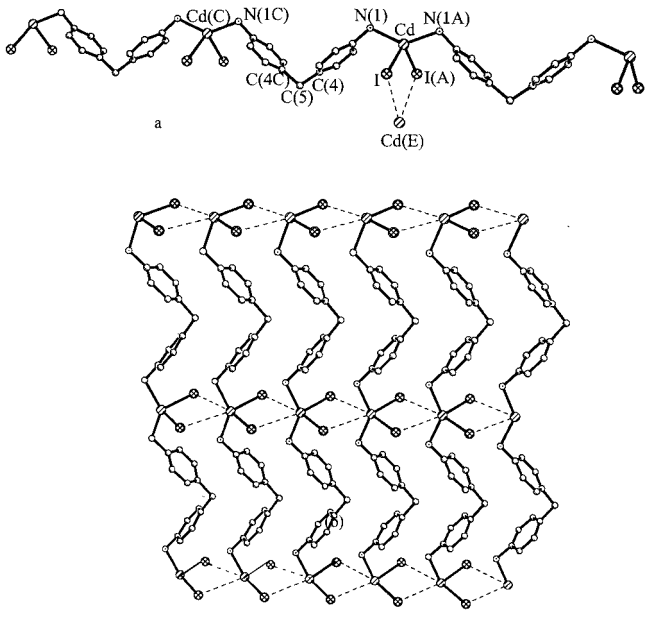

Figure 1. (a) ORTEP drawing of the zigzag chain in **1** with atom numbering scheme, showing the cadmium coordination environment; (b) quasi-two dimensional sheet of **1** formed through weak Cd···I interactions

In the crystal structure of **2**, each cadmium(II) center is bridged by four dadpm ligands to give rise to a double stranded chain as shown in Figure 2 (a). The dadpm adopts a *trans*-gauche conformation and two dadpm ligands bridge two cadmium(II) ions to form a distorted square metallacyclic ring with a Cd−Cd distance of 12.401 Å. In the square ring, each of the two opposite phenyl rings of the two dadpm ligands are parallel and the two adjacent phenyl rings are almost perpendicular with a torsion angle of 89.7°. The dimensions of the ring are approximately 7.15 × 4.15 $Å^2$ based on the distance of the two opposite phenyl rings, which is slightly shorter than those of the $[Cu_2(dadpm)_2]$ macrocycle (8.36 × 4.15 $Å^2$) in $[Cu(dadpm)\{CH_2(COOH)_2Cl\}Cl]_2$.[12b] The cadmium atom is six-coordinate in an elongated octahedral environment. The equatorial plane is defined by four N atoms from four dadpm ligands with two short Cd−N bonds [Cd−N(4A), 2.357(5) Å] and two long Cd−N bonds [Cd−N(5), 2.3852(4) Å]. The four equatorial donor atoms and the central cadmium(II) atom are almost coplanar with a mean deviation of 0.012 Å and N−Cd−N bond angles of 86.1(2) and 93.9(2)°. Two chloride anions are at the axial positions and link the adjacent double-stranded chains into an unprecedented 2D layer with a Cd−Cl bond length of 2.752(6) Å, as shown in Figure 2 (b). The channels are viewed through the metallacycles packing along the *b* axis. The Cl−Cd−N bond angles vary from 80.0(1) to 100.0(1)° and the Cd−Cd separation of adjacent chains is 5.505 Å with a Cd−Cl−Cd bond angle of 180°.

The dicyanamide anion is disordered in the structure. It does not engage in coordination and acts as a supported anion between the 2D layers through the hydrogen bond interactions between the N atoms (N1 and N3) of the dicyanamide anion and the N atoms (N4) of dadpm as in Figure 2 (c) [N3···N4B, 2.821 Å; N1···N4 H, 2.832 Å, symmetry code: (H) $-x$, y, $-1 + z$]. Through these hydrogen bonds, a 32-membered ring constructed by two dadpm ligands, four Cd^{II} centers and two N−C≡N groups of two dca^- anions is formed and the other C≡N groups of the dca^- anions protrude into the cavity of the ring.

An X-ray crystal analysis revealed that complex **3** exhibits a similar structure to that of complex **2** except that **2** has a Br^- bridge instead of a Cl^- bridge. An ORTEP drawing of the molecular structure of **3** with atom labeling is shown in Figure 3 (a). The Cd−N bond lengths [Cd−N(4) 2.38(1)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

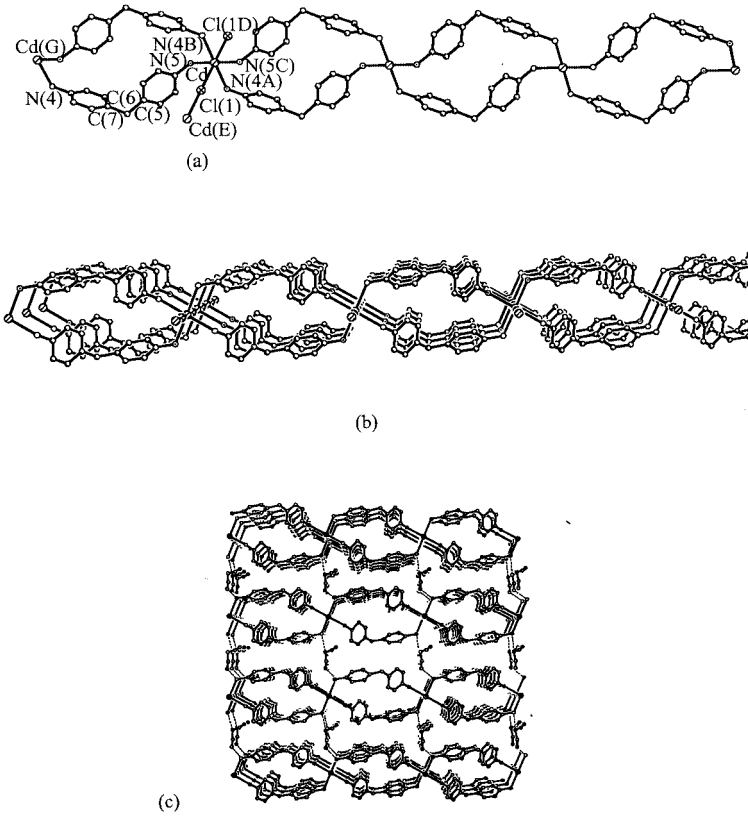

Figure 2. (a) ORTEP drawing of the double-stranded chain in **2** with atom numbering; (b) ORTEP drawing of the layer structure of **2** to view the channels in the *b* axis direction; (c) perspective view of the dicyanamide anion's supported 3D structure of **2**

Å and Cd−N(5A) 2.38(1) Å] in the equatorial plane are slightly longer than those in **2**, and the N−Cd−N bond angles are 85.7(4) and 94.3(4)°. The separation between the two Cd^{II} atoms in the$[Cd_2(dadpm)_2]$ macrocycle is 12.452 Å, similar to that in **2**, and the dimensions of the macrocycle are about 7.25 × 4.06 Å. The Br^- anions coordinate axially with the cadmium centers in a *trans* geometry to link the adjacent chains into a 2D layer with Cd−Br−Cd bond angles of 180°. The Cd−Cd separation of adjacent chains is 5.505 Å, which is larger than the corresponding value in **2** through the Cl^- bridge because of the larger radius of the Br^- ion. Similar to **2** the dicyanamide anions in **3** lie between two adjacent layers acting as supporting anions.

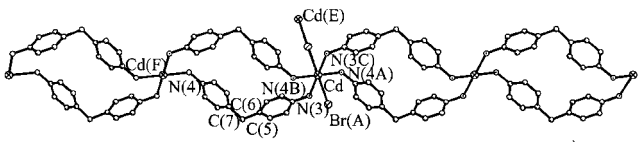

Figure 3. ORTEP drawing of **3** with atom labeling, showing the cadmium coordination environment

An ORTEP view of a Cd center of **4** is shown in Figure 4 (a). Each cadmium(II) atom is located on an inversion center, and coordinated by two thiocyanate nitrogen atoms [Cd−N(SCN), 2.335(7) Å] and two thiocyanate sulfur atoms [Cd−S, 2.746(2) Å] in a *trans* geometry in the equatorial plane, resulting in a chain structure containing eight-membered $[Cd_2(SCN)_2]$ rings as in Figure 4 (a), which have been well documented in Cd^{II}/L/SCN systems.[17] Two nitrogen atoms of two dadpm groups complete the remaining two axial positions around the six-coordinate Cd^{II} center and the distance of Cd−N(dadpm) is slightly longer than Cd−N(SCN) with a bond length of 2.354(6) Å. The cadmium thiocyanate chains are cross-linked by the dadpm with different orientations into a 3D polymer as in Figure 4 (c). The Cd···Cd separation is 13.518 Å through the dadpm ligand. In the 3D structure, four SCN^- ions and four dadpm ligands link eight cadmium ions into a 64-membered ring with dimensions of 30.57 × 6.2 Å, as shown in Figure 4 (b).

Each cadmium(II) center in **5** is in a distorted octahedral environment, being coordinated by four nitrogen atoms of four dca^- ligands in the equatorial plane and two nitrogen atoms of two *trans*-related dadpm ligands at the axial positions as shown in Figure 5 (a). The Cd−N(dadpm) bond length is 2.39(1) Å, and Cd−N(dca) bond lengths are 2.31(1) and 2.33(1) Å. The dca^- ligands and Cd centers are interlinked into a 2D layer, resulting in an hourglass-shaped, 24-membered $[Cd_4(\mu_{1,1}\text{-dca-}N,N)_4]$ metallacycle, as shown in Figure 5 (b), different from other reported Cd−dca coordination polymers in which the Cd centers and dca^- ligands are interconnected into $[Cd(dca)_2]_n$ chains.[18] The Cd···Cd separation through the dca^- ligand in **5** is 7.597 Å. For comparison, $Zn[N(CN)_2]$ features a 2D

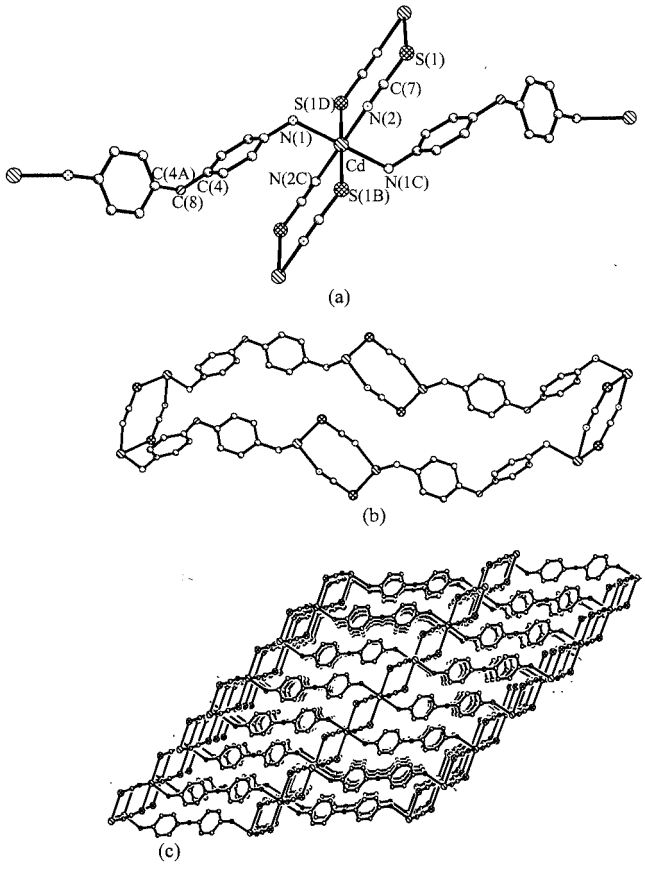

Figure 4. (a) ORTEP drawing of **4** with atom numbering, showing the cadmium coordination environment; (b) perspective of the metallacyle in **4**; (c) view of the 3D structure of **4**

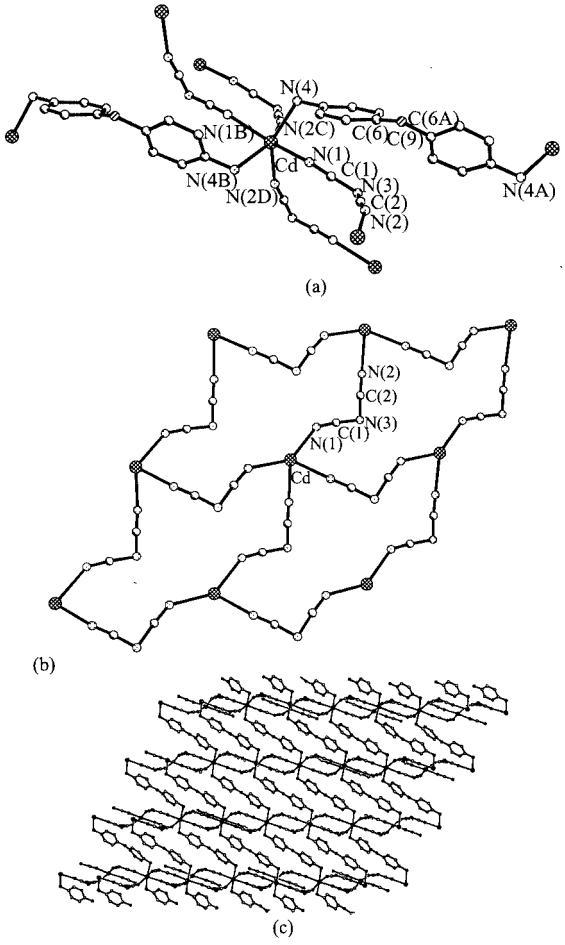

Figure 5. (a) ORTEP drawing of the cadmium(II) coordination in **5** with atom numbering; (b) perspective of the 2D sheet in **5**; (c) view of the α-P_o-like 3D structure of **5**

layer structure with linkages similar to the $[Cd(dca)_2]$ layer in **5**, but the layers are markedly buckled and packed in a staggered fashion due to the tetrahedral configuration of Zn^{II}.[19] To the best of our knowledge, such a $[Cd_4(\mu_{1,1}$-dca-*N*,*N*$)_4]$ arrangement of the metallacycle is unprecedented, and only a few similar structures have been reported, such as $[Mn_4(SCN)_4]$ in $[Mn(EtOH)_2(NCS)_2]$,[20a] $[Mn_4(N_3)_4]$ in $[Mn(4\text{-acpy})_2(N_3)_2]$ (4-acpy = 4-acetylpyridine),[20b] and $[Cd_4(NCS)_4]$ in $[Cd(SCN)_2(3\text{-PyCONH}_2)_2]$ (3-PyCONH$_2$ = nicotinamide).[20c]

As shown in Figure 5 (c), the $[Cd(\mu_{1,1}$-dca-*N*,*N*$)_2]_n$ layers are further linked by the dadpm ligands into an α-P_o-like 3D net as in $[Mn(dca)_2(pz)]$.[21] A 36-membered ring is formed through four cadmium ions linked by two single $\mu_{1,1}$-dca-*N*,*N* bridges and two dadpm ligands. The Cd···Cd distance is 12.328 Å through the bridging dadpm ligand.

The C(Ph)−C−C(Ph) bond angles, the dihedral angles between the two phenyl rings of dadpm and the M···M distances through the dadpm ligand in the five complexes are listed in Table 3. The C(Ph)−C−C(Ph) bond angles show slight differences, which range from 102.0(1)° in **5** to 115.9(1)° in **3**. But the dihedral angles between the two phenyl rings in the dadpm ligand show large differences in the five complexes, ranging from 55.3(2)° in **5**, 57.2(3)° in **4** to 81.6(4)°in **1**, 87.7(6)° in **3** and 89.7(5)° in **2**, which may be ascribed to the different coordination schemes of dadpm. In **1**, **4** and **5** the dadpm ligand links the metal atoms into a zigzag chain, but in **2** and **3**, the dadpm ligand connects the metal atoms into a double-stranded chain. The Cd···Cd distances through the dadpm ligand range from 12.328 Å in **5** to 13.131 Å in **1**. The structural data show the flexibility of the dadpm ligand in the five coordination polymers. The flexibility of dadpm induces a small effective cavity volume of the channels in the five dadpm−Cd complexes and no guest molecules are accommodated in the channels.

IR, ^{1}H NMR and Fluorescent Spectra

All of the five complexes show strong C≡N stretching vibrations of the dca^- or SCN^- ions in the region 2000−2300 cm^{-1}, except complex **1**. The strong C≡N stretching vibration of thiocyanate in **4** at 2116 cm^{-1} suggests a bridging mode.[22] The C≡N stretching vibrations of $[N(CN)_2]^-$ are at 2260, 2210, 2148 cm^{-1} in **2**, and 2258, 2213, 2149 cm$^-$ in **3**, but shifted to 2301, 2248, 2176 cm^{-1} in **5**, which are assigned to $\nu_{sym} + \nu_{asym}$ (C≡N), ν_{asym} (C≡N) and ν_{sym} (C≡N), respectively. Compared with the corresponding spectroscopic data of free $[N(CN)_2]^-$,[23] the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[N(CN)_2]^-$ ligand acts as a supported anion in **2** and **3**, but a $\mu_{1,1}$-end-to-end bridge in **5** and **6**, which is consistent with the results of X-ray analyses. The aromatic C−H stretching vibrations are in the region 2800−3000 cm^{-1}. The strong bands in 3100−3350 cm^{-1} are ascribed to ν_{N-H} stretching vibrations in the five complexes.

The ^1H NMR spectra of **1**, **2**, **3**, and **5** show resonance signals at δ = 6.80 and 6.45 [m, 8 H, 2 (C_6H_4)], 4.837 [s, 4 H, 2 (NH_2)] and 3.547 (s, 2 H, CH_2) ppm for the dadpm ligand. The ^1H NMR signals for the NH_2 group protons of all five complexes are slightly shifted downfield relative to the free ligand, while the signals of other protons remain essentially unchanged in the five complexes.

The fluorescent characterization shows that each complex has a strong or medium yellow fluorescent emission[24] [585 (m) in **1**, 590 (s) in **2**, 593 (s) in **3**, 567 (m) in **4**, and 570 nm (m) in **5** and the wavelength at which the complex is excited is 310 nm], which may be ascribed to ligand-to-metal charge transfer (LMCT) bands.

Thermogravimetric Analysis

Thermogravimetric analyses show that all five of the complexes are stable. Complex **1** remains stable up to 190 °C, and then it slowly decomposes with the loss of the ligand dadpm. Complex **2** and **3** are stable up to 153 and 168 °C . The TGA trace displays a gradual weight loss of 11.5% (calculated 10.81%) from 153 to 209 °C for complex **2** and 10.08% (calculated 10.5%) from 168 to 235 °C for complex **3**, which corresponds to the weight loss of one dca^- supported anion. When the temperature exceeds about 250 °C, both of them begin to decompose. Complex **4** decomposes from 220 °C with a weight loss of 49.5% (calculated 44.71%) corresponding to the decomposition of the dadpm ligand. Subsequent weight loss from 350 °C may correspond to the decomposition of the thiocyanate groups. The TG curve of **5** shows that the complex is stable below 238 °C, and that from this temperature the compound decomposes and loses the dadpm and dca ligands almost simultaneously.

Conclusion

In spite of the similarity of the building blocks used, the products display quite different structures. The isolated five coordination compounds include one- or three-dimensional polymeric structures sustained only by coordinative bonds (**1**, **4** and **5**), and three-dimensional arrays connected both by coordinative and hydrogen bonds (**2** and **3**). The variety of the observed structural motifs confirms that rationalization of the resulting topologies is still difficult. Many factors play a role in the formation of the final product: (i) the anions effects (I^-, Cl^- and Br^- in **1**, **2** and **3**, and also dca and SCN^- anions in **4** and **5**); (ii) the conformational flexibility of the dadpm ligand; (iii) the versatility of the metal coordination sphere (the cadmium coordination geometry is tetrahedral in **1**, but octahedral in **2**, **3**, **4** and **5**); and (iv) the reaction sequence (in **2** and **5**). This work demonstrates the feasibility of achieving various polymeric frameworks by self-assembly of the flexible aromatic diamine ligand and metal salts and may provide useful information for crystal engineering.

Experimental Section

General: All chemicals were of an analytical grade and used without further purification. Elemental analyses of C, H N and S were performed with an Elementar Vario ELIII elemental analyzer. IR spectra were recorded as KBr pellets with a Nicolet Magna 750 FT-IR spectrometer in the range of 200−4000 cm^{-1}. Thermogravimetric analyses (TGA) were performed with a NETSCHZ STA-449C thermoanalyzer under N_2 (26−1000 °C range) at a heating

rate of 10°/min. NMR spectra were carried out with a Varian 500 spectrometer. Fluorescent spectra were measured with an Edinburgh F900 analytical instrument at Fuzhou University.

Syntheses

$[Cd(dadpm)(I)_2]_n$ (1): Ligand dadpm (0.10 g, 0.5 mmol) was added to an aqueous solution (30 mL) of CdI_2 (0.09 g, 0.25 mmol). After stirring the mixture for about 30 min, a DMF (5 mL) solution of sodium dicyanamide (0.03 g, 0.25 mmol) was added. The above mixture was stirred and heated for 1 h and then filtered while still hot. The filtrate was allowed to stand at room temperature. On concentration for about one week, colorless block crystals of **1** were obtained. Yield: 0.10 g (72%). $C_{13}H_{14}CdI_2N_2$ (564.48): calcd. C 27.64, H 2.48, N 4.96; found C 28.45, H 2.57, N 5.06.

$[\{Cd(dadpm)_2(Cl)\}(dca)]_n$ (2): This compound was prepared as light-yellow block crystals in a similar manner to that of **1** except $CdCl_2{\cdot}2.5H_2O$ was used instead of CdI_2 Yield 0.12 g (78%). $C_{28}H_{28}CdClN_7$ (610.42): calcd. C 55.04, H 4.59, N 16.05; found C 55.14, H 4.66, N 16.14.

$[\{Cd(dadpm)_2(Br)\}(dca)]_n$ (3): This compound was prepared as light-yellow block crystals in a similar manner to that of **1** except $CdBr_2{\cdot}4H_2O$ was used instead of CdI_2. Yield 0.13 g (82%). $C_{28}H_{28}CdBrN_7$ (654.88): calcd. C 51.31, H 4.28, N 14.96; found C 51.42, H 4.26, N 15.04.

$[Cd(dadpm)(SCN)_2]_n$ (4): Sodium thiocyanate (0.05 g, 0.5 mmol) was added to an aqueous (30 mL) solution of $CdCl_2{\cdot}2.5H_2O$ (0.057 g, 0.25 mmol). After stirring of the mixture for about 30 min, a DMF (5 mL) solution of the ligand dadpm (0.05 g, 0.25 mmol) was added. The above mixture was stirred and heated for 1 h and then filtered while still hot. Well-shaped light-yellow crystals of **4** were obtained from the filtrate by slow concentration at room temperature for several days. Yield 0.078 g (73%). $C_{15}H_{14}CdN_4S_2$ (428.8): calcd. C 41.98, H 3.26, N 13.06; found C 42.07, H 3.35, N 13.16.

$[Cd(dadpm)(dca)_2]_n$ (5): This compound was prepared as pale yellow prismatic crystals in a similar manner to that of **4** except that sodium dicyanamide was used instead of sodium thiocyanate. Yield 0.074 g (67%). $C_{17}H_{14}CdN_8$ (444.74): calcd. C 45.87, H 3.15, N 25.18; found C 45.92, H 3.22, N 25.28.

X-ray Crystallography: Colorless crystals of **1** and light-yellow crystals of **2**, **3**, **4** and **5** were selected for diffraction analyses. The data collections were performed with a Siemens Smart CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 298 K. All the structures were solved by direct methods and refined by full-matrix least-squares based on F^2 using the SHELX-97 program.[16] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located geometrically. The crystallographic data for compounds **1**−**5** are listed in Table 1, and selected bond lengths and angles in Table 2. Additional crystallographic details and complete listings of the five complexes have been deposited with the Cambridge Crystallographic Data Centre. CCDC-177678 (**1**), -175521 (**2**), -177947 (**3**), -177679 (**4**) and

Mechanisms of the Axial Ligand Substitution Reactions of Dinuclear, Head-to-Head α-Pyrrolidonato- and Pivalamidato-Bridged *cis*-Diammineplatinum(III) Complexes with Halide Ions

Kazuhiro Shimazaki,[a] Hideo Sekiya,[a] Haruhiko Inoue,[a] Nami Saeki,[a] Koji Ishihara,*[d] and Kazuko Matsumoto*[e]

Keywords: Platinum / Kinetics / Mechanism / α-Pyrrolidone / Pivalamide

The acid dissociation constant of the axial aqua ligand in the Head-to-Head (HH) dinuclear pivalamidato-bridged *cis*-diammineplatinum(III) complex ($[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_{10}NO)_2\text{-}Pt(NH_3)_2(H_2O)]^{4+}$) and the formation constants of the successive substitution reactions on the axial sites of the HH α-pyrrolidonato-bridged *cis*-diammineplatinum(III) dinuclear complex and the HH pivalamidato-bridged *cis*-diammineplatinum(III) dinuclear complex with halide ions X^- (X^- = Cl^- and Br^-) to give monohalo and dihalo complexes were determined spectrophotometrically at 25 °C and I = 2.0 M. A kinetic study was also performed for the monohalo and dihalo complex formations. The effect of the bridging ligand upon the axial site reactivity was compared and discussed. The ligand substitution behavior of the monohalo complex was affected by the axial ligand on the opposite Pt site and also by the bridging ligand. For both the α-pyrrolidonato- and the pivalamidato-bridged complexes, the formation of dichloro complexes proceeds only through the simple substitution path (k_2 path), whereas the formation of dibromo complexes proceeds through the two parallel reaction paths: the k_2 and k_3 paths for the former and the k_2 and $k_2^{\#}$ paths for the latter. The difference of the reaction paths is reasonably explained by the different *trans* effect of the halide ion on the opposite axial site for the former complex, but for the latter complex, the reaction paths are not easy to explain.

Introduction

Head-to-head (HH) amidato-bridged platinum(III) dinuclear complexes containing a metal-metal bond are formed by oxidation of the mixed-valent "platinum blues".[1−11] The two platinum atoms in the dinuclear complexes are nonequivalent: one is coordinated by two ammine nitrogen atoms and two amidate oxygen atoms [$Pt(N_2O_2)$], whereas the other is coordinated by four nitrogen atoms [$Pt(N_4)$], as shown below. The head-to-tail (HT) isomer, in which the two platinum atoms are equivalent, is also known.[4] In our previous reports,[12,13] the kinetics of the axial aqua ligand substitution with halide ions in the HH and HT α-pyridonato-bridged dimers were reported. On both of the HH and HT dimers, the axial ligand substitution occurs in two steps [Equation (1) and (2)].

$$[(H_2O)Pt(NH_3)_2(\mu\text{–}C_5H_4NO)_2Pt(NH_3)_2(H_2O)]^{4+} + X^- \underset{}{\overset{\text{Step 1}}{\rightleftharpoons}} [(H_2O)Pt(NH_3)_2(\mu\text{–}C_5H_4NO)_2Pt(NH_3)_2(X)]^{3+} + H_2O \quad (1)$$

$$[(H_2O)Pt(NH_3)_2(\mu\text{–}C_5H_4NO)_2Pt(NH_3)_2(X)]^{3+} + X^- \underset{}{\overset{\text{Step 2}}{\rightleftharpoons}} [(X)Pt(NH_3)_2(\mu\text{–}C_5H_4NO)_2Pt(NH_3)_2(X)]^{2+} + H_2O \quad (2)$$

In the HT dimer, the first halide substitution occurs at one of the two equivalent Pt^{III} atoms, and the first deprotonation occurs at the H_2O of the other Pt^{III} atom; in the HH dimer, the first deprotonation occurs at the H_2O on the $Pt(N_4)$ atom, and the first halide substitution takes place at the $Pt(N_2O_2)$ atom. These phenomena show that the axial halide exerts a *trans* effect through the Pt−Pt bond to the other axial H_2O ligand after the first substitution in both of the HH and HT dimers. In the second halide substitution at the other Pt atom, the substitution lability is influenced strongly by the first halide ligand on the opposite axial site,

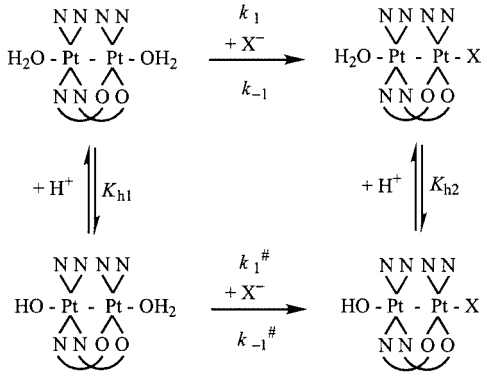
as the charge localization along the Pt−Pt axis is triggered by the first halide ligand, and the extent of the charge localization in the Pt−Pt bond in the dimer {the contribution of HH-$[(X)Pt^{IV}(N_2O_2)\text{-}Pt^{II}(N_4)(H_2O)]^{3+}$ and HT-$[(X)Pt^{IV}(N_3O)\text{-}Pt^{II}(N_3O)(H_2O)]^{3+}$} depends largely on the electron donating ability of the first substituted ligand (X^-).

In this paper we report a kinetic and equilibrium study of the axial aqua ligand substitution with halide ions in the HH α-pyrrolidonato-bridged dinuclear Pt^{III} complex $[(H_2O)Pt(NH_3)_2(\mu\text{-}C_4H_6NO)_2Pt(NH_3)_2(H_2O)]^{4+}$ and the HH pivalamidato-bridged dinuclear Pt^{III} complex $[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_{10}NO)_2Pt(NH_3)_2(H_2O)]^{4+}$ (Scheme 1), in order to examine the effect of the bridging ligand on the axial ligand substitution.



Scheme 1. (X^- = Cl^- or Br^-)

Results

Formation Constants of the HH α-Pyrrolidonato-bridged and the HH Pivalamidato-bridged Monohalo and Dihalo Dimer Complexes

The absorption spectra were measured at I = 2.00 M and 25 °C for solutions with various ratios of halide ion concentration, C_X^-, (X^- = Cl^- or Br^-) to a fixed dimer concentration, C_{HH}, and are shown in Figure 1 and 2. Several distinct isosbestic points are observed. The spectral changes with varying C_X^- are much the same as those for the α-pyridonato-bridged dimers reported previously.[12,13] Therefore, this spectral change corresponds to the following stepwise reactions [Equation (3) and (4)], i.e., the first substitution occurs at the $Pt(N_2O_2)$ atom and the second at the $Pt(N_4)$ atom.

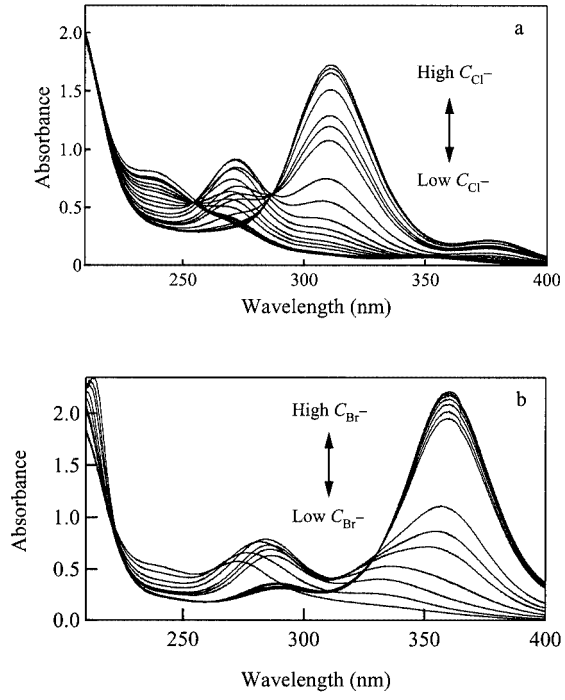


Figure 1. The UV/Vis spectra of the HH α-pyrrolidonato-bridged dimer in acidic aqueous solution with different C_X^- at 25 °C and I = 2.0 M. [H^+] = 1.27 M (a); [H^+] = 0.401 M (b), C_{Cl^-} = 0−4.1 × 10^{-3} M (a); C_{Br^-} = 0−2.1 × 10^{-3} M (b); C_{HH} = 9.6 × 10^{-5} M (a), C_{HH} = 3.9 × 10^{-5} M (b)

$$[H_2O\text{–}Pt(N_4)\text{–}Pt(N_2O_2)\text{–}H_2O]^{4+} + X^- \underset{}{\overset{K_1^X}{\rightleftharpoons}} [H_2O\text{–}Pt(N_4)\text{–}Pt(N_2O_2)\text{–}X]^{3+} + H_2O \quad (3)$$

$$[H_2O\text{–}Pt(N_4)\text{–}Pt(N_2O_2)\text{–}X]^{3+} + X^- \underset{}{\overset{K_2^X}{\rightleftharpoons}} [X\text{–}Pt(N_4)\text{–}Pt(N_2O_2)\text{–}X]^{2+} + H_2O \quad (4)$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

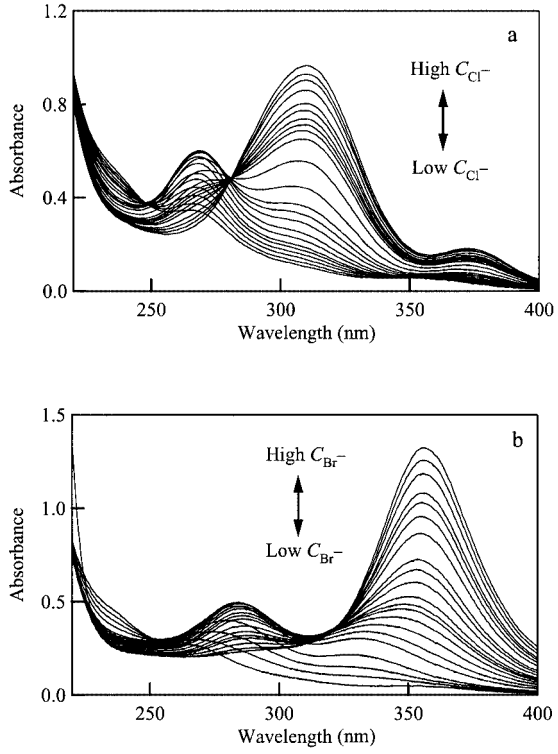

Figure 2. The UV/Vis spectra of the HH pivalamidato-bridged dimer in acidic aqueous solution with different C_X^- at 25 °C and I = 2.0 M. [H^+] = 0.803 M, C_{Cl^-} = 0−1.7 × 10^{-2} M (a); C_{Br^-} = 0−1.1 × 10^{-2} M (b); C_{HH} = 3.9 × 10^{-5} M (a), C_{HH} = 3.2 × 10^{-5} M (b)

The K_1^X and K_2^X values were obtained by simultaneously analyzing the spectra in Figure 1 and 2.

The values of K_{h_1}, the first acid dissociation constant (deprotonation of the H_2O ligand on the $Pt(N_4)$ atom) of the diaqua complex, was also obtained for the pivalamidato-bridged dimer. The obtained values are given in Table 1. The K_1^{Cl} and K_2^{Cl} values agree reasonably with the corresponding values for the reaction of the HH α-pyrrolidonato-bridged dimer with Cl^- (Table 1).

Kinetics for the Formation of the HH α-Pyrrolidonato- and Pivalamidato-Bridged Monohalo Complexes

The formation rate of the monohalo complex (Pt_2X) is given by Equation (5) under the present experimental conditions ($C_{HH} << C_X^-$), in which [HH] is the concentration of the unchanged dimer.

$$d[Pt_2X]/dt = k_{obs1}[HH] \quad (5)$$

The conditional first-order rate constant k_{obs1} is linearly dependent on C_X^- at a given [H^+] as shown in Figure 3, thus, k_{obs1} is expressed as Equation (6):

$$k_{obs1} = k_{f1} C_{HH} \quad (6)$$

It is obvious from Figure 3 that k_{f1} in Equation (6) depends on [H^+]. This [H^+] dependency is similar to that for the HH α-pyridonato-bridged dimer system reported previously,[13] and was successfully analysed according to Equation (7), which was derived based on Scheme 1 for the previous system.

$$k_{obs1} = \frac{k_1 + \frac{k_1^{\#} K_{h1}}{[H^+]}}{1 + \frac{K_{h1}}{[H^+]}} C_{HH} \quad (7)$$

The values of k_1 and $k_1^{\#}$ were obtained by applying a nonlinear least-squares fitting to Equation (7), and are listed in Table 2, together with the related data.

Kinetics for the Formation of the HH α-Pyrrolidonato- and Pivalamidato-Bridged Dihalo Complexes

Under these conditions, $C_{HH} << C_X^-$, the formation rate of the dihalo complex (Pt_2X_2) is expressed as Equation (8), where [HH-X] is the concentration of the monohalo HH dimer.

$$d[Pt_2X_2]/dt = k_{obs2}[HH\text{-}X] \quad (8)$$

The rate constant of the second substitution step, k_{obs2}, depends linearly on C_X^- for the reactions of the α-pyrrolidonato-bridged dimer with Cl^- and the pivalamidato-bridged dimer with Cl^- and Br^-, and nonlinearly for the reaction of the α-pyrrolidonato-bridged dimer with Br^-, as shown in Figure 4.

Table 1. Equilibrium constants for the reaction of the HH amidato-bridged *cis*-diammineplatinum(II) dimer with halide ions determined spectrophotometrically at I = 2.00 M and 25 °C

Bridging ligand	−log K_{h1}	log K_1^{Cl}	log K_2^{Cl}	log K_1^{Br}	log K_2^{Br}
α-Pyridonate[a]	1.71 ± 0.03	5.93 ± 0.02	3.71 ± 0.01	6.20 ± 0.05	4.55 ± 0.01

		$k_1^{\#}$	(1.00 ± 0.16)×10^6
	Pivalamidate	k_1	(1.12 ± 0.01)×10^3
		$k_1^{\#}$	(1.13 ± 0.01)×10^6

Ref.[13]

The non-linear plot in Figure 4b is very similar to those reported previously for the reactions of HH α-pyridonato-bridged dimer with Cl^- and Br^-, and the reaction of HT α-pyridonato-bridged dimer with Br^-,[12,13] i.e., k_{obs2} increases linearly with C_{Br^-} at lower C_{Br^-}, and it still increases linearly at higher C_{Br^-}, but with a different slope. This fact is explained by the mechanism in Scheme 2.

The linear plots in Figure 4d are dependent on [H^+], and have a close resemblance to those for the reaction of the HT α-pyridonato-bridged dimer with Cl^-. Therefore Scheme 3 can be proposed for the present reaction analogous to the reported α-pyridonato-bridged dimer.

On the other hand, the plots in Figure 4a and 4c have no [H^+] dependency and zero and non-zero intercepts, respectively. These facts correspond to simple substitutions without and with the contribution of the reverse reaction, respectively, as shown in Scheme 4.

In Scheme 2, when the steady-state approximation is applied to the monobromo dimer without an axial ligand at the opposite site, Equation (9) is obtained when the reverse reaction is negligible.

$$k_{obs2} = k_2[Br^-] + \frac{k_3 k_4[Br^-]}{k_{-3} + k_4[Br^-]} \quad (9)$$

Discussion

In view of Table 1, the first acid dissociation constant K_{h1} of the α-pyridonato-bridged dinuclear complex is larger than those of the α-pyrrolidonato- and the pivalamidato-bridged complexes, whose K_{h1}'s are similar. It should be noted that the difference between $\log K_1^{Cl}$ and $\log K_1^{Br}$ for the pivalamidato-bridged system is larger than those for the other two systems, and $\log K_1^{Cl}$ and $\log K_2^{X}$ for the pivalamidato-bridged system are significantly smaller than the corresponding values for the other two systems.

The k_1 values for the reactions of the α-pyridonato-bridged complex with both Cl^- and Br^- are somewhat larger than those for the reactions of the α-pyrrolidonato- and pivalamidato-bridged complexes with the corresponding halide ions, whereas this relation is reversed for the $k_1^{\#}$ values, as shown in Table 2. As mentioned above, in the HH dimer the deprotonation occurs at the H_2O of the $Pt(N_4)$ [H_2O-$Pt(N_2O_2)$-$Pt(N_4)$-OH_2 → H_2O-$Pt(N_2O_2)$-$Pt(N_4)$-OH + H^+], whereas the first ligand substitution takes place at the opposite $Pt(N_2O_2)$ atom [H_2O-$Pt(N_2O_2)$-$Pt(N_4)$-OH_2 + X^- → X-$Pt(N_2O_2)$-$Pt(N_4)$-OH_2 + H_2O]; the second ligand substitution at $Pt(N_4)$ is strongly influenced by the first ligated ligand on the $Pt(N_2O_2)$. So, the k_1 and $k_1^{\#}$ values may reflect that the H_2O-$Pt(N_2O_2)$ bond in the α-pyridonato-bridged diaqua complex is weaker than those in the α-pyrrolidonato- and pivalamidato-bridged complexes, since the H_2O-$Pt(N_4)$ bond in the former complex, which has a larger K_{h1}, is stronger than those in the latter complexes which have smaller K_{h1}, and that once the diaqua complexes are deprotonated, the H_2O-$Pt(N_2O_2)$ bonds in the aquahydroxo complexes become weaker for these complexes, since the opposite HO-$Pt(N_4)$ bonds become stronger in the deprotonated complexes. In the dinuclear complex [X_2-$Pt(N_4)$-$Pt(N_2O_2)$-X_1] the axial bond length [X_1-$Pt(N_2O_2)$, X_2-$Pt(N_4)$, and Pt-Pt] depends on both X_1 and X_2.[13] On the basis of the findings mentioned above, it follows that the bond length (and the extent of the charge localization) also changes depending on the bridging ligand.

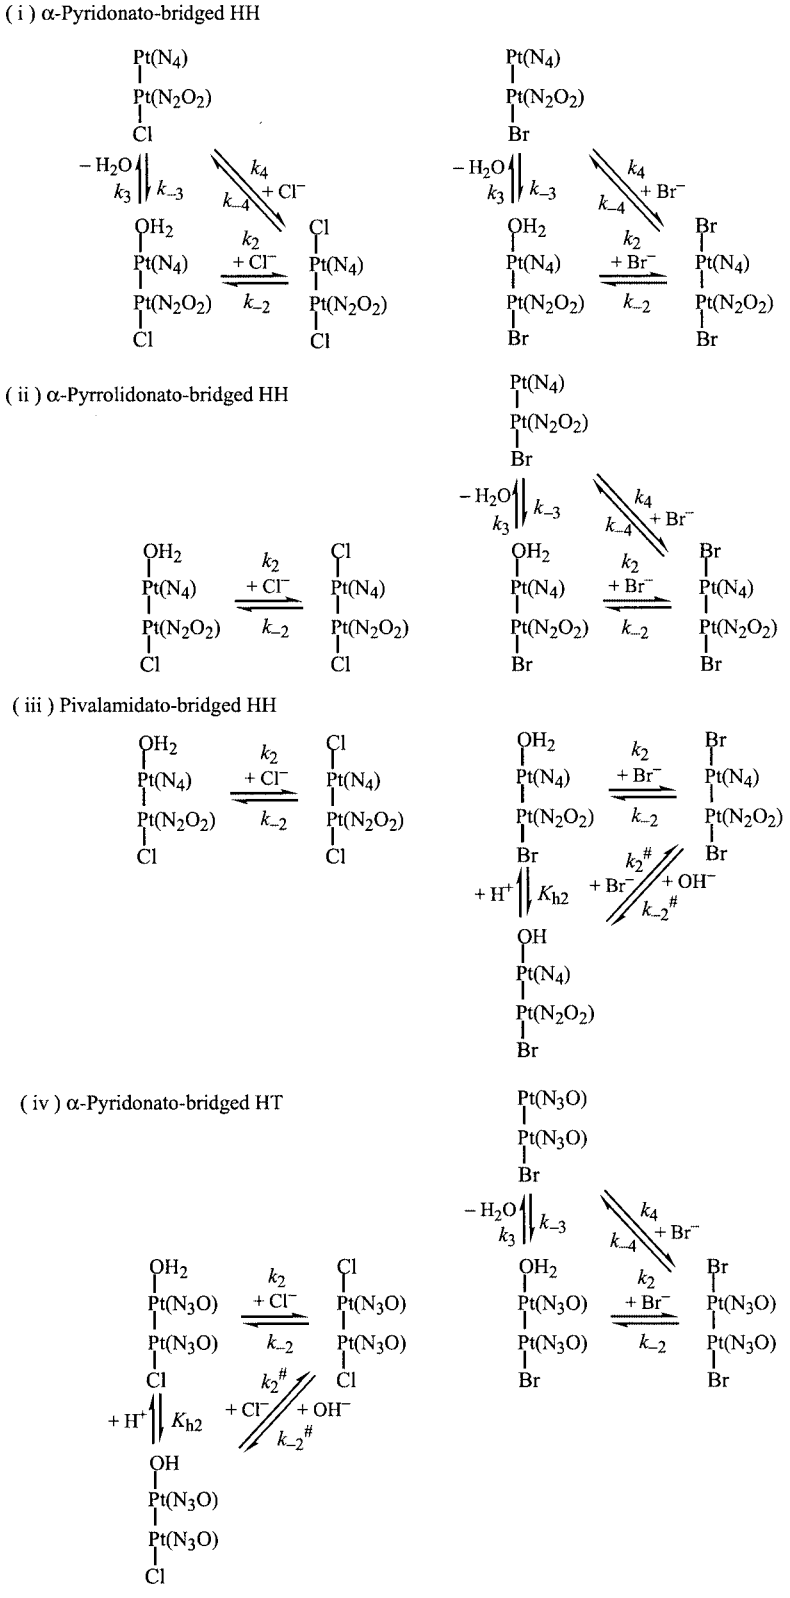
The rate constants for step 2 are summarized in Table 3. The rate constants k_2 for the direct substitution of the monohalo complexes with halide ion (see Schemes 2−4) show that the α-pyridonato-bridged monochloro complex is less reactive than the α-pyrrolidonato- and pivalamidato-bridged monochloro complexes, whereas the α-pyridonato-bridged monobromo complex is more reactive than the other monobromo complexes. Thus, the substitution reactivity of the axial sites of the amidato-bridged dinuclear complex is considerably influenced by the bridging ligand.

The formation constant K_2^X ($= k_2/k_{-2}$) for the pivalamidato-bridged dihalo complex, derived from the rate constants (k_2 and k_{-2}) in Table 3, is in excellent agreement with K_2^X in Table 1 obtained by spectrophotometry [$\log K_2^{Cl} = \log(k_2/k_{-2}) = 3.24$; $\log K_2^{Br} = 3.91$], which supports the present kinetic analysis.

The reaction mechanism for step 1 is described in Scheme 1, in which there are two reaction pathways in all the systems under the present conditions: one is the substitution of H_2O at the $Pt(N_2O_2)$ center in the diaqua complex, and the other is also a substitution of H_2O but at the $Pt(N_2O_2)$ center in the aquahydroxo complex. The reaction mechanisms for step 2 are shown in Schemes 2−4. There are three possible pathways for step 2, depending on the axial ligand (X_1) at the $Pt(N_2O_2)$ center, as discussed previously:[12,13] one is the direct substitution path (k_2), the se-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cond is the path (k_3) via dissociation of the water molecule ligated to the $Pt(N_4)$, and the third is the unusual path ($k_2^{\#}$) of the OH^- replacement at the $Pt(N_4)$. This last path is impossible in mononuclear metal complexes, but can occur in the present complexes, probably due to the contribution of the electron localization of the form $HO\text{-}Pt^{II}\text{-}Pt^{IV}\text{-}X_1$. When X_1 on the $Pt(N_2O_2)$ is less electron donating, the reaction tends to proceed through the k_2 and $k_2^{\#}$ paths,



Scheme 5. Reaction pathways of the second step for the reactions of the amidato-bridged Pt^{III} dinuclear complexes with halides

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

whereas when X_1 is more electron donating, the k_2 and k_3 paths are preferred. The reaction schemes of step 2 for the reactions of the α-pyrrolidonato- and pivalamidato-bridged complexes are summarized in Scheme 5, together with those for the HH and HT α-pyridonato-bridged dinuclear complexes.[12,13]

The mechanistic difference in the α-pyridonato-bridged HH and HT dinuclear complexes was interpreted as follows: the difference in the HT α-pyridonato-bridged complex + Cl^- and the HT complex + Br^- systems can be reasonably explained by the relative electron donor ability of Cl^- and Br^-. Because the more electron donating Br^- facilitates dissociation of the axial aqua ligand from the opposite Pt atom, the coordinatively unsaturated intermediate is involved in the mechanism [Scheme 5 (iv)]. The charge localization through the Pt−Pt bond would be more pronounced in the HH aquahalo dimer than in the HT aquahalo dimer since the two Pt atoms are not equivalent in the HH diaqua dimer, i.e., the HH aquahalo dimer has greater $Pt^{II}(N_4)$-$Pt^{IV}(N_2O_2)$-X_1 character than the HT aquahalo dimer, and this shifts the mechanism of (iv) to the dissociative mechanism of (i) in Scheme 5. According to these explanations, the extent of charge localization in the α-pyrrolidonato- and pivalamidato-bridged monochloro complexes having only the k_2 path would be intermediate between the HH and HT α-pyridonato-bridged dimers. In the α-pyrrolidonato-bridged monohalo dimer, the charge localization of the monobromo dimer would be more pronounced than that of the monochloro dimer, whereas the opposite tendency is observed for the pivalamidato-bridged monohalo complexes. Therefore, both the bridging ligand and the axial ligand X_1 affect the mechanism. From the viewpoint of the bridging ligand, the order of the electron localization enhancement in the HH monochloro complexes is α-pyridonato-bridged complex > α-pyrrolidonato-bridged complex ≈ pivalamidato-bridged complex, and in the HH monobromo complexes, α-pyridonato-bridged complex ≈ α-pyrrolidonato-bridged complex > pivalamidato-bridged complex. Thus, in the HH amidato-bridged Pt^{III} dinuclear complexes, the effect of X_1 on the substitution reactivity of X_2 is not necessarily as expected from the *trans* effect of the axial ligand X_1, if the bridging ligand is varied.

Conclusion

In α-pyrrolidonato- and pivalamidato-bridged Pt^{III} dinuclear complexes, the first deprotonation occurs from the water molecule on the $Pt(N_4)$ center and the first nucleophilic substitution with X^- ($X^- = Cl^-$ and Br^-) occurs at the $Pt(N_2O_2)$ center. The formation of the HH monohalo complex (step 1) proceeds through two parallel paths: a simple substitution path (k_1) and a path ($k_1^{\#}$) accelerated by the trans-coordinated OH^-. The formation of the HH dihalo complex from the aquahalo complex (step 2) proceeds through only a simple substitution path (k_2) for the reactions of the α-pyrrolidonato- and pivalamidato-bridged complexes with Cl^-, and the mechanism is different from the reactions of the HH and HT α-pyridonato-bridged dimers with Cl^-. Step 2 proceeds through k_2 and a path with dissociation of a water molecule (k_3) for the reaction of the α-pyrrolidonato-bridged dimer with Br^-, and k_2 and a path with OH^- replacement by Br^- at the $Pt(N_4)$ center ($k_2^{\#}$) for the reaction of the pivalamidato-bridged dimer with Br^-. The substitution behavior in step 2 for the pivalamidato-bridged dimer system is quite different from that of the α-pyrrolidonato-bridged dimer and the HH and HT α-pyridonato-bridged dimer systems.

Experimental Section

General Remarks. Reagents: *cis*-$[PtCl_2(NH_3)_2]$ was prepared from $K_2[PtCl_4]$ (Tanaka Kikinzoku Kogyo K.K., Tokyo) according to Dhara's method.[16] Reagent grade α-pyrrolidone (Kanto Chemical Co. Inc., Tokyo) was purified once by vacuum distillation. Pivalamide (98%, Aldrich) was recrystallized twice from water. Sodium chloride (99.99%, Kanto), sodium bromide (99.99%, Aldrich), and perchloric acid (60% UGR for trace analysis, Kanto) were used without further purification. Sodium perchlorate was prepared and purified according to the literature procedure.[17] Head-to-head $[(H_2O)Pt(NH_3)_2(\mu\text{-}C_4H_6NO)_2Pt(NH_3)_2(H_2O)](NO_3)_4{\cdot}2H_2O$ (HH α-Pyrrolidonato-bridged dimer) and Head-to-head $[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_{10}NO)_2Pt(NH_3)_2(H_2O)](NO_3)_4{\cdot}2H_2O$ (HH Pivalamidato-bridged dimer) were prepared according to the literature procedures.[18,19]

Measurements: Ionic strength was maintained at 2.00 M with perchloric acid and sodium perchlorate. All the sample solutions were prepared in doubly distilled water just before measurement. Spectrophotometric measurements were performed with rapid-scan/stopped-flow spectrophotometers USP-500 (Unisoku Scientific Instruments, Osaka), RSP601S (Unisoku), and SF-61DX2 (Hi-Tech Scientific, Wiltshire) and spectrophotometers UV-160A (Shimadzu, Kyoto), UV-2200 (Shimadzu), and UV-2400 (Shimadzu). Rate constants were measured by monitoring the absorbance change at 282 nm for the reaction of the HH α-pyrrolidonato-bridged dimer with Cl^- (as NaCl) and at 358 nm for the reaction with Br^- (as NaBr) for k_{obs1}, and at 268 nm for the reaction of the HH pivalamidato-bridged dimer with Cl^-, at 312 nm for the reaction of the HH dimer with Br^- for k_{obs2}, as a function of time after mixing the solutions of the dimer and sodium halide. The formation constants (K_1^X and K_2^X) of the HH monohalo and the dihalo α-pyrrolidonato- and pivalamidato-bridged dimers were determined spectrophotometrically under the following conditions. (a) For the α-pyrrolidonato-bridged dimer: $C_{HH} = 9.6 \times 10^{-4}$ M, $[H^+] = 1.27$ M, $C_{Cl^-} = 0-4.1 \times 10^{-3}$ M for K_1^{Cl} and K_2^{Cl}; $C_{HH} = 3.92 \times 10^{-5}$ M, $[H^+] = 0.401$ M, $C_{Br^-} = 0-2.11 \times 10^{-3}$ M for K_1^{Br} and K_2^{Br}; (b) for the pivalamidato-bridged dimer: $C_{HH} = 3.86 \times 10^{-5}$ M, $[H^+] = 0.803$ M, $C_{Cl^-} = 0-1.7 \times 10^{-2}$ M for K_1^{Cl} and K_2^{Cl}; $C_{HH} = 3.2 \times 10^{-5}$ M, $[H^+] = 0.8037$ M, $C_{Br^-} = 0-1.1 \times 10^{-2}$ M for K_1^{Br} and K_2^{Br}. The acid dissociation constant (K_{h1}) of the HH pivalamidato-bridged dimer was determined spectrophotometrically as described previously[12] under the conditions: $C_{HH} = 1.14 \times 10^{-4}$ M, $[H^+] = 6.69 \times 10^{-5} - 0.115$ M. All the formation and acid dissociation constants were determined with the SPECFIT program.[20] The rate constants k_{obs1} and k_{obs2} for the consecutive reaction [reactions (3) and (4)] were determined simultaneously according to the equation: $A_t = A_e + \alpha\exp(-k_{obs1}t) + \beta\exp(-k_{obs2}t)$, in which A_t and A_e are the absorbances at time t and ∞, respectively, and α and β are composite parameters.[21]

A Two-Step Route to Self-Assembly of CdS Nanotubes via Electrodeposition and Dissolution

Shao-Min Zhou,*[a,b] Yi-Si Feng,[a] and Li-De Zhang[a]

Keywords: Cadmium / Sulfides / Nanotubes / Self-assembly / Electrochemistry

Polycrystalline CdS nanotubes (CNTs) were successfully achieved by a two-step treatment, i.e. (CdS+Cd) nanowires (electrodeposition and sulfuration process in anodic alumina membrane) → CNTs (dissolution method of removing Cd in 0.5 M HCl). Having been characterized using X-ray diffraction and scanning electron microscopy, the nanowires, the intermediate products, contain Cd and CdS, and have uniform diameters of about 80 nm and lengths of up to 25 μm, which correspond to the pore size and thickness of the membrane used. The average inner and outer diameters of the as-obtained CNTs are respectively 40 and 80 nm via transmission electron microscopy. Selected area electronic diffraction, X-ray diffraction and X-ray photoelectron energy spectroscopy investigations demonstrate that these CNTs with hexagonal wurtzite polycrystalline structure are pure and stoichiometric. The successful synthesis of these semiconductor CNTs may open up new possibilities for studies of fundamental properties and potential applications of semiconductor nanotubes.

Introduction

The discovery of free-standing microscopic one-dimensional molecular structures, such as carbon nanotubes, has attracted a great deal of attention in the last decade because of the various interesting properties associated with their small dimensions, high anisotropy, and intriguing tube-like structures. These range from a variety of quantum effects to potentially useful properties such as efficient field-emission and exceptional mechanical strength.[1] A particularly significant breakthrough in WS_2 and MoS_2 nanotubes synthesis was made by Tenne and co-workers[2−4] through the gas-phase reaction between WO_{3-x} or MoO_3 and H_2S in a reducing atmosphere at elevated temperature. Since then many other kinds of nanotubes, such as BN,[5] $NiCl_2$,[6] InS,[7] NbS_2,[8] and Bi,[9] have been reported utilizing various approaches with different growth mechanisms. More recently, Si[10,11] and TiO_2 [12,13] nanotubes were also fabricated and a micro-templated synthesis of CdS nanotubes[14] in aqueous solution at room temperature has also been reported. Although no generalized synthetic method for nanotubes has yet been established, self-assembly growth is a good method for producing nanotubes. For example, Remskar et al.[15] reported the self-assembly of subnanometer-diameter single-wall MoS_2 nanotubes, and rare-earth oxide nanotubes have been formed from dodecylsulfate assemblies.[16] Similarly, Te,[17] NbS_2,[18,19] WS_2,[20] $Cu_{5.5}FeS_{6.5}$,[21] and ReS_2 [22] nanotubes have also been synthesized by self- or induced-assembly. Motivated by these reports, we now report a two-step synthesis of CdS nanotubes based on a self-assembly approach.

Results and Discussion

The CdS nanotubes were synthesized as follows. First, pure metal Cd nanowires were electrodeposited inside the nanochannels of anodic alumina membrane (AAM), and then the outer walls of the Cd nanowires were sulfurized under an atmosphere of sulfur to form a CdS layer under controlled conditions; the (CdS+Cd) nanowires were formed in situ. Secondly, the CdS nanotubes were formed by removal of the Cd, together with AAM, upon dissolution in 0.5 M HCl for 1 hour. Figure 1a shows a typical cross-sectional SEM image, where the intermediate products — the (Cd+CdS) nanowires — consist of a large quantity of wire-like arrays with diameters of about 80 nm and lengths of about 25 μm, corresponding to the pore size and thickness, respectively, of the AAM used. These nanowires are highly ordered and are formed by a template, i.e. they are electrodeposited uniformly and continuously filled into the AAM pores. The composition of the nanowires was confirmed by X-ray diffraction (XRD), as shown in Figure 1b. The peak at 32.15° supports the proposal that there is metallic Cd in the nanowires, whereas no peaks from Al_2O_3 exist due to its amorphous structure at the treatment

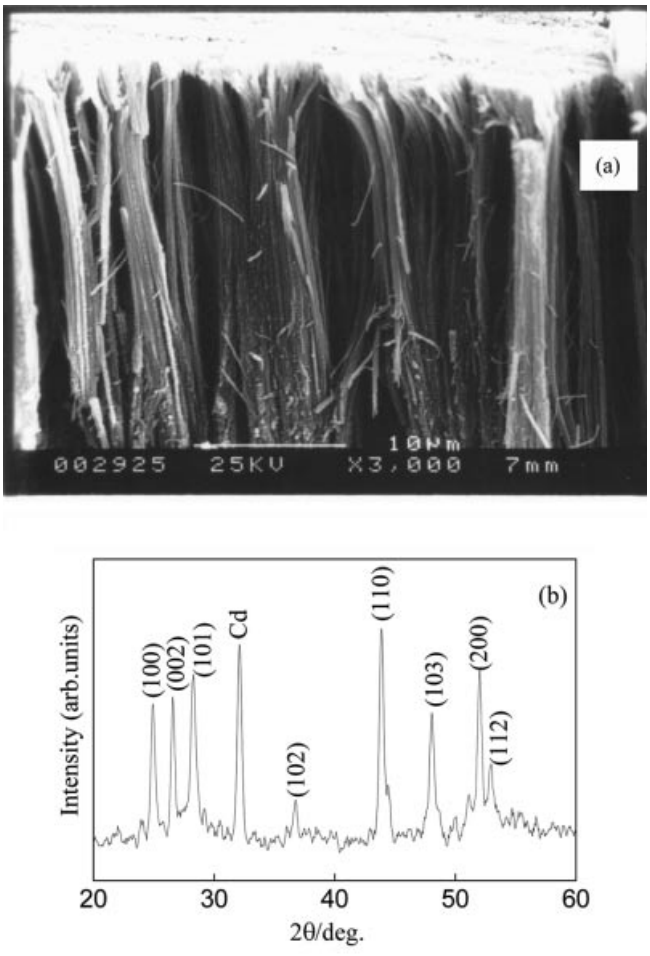

Figure 1. (a) A typical cross-sectional SEM image of (CdS+Cd) nanowires (80 nm in diameters and 25 μm in lengths) and (b) XRD pattern of (Cd+CdS) nanowires

temperature. The Miller indices of the peaks are indicated in Figure 1b where it can be seen that the whole diffractogram can be indexed from the peak positions to a crystalline CdS phase. It is also clear that the XRD pattern of the nanowires exhibits prominent peaks at scattering angles (2θ) of 24.8°, 26.4°, 28.2°, 36.6°, 43.7°, 47.8°, 51.9°, and 52.8°, of the hexagonal CdS crystal lattice (JCPDS Card File, No. 06-0314). After the AAM and the Cd had been completely removed by treatment with 0.5 M HCl for 60 min, we obtained the CdS nanotubes whose typical TEM image is shown in Figure 2a. One can clearly see that these nanotubes appear in alignment and have a hollow structure with a uniform outer diameter of about 80 nm, which is consistent with the results of SEM. A TEM image at higher magnification, taken of the open section of a single nanotube, is presented in Figure 2b; the section marked with a black loop was used for selected area electronic diffraction (SAED) analysis. From this image, it can be seen more clearly that the inner and outer diameters of the nanotube are 40 nm and 80 nm, respectively and its structure is hollow. Moreover, the open section of the nanotube has a rough surface, which might be due to the corrosion by HCl. Because of this, one can suggest that HCl dissolves AAM and Cd in the center of the wire along the nanowire axis, resulting in this kind of hollow structure. An SAED pattern (insert in Figure 2b), taken from the section mentioned above, was recorded with a W electron beam perpendicular to the nanotube axis (other SAED patterns from other sections of the nanotube are essentially identical), which reflects the characteristics of the nanotube structure. The pattern shows that the diffuse diffraction rings in the SAED pattern are due to the polycrystalline structure of the sample. The three rings in the pattern correspond to the [110], [101], and [112] direction; the [110] is the radial direction of the nanotube. Figure 3 shows the XRD pattern of

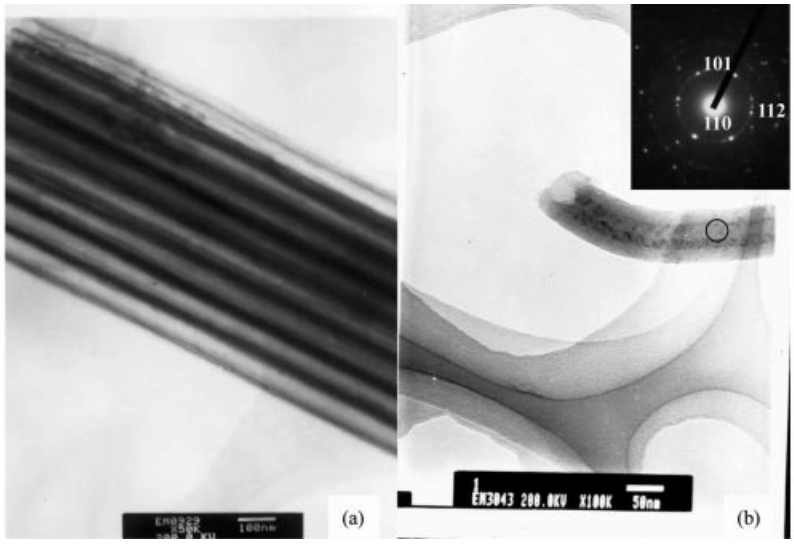

Figure 2. (a) TEM image of CdS nanotube arrays (inside diameter of 40 nm and outside diameter of 80 nm) and (b) a TEM image at higher magnification taken of an individual nanotube; inset: SAED pattern of the CdS nanotube

the final CdS nanotubes, where all the intense XRD peaks show a wurtzite (hexagonal) structured CdS with lattice constants of $a = 0.413$ nm and $c = 0.671$ nm consistent with the standard values (JCPDS Card File, No. 06-0314) and a previous report.[23] No diffraction peaks from CdO, Cd, S or other impurities have been found in the final products.

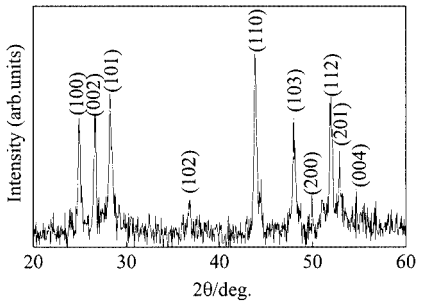

Figure 3. XRD patterns of the CdS nanotubes

A chemical composition analysis of the as-synthesized CdS nanotubes was also performed by X-ray photoelectron energy spectroscopy (XPS). The XPS spectrum (Figure 4) shows that the nanotubes are composed of S and Cd, and quantitative analysis indicates that the atomic ratio of S and Cd is 40:48 within experimental error, which is consistent with stoichiometric CdS (Cd:S = 1:1).

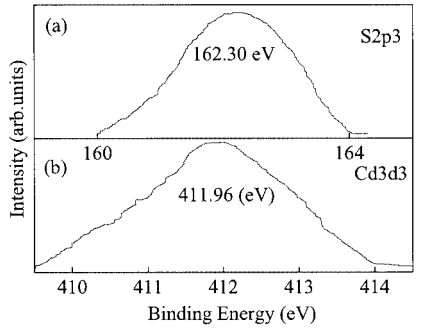

Figure 4. (a) S2p3 XPS spectrum of the CdS nanotubes: the peak binding energy is 162.30 eV and (b) Cd3d3 spectrum of the CdS nanotubes: the peak binding energy is 411.96 eV; the C1s (E= 284.5 eV) level serves as the internal standard

There is one other possible model for the growth of CdS nanotubes: Through the usual template approach, the parameters of Cd nanowires are strongly dependent on the size of the nanochannel in AAM. The mixture of composition CdS + Cd forms through sublimation of sulfur, the residual Cd is dissolved and then the CdS nanotubes appear. This might be a self-assembly process.

$$\text{Cd (electrodeposition nanowire)} \xrightarrow{S} \text{[Cd+CdS]AAM mixed} \xrightarrow{NaOH} \text{CdS (nanotube)}$$

In summary, we have presented a simple, inexpensive, and reasoned method to fabricate CdS nanotubes. They were characterized by SEM, TEM, SAED, XRD, and XPS. The final products formed through self-assembly are pure CdS nanotubes with outside diameters of about 80 nm and inside diameters of about 40 nm. The CdS nanotubes have a uniform hollow structure. The growth mechanism is suggested to be a self-assembly process. The technique may serve as a model for studying the synthesis and properties of other semiconductor nanotubes such as PbS, SnS, ZnS. It is likely that these CdS nanotubes may stimulate technological interest and see many applications in optical fibers or nanodevices.

Experimental Section

The CdS nanotube was formed by a chemical method taking advantage of its low solubility in 0.5 M HCl (Cd and AAMs are readily soluble). In a typical experiment, AAM was prepared via a two-step aluminum anodic oxidation process in a 0.3 M oxalic acid solution, as described previously.[24] The AAM had a diameter of about 80 nm in the pore size and a thickness of 25 μm. Metallic Cd was electrodeposited inside the nanochannels of the AAM with a conventional three-electrode aqueous bath, containing solutions of 0.2 M $CdCl_2$ and 0.1 M H_3BO_3. The deposition potentials were controlled in the range −0.68 to 0.7 V for 240 min at room temperature. Then their surfaces were polished using a 40-nm SiC polishing sandpaper to get rid of Cd particles that had grown excessively and stuck to the surface. The AAM with Cd was washed with distilled water and ethanol, put into a quartz boat and covered with a layer of S powder (99.99%). The boat was placed into the hot zone of a recrystallized alumina tube furnace. The reaction chamber was evacuated with a mechanical pump, and then it was backfilled with high purity Ar gas (0.1 MPa). The reactor was heated to 700 °C from room temperature and held at this temperature for 30 minutes to sulfurize the Cd nanowires. The AAM with CdS membranes was then cleaned with CS_2 to remove the remaining S powder, and washed with ethanol and deionized water. Then, the AAM was immersed in 0.5 M HCl for 60 min and the precipitate was separated from the solution by centrifugation and washed with toluene and absolute ethanol. The semi-finished product [i.e., (CdS+Cd) nanowires] with AAM was firstly characterized by X-ray diffraction (XRD) (PW, 1710 instrument with Cu-K_α radiation, λ = 0.154178 nm at a scanning speed of 0.02°/s in the 2θ range 20−60°). For the SEM analysis (JEOL JSM-63000 instrument) the sample was mounted directly on Cu stubs with conductive gold paint and the AAM was dissolved away. The final products were dried in vacuo at 100 °C for 3 hours and detected by using transmission electron microscopy (TEM) [JEM 200CX equipped with selected area electronic diffraction (SAED), working at 200 kV acceleration voltage], XRD, and X-ray photoelectron energy spectroscopy (XPS) [MKII XPS, employing Mg-K_α, E = 1253.6 eV, the C1s (E = 284.5 eV) level served as the internal standard]. For TEM and SAED, the sample was ultrasonically dispersed in ethanol and a drop of the solution was placed on a Cu grid coated with a holey carbon film. All the chemicals used were of analytical grade and were used without further purification.

Self-Assembly of Organodiphosphonate, Polyoxomolybdate and Diphenanthrolinecobalt(II) into Two Clusters and One Linear Polymer

Rui-Biao Fu,[a] Xin-Tao Wu,*[a] Sheng-Min Hu,[a] Jian-Jun Zhang,[a] Zhi-Yong Fu,[a] Wen-Xin Du,[a] and Sheng-Qing Xia[a]

Keywords: Polyoxometalates / Molybdenum / Cobalt / N ligands / Clusters

[{Co(1,10-phen)$_2$}$_2${(Mo$_4$O$_{12}$)(O$_3$PCH$_2$CH$_2$PO$_3$)}·(H$_2$O)] (**1**), [{Co(1,10-phen)$_2$}$_2${(Mo$_4$O$_{12}$)(O$_3$PCH$_2$CH$_2$CH$_2$PO$_3$)}·(1.5H$_2$O)] (**2**) and [{Co(1,10-phen)$_2$(H$_2$O)$_2$}{Co(1,10-phen)$_2$(H$_2$O)}-{(Mo$_5$O$_{15}$)(O$_3$PCH$_2$CH$_2$CH$_2$CH$_2$PO$_3$)}·(6H$_2$O)] (**3**) were synthesized by self-assembly of H$_2$O$_3$P(CH$_2$)$_n$PO$_3$H$_2$ (n = 2–4), polyoxomolybdate and [Co(1,10-phen)$_2$]$^{2+}$ (1,10-phen = 1,10-phenanthroline) under hydrothermal conditions. Compounds **1** and **2** are novel heterometallic hexanuclear clusters, while compound **3** is a new linear polymer.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Metal-organic units have been successfully introduced into organic-inorganic hybrid systems as charge-compensating motifs, structure-directing components and building blocks to synthesize many new compounds such as micropores.[1−13] In the molybdenum organodiphosphonate system three one-dimensional and two two-dimensional polymers have been produced by incorporating copper-phenanthroline, copper-2,2′-bipyridine and copper-tetra(2-pyridyl)pyrazine as metal-organic subunits.[14−15] In previous work we have successfully used [Co(1,10-phen)$_2$]$^{2+}$ as a metal-organic subunit to synthesize two one-dimensional polymers in the oxovanadium-organodiphosphonate systems.[16] But what the structures will be after self-assembling of different lengths of organodiphosphonate ligands, polyoxomolybdate and [Co(1,10-phen)$_2$]$^{2+}$ as metal-organic subunit together is still unknown. In this paper we report the synthesis and crystal structures of two novel clusters, [{Co(1,10-phen)$_2$}$_2${(Mo$_4$O$_{12}$)(O$_3$PCH$_2$CH$_2$PO$_3$)}·(H$_2$O)] (**1**) and [{Co(1,10-phen)$_2$}$_2${(Mo$_4$O$_{12}$)(O$_3$PCH$_2$CH$_2$-CH$_2$PO$_3$)}·(1.5H$_2$O)] (**2**), and one linear polymer, [{Co(1,10-phen)$_2$(H$_2$O)$_2$}{Co(1,10-phen)$_2$(H$_2$O)}-{(Mo$_5$O$_{15}$)(O$_3$PCH$_2$CH$_2$CH$_2$CH$_2$PO$_3$)}·(6H$_2$O)] (**3**).

Results and Discussion

The crystal structure of **1** consists of a heterometallic hexanuclear Mo$_4$Co$_2$ cluster built up from an {Mo$_4$O$_{16}$} motif, {PCO$_3$} tetrahedrons and {CoN$_4$O$_2$} octahedrons (Figure 1a). Interestingly, the Mo atoms arrange themselves into a twisted zigzag line in the {Mo$_4$O$_{16}$} motif (Figure 1b), which is composed of four {MoO$_6$} octahedrons. {Mo1O$_6$} shares a face with {Mo2O$_6$} through the O8, O4 and O10 atoms. {Mo2O$_6$} and {Mo3O$_6$} are edge-shared through the O4 and O5 atoms. {Mo3O$_6$} shares a face with {Mo4O$_6$} through the O1, O5 and O6 atoms. Meanwhile {Mo1O$_6$} shares a corner with {Mo3O$_6$} through O4 atoms and {Mo2O$_6$} shares a corner with {Mo4O$_6$} thought O5 atoms. As a result, the Mo1−Mo2, Mo2−Mo3 and Mo3−Mo4 distances are 3.0729(10), 3.2033(10) and 3.0755(11) Å, respectively. The [Mo$_4$O$_{12}$(O$_3$PCH$_2$-CH$_2$PO$_3$)]$^{4-}$ anion is formed by the 1,2-ethylenediphosphonate ligand firmly chelating the Mo1 and Mo4 atoms [Mo1−O14 = 1.981(6), Mo1−O8 = 2.262(5), Mo4−O11 = 2.000(6) and Mo4−O6 = 2.321(5) Å] and linking to the middle two {MoO$_6$} octahedrons [Mo2−O8 = 2.260(6) and Mo3−O6 = 2.277(6) Å] (Figure 1c). Both Co^{II} atoms are in slightly distorted octahedral coordination geometries with four nitrogen atoms from two 1,10-phenanthroline ligands and two oxygen atoms. The {Co1N$_4$O$_2$} octahedron connects to the [Mo$_4$O$_{12}$(O$_3$PCH$_2$CH$_2$PO$_3$)]$^{4-}$ anion by sharing one oxygen atom with an {Mo2O$_6$} octahedron [Co1−O7 = 2.107(6) Å] and another oxygen atom with the {P1CO$_3$} tetrahedron [Co1−O18 = 2.048(6) Å] (Figure 1c). The {Co2N$_4$O$_2$} octahedron is attached to the [Mo$_4$O$_{12}$(O$_3$PCH$_2$CH$_2$PO$_3$)]$^{4-}$ anion through one oxygen atom of the {Mo3O$_6$} octahedron [Co2−O3 = 2.083(6) Å] and another oxygen atom of the {P2CO$_3$} tetrahedron [Co2−O17 = 2.067(6) Å] (Figure 1c). Consequently, each

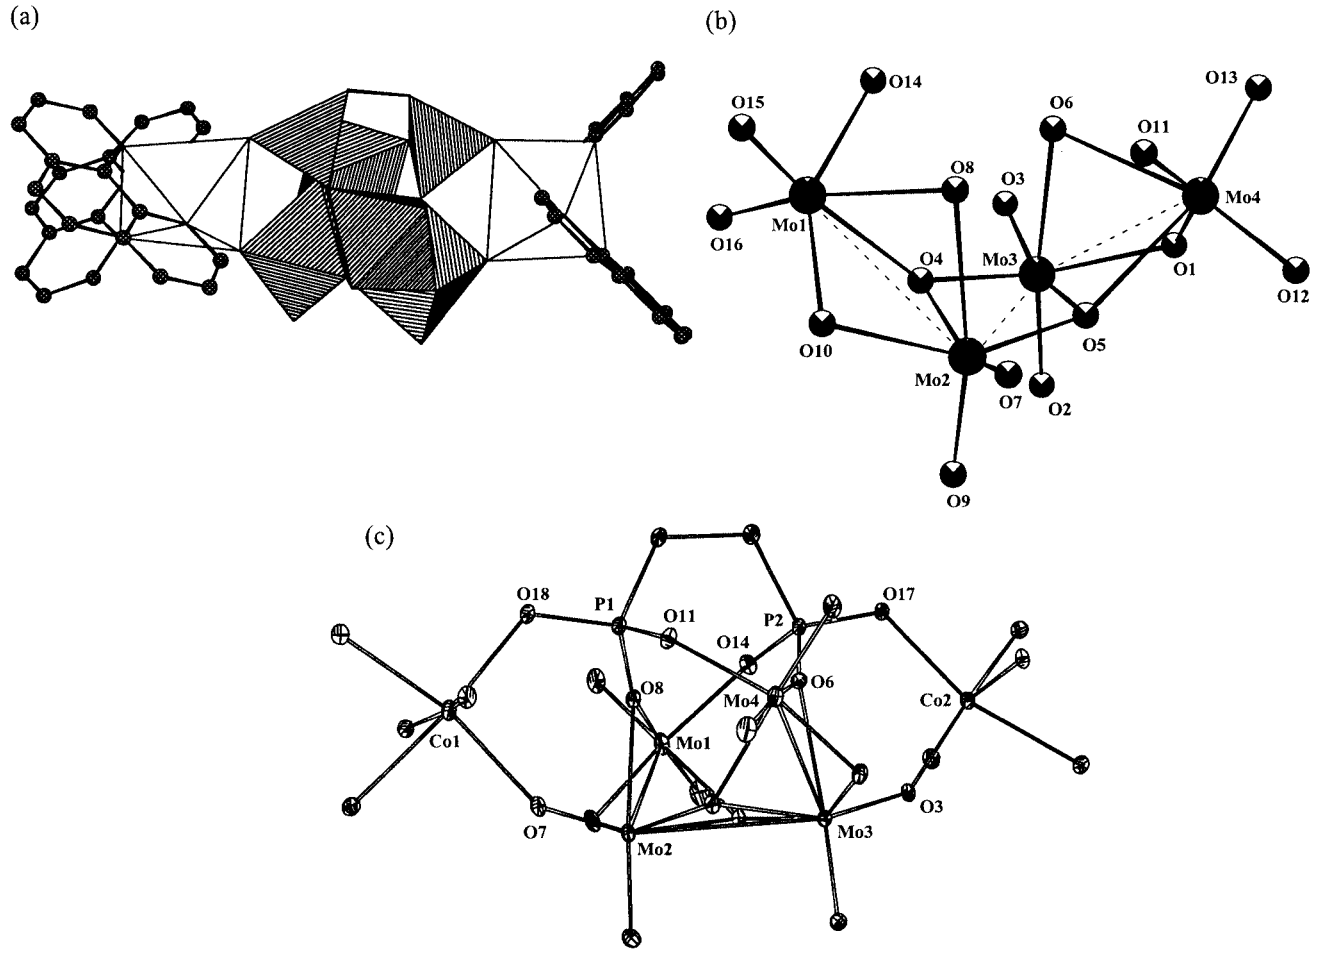

Figure 1. (a) Polyhedron perspective of cluster of **1**; white octahedra: $\{CoN_4O_2\}$; black octahedra: $\{MoO_6\}$; black tetrahedra: $\{PCO_3\}$; hydrogen atoms are omitted for clarity; (b) perspective view of $\{Mo_4O_{16}\}$ motif of **1**; the dotted single lines represent the Mo-Mo bonds; (c) ORTEP view of **1** showing the coordination environments of cobalt, molybdenum and phosphorus (ellipsoids at 10% probability); free water molecules, hydrogen atoms and the carbon atoms of 1,10-phen ligands are omitted for clarity

$\{PO_3\}$ terminus of the 1,2-ethylenediphosphonate group links to one $\{CoN_4O_2\}$ and three different $\{MoO_6\}$ octahedra. The adjacent clusters interact each other through a strong π-π stacking of neighboring parallel 1,10-phen groups at a distance of 3.4−3.5 Å.[6,17,18]

The crystal structure of **2** is almost the same as that of **1** except for the 1,3-propylenediphosphonate ligand (Figure 2).

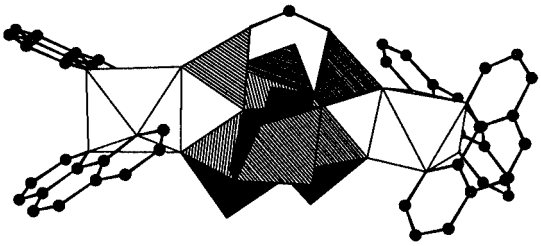

Figure 2. Polyhedron perspective of cluster of **2**; white octahedra: $\{CoN_4O_2\}$; black octahedra: $\{MoO_6\}$; black tetrahedra: $\{PCO_3\}$; hydrogen atoms are omitted for clarity

As expected, the structure of **3** is a linear polymer constructed from an $[Mo_5O_{15}(O_3PCH_2CH_2CH_2CH_2PO_3)]_n^{4n-}$ anionic chain (Figure 3a) and $[Co(1,10\text{-phen})_2(H_2O)_2]^{2+}$ and $[Co(1,10\text{-phen})_2(H_2O)]^{2+}$ fragments (Figure 3b). In the anionic chain, the 1,4-butylenediphosphonate groups bridge the adjacent common $\{Mo_5O_{21}\}$ cyclic clusters.[14,15,19−24] Each $\{PO_3\}$ terminus only coordinates to five Mo^{VI} centers. This is obviously different from $[\{Cu(H_2O)_2(1,10\text{-phen})_2\}\{Cu(1,10\text{-phen})_2\}(Mo_5O_{15})(O_3PCH_2CH_2CH_2PO_3)]\cdot 2.5H_2O$,[14] $[\{Cu(2,2'\text{-bipyridine})_2\}\{Cu(2,2'\text{-bipyridine})(H_2O)\}(Mo_5O_{15})(O_3PCH_2CH_2CH_2CH_2PO_3)]\cdot H_2O$ and $[\{Cu_2(\text{tetra(2-pyridyl)pyprazine})(H_2O)_2\}(Mo_5O_{15})(O_3PCH_2CH_2PO_3)]\cdot 5.5H_2O$.[15] Similar to compounds **1** and **2**, the Co^{II} atoms are also in slightly distorted octahedral coordination geometries with four nitrogen donors from two 1,10-phenanthroline ligands and two oxygen atoms. The $\{Co1N_4O_2\}$ moiety is linked to the anionic chain through an oxo group bridging to the $\{Mo1O_6\}$ octahedron [Co1−O7 = 2.063(5) Å]. While the $\{Co2N_4O_2\}$ octahedron interacts with the anionic chain through hydrogen bonds ($O_{24}\cdots O_{20}$ = 2.703, $O_{23}\cdots O_{18}$ =

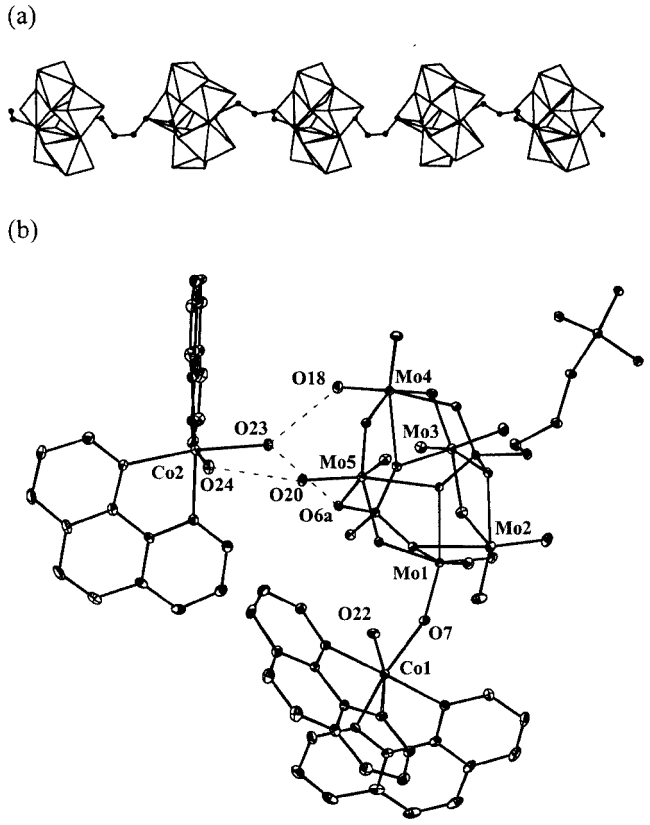

Figure 3. (a) Perspective view of $[Mo_5O_{15}(O_3PCH_2CH_2CH_2PO_3)]_n^{4n-}$ anionic chain of **3**; octahedra: $\{MoO_6\}$; black dots: P and C atoms; hydrogen atoms are omitted for clarity;(b) ORTEP view of **3** showing the coordination geometries of the cobalt, molybdenum and phosphorus atoms (ellipsoids at 10% probability); the dashed lines represent hydrogen bonds; free water molecules and hydrogen atoms are omitted for clarity; symmetry code *a*: $1/2 - x, -1/2 + y, z$.

2.829 and $O_{23}\cdots O_{6a}$ = 2.727 Å). The adjacent chains interact thorough strong π-π stacking of neighboring parallel 1,10-phen groups at a distance of 3.2−3.6 Å.[6,17,18]

Thermogravimetric analysis (TGA) studies were performed on polycrystalline samples under N_2 from room temperature to 1000 °C to study the stability of these compounds. The TGA data show an obvious weight loss starting at about 435 °C for these compounds.

In conclusion, two novel clusters and one linear polymer have been successfully self-assembled under almost identical hydrothermal conditions using $[Co(1,10\text{-phen})_2]^{2+}$ as the metal-organic subunit and organodiphosphonate ligands of different lengths. The structure of **3** differs from **1** and **2**, which may be mainly due to the increased length of the 1,4-butylenediphosphonate ligand.

Experimental Section

1,2-Ethylene-, 1,3-propylene- and 1,4-butylenediphosphonic acids were prepared according to the reported method.[25,26] Other chemicals were of reagent grade quality and obtained from commercial sources without further purification. Compounds **1**, **2** and **3** were synthesized in 25-mL, Teflon-lined, stainless steel vessels under autogenous pressure with a filling capacity of about 40%. The reactants were stirred to homogeneity before heating. CHN analyses were performed with a Vario EL III element analyzer and UV-1100 spectrophotometer. Infrared spectra were obtained on a Nicolet Magna 750 FT-IR spectrometer.

Synthesis

Compound **1**, **2** and **3** were synthesized as red blocks in about 20% (0.1 g), 86.4% (0.357 g) and 40% (0.2 g) yields based on cobalt, respectively, at 180 °C for 48, 144 and 72 h, respectively. Hydrothermal reactions were performed as follows

For **1**: $Co(CH_3COO)_2{\cdot}4H_2O$ (0.1256 g, 0.5043 mmol), $Na_2MoO_4{\cdot}2H_2O$ (0.2408 g, 0.9952 mmol), MoO_3 (0.1446 g, 1.005 mmol), 1,10-phenanthroline·H_2O (0.1999 g, 1.008 mmol), $H_2O_3PCH_2CH_2PO_3H_2$ (0.1955 g, 1.029 mmol) and distilled water (10.0 mL, 555 mmol).

For **2**: $Co(CH_3COO)_2{\cdot}4H_2O$ (0.1254 g, 0.5035 mmol), $Na_2MoO_4{\cdot}2H_2O$ (0.2408 g, 0.9952 mmol), MoO_3 (0.1447 g, 1.005 mmol), 1,10-phenanthroline·H_2O (0.1996 g, 1.007 mmol), $H_2O_3PCH_2CH_2CH_2PO_3H_2$ (0.2010 g, 0.9850 mmol) and distilled water (10.0 mL, 555 mmol).

For **3**: $Co(CH_3COO)_2{\cdot}4H_2O$ (0.1253 g, 0.5031 mmol), $Na_2MoO_4{\cdot}2H_2O$ (0.2419 g, 0.9998 mmol), MoO_3 (0.1435 g, 0.9969 mmol), 1,10-phenanthroline·H_2O (0.1990 g, 1.004 mmol), $H_2O_3PCH_2CH_2CH_2CH_2PO_3H_2$ (0.2182 g, 1.001 mmol) and distilled water (10.0 mL, 555 mmol).

2: $C_{51}H_{41}Co_2Mo_4N_8O_{19.5}P_2$ (1641.5): calcd. C 37.32, H 2.52, N 6.83; found C 37.40, H 2.09, N 6.82. IR (KBr pellet): $\tilde{\nu}$ = 3500vs cm^{-1}, 3062m, 2893w, 1635w, 1624w, 1579m, 1512s, 1495m, 1452w, 1423s, 1342w, 1225w, 1188w, 1111s, 1049vs, 1028s, 987m, 922vs, 899vs, 860w, 847w, 771m, 727vs, 702vs, 629s, 586s, 567w, 523w.

3: $C_{52}H_{58}Co_2Mo_5N_8O_{30}P_2$ (1934.6): calcd. C 32.38, H 3.02, N 5.79; found C 32.21, H 1.68., N 5.74 IR (KBr pellet): $\tilde{\nu}$ = 3500vs cm^{-1}, 3064m, 2943w, 2899w, 2864w, 1624m, 1579m, 1518s, 1495m, 1427vs, 1344m, 1225w, 1188w, 1146m, 1111s, 1034s, 995m, 943vs, 908vs, 870vs, 762s, 727s, 661m, 590m, 563m, 503m.

X-ray Crystallography: X-ray data of single crystals were collected at a temperature of 293 ± 2 K on a Siemens SMART-CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data were reduced and absorption-corrected with the SMART and SADABS software packages, respectively. The structures were solved by direct methods and refined by full-matrix least-squares techniques on F^2 using SHELXTL-97.[27] All non-hydrogen atoms of the three compounds were treated anisotropically. H_1-H_{26} of **1**, all hydrogen atoms of **2** and H_1-H_{30} of **3** were treated geometrically. $H_{1a}-H_{10a}$ of **1** and $H_{1a}-H_{10a}$ of **3** were identified from the difference Fourier map and fixed with isotropic thermal parameters.

Structural Characterization and a New One-Pot Synthesis of *trans*-Chloro(phenyl)bis(triphenylphosphane)nickel(II)

Alexander Zeller,[a] Eberhardt Herdtweck,[a] and Thomas Strassner*[a]

Keywords: Polymerization / Density functional theory calculations / Nickel / Phosphane ligands

trans-[NiCl(Ph)(PPh_3)$_2$], the organometallic precursor for a new class of neutral polymerization catalysts, has been synthesized via a new synthetic route. The previously used alkylaluminum compounds are replaced by zinc dust for the reduction of the nickel(II) salt in the presence of triphenylphosphane forming the intermediate Ni(PPh_3)$_4$. In a one-pot reaction, chlorobenzene then adds oxidatively to the intermediate to form the title compound, which was structurally characterized, in high yields. Its geometry is compared to known structures of the higher homologues of group 10. All complexes adopt a distorted square-planar geometry, but the parent structure shows significantly shorter metal-ligand bond lengths than its Pd and Pt congeners, as expected. Density functional theory calculations (B3LYP/6–31G*) on the full structure are in very good agreement with the solid-state structure.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

In the almost 50 years since the discovery of transition metal catalysis for olefin polymerization by Ziegler and Natta[1–3] a lot of research activities have been directed towards molecular homogeneous catalytic systems. As a result of this research the zirconocenes and other early transition metal catalysts were found to be extremely active in ethylene polymerization after activation by methylalumoxane (MAO),[4,5] but proved quite sensitive to the presence of air, moisture and polar groups.

Over the past years several new, highly active polymerization catalysts of late transition metals have been developed.[6–8] Compared to catalysts containing early transition metals they exhibit a greater tolerance towards functional groups, which is useful for the copolymerization with polar monomers. They also provide the possibility of making polymers with novel branching structures and thereby new materials with unknown properties.

Recently a new class of neutral polymerization nickel(II) catalysts based on salicylaldimine or anilinotropone ligands has been introduced, which are highly active in the polymerization of olefins (Scheme 1).[9–12] Some of them no longer need to be activated, either by MAO or by other phosphane-binding complexes, and show comparable polymerization activities to early transition metal catalysts. They are even capable of forming polymers in aqueous solutions[13] and produce linear to moderately branched polyethylene.

Scheme 1. Neutral nickel(II) polymerization catalysts

The key intermediate and organometallic precursor for the synthesis of this type of catalysts is *trans*-[NiCl(Ph)(PPh_3)$_2$], which has been mentioned frequently in recent patents.[14–18] Herein we report a new one-pot synthesis of this complex with improved overall yield from readily available and inexpensive reagents. The crystal structure was determined for the first time and is compared to its higher group 10 homologues Pd and Pt, as well as to the results of a DFT calculation for the gas-phase structure.

Results and Discussion

Generally, the divalent complexes [MCl(Ph)(PPh_3)$_2$] (M = Ni, Pd, Pt) result from the oxidative addition of chlorobenzene to the corresponding zerovalent tetraphosphane complex. Accordingly, the title compound can be synthesized by addition of chlorobenzene to Ni(PPh_3)$_4$.[19] A previously published synthesis prepared the latter by reduction of Ni(acac)$_2$ with alkylaluminum compounds.[20] The disad-

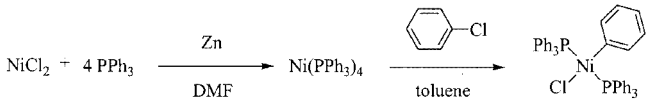
vantage of this reaction is the moderate yield of 55% for the preparation of $Ni(PPh_3)_4$ and the sensitivity of the alkylaluminum compounds.

Another method would be the replacement of weaker ligands, as in the addition of triphenylphosphane to $Ni(COD)_2$, which requires the synthesis of the Ni^0 precursor, usually also carried out by reduction of $Ni(acac)_2$ with trimethylaluminum.[21]

We were able to combine these steps into a one-pot synthesis starting from readily available and inexpensive reagents. The first step is the reduction of $NiCl_2$ by one equivalent of zinc dust in DMF in the presence of triphenylphosphane (Scheme 2), which results in the formation of the brick-red, air sensitive $Ni(PPh_3)_4$.



Scheme 2. Synthesis of *trans*-chloro(phenyl)bis(triphenylphosphane)nickel(II)

After removal of DMF and addition of toluene, chlorobenzene was added to the resulting solution. In a previous study of coupling of aryl chlorides, it was reported that an excess amount of zinc in the first reaction step or higher temperatures lead to the decomposition of the oxidative addition product, forming biphenyl and nickel(II) chloride.[22] To suppress this side reaction we changed the solvent to toluene and used only one equivalent of zinc for the reduction of $NiCl_2$ at a reaction temperature of 0 °C for the oxidative addition. We obtained the yellow complex *trans*-$[NiCl(Ph)(PPh_3)_2]$ in good yield (72%). This is much better than the overall yield which can be reached via the two-step synthesis, where the first reaction step (reduction of a Ni^{II} precursor) proceeds with yields of about 60% and the second reaction step (oxidative addition) with about 71%.[19]

Table 1. Selected bond lengths (Å) and angles (°) for the structure of the nickel complex in comparison to the higher homologues and the results of a DFT calculation at the B3LYP/6−31G(d) level

	Pt[27]	Pd[23]	Ni	DFT (Ni)
M−Cl	2.459(1)	2.407(1)	2.2201(6)	2.28

Ni−C76	–	–	2.900(2)	2.93

Yellow crystals of the title compound were obtained by slowly adding hexane to a saturated solution of the complex in toluene. Surprisingly, the X-ray structure was not known up to now even though the X-ray structures of the higher congeners were determined some years ago. The molecular structure is shown in Figure 1. Important bond lengths and angles are given in Table 1, together with the corresponding values for *trans*-$[PdCl(Ph)(PPh_3)_2]$,[23,24] *trans*-$[PtCl(Ph)(PPh_3)_2]$[25−27] and data from a B3LYP/6−31G(d) calculation of the nickel complex.

All the structures show a slightly distorted square-planar geometry, where the two triphenylphosphane ligands, the phenyl group and the chloro ligand bind to the metal center

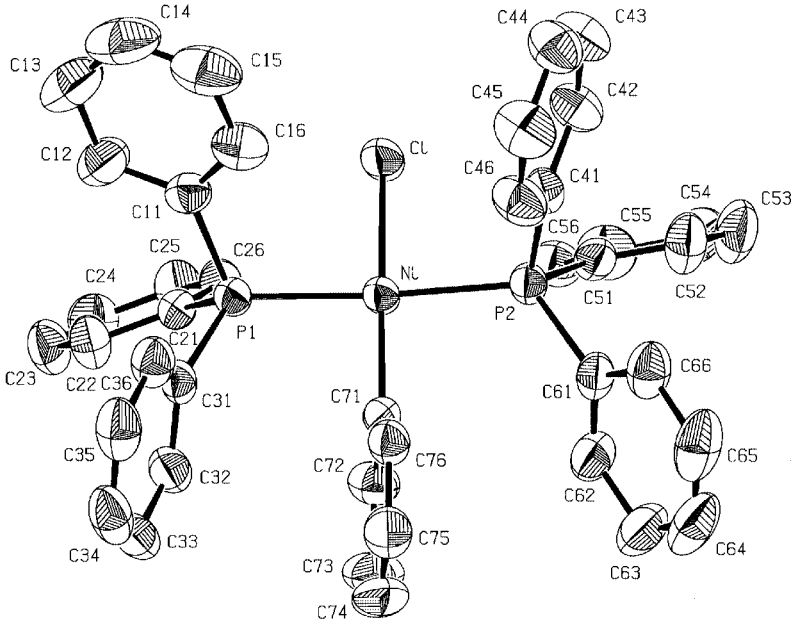

Figure 1. ORTEP representation of *trans*-chloro(phenyl)bis(triphenylphosphane)nickel(II) in the solid state; thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are omitted for clarity

in a trans fashion. The trans position of the chloro and phenyl ligands of the nickel compound was already predicted by Hidai et al., based on the frequency of the Ni−Cl stretching vibration in the IR spectra.[19] The nickel-phosphorus distances are 2.2232(5) Å and 2.2151(5) Å, while the nickel-carbon and nickel-chlorine bond lengths are 1.887(2) and 2.2201(6), respectively. The decrease of the metal-ligand bond lengths compared to the higher homologues is within the expected range. The differences between the palladium and platinum structures are small due to relativistic orbital contraction. In all complexes the two metal-phosphorus bonds are slightly asymmetric. The distortion of the square-planar geometry around the metal center can be seen from the P−M−P and C_{71}−M−Cl angles. The largest distortion from the optimum value (180°) is seen in the nickel structure [169.29(2) and 173.07(6)], and the least distortion in the palladium complex [177.55(2) and 179.81(8)°]. The changes in the angles correspond nicely to the changes in the bond lengths and show the steric interaction between all the ligands. In all structures the steric demand of the chlorine atom forces both triphenylphosphane ligands into an almost eclipsed conformation.[23] This conformation seems to be stabilized by π-π interactions between two phenyl rings of the phosphane ligands and the phenyl ring attached to the metal center, which are in a stacked alignment.

The value for the ipso angle around C_{71} (Figure 1) depends on the electronic nature of the substituent: electron-donating groups lead to a decrease of the ipso angle, while electron-deficient groups lead to an increase.[23] In our case the value of the C_{72}−C_{71}−C_{76} angle decreases, even though nickel is more electron donating than palladium. This trend is also apparent from the ^{13}C NMR spectrum, where the signal of the ipso-C atom is observed at a chemical shift of δ = 148.9 ppm compared to δ = 154.0 ppm in the Pd case, indicating a lower deshielding by the metal center.[23,28] The decrease of the ipso angle can be explained by the stronger interaction of the trans chloro ligand, which can be seen in the shorter bond length. This compensates the higher electronegativity of the nickel center.

The density functional theory calculations at the double-ζ level 6−31G(d) show the quality of the electronic structure methods. Even larger transition metal complexes can nowadays be calculated with reasonable effort within acceptable time. All bond lengths are in excellent agreement with the results of the solid-state X-ray structure and show that even metal complexes with two triphenylphosphane ligands and a total of 81 atoms can be treated.

Conclusion

An important precursor for the new class of neutral polymerization catalysts could be synthesized via a new one-pot synthesis with significantly improved yields. The complex *trans*-chloro(phenyl)bis(triphenylphosphane)nickel(II) was structurally characterized by a solid-state single crystal X-ray structure determination. Density functional theory calculations on the complex show that nowadays even first-row transition metals with large ligands can be calculated and that the results are in good agreement with the solid-state structure.

Experimental Section

General Remarks: All manipulations were carried out under Argon using standard Schlenk techniques. Solvents and chlorobenzene were dried and degassed prior to use. NMR spectra were acquired with a JEOL JNM GX 400 spectrometer. Anhydrous nickel(II) chloride and zinc dust were purchased from Merck; triphenylphosphane was purchased from Aldrich. All reagents were used without further purification.

***trans*-Chloro(phenyl)bis(triphenylphosphane)nickel(II):** In a Schlenk flask, anhydrous nickel(II) chloride (1.30 g, 10 mmol), zinc dust (0.66 g, 10 mmol) and triphenylphosphane (11.02 g, 42 mmol) were suspended in DMF (100 mL). The reaction mixture was heated to 50 °C for 2 h and stirred at room temp. for another 15 h after the formation of a brick-red precipitate. The solvent was then evaporated and toluene (200 mL) was added. After adding chlorobenzene (3.10 mL, 25 mmol) the solution was stirred for 3 h at 0 °C. The color changed to a deep brown. After filtration the solution was concentrated to about 70 mL and hexane (100 mL) was added. A yellow solid precipitated which was isolated by filtration, washed twice with hexane (50 mL) and dried for 24 h under high vacuum (5.01 g, 72%). ^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C): δ = 6.15 (br. s, 2 H, *m*-H of Ni-Ph), 6.24 (br. s, 1 H, *p*-H of Ni-Ph), 6.75 (br. s, 2 H, *o*-H of Ni-Ph), 7.28 (br. s, 12 H, *m*-H of PPh_3), 7.37 (br. s, 6 H, *p*-H of PPh_3), 7.57 (br. s, 12 H, *o*-H of PPh_3) ppm. ^{13}C NMR (100.5 MHz, CD_2Cl_2, 25 °C): δ = 120.7 (s, *m*-C of Ph), 126.4 (s, *p*-C of Ni-Ph), 127.7 (t, $J_{C,P}$ = 5.0 Hz, *m*-C of PPh_3), 129.5 (s, *p*-C of PPh_3), 131.8 (t, $J_{C,P}$ = 21.9 Hz, *i*-C of PPh_3), 134.5 (t, $J_{C,P}$ = 5.8 Hz, *o*-C of PPh_3), 137.4 (t, $J_{C,P}$ = 4.2 Hz, *o*-C of Ni-Ph), 148.9 (s, i-C of Ni-Ph) ppm.[29] ^{31}P NMR (161.8 MHz, CD_2Cl_2, 25 °C): δ = 21.6. $C_{42}H_{35}ClNiP_2$ (695.78): calcd. C 72.50, H 5.07; found C 71.88, H 5.04.

Computational Details: The density functional/Hartree−Fock hybrid model Becke3LYP,[30−33] as implemented in Gaussian 98,[34] was used together with the double-ζ basis set 6−31G(d). The geometry was fully optimized.

X-ray Crystallographic Study: Details of the X-ray experiment, data reduction, and final structure refinement calculation are summarized in Table 2. Crystals suitable for an X-ray structure determination were obtained from toluene/hexane. Preliminary examination and data collection were carried out on a kappa-CCD device (Nonius) at the window of a rotating anode (NONIUS FR591; 50 kV; 60 mA; 3.0 kW) and graphite monochromated Mo-K_α radiation (λ = 0.71073 Å).[35] The unit-cell parameters were obtained by full-matrix least-squares refinement of 6718 reflections. Data collection was performed at 293 K with an exposure time of 20 s per frame (7 sets; 980 frames; phi and omega scans; 1.0° scan-width). A total of 74222 reflections were integrated. Raw data were corrected for Lorentz and polarization effects. If necessary, corrections for absorption and decay effects were applied during the scaling procedure.[36] After merging, a sum of 6378 independent reflections remained, and were used for all calculations. The structure was solved by a combination of direct methods[37] and difference-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Fourier syntheses.[38] All non-hydrogen atoms of the asymmetric unit were refined with anisotropic thermal displacement parameters. All hydrogen atoms were found in the final difference-Fourier maps and refined with isotropic displacement parameters. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_0^2 - F_c^2)^2$ with the SHELXL-97 weighting scheme and stopped at a maximum shift/err of less than 0.001. Neutral-atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for Crystallography*. All other calculations (including ORTEP graphics) were done with the program PLATON.[39]

CCDC-195346 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Rapid and Selective Oxidation of Metallosulfophthalocyanines Prior to Their Usefulness as Precatalysts in Oxidation Reactions

Nicola d'Alessandro,[a] Lucia Tonucci,[a] Mario Bressan,*[a] Luana K. Dragani,[b] and Antonino Morvillo[c]

Keywords: Mass spectrometry / Homogeneous catalysis / Inorganic peroxides / Phthalocyanines / Oxidation

Two metallosulfophthalocyanines, RuPcS and FePcS, used in many catalytic oxidation reactions, were readily oxidized by hydrogen peroxide or monopersulfate, under acidic or neutral conditions in water, to form novel metal complexes derived from the facile oxidation of the PcS ring. Meso-nitrogen-oxide derivatives and metal-biliverdin-like derivatives were identified among the products at early reaction times, whereas at longer times fragmentation of the phthalocyanine ring occurred, with formation of sulfophthalimide and metal complexes containing the resulting tridentate ligand. The oxidative degradation of the MPcS complexes has been investigated by ESI-MS, UV/Vis-NIR and ^{1}H, ^{13}C and ^{15}N NMR spectroscopy. These rapidly formed, coordinatively unsaturated complexes represent the dominant species in oxidizing media, at least in the case of the Ru derivative, and must be the real catalyst precursors in previously published oxidation reactions using MPcS complexes. The oxidative degradation reactions occurred with selective mono-denitrogenation of one meso-nitrogen atom and formation of ammonia, thus recalling the celebrated selective degradation of heme to verdoheme and/or biliverdin and CO.

Introduction

Metalloporphyrins and -phthalocyanines are close structural and functional models for the ubiquitous mono-oxygenase or peroxidase heme enzymes, of principal importance on a global scale for the oxidation of xenobiotics in biological systems. Metalloporphyrins are often very effective systems for the catalytic oxidation of a variety of organic substrates, including alkanes, alkenes and aromatic hydrocarbons.[1] Metallophthalocyanines, despite their cheap and facile preparation, have been studied much less intensively as oxidation catalysts, the main drawback being their extensive insolubility in common organic solvents, which considerably limits the scope of the investigations.[2] Introduction of suitable substituents at the periphery of the molecule can make the metallophthalocyanine complexes soluble, and therefore, suitable for homogeneous catalysis; in this context, tetrasulfonated metallophthalocyanines MPcS (**1** in Scheme 1) are of particular interest, since they make possible catalysis in aqueous media,[3] an obvious green alternative to organic solvents.[4] During the last decade, iron or manganese sulfophthalocyanines have been successfully employed by Meunier et al. for the oxidative dechlorination of chlorophenols[5] and the oxidation of other organic substrates[6] in the presence of hydrogen peroxide and mono-persulfate.

We have also reported on the catalytic activity of ruthenium sulfophthalocyanine, with particular regard to the oxidation of chloro-organics[7,8] and alcohols,[9] and, more recently, of cyclohexanone, cyclohexanol or cyclohexane to adipic acid with hydrogen peroxide and mono-persulfate.[10] During these studies, we become aware that, contrary to common belief, the metallophthalocyanine core does not possess an intrinsic chemical stability in oxidizing media, even under very mild conditions. Indeed, among the few reports found in the literature, we can quote only two examples where the macrocycle is reported to undergo a facile oxidative cleavage in the presence of either oxygen (and sulfite as the sacrificial reductant)[11] or *tert*-butyl hydroperoxide.[12] Many of the MPcS complexes examined during our studies, and particularly the catalytically active ones, were found to be extremely sensitive to oxidants, such as hydrogen peroxide or mono-persulfate, giving rise to dramatic changes in their physical properties, and thus, truly behaving as pre-catalysts. These observations prompted us to conduct a spectroscopic study in aqueous solution, focused on defining the fate of a selected choice of metallosul-

fophthalocyanines, and the nature of the metal species formed during their mild oxidation by hydrogen peroxide or mono-persulfate.

Results and Discussion

General

The MPcS complexes (M = Fe, Ru and Cu) dissolved in water in the 1−50 mM concentration range were treated with various amounts of H_2O_2 or oxone (from 0.5 to 10 equivalent per mol) in acidic or neutral media and at room temperature. The electronic spectra (300−1500 nm) of the starting MPcS complexes show the diagnostic Q bands in the 620−670 nm region, which arise from the $\pi \rightarrow \pi^*$ transition within the heteroaromatic ring (Table 1). The intensely green/blue solutions became rapidly yellow/colorless (M = Fe and Ru) in the presence of an excess (≥10-fold) of oxidants, with complete disappearance of the corresponding Q band. In most cases, a series of distinct steps could be recognized during the oxidation of the MPcS complexes, leading to the formation of a number of intermediate products, which could be characterized spectroscopic ally. In strongly alkaline media (pH 13), the MPcS complexes, or more likely their hydroxo- and/or oxo-bridged derivatives, are almost insensitive to the oxidizing media, except RuPcS, for which, in the presence of $KHSO_5$ (but not of H_2O_2), a very slow decoloration was observed. The rate of the transformations depends upon the nature of the central ion. The CuPcS complex was found to be completely insensitive to the oxidation, even in acidic media.

The oxidation reactions were followed by ^1H and ^{13}C NMR spectroscopy with the aim of characterizing the metal species resulting from the oxidative degradation. We also recorded the ^{15}N NMR spectra of ^{15}N-RuPcS, but no signals were observed that were attributable to either meso- or metal-coordinating nitrogen atoms, in agreement with literature data, which often report insignificant ^{15}N NMR

Table 1. Visible spectra of MPcS complexes

Compound	λ_{max}, nm (ε_M)[a]
FePcS	634 (40000)
CuPcS	624 (48000)
RuPcS	638 (26000)

[a] 3.33 μM aqueous solutions at pH 7 (phosphate buffer 0.2 M); the experiments were repeated at pH 2 (H_2SO_4 0.01 M), pH 9 (borate buffer 0.2 M) and pH 12 (NaOH 0.01 M) with no appreciable changes.

spectra for non-symmetrical nitrogen-containing compounds, even if labeled 100%.[13]

ESI-MS spectra, exhibiting the diagnostic isotopic patterns of the metal derivatives, offered the possibility of distinguishing between the metal-containing and purely organic species, and also between monomeric and oligomeric metal-containing species. Quite unexpectedly, the ESI-MS spectra gave clear indications, in all examined cases, of the corresponding molecular ions, when conducted in the positive-ion mode; various sodium-containing clusters, replacing the protons up to complete substitution, were also observed, especially at higher cone voltages (see Exp. Sect.). Under these conditions, peaks at −80 and sometimes at −160 amu were detected, indicative of a loss of SO_3. Clearly, cleavage of the S-benzene bond occurs to give the corresponding trisulfophthalocyanine derivative [M − 80], although the S-aromatic bond was not as easily cleaved as the S-aliphatic analog; the fact that this fragmentation was observed only at very high cone voltages suggests strongly that this event is an example of collision induced dissociation (CID).[14]

All attempts to isolate solid compounds from the oxidized reaction mixtures were unsuccessful and evaporation in vacuo resulted in intractable waxy solids, which did not yield solid materials.

RuPcS

RuPcS is diamagnetic both in the solid state (Gouy's method) and in aqueous solution (Evans' method), in agreement with a low-spin configuration of ruthenium(II) (d^6). The visible spectra in water show the diagnostic Q band at 638 nm, and also exhibit a definite shoulder, at higher energies, indicative of aggregation in aqueous solution.[15] The intensely green solutions of RuPcS become rapidly yellow in the presence of oxone or H_2O_2, with complete disappearance of the Q band, whereas no other absorptions are detected in the visible or in the near infrared regions, up to 1500 nm, which represents the upper wavelength for aqueous solutions containing peroxides. Simple demetalation, a rare event for metallophthalocyanine complexes,[16] can be ruled out on the basis of direct experiments, since the UV spectra of an organic phase, purposely added to the reaction mixtures, do not exhibit the absorptions at 310 and 385 nm that are diagnostic for RuO_4, the expected dominant species for free ruthenium in acidic oxidizing media. The diamagnetism of the aqueous solutions of the starting RuPcS complex is maintained in the presence of excess of oxidant, whereas the ^{1}H NMR spectra, showing for the starting RuPcS only a broad signal in the δ = 8 ppm region, exhibit well resolved signals at δ = 8.1 and 7.9 ppm upon oxidation, clearly indicative of the expected AMX patterns of the 1,2,4-aromatic proton system, thus suggesting extensive removal of the strong intermolecular interaction occurring in polar media (stacking) that is probably responsible for the broad NMR signal.

The ^{1}H NMR spectra of the acidic reaction mixtures with mono-persulfate also exhibit three more signals, centered at δ = 7 ppm (J = 51 Hz), which, in the case of the ^{15}N-RuPcS derivative, were replaced by a doublet with $J(^1H\text{-}^{15}N)$ = 74 Hz; significantly, the ^{15}N NMR spectra (DEPT-45) exhibit five signals centered at δ = −360 ppm, having the same $J(^1H\text{-}^{15}N)$ reported above. These findings are diagnostic of the presence of ammonium ions, which, on the basis of the measured intensity ratios between benzene and ammonium protons, are found in a 1:1 molar ratio with the regards to the complex, even after longer reaction times (Table 2). Hydrogen peroxide in acidic media behaves similarly, giving rise to the ^{1}H NMR signals of the ammonium ion. In this case, however, because of the presence of oxygen, continuously formed upon dismutation of the oxidant, quantitation of the ammonia produced was performed with an ion-selective electrode; again, the quantity of ammonia never exceeded the 1:1 molar ratio (Table 2).

Table 2. Production of ammonia by oxidation of MPcS complexes

Compound	Time, h	NH_4^+ produced	
		$KHSO_5$[a]	H_2O_2[b]
RuPcS	1	1.1	1.1
	18	1.1	1.03
FePcS	1.5	n.d.	0.45
	16	n.d.	0.73
CuPcS	16	0	0

[a] mol/mol of MPcS; ^{1}H NMR measurements. Reaction conditions: aqueous solution of MPcS, 1 mM, and $KHSO_5$, 0.5 M; pH ca. 2; 20 °C. [b] mol/mol of MPcS, electrochemical measurements. Reaction conditions: aqueous solution of MPcS, 1 mM, and H_2O_2, 2 M; pH ca. 2 (H_2SO_4); 20 °C.

It should be noted that the oxidation appears to be highly selective, involving only one of the eight nitrogen atoms of the macrocycle: further treatment of the oxidized RuPcS complex with sodium hydroxide under strongly alkaline conditions and refluxing led to complete denitrogenation of the compound, with formation of ammonia in the expected 8:1 molar ratio. The oxidative denitrogenation of amines to ammonia is a known process in biochemistry, where it is catalyzed by amine oxidase, a non-heme copper-containing enzyme, and is also reported to occur in the presence of a biomimetic copper complex.[17]

The ^{13}C NMR spectrum of the RuPcS complex (60 mM) shows the expected eight signals, which arise from the three tertiary [δ = 121, 125 and 132 ppm (aromatic CH carbons)] and the five quaternary carbon atoms [δ = 133 and 135 ppm (β-C with respect to N); δ = 144 ppm (sulfonate-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bonded carbon); δ = 174 and 179 ppm (α-C)]. The oxidized solutions exhibit closely related eight-signal ^{13}C NMR spectra, whose differences in chemical shift from the untreated samples are scarcely significant, although they do confirm the integrity of the organic backbone. Also, 3-sulfophthalimide exhibits a related ^{13}C NMR spectrum (see Exp. Sect.), with almost imperceptible differences in the positions of each signal, including those from the α-C's, and is therefore independent of the nature of the bonded heteroatoms (oxygen or nitrogen).

The ESI spectra of RuPcS were found to be highly sensitive to the applied cone voltage, thus making the interpretation of the data complicated (Figure 1). Under medium cone voltage (50−100 V), the penta-protonated species $Ru^{II}PcSH_5^+$ (*m*/*z* = 935), showing the diagnostic isotopic (metal) pattern of the monomer, is the dominant species (Figure 2). By further increasing the applied voltage, and therefore under very drastic conditions, significant changes of the fine structure of the signal were observed, with the peak at *m*/*z* = 934 (−1 amu) gaining intensity and thus pointing to the formation of the $Ru^{III}PcSH_4^+$ species, produced in the capillary tip upon the one-electron oxidation of the central metal ion. At lower cone voltage (5−50 V), the main feature is the appearance of a new species that is still monomeric, but with *m*/*z* = 969. This species becomes dominant at very low voltage; the observed *m*/*z* value fit with a Ru^{IV} species, such as $Ru^{IV}(OH)_2PcSH_5^+$, which might arise from an oxidation in the capillary tip, is rather surprising because it occurrs under such mild conditions. The ^{15}N-RuPcS complex gives the expected ESI signal at *m*/*z* = 943, i.e. +8 amu with respect to the unlabelled derivative, and at lower voltage than the above Ru^{IV} species at *m*/*z* = 977−979 (the presence of small amount of ^{14}N in the labeled compound led to some loss of the conventional isotopic pattern of ruthenium).

Upon treatment with the oxidants, a series of distinct intermediate species could be detected by ESI-MS spectra. At low oxidant-to-metal ratios (ca. 1:1), a new signal appears at *m*/*z* = 951 − an increase of 16 amu with respect to the starting species − that still retains the diagnostic isotopic pattern of the monomer; the ^{15}N-RuPcS derivative behaves similarly, leading to the appearance of an ion at *m*/*z* = 959.

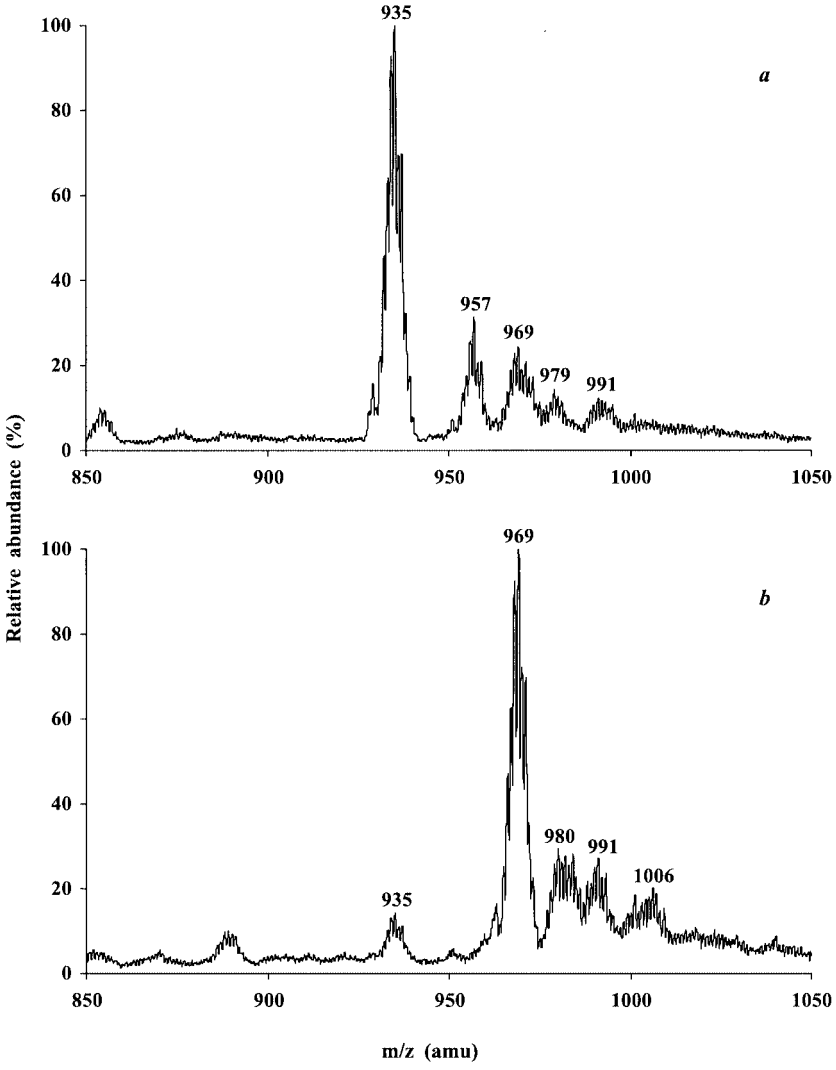

Figure 1. ESI-MS spectra of aqueous 5 mM solution of RuPcS, at high (150 V) (a) and low (30 V) (b) cone voltage

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

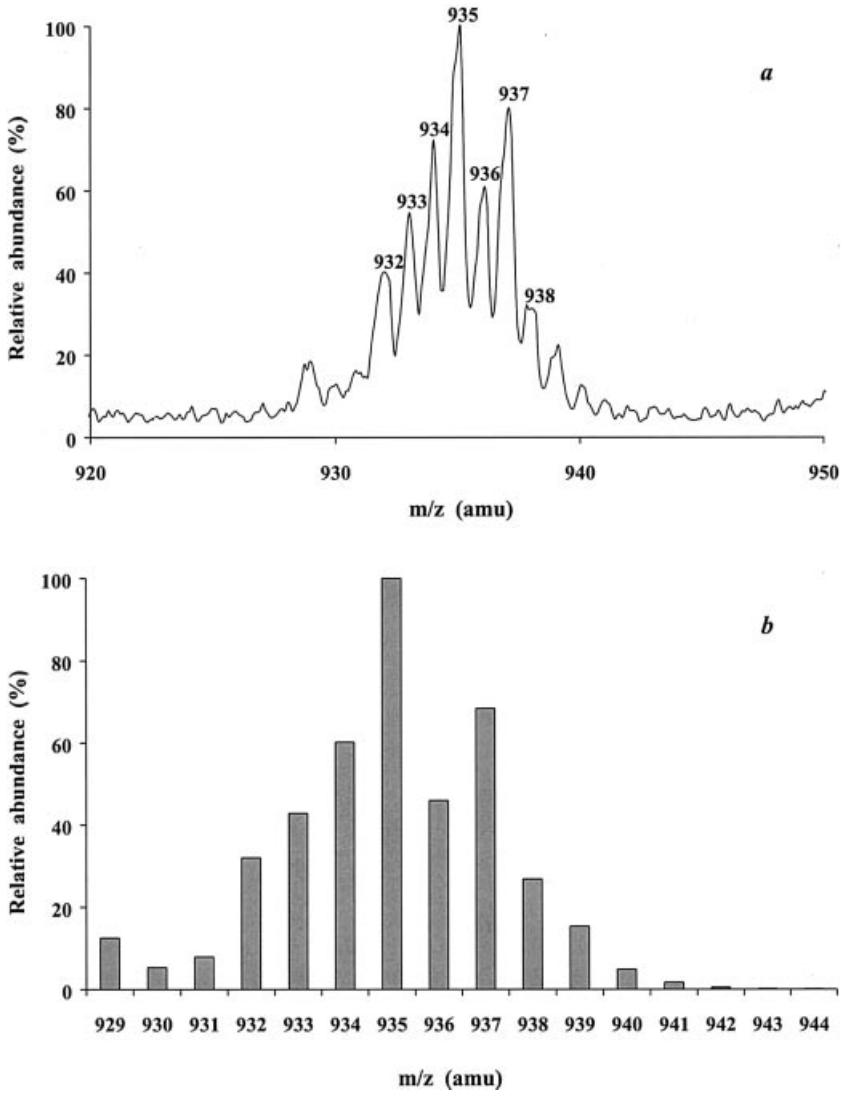

Figure 2. Fine structure of m/z = 935 peak of RuPcS (50 V) (a) vs. calculated isotopic pattern (b)

As in the case of the starting RuPcS discussed above, these signals are replaced at lower voltage by a signal at m/z = 985 (993 for the labeled derivative), again attributed to oxidation of the complex at the capillary tip. Both signals could be detected in the ESI spectra, when the measurements were performed at intermediate voltage, in order to achieve maximum sensitivity (Figure 3). The species detected at m/z = 951 (959 for ^{15}N) and clearly incorporating one oxygen atom, can be attributed to either an oxometal derivative Ru^{IV}(O)PcS or, more likely, a complex with a mono-oxygenated ligand, where the metal is still in a lower oxidation state, for example a Ru^{II}PcOS species (**2a** in Chart 1), where PcOS is the mono-nitrogen-oxide derivative in the meso position of the PcS ligand. An immediate explanation for the ready formation of the nitrogen-oxide derivative could be provided by the conventional chemistry of nitrogen-containing heteroaromatics towards inorganic peroxidic reagents.[18] However, the fact that some of the MPcS derivatives, such as CuPcS, are totally resistant to the oxidative treatment, suggests a direct involvement of the central metal atom in the oxygenation process, rather than an uncatalyzed attack by the peroxidic oxidant on a meso-nitrogen atom of the PcS ring. Under this hypothesis the oxygenation of a meso-nitrogen is highly reminiscent of the first step of the oxidation of heme (to hydroxyheme).[19]

Upon addition of further oxidant to RuPcS (up to 10:1), a fast and almost complete disappearance of the oxygenated species occurred; the ESI-MS spectra shows the presence of strong signals both at higher (m/z around 1003, 1022 and 1040) and lower molecular weights (m/z around 778, 796, 814 and 833), most of them apparently lacking the diagnostic isotopic pattern of ruthenium and possibly indicating the presence of closely related ions differing by a few amu. At longer reaction times, only the species with lower molecular weights were observed (Figure 3). ^{15}N-RuPcS behaved similarly, leading to the formation of ions with m/z centered at ca. 1010, 1030 and 1048 and at 784, 802, 817 and 838 amu. A direct comparison of the masses of the ions from the ^{14}N or the ^{15}N samples might make possible, in principle, an evaluation of the nitrogen content of the various species; unfortunately most of the signals did not exhibit the standard isotopic pattern of ruthenium, and therefore the exact

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

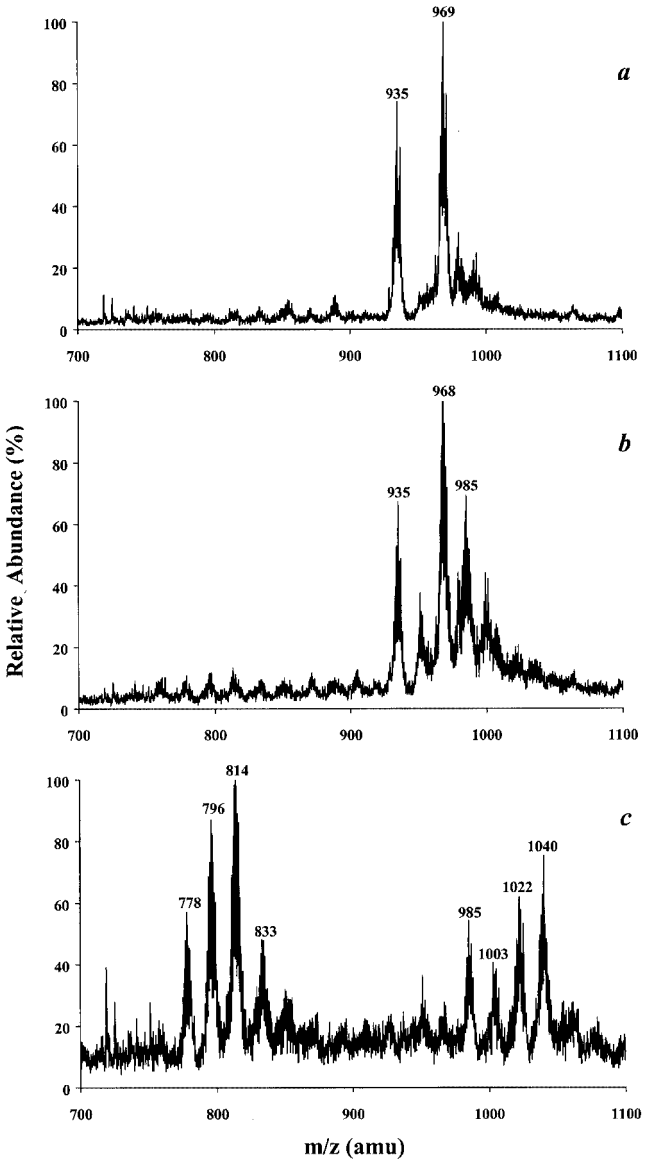

Figure 3. ESI-MS spectra of aqueous 5 mM solution of RuPcS (50 V) (a) and after addition of $KHSO_5$: in equimolar amount (50 V) (b) and twofold molar excess (50 V) (c); (in both cases reaction time 10 min)

masses were too uncertain to allow unequivocal conclusions. The intermediate species around *m*/*z* = 1003, 1022 and 1040 (1010, 1030 and 1048 for the ^{15}N-labeled derivative) were tentatively attributed to the aqua clusters (mono-, di- and tri-) of ions from compounds **3a** or **4a**, i.e., dioxoruthenium(VI) complexes with biliverdin-like ligands, either containing all the starting nitrogen atoms or lacking one of them, respectively; on this basis, the corresponding non-aquated cations might come at *m*/*z* = 985 and 986, respectively (992 and 993 for the ^{15}N-labeled derivative), and are therefore superimposed on the species formed in the initial stages of the reaction and discussed previously. Biliverdin- and verdoheme-like derivatives of phthalocyanines have been reported in the literature, although they were prepared upon photolysis of a triazatetrabenzocorrole and not directly from a phthalocyanine ring;[20] significantly, these derivatives were reported to lack not only the diagnostic Q-band, but also other absorptions of comparable intensity, and are thus in agreement with the observed quenching of the $\pi\rightarrow\pi^*$ bands in oxidized RuPcS complexes. The peaks at *m*/*z* = 778, 796, 814 and 833 (784, 802, 817 and 838 for the ^{15}N-labeled derivative) fit well with a series of aquated cations (from none to three molecules of water) from compound **6a**, i.e., a dioxoruthenium(VI) complex of a tridentate ligand formed upon fragmentation of the PcS ring (Scheme 1). Accordingly, the resulting organic fragment 3-sulfophthalimide (**5**) was detected as a single peak at *m*/*z* = 228 (positive ionization mode; 229 for the ^{15}N-labeled derivative) or at *m*/*z* = 227 (negative ionization mode); an original sample of the compound exhibited the same spectral behavior. One molecule of ammonia was also produced, during either the first or the second step (Scheme 1); to the best of our knowledge, fragmentation of a phthalocyanine ring with production of ammonia has never been reported.

FePcS

In the presence of small amounts of added mono-persulfate or hydrogen peroxide (1:1 molar ratio), a distinct shift of the Q-band of FePcS towards lower energies was observed, whose blue solutions (λ_{max} = 634 nm) turned green (λ_{max} = 670 nm; Figure 4) and finally, in the presence of increasing amounts of the oxidant (10-fold), almost colorless. The oxidized solutions became paramagnetic almost immediately (Evans' method), whereas, and quite surprisingly, the starting paramagnetic (Gouy's method) iron(II) (d^6) derivative,[21] was apparently diamagnetic by Evans' method, once dissolved in water. If it is conceivable that the expected strong stacking of the MPcS moieties occurring in the aqueous solutions does not allow reliable measurements of the magnetic moments by the Evans method, the fact that the oxidized complex was found to be clearly paramagnetic also points to an extensive removal of stacking upon oxidation. The benzene protons were still observed as a large unstructured signal at δ = 8−10 ppm (^1H NMR spectra), but most significantly, and as in the ruthenium case

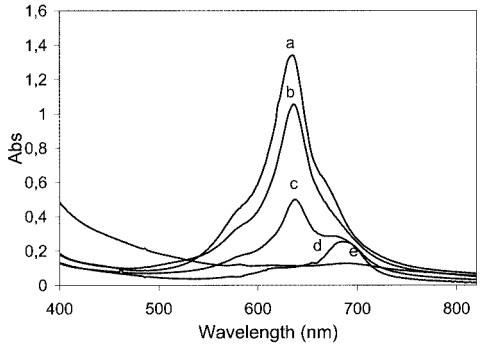

Figure 4. Vis spectra of aqueous 3.33 μM solution of FePcS (a) and after addition of $KHSO_5$: in equimolar amount (b); threefold molar excess (c); fourfold molar excess (d); 10-fold molar excess (e). In all the experiments no difference was observed between 1 and 10 minutes of wait before the recording, following the dilution, of the spectra

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

discussed above, ammonia was produced upon oxidation, again, at least with hydrogen peroxide, in a 1:1 molar ratio with the metal (Table 2). In the presence of oxone the ammonia signals were also clearly detected by ^{1}H NMR spectroscopy, although accurate quantitation was not possible neither by NMR measurements, because of the paramagnetism of the solution, or by electrochemical measurements, since the selective ion electrode requires a constant ionic strength. Furthermore, in the presence of increasing amounts of the oxidants (10-fold), almost colorless solutions were obtained.

The oxidized solution showed, even during the early stages of the reaction, the complete disappearance of the ESI-MS signal (positive pattern) of the starting complex at m/z = 888 and the diagnostic isotopic pattern of an iron monomer, which corresponds to a $Fe^{III}PcSH_4^+$ ion, probably because of an easy oxidation of iron(II) to iron(III) in the capillary tip of the spectrometer. However, and unlike RuPcS, no important peaks were detected in the ESI spectra of the oxidized solutions, although the visible spectra gave clear evidence of transformation products: instead, only very weak and confusing signals were observed in the 700−750 and 500−550 amu regions, even under milder ionization conditions, together with sharp signals at m/z = 228 and 250, clearly attributable to sulfophthalimide (**5**) and the corresponding sodium cluster. These results suggest a very fast and extensive fragmentation of the oxidation products, indicative of a high sensitivity of the system either to the ionization conditions or to the chemical oxidation itself.

Conclusions

The most important finding in these experiments is that it is clearly evident that the rapid and irreversible oxidative degradation of the MPcS complexes studied with H_2O_2 or mono-persulfate occurs under very mild conditions, and prior to any role as precatalysts for oxidation reactions. A mechanism is tentatively proposed, involving the initial formation of oxidizing metal species in higher oxidation states, followed by a selective intra- (or inter) molecular attack at one meso-nitrogen atom of the phthalocyanine ring, with formation of a mono N-oxide derivative (compound **2**). As a consequence of the disruption of the aromaticity of the PcS macrocycle, a facile hydrolysis can be envisaged with ring opening and production of ammonia (compounds **3** and **4**). These biliverdin-like complexes then undergo further oxidative fragmentation, with loss of sulfophthalimide (detected) or 3-iminosulfoisoindoline (not detected), to tridentate ligands (compound **6**) that are still coordinated to the metal ions. It is fairly conclusive that this event results in the in situ formation of coordinatively unsaturated metal complexes, now thought to be candidate precatalysts for the oxidation reactions previously reported.[5a,7] Although the efficacy of each precatalyst also depends upon the intrinsic reactivity of the metal species towards the specific substrate, it is interesting to note that the different catalytic behaviors of the two MPcS complexes strictly reflect the degree of degradation in the oxidizing media. RuPcS gave rise to relatively long-lived coordinatively unsaturated metal species and was indeed shown to be an effective and efficient precatalyst in the $KHSO_5$ oxidation of caprolactone to adipic acid; in contrast, FePcS, which underwent fast and extensive demetalative fragmentation, provided to be a far less effective catalyst.[10] The fast and quantitative transformation of the MPcS complexes into catalytically active species, when in oxidizing media, could be a new paradigm for the general behavior of related classes of metallomacrocycles in oxidation catalysis.

Experimental Section

General Procedures: The reactions were typically carried out at 20 °C in a 5 mL vial, by stirring magnetically 2 mL of an aqueous solution containing the complexes (0.1−10 mM) and suitable amounts of H_2O_2 or $KHSO_5$ (from 0.5:1 to 10:1). Ammonia analysis was performed electrochemically (Orion, model 420A) with an ion-selective electrode (Orion, model 95−12; a glass electrode with a gas diffusion membrane); calibration curve was performed by a 1 M solution of NH_4Cl.

Materials: RuPcS[8] was prepared by template synthesis starting from $RuCl_3{\cdot}3H_2O$, sodium 4-sulfophthalate and urea, following early general procedures for the synthesis of metallosulfophthalocyanines.[21] The ^{15}N-RuPcS derivative was prepared similarly, starting from commercially available ^{15}N-urea (99% isotopic purity, Isotec Inc.). $FePcS{\cdot}3H_2O$ (monosodium salt) and CuPcS (tetrasodium salt) were purchased from Aldrich.

NMR Measurements: NMR spectra were recorded on a Bruker Avance 300 MHz (Karlsruhe, Germany) equipped with a BBO 5 mm probe; the frequencies of the observed nuclei were 300.13, 75.47 and 30.42 MHz respectively for ^{1}H, ^{13}C and ^{15}N. In the case of ^{1}H spectra a water suppression (Bruker made − zgcppr) pulse sequence was used; in addition a reference consisting of a co-axial capillary, inside the NMR tube, filled with a 30 mM D_2O solution of the sodium salt of 3-(trimethylsilyl)propionic acid-2,2′,3,3′-d_4 (TSP) was used.

FTIR spectra were acquired on a Perkin−Elmer Spectrum 2000 equipped with an MIR source and a MIR-TDGS detector; to record the spectra the samples were suspended in anhydrous KBr pellets; spectral width, for all the experiments, was 5000−370 cm^{-1}.

Vis spectra was carried out on a Perkin−Elmer Lambda 2 series 3300; the spectral window was 350−800 nm.

ESI-MS Measurements: The HPLC apparatus used was a Perkin−Elmer series 200 quaternary pump system (Norwalk, CT, USA). Analyses were performed at room temperature using a reversed phase Supelcosil LC-PAH column (250 × 4.6 mm; 5 μm) purchased from Supelco (Bellefonte, PA, USA). Samples were automatically injected using a Perkin−Elmer series 200 autosampler (thermostatted at 4 °C) with a 20 μL injection-loop. Isocratic separations were carried out using a mobile phase consisting of methanol (50%) and water (50%), both with 0.5% of formic acid at the flow rate of 200 μL/min. The HPLC system was connected to a Perkin−Elmer mod. 785A UV/Vis detector (Norwalk, CT, USA) set at the wavelength 280 nm and then to a PE Sciex Turboionspray source (2.1 L/min NEB gas). Acquisitions were carried out in positive ion mode over the mass range 700−1100 amu (or

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

100−1500 amu when the detection of 3-sulfophthalimide was necessary), using a step size of 0.1 amu and a dwell time of 0.350 ms. The nebulizer gas (air) and the curtain gas (N_2) flows were set at 1.7 L/min and 2.7 L/min, respectively. The ionization voltage was set at +5200 V and the orifice and ring potentials were normally set at +50 V and +280 V, respectively; higher and lower voltage condition are referred to orifice potentials varied between 5 and 180 V and ring potentials between 100 and 360 V. Instrument control and data acquisition were performed with Macintosh System 7600/132 (Apple, Copertino, CA, USA) using Masschrom 1.1.1 software (PE Sciex, Foster City, CA, USA). The Mass Spectrometer was calibrated with polypropylene glycol (PPG) obtained from PE Sciex and the resolution was set in the range 0.6−0.8 amu.

Magnetic Moments Measurements: Magnetic moments were measured by Gouy's method (solid state) or Evans' method, performed as follows: a coaxial NMR tube (5 mm i.d.) was filled with a 0.31 M solution of *tert*-butanol in D_2O (tube) and with a 0.31 M solution of *tert*-butanol also containing ca. 30 mM of the MPcS complexes in D_2O (external capillary); the calculations for the susceptivity were performed according to the literature.[22]

Synthesis of 3-Sulfophthalimide (5): 3-Sulfophthalic acid (30 g, 0.122 mol) was heated at 150 °C in vacuo for 3 h; after cooling, urea (3.6 g, 0.06 mol) was added under nitrogen atmosphere and the mixture heated again to 130 °C until evolution of gas had finished (yield: 2.5%). ^{1}H NMR (300.13 MHz, D_2O, 25 °C: δ = 8.08 (d, 1 H, 1-CH), 7.93 (dd, 1 H, 3-CH), 7.77 (d, $J_{3,4}$ = 7.9, $J_{1,3}$ = 1.7 Hz, 1 H, 4-CH) ppm. ^{13}C NMR (75.47 MHz, D_2O, 25 °C): δ = 126.4, 129.1, 129.7 (CH); 132.4, 135.4 (β-C); 145.4 (sulfonate-C); 171.0, 172.0 (α-C) ppm. IR (KBr film): double peak at $\tilde{\nu}$ = 1714−1738 cm^{-1} (C=O). $C_8H_5NO_5S{\cdot}2.5H_2O$ (272.2): C 36.03, H 3.68, N 5.17, S 11.76; found C 35.14, H 3.16, N 5.16%, S 12.46.

A New Concept for the Efficient Synthesis of Chiral Phosphorus−Nitrogen−Carbon Cage Compounds

Nils Hoffmann,[a] Catleen Wismach,[a] Ludger Ernst,[b] Hans-Martin Schiebel,[b] Peter G. Jones,[a] and Rainer Streubel*[a]

Keywords: Azaphospholes / Phosphorus / Cage compounds / Tungsten / Cyclization

A new concept for the efficient synthesis of a chiral phosphorus-nitrogen-carbon cage-compound is reported, which is comprised of a high-yield three-step procedure starting from a *P*-Cp*-substituted 2*H*-azaphosphirene complex. Thermolysis of a solution of the latter complex in the presence of Ph_3PNCN and DMAD afforded the *P*-Cp*-substituted 2*H*-1,2-azaphosphole complex **11** in a clean reaction; a further reaction at 75 °C with DMAD produced complex **12** via an *intermolecular* Diels–Alder reaction of the Cp* group. A subsequent *intramolecular* Diels–Alder reaction of **12**, at 120 °C, yielded the title compound, complex **13,** in quantitative yields. Elemental analyses and detailed (solution) NMR spectroscopic and MS investigations confirmed all complexes. Furthermore, solid state structures of complexes **11** and **13** were established by X-ray single crystal structure analyses.

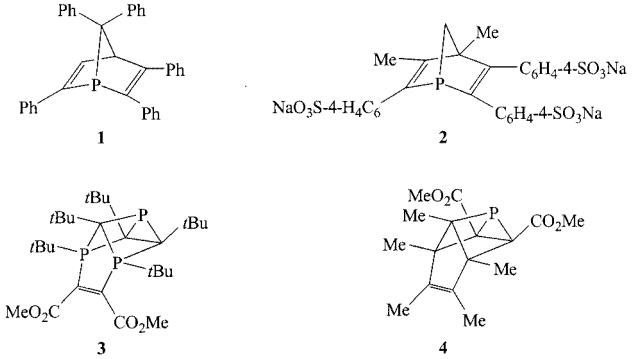
Introduction

The development − or better, constant search − of new and effective synthetic methods of rigid chiral trivalent phosphorus(III) compounds, which might offer improved performance in asymmetric catalysis, is one of the current challenges in Organophosphorus Chemistry, as pointed out recently by Mathey.[1] Early findings by Shell scientists in 1966 showed that cyclic phosphanes perform better in hydroformylation processes than tributyl-phosphane.[2] Burk[3] then showed in 1990 that phospholane-based C_2-symmetric chelating ligands, dubbed as DuPHOS, are important in the catalytic hydrogenation of functional alkenes. Mathey[4] and Réau[5] reported the use of the 1-phosphanorbornadiene **1**, obtained by [4+2] cycloaddition reactions of a transient 2*H*-phosphole and tolane,[6] in hydrogenation[4] and hydroformylation[5] reactions. The same ligand system was modified by Herrmann and co-workers and introduced as NORBOS **2** in the biphasic hydroformylation of propene.[7] It was Mathey again, who developed BIPNOR[8] as a new bidentate ligand and employed it e.g. in the asymmetric isomerization of a cyclic diene, in which it proved to be far superior to BINAP.[9]

In view of this background and the great variety of established structures of polycyclic phosphanes[10] and phosphorus-carbon cage compounds[10,11] with a ring junction phosphorus atom, it is surprising − at first sight − that studies of their use as cocatalysts have remained scarce. The problem is that most often their synthesis relies, at one stage or another, on the employment of phosphaalkyne derivatives, which are not readily accessible, e.g. in the case of **3**,[12] and/or because of the lack of straightforward high-yield synthetic methodologies. One of the few exceptions may be **4** (Scheme 1), which was obtained by a ligand-centered reaction as a coordination compound in quantitative yields.[13]



Scheme 1. Unusual bicyclic phosphanes (**1**, **2**) and phosphorus−carbon cage compounds (**3**, **4**)

For the same aforementioned reasons the selective synthesis of phosphorus-nitrogen-carbon cage compounds such as **5**[14] and **6**[15] aroused interest (Scheme 2); the latter was obtained as a coordination compound. Grützmacher demonstrated that **5** is surprisingly stable under oxidative

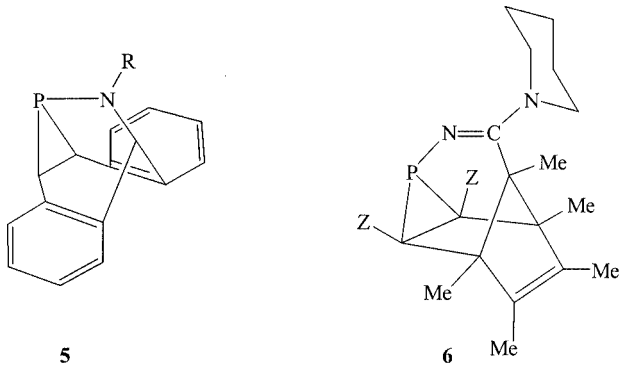
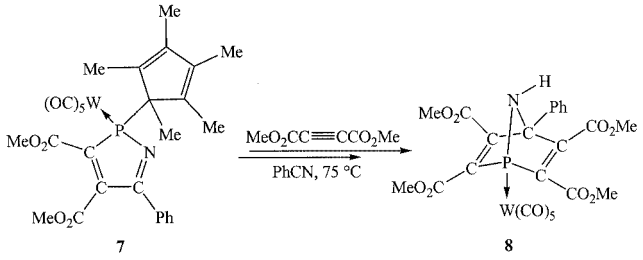
conditions and thus showed that such ligand systems might have additional advantageous properties associated with their unusual small valence bond angle sums at phosphorus (Σ°P), which are below 270°, e.g. Σ°P·255° (**5**) and Σ°P·263° (**6**). He also showed that **5** can be used successfully as a new ligand system in catalytic hydrosilylations.[16] It is also remarkable that unusual properties of phosphanes with valence bond angle sums at phosphorus below 270° were predicted theoretically by Orpen and Connely some years ago.[17]



Scheme 2. Unusual phosphorus−nitrogen−carbon cage compounds **5** and **6**

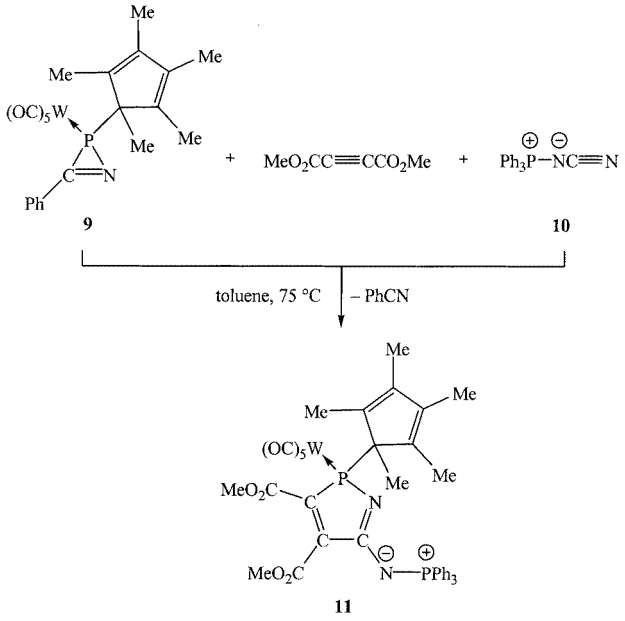
Because of our long-standing interest in the synthesis of new mono- and polycyclic unsaturated phosphorus-nitrogen heterocycles[18] using 2*H*-azaphosphirene complexes[19] as precursors, we recently decided to return to the unresolved problem of the surprising instability of the exocyclic P−C bond of the *P*-pentamethylcyclopentadienyl-substituted 2*H*-1,2-azaphosphole complex **7**.[20] Upon heating in benzonitrile, complex **7** decomposed in the presence of dimethyl acetylenedicarboxylate (DMAD), forming the bicyclic heterocycle **8**, the first 7-aza-1-phosphanorbornadiene complex (Scheme 3).



Scheme 3. Formation of 7-aza-1-phosphanorbornadiene complex **8** via thermolysis of the 2*H*-1,2-azaphosphole complex **7** in the presence of DMAD

Results and Discussion

In an attempt to synthesize new functional derivatives of **8**, we have now achieved selective synthesis of 2*H*-1,2-azaphosphole complex **11** using the *P*-Cp*-substituted 2*H*-azaphosphirene complex **9**[21] and Ph_3PNCN[22] (**10**) in *o*-xylene at 75 °C (Scheme 4). Surprisingly, complex **11** showed no signs of decomposition up to temperatures as high as 120 °C! Since the only difference between **7** and **11** is the replacement of a phenyl by the Ph_3PN group, clearly the new substituent is responsible for this dramatic effect − but the reason is not immediately apparent.



Scheme 4. Synthesis of 2*H*-1,2-azaphosphole complex **11**

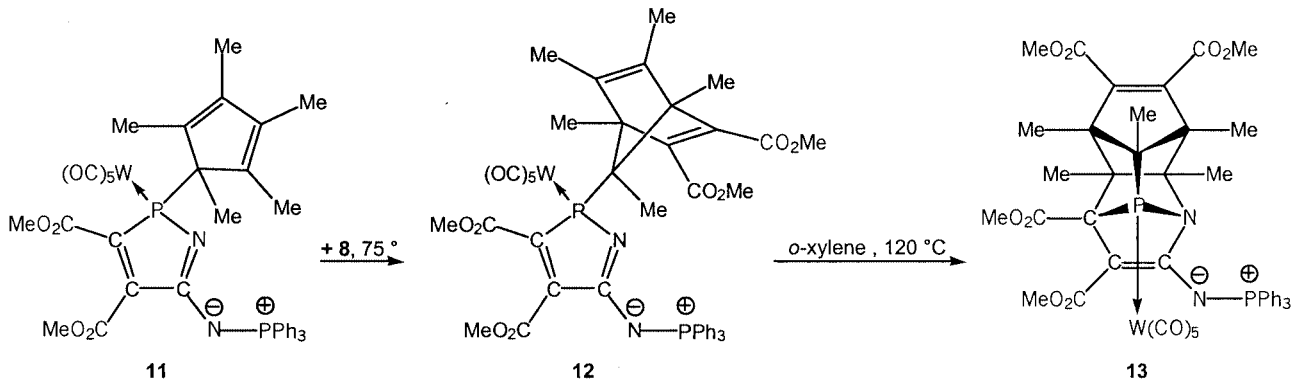
We were also able to carry out a clean *intermolecular* Diels−Alder reaction of **11** with DMAD at 75 °C, which yielded complex **12** in high yields, just by strictly controlling the reaction times for the first (**9** → **11**) and the second chemical transformations (**11** → **12**). Further studies of the thermal stability of complex **12** led to another surprisingly high-yield and unprecedented cycloaddition reaction in azaphosphole chemistry. Upon heating an *o*-xylene solution of complex **12** at 120 °C an *intramolecular* Diels−Alder reaction of the aza-1,3-diene unit of the 2*H*-1,2-azaphosphole ring with the dimethyl-substituted ethylene unit of the norbornadiene substituent selectively furnished complex **13**, which contains a new phosphorus−nitrogen−carbon cage compound as the ligand system (Scheme 5).

It is remarkable that the ^{31}P resonance of the ring junction phosphorus atom in **13** at δ = 158.4 ppm [$J(^{183}W,P)$ = 269.9 Hz] is much more deshielded than the phosphorus nuclei in **11** and **12**, although it now has a more conventional chemical environment. Therefore, this deshielding might be explained in terms of ring strain in **13**.[23] Furthermore, the exocyclic phosphorus atom in **13** experiences a significant shielding in comparison with **11** and **12** and resonates at δ = 1.3 [**11**: δ(P) = 18.1 and **12**: δ(P) = 18.4 ppm].

Discussion of Selected ^1H and ^{13}C NMR Spectroscopic and Mass Spectrometric Data

The ^1H and ^{13}C NMR spectra of complexes **11**−**13** were assigned as fully as possible by the use of two-dimensional shift correlation experiments (HSQC and HMBC). One-di-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5. Synthesis of complexes **12** and **13** using inter- and intramolecular Diels–Alder reactions

mensional ^{1}H and ^{13}C NMR spectra were recorded at magnetic field strengths of both 4.7 T and 9.4 T so that, for closely lying lines, one could unequivocally decide which line distances corresponded to coupling constants involving ^{31}P and which ones to small chemical shift differences.

The ^{1}H and ^{13}C NMR signals of the PPh_3 groups of **11–13** are assigned in a straightforward manner and need not be discussed. In the spectra of **11** the ^{13}C and ^{1}H signals belonging to the same ester groups can be identified by the correlation spectra. But as the ester nuclei do not show any correlations to 'outside' nuclei, it is not clear which ester group gives rise to which signals. Assignment of the signals of the Cp* moiety starts from the large $^{3}J_{P,H}$ coupling constant (15.0 Hz) of the protons of the methyl group at the quaternary sp^3 carbon (Cp*-C-1). By exploiting the $^{2}J_{C,H}$ and $^{3}J_{C,H}$ correlations, the ^{1}H and ^{13}C signals of the Cp* group are fully assigned. The vicinity of the chiral phosphorus atom causes chemical nonequivalence of C-2 and C-5, of C-3 and C-4 and of their attached methyl groups. It may be noted that three-bond C,H-correlations are found across the double bonds of the Cp* group but not across the C-3/C-4 single bond, i.e. there is no crosspeak for C-3/4-Me or C-4/3-Me. The carbon atoms of the 2*H*-1,2-azaphosphole ring show no HMBC correlations to any protons. They are tentatively assigned on account of their chemical shifts and coupling constants with phosphorus. Hence, the most deshielded carbon (δ_C = 166.5 ppm) is assumed to be C-5 because of its amidine character. Of the remaining ring carbon atoms, C-4 has $^{2}J_{P,C}$ and $^{3}J_{P,C}$ couplings, while C-3 experiences $^{1}J_{P,C}$ and $^{4}J_{P,C}$ interactions. The values of 18.9 or 26.1 Hz associated with δ_C = 149.4 ppm are believed to be too large for $^{4}J_{P,C}$. Thus C-3 is assigned to δ_C = 151.6 ppm with its *J* values of 4.4, 2.7 Hz.

The spectral assignments for **12** were similar to those described for **11**. The two ester groups at the 2*H*-1,2-azaphosphole ring are distinguished from those at the norbornadiene moiety by the coupling of their carbonyl carbon nuclei with the phosphorus atom. Assignment of the pentamethylnorbornadiene atoms started with the protons of the 7-methyl group which were again identified by their coupling with ^{31}P. The protons of one of the bridgehead methyl groups were found to be strongly shielded (δ = 0.08 ppm), while their counterparts show a more normal ^{1}H chemical shift of δ = 1.59 ppm. Possible causes for this shielding are the aromatic rings of the triphenylphosphane-iminyl group or one or several of the carbonyl groups of the $W(CO)_5$ substituent. The unknown geometry of **12** does not permit a definite conclusion. Finally, the extreme deshielding of the carbon C-7 from the norbornadiene bridge (δ = 90.5 ppm), an sp^3 carbon atom with a phosphorus atom as the only somewhat polar substituent, is in line with the large chemical shift in norbornadiene itself (δ = 75.1 ppm),[24] which is further increased by the presence of one α- and two β-methyl groups.

For compound **13**, all ^{13}C and ^{1}H chemical shifts of the central 1-aza-11-phosphatetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodeca-4,9-diene system were assigned from the crosspeaks in the HSQC and HMBC spectra. Apart from the methyl carbons (*C*-methyl and ester *O*-methyl) and the $W(CO)_5$ group, only the carbon nuclei of the 9,10-double bond showed no correlations with distant protons. These carbon atoms have widely different chemical shifts (δ = 159.8 ppm and 98.6) which are characteristic of a push-pull substituted double bond.

A common feature of the EI-mass spectra of **11**, **12** and **13** is the cleavage of the P,N ylidic bond, thus generating $[Ph_3P]^{+\cdot}$ and neutral species such as nitrenes. The further degradation of $[Ph_3P]^{+\cdot}$ has been reported previously[25] and was very recently observed in the case of *P*-bis(trimethylsilyl)methyl-substituted 2*H*-1,2-azaphosphole complexes.[26] Another important fragmentation process is the cleavage of the exocyclic P–C bond of the complexes **11** and **12.** Furthermore, all complexes lose the $W(CO)_5$ fragment upon ionization. In the case of complex **13** the main fragmentation includes a rearrangement of the polycyclic ring system by formation of a substituted pyridine radical cation.

Discussion of Selected Structural Data

We were able to confirm the molecular structures of complexes **11** (Figure 1) and **13** (Figure 3 and 4) for the solid state by X-ray single crystal structure analyses (Table 1). The almost planar 2*H*-1,2-azaphosphole ring of complex **11** (mean deviation of 0.02 Å) showed no unusual atom dis-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tances when compared to complex **14** (Figure 2),[15] the only known structure of a *P*-Cp*-substituted phosphole[27,28] or heterophosphole.[29] As a common structural motif in diester-substituted 2*H*-1,2-azaphosphole rings[25] the ester group at C16 almost shows an in-plane orientation, whereas the ester group at C-17 is oriented out-of-plane. The torsion angle of N(1)−C(18)−N(2)−P(2) is 0.3° and, therefore, should enable electronic interactions between the substituent and the ring system. The planes of the two five-membered rings in **11** are partially eclipsed, in contrast to **14**, where the respective planes adopt a conformation in which they have an opposite orientation along the exocyclic P−C bond. However, this does not greatly effect the corresponding P−C distances [**11**: P(1)−C(6) 1.886(3) Å and **14**: P(1)−C(8) 187.7(2) Å]. A comparison of the azaphospholene moiety of the molecular structure of complex **13** (Figure 3 and 4) with compounds **15**[30] and **16**[31] (Figure 5), which also have azaphospholene ring structures with a C−C double bond, reveals the uniqueness of **13**. The C(7)−C(8) distance of 1.373(2) Å is that of an elongated C-C double bond [**15**: 1.290(3) Å;[30] **16**: 1.329 Å[31]], which might be caused by the electronic interaction with the Ph_3PN group [N(1)−C(8)−N(2)−P(2): −29.8 °]. It is also remarkable that the P(1)−C(6) and P(1)−N(1) distances of 1.8925(15) and 1.7706(13) Å, respectively, are fairly long [**15**: 1.818(2) and 164.5(2) Å;[30] **16**: 180.0 and 171.6 pm[31]]. This is associated with a long P(1)−C(13) distance of 1.8968(15) Å and a short P(1)−W distance of 2.4744(4) Å. The valence bond angle sum of Σ°P(1)·273 °, which very much resembles the situation of compound **8** in its transition metal-coordinated form.

Conclusions

We have shown that the stability of *P*-Cp*-substituted 2*H*-1,2-azaphosphole complexes can be significantly enhanced by choosing the right substituent and that they are now available for further investigations − two new reactions were presented here. Furthermore, this example can be regarded as a blueprint for the synthesis of other phosphorus-carbon and phosphorus-nitrogen-carbon cage compounds thus underlining once more the usefulness of *P*-Cp*-substituted 2*H*-azaphosphirene complexes in the construction of new and unusual polycyclic phosphane ligands.

Experimental Section

General Procedures: All reactions and manipulations were carried out under an atmosphere of deoxygenated dry nitrogen, using standard Schlenk techniques with conventional glassware, and solvents were dried according to standard procedures. The NMR spectra were obtained on the Bruker spectrometers Avance DRX400 and Avance DPX200 at operation frequencies of 400 MHz (^{1}H), 101 MHz (^{13}C), 161 MHz (^{31}P) and of 200 MHz (^{1}H), 50 MHz (^{13}C), 81 MHz (^{31}P), respectively. Chemical shifts were referenced to internal tetramethylsilane (^{1}H, δ = 0.00 ppm), $CDCl_3$ (^{13}C, δ = 77.0 ppm) and to the frequency of virtual external 85% orthophosphoric acid (^{31}P, δ = 0.0 ppm). The latter frequency was determined independently from a concentric capillary of H_3PO_4 in neat $CDCl_3$. DEPT-135 spectra were carried out to determine the degree of substitution of the carbon atoms. The spectrometer software used was XWin NMR version 2.6. The manufacturer's pulse programs 'invigstp' (gradient-selected phase-sensitive HSQC) and 'inv4gslplrnd' (gradient-selected HMBC) controlled the two-dimensional NMR spectroscopic experiments[33]. The 2D experiments were optimized for coupling constants of 145 Hz [$^1J_{C,H}$] and 7.7 Hz [$^{2,3}J_{C,H}$]. Digital resolutions were chosen to be small enough in both dimensions to permit the resolution of closely lying chemical shifts. All coupling constants reported involve ^{31}P unless otherwise specified. Electron impact (EI) (70 eV), chemical ionization (CI) (ammonia), and fast atom bombardment (FAB) (Xenon, NBA) mass spectra were recorded on a double focusing mass spectrometer Finnigan MAT-8430; Exact mass resolution R = 10000 (10%-valley-definition). Infrared spectra were recorded on a Biorad FT-IR 165 (selected data given). UV/vis spectra were recorded on a Hewlett Packard HP 8452. Melting points were obtained on a Büchi 535 capillary apparatus. Elemental analyses were performed by using a Carlo Erba analytical gas chromatograph. The κP-notation in the nomenclature is intended to differentiate between *P*- and *N*-coordination of the appropriate heterocycle to the metal.

[Pentacarbonyl{3,4-bis(methoxycarbonyl)-2-pentamethylcyclopentadienyl-5-(*N*-triphenylphosphonioimidoyl)-2*H*-1,2-azaphosphole-κP}tungsten(0)] (11): Carbonitrile **10** (0.9 mmol) and DMAD (0.85 mmol) were added to a solution of 2*H*-azaphosphirene complex **9** (0.51 g, 0.86 mmol), dissolved in toluene (5 mL). The solution was heated at 75 °C for 25 min while stirring slowly and was controlled by ^{31}P NMR spectroscopy. All volatile components were then removed in vacuo (ca. 0.01 mbar) and the products separated by low-temperature column chromatography (SiO_2, −10 °C, 10 × 2 cm, *n*-pentane/diethyl ether, 50:50). Evaporation of the third fraction yielded complex **11** as a yellow solid.

The Growth Process, Stability of GaP Nanocrystals and Formation of Ga_3P Nanocrystals under Solvothermal Conditions in Benzene

Shanmin Gao,[a] Jun Lu,[a] Yan Zhao,[a] Nan Chen,[a] and Yi Xie*[a]

Keywords: Gallium / Phosphides / Nanostructures / Solvothermal synthesis

The growth process, stability of GaP nanocrystals and the formation of Ga_3P nanocrystals under solvothermal conditions were investigated. At moderate reaction times and temperature, the growth process is mainly in accordance with the Ostwald ripening mechanism, which is the dissolving of the smaller GaP crystallites and growth into larger ones. However, GaP nanocrystallites become unstable under increasing reaction temperatures or prolonged reaction times. EDAX and XRD were used to identify the new Ga_3P phase.

Introduction

Semiconductor nanocrystals have attracted considerable interest since they exhibit a wide variety of intriguing size-dependent properties, such as the blue shift of the optical absorption and photoluminescence, electronic and nonlinear optical effects and fast relaxation times. These properties result from a quantum confinement effect in systems with small dimensions; these dimensions are sensitive to the fabrication method.[1−2] Research on the applications of semiconductor nanometer materials, such as biological fluorescence marking[3] and optoelectronic devices, has also been greatly promoted.[4−5] In addition, the high surface area and the specific growth kinetics can also influence the interior structure of nanocrystals. In order to use these effects, however, it is important to control the size and the size distribution, as well as the stability of the particles against conglomeration. The structural, physical, electronic and magnetic properties may be controlled by changing the synthetic method.

Increasing progress has been made on the research and development of semiconductor nanometer materials.[6] Among the semiconductor materials, the group II−VI compounds have been studied the most widely. Much work has been done on them, especially on aspects of their preparation and properties.[7−10] The core/shell nanostructures of the II−VI materials have also been studied because the shell type and shell thickness provide further control for tailoring the optical, electronic, electrical, and chemical properties of semiconductor nanocrystals.[11−14] In contrast, III−V semiconductor nanoscale materials are less well studied because the II−VI semiconductors are easier to prepare, for a number of reasons.[15] Current interest has focused on the synthesis and characterization of III−V semiconductor nanocrystals and the optical properties of quantum size particles.[16−18] III−V semiconductor nanowires have attracted much interest in recent years for their potential application in high-electron-mobility nanoelectronic devices and full-color flat panel displays.[19] Several approaches have been successfully developed for the fabrication of these nanowires.[20−24] The morphology, microstructure and the growth mechanism of the nanowires has been investigated in detail.

The most important route for the formation of the III−V semiconductor nanocrystals involves organometallic reagents.[25−29] The solvothermal synthetic route has been studied extensively and has proven to be a powerful route for the preparation of new materials,[30−32] in particular for the preparation of III−V semiconductor nanocrystals.[33−36] The advantage of this method is the effective prevention of the oxidation of the products, with the result that the isolated crystalline materials do not need subsequent treatment at high temperatures. In addition, organometallic precursors are not required. However, since the reaction takes place in a sealed system, relatively little work has been done with regards to the growth process and the stability of the product in the solvothermal process, which in fact influences their application directly.[37]

GaP is an indirect-gap semiconductor and has many important uses in microelectronic devices. A few reports have been published on the synthesis and properties of GaP nanocrystals[25,38−39] and nanowires.[28,29] In previous work, we have reported on the factors that affect the particle size of GaP nanocrystals in the reactions of both $GaCl_3{\cdot}Et_2O$ and $GaCl_3$·benzene with Na_3P, where the GaP nanorods and nanospheres were synthesized under solvothermal conditions in benzene.[40,41] It is necessary to study the growth

mechanism and the stability of nanoparticles under different synthetic conditions in order to determine the best method of synthesis. As far as we are aware, the synthesis of Ga_3P nanocrystals has not been reported previously, although the electronic state of Ga_3P clusters has been studied theoretically.[42] It is clear that in the smaller clusters the P−P bond plays a more decisive role in the structure and bonding, however, as the cluster size increases beyond four atoms, the magic stability of P_4 can be overcome by the Ga−P bonds and thus a mixed cluster is expected to exhibit greater stability. We have previously studied the stability of GaP nanocrystals under solvothermal conditions in benzene,[43] but the growth process and the formation mechanism were not discussed.

In this paper, the growth process and stability of GaP nanocrystals under solvothermal conditions in benzene are investigated in detail. A method for controlling the reaction process and improving the uniformity of the GaP grains is presented, as well as the formation of the Ga_3P nanocrystals.

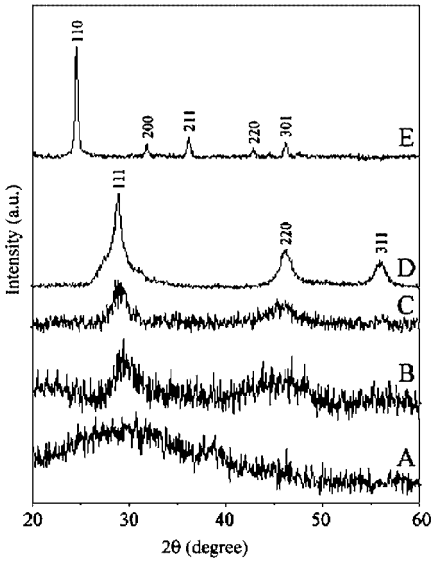

Figure 1. XRD patterns of samples obtained at 300 °C for different reaction times of the mixture: 0 h (A), 3 h (B), 7 h (C), 12 h (D), 24 h (E)

Results and Discussion

The Formation and Growth of GaP Nanocrystals

The reaction was carried out at 300 °C and a series of changes was experienced over different time periods. Figure 1 (A) shows the XRD pattern of the product obtained from mixing the starting materials Na_3P and $GaCl_3$ in a benzene solution, at room temperature. A bump centered at 29° can clearly be seen, which corresponds to the (111) diffraction peak of the GaP crystal with a zincblende structure, indicating the existence of many GaP particles that are small in size. As the reaction proceeds, the bump center becomes weaker from B to D, whereas the three diffraction peaks corresponding to (111), (220) and (311) of the zincblende GaP grow stronger and narrower. However, when the reaction time is increased to 24 h, a new phase appears, indicating that GaP nanoparticles have undergone a chemical change [Figure 1 (E)]. The average size of the GaP crystallites of samples A, B, C and D were calculated to be about 2, 8, 11 and 48 nm, respectively, by the Scherrer equation, which indicates that the particle size enlarges with increasing reaction time.

In order to study the grain size distribution and its change during the reaction, the absorption spectra of samples A, B, C and D were analyzed, which are shown in Figure 2. The absorption peak positions and shape reflect the particle sizes and granularity distribution. The spectrum of sample A is only an inconspicuous peak at about 400 nm, indicating the amorphous nature of A. The absorption spectra of samples B and C show several broad peaks, indicating that there is a broad granularity distribution of GaP nanocrystallites. The absorption edge shifts progressively to the red due to the growth of grains during the reaction process. Although the XRD data indicate larger average particle sizes, this could not be verified by UV/Vis studies. Because there is a broad granularity distribution of GaP nanocrystallites, large numbers of the GaP nanocrystallite particles are smaller than the Bohr radius of the exciton in GaP. So, in the absorption spectra of samples B and C, the broad excitonic peaks arise due to the quantum confinement effect Definitive evidence of the nanoscale dimensions of the quantum particles was obtained from our TEM studies.

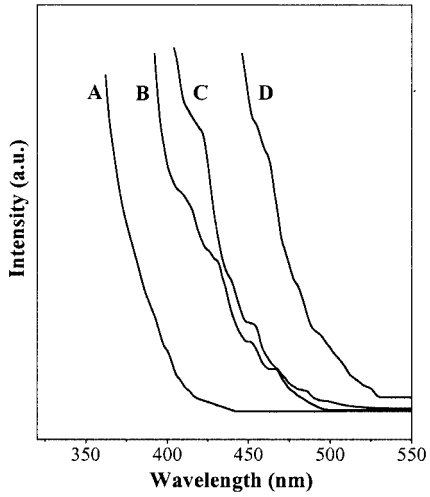

Figure 2. Optical absorption spectra of samples A, B, C and D of Figure 1; sample dispersion in benzene

The morphology of the as-prepared nanoparticles was studied by Transmission Electron Microscopy (TEM), as shown in Figure 3. Figure 3 (A) shows the morphology of the product of sample A. In sample B there are very few large crystallites but a large amount of smaller ones. Compared with sample B, the proportion of large crystallites increases in sample C and the granularity distribution is irregular, although many smaller particles also exist. The

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

shape of these nanoparticles is nearly spherical with diameters ranging from 5 to 10 nm for sample B and 8 to 16 nm for sample C, in accordance with the average size estimated from the XRD patterns. Because there are so many smaller particles, the excitonic peaks arise in our UV/Vis studies for samples B and C. The proportion of smaller crystallites in sample D is reduced and the grains become uniform. As in sample C, the GaP particles are essentially spherical and the average diameter is nearly 46 nm, which is also consistent with the calculated crystallite sizes from XRD patterns. Figure 3 (E and F) represent the selected area electron diffraction (SAED) of samples A and D, respectively. Figure 3 (E) shows one electron diffraction ring and (F) shows three electron diffraction rings corresponding to the zincblende phase. The SAED results are consistent with the XRD results. Figure 3 (E) indicates that the diffraction bump centered at 29° in Figure 1 (A) corresponds to the (111) diffraction peak of a GaP crystal with a zincblende structure.

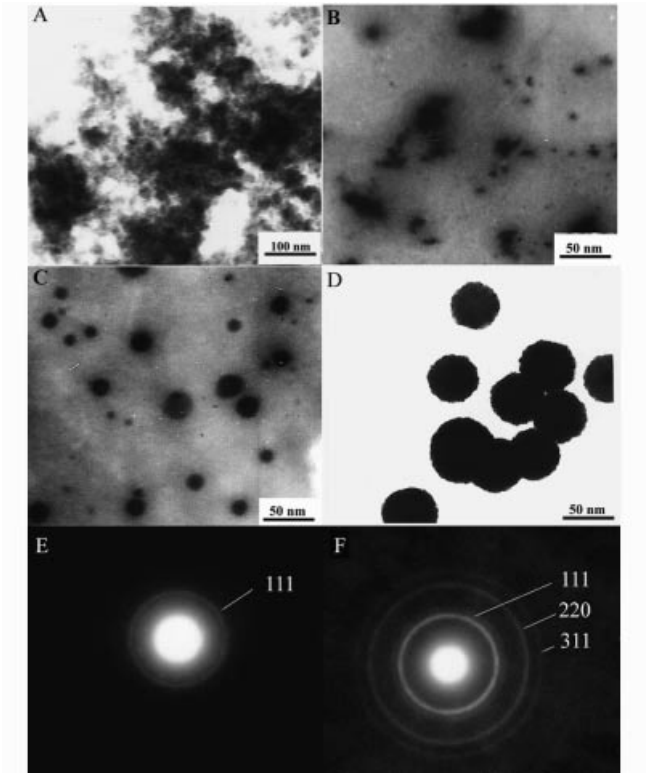

Figure 3. TEM images for GaP nanocrystals prepared at 300 °C for different reaction times of the mixture: 0 h (A), 3 h (B), 7 h (C), 12 h (D); E and F are the SAED patterns of samples A and D

From the XRD, UV/Vis absorption spectra and TEM images, it is clear that samples B and C consist mainly of smaller crystallites with few large ones present. A mass transport process should exist between these crystallites under high-temperature-high-pressure (HTHP) solvothermal conditions in benzene. This phenomenon can be explained as follows, according to the Kelvin equation [Equation (1)], (where P_0 and P_r are the equilibrium vapor pressure of constituents on the surface of the bulk crystal and nanocrystals with radius r, respectively, σ is the surface tension, ρ is the density of nanocrystals, R is a constant, T is absolute temperature and M is the molecular mass) it is obvious that P_r increases rapidly with a decrease of r.

$$P_r = P_0 \exp\left(\frac{2\sigma M}{\rho R T r}\right) \quad (1)$$

P_r on the surface of the smaller GaP crystallites is larger than it is for the larger crystallites. The different values of P_r for crystallites with different radii is the driving force for the transport of Ga and P from the surface of smaller crystallites to the larger ones. For GaP nanocrystallites, the smaller grains dissolve because of the unsaturation condition near the surface, while the larger grains increase in size due to the supersaturation condition.

From the discussion mentioned above, we propose a method for controlling the transport of the constituents and improving the uniformity of the grain size. As we know, at high monomer concentration the smaller particles grow faster than the larger ones and, as a result, the size distribution becomes more uniform. Therefore, we can raise the concentration of Ga and P in the reaction system to create supersaturation of Ga and P at the surface of the small crystallites as well as the large ones. Assuming that the additional concentration of Ga and P are $[Ga]_{av}$ and $[P]_{av}$, the equilibrium concentrations of the corresponding constituents on the surface of the large crystallites are $[Ga]_{le}$ and $[P]_{le}$, and the values on the surface of the small crystallites are $[Ga]_{se}$ and $[P]_{se}$. The real concentrations of Ga and P are as follows:

Small crystallites: $[Ga]_s = [Ga]_{se} + [Ga]_{av}$, $[P]_s = [P]_{se} + [P]_{av}$

Large crystallites: $[Ga]_l = [Ga]_{le} + [Ga]_{av}$, $[P]_l = [P]_{le} + [P]_{av}$

It is obvious that $[Ga]_l < [Ga]_s$ and $[P]_l < [P]_s$. For the reaction Ga + P $\rightleftarrows$ GaP, the speed (v) is described in Equation (2), where v is the growth speed of crystallites and k is a constant.

$$v = k\,[Ga] \times [P] \quad (2)$$

Thus, the growth speed of the smaller crystallites is faster than that of the larger ones. As a result, the uniformity of the grains improves. This ability to control the uniformity of the semiconductor nanocrystalline grains affords an opportunity to further test theories of quantum confinement and yields samples with desirable optical characteristics suitable for practical application. More experiments were performed to provide further evidence in order to draw better conclusions. Samples A and B are obtained when the concentrations of the precursors are twice those of the first experiments, at 300 °C for 4 h and 6 h, respectively. TEM images of the above samples are shown in Figure 4 (A and B). Figure 4 (C and D) are the images, under the same experimental conditions, where the concentrations of the pre-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cursors are the same as those of the first experiments. It can be seen from the images of samples A and B that the grain size is more uniform than in the samples formed at 300 °C for 4 h and 6 h at lower concentrations. From the TEM images of samples C and D one can see the aggregation of the particles, confirming our previous assumptions. This phenomenon is in accordance with the results obtained from the absorption spectra. The absorption spectra of samples A and B were analyzed and the results are shown in Figure 5. The absorption spectra are regular, with a single absorption peak indicating the uniformity of the particle sizes. The particle sizes of samples A and B are about 5 and 9.5 nm, respectively. The Bohr radius of the exciton is reported to be 55 Å (a diameter of 11 nm) in GaP.[44] The absorbance peaks at 380 nm [Figure 5 (A)] and 416 nm [Figure 5 (B)] correspond to approximately 5 and 9 nm GaP crystallites, respectively, which is consistent with the TEM results.

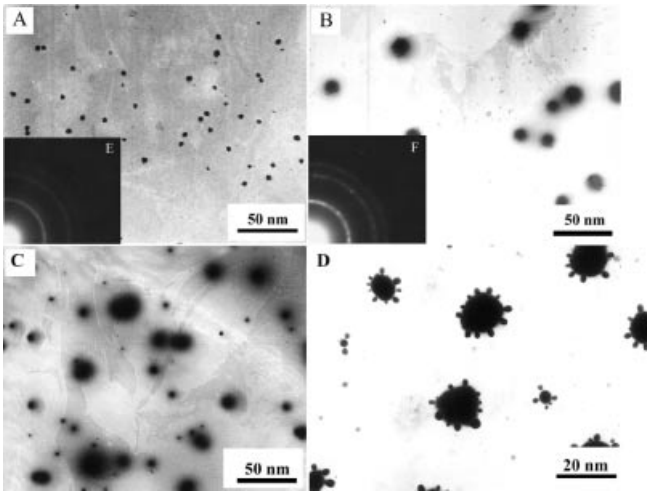

Figure 4. TEM images for GaP nanocrystals prepared at 300 °C at twice the precursor concentrations for 4 h (A), 6 h (B); C and D are the TEM images for GaP nanocrystals prepared at four times the precursor concentrations for 4 h and 6 h; the insets E and F are the SAED pattern of samples A and B

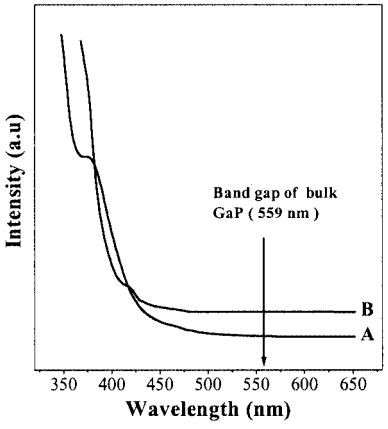

Figure 5. Optical absorption spectra of samples A and B of Figure 4

The Stability of GaP Nanoparticles and the Formation of Ga_3P Nanocrystals

In the previous section it could be seen that a new phase was obtained after Na_3P and $GaCl_3$ reacted at 300 °C for 24 h. The XRD pattern of this new phase is shown in Figure 1 (E). An Energy Dispersive X-ray Diffraction (EDAX) analysis study was performed in order to determine the composition of sample E, obtained at 300 °C over 24 h. Figure 6 shows the EDAX spectrum, in which both P and Ga bands are detected when the electron beam is focused on one of the particles. Na and Cl were also detected because the sample was not properly washed and so an extremely small amount of by-product (NaCl) is present. Because of the low concentration of NaCl and the small particle size, direct determination of the NaCl by X-ray diffraction is difficult; no NaCl diffraction peaks appear in Figure 1 (E). The insert in Figure 6 indicates the results of the elemental analysis. From the EDAX and element analysis, we conclude that the new compound is Ga_3P. Moreover, all the reflections shown in Figure 1 (E) can be indexed to the tetragonal Ga_3P phase and the average crystallite sizes of Ga_3P were found to be about 55 nm, as estimated from the Scherrer formula.

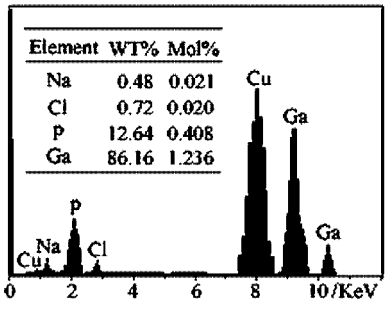

Figure 6. The EDAX results of Ga_3P at 300 °C for 24 h; inset: elemental analysis result of sample E

From the above discussion it can be seen that Ga_3P is obtained from the reaction of Na_3P and $GaCl_3$ at 300 °C for 24 h, indicating that GaP is in fact metastable in the solvothermal process. In order to confirm this metastability, a further series of experiments was performed. All products were identified from the XRD patterns. Figure 7 shows the XRD patterns of the samples that were prepared at 420 °C for 12 h (A), 400 °C for 14 h (B) and 340 °C for 20 h (C). The relationship between the reaction conditions and products is summarized in Table 1. Figure 8 shows the TEM images of Ga_3P, from which one can see that at 420 °C for 12 h (A) or at 400 °C for 14 h (B), Ga_3P nanocrystallites have a high crystallinity and are well distributed. This is better than the results for Ga_3P obtained at 340 °C for 20 h (C) or at 300 °C for 24 h (D). The size distribution of the sample obtained at 300 °C for 20 h is irregular: the largest particle size is 75 nm but the smallest is only 20 nm. This result is consistent with the average particle sizes from the

XRD patterns. Figure 8 (E and F) are the ED patterns of samples A and D. The diffraction intensity gives more proof of the crystallinity of the samples at different temperatures and times.

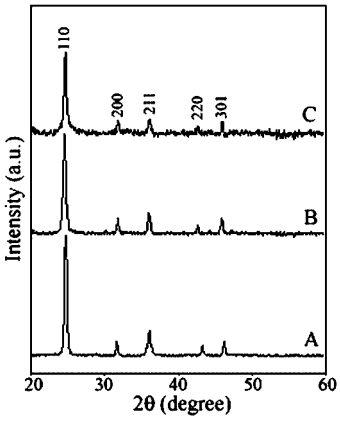

Figure 7. XRD patterns of Ga_3P at 420 °C/12 h (A), 400 °C/14 h (B), 340 °C/20 h (C)

Table 1. Relation between reaction conditions and products

Temp. [°C]	Time [h]	Product
300	7	GaP
	12	GaP
	20	GaP (major), Ga_3P (minor)
	24	Ga_3P
340	8	GaP
	12	GaP (major), Ga_3P (minor)
	20	Ga_3P
380	8	GaP
	12	GaP (major), Ga_3P (minor)
400	8	Ga_3P (major), GaP (minor)
	14	Ga_3P
420	8	Ga_3P (major), GaP (minor)
	12	Ga_3P

In the current system, GaP was formed by the reaction $Na_3P + GaCl_3 \rightarrow GaP + 3\ NaCl$, but upon prolonging the reaction time or increasing the reaction temperature, the products turned into Ga_3P. Careful observation showed that, after heating at 300 °C for between 3 and 12 h, the autoclave was filled with a blue-green benzene solution and a gray-black powder (GaP), whereas when the heating time reached 24 h at 300 °C, 20 h at 340 °C, 14 h at 400 °C or 12 h at 420 °C, the autoclave was filled with a yellow or light-brown benzene solution and a gray-white powder (Ga_3P). Upon removing some of the yellow or light-brown benzene solution and dripping it onto filter paper in air, spontaneous combustion takes place, indicating that white phosphorus is dissolved in the yellow or light-brown benzene solutions. In our experiments the Na_3P and $GaCl_3$ molar ratio is 1:1, so we believe that under solvothermal conditions in benzene, the decomposition of GaP should take place when the reaction time is prolonged or the reaction temperature is increased as shown in Equation (3).

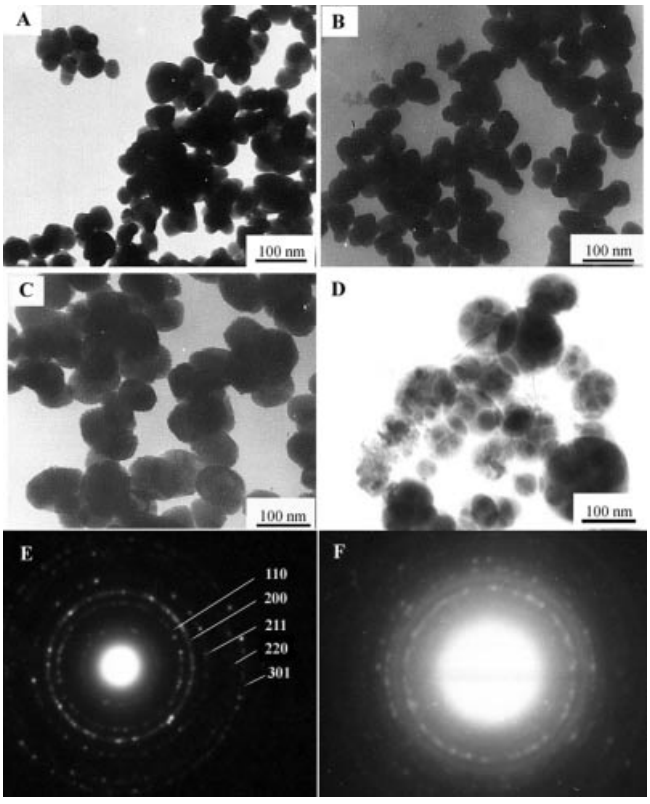

Figure 8. TEM images of Ga_3P at 420 °C/12 h (A), 400 °C/14 h (B), 340 °C/20 h (C), 300 °C/24 h (D); E and F are the SAED pattern of samples A and D

$$6\ GaP \rightarrow 2\ Ga_3P + P_4 \quad (3)$$

In order to study the reaction mechanism, more experiments were performed. A purified sample of GaP was placed into an autoclave, under the same solvothermal conditions; the results differed from the above-mentioned results. Thus, either NaCl or unchanged Na_3P is necessary for the decomposition process to occur.[45−47]

Experimental Section

Preparation and Growth of GaP Nanocrystals: All analytical grade solvents used in our experiments were dried with sodium chips and distilled under a flow of N_2. All reagents were analytical grade or better and used without any purification, except for Na_3P, which was prepared according to the literature (small pieces of sodium and an excess of white phosphorus were mixed in benzene, heated to the melting point of sodium, and stirred and refluxed for 10−12 h).[48] A typical experimental procedure is as follows: Na_3P powder and a benzene solution of $GaCl_3$ were placed in a stainless steel autoclave and benzene was added to raise its ratio to 70−85%. After the air in the solution was expelled by N_2 (99.999% pure), the autoclave was sealed and heated to 300 °C over different time

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

periods, and then allowed to cool to room temperature. The products were filtered off and washed with benzene, absolute ethanol and distilled water. Finally, the products were dried under vacuum at room temperature for 2 h. In order to study the growth and stability of GaP nanoparticles the as-prepared GaP was treated at different temperatures and times under the same conditions.

Characterization of the Products: The phases of the products were detected at a scanning rate of $0.02°s^{-1}$ in the 2θ range from 20 to 60° by using a *D*/max-γA X-ray diffractometer with Ni-filtered Cu-K_α radiation. Optical absorption spectra were recorded with a Hitachi 340 UV/Vis/NIR recording spectrophotometer at room temperature. The absorption cell used was a 1-cm quartz cuvette. A blank solution of benzene was used as the reference. TEM images of the samples were obtained from a Hitachi model H800 transmission electron microscope using an accelerating voltage of 200 kV. To prepare the TEM samples, the colloids were briefly ultrasonicated, and then a drop of the colloidal suspension was applied to a copper mesh covered with a carbon film for 30 s.

COVER PICTURE

The cover picture shows a schematic view of part of a novel complex that undergoes reversible dioxygen binding. The complex is a zig-zag oligomer formed in sublimed layers of [*meso*-triphenyl(4-pyridyl)porphyrinato]cobalt(II) and is depicted here with molecular dioxygen coordinated at each cobalt centre. The relatively open, microporous structure of the oligomer arises as a result of pyridine coordination, which inhibits closer-packed structures (e.g. with parallel contiguous porphyrin rings), and ensures facile transport of molecular oxygen to the coordination site. The zig-zag chain also inhibits the formation of dioxygen-bridged centres, with the result that this basic structure is relatively stable. On warming, the Co–dioxygen link may be broken, with the evolution of dioxygen, which can readily diffuse through the microporous structure, leaving the zig-zag oligomer chain effectively intact. Details are discussed in the article by T. S. Kurtikyan et al. on p. 1861 ff.

The Quest for Isophosphaalkynes (Isophosphocyanides) C≡P−R — Still an Elusive Class of Compounds

Lothar Weber*[a]

Dedicated to Professor Heinrich Nöth on the occasion of his 75th birthday

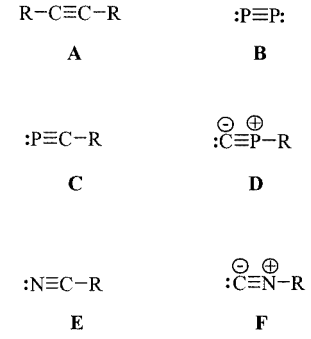
Keywords: Isophosphaalkynes / Phosphaalkynes / Phosphorus / Synthetic methods

This review gives an account on the quest for isophosphaalkynes, a class of compounds that still resists isolation and/or spectroscopic detection. Synthetic attempts toward this target are reported. On the other hand, a number of coordination compounds featuring isophosphaalkyne ligands have been prepared, the syntheses, structures, and chemistry of which are discussed.

1. Introduction

The concepts of isolobal compounds and the diagonal relationship between carbon and phosphorus in the periodic table of elements have proven exceedingly fruitful for the development of the chemistry of phosphorus in low coordination states.[1] Accordingly, alkynes **A** are closely related to diphosphorus **B**, which exists only in the gas phase, as well as to phosphaalkynes **C** and to isophosphaalkynes **D** (Scheme 1).

The chemistry of phosphaalkynes has been well developed and has been documented comprehensively in a series of review articles and text books.[2] In contrast, our knowledge of their isomers of type **D** is scarce. At a first glance this lack of examples is surprising, especially if one formally extends the relationship of phosphaalkynes and isophosphaalkynes to their nitrogen homologues, the cyanides (nitriles) R−C≡N (**E**) and isocyanides R−N≡C (**F**). Both classes of compound are familiar to the chemist as versatile and useful reagents in organic[3] and coordination chemis-



Scheme 1. Isoelectronic compounds featuring triple bonding

[a] Fakultät für Chemie der Universität Bielefeld, Universitätsstraße 25, 33615 Bielefeld, Germany

Lothar Weber was born in 1944 in Langenöls in Schlesien. He studied at the Universität Marburg and received his doctorate there under the direction of Professor Günter Schmid in 1973. Afterwards, he carried out postdoctoral studies with Professor Barry M. Trost at the University of Wisconsin in Madison, USA. On his return to Marburg, he began the experimental work leading to his Habilitation, which was completed in 1982 at the Universität Essen. His work focussed on the coordination chemistry of sulfur ylides. In 1985, he became a C2 Professor and then joined the Fakultät für Chemie der Universität Bielefeld. His research interests include the chemistry of compounds with low-coordinate elements of the fifth main group, the synthesis of homo- and heterocycles with heavy elements, as well as new aspects in boron chemistry.

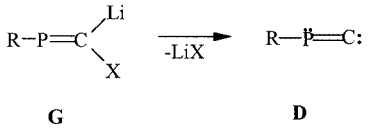
MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 DOI: 10.1002/ejic.200200674 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

try.[4] At this point, it should be mentioned that the comparison of species of type **C** with alkynes **A**, rather than cyanides **E**, usually is given preference on the grounds of their polarity, their MO sequences and, consequently, their reactivity. In this account, both kinds of relationships are addressed where appropriate.

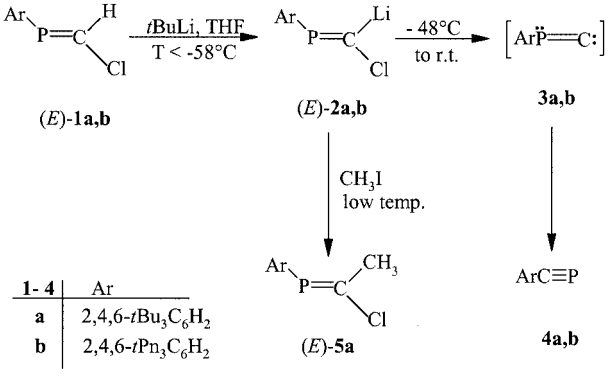
2. Attempted Syntheses of Isophosphaalkynes

The most prominent synthetic principle for preparing isophosphaalkynes is based upon the α-elimination of lithium halides from phosphaalkenylidene carbenoids **G** (Scheme 2).



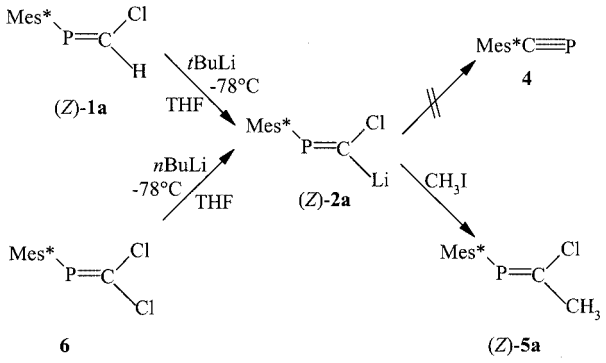
Scheme 2. Synthesis of isophosphaalkynes by α-elimination of lithium halides from phosphavinylidene carbenoids **G**

The reactive precursors may be synthesized by several routes. The outcome of their decomposition, however, strongly depends on the nature of the halide substituent as well as on the stereochemistry about the P=C double bond. The (*E*)-configured 2-chloro-1-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethene (**1a**) was lithiated in THF at −58 °C with a slight excess of *tert*-butyllithium to result in the complete conversion of **1a** into the corresponding *cis*-lithium compound **2a** (Scheme 3). Warming of the mixture to −48 °C completed the formation of **4a** within 10 min. No intermediates were detected by ^{31}P NMR spectroscopy. The identity of *cis*-**2a** was further substantiated by quenching the compound with methyl iodide at low temperature to give the (*E*)-configured phosphaalkene **5a**. Similar reactions were observed with the 2,4,6-tri-*tert*-pentylphenyl group as a substituent at the phosphorus atom[5a][5b] or with Mes* P=C(Br)Cl as a precursor.[5c]



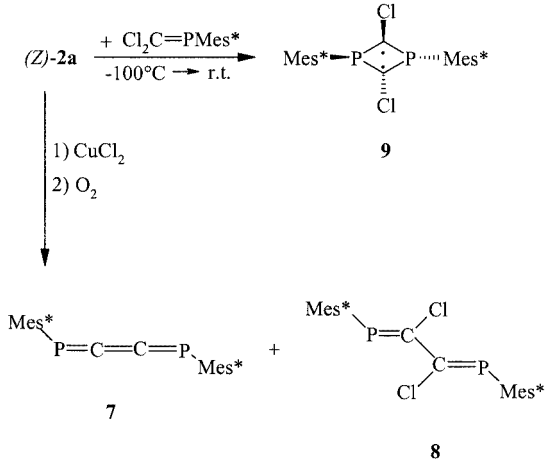
Scheme 3. Generation of phosphaalkynes **4a**,**b** and phosphaalkene (*E*)-**5a** from phosphavinylidene carbenoids (*E*)-**2a**,**b**

In contrast to this reactivity, the (*Z*)-configured phosphaalkylidene carbenoid (*Z*)-**2a**, obtained either by deprotonation of (*Z*)-2-chloro-1-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethene [(*Z*)-**1a**] with *tert*-butyllithium or by a chlorine/lithium exchange of Mes*P=CCl$_2$ (**6**, Scheme 4) with *n*-butyllithium in THF at −78 °C, did not produce **4a** upon warming. Quenching of (*Z*)-**2a** with methyl iodide at any temperature gave (*E*)-**5a**.[5a]



Scheme 4. Preparation and methylation of phosphavinylidene carbenoid (*Z*)-**2a**

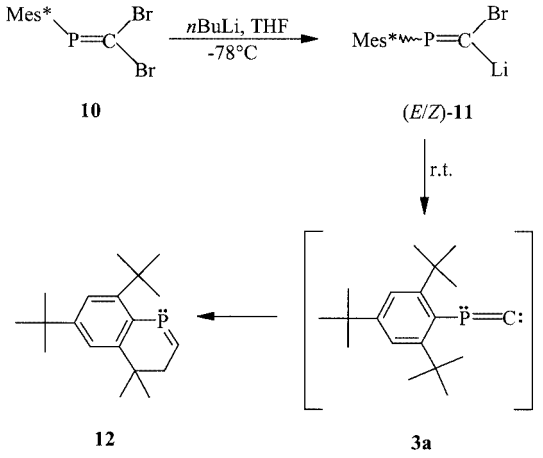
It was assumed that solvation about the lithium atom in (*E*)-**2a** destabilizes the molecule, because of steric congestion between the bulky supermesityl group and the solvents coordinated around the lithium atom, which, thus, facilitates the α-elimination and formation of **4a**. Such a severe steric crowding should be absent in (*Z*)-**2a**, which increases its thermostability.[5a] In line with this assumption, single crystals of (*Z*)-Mes*−P=C(Cl){Li(dme)$_2$} were grown from a 1,2-dimethoxyethane solution at −60 °C and were subjected to an X-ray structure determination.[6] Lithium compound (*Z*)-**2a** served as a valuable precursor for the syntheses of interesting organophosphorus species, such as 1,4-diphosphabutatriene **7**, 1,4-diphosphabutadiene **8**,[7] and 1,3-diphosphacyclobutane-2,4-diyl[8] **9** (Scheme 5). From a formal point of view, compound **7** may be envisaged as a dimerization product of isophosphaalkyne **3a**, although synthetic routes are conceivable that circumvent the free vinylidene-like **3a**.



Scheme 5. Synthesis of **7**, **8**, and **9** from phosphavinylidene carbenoid (*Z*)-**2a**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

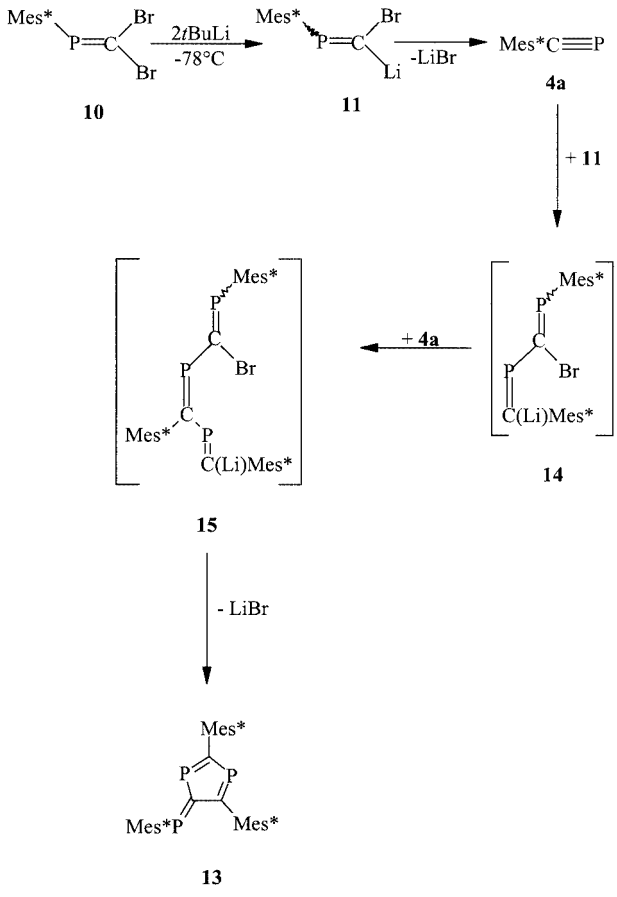
A different reaction pattern has been observed with 2-bromo-1-(2,4,6-tri-*tert*-butylphenyl)-1-phosphaethenyllithium, which was obtained as an (*E*)/(*Z*) mixture (1:5) by treatment of Mes*−P=CBr_2 with *n*-butyllithium in THF at −78 °C (Scheme 6).



Scheme 6. Synthesis of 3,4-dihydro-1-phosphanaphthalene **12** from Mes*P=CBr_2

Warming of the reaction mixture to room temperature led to the formation of the 3,4-dihydro-1-phosphanaphthalene derivative **12** in 17% yield. None of the compounds Mes*P≡C (**3a**) or Mes*C≡P (**4a**) was detected in the reaction mixture. It is conceivable that **12** resulted from an intramolecular C−H insertion reaction of transient **3a**. Attempts to trap the isophosphaalkyne with cyclohexene or tetracyanoethylene, however, failed. The contrasting behavior of (*E*/*Z*)-**11** was attributed to the increased tendency of the bromide ion to act as a leaving group, which allows the smooth liberation of **3a** at lower temperatures.[9] Interestingly, the preparation of **12** from precursor **10** via intermediate (*E*/*Z*)-**11** also depends on the nature of the organolithium compound employed. The reaction of dibromophosphaethene **10** with 2 equiv. of *tert*-butyllithium, instead of *n*-butyllithium, in THF at −78 °C afforded (*E*/*Z*)-**11**, and slow warming to ambient temperature yielded 1,3,6-triphosphafulvene **13** (18% yield) in addition to small amounts of Mes*(H)P−C≡C−Mes*, Mes*C≡P (**4a**), and 1-phospha-3,4-dihydronaphthalene **12**.[10] As indicated before, triphosphafulvene **13** was not observed in the corresponding reaction of Br_2C=PMes* with *n*-butyllithium. The mechanism proposed for the formation of **13** involves the liberation of **4a** from (*E*/*Z*)-**11** and the subsequent addition of a second equivalent of **11** to the phosphaalkyne. Addition of the resulting 1,3-diphosphabutadienyllithium **14** to Mes*C≡P should give the 1,3,5-triphosphahexatrienyllithium **15**, which then cyclizes to form the final product (Scheme 7).[10]

Treatment of Mes*P=CI_2 with 2 equiv. of *n*-butyllithium at −120 °C yielded exclusively (*E*)-Mes*P=C(I)Li (**16**), which is stable to ca. −100 °C. At ca. −85 °C, **16** fragmented into Mes*C≡P (**4a**) with a half-life of roughly 4 h. No ^{31}P NMR spectroscopic signals were observed other then those of **16** and **4a**. This result led to the assumption



Scheme 7. Synthesis of triphosphafulvene **13** from Mes*P=CBr_2

that the rearrangement of **3a** into **4a** at this low temperature must be extremely rapid, or that the migration of the supermesityl group from the phosphorus atom to the carbon atom occurs concomitantly with the extrusion of lithium iodide,[11] which circumvents the intermediacy of free **3a**.

3. Theoretical Studies

The failure to synthesize isophosphaalkynes, or at least to obtain reliable proof of their existence as reactive intermediates, has been rationalized on the basis of qualitative considerations as well as detailed quantum chemical considerations. Phosphorus is a high main group element and, thus, it is reluctant to undergo s−p mixing of the valence orbitals.[12a] In other words, phosphorus suffers from "orbital nonhybridization."[12b] This effect has the further consequence that phosphorus, in contrast to its first-row analog nitrogen, prefers structures in which an inert s-orbital contains two nonbonding electrons. While this state is well documented in white phosphorus, its consequence for the formation of linear triple bonds is also apparent. Such an unfavorable sp-hybrid would exist in the isophosphaalkyne, HPC. On the other hand, such a bonding situation is not observed in the phosphaalkyne, HCP. The phosphorus

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

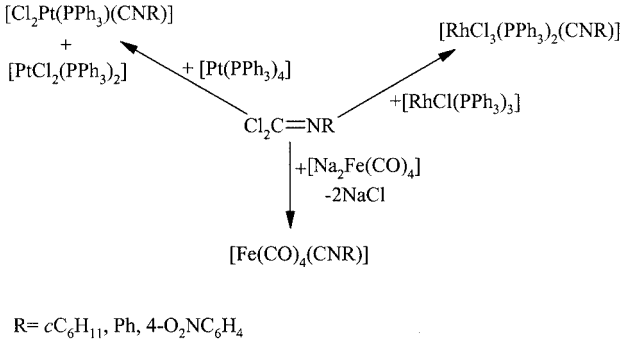
atom here can constitute a nonbonding s-orbital that is not forced to participate in bonding with the neighboring carbon atom.

These qualitative considerations[12a] find support in detailed quantum chemical calculations. According to the ab initio calculations for the HCP/HPC system, the linear HPC and HCP isomers correspond to the energy maximum and energy minimum, respectively, on the energy surface of the singlet ground state, and the relative energy between them is 83.9 kcal/mol at the MP4/6-31g** level.[13a,13b] The existence of a slightly bent HPC structure, however, in which the nonbonding s-orbital at the phosphorus atom is partly freed, is conceivable by other calculations. These calculations predict a local energy minimum that is merely 2.3 kcal/mol below the transition state for the rearrangement to HCP.[13c] In contrast to this prediction, the first-row analog HNC is a stable energy minimum on the electronic hypersurface, since a nitrogen atom can form an sp-hybrid orbital suitable for a linear arrangement of the three atoms in the isocyanide. According to electron-correlated ab initio calculations, the energy difference between the two structures HCN and HNC is ca. 14 kcal/mol.[14]

A further hint at the stability of the isophosphaalkyne has been given by quantum chemical considerations. Electronegative substituents (e.g., fluorine) tend to withdraw p-electrons from a bond. As a consequence, a fluorine atom stabilizes, to a considerable extent, the isophosphaalkyne form, RPC (R = F). For the reasons mentioned above, this stability occurs to a larger extent than that for the corresponding phosphaalkyne form, RCP. Ab initio calculations agree with these considerations.[13b] Although the energy barrier for the rearrangement from FPC to FCP is increased (13−17 kcal/mol), so far FPC has not been characterized experimentally. Principally, it is conceivable that the compound could be observed in an inert matrix at low temperature.[13b]

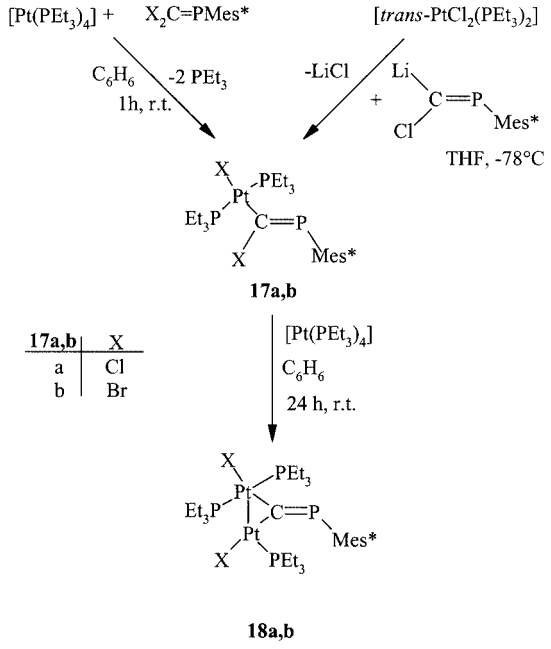
4. Isosphosphaalkyne Complexes

It is obvious that the facile α-elimination of lithium halides from *C*-lithiated *C*-halophosphaalkenes and the marked propensity to rearrangement of the initial products has thwarted the detection and isolation of isophosphaalkynes. Metallation of the dihalophosphaalkenes by transition metal complexes through oxidative addition processes, however, should lead to coordination compounds featuring isophosphaalkyne ligands. A model reaction, in which an isocyanide dichloride was converted into an isocyanide ligand at a transition metal center was reported in the mid-1970s (Scheme 8).[4h]



Scheme 8. Formation of isocyanide complexes from isocyanide dichlorides

The first examples of stable (arylisophosphaalkyne)metal complexes **18a**,**b** were prepared by reaction of *trans*-[(X)(PEt$_3$)$_2$Pt{C(=PMes*)X}] (**17a**,**b**) with [Pt(PEt$_3$)$_4$] in benzene (or in hexanes) at room temperature (Scheme 9). This oxidative addition-type reaction was complete within 24 h and afforded **18a**,**b** as the only products. The key compounds **17a**,**b** were available either by an oxidative addition of X$_2$C=PMes* (X = Cl, Br) onto [Pt(PEt$_3$)$_4$] in benzene at 25 °C or, in the case of **17a**, by treatment of *trans*-[PtCl$_2$(PEt$_3$)$_2$] with LiC(Cl)=PMes* in THF at −78 °C.[15]

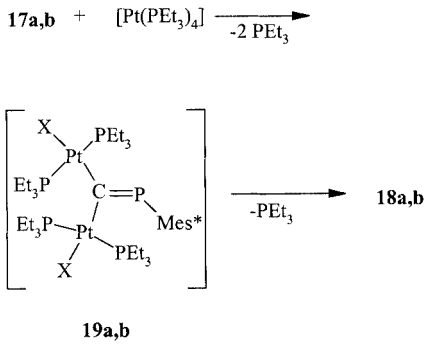


Scheme 9. Synthesis of (μ-isophosphaalkyne)diplatinum complexes **18a**,**b**

The direct synthesis of red, crystalline **18a**,**b** from the dihalophosphaalkenes and 2 equiv. of [Pt(PEt$_3$)$_4$] was also possible, albeit in much lower yield (Scheme 10).[15] A plausible mechanism for the generation of the μ-isophosphaalkyne complexes invokes the intermediacy of the doubly *C*-metalated phosphaalkenes **19a**,**b**, which extrude 1 equiv. of PEt$_3$ under Pt−Pt bond formation.

