Manganese-Salen Complexes as Oxygen-Transfer Agents in Catalytic Epoxidations − A Density Functional Study of Mechanistic Aspects

Luigi Cavallo[a] and Heiko Jacobsen*[b]

Keywords: Density functional calculations / Epoxidation / Manganese / N,O ligands / Radicals

The mechanism of the Jacobsen–Katsuki epoxidation has been investigated by application of density functional theory; the results of a series of calculations for simplified model systems of different spin states are presented. In the chosen computational approach, the epoxidation of ethylene with a cationic five-coordinate model catalyst is predicted to occur through a radical intermediate, similarly to the reaction mechanism calculated for the corresponding neutral six-coordinate species. Although the radical intermediate shows a small energetic preference for the quintet state over the triplet state, the computed reaction profile does not suggest that two-state reactivity involving spin change plays a major role during the oxygen-transfer step. Comparative orbital analysis of the cationic and the neutral complexes elucidates the role of a ligand *trans* to the oxo group. A π-donor *trans* to the forming OR^- ligand in the radical intermediate causes a relative destabilization of a possible quintet occupation, thus conferring spin rigidity to the six-coordinate species derived from the neutral catalyst. A reaction pathway resulting in rotational collapse might involve a spin-crossing process. The ligand framework of the tetra-chelating N,O ligand in the radical intermediate exhibits a considerable amount of ligand folding.

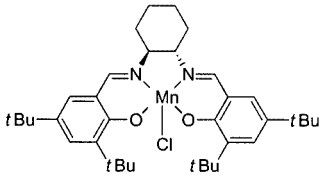
Introduction

Transition metal-catalyzed oxidations play a vital role not only in preparative organic chemistry, but also in biochemical transformations.[1] We mention as one prominent example that manganese is part of the active site in photosystem II,[2] and that the role of metal oxo species in water oxidation and O_2-formation has been convincingly demonstrated.[3,4] For synthetic purposes, cationic Mn^{III}-salen complexes were introduced as effective catalysts for the epoxidation of olefins by Kochi in 1986.[5] Katsuki[6] and Jacobsen[7] designed chiral manganese catalysts, which also allowed for enantioselective epoxidations, by modifying the backbone of the salen ligand. The Jacobsen−Katsuki reaction is currently recognized as one of the most practical methods for the epoxidation of alkenes.[8,9] Jacobsen's catalyst **1** is effective for virtually every class of conjugated olefins, and industrial production of the catalyst on a ton scale has become possible.[10] New developments in catalytic epoxidation with Mn^{III}-salen complexes include the use of ionic liquids, which allow the homogenous chiral catalyst to be immobilized, recovered, and recycled and so enhance the activity of the system.[11]



1

The mechanistic scheme commonly proposed for this oxygen-transfer reaction consists of a two-step catalytic cycle (Scheme 1).[8,9,12] Oxygen is transferred from a terminal oxidant to the Mn^{III}-salen catalyst, generating an intermediate Mn^{V} oxo complex, which in the second step carries the activated oxygen to the olefinic double bond.

The existence of a Mn^{V} oxo intermediate, first postulated by Kochi and co-workers,[5] was confirmed by electrospray tandem mass spectrometry by Feichtinger and Plattner.[13] In a recent study, these authors used the same technique to elucidate the mechanism of oxygen transfer to the Mn^{III}-salen complex in great detail,[14] identifying a dimeric μ-

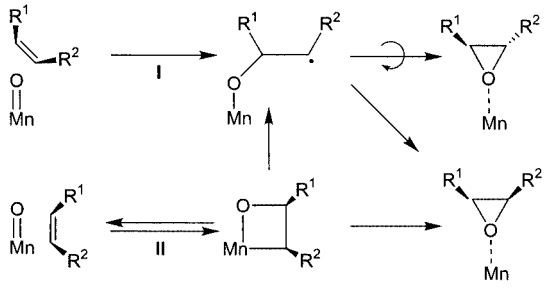
oxo-bridged species acting as reservoir species, and for the first time investigating the coordination chemistry of the terminal oxidant iodosylbenzene with regard to the Mn(salen) system. It should be mentioned that related Mn^{V}-oxo complexes have also been detected in solution by Groves and co-workers, who applied rapid-mixing stopped-flow spectrophotometry.[15]

Keenly debated is the second step in the epoxidation reaction, over which a controversy has erupted in the literature (Scheme 2).[16]



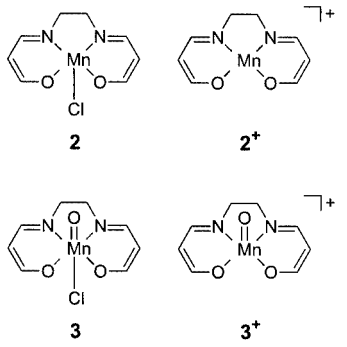
Scheme 2

Since the stereochemistry is determined by the way in which oxygen is delivered to the olefin, detailed knowledge of this step provides the basis for understanding and tuning of the enantioselectivity of the reaction. Both pathway **I**, in which the first attack of the olefin occurs at the oxo center only, and pathway **II**, which proceeds via a manganoxetane, are subjects of discussion. Experimental evidence has been put forward both for the existence of radical intermediates[17] and for the formation of metallacycles.[18] In contrast to direct routes, which should give rise to *cis* epoxides, rotational collapse from the radical intermediate would afford the *trans* product (Scheme 2). This mechanism provides an explanation for the experimentally observed *cis*/*trans* isomerization in the epoxidation of conjugated alkenes.

With regard to the origin of the enantioselectivity, it is generally assumed that it is dominated by steric interactions between the chiral Mn(salen) complex and the two prochiral faces of the olefin. However, it has to be borne in mind that electronic effects, in particular the nature of the substituents in positions 5,5′, also have a strong influence.

Jacobsen developed a mechanistic basis for the electronic effects on enantioselectivity,[19] which assumes the formation of a radical intermediate as the first step in oxygen transfer. Enantioselectivity is tied to the position of the transition state along the reaction coordinate, which can in turn be tuned by electronic variation of the salen ligand system. In connection with the synthesis of optically active α-hydroxy carbonyl compounds, Fell and Adam also showed that the preferentially reacting enantiomer is determined by electronic effects, whereas steric interactions are responsible for the observed stereochemical preference in the double bond epoxidation.[20] When hydroxy group directivity is utilized during the course of the diastereoselective epoxidation,[21] Adam and co-workers conclude that reactions through a metallacycle intermediate and through a direct three-centered transition state both constitute viable reaction mechanisms.[22] Metallacycles have also been discussed by Katsuki and co-workers.[23]

Recently, various density functional (DF) calculations focusing on Mn^{V}-oxo species and their role in olefin epoxidation have appeared. Most of these studies deal with systems **3** or $\mathbf{3}^{+}$, derived from the Mn^{III}-salen model complexes **2** or $\mathbf{2}^{+}$, respectively.



2 $\mathbf{2}^{+}$

3 $\mathbf{3}^{+}$

Strassner and Houk[24] have reported the results of hybrid-DF[25] calculations with the B3LYP functional[26] on the geometries and multiplicities of the systems described above, and discuss their implications for stereoselectivity. By the same methodology, Svensson and co-workers[27] studied the epoxidation of ethylene with catalyst $\mathbf{3}^{+}$. They suggest that the reaction begins with alkene attack on the triplet surface, followed by a spin change to the quintet surface, which affords the quintet epoxide product without a barrier. On the triplet surface it was possible to localize a radical intermediate, whereas on the quintet surface the reaction proceeds from the first, very early, transition state directly to the final products without any other intermediates or transition states. The point at which the spin-crossing occurs determines the stereochemistry of the reaction; only if the spin change takes place after the formation of the radical intermediate does *cis*-*trans* isomerization become possible. The mechanism of the Jacobsen−Katsuki epoxidation is thus explained in terms of two-state reactivity,[28] which has evolved as a new concept in organometallic chemistry.[29] Although reactions that undergo spin inversion have recently been observed in the gas phase,[30] two-state reactivity in the condensed phase has not yet been shown to occur, but "offers a conceptually attractive explanation for these experimental findings that are difficult to understand by any other existing concepts."[29]

We have investigated a similar reaction profile for olefin epoxidation with catalyst **3**,[31] by applying BP86 DF calculations.[32] Contrary to the results obtained by Svensson and co-workers, our calculations for the reaction profile for ethylene epoxidation with **3** indicate that the reaction occurs on the triplet surface, and is likely to involve radical intermediates. The reaction profile on the quintet surface, for which both a radical intermediate and transition states

for C−O bond formation could be localized, is generally higher in energy than that of the triplet surface, and spin inversion does not seem to be a likely process. Both studies on system **3** and **3**$^+$, however, concur on the fact that formation of a metallacycle during the epoxidation is not likely to occur.

One of the differences between the two mechanistic models described above is the presence of a free coordination site versus an occupied one *trans* to the oxo group. The coordination chemistry of Mn salen complexes and effects of axial ligation have recently been investigated by electrospray tandem mass spectrometry in combination with hybrid DF calculations.[33] This study shows that the presence of a *trans* ligand has a significant influence not only on the coordination geometry of the salen framework, but also on the relative energies of different spin states. Similar observations have also been made by Strassner and Houk.[24]

A further difference between our previous study and the contribution by Svensson and co-workers is the choice of computational methodology. Although it has been convincingly demonstrated that DF theory in general constitutes a powerful tool for the prediction of structures and energetics in transition metal chemistry[34] with an accuracy of the gradient corrected method similar to, or better than, standard correlated methods,[35] systematic studies investigating the performance of different functionals for certain problems in transition metal chemistry have only recently begun to appear.[36,37] When it comes to manganese complexes related to the problem at hand, successful applications both of the B3LYP[38] and of the BP86[39] functionals have been demonstrated in the literature. However, it was recently shown by high-level ab initio calculations [coupled cluster CCSD(T)] that a computational procedure based on the BP86 density functional generates numerical results significantly more reliable than those obtained by a B3LYP approach for the Mn-catalyzed epoxidation reactions.[40]

Given the importance of the Jacobsen−Katsuki epoxidation, we decided to reinvestigate the oxidation of ethylene with catalyst **2**$^+$ by means of BP86-DF calculations. This study complements our previous investigations on the corresponding neutral system **2**.[31] Comparison between the energy profiles for the neutral and cationic active species should allow insights on the role of the axial ligand to be obtained. Questions to be addressed include the existence of possible oxametallacyclic intermediates, as well as a possible precoordination of the olefinic double bond. Furthermore, the coordination geometry of the tetra-chelating N,O ligand is investigated, and the possibility of spin inversion is discussed in connection with the geometries of radical intermediates and of transition states. Moreover, since there are some discrepancies between the chemical pictures obtained by the different DF approaches, we believe it is also worthwhile to investigate the energy profile for the cationic system **2**$^+$ with the BP86 functional. We believe that a critical comparison between different computational approaches should allow further details on the mechanism of this relevant reaction to be gained.

Results and Discussion

Electronic Structures of Mn(salen) Model Compounds: (Supporting information including optimized geometries and final bonding energies available, see also footnote on the first page of this article).The qualitative molecular orbital diagram for a d^4-ML_4 complex[41] suggests that, for the square planar compound **2**$^+$, triplet and quintet configurations − corresponding to total spin density values of 2α, *S2*, and 4α, *S4*, respectively − have to be considered. Our nomenclature was chosen to reflect the spin density, and should not be mistaken with spin states or $<S^2>$ values. We calculated an energetic difference of 67 kJ/mol, in favor of the quintet state, between the *S2* and *S4* geometries in **2**$^+$. A singlet ground state can be achieved if the metal d orbitals adopt the familiar two-below-three pattern of a tetrahedral ligand field. The *S0*−**2**$^+$ molecule, however, which is consequently strongly distorted toward a tetrahedral geometry, is 147 kJ/mol higher in energy than *S4*−**2**$^+$. This coordination mode of the core ligand is not considered any further. Complex **2**$^+$ thus possesses an electronic structure similar to that of **2**, for which the energetic difference between the *S4* and *S2* geometries amounts to 38 kJ/mol,[31] *S4*−**2** again being more stable. These results are in agreement with EPR spectroscopic studies of the Mn(salen) complex **1** in CH_2Cl_2 at 77 K performed by Talsi and coworkers,[42] which reveal the presence of manganese species with spin states S = 2. Recent EPR studies by Campbell and co-workers[43] confirm these findings.

For the active species involved in oxygen transfer, the cationic Mn^V complex **3**$^+$, we calculate the *S0* state to be most stable, with a triplet *S2*−**3**$^+$ 27 kJ/mol higher in energy, and a quintet *S4*−**3**$^+$ 101 kJ/mol less stable than the ground state. For the corresponding hexacoordinate compound **3**, on the other hand, the two states *S0* and *S2* are at virtually the same energy level, with a marginal preference for the singlet. In addition, the quintet state *S4*−**3** is only 45 kJ/mol higher in energy than the *S0* local minimum geometry. The molecular orbital diagram for the Mn^V-oxo species **3** and **3**$^+$, presented in Figure 1, offers an explanation for this observation.