An X-ray diffraction study reveals **18a** as a dinuclear complex in which a Pt−Pt single bond of 2.6751(5) Å is nonsymmetrically bridged by the isophosphaalkyne ligand (Figure 1). The Pt−C bond lengths between the two inequivalent metal atoms and the bridging ligand are markedly different. The distance Pt(2)−C(1) of 1.86(1) Å is shorter than Pt(1)−C(1) [2.107(9) Å] by 0.22 Å.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 10. Proposed mechanism for the formation of **18a**,**b**

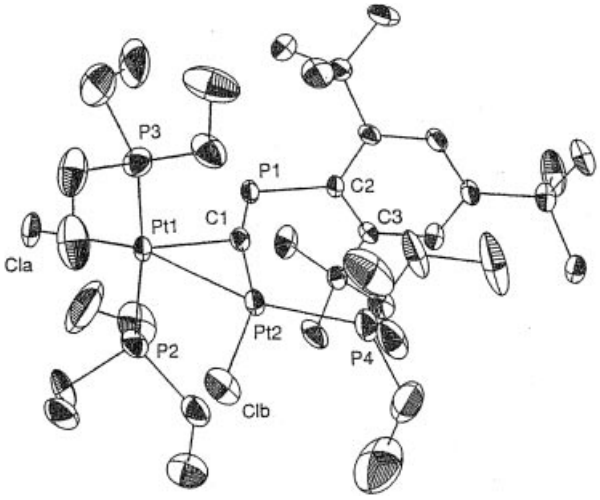


Figure 1. Molecular structure of [(Cl)(PEt_3)Pt(μ-C=PMes*)-Pt(PEt_3)$_2$(Cl)](*Pt*−*Pt*) (**18a**) in the crystal; selected bond lengths [Å] and angles [°]: Pt(1)−Pt(2) 2.6751(5), Pt(1)−C(1) 2.107(9), Pt(2)−C(1) 1.89(1), P(1)−C(1) 1.67(1), P(1)−C(2) 1.89(1); C(1)−P(1)−C(2) 110.7(5), Pt(1)−C(1)−Pt(2) 83.8(4), Pt(1)−C(1)−P(1) 112.0(5), Pt(2)−C(1)−P(1) 164.1(6)

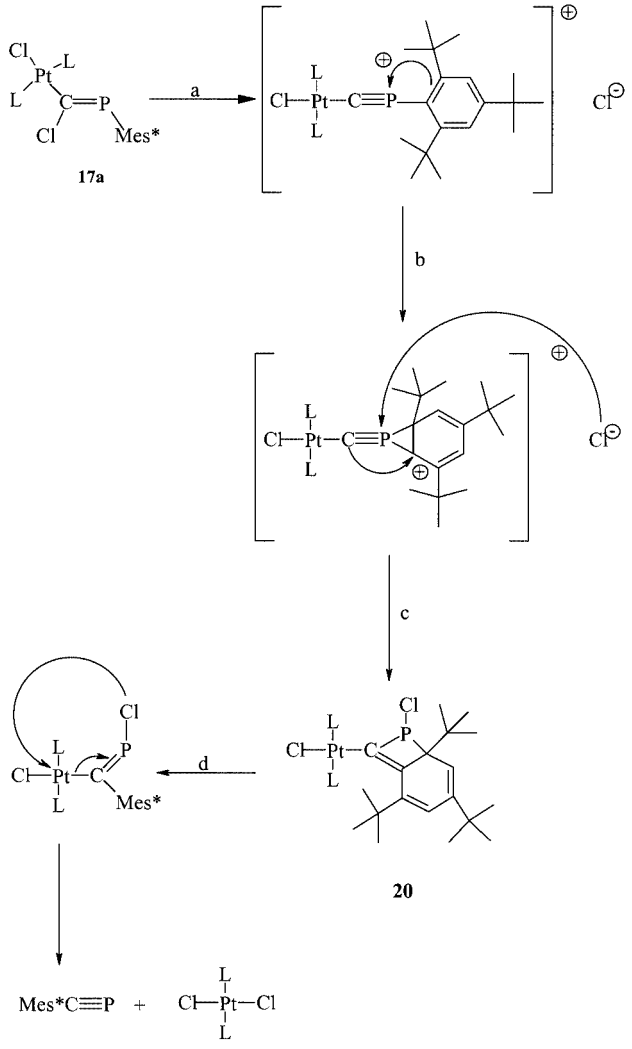
The Pt−C(1)−P(1) angles also differ significantly. The angle Pt(2)−C(1)−P(1) of 164.1(6)° is close to linearity, whereas the angle Pt(1)−C(1)−P(1) of 112.0(5)° is sharply bent. The separation between Pt(1) and P(1) of 3.15 Å excludes any bonding interaction. The bond length C(1)−P(1) of 1.67(10) Å falls in the typical range for a P−C double bond (1.65−1.72 Å), as determined from numerous phosphaalkenes without π-donating substituents at the tricoordinate carbon atom. Therefore, the most reasonable description of the organophosphorus ligand is that of a semibridging group that is strongly coordinated to Pt(2) and interacts more weakly with Pt(1). At this point, it should be mentioned that solutions of the pure key compounds **17a** and **17b** in nonpolar solvents (C_6D_6, hexanes) are stable at ambient temperature under argon for at least one week. In polar solvents, such as CH_2Cl_2, $CHCl_3$, or THF, however, they decompose rapidly to the phosphaalkyne Mes*C≡P (**4a**) and [X_2Pd(PEt_3)$_2$] via the intermediate **20**, the identity of which was authenticated in one case by an X-ray structural analysis (Scheme 11). The propensity for this conversion depends on the metal (Pt < Pd), the halide (Cl < Br) and the phosphane ligand (PEt_3 < PPh_3). At no stage of this transformation is free isophosphaalkyne involved.[15c,15d] In the light of this finding, it is clear that the dechlorination of Cl_2C=PMes* by [Pd(PPh_3)$_4$] to give Mes*C≡P and *trans*-[$PdCl_2$(PPh_3)$_2$] cannot involve free C≡P−Mes* as was claimed in the respective communication.[16]



Scheme 11. Proposed mechanism for the decomposition of *C*-platiniophosphaalkene **17a** in polar solvents

One might even speculate that the conversion of Li(Cl)C=PMes* into Mes*C≡P proceeds by a similar mechanism, where lithium plays the role of the platinum center. At this point, it is clear that the synthetic principle realized in Scheme 9 for producing μ-isophosphaalkyne complexes is also limited by the stability of the respective *C*-metallo-*C*-halophosphaalkenes. To be certain of this effect would require a more thorough study concerning the particular role of the metal atom, the halogen atom, the ancillary ligands and the substituents at the phosphorus atom in the process. A first step toward this study was to change the metal complex, which by reaction with precursor metal-

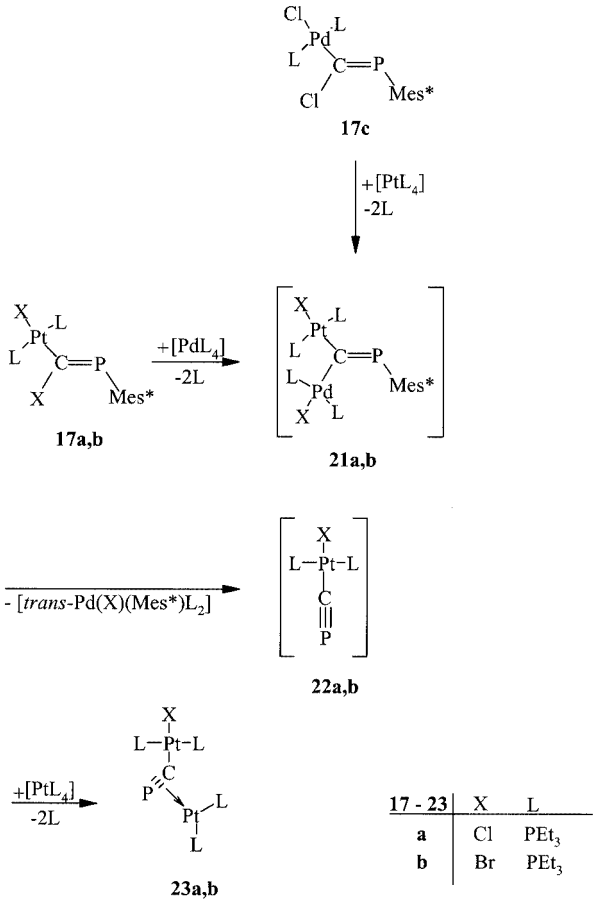
lophosphaalkenes **17a**,**b**, should furnish heterodimetallic analogs of **18a**,**b** as products. When [Pt(PEt_3)$_4$] was replaced by [Pd(PEt_3)$_4$], however, the reaction with **17a**,**b** proceeded in a completely different manner.

After stirring the reaction solution of **17a**,**b** and [Pd(PEt_3)$_4$] for 24 h at ambient temperature, complexes **22a**,**b** and [*trans*-Pd(X)(Mes*)(PEt_3)$_2$] were observed as the only products (Scheme 12). The latter compounds could be separated easily from the mixture by fractional crystallization and were characterized by an X-ray diffraction analysis. Although stable in solution for at least one week, all attempts to isolate **22a**,**b** without decomposition failed and the identification of **22a**,**b** was confined to spectroscopy. The ^{31}P NMR spectroscopic resonance of the unprecedented terminal phosphocyanide ligand was assigned to a triplet at δ = 68.0 ppm (J_{pp} = 9.2 Hz) resulting from coupling to the two equivalent P nuclei of the PEt_3 ligands. Moreover, **22a**,**b** could be trapped by reaction with [Pt(PEt_3)$_4$] to yield the dinuclear complexes **23a**,**b** featuring a bridging phosphocyanide ligand in an η^1:η^2-mode of coordination. Complex **23a** was also accessible by treatment of the *C*-palladiophosphalkene **17c** with 1 mol-equiv. of [Pt(PEt_3)$_4$] under similar reaction conditions.[15b]



Scheme 12. Synthesis of μ-η^1:η^2-phosphocyanide complexes **23a**,**b**

The X-ray analysis of **23a** shows a dinuclear complex containing a bridging C≡P ligand that is η^1-*C*-bonded to Pt(1) and η^2-*C*,*P*-bonded to Pt(2) (Figure 2). The distance between both platinum centers [3.7868(3) Å] eliminates any likelihood of significant bonding occurring between the metal atoms. The atoms Cl, Pt(1), C(1), P(1), Pt(2), P(4), and P(5) are nearly coplanar (to within 0.061 Å), while P(2) and P(3) are located 2.292 and 2.279 Å above and below this plane, respectively. The C(1)−P(1) bond length of 1.666(6) Å compares well to that in [η^2-(*t*BuC≡P)Pt(PPh_3)$_2$] [1.67(2) Å] and is quite typical for η^2-ligated phosphaalkynes. As mentioned above, the preparation of dinuclear complexes with bridging isophosphaalkyne ligands, according to the method devised in Scheme 9, seems to be limited by the nature of the metal atom. Moreover, an additional limitation is given by the few examples of dichlorophosphaalkenes that are available to date and by the demand for bulky substituents that have to be present in these reagents. In a very recent study, the dichlorophosphaalkene $(Me_3Si)_2N-P=CCl_2$ was utilized as an additional candidate for the oxidative addition to two platinum metal centers. The reaction of [Pt(PEt_3)$_4$] with $Cl_2C=PN(SiMe_3)_2$ in THF or hexanes at −50 °C immediately and quantitatively produced the η^1-phosphaalkenyl complex *cis*-[Cl(Et_3P)$_2$Pt{C(Cl)=PN($SiMe_3$)$_2$}] (*cis*-**24**) by oxidative addition of one of the C−Cl bonds. A quantitative *cis*/*trans* isomerization to give *trans*-**24** occurred at 0 °C (Scheme 13).[17]

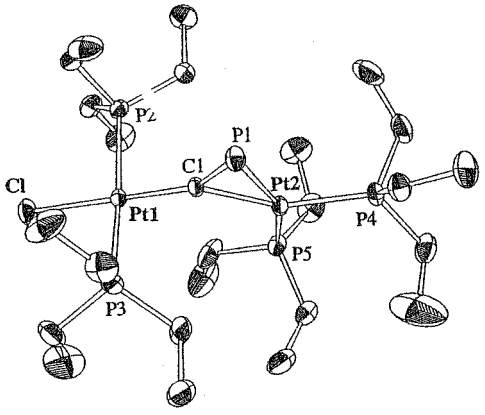


Figure 2. Molecular structure of **23a** in the crystal; selected bond lengths [Å] and angles [°]: Pt(1)−C(1) 1.950(6), Pt(1)−Cl 2.412(2), Pt(1)−P(2) 2.302(2), Pt(1)−P(3) 2.297(2), Pt(2)−C(1) 2.083(5), Pt(2)−P(1) 2.337(2), Pt(2)−P(4) 2.269(2), Pt(2)−P(5) 2.277(2), C(1)−P(1) 1.666(6); Pt(1)−C(1)−P(1) 144.0(3), Pt(1)−C(1)−Pt(2) 139.7(3), C(1)−Pt(2)−P(1) 43.8(2)

Although the molecular structure and the ^{31}P NMR spectrum of *trans*-**24** are very similar to those of *trans*-[Cl(Et_3P)$_2$Pt{C(Cl)=PMes*}] (**18a**), both species differ significantly in their reactivities. In contrast to **18a**, which in THF solution completely decomposed to Mes*C≡P and [Pt(PEt_3)$_2$Cl$_2$] within 24 h, THF solutions of *trans*-**24** are stable for weeks. Treatment of the latter compound with a 2nd equiv. of [Pt(PEt_3)$_4$] did not yield the anticipated μ-isophosphaalkyne complexes, but resulted in decomposition to a mixture of unidentified materials. Complex *trans*-**24** proved, however, to be an excellent precursor reagent for preparing the μ-η^1:η^2-phosphocyanide complex **23a**. Thus,

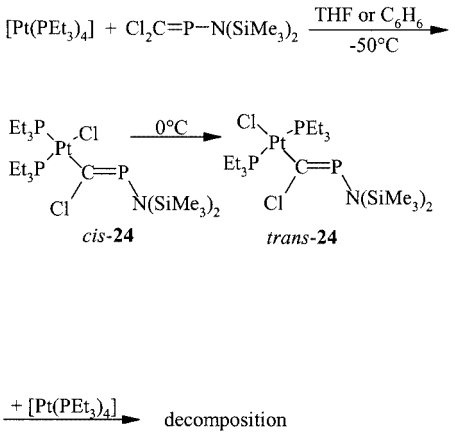
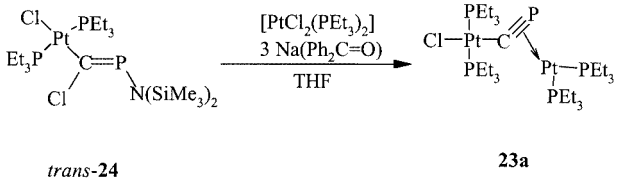


Scheme 13. Generation of *C*-platiniophosphaalkenes *cis*- and *trans*-**24**

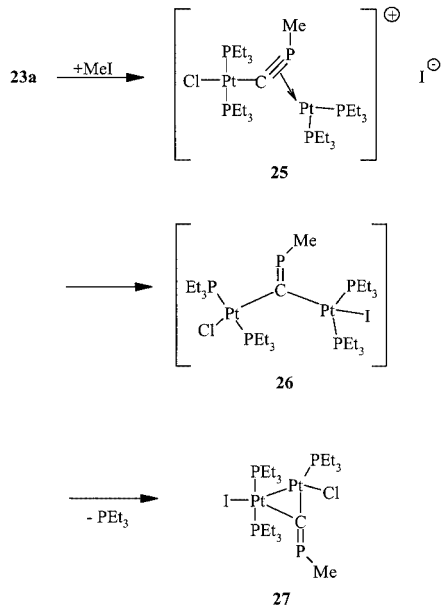
reduction of an equimolar mixture of **24** and $[Pt(PEt_3)_2Cl_2]$ with 3 equiv. of sodium benzophenone ketyl in THF afforded pure crystalline **23a** in 79% yield. This reaction was performed on a scale of several grams without a decrease in yield or purity of the product. It was crucial for the success of this process that the reducing agent be added to the mixture of both metal complexes. This requirement was rationalized by the need to trap the in situ generated dicoordinate complex $[Pt(PEt_3)_2]$ by π-coordination to the P=C double bond of **24** (Scheme 14). To date, this transformation is limited to using PEt_3 as a ligand in the platinum halide complex. Compound **24** remained unaffected in solution in similar reduction experiments with $[PtCl_2(PPh_3)_2]$, $[PtCl_2\{PiPr_3\}_2]$, $[PtCl_2(PCy_3)_2]$, and $[PtCl_2(depe)]$.



Scheme 14. Conversion of *trans*-**24** into **23a**

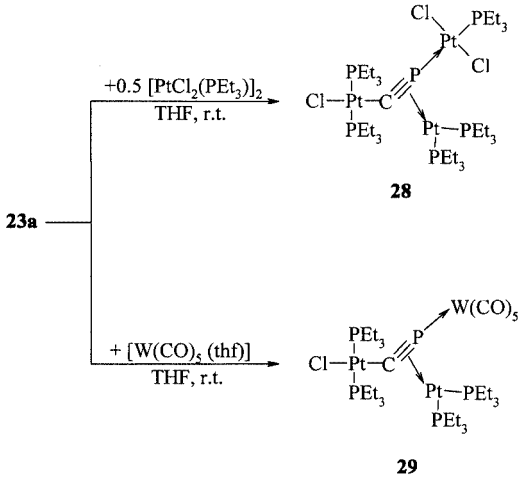
The availability of larger quantities of complex **23a** allowed a thorough investigation of its chemical reactivity to be made. Like classical η^2-phosphaalkyne complexes, the molecule exhibits significant nucleophilicity at the phosphorus atom of the C–P ligand. In keeping with this nucleophilicity, the treatment of **23a** with 3 equiv. of methyl iodide in THF for 12 h at ambient temperature resulted in the formation of the methyl isophosphaalkyne complex $[(Cl)(Et_3P)Pt(\mu\text{-}C{=}PMe)Pt(PEt_3)_2I](Pt{-}Pt)$ (**27**), with $(MePEt_3)I$ as a byproduct (Scheme 15).

Most likely this reaction was initiated by the methylation of the phosphorus atom of the C≡P bond to afford the cationic η^1-*C*:η^2-*C*,*P*-isophosphaalkyne complex **25**. Attack of the iodide ion at the zero-valent platinum center gave complex **26**, which may be regarded formally as a *C*,*C*-dimetallophosphaalkene. Extrusion of PEt_3 and Pt–Pt bond formation eventually afforded product **27**. Evidence for this



Scheme 15. Synthesis of μ-isophosphaalkyne complex **27** from **23a** and methyl iodide

proposal was taken from the clean methylation of **23a** with methyl triflate to give salt $\mathbf{25}^+OTf^-$. The latter salt was converted into **27** by treatment with a tenfold amount of NaI. Moreover, comparison of the NMR spectroscopic data of the triflate of $\mathbf{25}^+$ with the related platinum and tungsten adducts **28** and **29** adds further support for **25** being the initial product of the methylation reaction (Scheme 16).

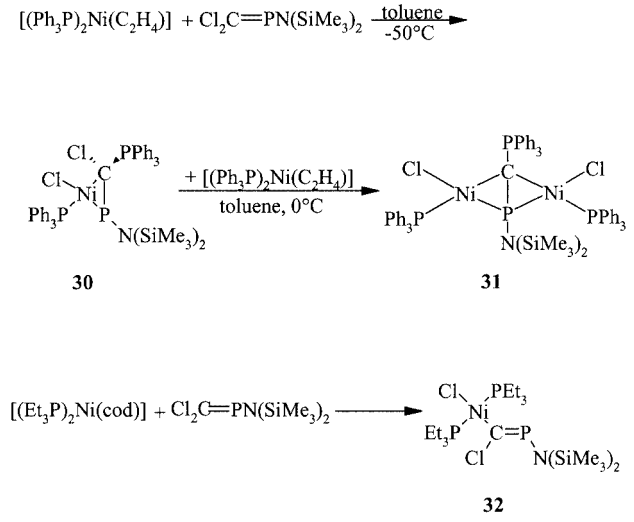


Scheme 16. Phosphocyanide as an η^1:η^1:η^2-ligand in trinuclear complexes **28** and **29**

For a successful alkylation, the synthetic sequence depicted in Scheme 15 could represent a more general access to (μ-isophosphaalkyne)diplatinum complexes. More importantly, this approach would no longer be dependent on sterically demanding groups. To evaluate this concept, alkylation of **23a** was performed with benzyl bromide, isopropyl iodide, alkyl bromide, and 2,4,6-tri-*tert*-butylbenzyl bromide under the same conditions as for the methylation. Ac-

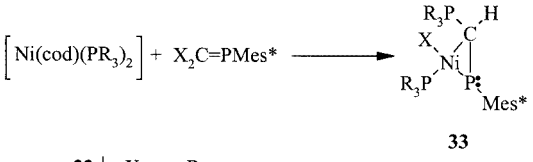
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cording to ^{31}P NMR spectroscopic observations, however, only the reactions with benzyl bromide and isopropyl iodide yielded μ-isophosphaalkyne complexes analogous to **27**. Unfortunately, the benzyl derivative could not be isolated in a pure state, and the isopropyl derivative decomposed during the course of the alkylation.[17] In a recent paper, the dichlorophosphaalkenes $Cl_2C{=}PN(SiMe_3)_2$ and $Cl_2C{=}$PMes* were treated with zero-valent nickel complexes,[18] which produced interesting and novel organophosphorus compounds instead of the anticipated isophosphaalkyne complexes. The reaction of 0.5 equiv. of $Cl_2C{=}PN(SiMe_3)_2$ with $[(Ph_3P)_2Ni(C_2H_4)]$ in toluene in the range between −78 °C and room temperature produced $[Ni_2Cl_2(PPh_3)_2\{\mu\text{-}\eta^2{:}\eta^2\text{-}C(PPh_3){=}PN(SiMe_3)_2\}]$ (**31**) in 74% yield. Low-temperature (−30 °C) ^{31}P NMR spectroscopic monitoring showed complex **30** as the only observable intermediate in this reaction. A stoichiometric reaction of $[(Ph_3P)_2Ni(C_2H_4)]$ with $Cl_2C{=}PN(SiMe_3)_2$ at −30 °C yielded **30** quantitatively. This compound could not be isolated because of decomposition, but the addition of a 2nd equiv. of $[(Ph_3P)_2Ni(C_2H_4)]$ to the reaction mixture led to oxidative addition of the remaining C−Cl bond in **30** to $[(Ph_3P)_2Ni(C_2H_4)]$ to give **31** (Scheme 17). The latter complex can be viewed as a triphenylphosphane-stabilized $\eta^2{:}\eta^2$-isophosphaalkyne complex. Attempts to remove the phosphane from **31** with 9-borabicyclo[3,3,1]nonane resulted in complete decomposition.



Scheme 17. Reaction of zero-valent nickel complexes with $(Me_3Si)_2NP{=}CCl_2$

In contrast to the reaction in Scheme 17 with PPh_3 as a ligand in the nickel complex precursor, the treatment of a 1:2 mixture of $[Ni(cod)_2]$ and PEt_3 with $Cl_2C{=}PN(SiMe_3)_2$ afforded the nickeliophosphaalkene **32**, which is formally analogous to the *Pt*-functionalized species **24**. This compound did not rearrange to an analog of **30**, and it did not react further with an excess of Ni^0 complexes to molecules like **31** or to μ-isophosphaalkene complexes. In solution, compound **32** decomposed to nontractable materials within 1 d. In contrast to this finding, the dihalophosphaalkenes $X_2C{=}P{-}Mes^*$ (X = Cl, Br) were dehalogenated by 2 equiv. of $[Ni(cod)_2]/2PR_3$ mixtures to give the metalloheterocycles **33** in moderate yields (Scheme 18).



33	X	R

Scheme 18. Preparation of metalloheterocycle **33**

A completely different approach to dinuclear complexes with bridging μ-isophosphaalkyne ligands **37a−c** made use of the condensation of the cationic (μ-carbyne)diiron complex **34** with the secondary aryl(silyl)phosphanes **35a−d** in acetonitrile in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (Scheme 19).[19a,19b]

d	2,4,6-$(CF_3)_3C_6H_2$

Scheme 19. Synthesis of (μ-isophosphaalkyne)diiron complexes **37a−d**

Complexes **37a−c** were isolated in moderate yields as dark-red, air-stable crystals after column chromatography. Thermolabile derivative **37d**, however, had to be converted into its stable $[Cr(CO)_5]$ adduct **38d** by treatment with (cyclooctene)$Cr(CO)_5$ immediately after isolation.[19b] It is conceivable that the generation of **37a−d** was initiated by the nucleophilic attack of phosphanes **35a−d** at the bridging carbyne carbon atom, with subsequent deprotonation of the resulting phosphonium salt. Alternatively, the nucleophilic attack of anions $[P(SiMe_3)Ar]^-$ is also possible. Evi-

dence for the intermediates **36** is given by ^{31}P NMR spectroscopic signals at δ = 8.3 (**36a**) and 2.1 ppm (**36c**) at the beginning of the process. Elimination of Me_3SiSCH_3 from **36a–d** afforded the final products. The presence of P=C double bonds was indicated by ^{31}P NMR spectroscopic resonances at δ = 200–258 ppm and doublets in the $^{13}C\{^1H\}$ NMR spectra at very low field (δ = 333.8–345.8 ppm).

The X-ray structure analysis of **37a** shows a dinuclear complex, the Fe–Fe bond of which [2.527(5) Å] is symmetrically bridged by a μ-CO ligand [Fe(1,2)–C(12) = 1.954(16), 1.927(15) Å] and a μ-C=P–Mes* ligand [Fe(1,2)–C(13) = 1.903(16), 1.927(16) Å] (Figure 3). The P–C bond length of 1.683(17) Å is consistent with a double bond. The angles Fe(1)–C(13)–P(1) [147.2(10)°] and Fe(2)–C13)–P(1) [129.7(9)°] differ significantly, but not as much as in the diplatinum complex **18a** [164.1(6)° and 112.0(5)°]. The condensation discussed here for the construction of the P=C bond of an μ-isophosphaalkyne complex is independent from the existence of a phosphaalkene precursor. This method, however, also lacks generality. Thus, reaction of **34** with an equimolar amount of *t*BuP(H)$SiMe_3$ in acetonitrile in the presence of DBU afforded complex **40** within 2 d at room temperature[19c] (Scheme 20).

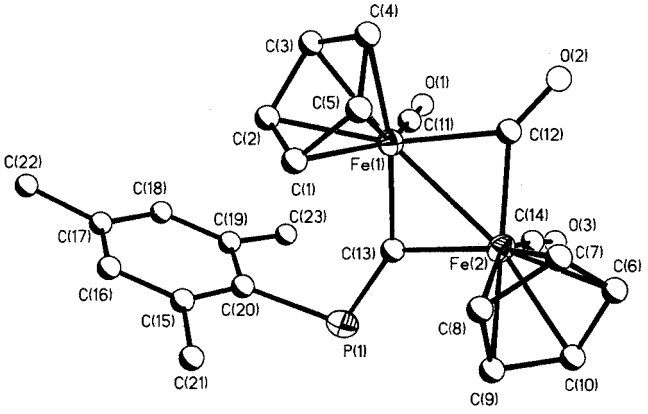

Figure 3. Molecular structure of **37a**; selected bond lengths [Å] and angles [°]: Fe(1)–Fe(2) 2.527(5), Fe(1)–C(12) 1.954(16), Fe(2)–C(12) 1.927(15), Fe(1)–C(13) 1.903(16), Fe(2)–C(13) 1.927(16), P(1)–C(13) 1.683(17); Fe(1)–C(13)–P(1) 147.2(10), Fe(2)–C(13)–P(1) 129.7(9), Fe(1)–C(12)–O(2) 138.3(13), Fe(2)–C(12)–O(2) 140.4(13), C(13)–P(1)–C(20) 104.5(7)

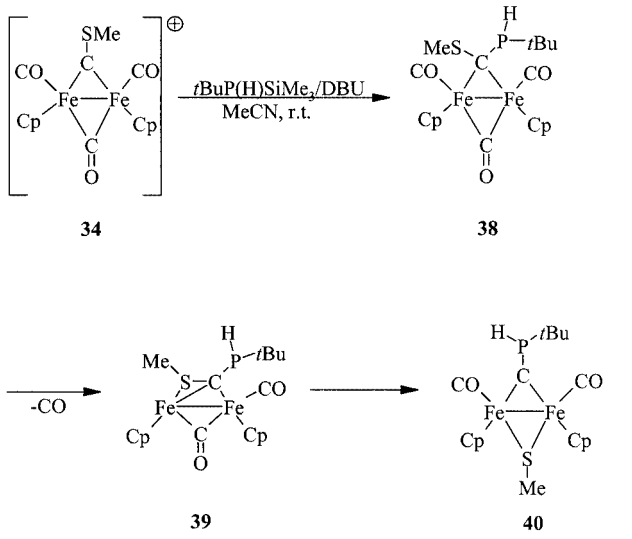
The reaction of **34** with *i*$PrPH_2$ or $(Me_3Si)_3CP(H)SiMe_3$ did not yield tractable products. The identity of **40** was deduced from elemental analyses and spectroscopic evidence. The ^{31}P NMR spectrum revealed a doublet of decets at δ = −6.0 ppm ($^1J_{PH}$ = 265, $^3J_{PH}$ = 14 Hz), whereas in the $^{13}C\{H\}$ NMR spectrum a doublet at δ = 420.0 ppm ($^1J_{PH}$ = 83 Hz) is diagnostic of a μ-phosphanylcarbyne ligand. Monitoring of the course of the reaction by $^{31}P\{H\}$ NMR spectroscopy showed, before DBU was added, only the resonance of *t*BuP(H)$SiMe_3$ at δ = −85.5 ppm. After the addition of the base, this resonance was replaced by a singlet at δ = 20.6 ppm, which in the proton-coupled experiment became a doublet of multiplets ($^1J_{PH}$ = 383.1 Hz). This signal is attributed to intermediate **38**. After 14 h at 20 °C, the spectrum displayed two singlets at δ = −7.9 and −17.4 ppm in addition to the resonance for **38**. After 2 d, only the singlet at δ = −7.9 ppm of the final product **40** remained. The signal at δ = −17.4 ppm was due to intermediate **39**, which was isolated after 2 h of reaction and fully characterized by an X-ray diffraction study (Figure 4).[19c]



Scheme 20. Synthesis of μ-phosphanylcarbyne complex **40**

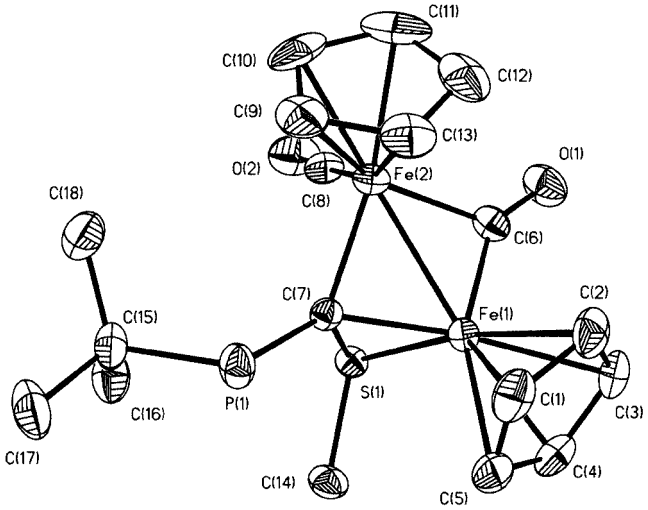


Figure 4. Molecular structure of **39** in the crystal; selected bond lengths [Å] and angles [°]: Fe(1)–Fe(2) 2.5015(7), Fe(1)–C(7) 1.910(3), Fe(2)–C(7) 1.975(3), Fe(1)–S(1) 2.2309(8), S(1)–C(7) 1.800(3), P(1)–C(7) 1.807(3), P(1)–C(15) 1.885(3); Fe(2)–C(7)–P(1) 124.34(14), C(7)–P(1)–C(15) 108.37(14), S(1)–C(7)–P(1) 125.4(2), Fe(1)–C(7)–P(1) 126.8(2), Fe(1)–C(7)–Fe(2) 80.14(10)

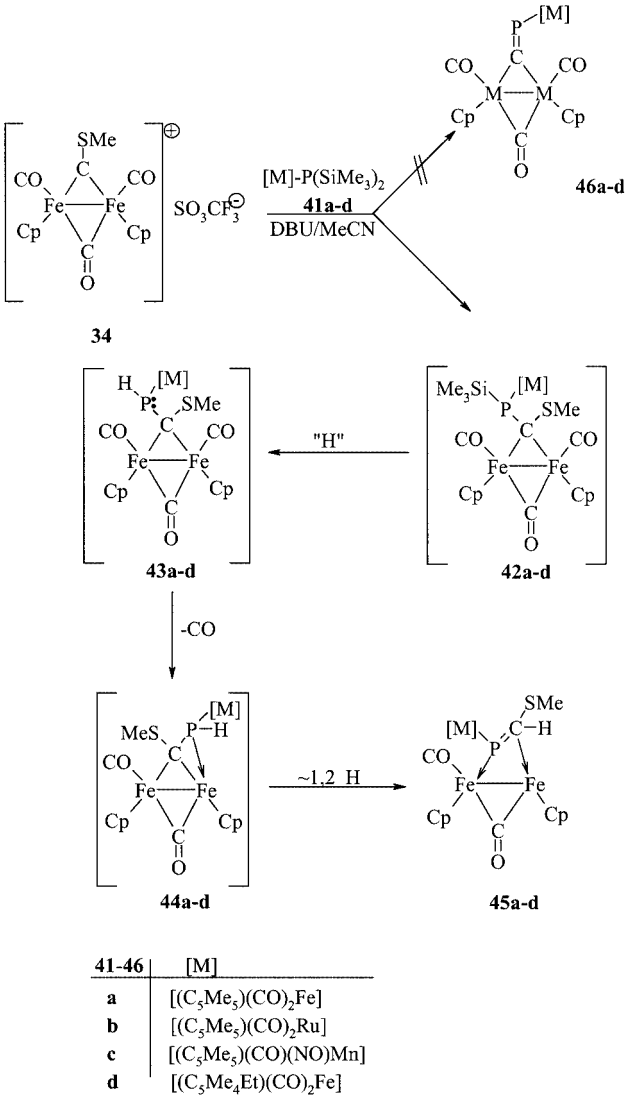
The most interesting feature of the molecule is that the *tert*-butylphosphanyl(methylthiolato)methylidene ligand bridges the Fe–Fe unit via the distorted tetrahedral carbon atom C(7) [Fe(1,2)–C(7) = 1.910(3), 1.975(3) Å]. In addition, the sulfur atom of the thiolato substituent is coordinated to Fe(1) [Fe(1)–S(1) = 2.231(1) Å]. The distances

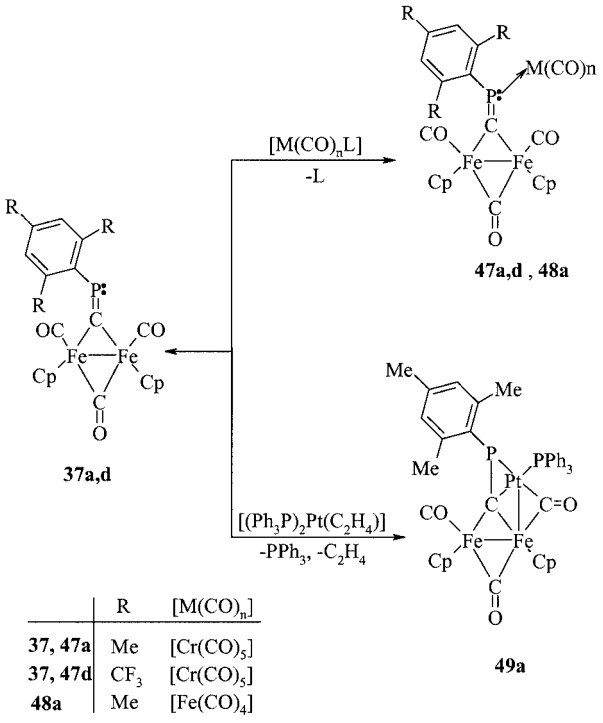
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

P(1)−C(7) [1.807(3) Å] and S(1)−C(7) [1.800(3) Å] are consistent with single bonds. The attempted condensation of the metallodisilylphosphanes **41a−d** with μ-carbyne complex **34** resulted in the formation of the dinuclear complexes **45a−d** featuring μ-η^1-*P*:η^2-*C*,*P*-metallophosphaalkene ligands instead of the anticipated trinuclear C≡P complexes **46** (Scheme 21).[19d]



Scheme 21. Synthesis of μ-η^1:η^2-metallophosphaalkene complexes **45a−d**

It is reasonable to propose that the synthesis of compounds **45** is initiated by the nucleophilic attack of metallo(-silyl)phosphide {P[M](SiMe$_3$)}$^-$ at the carbyne bridge of **34** to give the μ-alkylidene complex **42**. The replacement of the Me$_3$Si group in **43** by a hydrogen atom was unexpected. Since traces of moisture are excluded from the reaction, the source of the hydrogen atom might be DBU itself. An intramolecular replacement of CO by the phosphane function in **43** results in intermediate **44**. A 1,2-hydrogen shift and a second Fe−P contact leads to the final product **45**. It is worth mentioning that the preparation of **45** failed when NEt$_3$ was used as the base instead of DBU. In a control experiment, (η^5-C$_5$Me$_5$)(CO)$_2$FePH$_2$, **34**, and DBU afforded **45a** with a slightly improved yield (39%, cf. 28%). The difference in reactivity between aryl−PH(SiMe$_3$) or aryl−PH$_2$ and [M]PH(SiMe$_3$) or [M]PH$_2$ towards **34** may be rationalized by regarding the common intermediate **42**. Obviously, activation by the aryl group at the phosphorus atom promotes the 1,2-eliminations of Me$_3$SiSMe or HSMe to give **37**, whereas the electron-releasing metallo group enhances the phosphane's nucleophilicity, favoring the intramolecular CO displacement instead of the 1,2-elimination. The chemistry of the (μ-isophosphaalkyne)diiron complexes **37** largely resembles that of classical phosphaalkenes. Thus, the synthesis of the pentacarbonylchromium complexes **47a**,**d** and of the [Fe(CO)$_4$] adduct **48a** was accomplished by reaction of **37a**,**d** with pentacarbonyl(cyclooctene)chromium or nonacarbonyldiiron, respectively, with the organophosphorus moiety acting as an η^1-ligand through the lone pair of electrons at the P atom (Scheme 22).[19b]



Scheme 22. Preparation of the trinuclear complexes **47a**,**d**, **48a**, and **49a** featuring bridging isophosphaalkyne ligands

The η^1-ligation of the phosphorus atom of **37a**,**d** to an [M(CO)$_n$] fragment in **47c**,**d** and **48a** was accompanied by the typical shielding of the ^{31}P NMR spectroscopic signal ($\Delta\delta^{31}$P = 25.0−74.3 ppm). The black crystalline complex **49a**, isolated from the reaction between **37a** and [(Ph$_3$P)$_2$Pt(C$_2$H$_4$)] displayed, in the ^{31}P NMR spectrum, two doublets at δ = 129.9 and 44.15 ppm ($^2J_{P,P}$ = 9.8 Hz) for the ^{31}P nuclei of the isophosphaalkyne and PPh$_3$ ligands. The increased high-field shift upon coordination (Δδ = 125.6 ppm) and the $^1J_{P,Pt}$ coupling constant of only

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

63 Hz suggest a π-interaction between the platinum atom and the P−C unit.[19b]

The X-ray diffraction study of **47a** (Figure 5) shows a pentacarbonylchromium complex that is attached to ligand **37a** via the lone pair of electrons at the P atom [Cr(1)−P(1) = 2.412(8) Å]. The geometry of **37a** is not significantly perturbed by the [$Cr(CO)_5$] fragment. The bonds and angles of the [Fe_2(μ-CO)(μCPMes)] unit of **47a** are shorter and smaller than those in the precursor molecule. Atoms C(15) and P(1) have trigonal-planar geometries. The exocyclic angles Fe(1)−C(15)−P(1) [139.0(13)°] and Fe(2)−C(15)−P(1) [140.3(14)°] in **47c** are nearly identical, whereas in **37a** they differ markedly [147.2(10) and 129.7(9)°, respectively].[19b]

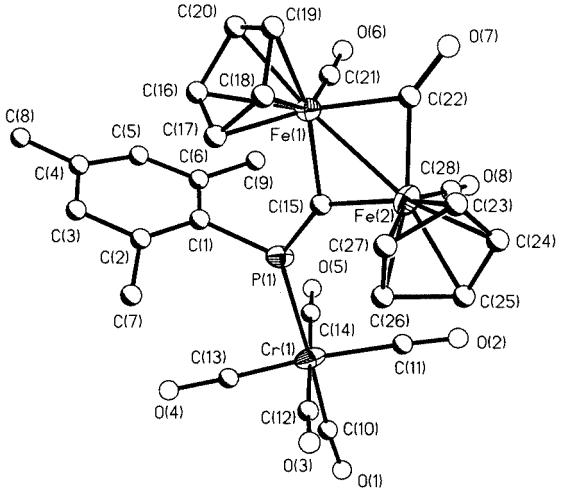


Figure 5. Molecular structure of **47a** in the crystal; selected bond lengths [Å] and angles [°]: Fe(1)−Fe(2) 2.500(6), Fe(1)−C(15) 1.958(21), Fe(2)−C(15) 1.908(21), Fe(1)−C(22) 1.953(26), Fe(2)−C(22) 1.912(25), P(1)−C(15) 1.632(21), P(1)−C(1) 1.836(23), P(1)−Cr(1) 2.412(8); Fe(1)−C(15)−P(1) 139.0(13), Fe(2)−C(15)−P(1) 140.3(14), C(15)−P(1)−Cr(1) 132.7(9), Cr(1)−P(1)−C(1) 118.1(7), Fe(1)−C(15)−Fe(2) 80.6(8)

The molecular structure of **49a** (Figure 6) shows a μ-isophosphaalkyne complex acting as an η^3-ligand towards a [$Pt(PPh_3)$] fragment. Thereby, the skeleton of **37a** remains mainly unaffected. The trigonal-planar donor atom C(12) of the isophosphaalkyne bridges both iron atoms symmetrically [Fe(1)−C(12) = 1.915(9), Fe(2)−C(12) = 1.918(10) Å]. The Fe−Fe bond [2.519(4) Å] is similar to that in **37a** [2.527(5) Å]. The π-coordination to the Pt atom causes an elongation of the P=C bond to 1.737(10) Å, with a Pt−C bond of 2.162(9) Å and a relatively long Pt−P(2) contact of 2.471(2) Å. The Pt(1)−P(1) bond to the PPh_3 ligand has a length of only 2.240(2) Å. Compound **49a** may be regarded as either a [$Pt(PPh_3)$] complex of an η^3-1-ferra-3-phosphaallyl ligand or, in line with the Wade−Mingos rules, as an *arachno* cluster constructed of the atoms Pt(1), P(2), C(12), and Fe(1). The polyeder skeleton electron count gives only 40 valence electrons (v.e.) instead of the theoretically required 42. This agrees with the fact that Pt^0 complexes often acquire only 16 v.e. instead of the familiar 18 v.e. shell.

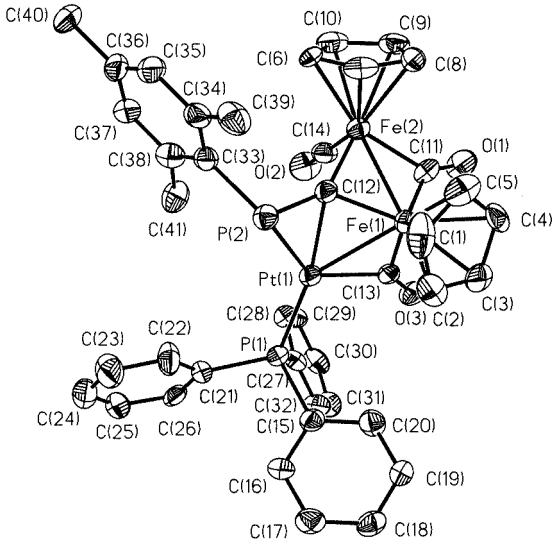

Figure 6. Molecular structure of **49a** in the crystal; selected bond lengths [Å] and angles [°]: Pt(1)−Fe(1) 2.577(2), Pt(1)−P(1) 2.240(2), Pt(1)−P(2) 2.471(2), Pt(1)−C(12) 2.162(9), Pt(1)−C(13) 1.997(2), Fe(1)−C(11) 1.879(10), Fe(1)−C(12) 1.915(9), Fe(1)−C(13) 1.951(9), Fe(1)−Fe(2) 2.518(4), Fe(2)−C(11) 1.952(9), Fe(2)−C(12) 1.918(10), P(2)−C(12) 1.737(10), P(2)−C(33) 1.862(10); Fe(1)−C(12)−Fe(2) 82.4(4), Fe(2)−C(12)−P(2) 146.5(5), Fe(1)−C(12)−P(2) 130.6(5), C(12)−P(2)−C(33) 105.9(4)

The oxidation of the μ-isophosphaalkyne complex **37a** with an equimolar amount of sulfur or an excess of grey selenium in benzene at 20 °C led to the formation of the methylene(thioxo)-λ^5,σ^3-phosphorane **50a** ($\delta^{31}P$ = 159.4 ppm) and the methylene(selenoxo)-λ^5,σ^3-phosphorane **50b** ($\delta^{31}P$ = 128.0 ppm) as orange-brown microcrystalline solids[19c] (Scheme 23). Methylation at the phosphorus atom of **37a** to give red microcrystalline **51** ($\delta^{31}P$ = 108.8 ppm) was effected by reaction with methyl triflate. The (μ-phosphanylalkylidene)diiron derivative **52** resulted from the subsequent reduction of salt **51** with $NaBH_4$ (Scheme 24).[19c]

Despite the existence of complexes with μ-isophosphaalkyne ligands, coordination compounds with terminal isophosphaalkyne ligands are still unknown and, thus, remain a challenge for the experimental chemist. A possible approach to these targets was stimulated by inspection of the electronic structures of aminocarbyne complexes, such as **53**,[20,21] or of the methanidocarbyne complex **54**,[22] where limiting structures such as **53′** and **54′** contribute significantly to the ground states of the molecules. In line with the diagonal relationship between C and P atoms, it is conceivable that structure **55′**, which features a terminal isophosphaalkyne ligand, also may be significant for the adequate description of the phosphidocarbyne complexes **55** (Scheme 25).

The chlorocarbyne complexes [Tp*$(CO)_2$M≡C−Cl] [**56**: M = Mo; **57**: M = W; Tp* = $HB(3,5\text{-}Me_2HC_3N_2)_3$][23] and inverse phosphaalkenes $Me_3SiP{=}C(NR_2)_2$ (**58a**: R=Me; **58b**: Et), the P−C bonds of which are strongly polarized ($P^{\delta-}C^{\delta+}$), were envisioned as suitable precursors for the

synthesis of complexes **55**.[24] Reaction of the carbyne complexes **56** and **57** with 2 mol-equiv. of phosphaalkene **58a** in CH_2Cl_2 at 20 °C led to precipitation of the red compounds **59a** and **60a** within 2 h. The analogous conversion of **56** and **57** to the corresponding complexes **59b** and **60b** by treatment with $Me_3SiP{=}C(NEt_2)_2$ required 15−18 h to reach completion (Scheme 26).[25]

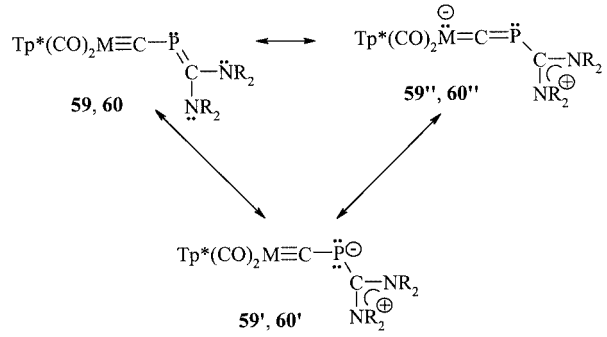
Scheme 26. Synthesis of complexes **59a**,**b** and **60a**,**b**

On the basis of IR and ^1H, ^{13}C, and ^{31}P NMR spectroscopic evidence, three resonance structures were chosen to fully describe the bonding situation in **59** and **60** (Scheme 27).



Scheme 27. Limiting structures of complexes **59** and **60**

Since the interpretation of the spectroscopic data is not unambiguous, however, an X-ray structual analysis of **60b** was carried out (Figure 7).

The most informative feature of the molecule is the geometry of the organophosphorus ligand. The bond length W(1)−C(3) of 1.838(6) Å compares well with that of the corresponding bond length in $[Tp^*(CO)_2W{\equiv}C{-}PMe_2Ph]PF_6$ [1.821(9) Å][26] and must be regarded as a metal−carbon triple bond. Accordingly, it is better to consider the ligand in **60b** as a phosphaalkenyl-functionalized methylidyne than as the anticipated terminal isophosphaalkyne ligand as depicted in structural formulas **59**′′ and **60**′′. The valence angle W(1)−C(3)−P(1) of 167.9(4)° deviates only slightly from linearity, which is in line with it having an sp-hybridized donor carbon atom. The bonds between the two-coordinate phosphorus atom and carbon atoms C(3) and C(4) are of equal length [1.759 Å]. Considering the different hybridizations at C(3) (sp) and C(4) (sp^2), and

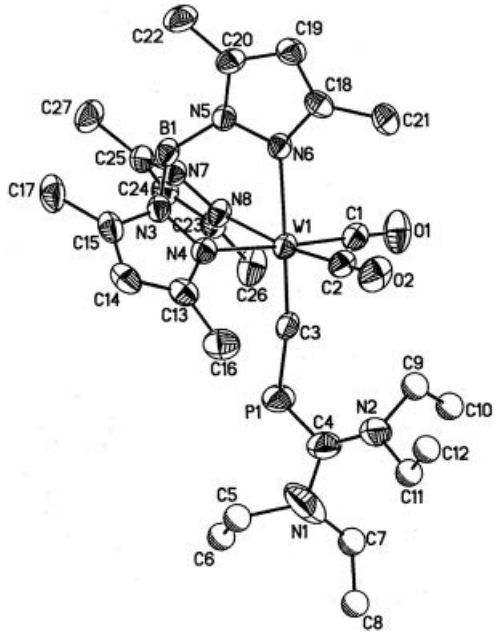

Figure 7. Molecular structure of **60b** in the crystal; selected bond lengths [Å] and angles [°]: W(1)−C(3) 1.838(6), P(1)−C(3) 1.759(7), P(1)−C(4) 1.759(9), N(1)−C(4) 1.362(11), N(2)−C(4) 1.354(10); W(1)−C(3)−P(1) 167.9(4), C(3)−P(1)−C(4) 105.7(3), P(1)−C(4)−N(1) 115.1(7), P(1)−C(4)−N(2) 127.9(7), N(1)−C(4)−N(2) 117.0(8)

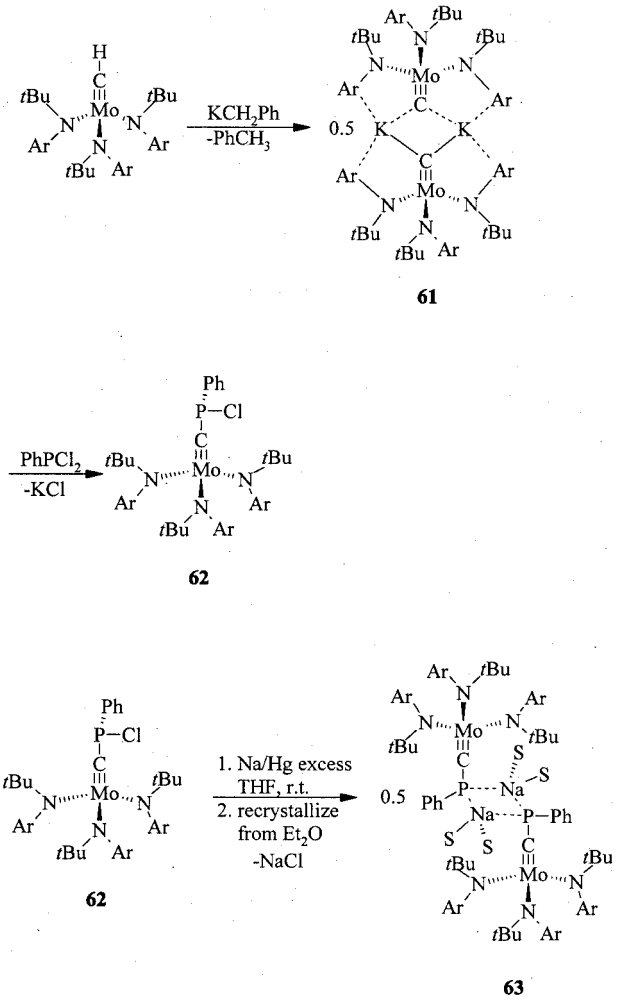
in view of the P−C (sp) bond length in [Tp*$(CO)_2W{\equiv}C{-}PMe_2Ph]^+$ [1.741(9) Å], the bond P(1)−C(1) may be designated as a single bond, whereas the bond length P(1)−C(1) compares well with the P=C double bond in the inversely polarized phosphaalkene $HP{=}C(NMe_2)_2$ [1.740(1) Å].[27] Atom C(4) has a trigonal-planar environment with shortened carbon−nitrogen bonds N(2)−C(4) [1.354(10) Å and N(1)−C(4) [1.362(11) Å] because of π-conjugation.

In a more recent paper, another attempt was described at the synthesis of a molybdenum alkylidynephosphanide complex of type **55** (Scheme 25). In contrast to the synthesis of **59** and **60**, where the C−P bond was formed between a positively polarized alkylidyne carbon atom and a negatively polarized phosphorus atom, the approach to anion **63** was based on the reaction of anion **61** and $PhPCl_2$. Reduction of the phosphanylalkylidyne complex **62** with sodium amalgam afforded complex **63**, which features the MoCPPh arrangement expected for a complex with a terminal isophosphaalkyne (phosphoisocyanide) ligand (Scheme 28).

Inspection of the molecular structure obtained from an X-ray diffraction study showed a molybdenum−carbon distance Mo−C(1) of 1.762(5) Å, which has to be regarded again as a triple bond. The bond length P−C(1) of 1.771(5) Å in **63** is similar to that in **60b** [1.759(7) Å], but markedly longer than the P−C single bond in [Tp*$(CO)_2W{\equiv}C{-}PMe_2Ph]^+$ [1.741(9) Å]. Obviously, the P−C bond shortening is mainly the result of an sp-hybridized carbon atom, rather than resulting from a significant amount of C−P multiple bonding. The angles



Scheme 28. Synthesis of the dimeric sodium phosphanidocarbyne complex **63**; S = ether or THF

Mo−C(1)−P [171.0(3)°] and C(1)−P−C(41) [106.0(2)°] are similar to the corresponding values in **60b** [W−P−C = 167.9(4)°; C−P−C = 105.7(3)°].[28] In conclusion, the bonding situation in the anion of **63** is similar to those of the previously reported complexes **59** and **60**, and are better interpreted in terms of alkylidyne complexes that are functionalized at the sp-hybridized carbon atom by either a $[PPh]^-$ unit or a phosphaalkenyl group, and not, as claimed by the authors, as a P-analog **55** of complexes with terminal isocyanide ligands.

5. Conclusions

What have we learnt about isophosphaalkynes? Firstly, the rich chemistry displayed by organic isocyanides is not mirrored by their phosphorus analogs. All attempts to synthesize these molecules have met with failure. In many instances the more stable isomers, the well-known phosphaalkynes, were isolated instead. Moreover, all experiments attempting to trap these molecules to provide some evidence for their transient existence have been unsuccessful. From mechanistic work with (isophosphaalkyne)plati-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

num complexes, it might even be concluded that the degradation of phosphavinylidene carbenoids of the type R−P=C(X)Li to phosphaalkynes RCP and lithium halide circumvents the occurrence of free isophosphaalkynes. Quantum-chemical calculations predict isophosphaalkynes as maxima on the energy surface in the system HPC/HCP with energies of ca. 80 kcal/mol above the ground state. In contrast to these findings, the chemistry of dinuclear and trinuclear complexes with bridging phosphaalkyne ligands seems to be more promising for their synthesis. Here, however, it must be stated that the successful preparation of these compounds lacks generality. Product formation is governed sensitively by the nature of the transition metal, its ancillary ligands and the substituents at the dicoordinate phosphorus atom.

To date, no coordination compounds featuring terminal isophosphaalkyne ligands are known. Recently prepared complexes with the required atomic array MCP−R display C−P bond orders of unity only.

In summary, the synthesis of free isophosphaalkynes still remains a challenge. Future approaches to a satisfactory solution may involve sterically encumbering substituents, such as *m*-terphenyl units, at the P atom that could prevent 1,2-P−C migrations and that enclose the C=P terminus in a protective environment. Another possible method to add stability to isophosphaalkynes involves employing highly electronegative substituents at the phosphorus atom. Likewise, the search for complexes with terminal isophosphaalkyne ligands still awaits a solution.

Acknowledgments

The author is grateful to Prof. W. W. Schoeller for valuable discussions and for his assistance in composing the section on the theoretical studies.

Cubane Complexes with Two (or More) Group 14−Group 16 Double Bonds: Synthesis and X-ray Structures of $Sn_4Se_2(NtBu)_4$ and $Ge_4Se_3(NtBu)_4$

Tristram Chivers,*[a] Timothy J. Clark,[a] Mark Krahn,[a] Masood Parvez,[a] and Gabriele Schatte[a]

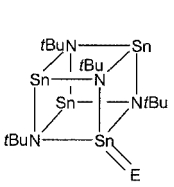
Keywords: Germanium / Main group elements / Multiple bonds / Selenium / Tin

Monomeric complexes with two or three terminal M=Se bonds, $Sn_4Se_2(NtBu)_4$ or $Ge_4Se_3(NtBu)_4$, respectively, are produced by oxidation of $(MNtBu)_4$ (M = Sn, Ge) with selenium in hot toluene.

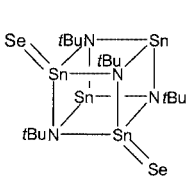
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

The varied uses of binary Group 14−16 compounds as semiconductors, in thermoelectric devices and for optoelectronic materials,[1] have provided a stimulus for investigations of potential single-source precursors.[2,3] In addition to these practical applications, there is a fundamental interest in compounds containing a formal double bond between heavier Group 14 and 16 elements.[4] These highly reactive functionalities may be stabilized either by attaching two extremely bulky groups to the Group 14 element to give a three-coordinate ketone analogue[5] or by intramolecular heteroatom coordination leading to four- or five-coordinate metal centers.[6] Although there have been impressive advances in the range and diversity of these so-called "heavy ketones",[4] no examples of compounds containing more than one Group 14-Group 16 double bond have been reported.

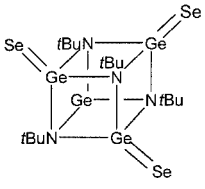
Recently we described the unexpected formation and X-ray structure of the stannatellone $[t\text{BuNSn}(\mu\text{-N}t\text{Bu})_2\text{TeN}t\text{Bu}](\mu_3\text{-SnTe})$ in which the Sn=Te functionality is stabilized by three *t*BuN ligands.[7] This finding prompted us to investigate the oxidation of divalent tin or germanium in the cubic molecules $(MNtBu)_4$ (M = Sn, Ge)[8] by chalcogens as a source of complexes containing several terminal M=E bonds (E = S, Se, Te). In this communication we report the synthesis and X-ray structures of **2** and **3**, which contain two or three M=Se bonds, respectively, as well as the monochalcogenides **1a** and **1c**.



1a, E = S
1b, E = Se
1c, E = Te



2



3

The reaction of $(SnNtBu)_4$ with one equivalent of sulfur in toluene at 85 °C produces **1a** in 87% yield. The use of an excess of sulfur in this reaction yields insoluble products, suggesting the formation of polymers involving bridging, rather than terminal, sulfide ligands, upon further oxidation of **1a** with sulfur. Richeson et al. have shown that there is a delicate balance between the formation of terminal and bridging SnS bonds in the case of the amidinate complexes $[SSn\{CyNC(R)NCy\}_2]_n$.[6c] A monomeric structure ($n = 1$) is observed for R = *t*Bu, whereas a dimer ($n = 2$) with bridging sulfide ligands is found for R = Me.

The reaction of $(SnNtBu)_4$ with four equivalents of selenium in boiling toluene yields the distannaselone **2b** in 64% yield whereas the monostannatelone **1c** is obtained in 68% yield from the reaction of $(SnNtBu)_4$ with an excess of tellurium under similar conditions. The lack of formation of the distannatellone presumably reflects the weaker oxidizing power of tellurium compared to that of selenium. The compounds **1a**, **1c** and **2** were characterized by ^{1}H NMR spectra, X-ray crystallography[9−11] and, in the case of **1c** and **2**, by CHN analyses. The stannathione **1a** exhibits a molecular ion in the FAB mass spectrum.

The molecular structures of **1c** and **2**, accompanied by pertinent metrical parameters, are depicted in Figure 1 and 2, respectively. The structure of **1a** resembles that of **1c** and

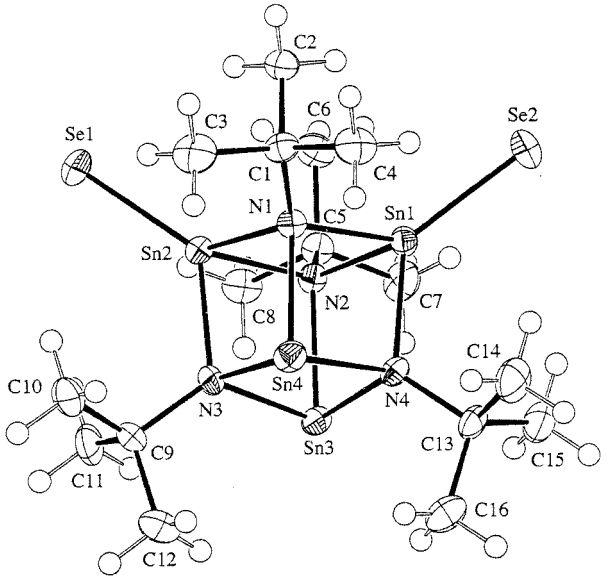

Figure 2. X-ray structure of **2**; selected bond lengths (Å) and bond angles (deg): Sn(1)−Se(2) 2.372(1), Sn(2)−Se(1) 2.363(1), |Sn^{IV}−N| 2.141(5), range 2.122(5) − 2.157(5), |Sn^{II}−N| 2.233(5) range 2.206(5)−2.253(5), b|N−Sn^{IV}−N| 84.3(2), |N-Sn^{II}−N| 80.0(2)

selected bond lengths and bond angles are given in the caption to Figure 1. All three structures contain terminal Sn=E bonds (E = S, Se or Te) and the framework of the $(SnNtBu)_4$ cube is maintained. There are no significant intermolecular contacts. The Sn=S bond length of 2.262(3) Å in **1a** is similar to the value of 2.280(5) Å found in the five-coordinate amidinate complex [S=Sn{CyNC(*t*Bu)-NCy}$_2$].[6c] The Sn=Te bond length of 2.589(1) Å in **1c** is indistinguishable from the value of 2.592(1) Å found for [*t*BuNSn(μ-N*t*Bu)$_2$TeN*t*Bu](μ$_3$-SnTe) in which the tin atom is in an identical four-coordinate environment.[7] The mean Sn=Se bond length of 2.367(7) Å in **2** can be compared with values of 2.398(1) Å[6d] or 2.394(1) Å[6f] for related five-coordinate complexes. Two general trends are evident from the structural data for these three complexes. First, the mean Sn^{IV}−N bond length is 0.09 Å shorter than the mean Sn^{II}−N distance, reflecting the higher ionic character in the Sn^{IV}−N bonds. Secondly, the mean bond angle N−Sn^{IV}−N is about 4.5° larger than the value of N−Sn^{II}−N, suggesting that the stereochemical influence of the Sn=E bonding electrons is less pronounced than that of the lone pair of electrons on the Sn^{II} centres.

The ^{1}H NMR spectrum of **1a** in C_6D_6 at 23 °C shows two resonances at δ = 1.47 and 1.25 ppm, attributable to N*t*Bu groups, with the expected 3:1 relative intensities. By contrast, the ^{1}H NMR spectra of **1c** and **2** in C_6D_6 at 23 °C both exhibit singlets at δ = 1.42 ppm. These observations imply fluxional behaviour involving rapid exchange of chalcogen substituents between Sn^{II} and Sn^{IV} sites in **1c** and **2**. Similar observations have been reported for the *bis* adduct $(SnNtBu)_4{\cdot}2AlCl_3$, which exhibits a singlet at δ = 1.32 ppm in the ^{1}H NMR spectrum (in C_7D_8) at 28 °C.[12] The low solubility of these imidotin chalcogenides precluded further investigation of this phenomenon by low temperature NMR spectroscopy. We note, however, that selenium exchange is approximately two orders of magnitude faster than sulfur exchange for (porphyrinato)tin(II) complexes.[13] The solid-state ^{119}Sn NMR spectrum for **2** shows the expected two resonances for Sn^{II} and Sn^{IV} sites at δ = +1347 and −111 ppm, respectively [cf. δ = +1142 for $(SnNtBu)_4$].

These findings indicate that the oxidation of the remaining Sn^{II} centers becomes more difficult after the initial oxidation of one or two Sn^{II} sites in $(SnNtBu)_4$, presumably as a result of the electron-withdrawing effect of the chalcogen substituents. Consequently, we also investigated the chalcogen oxidation of the germanium(II) cube $(GeNtBu)_4$,[8] which should be more easily oxidized than the Sn^{II} analogue.

The reaction of $(GeNtBu)_4$ with four equivalents of tellurium in boiling toluene for one day produces $Ge_4Te(NtBu)_4$, the germanium analogue of **1c**, in 42% yield.[14,15] By contrast, oxidation with selenium under similar conditions yields the trigermaselone $Ge_4Se_3(NtBu)_4$ (**3**) as yellow air-sensitive crystals in about 60% yield. An X-ray structural determination of **3** (Figure 3)[16] revealed three Ge=Se double bonds with a mean bond length of 2.187(1) Å [cf. 2.196(4) Å and 2.2212(3) Å in the amidinate complexes [CyNC(R)NCy)$_2$Ge=Se (R = Me, *t*Bu), in which the germanium centers are also four-coordinate].[6b] The mean Ge^{IV}−N bond length is 0.11 Å shorter than the mean Ge^{II}−N distance and the bond angle N−Ge^{IV}−N is 4.8° larger than the value of N-Ge^{II}−N. The ^{1}H NMR spectrum of **3** in C_6D_6 at 23 °C shows two resonances with the expected 1:3 relative intensities, implying that any selenium exchange is slow on the NMR time scale. However, limited

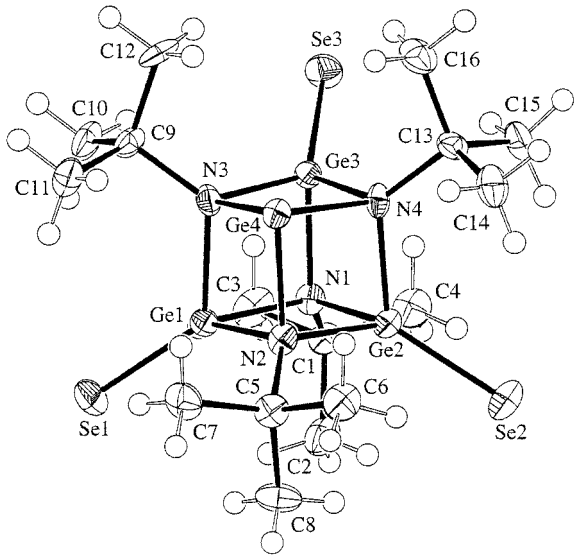

Figure 3. X-ray structure of **3**; selected bond lengths (Å) and bond angles (deg): Ge(1)−Se(1) 2.1852(13), Ge(2)−Se(2) 2.1872(13), Ge(3)−Se(3) 2.1871(13), |Ge^{IV}−N| 1.958(7), range 1.944(7)−1.985(7), |Ge^{II}−N| 2.068(7), range 2.064(7)−2.071(7), |N−Ge^{IV}−N| 85.8(3), |N-Ge^{II}−N| 81.0(3)

solubility precluded the measurement of the ^{77}Se NMR spectrum.

In summary, the oxidation of the cubic systems $(MNtBu)_4$ with selenium provides a facile route to the first complexes containing more than one Group 14-Group 16 double bond. Tetraselones $[M_4Se_4(NR)_4]$ (M = Sn, Ge) would be of particular interest as potential single-source precursors to binary semi-conductors such as SnSe, via the thermodynamically favoured elimination of RN=NR. Achievement of this goal will require either a more easily oxidized imidotin(II) cubane, for example $(SnNPh)_4$,[17] or a more reactive source of selenium.

Experimental Section

1a: The reagents $(SnNtBu)_4$ [18] and $Ge(NtBu)_4$ [8] were prepared from $M(NMe_2)_2$ and *tert*-$BuNH_2$ by modifications of the literature procedures. A mixture of $(SnNtBu)_4$ (0.400 g, 0.527 mmol) and cyclooctasulfur (0.017 g, 0.530 mmol) in toluene was heated at 85 °C for one day. The yellow solution was filtered and solvent was removed under vacuum to give yellow crystals of **1a** (0.361 g, 0.456 mmol, 87%). ^{1}H NMR (C_6D_6, 23 °C): δ = 1.47 (s, 27 H, *t*Bu), 1.25 (s, 9 H, *t*Bu) ppm. MS (FAB): *m*/*z* = 792 $[M + H]^+$.

1c: A mixture of $(SnNtBu)_4$ (0.362 g, 0.477 mmol) and tellurium powder (0.243 g, 1.90 mmol) in toluene (30 mL) was heated at 125 °C for two days. The orange solution was removed by cannula from unchanged tellurium. Orange crystals of **1c** (0.287 g, 0.324 mmol, 68%) were obtained after one day at −23 °C. $C_{16}H_{36}N_4Sn_4Te$ (886.92): calcd. C 21.67, H 4.09, N 6.32; found C 20.60, H 4.10, N 5.65. ^{1}H NMR (C_6D_6, 23 °C): δ = 1.42 (s) ppm.

2: A mixture of $(SnNtBu)_4$ (0.406 g, 0.535 mmol) and grey selenium powder (0.169 g, 2.14 mmol) in toluene (40 mL) was heated at 125 °C for one day. The yellow solution was decanted by cannula from unchanged selenium. Yellow crystals of **2** (0.314 g, 0.342 mmol, 64%) were obtained after one day at −23 °C. **2**·C_7H_8, $C_{23}H_{43}N_4Se_2Sn_4$ (1009.3): calcd. C 27.37, H. 4.39, N 5.55; found C 26.64, H 4.58, N 5.46. ^{1}H NMR (C_6D_6, 23 °C): δ = 1.42 (s) ppm.

3: A mixture of $(GeNtBu)_4$ (0.030 g, 0.052 mmol) and grey selenium powder (0.016 g, 0.203 mmol) was heated at 130 °C in toluene (20 mL) for one day. The yellow-orange solution was decanted from unchanged selenium and stored at −16 °C for one day to give yellow crystals of **3** (0.025 g, 0.031 mmol, 59%). ^{1}H NMR (C_6D_6, 23 °C): δ = 1.67 (s, 9 H, *t*Bu), 1.33 (s, 27 H, *t*Bu) ppm. **3**·C_7H_8.

X-ray quality crystals of **1a**·0.5C_7H_8, **1c**·0.5C_7H_8, **2**·C_7H_8 and **3**·C_7H_8 were obtained by recrystallization from toluene at −23 °C.

X-ray data were collected on a Nonius Kappa CCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å) at 170 K. All of the structures contained disordered toluene molecules in the lattice.

IR Study of the Interaction of Dioxygen with [*meso*-Triphenyl(4-pyridyl)-porphyrinato]cobalt(II)

Tigran S. Kurtikyan,*[a,b] J. Steven Ogden,[c] Robert K. Kazaryan,[d] and Valery N. Madakyan[d]

Keywords: Cobalt / Porphyrins / Matrix isolation / IR spectroscopy / Microporous materials

The interaction of O_2 ($^{18}O_2$) with [*meso*-triphenyl(4-pyridyl)-porphyrinato]cobalt(II) [Co(MPyTPP)] has been investigated by means of IR spectroscopy under matrix-isolation conditions and by the action of dioxygen on thin sublimed layers. These studies have led to the characterisation of two dioxygen adducts: (1) a very unstable dioxygen adduct similar to that observed earlier for the closely related [*meso*-tetraphenylporphyrinato]cobalt(II) Co(TPP), and (2) a new type of coordinated O_2 ($^{18}O_2$) complex which is formed after warming Co(MPyTPP) either in pure oxygen matrices, or as sublimed layers in the presence of oxygen. The $\nu(O_2)$ vibration in this second species is more than 100 cm^{-1} lower than in the first, and the dioxygen adduct thus formed is thermally stable at 200 K. This adduct is identified as a six-coordinate dioxygen complex, with one coordination site occupied by the pyridyl group of an adjacent Co(MPyTPP) molecule. In the sublimed layers, the capacity for self-assembly of Co(MPyTPP) oligomers leads to the formation of microporous solids containing coordinatively unsaturated metal ions which have the ability to bind oxygen reversibly upon storage at ambient conditions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Some metalloporphyrins (MP) are known to be efficient oxygen carriers and have been studied for potential applications in the fields of artificial hemoglobin, oxygen-permselective membranes, catalytically active electrode coatings, selective O_2 adsorbents and sensors.[1−6] Co^{II} porphyrins attract special attention due to the reversible character of their O_2 binding,[7] and their thin films are promising in applications which depend on specific chemoresponsive properties of materials.[8]

In order to generate selective chemoresponsive materials, molecularly sized binding sites or pores must be created, and pyridylporphyrins have recently become a focus of attention due to their ability to form microporous self-assembling arrays.[9] Very interesting results in this area are now available for Zn, Ru and Os porphyrins. However, the potential for the self-assembly of biologically important Co, Fe and Mn pyridylporphyrins has surprisingly received very little attention. This may be due to the ease of oxidation and the ability to form five- and six-coordinate species, including dioxygen-bridged and μ-oxo structures.

The construction of microporous materials containing coordinatively unsaturated metal ions in their network promises to be an attractive tool for tailoring materials with useful chemoresponsive properties. As was shown earlier, low temperature sublimed layers of MTPP (M = metal dication; TPP = *meso*-tetraphenylporphyrinato dianion), which exhibit ligand-binding properties in the amorphous state lose this ability upon crystallization during storage at ambient conditions.[10] This occurs as a result of the dramatically decreased cross-section of the pores in the absence of solvated or ligand molecules in these solids.[11] In contrast, pyridylporphyrins are now widely explored as building blocks for constructing nanoporous materials.[12] In these studies the pyridyl groups of the porphyrins are usually coordinated to the metal centre of another complex.[9,13] It is reasonable, however, to expect that metallopyridylporphyrins containing metal ions capable of axial coordination can form self-assembled arrays, as was observed for Zn(MPyTPP) (MPyTPP = *meso*-monopyridyltriphenylporphyrinato dianion).[14,15] Lin[16] observed such self-assembly in the course of the hydrothermal synthesis of MTPyP (M = Co, Mn; TPyP = *meso*-tetrapyridylporphyrin) leading to unique metalloporphyrin hexamers with large cavities. In these assemblies, however, the metal ions

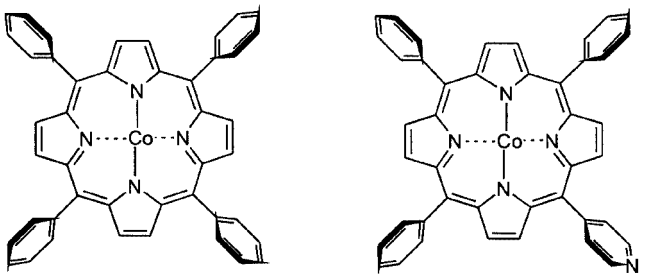
are coordinatively saturated. The same pattern was observed in sublimed films of CoT4PyP [T4PyP = *meso*-tetrakis(4-pyridyl)porphyrin][17] and CoT3PyP [T3PyP = *meso*-tetrakis(3-pyridyl)porphyrin],[18] which, although porous, slowly lose their O_2-binding ability due to the formation of coordinatively saturated structures. It could be expected that in the metal-*meso*-pyridyltriphenylporphyrin compounds, in which the number of metal ions and pyridyl groups is equal, the probability of formation of six-coordinate saturated structures might be diminished.



A **B**

In this paper the interaction of Co(MPyTPP) (**B**) with O_2 is studied under matrix isolation and solid-state conditions, and it is shown that this interaction differs significantly from that of the closely related Co(TPP) (**A**).

Results and Discussion

As expected from the closely related structures, the IR spectrum of Co(MPyTPP) (Figure 1a) in an Ar matrix is very similar to that of Co(TPP) reported elsewhere.[19] Isolation of this compound in a pure oxygen matrix ($^{16}O_2$) leads to the immediate appearance of a new band at 1286 cm^{-1} (Figure 1b), which has a counterpart at ca. 1208 cm^{-1} when $^{18}O_2$ is used (Figure 1c). From the value of this isotopic shift, and by analogy with previous work,[19] these bands are readily assigned to coordinated dioxygen in the adducts Co(MPyTPP)($^{16}O_2$) and Co(MPyTPP)($^{18}O_2$).

It is interesting to note that experiments using pure oxygen matrices showed clear evidence of the intramolecular O-O stretching mode [ca. 1551 ($^{16}O_2$) and 1460 cm^{-1} ($^{18}O_2$)]. This stretching mode is technically forbidden in IR spectra and appears only very weakly in deposits of pure solid oxygen. Its apparent enhancement here may be connected with a possible interaction of the O_2 molecule with the π-cloud of the porphyrin macrocycle or with the coordinated dioxygen adduct. The latter interpretation seems to be more probable, in view of the polar nature of coordinated O_2 and of the high sensitivity of its stretching band to the environment. For example, in our experiments the ν(O_2) of coordinated dioxygen was observed at 1286, 1279 and 1251 cm^{-1} in an O_2 matrix, an Ar matrix and in the sublimed layer, respectively.

In contrast to previous studies on Co(TPP), slow warming of matrix-isolated samples up to 200 K results in disappearance of the 1286 cm^{-1} band, indicating decomposition of this species, and the appearance of a new band at about

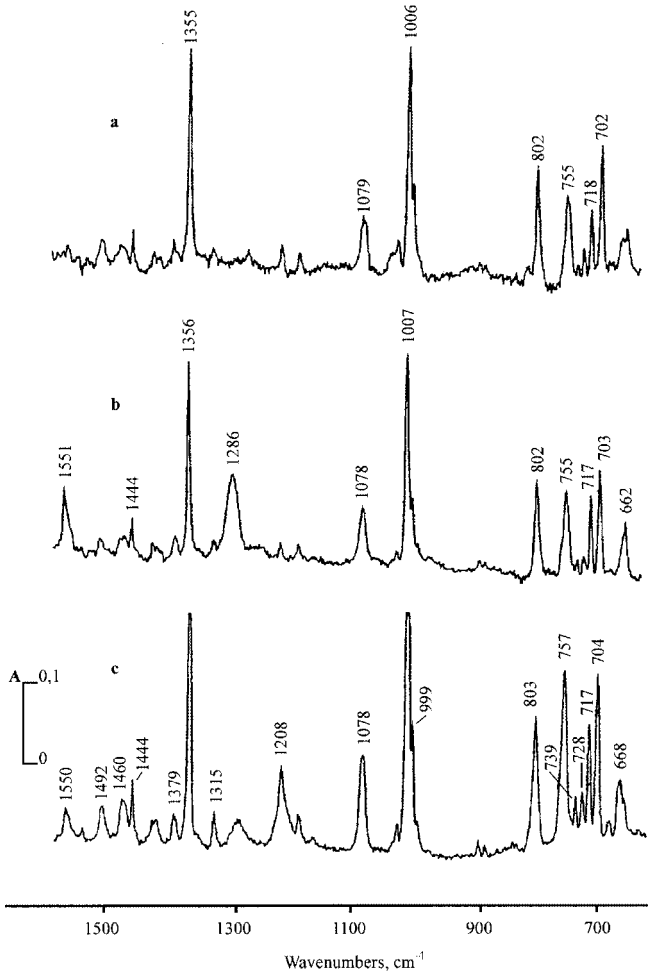


Figure 1. IR spectra of Co(MPyTPP) isolated in Ar (a), $^{16}O_2$ (b), and $^{18}O_2/^{16}O_2$ = 7/3 (c) matrices at 12 K

1170 cm^{-1} (Figure 2a) in the same spectral region where a triad of porphyrin bands may be found in the solid state (Figure 4a). The same procedure with isotopically enriched $^{18}O_2$ samples leads to the appearance of a new band at 1103 cm^{-1} (Figure 22b). This isotopic dependence confirms its assignment as a dioxygen stretching mode, and indicates the formation of another type of complex.

We believe that this band should be assigned to the six-coordinate dioxygen complex in which one coordination site is occupied by the pyridyl group of an adjacent Co(MPyTPP) molecule. In this process, the slow warming of the dioxygen matrix results in the slow elimination of free O_2, and the formation of coordination links with adjacent molecules to form the six-coordinate dioxygen complex represented in Figure 3.

It is to be anticipated that this type of coordination involving a base ligand in an axial position (*trans* to dioxygen) would shift ν(O_2) to markedly lower frequency, while the ν(Co-O_2) band should shift upward. Such a ligand would increase the amount of electron donation to the metal d orbitals, thus enhancing the M-O_2 bond strength (and hence the thermal stability of the complex) but would consequently weaken the O−O bond by increasing the net

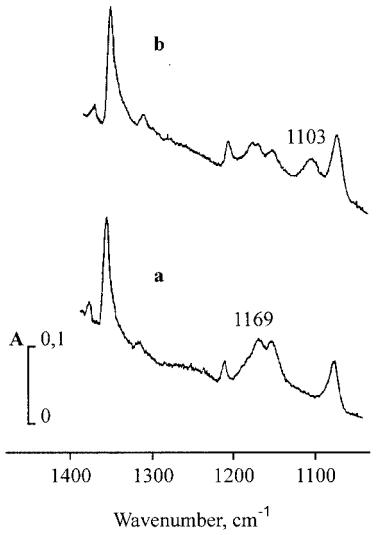

Figure 2. IR spectra of Co(MPyTPP) initially isolated in $^{16}O_2$ matrix at 12 K, warmed to 200 K and recooled (a); (b) the same as (a) with an isotopic mixture $^{18}O_2/^{16}O_2$ of 7/3

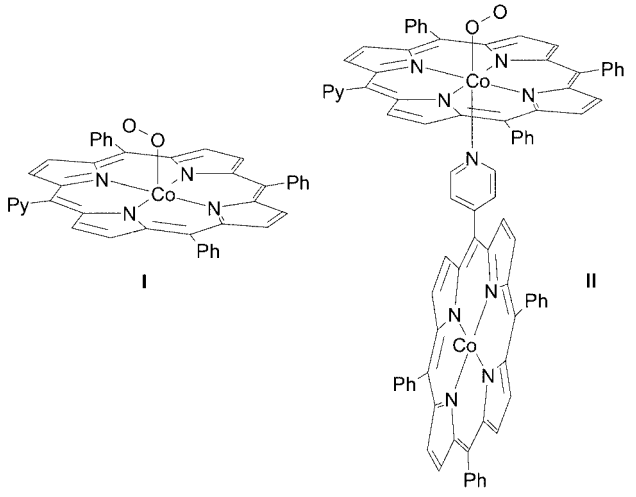

Figure 3. Schematic view of dioxygen complexes of Co(MPyTPP) produced in an O_2 matrix (I) and after elimination of O_2 by warming of sample to 200 K (II)

occupancy of the antibonding $\pi_g^*(O_2)$ orbitals. This effect has been quantitatively demonstrated by Nakamoto and co-workers for a series of Co(TPP)(base)(O_2) complexes, where the $\nu(O_2)$ frequency decreases linearly as the pK_a of the base increases.[20] It is also worth noting that in the Raman spectra of the six-coordinate (O_2)Co(TPP)(B) complexes (where B is a nitrogen base), the $\nu(O_2)$ bands are observed in the vicinity of 1160 cm^{-1}.[20]

The ability of Co-*meso*-aryl-substituted porphyrins to bind dioxygen is inherent not only for the isolated molecules (i.e. matrix-isolated or solvated molecules) but is also found in the layers obtained by sublimation onto a low-temperature (77 K) substrate. These layers are both amorphous and microporous,[10] with the result that interacting gases can easily diffuse into the bulk of the layers. The adducts thus formed can be studied by IR spectroscopy without solvent interference.

A study of thin layers of Co(MPyTPP) obtained by sublimation onto a support cooled with liquid nitrogen in the presence of 60 Torr O_2 reveals two new IR bands at 1251

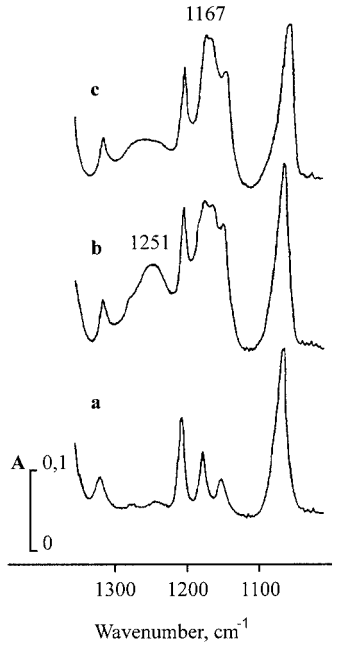

Figure 4. IR spectra of CoMPyTPP sublimed layer at 80 K (a), after exposure to 60 Torr O_2 and annealing in the cycle 80 K→ 120 K → 80 K (b); (c): the same as (b) with the layer obtained by sublimation onto a room temperature substrate

and 1167 cm^{-1} (Figure 4b). After the support is heated to room temperature, both bands disappear and the initial spectrum is restored. On admission of new portions of O_2, these bands appear again, but the intensity of the low-frequency band increases at the expense of the high frequency band.

When oxygen gas is admitted to layer samples prepared at 77 K and stored for one day at room temperature, the IR spectrum again shows a relatively weak band at 1251 cm^{-1}, with the band at 1167 cm^{-1} substantially increased in intensity. The same pattern is observed for the layers obtained by sublimation onto a room-temperature substrate (Figure4c).

These results can be interpreted as follows. In the related Co(TPP) system, the reversible nature of dioxygen binding by sublimed layers has been shown previously,[10] and the band at 1250 cm^{-1} has been attributed to $\nu(O_2)$ of the Co(TPP)(O_2) adduct, with the assignment confirmed by experiments with $^{18}O_2$. In similar experiments with the *meso*-tetrapyridyl-substituted derivatives CoT4PyP[17] and CoT3PyP[18] the $\nu(O_2)$ bands of bound dioxygen appear in the 1160 cm^{-1} region (ca. 1100 cm^{-1} for $^{18}O_2$) and the adducts obtained are thermally much more stable than those produced with Co(TPP). These differences were explained in terms of formation of coordinatively linked polymers and formation of a six-coordinate dioxygen adduct with the pyridyl base in the *trans* axial position.

In this work there is additional spectral evidence of such coordination links in Co-pyridyl porphyrins. The single medium-intensity band of Co(TPP) at ca. 1600 cm^{-1}, which

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corresponds to the C=C stretching of the phenyl groups in Co(MPyTPP) gains intensity, and becomes complex due to mixing with the C=N stretching of the pyridyl group. This band exhibits well-defined changes upon annealing of the

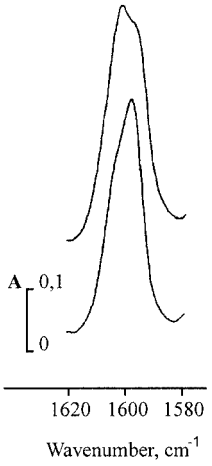

Figure 5. IR spectra of Co(MPyTPP) sublimed layer in the region of the skeletal vibrations of aryl substitutes at 80 K: after deposition onto a low temperature substrate (lower curve); after warming to room temperature and recooling (upper curve)

layer (Figure 5). The high frequency shoulder in the low temperature sublimate gains intensity after annealing and, as a result, the peak maximum shifts to higher wavenumbers (by about 8 cm^{-1}). This observation is consistent with the increasing number of coordinated pyridyl groups, since it is known[21] that coordination of pyridine to metal ions leads to a high frequency shift of this mode. The same spectral pattern represented in the upper spectrum of Figure 6. This same structure has been observed for $[Zn(MPyTPP)]_n$, for which X-ray analysis established that the pyridyl group of the porphyrin periphery is bound to the metal centre of an adjacent porphyrin, thereby creating a polymer with a long chain and a zigzag conformation.[14,15]

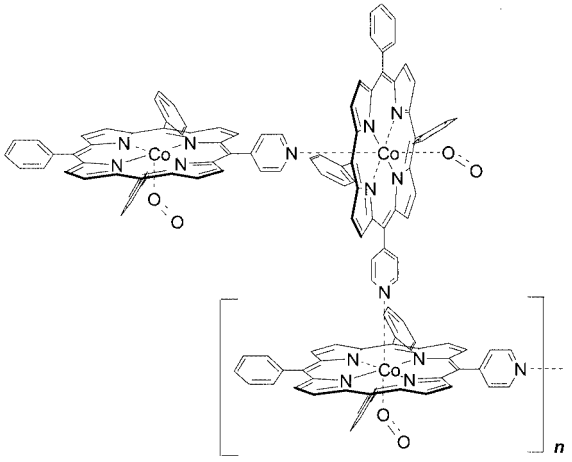

Figure 6. Schematic view of a coordination oligomer produced in sublimed layers of Co(MPyTPP) and its dioxygen adducts

ure 6 is observed when a sublimed layer is formed by deposition onto a room-temperature substrate.

On the basis of these results it can therefore be concluded that both the warming of a low-temperature Co(MPyTPP) sublimed layer and the deposition of Co(MPyTPP) onto a room-temperature substrate lead to the formation of one-dimensional coordination oligomers as represented in Figure 6. This same structure has been observed for $[Zn(MPyTPP)]_n$, for which X-ray analysis established that the pyridyl group of the porphyrin periphery is bound to the metal centre of an adjacent porphyrin, thereby creating a polymer with a long chain and a zigzag conformation.[14,15]

As a result of their low-temperature O_2-binding ability, sublimed layers of Co(MPyTPP) may therefore offer major advantages over the previously investigated systems Co(TPP), Co(T4PyP) and Co(T3PyPP). As mentioned above sublimed layers of Co(TPP) lose their O_2-binding ability upon storage at room temperature. Co(T4PyP) and Co(T3PyP) layers stored in vacuo for a week under the same experimental conditions bind only 50% of the initial quantities. In contrast, the amount of bound dioxygen in Co(MPyTPP) layers stored at room temperature for one month decreases by less than 20%, based on the decreased intensity of the 1167 cm^{-1} $\nu(O_2)$ band. It worth noting that this capability for low-temperature O_2-binding is also retained for the layers stored in air. Apparently the zigzag conformation of oligomer chain prevents the formation of dioxygen-bridged structures, which leads to the irreversible oxidation of the metal ions.

Conclusions

[*meso*-Triphenyl(4-pyridyl)porphyrinato]cobalt(II) Co(MPyTPP) binds dioxygen both under matrix isolation conditions and in the solid state. The self assembly of Co(MPyTPP) in sublimed layers lead to the formation of one-dimensional coordination oligomers containing coordinatively unsaturated Co^{II} in its chains. Similar to other pyridyl-porphyrin arrays the layers have a microporous structure and their low-temperature O_2-binding ability is conserved on storing in air.

The areas in which this property can be used are now the primary focus of our attention. Preliminary data indicate, for instance, that sublimed layers of CoMPyTPP can selectively bind dioxygen from CO/O_2 mixtures and can therefore serve as a device for the purification of CO by removing trace quantities of O_2.

Experimental Section

Co(MPyTPP) was obtained from H_2MPyTPP, which was synthesised according to a previously reported procedure.[22] NMR and UV/Vis spectra were in good agreement with reported data.[22] In a typical experiment, Co(MPyTPP) was placed in a Knudsen cell and was first heated to about 400 K under high vacuum ($P < 10^{-6}$ Torr) to remove solvent molecules.[11] The CsI substrate of the optical cryostat was then cooled to ca. 12 K using a closed-cycle Displex refrigeration system. The matrix-isolation apparatus and general methodology used have been described elsewhere.[23] Co(MPyTPP) was sublimed at ca. 520 K together with a large excess of Ar (BOC, 99.999%), Ar/O_2, or pure O_2 (BOC, 99, 999%). O-18 enriched samples were obtained using a mixture of $^{18}O_2 + {}^{16}O_2$ in the mol ratio 7:3, as established by mass spectrometry.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The interaction of O_2 with sublimed layers of Co(MPyTPP) was carried out in the optical cryostat, such that the deposited film was obtained by sublimation on the low (77 K) or room-temperature substrate according to published procedures.[10] In a typical procedure, thoroughly dried and pre-cooled oxygen was slowly fed into the cryostat from a vessel attached to a mercury gauge for measurements of O_2 pressure. The sublimed layer was then stored for 30 min while the temperature was alternated in the following sequence: 80 → 120 → 80 K. The oxygen gas was then pumped off and IR spectra obtained over a range of temperatures.

Infrared spectra were recorded using Perkin−Elmer PE983G and Specord M-80 instruments, linked to appropriate data-handling systems. UV/Visible spectra were obtained on a Specord M-40 spectrophotometer, and $CDCl_3$ − solution NMR spectra were obtained on a Varian Mercury instrument.

Crystal Structures and Intercalation Reactions of Three-Dimensional Coordination Polymers $[M(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$ (M = Co, Mn)

Stéphanie Willemin,[a] Joulia Larionova,*[a] Rodolphe Clérac,*[b] Bruno Donnadieu,[c] Bernard Henner,[a] Xavier Fréderic Le Goff,[b] and Christian Guérin[a]

Keywords: Bridging ligands / Cyanides / Molybdenum / Intercalations / Cobalt / Manganese

Two coordination polymers $[M^{II}(H_2O)_2]_2[Mo^{IV}(CN)_8]\cdot 4H_2O$ [M^{II} = Co (**1**), Mn (**2**)] were prepared as monocrystals and structurally characterised. These compounds crystallise in the tetragonal systems *I*4/*m* (**1**) and *I*4/*mcm* (**2**) and form three-dimensional networks containing channels occupied by two types of water molecules, i.e. coordinated to M^{II} and crystallised ones. The dehydration of these materials occurs topochemically to give $[M^{II}(H_2O)]_2[Mo^{IV}(CN)_8]$ compounds having an open metal coordination site on the M^{II} ions that may be accessible to coordination by other species and serve as a reaction site. The intercalation of water, ammonia and amines has been studied.

Introduction

One of the challenges of contemporary chemistry is the molecular design of materials to achieve specific properties. An interesting group of compounds that has attracted considerable attention from material chemists and crystal engineers is two- and three-dimensional coordination polymers able to absorb and/or desorb guest molecules, which exhibit potential applications in the areas of separation and catalysis.[1] A very successful approach to these materials involves the deliberate design by self-assembly of two- and three-dimensional host-guest supramolecular architectures containing relatively large channels, cavities, or windows. Zeolites, which contain channels and cavities because of rigid three-dimensional frameworks and clays, via intercalation between two-dimensional layers, are natural prototypes of such architectures and are currently used. However, it is relatively difficult to modify and derivatise them in a systematic way in comparison with coordination polymers. Numerous examples already exist of inorganic[2] and metal-organic[3,4] zeolite and clay mimics which reversibly incorporate small molecules or organic guests. The structural flexibility of the molecular frameworks and their different nature compared to zeolites and clays may provide novel complementary properties, for example, optical, electronic or magnetic for such "porous" materials.[5] Some of these coordination polymers act as hosts in intercalation reactions since a vacant site for coordination of others species may have been created.

In recent years, a large number of structurally characterised host-guest open framework solids have been obtained by a self-assembly of systems containing cyanometalate units as building blocks.[6−13] As a matter of fact, the multidimensional structure formed by the successive −M−CN−M′− linkages affords a void with a shape and/or a size appropriate to the intercalation of a guest molecule in order to stabilise the crystal structure. This stabilisation can also be provided by the coordination of labile ligands at M′ (for instance, H_2O, NH_3, aliphatic and aromatic amines, etc.) which can be exchanged by intercalation. Two- and three-dimensional Hoffman-like frameworks containing linear and bent $[Ag(CN)_2]^-$ or $[Au(CN)_2]^-$ twofold coordination,[7] trigonal and pyramidal $[Cu(CN)_3]_2^-$ threefold coordination,[8] tetrahedral[9] $[Cd(CN)_4]^{2-}$ and square-planar[10] $[Ni(CN)_4]^{2-}$ fourfold coordination and also sixfold coordination[11] $[M(CN)_6]^{n-}$ building blocks, combined with a different metallic or organometallic coordination centre, have already been reported.

The eightfold-coordinated building blocks $[M(CN)_8]^{4-}$ (M^{IV} = Mo, W, Nb) offering eight bridging cyano ligands potentially able to form tightly connected architectures, have attracted some attention in recent years because of their magnetic[12f] and photomagnetic properties.[12a−12e] Nevertheless, structurally characterised polynuclear coordination polymers based on the use of $[M(CN)_8]^{4-}$ (M = Mo

or W) as building blocks are still rare. In fact, as far as we are aware, structural reports of cyano-bridged $M^{II}M^{IV}$ (M = Mo or W) dimetallic compounds are very recent and concern the following examples: the chain $[\{Mn_2(L)_2(H_2O)\}]\{Mo(CN)_8\}]\cdot 5H_2O$,[12c] the two-dimensional mixed-valence compound $[\{Mn(L)\}_6\{Mo^{III}(CN)_7\}\{Mo(CN)_8\}_2]\cdot 19.5H_2O$[12d] {L = 2,13-dimethyl-3,6,9,12,18-pentaazabicyclo[12.3.1]octadeca-1(18),2,12,14,16-pentaene} and the three-dimensional compound $[Fe(H_2O)_2]_2[Mo(CN)_8]$.[12e] Furthermore, to the best of our knowledge, the intercalation behaviour of these compounds has never been studied. As a matter of fact, the $[M(CN)_8]^{4-}$ building block has also been employed in combination with the organometallic $[(CH_3)_3Sn]^+$ cation in order to design three-dimensional coordination polymers $[\{(CH_3)_3Sn\}_4M^{IV}(CN)_8]$ (M^{IV} = Mo, W) containing THF guest molecules in the channels.[13] However, after removal of the guest molecules by heating, no reabsorption of THF or absorption of others solvent molecules has been observed.

In this context, this paper is devoted to the synthesis and the crystal structures of two three-dimensional networks based on the $[Mo(CN)_8]^{4-}$ building block and M^{II} = Co, Mn metal ions. The title compounds were prepared for the first time as single crystals and their crystal structures were resolved. The presence of labile ligands coordinated to an M^{II} ion, i.e., H_2O molecules, opens the possibility for substitution reactions. In principle, this strategy should offer a means of incorporating various guest molecules in the network and thus modulate both structural and physical properties of these compounds.

Results and Discussion

Synthesis and Crystal Structures of $[M(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$ (M = Mn, Co)

The slow diffusion in an H-shaped tube of two 10^{-4} M aqueous solutions containing $K_4[Mo(CN)_8]\cdot 2H_2O$[10] and $[M(H_2O)_6](NO_3)_2$, allows yellow (M^{II} = Mn) or orange (M^{II} = Co) crystalline plates to be obtained. The complexes have been fully characterised by elemental analyses, IR spectroscopy, and X-ray crystallography (Table 1).

Infrared C−N stretches for both compounds [2144 (s) cm^{-1}] are shifted to higher frequencies than those of $K_4[Mo(CN)_8]\cdot 2H_2O$ [2125 (s), 2102 (s) cm^{-1}], clearly showing a coordination of all the CN groups to M^{II}.

The X-ray crystallographic study at 160 K reveals that these compounds $[M(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$ [M = Co^{II} (**1**), Mn^{II} (**2**)] have three-dimensional structures. Although, these two compounds are not strictly isostructural, the organisation of the three-dimensional structures and their cell parameters are similar. The compounds crystallise in a tetragonal system with space groups *I*4/*m* for **1** and *I*4/*mcm* for **2**. The structures possess one molybdenum (Mo^{IV}) site and one M^{II} (M^{II} = Co or Mn) site. Eight −C−N−M linkages surround the Mo atom forming a perfect square antiprism environment, as shown in Figure 1. Thus, the geometry of $[Mo(CN)_8]^{4-}$ unit is changed from the dodecahedral one in the starting $K_4[Mo(CN)_8]\cdot 2H_2O$ compound[14] to square-antiprismatic in the final products. It should be noted that such a geometrical rearrangement is characteristic for two- and three-dimensional compounds containing $[M(CN)_8]^{4-}$ units which have already been reported.[12,13] The Mo−C bond lengths are equal to 2.160(7) and 2.168(6) Å for **1** and 2.153(4) Å for **2**. The C−N bond lengths are equal to 1.145(9), 1.141(9) Å for **1** and 1.150(5) Å for **2**. Four N−C−Mo linkages and two water molecules in the *trans* configuration surround the M^{II} sites (Figure 1). The sites adopt a perfect octahedral environment. The M−N bond lengths are equal to 2.124(6), 2.158(6) Å for **1** and 2.207(3) Å for **2**. The M−O1 and M−O2 bond lengths are equal to 2.051(9) and 2.099(8) Å for **1** and 2.283(8) and 2.231(8) Å for **2**, respectively. It should be noted that all of the Mo−C−N bonded angles are close to 180° [Mo−C1−N1 175.2(6)°; Mo−C2−N2 174.3(5)° for **1** and

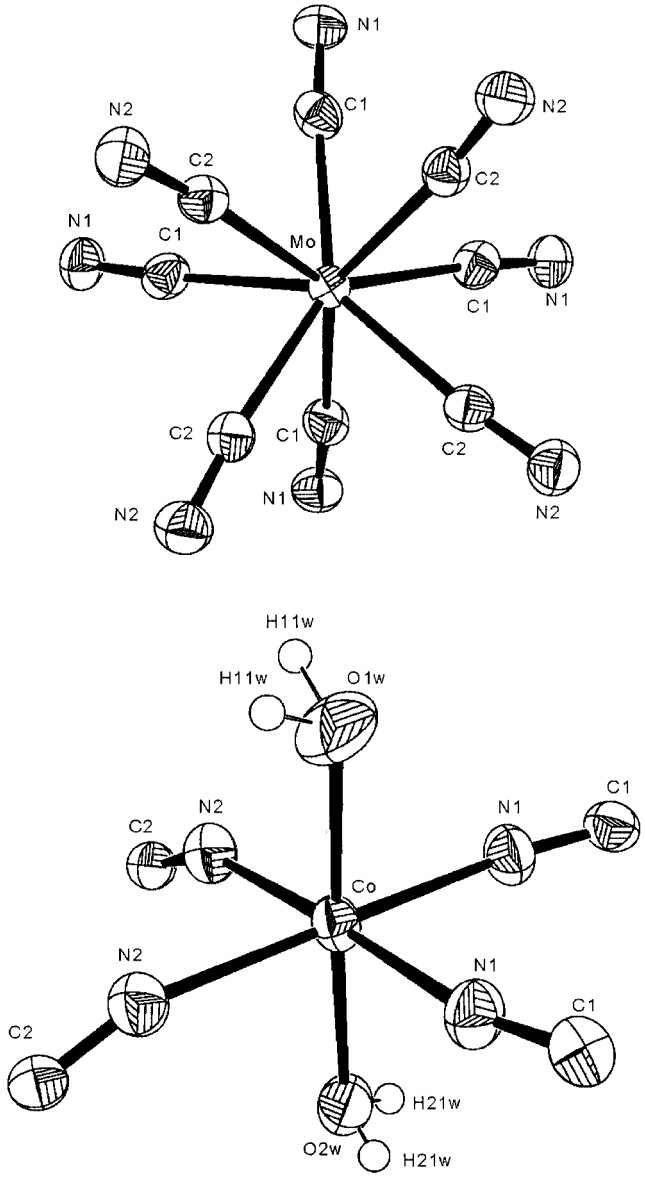

Figure 1. ORTEP drawing of local coordination environment of Mo and Co sites for compound **1**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

178.5(3)° for **2**], while the M−N−C bonded angles deviate significantly from 180° [165.9(6)°, 155.2(6)° for **1** and 162.5(3)° for **2**].

The structural arrangement may be described as a centrosymmetrical $\{MoC2N2MN2C2\}_2$ lozenge motif which is linked to four other identical motifs by C2N2 bridges to form corrugated grid-like sheet layers, as shown in Figure 2 for **1**. The three-dimensional organisation may be described as interconnected perpendicular layers parallel to {[110], [111]} and {[011], [010]} planes. Each Mo atom belongs to two perpendicular layers and is a node of the three-dimensional network. This arrangement results in channels running along the *c* axis occupied by coordinated and crystallised water molecules as shown in a whole view of the structure of **1** viewed in the *ab* plane (Figure 3).

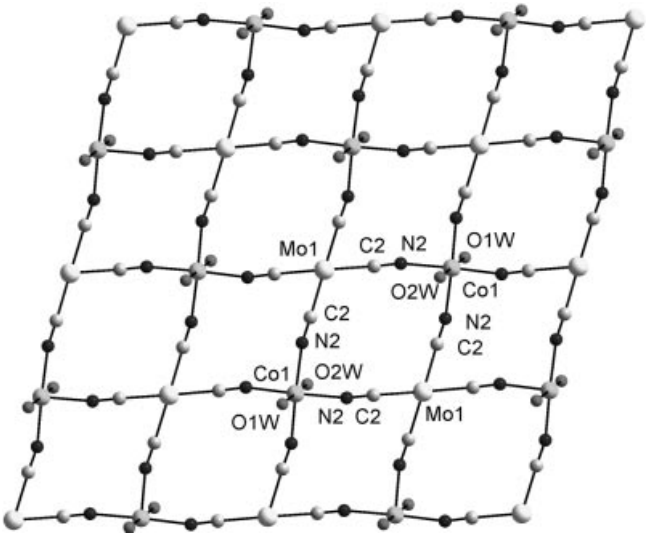

Figure 2. A view of the structure in the {[110], [111]} plane, showing a corrugated grid-like plan for compound **1**; hydrogen atoms are omitted for clarity

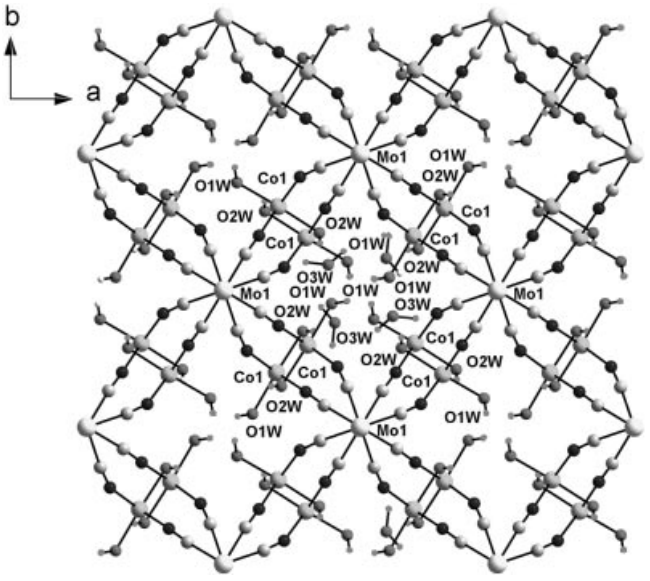

Figure 3. Global view of the crystal structure of **1** in the *ab* plane; the crystallised water molecules are only shown in one channel for clarity

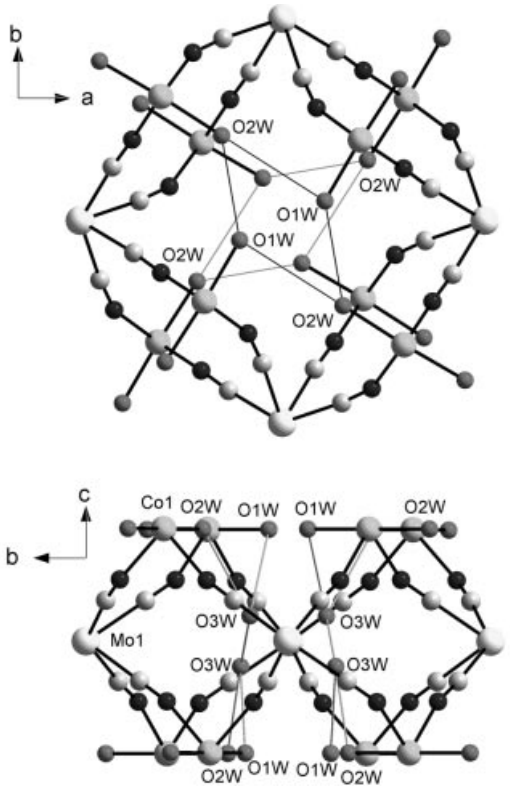

Figure 4. Top: fragment of the crystal structure of **1** along the *c* axis showing the cavity with a hydrogen bonding network coordinated between Co^{II}-coordinated water molecules; bottom: fragment of the crystal structure of **1** along the *b* axis showing the hydrogen bonding between the Co^{II}-coordinated and crystallised water molecules

As can be seen in Figure 4 (top), each of the four water molecules coordinated to the M^{II} ions situated in the *ab* plane are linked by means of hydrogen bonds forming a non-centrosymmetrical lozenge $\{O1WO2W\}_2$ in the centre of the channel [3.089(12) Å for O1···O2 and 3.554(13) Å for O2···O1] (dashed lozenge). Another identical lozenge (greg lozenge) is placed behind that of the first and turned by 90° in the *ab* plane. The two types of lozenges alternate along the *c* axis. Additionally, in each water lozenge at the centre of the cavity the O1 and O2 atoms are linked by hydrogen bonds to the O3 W atoms of the crystallised water molecule [2.894(9) Å for O2···O3 and 3.030(9) Å for O1···O3], resulting in columns of water molecules inserted in the channels delimited by the cavities along the *c* direction [Figure 4 (bottom)]. The cavity size may be estimated as 5.98 × 6.02 Å (or as the cavity volume of 133.4 $Å^3$), which leads to the possibility of intercalation of the appropriated molecules.

Magnetic Properties of $[M(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$ [M = Co (1), Mn (2)]

The temperature dependence of the magnetic susceptibility (χ_M) for polycrystalline samples of **1** and **2** were recorded under an applied field of 1000 Oe. For compound **2**, χ_M can be fitted using the Curie−Weiss law [$\chi_M = C/(T$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$-\theta)]$ with $C = 8.58$ emu·K·mol^{-1} and $\theta = -1.4$ K, down to 1.8 K. The Curie constant (C) is in agreement with the expected value for two Mn^{2+} ions with $S = 5/2$ and $g = 1.98\pm0.05$. The negative sign of the Weiss constant obtained from the Curie−Weiss fitting, reveals the presence of weak antiferromagnetic interactions between the Mn^{II} ions through the diamagnetic NC−Mo^{IV}−CN bridges. The $\chi_M T$ value at room temperature for **1** is equal to 5.3 emu·K·mol^{-1}, which corresponds to the calculated spin value for two Co^{II} ions ($S = 3/2$, $g = 3.36$), since Mo^{IV} is diamagnetic. The decrease in $\chi_M T$ at low temperature may have two origins, spin−orbit coupling and antiferromagnetic interactions between the Co^{II} ions. Nonetheless, no theoretical model exists for the three-dimensional lattice, taking both factors into account.

Dehydration of 1 and 2 and Intercalation Reactions of $[M(H_2O)]_2[Mo(CN)_8]$ [M = Co (1), Mn (2)]

The thermogravimetric analysis (TGA) of **1** and **2** was performed under argon from room temperature up to 700 °C. The TGA curves exhibit four well-pronounced weight losses as the temperature was increased at a heating rate of 1 °C·min^{-1}, as shown in Figure 5 (top). The first and second weight-loss steps can be determined by inflection points at 88 and 131 °C, respectively; the third step contains two poorly pronounced inflexion points at 260 and 484 °C; the fourth step has an inflexion point at 575 °C.

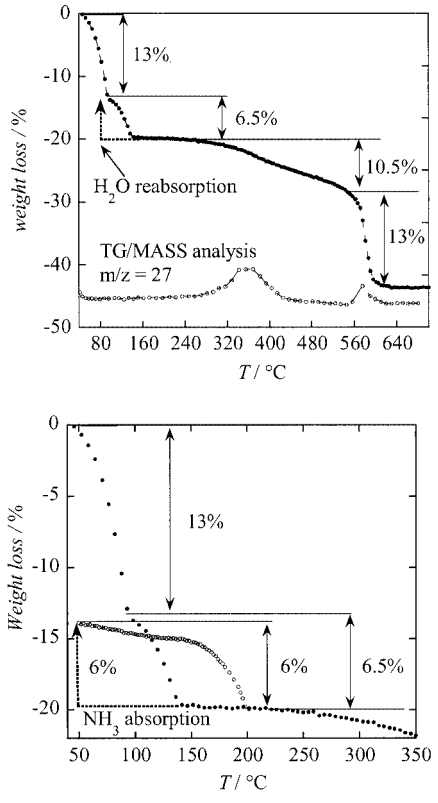

Figure 5. Top: TGA and TGA/MASS curves for $[Mn(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$; heating rate 1 °C/min; bottom: TGA and ammonia absorption curves for $[Mn(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$

The first and second weight-loss steps of 13.0 and 6.5%, respectively, are consistent with the loss of the four crystallized and the two coordinated water molecules, leading to $[Co(H_2O)]_2[Mo(CN)_8]$ (**1a**) and $[Mn(H_2O)]_2[Mo(CN)_8]$ (**2a**). After heating at 150 °C, the compounds retain their crystallinity and appear to be isomorphous with their corresponding hydrated phases based on X-ray powder diffraction pattern. The coordination number decreases upon dehydration as evidenced in the case of the cobalt derivative, which undergoes a colour change from orange-yellow, with $\lambda = 410$ nm, to green, with $\lambda = 590$ nm, according to the UV/Vis spectra. The M^{2+} ions are in an octahedral environment in **1** and **2** with two water molecules (O1 and O2) occupying two coordination sites in the *trans* positions (Figure 1). The heating of these compounds, up to 150 °C, leads to the loss of one of these coordinated water molecules and to five-coordinate metal ions. It should be outlined that this unusual change of the coordination number from six to five has already been observed for metal phosphonates $Co(O_3PCH_3)\cdot H_2O$.[16] The magnetic moment of the dehydrated cobalt compound **1** decreased from 5.3 emu·K·mol^{-1} to 4.7 emu·K·mol^{-1}, which indicated a decrease in coordination number, as previously reported by Cunningham.[16c] However, it is difficult to indicate which water molecule (O1W or O2W) is leaving. It should also be noted that the infrared C−N stretch (2154 cm^{-1}) for both dehydrated phases are reversibly shifted toward higher frequencies from those of the hydrated phases (2144 cm^{-1}) showing a reversible change in the symmetry of $[M^{II}(H_2O)]_2[Mo(CN)_8]$ fragments upon heating.

The third weight-loss step of 10.5% could be attributed to the simultaneous loss of the last two coordinated water molecules (6.4%) and one CN^- group (4.6%). The TGA/MASS analysis of the gas evolved during this weight loss step indicates the presence of the water (ionic current $m/z = 18$ for H_2O^+) and the cyanide (ionic current $m/z = 27$ for HCN^+) (Figure 5). Such losses of cyano ligands upon heating around 350 °C has also been observed for the precursor $K_4[Mo(CN)_8]\cdot 2H_2O$[17a] and for octacyanometallates of alkaline metals.[17b] The X-ray powder pattern for the title compounds heated to 500 °C indicated decomposition of the original structures.

The generation of an open metal coordination site on the M^{II} ions implies that the dehydration reaction should be reversible. After heating of samples **1** and **2** up to 150 °C under argon, the exposure of the dehydrated powders to air moisture at 25 °C leads to intercalation/coordination of two water molecules [Figure 5 (top)]. As a result, the X-ray powder pattern of the rehydrated sample was restored and the colour of the cobalt-containing compound recovered its original orange-yellow colour.

In a similar approach, the behaviour towards an intercalation/coordination of ammonia and amines was studied. The intercalation of NH_3 gas was observed at room temperature for samples **1** and **2** that had originally been outgassed at 150 °C. As shown in Figure 5 (bottom), it is possible to approximate the amount of NH_3 molecules that have intercalated. The mass gain (6.0%) is in good agree-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment with the calculated value (5.9%) for $[M(H_2O)(NH_3)]_2[Mo(CN)_8]$. Further evidence for the formation of $[Co(H_2O)(NH_3)]_2[Mo(CN)_8]$ and $[Mn(H_2O)(NH_3)]_2[Mo(CN)_8]$ was obtained from thermogravimetric, elemental and FTIR analyses. As shown in Figure 5 (bottom), the loss of NH_3 (inflexion point at 181 °C) occurs at 50 °C higher than the temperature of water loss in the hydrated compounds (inflexion point at 131 °C). The weight loss between 30 and 200 °C constitutes 6% of the total mass and the theoretical value calculated by assuming the formula $[M(H_2O)(NH_3)]_2[Mo(CN)_8]$ is 5.9%. In addition, the elemental analysis shows good agreement between the calculated and experimental values. IR data provide strong evidence that the NH_3 molecule occupies the empty coordination site created upon dehydration. The IR spectra of both compounds $[Co(H_2O)(NH_3)]_2[Mo(CN)_8]$ and $[Mn(H_2O)(NH_3)]_2[Mo(CN)_8]$ show the antisymmetric and symmetric NH_3 stretching in the 3400−3000 cm^{-1} region; NH_3 deformation is observed in the 1612 cm^{-1} region with symmetric deformation taking place at 1401 and 1221 cm^{-1}. Finally, rocking vibrations occur at 950−595 cm^{-1}.[18]

A remarkable feature of the amine intercalation reactions of $[M(H_2O)]_2[Mo(CN)_8]$ is their selectivity with respect to shape and size. Experiments in which $[M(H_2O)]_2[Mo(CN)_8]$ (M^{II} = Mn, Co) were subjected to methyl-, ethyl-, and dodecylamines for prolonged reaction times showed the formation of intercalation compounds with all primary amines except dodecylamine. The formation of compounds having a general formula $[M(H_2O)(amine)]_2[Mo(CN)_8]$ have been observed. The intercalation reactions were surveyed by thermogravimetric analyses and the final compounds were characterised by IR spectra. In addition, in the case of bulkier amines such as pyridine no intercalation reaction was observed. This selectivity with respect to shape and size may be accounted for by considering the structural environment of the water molecule in $[M(H_2O)_2]_2[Mo(CN)_8]$, which is assumed to occupy the amino coordination site. Its cavity size (71.1 $Å^3$) can obviously limit the accessibility to the open coordination site.

Conclusion

In summary, two new coordination polymers $[M(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$ ($M = Co^{II}$ and Mn^{II}) have been prepared and crystallised. These compounds form three-dimensional networks containing channels occupied by coordinated and crystallised water molecules. The title compounds can easily be dehydrated to yield $[M(H_2O)]_2[Mo(CN)_8]$ compounds. The dehydration is reversible and both derivatives readily reabsorb moisture from the atmosphere. Furthermore, the dehydration reaction leaves an empty coordination site on the bivalent metal ion, which has been exploited by reaction with ammonia and primary amines upon exposure to a flow of respective gases in order to form intercalation compounds. Since the interaction of inserted molecules with the dehydrated compounds takes place mainly through coordination to the M^{II} ions, the porosity should not be regarded as a prerequisite for reversible absorption.[24] Studies concerning intercalation reactions of coordination polymers presenting ferromagnetic ordering, and the influence of this on the magnetic properties, are currently in progress.

Experimental Section

Syntheses: Unless otherwise noted, all manipulations were performed at ambient temperature using reagents and solvents as received. The precursor $K_4[Mo(CN)_8]\cdot 2H_2O$ was prepared as already described.[15,16]

$[M^{II}(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$ [M^{II} = Co (1) or Mn (2)]: $[M^{II}(H_2O)_6](NO_3)_2\cdot 4H_2O$ (2.0 mmol) (M^{II} = Mn or Co) in water (30 mL) was added to a solution of $K_4[Mo(CN)_8]\cdot 2H_2O$ (1.0 mmol) in water (30 mL, natural pH), which immediately led to a precipitation of orange-yellow (**1**) or yellow (**2**) products. The solids were washed three times with water and then and dried in air with ethanol. Yield: 0.45 g, 82%. **1**: $C_8H_{16}Co_2MoN_8O_8$: calcd. C 16.96, H 2.82, Co 20.82, Mo 16.94, N 19.78; found C 17.26, H 3.54, Co 20.41, Mo 17.23, N 20.36. IR (KBr): $\tilde{\nu}$ = 3404(sh), 2144, 1616, 537, 431 cm^{-1}. **2**: $C_8H_{16}Mn_2MoN_8O_8$: calcd. C 17.20, H 2.87, Mn 19.68, Mo 17.19, N 20.07; found C 17.63, H 3.85, Mn 20.16, Mo 17.27, N 19.87. IR (KBr): $\tilde{\nu}$ = 3404(sh), 2145, 1616, 537, 431 cm^{-1}. The crystals, suitable for X-ray analysis, were obtained by slow diffusion in an H-shaped tube with two 10^{-4} M aqueous solutions containing $K_4[Mo(CN)_8]\cdot H_2O$ and $[M(H_2O)_6](NO_3)_2$, respectively. After two months, yellow (M = Mn^{II}) and orange-red (M = Co^{II}) crystalline plates were obtained. The crystals were insoluble in most common solvents and stable in air. The composition of the crystalline compound was also established by single-crystal X-ray diffraction at 160 K.

Dehydration of $[M^{II}(H_2O)_2]_2[Mo(CN)_8]\cdot 4H_2O$ [M^{II} = Co (1) or Mn (2)] and Intercalation of Ammonia and Amines into the Resulting Product: Both manganese- and cobalt-containing compounds were dehydrated by heating under argon at 150 °C for 1 h. Dehydrated samples **1a** and **2a** were stored in a drybox prior to use. **1a** (after heating at 150 °C): $C_8H_4Co_2MoN_8O_2$: calcd. C 20.98, Co 25.73, Mo 20.95, N 24.47; found C 20.51, Co 25.47, Mo 20.67, N 24.64. IR (KBr): $\tilde{\nu}$ = 3604, 3411, 3224, 2145, 1616, 537, 431 cm^{-1}. **2a** (after heating at 150 °C): $C_8H_4Mn_2MoN_8O_2$: calcd. C 21.35, Mn 24.42, Mo 21.32, N 24.90; found C 21.45, Mn 24.89, Mo 21.01, N 24.47. IR (KBr): $\tilde{\nu}$ = 3606, 3417, 3190, 2145, 1616, 537, 431 cm^{-1}. The intercalation of ammonia and primary amines was carried out by exposing the dehydrated compounds to a flow of ammonia or corresponding amine gases at 150 °C. For the dehydrated cobalt-containing compound **1**, the reaction appeared to be complete in 5 min, as evidenced by a colour change from green (dehydrated) to orange-yellow and by mass-gain measurements determined by thermogravimetry analysis [Figure 5 (insert)]. To ensure complete reaction, the compounds dehydrated at 150 °C were usually exposed to ammonia or amine gas for 30 min. Longer exposure to the flow of ammonia or amine gas did not produce different results. In the case of dodecylamine (b.p. 247 °C), **1a** or **2a** was added to the dodecylamine and the mixture was stirred for 30 min. The solid was filtered, washed three times with cyclohexane and dried under vacuum. $[Co(H_2O)(NH_3)]_2[Mo(CN)_8]$: $C_8H_{10}Co_2MoN_{10}O_2$: calcd. C 19.53, Co 23.95, Mo 19.50, N 28.47; found C 19.70, Co 23.41, Mo 19.36, N 28.63. IR (KBr): $\tilde{\nu}$ = 3607, 3371, 3283, 3199, 2138, 1615, 1400, 1220, 1096, 1021, 807, 593, 461 cm^{-1}.

X-ray Crystallography and Structure Solution: For **1** and **2**, data were collected at a low temperature (T = 160 K) with a Stoe Imaging Plate Diffraction System (IPDS), equipped with an Oxford Cryosystems Cryostream Cooler Device and using a graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Final unit cell parameters were obtained by means of a least-squares refinement of a set of 8000 well-measured reflections, and a crystal decay was monitored during data collection by measuring 200 reflections per image, no significant fluctuations of intensities were observed (Table 1). Structures were solved by means of Direct Methods using the program SIR92,[19] and subsequent difference Fourier maps, models were refined by least-squares procedures on F^2 by using SHELXL-97[20] integrated in the package WINGX version 1.64.[21] For complex **1** hydrogen atoms connected to the H_2O molecules were located on a difference Fourier map and isotropically refined. For compound **2**, owing to the symmetry operators on which H_2O molecules were located, hydrogen atoms were statistically disordered and consequently could not be located. For compounds **1** and **2** a semiempirical correction absorption was applied[22] and all non-hydrogen atoms were anisotropically refined; in the last cycles of refinement a weighting scheme was used, where weights are calculated from the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = (F_o^2 + 2F_c^2)/3$. CCDC-194778 and -194779 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Physical Measurements: Infrared spectra were recorded using KBr disks or Nujol mulls between NaCl plates with a Nicolet Model 510P spectrophotometer. UV/Vis spectra were recorded with a Cary-17D spectrometer. Thermogravimetry (TG) analyses were performed using a Netzsch STA 409 instrument under argon, from 30 to 700 °C, at a heating rate of 1 °C·min^{-1}; volatiles were determined using a Balzers QMG 421 quadruple Mass Spectrometer coupled with ATG equipment. Magnetic susceptibility data were collected with a Quantum Design MPMS-XL SQUID magnetometer. The compounds were measured on finely grounded polycrystalline samples between 1.8 and 320 K at 1000 G. The data were corrected for the sample holder and the diamagnetism contributions calculated from Pascal's constants.[23] Powder X-ray data were recorded with a Bruker D5000 diffractometer using a Bragg−Brentano geometry; a Cu target and a back monochromator were used ($K_{\alpha1} + K_{\alpha2}$); 2θ range 5−88°; 2θ steps 0.02°.

Preparation, Reactivity and Peptide Labelling Properties of (η^6-Arene)ruthenium(II) Complexes with Pendant Carboxylate Groups

Ralf Stodt,[a] Susan Gencaslan,[a] Iris M. Müller,[a] and William S. Sheldrick*[a]

Keywords: Ruthenium / Amino acids / Peptides / Bioinorganic chemistry

(η^6-Arene)ruthenium(II) complexes of the type [{[η^6-$C_6H_5(CH_2)_nCOOH$]Ru(μ-Cl)Cl}$_2$] (**2a**, n = 1; **3**, n = 3) with tethered carboxylate groups can be obtained by dehydrogenation of the appropriate cyclohexadiene with $RuCl_3 \cdot 3H_2O$. Formation of a κ*O*-coordinated chelate in weakly acidic solution is observed by means of a ^{1}H NMR titration for both [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(aq)](OTf)$_2$ (**3a′**) and [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(phen)(aq)](OTf)$_2$ (**5′**). Sandwich complexes of the type [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(η^6-amino acid)](OTf)$_2$ [amino acid = AcpheOH (**6**), ActyrOEt (**7**), ActrpOH (**8**)] can be prepared by treating [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(acetone)$_3$](OTf)$_2$ with the appropriate aromatic bioligand in CF_3COOH (**6**/**8**) or CH_2Cl_2 (**7**). Chemospecific η^6-labelling of the *C*-terminal indole function is observed for the peptide HphetrpOH in the analogous complex **9**. Quantitative formation of **8** can also be achieved in aqueous solution in the presence of a 3:1 excess of the {η^6-$C_6H_5(CH_2)_3COOH$}Ru^{II} fragment. This can also be employed for the *N*-terminal labelling of amino acids and peptides in its sandwich complex [(η^6-C_6Me_6)Ru{η^6-$C_6H_5(CH_2)_3$-COOH}](OTf)$_2$ (**10**). Coupling reactions by the carbodiimide method with EDC afford water-stable complexes of the type [(η^6-C_6Me_6)Ru{η^6-$C_6H_5(CH_2)_3C(O)R$}](OTf)$_2$ [R = trpOMe (**11**), pheOMe (**12**), glyglyOEt (**13**)] in good yields. X-ray structures of [(η^6-$C_6H_5CH_2COOC_2H_5$)RuCl(phen)](OTf) (**4b′**) and **10** are reported.

Introduction

Current interest in (η^6-arene)ruthenium(II) complexes with heteroatom donors tethered to the η^6-arene moiety has primarily been motivated by their potential as homogeneous catalysts.[1,2] Examples of chelating side-chains have included amines,[1] alcohols,[1−3] thioethers,[4] and phosphanes.[1,5−9] Chloro-bridged complexes of the type [{(η^6-arene)Ru(μ-Cl)Cl}$_2$] with *N*-terminal protected derivatives of phenylglycine ethyl ester as the functionalised arene ligand have also been reported recently.[10] In comparison to the analogous dimeric ruthenium(II) compounds with η^6-coordinated benzene or cymene ligands,[11,12] these η^6-phenylglycine complexes exhibit a strongly enhanced solubility in polar solvents. Their ensuing decomposition in solution may well be due to participation of side-chain donor atoms in the metal coordination sphere[10] and apparently renders them unsuitable for possible further application, e.g. for the labelling of peptides or proteins as previously reported for the CpRu^{II}, Cp*Ru^{II} and (η^6-cymene)Ru^{II} fragments.[13−18]

Given that they have an adequate stability in polar solvents, (η^6-arene)ruthenium(II) complexes with pendant free carboxylate groups should be of interest not only for the chemospecific η^6-labelling of tryptophan, tyrosine or phenylalanine residues but also for the more general *N*-terminal labelling of peptides. Furthermore, the recent report that [{η^5-$C_5H_4(CH_2)_2NH_2$-κ*N*}Ru(CH_3CN)$_2$](PF_6) with its tethered amine side-chain can quantitatively label the phenylalanine side-chain of the hormone secretin[19] suggests that a hemilabile carboxylate coordination might also enhance the π-complexing ability of (η^6-arene)ruthenium(II) complexes in aqueous solution. We have, therefore, prepared compounds of the type [{[η^6-C_6H_5-$(CH_2)_n$COOH]Ru(μ-Cl)Cl}$_2$] (n = 1, 3) and studied their reactivity and peptide labelling properties.

Results and Discussion

(η^6-Arene)ruthenium(II) complexes with tethered carboxylate groups (n = 1, 3) can be obtained by dehydrogenation of the appropriate cyclohexadiene with $RuCl_3 \cdot 3H_2O$ in accordance with the general method of Bennett et al.[11,12] 2,5-Dihydrophenylacetic acid[20] and 2,5-dihydro-4-phenylbutyric acid (**1**) were prepared for this purpose by a Birch reduction of phenylacetic acid (paa) and 4-phenylbutyric acid (pba), respectively. Treatment of 3-phenylpropionic acid (ppa) with sodium in ammonia solution leads, in contrast, to reduction not only of the phenyl moiety but also of the carboxylate function. Employment of the ethyl ester of ppa affords 2,5-dihydro-3-phenylpropanol[21,22] in high yield (74%). As 3-phenylpropanol has already been studied as a functionalised η^6-arene ligand by Kurosawa et

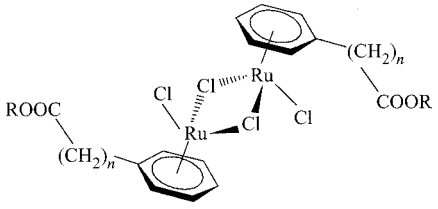
E-mail: William.Sheldrick@ruhr-uni-bochum.de

al.[1−3] our own investigations have concentrated on the coordination behaviour of the (η^6-ppa)Ru^{II} and (η^6-pba)Ru^{II} fragments.

Treatment of 2,5-dihydrophenylacetic acid or 2,5-dihydro-4-phenylbutyric acid with ruthenium(III) trichloride in an acetone/water solution at reflux leads to the formation of [{(η^6-paa)Ru(μ-Cl)Cl}$_2$] (**2a**) and [{(η^6-pba)Ru(μ-Cl)Cl}$_2$] (**3**), respectively, in high yields (Scheme 1). Use of ethanol as the solvent affords ethyl esters such as [{(η^6-$C_6H_5CH_2COOC_2H_5$)}Ru(μ-Cl)Cl}$_2$] (**2b**), which can subsequently be hydrolysed with NaOH at pH = 12 to provide the chloro-bridged η^6-complexes of the free carboxylic acids. Interestingly, the reaction of 2,5-dihydrophenylacetic acid with $RuCl_3 \cdot 3H_2O$ takes only 20 min to reach completion in refluxing ethanol in comparison to 4 h for 1,3-cyclohexadiene or α-phellandrene.[11,12] This suggests that initial rapid κ*O*-coordination by the tethered carboxylate function may facilitate subsequent η^4-coordination of the neighbouring cyclohexadiene ring. η^6-Coordination of the phenyl moieties in **2a**, **2b**, and **3** is confirmed by the pronounced upfield ^{1}H NMR shifts of their aromatic protons in comparison to the parent carboxylic acids. For instance complex **3** exhibits resonances at δ = 5.44 (d, 2 H), 5.68 (t, 2 H) and 5.61 ppm (t, 1 H) for its phenyl *ortho*, *meta*, and *para* protons in acetonitrile solution. The esterification of the carboxylate function in **2b** is indicated by the observation of a strong ν(CO) band at 1749 cm^{-1} in its IR spectrum. In contrast, **2a** and **3** display typical CO valence absorptions for free carboxylic acids at 1704 and 1711 cm^{-1}, respectively.



2a, n = 1, R = H; **2b**, n = 1, R = C_2H_5; **3**, n = 3, R = H

Scheme 1

Aqueous solutions of **2a**, **2b**, and **3** are stable for a period of several weeks over a wide pH range (2 ≤ pH ≤ 12). As a result of their free carboxylate groups, **2a** and **3** exhibit enhanced solubility in water or methanol in comparison to the ester complex **2b**. The extent of any participation of the tethered arm in the metal coordination sphere may be expected to be dependent both on the arm length and on the pH value of an aqueous solution of **2a** or **3**. In order to study the possibility of carboxylate κ*O*-coordination, aqueous solutions of [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(aq)](OTf)$_2$ (**2a′**) and [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(aq)](OTf)$_2$ (**3′**) were prepared by addition of 2 equiv. of Ag(OTf) to **2a** and **3**, respectively, followed by filtration of the resulting precipitated AgCl. A pH titration of **2a′** in the range of 1.53 ≤ pH* ≤ 12.12 (Figure 1a) provides no evidence for the presence of new species in comparison with those of the type [{(η^6-arene)Ru}$(H_2O)_3]^{2+}$, [{(η^6-arene)-Ru(μ-OH)(H_2O)}$_2]^{2+}$, and [{(η^6-arene)Ru}$_2$(μ-OH)$_3]^+$ observed for [(η^6-C_6H_6)Ru(aq)]$^{2+}$.[23,24] In Figure 1a MH refers to [(η^6-$C_6H_5CH_2COOH$)Ru$(H_2O)_3]^{2+}$, M to [(η^6-$C_6H_5CH_2COO$)Ru$(H_2O)_3]^+$, M_2H_{-2} to [{(η^6-$C_6H_5CH_2COO$)Ru(μ-OH)(H_2O)}$_2$], and M_2H_{-3} to [{(η^6-$C_6H_5CH_2COO$)Ru}$_2$(μ-OH)$_3]^-$. The formation of the dinuclear species M_2H_{-3} in weakly acidic and alkaline solutions is indicated by characteristic highfield shifts of ca. 0.6 ppm for the aromatic protons. Figure 1a suggests that the tethered carboxylate group of the short side-chain in **2a′** does not participate in intramolecular κ*O*-coordination to any significant degree. The presence of the intermediate hydroxy-bridged complex M_2/M_2H_{-2} leads to an additional set of ^{1}H NMR signals in the range 3.6 ≤ pH* ≤ 6.2.

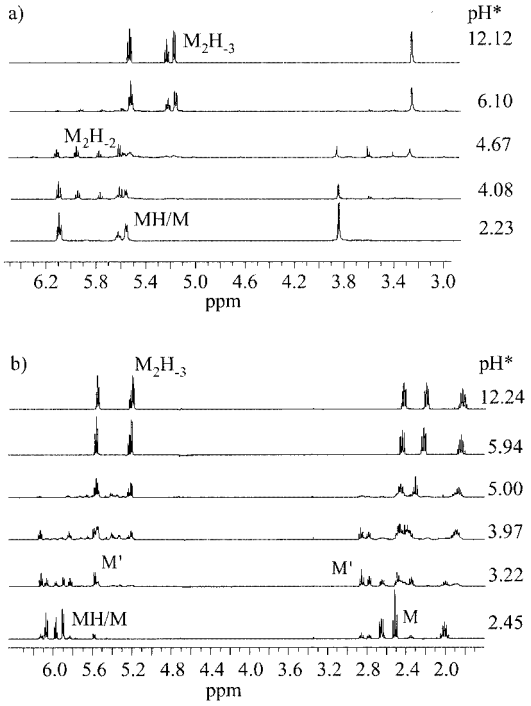


Figure 1. pH dependence of the ^{1}H NMR spectra of (a) [(η^6-$C_6H_5CH_2COOH$)Ru(aq)]$^{2+}$ (**2a′**) and (b) [{η^6-$C_6H_5(CH_2)_3$-COOH}Ru(aq)]$^{2+}$ (**3′**); the species nomenclature is based on the assignment of MH to [(η^6-$C_6H_5CH_2COOH$)Ru$(H_2O)_3]^{2+}$ in (a) and [(η^6-$C_6H_5(CH_2)_3COOH$) Ru$(H_2O)_3]^{2+}$ in (b)

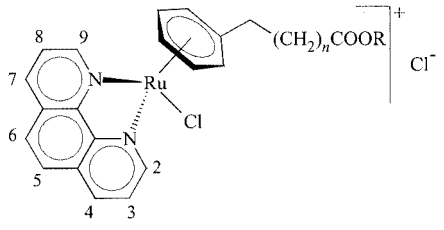
A comparison of Figure 1a and b indicates that the lengthening of the side-chain in [{η^6-C_6H_5-$(CH_2)_3COOH$}Ru(aq)](OTf)$_2$ (**3′**) enables the formation of a new distinct species M′ (or possibly a dinuclear species M′$_2$ in the range 2.4 ≤ pH* ≤ 5.5). The pronounced low-field shifts of the side-chain α−γ-methylene protons and the opposite highfield shifts of the phenyl *ortho* and *meta* protons are characteristic of this complex. As deprotonation of the carboxylate group will be expected in the range 4 ≤ pH* ≤ 5, it is reasonable to postulate that the tethered arm must participate in the ruthenium(II) coordination sphere in this species, i.e. that M′ will probably be [{η^6-

$C_6H_5(CH_2)_3COO$-κ*O*} $Ru(H_2O)_2]^+$. Since intermolecular κ*O*-carboxylate coordination cannot be ruled out, the alternative dinuclear species [{[η⁶-$C_6H_5(CH_2)_3COO$-κ*O*]$Ru(H_2O)_2$}$_2$] (M′$_2$) must also be taken into consideration.

To simplify the analysis of the pH-titration data for (η⁶-arene)ruthenium(II) complexes with functionalised arene moieties, it is helpful to block two of the three potential κ*O*-coordination sites with the bidentate ligand 1,10-phenanthroline (1,10-phen). The light-brown mononuclear complexes **4a**, **4b**, and **5** of the type [(η⁶-arene)RuCl(1,10-phen)]$^+$ were prepared for this purpose by reaction of the chloro-bridged dinuclear compounds **2a**, **2b**, and **3** with 1,10-phen in ethanol at reflux (Scheme 2). Bidentate κ²*N*,*N*′-coordination of 1,10-phenanthroline leads to characteristically pronounced downfield shifts of the signals for the *ortho* and *meta* protons of the η⁶-arene moiety, e.g. 0.60 ppm for **4b** in CD_3OD solution in comparison to 0.49 ppm for **2b** in CD_3CN. In contrast, the signals of the *para* protons are only shifted by 0.16 ppm to the lower field for the **2b**/**4b** pair. The ^{1}H NMR signal for the benzyl protons of **4b** can be observed at δ = 3.67 ppm in acetonitrile (or CD_3OH) but disappears within 5 min in D_2O or CD_3OD. The responsible rapid H/D exchange in the latter solvents is clearly a consequence of the relatively high acidity of the methylene protons in **4b** as a result of both the η⁶-coordination of the phenyl group[25,26] and the presence of a neighbouring carboxylate group. A similar H/D exchange is also observed for **4a** in CD_3OD but not for the η⁶-phenylbutyric acid complex **5** with its longer side-chain. The formation of the neutral enol form of the acetic acid side-chain in **4a**/**4b**, following the loss of a methylene proton and concomitant addition of a deuteron to the carboxylate C=O double bond, is apparently of importance in rate determining for the H/D exchange.



4a, *n* = 1, R = H; **4b**, *n* = 1, R = C_2H_5; **5**, *n* = 3, R = H

Scheme 2

After addition of 1 equiv. of Ag(OTf) to **4b** and filtration of the precipitated AgCl, crystals of the resulting complex, [(η⁶-$C_6H_5CH_2COOC_2H_5$)RuCl(phen)](OTf) (**4b**′), were grown by gas diffusion of diethyl ether into a methanol solution of the complex. As depicted in Figure 2, the complex cation of **4b**′ displays an effectively eclipsed conformation for its substituent methylene carbon atom C17 relative to N21 of the bidentate 1,10-phen ligand. This is in accordance with the expectations for half-sandwich complexes of the general type [(η⁶-arene)]$ML_3]^{n+}$ with a +I substituent in the η⁶-arene moiety and electron donor ligands L.[27] Interestingly both of the relatively acidic methylene protons participate in the formation of C−H···O hydrogen bonds to the triflate oxygen atoms. Respective C···O/H···O distances of 3.448/2.480 and 3.440/2.472 Å are observed for these interactions.

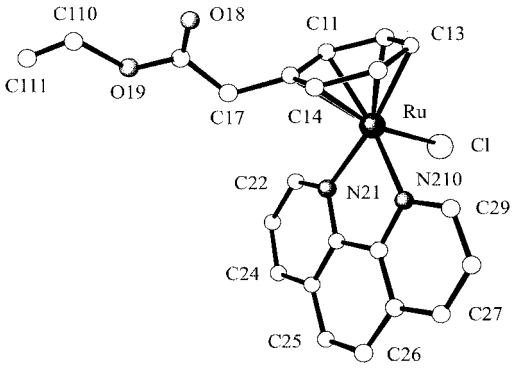


Figure 2. Molecular structure of the cation of [(η⁶-$C_6H_5CH_2COOC_2H_5$)RuCl(phen)](OTf) (**4b**′); selected bond lengths [Å] and angles [°]: Ru−N21 2.096(5), Ru−N210 2.097(5), Ru−Cl 2.398(9); N21−Ru−N210 77.7(2), N21−Ru−Cl 84.1(1), N210−Ru−Cl 85.4(9)

Aqueous solutions of [(η⁶-$C_6H_5CH_2COOH$)Ru(phen)(aq)](OTf)$_2$ (**4a**′) and [{η⁶-$C_6H_5(CH_2)_3COOH$}Ru(phen)(aq)](OTf)$_2$ (**5**′) were prepared by addition of 2 equiv. of Ag(OTf) to **4a** and **5** and subsequent filtration of the resulting precipitated AgCl. Selected ^{1}H NMR spectra in D_2O are depicted in Figure 3 for **5**′ in the range 3.40 ≤ pH* ≤ 11.46. The aqua complex [{η⁶-$C_6H_5(CH_2)_3COOH$}$Ru(OH_2)(phen)]^{2+}$ (MH) predominates at low pH* (2.48, Figure 4) and exhibits two deprotonation steps to afford [{η⁶-$C_6H_5(CH_2)_3COO$}Ru(OH$_2$)(phen)]$^+$ (M) and subsequently [{η⁶-$C_6H_5(CH_2)_3COO$}Ru(OH)(phen)] (MH_{-1}). The latter hydroxy complex predominates in alkaline solution at pH* = 11.46. Initial loss of the side-arm carboxylate protons leads to modest lowfield shifts for the 1,10-phen protons H2/H9 and the η⁶-pba aromatic protons in the approximate range 3.5 ≤ pH* ≤ 5.5, which are then followed by more pronounced upfield shifts on deprotonation of the aqua ligand between pH* values of ca. 6.5 and 8.5.

The presence of a second monocation M′ in acid or weakly alkaline solution (ca. 3 ≤ pH* ≤ 8) is indicated by the appearance of a second set of ^{1}H NMR signals for the protons of the η⁶-pba ligand at pH* = 3.40. The side chain resonances are recorded at a lower field to those of M, as was previously observed for the analogous protons in [{η⁶-$C_6H_5(CH_2)_3OH$-κ*O*}Ru(phen)](BF$_4$).[1] This suggests that the deprotonated carboxylate group of the tethered arm in **5**′ must also coordinate the ruthenium(II) atom in species M′ (Figure 4). A dimeric structure in which the phenylbutyric acid ligands adopt an η⁶:κ*O*-bridging mode cannot be

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

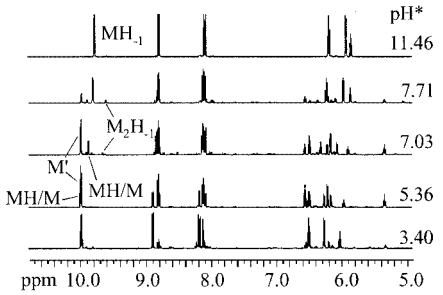

Figure 3. pH dependence of the ^{1}H NMR spectra of [{η-$C_6H_5(CH_2)_3COOH$}Ru(aq) (phen)](OTf)$_2$ (**5′**), where MH represents [(η^6-pba)Ru(H_2O)(phen)]$^{2+}$

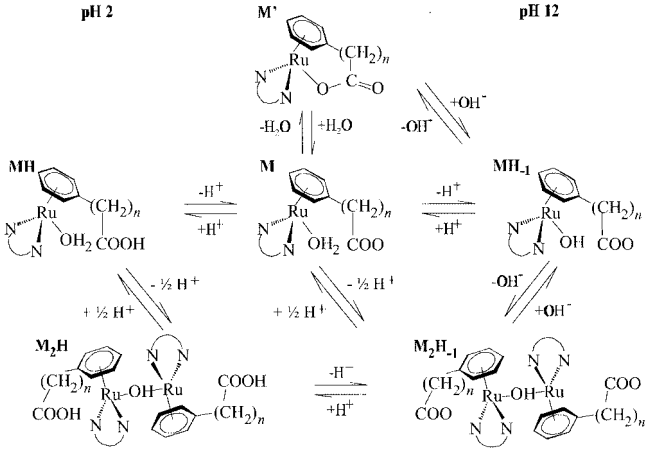

Figure 4. Proposed structures for the species MH/M/MH$_{-1}$, M′, and M_2H/M_2H_{-1} formed by **5′** in aqueous solutions

ruled out with certainty but would appear to be improbable. Neither M′ nor the minor hydroxy-bridged dinuclear species M_2H_{-1} can undergo deprotonation and their ^{1}H NMR signals therefore exhibit no significant shifts in the range $6.5 \leq pH^* \leq 8.5$.

Using the ^{1}H NMR integral values for the 1,10-phen H2/H9 signals it is possible to establish the pH dependence of the individual microspecies MH/M/MH$_{-1}$, M′ and M_2H/M_2H_{-1}. As depicted in Figure 5, the tethered arm chelate M′ clearly predominates in weakly acidic solutions and reaches a concentration maximum at $pH^* \approx 5.5$. The general pH dependence of the macrospecies MH, M/M′, M_2H_{-1}, and MH$_{-1}$ was confirmed by potentiometric pH titrations (Figure 6). Although signals for an analogous tethered arm chelate M′ could also be observed in the ^{1}H NMR spectra of **4b′** in the range $3 \leq pH^* \leq 8$, the concentration of this microspecies is much lower than for that of **5′**. The aqua complex [(η^6-$C_6H_5CH_2COO$)Ru(OH_2)(phen)]$^+$ (M) predominates for **4b′** in weakly acidic solution and even at its concentration maximum the microspecies M′ only accounts for ca 8% of the (η^6-arene)Ru^{II} complexes in solution.

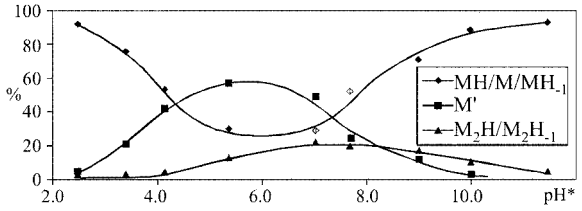

Figure 5. pH-dependent microspecies distribution for **5′** on the basis of the ^{1}H NMR titration data

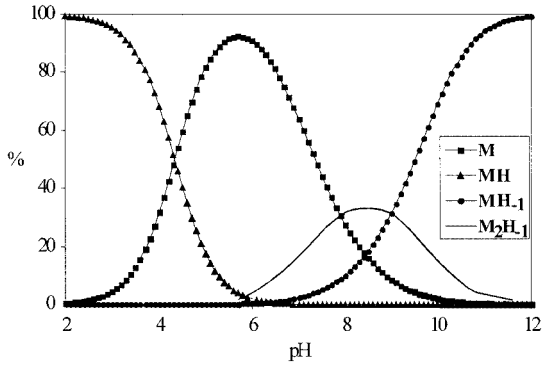

Figure 6. pH-dependent macrospecies distribution for **5′** as determined by potentiometric titration; the following stability constants were obtained from the least-squares refinement with HYPERQUAD:[27] logβ (MH) = 4.40(1), logβ (MH$_{-1}$) = −8.62(1), logβ (M_2H_{-1}) = −4.42(8) for a goodness-of-fit S = 4.6

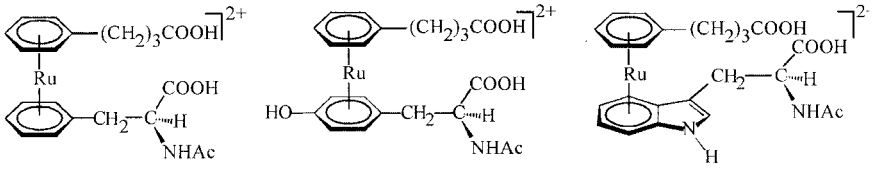
Amino Acid and Peptide Labelling

We have previously reported the suitability of [(η^6-cymene)Ru(acetone)$_3$]$^{2+}$ for the labelling of aromatic amino acids and their residues in peptides.[17,18] In contrast to the tris(acetonitrile) complex cation [(η^5-C_5Me_5)Ru(CH_3CN)$_3$]$^+$, which delivers the entropically favoured sandwich complex as an insoluble product on treatment with the free aromatic acids phenylalanine (HpheOH), tyrosine (HtyrOH), and tryptophan (HtrpOH) in THF,[15,16] the analogous reaction of [(η^6-cymene)Ru(acetone)$_3$]$^{2+}$ leads predominantly to κ^2*N*,*O*-chelates in CH_2Cl_2 or H_2O. η^6-Coordination of the half-protected or free amino acids can, however, be achieved for the (η^6-cymene)Ru^{II} fragment by employing CF_3COOH as the reaction medium. The protonation of the amino and carboxylato groups under such strongly acidic conditions prevents their incorporation into the Ru^{II} coordination sphere. (η^6-paa)Ru^{II} and (η^6-pba)Ru^{II} sandwich complexes of aromatic amino acids can also be obtained in high yields under analogous reaction conditions and the complexes **6**−**9** are presented as typical examples for η^6-labelling.

The characteristic ^{1}H and ^{13}C NMR spectroscopic data for these sandwich complexes are similar to those of the analogous (*p*-cymene)Ru^{II} complexes.[17,18] For instance, the ^{1}H NMR signals for the aromatic protons of **6** (Scheme 3) all lie in the narrow range δ = 7.00−7.19 ppm. This means that, whereas the pba phenyl proton resonances are shifted downfield by up to ca. 1.2 ppm, the phenylalanine aromatic

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



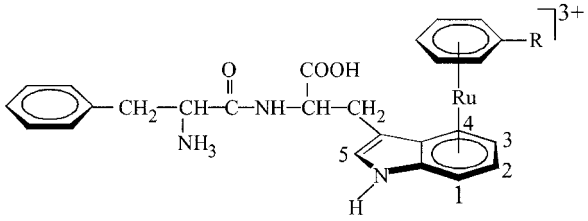
6 **7** **8**

Scheme 3

resonances experience only modest upfield shifts (ca. 0.2 ppm) relative to those of the uncoordinated ligands.[17] η^6-Labelling of tyrosine derivatives leads to a marked enhancement in the acidity of the *p*-hydroxy function, that is effectively fully deprotonated in polar solvents.[18] The associated increase in shielding for the *N*-acetyltyrosine ethyl ester aromatic protons in **7** causes their ^{1}H NMR resonances to move upfield to δ = 6.49/6.57 (*ortho*) and 6.00 (*meta*) in CD_3OD solution. Evidence for the stabilisation of the ketonic form of the η^6-coordinated tyrosine moiety of **7** in polar solvents is also provided by the upfield shift of ca 15 ppm observed for the ^{13}C NMR signal of the *para* carbon atom on going from a [D_3]nitromethane to a [D_4]methanol solution. The possibility of facial chirality leads to the formation of diastereomers of the η^6-ActrpOH sandwich complex **8** in a ca. 1:1 ratio. The pronounced lowfield ^{1}H NMR shifts, for the signals of the pyrrolic protons H5 to δ = 8.24 and 8.28 ppm, are characteristic for the η^6-coordination of the indole moieties in these isomers.

Koefod and Mann[29] demonstrated that kinetically controlled η^6-coordination of the Cp*Ru^{II} moiety leads to a preference for partially localised arene π-systems (e.g. indole) over highly delocalised arenes (e.g. phenyl). This kinetically derived chemospecificity was also observed by us for the reaction of [(η^6-cymene)Ru(acetone)$_3$]$^{2+}$ with the dipeptide HphetrpOH.[18] Exclusive η^6-indole coordination was confirmed during this work for [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(η^6_{ind}-HphetrpOH)]-$(OTf)_2$·CF_3COOH (**9**, Scheme 4), which was obtained in good yield by stirring a 1:1 mixture of [{η^6-$C_6H_5(CH_2)_3COOH$}Ru(acetone)$_3$](OTf)$_2$ with the dipeptide in CF_3COOH solution for 4 h at room temperature. Formation of a mononuclear complex was confirmed by FAB MS and elemental analysis, which also indicated that **9** contains a third counter anion (CF_3COO^-), i.e. that its peptide amino function must be protonated. Both the characteristic lowfield shifts of the indole H5 protons to δ = 8.25 and 8.30 ppm in two diastereomers and the unchanged values of the five phenylalanine aromatic protons (δ = 7.37 ppm) are in accordance with chemospecific tryptophan labelling.

As a result of competitive coordination by amino and/or carboxylate functions and the stability of the predominant hydroxy-bridged dimer [{(η^6-arene)Ru}$_2$(μ-OH)$_3$]$^+$, yields of sandwich complexes of aromatic amino acids are relatively low for [(η^6-cymene)Ru(aq)]$^{2+}$ in weakly acid or alkaline aqueous solution. This state of affairs is illustrated in Figure 7 for the reaction of [(η^6-cymene)Ru(aq)]$^{2+}$ with *N*-



9, R = $(CH_2)_3COOH$

Scheme 4

acetyltryptophan (ActrpOH) in D_2O at pH* = 5.0 and T = 60 °C. Formation of the sandwich complex [(η^6-cymene)Ru(η^6-ActrpOH)]$^{2+}$ was monitored by ^{1}H NMR spectroscopy using the integral values of its characteristic lowfield indole H5 resonances. After 18 h, no further change was observed for the integral ratio of the combined η^6-coordinated indole signals at $\delta \approx$ 8.2 ppm to that at $\delta \approx$ 7.5 ppm for free ActrpOH. The final value corresponds to a 15% yield of the amino acid sandwich complex. Formation of the macrochelates [(η^6-pbaH$_{-1}$-κO)Ru(H_2O)$_2$]$^+$ and [(η^6-pbaH$_{-1}$-κO)Ru(OH)(H_2O)] in weakly acidic solution (see Figure 1b) significantly reduces the concentration of the bis(hydroxy)-bridged species M_2H_{-2} in comparison to the (η^6-cymene)Ru^{II} fragment. Furthermore, intramolecular charge neutralisation in these pendant-arm species should also disfavour competitive κO coordination by amino acid carboxylato functions. Taken together both factors would be expected to lead to an increased level of η^6-labelling as is indeed confirmed in Figure 7 for ActrpOH. A 37% yield of the sandwich complex [(η^6-pba)Ru(η^6-ActrpOH)]$^{2+}$ (**8**) was indicated by the ratio of the indole H5 integral values at ca. 8.2 and δ = 7.5 ppm after 18 h. Employment of a 3:1 excess of [(η^6-pba)Ru(aq)]$^{2+}$ leads to an effectively quantitative η^6-labelling of the aromatic amino acid. This observed water tolerance for direct derivatisation of ActrpOH is analogous to that reported for [{η^5-$C_5H_4(CH_2)_2NH_2$-κN}Ru($CH_3CN)_2$]$^+$ by Grotjahn.[19] The applicability of the (η^6-pba)Ru^{II} fragment to peptide labelling will be the subject of further studies.

Given the presence of suitable functional groups and an adequate stability for classical peptide synthetic conditions, organometallic fragments can be introduced at either the N or C terminus of the bioligand. A range of sandwich complexes have been prepared for this purpose in recent years including the ferrocenylmethyl[30,31] and [(η^5-Cp*)M{η^6-

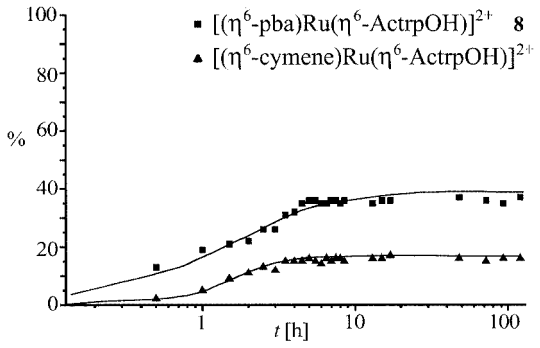

Figure 7. Time dependence for the η^6-labelling of *N*-acetyltryptophan with (a) (η^6-pba)Ru^{II} and (b) (η^6-cymene)Ru^{II} in D_2O solution at pH* = 5.0 and T = 60 °C

$CH_3OC_6H_4(CH_2)_2COOR\}]^{n+}$ (R = *N*-succinimide; M = Ir, n = 2; M = Ru, n = 1) fragments.[32,33] We, therefore, prepared both $[(\eta^6\text{-}C_6Me_6)Ru(\eta^6\text{-ppa})](OTf)_2$ and $[(\eta^6\text{-}C_6Me_6)Ru(\eta^6\text{-pba})](OTf)_2$ (**10**) as potential *N*-terminal labels for peptides. However, preliminary reactivity studies indicated that yields of coupling products for the former complex would be at best very low, as also observed for $[(\eta^5\text{-Cp*})Ir(\eta^6\text{-}CH_3OC_6H_4CH_2COOR)](BF_4)_2$ (R = *N*-succinimide)[32] which also only has one CH_2 group in its pendant arm. Further investigations were, therefore, restricted to the 4-phenylbutyric acid complex **10**, which was prepared by reaction of $[(\eta^6\text{-pba})Ru(acetone)_3](OTf)_2$ with C_6Me_6 in trifluoroacetic acid.

The X-ray structure of the dication of **10** is depicted in Figure 8. Its butyric acid side chain adopts an almost perpendicular position relative to the η^6-coordinated phenyl ring, as indicated by the torsion angle of −93.8(6)° for C11−C16−C17−C18. The asymmetric unit also contains a methanol molecule, whose oxygen atom O51 participates in O111−H···O51 and O51−H51···O hydrogen bonds of length 2.607(4) and 2.741(4) Å, respectively, to neighbouring sandwich cations and OTf^- anions.

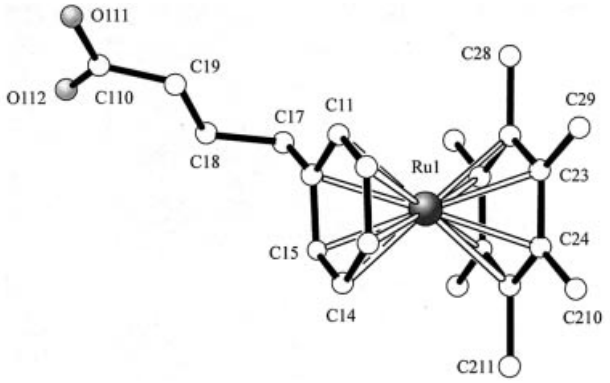

Figure 8. Molecular structure of the cation of $[\{\eta^6\text{-}C_6H_5(CH_2)_3COOH\}Ru(\eta^6\text{-}C_6Me_6)](OTf)_2{\cdot}CH_3OH$ (**10**)

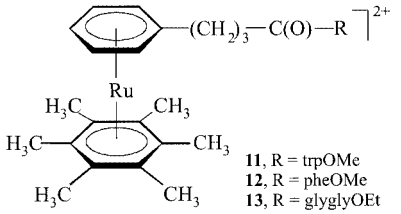
N-Terminal coupling reactions were performed for **10** with HtrpOMe, HpheOMe, and HglyglyOEt by the carbodiimide method in the presence of *N*-[3-(dimethylamino)-propyl]-*N*′-ethylcarbodiimide EDC. The resulting labelled amino acids and peptides were separated in good yields (46−73%) from the reaction mixture by semi-preparative reversed-phase HPLC with pentafluoropropionic acid as an ion-pairing agent. $[(\eta^6\text{-}C_6Me_6)Ru\{\eta^6\text{-}C_6H_5(CH_2)_3C(O)trpOMe\}](OTf)_2$ (**11**), $[(\eta^6\text{-}C_6Me_6)Ru\{\eta^6\text{-}C_6H_5(CH_2)_3C(O)pheOMe\}](OTf)_2$ (**12**), and $[(\eta^6\text{-}C_6Me_6)Ru\{\eta^6\text{-}C_6H_5(CH_2)_3C(O)glyglyOEt\}](OTf)_2$ (**13**) were characterised by FAB MS and $^1H/^{13}C$ NMR spectroscopy (Scheme 5).



Scheme 5

As depicted for **12** and **13** in Figure 9 the resonances of the five aromatic pba protons at δ ≈ 6.7−6.8 ppm lie in the characteristic spectral window for amino acids and peptides (δ = 4.8−6.8 ppm) and should therefore allow for the adequate quantitative estimates of such labelled peptides in biological systems. Compounds **11**−**13** are soluble in a range of polar solvents and exhibit long-term stability in aqueous solution.

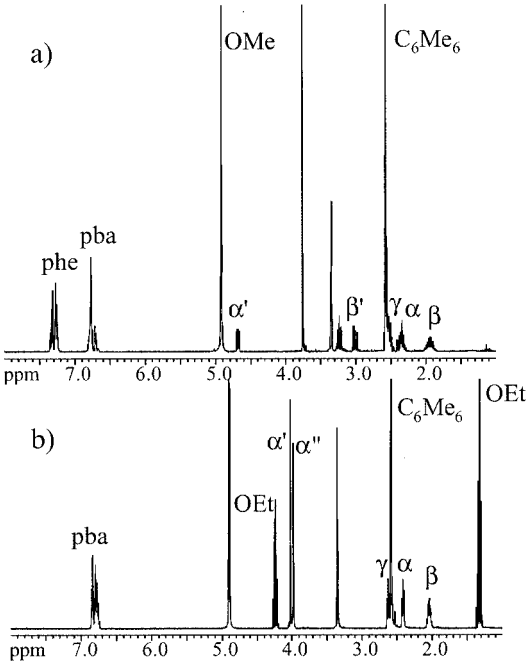


Figure 9. ^1H NMR spectra of (a) $[(\eta^6\text{-}C_6Me_6)Ru\{\eta^6\text{-}C_6H_5(CH_2)_3C(O)pheOMe\}](OTf)_2$ (**12**) and (b) $[(\eta^6\text{-}C_6Me_6)Ru\{\eta^6\text{-}C_6H_5(CH_2)_3C(O)glyglyOEt\}](OTf)_2$ (**13**)

In summary, our present work demonstrates that the pendant-arm fragment $\{\eta^6\text{-}C_6H_4(CH_2)_3COOH\}Ru^{II}$ is eminently suitable for both η^6- and *N*-terminal labelling of amino acids and peptides. The formation of κ*O*-coordinated

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

species involving the tethered carboxylate function may, as shown for ActrpOH, favour markedly higher yields of the former type of complex in aqueous solution in comparison with (η^6-cymene)Ru^{II}.

Experimental Section

General: All manipulations and reactions were performed under argon in carefully dried solvents using standard Schlenk techniques. FTIR: Perkin−Elmer 1760X as KBr discs. FAB MS: Fisons VG Autospec with 3-nitrobenzyl alcohol as the matrix. ^1H and ^{13}C NMR spectroscopy: Bruker DRX 400 with chemical shifts reported as δ values relative to the signal of the deuterated solvent. ^{13}C NMR signals for the $CF_3SO_3^-$ anions are observed in the range δ = 121.8−122.8 ppm (q) and are not given for individual complexes. Elemental analyses: Vario EL of Elementar Analysensysteme GmbH. 2,5-Dihydrophenylacetic acid[20] and 2,5-dihydro-3-phenylpropanol[21,22] were prepared as for 2,5-dihydro-4-phenylbutyric acid by Birch reduction of the appropriate phenyl-substituted acid. $RuCl_3·3H_2O$ was purchased from Chempur, amino acids and peptides from Bachem and carboxylic acids from Acros. Potentiometric titrations were performed with a fully automated microprocessor-controlled pH-titration unit (Metrohm 691 with Dosimat 665) in a thermostatted vessel at 25±1 °C under Ar with carbonate-free 0.1 mol·dm^{-3} NaOH. A constant background ionic strength of 0.1 mol·dm^{-3} KNO_3 (p.a.) was employed for all titrations. Further details of the experimental procedure are given in ref.[34] pH* values for ^1H NMR spectra in D_2O were not corrected for deuterium isotope effects. Semipreparative HPLC separations were carried out at an eluent flow rate of 15−25 mL·min^{-1} with a Knauer 64 pump, A0258 sample injector and Merck L-4000A UV detector using columns (25 × 2 cm i.d.) packed with Nucleosil 100-C_{18} (d_p = 10 μm).

2,5-Dihydro-4-phenylbutyric Acid (1): A solution of 4-phenylbutyric acid (9.85 g, 0.06 mol) in diethyl ether (100 mL) was added to a solution of sodium (14.80 g, 0.6 mol) in ammonia (400 mL) at −78 °C. Ethanol (112 mL, 1.80 mol) was added dropwise over 90 min and the solution was stirred until its original blue colour disappeared. After removal of NH_3 and addition of water (200 mL), the product was extracted with diethyl ether following an adjustment to pH = 2 with hydrochloric acid. The diethyl ether phase was then washed with water and dried with $MgSO_4$ before removal of the solvent in vacuo to afford **1**. Yield 8.57 g (86%). $C_{10}H_{14}O_2$ (166.2): calcd. C 72.3, H 8.5; found C 71.7, H 8.2. FAB MS: *m/z* (%) = 166 (38) $[M]^+$, 106 (38) $[M - C_2H_4O_2]^+$, 79 (100) $[M - C_4H_8O_2]^+$. ^1H NMR (CD_3Cl): δ = 1.70 (m, $^3J_{H,H}$ = 7.5 Hz, 2 H, β-CH_2), 2.28 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, α-CH_2), 2.56 (m, 4 H, CH_2 dihydrophenyl), 5.37 (m, 1 H, CH), 5.63 (m, 2 H, CH), 10.90 (br., 1 H, COOH) ppm. ^{13}C NMR (CD_3Cl): δ = 22.2, 26.7, 28.7, 34.4, 36.6, 119.4, 124.2, 124.2, 133.7, 180.1 ppm.

[{(η^6-$C_6H_5CH_2COOH$)Ru(μ-Cl)Cl}$_2$ (2a): 2,5-Dihydrophenylacetic acid (2.24 g, 16.20 mmol) was added to a solution of $RuCl_3·3H_2O$ (1.06 g, 4.05 mmol) in acetone/water (5:1, 48 mL) and the reaction mixture heated at reflux with stirring for 6 h. After removal of acetone, the deep-red aqueous solution was left to stand at 4 °C to afford a red precipitate of **2a** within 12 h, which was washed with diethyl ether and dried in vacuo. Yield 1.08 g (86%). $C_{16}H_{16}Cl_4O_4Ru_2$ (616.3): calcd. C 31.2, H 2.6, O 10.4; found C 31.0, H 2.6, O 10.7. FAB MS: *m/z* (%) = 580 (16) $[M - Cl]^+$, 546 (10) $[M - 2\ Cl]^+$, 458 (100) $[M - 2\ Cl, - 2\ CO_2]^+$. ^1H NMR (CD_3CN): δ = 3.59 (s, 4 H, α-CH_2), 5.54 (d, $^3J_{H,H}$ = 5.5 Hz, 4 H, *ortho*-H), 5.67 (t, $^3J_{H,H}$ = 5.5 Hz, 2 H, *para*-H), 5.74 (t, $^3J_{H,H}$ = 5.5 Hz, 4 H, *meta*-H) ppm. ^{13}C NMR (CD_3CN): δ = 39.0, 83.0, 84.5, 86.6, 97.3, 175.1 ppm. IR: $\tilde{\nu}$ = 1704 vs. (CO) cm^{-1}. **2a** can also be prepared by alkaline hydrolysis of **2b** at pH = 12.

[{(η^6-$C_6H_5CH_2COOC_2H_5$)Ru(μ-Cl)Cl}$_2$] (2b): 2,5-Dihydrophenylacetic acid (1.68 g, 12.15 mmol) was added to a solution of $RuCl_3·3H_2O$ (1.00 g, 4.05 mmol) in ethanol (60 mL) and the reaction mixture heated at reflux while stirring for 20 min. The resulting red precipitate was filtered, washed with ethanol, and dried in vacuo. Yield 1.34 g (98%). $C_{20}H_{24}Cl_4O_4Ru_2$ (672.4): calcd. C 35.7, H 3.6, O 9.5; found C 35.3, H 3.5, O 9.7. FAB MS: *m/z* (%) = 637 (100) $[M - Cl]^+$. ^1H NMR (CD_3CN): δ = 1.22 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, OEt), 3.59 (s, 4 H, α-CH_2), 4.14 (dd, $^3J_{H,H}$ = 7.0 Hz, 4 H, OEt), 5.55 (d, $^3J_{H,H}$ = 5.0 Hz, 4 H, *ortho*-H), 5.69 (t, $^3J_{H,H}$ = 5.5 Hz, 2 H, *para*-H), 5.74 (t, $^3J_{H,H}$ = 5.0, 5.5 Hz, 4 H, *meta*-H) ppm. ^{13}C NMR (CD_3CN): δ = 14.4, 39.3, 62.1, 83.2, 84.6, 86.4, 95.6, 170.5 ppm. IR: $\tilde{\nu}$ = 1749 vs. (CO) cm^{-1}.

[{(η^6-$C_6H_5(CH_2)_3COOH$)Ru(μ-Cl)Cl}$_2$] (3): 2,5-Dihydrophenylbutyric acid (2.02 g, 12.15 mmol) was added to a solution of $RuCl_3·3H_2O$ (1.06 g, 4.05 mmol) in acetone/water (5:1, 48 mL) and the reaction mixture heated at reflux while stirring for 6 h. After removal of acetone, the deep-red aqueous solution was left to stand at 4 °C to afford a red precipitate of **3** within 12 h, that was washed with diethyl ether and dried in vacuo. Yield 1.20 g (88%). $C_{20}H_{24}Cl_4O_4Ru$ (672.4): calcd. C 35.7, H 3.6, O 9.5; found C 35.7, H 3.6, O 9.6. FAB MS: *m/z* (%) = 637 (100) $[M - Cl]^+$ 602 (65) $[M - 2\ Cl]^+$. ^1H NMR (CD_3CN): δ = 1.90 (m, $^3J_{H,H}$ = 7.4, 7.0 Hz, 4 H, β-CH_2), 2.38 (t, $^3J_{H,H}$ = 7.4 Hz, 4 H, α-CH_2), 2.56 (t, $^3J_{H,H}$ = 7.0 Hz, 4 H, γ-CH_2), 5.44 (d, 4 H, *ortho*-H), 5.61 (t, 2 H, *para*-H), 5.68 (t, 4 H, *meta*-H) ppm. ^{13}C NMR (CD_3CN): δ = 25.4, 33.3, 33.6, 82.5, 83.1, 84.1, 86.6, 174.5 ppm. IR: $\tilde{\nu}$ = 1711 vs. (CO) cm^{-1}.

[(η^6-$C_6H_5CH_2COOH$)RuCl(1,10-phen)]Cl (4a): 1,10-Phenanthroline (0.441 g, 1.575 mmol) and **2a** (0.462 g, 0.75 mmol) were stirred in ethanol (75 mL) at reflux for 1 h. After cooling, the light-brown product was precipitated by addition of diethyl ether (40 mL) washed with ethanol and diethyl ether and dried in vacuo. Yield 0.610 g (83%). $C_{20}H_{16}Cl_2N_2O_2Ru$ (488.3): calcd. C 49.2, H 3.3, N 5.7, O 6.6; found C 47.6, H 3.2, N 5.4, O 6.7. FAB MS: *m/z* (%) = 453 (100) $[M - Cl]^+$. ^1H NMR (CD_3OD): δ = 5.83 (t, $^3J_{H,H}$ = 6.5 Hz, 1 H, *para*-H), 6.04 (d, $^3J_{H,H}$ = 6.5 Hz, 2 H, *ortho*-H), 6.37 (t, $^3J_{H,H}$ = 6.5 Hz, 2 H, *meta*-H), 8.11 (dd, 2 H, phen H3/8), 8.22 (s, 2 H, phen H5/6), 8.85 (dd, 2 H, phen H4/7), 9.88 (dd, 2 H, phen, H2/9) ppm. ^{13}C NMR (CD_3OD): δ = 39.4, 85.0, 91.3, 107.5, 127.8, 129.0, 132.4, 140.3, 147.7, 157.2, 179.1 ppm. IR: $\tilde{\nu}$ = 1702 vs. (CO) cm^{-1}.

[(η^6-$C_6H_5CH_2COOC_2H_5$)RuCl(1,10-phen)]Cl (4b): Preparation as for **4a** with **2b** (0.504 g, 0.75 mmol) and a reaction time of 2.5 h. Yield of light-brown **4b** 0.651 g (84%). $C_{22}H_{20}Cl_2N_2O_2Ru$ (516.4): calcd. C 51.2, H 3.9, N 5.4, O 6.2; found C 50.5, H 4.0, N 5.4, O 6.9. X-ray Structural Analyses of 4b′ and 10: Crystal and refinement data are summarised in Table 1. Unit cell constants were obtained from least-squares fits to the settings of 25 reflections centred with a Siemens P4 diffractometer. Intensities were collected with the diffractometer at varied speeds using the ω-scan mode for Mo-K_α radiation. Monitored control reflections exhibited no significant alterations in intensity during data collection. Semi-empirical absorption corrections were performed for **4b′** on the basis of ψ scans and the structures solved by direct methods. Refinement against F^2 was performed by SHELX-97[35] with anisotropic temperature factors for non-hydrogen atoms and protons at geometrically calculated positions. Compound **10** contains a methanol molecule in its asymmetric unit. CCDC-195945 and -195946 (**4b′** and **10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; Email: deposit@ccdc.cam.ac.uk].

Formation of Ruthenium−Aminocarbene Complexes from Aldimines and Aminals

Christina M. Standfest-Hauser,[a] Kurt Mereiter,[b] Roland Schmid,[a] and Karl Kirchner*[a]

Keywords: Carbenes / Density functional calculations / N ligands / Ruthenium

Specific pyridine-based aldimines and aminals act as chelating ligands towards the RuCpL and RuTpL (Tp = hydrido trispyrazolylborate) fragments giving κ^2N,N'-coordinated cyclic imine complexes. Under particular conditions, as elucidated in this paper, these complexes rearrange into cyclic aminocarbene complexes. Thus, the reaction of $[RuCp(L)(CH_3CN)_2]PF_6$ (L = CH_3CN, PMe_3, $SbPh_3$) with 1 equiv. of py–N=CHR [R = Ph (phenyl), Fc (ferrocenyl), Np (naphthyl)] affords the cyclic aminocarbene complexes $[RuCp(L)(=C(R)NH–py)]PF_6$, whereas when L = PPh_3, P*i*Pr_3, and CO the reaction stops at the stage of the imine complex $[RuCp(L)(\kappa^2N,N'$-py–N=CHR$)]PF_6$. Analogously, [RuTp(COD)Cl] (COD = 1,5-cyclooctadiene) also reacts readily with the imines py–N=CHR (R = Ph, *p*$MeOC_6H_4$, Np) at elevated temperatures to yield the aminocarbene complexes [RuTp{=C(R)NH–py}Cl]. This process may open a new synthetic route for obtaining carbene complexes. The mechanism of the imine–aminocarbene conversion was analyzed by DFT/B3LYP calculations. Accordingly, the operation of a direct 1,2 hydrogen shift can be ruled out; the reaction seems to involve hydrido iminoacyl intermediates resulting from C–H bond activation and deprotonation/protonation steps.

Introduction

It is highly fascinating to witness the vast and diversified varieties of rearrangements within and between molecules ligated to a transition metal center. In a recent communication,[1] we reported the conversion of an aldimine to an amino carbene (Scheme 1, top). This conversion is analogous to the rearrangement of a coordinated olefin to a carbene (Scheme 1, bottom).[2] Both of these processes involve a formal 1,2 hydrogen shift whose intimate mechanism remains unknown. For the olefin−carbene conversion, the presence of a heteroatom X featuring a strong π-donor group is of crucial importance. In fact, if X = H, alkyl, or aryl, the reverse process is more favorable.[3]

In a previous report,[1] we reacted the complex $[RuCp(L)(CH_3CN)_2]PF_6$, where L = CH_3CN, PMe_3, PPh_3, or CO, with (*E*)-*N*-(phenylmethylene)-2-pyridine amine (py−N=CHPh). The outcome of the reaction varied with the nature of the co-ligand L. Whereas [RuCp(L){=C(Ph)NH−py}]PF_6 was obtained when CH_3CN and PMe_3 were employed, the reaction stops at the stage of the imine complex $[RuCp(L)(\kappa^2N,N'$-py−N=CHR$)]PF_6$ with L = PPh_3 and CO. Similarly, [RuTp(COD)Cl] (Tp = hydrido trispyrazolylborate, COD = 1,5-cyclooctadiene) reacts readily with py−N=CHPh at elevated temperatures to give the aminocarbene complex [RuTp{=C(Ph)NH−py}Cl].

Our goal was to extend the scope of the above reactions to better understand the reasons for the intriguing imine−aminocarbene conversion. Towards this goal, we have used other imines with the general structure py−N=CHR, viz. R = ferrocenyl (Fc) and naphthyl (Np), and also py−CH_2−N=CHPh. Furthermore, we also used pyridine-based aminals which are known to be capable of forming amino carbenes by C−N and N−H bond cleavage and amine elimination.[4,5] We have included also P*i*Pr_3 and $SbPh_3$ as co-ligands to see whether the ligand size changes the reaction outcome. Finally, DFT/B3LYP calculations were performed to back up the mechanistic suggestions.

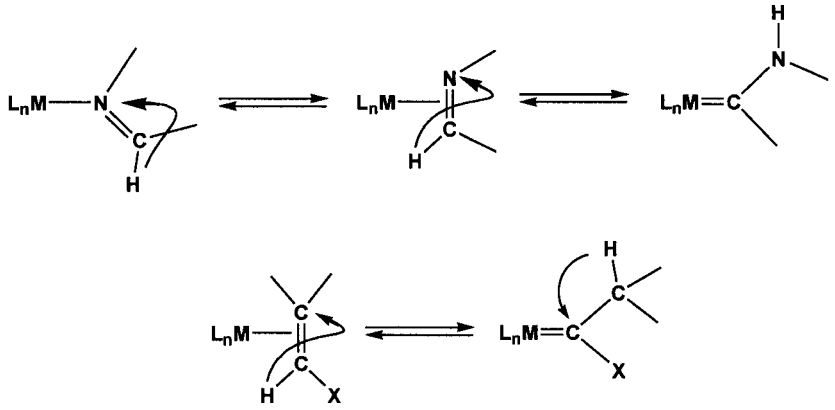
Results and Discussion

Synthesis and Characterization

Treatment of $[RuCp(L)(CH_3CN)_2]PF_6$ [L = CH_3CN (**1**), PMe_3 (**2a**)] with 1 equiv. of py−N=CHR [R = Ph (phenyl), Fc (ferrocenyl), Np (naphthyl)] afforded the aminocarbene



Scheme 1

complexes [RuCp(L){=C(R)NH−py}]PF_6 (**8a−c**, **9a−c**) in high yields (Scheme 2). A similar transformation between [RuCp($SbPh_3$)(CH_3CN)$_2$]PF_6 (**3**) and py−N=CHFc leads to the aminocarbene complex [RuCp($SbPh_3$){=C(Fc)-NH−py}]PF_6 (**10**). Analogously, [RuTp(COD)Cl] (**5**) also readily reacts with the imines py−N=CHR (R = Ph, *p*Me-OC_6H_4, Np) at elevated temperatures to yield the aminocarbene complexes [RuTp{=C(R)NH−py}Cl] (**11a−c**) (Scheme 3). The ferrocenyl-based imine py−N=CHFc was not stable under the reaction conditions. We note that no carbene complexes were obtained from **1−3** by reaction with monodentate aldimines RN=CHR′ (R = Ph, *i*Pr; R′ = Ph, *i*Pr).

All of the carbene complexes formed are air-stable, in both solution and in the solid state, with the exception of **8a−c**, and were characterized by ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy and elemental analysis. In the $^{13}C\{^1H\}$ NMR spectra of **8−10**, the carbene moiety is identified by downfield signals in the range of δ = 263.2 to 281.4 ppm. Other spectral changes accompanying the transformation to aminocarbene complexes include a characteristic broad resonance between δ = 11.8 and 13.2 ppm assignable to the NH proton.

The solid-state structure of **11a** was determined by single-crystal X-ray diffraction. An ORTEP diagram is depicted in Figure 1 with some bond lengths reported in the caption.

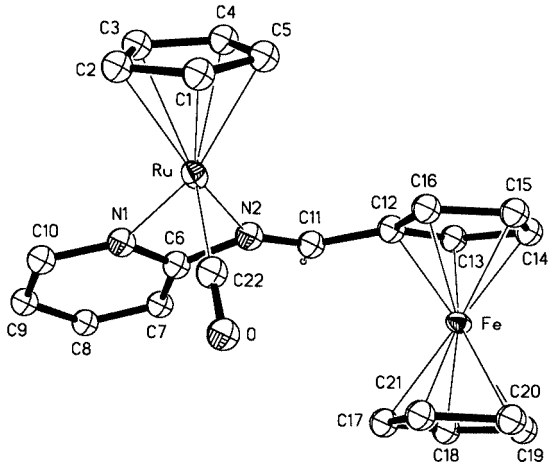

Figure 4. Structural view of **7b** showing 50% thermal ellipsoids (aromatic H atoms and PF_6^- ions omitted for clarity); selected bond lengths (Å) and angles (°): Ru−C(1−5)$_{av}$ 2.174(11), Ru−C(22) 1.846 (10), Ru−N(1) 2.080(9), Ru−N(2) 2.133(8), N(2)−C(11) 1.267(11), C(22)−O 1.139(11), N(1)−Ru−N(2) 60.3(3), Ru−C(22)−O 176.1(11)

The coordination geometry is distorted octahedral with all angles at ruthenium between 79 and 98° and 172 and 176°. The two Ru−N(Tp) bond lengths cis to the carbene moiety are significantly shorter [Ru−N(4) = 2.074(3) Å, Ru−N(6) = 2.048(3) Å] than that trans to the carbene moiety [Ru−N(2) = 2.210(3) Å]. The Ru−N(py) and Ru−Cl bond lengths are 2.046(3) and 2.414(1) Å. The Ru−C(15) bond length is 1.915(3) Å, which is similar to that in other heteroatom-stabilized ruthenium carbene complexes (cf. 1.959(1) Å in **9a**[1]). The C(15)−Ru−N(7) angle is 79.1(1)°.

If the ligand L in $[RuCp(L)(CH_3CN)_2]PF_6$ is relatively bulky, such as PPh_3 or P*i*Pr$_3$, or if it is a relatively strong π acceptor, as in the case of CO, the reaction with py−N=CHR does not result in the formation of aminocarbene complexes. Instead, and in keeping with previous results,[1] the complexes $[RuCp(L)(\kappa^2N,N'\text{-py}-N{=}CHR)]PF_6$ (**6a**−**d**, **7a**,**b**) are obtained according to Scheme 2. In view of the strained four-membered N−Ru−N−C ring system, it is noteworthy that no rearrangement to carbene complexes is observed, even at elevated temperature for 24 h. Complexes **6** and **7** were characterized by NMR spectroscopy and elemental analysis. In addition, the structures of **6b**, **7a**, and **7b** were determined by X-ray crystallography and are presented in Figure 2, Figure 3 and Figure 4. The overall structures are very similar and they can be described as three-legged piano stool conformations with the two N atoms of the imine ligand and the PPh_3 and CO ligands, respectively, as the legs. The N−Ru−N angles in **6b**, **7a**, and **7b** are

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

62.2(1), 62.8(1), and 60.3(3)°, respectively. The four-membered N−Ru−N−C ring system is essentially planar with torsion angles of 2.5(1), −2.1(1), and −1.4(5)°.

Notwithstanding these stable structures, the relief of the strain of the four-membered N−Ru−N−C ring might be a factor that favors the rearrangement of the κ^2NN imine into the aminocarbene complex. In fact, the imine complex derived from py−CH_2−N=CHR, rather than py−N=CHR, that features a five-membered N−Ru−N−C−C ring instead of a four-membered one, does not convert into the aminocarbene, even if kept for long times at elevated temperatures. This lack of reactivity is the case for [RuCp(CH_3CN)(κ^2*N*,*N*′-py−CH_2−N=CHPh)]PF_6 (**12**) and [RuTp(κ^2*N*,*N*′-py−CH_2−N=CHPh)Cl] (**13**) that are obtained from **1** and **5**, respectively (Schemes 4 and 5). A structural view of **12** is given in Figure 5 with selected bond lengths reported in the caption. This complex can be described in terms of a three-legged piano stool conformation with the two N atoms of the imine ligand and the N atom of the CH_3CN ligand as the legs. It is worth noting that the N−Ru−N angle [77.8(1)°] is considerably larger than those in **6b**, **7a**, and **7b**.

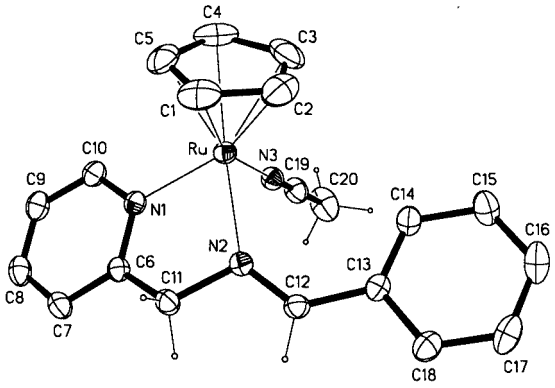

Figure 5. Structural view of **12** showing 50% thermal ellipsoids (aromatic H atoms and PF_6^- ions omitted for clarity); selected bond lengths (Å) and angles (°): Ru−C(1−5)$_{av}$ 2.153(3), Ru−N(1) 2.104(1), Ru−N(2) 2.117(1), Ru−N(3) 2.077(1), N(1)−Ru−N(2) 77.8(1), Ru−N(3)−C(19) 178.9(3)

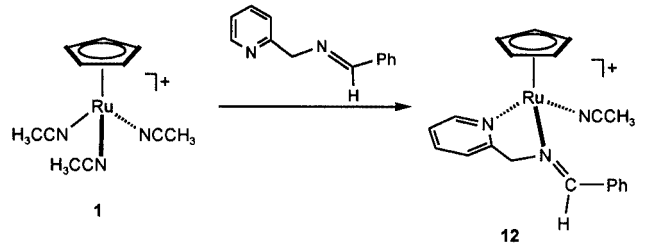
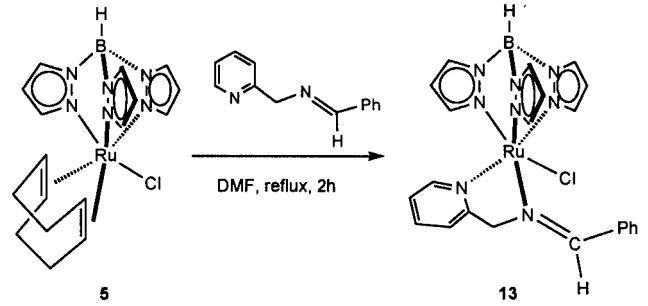


Scheme 4



Scheme 5

The generality of cyclic aminocarbene construction is further implied by the finding that aminals also react with the RuCpL and RuTpL fragments to form the corresponding aminocarbene complexes. In these reactions, the aminal at first obviously transforms back into the starting aldimines and amines. Thus, **1** and **2** react with *N*,*N*′-bis(2-pyridyl)-1,1-propanediamine [py−NHCH(Et)NH−py] and *N*,*N*′-bis(2-picolyl)-1,1-propanediamine [pyMe-NHCH(Et)-NH−pyMe] to form [RuCp(py−NH_2){=C(NH−py)Et}]-PF_6 (**14a**), [RuCp(pyMe-NH_2){=C(NH−pyMe)Et}]PF_6 (**14b**), and [RuCp(PMe_3)(=C(NH−py)Et]PF_6 (**15**) in high yields (Scheme 6). Interestingly, with **2b** the reaction does not stop at the aminocarbene stage, but proceeds further to give the olefin complex **16**. Such a mode of rearrangement is a common decomposition pathway of electron-deficient carbene complexes.[3] A structural view of **16**, determined

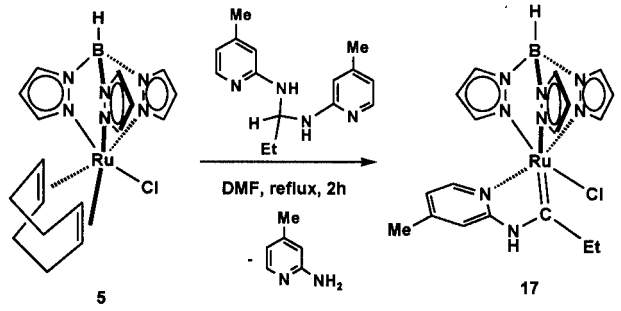

Scheme 7

by X-ray crystallography, is shown in Figure 6 with selected bond lengths reported in the caption. Similarly, [RuTp(COD)Cl] (**5**) reacts with pyMe-NHCH(Et)NH-pyMe to give [RuTp{=C(NH−pyMe)Et}Cl] (**17**) as shown in Scheme 7. These reactions involve both C−H and C−N activation steps, which thereby release a 2-aminopyridine molecule. It may be pertinent to note that **2b** does not react with py−N=CHPh to form an aminocarbene complex or a rearrangement product thereof.

Mechanistic Aspects

In the absence of detectable intermediate products on the way from the κ^2NN-imine to the aminocarbene complexes, we performed DFT (B3LYP) calculations using py−N=CH_2 and HCN as model ligands. Along these lines, several key intermediates can be proposed and these are depicted in Scheme 8 (energy in kcal/mol). The overall reaction is exothermic by 8.0 kcal/mol. The reliability of the computational method (details in the Exp. Sect.) is supported by the good agreement between the calculated geometries of **A** and **F** (Figure 7) with the X-ray structures for the related complexes (**6a**, **6b**, **7a**, **7b**, and **9a**).

At first, the imine moiety of the κ^2N,N'-py−N=CH_2 complex **A** becomes side-on coordinated (**B**). The endothermic nature of this step (8.3 kcal/mol) points to the preference for end-on coordination, although the activation barrier is relatively low (12.8 kcal/mol). Next, an agostic C−H bond is formed (**C**) that is energetically unfavorable by 4.9 kcal/mol. In proceeding from **A** to **C**, a rotation about the −N=CH_2 bond takes place that moves the substituent (hydrogen in the model system) from a syn position to an anti one, with respect to the metal center. Subsequent C−H bond activation leads eventually to the hydrido iminoacyl intermediate **D**.[6−8] This process is slightly endothermic by 1.2 kcal/mol and has a small activation barrier (2.3 kcal/mol). Such types of intermediates have been suggested recently for the reaction of [RuHCl(P*i*Pr$_3$)$_2$]$_2$ also

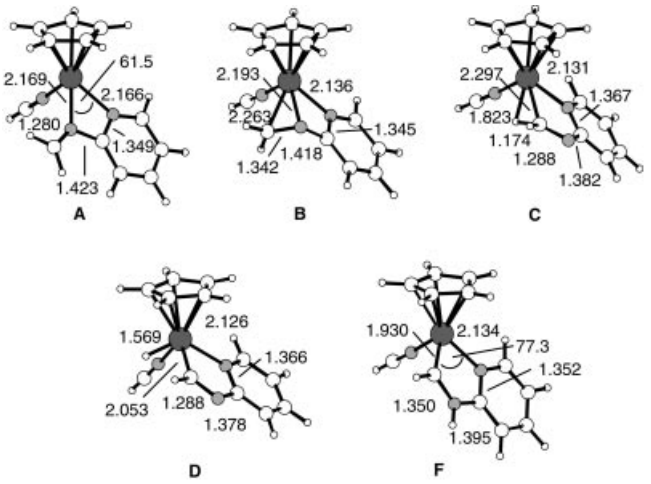

Figure 7. Optimized B3LYP geometries of the equilibrium structures **A**, **B**, **C**, **D**, and **F** (distances in Å and angles in deg)

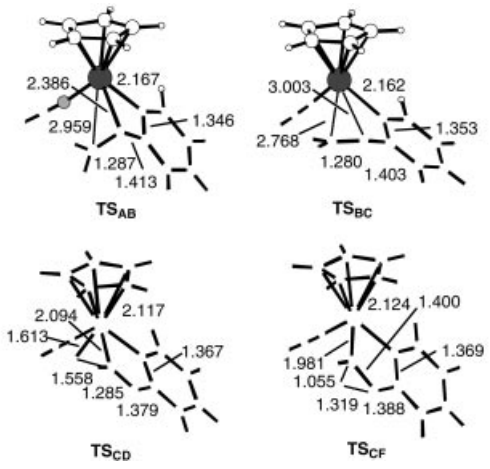

Figure 8. Optimized B3LYP geometries of the transition states TS_{AB}, TS_{BC}, TS_{CD}, and TS_{CF} (distances in Å)

with imines, in which case, however, isocyanides are formed and not aminocarbenes.[9]

It appears that the step from **C** to **D** involving C−H activation/oxidative addition, is particularly crucial to the overall imine-to-aminocarbene transformation. The reactivity of the imine complex is arguably lessened in the case of sterically demanding co-ligands like PPh_3 in **2b** and P*i*Pr$_3$ in **2c**. Note that the cone angle[10] increases in the order $CH_3CN < PMe_3 < SbPh_3 < PPh_3 < PiPr_3$. Alternatively, the presence of a strongly π-accepting co-ligand, such as CO, in **4** may prevent the oxidative addition step. The structures of the entities **A**−**F** as well as the corresponding transition states TS_{AB}−TS_{CF} are shown in Figure 7 and Figure 8.

The mechanism that is least clear is that for the onward reaction from **D** to **F**. According to our DFT calculations, a direct 1,2 hydrogen shift has a barrier as high as 53.7 kcal/mol and, thus, it is safe to exclude it. Alternative possibilities include the intermediacy of a neutral imino acyl complex **E** or, more appealingly, deprotonation/protonation assisted by adventitious water, counterion, or solvent. We favor a hydrogen-transfer pathway based on the implication of water as depicted in Scheme 9. Such a process, though in need of verification, would be consistent with the proton-transfer catalysis of water molecules arranged in cyclic aggregates that have been suggested, for example, for the dehydration of carbonic acid[11] or the hydration of sulfur trioxide.[12]

Conclusion

The factors that contribute to the present imine-to-aminocarbene rearrangement are summarized as follows. (i) The reaction is chelate assisted with the presence of the pyridine moiety being essential for the coordination of the imine to the metal center. (ii) In the four-membered N−Ru−N−C ring, the chelated imine ligand is under steric strain. (iii) The five-membered ring system N−Ru−C−N−C, arising from the rearrangement, interacts with the planar pyridine ring and can be considered as a 10-π-electron metallacycle that benefits from aromatic stabilization. (iv) Heteroatom stabilization seems to be an important factor too. (v) The co-ligand L should not be too bulky and only a moderate π acceptor.

The reaction of pyridine-based aldimines and aminals with both RuCp and RuTp complexes could furnish alternative and simple preparation methods for special carbene complexes without the use, for example, of diazoalkanes.

Experimental Section

General: All manipulations were performed under an inert atmosphere of argon by using Schlenk techniques. All chemicals were standard reagent grade and used without further purification. The solvents were purified according to standard procedures.[13] The deuterated solvents were purchased from Aldrich and dried over 4-Å molecular sieves. $[RuCp(CH_3CN)_3]PF_6$ (**1**),[14] $[RuCp(PMe_3)(CH_3CN)_2]PF_6$ (**2a**), $[RuCp(PPh_3)(CH_3CN)_2]PF_6$ (**2b**), and $[RuCp(P\mathit{i}Pr_3)(CH_3CN)_2]PF_6$ (**2c**),[15] $[RuCp(SbPh_3)(CH_3CN)_2]PF_6$ (**3**),[16] $[RuCp(CO)(CH_3CN)_2]PF_6$ (**4**) and $[RuTp(COD)Cl]$ (**5**),[17] $[RuCp(PPh_3)(\kappa^2\mathit{N},\mathit{N}'\text{-py−N=CHPh})]PF_6$ (**6a**), $[RuCp(CO)(\kappa^2\mathit{N},\mathit{N}'\text{-py−N=CHPh})]PF_6$ (**7a**), $[RuCp(CH_3CN)\{=C(Ph)NH-py\}]PF_6$ (**8a**), $[RuCp(PMe_3)\{=C(Ph)NH-py\}]PF_6$ (**9a**), $[RuTp\{=C(Ph)NH-py\}Cl]$ (**11a**), $[RuCp(py-NH_2)\{=C(NH-py\}Et)]PF_6$ (**12a**), $[RuCp(PMe_3)\{=C(NH-py)Et\}]PF_6$ (**13**), and $[RuCp(PPh_3)(py-NH-\eta^2\text{-}CH=CHMe)]PF_6$ (**14**)[1] were prepared according to literature procedures. ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker AVANCE-250 spectrometer and were referenced to $SiMe_4$ and H_3PO_4 (85%), respectively. ^1H and $^{13}C\{^1H\}$ NMR signal assignments were confirmed by ^1H-COSY, 135-DEPT, and HMQC(^1H-^{13}C) experiments.

$[RuCp(PPh_3)(\kappa^2\mathit{N},\mathit{N}'\text{-py−N=CHFc})]PF_6$ (6b): (*E*)-*N*-(Ferrocenylmethylene)-2-pyridineamine (py−N=CHFc) (44 mg, 0.152 mmol) was added to a solution of **2b** (100 mg, 0.152 mmol) in CH_2Cl_2 (5 mL). After the mixture was stirred at room temperature for 9 h, the solvent was evaporated under vacuum and the resulting red solid was collected on a glass frit and washed twice with diethyl ether (10 mL). Yield: 105 mg (80%). $C_{39}H_{34}F_6FeN_2P_2Ru$ (863.57): calcd. C 54.24, H 3.97; found C 54.29; H 4.04. ^1H NMR ([D$_6$]acetone, 20 °C): δ = 9.20 (s, 1 H, N=C*H*Fc), 8.52 (d, $J_{H,H}$ = 4.42 Hz, 1 H, py^6), 7.77 (vt, $J_{H,H}$ = 7.84 Hz, 1 H, py^4), 7.55−7.15 (m, 17 H, PPh$_3$, py^3, py^5), 5.26−5.17 (m, 1 H, FeCp^s), 5.06−4.99 (m, 1 H, FeCp^s), 4.97−4.87 (m, 2 H, FeCp^s), 4.69 (s, 5 H, RuCp), 4.26 (s, 5 H, FeCp) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 20 °C): δ = 169.7 (1C, py^6), 164.5 (1C, py^2), 151.9 ($J_{C,P}$ = 1.4 Hz, 1C, N=*C*HFc), 138.1 (1C, py^4), 133.7 ($J_{C,P}$ = 40.6 Hz, 3C, Ph^1), 133.3 ($J_{C,P}$ = 11.0 Hz, 6C, Ph^{2,6}), 130.1 ($J_{C,P}$ = 2.2 Hz, 3C, Ph^4), 128.5 ($J_{C,P}$ = 9.9 Hz, 6C, Ph^{3,5}), 123.9 (1C, py^3), 109.2 (1C, py^5), 75.8 (1C, FeCp^{s1}), 74.8 (1C, FeCp^s), 74.7 (1C, FeCp^s), 74.5 (5C, RuCp), 74.5 (1C, FeCp^s), 71.9 (1C, FeCp^s), 70.2 (5C, FeCp) ppm. $^{31}P\{^1H\}$ NMR ([D$_6$]acetone, 20 °C): δ = 49.7 (*P*Ph$_3$), −144.2 ($^1J_{PF}$ = 719.5 Hz, *P*F$_6$) ppm.

$[RuCp(PPh_3)(\kappa^2\mathit{N},\mathit{N}'\text{-py−N=CHNp})]PF_6$ (6c): An NMR tube was charged with **2b** (50 mg, 0.080 mmol) and *N*-(naphthylmethylene)-2-pyridine amine (py−N=CHNp) (23 mg, 0.080 mmol), and when they were dissolved in [D$_6$]acetone (0.5 mL), the color changed from yellow to dark red. After 12 h at room temperature NMR spectra were taken indicating quantitative formation of **6c**. ^1H NMR ([D$_6$]acetone, 20 °C): δ = 10.24 (s, 1 H, N=C*H*Np), 9.27 (d, $J_{H,H}$ = 7.31 Hz, 1 H, py^6), 8.64 (td, $J_{H,H1}$ = 5.28, $J_{H,H2}$ = 0.80 Hz, 1 H, py^4), 8.15−7.99 (m, 1 H, py^3), 7.90−7.80 (m, 1 H, py^5), 7.78−7.58 (m, 7 H, Np), 7.47−7.16 (m, 15 H, PPh$_3$), 4.76 (d, $J_{H,H}$ = 0.16 Hz, 5 H, RuCp) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 20 °C): δ = 162.9 (1C, py^6), 164.0 (1C, py^2), 152.1 (1C, N=*C*HNp), 138.4 (1C, py^4), 136.9, 135.5, 134.0 (3C, Np), 133.3 ($J_{C,P}$ = 41.5 Hz, 3C, Ph^1), 133.2 ($J_{C,P}$ = 11.5 Hz, 6C, Ph^{2,6}), 132.3 (1C, Np), 130.2 ($J_{C,P}$ = 2.2 Hz, 3C, Ph^4), 129.3, 128.7 (2C, Np), 128.5 ($J_{C,P}$ = 9.9 Hz, 6C, Ph^{3,5}), 128.0, 127.1, 125.6, 124.8 (4C, Np), 122.2 (1C, py^3), 110.2 (1C, py^5), 75.3 ($J_{C,P}$ = 2.1 Hz, 5C, RuCp) ppm. $^{31}P\{^1H\}$ NMR ([D$_6$]acetone, 20 °C): δ = 49.7 (*P*Ph$_3$), −144.1 ($^1J_{PF}$ = 719.5 Hz, *P*F$_6$) ppm.

$[RuCp(P\mathit{i}Pr_3)(\kappa^2\mathit{N},\mathit{N}'\text{-py−N=CHFc})]PF_6$ (6d): This compound was prepared analogously to **6b** by using **2c** (50 mg, 0.090 mmol) and py−N=CHFc (26 mg, 0.090 mmol) as the starting materials. Yield: 49 mg (71%). $C_{30}H_{40}F_6FeN_2P_2Ru$ (761.52): calcd. [pyMe−NHCH(Et)NH−pyMe] (59 mg, 0.20 mmol) in CH_2Cl_2 (8 mL) was stirred at room temperature for 3 h. The volume of the solution was then reduced to about 1 mL. Upon addition of diethyl ether, a brick-red solid was obtained that was collected on a glass frit, washed with diethyl ether, and dried under vacuum. Yield: 98 mg (75%). $C_{20}H_{25}F_6N_4PRu$ (567.48): calcd. C 42.33, H 4.44; found C 43.27, H 4.40. ^{1}H NMR ([D$_6$]acetone, 20 °C): δ = 12.70 (br. s, 1 H, NH), 9.15 (d, $J_{H,H}$ = 6.00 Hz, 1 H, py), 8.16 (d, $J_{H,H}$ = 6.16 Hz, 1 H, py), 7.39 (m, 1 H, py), 7.15 (d, $J_{H,H}$ = 5.53 Hz, 1 H, py), 6.49 (m, 1 H, py), 6.30 (br. s, 2 H, NH_2), 6.19 (d, $J_{H,H}$ = 5.05 Hz, 1 H, py), 4.98 (s, 5 H, Cp), 4.07 (m, $J_{H,H}$ = 7.27 Hz, 1 H, CH_2), 3.87 (m, $J_{H,H}$ = 7.31 Hz, 1 H, CH_2), 2.43 (s, 3 H, py−Me), 2.08 (s, 3 H, py−Me), 1.43 (t, $J_{H,H}$ = 7.50 Hz, 3 H, CH_3) ppm. ^{13}C{^{1}H} NMR ([D$_6$]acetone, 20 °C): δ = 276.6 (1C, Ru=*C*), 162.6 (1C, py^q), 158.6 (1C, py^q), 154.7 (1C, py), 151.5 (1C, py), 150.5 (1C, py^q), 150.0 (1C, py^q), 121.5 (1C, py), 115.1 (1C, py), 112.4 (1C, py), 109.9 (1C, py), 82.1 (5C, Cp), 45.5 (1C, *C*H$_2$CH$_3$), 20.5 (1C, py−Me), 20.0 (1C, py−Me), 12.2 (1C, CH$_2$*C*H$_3$) ppm.

Crystallographic Structure Determinations: Crystals of **6b**·$(CH_3)_2CO$, **7a**, **7b**, **11a**, **12**, and **16** were obtained by vapor diffusion of Et_2O into either CH_2Cl_2 or acetone solutions. Crystal data and experimental details are given in Table 1. All X-ray data were collected on a Bruker Smart CCD area detector diffractometer (graphite-monochromated Mo-K_α radiation, λ = 0.71073 Å, 0.3° ω-scan frames covering either hemispheres (**7a**, **7b**) or complete spheres of the reciprocal space, Bruker Kryoflex cooling unit). Corrections for Lorentz and polarization effects, for crystal decay, and for absorption were applied (multi-scan method with the program SADABS[18]). All structures were solved by direct methods using the program SHELXS-97.[19] Structure refinements on F^2 were carried out with program SHELXL-97.[20] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were inserted in idealized positions and were refined riding on the atoms to which they were bonded. Critical hydrogen atoms were refined in positional parameters without such restraints.

CCDC-200230 to -200235 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cam-

Computational Details: All calculations were performed using the Gaussian98 software package on the Silicon Graphics Origin 2000 of the Vienna University of Technology.[21] The geometry and energy of the model complexes and the transition states were optimized at the B3LYP level[22] with the Stuttgart/Dresden ECP (SDD) basis set[23] to describe the electrons of the ruthenium atom. For the C, N, and H atoms the 6-31g** basis set was employed.[24] A vibrational analysis was performed to confirm that the structures of the model compounds have no imaginary frequencies. The transition-state structure was relaxed after applying a small perturbation to ensure that it is connected to the corresponding reactant and product. A vibrational analysis was also performed to confirm that it has only one imaginary frequency. The geometries were optimized without constraints (C_1 symmetry).

Reactivity of Metallophosphide Anions with Electrophilic (Arene)tricarbonylmetal Complexes

Virginie Comte,[a] Jean Philippe Tranchier,[b] Françoise Rose-Munch,*[b] Eric Rose,[b] Danièle Perrey,[a] Philippe Richard,[a] and Claude Moïse[a]

Keywords: Anions / Carbonyl ligands / Arene ligands / Manganese / Chromium / Iron

Reaction of metallophosphide anions $[(CO)_xM'PPh_2]^-$ (M′ = Cr, Fe) with neutral tricarbonyl(η^6-fluoroarene)chromium and cationic (η^6-arene)tricarbonylmanganese complexes give rise to the formation of dinuclear complexes. These complexes are obtained either by substitution of the fluoride anion in the (arene)chromium complexes, or by addition to the ring in the (arene)manganese complexes. The X-ray structure of one homodimetallic (Cr–Cr) complex was obtained and compared with its solution structure.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Arenes coordinated to electrophilic neutral $Cr(CO)_3$ or cationic $Mn(CO)_3$ groups undergo a large variety of transformations that would otherwise not be feasible with the free arenes.[1] Among them, nucleophilic additions, followed by acidic and (or) oxidative treatment, provide efficient access to functionalized arenes or cyclohexadienes.[1,2] A wide range of carbon nucleophiles have been shown to react with (η^6-arene)tricarbonylchromium and -manganese complexes,[1] but relatively few investigations have been carried out using organometallic derivatives as the nucleophiles.