The energy level schemes are derived from the corresponding singlet geometries. For **3**$^+$, the HOMO is dominated by contributions from a Mn-$d_{x^2-y^2}$ orbital, whereas the LUMO and LUMO+1 are metal-based, derived from the orbitals d_{xz} and d_{yz}. However, the last two orbitals are strongly antibonding with respect to the p orbitals of the oxo ligand. They are therefore raised in energy relative to the HOMO, and the resulting rather large HOMO/LUMO gap energetically stabilizes the singlet state. The degeneracy of the LUMO and LUMO+1 is lifted, due to orbital contributions from the tetra-chelating ligand. For the HOMO of **3**, we have substantial antibonding interaction between the Mn-$d_{x^2-y^2}$ orbital and occupied p orbitals of the Cl^- ligand. This interaction causes an energetic destabilization of the HOMO. As a consequence, the HOMO/LUMO gap is lowered, in favor of a triplet configuration. This orbital interaction provides a first hint as to how an additional π-

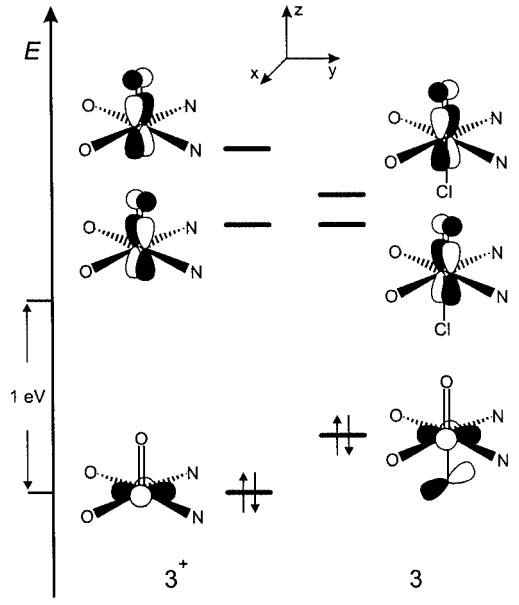


Figure 1. Frontier orbital diagram for Mn^V oxo complexes $\mathbf{3}^+$ and **3**

donor *trans* to the oxo ligand might exert an influence on the oxygen-transfer process.

Table 1 compares the relative energies of different spin state geometries of $\mathbf{2}^+$, **2**, $\mathbf{3}^+$, and **3** with the results of the two B3LYP studies by Strassner and Houk[24] and by Svensson and co-workers,[27] as well as with the recent study of Abashkin and co-workers.[40] This comparison focuses on technical aspects of the calculations, and the results in Table 1 are organized according to basis set quality into three groups. Group **I** refers to calculation utilizing a triple-ζ basis for Mn, and a double-ζ basis plus polarization for the remaining atoms. In group **II**, a double-ζ basis is used and polarization functions are added for Mn, Cl, O, and N, whereas group **III** essentially refers to double-ζ basis set calculations.

	B3LYP[f]	–	–	–	–	6	0	11	–	–	–

[a] Literature values have been converted. [b] Values for **2** and **3** from ref.[31] [c] 6−31G* (HCNOCl)/TZ(Mn) basis, ref.[24] [d] DZVP basis for Mn, Cl, N O, DZ basis for C, H; ref.[40] [e] DZ basis, ref.[40] [f] (14s,11p,6d) primitive basis augmented by two p and one diffuse d function contracted to [6s,5p,3d] for Mn, DZ basis for ligands, ref.[27]

Referring to group **I**, for the two cationic species and for **2,** our calculations are in qualitative agreement with the data reported by Strassner and Houk.[24] In particular, both sets of calculations predict the same energetic ranking for the Mn^{III} and Mn^V species, and indicate that the addition of the π-donating Cl^- ligand reduces the energy gap between the *S2* and *S4* states by about 30 kJ/mol. The reason is again to be found in the antibonding contributions from p orbitals of the Cl^- ligand, which destabilize only three of the four singly occupied metal d orbitals, rendering triplet occupation more stable for **2** than for $\mathbf{2}^+$. One difference between the BP86 and B3LYP functionals is the fact that the hybrid method, which contains an admixture of pure Hartree−Fock exchange, energetically favors the *S4* spin states. Thus, in cases in which *S4* is the ground state, such as **2** and $\mathbf{2}^+$, the energy difference between the *S4* and *S2* geometries is higher, by about 45 kJ/mol, for the B3LYP calculation than for BP86 results. On the other hand and for the same reason, *S4*−$\mathbf{3}^+$ is energetically more disfavored in the BP86 calculation, by 54 kJ/mol.

A major discrepancy is found for compound **3**. As discussed above, the BP86 calculations predict a singlet and a triplet geometry at almost the same energy. In contrast, the B3LYP method results in a triplet ground state, with the quintet close by in energy, and the singlet significantly higher.

A reason for this discrepancy may be found if group **II** data are included in the discussion. For $\mathbf{3}^+$ and **3** we find that the results of the BP86 calculations of Abashkin and co-workers[40] follow the same qualitative trend as our current and previous results. However, the energy differences between different spin states are significantly different. For **3** in particular, Abashkin and co-workers predict a singlet state, clearly favored over a triplet state, as ground state, whereas our calculations indicated that a singlet and a triplet state are essentially at the same energy level, well separated from a quintet state. This might be a first indication of the importance of an extended basis set for calculations on the type of molecules under investigation, describing the metal center on a triple-ζ basis, and including polarization functions for all atoms. Comparing B3LYP calculations of group **I** and **II**, we again find qualitative agreement. Triplet and quintet states are close in energy, whereas the singlet state is significantly higher in energy. However, Strassner and Houk find a triplet state at lowest energy, the quintet being 8 kJ/mol higher, whereas Abashkin and co-workers find the triplet to be 5 kJ/mol higher than the quintet, the latter now being the ground state. This again might be an indication for significant basis set influences.

Abashkin and co-workers have also addressed the comparison between the BP86 and the B3LYP approaches.[40] We recall that for **3** the two approaches provide qualitatively different results, the relative energy rankings being $S0 \approx S2 < S4$ for BP86 and $S0 > S2 \approx S4$ for B3LYP. In addition to DFT calculations, Abashkin and co-workers performed high level ab initio calculations, and the results for **3**, obtained from coupled cluster CCSD(T) calculations, are in line with BP86, but not with B3LYP. This study suggests that for this type of molecules the pure BP86 functional provides a more appropriate and a more suitable approach than the popular B3LYP hybrid functional.

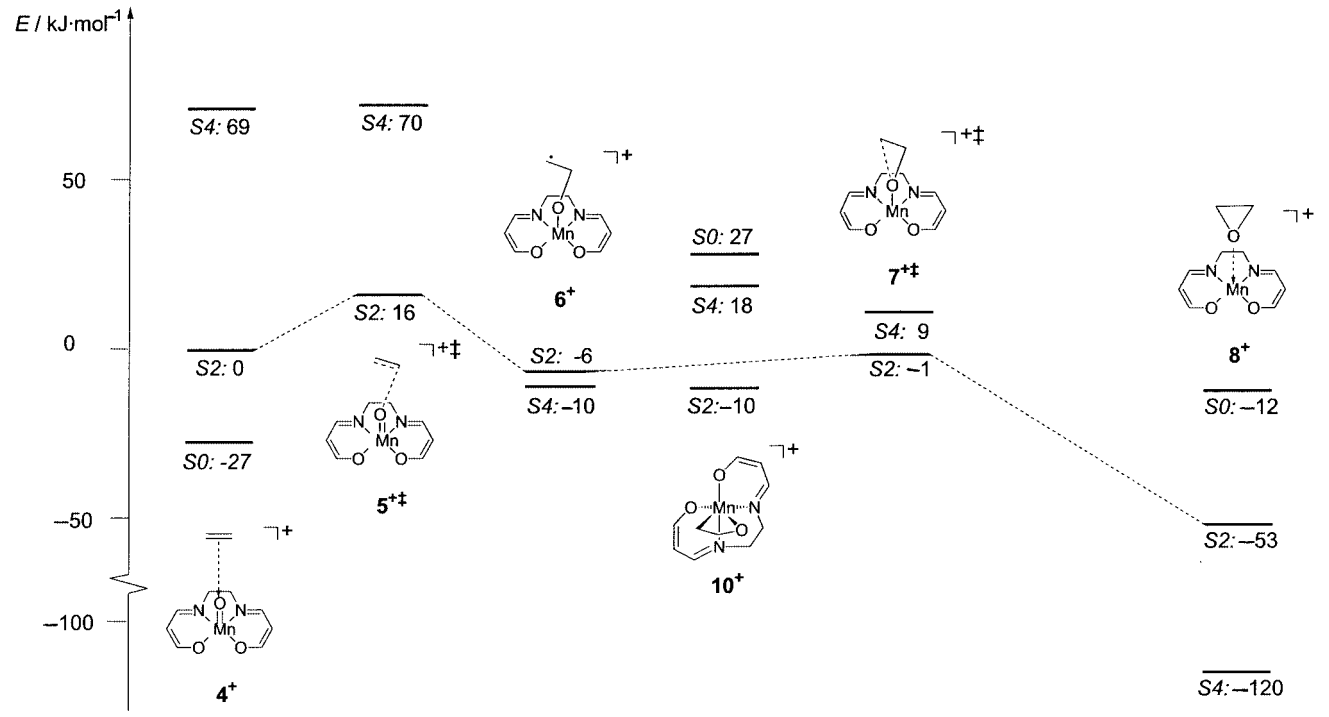

Figure 2. Energy profile for the epoxidation reaction

Finally, turning to group **III**, we find that the two sets of B3LYP calculations are in good qualitative agreement. However, B3LYP calculations without inclusion of polarization functions are significantly different from the B3LYP result for group **I**. This comparison again underlines the importance of an extended basis set for calculations on the type of molecules under investigation.

The importance of basis sets is further evident when the DZVP-BP86 results of Abashkin and co-workers for complex **2** are considered. The authors find a triplet state at lowest energy, a quintet state being 5 kJ/mol higher, whereas our previous BP86 results report the triplet as 38 kJ/mol above the quintet.

The Reaction Profile for Oxygen Transfer: The calculated energy profile for epoxide formation with the model catalyst $\mathbf{3}^+$ is displayed in Figure 2.

Relative energies for reactants, intermediates, transition states, and final products are reported for the *S0*, *S2*, and *S4* energy hypersurfaces. We comment on each of the single steps in more detail below.

The Reference System $\mathbf{4}^+$: In our reference system, the incoming olefin approaches the manganese catalyst from the site of the oxo ligand, and forms a weakly bonded adduct. In this complex, the distances between the olefinic C atoms and the Mn=O function amount to 300 and 320 pm, respectively. The system *S2*−$\mathbf{4}^+$ is set at 0 kJ/mol on the energy scale, and the energies of all other species are then given relative to *S2*−$\mathbf{4}^+$. It is worth mentioning that the relative energies of the different spin states *S0*, *S2*, and *S4* are in essence identical to those obtained for the free oxo cation $\mathbf{3}^+$ (compare Table 1). We chose this aggregate as reference state over the completely separated molecules (C_2H_4 + $\mathbf{3}^+$), since some of the computational errors involved in determining the energetics of bond-forming reactions, especially those stemming from basis set superposition effects,[44] are reduced in such a combined approach.

The First Transition State $\mathbf{5}^{+\ddagger}$: On the *S2* energy hypersurface, the energy of the $\mathbf{5}^{+\ddagger}$ structure lies 16 kJ/mol above the reference state *S2*−$\mathbf{4}^+$, indicating that the first C−O bond formation does not represent much of an energetic barrier. The distance d_{C-O} amounts to 189 pm, similar to that calculated for the corresponding structure *S2*−$\mathbf{5}^{\ddagger}$.[31] The Mn−O bond is 169 pm, significantly elongated compared to that in *S2*−$\mathbf{3}^+$ (d_{Mn-O} = 161 pm). The values of spin density at the Mn center and the terminal C atom of the olefinic substrate amount to 2.4 α and 0.5 β, respectively, indicating that the epoxidation reaction is initialized by a one-electron reduction process. From both the electronic and the geometric structures of *S2*−$\mathbf{5}^{+\ddagger}$ it can be concluded that *S2*−$\mathbf{5}^{+\ddagger}$ has to be classified as a late, or product-like, transition state on the triplet surface. This observation, together with an orbital analysis for the radical intermediate presented in the next section, also rules out the existence of an energetically low-lying *S0*−$\mathbf{5}^{+\ddagger}$ geometry. A different situation is found when the process is assumed to take place on the quintet surface. The *S4*−$\mathbf{5}^{+\ddagger}$ state is already reached when the bond-forming C-atom is about 240 pm away from the oxo center, and is only marginally higher in energy than *S4*−$\mathbf{4}^+$. Also, the electronic situation more closely resembles that of the reactant system, with spin density mostly located at the metal center and at the oxo ligand. In this case the reaction occurs through an early transition state, as already noted by Svensson and coworkers.[27]

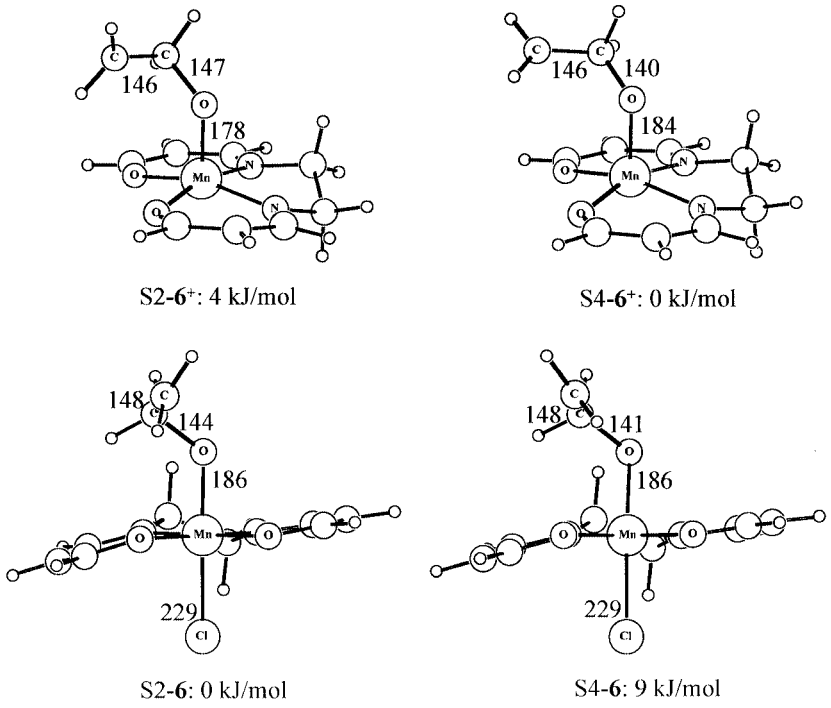

Figure 3. Optimized structures and relative energies for *S2* and *S4* geometries of $\mathbf{6}^+$ and **6**

The Radical Intermediate $\mathbf{6}^+$: Figure 3 compares the geometries and relative energies of the radical intermediates *S2*−$\mathbf{6}^+$ and *S4*−$\mathbf{6}^+$ with those of the corresponding neutral systems *S2*−**6** and *S4*−**6**.