In the Mn series, benzylic and homobenzylic organometallic carbanions have been used as nucleophiles. Beck et al., for example, described the reactivity of Mn complexes with deprotonated diphenylmethane or benzothiophene coordinated to $Cr(CO)_3$,[3] as well as with carbonylosmate,[4] carbonylrhenate[5] and anionic alkynyl complexes.[6] More recently, Sweigart et al.[7] demonstrated that a weak nucleophile such as $[Pt(PPh_3)_2(C_2H_4)]$ could cleave a strained C−C bond in the four-membered ring of biphenylene coordinated to an $Mn(CO)_3^+$ fragment, giving the insertion product. Similarly, metal insertion into the C−S and C−O bonds of benzothiophene and benzofuran, respectively, was also observed [the carbocyclic rings of the benzothiophene and the benzofuran were coordinated to $Mn(CO)_3^+$ entities].[8] Metal insertion into the C−Cl bond of cationic tricarbonyl(chloroarene)manganese complexes was also seen.[9a]

Our own contribution in this field has been aimed at studying the reactivity of Fischer-type carbene anions[10] and of deprotonated (alkoxy-substituted arene)tricarbonylchromium complexes[11] towards (η^6-arene)tricarbonylmanganese complexes. These reactions result in the formation of heterodi- or -polymetallic complexes.

In the Cr series, strongly nucleophilic organometallic anions [such as $Fe(CO)_4^{2-}$, $M(CO)_5^{2-}$, M = Cr, W, $CpFe(CO)_2^-$] reacted with $[(C_6H_5X)Cr(CO)_3]$, allowing the formation of dinuclear complexes, which arise as a result of halogen substitution by the organometallic anions.[12]

This has led us to investigate the reaction of metallophosphide anions with (η^6-arene)metal complexes, and for this purpose we have selected the $[(CO)_xM'PPh_2]^-$ anions. These metallophosphide anions are, for example, able to achieve Cp substitution in neutral molybdenocene and tungstenocene dichlorides.[13] The presence of *tert*-butyl or trimethylsilyl groups on the cyclopentadienyl rings does not affect the site of substitution, and products with 1,3-disubstituted Cp-ring[13d] (Scheme 1) are obtained.

Scheme 2. Reaction of metallophosphide anions with $(\eta^6\text{-arene})Mn(CO)_3^+$ complexes

This unexpected reactivity led us to believe that metallophosphide anions are rather good nucleophiles.

In this paper, we describe the reactivity of two metallophosphide anions towards several substituted (η^6-arene)manganese and -chromium complexes (complexes **1**, Scheme 2; and **4**, Scheme 3). The conformational study of one of the resulting dinuclear complexes in the solid state and in solution is also presented.

Results and Discussion

The starting (arene)tricarbonylmanganese (**1a**−**c**) and -chromium (**4a**−**c**) complexes were prepared according to literature procedures.[14,15]

Reactivity towards $[(\eta^6\text{-Arene})Mn(CO)_3]^+$ Complexes

In a preliminary experiment, treatment of a suspension of $[(\eta^6\text{-}C_6H_6)Mn(CO)_3](PF_6)$ (**1a**) in THF with PPh_2Li[16] at −80 °C resulted in the formation of the addition product, the η^5-cyclohexadienyl complex **2a**[17] in a 40% yield, according to Scheme 2.

It is worth noting that when PPh_2Li was added to bent metallocenes $[(\eta^5\text{-}C_5H_5)_2MCl_2]$ (M = Mo, W), the complexity of the reaction mixture did not permit isolation of the desired product.[18a] Similarly, treatment of complex **1a** with $[(CO)_xM'PPh_2]Li$ afforded the neutral complexes **3a[Cr]** and **3a[Fe]** in 55 and 35% yields, respectively. If the reaction was performed with anisole and the 1,3-dimethoxybenzene complexes, **1b** and **1c**, dimetallic derivatives **3b[Cr]**, **3b[Fe]** and **3c[Cr]**[18b] were recovered in 55, 55 and 65% yields, respectively (Scheme 2). It is important to emphasize the *meta* regioselectivity[19] of the nucleophilic addition with respect to the methoxy group in the cases of **1b** and **1c**.

The ^{1}H NMR spectra of the resulting neutral addition complexes (Table 1) features the characteristic signals for the η^5-cyclohexadienyl groups, the 1-H and 5-H protons display low-frequency resonances (between δ = 3.00 and 3.57 ppm), the 2-H and 4-H protons show resonances at almost the same frequency (δ = 4.85−5.07 ppm), and the 3-H protons give signals at the highest frequency (δ = 5.04−5.47 ppm) for the dinuclear complexes **3a[Cr]**, **3a[Fe]**, **3b[Cr]**, **3b[Fe]**, and **3c[Cr]** (Entries 2−6, Table 1), and at

even higher frequency (δ = 6.06 ppm) for the mononuclear complex **2a** (Entry 1, Table 1).

The resonance for 6-H in the mononuclear complex **2a** presents a signal at δ = 3.73 ppm, in agreement with that previously observed for the product obtained after addition of phosphate to coordinated $[(arene)Mn(CO)_3]^+$ cations.[19c] The signals for the 6-H protons of the dinuclear complexes (Entries 2−6), which can be used as a probe for the coordination of PPh_2 to the $M'(CO)_x$ entity, display a high-frequency shift, δ = 4.30−4.47 ppm. This is consistent with the coordination of a phosphorus atom to a metal center.

Reactivity Towards (η⁶-Arene)Cr(CO)₃ Complexes

The tricarbonyl(η⁶-haloarene)chromium complexes **4a**, **4b** and **4c** reacted with PPh_2Li in THF in the presence of freshly distilled HMPT; derivatives **5a**,[20] **5b** and **5c**, respectively, were obtained in 60% yields (Scheme 3).

No reaction takes place in the absence of HMPT (which increases the nucleophilicity of the anions), emphasizing the low electrophilic nature of the Cr complexes. The easy formation of **5b** shows that steric effects, due to the presence of the *ortho*-methyl group, play no part. These metallophosphane complexes could lead to many μ-phosphido-bridged heteropolymetallic complexes. For example, we were able to synthesize such a dimetallic system incorporating a group-8 metallocene derivative.[21]

Similarly, by using $[(CO)_xM'PPh_2]Li$ (x = 5, M′ = Cr and x = 4, M′ = Fe), dimetallic complexes **6a[Cr]**, **6b[Cr]**, **6b[Fe]**[18b] (Scheme 3) were isolated in 85, 80 and 60% yields, respectively. Their ^1H NMR spectroscopic data (Entries 1, 2, 4−6, Table 2) are consistent with *ipso*-nucleophilic aromatic substitution occurring at the carbon atom bearing the fluoride atom. The same regioselectivity was clearly observed when using the *para*-disubstituted complex **4c** as the starting material. This afforded the new *para*-disubstituted complexes **5c**, **6c[Cr]** and **6c[Fe]** (Scheme 3). No *cine*- or *tele*-S_NAr was observed.[1d]

It is important to note the influence of the PPh_2 or the $PPh_2M'(CO)_x$ unit on the conformation of the $Cr(CO)_3$ tripod. Indeed the 4-H protons, *para* to the phosphanyl residue, display signals at the highest frequency (between δ = 5.80 and 6.12 ppm; Entries 1, 2, 4−6, Table 2).

This is in agreement with an *anti*-eclipsed conformation of the tripod, with respect to the bulky phosphanyl group.[1g] Similarly, the eclipsed 2-H and 6-H protons present signals at a high frequency. The biggest difference in the chemical shifts observed for two adjacent protons (3-H and 4-H) is δ = 0.92 ppm for complex **5b**. This is due to the synergic effect of the electron-donating methyl group, which favors an eclipsed conformation, and the phosphanyl group, whose steric hindrance favors an *anti*-eclipsed conformation. This confirms that the main conformation of the tripod in solution is eclipsed, with respect to the methyl group.[1d]

The IR spectra of $Cr(CO)_3$ present two well-resolved stretching modes, in accordance with the C_{3v} symmetry.[22] The absorptions are assigned to a nondegenerate symmetry vibration A1, and a doubly degenerate asymmetric vibration E.[22]

In order to evaluate the effect of complexation of the phosphorus atom by the $M'(CO)_x$ metal fragment, we compared some selected IR and ^1H NMR spectroscopic data of the mononuclear and dinuclear complexes of this chromium series (Table 3).

In all cases, a shift to higher wavenumbers is observed for the carbonyl stretching vibrations of the $Cr(CO)_3$ entity for the dimetallic complexes. This is in agreement with a stronger CO force constant, and with a decrease in the retro-donation of the chromium towards the carbonyl groups. In the NMR spectra, the 6-H protons (β to the phosphorus atom) of the dinuclear complexes present signals at a much higher frequency than those of the mononuclear complexes, e.g. the $\Delta\delta$(6-H) [$\delta(6\text{-H}_{dinuclear}) - \delta(6\text{-H}_{mononuclear})$] could reach δ = 0.57 ppm for **6c[Fe]** (Entry 8, Table 3).

In order to know more about the conformation of these complexes in the solid state, an X-ray analysis was performed on crystals of complex **6b[Cr]**. Two views of the ORTEP diagram are presented in Figure 1.

First of all, the two metallic moieties lie on both sides of the arene ring. The $Cr(CO)_3$ moiety adopts an eclipsed conformation relative to the methyl group. It is worth not-

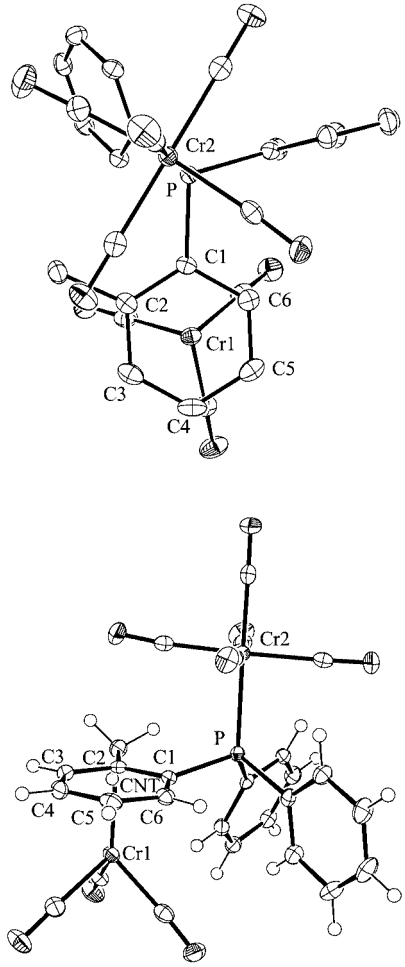

Figure 1. Two views of the ORTEP diagram of **6b[Cr]**; thermal ellipsoids are drawn at the 50% probability level; selected parameters: CNT−Cr1 1.724(2), C1−P 1.843(2), Cr2−P 2.4107(5), C1−P−Cr2 108.19(6)

ing that the longest chromium−carbon bond length is seen for Cr−C1 [2.268(2) Å], for the carbon atom substituted by the phosphane group, whereas the chromium−carbon bond length Cr−C2, for the carbon atom substituted by the methyl group, is 2.255(2) Å. The four other bond lengths are in the range 2.204−2.222 Å. Furthermore, the phosphorus atom, whose C1−P bond length is 1.843(2) Å, displays a shift of 0.471(2) Å out of the mean-aromatic plane, away from the Cr center.[23] The metal-to-ring distance is 1.724(2) Å. It is interesting to compare this structure with the tricarbonyl[(diisopropylphosphanyl)benzene]chromium structure (complex **A**), which presents a partially eclipsed conformation of the $Cr(CO)_3$ entity (midway between eclipsed and staggered, relative to the η^6-phenyl ring).[20a] In Table 4, selected bond lengths of complexes **A** and **6b[Cr]** are reported for comparison; coordination of the phosphorus substituent to $Cr(CO)_5$ does not seem to significantly affect these values. However, a small increase in the Cr−C1 bond length is induced.

Table 4. Selected bond lengths [Å] of complexes **A**[20a] and **6b[Cr]**

Cr–Ar	1.71	1.724(2)

Conclusion

Metallophosphide anions readily react with electrophilic (η^6-arene)tricarbonylmanganese (by nucleophilic additions) and chromium complexes (by *ipso*-nucleophilic substitutions), and allow the easy formation of neutral dinuclear complexes, one of which has been fully characterized by X-ray analysis. Both types of reactions are useful in the synthesis of highly functionalized arylphosphane complexes, and they might therefore complement the methods previously described where nucleophilic arene derivatives are treated with electrophilic phosphanes XPR_2.

Experimental Section

General Comments: All reactions were carried out under purified argon. The solvents and eluents were dried by an appropriate procedure and distilled under argon from sodium and benzophenone immediately before use. Standard Schlenk techniques and conventional glass vessels were employed. Column chromatography was performed under argon with silica gel (70−230 mesh). Elemental analyses were carried out with an EA 1108 CHNS-O FISONS Instruments. ^{1}H (200 MHz), ^{31}P (81 MHz) and ^{13}C (50 MHz) spectra were collected with a Bruker AC 200 spectrometer. Chemical shifts are relative to internal TMS (^{1}H, ^{13}C) or external H_3PO_4 (^{31}P). IR spectra were recorded with a Nicolet 205 IR-FT. The lithium reagent $[(CO)_xM'PPh_2]Li$ (x = 5, M′ = Cr; x = 4, M′ = Fe) was prepared according to a literature method,[24] using low-chloride methyllithium (Janssen). The manganese complexes were prepared according to two different procedures, using $[BrMn(CO)_5]$ with $AlCl_3$ or $AgBF_4$ and the free arenes.[14] The syntheses of the chromium complexes were achieved by heating $[Cr(CO)_6]$ and the free arene in a 9:1 mixture of di-*n*-butyl ether and THF.[15]

(Arene)manganese Complexes. General Procedure: 5 mL of a THF solution of PPh_2Li or $[(CO)_xM'PPh_2]Li$ (1 mmol) was added dropwise to a suspension of $[(\eta^6\text{-}C_6H_4\text{-}2\text{-}R^1\text{-}4\text{-}R^2)Mn(CO)_3](PF_6)$ (1 mmol) in THF (15 mL) at −80 °C. The stirred mixture was gradually warmed to room temperature for about 5 h, and THF was then removed in vacuo. With $R^3 = PPh_2$, the crude product was dissolved in Et_2O and filtered through Celite. For the dimetallic systems [$R^3 = (CO)_xM'PPh_2$], the residue was washed with pentane and chromatographed (eluent: toluene) to give an orange-yellow powder. All complexes $[(\eta^5\text{-}C_6H_3\text{-}2\text{-}R^1\text{-}4\text{-}R^2\text{-}6\text{-}R^3)Mn(CO)_3]$ were isolated after recrystallization from toluene.

Crystal Structure of 6b[Cr]: Single crystals of **6b[Cr]** were obtained by recrystallization from acetone. Intensity data were collected with a Nonius Kappa CCD at 110 K. The structure was solved with a Patterson search program and refined with full-matrix least-squares methods based on F^2(SHELXL-97)[25] with the aid of the WINGX program.[26] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in their calculated positions or found in the final difference Fourier maps and refined with a riding model. CCDC-187419 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

A Rigid Molecular Scaffold Affixing a (Polypyridine)ruthenium(II)- and a Nickel(II)-Containing Complex: Spectroscopic Evidence for a Weakly Coupled Bichromophoric System

Yann Pellegrin,[a] Katja E. Berg,[a] Geneviève Blondin,[a] Elodie Anxolabéhère-Mallart,[a] Winfried Leibl,[b] and Ally Aukauloo*[a]

Keywords: Ruthenium / Nickel / Polynuclear complexes / Rigid heteroditopic ligands / Redox chemistry / Photophysical studies

The synthesis of Dppz*t*BuSalH$_2$ (**7**), a rigid conjugated ditopic ligand containing a Dppz (dipyrido[3,2-*a*:2′,3′-*c*]phenazine) skeleton and a salophen-type chelate, is reported. The complexes Dppz*t*BuSalNi (**10**), [Ru(bpy)$_2$(Dppz*t*BuSalH$_2$)]$^{2+}$ (**11**), and [Ru(bpy)$_2$(Dppz*t*BuSalNi)]$^{2+}$ (**12**) have been prepared and characterised using common spectroscopic methods. Electrochemical, UV/Vis spectroelectrochemical and EPR studies were conducted on compounds **7**, **10**, **11**, and **12**. The singly reduced radical forms of **7** and **10** can be generated electrochemically, with the lone electron located on the low-lying phenazine π*-molecular orbital. Complexes **11** and **12** show several reduction waves and electronic and EPR data obtained for the electrogenerated singly reduced species show them to be closely related to the radical species **7**$^{\bullet-}$ and **10**$^{\bullet-}$, respectively. The presence of nickel(II) in compound **12** renders the addition of the second electron on the phenazine group reversible. Both **11** and **12** show common features on the cathodic side of their cyclic voltammograms, with reversible one-electron ruthenium-centred oxidation. An additional low-potential reversible-oxidation wave is observed for **12**, and this is ascribed to oxidation of the nickel(II) ion. The combined spectroscopic data best describe the ruthenium-containing complexes as weakly coupled bichromophoric systems. Photophysical studies attest to the formation of a charge-separated state for **11**, whereas a strong quenching is detected for **12**.

Introduction

Ruthenium complexes such as [Ru(bpy)$_3^{2+}$], which contain α,α′-diimine ligands, have repeatedly intrigued chemists due to their unique photophysical properties.[1] These lumophores have been widely used in studies of photochemically or electrochemically induced multielectron or energy transfers.[2] More recently, a wide variety of complexes bearing the Ru(bpy)$_3^{2+}$ unit have been designed with the aim of devising a new class of anion and cation sensors.[3] In such "molecular reconnaissance machines" the response is triggered by a modification of the luminescence and/or electrochemical properties of the photoactive core in the presence of the substrate. Molecular switches using this lumophore take advantage of this fundamental characteristic of the [Ru(bpy)$_3^{2+}$] core.[4] In general, the recent extensive developments in the area of inorganic photochemistry can be credited to the well-known metal-to-ligand charge transfer (MLCT) bands of [Ru(bpy)$_3^{2+}$]; excitation of this complex at wavelengths corresponding to these bands leads to the formation of the lowest-energy excited state corresponding to [Ru^{III}(bpy)$^{\bullet-}$(bpy)$_2$]$^{2+}$.[5] This energetic excited state has been exploited to serve both as an electron-transfer reductant and an oxidant.[6] In this respect, research on mixed-metal dimetallic systems containing both ruthenium and a first-row transition metal ion was triggered due to their potential in the study of electron transfer[7] and in the development of novel photocatalysts.[8] At the forefront of this research is the design of suitable ligands capable of coordinating the ruthenium centre and the transition metal ion. A great number of homoditopic ligands and complexes thereof have been synthesised, and electron and energy transfers have been studied in relation to the chemical nature of the complexes and the intermetallic separation provided by the spacer.[9] The 2,2′-bipyridine ligand has been extensively used as the starting point in the synthesis of a considerable number of functionalised heterotopic ligands.[10] In most cases however, bipyridine is covalently linked to an ancillary ligand by a flexible arm. In such systems, the distance between, and the orientation of, the electron donor and acceptor, parameters which are essential in electron transfer studies, are not known precisely.[11] In addition, it has been shown that photophysical properties are a function of the

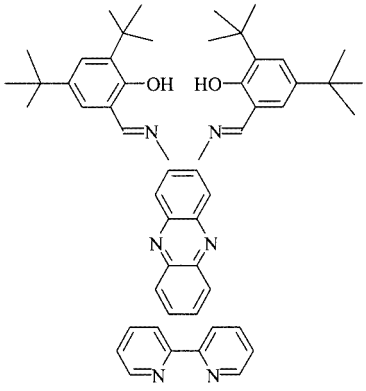
position of the pendant ligand on the bipyridine moiety.[12] With these considerations in mind, we have devoted our attention to the synthesis of rigid conjugated hybrid ligands capable of holding the two protagonist metal ions with known intermetallic distances.[13] We report here the synthesis of the novel heteroditopic ligand Dppz*t*BuSalH_2 (**7**) based on the Dppz[14] (dipyrido[3,2-*a*:2′,3′-*c*]phenazine) skeleton which contains a salophen-type cavity. This ligand can be viewed as a fused ring system of bipyridine, phenazine and salophen.



The coordinating ability of **7** is demonstrated by the stepwise metallation of both anchoring sites leading to a new ruthenium/nickel complex. Electrochemical studies coupled with UV/Vis/NIR and EPR techniques have been used to elucidate the redox behaviour and nature of the electrogenerated species derived from the complexes $[Ru(bpy)_2(Dppz\textit{t}BuSalH_2)]^{2+}$ (**11**) and $[Ru(bpy)_2(Dppz\textit{t}BuSalNi)]^{2+}$ (**12**). These results have been corroborated by comparative studies carried out on the unmetallated ligand **7** and the mononuclear nickel(II) complex [Dppz*t*BuSalNi] (**10**), in which the phenanthroline end of the ligand is metal-free. The synthesis of this latter complex and the study of its electronic properties were necessary in order to shed light on the actual contribution of each chromophore in the dinuclear ruthenium/nickel complex. The results of these studies suggest a weakly coupled bichromophoric complex, and that the ligand participates actively in the electrochemical processes of the mono- and dinuclear compounds. Finally, results from preliminary photophysical studies are given.

Results and Discussion

Synthesis

The synthetic pathway for **7** is shown in Scheme 1. Condensation of phendione **1** with 1,2-diamino-4,5-bis(*p*-tosylamino)benzene (**2**) in refluxing methanol gave **5** in quantitative yield. Deprotection of the tosyl groups was carried out in concentrated sulfuric acid to give **6** in near quantitative yield. Our synthetic approach leading to **6** differs from the one described by Lehn et al[20] in that no further purification was necessary prior to use. Bearing in mind the solubility problems encountered with rigid conjugated systems, we intentionally synthesised the corresponding Schiff base by condensation of 2 equiv. of 3,5-di-*tert*-butylsalicylaldehyde in the presence of triethyl orthoformate in boiling ethanol. Selective metallation (Scheme 2) of the different coordinating sites of **7** was achieved by initially coordi-

nating the phenanthroline end to $[Ru(bpy)_2]^{2+}$. The salophen cavity of the resulting complex $[Ru(bpy)_2(DppztBuSalH_2)^{2+}]$ (**11**) was easily metallated using nickel(II) acetate according to usual procedures.[36] Compounds **11** and **12** were purified for photophysical measurements, by chromatography on a neutral alumina column using dichloromethane/methanol (95:5 and 90:10, respectively) as eluents, and the desired compounds were collected as the first major fraction in both cases.

The synthetic pathway for **7** is shown in Scheme 1.

A different synthetic strategy was required to prepare [DppztBuSalNi] (**10**), the complex containing Ni^{II} in the salophenic cavity (see Scheme 3). Direct complexation of the salophenic cavity was discarded as it results in the formation of polynuclear Ni^{II} complexes and purification of the mixture was arduous and gave only low yields. As an alternative we used the well-known template synthesis to prepare the Ni^{II} complex **8** in almost quantitative yield.[21] Reduction of the nitro groups was carried out under hydrogen in the presence of Pd/C as catalyst. Complex **10** was synthesised in good yield following the condensation of the diamino derivative **9** with phendione **1** in refluxing methanol.

^{1}H NMR Spectra

^{1}H NMR spectroscopy was used to monitor the stepwise metallation of **7**. Attachment of the N−N chelating site of the phenanthroline end to the diamagnetic Ru^{II} showed, as expected, a downfield shift of the phenanthroline protons and certain bipyridine protons.[22−23] This phenomenon was even more pronounced when the Ni^{II} ion was bound in the tetracoordinating salophen cavity, with a downfield shift of as much as $\delta = 0.95$ ppm for the signal of the imine hydrogen atoms. Evidence for the coordination of nickel(II) to the salophen cavity was also obtained from ^{1}H NMR spectroscopy, with loss of the signal from the phenol protons.

Infrared Spectra

The sequential binding of the different metal ions was also monitored by infrared spectroscopy. Coordination of ruthenium was characterised by aliphatic C−H vibrations of the *tert*-butyl groups in the region of 2950 cm^{-1}, together with intense absorption bands at about 1585−1610 cm^{-1} corresponding to the imino C=N stretch. Nickel(II) insertion to yield **12** was indicated by a red shift of about 30 cm^{-1} for the band of the imino groups.[24]

Mass Spectrometry

Mass spectra of the ruthenium complexes **11** and **12** were obtained by Electrospray Ionisation Mass Spectrometry. Parent ion peaks minus one or two accompanying anions were detected. In both cases, the doubly charged species appeared as the major peak. The experimental and the simulated spectra for the doubly charged complex [**12** − 2 PF_6]$^{2+}$ are given in Figure 1.

UV/Vis Spectroscopy

The absorption spectra of **7**, **10**, **11** and **12** in CH_2Cl_2 are shown in Figure 2, and the absorption maxima together with their extinction coefficients given in Table 1. Figure 2 (a) shows the electronic perturbation that occurs upon metallation of the salophenic N_2O_2 cavity of **7** with Ni^{II}. Strong π-π* transitions at 310 and 430 nm characterise the extended delocalised π-system of the DppztBuSalH_2 skeleton. Spectral modifications for the mononuclear Ni^{II} complex are noticed in both the high- and low-energy regions compared to the free ligand. The prominent feature is the MLCT band at 500 nm typical of Ni−salophen complexes. The dissymmetric nature of this band may suggest the presence of π-π* intra-ligand transitions which undergo a bathochromic shift relative to that of the free ligand. This shift

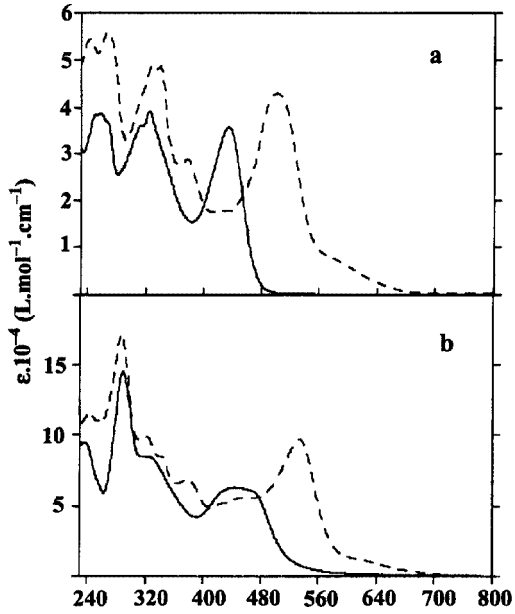

Figure 2. Absorption spectra in CH_2Cl_2; a) $DppztBuSalH_2$ (**7**) (solid line) and DppztBuSalNi (**10**) (dotted line); b) spectra of $[Ru(bpy)_2DppztBuSalH_2]^{2+}$ (**11**) (solid line) and $[Ru(bpy)_2DppztBuSalNi]^{2+}$ (**12**) (dotted line)

can be attributed to a diminution of the HOMO−LUMO gap upon metallation. The weak absorption band observed at the base of the MLCT transition at 620 nm corresponds to a d-d transition for Ni^{II} sitting in a square-planar coordination site.[25]

UV/Vis spectra of **11** and **12** are depicted in Figure 2 (b). The electronic absorption spectrum of **11** contains spectral features due to both $[Ru(bpy)_3]^{2+}$ and $DppztBuSalH_2$. Two intense bands are observed at higher energy, one for the usual intense spin-allowed ligand-centred transitions of the bpy ligands at 290 nm characteristic of (polypyridine)-ruthenium complexes[1,5] and a band at 325 nm attributed to intra-ligand transitions of **7**. A broad, asymmetric absorption band extending from 390 to 550 nm is accounted for by the superposition of low-energy π-π* intra-$DppztBuSalH_2$-ligand transitions and an admixture of dπ(Ru)-π*(bpy) together with dπ(Ru)-π* (bpy′) (where bpy′ denotes the bipyridine moiety of the ligand **7**) MLCT transitions. This agrees with previous findings for (polypyridine)ruthenium(II) complexes containing extended delocalised π-systems, where it has been shown that the low-lying orbitals confined on the central part of the rigid aromatic ligand are decoupled from the metal t_{2g}-type orbitals[26] due to the nearly non-existent orbital contribution from the nitrogen atoms of the coordinating imino groups. Hence, the optical properties of **11** suggest a bichromophoric character for the complex. Metallation of the salophen cavity with Ni^{II} induces a significant change in the appearance of the electronic absorption spectrum as shown in Figure 2 (b). The position and intensity of the π-π* transitions due to the bpy moieties are almost unaffected. A series of three bands between 320 and 380 nm, probably originating from intra-ligand π-π* transitions together with charge transfer transitions from Ni^{II} to the ligand, is observed. This explanation is supported by the observation of these bands in the spectrum of complex **10**. Ruthenium charge transfer transitions towards π*-orbitals of the ligands are detected as a shoulder at 460 nm on a more intense MLCT band from the salophen−Ni part of the dinuclear Ru/Ni complex **12**. The observation of a weak band at ca. 620 nm, characteristic of a d-d transition for a d^8 square-planar Ni^{II} complex, provides further evidence for metallation of the salophen cavity.

Spectroelectrochemical Properties and EPR Spectroscopy

Electrochemical studies on $[Ru(diimine)_3^{2+}]$ complexes are widely used to characterise the π*-orbital energies of

the ligands linked to Ru^{II}. In addition, the redox potential of the Ru$^{III/II}$ metal centre gives, in general, a clear indication of the nature of the interaction with the coordinated ligands. Furthermore, electrochemical data coupled with other spectroscopic information are currently used to rationalise the modifications in the absorption and emission spectra of [Ru(diimine)$_3^{2+}$] derivatives.[1b,14c,27] The electrochemical properties of **7**, **10**, **11** and **12** were investigated by cyclic voltammetry (CV) and these data are summarised in Table 2. Electronic data for the electrochemically generated species are given in Table 3. In what follows, we analyse the electrochemical behaviour of **7** and **10** and discuss the spectroscopic characterisation of the electrogenerated species. These results are then correlated to the Ru^{II}-containing complexes.

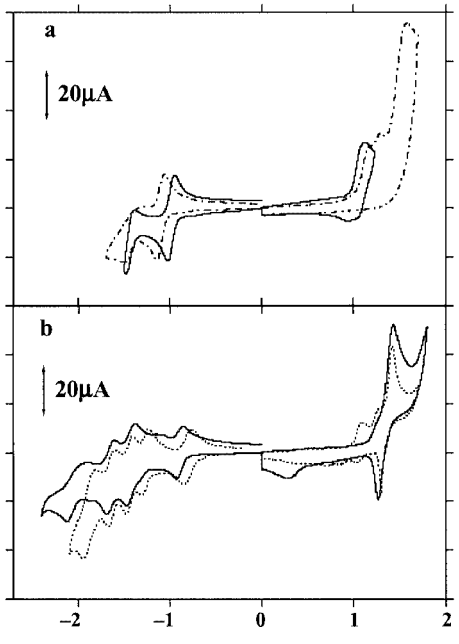

Figure 3. Cyclic voltammograms in CH_2Cl_2 (10^{-3} M solutions, room temperature, sweep rate 100 mV·s^{-1}, Ag/AgClO$_4$ electrode as reference, 0.1 M TBAClO$_4$ as supporting electrolyte); a) DppzBuSalH$_2$ (**7**) (dotted line) and DppzBuSalNi (**10**) (solid line); b) [Ru(bpy)$_2$DppzBuSalH$_2$]$^{2+}$ (**11**) (solid line) and [Ru(bpy)$_2$DppzBuSalNi]$^{2+}$ (**12**) (dotted line)

Ligand DppzBuSalH$_2$ (7) and Complex [DppzBuSalNi] (10)

The cyclic voltammograms of the free ligand **7** and its Ni^{II} complex **10** are shown in Figure 3 (a). Owing to the poor solubility of these species in acetonitrile, cyclic voltammograms of **7** and **10** were run in dry dichloromethane. Two waves are observed upon reduction of **7**, one reversible and a second quasi-irreversible at −1.1 and −1.39 V vs. SCE, respectively. The reversible one-electron reduction wave at −1.1 V falls in the range of potentials typical for phenazine-containing moieties.[27] No reversible waves are observed upon oxidation, even when scanning up to +1.7 V. However, two consecutive poorly resolved waves at +1.18 and +1.29 V vs. SCE are attributed to oxidation of the phenol groups. Compared to the first reduction of Dppz, an anodic shift of about 100 mV indicates the uptake of the first electron by the "modified" phenazine framework which contains imino π-accepting groups. The second electron addition occurs at a more positive potential than that of Dppz [−1.4 vs. −2.0 V (SCE), respectively]. The fact that salophen lacks a reduction wave within this potential range clearly implies that this electron-transfer process involves the phenazine part of the ligand. As reported earlier, the doubly reduced form of the Dppz ligand leads to a considerable increase in charge at the nitrogen atoms, thus enhancing its protonation aptitude. In the case of **7**, the same phenomenon will be occurring and this explains the flat-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tened nature of the corresponding anodic peak.[28] Redox properties of **10** are illustrated in Figure 3 (a, solid line); in comparison to **7** only minor changes are observed upon reduction. A shift of about 120 mV towards less negative potential is noticed for the first reversible reduction wave. The increased ease of reduction of the nickel(II) complex confirms the lowering in energy of the ligand LUMO upon metallation. In contrast to the ligand, a reversible oxidation wave is observed at +1.13 V vs. SCE, which is attributed to the formation of a nickel(III) complex. Such a potential is consistent with the $Ni^{III/II}$ redox couple of Ni−salophen.[29]

Spectroelectrochemical studies were carried out to investigate the stability and the spectroscopic signatures of electroreduced **7** and **10** after the first reduction wave. UV/Vis/NIR spectral changes of **7** and **10** were monitored at room temperature by using a thin-layer cell in dry dichloromethane in the presence of 0.1 M $TBAPF_6$ at −1.2 and −1.0 V, respectively. The electronic response of **7** is strongly modified upon addition of the first electron, as shown in Figure 4 (a). New high-intensity broad bands spanning the range 600−950 nm and another broad band at 380 nm are observed. These new spectral features are also found for singly reduced phenazine-containing compounds.[27] The double-hump band observed for $Dppz^-$ (547 and 570 nm) is shifted to lower energy for $\mathbf{7}^{\cdot-}$ with the maxima at 765 and 840 nm, indicating that the unpaired electron is localised on a more extended π-system.

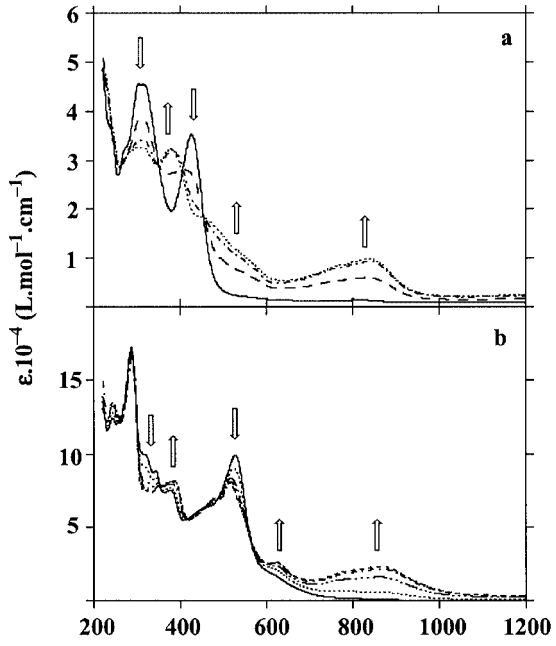

Figure 4. Electronic absorption spectra upon electrolysis at controlled potential in CH_2Cl_2 (10^{-3} M solutions, room temperature, SCE as reference, 0.1 M $TBAClO_4$ as supporting electrolyte); a) $DppztBuSalH_2$ (**7**) upon reduction at −1.3 V/SCE; b) $[Ru(bpy)_2DppztBuSalNi]^{2+}$ (**12**) upon reduction at − 0.96 V/SCE

The complete recovery of the initial spectrum upon reoxidation, together with the observation of several isosbestic points (265, 350, 405 and 450 nm), confirmed the presence of only two species in equilibrium at all times during the electrochemical study, showing the reversible nature of this electron-transfer process under our experimental conditions. The singly reduced species was also generated by a controlled potential bulk electrolysis at −30 °C. The EPR spectrum of the electrolysed solution showed an isotropic signal at $g = 2.007$, indicating the presence of an organic radical species with a peak to trough line width of 0.75 mT. In contrast to the paramagnetic singly reduced Dppz species, where well-resolved EPR signals have been observed,[27] the smooth EPR signal registered for $\mathbf{7}^{\cdot-}$ confirms the delocalisation of the electron on a more delocalised π-system, hence resulting in the interaction of the single electron with a larger number of nuclear spins.

The spectroelectrochemical behaviour of **10** was monitored using identical techniques as for **7**. The changes in the electronic spectrum of **10** upon the addition of one electron are similar to those of **7,** at least in the low-energy region. However, the maxima of these broad bands are shifted to lower wavenumbers (ca. 1040 cm^{-1}) indicating a smaller energy difference between the HOMO and LUMO when Ni^{II} is inserted into the N_2O_2 coordinating cavity. These absorption bands resemble those observed for the monoanion radical of **7** which favours localisation of the added electron on the phenazine part of the metallo complex. No substantial change in the d-d transition of the Ni^{II} centre at 620 nm is observed, but this band becomes more apparent in the electrolysed species. The one-electron process for this reduction wave was confirmed by bulk electrolysis at a controlled potential, and a reverse cyclic voltammogram on the electrolysed solution indicates the presence of only one species at the same potential as the initial complex. The frozen solution EPR spectrum of the electrolysed compound is shown in Figure 5. The signal is slightly anisotropic and is best simulated with values of $g_\perp = 2.0055$ and $g_{//} = 2.0012$. This weak anisotropy can be explained by a partial delocalisation of the lone electron in a d_π-type orbital of the nickel centre.[30] The lack of hyperfine coupling is most probably due to extensive overlap of a large number of signals with small EPR coupling constants, resulting from interaction with neighbouring atoms.

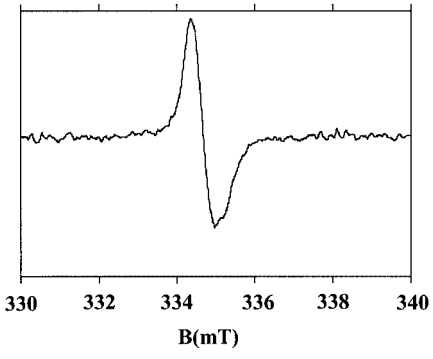

Figure 5. EPR spectra of $[DppztBuSalNi]^{\cdot-}$ ($\mathbf{10}^{\cdot-}$) at 100 K after bulk electrolysis at −1.2 V vs. SCE in dry dichloromethane and $TBAClO_4$ as supporting electrolyte

$[Ru(bpy)_2Dppz tBuSalH_2]^{2+}$ and $[Ru(bpy)_2Dppz tBuSalNi]^{2+}$ Complexes

Electrochemical properties of the ruthenium-containing complexes have been studied in both dichloromethane and acetonitrile in the presence of 0.1 M TBAP as supporting electrolyte, and the corresponding data are given in Table 2. Electrochemical studies of $[Ru(diimine)_3^{2+}]$ complexes are indeed crucial in evaluating the relative energy of the ligand π*-orbitals, especially for heteroleptic complexes, and also the nature of the interactions of the ligands with the metal centre. The first reductive process for the metal complex is often informative regarding the energy levels of the π*-orbitals of the ligands linked to the ruthenium(II) ion, whereas the first oxidation process is indicative of the metal t_{2g}-orbital energy. However, this is only true if the processes of reduction and oxidation are as in Equations 1 and 2, respectively.[31]

$$[M^{II}L_3]^{2+} + e^- \rightarrow [M^{II}L_2(L^{\cdot -})]^+ \quad (1)$$

$$[M^{II}L_3]^{2+} \rightarrow [M^{III}L_3]^{3+} + e^- \quad (2)$$

Cyclic voltammograms of **11** and **12** are given in Figure 3 (b). The electrochemical behaviours of **11** and **12** may be regarded as the superposition of each of **7** and **10** together with the $[Ru(bpy)_3^{2+}]$ chromophore, respectively. On the cathodic side of the CV of **11**, both reduction waves for the ligands are observed at −0.89 and −1.3 V vs. SCE, followed by the sequential addition of one electron to the bipyridine co-ligands. The oxidation wave for the $Ru^{III/II}$ couple is observed at +1.4 V vs. SCE and is probably masking the oxidation wave for the phenol groups. The fact that the oxidation potential for the Ru^{II} ion remains unchanged when compared to $[Ru(bpy)_3^{2+}]$ supports the idea that the phenazine moiety together with the bis(salicylidene)diimine groups have very little electronic influence on the metal centre. One can thus envision $[Ru(bpy)_2Dppz tBuSalH_2]^{2+}$ as consisting of two chromophores with little electronic communication between them. Complex **12** displays similar electrochemical behaviour; an almost identical pattern is observed on the cathodic part of the CV while on oxidation, a reversible wave is observed at +1.07 V vs. SCE followed by another wave at 1.42 V vs. SCE corresponding to oxidation of the phenol group, which is detected as a shoulder on the oxidation wave for the $Ru^{III/II}$ couple. It should be noted that, when scanning up to 1.8 and 1.7 V for **11** and **12**, respectively, we observed irreversible cathodic waves at 0.28 V for **11** and 0.37, 0.70 and 0.86 V for compound **12**. These waves probably originate from chemically altered species as no such waves are present when scanning to a potential just beyond the $Ru^{III/II}$ couple. The intensities of the corresponding waves for the $Ru^{III/II}$ couple suggest that adsorption and desorption phenomena are taking place at the surface of the vitreous carbon electrodes.

Singly Reduced Forms of $[Ru(bpy)_2Dppz tBuSalH_2]^{2+}$ (11) and $[Ru(bpy)_2Dppz tBuSalNi]^{2+}$ (12)

The first reduction potential for **11** occurs at −0.99 V which is very close to that of the free ligand under the same conditions (−1.11 V) [^1E(complex) − ^1E(ligand) = 0.12 V].[26,27] This implies that the coordination of ligand **7** to the Ru^{II} ion has little influence on the uptake of the first electron. Another way to describe this result is to consider that the singly occupied molecular orbital (SOMO) is developed mainly on the phenazine together with the bis(salicylidene)diimine framework. Moreover, the displacement of this wave to a more positive potential can be related to the dipositive charge of the complex of ligand **7**. Spectroelectrochemically, the uptake of the first electron is characterised by the growth of intense bands in the region of 600 to 950 nm and at 380 nm, attributable to the coordinated $Dppz tBuSalH_2$. Similarly to **7**, a fall in intensity of the π-π* intra-ligand charge-transfer transitions at 325 and 440 nm for **11** also underpins the proposed site of reduction. In addition, no alteration in either the Ru^{II} to bpy MLCT transitions at about 460 nm or the internal transition of the bound bpy ligands in their neutral form at 290 nm is observed, thus providing further evidence for the reduction site.[32]

EPR of a frozen solution of the singly reduced complex $\mathbf{11}^{\cdot +}$ generated electrochemically showed an isotropic signal with a *g* factor of 2.007. The negligible change in the observed *g* values for the free ligand $\mathbf{7}^{\cdot -}$ and the ruthenium complex $\mathbf{11}^{\cdot +}$ reflects the feeble interaction of the unpaired electron with the metal ion. It should be noted that the observed *g* values for other $[Ru(bpy)_2(L^{\cdot -})]^{2+}$ species, where L is a diimine-type ligand, deviate markedly from the *g* value of the metal-free ligand anion radical; this is mainly due to a strong interaction of the unpaired electron with the Ru^{II} ion.[33] Thus, the EPR spectrum of $\mathbf{11}^{\cdot +}$ is consistent with the single electron being confined to a molecular orbital located predominantly on part of the ligand skeleton, with a weak contribution from the Ru^{II} centre and the ligating diimine part of the corresponding ligand. As observed in the case of the radical species of the free ligand, no hyperfine structure is observed for $\mathbf{11}^{\cdot +}$, probably for the same reason as mentioned above.

The electrochemical response of **12** in acetonitrile is given in Figure 3 (b). Five reversible one-electron reduction waves at room temperature are observed in the potential range scanned. Of particular interest is the approximately 200 mV shift of the first reduction wave to more positive potential relative to **11** and **10**. Such a shift of the redox potential clearly denotes the stabilisation of the LUMO predominantly localised on the phenazine skeleton of the spacer ligand **7**.[34] The change in the electronic spectrum of **12** upon addition of one electron is shown in Figure 4 (b). The singly reduced species is characterised by the same bands in the low-energy region as those already observed for compounds **7**, **10** and **11** for the same electron transfer process. The spectral modification of **12** is closely related to that of **10**, again confirming the same position for the unpaired elec-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tron of the heterodimetallic complex. No appreciable alteration of the π-π* transition of the chelated bipyridine moieties at 290 nm is observed, and the Ru^{II}-to-ligand charge-transfer transitions at 460 nm are present as shoulders on the pronounced MLCT transitions of the Ni−salophen chromophore. Decisive spectroscopic characterisation of the first reduction process comes from the EPR spectrum of an electrolysed solution of **12**. An isotropic signal with a *g* factor of 2.013 and a line-to-line width of 0.75 mT typical of a radical species was detected. Here too, no hyperfine coupling is apparent. An interesting feature in the CV of **12** is the presence of a second reversible wave at −1.27 V (in acetonitrile vs. SCE). While no apparent shift has been detected for the second wave of **7** upon metallation of only one end of the heterotopic ligand (i.e. for compounds **10** and **11**), a marked displacement of about 260 mV to more anodic potential is observed in the case of the dimetallic complex. The more reversible nature of the uptake of the second electron on the bridging ligand reflects the gain in stability of the doubly reduced species in the case where both ends of the ligand contain a divalent ion.

Singly Oxidised Form of 12

The Ru^{II}/Ni^{II} complex exhibits three oxidation waves in the positive potential region at +1.07, +1.29 and +1.42 V vs. SCE, respectively. When compared to the first oxidation process of **10**, where only the salophen cavity is occupied by Ni^{II}, a small cathodic shift of ca. 60 mV is noted. The observed potential falls within the range expected for the $Ni^{III/II}$ couple of a salophen-type complex. Even the small shift observed for **12** is surprising, as a more positive potential for the oxidation of the Ni^{II} centre would be expected for this dicationic complex.[29] We tentatively rationalise this observation by noting the more π-accepting character of the bridging ligand when both extremities of the latter are metallated. Hence, a stronger ligand field is exerted on the Ni^{II} centre, thereby enhancing its propensity to oxidise. Few changes were observed spectroelectrochemically upon the removal of the first electron. The frozen-solution X-band EPR spectrum of the electrochemically generated Ru^{II}/Ni^{III} complex at 15 K shows a rhombic symmetry, with a large *g* tensor anisotropy (g_x = 2.289, g_y = 2.232, g_z = 2.022), which is commonly observed for Ni^{III} complexes in salophen-type environments.[29] Upon addition of degassed pyridine to the electrolysed solution and subsequent freezing, we obtained the EPR spectrum shown in Figure 6. The new adduct still exhibits a rhombic-type spectrum with superhyperfine couplings in all *g* regions. The best agreement between the experimental spectrum and the simulated one was obtained using the following parameters: g_x = 2.1986, g_y = 2.1645, g_z = 2.0265; $A_x = 16.34 \times 10^{-4}$ cm^{-1}, $A_y = 16.10 \times 10^{-4}$ cm^{-1}, $A_z = 20.43 \times 10^{-4}$ cm^{-1}. Simulation was realised using a Gaussian profile and line widths of 0.8, 0.7 and 0.6 mT for the *x*, *y* and *z* peaks, respectively. In addition, a signal at g = 2.0038 was detected, and attributed to the phenoxyl radical generated during the electrolysis, due to the close proximity of the two oxidation waves (Ni^{III}/Ni^{II} and $PhO^{\cdot+}$/PhO). The well-resolved quintuplet at higher magnetic field is the fingerprint of a six-coordinate Ni^{III} species, with two pyridine rings in axial positions and an axial repartition of the spin density on the Ni^{III} centre.

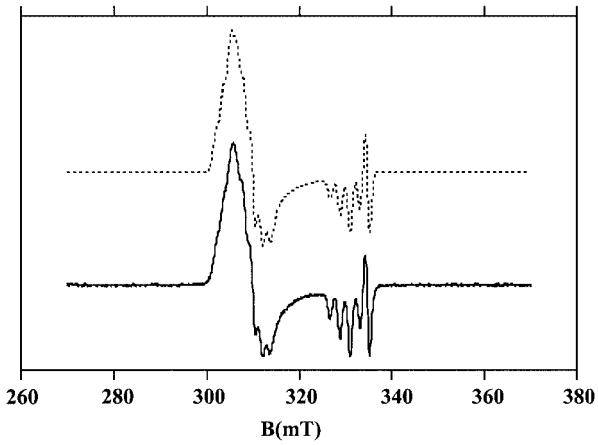

Figure 6. EPR spectrum of $[Ru(bpy)_2DppztBuSalNi]^{3+}$ ($\mathbf{12}^{3+}$) at 15 K, generated by electrolysis at 1.11 V/SCE in dry degassed acetonitrile and 0.1 M $TBAClO_4$ as supporting salt in the presence of pyridine (solid line); the dotted line shows the simulated spectrum

Preliminary Photophysical Studies

Upon excitation of the mononuclear ruthenium complex **11** at 532 nm (MLCT Ru^{II}→bipyridine moiety) in degassed ethanol at room temperature, fluorescence emission was observed around 610 nm. The observed fluorescence lifetime (minor of 40 ps is much shorter than that of $[Ru(bpy)_3^{2+}]$, which indicates rapid quenching of the excited state. Time-resolved absorption spectroscopy revealed that the transient species generated by photoexcitation at 532 nm displays an absorption at around 820 nm, a wavelength similar to that of the electrochemically singly reduced $[Ru(bpy)_2(DppztBusalH_2^{\cdot-})]^{2+}$ species (Figure 4, a). This is a strong indication that the quenching of the excited state is due to internal photoinduced electron transfer, probably forming the charge-separated state $Ru^{III}(bpy)_2(DppztBusalH_2^{\cdot-})^{2+}$. The lifetime observed for this transient species was about 400 ns. In contrast, the dinuclear complex **12** exhibits a very efficient quenching of the excited state which is not accompanied by absorption changes in the near infrared. The most likely explanation is that fast energy transfer to the Ni^{II} ion occurs in this complex where the excited state is efficiently quenched before internal charge separation can occur. We are currently investigating the photophysical behaviour of **10** and **12** in more detail.

Conclusion

Based on the X-ray structure of **10**[35] an approximate distance of 12.5 Å between the Ru^{II} and Ni^{II} ions is expected. This separation thus falls within the desired distance for electron or energy transfer studies in these model

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complexes. Spectroelectrochemical studies suggest a weak electronic coupling between the different chromophores in our system, a prerequisite in the design of supramolecular systems containing a photoactive site. We believe that our approach to building novel heteroditopic ligands will be a source of inspiration for the synthesis of novel ancillary ligands on anchoring molecules such as phenanthroline.

Experimental Section

General: Electrochemical measurements were performed with an EGG PAR (model 273A) electrochemical workstation. The solvents were distilled under nitrogen in the presence of dry calcium chloride and the solution [1 mmol·L^{-1} for complexes and ligand and 0.1 mol·L^{-1} of tetrabutylammonium perchlorate ($TBAClO_4$)] introduced within an argon-purged heart-shaped cell. Cyclic voltammetry was performed using a glassy carbon electrode (3 mm in diameter) as the working electrode, a platinum grid as the counter electrode and an $Ag/AgClO_4$ (0.01 M) electrode in acetonitrile as the reference (E_{ref} = 0.3 V/ECS). Electrolyses were carried out at controlled potentials in a three-electrode cell, using a platinum gauze as the working electrode, a platinum grid as the counter electrode and an $Ag/AgClO_4$ (0.01 M) electrode in acetonitrile as the reference. Low-temperature electrolyses were run using 0.2 M $TBAClO_4$. UV/Vis/NIR spectra were obtained using 1-cm quartz cells with a Varian Cary 5E spectrophotometer (200−1500 nm). Spectroelectrochemical data were obtained by a combination of a three-electrode thin cell (0.5 mm) mounted in a UV/Vis/NIR spectrophotometer. IR spectra were obtained with a Perkin−Elmer 1000 spectrometer, using KBr matrix pellets. NMR spectra were obtained using Bruker AC 200 (200 MHz) and AC 250 (250 MHz) spectrometers. The solvents used were $CDCl_3$ or $[D_6]$DMSO. EPR spectra were recorded with an X-band Elexsys (Bruker) spectrometer at 15, 77 or 100 K. Elemental analyses were carried out at the Services de Microanalyse, ICSN-CNRS, Gif-sur-Yvette. Mass spectra were recorded with a Finnigan Mat Mat95S in a *BE* configuration at low resolution. Flash-absorption and fluorescence transients were measured with setups of local design. All measurements were taken at 296 K. For absorption transients the measuring light was provided by a 150-W tungsten-halogen lamp, and the wavelength was selected with interference filters placed before and after the 10 × 1 mm sealed cuvette containing the sample. The sample was excited at 90° to the measuring beam by a flash from a frequency-doubled Nd:YAG laser (532 nm, duration 5 ns, ca. 2 mJ/cm^2; Surelight, Continuum). Absorbance changes were detected with a silicon photodiode and signals were amplified by a wideband preamplifier (model 5185, EG&G) before they were recorded by a digital oscilloscope (TDS, 744A, Tektronix). For fluorescence transients, excitation was achieved by a flash from a frequency-doubled picosecond Nd:YAG laser (532 nm, duration 25 ps, ca. 300 μJ/cm^2; Continuum). The detection wavelength was selected by an interference filter centred at 610 nm and signals were detected with a microchannel plate photomultiplier tube (R2566 U, Hamamatsu) and a 7-GHz digitising oscilloscope (IN7000, Intertechnique). Ruthenium trichloride was purchased from the Aldrich Chemical Company. 2,2′-Bipyridine (bpy) and 1,10-phenanthroline (phen) were obtained from the Janssen Chemical Company. 1,10-Phenanthroline-5,6-dione (phendione, **1**),[15] 1,2-diamino-4,5-bis(*p*-toluenesulfamido)benzene (**2**),[16] 3,5-di-*tert*-butylsalicylaldehyde (**3**),[17] 4,5-diamino-1,2-dinitrobenzene (**4**),[18] and $[Ru(bpy)_2Cl_2]$[19] were synthesised as described in the literature.

Synthesis of 11,12-Bis(*p*-tosylamino)dipyrido[3,2-*a*:2′,3′-*c*]phenazine (5): 1,2-diamino-4,5-bis(*p*-tosylamino)benzene (**2**) (2.23 g, 5 mmol) was added to a suspension of phendione (**1**) (1.55 g, 5 mmol) in methanol (50 mL) , and the mixture was refluxed for 1 h. The hot suspension was filtered while hot to give a beige solid which was washed with cold methanol and dried under vacuum. Yield: 2.92 g (94%). IR: $\tilde{\nu}$ = 3436 (N−H), 3034, 2820 (C−H), 1619 (C=N), 1580 (C=N) cm^{-1}. ^1H NMR ($[D_6]$DMSO): δ = 9.48 (d, 2 H), 9.16 (d, 2 H), 7.93 (dd, 2 H), 7.86 (s, 2 H), 7.78 (d, 2 H), 7.36 (d, 2 H), 2.28 (s, 6 H) ppm. $C_{32}H_{24}N_6O_4S_2$ (620.7): calcd. C 61.92, H 3.90, N 13.54; found C 61.88, H 3.82, N 13.42.

Synthesis of 11,12-Diaminodipyrido[3,2-*a*:2′,3′*c*]phenazine (6): Deprotection of the tosyl group was achieved by treating **5** (1.24 g, 2 mmol) with concentrated sulfuric acid (10 mL) at room temperature for 4 h. The deep violet solution was then added dropwise to ice-cold water and the brown solid was filtered off. After treatment with a concentrated solution of sodium carbonate (20 mL), the yellow solid was collected by filtration and washed with the minimum amount of water. The compound was then dried under vacuum. Yield: 0.54 g (86%). IR: $\tilde{\nu}$ = 3390 (N−H), 1630 (C=N) cm^{-1}. ^1H NMR ($[D_6]$DMSO): δ = 7.84 (d, 2 H), 7.63 (d, 2 H), 7.27 (dd, 2 H), 7.15 (s, 2 H), 6.33 (s, 4 H) ppm. $C_{18}H_{12}N_6$ (312.33): calcd. C 69.22, H 3.87, N 26.91; found C 69.17, H 4.01, N 26.75.

Synthesis of Dppz*t*BuSalH$_2$ (7): The diamino derivative **6** (94 mg, 0.3 mmol) and 3,5-di-*tert*-butylsalicylaldehyde (**3**) (188 mg, 0.8 mmol) were suspended in dry ethanol (30 mL) together with a few drops of triethyl orthoformate. The mixture was heated under reflux for 2 h and the yellow precipitate was separated by filtration. The solid was washed with diethyl ether and dried under vacuum. Yield: 192 mg (86%). IR: $\tilde{\nu}$ = 2950−2905 (C−H, aliph), 1610 (C=N) cm^{-1}.^1H NMR ($CDCl_3$): δ = 13.26 (s, 2 H), 9.63 (dd, 2 H), 9.30 (dd, 2 H), 8.93 (s, 2 H), 8.07 (s, 2 H), 7.82 (dd, 2 H), 7.54 (d, 2 H), 7.35 (d, 2 H), 1.48 (s, 18 H), 1.37 (s, 18 H) ppm. $C_{48}H_{52}N_6O_2$ (744.97): calcd. C 77.39, H 7.04, N 11.28; found C 77.12, H 7.17, N 11.36.

Synthesis of [DN*t*BuSalNi] (8): A solution of $NiCl_2·6H_2O$ (0.480 g, 2 mmol) in ethanol (10 mL) was added to a solution containing 4,5-diamino-1,2-dinitrobenzene (**4**) (396 mg, 2 mmol) and 3,5-di-*tert*-butylsalicylaldehyde (**3**) (936 mg, 4 mmol) in ethanol (100 mL). The resulting mixture was then heated to reflux with constant stirring for 2 h. The dark precipitate was then filtered off, washed with ethanol and dried under vacuum. Yield: 1.1 g (80%). IR (KBr): $\tilde{\nu}$ = 2955 (aliphatic CH), 1619 (C=N), 1358 and 1338 cm^{-1} (NO_2). ^1H NMR ($CDCl_3$): δ = 8.23 (s, 2 H), 8.21 (s, 2 H), 7.48 (d, 2 H), 7.14 (d, 2 H), 1.43 (s, 9 H), 1.30 (s, 9 H) ppm. $C_{36}H_{46}N_4NiO_7·H_2O$ (705.47): calcd. C 61.29, H 6.57, N 7.94; found C 60.96, H 6.62, N 7.89.

Synthesis of [DA*t*BuSalNi) (9): A slurry of compound **8** (690 mg, 1 mmol) and Pd/C (10%, 100 mg) in dry THF was maintained under hydrogen (40 bar) with stirring for 12 h. The mixture was filtered through a bed of Celite and then washed twice with THF (2 × 40 mL). The solvents were removed under reduced pressure and the red solid was sonicated in cold methanol (10 mL). The residue was filtered off, washed with the minimum amount of methanol and dried under vacuum. Yield: 440 mg. (70%). IR (KBr): $\tilde{\nu}$ = 3330 (NH), 2950 (aliphatic CH), 1614−1596 cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 7.88 (s, 2 H), 7.34 (d, 2 H), 7.02 (d, 2 H), 6.95 (s, 2 H), 3.49 (s, 4 H), 1.43 (s, 9 H), 1.37 (s, 9 H) ppm. $C_{36}H_{48}N_4NiO_2$ (627.49): calcd. C 68.91, H 7.71, N 8.93; found C 69.16, H 7.84, N 8.77.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Synthesis of DppzᵗBuSalNi (10): A slurry of compound **9** (628 mg, 1 mmol) in methanol (30 mL) was added dropwise to a refluxing solution of phendione (**1**) (210 mg, 1 mmol) in methanol (20 mL) with constant stirring. After the addition was complete, the mixture was heated to reflux for 2 h, whereby a red solid formed. The hot mixture was filtered and the solid was washed with methanol and dried under vacuum. Yield: 680 mg (85%). IR (KBr): $\tilde{\nu}$ = 3330 (NH), 2950 (aliphatic CH), 1614−1596 cm^{-1} (C=N). ^1H NMR ($CDCl_3$): δ = 9.49 (dd, 2 H), 9.22 (dd, 2 H), 8.39 (s, 4 H),7.68 (dd, 2 H), 7.45 (d, 2 H), 7.14 (d, 2 H), 1.46 (s, 9 H), 1.34 (s, 9 H) ppm. $C_{48}H_{50}N_6NiO_2{\cdot}0.5CH_2Cl_2$ (844.1): calcd. C 69.01, H 6.09, N 9.96; found C 68.90, H 6.15, N 9.82.

Synthesis of $[Ru(bpy)_2(DppzᵗBuSalH_2)](PF_6)_2$ (11): *cis*-$[Ru(bpy)_2Cl_2]{\cdot}2H_2O$ (52 mg, 0.1 mmol) and $AgNO_3$ (34 mg, 0.2 mmol) were suspended in methanol (20 mL). The mixture was stirred magnetically for 2 h under argon and a white precipitate of AgCl was filtered off. $DppzᵗBuSalH_2$ (**7**) (74 mg, 0.1 mmol) was added to the clear red solution followed by a few drops of triethyl orthoformate. The reaction mixture was heated to reflux under argon with constant stirring for 2 h. The reddish solution was filtered to remove any insoluble material and then concentrated in a rotary evaporator. An orange solid was precipitated upon addition of a concentrated aqueous solution of NH_4PF_6. The precipitate was collected by filtration and washed with diethyl ether. Yield: 70 mg (47%). A pure sample of **11** for photophysical measurements was obtained by chromatography on neutral alumina using a mixture of dichloromethane/methanol (95:5) (R_f = 0.58). IR: $\tilde{\nu}$ = 2950−2905 (C−H, aliph), 1585−1610 (C=N) cm^{-1}. ^1H NMR ([D$_6$]DMSO): δ = 13.48 (s, 2 H), 9.57 (d, 2 H), 9.33 (s, 2 H), 8.88 (m, 4 H), 8.49 (s, 2 H), 8.23 (m, 4 H), 8.14 (m, 2 H), 8.05 (m, 2 H), 7.83 (m, 2 H), 7.78 (m, 2 H), 7.67 (s, 2 H), 7.60 (m, 2 H), 7.48 (s, 2 H), 7.39 (m, 2 H), 1.41 (s, 18 H), 1.33 (s, 18 H) ppm. ES-MS: *m*/*z* = 579.2 [**11**]. $C_{68}H_{68}F_{12}N_{10}O_2P_2Ru{\cdot}0.33NaPF_6$ (1504.35): calcd. C 54.29, H 4.56, N 9.31; found C 54.3, H 4.7, N 9.35.

Synthesis of $[Ru(bpy)_2(DppzᵗBusalNi)](PF_6)_2$ (12): Metallation of the salophen cavity was carried out following established procedures. Ni(acetate)$_2{\cdot}4H_2O$ (6 mg, 0.24 mmol) was added to compound **11** (58 mg, 0.2 mmol) dissolved in methanol (20 mL) and the mixture was stirred for 2 h. The deep red solution was concentrated under reduced pressure and a solid was precipitated on addition of a concentrated aqueous solution of NH_4PF_6. The red solid was filtered off, washed with water and dried under vacuum. Yield: 26 mg (85%). A pure sample of **12** for photophysical measurements was obtained by chromatography on neutral alumina using a mixture of dichloromethane/methanol (90:10) (R_f = 0.61). IR: $\tilde{\nu}$ = 2950−2905 (C−H, aliph), 1605−1640 (C=N), 845 cm^{-1} (PF_6). ^1H NMR ([D$_6$]DMSO): δ = 9.52 (d, 2 H), 9.33 (s, 2 H), 9.19 (s, 2 H), 8.88 (dd, 4 H), 8.22 (m, 4 H), 8.14 (m, 2 H), 8.06 (dd, 2 H), 7.82 (d, 2 H), 7.77 (d, 2 H), 7.64 (d, 2 H), 7.60 (m, 2 H), 7.41 (d, 2 H), 7.39 (m, 2 H), 1.41 (s, 18 H), 1.32 (s, 18 H) ppm. ES-MS: *m*/*z* = 607.2 [**12**]. $C_{68}H_{66}F_{12}N_{10}NiO_2P_2Ru$ (1505.01): calcd. C 54.27, H 4.42, N 9.31; found C 54.05, H 4.31, N 9.29.

Acknowledgments

The authors wish to thank Professor Jean-Jacques Girerd for fruitful discussions. This work was supported by the CNRS (Programme Energie, PRI4) and the CEA for the LRC project (LRC-CEA no. 33V). K. B. wishes to acknowledge the European TMR program and STINT (The Swedish Foundation for International Cooperation in Research and Higher Education) for financial support.

Kinetic and Equilibrium Studies of Reactions of N-Heterocycles with Dimeric and Monomeric Oxorhenium(v) Complexes

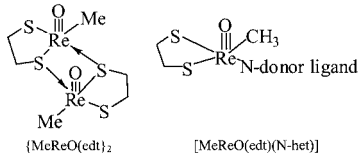
James H. Espenson*[a] and S. Masoud Nabavizadeh[a]

Keywords: Rhenium / N ligands / Kinetics / Linear free-energy relationships

Equilibrium constants have been evaluated for the reaction $\{MeReO(edt)\}_2 + 2\ L \rightarrow 2\ MeReO(edt)L$, where edt is 1,2-ethanedithiolate and L is any of 13 N-donor heterocyclic ligands. The values of K range from $1.37(27)\times10^{-2}$ for pyrimidine to $1.95(6)\times10^{6}$ for imidazole at 25 °C in chloroform. A successful correlation of log$K$ with log (K_a) of HL^+ was realized except in the case of the 2-substituted ligands 2-picoline and quinoline, where steric effects make K smaller than expected from the proton basicity of L. The kinetics of the same reactions were studied; the rate law for the reaction in the forward direction is given by $-d[\{MeReO(edt)\}_2]/dt = \{k_a + k_b[L]\}[L] \times [\{MeReO(edt)\}_2]$. Except for 2-picoline and quinoline, the major pathway is provided by the term that shows the quadratic dependence on [L]. Values of log (k_b) also correlate with log K, and therefore necessarily with log (K_a).

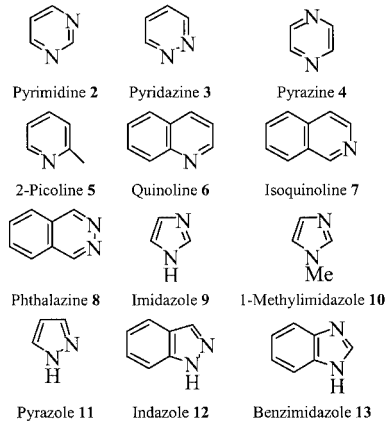
Introduction

We have studied the interaction of N-heterocycles with certain high-valent oxorhenium complexes. Our studies encompass the evaluation of equilibrium constants and rate constants for complexes of the core composition [MeRe(O)-(dithiolate)]. Actually, that core, with coordination number four, is never a detectable species, not even as a reaction intermediate. The stable species all show five-coordination as depicted in Scheme 1. The complexes of interest comprise dimers, $\{MeRe(O)(dithiolate)\}_2$,[1,2] and monomers, $\{MeRe(O)(dithiolate)L\}$,[3,4] where L is pyridine (**1**) or any of the other N-heterocycles shown in Scheme 2.



Scheme 1. Structural formulas of methyl(oxo)rhenium(v) complexes

These complexes have soft metal centers; the chelating dithiolate is never displaced and (phosphane)rhenium complexes, although not a subject of this study, are more stable than those with hard bases such as pyridines.[4] We have explored correlations between the equilibrium and rate constants for experimental studies carried out in chloroform.



Scheme 2. Structural formulas of N-heterocycles

In addition, the equilibrium constants for the coordination of N-heterocycles (L) were correlated with the aqueous pK_a values of HL^+.

One finds in the literature values of stability constants for 1:1 complexes of several imidazoles with many divalent metal ions.[5−7] A correlation was identified between the equilibrium constants and pK_a values, except for benzimidazole (**13**), which could be attributed to the steric hindrance this particular ligand poses for coordination to a metal site. Complexes of the general formula $[M(CN)_5L]^{n-}$ offer the advantage that there is but a single open coordination site. Their coordination chemistry — including structure, spectroscopy and kinetics — have been reported for M = Fe, Ru, and Os.[8] Because of the particular steric effects of 2-substituted imidazole ligands, their interactions have been the subject of a separate investigation.[9] In addition, rate constants for the formation and dissociation of

$[Ru^{II}(CN)_5L]^{3-}$ ions (L = Py, ImH etc.) have been reported.[10]

Results

Equilibrium Studies

Values of the equilibrium and rate constants have been evaluated for the reactions represented by Equation (1).

$$\{MeReO(edt)\}_2 + 2L = 2\ MeReO(edt)L \quad K = \frac{[MeReO(edt)L]^2}{[\{MeReO(edt)\}2] \times [L]^2} \qquad (1)$$

The absorbance of a solution at equilibrium is the sum of the larger component from the monomer and the smaller one from the dimer [Equation (2)].

$$Abs_{eq} = \varepsilon_D[\{MeReO(edt)\}_2]_{eq} + \varepsilon_{ML}[MeReO(edt)L]_{eq} = \varepsilon_D[D]_{eq} + \varepsilon_{ML}[ML]_{eq} \qquad (2)$$

Mass balance for rhenium must also be maintained [Equation (3)].

$$[Re]_T = 2 \times [\{MeReO(edt)\}_2]_{eq} + [MeReO(edt)L]_{eq} = 2 \times [D]_{eq} + [ML]_{eq} \qquad (3)$$

The simultaneous solution of these equations, which is presented in the Supporting Information (see footnote on page 1 of this article), affords an exact expression for the equilibrium absorbance in which the indicated equilibrium is sustained [Equation (4)], where [L] represents the equilibrium ligand concentration.[4]

$$Abs_{eq} = \varepsilon_D[D]_0 + \left(\varepsilon_{ML} - \frac{\varepsilon_D}{2}\right) \times \left[\frac{-K + \sqrt{K^2 + \frac{16K[D]_0}{[L]^2}}}{4/[L]^2}\right] \qquad (4)$$

The values of K were determined for most of the ligands by fitting the equilibrium absorbances to Equation (4) by the method of nonlinear least squares. Such solutions contained L at a known concentration because $[L]_T \approx [L]_{eq} >> [Re]_T$. Figure 1 presents repetitive scan spectra showing the equilibrium progression from D to ML for L = pyridine (**1**), with increasing ligand concentration. Tight isosbestic points were found, showing that only the two rhenium species were present throughout the set of experiments. The inset of Figure 1 shows the fit to Equation (4) of the absorbance values at one wavelength, 364 nm. For L = pyridine, the value of K so determined is $1.04(16) \times 10^4$ L·mol^{-1} in chloroform at 25.0 °C.

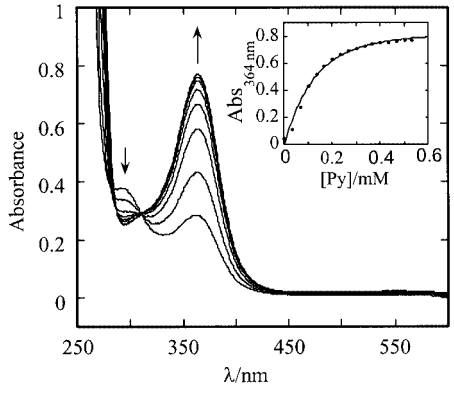

Figure 1. Absorbance changes as a solution of $[MeReO(edt)]_2$ was titrated with pyridine; isosbestic points were noted at 283 and 311 nm; the inset shows the analysis of the spectrophotometric data to evaluate the equilibrium constant according to Equation (4)

A more complex situation arises when K is quite large, as was the case for imidazole, 1-methylimidazole, and benzimidazole. Then, $[L]_T$ must not be $>> [Re]_T$ in order to realize the balance between D and ML needed for the evaluation of K. That is, $[L]_T \neq [L]_{eq}$. This situation requires an iterative solution. To do so, we made use of the program PSEQUAD.[11] The data for **11** were checked by both methods of calculation, and the agreement in the values of K was within the experimental error: 96±7 and 95±3 by nonlinear least-squares and by using the program PSEQUAD, respectively. The values of the equilibrium constants by the method most appropriate for the given complex are summarized in Table 1. The Supporting Information lists the initial concentration of $[MeReO(edt)]_2$ and the range of each ligand L used in the determination of the values of K.

Kinetic Studies

In many of the kinetics experiments, the reaction proceeded to completion. The gauge of this is whether the given [L] used for a particular experiment and the value of K inherent to it satisfied the condition $K[L]_{eq} >> 1$. In such cases, the data were analyzed by first-order kinetics. In terms of absorbance this is given by Equation (5) , where Abs_0 and Abs_∞ are the respective initial and final absorbance and k_{for} is the pseudo-first-order rate constant for the forward reaction.

$$Abs_t = Abs_\infty + (Abs_0 - Abs_\infty)\exp(-k_{for}t) \qquad (5)$$

It was not always feasible to drive the reaction to completion at an attainable ligand concentration, particularly when K is small. Additionally, for ligands with intermediate values of K, some reactions proceeded to completion, for which Equation (5) applies, but other experiments at lower [L] did not. The data in these cases require treatment by a kinetic model that takes into account the opposing rates of the forward and reverse reactions, which appear as a rate *difference*. In general, the apparent rate *constants* for equilibration are the *sum* of those for the forward and reverse reactions. The data could thus be treated by Equation (6), in which the designations k^Ψ indicate rate constants that depend on [L].[4,15]

$$Abs_t = Abs_\infty + \frac{(1+q)\cdot[Abs_0 - Abs_\infty]\cdot e^{-k_e t}}{1+q\cdot e^{-k_e t}}$$

$$\text{where } k_e = k^\Psi_{for} + 4k^\Psi_{rev}[M-L]_\infty,\ q = \frac{4k^\Psi_{rev}[ML]_\infty}{2k^\Psi_{for} + 4k^\Psi_{rev}[ML]_\infty} \text{ and } k^\Psi_{for} = k_e \times \frac{1-q}{1+q}. \qquad (6)$$

[a] K was evaluated by use of the nonlinear least-squares method except for ligands **9**, **10**, and **13** for which the program PSEQUAD was used. [b] K_a applies to the reaction $HL^+ = H^+ + L$ in aqueous solution at the specified temperature. Data are from refs.[12–14] [c] λ specifies the wavelength used for fitting data from equilibrium and kinetics studies.

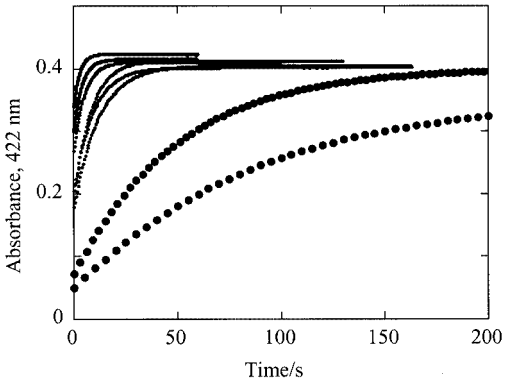

Figure 2. Absorbance-time curves for the reaction of $\{MeReO(edt)\}_2$ with pyridazine (**3**) in chloroform at 25.0 °C; data are shown for experiments with $[L]_0$ in the range 4.6–32.1 mM

The increase in absorbance for one typical family of kinetic experiments with L = pyridazine, **3**, is presented in Figure 2. The values of the pseudo-first-order rate constants for the reactions in the forward direction were determined as a function of [L]. The rate law in the general case contains two terms [Equation (7)], although in any specific case a contribution from one of the terms may be absent within the experimental error.

$$-\frac{d[\{MeReO(edt)\}_2]}{dt} = \{k_a[L] + k_b[L]^2\} \times [\{MeReO(edt)\}_2] \quad (7)$$

Because this is the rate equation for the forward reaction, that for the reverse reaction follows from it [Equation (8)].

$$v_{rev} = \left\{k_{-a}[L]^{-1} + k_{-b}\right\}[MeReO(edt)L]^2 \quad (8)$$

That is, one term of the reverse rate law shows inhibition by L. This feature is already incorporated in Equation (6). As a consequence of the equilibrium situation, we also have, by microscopic reversibility, the relation according to Equation (9).

$$K = \frac{k_a}{k_{-a}} = \frac{k_b}{k_{-b}} \quad (9)$$

The weighted nonlinear least-squares fitting of the values of k^{Ψ}_{for} to Equation (7) is presented in Figure 3 for the same L. Values of k_a and k_b so obtained are also given in Table 1.

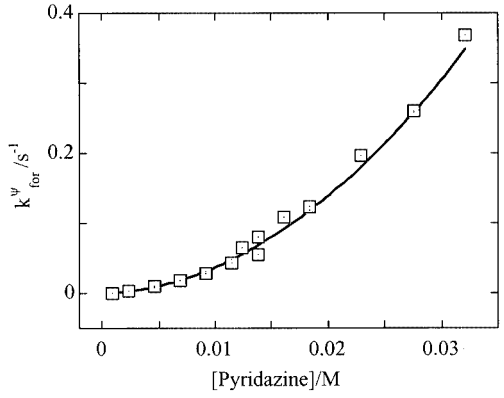

Figure 3. A representative set of kinetic data for L = pyridazine (**3**) depicting the weighted nonlinear least-squares fit to Equation (7), with linear and quadratic dependencies on [L]

Interpretation and Discussion

Correlation of Lewis and Brønsted Basicities

Figure 4 displays a plot of log$K$ for the reaction according to Equation (1) versus logK_a, for the acid ionization of HL^+.[12–14] Except for ligands **5** and **6**, a good correlation was found; the slope of the line in Figure 4 is -1.08 ± 0.09. Exceptions for those two ligands are logical as well, in that they present a steric barrier for coordination to the rhenium

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

center which is absent in the proton basicity. No deviation was found for benzimidazole (**13**), where a steric effect for the rhenium center might have been expected to exist. That steric effect would be smaller than the ones for **5** and **6**, because the bond angle between N, the ring C, and the C in the 2-position is 132° in **13** and 120° in **5** and **6**.

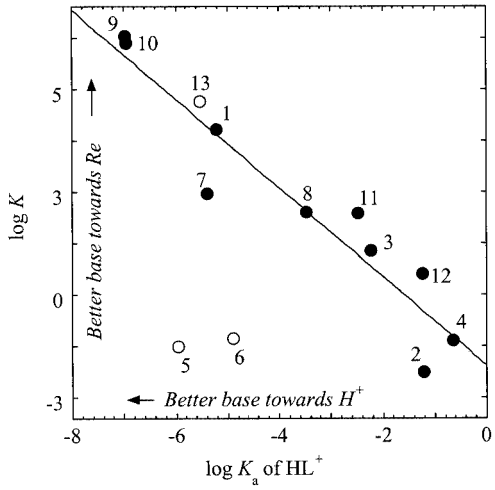

Figure 4. Plot showing a correlation between the equilibrium constants for monomerization of $[MeReO(edt)]_2$ by different ligands L in chloroform and the aqueous acid ionization constants of the same ligands, both on logarithmic scales; ligands **5**, **6**, and **13** were omitted from the linear fit

A study from the literature reported that **13** does indeed coordinate less strongly to Cu^{2+} and Zn^{2+} in aqueous solution than do the other members of a series of ligands all of which were imidazoles that lacked a substituent in the 2-position.[6] Aside from **13**, a good correlation between K and K_a exists except for N-heterocycles substituted in the 2-position.

One might raise an objection to the correlation presented in Figure 4, in that the y axis refers to data for a dirhenium species that incorporates two ligands in the equilibrium whereas the x axis refers to a single L. To address this point, we have used K values for two ligands to derive values of K' that refer to this reaction [Equation (10)].

$$MeReO(edt)L + L' = MeReO(edt)L' + L \quad (10)$$

It is immaterial which L one chooses as the constant reference point because other ligands then constitute L′. We have arbitrarily selected MeIm as L. The value of K' for Equation (10) is given by Equation (11).

$$K' = \sqrt{\frac{K(L')}{K(MeIm)}} \quad (11)$$

We then constructed a plot of logK' against log$K$ for proton transfer, as in the reaction $MeImH^+ + L' \rightleftarrows MeIm + HL'^+$. The result is shown in Figure 5. The correlation is fully acceptable, excluding the ligands with steric effects for coordination. The slope of the line in Figure 5, drawn without reference to such ligands is 0.54±0.07. That is, the equilibrium of ligand exchange at the rhenium center is less sensitive to the ligand than is ligand protonation.

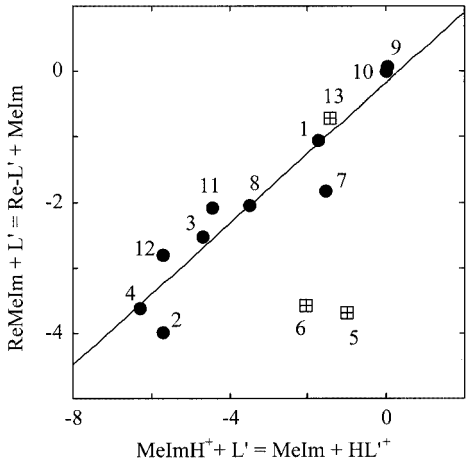

Figure 5. Correlation of the equilibrium constants for exchange of ligands at a rhenium center versus the equilibrium constants for proton exchange, both on logarithmic scales

Linear-Free Energy Correlations of Rate Constants

Two approaches will be explored. First, we ask whether there is a correlation between the equilibrium constants and the rate constants. Figure 6 depicts a plot of K versus k_b, which establishes that a reasonable correlation exists except for ligands **5** and **13**, where steric issues intrude most strongly. We take this to mean that the equilibrium and kinetic processes, both of which establish two new Re−N bonds, are governed by related factors. The same approach for log$K$ versus logk_a is less satisfactory, probably because a single Re−N bond is made in this kinetic step and because the k_a values are less precise, this being the minor kinetic pathway.

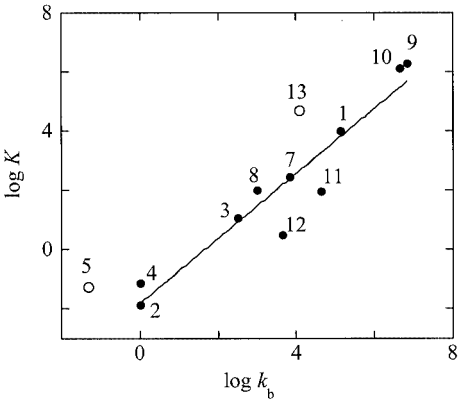

Figure 6. The linear-free energy correlation of equilibrium and kinetic data for the reaction according to Equation (1)

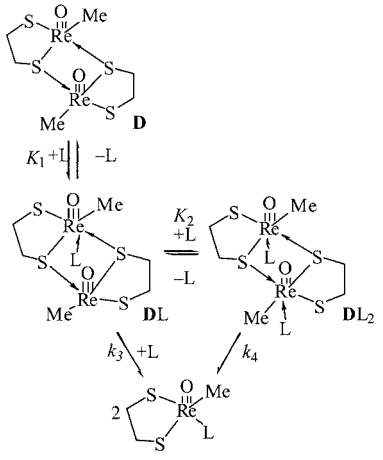
Mechanism

The kinetic data lead us to formulate the reaction steps that are consistent with the kinetic data by the model pre-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sented in Scheme 1. The ligands are shown as attacking the Re^{V} atom at the vacant coordination position trans to the Re≡O multiple bond. This is not generally a site for stable coordination, in that the binding constant for a sixth ligand is small. Indeed, in our studies such metastable transient species never accumulated to a concentration level at which they could be detected. Nonetheless, once one or two nucleophiles attack the Re^{V} atom, then further events rapidly ensue. In particular, either or both of the weaker S→Re coordinate bonds is released as the entering ligand L enters an equatorial position on the monomeric reaction product. This equation follows from Scheme 1 [Equation (12)].

$$-\frac{d[D]}{dt} = \frac{1}{2}\frac{d[ML]}{dt} = \left(\frac{k_3K_1[L] + k_4K_1K_2[L]^2}{1 + K_1[L] + K_1K_2[L]^2}\right)[D] \quad (12)$$



Scheme 1. Kinetic scheme for monomer formation

Equation (7) is a limiting form of Equation (12), when $K_l[L] + K_1K_2[L]^2 << 1$, according to which $k_a = k_3K_1$ and $k_b = k_4K_1K_2$. Further resolution is not possible; the values of the equilibrium constants K_1 and K_2 are too small to allow **D**L and **D**L_2 to attain concentrations that are significant compared to that of **D**. This, of course, is the basis for the inequality given.

In our original study of the monomerization of [MeReO(dithiolate)]$_2$ with a series of phosphane and pyridine ligands,[4] a rate law with linear and quadratic dependencies on [L] was found, just as in Equation (7) [see also Equation (12)]. We formulate the quadratic pathway in terms of an attack of two ligands, one on each rhenium atom. Following that, monomerization occurs as the coordinate S→Re bonds within the dimer are broken. The transition state for this pathway can be drawn as in the right-hand pathway of Scheme 1. On the other hand, our original assignment for the k_a pathway no longer seems credible. We no longer claim that the k_a pathway represents a scheme that generates equal amounts of the product MeReO(edt)L and an intermediate four-coordinate intermediate MeReO(edt). In none of our studies on catalysis or coordination chemistry has such a species been detected. Rather, we postulate that one of the S→Re coordinate bonds in the dimer has been broken, generating a half-opened dirhenium intermediate that reacts subsequently but rapidly with a second L. This idea is formulated in the pathway that is shown on the left-hand side of Scheme 1. The further advantage of the revised proposal is that it maintains a coordination number of five about both oxorhenium(v) atoms, which is the preferred geometry.

Conclusion

Equilibrium constants for reactions in which a series of N-heterocyclic ligands react with a dimeric oxorhenium(v) complex, leading to its monomerization, have been evaluated. Rate constants for the same reactions have been determined. The values of *K* and *k* correlate with one another and with the proton basicity of the ligands.

Experimental Section

The compound methyltrioxorhenium ($MeReO_3$ or MTO) was synthesized according to a literature procedure.[16] It was then used to prepare the rhenium complex that is the focus of this study, the dimer [MeReO(edt)]$_2$, which was known from previous research.[17] A new and more efficient synthetic procedure has since been devised.[18] MTO (1.0 mmol) was added to a stirred solution of PPh_3 (1.0 mmol) in toluene (10 mL), containing a catalytic amount of diphenylacetylene. After 5 min, 1,2-ethanedithiol (1.0 mmol) was added. The resulting mixture was stirred at room temperature for 6 h and layered with hexane (20 mL). After 2 d, a brown-black solid deposited, which was collected by washing with hexane. Further material could be obtained by concentrating the mother liquor and recrystallizing the residue from CH_2Cl_2/hexanes.The isolated compound was characterized by comparing its NMR and UV/Vis spectra with those of the previously prepared material, which had also been characterized by X-ray diffraction.[17] Other reagents, including the N-heterocyclic ligands, were purchased from commercial sources (Aldrich, except for pyridine, Fisher Scientific). They were used without further purification. Certain ligands that might have been included in the study were not reactive or were insufficiently soluble (2,5-dimethylpyrrole and 1,2,4-triazolo[1,5-*a*]pyrimidine). Chloroform was used as the solvent in these studies and the data were obtained at 25 °C. Spectrophotometric methods were used throughout. For equilibrium studies of the reaction according to Equation (1) and for the slower kinetics experiments, a Shimadzu Model 3101 instrument was used. Faster reactions were studied by stopped-flow spectrophotometry with an OLIS apparatus equipped with a rapid scanning monochromator. Absorbance-time data were extracted at single wavelengths for further analysis. Reagent-grade chloroform was used as the solvent for these studies. The ethanol stabilizer that accompanies the commercial solvent has no effect. Supporting Information (see footnote on the first page of this article) for this article comprises the derivation of Equation (4) and the list of concentrations used in the evaluation of *K*.

Co-Ligand Involvement in Ground and Excited States of Electron-Rich (Polypyridyl)Pt^{II} Complexes

Axel Klein,*[a] Joris van Slageren,*[b][‡] and Stanislav Záliš[c]

Keywords: Emission / Platinum / N ligands / Photophysics / Optical spectroscopy / Theoretical calculations / DFT / Crystal structure

The electronic absorption and luminescence properties of electron-rich organometallic platinum(II) complexes with aromatic α-diimine ligands [(α-diimine)PtR$_2$] (R = alkyl, alkynyl, Ph or Mes, Mes = 2,4,6-trimethylphenyl) were examined. The crystal and molecular structures of [(bpy)PtMe$_2$], [(tap)PtPh$_2$] and [(tmphen)PtMes$_2$] were determined from single-crystal XRD and discussed in view of intermolecular interactions that influence the emission behaviour. The combination of theoretical calculations (DFT) and spectroscopic techniques (absorption and emission) revealed the character of electronic transitions and excited states. In particular they showed that the co-ligand involvement in the frontier orbitals is small for R = Me, but large in case of R = alkynyl, Ph or Mes. Depending on the chelate ligand and its substitution pattern, the emission efficiencies of the complexes cover a wide range from strong emission in fluid solution at ambient temperature to very weak emission in rigid matrices (glasses) at low temperatures with no emission at ambient temperature. The emission lifetimes, determined at low temperature in solvent glasses, mainly depend on the chelate ligand and not on the co-ligands. The emission quantum yields of the complexes in solution at room temperatures are much larger for R = Mes than for R = Ph or Me. The emission bands for the complexes with unsaturated co-ligands show slight structuring at low temperatures in contrast to the alkyl-substituted ones.

Introduction

Platinum(II) complexes with α-diimine ligands and their photophysical properties have been the subject of much interest in the last three decades.[1−21] Their square-planar geometry provides the possibility to introduce selectively properly designed α-diimine ligands and suitable co-ligands in a coplanar arrangement and thus allows the tailoring of molecules for potential application as photosensitizers or photocatalysts.[16,22−24] The platinum centre itself provides relatively high stability against isomerisation or thermal decomposition. Electronic transitions in such complexes span a broad range depending on both the diimine ligand and the co-ligand(s) (see Scheme 1). Ligand field (LF or d−d) transitions occur as the lowest transition in case where the diimine ligand is a weak acceptor and the co-ligand is a relatively weak σ donor. When choosing the z axis coincident with the main symmetry axis (in C_{2v} symmetry), the highest occupied MOs are $d_{x^2-y^2}$ or d_{z^2}, while d_{yz} is the LUMO (Scheme 1, case A). In this case metal-to-ligand charge transfer (MLCT) transitions lie at higher energies. Examples of this situation are [(bpy)PtX$_2$] (X = Cl, Br, I).[6,8,11,18] If the π and π* orbitals of the diimine ligand are higher and lower in energy than the filled and empty d(Pt) orbitals, respectively, the lowest-energy electronic transitions are of intraligand (π-π*) character (Scheme 1, B). This situation was found for [(bpy)Pt(en)]$^{2+}$,[11] and is caused by the stronger ligand field of the en ligand compared to X. If the diimine ligand is a good π acceptor, its

π* level lies lower than d_{yz} and the lowest-energy transition is the "classical" metal-to-ligand charge transfer (MLCT or d→π*) transition (Scheme 1, C). The same situation is encountered if a weakly π-accepting chelate ligand is combined with co-ligands of medium to high donor strength such as in [(bpym)Pt(CN)$_2$] (bpym = 2,2′-bipyrimidine),[17] [(bpy)Pt(pz)$_2$] (pz = pyrazolates),[6] or [(terpy)Pt(X)]$^+$ (terpy = 2,2′:6′2′′-terpyridine, X = Cl, OH, SCN,[24−26] or alkynyl).[27]

If the co-ligands are no longer innocent, as assumed for the previous cases, but provide high-lying, filled p or π orbitals, the HOMO may have significant to dominating co-ligand contributions, admixed to platinum 5d orbitals, and the resulting lowest transition is assigned to a ligand-to-ligand charge transfer (L′LCT) (Scheme 1, D).[28] Since the HOMO has mixed metal/ligand character, it is also referred to as "mixed metal/ligand-to-ligand" charge transfer (MML′LCT).[7] Examples are the well-known dithiolate complexes such as [(bpy)Pt(mnt)] (mnt = malonitriledithiolate), where the HOMO is mainly formed by the p orbitals of the sulfur ligator atoms.[5,7,29−31] The same situation occurs when the co-ligands are unsaturated hydrocarbons such as phenyl or alkynyl. The π orbitals of the unsaturated system might act as the HOMO (Scheme 1, D). On the other hand back-bonding from Pt to the π* orbitals of the substituents should lower the electron density at the platinum atom with resulting destabilisation of the d orbitals. The situation then approaches case C. So far lowest absorption bands of such compounds containing aryl or alkynyl substituents have been assigned to "classical" MLCT transitions with no contribution from the π orbitals other than (small) π back-bonding.[1,3,27] The MLCT assignment is based on the fact that the absorption maxima increase with increasing energy of the diimine π*-orbital, E_{max} (complex): tmphen > dmphen > phen > bpy > dppz > tap. In the series of an individual diimine ligand the absorption energy increases slightly from methyl to mesityl and markedly from mesityl to phenyl. This parallels the electron donating ability of the substituents, upon which the platinum d orbitals are destabilised, decreasing the energies of the absorption maxima. However, we recently reported on a series of electron rich organoplatinum complexes with diazabutadiene ligands [(R′-DAB)PtR$_2$] (R′-DAB = *N*,*N*′-disubstituted 1,4-diazabutadienes, R′ = aryl or alkyl, R = alkyl, aryl or alkynyl) which were proven to exhibit low-lying L′LCT transitions.[19] It was shown, that the lowest transition gradually changes character from MLCT to L′LCT due to the contribution of the co-ligands to the HOMO. With increasing electron-donating ability of the alkyl co-ligands, the character of the lowest transition gradually obtains partial σ-bond-to-ligand (SBLCT or σ→π*) character with consequent photolability of such complexes. The corresponding aryl and alkynyl complexes have much larger contributions of the co-ligand to the highest filled orbitals and the lowest transitions therefore have mixed MLCT/L′LCT character.

An appropriate choice of diimine chelate ligand and co-ligands should therefore allow predetermination of the characters of the lowest energy transitions and lowest emitting states in such molecules.

This paper reports a combined experimental and theoretical study including absorption and emission spectroscopy together with quantum chemical calculations to determine the character of electronic transitions in a broad series of electron-rich platinum complexes of the type [(N^N)PtR$_2$] with R = alkyl, alkynyl, phenyl or mesityl (2,4,6-trimethylphenyl). The diimine ligands (N^N) range from the very good accepting aliphatic diimine ligands R′-DAB (*N*,*N*′-disubstituted diazabutadienes) to relatively electron-rich ones such as 1,10-phenanthroline (phen) and derivatives. The aim was to ascertain the extent to which the co-ligands contribute to the frontier orbitals and hence to the excited state, and, secondly, if emission spectroscopy can give a clue as to the excited state character.

Results and Discussion

The dimethylplatinum complexes were chosen as a means to render the platinum centre electron-rich without the possibility of π-electron contribution. Phenyl, mesityl and the alkynyl co-ligands C≡CR (R = *t*Bu or Ph) can potentially interact with the diimine ligands via their π systems. A special reason to use mesityl co-ligands comes from the fact that they provide steric shielding of the complexes axial positions and therefore prevent stacking or dimer formation, which simplifies assignment. Earlier, we reported that they emit light much more effectively than their diphenyl or dimethyl analogues,[21] which was recently used by Kane−Maguire and Wright to study energy- and electron-transfer processes in such systems.[2] The diimine ligands which were chosen are depicted in Scheme 2. Complexes of phenanthroline ligands are known to exhibit more long-lived emissions compared to their bpy analogues and the diazabutadienes (DAB), due to their rigidity which leads to decreased vibrational overlap between ground and excited states and concurrent slow nonradiative decay.[32] Introduction of the methyl substituent to phenanthroline increases the electron density in these ligands (4,7-dmphen and tmphen). Substitution on the 2,9-positions gives additionally rise to steric interactions (repulsions) with the bulky mesityl groups and yields the highly distorted complex [(2,9-dmphen)PtMes$_2$]. Its molecular structure, as determined from X-ray crystallography, shows marked deviation from the square-planar environment of the metal atom.[33] The use of the tap ligand [34−38] was motivated by the aim to decrease the electron density by the introduction of two further nitrogen atoms, but at the same time maintain the above described rigidity of a phenanthroline type of ligand. The dppz ligand is known to form emissive transition metal complexes which display different types of lowest excited states depending on the metal fragment (^{3}MLCT or $^3\pi-\pi^*$).[39] Furthermore such complexes can intercalate between DNA base pairs and might be used as DNA sensors.[40−42] The crystal structure of [(dppz)PtMes$_2$] was recently reported and shows π-stacking of pairs of two molecules in the unit cell.[43]

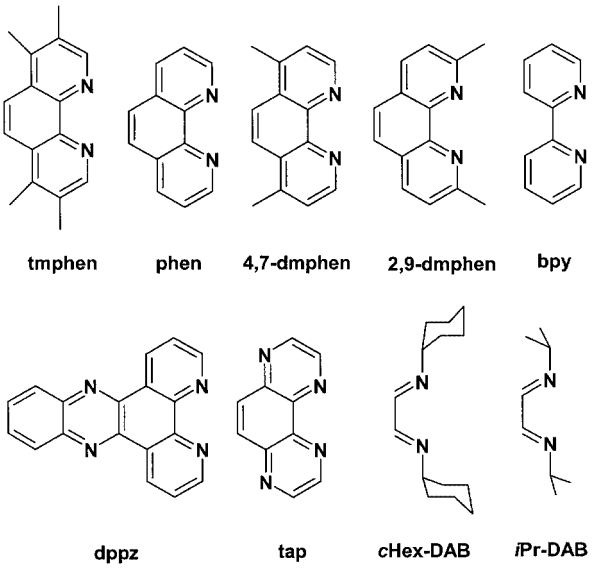

Scheme 2. Representation and nomenclature of the diimine ligands used: tmphen = 3,4,7,8-tetramethyl-1,10-phenanthroline, phen = 1,10-phenanthroline, 4,7-dmphen = 4,7-dimethyl-1,10-phenanthroline, 2,9-dmphen = 2,9-dimethyl-1,10-phenanthroline, bpy = 2,2′-bipyridine, dppz = dipyrido[3,2-*a*:2′,3′-*c*]phenazine, tap = 1,4,7,10-tetrazazaphenanthrene (pyrazino[2,3-*f*]quinoxaline), *c*Hex-DAB = *N*,*N*′-dicyclohexyl-1,4-diazabutadiene (*N*,*N*′-dicyclohexyl-1,2-ethanediimine), *i*Pr-DAB = *N*,*N*′-diisopropyl-1,4-diazabutadiene (*N*,*N*′-diisopropyl-1,2-ethanediimine)

Crystal Structure Determination of [(tmphen)PtMes$_2$], [(tap)PtPh$_2$], and [(bpy)PtMe$_2$]

The molecular structure and intermolecular phenomena such as Pt−Pt interaction or π−π stacking of the aromatic diimine ligands have a strong impact on the emission properties of molecules of the type which is presently under study.[10,12,44] Therefore, the results are discussed of a single-crystal X-ray diffraction study on [(tmphen)PtMes$_2$] (Figure 1), [(tap)PtPh$_2$] (Figure 2) and [(bpy)PtMe$_2$] (Figure 3),

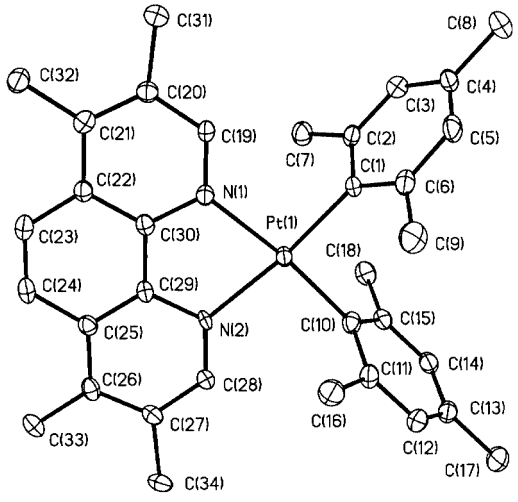

Figure 1. View of [(tmphen)PtMes$_2$] from crystal structure determination (with numbering); the atoms are represented by 50% thermal ellipsoids

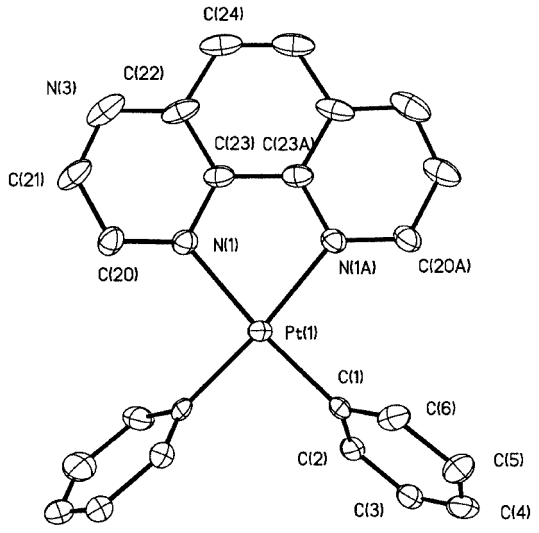

Figure 2. View of [(tap)PtPh$_2$] from crystal structure determination (with numbering); the atoms are represented by 50% thermal ellipsoids

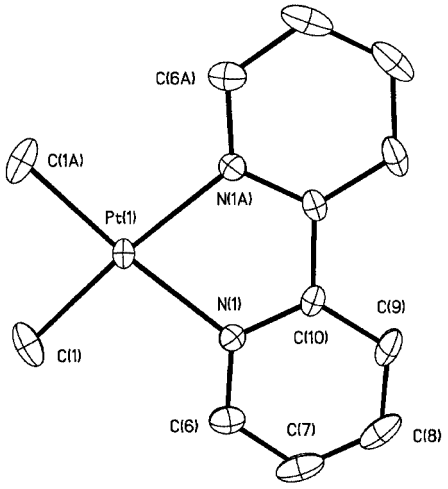

Figure 3. View of [(bpy)PtMe$_2$] from crystal structure determination (with numbering); the atoms are represented by 50% thermal ellipsoids

of which the first two are previously unpublished structures. The structures were solved and refined with the results shown in the Supporting Information (see also the footnote on the first page of this article). Table 1 lists some selected structural parameters of these complexes.

The molecular structures of all three complexes are quite similar. That of the tmphen complex fits into the series of other dimesitylplatinum complexes so far characterized by X-ray diffraction such as [(bpy)PtMes$_2$],[45] or [(phen)PtMes$_2$],[46] and [(dppz)PtMes$_2$].[43] The crystal and molecular structure of [(bpy)PtMe$_2$] (Figure 6) has been reported before,[47] our results being essentially the same but more precise. The chelate "bite" angle in all these compounds lies between 78 and 79° and the Pt−N distances and other structural parameters within the chelate ligands do not vary significantly. The aryl substituents in the mesityl and phenyl complexes show a tilt angle towards the co-

ordination plane of about 68−70°. Similar tilt angles were also found for [(dpp)$PtPh_2$] [dpp = 2,3-bis(2-pyridyl)pyrazine].[13] This means, that the aryl tilt angle is not governed by the steric strain from the methyl substituent. Furthermore in view of the above-mentioned similar structures which exhibit different symmetry, space groups and packing of the molecules it is unlikely that the tilt angle has its origin in crystal packing effects, but is indeed the optimal molecular geometry. Recent calculations showed, that this tilt angle is crucial for the calculated energies and characters of the MOs and hence the electronic transitions in such complexes[19,33,48] The only difference between the mesityl and the phenyl complexes is the shorter Pt−N bond of the phenyl derivative. A similar observation was made for the complex [(2,9-dmphen)$PtPh_2$] in comparison to the mesityl analogue.[33]

Intermolecular interactions are of importance for optical spectroscopy. Therefore we examined the crystal structures of the complexes in that respect. In square-planar platinum(II) complexes, two intermolecular interactions are important, namely π interactions of the aromatic α-diimine ligands and Pt···Pt interactions. The tmphen complex forms dimers in the unit cell, which are π-stacked in a non-graphite-like fashion, with an interplanar distance of 3.52(1) Å (Figure 4). Perhaps due to their methyl substituents the ligands are not ordered back-to-back but offset. For the [(dppz)$PtMes_2$] complex a graphite-like stacking with the formation of dimers was observed with a interplanar distance of 3.427(2) Å,[43] not very different from that of the chloro derivative [(dppz)$PtCl_2$] of about 3.45 Å[49] and

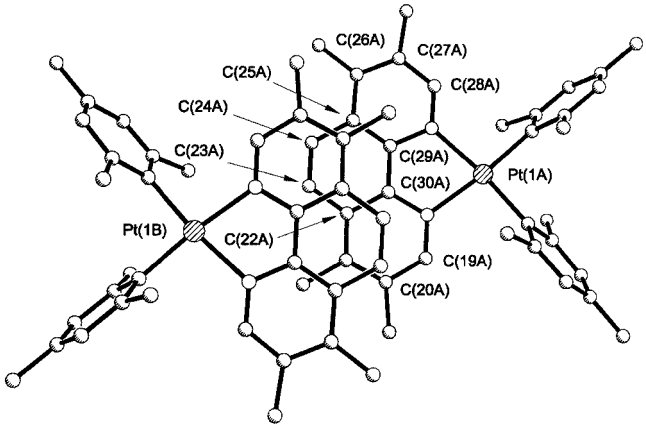

Figure 4. View of two molecules packing in [(tmphen)$PtMes_2$]

graphite (3.354 Å). In [(tap)$PtPh_2$] again a different π-stacking is observed (Figure 5). The ligand planes intersect much more and there is no diagonal offset like for the tmphen complex. Also in contrast to the tmphen complex the molecules form indefinite stacks along the crystallographic *c* axis, with the interplanar distance being only 3.056(2) Å. Although the structure of [(bpy)$PtMe_2$] was published,[47] the crystal packing was not discussed. In fact, the complex exhibits quite a complex stacking behaviour (Figure 6). The distance between the planes of the ligand is 3.45(1) Å. Interestingly, this behaviour does not resemble that of the dichloro complex [(bpy)$PtCl_2$] which occurs either in the red form with strong Pt···Pt interaction (*d* = 3.45 Å) but no π

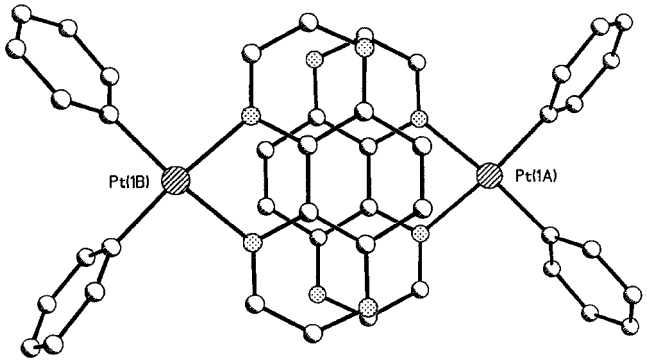

Figure 5. View of two molecules packing in [(tap)$PtPh_2$]

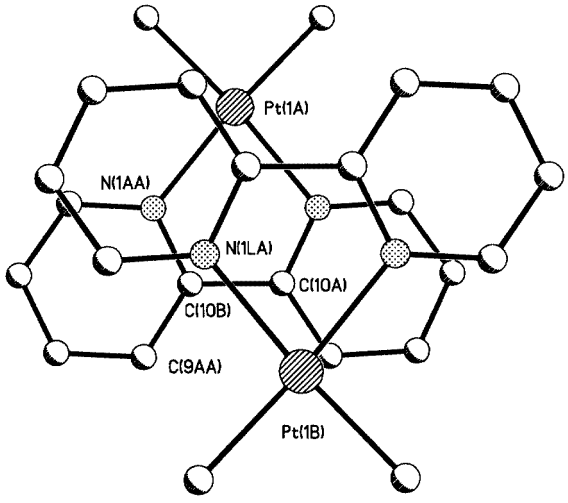

Figure 6. View of two molecules packing in [(bpy)$PtMe_2$]

interaction [50] or the yellow form with longer Pt···Pt distances of 4.5 Å and stacking of each one pyridyl unit.[51] These two polymorph types are also found in a series of (diimine)platinum complexes with Cl, CN, NCS, NCO as substituents.[44]

The Pt···Pt distances vary from complex to complex. In the tmphen complex, it is 9.331(3) Å within the dimer, and the shortest Pt···Pt distance with 6.465(3) Å is found between adjacent stacks. In case of the dppz complex the shortest Pt···Pt distance is 7.784(4) Å. The tap complex, in which the molecules are not diagonally offset like in the tmphen derivative, the Pt···Pt distance within the stacks is slightly shorter at 7.673(2) Å. The shortest Pt···Pt distance is between adjacent stacks [6.465(3) Å]. The Pt···Pt distance in the bpy complex is 5.496(3) Å, longer than the distances in either form of the dichloro complex.

From these data we can conclude that no strong Pt···Pt interactions are present in the molecules in their crystalline form, and the only possible intermolecular interaction is that of π stacking. This type of interaction can cause excimer formation. This will be further discussed in the emission spectroscopy section (see below). The DFT-calculated bond lengths and angles fit the experimentally obtained ones for [(bpy)$PtMes_2$],[45] and [(bpy)$PtMe_2$] well.

Absorption Spectroscopy and Calculations

The complexes [(α-diimine)PtR_2] (R = Me, Ph, or Mes) exhibit broad and partly structured long-wavelength absorption bands (Figure 7).[2,19−21,52] These bands show negative solvatochromism, indicating their charge transfer character (Table 2). The absorption bands of the complexes can be divided into two sets, one in the visible and one in the near UV, which are denoted by CT(1) and CT(2), respectively. For the corresponding R′-DAB (DAB = 1,4-diaza-butadiene) complexes it was shown that the various absorptions within one set are due to the presence of several electronic transition rather than vibronic structuring.[19] CT(1) always consists of several components which are all of moderate to weak intensity. The second band system [CT(2)] is always stronger than the first one and less structured. The energies of the absorption maxima increase with the diimine π*-level energy, and decrease with increasing electron-donating abilities of the co-ligands.

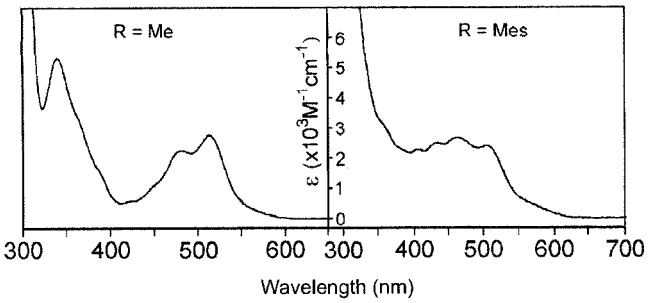

Figure 7. Absorption spectra of [(bpy)$PtMe_2$] (left) and [(bpy)$PtMes_2$] (right) in toluene solution

In order to assign the absorption bands, and in particular to determine the co-ligand contributions to the highest occupied MOs (HOMO), DFT calculations were performed on two complexes, namely [(bpy)$PtMe_2$] and [(bpy)$PtMes_2$]. As expected, the lowest unoccupied MOs (LUMO) are calculated to be almost exclusively located on bpy, even more so than in the case of the corresponding *i*Pr-DAB complexes (Tables 3 and 4).[19] This is due to the lower electron density on the coordinating nitrogen atoms in the case of bpy which limits delocalization of the frontier orbitals. The methyl contribution to the highest occupied MOs is quite limited (Table 3), making them almost purely metal-centred in character.

For the mesityl derivative the calculations yield a markedly changed situation. The HOMO 47a has mixed Pt-5d/mesityl-π orbital character and the following HOMOs are of almost pure π_{Mes} character and only one more or less pure d_{Pt} orbital has remained. Hence, like in the case of the *i*Pr-DAB complexes, also the highest occupied MOs of arylplatinum(II) complexes of aromatic α-diimines have predominant co-ligand character. This is at variance with the metal character which is generally assumed in literature.

The TD-DFT-calculated lowest transitions of [(bpy)$PtMe_2$] can be described as having mainly d_{Pt}-π*(bpy) (MLCT) character in agreement with the "classical" assign-

ment. The calculated energies agree only moderately with the experimentally found ones (Table 5). One reason is the strong solvatochromism of the compounds, as displayed by the shift of the experimental energies going from toluene to pentane as solvent. However, they agree at least qualitatively, showing a number of low energy transitions of weak to moderate intensity which can be found in the range of 420−520 nm in the spectra, and a stronger transition which

[a] Measured in toluene.

can be recognized in the dominant band at about 340 nm in the spectra.

As a consequence of the mixed-metal/co-ligand character of the highest occupied MOs of [(bpy)$PtMes_2$], its electronic transitions have mixed L′LCT/MLCT character, where both contribute in roughly equal measures (Table 6). Interestingly, these are directed towards different π* orbitals of bpy. Again, the transition energies and oscillator strengths show only qualitative agreement with the observed values as above.

Emission Spectroscopy

Most of the assignments of excited states and electronic transitions in (diimine)platinum complexes are based on emission studies,[1,3,6−8,12,18,27] since the collected data, such as emission lifetimes, quantum yields, apparent Stokes shifts etc., allow easy discrimination between ligand-field (LF), intra-ligand (π-π*) and charge-transfer excited states. Here we use emission spectra both at room temperature and in low-temperature solvent glasses to probe for any differences in excited-state properties between the methyl complexes on one side and the aryl derivatives on the other. The room-temperature emission data of the complexes are reported in Table 7. None of the DAB or tap complexes proved to be emissive in fluid solution at room temperature. Furthermore, only two of the methyl complexes (tmphen and dppz) showed luminescence under these conditions. For all other complexes emission was observed as broad unstructured bands, albeit with low quantum yields between 10^{-5} and 10^{-3}. The excitation spectra (Figure 8) show that the observed emission bands are indeed due to the complexes. Comparing the three different types (Me, Mes, and Ph) of complexes it can be seen that the methyl complexes are the poorest emitters, followed by the phenyl complexes, which have quantum yields that are a by factor of 3−5 higher. The mesityl complexes show the highest luminescence efficiency with quantum yields of a factor of 5−10 higher than those of the corresponding methyl complexes. Considering the low quantum yield, the excited-state decay is mainly governed by nonradiative processes, which are apparently more efficient for the methyl complexes than for the aryl ones. Transient absorption and time-resolved emission measurements under these conditions showed that the lifetimes were shorter than our instrument resolution (5 ns). Another interesting observation is that while for both the methyl and mesityl complexes the apparent Stokes shifts are mostly above 6000 cm^{-1}, those of the phenyl complexes are much lower at around 3000 cm^{-1}. Apparently, the phenyl complexes are much less distorted in their excited states than the other ones. Decrease in excited state distortion should lead to slower nonradiative decay by decrease of vibrational overlap. However no increase in quantum yield, which would be the consequence, was observed for the phenyl derivatives.

Apart from these general observations, some interesting peculiarities can be observed. The sterically overcrowded complex [(2,9-dmphen)$PtMes_2$] emits only very weakly at rather high energy with a resulting Stokes shift of 3000

cm^{-1}. Methyl substitution of phenanthroline ligand increases the emission energies and the quantum yields of the mesityl complexes as demonstrated by the series phen < 4,7-dmphen < tmphen, which can be attributed to the energy gap law. The compound [(dppz)$PtPh_2$] exhibits a complex behaviour. In THF solution, at a concentration of 10^{-5} mol/L, two emission maxima were observed at 517 and 760 nm, respectively. After dilution to approx. 10^{-6} mol/L, the 760-nm band disappeared and a weak band was observed at 550 nm with the 517-nm band more or less unchanged. The band at 550 nm seems to be similar to those of the other complexes and we therefore assign the very-long-wavelength emission at 760 nm to excimer emission. The high-energy component at 517 nm might originate from a ligand-centered ($^3\pi$-π^*) state. In toluene solution also an emission at rather low energy is observed with a relatively high quantum yield. No change in emission maximum was observed on dilution. Most probably the excited molecule interacts with toluene molecules. This is in accordance with the observation that dppz complexes readily form dimeric π stacks,[43] and also strongly interact with aromatic solvent molecules such as toluene.[43] Possibly the deviating behaviour of this complex can be traced to its different excited state character (see below).

At low temperature (90 K) in glassy frozen 2-MeTHF, all the examined mesityl- and methylplatinum complexes, upon irradiation into their lowest absorption bands, show broad emissions with lifetimes of mostly some μs (Table 8). They were only very slightly structured. As an example the time-resolved spectra of [(tmphen)$PtPh_2$] are depicted in Figure 9. The Stokes shifts were all in the same range (4000−6000 cm^{-1}). The DAB complexes have the shortest emission lifetimes. This and the highest Stokes shift in the series reflect the high flexibility of the R′-DAB ligand, which allows rapid non-radiative decay. Similar differences have been recently observed for tetramethylplatinum(IV) complexes, where the tmphen derivative exhibited an enormously increased lifetime (9.3 μs) compared to the *c*Hex-DAB analogue (44 ns).[32] The lowest-energy emissions of all other complexes have lifetimes which are all in the same range. Solid-state data for the mesityl complexes of bpy (τ = 0.9 μs), phen (1.8 μs) and tmphen (2.1 μs) have been reported in literature, which compare well with the present numbers.[2] Interestingly, no differences are observed between the methyl complexes on one hand, and the aryl ones on the other. This means that the difference in excited-state character is not reflected in emission lifetimes. For [(dppz)$PtPh_2$] the lowest excited state is clearly of intra-ligand (phenazine) character. This might account for the peculiar behaviour at ambient temperature. In some cases on higher energy excitation longer-lived emission bands are observed at higher energies. These are often quite structured and we assign them to intraligand (IL) emissions. The fact that in some cases the lifetime is not much longer than that of the lowest-energy emission can be explained by the observation that even if the lowest excited state has IL character, its lifetime is of the same order of magnitude. For example, the emission of the yellow form of [(bpy)$PtCl_2$] in the solid state which is assigned to an $^3\pi$-π^* excited state has also a comparably low lifetime of only 3.5 μs compared to the phenanthroline analogue with 13.3 μs (both measured at 10 K).[8] Emission from higher excited states has been observed for other complexes at low temperatures, e.g. in (diimine)tungsten complexes.[53] Apparently, in all these cases radiative decay from a higher excited state is in competition with internal conversion or intersystem crossing to the lowest excited state.

The fact that the low-temperature lifetimes are not affected by the nature of the co-ligand, suggests that the differences in room-temperature emission quantum yield are due

[a] From measurements at 90 K in glassy frozen 2-MeTHF solutions. The most intense component of the absorption or emission spectra is in italics and serves to calculate the Stokes shift. τ is the excited state lifetime as calculated from time-resolved measurements.

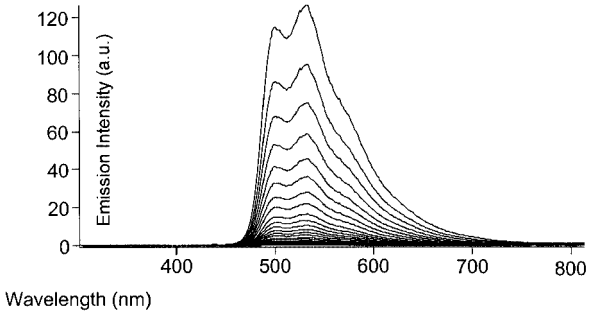

Figure 9. Time-resolved emission spectra of [(tmphen)PtPh$_2$] in MTHF glass at 110 K; λ_{exc} = 440 nm, *P* = 6.9 mJ, time delay between the spectra: 2000 ns

to thermally activated processes rather than traceable to the difference in excited-state character. It has been suggested that the rotation around the *o*-Me group in (α-diimine)mesitylplatinum(II) complexes could be such a thermally excited decay pathway. In the methyl and phenyl complexes clearly additional pathways must be present.

No differences between the methyl and aryl complex lifetimes at low temperature were found to indicate a difference in excited-state character. For example, the MLCT state of [(bpy)PtMe$_2$] has a lifetime of 3.1 μs at low temperatures, while that of the corresponding mesityl complex is slightly shorter at 1.3 μs. However, closer inspection of literature data reveals that in square-planar (α-diimine)platinum(II) complexes, the excited-state lifetime depends only weakly on the excited-state character. The excited states of [(3,3′-(CH$_3$OCO)$_2$bpy)PtCl$_2$] (τ = 1.1 μs),[8] and [(dmbpy)Pt(pz)$_2$] (dmbpy = 4,4′-dimethyl-2,2′-bipyridine; pz = dimethyl- or tetramethylpyrazole; τ = 1.8 or 0.4 μs, respectively)[6] were assumed to have MLCT character. However, the observed twist angle of 64(3)° of the pyrazolate groups relative to the binding plane in the above-mentioned complexes,[54] suggests that the π system of these pyrazolates may contribute significantly to the highest MOs. Alkynylplatinum(II) complexes have similar lifetimes, e.g. [(tmbpy)Pt(C≡C*p*Tol)$_2$] (τ = 1.3 μs, tmbpy = 4,4′,5,5′-tetramethyl-2,2′-bipyridine).[1] There is a number of indications that the alkynyl moiety is significantly involved in the excited state. Thus, DFT calculations on [(*i*Pr-DAB)Pt(C≡CH)$_2$] show over 60% participation of the alkynyl groups in the highest MOs. In addition, the excited state IR spectra of [(R′-bpy)Pt(C≡CR)$_2$] (R = Aryl, R′-bpy = alkyl-substituted bpy) shows a clear upward shift of the ν(C≡C) frequency of about 25−35 cm^{-1} compared to the ground states.[1] And finally, it was remarked that the photophysical behaviour of [(4,4′-*t*Bubpy)Pt(C≡CNMe)$_2$] "does not fit with the model of a lowest ^{3}MLCT excited state".[1] Other complexes which have excited states that are clearly different from purely MLCT, such as the (α-diimine)platinum(II) dithiolate complexes, which have ^{3}MML′LCT (^{3}L′LCT) lowest-excited

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

states, also have comparable emission lifetimes.[5] Finally, the IL emission of the above-mentioned yellow form of [(bpy)$PtCl_2$] has again a similar emission lifetime, namely 3.5 μs.

The only difference between the MLCT emissions of the methyl complexes and the L′LCT/MLCT emissions of the aryl complexes is the partial structuring of the emission bands of the latter complexes. This is rather unusual for ^{3}MLCT emissions of (diimine)platinum complexes.[3,5,8,18] Such structuring was also observed for the before-mentioned complexes [(dmbpy)$Pt(pz)_2$],[6] or [(tmbpy)Pt-(C≡CTol)$_2$],[1] which most probably have similar mixed L′LCT/MLCT excited states.

Conclusions

The DFT calculations showed that the lowest excited states of the methyl-substituted (α-diimine)platinum(II) complexes have virtually pure MLCT character. In contrast those of the corresponding phenyl and mesityl complexes were revealed to have mixed L′LCT/MLCT character. This is supported by the molecular structures from single-crystal XRD which show an optimum tilt angle for the aryl groups for effective ligand(aryl)-to-ligand(diimine) interaction. From the emission data, there were two differences in excited-state behaviour between these two types of complexes. Firstly, the room-temperature quantum yields are up to 10 times larger for the mesityl complexes, compared to the methyl derivatives. Secondly, a slight structuring of the emission bands was visible for the aryl derivatives, which could not be found for the methyl derivatives. The low-temperature emission lifetimes, however, do not depend on the nature of the co-ligand. It must therefore be concluded that emission spectroscopy is not a very sensitive tool to determine the excited-state character in (α-diimine)platinum(II) complexes. Techniques such as time-resolved IR spectroscopy are more promising in that respect. Furthermore, we have found from the combination of single-crystal XRD and concentration-dependent emission behaviour that for these electron-rich (diimine)platinum(II) complexes with alkyl, aryl or alkynyl ligand intermolecular Pt···Pt interactions do not occur and intermolecular π-stacking does only play a very minor role in sharp contrast to corresponding complexes with halide or pseudohalide ligands.

Experimental Section

Preparations: All preparations and manipulations were carried out under argon or nitrogen. The synthesis of the complexes [(*i*Pr-DAB)PtR_2] (R = alkyl, alkynyl or aryl) was recently described.[19] Other dimethyl and dimesityl complexes were prepared from [$(Me_2Pt(\mu\text{-}SMe_2)_2PtMe_2]$,[55] or [$(dmso)_2PtMes_2$],[56] respectively, as recently described for the DAB complexes.[20] The diphenylplatinum complexes were prepared from [(COD)$PtPh_2$],[57] as reported for various diimine ligands.[58] The compounds were thoroughly recrystallised to ensure the absence of impurities. They gave correct elemental analyses and ^{1}H NMR spectroscopy proved their identity and purity (see Supporting Information).

General Procedures for Crystal Structure Analyses: Suitable crystals of the complexes were obtained by slow concentration of saturated toluene solutions. For all three compounds, the data collection was performed at T = 183(2) K with a Siemens P4 diffractometer using Mo-K_α radiation (λ = 0.71073 Å). The absorption correction was done by ψ-scans. The structures were solved using the SHELXTL-PLUS package,[59] and refinement was carried out with SHELXL-97 employing full-matrix least-squares methods on F^2.[60] All non-hydrogen atoms were treated anisotropically, and hydrogen atoms were included by using appropriate riding models. Additional details on crystal data and structure refinement of [(tmphen)$PtMes_2$], [(tap)$PtPh_2$] and [(bpy)$PtMe_2$] can be found in the Supporting Information. CCDC-204746 [(bpy)$PtMe_2$], -204747 [(tap)$PtPh_2$], and -204748 [(tmphen)$PtMes_2$] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Instrumentation: ^{1}H NMR spectra for analytical purposes were recorded with a Bruker AC 250 spectrometer. UV/Vis absorption spectra were recorded with Bruins Instruments Omega 10, Hewlett−Packard 8453 Diode Array, or Varian Cary 4E spectrometers. Steady-state emission spectra were recorded with Spex Fluorolog or Spex Fluorolog 3 emission spectrophotometers, equipped with Peltier-cooled Hamamatsu 928 and 636−10 photomultiplier detectors, respectively. The solutions were deaerated by Ar purging for at least 20 min prior to measurement. The quantum yields were determined by comparison to [$(bpy)_3Ru]^{2+}$ in acetonitrile solution (Φ = 0.062),[61] and were found to be generally lower by the factor of 100 or more compared to this standard. Time-resolved emission spectra of samples in 2-MeTHF glasses (90 K) were recorded in an Oxford Instruments cryostat, using Spectra Physics GCR3 Nd:YAG or Coherent Infinity XPO lasers as excitation sources and an OMA detection system described elsewhere.[62] The solutions were prepared under nitrogen and freeze-pump-thaw-degassed three times before measurements.

Theoretical Calculations: The ground-state electronic-structure calculations on complexes [(bpy)PtR_2] (R = Me, Mes) were performed on the base of density functional theory (DFT) methods by using the ADF2000.2,[63,64] and Gaussian 98[65] program packages. The lowest excited states of the closed-shell complexes were calculated by the time-dependent DFT (TD-DFT) method (both ADF and G98 programs). Within the ADF program, Slater-type orbital (STO) basis sets of triple-ζ quality with polarization functions were employed, except for the methyl groups on the Mes ligands, which were described by basis sets of double-ζ quality with polarization functions. The inner shells were represented by frozen-core approximation (1s for C, N and 1s−4d for Pt were kept frozen). The following density functionals were used within ADF: the local density approximation (LDA) with VWN parametrisation of electron gas data or the functional including Becke's gradient correction[66] to the local exchange expression in conjunction with Perdew's gradient correction[67] to the LDA expression (ADF/BP). The scalar relativistic (SR) zero order regular approximation (ZORA) was used within this study.[68] Within Gaussian-98 Dunning's polarized valence double-ζ basis sets [69] were used for C, N and H atoms and quasirelativistic effective core pseudopotentials and corresponding optimized set of basis functions[70] for Pt. The hybrid Becke's three-parameter functional with the Lee, Yang and Parr correlation func-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tional (B3LYP) [71] was used in Gaussian 98 calculations (G98/B3LYP). Gaussian 98 was used for the calculations of the vibrations at G98/B3LYP optimised geometries. The calculations on [(bpy)$PtMe_2$] and [(bpy)$PtMes_2$] were performed in C_{2v} or C_2 constrained symmetries, respectively. The z axis was taken coincident with C_2 symmetry axis, while the platinum atom and bpy ligand lie in the yz plane. All results discussed correspond to optimised geometries.

Acknowledgments

This work was carried out in the framework of the COST D14 action. A. K. would like to thank Prof. D. J. Stufkens (University of Amsterdam) for the opportunity to do research in his group and also for fruitful discussions and Prof. W. Kaim is acknowledged for financial support. We are also grateful for a loan of K_2PtCl_4 by Johnson Matthey (JM). S. Z. thanks the Ministry of Education of the Czech Republic (OC.D14.20) for the financial support.

Synthesis of [RuX(CO){η²-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-NO_2}$(PPh_3)_2$] (X = F, Cl, Br, I): Evidence of Non-Conventional Ru−X Hydrogen Bonds Leading to Octahedral Coordination at the Halide Atom

Kevin R. Flower,*[a] Robin G. Pritchard,[a] and John E. Warren[a]

Keywords: Ruthenium / Cyclometallated ligands / Charge transfer / Hydrogen bonds / Pi interactions

Treatment of [RuCl(CO){η²-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-NO_2}$(PPh_3)_2$] (**4-Cl**) with Ag[BF_4] in acetone/CH_2Cl_2 gives the cationic complex [Ru{O=$C(CH_3)_2$}(CO){η²-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-NO_2}$(PPh_3)_2$][BF_4] (not isolated), which then reacts with NaX (X = F, Br, I) to afford the new compounds [RuX(CO){η²-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-NO_2}$(PPh_3)_2$] (X = F, Br, I) (**4-F**, **4-Br**, and **4-I**). All of the new compounds have been characterised by elemental analysis (C, H, and N), ^{1}H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ NMR spectroscopy and IR spectroscopy. The IR data support the hypothesis that the fluoride ligand is the strongest halogen π-donor to the metal centre. In addition, the compounds **4-Br**·1.5$CHCl_3$, **4-Cl**·1.5$CHCl_3$, **4-F**·2$CDCl_3$, and **4-I**·1.5$CHCl_3$ have been characterised by single-crystal X-ray diffraction studies; all show Ru–X···$HCCl_3$ interactions with the Ru–F interaction being the strongest. In addition, there is evidence for the presence of competing RuX···$ClCHCl_2$ (X = Cl, Br) interactions in compounds **4-Br** and **4-Cl**; these appear to be charge transfer in nature. The generality of these interactions has been probed using searches of the Cambridge Crystallographic Database and the data obtained suggests that these interactions have some, but limited, precedence.

Introduction

There was an initial reluctance to accept the possibility of the hydrogen bond, from its first mention in 1902,[1] based upon the chemical dogma that hydrogen has a valence of one.[2] The hydrogen bond first reached the mainstream in Pauling's book *The Nature of the Chemical Bond*[3] in which the electrostatic nature of the interaction was emphasised. In 1960 Pimentel and McClellan modified the definition of a hydrogen bond to: "A hydrogen bond is said to exist when (1) there is evidence of a bond, and (2) there is evidence that this bond sterically involves a hydrogen atom involved in a bond to another atom."[4] Conventionally, hydrogen bonds involved hydrogen atom interactions with electronegative elements and donor groups such as N−H, O−H, halogen−H, with conventional acceptors based upon the same atoms in different hybridisation states.[5] Non-conventional interactions recognise the potential of, for example, C−H, P−H, M−H systems, to act as donors and π-systems (aryl, acetylenic) and C−F, for example, to act as acceptors. These and other secondary intermolecular interactions that influence solid-state structures are currently of much interest, with hydrogen bonding of particular note, due to its importance in biological systems,[6] non-covalent synthesis,[7] crystal engineering,[8] catalysis,[9,10] and anion recognition,[11] to name but a few. A recent review of hydrogen bonding in the solid state has also recently appeared.[12] In addition to the hydrogen bond it has been recognised[13] that the halogens, Cl, Br, and I, may also interact with electronegative atoms via weak secondary interactions. The nature of these interactions has been subject to much debate. It has been shown that covalently bound halogen atoms do not occupy spherical volumes in space but are ellipsoidal due to the anisotropic distribution of electron density about their nucleus.[14,15] This leads to a non-uniform van der Waals radius that is shorter in the C−X bond direction. This so-called polar flattening has been used to explain why there are close intermolecular halogen···halogen contacts. Allen et al. have shown, however, that intermolecular contacts between the halogen (Cl, Br, and I) and the electronegative (O, N) atoms can exist,[16] and strong intermolecular halogen···halogen interactions have been reported, for example, for chlorine monofluoride.[17]

Based on methodology developed by Roper and Wright[18] we recently reported[19,20] the preparation of some cycloruthenated azobenzene-containing complexes of the type [RuX(CE)(η²-*C*,*N*-$C_6H_4N=NC_6H_5$)$(PPh_3)_2$] (X = Cl, Br, I; E = O, S) and subsequently extended the methodology to the preparation[21] of complexes of the type [RuCl(CO){η²-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-R}$(PPh_3)_2$] (**1-Cl**, **2-Cl**, **3-Cl**, **4-Cl**; R = NMe_2, Me, I, NO_2) which contain cycloruthenated 2-(phenylimino)phenyl ligands (Figure 1). The structural and spectroscopic characteristics of these

[a] Spectra recorded in $CDCl_3$ at 298 K; all resonances singlets unless otherwise stated; all $J = J_{PC}$ [Hz] except: [b] $J = J_{FC}$ [Hz].

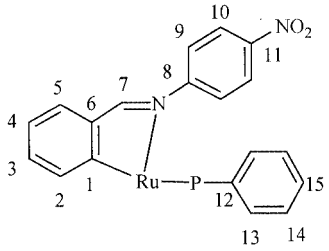

Figure 2. Numbering scheme for $^{13}C\{^1H\}$ NMR spectroscopic data

compounds afforded evidence for a *cis*-push-pull effect between the halide ligand and the CO ligand, which is moderated by the cyclometallated ligand. This effect was clearly shown by comparison of the solid-state structures (X-ray) and $^{13}C\{^1H\}$ NMR spectroscopic data obtained for **1-Cl**, **2-Cl**, **3-Cl**, and **4-Cl** with that obtained from previous studies concerned with the tautomeric process undergone by *ortho*-(hydroxy)azobenzene and [*ortho*-(hydroxy)phenylimino]-phenyl Schiff bases[22−24]. The effect was shown to be dependent on the *para* substituent of the phenylimino ring. We were then interested to see if the magnitude of the effect could be moderated by the π-donor strength of the halogen ligand. Herein we report that chloride/halogen exchange in **4-Cl** is readily facilitated by treatment with Ag^+ followed by the reaction with NaX (X = F, Br, I) and that the spectroscopic evidence shows that the fluoride ligand is the strongest π-donor. Furthermore, the solid-state structures

of **4-Br**, **4-Cl**, **4-F**, and **4-I** display some interesting weak secondary interactions; in particular, the presence of Ru−X···$HCCl_3$ (X = F, Cl, Br, I) and Ru−X···$ClCCl_2H$ (X = Cl, Br) contacts, as well as hydrogen bonds to both the triphenylphosphane and cyclometallated ligands leading to essentially octahedrally coordinated halogen atoms.

Results and Discussion

The compounds [RuX(CO){η^2-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-NO_2}$(PPh_3)_2$] (X = Br, F, I) (**4-Br**, **4-F**, **4-I**) were prepared, in essentially quantitative yield, according to the method illustrated in Scheme 1; i.e. treatment of **4-Cl** with a stoichiometric amount of Ag[BF_4] followed by, after filtration to remove AgCl, addition of a slight excess of NaX (X = F, Br, I).

The new compounds **4-Br**, **4-F**, and **4-I** were all characterised by elemental analysis (C, H, N) and IR spectroscopy (Table 1), ^1H and $^{31}P\{^1H\}$ NMR spectroscopy (Table 2), and $^{13}C\{^1H\}$ NMR spectroscopy (Table 3, see Figure 2 for the numbering scheme).

Compounds **4-Cl**, **4-Br**, **4-F**, **4-I** have also been characterised by single-crystal X-ray diffraction studies, see Table 4 for data collection and processing parameters, Table 5 for

selected bond lengths [Å], angles [°], Table 6 for hydrogen-bond data, Table 7 for halogen···halogen interaction data and Table 8 for selected torsion angles. ORTEP[25] representations of the molecular structures of **4-Br**, **4-Cl**, **4-F**, **4-I** are presented as Figures 3−6, respectively (all the structures have the same numbering scheme, which is fully illustrated for **4-F**). For **4-Cl** and **4-Br** there are two representations as one chloroform solvate interacts with the Ru−X bond in two different ways. The chloroform molecules and hydrogen atoms not involved in hydrogen bonding have been omitted for clarity. All of the structures are best considered as octahedral about a central ruthenium atom with two PPh_3 ligands mutually *trans* and axial with the *ortho*-metallated imine, carbonyl and halide ligands in the equatorial plane. For a more detailed discussion see later.

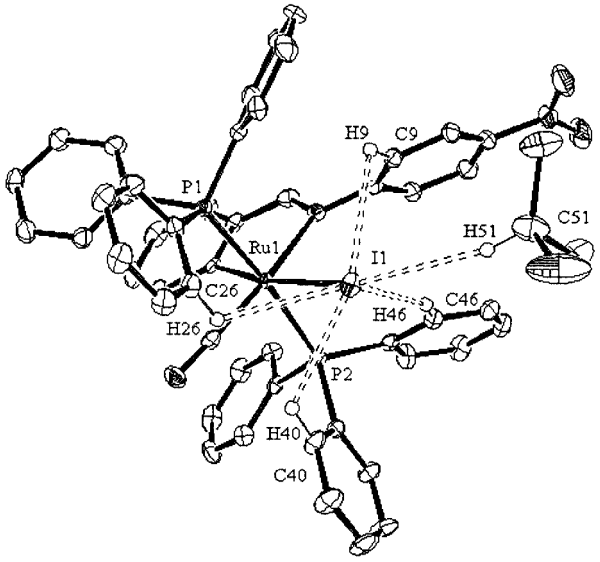

Figure 6. ORTEP representation of **4-I** showing non-conventional interactions at the iodide ligand; thermal ellipsoids at 50%

The IR spectra (Table 1) for **4-Cl**, **4-Br**, **4-F**, **4-I** all show a single strong ν(CO) band between 1923 (**4-F**) and 1940 cm^{-1} (**4-I**). In a previous report[21] describing the synthesis of [RuCl(CO){η^2-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-R}$(PPh_3)_2$] (R = NMe_2, Me, I, NO_2) **1-Cl**, **2-Cl**, **3-Cl**, **4-Cl** we were able to correlate the metallated carbon $^{13}C\{^1H\}$ resonance with the Hammet σ^+ parameter[26] which confirmed that the remote *para* substituent influences the *cis* push-pull effect (Figure 1); however, the trend in ν(CO) stretching frequencies was consistent with the $^{13}C\{^1H\}$ NMR spectroscopic data, but not conclusive due to the narrow frequency separation across the series of 6 cm^{-1}. For compounds **4-Cl**, **4-Br**, **4-F**, **4-I**, where the expected π-donor strength of the halide follows the trend F > Cl > Br > I with a constant *para* substituent (NO_2), the ν(CO) decreases across the series I > Br > Cl > F. This observation is consistent with the fluoride ligand being the strongest π-donor, Table 1 (note: the wavenumber separation across the whole series is 17 cm^{-1}). It should also be remembered that the orthogonal halide p-orbital will be involved in *cis*-π-donation to the CO ligand, in this case mediated by a metal d_π-orbital, not the cyclometallated ligand.[27] It must therefore be a combination of both processes that accounts for the differences in the observed ν(CO) values observed for **4-Cl**, **4-Br**, **4-F**, **4-I**. Compelling evidence for this trend in π-donor strength for the halides (F > Cl > Br > I) to transition metal centres has been noted previously.[28]

The compounds **4-Cl**, **4-Br**, **4-I** all show the expected singlet resonance in their $^{31}P\{^1H\}$ NMR spectra Table 1, whereas for **4-F** a doublet is observed with $J_{P,F}$ = 15.3 Hz. The resonance position is barely perturbed on halogen exchange.

The ^1H NMR spectroscopic data are consistent with the formulation of **4-Cl**, **4-Br**, **4-F**, **4-I**. All the compounds show a triplet resonance for the imine CH proton (coupling to the mutually *trans*-phosphane ligands). The presence of solvents of crystallisation is often seen in the ^1H NMR spectra due to the propensity of these compounds to entrain solvent in the crystal lattice. For example, recrystallisation[21] of **4-Cl** from CH_2Cl_2 and EtOH afforded **4-Cl**·$1.5CH_2Cl_2$, indeed the rapidity of recrystallisation process can affect the amount of solvent incorporated and microanalytical data need to be correlated with the NMR spectroscopic data. This is equally true for compounds **1-Cl**, **2-Cl** and **3-Cl**.[21]

The $^{13}C\{^1H\}$ NMR spectra were assigned with the aid of DEPT-135 spectra substituent effects[29] and the data previously reported[21] for **1-Cl**, **2-Cl**, **3-Cl**, **4-Cl**, and are consistent with the formulation of **4-Br**, **4-Cl**, **4-F**, **4-I**.

The Solid-State Structures of 4-Br, 4-Cl, 4F, 4-I

The presence of conventional N−H or O−H hydrogen bonds to high-valent metal fluoride complexes is well documented,[30] as is the presence of both conventional and non-conventional hydrogen bonds to organometallic complexes containing a fluoride ligand.[31] A search of the CDS[32] revealed only one other example[33] of a chloroform molecule hydrogen-bonding to a transition metal fluoride. In this case, to a fluoro−iron−porphyrin [C−H···F, C−H 0.96(5); H···F 2.11(5); C−H···F 136(4)]. This interaction is considerably longer (17%) than that observed in **4-F** (Table 6). The shorter nature of the hydrogen bond interaction in **4-F** is presumably because the interaction, in this case, is with the radially less diffuse sp lone pair of the fluoride ligand. Work by others[34,35] on M−Cl systems, however, has shown a preference for the p-type lone pair to be more basic and interact with a hydrogen-bond donor (angular preference 100−110°).[35] This type of donor approach is ruled out in this system because of the steric bulk of the ancillary ligand set. Further analysis[36] of the crystallographic data revealed that four non-conventional intramolecular hydrogen bonds from the ancillary ligand phenyl ring hydrogen atoms H(9), H(26), H(40) and H(46) to the fluoride ligand

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complete an essentially octahedral environment about the fluorine atom. In addition to these intramolecular hydrogen bonds the presence of three intermolecular hydrogen bonds was also observed: one to each of the carbonyl and nitro group oxygen atoms (Table 6, Figure 7).

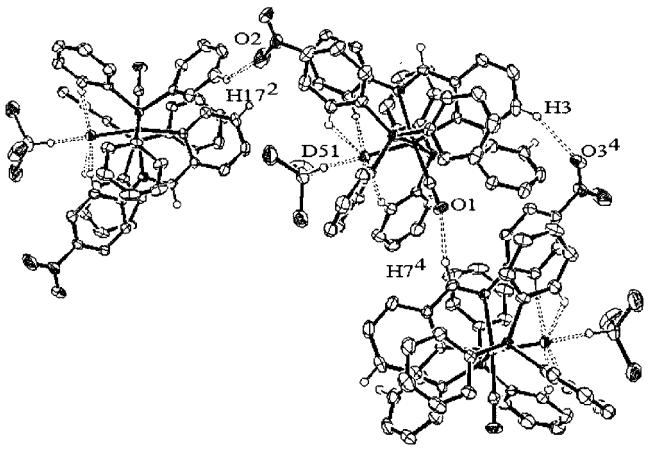

Figure 7. ORTEP representation of **4-F** showing both inter- and intramolecular hydrogen bonds; thermal ellipsoids at 50%

Since perusal of CDS[32] suggested that no complete series of M−X···$HCCl_3$ (X = F, Cl, Br, I) hydrogen bond interactions had been reported to-date **4-Br**, **4-Cl**, **4-I** were recrystallised under conditions identical to those used to obtain the crystals of **4-F**. In each case crystals suitable for an X-ray diffraction study were obtained.

On solving the X-ray data for **4-Br**, **4-Cl**, **4-I** it was found that the three structures are isostructural, but different from **4-F**. The difference is essentially due to the incorporation of 2 mol-equiv. of $CDCl_3$ of crystallisation into the lattice of the latter, compared to 1.5 into the former three. For **4-Br**, **4-Cl**, **4-I** one $CHCl_3$ of crystallisation interacts with the Ru−X bond and a second (half occupancy) is located on a crystallographic inversion site; the latter will not be discussed.

For compound **4-I**, an Ru−I···$HCCl_3$ hydrogen bond is clearly present (Figure 6, Table 6); however, for compounds **4-Br** and **4-Cl** this is not explicitly the case. The $CHCl_3$ solvent molecule located close to the Ru−X (X = Cl, Br) moiety is disordered. When the disorder was modelled for **4-Cl** it was found that there were two principal orientations of the $CHCl_3$ molecule and when this model was used (allowing for variable occupancy) to decipher the disorder observed in **4-Br** it was found that the disorder is identical, save that the relative occupancies of the orientations differ. Thus, in addition to the Ru−X···$HCCl_3$ hydrogen bond illustrated in Figures 3 and 4, an Ru−X···$ClCCl_2H$ (X = Cl, Br) interaction, substantially less than the sum of the van der Waals radii,[37] was found to be present for both compounds (Figures 3 and 4, Table 7). The Ru−X···$ClCCl_2H$ (X = Cl, Br) interaction is present for **4-Cl** 39% and for **4-Br** 76% of the time. Since the same disorder model is applicable to both cases it appears that certain orientations of the $CHCl_3$ molecule are preferred and there must be some explanation for this. The Ru−X···$HCCl_3$ interaction is perfectly understandable; however, the Ru−X···$ClCHCl_2$ is not immediately so. The proposed Ru−X···$ClCCl_2H$ interaction observed for compounds **4-Br** and **4-Cl** is unlikely to be electrostatic in nature since both the Ru−X and $HCCl_3$ chlorine atoms would be expected to carry partial negative charges. The X···ClC interaction in compounds **4-Br** and **4-Cl** [X = Br 169.1(4); X = Cl 171.5(5) °] is "essentially linear" and one possible explanation would be that charge transfer (n → σ*) from the Ru−X moiety to the C−Cl bond could be responsible for these interactions. Since this type of interaction seemed unusual to us a search of the CDS database was carried out to discover if there was any generality to such interactions in the solid state. The initial searches carried out were generic and considered the possibility of any transition metal halide interaction with a chloro-containing hydrocarbon within the sum of the van der Waals radii. The results of these searches were as follows: for the transition metal chlorides 226 hits, metal bromides 32 hits, and transition metal iodides 17 hits. These data are presented as scatter plots, Figures 8−10; there were no metal fluoride interactions. What is striking, however, is the number of hits and the mean of X−Cl−C (X = Cl, Br, I) with angles of 155.1, 163.1 and 164.8°, respectively. It is important to note here that no restrictions were put on the searches, so both inter- and intramolecular contacts are represented in the plots. On further narrowing the search to just interactions between a chloroform molecule chlorine atom and a transition metal bound chlorine atom, 44 (Cl) and 5 (Br) hits, respectively, were obtained. Scatter plots of the data are presented as Figures 11 and 12. For the TM−Cl···$ClCHCl_2$ system the angular range is generally greater than 150°, with one exception KOMFIB, which has an interaction angle of 75°. The Cl···Cl approach is only 3.9% less than the sum of the van der Waals radii and, due to the nonspherical nature of van der Vaals radii, it is unlikely that this is a noteworthy contact and can be ignored.

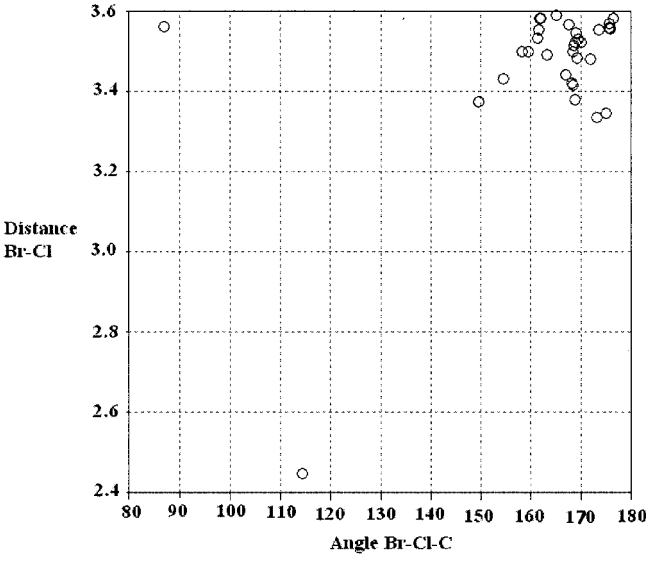

Figure 8. Scatter plot of TMBr···ClCR distance [Å] versus Cl···ClCR angle [°]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

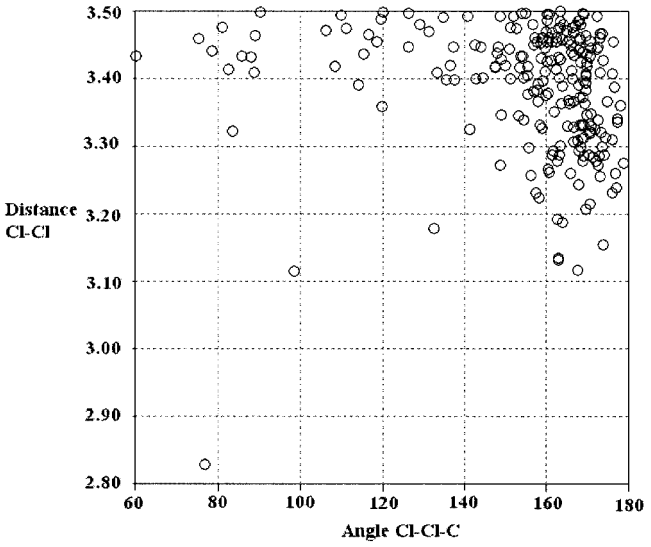

Figure 9. Scatter plot of TMCl···ClCR distance [Å] versus Cl···ClCR angle [°]

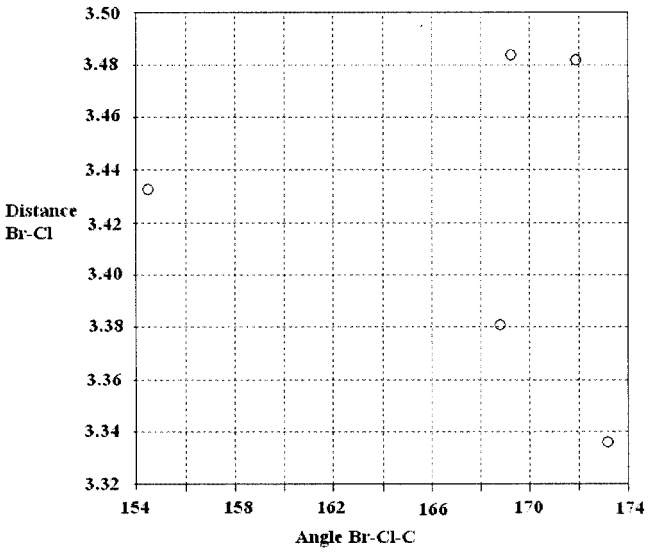

Figure 11. Scatter plot of TMBr···$ClCHCl_2$ distance [Å] versus Cl···ClCR angle [°]

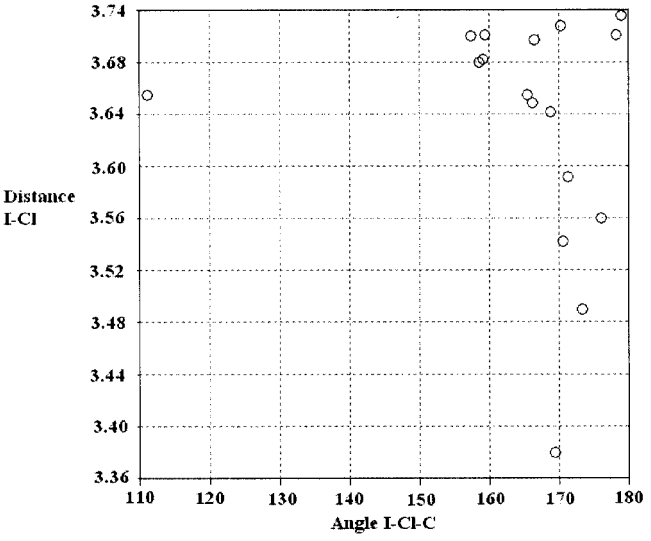

Figure 10. Scatter plot of TMI···ClCR distance [Å] versus Cl···ClCR angle [°]

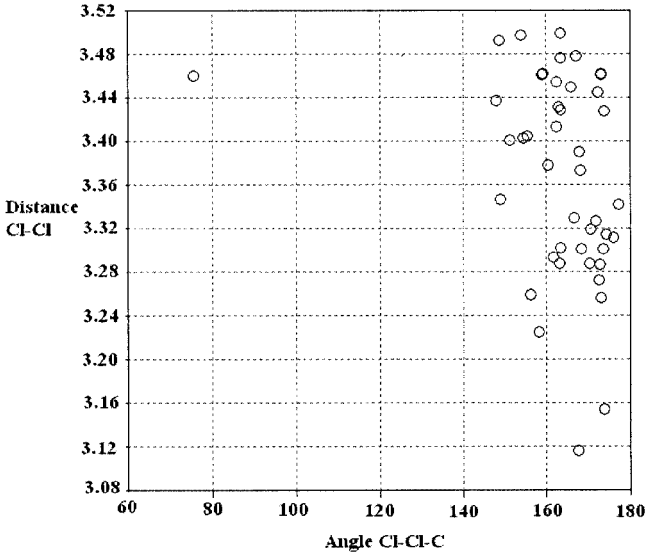

Figure 12. Scatter plot of TMCl···$ClCHCl_2$ distance [Å] versus Cl···ClCR angle [°]

For the TM−Br···$ClCHCl_2$ system the angular range is greater than 154°, with four interactions greater than 169°. These plots show then that the chloroform interaction with the metal halide has mean X−Cl−C (X = Br, Cl) angles of 167.5 and 162.9°, respectively, which are very close to linear. All the points are also comfortably within the sum of the van der Waals radii (3.75 and 3.60 Å),[37] with the Ru−X···$ClCCl_2H$ (X = Br, Cl) interaction observed for **4-Br** and **4-Cl** towards the shorter ends of the observed ranges (Figures 11 and 12). This would suggest that the Ru−X···Cl (X = Cl, Br) interactions observed in this system are real, supported at least by the presence of other comparable interactions present in the CDS, and qualitatively, at least, of comparable strength to the Ru−X···H (X = Br, Cl) interaction. The "linear" nature of these interactions is consistent with the idea that that the interaction is charge-transfer in nature [Ru−X to the C−Cl bond (n → σ*)].

An alternative interpretation could be put forward based upon polar flattening. To invoke this argument a van der Waals radius approximately 0.25 Å less than the accepted value for each atom would be required if the interaction was to fall outside the sum of the van der Waals radii. When considered in conjunction with the following: compounds **4-F** and **4-I** form exclusively hydrogen-bonded interactions with the chloroform solvate; the strength of the hydrogen bond Ru−X···$HCCl_3$ would be expected to follow the trend X = F > Cl > Br > I; the "disorder" is the same, save for relative occupancy, for **4-Br** and **4-Cl** (suggesting a preference for the chloroform's orientation); it tends to make this approach less attractive in this case.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In addition to the electronic effects the increasingly bulky halide ligand exacts steric influences on the surrounding ligands, which manifests itself clearly in the orientation of the phenyl rings bearing the hydrogen atoms H(9), H(26), H(40) and H(46) that are involved in hydrogen bonding to the Ru−X halogen atoms. They all twist as expected to accommodate the increasing volume requirements of the halogen atom, or alternatively twist in to encapsulate the smaller halogen atom. Further, as a result of the increasing Ru−X bond length, not surprisingly, the octahedral coordination nature of the halogen atom becomes increasingly distorted on going from fluoride to iodide.

Conclusion

We have readily effected halogen exchange in the compound [RuCl(CO){η²-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-NO_2}(PPh_3)$_2$] to generate the family of compounds [RuX(CO){η²-*C*,*N*-$C_6H_4C(H)=NC_6H_4$-4-NO_2}(PPh_3)$_2$] (X = F, Cl, Br, I) and shown that the fluoride ligand is the strongest π-donor. Further, on recrystallisation of the compounds **4-Br**, **4-Cl**, **4-F**, **4-I** from chloroform the Ru−X moiety forms a hydrogen bond to the chloroform of crystallisation and it is apparent that the strongest interaction, as expected, is to the fluorine atom. Unexpectedly, a competing Ru−X···$ClCHCl_2$ (X = Cl, Br) interaction has been observed. In conjunction with data from a series CDS searches, this interaction has been shown to have precedence and is possibly charge-transfer in nature. Further, intramolecular hydrogen bonds from phenyl ring hydrogen atoms of the PPh_3 and the cyclometallated imine ligands to the halogen atom were observed in all of the compounds. This leads to essentially octahedral coordination about the halogen atom. The presence of these ancillary ligand phenyl−hydrogen interactions may well have implications for results obtained from theoretical calculations where, for example, the PPh_3 ligand is simplified to PH_3 as in a recent report detailing the mechanism of protonation of the η²-allene ligand in [ReCl(η²-$H_2C=C=CH_2$)(dppe)$_2$] using the model compound [ReCl(η²-$H_2C=C=CH_2$)(PH_3)$_4$]. In this study initial protonation was suggested to occur at the chloride ligand, but took no account of potentially competing hydrogen bond interactions from the dppe phenyl ring hydrogen atoms.[38]

Experimental Section

General Remarks: All solvents, except alcohols, were dried by refluxing in the presence of an appropriate drying agent (toluene, Na; CH_2Cl_2, P_4O_{10}; hexane, NaK) and distilled prior to use. [RuHCl(CO)(PPh_3)$_3$][39] and [RuCl(CO){η²-*C*,*N*-$C_6H_4CH=NC_6H_4$-4-NO_2}(PPh_3)$_2$][21] were prepared according to literature procedures. All other chemicals were obtained from commercial sources and used as received except for $RuCl_3$ which was loaned by Johnson Matthey. Infrared spectra were recorded as nujol mulls between KBr plates with a Nicolet 5PC spectrometer. ^1H NMR (200.2 MHz) and $^{31}P\{^1H\}$ NMR (81.3 MHz) were recorded with a Bruker DPX200 spectrometer and $^{13}C\{^1H\}$ NMR (100.55 MHz) were recorded with a Bruker DPX400 spectrometer. ^1H and $^{13}C\{^1H\}$ NMR spectra were referenced to $CHCl_3$ (δ = 7.26 ppm) and $CHCl_3$ (δ = 77.0 ppm) and $^{31}P\{^1H\}$ NMR spectra were referenced externally to 85% H_3PO_4 (δ = 0.0 ppm). Elemental analyses were performed by the Microanalytical Service, Department of Chemistry, UMIST; solvates of crystallisation were confirmed by repeated elemental analysis and confirmed by ^1H NMR spectroscopy. The syntheses of all complexes were carried out under dinitrogen using standard Schlenk techniques. Workups were generally carried out in the open unless otherwise stated.

[RuF(CO){η²-*C*,*N*-$C_6H_4CH=NC_6H_4$-4-NO_2}(PPh_3)$_2$]·2$CHCl_3$ (4-F): Ag[BF_4] (0.022 g, 0.11 mmol) was added to [RuCl(CO){η²-*C*,*N*-$C_6H_4CH=NC_6H_4$-4-NO_2}(PPh_3)$_2$] (0.1 g, 0.11 mmol), dissolved in CH_2Cl_2/acetone (1:1, 10 mL) under a stream of dry N_2. After 20 min, the solution was filtered to remove AgCl, and NaF (0.05 g, 1.2 mmol), dissolved in H_2O (0.2 mL), was added followed by enough EtOH to generate a homogeneous solution. After 20 min, the organic solvent was removed under reduced pressure precipitating crude **4-F**. Collection by filtration and recrystallisation from $CHCl_3$ afforded **4-F**·2$CHCl_3$ (0.118 g, 96%). Compounds **4-Br**, **4-Cl**, **4-I** were prepared in an analogous fashion; see Table 1 for physical and analytical data.

X-ray Crystallographic Study: All of the crystals were grown by the slow evaporation of chloroform from a 20-mg sample, initially dissolved in 0.5 mL of solvent in a lightly capped 5-mm NMR tube. All measurements were carried out with a Nonius Kappa CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) at 150 K for **4-Br**, **4-Cl**, **4-F** and 120 K for **4-I** at the National Crystallographic Service, University of Southampton, England. The structures were solved by direct methods using SHELXL-97[40] and subjected to full-matrix least-squares refinement on F^2. In **4-Br** and **4-Cl** the $CHCl_3$ which interacts with the halogen ligand is disordered and was modelled using the same geometric restraints and with variable atomic site occupancies. Additionally for **4-Br**, **4-Cl** and **4-I**, the lattice $CHCl_3$ is disordered about a crystallographic inversion point and was also modelled using geometric restraints, but in this case the atomic site occupancies were set to 0.5. In this case the disorder in **4-Br** and **4-Cl** was not the same. The crystallographic details are presented in Table 4. CCDC-172276, -172277, -172278, -1772279 (**4-F** to **4-I**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: S ligands / Nickel / Palladium / Platinum / Density functional calculations / Nonlinear optics

With the aim of preparing new dyes for Q-switching and/or mode-locking Nd-based lasers, such as Nd:YLF and Nd:YAG (emission wavelengths 1053 and 1064 nm, respectively), the syntheses of about 30 new neutral dithiolenemetal complexes belonging to the class [M(R,R′timdt)$_2$] have been carried out [M = Ni (**4a–c**; **4g–j**), Pd (**5a–j**), Pt (**6a–j**); R,R′timdt = monoreduced form of disubstituted imidazolidine-2,4,5-trithione]. The examination of the effects induced on the intense NIR absorption by changing M, R, and R′ has allowed for the recognition of the additive contributions ($\Delta\lambda$) of the central metal ion and of the substituents to the $\lambda_{max}^{M,R,R'}$ position of the NIR absorption maximum, which is in the region of 1000 nm. The high $\Delta\lambda$ values due to aromatic substituents have been elucidated by means of Hybrid-DFT calculations performed on the model compound [Ni(H$_2$timdt)(Ph,H-timdt)]. Both the $\lambda_{max}^{M,R,R'}$ values and the molar extinction coefficients vary with the solvent. Complex **5f** [M = Pd, R = *p*-F-C$_6$H$_4$, R′ = *m*,*m*,*p*-(MeO)$_3$-C$_6$H$_2$] shows that it has been possible to exactly match the emission wavelength of the Nd:YLF and Nd:YAG lasers in chloroform and toluene, respectively (by choosing the appropriate combination of metal ion and substituents). The highest extinction coefficient ever observed for a metal-dithiolene (120000 $M^{-1}\cdot cm^{-1}$ at 1034 nm in toluene) is also reported for complex **6g** [M = Pt, R = *p*-F-C$_6$H$_4$, R′ = naphthyl]. Time-resolved absorption dynamics measurements on **5f** have also been carried out by means of pump-probe experiments, with a picosecond Nd:YAG Q-switched and mode-locked laser.

Introduction

The tuning of specific molecular properties by means of chemical modifications is of current interest in material chemistry and engineering.[1] During the past years, the design of organic chromophores with specific optical properties has been made possible thanks to the discovery of well-defined structure-property relationships (SPRs).[2−4] Nevertheless, the relationships between the structural factors and the nonlinear optical properties of inorganic materials are still not well understood.[1,5] In particular, this applies to the search for materials which can be used in laser applications, such as Q-switching or mode-locking. In order to be exploited as saturable absorbers, dyes have to satisfy several criteria. In particular, (i) the fundamental absorption should exhibit a very high cross-section at the laser emission wavelength, (ii) no excited-state absorption should be present at the same wavelength, and (iii) the molecules should be very stable when exposed to light. Moreover, in order to prevent damage to laser optics, the dyes must be quite soluble in inert solvents. Most materials used in laser applications are based on organic substrates, but these are generally photochemically not as stable as required.

Bis-dithiolene complexes of d^8 metals have been used for Q-switching near-infrared (NIR) lasers since the early 1970s,[6−8] and have also been used as materials for molecular magnets, conductors, and superconductors.[9,10] These complexes exhibit a high degree of π-electron delocalization,[11−13] involving the organic framework as well as the metal center,[14] which confers peculiar and unique molecular properties, such as planarity, optical non-

linearity,[15] high thermal and photochemical stabilities, along with the ability to have a variable charge, which in some cases can vary reversibly from −2 to +2. The possibility of applying dithiolenes to laser technology relies on the unique property that these complexes feature an intense Vis/NIR absorption in the neutral state, due to a singlet[16] $\pi \rightarrow \pi^*$ transition between the HOMO and LUMO,[17] at frequencies which depend on the nature of the substituents at the carbon atoms of the dithiolene moiety.[6] In particular, donor substituents shift the position of this absorption to energies lower[9,17] than those found in the dithiolenes which are derived from the edt ligand {[$M(edt)_2$]; edt = ethylenedithiolato, M = Ni (**1**), λ_{max} = 720 nm; M = Pd (**2**), λ_{max} = 785 nm; M = Pt (**3**), λ_{max} = 680 nm}.[18−20] Obviously, among the various dithiolenes, only a few compounds meet all the requirements. Since 1995,[21] a series of papers has reported on the synthesis, spectroscopic and structural characterization,[22−24] reactivity[25,26] and photophysical properties[27−29] of the new class of dithiolenes [$M(R,R'timdt)_2$] [R,R′timdt = disubstituted monoreduced imidazolidine-2,4,5-trithione; M = Ni (**4**), Pd (**5**), Pt (**6**)]. The most striking property of these dithiolenes is the unusually intense absorption at about 1000 nm, with extinction coefficients in chloroform as high as 80000 $M^{-1}\cdot cm^{-1}$. This absorption is assigned to a $\pi-\pi^*$ singlet transition and has been confirmed by TD-DFT calculations.[27,28] The application of these dithiolenes to Nd-based lasers,[21,27] such as Nd:YLF and Nd:YAG (emission wavelengths 1053 and 1064 nm, respectively), was prevented by their very low solubility. Therefore, it was necessary to look for new substituents, with the aim of both increasing the solubility, and of simultaneously shifting the position of the absorption to values as close as possible to the emission wavelengths of the Nd lasers.

Here we report on the syntheses of almost 30 new dithiolenes belonging to the title class. By referring to the NIR spectral properties of all the dithiolenes synthesized so far, the present work shows that there is an additive effect of the metal ion and of the substituents on the maximum NIR absorption wavelength, and that it is possible to quantify these contributions to the position of the NIR absorption band. In particular, the high contribution by the aromatic groups is elucidated on the basis of DFT calculations. The absorption saturation temporal dynamics of the dithiolene **5f**, which exactly matches the emission wavelength of the Nd:YLF and Nd:YAG lasers in chloroform and toluene, respectively, has been investigated using the picosecond pump-probe technique. The physical processes responsible for the dynamics have been explained using multi-level rate equations,[27,28] supported by relativistic time-dependent density functional calculations.

Results and Discussion

In order to apply [$M(R,R'timdt)_2$] dithiolenes successfully to Q-switch or mode-lock Nd-based lasers, two main goals were to be achieved: a) to significantly increase their solubility in common organic solvents, such as chloroform or dichloromethane; and b) to ensure that the wavelength of the maximum in the NIR absorption is as close as possible to the target laser emission wavelength. The change in the central metal ion and in the substituents R and R′ at the nitrogen atoms enables both objectives to be met. In fact, from the NIR spectra of the first series of synthesized Ni, Pd, and Pt complexes belonging to this class,[24] it could be seen that both the solubility and the position of the NIR absorption depend on the metal ion and on the R and R′ substituents; e.g., aromatic substituents shift the position of the absorption in the desired direction, however, the solubility in low-polar solvents is greatly reduced. With the aim of obtaining a satisfactory solubility, and in order to match the positions of the NIR absorption maxima with the laser emission wavelengths, several new [$M(R,R'timdt)_2$] dithiolenes have been prepared with alkyl and aryl substituents, in particular with the introduction of fluorine atoms or fluorine-rich groups into the phenyl ring.

Synthesis

According to the well-established route summarized in Scheme 1,[24] approximately 30 new Ni-, -Pd-, and Pt-dithiolenes, containing different types of substituents (**4a−c** and **4g−j**, **5a−j**, **6a−j** for Ni, Pd, and Pt, respectively), have been synthesized by the sulfuration of the corresponding disubstituted 2-thioxoimidazolidine-4,5-diones (**7a−j**) with Lawesson's reagent (**8**; 1,3,2,4-dithiadiphosphetane 2,4-disulfide).[30] Unfortunately, with the only exception of **4g**, the syntheses of the Ni complexes that are derived from the 2-thioxoimidazolidine-4,5-diones with a *p*-fluorophenyl substituent (**4d−f**) have not been successful. All the new compounds have been fully characterized by conventional methods, confirming the properties already reported for this class of neutral complexes.[23,24] In particular, the melting points are very high, generally over 250 °C, thus confirming their outstanding thermal stabilities. Among the synthesized dithiolenes, those with phenyl substituents are, in general, not very soluble. However, the solubility increases when naphthyl or *p*-CF_3O-C_6H_4 groups are present.

NIR-Spectroscopy

Effect of M, R, and R′

Considering the new dithiolenes and those previously reported,[24] the typical NIR absorption maximum in $CHCl_3$ ($\lambda_{max}^{M,R,R'}$) spans over 60 nm between 991 (M = Ni; R = R′ = Me) and 1053 nm (**5f**). The molar extinction coefficients in the same solvent are in some cases higher than the previously reported[24] maximum value of 80000 $M^{-1}\cdot cm^{-1}$. For example, among the new most soluble complexes, **6c**, **6g**, and **6h** have values of 91000, 105000, and 110000 $M^{-1}\cdot cm^{-1}$, respectively, which are by far the highest values ever reported for dithiolene complexes.

The qualitative observation that the $\lambda_{max}^{M,R,R'}$ values depend on both the central metal ion and the substituents R and R′ has now been quantified, due to the great number

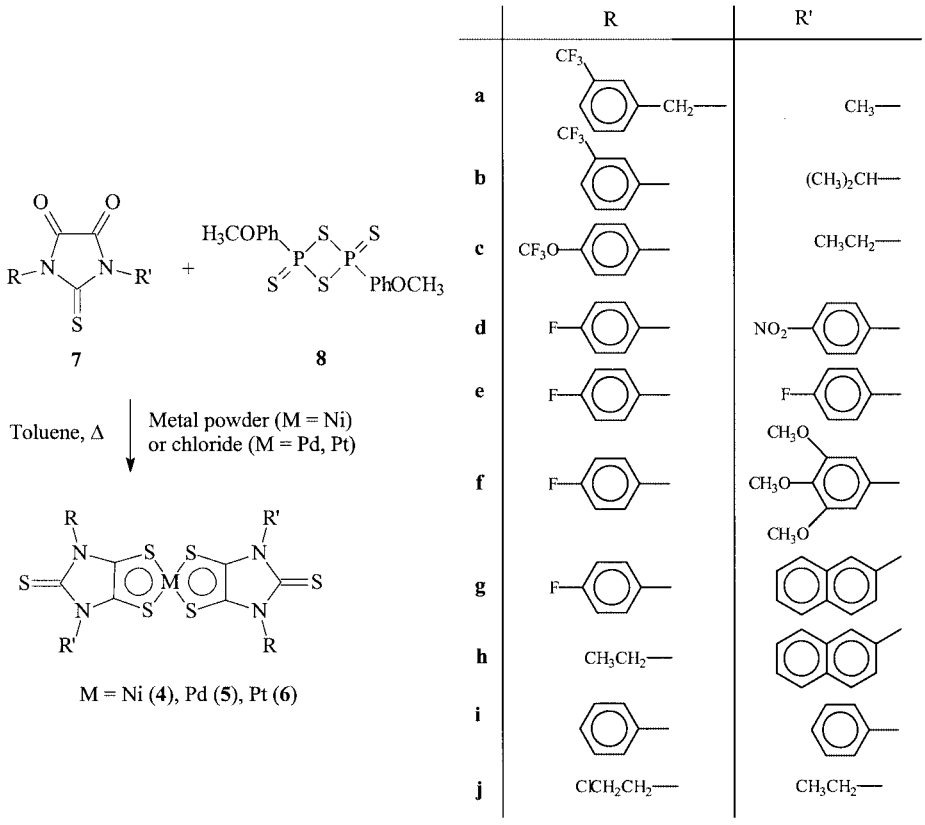

Scheme 1. Overall reaction path in the syntheses of dithiolenes **4**−**6**

(about 60) of synthesized dithiolenes, according to the relationship

$$\lambda_{max}^{M,R,R'} = \lambda_{max}^{Ni,Me,Me} + \Delta\lambda^{M} + \sum_{j=1}^{4}\Delta\lambda_{j}^{R}$$

where $\lambda_{max}^{Ni,Me,Me}$ represents the absorption wavelength recorded for [Ni(Me$_2$timdt)$_2$] ($\lambda_{max}^{Ni,Me,Me}$ = 991 nm), which can be considered the simplest member of this class of compounds. A least-squares fit (R = 0.97) of the experimental values listed in Table 1 has allowed for the evaluation of the contribution of the metal ion ($\Delta\lambda^{M}$) and of each substituent ($\Delta\lambda^{R}$). The goodness of such a regression (Figure 1) can be used to predict the absorption wavelength position of a particular dithiolene with a peculiar metal ion and substituent. As reported in Table 1, the central metal ion Pd confers a remarkable contribution ($\Delta\lambda^{Pd}$ = 20.59 nm) to $\lambda_{max}^{M,R,R'}$, compared with Ni and Pt ($\Delta\lambda^{M}$ = 0.00 and 1.62 nm for M = Ni and Pt, respectively). The bathochromic shift is influenced by the electron-releasing ability of the substituents; thus, for alkyl substituents, the shift increases with the length of the chain ($\Delta\lambda^{R}$ = 1.52, 1.86, 2.93, 3.72 nm for R = Et, *i*Pr, pentyl and nonyl, respectively) in agreement with an increasing $+I$ effect. The bathochromic effect due to the phenyl ring is more effective, and depends on the presence of groups bonded to the phenyl ring [$\Delta\lambda^{R}$ = 7.86, 5.36, 8.86 and 12.95 nm for R = phenyl, *p*-F-C$_6$H$_4$, *p*-Cl-C$_6$H$_4$, and *m*,*m*,*p*-(MeO)$_3$-C$_6$H$_2$, respectively]. Unexpectedly, the extension of π-aromaticity in the ligand (π-aromaticity extends from phenyl to naphthyl substituents) does not significantly increase the $\lambda_{max}^{M,R,R'}$ values ($\Delta\lambda^{R}$ = 7.86, 8.38 nm for R = phenyl, naphthyl, respectively).

Theoretical Calculations

The assignment of the intense low-energy Vis/NIR transition to a singlet π−π* HOMO−LUMO excitation,[16] peculiar to bis-dithiolenes, was also confirmed for [M(R,R′timdt)$_2$], based on Hybrid-DFT[24] and TD-DFT[28] calculations performed on the [M(H$_2$timdt)$_2$] complexes [M = Ni (**4^H**), Pd (**5^H**), Pt(**6^H**)], i.e. on the hypothetical complexes with four hydrogen atoms instead of the four organic substituents. These calculations accounted for the trends found on changing the central metal ion, not only in the [M(R,R′timdt)$_2$] complexes, but also in those derived from the edt ligand.[18−20,24] Since it is very interesting to understand the origin of the remarkable bathochromic shift observed in the presence of aromatic substituents, Hybrid-DFT calculations at the same level of theory as those carried out on **4^H**−**6^H** have now been extended to the mixed-ligand [Ni(H$_2$timdt)(H,Ph-timdt)] model complex (**9**, Figure 2), where a phenyl ring has been introduced as a substituent at the nitrogen atom of the nickel complex. In addition, in order to evaluate the influence of the ring orientation with respect to the molecular plane, the geometry was optimized at different frozen C(9)−N(13)−C(21)−C(22) dihedral angles (θ) correspond-

[a] ΔE = 1.078 eV for **4^H**.

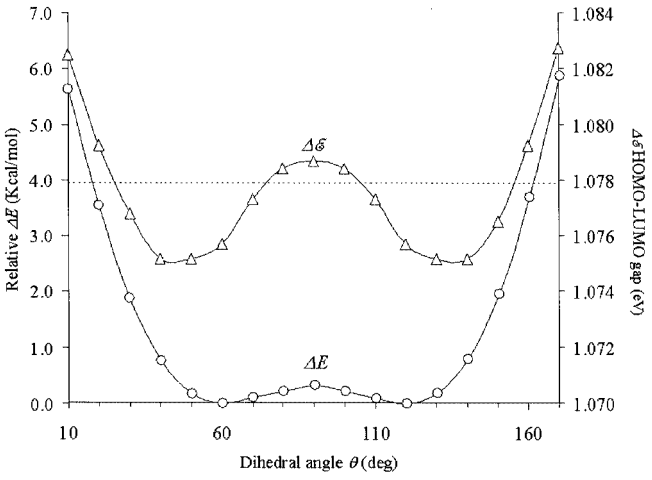

Figure 3. Relative total electronic energy variation Δ*E* (circles) and Kohn−Shan HOMO−LUMO energy gap ΔE (triangles) compared with the ΔE value calculated for **4^H** at the same level of theory (dotted line), calculated for **9** as a function of the phenyl rotation (θ)

difference between the two extremes being about 8 kcal/mol. The rotation around the C(21)−N(13) bond does not affect the nature of the main frontier orbitals. The calculated Kohn−Shan HOMO and LUMO are depicted in Figure 4. The former is a π-orbital extended over the whole molecule, with the contribution of the p_z atomic orbitals of all the atoms, with the exception of the metal center and the carbon atoms of the terminal thioxo groups. All the atoms contribute to the π*-LUMO; the metal ion is directly involved through its nd_{xz} atomic orbitals. In Figure 3, the differences between the HOMO and LUMO energies, ΔE, calculated by varying the dihedral angle θ (Table 2), are also reported and compared with the energy calculated[24] for **4^H** at the same level of theory. The minima in the HOMO−LUMO energy gap are found when the phenyl ring is twisted by about 45° with respect to the dithiolene molecular plane, a value which is close to those calculated for the total electronic energy minima. Therefore, at θ values corresponding to a total electronic energy lower than 1 kcal/mol (40° ≤ θ ≤ 140°), the HOMO−LUMO energy gap in **9** is lower than the gap calculated for **4^H**. This is in agreement with the NIR bathochromic shift measured in the presence of phenyl rings, and in general, of aromatic substituents. Contrary to our expectations, it should be

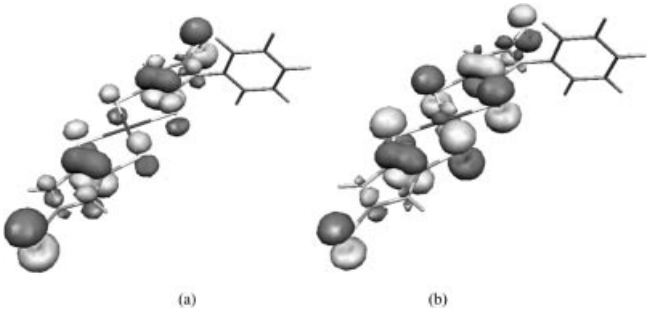

Figure 4. Sketches of Kohn−Shan HOMO (a) and LUMO (b) calculated for **9** at θ = 60° (contour value 0.05)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

noted that such a shift is not directly due to the conjugation between the molecular electronic π-system and that of the phenyl ring, since the minima in the total electronic energy and those in the HOMO−LUMO energy gap, ΔE, are found at 45 and 60°, respectively. This also accounts for the $\Delta\lambda^{R}$ value of the naphthyl group (8.58 nm), which does not differ significantly from that estimated for the phenyl ring (7.86 nm).

Solvatochromic Effect

The UV/Vis/NIR spectra of the [M(R,R′timdt)$_2$] dithiolenes were recorded in solvents of varying polarity, ranging from CCl_4 (dielectric constant $\varepsilon_d = 2.2$) to dimethyl sulfoxide ($\varepsilon_d = 47.2$). As previously observed for different neutral nickel-dithiolenes,[31] both the $\lambda_{max}^{M,R,R'}$ and the molar extinction coefficient values depend on the nature of the solvents. Thus, the solvent is another factor that can be used to modulate the position of the NIR maximum. For solvents having dielectric constants of up to about 35, a continuous decrease in $\lambda_{max}^{M,R,R'}$ is observed on increasing ε_d; for solvents with high ε_d values (nitrobenzene, dimethylformamide, dimethyl sulfoxide: $\varepsilon_d = 35.7, 38.3, 47.2$) the trend is roughly reversed. This does not depend on the nature substituents R and R′, since it has been observed for all dithiolenes, and the change in the solvent does not affect the trend in $\Delta\lambda^{R}$: consequently, the λ_{max} values recorded in different solvents are linearly correlated (see Figure 5 for chloroform and toluene). The values recorded for [Pt(naphthyl,*p*-F-C_6H_4-timdt)$_2$] (**6g**) and [Pt(pentyl,Et-timdt)$_2$] are reported as an example in ref.[32], and in Figure 6 the NIR spectra of **6g** recorded in MeCN, $CHCl_3$, and toluene are superimposed (λ_{max}^{6g} = 1002, 1019 and 1034 in MeCN, $CHCl_3$ and toluene, respectively). As can be seen, the bathochromic shift is accompanied by an increase in the absorption extinction coefficients (90000, 105000 and 120000 $M^{-1}\cdot cm^{-1}$ in MeCN, $CHCl_3$, and toluene, respectively). It is worth noting that one of the proposed goals has been reached, since the NIR absorption maxima of **5f** in chloroform and toluene exactly match the emission wavelengths of the Nd:YLF and Nd:YAG lasers.

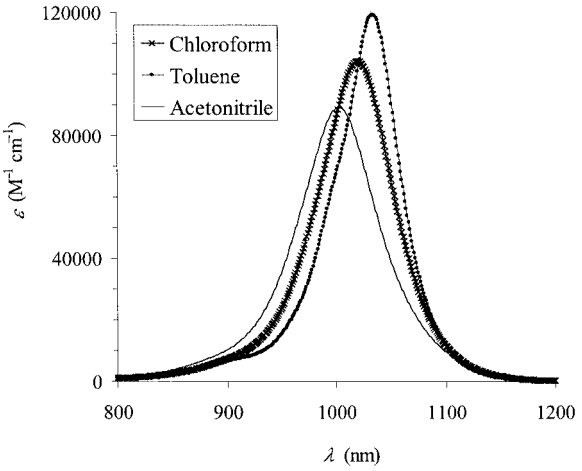

Figure 6. Vis/NIR spectra of **6g** ($c = 1.51 \times 10^{-5}$ M) recorded in acetonitrile, chloroform, and toluene

Photophysical Measurements

The thermal and photochemical stabilities of [Ni(*i*Pr$_2$-timdt)$_2$] had been previously tested in CH_2Cl_2 solution under the action of the FT-Raman spectrometer (0.5 W; 24 h).[22] Since an actual application implies much higher energies, the three dithiolenes **4c**−**6c** were dispersed in polythene pellets and exposed to the action of an Nd:YAG Q-switched mode-locked laser delivering 30-ps (FWHM) pulses at a 10 Hz repetition rate (λ_{em} = 1064 nm) for 9 h (324000 shots, power density 110 MW/cm^2). A comparison of the transmittance before and after the exposure reveals no change. The same test was performed on a commercially available Q-switching dye,[33] which showed a 30% decrease

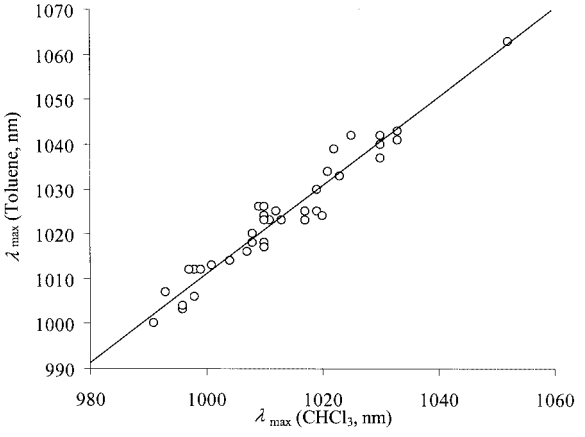

Figure 5. Linear relationship between the λ_{max} values found in chloroform and in toluene for Ni-, Pd-, and Pt-dithiolenes (R = 0.94)

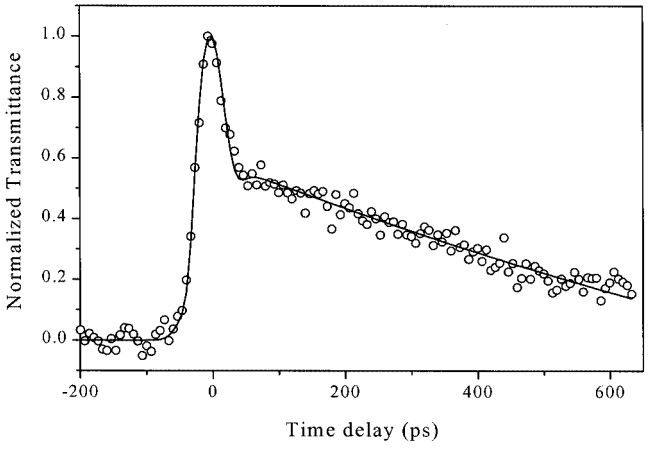

Figure 7. Experimental $\Delta T/T$ (dots) measured as a function of the pump-probe time delay in a chloroform solution of **5f** (λ = 1064 nm); the solid line is the least-squares fit of the experimental data

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in transmittance after exposure for 1 h. The intense absorption of complex **5f** in toluene at the exact emission wavelength of the Nd:YAG laser suggested the investigation of its absorption saturation properties in this spectral region. Unfortunately, the low solubility in this solvent prevented pump-probe measurements, which were therefore performed in chloroform solution. The experimental results are reported in Figure 7. A fast increase in the transient normalized transmittance $\Delta T/T$ is observed, followed by a decay similar to those found[27] in other dithiolenes belonging to the same series. It has been shown that the decay depends on both the central metal ion and the substituents R and R′.[27] Based on TD-DFT calculations performed on the model complexes $\mathbf{4^H}-\mathbf{6^H}$, the six-level model reported in Figure 8 was proposed to account for the absorption dynamics.[27,28] According to this model, excitation from the ground state S_0 to the first dipole-allowed state S_2 occurs, which can decay to S_1. Since the transition to S_0 is dipole-forbidden, decay from S_1 to T_1 occurs through intersystem crossing. In addition, absorption from S_1 and T_1 to higher excited states S_n and T_k, resonant with the $S_0 \rightarrow S_2$ excitation, may be allowed. The numerical solution of the first-order differential equations reported in Figure 8 allows a least-squares fit of the experimental data (solid lines in Figure 7). The measured signal recovery that corresponds to the recovery of the absorption saturation, exhibits two components with different temporal dynamics. The fast decay is almost time-resolution-limited, and has essentially been assigned to the $S_2 \rightarrow S_1$ transition ($\tau_{32} \approx 4$ ps). On the contrary, the slower component decreases with a time constant ($\tau_{25} \approx 122$ ps) that is roughly inversely proportional to the spin-orbit coupling constant for the metal ion, indicating a large contribution of the intersystem crossing process $S_1 \rightarrow T_1$, to dynamics at long time delays. It should be mentioned that the absorption cross-sections for the $S_1 \rightarrow S_n$ and $T_1 \rightarrow T_k$ transitions are proportional to those relating to $S_0 \rightarrow S_2$, through γ_1 and γ_2 (see Figure 8), which have been considered as fitting parameters.

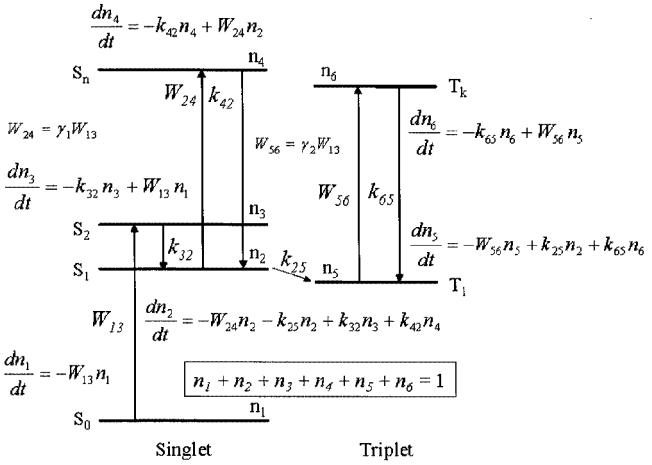

Figure 8. Scheme of the six-level model for the investigated complexes; the equations used as a model for the fitting of the pump-probe experiments are also reported; for **5f**, the main fit parameters are: $\tau_{32} = 4$ ps, $\tau_{25} = 122$ ps; $\gamma_1 = 1.9$; $\gamma_2 = 1.9$

Conclusions

The very high thermal and photochemical stabilities accompanied by the unprecedented intensities in the NIR absorption around 1000 nm show that the [M(R,R′timdt)$_2$] class of neutral dithiolenes is among the most promising classes of molecular materials for NIR laser applications. In addition, this class of complexes shows another interesting advantage compared with other dithiolenes, such as those derived from the dmit ligand, since a never-ending number of compounds can be synthesized by structurally modifying the substituents R and R′. Thus, the change in the central metal ion and the introduction of suitable polar groups in the substituents R and R′, along with the choice of a suitable solvent, allowed us to overcome solubility problems, as well as to modify the position of the NIR absorption maximum. In fact, the additivity of the contributions $\Delta\lambda^M$ and $\Delta\lambda^R$ in determining the $\lambda_{max}^{M,R,R'}$ position, accompanied by the solvatochromic effect depending on the dielectric constant of the solvent, allows for the tuning of the value of $\lambda_{max}^{M,R,R'}$ in a fairly wide range of wavelengths. Among the dithiolenes reported in this paper, compound **5f** [M = Pd, R = *p*-F-C$_6$H$_4$, and R′ = *m*,*m*,*p*-(MeO)$_3$-C$_6$H$_2$] matches the emission wavelengths of the Nd:YLF and Nd:YAG lasers exactly in chloroform and toluene, respectively. Moreover, the influence of the solvent on the molar extinction coefficient has allowed for the measurement of a value of 120000 $M^{-1}\cdot cm^{-1}$ for compound **6g** in toluene, the highest value ever encountered for a dithiolene complex. Through DFT calculations, it had been demonstrated that the metal ion contributes to the Kohn−Shan LUMO through its nd_{xy} atomic orbital (n = 3, 4, 5 for Ni, Pd, Pt), which depends on n. In this study, the DFT calculations have shown that the effect of the substituents arises mainly as a result of the inductive and/or steric factors, and not as a result of the extension of the π-aromaticity of the dithiolene system to the substituents, thus justifying the similar $\Delta\lambda^R$ contributions estimated for the phenyl and naphthyl groups. Finally, the behavior of these complexes as saturable absorbers has been proven, and the picosecond saturation dynamics for compound **5f** has been studied by a pump-probe technique, supporting future applications in the field of Nd-based lasers.

Experimental Section

Procedures and Methods: All solvents and reagents were Aldrich products used as purchased. All operations were carried out under dry nitrogen. The purity of each compound has been checked by CHNS and TLC analyses. Elemental analyses were performed with a FISONS EA-1108 CHNS-O instrument. FT-IR and FT-Raman spectra were collected as previously reported.[23,24] UV/Vis/NIR spectra were recorded using a 1-cm path-length cell, with a Varian Cary 5 spectrophotometer at 20 °C in a thermostatted compartment.

Disubstituted 2-Thioxoimidazolidine-4,5-diones 7a−j: These products were prepared according to literature methods by treating an

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

appropriate *N*,*N*′-dialkylthiourea or *N*-alkyl-*N*′-arylthiourea with oxalyl chloride in a CH_2Cl_2 solution,[23] and were recrystallized from CH_2Cl_2 or diethyl ether.

[Ni(R,R′timdt)$_2$] (4a−j): As previously pointed out,[24] both nickel powder and nickel chloride can be used in these syntheses, although higher yields are generally obtained starting from the metal powder. A general synthesis consists of refluxing the disubstituted 2-thioxoimidazolidine-4,5-dithione **7a−j** (about 5 mmol) with a slight excess (about 10%) of Lawesson's reagent (**8**) in 100 mL of previously degassed toluene for a time varying between 20 min and 1 h, depending on the substituents. After concentration of the reaction mixture, EtOH was added to lower the solubility of the complex and the dithiolene was filtered off. Starting from imidazolidine **7d−f**, the formation of the dithiolene complexes has not been proven. Yields % (mg, starting from 5 mmol of the corresponding 2-thioxoimidazolidine-4,5-dione): **4a**, 14 (255); **4b**, 15 (283); **4c**, 11 (209); **4g**, 8 (165); **4h**, 11 (190); **4i**, 5 (86); **4j**, 20 (282). Nickel-dithiolenes were recrystallized from chloroform/ethanol mixtures.

[Pd(R,R′timdt)$_2$] (5a−j): Compounds **5a−j** were synthesized according to the previously described procedure,[23,24] starting from compounds **7a−g** and using $PdCl_2$. Yields % (mg, starting from 5 mmol of the corresponding 2-thioxoimidazolidine-4,5-dione): **5a**, 42 (814); **5b**, 25 (502); **5c**, 18 (363); **5d**, 17 (381); **5e**, 21 (424); **5f**, 35 (834); **5g**, 22 (480); **5h**, 18 (333); **5i**, 48 (882); **5j**, 20 (306).

[Pt(R,R′timdt)$_2$] (6a−g): The syntheses of **6a−g** were very similar to those for the Pd analogues, starting from $PtCl_2$ instead of $PdCl_2$. Yields % (mg, starting from 5 mmol of the corresponding 2-thioxoimidazolidine-4,5-dione): **6a**, 32 (691); **6b**, 17 (379); **6c**, 24 (538); **6d**, 22 (493); **6e**, 21 (470); **6f**, 38 (990); **6g**, 33 (794); **6h**, 4 (83); **6i**, 66 (1360); **6j**, 65, (1139).

Elemental analyses of all synthesized dithiolenes correspond to the expected values.

Photophysical Measurements: A saturated solution of complex **5f** in chloroform was filtered and placed in a 1-mm quartz optical cell. The temporal dynamics of the saturable absorption was investigated using a picosecond time-resolved pump-probe technique. The ps Nd:YAG laser beam was divided into two parts using a beam splitter to create the pump and probe pulses. The pump beam was focused on a spot ca. 200 μm in diameter, in order to obtain a peak irradiance of about 20 GW/cm^2. The probe beam was focused on a smaller spot (ca. 50 μm) to reduce the effect of excitation spatial inhomogeneity, and its peak irradiance was always kept at about 0.1% of that of the pump. All the experiments were performed at $T = 295$ K. The experimental data were fitted according to a previously outlined procedure.[27]

Computations: Quantum chemical calculations were carried out by using the commercially available suite of programs Gaussian 98 package.[34] Density functional calculations (DFT)[35,36] regarding the model dithiolene **9** were performed using the hybrid Becke3LYP functional (which uses a mixture[37] of Hartree−Fock and DFT exchange, along with DFT correlation, the Lee−Yang−Parr correlation functional,[38] together with Becke's gradient correction[39]). The basis set for all calculations was the Schafer, Horn, and Ahlrichs pVDZ basis[40] for C, H, N, and S, while for Ni, Hay−Wadt LANL2DZ basis sets together with ECP sets[41] were employed. After scanning the potential energy surface by rotating the phenyl ring in dithiolene **9** by 10° between 0 and 180°, single optimization calculations were performed at each rotational step to calculate the orbital compositions and the Kohn−Shan orbital energies. All the results were elaborated with the Molekel 4.2 program.[42] The values of $\Delta\lambda^M$ and $\Delta\lambda^R$ were estimated by an iterative least-squares fit minimizing the squared sum

$$\sum_{i}^{N}\left|\lambda_{max}^{M,R,R'}(i)-\lambda_{max}^{Ni,Me,Me}-\Delta\lambda^{M(i)}-\sum_{j}^{4}\Delta\lambda^{R(i,j)}\right|^2$$

of the differences between experimental $\lambda_{max}^{M,R,R'}$ and estimated values for each of the N synthesized dithiolenes, where $\lambda_{max}^{Ni,Me,Me}$ is the NIR absorption wavelength recorded for [Ni(Me$_2$timdt)$_2$].

Acknowledgments

This project was carried out as part of a MIUR (Ministero dell'Istruzione dell'Università della Ricerca) project. CINECA (Centro Interuniversitario Nord Est Calcolo Automatico) is also acknowledged for computational facilities. We wish to thank Dr. Antonio Masello for the help in the syntheses of compounds **4j−6j**.

Thermodynamics of Complex Formation of Silver(I), Cadmium(II) and Cobalt(II) with Open-Chain Polyamines in Dimethyl Sulfoxide and Molecular Dioxygen Binding to Cobalt(II) Complexes

Clara Comuzzi,*[b] Andrea Melchior,[a] Pierluigi Polese,[a] Roberto Portanova,[a] and Marilena Tolazzi*[a]

Keywords: Amine complexes / Cadmium / Cobalt / Dioxygen / Silver / Thermodynamics

Ag^{I}, Cd^{II} and Co^{II} complex formation with the primary and tertiary tetraamines 1,4,7,10-tetraazadecane (trien) and 1,1,4,7,10,10-hexamethyltriethylenetetraamine (hmtrien) has been studied at 298 K in the aprotic solvent dimethyl sulfoxide (DMSO) and in an ionic medium set to 0.1 mol·dm^{-3} with Et_4NClO_4 under anaerobic conditions. UV/Vis spectrophotometric and calorimetric measurements have been carried out to obtain the thermodynamic parameters for the systems investigated. Mononuclear 1:1 complexes are formed for all systems. In addition, trien also forms the ML_2 mononuclear complex and a polynuclear M_2L_3 species with M = Cd^{2+} and Co^{2+}. All the complexes are enthalpy stabilized, whereas the entropy changes counteract the complex formation. The results are discussed in terms of the different basicities, steric requirements and solvation both of the ligands and of the complexes formed. The influence of *N*-alkylation on the selectivity of the ligands towards metal ions is analysed. In the case of the Co^{II} complexes, their ability to take up dioxygen has also been studied by voltammetric and UV/Vis measurements and gasometric absorption.

Introduction

A comparison of the properties of transition-metal complexes with primary, secondary and tertiary amine ligands reveals several remarkable effects of *N*-alkylation of the ligands on the thermodynamics and kinetics[1−5] of complex formation and on ligand substitution reactions.

In a very recent work[3] it was shown that *N*-alkylation causes several contradictory effects: on one hand, the nitrogen atoms become better σ-donors as a consequence of the introduction of electron-donating substituents, which shifts the redox potential of the $M^{n+1}L_m/M^nL_m$ couples cathodically, while on the other hand, solvation and steric effects shift the potential anodically. As the solvation effects are larger, *N*-alkylation stabilizes low-valent transition metal complexes and the redox potentials of the couples are shifted anodically for L = tertiary amines.[1,3,5,6]

In addition, the stability constants of the complexes with the tertiary amines are smaller than those with primary and secondary amines,[3,5−9] this behaviour mainly being attributed to outer-sphere solvation effects and to ligand strain energy.[5c,5e,5g,5h]

In the last few years, a variety of polyamine structures have been investigated in water[9−18] and in non-aqueous solvents[8,19−25] with the aims both of improving knowledge of the coordination chemistry of soft and hard metal ions and of studying how basicities and steric effects may affect the selectivity pattern in metal coordination.

As examples of the great interest in these ligands and their application it should be remembered that they show potential for use as sequestering agents for metal ions of environmental importance,[18] both toxic and essentials, such as Cd^{II}, Pb^{II}, or Ca^{II}, Mg^{II}, Zn^{II}, Mn^{II}, Fe^{III}, Cu^{II}, and employment as models for carrier molecules,[6,15,18,26−31] such as in Cu^{I} or Co^{II} complexes.

In this context, the papers published by our group concerning the complexation of transition-metal ions such as Ag^{I}, Cd^{II} and Co^{II}[8,22a−22d] have shown that nitrogen functionalization strongly influences not only the stoichiometry and the nature of all the metal ion complexes formed, but also, very interestingly, the selectivity of these ligands towards metal ions.[8c] In fact, while − for example − dien shows a higher affinity for the borderline soft/hard divalent Cd^{II} than for the very soft univalent Ag^{I} ion, the opposite is true with regard to pmdien. As far as cobalt(II) complexes are concerned, different *N*-alkylation of polyamines also has important effects on the dioxygen affinity of these complexes:[6] electron transfer between the metal centre and di-

oxygen should depend on the available electron density at the central metal ion, which is in turn greatly affected by the electron-donor properties of the ligands in the coordination sphere.[26,27]

As an extension of previous works we report here on results concerning the complex formation of Ag^{I}, Cd^{II} and Co^{II} with the differently *N*-methylated polyamines 1,4,7,10-tetraazadecane (trien) and 1,1,4,7,10,10-hexamethyltriethylenetetraamine (hmtrien) in the aprotic solvent dimethyl sulfoxide (DMSO). For silver(I), data relating to trien complexation in DMSO had been published previously.[22d]

Especially interesting comparisons between the monovalent d^{10} acceptor silver(I), of very soft character, and the divalent and mildly soft Cd^{2+} should be possible. In addition, although the complex formation of Cd^{II} has been extensively studied in the past[32–34] and in more recent[7,17,33] years, nevertheless few thermodynamic data concerning its ability to coordinate simple open-chain N-donor ligands are available.[7,8c,34f,35] Moreover, Co^{II} model compounds are of great interest since they may provide a better understanding of biological molecules and assist in the study of new homogeneous catalysts for selective oxidations under mild conditions.[26–31]

The values of the stability constants of the various systems investigated were determined by different techniques. Direct potentiometric techniques were used for Ag^{I} and Cd^{II} (see Exp. Sect., potentiometric measurements), whereas for the Co^{II}/polyamine systems, UV/Vis spectroscopic measurements were employed, with the use of Cd^{II} as auxiliary metal ion[36] for reasons discussed in a previous paper.[8b] The enthalpy values were obtained by direct calorimetric titrations. In the case of the Co^{II} complexes, their ability to take up dioxygen was also studied by voltammetric and UV/Vis measurements and by gasometric absorption. All measurements were performed at 298 K and in an ionic medium adjusted to 0.1 mol·dm^{-3} with Et_4NClO_4 as neutral salt.

Results

Computer treatment of the potentiometric experimental data shows that the best fit is obtained when the polynuclear species M_2L_3 (M = Cd, Co) is considered in addition to ML and ML_2 mononuclear ones for metal(II)/trien systems, whereas the ML species is the only one formed in all other cases. The overall stability constants obtained from the potentiometric data minimization procedures, with the corresponding limits of error, are listed in Table 1 for the reactions $i\ M^{n+} + j\ L \rightleftarrows M_iL_j^{n+}$ (M = Ag^{I}, Cd^{II}, Co^{II}, L = trien and hmtrien). Figure 1 gives the distributions of Cd^{2+} and Co^{2+} among the various species. Figure 2 gives Δh_v, the total molar enthalpy change, as a function of $R_c = c_L/c_M$ (total ligand/total metal concentration) for the Cd^{2+}/trien and Co^{2+}/trien systems.

Some conclusions about the prevalent coordinated species formed can be drawn from examination of the shapes of the curves, which are fully consistent with the information obtained from analysis of the potentiometric data.

Table 1. Overall stability constants and thermodynamic functions for the reaction reactions $i\ M^{n+} + j\ L \rightleftarrows M_iL_j^{n+}$ (M = Ag^{I}, Cd^{II}, Co^{II}, L = trien and hmtrien) in DMSO at 298 K and I = 0.1 mol·dm^{-3} and in water;[7,15] the errors quoted correspond to three standard deviations

The total molar enthalpy changes, Δh_n, as a function of $R_c = c_L/c_M$ for Cd^{II}/trien and Co^{II}/trien systems in DMSO: (a) 5.05 (open circles), 19.91 (filled circles) mmol·dm^{-3} in Cd^{2+}; (b) 5.04 (open squares), 20.01 (filled squares) mmol·dm^{-3} in Co^{2+}; the solid lines have been calculated from the values of β_{ij} and $\Delta H°_{\beta ij}$ in Table 1

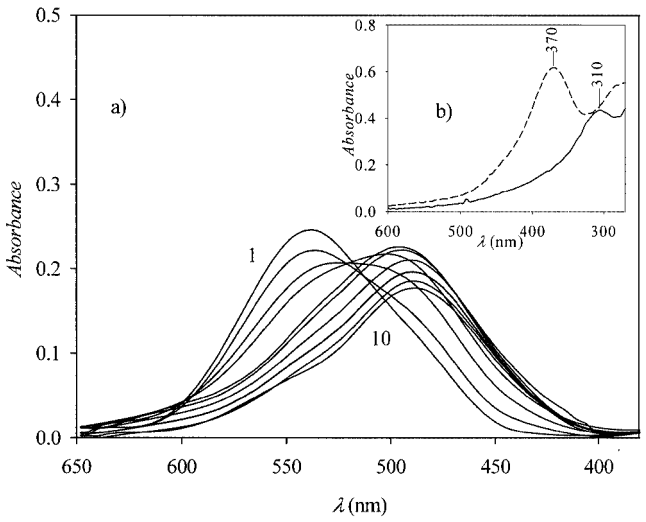

Figure 3. (a) Spectral changes observed during the reaction between Co^{2+} and trien in DMSO: calcd. $c°_{Co}$ = 21.8 mmol·dm^{-3}, $c°_{Cd}$ = 21.6 mmol·dm^{-3} (spectrum 1); $c°_{trien}$ varied from 0 (spectrum 1) to 54.5 (spectrum 10) mmol·dm^{-3}; (b) UV/Vis spectrum of a solution of [Co(trien)$^{2+}$] = 0.2 mmol·dm^{-3} under nitrogen with 4% O_2 after 9 s of exposure and after 30 min of exposure (dotted line); the spectrum remains unchanged after 6−8 h of exposure

stable, ML_2 complex according to the reaction steps in Equations (1) and (2).

$$2\,ML + L \rightleftharpoons M_2L_3 \quad (1)$$

log β = 7.28 and 8.2, $\Delta H°$ = −91 and −101, $T\Delta S°$ = −49.4 and −54.6 kJ·mol^{-1} for M = Cd and Co, respectively

$$M_2L_3 + L \rightleftharpoons 2\,ML_2 \quad (2)$$

log β = 3.1 and 3.2, $\Delta H°$ = −27 and −25, $T\Delta S°$ = −9.4 and −6 kJ·mol^{-1} for M = Cd and Co

No more complexes are formed beyond ML_2. The fit between experimentally determined and calculated curves (full lines in Figure 2) is quite good.

Figure 3 (a) shows the spectral changes observed during reactions between Co^{2+} and trien, in the presence of Cd^{2+} as competitor, in terms of absorbances vs. wavelengths. Figure 3 (b) also shows (inserted) the spectral modification due to dioxygen uptake for the $[Co(trien)]^{2+}$ species. Figure 4 shows log β_{1Cd} plotted as a function of log β_{1Co} to provide a better illustration of the behaviour of the two ions.

The O_2 absorption by the $[Co(trien)]^{2+}$ adduct was measured at constant pressure by use of a standard apparatus containing a thermostatted gas burette in order to determine the stoichiometry of the dioxygenated complex. Figure 5 gives the dioxygen binding curve, $R_{O2} = n_{O_2}/n_{[Co(trien)]^{2+}}$ vs. time.

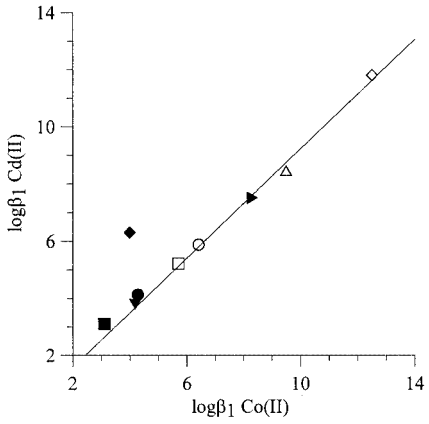

Figure 4. log β_{1Cd} as a function of logβ_{1Co} for ethylenediamine (en; open circle); *N*,*N*′-dimethylenediamine (dmen; open square); *N*,*N*,*N*′-trimethylenediamine (trmen; filled circle); *N*,*N*,*N*′*N*′-tetramethylenediamine (tmen; filled square); diethylenetriamine (dien; open triangle); *N*,*N*′′-dimethyldiethylenetriamine (dmdien; filled triangle); *N*,*N*,*N*′,*N*′′,*N*′′-pentamethyldiethylenetriamine (pmdien; filled triangle next to filled circle); 1,4,7,10-tetraazadecane (trien; open diamond), 1,1,4,7,10,10-hexamethyltriethylenetetraamine (hmtrien; filled diamond)

Discussion

All the complexes are formed in strongly exothermic reactions, whereas the entropy terms oppose the reactions (Table 1). The negative enthalpy and entropy values are typical of reactions involving complexation of metal ions by neutral ligands in aprotic solvents.[3,6,19] Data in water solutions are also available for all the trien systems,[7] whereas analogous data for the Co^{II}/hmtrien system are reported only as estimated values. It should be remembered that Cd^{2+} and Co^{2+} are hexasolvated in both solvents, with the solvent molecules in a regular octahedral arrangement, whereas silver(I) is tetrahedrally solvated both in DMSO and in water.[8b,19]

The complexes are characterized by lower stabilities in water than in DMSO. In addition, they are always more enthalpy-stabilized in DMSO than in water, while in the latter solvent the entropy terms are favourable. It has already been found that this trend is inconsistent with what would be expected on the basis of the thermodynamic parameters of transfer of the metal ions investigated here from water to DMSO,[6,37] and should be associated with greater solvation, through hydrogen bonding, of primary and secondary amines in water than in DMSO.[38] This was also

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

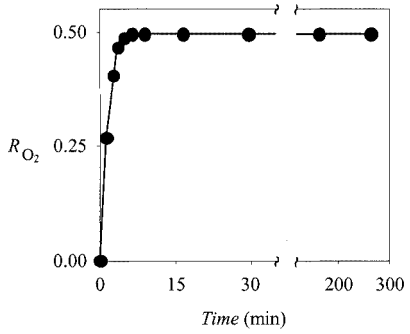

Figure 5. Plot of the ratio R_{O2} = moles O_2/moles complex vs. time measured for a 30 mM solution of $[Co(trien)]^{2+}$ complex in pure oxygen

confirmed by the fact that the opposite has been observed for the complexes with tertiary amines, as these are more stable in water than in DMSO,[6,8b,8c] *N*-methylation inhibiting the formation of hydrogen bonds of the type M−*N*−H···O with the solvent and the higher solvation of the metal ion in DMSO therefore prevailing in governing the trend of the stabilities.