A few important differences deserve more detailed discussion. Firstly, we note that the Mn−O distances in the cationic systems are between 8 and 2 pm shorter than those found for the system with the Cl ligand *trans* to the oxo group, pointing to a *trans* influence of the additional π-donor ligand. We also see that both chloro species *S2*−**6** and *S4*−**6** have the same Mn−O separation, whereas the triplet geometry shows significantly shorter Mn−O distances for the cationic complexes $\mathbf{6}^+$. Secondly, we observe that the coordination geometry of the quintet species is substantially different from that of the triplet systems. In the latter, the original orientation of the olefin is preserved, whereas in the former we see that the terminal CH_2 group is rotated by 90°. Thirdly, for the cationic system $\mathbf{6}^+$ we calculate a small energetic preference for the *S4* state (of 4 kJ/mol), whereas for the neutral system **6** the *S2* state is more stable by 9 kJ/mol.

A qualitative analysis of the frontier Kohn-Sham orbitals corresponding to the α spin density for the *S2* geometries provides a rationale for the above observations. The highest occupied orbital 1a and the lowest unoccupied orbitals 2a for system $\mathbf{6}^+$ and **6** are presented in Figure 4.

For the formal Mn^{IV} species, these orbitals are mainly Mn-based d orbitals, undergoing antibonding interaction with the $-OC_2H_5$ ligand. For **6**, we see that the interplay of the p-Cl and d-Mn orbitals adds additional antibonding character. A promotion of one electron into orbital 2a, resulting in an electronic quintet state, is thus disfavored for

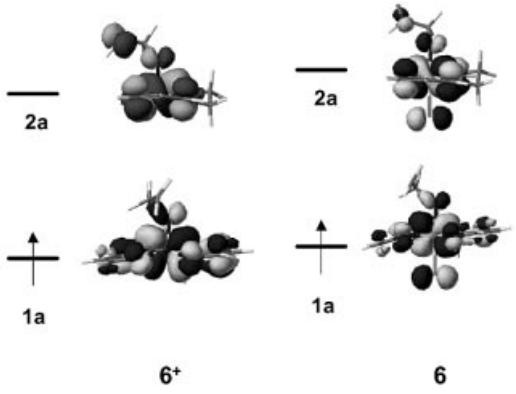

Figure 4. Frontier orbitals for the Mn^{IV} complexes $\mathbf{6}^+$ and **6**

6 by an increase in the repulsive Mn−Cl interaction. This argument suggests that the role of the π-donor in the *trans* position is a relative destabilization of a possible quintet occupation, thus conferring spin rigidity to the six-coordinate species derived from the neutral catalyst **2**. In our previous study we calculated that *S2*−**6** is energetically favored over *S4*−**6** by 9 kJ/mol. We also see that the orbital 2a has large contributions from the p orbitals of the terminal CH_2 group, which interact with the formerly oxo ligand in an antibonding fashion. As a consequence, when this molecular orbital becomes occupied, the terminal CH_2 group twists to relieve this destabilizing interaction. As mentioned before, the *S4* geometries both for **6** and for $\mathbf{6}^+$ do indeed exhibit this structural characteristic.

Another important feature observed in Figure 3 is the folded geometry of the tetra-chelating N,O ligand. This arrangement has been identified as one of the key points in

the mechanism of enantioselectivity[45] and we return to a more detailed analysis of this structural feature at a later point.

The Second Transition State $7^{+\ddagger}$: On the *S2* surface, the transition state $\mathbf{7}^{+\ddagger}$ for the formation of the second C−O bond is only 9 kJ/mol higher in energy than the triplet intermediate (Figure 2). The long length of the newly forming C−O bond classifies *S2*−$\mathbf{7}^{+\ddagger}$ as an early transition state. Product formation from the radical intermediate thus occurs without much of an energetic barrier. In comparison with *S2*−$\mathbf{7}^{+\ddagger}$, the transition state *S4*−$\mathbf{7}^{+\ddagger}$ is 10 kJ/mol higher in energy. The characteristic mode receives a strong contribution from the CH_2-twist required for ring closure to form the epoxide.

The Epoxide Adduct 8^+: Characteristic bond lengths and bonding energies for epoxide complexes $\mathbf{8}^+$ are compiled in Table 2.

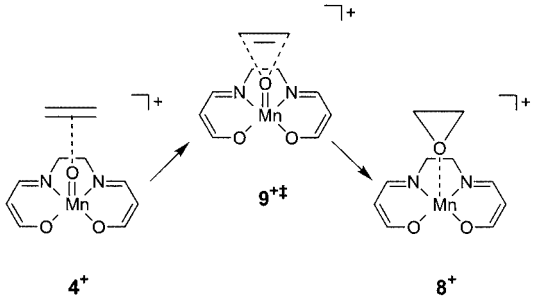
Table 2. Bond lengths (pm) and bond energies (kJ/mol) for Mn^{III} epoxide complexes $\mathbf{8}^+$

	d_{Mn-O}	BE
S0−$\mathbf{8}^+$	198	123
S2−$\mathbf{8}^+$	199	85
S4−$\mathbf{8}^+$	223	85

We see that the forming epoxide is only loosely bound to the metal centers, the coordination geometries and relative energies of which resemble those of the Mn^{III} precursor models $\mathbf{2}^+$. Only the *S0* complex is somewhat more strongly stabilized, relative to the *S2* and *S4* systems. The most stable complex is therefore *S4*−$\mathbf{8}^+$, followed by *S2*−$\mathbf{8}^+$, 67 kJ/mol higher in energy. If the cationic complexes considered here are the true catalytically active species, a spin change during the course of the epoxidation reaction might indeed occur in the reaction sequence. On the other hand, it is worth mentioning that the energetic difference between the corresponding chloro complexes *S4*−**8** and *S2*−**8** only amounts to 4 kJ/mol, in favor of the quintet state.[31] As we have already argued in this context, catalytic cycles based on Mn complexes derived from the hexacoordinate model system **3** are likely to take place as spin-conserving reactions.

As mentioned before, the resulting epoxides are only loosely bonded to the metal center. Furthermore, we should keep in mind that our calculations are performed on isolated systems in the gas phase, and we can expect that solvent effects should substantially stabilize the coordinatively unsaturated cation $\mathbf{2}^+$, thus further reducing the bond energy of the epoxide ligand. If in addition we take into account unfavorable coordination entropy, for which at room temperature a $T\Delta S$ contribution between 40 and 50 kJ/mol can be estimated,[46] we conclude that product liberation is not a critical step in the catalytic cycle.

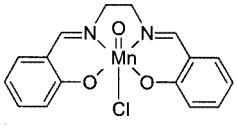
The Transition State $9^{+\ddagger}$ for Synchronous Attack: So far, we have considered the epoxidation reaction as a sequence of two consecutive C−O bond-formation steps. Alternatively, one might think of a concerted mechanism that involves an epoxide-like transition state $\mathbf{9}^{+\ddagger}$ (Scheme 3).



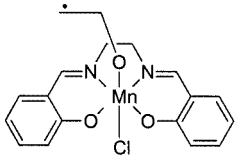
Scheme 3

Such a mechanism, however, although consistent with certain experimental findings,[22] does not offer a simple explanation for the observed *cis*/*trans* isomerization that frequently occurs in the epoxidation reaction. For our model reaction we have localized the corresponding structures both on the triplet and on the quintet surfaces. Compared to the reference system, structures *S2*−$\mathbf{9}^{+\ddagger}$ and *S4*−$\mathbf{9}^{+\ddagger}$ are 32 and 74 kJ/mol higher in energy, respectively. This implies that, on the *S2* surface, the concerted mechanism is kinetically disfavored relative to the stepwise reaction by 16 kJ/mol. Even in the *S4* case the stepwise reaction is favored by 4 kJ/mol.

Ligand Folding: As noted above in the context of the radical intermediate $\mathbf{6}^+$, the tetra-chelating N,O model ligand shows significant deviations from a planar structure, and has a folded geometry, as shown in Figure 3. We now discuss ligand folding for the representative geometries of the oxomanganese species $\mathbf{3}^+$ and **3**, as well as of the radical intermediates $\mathbf{6}^+$ and **6**, including the corresponding structures **3s** and **6s** of a Mn(salen) complex.[31]



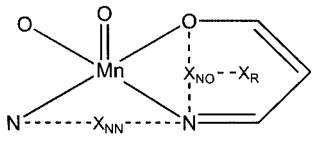
3s



6s

Ligand folding is discussed in connection with the bent angles φ_{up} and φ_{down}, and the distance of pyramidalization, d_P. A bent angle φ is defined as $\varphi = 180° - \angle(Mn-X_{NO}-X_R)$, the angle $\angle(Mn-X_{NO}-X_R)$ being that measured between the metal center, the midpoint of adjacent N,O heteroatoms (X_{NO}), and the midpoint of the six-

membered ring containing the metal and the N,O heteroatoms (X_R, Scheme 4).



Scheme 4

The angle φ_{up} indicates the part of the tetra-chelating N,O ligand being bent towards the oxo or towards the ethoxy ligand, whereas φ_{down} characterizes the part of the tetra-chelating N,O ligand bent towards the free coordination site or towards the chlorine ligand. Furthermore, the distance of pyramidalization d_P is defined as the separation between the metal atom and the $O-X_{NN}-O$ plane, X_{NN} being the midpoint between the two N atoms. A value of d_P close to zero indicates that the metal essentially lies within the O,N,N,O coordination plane. The values for the folding angles and for the distance d_P are collected in Table 3.

Table 3. Relevant angles (°) φ_{up}, φ_{down} and distance of pyramidalization (pm) d_P for cationic (this work) and neutral (from data of ref.[31]) Mn complexes

	S2			S4		
	φ_{up}	φ_{down}	d_P	φ_{up}	φ_{down}	d_P
3$^+$	18	8	42	7	2	22
3	19	17	11	3	13	4
3s	10	16	0	10	17	1
6$^+$	20	5	29	18	3	31
6	8	16	0	8	15	0
6s	8	15	0	8	15	0

The folded ligand geometries as shown in Figure 3 are characterized by bent angles φ being 10° or larger, and by d_P being essentially zero. Inspection of the values reported in Table 3 indicates that highly bent angles φ are found in all cases, with the single exception of *S4*−**3**$^+$. For the cationic molecules, however, the metal atom is considerably shifted out of the O,N,N,O coordination plane with values of d_P of between 20 and 45 pm. The cationic molecules do not display the folded geometry as shown in Figure 3, and they probably also do not posses the ability to form a chiral pocket, needed for transfer of enantioselectivity.[45] On the other hand, the neutral systems under consideration display φ and d_P values indicative of a folded ligand geometry. In particular, we note that similar structures are observed for the salen ligand in the radical intermediate **6s** and for the model ligand in complex **6**. It has recently been suggested that the degree of ligand folding is determined by the nature of the axial ligand in Mn(salen) complexes, which in turn has implications for the reaction rate of epoxidation reactions.[47]

Structural Alternatives: We briefly discuss two further complex geometries that might be of importance: namely a metallacycle **10**$^+$ and an olefin complex of the Mn^V-oxo species, **11**$^+$. Representative structures are displayed in Figure 5.