Silver(I)/hmtrien System

A comparison with the thermodynamic functions previously determined for the Ag^{I}/trien system[22d] (also shown in Table 1), in which the ligand was shown to behave as tetradentate ligand, shows that hmtrien is also able to tetracoordinate Ag^{I}, forming three fused five-membered chelate rings.

The drop in $\log\beta_1$, of about two orders of magnitude, on going from primary to tertiary amino groups should be associated with: (i) the different basicities of the amino groups, which decrease in the order $-NH_2 > -NHR > -NR_2$ in DMSO,[38] (ii) steric hindrance, which results in elongation of the metal−nitrogen bonds,[1,3,5c,5e,5g,5h] and (iii) the absence of M−*N*−H···O hydrogen bonds, which are responsible for a decrease in outer-sphere solvation energy, thus increasing the hydrophobic nature of the complexes,[16] and of a decrease in the nitrogen σ-donating properties, which reverses the trend found in the gas phase, in which it has been shown that tertiary amine ligands are better σ-donors.[3] Effects (i) and (ii) in particular are also responsible for the decreased enthalpy gain for hmtrien complexation. Effect (iii) transforms the central cation into a harder acid.[3] As far as point (ii) is concerned, some authors have recently proposed, on the basis of X-ray results and molecular-mechanics calculations (MM), that nonbonded repulsions between the *N*-methyl groups are the primary cause of the observed elongation of the M−N bonds.[5c,5e,5g,5h]

Cd^{II}/Tetraamine Systems

Trien certainly behaves as tetradentate ligand in the CdL complex, as shown by the trend in the thermodynamic functions in relation to those of the $[Cd(dien)]^{2+}$ system [diethylenetriamine (dien), $\log\beta_1 = 8.46$, $\Delta H°_1 = -65.3$, $T\Delta S°_1 = -17$ kJ·mol^{-1} [8c]], in which dien is known to act as terdentate ligand; this was confirmed by independent FT-IR measurements run on a 1:1 Cd/trien solution, in which the bands due to free secondary (at 3313 cm^{-1}) and primary (at 3360 and 3300 cm^{-1}) amino groups were not present.

The huge drop in stability and exothermicity observed on going from trien to hmtrien was similarly observed for other analogous primary and tertiary polyamines; from the thermodynamic values it therefore seems reasonable to suppose that hmtrien also acts as tetradentate ligand, the trend in the data being greatly influenced, as in the case of the silver(I) system, by the different basicities and steric requirements of the ligands.

The Cd^{II} ion is certainly hexacoordinate in the ML_2 complex with trien, according to its tendency to bind polyamines, exhausting all coordinative positions.[8c,39] This is clearly indicated by the values of the thermodynamic functions for the stepwise reaction according to Equation (3), which are of the same order of magnitude as those found for the CdL complex formation with the diamine ethylenediamine (en) ($\log\beta_1 = 5.88$, $\Delta H°_1 = -52.2$, $T\Delta S°_1 = -19$ kJ·mol^{-1} [8c]).

$$CdL + L \rightleftharpoons CdL_2 \quad (3)$$
$$\log K_2 = 5.19,\ \Delta H_{K_2} = -59,\ T\Delta S_{K_2} = -29.4\ \text{kJ·mol}^{-1}$$

The more favourable enthalpy gain (with respect to that of the 1:1 Cd/en system) reported for Equation (3), despite one of the nitrogen atoms of the second entering trien being secondary, is due to the observed fact[8c] that in Cd^{II} − as well as in Co^{II} − complexation with polyamines, the desolvation of the species involved occurs mainly in the first step of complexation.[6,8b,8c] This is also confirmed by the less favourable entropy term.

A real novelty for the Cd^{II} system is the formation of an appreciable amount of a Cd_2L_3 species (Table 1 and Figure 1), which is formed despite the dielectric constant of DMSO (46.4[19]) and enhances the importance of electrostatic repulsion in the case of polynuclear species formation. The high stability of this complex is due to the enthalpic factors, as the entropy value strongly counteracts the complex formation. Unfortunately, it was not possible to obtain unambiguous information about the number of coordinated amino groups by spectroscopic (NMR, FT-IR or UV/Vis) measurements, as Cd_2L_3 (and also Co_2L_3, see below) is present in solution together with both the mononuclear CdL and, even worse, the CdL_2 species. Nevertheless, two reasonable coordination modes may be hypothesized: (i) that in which the exhaustive hexacoordination of the metal ions is achieved, and (ii) that in which two ML tetracoordinate complexes are bridged by another trien ligand, which coordinates only with the two primary amino groups. As a large number of thermodynamic data relating to complex formation of Cd^{II} with differently methylated mono-, di- and triamines are available,[8c] an attempt to draw some conclusions about the coordination mode described above has been made by use of a chemometric approach based on a multiple linear least-squares regression. The contribution

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of each bonded nitrogen atom to the total value of the thermodynamic functions has therefore been calculated.

The calculated values of $\Delta G°$ and $\Delta H°$ (and their errors) expected for the coordination of one single primary and secondary N groups in chain (not methylated) are, respectively:
$\Delta G_{Cd} = -15.7(0.6)$ and $-14.6(1.0)$;
$\Delta H_{Cd} = -25.1(0.7)$ and $-15.7(1.1)$ kJ·mol^{-1}
[for Co^{II} the calculated values are, respectively, $\Delta G_{Co} = -16.6(0.6)$ and $-15.0(1.0)$; $\Delta H_{Co} = -27.5(1.0)$ and $-17.9(1.5)$ kJ·mol^{-1} [6,8b]]

According to the $\Delta G°$ and $\Delta H°$ values calculated above, expected values for Cd_2L_3 should be:
$\Delta G_{Cd} = -182.1(8.7)$ (logβ = 31.9) and
$\Delta H_{Cd} = -245(9.5)$ in the case of formation of species (i) and
$\Delta G_{Cd} = 152.8(8.1)$ (logβ= 26.7) and
$\Delta H_{Cd} = -213.4(8.9)$ kJ·mol^{-1} for the species (ii)

From comparison with the experimental results in Table 1, one can suggest that hypothesis (i) seems to be more reasonable**.**

The 1:1 complex stability with trien is greater than that of the corresponding Ag^I complex and reflects the higher affinity of the N atom for the borderline soft/hard divalent acceptor Cd^{II} than for the very soft univalent Ag^I ion. As far as hmtrien is concerned, the selectivity towards the metal ions is reversed. This agrees with other experimental evidence[8c] explained in terms of the more difficult arrangement that a bulky ligand may suffer when octahedrally rather than tetrahedrally coordinated.[8c,35b] The decreasing hard nature of the ligand[1] is also responsible for this behaviour.

Co^{II}/Tetraamine System

Co^{II} forms the same complexes as Cd^{II} with trien; the trend in the thermodynamic functions, together with analysis of the data obtained previously for other di- and triamines,[6,8b] suggest conclusions very similar to those reported here for the Cd^{II}/trien system (see above).

Better, comparison between the two systems shows that a higher stability (and exothermicity) is associated with Co^{II}/trien complex formation than that of the analogous situation with Cd^{II}, and this was also observed for other primary and secondary polyamines (see Figure 4, in which, for the sake of simplicity, only the logβ_1 values for CdL polyamine systems are reported as a function of the logβ_1 values for the analogous Co^{II} complexes). The harder Co^{II} is in fact characterized by stronger affinity than the medium/soft Cd^{II} towards the $-NH_2$ and $-NHR$ groups.

In addition, in the polynuclear M_2L_3 complex, it is likely that the larger Cd^{II} ions may be closer to each other than Co^{II} ions, and its stability should therefore be more dependent on electrostatic repulsions (see Table 1 for comparison).

With regard to *N*-alkylated hmtrien, the trend is completely reversed, the value of the stability constant being about two orders of magnitude less than the value found for the analogous Cd^{II}/hmtrien and much of the same order of magnitude as found for the Co^{II}/bidentate pmdien (pmdien = *N*,*N*,*N*′,*N*′′,*N*′′-diethylenetriamine) system.

This value was surprisingly low in comparison with that, though uncertain, available for the same Co^{II}/hmtrien system in water (Table 1). Unfortunately, data on hmtrien coordination to Cd^{II} in water are not known and so no comparison between the Δlogβ_1 values of Cd^{II}/- and Co^{II}/primary and tertiary tetraamine complexes in water is possible. On the other hand, a considerable drop in stability is also seen when considering the complex formation of the borderline[19] Cu^{II} ion, the chemical behaviour of which is, in certain aspects, similar to that of Co^{II} with trien and hmtrien in water (from 20.1 to 12.60[16]).

Other experimental techniques − direct UV/Vis titration of Co^{II} solutions and potentiometric titrations with Ag^I as competitor ion − were therefore also performed on the Co/hmtrien system, and the value reported in Table 1 was fully confirmed.

An analysis of all data so far reported for the two Cd^{II}/- and Co^{II}/polyamine systems in DMSO may provide an explanation for this behaviour. From Figure 4 it can be inferred that: (i) the drop in complex stability on *N*-methylation is more evident for Co^{II} than for Cd^{II}, and (ii) this drop, especially for Co^{II}, is more important on going from secondary to tertiary N groups. This can probably be explained by taking into account that: (i) large metal ions such as Cd^{II} can better minimize steric hindrances when bulky $-N(CH_3)_2$ moieties are involved in complex formation,[8c] and (ii) the increasingly soft nature of the nitrogen donors accounts for the difficulty encountered by tertiary amines in exhausting the coordination sites in Co^{II} complexation, whereas they are able to do it when the Cd^{II} ion is involved. This is confirmed in particular by analysis of the data in Figure 4 for the amines containing tertiary amino groups; they show similar stabilities with Co^{II}, whereas their CdL complex stabilities increase gradually with the increase in the number of probably coordinated nitrogen atoms. With Co^{II} a maximum of two nitrogen atoms are found to be able to coordinate the hard central ion, when tertiary polyamines are considered. As far as this last point is concerned, it has already been shown that the severe steric strain present in tertiary *N*-methylated amines, also confirmed by MM calculations, does not allow formation of a hexaamine complex when all N donors are tertiary, whereas this does occur when the degree of *N*-methylation is decreased.[5c,5g,5h]

The electron densities on the metal ions in the complexes, and therefore their dioxygen affinities, would be expected to be significantly lowered when the Co^{II}/hmtrien complex is formed, in relation to its Co^{II}/trien analogue.

With the aim of improving knowledge of correlation between electrochemical properties of the complexes and their dioxygen affinities, voltammetric measurements were carried out on both 1:1 Co^{II}/trien and Co^{II}/hmtrien systems.

The results obtained showed that the signals relative to the $Co^{II}L_j/Co^{III}L_j$ couples, and therefore to the reaction according to Equation (4) were not visible for the two systems

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

investigated, probably for the reasons explained previously.[6]

$$Co^{II}L_j \rightarrow Co^{III}L_j + e \quad (4)$$

The values of E_{pc}, the cathodic potential at maximum diffusion current, for the reaction according to Equation (5) are, on the other hand, easily evaluated for the two systems investigated and are −1.65 and − 1.50 V for the trien and hmtrien system, respectively.

$$Co^{II}L_j + 2e \rightarrow Co(0) + jL \quad (5)$$

By taking into account that the dioxygen uptake by a given complex represents the formation of a charge-transfer complex, a correlation between E_{pc} and Co^{II} charge density and therefore $Co^{II}L_j$ dioxygen affinity, should be observed. The higher the charge density, the more difficult the reduction process to Co^0 should be, and the more negative the E_{pc} value;[6] the E_{pc} value for the tertiary amine is in fact shifted anodically. That confirms how steric aspects of ligand design might be used to produce desired redox properties.[40]

It is of interest to note that the critical value of −1.54 V proposed in ref.[6] is not reached by the Co^{II}/hmtrien complex and that therefore, on the basis of the correlation between electrochemical properties and $Co^{II}L$ dioxygen affinity (see ref.[6] for details), we should predict that this adduct should not be able to bind dioxygen.

This is confirmed by the fact that no changes are observed in the spectra of deaerated and aerated solutions of the Co^{II}/hmtrien system, whereas for the Co^{II}/trien 1:1 species the aerated spectrum shows the very rapid (Figure 3, b) appearance of a charge-transfer band at 310 nm, to which a second band at 370 nm is added within a few minutes. The intensity of the latter band increased for about 60 min when the O_2 concentration was 4%, the kinetic behaviour being dependent on the initial dioxygen concentration. This band then remained constant for at least 6 h. This development seems to be consistent with the formation of two different dioxygenated species formed by different kinetic and thermodynamic pathways; the thermodynamically stable species seems not to undergo autoxidation, at least within the first 6 h. In addition, the dioxygen uptake is likely to be irreversible, as the UV absorption did not decrease with N_2 bubbling

A confirmation of this qualitative interpretation, together with an indication of the stoichiometry of the CoL/O_2 species, is provided by the O_2 absorption, which shows a quick uptake of dioxygen and then a plateau reached at R_{O2} = 0.5 (Figure 5), suggesting the formation of a μ-peroxo complex in which the dioxygen molecule bridges two metal ions; the dinuclear μ-superoxo complex is not considered, as the maximum of the charge-transfer band is located here at 325 nm, whereas normally the electronic spectrum of the green μ-superoxo adduct shows an additional band around 710 nm.[26,41] The 2:1 CoL/O_2 adduct formation agrees with the general tendency of Co^{II} complexes with simple polyazaalkanes to form dinuclear dioxygen species in dipolar solvents rather than end-on species, which normally requires superstructured ligands able to form a protective cavity around the metal ion.[26,31,41] Detailed thermodynamic and kinetic studies on this system are in progress.[42]

Conclusions

The *N*-functionalization of the ligands has a strong influence on the stoichiometry and the nature of the complexes formed, as well as, much more interestingly, on the selectivities of the ligands towards metal ions, as suggested by the behaviour of primary and secondary amines with respect to the tertiary ones. The former pair show the general stability trend increasing in the order $Ag^{I} < Cd^{II} < Co^{II}$, the latter reverse this trend and the complex stability increases in the order $Co^{II} < Cd^{II} < Ag^{I}$. The Cd^{II} ion generally coordinates all the donor sites of the nitrogen ligands, whereas Co^{II} does not when tertiary amino groups are involved.

The decreasingly hard nature of the nitrogen donors is mainly responsible for the fact that *N*-alkylation of trien prevents the Co/hmtrien system from being able to take up dioxygen. The E_{pc} value of −1.50 V allows this behaviour to be predicted, on the basis of all of the reported data, and provides additional insights into the correlation between electrochemical properties, number of methyl substituents and consequent dioxygen affinity of the anaerobic Co^{II} complexes.

Finally, it is suggested that a 2:1 $[Co(trien)_2]^{2+}/O_2$ complex is formed under aerobic conditions.

Experimental Section

General Remarks: $Co(ClO_4)_2 \cdot 6DMSO$ and $Cd(ClO_4)_2 \cdot 6DMSO$ were prepared and purified as described.[8b] Anhydrous silver perchlorate was obtained from $AgClO_4 \cdot H_2O$ (Fluka; puriss) as described previously.[22a] Dimethyl sulfoxide (Fluka; > 99%) was purified by distillation according to the described procedures,[22a] degassed by a pumping-freezing procedure, and stored in the presence of 4-Å molecular sieves. The ligands trien and hmtrien (Aldrich; > 97%) were purified by fractional distillation.[43] Stock perchlorate solutions of Cd^{II} and Co^{II} ions were prepared by dissolution of weighed amounts of the adducts in anhydrous degassed DMSO, and their concentrations were determined by titration with EDTA.[44] The solutions of $AgClO_4$ were prepared and standardized as before.[22a] The background salt Et_4NClO_4 was recrystallized twice from methanol and dried at 110 °C. Solutions of the ligands were prepared by dissolution of weighed amounts in DMSO and standardized by thermometric titration with standard $HClO_4$ solutions. All standard solutions were prepared and stored in an MB Braun 150 glovebox under a controlled atmosphere containing less than 1 ppm of water and less than 1 ppm of oxygen. The water content in the solutions, typically 10−20 ppm, was determined with the aid of a Metrohm 684 KF Coulometer.

Potentiometric Measurements: All measurements were carried out under dry, oxygen-free nitrogen in an MB Braun-150 glovebox, in a thermostatted cell maintained at 298.0 ± 0.1 K. The experimental data required for the determination of the stability constants of the Ag^{I}/hmtrien and the Cd^{II}/trien and Cd^{II} /hmtreien systems were

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the equilibrium concentrations of the silver and cadmium ions, respectively, obtained from the electromotive force (emf) data of a galvanic cell similar to that reported previously.[22a] The emf values were measured with the aid of an Amel 338 pHmeter equipped with a Metrohm 6.0328.000 silver electrode as a working electrode and a Metrohm 6.0718.000 silver electrode as a reference in the first case and with a Weiss WCD1001 Cd ion selective electrode as working electrode and a Methrom 6.0718.000 silver electrode as reference one in the second case. Aliquots of ligand solutions of known concentrations were first added to the cell containing only solutions of metal (metal = Ag^{I} or Cd^{II}) perchlorate ($2.00 < c^{\circ}_{Metal} < 30.00$ mmol·dm^{-3}) of exact known concentration and the free metal ion concentration was measured after each titrant addition. Some titrations were carried out in duplicate to verify the reproducibility of the system. Equilibrium was typically reached in 2−5 min. The Nernstian response of the Ag and Cd electrodes were obtained in the range 10^{-7} < metal ion < 10^{-2} mmol·dm^{-3}. The computer program Hyperquad[45] was used for calculation of the stability constants.

Spectrophotometric Measurements: UV/Vis spectra were recorded with a Varian Cary 50 Spectrophotometer directly inside the glovebox, by use of optic fibre probes and a quartz cuvette with a pathlength of 1 cm (117.100 Bracco cell). The data were recorded over the wavelength range 300−650 nm. Different types of titrations were carried out in order to obtain the best competition between Cd^{II} and Co^{II} for the same ligand and/or to provide evidence of possible formation of mixed or polynuclear species. The absorption maximum for $Co(ClO_4)_2$ in DMSO occurs at 535 nm, with an extinction molar coefficient $\varepsilon = 11.9$ mol^{-1}·dm^3·cm^{-1}. The absorption maximum of CoL_j complexes are shifted to lower wavelengths, in line with an increase in the ligand field strength. The fact that equilibrium was attained was supported by the observation that addition of titrant solution produce an immediate spectral change with no further change noted after several hours. The absorbance data at about 20 different wavelengths in the 450−550-nm range were analysed and the formation constants of the Co_iL_j complexes ($i = 1$, $j = 1$ for L = hmtrien; $i = 1$, $j = 1$, 2 and $i = 2$, $j = 3$ for L = trien) were determined, together with the molar extinction coefficients of the complexes at each relevant wavelength, by use of the Hyperquad program.[45] The UV/Vis measurements for dioxygen uptake were carried out by use of an analogous apparatus with the aid of optic fibre probes (Hellma) of 1-cm length dipped directly into the reaction vessel.

Calorimetric Measurements: A Tronac model 87−558 precision calorimeter was employed to measure the heats of reaction. The calorimeter was checked by titration of tris(hydroxymethyl)aminomethane (tham) with a standard solution of HCI in water. The experimental value of the heat of neutralization of tham was found to be $\Delta H^{\circ} = -47.59$ kJ·mol^{-1}, in good agreement with the accepted value of -47.53 ± 0.13 kJ·mol^{-1}.[7] The calorimetric titrations were performed at 298.00 ± 0.02 K by addition of known volumes of ligand solutions ($50 < c^{\circ}_{L} < 400$ mmol·dm^{-3}) to 20 mL of metal ion (Ag^{I}, Cd^{II}, Co^{II}) solutions ($2.00 < c^{\circ}_{Metal} < 30.0$ mmol·dm^{-3}). For each titration run, n experimental values of the total heat produced in the reaction vessel were calculated as a function of the added titrant. These values were corrected only for the heat of dilution of the titrant, which was determined separately. The heat of dilution of the titrate was found to be negligible in the metal ion concentration range used. The quantity Δh_n, total heat per mol of metal ion, was defined and calculated by dividing the net reaction heat by the number of mol of metal ion in the calorimetric vessel. The least-squares computer program Letagrop Kalle[46] was used for the calculation of the enthalpy changes.

FT-IR Spectroscopy: The FT-IR spectra were obtained with a Bio-Rad FTS 40 spectrometer (maximum resolution 4 cm^{-1}; 16 scans). A cell with barium fluoride windows (thickness of 25 μm) was used. The cells were filled and closed in the glovebox and quickly transferred to the spectrometer. The c°_{Co} and c°_{trien} values in the DMSO solutions were about 50 mmol·dm^{-3}.

Cyclic Voltammetry: The cyclic voltammograms of CoL_1 complexes were carried out with an EG&G Princetown Applied Research Model 263A potentiostat controlled by a Win/PC-based program. A saturated Ag/AgCl electrode was employed as reference and a Pt electrode was used as working electrode, with a Pt wire being present as auxiliary electrode. The measurements were carried out with a scan rate of 100 mV/s.

O_2 Absorption: Measurement of O_2 absorption was performed with the aid of a gas burette connected to a vessel containing 0.6 mmol of total cobalt(II) in 20 mL of DMSO ($I = 0.1$ M) in the presence of 0.6 mmol of trien. The system was thermostatted at 298.0 K with a water circulating bath. The solution was vigorously stirred to minimize diffusion effects.

Structural, Magnetochemical and Electrochemical Studies of Dinuclear Complexes Containing the $[V^{V}O]_2$, $[V^{IV}O]_2$, Cr^{III}_2, Mn^{III}_2 and Fe^{III}_2 Cores of a Potentially Pentadentate Phenol-Containing Ligand with (O,N,O,N,O)-Donor Atoms

Soumen Mukherjee,[a] Thomas Weyhermüller,[a] Eberhard Bothe,[a] and Phalguni Chaudhuri*[a]

Keywords: N,O ligands / Transition metals / Magnetic properties / Radicals / Electrochemistry

Dinuclear complexes $[L_2Fe^{III}_2]$ (**1**), $[L_2Mn^{III}_2]$ (**2a**), $[L_2Mn^{III}_2(THF)_2]$ (**2b**), $[L_2Cr^{III}_2]$ (**3**), $[L(V^{IV}O)_2(OCHMe_2)]$ (**4**) and $[L_2(V^{V}O)_2]$ (**5**) with a pentadentate phenol-containing ligand H_3L (= $C_6H_2(CH_3)(OH)\{[C(CH_3)_3]_2(OH)NCH\}_2$) bearing the N_2O_3 donor atoms have been synthesized and the X-ray structures of **1**, **2b**, **4** and **5** are reported. The compounds were characterized by IR, UV/Vis and Mössbauer spectroscopy, mass spectrometry, electrochemical and variable-temperature (2–295 K) magnetic susceptibility measurements. Analysis of the susceptibility data demonstrates antiferromagnetic interactions between the metal centers establishing diamagnetic ground states for complexes **1**–**4**. The electrochemical results suggest the generation of ligand-centered oxidation processes attributable to the phenoxyl radicals, rather than the formation of unusually high oxidation states at the central metal centers. The ligand H_3L has the potential to act in a multidentate fashion as evidenced by the X-ray structures of **2b** and **5**. In compound **2b** the central phenolate oxygen of the *p*-cresol ring does not function as a bridging atom between two manganese centers, whereas in **5** the ligand is tetradentate with one noncoordinating nitrogen atom.

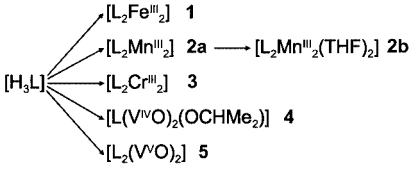
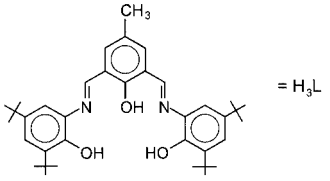
Introduction

This work stems from our ongoing interest[1] in phenol-containing ligands, and their one-electron oxidation products, i.e. phenoxyl radicals. The widespread occurrence of tyrosine radicals[2] in metalloproteins involving oxygen-dependent enzymatic radical catalysis has prompted inorganic chemists to model tyrosine by using phenolate ligands.[3] In an earlier paper[4] we described a dinucleating Schiff-base ligand H_3L, obtained by the condensation (1+2) of 2,6-diformyl-4-methylphenol with 6-amino-2,4-di-*tert*-butylphenol. This ligand can be used to prepare complexes containing Cu^{II}_2, Cu^{II}_4, Ni^{II}_2 and Ni^{II}_4 cores, which have been spectroscopically and structurally characterized and reported.[4] This paper is a continuation of our investigations with the ligand H_3L and describes coordination of the ligand with the Fe^{III}, Mn^{III}, Cr^{III}, (V^{IV}=O) and (V^{V}=O) ions. The compounds described here are given below with their labels.





Results and Discussion

Reactions of metal salts with the ligand H_3L in the presence of triethylamine afforded complexes **1**–**5** in moderate yield. The dinuclear complexes were easily isolated and characterized by different methods. Remarkably $[L_2Mn^{II}_2]$ (**2a**), which is considered to possess an identical coordination sphere and atom connectivity as the structurally characterized $[L_2Fe^{III}_2]$ (**1**), yields on recrystallization from THF $[L_2Mn^{III}_2(THF)_2]$ (**2b**), in which the phenolate-bridging between two manganese centers prevailing in **2a** does not persist any more, thus resulting in a comparatively long Mn···Mn separation (6.45 Å).

Selected IR spectroscopic data for complexes **1**−**5** are given in the Exp. Sect. The sharp peaks in the solid state FTIR spectrum due to ν(OH) of the ligand H_3L occur at 3523, 3492 and 3348 cm^{-1}. These bands are missing in **1**−**5**, indicating that on complexation the phenol-character of the ligand has been lost. There are several peaks in the region 3000−2800 cm^{-1} due to the *tert*-butyl groups along with the other ν(C−H), ν(C=C), ν(C=N) and ν(C−O) vibrations found in the normal range for these types of linkages. For **4** the sharp strong-band at 990 cm^{-1} is associated with the ν(V=O) vibration. The corresponding band for **5** occurs at 996 cm^{-1}.

The EI mass spectrum of **1** exhibits the molecular ion peak centered around *m*/*z* = 1247 with the expected isotopic distribution pattern, unambiguously indicating the composition to be Fe_2L_2. For **2a** the parent ion peak corresponds to a small peak centered around *m*/*z* = 1244; the peaks with the greatest intensities are observed at *m*/*z* = 206, 351 and 568. EI-MS unambiguously indicates the presence of THF in **2b**. Compound **3** shows the main peak at *m*/*z* = 1239 in the MS-ESI (positive) spectrum in CH_2Cl_2, indicating the composition to be Cr_2L_2, similar to that of **1**. In the EI mass spectrum of **4,** the parent ion peak with an abundance of ≈21% is observed at *m*/*z* = 760 with the expected isotopic distribution pattern. The peak at *m*/*z* = 718 with an abundance of 100% corresponding to the V_2O_3L species is also observed. In addition there are other peaks including one at *m*/*z* = 702 corresponding to the V_2O_2L species. EI-MS for **5** does not leave any doubt about the composition being $V_2O_2L_2$, with the molecular ion peak at *m*/*z* = 1268; the base peak (100%) with *m*/*z* = 1251 corresponds to V_2L_2O. The other significant peaks at *m*/*z* = 1236 and 618 are attributed to the $V_2L_2^{+}$ and $V_2L_2^{2+}$ ions.

Single Crystal X-ray Diffraction Studies

Structure of $[L_2Fe_2^{III}]\cdot 2.5CH_3CN$ (1)

Although H_3L is particularly suited to the formation of dinuclear complexes, and the analytical and spectroscopic data are in agreement with the presence of a dinuclear Fe_2L_2 unit as the smallest unit in **1**, an X-ray analysis was undertaken to remove any doubt regarding connectivity. Indeed, the structural analysis shows the presence of two six-coordinate iron(III) centers within the $Fe_2O_6N_4$ coordination unit. An ORTEP drawing of the molecule is shown in Figure 1 with selected bond lengths and angles provided in Table 1.

The iron atoms, Fe(1) and Fe(2), are in distorted octahedral environments with FeN_2O_4 coordination spheres. The two octahedra share a common edge and are bridged by two phenolate oxygen atoms O(50) and O(10). The six oxygen atoms of two ligands are roughly coplanar with the two Fe atoms. Thus, for the two iron centers, the Fe(1)O(1)O(41)O(50)O(10) and Fe(2)O(62)O(22)O(50)O(10) atoms constitute the equatorial planes. Each iron center is coordinated to two nitrogen atoms, e.g. Fe(1)−N(7) and Fe(1)−N(47), which are *trans* to each other with an angle

N(47)−Fe(1)−N(7)	162.7(2)	N(16)−Fe(2)−N(56)	151.3(2)

N(47)−Fe(1)−N(7) of 162.7(2)°, and which belong to two different L^{3-} ligands.

The non-bridging Fe−O bond lengths [Fe(1)−O(1), Fe(1)−O(41) av. 1.913(4) and Fe(2)−O(62), Fe(2)−O(22) av. 1.923(7) Å] are distinctly different from the bridging Fe−O bond lengths [Fe(1)−O(10), Fe(1)−O(50) av. 2.043(5) and Fe(2)−O(10), Fe(2)−O(50) av. 2.043 Å]. The symmetry in the bridging bond lengths in the nearly planar Fe_2O_2 rhomboid is noteworthy. Although the Fe−O−Fe angle of 108.9(2)° in **1** falls into the range of 105−110° observed for previously structurally characterized $Fe_2^{III}(OPh)_2$ bridges, the Fe···Fe separation of 3.32 Å is one of the longest yet found for complexes with this bis(phenox-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ide) bridge.[5−8] In the previously reported complex $[Fe_2^{III}(salmp)_2]$,[8] where salmp^{3-} is the pentadentate ligand 2-bis(salicylidenamino)methylphenolate, the Fe−O−Fe angle of 97° is the smallest yet found. Primarily because of the differences in the Fe−O−Fe angles, the magnetic properties of **1** differ considerably from those of $[Fe_2^{III}(salmp)_2]$, although **1** and $[Fe_2^{III}(salmp)_2]$ are otherwise very similar. The Fe−N and Fe−O bond lengths are consistent with a high-spin electron configuration for both Fe^{III} centers in **1** with imine nitrogen and phenolate oxygen donor ligands. The d^5 high spin electron configuration has also been confirmed both by Mössbauer spectroscopy and magnetic susceptibility measurements.

Molecular Structure of $[Mn_2^{III}L_2(THF)_2]\cdot 4CH_3CN$ (2b)

Deep orange single crystals of **2b** were obtained by slow evaporation of a tetrahydrofuran solution of **2a**. The structure of **2b** is shown in Figure 2 with selected bond lengths and angles provided in Table 2. The molecule is based on two MnO_4N_2 octahedra, in which two triply deprotonated ligands $[O^{\cap}N^{\cap}O^{\cap}N^{\cap}O]^{3-}$ span between the two manganese centers. The pentadentate ligand $[O^{\cap}N^{\cap}O^{\cap}N^{\cap}O]$ acts as a tridentate (*O*,*N*,*O*)-donor ligand to one manganese center, whilst the residual two donor atoms *N*,*O* coordinate to the second manganese center. Thus, each of the manganese centers attains only pentacoordination through the ligand. The sixth coordination site of each manganese center is occupied by the oxygen atom of a tetrahydrofuran molecule. That the manganese centers are in the +III oxidation state is evident from the axial elongation of the octahedra along the N(47)−Mn(1)−O(80) and the N(16)−Mn(2)−O(90) axes, as expected for a Jahn−Teller distorted high-spin d^4 ion. The atoms Mn(1)N(7)O(1)O(41)O(14) and Mn(2)N(56)O(54)O(22)O(62) comprise the equatorial planes for each octahedron around the Mn(1) and Mn(2) centers respectively. The $MnNO_3$ fragment is essentially planar, the maximum deviation from the mean plane being 0.01 Å. Of note is the axial position of each coordinated tetrahydrofuran molecule. The average equatorial Mn−O and Mn−N distances of 1.896(16) and 2.006(3) Å respectively, fall in the range reported for other structurally characterized d^4 Mn^{III} complexes,[9] and is also consistent with the susceptibility measurements. The smallest acute bite angle between the phenolate O atom and the N atom of the L^{3-} ligand has been found for the Mn(1) center with the angle O(41)−Mn(1)−N(47) being 77.2(1)°.

Compound **2b** is a rare example of a complex bearing a dinucleating ligand containing the central *p*-cresol group,[10] in which the central phenolate oxygen, O(54) or O(14), of the cresol ring does not coordinate as a bridging atom between two metal centers.

Molecular Structure of $[L(V^{IV}{=}O)_2OCHMe_2]\cdot CH_3CN$ (4)

The structure of **4** (Figure 3) shows a divanadyl(IV) complex with a bridging isopropoxide originating from the vanadium isopropoxide starting material. The atoms V(1) and V(2) are additionally bridged by a phenolate oxygen O(10). The pentacoordination of each vanadium atom is achieved

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

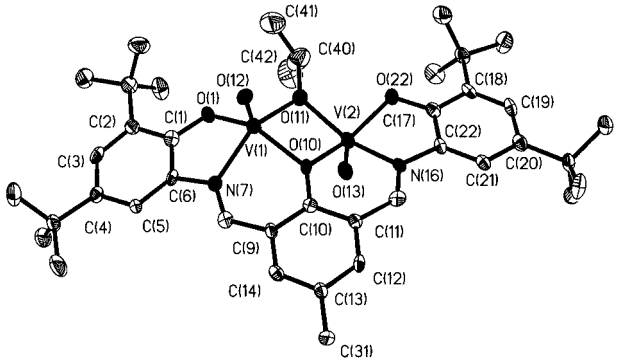

Figure 3. Molecular structure of $[L(V^{IV}{=}O)_2(OCHMe_2)]{\cdot}CH_3CN$ (**4**)

by oxygen atoms O(12) and O(13), with V(1)−O(12) and V(2)−O(13) distances of 1.586(3) and 1.588(3) Å respectively, indicating their double-bond character. The V=O groups are *trans* to each other in the di-vanadium complex. The coordination polyhedra for the vanadium centers are distorted square pyramidal with O(1)N(7)O(11)O(10) for V(1) and O(22)N(16)O(11)O(10) for V(2) forming the basal planes, in which both V(1) and V(2) are located 0.60 Å out of the equatorial planes. The ring V(1)O(11)V(2)O(10) is not planar, the dihedral angle being 10.3°. The distances V−O and V−N are in the ranges reported for comparable complexes[11] and are in agreement with the d^1 electron configuration for the vanadium centers. This electronic structure has also been confirmed by the magnetic susceptibility measurements. The separation V(1)···V(2) of 3.063 Å necessitates consideration of a direct interaction between the metal centers. Selected interatomic distances and bond angles are listed in Table 3.

Structure of $[L_2(VO)_2]{\cdot}2CH_3CN$ (5)

Crystals of $[L_2(VO)_2]{\cdot}2CH_3CN$, obtained by crystallizing **5** from an acetonitrile solution, were subjected to a single-crystal X-ray diffraction study at 100 K. Figure 4 shows a perspective view and the atom-labeling scheme for **5**. Selected bond parameters are listed in Table 4.

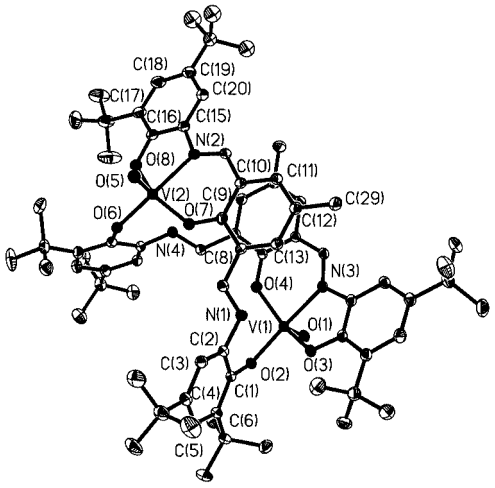

Figure 4. A perspective view of the neutral complex $[L_2(V^{V}O)_2]{\cdot}2CH_3CN$ (**5**)

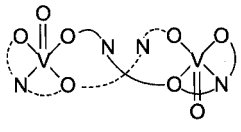
In the distorted square pyramidal VO_4N coordination spheres, the metal atoms are displaced toward the O(1) or O(5) atoms from the equatorial planes O(2)O(3)N(3)O(4) for V(1) and O(6)O(7)N(2)O(8) for V(2) by 0.33 and 0.31 Å respectively. The V(1)−O(1) and V(2)−O(5) distances of 1.603(2) and 1.595(2) Å correspond to vanadium−oxygen multiple bonds and closely resemble vanadium(v) complexes containing a single V=O group.[12] Each ligand with its five donor atoms spans between two vanadium(v) centers but one N atom, N(1) or N(4), does not coordinate to any of the metal centers, making each of the ligands tetradentate. *Such behaviour for ligands based on 2,6-diformyl-p-cresol has not been observed before.* A schematic drawing of the coordination sphere is shown below to highlight the tetradentate coordination of the ligand.



The V−O and V−N bond lengths (Table 4) are similar to those seen in vanadium(v) complexes bearing monooxo- and *cis*-dioxo-vanadium moieties.[13] The C−O (average 1.34 Å) and the aromatic C−C (average 1.40 Å) bond

lengths are in the expected range. The ligand is thus chelated in the trianionic phenolate form and the compound is correctly described with a formal oxidation state of +v for the vanadium ion with a d^0 electron configuration. The diamagnetism and ^{51}V NMR spectroscopic data for **5** corroborate this assignment

Mössbauer Isomer Shifts and Quadrupole Splitting

The Mössbauer spectrum of **1** at 80 K in a zero applied magnetic field and the nonlinear least-squares fit are shown in Figure 5. The spectrum was fitted with a single quadrupole split doublet with an isomer shift of $\delta = 0.518$ mm·s^{-1} and a quadrupole splitting of $\Delta E_Q = 0.754$ mm·s^{-1}. This isomer shift is consistent with those observed for high spin iron(III) ions in an octahedral or distorted octahedral environment.[14] The magnitude of the quadrupole splitting is a reflection of the unsymmetrical electric field gradient about each high-spin iron(III) site, although the two metal sites are equivalent.

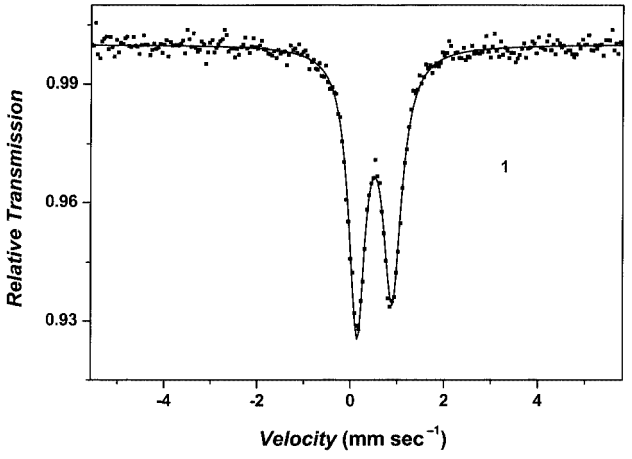

Figure 5. Mössbauer spectrum of **1** at 80 K in an applied zero-field

Magnetic Susceptibility Measurements

Variable temperature solid-state magnetic susceptibility measurements were performed on powdered samples of **1**−**4** over the temperature range 2−290 K in an applied magnetic field of 1 T (Figure 6). We used the Heisenberg spin Hamiltonian in the form $H = -2J\hat{S}_1\cdot\hat{S}_2$ for an isotropic exchange coupling between the two spins S_1 and S_2. The experimental magnetic data were simulated (shown as solid lines in Figure 6) by using a least-squares fitting computer program with a full-matrix diagonalization of exchange coupling, Zeeman splitting and axial single-ion zero-field interactions (DS_z^2), if necessary.

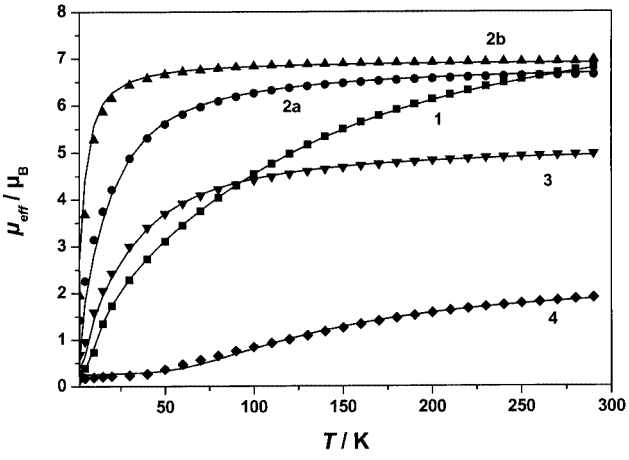

Figure 6. Plots of μ_{eff} vs. T for solid **1**−**4**. The solid lines represent the best fits of the data to the exchange coupling models

The magnetic behavior of $[Fe_2^{III}L_2]$ (**1**), is characteristic of an antiferromagnetically coupled dinuclear complex. At 290 K the μ_{eff} value of 6.784 μ_B ($\chi_M\cdot T = 5.755$ cm^3·K·mol^{-1}) decreases monotonically with decreasing temperature until it reaches a value of 0.274 μ_B ($\chi_M\cdot T = 9.380 \times 10^{-3}$ cm^3·K·mol^{-1}) at 2 K. This is a clear indication of exchange coupling between two paramagnetic Fe^{III} centers ($S_{Fe} = {}^5/_2$) with a resultant $S_t = 0$ ground state. The solid line in Figure 6 represents the best fit with the following parameters: $J = -12.7$ cm^{-1}, $g = 2.00$ (fixed) and PI ($S = {}^5/_2$) = 0.003. The calculated antiparallel exchange is in keeping with the range observed for comparable diphenoxo-bridged ferric dimers.[1,6,7]

Two semi-empirical magnetostructural correlations relating the magnitude of the exchange coupling to the iron-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

oxygen bond length in exchange coupled phenoxo-, alkoxo- and hydroxo-bridged dinuclear iron(III) compounds have been proposed.[5,7] By using the empirical relationship $J = -10^7 \exp(-6.8d)$,[7] where d is the averaged iron−oxygen distance, 2.043 Å for **1**, the J value for **1** can be calculated to be -9.25 cm^{-1}, which differs from the experimentally observed value of -12.7 cm^{-1}. The second equation[5] leads to a calculated value of -5.1 cm^{-1}. Regrettably, none of these two correlations can satisfactorily reproduce the exchange interaction in **1**.

The magnetic moment, μ_{eff}/molecule, for $[L_2Mn_2^{III}]$ (**2a**) of 6.636 μ_B ($\chi_M{\cdot}T$ = 5.507 cm$^3{\cdot}$K$\cdot$mol^{-1}) at 290 K decreases monotonically with decreasing temperature until it reaches a value of 1.421 μ_B ($\chi_M{\cdot}T$ = 0.2523 cm$^3{\cdot}$K$\cdot$mol^{-1}) at 2 K. This temperature dependence of μ_{eff} is a clear indication of an antiferromagnetic exchange coupling between two paramagnetic Mn^{III} (S_{Mn} = 2) centers. A least-squares fit, shown as the solid line in Figure 6, with $J = -2.95$ cm^{-1} and g = 1.98 was obtained. Thus a weak exchange coupling is operating between the Mn^{III} centers through the diphenoxo-bridge and, as expected, the exchange interaction is weaker in **2a** than that in **1**. The exchange coupling operating in **2b** is even weaker than that in **2a**, as evidenced from the temperature-dependence of μ_{eff} for **2b**. The magnetic moment μ_{eff} varies only slightly (μ_{eff} = 6.94 to 6.54 μ_B) in the temperature range 290−40 K, but then starts to decrease monotonically reaching a value of 1.94 μ_B at 2 K. Simulation of the experimental magnetic data yields $J = -0.66$ cm^{-1} and g = 1.995 (the solid line in Figure 6). The antiferromagnetic coupling in **2b** which is weaker than in **2a** is in agreement with the dimeric solid state structure of **2b** in which the manganese(III) centers are 6.45 Å apart.

The experimental magnetic moment of **3** decreases from 4.95 μ_B ($\chi_M{\cdot}T$ = 3.064 cm$^3{\cdot}$K$\cdot$mol^{-1}) at 290 K to an essentially diamagnetic value of μ_{eff} = 0.677 μ_B ($\chi_M{\cdot}T$ = 0.05736 cm$^3{\cdot}$K$\cdot$mol^{-1}) at 2 K, resulting from the antiferromagnetic interaction between the two Cr^{III} ions bridged by a diphenoxo group. The solid line in Figure 6 represents the best fit with the following parameters: $J = -7.6$ cm^{-1}, g = 1.893 and PI (S = $^3/_2$) = 0.01. The calculated antiparallel exchange falls in the range observed for comparable phenoxo-alkoxo-bridged chromium(III) dimers.[15−16]

The temperature dependence of the molar magnetic susceptibility χ_M for **4** shows a clear maximum around 230 K, consistent with the presence of significant antiferromagnetic coupling. Increases in χ_M at low temperatures ($\leq$ 30 K) have often been seen in strongly antiferromagnetically coupled systems and arise from a small amount of paramagnetic impurity in the sample. The magnetic moment of **4** is 1.83 μ_B ($\chi_M{\cdot}T$ = 0.4197 cm$^3{\cdot}$K$\cdot$mol^{-1}) at 290 K, which is significantly lower than the spin-only value of 2.45 μ_B for two uncoupled S = $^1/_2$ spins. Furthermore μ_{eff} gradually decreases on decreasing the temperature, reaching 0.15 μ_B at 2 K. The data were fitted using the following parameters: $J = -128.5$ cm^{-1}, g = 1.90, PI (S = $^1/_2$) = 0.018, TIP = 80 $\times 10^{-6}$ cm$^3{\cdot}$mol^{-1} and $\theta = -3.0$ K. The antiferromagnetic coupling constant of -128.5 cm^{-1} lies in the range of values found for other dinuclear vanadyl(IV) complexes[11,17] containing phenoxo, alkoxo and hydroxo-bridging ligands.

^{51}V NMR Measurements

Compound **5** containing V^V with a d^0 electron configuration is diamagnetic and was examined by ^{51}V NMR spectroscopy[18] with $VOCl_3$ in C_6D_6 as an internal standard. The compound gives rise to a single signal at $\delta = -420$ ppm, suggesting that there is only one species in solution, as in the solid state (vide infra).

Electrochemistry and Spectroelectrochemistry

The electrochemical properties of complexes **1** (Fe^{III}), **2a** (Mn^{III}) and **3** (Cr^{III}) were investigated in CH_2Cl_2 solutions containing 0.1 M TBA(PF_6). Voltammetric experiments (cyclic voltammetry, CV and square wave voltammetry, SQW) reveal that all three compounds can undergo three consecutive oxidations.

Figure 7 shows representative examples of the electrochemical measurements. The respective redox potentials vs. the Fc^+/Fc couple are compiled in Table 5. The first two oxidations are reversible on the time scale of cyclic voltammetry (scan rates 0.05−0.5 V/s). The peak positions are almost independent of the scan rates and the peak separations are close to the values observed for ferrocene under the same conditions (0.08 V). The third oxidations are

[a] CV and SQW in CH_2Cl_2 solutions containing 0.1 M nBu$_4$NPF$_6$; working electrode: 2-mm glassy carbon disk. [b] Fc^+/Fc in CH_2Cl_2 vs. Ag/AgNO$_3$: $E_{1/2}$ = 0.216 V for **1**, 0.240 V for **2b** and 0.203 V for **3**. [c] Chemically irreversible; square wave peak potentials are given.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

either chemically irreversible (**2a** and **3**; no reverse peaks observable) or contain an irreversible component (**1**; oxidation peak at all scan rates twice as high as the peak of re-reduction and of the reversible peaks).

The redox potentials of the second and third oxidations are very similar for all three compounds irrespective of the nature of the central metal ion. This provides firm evidence that these oxidations are ligand centered and give rise to phenoxyl radicals.

The redox potentials of the first oxidations are spread over a somewhat larger range (Table 5). In particular, the redox potential of **2a** is low and could be due to formation of the Mn^{IV} oxidation state. We therefore performed spectroelectrochemical measurements at −25 °C and found that the spectral changes upon the first oxidation of **2a** show the fingerprints for phenoxyl radical formation.[19] In the difference spectra a new peak with a maximum at 417 nm developed together with a broad band which extends from 650−950 nm and has a maximum at ≈800 nm. Therefore, the first oxidation of **2a** can be clearly assigned to phenoxyl radical formation. In spectroelectrochemical experiments with **1** and **3**, an increase in absorption at 350−450 nm and at >700 nm was observed during the first oxidation, as expected for formation of phenoxyl radicals. However, the maxima of the difference spectra were at 350−370 nm rather than at 400−420 nm. It is most likely that these spectra are distorted by small oxidation-induced shifts in the very intense charge-transfer bands of the complexes (the ε-values of the starting material are ten times higher than those of phenoxyl radicals at the respective wavelengths). In view of the similarity of the redox potentials of **1** and **3** we therefore conclude that in these complexes the first oxidations also represent formation of phenoxyl radicals.

The reductions at potentials of less than −1 V are either electrochemically quasi-reversible (**1** and **2a**; peak separation 0.15−0.25 V at 0.2 V/s scan rate) or chemically irreversible (**3**; high peak current and lack of reverse peak). They were not further investigated and are most likely metal-centered reductions to the M^{2+} oxidation states.

A few experiments were done with the Vanadium V^V compound $[L_2(V{=}O)_2]$ (**5**). The square wave voltammogram exhibits three oxidations in the accessible potential range, two reversible ones at −0.136 V and +0.226 V and one irreversible at +1.02 V. These oxidations, which occur in the same potential range as those of **1**−**3**, we also tentatively assign to phenoxyl radical formation. Reductions also occur in the potential range −0.7 to −0.9 V and these are most likely to be metal-centered reductions to the V^{IV} oxidation state. The square wave voltammogram, however, exhibits complex multiple peak formations and therefore accurate redox potentials cannot be evaluated.

Concluding Remarks

The structural analysis of a series of transition metal complexes derived from the pentadentate ligand H_3L demonstrates the ability of this dinucleating ligand to form complexes of metal ions of the first transition series mostly in a six-coordinate fashion. As evidenced by the square-pyramidal five-coordinate V^{IV} **4** and V^V **5** complexes, this may be overcome by electronic factors, e.g. the Jahn−Teller effect and absence of LFSE. The fact that this ligand can adapt itself to various metal ion sizes to yield dinuclear complexes makes it a versatile building block for the construction of bimetallic complexes, which might be useful for the study of biologically relevant dinuclear complexes.

From the X-ray data above and particularly those of **2b** and **5**, it is clear that within a family of complexes it is possible to obtain a variety of coordination environments. Complexes of Schiff base ligands have been in the literature for over 150 years and rigid chelating environments for the metals have been proposed for complexes of this type. The present ligand H_3L, also a Schiff-base ligand, demonstrates how the local environment around the metal becomes distorted to accommodate the increasing internal chelate ring and how the ligand itself adjusts from originally pentadentate to tetradentate in a complex. The realization that the present ligand H_3L has the potential to switch between different chelating modes highlights the prospect of designing a generic ligand system which should have a rich, interesting and independent chemistry worthy of greater exploration. Overall this Robson-type ligand with *tert*-butyl substituents has offered a new chelating flexibility.

The electrochemical results suggest the generation of ligand-centered oxidation processes attributable to the phenoxyl radicals, rather than the formation of unusually high oxidation states at the central metal centers.

Experimental Section

Materials and Physical Measurements: Reagent or analytical grade materials were obtained from commercial suppliers and used without further purification, except those for electrochemical measurements. Elemental analyses (C,H,N) were performed by the Microanalytical Laboratory Dornis & Kolbe, Mülheim, Germany. Fourier transform infrared spectra in KBr discs were recorded on a Perkin−Elmer 2000 FT-IR instrument. Electronic absorption spectra in solution were measured on a Perkin−Elmer Lambda 19 spectrophotometer. Magnetic susceptibilities of powdered samples were recorded on a SQUID magnetometer in the temperature range 2−295 K with an applied field of 1 T. Experimental susceptibility data were corrected for the underlying diamagnetism using Pascal's constants and for the TIP contributions. Cyclic voltammetric and coulometric measurements were performed on EG&G equipment (potentiostat/galvanostat model 273A). Mass spectra were recorded with either a Finnigan MAT 8200 (electron ionization, EIMS) or a MAT 95 (electrospray ESI-MS) instrument. A Bruker DRX 400 instrument was used for NMR spectroscopy.

Preparations

H_3L: The ligand H_3L was prepared as described earlier.[4]

$[L_2Fe_2^{II}]$ (1): To a degassed solution of the ligand H_3L (0.29 g; 0.5 mmol) and NEt_3 (0.12 mL) in an acetonitrile/dichloromethane solvent mixture (10 ml:15 mL) was added $Fe(ClO_4)_2{\cdot}6H_2O$ (0.18 g; 1 mmol) and the resultant solution was heated to reflux for 0.5 h under argon, then cooled and stirred in air for an hour. The result-

ant deep reddish-brown solution was kept at ambient temperature for crystallization. After 2 d red-brown microcrystals were collected by filtration and air-drying. Yield: 0.14 g (45%). $C_{74}H_{94}Fe_2O_6N_4$: calcd. C 71.26, H 7.60, Fe 8.95, N 4.49; found C 71.3, H 7.6, Fe 9.0, N 4.5. EI-MS: *m*/*z* = 1247 [M^+]. IR (KBr disk): $\tilde{\nu}$ =2953 s cm^{-1}, 2865 m, 1610 m, 1591 m, 1565 m, 1471 s, 1443 s, 1408 m, 1255 s, 1163 m, 834 m, 537 m, 492 m. UV/Vis (CH_2Cl_2): λ_{max} ($\varepsilon/M^{-1}\cdot cm^{-1}$) = 560 sh (≈7800), 421 nm (34200).

X-ray quality crystals of **1**·2.5CH_3CN were grown from an acetonitrile solution.

[$L_2Mn_2^{III}$] (2a): A methanolic solution (25 mL) of the ligand H_3L (0.29 g; 0.5 mmol), manganese(III) acetate (0.13 g; 0.2 mmol) and tetrabutylammonium methoxide (0.2 mL) was heated to reflux for 1 h. Red-brown microcrystals of **2a** were formed on cooling to room temperature. The solid was collected by filtration and air-dried. Yield: 70 mg (≈23%). $C_{74}H_{94}Mn_2N_4O_6$: calcd. C 71.36, H 7.61, Mn 8.82, N 4.50; found C 71.50, H 7.5, Mn 8.7, N 4.5. EI-MS: *m*/*z* = 1242−1246 [M^+]. IR (KBr disk): $\tilde{\nu}$ =2953 s cm^{-1}, 2866 m, 1610 m, 1587 m, 1472 m, 1442 m, 1406 m, 1360 m, 1246 s, 1161 m, 836 m, 561 m, 537 m. UV/Vis (CH_2Cl_2): λ_{max} ($\varepsilon/M^{-1}\cdot cm^{-1}$) = 470 nm (22000).

[$L_2Mn_2^{III}(THF)_2$] (2b): X-ray quality crystals of **2b**·4CH_3CN were obtained by crystallizing **2a** from a tetrahydrofuran/acetonitrile solution. $C_{82}H_{110}Mn_2N_4O_8$·4CH_3CN: calcd. C 69.57, H 7.91, Mn 7.07, N 7.21; found C 69.7, H 7.9, Mn 7.3, N 6.7.

[$L_2Cr_2^{III}$] (3): A solution of the ligand (0.29 g; 0.5 mmol), NEt_3 (0.1 mL) and $CrCl_2$ (0.12 g; 0.5 mmol) in tetrahydrofuran (25 mL) was heated to reflux under argon for 15 min and then in air for a further 1 h. The resultant deep-red solution was filtered and the filtrate was evaporated to dryness using a rotary evaporator. The solid obtained was dissolved in of THF (5 mL) and the solution was filtered to remove any solid. After addition of acetonitrile (2 mL) to the filtrate, slow evaporation at room temperature yielded **3** as an orange-red microcrystalline solid. Yield: 0.13 g (42%). $C_{74}H_{94}Cr_2N_4O_6$: calcd. C 71.70, H 7.64, Cr 8.39, N 4.52; found C 71.4, H 7.6, Cr 8.3, N 4.5. EI-MS (pos., CH_2Cl_2): *m*/*z* = 1239−1246 [M^+]. IR (KBr disk): $\tilde{\nu}$ = 2953 s cm^{-1}, 2905 m, 2867 m, 1598 m, 1565 m, 1474 s, 1445 s, 1406 m, 1256 s, 1162 m, 832 m, 569 m, 539 m, 517 m. UV/Vis (CH_2Cl_2): λ_{max} ($\varepsilon/M^{-1}\cdot cm^{-1}$) = 458 (16450), 337 sh nm (≈16000).

[$L(V^{IV}{=}O)_2\mu$-$OCH(CH_3)_2$] (4): A solution of the ligand H_3L (0.29 g; 0.5 mmol), vanadyltris(isopropoxide) (0.25 ml; 1 mmol) and Et_3N (0.3 mL) in a deoxygenated acetonitrile/dichloromethane solvent mixture (10 ml:10 mL) was heated to reflux under argon for 1 h and then stirred in air for a further 1 h. The solution was filtered to remove any solid particles and the filtrate was allowed to evaporate slowly at ambient temperature to provide deep red crystals. Yield: 0.18 g (47%). $C_{40}H_{54}N_2O_6V_2$: calcd. C 63.15, H 7.15, N 3.68, V 13.39; found C 63.1, H 7.1, N 3.6, V 13.5. EI-MS: *m*/*z* = 760 (20.8%) [M^+], 718 (100%) [$M^+ - C_3H_7$], 703 (54%) [$M^+ - C_3H_7O$]. IR (KBr disk): $\tilde{\nu}$ = 2953 s cm^{-1}, 2867 m, 1614 m, 1569 m, 1476 s, 1446 m, 1362 m, 1250 s, 1161 s, 990 vs, 948 m, 831 s, 567 m, 546 s. UV/Vis (CH_2Cl_2): λ_{max} ($\varepsilon/M^{-1}\cdot cm^{-1}$) = 363 (14900), 470 nm (10500).

X-ray quality crystals of **4**·CH_3CN were obtained by recrystallization of **4** from acetonitrile.

$[L_2(V^V{=}O)_2]$ (5): A deoxygenated solution of the ligand (0.29 g; 0.5 mmol) and Et_3N (0.25 mL) in a solvent mixture of acetonitrile/dichloromethane (30 ml:10 mL) was charged with $V(THF)_3Cl_3$ (0.19 g; 0.5 mmol) and the resultant solution was heated to reflux under argon for 1 h and then stirred in air for a further 1 h. The clear solution was kept at room temperature for slow evaporation of the solvents. After 3 d the dark-brown crystals were collected by filtration. Yield: 0.2 g (63%). $C_{74}H_{94}N_4O_8V_2$: calcd. C 70.01, H 7.46, N 4.41, V 7.99; found C 69.83, H 7.35, N 4.40, V 7.95. EI-MS: m/z = 1266−1269 [M^+], 1251−1254 [$M^+ - CH_3$], 618 [LV^+]. IR (KBr disk): $\tilde{\nu}$ = 3442 m cm^{-1}, 2954 s, 2904 s, 2867 s, 1616 m, 1591 m, 1544 s, 1476 s, 1443 s, 1361 s, 1244 s, 996 s, 838 m. UV/Vis (CH_2Cl_2): λ_{max} (ε/M^{-1}·cm^{-1}) = ca. 414 sh (≈25600), 659 nm (5200). ^{51}V NMR: δ = −420 ppm.

X-ray quality crystals of **5**·$2CH_3CN$ were obtained from an acetonitrile solution of **5**.

X-ray Crystallographic Data Collection and Refinement of the Structures: Single crystals of **1** (orange-red), **2b** (red), **4** (orange-red) and **5** (orange-red) were coated with perfluoropolyether, picked up with glass fibers and mounted on a Kappa-CCD diffractometer equipped with a nitrogen cold stream at 100 K. Graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. Crystallographic data of the compounds are listed in Table 6. Cell constants were obtained from a least-squares fit of the diffraction angles of several thousand strong reflections. Intensity data were corrected for Lorentz and polarization effects. The Siemens ShelXTL software package (G. M. Sheldrick, Universität Göttingen) was used for solution, refinement, and artwork of the structures, and the neutral atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference Fourier techniques. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters.

CCDC-195241 (**1**), -195242 (**2b**), -195243 (**4**)and -195244 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

Financial support from the DFG (Grant: Priority Program Ch111/2−1), the Max-Planck Society and Fonds der Chemischen Industrie is gratefully acknowledged. Thanks are due to Mrs. H. Schucht, Mrs. P. Höfer, Mr. A. Göbels, Mr. B. Mienert for skilful technical assistance.

Synthesis, Characterisation and Antiamoebic Studies of Dioxovanadium(V) Complexes Containing ONS Donor Ligands Derived from *S*-Benzyldithiocarbazate

Mannar R. Maurya,*[a] Shilpa Khurana,[a] Shailendra,[b] Amir Azam,[b] Wenjian Zhang,[c] and Dieter Rehder*[c]

Keywords: Medicinal chemistry / S ligands / Potassium / Vanadium

Three new dioxovanadium(V) compounds, $[K(H_2O)][VO_2(sal\text{-}sbdt)]$ (**1**), $[K(H_2O)_2][VO_2(Clsal\text{-}sbdt)]$ (**2**), and $[K(H_2O)_2][VO_2(Brsal\text{-}sbdt)]$ (**3**) (where H_2sal-sbdt are the Schiff bases formed between salicylaldehyde and dithiocarbazates) have been synthesised, and the structures of **1** and **2** revealed by X-ray diffraction analyses. The ligands coordinate in the tridentate *ONS* fashion out of the enethiolate tautomeric form. The potassium counterions, coordinated to water molecules, the phenolate-O, the oxo groups on vanadium and, in the case of **1**, to the thiolate, provide interlinkages between the anions and thus a complex supramolecular network, further reinforced by intermolecular hydrogen bonds between oxo groups and water molecules. In vitro tests of the antiamoebic activity against the protozoan parasite *Entamoeba histolytica* showed comparable (**1** and **2**) or substantially better (**3**) amoebocidal action than metronidazole, a commonly used drug against amoebobiasis.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Amoebobiasis, a world-wide disease due to protozoan parasites and affecting more than 10% of the world's population is responsible for approximately 100,000 deaths annually, placing it second to malaria in mortality of infectious diseases.[1,2] Nitroimidazole drugs such as metronidazole [1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole] are presently the most effective antiamoebic medications. Side effects are, however, common:[3] mutagenic effects have been established for bacteria, and high doses in rodents can cause carcinoma.[4] As a result of this and also taking into account the possibility of the development of resistant strains of the amoeba against metronidazole, a search for new effective amoebicidal agents is required in order to provide a new dimension in the therapy of amoebiasis.

Schiff base and related metal complexes have experienced long standing applications in biology and medicine,[5,6] as well as in the catalysis of chemical and petrochemical processes.[7,8] Our interest in studies of complexes containing these ligands with sulfur and nitrogen functions arises from their significant antifungal, antiprotozoal, antibacterial, and anticancer activity.[9] More recently, an in vitro insulinmimetic potential of these compounds has been established.[10] Carcinostatic activities have been found for metal complexes of dithiocarbazoic acid and the Schiff bases derived from its *S*-methyl ester.[5] The ruthenium(II) and palladium(II) complexes of Schiff bases derived from *S*-alkyldithiocarbazates have also shown antiamoebic activity.[11,12] In this overall context, vanadium complexes are of specific physiological interest because of their redox activity (V^{IV}/V^{V}): The redox potential can be tuned by the choice of the ligand set so as to provide redox interaction with oxygen species such as peroxide and superoxide. The superoxide radical anion generated in the process $V^{V} + O_2^{2-} \rightarrow V^{IV} + O_2^{-}$ can trigger further physiological events.[13,14]

The potential of vanadium(V) complexes as antiamoebic agents has thus far only been marginally explored.[15] In order to obtain information on the biological activity of dioxovanadium(V) complexes with Schiff base ligands derived from dithiocarbazates, we report here on the synthesis, characterisation, structure elucidation and in vitro screening of the antiamoebic activity of VO_2^{+} complexes with an *ONS* donor set as represented in Scheme 1. In vitro

Results and Discussion

Synthesis and Thermogravimetric Properties

$[VO(acac)_2]$ reacts with the potassium salt of H_2Rsal-sbdt, H_2L (cf. Scheme 1) under mild basic conditions to give dioxovanadium(v) complexes, $K[VO_2L]$. The probable reaction pathway is given by Equations (1) to (3).

$$[VO(acac)_2] + K_2L \rightarrow [VOL] + 2\ acacK \quad (1)$$

$$2\ [VOL] + 1/2\ O_2 + 2\ MeOH \rightarrow 2\ [VOL(OMe)] + H_2O \quad (2)$$

$$[VOL(OMe)] + 2\ KOH \rightarrow K[VO_2L] + MeOK + H_2O \quad (3)$$

This reaction scheme is based on the fact that H_2sal-sbdt under aerobic conditions gives [VO(OEt)(sal-sbdt)] in ethanol which, in the presence of NaOH, is ultimately oxidised to $[VO_2(sal\text{-}sbdt)]^-$.[16] The orange-yellow compounds **1**−**3** are soluble in methanol, ethanol, acetonitrile, DMF, and DMSO. Lowering the pH of the methanolic solution of **1**−**3** with HCl dissolved in methanol gave brown, incompletely characterised complexes, which are also obtained on using one equivalent (instead of two) of KOH during the synthesis. As shown by, inter alia, thermogravimetric analysis, the complexes contain one (**1**) or 2 water molecules per formula unit (**2** and **3**). The loss of water in the temperature range 120−180 (**1**) and 120−220 °C (**2** and **3**) indicates covalently although not particularly strongly bonded water. On further heating of **1**, the anhydrous complex $K[VO_2(sal\text{-}sbdt)]$ loses the $SCH_2C_6H_5$ group between 180 and 320 °C, followed by the loss of an SCN group between 320 and 600 °C. The remaining residue decomposes to yield KVO_3 as the end product at ca. 670 °C. A very similar decomposition pattern had been observed previously for $[VO_2(acpy\text{-}sbdt)]$ (Hacpy-sbdt = Schiff base derived from acetylpyridine and *S*-benzyldithiocarbazate).[17] The anhydrous forms of **2** and **3** lose $SCH_2C_6H_5$ in the temperature range 220−390 °C, while thermal removal of SCN and other residues is not discernible in these complexes. However, the total weight loss corresponds to the remaining organic residue less one oxygen. The percent weight loss of the end product (i.e. KVO_3) in both complexes compares well with the expected values.

IR and Electronic Spectra

A list of selected IR and electronic spectroscopic data is presented in Table 1. The Schiff bases exhibit a strong band between 1030 and 1041 cm^{-1} due to the ν(C=S), thus indicating the thione (thiocarbonyl, cf. Scheme 1, left) nature of the uncoordinated ligands. This is further supported by the absence of an IR band at ca. 2500 cm^{-1} for ν(SH) and the presence of a band at ca. 3100 cm^{-1} for ν(NH) of the hydrazide moiety. The disappearance of both, the ν(C=S) and ν(NH) bands, in the spectra of the complexes suggests the thioenolisation of the C=S group (Scheme 1, right) and coordination of the enethiolate sulfur to vanadium. This is further supported by the appearance of a new band at 709−776 cm^{-1} due to the ν(C−S) stretch. A strong band associated with the ν(C=N) (azomethine) stretch appears at 1615−1622 cm^{-1} in the free ligands, and this band undergoes a bathochromic shift by 18−21 cm^{-1} in the complexes, thereby indicating the participation of the azomethine nitrogen in coordination. A broad band appears around 3400 cm^{-1} in the ligands and is assigned to the ν(OH) (phenolic) stretch. For the complexes, a broad band associated with water molecules governs this region. In addition, all complexes display two sharp bands at 888−930 and 921−954 cm^{-1}, corresponding to the ν_{sym}(*cis*-VO_2) and ν_{as}(*cis*-VO_2) modes, respectively.

The electronic absorption spectrum of **1** is dominated by an intense band at 392 nm, which is assigned to the $PhO^- \rightarrow V(d\pi)$ ligand to metal charge transfer (LMCT) band. Substitution by Cl or Br in the *para* position of the phenolate shifts this band to higher wavelengths. Two additional bands appearing in the UV region are due to intraligand transitions.

NMR Spectra

The coordination modes of the ligands were also confirmed by recording ^1H NMR spectra of the free ligands and the complexes. As presented in Table 2, all ligands display two sharp resonances in the δ = 10.25 to 13.45 ppm region, indicating the presence of NH (and thus the thionic nature of the free ligands) and phenolic OH protons. In contrast, the absence of these signals in the spectra of the complexes shows that bonding occurs through the phenolic oxygen and enethiolate sulfur atoms. A significant downfield shift of ca. 0.5 ppm for the azomethine (−CH=N−) proton signal in the complexes relative to the corresponding free ligands supports the coordination of the azomethine nitrogen atom. Aromatic and CH_2 protons resonate in the expected region in the spectra of the ligands and the complexes. These results are consistent with those previously obtained for dioxomolybdenum(vi) complexes.[18]

Table 3 contains ^{13}C NMR spectroscopic data of the ligands and complexes. Assignments of the signals are based on the chemical shifts and intensity patterns, and coordination induced shifts Δδ = [δ(complex) − δ(free ligand)] of the signals for carbon atoms in the vicinity of the coordinating functions. Δδ values are provided in parentheses in Table 3. A large Δδ was observed for the azomethine carbon

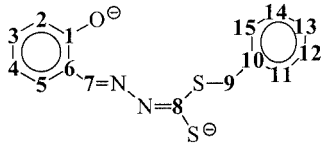
Table 2. ^{1}H NMR spectroscopic data

Compound	OH	NH	−CH=N−	CH_2	Aromatic
H_2sal-sbdt	13.40 (s, 1 H)	10.24 (s, 1 H)	8.55 (s, 1 H)	4.50 (s, 2 H)	6.89 (m, 2 H), 7.28 (m, 4 H), 7.40 (d, 2 H), 7.64 (d, 1 H)
[K(H_2O)][VO_2(sal-sbdt)] (**1**)			9.07 (s, 1 H)	4.40 (s, 2 H)	6.86 (q, 2 H), 7.23 (q, 1 H), 7.32 (t, 2 H), 7.43 (q, 3 H), 7.65 (d, 1 H)
H_2Clsal-sbdt	13.42 (s, 1 H)	10.51 (s, 1 H)	8.49 (s, 1 H)	4.51 (s, 2 H)	6.93 (d, 1 H), 7.33 (m, 4 H), 7.42 (d, 2 H) 7.61 (d, 1 H)
[K(H_2O)$_2$][VO_2(Clsal-sbdt)] (**2**)			9.09 (s, 1 H)	4.41 (s, 2 H)	6.86 (d, 1 H), 7.44 (m, 6 H), 7.79 (d, 1 H)
H_2Brsal-sbdt	13.45 (s, 1 H)	10.55 (s, 1 H)	8.47 (s, 1 H)	4.50 (s, 2 H)	6.86 (d, 1 H), 7.30 (m, 3 H), 7.41 (m, 3 H), 7.73 (d, 1 H)
[K(H_2O)$_2$][VO_2(Brsal-sbdt)] (**3**)			9.09 (s, 1 H)	4.41 (s, 2 H)	6.82 (d, 1 H), 7.33 (m, 3 H), 7.47 (m, 3 H), 7.91 (d, 1 H)

(C7), the carbon atom bearing the phenolate oxygen (C1) and the enethiolate sulfur (C8), thus confirming the coordination mode deduced from the IR and ^{1}H NMR spectra. Other signals appear at nearly identical positions in the free and complexed ligands (for numbering scheme see Scheme 2).



Scheme 2

The ^{51}V NMR spectra exhibit one strong resonance between δ = −465.9 and −468.0 ppm, well within the range of dioxovanadium(v) complexes where a soft thio functionality participates in coordination in addition to the *O* and *N* atoms.[19] The brown solid isolated by using only one equivalent of KOH during the synthesis of **1** gave a signal at δ = −404.6 ppm in addition to that of authentic **1** (δ = −468.0 ppm). Of the two resonances, the less intense resonance at δ = −404.6 ppm is close to the one reported for [VO(OEt)(sal-sbdt)] (δ = −399 ppm).[16] This further supports the proposed pathway for the formation of **1** through [VO(OMe)(sal-sbdt)] as shown by Equations (1) to (3).

Reactivity of 2 Towards HCl

Addition of methanol saturated with HCl gas to [K(H_2O)$_2$][VO_2(Clsal-sbdt)] (**2**) dissolved in MeOH leads to a darkening of the solution and a progressive drop in the intensities of the 400 and 295 nm bands. As the methoxo complex [VO(OMe)(sal-smdt)] (H_2sal-smdt is the Schiff base from salicylaldehyde and *S*-methyldithiocarbazate) exhibits very similar electronic absorptions (400, 307, and 238 nm),[20] the dioxo complex **2** apparently slowly changes

to the corresponding methoxo complex. An increase of the amount of added HCl causes the disappearance of the 400 nm band, accompanied by a broadening and finally splitting of the 295 nm band into two components (310 and 282 nm); Figure 1. On the basis of ^{1}H and ^{51}V NMR spectroscopic studies, it has been suggested that there is an equilibrium between [VO(OEt)(sal-sbdt)] and [VO(OH)(sal-sbdt)] in $CDCl_3$.[16] A similar equilibrium may also be considered here, which should move towards the formation of [VO(OH)(Clsal-sbdt)] with the addition of more HCl. An oxo-hydroxo species has been generated on acidification of $K[VO_2(sal\text{-}inh)H_2O]$ (where H_2sal-inh is *N*-isonicotinamido-2-hydroxyphenylimine),[21] and even of the dimeric dioxo complex $[VO_2L]_2$ {where H_2L = *N*-[(*o*-hydroxyphenyl)methyl]-*N*′-(2-hydroxyethyl)ethylenediamine} in solution.[22] An oxo-hydroxo complex, viz. $[VO(OH)Tp(H_2O)]$ [Tp = *tris*(3,5-diisopropyl-1-pyrazolyl)borate] has recently been structurally characterised.[23] On allowing the above solution to stand overnight, or on addition of KOH dissolved in methanol, the solution acquires the original pattern, i.e. the reaction is reversible and gives the spectrum of **2**. The reversibility of such a reaction is an important observation in the context of the vanadate-dependent haloperoxidases, for which a hydroxo group in an apical position has been proposed on the basis of X-ray diffraction analysis.[24]

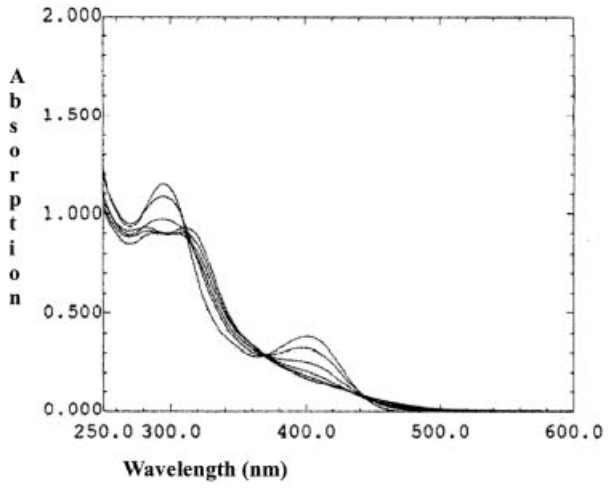

Figure 1. Electronic absorption spectra of the titration of compound **2** (maxima at 400 and 295 nm) with methanolic HCl, showing the formation of [VO(OH)(Clsal-sbdt)] (new bands at 310 and 282 nm)

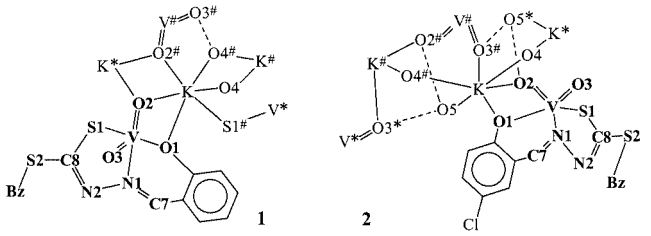

Figure 2. Schematic representations of the coordination environments of vanadium (bold) and potassium, and numbering schemes of **1** and **2**. O3 is the apical oxo group, O4 and O5 are water molecules; Bz = benzyl. # and * refer to atoms not belonging to the formula unit.

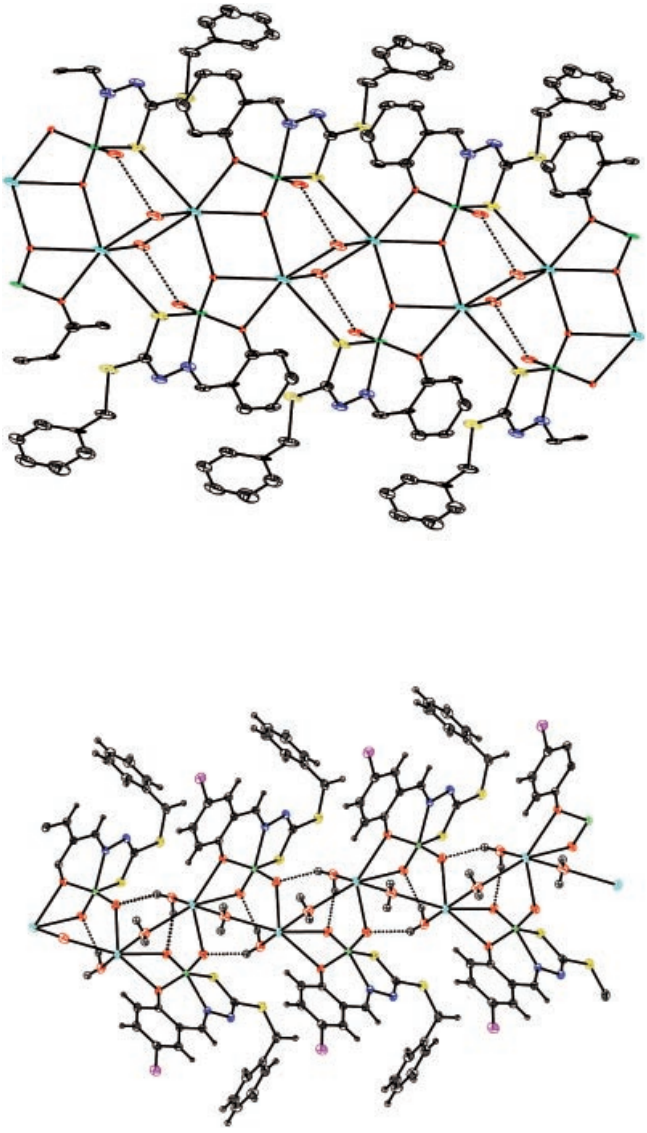

Figure 3. ORTEP drawings (50% probability level), representing sections of the supramolecular arrangements in **1** and **2**. Colour code: V (green), K (light blue), O (red), N (dark blue), S (yellow).

Description of the Structures

Schematic drawings of the coordination environments of vanadium and potassium in **1** and **2** are shown in Figure 2, ORTEP representations of the networks interlinking anions and cations in Figure 3. Table 4 provides a synopsis of selected structure parameters.

In compound **1**, vanadium is in a square pyramidal environment with one of the oxo groups (O3) in the apex and the second oxo group (O2) plus three atoms of the tridentate ligand (O1, N1, S1) forming the plane. Vanadium is 0.0953 Å above this plane. The distance to the nitrogen *trans* to O2, *d*(V−N1), is somewhat elongated with respect to the average V−N(azomethine) bond lengths.[17,25] While

O3−V−N	197.7(3)	98.86(5)

the apical V=O bond, d(V−O3) = 1.606(6) Å is in the expected range, the basal d(V−O2) = 1.660(6) Å is widened as a consequence of covalent bonding contacts to two K^+ ions. Each potassium ion is thus coordinated to two basal oxo groups (O2, and O2# of a second vanadium centre), the phenolate-O (O1), and to two bridging water molecules (O4 and O4#). In addition, there is a weak bond of 3.467 Å to the S1 of the thiolate group (sum of covalent radii: 2.98, sum of van der Waals radii: 4.60 Å). The potassium ions form an endless zigzag chain via alternate $\{K(\mu\text{-}H_2O)\}_2^{2+}$ and $\{K(\mu\text{-}OVO)\}_2$ links. This chain is "layered" by the ligand fragments of the vanadate anion, with the benzyl rings attached to S2 forming the outer sphere. Adjacent anions in these layers are connected to each other through O2/O1−K−S1 links. Connection of two anions *across* the chain occurs through $\{K(\mu\text{-}VO_2)\}_2$ links; the apical oxo groups of the two $[VO_2(sal\text{-}sbdt)]^-$ anions oppose each other.

On the molecular level, the structure of **2** compares to that of **1**. In **2**, both the basal (O2) *and* the apical (O3) oxo groups of the VO_2 moiety are involved in binding to the K^+ ion. The resulting elongation of d(V−O3) = 1.622(1) is, however, less pronounced than that of d(V−O2) = 1.660(1) Å. The coordination environment of the counterion of **2** differs from that in **1** in that an additional − terminal − water molecule replaces the thiolate group. On the supra-molecular level, anions and cations again arrange so as to form a band structure with a central $\{K(H_2O)(\mu\text{-}H_2O)\}_n$ zigzag chain and an envelope formed by the ligands of the complex anion, with the hydrophobic benzyl fragments exposed to the outside. Additional linkages for the K^+ ion along the chain are bridging VO_2^+ moieties. Coordination of the K^+ ion to the phenolate-O group (O1), and H-bonds formed between both oxo groups (O2 and O3) and terminal H_2O molecule (O5) at the potassium ion provide interconnections between the anions *across* the chain.

Biological Activity

A quantification of drug action was obtained by determining the approximate concentration causing a 50% reduction in the number of cells of *E. histolytica* relative to a control. TYIS-33 medium was used as a control to estimate 100% live confluence of amoeba cells. The inhibition concentration (IC_{50}) of the ligands (H_2sal-sbdt**,** H_2Clsal-sbdt and H_2Brsal-sbdt, c.f. Scheme 1) and their complexes (**1**, **2**, and **3**) are indexed in Table 5. All the compounds screened for anti-amoebic activity in vitro had IC_{50} values of clearly less than 10 μM. IC_{50} value < 20 μM are usually considered significant in amoebicidal action.[26] The high activity of compounds **1**, **2**, and **3**, surmounting that of the ligands, showed that complexation of the organic ligands to vanadium substantially enhances the activity. This behaviour, which is particularly pronounced for H_2Brsal-sbdt (IC_{50} = 4.2) vs. complex **3** (1.35 μM), may be explained by Tweedy's theory,[27] according to which chelation reduces the polarity of the ligand due to partial sharing of its negative charge with the metal, favouring transportation of the complexes across the lipid layer of the cell membrane. In an earlier communication,[15] we had introduced dioxovanadium complexes with bidentate *ON* ligands, showing activity in the range of 2.4−9.6 μM as compared to metronidazole (IC_{50} 2.1 μM). The use of ligands containing a sulfur functionality, as in the case of **1**, **2**, and **3**, apparently improves the activity.

Table 5. In vitro screening for amoebicidal activity of the ligands and their vanadium complexes against an HM1:1MSS strain of *E. histolytica*

Compound	IC_{50} (μM)	S.D.[a]
H_2sal-sbdt	5.19	0.95
$[K(H_2O)][VO_2(sal\text{-}sbdt)]$ **1**	2.67	0.52

Metronidazole	2.05	0.31

[a] Standard deviation.

A similar observation holds for Pd^{II}, Pt^{II}, and Ru^{II} complexes of *SN* donor ligands derived from *S*-alkyldithiocarbazate,[11,12,28] as compared to the corresponding complexes with *ON* ligands, suggesting that sulfur attains a general

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

role in activity enhancement. This can be compared with the natural product allicin, a sulfinothioc acid [−S(O)−S−] derivative isolated from garlic (*Allium sativum*),[29] which is very active as an antimicrobial agent, possibly due to its specific interference with sulfhydryl enzymes. An additional important feature in these biologically active metal complexes may be imparted by the tridentate ligand system.[30] The binding of the chelated metals to the nitrogen bases of DNA and RNA, and the inhibition of DNA synthesis through the blockage of the enzyme ribonucleotide diphosphate reductase (RBD) have been suggested as possible mechanisms of action.[30,31] What is evident at this stage, however, is that the general mechanisms of operation of these compounds and their complexes, whether in their action as cytotoxic,[30] antibacterial or antifungal agents,[32−34] is still eluding researchers.

Conclusion

Three new anionic dioxovanadium complexes containing an *ONS* ligand set have been prepared, where *O* is a phenolate, *N* an imine, and *S* a thiolate function from a ligand system obtained by condensation of salicylaldehyde and dithiocarbazate. The dianionic ligand coordinates out of its enethiolate tautomeric form. The potassium counterion is in a coordination environment provided by six *O* atoms (**1**) or five *O* atoms [plus a weak K···S(thiolate) bond] (**2**), from water, and phenolate plus the doubly bonded oxo groups on vanadium. The aquapotassium ions form zigzag chains interconnecting adjacent complex anions. The complexes exhibit anti-amoebal in vitro activity towards *Entamoeba histolytica* similar to or, in the case of **3**, better than metronidazole, a medication commonly used in amoebobiasis

Experimental Section

Materials and Measurements: V_2O_5 (Loba Chemie, India), benzyl chloride (Spectrochem, India), salicylaldehyde (E. Merck, India) and acetylacetone (Aldrich, U.S.A.) were used as obtained. 5-Chlorosalicylaldehyde,[35] *S*-benzyldithiocarbazate,[36] and [VO(acac)$_2$] [acac = acetylacetonate(1−)][37] were prepared according to methods reported in the literature. The ligands H_2sal-sbdt and H_2Brsal-sbdt were prepared as described.[38]

The Central Drug Research Institute, Lucknow, India, carried out elemental analyses. ^{1}H NMR spectra were obtained with a Bruker 200 MHz spectrometer, ^{13}C and ^{51}V NMR spectra with a Bruker AM-360 spectrometer at 90.56 and 94.73 MHz, respectively, in [D$_6$]DMSO with the usual parameter settings. All ^{51}V NMR spectroscopic values are referenced relative to $VOCl_3$ as external standard. UV/Vis spectra were recorded in acetonitrile and methanol on a UV-1601 PC UV/Visible spectrophotometer, IR spectra as KBr pellets using a Perkin−Elmer model 1600 FT-IR spectrometer. The Scientific Instrumentation Centre of the Indian Institute of Technology, Roorkee, carried out thermogravimetric analyses, in static air.

Crystal Structure Determinations: Data were collected on a Bruker SMART Apex CCD diffractometer using a graphite monochromator and Mo-K_α radiation (λ = 0.71073 Å) at 153(2) K. Hydrogen atoms were placed into calculated positions and included in the last cycles of refinement. Crystal data and details of the data collection and refinement are collated in Table 6. The program systems SHELXS 86 and SHELXL 93 were used throughout.[39]

CCDC-198451 (**1**) and CCDC-198450 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The morphology of the crystals of **1** (thin plates) did not allow for a high quality data set ($R1$ = 0.068).

In vitro Tests Against *E. histolytica*: The ligands and their metal complexes were screened in vitro for antiamoebic activity against a (HM1:1MSS) strain of *Entamoeba histolytica* by the microdilution method.[40] *E. histolytica* trophozoites were cultured in TYIS-33 growth medium as described previously[41] in wells of 96-well microtiter plates (Costar). ca. 1 mg of the compounds subjected to the tests were dissolved in DMSO (40 μL), and culture medium was added so as to obtain a concentration of 1 mg/mL (corresponding to ca. 2.8 mM for the ligands and 2.2 mM for the complexes). Dissolution was facilitated by mild sonication in a sonicleaner bath for a few minutes. As evidenced by a comparison of UV/Vis spectra of the complexes dissolved in DMSO on the one hand, and DMSO + TYIS-23 medium on the other hand, the complexes preserve their integrity under biological conditions. Stock solutions were prepared by further dilution of the culture medium to 0.1 mg/mL. Under these conditions, the complexes are stable and no inhibition of amoeba occurs.[42,43] Twofold serial dilutions were made in wells of 96-well microliter plates in 170 μL of medium. Each test included metronidazole as a standard amoebicidal drug, control wells (culture medium plus amoebae), and a blank (culture medium only). The control wells were prepared from a confluent culture by pouring off the medium, adding 2 mL of fresh medium and chilling the culture on ice to detach the organisms from the flask wall. The number of amoeba per mL was estimated with a haematocytometer, and trypan blue exclusion was used to confirm viability. Fresh culture medium was added to dilute the suspension to 10^5 organism/mL, and 170 μL of this suspension was added to the test and control wells so that the wells were completely filled (total volume 340 μL) An inoculum of $1.7 \cdot 10^4$ organisms/well was chosen in order to ascertain confluent − but not excessive − growth in the control wells. The plates were sealed with expanded polystyrene, secured with tape, placed in a modular incubation chamber and gassed for 10 min with nitrogen before incubation at 37 °C for 72 h.

After incubation, the growth of amoebae in the plates was checked with a low power microscope. The culture medium was removed by inverting the plate and shaking gently. The plate was then immediately washed once in sodium chloride solution (0.9%) at 37 °C. This procedure was completed quickly, and the plates were not allowed to cool in order to prevent the detachment of amoebae. After drying at room temperature, the amoebae were fixed with methanol and, when dry, stained with 0.5% aqueous eosin for 15 min. The stained plates were washed once with tap water and then twice with distilled water and allowed to dry. A 200 μL portion of a 0.1 M sodium hydroxide solution was added to each well to dissolve the protein and release the dye. The optical density of the resulting solution in each well was determined at 490 nm with a microplate reader. The % inhibition of amoebal growth was calculated from the optical densities of the control and test wells, and plotted against the logarithm of the dose of the drug tested. Linear

regression analysis was used to obtain the best-fitting straight line from which the IC_{50} value was determined.

Preparation of Complexes: Spectroscopic data are collated in Table 1 (IR and UV/Vis), Table 2 (^{1}H NMR), and Table 3 (^{13}C NMR) in the Results and Discussion section.

$[K(H_2O)][VO_2(sal\text{-}sbdt)]$ (1): H_2sal-sbdt (0.604 g, 2 mmol) was dissolved in methanol (30 mL) containing KOH (0.056 g, 1 mmol), and $[VO(acac)_2]$ (0.53 g, 2 mmol) was added to this solution. The reaction mixture was refluxed on a water bath under aerobic condition for 6 h. After cooling to room temperature, 1 mmol of additional KOH was added, and the solution was kept for 2 days at ambient temperature to allow for slow evaporation of the solvent. The yellow precipitate thus obtained was filtered, washed with cold methanol and finally recrystallised from methanol to afford 0.40 g (45%) of crystalline complex **1**. $C_{15}H_{14}KN_2O_4S_2V$ (440 g·mol^{-1}): calcd. C 40.91, H 3.18, N 6.36; found C 40.89, H 3.23, N 6.42. ^{51}V NMR ([D$_6$]DMSO): δ = −468.0 ppm.

$[K(H_2O)_2][VO_2(Clsal\text{-}sbdt)]$ (2), and $[K(H_2O)_2][VO_2(Brsal\text{-}sbdt)]$ (3): Complexes **2** (0.439 g, 50% yield) and **3** (0.45 g, 42% yield) were prepared analogously to **1**, replacing H_2sal-sbdt by H_2Clsal-sbdt or H_2Brsal-sbdt. Both complexes were also recrystallised from methanol. Data for **2**: $C_{15}H_{15}ClKN_2O_5S_2V$ (492.5 g·mol^{-1}): calcd. C 36.55, H 3.05, N 5.69; found C 36.67, H 3.11, N 5.53. ^{51}V NMR: δ = −467.3 ppm. Data for **3**: $C_{15}H_{15}BrKN_2O_5S_2$ (537 g·mol^{-1}): calcd. C 33.52, H 2.79, N 5.21; found C 33.38, H 2.83, N 5.16. ^{51}V NMR: δ = −465.9 ppm.

Zn^{II} Complex with a Phenanthroline-Containing Macrocycle as Receptor for Amino Acids and Dipeptides − Hydrolysis of an Activated Peptide Bond

Carla Bazzicalupi,[a] Andrea Bencini,*[a] Emanuela Berni,[a] Antonio Bianchi,*[a] Patrizia Fornasari,[a] Claudia Giorgi,[a] and Barbara Valtancoli[a]

Keywords: Macrocyclic ligands / Zinc / Amino acids / Enzyme models / Stacking interactions

The interaction between several L-amino acids and dipeptides and the Zn^{II} complex with ligand L, a macrocycle containing a triamine chain linking the 2,9 positions of a phenanthroline moiety, has been studied by means of potentiometric and ^1H NMR spectroscopic measurements in aqueous solutions. In the $[ZnL]^{2+}$ complex, the metal ion displays an unsaturated coordination environment and the metal can act as a binding site for these substrates. Amino acids and dipeptides in their neutral (zwitterionic) form bind to Zn^{II} through the carboxylate function and, when in their anionic form, through the amine group. In this case the carbonyl of the amide function is probably also involved in metal coordination. Amino acids containing aromatic pendants form the most stable complexes, due to hydrophobic and/or π-stacking interactions between the aromatic subunits of the substrates and the phenanthroline moiety of the metal receptor. The hydrolytic properties of the Zn^{II} complex with L, involving the cleavage of the peptide bond, have been tested by using L-leucine-*p*-nitroanilide (LNA), which contains an activated peptide bond. This substrate forms stable $[ZnL(LNA)]^{2+}$ and $[ZnL(OH)(LNA)]^{+}$ complexes. The formation of the $[ZnL(OH)(LNA)]^{+}$ complex is followed by LNA hydrolysis, through a nucleophilic attack of the Zn–OH function on the peptide bond.

Introduction

Over the years a great deal of interest has focused on the role of metal ions in the active centers of hydrolytic metalloenzymes (e.g. phosphatase, amino- and carboxypeptidase, carbonic anhydrase, P1-nuclease).[1−15] Hydrolytic metalloenzymes generally contain one or more Zn^{II} ions in their active site. The catalytic role of zinc is generally ascribed to two main functions: i) binding and activation of the substrates, and ii) deprotonation of Zn^{II}-coordinated water molecules to give Zn−OH functions, which can act as nucleophiles in the hydrolytic mechanism. The catalytic site is often lodged in a hydrophobic pocket, which may contribute to substrate binding and can also assist in the formation of the nucleophilic Zn^{II}−OH functions.

Aminopeptidases are one of the Zn^{II} enzymes and contain either one or two zinc ions per active site and specifically hydrolyze the *N*-terminal residue of polypeptide chains, through a catalytic mechanism which involves coordination of the peptide function to zinc, followed by a nucleophilic attack of a Zn−OH group on the carbonyl carbon and cleavage of the peptide bond.[4,5,7,12−15]

As one of the approaches to the study of Zn^{II} enzymes, a number of synthetic Zn^{II} complexes have recently been used as simple model systems for hydrolytic enzymes.[16−50] Examples of functional models for aminopeptidases are less common, due to the marked hydrolytic inertness of the peptide bond to hydrolysis. Examples of Cu^{II},[17,18,51−53] Pt^{II},[54] Pd^{II},[55−57] Co^{III} [18,58] and Ce^{IV} [59] complexes able to cleave the peptide bond in aqueous solutions are known; peptide bond cleavage induced by Zn^{II} complexes has rarely been observed,[40] and occurs only at high temperature in aqueous solution, due to the low tendency of Zn^{II} to hydrolyze the amide bonds. As a matter of fact, binding of free Zn^{II} to peptides may even inhibit the cleavage of the peptide bond.[37]

We have recently reported on the synthesis of a series of phenanthroline-containing polyamine macrocycles,[60,61] such as L (Figure 1), able to form stable Zn^{II} complexes in aqueous solutions.[62]

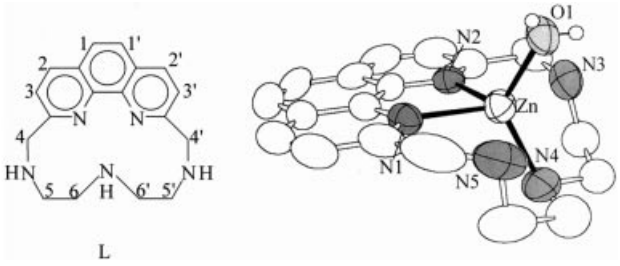

Figure 1. L drawing (with atom labelling used in NMR spectroscopic experiments) and crystal structure of the $[ZnL(H_2O)]^{2+}$ cation.

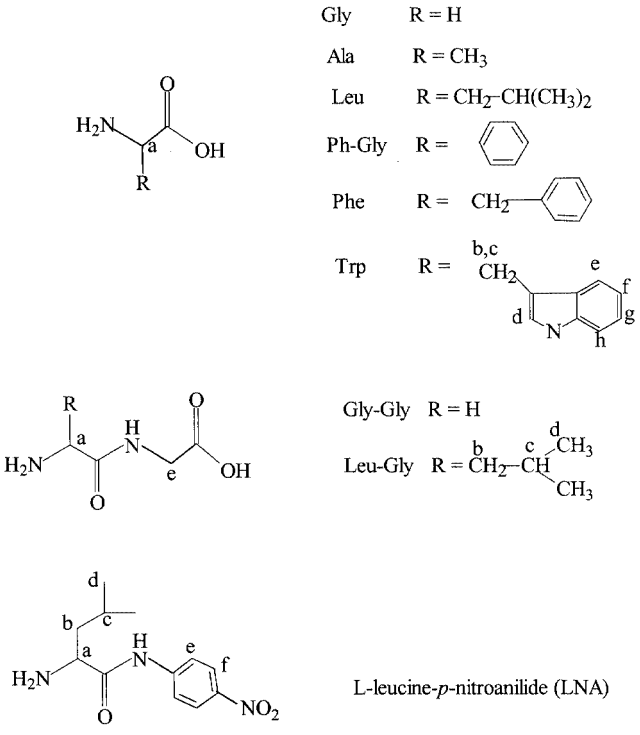
The rather high stability of the complexes is mainly due to the heteroaromatic nitrogens, which can offer an optimal binding site for the metal ion. At the same time, the rigidity of the phenanthroline unit does not allow for the involvement of all the aliphatic amine groups in the metal binding. Actually, the crystal structure of the $[ZnL(H_2O)]^{2+}$ cation (Figure 1) shows a Zn^{II} coordination environment not saturated by the ligand donors, since the two benzylic nitrogens are not involved in metal binding.[62] A water molecule is coordinated to Zn^{II}, to give an almost tetrahedral coordination environment for the metal. The presence of "free" binding sites at the Zn^{II} ion makes this complex a promising metallo-receptor for substrate molecules.

A solution study showed that the coordinated water molecule deprotonates at a slightly alkaline pH to give a $Zn^{II}-OH$ function. A dihydroxo complex $[ZnL(OH)_2]$ is also formed at an alkaline pH. Finally, phenanthroline can generate a rather hydrophobic environment for the metal. These characteristics make this complex a potential candidate for a model system of hydrolytic enzymes.

With this in mind, we decided to investigate the effective binding properties of this complex for amino acids and dipeptides as well as its hydrolysis of a peptide bond. The substrates involved in this study, along with the atom labeling used in the NMR spectroscopy experiments, are shown in Scheme 1.



Scheme 1

Results and Discussion

Crystal Structure of $[ZnL(HGly)]_2(ClO_4)_4 \cdot 1.5H_2O$

The crystal structure consists of $[ZnL(HGly)]^{2+}$ cations, perchlorate anions and water solvent molecules. The $[ZnL(HGly)]^{2+}$ cation contains the amino acid in its neutral form, herein indicated by HGly. The asymmetric unit contains two $[ZnL(HGly)]^{2+}$ independent cations. The ORTEP[63] drawings of the two $[ZnL(HGly)]^{2+}$ cations (herein indicated A and B) with atom labelling are shown in Figure 2 and Table 1 lists selected bond angles and distances for the coordination sphere of Zn^{II}. The coordination environment for the Zn^{II} ion is almost equal in both the A and B cations and can be described as a distorted tetrahedron. In complex A, the Zn1 ion is coordinated by the N1 and N2 heteroaromatic nitrogens, the central N4 amine of the aliphatic chain and the O1g oxygen of the carboxylate group of the amino acid.

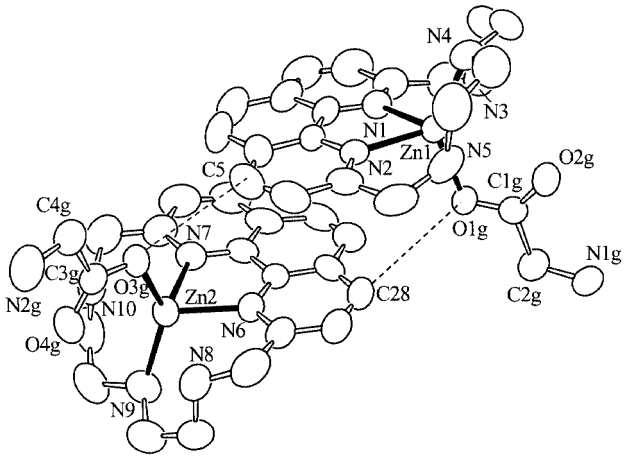


Figure 2. ORTEP drawing of the $[ZnL(HGly)]^{2+}$ complex, representing the A and B independent units coupled by π-stacking and C–H···O hydrogen bond interactions

Table 1. Bond lengths [Å] and angles [°] for the metal coordination environment in the A and B cations of $[ZnL(HGly)]_2(ClO_4)_4 \cdot 1.5H_2O$

A Unit			
Zn1–O1g	1.989(4)	Zn1–N1	2.165(5)
Zn1–N2	2.171(5)	Zn1–N4	2.094(6)
O1g–Zn1–N1	103.79(19)	N1–Zn1–N2	74.64(19)
O1g–Zn1–N2	104.79(17)	N4–Zn1–N1	110.5(2)
O1g–Zn1–N4	135.5(2)	N4–Zn1–N2	110.9(2)
B unit			
Zn2–O3g	1.990(4)	Zn2–N7	2.167(5)
Zn2–N6	2.150(5)	Zn2–N9	2.095(6)
O3g–Zn2–N6	104.83(18)	N6–Zn2–N7	75.0(2)
O3g–Zn2–N7	104.42(19)	N9–Zn2–N6	110.7(2)
O3g–Zn2–N9	136.1(2)	N9–Zn2–N7	109.0(2)

The Zn–N bond lengths are in the range 1.99–2.17 Å. Their values are typical for Zn^{II} complexes with polyamine compounds. The benzylic nitrogens N3 and N5 are not coordinated, lying far apart from the metal ion [Zn1···N3 2.440(6) Å, Zn1···N5 2.448(7) Å].

In complex B, the Zn2 ion is coordinated by three donor atoms of the ligand molecule (N6, N7 and N9) and the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

O3g oxygen atom of glycine, while the N8 and N10 benzylic nitrogen atoms are not coordinated (Table 1).

It is worth noting that, in both $[ZnL(HGly)]^{2+}$ independent cations, the amino acid is in its zwitterionic form. In both A and B complexes, the C−O bond lengths of the carboxylic group of HGly are equal within their e.s.d. [C1g−O1g 1.234(8) Å, C1g−O2g 1.238(8) Å, C3g−O3g 1.259(7) Å, C3g−O4g 1.226(8) Å], indicating that this group is in its anionic form. The unbound amine group is therefore protonated. Such a monodentate binding mode of Gly is rather common for amino acids in their zwitterionic form.[24−26,35−37,64]

In both A and B, the coordination geometry of the metal ion is very similar to that found in the crystal structure of $[ZnL(H_2O)](ClO_4)_2$. Actually, in the present structure an oxygen donor of the carboxylate unit simply replaces the Zn^{II}-coordinated water molecule of $[ZnL(H_2O)](ClO_4)_2$. The overall conformation of the ligand is also similar in the two complexes. As already found in $[ZnL(H_2O)]^{2+}$, the ligand is folded along the line connecting the benzylic nitrogen atoms, giving rise to dihedral angles of 82.4(3)° (A complex) and 84.5(3)° (B complex) between the mean planes defined respectively by the benzylic nitrogen atoms and the aromatic unit (max deviations 0.15(1) Å for C8 in the A complex and 0.154(8) Å for C25 in the B complex) and by the three secondary nitrogen atoms of the aliphatic chains.

Inspection of the crystal packing reveals the presence of π-stacking interactions between the phenanthroline moiety of the two independent cations. As shown in Figure 2, the two heteroaromatic groups are almost parallel [the dihedral angle between the planes containing the aromatic groups is 7.1(2)°] and lie 3.55 Å apart from each other. In addition, two H-bonding interactions between a C−H aromatic carbon atom of each complex and a carboxylate oxygen atom belonging to the other [C5···O3g 3.34(1) Å and C28···O1g 3.412(9) Å] contribute to the molecular pairing.[65]

Binding of L-Amino Acids and L-Dipeptides to the Zn^{II} Complex Containing L

The binding of the amino acids glycine (HGly), L-phenylglycine (Hph-Gly), L-alanine (HAla), L-phenylalanine (HPhe), L-leucine (HLeu) and L-tryptophan (HTrp) to the $[ZnL]^{2+}$ complex was studied by means of potentiometric and ^1H NMR spectroscopic measurements in aqueous solutions; the results of the potentiometric investigation are reported in Table 2.

Table 2. Equilibrium constants for the addition of L-amino acids to the Zn^{II} complex with the ligand L (NMe_4NO_3 0.1 M, 298 K).

Reaction	log *K*					
	Gly	*ph-Gly*	*Ala*	*Phe*	*Leu*	*Trp*
$[ZnL]^{2+} + A^- = [ZnL(A)]^+$	2.96(4)	3.61(3)	2.95(4)	3.83(4)	2.11(4)	5.12(6)
$[ZnL]^{2+} + AH = [ZnL(AH)]^{2+}$	2.58(4)	2.71(5)	2.43(2)	2.79(3)	−	3.71(3)
$[ZnL(OH)]^+ + A^- = [ZnL(OH)(A)]$						5.02(6)

All of the amino acids under investigation, with the exception of leucine, interact with the $[ZnL]^{2+}$ complex, both in their neutral and deprotonated forms, herein indicated as HA and A^-, respectively, to give the $[ZnL(HA)]^{2+}$ and $[ZnL(A)]^+$ species (Table 2). Among the six amino acids, leucine gives the weakest interaction, and only the complex with its deprotonated form is formed in aqueous solutions. On the contrary, tryptophan gives the strongest interaction with $[ZnL]^{2+}$. Figure 3 shows the distribution diagram of complexes formed by tryptophan in the presence of our Zn^{II} complex. The formation of the complex with the zwitterionic form of the amino acid $[ZnL(HTrp)]^{2+}$ occurs at an acidic pH and is followed by deprotonation of the amino acid at neutral pH to give the [ZnL(Trp)] complex. In this case a third species, $[ZnL(Trp)OH]^+$, is found at an alkaline pH.

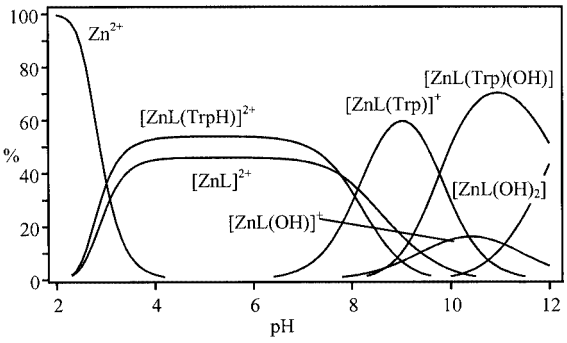

Figure 3. Species distribution diagram for the system $[ZnL]^{2+}$/Trp in 1:1 molar ratio (NMe_4NO_3 0.1 M, 298 K).

The data in Table 2 clearly outline that the stability of the complexes of our metallo-receptor with the neutral form of amino acids (HA) is lower than that found with their anionic form (A^-). A similar behavior was found for the addition of amino acids to the "free" Zn^{II} ion; it is generally accepted that coordination to Zn^{II} involves the anionic carboxylate function in the $[Zn(HA)]^{2+}$ complex and both the carboxylate and the amine groups, with the formation of a six-membered chelate ring, in the deprotonated $[Zn(A)]^+$ complex.[35−37,47,64] To shed further light on the binding mode of amino acids to our Zn^{II} complex we recorded ^1H NMR spectra at different pH values. Figure 4 (a) shows the pH dependence of the Trp signals in the presence and in the absence of our Zn^{II} complex, while Figure 4 (b) shows the ^1H NMR spectrum of a D_2O solution containing $[ZnL](ClO_4)_2 \cdot H_2O$ and tryptophan in a 1:1 molar ratio at pH 9.3, where the $[ZnL(Trp)]^+$ is the prevalent species in solution, compared with those of deprotonated tryptophan (Trp^-) and $[ZnL]^{2+}$.

As shown in Figure 4(a), the formation of the $[ZnL(HTrp)]^{2+}$ complex in the pH range 3−7 does not lead to a significant variation in the chemical shifts of the ^1H NMR signals of the protons in the α-position to the carboxylate and the amine function (*a* in Scheme 1) with respect to the same signals of the amino acid HA (prevalent in solution in the pH range 3−8), where the acidic proton is located on the amine group. This would indicate that in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

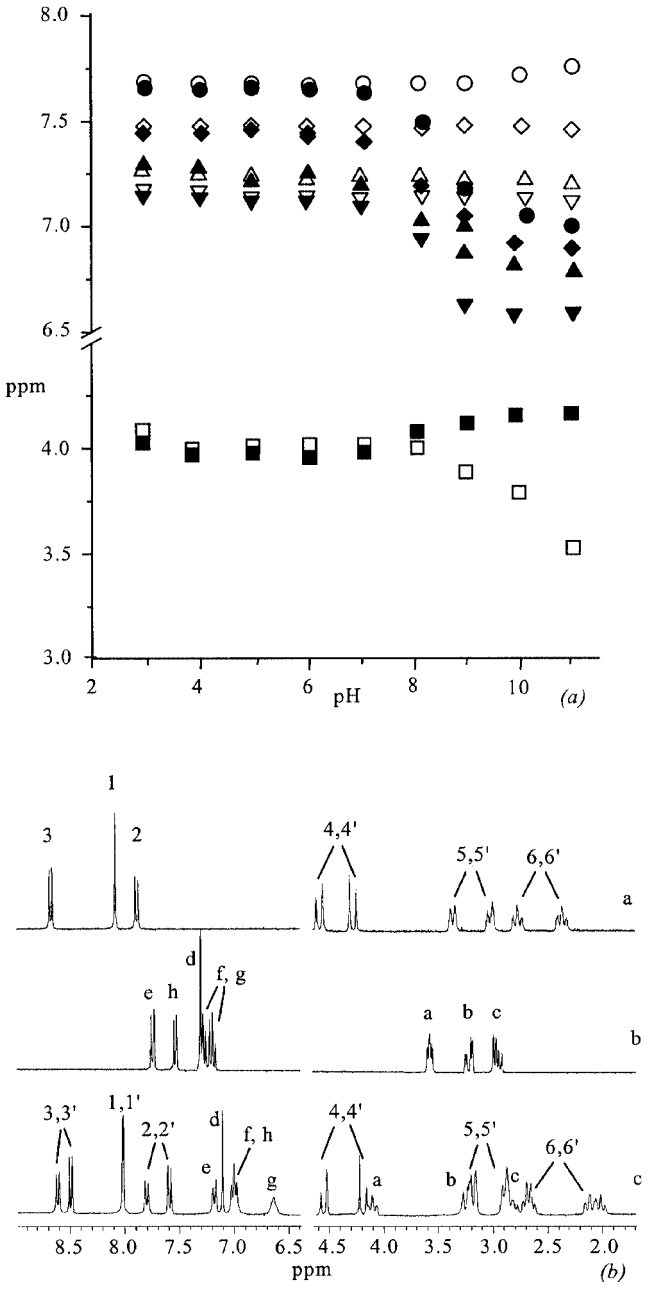

Figure 4. (*a*): pH dependence of the ^1H NMR chemical shifts of selected protons of Trp in the absence (□: a proton; ▽: g; △: f; ◇: h; ○: e). and in the presence of the Zn^{II} complex with L (■: *a* proton; ▼: *g*; ▲: *f*; ◆: *h*; ●: *e*). The signals of the protons *b*, *c* and *d* are omitted for clarity. (*b*): ^1H NMR spectra of $[ZnL]^{2+}$ (a), Trp^- (b) and $[ZnL(Trp)]^+$ (pH, 9.3) (c). See Scheme 1 and Figure 1 for the labelling used.

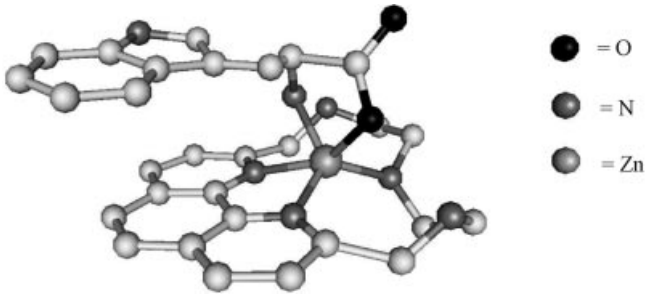
$[ZnL(HA)]^{2+}$ the acidic proton localization is not changed by HA binding to zinc and, therefore, HA coordination takes place through the carboxylate group, while the amine remains protonated. This hypothesis is corroborated by the crystal structure of the $[ZnL(HGly)]^{2+}$ cation, which shows the metal coordinated by one oxygen atom of the carboxylate function, while the amine group is protonated.

At an alkaline pH, the *a* signal of tryptophan alone shifts upfield, due to deprotonation of the amine group. On the contrary, the formation of the $[ZnL(Trp)]^+$ complex above pH 7 leads to a minor, but significant, downfield shift of the *a* resonance [Figure 4 (a)]. Similar downfield shifts for the signal of the *a* protons are also found for all the amino acids under investigation [up to 0.4 ppm in the case of Trp, see Figure 4 (b)]. This indicates the involvement of the NH_2 group in Zn^{II} binding. However, a bidentate coordination mode of the deprotonated amino acids, involving both the amine and the carboxylate functions, has generally been found in binary and ternary Zn^{II} complexes with these substrates,[24−26,35−37,47,64] and can be presumed to a reasonable extent in the present case.

The most interesting finding in Table 2 is the higher stability of the adducts with amino acids containing an aromatic side arm. In particular, tryptophan, which contains the largest aromatic subunit, indole, shows addition constants to the $[ZnL]^{2+}$ complex that are two orders of magnitude higher than Gly, Ala or Leu. This is rather surprising, since the addition constants of Gly or Ala to the "free" Zn^{II} ion are somewhat higher than those reported for ph-Gly, Phe and Trp.[66] Figure 4 (a) also shows that the formation of the $[ZnL(Trp)]^+$ complex remarkably affects the spectrum of the indole units, with a marked upfield shift of the signals of the aromatic protons with respect to the corresponding signals of "free" Trp^-. At the same time, the phenanthroline subspectrum displays a dramatic loss of symmetry. Besides the downfield shift of the *a* signal of the $[ZnL(Trp)]^+$ complex, discussed above, Figure 4 (b) displays a splitting into two doublets of each signal of the protons 2 and 3. The singlet attributed to 1 is also split into a doublet. Similarly to the indole resonances, the signals of the phenanthroline protons show a marked upfield shift with respect to the corresponding signals in $[ZnL]^{2+}$.

These spectral characteristics account for the presence of π-stacking interactions between phenanthroline and the aromatic pendant arm of Trp (Scheme 2), which can contribute to the stability of the complex.



Scheme 2

In the case of Phe and ph-Gly, substrate complexation by $[ZnL]^{2+}$ is also accompanied by upfield shifts of the resonances of the aromatic protons of the substrates and phenanthroline. The shifts, however, are generally smaller (ca. 0.1−0.2 ppm) than those observed for Trp and no loss of symmetry was found for the phenanthroline unit. This accounts for a reduced π-stacking pairing between the phenyl units and phenanthroline. Accordingly, the stability of the Phe and ph-Gly complexes is lower than that of the Trp complex.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Interestingly, no significant shift of the signals of the aromatic protons are observed at acidic pH, where the complexes with the protonated forms (HA) of the amino acids are present in solution [Figure 4(a)]. This experimental observation points out that the pairing between the two aromatic moieties is disrupted by coordination to Zn^{II} through the carboxylate function, due to protonation of the amine group in the $[ZnL(HA)]^{2+}$ complex.

Similar π-stacking interactions have already been observed by Sigel et al. in the case of ternary metal complexes[67,68] involving Trp and dipyridine or ATP. In the latter case the indole unit of Trp and the adenine moiety of the nucleotide are paired *via* π-stacking.[67] Yamauchi et al. also found intramolecular stacking interactions in Cu^{II} ternary complexes with Trp and dipyridine or phenanthroline, both in solution and in the solid state.[47][69−72]

In conclusion, our Zn^{II} complex may behave as a multifunctional receptor for amino acids, presenting two distinct binding sites, i.e., the metal center, which forms coordination bonds with amino acids, and the heteroaromatic unit, which can give stabilizing hydrophobic and/or π-stacking interactions with the aromatic portion of the substrates. These interactions lead to an unusual selectivity pattern in amino acid binding by our Zn^{II} complex, since the amino acids with aromatic pendant arms are strongly bound with respect to the aliphatic amino acids Gly or Ala.

In order to evaluate the effective binding properties of our complex towards the peptide amide group, we decided to extend our analysis to dipeptides. Unfortunately, most of the dipeptides tested, such as tryptophan-containing dipeptides, form low soluble complexes with $[ZnL]^{2+}$. Our study was therefore limited to L-glycylglycine (HGly-Gly) and L-leucylglycine (HLeu-Gly). Table 3 reports the equilibrium constants for the addition of these dipeptides to the $[ZnL]^{2+}$ complex in aqueous solution.

Table 3. Equilibrium constants for the addition of Gly-Gly and Leu-Gly to the Zn^{II} complex with the ligand L (NMe_4NO_3 0.1 M, 298 K).

Reaction	log *K*	
	Gly-Gly	*Leu-Gly*
$[ZnL]^{2+} + A^- = [ZnL(A)]^+$	2.84(9)	3.91(4)
$[ZnL]^{2+} + HA = [ZnL(AH)]^{2+}$	1.9(1)	3.06(2)
	pK_a	
$[ZnL(A)]^+ + H_2O = [ZnL(A)(OH)] + H^+$	8.77(6)	8.95(3)

The formation of the complex with the neutral form of the dipeptide ($[ZnL(HLeu\text{-}Gly)]^{2+}$) at acidic pH is followed by deprotonation of the substrate to give $[ZnL(Leu\text{-}Gly)]^+$ at a slightly alkaline pH. A further deprotonation step is monitored above pH 9. This process could be attributed, in principle, to deprotonation of the amide function to give the $[ZnL(Leu\text{-}GlyH_{-1})]^+$ complex or to deprotonation of a coordinated water to give a hydroxylated ternary complex. Gly-Gly shows similar binding features towards $[ZnL]^{2+}$ (Table 3). As already found in the case of binding amino acids, the addition constants of the deprotonated dipeptides to the $[ZnL]^{2+}$ complex are about one order of magnitude higher than those of the dipeptides in their neutral (zwitterionic) form. To clarify the binding mode of these dipeptides to Zn^{II}, we decided to record ^1H NMR spectra on solutions containing the dipeptides in the presence of $[ZnL]^{2+}$ at different pH values. The formation of the $[ZnL(HLeu\text{-}Gly)]^{2+}$ complex at pH 5 does not significantly change the spectrum of the dipeptide in its neutral form, which contains a protonated amine and a carboxylate group in its anionic form. Only a minor shift (ca. 0.05 ppm) of the CH_2 protons in the α-position to the carboxylate group is observed. As in the case of amino acids, this may suggest that in $[ZnL(HLeu\text{-}Gly)]^{2+}$ the dipeptide is coordinated to Zn^{II} through the carboxylate group, while the amine group still remains protonated. On the contrary, the comparison of the ^1H NMR spectra of the anionic form of the Leu-Gly dipeptide in the absence and in the presence of our $[ZnL]^{2+}$ complex at pH 8.5 shows that the formation of the $[ZnL(Leu\text{-}Gly)]^+$ species leads to a marked upfield shift of the signal of the proton in the α-position (*a* in Scheme 1) to the carbonyl carbon atom and the deprotonated NH_2 group (Figure 5).

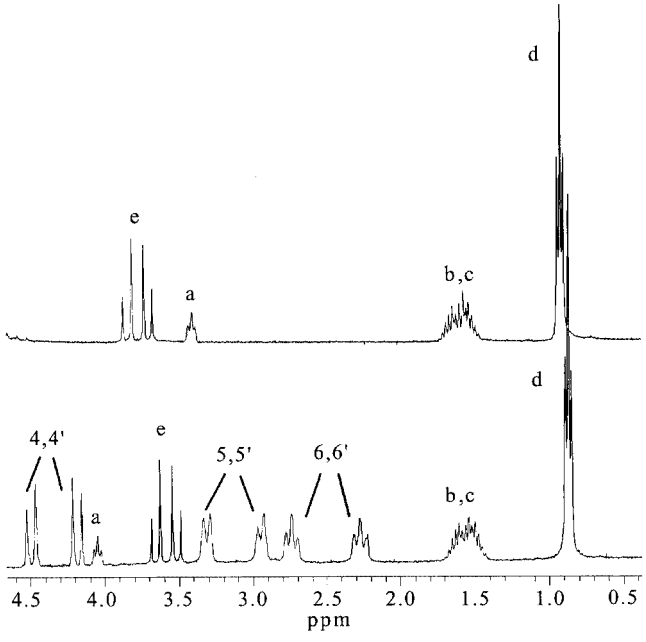


Figure 5. ^1H NMR spectra of Leu-Gly$^-$ (a) and $[ZnL(Leu\text{-}Gly)]^+$ (pH, 8.5) (b). (See Scheme 1 and Figure 1 for the labelling used).

A similar behavior is also found in the case of Gly-Gly. As already proposed in the case of amino acids, the potentiometric and ^1H NMR spectroscopic data suggest that Leu-Gly, in its anionic form, binds to Zn^{II} by using the amine group. However, the coordination of the amide carbonyl function in metal binding can also be supposed, in agreement with the binding mode generally found for dipeptides to Zn^{II} alone as well as in ternary Zn^{II} complexes.[35−37] The deprotonation process observed in the pH range 9−12 does not significantly alter the ^1H NMR spectrum of coordinated Leu-Gly$^-$, suggesting that the de-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

protonation process involves a coordinated water molecule to give a [ZnL(Leu-Gly)(OH)] complex.

The latter complex contains both a Zn^{II}-coordinated dipeptide and a Zn−OH function, as a potential nucleophile in a hydrolytic process. On the other hand, dipeptide hydrolysis in the presence of our model complex is too slow to be confidently followed at a physiological temperature. This observation prompted us to test the effective hydrolytic ability of our Zn^{II} complex by using L-leucine-*p*-nitroanilide (LNA), a substrate containing an activated peptide bond.

L-Leucine-*p*-nitroanilide (LNA) Binding and Hydrolysis by the Zn^{II} Complex Containing L

LNA, a substrate generally used to test the hydrolytic ability of leucine-aminopeptidases involving the *N*-terminal peptide bond,[73] behaves as a weak base (log K = 7.37(3) for the equilibrium LNA + H^+ = $LNAH^+$ at 308.1 K) and can also cause deprotonation at a strongly alkaline pH to give a $[LNA(H_{-1})]^-$ species (pK_a = 10.6).

LNA binding by $[ZnL]^{2+}$ was studied by means of potentiometric and ^1H NMR spectroscopic experiments at 308.1 K.[74] The $[ZnL]^{2+}$ complex forms rather stable adducts with this substrate, with a log K value of 5.55 for the equilibrium $[ZnL]^{2+}$ + LNA = $[ZnL(LNA)]^{2+}$. A small interaction is also detected with the protonated form of the substrate $HLNA^+$ {log K = 2.1 for the equilibrium $[ZnL]^{2+}$ + $HLNA^+$ = $[ZnL(HLNA)]^{3+}$}. Finally, the potentiometric measurements show that the $[ZnL(LNA)]^{2+}$ complex releases a single proton at pH > 8 to give a deprotonated species.[74] Once again, this process could be ascribed to deprotonation of the amide group of LNA, giving a complex, or a metal-bound water molecule, yielding, respectively, a $[ZnL(LNAH_{-1})]^+$ or a $[ZnL(LNA)(OH)]^+$ species. The distribution diagram, derived from the potentiometric measurements (Figure 6) shows that the formation of the $[ZnL(LNA)]^{2+}$ complex, in the pH range 4−7, is followed by complex deprotonation in the pH range 8−10.

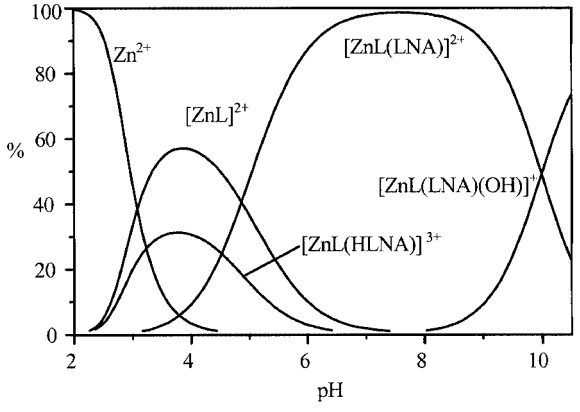

Figure 6. Species distribution diagram for the system $[ZnL]^{2+}$/LNA in 1:1 molar ratio (NMe_4NO_3 0.1 M, 308.1 K).

Figure 7 (a) displays the ^1H chemical shifts of selected protons of LNA in the presence and in the absence of the Zn^{II} complex with L at different pHs, while Figure 7 (b) shows the ^1H NMR spectroscopic chemical shift of the $[ZnL(LNA)]^{2+}$ complex, compared with those of LNA and $[ZnL]^{2+}$.

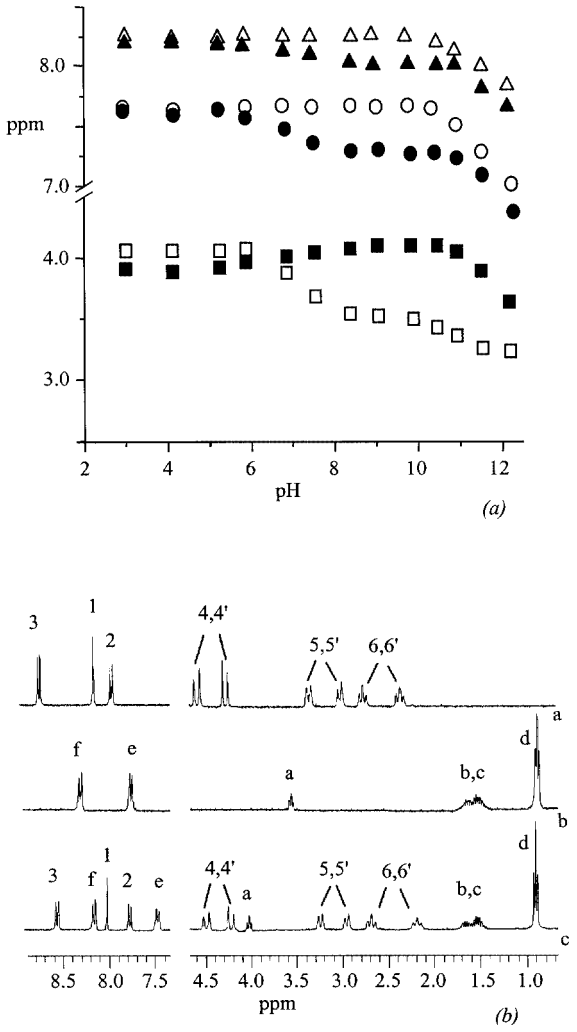

Figure 7. (*a*) pH dependence of the ^1H NMR chemical shifts of selected protons of LNA in the absence (□: *a* proton; △: f; ○: e). and in the presence of the $[ZnL]^{2+}$ complex (■: *a* proton; ▲: *f*; ●: *e*). The signals of protons *b*, *c* and *d* are omitted for clarity. Their chemical shift does not significantly change in the pH range investigated. (*b*) ^1H NMR spectra of $[ZnL]^{2+}$ (a), LNA (b) and $[ZnL(LNA)]^{2+}$ (pH, 7.5) (c). (see Scheme 1 and Figure 1 for the labelling used).

The signal of the *a* proton of "free" LNA displays an upfield shift in the pH range 6−8.5, resulting from the deprotonation of the amine group of $HLNA^+$ to give the neutral LNA form. The ^1H signals of the aromatic protons, on the other hand, do not significantly shift, up to pH 10. LNA deprotonation above pH 10 yields the $[LNA(H_{-1})]^-$ anion, which is accompanied by a marked upfield shift of the aromatic protons *e* and *f*. [Figure 7 (a)]. In the presence of Zn^{II}, the formation of the $[ZnL(LNA)]^{2+}$ complex in the pH range 4−7 (see Figure 6) gives rise to a slight, but significant, downfield shift of the *a* resonance. Actually, the *a* signal in $[ZnL(LNA)]^{2+}$ is ca 0.5 ppm downfield shifted with respect to that of unbound LNA [Figure 7 (b)].

These observations are indicative of the involvement of the amine group in metal coordination. Although these

NMR spectroscopic data do not allow conclusions to be inferred as to the role of the peptide bond in metal binding, the rather high value of the equilibrium constant for the addition of LNA to the Zn^{II} complex and the analogies of the LNA structure with amino acids and dipeptides, leads to the supposition that the carbonyl oxygen of the amide function is also involved, or partially involved, in Zn^{II} binding, with the formation a stabilizing six-membered chelate ring. Figure 7 (a and b) also shows that both the phenanthroline and phenyl protons are upfield shifted above pH 5, where the $[ZnL(LNA)]^{2+}$complex occurs, due to π-stacking and hydrophobic interactions between the aromatic units of metallo-receptor and substrate. Therefore, as already observed in the binding of the amino acids, our Zn^{II} complex behaves as a multifunctional binding site for LNA, since both coordination bonds and supramolecular interactions contribute to the complex stability.

According to Figure 6, the $[ZnL(LNA)]^{2+}$ complex deprotonates in the pH range 8−10; the ^1H NMR signals of coordinated LNA do not shift appreciably in this pH region [Figure 7(a)], indicating that deprotonation occurs on a coordinated water molecule, with the formation of the $[ZnL(LNA)(OH)]^{+}$ hydroxo complex.

Although the potentiometric measurements do not reveal the formation of other complexes between LNA and $[ZnL]^{2+}$in the pH range investigated (2.5−10.5), the analysis of the ^1H NMR spectra of LNA recorded at a strongly alkaline pH (pH >10.5) in the presence of $[ZnL]^{2+}$ reveals a marked upfield shift of the signals of the *a*, *e* and *f* protons [Figure 7 (a)]. A similar upfield shift is also observed at a strongly alkaline pH for the corresponding signals of "free" LNA, due to deprotonation of the amide function to give the *N*-deprotonated $[LNA(H_{-1})]^{-}$ species. This comparison suggests that the $[ZnL(LNA)(OH)]^{+}$ complex undergoes deprotonation in strongly alkaline solutions to give a neutral $[ZnL(LNAH_{-1})(OH)]$ complex. A similar complex, containing a *N*-deprotonated LNA unit coordinated to a Zn^{II} complex has recently been characterized by Vahrenkamp et al.[26] Our attention, however, was focused on the $[ZnL(LNA)(OH)]^{+}$ complex, which contains a Zn^{II}-coordinated neutral LNA molecule and a Zn−OH function, in close proximity, as a potential nucleophile for cleavage of the peptide bond.

Indeed, the $[ZnL(LNA)(OH)]^{+}$ complex promotes LNA hydrolysis in aqueous solution at 308.1 K to give L-leucine and *p*-nitroanilide. The hydrolysis products were identified by means of ^1H NMR spectroscopic measurements. Pseudo-first order rate constants k_{LNA} have been determined at different pH values for the complex. In Figure 8 k_{LNA} values for the Zn-L complexes are reported as a function of pH, together with the distribution curve of the $[ZnL(LNA)(OH)]^{+}$ species at 308.1 K. A good fit between the k_{LNA} values and the distribution curve of the $[ZnL(LNA)(OH)]^{+}$ was found. No promoted hydrolysis was observed below pH 8, where the $[ZnL(LNA)(OH)]^{+}$ is absent from the solution. Accordingly, it can be concluded that the $[ZnL(LNA)(OH)]^{+}$ is the kinetically active species. We can propose a two-step hydrolytic mechanism where LNA is bound to the Zn^{II} complex, probably in a bidentate binding mode, which involves the peptide bond. Hydrophobic interactions also contribute to complex stabilization. Coordination of the peptide bond to the electrophilic Zn^{II} ion would activate the amide carbon atom leading to the subsequent intramolecular nucleophilic attack of the Zn-bound hydroxide or to intermolecular attack of hydroxide from the medium. On the other hand, the nucleophilic character of a Zn−OH function is only slightly lower than that of hydroxide.[75] At the same time, in $[ZnL(LNA)(OH)]^{+}$ the metal-bound hydroxide is close to the substrate. This suggests that the peptide bond cleavage occurs via an intramolecular pathway, as sketched in Scheme 3.

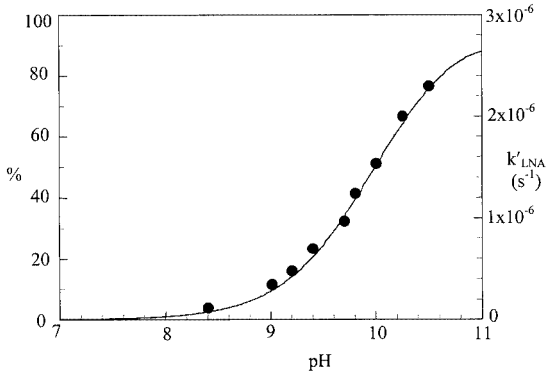

Figure 8. Plot of the distribution curve of $[ZnL(LNA)(OH)]^{+}$ (solid line, right *y* axis) and k_{LNA} values (●, left *y* axis) as a function of pH (0.1 M NMe_4NO_3, 308.1 K).

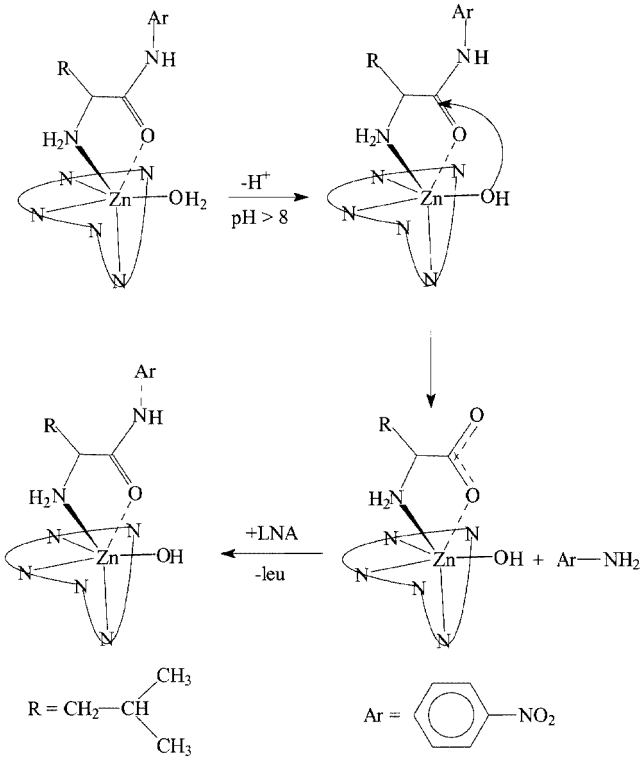

Scheme 3

The $[ZnL(LNA)(OH)]^+$ complex is formed in a yield of 70% percentage, at most, in the pH range used in the kinetic measurements (Figure 8). As a consequence, the first order rate constants, k'_{LNA}, have been determined from the maximum k_{LNA} value by using the following equation:

$$v = k_{LNA}[\text{total } Zn^{II} \text{ complex}] = k'_{LNA}\,[ZnL(LNA)(OH)^+]$$

By using this expression, a k'_{LNA} value of $3.0 \cdot 10^{-6}$ s^{-1} can be calculated. The hydrolysis rate is much lower than those reported for aminopeptidases,[73] but, at the same time, almost two orders of magnitude higher than the rate constant for spontaneous hydrolysis of LNA.

The addition constant of LNA to the $[ZnL]^{2+}$ is ca 3100 times higher than the corresponding constant of Leu; this consideration implies that LNA hydrolysis promoted by our Zn^{II} is free, for the major part, of inhibiting agents generated by its own hydrolysis, due to the replacement of Leu by the strongly bound LNA substrate in the coordination sphere of $[ZnL]^{2+}$.

The hydrolytic process is too slow at 308.1 K to determine the reaction turnover. However, an experiment carried out at 343.1 K and pH 9.7, with an excess of substrate showed that 1 equiv. of the complex can completely cleave as many as 11 equiv. of LNA.

Conclusion

The particular molecular topology of the phenanthroline-containing macrocycle L leads to an unsaturated coordination sphere of the metal in the $[ZnL]^{2+}$ complex. Therefore, the metal ion can behave as a binding site for substrate molecules and anions. Actually, the $[ZnL]^{2+}$ forms stable complexes with amino acids and dipeptides in their zwitterionic or anionic forms. The phenanthroline moiety can act as a further binding site for substrates containing aromatic pendants, through stacking and/or hydrophobic interactions, giving a peculiar selectivity pattern in amino acid binding. In some cases, a [ZnL(A)OH] species is also formed in aqueous solution. This species contains, in close proximity, both a coordinated substrate and a $Zn^{II}-OH$ unit, a potential nucleophile towards cleavage of the peptide bond. Our complex is indeed able to hydrolyze the peptide bond of the activated substrate L-leucine-*p*-nitroanilide (LNA). The cleavage process occurs in two successive steps i) substrate binding, through coordination bonds to Zn^{II} and stacking interactions and ii) nucleophilic attack of a Zn−OH function, formed at alkaline pH values. Although hydrolysis only occurs at alkaline pH values, this mechanism resembles that proposed for peptide hydrolysis by aminopeptidases.

In particular, selective recognition of amino acids, due to stabilizing π-stacking interactions, is a striking result; it could be used, in principle, for anchoring the complex onto a specific peptide bond of polypeptide chains. This effect, coupled with the hydrolytic properties of the Zn−OH function, encourage the development of other metal complexes with phenanthroline-containing ligands, with the purpose to generate more strongly nucleophilic M−OH functions in aqueous solutions.

Experimental Section

General Remarks: Ligand L and its Zn^{II} complex $[ZnL(H_2O)](ClO_4)_2$ were prepared as already described.[61][62] 300.07 MHz ^1H spectra in D_2O solutions at different pH values were recorded at 298.1 K in a Varian Unity 300 MHz spectrometer. Peak positions are reported relative to HOD at δ = 4.79 ppm. ^1H-^1H and ^1H-^{13}C 2D correlation experiments were performed to assign the signals. Small amounts of 0.01 mol dm^{-3} NaOD or DCl solutions were added to solutions containing the substrates and $[ZnL(H_2O)](ClO_4)_2$ to adjust the pD. The pH was calculated from the measured pD values using the following relationship:[76] pH = pD − 0.40

UV/Vis spectra were recorded on a Shimadzu UV-2101PC spectrophotometer.

Potentiometric Measurements: All the pH metric measurements (pH = −log $[H^+]$) were carried out in degassed 0.1 mol·dm^{-3} NMe_4NO_3 solutions, at 298.1 or 308.1 K, by using the equipment and procedure that have already been described.[60] The combined Ingold 405 S7/120 electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free NMe_4OH solutions and determining the equivalent point by the Gran's method[77][78] which allows for the determination of the standard potential E^o, and the ionic product of water (pK_w = 13.83(1) at 298.1 K and 13.40(1) at 308.1 K in 0.1 mol·dm^{-3} NMe_4NO_3). All equilibria involved in the studied systems were determined, or redetermined,[79] under the present experimental conditions in order to obtain a consistent set of data. The concentration of $[ZnL(H_2O)](ClO_4)_2$ was 1×10^{-3} mol·dm^{-3} in all experiments, while the concentrations of the substrates were varied in the range $1 \times 10^{-3}-4 \times 10^{-3}$ mol·dm^{-3}. At least three measurements (about 150 data points for each) were performed for each system in the pH range 2.5−10.5 and the relevant e.m.f. data were treated by means of the computer program HYPERQUAD[79] that furnished the relevant equilibrium constants reported in Table 2 and 3.

Kinetics of Leucine-*p*-Nitroanilide (LNA) Hydrolysis: The hydrolysis rate of LNA in the presence of the Zn^{II} complexes with L to give Leu and *p*-nitroaniline was measured by an initial slope method following the increase in the 405 nm absorption of the released *p*-nitroaniline at 308.1 K. The molar absorbance of *p*-nitroaniline was determined at the pH of each measurement. The ionic strength was adjusted to 0.1 M with NMe_4NO_3. TAPS (pH, 7.8−8.9), CHES (pH, 8.9−9.7) and CAPS (9.7−10.5) buffers were used (50 mM). In a typical experiment, with LNA (2−5 mM) and $[ZnL(H_2O)](ClO_4)_2$ (0.5 mM) in aqueous solutions at the appropriate pH (the reference experiment does not contain the Zn^{II} complex) were mixed, the UV absorption decay was recorded immediately and was followed until 5% of *p*-nitroaniline had been formed.

At a given pH value, a plot of the hydrolysis rates vs. $[ZnL(LNA)(OH)^+]$ concentration, calculated at the different LNA concentrations, gave a straight line, allowing for the determination of the pseudo-first order rate constants k_{LNA} from the slope of the line. Errors on k_{LNA} values were about 5%.

X-ray Crystallographic Study: Crystals of $[ZnL(HGly)]_2(ClO_4)_4 \cdot 1.5H_2O$ were obtained by slow evaporation of an aqueous solution containing $[ZnL(H_2O)](ClO_4)_2$ and HGly in a 1:1 molar

XAS, ESR and Potentiometric Studies of Three Dinuclear *N,N′-para*-Xylylenebis(tetraazamacrocycle)copper(II) Complexes − X-ray Crystal Structure of [*N,N′-p*-Xylylenebis(cyclen)]copper(II)

Keywords: Copper / ESR spectroscopy / Macrocyclic ligands / Potentiometry / X-ray studies

Dicopper complexes with *N,N′-p*-xylylenebis(cyclam or cyclen) and with the heteroditopic *N,N′-p*-xylylenebis(cyclam-cyclen) were synthesized. An X-ray study of the *N,N′-p*-xylylenebis(cyclen)dicopper complex showed that the copper(II) ion is five-coordinate with an H_2O molecule in apical position. With this ligand, a polymeric chain was also obtained in the presence of KSCN. The terminal donor atoms of the bridging NCS^- anion are coordinated in apical position to the square-pyramidal copper(II) ion. Two alternating kinds of Cu_2L^{4+} moieties are present in the chain, the first with two N_4S chromophores and the second with two N_5 chromophores. EXAFS and XANES results are in agreement with a five-coordinate copper ion in the cyclen unit and a six-coordinate copper ion in the cyclam unit. Thermodynamic constants were determined by potentiometry. The existence of dinuclear Cu_2L^{4+} species (ligand/metal ratio < 1) and mononuclear $CuLH_n^{(2+n)+}$ species (ligand/metal ratio > 1) were confirmed by an ESR study at variable pH.

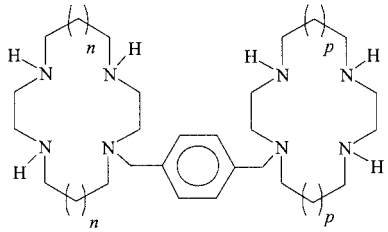
Introduction

Since the early 1960s, homodinuclear macrocyclic complexes have been studied extensively.[1] The interest in such dinuclear complexes stems from different particularities. Fundamentally, the presence of two metal centres not too far away from one another can induce interactions that can influence the complex's magnetic or redox properties. These complexes have been used in the development of two-centred metal catalytic reagents.[2] Moreover, these dimacrocyclic complexes may serve as models for the charge transfer, electron transport, and allosteric behaviour found in many metal-containing biochemical systems.[3,4] Besides their fundamental interest, these ligands and complexes are also used in anti-HIV drugs, in particular, the *m*- or *p*-xylylenebis(cyclam)[5−7] (referred to as AMD 2986 and AMD 3100, respectively) and the *p*-xylylenebis(cyclen)dizinc complexes[8] are implicated in the inhibition of particular HIV strains with low levels of cytotoxicity.

The coordination of bis(macrocycles) containing two covalently, potentially chelating subunits has been studied intensively in recent years.[9] Cyclam and cyclen are involved in compounds with linkages between two nitrogen atoms or two carbon atoms. The bridge (alkanediyl chain or xylylene group) can modify the intermetallic distance and the orientation of the macrocyclic ring. Our purpose is the investigation of the copper(II) coordination with the little studied *p*-xylylenebis(*N,N′*-cyclam) or -bis(*N,N′*-cyclen) (Scheme 1).



*para*cyclen	$n = p = 0$
*para*cyclam-cyclen	$n = 1$ and $p = 0$
*para*cyclam	$n = p = 1$

Scheme 1

Except for the dizinc complex used in anti-HIV drugs, the metal complexes with these ligands have seldom been studied. With the *p*-xylylenebis(tetraazamacrocycles) ligands, the copper complexes have been described; Fabbrizzi et al.[10] only studied the mutual copper interaction by electrochemistry, while the intermetallic distances were esti-

mated by Guilard et al.[11] by ESR spectroscopy. These authors demonstrated the influence of different spacers linked to the two macrocycles on the electrochemical properties and on the Cu−Cu distances in these bis(tetraazamacrocycle) complexes. In addition, electrochemical aqueous solution studies and UV/Vis and ESR spectroscopic investigations have been carried out on other (tetraazamacrocycle)copper complexes such as bis(isocyclam)[12] and spirocyclam.[13] Kinetic phenomena are always present when a metallic ion is incorporated in a tetraazamacrocycle[14] or in the tetraaza units of a bis(macrocycle).[15] Solution studies therefore have to be performed carefully, taking the kinetic of complexation of the tetraaza rings into account. Crystallographic data for this type of compounds are very scarce, and to the best of our knowledge, only the structure of a dinuclear copper(II) complex with two 1,4,7,10-tetraazacyclododecane units *N,N′*-bridged by 2,6-dimethyl-1-methoxybenzene[16] has been described in the literature.

In order to understand the behaviour of a ligand implicated in anti-HIV drugs, it was interesting to investigate the complexation of these ligands with a biologically interesting cation such as copper(II). These studies were made by combining potentiometry and ESR spectra, and taking kinetic phenomena into account. A heteroditopic bis(macrocyclic) ligand was also studied (see Scheme 1, *para*cyclam-cyclen ligand). Solid compounds were also prepared, but only complexes with *para*cyclen give crystals suitable for X-ray studies. The structures of monomeric (*para*cyclen)$Cu_2(ClO_4)_4$ and polymeric $[(para\text{cyclen})Cu_2]_2(SCN)_8$ chains induced by the potentially bidentate thiocyanate anion, have been reported. XAS results permitted the determination of the environment around the copper cation when a cyclam unit is present in the ligand.

Results and Discussion

Solution Studies

Ligand Protonation Constants

Protometric study of the three ligands allowed us to determine the protonation constants given in Table 1.

For each ligand, the first four constants follow the usual order, their values decreasing from K_1 to K_4; for the last one (K_4), both macrocycles are diprotonated. As far as the values of the last four constants (K_5 to K_8) are concerned, only some of them could be calculated, the others being too weak to be given with sufficient accuracy. In the case of the ligand *para*cyclam-cyclen, one inversion among these constants' values is observed ($K_7 > K_5$ and K_6).

Such an inversion in the order of the values of protonation constants has been reported previously[18] for cyclam, K_4 being greater than K_3 (Table 1). We also determined the protonation constants of cyclam, and our values are in good agreement with those previously obtained[18] especially if we take the differences in experimental conditions (ionic strength, temperature) into account. The inversion of the K_3 and K_4 constant values was attributed to a conformational modification of the cyclam accompanying its third protonation.[18] Consequently, whereas the addition of the third proton is difficult because of energetic requirements accompanying to the geometrical change, the addition of the fourth one is facilitated.

The same interpretation can be proposed for the successive protonations of *para*cyclam-cyclen. Constants K_5 and K_6 correspond to the attachment of a third proton on each of the two cycles, whereas constant K_7 corresponds to the attachment of a fourth proton on the cyclam cycle. As with the cyclam, the third protonation is difficult, which explains why the constant value K_5 is below that of K_7.

Copper Complexation Studies

The complexation kinetics of the macrocycles cyclen and cyclam are well-known pH-dependent phenomena. As a result, the batch method is often used in order to study the formation of the complexes in solution. However, we did not use this method in our experiments, since it requires a large quantity of product. We thus performed classical titrations, all our measures being made after waiting times, at constant initial pH, of 60, 90, and 120 d between the preparation of the solutions and the beginning of the titrations. All the titrations gave identical results.

Protometric titrations in the presence of copper were monitored by ESR at 150 K. Whatever the pH of the solution may have been, for ratios R = [ligand]/[metal] greater than 1, ESR spectra each give a signal of four equidistant lines, characteristic of the presence of mononuclear species. The obtained spectroscopic parameters $g_{\|}$ and $A_{\|}$ are very close to those of complexes formed with cyclam or cyclen[19]

(Table 2). For ratios R smaller than 1, the obtained ESR spectra each show a signal with seven equidistant lines, characteristic of the formation of dinuclear species.[11] The values of the $g_{\parallel}$ parameter are identical to those of the previous complexes, whereas the values of $A_{\parallel}$ are half those obtained for mononuclear complexes (Table 2). The complexes formed are therefore different, given the experimental conditions of the preparation of the solutions, but the copper environments in mono- or dinuclear complexes are similar to those of the copper ion in the cyclen or the cyclam complexes.

The stability constants of the complexes were calculated, taking only mononuclear species into account for ratios R greater than 1, and only dinuclear species for ratios R less than 1. This is in agreement with the ESR study. The values of the global constants of formation are presented in Table 3.

[a] Values in parentheses represent 2σ standard deviation. [b] Ref.[17]

In the case of the dinuclear species Cu_2L^{4+}, on the one hand, the complexation of two copper(II) ions by the four nitrogen atoms of each cycle induces the complete deprotonation of the ligand. On the other hand, in the case of mononuclear complexes $CuLH_n^{(n+2)+}$, the copper ion is engaged only in one macrocycle, and we obtain three complexation constants, corresponding to the formation of $CuLH_2^{4+}$ and then to the deprotonation of two nitrogen atoms from the non-complexed cycle (see distribution curves Figure 1).

The stability constants obtained are all very high, so the complexes formed are very stable. The values of the logarithms of the constants β_{110} of the complexes CuL^{2+} formed

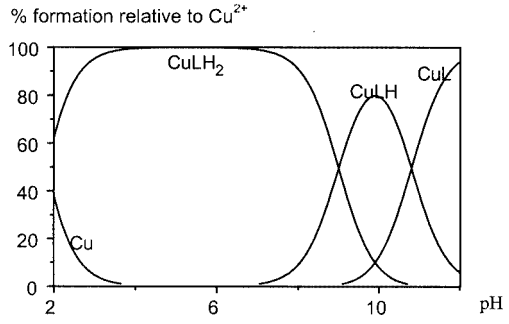

Figure 1. Distribution curves for the mononuclear (*para*cyclen)copper(II) complexes (R = [ligand]/[metal] > 1)

with the three bis(macrocycles) are in the same range as those of complexes CuL^{2+} formed with cyclen or cyclam. Similarly, we observe that the values of the logarithms of the constants β_{210} of the dinuclear complexes Cu_2L^{4+} are twice as high as those of the CuL^{2+} complexes. As a result, the two macrocyclic cavities of the ligands indeed seem to be independent of one another with regard to the complexation phenomenon. Lastly, in the case of mononuclear complexes formed with the *para*cyclam-cyclen ligand, the ESR spectra and the values of the stability constants of the complexes do not allow us to locate the metallic cation in the cyclen or cyclam cavity.

For each ligand, the electronic spectra of solutions with different ratios (R = 2, 1, and 0.5) were plotted between pH = 2 and 11. For the *para*cyclen and *para*cyclam ligands, the spectra of the mono- and dinuclear complexes each show only one absorption band, the position of which remains unchanged whatever the pH may be.

In the case of *para*cyclen, the band is located at a wavelength (λ = 594 nm) very close to that noted for the complex $[Cu(cyclen)(H_2O)]^{2+}$ (λ = 599 nm).[20] The geometries of the complexes formed with cyclen and *para*cyclen are identical; they are pentacoordinated complexes with square-base-pyramidal geometries. The four nitrogen atoms of the macrocycle form the base of each pyramid, whereas a water molecule occupies the fifth position.[19]

For the complex formed with *para*cyclam, the position of the band (λ = 528 nm) is similar to those in complexes formed with different ligands derived from cyclam (512 nm

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$< \lambda <$ 550 nm).[19,21] This value is typical of the square-planar CuN_4 chromophore with a strong ligand field.[22] However, the 14-membered cyclam has a ring large enough to surround a range of metal ions, and its complexes generally adopt the strain-free, thermodynamically more stable *trans*-III (*R*,*S*,*S*,*R*) conformation, in which the metal ion is indeed inside the ring of the macrocycle in a square-planar structure, with two adjacent NH hydrogen atoms directed towards one side of the macrocycle plane and the other two in the opposite direction.[23]

In the case of the *para*cyclam-cyclen ligand, the spectra obtained for the dinuclear complex Cu_2L^{4+} ($R < 1$) show only one wide band at $\lambda = 578$ nm, a position intermediary between those noted for the cyclam and cyclen complexes. The spectrum calculated as the sum of the spectra of the *para*cyclen and *para*cyclam complexes also presents an absorption maximum at 578 nm. When the ratio *R* increases, the position of the band changes (Figure 2). The formation of the complexes was monitored by addition of *para*cyclam-cyclen to a solution of copper ions (10^{-3} mol·L^{-1}). For the addition of ligand quantity greater than the quantity of copper ions, the position of the absorption maximum moves closer to $\lambda = 540$ nm and the ESR spectrum is characteristic of a mononuclear species. This value of the absorption maximum indicates that the copper ion is mostly engaged in the cyclam cavity.

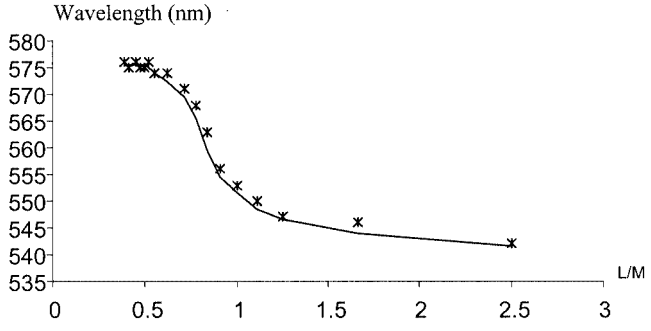

Figure 2. Variation of the wavelength of the maximum of absorbance as a function of the ratio R = L/M in acidic medium (pH ≈ 2); L = *para*cyclam-cyclen, M = Cu; [Cu^{2+}] = 10^{-3} mol·L^{-1}

Solid Complexes Studies

Only dinuclear complexes have been isolated in the solid state. When the ligand was a hydrochloride salt (*para*cyclam and *para*cyclam-cyclen), chloride anions were present in the solid complex. Only *para*cyclen complexes have been obtained as monocrystals suitable for X-ray diffraction. Conversely, structures of monocyclen compounds are scarce.

X-ray Diffraction Studies

(*para*cyclen)$Cu_2(ClO_4)_4$·$4H_2O$

The structure of Cu_2L^{4+} moieties is given in Figure 3, structural data in Table 4, and interatomic distances and angles in Table 5.

Figure 3. ORTEP drawing of the cation [(*para*cyclen)Cu_2]$^{4+}$

The two five-coordinate copper ions are located in square-pyramidal coordination environments. The base is formed by the four nitrogen atoms of the tetraazamacrocycle and an H_2O molecule is bonded in apical position. The two metal centres are always located on each side of the planar xylylene spacer so that the intramolecular Cu−Cu distance is the greatest (Scheme 2).

The Cu^1-N distances, in the 2.020−2.052 Å range generally found for $Cu-N_{amine}$ coordination bonds, and the $N-Cu^1-N$ (85.8−86.8°) and O^1-Cu^1-N angles (101.5−107.5°) indicate geometry close to an ideal square-pyramidal coordination environment for the first copper cation. The Cu^2-N distances (2.006−2.068 Å) and the O^2-Cu^2-N angles (98.2−111.6°), however, indicate a slight distortion of the square-pyramidal geometry. For the two copper ions, $Cu-N_{substituted}$ bonds ($Cu-N^4$ and $Cu-N^5$) are slightly longer than the other $Cu-N_{amine}$ values, as is generally observed.

The monoclinic cell contains four Cu_2L^{4+} moieties (Figure 4), which are stacked with the xylylene groups along an axis, the dihedral angle between two xylylene planes being nearly 90°. We can also note that the copper atoms appear in straight lines. Two neighbouring Cu_2L^{4+} moieties are perpendicular, the tops of the two square-pyramidal moieties point in opposite directions (Scheme 3); this molecular stacking produces intermolecular Cu−Cu distances (9.352, 7.993, or 6.059 Å) shorter than the intramolecular distance (11.540 Å) (Scheme 2). A complete stacking pattern (Figure 4) suggests that hydrogen bonds exist between water molecules, perchlorate ions and amine groups and thus stabilize the crystal lattice of the complex.

[(*para*cyclen)Cu_2]$_2$$(SCN)_8$·$7H_2O$

The structure of the polymeric chain is given in Figure 5, structural data in Table 4, and interatomic distances and angles in Table 6.

The chain is made up of Cu_2L^{4+} moieties linked by a bidentate thiocyanate anion. The terminal S and N donor atoms are coordinated in apical positions, taking the place of the water molecule present in the monomer complex. The copper atom is five-coordinate, and two alternating kinds of Cu_2L^{4+} moieties are present in the chain, the first with two N_4S chromophores (copper atom denoted Cu^1) and the second with two N_5 chromophores (copper atom denoted Cu^2). The Cu^2-N_{SCN} and Cu^1-S distances are 2.054 and 2.482 Å, respectively. The thiocyanate is collinear with the

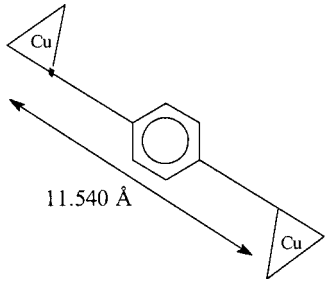

Scheme 2. Intramolecular Cu−Cu distance

Cu−N apical bond and practically perpendicular (93.7°) to the Cu−S apical bond. The Cu−N_{cyclen} distances, in the 2.021−2.059 Å range, and the angles around the copper ion indicate a regular geometry around the metal centre. The polymerisation does not affect the packing of the Cu_2L^{4+} moieties; the intramolecular Cu−Cu distances (11.575 Å) are very close to those observed in the monomer (11.539 Å) and the distance between the two copper ions bridged by the thiocyanate anion (5.810 Å) is also very close to the shortest intermolecular distance obtained in the monomer (6.061 Å). The crystal packing is stabilized by the uncoordinated thiocyanate ion and crystallization water molecules.

X-ray Absorption Spectroscopy (XAS)

The lack of single crystals of (*para*cyclam)Cu_2 and (*para*-cyclam-cyclen)Cu_2 complexes, and their poor crystallinity, prevented from obtaining structural information by the common X-ray diffraction techniques. We therefore decided to study the X-ray absorption near-edge structure (XANES) and the extended X-ray absorption fine structure (EXAFS) spectra of these two compounds with the (*para*cyclen)Cu_2 complex as a model. To the best of our knowledge, the use of XAS techniques in the structural study of bis-(macrocyclic) compounds is new. Only a few uses of XAS for (monocyclam)copper(II) complexes have been reported.[24,25]

A comparison of the XANES spectra for the compounds and the reference [(*para*cyclen)Cu_2 complex] is shown in Figure 6a, with the corresponding first derivatives in Figure 6b. The three spectra seem almost identical with respect to their shape and transition energies. They are typical of copper(II) complexes, each with a very weak 1s→3d pre-

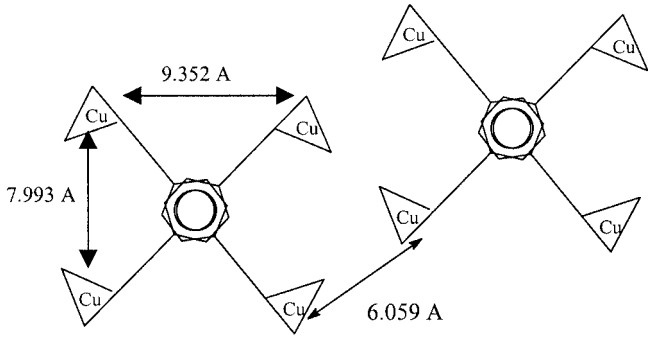

Scheme 3. Intermolecular Cu−Cu distances

edge feature and an absorption edge centred around 8990 eV. Furthermore, each spectrum has the characteristic shoulder (α) of copper(II) in elongated tetragonal surroundings on the low-energy side of the edge.[26] The energy gap between this shoulder (α) and the pre-edge (β) is equal to 6.5 eV for (*para*cyclen)Cu_2 and 6.9 eV for (*para*cyclam)Cu_2. For the (*para*cyclam-cyclen)Cu_2 complex, we can observe a small shoulder on the β peak of the first derivative, and the gaps between α and these two "peaks" are equal to 6.5 and 6.9 eV, which confirms that the copper(II) ion is held in two different geometries arising from the two macrocyclic cavities (cyclam and cyclen). Indeed, the copper(II) ion is in a C_{4v} square-pyramidal environment in the cyclen macrocyclic cavity, and in an O_h or D_{4h} geometry in the cyclam.

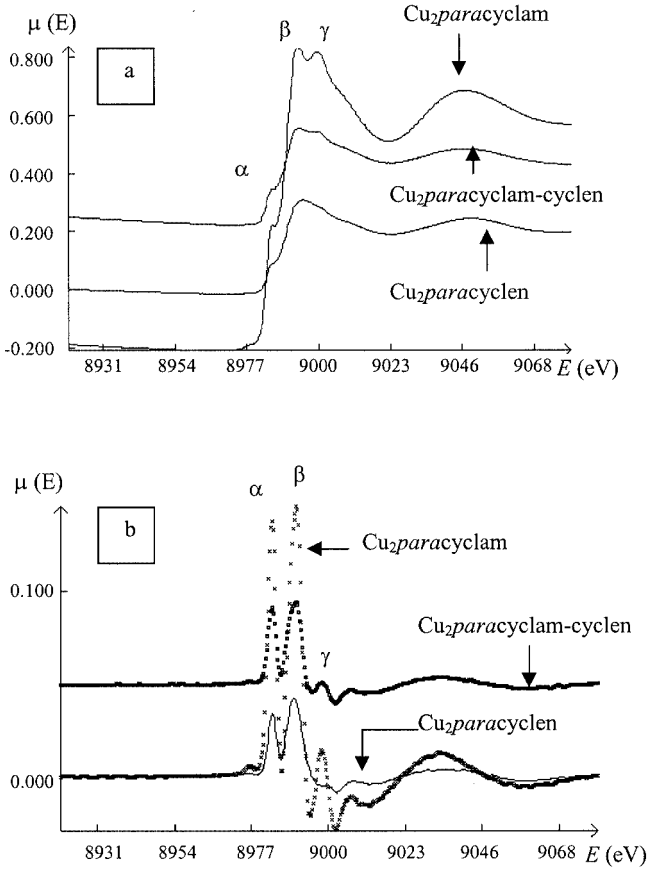

Figure 6. (a) Normalised XANES spectra (pre- and near-edge region) of (*para*cyclam)Cu_2, (*para*cyclam-cyclen)Cu_2, and (*para*cyclen)Cu_2; (b) comparison of their first derivatives

This value provides an estimate for the destabilisation of the $4p_z$ metal orbital, z being the elongation axis.[26,27] Our values are smaller than those (between 8 and 9 eV) found for copper(II) complexes in which the axial ligands are remote from the metal centre, giving rise to a D_{4h} square-planar environment.[27,28] These results are consistent with a distorted octahedral geometry for (*para*cyclam)Cu_2, and a mixed distorted octahedral-square-pyramidal one for (*para*cyclam-cyclen)Cu_2. The main transition, termed β, is attributed to the $1s\rightarrow4p_\pi$ transition, and is mainly affected by axial ligands as discussed above. On the other hand, the γ transition, corresponding to the $1s\rightarrow4p_s$ transition, is mainly sensitive to the equatorial ligands. This transition, centred at 8998 eV in the three compounds, indicates that the bond strengths between central metal ion and ligands are identical, and can be estimated from the (*para*cyclen)Cu_2 reference at approximately 2.35 Å.

The *k*-space experimentally determined and fitted EXAFS spectra $k\chi(k)$ vs. k for (*para*cyclam)Cu_2 and (*para*cyclam-cyclen)Cu_2, at the copper *K*-edge, and the corresponding Fourier transforms are given in Figure 7.

The two experimentally determined $k\chi(k)$ values and their Fourier transforms (FTs) are very similar, and allow us to assume that the local structures of the Cu^{II} ions are nearly the same. The slight differences can be attributed to the size of the macrocyclic cavity, which is greater for cyclam (ten carbon atoms) than for cyclen (eight carbon atoms). Actually, the two (*para*cyclam)Cu_2 and (*para*cyclam-cyclen)Cu_2 compounds differ only by one macrocyclic cavity. The amplitudes of the EXAFS oscillations appear nearly unchanged, indicating the almost identical numbers of nearest neighbours around each metal ion. The Fourier transform spectra are composed of three main peaks. From the expected structures for these complexes, it can be proposed that the first peak should correspond to the four nitrogen atoms of the macrocyclic cavity, and the second to one or two axial water oxygen atoms. The third peak, above 2.7 Å, should correspond to the eight or ten carbon atoms belonging to the cyclen or cyclam cavity.

The number and postulated nature of neighbours, the inter-neighbour distances, the Debye−Waller factors, and the energy threshold resulting from quantitative analysis of EXAFS data for the three first coordination shells of the (*para*cyclam)Cu_2 and (*para*cyclam-cyclen)Cu_2 compounds at the copper *K*-edge are given in Table 7.

The goodness of fit from the fits of the EXAFS functions and the corresponding FTs can be seen in Figure 7. For the (*para*cyclam)Cu_2 complex, the first shell was best fit with four nitrogen atoms per copper(II) ion at an average distance of 2.02 Å from the absorbing copper atom. These four atoms are positioned in the equatorial plane of a Jahn−Teller distorted, elongated octahedron. Actually, the two axial oxygen atoms, of water molecules, of the octahedron are found at 2.78 Å from the Cu^{II} ions, similarly to the arrangement described for $Cu(OH)_2$.[29] The third shell of neighbouring atoms was best fitted with ten carbon atoms at an average distance of 3.12 Å. Taking these values into account, the most likely structural interpretation is that

Table 7. EXAFS results at the Cu-*K*-edge for the (*para*cyclam)Cu_2 and (*para*cyclam-cyclen)Cu_2 complexes

		N	*R* [Å]	σ [Å^{-1}]	ΔE_0 [eV]
(*para*cyclam)Cu_2	Cu−N	4	2.02	0.023	0.15
	Cu−O	2	2.78	0.007	0.02
	Cu−C	10	3.12	0.055	0.83
(*para*cyclam-cyclen)Cu_2	Cu−N	4	2.04	0.016	0.42
	Cu−O_{cyclam}	2	2.72	0.010	1.02
	Cu−O_{cyclen}	1	2.24	0.068	0.24
	Cu−C_{cyclam}	10	3.13	0.070	0.67
	Cu−C_{cyclen}	8	2.77	0.148	5.61

the two cyclam macrocyclic cavities are located in the equatorial plane with all four nitrogen donor atoms involved in chelating and remaining water of hydration of the first coordination sphere occupying axial positions. This structure agrees well with Ohtaka and Seki's findings[24] for the (monocyclam)copper(II) complex in solution by SAX (Cu−N and Cu−O bond lengths were found to be 2.01 and 2.77 Å), and also those of Tasker and Sklar[30] for the same complex by X-ray diffraction (Cu−N 2.02 Å, distorted octahedral geometry).

Fitting of the EXAFS data for the first coordination shell of the (*para*cyclam-cyclen)Cu_2 complex resulted in a very slight increase in the Cu−N bond length from 2.02 to 2.04 Å. This is consistent with the size of the macrocyclic cavities. Actually, in the cyclam one, the copper(II) ion is in the same plane as the four nitrogen atoms (*trans* N−Cu−N angle around 180°),[31] whereas in the cyclen cavity the metal ion is slightly above (Table 5: *trans* N−Cu−N angle around 150°), increasing the Cu−N bond length. The second and third shells of (*para*cyclam-cyclen)Cu_2 have been fitted for both cyclen and cyclam cavities. The results obtained for the latter are the same as in the (*para*cyclam)Cu_2 complex. For the cyclen cavity the results agree with our X-ray crystallographic data for (*para*cyclen)$Cu_2(ClO_4)_4{\cdot}4H_2O$. However, the more distant carbon atoms give rise to high thermal disorder with a high Debye−Waller factor for these atoms (around 0.15 Å^{-1}). In summary, XAS techniques have been shown to be a good alternative to X-ray diffraction for obtaining structural and geometrical information.

ESR Experiments

The frozen aqueous solution ESR spectra (150 K) of mononuclear complexes show the typical four-line patterns expected for coupling of the electron to the 3/2 spin of a copper(II) nucleus. The hyperfine coupling constants and *g* values are very close to those found for the copper complexes with cyclen or cyclam (Table 2, Figure 8).

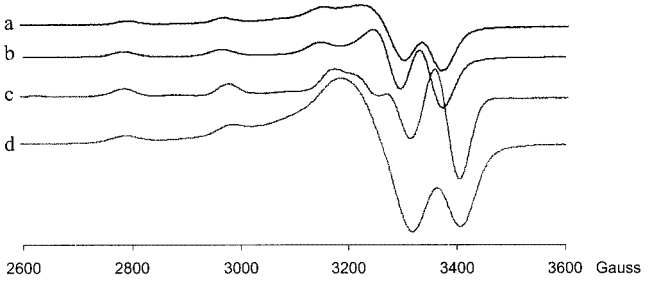

Figure 8. EPR spectra of mononuclear CuL^{2+} complexes at 150 K: (a) (*para*cyclen)Cu, (b) simulation of (*para*cyclen)Cu, (c) (*para*cyclam)Cu, (d) (*para*cyclam-cyclen)Cu

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The ESR spectra of the three dinuclear complexes obtained at 150 K in a H_2O/glycerol mixture or in DMF (Figure 9) present a septuplet around 3000 G and a signal at half field, in agreement with those described by Guilard et al.[11] The existence of seven equidistant lines corresponding to the two allowed transitions ($\Delta M_S = 1$) and that of a signal at half field assigned to a forbidden transition ($\Delta M_S = 2$) are characteristic of a dicopper compound with intramolecular exchange between the two copper ions ($I_{Cu} = 3/2$).[32] Unfortunately, the forbidden transition is poorly defined and it is not possible to estimate the Cu−Cu distance from the ratio of the intensity of the forbidden transition to the intensity of the allowed transition.[32]

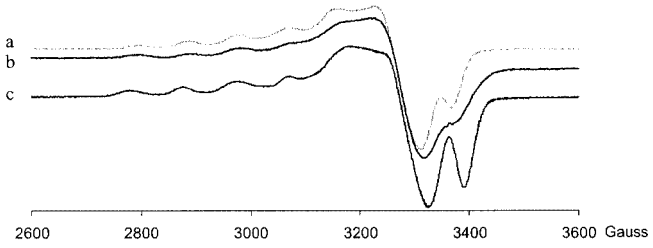

Figure 9. EPR spectra of dinuclear Cu_2L^{4+} complexes at 150 K: (a) (*para*cyclen)Cu_2, (b) (*para*cyclam-cyclen)Cu_2, (c) (*para*cyclam)Cu_2

The *g* values (Table 2) for *para*cyclen and *para*cyclam compounds are similar to those of (cyclen)- and (cyclam)-copper complexes. The hyperfine splittings in the spectra of the dinuclear complexes are approximately half of those characteristic of mononuclear copper(II) complexes in tetragonally distorted octahedral environments for cyclam compounds, and square-pyramidal geometries for cyclen compounds. The $A_{\|}$ values are indicative of a very weak *D* parameter in these dinuclear complexes.[32]

In the dinuclear *para*cyclam-cyclen complex, the copper coordination environment dictated by the macrocyclic holes is different and so the distances between two lines are irregular. However, this effect is insufficient to resolve the two sets of seven lines, the parameters of cyclen and cyclam complexes being too close.

Although the polymeric thiocyanate complex shows two different dinuclear *para*cyclen moieties with CuN_5 and CuN_4S chromophores, respectively, the signal is close to that of (*para*cyclen)$Cu_2(ClO_4)_4$.

Conclusion

In summary, only pure dinuclear complexes were isolated in the solid state. In the case of mononuclear compounds, their isolation was carried out by use of an ion-exchange method with a solution of NaCl as eluent. Unfortunately, sodium chloride could not be completely separated from these complexes.

Among the dinuclear compounds, two complexes formed with the *para*cyclen ligand were obtained as monocrystals suitable for X-ray diffraction. The first is a monomeric compound in which the two five-coordinate copper atoms are located in a square-pyramidal environment (chromophore N_4O), the second, obtained in the presence of an excess of KSCN, is a polymeric chain with two kinds of Cu_2L^{4+} moieties alternately present in the chain (one with two N_4S chromophores, the other with two N_5 chromophores).

With the two other ligands, *para*cyclam and *para*cyclam-cyclen, the complexes were not obtained as monocrystals. They were therefore studied by XAS, which is a good alternative to X-ray diffraction to obtain structural information. In the case of the *para*cyclam ligand, the complex formed is an elongated octahedron (four equatorial N atoms and two axial O atoms of water molecules). With the ligand *para*cyclam-cyclen, the copper atom in the cyclam cavity is six-coordinate (chromophore N_4O_2) and that in the cyclen cavity is five-coordinate (chromophore N_4O).

With regard to the study in solution, the results of the potentiometric titrations, the ESR experiments and the electronic spectra are in good agreement. When the ratio R = ligand/metal is higher than 1, mononuclear complexes $CuLH_n^{(2+n)+}$ ($0 < n < 3$) are formed, and when R is lower than 1, the formation of the dinuclear compounds Cu_2L^{4+} is emphasised. The complexes are very stable and the two macrocyclic cavities of the ligands seem to be independent of one another regarding the complexation phenomenon.

Experimental Section

Spectroscopic Measurements: Electronic spectra in aqueous solution were all measured in the 300−900 nm range with a Lambda 6 Perkin−Elmer spectrophotometer. The ESR spectra were obtained at 150 K with a Bruker ELEXSYS 500 spectrophotometer in the X-band at 9.40 GHz. Simulations were carried out with the software Simfonia.

Potentiometric Measurements: To determine the protonation constants of the ligands and the stability constants of the copper(II) complexes, potentiometric titrations were carried out with an automatic titrator consisting of a Metrohm dosimat 665 microprocessor burette and a Metrohm 713 pH meter connected to a computer. The titration procedure was fully automated.[33] All measurements were performed within a cell thermoregulated at 20.0±0.1 °C under a nitrogen stream to avoid the dissolution of carbon dioxide. the ionic strength was adjusted to 1 with potassium nitrate. The combined type "U" glass electrode Metrohm used had a very low alkaline error. Solutions of ligand (1.10^{-3} to 3.10^{-3} mol·L^{-1}) and ligand/copper nitrate mixture (ligand/metal ratios [L]/[M] in the range 0.5−2) were titrated with a 0.1 mol·L^{-1} KOH solution. The stability constants were calculated and refined with PROTAF.[34] The fitted global formation constants β_{mlh} are defined for the equilibrium (except for the proton, the charges are not shown for clarification):

$$\beta_{mlh} = \frac{[M_m L_l H_h]}{[M]^m [L]^l [H^+]^h}$$

$$m\,M + l\,L + h\,H^+ \rightleftharpoons M_m L_l H_h$$

A negative *h* value refers to the hydroxide ion.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Crystal Structure Determination: The crystal data were collected at 173 K with a Kappa CCD diffractometer using monochromated Mo-K_α radiation (λ = 0.71073Å). The structures were solved by direct methods. After refinement of the non-hydrogen atoms, difference-Fourier maps revealed maxima of residual electron density close to the positions expected for hydrogen atoms. Hydrogen atoms were introduced as fixed contributors at calculated positions [C−H = 0.95 Å; B(H) = 1.3B_{eqv}]. Final difference maps revealed no significant maxima. All calculations used the Nonius OpenMoleN package.[35] Neutral atom scattering factor coefficients and anomalous dispersion coefficients were taken from a standard source.[36] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC-187962 [(*para*cyclen)$Cu_2(ClO_4)_4$·$4H_2O$] and -187961 {[(*para*cyclen)Cu_2]$_2$$(SCN)_8$·$7H_2O$}. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

X-ray Absorption Data Collection and Processing: The XANES (X-ray absorption near-edge structure) and EXAFS (extended X-ray absorption fine structure) data were collected at the Laboratoire d'Utilisation du Rayonnement Electromagnétique (LURE), Paris-Sud University, with the XAS4 beam line of the storage ring DCI with an energy of 1.85 GeV and a mean intensity of 300−200 mA. The measurements were carried out at the copper *K*-edge in the transmission mode with an Si(111) for EXAFS, and Si(311) for XANES channel-cut monochromator at room temperature. The detector were low-pressure (ca. 0.2 atm) air-filled ionisation chambers. The photon energy was calibrated from the spectrum of a copper foil, 8979 eV being assigned to the pre-edge peak. Each spectrum was the sum of three recordings in the 8830−9830 eV range for EXAFS, and the 8920−9080 eV range for XANES, including the copper *K*-edge (ca. 8979 eV). The XANES spectra were recorded step-by-step, every 0.3 eV with a 2 s accumulation time per point. The spectrum of a 5 μm copper foil was recorded just behind the sample to check the energy calibration, thus ensuring an energy accuracy of 0.25 eV. The EXAFS spectra were recorded with sampling steps of 2 eV, and an integration time of 2.0 s per point was used. The EXAFS data analysis was performed with the "EXAFS pour le Mac" and EXAFS98 programs.[37] The $\chi(k)$ functions were extracted from the data[38] with a linear pre-edge background, a combination of polynomials (of order 5) and spline atomic-absorption background, and normalised by the Lengeler−Eisenberger method.[39] The energy threshold, E_0, was taken at the half maximum of the absorption edge. Radial distribution functions $F(R)$ were calculated by Fourier transforms of $k^3w(k)\mu(k)$ in the 2−14 Å^{-1} range; $w(k)$ is a Kaiser−Bessel apodization window with a smoothness coefficient τ = 3 (k is the photoelectron wavenumber). The peaks corresponding to the successive atomic shells were then isolated and back-Fourier-transformed into k space to determine the mean coordination number N, the bond length R, and the Debye−Waller factor σ by a least-squares fitting procedure using the standard EXAFS formula, without multiple scattering:

$$\chi(k) = S_0^2 \sum_i \left[\frac{N_i}{R_i^2} A_i(k) e^{-2\sigma_i^2 k^2} e^{-2R_i/\lambda(k)} \sin(2kR_i + \Phi_i(k)) \right]$$

The experimental phase $\Phi_i(k,R_i)$ and amplitude $A_i(k,R_i)$ have been extracted from the model compounds of known crystallographic structure, Cu(1,4,8,11-tetraazacyclotetradecane),[24] and (*para*cyclen)Cu_2.

Syntheses: The metal salts were purchased from Aldrich. The other reagents were used as the highest grade commercially available without further purification. The three ligands were synthesized by a new method described by Handel et al.,[40] with an aminal as intermediate.

(*para*cyclen)$Cu_2(ClO_4)_4$·$4H_2O$ (1): The neutral ligand ($5.2\cdot10^{-5}$ mol) was dissolved in distilled water (10 mL) and a copper(II) perchlorate solution in ethanol ($1.17\cdot10^{-4}$ mol) was added dropwise. The blue solution was stirred at room temperature for 7 d and was then concentrated under vacuum. The violet solid was washed twice with absolute ethanol. The complex was recrystallized from saturated aqueous $NaClO_4$ solution. $C_{24}H_{54}Cl_4Cu_2N_8O_{20}$ (1043.1): calcd. C 27.61, H 5.18, N 10.74; found C 27.55, H 5.20, N 10.26.

(*para*cyclam)$Cu_2Cl_2(ClO_4)_2$·H_2O (2): Solid NaOH ($1.75\cdot10^{-3}$ mol) was added to a suspension of ligand hydrochloride ($8.2\cdot10^{-5}$ mol) in absolute ethanol (10 mL). After elimination of NaCl and NaOH in excess, a copper(II) perchlorate solution in methanol ($1.74\ 10^{-4}$ mol) was added dropwise in order to obtain 60 mL of a mauve solution. After stirring at room temperature for 24 h, the blue mauve solid was filtered and washed twice with ethanol. $C_{28}H_{56}Cl_4Cu_2N_8O_9$ (917.1): calcd. C 37.37, H 6.01, N 12.41; found C 36.98, H 6.22, N 12.35.

(*para*cyclam-cyclen)$Cu_2Cl_2(ClO_4)_2$·$2H_2O$ (3): This complex was prepared by the same procedure as used for compound **2**. $C_{26}H_{54}Cl_4Cu_2N_8O_{10}$ (907.1): calcd. C 34.10, H 5.95, N 12.35; found C 34.41, H 6.00, N 11.79.

(*para*cyclen)$Cu_2(SCN)_4$·H_2O (4): After the neutral ligand ($2\cdot10^{-4}$ mol) had been dissolved in methanol (50 mL), an aqueous solution of copper nitrate ($4.2\cdot10^{-4}$ mol) was added. The solution was heated at reflux for 1 h and the solvents were evaporated under vacuum. The crude solid was dissolved in water and a blue solid was precipitated with an excess of KSCN. This solid was filtered and washed with ethanol. $C_{28}H_{48}Cu_2N_{12}O_1S_4$ (823.1): calcd. C 40.72, H 6.06, N 20.36 found C 41.13, H 5.75, N 20.01. Attempted recrystallization in water with an excess of KSCN produced another compound [(*para*cyclen)Cu_2]$_2$$(SCN)_8$·$7H_2O$, a monocrystal suitable for X-ray study.

Synthesis of Mononuclear Complexes: These complexes were very difficult to isolate because of the presence of small amounts of dinuclear compounds or uncomplexed ligands. The isolation of mononuclear compounds could be carried out with an ion-exchange column (SP Sephadex C 25)[41] and an NaCl solution ($0.4\cdot mol\cdot L^{-1}$) as eluent. Unfortunately, sodium chloride could not be completely separated from the complexes.

Acknowledgments

We thank Dr. A. De Cian (Université Louis Pasteur, Strasbourg, France) for the single-crystal X-ray analyses. The Region Champagne-Ardenne is acknowledged for a grant to M. S.

Keywords: Manganese / N ligands / Stacking interactions / Magnetic properties / EPR spectroscopy / Radicals

The reaction between [Mn(MAC)(H$_2$O)$_2$]Cl$_2$·4H$_2$O and LiTCNQ (MAC = 2,13-dimethyl-3,6,9,12,18-pentaazabicyclo[12.3.1]octadeca-1(18),2,12,14,16-pentaene) affords a complex with the formula [Mn(MAC)(TCNQ)$_2$] (**1**), whose crystal structure has been determined. Its structure consists of neutral mononuclear entities. The manganese(II) ion is heptacoordinated, with a pentagonal bipyramidal geometry. The apical positions are occupied by the TCNQ$^{\cdot-}$ radicals, while the macrocyclic ligand is coordinated at the equatorial positions. The seven Mn–N distances range from 2.273(3) to 2.301(6) Å. The strong intermolecular π–π stacking interactions between the TCNQ radicals (3.2 Å) leads to weave-like infinite chains, which propagate along the crystallographic *c* axis. The cryomagnetic investigation of **1** revealed a weak intermolecular antiferromagnetic coupling of the Mn^{2+} ions (J = −0.18 cm^{-1}), which is mediated by the diamagnetic $(TCNQ)_2^{2-}$ pairs resulting from the stacking interactions in the crystal. The intermolecular exchange interaction between the Mn^{2+} ions was further confirmed by variable temperature EPR spectroscopic measurements [$|J|$ = 0.15(5) cm^{-1}], which have been carried out in both the X and Q bands.

Introduction

Since the pioneering work of Melby et al.,[1] the TCNQ$^{\cdot-}$ radical has been widely used as a building-block for the construction of molecular solids with exciting physical properties.[2] Among these the magnetic ordering,[3] as well as the electrical conductivity are particularly attractive.[4] The neutral TCNQ molecule acts as a strong acceptor due to its low reduction potential to form the radical anion, TCNQ$^{\cdot-}$. The reaction between various metallocenes, [M(Cp*)$_2$] (Cp* = C$_5$Me$_5$) with TCNQ leads to a family of charge transfer complexes, [M(Cp*)$_2$]$^{\cdot+}$[TCNQ]$^{\cdot-}$, with strong magnetic interactions between the spin carriers. Some of these compounds are molecular magnets.[5]

Due to its high σ-donor character towards transition-metal ions, the TCNQ$^{\cdot-}$ ion can act as a ligand generating a rich coordination chemistry.[6,7] The synthetic approach consists of the reaction of transition-metal complexes with LiTCNQ. The TCNQ$^{\cdot-}$ radical coordinates at a vacant site on the metal centre, or replaces a weakly coordinated ligand in the coordination sphere of the metal ion. Most of these complexes have the general formula [M(N$_4$)(TCNQ)$_2$], where (N$_4$) denotes various polyamine ligands (e.g. tetraazamacrocyclic ligands, open tetraamines, two ethylenediamine molecules, etc.) and M^{2+} = Fe^{2+},[8] Ni^{2+},[9] Cu^{2+},[10] and Co^{2+}.[10a] Using TCNQ$^{\cdot-}$ as a ligand, we have recently synthesised the first coordination compound containing three different types of spin carriers: 2p (TCNQ$^{\cdot-}$), 3d (Cu^{2+}) and 4f (Gd^{3+}).[11] The TCNQ$^{\cdot-}$ species coordinates to both Cu^{2+} and Gd^{3+} ions.

As a part of our research program on the exchange interactions mediated by π−π stacking, we report here the synthesis, crystal structure, magnetic and EPR spectroscopic properties of a new Mn^{2+}−TCNQ$^{\cdot-}$ compound, [Mn(MAC)(TCNQ)$_2$], where MAC stands for the pentaazamacrocyclic ligand (2,13-dimethyl-3,6,9,12,18-pentaazabicyclo[12.3.1]octadeca-1(18),2,12,14,16-pentaene).

Results and Discussion

Description of the Structure

The structure of compound **1** consists of mononuclear entities with the TCNQ·- anions coordinated to the metal ion (Figure 1). The manganese(II) ion exhibits a coordination number of seven with a pentagonal bipyramidal geometry. The $TCNQ^{\cdot -}$ groups are coordinated in the apical positions, while the equatorial positions are occupied by the nitrogen atoms of the macrocyclic ligand. The seven Mn−N distances range from 2.273(3) to 2.301(6) Å. The shortest Mn−N distance corresponds to the Mn−pyridyl nitrogen bond. Selected bond lengths and angles are given in Table 1. The values of the interatomic distances in the TCNQ species are diagnostic of their electronic nature. In the case of compound **1**, the carbon−carbon distances fall in the range expected for $TCNQ^{\cdot -}$ anions.[2,4c]

N2^i−Mn1−N2	138.94(8)		

An analysis of the packing diagram reveals interesting interactions at the supramolecular level. The small separations between anionic radicals arising from different $[Mn(MAC)(TCNQ)_2]$ units (3.2 Å) indicate the occurrence of strong π−π interactions. Consequently, the overlap of the $TCNQ^{\cdot -}$ π clouds generates weave-like chains propagating along the crystallographic *c* axis (Figure 2). The distance between the manganese atoms within the supramolecular chain is 13.03 Å. Consequently, the structure can be described as consisting of 1-D infinite chains:

···−[Mn(MAC)]−$(TCNQ)_2$−[Mn(MAC)]−$(TCNQ)_2$−[Mn(MAC)]−$(TCNQ)_2$−···

in which the [Mn(MAC)] moieties are connected through dimerized $TCNQ^{\cdot -}$ ligands.

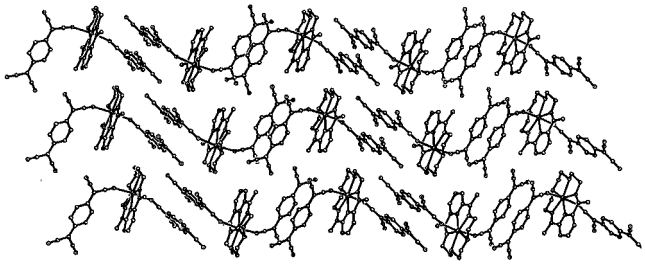

Figure 2. Packing diagram showing the formation of chains through the π−π stacking interactions between the TCNQ radicals.

Magnetic Measurements

The magnetic properties of compound **1** are shown in the form of an $\chi_M T$ versus T plot (Figure 3). The value of the $\chi_M T$ product at room temperature (4.2 $cm^3\ mol^{-1}K$) is lower than expected for the two types of spin carriers: Mn^{2+} ($S = 5/2$) and two $TCNQ^{\cdot -}$ radicals (each one with $S = 1/2$). In fact, the room temperature value corresponds exactly to $S = 5/2$, that is, only to one Mn^{2+} (indeed, the expected value of the $\chi_M T$ product for $S = 5/2$ is 4.37 $cm^3\ mol^{-1}K$). The lower value of the $\chi_M T$ product at room temperature for **1** can be explained by the strong antiferromagnetic coupling between the stacked $TCNQ^{\cdot -}$ radicals connecting the $[Mn(MAC)]^{2+}$ entities. This phenomenon has been observed with other compounds, where the stacking interactions between $TCNQ^{\cdot -}$ radicals lead to diamagnetic $(TCNQ)_2^{2-}$ dimers.[2,9] As the temperature is lowered $\chi_M T$ remains constant down to 70 K, then decreases abruptly, reaching a value of 1.9 $cm^3\ mol^{-1}$ K at 2.0 K. Considering the $TCNQ^{\cdot -}$ ions do not contribute to the magnetic moment of **1**, the magnetic properties can be simulated by taking into account only the $[Mn(MAC)]^{2+}$ units. The decrease of $\chi_M T$ in the lower temperature range can be due to the zero-field splitting (D) of the manganese(II) ion and/or to a weak intermolecular antiferromagnetic interaction between the local spins mediated by the π−π stacking interactions. A least-squares fit of the susceptibility data, taking into account the zero field splitting, led to $D = 5.1$ cm^{-1}, a value which is too high for a manganese(II) complex. We recall that for the parent compound,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[Mn(MAC)(H_2O)_2]Cl_2{\cdot}4H_2O$, the value of the D parameter obtained from EPR spectroscopic measurements was found to be 0.07 cm^{-1}.[12] The alternative way of rationalizing the magnetic behaviour is to consider only the exchange interactions of the manganese(II) ions within the supramolecular chain. The exchange pathway is provided by the diamagnetic $(TCNQ)_2^{2-}$ dimers. Consequently the magnetic data can be analysed using the Hamiltonian: $\boldsymbol{H} = -J\Sigma S_i S_{i+1}$. The temperature dependence of the magnetic susceptibility is given by Equation (1) and Equation (2):[14]

$$\chi_M^{chain} = \{Ng^2\beta^2 S_{Mn}(S_{Mn}+1)/3kT\}\{(1+u)/(1-u)\} \quad (1)$$

(Fisher's infinite chain model) with:

$$u = \coth[JS_{Mn}(S_{Mn}+1)/kT] - [kT/JS_{Mn}(S_{Mn}+1)] \quad (2)$$

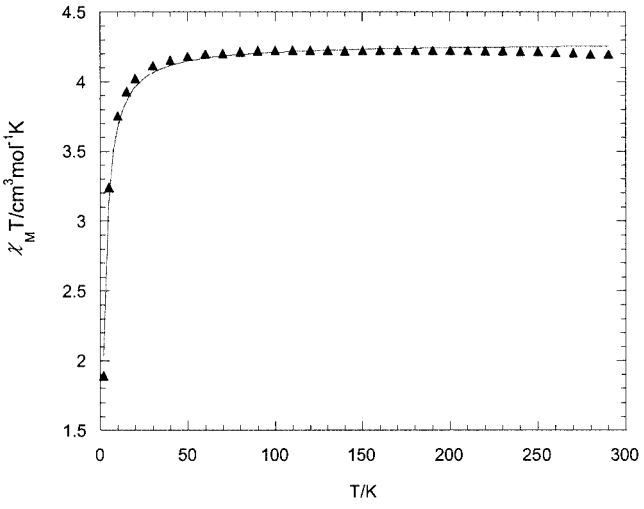

Figure 3. Temperature dependence of the $\chi_M T$ product. The solid line represents the best fit curve.

The least-squares fit of the data leads to $J = -0.18$ cm^{-1} and $g = 1.99$. The low J value is quite reasonable, since the distance between the manganese(II) ions within a chain is large (13.03 Å).

By fitting the data using the Curie–Weiss law, $\chi_M{}^{-1} = (T-\theta)/C$, we obtained $\theta = -0.7$ K, $C = 4.230$ $cm^3mol^{-1}K$ and $g = 1.98$. Given that $\theta = zJ'S(S+1)/3k$ and $S = 5/2$, it follows that $zJ' = -0.34$ cm^{-1}. As the packing diagram shows, $z = 2$ and consequently $J' = -0.17$ cm^{-1}, in good agreement with Fisher's model.

EPR Measurements

EPR spectra have been recorded on powder samples. Both X-band and Q-band (Figure 4) spectra consist of a single signal centred at $g = 2.028(5)$. The shape and the peak-to-peak linewidth of the signal, ΔB, are frequency-dependent. A slight asymmetry of the signal with ΔB=945 Oe is observed in the X-band at room temperature, the shape of the signal being intermediate between Lorentzian and Gaussian. As the frequency is increased, the asymmetry disappears and ΔB decreases to 595 ± 50 Oe at room temperature (Figure 4). As the temperature is decreased, the linewidth of the signal increases. The measurements in the X-band show that this increase occurs mainly in the range of 100–300 K, and at $T = 12$ K ΔB increases to 1590 ± 20 Oe. The temperature dependence of the spectrum in the Q-band shows that as the temperature is decreased, the linewidth increases from 595±50 Oe at room temperature to 1120 ± 100 Oe at 4.2 K.

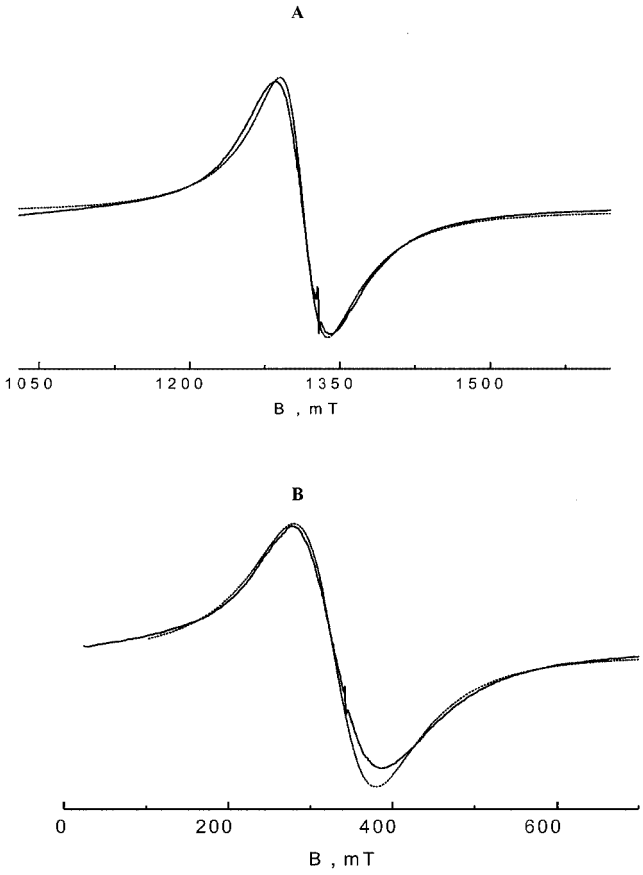

Figure 4. Experimental (solid lines) and simulated (dotted lines) EPR spectra at the Q-band (A) and at X-band (B) of compound **1** at room temperature. A narrow signal in the Q-band spectrum is due to the radical placed in the resonator for measuring the frequency.

The decrease in linewidth as a function of frequency is known as the "10/3" effect.[15] The frequency dependence of the linewidth of the signal has been previously observed for some compounds of Mn^{2+}.[16] This effect was interpreted using the Kuba and Tomita equation obtained for a simple cubic lattice composed of $S = 1/2$ ions,[17] in which the frequency dependence of the linewidth of the signal is described as the frequency dependence of its dipole contribution. Our estimation of the dipole contribution to the linewidth of compound **1** shows that it is not determinant and cannot describe the frequency dependence observed for this compound.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The powder spectra of compound **1** do not show the fine and hyperfine structures due to the dipole−dipole and exchange interactions between neighbouring manganese(II) ions. It is known that if the exchange interaction, $-JS_iS_{i+1}$, exceeds the dipole-dipole and other interactions, an exchange-narrowed line is observed. The form of the EPR spectrum of the studied compound and its change with frequency and temperature were interpreted by supposing that the main contribution to the linewidth is due to the unresolved fine structure and not to the dipole−dipole interaction.

The frequency dependence of the EPR spectra was analysed using a simulation program that was written taking into account the fine structure [due to the zero-field splitting of manganese(II) ion] and the hyperfine structure for $S = 5/2$, the exchange interaction, and by averaging these structures according to the kinetic equations given in ref.[18] The linewidth of each component of the hyperfine structure was chosen by taking into account the dipole-dipole contribution. The value of the D parameter was taken as 0.07 cm^{-1}.[12] In the absence of the exchange interaction, the form of the spectrum of a polycrystalline Mn^{2+} sample in the X-band would be asymmetric. In the Q-band the form of the spectrum changes because the ratio between the fine structure parameter and the Zeeman energy changes. The exchange interaction averages out the fine structure but some differences in the X- and Q-bands remain. The observation of these differences enables us to estimate the J value. The asymmetry observed in the X-band is the manifestation of the incomplete averaging of the fine structure. The adjustment of the simulated and observed spectra at room temperature at the two frequencies allowed us to estimate the value of the exchange interaction $|J|$ as 0.15(5) cm^{-1}, which is in reasonably good agreement with the value obtained through cryomagnetic measurements. In our model, the temperature dependence of the spectrum in the X-band can be explained by the change in either of the parameters D or J. The assumption about the change in the D parameter, which shows a certain change in the distortion of the nearest environment of Mn^{2+}, agrees with the EPR spectroscopic data of $[Mn(MAC)(H_2O)_2]Cl_2{\cdot}4H_2O$.[12] The increase of the linewidth in the Q-band, however, can be described only by a decrease in the J parameter. The EPR spectroscopic data therefore enable us to suppose that the exchange interaction decreases weakly as the temperature is decreased.

In conclusion, we have shown by means of two independent techniques (magnetic susceptibility and EPR spectroscopic measurements) that the intermolecular π−π stacking of the $TCNQ^{\cdot-}$ ligands, which leads to diamagnetic $(TCNQ)_2^{2-}$ dimers, is able to mediate weak exchange interactions between the manganese(II) ions.

Experimental Section

Preparation of [Mn(MAC)(TCNQ)$_2$] (1): The manganese precursor, $[Mn(MAC)(H_2O)_2]Cl_2{\cdot}4H_2O$, was synthesised according to the literature.[12] LiTCNQ was obtained according to ref.[1] The reaction was carried out under oxygen-free nitrogen, using standard Schlenk techniques and degassed solvents. A solution of LiTCNQ (0.4 g, 1.9 mmol) in methanol/acetonitrile (1:1, 10 mL) was added dropwise to a solution of $[Mn(MAC)(H_2O)_2]Cl_2{\cdot}4H_2O$ (0.44 g, 0.9 mmol) dissolved in methanol/acetonitrile (30 mL). The resultant mixture was allowed to stand at room temperature. After several hours, red crystals resulted, which were filtered off and washed with methanol/acetonitrile (1:1). IR data (KBr, cm^{-1}): $\tilde{\nu}$ = 3247 m, 2188 vs, 2166 s, 1580 s, 1499 s, 1341 s, 1170 s, 1103 w, 937 w, 914 w, 818 m, 718 w, 476 w. $C_{39}H_{29}MnN_{13}$ (734.68): calcd. C 63.76, H 3.98, N 24.78; found C 63.5, H 4.3, N 24.3.

Crystallographic Data Collection and Structure Determination: The diffraction intensities for compound **1** were collected on a STOE Image Plate IPDS II-System. The structures was solved by direct methods and refined against F^2 by using SHELXL-97.[13] Heavy atoms were refined anisotropically. Hydrogen atoms were included using the riding model with U_{iso} tied to U_{iso} of the parent atoms. Crystallographic data and other pertinent information are summarised in Table 2. CCDC-196351 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Other Measurements: IR spectra (KBr pellets) were recorded on a BIO-RAD FTS 135 spectrometer. Magnetic susceptibility measurements were carried out using a SQUID magnetometer (MPMS Quantum Design). EPR measurements of the powder samples were carried out on ERS-230 and Varian spectrometers in the temperature range 300−10 K (X-band), 300−100 K and at 4.2 K (Q-band).

COVER PICTURE

The cover picture shows two isomers of a carbonylcopper(I) complex of the new ligand tris(pyrazolyl)methanesulfonate (Tpms). This new class of ligands contains three nitrogen donor atoms and in addition a sulfonate group which makes the ligands more hydrophilic. The sulfonate group can act as a competing donor centre. Therefore Tpms ligands are ambidentate ligands, that can adapt their coordination modes according to the electronic preferences of the metal centre. In solution, e.g., carbonylcopper(I) and zinc halide complexes show an equilibrium between the N,N,N- and N,N,O-coordination mode. Synthesis, characterization and the dynamic stereochemistry of Tpms and Tpms^{tBu} complexes are presented in the article by W. Kläui et al. on p. 2059 ff. We thank B. Kugel and P. Kunz for their help with the cover picture.

The Use of Conductivity Measurements for the Characterization of Cationic Palladium(II) Complexes and for the Determination of Kinetic and Thermodynamic Data in Palladium-Catalyzed Reactions

Anny Jutand[a]

Keywords: Cationic complex / Conductivity / Kinetics / Mechanism / Palladium

This review illustrates how conductivity measurements are used to characterize the *cationic* character of aryl-, vinyl-, hydrido-, and (η^3-allyl)palladium(II) complexes generated by oxidative addition of aryl and vinyl triflates, acetic/formic acid, and allylic carboxylates/carbonates, respectively, with palladium(0) complexes in DMF. These cationic palladium(II) complexes have been postulated as key intermediates in Stille, Heck, Tsuji–Trost, and Trost reactions, but most of them have never been characterized in the context of real oxidative additions, i.e., with the counteranion delivered by the reagent (triflates, carboxylates, and carbonates). The role of chloride ions has been examined and the mechanistic consequences are reported. Conductivity measurements are also used to obtain thermodynamic and kinetic data on the formation of cationic palladium(II) complexes and, consequently, to gain a deeper insight into the mechanism of palladium-catalyzed reactions. The *reversibility* of oxidative additions of acetic/formic acid and allylic carboxylates/carbonates with Pd^0 complexes has been established and equilibrium constants have been determined. The isomerization of cyclic *trans*/*cis* cationic (η^3-allyl)palladium(II) complexes is evidenced by a rate constant that depends on the Pd^0 precursor: kinetic evidence for an S_N2 mechanism that is responsible for the loss of stereoselectivity observed in catalytic reactions. Under conditions in which the oxidative additions are irreversible, the *kinetics* of the formation of cationic (η^3-allyl)palladium(II) complexes has been monitored by conductivity measurements for the determination of the rate constants. By comparing the rate of disappearance of Pd^0, it has been shown that oxidative additions of allylic carboxylates proceed in two steps with the detection of intermediate neutral, kinetic Pd^0 complexes ligated to the allylic carboxylate unit. As an example of its application, the mechanism of a Stille reaction has been investigated by conductivity measurements of an ionic by-product in DMF.

© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003

Introduction

Many palladium-catalyzed reactions involve cationic palladium(II) complexes generated in the first step of the catalytic cycle. In Heck reactions[1] with aryl triflates (ArOTf, Tf = SO_2CF_3),[1,2] [Equation (1)], cationic arylpalladium(II) complexes are formed in the oxidative addition of aryl triflates to Pd^0 complexes [Equation (2), L = monodentate ligand or L_2 = bidentate ligand].

(1)

(2)

In Tsuji−Trost reactions [Equation (3)], cationic (η^3-allyl)palladium(II) complexes are formed in the oxidative addition of allylic carboxylates (or carbonates) to Pd^0 complexes [Equation (4)].[3]

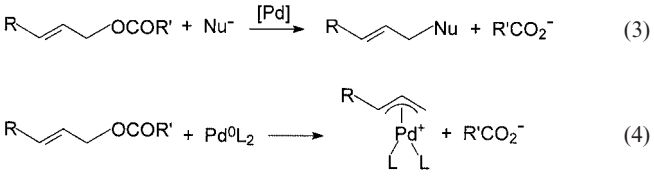
Anny Jutand was born in France in 1948. She studied chemistry at the Ecole Nationale Supérieure de Chimie de Paris (MS degree, University Paris VI, 1971). She obtained her Doctorate under the direction of Professor J. F. Fauvarque at the University Paris XIII in Villetanneuse. After a postdoctoral stay with Professor B. Åkermark at the Royal Institute of Technology in Stockholm, she moved back to the University Paris XIII. In 1984, she joined Dr. C. Amatore's group at the Ecole Normale Supérieure in Paris. She became Research Director at CNRS (a position equivalent to a full Professor) in 1992. Her current research interests are centered on the investigation of the mechanism of transition metal catalyzed reactions and the development of reactions that require activation by both a transition metal and electron transfer.

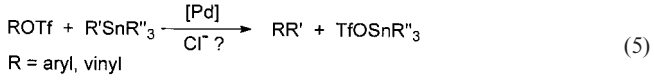
MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.



Most cationic complexes postulated, however, as key intermediates have not been characterized under the conditions of real oxidative additions. This review illustrates how, by using conductivity measurements,[4,5] cationic palladium(II) complexes formed in oxidative additions may be detected and characterized[6] under the real conditions of a catalytic reaction. Moreover, since the conductivity of free ionic species is proportional to their concentration,[5] this technique can also be used to obtain thermodynamic and kinetic data for the formation of cationic palladium(II) complexes and, consequently, to obtain a deeper insight into the mechanism of palladium-catalyzed reactions.

I. Observation by Conductivity Measurements of Cationic Arylpalladium(II) Complexes in the Oxidative Addition of Aryl Triflates to Neutral Pd^0 Complexes

Since 1984, aryl (or vinyl) triflates often have been used, instead of aryl (or vinyl) halides, in palladium-catalyzed Heck reactions [Equation (1)][2] or Stille reactions [Equation (5)].[7]



Such reactions, however, are greatly affected by the presence of chloride ions, which are added in large excess relative to the palladium catalyst. Extra chloride ions are always required in the case of Stille reactions involving vinyl triflates [Equation (5)].[7a,7b] A mechanistic investigation of the oxidative addition of vinyl triflates to $Pd^0(PPh_3)_4$, reported by Scott and Stille in 1986,[7b] revealed that undefined unstable complexes were formed in THF, whereas stable, well-characterized neutral $(\eta^1\text{-vinyl})Pd^{II}Cl(PPh_3)_2$ complexes were generated when the oxidative addition was performed in the presence of chloride ions. The undefined complexes were postulated to be unstable cationic complexes $[(\eta^1\text{-vinyl})Pd^{II}(PPh_3)_n]^+TfO^-$ (n = 2 or 3). In 1989, Stang et al. established that well-characterized cationic complexes $[(\eta^1\text{-vinyl})Pt^{II}(PPh_3)_3]^+TfO^-$ are formed in the oxidative addition of vinyl triflates to $Pt^0(PPh_3)_4$ in toluene.[8]

To explain the effect of chloride ions on the efficiency of palladium-catalyzed Stille reactions involving aryl triflates, Echavarren and Stille[7c] proposed in 1987 that neutral complexes $ArPdCl(PPh_3)_2$ were produced when the oxidative addition of $Pd^0(PPh_3)_4$ was performed in the presence of chloride ions, whereas decomposition took place in the absence of chloride ions. To characterize cationic complexes $[ArPd(PPh_3)_n]^+$ that would be formed in the oxidative addition of aryl triflates to $Pd^0(PPh_3)_4$, the reaction was reinvestigated by Farina et al. in 1993 in the polar solvent NMP. The authors could not conclude, however, what the structure is of the arylpalladium(II) complex formed in the absence of chloride ions in NMP.[9]

Until 1995, none of the complexes $[ArPdL_n]^+TfO^-$ or $[(\eta^1\text{-vinyl})PdL_n]^+TfO^-$ had been characterized in the oxidative addition of aryl or vinyl triflates, respectively, to Pd^0 complexes.