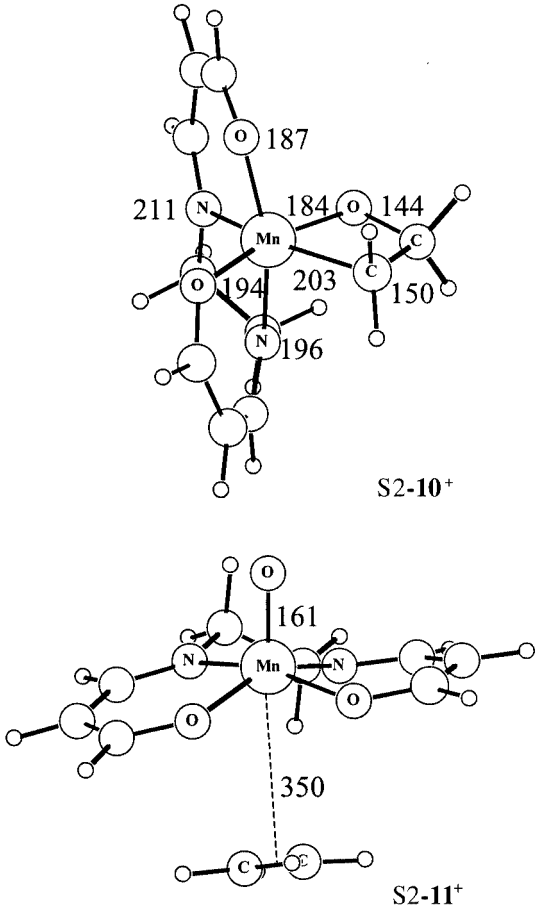


Figure 5. Representative *S2* geometries for a possible manganaoxetane **10**$^+$ (above), and an Mn^V-oxo olefin adduct **11**$^+$ (below)

Metallacyclic Intermediates: The possibility that metallacycles might be viable intermediates in the epoxidation reaction, and might play a key role in the mechanism of enantioselectivity, has been the subject of a vivid debate in the literature.[17] Indeed, one of the first models of the chirality transfer deduced from calculations uses a manganoxetane as a key intermediate.[48] We have already mentioned that the orbital analysis for structures **6**$^+$ points to the possible existence of metallacyclic intermediates. We were able to locate local minima corresponding to such a species on the *S0*, *S2*, and *S4* hypersurfaces, their relative energies being given in Figure 2. Interestingly, the structure *S2*−**10**$^+$ is energetically even slightly more stable than the radical intermediate. Its geometry is displayed in Figure 5. The Mn−O distance of the four-membered ring is about 6 pm longer than *S2*−**6**$^+$, but still within the calculated range for other Mn−O bonds. The Mn−C bond is 203 pm long, substantially shorter than the Mn−C separations in the radical intermediates (around 230 pm). The Mn center possesses a pseudo-octahedral coordination geometry, with a significantly elongated Mn−N bond *trans* to the oxacycle. The formation of the oxacycle is favored since the Mn center in **6**$^+$ is coordinatively unsaturated. Indeed, a seven-coordin-

ated manganaoxetane **10** is 104 kJ/mol higher in energy than the radical intermediate **6**.[31] Although structure $\mathbf{10}^+$ might be an alternative for an intermediate local minimum geometry, it is not likely to play a major role in product formation. We calculated that formation of $\mathbf{8}^+$ starting from $\mathbf{10}^+$, rather than $\mathbf{6}^+$, is associated with an activation barrier of about 35 kJ/mol. This result is in agreement with a recent study that made use of electrospray ionization in combination with tandem mass spectrometric techniques.[49] It was found that the presence of axial ligands decreases the stability and thus enhances the reactivity of the Mn=O moiety. In the cationic system, the manganaoxetane $\mathbf{10}^+$ is an energetically favorable intermediate in comparison with the radical intermediate $\mathbf{6}^+$, but possesses a higher activation barrier towards product formation, and thus a reduced reactivity. In contrast, systems with axial ligands do not possess energetically favorable, metallacyclic resting intermediates.[31]

Olefin Pre-Coordination: Since the catalytic model system $\mathbf{3}^+$ is coordinatively unsaturated, one might consider the possibility that the olefinic substrate coordinates to the metal center before the oxygen transfer occurs. We investigated possible complexes of this type on the S0, *S2*, and *S4* surfaces, and found in all cases that the olefin is only weakly bound. A representative geometry $S2-\mathbf{11}^+$ is shown in Figure 5. The distance between the olefin and the metal center amounts to about 350 pm, and the relative energy is only 4 kJ/mol lower than the one calculated for the reference system $S2-\mathbf{4}^+$. The pre-coordination of an olefin can thus be excluded as a vital step in the epoxidation reaction. This conclusion is in agreement with the results of the recent electrospray tandem mass spectrometric study by Plattner and co-workers, who, in a suitable experimental set-up, did not find any indication of pre-coordination of the substrate as prerequisite for oxidation.[33]

Comparison with d^0 Metal Oxo and Peroxo Species: In this final section we present a brief comparison with related theoretical work on oxygen-transfer reactions involving transition metal complexes. Olefin epoxidations mediated by transition metal oxo complexes in high oxidation states, especially those catalyzed by Herrmann-type complexes $[ReO(O_2)_2CH_3]$ and Mimoun-type complexes $[MoO(O_2)_2(OPR_3)]$, have recently generated much interest among experimentalists and theoreticians alike, and Rösch's[50] and Deubel and Frenking's[51] groups have presented detailed theoretical mechanistic studies. The interested reader will also find extensive references to the literature in these computational contributions. Unlike in this work, the olefin attacks an oxygen center in a *concerted* fashion. The preferred site of initial attack is a peroxo ligand, giving rise to *spiro* oxygen in the transition state. Using charge decomposition analysis, Deubel and Frenking[51a] have characterized the electronic nature of the initial attack in terms of classical donor-acceptor interactions, in which the d^0 metal oxo and peroxo species attack the olefin in an electrophilic manner. For the Mn(salen) systems, charge analysis based on Voronoi deformation densities suggests a similar electronic picture. However, the characteristic feature of the transition states $\mathbf{5}^+$ and **5** is a build-up of spin density at the terminal carbon atom. This process is essentially responsible for the locally asymmetric attack of the olefin at the oxo center, which further determines the geometric features of the transition state necessary for chirality transfer.[45] Consistently with our findings, Deubel and Frenking conclude that olefin precoordination at the metal center does not apparently play a role in Mo^{IV}-catalyzed epoxidation reactions,[51c] the reaction profile in both cases being determined by direct oxygen attack of the olefin.

Conclusion

The main results of this study are summarized in the following points. By our computational approach, the epoxidation of ethylene with the cationic five-coordinate model catalyst $\mathbf{3}^+$ is predicted to occur through a radical intermediate, similarly to the reaction mechanism calculated for the corresponding neutral six-coordinate species **3**. In contrast to the reaction profile for **3**, we do not find a clear preference for the *S2* state throughout the whole process. The radical intermediate $\mathbf{6}^+$ shows a small energetic preference for the quintet state over the triplet state. However, contrary to previous studies,[27] we were able to locate a radical intermediate as a local minimum structure on the *S4* hypersurface. On inspection of the computed reaction profile, it seems unlikely that two-state reactivity involving spin change might play a major role in the oxygen-transfer step. Comparative orbital analysis of the cationic and the neutral complexes provides an explanation as to how the ligand *trans* to the oxo group confers spin rigidity to the catalytic systems. However, the different coordination geometries of models $\mathbf{6}^+$ and **6** on the *S2* and *S4* surfaces, respectively, indicate that spin change might indeed be of importance to epoxide formation. Whereas in the *S2* species the two carbon centers of the olefinic substrate are still in π-conjugation, the terminal methylene group in the *S4* complexes is rotated by 90°. This points to the possibility that the pathway of rotational collapse might involve a spin-crossing process. Metallacyclic intermediates might occur during the epoxidation reaction mediated by cationic complexes. However, these complexes constitute resting states, and are likely to display a reduced reactivity towards epoxide formation, in comparison with radical intermediates. Pre-coordination of an olefin is likely to be excluded as a vital step in the epoxidation reaction

This and our previous studies[31] strongly suggest that the crucial step to enantioselectivity is the transition state of the first carbon-oxygen formation. From this assumption, and from the results obtained so far, we have already developed a model that explains the enantioselectivity in the Mn(salen)-catalyzed epoxidation of olefins.[9,19,45] Nevertheless, one has to keep in mind the fact that solvent effects as well as the presence of auxiliary ligands are likely to influence the course of the epoxidation reaction. In addition, reaction profiles in which other Mn^{IV} species are involved in the epoxidation reaction have recently been addressed in

the literature,[52] and deserve further computational attention. Recent theoretical studies[53] have demonstrated a general interest in mechanistic aspects of transition metal-mediated reactions resulting in the formation of three-membered ring systems, and recent experimental work[54,55] illustrates the ongoing discussion of the mechanistic aspects of enantioselective epoxidation reactions. In particular, the contribution by Adam and co-workers experimentally addresses the question of whether radical or cationic intermediates are present in the Mn(salen)-catalyzed epoxidation, and attributes counterion effects to computationally assessed ligand-dependent reaction profiles.[55] It is to be hoped that this study will prove to be helpful in supporting such studies, and will provide further impetus for future work, experimentally as well as theoretically.

Computational Details

Spin-polarized calculations were performed with the ADF program package, version 2.3.0.[56] The local exchange-correlation potential of Vosko and co-workers[57] was augmented self-consistently by Becke's exchange gradient-correction and Perdew's correlation gradient-correction (BP86).[32] The ADF basis set IV (triple-ζ STO plus one additional 4*p* function) was used for Mn, whereas basis set III (double-ζ STO plus one polarization function) was employed for the remaining atoms. These basis sets imply the use of the frozen core approximation, in which only the *n*- and $(n + 1)$-valence orbitals are treated explicitly in a self-consistent manner.[58] The numerical integration scheme developed by te Velde[59] was used, and the grid was chosen such that representative test integrals were evaluated with an accuracy of at least four significant digits. Analytical gradients were calculated by the method described by Versluis.[60] Transition states were first traced by a synchronous linear transit method, and then refined by establishing one negative frequency in the spectrum of the approximate Hessian used to construct geometry updates. The validity of this approach has been demonstrated in the literature.[61]

Acknowledgments

Support from the Italian MURST (L.C.), and access to the computational facilities of the Rechenzentrum der Universität Zürich (H.J.) are gratefully acknowledged. L.C. thanks the CIMCF of the Università Federico II of Napoli for technical support. The constructive comments of one of our referees are highly appreciated.

A Dinuclear Iron Complex with Two Cofacial [FeS_4] Cores Linked by Covalent Ligand Periphery Clamps and Dissociable Thiolate Bridges

Dieter Sellmann,*[a] Kai P. Peters,[a] Raquel Montón Molina,[a] and Frank W. Heinemann[a]

Dedicated to Professor Dr. Horst Kisch on the occasion of his 60th birthday

Keywords: Iron / S ligands / Bridging ligands / Enzyme models

As part of a long-term study of dinuclear iron complexes with sulfur-rich coordination spheres and cofacial, sterically variable binding sites for molecules relevant to nitrogenase, the complex $(AsPh_4)_2$ [{Fe('apS_4')}$_2$] (**5**) was synthesized and completely characterized ['apS_4'$^{4-}$ = 1,3-bis(2,3-dimercaptobenzamido)propane(4–)]. Complex **5** contains two cofacial [$Fe^{III}(S_2C_6H_4R)_2]^-$ units linked by [Fe–S–Fe] thiolate bridges and two peripheral propanediamide ligand backbones that are located on opposite sides of the molecular anion and prevent the complete separation of the two [FeS_4] cores of **5** if the Fe–S–Fe bridges dissociate. No marked differences were found in the molecular parameters, spectroscopic, magnetic and electrochemical properties of the [Fe_2S_8] cores in the anion of **5** and the parent complex [{$Fe(S_2C_6H_4)_2$}$_2]^{2-}$.

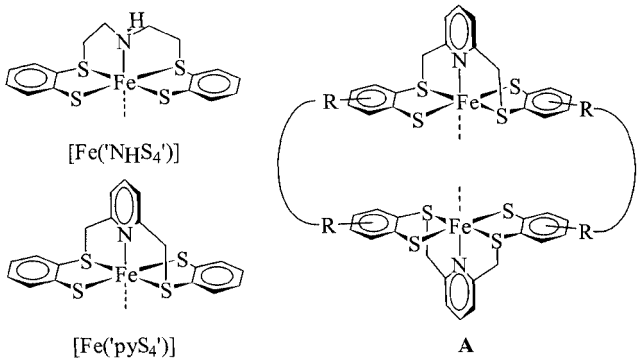
Introduction

Iron in sulfur-rich coordination spheres is the characteristic feature of the polynuclear FeMo, FeV or FeFe cofactors of nitrogenases.[1] Interaction of N_2 with these cofactors to give metal-sulfur N_2 complexes is considered to be the primary step of N_2 fixation, and the prevalence of iron in all three types of cofactors supports current hypotheses that the resulting metal−sulfur N_2 complexes are species in which N_2 acts as a bridge between at least two [$Fe(S_n)$] sites held together by the other metal−sulfur bonds of the cofactor and, in addition, the surrounding enzyme protein.[2] Low molecular weight analogues are unknown despite a prolonged search for complexes capable of modeling both structural (metal sulfur sites) and functional (binding N_2) aspects of nitrogenase cofactors.[2]

Complex fragments such as [Fe('N_HS_4')] and [Fe('pyS_4')] (Scheme 1) have been shown to bind and activate or stabilize many molecules relevant to nitrogenase, such as CO, NO, N_2H_2, N_2H_4, and NH_3, though not yet N_2.[2f,3]

To enforce the binding of N_2 to such fragments we initiated work[4] on complexes (type **A**) that contain two [$Fe(S_n)$] sites held together by bridges (potentially modeling the enzyme protein); the [Fe('pyS_4')] fragments favor the low-spin state of Fe^{II}, which in turn favors the binding of nitrogenase relevant molecules,[5] and the bulky [Fe('pyS_4')] fragments plus the spacers protect the vacant sites at the iron centers.