I.1 Evidence from Conductivity Measurements for the Formation of Cationic *trans*-$[ArPdL_2S]^+$ Complexes in the Oxidative Addition of Aryl Triflates to Neutral Pd^0 Complexes in DMF

In 1995, the cationic character of $[ArPd^{II}(PPh_3)_2S]^+$ complexes, formed in the oxidative addition of aryl triflates to a halide-free Pd^0 complex such as $Pd^0(PPh_3)_4$, was established by conductivity measurements in DMF [Equation (6), L = PPh_3, S = solvent].[10]

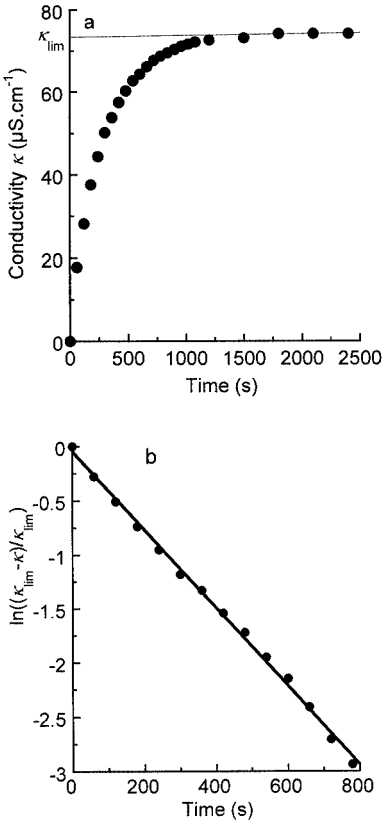


Figure 1. Kinetics of the formation of *trans*-[4-$O_2NC_6H_4Pd(PPh_3)_2(DMF)]^+TfO^-$ in the oxidative addition of 4-$O_2NC_6H_4OTf$ (10 mM) to $Pd^0(PPh_3)_4$ (2 mM) in DMF at 20 °C: (a) variation of the conductivity versus time; $\kappa = \kappa_{exp} - \kappa_0$ (κ_{exp}: experimental conductivity at t; κ_0: initial residual conductivity of 2 $\mu S \cdot cm^{-1}$); (b) variation of $\ln[(\kappa_{lim} - \kappa)/\kappa_{lim})]$ versus time; κ: conductivity at t; κ_{lim}: final conductivity

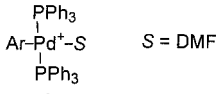
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$ArOTf + Pd^0L_4 \xrightarrow{k_{app}} ArPdL_2S^+ + TfO^- + 2\,L \quad (6)$$

Indeed as is shown in Figure 1 (a), the conductivity (κ) of a solution of $Pd^0(PPh_3)_4$ (2 mM) in DMF (residual conductivity: $\kappa_0 = 2\ \mu S{\cdot}cm^{-1}$) increased upon addition of an aryl triflate (4-$O_2NC_6H_4OTf$) to reach a final, constant conductivity, κ_{lim}. This limiting value was obtained after the oxidative addition was complete, as confirmed by the total disappearance of $Pd^0(PPh_3)_4$, monitored simultaneously by amperometry.[10] This experiment shows that ionic species are formed in the oxidative addition. Moreover, such ionic species are rather stable, as is attested by the observed constant limiting value, κ_{lim} (Figure 1, a).

Cationic complexes were then isolated after an oxidative addition performed in a toluene/DMF solution. Analyses by FAB and electrospray mass spectrometry delivered values of *m*/*z* corresponding to the $[ArPd(PPh_3)_2]^+$ cations (Ar = 4-ClC_6H_4 and 4-$O_2NC_6H_4$) with the predicted isotope pattern expected for the Pd atom. The TfO^- anion was also characterized by FAB spectrometry.[10] Additionally, these complexes were characterized by ^{31}P NMR spectroscopy performed in DMF. The observation of one singlet in the ^{31}P NMR spectrum, even in the presence of excess PPh_3 released from $Pd^0(PPh_3)_4$ [Equation (6)], establishes that the cationic complex contains only two phosphane ligands. Moreover, those two phosphane ligands sit in a relative *trans* orientation on the Pd^{II} atom, with the fourth position being occupied by the solvent as in compound **1**.[10] Consequently, the cationic complexes $[ArPd(PPh_3)_3]^+TfO^-$ are not generated in DMF.



1

The association of the cations *trans*-$[ArPdL_2S]^+$ with the anion TfO^- was studied by observing the variation of their conductivities versus their concentration. In DMF, the conductivity of the ionic species, determined by the value of κ_{lim} (as in Figure 1, a), varied linearly with the palladium concentration in the range $0.5-3 \times 10^{-3}$ M (Figure 2, a).[10] This study established that free ions, *trans*-$[ArPdL_2(DMF)]^+$ and TfO^-, are formed in DMF [Equation (7), L = PPh_3].

$$ArOTf + Pd^0L_4 \xrightarrow{DMF} \underset{trans}{ArPdL_2(DMF)^+} + TfO^- + 2\,L \quad (7)$$

The molar conductivity Λ_M of these ions was calculated in DMF at 20 °C. The values are indicative of 1:1 electrolytes in solution in DMF:[6]

$\Lambda_M = 35\ (\pm 2)\ S{\cdot}cm^2{\cdot}mol^{-1}$ for *trans*-$[4\text{-}O_2NC_6H_4Pd(PPh_3)_2(DMF)]^+TfO^-$

$\Lambda_M = 57\ (\pm 2)\ S{\cdot}cm^2{\cdot}mol^{-1}$ for *trans*-$[4\text{-}ClC_6H_4Pd(PPh_3)_2(DMF)]^+TfO^-$

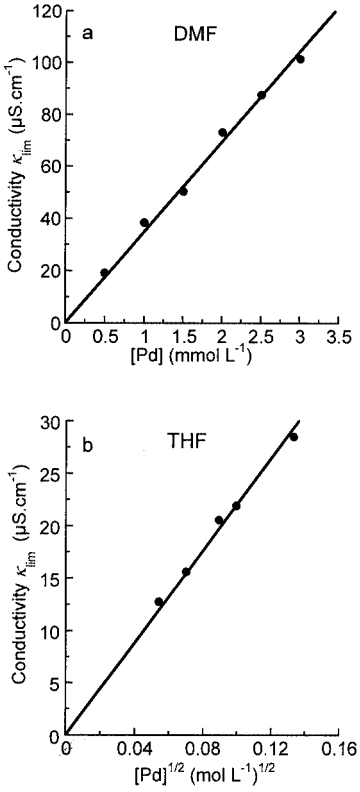


Figure 2. (a) Variation of the conductivity of *trans*-$[4\text{-}O_2NC_6H_4Pd(PPh_3)_2(DMF)]^+TfO^-$ in DMF, determined by the value of κ_{lim} (Figure 1, a) versus the concentration of Pd initially introduced as $Pd^0(PPh_3)_4$ before reaction with 4-$O_2NC_6H_4OTf$, at 20 °C; (b) variation of the conductivity of *trans*-$[4\text{-}O_2NC_6H_4Pd(PPh_3)_2(THF)]^+TfO^-$ in THF (determined as in Figure 2, a) versus the square root of the Pd concentration, at 20 °C

In THF, the conductivity of the ionic species formed in the oxidative addition was lower than that observed in DMF. Moreover, the conductivity varied linearly with the square root of the palladium concentration (Figure 2, b).[10] This observation establishes that free ions *trans*-$[ArPd(PPh_3)_2(THF)]^+$ and TfO^- are formed in THF,[11] but they are involved in an equilibrium with the neutral complex $[ArPd(OTf)(PPh_3)_2]$.[13]

The effect of additives (chloride or acetate ions) on the structure of the cationic complexes has been tested. Addition of chloride ions, from nBu_4NCl (2 mM), to a solution of *trans*-$[4\text{-}O_2NC_6H_4Pd(PPh_3)_2(DMF)]^+TfO^-$ (2 mM) in DMF resulted in a conductivity lower than the sum of the intrinsic conductivities of *trans*-$[4\text{-}O_2NC_6H_4\text{-}Pd(PPh_3)_2(DMF)]^+TfO^-$ and $nBu_4N^+Cl^-$.[10] This observation is indicative of the formation of a neutral complex, which was identified as *trans*-4-$O_2NC_6H_4PdCl(PPh_3)_2$ [Equation (8), L = PPh_3] by comparison with an authentic sample.

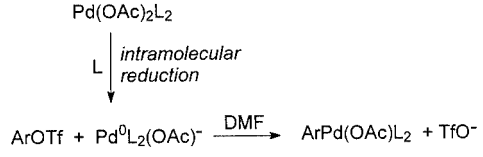
$$ArPdL_2(DMF)^+ + TfO^- + nBu_4N^+ + Cl^- \longrightarrow ArPdClL_2 + TfO^- + nBu_4N^+ \quad (8)$$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

It has also been observed that the oxidative addition in DMF of aryl triflates to the anionic Pd^0 complex $[Pd^0(PPh_3)_2Cl]^-$, generated by addition of chloride ions to $Pd^0(PPh_3)_4$ or by the electrochemical reduction of $PdCl_2(PPh_3)_2$,[14] gave the neutral *trans*-$ArPdCl(PPh_3)_2$ (Scheme 1).[10,15]

Scheme 1. Oxidative addition of aryl triflates to anionic Pd^0 complexes

Similarly, the oxidative addition in DMF of aryl triflates to the anionic Pd^0 complex $[Pd^0(PPh_3)_2(OAc)]^-$, generated from $Pd(OAc)_2$ and 3 equiv. of PPh_3,[16] led to neutral complexes *trans*-$ArPd(OAc)(PPh_3)_2$ (Scheme 2).[15] At low concentrations, some *trans*-$[ArPd(PPh_3)_2(DMF)]^+$ may still coexist with *trans*-$ArPd(OAc)(PPh_3)_2$ since the partial dissociation of the latter to the cationic complex and AcO^- has been established independently ($K_{diss} = 1.3 \times 10^{-3}$ M).[16b,16c]



Scheme 2. Oxidative addition of aryl triflates to anionic Pd^0 complexes

Consequently, in the case of the *monodentate phosphane* PPh_3, cationic complexes *trans*-$[ArPdL_2(DMF)]^+$ (TfO^- counteranion) are generated in the oxidative addition of aryl triflates to neutral Pd^0 complexes in DMF, whereas neutral complexes *trans*-$[ArPdXL_2]$ (X = Cl, OAc) are formed in the oxidative addition to anionic Pd^0 complexes ligated by chloride or acetate ions.

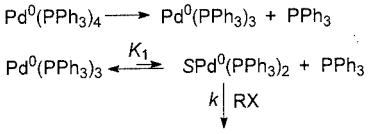
The oxidative addition of aryl triflates to Pd^0 complexes ligated to *bidentate bis(phosphane)* (P,P) ligands has also been investigated. When the oxidative addition of aryl triflates [Ar = 4-$O_2NC_6H_4$, 3,5-$(CF_3)_2C_6H_3$, C_6H_5] to $Pd^0(dppf)(\eta^2\text{-}CH_2{=}CHCO_2Me)$ was performed in THF, the resulting cationic $[ArPd(dppf)(THF)]^+$ complexes were not stable at room temperature.[17] Stable, neutral ArPdCl(dppf), ArPdI(dppf) and ArPd(OAc)(dppf) complexes were obtained, however, when the oxidative additions were performed in the presence of chloride, iodide or acetate ions, respectively.[17] Recently, Alcazar–Roman and Hartwig reported data on the oxidative addition of phenyl triflate to $Pd^0(BINAP)_2$ in THF. A stable cationic complex was obtained only in the presence of an amine: $[PhPd(BINAP)(NH_2R)]^+TfO^-$ (R = alkyl).[18]

Oxidative additions, however, of aryl triflates to Pd^0 ligated to bis(phosphane) (P,P) ligands are sluggish reactions.[17–19] To bypass this problem, chemists interested in the mechanism of reactions involving cationic $[ArPd(P,P)S]^+TfO^-$ complexes (supposedly formed in the oxidative addition of aryl triflates) have synthesized such complexes by treating ArPdX(P,P) (X = I, Br, Cl) with AgOTf.[18–21] Using this strategy, Brown and Hii characterized complexes $[ArPd(dppf)(THF)]^+TfO^-$ [Ar = Ph, 4-$CH_3OC_6H_4$, 3,5-$(CF_3)_2C_6H_3$] in THF at low temperatures ($\leq$ 0 °C); they found that [{3,5-$(CF_3)_2C_6H_3$}Pd(dppf)(DMF)]$^+TfO^-$ is stable at room temperature in DMF.[20b] In a similar manner, Espinet et al. reported that stable complexes $[ArPd(dppe)(THF)]^+TfO^-$ (Ar = C_6F_5, $C_6Cl_2F_3$) can be synthesized in THF.[19] These complexes have been characterized by conductivity measurements.[19,20b] Ludwig et al. have synthesized complexes $[PhPd(P,P)(DMF)]^+TfO^-$ (P,P = dppe, dppp, dcpe), which are stable at 0 °C.[21]

Consequently, polar solvents such as DMF (and, to lesser extent, THF) and amines appear to be good coordinating solvents and ligands, respectively, for the stabilization of cationic complexes $[ArPdL_2S]^+TfO^-$ [L = monophosphane or L_2 = bis(phosphane), *S* = solvent or amine] formed in the oxidative addition of aryl triflates to neutral Pd^0 complexes.

I.2 Kinetics of the Formation of Cationic $[ArPd(PPh_3)_2S]^+$ Complexes in the Oxidative Addition of Aryl Triflates to Neutral Pd^0 Complexes in DMF Monitored by Conductivity Measurements – Influence of Chloride Ions

Any oxidative addition performed using $Pd^0(PPh_3)_4$ involves $SPd^0(PPh_3)_2$ [22] as the reactive complex generated from $Pd^0(PPh_3)_3$ [23] in an endergonic and fast equilibrium (Scheme 3).



Scheme 3. Mechanism of oxidative additions from $Pd^0(PPh_3)_4$ (*S* = solvent)

The oxidative addition of aryl triflates with $Pd^0(PPh_3)_4$ [Equation (6)] is then an overall reaction that proceeds via $SPd^0(PPh_3)_2$ and k_{app} is the apparent rate constant of the overall reaction ($k_{app} = K_1k/[PPh_3]$).[22]

Since the conductivity κ of $[ArPd(PPh_3)_2(DMF)]^+TfO^-$ in DMF is proportional to its concentration, the evolution of the conductivity κ with time, as observed in Figure 1 (a), characterizes the kinetics of the formation the cationic complex $[ArPd(PPh_3)_2(DMF)]^+$ in the oxidative addition of ArOTf to $Pd^0(PPh_3)_4$. The variation of $\ln[(\kappa_{lim} - \kappa)/\kappa_{lim}]$ versus time was linear (Figure 1, b): $\ln[(\kappa_{lim} - \kappa)/\kappa_{lim}] = -k_{app}[ArOTf]t$.[10] The slope of the line gives the value of the rate constant for the formation of the cationic complex (0.35 ± 0.02 $M^{-1}s^{-1}$ for 4-$O_2NC_6H_4OTf$ in DMF at 20 °C). This rate constant is very similar to the rate constant of the disappearance of the Pd^0 complex monitored independently by amperometry ($k_{app} = 0.32 \pm 0.02$ $M^{-1}s^{-1}$).[10] This observation shows that, if the oxidative addition involves the

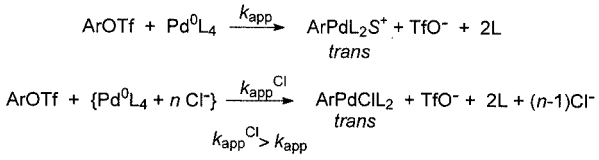
Table 1. Accelerating effect of chloride ions [added as nBu$_4$NCl to Pd^0(PPh$_3$)$_4$ prior to the addition of ArOTf] on the rate of the oxidative addition of aryl triflates to Pd^0(PPh$_3$)$_4$ (c_0 = 2 mM) in DMF at 20 °C (Scheme 4)

ArOTf	4-O$_2$NC$_6$H$_4$OTf		C$_6$H$_5$OTf		1-Naphthyl−OTf	
Cl$^-$ equiv./[Pd^0(PPh$_3$)$_4$]	0	150	0	150	0	150
k_{app}^{Cl} [M^{-1}·s^{-1}]	0.32	0.59	1.7×10^{-3}	33×10^{-3}	7.5×10^{-2}	43×10^{-2}

formation of an intermediate neutral complex, ArPd(OTf)L$_2$, then the ionization of this neutral complex in DMF to [ArPdL$_2$(DMF)]$^+$ and TfO$^-$ is faster than the oxidative addition step. Consequently, the affinity of the anion TfO$^-$ for the Pd^{II} in DMF is very low.

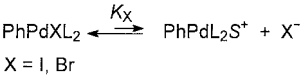
Since chloride ions play an important role in the efficiency of palladium-catalyzed reactions performed from aryl triflates,[7d−7f,9] it was of interest to investigate a possible kinetic effect of chloride ions in the oxidative addition of aryl triflates. This effect cannot be monitored by conductivity measurements because of the high conductivity of nBu$_4$NCl when added in relatively large amounts. This problem was solved by investigating the kinetics of the oxidative addition of aryl triflates by amperometry.[10,22] This technique allows monitoring of the decay of the Pd^0 concentration in the oxidative addition by recording the decay of its oxidation current (which is proportional to its concentration) versus time, after addition of the aryl triflate. As summarized in Table 1, the effect of chloride ions [added as nBu$_4$NCl to Pd^0(PPh$_3$)$_4$ prior to the addition of the aryl triflate] is to accelerate the rate of the oxidative addition,[10] as a consequence of the formation of anionic [Pd^0(PPh$_3$)$_2$Cl]$^-$ complexes.[14] Addition of a rather large amount of chloride ions, relative to Pd^0(PPh$_3$)$_4$, is required to observe a significant accelerating effect with highly reactive triflates. The effect is more pronounced when poorly reactive aryl triflates are considered (Table 1).

Consequently, the chloride ions play a dual role in the oxidative addition of aryl triflates to Pd^0(PPh$_3$)$_4$: (i) acceleration of the oxidative addition and (ii) formation of neutral *trans*-ArPdCl(PPh$_3$)$_2$ complexes (Scheme 4).[10]



Scheme 4. Effect of chloride ions on the oxidative addition of aryl triflates to Pd^0(PPh$_3$)$_4$ in DMF

Since aryl triflates may supplant aryl halides in palladium-catalyzed reactions, it was of interest to compare their reactivity in oxidative additions to Pd^0(PPh$_3$)$_4$ (c_0 = 2 mM). The following order of reactivity in DMF was established: PhI >> PhOTf > PhBr >> PhCl, with rate constants at 20 °C of 17, 0.0017, and 0.001 M^{-1}s^{-1} for PhI, PhOTf and PhBr, respectively.[10] In DMF, the complexes *trans*-PhPdI(PPh$_3$)$_2$ and *trans*-PhPdBr(PPh$_3$)$_2$, formed by the oxidative additions of PhI and PhBr, respectively, partly dissociate to generate the cationic complexes *trans*-[PhPd(PPh$_3$)$_2$(DMF)]$^+$ [Equation (9), $K_I = 5.8 \times 10^{-4}$ M, $K_{Br} = 2.8 \times 10^{-4}$ M at 25 °C].[24] Since the values of the equilibrium constants K_I and K_{Br} are low, the degree of dissociation will be significant only at low concentrations.



(9)

Conductivity measurements have also been used to characterize cationic complexes formed in the oxidative addition of aryl iodides to (P,N,P)Pd^0(dba) complexes in DMSO.[25] The ionic character found for complexes [ArPd(P,N,P)]$^+$ indicates that the (P,N,P) ligands behave as *tridentate* ligands for the Pd^{II} complex [Equation (10)]. The kinetics of formation of the cationic complexes has been monitored by conductivity measurements that have allowed determination of the rate constant k_{app} [Equation (10)].[25] The effect that the N-bearing substituent and the aryl group have on the rate of the oxidative addition was then investigated.

I.3 Conclusion and Mechanistic Consequences in Palladium-Catalyzed Stille and Heck Reactions: Cationic versus Neutral Arylpalladium(II) Complexes as Key Intermediates

On the basis of the kinetic data and the structures of arylpalladium complexes reported above, the mechanisms of palladium-catalyzed reactions involving aryl triflates (ArOTf) may differ from those involving aryl halides (ArX). On one hand, aryl triflates are less reactive than aryl iodides and so the oxidative addition (first step of the catalytic cycles) may become rate-determining when using aryl triflates. On the other hand, the formation of cationic *trans*-[ArPdL$_2$*S*]$^+$TfO$^-$ complexes from aryl triflates versus neutral *trans*-ArPdXL$_2$ from aryl halides may affect their reactions with nucleophiles: transmetallation with organostannanes in the case of Stille reactions [Equation (11)] and carbopalladation with alkenes in the case of Heck reactions [Equation (12)]. Moreover, the presence of chloride ions in reactions performed using aryl triflates[7a−7f,9,12] introduces

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

some complexity, since chloride ions accelerate the rate of the slow oxidative addition of aryl triflates and affect the structure of the arylpalladium(II) complex involved in the reaction with the nucleophile by formation of neutral *trans*-$ArPdClL_2$ complexes.

I.3.1 Stille Reactions

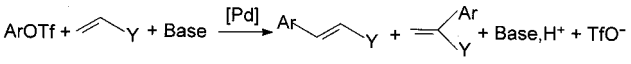
With regard to these observations, Espinet et al. have analyzed the puzzling role, positive or negative, depending on ligand and solvent, of chloride ions in Stille reactions involving aryl triflates (aryl = C_6F_5 or $C_6Cl_2F_3$) and CH_2=$CHSnBu_3$ [Equation (11)].[12]

$$ArOTf + RSnR'_3 \xrightarrow[Cl^- ?]{[Pd]} ArR + TfOSnR'_3 \quad (11)$$

In THF, whatever the ligand (PPh_3 or $AsPh_3$), neutral *trans*-$ArPdClL_2$ complexes are formed in the presence of chloride ions. When the palladium atom is ligated by $AsPh_3$, the transmetallation of CH_2=$CHSnBu_3$ with *trans*-$ArPdCl(AsPh_3)_2$ is fast and the oxidative addition of aryl triflates to $Pd^0(AsPh_3)_4$ is rate-determining. Thus, the positive role of chloride ions in this Stille reaction arises from an acceleration of the oxidative addition. When the palladium atom is ligated by PPh_3, the transmetallation with *trans*-$[ArPdCl(PPh_3)_2]$ becomes rate-determining. In this case, the inhibiting role of chloride ions in the Stille reaction arises from a deceleration of the transmetallation, which is even slower with neutral *trans*-$ArPdCl(PPh_3)_2$ complexes than with cationic complexes $[ArPdX'(PPh_3)_2]^+$ (X′ = PPh_3 or *S*) formed in the absence of chloride ions.[12]

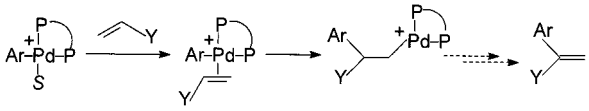
I.3.2 Heck Reactions

The question of the reactivity of neutral versus cationic arylpalladium(II) complexes is also crucial in Heck reactions performed with aryl triflates [Equation (12)].[2]



(12)

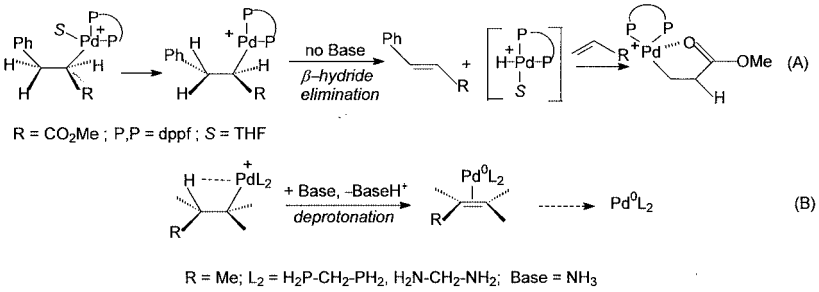
The simultaneous use of aryl triflates and *bidentate ligand* (P,P) may affect the reactivity, regioselectivity and enantioselectivity of the reactions. Indeed, the catalytic reactions work well with electron-rich alkenes (Y = OR, ...) and allow the unusual substitution by the aryl group at the more-substituted carbon atom of the alkene (α-arylation).[2] An "ionic" mechanism has been proposed by Cabri et al.[2a,2d,2f] and Hayashi et al.[2b,2c,2e] (Scheme 5). Cationic complexes $[ArPd(P,P)S]^+$ generated in the oxidative addition have a labile coordination site *cis* to the Ar group and easily react with electron-rich alkenes. The carbopalladation step (also called an insertion step) gives a cationic alkylPd^{II} complex in which the aryl group and the electron-donor group Y are attached to the same C atom (Scheme 5).



Scheme 5. Mechanism of the carbopalladation step from *cationic* arylpalladium(II) complexes ligated to bidentate (P,P) ligands

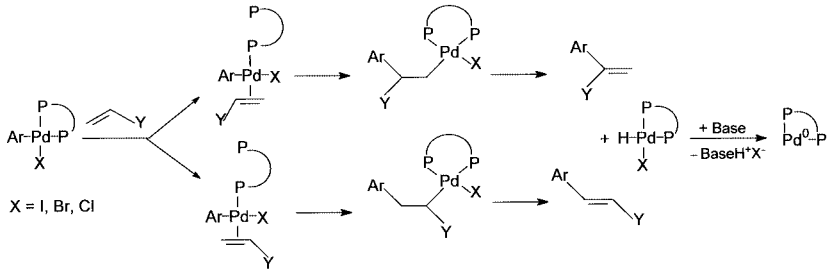
This mechanism will also operate with aryl halides, provided that silver[26a] or thallium[26b] salts are present to abstract the halide ion from ArPdX(P,P) to generate the cationic complexes $[ArPd(P,P)S]^+$.[20]

The mechanism of the formation of the arylated alkene from the intermediate cationic alkylPd^{II} complex[20b,27] is still under debate (Scheme 5). In the absence of a base, Brown and Hii have characterized by ^1H NMR spectroscopy the cationic alkylPd^{II} complex formed from $[PhPd(dppf)(THF)]^+$ and CH_2=$CHCO_2Me$ in THF at low temperatures (Scheme 6).[20b] The arylated alkene was formed by a β-hydride elimination (Scheme 6, path A). Neither $[HPd(P,P)S]^+$ nor $Pd^0(P,P)$ were detected, but a new cationic alkylPd^{II} species was observed to have formed by addition of the transient $[HPd(P,P)S]^+$ ion to the alkene CH_2=$CHCO_2Me$ (Scheme 6, path A). Consequently, no Pd^0 complex was generated from $[HPd(P,P)S]^+$ in the absence of a base. On the basis of DFT calculation, Deeth et al. have proposed the existence of a β-agostic hydrogen atom (Scheme 6, path B) because of the cationic character of the alkylpalladium(II) species formed in the carbopalladation step.[27a] Consequently, in the presence of a base, the Pd^0 complex would not be generated via a cationic palladium hydride formed by the traditional β-hydride elimination, but instead by deprotonation by the base of the acidic agostic proton (Scheme 6, path B).



Scheme 6. Mechanism of the formation of an arylated alkene from *cationic* alkylpalladium(II) complexes ligated by bidentate ligands

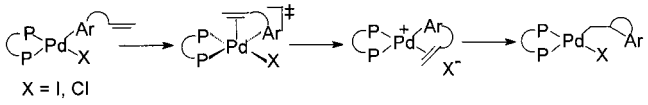
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 7. Mechanism of the carbopalladation step from *neutral* arylpalladium(II) complexes ligated to bidentate (P,P) ligands, followed by β-hydride elimination and formation of a Pd^0 complex

A "neutral" mechanism is proposed when neutral ArPdX(P,P) complexes are generated in the oxidative addition of aryl halides (X = I, Br, Cl) or of aryl triflates in the presence of chloride ions (X = Cl).[2a,2d,2f] The neutral complexes would be less reactive than the cationic ones because the complexation of the alkene requires the unfavorable deligation of one P atom of the bis(phosphane) ligand. Moreover, such Heck reactions lead to nonselective α- and β-arylation (Scheme 7).[2a,2d,2f]

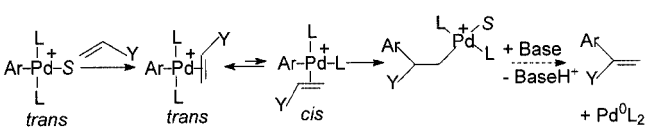
Although the "ionic" mechanism is supposed to induce better enantioselectivity in intramolecular Heck reactions,[2b,2c,2e,27b] Overman et al. have observed that the enantioselectivity is improved under the conditions of the "neutral" mechanism, i.e., from aryl iodides or from aryl triflates in the presence of chloride ions.[28] They propose the deligation of the halide as the key step responsible of this enantioselectivity, rather than deligation of one P atom of the bis(phosphane) via a pentacoordinate Pd^{II} transition state (Scheme 8).



Scheme 8. Mechanism of the intramolecular carbopalladation step

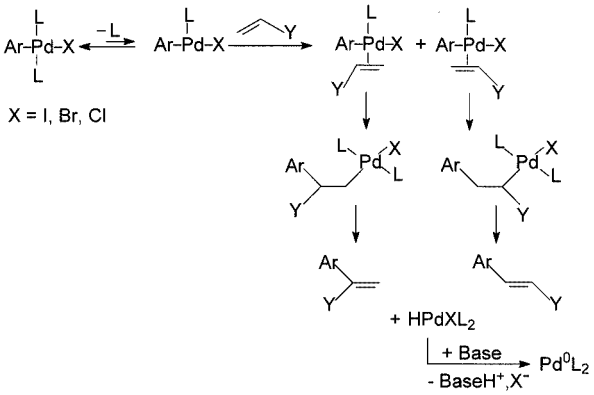
As far as monodentate ligands (L) are concerned, cationic *trans*-$[ArPdL_2S]^+$ complexes appear to be more reactive than neutral *trans*-$ArPdXL_2$ (X = I) ones; they are, however, less reactive than *trans*-$ArPd(OAc)L_2$ complexes. The following order of reactivity with styrene has been observed in DMF:[16b,16c] *trans*-$PhPd(OAc)(PPh_3)_2$ > *trans*-$[PhPd(PPh_3)_2S]^+$ > *trans*-$PhPdI(PPh_3)_2$.

Because of the labile coordination site in the cationic complex *trans*-$[ArPdL_2S]^+$, no phosphane dissociation is required. The coordination of the alkene leads, however, to a *trans* complex, *trans*-$[ArPd(\eta^2\text{-alkene})L_2]^+$, which must reorganize to the *cis* complex (a thermodynamically unfavorable process) to allow alkene insertion into the Ar−Pd bond (Scheme 9). The evolution of the cationic alkylPd^{II} complex may then follow the mechanism proposed in Scheme 6 (path B) for bidentate ligands.



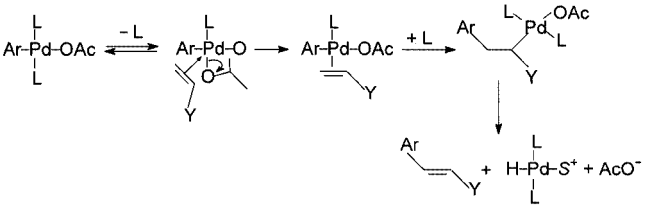
Scheme 9. Mechanism of the carbopalladation step from *cationic* arylpalladium(II) complexes ligated to monodentate ligands

The carbopalladation step from neutral *trans*-$ArPdXL_2$ complexes requires dissociation of one phosphane unit, which must be rate-determining when PPh_3 is considered (Scheme 10).



Scheme 10. Mechanism of the carbopalladation step from *neutral* arylpalladium(II) complexes ligated to monodentate ligands, followed by β-hydride elimination

When the Pd^0 precursor is $Pd(OAc)_2$ and PPh_3, *trans*-$ArPd(OAc)(PPh_3)_2$ complexes are generated in the oxidative addition of aryl triflates (Scheme 2)[15] or iodides.[16] The higher reactivity of *trans*-$ArPd(OAc)(PPh_3)_2$ compared to that of *trans*-$ArPdI(PPh_3)_2$ may be understood as a result of an easier displacement of the phosphane by the acetate, which may behave as a bidentate ligand[16c] {Scheme 11, see Sect. III for the existence of cationic $[HPdL_2(DMF)]^+$ formed in the β-hydride elimination step}.



Scheme 11. Mechanism of the carbopalladation step from $ArPd(OAc)(PPh_3)_2$ complexes followed by β-hydride elimination in DMF

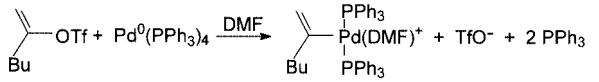
II. Formation of Cationic Palladium(II) Complexes in the Oxidative Addition of Vinyl Triflates or Benzoic Anhydride to $Pd^0(PPh_3)_4$ in DMF Observed by Conductivity Measurements

II.1 Formation of Cationic $[VinylPd(PPh_3)_2S]^+$ Complexes in the Oxidative Addition of Vinyl Triflates to Neutral Pd^0 Complexes in DMF Monitored by Conductivity Measurements

Since DMF appears to be a good coordinating solvent for cationic palladium(II) complexes, this property prompted us to investigate the mechanism of the oxidative addition of vinyl triflates to $[Pd^0(PPh_3)_4]$ in DMF. Cationic complexes *trans*-$[(\eta^1\text{-vinyl})Pd^{II}(PPh_3)_2(DMF)]^+TfO^-$ were generated and characterized by conductivity measurements (Figure 3), NMR spectroscopy, and electrospray mass spectrometry [Equation (13)].[29]



(13)

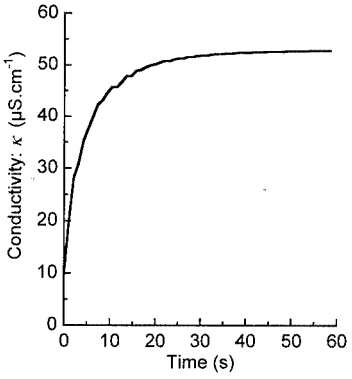


Figure 3. Kinetics of the formation of $[CH_2{=}C(n\text{Bu})Pd(PPh_3)_2(DMF)]^+TfO^-$ in the oxidative addition of $CH_2{=}C(n\text{Bu})OTf$ (2 mM) to $[Pd^0(PPh_3)_4]$ (2 mM) in DMF at 10 °C; variation of the conductivity κ versus time; $\kappa = \kappa_{exp} - \kappa_0$ (κ_{exp}: experimental conductivity at t; κ_0: initial residual conductivity of 3 $\mu S{\cdot}cm^{-1}$)

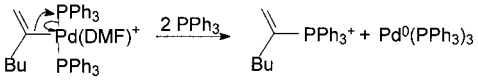
The oxidative addition was considerably faster than that of aryl triflates. Cationic vinylic complexes, however, were less stable than *trans*-$[ArPd(PPh_3)_2(DMF)]^+TfO^-$ since a slow degradation took place that gave the phosphonium salt $[vinylPPh_3]^+TfO^-$ together with a Pd^0 complex that was detected when the oxidative addition was performed under stoichiometric conditions [Equation (14)].[29]



(14)

To date, in the vinylic series, the only stable cationic complexes characterized by conductivity measurements in CH_3NO_2 have been $[(\eta^1\text{-vinyl})Pt(PPh_3)_3]^+TfO^-$ formed in the oxidative addition of vinyl triflates to $Pt^0(PPh_3)_4$ in toluene, as reported by Stang et al.,[8] in which, in the absence of any coordinating solvent, a phosphane ligand occupies the fourth coordination site on the Pd^{II} center.

II.2 Formation of Cationic $[AcylPd(PPh_3)_2S]^+$ Complexes in the Oxidative Addition of Benzoic Anhydride to Neutral Pd^0 Complexes Monitored by Conductivity Measurements in DMF

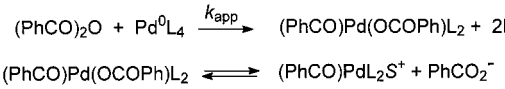
Aromatic carboxylic anhydrides $(ArCO)_2O$ were introduced by Sakamoto et al. as *acylating* agents in palladium-catalyzed cross-coupling reactions (m = ZnX),[30a] and they have been used recently by Yamamoto et al. in Susuki-type reactions [m = $B(OH)_2$] [Equation (15)].[30b]

(15)

Recently, these compounds were used by de Vries et al. as *arylating* agents in palladium-catalyzed Heck reactions [Equation (16)].[31]

(16)

The mechanism of the oxidative addition of the benzoic anhydride to $Pd^0(PPh_3)_4$ (2 mM) has been investigated in DMF. Two $acylPd^{II}$ complexes have been identified (Scheme 12). The cationic complex *trans*-$[(PhCO)Pd(PPh_3)_2(DMF)]^+$, with $PhCO_2^-$ as the counteranion, was detected by conductivity measurements.[32]



Scheme 12. Oxidative addition of benzoic anhydride to $Pd^0(PPh_3)_4$ in DMF ($k_{app} = 3 \times 10^{-3}\ M^{-1}s^{-1}$)

The neutral and cationic $acylPd^{II}$ complexes did not undergo any decarbonylation, which would have generated $phenylPd^{II}$ complex(es), a process required in the Heck reaction [Equation (16)]. Exchanging the two monodentate PPh_3 units with one bidentate ligand, dppp, gave a mixture of $[(PhCO)Pd(dppp)(DMF)]^+PhCO_2^-$ and (PhCO)Pd(OCOPh)(dppp) without any detectable decarbonylation process occurring.[32] Consequently, this reaction excludes the use of phosphane ligands in Heck reactions performed with $(PhCO)_2O$ that are, indeed, efficient with Pd^0 precursors consisting of Pd^{II} salts in the absence of any phosphane ligand.[31]

III. Reversible Formation of Cationic Palladium(II) Hydride Complexes *trans*-$[HPd(PPh_3)_2(DMF)]^+$ in the Oxidative Addition of Carboxylic Acids to $Pd^0(PPh_3)_4$ Observed by Conductivity Measurements in DMF

As developed by Trost et al.,[33] palladium-catalyzed reactions involving alkynes (e.g., cycloisomerization of enynes,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

isomerization of alkynes to 1,3-dienes) are initiated by the reaction of a carboxylic acid HA (acetic or formic acid) with a Pd^0L_n complex (L = monophosphane ligand). A stoichiometric amount of formic acid is required in the Pd-catalyzed hydrocarboxylation of alkynes,[34] or hydrocarbonylation of aryl halides.[35]

The reaction of a carboxylic acid HA with Pd^0L_n was supposed to generate a hydridopalladium complex $[HPd^{II}AL_{n'}]$ [Equation (17)][36] that initiates the catalytic cycle by a *syn*-hydropalladation of the alkyne to form an (η^1-vinyl)palladium(II) complex as a key intermediate for further steps [Equation (18)].[33a,33b]

$$Pd^0L_n + HA \longrightarrow HPdAL_{n'} + (n\text{-}n')L \quad (17)$$

$$HPdAL_{n'} + R{-}\equiv \longrightarrow \begin{matrix} R \\ \diagdown \\ PdAL_{n'} \end{matrix} \!\!=\!\!\begin{matrix} \\ \diagup \\ H \end{matrix} \quad (18)$$

When weak carboxylic acids are considered (acetic or formic acid), the reaction is considered as an oxidative addition, i.e., insertion of Pd^0 into the H−A bond [Equation (17)].[33a,33b] Initially, it was not clear, however, whether the anion A^- remained ligated to the Pd^{II} atom or not. In 1993, Zargarian and Alper proposed the formation of cationic palladium hydride complexes $[HPd(PR_3)_2(\eta^2\text{-alkyne})]^+HCO_2^-$ in the Pd-catalyzed hydrocarboxylation of alkynes in the presence of formic acid.[34] In 1998, Trost proposed in a review the involvement of cationic complexes $[HPdL_{n''}]^+$ (rather than $[HPd(OAc)L_{n'}]$) "undoubtedly formed to some extent, albeit in an unfavorable equilibrium".[33c] Neither $HPd(OAc)L_{n'}$ nor $[HPdL_{n''}]^+$ was characterized in this context.

III.1 Evidence for the Formation of *trans*-$[HPd(PPh_3)_2(DMF)]^+A^-$ ($A^- = CH_3CO_2^-$, HCO_2^-) by Conductivity Measurements in DMF

The reaction of $Pd^0(PPh_3)_4$ with acetic acid in DMF at 25 °C was monitored by conductivity measurements.[37] The conductivity κ of a solution of $Pd^0(PPh_3)_4$ (2 mM) increased after addition of *n* equiv. of acetic acid ($n > 1$) and reached a limiting value (named κ_{equil} in Figure 4) that increased when *n* was increased up to 100. The limiting values were lower in the presence of excess PPh_3 (Figure 4).

The conductivity of acetic acid (a weak acid in DMF, $pK_a = 13.5$) was measured independently in DMF at 25 °C and was found to be negligible (e.g., 6.9 μS·cm^{-1} at 200 mM) compared to that observed when acetic acid was added to $Pd^0(PPh_3)_4$ in DMF (Figure 4).

These experiments establish that the reaction of $Pd^0(PPh_3)_4$ with acetic acid gives ionic species, which are observed to be involved in an equilibrium with the reagents because the concentration of the ionic species increased with the concentration of acetic acid. PPh_3 was involved in the backward reaction of this equilibrium. Since $Pd^0(PPh_3)_3$ is the major complex in solution,[23] the overall equilibrium observed is described in Equation (19). The inhibiting effect of PPh_3 indicates that $SPd^0(PPh_3)_2$ is the reactive species,

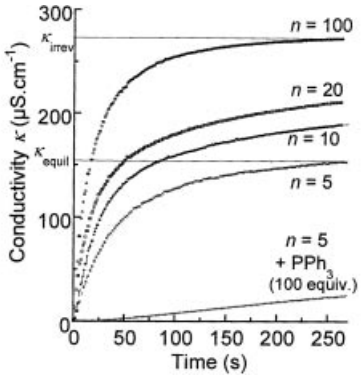


Figure 4. Conductivity in DMF of $[HPd(PPh_3)_2(DMF)]^+AcO^-$ generated in the reaction of $Pd^0(PPh_3)_4$ (2 mM) with *n* equiv. of acetic acid: $n = 100$, 20, 10, and 5 in the absence of PPh_3, or $n = 5$ in the presence of 100 equiv. of PPh_3 (as indicated in the Figure) at 25 °C

since it occurs in regular oxidative additions [Equations (20) and (21)].[22]

$$Pd^0L_3 + HA \underset{k_b}{\overset{k_f}{\rightleftharpoons}} HPdL_2S^+ + A^- + L \qquad K \quad (19)$$

$$Pd^0L_3 \rightleftharpoons SPd^0L_2 + L \quad (20)$$

$$SPd^0L_2 + HA \rightleftharpoons HPdL_2S^+ + A^- \quad (21)$$

The structure of the cationic complex *trans*-$[HPd^{II}(PPh_3)_2(DMF)]^+$ was established by NMR spectroscopy (Table 2).[37] The very negative ^1H NMR spectroscopic chemical shift suggests a hydride character for the H atom ligated to the Pd^{II} atom. The unique ^{31}P NMR spectroscopic singlet indicates that the Pd^{II} center is ligated by only two equivalent PPh_3 units that are situated in a relative *trans* position and that the fourth coordination site is occupied by the solvent. This situation differs from that of $[HPd(PPh_3)_3]^+[CH(SO_2CF_3)_2]^-$ generated in nonpolar solvents such as toluene,[38] or $[HPd(PPh_3)_3]^+CF_3CO_2^-$ generated in aqueous CF_3CO_2H, in which the palladium(II) species is ligated by three phosphane units.[39]

The reaction of $Pd^0(PPh_3)_4$ with formic acid was also monitored by conductivity measurements.[35] the experiments were performed, however, at 0 °C because of a lack of stability observed at 25 °C.[40] The reaction gave the cationic complex *trans*-$[HPd(PPh_3)_2(DMF)]^+$, with HCO_2^- as the counteranion, by a reversible process (Table 2). The overall equilibrium, expressed in Equation (19), was fully positioned to its right-hand side in the presence of 70 equiv. of formic acid.

Consequently, a cationic palladium(II) hydride *trans*-$[HPd(PPh_3)_2(DMF)]^+$ is formed in a reversible reaction, either from acetic acid or from formic acid [Equation (19)]. The molar conductivity Λ_M was calculated for the two complexes $[HPd(PPh_3)_2(DMF)]^+CH_3CO_2^-$ and $[HPd(PPh_3)_2(DMF)]^+HCO_2^-$ (Table 2).

III.2 Determination of the Equilibrium and Rate Constants of the Oxidative Addition of Acetic or Formic Acid to $Pd^0(PPh_3)_4$ in DMF by Conductivity Measurements

III.2.1 Determination of the Equilibrium Constant K

The reaction of acetic or formic acid (n equiv.) with $Pd^0(PPh_3)_4$ obeys the general Equation (19). The equilibrium constant K was determined from the conductivity data, since the limiting values of the conductivity κ_{equil} (Figure 4) provide the thermodynamic concentration of $[HPd(PPh_3)_2(DMF)]^+$ and AcO^- at various concentrations of acetic acid.[37]

$$K = [HPdL_2(DMF)^+][A^-][L]/[Pd^0L_3][HA] = c_0 \cdot x_{equil}^2(1 + x_{equil})/(1 - x_{equil})(n - x_{equil})$$

c_0: initial concentration of $Pd^0(PPh_3)_4$; $x_{equil} = \kappa_{equil}/\kappa_{irrev}$; κ_{equil}: final conductivity measured when the equilibrium is fully established in the presence of n equiv. of HA ($t > 250$ s, Figure 4); κ_{irrev}: final conductivity measured when the equilibrium is fully positioned on its right-hand side, $n = 100$ for CH_3CO_2H (Figure 4), $n = 70$ for HCO_2H.

Identical values for K were found, whatever concentration range was investigated for each carboxylic acid ($0 < n < 100$ for acetic acid and $0 < n < 70$ for formic acid). This result establishes that the cation and anion are free ions in DMF.[37] The values of the equilibrium constants K for acetic and formic acid are gathered in Table 2. Even though they were determined at slightly different temperatures, one notices that, at identical concentrations of acids, the equilibrium lies more in favor of the cationic palladium hydride for formic acid than it does for acetic acid, which is in agreement with the fact that formic acid is slightly more acidic than acetic acid.

III.2.2 Determination of Rate Constants k_f and k_b

Acetic acid is a weak acid in DMF and the concentration of protons is negligible (vide supra) when compared to the Pd^0 concentration. This situation, however, does not exclude the possibility of a direct protonation of $Pd^0(PPh_3)_2$ to form $[HPd(PPh_3)_2S]^+$. The two pathways — (i) direct protonation of $Pd^0(PPh_3)_2$ by H^+ or (ii) oxidative addition of acetic acid to $Pd^0(PPh_3)_2$ to form $HPd(OAc)(PPh_3)_2$ followed by a fast ionization step — may be discriminated by determining the reaction order in acetic acid for the forward reaction [Equation (19)]. That is to say, a reaction order of 1/2 for CH_3CO_2H would suggest the protonation route and a reaction order of 1 for CH_3CO_2H would suggest the oxidative addition route.

The equilibrium in Equation (19) was completely shifted towards the cationic complex $[HPdL_2(DMF)]^+$ when 100 equiv. of acetic acid were treated with $Pd^0(PPh_3)_4$ (c_0 = 2 mM) in DMF. Consequently, the uppermost curve in Figure 4 is representative of the rate of formation of the cationic complex $[HPdL_2(DMF)]^+$. This kinetic curve did not exhibit any induction period, which would result in a significant accumulation of a neutral intermediate species. Moreover, the reaction was found to be faster when the concentration of acetic acid was increased (vide infra). Consequently, the intermediate neutral complex $HPd(OAc)(PPh_3)_2$, if formed in the reaction of acetic acid with $Pd^0(PPh_3)_2$, did not accumulate. Thus, the ionization of $HPd(OAc)(PPh_3)_2$ to $[HPd(PPh_3)_2(DMF)]^+$ and AcO^- was faster than its formation from $Pd^0(PPh_3)_4$, and the rate of formation of the ionic species was the same as that of the disappearance of the Pd^0 complex. Consequently, the rate constant of the forward reaction [k_f in Equation (19)] was determined using the conductivity data of the uppermost curve in Figure 4 ($n = 100$ for CH_3CO_2H). When starting from $Pd^0(PPh_3)_4$, the concentration of PPh_3 was not constant [Equation (20)] and the kinetic law is: $2\ln(1 - x_t) + x_t = -k_{obsd.} \cdot t = -k_f \cdot [HA]^\alpha t$ ($x_t = \kappa_t/\kappa_{irrev}$; κ_t = conductivity at time t; κ_{irrev} = final conductivity; α = reaction order in HA). The values of $k_{obsd.}$ were calculated for acetic acid (Figure 5, a) and formic acid from the slope of the regression line obtained by plotting $[2\ln(1 - x_t) + x_t]$ against time (Figure 5, b).[37]

The reaction of $Pd^0(PPh_3)_4$ with acetic acid was rather fast (uppermost curve in Figure 4) and, consequently, only two concentrations of acetic acid could be tested ($n = 100$: $k_{obsd.} = 0.057$ s^{-1}; $n = 200$: $k_{obs} = 0.104$ s^{-1}). From these results, it appears that the reaction order α in acetic acid is close to 1 ($k_{obsd.} = k_f \cdot [HA]$), which favors the pathway of an oxidative addition of acetic acid to $SPd^0(PPh_3)_2$ followed by a fast ionization step of the neutral complex $HPd(OAc)(PPh_3)_2$. The values of k_f were then determined for acetic and formic acid (Table 2).[37] The values of the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

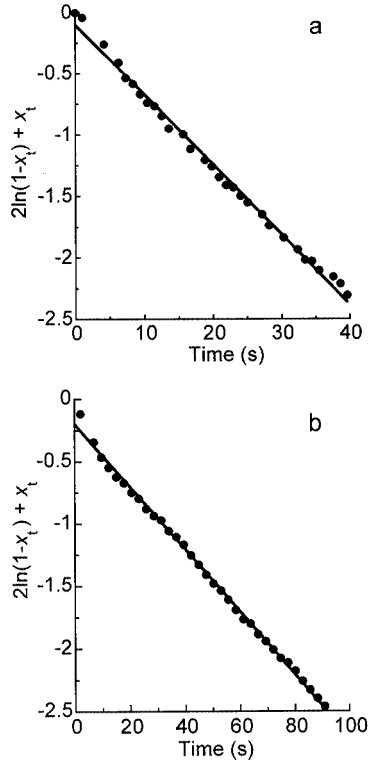

Figure 5. Kinetics of the oxidative addition of $Pd^0(PPh_3)_4$ (2 mM) in DMF to: (a) acetic acid (0.2 M) at 25 °C; (b) formic acid (0.2 M) at 0 °C; in both figures, plot of $[2\ln(1 - x_t) + x_t]$ versus time; $x_t = \kappa_t/\kappa_{irrev}$; κ_t = conductivity at t; κ_{irrev} = final conductivity, under conditions where the reactions were irreversible (see uppermost curve in Figure 4 for acetic acid)

rate constants of the backward reaction [k_b in Equation (19)] were then deduced from the values of the equilibrium constant $K = k_f/k_b$ (Table 2).

The overall equilibrium in Equation (19) may be then considered as the successive equilibria shown in Equation (22), which involve a reversible oxidative addition as the very first step (L = PPh_3).

$$Pd^0L_2 + HA \rightleftharpoons \underset{cis}{HPdAL_2} \rightleftharpoons \underset{trans}{HPdAL_2} \rightleftharpoons \underset{trans}{HPdL_2S^+} + A^- \quad (22)$$

III.3 Conclusion and Mechanistic Consequences

The results above illustrate how conductivity data may be used efficiently (i) to characterize ionic complexes formed in the reaction between a carboxylic acid and a Pd^0 complex, (ii) to establish the reversibility of this reaction and to determine its equilibrium constant, (iii) to determine the rate constant of the forward and backward reactions of the equilibrium, and (iv) to delineate the mechanism by discriminating between oxidative addition and protonation.

It has been established that a cationic palladium hydride $[HPd(PPh_3)_2(DMF)]^+$ is generated by oxidative addition of weak carboxylic acids (acetic or formic acid) and $Pd^0(PPh_3)_4$ in a coordinating solvent as DMF. However, it is generated in an unfavorable equilibrium. Consequently, as predicted by Trost,[33c] if a high concentration of the key intermediate $[HPdL_2S]^+$ is needed, a large excess of the carboxylic acid is required and use of formic acid is more efficient than acetic acid.[41]

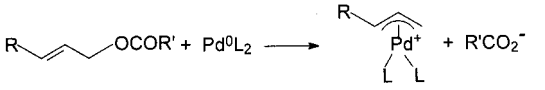
In Heck reactions, when the precursor of the Pd^0 catalyst is $Pd(OAc)_2$ associated with phosphane ligands L, the active Pd^0 complex in the oxidative addition with PhI is the anionic species $[Pd^0L_2(OAc)]^-$, and $ArPd(OAc)L_2$ is formed in the oxidative addition of aryl iodides[16] or triflates.[15] The carbopalladation of the alkene by $ArPd(OAc)L_2$ is followed by β-hydride elimination (Scheme 11) that, according to the results just reported above, should not generate the neutral $HPd(OAc)(PPh_3)_2$ in DMF, but instead the cationic palladium hydride $[HPd(PPh_3)_2(DMF)]^+$ with AcO^- as the counteranion (Scheme 11). Since the reversibility of the oxidative addition of the acetic acid with $Pd^0(PPh_3)_2$ has been established [Equation (22)], however, the complex $[HPd(PPh_3)_2(DMF)]^+AcO^-$ must be involved in an equilibrium with acetic acid and Pd^0L_2, so that the Pd^0L_2 complex should be generated in the absence of a base. The role of the base would then be devoted to its reaction with acetic acid to generate AcO^- as a key ligand for the active complexes $[Pd^0L_2(OAc)]^-$ and $ArPd(OAc)L_2$.[16]

IV. Reversible Formation of Cationic $[(\eta^3\text{-allyl})PdL_2]^+$ Complexes in the Oxidative Addition of Allylic Carboxylates or Carbonates to Pd^0 Complexes Observed by Conductivity Measurements in DMF

Palladium complexes are efficient catalysts for Tsuji−Trost reactions, i.e., nucleophilic substitutions on allylic carboxylates[3] or carbonates[42] (R′ = OR′′) [Equation (23)].

(23)

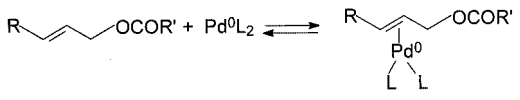
The first step of the catalytic cycle is an oxidative addition of the allylic derivative, allylOCOR′, to a lowly ligated Pd^0 complex, Pd^0L_2 (L = monodentate phosphane ligand or L_2 = bidentate phosphane ligand) [Equation (24)], which is believed to proceed in two successive steps.[3]



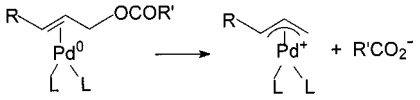
(24)

The first of these steps is a reversible complexation of the C=C double bond of the allylic derivative to Pd^0L_2 [Equation (25)]; the second step is the oxidative addition (commonly named the "ionization step") in which a cationic $[(\eta^3\text{-allyl})Pd^{II}L_2]^+$ complex is formed with the leaving group $R'CO_2^-$ as the counteranion [Equation (26)].

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

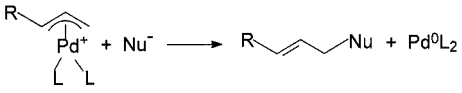


(25)

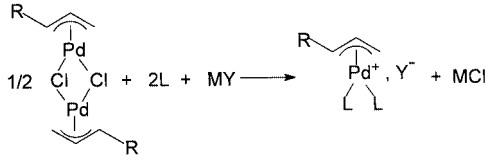


(26)

The mechanism of the next step, the nucleophilic attack onto the cationic $[(\eta^3\text{-allyl})PdL_2]^+$ complex has been widely investigated [Equation (27)].[3] Such reactions have been usually performed, however, on cationic palladium(II) complexes that were not generated in the oxidative addition of Equation (24),[43] but instead independently synthesized from dimeric $Pd_2(\eta^3\text{-allyl})_2(\mu\text{-Cl})_2$ complexes[43b] by addition of monodentate or bidentate phosphanes and abstraction of the chloride ion by MY (M = K, Na, Ag; Y = BF_4, BPh_4, OTf) [Equation (28)].[43b,44a] Under such conditions, the counteranion is BF_4^-, BPh_4^- or TfO^-, but not $R'CO_2^-$ as it would be in the oxidative addition performed from allylOCOR′. The complex [(2-methylallyl)$Pd(PPh_3)_2]^+BF_4^-$ has been characterized by conductivity measurements in aqueous acetone;[44a] the conductivity of related complexes in THF is very low.[44b] A few complexes [(1,3-diphenyl-η^3-allyl)Pd(P,P)]$^+AcO^-$ (P,P: ferrocenylphosphane ligands) have been synthesized from $Pd_2(\eta^3\text{-allyl})_2(\mu\text{-OAc})_2$, but at low temperatures.[45]



(27)



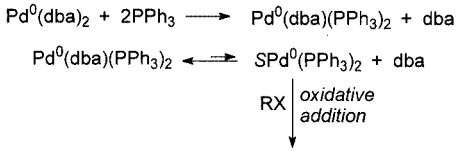
(28)

Consequently, until 1999 the cationic character of $[(\eta^3\text{-allyl})PdL_2]^+$ complexes, generated in the oxidative addition of allylic acetates with AcO^- as counteranion [Equation (24)], had never been established. Such complexes have recently been characterized by conductivity measurements in DMF with monodentate and bidentate phosphane ligands.[46−50] In addition, the reversibility of the oxidative addition has also been established by conductivity measurements in conjunction with other analytical techniques (vide infra).[46−50]

The Pd^0 precursor investigated was $Pd^0(dba)_2$ (dba: *trans*,*trans*-dibenzylideneacetone) associated with either 2 equiv. of a monophosphane ligand (L = PPh_3)[51] or with 1 equiv. of a bidentate bis(phosphane) (P,P) ligand {dppb [1,4-bis(diphenylphosphane)butane] or dppf [1,4-bis(diphenylphosphanyl)ferrocene)}[52] which are catalytic precursors for the Tsuji−Trost reactions.[3,51]

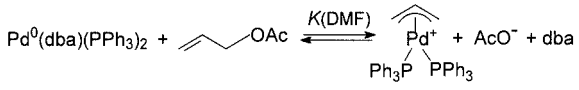
IV.1 Reversible Formation of Cationic $[(\eta^3\text{-allyl})PdL_2]^+$ Complexes in the Oxidative Addition of Allyl Acetate to Pd^0 Complexes Ligated by a Monophosphane Ligand

The reaction of $Pd^0(dba)_2$ with 2 equiv. of PPh_3 in DMF or THF gives the major complex $Pd^0(dba)(PPh_3)_2$. The species is involved in an equilibrium with the minor complex $SPd^0(PPh_3)_2$, the usual active species in oxidative additions (Scheme 13).[53]



Scheme 13. Mechanism of the oxidative addition of an electrophile RX with the Pd^0 complex generated from the catalytic precursors $Pd^0(dba)_2$ and PPh_3 (2 equiv.) in DMF or THF

Conductivity measurements were performed on a solution of $Pd^0(dba)_2$ (c_0 = 2 mM) and 2 equiv. of PPh_3 in DMF after addition of 6.2 equiv. of $CH_2{=}CHCH_2OAc$. The conductivity κ increased with time to reach a plateau (κ_{equil}) whose value increased upon successive additions of allyl acetate (Figure 6, a).[46] This observation establishes that ionic species were formed that were involved in an equilibrium with the starting reagents [Equation (29)] because their concentration increased upon increasing the allyl acetate concentration. The conductivity κ_{equil} decreased when the concentration of dba was increased (Figure 6, b). Consequently, dba is involved in the reverse reaction of the equilibrium [Equation (29)].[46]



(29)

The complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+$ formed in the reaction was identified by a singlet in the ^{31}P NMR spectrum at δ = 24.06 ppm; by comparison, an authentic sample of $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+BF_4^-$ has δ = 24.08 ppm.[44a] The reversibility of the equilibrium in Equation (29) was established independently by treating $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+BF_4^-$ with 1 equiv. of nBu_4NOAc in the presence of 2 equiv. of dba. The complex $Pd^0(dba)(PPh_3)_2$ formed in the backward reaction was characterized by ^{31}P NMR spectroscopy when the reaction was performed in DMF, whereas $CH_2{=}CHCH_2OAc$ was characterized by ^1H NMR spectroscopy when the reaction was performed in $CDCl_3$.[46]

The equilibrium constant K_{DMF} [Equation (29)] could have been determined using the conductivity data of Figure 6 (a), as was accomplished for $[HPd(PPh_3)_2(DMF)]^+AcO^-$ (see Sect. III.2.1). The full shift, however, of the equilibrium towards the ionic species required a larger amount of allyl acetate ($n >> 100$) than that used in Figure 6 (a). Consequently, the intrinsic con-

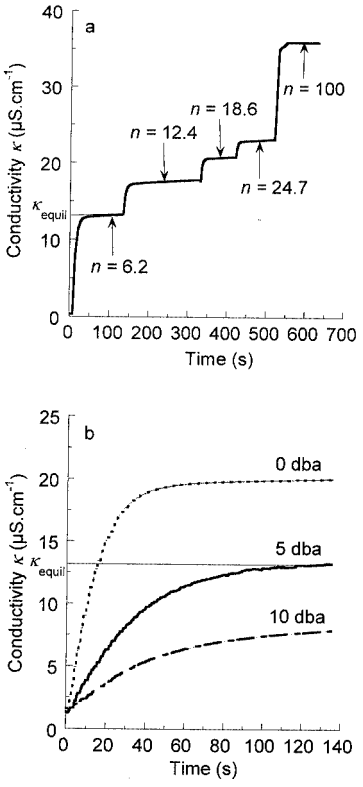

Figure 6. (a) Conductivity in DMF of $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+AcO^-$ formed in the reaction of the Pd^0 complex generated from $Pd^0(dba)_2$ (2 mM) and PPh_3 (4 mM) with $CH_2{=}CHCH_2OAc$ added successively at 20 °C; as indicated, n is the cumulative number of equiv. of $CH_2{=}CHCH_2OAc$; (b) conductivity of $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+AcO^-$ generated in the reaction of $Pd^0(dba)_2$ (2 mM) and PPh_3 (4 mM) with $CH_2{=}CHCH_2OAc$ (0.1 M) at 20 °C, in the presence of various amounts of dba, which was added to $Pd^0(dba)_2$ and PPh_3 prior the introduction of $CH_2{=}CHCH_2OAc$

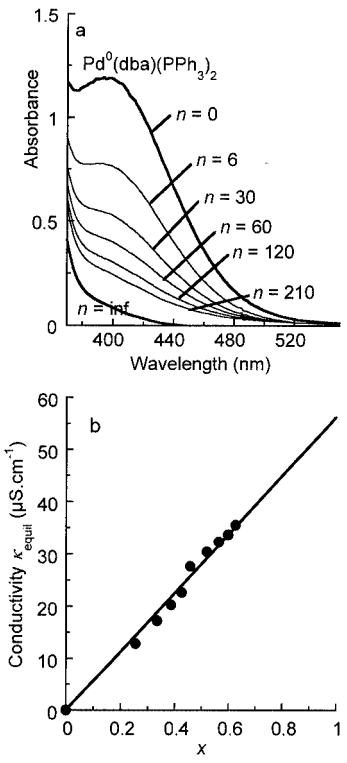

Figure 7. (a) UV spectrum performed in a 1-mm path cell of a solution of $Pd^0(dba)_2$ (1 mM) and PPh_3 (2 mM) in the presence of n equiv. of $CH_2{=}CHCH_2OAc$ in DMF at 20 °C; (b) plot of the conductivity κ_{equil}, measured for various values of n in Figure 6 (a), versus the corresponding molar fraction x calculated from the value of the equilibrium constant K [Equation (29)]; the molar conductivity Λ_M of $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+AcO^-$ was determined by extrapolation to $x = 1$

ductivity κ of $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+$ and AcO^- could not be determined from Figure 6 (a). The equilibrium constant $K_{DMF} = [(\eta^3\text{-}C_3H_5)PdL_2^+][AcO^-][dba]/[Pd^0(dba)L_2][CH_2{=}CHCH_2OAc]$ was determined easily by UV spectroscopy, taking advantage of the absorbance of $Pd^0(dba)(PPh_3)_2$ (λ_{max} = 396 nm) in DMF (Figure 7, a).

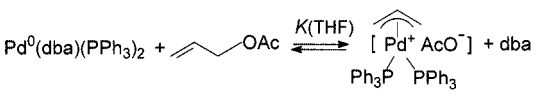
Successive additions of the allyl acetate resulted in successive additional decays of the absorbance of $Pd^0(dba)(PPh_3)_2$ (Figure 7, a), which provides further evidence for the equilibrium in Equation (29). At a given wavelength, the thermodynamic concentration of $Pd^0(dba)(PPh_3)_2$ was given by the ratio $(D_{equil} - D_{inf})/(D_0 - D_{inf})$ at different allyl acetate concentrations with $(D_{equil} - D_{inf})$ being the absorbance of $Pd^0(dba)(PPh_3)_2$ at the equilibrium position and $(D_0 - D_{inf})$ being the initial absorbance of $Pd^0(dba)(PPh_3)_2$.[46]

$K_{DMF} = 3.5\ (\pm\ 0.4) \times 10^{-5}$ M (20 °C)

One notices in Figure 7 (a) that more than 100 equiv. of allyl acetate were required to completely shift the equilibrium towards the cationic complex. From the value of K_{DMF}, the molar fraction x of the cationic complex could be calculated for each value of n used in the conductivity measurements of Figure 6 (a). The plot of κ_{equil} (determined in Figure 6, a) versus x was linear (Figure 7, b), which confirms the formation of the free ions $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+$ and AcO^- in DMF. The molar conductance was determined by extrapolation to $x = 1$.

$\Lambda_M = 56\ (\pm\ 2)$ S·cm^{-2}·mol^{-1} for
$[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+AcO^-$ in DMF at 20 °C

No conductivity was observed in THF, but clearly the reaction took place since the UV absorbance of $Pd^0(dba)(PPh_3)_2$ (λ_{max} = 394 nm) decreased stepwise upon successive additions of the allyl acetate, as had been observed in DMF. Moreover, the resulting cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+$ was characterized by ^{31}P NMR spectroscopy (δ = 24.5 ppm) in THF. Consequently, non-dissociative ion pairs $[(\eta^3\text{-}CH_2CHCH_2)\text{-}Pd(PPh_3)_2{}^+AcO^-]$ are formed in THF [Equation (30)], whereas free ions were formed in DMF [Equation (29)]. The equilibrium constant K_{THF} was determined by UV spectroscopy.



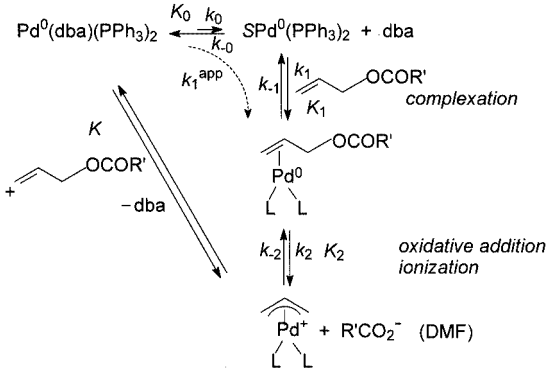
(30)

$K(THF) = 1\ (\pm\ 0.4) \times 10^{-3}$ (20 °C)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

One notices that for the same concentration of Pd^0 (c_0 = 1 mM), the equilibrium lies more in favor of the cationic complex in DMF than it does in THF.[46]

In both solvents, DMF and THF, we observe an overall equilibrated reaction from $Pd^0(dba)(PPh_3)_2$, but it is a multistep process (Scheme 14, R′ = Me). Indeed, the three initially sharp signals in the ^1H NMR spectrum of the allyl ligand of $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+BF_4^-$ observed in $CDCl_3$ became broad after addition of 1 equiv. of nBu$_4$NOAc and 2 equiv. of dba, and sharp signals of CH_2=$CHCH_2OAc$ (formed by attack of acetate ions on the allyl ligands) appeared. The presence of both broad and sharp signals in the same ^1H NMR spectrum indicates that different equilibria are operating with different equilibration rates. Consequently, the oxidative addition involves at least two steps and probably proceeds via the intermediate postulated in the literature, complex $Pd^0(\eta^2\text{-}CH_2$=$CHCH_2OAc)(PPh_3)_2$, which could not be detected when PPh_3 is the ligand for the palladium center. Clear-cut evidence for the intermediates is provided in the reactions with allylic benzoates or with bidentate ligands (see Sect. IV.3 and IV.2, respectively).



Scheme 14. Mechanism of the reversible reaction of allyl carboxylates with the Pd^0 complexes generated from $Pd^0(dba)_2$ and PPh_3 (2 equiv.) in DMF

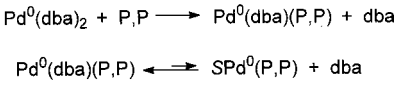
Consequently, the overall equilibrium between $Pd^0(dba)(PPh_3)_2$, CH_2=$CHCH_2OAc$ and the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+AcO^-$ involves three successive equilibria (Scheme 14, R′ = Me) with K = $K_0{\cdot}K_1{\cdot}K_2$.

Compared to the postulated mechanisms in Equations (25) and (26), we now have clear evidence that the reaction of an allyl acetate with a Pd^0 complex is a reversible reaction, which leads to a cationic $[(\eta^3\text{-allyl})Pd(PPh_3)_2]^+$ complex with AcO^- as the counteranion. This result demonstrates unambiguously that the true oxidative addition (ionization step) is a reversible reaction (with K_2 as its equilibrium constant, Scheme 14, R′ = Me). Consequently, the acetate ion is not an "innocent" leaving group since it reacts with the cationic $[(\eta^3\text{-allyl})Pd(PPh_3)_2]^+$ complex to give back the allylic acetate and a Pd^0 complex.[46]

This conclusion is in agreement with a few reports in the literature that have suggested that the oxidative addition step is reversible. Indeed, in the absence of any nucleophile, isomerization of the C=C bond of allylic acetates had been observed as well as isomerization at the allylic position in substituted cyclic allylic acetates.[54]

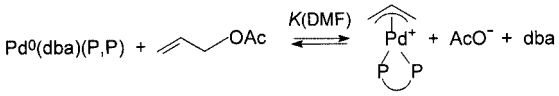
IV.2 Reversible Formation of Cationic $[(\eta^3\text{-allyl})PdL_2]^+$ Complexes in the Oxidative Addition of the Allyl Acetate to Pd^0 Complexes Ligated by Bidentate Bis(phosphanes)

The reaction of $Pd^0(dba)_2$ with 1 equiv. of a bidentate P,P ligand in DMF or THF gives the major complex $Pd^0(dba)(P,P)$. This complex is involved in an equilibrium with the minor complex SPd^0(P,P), which is the more reactive species in oxidative additions (Scheme 15).[53b,55]



Scheme 15. Pd^0 complexes generated from $Pd^0(dba)_2$ and 1 equiv. of a bidentate P,P ligand in DMF or THF

The reaction of CH_2=$CHCH_2OAc$ with the Pd^0 complexes generated from $Pd^0(dba)_2$ (c_0 = 2 mM) and dppb (2 mM) in DMF was monitored by conductivity measurements to characterize the formation of ionic species.[47] The conductivity increased with time after addition of 5 equiv. of allyl acetate and reached a limiting value (Figure 8, a). This limiting value increased slightly after addition of a further 5 equiv. of allyl acetate, but remained unchanged after addition of yet another 5 equiv. of allyl acetate. The limiting conductivity (κ_{equil}) decreased upon successive additions of dba (Figure 8, a). These experiments establish that ionic species form that are involved in an equilibrium with the starting reagents, whereas dba is involved in the backward reaction [Equation (31)].



(31)

The complex formed in the oxidative addition was characterized by ^{31}P NMR spectroscopy [δ = 21.5 ppm (s)] and its structure was assigned to the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+AcO^-$ by comparison with an authentic sample of $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+BF_4^-$ [δ = 21.7 ppm (s)]. The molar conductance Λ_M of $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+AcO^-$ was determined from the value of κ_{irrev} (Figure 8, a) obtained when the equilibrium was fully shifted to the side of formation of the ionic species (15 equiv. allyl acetate). At this point, its concentration was c_0 = 2 mM, i.e., the initial Pd^0 concentration.

Λ_M = 42 (± 2) S·cm^{-2}·mol^{-1} for $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+AcO^-$ in DMF at 25 °C

The backward reaction of the equilibrium in Equation (31) was monitored by UV and ^{31}P NMR spectroscopy.

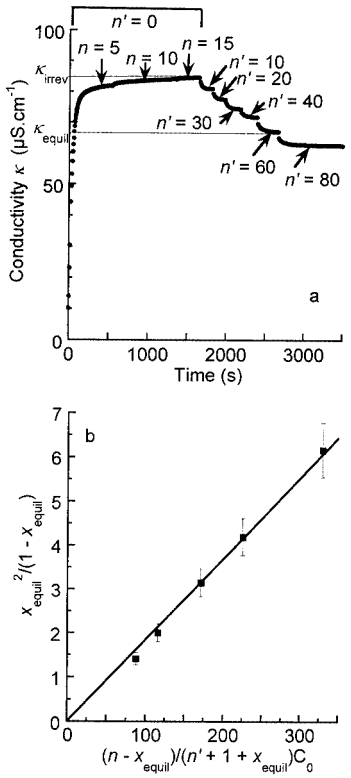

Figure 8. (a) Conductivity in DMF of $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+AcO^-$ formed in the reaction of the Pd^0 complex, generated from $Pd^0(dba)_2$ (2 mM) and dppb (2 mM), with $CH_2{=}CHCH_2OAc$ added successively ($0 < t < 1500$ s) at 25 °C; as indicated by the arrows, n is the cumulative number of equiv. of $CH_2{=}CHCH_2OAc$; this addition is followed by successive additions of dba ($t > 1500$ s); as indicated by the arrows, n' is the cumulative equiv. of added dba; (b) determination of the equilibrium constant K [Equation (31)] using the conductivity data of Figure 8 (a); plot of $[x^2_{equil}/(1 - x_{equil})]$ versus $[(n - x_{equil})/(n' + 1 + x_{equil})c_0]$. The value of $x_{equil} = \kappa_{equil}/\kappa_{irrev}$ [κ_{equil}: conductivity measured when the equilibrium in Equation (31) is fully established in the presence of n equiv. of $CH_2{=}CHCH_2OAc$ and n' equiv. of dba ($n = 5$ with $n' = 0$; $n = 15$ with $10 \le n' \le 80$; κ_{irrev}: conductivity when the equilibrium in Equation (31) is totally displaced towards its right-hand side in the absence of added dba ($n = 15$, $n' = 0$)]; K is determined from the slope

The UV spectrum of a solution of $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+BF_4^-$ (2 mM) in DMF exhibited, after addition of 5 equiv. of dba and 5 equiv. of nBu$_4$NOAc, an absorption band at $\lambda_{max} = 385$ nm that is characteristic of $Pd^0(dba)(dppb)$. Two broad signals in the ^{31}P NMR spectrum of $Pd^0(dba)(dppb)$ were also observed ($\delta = 21.17$ and 18.0 ppm).[55] These experiments provide clear evidence that the acetate ions react with the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+$ to generate a Pd^0 complex.[47]

IV.2.1 Determination of the Equilibrium Constant in DMF by Conductivity Measurements

The equilibrium constant K_{DMF} of the overall equilibrium [Equation (31)] was determined using the conductivity measurements of Figure 8 (a). The molar fraction x of the cationic complex in the equilibrium is given by $x_{equil} = \kappa_{equil}/\kappa_{irrev}$ for various values of n (equiv. of allyl acetate) and n' (equiv. of added dba).

$$K_{DMF} = [(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)^+][AcO^-]\text{-}[dba]/[Pd^0(dba)(dppb)][CH_2{=}CHCH_2OAc]$$

$$K_{DMF} = c_0{\cdot}x^2_{equil}(n' + 1 + x_{equil})/(1 - x_{equil})(n - x_{equil})$$

Plotting $[x^2_{equil}/(1 - x_{equil})]$ versus $[(n - x_{equil})/(n' + 1 + x_{equil})c_0]$ gave a straight line with K_{DMF} as the slope (Figure 8, b): $K_{DMF} = 1.8 \times 10^{-2}$ M at 25 °C (Table 3, Entry 19). The equilibrium constant K was similarly calculated for the reaction involving the ligand dppf (Table 3, Entries 16, 17).[47]

Table 3. Effect of the leaving group $-OCOR'$ on the kinetics and thermodynamics of the reaction of allyl carboxylates[a] with the Pd^0 complexes generated from $Pd^0(dba)_2$ ($c_0 = 1$ mM) and 2 equiv. of PPh_3 (Scheme 14) or $Pd^0(dba)_2$ ($c_0 = 2$ mM) and 1 equiv. of dppf or dppb (Scheme 16) in DMF; comparative equilibrium constants K and rate constants k_1^{app}, K_0k_1, and k_2

[a] For a given ligand, the leaving groups are classified, when going down the table, in the order of their decreasing ability to leave. [b] Fast reaction: 100 $M^{-1}{\cdot}s^{-1}$ is the maximum value of the rate constant that could be determined by UV spectroscopy under our experimental conditions ($t_{1/2} = 2$ s for $c_0 = 1$ mM and [allylOCOR′] = 5 mM). [c] Not determined because the reaction is too fast. [d] For concentrations of $CH_2{=}CHCH_2OCOCF_3$ smaller than 0.02 M.[50]

Therefore, as for PPh_3, the reaction of the allyl acetate with the Pd^0 complex formed from $Pd^0(dba)_2$ and 1 equiv. of either dppb or dppf is a reversible reaction that generates cationic complexes $[(\eta^3\text{-}CH_2CHCH_2)Pd(P,P)]^+$ with AcO^- as the counteranion. The overall equilibrium, however, lies considerably more in favor of the cationic (η^3-allyl)palladium complex for the bidentate ligands dppb and dppf than it does for PPh_3 (compare the values of K in Table 3, Entries 12, 17, 19).[46,47]

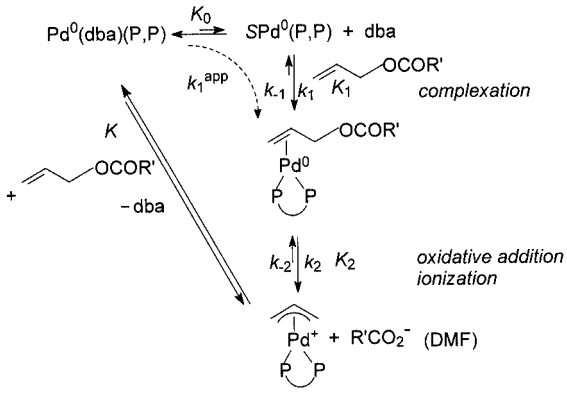
IV.2.2 Determining the Rate Constants of the Complexation and Ionization Steps: Kinetic Evidence for Intermediate Neutral Complexes [$Pd^0(\eta^2\text{-}CH_2{=}CHCH_2OAc)(P,P)$]

As seen in Figure 8 (a), the overall equilibrium in Equation (31) could easily be fully displaced towards the side of the cationic complex. With 5 equiv. of $CH_2{=}CHCH_2OAc$,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the overall reaction could be considered as being almost irreversible. Under such conditions, the kinetics of the formation of the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+$ with AcO^- as the counteranion could be monitored by conductivity measurements in DMF (curve C in Figure 9, a). The disappearance of $Pd^0(dba)(dppb)$ was monitored by UV spectroscopy at $\lambda_{max} = 385$ nm in DMF (curve A in Figure 9, a). The rate of disappearance of $Pd^0(dba)(dppb)$ was faster ($t_{1/2} = 8$ s) than the rate of formation of the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+$ ($t_{1/2} = 25$ s) whose kinetic curve C was S-shaped initially (Figure 9, a). Consequently, an intermediate neutral complex was generated before the formation of the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+$, presumably $Pd^0(\eta^2\text{-}CH_2{=}CHCH_2OAc)(dppb)$ where the Pd^0 atom is ligated to the C=C bond of the allyl acetate, as has been postulated in the literature.[3] The evolution of this neutral complex over time was deduced from the kinetic curves A and C (curve B in Figure 9, a). The neutral complex could not be characterized spectroscopically because it has too short a lifetime, but this was the first kinetic evidence for its formation.

Consequently, the reaction of allyl acetate with the Pd^0 complex, formed from $Pd^0(dba)_2$ and 1 equiv. of dppb, is a reversible one [Equation (31)] that proceeds through three reversible steps (Scheme 16, R′ = Me) with $K = K_0{\cdot}K_1{\cdot}K_2$.[47]



Scheme 16. Mechanism of the reversible reaction in DMF of allyl carboxylates with the Pd^0 complex formed from $Pd^0(dba)_2$ and 1 equiv. of (P,P) ligand (dppb, dppf)

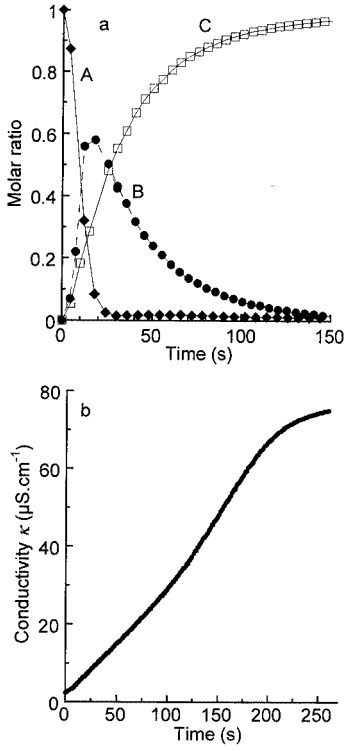


Figure 9. (a) Kinetics of the reaction of $CH_2{=}CHCH_2OAc$ (10 mM) with the Pd^0 complex formed from $Pd^0(dba)_2$ (2 mM) and dppb (2 mM) in DMF at 25 °C: A (filled diamonds): molar ratio of $Pd^0(dba)(dppb)$ versus time, determined by UV spectroscopy at 425 nm; B (filled circles): molar ratio of the neutral intermediate complex $(\eta^2\text{-}CH_2{=}CHCH_2OAc)Pd^0(dppb)$ versus time, determined from curves A and C [B = 1 − (A + C)]; C (empty squares): molar ratio of the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+AcO^-$ versus time, determined by conductivity measurements; (b) kinetics of the reaction of $CH_2{=}CHCH_2OAc$ (10 mM) with the Pd^0 complex formed from $Pd^0(dba)_2$ (2 mM) and dppf (2 mM) in DMF at 16 °C, monitored by conductivity measurements of the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppf)]^+AcO^-$

Curve A in Figure 9 (a) represents the kinetics of the overall complexation step in which $Pd^0(dppb)(\eta^2\text{-}CH_2{=}CHCH_2OAc)$ is formed from $Pd^0(dba)(dppb)$ via $SPd^0(dppb)$. The values of $K_0{\cdot}k_1$ (Scheme 16) and the apparent rate constant of the overall complexation step, $k_1^{app} = K_0{\cdot}k_1/c_0$, were determined (Table 3, Entry 19).[47] A reaction order of +1 in allyl acetate was found for this step.[47]

Curve C in Figure 9 (a) represents the kinetics of the formation of the cationic complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+AcO^-$. Since this step is slower than the overall complexation step, the rate constant of the oxidative addition/ionization step (k_2 in Scheme 16) can be readily obtained from curve C, which is established by conductivity measurements, when $t > 30$ s (Table 3, Entry 19).[47] The rate of formation of the cationic $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppb)]^+$ complex did not depend on the concentration of allyl acetate when it was in the range 0.02−0.1 M ($10 < n < 50$). This observation confirms a posteriori that the complexation and oxidative addition/ionization steps proceed successively on different timescales, with the oxidative addition/ionization step being slower (rds) than the overall complexation step. The term $k_1^{app}[CH_2{=}CHCH_2OAc] > k_2$ as soon as $[CH_2{=}CHCH_2OAc] > 1$ mM in DMF at 25 °C.[47]

Similar results were obtained when the Pd^0 precursor was formed from $Pd^0(dba)_2$ and 1 equiv. of dppf. The S-shaped curve, representative of the kinetics of formation of $[(\eta^3\text{-}CH_2CHCH_2)Pd(dppf)]^+AcO^-$, was, however, amplified (Figure 9, b) because of a smaller difference in the timescales of the complexation and ionization steps at the concentration of allyl acetate investigated here (0.1 mM). Determination of k_1^{app}, $K_0{\cdot}k_1$ and k_2 (Table 3, Entries 16, 17)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

showed that $k_1^{app}[CH_2{=}CHCH_2OAc] > k_2$ as soon as $[CH_2{=}CHCH_2OAc] = 4$ mM in DMF at 16 °C.[47]

Therefore, by means of two different analytical techniques — UV spectroscopy for the complexation step and conductivity measurements for the ionization step — kinetic evidence for the formation of the intermediate complex $Pd^0(\eta^2\text{-}CH_2{=}CHCH_2OAc)(P,P)$ (P,P = dppb, dppf) has been obtained for the first time.

IV.3 Influence of the Leaving Group on the Kinetics and Thermodynamics of the Reaction of Allyl Carboxylates with Pd^0 Complexes in DMF

The influence of the leaving group $R'CO_2^-$ on the equilibrium and rate constants of the reaction of allyl carboxylates or carbonates with Pd^0 complexes has been investigated. The equilibrium constant $K = K_0{\cdot}K_1{\cdot}K_2$ of the overall equilibrium between $Pd^0(dba)L_2$ (L = PPh_3 or L_2 = dppb or dppf), allyl carboxylates or carbonates, and the ionic species, was determined by UV spectroscopy, as reported above for the case of allyl acetate, $CH_2{=}CHCH_2OAc$ (Schemes 14 and 16; Table 3).[50] The overall reaction may be irreversible in the case of very reactive allyl carboxylates, or by using a large excess of them. Under conditions of irreversibility, the apparent rate constant $k_1^{app} = K_0{\cdot}k_1/c_0$ of the overall complexation step (Schemes 14 and 16) was determined by UV spectroscopy, which provided kinetic data on the disappearance of the Pd^0 complex. The rate of formation of the cationic complex $[(\eta^3\text{-allyl})PdL_2]^+$ was monitored by conductivity measurements. The rate constant, k_2 (Schemes 14 and 16), was determined when the ionization step was rate-determining. The data are gathered in Table 3.[50]

The reaction of allyl carboxylates $CH_2{=}CHCH_2OCOR'$ was irreversible when considering very good OCOR′ leaving groups, such as carbonate and trifluoroacetate (Table 3, Entries 1−4), whatever the conditions (large excess of dba or at low temperatures). The rate constants of the chemical steps, k_1^{app} and k_2 (Scheme 14), were too fast to be determined with high precision at 20 °C. Thus, the kinetics were monitored below 0 °C (Table 3, Entries 2, 3). For $OCOCF_3$, at −10 °C, the kinetic curve of the formation of the cationic complex was exponential (not S-shaped) with a rate of formation equal to that of the rate of disappearance of $Pd^0(dba)(PPh_3)_2$. This observation means that ionization of the intermediate complex $Pd^0(\eta^2\text{-}CH_2{=}CHCH_2OCOCF_3)(PPh_3)_2$ was faster than its formation, which was, thus, rate-determining: $k_1^{app}[CH_2{=}CHCH_2OCOCF_3] < k_2$.[50] Under such conditions, monitoring the rate of formation of the cationic complex by conductivity measurements did not provide the value of k_2, but, instead, that of k_1^{app}. A reaction order of +1 was found at low concentrations of $CH_2{=}CHCH_2OCOCF_3$ whereas the reaction order was zero at higher concentrations (> 0.2 M). This observation means that at high concentrations of $CH_2{=}CHCH_2OCOCF_3$, the reaction rate was no longer determined by the complexation of $CH_2{=}CHCH_2OCOCF_3$, but by the step that delivered the reactive species $SPd^0(PPh_3)_2$ from $Pd^0(dba)(PPh_3)_2$; i.e., the forward reaction with k_0 of the first equilibrium (Scheme 14). This result allowed the determination of $k_0 = 0.17\ M^{-1}{\cdot}s^{-1}$ (DMF, −10 °C).[50] Therefore, a fast oxidative addition may be limited by a decomplexation step (here dba) that delivers the reactive lowly ligated Pd^0 complex.[18]

For less effective leaving groups, such as chloromethyl acetate, benzoates, and acetate (Table 1, Entries 5−12, 14−17, 19), the overall reaction was equilibrated and, as expected, the better the leaving group, the higher the value of *K*. Indeed, a good leaving group will favor the two forward reactions, i.e., the complexation step, because the C=C bond becomes less electron-rich, and the oxidative addition step, in which the leaving group is released. A good leaving group will also disfavor the backward reaction of the last step (rate constant k_{-2}) because of its poor ability as a nucleophile. Thus, it is a consistent observation that, for a given ligand, the rate constants k_1^{app} (or $K_0{\cdot}k_1$) and k_2 increase with increasing leaving-group ability (Table 3, Entries 7,9,11 and 15, 14).[50]

In the benzoate series ($CH_2{=}CHCH_2OBz$), the rate constants k_1^{app} and k_2 were determined at 10 °C (Table 3, Entries 7, 9, 11).[50] The kinetic curves for the formation of the cationic complexes were S-shaped for appropriate concentrations of allyl benzoates (ca. 10 mM). This observation is again evidence for the formation of the intermediate complexes $Pd^0(\eta^2\text{-}CH_2{=}CHCH_2OBz)(PPh_3)_2$ with the overall complexation step being slightly faster than the ionization step: $k_1^{app}[CH_2{=}CHCH_2OBz] > k_2$.

Therefore, the ionization step is faster than the complexation step for good leaving groups (carbonate, trifluoroacetate) and the ionization step is rate-determining for poor leaving groups (acetate, benzoates).

IV.4 Reversible Formation of Cationic $[(\eta^3\text{-allyl})PdL_2]^+$ in the Oxidative Addition of Allylic Carbonates to Pd^0 Complexes Observed by Conductivity Measurements

The palladium-catalyzed reaction of allylic carbonates may be performed with neutral pronucleophiles NuH [Equation (32)].[42]

(32)

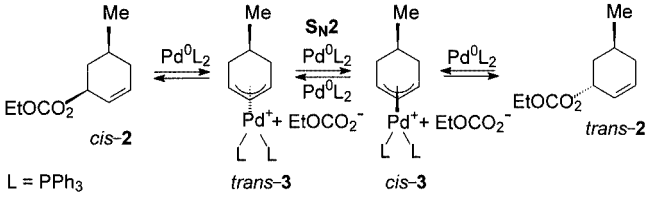
Indeed, the anion $EtOCO_2^-$, formed in the oxidative addition of the allylic carbonate to Pd^0 complexes, may decarboxylate to generate the basic EtO^- ion that is able to deprotonate NuH. As was found for allylic acetates, the oxidative addition of the allylic carbonate to Pd^0 complexes was supposed in the literature to give ionic species, i.e., a cationic $(\eta^3$-allyl)palladium(II) complex with the unstable $EtOCO_2^-$ counteranion.[56]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

IV.4.1 Evidence from Conductivity Measurements in DMF for the Reversible Formation of a Cationic [(η³-allyl)PdL₂]⁺ Complex in the Oxidative Addition of a Cyclic Allylic Carbonate to Pd⁰ Complexes

Conductivity measurements were performed in DMF at 20 °C on a solution of $Pd^0(dba)_2$ (2 mM) and 2 equiv. of PPh_3 by successive addition of various amounts of the allylic carbonate *cis*-**2** (formula in Scheme 17).[57] The conductivity κ increased with time to reach a limiting value that increased when the concentration of the allylic carbonate was increased (Figure 10, a). From these experiments, it was established that ionic species are formed in an equilibrium with the allylic carbonate and $Pd^0(dba)(PPh_3)_2$. On the other hand, the conductivity decreased when dba was added (Figure 10, a), which establishes that dba is involved in the backward reaction of the equilibrium. The allylic protons of the Pd^{II} complex were characterized by ^1H NMR spectroscopy in $CDCl_3$, as were those of the $EtOCO_2^-$ anion. This anion remained unchanged after 1 h, which proves its relative stability in chloroform[56] with regards to its decarboxylation. Consequently, it is assumed that the allylic carbonate *cis*-**2** reacts with the Pd^0 complex through an overall reversible reaction with formation of a cationic complex **3** with $EtOCO_2^-$ as the counteranion [Equation (33)].[57] This complex should be a priori *trans*-**3** (left part of Scheme 17) since the overall reaction always proceed with inversion of the configuration.[3]

$$Pd^0(dba)L_2 + \underset{\mathbf{2}}{allyl\text{–}OCO_2Et} \overset{K}{\rightleftharpoons} \underset{\mathbf{3}}{(\eta^3\text{–}allyl)PdL_2^+} + EtOCO_2^- + dba \qquad L = PPh_3 \qquad (33)$$



Scheme 17. Mechanism of the oxidative addition of a cyclic allylic carbonate to Pd^0L_2, whose precursor is either Pd^0L_4 or $Pd^0(dba)_2$ plus 2 equiv. of L in DMF (the solvent on Pd^0L_2 has been omitted voluntarily)

As was done with the allyl acetate (see Sect. IV.1), the equilibrium constant *K* was determined by UV spectroscopy. Indeed, addition of *n* equiv. of *cis*-**2** to $Pd^0(dba)(PPh_3)_2$ (c_0 = 1 mM), formed from $Pd(dba)_2$ and 2 equiv. of PPh_3, in DMF resulted in a fast decay of the absorbance of $Pd^0(dba)(PPh_3)_2$, which reached a constant value (Figure 10, b). Successive additions of *cis*-**2** resulted in related additional decays of the absorbance of $Pd^0(dba)(PPh_3)_2$, thus confirming that $Pd^0(dba)(PPh_3)_2$ and *cis*-**2** were involved in an equilibrium with the cationic complex **3**, dba, and $EtOCO_2^-$ [Equation (33)]. The UV spectroscopic data in Figure 10 (b) provided the thermodynamic

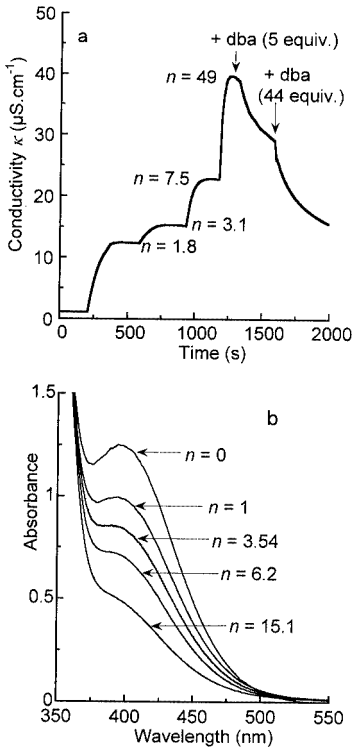


Figure 10. (a) Conductivity in DMF of the cationic complex $[(\eta^3\text{-allyl})Pd(PPh_3)_2]^+EtOCO_2^-$ (**3**) generated in the reaction of the Pd^0 complex formed from $Pd^0(dba)_2$ (2 mM) and PPh_3 (4 mM), with the cyclic allylic carbonate *cis*-**2** added successively ($0 < t < 1250$ s) (*n*: cumulative number of equiv.), followed by the successive addition of dba at 20 °C; (b) UV spectrum of $Pd^0(dba)(PPh_3)_2$, generated from $Pd^0(dba)_2$ (1 mM) and PPh_3 (2 mM) in the presence of *n* equiv. of *cis*-**2** at 20 °C, performed in DMF in a 1-mm path cell

concentration of $Pd^0(dba)(PPh_3)_2$ at different concentrations of *cis*-**2** and, thus, allowed the determination of *K*.[57]

$K = 1.4 (\pm 0.1) \times 10^{-4}$ M (DMF, 20 °C)

IV.4.2 Evidence for the Isomerization at the Allylic Position in the Oxidative Addition of Allylic Carbonate to Pd⁰ Complexes by an S_N2 Mechanism

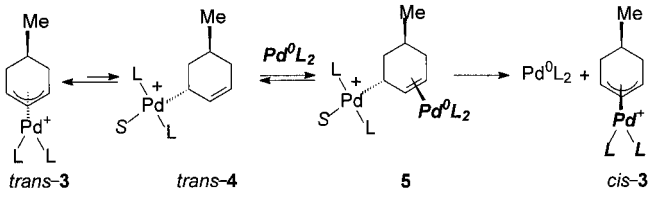
The isomerization of *cis*-**2** to *trans*-**2** in the presence of a catalytic amount of $Pd^0(PPh_3)_4$ in THF at room temperature has been observed by Moreno-Mañas et al.[58] This reaction was reinvestigated in DMF, with $Pd^0(dba)_2$ and 2 equiv. of PPh_3, to compare the rate of isomerization as a function of the $SPd^0(PPh_3)_2$ precursor, all the while keeping in mind the fact that any oxidative addition performed from $Pd^0(PPh_3)_4$ [via $SPd^0(PPh_3)_2$] is faster than that performed from $Pd^0(dba)_2$ and 2 equiv. of PPh_3 [via $SPd^0(PPh_3)_2$] because of the higher concentration (ca. tenfold) of the reactive complex $SPd^0(PPh_3)_2$ in its equilibrium with $Pd^0(PPh_3)_3$ (Scheme 3) than in its equilibrium with $Pd^0(dba)(PPh_3)_2$ (Scheme 13).[53]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The *cis*-**2**/*trans*-**2** isomerization was observed by ^{1}H NMR spectroscopy by treating $Pd^0(dba)_2$ and 2 equiv. of PPh_3 with a stoichiometric amount of *cis*-**2** in $CDCl_3$.[57] The thermodynamic ratio (40:60)[58] was obtained after 1 h. Therefore, the reaction of the cyclic allylic carbonate *cis*-**2** with $Pd^0(dba)(PPh_3)_2$ [via $SPd^0(PPh_3)_2$] affords two cationic complexes, *cis*-**3** and *trans*-**3** (characterized by ^{31}P NMR spectroscopy), by an overall equilibrium [Equation (33)] that is established in less than 20 min, as observed by UV spectroscopy and conductivity measurements, while the overall *cis*-**2**/*trans*-**2** isomerization requires a much longer time to occur.[57]

When the same series of experiments was conducted with $Pd^0(PPh_3)_4$ in DMF, the thermodynamic ratio was reached already after 15 min. Consequently, the rate of *cis*-**2**/*trans*-**2** isomerization is faster when the precursor of $SPd^0(PPh_3)_2$ is $Pd^0(PPh_3)_4$ rather than $Pd^0(dba)_2$ and 2 equiv. of PPh_3; i.e., when the concentration of $SPd^0(PPh_3)_2$ is relatively higher. This situation supports an isomerization of the *trans*-**3** and *cis*-**3** cationic complexes proceeding through an S_N2 mechanism induced by $SPd^0(PPh_3)_2$ (Scheme 17), followed by nucleophilic attack of the ethyl carbonate anion. Thus, kinetic evidence is now available that favors the S_N2 mechanism already proposed[59a,59b] and established in the literature.[59c−59e]

One hypothesis for the *trans*-**3**/*cis*-**3** isomerization proceeding by the S_N2 mechanism is given in Scheme 18. The cationic (η^3-allyl)Pd^{II} complex *trans*-**3** would be involved in equilibrium with the cationic (η^1-allyl)Pd^{II} complex *trans*-**4**, which may be considered as an allylic derivative with the PdL_2^+ moieties as the leaving group. As classically reported for any allylic activation by a Pd^0 complex,[3] the incoming Pd^0L_2 species would first coordinate the C=C bond in an *anti* position relative to the η^1-ligated $Pd^{II}L_2^+$ moieties (complex **5**). Activation of the allylic Pd−C bond would then proceed with formation of the complex *cis*-**3** and release of Pd^0L_2, which results in an overall exchange of the $Pd^{II}L_2$ unit of the complex *trans*-**3** by the incoming Pd^0L_2 unit with inversion of the configuration to produce *cis*-**3**.

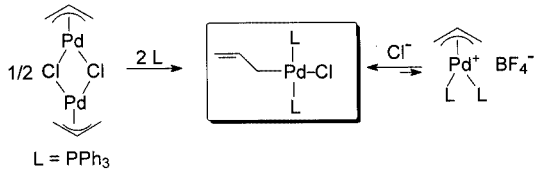


Scheme 18. Tentative explanation for the isomerization by the so-called S_N2 mechanism

It results from this mechanistic investigation that the loss of stereoselectivity in nucleophilic substitutions on the cyclic allylic carbonate *cis*-**2**, reported by Moreno-Mañas et al.,[58] arises from the isomerization of the intermediate cationic (η^3-allyl)palladium(II) complexes.

IV.5 Formation of Neutral (η^1-Allyl)(chloro)palladium Complexes in the Presence of Chloride Ions in DMF and THF

In DMF or THF, the cationic (η^3-allyl)palladium complex $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+Cl^-$ was not formed from $[Pd(\eta^3\text{-}CH_2CHCH_2)(\mu\text{-}Cl)]_2$ by addition of 4 equiv. of PPh_3 in the absence of any chloride scavenger. Indeed, the neutral complex (η^1-CH_2=$CHCH_2$)$PdCl(PPh_3)_2$ was isolated and characterized (Scheme 19).[60a] The latter complex was also generated upon addition of 1 equiv. of chloride ions (from nBu_4NCl) to the cationic $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+BF_4^-$ in DMF or THF (Scheme 19).[60a]



Scheme 19. Formation of (η^1-allyl)(chloro)palladium complexes

The neutral complex (η^1-CH_2=$CHCH_2$)$PdCl(PPh_3)_2$ was also generated in an oxidative addition of allyl acetate to Pd^0 complexes in the presence of voluntarily added chloride ions.[60a] This result emphasizes the crucial role of the presumably "innocent" ligands, such as chloride ions, which do not behave simply as counteranions of cationic (η^3-allyl)palladium(II) complexes, but may modify the chemical structure of the reactive intermediates by formation of neutral (η^1-allyl)(chloro)palladium(II) complexes. Consequently, the catalytic precursors of Tsuji−Trost reactions,[3] i.e., $[Pd(\eta^3\text{-}CH_2CHCH_2)(\mu\text{-}Cl)]_2$ plus 4 equiv. of PPh_3 or $[(\eta^3\text{-}CH_2CHCH_2)Pd(PPh_3)_2]^+BF_4^-$ are not equivalent. In the presence of chloride ions coming from the precursor or added in the catalytic reactions, the intermediate that is prone to react with the nucleophile might be not the cationic (η^3-allyl)palladium(II) complex, as usually considered, but the neutral (η^1-allyl)(chloro)palladium(II) species. Consequently, the presence of chloride ions might affect the regioselectivity of the catalytic reaction as well as its enantioselectivity.[61] Preliminary results on the influence of chloride ions on the reactivity of morpholine with $[(\eta^3\text{-}CH_2CHCH_2)Pd(PAr_3)_2]^+BF_4^-$ (Ar = 4-ClC_6H_4) show that the rate of nucleophilic attack is decelerated upon increasing the concentration of chloride ions. The reaction involves both cationic $[(\eta^3\text{-}CH_2CHCH_2)Pd(PAr_3)_2]^+$ and neutral (η^1-CH_2=$CHCH_2$)$PdCl(PAr_3)_2$ complexes as reactive species.[60b]

IV.6 Conclusion and Mechanistic Consequences

By means of conductivity measurements, the mechanism of the first step of the Tsuji−Trost reactions, i.e., the reaction of allylic carboxylates or carbonates with Pd^0 com-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plexes, has been more deeply established. Indeed, whether the phosphane ligand examined here is monodentate (L) or bidentate (L_2), we have used conductivity measurements to (i) characterize the cationic $[(\eta^3\text{-allyl})PdL_2]^+$ complexes formed in the reaction, with the corresponding counteranion being either carboxylates or carbonate, (ii) give evidence for the reversibility of this reaction and subsequently determined the equilibrium constants, and (iii) investigate the kinetics of formation of the cationic $[(\eta^3\text{-allyl})PdL_2]^+$ complexes.

The combination of UV spectroscopy, used to monitor the kinetics of disappearance of the Pd^0 complex, with conductivity measurements, used to monitor the kinetics of formation of the cationic complex, provides kinetic evidence that the overall reaction proceeds in two steps: first a complexation step with formation of intermediate neutral complexes $Pd^0(\eta^2\text{-}CH_2{=}CHCH_2OCOR')L_2$ ($R' = CH_3$, L_2 = dppb, dppf; $R' = Ar$, $L = PPh_3$), followed by the formation of a cationic $[(\eta^3\text{-allyl})Pd^{II}L_2]^+$ complex with $R'CO_2^-$ as the counteranion (ionization step). The better the leaving group OCOR′, the higher the concentration of the cationic complex. For good leaving groups (carbonate, trifluoroacetate), the ionization step is faster than the complexation step, whereas the ionization step is rate-determining for poorer leaving groups (acetate, benzoates).

The reaction of a cyclic allylic carbonate was found to proceed with isomerization at the allylic position when the monodentate PPh_3 ligand was considered. This finding is a consequence of the *trans*/*cis* isomerization of the cyclic $[(\eta^3\text{-allyl})Pd(PPh_3)_2]^+$ complexes by an S_N2 mechanism induced by $Pd^0(PPh_3)_2$. This mechanism, which has already been established in the literature, was confirmed kinetically by evidence that the rate of isomerization depends on the concentration of Pd^0 and its precursor. This mechanism is not restricted to cyclic allylic carbonates since we have recently observed that the reaction of a cyclic allylic benzoate also proceeds with isomerization at the allylic position, and with kinetics that are dependent on the Pd^0 precursor.[62]

This study establishes definitively that the role of the leaving group in Tsuji−Trost reactions is certainly more intricate than it is usually considered to be. Since the leaving group's concentration increases as the catalytic reaction proceeds, it may play a significant kinetic role in competing with the nucleophiles (whose concentration decreases along the catalytic reaction) in the attack on the cationic $[(\eta^3\text{-allyl})PdL_2]^+$ species. The degree of reversibility of the overall oxidative addition (which is dependent on the nature of the leaving group) controls the concentration of the available Pd^0L_2 species and, consequently, may affect the stereoselectivity of catalytic reactions performed on cyclic allylic carbonates or carboxylates by isomerization of the intermediate cyclic cationic $[(\eta^3\text{-allyl})PdL_2]^+$ complexes. The stereoselectivity may be affected also by the nature of the Pd^0 precursors, which control the concentration of available Pd^0L_2, or by the presence of chloride ions, which determine the structure of the complex reacting with the nucleophile, i.e., cationic $[(\eta^3\text{-allyl})PdL_2]^+$ or neutral $(\eta^1\text{-allyl})PdClL_2$ complexes.

V. Miscellaneous Use of Conductivity Measurements for the Investigation of the Mechanism of a Stille Reaction: Ionization of $ISnBu_3$ in DMF

When a Stille reaction is performed using an aryl iodide [Equation (34)], $ISnBu_3$ is formed quantitatively as a by-product.[7e,7f,63,64]

$$PhI + CH_2{=}CH\text{-}SnBu_3 \xrightarrow{Pd^0(dba)_2 + 2AsPh_3} Ph\text{-}CH{=}CH_2 + ISnBu_3 \quad (34)$$

Taking advantage of the fact that $ISnBu_3$ dissociates into the free ions I^- and Bu_3Sn^+ in DMF, the mechanism of the transmetallation step — reaction of $CH_2{=}CHSnBu_3$ with $PhPdI(AsPh_3)_2$ [formed in the fast oxidative addition of PhI to the Pd^0 complex generated from $Pd^0(dba)_2$ and 2 equiv. of $AsPh_3$][65] — has been investigated in DMF by conductivity measurements [Equation (35)].[66]

$$PhPdIL_2 + CH_2{=}CH\text{-}SnBu_3 \xrightarrow{DMF} Ph\text{-}CH{=}CH_2 + I^- + {}^+SnBu_3 + Pd^0L_2 \quad (35)$$
$$L = AsPh_3$$

The objective was to discriminate between the reaction of $CH_2{=}CHSnBu_3$ with $PhPdI(AsPh_3)_2$ (**6**) (Scheme 20, path **A**) or with $PhPdI(AsPh_3)(DMF)$ (**7**) (Scheme 20, path **B**), generated by the partial dissociation of $PhPdI(AsPh_3)_2$ in DMF (observed in a previous study).[65] The mechanism in path **A** has been established by Casado and Espinet for $ArPdI(AsPh_3)_2$ (Ar = C_6F_5, $C_6Cl_2F_3$) in THF,[64] whereas the mechanism in path **B** has been proposed by Farina and Krishnan for $PhPdI(AsPh_3)_2$ in THF.[63] Whatever the mechanism, the nucleophilic attack of $CH_2{=}CHSnBu_3$ gives the common complex **8**[63,64] which evolves to generate complex **9** together with I^- and Bu_3Sn^+ in DMF. Styrene is then formed by a rapid reductive elimination from **9**. Consequently, the rates of formation of styrene and of the ionic species I^- and Bu_3Sn^+ are the same and the investigation of the rate of formation of I^- and Bu_3Sn^+ by conductivity measurements will provide the rate of the overall transmetallation step and the mechanistic pathway.

In DMF, the conductivity of a solution of $PhPdI(AsPh_3)_2$ (2 mM) increased with time after addition of 10 equiv. of $CH_2{=}CHSnBu_3$ (Figure 11, a). The final conductivity was identical ($\kappa_{lim} = 76 \pm 5$ μS·cm^{-1} at 25 °C) to that measured for an authentic sample of $ISnBu_3$ (2 mM) in DMF (κ = 75 μS·cm^{-1} at 25 °C), indicating that I^- and Bu_3Sn^+ were produced quantitatively. The kinetics of formation of I^- and Bu_3Sn^+ was accelerated upon increasing the concentration of $CH_2{=}CHSnBu_3$ (reaction order of +1) and was retarded by an excess of $AsPh_3$ (Figure 11, a),[66] which is indicative of a decomplexation of the $AsPh_3$ ligand in the transmetallation step, either before of after reaction with $CH_2{=}CHSnBu_3$.

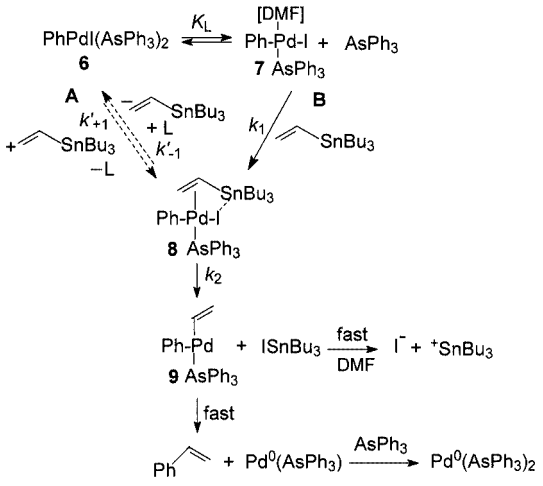

Scheme 20. Mechanism of the transmetallation step in a Stille reaction in DMF [Equation (35)]

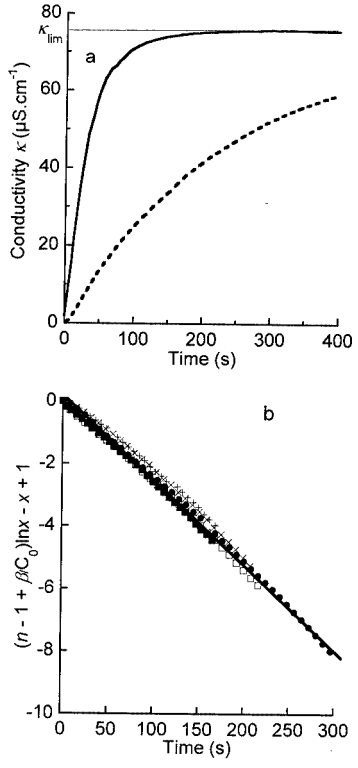

Figure 11. (a) (—) Kinetics of the reaction of CH_2=$CHSnBu_3$ (20 mM) with $PhPdI(AsPh_3)_2$ (2 mM) in DMF at 25 °C, as monitored by conductivity measurements of I^- and Bu_3Sn^+; value of $\kappa = \kappa_{exp} - \kappa_0$ (κ_{exp}: experimental conductivity at t; κ_0: initial residual conductivity of 3 $\mu S \cdot cm^{-1}$; κ_{lim}: conductivity of an authentic sample of $ISnBu_3$ (2 mM) in DMF; (---) kinetics in the presence of 5 equiv. of added $AsPh_3$; (b) influence of the concentration of $AsPh_3$ on the kinetics of the reaction of CH_2=$CHSnBu_3$ (20 mM) with $PhPdI(AsPh_3)_2$ (2 mM) in DMF at 25 °C; plot of $[(n - 1 + \beta/c_0)\ln x - x + 1]$ versus time [Equation (40)] with n = 3 (++), 4 (filled squares), 5 (empty squares), 6 (××), 7 (filled circles) [$x = (\kappa_{lim} - \kappa)/\kappa_{lim}$; κ: conductivity of I^- and Bu_3Sn^+ at t; κ_{lim}: final conductivity, determined as in Figure 11 (a)]

The kinetic laws for paths **A** and **B** (Scheme 20) are given by Equation (36) and (37), respectively (L: $AsPh_3$; Sn: CH_2=$CHSnBu_3$).[63]

$$d[I^-]/dt = d[^+SnBu_3]/dt = -d[\mathbf{6}]/dt = \frac{k'_{+1}k_2[\mathbf{6}][Sn]([L] + K_L)}{(k'_{-1}[L] + k_2)[L]} \quad (36)$$

$$d[I^-]/dt = d[^+SnBu_3]/dt = -d[\mathbf{6}]/dt = \frac{k_1K_L[\mathbf{6}][Sn]}{[L] + K_L} \quad (37)$$

Taking into account the value of $K_L = 3.1 \times 10^{-4}$ M in DMF,[65] Equation (36) simplifies into Equation (38) at high concentrations of L ([L] > 6 mM) so that paths **A** and **B** could not be distinguished on the basis of the observed rate law at high concentrations of L. Both laws can be expressed as Equation (39) with $\alpha = k_1 \cdot K_L$ and $\beta = K_L$ for Equation (37) and $\alpha = k_2 \cdot K'_1$ and $\beta = k_2/k'_{-1}$ for Equation (38).

$$-d[\mathbf{6}]/dt = \frac{k_2K'_1[\mathbf{6}][Sn]}{[L] + k_2/k'_{-1}} \quad (38)$$

$$-d[\mathbf{6}]/dt = \frac{\alpha[\mathbf{6}][Sn]}{[L] + \beta} \quad (39)$$

Because of the limiting solubility of $AsPh_3$ in DMF (14 mM), $AsPh_3$ could not be added in large excess. Therefore, the concentration of $AsPh_3$ was not constant during the reaction and the integration of Equation (39) gives Equation (40) with $x = (\kappa_{lim} - \kappa)/\kappa_{lim}$ (determined as in Figure 11, a) and n being the initial number of equiv. of $AsPh_3$ added to $Pd^0(dba)_2$ before addition of 1 equiv. of PhI, which generates $PhPdI(AsPh_3)_2$.

$$(n - 1 + \beta/C_0)\ln x - x + 1 = -\frac{\alpha[Sn]t}{C_0} \quad (40)$$

A value of $\beta = 3.2 \times 10^{-4}$ was determined, so that the plot of $(n - 1 + \beta/c_0)\ln x - x + 1$ versus time was linear whatever the value of n (Figure 11, b) in agreement with Equation (40), which is then valid over the whole range of concentrations of $AsPh_3$ added to $PhPdI(AsPh_3)_2$ (2–10 mM). Consequently, the experimental kinetics of the transmetallation step are in agreement with the mechanism of path **B** in Scheme 20; this conclusion would not be the case for the mechanism of path **A**, since Equation (38) is valid only for high concentrations of $AsPh_3$ (> 6 mM). Since $\beta = K_L$ [Equations (37) and (39)], a second method to determine $K_L = 3.2 \pm 0.1 \times 10^{-4}$ M (DMF, 25 °C) is available and is in agreement with the value of $K_L = 3.1 \times 10^{-4}$ M (DMF, 25 °C) determined in a previous study.[65]

Since $\alpha = k_1 \cdot K_L$, then $k_1 = 8.3 \pm 0.5$ $M^{-1}s^{-1}$. A similar value of $k_1 = 7.5$ $M^{-1}s^{-1}$(DMF, 25 °C) was determined by treating CH_2=$CHSnBu_3$ with $PhPdI(AsPh_3)$(DMF) generated by the fast dissociation of the dimer $Ph_2Pd_2(\mu\text{-}I)_2(AsPh_3)_2$ (**10**) in DMF.[66] The kinetics of this system were also monitored by conductivity measurements of I^- and Bu_3Sn^+ generated in the reaction.[66]

Therefore, K_L has been determined independently by two different strategies: (i) from the partial dissociation of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$PhPdI(AsPh_3)_2$ to $PhPdI(AsPh_3)(DMF)$ observed in DMF,[65] and (ii) from the kinetics of the transmetallation step performed with $PhPdI(AsPh_3)_2$ [66] (vide supra). Similarly, the same value of k_1, which characterizes the reactivity of $PhPdI(AsPh_3)(DMF)$ with $CH_2{=}CHSnBu_3$, has been determined independently by two different strategies: (i) from the kinetics of the transmetallation step performed with $PhPdI(AsPh_3)_2$ (vide supra)[66] and (ii) from the kinetics of the reaction of $CH_2{=}CHSnBu_3$ with $PhPdI(AsPh_3)(DMF)$ generated by the fast dissociation of the dimer **10** in DMF.[66]

This result definitively proves that, in DMF, the transmetallation step involves the reaction of $CH_2{=}CHSnBu_3$ with $PhPdI(AsPh_3)(DMF)$ generated by dissociation of $PhPdI(AsPh_3)_2$ (path **B** in Scheme 20). This study illustrates how to take advantage of conductivity measurements, used to monitor the kinetics of the formation of a by-product, to gain a deeper insight into the mechanism of a palladium-catalyzed reaction that does not involve any ionic palladium complexes as intermediates.

Conclusion

Taking advantage of the fact that DMF is a good solvent for dissociating and coordinating cationic palladium(II) complexes, conductivity measurements have proved to be efficient for characterizing the cationic nature of palladium(II) complexes that have already been postulated in the literature, but not characterized in the context of a real oxidative addition, such as (i) $[(aryl)PdL_2(DMF)]^+TfO^-$ or $[(vinyl)PdL_2(DMF)]^+TfO^-$ ($L = PPh_3$) generated in oxidative additions of aryl or vinyl triflates, respectively, to Pd^0 complexes, (ii) $[HPdL_2(DMF)]^+RCO_2^-$ ($R = CH_3$, H; $L = PPh_3$) generated in oxidative additions of acetic or formic acid to Pd^0 complexes, and (iii) $[(\eta^3\text{-allyl})PdL_2]^+R'CO_2^-$ (R' = alkyl, aryl, OEt; $L = PPh_3$ or L_2 = dppe, dppf) in oxidative additions of allylic carboxylates (or carbonates) to Pd^0 complexes. In all cases, the cationic palladium(II) complex and its counteranion were generated as free ions. Such cationic complexes are key intermediates in Stille, Heck, and Tsuji–Trost reactions. The role of chloride ions has been investigated with the formation of neutral complexes $ArPdClL_2$ and $(\eta^1\text{-allyl})PdClL_2$ ($L = PPh_3$). The cationic and neutral character of the intermediate Pd^{II} complexes is of crucial importance because it determines their reactivities with nucleophiles in Heck, Stille, and Tsuji–Trost reactions.

Conductivity measurements have also been used to gather thermodynamic data on the formation of cationic palladium(II) complexes. Indeed, the reversibility of oxidative additions of allylic carboxylates (or carbonates) to Pd^0 complexes has been established as well as that of acetic and formic acid, and the equilibrium constants have been determined. The reversible oxidative addition of a cyclic allylic carbonate generates cyclic *cis* and *trans* $[(\eta^3\text{-allyl})PdL_2]^+EtOCO_2^-$ complexes. The *cis*/*trans* isomerization proceeds by an S_N2 mechanism induced by the Pd^0L_2 complex.

Conductivity measurements have also been used to gather kinetic data on the formation of cationic palladium(II) complexes. Under conditions where the oxidative additions were irreversible, the rates of formation of the cationic palladium(II) complexes (monitored by conductivity measurements) were compared to those of the disappearance of the palladium(0) complex (monitored by UV spectroscopy). Kinetic evidence has been obtained for the formation of neutral intermediate complexes $Pd^0(\eta^2\text{-allyl-OCOR}')L_2$ ($R' = CH_3$, L_2 = dppb, dppf; $R' = Ar$, $L = PPh_3$) in the oxidative addition of allylic carboxylates to palladium(0) complexes, establishing that two successive reactions are involved (complexation and ionization steps) whose relative rates depend on the nature of the leaving group $-OCOR'$. Thus, the effect of the leaving group has been clarified.

As a somewhat unrelated application of this method, monitoring the formation of an ionic by-product (I^-, $^+SnBu_3$) by conductivity measurements has brought about a deeper insight into the mechanism of the transmetallation step of a Stille reaction, which does not involve any ionic intermediate palladium complexes, by establishing the involvement of $PhPdI(AsPh_3)(DMF)$ as the species that reacts with an organotin derivative.

Acknowledgments

The author wishes to express her gratitude to the students who have greatly contributed to the research work summarized here: S. Gamez, A. Mosleh, A. Ndedi Ntepe, C. Orthwein as well as Dr. G. Meyer and Prof. C. Amatore. Drs. I. Chiarotto, K. K. Hii, R. Pleixats, Profs. J. B. Brown, I. Carelli, M. Moreno-Mañas and J. G. de Vrieze are thanked for fruitful collaborations. S. Négri is also thanked for technical assistance. The financial support from CNRS, ENS (MNRT) and University Paris VI is gratefully acknowledged. Johnson Matthey is thanked for a generous loan of sodium tetrachloropalladate.

[5] Modern conductivity meters (e.g., CDM210 Radiometer Analytical) deliver the conductivity κ of solutions containing ionic species. $\kappa = kG$ where G is the conductance ($G = 1/R$; R: resistance of the solution containing the ionic species) expressed in Siemens (S; 1 S = 1 Ω^{-1}) and k is the cell constant expressed in cm^{-1} (the value of k is usually close to 1 cm^{-1}). The measured conductivity κ is expressed in $S{\cdot}cm^{-1}$. Considering a strong electrolyte with c_i being the concentration of one ion, z_i its charge and λ_i its equivalent conductivity, the overall conductivity is expressed as $\kappa = \Sigma\lambda_i z_i c_i$ if the solution behaves ideally. In the case of a 1:1 electrolyte at a concentration c, $\kappa = (\lambda_+ + \lambda_-)c = \Lambda_M c$. The molar conductivity Λ_M of the electrolyte is usually expressed in $S{\cdot}cm^2{\cdot}mol^{-1}$ when the concentration C is expressed in $mol{\cdot}L^{-1}$.[4] The conductivity can be recorded versus time using a computerized home-made program.

[11] The oxidative addition of 4-$O_2NC_6H_4OTf$ to $Pd^0(PPh_3)_4$ in THF was monitored by ^{31}P NMR spectroscopy at room temperature. The spectrum exhibits a singlet at δ = 22.2 ppm attesting that only *trans*-[4-$O_2NC_6H_4Pd(PPh_3)_2(THF)]^+TfO^-$ was formed and not [4-$O_2NC_6H_4Pd(PPh_3)_3]^+TfO^-$. Espinet et al. have reported that $[C_6F_5Pd(PPh_3)_3]^+TfO^-$ was generated as a minor complex in the oxidative addition of C_6F_5OTf to $Pd^0(PPh_3)_4$ in THF at 20 °C.[12]

[12] A. L. Casado, P. Espinet, A. M. Gallego, *J. Am. Chem. Soc.* **2000**, *122*, 11771−11782.

[13] Espinet et al. have reported that a related neutral complex *trans*-$(C_6Cl_2F_3)Pd(OTf)(PPh_3)_2$ predominates in the equilibrium with the ionic *trans*-$[(C_6Cl_2F_3)Pd(PPh_3)_2(THF)]^+$ and TfO^- at low temperatures in THF, but had almost disappeared above room temperature. The cationic complex was then predominant.[12]

[40] The conductivity did not stabilize, but instead it increased continually with time at 25 °C. The degradation probably arose from a side reaction induced by the formate ion, i.e., the partial decarboxylation of the neutral intermediate HPd(OCHO)$(PPh_3)_2$ (formed in the very first step of the reaction) before ionization. This well-known decarboxylation of formate gave $HPdH(PPh_3)_2$, leading to H_2 and Pd^0L_2 that again underwent a reaction with HCO_2H. A similar degradation has been proposed by Zargarian and Alper.[34]

[41] If, however, the catalytic reactions are carried out in benzene, a non-coordinating and non-ionizing solvent, the neutral complexes $HPdA(PPh_3)_2$ (A = $OCOCH_3$ or OCHO)[33a,33b] must be formed, but in low concentration because they are involved in an endergonic equilibrium with the carboxylic acid and the Pd^0 complex.

The First Mononuclear η^2-C_{60} Complex of Osmium: Synthesis and X-ray Crystal Structure of $[(\eta^2\text{-}C_{60})Os(CO)(t\text{BuNC})(PPh_3)_2]$

Alexander V. Usatov,*[a] Ekaterina V. Martynova,[a] Ivan S. Neretin,[a] Yuri L. Slovokhotov,[a] Alexander S. Peregudov,[a] and Yurii N. Novikov[a]

Keywords: Fullerenes / Olefins / Osmium / Pi interactions

The interaction of C_{60} fullerene with the *cis*-dihydride osmium complex $[OsH_2(CO)(PPh_3)_3]$ (**I**) in the presence of *t*BuNC gives a novel metal complex $[(\eta^2\text{-}C_{60})Os(CO)(t\text{BuNC})(PPh_3)_2]$ (**II**) as the first mononuclear osmium complex with an η^2-coordinated fullerene ligand. Complex **II** was isolated and characterized by elemental analysis, UV, IR, ^1H and ^{31}P NMR spectroscopy. An X-ray diffraction study of **II** as its dichlorobenzene solvate revealed a distorted trigonal bipyramidal coordination of the Os atom, with a 6/6 bond of C_{60} and two PPh_3 ligands in the equatorial plane and CO and *t*BuNC as axial ligands.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

A large number of mononuclear complexes of fullerenes with transition metals, with general formula $(\eta^2\text{-}C_n)ML$ (where L stands for any ligand environment of M metal), with an olefin-like π-coordinated fullerene moiety have been obtained and structurally characterized for most metals of the platinum family, including Ru,[1] Rh,[2−4] Ir,[5,6] Pd,[7,8] and Pt.[9−11] Based on their structures and spectroscopic properties, $(\eta^2\text{-}C_n)$ fullerene ligands in such mononuclear complexes are believed to be analogues of acceptor η^2-olefins with electron-withdrawing substituents (e.g. tetrafluoroethylene or tetracyanoethylene).[12,13] However, no mononuclear η^2-derivatives of fullerenes with osmium have been reported to date, notwithstanding the fact that an exopolyhedrally coordinated osmate complex of C_{60}, $(\sigma,\sigma\text{-}C_{60})O_2OsO_2(4\text{-}tert\text{-butylpyridine})_2$, was the first fullerene derivative studied by single-crystal X-ray diffraction.[14] Meanwhile, a number of osmium tri-[15−17] and pentanuclear clusters,[17,18] with the C_{60} moiety connected to a cluster core in an η^2- [in $Os_3(CO)_{11}(\eta^2\text{-}C_{60})$[15]], $\eta^1{:}\eta^2{:}\eta^1$-,[16] $\eta^2{:}\eta^2$- [17] or $\eta^2{:}\eta^2{:}\eta^2$-mode,[15,17,18] have been obtained and structurally characterised by X-ray methods.

In this paper we report the synthesis of the first mononuclear π-complex of osmium with buckminsterfullerene as an η^2-ligand and its structural characterization by single-crystal X-ray diffraction. To reach this goal, we have used the method recently developed by us for a synthesis of the mixed-ligand η^2-C_{60} and σ-carboranyl derivative of iridium $[(\eta^2\text{-}C_{60})Ir(o\text{-}HCB_{10}H_9CCH_2PPh_2\text{-}B,P)(t\text{BuNC})_2]$.[6] This approach is based on the interaction of the C_{60} molecule with a coordinatively unsaturated reactive intermediate, generated in situ from the corresponding metal *cis*-dihydride complex and *tert*-butyl isocyanide. The *t*BuNC ligand, having both π-acceptor and σ-donor properties, plays a dual role in the synthesis: as a strong π-acceptor it promotes the reductive elimination of a dihydrogen molecule from the initial dihydride complex after ligand substitution, to give a low-valent intermediate, whereas as a σ-donor it enhances the electron density at the metal center facilitating the effective coordination of the bulky and electron-deficient fullerene ligand.

As a starting *cis*-dihydride complex, the well-known and readily available $[OsH_2(CO)(PPh_3)_3]$[19] (**I**), which does not react directly with C_{60}, was chosen. However, when C_{60} and **I** are refluxed together in toluene with *t*BuNC, a substitution of triphenylphosphane ligand for isocyanide occurs, accompanied by elimination of dihydrogen, giving rise to a new $[(\eta^2\text{-}C_{60})Os(CO)(t\text{BuNC})(PPh_3)_2]$ complex (**II**) (Scheme 1).

The product **II**, obtained in analytically pure form by chromatography, was characterized by microanalysis and spectroscopy data (UV/Vis, IR, ^1H and ^{31}P NMR). The UV/Vis pattern of **II** is rather typical for transition metal η^2-C_{60} complexes.[3,6,20] The presence of a strong ν(CO) band at 1953 cm^{-1} and a strong single ν(NC) band at 2153 cm^{-1} in the IR spectrum of **II** reveals both isocyanide and carbonyl ligands to be present in the molecule, pointing to a specific substitution of the triphenylphosphane ligand. According to the ^1H NMR spectroscopic data, complex **II** contains two PPh_3 and one *t*BuNC ligand, whereas the presence of only one singlet resonance at $\delta = 7.9$ ppm in the $^{31}P\{^1H\}$ NMR corresponds to the existence of only one isomer, with two equivalent PPh_3 ligands, in solution. The latter may be considered as evidence of metal-fullerene coordination by the 1−2 bond (see discussion in ref.[20]).

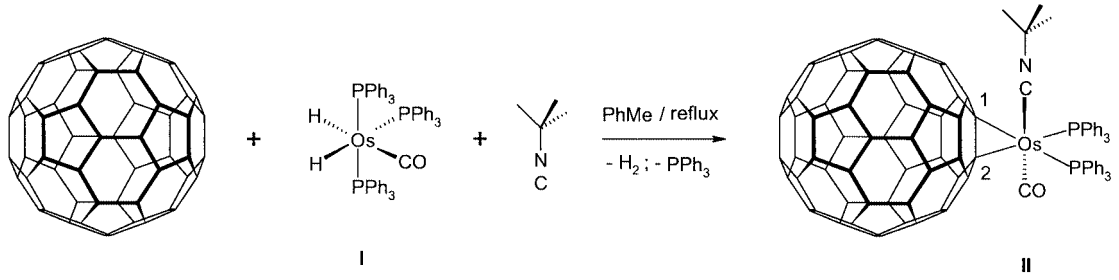

Scheme 1

The analytical data for **II** (C, H P, Os) correspond unequivocally to a monoadduct such as $[(C_{60})Os(CO)(t\text{-BuNC})(PPh_3)_2]$. However, the available spectroscopic data do not allow us to distinguish between the possible equatorial (with carbonyl and *t*BuNC as axial ligands) and *trans*-axial positions of the two equivalent PPh_3 ligands. Notwithstanding a close resemblance of the spectroscopic data for **II** with those of the related complex $[Os(C_2F_4)(CO)\{(p\text{-Tolyl})NC\}(PPh_3)_2]$ [ν(CO) = 1968 cm^{-1}, ν(NC) = 2160 cm^{-1}; δ_P = 3.5 ppm],[21] with two equivalent equatorial PPh_3 ligands and strong preference of equatorial location of bulky PPh_3 and fullerene ligands due to the steric repulsion, no decisive evidence was obtained in favor of one of the two possible isomers from the spectroscopic data.

To determine the molecular geometry of **II** unequivocally and to analyze its structural features, we grew a single crystal of **II** from *o*-dichlorobenzene solution and performed an X-ray diffraction study.

The molecular structure of $\mathbf{II}\cdot 2.5C_6H_4Cl_2$ with selected geometric parameters (bond lengths and bond angles) is shown in Figure 1. The molecule $[(\eta^2\text{-}C_{60})Os(CO)(t\text{-BuNC})(PPh_3)_2]$ has an ordered C_{60} moiety with a normal olefin-type π-coordination to the osmium atom. A trigonal bipyramidal ligand environment of Os in **II** is completed by two equatorial PPh_3 ligands, with one isocyanide and one CO ligand in the axial positions. Most of the bond lengths and angles (see Figure 1) have their normal values. However, the bond angles P(1)−Os−P(2) [109.58(5)°], P(1)−Os−C_{60} [120.3(1)°] and P(2)−Os−C_{60} [130.1(1)°] in the equatorial plane of the trigonal bipyramid (where C_{60} denotes a center of the coordinated 6/6 bond) display a substantial asymmetry due to intramolecular C−H···C steric repulsion between one Ph substituent at P(2) and C_{60} (shortest H···C distances at 2.64−2.87 Å are slightly less than the sum of their van der Waals radii). Metal-fullerene bonding leads to elongation of η^2-coordinated 6/6 bonds to 1.498(7) Å from the normal value of 1.39 Å in pristine C_{60} and a more pyramidal environment of the C atoms [the spherical excess (spherical excess is 360° − Σ(all CCC bond angles) of the carbon environment, which is a good quantitative measure of pyramidalization,[22] is 12° in pristine C_{60}, 23.2 and 24.0° at these atoms of **II**, 7.4−8.6° at their neighbors and 10.5−13.5° at all other C atoms].

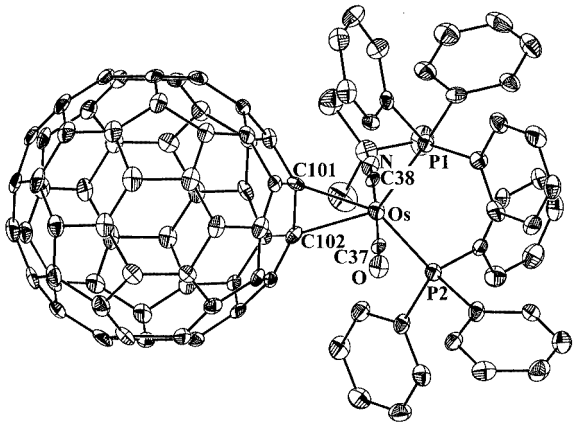

Figure 1. Molecule **II** with atomic numbering in the coordination environment of the Os atom (hydrogen atoms not shown); bond lengths (A): Os−P(1) 2.347(2), Os−P(2) 2.351(1) Os−C(37) 1.898(2), Os−C(38) 2.011(2), Os−C(101) 2.193(5), Os−C(102) 2.193(5), C(37)−O(1) 1.146(4), C(38)−N(1) 1.169(6), C(101)−C(102) 1.479(7); bond angles (°): P(1)−Os−P(2) 109.58(5), P(1)−Os−C(37) 88.52(8), P(2)−Os−C(37) 92.41(7), P(1)−Os−C(38) 96.13(8), P(2)−Os−C(38) 84.26(7), C(37)−Os−C(38) 175.0(1), Os−C(37)−O 178.0(2), Os−C(38)−N 173.9(2)

It is interesting to note that only two mononuclear phosphane π-complexes of osmium with η^2-coordinated olefins having electron acceptor substituents, viz. $[(Ph_3P)_2Os(CO)_2(\eta^2\text{-}C_4H_2O_3)]$[21] (with maleic anhydride) and $[(iPr_3P)_2OsH(OH)(CO)(\eta^2\text{-}CH_2{=}CHCOOMe)]$[23] (with methylmetacrylate) are found in the last (2002) version of the Cambridge Structural Database (CSD). Mononuclear π-complexes of Ru with electron-accepting olefins, which have been studied in more detail, include derivatives of tetrafluoroethylene $[(Ph_3P)_2Ru(CO)_2(\eta^2\text{-}C_2F_4)]$,[21] maleic anhydride $[(Ph_3P)_2Ru(CO)\{(p\text{-Tolyl})NC\}(\eta^2\text{-}C_4H_2O_3)]$,[24] and buckminsterfullerene $[(Ph_3P)_2RuCl(NO)(\eta^2\text{-}C_{60})]$.[1] The main geometric molecular parameters of these complexes are compared with the corresponding parameters of **II** in Table 1.

The Os−C(C_{60}) bond lengths [2.193(5) Å] in **II** are typical for mononuclear complexes with π-coordinated acceptor

$[(Ph_3P)_2Ru(CO)_2(\eta^2\text{-}C_2F_4)]$	2.43	1.92	2.09	101.4	127.5 131.1	[21]

[a] Two PPh_3 and two CO ligands in equatorial and axial positions, respectively. [b] η^2-Methyl methacrylate. [c] Hydride H atom between two equatorial PPh_3 ligands. [d] η^2-Methyl methacrylate. [e] Hydride H atom between two equatorial PPh_3 ligands.

olefins (see Table 1), and are almost identical to the Os−C(olefin) distances in $[(Ph_3P)_2Os(CO)(\eta^2\text{-}C_2H_4)_2]$ (2.15−2.19 Å).[25] In a disordered structure of $[Os_3(CO)_{11}(\eta^2\text{-}C_{60})]$, η^2-coordination to one of three Os atoms in a triangular cluster is accompanied by larger distances (2.22−2.27 Å)[15] that lie within the usual range (2.21−2.32 Å) for a multicenter Os_3-(η^2: η^2:η^2-C_{60}) coordination.[15,17,18] A planar trigonal arrangement of two phosphanes and the center of the coordinated 6/6 bond of the η^2-C_{60} ligand in the equatorial plane around the Os atom in **II** is similar to other mononuclear fullerene derivatives like $[(PPh_3)_2Pd(\eta^2\text{-}C_{60})]$,[7] $[(PPh_3)_2Pd(\eta^2\text{-}C_{70})]$,[8] $[(DIOP)_2Pt(\eta^2\text{-}C_{60})]$,[11] $[(PPh_3)_2RuCl(NO)(\eta^2\text{-}C_{60})]$,[1] $[(PPh_3)_2RhH(CO)(\eta^2\text{-}C_{60})]$,[2] and $[L_2IrCl(CO)(\eta^2\text{-}C_n)]$ (where L is a phosphane ligand).[13] Unlike the symmetric L_2M-(6/6 bond) fragment in all these complexes, the P−Os−C_{60} angles in **II** differ by 10°. However, in the related pentacoordinate complex $[(PPh_3)_2Ru(CO)[(p\text{-tolyl})NC](\eta^2$-malonic anhydride)] with carbonyl and isocyanide axial ligands,[24] which is the closest non-fullerene analogue of **II**, the P−Ru(olefin) angles in the equatorial plane differ by 18.3° (see Table 1). Even the large angle difference in mononuclear $[(Ph_3P)_2Os(CO)_2(\eta^2\text{-}C_4H_2O_3)]$ is due to the axial position of one PPh_3 ligand,[21] whereas in $[(i\text{Pr}_3P)_2OsH(OH)(CO)(\eta^2\text{-}CH_2{=}CHCOOMe)]$ a hydride ligand is situated between two $i\text{PPr}_3$ groups in the equatorial plane.[23] Such asymmetry of the flexible metal coordination probably refers to an interplay of interligand repulsion and molecular packing forces in the crystal.

Thus, we have shown that the interaction of fullerene with *cis*-dihydride transition metal complexes in the presence of isocyanide gives a rather convenient and general synthetic route to (η^2-C_{60}) metal complexes. It allowed us to obtain the first mononuclear osmium fullerene complex $[(\eta^2\text{-}C_{60})Os(CO)(t\text{BuNC})(PPh_3)_2]$ whose crystal and molecular structure was completely characterized by single-crystal X-ray diffraction.

Experimental Section

General: All manipulations were performed under oxygen-free argon in dry degassed solutions. IR spectra were obtained on a Specord M80 spectrometer. ^{1}H NMR spectra (400.3 MHz) and $^{31}P\{^1H\}$ NMR spectra (160.02 MHz) were recorded on a Bruker AMX-400 spectrometer and are quoted relative to residual signals of the solvent (internal standard) and 85% H_3PO_4 (external standard), respectively. $[OsH_2(CO)(PPh_3)_3]$ was prepared by a standard literature procedure.[19b]

Synthesis of $[(\eta^2\text{-}C_{60})Os(CO)(t\text{BuNC})(PPh_3)_2]$ (II): $[OsH_2(CO)(PPh_3)_3]$ (**I**) (0.0699 g, 0.069 mmol) and *t*BuNC (17.2 μL, 0.153 mmol) were added to a solution of C_{60} (0.050 g, 0.069 mmol) in toluene (50 mL), with stirring, and the reaction mixture was refluxed for 24 h. After cooling the reaction mixture to room temperature, a small quantity (0.013 g) of insoluble precipitate (not further unidentified) was filtered off, and the solution was concentrated to 5 mL and then diluted with pentane. The precipitate was filtered, washed with pentane, dissolved in 1 mL of $CHCl_3$ and chromatographed on a short column packed with alumina, eluting with a $CHCl_3$/hexane mixture (1:1). A green fraction was collected, solvents were removed under reduced pressure and the residue was washed with pentane, and dried in vacuo at 60 °C to give 41 mg (38%) of **II**. $C_{102}H_{39}NOOsP_2$ (1546.6): calcd. C 79.21, H 2.54, Os 12.30, P 4.00; found C 78.47, H 2.64, Os 12.77, P 4.35. UV/Vis (THF): λ = 259, 333, 394 (sh), 444, 671 nm. IR (KBr pellet): $\tilde{\nu}$ = 2153 cm^{-1} (NC), 1953 (CO). ^{1}H NMR ($CDCl_3$): δ = 0.86 (s, 9 H, *t*Bu), 7.32 (m, 18 H, Ph), 7.58 (m, 12 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ = 7.9 ppm.

X-ray Structure Determination of II: Dark green crystals of **II**·2.5(*o*-$C_6H_4Cl_2$) were grown by slow diffusion of heptane into an *o*-dichlorobenzene solution of complex **II** at room temperature. The crystals are triclinic, space group $P\bar{1}$, a = 13.254(3), b = 16.753(4), c = 18.642(4) Å, α = 87.575(5)°, β = 74.626(5)°, γ = 73.672(5)°, V = 3828(1) Å^3, Z = 2, $d_{calcd.}$ = 1.661 g/cm^3, and μ(Mo-K_α) = 19.52 mm^{-1}. The intensities of 21936 unique reflections (R_{int} = 0.063) were measured at 110(2) K on a Bruker SMART 1000 CCD diffractometer (graphite monochromated Mo-K_α radiation, λ = 0.71073 Å, ω and scan technique with a 0.3° step in ω and 10 s per frame exposure, θ ≤ 30.15°). Reflection intensities were integrated using the SAINT software[26] and corrected for absorption

semiempirically (SADABS program)[26] based on multiple measurements of identical reflections and equivalents. The structure was solved by direct methods and refined by full-matrix least-squares against F^2. Two molecules of *o*-dichlorobenzene were located in general positions, and one more such molecule, disordered about the inversion center, was found in the difference Fourier map. One of the two *o*-dichlorobenzene molecule appeared to be disordered. All disordered atoms in the crystal structure of **II** were refined with isotropic thermal parameters. All H atoms were placed geometrically and included in the refinement using a riding model. The refinement converged to $wR_2 = 0.1074$ and $GOF = 0.733$ for all independent reflections ($R_1 = 0.0543$ was calculated against F for a total of 10492 observed reflections with $I > 2\sigma(I)$]; the number of refined parameters was 1127. All calculations were performed with SHELXTL-97.[27]

Modulation of the Prototropic Exchange Rate at the Water Molecule Coordinated to a Gd^{III} Ion

Silvio Aime,*[a] Eliana Gianolio,[a] Alessandro Barge,[a] Dimitrios Kostakis,[b] Ioannis C. Plakatouras,[b] and Nick Hadjiliadis[b]

Keywords: Gadolinium / Chelates / Basicity / Neighbouring-group effects / Prototropic exchange / Imaging agents

The aim of this work is to assess whether it is possible to control the rate of the prototropic exchange in a class of DTPA bis-amide Gd^{III} complexes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

In the last decade much attention has been devoted to the understanding of the determinants of the water-exchange process in Gd^{III} complexes because their successful application as MRI contrast agents is related to the occurrence of a suitable exchange lifetime (τ_M) of the coordinated water.[1−4] The latter parameter inversely affects the inner-sphere relaxation term (R_{1p}^{is}) and is often the main determinant of the overall relaxivity of a paramagnetic Gd^{III} complex. The R_{1p}^{is} contribution is given by Equation (1):

$$R_{1p}^{is} = \frac{q[C]}{55.5(T_{1M} + \tau_M)} \quad (1)$$

where [*C*] is the molar concentration of the paramagnetic agent, *q* is the number of coordinated water molecules and T_{1M} is the relaxation time of their protons. Thus, as long as τ_M is shorter than T_{1M} the paramagnetic relaxation effect can be efficiently transferred to the bulk water solvent.

Bis-amide derivatives of Gd-DTPA (DTPA = diethylenetriamine pentaacetic acid) display relatively long exchange lifetimes of the coordinated water,[5−8] therefore their relaxivity is usually smaller than expected. However, such a drawback has been exploited in order to assess the rate of prototropic exchange at the coordinated water molecule. The latter process is pH-dependent and becomes significantly high either at acidic or basic pH, to overcome the "quenching" effect of the slow exchanging water, thus allowing the system to raise the relaxivity expected on the basis of its T_{1M} value.

Thus, τ_M in Equation (1) can be replaced by Equation (2):

$$\tau_M = \left[\left(\tau_M^0\right)^{-1} + \left(k_{ex} \frac{k_W}{[H_3O^+]} \right) \right]^{-1} \quad (2)$$

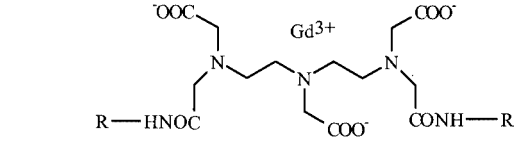
where k_{ex} is the prototropic exchange rate. Although the prototropic exchange is either acid or base catalysed, its assessment, in the case of bis-amide derivatives of Gd-DTPA, is preferentially pursued under basic conditions because the limited thermodynamic stability of these complexes may cause some release of Gd^{III} ions upon protonation of the acetic arms at acidic pH. Typically the determination of k_{ex} is then carried out by fitting the pH-dependent curve of the relaxivity in the pH range between 3 and 10.

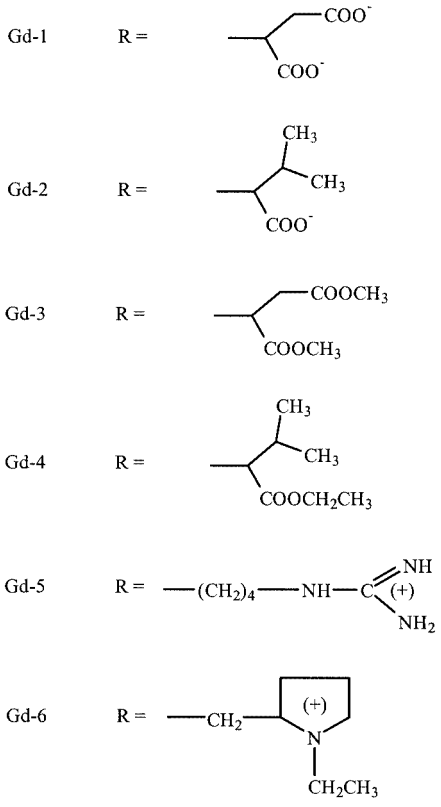
The aim of this work is to assess whether it is possible to control the rate of the prototropic exchange in this class of Gd^{III} complexes.

Six novel bis-amide derivatives of Gd-DTPA have been synthesised (Scheme 1). These ligands were obtained according to the previously reported procedure[9] based on the reaction of DTPA bis-anhydride with the amine group of the entering R substituent. Compounds **1** and **2** were obtained by hydrolyzing the ester functionalities of **3** and **4**, respectively.

The corresponding Gd^{III} complexes were obtained by reacting equimolar amounts of any given ligand and $GdCl_3$ at pH 6. The eventual excess of uncomplexed Gd^{III} ions was precipitated as the hydroxide as the pH of the solution was brought to basic values, and separated by ultracentrifugation.

At neutral pH and 298 K, the relaxivity (measured at 20 MHz) shown by all six complexes is very similar (ca. 5 ± 0.4 $mM^{-1}s^{-1}$). In all cases the relaxivity increases as the temperature is increased. This is an unambiguous symptom of the occurrence of a slow water-exchange that "quenches"





Scheme 1. Schematic representation of the structures of the six bisamide DTPA derivatives

the attainable relaxivity in analogy with previous observations in a number of related Gd-bisamide DTPA systems.[10−12] ^{17}O-R_{2p} measurements at variable temperature yield accurate values for the exchange rate of the coordinated water (Table 1) applying a well-established fitting procedure to the theoretical values obtained from the Swift−Connick equation.[13]

Table 1. Relaxometric and dynamic prameters for Gd^{III} complexes

Complexes	r_{1p} (mM^{-1} s^{-1}) at pH 7	τ_M^O (μs)[a]	T_{1M} (s)[b]	k_{ex} (M^{-1} s^{-1})
Gd-1	5	2.36	3.8×10^{-6}	4.6×10^{8}
Gd-2	5.3	1.98	3.6×10^{-6}	2.7×10^{9}
Gd-3	4.6	2.56	5.2×10^{-6}	7.5×10^{9}
Gd-4	5.1	2.22	3.8×10^{-6}	4.2×10^{9}
Gd-5	5.3	2.2	3.95×10^{-6}	1.2×10^{10}
Gd-6	5.3	2.66	3.1×10^{-6}	8.6×10^{10}

[a] Values calculated from the fitting of ^{17}O NMR profiles (pH 7 and 298 K). [b] Values calculated from the fitting of NMRD profiles recorded at basic pH.

The proton relaxivity measurements, in the pH range from 6 to 12, display the expected increase as the prototropic exchange-rate becomes fast enough to remove the limit of the slow-exchange of the coordinated water. It has been very interesting to observe that the increase of r_{1p} takes place at significantly different pH values; for instance, pH 10 for **Gd-1** and pH 7 for **Gd-6** (Figure 1). The observed behaviour clearly reflects the occurrence of different prototropic exchange rates as a function of the R substituents. The accurate determination of the prototropic exchange rates was performed by fitting the observed pH-dependent relaxivity curves according to Equation (1) modified as in Equation (2) and using T_{1M} values obtained from NMRD profiles measured at pH 12 (Table 1) and $\tau \cong \tau_M^O$ values calculated from ^{17}O NMR profiles.

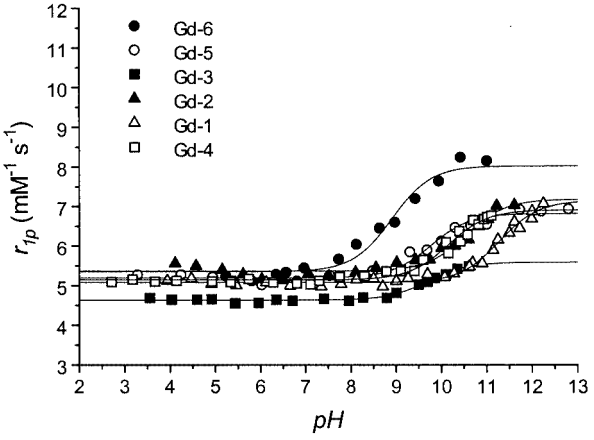


Figure 1. Effect of $[OH^-]$ catalysis on the prototropic exchange as assessed from the increase of r_{1p} as a function of pH. The continuous lines represent the theoretical values calculated according to Equations (1) and (2) for the evaluation of R_{1p}^{is}. R_{1p} is the sum of R_{1p}^{is} + R_{1p}^{os} (outer sphere) and R_{1d}. R_{1p}^{os} was obtained by fitting NMRD profiles. R_{1d} was set equal to 0.38 s^{-1}

Although not proven, we discarded any significant contribution from the exchange of amide protons.[14] When, in related complexes, saturation transfer experiments were carried out by irradiating the NH moieties in Eu^{III} complexes, k_{ex} values were found to be ca. 8×10^5 mM^{-1} s^{-1} around pH 10. Such values do not have significant effects on the R_{1p}^{is} of Gd^{III} complexes [Equation (1): T_{1M} calculated for NH protons, at a distance from the metal ion of 4.2 Å, is 3.6×10^{-5}].

From these data one draws the conclusion that the base catalysis of the prototropic exchange takes place in this series of related complexes with remarkable differences, being fastest for **Gd-6** and slowest for **Gd-1** (Figure 2). The observed behaviour is easily rationalised in terms of the accessibility of OH^- ions to the coordinated water molecule. The positively charged substituents in **Gd-5** and **Gd-6** promote the access of the negatively charged hydroxyl ions to the water coordination site. On the other hand the negatively charged carboxylate moieties in **Gd-1** and **Gd-2** hamper the approach of the hydroxyl groups, thus causing an overall decrease of the prototropic exchange. On passing from **Gd-1** to **Gd-3** and from **Gd-2** to **Gd-4**, the esterifi-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cation of these substituents removes the residual negative charge, with a consequent increase of the base catalysis of the prototropic exchange.

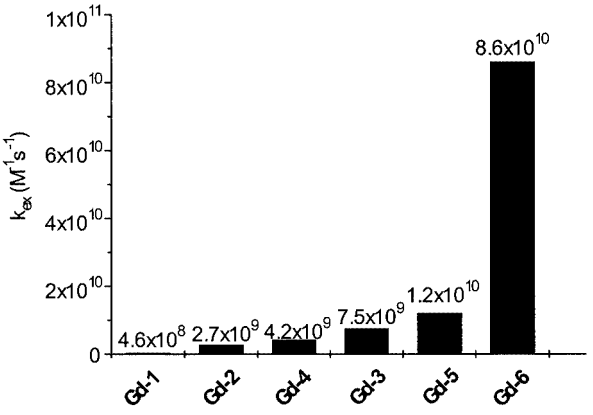

Figure 2. Prototropic exchange rates at the coordinated water molecule in Gd^{III} complexes of a series of bis-amide DTPA ligands

These observations unambiguously indicate that it is possible to control the rate of the prototropic exchange by introducing suitable substituents on the surface of the ligand coordination cage of the Gd^{III} ion. As far as OH^- catalysis is concerned it is apparent that the main determinant is the overall residual charge.

In principle, one may expect that the prototropic exchange rate is also affected by the solution structure of the investigated complex. Actually, the lanthanide(III) complexes of bis-amide DTPA ligands are present in solutions as mixtures of four pairs of interconverting isomers[15−17] and it is likely that the nature of the R substituents could affect the isomer distribution. However, if this were the case, the results reported here indicate that such effects are not of primary importance in the determination of OH^- catalysis of the prototropic exchange of the coordinated water.

Experimental Section

Synthesis of 1−4: Ligands **1**−**4** were prepared by adding DTPA-bisanhydride (1 mmol) in portions to a stirring solution of distilled DMF (15 cm^3) containing 2 mmol of HCl·Asp, HCl·Val, $Asp(OMe)_2$·HCl, or ValOEt·HCl. The reaction mixture was heated for 36 h at 80 °C, the solution was allowed to cool and the solvent was removed under vacuum to result in an oil that solidified upon addition of acetone/diethyl ether (30:70; 300 cm^3). The white solid was dried under reduced pressure over $CaCl_2$.

Synthesis of 5: Diethylenetriamine-*N*,*N*′′-bis(4-guanidinobutyl)-*N*,*N*′,*N*′′-triacetic acid (5) was prepared by adding DTPA-bisanhydride (4.2 g, 0.012 mol) in portions to a stirring solution of distilled DMF (70 cm^3) containing agmatine (3.27 g, 0.025 mol; previously purified from the sulfate by extraction with 1-butanol from water at pH 13). The reaction mixture was heated for 4 h at 50 °C, and 20 h at room temperature. The solution was then allowed to cool and the solvent was removed under vacuum to result in an oil that solidified on addition of acetone/diethyl ether (30:70; 50 cm^3). The white solid was dried under reduced pressure over $CaCl_2$.

Synthesis of 6: Diethylenetriamine-*N*,*N*′′-bis(2-aminomethylethylpyrrolidine)-*N*,*N*′,*N*′′-triacetic acid (6) was prepared by adding DTPA-bisanhydride (0.582 g 0.002 mol) in portions to a stirring solution of distilled DMF (10 cm^3) containing 2-aminomethylethylpyrrolidine (0.418 g, 0.003 mol). The reaction mixture was heated for 24 h at 50 °C, the solution was allowed to cool and the solvent was removed under vacuum to give an oil that solidified on addition of acetone/diethyl ether (30:70; 50 cm^3). The white solid was dried under reduced pressure over $CaCl_2$.

Synthesis of Gd^{III} Complexes: The general procedure for the synthesis of the gadolinium complexes consists of the addition of equimolar amounts of the corresponding ligand (2 mmol) and $GdCl_3·6H_2O$ (2 mmol) in deionized water (20 cm^3), followed by adjustment of the pH to 6.0 by adding KOH.

The longitudinal water proton relaxation rate was measured by using a Stelar Spinmaster (Mede, Pavia, Italy) spectrometer operating at 20 MHz, by means of the standard inversion-recovery technique (16 experiments, 2 scans). A typical 90° pulse width was 3.5 μs and the reproducibility of the T_1 data was ±0.5%. The temperature was controlled with a Stelar VTC-91 air-flow heater equipped with a copper-constantan thermocouple (uncertainty ±0.1 °C).

Variable temperature ^{17}O NMR measurements were recorded at 2.1 T on a JEOL EX-90 spectrometer, equipped with a 5 mm probe, by using a D_2O external lock. Experimental settings: spectral width 10000 Hz, 90° pulse (7 μs), acquisition time 10 ms, 1000 scans and no sample spinning. Aqueous solutions containing 2.6% of ^{17}O isotope (Yeda, Israel) were used. The observed transverse relaxation rates (R^O_{2obs}) were calculated from the signal width at half-height ($\Delta\nu_{1/2}$): $R^O_{2obs} = \pi\,\Delta\nu_{1/2}$.

P−B Adducts of 3,4-Dimethyl-1-phosphaferrocene with Bromoboranes

Matthias Scheibitz,[a] Jan W. Bats,[b][‡] Michael Bolte,[b][‡] and Matthias Wagner*[a]

Dedicated to Prof. Dr. Herbert Wagner on the occasion of his retirement

Keywords: Boranes / Donor-acceptor systems / Metallocenes / P ligands / X-ray diffraction

The crystalline adducts FcP–BBr_3 (**2**) and FcP–BBr_2Fc (**3**), which are very rare examples of *P*-bonded complexes between phosphaferrocene and a main-group metal atom, were obtained by the reaction of 3,4-dimethyl-1-phosphaferrocene (FcP) with BBr_3 and $FcBBr_2$ (Fc: ferrocenyl). According to X-ray crystallography, the Fe–P bond length in **2** is 0.085 Å shorter than in the parent phosphaferrocene. All structural changes resulting from P–B acid–base pairing follow the same qualitative trend, but are significantly larger than those occurring from the formation of transition metal complexes of phosphaferrocene. In contrast to **2**, NMR spectroscopy reveals **3** to be almost completely dissociated in $CDCl_3$ solution at room temperature.

Introduction

Oligonuclear transition metal complexes are receiving great attention because of their numerous applications both in homogeneous catalysis[1] and in materials science.[2] The sandwich complex ferrocene has proven to be a particularly important building block in this context. 1,2-Disubstituted ferrocene derivatives give access to chelate ligands possessing planar chirality that have been employed successfully in asymmetric catalysis.[3−5] In the field of materials science, Manners et al. took advantage of the ring-opening polymerisation of strained *ansa*-ferrocenes for the generation of poly(ferrocenylene)s that exhibit interesting optical and electronical properties.[6] Phosphaferrocenes **A**[7] and 1,1′-diphosphaferrocenes **B**[8] (Figure 1), which became available from the work of Mathey et al., were soon recognized to form stable κ-*P* complexes with various transition metals.[9] Ganter et al. developed appropriately substituted derivatives of **A** as a new class of chiral chelate ligands,[10,11] while **B** was used as bridging unit in the formation of heterotrimetallic aggregates.[12]

Our group recently reported a convenient approach to ferrocene-containing macromolecules that benefits from the facile formation of Lewis acid−base adducts. For example, the reaction of the diborylated ferrocene 1,1′-fc(BMe_2)$_2$ [fc = (C_5H_4)$_2$Fe] with selected difunctional Lewis bases (e.g., pyrazine) gives access to polymeric materials in high yield and under very mild conditions (e.g., **C**, Figure 1).[13−15] We decided to investigate whether the or-

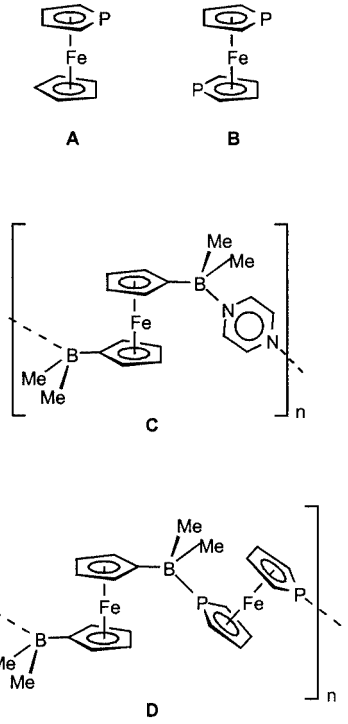

Figure 1. Phosphaferrocene **A**, 1,1′-diphosphaferrocene **B** (only the parent molecules are shown as representatives of the whole class of derivatives), a B−N-bonded charge-transfer coordination polymer **C**, and the final target molecule **D**

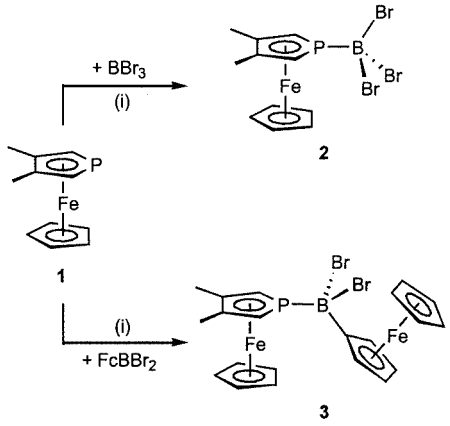
ganic linker in **C** can be replaced by the redox-active organometallic template ligand **B** to generate target molecules like **D** (Figure 1).

A particular challenge is offered by the fact that despite the plethora of well-characterized complexes of phosphaferrocene and transition metals, no adducts of **A** and only one adduct of **B**[16] with main-group Lewis acids has been isolated so far. In contrast to the related azaferrocene, which is readily quaternized by methyl iodide,[17] diphosphaferrocene **B** was found to react only at elevated temperature, even in neat benzyl bromide. The reaction leads to the decomposition of the phosphaferrocene moiety with liberation of *P*,*P*-dibenzylphospholium bromide.[18] Acetylations, formylations and carboxylations of phosphaferrocenes occur selectively at the α-carbon atoms of the coordinated phospholyl ring.[8,18,19] Moreover, treatment of **A** or **B** with trifluoromethanesulfonic acid leads to protonation on the iron atom, rather than on the phosphorus atom.[20] In summary, the P atom of phosphaferrocenes possesses an energetically low-lying lone pair of electrons and consequently acts as a rather poor σ donor. The LUMO, on the other hand, has pronounced p_z character on the phosphorus atom and is well suited to accept π-electron density.[9,11] The stability of phosphaferrocene-κ-*P*−ML_n complexes is, therefore, expected to grow with an increasing degree of back bonding from electron-rich ML_n fragments. Thus, the fact that main-group elements are not able to have $d_\pi-p_\pi$ interactions with **A** or **B** might explain why corresponding κ-*P* η^1-adducts are virtually unknown up to now. One report on the reaction of phosphaferrocene with $BF_3{\cdot}OEt_2$ has been published that provides evidence for the existence of a phosphorus-bonded adduct in solution (^{31}P NMR spectroscopic control).[20] Moreover, the hypothetical P−B complex $\mathbf{A}{\cdot}BH_3$ has been studied theoretically using DFT methods.[21] Mathey et al. recently reported the reaction of octa-*n*-propyldiphosphaferrocene with $GaCl_3$, which leads to the formation of a tetrahedral gallium(III) complex featuring a chelating diphosphaferrocene ligand.[16] Here, we describe the synthesis, isolation and structural characterization of two P−B adducts of 3,4-dimethyl-1-phosphaferrocene (**1**, Scheme 1).

Results and Discussion

Synthesis and Spectroscopic Characterization

The phosphaferrocene derivative **1** (Scheme 1) was chosen for our investigation because it is accessible in high yield by an established procedure.[7,22] When **1** is treated with the strong Lewis acid BBr_3 in $CDCl_3$ (stoichiometric ratio: 1:1), no obvious reaction takes place since the resulting clear mixture still possesses the orange colour of the initial phosphaferrocene solution. NMR spectroscopy at ambient temperature, however, reveals significant shifts of some characteristic resonances. The phosphorus nucleus in **2** [$\delta(^{31}P) = -13.2$ ppm, $h_{1/2} = 30.1$ Hz] is deshielded by 69.3 ppm compared to that of the free ligand **1** [$\delta(^{31}P) = -82.5$ ppm, $h_{1/2} = 6.5$ Hz]. A strong downfield shift of the



Scheme 1. Synthesis of the P−B-bonded phosphaferrocene adducts **2** and **3**; (i) ambient temperature, C_6H_6

^{31}P NMR signal is also generally observed upon complexation of phosphaferrocenes with transition metal ions.[9] No signal is detectable in the ^{11}B NMR spectrum, which is most likely due to severe line broadening resulting from a dynamic adduct equilibrium. In the ^1H NMR spectrum of **2**, and with respect to parent 3,4-dimethyl-1-phosphaferrocene [**1**: $\delta(^1H) = 3.74$ ($^2J_{P,H} = 36.3$ Hz, phospholyl α-C*H*), 4.15 (C_5H_5) ppm], the resonances of the phospholyl α-protons [**2**: $\delta(^1H) = 4.18$ ($^2J_{P,H} = 29.1$ Hz) ppm] and the cyclopentadienyl ring [**2**: $\delta(^1H) = 4.55$ ppm] are shifted to lower field by 0.44 ppm and 0.40 ppm, respectively. Moreover, the $^2J_{P,H}$ coupling constant decreases by 7.2 Hz. Both the ^{31}P and ^{11}B NMR spectra were recorded also at −50 °C ($CDCl_3$). Under these conditions, the ^{31}P NMR resonance appears at $\delta = -12.9$ ppm as a well-resolved quadruplet with intensity ratios of 1:1:1:1 and a coupling constant of $^1J_{P,B} = 138.5$ Hz ($^1J_{P,B}$ values have been reported within a range of 10−180 Hz[23]). The ^{11}B NMR signal possesses a chemical shift value of $\delta = -20.9$ ppm (d, $^1J_{P,B} = 138.5$ Hz). Consequently, at −50 °C the solution contains mainly the adduct **2**, rather than free **1** and BBr_3.

The ^{11}B and ^1H NMR spectra of an equimolar mixture of **1** with $FcBBr_2$ in $CDCl_3$ at ambient temperature show only negligible differences to the NMR spectra of the individual components. In the ^{13}C NMR spectrum of **1**/$FcBBr_2$, the doublet of the phospholyl α-carbon atoms is broad, while the other signals remain unchanged. The chemical shift of the ^{31}P NMR resonance is the same in **1**/$FcBBr_2$ as in the case of **1**, but the width at half height increases from $h_{1/2} = 6.5$ Hz (**1**) to $h_{1/2} = 165.6$ Hz (**1**/$FcBBr_2$). Thus, NMR spectroscopy reveals the Lewis acid−base pair **1**/$FcBBr_2$ to be almost completely dissociated at room temperature in $CDCl_3$ solution. Slow evaporation of an equimolar mixture of **1** and $FcBBr_2$ in benzene, however, yielded X-ray-quality crystals of the desired P−B-bonded dinuclear species **3**.

X-ray Crystal Structure Determination

The phosphaferrocene−borane adducts **2** and **3** crystallize from benzene in the space groups *Pna*2_1

(orthorhombic) and $P2_1/c$ (monoclinic), respectively (Table 1). A comparison of the molecular geometries of **1**, **2** (Figure 2) and **3** (Figure 3) reveals remarkable structural changes as a result of P−B bond formation (Table 2). The Fe(1)−P(1) bond length in the BBr_3 adduct **2** possesses a value of 2.199(2) Å, which is 0.085 Å shorter than the iron−phosphorus bond in the parent 3,4-dimethyl-1-phosphaferrocene (**1**) [2.284(1) Å].[24] $FcBBr_2$ is known to be a weaker Lewis acid than BBr_3 because the ferrocenyl substituent acts as an electron donor towards the formally empty p orbital of the boron atom.[25] Consequently, the length of the Fe(1)−P(1) bond in **3** [2.216(1) Å] is intermediate between the values determined for **1** and **2**. These findings are consistent with the general trend observed for transition metal complexes of phosphaferrocenes. A search of the Cambridge Structural Database (CSD, Version 5.24, November 2002)[26] reveals the average Fe−P bond length in monophosphaferrocene derivatives to be 2.285(13) Å (10 structures). This value is reduced to 2.238(16) Å in the corresponding phosphorus-bonded transition metal complexes (22 structures). Interestingly, the effect of Fe−P bond contraction is larger in the borane adducts **2** and **3** than in the corresponding transition metal complexes. P−B acid−base pairing also has a pronounced influence on the C(2)−P(1)−C(5) angle, which is stretched from 88.9(2)° in **1** to 94.7(4)° in **2**, and to 92.7(2)° in **3**. Again, these findings are in good qualitative agreement with the structural features obtained for phosphaferrocene−transition metal aggregates [C−P−C angle in free phosphaferrocene (mean value of 10 derivatives): 89(1)°; C−P−C angle in phosphaferrocene−transition metal complexes (mean value of 22 structures): 92(1)°]. Thus, in all phosphaferrocene derivatives investigated so far (including **2** and **3**), a long Fe−P bond appears to be associated with a small C−P−C angle. It has to be noted that the degree of phospholyl ring puckering is largely unaffected by P−B bond formation. In the case of **1**, the P atom is located at a position 0.048(1) Å above the C(2)C(3)C(4)C(5) plane, while in **2** this displacement is only slightly reduced to a value of 0.043(1) Å. Thus, the phosphorus atom is not just pulled toward the iron centre upon coordination of BBr_3, which would result in a flattening of the phospholyl ligand, but rather it moves toward the C(3)−C(4) bond along a line almost parallel to the C(2)C(3)C(4)C(5) plane {**1**: *d*[P(1)···MP] = 2.589 Å; **2**: *d*[P(1)···MP] = 2.504 Å; MP: midpoint of the C(3)−C(4) bond}. As a result, the P−Fe bond, as well as the P−C bonds, become shorter [cf. **1**: P(1)−C(2) = P(1)−C(5) = 1.774(3) Å; **2**: P(1)−C(2) = P(1)−C(5) = 1.745(8) Å], the C−P−C angle increases, and the adjacent P−C−C angles decrease [cf. **1**: P(1)−C(2)−C(3) = 113.9(2)°, P(1)−C(5)−C(4) = 114.0(2)°; **2**: P(1)−C(2)−C(3) = 109.0(5)°, P(1)−C(5)−C(4) = 110.0(5)°]. The differences observed between the geometrical parameters of **1** and **3** are rather similar to those described above for **1** and **2** and, thus, do not merit further discussion. The P(1)−B(1) bond in **2** [1.972(9) Å] is 0.051 Å shorter than in **3** [2.023(4) Å]. The bond angles around the boron atoms cover a range between P(1)−B(1)−Br(3) = 104.9(4)° and Br(1)−B(1)−Br(3) = 112.2(4)° in the case of **2**, and P(1)−B(1)−Br(1) = 102.9(2)° and C(21)−B(1)−Br(1) = 114.2(2)° in the case of **3**. The relevant Br−B−Br angles of 110.9(4)°, 111.9(4)°, and 112.2(4)° in **2** are slightly larger than the value expected for an sp^3-hybridized boron atom with ideal tetrahedral geometry (109.5°). In **3**, the boron centre is somewhat less pyramidalized, which, together with the longer P(1)−B(1) bond, again indicates a weaker acid−base interaction as is the case in **2**. This interpretation is in agreement with the conclusions drawn from our NMR spectroscopic studies (see above). The BBr_3 adduct **2** features a torsion angle C(2)−P(1)−B(1)−Br(2) of 85.4(5)°. A similar conformation is observed in **3** for the BBr_2P fragment with respect to the ferrocenyl substituent [C(22)−C(21)−B(1)−P(1) = −87.9(3)°], whereas, com-

Conclusion

In contrast to the rich chemistry that has been developed for complexes between phosphaferrocene and transition metals, examples of *P*-bonded adducts between phosphaferrocene and main-group Lewis acids remained unknown until recently.[16] We have shown that adducts FcP−BBr_3 (**2**) and FcP−BBr_2Fc (**3**) are readily obtained from the reaction of 3,4-dimethyl-1-phosphaferrocene (FcP) with BBr_3 and $FcBBr_2$, respectively (Fc: ferrocenyl). NMR spectroscopy using $CDCl_3$ solutions reveals a considerable amount of adduct **2** to be present in the equilibrium at ambient temperature while **3** is largely dissociated even at −50 °C (cf. theory predicts a small P−B bond-dissociation energy in **A**·BH_3 of D_e = 17.4 kcal·mol^{-1}; B3LYP/6−31G* level).[21] In the solid state, however, **1** binds not only to BBr_3, but also to $FcBBr_2$. All structural changes resulting from P−B acid−base pairing follow the same qualitative trend as those that occur in the formation of complexes of phosphaferrocene with transition metals. The experimental results obtained for **1** and **2** are also in good agreement with the theoretical calculations on **A** and **A**·BH_3. For example, the Fe−P bond is contracted by 0.085 Å upon going from **1** to **2** and by 0.050 Å upon going from **A** to **A**·BH_3. Moreover, the P(1)−B(1) bond length in **2** possesses a value of 1.972(9) Å, which is in good agreement with the theoretically predicted bond length of 1.987 Å in **A**·BH_3.[21]

The dinuclear ferrocenyl aggregate **3** contains all the key structural motifs underlying the target compound **D** (Figure 1). Work is currently in progress to synthesise corresponding coordination polymers from 1,1′-diphosphaferrocene derivatives and 1,1′-diborylferrocenes.

Experimental Section

General Remarks: All reactions and manipulations of air-sensitive compounds were carried out in dry, oxygen-free argon using standard Schlenk glassware. Solvents were freshly distilled under argon from Na/benzophenone (C_6H_6) or passed through a 4-Å molecular sieve column ($CDCl_3$) prior to use. NMR: Bruker AMX 250, AMX 400, DPX 250; abbreviations: s = singlet, d = doublet, vtr = virtual triplet, q = quadruplet, n.r. = multiplet expected in the NMR spectrum, but not resolved; n.o. = signal not observed. ^{11}B [^{31}P] NMR spectra are reported relative to external BF_3·Et_2O [H_3PO_4, 85% in water]. 3,4-Dimethylphosphaferrocene (**1**)[7,22] and dibromoborylferrocene[27] were synthesized according to literature procedures.

Syntheses

2: A solution of BBr_3 (14 mg, 0.056 mmol) in $CDCl_3$ (0.25 mL) was added in an NMR tube to a frozen solution of **1** (13 mg, 0.056 mmol) in $CDCl_3$ (0.25 mL). The reaction mixture was warmed to ambient temperature within 30 min and investigated by NMR spectroscopy. When the same quantities of BBr_3 and **1** were mixed together in toluene at −78 °C, **2** was obtained as a microcrystalline solid. Yield: 21 mg (78%). X-ray-quality crystals of **2** were grown from a highly dilute benzene solution by slow evaporation of the solvent. ^{1}H NMR (250.1 MHz, $CDCl_3$, 303 K): δ = 2.23 (s, 6 H, CH_3), 4.18 (d, $^2J_{P,H}$ = 29.1 Hz, 2 H, α-CH), 4.55 (s, 5 H, C_5H_5) ppm. ^{13}C NMR (62.9 MHz, $CDCl_3$, 303 K): δ = 15.9 (CH_3), 75.2 (C_5H_5), n.o. (C-α), n.o. (*C*CH_3) ppm. ^{11}B NMR (80.3 MHz, $CDCl_3$, 303 K): n.o. (BBr_3). ^{11}B NMR (80.3 MHz, $CDCl_3$, 223 K): δ = −20.9 (d, $^1J_{P,B}$ = 138.5 Hz, BBr_3) ppm. ^{31}P NMR (101.3 MHz, $CDCl_3$, 303 K): δ = −13.2 (n.r., $h_{1/2}$ = 30.1 Hz, phospholyl-P) ppm. ^{31}P NMR (101.3 MHz, $CDCl_3$, 223 K): δ = −12.9 (q, $^1J_{P,B}$ = 138.5 Hz, phospholyl-P) ppm.

3: 1 (13 mg, 0.056 mmol) and $FcBBr_2$ (20 mg, 0.056 mmol) were dissolved in $CDCl_3$ (0.50 mL) at ambient temperature and the resulting mixture was sealed in an NMR tube. X-ray-quality crystals of **3** were grown from a benzene solution by slow evaporation of the solvent. Yield: 31 mg (94%). ^1H NMR (250.1 MHz, $CDCl_3$, 303 K): δ = 2.18 (s, 6 H, CH_3), 3.78 (d, $^2J_{P,H}$ = 35.5 Hz, 2 H, α-CH), 4.19, 4.23 (2 × s, 2 × 5 H, 2 × C_5H_5), 4.52, 4.91 (2 × vtr, 2 × 2 H, $^3J_{H,H}$ = $^4J_{H,H}$ = 1.8 Hz, C_5H_4) ppm. ^{13}C NMR (100.6 MHz, $CDCl_3$, 303 K): δ = 16.4 (CH_3), 71.5 (2 × C_5H_5), 78.1 (br. d, $^1J_{P,C}$ = 57.3 Hz, C-α), n.o. (*C*CH_3), 77.1, 78.2 (C_5H_4) ppm. ^{11}B NMR (80.3 MHz, $CDCl_3$, 303 K): δ = 46.1 (s, $h_{1/2}$ = 119.0 Hz, BBr_2) ppm. ^{11}B NMR (80.3 MHz, $CDCl_3$, 223 K): δ = 45.1 (s, $h_{1/2}$ = 466.2 Hz, BBr_2) ppm. ^{31}P NMR (101.3 MHz, $CDCl_3$, 303 K): δ = −81.9 (s, $h_{1/2}$ = 165.6 Hz, phospholyl-P) ppm. ^{31}P NMR (101.3 MHz, $CDCl_3$, 223 K): δ = −80.4 (s, $h_{1/2}$ = 252.8 Hz, phospholyl-P) ppm.

X-ray Crystallographic Studies

2: A single crystal (red needle; 0.06 × 0.07 × 0.31 mm) was analysed with a STOE IPDS II two-circle diffractometer with graphite-monochromated Mo-K_α radiation. An empirical absorption correction was performed using the MULABS option[28] in PLATON;[29] the minimum and maximum transmissions were 0.1676 and 0.6153, respectively. The structure was determined by direct methods using the program SHELXS[30] and refined against F^2 with full-matrix least-squares techniques using the program SHELXL-97.[31] The data/parameter ratio was 24.0. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were located by difference Fourier synthesis and refined using a riding model.

3: A single crystal (orange block; 0.19 × 0.24 × 0.45 mm) was analysed with a SIEMENS SMART CCD diffractometer; repeatedly measured reflections remained stable. An empirical absorption correction using the program SADABS[32] gave a correction factor between 0.674 and 1.000. Equivalent reflections were averaged (R_{int} = 0.072). The structure was determined by direct methods using the program SHELXS.[30] Hydrogen atoms were geometrically positioned and treated as riding atoms. All non-hydrogen atoms were refined with anisotropic thermal parameters. The structure was refined on F^2 values using the program SHELXL-97.[31]

Assembly of Seven Nickel(II) Metals by Chiral, Salen-Type Ligands with μ_3-OH Bridges

Xuan Xu,[a] Shaohua Gou,*[a] Wei Huang,[a] Yonglin Ma,[a] and Yizhi Li[a]

Keywords: Nickel / Chirality / Bridging ligands

A chiral heptanuclear nickel(II) complex $[Ni^{II}(Ni^{II}_2L)_3(\mu_3\text{-}OH)_2]\cdot 3H_2O$ [H_4L = (2*R*,3*R*)-1,4-bis(3,5-di-*tert*-butylsalicylideneamino)-2,3-butanediol], containing two μ_3-OH bridges, has been prepared and structurally characterized; its thermal and magnetic properties were investigated.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Polynuclear complexes have recently attracted much attention in molecular assembly, with one of the major goals being to try to obtain single-molecule magnets by designing discrete polynuclear entities with high-spin ground states that exhibit useful magnetic properties.[1] Among these multinuclear systems, OH^-, RO^-, RCO_2^- and other groups are often used as bridging ligands.[2] In our research of transition metal complexes, some new salen-type ligands with optically active diamino moieties have been prepared to bind metals in the same manner as in Jacobson's catalysts.[3] Considering the flexibility of the ligands and the known bridging ability of hydroxyl groups, we have chosen (2*R*,3*R*)-1,4-diamino-2,3-butanediol to react with salicylaldehyde derivatives to get a number of Schiff bases as chiral ligands. Herein we report the first preparation and crystal structure of an unusual heptanuclear nickel(II) complex, $[Ni^{II}(Ni^{II}_2L)_3(\mu_3\text{-}OH)_2]\cdot 3H_2O$, together with its magnetic and thermal behavior.

Results and Discussion

Preparation and Characterization

The title complex was synthesized by reaction of H_4L with $NiCl_2\cdot 6H_2O$ in methanol in the presence of triethylamine. The ligand was prepared by the Schiff-base condensation of 3,5-di-*tert*-butylsalicylaldehyde with (2*R*,3*R*)-1,4-diamino-2,3-butanediol, which was, in turn, obtained by hydrolization of (4*R*,5*R*)-4,5-bis(aminomethyl)-2-isopropyl-1,3-dioxolane.[4] The tetra-deprotonated ligand was formed in situ in the presence of the metal ions.

The crystal structure of the complex is shown in Figure 1. It is a heptanuclear nickel(II) compound with three water molecules of crystallisation. The structure is composed of three dinuclear $[Ni_2L\cdot 1/3(\mu_3\text{-}OH)_2]$ units, with a six-coordinate Ni^{II} moiety in the center (Figure 2). In the structure, there is a threefold symmetry axis containing Ni(3), O(1) and O(4). The three units are obtained by symmetry operations. Thus, the whole system has D_3 symmetry. Each ligand has six ligating groups which are evenly divided into two groups to encapsulate two nickel atoms in two open compartments, where each metal is coordinated by a phenolic oxygen anion, an imine nitrogen atom and an alkyloxy anion of the ligand, as well as a bridging OH^- group. It is noted that there are two hydroxy anions in the molecule and each of them functions as a bridge to connect three metal atoms bound by three ligands. In comparison to quite a number of examples of μ_3-hydroxo bridges in six-coordinate polynuclear nickel(II) complexes,[5] the current example, where three nickel(II) ions in a square-planar geometry are linked by one μ_3-OH^- bridge, is rare. It is also interesting to note that the RO^- anion in the ligand works as a bridging group to connect two metal atoms, whereas the PhO^- anion does not. Consequently, there are three types of "O" donor atoms in this heptanuclear compound.

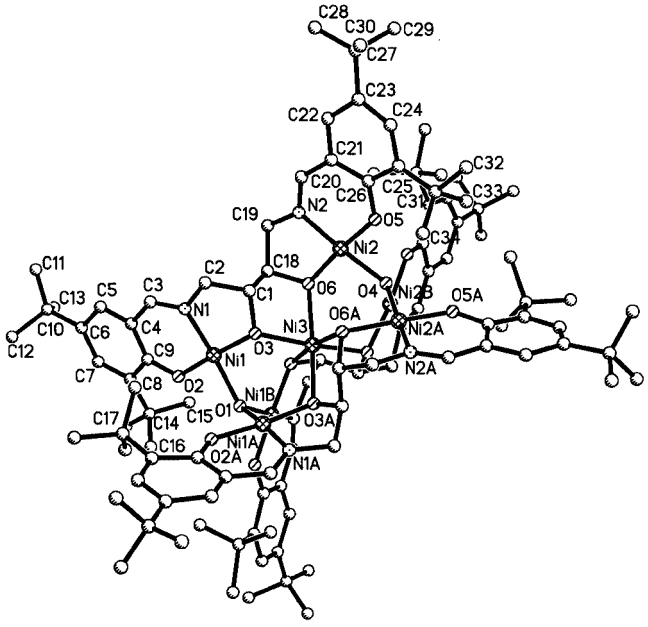

Figure 1. View of the heptanuclear complex, crystalline water molecules are omitted (the labels A and B indicate that these atoms are obtained by symmetry operations)

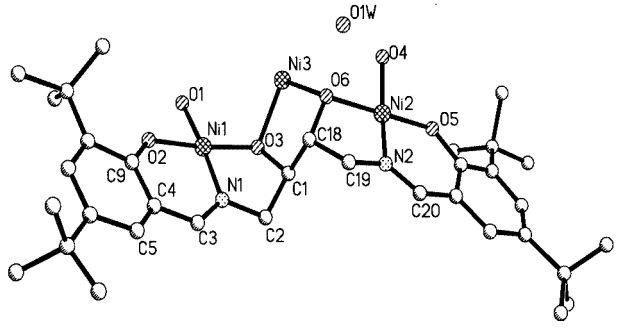

Figure 2. Structure of the dinuclear unit $[Ni_2L{\cdot}1/3(\mu_3\text{-}OH)_2]{\cdot}H_2O$ (50% probability ellipsoids)

More significantly, three dinuclear units share a central nickel atom coordinated by six alkyloxy groups from three ligands, whose 2+ charge is balanced by two μ_3-OH^- anions. The geometry of the central Ni atom is distorted octahedral, and the Ni−O distances are in agreement with normal values.[5] In the $[Ni_2L]$ unit, each metal atom is in a configuration of a distorted square plane consisting of N(1)O(1)O(2)O(3) or N(2)O(4)O(5)O(6); the deviation from the appropriate plane is 0.0410 Å for Ni(1) and 0.0279 Å for Ni(2). The average bond lengths for PhO−Ni (1.82 Å) and N−Ni (1.83 Å) are similar to the values reported for mononuclear salen Ni^{II} complexes.[6] For RO−Ni bonds, the mean distance is 1.87 Å, which is shorter than the usual Ni−O distance in six-coordinate Ni^{II} complexes[7] and close to those in a planar Ni^{II} coordination geometry.[8] In addition, the μ_3-HO-Ni distance of 1.90 Å here is also shorter than the reported values in six-coordinate Ni^{II}.[5]

The seven metal atoms adopt the topology of two tetrahedra sharing a common apex at Ni(3). Ni(1), Ni(1A) and Ni(1B) form an equilateral triangle (Ni−Ni distance: 3.209 Å), which is parallel to its counterpart composed of Ni(2), Ni(2A) and Ni(2B) (Ni−Ni distance: 3.216 Å). Ni(3) is located in the center of the two triangular planes, forming a trigonal prismatic structure (Figure 3). The distance between two triangular planes is 5.538 Å, and that of Ni(3) to these two planes are 2.754 Å and 2.784 Å, respectively. Although a few heptanuclear nickel(II) compounds have recently been reported,[9] our complex is the first example of a heptanuclear nickel(II) complex of a chiral ligand.

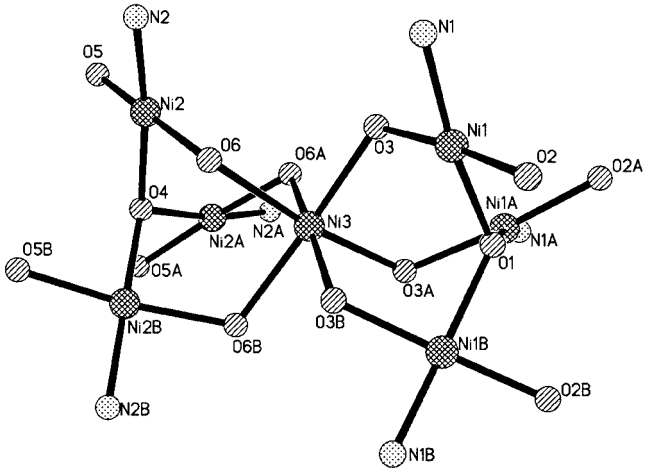

Figure 3. A view of the coordination environments around the nickel atoms; pertinent bond lengths (Å) and angles (°): Ni(1)−O(2) 1.806(3), Ni(1)−N(1) 1.831(4), Ni(1)−O(3) 1.860(3), Ni(1)−O(1) 1.895(13), Ni(2)−N(2) 1.826(4), Ni(2)−O(5) 1.838(3), Ni(2)−O(6) 1.884(3), Ni(2)−O(4) 1.9025(13), Ni(3)−O(3) 2.066(3), Ni(3)−O(6) 2.124(3), N(1)−Ni(1)−O(1) 170.19(16), O(2)−Ni(1)−O(3) 174.55(15), N(2)−Ni(2)−O(4) 171.21(16), O(5)−Ni(2)−O(6) 172.87(15), O(3)−Ni(3)−O(6)B 171.68(12), O(3)−Ni(3)−O(6) 81.54(11), Ni(1)−O(3)−Ni(3) 115.38(15), Ni(2)−O(6)−Ni(3) 113.10(15) (the labels A and B mean these atoms are obtained by symmetry operations)

The variable magnetic susceptibilities of the title complex in the range 77 to 300 K have been measured, and the related $\chi_m T$ vs. T curve is shown in Figure 4. As the temperature decreases, the $\chi_m T$ value is essentially constant (Curie-like behavior). The room temperature magnetic moment of the complex is 3.15 BM (300 K), compatible with that of a free single nickel(II) ion. This result indicates that the magnetic behavior of the compound is characterized as one paramagnetic nickel(II) ion. This is consistent with the six-coordinate Ni^{II} atom being in an octahedral configuration in the structure; the other six Ni^{II} atoms in a square-planar configuration make no contribution to the system.

A TGA analysis of the compound showed that it loses 3.29% of its weight between 15 °C and 67 °C, which can be accounted for by the loss of three waters of crystallisation together with another water molecule probably resulting from the conversion of the $Ni(OH)_2$ part of the compound to NiO and H_2O. The compound then decomposes gradually in the range from 67 °C to 310 °C, followed by a rapid weight loss in the range 310−580 °C, indicating the decomposition of the organic ligand. The residue (ca. 24% of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

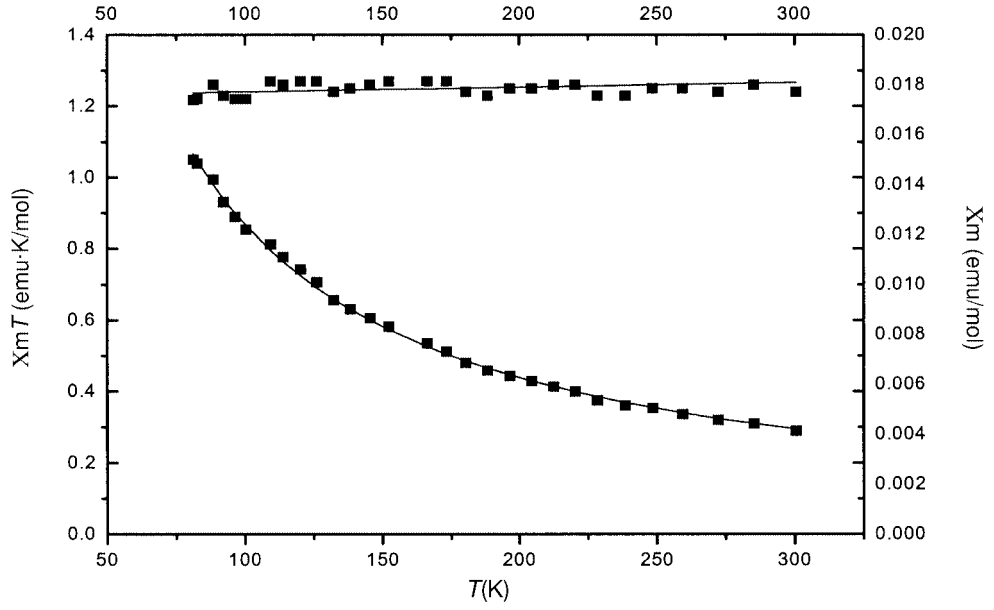

Figure 4. $\chi_m T$ product and χ_m vs. T for the complex; solid lines represent the best fit to the result in agreement with Curie law.

the original weight) is due to the formation of NiO, compatible with the theoretical value of 23.5%.

Experimental Section

Materials and General Methods: All solvents and chemicals were of analytical grade and used without further purification. Elemental analyses were measured with a Perkin−Elmer 1400C analyzer. Infrared spectra (4000−400 cm^{-1}) were recorded on a Nicolet FT-IR 170X spectrophotometer. Electrospray ionization (ES) mass spectra were performed in CH_3CN/CH_3OH on a Finnigan MAT SSQ 710 mass spectrometer in the scan range 300−1200 amu.

$[Ni^{II}(Ni^{II}{}_2L)_3(\mu_3\text{-}OH)_2]\cdot 3H_2O$ (1): The ligand **L** was prepared by a Schiff-base condensation. The title complex was obtained by the following method. $NiCl_2\cdot 6H_2O$ (0.120 g, 0.5 mmol) and the ligand (0.140 g, 0.25 mmol, 1 equiv.) were dissolved in methanol (20 mL). After stirring the resultant solution for thirty minutes, Et_3N (2 equiv.) was added. The mixture was kept refluxing for an hour, then cooled down to room temperature. The brown precipitate was filtered off and dried (Yield: 15%). Single crystals for crystal determination were obtained by slow evaporation of the solvent at room temperature. $C_{102}H_{152}N_6Ni_7O_{17}$ (2145.3): calcd. C 57.02, H 7.26, N 3.85; found C 57.23, H 7.16, N 3.93. IR (KBr): $\tilde{\nu}$ = 3442 cm^{-1} (O−H), 1619 (C=N), 1439 (phenyl),1172(C−O). ESI-MS: *m*/*z* (%) = 553.5 (100) $[H_5L]^+$, 609.5 (26)$[NiH_3L]^+$. $[\alpha]_D^5 = -98.7$ (c = 0.1, $CHCl_3$).

X-ray Crystallography Study: $C_{102}H_{152}N_6Ni_7O_{17}$, M = 2145.27, trigonal, space group $P321$, a = 17.9182(12), b = 17.9182(12), c = 22.363(3) Å, V = 6218.0(10) Å^3, Dc = 1.146 g cm^{-3}, Z = 2, μ = 1.091 mm^{-1}, S = 1.016, $F(000)$ = 2276, T = 293(2) K, $2\theta_{max}$ = 49.98°, 7343 unique data, final $R1$ = 0.0543, $wR2$ = 0.1141 for 5789 observed reflections [$I > 2\sigma(I)$] with 403 variables. A single crystal was mounted on a glass fiber for measurement. Data were collected on a SMART 4 K CCD diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The collected data were reduced with the program SAINT, and empirical absorption corrections were done with the SADABS program. The structure was solved by direct methods and refined by least-squares method on F^2_{obs} with the SHELXTL-PC97 software package.
CCDC-198224 contains the supplementary crystallographic data for this paper. Tris(pyrazolyl)methanesulfonates: More Than Just Analogues of Tris(pyrazolyl)borate Ligands; N,N,N-, N,N,O-, and Other Coordination Modes

Wolfgang Kläui,*[a] Michael Berghahn,[a] Walter Frank,[a] Guido J. Reiß,[a] Thomas Schönherr,[b] Gerd Rheinwald,[c] and Heinrich Lang[c]

Dedicated to Professor Rüdiger Mews on the occasion of his 60th birthday

Keywords: Enzyme models / N,O ligands / Transition metals / Tripodal ligands

The thallium(I) salts of tris(pyrazolyl)methanesulfonate (Tpms) and tris(3-*tert*-butylpyrazolyl)methanesulfonate (Tpms^{tBu}) have been used to prepare the following complexes: [(Tpms^{tBu})ZnX] [X = Cl (**1a**), Br (**1b**), I (**1c**), Et (**3**), OAc (**5a**)], [(Tpms^{tBu})NiX] [X = Cl (**2a**), Br (**2b**)], [(Tpms^{tBu})-CoCl(Hpz^{tBu})] (**3**), [(Tpms^{tBu})Zn(μ-OAc)(μ-OH)Zn(Tpms^{tBu})] (**5b**), [(Tpms^{tBu})Cu(CO)] (**6a**), and [(Tpms)Cu(CO)] (**6b**). The solid-state structures of **1b**, **2a**, **3**, and **5b** have been determined by X-ray analysis. The optical spectra of **2a** and **3** were investigated by means of the angular overlap model to elucidate their electronic structures in view of the underlying molecular geometries. Variable-temperature NMR and IR spectroscopic studies show that Tpms and Tpms^{tBu} can act as N,N,N and N,N,O ligands. Both coordination modes are present in solution for the zinc complexes **1a**,**b** and the copper carbonyl complexes **6a**,**b**. The N,N,O bonding mode is entropically favoured in solution. For the nickel complexes **2a**,**b**, the Tpms^{tBu} ligand acts as a tripodal nitrogen ligand in the solid state and in solution. For the dinuclear zinc complex **5b**, one of the Tpms^{tBu} ligands acts as an N,N,O ligand and one as an N,O ligand. Complex **5b** is one of the very few structural models of the dinuclear zinc enzymes phospholipase C and phosphotriesterase.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Recently we reported the synthesis of the tris(pyrazolyl)-methanesulfonates (Tpms), a novel class of ligands.[1] These ligands were designed by analogy to the well-known tris-(pyrazolyl)borate (Tp) ligands.[2] They have the same nitrogen-donor set as the Tp ligands, but in addition they bear a sulfonate group to make the ligands more hydrophilic.

Herein we describe the coordination behaviour of the sterically demanding ligand tris(3-*tert*-butylpyrazolyl)methanesulfonate (Tpms^{tBu}) (Figure 1) towards zinc(II), nickel(II), cobalt(II), and copper(I) ions, as well as the structural flexibility and the dynamic stereochemistry of this ligand.

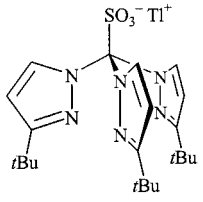

Figure 1. Schematic structure of the thallium salt of the Tpms^{tBu} ligand

Results and Discussion

1. The Complexes [(Tpms^{tBu})ZnX] (1) and [(Tpms^{tBu})NiX] (2) (X = Halide)

The complexes [(Tpms^{tBu})MX] were synthesised by reaction of TlTpms^{tBu} with the appropriate metal halide at room temperature [Equation (1)]. In contrast to the analogous Tp^{tBu} complexes,[3] these Tpms^{tBu} complexes have good solubility in polar solvents like wet methanol.

$$TlTpms^{tBu} + MX_2 \longrightarrow [Tpms^{tBu}MX] + TlX \quad (1)$$

The Solid-State and Solution Structures of [(Tpms^{tBu})ZnX] [X = Cl (1a), Br (1b), I (1c)]

The sterically demanding ligand Tp^{tBu} stabilises almost exclusively ions with coordination number four ("tetrahedral enforcer"[4]) and forms complexes with the composition [Tp^{tBu}MX]. In the case of **1a**−**c**, the analogous composition [(Tpms^{tBu})ZnX] is found, but the ^{1}H NMR spectra in $CDCl_3$ do not show the expected pattern of signals. Three different sets of pyrazolyl signals are found for **1a** and **1b**.

Variable-temperature NMR studies of **1a** and **1b** show that two of the three sets of signals occur in an intensity ratio of 1:2 at all temperatures (Figure 2). This ratio indicates that an equilibrium between two different species exists in solution: the expected C_{3v}-symmetrical complex and a C_s-symmetrical complex (Scheme 1). In the C_s-symmetrical species, Tpms^{tBu} coordinates with two nitrogen atoms and one oxygen atom of the sulfonate group, i.e. the ligand acts as an N,N,O ligand.

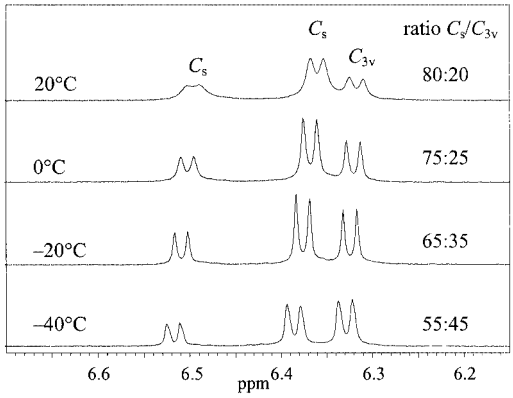

Figure 2. ^{1}H NMR spectra (200 MHz) of **1a** (pyrazolyl 4-*H* region) in $CDCl_3$ in the temperature range −40 to +20 °C

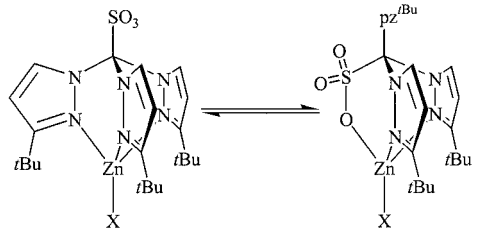

Scheme 1. Equilibrium between a C_{3v}- and a C_s-symmetrical zinc halide complex in solution (X = Cl, Br)

The ^{1}H NMR spectrum of **1c** shows only the signals for the C_s-symmetrical complex. Even at low temperatures the C_{3v}-symmetrical complex cannot be detected.

Obviously the sulfonate group, which was introduced to increase the solubility in polar solvents, is a competing donor centre. This result was surprising since the sulfonate unit is regarded as a weakly coordinating group, especially in comparison with nitrogen atom donors.[5]

Having the results of the variable-temperature studies at hand, we calculated the equilibrium constant $K = c[C_s]/c[C_{3v}]$ for **1a**. The enthalpy and entropy of the transformation of the C_{3v}-symmetrical into the C_s-symmetrical species were determined from a van't Hoff plot. In chloroform, the C_{3v}-symmetrical species is favoured enthalpically ($\Delta H = +8.0$ kJ·mol^{-1}), but the entropy of the transformation is positive: $\Delta S = +40$ J·K^{-1}·mol^{-1}. As a result, the C_s-symmetrical complex is the dominant isomer in the studied temperature range. The C_s isomer is favoured entropically per se because of its lower symmetry. We assume, however, that the rather large positive entropy is a result of the smaller dipole moment of the C_s-symmetrical complex, which allows the solvent to be more disordered.

Compound **1b** crystallises from THF/pentane in the monoclinic space group $P2_1/c$. The asymmetric unit of the crystal structure contains two complexes with very similar structures and one molecule of THF. The ZORTEP plot given in Figure 3 shows one of the symmetry-independent complexes. Selected bond lengths and angles are summarised in Table 1.

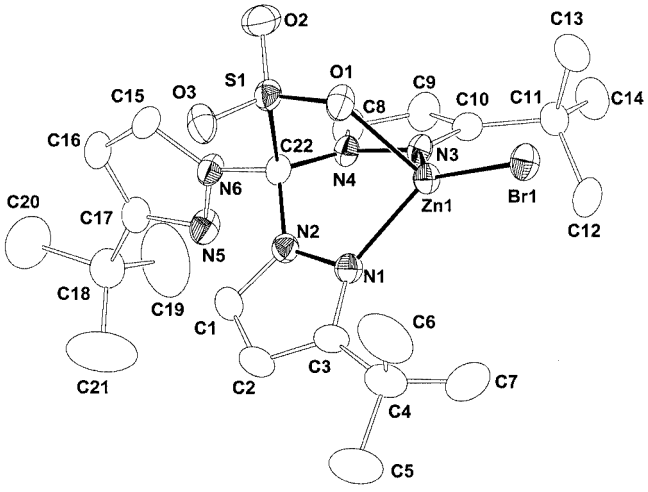

Figure 3. ZORTEP plot of [(Tpms^{tBu})ZnBr] (**1b**)

The zinc atom is coordinated in a distorted tetrahedral geometry. In the solid state, the Tpms^{tBu} ligand coordinates as an N,N,O ligand.

Recently, Burzlaff published the structure of a zinc complex containing a similar monoanionic N,N,O ligand derived from bis(pyrazolyl)acetic acid. It is a model compound for zinc enzymes with the facially coordinating 2-His-1-carboxylate triad, such as thermolysin and carboxypeptidase.[6] The Zn−O bond lengths show that the sulfonate group is a weaker donor than the carboxylate group. Burzlaff observed a Zn−O bond length of 1.990(2) Å, which is significantly shorter than in **1b** [2.017(2) Å]. The Zn−O distances in thermolysin (2.08 Å) and carboxypeptidase (2.2 Å) are very similar to the Zn−O distance of compound **1b**.[6]

Structural Studies on [(Tpms^{tBu})NiX], X = Cl (2a), Br (2b)

To see the influence of the nature of the metal ion on the coordination behaviour of the Tpms^{tBu} ligand, we prepared the nickel complexes [(Tpms^{tBu})NiX] (**2a**: X = Cl; **2b**: X = Br) by analogy to the zinc complexes **1a**−**c**. The crystal structure of **2a** was determined. The complex crystallises from THF/pentane in the monoclinic space group $P2_1/n$. Figure 4 shows an ORTEP plot of **2a**. Selected bond lengths and angles are summarised in Table 2.

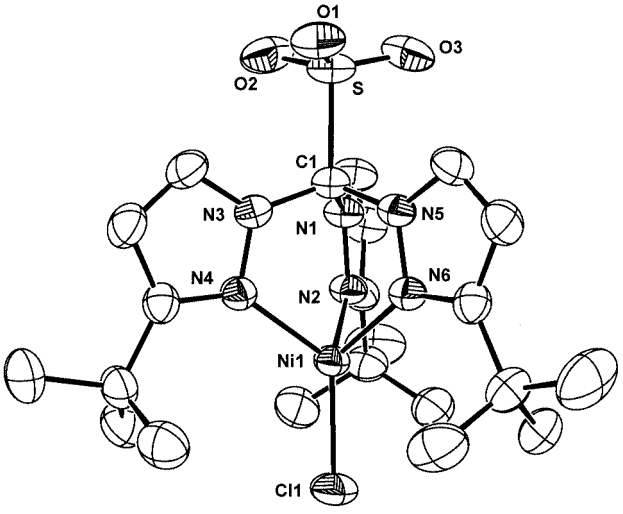

Figure 4. ORTEP plot of [(Tpms^{tBu})NiCl] (**2a**)

In contrast to the above-mentioned zinc complexes, Tpms^{tBu} coordinates to the nickel ion through the three pyrazolyl nitrogen atoms and forms a complex with C_{3v}-symmetry. This coordination is the same N,N,N mode as observed in the C_s-symmetrical trigonal-bipyramidal rhodium complex [(Tpms)Rh(nbd)], the structure of which we have recently determined.[7]

Table 2. Selected bond lengths [Å] and angles [°] in [(Tpms^{tBu})NiCl] (**2a**)

Ni1−N2	2.0088(13)	N2−Ni1−N6	90.06(5)
Ni1−N6	2.0105(14)	N2−Ni1−N4	90.12(5)

S1−C1	1.9283(15)	O1−S1−O3	115.98(9)
		O2−S1−O3	115.92(9)
		O1−S1−C1	102.44(8)
		O2−S1−C1	102.26(8)
		O3−S1−C1	101.96(8)

The nickel centre is coordinated in a trigonally distorted tetrahedral geometry. This arrangement is apparent from the N−Ni−Cl angles [124.24(4)−126.35(4)°] and in the smaller N−Ni−N angles [89.66(5)−90.12(5)°]. The distortion is similar to that observed for the [Tp^{tBu}MX] complexes.[8] The UV/Vis spectra of **2a** in dichloromethane and tetrahydrofuran solution, and in the solid state, are identical, and therefore we propose the same coordination mode of the Tpms^{tBu} ligand in solution as is observed in the solid state. The spectrum of **2b** in solution is slightly shifted bathochromically, but shows the same pattern as the spectrum of **2a**; therefore, an analogous structure can be assumed for **2b**. Both compounds are intensively red, an unusual colour for tetrahedral nickel(II) complexes. To obtain a better understanding of their colour, we have analysed the UV/Vis spectra in terms of the Angular Overlap Model (AOM) (see below).

2. Structural Studies on [(Tpms^{tBu})CoCl(Hpz^{tBu})] (3), a Five-Coordinate Cobalt(II) Complex

In bioinorganic chemistry it is often possible to probe the metal environment in zinc-containing enzymes with a cobalt ion as a substitute for the native zinc ion. This substitution can be misleading, however, because of the slightly different tendencies of cobalt(II) and zinc(II) ions to prefer tetrahedral vs. trigonal-bipyramidal coordination.[9] We wanted, therefore, to compare the coordination behaviour of Tpms^{tBu} towards zinc and cobalt chloride.

The reaction of TlTpms^{tBu} with cobalt chloride leads to a blue complex with the composition [(Tpms^{tBu})CoCl(Hpz^{tBu})] (**3**). The UV/Vis spectrum of this compound in dichloromethane exhibits its major band in the range 520−603 nm with an absorption coefficient ε_{max} = 402 $M^{-1}\cdot cm^{-1}$. This band shows the same pattern as the major band of the five-coordinate complex [Tp^{tBu}Co(η^2-NO_3)] (517−600 nm, ε_{max} = 212 $M^{-1}\cdot cm^{-1}$ in THF) published by Parkin.[8] Obviously a five-coordinate complex has formed rather than the expected four-coordinate halide complex.

Complex **3** crystallises from THF/pentane in the monoclinic space group $P2_1/n$ and the asymmetric unit of the crystal structure contains one molecule of THF. The ORTEP plot is given in Figure 5. Selected bond lengths and angles are summarised in Table 3.

The Tpms^{tBu} ligand coordinates in the N,N,O mode. The coordination sphere is completed by a chloro ligand and a pyrazole ligand, which derives from partial hydrolysis of the Tpms^{tBu} ligand. This hydrolysis cannot be avoided, even by using thoroughly dried anhydrous cobalt(II) chloride. This observation is noteworthy because the hygroscopic $ZnCl_2$ used for the synthesis of **1a** contained significant amounts of water, but in this case no hydrolysis occurred. The formation of **3** shows the different reactivity of cobalt and zinc ions. We have observed a similar difference in the coordination behaviour of cobalt and zinc ions towards the Tp^{Ph} ligand.[9]

The crystal structure analysis shows that the cobalt(II) ion in **3** has a distorted trigonal-bipyramidal coordination geometry. The coordinated oxygen atom of the tripodal ligand and the chloro ligand occupy the axial positions. Two pyrazolyl rings of the Tpms^{tBu} ligand and the free pyrazole are in the equatorial positions. The Co−O bond [2.355(2) Å] is significantly longer than those of Co^{II}−sulfonate complexes cited in the Cambridge Crystallographic Database [coordination number (CN) 5: 2.06 Å; CN 6: 1.94−2.22 Å].[10]

As the sulfonate group is less bulky than a *tert*-butylpyrazolyl group, Tpms^{tBu} does not prevent coordination numbers higher than four from forming when it acts as an N,N,O ligand. This effect allows the additional coordination of a ligand such as the *tert*-butylpyrazol unit.

The five-coordinate cobalt(II) complex **3** has the intensive blue colour that we had expected for a four-coordinate cobalt(II) complex. Since no ligand-field analysis of the novel ligand Tpms^{tBu} has been carried out until now, we analysed the UV/Vis spectrum of the cobalt complex **3** together with the spectrum of the tetrahedral nickel complex **2a** (see above) in terms of the Angular Overlap Model, hoping for a consistent picture of the ligand-field properties of this ligand.

3. AOM Analysis of the UV/Vis Spectra of the (Tpms^{tBu})Ni^{II} and -Co^{II} Complexes 2a and 3

The Angular Overlap Model (AOM) has been shown to be a powerful tool for rationalising d^n-level splittings in low-symmetry transition metal complexes.[11] Its advantage over the conventional ligand-field theory emerges from explicitly accounting the specific angular geometry of the chromophore, as well as involving peculiarities of the metal−ligand bonding. The latter is achieved by introducing *local* metal−ligand interaction parameters of σ and π type, which are often transferable between similar transition metal complexes. In this section we investigate the optical spectra of [(Tpms^{tBu})NiCl] (**2a**) and [(Tpms^{tBu})-CoCl(Hpz^{tBu})] (**3**) by means of the AOM to elucidate their electronic structures in view of the underlying molecular geometries.

[(Tpms^{tBu})NiCl] (2a)

In a tetrahedral ligand field, the d^8 system of Ni^{II} gives rise to a $^3T_1$ (^3F) ground state and $^3T_2$ (^3F), $^3A_2$ (^3F), and $^3T_1$ (^3P) excited states. The optical spectrum is dominated by the spin-allowed transition $^3T_1$ (^3F) → $^3T_1$ (^3P), typically located in the region 14000−17000 cm^{-1}, whereas the other triplets are expected in the near-infrared (4000−11000 cm^{-1}).[12] As so far, the present complex **2a** shows the typical absorption pattern, which is depicted in Figure 6, though the band maxima are significantly shifted to lower wavelengths. This observation is particularly true when compared with the closely related complex [Tp^{tBu}NiCl]:[8] The main absorption, which reflects the respective colour of a complex, is shifted from 505 nm (purple) to 475 nm (red), the latter being a rather uncommon colour for tetrahedrally coordinated nickel(II) complexes. The reason for the hypsochromic shift is not clear at first glance.

To elucidate this situation, we have measured spectra of microcrystalline powders, where a better resolved band structure was obtained on cooling down to liquid helium temperatures. Band maxima, on the other hand, are only slightly shifted, which excludes a solvent effect being responsible for the red colour of [(Tpms^{tBu})NiCl]. A deeper

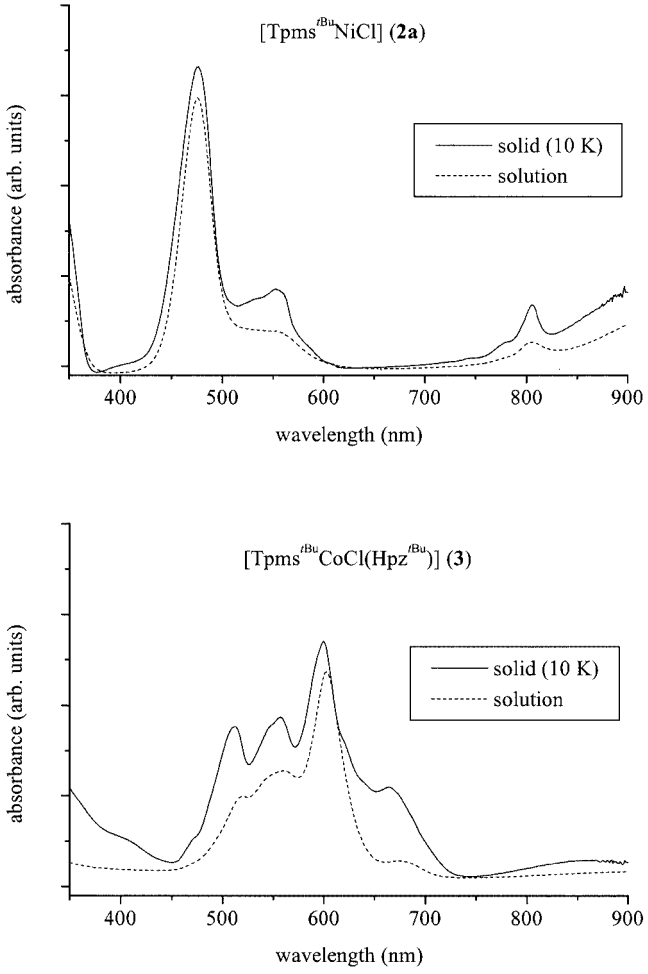

Figure 6. UV/Vis spectra of [(Tpms^{tBu})NiCl] (**2a**) and [(Tpms^{tBu})-CoCl(Hpz^{tBu})] (**3**) in solution (dichloromethane) and in the solid state

look into the electronic structure reveals that the underlying trigonal symmetry is the reason for the higher transition energies according to $^3T_1$ (^3F) → $^3T_1$ (^3P) and $^3T_1$ (^3F) → $^3A_2$ (^3F). We note that further band splittings are expected by the effect of spin-orbit coupling present in Ni^{II} complexes. Such information, however, is not available, even from the better resolved low-temperature spectrum. Moreover, from our AOM calculations, we have found such splittings and band shifts to be significantly smaller than those resulting from the geometrical effect. Therefore we restrict the following discussion to the analysis of the LS states.

The orbitally triply degenerate states split under the influence of the local trigonal symmetry, which is reflected, for example, in the large splitting of about 3000 cm^{-1} for the intense $^3T_1$ (^3P) band. A deconvolution of the band shape yields maxima at 474 nm and 556 nm, which are due to the transitions $^3A_2$ (^3F) → $^3A_2$ (^3P) and $^3A_2$ (^3F) → ^3E (^3P), respectively (in the notation of the C_{3v} group). The transition into $^3A_2$ (^3F) is located at 805 nm (12400 cm^{-1}), again somewhat higher in energy than observed for other pseudo-tetrahedrally coordinated nickel compounds. Besides these absorptions, the low-temperature spectrum exhibits several spin-forbidden transitions into singlet states that result from ^1D (^1E, $^1T_2$) and the higher ^1G ($^1T_2$, $^1A_1$, $^1T_1$, ^1E) multiplets. This manifold of experimentally available data provides a sound base for a reliable AOM analysis of the d-states involved. It turns out that the hypsochromic band shift has a simple geometrical background: When comparing the angular structure of the chromophore of [(Tpms^{tBu})NiCl] determined here with those of the related complexes [Tp^{tBu}MCl] (M = Zn, Cu, Ni, Fe, Co),[8,13] we recognize larger angles Cl−M−N for the complex under investigation (close to 125°) than for any of the Tp^{tBu} compounds (mean values around 121°). The trigonal elongation causes the considerable splitting of the orbitally degenerate triplet states together with a lowering of the ground-state energy that is responsible for the higher transition energies in [(Tpms^{tBu})NiCl]. To prove this result, we performed a complete analysis for all the d-states, which are accessible from the low-temperature absorption spectrum. In the optimization procedure, all underlying AOM parameters, i.e. e_σ^{Cl}, e_σ^{pz}, e_π^{Cl}, $e_{\pi\perp}^{pz}$, were freely optimized as were also the Racah parameters *B* and *C* that describe the electron−electron interaction.[14] While anisotropic π interaction requires, in general, two independent AOM parameters ($e_{\pi\|}$ and $e_{\pi\perp}$) for considering contributions parallel and perpendicular to the chelate plane, the in-plane π interaction with the pyrazole group is small and can be reasonably neglected here as for ammine and sp^2-hybridized amine complexes ($e_{\pi\|}^{pz} = 0$). All calculations were performed with the AOMX programme,[14] which is available in the internet (www.aomx.de). The result of our optimization procedure is presented in Table 4. Herein we used different weighting factors to distinguish spin-allowed from spin-forbidden transitions, since the band maxima of the latter have been located by a deconvolution procedure. The underlying electronic parameters are collected in Table 5. For identifying the eigenstates, the geometry was kept trigonal by taking a value of 125° for all three Cl−Ni−N angles. This restriction does not weaken the analysis, because further splittings of degenerate E states are not observed in the low-temperature absorption spectrum [the small absorption at 13500 cm^{-1} may be due to spin-orbit effects and/or the low-symmetry splitting of ^1E (^1D)].

In summary, the AOM analysis clearly demonstrates that all details obtained from the optical spectrum can be rationalized. The derived parameter values are reasonable and their positive values prove the expected antibonding behaviour. Because of an unfavorable relationship between experimental data (eight) and fitted parameters (six), clear-cut decisions about the presented parameter values should not be made on this stage. They may, nevertheless, serve as a useful estimation for future investigations of similar compounds.

[(Tpms^{tBu})CoCl(Hpz^{tBu})] (3)

The situation with the cobalt compound is rather different. The structural investigation exhibits coordination number five and a strongly distorted geometry with absence of

symmetry or any useful pseudo-symmetry. Moreover, since Tpms^{tBu} coordinates in the N,N,O mode, additional parameters for the Co−OSO$_2$ group have to be considered when applying the AOM. This situation demands substantial spectroscopic information, which is deduced, once more, from the low-temperature spectrum obtained from microcrystalline powders. As can been seen in Figure 6, the overall band pattern again is not changed, while the spectral resolution is largely improved on cooling down to T = 10 K.

To elucidate the complicated absorption structure, we proceeded as follows. First, we asked what would a simple electrostatic ligand field calculation, where all ligators are assumed to contribute by the same potential, predict for this particular geometry (Figure 5). It turns out that such a point charge approximation may already explain the overall band pattern. The present high-spin d^7 system exhibits a quartet ground term and nine more higher quartet states, which, unfortunately, cannot be related to parent states arising from any higher symmetric fivefold coordination. Under the reasonable assumption that the more intense transitions are due to spin-allowed transitions, we performed an optimization under the restrictions given above. This procedure results in a reasonable fit, whereby the expected quartet transition energies vary in the optical spectrum from 14000 to 20000 cm^{-1}, which is in line with the experimental findings. This result demonstrates that the geometrical structure of the chromophore is the main reason for the colour of **3**. In a second step, we have distinguished between σ- and π-bonding peculiarities and allowed free variation for the e_σ parameters involved. The AOM calculation then leads to a significantly better result, with the differences between calculated and observed spin-allowed transitions, obtained from a band deconvolution, becoming ca. 1000 cm^{-1} or less. The reliability of the subsequent assignments is confirmed by the parameter values derived from the fitting procedure, which show, for example, the expected trend for the σ donors: $e_\sigma^{O} > e_\sigma^{N} > e_\sigma^{Cl}$.[11]

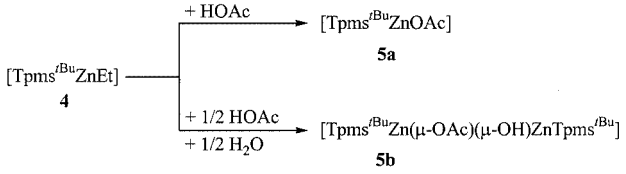
Though keeping in mind the problem of overparametrization, a more-convincing band fit can be achieved when absorptions located around 18000 cm^{-1} are assigned to transitions into doublet states. Such spin-forbidden bands gain intensity by low symmetry and by the relatively large spin-orbit coupling present in cobalt(II) complexes. Under these assumptions, the AOM allows us to fit the absorption band pattern fairly well. It follows that the main peaks at 511, 597 and 633 nm represent quartet bands, whereby the latter broader bands cover two spin-allowed transitions each. All the other spectral features should arise from spin-forbidden transitions into doublet states. Spin-orbit coupling, however, mixes quartet and doublet states and causes further band shifts and level splittings.[15] Therefore, clear-cut assignments to be used in the optimization procedure cannot be made, which prevents the evaluation of definite AOM parameter values. In Table 5 we present an estimation only for the underlying model parameters. Nevertheless, it can certainly be concluded that the optical spectrum is due to metal-localized d−d transitions, which can be reasonably described by the AOM. We show that the distinct geometric arrangement of ligator atoms causes the specific spectral

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pattern, rather then bonding peculiarities of the various ligating groups.

4. Zinc−Acetate Complexes of Tpms^{tBu}

Tl(Tpms^{tBu}) reacts with diethylzinc in tetrahydrofuran to give [(Tpms^{tBu})ZnEt] (**4**). The instability of ethylthallium leads to the precipitation of metallic thallium, which can be separated easily by centrifugation. The reaction of **4** with acetic acid yields acetato complexes. Varying the stoichiometric ratio results in two different products. With 1 equiv. of acetic acid, the expected acetato complex [(Tpms^{tBu})-ZnOAc] (**5a**) is formed. The reaction of **4** with 0.5 equiv. of acid, surprisingly, generates a dinuclear Tpms^{tBu} complex with a bridging acetato and a bridging hydroxo ligand (**5b**) (Scheme 2). The origin of the hydroxo ligand is unclear, it is probably due to traces of water in the solvent.



Scheme 2. Synthesis of the acetato complexes **5a** and **5b**

The complexes **5a** and **5b** can easily be distinguished spectroscopically. On the one hand, the intensity ratios of the pyrazolyl signals to the methyl signal of the acetato group in the ^{1}H NMR spectra are different. On the other hand, the OH valence stretching vibration of **5b** is clearly identified as a sharp band at 3620 cm^{-1} in the IR spectrum. It is a very sensitive probe for the non-associated OH group.

Table 6 displays the carboxylate stretching vibrations $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ of **5a** and **5b**. The position of $\nu_{as}(CO_2)$ and the difference $\Delta\nu(CO_2) = \nu_{as}(CO_2) - \nu_s(CO_2)$ are useful probes for determining the coordination mode of the acetato ligand.[16] The position of $\nu_{as}(CO_2)$ and the large value of $\Delta\nu(CO_2)$ in the case of **5a** indicates a monodentate coordination. This η^1-coordination was proven for [Tp^{tBu}ZnOAc] by Parkin through a crystal structure analysis[17] and is well known for other Tp^{R}Zn−carboxylato complexes.[9] The band for the asymmetric valence stretching $\nu_{as}(CO_2)$ of **5b** is shifted to smaller wavenumbers and the decrease of $\Delta\nu(CO_2)$ is typical for a bridging acetato ligand.[16]

Table 6. Carboxylate stretching vibrations (cm^{-1}) for **5a** and **5b** in the solid state

Compound	$\nu_{as}(CO_2)$	$\nu_s(CO_2)$	$\Delta\nu(CO_2)$
5a	1592	1331	261
5b	1573	1437	136

The crystal structure analysis of **5b** confirmed the spectroscopic results suggesting the bridging nature of the acetato and hydroxo ligands. Complex **5b** crystallises from diethyl ether in the monoclinic space group *I*2a, and the asymmetric unit of the crystal structure contains one molecule of diethyl ether. Figure 7 shows an ORTEP plot of **5b**. Selected bond lengths and angles are summarised in Table 7.

It was surprising to us that the two zinc atoms have different coordination numbers in the solid state: four and five. One Tpms^{tBu} ligand coordinates in the known N,N,O mode, whereas the other acts as a bidentate N,O ligand. These different coordination modes are due to the asymmetrical bridge between the zinc atoms. Because of the short hydroxo bridge, the structure of **5b** is folded and the sterically demanding *tert*-butyl groups prevent the coordination of the second pyrazolyl ring.

NMR spectroscopic studies on **5b** ($CDCl_3$ and CD_2Cl_2) at room temperature show that all the pyrazole rings are equivalent in solution; i.e., the pyrazole rings undergo dynamic exchange. This exchange is fast on the NMR spectroscopic time scale, even at 203 K (CD_2Cl_2).

The dinuclear complex **5b** is an excellent structural model of dinuclear centres of the zinc enzymes phospholipase C and phosphotriesterase. Both of these enzymes contain a

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dinuclear zinc centre with N,N,O binding motifs with the zinc ions connected by a bridging hydroxo and a bridging carboxylato ligand (phosphotriesterase: carbamylated lysin).[18] The Zn−Zn distance in the enzymes is 3.3 Å, which is nearly the same as in our model complex **5b** [Zn−Zn: 3.4008(8) Å].

5. Studies on Carbonylcopper(I) Complexes

To compare the donor abilities of Tpms^{tBu} with that of other tripodal ligands, we synthesised carbonylcopper(I) complexes. The CO stretching frequency strongly correlates with the electronic properties of the metal centre.

[(Tpms^{tBu})Cu(CO)] (**6a**) was obtained by the reaction of Tl(Tpms^{tBu}) and copper(I) chloride in dichloromethane under a carbon monoxide pressure of 3−4 bar. In addition, we synthesised [(Tpms)Cu(CO)] (**6b**) by the reaction of KTpms with a carbon monoxide saturated solution of [Cu(MeCN)$_4$]PF$_6$ in methanol. The IR spectra in dichloromethane (Figure 8) show that in solution both carbonyl complexes exist in two isomeric forms, like the zinc complexes **1a** and **1b** (Scheme 3)

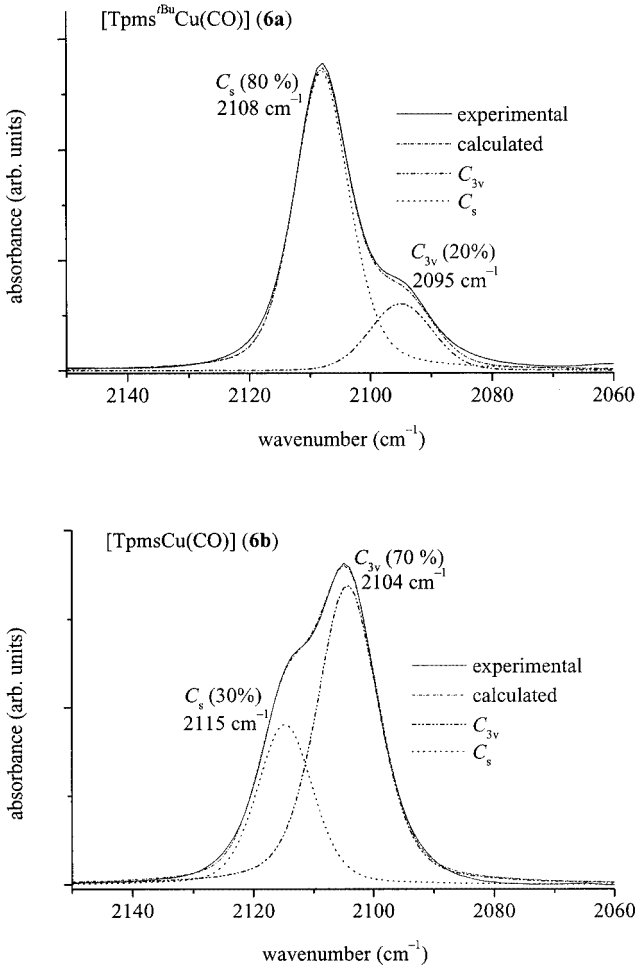

Figure 8. Analysis of the IR spectra (CO stretching bands) of the carbonyl complexes **6a** and **6b** in dichloromethane solution

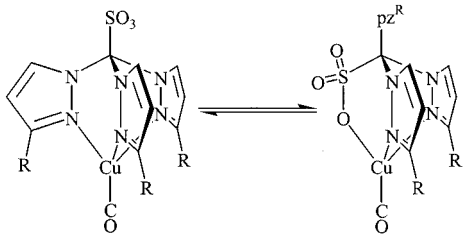
From variable-temperature NMR spectroscopic studies we know that in the case of [(Tpms^{tBu})Cu(CO)] (**6a**) the C_s-symmetrical species is the preferred isomer, and, therefore, the more intense CO band (2108 cm^{-1}) is assigned to this isomer. [(Tpms)Cu(CO)] (**6b**) favours the N,N,N coordination mode in solution, and, therefore, the more intense CO band (2104 cm^{-1}) is assigned to the C_{3v}-symmetrical complex. The different behaviour of the Tpms^{tBu} ligand, compared to the Tpms one, may be a consequence of the repulsion between the *tert*-butyl groups and the carbonyl ligand.



Scheme 3. Equilibrium between the N,N,N mode (C_{3v}) and the N,N,O mode (C_s) (R = H, *t*Bu)

Table 8 displays a comparison of CO stretching vibrations of tripodal nitrogen ligand complexes of the type [(ligand)Cu(CO)].

Table 8. CO stretching vibrations (cm^{-1}) of carbonylcopper(I) complexes of the type [(ligand)Cu(CO)] in the solid state

Ligand	ν(CO)	Ligand	ν(CO)	Ligand	ν(CO)
Tpms	2101	Tp	2083[a] [23]	HC(pz^{Me,Me})$_3$	2113[24]
Tpms^{tBu}	2093/2088	Tp^{tBu}	2069[25]	HC(pz^{tBu})$_3$	2100[24]
		Tp^{Me,Me}	2060[26]		
		Tp^{iPr,iPr}	2056[27]		

[a] In light petroleum ether.

In the Tp complexes, the CO stretching vibrations are shifted towards lower energies compared to those of **6a** and **6b**. Thus, the Tpms ligands are weaker donors than the Tp ligands. The anionic Tpms ligands are stronger donors compared to the neutral tris(pyrazolyl)methane ligands.

From the IR spectra measured in the temperature range from −10 to +83 °C, we have determined the equilibrium constants for the two isomeric forms of [(Tpms^{tBu})Cu(CO)] (**6a**) in toluene. With a van't Hoff plot we calculated the enthalpy and entropy of the transformation of the C_{3v}-symmetrical species into the C_s-symmetrical one. The resulting values are $\Delta H = +6$ kJ·mol^{-1} and $\Delta S = +35$ J·K^{-1}·mol^{-1}. Variable-temperature ^{1}H NMR measurements in CD_2Cl_2 (−70 to +5 °C) yield the same values. They are very similar to the thermodynamic parameters of [(Tpms^{tBu})ZnCl] (**1a**) (see above).

Conclusion

The thallium salt of the sterically demanding ligand Tpms^{tBu} is a convenient starting material for halide com-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

plexes of zinc(II), nickel(II) and cobalt(II) ions, as well as for alkylzinc and carbonylcopper(I) complexes. Tpms^{tBu} can act as a tripodal N,N,N ligand, as a tripodal N,N,O ligand and as a bipodal N,O ligand. In Rh^{I} complexes, we have observed Tpms to exhibit bipodal N,N coordination.[7] From the CO stretching vibrations of **6a** and **6b** we conclude that the tripodal Tpms ligands are weaker donors than are tris(-pyrazolyl)borate ligands. The equilibrium between C_{3v}- and C_s-symmetrical complexes in solution (**1a**, **1b**, **6a**, **6b**) indicates that, in the solvents that we have used here, there is no significant difference in the stabilities of the N,N,N and the N,N,O coordination modes. The equilibration between the two isomeric forms is slow on the NMR spectroscopic time scale. The formation of **3** shows that hydrolysis of the Tpms^{tBu} ligand occurs in the presence of certain metal ions; we have not yet observed this behaviour with the unsubstituted Tpms ligand. The coordination number of the Tpms complexes is not restricted to four. In the sterically less demanding N,N,O coordination mode the ligand allows also a coordination number of five (**3**, **5b**). All in all, this feature demonstrates that Tpms^{tBu} is a structurally flexible ligand that can adapt to the preferences of the metal centre. The complexes described here are soluble in polar solvents, like wet methanol. This solubility should allow reactivity studies of metalloenzyme model compounds with Tpms ligands to be carried out under more realistic conditions than with model compounds containing the highly hydrophobic Tp ligands.

Experimental Section

General Remarks: The compound KTpms was synthesised according to a published procedure.[1] All other reagents were commercial samples and were used as received. All reactions were carried out under nitrogen using standard Schlenk techniques, unless stated otherwise. Solvents were purified and degassed by standard procedures. Filtration was carried out using 1-μm membrane filters (regenerated cellulose, Schleicher & Schuell). Centrifugation was carried out using a Hettich Rotina 46 Schlenk tube centrifuge. ^1H and ^{13}C NMR spectra were recorded with Bruker DRX 200 (at 293 K) or Bruker DRX 500 (at 298 K) spectrometers. Chemical shifts (δ) are given in ppm referenced to the solvent peak.[19] Infrared spectra were recorded with a Bruker IFS 66 FT spectrometer. FAB mass spectra were recorded with a Finnigan MAT 8200 instrument (Ar, 8 kV, matrix: NBA unless stated otherwise). Elemental analyses were performed with a Perkin−Elmer CHN-2400/II elemental analyser. The absorption spectra of **2a** and **3**, dissolved in dichloromethane, were recorded with a Analytik Jena Specord S 100 spectrometer. Microcrystalline powders of both compounds were embedded in polyethylene pellets and their transmission was measured with a Cary 4 spectrometer. Temperatures down to 10 K were achieved by using a commercial flow-cryostat technique.

Tl(Tpms^{tBu}): Under cooling to −65 °C, a solution of *n*-butyllithium (1.6 M, 42 mL) was added to a solution of tris(3-*tert*-butylpyrazolyl)methane[20] (21 g, 54 mmol) in diethyl ether (60 mL). The solution immediately turned red and later became brown. After 40 min, sulfur trioxide−trimethylamine complex (8.4 g, 60 mmol) was added at −35 °C. Under constant stirring, the resulting suspension was warmed to room temperature overnight. The solvent was then evaporated. To remove excess tris(3-*tert*-butylpyrazolyl)methane, the residue was treated with dichloromethane, stirred for 1 h, filtered and washed with pentane, to yield an off-white powder (15 g). Recrystallisation from boiling toluene (400 mL) yielded colourless crystals of Li(Tpms^{tBu}) (8.9 g, 19 mmol, 36%). The thallium salt was obtained by adding a solution of $TlNO_3$ (10 g, 37 mmol) in a methanol/water mixture (3:7, 100 mL) to a solution of Li(Tpms^{tBu}) (8.9 g, 19 mmol) in a methanol/water mixture (7:3, 100 mL) in a beaker. Tl(Tpms^{tBu}) precipitated as a white solid. The precipitate was washed with water and dried under reduced pressure at room temperature. Yield: 8.6 g, 68%. ^1H NMR (200 MHz, $CDCl_3$): δ = 1.31 (s, 27 H, CH_3), 6.27 (d, $^3J_{H,H}$ = 2.7 Hz, 3 H, pyrazolyl 4-*H*), 7.43 (d, $^3J_{H,H}$ = 2.7 Hz, 3 H, pyrazolyl 5-*H*) ppm. $^{13}C\{^1H\}$ NMR (500 MHz, $CDCl_3$): δ = 31.4 [s, C(*C*H_3)$_3$], 33.1 [s, (CH$_3$)$_3$*C*], 97.1 (s, *C*SO_3), 105.2 (s, pyrazolyl *C*-4), 134.3 (s, pyrazolyl *C*-5), 165.2 (s, pyrazolyl *C*-3) ppm. IR (KBr): $\tilde{\nu}$ = 3155, 3124 [w, ν(C−H)], 2959 [vs, ν(C−H), CH_3], 1530 [m, ν(C=C)], 1481, 1463 [m, δ_{as}(*t*Bu)], 1397, 1363 [vs, δ_s(*t*Bu)], 1033 [(vs, ν_s(SO)], 636 [s, ν(C−S] cm^{-1}. MS (FAB$^+$): *m*/*z* = 871 [M + Tl]$^+$, 667 [M + H]$^+$, 381 [M − SO_3Tl]$^+$. $C_{22}H_{33}N_6O_3STl$ (665.99): calcd. C 39.7, H 5.0, N 12.6; found C 39.7, H 4.9, N 12.7.

[(Tpms^{tBu})MX] Complexes: The preparation of [(Tpms^{tBu})ZnCl] (**1a**) is described in detail as a representative example of this type of complex. Workup procedures and spectroscopic data for the analogous complexes are described below.

[(Tpms^{tBu})ZnCl] (1a): A stirred solution of Tl(Tpms^{tBu}) (0.92 g, 1.4 mmol) in methanol (20 mL) was treated with $ZnCl_2$ (0.19 g, 1.4 mmol) at room temperature. After 1 h of stirring, the precipitated TlCl was filtered and the solvent was evaporated under reduced pressure. The colourless residue was dissolved in a small amount of dichloromethane, filtered and the product was precipitated with pentane. The white powder was washed with pentane and dried at 40 °C for 24 h under reduced pressure (yield: 0.54 g, 70%). ***C*$_s$-Symmetrical Complex:** ^1H NMR (200 MHz, $CDCl_3$): δ = 1.46 (s, 9 H, CH_3), 1.51 (s, 18 H, CH_3), 6.36 (d, $^3J_{H,H}$ = 2.8 Hz, 2 H, pyrazolyl 4-*H*), 6.49 (d, $^3J_{H,H}$ = 2.5 Hz, 1 H, pyrazolyl 4-*H*), 6.85 (d, $^3J_{H,H}$ = 2.8 Hz, 2 H, pyrazolyl 5-*H*), 8.78 (d, $^3J_{H,H}$ = 2.5 Hz, 1 H, pyrazolyl 5-*H*) ppm. ***C*$_{3v}$-Symmetrical Complex:** ^1H NMR (200 MHz, $CDCl_3$): δ = 1.34 (s, 27 H, CH_3), 6.32 (d, $^3J_{H,H}$ = 3.0 Hz, 3 H, pyrazolyl 4-*H*), 9.07 (d, $^3J_{H,H}$ = 3.0 Hz, 3 H, pyrazolyl 5-*H*) ppm; ratio C_s:C_{3v} = 3.4:1. $^{13}C\{^1H\}$ NMR (500 MHz, CD_2Cl_2): δ = 30.0, 30.1, 30.3 [s, C(*C*H$_3$)$_3$], 32.6, 32.7, 32.9 [s, *C*(CH$_3$)$_3$], 94.5 (s, *C*SO_3), 104.3, 105.1, 106.3 (s, pyrazolyl *C*-4), 136.1, 136.5, 137.2 (s, pyrazolyl *C*-5), 167.3, 168.2 (s, pyrazolyl *C*-3) ppm. MS (FAB^+): *m*/*z* = 644 $[M - Cl]^+$, 520 $[M - Cl - Hpz^{tBu}]^+$, 440 $[M - Cl - Hpz^{tBu} - SO_3]^+$, 381 $[C(pz^{tBu})_3]^+$, 259 $[C(pz^{tBu})_2 + H]^+$. $C_{29}H_{45}ClCoN_8O_3S\cdot C_4H_8O$ (752.29): calcd. C 52.7, H 7.1, N 14.9, found C 51.7, H 7.0, N 14.6.

[(Tpms^{tBu})ZnEt] (4): A solution of Tl(Tpms^{tBu}) (1.7 g, 2.5 mmol) in THF (30 mL) was added dropwise at room temperature to a solution of $ZnEt_2$ (1 M solution in hexane, 3.0 mL, 3.0 mmol) in THF (20 mL). The precipitated thallium metal was separated by centrifugation. The colourless supernatant solution was concentrated until the onset of crystallisation and then left to stand at −30 °C. After 2 d, colourless crystals (1.0 g, 64%) were collected by filtration. ^1H NMR (200 MHz, C_6D_6): δ = 1.00 (q, $^3J_{H,H}$ = 8.0 Hz, 2 H, C*H*$_2$), 1.15 [s, 27 H, C(C*H*$_3$)$_3$], 1.72 (t, $^3J_{H,H}$ = 8.0 Hz, 3 H, C*H*$_3$), 5.73 (br. s, 2 H, pyrazolyl 4-*H*), 5.94 (br. s, 1 H, pyrazolyl 4-*H*), 6.74 (br. s, 2 H, pyrazolyl 5-*H*), 9.24 (br. s, 1 H, pyrazolyl 5-*H*) ppm. $^{13}C\{^1H\}$ NMR (500 MHz, C_6D_6): δ = 5.6 (s, *C*H$_2$CH$_3$), 12.7 (s, CH$_2$*C*H$_3$), 30.8, 31.0 [s, C(*C*H$_3$)$_3$], 32.9, 33.3 [s, *C*(CH$_3$)$_3$], 95.4 (s, *C*SO$_3$), 104.7, 106.0 (s, pyrazolyl *C*-4), 135.8, 137.9 (s, pyrazolyl *C*-5), 166.9 (s, pyrazolyl *C*-3) ppm. IR (KBr): $\tilde{\nu}$ = 3163 [w, ν(C−H)], 2964 [vs, ν(C−H), CH_3], 1524 [s, ν(C=C)], 1399, 1367 [vs, δ_s(*t*Bu)], 1043 [vs, ν_s(SO)], 649 [vs, ν(C−S)] cm^{-1}. MS (FAB^+; matrix: NPOE): *m*/*z* = 649 $[M - Et + Hpz^{tBu}]^+$, 555 $[M + H]^+$, 525 $[M - Et]^+$, 445 $[M - SO_3 - tBu]$, 381 $[C(pz^{tBu})_3]^+$, 57 $[tBu]^+$. $C_{24}H_{38}N_6O_3SZn\cdot C_4H_8O$ (628.17): calcd. C 53.5, H 7.4, N 13.4, found C 53.1, H 7.5, N 13.5.

[(Tpms^{tBu})ZnOAc] (5a): A solution of **4** (0.61 g, 0.97 mmol) in THF (10 mL) was treated with acetic acid (55 μL, 0.97 mmol). After 10 min of stirring at room temperature, the solution was concentrated under reduced pressure and the product was precipitated with hexane. Yield: 0.11 g (20%) of a white powder. ^1H NMR (200 MHz, C_6D_6): δ = 1.24 [s, 27 H, C(C*H*$_3$)$_3$], 1.96 (s, 3 H, acetate C*H*$_3$), 5.89 (d, $^3J_{H,H}$ = 2.8 Hz, 3 H, pyrazolyl 4-*H*) 7.66 (br. s, 3 H, pyrazolyl 5-*H*) ppm. $^{13}C\{^1H\}$ NMR (500 MHz, C_6D_6): δ = 23.7 (s, *C*H$_3$CO$_2$), 30.8 [s, C(*C*H$_3$)$_3$], 33.2 [s, *C*(CH$_3$)$_3$], 96.6 (s, *C*SO$_3$), 105.8 (s, pyrazolyl *C*-4), 136.3 (s, pyrazolyl *C*-5), 166.7 (s, pyrazolyl *C*-3), 182.3 (s, CH$_3$*C*O$_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3126 [w, ν(C−H)], 2966 [vs, ν(C−H), CH_3], 1592 [vs, $\nu_{as}(CO_2)$], 1532 [s, ν(C=C)], 1403, 1366 [s, δ_s(*t*Bu)], 1331 [s, $\nu_{as}(CO_2)$], 1036 [vs, ν_s(SO)], 647 [vs, ν(C−S)] cm^{-1}. MS (FAB^+): *m*/*z* = 381 $[C(pz^{tBu})_3]^+$, 259 $[C(pz^{tBu})_2 + H]^+$, 57 $[tBu]^+$. $C_{24}H_{36}N_6O_5SZn$ (586.04): calcd. C 49.2, H 6.2, N 14.3, found C 49.1, H 6.3, N 14.1.

[(Tpms^{tBu})Zn(μ-OAc)(μ-OH)Zn(Tpms^{tBu})] (5b): A solution of **4** (0.32 g, 0.51 mmol) in benzene (5 mL) was treated with acetic acid (19 μL, 0.34 mmol). After 10 min of stirring at room temperature, the solvent was evaporated under reduced pressure. The residue was treated with a small amount of diethyl ether and filtered, and then the colourless solution was stored at −30 °C overnight. Analytically pure crystals suitable for X-ray analysis were collected by filtration. Yield: 0.05 g (16%). ^1H NMR (200 MHz, $CDCl_3$): δ = 1.33 [s, 54 H, C(C*H*$_3$)$_3$], 2.02 (s, 3 H, acetate C*H*$_3$), 6.34 (d, $^3J_{H,H}$ = 2.9 Hz, 6 H, pyrazolyl 4-*H*), 7.45 (d, $^3J_{H,H}$ = 2.9 Hz, 6 H, pyrazolyl 5-*H*) ppm. $^{13}C\{^1H\}$ NMR (500 MHz, CD_2Cl_2): δ = 25.1 (s, *C*H$_3$CO$_2$), 30.3 [s, C(*C*H$_3$)$_3$], 32.6 [s, *C*(CH$_3$)$_3$], 95.3 (s, *C*SO$_3$), 105.5 (s, pyrazolyl *C*-4), 135.1 (s, pyrazolyl *C*-5), 166.6 (s, pyrazolyl *C*-3), 181.3 (s, CH$_3$*C*O$_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3619 [m, sharp, ν(O−H)], 3155 [w, ν(C−H)], 2966 [vs, ν(C−H), CH_3], 1573 [vs, $\nu_{as}(CO_2)$], 1531 [s, ν(C=C)], 1437 [m, $\nu_{as}(CO_2)$], 1401, 1365 [s, δ_s(*t*Bu)], 1050 [s, ν_s(SO)], 646 [s, ν(C−S)] cm^{-1}. MS (FAB^+): *m*/*z* = 381 $[C(pz^{tBu})_3]^+$, 259 $[C(pz^{tBu})_2 + H]^+$. $C_{46}H_{70}N_{12}O_9S_2Zn_2\cdot C_4H_{10}O$ (1204.17): calcd. C 49.9, H 6.7, N 14.0, found C 49.9, H 6.7, N 13.9.

[(Tpms^{tBu})Cu(CO)] (6a): A solution of Tl(Tpms^{tBu}) (0.35 g, 0.52 mmol) in dichloromethane (5 mL) was saturated with carbon monoxide in a Schlenk tube equipped with a Teflon seal and valve. After 10 min, CuCl (0.10 g, 1.0 mmol) was added, the suspension was pressurized with 3−4 bar of carbon monoxide and stirred for 48 h at room temperature. Thereafter, the precipitated TlCl and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

remaining CuCl was filtered off and the product was precipitated with hexane under carbon monoxide. The colourless product was isolated by filtration and washed with pentane. Yield: 0.14 g (50%). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.33 (s, 9 H, C*H*$_3$), 1.49 (s, 18 H, C*H*$_3$), 6.25 (br. s, 2 H, pyrazolyl 4-*H*), 6.39 (br. s, 1 H, pyrazolyl 4-*H*), 6.74 (br. s, 2 H, pyrazolyl 5-*H*), 8.87 (br. s, 1 H, pyrazolyl 5-*H*) ppm. IR (KBr): $\tilde{\nu}$ = 3177, 3136 [w, ν(C−H)], 2972 [vs, ν(C−H), CH_3], 2093/2088 [vs, ν(CO)], 1528 [s, ν(C=C)], 1483, 1458 [m, δ_{as}(*t*Bu)], 1390, 1365 [s, δ_s(*t*Bu)], 1053 [vs, ν_s(SO)], 621 [vs, ν(C−S)] cm^{-1}. MS (FAB$^+$): *m*/*z* = 525 [M − CO + H]$^+$, 445 [M − SO_3 − CO + H]$^+$, 387 [M − SO_3 − CO − *t*Bu]$^+$, 381 [C(pz$^{t\mathrm{Bu}}$)$_3$]$^+$, 321 [M − SO_3 − CO − pz$^{t\mathrm{Bu}}$]$^+$, 57 [*t*Bu]$^+$. $C_{23}H_{33}CuN_6O_4S$ (553.17): calcd. C 49.9, H 6.0, N 15.2, found C 49.8, H 5.8, N 15.4.

[(Tpms)Cu(CO)] (6b): [Cu(MeCN)$_4$]PF_6 (259 mg, 0.7 mmol) was dissolved in methanol (10 mL). The colourless solution was saturated with carbon monoxide, stirred at room temperature for 20 min and then KTpms (229 mg, 0.7 mmol) was added. A white precipitate had formed within seconds. The mixture was stirred under CO for 1 h and then the precipitate was filtered off, washed with a small portion of methanol and dried for 4 h in a stream of dry N_2. Yield: 0.09 g (34%). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 6.41 (dd, $^3J_{H,H}$ = 1.7, 2.8 Hz, 3 H, pyrazolyl 4-*H*), 7.81 (d, $^3J_{H,H}$ = 1.7 Hz, 3 H, pyrazolyl 3-*H*), 8.45 (br. s, 3 H, pyrazolyl 5-*H*) ppm. ***C*$_s$-Symmetrical Complex:** ^{1}H NMR ($CDCl_3$, 200 MHz, 213 K) δ = 6.50 (dd, $^3J_{H,H}$ = 2.0, 2.6 Hz, 2 H, pyrazolyl 4-*H*), 6.64 (dd, $^3J_{H,H}$ = 1.9, 2.1 Hz, 1 H, pyrazolyl 4-*H*), 6.88 (d, $^3J_{H,H}$ = 2.6 Hz, 2 H, pyrazolyl 5-*H*), 7.91 (s, 2 H, pyrazolyl 3-*H*), 7.99 (s, 1 H, pyrazolyl 3-*H*), 8.9 (overlapped, 3 H, pyrazolyl 5-*H*) ppm. ***C*$_{3v}$-Symmetrical Complex:** ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.39 (dd, $^3J_{H,H}$ = 1.7, 2.8 Hz, 3 H, pyrazolyl 4-*H*), 7.75 (d, $^3J_{H,H}$ = 1.7 Hz, 3 H, pyrazolyl 3-*H*), 8.90 (d, $^3J_{H,H}$ = 2.8 Hz, 3 H, pyrazolyl 5-*H*) ppm; ratio C_s/C_{3v} = 1:3. IR (KBr): $\tilde{\nu}$ = 3180, 3127 [s, ν(C−H)], 2101 [vs, ν(CO)], 1524 [s, ν(C=C)], 1052 [vs, ν_s(SO)], 621 [vs, ν(C−S)] cm^{-1}. $C_{11}H_9CuN_6O_4S$ (384.84): calcd. C 34.3, H 2.4, N 21.8, found C 34.2, H 2.4, N 22.0.

X-ray Crystallographic Study: Crystals of compounds **1b**, **2a**, **3** and **5b** suitable for X-ray study were investigated with area-detector diffractometers using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Unit cell parameters were determined by least-squares refinements on the positions of 18000, 1953, 7998 and 2000 reflections in the range 2° < θ < 30.5°, 3° < θ < 27.5°, 2° < θ < 25° and 2° < θ < 25°, respectively. Space groups of type no. 14 were uniquely determined in the cases of **1b**, **2a** and **3**. In the case of **5b**, systematic extinctions were consistent with space groups *Ia* and *I*2/*a*, but the latter proved to be the correct one in the course of structure refinement. Lp corrections were applied to all the intensity data. In the case of **1b**, empirical absorption corrections have been performed ($T_{min.}$ = 0.175; $T_{max.}$ = 0.250), and in the case of **2a**, an empirical extinction parameter was refined. The structures were solved by direct methods[21] and the positions of all hydrogen atoms were found in the case of **1b**, **2a** and **5b**. In the case of **3**, the hydrogen atom positions of the tetrahydrofuran molecule were calcu-

lated. Refinements by full-matrix least-squares calculations[22] on F^2 converged to the indicators given in Table 9. Anisotropic displacement parameters were refined for all atoms heavier than hydrogen. All atomic coordinates and isotropic displacement parameters were refined for the hydrogen atoms of **1b**. Idealised bonds lengths and angles for CH_3, CH_2 and CH groups were used for the other compounds; the riding model was applied for their hydrogen atoms. In addition, the hydrogen atoms of the CH_3 groups were allowed to rotate around the neighbouring C−C bonds. The isotropic displacement parameters of the H atoms were kept equal to 150, 120 and 120% of the equivalent isotropic displacement parameters of the parent primary, secondary and "aromatic" carbon atoms, respectively. Scattering factors, dispersion corrections and absorption coefficients were taken from International Tables for Crystallography (**1992**, Vol. C, Tables 6.1.1.4, 4.2.6.8 and 4.2.4.2). CCDC-197748 to -197751 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Tungsten(VI) Complexes Derived from Calix[6]- and -[8]arenes: Oxo and Oxychloride Species

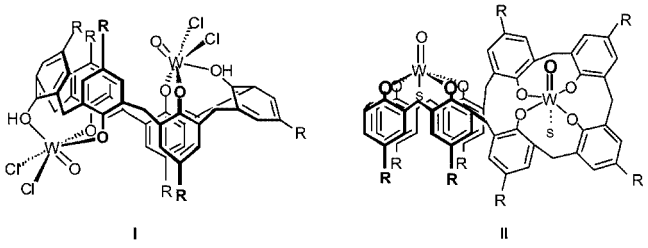
Carl Redshaw*[a] and Mark R. J. Elsegood[b]

Keywords: Tungsten / Calixarenes / Oxo ligands

Treatment of *p-tert*-butylcalix[6]areneH_6 (H_6L) or *p-tert*-butylcalix[8]areneH_8 (H_8L^1) with 2 equiv. of [$WOCl_4$] in refluxing toluene affords, after workup, the complexes [$(WOCl_2)_2LH_2$] (**1**) and [{$WO(NCMe)$}$_2L^1$] (**2**), respectively. The molecular structures of **1** and **2** have been determined and reveal conformationally constrained macrocyclic rings.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The coordination chemistry of the calix[*n*]arene ring systems has attracted considerable attention during the last decade.[1] Attention has focused primarily on calix[4]arene transition metal species, however despite this activity, only a limited number of oxometal species have been reported.[2] Such oxo species have attracted attention due, in part, to their tendency to self-assemble into columnar structures.[3] In certain cases, this has resulted in liquid crystalline properties. For the group-VI metals, the contributions of the groups of Floriani and Young are particularly relevant. Crystallographic studies of species derived from the oxychloride precursors [$MOCl_4$] (M = Mo, W) reveal monomeric complexes with octahedrally coordinated metal centres.[2c,2g] By contrast, oxometal species for the larger ring systems ($n > 4$) are extremely rare and no structural data have been reported.[4] As part of an ongoing programme[5] investigating the coordination environments afforded by the medium-sized calix[*n*]arene rings (n = 6, 8), we here describe the synthesis and molecular structures of novel tungsten(VI) complexes (see **I** and **II** in Scheme 1) bearing either oxo or both oxo and chloro ligands via the interaction of the parent calix[6 and 8]arene$H_{6,8}$ with the metal oxytetrachloride complex [$WOCl_4$]. The molecular structures of the two new calixarene tungsten species have been determined and reveal conformationally constrained macrocyclic rings.



Scheme 1. R = *t*Bu; S = solvent (CH_3CN)

Results and Discussion

Reaction of H_6L with 2 equiv. of [$WOCl_4$] in refluxing toluene affords, after workup, large red-purple prisms of the complex [$(WOCl_2)_2LH_2$] (**1**) in ca. 60% yield. Stoichiometrically, **1** is formed by loss of 2 equiv. of HCl per tungsten centre. In the IR spectrum of this compound, a band is observed for ν(W=O) at 941 cm^{-1} {cf. 999 and 1006 cm^{-1} reported for the 1,3-dialkoxy-*p-tert*-butylcalix[4]-areneH_2 (R_2calH_2) complexes [$Et_2calWOCl_2$] and [$Me_2calWOCl_2$], respectively},[2g] whilst a broad feature at 3181 cm^{-1} is assigned to ν(OH). The ^1H NMR spectrum is consistent with the solid-state structure: two singlets in the *tert*-butyl region in a 2:1 ratio. The methylene protons appear as two doublets and a singlet (each integrating to 4 H), for which the latter is assigned to the CH_2 groups on the "fold" of the pinch (see Figure1, b). A broad singlet (integrating to 2 H) appears at δ_{OH} = 9.28 ppm.

Crystals of **1**·8MeCN suitable for an X-ray determination were grown from a hot, saturated solution of acetonitrile on slow cooling to ambient temperature. The asymmetric unit comprises one molecule of **1** and eight molecules of acetonitrile, one of which is disordered, with two others H-bonded to the calix[6]arene oxygen atoms O(2) and O(5). The molecular structure is shown in Figure 1 (a and b) to-

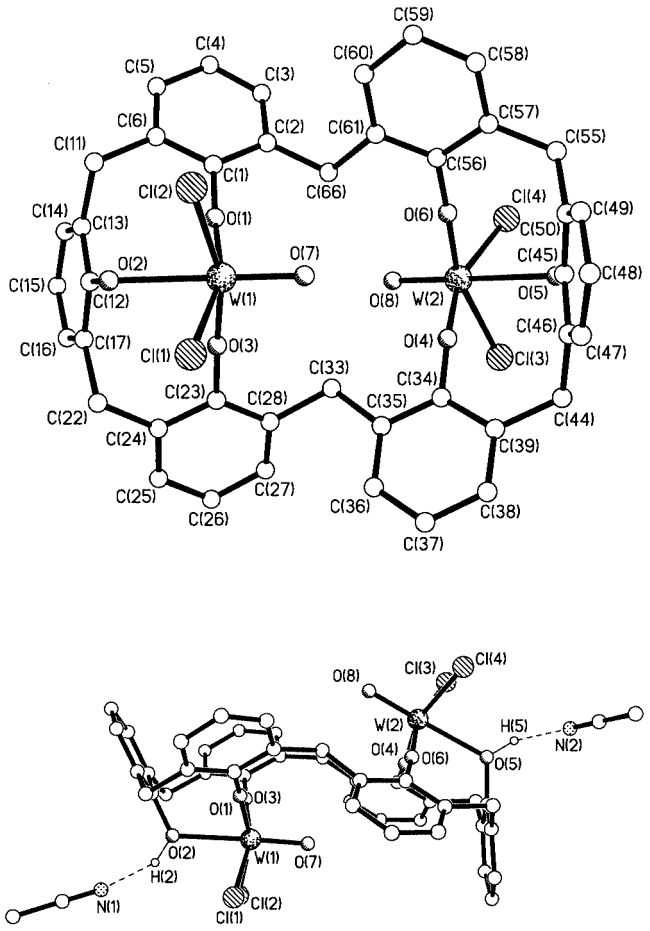

Figure 1. (a, top) Molecular structure of **1**; H atoms and calixarene *t*Bu groups omitted for clarity; (b, bottom) view of **1** emphasising pinched conformation; C*H* atoms and calixarene *t*Bu groups omitted for clarity; selected bond lengths [Å] and angles [°]: W(1)−Cl(1) 2.344(4), W(1)−Cl(2) 2.369(4), W(1)−O(1) 1.847(8), W(1)−O(2) 2.332(8), W(1)−O(3) 1.842(8), W(1)−O(7) 1.706(9), W(2)−Cl(3) 2.380(3), W(2)−Cl(4) 2.345(3), W(2)−O(4) 1.858(7), W(2)−O(5) 2.335(7), W(2)−O(6) 1.845(8), W(2)−O(8) 1.688(8); Cl(1)−W(1)−Cl(2) 85.95(18), O(7)−W(1) − Cl(1) 97.3(3), O(7)−W(1) − Cl(2) 96.6(3), O(1)−W(1)−O(7) 100.8(4), O(93) − W(1)−O(7) 100.0(4), W(1)−O(1)−C(1) 164.3(8), W(1)−O(2)−C(12) 119.0(6), W(1)−O(3)−C(23) 170.5(7)

gether with selected bond lengths and angles. The calix[6]arene ligand remains doubly protonated and adopts a pinched conformation to accommodate the two facially coordinated tungsten centres, one lying above and one below the plane of the macrocyclic ring (as emphasised in Figure 1, b). The geometry about each tungsten centre is best described as pseudo-octahedral with the oxo ligand lying *trans* to the elongated W−OH bond [W(1)−O(2) 2.332(8), cf. W(1)−O(1) 1.847(8); W(1)−O(3) 1.842(8) Å]. Interestingly, the OH binding site in **1** is equivalent to that occupied by the OR groups for the complexes [R_2calMOCl_2] (M = Mo, R = Et; M = W, R = Me) reported by Young et al.[2g] Furthermore, in these 1,3-dialkoxy-*p*-*tert*-butylcalix[4]arene systems, the W=O grouping leads to the adoption of an unusual nonconical conformation. Similarly, in **1** the W=O groups push other groups away (VSEPR) and this is thought to lead to the adoption of the pinched conformation. The W−O−C angles are also indicative of deprotonation at O(1) and O(3), viz. W(1)−O(1)−C(1) 164.3(8)°, W(1)−O(3)−C(23) 170.5(7)°, cf. W(1)−O(2)−C(12) 119.0(6)°. The W=O bond lengths (av. 1.70 Å) are typical of those observed in other oxotungsten(VI) complexes[6] and is in good agreement with that observed for the calix[4]areneH$_4$ (calH$_4$) complex [calWO(CH$_3$CO$_2$H)] [1.698(4) Å];[2c] that observed for [R_2calWOCl_2] is slightly longer [1.673(3) Å].[2g]

We then targeted the calix[8]arene (H_8L^1) species {[WO(NCMe)]$_2L^1$} (**2**), using a procedure similar to that for **1**. As expected, four molecules of HCl are lost per tungsten centre. The NMR signals/integrals are consistent with the expected target complex: eight distinct doublets for the *endo*- and *exo*-methylene groups together with four signals (each of 18 H) for the *tert*-butyl groups. In the IR spectrum of **2**, a strong band at 969 cm^{-1} is assigned to the ν(W=O) stretch. Crystals suitable for an X-ray determination were grown from an acetonitrile solution at room temperature; they incorporate two noncoordinated molecules of acetonitrile per molecule of the complex. The molecular structure is shown in Figure 2 together with selected bond lengths and angles. The calix[8]arene twists to accommodate the two [W=O] fragments in a manner similar to that observed previously for the organoimido complex {[Mo(NAr)(NCMe)]$_2L^1$} (Ar = C$_6$H$_3$*i*Pr$_2$-2,6).[5a] In **2**·2MeCN, each tungsten centre adopts a pseudo-octahedral geometry with the tungsten atoms an average of 0.30 Å out of the plane of the calixarene oxygen atoms. The W=O bond lengths (ca. 1.70 Å) are similar to those observed in **1** and elsewhere.[6] A molecule of acetonitrile binds to each tungsten centre *trans* to the oxo function and each is surrounded by three calixarene phenoxide sub-units.

The analogous reactions using [MoOCl_4] appear to be more sensitive to reduction, and deep blue solutions are readily formed. However, we note with interest that in the

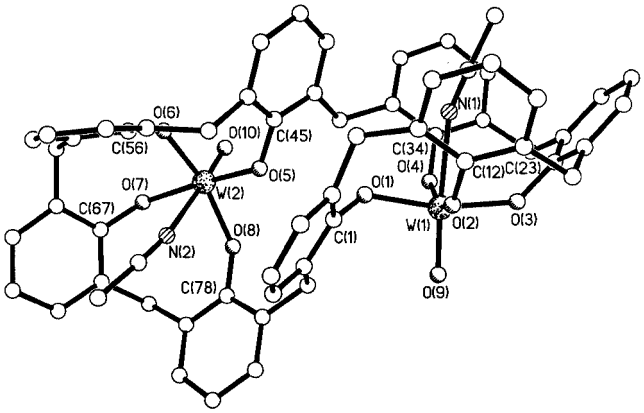

Figure 2. Molecular structure of **2**; H atoms and calixarene *t*Bu groups omitted for clarity; selected bond lengths [Å] and angles [°]: W(1)−O(1) 1.922(3), W(1)−O(2) 1.921(3), W(1)−O(3) 1.927(3), W(1)−O(4) 1.891(2), W(1)−O(9) 1.703(3), W(1)−N(1) 2.402(3), W(2)−O(5) 1.913(3), W(2)−O(6) 1.912(3), W(2)−O(7) 1.935(3), W(2)−O(8) 1.903(3), W(2)−O(10) 1.699(3), W(2)−N(2) 2.413(3); O(9)−W(1)−N(1) 176.15(12), O(9)−W(1)−O(1) 99.29(12), O(9)−W(1)−O(2) 99.74(12), O(9)−W(1)−O(3) 95.23(12), O(9)−W(1)−O(4) 103.24(12)

case of *p-tert*-butylcalix[4]areneH$_4$ (*t*BucalH$_4$), reaction with [MoOCl$_4$] affords a blue, diamagnetic complex of stoichiometry [(*t*BucalH$_4$)(*t*Bucal)MoO·2CH$_2$Cl$_2$].[2a]

In conclusion, we have demonstrated that the oxychloride complex [WOCl$_4$] readily reacts with medium-sized calix[*n*]arene ring systems (n = 6 or 8) to afford highly crystalline products. In each case, the calixarene ligands are flexible enough to accommodate two tungsten centres possessing oxo or chloro ligands or combinations thereof.

Experimental Section

General: All manipulations were carried out under nitrogen using standard Schlenk and cannula techniques or in a conventional nitrogen-filled glove-box. Solvents were refluxed in the presence of an appropriate drying agent, and distilled and degassed prior to use. Elemental analyses were performed by the microanalytical services of the School of Chemical Sciences and Pharmacy at the University of East Anglia. NMR spectra were recorded with a Varian VXR 400 S spectrometer at 400 or a Gemini at 300 MHz (^{1}H) at 298 K; chemical shifts are referenced to the residual protio impurity of the deuterated solvent. IR spectra (nujol mulls, KBr windows), Perkin−Elmer 577 and 457 grating spectrophotometers. [WOCl$_4$] was prepared by the method of Gibson;[7] the ligands *p-tert*-butylcalix[6]arene H$_6$ (H$_6$L) and *p-tert*-butylcalix[8]arene (H$_8$L′) were prepared from *p-tert*-butylphenol and formaldehyde.[8] All other chemicals were obtained commercially and used as received, unless stated otherwise.

[(WOCl$_2$)$_2$L] (1): [WOCl$_4$] (1.0 g, 2.94 mmol) and H$_6$L (1.4 g, 1.44 mmol) were refluxed in toluene (40 mL) for 12 h. After cooling to room temperature, the volatiles were removed under reduced pressure and the residue extracted with MeCN (30 mL). Prolonged standing at ambient temperature afforded large red/purple prisms of **1**·8MeCN. (1.55 g, 58%). C$_{82}$H$_{104}$Cl$_4$N$_8$O$_8$W$_2$·CH$_3$CN (1880.3): calcd. C 52.6, H 5.4, N 0.9;[9]found C 52.3, H 5.3, N 1.1. IR: $\tilde{\nu}$ = 2359 w, 1608 m, 1302 m, 1268 m, 1205 s, 1122 m, 1096 w, 993 s, 941 m, 898 w, 881 m, 812 w, 806 w, 752 w, 730 w cm^{-1}. ^{1}H NMR (300 MHz, CD$_3$CN): δ = 9.28 (br. s, 2 H, OH), 7.60−7.14 (3 × m, 12 H, aryl H), 4.86 (d, $^2J_{H,H}$ = 13.5 Hz, 4 H, *endo*-CH$_2$), 4.66 (s, 4 H, *endo*/*exo*-CH$_2$), 3.66 (d, $^2J_{H,H}$ = 13.5 Hz, 4 H, *exo*-CH$_2$), 1.40 [s, 36 H, C(CH$_3$)$_3$], 1.29 [s, 18 H, C(CH$_3$)$_3$] ppm.

[{WO(NCMe)}$_2$L^1] (2): [WOCl$_4$] (1.0 g, 2.94 mmol) and H$_8$L^1 (1.86 g, 1.43 mmol) were refluxed in toluene (40 mL) for 12 h. After cooling to room temperature, the volatiles were removed under reduced pressure and the residue extracted with MeCN (30 mL). Prolonged standing at ambient temperature afforded orange prisms (1.13 g, 41%). C$_{92}$H$_{110}$N$_2$O$_{10}$W$_2$·4CH$_3$CN (1935.7): calcd. C 62.0, H 6.3, N 4.3; found C 61.6, H 6.3, N 4.1.[9] IR: $\tilde{\nu}$ = 2393 w, 2359 w, 2307 w, 2280 w, 2256 w, 1600 w, 1586 w, 1293 s, 1259 s, 1242 m, 1200 s, 1182 s, 1113 s, 1027 s, 968 s, 941 w, 916 m, 855 m, 838 s, 821 m, 795 s, 786 m, 760 w, 727 w, 675 w cm^{-1}. ^{1}H NMR (400 MHz, CDCl$_3$): δ = 7.45 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H, aryl H), 7.31 (t, $^4J_{H,H}$ = 2.6 Hz, 4 H, aryl H), 7.18 (d, $^4J_{H,H}$ = 2.3 Hz, 2 H, aryl H), 7.09 (d, $^4J_{H,H}$ = 2.3 Hz, 2 H, aryl H), 6.96 (d, $^4J_{H,H}$ = 2.3 Hz, 2 H, aryl H), 6.87 (d, $^4J_{H,H}$ = 1.8 Hz, 2 H, aryl H), 6.70 (d, $^4J_{H,H}$ = 2.2 Hz, 2 H, aryl H), 5.44 (d, $^2J_{H,H}$ = 16.6 Hz, 2 H, *endo*-CH$_2$), 4.77 (d, $^2J_{H,H}$ = 12.9 Hz, 2 H, *endo*-CH$_2$), 4.61 (d, $^2J_{H,H}$ = 12.5 Hz, 2 H, *endo*-CH$_2$), 4.28 (d, $^2J_{H,H}$ = 16.7 Hz, 2 H, *endo*-CH$_2$), 3.43 (d, $^2J_{H,H}$ = 13.0 Hz, 2 H, *exo*-CH$_2$), 3.24 (d, $^2J_{H,H}$ = 12.6 Hz, 2 H, *exo*-CH$_2$), 2.58 (d, $^2J_{H,H}$ = 15.4 Hz, 2 H, *exo*-CH$_2$), 2.31 (d, $^2J_{H,H}$ = 15.1 Hz, 2 H, *exo*-CH$_2$), 1.95 (br. s, 9 H, 3 MeCN), 1.34 [s, 18 H, C(CH$_3$)$_3$], 1.27 [s, 18 H, C(CH$_3$)$_3$], 1.16 [s, 18 H, C(CH$_3$)$_3$], 1.02 [s, 18 H, C(CH$_3$)$_3$] ppm.

X-ray Crystallography: Measurements for **1**·8MeCN and **2**·2MeCN were carried out with a Bruker AXS SMART 1 K CCD area detector diffractometer equipped with Mo-K_α radiation (λ = 0.71073 Å) at 160 K. Narrow-frame exposures (0.3° in ω) were employed. Cell parameters were refined from all strong reflections in each data set. Intensities were corrected semiempirically for absorption, based on symmetry-equivalent and repeated reflections. The structures were solved by direct methods and refined by full-matrix least squares on F^2 values for all unique data. All non-hydrogen atoms were refined anisotropically. H atoms were included in a riding model with U_{iso} set to be 1.2 times (1.5 times for methyl-H) U_{eq} of the carrier atom. Crystal data for **1**·8MeCN: C$_{66}$H$_{80}$Cl$_4$O$_8$W$_2$·8CH$_3$CN, M = 1839.23, monoclinic, space group $P2_1/c$, a = 12.4800(6), b = 24.8091(12), c = 28.1016(14) Å, V = 8696.2(7) Å^3, Z = 4, F(000) = 3728, $D_{calcd.}$ = 1.405 g·cm^{-3}, μ (Mo-K_α) = 2.821 mm^{-1}, 60614 data measured of which 15280 were unique, R_{int} = 0.0358, wR = 0.1866 (on F^2), R = 0.0779 [for 14455 data with $F^2 > 2\sigma(F^2)$]. Largest difference map features within ±4.3 e·Å^{-3}. Two calixarene *t*Bu groups and one CH$_3$CN molecule of crystallisation were disordered over two sets of positions. Crystal Data for **2**·2MeCN: C$_{92}$H$_{110}$N$_2$O$_{10}$W$_2$·2CH$_3$CN, M = 1853.63, triclinic, space group $P\bar{1}$, a = 15.7724(6), b = 16.3034(6), c = 18.2020(6) Å, α = 101.005(2), β = 90.436(2), γ = 93.838(2)°, V = 4583.2(3) Å^3, Z = 2, F(000) = 1896, $D_{calcd.}$ = 1.343 g·cm^{-3}, μ (Mo-K_α) = 2.565 mm^{-1}, 34801 data measured of which 20907 were unique, R_{int} = 0.0273, wR = 0.0906 (on F^2), R = 0.0348 [for 15392 data with $F^2 > 2\sigma(F^2)$]. Largest difference map features within ±1.6 e·Å^{-3}. One calixarene *t*Bu group was disordered over two sets of positions and two CH$_3$CH molecules of crystallisation were refined at half occupancy. Programs used were Bruker AXS SHELXTL[10] for structure solution, refinement, and molecular graphics, Bruker AXS SMART (control) and SAINT (integration), and local programs.[11] CCDC-203411 and -203412 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/cont/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

First (Peroxo)vanadium(V) Complex with Heteroligand Formed in Reaction System − Synthesis, Structure and Reactivity of K[VO(O$_2$)(*omeida*)]·H$_2$O {*omeida* = *N*-[2-(2-oxomorpholine-4-yl)ethyl]iminodiacetato(2−)}

Michal Sivák,*[a] Mariana Mad'arová,[a] Jozef Tatiersky,[a] and Jaromír Marek[b]

Keywords: Vanadium / Peroxo ligands / δ-Lactones / ^{51}V NMR spectroscopy / *N*-acetyl-L-cysteine

The crystalline peroxo complex of vanadium(V), K[VO(O$_2$)(*omeida*)]·H$_2$O, where *omeida* is a δ-lactone derivative, *N*-[2-(2-oxomorpholine-4-yl)ethyl]iminodiacetate(2−), has been obtained by reaction of vanadate with H$_2$O$_2$ and *N*-(2-hydroxyethyl)ethylenediaminetriacetic acid (*HEDTA*) in acidic aqueous solution at pH = 3 and 278 K. X-ray analysis revealed a distorted pentagonal-bipyramidal coordination around the vanadium atom, with a typical *cis* arrangement of oxo and peroxo ligands in apical and equatorial positions, respectively. Two amino nitrogen atoms of the tetradentate *omeida*(2−)-N^1,N^2,O^1,O^2 ligand occupy the neighbouring equatorial positions of the pentagonal plane, and two oxygen atoms of carboxymethyl groups bound to the same N1 nitrogen atom are in equatorial and apical positions. The six-membered lactone ring in *omeida* was formed in the reaction solution from carboxy and hydroxy groups not involved in coordination with the vanadium atom. The ^{51}V NMR spectra of K[VO(O$_2$)(*omeida*)]·H$_2$O, and of peroxovanadate/*HEDTA*/H$_2$O and vanadate/*HEDTA*/H$_2$O solutions, as well as the ^{1}H NMR spectrum of *HEDTA*, proved that lactone ring closure proceeds only in peroxovanadate but not vanadate solutions. Spectroscopic investigation of the oxygen transfer reaction from the peroxo ligand in [VO(O$_2$)(*omeida*)]$^-$ to the thiolato sulfur atom in [Co(*en*)$_2${S(CH$_2$)$_2$NH$_2$}]$^{2+}$ or [Co(*en*)$_2$(*cyst*)]$^+$, and of the oxidation of *N*-acetyl-L-cysteine by K[VO(O$_2$)(*omeida*)]·H$_2$O, revealed much more complicated reaction mechanisms than those of other (amino-polycarboxylato)monoperoxo complexes of vanadium(V).

Introduction

Monoperoxo complexes of vanadium(V) with polydentate heteroligands *L* providing an N$_x$O$_y$ donor set[1−7] are structural and functional models for the peroxo form of vanadium haloperoxidase, and are also studied for the insulin mimetic properties of vanadium(IV,V) complexes. They are useful models for the peroxo form of the enzyme despite the differing coordination numbers of the vanadium atom in the enzyme and in synthesized monoperoxo complexes. In the active site of the peroxo form, the five-coordinate vanadium atom, in a distorted tetragonal-pyramidal arrangement, is bound to the imidazole nitrogen atom of His496, two non-protein oxygen atoms and two peroxo oxygen atoms of the η^2-peroxo ligand.[8] In previous structurally characterized neutral, anionic or cationic monoperoxo complexes with predominantly seven-coordinate vanadium atom, [VO(O$_2$)*L*], and in anionic diperoxo complexes with six- or seven-coordinate vanadium atom, [VO(O$_2$)$_2$*L*]$^{n-}$, the mono- or polydentate heteroligand *L* used in the synthesis and the ligand bound to the vanadium atom are identical. We describe here the first (peroxo)vanadium(V) complex with heteroligand formed in situ. The reaction of vanadate(V) with H$_2$O$_2$ and *HEDTA* (**1**) in acidic aqueous solution did not result, as expected, in the formation and isolation of an oxo(peroxo)(*hedta*) complex of vanadium(V), but the monoperoxo complex with coordinated *N*-[2-(2-oxomorpholine-4-yl)ethyl]iminodiacetate(2−) (*omeida*) (**2**), K[VO(O$_2$)(*omeida*)]·H$_2$O, crystallized out.

2

The reactivity of (peroxo)vanadium(V) complexes as oxidants can be studied in the reaction with a thiolato or cysteinato complex of Co^{III}, in which the peroxo oxygen atom is transferred to the coordinated sulfur atom, while a sulfen-

ato complex is formed. We have previously determined the rate constants for this reaction using a series of structurally characterized monoperoxo complexes of vanadium(v) that have single-signal ^{51}V NMR spectra in aqueous solution.[6]

The interaction of vanadate with *HEDTA* in the absence of hydrogen peroxide was investigated by Crans et al.[9] Based on ^{51}V and ^{13}C NMR measurements they found that two species exist in aqueous vanadate/*HEDTA* solutions, in which the tetradentate *hedta* ligand coordinates to the vanadium atom either via two amino nitrogen atoms, and carboxylic and alkoxy oxygen atoms in alkaline solutions, or via nitrogen atoms and two carboxylic oxygen atoms in acidic or slightly alkaline solutions.

Results and Discussion

The IR spectrum of K[$VO(O_2)$(*omeida*)]·H_2O exhibits the characteristic bands observed for mono(peroxo)vanadium(v) complexes with coordinated deprotonated polycarboxylato ligands:[3,6,10–12] $\nu(V-O_p)$ at 562 (O_p = peroxo oxygen atom), $\nu(O_p\text{-}O_p)$ at 928, $\nu(V=O)$ at 947, $\nu_s(COO^-)$ at 1399, $\nu_{as}(COO^-) + \delta(H_2O)$ at 1616–1670 cm^{-1}. Moreover, it contains a sharp intense band at 1754 cm^{-1}, which is too high for the stretching vibration in uncoordinated COOH groups (1700–1720 cm^{-1}) – strongly indicating the presence of a "new" short C=O bond in the complex. This was confirmed by X-ray structure analysis which, surprisingly, showed that the heteroligand bound in the complex is not the anion of **1** but a derivative of morpholin-2-one (**2**). Thus, the IR band at 1754 cm^{-1}, which corresponds with the range 1747–1737 cm^{-1} reported for free δ-lactones,[13] and with 1750 cm^{-1} for 4-methylmorpholin-2-one,[14] can be assigned to a C=O stretching vibration in the coordinated *omeida* ligand [*d*(C8–O9) = 1.203(3) Å, Table 1].

Figure 1 illustrates the molecular structure of the [$VO(O_2)$(*omeida*)]$^-$ anion and Table 1 lists selected bond lengths and angles. The structure of [$VO(O_2)$(*omeida*)]$^-$ is mononuclear, with a distorted pentagonal-bipyramidal arrangement around the vanadium atom. The *omeida* dianion is coordinated as tetradentate ligand, providing an N_2O_2 donor set, and forming three five-membered chelate rings. Two carboxylate oxygen atoms, O4 and O6, are in *cis* positions of the bipyramid. Unlike in the [$VO(O_2)$(H*edta*)]$^{2-}$ ion,[15] these deprotonated and coordinated carboxylic oxygen atoms originate from carboxymethyl groups bound to the same N1 nitrogen atom. The pentagonal plane is formed by O2, O3 oxygen atoms of the η^2-peroxo ligand, N1, N2 nitrogen atoms occupying the *cis* positions, and carboxylic O4 oxygen atom. The apical positions of the bipyramid are occupied by doubly bonded oxo ligand O1 and deprotonated carboxylic O6 oxygen atoms. The average standard deviation of atoms from the pentagonal plane is 0.0515 Å. The vanadium atom is displaced from the plane towards the apical O1 oxygen atom by 0.2045(9) Å. This is less than the average value, 0.236 Å, found for other mono(peroxo)vanadium(v) complexes with polydentate aminopolycarboxylates.[3,6,16,17]

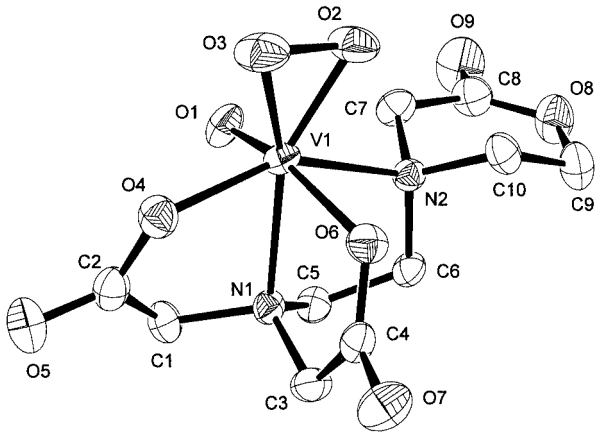

Figure 1. X-ray crystal structure of the anionic complex [$VO(O_2)$(*omeida*)]$^-$, showing the atomic numbering scheme; hydrogen atoms are omitted for simplicity; the ORTEP plot is drawn at a 50% probability

The generally observed *trans* effect, i.e. the elongation of the apical V–O6 bond *trans* to the short V–O1 bond when compared with the equatorial V–O4 distance, given by $\Delta d(V-O)$ = 0.058 Å, is also much less significant than in other polycarboxylato complexes with ligands that provide an NO_3 donor set [$\Delta d(V-O)$ = 0.073–0.200 Å],[6] and even in the (carboxymethyl)histidinato(2–) complex, K[$VO(O_2)$(*cmhist*)]·H_2O,[18] with $\Delta d(V-O)$ = 0.099 Å. The latter complex was previously the only structurally well-characterized peroxo complex with the same arrangement of N_2O_2 donor set atoms around the vanadium atom as in the complex studied here. Both in K[$VO(O_2)$(*cmhist*)]·H_2O and K[$VO(O_2)$(*omeida*)]·H_2O, the N2 atoms are from the heterocycles imidazole and morpholin-2-one, respectively.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The pentagonal bipyramid in $[VO(O_2)(omeida)]^-$ is not symmetric: the O2, O3 peroxo oxygen atoms deviate from the O1,V1,N1,O6 plane by 0.6354(29) and 0.7952(29) Å, respectively. Two glycinate rings, the almost planar "apical" one formed by V1, N1, C3, C4, O6 atoms (deviation of fitted atoms 0.0725 Å) and the "equatorial" one formed by V1, N1, C1, C2, O4 atoms (deviation of fitted atoms 0.2318 Å), are perpendicular (89.92°). Only one hydrogen bond between the oxygen atom of a water molecule and the uncoordinated O7 carboxylic oxygen atom with $d(H_w-O7)$ = 1.990(60) and $d(O_w-O7)$ = 2.797(3) Å has been found. Similarly, as in the (carbamoylethyl)iminodiacetato complex, $K[VO(O_2)(ceida)]\cdot 2H_2O$,[6] the potassium cation in $K[VO(O_2)(omeida)]\cdot H_2O$ is coordinated by seven oxygen atoms, one of a water molecule, three end-bonded carboxylic oxygen atoms (O5, O5, O7) of three different anions, and two carboxylic (O4, O6) and an O3 peroxo oxygen atoms coordinated to the same vanadium atom. The K−O distances range from 2.667(2) to 3.007(2) Å. The distance to the eighth oxygen atom, 3.428 Å, exceeds the 3.25 Å of any other higher coordination number.[19]

^{51}V NMR Measurements

All ^{51}V NMR spectra were measured at 278 K, the same temperature at which $K[VO(O_2)(omeida)]\cdot H_2O$ was synthesized. The ^{51}V NMR spectrum of a 0.015 M aqueous solution of $K[VO(O_2)(omeida)]\cdot H_2O$ (Figure 2, a), measured 7 min after dissolution, exhibits a single peak at δ = −515 ppm ($W_{1/2}$ = 450 Hz). This shift is unusually low for a heteroligand mono(peroxo)vanadate and it occurs in the region where, mostly, the chemical shifts for heteroligand dioxo complexes of vanadium(v) are observed.[20−23] However, the UV/Vis spectrum of the same solution exhibits the peroxo-to-vanadium CT band at λ_{max} = 439 nm (ε = 357 $mol^{-1}\cdot dm^3\cdot cm^{-1}$), which is within the 410−460 nm range typical for monoperoxo complexes of vanadium(v).[24,25] The chemical shift δ = −515 ppm can thus be assigned to the $[VO(O_2)(omeida)]^-$ ion **I** (Scheme 1). The presence of a single peak allows us to suggest that the molecular structure of the complex anion is maintained on dissolution. After 24 h, 95% of the vanadium is still in solution in the form of **I**, as well as a minor species with $\delta(^{51}V)$ = −567 ppm ($W_{1/2} \approx$ 260 Hz) (Figure 2, b), which we assign to an isomeric peroxo(*omeida*) complex **II**, because no absorbance decrease due to peroxo ligand decomposition was observed in the UV/Vis spectrum. The smaller $W_{1/2}$ value for **II** is in accordance with its higher symmetry when compared with **I** (Scheme 1). Further evidence for the assignment of **I** and **II** was provided by the ^{51}V NMR spectra of aqueous peroxovanadate/*HEDTA*, vanadate/*HEDTA* and peroxovanadate/*HEDTA*/*OMEIDA* solutions (*OMEIDA* = *N*-[2-(2-oxomorpholin-4-yl)ethyl]iminodiacetic acid), measured at the same pH as used in the synthesis.

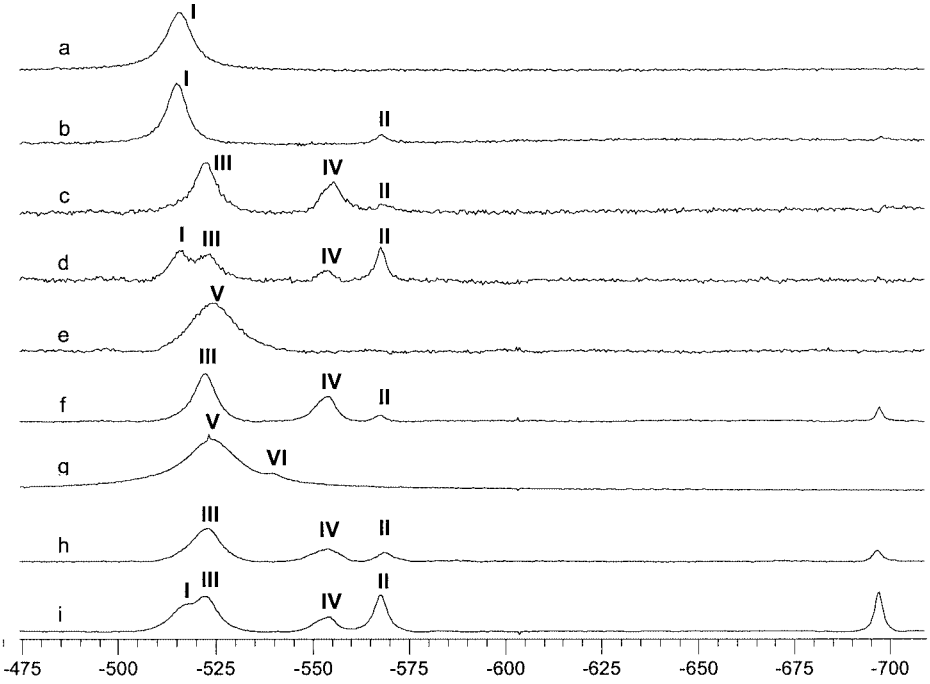

Figure 2. Selected ^{51}V NMR spectra of aqueous solutions at 278 K; a, b: 0.015 M $K[VO(O_2)(omeida)]\cdot H_2O$, (a) 7 min, (b) 24 h after dissolution; c, d: peroxovanadate/*HEDTA* solutions, (c) 15 min, (d) 5 d after preparation, concentrations: see Table 2; e, f: vanadate/*HEDTA* solutions, (e) 8 min to 70 h after preparation, (f) after addition of 1 mmol H_2O_2 to the solution (e) prepared 70 h before addition; g: vanadate/*HEDTA*/*OMEIDA* solutions, c(**3**ii) = 0.15 M, $c(KVO_3)$ = 0.075 M; h: peroxovanadate/*HEDTA*/*OMEIDA* (**3**i) solutions, c(**3**i) = 0.15 M, $c(KVO_3)$ = 0.075 M, $c(H_2O_2)$ = 0.225 M; i: peroxovanadate/*HEDTA*/*OMEIDA* (**3**ii) solutions, c(**3**ii) = 0.15 M, $c(KVO_3)$ = 0.075 M, $c(H_2O_2)$ = 0.225 M; pH(c−i) = 3.0

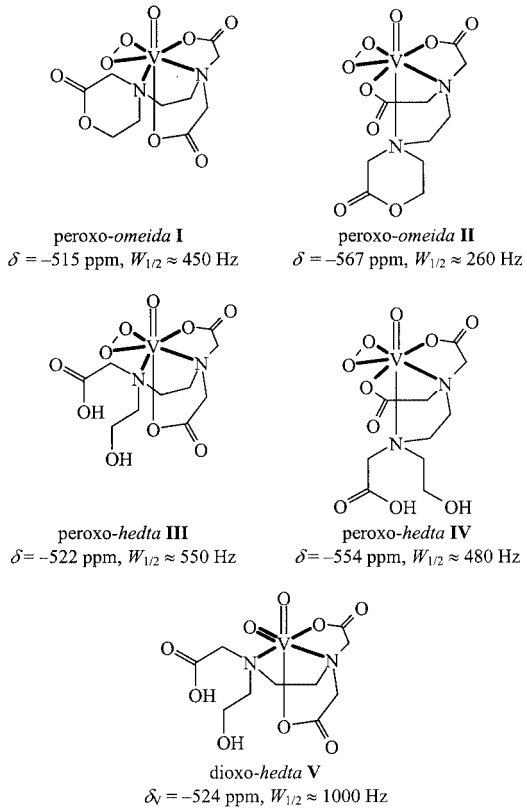

Scheme 1. ^{51}V NMR spectral characteristics and proposed structures of dioxo(*hedta*)-, monoperoxo(*hedta*)- and monoperoxo(*omeida*)vanadates formed in vanadate/*HEDTA*/H_2O and peroxovanadate/*HEDTA*/H_2O solutions

Peroxovanadate/HEDTA/H_2O Solutions (pH = 3)

Preparation: 0.225 mmol of H_2O_2 (0.022 mL, w = 30%) was added to 0.15 mmol of KVO_3, dissolved in H_2O (5 mL), and 0.3 mmol of *HEDTA* was then dissolved in the resultant solution. Before making up to the total volume of 10 mL, the pH was adjusted with 0.5 M KOH. Changes in the ^{51}V NMR spectrum of the peroxovanadate/*HEDTA*/H_2O solution with time allowed us to observe the formation of the peroxo(*hedta*) species and their subsequent transformation into the peroxo(*omeida*) complexes **I** and **II**. The spectrum measured 15 min after preparation of the solution (Figure 2, c) exhibits shifts of two dominant species at δ = −522 ppm (**III**) (I_{rel} = 63%, $W_{1/2}$ ≈ 550 Hz) and −554 ppm (**IV**) (I_{rel} = 31%, $W_{1/2}$ ≈ 480 Hz), and two minor species with shifts at δ = −567 ppm (I_{rel} ≈ 3%) and −697 ppm, the latter being the shift of the heteroligand-free diperoxo ion $[VO(O_2)_2(H_2O)_x]^-$.[26,27] We assign the major species **III** and **IV**, to isomeric monoperoxo(*hedta*) complexes (Scheme 1) formed immediately after mixing the solutions, which then undergo the lactone ring closure, while the monoperoxo(*omeida*) complexes **I** and **II** are formed. After 20 h, the peak at δ = −515 ppm corresponding to complex **I**, with known solid structure, appeared (I_{rel} = 11%), which after 5 d became the predominant species (I_{rel} = 40%). The increase of I_{rel}(**I** + **II**) for the monoperoxo(*omeida*) species with time is proportional to the decrease of I_{rel}(**III** + **IV**) for the monoperoxo(*hedta*) complexes (Table 2). This indicates that lactone formation under such mild conditions proceeds on the ligand coordinated to the $VO(O_2)^+$ moiety. Under same conditions, free *HEDTA* does not undergo cyclization, as evidenced by its unchanged ^{1}H NMR spectrum.

Table 2. Dependence of I_{rel} on time for monoperoxo(*omeida*) (**I**, **II**) and monoperoxo(*hedta*) (**III**, **IV**) complexes formed in peroxovanadate/*HEDTA*/H_2O solutions at pH = 3; conditions: T = 278 K, concentrations: 0.015 M vanadate, 0.03 M *HEDTA*, 0.023 M H_2O_2

Species	δ [ppm]	$W_{1/2}$ [Hz]	I_{rel} [%][a]					
			15 min	90 min	20 h	24.5 h	2 d	5 d
I	−515	ca. 520	–	–	11[b]	12[b]	19.5[b]	40[b]
II	−567	ca. 260	3	5.5	13	15.5	19	22.5
III	−522	550	63	60	48[b]	45[b]	39[b]	23[b]
IV	−554	480	31	29	24	20	18.5	13

[a] Difference between the sum of I_{rel} for **I**−**IV** and 100% corresponds to I_{rel} for $[VO(O_2)_2(H_2O)x]^-$. [b] Values obtained by deconvolution.

Vanadate/HEDTA/H_2O Solutions (pH = 3)

Preparation: 1 mmol of *HEDTA* was dissolved in 0.1 M KOH (4 mL), 0.5 mmol of KVO_3 (1 mL, 0.5 M) and 0.5 M KOH (0.4 mL) were added, and the total volume made up to 10 mL. Relevant data on the formation of the dioxo- and monoperoxo(*omeida*) complexes were also provided by changes in the ^{51}V NMR spectra of the vanadate/*HEDTA*/H_2O solutions with time, and spectra of the same solutions to which 1 mmol of H_2O_2 (0.1 mL, w = 30%) was added just before NMR measurements. The spectrum of the vanadate/*HEDTA*/H_2O solution, measured 8 min to 70 h after preparation of the solutions, remained unchanged (Figure 2, e). It exhibits a very broad single peak with δ = −524 ppm ($W_{1/2}$ ≈ 1200 Hz), which is similar to data observed for the $[VO_2(Hedta)]^{2-}$ ion (δ = −518 ppm, $W_{1/2}$ ≈ 1000 Hz).[23] We consider the species with δ = −524 ppm to be the dioxo(*hedta*) complex **V**, $[VO_2(hedta)]^{n-}$, which is identical to the species found by Crans[9] in vanadate/*HEDTA* solutions at 298 K in the pH range 5−9 (δ = −520 ppm, $W_{1/2}$ = 710 Hz). The shift by 4 ppm and the signal broadening (710 → 1200 Hz) is caused by the lower temperature in our measurements. In the complex **V**, the *hedta* ligand was proposed to be bound via two amino nitrogen atoms and two carboxylic oxygen atoms.[9] However, when H_2O_2 was added after 8 min, or after 8, 24 and 70 h to the prepared vanadate/*HEDTA*/H_2O solutions, the spectra (Figure 2, f) exhibited, besides the shift of $[VO(O_2)_2(H_2O)_x]^-$ (I_{rel} ≈ 4%), three peaks with identical chemical shifts and $W_{1/2}$ values to those for **II**, **III** and **IV** (Table 2). The small change in chemical shifts (−524 → −522 ppm) but the significant change in $W_{1/2}$ (1200 → 540 Hz), both evidently occurring in all spectra after the addition of H_2O_2, confirmed the formation of the dioxo- and peroxo(*hedta*) species before and after the addition of hydrogen peroxide, respectively. The relative intensities for

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

II−**IV** do not significantly change with the time of addition of H_2O_2, and were approx. 62% for **II**, 29% for **III**, and 5% for **IV**. Monoperoxo(*omeida*) complex **I** was not observed, even when H_2O_2 was added after 70 h to the vanadate/*HEDTA*/H_2O solution, i.e. after a time when a significant amount of **I** has formed in the peroxovanadate/*HEDTA*/H_2O solution (Table 2). Thus, lactone ring closure and the formation of peroxo(*omeida*) complex **I** from *HEDTA* is, under the given conditions, a slow process that proceeds only in the peroxovanadate solution.

Alkaline Solution of K[VO(O$_2$)(omeida)]·H$_2$O (pH = 8.5)

Preparation: 0.5 M KOH (0.2 mL) was added to 0.15 mmol of the complex, dissolved in H_2O (8 mL), and the volume made up to 10 mL. Generally, lactone rings open in alkaline media and, indeed, ring opening was observed in the NMR spectrum of a 15 mM aqueous solution of K[$VO(O_2)$(*omeida*)]·H_2O measured just 12 min after preparation. The spectrum's six peaks correspond to monoperoxo(*omeida*) complexes **I**, **II** (I_{rel} = 67, 7.5%, respectively), monoperoxo(*hedta*) complexes **III**, **IV** (I_{rel} = 11, < 1%, respectively), and two minor species with signals at δ = −499 ppm (I_{rel} = 3.5%) and −750 ppm (I_{rel} = 6%). The δ = −499 ppm shift corresponds to $[VO_2(hedta)]^{n-}$, with *hedta* coordinated in alkaline solutions (pH = 7−11) via the alkoxy group,[9] and the δ = −750 ppm shift to the diperoxovanadate species which exhibit, over a wide pH range (0.5−11), a strong pH dependence of δ values (−690 to −765 ppm).[26,28] After 8 h, I_{rel}(**I** + **II**) decreased to 33% and I_{rel}(**III** + **IV**) increased to 61%, whereas I_{rel} for the diperoxovanadate remained almost constant. These and previous measurements show that the pH change between 3.0 and 8.5 has no influence on the chemical shifts for **I**−**IV**. These constant chemical shifts over a wide pH range provide an additional indirect confirmation of the assignment for **III** and **IV**, because the shifts for mono- or dimeric vanadates with chemical shifts δ = −550 to −570 ppm, which could be also present in solution as uncomplexed vanadium forms, exhibit a pH dependence in the region discussed.[26]

Vanadate/HEDTA/OMEIDA/H$_2$O and Peroxovanadate/HEDTA/OMEIDA/H$_2$O solutions (pH = 3)

In a further series of experiments that confirmed the above conclusions, we measured the ^{51}V NMR spectra of vanadate and peroxovanadate solutions with *HEDTA*/*OMEIDA* heteroligand solution (**3**) prepared by: (i) refluxing for 20 h the 0.7 M aqueous solution of *HEDTA* (pH = 1, acidified with 1 M $HClO_4$) or (ii) refluxing the same solution for 25 h after it had stood for 3 weeks at room temperature. In such solutions, the formation of *OMEIDA* is expected, as the cyclization of chelating aminopolycarboxylic acids is favored by higher temperature and lower pH.[29] The vanadate/*HEDTA*/*OMEIDA*/H_2O solution for NMR measurements was prepared as follows; to avoid, in the absence of H_2O_2, the formation of $H_xV_{10}O_{28}^{(6-x)-}$ ions which have a poor complex formation ability, solution **3** (2 mL, 0.7 M) was mixed with 1.5 mL of alkalized 0.5 M KVO_3 (prepared by dissolving the metavanadate in 0.1 M KOH). The pH of the resulting solution was then adjusted to 3 by addition of 0.2 mL of 0.5 M KOH. The spectrum of vanadate/*HEDTA*/*OMEIDA*/H_2O solution prepared from **3**(i) exhibits a single shift at δ = −524 ppm ($W_{1/2}$ ≈ 1200 Hz). The spectrum of the same solution, however, prepared using the heteroligand solution **3**(ii) (Figure 2, g) gave on deconvolution two shifts, at δ = −524 ppm ($W_{1/2}$ ≈ 1250 Hz, I_{rel} = 86%) due to dioxo(*hedta*) complex **V**, and at δ = −539 ppm ($W_{1/2}$ ≈ 355 Hz, I_{rel} = 14%), which we assign to a dioxo(*omeida*) complex **VI**, $[VO_2(omeida)]^-$. The spectra of the peroxovanadate/*HEDTA*/*OMEIDA*/H_2O solutions (prepared in the same way but with addition of 0.23 mL of 30% H_2O_2) showed (Figure 2, h and i) that, with increased reaction time for lactone formation in **3**(i), with respect to **3**(ii), the sum of I_{rel} for monoperoxo(*omeida*) complexes (**I**, **II**) increased from 12 to 43%, while I_{rel} for the monoperoxo(*hedta*) species (**III**, **IV**) decreased from 81 to 41%. These results showed that *HEDTA* in solutions **3** was not completely transformed into *OMEIDA*, i.e. the lactone closure does not proceed easily in the absence of peroxovanadate even at high temperatures and long reaction times. *OMEIDA* has not yet been synthesized as a pure solid; only its dimethyl and diethyl esters are known.[30]

Reactivity of K[VO(O$_2$)(*omeida*)]·H$_2$O

Previously,[6,31] we investigated the kinetics of oxygen transfer reaction from the peroxo ligand in a series of (amino-polycarboxylato)- or (pyridinecarboxylato)monoperoxovanadates, $[VO(O_2)L]$, to the thiolato sulfur atom in $[Co(en)_2\{S(CH_2)_2NH_2\}]^{2+}$ as a pseudo-monomolecular reaction in excess of the vanadium complex [Equation (1)].

$$[VO(O_2)L] + [Co(en)_2\{S(CH_2)_2NH_2\}]^{2+} \rightarrow VO_2L + [Co(en)_2\{SO(CH_2)_2NH_2\}]^{2+} \quad (1)$$

The first-order rate constants at 298 K lead to the following sequence of increasing reactivity: $[VO(O_2)(ada)]^- < [VO(O_2)(ceida)]^- < [VO(O_2)(nta)]^{2-} < [VO(O_2)(quin)_2]^{3-} < [VO(O_2)(H_2O)_2(pic)]$, which correlates with the charge-transfer energy and temperature of active oxygen release. However, Equation (1) with $[VO(O_2)(omeida)]^-$ as oxidant provided some unexpected results. Under both pseudo-mono- and bimolecular reaction conditions, a linear increase of the sulfenato complex concentration with time was found, as is known for zero-order reactions. The same course of concentration change was also observed in a reaction solution from which dissolved dioxygen was bubbled out by nitrogen, and also in a solution kept out of the cell compartment, i.e. not irradiated by 371 nm light. The participation of molecular oxygen in the reaction, or photochemical effects, can thus be excluded. Even the 1:1 reaction of $[VO(O_2)(omeida)]^-$ with the cysteinato complex, $[Co(en)_2(cyst)]^+$, could not be evaluated as a bimolecular reaction, as the relationship between absorbance and time is given by $1/A = a - b \times \ln t$ (Figure 3).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

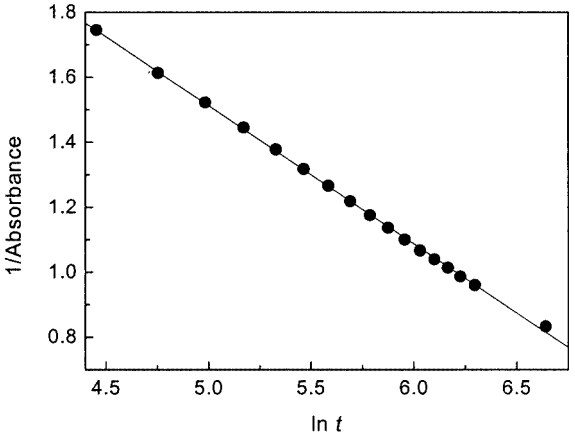

Figure 3. Reciprocal absorbance at 371 nm vs. ln[function of time] for 1:1 aqueous solution of $[VO(O_2)(omeida)]^-$ (**I**) and $[Co(en)_2(cyst)]^+$; c = 0.0007 M, T = 298.2 K, measured in a closed 1-cm cell under nitrogen

We further investigated the interaction of $[VO(O_2)(omeida)]^-$ with *N*-acetyl-L-cysteine at 37 °C. This is of interest with respect to the insulin mimetic properties of vanadium(IV) and -(V) complexes, which include (carboxymethyl)aspartato(3−) complex, $K_2[VO(O_2)(cmaa)(H_2O)]$, prepared according to the literature[32,33] and which have been recently studied in vitro by Rehder et al.[34] The biological activity of *N*-acetyl-L-cysteine, which, for example, inhibits the phosphorylation of tyrosine in cellular proteins caused by peroxovanadates,[35] has an important effect in chronic bronchitis[36] or improves by increased oxygen delivery the survival of patients with hepatic failure.[37] The changes in the UV/Vis spectrum of a 1:5 solution of $[VO(O_2)(omeida)]^-$ and N-acetyl-L-cysteine with time showed that about one-third of the $[VO(O_2)(omeida)]^-$ was decomposed in 6 h. The concentration decrease with time is linear even in this reaction (Figure 4).

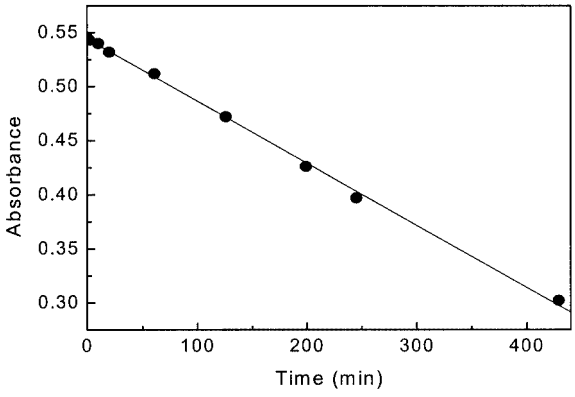

Figure 4. Absorbance at 440 nm vs. time for 1:5 aqueous solution of $[VO(O)_2(omeida)]^-$ (**I**) and *N*-acetyl-L-cysteine; c = 0.0015 and 0.0075 M, respectively; T = 310 K, measured in closed 1-cm cell under nitrogen

The absorbance changes linearly up to a high degree of conversion, i.e. for more than just the initial phase of reaction, where linearity of the measured property is common. These reactions obviously exhibit "mixed kinetics", i.e. the observed absorbance change corresponds to several reaction types. The mechanism of oxidation, both of Co^{III} complexes and *N*-acetyl-L-cysteine by $[VO(O_2)(omeida)]^-$, is thus more complicated than that found for other heteroligand monoperoxo complexes of vanadium(V).[31] A detailed kinetic study is needed to elucidate the reaction mechanism.

Conclusions

The reaction of aqueous peroxovanadate with *HEDTA* resulted in the formation and isolation of a crystalline monoperoxo complex of vanadium(V) with the dianion of *OMEIDA*, $K[VO(O_2)(omeida)]\cdot H_2O$. The crystal structure determination revealed that the vanadium atom in $[VO(O_2)(omeida)]^-$ is in a typical distorted pentagonal-bipyramidal arrangement, and is coordinated by oxygen atoms of the oxo and η^2-peroxo ligands, and by N_2O_2 donor set atoms of the tetradentate *omeida* heteroligand. ^{51}V NMR measurements showed that the heteroligand is formed in situ (pH = 3, 278 K) only in peroxovanadate but not vanadate solutions. The ^{51}V NMR spectra revealed two isomeric monoperoxo(*hedta*) complex anions and their transformation into isomeric monoperoxo(*omeida*) complexes. The $VO(O_2)(omeida)]^-$ ion as oxidant in the reaction with thiolato or cysteinato complexes of Co^{III} and with *N*-acetyl-L-cysteine, both under pseudo-mono- or bimolecular conditions, showed unusual kinetic behaviour: linear concentration changes with time. The elucidation of the reaction mechanism requires a further kinetic study.

Experimental Section

General Remarks: The FT IR spectrum (Nujol mull) was registered with a Nicolet Magna 750 spectrometer. The NMR spectra were recorded with a Varian Gemini 2000 spectrometer (300 MHz for ^1H). ^{51}V NMR spectra were recorded at 78.879 MHz in a 5-mm diameter NMR vial and with a capillary with D_2O immersed in the measured aqueous solution. Typical parameters were: sweep width 32 kHz, line broadening factor 20 Hz, acquisition time of 63 ms with a relaxation delay 10 ms. The chemical shifts are related to $VOCl_3$ as external standard. The V NMR 6.1 program was used to deconvolute spectra between δ = −490 and −530 ppm. The ^1H NMR spectra in D_2O were obtained by using standard parameters. The UV/vis spectral and kinetic measurements were performed with a Hewlett−Packard 8452 spectrometer with a thermostatted (±0.1 °C) compartment. ^1H NMR data of *HEDTA*: (278 K, c = 0.01 M): δ = 3.873 (s, a), 3.831 (t, b), 3.495 (t, c), 3.337 (t, e), 3.723 (s, f) (lettered according to formula **1**).

Synthesis of $K[VO(O_2)(omeida)]\cdot H_2O$: KVO_3 (0.28 g, 2 mmol), prepared from V_2O_5 and KOH at pH ≈ 8, was dissolved under heating in water (10 mL). The solution was then ice-cooled and H_2O_2 (0.3 mL, 30%; Slavus, Slovakia) was added. To the resulting red peroxovanadate solution, *HEDTA* (0.56 g, 2 mmol; Aldrich) was added in small portions whilst stirring. The pH was adjusted to 3.0 with 2 M KOH, and ethanol (15 mL) was added dropwise to initiate the crystallization. The small amount of initially formed orange

precipitate dissolved within 24 h. From the refrigerated solution (5 °C), kept in closed vessel, very dark red crystals of K[VO(O_2)(*omeida*)]·H_2O crystallized out within 2 weeks. Yield: 0.26 g, 31.5%. Monocrystals suitable for X-ray analysis were obtained by crystallization from the first filtrate. After isolation, the product was washed with cooled ethanol (5 °C) and dried over silica gel at 5 °C. The peroxo complex formed is very stable in the reaction solution: we have obtained identical products even on subsequent crystallization from the mother solution within three months. The repeated CHN analysis and IR spectra showed that the solid complex is stable for several months when kept at 5 °C. $C_{10}H_{16}KN_2O_{10}V$ (414.3): calcd. C 28.96, H 3.89; K 9.44, N 6.76, O_2^{2-} 7.72; found C 28.66, H 3.77, K 8.98, N 6.44, O_2^{2-} 7.62. C, H and N contents were determined with a Carlo−Erba 1106 analyzer, peroxide by iodometric titration and potassium by flame photometry (Flapho 4, Zeiss Jena). IR: $\tilde{\nu}$ = 422 vw, 431 w, 494 m, 530 m, 562 s, 596 w, 657vw, 730 m, 743 m, 814 m, 883 s, 928 vs, 947 vs, 972 w, 987 m,1010 w, 1077 w, 1064 w, 1064 vw, 1094 s, 1115 w,1129 vw, 1167 vw, 1222 s, 1248 w, 1265 s, 1283 m, 1300s, 1318 s, 1339 m, 1353 s, 1399 vs, 1488 w, 1616 vs, 1643 vs, 1671 vs sh, 1731 m, 1754 vs, 3367 s, 3544 m cm^{-1}.

Kinetic Measurements: Oxidation of the thiolato and cysteinato complexes, $[Co(en)_2\{S(CH_2)_2NH_2\}]^{2+}$ and $[Co(en)_2(cyst)]^+$, was monitored at 371 nm, corresponding to absorption maximum for the sulfenato complex formed. $[Co(en)_2\{S(CH_2)_2NH_2\}](ClO_4)_2$ and $[Co(en)_2(cyst)]ClO_4$ were synthesized according to published procedures.[38,39] The reaction with *N*-acetyl-L-cysteine was monitored at the wavelength of absorption maximum for $[VO(O_2)(omeida)]^-$ (440 nm).

X-ray Crystallographic Study: The X-ray measurements were taken at 293 K with a KUMA CCD diffractometer with graphite-monochromated Mo-K_α radiation by using the ω-2θ scan technique. No significant decay of the intensity was observed. The data were not corrected for absorption effects. Some 2246 reflections with $I > 2\sigma_I$, of all unique reflections obtained, were classified as observed. Crystallographic data for K[VO(O_2)(*omeida*)]·H_2O: dark red crystals, 293(2) K, $KVC_{10}H_{16}N_2O_{10}$, M_r = 414.29, monoclinic, a = 18.0558(12), b = 6.9241(4), c = 12.0978(8) Å, β = 99.695°, V = 1490.9(2) $Å^3$, Z = 4, space group $P2_1/c$, $D_{calcd.}$ = 1.846 g/cm^3, λ = 0.71073 Å, $R1$ = 0.0323, $wR2$ = 0.0866, $R1 = F_o - F_c/F_o$, $wR2 = \{[w(||F_o|^2 - |F_c|^2|)^2]/[w(F_o^4)]\}^{1/2}$. CCDC-178735 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Extended X-ray Absorption Fine Structure Study of Copper(I) and Copper(II) Complexes in Atom Transfer Radical Polymerization

Tomislav Pintauer,[a] Ulrich Reinöhl,[b] Martin Feth,[b] Helmut Bertagnolli,[b] and Krzysztof Matyjaszewski*[a]

Keywords: EXAFS spectroscopy / Copper / Radical reactions / Polymerizations

Extended X-ray Absorption Fine Structure (EXAFS) spectroscopy has been used to investigate structural features of Cu^{I}-Br and $Cu^{II}Br_2$ complexes with dNbpy, PMDETA, Me_6TREN, tNtpy, and Me_4CYCLAM in various solvents {dNbpy = 4,4′-bis(5-nonyl)-2,2′-bipyridine, PMDETA = *N*,*N*,*N*′,*N*′′,*N*′′-pentamethyldiethylenetriamine, Me_6TREN = tris[2-(dimethylamino)ethyl]amine, tNtpy = 4,4′,4′′-tris(5-nonyl)-2,2′:6′,2′′-terpyridine, Me_4CYCLAM = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane}. The structures of the Cu^{I} and Cu^{II} complexes were found to depend on the solvent polarity and the number of nitrogen atoms in the ligand. Generally, in non-polar media and with monomers typically used in ATRP, Cu^{I} complexes preferred a tetracoordinate geometry, and were either ionic as observed in $[Cu^{I}(dNbpy)_2]^+[Cu^{I}Br_2]^-$ (Cu^{I}–N_{AV} = 2.00 Å, Cu^{I}–Br_{AV} = 2.25 Å) and $[Cu^{I}(Me_4CYCLAM)]^+[Cu^{I}Br_2]^-$ (Cu^{I}–N_{AV} = 2.06 Å, Cu^{I}–Br_{AV} = 2.23 Å), or neutral as in $[Cu^{I}$(PMDETA)Br] (Cu^{I}–N_{AV} = 2.12 Å, Cu^{I}–Br_{AV} = 2.33 Å), and $[Cu^{I}$(tNtpy)Br] (Cu^{I}–N_{AV} = 2.03 Å, Cu^{I}–Br_{AV} = 2.29 Å). The EXAFS analysis of $Cu^{II}Br_2$ complexes indicated a preference for a coordination number of five, such as in $[Cu^{II}(dNbpy)_2Br]^+[Br]^-$ (Cu^{II}–N_{AV} = 2.03 Å, Cu^{II}–Br_{AV} = 2.43 Å), $[Cu^{II}(PMDETA)Br_2]$ (Cu^{II}–N_{AV} = 2.03 Å, Cu^{II}–$Br_{1,AV}$ = 2.44 Å, Cu^{II}–$Br_{2,AV}$ = 2.64 Å) and $[Cu^{II}(Me_6TREN)Br]^+[Br]^-$ (Cu^{II}–N_{AV} = 2.09 Å, Cu^{II}-Br_{AV} = 2.39 Å), with the exception of the neutral tetracoordinate $[Cu^{II}(dNbpy)Br_2]$ (Cu^{II}–N_{AV} = 2.02 Å, Cu^{II}–Br_{AV} = 2.36 Å), which has been observed in non-polar media. Additionally, polar media were found to favor bromide dissociation in $[Cu^{II}(Me_6TREN)Br]^+[Br]^-$ and $[Cu^{II}(PMDETA)Br_2]$, as indicated by a decrease in the Br and Cu coordination numbers at the Cu- and Br-*K*-edges, respectively.

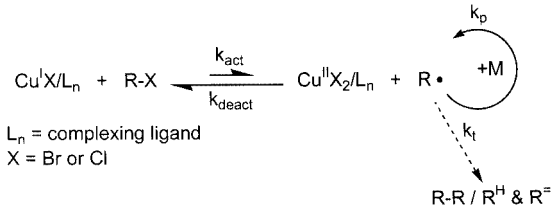
Introduction and Background

The synthesis of macromolecules with well-defined compositions, architectures, and functionalities represents an ongoing effort in the field of polymer chemistry. Over the past few years, atom transfer radical polymerization (ATRP) has emerged as a very powerful and robust technique to meet these goals.[1−6] The basic working mechanism of ATRP (Scheme 1) involves a reversible switching between two oxidation states of a transition metal complex.[3,7,8] Typically, a copper(I) halide is used in conjunction with a nitrogen-based ligand (Scheme 2).[9,10]



Scheme 1. Proposed mechanism for ATRP

Homolytic cleavage of the alkyl halide bond (R−X) by the Cu^{I} complex generates an alkyl radical R· and the corresponding Cu^{II} complex. The radical R· can either (a) propagate with a propagation rate constant k_p, by adding across the double bond of a vinyl monomer, (b) terminate by either coupling or disproportionation (k_t), or (c) be reversibly deactivated by the Cu^{II} complex (k_{deact}). Since the position of equilibrium is strongly shifted towards the dormant species ($k_{act} << k_{deact}$), radical termination is suppressed. As a result of the persistent radical effect,[11,12] polymers with predictable molecular weights, narrow molecular-weight distributions and high functionalities have been synthesized.[13]

Structural and mechanistic studies are crucial in understanding this mechanism further and are inherently part of the future developments of ATRP. Correlation of the catalyst structure[14−19] with reaction parameters such as the activation and deactivation rate constants[20−24] can lead to a development of more active catalysts and controlled polymerization of less reactive monomers (e.g. vinyl esters). Furthermore, systematic evaluation of the concurrent reac-

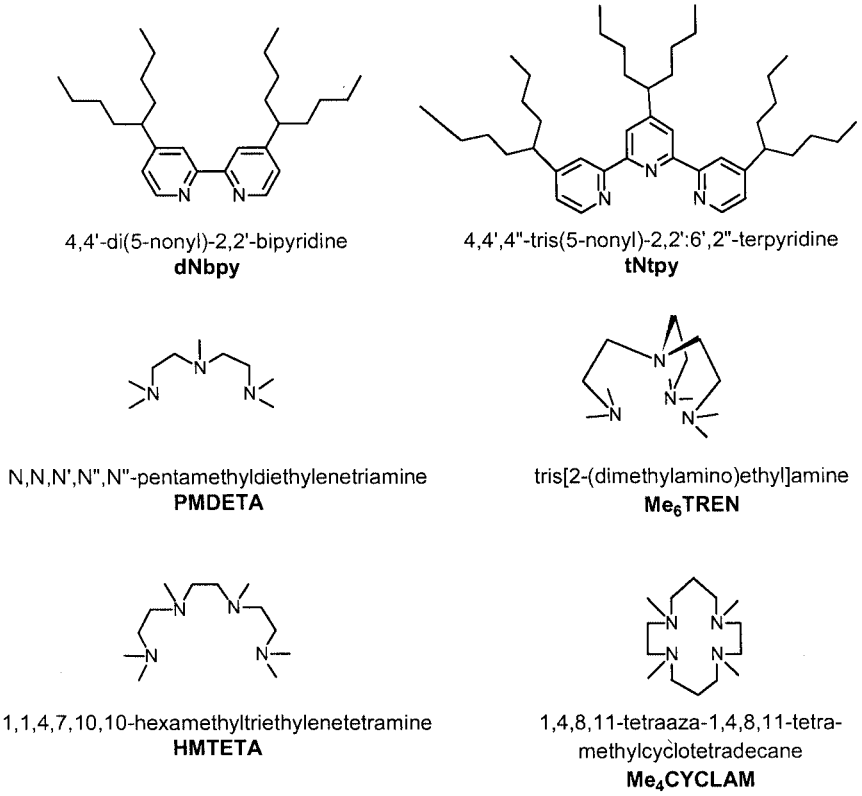

Scheme 2. Nitrogen-based ligands typically used in copper-mediated ATRP

tions that might occur in ATRP such as radical, monomer or solvent coordination[25] to the active catalysts, as well as transfer reactions associated with the ligand,[26−28] can provide much needed information about how to extend polymerization control to even higher molecular weight polymers, and generally improve the overall catalytic process.

Extended X-ray Absorption Fine Structure (EXAFS) spectroscopy has been shown to be a powerful technique for determining the structures of transition metal complexes in both the solid state and in solution.[29−32] An analysis of the EXAFS spectrum provides information on the bond lengths, the coordination number and the nature of the scattering atoms surrounding an excited atom.[33,34] In this paper, we report the results of an EXAFS spectroscopic study of $Cu^{I}Br$ and $Cu^{II}Br_2$ complexes with 4,4′-bis(5-nonyl)-2,2′-bipyridine (dNbpy), 4,4′,4′′-tris(5-nonyl)-2,2′:6′,2′′-terpyridine (tNtpy), *N*,*N*,*N*′,*N*′′,*N*′′-pentamethyldiethylenetriamine (PMDETA), tris[2-(dimethylamino)ethyl]amine (Me_6TREN) and 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane (Me_4CYCLAM) in various solvents. The structures reported by EXAFS spectroscopy are primarily based on the interatomic distances around the absorber and their comparison with the structurally isolated and characterized model compounds. Due to the inherent errors in determination of the coordination numbers, the reported structures might also represent the average structures in solution. Therefore the possibility of the presence of other species that might co-exist in equilibrium cannot be excluded.

Results and Discussion

Model Complexes

In order to test the applicability and accuracy of EXAFS spectroscopic analysis in determining the structures of $Cu^{I}Br$ and $Cu^{II}Br_2$ complexes with nitrogen-based ligands, we have conducted measurements at Cu- and Br-*K*-edges for a series of complexes in the solid state for which the molecular structures are known. Table 1 shows the comparison between experimental bond lengths from EXAFS measurements at room temperature with distances derived from the single-crystal X-ray structures of $Cu^{I}Br$ and $Cu^{II}Br_2$ complexes with nitrogen-based ligands. Solid-state samples of $[Cu^{I}(bpy)_2]^{+}[ClO_4]^{-}$ [35] were used to model tetrahedral complexes, $[Cu^{I}(Me_6TREN)]^{+}[ClO_4]^{-}$ [36] for trigonal-bipyramidal complexes, $[Cu^{I}(bpy)Br]_2$[37] for bridged complexes, and $[N(C_4H_9)_4]^{+}[Cu^{I}Br_2]^{-}$ [38] for linear Cu^{I} complexes. Additionally, $[Cu^{II}(bpy)_2Br]^{+}[BF_4]^{-}$ [39] and $[Cu^{II}Br(Me_6TREN)]^{+}[Br]^{-}$ [40] were used as model compounds for trigonal-bipyramidal complexes, whilst $[Cu^{II}(PMDETA)Br_2]$[41] and $[Cu^{II}(terpy)Br_2]$[14,42] were used to model distorted square-pyramidal Cu^{II} complexes. As shown in Table 1, a good agreement has been observed between the distances determined by EXAFS and X-ray crystallography, confirming the accuracy of the EXAFS analysis.

The corresponding coordination numbers were also determined by iterative fitting. Typically, the error for the coordination number is about 10−15% when the peaks in the Fourier-transformed spectra are well resolved and separated

Table 1. Comparison of experimental bond lengths [Å] from EXAFS measurements at room temperature with distances in the single-crystal X-ray structures; coordination numbers were fixed to the crystallographically derived values

Complex	Cu−N_{AV} [Å] EXAFS	Cu−N_{AV} [Å] X-ray	Cu−Br_{AV} [Å] EXAFS	Cu−Br_{AV} [Å] X-ray
$[Cu^{I}(bpy)_2]^+[ClO_4]^-$ [35]	1.98	2.02		
$[Cu^{I}(Me_6TREN)]^+[ClO_4]^-$ [36]	2.13	2.16		
$[Cu^{I}(bpy)Br]_2$ [37]	2.10	2.09	2.44	2.44
			2.25	2.23
$[N(C_4H_9)_4]^+[Cu^{I}Br_2]^-$ [38]				
$[Cu^{II}(bpy)_2Br]^+[BF_4]^-$ [39]	2.01	2.04	2.41	2.42
$[Cu^{II}Br(Me_6TREN)]^+[Br]^-$ [40]	2.09	2.11	2.39	2.39
$[Cu^{II}(PMDETA)Br_2]$[41]	2.09	2.10	2.44, 2.64	2.45, 2.64
$[Cu^{II}(terpy)Br_2]$[42]	2.02	2.01	2.45	2.49

{e.g. in $[Cu^{I}(bpy)_2]^+[ClO_4]^-$ $CN(N)_{fit}$ = 3.7, r_{fit} = 1.98 Å, $CN(N)_{X\text{-}ray}$ = 4.0, $r_{X\text{-}ray}$ = 1.98 Å}. In the case of significant overlapping of the peaks, the error in the coordination number can amount to 30% {e.g. in $[Cu^{II}(bpy)_2Br]^+[BF_4]^-$ $CN(N)_{fit}$ = 2.7, r_{fit} = 2.00 Å, $CN(N)_{X\text{-}ray}$ = 4.0, $r_{X\text{-}ray}$ = 2.01 Å and $CN(Br)_{fit}$ = 0.7, r_{fit} = 2.40 Å, $CN(Br)_{X\text{-}ray}$ = 1.0, $r_{X\text{-}ray}$ = 2.41 Å}. However, the distances determined either by iterative fitting or fitting with fixed coordination numbers agree within 1% with the distances measured by X-ray crystallography. Therefore, since the error range for the coordination numbers is significantly larger than the accuracy of the distances, the interpretation of the following systems is mainly based on the determined distances and their comparison with the model compounds.

$Cu^{I}Br$ and $Cu^{II}Br_2$ Complexes with the dNbpy Ligand

Unsubstituted 2,2′-bipyridine was the first ligand used in copper-mediated ATRP.[9] Alkyl substitutions in the 4- and 4′-positions of the bipyridine ring, such as in dNbpy (Scheme 2) further improved the solubility of the catalyst in non-polar media, which resulted in higher conversions with very low polydispersities.[43] Table 2 shows the summary of room-temperature EXAFS spectroscopic measurements, in different solvents, of $Cu^{I}Br$ and $Cu^{II}Br_2$ complexes with the dNbpy ligand.

The EXAFS spectrum of the $Cu^{I}Br$ complex with 1 equiv. of dNbpy in styrene is well fit using the structural model in which the Cu^{I} center is coordinated by 3.8 nitro-

Table 2. Structural parameters of $Cu^{I}Br$ and $Cu^{II}Br_2$ complexes with dNbpy ligand, determined by EXAFS measurements under ambient conditions at the Cu- and Br-*K*-edge; MA = methyl acrylate

gen atoms at a distance of 2.01 Å and 1.1 bromine atoms at a distance of 2.25 Å. The results in methyl acrylate are analogous, indicating similar structural features for the complex. Furthermore, when 2 equiv. of dNbpy were used relative to $Cu^{I}Br$, the average $Cu^{I}-N$ and $Cu^{I}-Br$ distances did not change significantly, although the coordination number of nitrogen appears to be lower than in solutions that contained only 1 equiv. of dNbpy. Taking into account the inherent error of 10−30% for the coordination numbers and 1% for the distances, the most plausible species in non-polar media is the ionic complex $[Cu^{I}(dNbpy)_2]^+[Cu^{I}Br_2]^-$. The neutral complex $[Cu^{I}(dNbpy)Br]_2$ can be ruled out since $Cu^{I}-Br$ bond lengths in Br-bridged Cu^{I} complexes are typically 2.4−2.5 Å (Table 1).[37] The average $Cu^{I}-N$ bond length in the $[Cu^{I}(dNbpy)_2]^+$ cation (2.01 Å) is consistent with the average $Cu^{I}-N$ bond lengths in bpy derivatives such as $[Cu^{I}(bpy)_2]^+[ClO_4]^-$ [35] (2.021 Å), $[Cu^{I}(6,6'\text{-}Me_2\text{-}bpy)_2]^+[BF_4]^-$ [44] (2.032 Å) and $[Cu^{I}(4,4'\text{-}Me_2\text{-}bpy)_2]^+[Br]^-$ [45] (2.035 Å). Furthermore, the $Cu^{I}-Br$ bond length in the linear $[Cu^{I}Br_2]^-$ anion (2.25 Å) is similar to that seen in related complexes such as $[N(C_4H_9)_4]^+[Cu^{I}Br_2]^-$ [38] (2.226 Å), $[P(C_6H_5)_4]^+[Cu^{I}Br_2]^-$ [46] (2.214 Å) and $[Cu^{I}(phen)_2]^+[Cu^{I}Br_2]^-$ [47] (2.216 Å).

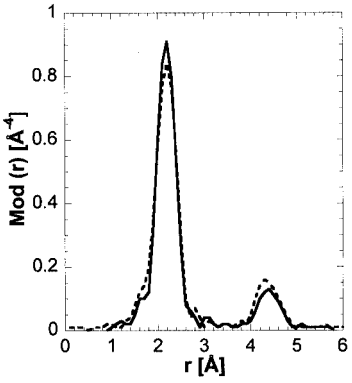

Figure 1. Comparison of the experimental Fourier transformed $k^3\chi(k)$ functions at the Br-*K*-edge of $Cu^{I}Br$/dNbpy in toluene (solid line) and $[N(C_4H_9)_4][Cu^{I}Br_2]$ in the solid state (broken lines)

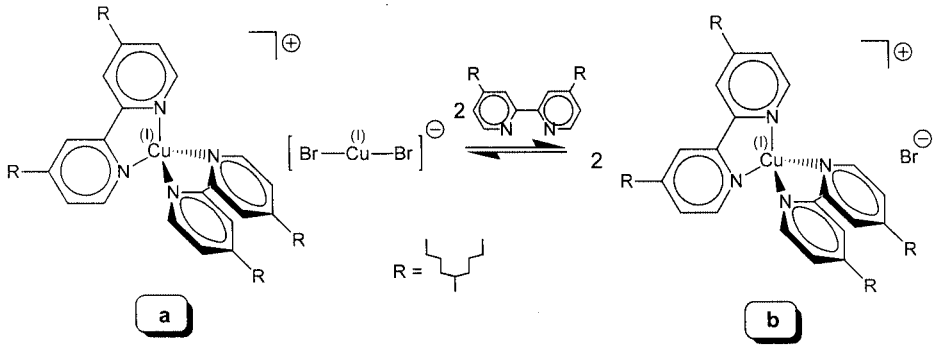
Figure 1 shows the Fourier transformations of the EXAFS functions at the Br-*K*-edge of the $Cu^{I}Br$/2dNbpy complex in toluene and of $[N(C_4H_9)_4]^+[Cu^{I}Br_2]^-$ in the solid state. The similarity of the two spectra further suggests the presence of $[Cu^{I}Br_2]^-$ anions in the $Cu^{I}Br$/(2)dNbpy complex in non-polar media, which is consistent with the proposed species $[Cu^{I}(dNbpy)_2]^+[Cu^{I}Br_2]^-$.

We have investigated the complexation between $Cu^{I}Br$ and dNbpy in non-polar media previously by Electrospray Ionization Mass Spectrometry (ESI-MS)[48] and EXAFS spectroscopy.[15] ESI-MS spectra of $Cu^{I}Br$ complexed with 1 or 2 equiv. of dNbpy in toluene, methyl acrylate, or styrene showed only the presence of the $[Cu^{I}(dNbpy)_2]^+$ cation and the $[Cu^{I}Br_2]^-$ anion, which is consistent with the proposed species, $[Cu^{I}(dNbpy)_2]^+[Cu^{I}Br_2]^-$. Furthermore, the EXAFS analysis at the Cu-*K*-edge also indicated the presence of $[Cu^{I}(dNbpy)_2]^+[Cu^{I}Br_2]^-$. Recently, the molecular structure of a related bpy-based ATRP active catalyst, $[Cu^{I}(dNEObpy)_2]^+[Cu^{I}Br_2]^-$ (dNEObpy = 4,4′-bis{[dimethyl(neophyl)silyl]methyl}-2,2′-bipyridine) further confirmed this unusual 1:1 stoichiometry in non-polar media between $Cu^{I}Br$ and bpy based ligands.[17]

Taking into account the inherent error in determining the coordination numbers by EXAFS spectroscopy (10−30%), $[Cu^{I}(dNbpy)_2]^+[Cu^{I}Br_2]^-$ might not be the only complex present in solution. Consequently, the possibility of more than one species co-existing in equilibrium cannot be excluded. Depending on the temperature, solvent polarity, and the amount of dNbpy, the substitution of Br in $[Cu^{I}Br_2]^-$ by dNbpy may lead to the formation of $[Cu^{I}(dNbpy)_2]^+[Br]^-$ (Scheme 3).

A similar equilibrium has been proposed earlier for $[Cu^{I}(dNEObpy)_2]^+[Cu^{I}Br_2]^-$.[17] Additionally, solvent and monomer coordination to the Cu^{I} center[49] cannot be ruled out due to the limited sensitivity of EXAFS measurements.[32] More experimental evidence is therefore needed to further characterize this system.

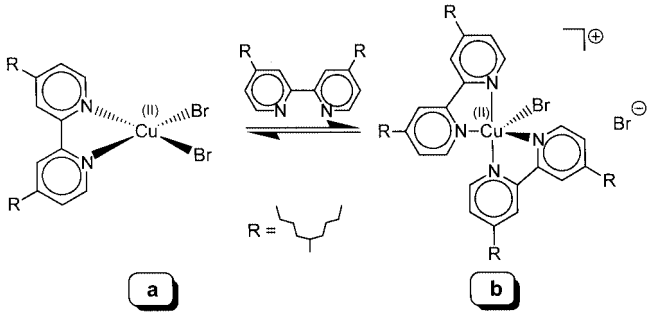
The results of the EXAFS spectroscopic analysis of the $Cu^{II}Br_2$ complex with 2 equiv. of dNbpy in methyl acrylate (Table 2) indicate that the coordination sphere around the Cu^{II} center consists of 1.4 N atoms at a distance of 2.01 Å and 1.5 Br atoms at a distance of 2.37 Å (a carbon backscatterer was used in the analysis in order to increase the accuracy of the fit). In toluene, the average $Cu^{II}-N$ and $Cu^{II}-Br$ distances did not change significantly, but the coordination numbers of N and Br increased to 1.8 and 2.1, respectively. In a more polar solvent, such as methanol, the coordination number of N increased even further to 2.8, and that of Br decreased to 0.6. Furthermore, the decrease



Scheme 3. Proposed structures for the $Cu^{I}Br$/(2)dNbpy complex in (a) non-polar and (b) polar media

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the Br coordination number was accompanied by an increase in the average $Cu^{II}-Br$ bond length from 2.37 to 2.43 Å. In non-polar media such as toluene and methyl acrylate, the results of the EXAFS spectroscopic measurements are consistent with the neutral complex $[Cu^{I}-{}^{I}(dNbpy)Br_2]$ which has been isolated and characterized previously.[16] In the solid state, $[Cu^{II}(dNbpy)Br_2]$ has a distorted square-planar geometry. The Cu^{II} center is coordinated by the two nitrogen atoms of a single dNbpy ligand ($Cu^{II}-N_{AV}$ = 2.017 Å) and to two bromine atoms ($Cu^{II}-Br_{AV}$ = 2.359 Å). $[Cu^{II}(dNbpy)Br_2]$ undergoes bromide substitution by dNbpy to form the ionic complex $[Cu^{II}(dNbpy)_2Br]^+[Br]^-$, which is strongly favored a in more polar medium such as methanol (Scheme 4).



Scheme 4. Proposed structures for the $Cu^{II}Br_2$/(2)dNbpy complex in (a) non-polar and (b) polar media based on EXAFS measurements

The average $Cu^{II}-N$ (2.03 Å) and $Cu^{II}-Br$ (2.43 Å) bond lengths of $[Cu^{II}(dNbpy)_2Br]^+[Br]^-$ in methanol, as determined by EXAFS, are in good agreement with the average distances in the structurally characterized compounds $[Cu^{II}(bpy)_2Br]^+[Br]^-$ [50] ($Cu^{II}-N_{AV}$ = 2.034 Å, $Cu^{II}-Br$ = 2.429 Å), $[Cu^{II}(bpy)_2Br]^+[PF_6]^-$ [39] ($Cu^{II}-N_{AV}$ = 2.044 Å, $Cu^{II}-Br$ = 2.467 Å) and $[Cu^{II}(dNbpy)_2Br]^+[Cu^{I}Br_2]^-$ [14] ($Cu^{II}-N_{AV}$ = 2.016 Å, $Cu^{II}-Br$ = 2.426 Å). Additionally, as ΔH and ΔS for the equilibrium reaction in Scheme 4 were found to be negative, an increase in the temperature favors formation of the neutral complex $[Cu^{II}(dNbpy)Br_2]$. It was determined that under the typical initial reverse ATRP conditions [$T \geq 90$ °C and total copper(II) concentration in the range 1.0×10^{-2} to 1.0×10^{-1} M], the $Cu^{I}-{}^{I}Br_2$ complex and 2 equiv. of dNbpy will predominantly form the neutral complex $[Cu^{II}(dNbpy)Br_2]$.[16]

We have previously investigated the complexation between $Cu^{II}Br_2$ and dNbpy in non-polar media, including monomers that are typically used in ATRP. Based on the EXAFS[15] and ESI-MS[48] study, we proposed the formation of a 1:1 complex, $[Cu^{II}(dNbpy)_2Br]^+[Cu^{II}Br_3]^-$. The structure was primarily based on the relative intensities of the absorbance peaks in the ESI-MS spectra since both species have, on average, the same atomic distances as derived from the EXAFS measurements. The absence of the charge in $[Cu^{II}(dNbpy)Br_2]$ may be responsible for its weak intensity. This could consequently lead to the wrong conclusion about the most probable structure in solution.

$Cu^{I}Br$ and $Cu^{II}Br_2$ Complexes with the PMDETA Ligand

Apart from substituted bipyridines, other linear and cyclic amines were successfully used as ligands in the formation of ATRP catalysts.[51−55] In particular, commercially available tridentate PMDETA (Scheme 2) showed a high potential for the controlled polymerization of a variety of monomers. Typically, the ligand/copper(I) halide ratio used in the polymerization was 1:1. Shown in Table 3 is a summary of the room-temperature EXAFS measurements of $Cu^{I}Br$ and $Cu^{II}Br_2$ complexes with 1 equiv. of PMDETA in different solvents, including monomers typically used in ATRP. The typical experimental and calculated Fourier transformations of the EXAFS spectra for the $Cu^{I}Br$/PMDETA and $Cu^{II}Br_2$/PMDETA complexes are shown in Figures 2 and 3, respectively.

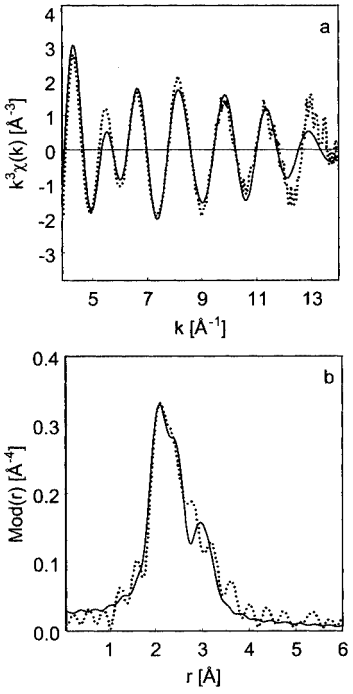

Figure 2. Experimental (dotted line) and calculated (solid line) $k^3\chi(k)$ functions (a) (k range: 3.90−14.0 Å^{-1}) and their Fourier transformations (b) at the Cu-K-edge for $Cu^{I}Br$/PMDETA in toluene at room temperature (see Table 3 for fit parameters)

The results of the EXAFS spectroscopic analysis of $Cu^{I}Br$/PMDETA in methyl acrylate, styrene, toluene, and methanol (Table 3) indicate similar structural features for the complex in these solvents. In all solvents, the EXAFS data are well fit by a structural model that includes 3.0 nitrogen atoms at a distance of 2.12 Å and 1.0 bromine atoms at a distance of 2.33 Å.

The average $Cu^{I}-N$ bond length is in agreement with those in other Cu^{I} complexes with similar nitrogen-based chromophores.[56] Additionally, the $Cu^{I}-Br$ bond length indicates covalent bonding to the Cu^{I} center. Based on these results, one structure that is consistent with the EXAFS analysis is the neutral complex [Cu^{I}(PMDETA)Br]. However, other structures might also co-exist in equilibrium and are shown in Scheme 5.

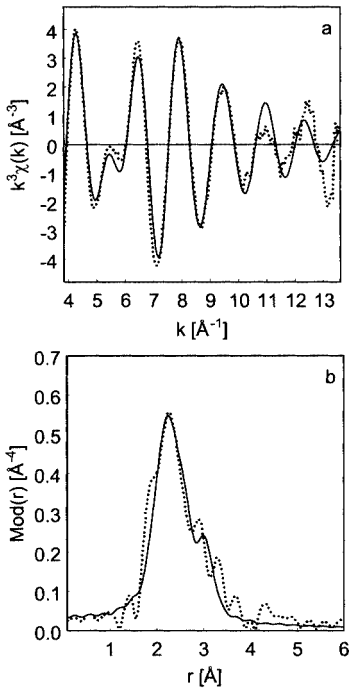

Figure 3. Experimental (dotted line) and calculated (solid line) $k^3\chi(k)$ functions (a) (k range: 3.80−14.1 Å^{-1}) and their Fourier transformations (b) at the Cu-K-edge for $Cu^{II}Br_2$/PMDETA in toluene/methanol mixture (80%/20% v/v) at room temperature (see Table 3 for fit parameters)

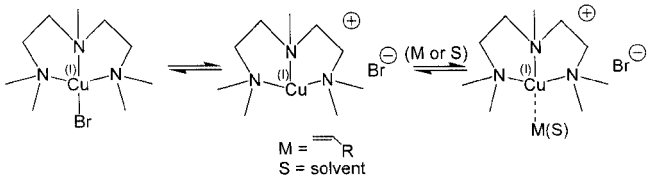


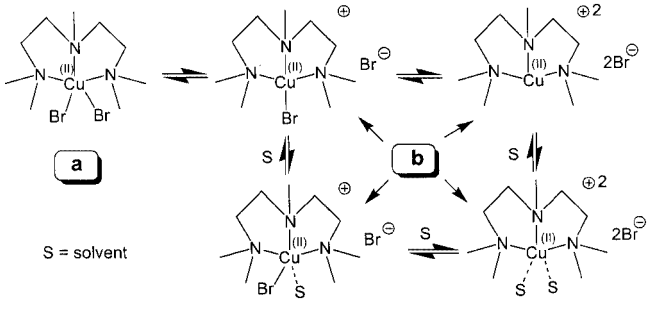
Scheme 5. Proposed structures for the $Cu^{I}Br$/PMDETA complex

Based on the solvent polarity and temperature, the dissociation of bromide could lead to the formation of the ionic complex [Cu^{I}(PMDETA)]$^+$[Br]$^-$. The coordinatively unsaturated [Cu^{I}(PMDETA)]$^+$ cation can be further coordinated by solvent (S) or monomer leading to the formation of [Cu^{I}(PMDETA)(S)]$^+$[Br]$^-$ and [Cu^{I}(PMDETA)(M)]$^+$[Br]$^-$, respectively. We were recently able to isolate and structurally characterize [Cu^{I}(PMDETA)(π-styrene)]$^+$[BPh_4]$^-$ and [Cu^{I}(PMDETA)(π-MA)]$^+$[BPh_4]$^-$ which model the monomer coordination to [Cu^{I}(PMDETA)]$^+$.[57] The monomer coordination occurred via π-bond formation, with a significant contribution from Cu^{I} π-back donation, as manifested in the strong shielding of the vinyl protons. Similar coordination has also been observed previously in [Cu^{I}(dien)(π-1-hexene)]$^+$[BPh_4]$^-$ (dien = diethylenetriamine).[58] A more detailed characterization of the $Cu^{I}Br$/PMDETA catalytic system in ATRP is under investigation.

Room temperature EXAFS measurements of the $Cu^{II}Br_2$ complex with 1 equiv. of PMDETA are shown in Table 3. The study was limited to relatively polar media, due to the poor solubility of the complex in typical non-polar ATRP solutions.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In a toluene/MeOH mixture (4:1 vol.), the EXAFS spectrum was fit reasonably well by assuming that the Cu^{II} center is coordinated by 3.6 nitrogen atoms at a distance of 2.13 Å and 1.0 bromine atoms at a distance of 2.42 Å. In more polar methanol, the average $Cu^{II}-N$ and $Cu^{II}-Br$ bond lengths did not change significantly. On the other hand, the EXAFS spectrum in H_2O indicated the absence of a $Cu^{II}-Br$ bond, which was also confirmed by measurements at the Br-*K*-edge. The structure of the $Cu^{II}Br_2$ complex with 1 equiv. of PMDETA has been recently reported. In the solid state, the complex exists as $[Cu^{II}(PMDETA)Br_2]$ with a distorted square-pyramidal coordination sphere.[14] The Cu^{II} center is coordinated by three nitrogen atoms of the PMDETA ligand ($Cu^{II}-N_{AV}$ = 2.098 Å) and two bromine atoms ($Cu^{II}-Br_{AV}$ = 2.545 Å). The $Cu^{II}-Br$ bond length in the apical position (2.644 Å) is much longer than the $Cu^{II}-Br$ bond length in the basal position (2.446 Å). This was attributed to the relatively small energy differences between the trigonal bipyramidal and square-pyramidal geometries of pentacoordinate Cu^{II} complexes. The average $Cu^{II}-N$ bond lengths determined by EXAFS spectroscopy in toluene/MeOH (2.13 Å), MeOH (2.09 Å) and H_2O (2.06 Å) are in good agreement with the average $Cu^{II}-N$ bond length in $[Cu^{II}(PMDETA)Br_2]$ (2.098 Å). However, the average $Cu^{II}-Br$ bond lengths in toluene/MeOH (2.42 Å) and MeOH (2.41 Å) are inconsistent with the average bond length in $[Cu^{II}(PMDETA)Br_2]$ (2.545 Å). Taking into account the coordination number of Br at the Cu- and Br-*K*-edges, the structural features of the $Cu^{II}Br_2$ complex with PMDETA determined by EXAFS can be explained in terms of bromide dissociation from $[Cu^{II}(PMDETA)Br_2]$. In toluene/MeOH and MeOH, the EXAFS data suggest the presence of $[Cu^{II}(PMDETA)Br]^+[Br]^+$. In H_2O, additional dissociation of bromide could result in the formation of $[Cu^{II}(PMDETA)]^{2+}[Br]_2^-$. Since Cu^{II} complexes prefer a pentacoordinate geometry,[56] the vacant coordination sites in $[Cu^{II}(PMDETA)Br]^+[Br]^-$ and $[Cu^{II}(PMDETA)]^{2+}[Br]_2^-$ are likely to be occupied by solvent molecules (MeOH or H_2O) (Scheme 6).



Scheme 6. Proposed structures for the $Cu^{II}Br_2$/PMDETA complex in (a) non-polar and (b) polar media based on EXAFS measurements

This has been demonstrated in the solid state with X-ray studies of the structures of the related complexes $[Cu^{II}(PMDETA)(H_2O)]^{2+}[ClO_4]_2^-$ [59] and $[Cu^{II}(PMDETA)(H_2O)_2]^{2+}[BF_4]_2^-$.[60] The replacement of bromide via π-bond formation with a monomer is less likely to occur with Cu^{II} complexes because the binding constants are typically very low.[61] However, substitution can potentially occur with functionalized olefins because they can additionally coordinate to the Cu^{II} complexes via functional groups (S, O, N etc.).[62]

Dissociation of halide anions from Cu^{II} complexes has been the subject of numerous investigations.[63–65] The equilibrium constants were found to strongly depend on the temperature and polarity of the reaction medium. Furthermore, polar and protic solvents such as MeOH and H_2O were found to favor halide anions dissociation, an observation which was most likely due to solvation effects. High values of the equilibrium constant for halide dissociation from $[Cu^{II}(L)-X]^+$ (X = Br^- or Cl^-) complexes could explain the fast ATRP reactions in polar media. The halide dissociation from $[Cu^{II}(L)-X]^+$ shifts the position of the ATRP equilibrium (see Scheme 1), resulting in an increase in radical concentration. Our recent measurements determined that the equilibrium constant for bromide dissociation from $[Cu^{II}(PMDETA)Br_2]$ in H_2O at room temperature was K = 0.18 mol·L^{-1}.[66] Using this value, one can estimate that under typical conditions of the EXAFS experiment (room temperature, $[Cu^{II}Br_2]_0$ = $[PMDETA]_0 \approx 0.05$ M) approximately 80% of the $Cu^{II}Br_2$/PMDETA complex in H_2O contains dissociated bromide anions. This further supports the results of the EXAFS analysis and structures proposed in Scheme 6. A more detailed study of the effect of halide dissociation from other ATRP active Cu^{II} complexes is currently being carried out.

$Cu^{I}Br$ and $Cu^{II}Br_2$ Complexes with the Me_6TREN Ligands

Tris[2-(dimethylamino)ethyl]amine (Me_6TREN, Scheme 2) is a tetradentate nitrogen-based ligand that has been successfully used in ATRP. Typically, the ligand/$Cu^{I}Br$ ratio was 1:1. This catalytic system showed a very high activity, enabling fast and controlled polymerization of methyl acrylate at ambient temperature.[52] The results of EXAFS measurements of $Cu^{I}Br$ and $Cu^{II}Br_2$ complexes with Me_6TREN in different solvents are summarized in Table 4.

The Cu-*K*-edge EXAFS spectrum of the $Cu^{I}Br$ complex with 1 equiv. of Me_6TREN in styrene can be best modeled by assuming that the coordination sphere around the Cu^{I} center is occupied by 3.0 nitrogen atoms at a distance of 2.15 Å and 1.2 bromine atoms at a distance of 2.33 Å. The results in methyl acrylate and toluene (Figure 4) are analogous, indicating similar structural features of the complex in those solvents.

Taking into account the 18-electron rule and the tetradentate nature of Me_6TREN, one would expect that the most probable structure of the $Cu^{I}Br/Me_6TREN$ complex in solution would be $[Cu^{I}(Me_6TREN)]^+[Br]^-$. The average $Cu^{I}-N$ bond lengths in styrene (2.15 Å), methyl acrylate (2.15 Å) and toluene (2.14 Å) are in agreement with the

[a] *N* = coordination number, *r* = absorber−backscatterer distance, σ = Debye−Waller factor. Inherent errors are approximately 10−30% for coordination numbers and Debye−Waller factors and 1% for distances.

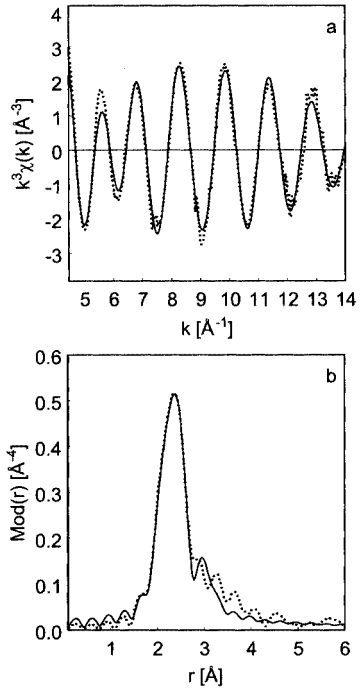

Figure 4. Experimental (dotted line) and calculated (solid line) $k^3\chi(k)$ functions (a) (*k* range: 4.20−14.6 $Å^{-1}$) and their Fourier transformations (b) at the Cu-*K*-edge for $Cu^{I}Br/Me_6TREN$ in toluene at room temperature (see Table 4 for fit parameters)

previously characterized complex $[Cu^{I}(Me_6TREN)]^{+}$-$[ClO_4]^{-}$ (2.161 Å).[36] However, the coordination number of N appears to be rather low for the tetradentate Me_6TREN ligand. Additionally, the presence of a Br backscatterer in the spectrum of the Cu-*K*-edge indicates covalent bonding to the Cu^{I} center. This evidence contradicts the presence of the solely ionic species $[Cu^{I}(Me_6TREN)]^{+}[Br]^{-}$.

The presence of a Cu^{I}−Br absorbance in the EXAFS spectrum of $Cu^{I}Br/Me_6TREN$ could suggest the presence of linear $[Cu^{I}Br_2]^{-}$ anions, as described earlier in the case of $[Cu^{I}(dNbpy)_2]^{+}[Cu^{I}Br_2]^{-}$. However, the average Cu^{I}−Br bond lengths in styrene (2.33 Å), methyl acrylate (2.33 Å), and toluene (2.31 Å) appear to be longer than the Cu^{I}−Br bond length in other Cu^{I} complexes with $[Cu^{I}Br_2]^{-}$ anions (2.206−2.232 Å).[17,38,46,47] The elongation of the Cu^{I}−Br bond in $[Cu^{I}Br_2]^{-}$ anions is possible, but was not observed in the structurally related complex $[Cu^{I}(HMTETA)]^{+}[Cu^{I}Cl_2]^{-}$ (HMTETA = 1,1,4,7,10,10-hexamethyltriethylenetetramine), in which the Cu^{I}−Cl bond length was found to be similar to those seen in other Cu^{I} complexes with linear $[Cu^{I}Cl_2]^{-}$ anions.[36]

The structure of the $Cu^{I}Br/Me_6TREN$ complex consistent with the EXAFS analysis is likeley to be the neutral $[Cu^{I}(Me_6TREN')Br]$ (Me_6TREN' denotes a tricoordinate Me_6TREN). Similar structures were proposed earlier for copper[67] and cobalt[68] complexes with the Me_6TREN ligand in order to explain the kinetics of ligand substitution reactions. Furthermore, the dissociation of one "amine" arm in Cu^{II} complexes with other tetradentate nitrogen-based ligands has also been reported.[69,70]

Due to the sensitivity of EXAFS measurements, inherent errors in coordination numbers (10−30%), and also the possibility of the co-existence of more than one species in equilibrium means that all complexes discussed above could be present in solution. The proposed structures are shown in Scheme 7. More experimental evidence is needed to confirm the proposed structures, relative proportions of each species and more importantly their activity in the $Cu^{I}Br/Me_6TREN$ catalytic system in ATRP.

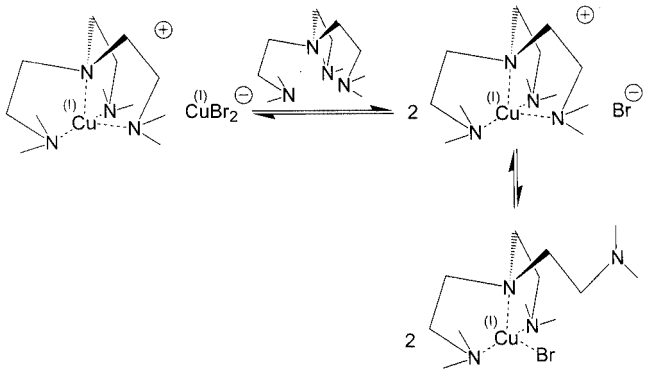

Scheme 7. Proposed structures for the $Cu^{I}Br/Me_6TREN$ complex

Room-temperature EXAFS data for the $Cu^{II}Br_2$ complex with 1 equiv. of Me_6TREN are summarized in Table 4. In methanol, the EXAFS spectrum of the Cu-*K*-edge (Figure 5) was reasonably well fit using the structural model that includes 3.2 nitrogen atoms at a distance of 2.13 Å and 1.4 bromine atoms at a distance of 2.38 Å. These data are consistent with $[Cu^{II}(Me_6TREN)Br]^+[Br]^-$ which was isolated and characterized previously.[40] $[Cu^{II}(Me_6TREN)Br]^+[Br]^-$ has a distorted trigonal-bipyramidal geometry. The Cu^{II} center is coordinated by 4 nitrogen atoms of the Me_6TREN ligand ($Cu^{II}-N_{AV}$ = 2.116 Å) and 1 bromine atom ($Cu^{II}-Br$ = 2.393 Å). As indicated in Table 4, there is a significant decrease in the coordination number of Br in the more polar H_2O. This result points to the bromide dissociation as discussed previously in the case

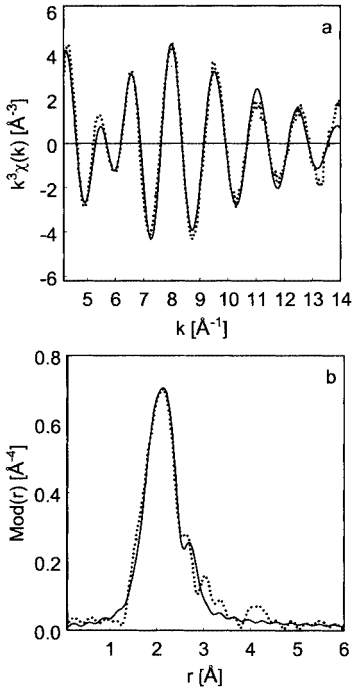

Figure 5. Experimental (dotted line) and calculated (solid line) $k^3\chi(k)$ functions (a) (k range: 4.00−14.2 $Å^{-1}$) and their Fourier transformations (b) at the Cu-*K*-edge for $Cu^{II}Br_2/Me_6TREN$ in methanol at room temperature (see Table 4 for fit parameters)

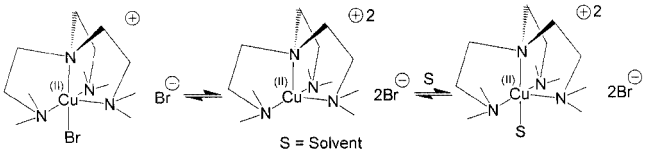
of $[Cu^{II}(PMDETA)Br_2]$. The proposed equilibrium is shown in Scheme 8.



Scheme 8. Proposed structures for the $Cu^{II}Br_2/Me_6TREN$ complex

The vacant coordination site in $[Cu^{II}(Me_6TREN)]^{2+}[Br]_2^-$ is most likely occupied by the solvent molecule (H_2O or MeOH), as demonstrated in the structurally related complex $[Cu^{II}(Me_6TREN)(H_2O)]^{2+}[ClO_4]_2^-$.[70] The equilibrium constant for the dissociation of Br^- from the $[Cu^{II}(Me_6TREN)Br]^+$ chromophore has been determined spectrophotometrically in H_2O.[63,64] Under typical EXAFS conditions ($[Cu^{II}Br_2]_0$ = $[Me_6TREN]_0$ = 0.05 M), the equilibrium constant of 0.23 $mol\cdot L^{-1}$ would indicate that approximately 85% of the complex has dissociated with formation of bromide anions. This further supports the results of the EXAFS analysis and structures proposed in Scheme 8.

$Cu^{I}Br$ Complexes with the $Me_4CYCLAM$ and tNtpy Ligands

The substituted terpyridine (tNtpy)[71] and cyclic tetradentate amine ($Me_4CYCLAM$)[52] were also used in the ATRP of various monomers (Scheme 2). The polymerization of methyl acrylate and styrene catalyzed by $Cu^{I}Br$/tNtpy was controlled and the resultant polymers had relatively low polydispersities (M_w/M_n < 1.2). ATRP using $Cu^{I}Br/Me_4CYCLAM$ resulted in fast and uncontrolled polymerizations, which was attributed to a low deactivation rate constant.[14,72,73] Table 5 shows the summary of EXAFS-determined structural data for $Cu^{I}Br$ complexes with the tNtpy and $Me_4CYCLAM$ ligands.

The Cu-*K*-edge EXAFS spectrum of the $Cu^{I}Br/Me_4CYCLAM$ complex in methyl acrylate (Figure 6) is well fit using the structural model in which Cu^{I} is coordinated by 3.8 nitrogen atoms at a distance of 2.06 Å and 1.7 bromine atoms at a distance of 2.23 Å. In a more polar medium (MA/MeOH = 3:1, v/v), the signal due to the coordinated bromine atoms disappears and only nitrogen backscatterers are visible in the FT Cu-*K*-edge EXAFS spectrum. The average $Cu^{I}-N$ bond lengths for the $Cu^{I}Br/Me_4CYCLAM$ complex in methyl acrylate (2.06 Å) and methyl acrylate/MeOH (3:1, v/v) (2.05 Å) are shorter than the average $Cu^{I}-N$ bond lengths in the related complexes $[Cu^{I}(HMTETA)]^+[Cu^{I}Cl_2]^-$ ($Cu^{I}-N_{AV}$ = 2.111 Å)[36] and $[Cu^{I}(Me_6TREN)]^+[ClO_4]^-$ ($Cu^{I}-N_{AV}$ = 2.161 Å).[74] The shortening of the average $Cu^{I}-N$ bond length in $Cu^{I}Br/Me_4CYCLAM$ could be due to the steric strain imposed by the cyclic $Me_4CYCLAM$ ligand as described in the literature.[75,76] Copper(I) complexes with $Me_4CYCLAM$ are therefore expected to adopt a square-planar geometry as

[a] *N* = coordination number, *r* = absorber−backscatterer distance, σ = Debye−Waller factor. Inherent errors are approximately 10−30% for coordination numbers and Debye−Waller factors and 1% for distances.

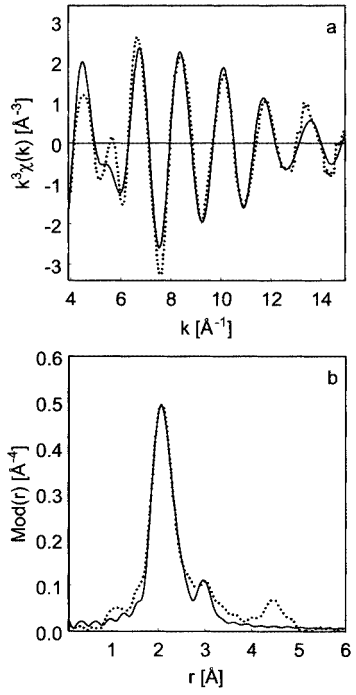

Figure 6. Experimental (dotted line) and calculated (solid line) $k^3\chi(k)$ functions (a) (*k* range: 3.90−14.9 $Å^{-1}$) and their Fourier transformations (b) at the Cu-*K*-edge for $Cu^{I}Br$/Me_4CYCLAM in methyl acrylate at room temperature (see Table 5 for fit parameters)

opposed to tetrahedral and square-pyramidal structures observed in $[Cu^{I}(HMTETA)]^{+}[Cu^{I}Cl_2]^{-}$ and $[Cu^{I}(Me_6TREN)]^{+}[ClO_4]^{-}$, respectively. The average $Cu^{I}-Br$ bond length and coordination number of Br in $Cu^{I}Br$/Me_4CYCLAM in methyl acrylate are consistent with Cu^{I} complexes containing $[Cu^{I}Br_2]^{-}$ anions (2.206−2.232 Å).[17,38,46,47] Similar to $Cu^{I}Br$/Me_6TREN discussed earlier, the EXAFS results of $Cu^{I}Br$/Me_4CYCLAM in methyl acrylate are consistent with $[Cu^{I}(Me_4CYCLAM)]^{+}[Cu^{I}Br_2]^{-}$. In more polar media, the complex predominantly exists as $[Cu^{I}(Me_4CYCLAM)]^{+}[Br]^{-}$ (Scheme 9). The 1:1/2 stoichiometry in $[Cu^{I}(Me_4CYCLAM)]^{+}[Cu^{I}Br_2]^{-}$ indicates the presence of free Me_4CYCLAM in the ATRP system since the catalyst is typically prepared by mixing $Cu^{I}Br$ with an equimolar amount of Me_4CYCLAM. Consequently, the free ligand can participate in chain transfer reactions which limit the control of the polymerization at higher molecular weights, as observed previously in the case of PMDETA.[26,27]

The EXAFS-determined structural data of the $Cu^{I}Br$ complex with tNtpy (Table 5) in methyl acrylate indicate that the coordination sphere around the Cu^{I} center is occupied by 2.7 nitrogen atoms at a distance of 2.03 Å and 1.0 bromine atoms at a distance of 2.29 Å. The coordination numbers and distances in styrene indicate similar structural features of the complex. The EXAFS data in methyl acrylate and styrene are consistent with the neutral complex $[Cu^{I}(tNtpy)Br]$. However, as discussed earlier in the case of the $Cu^{I}Br$ complex with tridentate PMDETA, other species might co-exist in equilibrium. The proposed structures are shown in Scheme 9, and are subject to further investigation.

The structures of the $Cu^{II}Br_2$ complexes with tNtpy and Me_4CYCLAM in solution, although not investigated by EXAFS, are expected to be similar to the complexes with PMDETA and Me_6TREN as discussed above. In the solid state, the $Cu^{II}Br_2$ complex with tNtpy exists as neutral $[Cu^{II}(tNtpy)Br_2]$.[14] The Cu^{II} center has a distorted square-bipyramidal geometry and is coordinated by 3 nitrogen atoms of the tNtpy ligand ($Cu^{II}-N_{AV}$ = 2.027 Å) and 2 bromine atoms ($Cu^{II}-Br_{AV}$ = 2.467 Å). Analogous to the molecular structure of $[Cu^{II}(PMDETA)Br_2]$, the $Cu^{II}-Br$ bond in the apical position (2.528 Å) was found to be longer than the $Cu^{II}-Br$ bond in the basal position (2.407 Å). Moreover, the $Cu^{II}Br_2$ complex with Me_4CYCLAM has been isolated as ionic $[Cu^{II}(Me_4CYCLAM)Br]^{+}[Br]^{-}$.[14] The Cu^{II} center in the complex is distorted square-pyramidal with the average $Cu^{II}-N$ and $Cu^{II}-Br$ bond lengths

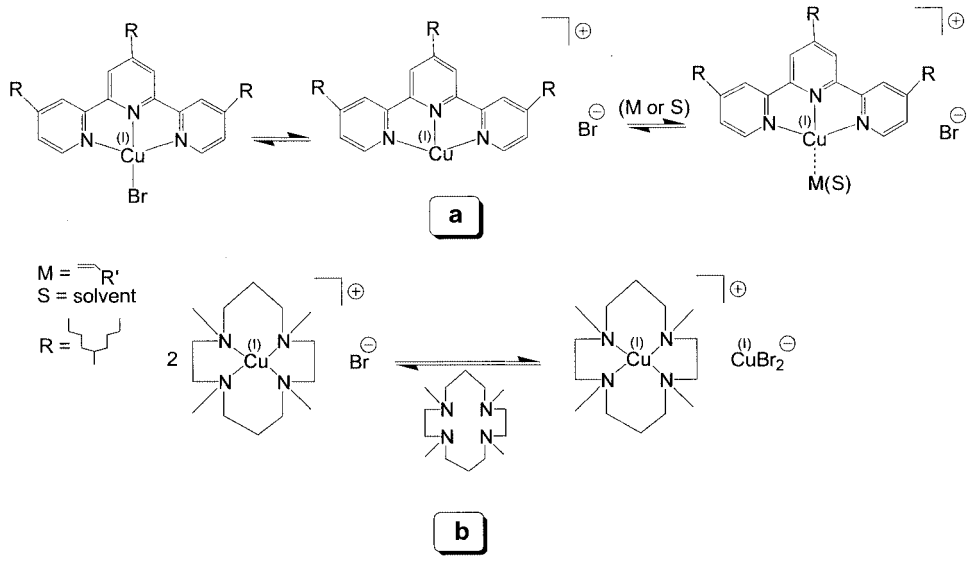

Scheme 9. Proposed structures for the (a) Cu^IBr/tNtpy and (b) $Cu^IBr/Me_4CYCLAM$ complexes

being 2.087 and 2.809 Å, respectively. The complex is expected to undergo bromide substitution in polar media such as H_2O and MeOH, similar to the previously discussed PMDETA- and Me_6TREN-based complexes.

Conclusions

In summary, EXAFS has been used to investigate the structural features of Cu^IBr and $Cu^{II}Br_2$ complexes with dNbpy, PMDETA, Me_6TREN, tNtpy, and Me_4CYCLAM in various solvents, including styrene and methyl acrylate which are monomers typically used in ATRP. The structures reported by EXAFS were primarily based on the interatomic distances around the absorber, due to the inherent error in the coordination numbers. In non-polar media, the EXAFS spectroscopic analysis of the Cu^IBr complex with dNbpy at room temperature indicated the presence of $[Cu^I(dNbpy)_2]^+[Cu^IBr_2]^-$ {Cu^I-N_{AV} = 2.01 Å (styrene), 1.99 Å (MA), Cu^I-Br_{AV} = 2.25 Å (styrene), 2.26 Å (MA)}. In polar media, such as MeOH, $[Cu^I(dNbpy)_2]^+[Br]^-$ was the preferred species (Cu^I-N_{AV} = 2.01 Å). Similarly, the EXAFS spectra of the $Cu^{II}Br_2$ complex of dNbpy in nonpolar and polar media were consistent with the presence of $[Cu^{II}(dNbpy)Br_2]$ {$Cu^{II}-N_{AV}$ = 2.01 Å (MA), 2.03 Å (toluene), $Cu^{II}-Br_{AV}$ = 2.37 Å (MA), 2.37 Å (toluene)} and $[Cu^{II}(dNbpy)_2Br]^+[Br]^-$ {$Cu^{II}-N_{AV}$ = 2.03 Å (MeOH), $Cu^{II}-Br_{AV}$ = 2.43 Å (MeOH)}, respectively. The EXAFS-determined structural data of Cu^IBr complexes with the tridentate ligands PMDETA and tNtpy in methyl acrylate indicated the presence of neutral $[Cu^I(PMDETA)Br]$ (Cu^I-N_{AV} = 2.12 Å, Cu^I-Br_{AV} = 2.33 Å) and $[Cu^I(tNtpy)Br]$ (Cu^I-N_{AV} = 2.03 Å, Cu^I-Br_{AV} = 2.29 Å), respectively. The coordination numbers and distances indicated similar structural features to those of the complexes in toluene and styrene. The results of the EXAFS analysis of the Cu^IBr/Me_6TREN complex in methyl acrylate, styrene, and toluene were well fit by a structural model that included 3 nitrogen atoms at a distance of 2.15 Å and 1 bromine atom at 2.32 Å, which potentially indicated the presence of several species namely $[Cu^I(Me_6TREN)]^+[Br]^-$, $[Cu^I(Me_6TREN)]^+[Cu^IBr_2]^-$, and $[Cu^I(Me_6TREN')Br]$ (Me_6TREN' denotes a tricoordinate Me_6TREN). The decrease in the coordination number of N was not observed in the Cu^IBr complex with tetradentate Me_4CYCLAM, which in a non-polar medium such as methyl acrylate, predominantly exist as $[Cu^I(Me_4CYCLAM)]^+[Cu^IBr_2]^-$ (Cu^I-N_{AV} = 2.06 Å, Cu^I-Br_{AV} = 2.23 Å). In more polar media, the structure changed to $[Cu^I(Me_4CYCLAM)]^+[Br]^-$ (Cu^I-N_{AV} = 2.05 Å). Additionally, the $Cu^{II}Br_2$ complexes with PMDETA and Me_6TREN, namely $[Cu^{II}(PMDETA)Br_2]$ ($Cu^{II}-N_{AV}$ = 2.09 Å, $Cu^{II}-Br_{1,AV}$ = 2.44 Å, $Cu^{II}-Br_{2,AV}$ = 2.64 Å) and $[Cu^{II}(Me_6TREN)Br]^+[Br]^-$ ($Cu^{II}-N_{AV}$ = 2.09 Å, $Cu^{II}-Br_{AV}$ = 2.39 Å), respectively, were found to undergo bromide dissociation in MeOH and H_2O, as indicated by a decrease in the Br/Cu coordination number the latter being determined by analysis of the EXAFS spectra at the Cu- and Br-*K*-edges.

Experimental Section

Materials: Cu^IBr (99.999%), $Cu^{II}Br_2$ (99.999%), $Cu^{II}(CF_3SO_3)_2$ (99%), and $[N(C_4H_9)_4]^+[Br]^-$ (98%) were purchased from Aldrich and used as received. *N,N,N′,N″,N″*-Pentamethyldiethylenetriamine (PMDETA) (99%, Aldrich) was distilled under nitrogen. 2,2′-Bipyridine (99%, Aldrich) was recrystallized from methanol. Tris[2-(dimethylamino)ethyl]amine (Me_6TREN)[77] and 4,4′-bis(5-nonyl)-2,2′-bipyridine (dNbpy)[78] were prepared according to literature procedures. All solvents were distilled and deoxygenated prior to use. Unless otherwise noted, experiments were performed under nitrogen in a dry box or using a Schlenk line. Elemental analyses for C, H, and N were performed by Chemisar Laboratories Inc., Guelph, Ontario, Canada.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Model Compounds: $[Cu^{I}(bpy)_2]^+[ClO_4]^-$,[35] $[Cu^{I}(bpy)Br_2]$,[37] $[N(C_4H_9)_4]^+[Cu^{I}Br_2]^-$,[38] $[Cu^{II}(terpy)Br_2]$,[14,42] $[Cu^{II}(Me_6TREN)Br]^+[Br]^-$,[40] $[Cu^{II}(PMDETA)Br_2]$,[41] and $[Cu^{II}(dNbpy)Br_2]$[16] were synthesized according to literature procedures. $[Cu^{II}(dNbpy)_2Br]^+[Y]^-$ (Y = Br^-, PF_6^-, and $CF_3SO_3^-$) were prepared in CH_3CN according to the procedures for $[Cu^{II}(bpy)_2Br]^+[Br]^-$,[50] $[Cu^{II}(bpy)_2Br]^+[PF_6]^-$,[39] and $[Cu^{II}(bpy)_2Br]^+[CF_3SO_3]^-$ [79] but using dNbpy instead of bpy.

EXAFS Measurements and Data Analysis: The EXAFS measurements of the samples were performed at the beamline 2−3 at the SSRL, a division of SLAC, which is operated by Stanford University (USA). For the measurements at the Cu- *K*-edge (8982.5 eV) and Br-*K*-edge (13474.0 eV) an Si(111) double crystal monochromator was used. A synchrotron beam current up to 100 mA was used (electron energy 3.00 GeV). All experiments were carried out under ambient conditions. The tilt of the second monochromator crystal was set to 30% harmonic rejection. Energy resolution was estimated to be about 2 eV for the Cu-*K*-edge and 4 eV for the Br-*K*-edge. Data were collected in transmission mode with ion chambers. All ion chambers were filled with nitrogen in the case of the measurements at the Cu-*K*-edge, and the second and third chamber with argon in the case of the measurements at the Br-*K*-edge. Energy calibration was performed with the corresponding metal foils in the case of Cu, and lead metal foil (Pb L_{III}-edge) in the case of Br. The samples in the solid state were embedded in a polyethylene matrix and pressed into pellets. Liquid samples were measured in a specially designed transmission sample cell for liquids which was filled under nitrogen. The concentration of all samples was adjusted to yield an absorption jump of $\Delta\mu \approx 1.5$. Data evaluation started with background absorption removal from the experimental absorption spectrum by subtraction of a Victoreen-type polynomial. The background-subtracted spectrum was then convoluted with a series of increasingly broader Gauss functions and the common intersection point of the convoluted spectra was taken as the energy E_0.[80,81] To determine the smooth part of the spectrum, corrected for pre-edge absorption, a piecewise polynomial was used. It was adjusted in such a manner that the low-*R* components of the resultant Fourier transformation were minimal. After division of the background-subtracted spectrum by its smooth part, the photon energy was converted into photoelectron wave numbers *k*. The resultant EXAFS function was weighted with k^3. Data analysis in *k* space was performed according to the curved wave multiple scattering formalism of the program EXCURV92 with XALPHA phase and amplitude functions.[82] The mean free path of the scattered electrons was calculated from the imaginary part of the potential (VPI was set to −4.00) and an overall energy shift (ΔE_0) was assumed. The Amplitude Reduction Factor (AFAC) was set to a value of 0.8 in the case of the Cu-*K*-edge as well as the Br-*K*-edge. The fitting of the spectra at the Cu-*K*-edge was typically performed by using Br and N backscatterers. For some complexes, a C backscatterer was also used in order to improve the accuracy of the fit.

Acknowledgments

Financial support from the CMU CRP Consortium and an NSF grant (CHE-0096601) is greatly appreciated. The authors also acknowledge the SSRL for the kind support of synchrotron radiation facilities.

Probing the Nature of the Co^{III} Ion in Cobalamins − Spectroscopic and Structural Investigations of the Reactions of Aquacobalamin (Vitamin B_{12a}) with Ambident Nucleophiles

Christopher B. Perry,[a] Manuel A. Fernandes,[a] Kenneth L. Brown ,[b] Xiang Zou,[b] Edward J. Valente,[c] and Helder M. Marques*[a]

Keywords: Cobalamins / Ambidentate ligands / Cobalt / Bioinorganic chemistry / X-ray diffraction

The rate of substitution of the H_2O β-ligand in aquacobalamin (vitamin B_{12a}) is surprisingly fast for Co^{III}. This may arise as a result of transfer of electron density to Co^{III} by the corrin, conferring on the metal atom a softer and more labile character, and would require electronic communication between the equatorial ligand and the axial coordination sites of the metal atom. We have substituted H_2O in B_{12a} with the ambidentate nucleophiles SCN^-, $SeCN^-$, NO_2^- and $S_2O_3^{2-}$, examined the UV/Vis spectra of the resultant complexes, crystallised them, and determined their structures by X-ray diffraction methods. The UV/Vis spectra of these complexes, as well as those of H_2OCbl^+, SO_3Cbl^- and MeCbl, were fitted by Gaussian functions. The principal bands move to lower energy in response to an increase in donation of electron density from the axial ligand, demonstrating direct electronic communication between the axial and the equatorial ligands. In the solid state, the thiocyanato ligand in SCNCbl is coordinated through N, although ^{13}C NMR spectroscopy shows that the complex exists as a mixture of two linkage isomers in solution. $SeCN^-$, NO_2^- and $S_2O_3^{2-}$ are coordinated through the softer available donor in each case (Se, N and S, respectively). There is a regular ground-state *trans* effect such that as the donor power of the β-ligand increases, the *trans* $Co–N_{ax}$ bond length increases. A survey of the structures available in the CSD shows that this preference for the softer donor atom in ambidentate nucleophiles is not unusual in Co^{III} complexes. The Co–N bond length in SCNCbl is marginally long for coordination to Co^{III}, but the axial bond lengths of the other complexes are as expected. Hence, whereas the corrin macrocycle clearly imparts lability on Co^{III}, presumably by transfer of electron density onto the metal atom, this is insufficient to have a major effect on the ground-state structures of its complexes.

Introduction

We have previously[1] studied the kinetics of the ligand substitution reactions of coordinated H_2O in aquacobalamin (H_2OCbl^+, vitamin B_{12a}, Figure 1) by a series of small anionic ligands ($S_2O_3^{2-}$, SCN^-, NO_2^-, NCO^-, $SeCN^-$, N_3^-) and determined the second-order rate constants, k_{II}, corresponding to the bimolecular reaction of Equation (1), where bzm is the base 5,6-dimethylbenzimidazole that occupies the lower (α) coordination site of aquacobalamin, N_4 represents the equatorial corrin ligand, and charges are omitted for convenience. We calculated the activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ from the temperature dependence of k_{II} and the Mulliken charge population of the donor atoms from semiempirical molecular orbital calculations using the PM3 model.[2,3]

$$\text{bzm-Co(N}_4\text{)-OH}_2 + \text{L} \xrightarrow{k_{II}} \text{bzm-Co(N}_4\text{)-L} + \text{H}_2\text{O} \quad (1)$$

If we assumed, irrespective of the thermodynamically preferred product, that (i) SCN^- reacts through N, (ii) NO_2^- reacts through N, (iii) NCO^- reacts through O, (iv) $S_2O_3^{2-}$ reacts through S and (v) $SeCN^-$ reacts through Se in the microscopic process that determines the magnitude of the activation parameters, then a three-dimensional plot of $\Delta H^{\ddagger}$ as a function of the energy, E_σ, of the frontier orbital with σ symmetry on the donor atom, and the Mulliken population (MP) of that atom, yielded a planar surface ($r^2 = 0.81$; $f = 6.30$; 92% confidence that the correlation is not due to random chance) that showed that $\Delta H^{\ddagger}$ decreases, and the reactions speed up, as the MP and E_σ decreased. A similar correlation with $\Delta S^{\ddagger}$ was observed ($r^2 = 0.95$; $f =$

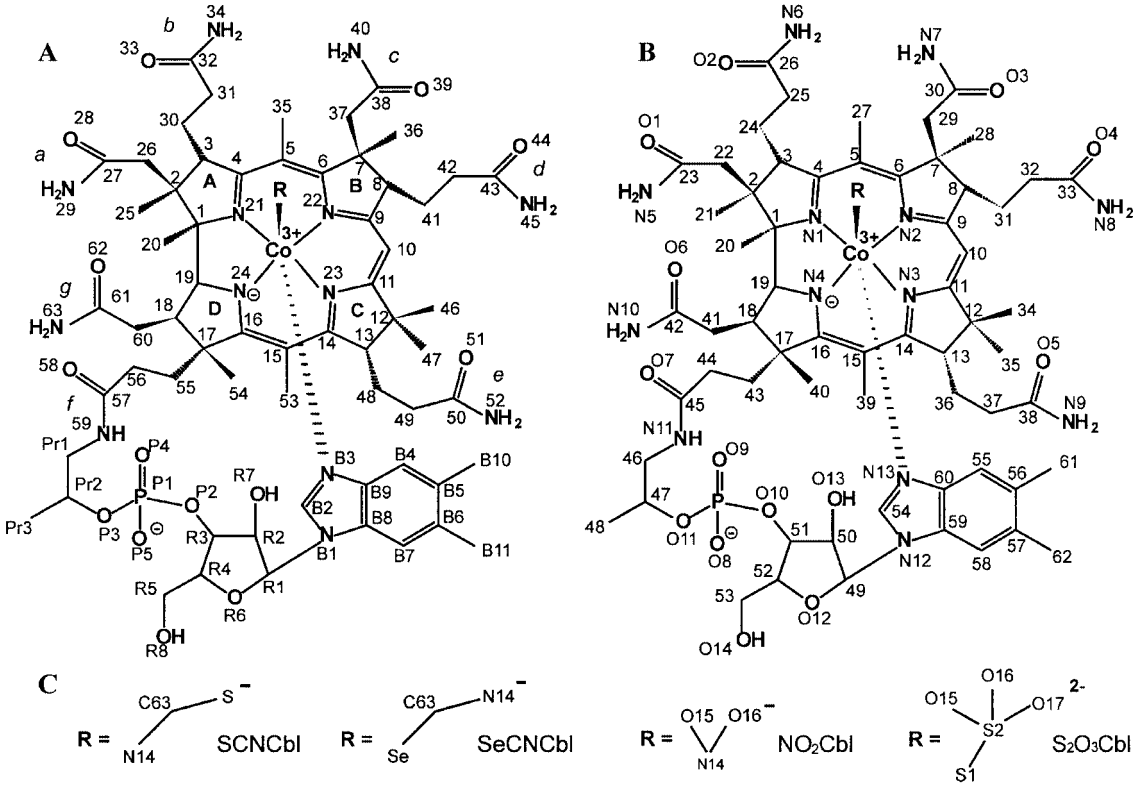

Figure 1. (A) The common numbering scheme and standard view of the cobalt corrinoids; aquacobalamin (vitamin B_{12a}) has a Co^{III} ion coordinated in the equatorial plane by the macrocyclic ligand corrin; the equatorial ligand on the lower (α) face is 5,6-dimethylbenzimidazole (bzm), whilst that on the upper (β) face is R = H_2O; coordinated H_2O is readily replaced by ligands from solution in reactions that are surprisingly fast for Co^{III}; in this view, the C13···C17 portion of the molecule is known as the southern quadrant, C7···C13 as the eastern quadrant, and so on; (B) and (C) show the crystallographic numbering scheme used in this work

26.6; > 99% confidence that the correlation is not due to random chance), with $\Delta S^{\ddagger}$ decreasing and the reaction becoming slower with decreasing MP and E_{σ}. There is therefore a compensating effect between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, the origin of which, related to the density of states in the transition state, was discussed.

Co^{III} usually behaves as a hard (class a) metal ion.[4] The curious mixture of the kinetically favoured donor atom in the reactions of B_{12a} with ambident nucleophiles (the harder of the two donors is preferred in the reaction with SCN^- and NCO^-, but the softer donor in the case of $S_2O_3^{2-}$, NO_2^- and $SeCN^-$), may be evidence of a somewhat softer metal ion character due to a transfer of electron density from the corrin ring. It has previously been pointed out[5,6] that the rates of ligand substitution reactions at the Co^{III} centre in the cobalamins are surprisingly fast for Co^{III}, which is a classic example of an inert transition metal ion. Thus, the lability ratio of the metal ion towards substitution in corrin, porphyrin, cobaloxime and macrocyclic saturated ammine systems is 10^9:10^6:10^4:1 (Figure 2). We suggest that this considerable *cis*-labilising effect of the corrin is due to the transfer of electron density from the macrocycle to the metal ion, conferring on the metal atom some element of labile character characteristic of Co^{II}. For this

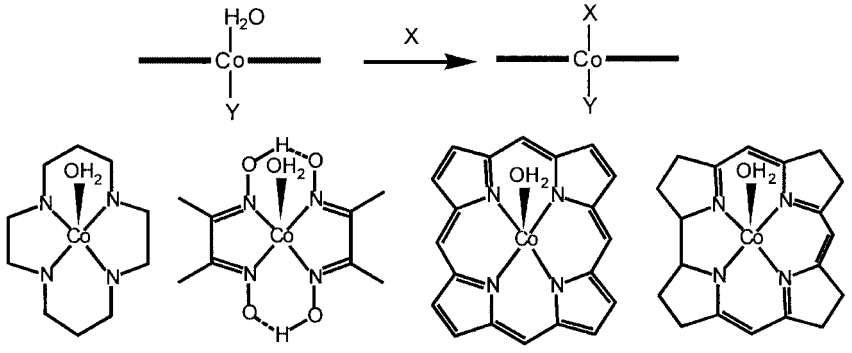

Figure 2. Changing the equatorial ligand system from (left to right) ammine to cobaloxime to porphyrin and corrin causes the rate of substitution of the axial H_2O to increase approximately in the ratio 1:10^4:10^6:10^9 [5]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to be a feasible explanation for the kinetic behaviour, direct electronic communication between the corrin ring and the axial coordination site of Co^{III} is required. To this end, we have shown[5] that substitution of the H centre at the C10 position with Cl (Figure 1), and an increase in the donor power of the axial ligand ($H_2O < CN^- < Me$) increased the C10−Cl bond length as well. Moreover, Mulliken charges obtained from semiempirical MO calculations using the ZINDO/1 model[7,8] (which correlate well with ^{13}C NMR chemical shifts and which may therefore be used to determine the pattern of electron distribution in these complexes) confirmed that the charge density on the metal ion, on the N donor atoms of the corrin, and on the corrin C atoms is affected by the donor power of the axial ligand. We have also shown recently[9] that if the H atom at C10 is replaced by an electron-withdrawing NO group, the metal ion is deactivated towards ligand substitution, i.e., 10-NO-H_2OCbl^+ is inert towards substitution of the axial H_2O molecule by pyridine and N_3^-, and reacts only slowly with CN^-.[10] The conferring of some labile character on the metal atom may be an important aspect of the biological chemistry of coenzyme B_{12} (AdoCbl, adenosylcobalamin; R = 5′-deoxyadenosyl in Figure 1,) since the first step in AdoCbl-catalysed enzymatic reactions is homolysis of the Co−C bond to produce Co^{II} and an alkyl radical,[11−13] a process that is catalysed by a factor of 10^{12} or higher.[14−16] There is a clear mechanistic advantage from increasing the electron density on the metal atom and increasing its lability. It has been shown, for example, that reduction of methylcobalamin to Co^{II} results in a $> 10^{15}$ rate enhancement of thermal homolysis of the Co−C bond[17] and Co^{II} corrinoids are either five-coordinate[18,19] or, at most, the β-ligand interacts very weakly with the metal centre.[18] It is an attractive hypothesis that the corrin transfers significant electron density onto Co^{III}, in effect conferring some labile Co^{II}-like character to it, and that the protein, on binding the coenzyme B_{12} cofactor and perhaps the substrate, modulates this effect further thereby activating the Co−C bond towards homolysis.

The axial Co−N bonds to the bzm base tend to be long (2.26−1.95 Å),[20] whereas the Co−N bond lengths in the equatorial plane of Co^{III} are similar to those in Co^{III}−ammine complexes (1.96−1.99 Å), as Lenhert pointed out.[21] This may be merely a consequence of the steric demands of bzm (and, in particular, the clashing of the B4 proton with the corrin ring), rather than a structural response to low-spin Co^{II}-like character of the metal atom. In this regard it is probably significant that the Co−N(imidazole) bond in Co-β-cyanoimidazolylcobamide, where the bzm base has been replaced by a sterically much less demanding imidazole,[22] is "normal", with a distance of 1.97 Å. In methionine synthase[23] and in methylmalonyl CoA mutase[24] the bzm base is replaced by an imidazole residue from the protein. The $Co-N_{ax}$ bond length in the former is not unusual (2.2 ± 0.2 Å), although the resolution is relatively low. In the latter, the B_{12} cofactor is present as Co^{II}, and there is a long $Co-N_{ax}$ bond (2.5 ± 0.1 Å), despite attempts to constrain this bond length to more normal values during the refinement process.[25] There is no crystal structure of imidazolylcob(II)amide, but a comparison of the $Co-N_{ax}$ bond lengths of cyanocobalamin and cyanoimidazolylcobamide strongly suggests[26] that the $Co-N_{ax}$ bond length is as much as 0.4 Å longer when the cofactor is bound to the protein.

The very rich chemistry of organocobalamins is further evidence that the Co^{III} ion in the cobalamins behaves very differently from a classical, hard and inert d^6 ion. As mentioned, the first step in the AdoCbl-catalysed enzymatic reactions is formation of Co^{II} and a radical (i.e., the Co−C bond could be formulated as $Co^{II} + R^{\cdot}$). Both UV/Vis and resonance Raman spectroscopic results suggest that an alkylcobalamin is best viewed as a compound intermediate between Co^{III} and a carbanion.[27] The transfer of a methyl group from methylcobalamin to homocysteine produces Co^{I}, which then acts as a powerful nucleophile towards the methyl group donor, N5-methyltetrahydrofolate,[28] i.e. the Co−C bond could be formulated as $Co^{I} + R^{+}$.

In this paper we investigate the *cis* influence (to demonstrate the electronic communication between the axial coordination site and the corrin ring) and *trans* influences (to extend further the well-established *trans* influence in the cobalamins to the compounds under investigation) and then explore further the nature of the Co^{III} ion by addressing two questions. Firstly, when offered an ambident nucleophile with two donor atoms of different hardness, what is the thermodynamically favoured product? Secondly, is there any evidence in the solid state for an elongation of the axial bond to such a nucleophile? To this end, we have displaced H_2O in B_{12a} with $S_2O_3^{2-}$, SCN^-, NO_2^-, and $SeCN^-$ and crystallised the resultant compounds in order to determine their structures by X-ray diffraction analysis. We have been unable to crystallise CNOCbl, which slowly decomposes to CNCbl. Pertinent to this work is a report by Randaccio[29] and co-workers on the crystal structures of sulfitocobalamin, SO_3Cbl^-. This was found to be *S*-bound with a Co−S bond length of 2.134(7) Å. We are currently using NMR-restrained molecular modelling techniques to examine the structures of these compounds in solution and will report on those results elsewhere.

Results

UV/Vis Spectra

The UV/Vis spectra of H_2OCbl^+, NO_2Cbl, SCNCbl, $S_2O_3Cbl^-$, SeCNCbl, SO_3Cbl^- and MeCbl are shown in Figure 3. The spectrum of, for example, H_2OCbl^+ with its well-defined γ-band (the prominent band around 350 nm), has been referred to as a "typical" cobalamin spectrum, whereas that of MeCbl (for example), where the γ-band is apparently less well defined, and a greater number of bands are discernible especially in the shorter wavelength region, has been termed an "atypical" spectrum.[30] On this basis, one would classify the spectra of H_2OCbl^+, NO_2Cbl and SCNCbl as "typical" and those of $S_2O_3Cbl^-$, SeCNCbl, SO_3Cbl^- and MeCbl as "atypical".

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

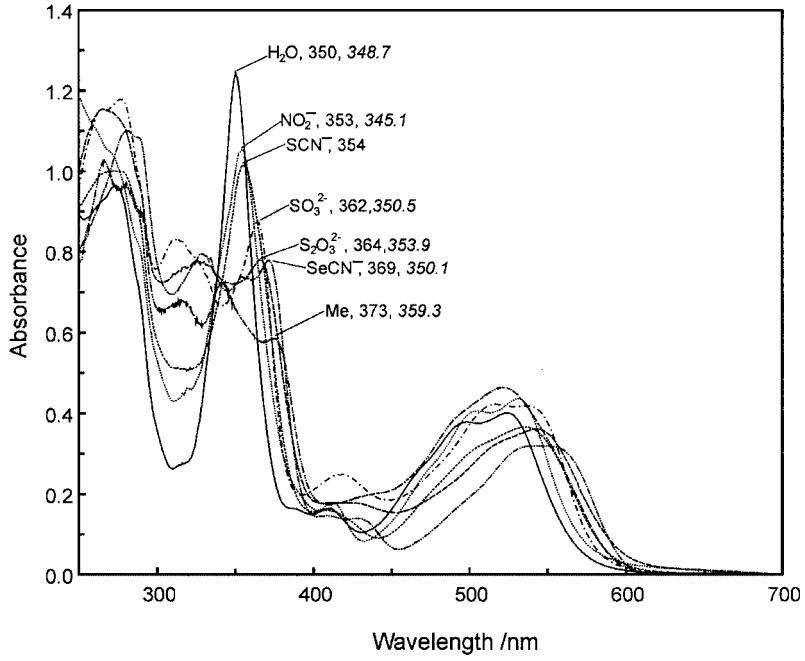

Figure 3. The UV/Vis spectra of cobalamin complexes; the identity of the β-axial ligand is given in each case, as is the observed position [nm] of the maximum absorption in the γ-band region of the spectrum; the γ-band envelope consists of three overlapping transitions, as shown by a Gaussian analysis of the spectra (see text, and Figure 4); the mean position of these three transitions is given in italics

An example of the fitting of the spectra under discussion with a series of Gaussian functions is shown in Figure 4. Either 11 (H_2OCbl^+, NO_2Cbl), 12 ($S_2O_3Cbl^-$, SeCNCbl, SO_3Cbl^-) or 13 (MeCbl) Gaussian functions were required to adequately fit the spectra. The results are listed in Table S1 of the Supporting Information. The γ-band of the corrins is best modelled as the overlap of three transitions, as are the αβ-bands (in the 450−600 nm region). In the case of NO_2Cbl, two of the components of the γ-band region overlap closely, and the region can only be resolved into two component Gaussian functions.

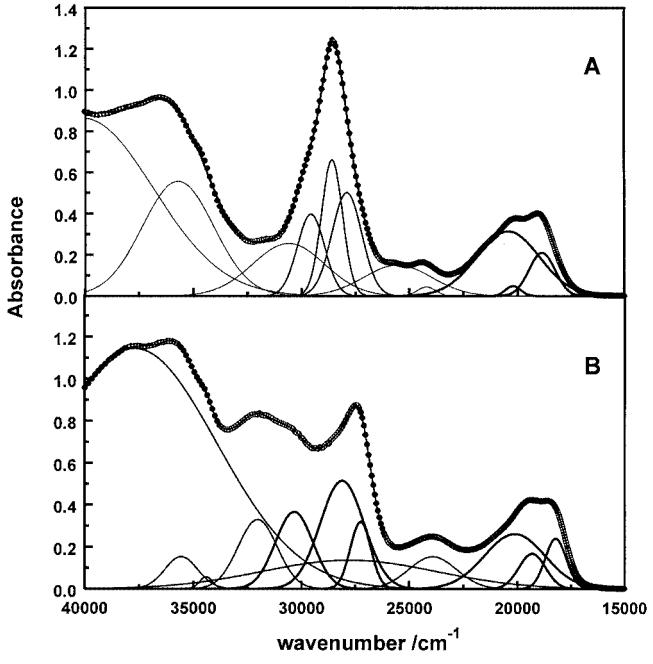

Figure 4. Resolved UV/Vis spectra of (A) H_2OCbl^+ and (B) SeCNCbl; The γ-band in each case is best fitted by three Gaussian functions (shown as bold lines); the circles are the experimental data and the line through the circles is the sum of the individual Gaussian bands

Structure of SCNCbl

SCNCbl crystallises in the orthorhombic space group $P2_12_12_1$ (R_1 = 8.75%, Figure 5). The experimental data are summarised in Table 1. The thiocyanato ligand is coordinated through N [Co−N = 1.954(11) Å] in a bent fashion [Co−N−C = 146.2(11)°], and positioned over C15 (Figure 6). Some of the bond lengths and bond angles involving the metal ion are summarised in Table 2.

As is usually found in the crystal structures of cobalt corrinoids, several solvent water molecules are incorporated, and they are extensively hydrogen-bonded to the amide side chains of the corrin. Possible hydrogen bonds were identified by standard methods.[31] An amide proton of N40 in the *c* side chain appears to be hydrogen-bonded to the N atom of coordinated SCN^- (N40···NCS = 3.309Å, N40−H−NCS = 161°). N52 of the *e* side chain amide group is hydrogen-bonded to N45 of the *d* side chain of a neighbouring molecule, whilst O51 acts as a hydrogen bond acceptor to N63 of the *g* side chain. The second N63 proton is hydrogen-bonded to O33 of the *b* side chain of a neighbouring molecule. Both hydroxy groups of the ribose act as hydrogen bond donors towards solvent water molecules.

Structure of SeCNCbl

SeCNCbl crystallises in the orthorhombic space group $P2_12_12_1$ (R_1 = 7.46%, Figure 5). The experimental data are

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

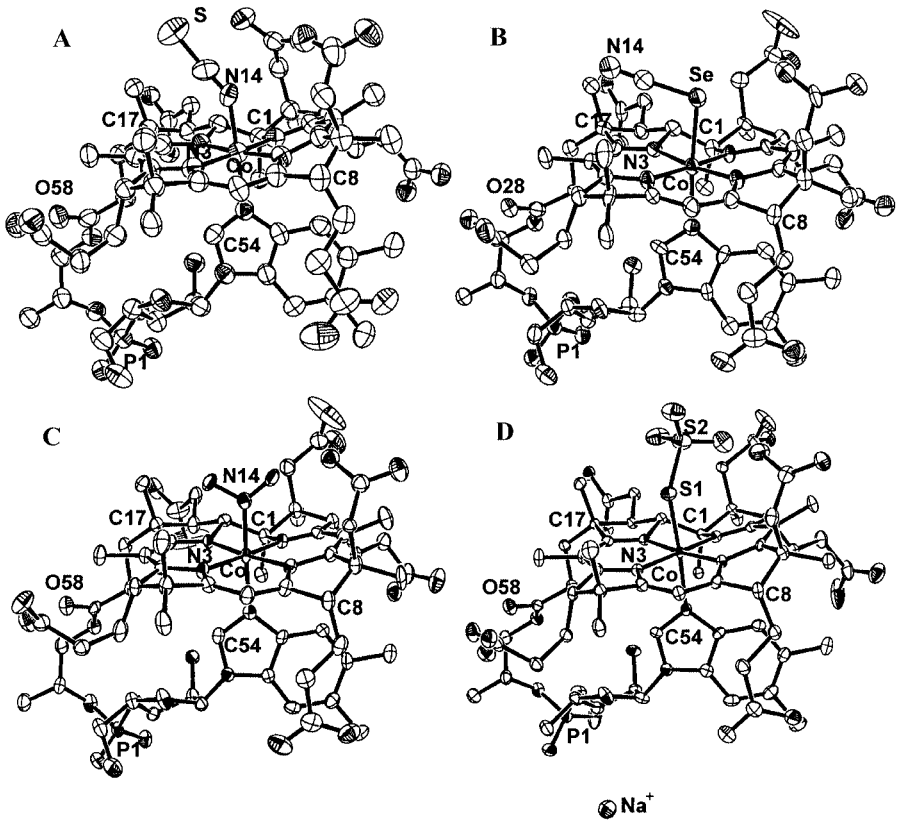

Figure 5. ORTEP diagram of (A) SCNCbl (25% probability contours), (B) SeCNCbl (50% probability contours), (C) NO_2Cbl (50% probability contours, with disorder in the orientations of the NO_2 ligand, and the *c* and *e* side chains removed for clarity), (D) $Na^+S_2O_3Cbl^-$ (50% probability contours)

summarised in Table 1. The selenocyanato ligand is coordinated through Se [Co−Se = 2.394(2) Å] in a bent fashion [Co−Se−C = 104.3(3)°] and the ligand is orientated over the southern quadrant of the molecule (Figure 6). Some of the bond lengths and bond angles involving the metal ion are summarised in Table 2. We were also able to grow crystals rapidly by using a near-saturated solution of B_{12a} in the presence of 0.05 mol·dm^{-3} KSeCN (crystals were obtained in a few hours). Although the crystal quality was poor, the diffraction data (not shown) were good enough for refinement to a level that showed unambiguously an *Se*-bound selenocyanato ligand.

The amide NH groups of the *a*, *b*, *c*, *d*, *e* and *f* side chains act as hydrogen bond donors towards solvent water molecules, whilst the *d* and *e* amide groups are also hydrogen-bonded to the carbonyl group of the *a* side chains of neighbouring molecules. The *g* side chain is hydrogen-bonded to the *b* and *e* side chains of neighbouring molecules. The R7 and R8 hydroxy groups [see Figure 1(A)] are hydrogen-bonded to solvent water molecules.

Structure of NO_2Cbl

NO_2Cbl crystallises in the orthorhombic space group $P2_12_12_1$ (R_1 = 7.16%, Figure 5). The experimental data are summarised in Table 1. The nitro ligand is coordinated through N [Co−N = 1.941(5) Å] and the ligand is disordered over two positions (Figure 6). In the first position [0.82(10) occupancy], the two oxygen atoms point towards C10 and the C1−C19 bond [N−O−N = 121.6(5)°]. In the second position [0.18(10) occupancy] they are virtually orthogonal to this, pointing towards C5 and C15 [N−O−N = 111.2(15)°]. Some of the bond lengths and bond angles involving the metal ion are summarised in Table 2.

As with the other structures, there is extensive hydrogen bonding of the amide side chains. One of the *c* side chain amide protons is hydrogen-bonded to the N atom of the coordinated NO_2 ligand. Hydrogen bonding occurs between the amide protons of the *e*, *d* and *g* side chains of one molecule, and the *a* side chain of one neighbouring molecule and the *a* and *b* side chains of a second neighbouring molecule, respectively. The amide proton of the *a* side chain is hydrogen-bonded to the O atom of the acetone solvent molecule in the same unit cell, whilst one of the *d* side chain amide protons is hydrogen-bonded to a neighbouring acetone molecule. The amide groups of the *b*, *c*, *e*, *f* and *g* side chains are hydrogen-bonded to water molecules.

Structure of $S_2O_3Cbl^-$

$Na^+S_2O_3Cbl^-$ crystallises in the orthorhombic space group $P2_12_12_1$ (R_1 = 5.88%, Figure 5). The experimental data are summarised in Table 1. The thiosulfate ligand is coordinated through S [Co−S = 2.2861(11) Å]. The ligand points towards C1 and comes within van der Waals contact with the *a* side chain (Figure 6); as a consequence, the li-

gand bends away [the NB3−Co−S angle is 167.05(9)°]. The coordinated $S_2O_3^{2-}$ ion is hydrogen-bonded to the amide group of the *a* side chain (through one of the O atoms) and to the amide group of the *c* side chain (through the donor S atom). Selected bond lengths and bond angles involving the metal ion are summarised in Table 2. The Na^+ counterion is in close contact with the R8 hydroxy group and a cluster of four solvent water molecules.

The *a* side chain amide group is hydrogen-bonded to a solvent water molecule in addition to the coordinated $S_2O_3^{2-}$ ion as described above. The *b* side chain is hydrogen-bonded to the phosphate group of a neighbouring molecule. The *d* and *e* side chains are hydrogen-bonded to the *a* side chains of two different neighbours, whilst the *g* side chain hydrogen-bonds to the *e* and *b* side chains of two different neighbours. The R7 hydroxy group is involved in an intramolecular hydrogen bond to the phosphate group.

In addition to these hydrogen bonds, the cobalamin molecules are also connected to each other through the Na^+ counterion [Na−O3: 2.327(4) Å; Na−O14 (1/2 − x, −y, 1/2 + z): 2.367(4) Å]. This reinforces the interactions between molecules related by the twofold screw axis parallel to *c* as shown in Figure 7.

Solid-State Packing

The majority of cobalamins crystallise in the $P2_12_12_1$ space group.[20,29] Kratky and co-workers have shown that most of the crystal structures of cobalamins belonging to this space group can be assigned to one of four packing types. Types I−III are classified according to the *c*/*a* and *b*/*a* cell axis ratios. More recently, Randaccio et al.[29] discovered a fourth packing type, IV. The four packing types differ in the way the cobalamin molecules stack in the solid state. From the *c*/*a* and *b*/*a* cell axis ratios we have found that all four structures reported here belong to packing type I.

The Corrin Fold

The corrin fold angle (the angle between the mean planes through N21−C4−C5−C6−N22−C9−C10 and C10−C11−N23-C14−C15−C16-N24[32]) in SCNCbl is

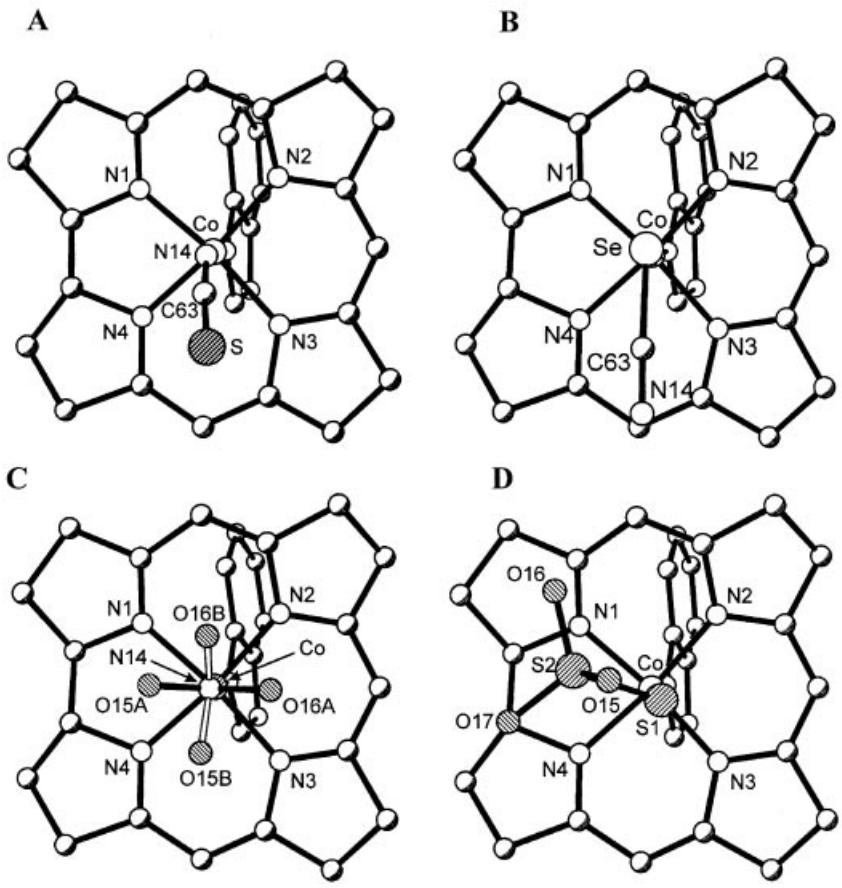

Figure 6. View of the upper face of the four corrins showing the orientation of the axial liagnds; for clarity, only the β-ligand, the corrin core, and the bzm ligand are shown

large (22.4°); of the cobalt corrinoid structures reported to date only cyano-13-*epi*-cobalamin[33] has a larger fold angle (23.7°). The fold angle in SeCNCbl is much smaller (13.7°), close to the average corrin fold angle of about 14°.[26] The fold angle is 14.5° in NO_2Cbl and somewhat larger (17.2°) in $S_2O_3Cbl^-$.

Coordinated bzm

In all the structures studied, the bzm ligand is coordinated off-vertical to the corrin ring, with a tilt angle (the angle between the mean plane through the 9 heavy atoms of the aromatic core of the bzm ligand, and the normal to the mean plane through the 24 heavy atoms of the corrin core) of 15° in SeCNCbl, 8° in NO_2Cbl, 13° in SCNCbl and 10° in $S_2O_3Cbl^-$. In each case the tilt is towards the eastern quadrant of the molecule and probably reflects the steric strain inherent in the nucleotide loop which attaches the bzm ligand to the *f* side chain through a ribose and an aminopropanol moiety (Figure 1).

Discussion

cis and *trans* Influences in Cobalamin Chemistry

The Co−NB3 bond is quite short in SCNCbl [1.958(9) Å], somewhat longer in NO_2Cbl [2.008(4) Å], and significantly longer in $S_2O_3Cbl^-$ [2.078(3) Å], SeCNCbl [2.102(7) Å] and[29,32] SO_3Cbl^- [2.134(4) Å or 2.156(5) Å] (Table 2). An examination of the Co−NB3 bond lengths in eleven cobalamins RCbl where the β-ligand is an alkyl group [adenylpropyl,[34] CF_3,[35] CH_3,[36] (*R*)- and (*S*)-2,3-dihydroxypropyl,[37] adenosyl (four separate determinations),[21,38] 2′,5′-dideoxy-5′-adenosyl and 2′,3′,5′-trideoxy-5′-adenosyl[39]] shows that the average Co−NB3 bond (2.23 ± 0.05 Å) is significantly longer than the average for the three structures XCbl (1.97 ± 0.04 Å) where the β-ligand is an inorganic moiety (X = Cl^-, N_3^- and[40] H_2O[41]). With cyanide as the *trans* ligand, the Co−NB3 bond is longer than in the XCbl systems, but shorter than in the RCbl systems (2.008 Å in CNCbl[42] and 2.023 Å in CNCbl-*b*-carboxylate[43]). There is clearly a ground-state *trans* influence; a soft or polarisable ligand in the β-position (alkyl, S- or

[a] For comparison from Randaccio et al.[29] The reported values are for $[(SO_3)Cbl](NH_4)$. There is a more recent determination of the structure of $[(SO_3)Cbl](NH_4)$·glycerol using synchotron radiation,[63] and the results from that determination are given in italics. [b] Two positions of the NO_2 ligand.

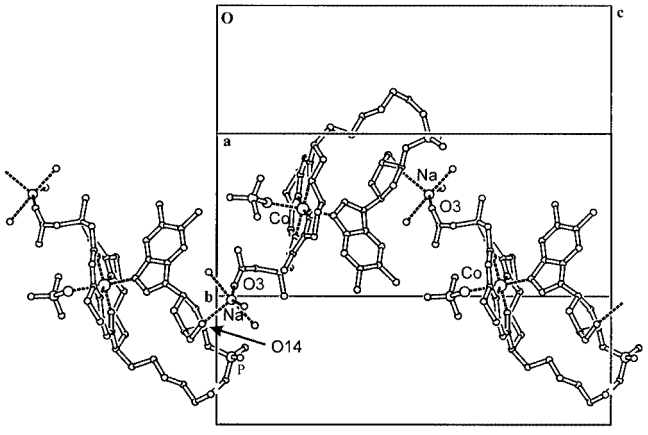

Figure 7. There is an interaction between the Na^+ counterion and oxygen atoms on neighbouring cobalamin molecules related by the twofold screw axis parallel to the *c* axis in the $S_2O_3Cbl^-$ structure; portions of the cobalamin molecules have been omitted for clarity

Se-donor as in $S_2O_3Cbl^-$ and SeCNCbl, respectively) causes an elongation of the Co−NB3 bond. The thiocyanato ligand, coordinated through N acts as a typical hard inorganic moiety, whilst coordinated NO_2^- has a similar ground-state *trans* structural influence as CN^-.

The large corrin fold angle of 22.4° in SCNCbl (the average fold angle of cobalamins in about 14°) is probably a consequence of the short Co−NB3 bond. Kratky and co-workers[20] have shown that as the axial Co−NB3 bond length decreases, the corrin fold angle increases. This is because the bzm ligand, and the B4 proton in particular, interact with the corrin ring and the corrin folds upwards towards the β-ligand in response. The corrin angles of SeCNCbl, NO_2Cbl and $S_2O_3Cbl^-$ are significantly smaller (see above).

The complexity of the UV/Vis spectra of the cobalamins makes it difficult to unambiguously determine the band positions. A plot of the apparent position of the γ-band maximum (a measure of the *cis* influence[30]) against the Co−NB3 bond length (a measure of the *trans* influence,[20] see above) shows the two parameters are correlated, albeit poorly ($r^2 = 0.58$, $n = 6$) (Figure 8, A), and the band moves to longer wavelength as the softness of the axial ligand increases. The spectrum of SCNCbl is excluded, because SCNCbl exists in solution as a mixture of the two linkage isomers, see below.

The origin of the transitions in the electronic spectrum of the corrinoids has been reviewed.[44] Kuhn and co-workers[45] used a one-dimensional free-electron model of the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

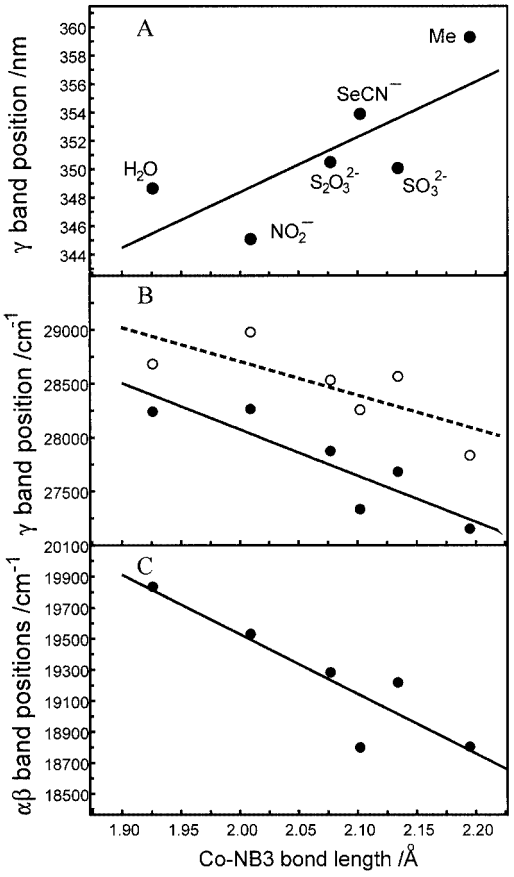

Figure 8. (A) Dependence of the apparent position of the γ-band (see Figure 3) on the Co−NB3 bond length; (B) relationship between the mean position of the three Gaussian components of the γ-band (open circles) and the two lowest-energy Gaussian components of the γ-band (filled circles) and the Co−NB3 bond length: (C) relationship between the mean position of the three components of the αβ-absorption envelope (see Figure 3) and the Co−NB3 bond length

open chain analogue of the 13-atom corrin chromophore (1,5,9,13-tetraazatrideca-1,3,5,7,9,11-pentaene) coordinated to Co^{III} to model the corrin and assign the principal bands in the electronic spectrum. In this model, the 7 lowest-energy levels of the π-electron system are occupied, and the γ-band is a symmetry-allowed transition between two states mixed by configurational interactions, $\pi_6 \rightarrow \pi_8$ and $\pi_7 \rightarrow \pi_9$. As has been noted,[46] the γ-band may be split into at least two components. The αβ-bands were assigned to the forbidden $\pi_7 \rightarrow \pi_8$ transition (the lower energy α-band) and its vibrational fine structure (the β-band). The interaction of this system with the axial ligands has been studied using an iterative extended Hückel molecular orbital method,[47] and it was shown that the main effect of the axial ligands is to change the energy of the π_7 orbital. Hence, transitions involving π_7 should shift to longer wavelength as the strength of the axial ligand field increases. Unlike the models used, the corrinoids are asymmetric with respect to rotation in the plane of the macrocycle. Since this asymmetry is expected to split these transitions, this may be the reason why both the γ- and the α,β-regions are modelled best by three Gaussian functions (Figure 4).

The three components of the γ-band were plotted against the length of the *trans*-Co−NB3 bond. Whilst the two lower energy components move to lower energy as the Co−NB3 bond length increased, there was no obvious correlation with the position of the highest-energy component, which suggests (but does not prove) that this component may not involve transitions from the π_7-molecular orbital of the corrin and may indeed not be part of the transitions that make up the γ-band. A plot of the mean position of the three Gaussian functions, and of the mean position of the two lowest-energy Gaussian functions, against the Co−NB3 bond length is shown in Figure 8, B. The latter gives a better correlation ($r^2 = 0.79$) than the former ($r^2 = 0.58$). In either case, the mean position of the components of the γ-band move to lower energy as the polarisability of the β ligand increases and the *trans*-Co−NB3 bond length increases. Similarly, all three components of the αβ-absorption envelope move to longer wavelengths as the Co−NB3 bond length increases, Figure 8, C ($r^2 = 0.81$).

This analysis indicates that there is no fundamental difference, apart from more transitions in the shorter wavelength region becoming observable, between the "typical" spectra of H_2OCbl^+, NO_2Cbl and SCNCbl, and the "atypical" spectra of $S_2O_3Cbl^-$, SeCNCbl, SO_3Cbl^- and MeCbl. The apparent differences in the γ-region stem from the components that constitute the γ-band moving apart in response to an increase in donation of electron density from the axial ligand field.

The results presented in Figure 8 are evidence for a correlation (albeit weak) between the ground-state *cis* and *trans* influences in the cobalamins. As the polarisability of the β-ligand increases, the *trans*-Co−NB3 bond length increases (*trans* influence), a consequence of the increasing electron density on the metal atom. This is transferred into the delocalised π-electron system of the corrin ring and the mean positions of the γ- and the αβ-transitions move to longer wavelength. The *trans* influence effect noted here is a further demonstration of the occurrence of a regular *trans* influence in the cobalamins as recently demonstrated by Randaccio and co-workers[32] who used DFT calculations to show that shortening of the Co−S bond in cobalamins with S-donor β-ligands causes the *trans*-Co−NB3 bond to lengthen.