Scheme 1. Known complex fragments and the ultimate target molecule **A**

Such a synthetic challenge requires the complexation of iron by benzene dithiolate ligands, the formation of the [Fe('pyS_4')] fragments, and the connection of two such fragments by bridges between benzene rings. The essential cofacial arrangement of the [$Fe(S_4)$] units and the regioselective formation of the py$(CH_2)_2$ bridge mean that all reaction steps have to be stereoselective.

To obtain cofacial dinuclear iron benzene ditholate complexes we used our previous results on iron complexes of 2,3-dimercaptobenzoic acid,[4] methods developed by Hahn et al. for bridging 2,3-dimercaptobenzoic acid units by α,ω-

[‡] Transition Metal Complexes with Sulfur Ligands, Part 157. Part 156: D. Sellmann, D. C. F. Blum, F. W. Heinemann, J. Sutter, *Eur. J. Inorg. Chem.*, in press.

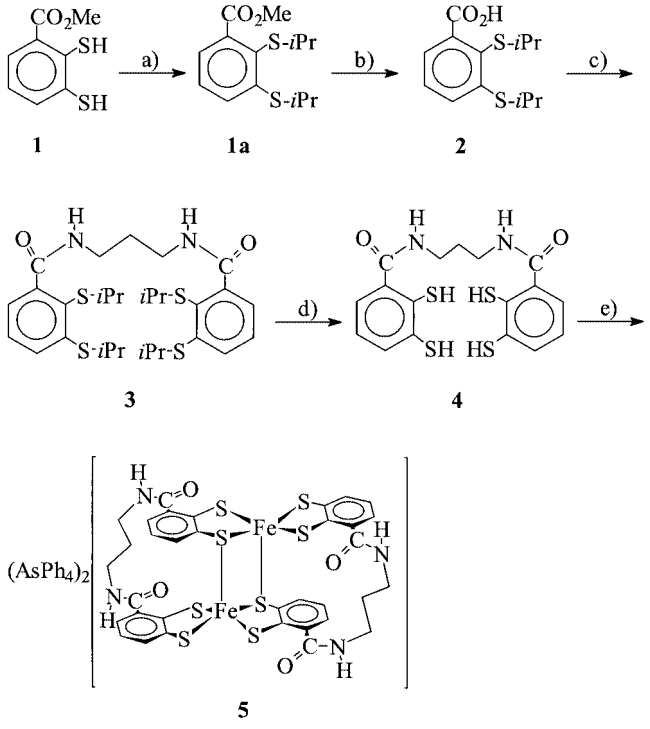
diamines,[6] and the fact that Fe^{III} ions and benzene dithiolate give dinuclear $[\{Fe(S_2C_6H_4)_2\}_2]^{2-}$ anions.[7]

Herein we report the synthesis and properties of the novel Fe^{III} complex $(AsPh_4)_2[\{Fe(`apS_4')\}_2]$ (**5**) where 'apS_4'$^{4-}$ denotes a ligand in which two 1,2-benzenedithiolate units are connected by a 1,3-dicarboxamido propane bridge.

Results and Discussion

Scheme 2 summarizes the multi-step procedure leading to the target complex **5**.



Scheme 2. Synthesis of $(AsPh_4)_2[\{Fe(`apS_4')\}_2]$ (**5**) (a) + 2NaOMe, + 2*i*PrBr, MeOH, 20 h reflux; (b) (1) + $NaOH_{exc.}$, THF/H_2O, 44 h reflux, (2) HCl/H_2O; (c) (1) + $SOCl_{2\ exc.}$, (2) + 0.51, 3-diaminopropane, THF; (d) (1) + 10Na, + $5C_{10}H_8$, THF, (2) HCl, H_2O; (e) (1) + 4LiOMe, + $FeCl_3{\cdot}6H_2O$, MeOH, (2) + $AsPh_4Cl$.

The synthesis of the tetrathiol 'apS_4'-H_4 (**4**) followed the method of Hahn et al. for related compounds.[6] The starting material was the 2,3-dimercaptobenzoic acid methyl ester **1** ('CO_2Me-S_2'-H_2)[4a] in which the thiol functions were protected by isopropyl groups to give **1a**. Ester hydrolysis yielded the acid **2** which was treated with $SOCl_2$ to give the corresponding carboxylic acid chloride. Subsequent reaction with 1,3-diaminopropane yielded the diamide **3**. Deprotection of the thioether functions with sodium naphthalenide and subsequent acidification gave the tetrathiol **4** which was isolated as a white powder in pure form.

Coordination of the tetraanion of **4** to Fe^{III} centers was achieved by deprotonating **4** with equivalent amounts of LiOMe and subsequent reaction with $FeCl_3{\cdot}6H_2O$ in boiling MeOH. A dark violet solution resulted, from which $(AsPh_4)_2[\{Fe(`apS_4')\}_2]$ (**5**) precipitated after addition of $AsPh_4Cl$.

As the X-ray structure analysis of **5** showed, the tendency of the $[Fe^{III}(benzenedithiolate)_2]^{1-}$ units to dimerize via [Fe−S−Fe] bridges,[8] and the steric constraints and electronic effects resulting from the carboxamido substituents were successfully used to obtain the required diastereoisomer. MeOH was employed as solvent because its boiling point favors the formation of dinuclear instead of polynuclear (polymeric) species.

Compounds **1**, **1a**, **2**, **3**, and **4** are moderately to very soluble in organic solvents such as CH_2Cl_2, $CHCl_3$, THF, and DMF. Complex **5** is soluble in DMF and MeCN. All compounds were characterized by elemental analyses and spectroscopic methods.

The molecular structure of **5**·2MeOH, determined by X-ray analysis, is depicted in Figure 1, and Table 1 lists selected distances and angles.

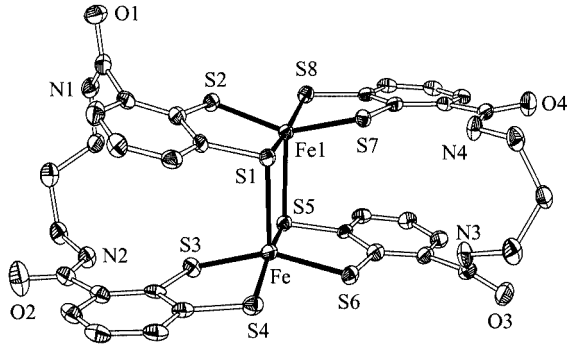


Figure 1. Molecular structure of the anion of $(AsPh_4)_2[\{Fe(`apS_4')\}_2]{\cdot}2MeOH$ (**5**·2MeOH) (50% probability ellipsoids; H atoms omitted)

Table 1. Selected distances [pm] and angles [°] of $(AsPh_4)_2[\{Fe(`apS_4')\}_2]{\cdot}2MeOH$ (**5**·2MeOH)

Distances		Angles	
Fe1−S1	222.9(2)	S8−Fe1−S1	168.55(5)
Fe1−S2	222.7(2)	S2−Fe1−S1	89.93(5)
Fe1−S7	222.4(2)	S1−Fe1−S5	95.19(5)
Fe1−S8	221.6(2)	S5−Fe2−S1	96.02(5)
Fe1−S5	248.4(2)	S4−Fe2−S5	166.21(5)
Fe2−S1	245.5(2)	S5−Fe2−S6	89.01(5)
Fe2−S3	222.9(2)		
Fe2−S4	220.8(2)		
Fe2−S5	222.8(2)		
Fe2−S6	223.1(2)		

The anion of **5**·2MeOH contains two $[FeS_4]$ units linked via two Fe−S−Fe bridges such that five-coordinate Fe centers with distorted square-pyramidal coordination result. In addition, the two $[FeS_4]$ units are connected by two peripheral propanediamide bridges between the benzene rings. These propanediamide bridges are located at opposite sides of the anion, which exhibits pseudo-C_i symmetry.

The bond lengths and angles within the $[Fe_2S_8]$ core are practically identical to those found in $(NEt_4)_2[\{Fe(S_2C_6H_4)_2\}_2]$[8a](**6**) and $(NBu_4)_2[\{Fe(S_2C_6H_3Me)_2\}_2]$[8b](**7**).

This indicates that the peripheral propanediamide bridges exert no steric strain on the [Fe_2S_8] core. For example, the average Fe−S distance within the [$Fe(S_2C_6H_3R)_2$] units amounts to 222 pm in **5** as well as in the nonbridged dinuclear species **6** and **7**. The distances between the iron centers and the (bridging) apical thiolate donors are significantly longer, by ca. 25 pm in **5**, as has also been found in **6** and **7**.

The propanediamide bridges could influence the overall structure of **5**·2MeOH in several ways. The apical thiolate donors S(1) and S(5) forming the bridges between the two iron centers occupy ring positions *meta* to the carboxamide substituents. Consequently, the carboxamide substituents could have an electron-withdrawing influence upon the thiolate donors, which is expected to be larger for the *ortho*-standing thiolate donors, disfavoring the formation of Fe−S−Fe bridges. The structure of **5**·2MeOH further shows that the carboxamide groups can adopt configurations that are in-plane with, or orthogonal to, the benzene rings. This indicates that the carboxamide substituents can rotate around the plane of the benzene ring such that, upon dissociation of the [Fe−S−Fe] bridges, the [Fe(benzenedithiolate)$_2$] fragments can separate to permit the insertion of small molecules between the iron centers, as in $(NBu_4)_2[\mu\text{-}N_2H_4\{Fe(S_2C_6H_4)_2\}_2]$.[9] Rotation of the carboxamide substituents around the benzene rings was corroborated by the X-ray structure determination of solvent-free **5**. In this structure, all carboxamido substituents adopt a skewed conformation with regard to the benzene rings. All other distances and angles are similar to those of **5**·2MeOH. Reduction of dinuclear $[\{Fe^{III}(S_2C_6H_4)_2\}_2]^{2-}$ is also known to give mononuclear $[Fe^{II}(S_2C_6H_4)_2]^{2-}$.[7]

The anion of **5** and the parent $[\{Fe^{III}(S_2C_6H_4)_2\}_2]^{2-}$ anion exhibit similar spectroscopic, magnetic and electrochemical properties. Both anions are paramagnetic with μ_{eff} = 2.4 μ_B for **5** and μ_{eff} = 2.3 μ_B for **6**,[8c] which is indicative of two low-spin Fe^{III} centers and partial antiferromagnetic coupling through the thiolate bridges.

The ^{1}H NMR spectrum of **5** in [D_6]DMSO exhibits paramagnetically shifted signals between δ = 8 and −45 ppm that could not be assigned, with the exception of the $AsPh_4^+$ signal at δ = 7.8 ppm. In the mass spectrum, only the $AsPh_4^+$ ion could be detected.

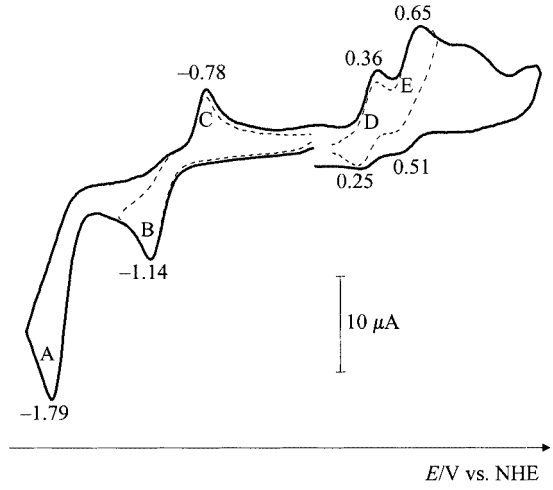

Figure 2. Cyclic voltammogram of **5** in MeCN (10^{-3} M, 10^{-1} M NBu_4PF_6, v = 0.10 V s^{-1})

The UV/Vis spectrum of **5** shows absorptions at 314, 364, and 512 nm while that of **7** exhibits absorptions at 315, 370, and 526 nm. The cyclic voltammogram of **5** in MeCN shows five redox waves (see Figure 2). The anodic waves D and E appear to be quasi-reversible, while waves A−C are regarded as irreversible. However, the redox waves B and C resemble the quasi-reversible redox wave of **6** in DMSO at −0.99 V (vs. NHE) assigned to the redox couple $[\{Fe^{III}(S_2C_6H_4)_2\}_2]^{2-/3-}$.[8c] Correspondingly, the waves B and C may be assigned tentatively to the redox couple $[\{Fe(\text{`}apS_4\text{'})\}_2]^{2-/3-}$.