The Corrin Fold

As noted above, the corrin ring in SCNCbl is considerably more folded than in SeCNCbl, NO_2Cbl or $S_2O_3Cbl^-$ (the fold angles are 22.4°, 13.7°, 14.5° and 17.2°, respectively). Examination of an overlay of the structures of SCNCbl and SeCNCbl shows that the principal reason for this is the Co−X−C−Y bond angle. When X = Se and Y = N, the small angle (104.3°) brings the axial ligand snugly between, and in close van der Waals contact with, C46 and C54 and very near the C15−C53 moiety. This forces the southern quadrant to be considerably flatter than when NCS^- is coordinated. In that case, the Co−X−C−Y (X = N, Y = S) angle is considerably larger (146.2°), and the bent axial group stands proud of C46, C54 and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

C15−C53. The mean Co−N−O angle in NO_2Cbl is 121.7° and the oxygen atoms of the ligand are not in van der Waals contact with the corrin or its substituents, with the exception of the hydrogen bond formed with the *c* side chain amide group. In S_2O_3Cbl$^-$ the coordinated ligand lies along the C10···C1/C19 fold axis. Despite this, the corrin is quite folded, since the Co−S−S angle is large due to the van der Waals contacts of the ligand with the substituents in the western portion of the molecule as noted above.

The Nature of the Co^{III} Ion in Cobalamins

We have found that SCN^- coordinates to Co^{III} in SCNCbl through N. Cobalt complexes with *N*-bound thiocyanate ions are common. A survey of the Cambridge Structural Database (CSD)[48] shows that there are 37 structures containing *N*-bound SCN^- to Co^{III} with a mean Co−N bond length of 1.93 ± 0.05 Å, but only three structures with *S*-bound SCN^- (d_{Co-S} = 2.29 ± 0.03 Å). In the case of Co^{II}, 86 structures have *N*-bound NCS^-, d_{Co-N} = 2.01 ± 0.07 Å, and there is only one structure [a low-spin dicobalt(II) compound of a Schiff-base marcrocycle with four bound thiocyanato ligands, two *N*-bound and two *S*-bound[49]] with *S*-bound SCN^- (d_{Co-S} = 2.584 Å). Hence, irrespective of the oxidation state of the metal ion, there is a strong preference for the thiocyanate ion to coordinate through N.

As expected, NO_2^- forms a longer bond to low-spin d^7 Co^{II} than it does to low-spin d^6 Co^{III}. The Co−NCS bond of 1.954(11) Å in SCNCbl is marginally long for coordination to Co^{III} (mean 1.93 ± 0.05 Å, see above), but short for coordination to Co^{II} (mean 2.01 ± 0.07 Å). It could be argued that the crowded β-face of the corrin ring contributes to Co−N bond lengthening. However, the Co−N−C angle is 146.2(11)°, which is close to the smallest angle (140.7°) found in the CSD for *N*-bound SCN^- to Co^{III} (the range is 140.7−178.8°, with an average value of 168 ± 8°). The analogous data for Co^{II} are 137.4−179.5°, 166 ± 8°. One would expect the angle to be considerably larger if there was a significant steric effect. The slightly long Co−N bond to NCS^- in SCNCbl is not due to steric reasons and could be the result of some partial Co^{II} character of the metal ion.

There is a report[50] of a crystal structure of SCNCbl in which the thiocyanato ligand is bound through S. The ^{1}H and ^{13}C NMR data of a solution containing B_{12a} and sufficient SCN^- for complete complex formation (the formation constant of the thiocyanato complex is log *K* = 3.1[51]) at 25 °C contains two sets of peaks close to each other, indicative of two different but related species in solution, which we assumed to be the linkage isomers. The peaks in the ^{1}H NMR spectrum due to the C10 and C13 protons are relatively free of overlap and were integrated, giving ratios of 1:0.75 and 1:0.86, respectively. (We have not been able to assign the individual resonances to each of the two linkage isomers.) SCNCbl clearly exists in solution as a mixture of the *N*- and the *S*-bound isomers and it is perhaps fortuitous that we obtained the *N*-bound isomer.

Addition of excess KSeCN to a solution of B_{12a} results in the immediate formation of a purple solution which, over time, changes to a solution with a more distinctly red colour. The initial ^{1}H and ^{13}C NMR spectra are consistent with a single product, and there is an apparently smooth transition to a second product with a half-life of about 2 d. The UV/Vis and ^{13}C NMR spectra of the final product are identical to those of CNCbl. Analysis of the X-ray diffraction of crystals obtained from the aged solution confirmed that the product is CNCbl (data not reported). This process occurs both under aerobic and anaerobic conditions. Since the crystal structure of the initial compound shows the ligand to be *Se*-bound, and there is no evidence for linkage isomerism in the ^{1}H and ^{13}C NMR spectra, we conclude that the selenocyanato complex decomposes slowly with extrusion of Se to form CNCbl. To date we have made no attempt to explore the mechanism of this reaction, but we note a report that [Ru(bmipy)(dcbpy)I]$^-$ [dcbpy^{2-} = 4,4′-dicarboxy-2,2′-bipyridyl; bmipy = 2,6-bis(1-methylbenzimidazol-2-yl)pyridyl] reacts with $SeCN^-$ to form a mixture of the *Se*- and the *N*-bound complexes. Prolonged reaction produces only the *N*-bound isomer which then rapidly yields the cyano complex with extrusion of Se.[52] Also, when *cis*-L_2Ru$(NCS)_2$ (L_2 = diethyl 2,2′-bipyridyl-4,4′-dicarboxylate) is oxidised to Ru^{III}, S is eliminated and the dicyanato complex is produced.[53] These workers noted that the reaction mechanism is complex, and postulated that extrusion of S occurs through a cyclic intermediate and rearrangement from *N*- to *C*-bound cyanide ion. Since $SeCN^-$ is coordinated to cobalamin in a bent fashion, an analogous cyclic intermediate appears to be feasible in the Se extrusion pathway.

There is only one example of a Co^{III}−selenocyanate complex in the CSD (a diselenocyanato cobaloxime complex[54]) and no complexes of Co^{II}. The Co^{III} compound has the ligand *Se*-bound to the metal atom with a Co−Se bond length of 2.383 Å, a Co−Se−C angle of 106.2° and an Se−N−C angle of 175.5°. Hence, the geometry is quite similar to that of SeCNCbl where the analogous parameters are 2.394 Å, 104.3° and 176.2°. Thus, the cobalt ions in the cobalamins behave like Co^{III} towards $SeCN^-$.

The great majority of NO_2^- complexes of Co^{III} reported in the CSD (148 structures) have the ligand bonded through the softer N donor with a mean Co−N bond length of 1.94(3) Å, an N−O bond length of 1.22(3) Å, a Co−N−O bond angle of between 112° and 132° [mean 120(2)°] and an O−N−O angle of between 92° and 135° [mean 119(3)°]. There are only two structures with *O*-bound NO_2^- [the mean Co−O bond length is 1.90(4) Å]. The two available structures of NO_2^- complexes of Co^{II} both have the ligand bonded through N. The Co−N bond lengths vary between 1.889 and 1.944 Å [mean 1.92(6) Å]. Surprisingly, the average Co^{II}−N bond is somewhat shorter than the average Co^{III}−N bond and this may be indicative of some metal-to-ligand back-bonding. The NO_2Cbl structure is therefore typical for coordination of NO_2^- to Co^{III} [the results for the major occupied site has Co−N = 1.941(5) Å, N−O = 1.230(2) Å, Co−N−O = 121.1(4)° and 117.2(4)° and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

O−N−O = 121.6(5)°]. The ^1H and ^{13}C NMR spectra indicate the presence of a single compound in solution and the kinetic data (see Introduction) are consistent with reaction through N. There is therefore no evidence for the nitrito isomer.

Although there are relatively few structures of complexes containing $S_2O_3^{2-}$ coordinated to cobalt (there is one with Co^{II}, and six with Co^{III}), those which have been reported are all *S*-bonded. There are significant differences in the lengths of the Co−S bonds: 2.488 Å in the *cis*-bis(thiosulfato)tetraaquacobalt(II) ion[55] and, on average, 2.28(3) Å in the Co^{III} complexes. In the latter, the average Co−S−S bond angle is 112(2)°. Therefore, the observed bond length of 2.286(1) Å in $S_2O_3Cbl^-$ is consistent with coordination to a Co^{III} centre. The somewhat large Co−S−S bond angle of 122.35(6)° is probably a consequence of close steric contact with the *a* side chain.

Conclusion

The lability of the formally low-spin Co^{III} centre in cobalamins, a notable feature of B_{12} chemistry (see Figure 2), is clearly conferred by the equatorial corrin ligand. There is clear evidence of electronic communication between the equatorial ligand system and the axial coordination sites of the metal ion. Thus, the principal transitions in the electronic spectra of the cobalamins shift to longer wavelengths as the donor power of the β-ligand increases (Figures 3 and 8). In addition to this *cis* influence, there is a normal *trans* influence as the Co−NB3 bond length responds to the donor ability of the β-ligand (Figure 8).

The structures of four cobalamin complexes obtained by the displacement of the axial H_2O molecule of B_{12a} with ambident nucleophiles (SCN^-, $SeCN^-$, NO_2^- and $S_2O_3^{2-}$) have been determined by X-ray diffraction methods. Our results show that Co^{III} in the complexes studied usually binds to the softer of the two available donor atoms (Se rather than N in $SeCN^-$, N rather than O in NO_2^- and S rather than O in $S_2O_3^{2-}$), but SCN^- is found to be *N*-bound in the solid state. However, there is a previous report of an *S*-bound complex and SCNCbl exists as a mixture of the two linkage isomers in solution. This preference for the softer donor atom in ambidentate nucleophiles is not unusual for cobalt complexes. An examination of the structures available in the CSD shows that irrespective of the oxidation state of the Co centre (+2 or +3), there is a strong preference for the thiocyanate ion to coordinate to the cobalt atom through N. The only example of a Co^{III}−selenocyanato complex in the CSD has the ligand bound through Se. NO_2^- usually coordinates to Co^{III} through N. The two Co^{II} structures available with NO_2^- as a ligand also have the ligand *N*-bound. There are relatively few structures of $S_2O_3^{2-}$ coordinated to Co^{II} and Co^{III}; all are *S*-bound.

If the metal ion in the cobalamins had significant Co^{II}-like character, then the bond to the β-axial ligand should be long, consistent with population of d_{z^2} in a pseudo-octahedral ligand field; in Co^{II} corrinoids the β-ligand is either absent or, at most, interacts very weakly with the metal centre. The Co−N bond in SCNCbl is marginally long for coordination to Co^{III} [$d_{Co^{III}-N}$ = 1.93 ± 0.05 Å; 1.954(11) Å observed in SCNCbl]. However, the other complexes have bond lengths expected for coordination to Co^{III}. Therefore, the increase in electron density that the corrin undoubtedly imparts to the metal atom has no significant effect on the ground-state structures of these complexes.

Experimental Section

UV/Vis Studies: UV/Vis spectra were recorded using a Cary 3E spectrophotometer with the cell compartment thermostatted by a water-circulating bath. These spectra, as well as those of SO_3Cbl^- and CH_3Cbl, the crystal structures of which have been reported by others, were analysed by Gaussian analysis, as we have done previously for iron porphyrins.[56] Each spectrum was converted into a plot of absorbance against wavenumber and fitted to the sum of the minimum number of Gaussian bands [Equation (2)] using non-linear least squares.[57] In Equation (2), A_T is the total absorbance, λ the measured wavenumber, λ_j the wavenumber at which the *j*th Gaussian component reaches a maximum absorbance, α_j the intensity of the *j*th peak and Δ_j the half-width of the *j*th band at 0.607 of the maximum intensity.

$$A_T = \sum_{j=1}^{n} \alpha_j \exp\left[\frac{-(\lambda - \lambda_j)^2}{2\Delta_j^2}\right] \quad (2)$$

Single Crystal X-ray Structure Determinations: Crystals were grown by dissolving hydroxocobalamin (approximately 50 mg, Roussel, > 99% pure, HPLC) in deionised water (700 μL) . To this was added an excess of the salt of the ligand. The solution was gently heated to ensure dissolution. The crystals were grown in H-tubes in a refrigerator, by vapour diffusion of acetone into the aqueous solution. Crystals usually appeared after about a week. A suitable crystal was selected after visual examination under a microscope. Intensity data were collected with a Bruker SMART 1 K CCD area detector diffractometer with graphite-monochromated Mo-K_α radiation (50 kV, 30 mA). The collection method involved ω-scans of 0.3° width. Data reduction was carried out using the program SAINT+[58] and absorption corrections were made using the program SADABS.[59] The crystal structures were solved by direct methods using SHELXS-97.[60] All non-hydrogen atoms of the cobalamin were first refined isotropically followed by anisotropic refinement by full-matrix least-squares calculations based on F^2 with SHELX-97 until convergence was achieved. Hydrogen atoms were positioned geometrically and allowed to ride on their respective parent atoms. In most cases it was not possible to locate the hydrogen atoms on the water molecules. These have been included in the formula sum, however. Diagrams and publication material were generated using WinGX[61] and PLATON.[62] CCDC-185962 to -185965 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

X-ray Structure Determination of SCNCbl: SCNCbl was found to contain some disordered guest water molecules. These were mod-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

elled over two positions by either fixing their occupancies, or by assigning their occupancies to a free variable and allowing the free variable to be refined.

X-ray Structure Determination of SeCNCbl: All the solvent molecules in SeCNCbl were refined anisotropically with full occupancies.

X-ray Structure Determination of NO_2Cbl: Disordered atoms in the main body of the NO_2Cbl structure were refined independently with individual isotropic temperature factors. Disordered moieties included the NO_2 ligand and the *c* and *e* side chains. The NO_2 ligand was modelled over two orientations, with a site occupancy ratio of 0.82:0.18. The *c* and *e* side chains were both modelled over two orientations in 0.63:0.37 and 0.61:0.39 site occupancy ratios, respectively. Soft SADI restraints were used to ensure that all the bond lengths between the same atoms in each orientation were similar. The unit cell of NO_2Cbl contained a solvent acetone molecule in addition to several water solvent molecules. All C−C bonds, and the C−O bond in the acetone molecule were restrained to 1.50(2) and 1.24(2) Å, respectively, and a FLAT restraint was used to ensure that all the atoms were planar. Many of the water molecules in the NO_2Cbl structure were found to be disordered, or partially present. These were refined independently with individual isotropic thermal factors if the refinement was unstable.

X-ray Structure Determination of NaS_2O_3Cbl: The acetone solvent molecule in the $S_2O_3Cbl^-$ structure was refined isotropically, and all C−C and C−O bonds were restrained to 1.50(2) and 1.24(2) Å, respectively. All atoms in the acetone molecule were kept in a plane with the FLAT restraint. As with the previous structures, some of the solvent water molecules were refined and fixed with partial occupancies or, if they were disordered, modelled over two orientations. These solvent molecules were refined isotropically if anisotropic refinements resulted in unstable thermal parameters. ISOR restraints were applied to some of the solvent water molecules to approximate their U_{ij} values to isotropic behaviour.

Synthesis, Solid-State Structure and Multinuclear NMR Studies of the New Polyhydrido Iridium Carbonyl Cluster $Ir_4H_4(\mu\text{-}H)_4(CO)_4(PPh_3)_4$

Luigi Garlaschelli,*[a] Francesco Greco,[a] Giulia Peli,[a] Mario Manassero,*[b] Mirella Sansoni,[b] Roberto Gobetto,*[c] Luca Salassa,[c] and Roberto Della Pergola[d]

Keywords: Cluster compounds / Iridium / Hydride ligands / NMR spectroscopy / P ligands

The carbonyl hydride cluster $Ir_4H_8(CO)_4(PPh_3)_4$ (**1**) has been formed in high yield and purity by heating a mixture of $Ir_4(CO)_{12}$ and PPh_3 in toluene at 90 °C under hydrogen at atmospheric pressure. The product has been characterised by microanalysis, spectroscopy (IR, ^1H and ^{31}P NMR) and X-ray diffraction. In the solid state one hydrogen, one CO and one triphenylphosphane ligand are terminally bonded to each iridium atom, whereas four hydride ligands are bridging. All the hydrogen atoms were directly located by X-ray analysis at an average H–Ir distance of 1.55 Å (for the terminal H) and 1.75 Å (for the μ-H). As shown by ^1H and ^{31}P NMR spectra, two isomeric forms (**1A** and **1B**) of the cluster are present in CD_2Cl_2 solution at room temperature, and they do not interconvert in the explored temperature range. However, if a solid sample of the cluster is dissolved at 188 K, only **1A** is detected by NMR spectroscopy. The structure of **1B** could be proposed on the basis of the T_1 relaxation times of the various hydrides: it results by localised exchange of H and CO around two vertices of the tetrahedral frame.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Hydrogen atoms are common ligands in transition metal chemistry[1] and can be bound to the cluster framework in a variety of ways.[2] Beside the most common terminal, bridging, and face-capping modes,[3] they can also occupy an interestitial coordination mode site, with up to six H-metal interactions.[4,5]

The hydride ligands in many clusters are abstracted from the solvent in which the cluster is prepared.[6] However, hydrides can also be introduced using a rational synthetic route, commonly acidification of an anionic cluster,[5,7,8] or hydrogenation of a suitable precursor.[9] Alternatively, the precursor might have contained hydrides and these are carried over into the cluster product.[10]

Owing to their low scattering factors, hydride ligands are difficult to locate by X-ray crystallography, and frequently neutron diffraction studies must be undertaken.[4,11,12] NMR spectroscopy is a powerful tool for determining the position of the hydrides in solution (especially when the cluster contains other nuclei with spin 1/2, such as ^{31}P, ^{103}Rh or ^{195}Pt).[13] A few cases of solid-state ^1H NMR studies have also been reported.[14]

In the present work we report the spectroscopic characterisation and the solid-state structure of the new cluster $[Ir_4H_8(CO)_4(PPh_3)_4]$, which can be obtained in a one-pot synthesis directly from $Ir_4(CO)_{12}$, PPh_3 and hydrogen. Among the huge number of tetrahedrally substituted iridium clusters,[12,15–17] the compound described here is peculiar in several aspects: the simplicity of the synthesis, the highly symmetric structure, its straightforward dynamic behaviour, and the large number of ligands around a small tetrahedral core. As one half of the ligands are hydrides, the compound can model the dissociative chemisorption of hydrogen on small iridium particles.[18]

$[H_2Ir_4(CO)_{10}]^{2-}$, with two terminal hydrides,[15] and $[HIr_4(CO)_{11}]^-$, with a bridging hydride located from neutron diffraction,[12] are other examples of hydrido-carbonyl clusters of iridium; $[HIr_4(CO)_{10}PPh_3]^-$ [19] and $[HIr_4(CO)_{10}PPh_2]$,[20] are tetranuclear clusters containing both hydride and P-donor ligands.

Results

Synthesis and Chemical Characterisation

While trying to synthesise an iridium cluster containing an interestitial phosphido atom, $Ir_4(CO)_8(PPh_3)_4$ [17] (**2**) was heated in refluxing toluene under a hydrogen atmosphere. The infrared spectrum of the brownish-yellow solution suggested the formation of a mixture. Attempts to separate the main products by preparative TLC or column chromatography failed, and therefore we sought milder conditions in order to increase the selectivity of the reaction. Eventually, a two-step, one-pot synthesis was devised, which is more simple and more selective: the first step is the carbonyl substitution of $Ir_4(CO)_{12}$ accomplished in refluxing toluene, with PPh_3 and $Ir_4(CO)_{12}$ in a 4:1 molar ratio. In the second step, the mixture of partially substituted clusters is placed under hydrogen and heated gently at a temperature below 90 °C until the infrared spectrum shows complete conversion (usually 24 hours). The product was crystallised from CH_2Cl_2/cyclohexane and was formulated as $Ir_4H_8(CO)_4(PPh_3)_4$ (**1**), by means of microanalysis, NMR spectroscopy, and X-ray analysis.

The poor reactivity of **1** is evidence of its stability. Despite the large number of hydride ligands, **1** cannot be deprotonated by base: when it was dissolved in THF, with an excess of Na_2CO_3 or KOH, the IR spectrum did not show any modification. A toluene solution of $Ir_4H_8(CO)_4(PPh_3)_4$ was placed under a carbon monoxide atmosphere at room temperature and no reaction was detected after three hours. However, heating the same solution at 110 °C for four hours resulted in the transformation into a mixture of $Ir_4(CO)_9(PPh_3)_3$ and **2**.

Solid-State Structure

The solid-state structure of **1**, and the numbering scheme, are shown in Figure 1. Relevant distances and angles are collected in Table 1. The metallic framework is tetrahedral, but the (idealised) molecular symmetry is S_4, with the unique axis intersecting the two unbridged Ir−Ir bonds. Thus, the four equivalent iridium vertices are coordinated by one triphenylphosphane, one terminal CO, one terminal and two bridging hydride ligands. The cluster is only slightly distorted by the presence of four μ-H ligands: the unbridged edges measure 2.726 Å and the bridged ones 2.919 Å. The five ligands are arranged in a square-based pyramidal coordination, with the PPh_3 ligands in the axial positions. The P-donors are almost perfectly mutually *trans*, separated by an unbridged Ir−Ir bond, and *cis* to the bridging hydride (with corresponding P−Ir−Ir angles of 115°) and therefore the metal atoms are octahedrally surrounded. The average distances between metals and ligands of different nature are well within the normal range for iridium clusters,[12,16,19,20] and are collected in Table 1. The Ir−H bond lengths are obviously affected by high standard deviations (0.03−0.04 Å) and therefore differences of 0.1 Å are of little significance; however, constant trends for the Ir−(μ-H)−Ir bond lengths seem to suggest some asymmetry, with long bonds *trans* to the carbonyl and short bonds *trans* to the terminal hydride, a pattern contrasting with the "structural" trans effect in octahedral metal complexes, being smaller for CO than for H.[21]

Multinuclear VT NMR Spectroscopy

When a sample of **1** is dissolved at low temperature in CD_2Cl_2 the ^1H NMR spectrum shows only two absorptions in the hydride region, at δ = −15.24 and −17.25 ppm

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

respectively, in agreement with the presence of the terminal and bridging hydride ligands of the highly symmetric structure determined by X-ray analysis. As the temperature is increased three new resonances appear in the proton spectrum at $\delta = -14.82$, -16.11 and -18.89 ppm, respectively, in the relative ratio 2:1:1. The intensity of these new absorptions is temperature dependent, as shown in Figure 2.

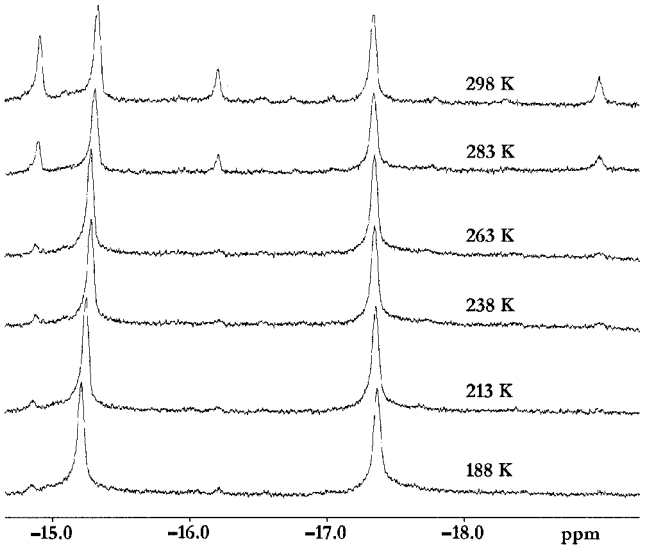

Figure 2. The ^{1}H NMR spectrum of **1**, recorded in CD_2Cl_2, at variable temperature

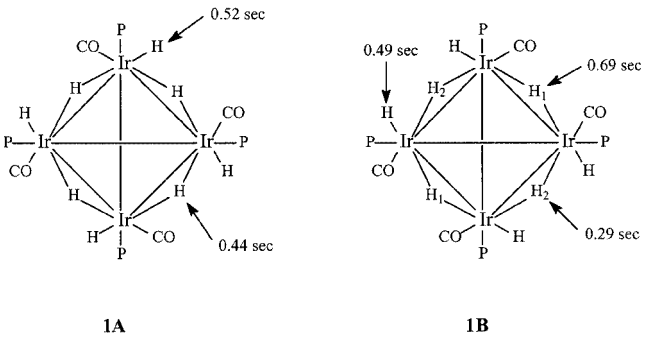
The high-field resonance can readily be assigned to a terminal hydride, whereas the two lower field signals are consistent with the formation of two distinct bridging hydride absorptions.

The same process has also been examined by ^{31}P and ^{13}C NMR spectroscopy. Monitoring the VT ^{31}P NMR spectrum in the same range of temperature, one can easily see that at 188 K only one ^{31}P signal is present at $\delta = 3.5$ ppm, whereas upon increasing the temperature a second absorption is observed at $\delta = 4.2$ ppm; at room temperature the spectrum shows two signals. Similarly, only a single resonance is detected in the ^{13}C NMR spectrum for the sample dissolved at 188 K in CD_2Cl_2, whereas a second absorption can be observed in the carbonyl region when the temperature is increased ($\delta = 166.78$ and 165.80 ppm).[22] Obviously the new resonances in the ^{1}H, ^{13}C, and ^{31}P NMR spectra must be associated with the formation of a second isomer (**1B**; Scheme 1), different from that found in the solid state (**1A**), which increases in concentration at higher temperature. The two resonances in the ^{31}P NMR spectrum were unambiguously assigned to **1A** ($\delta = 3.5$ ppm) and **1B** ($\delta = 4.2$ ppm) by running a ^{1}H-^{31}P 2D experiment. It is worth noting that if the sample is recrystallised again and a new experiment is performed with the previously reported procedure the same results are obtained. However, if the solution containing **1A** and **1B** at equilibrium is cooled to 188 K, both isomers are present; thus, the rate of exchange between the two isomers is slow on the NMR timescale.



Scheme 1. The structure of isomers **1A** and **1B**, with the T_1 relaxation times of the different hydride ligands

On the basis of the spectroscopic results it is reasonable to suggest that the second structure is also highly symmetric and the difference with respect to the former one is due to the position of the hydride ligands on the metal framework.

In order to assign the structure of the isomer **1B** an evaluation of the longitudinal relaxation times (T_1) of the hydride resonances has been performed. It has previously been demonstrated that this technique provides a suitable method for the determination of the structures of polyhydridic cluster systems[23] due to the dependence of T_1 on the relative interproton distances.[24]

The T_1 values obtained for the hydride ligands of the two isomers at room temperature are reported in Scheme 1, and are proposed on the basis of the relaxation and symmetry data.

The difference between the two isomers is the reciprocal orientation of CO and terminal H around the tetrahedron: by inverting the position of these ligands at two iridium vertices the molecular symmetry is lowered from S_4 to D_2. The T_1 values of the terminal hydrides are similar in both isomers, whereas the bridging hydrides show substantial changes. In particular, the relaxation time for the higher-field signal of **1B** is substantially shorter than the others, indicating a closer proximity of these hydrides to other hydride ligands in the cluster. On this basis it is straightforward to assign the resonance at $\delta = -18.89$ ppm (having shorter T_1) to the H_2 hydride in the structure. All the other attributions are summarised in Figure 3.

The complex spin system of twelve ^{31}P and ^{1}H nuclei, further complicated by chemical exchange, could not be examined in details. As a matter of fact, the observed bands are so broadened (either by chemical exchange or by low resolution at 188 K) that no hyperfine structure was observed at all (expected values for $^2J_{P,H} = 5-10$ Hz).[19,20]

Experimental Section

General: All the solvents were purified and dried by conventional methods and stored under nitrogen. All the reactions were carried out under an oxygen-free nitrogen atmosphere using standard Schlenk-tube techniques.[25] $Ir_4(CO)_{12}$ was prepared by literature methods.[26]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

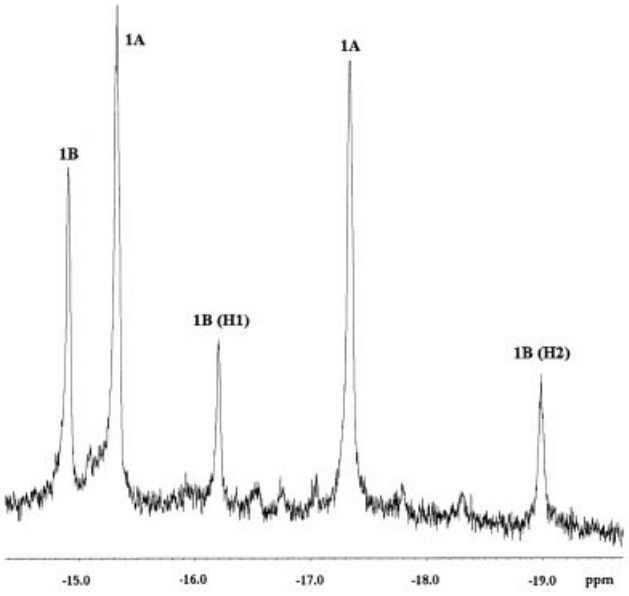


Figure 3. The ^1H NMR spectrum of **1**, recorded in CD_2Cl_2, at room temperature, with the assignments of the peaks

NMR experiments were performed on a JEOL EX 400 spectrometer (^1H operating frequency 399.78 MHz); non-selective inversion recovery was used to obtain ^1H T_1 values. Samples for T_1 measurements were prepared in the absence of O_2 by using standard freeze-pump-thaw techniques. Temperature calibration was carried out with a standard methanol ^1H thermometer. Errors in the reported T_1 values were estimated to be in the range ±2%.

Synthesis of $Ir_4H_8(CO)_4(PPh_3)_4$: $Ir_4(CO)_{12}$ (0.55 g, 0.50 mmol) and PPh_3 (0.52 g, 2 mmol) were suspended in 40 mL of toluene. The mixture was refluxed for 7 hours, and the IR spectrum of the yellow solution showed bands consistent with a mixture of tri- and tetra-substituted derivatives of $Ir_4(CO)_{12}$. The inert atmosphere was removed and the Schlenk was refilled with hydrogen. The solution was heated at 80 °C for about 24 hours and the colour changed from the yellow to pale yellow. After cooling, the solution was filtered, and the solvent was removed in vacuo. The residue was dissolved in dichloromethane and layered with cyclohexane. Yellow prismatic crystals were obtained in 65% yield (0.63 g). IR: ν(CO): 2121w 1993s cm^{-1} in CH_2Cl_2. $C_{76}H_{68}Ir_4O_4P_4$ (1938.1): calcd. C 47.1, H 3.5 found C 47.2, H 3.6.

X-ray Data Collection and Structure Determination: Crystal data are summarised in Table 2; other experimental details are listed in the supporting information. The diffraction experiment was carried out on a Bruker SMART CCD area-detector diffractometer at 223 K. No crystal decay was observed, so that no time-decay correction was needed. The collected frames were processed with the software SAINT,[27] and an absorption correction was applied (SADABS)[28] to the collected reflections. The calculations were performed using the Personal Structure Determination Package[29] and the physical constants tabulated therein.[30] The structure was solved by direct methods (SHELXS)[31] and refined by full-matrix least-squares using all reflections and minimising the function $\Sigma w(F_o^2 - kF_c^2)^2$ (refinement on F^2). Anisotropic thermal factors were refined for all the non-hydrogen atoms. The eight hydridic hydrogen atoms were refined with isotropic thermal factors. The remaining hydrogen atoms were placed in their ideal positions (C−H = 0.97 Å), with the thermal parameter B 1.10-times that of the carbon atom to which they are attached and not refined. In the final difference Fourier map the maximum residual was 1.88(81) e·Å^{-3} at 0.81 Å from Ir(2). CCDC-199711 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or at Cambridge crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Interaction of $V^{IV}O$, $V^{V}O_2$ and Cu^{II} with a Peptide Analogue SalGly-L-Ala

Tamás Jakusch,[a] Ágnes Dörnyei,[b] Isabel Correia,[c] Lígia M. Rodrigues,[d] Gábor K. Tóth,[e] Tamás Kiss,*[a] João Costa Pessoa,*[c] and Susana Marcão[c]

Keywords: Vanadium / Copper / Peptides / Speciation / Spectroscopy / Bioinorganic chemistry

The formation of complexes of a tripeptide analogue, salicylglycyl-L-alanine [$HOC_6H_4C(O)NHCH_2C(O)NHCH(CH_3)$-COOH, H_2SalGly-L-Ala], was studied with Cu^{II}, $V^{IV}O$ and $V^{V}O_2$ in aqueous solution using pH-potentiometric and spectroscopic (UV/Vis, CD, EPR and ^{51}V NMR) techniques. The results demonstrated the ambidentate character of the ligand. The metal ion-induced deprotonation and subsequent coordination of the two neighbouring amide groups was shown to occur in a cooperative way in the pH range 5–6. At pH ≈ 6.5 a complex with an (O^-, $2 \times CON^-$, COO^-) binding set becomes predominant for both Cu^{II} and $V^{IV}O$. The affinity of the phenolate-O^- for $V^{IV}O$ is high and the ligand is bound to this metal ion even at pH values greater than 10. Conversely, the affinity for $V^{V}O_2$ is significantly lower and no interaction between this metal oxo-ion and the ligand could be detected in the pH range 2–12. In contrast, with the dipeptide analogue H_2SalGly, chelation involving the deprotonated amide-N^- could be unambiguously detected.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Vanadium is an important trace metal with a great variety of physiological effects, including its interference with various phosphate-metabolizing reactions.[1] This suggests interactions between vanadium ions and protein side-chain donors. Peptides are not the best molecules for modeling metal ion binding to proteins, since the specially arranged side-chain donor groups of the amino acid units, determined by the tertiary structure of the proteins, are usually the primary bindings sites of proteins, while in the oligopeptides the N- and C- terminal donors are the basic sites for metal ion coordination. However, peptides are the most closely related models for proteins, and in some cases proteins may have specific terminal metal ion bindings sites as in the case of albumin.[2] For $V^{IV}O$ one of the known biologically important interactions with peptides is that with the important cell constituent and natural tripeptide, glutathione (GSH). In fact it is believed that GSH may play a role in the redox transformations of vanadium in the cells.[3] The equilibria in the systems $V^{IV}O^{2+}$–GSH and $V^{IV}O^{2+}$–GSSG have been recently studied.[4–5]

In order that simple di- or tripeptides bind metal ions strongly enough, the amide-N^- should be involved in coordination, but in some cases suitable anchoring donors should be available to promote amide-NH deprotonation and subsequent coordination. Various metal ions were found to engage in this type of bonding, such as Pt^{II}, Pd^{II}, Cu^{II}, Ni^{II},[6] $V^{V}O_2$ [7] and $V^{IV}O$.[8] The usual anchoring donor for binding metal ions, including Cu^{II}, and inducing amide deprotonation is the terminal NH_2 group,[6] although in some cases the terminal COO^- or the side chain thiolate-S^- or imidazol-N also proved to be efficient at inducing this process.[6] For $V^{IV}O^{2+}$, the terminal NH_2 is not a suitable anchor,[9] but phenolate proved to be an efficient anchoring donor in cases such as H_2salGly (2-OH-hippuric acid) where the p*K* for the amide-NH deprotonation/coordination of 4.76 was found to be similar to values seen for $V^{IV}O$ and Cu^{II}.[8,10]

In this work the binding capability of the tripeptide analogue H_2SalGly-L-Ala (**1**) containing a phenolate anchoring donor has been studied, and the solution speciations and binding modes of $V^{IV}O$, $V^{V}O_2$ and Cu^{II} complexes of **1** are reported. In some cases complexes were obtained in the solid state and characterized.

Results and Discussion

The tripeptide analogue H_2SalGly-L-Ala (**1**) was synthesized by the procedure described in the Exp. Sect. Its for-

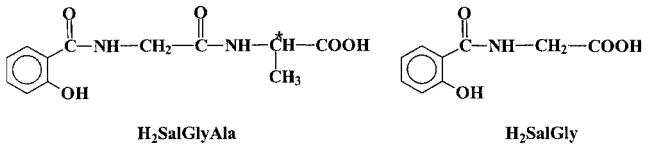
mula together with that of H_2SalGly are included in Scheme 1.



Scheme 1

Interactions of SalGly-L-Ala with Cu^{II} and $V^{IV}O$

The protonation and $V^{IV}O$ and Cu^{II} complex formation constants are in Table 1. H_2SalGly-L-Ala contains two dissociable protons: on the phenolic OH and the terminal COOH groups. The log K_{OH} value of 7.81 can be assigned to the less acidic phenolic OH and the log K value of 3.37 to the terminal COOH group. These data are similar to those of the corresponding dipeptide analogue, H_2SalGly (log K_{OH} = 8.16 and log K_{COOH} = 3.37).[8]

Table 1. Protonation (log K) and Cu^{II} and $V^{IV}O$ complex formation constants (log β with 3 S.D. values in parentheses) of the complexes of SalGly-L-Ala at T = 25 °C and I = 0.2 M (KCl)

Species	Cu^{II}	$V^{IV}O$
log K(phen-O^-)	7.81(1)	
log K(COO^-)	3.37(2)	
MLH	9.49(8)	9.98(11)

[a] Average difference between the experimental and calculated titration curves expressed in mL of the titrant.

Based on earlier speciation studies of the corresponding dipeptide H_2SalGly[8,10] and also Gly-like tripeptides,[6] the pH-metric titration curves measured for the Cu^{II}− and $V^{IV}O$−SalGly-L-Ala systems were evaluated by assuming 1:1 complex formation at the different states of protonation. Whenever 2:1 complexes were included in addition to the 1:1 complexes, they were always rejected by the PSEQUAD computer program. The best fit between the experimental and the calculated titration curves was obtained with the set of species listed in Table 1. The concentration distribution curves of the complexes formed in the Cu^{II}−SalGly-L-Ala and $V^{IV}O$−SalGly-L-Ala systems are depicted in Figures 1 and 2.

In agreement with the speciation curves the visible spectra of the metal-ligand systems (e.g. Figure 3 for the Cu^{II} system) start to deviate from that of the corresponding aqua ions $[Cu(H_2O)_6]^{2+}$ or $[VO(H_2O)_5]^{2+}$ only at pH > 3, where

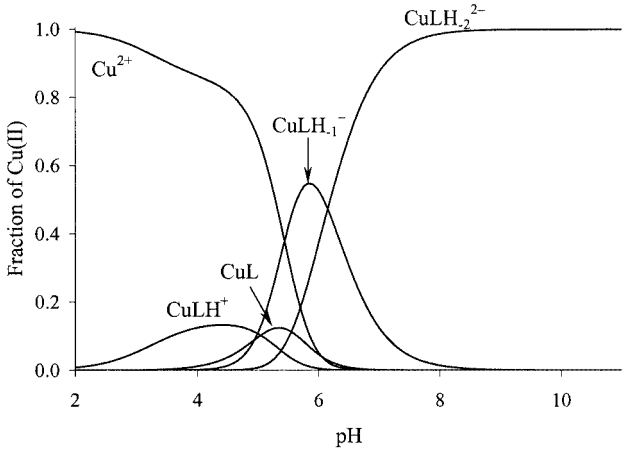

Figure 1. Species distribution curves as a function of pH for the Cu^{II}−SalGly-L-Ala system at a 1:2 ratio and c_{Cu} = 0.002 M

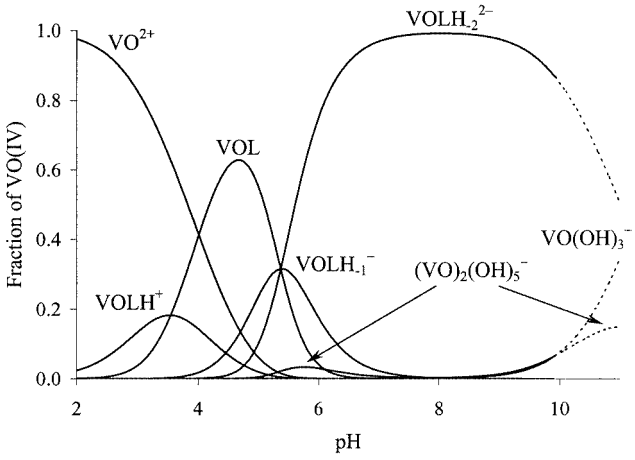

Figure 2. Species distribution curves as a function of pH for the $V^{IV}O$−SalGly-L-Ala system at a 1:2 ratio and c_{VO} = 0.002 M. Dashed lines indicate a higher uncertainty and thus only the tendency of the speciation as a result of slow pH equilibration (see Exp. Sect.)

the formation of the protonated species $[MLH]^+$ is indicated by the speciation curves. It can also be seen in Figure 3 that as complex formation proceeds, the d-d transition of the Cu^{II}-ligand system is shifted to higher energies and becomes constant at a pH of around 7.5, indicating the exclusive formation of a single species $[CuLH_{-2}]^{2-}$ (λ_{max} = 545 nm, ε = 240 $M^{-1}\cdot cm^{-1}$). At the same time in the corresponding $V^{IV}O$ system the visible spectra remain almost constant in the pH range 6.5−8.0 ($[VOLH_{-2}]^{2-}$: λ_{max} = 960 nm (ε = 120 $M^{-1}\cdot cm^{-1}$) and 690 nm (ε = 115 $M^{-1}\cdot cm^{-1}$). However, at higher pH the intensity of the absorption decreases as the ligand is displaced by OH^-. The CD spectra depicted in Figures 4 and 5 are in full agreement with these observations.

At pH < 5 the CD spectra of the $V^{IV}O$−SalGly-L-Ala system have relatively low intensities (species $[VOLH]^+$ and [VOL]). At pH > 5 their intensities increase (parallel with the increase in the visible absorption), and three peaks develop in the CD spectra at λ_{max} 760 nm (Δε < 0), 610 nm

($\Delta\varepsilon > 0$) and at 415 nm ($\Delta\varepsilon > 0$) (Figure 5), indicating coordination of the amide N^- group close to the chiral centre. Similarly, in the Cu^{II}−SalGly-L-Ala system the visible band at λ = 545 nm which is apparent by a pH of approximately 7 (see Figure 3), corresponds to two bands in the CD spectra at 490 nm ($\Delta\varepsilon = -0.3$ $M^{-1}\cdot cm^{-1}$) and at 610 nm ($\Delta\varepsilon = -0.28$ $M^{-1}\cdot cm^{-1}$). The significant blue shift in the absorption spectra and the intense CD bands indicate coordination of the amide N^- in the corresponding complex. In the CD spectrum of the GlyGly-L-Ala−Cu^{II} solutions, a band with λ_{max} at 475 nm ($\Delta\varepsilon = -0.8$ $M^{-1}\cdot cm^{-1}$) was observed.[11] The different CD spectra obtained here confirm that in the Cu^{II} complexes formed with **1**, which predominate at pH > 5, the phenolate O^- is bound to the metal ion.

The visible and CD spectra obtained at different pH values were used to calculate the spectrum of each individual species formed in the Cu^{II}− and $V^{IV}O$−SalGly-L-Ala systems, using the PSEQUAD computer program. Hydrolysis and observable increases in the absorbances of the very slightly cloudy solutions, especially in the case of the $V^{IV}O$−SalGly-L-Ala system, precluded the use of visible spectroscopic data to determine individual spectra precisely. CD data were more suitable for such a treatment. The fact that reasonable CD spectra could be simulated for each species (see Figure 6) confirms that the speciation models proposed and the stability constants calculated from the pH-metric measurements are correct.

It is worth noting here that significant changes and increases in the CD intensities can be observed only upon appearance of the $[MLH_{-2}]^{2-}$ species in both systems, and this is reflected in the calculated CD spectra of $[MLH_{-2}]^{2-}$. This indicates that coordination of the closest donor atom to the chiral centre (the first amide N^- from the C terminus) presumably occurs only in this species.

The EPR spectra help further to elucidate the binding modes of the complexes formed in the two systems. For the $V^{IV}O$ systems, Chasteen[12] introduced an additivity rule to estimate the hyperfine coupling constants $A_{\parallel}^{est}$ ($A_{\parallel}^{est} = \Sigma A_{\parallel,i}$), based on the contributions $A_{\parallel,i}$ of each of the four equatorial donor groups, its estimated uncertainty being $\pm$ 3 × 10^{-4} cm^{-1}. Most of the $A_{\parallel,i}$ parameters were presented by Chasteen[12] while the others were presented by Cornman et al. [$A_{\parallel}(N^-)$ = 34−35 × 10^{-4} cm^{-1}],[13] Tasiopoulous et al. [$A_{\parallel}(N^-)$ = 34−43 × 10^{-4} cm^{-1}],[14] Hamstra et al. [$A_{\parallel}(O_{amide})$ = 43−44 × 10^{-4} cm^{-1}],[15] and Costa Pessoa et al. [$A_{\parallel}(N^-)$ dipeptides = 34−36 × 10^{-4} cm^{-1} [16] and $A_{\parallel}(COO^-)$ = 42 × 10^{-4} cm^{-1}].[17] As can be seen, there is a rather high uncertainty in the reported $A_{\parallel}(N^-)$ values: 36±4 × 10^{-4} cm^{-1}. We chose the value 39 × 10^{-4} cm^{-1} for CON^-, which is within the uncertainty range. This was chosen without any theoretical precedent but because it gave a better agreement with the experimental coupling constants of the present system. Although a similar additivity rule has not been developed for Cu^{II} complexes, the large amount of EPR data available in the literature also allows us to make similar estimates for the coordinating donors in the corresponding Cu^{II} complexes. A rigorous comparison of the EPR spectra with the pH-metrically determined speciation curves may indicate some differences in the relative amount of some of the species at given pH values. This may be explained by the differences in the temperature, which was

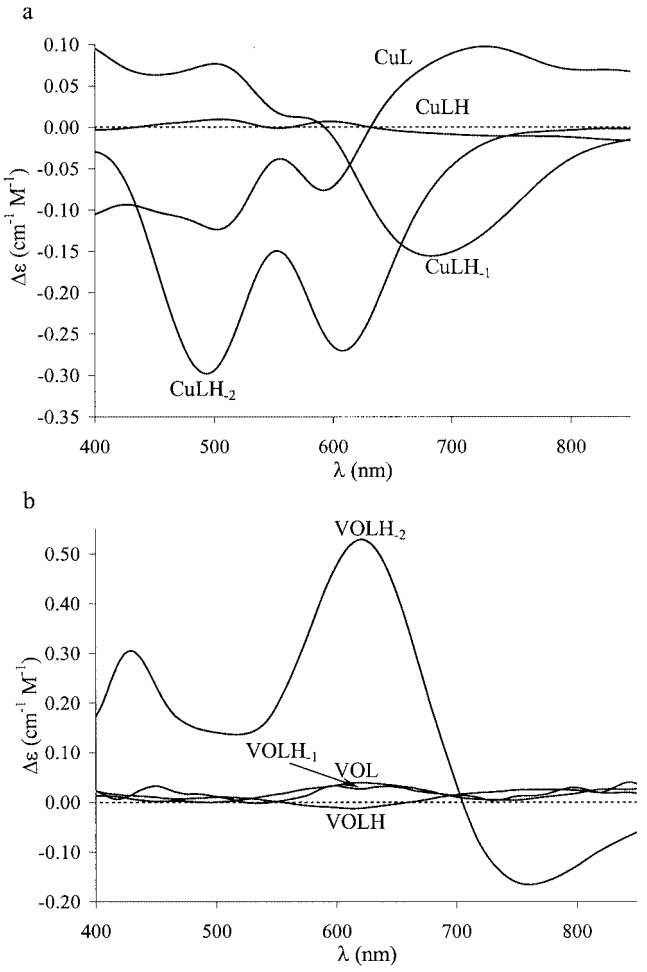

Figure 6. Simulated CD spectra for each individual species formed in (a) the Cu^{II}−SalGly-L-Ala system and (b) the $V^{IV}O$−SalGly-L-Ala system, using the program PSEQUAD

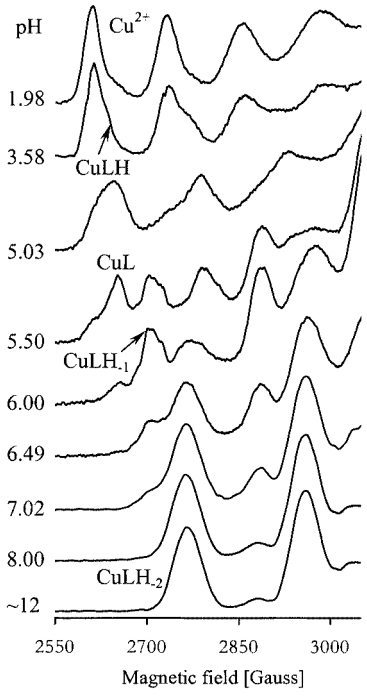

Figure 7. Low-field region of frozen EPR spectra (X-band) recorded at 77 K on the Cu^{II}−SalGly-L-Ala system at a 1:2 metal ion to ligand ratio at different pH values, c_{Cu} = 0.006 M

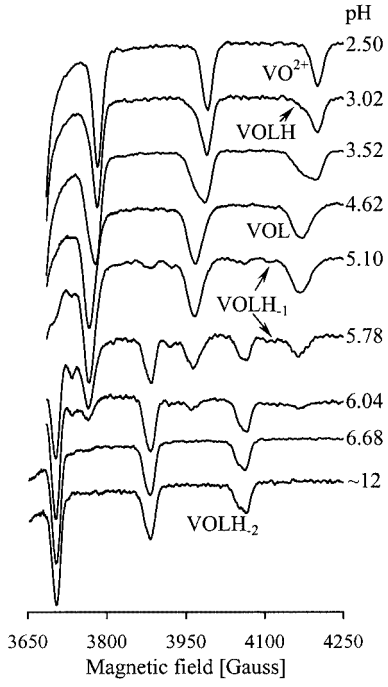

Figure 8. High-field region of frozen EPR spectra (X-band) recorded at 77 K on the $V^{IV}O$−SalGly-L-Ala system at a 1:2 metal ion to ligand ratio at different pH values, c_{VO} = 0.0045 M

25 °C for pH-metry and ca. −3 °C for EPR (the approximate freezing point of the sample), and also in the concentration of the metal ion. For this reason EPR is used only in a quantitative way to confirm the formation of each of the species assumed from the pH-metric speciation measurements. Figures 7 and 8 depict the low-field region (high-field in the case of $V^{IV}O$) of some of the frozen solution EPR spectra of the two systems at different pH values. Table 2 summarizes the EPR parameters obtained from simulation of the spectra by using the computer program of Rockenbauer,[18] and also the most likely binding modes of the complexes. For the $V^{IV}O$ system, CD and EPR spectra were also recorded at pH = 5.5 and c_L = 10 mM, with a variable c_{VO} concentration always confirming the presence of the MLH_{-1} species (see Figure S1, Supporting Information, see also the footnote on the first page of this article).

The pH-metric speciation curves (Figures 1 and 2) indicate that complex formation starts at a pH of about 3 in both systems with a protonated species $[MLH]^+$. In this species, like the corresponding complexes of the dipeptide analogue H_2SalGly, coordination at the terminal COO^- through (COO^-, CONH) chelation is most likely (see structure 1, Scheme 2). This binding mode explains why the observed EPR and visible spectra at pH around 3 show only minor differences from those of the aqua ions. In fact no significant differences are expected in the EPR and visible

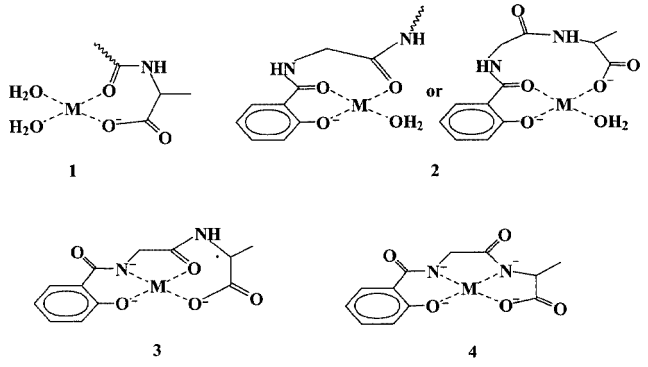
spectra for such binding modes when compared with the aqua ions.[16,19]



Scheme 2

Three protons are liberated from these complexes with stepwise p*K* values of 5.03, 4.92 and 6.16 for the Cu^{II} complexes, and 3.55, 5.37 and 5.37 for the $V^{IV}O$ complexes. The first deprotonation process, leading to the species [ML] in both systems, is attributable to the phenolic OH group of the metal-bound ligand. This indicates a rearrangement to (O^-, 2 × CONH) or (O^-, CONH, COO^-) binding modes (see structure 2, Scheme 2), as supported by the spectral changes. The EPR parameters (see Table 2) are characteristic of pure O-coordination, and agree well with those in the corresponding complex formed with H_2SalGly[8] and other aromatic hydroxycarboxylic acids.[20]

The next two p*K* values can be assigned to the deprotonation/coordination of the two amides, yielding (O^-, CON^-, CONH, COO^-) and (O^-, CON^-, CON^-, COO^-) joint chelate systems (structures 3 and 4, Scheme 2) respectively. As the simultaneous equatorial coordination of the second amide-O and the terminal COO^- may be sterically hindered, the tridentate (O^-, CON^-, COO^-) binding mode of the ligand (see Scheme 2) is also possible in species $VOLH_{-1}$. Due to the coordination of the two amide nitrogens, superhyperfine coupling (five lines with shf $A_{N\perp}$=15.5 G) can be observed in the perpendicular region of the EPR spectrum of the $CuLH_{-2}$ species. In the case of $V^{IV}O$, the EPR parameters estimated by the additivity rule are 164 ×10^{-4} cm^{-1} and 159 × 10^{-4} cm^{-1} which are in reasonable agreement with the experimental hyperfine coupling constants (Table 2). Since the species $[VOLH_{-1}]^-$, with one deprotonated amide N^-, could hardly be detected in the pH range 5–6 at a comparable metal ion to ligand ratio, EPR measurements in the wide L:M range of 20–1 were also carried out (see Exp. Sect.). Under such conditions the species was clearly detected by the appearance of a distinct signal (see Figure S1, Supporting Information). As mentioned above, the fact that significant increases in the $|\Delta\varepsilon|$ CD parameters are only observed for the fully deprotonated complex $[MLH_{-2}]^{2-}$ indicates the following sequence of amide deprotonation: first that is closer to the phenolate O^- then that is closer to the COO^-, the latter being closer to the chiral centre. Interestingly, the opposite sequence was observed for the organotin(IV)–peptide complexes,[16] which pointed to the C-terminal COO^- group being the primary anchor. With $V^{IV}O$ and Cu^{II}, the phenolate O^- seems to be the primary anchor. In the case of Gly-type tripeptides, the N-terminal site is the primary binder for Cu^{II}.[6] At pH > 10, a significant decrease in the intensities of the EPR signals was observed in the $V^{IV}O$–SalGly-L-Ala system (to compensate for this, the receiver gain and the modulation were increased) indicating the partial hydrolysis of the metal ion through formation of the EPR silent hydroxo-bridged species (represented by $[(VO)_2(OH)_5]^-$ in the speciation diagram).

Compounds in the Solid State

The tripeptide analogue H_2SalGly-L-Ala **1** was synthesized by the procedure described in the Exp. Sect. Complex **2**, formulated as VO(SalGly-L-Ala)·3.2H_2O·0.2EtOH, was prepared from solutions containing $V^{IV}O$ and H_2SalGly-L-Ala at a pH of around 5.5, i.e. where we expect the [VOL] stoichiometry to be predominant. Elemental analysis (see Exp. Sect.) indicates that the amide is not deprotonated, and the CD spectrum of **2** in a KBr disk shows a band pattern and a λ_{max} value similar to those of the VOL species shown in Figure 6b. The binding in the solid state presumably involves O^-, CONH, COO^- and H_2O, and eventually another amide O in the axial position. In frozen solution the experimental $A_{\|}$ is around 175–176 × 10^{-4} cm^{-1}, which corresponds either to (i) (O^-, CONH, COO^-, $H_2O)_{equatorial}$ coordination ($A_{\|}^{est}$ = 38.9 + 43.7 + 42.1 + 45.6 = 170 × 10^{-4} cm^{-1}) or to (O^-, CONH, 2 × $H_2O)_{equatorial}$ coordination ($A_{\|}^{est}$ = 38.9 + 43.7 + 45.6 + 45.6 = 174 × 10^{-4} cm^{-1}).

Complex **3**, formulated as K[Cu(SalGly-L-Ala)]·3.2H_2O, was also prepared from aqueous/ethanolic solutions at pH = 6. The elemental analysis agrees with the formulation of $CuLH_{-1}$ for this complex and the CD spectrum of **3** in a KBr disk shows a band pattern and a λ_{max} value close to those of the $CuLH_{-1}$ species (see Figure S2, Supporting

Information). The elemental analysis and spectra of this Cu^{II} complex are therefore consistent with a binding of the ligand through O^-, COO^- and CON^-. No individual ν(N−H) band could be detected emerging from the broad band in the 2400−3700 cm^{-1} range.

A comparison of the FTIR spectroscopic data for compounds **1**−**3** is summarised in Table 3. The data for **2** and **3** agree with the binding modes proposed. The assignments are based on Refs. 21−25, and by comparison with some $V^{IV}O$ and Cu^{II} complexes formed with the reduced Schiff base ligands derived from the reaction of salicylaldehyde and GlyGly or GlyGlyGly.[26] All compounds present broad bands in the wavenumber range corresponding to hydrogen-bonded O−H and N−H. In the case of **1** a strong ν(N−H) band emerges from this broad band as well as several other weak or very weak bands (Table 3). This is characteristic of compounds containing secondary amide groups.[23,24] The strong $\nu(C{=}O)_{COOH}$ band at 1730 cm^{-1} in the FTIR of **1** is absent in its $V^{IV}O$ and Cu^{II} complexes. For **2**, a narrow band emerges at 3346 cm^{-1} and a second weaker one at 3454 cm^{-1}, presumably also due to ν(N−H) of the amide groups.[21,23] All our efforts to characterise other solid compounds from these metal-ligand systems, particularly those of oxovanadium with a deprotonated amide, were unsuccessful. Either no solid could be isolated or when precipitation was achieved, no reasonable formulation could be found.

Interactions of H_2SalGly and H_2SalGly-L-Ala with V^VO_2

Vanadate(V)-promoted deprotonation of the amide NH and the formation of stable complexes with dipeptides through (NH_2, CON^-, COO^-) coordination was first detected by Rehder[7] using ^{51}V NMR spectroscopy (δ = −505−510 ppm). Pettersson et al.[27,28] gave complete speciation descriptions of V^VO_2 with dipeptides such as ProAla, AlaGly and AlaHis. A single complex species of moderate stability (at approx. tenfold excess of ligand ca. 50% of the vanadate was bound to the peptide) was formed with the above binding mode in fairly slow processes (completion of complex titration took several hours). The chemical shift values were as follows: δ = −495 ppm for ProAla, δ = −512 ppm for AlaGly and δ = −518 ppm for AlaHis.[27,28]

As phenolate proved to be a more efficient anchoring donor to promote amide deprotonation with $V^{IV}O$, we were also interested in studying this interaction with vanadate(V). The ^{51}V NMR spectrum of the vanadate(V)−SalGly system (c_VV= 0.003 M) displayed an extra peak (δ = −508.5 ppm) as well as the resonances of the V1 (δ = −561.8 ppm), V2 (δ = −574.8 ppm), V4 (δ = −579.2 ppm) and V5 (δ = −593.7 ppm) oxoanions. At a pH of around 7 the maximum amount of the complex was around 54 % with a tenfold excess of ligand (see Figure 9). The spectrum was identical after 24 h. This is in agreement with the earlier literature findings (vide supra), and an (O^-, CON^-,COO^-) binding mode has been suggested for the complex detected.[7,27−29] Interestingly, no new peaks were observed in the spectrum of the vanadate(V)−SalGly-L-Ala system which also had a tenfold excess of ligand (see Figure S3, Supporting Information), whether at pH 7 or 8. In both cases the polyoxoanions predominated in the system and the spectra were practically unchanged after 24 h.

In the case of tripeptides, amide deprotonation seems to occur at higher pH values when compared with dipeptides (e.g. for the corresponding Cu^{II} systems pK(CuA) = 4.40 for Cu^{II}−SalGly and pK(CuA) = 4.92 and pK($CuAH_{-1}$) = 6.16 for SalGly-L-Ala), where the likelihood of hydrolysis of the copper(II) is higher. This sensitive equilibrium between the metal-peptide complex and the binary (hydroxo)metal complex is finely shifted to the direction of peptide coordination with dipeptides, but to the direction of

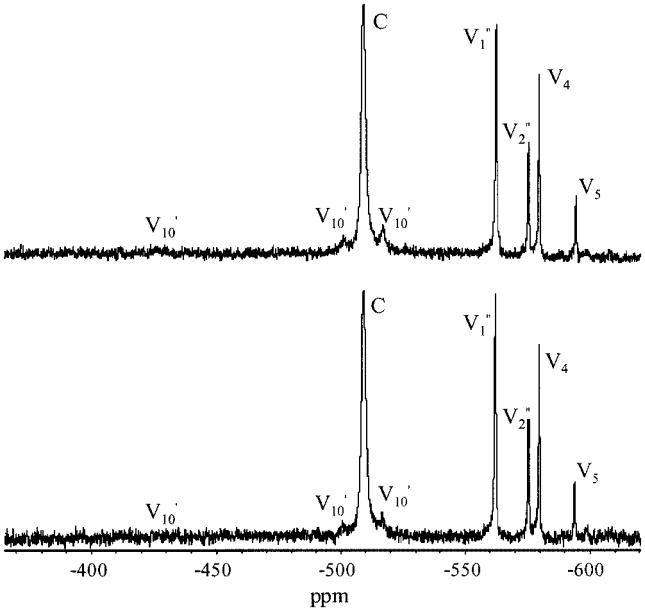

Figure 9. ^{51}V NMR spectra measured at pH ≈ 7 of a solution of the V^{V}−SalGly system at a 1:10 metal ion to ligand ratio. (a) in freshly prepared solution, (b) 24 h later, c_V = 0.003 M

oxoanion formation in the presence of tripeptides. Similar observations were made with organotin(IV)−di and tripeptide systems.[29]

Conclusions

The speciation and solution structural investigations discussed above strongly indicate that both the terminal COO^- and the phenolate O^- can behave as anchoring donors to chelate this tripeptide-analogue ligand. Coordination at a pH of around 3 starts at the terminal carboxylate through chelation with the neighbouring amide carbonyl. At a pH of approximately 4.5 the binding mode also involves the terminal phenolate and this induces deprotonation of the two amide-NH groups in a consecutive but rather cooperative way in the pH range 5−6. With the phenolate O^- anchor $V^{IV}O$ seems to be slightly more efficient in promoting deprotonation than Cu^{II} (the value of ΣpK_{amides} is 10.74 for $V^{IV}O$, and 11.08 for Cu^{II}), MLH_{-2} being the most important stoichiometry in the pH range 6−10, corresponding to an $(O^-, 2 \times CON^-, COO^-)_{equatorial}$ binding set. While Cu^{II} is able to promote amide deprotonation with normal tripeptides with about the same efficiency (ΣpK_{amides} is 11.82[8]), $V^{IV}O$ cannot induce deprotonation of the amide because of its low affinity for primary amine donors and the metal ion precipitates as $VO(OH)_2$. Interestingly, phenolate O^- did not prove to be such an efficient anchoring donor with vanadate(V) or $V^{V}O_2$ as with $V^{IV}O$. Amide deprotonation could not be detected by ^{51}V NMR spectroscopy in the case of the tripeptide analogue H_2SalGly-L-Ala. With the dipeptide analogue H_2SalGly, a species with an (O^-, N^-, COO^-) binding mode could be detected in the pH range 7−8. This is in full accordance with earlier literature reports concerning the interaction of vanadate^{V} with various dipeptides.[7,27−28] However, the moderate affinity of vanadate^{V} for amides, even with the more hard and probably more efficient phenolate O^- anchor, is reflected in the fact that even with a tenfold excess of ligand only around 50% of the metal ions are bound to SalGly, the rest being in the various oxoionic forms.

The considerably weaker ability of vanadium(V) to induce amide deprotonation, compared with vanadium(IV), can probably be explained by electrostatic ($V^{IV}O^{2+}$ vs. $V^{V}O_2^+$ towards LH_{-2}^{4-}) and steric arguments (there are 4 equatorial positions free around $V^{IV}O^{2+}$, while only 3 in the case of $V^{V}O_2^+$ because of the *cis* arrangement of the two oxo groups).

Experimental Section

Synthesis of H_2SalGly-L-Ala (1): The compound was synthesized by two different routes: (i) through the stepwise build up of the pseudopeptide from the individual components via the classical liquid phase method, (ii) through the Merrifield solid-phase approach.

Route 1

Z-GlyOH: To an ice-cold solution of glycine (7.5 g, 100 mmol) in 1 M NaOH (100 mL) was added benzyl chloroformate (16 mL, 100 mmol), dropwise with stirring. The pH of the solution was maintained at 10−10.5 by addition of 1 M NaOH. The mixture was stirred for 2 h and then extracted with diethyl ether. The aqueous layer was acidified to a pH ≈ 1 and the solid which precipitated was filtered, washed with water and dried. Yield (17.9 g, 86%), m.p. 119−120 °C (ref.[30] m.p. 120−121 °C). NMR ([D$_6$]DMSO): δ = 3.66 (d, J = 6 Hz, 2 H, CH_2Gly), 5.03 (s, 2 H, CH_2Ar), 7.34 (m, 5 H, Ar), 7.55 (t, J = 6 Hz, 1 H, NH), 12.25 (br. s, 1 H, COOH) ppm.

L-AlaOEt·HCl: Thionyl chloride (12.5 mL) was added dropwise to stirred and cooled (−10 °C) ethanol (50 mL), followed by the addition of L-Ala (4.46 g, 50 mmol). The temperature of the solution was increased and maintained at 40 °C for 4 h. The solvent was removed and crystallization from methanol/ethyl ether yielded 4.65 g (86%) of white crystals melting at 76 °C (ref.[31] m.p. 76 °C). NMR ([D$_6$]DMSO): δ = 1.22 (t, J = 7.2 Hz, 3 H, CH_2CH_3), 1.40 (d, J = 7 Hz, 3 H, CH_3 Ala), 4.00 (q, J = 7.2 Hz, 2 H, CH_2CH_3), 4.17 (apparent q, J = 7.2 Hz, 1 H, αCH Ala), 8.66 (br. s, 3 H, NH_3^+) ppm.

Z-Gly-L-AlaOEt: Z-GlyOH (4.2 g, 20 mmol) was dissolved in ethyl acetate (50 mL) and DCC (4.3 g, 21 mmol) was added after cooling to 0 °C. The mixture was stirred for 30 min whereupon L-AlaOEt·HCl (3.1 g, 20 mmol) and triethylamine (2.8 mL, 20 mmol) were added. The reaction mixture was stirred at room temperature overnight. The insoluble material was filtered off and the solution was washed successively with 1 M NaOH, 1 M HCl, and saturated NaCl. After drying with $MgSO_4$ the solvents were removed under reduced pressure. The oil obtained was crystallized from ethyl acetate/petroleum ether. The white crystals were filtered and dried (4.52 g, 73%), m.p. 60−64 °C; (ref.[31] m.p. 60−62 °C). NMR ($CDCl_3$): δ = 1.28 (t, J = 8 Hz, 3 H, CH_2CH_3), 1.40 (d, J = 7 Hz, 3 H, CH_3 Ala), 3.89−3.92 (m, 2 H, CH_2Gly), 4.19 (q, J = 7.2 Hz,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

2 H, CH_2CH_3), 4.52−4.60 (m, 1 H, αCH Ala), 5.13 (s, 2 H, CH_2Ar), 5.57 (br. s, 1 H, NH), 6.71 (br. s, 1 H, NH), 7.36−7.33 (m, 5 H, Ar) ppm.

HGly-L-AlaOEt·HBr: Z-Gly-L-AlaOEt (3.08 g, 10 mmol) was treated with 40% HBr/acetic acid (15 mL) at room temperature for 1 h with occasional stirring and protection from moisture. Diethyl ether was added and after cooling for a few hours the precipitated solid was filtered, washed with diethyl ether and dried. The chromatographically pure compound was used in the next step without further purification. Yield (2.42 g, 94%). NMR ([D_6]DMSO): δ = 1.20 (t, J = 7.2 Hz, 3 H, CH_2CH_3), 1.30 (d, J = 7.2 Hz, 3 H, CH_3 Ala), 3.57 (d, J = 3.3 Hz, 2 H, CH_2 Gly), 4.10 (q, J = 7.2 Hz, 2 H, CH_2CH_3), 4.23−4.32 (m, 1 H, αCH Ala), 8.01 (br. s, 3 H, NH_3^+), 8.70 (d, J = 7.2 Hz, 1 H, NH Ala) ppm.

HSalGly-L-AlaOEt: Salicylic acid (0.69 g, 5 mmol) was dissolved in ethyl acetate (20 mL) and the solution cooled to 0 °C. DCC (1.08 g, 5.2 mmol), HGlyAla·OEt·HBr (1.28 g, 5 mmol) and triethylamine (0.9 mL, 5 mmol) were then added successively. The reaction mixture was stirred at room temperature overnight. The insoluble material was filtered off and the solvents removed under reduced pressure. The residue was dissolved in a minimum amount of acetone and stored at 0 °C for 4 h. The precipitated solid was filtered off (dicyclohexylurea) and the solution concentrated. The oil obtained was crystallized from ethyl acetate/petroleum ether. (0.808 g, first crop, 55%, m.p. 104−106 °C). NMR ([D_6]DMSO): δ = 1.28 (d, J = 7.5 Hz, 3 H, CH_3 Ala), 1.17 (t, J = 7.2 Hz, 3 H, CH_2CH_3), 4.07 (q, J = 7.2 Hz, 2 H, CH_2CH_3), 3.94 (m, 2 H, CH_2 Gly), 4.20 (m, 1 H, αCH Ala), 6.91 (tap, J = 7.8 Hz, 2 H, 3-H and 5-H), 7.40 (tap, J = 8 Hz, 1 H, 4-H) 7.86 (dd, J = 1.2 Hz and 8 Hz,1 H, 6-H), 8.46,(d, J = 8.4 Hz, 1 H, NH Ala), 9.04 (t, J = 6 Hz, 1 H, NH Gly), 12.25 (br. s, 1 H, OH) ppm. $C_{14}H_{18}N_2O_5$ (294.3): calcd. C 57.14, H 6.16, N 9.52; found C 57.6, H 6.1, N 9.7.

H_2Sal-L-GlyAla (1): HSalGly-L-AlaOEt (0.734 g, 2.5 mmol) was dissolved in methanol (5 mL) and 1 M NaOH (5.5 mL, 5.5 mmol) was added. The mixture was stirred at room temperature for 4 h and 1 M HCl (2.5 mL, 2.5 mmol) was then added. The methanol was removed under reduced pressure and the solution thus obtained cooled in an ice bath and acidified with 1 M HCl (3 mL) with vigorous stirring. The white solid precipitated was filtered off, washed with water and dried (0.581 g, 87%), m.p. 197−199 °C. NMR ([D_6]DMSO): δ = 1.28 (d, J = 7.5 Hz, 3 H, CH_3 Ala), 3.94 (m, 2 H, CH_2 Gly), 4.20 (m, 1 H, αCH Ala), 6.91 (tap, J = 7.8 Hz, 2 H, 3-H and 5-H), 7.39 (tap, J = 7.8 Hz, 1 H, 4-H) 7.86 (dd, J = 1.2 Hz and 8 Hz, 1 H, 6-H), 8.34 (d, J = 7.5 Hz, 1 H, NH Ala), 9.03 (t, J = 6 Hz, 1 H, NH Gly), 12.20(s, 1 H, OH), 12.40 (br. s, 1 H, OH) ppm. $C_{12}H_{14}N_2O_5$ (266.3): calcd. C 54.13, H 5.30, N 10.52; found C 54.17, H 5.41, N 10.42.

Route 2

The dipeptide chain was elongated on an HMP resin (1.1 mmol/g). In the first step, Fmoc-Ala−OH (5.47, 17.6 mmol) was coupled to the resin (4 g, 4.4 mmol) in the presence of HOBt (2.38 g, 17.6 mmol), DCC (3.63 g, 17.6 mmol) and dimethylaminopyridine (1.07 g, 8.8 mmol). After removing the Fmoc protecting group by treatment with piperidine, the resultant free amino function was acylated with Fmoc−Gly−OH (2.97 g, 10 mmol). After completion of the dipeptide unit, the *N*-terminal Fmoc-protecting group was removed as previously described and the resultant primary amino group was acylated with salicylic acid (2.76 g, 20 mmol). The phenolic hydroxy group of the salicylic acid residue was unprotected. All the couplings were performed with *N*,*N*′-dicyclohexylcarbodiimide in the presence of 1-hydroxybenzotriazole. Amino acid or salicylic acid incorporation was monitored using the ninhydrin test. The completed peptide resins were treated with TFA/dichloromethane/water (35:60:5, vol/vol), at 0 °C for 1 h. The solvents were removed and the resultant free product was dissolved in 10% aqueous acetic acid, filtered and lyophilised (798 mg). The crude peptide derivative (100 mg) was purified by reverse-phase HPLC using a Nucleosil 7C-18 column (16 × 250 mm). The solvent system used was the following: 0.1% TFA in water, 0.1% TFA, 80% acetonitrile in water, gradient: 0% → 0% B over 10 min, then 10% → 30% over 50 min, flow 3.5 mL/min, detection at 226 nm. The appropriate fractions were combined and lyophilised. Peptide purity was above 97% (HPLC) and the measured Mw (227) value was in good agreement with the calculated one. NMR (D_2O): δ = 1.38 (d, J = 7.2 Hz, 9 Hz, 3 H, CH_3 Ala), 4.11 (s, 2 H, CH_2 Gly), 4.34 (m, 1 H, αCH Ala), 6.99 (tap, J = 7.8 Hz, 2 H, 3-H and 5-H), 7.46 (tap, J = 7.8 Hz, 1 H, 4-H) 7.50 (dd, J = 1.5 Hz, 2 and 9.46 Hz, 1 H, 6-H) ppm.

Synthesis of the Complexes

VO(SalGly-L-Ala)·3.2H_2O·0.2EtOH (2): To a solution of H_2SalGly-L-Ala (1 mmol) and sodium acetate−trihydrate (2 mmol) in ethanol/water (2.5:5 mL) was slowly added a solution of $VOSO_4$·5H_2O (1 mmol) in water (1 mL). The mixture was divided in two equal parts (**A** and **B**). The pH of solution **A** was adjusted to 5.5. A blue-green solid precipitated which was collected by filtration and washed with ethanol/water (1:2), diethyl ether and dried. Yield: 40% (80 mg). $C_{12}H_{12}N_2O_6V$·3.2H_2O·0.2EtOH: calcd. C 37.42, H 4.86, N 7.04; found C 37.4, H 5.3, N 7.00.

K[Cu(SalGly-L-Ala)]·3.2H_2O (3): To a solution of H_2SalGly-L-Ala (0.5 mmol) and KOH (0.5 mmol) in water (10 mL), was slowly added $Cu(CH_3COO)_2$·H_2O (0.5 mmol) in ethanol (5 mL). The pH was adjusted to 6 with 2 M KOH and kept at ≈ 45 °C for 1 h. A green precipitate was collected by filtration, washed with ethanol/water (1:2), ethanol and diethyl ether and dried. Yield: 42% (90 mg). $C_{12}H_{11}CuKN_2O_5$·3.2H_2O: calcd. C 34.03, H 4.14, N 6.61; found C 33.7, H 3.7, N 6.2.

Physical and Spectroscopic Studies

Melting points were recorded by using a Gallenkamp melting point apparatus and are uncorrected. NMR spectroscopic data were recorded either with a Varian Unity Plus 300 Spectrometer (for the several steps of the synthesis of **1**) in the solvent indicated, or with a Varian Unity-500 Spectrometer operating at frequencies of 131.404 MHz and 499.824 MHz, respectively, using a 5-mm broad-band probe at 25.0±0.5 °C. ^{51}V NMR chemical shifts were referenced to an external $VOCl_3$ solution at δ = 0 ppm. The ^{51}V NMR acquisition parameters were as follows: 33 kHz spectral width, 30-μs pulse width, 1 s acquisition time and 10 Hz line broadening. IR spectra were recorded with a BioRad FTS-3000 MX FTIR spectrometer. CD spectra were recorded with a JASCO-720 spectropolarimeter with a red-sensitive photomultiplier (EXWL-308). Visible spectra were recorded with a Hitachi U-2000 spectrophotometer. X-band (9.44 GHz) EPR spectra were usually recorded at 77 K (on glasses made by freezing solutions in liquid nitrogen) with a Bruker ESP 300E X-band spectrometer. Mass spectra were recorded with a Finnigan TSQ-7000 tandem quadrupole mass spectrometer equipped with an electrospray ion source. The HPLC apparatus was made by Knauer (Berlin, Germany).

All samples for the pH-potentiometric and spectrophotometric measurements were prepared under inert conditions (under high purity nitrogen or argon). For potentiometric measurements the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ionic strength was adjusted to 0.2 M KCl and the temperature maintained at 25.0±0.1 °C. For the spectral measurements the temperature was maintained at 25.0±0.3 °C with circulating water.

pH Measurements for Spectroscopic Studies: For preparation of the solutions and pH calibrations a special double-walled glass vessel was used with entrances for the combined electrode (Radiometer ''Red Rod'' pHC2015−8), thermometer, nitrogen and reagents (e.g. base). A computerized system developed locally (IBM-PCXT 286 computer) was used to control the titration conditions for pH calibrations. The E.M.F measurements were made with a Denver Model 15 pH meter.

pH-Potentiometric Titrations: Stock solutions of $V^{IV}O$ and vanadate(V) for the pH-metric titrations were prepared and standardised as described earlier.[32] The purity of the ligand was checked and the exact concentration of its solutions was determined by the appropriate Gran plot.[33] The stability constants of the proton and metal complexes of the ligand were determined by pH-metric titration of 10.0 cm^3 samples. The ligand concentrations were in the range of 0.001 to 0.002 M and the metal ion to ligand molar ratio varied from 1:1 to 1:3. Titrations were performed from pH 2.0 up to pH 11 with KOH solution of known concentration (ca. 0.2 M) under purified argon unless very extensive hydrolysis or slow equilibration was observed. The reproducibility of titration points included in the evaluation was within 0.005 pH units in the whole pH range. The pH was measured with an Orion-710A precision digital pH meter equipped with an Orion Ross 8103BN type combined glass electrode, calibrated for hydrogen ion concentration as described earlier.[34] The ionic product of water, pK_w is 13.76. The concentration stability constants $\beta_{pqr} = [M_pL_qH_r] / [M]^p[L]^q[H]^r$ were calculated with the aid of the PSEQUAD computer program.[35] The formation of the hydroxo complexes of $V^{IV}O$ was taken into account. The following species were assumed: $[VO^{IV}(OH)]^+$ ($\log \beta_{10-1} = -5.94$), $[(V^{IV}O)_2(OH)_2]^{2+}$ ($\log \beta_{20-2} = -6.95$). Stability constants were calculated from the data of Henry et al.[36] and corrected for the different ionic strengths by using the Davies equation. $[(V^{IV}O)_2(OH)_5]^-$ ($\log \beta_{20-5} = -22.5$) and $[V^{IV}O(OH)_3]^-$ ($\log \beta_{10-3} = -18.0$).[37]

Spectroscopic Measurements: Unless otherwise stated, by visible (Vis) and circular dichroism (CD) spectra we mean a representation of ε_m or $\Delta\varepsilon_m$ values vs. λ [ε_m = absorption/(bc_M) and $\Delta\varepsilon_m$ = differential absorption/(bc_M) where b = optical path and c_M=total $V^{IV}O$ or Cu^{II} concentration]. The spectral range covered is normally 400−900 (Vis) and 400−1000 nm (CD). All measurements and operations of the spectropolarimeter were computer controlled. For the CD spectra a Fast Fourier-Transform noise-reduction routine (JASCO) was used without affecting peak shapes. For the $V^{IV}O$ system, the EPR, Vis and CD spectra were recorded by varying the pH with an approximately fixed total vanadium and ligand concentration, at L/M ratios of 1.76 ($c_{VO} \approx 0.003$ M) and 2.00 ($c_{VO} \approx 0.0045$ M), and at pH = 5.5 and $c_{ligand} \approx 0.010$ mM . L/M ratios were varied in the range of 20−1 by addition of $V^{IV}O$ stock solution. For the Cu^{II} system, the EPR, Vis and CD spectra were recorded varying the pH with $c_{Cu} \approx 0.006$ M and L/M = 2.

CD spectra of Solid Complexes: Samples of compounds **2** and **3** were prepared as described previously,[38] dispersed in KBr disks, and placed between two microscope slides. One or two such paired microscope slides were placed in the sample compartment. Each final spectrum is the average of 4 to 6 individual spectra, recorded as described above.

Supporting Information: Additional EPR, CD and ^{51}V NMR spectra for the $V^{IV}O$−SalGly-L-Ala and $V^{V}O_2$−SalGly-L-Ala systems are available (see also the footnote on the first page of this article).

Acknowledgments

The authors are grateful to Profs C. Geraldes and M. Castro (University of Coimbra, Portugal) for help in recording the NMR spectra. This work was carried out in as part of a COST D21 project, and was financially supported by the National Research Fund (OTKA T31896/2000), the Hungarian Academy of Sciences, the Fundo Europeu para o Desenvolvimento Regional, Fundação para a Ciência e Tecnologia, the POCTI Programme (project POCTI/35368/QUI/2000), and the Hungarian-Portuguese Intergovernmental S & T Co-operation Programme for 2000−2001.

Coordination Modes in a (Thiosemicarbazone)copper(II)/Oxalato System − Structures of $[\{Cu(L)\}_2(ox)]\cdot 2H_2O$, $[Cu(HL)(ox)(H_2O)]$, $[\{Cu(HL)\}_2(ox)][Cu(ox)_2]\cdot 2H_2O$ and $[\{Cu(HL)\}_2(ox)](NO_3)_2$ − Ferro- vs. Antiferromagnetic Behavior in Dinuclear Compounds

Patricia Gómez-Saiz,[a] Javier García-Tojal,*[a] Miguel Maestro,[b] José Mahía,[b] Luis Lezama,[c] and Teófilo Rojo[c]

Keywords: Copper / Carboxylate ligands / Magnetic properties / Thiosemicarbazone complexes

Complexes with the formula $[\{Cu(L)\}_2(ox)]\cdot 2H_2O$ (**1**), $[Cu(HL)(ox)(H_2O)]$ (**2**), $[\{Cu(HL)\}_2(ox)][Cu(ox)_2]\cdot 2H_2O$ (**3**) and $[\{Cu(HL)\}_2(ox)](NO_3)_2$ (**4**) (HL = $C_7H_8N_4S$, pyridine-2-carbaldehyde thiosemicarbazone) have been synthesized from $Cu(L)(NO_3)$ and oxalic acid while modulating the stoichiometries and the pH of the media. Single crystal X-ray diffraction studies show that the structures of **1** and **4** contain dinuclear entities with distorted square pyramidal copper(II) ions. The dinuclear complexes are centrosymmetric in **1** and non-centrosymmetric in **4**. The metal centers are coordinated to the NNS atoms from the tridentate thiosemicarbazone ligand and to two oxygen atoms from the oxalato coligand. The latter ligand exhibits tetradentate behavior and acts as a bridge between the copper(II) ions. The thiosemicarbazone ligand is either present in the anionic (**1**) or the neutral (**4**) form. Compound **2** is composed of monomeric species containing square pyramidal copper(II) ions that are coordinated to the thiosemicarbazone ligand, one water molecule and one monodentate oxalato coligand. It is important to note that the oxalato is highly twisted in this complex, the O(1)–C(8)–C(9)–O(3) dihedral angle between the carboxylate groups is 79.9(4)°. Compound **3** contains both the dinuclear cationic species, analogous to those described for compound **4**, and square planar (bisoxalato)copper(II) anions. Strong hydrogen bonds and π-π stacking are present in these complexes. Structural and spectroscopic results suggest the presence of relevant ligand-to-metal charge transfers in these compounds. The EPR spectra of **1**, **2** and **4** exhibit rhombic symmetry. Magnetic measurements on **1** and **4** show antiferromagnetic and ferromagnetic coupling, respectively. The susceptibility data were fitted to the Bleaney–Bowers equation for copper(II) dinuclear complexes. The J/k values obtained are –6.20 and +7.73 K for compounds **1** and **4**, respectively.

Introduction

Numerous studies on the copper(II) derivatives of pyridine-2-carbaldehyde thiosemicarbazone (HL = $C_7H_8N_4S$, see Scheme 1) have been conducted during the last thirty years, mainly with regard to the biological properties of these compounds.[1] Spectroscopic results suggested the existence of a planar $[Cu(L)(H_2O)]^+$ species in aqueous solution (or, more correctly, tetragonally elongated $[Cu(L)(H_2O)_3]^+$ species), with a log K value (K = formation constant) of 16.90.[2] This species exhibits two acid−base equilibria with proton dissociation constants pK_{a1} = 2.40 (the equilibrium between $[Cu(HL)(H_2O)_3]^{2+}$ and $[Cu(L)(H_2O)_3]^+$) and pK_{a2} = 8.30 (the equilibrium between $[Cu(L)(H_2O)_3]^+$ and $[Cu(L)(OH)(H_2O)_n]$).[3] The coordination of the ligand by the copper(II) ion is maintained even at pH values below 1.4. The high stability of the metal-ligand system allowed for the isolation of several com-

pounds containing $[Cu(HL)]^{2+}$, as well as the $[Cu(L)]^+$, whose crystal structures have been characterized.[4] They exhibit a 1:1 metal/thiosemicarbazone stoichiometry, with the thiosemicarbazone acting as an NNS tridentate ligand. Magnetic studies on complexes with $[Cu(L)]^+$ fragments have also been carried out.[4f,4g,4j,4k] However, the magnetic behavior of derivatives containing the neutral ligand has not yet been studied. This is partly because monomeric compounds are formed with some of the ligands in an acidic medium. From this point of view, it would be important to find a ligand that is able to stabilize both the $[Cu(L)]^+$ and the acidic $[Cu(HL)]^{2+}$ species in dinuclear complexes. Therefore, the oxalato ligand, which is versatile and has a low pK_{a1} value and up to four chelating centers, could be used to study the influence of the neutral vs. anionic character of the ligand on the properties of these compounds.

Here we present the syntheses, crystal structures and spectroscopic features of the complexes $[\{Cu(L)\}_2(ox)]\cdot 2H_2O$ (**1**), $[Cu(HL)(ox)(H_2O)]$ (**2**), $[\{Cu(HL)\}_2(ox)][Cu(ox)_2]\cdot 2H_2O$ (**3**) and $[\{Cu(HL)\}_2(ox)](NO_3)_2$ (**4**). The magnetic behavior of compounds **1** and **4** is also discussed. Approximate molecular orbital calculations of the extended Hückel type have been carried out in order to understand the magnetic features in these systems.

Results and Discussion

Structural Analysis

The addition of potassium oxalate to an aqueous solution of $Cu(L)(NO_3)$ at pH = 4−8 yields compound **1**, which contains the anionic thiosemicarbazone ligand, irrespective of the ratio of the reactants. However, at very low pH values (close to 1), the amounts of the reactants play an important role. Thus, stoichiometric amounts of $Cu(L)(NO_3)$ and oxalic acid lead to the formation of compound **2**. In contrast, an excess of nitrate in the reaction medium yields **4**. A few crystals of **3** were isolated from an experiment designed to crystallize compound **2**. Unfortunately, we have not yet found a reproducible method of synthesizing this complex.

Single crystals suitable for X-ray data collection were obtained for the title complexes. Crystallographic details are given in Table 1.

The crystal structures of compounds **1** and **4** are formed by the $[Cu(L)]^+$ and $[Cu(HL)]^{2+}$ entities, respectively, linked through a bis-bidentate oxalato ligand, which leads to the dinuclear centrosymmetric $[\{Cu(L)\}_2(ox)]$ (**1**) and noncentrosymmetric $[\{Cu(HL)\}_2(ox)]^{2+}$ (**4**) species. Waters of crystallization are also present in the lattice of **1**. The nitrate counterions are also present in the lattice of **4**. The molecular structures of **1** and **4** are shown in Figure 1 and 2, respectively. Selected interatomic dimensions are given in Table 2. The copper(II) ions are five-coordinate with two nitrogen and one sulfur atoms from the thiosemicarbazone ligand [Cu−N(1), N(2), S: 2.044(2), 1.955(2), 2.2759(6) and 2.027(6), 1.956(5), 2.306(2) Å, for **1** and **4**, respectively] and one oxygen atom of the carboxylate [Cu−O(1): 1.966(2) and 1.943(4) Å, for **1** and **4**, respectively] in the basal position. The axial position is occupied by the oxygen atom belonging to the adjacent carboxylate group in the same oxalato ligand [Cu−O(2) 2.308(2) and 2.300(5) Å, for **1** and **4**, respectively]. The intramolecular Cu···Cu′ distances are 5.531(1) Å in **1**, and 5.320(2) Å in **4**. The distortions of the coordination polyhedra have been analyzed by means of the Addison's parameter from the limiting values correspond-

ing to square pyramidal (SP, $\tau = 0$) and trigonal bipyramidal (TBP, $\tau = 1$) topologies.[5] The τ values obtained are 0.22 (**1**) and 0.26 (**4**), which indicate that the environment of the copper(II) ions is close to the SP topology. Note the different positions of the ligands in the dinuclear entities (*trans* and *cis* for **1** and **4**, respectively), which breaks the centrosymmetry in **4** and forms a C2 axis with respect to the oxalato ligand. The *cis* configuration of the dinuclear species is not usual in thiosemicarbazone derivatives.[6]

The crystal structure of complex **2** consists of $[Cu(HL)(ox)(H_2O)]$ monomers, as represented in Figure 3. Several distances and angles are shown in Table 2. Each copper(II) ion is five-coordinate, with one sulfur and two nitrogen atoms of the thiosemicarbazone ligand [Cu−N(1), N(2), S: 2.027(3), 1.967(3), 2.281(1) Å] and an oxygen O(1) atom of the oxalato ligand [Cu−O(1): 1.933(2) Å] in the basal plane. The axial position is occupied by the oxygen atom belonging to a water molecule [Cu−O(5) 2.285(3) Å]. The distortion of the coordination polyhedron gives a value of $\tau = 0.18$, characteristic of a geometry close to SP topologies.

The crystal structure of compound **3** is made up of centrosymmetric $[\{Cu(HL)(ox)\}_2]^{2+}$ cationic entities and $[Cu(ox)_2]^{2-}$ bis(oxalato)copper(II) anions. A perspective view of the structure is shown in Figure 4. Selected distances and angles are given in Table 2. The Cu(1) and Cu(2) copper(II) ions exhibit square-pyramidal ($\tau = 0.09$) and square-planar geometries, respectively. Cu(1) is coordinated to one sulfur and two nitrogen atoms of the thiosemicarbazone ligand [Cu−N(1), N(2), S: 2.026(3), 1.952(3), 2.275(1) Å] and an oxygen O(1) atom of the oxalato ligand (Cu−O(1): 1.943(2) Å) in the basal plane. The axial position is occupied by the oxygen atom belonging to the adjacent carboxylate group in the same oxalato ligand [Cu−O(2): 2.261(2) Å]. The intramolecular Cu···Cu′ distance is 5.439(1) Å. The Cu(2) atoms in the bis(oxalato)copper(II) anions are bonded to the O(1S) and O(3S) atoms of each oxalato ligand with bond lengths of 1.937(2) and 1.941(2) Å, respectively. It is interesting to note that the Cu(2)−O(2) distance is 2.756(2) Å, and so the possibility of pseudocoordination must not be ruled out. This could give rise to the presence of chains in the structure, in which the bis(oxalato)copper(II) anions would act as a bridge between the $[\{Cu(HL)(ox)\}_2]^{2+}$ entities.

The thiosemicarbazone ligand exhibits high planarity, except in the cationic entities of **3**. The maximum deviation from the pyridine plane in **1**, **2**, **3** and **4**, corresponds to the S (0.21 Å), N(4) (0.23 Å), S (−0.86 Å) and N(4) (0.34 Å) atoms respectively. The copper(II) ions are above the plane formed by the thiosemicarbazone N(1)N(2)S set (0.22, 0.18, 0.23 and 0.13 Å in **1**, **2**, **3** and **4**, respectively). Both thiosemicarbazone molecules in the dinuclear entity are coplanar on **1** and **3** (dihedral angle ca. 0.0°), but in **4**, the angle formed by the two planes is 10.3°.

The oxalato ligand is planar in **1** and in the cationic $[\{Cu(HL)(ox)\}_2]^{2+}$ species of **3**. However, the O(1S)−C(1S)−C(2S)−O(2S) dihedral angle in the bis(oxalato)copper(II) anions in **3** is 9.6(4)°. The value of the analogous O(1)−C(8)−C(9)−O(3) and O(1)−C(8)−C(8)^{i}−O(1)^{i} angles in **2** and **4** are 79.9(4) and 2.5°, respectively. The highly twisted oxalate molecules, as those reported in **2** (e.g., O−C−C−O angles greater than 50°), are not very usual.[7] There are several possible explanations for this phenomenon. i) The O(2) atom points in the direction of the out-of-plane d_x orbitals (d_{xz} or d_{yz}) of the copper(II) ion. However, the Cu−O(2) distance is too long (2.916 Å). An Extended Hückel molecular orbital (EHMO) analysis[8] on the crystallographic coordinates of compound **2** has been carried out following a published method.[9] It gives no evidence of any significant overlap population between the Cu and O(2) atoms. ii) The existence of tangential π-π stacking between the pyridine and uncoordinated carboxylato moieties can also be considered, with a minimum atom···atom distance of 3.47 Å [O(3)···N(1)^{v}]. The angle between the pyridine and carboxylato planes is 5.3°. However, these interactions are probably weak due to the substantially offset π-stacked geometry. iii) Finally, very strong hydrogen bonds involving the O(3) and O(4) atoms are present in the crystal (see Table 2). These atoms belong to the uncoordinated carboxylate group in the oxalato ligands. The strength of these hydrogen bonds influences the

[e] In the case of compound **4**, O(2) related to the symmetry operation *i*.

D···A intermolecular distances and the C(8)−O(2), C(9)−O(3), C(9)−O(4) bond lengths. This fact suggests that the hydrogen bonds are mostly responsible for the twisting of the oxalato ligand. On the other hand, for all these complexes, the longest C−O bonds in the coligands involve the oxygen atoms that are linked to the metal ions.

As in the case mentioned above, the lattice of these compounds contain several hydrogen bonds involving the N(3), N(4) and the oxygen atoms of the oxalato coligands (see Table 2).

The shortest distances between the planes of the pyridine and thiosemicarbazone fragments in different molecules are 3.28 [C(2)···N(2)[ii]], 3.32 [C(1)···N(3)[v]], 3.34 [C(5)···N(4)[iv]] and 3.32 Å [N(4)···C(5)[iv]] for **1**, **2**, **3** and **4**, respectively. This suggests the existence of π-π interactions of the slipped packing type,[10] as represented in Figure 5. Some structural parameters have been evaluated,[11,12] and the results are shown in Table 3. The coordination of a metal ion to the nitrogen heteroatom in heterocyclic molecules enhances the electron-withdrawing effect as a result of its positive charge, such that the stability of the π-π interaction increases.[13,14]

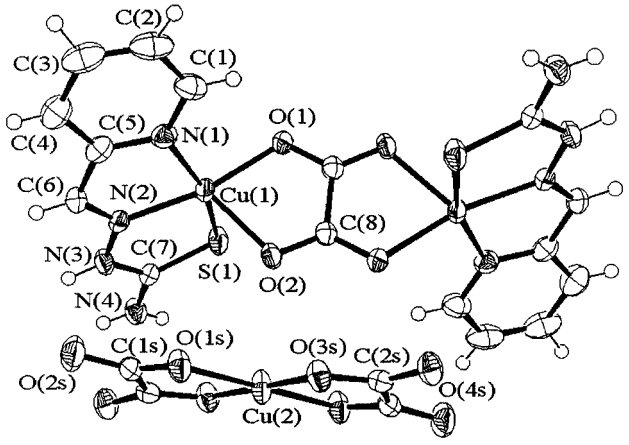

Figure 4. Molecular structure of **3** with thermal ellipsoids at the 50% probability level

These kinds of interactions have also been observed in other thiosemicarbazone systems.[15]

Complexation induces conformational changes in the ligand. Atoms N(1) and N(2) are *anti* with respect to the C(5)−C(6) bond in the free ligand,[16] however, they are *syn* after chelation. Furthermore, the N(2) and S atoms are *anti* with respect to the N(3)−C(7) bond in the neutral ligand[16] and the pyridinium $(H_2L)Cl{\cdot}H_2O$ cationic derivative.[17] However, in the metal complexes, they adopt a *syn* geometry. The C−C and C−N distances are similar to those found in the free ligand and its cationic form, with the exception of the N(3)−C(7) and C(7)−S bond lengths in compound **1**. These bond lengths are significantly different from those observed in the free ligand: 1.358(4) and 1.698(3) Å, respectively. This fact suggests that the double-bond character of the N(3)−C(7) bond in the thiosemicarbazone anionic ligand increases, and that of the C(7)−S bond decreases. However, the bond lengths in the complexed neutral thiosemicarbazone ligands are not different from those in the free ligand. These results are related to the thione vs. thiolate character of the ligand in the neutral or anionic forms, respectively, suggesting the presence of appreciable

metal-to-ligand π-back donation in the neutral thiosemicarbazone, due to an increase in the π-acceptor character of the sulfur atom of the ligand. The bond lengths are often in the range of experimental error. Other structural parameters, such as some bond angles and non-contact distances are more appropriate for the evaluation of the anionic vs. neutral character of the ligand on complexation.[18] The results summarized in Table 4 show that the distances and angles for the title complexes are in good agreement with those expected for compounds containing the pyridine-2-carbaldehyde thiosemicarbazone ligand in the anionic (**1**) and neutral (**2**, **3**, **4**) forms.

Spectroscopic Studies

The unambiguous assignment of the IR absorption bands in these compounds is made difficult by the highly delocalized thiosemicarbazone system and the oxalato coligands, which give rise to many infrared absorptions. One of the relevant features in some of the complexes is the presence of bands in the 2900−2300 cm^{-1} region which can be assigned to the ν(OH) and ν(NH) vibrations, which are shifted to lower energies as a result of the strong hydrogen bonds. This is in good agreement with the structural results.[19,20] The bands at 1646, 1347 and 800 cm^{-1} in **1** are assigned to the ν_{as}(COO), ν_s(COO) and ν(OCO) absorptions of the oxalato ligand, respectively.[21] Compound **2** shows absorptions at 1644, 1573, 1382, 1339, 830 and 805 cm^{-1} for both the coordinated and uncoordinated carboxylate groups. The complexity of the spectrum of compound **3** only allows for the identification of the bands at 1655, 1640, 1392 and 803 cm^{-1}, which correspond to the oxalato ligands. The same absorptions are found in **4** at

1654, 1302 and 797 cm^{-1}. Furthermore, compound **4** shows bands at 1383 and 820 cm^{-1} that can be assigned to the ν_3 and ν_2 vibration modes of the nitrate counterion.

The reflectance spectra of the title compounds show bands in the 210−230, 275−290, 360−430 and 630−950 nm regions. These are assigned to ($\pi \rightarrow \pi^*$) pyridine, ($n \rightarrow \pi^*$) pyridine, ($n \rightarrow \pi^*$) thiosemicarbazone, LMCT N/O/S → d and d → d transitions, respectively.[22,23]

The absorption band observed in the 360−380 nm region is assigned to a S → Cu^{II} charge transfer transition. This band is shifted to lower energies in compound **1**. The decrease in energy for the complexes containing the ligand in the anionic form may be due to a decrease in the strength of the π-interactions between the copper and sulfur atoms, and hence results in a C−S bond with greater thiolate behavior.[4e,4h,4j] The absorptions between 420−430 nm can be assigned to LMCT O/N → Cu^{II} transitions, as was observed in other related compounds.[24]

The maxima observed in the 630−665 nm region are characteristic of d → d transitions for square pyramidal copper(II) complexes with a $d_{x^2-y^2}$ ground state. These bands show unresolved shoulders obscured by the tails above 700 nm, which can be due to the distortion of the coordination polyhedra in these compounds to trigonal-bipyramidal geometry. In this sense, the higher the distortion, the greater the wavelength. This is in accordance with the Addison's parameters calculated in the crystallographic section.

The X-band EPR spectra of complexes **1**, **2** and **4** at room temp. are shown in Figure 6. All the spectra exhibit rhombic signals. The obtained *g* values are given in Table 5. These values are similar to those observed for other pyridine-2-carbaldehyde thiosemicarbazone derivatives containing copper(II) ions with distorted square pyramidal topologies, with a $d_{x^2-y^2}$ ground state.[4b,4d−4k]

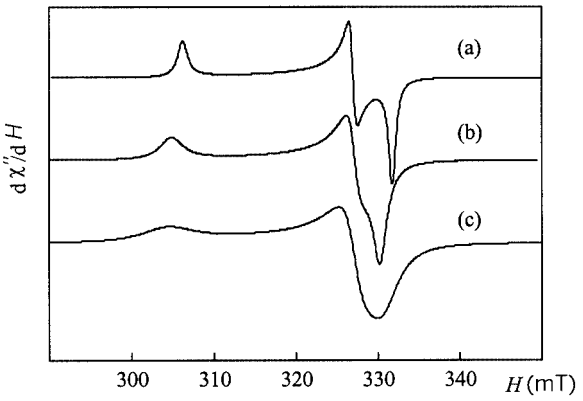

Figure 6. X-band EPR spectra of (a) **1**, (b) **2** and (c) **4** in the solid state at room temp.

Table 5. Experimental EPR parameters

Compound	Temperature	g_1	g_2	g_3
1	room temp.[a]	2.200	2.062	2.032
2	room temp.[a]	2.211	2.061	2.041
4	room temp.	2.212	2.062	2.044
	4 K	2.230	2.063	2.025

[a] No variation in the *g*-values from room temperature to 4 K.

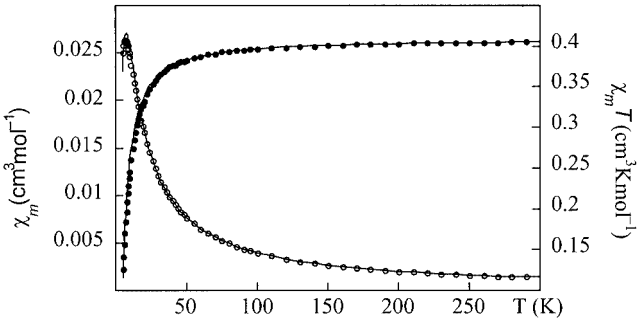

Figure 7. Thermal variation of the molar susceptibility (○○) and $\chi_m T$ (●●) for **1**; solid lines represent the best fit

Magnetic Behavior

The plots of the molar susceptibility (χ_m) vs. *T*, together with the $\chi_m T$ vs. *T* curves, for compounds **1** and **4** are given in Figure 7 and 8. In all the cases, the magnetic measurements obey the Curie−Weiss law at temperatures higher than 50 K. The Weiss temperatures are −3.47 (**1**) and +3.27 K (**4**). The C_m experimental values are 0.41 (**1**) and 0.42 $cm^3 \cdot K \cdot mol^{-1}$ (**4**), and the calculated μ_{eff} values at room temperature are 1.80 (**1**) and 1.84 BM (**4**). For compound **1**, the χ_m value increases with decreasing temperature, reaching a maximum at 7.0 K (0.026 $cm^3 \cdot K \cdot mol^{-1}$), and the $\chi_m T$ value continuously decreases when the temperature is lowered, indicating the presence of antiferromagnetic interactions. However, compound **4** does not exhibit a maximum in the plot of χ_m vs. *T*, and the $\chi_m T$ value increases on

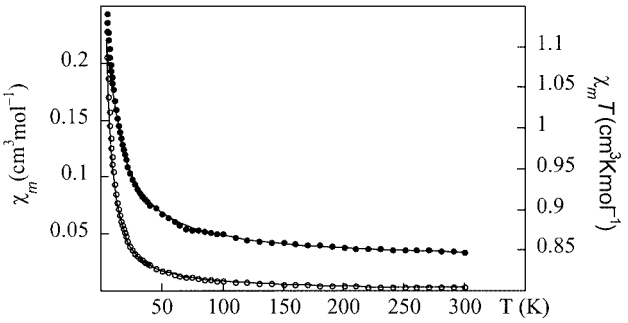

Figure 8. Thermal variation of the molar susceptibility (○○) and $\chi_m T$ (●●) for **4**. Solid lines represent the best fit

lowering the temperature, which is characteristic of ferromagnetic behavior.

Considering the dinuclear nature of these complexes, the susceptibility data was fitted to the expression derived from the Heisenberg isotropic spin Hamiltonian ($H = -2J\, S_1S_2$), for two coupled $S = 1/2$ ions, given by Bleaney−Bowers for copper(II) dinuclear compounds[25]:

$$\chi = \frac{Ng^2\beta^2}{kT}\left(\frac{2}{3+\exp(-2J/kT)}\right) + N\alpha$$

where $N\alpha$ = temperature independent contribution, N is Avogadro's number, β = Bohr magneton, and k = Boltzmann constant. The best least-squares fit (solid line in Figures 7 and 8) is obtained from the parameters $J/k = -6.20$ K (-4.30 cm^{-1}, taking into account 3% paramagnetic impurities) and $+7.73$ K ($+5.37$ cm^{-1}). The g values are 2.089 and 2.112 for complexes **1** and **4**, respectively. These g values are in good agreement with those obtained from EPR (2.098 (**1**) and 2.106 (**4**)). Taking into account the structural features, the existence of magnetic interactions between the different species was considered. However, an improvement in the fit was not observed.

The small values of the magnetic interactions suggest that the exchange propagation direction is in a different plane from that formed by the magnetic $d_{x^2-y^2}$ orbitals. These results agree with the presence of exchange coupling through the oxalato ligand. It must be pointed out that, in spite of the weak magnetic exchange in **4**, this is the strongest ferromagnetic interaction observed in oxalato-bridged copper(II) dinuclear complexes.[26]

It has been proposed[27] that the antiferromagnetic contribution to the magnetic exchange constant J for a dinuclear system with two unpaired electrons is proportional to the square of the energy difference (Δ^2) between the two molecular orbitals constructed from the $d_{x^2-y^2}$ magnetic orbitals. EHMO calculations using the crystallographic coordinates have been carried out to give a qualitative explanation for the magnetic behavior of these complexes. The Δ values are 0.016 and 0.021 eV for **1** and **4**, respectively. These results do not show a qualitative agreement between the gap of the two $d_{x^2-y^2}$ magnetic orbitals involved and the values of the exchange constant. There are at least three possibilities that can be proposed to explain such a disagreement. i) The limitations of the EHMO calculations do not allow us to give a perfect sequence for very similar J values in the pyridine-2-carbaldehyde (thiosemicarbazone)-copper(II) system.[4k] However, a good qualitative accordance is usually obtained for different J values, as those described here. ii) The crystal structure of **4** shows Cu···S^v distances of 3.184(2) Å, which relate copper(II) ions at 3.697(2) Å. The contraction of the cell at low temperatures decreases the Cu···S^v distance. However, as mentioned before, the fit of the curves when considering interactions between different species, was not improved. iii) The non-centrosymmetric nature exhibited by compound **4** could be responsible for the decrease in the antiferromagnetic contribution, which is not reflected in the magnitude of Δ^2, giving rise to the ferromagnetic behavior of this compound.[28]

Conclusion

The control of the experimental conditions in the pyridine-2-carbaldehyde (thiosemicarbazone)copper(II)/oxalato system results in the formation of a rich variety of compounds. In particular, both the amount of reagents and the pH of the medium play an important role in the syntheses of the complexes. As a result either monomeric (**2**) or dinuclear entities (**1** and **4**) can be obtained. The formation of one-dimensional systems is possible , as can be seen by the structure of compound **3**, but up to date, we have not been able to find a reproducible synthetic method to obtain this compound. These results can be used as structural models to predict the possible interactions between the $[Cu(L)(H_2O)_3]^+$ entities and carboxylate-containing biomolecules present in physiological medium.

Magnetic susceptibility data indicate the presence of weak antiferromagnetic and ferromagnetic interactions in **1** and **4**, respectively. The noncentrosymmetric structure of **4** seems to be responsible for the difference in sign of the magnetic properties observed, relative to compound **1** (centrosymmetric). These results demonstrate that the μ-oxalato (thiosemicarbazone)copper(II) systems are appropriate for tunable exchange interactions.

Experimental Section

Preparation of the Complexes: Thiosemicarbazide, pyridine-2-carbaldehyde, oxalic, nitric and trifluoroacetic acids, potassium oxalate, sodium nitrate and copper(II) nitrate were purchased from Fluka, Merck and Prolabo and used as received. Published methods with small modifications were used to synthesize HL[29] and $Cu(L)(NO_3)$.[4b,30]

$[\{Cu(L)\}_2(ox)]\cdot 2H_2O$ (1): An aqueous solution of potassium oxalate (0.092 g, 0.5 mmol) was added to a solution of $Cu(L)(NO_3)$ (0.30 g, 1 mmol) in water (40 mL). The pH was adjusted to 6 by adding NaOH (5 M). The reaction mixture was stirred for 3 h, then filtered, washed and dried. The yield was 0.21 g (70%). Dark-green crystals were obtained by the slow reaction of aqueous solutions of **1** and potassium oxalate in a diffusion device. $C_{16}H_{18}Cu_2N_8O_6S_2$ (609.58): calcd. C 31.5, H 3.0, N 18.4, S 10.5; found C 31.3, H

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3.0, N 18.0, S 10.3. Molar conductivity of $5\cdot10^{-4}$ M solutions in dimethylformamide at 25 °C: Λ_M = 5.2 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands (KBr): $\tilde{\nu}$ = 3568 m, 3438 m, 3385 m, 3104 m, 1646 br. vs, 1604 s, 1559 m, 1481 m, 1448 s, 1428 br. s, 1347 w, 1324 m, 1297 s,sh, 1229 m, 1172 s, 1155 s, 880 m, 800 m, 779 m, 626 m, 410 w cm^{-1}. UV-Vis: λ_{max} (reflectance spectrum on solid sample) λ = ca. 800 (vb,sh), 646 (b), 422 (sh), 378, 277, 227 nm.

[Cu(HL)(ox)(H$_2$O)] (2): Oxalic acid (0.63 g, 5 mmol) was dissolved in water (15 mL), and was allowed to react with an aqueous solution of Cu(L)(NO_3) (0.30 g, 1 mmol). The pH was adjusted to 1 by adding nitric acid. After 3 h of constant stirring, the blue solid was filtered, washed and dried. Yield 0.24 g (around 70%). This complex was also prepared from aqueous solutions of **1** and oxalic acid in a diffusion device, both solutions were acidified with several drops of trifluoroacetic acid. After two weeks, greenish-blue crystals suitable for X-ray studies were collected. $C_9H_{11}CuN_4O_5S$ (350.82): calcd. C 30.8, H 3.2, N 16.0, S 9.1; found C 30.5, H 2.8, N 16.2, S 8.8. Molar conductivity of $5\cdot10^{-4}$ M solutions in dimethylformamide at 25 °C: Λ_M = 69.0 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands (KBr): $\tilde{\nu}$ = 3354 m, 3231 w, 2864 w (br.), 2696 w, 1644 s, 1614 m, 1573 vs, 1473 s, 1448 m, 1382 w, 1339 m, 1298 vs (sh), 1273 s, 1226 m, 1182 m, 1109 m, 921 m (sh), 830 w, 804 w, 778 sh, 769 s, 653 m (sh), 623 w, 489 w, 414 w cm^{-1}. UV-Vis, λ_{max} (reflectance spectrum on solid sample) = ca. 720 (sh), 630 (b), 360, 287, ca. 220 nm. Deep-blue good quality crystals of [{Cu(HL)}$_2$(ox)][Cu(ox)$_2$]·2H$_2$O (**3**) co-crystallized, together with those of **2**. All the attempts to synthesize this compound separately were unsuccessful. Selected IR bands (KBr): $\tilde{\nu}$ = 3433 m, 3345 m, 3160 m, 1655 vs, 1638 vs, 1624 vs, 1613 vs,sh, 1582 s, 1392 m, 1299 m, 1254 m, 1226 m, 1178 s, 803 w, 778 s, 738 w, 694 w, 617 w, 490 w, 410 w cm^{-1}.

[{Cu(HL)}$_2$(ox$_{0.5}$)]·(NO$_3$)$_2$ (4): Aqueous solutions of oxalic acid (0.092 g, 0.5 mmol), sodium nitrate (0.42 g, 5 mmol) and Cu(L)(NO_3) (0.30 g, 1 mmol) were mixed with vigorous stirring. The pH of the resulting mixture was adjusted to about 1 by the addition of nitric acid. Four hours later, a turquoise-blue precipitate appeared. This was filtered, washed and dried. The yield was 0.24 g (around 70%). This complex can be also synthesized from an aqueous suspension of **1** by adding nitric acid (final pH ≈ 1). Finally, crystals of this compound were collected by slow evaporation of the mother liquors of **2**. $C_{16}H_{16}Cu_2N_{10}O_{10}S_2$ (699.59): calcd. C 27.5, H 2.3, N 20.0, S 9.2; found C 27.3, H 2.2, N 19.9, S 9.2. Molar conductivity of $5\cdot10^{-4}$ M solutions in dimethylformamide at 25 °C: Λ_M = 133.2 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$. Selected IR bands (KBr): $\tilde{\nu}$ = 3294 m, 3138 m, 1654 vs, 1624 s, 1616 s, 1586 s, 1474 m, 1434 s, 1383 s, 1339 s, 1302 s, 1280 s, 1224 s, 1178 m, 1163 m, 1019 w, 921 w, 879 w, 820 w, 797 w, 771 m, 742 m, 651 m, 623 w, 415 w cm^{-1}. UV-Vis, λ_{max} (reflectance spectrum on solid sample) = ca. 950 (vb, sh), 663 (vb), 428 (sh), 367 (sh), 283, ca. 214 nm.

Physical Measurements: Microanalyses were performed with a LECO CHNS−932 analyzer. Conductivity measurements were made by a CRISON 522 conductimeter. Infrared spectra were obtained with samples prepared as KBr pellets in the 400−4000 cm^{-1} region on a Nicolett Impact 410 FTIR spectrophotometer. Reflectance spectra were recorded on a Cary 2415 spectrometer in the range 200−2000 nm. For UV-visible solution measurements, a Varian UV-VIS-NIR spectrophotometer was employed in the range 200−900 nm. X-band EPR spectra were recorded on a Bruker EMX spectrometer, equipped with a standard Oxford continuous flow cryostat. Magnetic measurements of powdered samples were performed in the temperature range 5−300 K, using a Quantum Design MPMS−7 Squid magnetometer. Diamagnetic corrections were estimated from Pascal tables.

X-ray Crystallographic Studies: Crystal data collections were carried out on a Bruker Smart CCD area detector equipped with a single crystal diffractometer. Absorption corrections were made using the SADABS program.[31] Direct methods (SHELXS-97)[32] were employed to solve the structures and were then refined by full-matrix least-squares methods, using the SHELXL-97 computer program.[33] All non-hydrogen atoms were assigned anisotropic thermal parameters. Hydrogen positions were determined by difference Fourier syntheses and introduced in calculations with a riding model. The scattering factors and anomalous dispersion coefficients were taken from International Tables of X-ray Crystallography.[34] Refinements were made on F_o^2 for all reflections. The high thermal parameters in the nitrate ions of compound **4** are the cause of the disorder in some of the oxygen atom positions. CCDC−194996 (**1**), −194997 (**2**), −194998 (**3**) and −194999 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We thank Dr. J. J. Delgado (SCAI, Universidad de Burgos, Spain) for the elemental analysis and Prof. R. Olazcuaga and Dr. F. Guillen (CNRS, Pessac, France) for the reflectance measurements. We also thank Dr. J. L. Pizarro for helpful discussions about the crystallographic data. This work has been carried out with the financial support of the Basque Government (PI99/53) and the Dirección General de Investigación del Ministerio de Ciencia y Tecnología (BQU2002-00435). P. G.-S. thanks the Universidad de Burgos for her Doctoral Fellowship.

Iron-Fragment-Substituted Heterosiloxanes of Gallium $[Cp(OC)_2Fe-SiR_2OGaR'_2]_2$ (R, R′ = Alkyl, Aryl) − Structures of $[Cp(OC)_2Fe-SiR_2OGaMe_2]_2$ (R = Me, Ph)[‡]

Wolfgang Malisch,*[a] Dirk Schumacher,[a] Bernd Schmiedeskamp,[a] Heinrich Jehle,[a] Dirk Eisner,[b] Wolfgang W. Schoeller,[b] and Martin Nieger[c]

Keywords: Gallium / Iron / Silanols / Silicon / Siloxanes

The trialkylgallanes GaR''_3 [R′ = Me, *i*Pr (**2a** and **2b**)] react with the ferrio-silanols $Cp(OC)_2Fe–Si(R)(R')OH$ [R = R′ = Me, *i*Pr, Ph (**1a**–**c**), R = Me, R′ = Ph (**1d**)] by alkane elimination to yield the iron-substituted siloxy-gallanes $[Cp(OC)_2Fe–Si(R)(R')OGaR''_2]_2$ (**3a**–**e**). According to molecular mass determination in benzene (**3a**, **3b**, **3d**), X-ray analyses (**3a**, **3d**) and NMR spectroscopy (**3e**), the novel hetero-siloxanes exist as dimers both in solution and in the solid state. The bonding situation and geometry of the ferrio-heterosiloxane $[Cp(OC)_2Fe–SiH_2OGaH_2]_2$ has been analyzed by density functional calculation.

Introduction

Heterosiloxanes, siloxanes containing Si−O−E moieties (E = heteroelement), represent a class of compounds in organometallic chemistry that has attracted widespread interest in material science and catalysis in recent decades. Due to the presence of the heteroelement, they may serve as models for heteroelement-doped silicates and silicones, which often exhibit special properties such as high thermal stability or catalytic activity. In this context, the preparation of group 13 heterosiloxanes (E = Al, Ga, In) has become a growing field of research concerning catalytically active zeolites, such as gallium-containing zeolites for the dehydrogenation and dehydrocyclization of alkanes.[3−8] Early studies by Schmidbaur[9−11] describe various heterosiloxanes represented by compounds such as $[R_3SiOEMe_2]_2$ (E = Ga, In; R = Me, Ph)[10] for group 13 elements. Recent work by Roesky has shown that the related reactions of organosilanetriols $RSi(OH)_3$ preferentially yield compounds such as $[RSiO_3E·D]_4$ (E = Al, Ga, In; D = THF, dioxane), characterized by three-dimensional polyhedral cage structures.[3−5] The access to transition metal-substituted silanols $L_nM-SiMe_{3-x}(OH)_x$ (x = 1−3) now offers the possibility of obtaining a novel kind of heterosiloxane in which the silicon atom bears a transition metal fragment. Metallo-silanols show reduced H acidity of the Si−OH function and remarkable stability towards self-condensation, a behavior contrasting with that of organosilanols $R_{4-x}Si(OH)_x$ (x = 1−3), which usually convert into siloxanes. This high stability, caused by the electron-rich metal fragment, predisposes metallo-silanols to act as excellent precursors for selective reactions with chlorosilanes, yielding metallo-siloxanes and -polysiloxanes $L_nM-SiMe_{3-x}(OSiR'_3)_x$ [x = 1−3; R'_3Si = Me_3Si, $Me_2(H)Si$].[12−20] Moreover, these properties should allow the preparation of metal fragment-substituted heterosiloxanes of gallium and indium by alkane elimination. These species could represent attractive models for silica- or zeolite-based catalysts, in which L_nM represents an catalytically active metal fragment.

In this paper we present the first examples of successful coupling reactions between metallo-silanols $Cp(OC)_2Fe-Si(R)(R')OH$ (R = R′ = Me, *i*Pr, Ph; R = Me, R′ = Ph)[13,14,21] and diverse trialkylgallanes. Moreover, we describe investigations concerning the influence of the transition metal fragment on the aggregation mode.

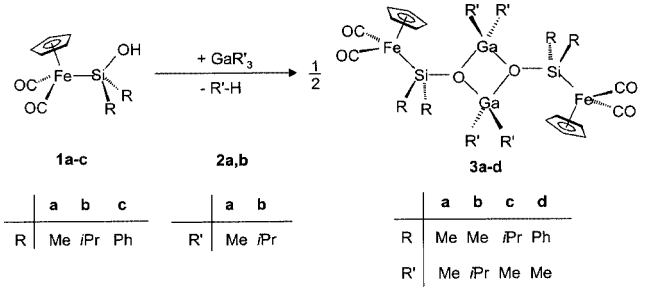
Results and Discussion

Synthesis of Iron Fragment-Substituted Heterosiloxanes of Gallium

Treatment of the trialkylgallanes **2a** and **2b** with stoichiometric amounts of the ferrio-silanols $Cp(OC)_2Fe-SiR_2OH$ [R = Me (**1a**), *i*Pr (**1b**), Ph (**1c**)] in *n*-pentane at room temperature yielded, by the elimination of alkane, after 2 h (**3a**, **3c**, **3d**) or 16 h (**3b**) the metal fragment-substituted heterosiloxanes **3a**−**d**. The trimethylgallane **2a** was preferably employed as an Et_2O adduct, which proved to be much easier to handle (Scheme 1).



Scheme 1. Synthesis of iron fragment-substituted heterosiloxanes of gallium

Compounds **3a**−**d** are isolated after recrystallization from *n*-pentane at −78 °C as light yellow, microcrystalline powders in 73−86% yields. The compounds are slightly soluble in *n*-pentane or *n*-hexane and reasonably soluble in benzene or toluene. Unlike the starting materials, they may even be handled in air for short times without decomposition.

The ^{29}Si NMR resonances of **3a**−**d** show the typical downfield shifts of $Cp(OC)_2Fe$-substituted silicon atoms (**3a**: δ = 66.57 ppm, **3b**: δ = 64.10 ppm, **3c**: δ = 78.92 ppm, **3d**: 54.86 ppm). The observed range appears close to that for the corresponding ferrio-silanols (**2a**: δ = 66.05 ppm, **2b**: δ = 76.36 ppm, **2c**: 50.38 ppm).

Molecular mass determinations of **3a**, **3b**, and **3d** in benzene by freezing-point depression reveal the presence of dimers, originating from intermolecular interaction between the Lewis acidic group 13 element and the Lewis basic oxygen atoms of the Si−O units. This result is in good accordance with the findings for metal-free siloxy-gallanes.[9−11] The aggregation to dimers in the solid state was additionally confirmed by X-ray analyses of **3a** and **3d**. These results clearly indicate that the $Cp(OC)_2Fe$ fragment at the silicon does not induce O−Ga π-interaction sufficient to prevent dimerization.

Treatment of the ferrio-silanol $Cp(OC)_2FeSi(Me)(Ph)OH$ (**1d**), bearing a chiral silicon atom, with $GaMe_3{\cdot}Et_2O$ (**2a**) in *n*-pentane produces the heterosiloxane **3e** as a beige, microcrystalline solid in 82% yield.

The aggregation of **3e**, due to Ga−O interaction, results in the formation of *like* and *unlike* diastereomers (Figure 1), as can be directly confirmed in solution by ^1H NMR spectroscopy (C_6D_6, Figure 2). Since the two diastereomers differ in the topicities of their Ga-bonded methyl groups, the *like* diastereomer (*RR*/*SS*), which has a C_2 axis as symmetry element, provided free rotation around the O−Si axis, and has homotopic methyl groups, while the *unlike* diastereomer (*RS*/*SR*), characterized by a mirror plane, has diastereotopic methyl groups. This stereochemical situation gives rise to three signals for the Ga-bonded methyl groups in the ^1H NMR and the ^{13}C NMR spectra: two for the *unlike* form and one for the *like* form. The diastereomeric ratio can be determined as 50:50 by integration of these signals. Moreover, two signals, located very close to each other, are observed for all other NMR resonances, due to the existence of diastereomers.

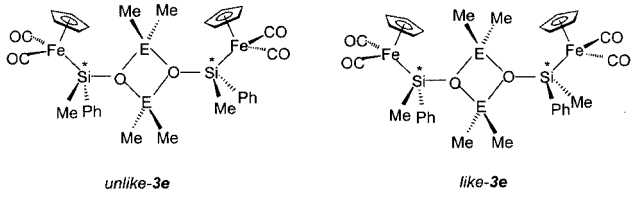


Figure 1. *unlike*- and *like*-**3e**

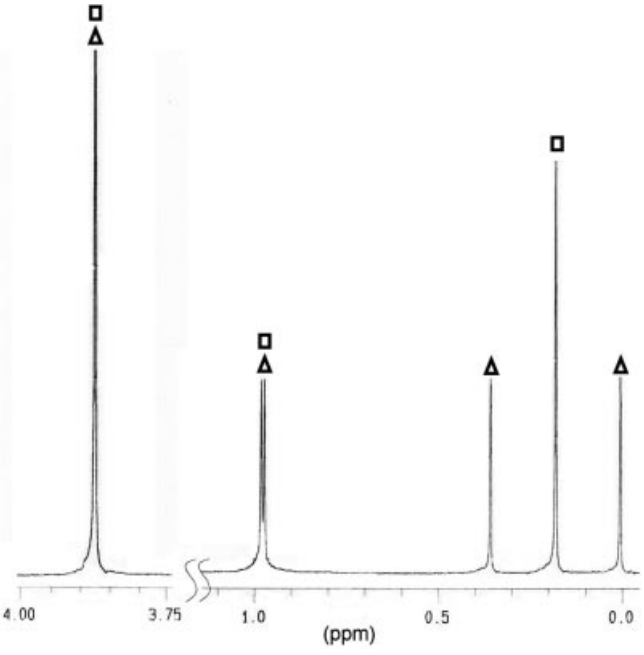

Figure 2. ^1H NMR([D_6]benzene, 300.4 MHz) of **3e** (aromatic region has been omitted for clarity); □ = *like*-**3e**, Δ = *unlike*-**3e**; *like*/*unlike* assignment of the SiMe and Cp signals is not possible

X-Ray Analyses of 3a and 3d

The results of the X-ray analyses of **3a** and **3d**, which to the best of our knowledge are the first structurally characterized siloxy-substituted diorgano compounds of gallium, are presented in Figure 3 and 4.

The structure-determining element is the rhombic, four-membered $[Ga-O]_2$ ring, a common feature of heteroatom-

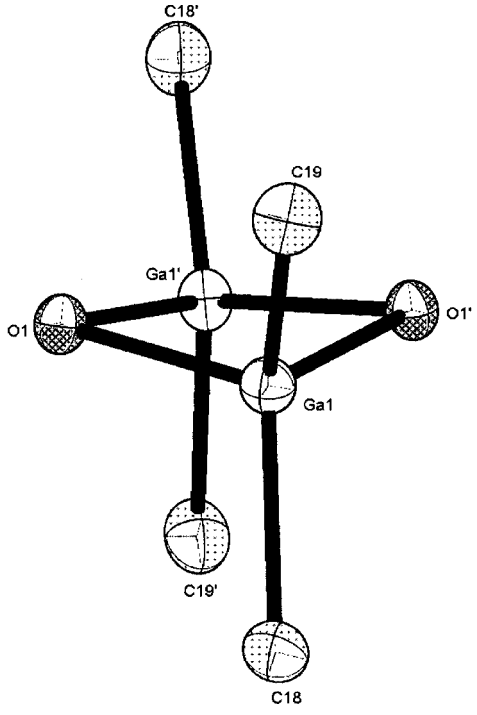

Figure 5. Butterfly geometry of the four-membered ring of **3d**

substituted group 13 dialkyl compounds, formed by the two oxygen atoms (O3/O3A in **3a**, O1/O1′ in **3d**) and the Lewis acidic gallium atoms (Ga1/Ga1A in **3a**, Ga1/Ga1′ in **3d**). In the case of **3a**, the four-membered ring, with a *trans* arrangement of the iron fragments, is planar (O3−Ga1A−O3A−Ga1 = 0°), while **3d**, with a *cis* position of the iron fragments, shows a butterfly geometry [O1−Ga1′−O1′−Ga1 = 11.24(4)°, Figure 5].

The group 13 element−oxygen bond lengths in **3a** [Ga1−O3 = 1.957(3) Å/Ga1−O3A = 1.977(3) Å] and **3d** [Ga1−O1 = 1.9815(11) Å/Ga1′−O1′ = 1.9792(19) Å] correspond to the bond lengths found for dimeric (alkoxy)-dialkylgallanes: {[(*t*Bu)$_2$Ga-μ-O(*t*Bu)]$_2$: 1.990 Å}[22] and lie in the range between a coordinative interaction and a sigma bond.[23] A distorted tetrahedral geometry at the group 13 element is indicated by the angles formed by the ligands of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Ga1, with the smallest, endocyclic angle defined by the oxygen atoms [83.39(13)° (**3a**), 82.10(4)°/82.06(4)° (**3d**)] and the largest one formed by the two exocyclic methyl ligands [130.7(2)° (**3a**), 127.04.(7)°/125.17(7)° (**3d**)]. A nearly planar distorted trigonal coordination at the bridging oxygens is confirmed by the sum of angles, of 357°/358°, with individual angles between the ligands varying from 96.61(13)°/96.78(5)° to 134.63(18)°/132.47(6)° for **3a** and **3d**, respectively. The substituents at the silicon atoms in **3a** and **3d** show the expected tetrahedral arrangements, with small angles between the organic substituents and the oxygen [106.4(2)−106.8(2)° (**3a**); 103.37(6)°−108.72(7)° (**3d**)] and large angles including the metal fragment [110.05(16)°−113.56(12)° (**3a**); 109.96(5)°−115.63(6)° (**3d**)]. The iron-silicon distances of 2.3229(16) Å (**3a**) and 2.3091(5)/2.3086(5) Å (**3d**) and the silicon-oxygen distances of 1.667(3) (**3a**) and 1.6674(11)/1.6703(11) Å (**3d**) show no peculiarity compared to the Fe−Si distance in related complexes {$[Cp(OC)_2Fe\text{-}Si(F)(Me)O]_2$: 2.265(1) Å;[12] $Cp(OC)_2Fe\text{-}SiH_2\text{-}SiH_3$: 2.2980(9) Å,[24] $\{Cp(OC)_2Fe\text{-}Si(OMe)(Me)[2\text{-}(Me_2HNCH_2)C_6H_4]\}PF_6$: 2.305(2) Å[25]} or the Si−O distance in silanols and siloxanes {$(t$Bu$)(Me)_2SiOH$: 1.663 Å;[26] $[Cp(OC)_2Fe\text{-}Si(F)(Me)O]_2$: 1.603(1) Å[12]}.

DFT Calculations

Quantum chemical calculations[27] at a density functional level (B3LYP[28,29] with the 6−31 g(d) basis set[30−32]) were performed on parent **3**, omitting the alkyl groups at the gallium center. A *cis* (C_2 symmetry) and a *trans* (C_i symmetry) equilibrium structure are predicted. (Figure 6). Both structures relate to energy minima on the corresponding electronic hypersurface, as substantiated by corresponding vibrational analysis.

The two conformations are similar in energy, (ΔE = 3.0 kcal/mol, with ZPE correction), with the *trans* geometry being slightly more stable. The trigonal planar-coordinated oxygen atoms and the almost rectangular, planar arrangement of the four-membered gallium−oxygen ring are consistent with the experimentally obtained results. A fairly weak puckering effect is observed for the *cis* conformation ($< O-Ga-O'-Ga' = 2.4°$). Because of this small puckering, no further analysis of its energy potential was attempted. The resulting iron-silicon distances are somewhat shorter (2.28 Å) and the silicon−oxygen distances longer (1.69 Å) than those found experimentally.

The bonding situation in the heterosiloxanes is best described in terms of donor-acceptor bonds (see Figure 1). This view is also lent support by an analysis of the electron density distributions with the electron localization function (ELF). The electron density is shifted predominantly to the electronegative oxygen atoms, and no through-space interactions between the Ga atoms or the oxygen atoms could be found. A further analysis was also performed for substrates methyl-substituted at the gallium atoms. Again, the energy difference between *cis* and *trans* conformations is fairly small (ΔE = 0.4 kcal/mol, without ZPE correction).

Conclusion

This paper shows that the metallo-silanols $Cp(OC)_2Fe-SiR_2OH$ (R = Me, *i*Pr, Ph), although characterized by lower acidity than triorganosilanols, react with trialkylgallanes to yield the first transition metal fragment-substituted heterosiloxanes. The observed dimeric structures correspond with findings obtained for triorganosiloxy derivatives, which means that no sufficient influence on the

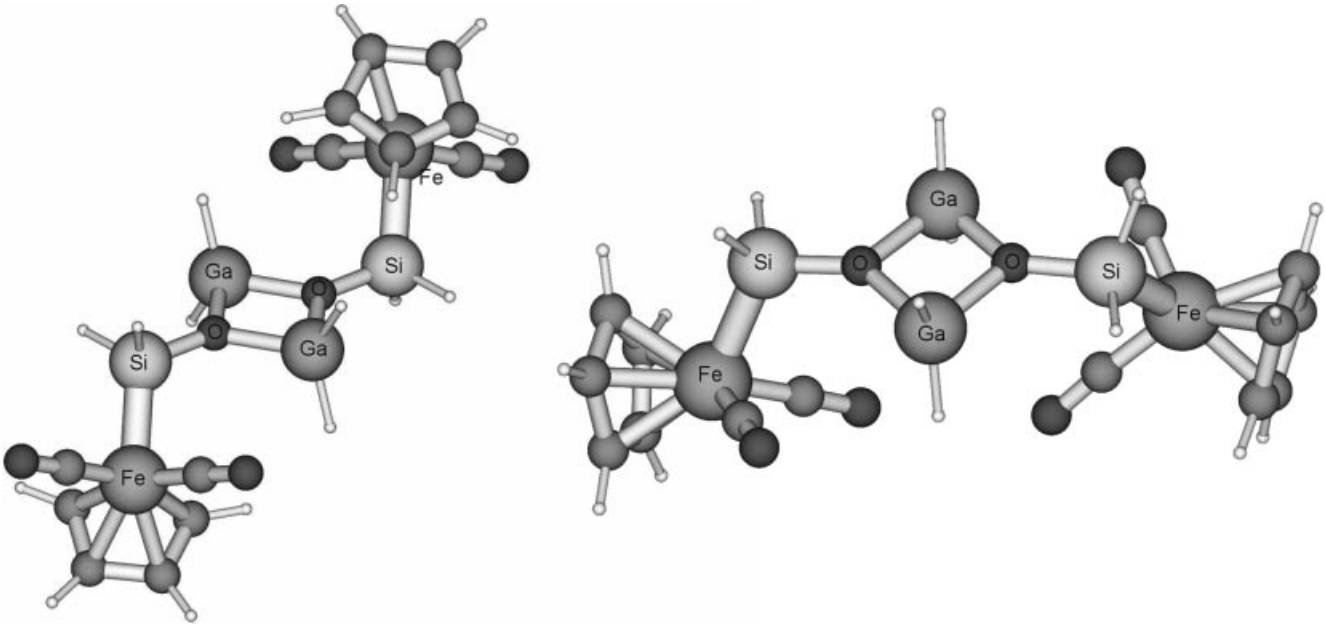

Figure 6. Plots of the equilibrium geometries of heterosiloxanes in *cis* and *trans* conformations, obtained at B3LYP/6−31 g(d) quantum chemical level of sophistication

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structure and aggregation is exerted by the presence of an $Cp(OC)_2Fe$ fragment. Because of this result, forthcoming papers will deal with siloxygallanes containing metal fragments with higher steric demand and increased electron density, such as $C_5Me_5(Me_3P)_2Fe$.

Experimental Section

General: All manipulations were performed under purified and dried nitrogen by standard Schlenk-type techniques. Solvents were rigorously dried with an appropriate drying agent, distilled, and saturated with nitrogen prior to use. IR: Perkin−Elmer 283 grating spectrometer. NMR: Jeol Lambda 300 (300.4 MHz, 75.6 MHz and 59.6 MHz, for ^1H, ^{13}C and ^{29}Si, respectively). ^1H and ^{13}C spectra are referenced to the residual proton signal or natural abundance carbon signal of [D$_6$]benzene at δ = 7.15 ppm (^1H) or δ = 128.0 ppm (^{13}C), respectively. ^{29}Si chemical shifts are referenced to external TMS. Molecular mass determinations by freezing point depression were performed in benzene solution with a Knauer 24.00 cryoscopic unit. Melting points: Du Pont-9000 thermal analysis system. Elemental analyses were performed in the laboratories of our institute. Starting materials were prepared by literature procedures: $Cp(OC)_2Fe$-$SiMe_2OH$ (**1a**),[13] $Cp(OC)_2Fe-Si(iPr)_2OH$ (**1b**),[21] $Cp(OC)_2Fe-SiPh_2OH$ (**1c**),[13] $Cp(OC)_2Fe-Si(Me)(Ph)OH$ (**1d**),[35] $GaMe_3{\cdot}OEt_2$ (**2a**)[33] and $Ga(iPr)_3$ (**2b**).[34]

1. Bis{{[dicarbonyl(η^5-cyclopentadienyl)ferrio]dimethylsiloxy}dimethylgallane} (3a): A solution of $Cp(OC)_2Fe-SiMe_2OH$ (**1a**, 235 mg, 0.93 mmol) in *n*-pentane (20 mL) was added dropwise at 0 °C to a stirred solution of $GaMe_3{\cdot}OEt_2$ (**2a**, 394 mg, 1.12 mmol) in *n*-pentane (10 mL). The reaction mixture was warmed to 25 °C over 15 min and stirred for an additional 2 h, resulting in the precipitation of **3a**. Compound **3a** was separated by filtration, washed with two portions of cold (0 °C) *n*-pentane (3 mL) and dried in vacuo. Yield 261 mg (80%), light yellow, microcrystalline powder, m.p. 101 °C (dec.). ^1H NMR ([D$_6$]benzene): δ = 4.19 (s, 5 H, C_5H_5), 0.69 [s, 6 H, $(H_3C)Si$], 0.19 ppm [s, 6 H, $(H_3C)Ga$]. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene): δ = 215.7 (s, CO), 83.9 (s, C_5H_5), 12.5 [s, $(CH_3)Si$], −1.6 ppm [s, $(CH_3)Ga$]. $^{29}Si\{^1H\}$ NMR ([D$_6$]benzene): δ = 66.57 ppm (s). IR (*n*-pentane/toluene): $\tilde{\nu}$ = 1994 (w)/1989 (vs), 1943 (vs)/1930 (s) cm^{-1} (CO). $C_{22}H_{34}Fe_2Ga_2O_6Si_2$ (701.82, found 729.89): calcd. C 37.65, H 4.88; found C 37.78, H 4.56.

2. Bis{{[dicarbonyl(η^5-cyclopentadienyl)ferrio]dimethylsiloxy}di(1-methylethyl)gallane} (3b): This compound was prepared as described for **3a**, from $Cp(OC)_2Fe-SiMe_2OH$ (**1a**, 185 mg, 0.73 mmol), dissolved in *n*-pentane (10 mL), and $Ga(iPr)_3$ (**2b**, 219 mg, 1.10 mmol), dissolved in *n*-pentane (5 mL), at −78 °C and with stirring for 16 h after warming up to room temperature, resulting in partial precipitation of **3b**. Additional **3b** was crystallized at −78 °C. Compound **3b** was separated, washed with two portions of cold (−78 °C) *n*-pentane (3 mL), and dried in vacuo. Yield 248 mg (83%), light yellow, microcrystalline powder, m.p. 79 °C (dec.). ^1H NMR ([D$_6$]benzene): δ = 4.25 (s, 5 H, C_5H_5), 1.58 [d, $^3J_{HCCH}$ = 7.6 Hz, 12 H, $(H_3C)_2CH$], 1.20 [sept, $^3J_{HCCH}$ = 7.6 Hz, 2 H, $HC(CH_3)_2$], 0.84 ppm [s, 6 H, $(H_3C)Si$]. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene): δ = 216.2 (s, CO), 84.0 (s, C_5H_5), 22.3 [s, $(CH_3)_2CH$], 21.2 [s, $CH(CH_3)_2$], 14.4 ppm [s, $(CH_3)Si$]. $^{29}Si\{^1H\}$ NMR ([D$_6$]benzene): δ = 64.10 ppm (s). IR (*n*-pentane/toluene): $\tilde{\nu}$ = 1998 (w)/1990 (vs), 1946 (vs)/1931 (s) cm^{-1} (CO). $C_{30}H_{50}Fe_2Ga_2O_6Si_2$ (814.02, found 858.79): calcd. C 44.26, H 6.19; found C 44.17, H 5.95.

3. Bis{{[dicarbonyl(η^5-cyclopentadienyl)ferrio]di(1-methylethyl)siloxy}-dimethylgallane} (3c): This compound was prepared as described for **3a**, from $Cp(OC)_2Fe-Si(iPr)_2OH$ (**1b**, 163 mg, 0.53 mmol), dissolved in *n*-pentane (10 mL), and $Me_3Ga{\cdot}Et_2O$ (**2b**, 104 mg, 0.55 mmol), dissolved in *n*-pentane (5 mL), at −78 °C, with stirring for 2 h after warming up to room temperature, resulting in partial precipitation of **3c**. Additional **3c** was crystallized at −78 °C. Compound **3c** was separated, washed with two portions of cold (−78 °C) *n*-pentane (3 mL), and dried in vacuo. Yield 186 mg (86%), light beige, microcrystalline powder, m.p. 94 °C (dec.). ^1H NMR ([D$_6$]benzene, 300.4 MHz): δ = 4.36 (s, 5 H, C_5H_5), 1.68 [sept, $^3J_{(HCCH)}$ = 7.1 Hz, 2 H, $HC(CH_3)_2$], 1.24 [d, $^3J_{(HCCH)}$ = 7.1 Hz, 6 H, $(H_3C)_2CH$], 1.24 [d, $^3J_{(HCCH)}$ = 7.1 Hz, 6 H, $(H_3C)_2CH$], 0.37 ppm (s, 6 H, H_3CGa). $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 75.45 MHz): δ = 216.7 (s, CO), 83.1 (s, C_5H_5), 24.8 [s, $CH(CH_3)_2$], 20.5 [s, $(CH_3)_2CH$], 19.6 [s, $(CH_3)_2CH$], 0.6 ppm (s, CH_3Ga). $^{29}Si\{^1H\}$ NMR ([D$_6$]benzene, 59.58 MHz): δ = 78.92 ppm (s). IR (Et_2O): $\tilde{\nu}$ = 1994 (vs), 1938 (vs) cm^{-1} (CO). $C_{30}H_{50}Fe_2Ga_2O_6Si_2$ (814.02, found 842.51): calcd. C 44.26, H 6.19; found C 43.98, H 6.01.

4. Bis{{[dicarbonyl(η^5-cyclopentadienyl)ferrio]diphenylsiloxy}-dimethylgallane} (3d): This compound was prepared as described for **3a**, from $Cp(OC)_2Fe-SiPh_2OH$ (**1c**, 180 mg, 0.48 mmol), dissolved in *n*-pentane (10 mL), and $Me_3Ga{\cdot}Et_2O$ (**2b**, 94 mg, 0.50 mmol), dissolved in *n*-pentane (5 mL), at −78 °C and with stirring for 2 h after warming up to room temperature, resulting in partial precipitation of **3d**. Additional **3d** was crystallized at −78 °C. Compound **3d** was separated, washed with two portions of cold (−78 °C) *n*-pentane (3 mL), and dried in vacuo. Yield 166 mg (73%), light beige, microcrystalline powder, m.p. 144 °C (dec.). ^1H NMR ([D$_6$]benzene, 300.4 MHz): δ = 7.80 [d, $^3J_{HCCH}$ = 6.8 Hz, 4 H, *o*-H], 7.30−7.18 (m, 6 H, *m*/*p*-H), 3.95 (s, 5 H, H_5C_5), −0.05 ppm (s, 6 H, H_3CGa). $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 75.45 MHz): δ = 215.8 (s, CO), 145.1 (s, *i*-C, C_6H_5Si), 134.9 (s, *o*-C, C_6H_5Si), 129.1 (s, *p*-C, C_6H_5Si), 127.8 (s, *m*-C, C_6H_5Si), 84.8 (s, C_5H_5), −1.4 ppm (s, CH_3Ga). $^{29}Si\{^1H\}$ NMR ([D$_6$]benzene, 59.58 MHz): δ = 54.86 ppm (s). IR (Et_2O): $\tilde{\nu}$ = 1999 (vs), 1945 (vs) cm^{-1} (CO). $C_{21}H_{21}FeGaO_3Si$ (475.05): calcd. C 53.10, H 4.46; found C 52.72, H 4.29.

5. (*RR*)-(*RS*)-Bis{{[dicarbonyl(η^5-cyclopentadienyl)ferrio](methyl)(phenyl)siloxy}-dimethylgallane} (3e): This compound was prepared as described for **3a**, from $Cp(OC)_2FeSi(Me)(Ph)OH$ (**1d**, 132 mg, 0.42 mmol), dissolved in *n*-pentane (25 mL), and $Me_3Ga{\cdot}Et_2O$ (**2b**, 85 mg, 0.45 mmol), dissolved in *n*-pentane (5 mL), at −78 °C and with stirring for 2 h after warming up to room temperature, resulting in partial precipitation of **3e**. Additional **3e** was crystallized at −78 °C. Compound **3e** was separated, washed with two portions of cold (−78 °C) *n*-pentane (3 mL) and dried in vacuo. Yield 142 mg (82%), light beige, microcrystalline powder, m.p. 92 °C (dec.). ^1H NMR ([D$_6$]benzene, 300.4 MHz): δ = 7.74−7.70 (m, 4 H, *o*-H), 7.23−7.11 (m, 6 H, *m*/*p*-H), 3.89/3.88 (s, 10 H, H_5C_5), 0.98/0.97 (s, 6 H, H_3CSi), 0.36 (s, 3 H, H_3CGa, *ul*), 0.18 (s, 6 H, H_3CIn, *lk*), 0.01 ppm (s, 3 H, H_3CIn, *ul*). $^{13}C\{^1H\}$ NMR ([D$_6$]benzene, 75.45 MHz): δ = 216.1/215.6 (s, CO), 146.8/146.6 (s, *i*-C, C_6H_5Si), 133.3/133.2 (s, *o*-C, C_6H_5Si), 128.9 (s, *p*-C, C_6H_5Si), 127.8/127.8 (s, *m*-C, C_6H_5Si), 84.3 (br. s, C_5H_5), 10.8/10.8 (s, CH_3Si), −0.7 (s, CH_3Ga, *ul*), −1.1 (s, CH_3Ga, *lk*), −1.5 ppm (CH_3Ga, *ul*). $^{29}Si\{^1H\}$ NMR ([D$_6$]benzene, 59.58 MHz): δ = 59.32/59.22 ppm (s). IR (Et_2O): $\tilde{\nu}$ = 1992 (vs), 1934 (vs) cm^{-1}. $C_{16}H_{19}FeGaO_3Si$ (412.98): calcd. C 46.53, H 4.64; found C 46.37, H 4.78.

6. X-ray Analyses of $[Cp(OC)_2Fe-SiMe_2O-GaMe_2]_2$ (3a) and $[Cp(OC)_2Fe-SiPh_2O-GaMe_2]_2$ (3d): Suitable crystals were obtained

Surface Organometallic Chemistry on Oxides: The First Well-Defined Selenium(IV) Derivative Grafted onto Silica

Hélène Provendier,[a] Catherine C. Santini,*[a] Jean-Marie Basset,[a] and Laurent Carmona[a]

Keywords: Acetaldehyde / Oxidation / Selenium / Supported catalysis / Surface chemistry

Treatment of $(EtO)_2SeO$ with Aerosil silica dehydroxylated at 500 °C results in the formation of a unique surface derivative [≡SiO–Se(O)OEt] (**1**), which has been fully characterized by elemental analysis, IR, labelling reaction and solid-state NMR spectroscopy. This is the first example of a silica-supported selenium(IV) derivative.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Glyoxal and glyoxylic acid are important pharmaceutical intermediates (1.2×10^5 t·y^{-1}).[1−2] They are generally manufactured from ethylene glycol or from acetaldehyde, by use of different oxidizing agents such as air or nitric acid, respectively.[3] In both processes there is a high amount of residue, which causes waste disposal problems. Moreover, the separation of the products becomes expensive. A possible solution is the use of a highly selective oxidizing agent. For at least 80 years, selenium dioxide and seleneous and selenic acids have been known to oxidize acetaldehyde to glyoxal and glyoxylic acid.[4−6] However, they had to be used as stoichiometric oxidants, and precipitated as metallic selenium. Nevertheless, several studies confirm that all selenium derivatives can easily be reoxidized by any oxidant, such as tBuO$_2$H,[7] H_2O_2 [8] and O_2,[9] thus allowing selenium derivatives to be used in catalytic amounts, so their use as oxidizing agents attracted more interest. Moreover, one way to facilitate the separation of the reaction products and the oxidant, and also to reduce the risks due to the toxicity of selenium, is to link the oxidizing agent to a support.[10] Nicolaou's group has recently synthesized several natural products by means of a novel cycloaddition technique in which a prenylated phenol group is immobilized on a polystyrene-based selenyl bromide derivatized resin.[11] Another approach would be to graft selenium derivatives onto inorganic supports, such as silica.

In this work we report the synthesis, characterization and reactivity of the first silica-supported selenium oxide [≡SiOSe(O)OEt] (**1**). In order to determine the coordination sphere of Se in **1**, a systematic study on the oxidation of acetaldehyde with SeO_2, H_2SeO_3 and $PhSeO_2H$ was performed first.

Results and Discussion

The aim of this study was to develop a supported oxidant capable of replacing nitric acid for performing the oxidation reaction of acetaldehyde to glyoxal. It is known that several selenium derivatives can perform this oxidation. It was also important to determine which one of them could provide the best selectivity for glyoxal under stoichiometric reaction conditions. So several selenium derivatives were tested under homogeneous conditions in order to determine the influence of the coordination sphere around the selenium atom on this oxidation reaction and to reproduce a similar coordination sphere around Se grafted onto silica.

Molecular Homogeneous Oxidation of Acetaldehyde

We first reproduced Corey's results: the oxidation of acetaldehyde to glyoxal and glyoxylic acid in the presence of SeO_2, at 90 °C for 12 h, in acetic acid.[5]

The observed level of consumption of acetaldehyde reached 90%. As the yields of glyoxal (33%), glyoxylic acid (13%) and formic and oxalic acids (< 1%) did not account for the material balance, acetic acid had presumably also been formed. To confirm this hypothesis, the reaction was performed under the same experimental conditions, but now with propionic acid as solvent. In this case, the degree of conversion of acetaldehyde was the same (90%) and the yields of glyoxal (48−50%), glyoxylic acid (10−20%), formic acid (0−3%) and acetic acid (20%) gave the correct ma-

terial balance. Whatever the solvent, metallic selenium is formed and precipitates (Figure 1).

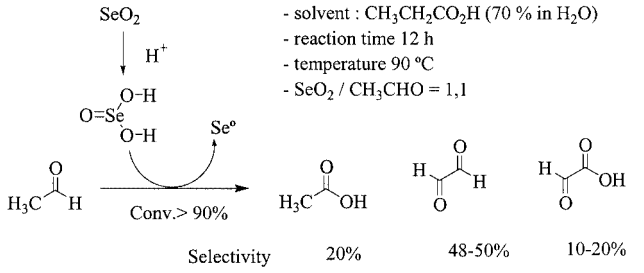

Figure 1. Distribution of oxidation products of acetaldehyde with SeO_2 in propionic acid

The degree of conversion of acetaldehyde and the selectivities for the products described are dependent on the reaction temperature, as depicted in Figure 2 (top). There is still formation of acetic acid, but whereas its selectivity decreases with temperature, its yield remains roughly constant (about 20%; Figure 2, bottom). From 25 up to 90 °C the total selectivity for glyoxal and glyoxylic acid together varies from 44 to 70%. However, the ratio of the selectivity for glyoxal to the selectivity for glyoxylic acid varies from 0.5 to 2.5, due to the fact that the yield of glyoxal increases from 8 to 45% whereas the yield of glyoxylic acid remains constant (Figure 2, bottom). As the level of conversion of acetaldehyde increases with temperature, this indicates that the limiting factor is the activation energy of the oxidation of acetaldehyde to glyoxal, and not the nature of the oxidant.

The oxidation of acetaldehyde was also performed with benzeneseleninic acid [PhSe(O)(OH)] and benzeneseleninic peracid [PhSe(O)(OOH)], generated in situ by addition of H_2O_2, both of which are known to be highly reactive oxidants.[8,12] Whatever the experimental conditions, mostly acetic acid is formed, in up to 50% yield, while less than 20% of glyoxal is obtained. No metallic selenium was observed and the reduced product PhSe−SePh was identified by ^{77}Se NMR [$\delta_{Se}(C_6D_6)$ = 460 ppm].[13]

The nature of the coordination sphere around the selenium atom seems to play a crucial role in the oxidation reaction studied. When the selenium atom is bonded to three oxygen atoms, there is increased formation of glyoxal than when it is bonded to two oxygen atoms and one carbon atom.

Surface Organometallic Chemistry

Reactions between organometallic complexes (MX_n: X = R, OR, NR_2, Cl, ...; M = transition metal or main group element) and a silica surface in most cases give organometallic fragments σ-bonded to the surface through one, two or three oxygen−metal bonds.[14−16] This kind of bonding can stabilize well-defined and highly electrophilic fragments capable of performing several kinds of catalytic reactions,[16] and in particular oxidation reactions.[17−25]

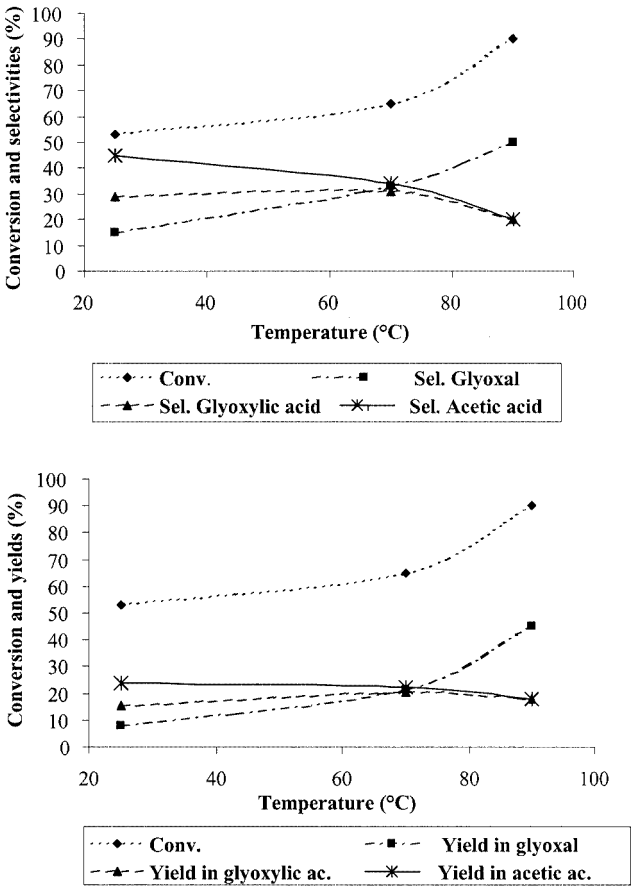

Figure 2. Variation of the conversion and selectivities (top) and conversion and yields (bottom) versus temperature in the oxidation reaction of acetaldehyde with SeO_2; reaction time 12 h

One possible route to the surface species M_1 or M_2 (Figure 3), presenting the required coordination sphere around the selenium atom for the oxidation of acetaldehyde to glyoxal, might be through reaction between Cl_2SeO or $(EtO)_2SeO$ and silica.

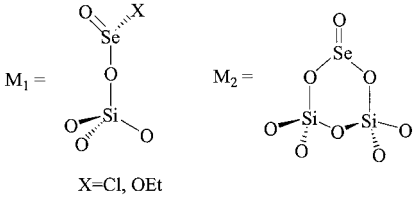

Figure 3. Target selenium species grafted on silica

Silica Surface

The support used is a Degussa flame Aerosil® silica, dehydroxylated at increasing temperatures (T [°C]), that we shall call $SiO_{2\text{-}(T)}$. The specific surface areas were 200 $m^2 \cdot g^{-1}$ for $SiO_{2\text{-}(500)}$. The silanol group content, determined by quantitative solid-state ^1H NMR and by treatment with CH_3Li, is 1.2 $OH \cdot nm^{-2}$ for $SiO_{2\text{-}(500)}$.[26−29]

Surface Chemistry of Selenium on Silica

a) Reaction between Selenium Oxychloride $Cl_2Se{=}O$ and $SiO_{2\text{-}(500)}$

The reaction between $Cl_2Se{=}O$[30−31] and $SiO_{2\text{-}(500)}$ at room temperature was monitored by Fourier-Transform infrared (FTIR) spectroscopy and by quantitative analysis of the products. During the reaction the colour of the silica changed from white to yellow/orange. At first, the infrared spectra showed the nearly complete disappearance of the free silanol groups (≡Si−OH) as judged by the decrease in the intensity of the band at 3747 cm^{-1}. At the same time, a broad band attributable to hydrogen-bonded silanol appeared at 3300 cm^{-1}. After the pellet had been kept under dynamic vacuum at 25° for 36 h, however, the intensity of the band at 3747 cm^{-1} had mostly returned, and elemental analysis indicated selenium loading lower than 1% and a chlorine/selenium molar ratio of up to 10. These results indicated that the selenium oxychloride reacts, like thionyl chloride, with an ≡Si−OH group to form an ≡Si−Cl function, with no grafting reaction being observed.[32]

b) Reaction between Diethyl Selenite $(EtO)_2SeO$ and $SiO_{2\text{-}(500)}$

The reaction between $(EtO)_2SeO$ and $SiO_{2\text{-}(500)}$ was also monitored at room temperature by Fourier-Transform infrared (FTIR) spectroscopy and by quantitative analysis of the products. During the reaction the colour of the silica changed from white to deep yellow. After the addition of $(EtO)_2SeO$ (300 Torr) to $SiO_{2\text{-}(500)}$, the pellet was again kept under dynamic vacuum at 25° for 12 h in order to eliminate volatile materials. The infrared spectra showed the nearly complete disappearance of the free silanol groups (≡Si−OH), as judged by the decrease in the intensity of the band at 3747 cm^{-1}. At the same time, besides a broad band attributable to hydrogen-bonded silanol at 3300 cm^{-1}, new bands attributable to the ethoxy ligand vibrations appeared in the ν(C−H) stretching (2982, 2938, 2903 cm^{-1}) and deformation δ(C−H) (1488, 1447, 1389 and 1364 cm^{-1}) regions (Figure 4).

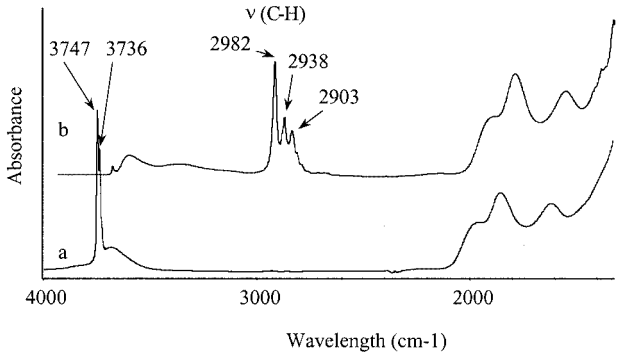

Figure 4. IR spectra of (a) partially labelled $Si^{18}O_{2\text{-}(500)}$, (b) after treatment with $(EtO)_2SeO$, (c) after 6 h under vacuum (10^{-5} Torr) at room temperature in the expanded 4000−2500-cm^{-1} region

The low-frequency region (1020−850 cm^{-1}) shows new bands at 934 (broad) and 874 (sharp) cm^{-1}. A reaction between $(EtO)_2SeO$ and partially ^{18}O-labelled surface hydroxy group (Figure 5) resulted in a shift of the 934-cm^{-1} band to 917 cm^{-1}. On this basis and by comparison with shifts of similar magnitude in the IR spectra of silica-supported ^{18}O-labelled molybdenum,[33] and titanium[34−35] species, the vibration at 934 cm^{-1} is attributed to ν(Si−OSe).

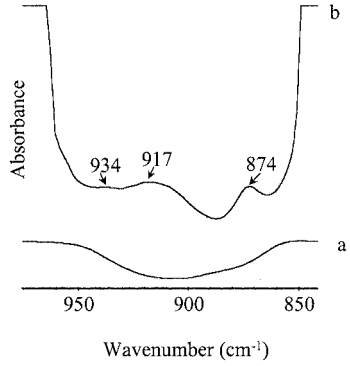

Figure 5. IR spectra of (a) partially labelled $Si^{18}O_{2\text{-}(500)}$, (b) after treatment with $(EtO)_2SeO$, (c) after 6 h under vacuum at room temperature (10^{-5} Torr) in the expanded 1000−850-cm^{-1} region

The band at 874 cm^{-1} could be attributed to the ν(Se=O) vibration.[30] From the literature,[13,36] it is known that the Se=O bond in $PhSeO_2H$ can be reduced in the presence of Ph_3P to form Ph_3PO by the following reaction.

$$PhSe(O)OH + Ph_3P \rightarrow PhSeOH + Ph_3PO$$

In order to confirm the presence of the Se=O bond in **1**, the reaction between **1** and a solution of triphenylphosphane in C_6D_6 was performed and monitored by ^{31}P NMR spectroscopy. After 2 h at 60 °C, the ^{31}P NMR spectrum presented, besides the resonance at δ = −5 ppm due to free Ph_3P, two new peaks, at δ = +24 ppm, due to Ph_3PO, and at δ = +35 ppm, attributed to Ph_3PSe (see below). The oxidation of Ph_3P to Ph_3PO was support for the continued presence of the Se=O bond in the grafted selenium species **1**.

The solid-state ^{13}C MAS NMR spectrum of **1** contained two resonances at δ = 17 and 57 ppm, attributed to the CH_3 and CH_2 of an ethoxy group, respectively.

Se elemental analysis of the solid sample indicated that for two different samples the loading in Se was 3.84 and 3.72%, corresponding to an Se/OH group ratio of ca. 1.2, and C elemental analysis (C 1.45%) gave a molar ratio of C/Se = 2.5.

In conclusion, these data are consistent with the formation of an Se-surface compound, the Se atom being linked to three different ligands: an ethoxy, an oxo and a siloxy group from the surface [≡SiOSe(O)OEt] (**1**).

Thermal Stability of 1

The excess of carbon in the elemental analysis and the presence in the infrared spectrum (Figure 4) of a broad band attributable to hydrogen-bonded silanol at 3300 cm^{-1}

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are probably due to physisorbed EtOH, which cannot be totally eliminated at room temperature even after 72 h under dynamic vacuum. On warming the sample at 60 °C or 100 °C, to eliminate the excess of ethanol, we observed a change in the colour of the pellet, which became orange (60 °C) to deep orange (100 °C) and the elemental analysis indicated a decrease in the % value of Se from 3.8 to 0.8. At the same time, small, red needles of metallic selenium appeared in the cold part of the glass equipment. Note that the formation of Ph_3PSe was observed during the reaction between **1** and PPh_3, suggesting that there was selenium leaching at 60 °C (see above).

An increase in the temperature caused changes of the species **1** towards metallic Se and traces of ≡SiOEt, characterized by solid-state ^{13}C MAS NMR (resonance at $\delta = 16$ and 60 ppm attributed to the CH_3 and CH_2, respectively, of an ethoxy group of $\equiv Si-OCH_2CH_3$).[25]

Reactivity of 1 towards Acetaldehyde

a) Surface Chemistry of Acetaldehyde on Silica

The reaction between acetaldehyde and silica $SiO_{2-(500)}$ was monitored in situ by infrared spectroscopy. It was observed that, as with $SiO_{2-(300)}$, there was formation of crotonaldehyde species by surface aldolization of adsorbed acetaldehyde.[37] In contrast, this reaction was not observed with $SiO_{2-(800)}$.[38]

$$2\ CH_3CHO \rightarrow CH_3CH{=}CHCHO + H_2O$$

b) Surface Chemistry of Acetaldehyde on 1

The reaction between acetaldehyde and silica modified with selenium derivative **1** was also monitored in situ by infrared spectroscopy (Figure 6, a and b). At first, comparison of the infrared spectra indicated that there was no more acetaldehyde (no band at 2804 and 1730 cm^{-1}), and no formation of crotonaldehyde species (no bands at 3042 and 1642 cm^{-1}) (Figure 6, b). No free silanol groups were generated, and a new, broad band at 3368 cm^{-1} could be attributed to a hydrogen-bonded OH group. The pattern due to the EtO group, at 2982, 2938 and 2903 cm^{-1}, was unchanged, suggesting that the ethoxy group was still present (Figure 6, a). The new weak band at 2881 cm^{-1} (versus 2804 cm^{-1} for free acetaldehyde) could be due to aldehydic C−H stretching for an aldehyde with an electronegative group in the α-position.[39] The vibration at 1725 cm^{-1} could be attributable to glyoxal, which shows only one carbonyl adsorption peak with no shift from the normal absorption position of monoaldehyde absorptions.[39]

At the same time, in the 950−850-cm^{-1} region, the band at 873 cm^{-1} attributed to ν(Se=O) had disappeared whereas the bands at 935 and 917 cm^{-1}, attributed to $\nu(Si-{}^{16}OSe)$ and $\nu(Si-{}^{18}OSe)$, respectively, were still present (Figure 7).

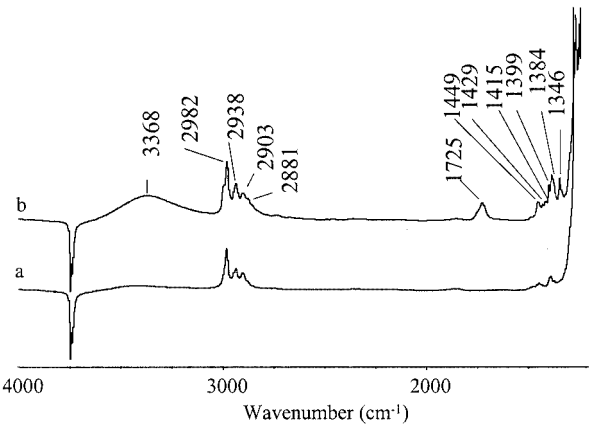

Figure 6. IR spectra of (a) difference spectrum of partially labelled $Si^{18}O_{2-(500)}$ after treatment with $(EtO)_2SeO$ and the spectrum of starting silica, (b) difference spectrum of **1** after treatment with acetaldehyde (at 25 °C and evacuation at 10^{-5} Torr) and the spectrum of starting silica in the expanded 4000−1200-cm^{-1} region

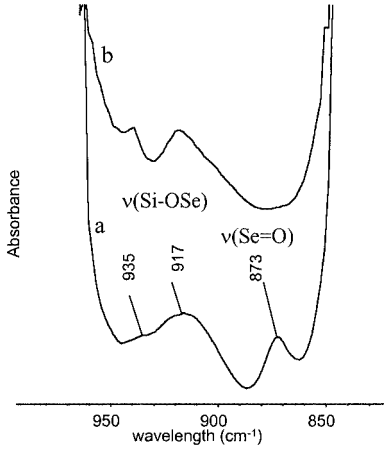

Figure 7. IR spectra of (a) difference spectrum of partially labelled $Si^{18}O_{2-(500)}$ after treatment with $(EtO)_2SeO$ and the spectrum of starting silica, (b) difference spectrum of **1** after reaction with acetaldehyde (at 25 °C and evacuation at 10^{-5} Torr) and the spectrum of starting silica in the expanded 1000−850-cm^{-1} region

All these data seemed to indicate that the stoichiometric reaction between acetaldehyde and surface species **1**, resulted firstly in the exchange of the ethoxy ligand by vinyl alcohol, with concomitant formation of ethanol, and secondly in the formation of the selenate(II) ester of the enol species **2**, stopping at this stage in the absence of protic solvent (Figure 8).

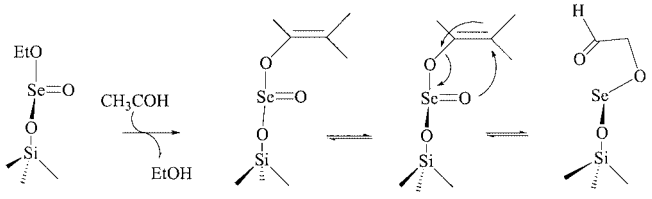

Figure 8. Proposed reaction between acetaldehyde and **1**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Conclusion

The reaction between $(EtO)_2SeO$ and silica resulted in the formation of a unique surface species (≡SiO)Se(O)OEt (**1**), which has been fully characterized. Preliminary results from the reaction between acetaldehyde and **1** seemed to indicate that there was formation of ethanol and the selenate(II) ester of the enol derivative on the surface (**2**). However, the use of **1** as an oxidative reagent is limited, due to its low thermal stability and easy leaching of selenium in the presence of protic solvent.

Experimental Section

General: All chemicals were purchased from Aldrich. Cyclohexane was distilled under argon from Na/K alloy, degassed and stored under argon in the presence of Na. C_6D_6 (SDS, 99.6%) was degassed by three "freeze-pump-thaw" cycles and dried with freshly regenerated 3-Å molecular sieves. All operations were performed in the strict absence of oxygen and water, under purified argon with use of vacuum-line techniques. Elemental analyses were performed by the Central Analysis Service of the CNRS at Solaize. Solid-state NMR spectra were recorded with a Bruker DSX-300 machine equipped with a standard 4-mm double-bearing probe head and operating at 75.47 and 300.18 MHz for ^{13}C and ^{1}H, respectively. Chemical shifts are given with respect to TMS, with adamantane as an external reference (δ = 37.7 ppm for the highest chemical shift). Solution NMR spectra were recorded with Bruker AC 300 MHz (^{1}H, ^{13}C) and DRX 500 MHz (^{77}Se) spectrometers. Chemical shifts are reported in ppm and referenced to residual solvent resonances (C_6D_6: δ = 7.15 ppm for ^{1}H; δ = 128 ppm for ^{13}C), or external standards (^{77}Se, Me_2Se).[40] Infrared spectra were recorded under vacuum with a Nicolet 550 FT spectrometer in an infrared cell equipped with ZnSe windows. The conversion and selectivities were determined by HPLC. Two columns were necessary. For the detection of acetaldehyde, glyoxal and glyoxylic acid (as oxime derivatives),[41] an Interchim N7 column (symmetry C18, 5 μm; l = 25 cm, d = 4.6 mm; eluent: acetonitrile/water/sulfuric acid, 35:65:0.1 (v/v); flow rate: 1 mL/min; detection: UV 235 nm) thermostatted at 42 °C was used. *o*-Toluic acid was used as an internal reference. For the quantification of other acids (acetic, formic and oxalic ...) a Waters Phenomex column was used (l = 30 cm, d = 3/8″; eluent: 0.05 N sulfuric acid; flow rate: 0.5 mL/min; detection: UV 210 nm). Mass spectrometry was performed with an MAT 95 XL Thermoquest- Finnigan instrument (chemical ionization, NH_3). The mass was calculated by use of ^{80}Se (49.8%). The silica support (Aerosil® Degussa, 200 $m^2 \cdot g^{-1}$) was compacted into a disk (30 mg) for infrared studies or was hydrated, dried (80 °C) and crushed to prepare large quantities (1−2 g) for NMR studies and elemental analysis. Before the reaction, the silica was calcinated at 400 °C in air for 4 h to remove hydrocarbon impurities and dehydroxylated at the desired temperature (500 °C) under high vacuum (10^{-5} Torr) for 12 h (referred to as $SiO_{2\text{-}(500)}$). $Si^{18}O_2$ was prepared by calcination in air at 500 °C for 4 h, followed by partial dehydroxylation at 500 °C for 10 h. ^{18}O-enrichment of the surface hydroxy groups was achieved by exposing the silica to $H_2^{18}O$ vapour at room temperature for 12 h, followed by dehydroxylation under dynamic vacuum at 500 °C for 10 h.

General Procedure for the Oxidation of Acetaldehyde with SeO_2 or H_2SeO_3: A mixture of SeO_2 (39 mmol) and CH_3CHO (35 mmol) in propionic acid (70% in water, 10 mL) was stirred under argon at 90 °C for 12 h in a Schlenk tube fitted with a condenser. After filtration of metallic selenium, which had precipitated during the reaction, the reaction mixture was analysed by HPLC.

General Procedure for the Oxidation of Acetaldehyde with $PhSeO_2H$ or $PhSeO_2H$ + H_2O_2 (1:1, mol/mol): A mixture of $PhSeO_2H$ (39 mmol) and CH_3CHO (35 mmol) in propionic acid (70% in water, 10 mL) was stirred under argon at 90 °C for 12 h in a Schlenk tube fitted with a condenser [with $PhSeO_2H$ in the presence of H_2O_2 (1:1, mol/mol) the reaction time was 20 min]. A white precipitate was filtered off and identified as PhSe−SePh by ^{77}Se NMR [δ_{Se} (C_6D_6) = 460 ppm].[13] No metallic selenium was observed. The reaction mixture was then analysed by HPLC.

Synthesis of Diethoxy Selenite $(EtO)_2SeO$:[30−31] A mixture of SeO_2 (3.4 g, 31 mmol) and EtOH (20 mL, 348 mmol) in cyclohexane (35 mL) was stirred at reflux under argon for 16 h, in a Schlenk tube fitted with a Dean−Stark condenser. After filtration of metallic selenium and evaporation of the solvent, $(EtO)_2SeO$ was distilled (76 °C/15 mbar) as a pale yellow liquid (4.2 g, 74%). $C_4H_{10}O_3Se$ (185.1): calcd. C 25.8, H 5.4, Se 43.0; found C 24.6, H 5.4, Se 42.6. IR (vapour): $\tilde{\nu}$ = 874 ν(Se=O), 659 ν(Se−O) cm^{-1}. ^{1}H NMR (C_6D_6): δ = 3.85 (CH_2, ABX_3 system), 1.1 (CH_3, t, J^2_{HH} = 7 Hz) ppm. ^{13}C NMR (C_6D_6): δ = 57.4 (OCH_2), 16.8 (CH_3) ppm. ^{77}Se NMR (C_6D_6): δ = 1339.8 ppm. MS (CI): m/z (%) = 187 (50) [M + H (^{80}Se)]$^+$.

Reaction between Diethyl Selenite $(EtO)_2SeO$ and $SiO_{2\text{-}(500)}$: For in situ infrared experiments, silica (30 mg) was pressed into an 18-mm self-supporting disk, placed in a sealed glass high-vacuum reactor fitted with ZnSe windows, and partially dehydroxylated under vacuum (500 °C, 12 h). $(EtO)_2SeO$ (300 Torr) was then introduced at room temperature onto the silica disk, which was maintained at liquid nitrogen temperature. The infrared cell was isolated. The silica disk was warmed to room temperature and kept at this temperature for 1 h. The pellet turned from white to yellow/orange. The cell was attached to a high vacuum line and the excess of $(EtO)_2SeO$ was removed by reverse distillation in a liquid nitrogen cooled tube. The pellet was then kept under dynamic vacuum (10^{-5} Torr, 12 h at 25 °C) in order to eliminate volatile materials. For NMR and elemental analysis samples, the same procedure as above was used with 2 g of $SiO_{2\text{-}(500)}$ in a Schlenk tube attached to a high vacuum line. Elemental analysis: Se (3.84%) and C (1.45%). Solid-state ^{13}C MAS NMR: δ = 17 and 57 ppm.

Acknowledgments

We thank the CLARIANT Company for financial support (H. P.), Dr. M. Alarcon for fruitful discussion, Mr. J.-F. Viard for his help in the HPLC analyses, and Dr. B. Fenet (NMR services, ESCPE Lyon).

Bridged Aminotroponiminate Complexes of Zinc

Michael T. Gamer[a] and Peter W. Roesky*[a]

Keywords: Aminotroponiminate / Coordination chemistry / N ligands / Zinc

Reactions of the *n*-propyl-bridged diaminotroponimine $H_2\{(i\text{Pr})\text{TP}\}$ with dialkylzinc compounds in toluene lead, depending on the stoichiometric ratio, either to dimetallic singly bridged products of composition $[(RZn)_2\{(i\text{Pr})\text{TP}\}]$ [R = Me (**1**), Et (**2**)] or to dimetallic doubly bridged helical products of composition $[Zn\{(i\text{Pr})\text{TP}\}]_2$ (**3**). Compound **3**, which was characterised by single-crystal diffraction methods, is the first bridged aminotroponiminate complex in which a helical structure is observed.

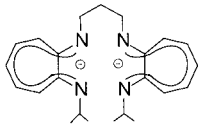
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Aminotroponiminates ($\{ATI\}^-$) are bidentate, monoanionic ligands containing a 10π-electron backbone. Like 1,4-diazabutadiene, $\{ATI\}^-$ forms five-membered metallacycles upon coordination to a metal atom. In contrast to 1,4-diazabutadiene, however, $\{ATI\}^-$ is believed to be much more resistant to electrophiles and nucleophiles. The ligand system was introduced into the coordination chemistry in the 1960s mostly by researchers at DuPont. Between 1961 and 1970 a large number of Mn^{II}, Fe^{II}, Co^{II}, and Ni^{II} complexes were prepared in order to study the magnetic moments and NMR contact shifts; only one Mn complex was characterised by single-crystal X-ray methods. This early work was reviewed by Holm in 1971.[1]

Recent reports from us and other research groups have described the preparation and characterisation of aminotroponiminates as cyclopentadienyl alternatives for main group and transition elements.[2] We have shown that bis(aminotroponiminate)yttrium amides are active as catalysts for hydroamination/cyclisation catalysis.[3] Recently we started to prepare singly bridged aminotroponiminates.[4] It was shown that the trimethylene-bridged ligand 1,3-bis[2-(isopropylamino)troponiminate]propane ($\{(i\text{Pr})\text{TP}\}^{2-}$) (**A**) ([$H_2\{(i\text{Pr})\text{TP}\}$ = trimethylenedinitrilobis[2-(isopropylamino)cyclohepta-2,4,6-triene]) is able to coordinate in a chelating or a metal-bridging mode to various metals of group 13 and the lanthanides.[4,5,6] Up to now $\{(i\text{Pr})\text{TP}\}^{2-}$ has only been treated with trivalent metals. In most cases a chelating coordination mode was observed with these metal centres. A metal−metal bridging mode has only been observed in those cases in which a chelating coordination mode is prevented due to steric reasons, for example $[(R_2Al)_2\{(i\text{Pr})\text{TP}\}]$ (R = Me, Et, *i*Bu).[6] We are interested in extending our research to the divalent metal zinc. To the best of our knowledge no zinc complexes of singly bridged aminotroponiminates are known. In contrast, two zinc complexes with non-bridged aminotroponiminate, which were structurally not characterised, have been reported by Holm[7] and Lippard;[8] some tropocoronand complexes are also known.[9]

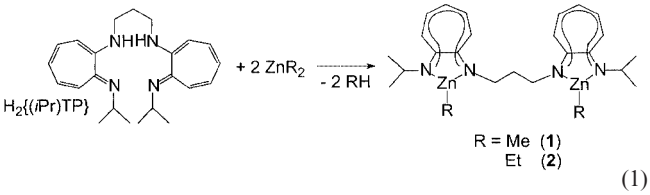
Herein we report on the reaction of $H_2\{(i\text{Pr})\text{TP}\}$ with dialkylzinc compounds which lead exclusively to metal-bridging products. Depending on the stoichiometry either singly or doubly bridged helical products were obtained.



A

Results and Discussion

The dimetallic zinc complexes $[(RZn)_2\{(i\text{Pr})\text{TP}\}]$ [R = Me (**1**), Et (**2**)] were synthesised by reaction of the neutral ligand $H_2\{(i\text{Pr})\text{TP}\}$[4] with the corresponding dialkylzinc compounds R_2Zn in *n*-pentane [Equation (1)]. Upon cooling, **1**−**2** were obtained as yellow crystalline solids with a fairly high sensitivity towards air and moisture.



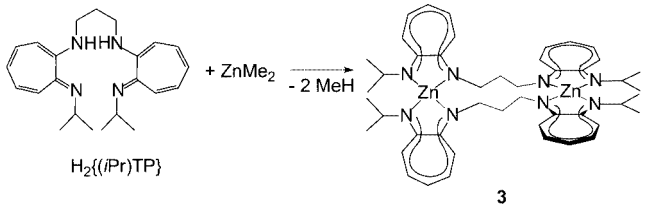
(1)

The reactivity of $ZnMe_2$ towards $H_2\{(i\text{Pr})\text{TP}\}$ is much higher than that of $ZnEt_2$. Compound **2** was synthesised by addition of $H_2\{(i\text{Pr})\text{TP}\}$ to a solution of $ZnEt_2$ in toluene

[a] Institut für Chemie, Freie Universität Berlin, Fabeckstraße 34−36, 14195 Berlin, Germany

at room temperature. In contrast, compound **1** was only obtained in high yields when performing the reaction at −50 °C. At room temperature the same reaction sequence leads to a mixture of **1** and higher substituted products such as $[Zn\{(i\text{Pr})TP\}]_2$ (**3**) (see below). The new complexes were characterised by standard analytical/spectroscopic techniques. The ^1H and ^{13}C NMR spectra also point to a symmetrical coordination of the $\{(i\text{Pr})TP\}^{2-}$ anion in solution. The signals of the isopropyl C*H* proton of **1** and **2** are well-resolved into a septuplet and show only a slight downfield shift [δ = 3.74 (**1**), 3.74 (**2**) ppm] compared to that of the free ligand $H_2\{(i\text{Pr})TP\}$ (δ = 3.55 ppm).[4] This is in agreement with comparable alkyllanthanide compounds of composition $[\{(i\text{Pr})TP\}LnR]$ [Ln = La, Lu; R = $CH(SiMe_3)_2$, CH_2SiMe_3] in which the isopropyl C*H* signal is also shifted downfield {δ = 3.67 ppm $[\{(i\text{Pr})TP\}_2LaCH(SiMe_3)_2]$,[4] δ = 3.93 ppm $[\{(i\text{Pr})TP\}_2LuCH_2SiMe_3]$}.[10] In contrast, the signals of the isopropyl C*H* in the comparable aluminium complexes $[(R_2Al)_2\{(i\text{Pr})TP\}]$ (R = Me, Et, *i*Bu) are shifted to higher field (δ = 3.50−3.54 ppm). For **1** and **2** sharp signals for the Zn−Me and Zn−Et groups, respectively, are observed in the ^1H NMR spectra (δ = −0.07 (**1**); 0.74, 1.58 (**2**) ppm] and in the $^{13}C\{^1H\}$ NMR spectra [δ = −10.8 (**1**); 3.0, 13.8 (**2**) ppm]. The signals of the $Zn-CH_3$ and $Zn-CH_2$ groups, respectively, are in general shifted to higher field than those of the starting material $ZnMe_2$ (^1H: δ = 0.51 ppm; $^{13}C\{^1H\}$: δ = −4.2 ppm)[11] and $ZnEt_2$ (^1H: δ = 0.08, 1.05 ppm;[12] $^{13}C\{^1H\}$: δ = 6.82, 10.35 ppm).[13]

The formation of **1** and **2** is in contrast to our previous observation of the coordination behaviour of the $\{(i\text{Pr})TP\}^{2-}$ anion. In group-3, group-13 and lanthanide chemistry the ligand always adopts a chelating coordination mode, if this is possible, for steric reasons. Since non-bridged diaminotroponiminate complexes of zinc are known,[7] we initially expected a chelating coordination of the ligand. To study the reactivity of the $\{(i\text{Pr})TP\}^{2-}$ ligand, $H_2\{(i\text{Pr})TP\}$ was treated in a 1:1 stoichiometric ratio with $ZnMe_2$ in toluene [Equation (2)]. After recrystallisation, the dimetallic zinc complex $[Zn\{(i\text{Pr})TP\}]_2$ (**3**) was obtained as yellow crystals. The new complex was characterised by standard spectroscopic techniques, and the solid-state structure was established by single-crystal X-ray diffraction.



(2)

Compound **3** crystallises in the monoclinic space group *C*2/*c* having four molecules in the unit cell (Figure 1). The dimetallic complex adopts a helical structure with a crystallographic inversion centre. Both of these helical enantiomers are observed in the unit cell. The zinc atoms have a distorted tetrahedral coordination sphere. The N−Zn−N angles inside the aminotroponiminate moiety are 81.3(2) and 81.0(2)°. The other N−Zn−N angles range from 119.3(2) to 134.5(2)°. The Zn−N bond lengths are in the expected range of 198.3(5)−199.9(5) pm. In comparable tropocoronand complexes the Zn−N distances vary from 197.2(5) to 209.6(4) pm.[9b]

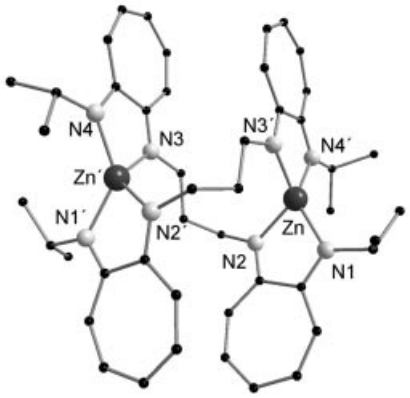


Figure 1. Perspective view of the molecular structure of **3**; selected distances [pm] and angles [°]: Zn−N1 198.5(5), Zn−N2 198.7(5), Zn−N3′ 199.9(5), Zn−N4′ 198.3(5); N1−Zn−N2 81.3(2), N1−Zn−N3′ 125.2(2), N1−Zn−N4′ 134.5(2), N2−Zn−N3′ 119.3(2), N2−Zn−N4′ 120.6(2), N3′−Zn−N4′ 81.0(2)

The ^1H and $^{13}C\{^1H\}$ NMR spectra of **3** show a diastereotopic splitting of the isopropyl CH_3 signals. Based on these observations we suggest that the helical structure observed in the solid state may be retained in solution. A similar diastereotopic splitting has been observed by other chiral (isopropylamino)troponiminate complexes such as $[\{(i\text{Pr})_2ATI\}_3Ln]$ (Ln = Y, La) [$\{(i\text{Pr})_2ATI\}$ = *N*-isopropyl-2-(isopropylamino)troponiminate]. The signal of the isopropyl C*H* proton of **3** is well resolved into a septuplet but shows a slight downfield shift (δ = 3.76 ppm) compared to that of the free ligand $H_2\{(i\text{Pr})TP\}$ (δ = 3.55 ppm).[4] This is in agreement with **1** and **2**. Compound **3** is the first bridged aminotroponiminate complex in which a helical structure is observed.

Conclusions

Reactions of $H_2\{(i\text{Pr})TP\}$ with dialkylzinc compounds in toluene led, in a 1:2 stoichiometric ratio, to the dimetallic singly bridged products of composition $[(RZn)_2\{(i\text{Pr})TP\}]$ [R = Me (**1**), Et (**2**)]. The reactivity of $ZnMe_2$ towards $H_2\{(i\text{Pr})TP\}$ is much higher than that of $ZnEt_2$. When $H_2\{(i\text{Pr})TP\}$ was treated in a 1:1 stoichiometric ratio with $ZnMe_2$ in toluene the dimetallic doubly bridged helical zinc complex $[Zn\{(i\text{Pr})TP\}]_2$ (**3**) was obtained. Due to the helical structure of **3** the ^1H and $^{13}C\{^1H\}$ NMR spectra of this compound show a diastereotopic splitting of the isopropyl CH_3 signals confirming that the helical structure observed in the solid state is retained in solution.

Experimental Section

General: All manipulations of air-sensitive materials were performed with the rigorous exclusion of oxygen and moisture in flame-dried Schlenk-type glassware either on a dual manifold Schlenk line, interfaced to a high vacuum (10^{-4} Torr) line, or in an argon-filled M. Braun glove box. Ether solvents (tetrahydrofuran and diethyl ether) were predried with Na wire and distilled under nitrogen from Na/K alloy benzophenone ketyl prior to use. Hydrocarbon solvents (toluene and *n*-pentane) were distilled under nitrogen from $LiAlH_4$. All solvents for vacuum-line manipulations were stored in vacuo over $LiAlH_4$ in resealable flasks. Deuterated solvents were obtained from Aldrich Inc. (all 99 atom% D) and were degassed, dried, and stored in vacuo over Na/K alloy in resealable flasks. NMR spectra were recorded with a Jeol 400 MHz FT NMR spectrometer or with a Bruker AC 250. Chemical shifts are referenced to internal solvent resonances and are reported relative to tetramethylsilane. Elemental analyses were carried out with an Elementar vario EL. $ZnMe_2$ and $ZnEt_2$ were purchased from Aldrich Inc. H_2{(*i*Pr)TP} was prepared according to a literature procedure.[4]

[(MeZn)$_2${(*i*Pr)TP}] (1): A 2 M $ZnMe_2$ solution in toluene (5 mL, 10 mmol) was diluted with 25 mL of toluene. At −70 °C a solution of H_2{(*i*Pr)TP} (1.82 g, 5 mmol) in toluene (30 mL) was added. The reaction mixture was warmed up to −50 °C, followed by gas evolution. After the gas evolution had stopped (about 3 h), the mixture was warmed up to room temperature, filtered, and the solvent was removed. The resulting yellow solid was washed twice with *n*-pentane (5 mL) and dried in vacuo. Yield 2.17 g (83%). $C_{25}H_{36}N_4Zn_2$ (523.34): calcd. C 57.38, H 6.93, N 10.71; found C 56.94, H 6.80, N 10.32. ^{1}H NMR (C_6D_6, 400 MHz, 25 °C): δ = −0.07 (s, 6 H, ZnCH_3), 1.13 [d, 12 H, CH(CH_3)$_2$, $^3J_{H,H}$ = 6.2 Hz), 2.26 (quint, 2 H, $CH_2CH_2CH_2$, $^3J_{H,H}$ = 7.0 Hz), 3.33 (t, 4 H, NCH_2, $^3J_{H,H}$ = 7.0 Hz), 3.74 [sept, 2 H, CH(CH$_3$)$_2$, $^3J_{H,H}$ = 6.2 Hz], 6.36 (t, 2 H, H_{ring}, $^3J_{H,H}$ = 9.2 Hz), 6.52 (d, 2 H, H_{ring}, $^3J_{H,H}$ = 11.2 Hz), 6.52 (d, 2 H, H_{ring}, $^3J_{H,H}$ = 11.4 Hz), 6.92−7.01 (m, 4 H, H_{ring}) ppm. ^{13}C{^{1}H} NMR (C_6D_6, 100.40 MHz, 25 °C): δ = −10.8, 24.5, 33.5, 48.3, 48.7, 111.9, 112.0, 117.9, 134.6, 134.7, 160.2, 161.4 ppm.

[(EtZn)$_2${(*i*Pr)TP}] (2): A 1 M $ZnEt_2$ solution (4 mL, 4 mmol) in toluene was diluted with 25 mL of toluene. At ambient temperature a solution of H_2{(*i*Pr)TP} (0.73 g, 2 mmol) in toluene (30 mL) was added, immediately followed by gas evolution. The mixture was stirred for 6 h at room temperature, filtered, and the solvent was removed. The remaining yellow solid was washed twice with *n*-pentane (5 mL) and dried in vacuo. Yield 0.99 g (89%). $C_{27}H_{40}N_4Zn_2$ (551.37): calcd. C 58.81, H 7.31, N 10.16; found C 58.57, H 7.35, N 9.88. ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): δ = 0.74 (q, 4 H, ZnCH_2CH$_3$, $^3J_{H,H}$ = 8.1 Hz), 1.15 [d, 12 H, CH(CH_3)$_2$, $^3J_{H,H}$ = 6.2 Hz], 1.58 (t, 6 H, ZnCH$_2$CH_3, $^3J_{H,H}$ = 8.1 Hz), 2.21 (quint, 2 H, $CH_2CH_2CH_2$, $^3J_{H,H}$ = 7.0 Hz), 3.38 (t, 4 H, NCH_2, $^3J_{H,H}$ = 7.0 Hz), 3.75 [sept, 2 H, CH(CH$_3$)$_2$, $^3J_{H,H}$ = 6.2 Hz], 6.36 (t, 2 H, H_{ring}, $^3J_{H,H}$ = 9.1 Hz), 6.55 (d, 2 H, H_{ring}, $^3J_{H,H}$ = 11.1 Hz), 6.59 (d, 2 H, H_{ring}, $^3J_{H,H}$ = 11.2 Hz), 6.91−7.05 (m, 4 H, H_{ring}) ppm. ^{13}C{^{1}H} NMR (C_6D_6, 62.9 MHz, 25 °C): δ = 3.0, 13.8, 25.3, 34.0, 48.8, 49.3, 112.7, 112.8, 118.7, 135.3, 135.5, 161.0, 162.1 ppm.

[Zn{(*i*Pr)TP}]$_2$ (3): At ambient temperature, 1 mL of a 2 M solution of $ZnMe_2$ in toluene (2 mmol) was added to a solution of H_2{(*i*Pr)TP} (0.79 g, 2 mmol) in 25 mL of toluene. The mixture was stirred for 3 h at room temperature. After the gas evolution had stopped, the solution was heated briefly under reflux. The mixture was then filtered, and the solvent was removed. The remaining yellow solid was washed twice with *n*-pentane (5 mL) and dried in vacuo. Single crystals were obtained from toluene at −40 °C. Yield 1.45 g (85%). $C_{40}H_{60}N_8Zn_2$ (855.80): calcd. C 64.56, H 7.07, N 13.09; found C 64.33, H 6.98, N 12.77. ^{1}H NMR (C_6D_6, 400 MHz, 25 °C): δ = 1.05 [d, 12 H, CH(CH_3)$_2$, $^3J_{H,H}$ = 6.2 Hz], 1.06 [d, 12 H, CH(CH_3)$_2$, $^3J_{H,H}$ = 6.2 Hz], 1.98 (quint, 4 H, $CH_2CH_2CH_2$, $^3J_{H,H}$ = 7.4 Hz), 3.24−3.31 (m, 4 H, NCH_2), 3.37−3.45 (m, 4 H, NCH_2), 3.76 [sept, 4 H, CH(CH$_3$)$_2$, $^3J_{H,H}$ = 6.2 Hz], 6.19 (t, 4 H, H_{ring}, $^3J_{H,H}$ = 9.1 Hz), 6.35 (d, 4 H, H_{ring}, $^3J_{H,H}$ = 11.5 Hz), 6.40 (d, 4 H, H_{ring}, $^3J_{H,H}$ = 11.7 Hz), 6.81−6.88 (m, 8 H, H_{ring}) ppm. ^{13}C{^{1}H} NMR (C_6D_6, 100.40 MHz, 25 °C): δ = 23.7, 24.0, 32.1, 47.4, 48.4, 111.3, 111.8, 115.8, 134.5, 134.7, 160.0, 161.3 ppm.

X-ray Crystallographic Studies of 3: Crystals of $C_{23}H_{30}N_4Zn$ were grown from a toluene solution. A suitable crystal was covered with mineral oil (Aldrich) and mounted on a glass fibre. The crystal was transferred directly to the −70 °C cold stream of an STOE IPDS diffractometer (Ag-K_α radiation). Subsequent computations were carried out with an Intel PIII PC. Data collection and refinement: SHELXS-97,[14] SHELXL-97;[15] monoclinic, space group *C*2/*c* (no. 15); lattice constants *a* = 1279.76(7), *b* = 1542.66(8), *c* = 2170.34(13) pm, β = 97.635(7)°, *V* = 4246.8(4) 10^6 pm^3, *Z* = 8; μ(Ag-K_α) = 0.623 mm^{-1}; $2\theta_{max.}$ = 38.00°; 3475 (R_{int} = 0.1560) independent reflections measured, 2660 of which were considered observed with $I > 2\sigma(I)$; max. residual electron density 1.718 and −0.721 e/A^{-3}; 262 parameters (all non-hydrogen atoms were calculated anisotropic; the positions of the H atoms were calculated for idealised positions) *R*1 = 0.0881; *wR*2 = 0.2182. CCDC-194178 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Structures and Thermodynamics of the Sulfuranes SF_3CN and $SF_2(CN)_2$ as well as of the Persulfurane $SF_4(CN)_2$ − An ab initio MO Study by the G3(MP2) Method[‡]

Yana Steudel[a] and Ralf Steudel*[a]

Keywords: Sulfuranes / Sulfur / Cyanides / Fluorides / Transition states / Reaction mechanisms

At the G3(MP2) level of theory the *trans* isomer **1a** of the hypothetical molecule $SF_4(CN)_2$ is more stable than the *cis* isomer **1b** by 8 kJ·mol^{-1}. The isomerization of **1a** to **1b** requires an activation enthalpy of 319 kJ·mol^{-1} at 298 K. The decomposition of *trans*-$SF_4(CN)_2$ to $SF_2(CN)_2$ and F_2 is endothermic (ΔH^o_{298} = 395 kJ·mol^{-1}) but the elimination of FCN from *trans*-$SF_4(CN)_2$ is exothermic by −7 kJ·mol^{-1}. The elimination of $(CN)_2$ from *cis*-$SF_4(CN)_2$ is exothermic by −137 kJ·mol^{-1}. The activation enthalpies for the latter two reactions were calculated as 251 and 311 kJ·mol^{-1}, respectively. Thus, $SF_4(CN)_2$ should be a thermally stable compound. In the sulfuranes SF_3CN and $SF_2(CN)_2$ the CN ligands prefer the equatorial positions; mutual exchange of an axial F atom by an equatorial CN group requires a reaction enthalpy of 51 kJ·mol^{-1} [SF_3CN] or 58 kJ·mol^{-1} [$SF_2(CN)_2$].

Introduction

The sulfur fluorides SF_4 and SF_6 are both important industrial products[1] and highly interesting molecules from a theoretical point of view. As so-called hypervalent or − better − hypercoordinate species they have attracted much attention.[2] In addition, numerous mixed derivatives of the types SF_3X and SF_5X have been prepared.[3] Fluorination of either dirhodane $(SCN)_2$ or SF_3CN by elemental fluorine produces SF_5CN, see Equations (1) and (2).[4−6]

$$(SCN)_2 + 5\,F_2 \rightarrow 2\,SF_5CN \quad (1)$$

$$SF_3CN + F_2 \rightarrow SF_5CN \quad (2)$$

Evidently, SF_3CN will be an intermediate in Equation (1). According to a combined electron diffraction and microwave spectroscopic investigation the molecule SF_5CN has C_{4v} symmetry in the gas phase.[5] While gaseous SF_5CN is stable up to 350 °C in a flow reactor at low pressures,[4] the related compound $SF_4(CN)_2$ has never been prepared. The same holds for the other members of the series $SF_{6-x}(CN)_x$ with $x > 2$.

To investigate the thermodynamic and the thermal stability of $SF_4(CN)_2$ we have studied for the first time the hypothetical decomposition reactions, presented in Equations (3) to (7) of this molecule using ab initio MO methods.

$$SF_4(CN)_2 \rightarrow SF_2(CN)_2 + F_2 \quad (3)$$

$$SF_4(CN)_2 \rightarrow SF_3CN + FCN \quad (4)$$

$$SF_4(CN)_2 \rightarrow SF_4 + (CN)_2 \quad (5)$$

All the expected decomposition products are experimentally known compounds. SF_3CN and $SF_2(CN)_2$ are accessible by metathesis reactions of SF_4 with Me_3SiCN at low temperatures [Equations (6) and (7)].[7]

$$SF_4 + Me_3SiCN \rightarrow SF_3CN + Me_3SiF \quad (6)$$

$$SF_3CN + Me_3SiCN \rightarrow SF_2(CN)_2 + Me_3SiF \quad (7)$$

An earlier report[8] on the synthesis of $SF_2(CN)_2$ according to Equations (6) and (7) was said to be partly in error.[7] SF_3CN is a colorless liquid which is stable at room temperature for a few days but slowly decomposes according to Equation (8).[7]

$$2\,SF_3CN \rightarrow SF_4 + SF_2(CN)_2 \quad (8)$$

The structure of SF_3CN has been determined by electron diffraction in the gas phase as well as by ab initio MO calculations at the MP2/6-31G* level of theory.[9] The molecule is of C_1 symmetry; its structure can be derived from

[‡] Sulfur Compounds, 227. Part 226: R. Steudel, *Chem. Rev.* **2002**, *102*, 3905.

the structure of SF_4 by replacement of an equatorial fluorine atom by a cyano ligand. $SF_2(CN)_2$ is a colorless solid which rapidly decomposes at room temperature.[7] No structural analysis or theoretical treatment of this molecule has been published yet.

Calculations

Standard ab initio MO calculations were performed by using the Gaussian 98 series of programs.[10] The energies of various equilibrium structures and transition states were examined at the G3(MP2) level of theory.[11] In brief, the G3(MP2) method is a composite procedure which provides an accurate approximation to a high level of theory at QCISD(T)/GTMP2LARGE//MP2(full)/6-31G(d), with the incorporation of zero-point energy [calculated from HF/6-31G(d) vibrational wavenumbers, scaled by 0.8929] and higher level corrections. For small molecules this level of theory is usually within 6 kJ·mol^{-1} of accurate experimental values.[11] In the case of the hypervalent SF_6 molecule the related G2(MP2) method — using the same geometry calculation as in G3(MP2) — reproduced the very accurate experimental enthalpy of formation within 7.5 kJ·mol^{-1}.[12] A charge density analysis, at the MP2(full)/6-31G(d) level, was performed using the natural bond orbital (NBO) approach.[13] NBO atomic charges of small molecules have recently been demonstrated to agree well with experimental values obtained from X-ray diffraction data.[14] Unless otherwise noted, all relative energies reported in this publication are given as $\Delta H°_{298}$ and correspond to the G3(MP2) level, while structural parameters were obtained at the MP2(full)/6-31G(d) level.

The transition states obtained were characterized by one imaginary vibrational wavenumber (**TS1**: 693i; **TS2**: 264i; **TS3**: 694i; **TS4**: 890i) whereas the wavenumbers of the structures of minimal energy were all real. The intrinsic reaction coordinates were calculated at the HF/6-31G* level.[15]

Results and Discussion

Geometrical Structures

To check the accuracy of the G3(MP2) method for the treatment of hypervalent compounds the enthalpies of F_2, SF_4 and SF_6 were calculated and the reaction enthalpy for the formation of SF_6 from F_2 + SF_4 was obtained as

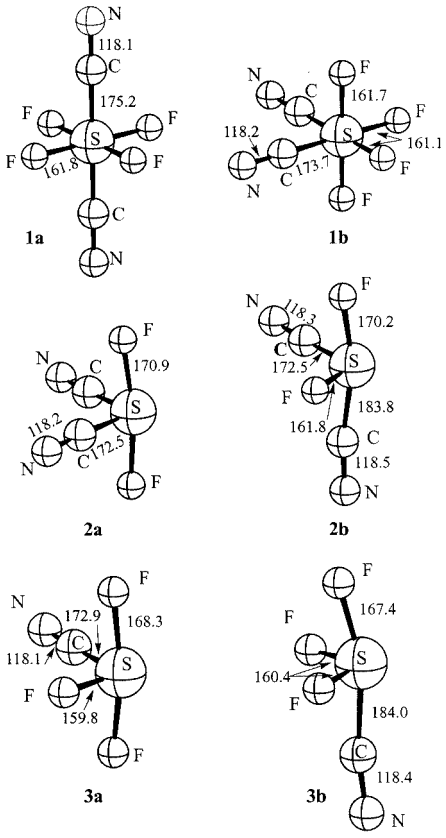

Figure 1. Molecular structures and bond lengths [pm] of two isomers each of the persulfurane $SF_4(CN)_2$ (**1a**, **1b**), the sulfurane $SF_2(CN)_2$ (**2a**, **2b**) and of the sulfurane $SF_3(CN)$ (**3a**, **3b**), calculated at the MP2(full)/6-31G(d) level of theory

−439.1 kJ·mol^{-1} at 0 K. From the best available experimental enthalpies of formation of these compounds[12] the reaction enthalpy is calculated as −450 ± 20 kJ·mol^{-1} at 0 K. This agreement is quite satisfactory.

The sulfuranes $SF_2(CN)_2$ and SF_3CN as well as the persulfurane $SF_4(CN)_2$ given in Equations (3) to (5) exist as several isomers depending on the axial/equatorial or *cis*/*trans* position of the cyano ligands. The molecular structures and internuclear distances of these six isomers are shown in Figure 1; additional geometrical parameters are listed in Table 1.

In the case of the two octahedral molecules $SF_4(CN)_2$ the isomer with the *trans* position of the two CN ligands (**1a**) is slightly more stable than the *cis* isomer **1b**, by 8 kJ·mol^{-1}. The NBO atomic charges [a.u.] on the fluorine atoms are −0.49 ± 0.01 in these isomers while the carbon atoms bear

a small positive charge of 0.07 in **1a** and 0.03 in **1b**. Therefore, the nonbonding F···F interactions must be strongly repulsive while the nonbonding F···C interactions will be weak as far as Coulomb forces are concerned. The sulfur atoms are highly positively charged (+2.31 in both cases) and the nitrogen atoms are slightly negative (−0.22).

Isomer **1a** is of D_{4h} symmetry and **1b** is of C_{2v} symmetry. All bond angles in **1a** are exactly 90 or 180°, i.e. the SCN groups are strictly linear; in **1b** the SCN bond angle is 179.6°. The space requirement of the cyano ligands seems to be slightly larger than that of the fluorine atoms since the C−S−C angle in **1b** is 92.3° while the F−S−F angle in the same plane is only 87.5°. All other bond angles of this molecule are within 0.5° of either 90 or 180°.

The calculated bond lengths of *trans*-$SF_4(CN)_2$ are in fair agreement with the experimental data reported for the related molecule SF_5CN,[5] although ab initio MO calculations at the MP2(full)/6-31G(d) level slightly overestimate the internuclear distances. In addition, the bonds become progressively shorter as the fluorine content of the molecule increases. Thus, the S−F distances in SF_5CN are 155.8 and 156.6 pm compared to 161.8 pm in **1a**. Similarly, the C−N and S−C distances of 115.4 pm and 176.5 pm, respectively, in SF_5CN support our results for the corresponding bonds of **1a** which are 118.1 and 175.2 pm, respectively.

The sulfurane molecules of the type $SF_{4-x}(CN)_x$ can be derived from a trigonal bipyramid in which one corner is empty (or occupied by a lone pair of electrons). In this type of molecule the axial and equatorial positions are not equivalent. Since the electronegativity of the CN group is lower than that of the fluorine atoms the preferred position for the CN ligands in the two sulfuranes $SF_2(CN)_2$ and SF_3CN should be the equatorial plane, as observed in the case of other sulfuranes.[16] In fact, the symmetrical isomer of $SF_2(CN)_2$ (**2a**) with both CN ligands in the equatorial plane is by 58 kJ·mol^{-1} more stable than the less symmetrical form with one CN ligand equatorial and the other in an axial position (**2b**). When we tried to optimize a structure with both CN groups in axial positions (**2c**), the molecule rearranged to isomer **2a**. In the case of SF_3CN the CN ligand is in an equatorial position in the most stable isomer **3a**; the isomer **3b** with an axial CN ligand is by 51 kJ·mol^{-1} less stable than **3a**.

The geometrical parameters calculated for **3a** may be compared with the electron diffraction data of this molecule.[9] The bond lengths [pm] are as follows (calcd./exp. data): S−$F_{eq.}$ 159.8/155.2(4), S−F_{ax} 168.3/165.7(3), S−C 172.9/173.6(8), C−N 118.1/115.9(4). Given the systematic difference between the calculated r_e and the experimental r_a bond lengths the agreement is satisfactory. The NBO atomic charges of **3a** are as follows: $F_{eq.}$ −0.46, F_{ax} −0.59, S +1.85, C +0.01, N −0.21.

In all sulfurane isomers of the type SF_3CN and $SF_2(CN)_2$ the angles between the two axial S−X bonds are smaller than 180° and these axial bonds are bent away from the formally empty corner of the trigonal bipyramid, i.e. away from the position of the anticipated lone pair at the sulfur atom. The deviation from linearity is 10 ± 1° in the case of **2a** and **3a** but 18 ± 1° in the case of the less stable isomers **2b** and **3b** (see Table 1). This structural feature is well known from SF_4.[2]

The SCN groups are practically linear in the octahedral species **1a** and **1b** (179.8 ± 0.2°) but slightly bent in the various isomers of SF_3CN and $SF_2(CN)_2$: the equatorial SCN groups show bond angles of α = 176.1 ± 0.2° while the axial SCN groups are more strongly bent (α = 170.1 ± 0.1°).

Transition States and Thermodynamics

The reaction according to Equation (3) is strongly endothermic and therefore can be ruled out for any spontaneous decomposition of $SF_4(CN)_2$ at moderate temperatures. Using the most stable isomers of the reactants, the enthalpy change of reaction shown in Equation (3) is +395 kJ·mol^{-1} at 298 K. Under the same conditions reactions shown in Equations (4) and (5) are exothermic by −137 and −7 kJ·mol^{-1}, respectively. The Gibbs energies ($\Delta G°_{298}$) of the reactions according to Equations (3) to (5) are +341, −187 and −41 kJ·mol^{-1}, respectively, reflecting the increase in entropy during dissociation. From these data it follows that only the reverse reaction according to Equation (3) is a potential route for the synthesis of $SF_4(CN)_2$ at low temperatures.

The transition states for the decomposition reactions according to Equations (4) and (5) have been located on the potential energy hypersurface and their structures are shown in Figure 2. Starting from the most stable isomer **1a** only FCN can be eliminated directly. The corresponding transition state (**TS1**) is shown in Figure 2. The activation

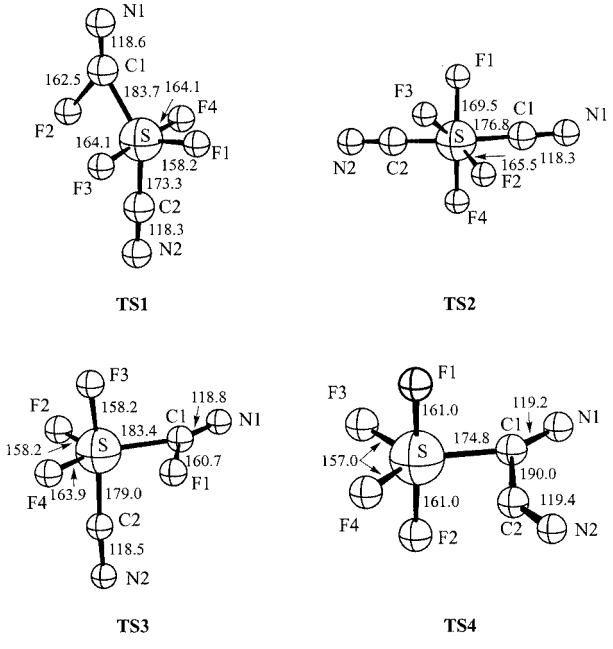

Figure 2. Molecular structures and bond lengths [pm] of the transition states for the elimination of FCN from *trans*-$SF_4(CN)_2$ **1a** (**TS1**), for the *cis* ⇄ *trans* isomerization between **1a** and **1b** (**TS2**), for the elimination of FCN from **1b** (**TS3**) and for the elimination of $(CN)_2$ from **1b**, calculated at the MP2(full)/6-31G(d) level of theory

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

barriers are $\Delta H^{\neq}_{298} = 251\ kJ{\cdot}mol^{-1}$ and $\Delta G^{\neq}_{298} = 251\ kJ{\cdot}mol^{-1}$.