Conclusion

In the search for dinuclear iron complexes with cofacial [FeS_4] cores as potential precursors for subsequent alkylation reactions yielding cofacial [Fe(‘pyS_4’)] fragments held together by ligand periphery clamps, $(AsPh_4)_2[\{Fe(\text{`}apS_4\text{'})\}_2]$ (**5**) was synthesized and characterized. Structural, magnetic, spectroscopic and electrochemical properties of the anion of **5** are similar to those of the parent anion $[\{Fe(S_2C_6H_4)_2\}_2]^{2-}$ (**6**). In contrast to **6** the peripheral ligand bridges of **5** prevent complete separation of the [$Fe(S_2C_6H_3R)_2$] entities if the [Fe−S−Fe] thiolate bridges dissociate. In addition, the structure of **5** differs from that of the dinuclear Ni complexes with similar benzenedithiolate-based tetrathiol ligands reported recently by Hahn et al.[6d] These Ni complexes, synthesized in the search for helicates, exhibit coplanar [$M(S_4)$] cores arranged in a stair-like manner.

Current experiments aim to introduce, stereoselectively, α,α′-bismethylenpyridine bridges to transform **5** into the target species **A**.

Experimental Section

General Methods: Unless noted otherwise, all reactions and operations were carried out under nitrogen using standard Schlenk techniques. Solvents were dried and distilled before use. As far as possible, reactions were monitored by IR or NMR spectroscopy. Spectra were recorded on the following instruments: IR (KBr discs or CaF_2 cuvettes, solvent bands were compensated): Perkin−Elmer 16PC FTIR. NMR: JEOL-JNM-GX 270 with the protio-solvent signal used as an internal reference. Spectra were recorded at 25 °C. Mass spectra: JEOL MSTATION 700 spectrometer. Elemental analysis: Carlo Erba EA 1106 or 1108 analyzer. Magnetic susceptibility: Johnson Matthey susceptibility balance. UV/Vis: Shimadzu UV-3101 PC. Solutions were 10^{-4} M in DMF. Cyclic voltammetry was performed with a Radiometer Copenhagen IMT 102 electrochemical interface using a three-electrode cell with a glassy carbon (Radiometer Copenhagen EDI) working electrode and Pt reference and counter electrodes. Solutions were 10^{-3} M in MeCN; $NBu_4[PF_6]$ (10^{-1} M) was used as the supporting electrolyte. Potentials were referenced to the normal hydrogen electrode (NHE) using Fc/Fc^+ as internal standard ($E^+_{Fc/Fc}$ = 0.4 V vs. NHE).[10] ‘CO_2Me-

S_2'-H_2 (**1**) (2,3-dimercaptobenzoic acid methyl ester) was prepared as described in the literature.[4a]

'CO_2Me-S_2'-*i*Pr_2 (1a): LiOMe (50 mmol, 50 mL of a 1 M solution in MeOH) and isopropyl bromide (5.87 mL, 62.5 mmol) were added to a light yellow solution of 'CO_2Me-S_2'-H_2 (5.01 g, 25.0 mmol) in MeOH (120 mL) and the resultant lemon yellow solution heated under reflux for 20 h. After evaporation of the solvent, CH_2Cl_2 (120 mL) was added to the residue and the resulting suspension stirred for 2 h and then filtered. The filtrate was evaporated to give a brown oil that was identified by NMR spectroscopy as 'CO_2Me-S_2'-*i*Pr_2 and was used for the synthesis of 'CO_2H-S_2'-*i*Pr_2 (**2**) without further purification. Yield: 7 g (**1a**) (100%). ^{1}H NMR ($CDCl_3$, 269.72 MHz): δ = 1.20 [d, $^3J_{H,H}$ = 6.7 Hz, 6 H, $CH(CH_3)_2$], 1.37 [d, $^3J_{H,H}$ = 6.7 Hz, 6 H, $CH(CH_3)_2$], 3.50 [m, 2 H, $CH(CH_3)_2$], 3.89 (s, 6 H, CO_2CH_3), 7.26 (m, 3 H, C_6H_3) ppm. MS (FD$^+$, CH_2Cl_2): *m*/*z* = 284 ['CO_2Me-S_2'-*i*Pr_2]$^+$.

'CO_2H-S_2'-*i*Pr_2 (2): NaOH (0.115 mmol, 115 mL of a 1 M solution in H_2O) was added to a solution of 'CO_2Me-S_2'-*i*Pr_2 (**1a**) (6.825 g, 0.024 mol) in THF (120 mL). The mixture was heated under reflux for 29 h, then reduced in volume to about 120 mL and heated for a further 15 h. The resulting pale pink solution was filtered. Concentrated hydrochloric acid (12 mL) was added to the filtrate and the light yellow solid that precipitated was separated, washed with water to pH = 7 and dried in vacuo. Yield: 5.66 g (**2**) (87%). ^{1}H NMR ($CDCl_3$, 269.72 MHz): δ = 1.27 [d, $^3J_{H,H}$ = 6.6 Hz, 6 H, $CH(CH_3)_2$], 1.38 [d, $^3J_{H,H}$ = 6.6 Hz, 6 H, $CH(CH_3)_2$], 3.52 [m, 2 H, $CH(CH_3)_2$], 7.41 (m, 2 H, C_6H_3), 7.87 (vdd, 1 H, C_6H_3), 11.75 (br, 1 H, COO*H*) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 67.83 MHz): δ = 22.6, 22.8 [$CH(CH_3)_2$], 36.5, 41.2 [$CH(CH_3)_2$], 127.9, 129.3, 129.8, 130.3, 136.5, 146.4 (C_6H_3), 169.1 (CO_2H) ppm. IR (KBr): $\tilde{\nu}$ = 2966 (br, O−H), 1704 cm^{-1} (s, C=O). MS (FD$^+$, acetone): *m*/*z* = 270 ['CO_2H-S_2'-*i*Pr_2]$^+$. $C_{13}H_{18}O_2S_2$ (270.42): calcd. C 57.74, H 6.71, S 23.72; found C 57.49, H 6.99, S 23.90.

'apS$_4$'-*i*Pr_4 (3): $SOCl_2$ (8.5 mL) was added to solid 'CO_2H-S_2'-*i*Pr_2 (**2**) (4.815 g, 0.018 mol) and heated to 60 °C until no further gas evolution was detected. Excess $SOCl_2$ was removed in vacuo; the brown oily residue obtained was dissolved in THF (30 mL) and a solution of 1,3-diaminopropane (0.745 mL, 0.009 mol) and NEt_3 (4.98 mL, 0.036 mol) in THF (20 mL) was added dropwise at 0 °C. The resulting yellow suspension was stirred at room temperature for 15 h, poured into ice water (600 mL) and stirred for a further 1 h. The mixture was extracted with Et_2O (800 mL). The Et_2O phase was dried over Na_2SO_4, filtered and evaporated. The foam-like solid thus obtained was washed with warm pentane which was decanted. The residue was dried in vacuo yielding, again, a yellow foam-like solid material. Yield: 4.6 g (**3**) (88%). ^{1}H NMR ($CDCl_3$, 269.72 MHz): δ = 1.19 (d, $^3J_{H,H}$ = 6.7 Hz, 12 H, $CHCH_3$), 1.36 [d, $^3J_{H,H}$ = 6.7 Hz, 12 H, $CH(CH_3)_2$], 1.87 (m, 2 H, NCH_2CH_2), 3.46 (m, 4 H, NCH_2CH_2), 3.60 [m, 4 H, $CH(CH_3)_2$], 6.95 (br, 2 H, N*H*), 7.26 (m, 6 H, C_6H_3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$, 67.83 MHz): δ = 22.7, 23.2 [$CH(CH_3)_2$], 29.9 ($NHCH_2CH_2$), 36.0, 36.8 [$CH(CH_3)_2$], 40.5 (NCH_2CH_2), 124.6, 127.6, 128.8, 129.1, 143.8, 145.8 (C_6H_3), 169.5 (*C*ONH) ppm. IR (KBr): $\tilde{\nu}$ = 3289 (s, N−H), 1636 (s, C=O), 1522 cm^{-1} (s, N−H). MS (FD$^+$, Et_2O): *m*/*z* = 578 ['apS$_4$'-*i*Pr_4]$^+$. $C_{29}H_{42}N_2O_2S_4$ (578.93): calcd. C 60.17, H 7.31, N 4.84, S 22.16; found C 60.27, H 7.70, N 4.58, S 21.92.

'apS$_4$'-H$_4$ (4): Small pieces of sodium (0.9 g, 39 mmol) were added to a solution of 'apS$_4$'-*i*Pr_4 (**3**) (2.25 g, 3.9 mmol) and naphthalene (2.52 g, 19.5 mmol) in THF (200 mL). After stirring the resulting green suspension for 16 h at room temperature, MeOH (15 mL) was added cautiously. All solvents were evaporated and H_2O (150 mL) was added to the yellow residue to give a yellow emulsion that was washed with Et_2O (450 mL), and the yellow aqueous phase was separated, filtered, and acidified slowly with concentrated hydrochloric acid (12 mL) at 0 °C. A white precipitate formed which after stirring at room temperature for 15 min was separated, washed with H_2O (60 mL) and dried in vacuo. Yield: 1.3 g (**4**) (81%). ^{1}H NMR ([D$_8$]THF, 269.72 MHz): δ = 1.87 (m, 2 H, NCH_2CH_2), 3.47 (m, 4 H, NCH_2CH_2), 7.01 (vt, 2 H, C_6H_3), 7.33 (vd, 2 H, C_6H_3), 7.40 (vd, 2 H, C_6H_3), 7.94 (br, 2 H, N*H*) ppm. ^{13}C{^{1}H} NMR ([D$_8$]THF, 67.83 MHz): δ = 29.5 ($NHCH_2CH_2$), 36.7 (NCH_2CH_2), 124.2, 125.1, 131.3, 132.7, 133.0, 134.6 (C_6H_3), 169.2 (*C*ONH) ppm. IR (KBr): $\tilde{\nu}$ = 3280 (m, N−H), 2526 (w, S−H), 1628 (s, C=O), 1534 cm^{-1} (s, N−H). MS (FD$^+$, THF): *m*/*z* = 411 ['apS$_4$'-H$_4$]$^+$. $C_{17}H_{18}N_2O_2S_4$ (410.61): calcd. C 49.73, H 4.42, N 6.82, S 31.24; found C 50.32, H 4.66, N 6.85, S 30.79.

(AsPh$_4$)$_2$[{Fe('apS$_4$')}$_2$] (5): A solution of $FeCl_3$·$6H_2O$ (230 mg, 0.85 mmol) in MeOH (10 mL) was added to a solution of 'apS$_4$'-H$_4$ (**4**) (349 mg, 0.85 mmol) and LiOMe (3.40 mmol, 3.40 mL of a 1 M solution in MeOH) in MeOH (25 mL). The resulting purple solution was heated under reflux for 2 h. After removal of the solvent, the resultant black−violet residue was dissolved in MeOH (30 mL) to give a black violet solution that was filtered and combined with a solution of $AsPh_4Cl$·H_2O (1.23 g, 2.49 mmol) in MeOH (25 mL). Violet microcrystals precipitated and were separated, washed with MeOH (20 mL) and dried in vacuo. Yield: 395 mg (**5**) (55%). ^{1}H NMR ([D$_6$]DMSO, 269.72 MHz): δ = 7.8 [br, 40 H, As(C_6H_5)$_4^+$] ppm. IR (KBr): $\tilde{\nu}$ = 3273 (m, N−H), 1640 (s, C=O), 1540 cm^{-1} (s, N−H). MS (FD$^+$, DMF): *m*/*z* = 383 [$AsPh_4$]$^+$; magnetic susceptibility: μ_{eff} = 2.4 μ_B. UV/Vis (DMF, 10^{-4} M): λ = 314 (22068), 364 (21139), and 512 (11464) nm (cm^2 mol^{-1}). $C_{82}H_{68}As_2Fe_2N_4O_4S_8$ (1691.54): calcd. C 58.22, H 4.05, N 3.31, S 15.17; found C 58.27, H 4.22, N 3.36, S 15.05.

X-ray Structure Analyses of (AsPh$_4$)$_2$[{Fe('apS$_4$')}$_2$]·2MeOH (5·2MeOH) and (AsPh$_4$)$_2$[{Fe('apS$_4$')}$_2$] (5): Single crystals were obtained by the following procedures. (AsPh$_4$)$_2$[{Fe('apS$_4$')}$_2$]·2MeOH (**5**·2MeOH): A solution of 'apS$_4$'-H_2 (44 mg, 0.11 mmol), LiOMe (0.43 mmol, 0.43 mL of a 1 M solution in MeOH) and $FeCl_3$·$6H_2O$ (29 mg, 0.11 mmol) in MeOH (20 mL) was heated under reflux for 2 h. After cooling to room temperature the resulting black−violet solution was filtered and layered with a solution of $AsPh_4Cl$ (115 mg, 0.28 mmol) in MeOH (25 mL). Black blocks of (AsPh$_4$)$_2$[{Fe('apS$_4$')}$_2$]·2MeOH (**5**·2MeOH) formed that were separated after one week. $C_{84}H_{76}As_2Fe_2N_4O_6S_8$ (1755.63): calcd. C 57.47, H 4.36, N 3.19, S 14.61; found C 57.87, H 4.47, N 3.29, S 14.24.

(AsPh$_4$)$_2$[{Fe('apS$_4$')}$_2$] (**5**): A concentrated and filtered solution of **5** in DMF was layered with the same amount of THF. Black rhombs of (AsPh$_4$)$_2$[{Fe('apS$_4$')}$_2$] (**5**) formed that were separated after 2 months.

Suitable single crystals were embedded in protective perfluoro polyalkyl ether oil. Intensity data were collected at 100 K on a Nonius KappaCCD diffractometer using Mo-K_α radiation (λ = 71.073 pm, graphite monochromator) (Table 2). Data were corrected for Lorentz and polarization effects and a numerical absorption correction for **5**·2MeOH and a semi-empirical absorption correction from equivalent reflections for **5** were applied. The structures were solved by direct methods, and full-matrix least-squares refinement was carried out on F^2 (SHELXTL NT 5.10).[11] All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were taken from the difference Fourier maps and refined

Table 2. Selected crystallographic data for $(AsPh_4)_2[\{Fe(`apS_4')\}_2]\cdot 2MeOH$ (**5**·2MeOH) and $(AsPh_4)_2[\{Fe(`apS_4')\}_2]$ (**5**)[12]

with a fixed common isotropic displacement parameter. In accordance with the elemental analysis, the crystal structure of **5**·2MeOH contains two MeOH solvate molecules per unit. One MeOH molecule is disordered. The non-hydrogen atoms of the disordered solvate molecule were refined only isotropically and no hydrogen atoms were taken into account.

Vanadium-Catalysed Aerobic Cleavage of C−C Bonds in Substituted Cyclohexanones To Afford Carboxylic Acids: Two Model Complexes with Tetrahedral Geometry around Vanadium(V)

Maxence Vennat,[a] Patrick Herson,[b] Jean-Marie Brégeault,*[a] and Georgiy B. Shul'pin[c]

Keywords: Catalysis / Oxidation / Dioxygen / Oxo ligands / Vanadium

Two monosilanol/disilanol derivatives were synthesised by treatment of Ph_3SiOH or $Ph_2Si(OH)_2$ with $[nBu_4N]VO_3$ (**3**) in ethanol solution. The mononuclear anionic dioxo vanadium(V) species $[\{Ph_3SiO\}_2VO_2]^-$ (**4**) and the dinuclear complex anion $[\{Ph_2SiO_2VO_2\}_2]^{2-}$ (**5**) thus obtained are unusual and novel model compounds with ≡Si–O–V(O)$_2$O linkages characterised by single-crystal X-ray diffraction. The catalytic activities of these *tert*-butylammonium complexes, together with those of the simple vanadium derivatives **3** and **5**, of the vanadyl precursors $VOSO_4{\cdot}5H_2O$ (**1**) and $[VO(acac)_2]$ (**2**), and also of "$H_6[PMo_9V_3O_{40}]{\cdot}aq$", were tested for aerobic C–C bond cleavage in 2-hydroxycyclohexanone and 2-methylcyclohexanone. Monomeric vanadium species show the same chemistry as the polyoxometalate but with lower yields of acids or keto acids, and so the redox and acid properties of HPA-*n* (n = 3, 4) are better tuned. Mechanisms for these oxidation reaction, including electron transfer from a substrate coordinated to vanadium, are proposed.

Introduction

Vanadium(V) oxoalkoxides such as $[VO(OEt)_3]$ or heteropolyacids containing vanadium(V) ions with common formula $H_{3+n}[PMo_{12-n}V_nO_{40}]{\cdot}xH_2O$ (denoted HPA-*n*, where n = 1, 2, 3 etc.) have been proposed as precursors for the catalytic oxidation of α-ketols and ketones by dioxygen.[1−4] It has also been demonstrated that aqueous solutions of HPA-*n* are multicomponent systems: the higher the value of *n*, the more complex the system. These solutions contain a great number of polyanions, positional isomers of these, as well as monomeric metallo species such as *cis*-dioxo $[VO_2]^+$ (pervanadyl moieties) in equilibrium with lacunary heteropolyanion.[5] The ^{31}P NMR spectrum of "aqueous $H_6[PMo_9V_3O_{40}]$", for example, attests to the existence of several species containing P, Mo and V (Figure 1).

Preparations of HPA-*n* obtained by diethyl ether extraction[6] or by an oxo-peroxo route[7] give EPR signals attributable to $[VO]^{2+}$ species, as do catalytic systems with vanadium(V) oxoalkoxides. At low pH (<2), heteropolyanion solutions contain a solvated *cis*-dioxo cation $[VO_2(H_2O)_4]^+$, usually written as $[VO_2]^+$.[8,9] This is considered to be one of the catalytically active species.[5] Such complexity makes mechanistic studies very difficult. Moreover, in aerobic ketone oxidations, HPA-*n* species are active not only as redox systems but also play a very important role as Brønsted acids for the enolisation process.[3,10] To the best of our

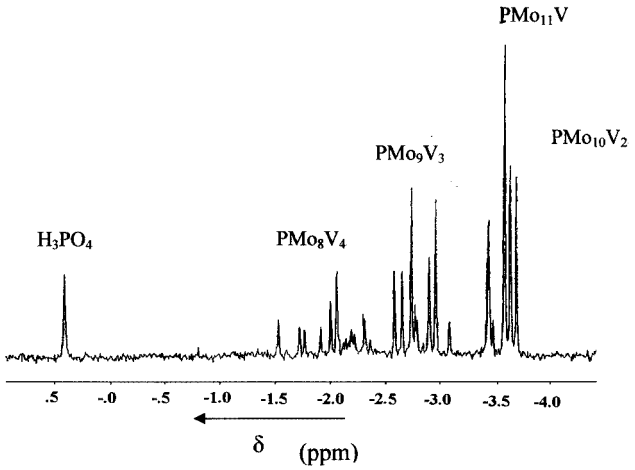

Figure 1. ^{31}P NMR spectrum of "$H_6[PMo_9V_3O_{40}]$" (1 mol·dm^{-3}; pH 0.8) prepared by treatment of $MoO_3.xH_2O$, V_2O_5 and H_3PO_4 with H_2O_2 at room temperature (the identification is supported by solutions and solids prepared with $2 \leqslant n \leqslant 10$ − see ref.[5,7,47]

knowledge there is no iono-covalent crystal structure containing the pervanadyl cation $[VO_2(H_2O)_4]^+$.

In this work we have prepared and characterised two novel dioxovanadium(v) complexes with two organosilanolato ligands. As other catalyst precursors we have also used simple vanadium(v) and vanadium(iv) derivatives, mainly mononuclear compounds, which − unlike HPA-*n* − are not strong acids. Naturally, it was very interesting to study the influence of acids on the oxidation reactions. We hoped that combinations of simple vanadium complexes with added acids would provide models of catalytically active systems based on various V-containing HPA-*n* species. Work on the use of these complexes in homogeneous catalytic systems (oxidation of 2-hydroxycyclohexanone and 2-methylcyclohexanone) with other precursors and comparison of conversions and selectivities with those obtained with HPA-*n* has made us refine our previous mechanism.[3] The novel four-coordinate complexes should open perspectives for incorporation of oxovanadium catalysts into polymeric materials.[11] Organosilanols model the hydroxy groups that lie on silica surfaces,[12] and the complexes synthesised can be regarded as models for metal oxides supported on silica surfaces.[13]

oxo species $[n\mathrm{Bu_4N}][\{Ph_3SiO\}_2VO_2]$ (**4a**) or a dinuclear complex $[n\mathrm{Bu_4N}]_2[\{Ph_2SiO_2VO_2\}_2]$ (**5a**), respectively, in fair to nearly quantitative yields. Formulae of the anions of both complexes are presented in Scheme 1.

Scheme 1

Results and Discussion

As catalyst precursors we used simple derivatives of vanadium(iv), such as $VOSO_4{\cdot}5H_2O$ (**1**) and $[VO(acac)_2]$ (**2**), as well as vanadium(v) derivatives in the form of tetrabutylammonium salts: $[n\mathrm{Bu_4N}]VO_3$ (**3**) and two pervanadyl complexes, $[n\mathrm{Bu_4N}][\{Ph_3SiO\}_2VO_2]$ (**4a**) and $[n\mathrm{Bu_4N}]_2[\{Ph_2SiO_2VO_2\}_2]$ (**5a**).

Synthesis of New Vanadium Pre-Catalysts

Only a few examples of mono- and dioxovanadium(v) complexes derived from silanols or disilanols have been described in the literature.[13,14] Compounds $(Ph_3SiO)_3VO$[15−19] and $[(t\mathrm{Bu})_2Si(O)_2VOCl]_3$ [20] have been structurally characterised. The latter contains a twelve-membered ring, $\{VOSiO\}_3$, in which the vanadium and silicon atoms exist in distorted tetrahedral coordinations. Trisilanols such as $R_7Si_7O_9(OH)_3$ [R = cyclopentyl, cyclohexyl (cy), phenyl, etc.] are known to react with $VOCl_3$, $VO(O\text{-}n\mathrm{Pr})_3$ or $VO(CH_2SiMe_3)_3$ to afford mixtures of the monomeric and dimeric vanadium(v) silsesquioxanes $[(cy)_7Si_7O_{12}VO]$ and $[(cy)_7Si_7O_{12}VO]_2$.[13,18,21] An anionic dioxo complex $(H_2NEt_2)_2[\{Ph_2SiO_2VO_2\}_2]$ was prepared in low yield (29%)[22] from diphenylsilanediol and vanadium(v) dialkylamides, $VO(NEt_2)_3$.

We focused our initial efforts on synthesising oxo-peroxo species and in this paper *cis*-dioxoanionic complexes by undemanding reactions, with the goal of using them to generate catalytic intermediates with the $[VO_2]^+$ group for carbon−carbon bond cleavage in α-hydroxy ketones, cycloalkanones, etc. with dioxygen. Treatment of Ph_3SiOH or $Ph_2Si(OH)_2$ with compound **3**, dissolved in ROH (R = Me, Et), resulted in the formation of a mononuclear anionic di-

The new vanadium-siloxane complexes were fully characterised by elemental analysis, vibrational spectroscopy and room-temperature single-crystal X-ray diffraction studies. Crystals of $[PPh_4][\{Ph_3SiO\}_2VO_2]$ (**4b**; the $n\mathrm{Bu_4N}$ cation was replaced by PPh_4 to prepare crystals for X-ray analysis) and of **5a** present novel anionic structures, shown in Figures 2 and 3. Selected bond lengths and angles are listed in Table 1 and 2.

Solid-State Structure of the Mononuclear Complex $[PPh_4][\{Ph_3SiO\}_2VO_2]$ (4b)

Compound **4b** consists of tetraphenylphosphonium cations and monomeric vanadosiloxane anions. There is one independent anionic species in the asymmetric unit, loosely connected through a series of phenyl ring interactions. The crystal packing is determined by van der Waals forces, the closest C···C approach being 3.6 Å, greater than the sum of the van der Waals radii. The geometry at vanadium(v) is a tetrahedral coordination unusual for mononuclear complexes (Figure 2), with the oxygen atoms of the Ph_3SiO ligands occupying two sites and two terminal oxygen atoms occupying the remaining sites. The VO_2 arrangement is no doubt favoured (as in some other d^0 systems) because this allows better $O_{p\pi} \rightarrow M_{d\pi}$ bonding than a linear arrangement would. The characteristic lengths in **4b** are similar to those observed in **5a** (vide infra); the VO bond lengths to the terminal oxygens are 1.621(3) and 1.607(3) Å to O(1) and O(2), respectively; this suggests a bond order approaching two for the V=O linkages in the VO_2 group. The average V−O(Si) bond length is 1.8145 Å. The Si−O bond lengths are similar to those found in the parent siloxane rings.[23−26]

Si(2)−C(207)	1.865(5)		
Si(2)−C(213)	1.862(5)		

Table 2. Selected bond lengths [Å] and angles [°] for **5a**

Bond length		Bond angle	
V(1)−O(1)	1.613(3)	O(1)−V(1)−O(2)	109.0(2)
V(1)−O(2)	1.619(3)	O(1)−V(1)−O(11)	108.9(2)
V(1)−O(11)	1.817(3)	O(2)−V(1)−O(11)	111.5(2)
V(1)−O(12)	1.807(3)	O(1)−V(1)−O(12)	108.2(2)
Si(1)−O(11)	1.613(4)	O(2)−V(1)−O(12)	109.3(2)
Si(1)−O(12′)	1.618(3)	O(11)−V(1)−O(12)	109.9(2)
Si(1)−C(101)	1.872(5)		
Si(1)−C(107)	1.872(5)		

The Si(1)O(11)V(1)O(12)Si(2) moiety in **4b** is almost planar, the largest deviation from the least-squares plane being 0.17 Å for V(1). The angle between the O(1)V(1)O(2) and Si(1)V(1)Si(2) planes is 88.7°. In the siloxane $(Ph_2SiO)_4$ the $\{Si-O\}_4$ ring is somewhat closer to planarity, the maximum deviation from the root-mean square plane being 0.1 Å.[24]

In **4b**, the V−O−Si bond angles are 151.4(2)° and 146.7(2)°. The formation of the tetrahedral VO_2 species was recently evaluated by a theoretical study of the extended Hückel (EH) type, this species being excluded in the cases of SiO_2, TiO_2 and γ-Al_2O_3.[27] To the best of our knowledge, no monomeric tetrahedral vanadium(v) species containing oxo organic ligands has yet been observed in aqueous solution, and such tetrahedral units are also not common for dioxovanadium(v) moieties in the solid state: only distorted square-pyramidal,[28] trigonal-bipyramidal[29] and octahedral[30] geometries have recently been characterised with *cis*-dioxo groups,[28−30] but tetrahedral species exist in some chains of inorganic vanadates. With large metal cations such as Ba^{2+}, the structures adopted by dinegative metavanadates, MV_2O_6, contains chains of vertex-shared VO_4 tetrahedra.[31,32] This structural motif is typically found in orthovanadates such as $LiMnVO_4$[33] and $LnVO_4$.[34] The $[V_4O_{12}]^{4-}$ ion has a cyclic tetrametaphosphate-like structure with an O*t*-V-O*t* angle of only 102.3(1)°,[35] the three others being 111°, while $[V_5O_{14}]^{3-}$ is pentanuclear with O−V−O angles ranging from 107.6(4) to 112.7(3)°.[36] In **4b**, the tetraphenyl phosphonium cations are well behaved and have the expected dimensions.