In the case of Equation (5) an intramolecular isomerization has to take place first to generate **1b** in which the two CN ligands are neighboring. Structure **1b** may then decompose with elimination of either FCN or $(CN)_2$. The transition state for the isomerization of **1a** to **1b** (**TS2**) is also shown in Figure 2. The activation enthalpy for this reaction is $319\ kJ{\cdot}mol^{-1}$ ($\Delta G^{\neq}_{298} = 317\ kJ{\cdot}mol^{-1}$). The subsequent decomposition of **1b** to SF_3CN + FCN requires an activation enthalpy of $271\ kJ{\cdot}mol^{-1}$ ($\Delta G^{\neq}_{298} = 271\ kJ{\cdot}mol^{-1}$) while the elimination of $(CN)_2$ from **1b** can be initiated by an activation enthalpy of $311\ kJ{\cdot}mol^{-1}$ ($\Delta G^{\neq}_{298} = 309\ kJ{\cdot}mol^{-1}$). The overall activation barriers starting from the most stable isomer **1a** are consequently $\Delta G^{\neq}_{298} = 317 + 271 = 588\ kJ{\cdot}mol^{-1}$ for the reaction according to Equation (4) and $\Delta G^{\neq}_{298} = 317 + 309 = 626\ kJ{\cdot}mol^{-1}$ for the reaction according to Equation (5). Evidently, these energies are unrealistically high since, for instance, the homolytic dissociation of SF_6 into SF_5 and an F atom requires a reaction enthalpy of only $453\ kJ{\cdot}mol^{-1}$.[17] Therefore, one would expect that *trans*-$SF_4(CN)_2$ (**1a**) also breaks down into two radicals rather than isomerizing intramolecularly with subsequent elimination of either FCN or $(CN)_2$ if a Gibbs activation energy of more than $600\ kJ{\cdot}mol^{-1}$ energy is provided.

The structures of the transition states for the elimination reactions according to Equations (4) and (5) (**TS3** and **TS4**) are shown in Figure 2. Their geometries (C_1 symmetry) are most interesting. In **TS3** a bent FCN unit is connected to the sulfur atom by both a weak S−F bond of length 208.3 pm and a C−S bond of length 183.4 pm; all four atoms are located essentially in one plane with an F−C−N angle of 139.4° (torsion angle N7−C−F2−S: −174°). The other two S−F bonds in that same plane have decreased in length from 161.4 ± 0.3 pm in **1b** to 158.2 and 159.9 pm, respectively, in **TS3**, while the fourth S−F bond has increased in length to 163.9 pm. The structure of **TS4** is characterized by a weak C−C bond of length 190.0 pm, much longer than calculated for isolated $(CN)_2$ (138.1 pm). The two CN units are exactly co-planar. The C−S−C angle is 81.6° but the two C−S bonds are very different with distances of 174.8 and 238.6 pm. In contrast, the two C−N bonds are almost identical with 119.2 and 119.4 pm, slightly longer than in **1b** (118.2 pm) and in $(CN)_2$ (118.5 pm). In other words, it is only *one* CN group which is moving away from the sulfur atom on transformation of **1b** into **TS4**. The other CN group is just bending; its S−C−N angle decreases from 179.6° in **1b** to 145.3° in **TS4**. The SF_4 unit of **TS4** is already very close in geometry to the isolated SF_4 molecule. Despite the low symmetry the S−F bond lengths of **TS4** are pairwise identical and the $F_{ax}-S-F_{ax}$ angle is 174.4°.

We did not succeed in localizing a transition state for the elimination of F_2 from either **1a** or **1b**. This strongly endothermic reaction may proceed without any additional activation energy.

Summarizing, it follows from the above thermodynamic data that the isomerization **1a**→**1b** is highly unfavorable and $SF_4(CN)_2$ is expected to decompose, if at all, with elimination of FCN from the ground state structure **1a**. However, the height of the barriers indicates that $SF_4(CN)_2$ molecules will be quite stable as far as unimolecular dissociation reactions are concerned.

Acknowledgments

We are grateful to Priv.-Doz. Dr. Dieter Lentz for suggesting this investigation to us. This work was supported by the Deutsche Forschungsgemeinschaft, the Verband der Chemischen Industrie and the Konrad-Zuse-Zentrum für Informationstechnik Berlin.

Calculated Enthalpies for Dimerisation of Binary, Unsaturated, Main-Group Element Hydrides as a Means to Analyse Their Potential for Multiple Bonding

Hans-Jörg Himmel[a]

Dedicated to Professor Hansgeorg Schnöckel

Keywords: Main-group element hydrides / Dimerization / Enthalpy / Multiple bonding / Calculations

Herein, the dimerisation of subvalent, binary, main-group element hydrides with the potential for multiple bonding is studied using both hybrid DFT (B3LYP) and ab initio [MP2 and CCSD(T)] methods. The [2+2] cycloaddition is an important and characteristic reaction of derivatives of ethylene. A comparison of dimerisation reactions for several compounds with the potential for multiple bonding should, therefore, shed light on the properties of these species. Our study includes the hydrides E_2H_2 (E = B, Al, Ga, N P or As), E_2H_4 (E = C, Si or Ge) and ENH_4 (E = B, Al or Ga) and their dimers. Several isomeric forms of the monomers and dimers have to be considered. The trends within a group and a period are established and the factors responsible for them are discussed. It turns out that, generally, the enthalpies for dimerisation increase for heavier homologues, reflecting that the most important factor is the reduced strength of the E–E bonds in the monomers prior to dimerisation and, to some degree, also the reduced ring strain in the cyclic dimers. The exceptions are the dimerisations of B_2H_2 and Al_2H_2, both of which lead to the tetrahedral E_4H_4 species (E = B or Al). Dimerisation of Al_2H_2 is associated with a smaller enthalpy than that for the dimerisation of B_2H_2. Comparisons and analyses are made complicated because of the changes in the structures of the isomeric global minima between homologues.

Introduction

There is an ongoing interest in the characterization of binary compounds of the heavier main-group elements with the potential for multiple bonding.[1−9] As early as 1976, for example, a first stable dialkylgermylene, $Dis_2GeGeDis_2$ [Dis = bis(trimethylsilyl)methyl] was synthesized and later characterized by X-ray diffraction to exhibit a nonplanar geometry with a Ge−Ge bond length of 2.347 Å and an angle sum of 348° at each of the Ge atoms.[10] At the same time, the first corresponding tin compound, $[Sn\{CH(SiMe_3)_2\}_2]_2$, was structurally characterized.[11] It took 26 more years, however, until the first compounds of Ge and Sn formally isoelectronic to an alkyne were discovered, both exhibiting bent *trans*-type structures with Ge−Ge and Sn−Sn bond lengths of 2.2850(5) and 2.6675(4) Å, respectively.[12,13] Only in the last two decades has more information about these species came to light, with the most-celebrated successes lying almost exclusively in the field of binary group-14 and group-15 element compounds and group-13/15 compounds with a direct bond between a group-13 and a group-15 element.[14]

B/N compounds with a direct bond between a boron and a nitrogen atom have been well known for a long time, and the isoelectronic and isolobal connections between alkenes and aminoboranes R_2NBR_2 (“inorganic ethylene”), cyclobutanes and dimeric aminoboranes $[(R_2NBR_2)_2]$, cyclobutenes and diazadiboretidines $[(RNBR)_2]$, and benzene and borazine $(RNBR)_3$ are well established.[15] Monomeric compounds, however, with tricoordinated Al or Ga atoms and the general formula $R_2AlNR'_2$ and $R_2GaNR'_2$ are stable under normal conditions only in the presence of bulky substituents at Al, Ga and/or N.[16−18] Otherwise, they are stable only as oligomers of the general formula $[R_2MNR'_2]_n$, with *n* being often 2 or 3. Recently, the monomers H_2AlNH_2, H_2GaNH_2 and H_2InNH_2 were generated and characterized in a matrix of solid Ar at 12 K.[19]

Despite considerable effort, binary group-13 element compounds with the potential for multiple bonding, RGaGaR (R being a sterically demanding organic group), have been synthesized and characterized only very recently. Species that are formally valence-isoelectronic with acetylene were discovered with the synthesis of compounds of the formula $Na_2[ArGaGaAr]$ (e.g., Ar = $Mes^*{}_2C_6H_3$ or 2,4,6-$i Pr_3C_6H_2$).[20] An adequate description of the Ga−Ga bond in related compounds is at present hotly debated.[21−24] Very recently, a neutral compound ArGaGaAr (Ar = 2,6-$Dipp_2C_6H_3$, Dipp = 2,6-$i Pr_2C_6H_3$) has been synthesized as

[a] Institut für Anorganische Chemie der Universität Karlsruhe, Engesserstr., Geb. 30.45, 76128 Karlsruhe, Germany

the first derivative of a compound that is formally valence-isoelectronic with ethylene.[25] Additionally, the hydride HGaGaH was generated in an Ar matrix at 12 K as one of the products of the reaction between Ga_2 and H_2, and it was characterized experimentally by its IR spectrum. The antisymmetric ν(Ga−H) stretching vibration of this species occurs at a wavenumber not far away from that of GaH (also isolated in a matrix of solid Ar).[26] This result indicates that the interaction between the Ga atoms in HGaGaH cannot be very strong. Finally, a molecule of the general formula ArInInAr (Ar again being 2,6-$Dipp_2C_6H_3$, Dipp = 2,6-*i*$Pr_2C_6H_3$) was characterized in the solid state.[27] The In−In interaction [bond length of 2.9786(5) Å] is weak, however, and therefore this compound cannot feature a strong In−In bond.

This work follows two others dealing with the differences in the chemistry of binary, main-group element compounds with the potential for multiple bonding. In the first of these two previous accounts, we have reported the trends of theoretically determined heats of hydrogenation for several binary, main-group element hydrides.[28] Heats of hydrogenation have been used extensively in the past to determine the degree of unsaturation of hydrocarbons and their derivatives. Our survey also included a comparison between the heats of hydrogenation of the model compounds Na_2[HGaGaH], $[HGaGaH]^{2-}$ and HGaGaH. The results indicate that the Na^+ ions in Na_2[HGaGaH] are deeply engaged in the bonding. Therefore, we and others[29] have suggested to describe this species and its derivatives as "Na_2Ga_2" cluster compounds. In the second report, we analyzed the energies for fragmentation.[30] To this end, dissociation was separated into two processes: the first one consists of fragmentation into fragments that still exhibit the same geometry as they had previously before fragmentation; in the second process, the fragments relax into their electronic ground state and their global energy-minimum structure. The separation in the two processes allows for a much more accurate determination of the bond energies, which can, at least principally, also be verified experimentally. Herein, we evaluate the standard enthalpies for dimerisation of several binary main-group element hydrides that are formally valence-isoelectronic to ethylene. Cycloaddition is a very well known and thoroughly investigated process for ethylene and its derivatives. Dimerisation reactions of some other corresponding binary main-group element compounds have been looked at earlier. To name just two of many examples, very recently the [2+2] cycloaddition reactions of a stiba(III)alkene and an arsa(III)imine were investigated experimentally,[31] and the [2+2] cycloaddition enthalpies for 1,3-disilacyclobutanes were determined by quantum chemical calculations.[32] In this paper, the calculated trends down the group and within a period will be discussed for the compounds under consideration. It should be noted that in this work we intend to accumulate information about the *chemistry* of subvalent, binary, main-group element hydrides. It is especially our aim to analyse theoretical aspects of the chemistry that can, at least in principle, be verified experimentally, although some species are too reactive to be investigated in experiments that rely on presently known techniques. A close inspection of the molecular orbitals or the electron density distribution is not the topic of this work.

Calculational Details

Calculations relied on the GAUSSIAN 98 programme package.[33] The B3LYP hybrid-DFT method, in combination with a 6-311+G(2df,p) basis set, was first used to pre-optimize the structures and to calculate their vibrational modes. In the second step, the structures were again fully optimized applying the MP2 method and a 6-311+G(2df,p) basis set. The calculated MP2 energies were corrected by their zero-point energies and thermally by their vibrational, rotational and translational energies at 298.2 K (all corrections were taken from the B3LYP calculations) to first give reaction energies at 298 K; then, *RT* (2.5 kJ·mol^{-1}) was subtracted, where necessary, to obtain the standard enthalpies for the reactions in the gas phase. Subsequently, the MP2 calculations were repeated, but this time using the TZVPP basis set and employing the TURBOMOLE programme package.[34] The reaction enthalpy values are quoted for all reactions and were derived from the calculations on the B3LYP and MP2 level of theory in combination with the 6-311+G(2df,p) and on the MP2 level of theory in combination with the TZVPP basis set. Tables 1−4 include the calculated dimensions of all the compounds addressed in this work and also first estimates of the enthalpies for dimerisation on the basis of the B3LYP and MP2 methods. Finally, the optimized geometries were used in "single-point" Coupled-Cluster Single Double Triple [CCSD(T)] calculations [again using the 6-311+G(2df,p) basis set and on the basis of the geometry optimized with B3LYP] to calculate the dimerisation energies once again, and (with the help of the zero-point energy and thermal corrections calculated with B3LYP) the dimerisation enthalpies. Table 5 contains all dimerisation energies and enthalpies calculated with the CCSD(T) method.

Results and Discussion

In the course of this discussion, we show that any attempt to connect the different reactivities of the species addressed in this work with the E−E bond character within the reactant is complicated, mainly because of the changes of the structures of the global energy minima between homologues. It is, therefore, crucial for this work to start with a detailed analysis of the global energy-minimum structures for all homologues. Most of these structures have been discussed in earlier works, but they generally have concentrated on only one compound and did not discuss the *differences* in the structures.

In some cases (e.g., for E_2H_2, where E = Al or Ga), the global minimum structures feature no significant E−E interaction [E_2H_2 exhibits a D_{2h}-symmetric ring structure E(μ-H)$_2$E in its lowest-energy isomer].[35,36] In these cases,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

we have considered both the global minimum structure and the isomer that has the best chance for a significant E−E interaction (e.g. the bent *trans* isomer HEEH in the case of E_2H_2).

Structures of the Monomers and Dimers

Group 13 (E = B, Al and Ga)

All E_4H_4 species exhibit a global energy-minimum structure with a tetrahedral E_4 unit. A ring structure defines a local minimum on the potential energy surface only in the case of calculations using the B3LYP method. Ab initio (MP2) methods failed to find a minimum for a cyclic structure. This cyclic structure found using the B3LYP method has an energy 190.5, 138.4 and 98.1 kJ·mol^{-1} (for E = B, Al and Ga, respectively) higher than the one of the tetrahedral global energy-minimum structure. The standard enthalpy differences between both isomers amount to 179.7, 136.9 and 98.7 kJ·mol^{-1}, respectively. For E = B and Al, the E−E distances are smaller for the tetrahedral isomer (1.6750 and 2.5902 Å vs. 1.6695 and 2.6387 Å for E = B and Al, respectively). In the case of Ga_4H_4, the ring structure has a slightly smaller Ga−Ga distance (2.5506 vs. 2.5615 Å). The E−H distances undergo only minuscule alterations (see Table 1). In the light of the calculations carried out using the MP2 method, however, it appears doubtful whether the ring-type structures really do define local minima on the potential energy surface.

For B_4H_4, T_d- and square-planar D_{4h}-symmetric structures have been reported previously.[37] The T_d-symmetric structure was found to be 349 kJ·mol^{-1} lower in energy than the D_{4h}-symmetric one. The B−B and B−H bond lengths for the T_d-symmetric form were calculated to be 1.7098 and 1.1875 Å, respectively. Thus, the B−B distance is very close to the one found experimentally in the known compound B_4Cl_4, which also exhibits a T_d-symmetric structure (1.71 Å).[38] The distances are in satisfying agreement with the results of our calculations (B−B and B−H bond lengths of 1.6695 and 1.1861 Å).

The derivatives $[Al(\eta^5\text{-}C_5Me_5)]_4$,[39] $[Al(SitBu_3)]_4$ [40] and $[AlSi(SiMe_3)_3]_4$,[41] have been synthesized and investigated structurally. They all consist of tetrahedral Al_4 units, in which the Al−Al distances are 2.77, 2.60 and 2.61 Å, respectively. These values are in good agreement with the Al−Al distance of 2.5902/2.6076 Å calculated herein for Al_4H_4. Previous calculations have led to Al−Al and Al−H distances of 2.617 and 1.589 Å.[42] A cyclic Al_4 unit can be stabilized in the presence of donors like NEt_3, resulting in a molecule $[Al_4Br_4(NEt_3)_4]$ in which the Al−Al separation is 2.64 Å.[43] The structures, as calculated for the tetrahedral Ga_4H_4 isomers, are in agreement with earlier accounts (see Figure 1). For example, the Ga−Ga bond

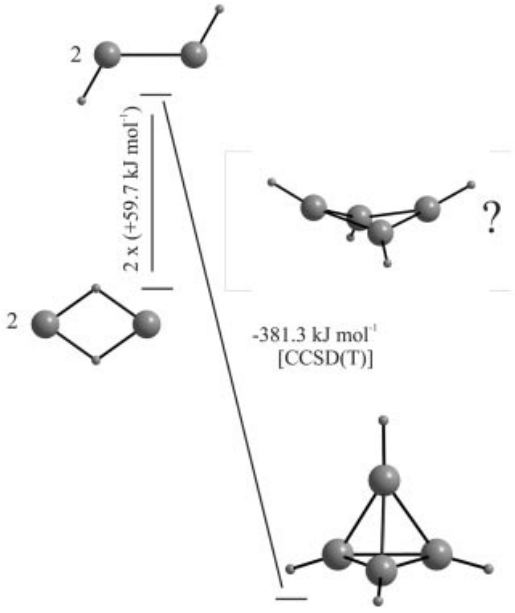

Figure 1. Geometries of cyclic Al(μ-H)$_2$Al, bent *trans*-HAlAlH and the dimerisation product Al_4H_4 with T_d symmetry and enthalpy for dimerisation (the cyclic structure that, according to B3LYP calculations, possibly defines a local energy minimum, is also visualized)

length in Ga_4H_4 was calculated previously to be 2.567 Å.[44] An example of a structurally characterized derivative is provided by the species [Ga{C(SiMe$_3$)$_3$}]$_4$,[45] for which Ga−Ga bond lengths of 2.680−2.702 Å were derived experimentally.

As to the monomers, B_2H_2 has a linear global energy-minimum structure with a triplet electronic ground state ($^3\Sigma_g^-$).[46] The B−B and B−H distances were calculated to be 1.516 and 1.177 Å, respectively. These values are in good agreement with the ones calculated herein (1.5051/1.5085 and 1.1714/1.1743 Å, respectively). Al_2H_2 and Ga_2H_2 both prefer a ring structure with two bridging H atoms, Al(μ-H)$_2$Al and Ga(μ-H)$_2$Ga.[35,36,47,48] According to the calculations presented herein, the bent *trans* structures, HAlAlH and HGaGaH (see Figure 1), have energies 59.7 and 57.0 kJ·mol^{-1} higher than the cyclic global energy-minimum form (the differences in standard enthalpy amount to 59.6 and 58.9 kJ·mol^{-1}, respectively). Previous calculations for bent *trans*-HAlAlH have yielded Al−Al and H−Al bond lengths of 2.782−2.602 Å (with more accurate methods tending to predict smaller values) and 1.608−1.602 Å, with the H−Al−Al bond angle being 119.3−120.0°.[49] These values compare with Al−Al and Al−H distances and H−Al−Al bond angles of 2.6693, 1.6213 Å and 119.4°, respectively, calculated herein. In the case of bent *trans*-HGaGaH, previous DFT calculations have resulted in Ga−Ga and Ga−H bond lengths of 2.5848 and 1.6261 Å and an H−Ga−Ga bond angle of 121.3°,[35] which are in good agreement with the values obtained herein (2.6090/2.5944 and 1.6291/1.6226 Å and 120.7/121.7°, respectively). As already mentioned, a derivative, ArGaGaAr (Ar = 2,6-Dipp$_2$C$_6$H$_3$, Dipp = 2,6-*i*Pr$_2$C$_6$H$_3$), was very recently synthesized and characterized by X-ray diffraction.[25] The Ga−Ga bond length of 2.6268(7) and the C−Ga−Ga bond angle of 123.16(7)° were obtained for this compound in the solid phase.

Group 14 (E = C, Si and Ge)

Cyclic structures define the global energy minima for all E_4H_8 species. The E−E and E−H distances were calculated to be 1.5509/1.5448 and 1.0920/1.0910 Å, 2.3724/2.3602 and 1.4865/1.4837 Å, and 2.4688/2.4653 and 1.5422/1.5427 Å for E = C, Si and Ge, respectively (see Table 2). The E−E−E angles are 88.5/87.8, 88.1/86.2 and 88.3/88.1° for E = C, Si and Ge, respectively. The values are in good agreement with the ones reported earlier. Thus, for cyclobutane, the C−C and C−H bond lengths have been determined to be 1.543 and 1.094 Å and the C−C−C and H−C−H bond angles have been determined to be 87.9 and 108.8°.[64] In the case of Si_4H_8, previous calculations have predicted a D_{2d}-symmetric global energy-minimum struc-

ture with a folded Si_4 ring, which is characterized by Si−Si and Si−H bond lengths of 2.368 and 1.470/1.472 Å and a H−Si−H bond angle of 109.4°.[50] The barrier leading to a D_{4h}-symmetric form with a planar Si_4 ring, however, apparently amounts to less than 10 kJ·mol^{-1},[51] which shows the high flexibility of the Si_4 ring. The derivatives with the general formula $[R_2Si]_4$, for which the structures in the solid crystalline phase were determined from experimental X-ray data, confirm this high flexibility. For example, folded Si_4 rings were found to be present, for R = *t*BuCH_2 or *i*Pr, in which the Si−Si bond lengths are 2.359−2.409 Å.[52] In the case where R = CH_3 or Me_3Si, however, the experimental data show that a planar Si_4 ring is formed (Si−Si bond length of 2.375 Å for R = CH_3).[53−55] It has been claimed that the Si−Si bond in Si_4H_8 is significantly weaker than the C−C bonds in corresponding alkanes, and the smaller contributions of the s valence orbitals to the formation of hybrid orbitals is one of the factors that have been proposed to be responsible for this trend.[56]

At 1.3244/1.3313 Å, the calculated C−C distance in H_2CCH_2 is close to the experimentally derived value of 1.339 Å. Previous calculations for H_2SiSiH_2 predict an Si−Si bond length of 2.116 or 2.217 Å (for calculations relying on the SCF or MCSCF method, respectively). Tetramesityldisilene is one derivative that had been already characterized experimentally by its X-ray diffraction pattern in 1983, yielding a value of 2.160 Å for the Si−Si bond length.[57] These experimental and calculated values are close to the one calculated herein (2.1624/2.1552 Å). For H_2GeGeH_2, previous calculations resulted in Ge−Ge and Ge−H bond lengths of 2.275−2.341 and 1.550 Å and an H−Ge−Ge bond angle of 109.0°.[58] As already mentioned, some stable dialkylgermylenes have been known for a long time to experimentalists[10] [including $(CH_3)_2GeGe(CH_3)_2$, which was investigated in Ar and N_2 matrices at 5 K by vibrational (IR and Raman) spectroscopy],[59] and in the ones that have been studied by X-ray diffraction, a typical Ge−Ge bond length of about 2.34 Å has been found, in satisfying agreement with the length predicted on the basis of quantum chemical calculations.[59,60] The values calculated herein (2.2945/2.2756 and 1.5440/1.5374 Å for the Ge−Ge and Ge−H bond lengths and 108.0/111.0° for the H−Ge−Ge bond angle) are in reasonable agreement with these numbers.

Group 15 (E = N, P and As)

In the gas phase, N_4H_4 prefers an open chain-like structure with two hydrogen atoms at both ends of the N_4 chain.[61,62] Crystals of this compound can be prepared, but they decompose at temperatures above −20 °C, with its isomer NH_4N_3 (exhibiting a high lattice energy) being among the detectable products.[63] According to our calculations, the N−N distances are 1.3770 Å for the separations of the terminal N atoms to their neighbouring ones and 1.2361 Å for the distance between the two inner N atoms of the chain. The cyclic structure defines a local minimum on the potential energy surface that exhibits an energy 242.4 kJ·mol^{-1} higher [222.3 kJ·mol^{-1} according to CCSD(T)] than the open chain-like isomer. Thus, the stand-

ard enthalpy for conversion of the open chain-like isomer into the cyclic one amounts to 247.9 kJ·mol^{-1} according to B3LYP and 227.8 kJ·mol^{-1} according to CCSD(T). The tendency of N_4H_4 to form chains that feature a double bond between the inner N atoms, instead of a cyclic structure in which only single bonds are present, demonstrates the strength of the π bond relative to the σ bond. The cyclic isomer, tetrazetidine, is unstable and dissociates into two *trans*-diazene (N_2H_2) molecules, with the standard enthalpy for this dissociation calculated previously to be −121.5 kJ·mol^{-1}.[63] This value is in good agreement with our results (dissociation energy: −116.7 kJ·mol^{-1}; standard enthalpy: −133.2 kJ·mol^{-1}). Tetrazetidine exhibits a D_{2d}-symmetric global energy-minimum structure that is characterized by N−N and N−H bond lengths of 1.4720/1.4711 and 1.0208/1.0226 Å (cf. 1.479 and 1.025 Å)[64] and N−N−N and H−N−N bond angles of 89.8/89.6 and 105.3/104.3° (cf. 89.8° and 104.1°).[64] At 135.8 kJ·mol^{-1}, the strain energy of the cyclic tetrazetidine N_4H_4 isomer was previously calculated to be slightly higher than the one derived for cyclobutane (110.2 kJ·mol^{-1}).

In contrast to its lighter homologue, P_4H_4 prefers a cyclic structure, which has, according to our calculations, an energy that is 47.2 kJ·mol^{-1} lower [56.9 kJ·mol^{-1} using the CCSD(T) method] than the chain-like isomer (standard enthalpy difference of 45.4 kJ·mol^{-1} according to B3LYP, see Table 3). The cyclic P_4H_4 isomer exhibits D_{2d} symmetry. The calculated geometric parameters (2.2618/2.2376 and 1.4207/1.4164 Å for the P−P and P−H bond lengths and 90.0/89.6 and 93.8/93.0° for the P−P−P and H−P−P bond angles) are in good agreement with the results of earlier calculations (2.238 and 1.417 Å for the P−P and P−H bond lengths and 89.8° and 95.3° for the P−P−P and H−P−P bond angles).[64] As_4H_4 also exhibits a cyclic global energy-minimum structure, with the energy and the standard enthalpy differences relative to the open chain-like isomer amounting to 54.1 and 53.8 kJ·mol^{-1}, respectively, using the B3LYP method [90.4 and 90.1 kJ·mol^{-1} using the CCSD(T) method, see Figure 2]. In the cyclic form, the As−As and As−H bond lengths amount to 2.5017/2.4691 and 1.5291/1.5235 Å, respectively.

The value calculated herein for the N−N distance in HNNH (1.2354/1.2541 Å) is close to the experimentally determined value of 1.252 Å. In the case of HPPH, a P−P bond length of 2.099 was previously calculated,[64] with values for the P−H distance and the H−P−P bond angle of 1.420 Å and 94.9°, respectively. These numbers compare with the P−P bond lengths of 2.0311/2.0372 Å, the P−H bond lengths of 1.4259/1.4195 Å, and the H−P−P bond angles of 94.3°/93.7° calculated herein. Experimentally, a number of derivatives bearing the formula RPPR (R being a bulky organic group) were studied by X-ray diffraction, yielding typical P−P bond lengths of about 2.01 Å,[65] in good agreement with the theoretically derived value. Finally, for HAsAsH, a *trans* C_{2h} structure was predicted previously to be characterized by an As−As bond length of 2.227 Å and an H−As−As bond angle of 94.4°.[66] These values tally nicely with the ones calculated herein (2.2542/2.2601 Å and 92.6°/92.2°, respectively). One example of several derivatives characterized experimentally is the compound (2,4,6-tBu$_3$C$_6$H$_2$)AsAsCH(SiMe$_3$)$_2$, which was structurally characterized already in 1983 and exhibits an As−As bond length of 2.224(2) Å and C−As−As bond angles of 93.6(3) and 99.9(3)°.[67]

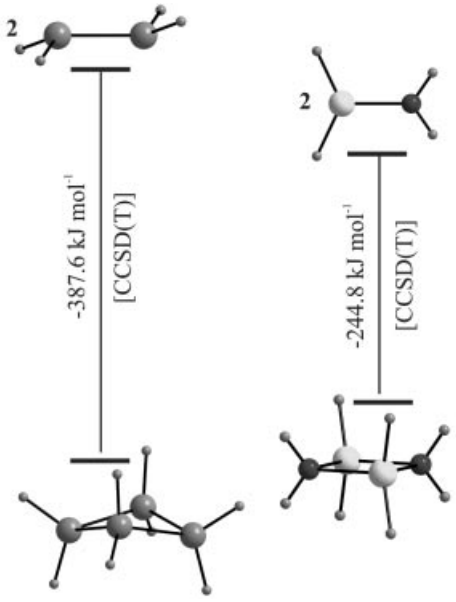

Figure 2. Comparison between the geometries of H_2GeGeH_2 and H_2GaNH_2 and their dimerisation products, the cyclic species Ge_4H_8 and $Ga_2N_2H_8$, and the standard enthalpies of their dimerisation

Group-13/Group-15 Compounds (H_2BNH_2, H_2AlNH_2 and H_2GaNH_2)

The dimers $(H_2ENH_2)_2$ are composed of planar E_2N_2 rings. Although there is a tendency, especially for E = Al or Ga, to form trimers instead of dimers, some derivatives of the dimers were synthesized and characterized either in the gas or crystal phase. Thus, for example, $(H_2GaNMe_2)_2$ has been characterized in the gas phase using electron diffraction,[68] and $[H_2GaN(H)NMe_2]_2$ has also been characterized experimentally.[69] In those studies, the Ga−N and Ga−H bond lengths and the Ga−N−Ga and H−Ga−H bond angles of $(H_2GaNMe_2)_2$ were determined to be 2.027 and 1.487 Å, and 90.6 and 109°. In the case of $[H_2GaN(H)NMe_2]_2$, values of 1.991−2.024 and 1.51 Å, and of 86.9/97.3 and 92.1/93.6° were obtained for the Ga−N and Ga−H bond lengths and the N−Ga−N and Ga−N−Ga bond angles, respectively. In both compounds, the Ga_2N_2 ring was shown to be planar. All experimental values are in excellent agreement with the results of our calculations for $(H_2GaNH_2)_2$ [D_{2h} symmetry, Ga−N and Ga−H bond lengths of 2.035 and 1.567 Å, respectively, and N−Ga−N and H−Ga−H bond angles of 86.0 and 125.5° (B3LYP values), see Figure 3] and previous calculations.[70] Very recently, the apparently air-stable derivative $[t$Bu(H)GaNEt$_2]_2$ was synthesized and structurally characterized.[71] The Ga−N and Ga−H bond lengths of this

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compound were reported to be 2.025(3) and 1.57(4) Å; the N−Ga−N bond angle is 88.8°. The trimer $[H_2GaNH_2]_3$ is also known and has been proved to be a valuable single-source precursor to solid GaN.[72] Another example, from Al chemistry, is provided by the compound $[Me_2AlN(H)NMe_2]_2$, for which an Al−N bond length and a N−Al−N bond angle were determined to be 1.958−1.953 Å and 87.2°, respectively.[73] These values compare with values of 1.9686 Å and 87.4° calculated herein for $(H_2AlNH_2)_2$.

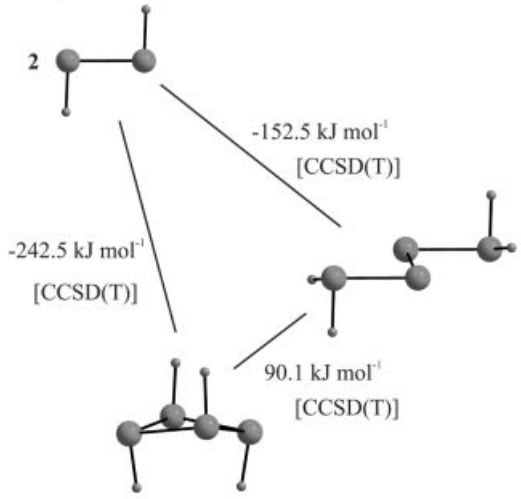

Figure 3. Geometries of HAsAsH and its dimerisation product As_4H_4 in its cyclic energy minimum and its chain-like forms, and enthalpies for dimerisation

Much effort has been put into the synthesis of monomeric compounds with the general formula $R^1R^2EE'R^3R^4$ (R^1−R^4 being bulky organic groups and E and E′ being group-13 and group-15 elements). The parent compounds $H_2EE'H_2$, however, are unstable and, therefore, special techniques, such as matrix isolation, are necessary to obtain access to them. The structure of H_2BNH_2 has been studied by microwave spectroscopy[74] and by matrix IR spectroscopy.[75] Recently, the heavier homologues H_2AlNH_2, H_2GaNH_2 and H_2InNH_2 were generated and characterized by matrix-isolation experiments.[19,76] All four of these monomers have been the subjects of several detailed theoretical works.[28,77−82] Experiments and calculations agree that they all are planar, C_{2v}-symmetric molecules. According to previous calculations using CCSD/TZ2P, H_2AlNH_2 is characterized by Al−N, Al−H and N−H bond lengths of 1.772, 1.576 and 1.004 Å, respectively, and H−Al−H and H−N−H bond angles of 124.1 and 110.0°, respectively.[83] Using DFT methods, the following parameters were calculated in a previous study of H_2GaNH_2: Ga−N 1.8211 Å, Ga−H 1.5621 Å, N−H 1.0086 Å, H−Ga−H 126.7° and H−N−H 111.7°.[19] All these values are in good agreement with the values calculated herein (see Table 4).

Standard Enthalpies for Dimerisation

The structures of the most relevant isomers of the monomers and dimers having now been established, we now turn our attention to a discussion of the dimerisation enthalpies. Tables 1−4 include the dimerisation enthalpies calculated using the B3LYP and MP2 methods, each in combination with the 6-311+G(2df,p) basis set, as well as the enthalpies derived from calculations with MP2, but this time with the TZVPP basis set. Finally, Table 5 lists the calculated values for the dimerisation enthalpies using the CCSD(T) method. The general trend is that the enthalpies as calculated with MP2/TZVPP are higher than the ones derived from MP2/6-311+G(2df,p) and B3LYP/6-311+G(2df,p) calculations. The differences are relatively small between the values calculated with CCSD(T)/6-311+G(2df,p) and MP2/TZVPP (see Table 5). This observation shows that expensive methods and/or large basis sets are necessary for calculating accurate enthalpies. The results give us confidence that the levels of calculations used herein are sufficient to establish, at least, the trends for the dimerisation enthalpies.

Figure 4 is presented to better visualize the observed trends of the enthalpies. We have calculated the enthalpies in several cases for two different isomeric forms of the monomers and dimers, and this process is necessary in some cases for a better comparison (if the global energy-minimum structures change for homologues). Nevertheless, Figure 4 shows only the trends for the global energy-minimum forms. The dimerisation of C_2H_4 to give cyclobutane can be used as a test system to judge the quality of the calculation methods, since reliable experimental enthalpy values exist for this reaction. With a standard enthalpy of $-75.3\ kJ{\cdot}mol^{-1}$, the value calculated with CCSD(T) comes very close to the experimental one of ca. $-72\ kJ{\cdot}mol^{-1}$.[84] With B3LYP and MP2 in combination with the 6-311+G(2df,p) method, this enthalpy comes out slightly lower than the experimental one.

The dimerisation enthalpies are all negative quantities (exothermic), with the only exception being the dimerisation of HNNH to give cyclic N_4H_4. The value of $+133.2\ kJ{\cdot}mol^{-1}$ calculated with B3LYP is in good agreement with the results of earlier calculations, which gave a value of $121.5\ kJ{\cdot}mol^{-1}$.[64] At $127.6\ kJ{\cdot}mol^{-1}$, the enthalpy as calculated using the CCSD(T) method is also in pleasing agreement with this previous report. As already mentioned, N_4H_4 prefers an open chain-like structure where the inner N atoms can establish significant π bonding. The dimerisation to give this chain like structure is exothermic [dimerisation enthalpy of $-115\ kJ{\cdot}mol^{-1}$ using the B3LYP and $-99.2\ kJ{\cdot}mol^{-1}$ using the CCSD(T) method]. Therefore the positive value calculated for the enthalpy of dimerisation to the N_4H_4 ring reflects the instability of the N_4H_4 ring. This instability is partially caused by the strain energy, which was estimated to be even slightly higher than the one of cyclobutane, C_4H_8 (135.8 vs. $110.4\ kJ{\cdot}mol^{-1}$).[64] The lone-pair repulsion is certainly one important factor to destabilize the cyclic form. Another factor is, in all certainty, the particularly strong N=N π bond, which can exist in the monomer and the dimer in its chain-like form, but not in the cyclic dimer. It has been pointed out that the π-bond increment (e.g., in N_2) is even higher than the σ-bond increment.[85]

[a] The CCSD(T)/6-311+G(2df,p) calculation for Ga_4H_4 failed.

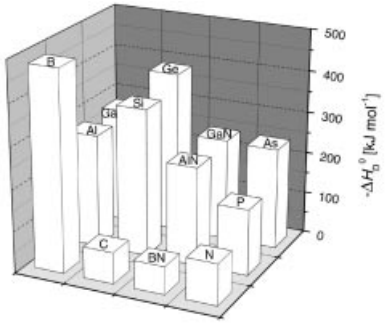

Figure 4. Standard enthalpies for dimerisation, ΔH^0_D, for the hydrides addressed in this work, as calculated using the CCSD(T) method (see Table 5); note that all species are considered in their global energy-minimum forms

It is clearly visible from Figure 4 that, while the compounds composed of group-14, -15 or -13/15 elements follow the same trend (increase of the dimerisation enthalpy down the group), the compounds composed of group-13 elements follow a different behaviour. The hydrides of the first long-period elements, H_2CCH_2, H_2BNH_2 and HNNH, have absolute dimerisation enthalpy values that are smaller than 100 kJ·mol^{-1}. The eye-catching exception is HBBH, which has the highest dimerisation enthalpy of all compounds addressed herein at −481.5 kJ·mol^{-1} [CCSDT(D) calculation]. Compound HBBH also is the only compound with a triplet electronic ground state. In total, the bond order in HBBH is two, as it is in H_2CCH_2 and HNNH. The two binding valence π orbitals, however, are each filled with *one* electron. In previous reports, we have probed the re-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sponse of HBBH to hydrogenation (to give H_2BBH_2)[28] and fragmentation (to give two HB fragments).[30] Hydrogenation is accompanied by a gain in enthalpy of ca. -180 kJ·mol^{-1}. This value is only slightly higher than the one derived for hydrogenation of H_2CCH_2 (ca. -140 kJ·mol^{-1}). The fragmentation of HBBH to give two BH units in their singlet electronic state consumes ca. 450 kJ·mol^{-1}, a value close to the one computed for H_2SiSiH_2 (440 kJ·mol^{-1}). Thus, the bond in HBBH is not very weak and cannot be the only reason for the extremely high dimerisation enthalpy. The stability of the B_4H_4 tetrahedron certainly must be considered in this context.

Moving from the first to the second long period, the dimerisation enthalpies increase generally. The only exception can again be found in the compounds of group-13 elements. First we turn our attention, however, to compounds of group-15 elements. The dimerisation enthalpies calculated herein for P_2H_2 of -141 kJ·mol^{-1}, using the B3LYP method, and of -158.3 kJ·mol^{-1}, using the CCSD(T) method, compare nicely with a value of 149.5 kJ·mol^{-1} reported previously.[64] The smallest change is found for the compounds of group-15 elements. Note that the enthalpies as plotted in Figure 4 are for dimerisation to give the open chain-like structure for N_4H_4, but the ring-type ones for P_4H_4 and As_4H_4. As already mentioned, the global energy-minimum structure of the dimer changes from the chain-like geometry of N_4H_4 to the cyclic one of P_4H_4. As pointed out earlier, the strain energies drop dramatically from 134.8 kJ·mol^{-1} in N_4H_4 to no more than 24.1 kJ·mol^{-1} in P_4H_4.[64] This feature means that at least two factors have to be considered to explain the changes that are only moderate within the binary group-15 hydrides. The first, and maybe most important, factor certainly is that the capability to form significant π-bonding is still quite high for the phosphane and arsane compounds. This phenomenon implies that the stability of the monomers HEEH (E = group-15 element) does not decrease as much down the group as for the compounds composed of of group-14, -13 or -13/15 elements. The other factor is the stability of the dimer. As already mentioned, the lone-pair repulsion and the strain energy should decrease down the group, the latter because of the larger affordability of bond-angle deformations. It has been suggested that the strain energy in P_4H_4 is close to zero.[86] When considering dimerisation to give the *cyclic* isomers E_4H_4 in the case of E = N, P, and As (see Table 3), the enthalpies are only very small (at -118.5, -116.8, and -120.5 kJ·mol^{-1} for E = N, P, and As, respectively) according to the MP2/TZVPP method.

In the case of group-14 element compounds, the increase in the dimerisation enthalpy is larger than that for group-15 element compounds. Dimerisation of Si_2H_4 is accompanied by an enthalpy gain of 353.8 kJ·mol^{-1} according to the CCSD(T) estimate (and 365.9 kJ·mol^{-1} according to MP2/TZVPP). This means that the dimerisation enthalpy is 4.7 times higher than for the C analogue, while P_2H_2 dimerises with an enthalpy only 1.6 times higher than that of N_2H_2. One of the most important factors at work here is certainly the instability of the H_2SiSiH_2 reactant. In contrast to HPPH, which features a "classical" and comparably strong π bond, H_2SiSiH_2 features a different, weaker sort of π-interaction ("donor–acceptor" interactions). Another factor is again the strain energy in the cyclic dimer, which in both cases drops for the heavier homologues and increases the stability of the cyclic dimers. The experimental values for the strain energies of $(CH_2)_4$ and $(SiH_2)_4$ amount to ca. 118 and 96 kJ·mol^{-1}, respectively.[87][88] These values are in good agreement with the results of theoretical studies, which gave values of 119 and ca. 70 kJ·mol^{-1} using ab initio methods.[89,90] Apparently, the smaller ring strain in the silicon-containing rings is partially explained by efficient $\pi-\sigma^*$ interactions.[91] The decrease of the ring strain is certainly also of some importance for the smaller increase observed in the absolute values of the dimerisation enthalpy in moving from the second to the third long period (hydrides of Ge and As).

In the case of mixed group-13/15 element compounds, the trend, as well as the absolute values, of the dimerisation enthalpies are very similar to the ones calculated for binary group-15 element hydrides. Certainly it should be noted here that the bond properties change significantly from H_2BNH_2 to H_2AlNH_2 and again to H_2GaNH_2. In this series, the ionic contributions increase. In H_2GaNH_2 the charge separation is already substantial. These ionic contributions might be responsible for the differences between the group-13/15 element compounds and the binary group-14 element compounds. The dimerisation of H_2BNH_2 is only very weakly exothermic [dimerisation enthalpy of -67.2 kJ·mol^{-1} using the CCSD(T) method and -77.3 kJ·mol^{-1} using MP2/TZVPP]. Thus, H_2BNH_2 has the smallest dimerisation enthalpy of all compounds under investigation herein, even slightly smaller than the one calculated for C_2H_4 [-75.3 kJ·mol^{-1} according to CCSD(T)]. Nevertheless, H_2BNH_2 is much more reactive than H_2CCH_2 and is stabilized only in the form of adducts (e.g., $B_2H_4{\cdot}BH_3$) or by replacement of the H atoms by halogen and/or organic groups (e.g., Cl_2BNMe_2). Otherwise, this class of compounds oligomerises [e.g., to its trimer $(B_2H_4)_3$] or polymerises rapidly.

Finally, we now proceed to the discussion of the binary group-13 element hydrides. As indicated already, the situation here is much more complicated than that for the other groups. We have already mentioned and analysed the exceptionally high dimerisation enthalpy of HBBH. Moving to Al_2H_2 brings about a great change in the geometry of the global energy-minimum isomer. The large Al–Al separation in the global energy-minimum isomer, planar and cyclic Al(μ-H)$_2$Al (D_{2h} symmetry), does not permit any significant interaction between the two atoms. The bent *trans*-HAlAlH isomer with two terminal Al–H bonds has an energy that is about 60 kJ·mol^{-1} higher than the one of the cyclic Al(μ-H)$_2$Al form. The dimerisation of Al(μ-H)$_2$Al to give tetrahedral Al_4H_4 is associated with an enthalpy change of -271.9 kJ·mol^{-1} according to the CCSD(T) method (-308.9 kJ·mol^{-1} according to MP2/TZVPP). This change is only 56% of the standard enthalpy for the dimerisation of HBBH. This value is even significantly

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

smaller than the one calculated for dimerisation of Si_2H_4 (-353.8 kJ·mol^{-1}), but larger than the one calculated for dimerisation of H_2AlNH_2 and P_2H_2 (-236.5 and -158.3 kJ·mol^{-1}). The standard enthalpy for dimerisation of Ga_2H_2 (for which the cyclic form has been shown again to be the lowest-energy isomer) is higher by a factor of 1.57 than the one calculated for dimerisation of Al_2H_2. In summary, the behaviour of the binary group-13 element hydrides differs significantly from the one found for the hydrides of group-14 and -15 elements and for mixed group-13/15 element compounds. If only the isomers with an intact E−E bond are considered for the E_2H_2 species, the dimerisation enthalpies are found to decrease down the group (-510.0, -442.3, and -402.6 kJ·mol^{-1} for E = B, Al and Ga, respectively, see Table 1).

Conclusions

This works attempts to shed light on the differences in reactivity between binary main-group element hydrides with the potential for multiple bonding. Although the chemical reactivity gives only indirect insight into the bond properties, it has the advantage that it can be verified, at least principally, by experiments. In two previous accounts we have studied the response of the compounds towards fragmentation and hydrogenation reactions. In this work, the standard enthalpies for dimerisation were calculated. The [2+2] cycloaddition is a characteristic and important reaction of derivatives of ethylene and, therefore, the comparison of the dimerisation enthalpies should shed light on the differences in the chemistry between compounds that formally are capable of forming a "double" bond. First, the structures of the monomers and dimers were analysed applying hybrid DFT (B3LYP) and ab initio (MP2) methods. In a second step, the MP2 and the CCSD(T) methods were used to determine the dimerisation enthalpies. The trends of the dimerisation enthalpies were established, and important factors responsible for these trends discussed. The results show that a general pattern is the increase of the dimerisation enthalpy for heavier homologues, with the largest changes occurring between the first and the second long period. Although structural differences in the energy-minimum structures of the monomers and dimers have to be considered (e.g., N_4H_4 exhibits a chain-like energy-minimum structure while P_4H_4 prefers a cyclic structure), the trend generally reflects the increasing weakness of the E−E bond in the monomers for the heavier homologues as the most-dominating effect. Other effects, such as the reduced ring strain in the cyclic dimers, play a significant, but most likely not the dominating, role. The eye-catching exception from this general pattern is found in group 13. Compound HBBH exhibits an unusually high dimerisation enthalpy; in fact, it is the highest value of all dimerisation processes studied herein. Possible reasons for this high enthalpy have been discussed.

The values derived herein for the dimerisation enthalpies give useful and reliable information about the differences in the chemistry of main-group element hydrides with the potential for multiple bonding. The results show that these differences are substantial and some trends are visible.

Keywords: Ab initio calculations / Fullerenes / Isomerism / Palladium / Platinum

This paper reports on the first examples of η^2-pentaarylated [60]fullerene organometallic complexes $[(\eta^2\text{-}Ar_5C_{60}H)M(PPh_3)_2]$ (**1**: Ar = Ph, M = Pt; **2**: Ar = *m*-MeC_6H_4, M = Pt; **3**: Ar = *p*-MeC_6H_4, M = Pt; **4**: Ar = Ph, M = Pd; **5**: Ar = *m*-MeC_6H_4, M = Pd; **6**: Ar = *p*-MeC_6H_4, M = Pd), which were synthesized by treatment of $[M(PPh_3)_4]$ with $Ar_5C_{60}H$ and fully characterized by elemental analyses and their ^1H NMR, ^{31}P NMR, IR, UV/Vis, and FAB-MS data. The ^1H NMR spectra displayed by the protons directly bonded to the C_{60} core and the ^{31}P NMR spectra caused by the PPh_3 ligands indicated that complexes **1**–**6** exist as mixtures of isomers. To gain insights into the isomerism of **1**–**6**, the regioselectivity of the pentaarylated derivatives $Ar_5C_{60}H$ as ligands coordinated to Pt^0 or Pd^0 has been studied by means of ab initio calculations. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

It is known that the [60]fullerene derivatives $Ar_5C_{60}H$ were first synthesized by a three-pot method starting from C_{60}, involving chlorination of C_{60} to give $C_{60}Cl_6$, arylation of $C_{60}Cl_6$ with benzene or substituted benzene, and reduction of $Ar_5C_{60}Cl$ with an excess of PPh_3.[1,2] Later on, a more convenient one-pot method for preparation of $Ar_5C_{60}H$ was discovered, involving treatment of C_{60} with organocopper/magnesium reagents $Ar_2CuMgBr$, followed by treatment of the reaction mixture with aqueous NH_4Cl.[3,4] It is conceivable that the pentaarylated [60]fullerene derivatives $Ar_5C_{60}H$ might form organometallic complexes with single, double, triple, and even multiple metal centers through their pentaarylated cyclopentadienyl rings and other sites of the C_{60} core in a variety of coordination modes from η^1 to η^6. Up to now, however, except for the η^5-pentaarylated [60]fullerene organometallic compounds such as $\eta^5\text{-}Ph_5C_{60}M$ (M = Li, K, Tl, $CuPEt_3$),[3] there are no other reported organometallic complexes that contain pentaarylated [60]fullerene ligands coordinated to metal centers in a mode from η^1 to η^4 or in an η^6-fashion.

During recent years we have been interested in the synthesis, structural characterization, and properties of organotransition metal fullerene derivatives.[5] As part of this project, we recently carried out an investigation into the reactions between transition metal complexes $[M(PPh_3)_4]$ (M = Pt, Pd) and pentaarylated [60]fullerene derivatives $Ar_5C_{60}H$ to see which type of coordination mode might be adopted by $Ar_5C_{60}H$ in the products and whether the ligand-exchange reaction might be regioselective toward the reactive sites of pentaarylated [60]fullerene derivatives $Ar_5C_{60}H$. Here we report our results.

Results and Discussion

Synthesis and Characterization of Complexes $[(\eta^2\text{-}Ar_5C_{60}H)M(PPh_3)_2]$ (1–6)

An equivalent of each transition metal complex $[M(PPh_3)_4]$ (M = Pt, Pd) was treated with a pentaarylated [60]fullerene derivative $Ar_5C_{60}H$ (Ar = Ph, *m*-MeC_6H_4, *p*-MeC_6H_4) in THF at room temperature to give six products $[(\eta^2\text{-}Ar_5C_{60}H)M(PPh_3)_2]$ (**1**–**6**) in 51–63% yields, as shown in Scheme 1.

Apparently, products **1**−**6** can be formally regarded − similarly to the parent [60]fullerene metal complexes [(η^2-C_{60})M(PR_3)$_2$] (M = Pt,[6] Pd[7]) − as deriving from displacement of one PPh_3 ligand from M(PPh_3)$_3$ {generated in situ through dissociation of one PPh_3 ligand of starting material [M(PPh_3)$_4$]} by one equivalent of $Ar_5C_{60}H$. Interestingly, products **1**−**6** are, to the best of our knowledge, the first organometallic complexes containing pentaarylated [60]fullerene ligands $Ar_5C_{60}H$ coordinated to transition metals through their [6:6] bonds in an η^2-fashion.

Products **1**−**6** have been characterized by elemental (C,H,P) analysis and spectroscopic methods. In their FAB-MS spectra, while products **1**−**3**, **5**, and **6** show their molecular ions M^+ and their pentaarylated [60]fullerene ligand ions $Ar_5C_{60}H^+$ (Ar = Ph, *m*-MeC_6H_4, *p*-MeC_6H_4), product **4** displays the largest fragment ion [M^+ − Pd] and pentaarylated [60]fullerene ligand ion $Ph_5C_{60}H^+$. The UV/Vis spectra of **1**−**6** are all very similar to one another and each exhibits three absorption bands in the 239−489 nm range. In addition, the IR spectra of **1**−**6** each include four absorption bands, at 1431−1435, 1193−1190, 579−591, and 534−540 cm^{-1}, which resemble those of the free ligands C_{60}[8] and $Ar_5C_{60}H$ (Ar = Ph,[1] *m*-MeC_6H_4,[9] *p*-MeC_6H_4[2]).

For the ^{1}H NMR spectra, it should be noted that, while the hydrogen atom directly bonded to the C_{60} core in each of the free ligands $Ar_5C_{60}H$ (Ar = Ph,[3] *m*-MeC_6H_4,[9] *p*-MeC_6H_4[2]) displays only one singlet at δ = 5.2−5.3 ppm, the corresponding hydrogen atom in each of the compounds **1**−**6** exhibits two to four singlets at δ = 5.1−5.3 ppm. This implies that **1**−**6** might exist as mixtures of isomers. Similarly to the ^{1}H NMR spectra, the ^{31}P NMR spectra of **1**−**6** each show two to four singlets at δ = 29−33 ppm for the P atoms, which also suggests that compounds **1**−**6** exist as isomer mixtures. The ^{31}P NMR spectra of **1**−**3**, however, in contrast to those of **4**−**6**, have two groups of satellite peaks at both sides of the groups of singlets at δ ≈ 30 ppm, caused by ^{195}Pt-^{31}P coupling. It is worth noting that the chemical shifts (δ ≈ 30 pm) of **1**−**6** and the ^{195}Pt-^{31}P coupling constants (J ≈ 3960 Hz) of **1**−**3** are similar to those of [(η^2-C_{60})Pt(PPh_3)$_2$][6,10] and [(η^2-C_{60})Pd(PPh_3)$_2$],[7] apparently due to their similar structures. Figures 1 and 2 show the partial ^{1}H NMR and the whole ^{31}P NMR spectra of products **2** and **4**, respectively. The four singlets at δ ≈ 5.2 ppm in Figure 1(a) could each be assigned to the hydrogen atom directly bonded to C_{60} core in each of four isomers of product **2**, whereas the four singlets at δ ≈ 30 ppm in Figure 1(b) could each be attributed to the two P atoms in each of the four isomers. Similarly, the three singlets at δ ≈ 5.3 ppm in Figure 2(a) and the three singlets at δ ≈ 30 ppm in Figure 2(b) could be assigned to the hydrogen atoms directly bonded to the C_{60} cores and to the P atoms in three isomers of product **4**, respectively. In order to obtain some further details concerning the possible isomers of **1**−**6**, we carried out a computational study on the simplest ligand $Ph_5C_{60}H$ and its Pt complex [(η^2-$Ph_5C_{60}H$)Pt(PPh_3)$_2$] (**1**).

Computational Study on Possible Isomers of 1−6

As shown in Figure 3, the pentaarylated hydro[60]fullerenes $Ar_5C_{60}H$ (Ar = Ph, *m*-MeC_6H_4, *p*-MeC_6H_4), unlike the highly I_h-symmetric [60]fullerene, are C_s-symmetric molecules, each of which contains a series of carbon−carbon double bonds represented by **A**−**O**, **B**′, **C**′, **E**′−**K**′ and **M**′−**O**′. The double bonds represented by capital letters and those represented by the corresponding capital letters with primes are located symmetrically on the two sides of the symmetrical plane of $Ar_5C_{60}H$, which are actually the same in terms of their ability to coordinate with metal atoms M (M = Pt, Pd). Hence, each of the pentaarylated $Ar_5C_{60}H$ has 14 kinds of [6:6] double bonds formed between two six-membered rings represented by **A**−**N** or **A**, **B**′, **C**′, **D**, **E**′−**K**′, **L**, **M**′, **N**′ and one kind of [6:5] double bonds formed between six- and five-membered rings, represented by **O** and **O**′. However, since the **L**−**O** or **M**′−**O**′ double bonds could not coordinate with metal atoms M, due to the great steric hindrance between the two large PPh_3 ligands attached to M and the five aryl groups located around the double bonds **L**−**O** or **M**′−**O**′, products [(η^2-$Ar_5C_{60}H$)M(PPh_3)$_2$] (**1**−**6**) each have only 11 possible structural isomers **A**−**K** or **A**, **B**′, **C**′, **D**, **E**′−**K**′ generated through coordination of the remaining 11 kinds of the corresponding [6:6] double bonds. In fact, the isomers, which are derived from coordination of the [6:6] double bonds **B**′,

C′, and **E′**−**K′** with M atoms, are the enantiomers of isomers **B**, **C**, and **E**−**K**.

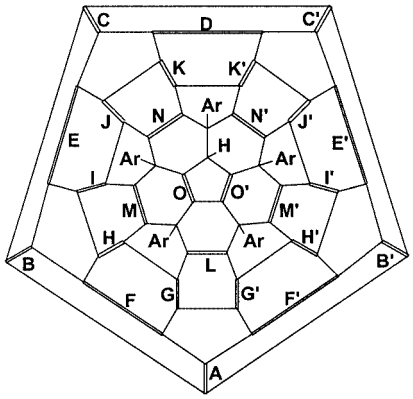

Figure 3. Possible η^2-coordinating sites of $Ar_5C_{60}H$ in a Schlegel diagram

Computational chemistry methods had previously been utilized to study [60]fullerene platinum and palladium complexes in the model complex $[(\eta^2\text{-}C_{60})Pt(PH_3)_2]$.[11−14] In order to further establish the actually existing isomers of **1**−**6** and the regioselectivity of the involved η^2-$Ar_5C_{60}H$ ligands in the products, we chose the platinum complex $[(\eta^2\text{-}Ph_5C_{60}H)Pt(PPh_3)_2]$ (**1**) as a representative with which to carry out ab initio DFT calculations on its 11 possible isomers. It is worth noting that we did not use $[(\eta^2\text{-}Me_5C_{60}H)Pt(PH_3)_2]$ as a model complex in calculations in this case, since it is oversimplified for the strong steric hindrance existing between the phenyl groups in **1**, which is very important for the isomer energies and the ^{1}H NMR calculations.

Density functional theory (DFT) calculations at the B3LYP level were performed in full structural optimizations. With the optimized structures, the ^{1}H magnetic shielding coefficients for the proton directly bonded to the C_{60} core were obtained by Hartree−Fock GIAO method. The energies and isotropic ^{1}H magnetic shielding coefficients are compiled in Table 1.

The reaction involved in the production of the 11 isomers is assumed to be thermodynamically controlled. Provided that a transformation equilibrium among all of the 11 isomers is present, the abundances of the isomers would be determinable only by their energy differences according to the Boltzmann distribution, as shown in Equation (1), where k, T, n_i, p_i, and E_i are the Boltzmann constant, absolute temperature, number of enantiomers of isomer i, and the abundance and energy of isomer i, respectively.

$$p_i = n_i e^{-E_i/kT} / \sum_j n_j e^{-E_j/kT} \quad (1)$$

As can be seen from Table 1, only six (namely **A**−**F**) of the 11 isomers have noticeable abundances at 298 K, the other isomers **G**−**K** derived from the corresponding double bonds **G**, **H**, **I**, **J**, and **K** having very low abundance.

The simulated partial ^{1}H NMR spectrum can be drawn from the isomer abundance data (peak areas) and the calculated ^{1}H shielding coefficients (chemical shifts). Figure 4(b) shows the calculated ^{1}H NMR spectrum of the isomer mixture of **1**, in which the peaks of isomers **F** and **A** or **B** and **D** are overlapped due to their very close values of the shielding coefficients. The similarity of Figure 4(b) with the actual spectrum Figure 4(a) suggests that the ab initio result is logical and acceptable. The four ^{1}H NMR signals of the proton directly bonded to the C_{60} core shown in Figure 4(a) can be assigned to isomers **F**+**A**, **B**+**D**, **C**, and **E**, respectively. It follows that this computational result is different from our initial assignment described above, in which each experimental singlet is related to one single isomer.

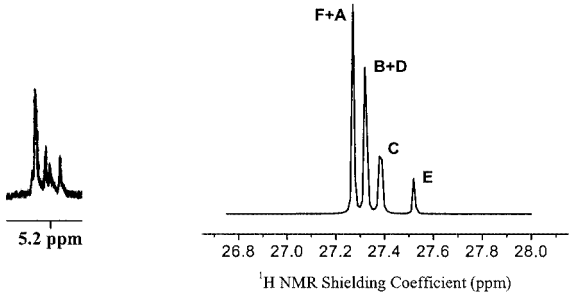

Figure 4. The partial ^{1}H NMR spectrum of the isomer mixture of **1**

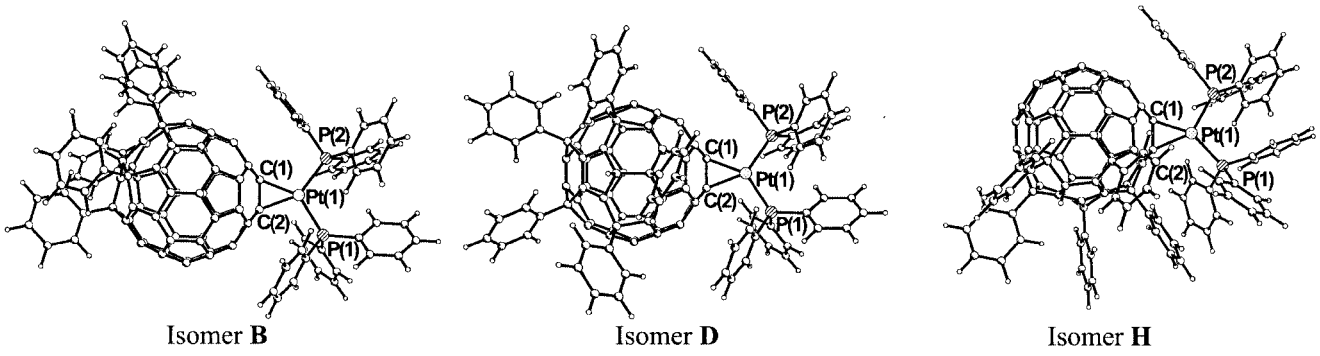

Figure 5. Optimized structures of isomers **B**, **D**, and **H**

Some of the structural parameters of the optimized structures for isomers **B**, **D**, and **H**, together with the corresponding values of the crystal structure of [(η^2-C_{60})Pt(PPh_3)$_2$],[10] are presented in Table 2, whereas Figure 5 shows the optimized structures of the three isomers.

As shown in Table 2, the calculated values for the optimized structures are similar to the crystal structural data of [(η^2-C_{60})Pt(PPh_3)$_2$], which indicates the accuracy of the calculation. That we chose the optimized structures of isomers **B**, **D**, and **H** is to illustrate that the stability and thus the abundance of each isomer is directly related to the steric effect. As can be seen intuitively in Figure 5, the phenyl groups in both $Ph_5C_{60}H$ and PPh_3 are most crowded in isomer **H**, then intermediate in isomer **D**, and least crowded in isomer **B**. This is consistent with the magnitudes of the abundances **B** > **D** > **H** shown in Table 1. In addition, the energy sequence **B** < **D** < **H** shown in Table 1 is also consistent with the magnitudes of the steric repulsion between the five C_{60}-bonded phenyl groups and the six phenyl groups of the two tertiary phosphane ligands in **B**, **D**, and **H**. In fact, isomers **A**, **B**/**B′**, and **C**/**C′** are the most stable ones, since the steric repulsions in these isomers are among the smallest. Finally, it can be concluded that the steric repulsion between the bulky phenyl substituents is most probably the key factor for the regioselectivity of $Ar_5C_{60}H$ ligands in coordinating with transition metals Pt and Pd in an η^2-fashion to form products **1**−**6**.

Table 2. Selected structural parameters of [(η^2-C_{60})Pt(PPh_3)$_2$] and isomers **B**, **D**, and **H**

Compound	(η^2-C_{60})Pt(PPh_3)$_2$	**B**	**D**	**H**

Experimental Section

General: All reactions were carried out under highly purified nitrogen by use of standard Schlenk or vacuum-line techniques. THF was distilled from Na/benzophenone ketyl. All solvents were bubbled with nitrogen for at least 15 min before use. [$Pt(PPh_3)_4$],[15] [$Pd(PPh_3)_4$],[16] $Ph_5C_{60}H$,[3] (m-$MeC_6H_4)_5C_{60}H$,[9] and (p-$MeC_6H_4)_5C_{60}H$[9] were prepared by literature methods. IR spectra were measured with a Bio-Rad FTS 135 spectrophotometer, whereas $^1H\{^{31}P\}$ NMR and UV/Vis spectra were recorded with a Bruker AC P200 and a Shimadzu UV 240 spectrometer, respectively. Elemental analysis of C and H was performed with an Elementar Vario EL analyzer, while P was determined by the vanadomolybdophosphoric acid colorimetric method. Melting points were determined with a Yanaco MP-500 apparatus.

Preparation of [(η^2-$Ph_5C_{60}H$)Pt(PPh_3)$_2$] (1): A 100-mL three-necked flask fitted with a stirrer bar, a serum cap, and an N_2 inlet tube was charged with $Ph_5C_{60}H$ (44 mg, 0.04 mmol) and THF (15 mL). $Pt(PPh_3)_4$ (50 mg, 0.04 mmol) was then added and the reaction mixture was stirred for 0.5 h at room temperature. After removal of the solvent under vacuum, the residue was chromatographed on an Al_2O_3 column with toluene/petroleum ether (3:2) as eluent, and the pink band was collected. After removal of the solvent, 42 mg (57%) of **1** was obtained as a red-brown solid. M.p. > 300°C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 5.13, 5.20, 5.22, 5.28 (4 s, 1 H, $C_{60}H$), 7.05−7.90 (m, 55 H, 11 Ph) ppm. ^{31}P NMR [81.0 MHz, toluene, $(CD_3)_2CO$ lock signal, H_3PO_4]: δ = 28.95, 29.35, 29.96, 30.24 (4 s surrounded with satellite peaks, $J_{Pt\text{-}P}$ = 3959 Hz, 2 P) ppm. IR (KBr): $\tilde{\nu}$ = 516.5 (s), 534.7 (m), 585.0 (w), 693.3 (vs), 742.4 (s), 1029.3 (w), 1094.6 (m), 1434.3 (s), 1491.9 (m), 1598.4 (w), 2863.8 (w), 2952.5 (w), 3056.7 (w) cm^{-1}. UV/Vis (THF): λ_{max} (log ε) = 239.7 (5.14), 288.7 (4.98), 488.9 (4.18) nm. FAB-MS: m/z = 1826 [$(Ph_5C_{60}H)Pt(PPh_3)_2^+$, ^{196}Pt], 1107 [$Ph_5C_{60}H^+$]. $C_{126}H_{56}P_2Pt$ (1826.86): calcd. C 82.84, H 3.09, P 3.39; found C 82.56, H 3.35, P 3.43.

Preparation of [{η^2-(m-$MeC_6H_4)_5C_{60}H$}Pt(PPh_3)$_2$] (2): Similarly, when (m-$MeC_6H_4)_5C_{60}H$ (47 mg, 0.04 mmol) was used in place of $Ph_5C_{60}H$, **2** (48 mg, 63%) was obtained as a red-brown solid. M. p. > 300°C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 2.03, 2.06, 2.17 (3 s, 15 H, CH_3 + 2 CH_3 + 2 CH_3), 5.13, 5.19, 5.21, 5.26 (4 s, 1 H, $C_{60}H$), 7.00−7.90 (m, 50 H, 6 Ph + 5 C_6H_4) ppm. ^{31}P NMR

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[81.0 MHz, toluene, $(CD_3)_2CO$ lock signal, H_3PO_4]: δ = 29.02, 29.43, 29.99, 30.28 (4 s surrounded with satellite peaks, J_{Pt-P} = 3962 Hz, 2 P) ppm. IR (KBr): $\tilde{\nu}$ = 516.9 (s), 534.1 (m), 580.0 (w), 693.2 (vs), 747.4 (s), 1094.5 (m), 1434.1 (m), 1480.2 (m), 1603.7 (w), 2856.0 (w), 2921.6 (w), 3052.9 (w) cm^{-1}. UV/Vis (THF): λ_{max} (log ε) 240.1 (5.16), 288.3 (5.01), 489.1 (4.20) nm. FAB-MS: *m/z* = 1895 [{$(MeC_6H_4)_5C_{60}H$}$Pt(PPh_3)_2^+$, ^{195}Pt], 1177 [$(MeC_6H_4)_5C_{60}H^+$]. $C_{131}H_{66}P_2Pt$ (1896.99): calcd. C 82.94, H 3.51, P 3.26; found C 82.79, H 3.74, P 2.91.

Preparation of [{η²-(*p*-$MeC_6H_4)_5C_{60}H$}$Pt(PPh_3)_2$] (3): Similarly, when (*p*-$MeC_6H_4)_5C_{60}H$ (47 mg, 0.04 mmol) was used in place of $Ph_5C_{60}H$, **3** (42 mg, 55%) was obtained as a red-brown solid. M. p. > 300°C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 2.26, 2.31, 2.36 (3 s, 15 H, CH_3 + 2 CH_3 + 2 CH_3), 5.06, 5.11, 5.13, 5.20 (4 s, 1 H, $C_{60}H$), 6.95−7.85 (m, 50 H, 6 Ph + 5 C_6H_4) ppm. ^{31}P NMR [81.0 MHz, toluene, $(CD_3)_2CO$ lock signal, H_3PO_4]: δ = 29.04, 29.44, 30.01, 30.33 (4 s surrounded with satellite peaks, J_{Pt-P} = 3959 Hz, 2 P) ppm. IR (KBr): $\tilde{\nu}$ = 517.0 (s), 534.9 (s), 583.0 (w), 692.8 (vs), 742.8 (s), 1095.6 (m), 1186.6 (m), 1434.6 (m), 1476.8 (m), 1509.2 (vs), 2848.3 (w), 2863.8 (w), 2952.5 (w), 3022.0 (w), 3052.9 (w) cm^{-1}. UV/Vis (THF): λ_{max} (log ε) 239.1 (5.16), 287.9 (5.00), 487.5 (4.13) nm. FAB-MS: *m/z* = 1895 [{$(MeC_6H_4)_5C_{60}H$}$Pt(PPh_3)_2^+$, ^{195}Pt], 1177 [$(MeC_6H_4)_5C_{60}H^+$], 720 [C_{60}^+]. $C_{131}H_{66}P_2Pt$ (1896.99): calcd. C 82.94, H 3.51, P 3.27; found C 83.17, H 3.63, P 3.18.

Preparation of [(η²-$Ph_5C_{60}H$)$Pd(PPh_3)_2$] (4): Similarly to the preparation of **1**, when $[Pd(PPh_3)_4]$ (46 mg, 0.04 mmol) was used in place of $[Pt(PPh_3)_4]$, **4** (40 mg, 58%) was obtained as a red-brown solid. M. p. > 300°C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 5.28, 5.30, 5.31 (3 s, 1 H, $C_{60}H$), 7.10−7.85 (m, 55 H, 11 Ph) ppm. ^{31}P NMR [81.0 MHz, toluene, $(CD_3)_2CO$ lock signal, H_3PO_4]: δ = 29.05, 31.22, 32.41 (3 s, 2 P) ppm. IR (KBr): $\tilde{\nu}$ = 486.0 (w), 513.0 (w), 540.0 (m), 692.0 (s), 739.0 (w), 1027.0 (w), 1093.0 (m), 1431.0 (m), 1490.0 (w), 1599.0 (w), 2863.0 (w), 2926.0 (w), 3058.0 (w) cm^{-1}. UV/Vis (THF): λ_{max} (log ε) 240.5 (5.04), 287.5 (4.83), 472.0 (3.99) nm. FAB-MS: *m/z* = 1630 [{$(Ph_5C_{60}H)Pd(PPh_3)_2$ − Pd}$^+$], 1107 [$Ph_5C_{60}H^+$]. $C_{126}H_{56}P_2Pd$ (1738.20): calcd. C 87.07, H 3.25, P 3.56; found C 87.14, H 3.51, P 3.74.

Preparation of [{η²-(*m*-$MeC_6H_4)_5C_{60}H$}$Pd(PPh_3)_2$] (5): Similarly to the preparation of **2**, when $[Pd(PPh_3)_4]$ (46 mg, 0.04 mmol) was used in place of $[Pt(PPh_3)_4]$, **5** (37 mg, 51%) was obtained as a red-brown solid. M. p. > 300°C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 2.01, 2.06, 2.17 (3 s, 15 H, CH_3 + 2 CH_3 + 2 CH_3), 5.25, 5.27 (2 s, 1 H, $C_{60}H$), 6.95−7.80 (m, 50 H, 6 Ph + 5 C_6H_4) ppm. ^{31}P NMR [81.0 MHz, toluene, $(CD_3)_2CO$ lock signal, H_3PO_4]: δ = 29.05, 31.27 (2 s, 2 P) ppm. IR (KBr): $\tilde{\nu}$ = 486.0 (w), 505.0 (w), 540.0 (s), 591.0 (w), 688.0 (s), 719.0 (s), 750.0 (m), 996.0 (w), 1027.0 (w), 1093.0 (w), 1120.0 (s), 1178.0 (m), 1435.0 (m), 1482.0 (w), 1597.0 (w), 1607.0 (m), 2856.0 (w), 2918.0 (w), 3043.0 (w) cm^{-1}. UV/Vis (THF): λ_{max} (log ε) 239.5 (5.09), 287.7 (4.93), 470.5 (4.00) nm. FAB-MS: *m/z* = 1806 [{$(MeC_6H_4)_5C_{60}H$}$Pd(PPh_3)_2^+$, ^{106}Pd], 1177 [$(MeC_6H_4)_5C_{60}H^+$]. $C_{131}H_{66}P_2Pd$ (1808.33): calcd. C 87.01, H 3.68, P 3.43; found C 87.06, H 3.75, P 3.48.

Preparation of [{η²-(*p*-$MeC_6H_4)_5C_{60}H$}$Pd(PPh_3)_2$] (6): Similarly to the preparation of **3**, when $[Pd(PPh_3)_4]$ (46 mg, 0.04 mmol) was used in place of $[Pt(PPh_3)_4]$, **6** (42 mg, 58%) was obtained as a red-brown solid. M. p. > 300°C. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 2.26, 2.31, 2.36 (3 s, 15 H, CH_3 + 2 CH_3 + 2 CH_3), 5.20, 5.22 (2 s, 1 H, $C_{60}H$), 6.90−7.85 (m, 50 H, 6 Ph + 5 C_6H_4) ppm. ^{31}P NMR [81.0 MHz, toluene, $(CD_3)_2CO$ lock signal, H_3PO_4]: δ = 29.08, 31.08 (2 s, 2 P) ppm. IR (KBr): $\tilde{\nu}$ = 513.0 (s), 536.0 (m), 579.0 (w), 692.0 (s), 743.0 (m), 1019.0 (w), 1093.0 (w), 1190.0 (m), 1431.0 (m), 1509.0 (s), 2863.0 (w), 2926.0 (w), 2972.0 (w), 3027.0 (w), 3058.0 (w) cm^{-1}. UV/Vis (THF): λ_{max} (log ε) = 239.0 (4.85), 287.7 (4.70), 472.0 (3.89) nm. FAB-MS: *m/z* = 1808 [{$(MeC_6H_4)_5C_{60}H$}$Pd(PPh_3)_2^+$, ^{108}Pd], 1177 [$(MeC_6H_4)_5C_{60}H^+$]. $C_{131}H_{66}P_2Pd$ (1808.33): calcd. C 87.01, H 3.68, P 3.43; found C 86.98, H 3.70, P 3.65.

Computational Details: The geometry optimizations of the 11 isomers for [(η²-$Ph_5C_{60}H$)$Pt(PPh_3)_2$] were performed at the DFT B3LYP hybrid functional level by use of the effective core potential basis set LANL2DZ[17−19] for Pt and P. The standard 6-31G basis sets were chosen for C and H, except for those atoms in the phenyl rings, for which STO-3G was used. A polarization function [ξd(P)= 0.387] was added for P.[20] The ^1H NMR magnetic shielding tensors were calculated by the Gauge-Including Atomic Orbital (GIAO) method[21] at the Hartree−Fock level[22] by use of the LANL2DZ basis set for Pt, the 6-31G** basis set for P and for the H atoms directly bonded to C_{60}, and the 6-31G basis set for all other atoms. All calculations were performed with the parallel version of the GAUSSIAN 98 software package[23] on a multi-nodes Beowulf Linux cluster computer system.

Acknowledgments

We are grateful to the National Natural Science Foundation of China for financial support and to Prof. P. J. Fagan for providing the crystal data for [(η²-C_{60})$Pt(PPh_3)_2$].

Gold, Silver and Palladium Complexes with the 2,2′-Dipyridylamine Ligand

Mercedes Burgos,[a] Olga Crespo,[a] M. Concepción Gimeno,[a] Peter G. Jones,[b] and Antonio Laguna*[a]

Keywords: Gold / N Ligands / Palladium / Silver

Reaction of the 2,2′-dipyridylamine (Py_2NH) ligand with various gold and silver starting products leads to three- or four-coordinate complexes. The structure of compound $[Ag(NHPy_2)(PPh_3)]OTf$ shows weak interactions which produce bands of molecules parallel to the *z* axis. Other hydrogen bonds of the type C–H···O serve to link the ribbons. The derivative $PPN[Au(Py_2N)_2]$ has also been obtained using $PPN[Au(acac)_2]$ [PPN = bis(triphenylphosphanyl)iminio, acac = acetylacetonate] as starting product to deprotonate the ligand. The palladium complex $[PdCl_2(Py_2NH)_2]$ is also reported.

Introduction

A search of the CSD affords more than two hundred structures of coordination complexes containing the 2,2′-dipyridylamine ligand (dpa). In most of them, the ligand shows a bidentate coordination mode,[1] but coordination as a bridging ligand[2] is not unusual, and monodentate coordination has been found in $[M(dpa)_2(CO)_3]$[3] (M = Mo, W, one chelate and other monodentate dpa) and also in the more recently reported $[W(dpa)(CO)_5]$.[4] The copper complexes of this ligand have been the most widely studied, at first as models for copper-containing plant hormone binding sites,[1d,5] and also because of their interesting electrochemical behavior.[6] The blue-light emission of organoaluminium(III) and Zn^{II} complexes with dpa is well known. The chelating effect of dpa in these complexes seems to be the origin of the enhancement and shift from UV to blue of the intraligand $\pi \rightarrow \pi^*$ transition of dpa upon coordination.[7−10] Nevertheless, the thermal instability or the low emission quantum yields in the solid state make the use of these complexes for practical applications impossible. Recent investigations in this area have involved polymeric or polynuclear complexes.[1c] Interesting trinuclear complexes in which the dpa acts as a bridging ligand have been described. They show variable-temperature magnetic susceptibility, which ranges from strong antiferromagnetic coupling (tricopper, trinickel)[11−13] to spin crossover (tricobalt),[14,15] via Curie law behavior (trichromium).[2e,16] The coordination to coinage metals other than copper remains uninvestigated, as far as we know. The silver derivatives may be especially interesting due to the possibility of the formation of supramolecular structures. These structures may be derived from building blocks linked by coordinate covalent[17] or hydrogen bonds.[18] Such structures are an active field of research, and many of them are afforded by using *N*,*N*′-bidentate spacers.[19] Herein we report the synthesis of some gold and silver complexes with the dpa ligand, and also the palladium derivative $[PdCl_2(dpa)]$. The structure of compound $[Ag(NHPy_2)(PPh_3)]OTf$ shows weak interactions which produce bands of molecules parallel to the *z* axis. Other hydrogen bonds of the type C−H···O serve to link the ribbons.

Results and Discussion

The reaction of $[Py_2NH]$ with AgOTf in a 1:1 or 2:1 molar ratio affords the three coordinate $[Ag(OTf)(Py_2NH)]$ (**1**) or four coordinate $[Ag(Py_2NH)_2]OTf$ (**2**) species (Scheme 1). Their IR spectra show the vibrations corresponding to N−H deformation and C=N, C=C stretching modes of the pyridine rings at 1586, 1540 cm^{-1} (**1**) or 1601, 1524 cm^{-1} (**2**) and the band corresponding to the N−H stretching vibration at 3320 (**1**) or 3340 (**2**).[1c,20,21] Those bands corresponding to covalent (**1**, 1240 and 1119 cm^{-1}) or anionic (**2**, 1272 and 1154 cm^{-1}) trifluoromethanesulfonate anion are also present.[22] The conductivity of compound **1** in acetone solution shows a higher value than expected for a non-electrolyte. This can be explained by taking into account the lability of the trifluoromethanesulfonate anion, which, in solution, is probably highly dissociated. In the ^1H NMR spectra the pyridine protons appear as four signals in the range $\delta = 7.16-8.20$ (**1**) and 6.88−8.11 ppm (**2**). In **1**, one signal at $\delta = 11.30$ ppm (br. s)

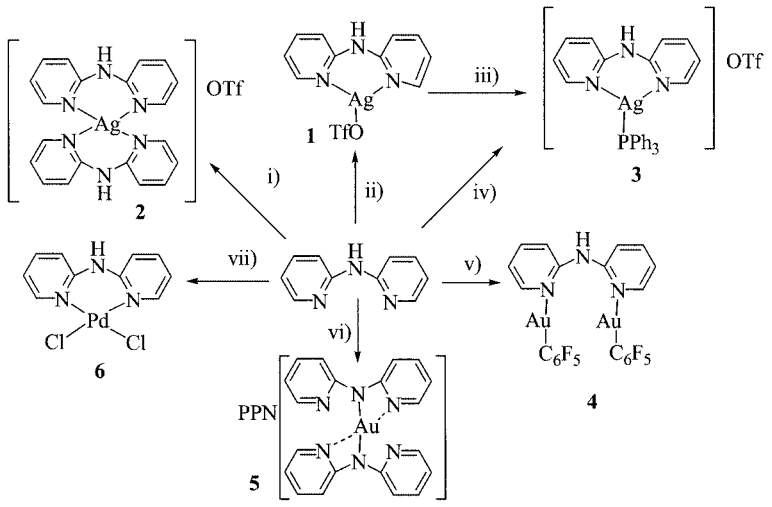

Scheme 1. i) 1/2 AgOTf, ii) AgOTf, iii) PPh_3, iv) [AgOTf(PPh_3)], v) 2 [Au(C_6F_5)(tht)], vi) PPN[Au(acac)$_2$], vii) [$PdCl_2$(PhCN)$_2$]

corresponds to the NH hydrogen atom, whereas in **2** it is overlapped with the resonances of the pyridinic protons. In the LSIMS (+) mass spectra the cationic molecular peaks appear at *m*/*z* = 428 (6%) for **1** and *m*/*z* = 450 (9%) for **2**. The displacement of the OTf ligand by PPh_3 in **1**, or the reaction of $NHPy_2$ with [Ag(OTf)(PPh_3)] in a 1:1 molar ratio, affords the derivative [Ag($NHPy_2$)(PPh_3)]OTf (**3**). The characteristic vibrations of the dpa ligand appear in the IR spectrum at 1640, 1581 and 3330 cm^{-1}; those corresponding to the OTf anion appear at 1283 and 1097 cm^{-1}. The ^1H NMR spectrum displays a broad resonance at δ = 9.64 ppm, which corresponds to the NH hydrogen atom. Three signals are observed in the δ = 5.5−8 ppm region, one of which involves the phenyl group and two the pyridinic protons. A broad signal at δ = 14.46 ppm is observed in the $^{31}P\{^1H\}$ NMR spectrum at room temperature. When the spectrum is recorded at −50 °C, the signal is split into two doublets, centered at δ = 17.6 ppm, due to the coupling of the phosphorus atom with the two silver isotopomers (J^{109}_{AgP} = 773.2, J^{107}_{AgP} = 678.4 Hz). The LSIMS (+) mass spectrum shows the cationic molecular peak at *m*/*z* = 541 (53%).

The molecular structure of **3** has been determined by X-ray diffraction studies. The geometry at the silver atom is distorted trigonal (Figure 1, Table 1). The major distortion comes from the restricted bite angle of the bidentate ligand [N11−Ag−N21 82.82(9)°], with concomitantly wide values for the other two angles [N11−Ag−P 139.80(7)°; N21−Ag−P 131.22(7)°]. The Ag−N distances [Ag−N11 2.264(2), Ag−N21 2.283(3) Å] are in the range of those observed in [Au_2Ag_2\{μ-(PPh_2)$_2$N\}($OClO_3$)(PPh_3)$_2$][23] [2.239(4) Å], in which the silver centers show trigonal geometries. Longer distances have been found in other silver complexes in which the silver atom is three-coordinate, such as [Ag\{1,2-(C_5H_4NS)$_2$-1,2-$C_2B_{10}H_{10}$\}(PPh_3)]OTf [2.345(2), 2.350(2) Å].[24] The Ag−P distance of 2.3414(8) Å is similar to that found in [Ag\{1,2-(C_5H_4NS)$_2$-1,2-$C_2B_{10}H_{10}$\}(PPh_3)]OTf (2.33832(7) Å] or to the shortest found in [Ag(dppf)(PPh_3)]OTf [dppf = 1,1′-bis(diphenylphosphanyl)ferrocene][25] [2.4244−2.4802(12) Å]. The silver center lies 0.30 Å out of the plane formed by the N11, N21 and P atoms, associated with a contact to a triflate oxygen, Ag−O3 2.725(3) Å. This value is somewhat longer than the 2.601(4) Å in [Ag_4\{μ-$SC_2B_{10}H_{10}$\}$_2$(μ-O_3SCF_3)$_2$(PPh_3)$_4$],[26] but both values can be considered to lie in a typical range for triflate-silver contacts. The same oxygen atom acts as an acceptor for a hydrogen bond from the NH group [N−O 3.021(4), H−O 2.20(2) Å] (Table 2). The overall effect of the two weaker interactions is to produce bands of molecules parallel to the *z* axis (Figure 2). Other "weak" hydrogen bonds of the type C−H···O play a role in the crystal packing; two H···O distances from *para*-H atoms of the phosphane phenyl rings are particularly short (2.31, 2.32 Å), and these H bonds serve to link the ribbons.

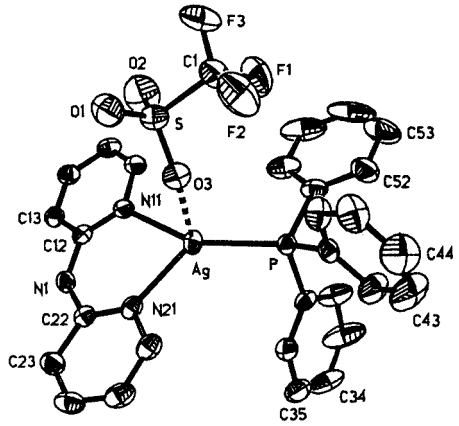

Figure 1. Structure of compound **3**; thermal ellipsoids are drawn with surfaces at the 50% probability level; hydrogens and solvent have been omitted for clarity

Gold(I) complexes have also been obtained by the reaction of Py_2NH with very different starting products (Scheme 1). Thus, the reaction of the ligand with

$[Au(C_6F_5)(tht)]$ in a 1:2 molar ratio affords the dinuclear complex $[Au_2(C_6F_5)_2(\mu\text{-}Py_2NH)]$ (**4**). Apart from the characteristic bands of dpa at 1610, 1532 and 3296 cm^{-1}, the IR spectrum of **4** shows the vibrations of the pentafluorophenyl ring bonded to gold(I) at 1507 and 961 cm^{-1}. In the ^1H NMR spectrum, three of the signals come from the pyridinic protons, one of which integrates for double the value of the others. The NH hydrogen atom resonance appears at $\delta = 8.57$ ppm. The ^{19}F NMR spectrum shows three signals, which correspond to the *ortho, metha* and *para* fluorine atoms. In the LSIMS (+) mass spectrum the molecular peak appears at $m/z = 899$ (68%).

When the reaction is carried out with $PPN[Au(acac)_2]$ in a 2:1 molar ratio, the ligand is deprotonated and the homoleptic derivative $PPN[Au(Py_2N)_2]$ (**5**) obtained. The IR and ^1H NMR spectra confirm the deprotonation of the coordinated ligands. In the ^1H NMR spectrum, once again, one of the signals belonging to the pyridinic protons is overlapped, in this particular case with the broad signal from the phenyl groups of the PPN cation. The anionic molecular peak at $m/z = 537$ (35%) is present in the LSIMS(−) mass spectrum. No crystal suitable for X-ray analyses has been obtained. Tentatively we propose three- or four-coordination at gold, involving coordination to the deprotonated nitrogen atoms and one or two of the pyridinic nitrogen atoms (see Scheme 1).

We have also obtained the palladium complex $[PdCl_2(Py_2NH)_2]$ by displacement of the PhCN ligands in $[PdCl_2(PhCN)_2]$ by Py_2NH. In the IR spectrum the characteristic vibrations of dpa appear at 3490, 1634 and 1587 cm^{-1}. Four resonances for the pyridinic hydrogen atoms, and the signal corresponding to the NH proton at $\delta = 9.50$ ppm, appear in the ^1H NMR spectrum. The LSIMS (+) mass spectrum shows the molecular peak at $m/z = 348$ (11%).

Experimental Section

General Remarks: AgOTf, Py_2NH, PPh_3 and $[PdCl_2(PhCN)_2]$ were purchased from Aldrich and used as received. The starting products $[Au(C_6F_5)(tht)]$,[27] $PPN[Au(acac)_2]$[28] and $[Ag(OTf)(PPh_3)]$[29] were synthesized according to literature methods.

Infrared spectra were recorded in the range 4000−200 cm^{-1} on a Perkin−Elmer FT-IR Spectrum 1000 spectrophotometer as Nujol mulls between polyethylene sheets. Conductivities were measured in ca. 5×10^{-4} M acetone solutions with a Jenway 4010 conductimeter. C, H, N, S analysis was carried out with a Perkin−Elmer 240C microanalyser. Mass spectra were recorded on a VG Autospec using the LSIMS techniques and nitrobenzyl alcohol as matrix and on a HP59987 A ELECTROSPRAY. ^1H, ^{19}F and ^{31}P NMR spectra were recorded on a Bruker ARX 300 in $CDCl_3$ solutions. Chemical shifts are quoted relative to $SiMe_4$ (^1H, external), $CFCl_3$ (^{19}F, external) and H_3PO_4 (85%) (^{31}P, external).

Synthesis of $[Ag(OTf)(Py_2NH)]$ (1): Py_2NH (0.1 mmol, 0.017 g) was added to a diethyl ether solution (20 mL) of Ag(OTf) (0.1 mmol, 0.025 g). The solution was stirred for 30 min. Upon concentration to ca. 5 mL compound **1** precipitated as a white solid (31 mg, yield 76%). $C_{11}H_9AgF_3N_3O_3S$ (428.1): calcd. C 30.85, H 2.10, N 9.8, S 7.45; found C 30.85, H 2.10, N 9.8, S 7.60. Λ_M 107 $\Omega^{-1}cm^2mol^{-1}$. ^1H NMR: $\delta = 7.16$ (dd, $J_{H,H} = 6.53$, 6.51 Hz, 2H-Py), 7.52 (d, $J_{H,H} = 8.74$ Hz, 2H-Py), 7.90 (dd, $J_{H,H} = 7.94$, 7.20 Hz, 2H-Py), 8.20 (br. m, 2H-Py), 11.30 (br. s, 1H-NH) ppm.

Synthesis of $[Ag(Py_2NH)_2]OTf$ (2): Py_2NH (0.2 mmol, 0.034 g) was added to a diethyl ether solution (20 mL) of Ag(OTf) (0.1 mmol, 0.025 g). The solution was stirred for 30 min. Upon concentration to ca. 5 mL compound **2** precipitated as a white solid (45 mg, yield

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

76%). $C_{21}H_{18}AgF_3N_6O_3S$ (599.3): calcd. C 42.05, H 3.0, N 14.0, S 5.35; found C 41.65, H 2.7, N 14.1, S 5.15. Λ_M 119 $\Omega^{-1}cm^2mol^{-1}$. ^1H NMR: δ = 6.88 (br. m, 4H-Py), 7.3 (br. m, 4H-Py), 7.64 (br. m, 4H-Py), 8.11(br. m, 4H-Py) ppm.

Synthesis of [Ag(Py$_2$NH)(PPh$_3$)]·OTf (3). Method (a): Py_2NH (0.1 mmol, 0.017 g) was added to a dichloromethane solution (20 mL) of [Ag(OTf)(PPh_3)] (0.1 mmol, 0.052 g). After stirring for 30 min, the solution was concentrated to ca. 5 mL Addition of diethyl ether afforded **3** as a white solid. **Method (b):** PPh_3 (0.1 mmol, 0.026 g) was added to a dichloromethane solution (20 mL) of [Ag(OTf)(Py_2NH)] (0.1 mmol, 0.043 g). After stirring for 30 min, the solution was concentrated to ca. 5 mL. Addition of diethyl ether afforded **3** as a white solid (64 mg, yield 94%). $C_{29}H_{24}AgF_3N_3O_3PS$ (690.4): calcd. C 50.45, H 3.5, N 6.0, S 4.65; found C 50.2, H 3.2, N 6.25, S 4.7. Λ_M 102 $\Omega^{-1}cm^2mol^{-1}$. ^1H NMR: δ = 6.82 (br. m, 2H-Py), 7.38−7.54 (br. m, 2H-Py+ 15H-Ph), 7.63 (br. m, 2H-Py), 7.93 (br. m, 2H-Py), 9.64 (br. s, 1H-NH) ppm.

Synthesis of [Au$_2$(C$_6$F$_5$)$_2$(μ-Py$_2$NH)] (4): Py_2NH (0.1 mmol, 0.017 g) was added to a solution of [Au(C_6F_5)(tht)] (0.2 mmol, 0.091 g) in dichloromethane (20 mL). The solution was stirred for 30 min. Concentration to ca. 5 mL and addition of diethyl ether afforded **4** as a white solid (59 mg, yield 66%). $C_{22}H_9Au_2F_{10}N_3$ (899.2): calcd. C 29.35, H 1.0, N 4.65; found C 29.4, H 1.45, N 5.15. Λ_M 22 $\Omega^{-1}cm^2mol^{-1}$. ^1H NMR: δ = 7.0 (br. m, 2H-Py), 7.77 (br. m, 4H-Py), 8.29 (br. m, 2H-Py), 8.57 (br. s, 1H-NH) ppm. ^{19}F NMR: δ = −117 (m, 4F, *o-F*), −159.3 (t, 2F, *p-F*, ^3J(FF) 19.64 Hz), −163.1 (m, 4F, *m-F*) ppm.

Synthesis of PPN[Au(Py$_2$N)$_2$] (5): Py_2NH (0.1 mmol, 0.017 g) was added to a solution of PPN[Au(acac)$_2$] (0.05 mmol, 0.047 g) in dichloromethane (20 mL). The solution was stirred for 30 min and then concentrated to ca. 5 mL. Addition of hexane afforded **5** as a white solid (33 mg, yield 31%). $C_{56}H_{46}AuN_7P_2$ (1075.9): calcd. C 62.5, H 4.3, N 9.1; found C 62.7, H 4.1, N 9.45. Λ_M 73 $\Omega^{-1}cm^2mol^{-1}$. ^1H NMR: δ = 6.84 (br. m, 2H-Py), 7.41−7.6 (br. m, 2H-Py+ 30H-Ph), 7.67 (br. m, 2H-Py), 8.26 (br. m, 2H-Py) ppm.

Synthesis of [PdCl$_2$(Py$_2$NH)] (6): Py_2NH (0.1 mmol, 0.017 g) was added to a solution of [$PdCl_2(PhCN)_2$] (0.1 mmol, 0.035 g) in dichloromethane (20 mL). The solution was stirred for 30 min and then concentrated to ca. 5 mL Addition of diethyl ether afforded **5** as a yellow-orange solid (49 mg, yield 95%). $C_{10}H_9Cl_2N_3Pd$ (348.5): calcd. C 34.45, H 2.6, N 12.05; found C 34.15, H 2.65, N 11.80. ^1H NMR: δ = 6.92 (br. m, 2H-Py), 7.33 (br. m, 2H-Py), 7.62 (br. m, 2H-Py), 8.65 (br. m, 2H-Py), 9.50 (br. m, 1H-NH) ppm.

X-ray Crystallographic Study of Compound 3·CH$_2$Cl$_2$: Colorless prism; 0.23 × 0.11 × 0.09 mm. Crystal data: $C_{30}H_{26}AgCl_2F_3N_3O_3PS$, M = 775.34, monoclinic, space group $P2_1/c$, a = 12.0173(14), b = 28.699(3), c = 9.6308(9) Å, β = 102.311(3)°, V = 3245.1(6) Å ^{3}, T = −130 °C, Z = 4, μ = 0.953 mm^{-1}, 32407 reflections (Bruker SMART 1000-CCD, Mo-K_α radiation, $2\theta_{max}$ 56.6°, ω- and φ-scans), 7985 unique. The program SADABS, based on multiple scans, was used for the absorption correction (transmission max., min.: 0.928, 0.732). Solution by direct methods. Refinement on F^2; program system SHELXL-97[30]. Hydrogen atoms riding except for the aminic hydrogen, which was refined freely with an N−H distance restraint. Final $R1$ = 0.0428, $wR2$ = 0.1060, for 401 parameters; S(F^2) 0.930; max. Δρ 0.792 e·Å^{-3}.

CCDC-199151 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

New Alkali Metal Boratabenzenes: Structures of K([18]-Crown-6)(C_5H_5BMe), of the Tetrahydropyran Solvate K(3,5-$Me_2C_5H_3B-NMe_2$)$(THP)_2$, and of Two THF Solvates of K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$][‡]

Keywords: Alkali metal salts / Borabenzene / Boratabenzene / Boron

The potassium salt K(C_5H_5BMe) (**8**) can be obtained from 2-(Me_3Sn)C_5H_5BMe (**7**)/KO*t*Bu in toluene in essentially quantitative yield. Metalation of 1-(dimethylamino)-3-methylene-1,2,3,6-tetrahydroborinine (**9**) with $MN(SiMe_3)_2$ (M = Na, K) in toluene afforded the unsolvated salts M(3,5-$Me_2C_5H_3B-NMe_2$) (M = Na: **11**; M = K: **12**). Morpholino derivatives M(3,5-$Me_2C_5H_3B-NC_4H_8O$) (M = Li: **17**; M = Na: **18**) and the potassium salt K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$] (**19**) were obtained similarly. The unsolvated salts are highly air- and water-sensitive, colorless powders. Crystallization with the help of auxiliary Lewis bases provided crystalline solvates K([18]-crown-6)(C_5H_5BMe) (**20**), K$(THP)_2$(3,5-$Me_2C_5H_3B-NMe_2$) (**21**), and the concomitant pseudopolymorphs K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$]$(THF)_{4/3}$ (α-**22**) and K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$]$(THF)_{3/2}$ (β-**22**), which were characterized structurally. The structures of α-**22** (space group *C*2/*c*) and β-**22** (space group 6_122) display novel chain forms, which have no precedents in boratabenzene and cyclopentadienide chemistry.

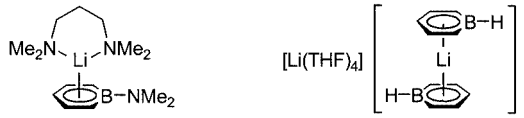
Introduction

The first boratabenzene salts (salts with anions of type **1**[2]) and the first transition metal complexes[3] with boratabenzene ligands were obtained in the very early 1970s. It soon became apparent that boratabenzene ions **1** are similar to the cyclopentadienide ion Cp^- (**2**).[4]

1 **2**

The structural characterization of boratabenzene salts was a relatively late achievement. The first structure determination was published in 1993, and characterized the TMPDA solvate of lithium 1-(dimethylamino)boratabenzene, Li(TMPDA)($C_5H_5B-NMe_2$) [TMPDA = $Me_2N(CH_2)_3NMe_2$] (**3**).[5a] The year 1995 saw the next two structure determinations, that of Li$(C_5H_5BH)(THF)_2$, which was found to possess an ionic structure [Li$(THF)_4$][Li$(C_5H_5BH)_2$] (**4**) with a sandwich-type anion,[5b] similar to the lithocenate ion,[6] and that of the ammonium salt $Me_3PhN(C_5H_5BMe)$ (**5**) with a naked boratabenzene ion.[5c]

More recently, the *B*-styryl derivative Na(OEt_2)[(*E*)-$C_5H_5BCH=CHPh$] (**6**) was found to be the first example of a zigzag chain structure in a boratabenzene salt.[5d] With the growing number of known structures it is becoming more and more evident that the structural chemistry of the ionic boratabenzenes is closely similar to that of the ionic cyclopentadienides.[7]



3 **4**

5 **6**, R = (*E*)-CH=CHPh

A variety of synthetic approaches to boratabenzene salts are now available. Deprotonation of dihydroborinines was the final step of the "tin route" to borabenzene derivatives in the very first generation of a boratabenzene salt, Li(C_5H_5BPh).[2a] Deprotonation of dihydroborinines has developed into the most versatile method, with a large variety of deprotonation reagents (including Li*t*Bu, LDA, NaH, and NaCp). Methods based on the "cobaltocene route" include the cyanide degradation of the cobalt sandwich

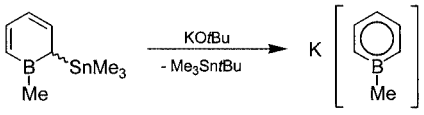
complexes $Co(C_5H_5BR)_2$ to give the first potassium salts $K(C_5H_5BR)$ (R = Me, Ph),[2b] and the reductive degradation of these complexes by elemental lithium, sodium amalgam, and Na/K alloy, which are now of only historical interest.[2d] From 1993 onwards, the renaissance of borabenzene and boratabenzene chemistry was very strongly stimulated by three new and efficient syntheses. The base-induced cyclization of pentadienylboranes,[5a,5c] and the related "dicarbanion route"[8] were based on classical lithiation and kaliation reactions, while a modification of the tin route provided the borabenzene adduct $C_5H_5B-PMe_3$ as a storage form of the borabenzene ring, and subsequent nucleophilic displacement of the Lewis base PMe_3 afforded a large variety of boratabenzene salts with Li, Na, and K counter ions.[5b,9]

In this paper we describe several new alkali metal boratabenzenes. We present four structure determinations, some of which display new structural motifs.

Results and Discussion

A New Synthesis of Potassium 1-Methylboratabenzene

While lithium 1-methylboratabenzene $Li(C_5H_5BMe)$ can readily be prepared in 10−40 g lots,[5c] the higher Na and K homologues have only been obtained in small quantities because of the practical limitations of the cobaltocene route.[2b−2d] In this work we used 2-$(Me_3Sn)C_5H_5BMe$ (**7**),[10] readily available by treatment of $Li(C_5H_5BMe)$ with Me_3SnCl,[10] as precursor for the preparation of the potassium salt $K(C_5H_5BMe)$ (**8**). Treatment of **7** with KO*t*Bu in toluene at ambient temperature slowly (24 h) produced **8** as a microcrystalline precipitate (Scheme 1). Workup by filtration and washing with hexane gave spectroscopically (NMR) pure samples of **8** in essentially quantitative yield. The reaction can by catalyzed by traces of pyridine, as evidenced by the much faster formation of the precipitate **8**. Earlier work had shown that the tin compound **7** displays a heterolytic equilibrium when traces of DMSO or pyridine are present;[10] the formation of $[Me_3Sn(py)_x]^+$ and $C_5H_5BMe^-$ ions is presumably the main cause of the observed catalytic effect.



7 **8**

Scheme 1

Syntheses of Aminoboratabenzene Salts

The dicarbanion route provides a particularly efficient route to boratabenzene salts. With 2,4-dimethylpentadienes as starting materials, the dicarbanion route affords the 3-methylene-1,2,3,6-tetrahydroborinine **9** as primary product[8] and, after catalyzed isomerization, a mixture of the dihydroborinines **10a** and **10b**[8] in yields of up to 40%.[11] Metalation, with LDA/TMEDA in THF, for example, produces the lithium salt $Li(3,5\text{-}Me_2C_5H_3B-NMe_2)$ as a crystalline TMEDA solvate,[8] and with $LiN(SiMe_3)_2$ in hexane (or other hydrocarbon solvents) the unsolvated salt.[11] In this work we used the bases $NaN(SiMe_3)_2$ and $KN(SiMe_3)_2$ in toluene and obtained the homologous unsolvated salts $Na(3,5\text{-}Me_2C_5H_3B-NMe_2)$ (**11**) and $K(3,5\text{-}Me_2C_5H_3B-NMe_2)$ (**12**) as colorless powders.

11: $Na(3,5\text{-}Me_2C_5H_3B-NMe_2)$

12: $K(3,5\text{-}Me_2C_5H_3B-NMe_2)$

In many situations it is desirable to replace the *B*-(dimethylamino) substituent by other groups. This may be achieved by a two-step procedure (Scheme 2). Firstly, the dimethylamino compound mixture **10a/10b** is treated with BCl_3 to give the chloro derivatives **13a** and **13b**.[11] In a second step, the new substituent at the boron atom is introduced in many cases by treatment with a secondary amine/NEt_3. In this way we obtained the morpholino derivatives **14a** and **14b**, which after deprotonation by $LiN(SiMe_3)_2$ and $NaN(SiMe_3)_2$ gave the new salts $Li(3,5\text{-}Me_2C_5H_3B-NC_4H_8O)$ (**17**) and $Na(3,5\text{-}Me_2C_5H_3B-NC_4H_8O)$ (**18**) in high yields. Analogously, (*S*)-2-(methoxymethyl)pyrrolidine (SMPH) was used to produce the already published *B*-SMP compounds.[12] With bis(trimethylsilyl)amine, the lithium salt $Li[3,5\text{-}Me_2C_5H_3B-N(SiMe_3)_2]$ had previously been prepared.[11a] Use of $KN(SiMe_3)_2$ in toluene as the base afforded the homologous unsolvated potassium salt $K[3,5\text{-}Me_2C_5H_3B-N(SiMe_3)_2]$ (**19**) as a colorless powder.

Crystalline Solvates

The new alkali metal boratabenzenes **8**, **11**, **12**, **17**, **18**, and **19** are all microcrystalline powders. Crystallization requires the use of donor solvents and generally produces solvates. Hence, the 1-methylboratabenzene **8** could be dissolved in a warm mixture of toluene/CH_2Cl_2 containing [18]-crown-6 and, when the system had cooled to ambient temperature, gave the solvate K([18]-crown-6)(C_5H_5BMe) (**20**) as crystalline blocks in high yield. Crystallization of the potassium compound **12** from toluene/tetrahydropyran gave the crystalline solvate $K(THP)_2$(3,5-$Me_2C_5H_3$-B−NMe_2) (**21**); the number of tetrahydropyran molecules in this compound was deduced from ^1H NMR spectroscopic data and later confirmed by a structure determination. The bis(trimethylsilyl)amino derivative K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$] (**19**) could be crystallized from THF and, unexpectedly, produced a mixture of two concomitant pseudopolymorphs[13] K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$]$(THF)_x$ with slightly different THF contents: α-**22** with 4/3 mol-equiv. of THF, and β-**22** with 3/2 mol-equiv. THF. The two compounds are not true polymorphs, because their compositions are not fully equal. Note also that two crystalline phases can only be formed in the same system as the result of kinetic control.

20: K([18]-crown-6)(C_5H_5BMe)

21: $K(THP)_2$(3,5-$Me_2C_5H_3B-NMe_2$)

α-**22**: K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$]$(THF)_{4/3}$ ≈ $[K(THF)]_2[K(THF)_2][3,5\text{-}Me_2C_5H_3B-N(SiMe_3)_2]_3$

β-**22**: K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$]$(THF)_{3/2}$ ≈ $[K(THF)]_2$[3,5-$Me_2C_5H_3B-N(SiMe_3)_2]_2(THF)$

Crystal Structures

The crown ether adduct **20** crystallizes in the orthorhombic space group $Pna2_1$ as a van der Waals crystal (Figure 1). The molecule is a contact ion pair of the cation $[K([18]\text{-crown-6})]^+$ and the anion $[C_5H_5BMe]^-$. The structural type is therefore the same as that of the known salts K([18]-crown-6)($C_5H_5B-NPh_2$) and K([18]-crown-6)($C_5H_5B-PPh_2$).[16] The observed rotational disorder of the crown ether ligand could readily be resolved.

The boratabenzene ring is essentially planar, with a maximum perpendicular deviation of 0.011(6) Å for the boron atom. The intra-ring geometry [C−B = 1.510(8) (av), C−C = 1.382(7) Å (av)] does not differ from that of $Me_3PhN(C_5H_5BMe)$ (**5**) [C−B = 1.500(3) (av), C−C = 1.390(3) Å (av)]. The K−C distances average 3.179(5) Å and are significantly shorter than those in K([18]-crown-6)($C_5H_5B-NPh_2$) [3.241(7) Å (av)] and K([18]-crown-6)($C_5H_5B-PPh_2$) [3.259(5) Å (av)],[16] presumably because of the much smaller *B*-exocyclic substituent in **20**.

The bis(tetrahydropyran) solvate **21** forms monoclinic crystals of space group *C*2/*c* with a zigzag chain structural motif (Figure 2). The potassium atom displays a pseudo-tetrahedral coordination sphere as previously observed in, for example, the structure of $K(py)_2Cp^*$.[17] The interplanar angle between two neighboring boratabenzene rings is 53.1(1)°, and the metal−boratabenzene distances amount to 2.818(3) and 2.834(3) Å. Since the boratabenzene ring interacts with two potassium cations almost symmetrically, the C_5B moiety is located in a perfect plane [maximum vertical deviation: 0.003(3) Å for C1]. In contrast with this situation, compounds with nonbridging boratabenzene ligands show a folding of the ring, with the boron atom always bending away from the central metal atom. This effect is particularly pronounced for 1-aminoboratabenzenes coordinated to highly charged centers. For instance, in ScCl(3,5-$Me_2C_5H_3B-NiPr_2)_2$ the folding angle of the C_5 plane against the C_2B plane amounts to 13°.[1]

The THF solvate K[3,5-$Me_2C_5H_3B-N(SiMe_3)_2$]$(THF)_{4/3}$ (α-**22**) crystallizes in the monoclinic space group *C*2/*c*; the asymmetric unit contains two independent THF molecules, 1.5 independent cations K^+, and 1.5 independent anions. The structure of α-**22** (Figures 3 and 4) displays two kinds of potassium atoms − K1 and K2, in a 2:1 ratio − with rather different coordination environments.

A representative fragment of the structure of **21** in the crystal (asymmetric unit and one anion in addition) (PLATON plot[14] at the 30% probability level); selected interatomic distances [A]: K−C1 3.282(4), K−C1′ 3.235(4), K−C2 3.139(4), K−C2′ 3.158(4), K−C3 3.021(4), K−C3′ 3.086(5), K−C4 3.055(4),K−C4′ 3.108(4), K−C5 3.188(5), K−C5′ 3.185(4), K−B 3.344(5), K−B′ 3.290(4), K−O1 2.719(3), K−O2 2.757(3), C1−C2 1.383(5), C2−C3, 1.396(4), C3−C4 1.395(4), C4−C5 1.365(5), C1−B,1.501(5), C5−B 1.502(5), N−B 1.468(5)

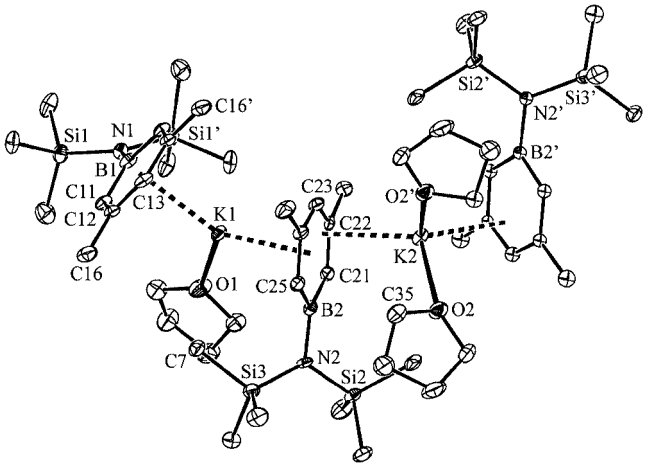

Figure 3. A representative fragment of the structure of α-**22** (PLATON plot[14] at the 30% probability level); the atoms K2, N1, C13, and B1 lie on twofold axes; selected interatomic distances [A]: K1−C11 3.243(5), K1−C11′ 3.250(4), K1−C12, 3.046(5), K1−C12′ 3.072(4), K1−C13 2.952(3), K1−B1 3.383(5); K1−C21 3.147(5), K2−C21 3.417(5), K1−C22 3.013(3), K2−C22 3.096(5), K1−C23 3.010(5), K2−C23 3.004(5), K1−C24 3.162(5), K2−C24 3.263(5), K1−C25 3.309(5), K2−C25 3.572(5), K1−B2 3.310(5), K2−B2 3.686(6); K1−O1 2.601(4), K2−O2 2.720(3); C11−C12 1.388(6), C12−C13 1.413(6), C11−B1 1.524(6), N1−B1 1.490(9); C21−C22 1.404(6), C22−C23 1.411(6), C23−C24 1.378(7), C24−C25 1.409(6), C25−B2 1.506(7), C21−B2 1.515(7), N2−B2 1.530(6); note also: K1···C7 3.422(5), K2···C35 3.451(6)

The atom K1 is surrounded, essentially in a trigonal mode, by an oxygen atom of a THF ligand and two bridging μ-boratabenzene ligands. Ligand **A** (B1, C11−C13, N1, etc.) occupies a special position, with the B1, C13, and N1 atoms lying on a crystallographic twofold axis, whereas ligand **B** (B2, C21−C25, N2, etc.) is in a general position. Both boratabenzene rings are planar [with vertical displacements of less than 0.007(5) Å] and are facially bonded to K1. The distances between the metal atom and the two C_5B planes are quite small [K1−**A** 2.781(3), K1−**B**: 2.794(3) Å], and the interplanar angle between the two rings is 44.6(2)°.

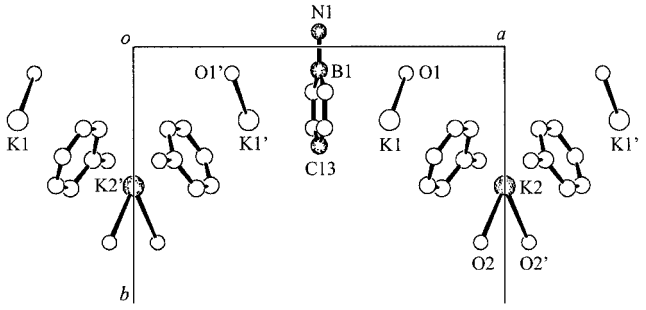

Figure 4. Simplified packing diagram (along *c* axis) of the structure of α-**22**;[15] only the K, O, and C_5B−N (boratabenzene) fragments are displayed; the atoms lying on twofold axes (K2, C13, B1, N1) are shown as dotted spheres

The potassium atom K2 is located on a twofold axis and exhibits a tetrahedral coordination sphere, being bonded to two THF oxygen atoms and to two boratabenzene ligands **B**. The more crowded geometry around the atom K2 causes the cation to slip away from the boratabenzene ring center, and the lengths K2−C25 [3.572(5) Å] and K2−B2 [3.686(6) Å] adopt rather large values. As expected, both the distance of the metal atom to the boratabenzene plane [2.924(3) Å] and the interplanar angle between the two boratabenzene planes [56.2(2)°] are much larger than the corresponding parameters involving the potassium atom K1. Obviously, the observed soft bonding situation is in line with the essentially electrostatic character of the potassium−boratabenzene interactions.

The packing of α-**22** can be explained with the help of a simplified diagram (Figure 4). It seems somewhat surprising that the one-dimensional polymer develops along the shortest lattice axis *a* [*a* = 14.924(5) Å; cf. *b* = 29.307(5) and *c* = 17.385(4) Å]. More unexpectedly, the polymer is not arranged in a zigzag chain, since the dihedral angle K2,K1,K1′,K2′ is less than 180°, even less than 90°. This novel structural motif has not previously been encountered in cyclopentadienyl chemistry.

Since K^+ is a rather large cation (ionic radius *r* = 1.51 Å for coordination number 8),[18] it tends to have short contacts, as observed in the present case [K1···C7 3.422(5), K2···C35 3.451(6) Å]. Besides packing forces, additional electrostatic interactions may favor the occurrence of short contacts. This is presumably the dominating cause for the short contact K1···C7, which places the negative charge of an *Si*-methyl group close to the cation.

The pseudo-polymorph K[3,5-$Me_2C_5H_3B$−$N(SiMe_3)_2$]-$(THF)_{3/2}$ (β-**22**) crystallizes in the hexagonal space group $P6_122$ with twelve boratabenzene moieties per unit cell (Figures 5 and 6). One molecule of THF per formula unit is coordinated to the cation, while 0.5 mol-equiv. of THF function solely as a space filling building block. The polymer chain extends along the lattice axis *c*, which is much

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

longer than the others [c = 62.2944(17) Å; cf. a = b = 11.9545(2) Å].

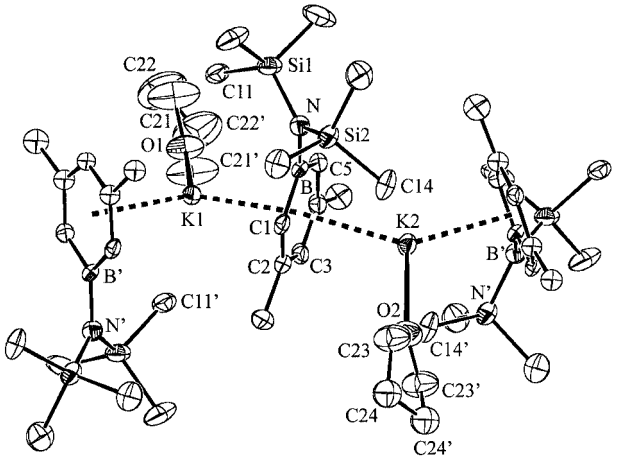

Figure 5. A representative fragment of the structure of β-**22** (PLATON plot[14] at the 30% probability level); the potassium atoms K1 and K2 lie on the twofold axes; selected interatomic distances [Å]: K1−C1 3.169(6), K2−C1 3.209(5), K1−C2 3.079(5), K2−C2 3.093(5), K1−C3 3.053(5), K2−C3 3.021(6), K1−C4 3.139(5), K2−C4 3.070(6), K1−C5 3.236(6), K2−C5 3.166(6), K1−B 3.278(6), K2−B 3.289(6); K1−O1 2.718(7), K2−O2 2.734(8); C1−C2 1.386(8), C2−C3 1.396(8), C3−C4 1.399(9), C4−C5 1.391(9), C1−B 1.508(8), C5−B 1.509(9), N−B 1.502(8); note also: K1···C11 3.328(6), K2···C14 3.311(6), K1···K2 5.599(2)

The K1−O1 and K2−O2 vectors coincide with twofold axes, and so the two potassium atoms possess trigonal coordination spheres. The distances from K1 and K2 to the best boratabenzene C_5B plane are 2.809(3) and 2.788(3) Å, respectively, and the bending angles of the sandwich units around K1 and K2 correspond to 133.3(2) and 140.5(2)°. The bridging boratabenzene ring is again planar [with a maximum vertical deviation of 0.007(6) Å for C5] and its intra-ring geometry is quite similar to that in α-**22**. We also again note the occurrence of short contacts between *Si*-methyl groups and the cations [K1···C11 3.328(6), K2···C14 3.311(6) Å].

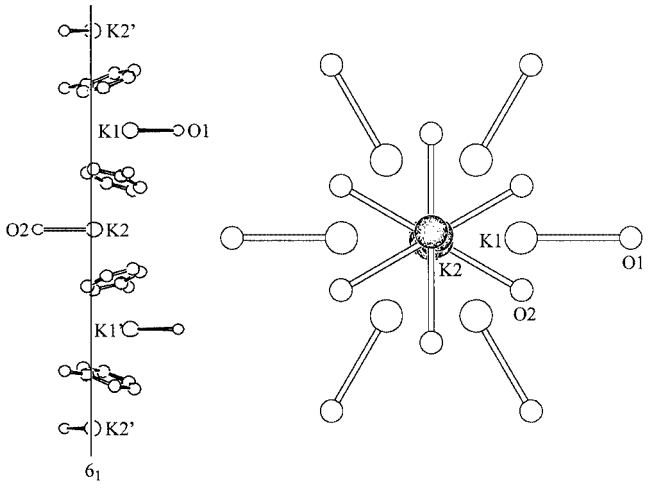

Figure 6. Simplified packing diagrams of the structure of β-**22**;[15] (a) left: view perpendicular to the sixfold screw axis 6_1 (direction [110]); only the K, O, and C_5B−N (boratabenzene) fragments are displayed; (b) right: view along the screw axis (direction [001]), showing only the K and O atoms

As shown in Figure 6 (a), the distance of K1 from the 6_1 axis (2.22 Å) is much larger than that of K2 (0.15 Å). As a consequence, the hexagonal helix of the symmetry-related cations K2 nearly coincide with the 6_1 axis whereas the cations K1 form an alternating outer hexagonal screw.

Conclusion

The structures of boratabenzene salts now known are collected in Table 1. They belong to one of four types: structures with naked anions (type A), contact ion pair structures (type B), structures with sandwich-type anions (type C), and chain structures with side-on-coordinated donor

molecules (type D). We note that the disorder found in the structure of **20** may be understood as the consequence of the shape of the auxiliary base present. Simple crown ethers should be much more prone to disorder than the dibenzo crown ethers used in some of the previously studied compounds. Chain structures may be simple zigzag chains as in **6** and **21** but, as this work shows, may also be of much more complex types. Finally, we note that the structure elucidation of the simple, unsolvated alkali metal cyclopentadienides MCp (M = Li, Na, K) belongs to the milestones of cyclopentadienide chemistry.[22] The analogous structures of the most simple, unsolvated alkali metal boratabenzenes [M(C_5H_5BR), for instance with M = Li, K and R = H, Me, Ph] still wait to be resolved, however.

Experimental Section

General: All manipulations were carried out under nitrogen by use of standard Schlenk techniques. Et_2O, THF, and THP were distilled from sodium benzophenone ketyl. Hexane was distilled from Na/K alloy, toluene from sodium, and CH_2Cl_2 from CaH_2. Elemental analyses were performed at the Analytische Laboratorien, 51779 Lindlar, Germany. NMR spectra were recorded with a Varian Unity 500 (^{1}H, 500 MHz; ^{13}C, 125.7 MHz; ^{11}B, 160.4 MHz). Chemical shifts are given in ppm; they are referenced to TMS for ^{1}H and ^{13}C, and to $BF_3{\cdot}OEt_2$ for ^{11}B. Electron-impact mass spectra were recorded with a Finnigan MAT-95 at a nominal electron energy of 70 eV.

Potassium 1-Methylboratabenzene (8) and Its [18]-Crown-6 Solvate (20): 1-Methyl-2-(trimethylstannyl)-1,2-dihydroborinine (1.02 g, 4.00 mmol) was added to a solution of KO*t*Bu (0.44 g, 3.92 mmol) in toluene (20 mL). The reaction mixture was stirred at room temperature for 24 h, and a fine white precipitate formed during this time. The precipitate was collected by filtration through a frit, washed with hexane (3 × 10 mL), and dried under high vacuum to afford **8** (0.50 g, 98%) as a moisture- and air-sensitive, white powder. The potassium salt **8** (0.286 g, 2.20 mmol) and [18]-crown-6 (0.607 g, 2.30 mmol) were dissolved at 50 °C in a mixture of toluene and CH_2Cl_2 (8:1, 45 mL). The solution was stored overnight at ambient temperature to give the solvate **8**·([18]-crown-6) (≡ **20**) (0.711 g, 82%) as large, colorless, crystalline blocks.

Data for 8: ^{1}H NMR (500 MHz, [D$_8$]THF, 20 °C): δ = 0.44 (s, BMe), 5.91 (tt, *J* = 6.9, 0.9 Hz, 4-H), 6.23 (dd, *J* = 9.4, 0.9 Hz, 2-/6-H), 7.01 (dd, *J* = 9.4, 6.9 Hz, 2 H, 3-/5-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, [D$_8$]THF, 20 °C): δ = 4.6 (br., BMe), 109.1 (C-4), 127.6 (br., C-2,6), 133.3 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, [D$_8$]THF, external $BF_3{\cdot}OEt_2$, 20 °C): δ = 35.4 ppm.

Data for 20: ^{1}H NMR (500 MHz, CD_2Cl_2, 20 °C): δ = 0.54 (s, BMe), 3.56 (s, 12 OCH_2), 5.32 (tt, *J* = 7.0, 1.2 Hz, 4-H), 6.29 (dd, *J* = 9.8, 1.2 Hz, 2-/6-H), 7.14 (dd, *J* = 9.8, 7.0 Hz, 2 H, 3-/5-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, CD_2Cl_2, 20 °C): δ = 4.6 (br., BMe), 70.4 (OCH_2), 108.8 (C-4), 126.8 (br., C-2,6), 133.4 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, CD_2Cl_2, external $BF_3{\cdot}OEt_2$, 20 °C): δ = 35.3 ppm. $C_{18}H_{32}BKO_6$ (394.36): calcd. C 54.82, H 8.17; found C 54.95, H 7.80.

Sodium 1-(Dimethylamino)-3,5-dimethylboratabenzene (11): Sodium bis(trimethylsilyl)amide in toluene (0.6 M, 27.5 mL, 16.5 mmol) was added dropwise at −78 °C to a solution of 1-(dimethylamino)-5-methyl-3-methylene-1,2,3,6-tetrahydroborinine (**9**, 2.50 g, 16.5 mmol) in toluene (15 mL). The reaction mixture was kept at −78 °C for 1 h and was then warmed to ambient temperature. Stirring was continued for an additional 5 d, and a white precipitate gradually formed. The precipitate was collected by filtration through a frit, washed with toluene (3 × 10 mL), and dried under high vacuum to give **11** (1.75 g, 62%) as a moisture- and air-sensitive, white powder.

Data for 11: ^{1}H NMR (500 MHz, [D$_8$]THF, 20 °C): δ = 2.08 (s, 3-/5-Me), 2.66 (s, NMe_2), 5.16 (s, 4-H), 5.24 (s, 2-/6-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, [D$_8$]THF, 20 °C): δ = 26.0 (3-/5-Me), 39.8 (NMe_2), 102.8 (C-4), 107.6 (br., C-2,6), 142.5 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, [D$_8$]THF, external $BF_3{\cdot}OEt_2$, 20 °C): δ = 32.0 ppm.

Potassium 1-(Dimethylamino)-3,5-dimethylboratabenzene (12) and Its THP Solvate 21: Potassium bis(trimethylsilyl)amide in toluene (0.5 M, 27 mL, 13.5 mmol) was added dropwise at −78 °C to a solution of 1-(dimethylamino)-5-methyl-3-methylene-1,2,3,6-tetrahydroborinine (**9**, 2.04 g, 13.7 mmol) in toluene (10 mL). The reaction mixture was kept at −78 °C for 1 h and was then warmed to ambient temperature. Stirring was continued for an additional 5 d and a white precipitate gradually formed. The precipitate was collected by filtration through a frit, washed with toluene (3 × 10 mL), and dried under high vacuum to give **12** (1.64 g, 64%) as a moisture- and air-sensitive, white powder. Crystallization of **12** (0.27 g) from a mixture of THP and toluene (1:1, 8 mL) at −30 °C overnight afforded **12**·$(THP)_2$ (≡ **21**) as colorless prisms. The ratio of THP to **12** in **21** was established by NMR spectroscopy and X-ray diffraction methods.

Data for 12: ^{1}H NMR (500 MHz, [D$_8$]THF, 20 °C): δ = 2.04 (s, 3-/5-Me), 2.64 (s, NMe_2), 5.13 (s, 4-H), 5.15 (s, 2-/6-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, [D$_8$]THF, 20 °C): δ = 25.9 (3-/5-Me), 39.8 (NMe_2), 103.8 (C-4), 109.0 (br., C-2,6), 142.9 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, [D$_8$]THF, external $BF_3{\cdot}OEt_2$, 20 °C): δ = 33.0 ppm.

3,5-Dimethyl-1-morpholinodihydroborinines (14a, 14b): A mixture of morpholine (1.95 g, 22.4 mmol) and triethylamine (2.33 g, 23.0 mmol) in hexane (10 mL) was added dropwise at 0 °C to the 1-chloro-3,5-dimethyldihydroborines **13a** and **13b** (3.15 g, 22.4 mmol) in hexane (30 mL). A white precipitate of Et_3NHCl formed immediately. After the reaction mixture had been stirred at room temperature for 5 h, the solid was removed by filtration and washed with hexane (3 × 20 mL). The combined filtrates were concentrated to dryness under reduced pressure to afford **14a** and **14b** (3.87 g, 90%, **a/b** = 2:3) as a pale yellow solid, moderately sensitive to air and moisture.

Data for 14a and 14b: ^{1}H NMR (500 MHz, $CDCl_3$, 20 °C): **14a**: δ = 1.64 (s, 2 H, 2-CH_2), 1.98, 1.89 (s, 3-/5-Me), 2.89, 3.37 (t, *J* = 4.5 Hz, 4 H, 2 NCH_2), 3.60 (m, 4 H, 2 OCH_2), 5.66 (s, 1 H, 6-H), 5.76 (m, 1 H, 4-H); **14b**: δ = 1.96 (s, 6 H, 3-/5-Me), 2.81 (s, 2 H, 4-CH_2), 3.42 (t, *J* = 4.6 Hz, 4 H, 2 NCH_2), 3.63 (t, *J* = 4.6 Hz, 4 H, OCH_2), 5.90 (s, 2 H, 2-/6-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, $CDCl_3$, 20 °C): **14a**: δ = 24.1 (br., C-2), 26.1, 26.6 (3-/5-Me), 42.6, 47.0 (2 NCH_2), 68.4 (2 OCH_2), 119.1 (br., C-6), 124.9 (C-4), 143.7 (C-3), 155.4 (C-5); **14b**: δ = 26.5 (3-/5-Me), 42.6 (C-4), 47.5 (2 NCH_2), 68.9 (2 OCH_2), 123.2 (br., C-2,6), 156.4 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, $CDCl_3$, external $BF_3{\cdot}OEt_2$, 20 °C): **14a**: δ = 39.8 ppm; **14b**: δ = 32.6 ppm. MS (EI): *m/z* (%) = 191 (100) [M$^+$], 176 (26) [M$^+$ − Me], 162 (5) [M$^+$ − 2 Me], 105 (14) [$Me_2C_5H_4B^+$], 91 (10) [$MeC_5H_4B^+$]. $C_{11}H_{18}B-NO$ (191.08): calcd. C 69.14, H 9.50, N 7.33; found C 69.05, H 9.57, N 7.45.

Lithium 3,5-Dimethyl-1-morpholinoboratabenzene (17): Lithium bis(trimethylsilyl)amide in hexane (1.0 M, 5.4 mL, 5.4 mmol) was added dropwise at −78 °C to a solution 3,5-dimethyl-1-(morpholino)-dihydroborinines (**14a/14b**, 1.03 g, 5.4 mmol) in diethyl ether (10 mL). The reaction mixture was kept at −78 °C for 1 h and was then warmed to ambient temperature. Stirring was continued for an additional 24 h and a white precipitate formed. The precipitate was collected by filtration through a frit, washed with hexane (3 × 10 mL), and dried under high vacuum to give **17** (1.04 g, 98%) as a moisture- and air-sensitive, white powder.

Data for 17: ^{1}H NMR (500 MHz, [D$_8$]THF, 20 °C): δ = 1.99 (s, 3-/5-Me), 3.06 (t, J = 4.5 Hz, 2 NCH_2), 3.46 (t, J = 4.5 Hz, 2 OCH_2), 5.08 (s, 4-H), 5.09 (s, 2-/6-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, [D$_8$]THF, 20 °C): δ = 25.7 (3-/5-Me), 48.0 (2 NCH_2), 69.3 (2 OCH_2), 103.0 (C-4), 107.1 (br., C-2,6), 142.7 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, [D$_8$]THF, external BF_3·OEt_2, 20 °C): δ = 31.2 ppm. $C_{11}H_{17}BLiNO$ (197.01): calcd. C 67.06, H 8.70, N 7.11; found C 66.90, H 8.74, N 6.89.

Sodium 3,5-Dimethyl-1-morpholinoboratabenzene (18): Sodium bis(trimethylsilyl)amide in toluene (0.6 M, 9.5 mL, 5.70 mmol) was added dropwise at −78 °C to a solution of 3,5-dimethyl-1-(morpholino)dihydroborinines (**14a/14b**, 1.09 g, 5.70 mmol) in toluene (10 mL). The reaction system was kept at −78 °C for 1 h and was then warmed to ambient temperature. The mixture was stirred for 24 h and a white precipitate formed. The precipitate was collected by filtration, washed with toluene (3 × 10 mL), and dried under high vacuum to afford **18** as a moisture- and air-sensitive, white powder (1.09 g, 90%).

Data for 18: ^{1}H NMR (500 MHz, [D$_8$]THF, 20 °C): δ = 2.08 (s, 3-/5-Me), 3.07 (t, J = 4.7 Hz, 2 NCH_2), 3.43 (t, J = 4.7 Hz, 2 OCH_2), 5.21 (s, 4-H), 5.24 (s, 2-/6-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, [D$_8$]THF, 20 °C): δ = 26.0 (3-/5-Me), 48.2 (2 NCH_2), 69.3 (2 OCH_2), 103.7 (C-4), 107.6 (br., C-2,6), 142.7 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, [D$_8$]THF, external BF_3·OEt_2, 20 °C): δ = 32.0 ppm. $C_{11}H_{17}B$−NNaO (213.06): calcd. C 62.01, H 8.04, N 6.57; found C 61.76, H 7.87, N 6.68.

Potassium 1-[Bis(trimethylsilyl)amino]-3,5-dimethylboratabenzene (19) and Its THF Solvates (α- and β-22): Potassium bis(trimethylsilyl)amide in toluene (0.5 M, 9 mL, 4.5 mmol) was added dropwise at −78 °C to a solution of 1-bis(trimethylsilyl)amino-3,5-dimethyl-dihydroborinines (**16a/16b**, 1.2 g, 4.5 mmol) in toluene (10 mL). The system was kept at −78 °C for 1 h and was then warmed to ambient temperature. Stirring was continued for 24 h, and a fine white precipitate formed. The precipitate was collected by filtration through a frit, washed with toluene (3 × 10 mL), and dried under high vacuum to give **19** (1.25 g, 91%) as a moisture- and air-sensitive, white powder. Crystallization of **19** (0.25 g) from THF (5 mL) at −4 °C for a week afforded large, colorless crystals possessing ca. 1.4 equiv. of THF per unit **19** (^{1}H NMR). The concomitant presence of the two pseudo-polymorphs α-**22** and β-**22** was established by X-ray diffraction methods.

Data for 19: ^{1}H NMR (500 MHz, [D$_8$]THF, 20 °C): δ = 0.06 (s, 2 $SiMe_3$), 2.08 (s, 3-/5-Me), 5.43 (t, J = 1.5 Hz, 4-H), 5.52 (d, J = 1.5 Hz, 2-/6-H) ppm. ^{13}C{^{1}H} NMR (126 MHz, [D$_8$]THF, 20 °C): δ = 4.9 (2 $SiMe_3$), 25.7 (3-/5-Me), 107.9 (C-4), 121.9 (br., C-2,6), 141.5 (C-3,5) ppm. ^{11}B{^{1}H} NMR (160 MHz, [D$_8$]THF, external

BF_3·OEt_2, 20 °C): δ = 35.5 ppm. $C_{13}H_{27}BKNSi_2$ (303.45): calcd. C 51.46, H 8.97, N 4.62; found C 51.41, H 8.90, N 4.73.

X-ray Crystal Structure Determinations: Data collections for the compounds **20**, **21**, and α-**22** were performed with ENRAF-Nonius CAD4 diffractometers (Mo- or Cu-K_α radiation with graphite monochromators). The reflection data set for β-**22** was collected with a Bruker Apex X-ray diffractometer (Mo-K_α radiation with a graphite monochromator) equipped with a CCD area detector.[23] Crystal data, data collection parameters, and convergence results are listed in Table 2. Before symmetry-related reflections were merged, empirical absorption corrections on the basis of azimuthal scans[24] were applied to the data sets collected with the Cu-K_α radiation. All structures were solved by direct methods with the help of the SHELXS-97 program[25a] and refined on reflection intensities (F^2) by use of the SHELXL-97 program.[25b] The [18]-crown-6 ligand in the structure **20** suffers from rotational disorder. The two orientations, with an occupancy ratio of 61(1)/39(1), are related to each other by a rotational angle of ca. 20.5°. In the case of **21**, one of the two THP ligands displays flapping disorder (O2, C15−C19/C25−C29); the oxygen atom is well defined whereas all the other atoms split into two sites with an occupancy ratio of 64(1):36(1). Two types of THF are present in the structure of β-**22**; one serves as a ligand to the potassium atom, while the other acts solely as a space-filling molecule. The latter type of THF is disordered into two sites with the oxygen atom (O3) residing on a twofold crystallographic axis. Several restrains were applied in the disordered structural models to set the C−C and C−O distances, respectively, to be equal with a standard deviation of 0.03 Å. In the final structural refinements, non-hydrogen atoms other than disordered ones were assigned with anisotropic displacement parameters. Hydrogen atoms were either refined isotropically or included as riding with fixed displacement parameters [C−H = 0.98 Å, U_{iso}(H) = 1.3 U_{eq}(C)].[26]

Synthesis of (η^3-Allyl)bromodicarbonylbis(pyrazole)molybdenum(II) and Reactivity towards [Au(acac)PPh_3]: Structure and Dynamic Behavior of the Monometallic Pyrazole and Heterometallic Pyrazolate Complexes

Paloma Paredes, Daniel Miguel, and Fernando Villafañe*

Keywords: Molybdenum / Gold / Heterometallic complexes / N ligands / Fluxionality

In our original article,[1] under the heading "Acac Complexes" (page 998) we inadvertently omitted that the use of acac complexes in synthesis has been reviewed.[2] Likewise, [Au(acac)PPh_3] has been used previously to synthesise a heterometallic complex.[3]

COVER PICTURE

The cover picture shows the first example of an isolated organometallic compound containing two terminal alkynes undergoing an intramolecular oxidative coupling. Twenty-two- and twenty-six-membered rings or "metallamacrocycles" are obtained in 18–41% yields. The intramolecular oxidative coupling of organic compounds containing two terminal alkynes has played a critical role in the development of macrocycle chemistry, particularly with annulenes and dehydroannulenes, and macrocyclizations are playing an increasingly important role in organometallic chemistry, particularly as attention turns to architecturally novel types of target molecules that may have applications in materials chemistry or nanotechnology. Details are discussed in the article by J. A. Gladysz et al. on p. 2211 ff.

Metal Ligand Aromatic Cation−π Interactions

Snežana D. Zarić[a,b]

Keywords: Chelates / Density functional calculations / DNA / Hydrogen bonds / Metalloproteins / Pi interactions / RNA

Cation–π interactions are important noncovalent bonding forces. This review covers a special type of cation–π interactions, the metal ligand aromatic cation–π (MLACπ) interaction, where ligands that are coordinated to a metal ion interact with aromatic groups. These interactions have been observed in metalloproteins, metal complexes, biomimetic metal complexes, and when DNA and RNA interact with metal cations. The energy of MLACπ interactions in different systems has been calculated by quantum chemical methods and was found to vary from 1 to 30 kcal/mol.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

1. Introduction

Noncovalent interactions are very important for molecular systems ranging from molecular biology to material science.[1] Cation−π interactions are now recognized as important noncovalent binding forces.[2] In their review, Ma and Dougherty provided an overview of cation−π interactions that covered the nature of the interactions, and described cation−π interactions in artificial receptors and in biological structures.[2]

Since that review was published, a large number of papers have appeared that deal with cation−π interactions, especially in biological systems. Investigations on cation−π interactions in proteins and polypeptides have shown that cation−π interaction pairs contribute at least as much to protein stability and the structural motifs of a native protein as do more conventional noncovalent interactions.[3] In a few recent review articles, some theoretical and experimental aspects of cation−π interactions have been considered.[4]

In this review, a special type of cation−π interaction is considered, namely that in which the cation is part of a metal complex (Figure 1). In this type of cation−π interaction, the ligands that are coordinated to a metal ion interact with π systems. In the case of an aromatic π system, we called this interaction a metal ligand aromatic cation−π (MLACπ) interaction. Figure 1 depicts the NH_3 ligands of the $[Co(NH_3)_6]^{3+}$ cation interacting with benzene. Please note that we do not consider direct interactions of a π system with a transition metal atom, as exist in ferrocene and other sandwich compounds, where the π system interacts with the metal's d orbitals. A number of papers that deal with MLACπ interactions have appeared in the last few years.

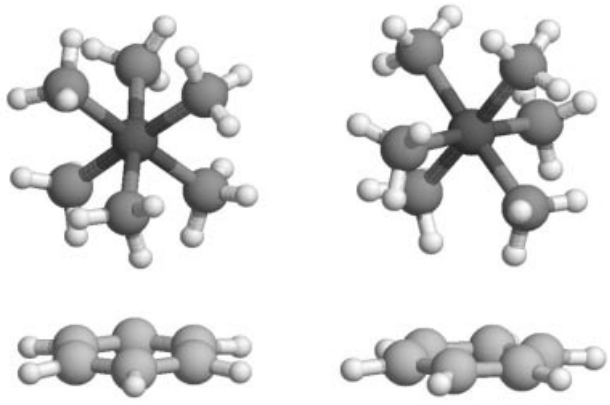

Figure 1. The η_3 and η_2 structures of $[Co(NH_3)_6]^{3+}-C_6H_6$ complexes

In all cases of MLACπ interactions that we report in this article, the ligand participating in the interaction possesses a hydrogen atom pointing towards the π system. By coordinating to a metal cation, ligands acquire partial positive charge that is located mainly on the hydrogen atoms of the ligand that interact with the π system.

Because hydrogen atoms of ligands are interacting with π systems (Figure 1), this interaction may be considered to be an X−H···π bond.[5,11] Because of the positive charge on

the ligands in these MLACπ interactions, the X−H···π bonds are charge-assisted, which increases the strength of the X−H···π bonds and makes these bonds among the strongest of known X−H···π bonds.

Interactions of transition metal complexes with π systems have been predicted by quantum chemical calculations. It was anticipated that predicting the strengths of these interactions would be possible because theoretically calculated bonding energies for cation−π systems are in agreement with experimental data.[6] By using DFT (Density Functional Theory) calculations it has been shown that a cationic metal complex interacts strongly with the π system of benzene.[7] Based on these calculations, we proposed[7] that the cation−π interaction may exist when ligands coordinated to a metal ion can get in close contact with a π system. MLACπ interactions can occur in metalloproteins, metal complexes, supramolecular structures, and when DNA and RNA interact with metal cations.

These theoretical predictions have been supported by experimental evidence. Experimental findings of the interactions between nucleobases of DNA and RNA and cationic metal complexes[8] were published virtually simultaneously with the theoretical results.[7] MLACπ interactions in metalloproteins,[9] metal complexes,[10,11] and biomimetic metal complexes[5a] have been found also in crystal structures. MLACπ interactions in the gas phase[12] and in solution[11] have been investigated by spectroscopic methods in a few examples of metal complexes.

2. Calculations of MLACπ Interactions with Benzene

Calculations that predict a strong interaction of transition metal complexes with π systems have been performed for the interactions of the $[Co(NH_3)_6]^{3+}$ cation with benzene.[7,14] The DFT method was used for these calculations, as the most convenient form of quantum chemical methods, because it is suitable for transition metal complexes. In particular, DFT methods have given good results for all transition metal complexes, including transition metal complexes of the first row.[15] It has also been shown that the DFT method is suitable for studying cation−π interactions. Using the B3LYP method, calculations on the bonding energy of the $NH_4^+-C_6H_6$ complex were in agreement with experimental data.[7] In other calculations, reliable results with the DFT method were obtained also for cation−π systems.[16] Geometries were optimized with a the LANL2DZ basis set, while energies were calculated in a larger basis set (6-31G** basis set for all atoms, except for cobalt where LANL2DZ was used).[14]

The $[Co(NH_3)_6]^{3+}-C_6H_6$ cation−π complex has many possible conformers. Three conformers may exist by considering the number of NH_3 groups of the $[Co(NH_3)_6]^{3+}$ cation interacting with the benzene molecule, namely where the number of NH_3 groups involved in bonding is one (η_1), two (η_2) or three (η_3). The total number of possible conformers is larger, however, because for each of these structures, η_1, η_2 and η_3, the benzene molecule may adopt different orientations.

An η_1 conformer was not obtained as a stable structure in the calculations. Starting with this structure, geometry optimization terminated with a conformer of type η_3. The calculations showed that stationary points were obtained for several η_2 and η_3 structures. In all calculated η_2 and η_3 structures, only one hydrogen atom from each of the participating NH_3 groups interacts with the benzene unit. The geometries and energies of two η_2 structures are very similar; the only difference is in the orientation of the benzene ring. The four optimized η_3 structures are also similar to each other. The difference in energy between the η_3 and η_2 structures is approximately 2 kcal/mol. The most stable η_3 structure has a bonding energy of 32.18 kcal/mol, after basis-set-superposition error (BSSE) correction. Frequency calculations on all the optimized geometries showed that only this structure is an energy minimum. The most stable η_2 and η_3 structures are shown in Figure 1, and their bonding energies and geometric data are shown in Table 1.

Table 1. The bond lengths (in the case of the η_3 structures, the data are average bond lengths, except for H···centroid of the benzene ring) and bonding energies of η_2 and η_3 structures (the most stable conformers for η_2 and η_3 structures, shown in Figure 1) of $[Co(NH_3)_6]^{3+}-C_6H_6$ complex

In the calculated cation−π complexes there are changes caused by the cation−π interaction in the calculated geometries of the $[Co(NH_3)_6]^{3+}$ cation and of the benzene ring. The bond lengths change in the $[Co(NH_3)_6]^{3+}$ cation. Changes are largest for the Co−N bonds directed at the benzene ring (shortened by more than 0.01 Å) and the N−H bonds of hydrogen atoms that are directly involved in the interactions (lengthened by more than 0.01 Å). The hydrogen atoms in the benzene molecule are bent away from the cation. The cation−π interaction also causes some C−C bonds of the benzene ring to lengthen up to 0.008 Å.

Comparing the charges of a separate $[Co(NH_3)_6]^{3+}$ cation and a benzene molecule with the charges of the cation−π complex shows that there is an electron transfer from the π system to the cation. The average charge on the benzene unit in the η_2 structures of the $[Co(NH_3)_6]^{3+}-C_6H_6$ complex is +0.3077, and in the η_3 structures it is +0.3316.[14] The increase in charge transfer

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corresponds to an increase in the strength of the interaction.

The calculated strong interactions existing between the transition metal complex and the aromatic molecule indicate that these interactions can exist in all cases where ligands coordinated to a metal center can get in close contact with aromatic groups. The small difference in energy among different conformers indicates the large number of mutual orientations that can be adopted by the interacting ligands and benzene, and the large degree of variability in conformations that are possible in MLACπ interactions.

Interactions of the $[Co(NH_3)_6]^{3+}$ cation with ethylene and acetylene were also calculated and the bonding energies obtained were 17.02 and 18.30 kcal/mol, respectively.[17]

Calculations on the interactions of $[Mg(H_2O)_6]^{2+}$ with benzene were done using the Hartree−Fock (HF) method and 6-31G* basis set for geometry optimization.[18] Single-point energies at the optimized geometries were calculated by the MP2 method. The calculated bonding energies were corrected for BSSE. In the optimized geometry, three coordinated water molecules are oriented towards the benzene molecule. The hydrogen atoms of the water molecules point towards the C−C bonds of the benzene unit, with the H···C distance to the two closest carbon atoms being 2.56 and 2.79 Å. The elongation of the O−H bonds involved in the O−H···π contact is ca. 0.004 Å. The calculated bonding energy is 21.5 kcal/mol. Similar calculations with $[Zn(H_2O)_6]^{2+}$ gave almost the same geometry and bonding energy (21.3 kcal/mol). For the benzene−sodium hexahydrate complex, the bonding energy was reduced to 9.1 kcal/mol.[18]

It is interesting to compare calculations of the interactions of metal complexes with benzene with those of non-metal cations [$(CH_3)_4N^+$ and NH_4^+] with benzene. In calculated structures where metal complexes or $(CH_3)_4N^+$ interact with benzene, there are three NH_3 ligands or three CH_3 groups oriented towards benzene, while in the NH_4^+−benzene complex there are two hydrogen atoms that interact with benzene.[6h] The calculated bonding energy of benzene−sodium hexahydrate complex (9.1 kcal/mol) is similar to that of the $(CH_3)_4N^+$−benzene complex (ca. 10 kcal/mol),[6h] while the energy of interaction of the NH_4^+−benzene complex is large (ca. 18 kcal/mol).[6h,19a] The energy of interaction of the NH_4^+−benzene complex is relatively close to the bonding energy of metal complexes having a charge of +2, which shows that the positive charge is less dispersed in the NH_4^+ cation than it is in the metal complex cations and $(CH_3)_4N^+$.

In the NH_4^+−benzene complex the closest distance between an H atom (from the cation) and a C atom (from benzene) is 2.436 Å,[19b] and in the $[Co(NH_3)_6]^{3+}$−benzene complex that distance is 2.299 Å.[14] In both of these systems there is electron transfer; in the former, the charge of the benzene unit is 0.265,[19b] and in the latter, as was mentioned previously, it is 0.331.[14] Both features — the interacting distances and charges — are in agreement with the belief that the stronger interactions occur in the $[Co(NH_3)_6]^{3+}$−benzene system than in the NH_4^+−benzene complex.

3. MLACπ Interactions in Metal Complexes

Geometries in Crystal Structures

Intramolecular

Crystal structures of metal complexes containing a phenyl ring and coordinated nitrogen or oxygen atoms, obtained from the Cambridge Structural Database (CSD), were screened for intramolecular cation−π interactions between ligands coordinated to the metal center and the aromatic groups (MLACπ).[10] Geometric criteria were used for screening such that structures were chosen in which the distance between the metal ion and the centroid of the aromatic ring is less than d_0 = 5.5 Å (Figure 2). No restrictive criteria were used for the angle of the normal of the aromatic ring plane with the distance vector between the centroid of the aromatic ring and the metal ion, since intramolecular interactions were being investigated. It was found that the interaction is stronger if the hydrogen atom that interacts with the aromatic group is closer to the metal center,[9] and hence, structures were considered only in which there are two bonds between the hydrogen atom and the metal ion.

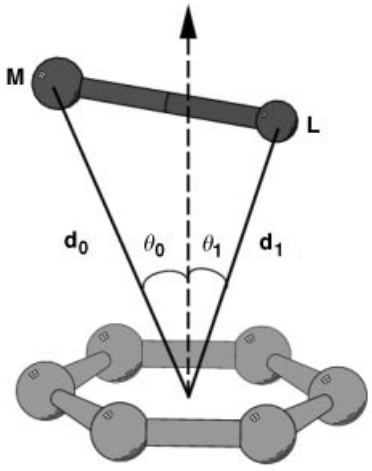

Figure 2. Distances (d_0, d_1), and angles (θ_0, θ_1) used to search for and characterize MLACπ interactions; M is a metal cation, L is a non-hydrogen atom ligand (L) closest to the ring centroid; the dashed line is the normal of the aromatic ring plane

It was found that intramolecular MLACπ interactions, between a coordinated ligand and the aromatic ring in the same complex, were observed in a number of crystal structures of transition metal complexes. Data concerning the MLACπ interactions in different crystal structures are compiled in Tables 2 and 3. The data show that there are numerous metal complexes in which there is close contact between an aromatic ring and a ligand and that different metal ions and ligands can be involved.

[a] Heavy atom to which the interacting hydrogen atom is bound. [b] The distance between the heavy atom and the centroid of the aromatic ring. [c] The distance between the interacting hydrogen atom and the centroid of the aromatic ring. [d] The distance between the heavy atom and the closest carbon atom of the aromatic ring. [e] The distance between the interacting hydrogen atom and the closest carbon atom of the aromatic ring. [f] The atom between the metal ion and the aromatic ring.

In most of the complexes there are two or four bonds between the metal ion and the aromatic ring. The aromatic ring of an organic ligand can interact with a hydrogen atom of the other ligand, or with a hydrogen atom of the same ligand.

In complexes where there are only two bonds between the aromatic ring and the metal ion (Table 2) there is the possibility for the MLACπ interaction only with the ligand coordinated in the *cis* position and there is no possibility for an MLACπ interaction within the same ligand. In this group of complexes there is little freedom for the ligands to adjust their mutual orientations.

In structures with more than two bonds between the metal ion and the aromatic ring (Table 3) there is the possibility for MLACπ interactions with the hydrogen atom of the other ligand, but also with the hydrogen atom of the same ligand. There are fewer steric constraints in cases where there are interactions with hydrogen atoms of another ligand, and in these cases the distances of the interaction to the center of the ring are shorter.

These results show that steric constraints in the intramolecular MLACπ interactions in the complexes have an important influence on their geometry and, probably, the strength of these interactions.

Kumita et al. studied intramolecular interactions between a ligand and an aromatic ring using different experimental methods.[11] They observed these interactions in the crystal structures of K[Co(L)(aa)] [L = *N*,*N*-bis(methoxycarbonyl)-(*S*)-phenylalanine; aa = (*S*)-Phe, (*R*)-Phe, (*S*)-Trp] complexes. In these structures there are intraligand interactions with the distances between amino hydrogen atoms and the plane of the phenyl ring in the range 2.61−2.82 Å. Similar interactions were observed in the complex K[Co{*N*,*N*-bis(methoxycarbonyl)-(*S*)-leucine}-(*S*)-Phe].[61] Although there is the possibility, however, for intraligand interactions in complexes with aromatic amino acids as ligands, they do not always occur[62] since they depend very much on the interplay with other ligands in the complex; this feature shows that these interactions are in balance with other noncovalent interactions.

[e] The distance between the interacting hydrogen atom and the closest carbon atom of the aromatic ring.

Some C−H···π interactions, where the C−H unit is part of the ligand, have also been observed in metal complexes.[63] If the C−H groups are not very close to the metal ion there is no difference between these C−H···π interactions and those in organic molecules.[63a,64]

Intermolecular

Intermolecular interactions between hydrogen atoms and π systems have been observed in organometallic crystals.[5a] Investigation of these interactions show that they are common and appear to be typical hydrogen bonds. Many of these organometallic structures are ionic compounds. In most cases it has been shown that charge-assisted ($X-H^{\delta+}\cdots\pi^{\delta-}$) interactions possess shorter distances than neutral X−H···π bonds. It should be noted that in this study an X−H group was not always part of a ligand coordinated to a metal ion, but instead was part of any other molecule in the crystal structure.[5a]

Calculated Intramolecular MLACπ Interactions

DFT calculations were done on model systems with relatively small ligands to evaluate the energy of intramolecular MLACπ interactions.[10] The geometries and energies were calculated for structures with various conformations of the aromatic ring in the model systems. Based on the difference in energy for conformers with and without MLACπ interactions, the energy of the interactions was evaluated for model systems of cationic complexes of Co^{III} having a total charge of +1.

The calculations on complexes with two bonds between the aromatic ring and the metal ion were done on the model system $[CoCl_2(NH_3)_3(C_6H_5NH_2)]^+$. The coordinated aniline unit is in the *cis* position relative to the two NH_3 and two Cl^- ligands. The energy was calculated for the structure where the aromatic ring is positioned above either an NH_3 or Cl ligand. Based on the difference in energy between these two conformers, the energy of the MLACπ interaction was evaluated to be ca. 4 kcal/mol for this model system.

The $[CoCl(NH_3)_3Phe]^+$ complex was used as a model system to study the interactions in complexes having several bonds between the aromatic ring and the metal ion (Figure 3). There are three possible conformations of the phenyl ring in the coordinated phenylalaninato ligand. In one conformer there are no MLACπ interactions, in the second there is only an intraligand interaction, and in the third

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

there are intraligand and interligand interactions. Based on the differences in the energy of these conformers, the energies of intraligand and interligand interactions were evaluated to be ca. 3.5 and 4 kcal/mol, respectively.[10]

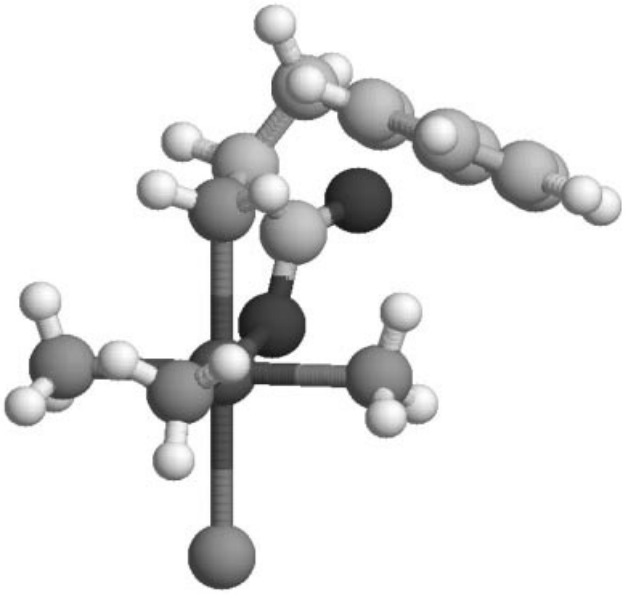

Figure 3. Model systems $[CoCl(NH_3)_3Phe]^+$ used for calculations of intramolecular metal ligand aromatic cation−π (MLACπ) interactions in metal complexes

Spectroscopic Evidence

IR Spectra

Interactions of a benzene unit with water molecules coordinated to K and Na ions were observed using infrared spectroscopy in gas-phase cluster ions of the form $M^+(C_6H_6)_n(H_2O)_m$, with M = Na or K.[12,13] Vibrational-predissociation spectroscopy indicates details of the structure because the OH stretching frequency of water is extremely sensitive to changes in its bonding environment. In the $K^+(C_6H_6)_3(H_2O)_1$ complex the stretching modes of water are very similar to that of free water. The introduction of a fourth benzene molecule significantly affects the OH spectrum, which is indicative of hydrogen bond formation.[12]

The O−H···π hydrogen bond was observed also in $K^+(C_6H_6)_5(H_2O)$, where a water molecule and three benzene molecules are bonded directly to the K^+ ion, and the fourth and fifth benzene molecules are bound to the coordinated water molecule. The interaction of the benzene molecules with the coordinated water molecule is observed by a shift in vibrational frequencies of the O−H stretching mode towards smaller wavenumbers by ca. 70 cm^{-1}. Vibrational spectra can also indicate differences in the strengths of hydrogen bonds in cases when there is a neutral benzene−water complex, and when water is bonded to a K^+ ion. The bonding of a water molecule to the ion enhances the π−hydrogen bond between the water and benzene molecules, leading to an additional shift in the OH stretching frequency.[12]

In the case of Na^+ ions, the most interesting complex is the self-assembled cluster ion, $Na^+(C_6H_6)_8(H_2O)_4$, which has a single structure of an inner shell of four water molecules and an outer layer of eight benzene molecules, each of the latter being fixed by a π−hydrogen atom bond to one of the eight interior O−H groups. The intense narrow bands observed in the vibrational spectra of $Na^+(C_6H_6)_8(H_2O)_4$ indicate a stable cluster ion configuration with eight H−π bonds.[13]

CD Spectra

The CD spectra of *trans*-(N)−K[Co(bcmpa)(aa)] (aa = amino acid) complexes were measured in a study of N−H···π interactions in Co^{III} complexes with amino acids.[11] The CD spectra of these complexes have four components in the d−d region. For one of these bands, there are indications that its origin can be attributed to a chiral amino acid, and the same band exhibited a solvent effect that is related to the vicinal effect of chiral amino acids. For complexes with aromatic amino acids [(*S*)-Trp, (*S*)-Phe, (*S*)-Tyr], there is a significant difference in the intensity of the band in aqueous and ethanol solutions, while the complexes with aliphatic amino acids [(*S*)-Ala, (*S*)−Leu, (*S*)-Pro] did not exhibit this solvent effect. The solvent effect in complexes with aromatic amino acids is a consequence of the N−H···π bond in solution, since the strength of the N−H···π bond varies in different solvents.[11]

^{1}H NMR Spectra

NMR spectroscopy is a powerful method for studying weak interactions in solution. ^{1}H NMR spectra of *trans*-(N)−K[Co(bcmpa)(aa)] (aa = amino acid) complexes were measured to obtain detailed structural information of the N−H···π interaction in solution.[11] If the N−H protons approach an aromatic system closely, they are expected to shift to higher field as a result of the ring-current effect. Indeed, in NMR spectra of metal complexes with aromatic amino acids, the peaks of NH protons at a higher field exhibited significant upfield shifts. Namely, for the Co^{III} complexes with aromatic amino acids, the two peaks of the amino protons at the higher and lower fields were observed in the ranges δ = 5.34−5.81 and 7.02−7.26 ppm, respectively, while those for the complexes with aliphatic amino acids were detected in the ranges δ = 6.01−6.29 and 7.22−7.40 ppm, respectively. In the crystal structure, one of the two coordinated amino protons is located exactly in the position expected for it to be affected by the shielding effect of an aromatic ring, but another one is slightly deviated from such a position. Since the geometry in solution is probably very similar to that observed in the crystal, the signals for these two protons are shifted differently because of their different shielding. Moreover, the values of chemical shift of the peaks at higher field for the Co^{III} complexes with *p*-X-substituted phenylalanines (X = OH, CH_3, H, Cl) demonstrate a significant substituent effect, which indicates that greater electron density on the aromatic ring results in a larger shielding effect. This observation suggests that the

attractive interaction is maintained even in polar solvents such as DMSO.[11]

4. Interaction with a Chelate Ring

Geometries in the Crystal Structures

There is a special type of X−H···π interaction in which a hydrogen atom from a ligand coordinated to a metal ion interacts with a chelate ring that has delocalized π bonds.[65] It is considered that the metal atom is involved in π delocalization and that these rings can have aromatic character.[66] A search for crystal structures of transition metal complexes from the CSD showed that interactions between C−H groups and the π system of chelate rings are observed in many crystal structures. Geometrical parameters for some examples are shown in Table 4. All of these examples have a very short distance between the interacting hydrogen atom and the centroid of the chelate ring (< 2.6 Å), and the hydrogen atom is located in a position almost centered over the chelate ring's centroid. From a geometrical point of view, interactions in these structures are similar to strong C−H···π interactions in organic molecules.[63a,64]

These interactions occur in metal complexes of different metals and various chelate rings. In Table 4 most of these interactions listed are intermolecular ones, with only the compound ACIPTI presenting an intramolecular interaction.

It is very interesting to notice that in all cases shown in Table 4 the complexes are neutral and both the chelate ring and the C−H group belong to the same molecule. In cases of intermolecular interactions, the interaction occurs between two identical molecules: the C−H group of one molecule interacts with the chelate ring of the second molecule. It is assumed that the neutrality of the complexes is important for these types of interactions because it enables a chelate ring not to have a partial positive charge, which would be the case if the complex was positively charged. On the other hand, the π system of the chelate ring would not interact with a negatively charged complex. In the case of a neutral complex, the interacting H atom has a partial positive charge, which is enough charge for a weak C−H···π interaction to occur.

Calculation of the Energy of Interaction

DFT calculations were performed on model systems from crystal structures to evaluate the energy of these types of interactions. The calculated energies of these interactions are approximately 1 kcal/mol.[65] The calculated values for interacting energies are similar to the values calculated for C−H···π interactions in organic molecules.[63a,64] One of the model systems based on the crystal structure YINLUC in shown in Figure 4.

5. MLACπ Interactions in Biomimetic Metal Complexes

Interactions of the MLACπ type were found in the crystal structure of biomimetic zinc complexes that are related to the enzyme/substrate complexes in biological systems with mononuclear zinc species.[5b] In the structures of $[Zn(X_6Me_3ImMe_3)L]^{2+}$ (L = EtOH, NH_2CHO) the neutral ligand $X_6Me_3ImMe_3$ forms a cavity that mimics the enzyme pocket and stabilizes four coordinated zinc species N_3ZnL^{2+}. These complexes were the first obtained of four-coordinated zinc dicationic complexes involving either a terminal aliphatic alcohol or an amide ligand. In the X-ray

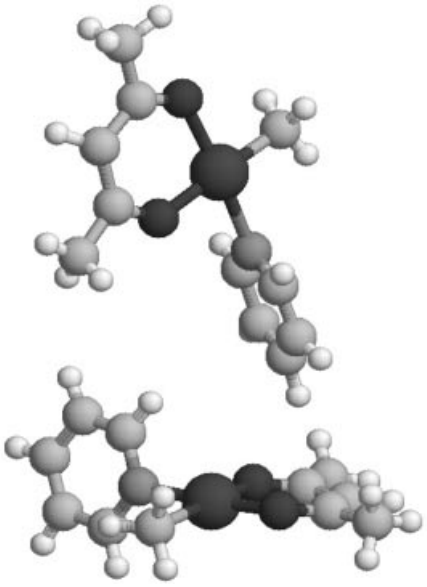

Figure 4. A model system, based on the crystal structure of YINLUC, used for calculations of the energy of C−H···π interactions with a chelate ring

structures of these complexes there are hydrogen bonds and CH···π interactions between the calix[6]arene hosts and the guests L. The CH groups that are directly connected to the oxygen atom have increased partial-positive charge because they are coordinated to an oxygen atom bonded to the metal ion. These CH groups interact with the aromatic group in the calixarene structure. The distance of the hydrogen atom closest to the centroid of the aromatic ring is 2.92 Å for $-CH_2OH$ (L = EtOH) and 2.70 Å for $-CH{=}O$ (L = NH_2CHO). These interactions, together with hydrogen bonds, play an important role in stabilizing the complex between the calix[6]arene host and the guest molecules L.[5b]

6. MLACπ Interactions in DNA and RNA Structures

Geometries in Crystal Structures

Cations play a very important role in the structure, stability, and reactivity of nucleic acids.[85] Among other noncovalent interactions, cation−π interactions between cations and nucleic acid bases have been observed in crystal structures of DNA and RNA.[8] Cation−π interactions with cationic metal complexes have been found by searching crystal structures of DNA and RNA using geometrical criteria.[8] These criteria was based on the geometries of a number of cation−π pairs in the human growth hormone/receptor complex (PDB entry 3HHR). These criteria requested that the distance between the metal ion and the centroid of the aromatic ring be smaller than 5.2 Å, and that the angle between the normal to the centroid and the centroid−metal ion bond be less than 52° (Figure 2).

It was assumed that cations interact favorably with π systems of nucleic acid bases, since cation−π interactions were detected in crystal structures of DNA and RNA. In the DNA structures of NDB entries BDL084[86] and BDJ025[87] a hydrated magnesium ion is located in the major grove and interacts with the π system of a cytosine unit (Figure 5). It was suggested that partial unstacking observed in the crystal structure was caused by cation−π interactions. The anticodon arm of yeast tRNA (NDB entry TRNA10[88]) contains one hydrated magnesium ion that is involved in MLACπ interactions. The water molecules coordinated to the magnesium ion form seven cation−π interactions, involving four tRNA bases. In the crystal structure of the tetrahymena group I intron P4−P6 domain (NDB entry URX053[89]), several magnesium ions are involved in cation−π interactions. In the same crystal structure it was also observed that the ligands of $[Co(NH_3)_6]^{3+}$ engage in MLACπ interactions with the RNA bases.

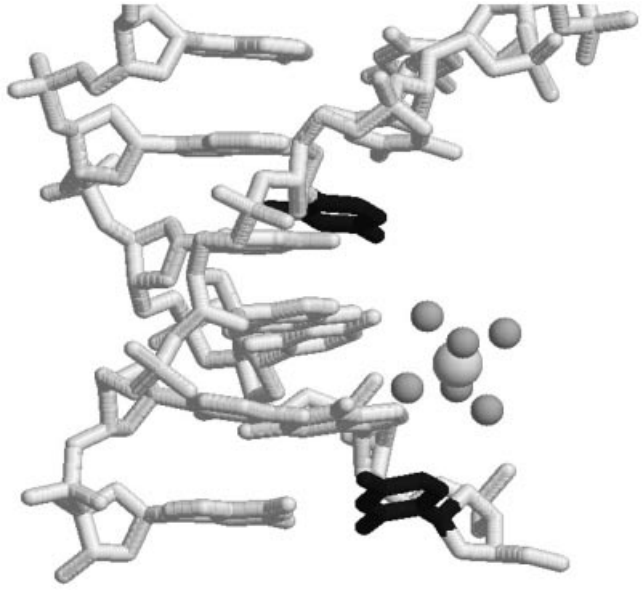

Figure 5. Part of the DNA crystal structure of BDL084[20] (NDB entries) showing the interaction of $[Mg(H_2O)_6]^{2+}$ with two cytosine units

The observation of cation−π interactions suggest a number of new mechanistic roles for cations in DNA bending, DNA−protein recognition, base flipping, RNA folding, and catalysis.[8]

Calculations

Ab initio (MP2) calculations were used to study local interactions between $[Mg(H_2O)_6]^{2+}$ and DNA bases observed in crystal structures.[18,90,91] The possibility of cation−π interactions was analyzed by assuming idealized[18] and crystal-structure geometries[18,90] of the interacting species.

The calculations on idealized geometries showed that hydrated metal cations can interact strongly with nucleobases in a cation−π manner.[18] Calculations on $[Mg(H_2O)_6]^{2+}$ with the cytosine π system were done with constraints that forced the magnesium hexahydrate unit to interact with the cytosine aromatic system and, at the same time, kept all of the cytosine atoms coplanar. The calculated interaction

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

energy was 20.2 kcal/mol. This value is very close to the calculated interaction energy with a benzene molecule (see Section 2).[18] In the optimizations without any constrains, however, the complex undergoes a quick rearrangement to the conventional through-water, in-plane bonding pattern of magnesium ions, with strong hydrogen bonds to the N and O atoms of the cytosine unit. The interacting energy for this structure is much larger (68.2 kcal/mol) than that of the one above. Hence, in spite of relatively strong cation−π interaction between $[Mg(H_2O)_6]^{2+}$ and the cytosine π system, this configuration is very unstable because there is a much more stable alternative configuration in which the hydrated metal cation is in the plane of the nucelobases and forming conventional hydrogen bonds. To make cation−π interactions with nucleobases, the cation must be kept above the plane of the nucleobase by another strong interaction, which can be the case in certain biopolymers.

Calculations on the crystal-structure geometry were performed for the dodecamer BDL084[86] (NDB entry) to evaluate interacting energies in the crystal. Contacts of the magnesium hexahydrate unit with two cytosine molecules were observed in this structure, and it was suggested that both contacts can be considered as cation−π interactions.

Calculations were performed by two groups in two different ways. In the calculations of Šponer et al., the position of the Mg^{2+} ion was kept fixed with respect to the cytosine ring according to the geometry found in the crystal, while the cytosine ring and the positions of all six water molecules were fully relaxed.[18] In the optimized geometries for both contacts, the cytosine rings are substantially deformed with pyramidal amino groups. There is one water molecule interacting with the cytosine amino group, which can be considered to be an amino−acceptor interaction. The interaction energies are 13.5 and 8.1 kcal/mol. Crystal geometries were also optimized while the cytosine unit was kept planar. This constraint abolished the amino−acceptor interaction and the water molecules reoriented. The calculated interaction energies were very small (2.5 and 0.3 kcal/mol).[18]

In the second calculation, all atoms were kept at the same position as in the crystal structure and only the positions of the added hydrogen atoms were optimized.[90] The calculated bonding energies range from 1 to 3 kcal/mol. To see the effect of the magnesium ion on these interactions, the interacting energies between cytosine and loose water molecules were calculated in the presence and absence of the otherwise pentahydrated magnesium ion. The presence of the magnesium ion increased the interacting energy by ca. 1 kcal/mol.

The calculations on the interactions of $[Mg(H_2O)^6]^{2+}$ with DNA showed that the interaction energies in the crystal structures are very small. This energy is not sufficient to compensate for the decrease in energy resulting from the lack of alternative hydrogen bonding and the bending of the bond angle related to unstacking of the bases and, hence, this interaction cannot cause the bases to unstack. Further investigations[91] have shown that there are strong hydrogen bonding interactions between these cations and another base, and that these interactions are keeping the cation in its position, above the aromatic plane, observed in the crystal structure. This localization could have resulted in a favorable cation−π interaction.

7. MLACπ Interactions in Metalloproteins

Geometries in Crystal Structures

Using geometric criteria, crystal structures of metalloproteins from the PDB were screened for cation−π interactions between ligands coordinated to the metal ion and aromatic residues.[9] The criteria used were the same as those proposed by McFail-Isom et al.[8] for screening crystal structures of DNA and RNA for possible cation−π interactions, as was mentioned above. The screening was performed for the aromatic groups of phenylalanine, tyrosine, and tryptophan, but not for histidine. Histidine is very often directly coordinated to a metal ion and, therefore, a large number of structures would be obtained that do not contain the interactions of interest.

The MLACπ interactions with the aromatic rings of phenylalanine, tyrosine and tryptophan can be observed in a number of crystal structures of metalloproteins. Data concerning the interactions in different crystal structures are compiled in Table 5, which shows that this type of interaction exists in numerous metalloproteins. Practically all metals commonly occurring in enzymes can participate in such interactions. The ligands involved in the MLACπ interactions can be amino acids, water, substrates and inhibitors.

The positions of the hydrogen atoms are not available in the crystal structures of the protein structures listed in Table 5 and, hence, the geometry of the MLACπ interaction is characterized by the distance d_1 between the center of the aromatic ring and the non-hydrogen atom ligand closest to the ring centroid (Figure 2). In Table 5, the value of d_1 varies between 3.09 and 4.41 Å. The angle θ_1 is often smaller than 30°, but can be as large as 45°.

For the same protein, the data in Table 5 show that all crystal structures exhibit the same pattern of MLACπ interactions, although the redox state and coordination number may vary. In some metalloproteins, there are different ligands in different crystal structures, but they interact with the same aromatic group, as in the case of alcohol dehydrogenase (ADH). In other proteins there is more than one MLACπ interaction at one metal center. In some cases two ligands interact with the same aromatic group, while in other cases two ligands interact with two aromatic residues of amino acids. It was concluded from the atomic distances that, among the aromatic amino acids, it is tryptophan that forms the strongest MLACπ interaction, and that, among the ligands, water molecules form the strongest interactions.

This conclusion is in agreement with previous results that indicate that tryptophan is able to make relatively strong interactions.[2,3b,6c,6d] It demonstrates that the nature of the MLACπ interaction, of the ligands coordinated to a metal ion interacting with aromatic molecules, is related to other

[a] Definitions of geometric parameters are given in Figure 2.

cation−π interactions that have already been observed and investigated.

The MLACπ interaction generally will be stronger when there are fewer bonds between the atom of the ligand coordinated to the metal ion and the interacting hydrogen atom. The water molecule, when acting as a ligand, has just a single bond between the H atom and the O atom attached to the metal ion and, thus, it is not surprising that the MLACπ interactions are the strongest when a water molecule is a ligand.

In the cases of SOD and AHD enzymes, there are indications that MLACπ interactions might be relevant for enzyme function.[9] The MLACπ interaction in the case of alcohol dehydrogenase is very interesting. In the crystal structure of the AHD−alcohol complex (PDB code 1adc/B),[92] the zinc(II) ion is tetracoordinated. Three of the ligands are amino acids, two cysteine units (Cys46 and Cys174) and one histidine unit (His67). The fourth ligand is the bound ethanol (Figure 6). Close to the metal ion is the aromatic ring of Phe93 that is in contact with the coordinated ethanol. The hydrogen atoms were modeled into this structure. For the CH_2 group of the ethanol unit, the shortest distance between a hydrogen atom and the centroid

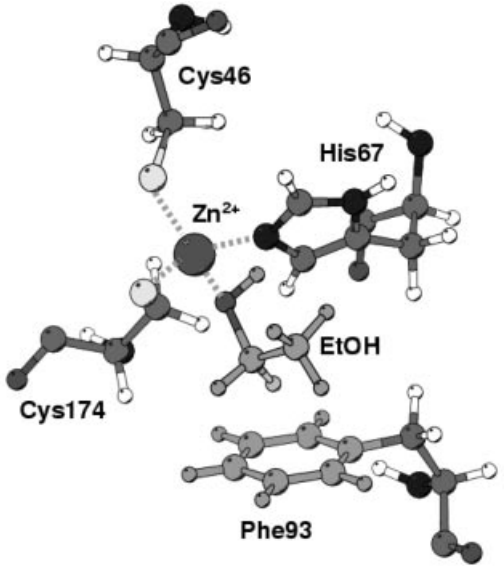

Figure 6. Part of the crystal structure of alcohol dehydrogenase (PDB code 1adc/B); all ligands are displayed that are coordinated to the metal ion and the aromatic residue (Phe93) displaying MLACπ interactions

of the phenyl ring is 3.19 Å, and its distance to the closest carbon atom of the phenyl ring is 2.64 Å.

In other structures of alcohol dehydrogenases, which we have found by searching for MLACπ interaction, there are interactions of different ligands coordinated to the zinc atom that interacts with Phe93 (Table 5). These ligands are His, trifluoroethanol (ETF), and cyclohexylformamide (CXF), respectively. In the ADH structure 1axe/B,[94] there is a Phe93Trp mutation. Trp93 is involved in cation−π interactions with the coordinated ligands, His67 and ETF. The distance of the cation−π interactions with Trp93 are shorter, and probably are stronger than the interactions with Phe93. It was found experimentally that the mutation from Phe93 to Trp93 increases the tunneling of a hydrogen atom in the hydride transfer reaction from alcohol to NAD.[94] It could be that there is a connection between a stronger cation−π interaction and an increase of hydrogen atom tunneling. We assume that the cation−π interaction of the alcohol with Phe93 may play a role in the reaction mechanism of the enzyme ADH.

Calculations

The energy of the MLACπ interactions in metalloproteins was evaluated by DFT calculations on model systems built from the crystal structure of SOD. The calculated interacting energy of the metal ion complex (an iron ion with its coordinated ligands) with he indole ring of Trp163 was 10.09 kcal/mol.[9]

8. Concluding Remarks

This article has given an overview of MLACπ interactions that have been observed in different molecular systems, mainly in crystal structures, but also in solution and in the gas phase. The overview also includes calculations of MLACπ interactions that are primarily important for estimating interaction energies. MLACπ interactions play a role in the stability of metalloproteins, metal ion complexes, and biomimetic metal ion complexes. For some metalloenzymes these interactions are probably important for the mechanisms of enzymatic reactions.

MLACπ interactions are weaker than interactions of simple metal cations with the same charge, because the transition metal complexes are relatively large, and the charge is more dispersed. The calculated energies of MLACπ interactions vary from 1 to 30 kcal/mol. This range shows that, in some cases, these interactions are among the strongest noncovalent interactions, and can play an important stabilizing role.

The largest calculated energies were for the interactions in the optimized geometries of the $[Co(NH_3)_6]^{3+}$, $[Mg(H_2O)_6]^{2+}$, and $[Zn(H_2O)_6]^{2+}$ cations with benzene (32.2, 21.5, and 21.3 kcal/mol, respectively). A comparison of these three numbers indicates that the charge of the complex is a very important factor. Calculated energies of interactions in crystal structures are smaller, ranging from 1 to 10 kcal/mol. The main reason why these energies are smaller is that the geometries in the crystal structures do not optimize the MLACπ interactions because of constraints caused by other interactions. Also, most of the calculations were performed for metal complexes with a small charge. The weakest interactions, of ca. 1 kcal/mol, are calculated when a C−H group of the ligand interacts with a chelate ring. In these cases the charge of complexes is zero, and that is the reason why the calculated energy of the interaction are very small.

The range of energies of MLACπ interactions is similar to the range of energies of hydrogen bonds, and strong MLACπ interactions are among the strongest X−H···π bonds.

From the studies that are reviewed in this paper, the nature of MLACπ interactions is related to the other cation−π interactions, as is indicated by calculated values of charge transfer. Among the aromatic amino acids, tryptophan forms the strongest MLACπ interactions. To clarify these findings, more studies regarding the nature of MLACπ interactions are needed.

Syntheses of Dimetallamacrocycles by Intramolecular Oxidative Couplings of Dinuclear Bis(1,3-butadiynyl) Complexes: A New Approach to Steric Shielding in (sp-Carbon chain)dirhenium Complexes $[(\eta^5\text{-}C_5Me_5)Re(NO)(PR_3)(C{\equiv}CC{\equiv}CC{\equiv}CC{\equiv}C)(R_3P)(ON)Re(\eta^5\text{-}C_5Me_5)]$

Clemens R. Horn[a] and John A. Gladysz*[a]

Keywords: Rhenium / Alkynes / Oxidative coupling / Macrocycles / Cyclic voltammetry

Reactions of the chiral racemic carbonyl complex $[(\eta^5\text{-}C_5Me_5)Re(NO)(NCCH_3)(CO)]^+\cdot BF_4^-$ and diphosphanes $Ph_2P(CH_2)_nPPh_2$ [2.4:1.0 mol ratio; n = 10 (**a**), 14 (**b**)] give the (bridging phosphane)dirhenium complexes $[(\eta^5\text{-}C_5Me_5)Re(NO)(CO)\{\mu\text{-}[PPh_2(CH_2)_nPh_2P]\text{-}P,P\}(OC)(ON)Re(\eta^5\text{-}C_5Me_5)]^{2+}\cdot 2BF_4^-$ (73–80%), which are reduced ($LiAlH_4$) to the dimethyl complexes $[(\eta^5\text{-}C_5Me_5)Re(NO)(CH_3)\{\mu\text{-}[PPh_2(CH_2)_nPh_2P]\text{-}P,P\}(ON)(H_3C)Re(\eta^5\text{-}C_5Me_5)]$ (92–96%). Reactions with $HBF_4\cdot OEt_2/C_6H_5Cl$, $HC{\equiv}CC{\equiv}CSiMe_3$, and *t*BuOK give, via π-HC≡C adducts (89–94%), the bis(trimethylsilylbutadiynyl) complexes $[(\eta^5\text{-}C_5Me_5)Re(NO)(C{\equiv}CC{\equiv}CSiMe_3)\{\mu\text{-}[PPh_2(CH_2)_nPh_2P]\text{-}P,P\}(Me_3SiC{\equiv}CC{\equiv}C)(ON)Re(\eta^5\text{-}C_5Me_5)]$ (**9a**,**b**; 95–66%). Desilylation (wet nBu$_4$NF) yields labile bis(butadiynyl) complexes, which are coupled [$Cu(OAc)_2$/pyridine] to the μ-octatetraynediyl complexes $[(\eta^5\text{-}C_5Me_5)Re(NO)\{\mu\text{-}[PPh_2(CH_2)_nPh_2P]\text{-}P,P\}\{\mu\text{-}(C^1{\equiv}CC{\equiv}CC{\equiv}CC{\equiv}C^8)\text{-}C^1,C^8\}(ON)Re(\eta^5\text{-}C_5Me_5)]$ (**3a**,**b**; 10–23% from **9a**,**b**). These represent some of the few cases of intramolecular oxidative homocouplings of terminal alkynes in metal coordination spheres. The electrochemical properties of **3a**,**b**, which undergo two one-electron oxidations, are compared to nonmacrocyclic analogs that lack the diphosphane bridge.

Introduction

Macrocyclization methodologies have played an important role in the development of synthetic organic chemistry.[1] A variety of general strategies are now established, with applications ranging from complex natural products to theoretically interesting unnatural substances such as annulenes. Many relevant physical organic studies have been conducted to define optimum substrate characteristics and conditions.[2] In contrast, macrocyclizations have attracted less focused or systematic attention to date in synthetic inorganic or organometallic chemistry.

Nonetheless, there has been a diverse range of activity. We have used olefin and alkyne metathesis reactions to effect macrocyclizations of a variety of transition-metal complexes, giving products in which metal atoms are part of the new ring (metall***a***macrocycle) or attached to the new ring (metall***o***macrocycle).[3−6] Sauvage has, in the pursuit of catenanes, molecular knots, and related novel species, investigated a number of macrocyclizations of coordination compounds.[7−9] Any complex in which *trans* positions are spanned by a chelate ligand is by definition macrocyclic, and Bessel and Takeuchi have recently reviewed this scattered literature.[10] There are also growing numbers of metallacrown species,[11] nearly all of which are macrocyclic. However, there are very few comparative evaluations of synthetic strategies.

The intramolecular oxidative coupling of organic compounds that contain two terminal alkynes has played a critical role in the development of macrocycle chemistry, particularly with annulenes and dehydroannulenes.[12,13] Many intermolecular oxidative couplings of transition-metal-containing terminal alkynes are also known. However, to the best of our knowledge there are few if any cases where an isolated inorganic or organometallic compound containing two terminal alkynes has undergone an intramolecular oxidative macrocyclization.[14] Oxidative cyclodimerizations and cyclooligomerizations can be effected with some such species, and representative examples are depicted in Scheme 1.[8,15] These entail the macrocyclization of an intermediate with two terminal alkynes.

We wondered whether such intramolecular oxidative couplings might prove applicable to a synthetic problem in our group. As detailed in the previous paper in this series,[5] we have sought (μ-octatetraynediyl)dirhenium or ReC≡CC≡CC≡CC≡CRe systems with sterically shielded sp-carbon chains. One motivation is the possibility of enhanced stabilities for the corresponding radical cations $[ReC{\equiv}CC{\equiv}CC{\equiv}CC{\equiv}CRe]^{+\cdot}\cdot X^-$ and dications [Re=C=

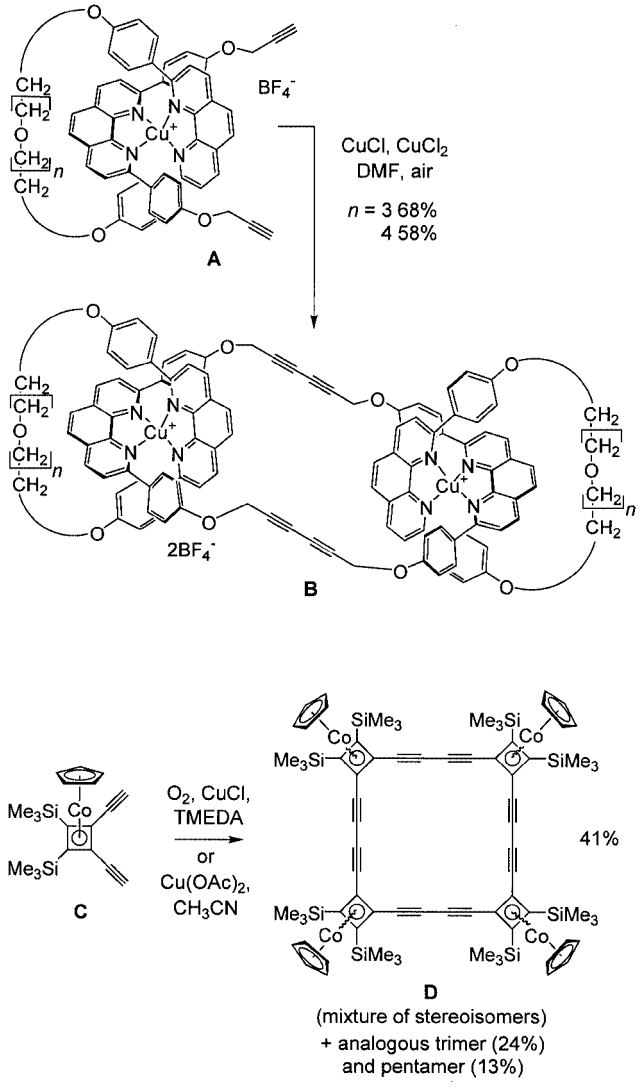
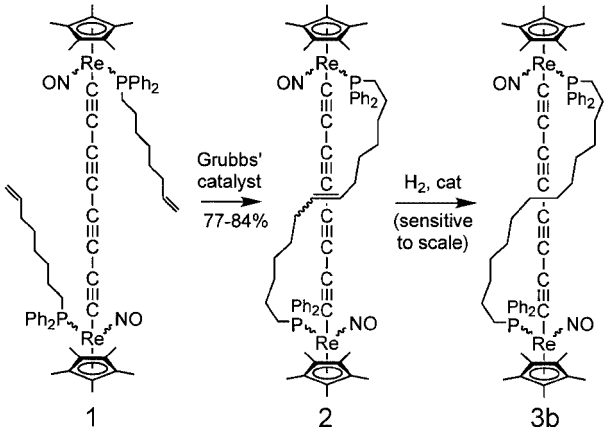


Scheme 1. Representative macrocycle syntheses involving oxidative dimerization or oligomerization of inorganic and organometallic compounds that contain two terminal alkynes[15]

C=C=C=C=C=C=C=Re]$^{2+}$·2X^{-}. Much evidence suggests that decomposition involves bimolecular chain/chain or chain/solvent reactions. As shown in Scheme 2, the complex **1**, which features an alkene-containing phosphane on each rhenium atom, undergoes olefin metathesis to give the macrocycle **2** in good yield. However, subsequent hydrogenations of the residual C=C bond, while sometimes giving the target molecule **3b**, were difficult to reproduce or scale up.[5]

We therefore considered alternative routes to **3b** by retrosynthetic analysis. One obvious possibility would be to generate the macrocycle by the intramolecular oxidative coupling of two butadiynylrhenium or ReC≡CC≡CH moieties.[13,16] This would in turn require linking two chiral rhenium fragments by an α,ω-diphosphane $Ph_2P(CH_2)_nPPh_2$. No hydrogenation step would be required, and intermolecular oxidative homocouplings of ReC≡CC≡CH complexes commonly proceed in high yield.[5,17] Accordingly, we set out to investigate this alternative route to **3b** and related



Scheme 2. Syntheses of macrocyclic dirhenium complexes by ring closing olefin metathesis

compounds, and describe its successful implementation below.

Results

The readily available chiral racemic cationic (acetonitrile)(carbonyl) complex [(η^5-C_5Me_5)Re(NO)(CO)(NCCH$_3$)]$^+$·BF$_4^-$ (**4**$^+$BF$_4^-$) reacts with a variety of phosphanes in refluxing 2-butanone to give the corresponding (carbonyl)(phosphane) complexes.[18] As shown in Scheme 3, similar reactions were conducted with the diphosphanes $Ph_2P(CH_2)_nPPh_2$ [**5**; *n* = 10 (**a**),[4,19] 14 (**b**)[4,19b]], but at 2.4:1.0 stoichiometries. Workups gave the target dicationic (bridging phosphane)dirhenium complexes [(η^5-C_5Me_5)Re(NO)(CO){μ-[PPh$_2$(CH$_2$)$_n$Ph$_2$P]-*P*,*P*}(OC)(ON)Re(η^5-C_5Me_5)]$^{2+}$·2BF$_4^-$ (**6a**,**b**$^{2+}$2BF$_4^-$) as yellow-

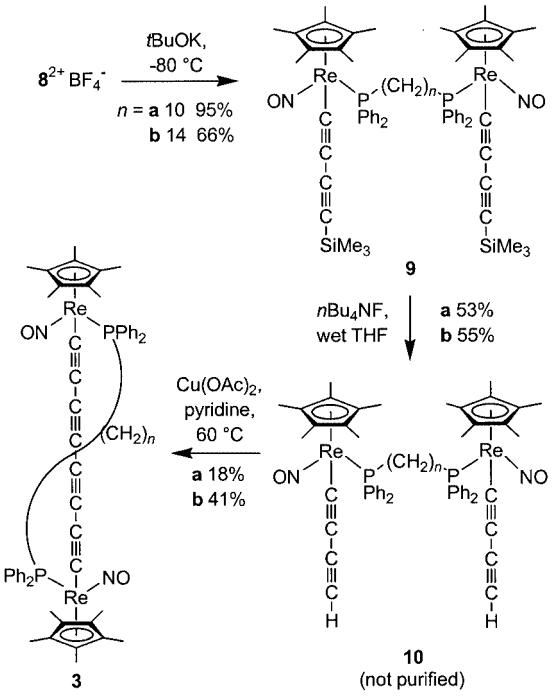
orange solids in 73−80% yields based on the limiting reactants **5a**,**b**. A third series of compounds derived from a diphosphane with a much longer methylene chain (**5c**; n = 32) were not as tractable and are detailed elsewhere.[20]

Complexes **6a**,**b**$^{2+}2BF_4^-$ and all new species below were characterized by IR, NMR (^1H, ^{13}C, ^{31}P), mass spectrometry, and microanalysis, as summarized in the Exp. Sect. Most features were very similar to those of triarylphosphane homologs reported previously.[17] However, the PPh_2 phenyl groups are diastereotopic, and the aryl ^{13}C NMR signals are therefore more complex. Although **6a**,**b**$^{2+}2BF_4^-$ must be mixtures of *rac* and *meso* diastereomers, only one set of ^{31}P and pentamethylcyclopentadienyl ^1H and ^{13}C NMR signals was observed. All of the nonmacrocyclic compounds below behaved similarly. The mass spectra of **6a**,**b**$^{2+}2BF_4^-$, and all other dications below, showed doubly charged ions corresponding to the (bridging phosphane)-dirhenium assemblies.

Complexes **6a**,**b**$^{2+}2BF_4^-$ were elaborated to butadiynyl complexes as described for many related species. As shown in Scheme 3, reductions with $LiAlH_4$ gave the dimethyldirhenium complexes [(η^5-C_5Me_5)Re(NO)(CH_3){μ-[$PPh_2(CH_2)_nPh_2P$]-*P*,*P*}(H_3C)(ON)Re(η^5-C_5Me_5)] (**7a**,**b**) as red powders in 92−96% yields. Reactions with HBF_4 in C_6H_5Cl generated substitution-labile chlorobenzene complexes,[21] which were treated with the diyne HC≡CC≡CSiMe$_3$.[22,23] Workups gave the π-bis(diyne) complexes [(η^5-C_5Me_5)Re(NO)(HC≡CC≡CCSiMe$_3$){μ-[$PPh_2(CH_2)_nPh_2P$]-*P*,*P*}(Me_3SiC≡CC≡CH)(ON)Re(η^5-C_5Me_5)]$^{2+}$·$2BF_4^-$ (**8a**,**b**$^{2+}2BF_4^-$), with each rhenium atom bound to an HC≡C moiety, as black powders in 89−84% yields. Such compounds can exist as mixtures of Re−(C≡C) rotamers, and NMR spectroscopic data indicated 67−76:33−24 ratios [(PPh_3)monorhenium analog: 67−79:33−21].[22,24]

As shown in Scheme 4, complexes **8a**,**b**$^{2+}2BF_4^-$ were deprotonated with *t*BuOK to give the σ-bis(trimethylsilylbutadiynyl) complexes [(η^5-C_5Me_5)Re(NO)(C≡CC≡CSiMe$_3$){μ-[$PPh_2(CH_2)_nPh_2P$]-*P*,*P*}(Me_3SiC≡CC≡C)(ON)Re(η^5-C_5Me_5)] (**9a**,**b**) as red powders in 95−66% yields. In previous studies, such compounds have been desilylated to the parent butadiynyl complexes using wet nBu_4NF.[5,17] However, the resulting ReC≡CC≡CH species are always much more labile. Indeed, all efforts to purify the bis(butadiynyl) complexes [(η^5-C_5Me_5)Re(NO)(C≡CC≡CH){μ-[$PPh_2(CH_2)_nPh_2P$]-*P*,*P*}(HC≡CC≡C)(ON)Re(η^5-C_5Me_5)] (**10a**,**b**) gave only impure, partially decomposed samples. Nonetheless, many NMR and IR signals could be assigned (Exp. Sect.).

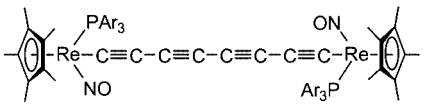
In order to minimize this problem, combined deprotection/oxidation sequences were investigated. Eglinton conditions − stoichiometric $Cu(OAc)_2$ in pyridine − have proven to be most reliable for oxidative homocouplings of butadiynylmonorhenium complexes.[5,17] Thus, solutions of **9a**,**b** were first treated with wet nBu_4NF, and then filtered through alumina. Solvent removal gave crude **10a**,**b** (53−55%), which were taken up in pyridine and treated with $Cu(OAc)_2$. Substrate concentrations were ca. 0.0088 M.



Scheme 4. Syntheses of macrocyclic dirhenium complexes by intramolecular oxidative coupling

Workups gave the target, macrocyclic (μ-octatetraynediyl)-dirhenium complexes [(η^5-C_5Me_5)Re(NO){μ-[PPh_2-$(CH_2)_nPh_2P$]-*P*,*P*}{μ-(C^1≡CC≡CC≡CC≡C^8)-C^1,C^8)}-(ON)Re(η^5-C_5Me_5)] (**3a**,**b**) in 18−41% yields from crude **10a**,**b** or 10−23% yields from **9a**,**b**.

Complexes **3a**,**b** were homogeneous by HPLC and TLC, and the latter gave a good microanalysis. Mass spectra showed intense molecular ion peaks (100%). In the case of **3a**, a small peak corresponding to a dimeric tetrarhenium by-product was also detected (8%). Dimeric and oligomeric by-products often form in couplings of organic compounds containing two terminal alkynes, and several cyclooligomers are obtained from **C** in Scheme 1. Thus, we believe that additional polyrhenium species likely form, but are perhaps not solubilized by the extractive workup employed. IR spectra of **3a**,**b** showed $\nu_{C\equiv C}$ and ν_{NO} bands (2104−2108 m, 1953 m, 1640−1637 s cm^{-1}) very close to those of the nonmacrocyclic triarylphosphane analogs **11** and **12**.[17]



Ar = Ph: **11**
p-tol: **12**

The ^1H NMR spectrum of **3a** exhibited a doubled pentamethylcyclopentadienyl signal, and the ^{31}P NMR spectrum a doubled PAr_2 signal. Area ratios were ca. 50:50, and the latter is illustrated in Figure 1. Complex **3b** also showed two doubled signals, but the chemical shift differences were much smaller. For both compounds, these were assigned to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the *rac* and *meso* diastereomers. Since none of the other dirhenium complexes show separate signals for the two diastereomers, steric communication between the chiral endgroups appears to be enhanced in the macrocycles **3a**,**b**. As would be intuitively expected, the shorter methylene tether in **3a** leads to more differentiated signals. The ^{13}C NMR chemical shifts of the sp-carbon atoms were within 1−2 ppm of those of **11** and **12**.[17] The ^{1}H and ^{31}P chemical shifts of **3a**,**b** were quite similar to those of the precursors **9a**,**b** and **10a**,**b**. The most pronounced differences were in the PCH_2 signals of **3a** ($\Delta\delta$ = 0.20−0.10).

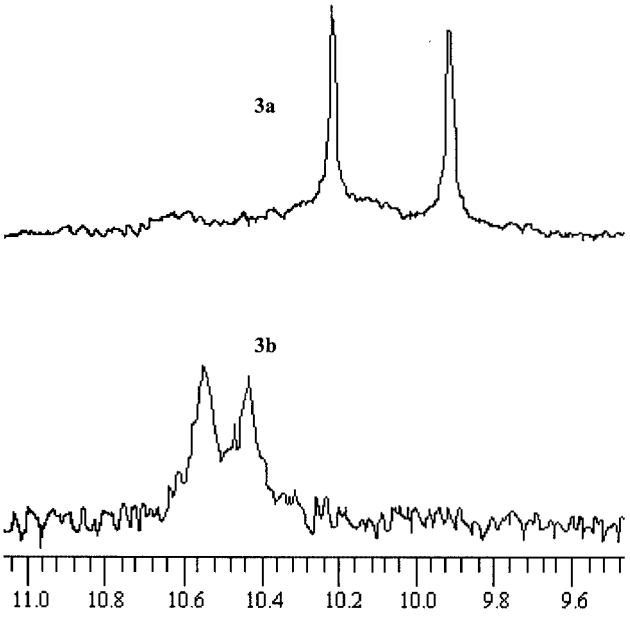


Figure 1. ^{31}P NMR spectra of macrocyclic dirhenium complexes

Finally, cyclic voltammograms of **3a**,**b** were recorded in CH_2Cl_2 under the standard conditions employed in earlier studies.[17] Two sequential oxidations were observed, and data are summarized in Table 1. Since comparisons to non-macrocyclic complexes were sought, **1** and **2** (Scheme 2) were also examined. Some previously reported data are included for reference, and analyzed in the discussion section. Preparative reactions of **3a**,**b** with the one-electron oxidant $(\eta^5\text{-}C_5H_5)_2Fe^{+\cdot}\cdot SbF_6^-$ in CH_2Cl_2 did not afford any tractable products.

Discussion

The reactions in Scheme 4 establish that organometallic compounds containing two terminal alkynes or diynes can undergo intramolecular oxidative macrocyclization. The overall yields of **3a**,**b** from the protected diyne **9a**,**b** are only 10−23%, but rise to 18−44% when based upon the crude bis(butadiyne) complexes **10a**,**b**. The substrate concentrations are somewhat greater than those employed for the olefin metathesis of **1** in Scheme 2 (0.0088 vs. 0.0012−0.0007 M). Thus, there is some possibility that the yields in Scheme 4 could be improved at higher dilution. Nonetheless, we would still expect them to remain lower than that of the metathesis product **2** (77−84%). This is consistent with Sauvage's experience with systems such as **A** (Scheme 1). Although the oxidative coupling is successful,[7,8] olefin metatheses of related species proved superior.[9a,9b]

However, with respect to the target molecule **3b**, an additional hydrogenation step is needed after olefin metathesis (Scheme 2). This has proved very problematic, and without the new methodology in Scheme 4, it would not be possible to reliably access this molecule. Although this constitutes a strategic weakness of olefin metathesis, many alkene-containing metalla- and metallomacrocycles are readily hydrogenated.[3,4,9] Perhaps the triple bonds in **3b** are the origin of the problem. Nonetheless, it has proved possible to hydrogenate alkene moieties in macrocycles containing PtC≡CC≡CC≡CC≡CPt linkages.[4]

In **3a**, the linear ten-atom ReC≡CC≡CC≡CC≡CRe linkage must be spanned by a 12-atom P$(CH_2)_{10}$P linkage. Thus, **3a** should be considerably more strained than **3b**. Accordingly, the yield is lower, and a dimeric product can be detected by mass spectrometry. Nonetheless, the same phosphane is also capable of bridging a PtC≡CC≡CC≡CC≡CPt linkage.[4] In both cases, the methylene or sp^3-carbon chain must remain very close to the sp-carbon chain. However, there appears to be little effect on NMR or IR properties. In **3b**, there is the possibility of helical coiling of the sp^3-chain about the sp-chain, as recently demonstrated with similar diplatinum complexes.[4] Unfortunately, consistent with past experience with this series of compounds, all efforts to obtain single crystals have been unsuccessful. The presence of both diastereomers is believed to be a contributing factor.

These structural issues lead naturally to the effect of molecular architecture upon redox properties. The cyclic voltammogram of **3b** (Table 1) is qualitatively similar to those other ReC≡CC≡CC≡CC≡CRe species reported earlier. A cation radical and dication are readily generated. The oxi-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dation potentials are intermediate between those of the PPh_3- and P(*p*-tol)$_3$-substituted analogs **11** and **12**, befitting a alkyldiphenylphosphane adduct [$E°(1)$ = 0.20 vs. 0.24 vs. 0.16 V; $E°(2)$ = 0.47 vs. 0.52 vs. 0.45 V]. The ΔE and i_c/i_a values indicate a high degree of reversibility. However, **12** gives a i_c/i_a ratio of 1 for both oxidations, whereas one value for **3b** is slightly less. Thus, there is no electrochemical indication of enhanced cation radical and dication stabilities, in agreement with our chemical data.

Complex **3a** exhibits similar oxidation potentials. However, the ΔE and i_c/i_a values indicate processes that are not electrochemically reversible, and only partially chemically reversible. This suggests that the more strained nature of this macrocycle somehow promotes decomposition of the cation radical and dication. The phosphane ligand in nonmacrocyclic **1** (Scheme 2) should electronically resemble a alkyldiphenylphosphane, and similar oxidation potentials are again observed. However, the alkene linkages can potentially react with the cation radical and/or dication. Accordingly, the reversibilities are between those of **3a** and **3b**. The metathesis product **2**, which is a mixture of C=C isomers, appears to give slightly more reversible oxidations.

There is only one example to date of an MC≡CC≡CC≡CC≡CM system that can be oxidized to spectroscopically detectable species, Lapinte's very electron-rich diiron complex [(η^5-C_5Me_5)Fe(dppe)(C≡C)$_4$-(dppe)Fe(η^5-C_5Me_5)].[25] Remarkably, the corresponding radical cation can be isolated in analytically pure form.[26] However, when the sp-carbon chains of dirhenium complexes **11** or **12** are shielded by an additional sp^3- or sp^3/sp^2-carbon chain, as in **2** and **3b**, no evidence for enhanced kinetic stabilities of oxidation products is found. In contrast, PtC≡CC≡CC≡CC≡CPt assemblies that are doubly bridged by the diphosphane **5b** exhibit significantly more reversible oxidations.[4] We therefore conclude that the sp-carbon chain of our first-generation system **3b** is sterically not shielded enough. Approaches to sterically more congested analogs are under investigation.[27]

Finally, **3a**,**b** are not the only metallamacrocycles that contain an M(C≡CC≡C)$_n$M linkage. Extremely interesting tetraplatinamacrocycles of the formula **13** have been previously reported by Tessier, Youngs, and Bruce.[28] All sixteen carbon atoms in these twenty-membered rings are sp-hybridized. However, the syntheses do not involve the oxidative homocoupling of alkynes. Rather, bis(butadiynyl)platinum complexes of the formula [*cis*-(L)$_2$Pt(C≡CC≡CH)$_2$] are condensed with platinum chloride or triflate complexes *cis*-(L)$_2$Pt(X)$_2$. Yields of **13** are routinely high (70−98%).

In conclusion, we have compared the applicability of two macrocyclization strategies for the synthesis of novel types of (μ-octatetraynediyl)dirhenium complexes. The new intramolecular oxidative coupling of bis(butadiynyl) complexes is successful, and increased application of such reactions in the synthesis of inorganic and organometallic macrocycles can be anticipated. However, olefin metathesis appears to constitute a generally superior macrocyclization method, and is problematic only in the few instances where subsequent alkene hydrogenation is unsuccessful. Future reports will describe the utility of alkyne metathesis for accessing similar types of targets.[6]

Synthesis of *tripod* Ligands Containing Mixed Donor Sets with Phosphane and Pyrazole Donors − Bidentate Chelate Binding Modes and Dynamic Behaviour of *tripod* Ligands in d^8-Metal Complexes (Ni^{II}, Pd^{II}, Pt^{II})

Ralf Faissner,[a] Gottfried Huttner,*[a] Elisabeth Kaifer,[a] Peter Kircher,[a] Peter Rutsch,[a] and Laszlo Zsolnai[a][†]

Dedicated to Professor Rolf Gleiter[‡]

Keywords: Tripod ligands / Conformation / Nickel / Palladium / Platinum

The synthesis of a series of *tripod* ligands $MeOCH_2C(CH_2X)(CH_2Y)(CH_2Z)$ (X = PR_2; Y, Z = PR'_2 or pz; pz = 1-pyrazolyl) based on the 3,3-difunctionalized oxetane $O^a[CH_2]_2C^a(CH_2OMs)(CH_2Br)$($O^a$–$C^a$) as the starting material is described. With their mixed donor sets these ligands coordinate to d^8-metal ions in a bidentate binding mode. One of the three donors remains uncoordinated in each case. Coordination of phosphane donors is generally preferred over coordination of pyrazole donors. With bulky phosphanes such as $–CH_2PMes_2$, however, pyrazole may compete with PR_2, depending on the kind of the d^8 fragment. Dynamic exchange between coordinated and noncoordinated pyrazole donors is observed. Tetracoordinate complexes of the general type L_2MR_2 are formed (L_2 symbolizes the *tripod* ligand in its bidentate chelate binding mode with two donors functions coordinating and the third one serving as a dangling arm; M = Ni^{II}, Pd^{II}, Pt^{II}). With nickel(II) as the d^8 species, tetrahedral or square-planar coordination geometries ensue, depending on the kind of donor functions and on the kind of co-ligands R. With palladium(II) and platinum(II) as the d^8 centres, square-planar coordination is observed throughout. The size of the chelate cycles varies from six to eight depending on the number of pyrazole entities within the cycle. The conformations and the conformational flexibility characterizing the chelate cycles have been analysed by X-ray analyses and by variable-temperature NMR. The classes of conformations observed may be formally reduced to chair, half-chair and twist-boat conformations. Dynamic exchange between these conformations is observed. In one case, the same compound forms two different types of crystals that differ by the conformation adopted by their chelate cycles. All compounds have been fully characterized by standard analytical techniques including X-ray structure analysis of 14 chelate compounds.

Introduction

The synthesis of neopentane-based *tripod* ligands $RCH_2C(CH_2X)(CH_2Y)(CH_2Z)$ that contain up to three different donor functions X, Y, Z, is generally well developed for different kinds of donor functions.[1−5] The selective introduction of nitrogen donor functions is, however, in most cases limited to special kinds of nitrogen donors[5] as well as to specific reaction schemes[5]. Pyrazole is a nitrogen-donor group of more general applicability in *tripod* synthesis[5e,5f] that may be especially easily incorporated in *tripod* ligands $HOCH_2C(CH_2pz)(CH_2PR_2)(CH_2X)$ by a series of nucleophilic substitutions and ring-opening reactions starting from the functionalized oxetane $O^a[CH_2]_2C^a(CH_2Br)(CH_2OMs)$($O^a-C^a$).[5e]

The scope of this type of reaction sequence was tested by applying different phosphorus nucleophiles as well as different nitrogen nucleophiles. The coordination properties of these ligands versus the d^8-metal ions nickel(II), palladium(II), and platinum(II) were tested to elucidate the competition between different types of donor groups. In such coordination compounds the potential *tripod* ligands will act as bidentate ligands with the third potential donor function uncoordinated.[5b,5f,6] The dynamic exchange between coordinated and uncoordinated ligand functions in *tripod* compounds as well as the conformation of the chelate cycles are also reported here.

Results

Ligand Synthesis

The *tripod* ligands **3** and **4** were obtained from oxetane precursors **2**, which were themselves synthesized from the functionally substituted oxetane **1** by standard procedures