Solid-State Structure of the Dinuclear Complex $[nBu_4N]_2[\{Ph_2SiO_2VO_2\}_2]$ (5a)

Compound **5a** consists of discrete dimeric anions and tetrabutylammonium cations. The complex possesses crystallographic site symmetry $\bar{1}$, and there is one half of the complex anion per crystallographically independent unit. The anionic moiety has two vanadium(v) atoms bridged by two diphenylsiloxy ligands to form an eight-membered ring, "$\{VOSiO\}_2$", in an extended chair conformation. In addition, each vanadium is bonded to two terminal oxygen atoms. For a side view of the anion showing the conformation of the ring, see Figure 3. The O(1) and O(2) bond lengths to V(1) are 1.613(3) and 1.619(3) Å, respectively; these correspond to V=O linkages in compound **4b**. Similar V=O bond lengths are found for the trigonal-bipyramidal environment of $[VO_2(pic)(HMPA)]$, with 1.600(5) and 1.606(5) Å,[37] and for $[nBu_4][VO_2(pca)_2]$ (pcaH = pyrazine-2-carboxylic acid), for which the vanadium is found to have an octahedral coordination geometry with two terminal oxo ligands in the *cis* positions [d(V=O) ≈ 1.620(1) and 1.634(1) Å].[38]

The V−O(Si) bond lengths of 1.817(3) and of 1.807(3) Å are short in comparison with the chelate ligand V−O(C) bond lengths of 1.990(1) and 1.996(1) Å found in the pyrazine-2-carboxylato complex.[38] We consider that the V−O(Si) distances in **4b** and in **5a** indicate very strong bonds. The Si−O and Si−C bond lengths are in good agreement with values found in other cyclotetrasiloxanes[23−26] and in **4b** (vide supra).

The tetrahedral geometry around vanadium is evidenced by an average O−V−O bond angle of 109.5°. Again, four-coordination is not very common for inorganic anionic dinuclear V^V complexes; another typical dioxovanadium(v) salt that has been found to have a tetrahedral structure with chains is KVO_3.[39] The average V−O−Si bond angle in **5a** − of 144.1(2)° − is smaller than those found in **4b** and similar to the values of 145° found for the Si−O−Si angle in $[(Me_2SiO)_4]$,[40] but significantly smaller than those found for the previously reported tetrasiloxane compounds (ca. 159.5°),[23−26] also with a puckered eight-membered ring, and for V−O−V in $[V_4O_{12}]^{4-}$ [158.2(2)°].[35] The O−Si−O angle of 111.5(2)°, the C−Si−C of 108.1(2)° and the O−Si−C angles (mean ca. 109.3°) are close to the expected values commonly found for tetrahedral geometry in cyclic siloxanes;[23−26] this may indicate that no strain is involved in bridging the nearly 4.4 Å V···V distance. The closest C···C approach being 3.7 Å, the crystal packing must be determined by van der Waals forces .

Main Features of Vibrational Studies of Synthesised Complexes

The infrared spectra of the complexes are consistent with the deprotonation of the silanol functionalities in the complexes. They show features similar to those observed for

other mono- or dinuclear pervanadyl species;[41] in addition a band at 1588 cm^{-1} may be assigned as ν(C−C) of the phenyl ring,[42,43] and a very sharp band at 1113 for **4a** and 1117 cm^{-1} for **5a** is due to an in-plane deformation of the phenyl ring δ(C−H), with some ν(Si−C) character. Consistently with the structural data (vide supra) and the existence of short V=O bonds, there are strong ν(V=O) bands at ca. 939 and 927 cm^{-1} (sh.) for **4a**, and at 941 and 925 cm^{-1} for **5a**; peaks observed in the two above regions for previous $[VO_2]^+$ complexes are assigned to ν_{as} and ν_s modes of the VO_2 group, respectively.[44] A maximum at 925 cm^{-1} for **5a** and a shoulder (**4a**) are tentatively attributed to Si−O(V) stretching. Si−C stretches appear at ca. 743 cm^{-1} for both compounds. In the Raman spectra, comparison of the ν(V=O) at 943 cm^{-1} for solid **4a** with the maximum at 935 cm^{-1} (**4a** in methanol), together with other unattributed maxima, suggests that the overall structure of the pervanadyl complex **4a** is conserved in methanol at room temperature, as would be expected for a compound originally prepared in methanol or ethanol.

Catalytic Oxidative Cleavage of α-Ketols (α-Hydroxy Ketones)

For the oxidation of 2-hydroxycyclohexanone (**6**) we used simple vanadium derivatives **1**, **2** and **3**, the synthesised compounds **4a** and **5a**, and also "$H_6[PMo_9V_3O_{40}]\cdot 11H_2O$" (HPA-3). Methanol was employed as solvent and the reactions were carried out at two temperatures, 20 and 60 °C (Table 3). The main product was adipic acid (Scheme 2), and the concentration of this compound was measured after esterification by addition of ethereal diazomethane. The course of the reaction was followed by dioxygen consumption, monitored by a gas burette system, and by GC analysis. Dioxygen uptake was observed in the reactions catalysed by mononuclear complexes, with moderate conversion even at room temperature (Table 3, entries 1, 3, 5). An induction period was only found in the case of $[VO(acac)_2]$. During this period the active catalyst precursor probably changes; this transformation may be de-coordination of one of the acac ligands strongly bound to vanadium.

Higher degrees of conversion were obtained at 60 °C (entries 2, 4, 6). It can be seen that mono-oxovanadium(IV) complexes and polyoxovanadium(V) species are moderately active but the selectivity is rather low. Thus, oxidation catalysed by VO_3^- results in the formation of undesired products (cyclohexanedione in a yield ≤ 20%, dimethyl pentanedioate, butanedioate etc.). Catalysis by **4a** or **5a**, and especially by HPA-3, favours the formation of dimethyl adipate. It should be noted that the oxidative cleavage of 2-hydroxycyclohexanone[45] to produce adipic acid, as well as of various substituted α-hydroxy ketones,[4] does not require the presence of a strong Brønsted acid and occurs with both mononuclear vanadium(IV) and (V) species; $[VOCl_3]$/MeCN/O_2 systems give only α-diketones.[46]

Recently the "HPA-3/O_2/MeOH" system has been successfully used in the oxidative cleavage at room temperature of (1*S*,2*S*,5*S*)-2-hydroxypinan-3-one (**7a**) and its (1*R*,2*R*,5*R*) enantiomer **7b** (see Scheme 2). The diastereoselective formation of the esters of 3-acetyl-2,2-dimethylcyclobutaneacetic acid (methyl esters of the *cis*-pinonic acids) was observed, with 100% conversion and high diastereoselectivity (99:1 for 1*S*,3*S*:1*S*,3*R* and 1*R*,3*R*:1*R*,3*S*, respectively).[4] As found in this work, compound **4a** does not catalyse the oxidative transformations of **7** at all at room temperature. We assume that steric hindrance is a crucial factor governing the activity of complex **4a**; the bulkiness of the three C_6H_5 groups on Si(1) and Si(2) (Figure 2) and the methyl group of the 2-hydroxypinan-3-one may prevent the interaction of the VO_2 group with the α-hydroxy group of **7**. The inactivity of **4a** in reaction with **7** is in agreement with the assumption that only relatively small mononuclear *cis*-dioxo species are responsible for the catalytic activity. It seems that the HPA-3 anion is also too bulky and that direct coordination of this anion with **7** is sterically restricted. However, the dissociation of HPA-3 to produce, inter alia, a small reactive species such as $[VO_2]^+$ would explain the high efficiency of HPA-3 in the oxidative transformation of sterically hindered **7**.

Table 3. Oxidation of 2-hydroxycyclohexanone (**6**) to adipic acid (Scheme 2)

Entry[a]	Catalyst precursor	*T* (°C)	Conversion (%)[b]	Yield (%)[c]

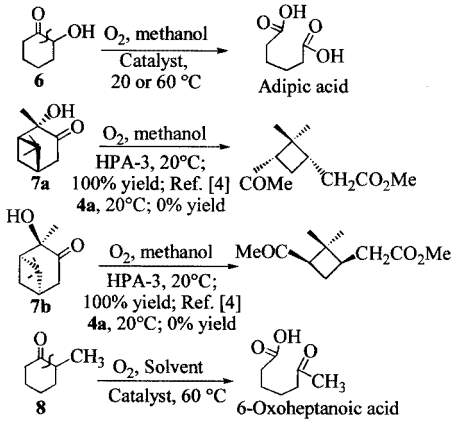
[a] Conditions: vanadium complex, 0.076 mmol; 2-hydroxycyclohexanone, 7.6 mmol; methanol, 5 mL; dioxygen, 0.1 MPa; reaction time 24 h. [b] Conversion is percentage of the substrate consumed. [c] Yield (%) is (mmol of dimethyl adipate per mmol of the substrate)×100 (determined after addition of ethereal diazomethane).



Scheme 2

Catalytic Oxidative Cleavage of 2-Methylcyclohexanone (8)

Unlike 2-hydroxycyclohexanone, 2-methylcyclohexanone is not oxidised in methanol by the V^V-based catalytic systems without an induction period if there is no Brønsted acid present in the reaction solution (Table 4, entries 6 and 8). None of the quaternary ammonium salts of HPA-*n* was active in these oxidations (not shown here) and only the heteropolyacids HPA-*n*, which are known to be strong acids, catalyse C−C bond cleavage (entries 10 and 11). However, these results with alkylammonium may be ambiguous, because these salts are not only less acidic but also less efficient oxidants (change of redox potentials and stabilisation of the $[VO_2]^+$ moieties in the Keggin unit). Addition of only 2−10 equivalents (relative to one vanadium) of *para*-toluenesulfonic acid (PTSA) to the reaction solutions containing catalyst precursors **3** or **4a** results in the formation of 6-oxoheptanoic acid in the form of its methyl ester (see Scheme 2; Table 4, entries 7 and 9). However, it should be noted that the yields for all mononuclear dioxo catalysts are lower than those of HPA-*n* (n = 4 or 3; see entries 10 and 11, respectively). Hence, the redox and acid properties of HPA-3 and mixed valence HPA-4 [$[V^{IV}/V^V]$ are better tuned than those of the mononuclear species. In the case of the "**4a**/O_2/MeOH" system at 60 °C in the absence of added acid, Ph_3SiOMe was formed and characterised by GC-MS (see Exp. Sect.). We conclude that even without addition of strong acid the Ph_3SiO ligands in **4a** are partly replaced to generate oxohydroxo- and/or alkoxo-anionic or neutral vanadium(v) species. As 2-hydroxypinan-3-one is not oxidised by this system at 20 °C, probably due to the bulkiness of this molecule and of **4a** (see above), it is certain that this catalyst precursor does not decompose with formation of small mononuclear species at room temperature (vide supra: vibrational studies).

It is noteworthy that vanadyl precursors (entries 1 and 3) exhibit some activity even in the absence of an acid. Dioxygen consumption has an induction period during which the acac ligand is replaced by other ligands. Addition of 10 equivalents of PTSA increases the yield only in the case of **2** (entry 4). Replacement of PTSA by trifluoromethanesulfonic acid gives the highest yield (entry 5). The addition of either PTSA or CF_3SO_3H (entries 4 and 5) results in O_2 uptake without an induction period. The "$VOSO_4 \cdot 5H_2O$/MeOH/O_2" system gives a blue solution, which turns green immediately after the addition of 2-methylcyclohexanone (**8**). This change in colour is apparently due to the formation of a complex between vanadium-containing species and **8**.

We also investigated the oxidation of **8** in acetonitrile, which is aprotic, although residual water cannot be excluded. It turned out that, in the absence of any other additives, catalyst precursor **3** induces slow consumption of molecular oxygen (Figure 4, curve 1). The oxidation occurs with auto-acceleration after an induction period (ca. 4 hours) during which the colour of the reaction solution changes from very pale yellow to intense orange-yellow. Addition of acetic acid (≈ 4 equivalents relative to **3**) accelerates the reaction insignificantly, the induction period remaining the same (curve 3, see Figure 4). The reaction also proceeds very similarly (curve 4, see Figure 4) in the presence of a chelating amino acid (pyrazine-2-carboxylic acid, PCA) that has been shown to accelerate V-catalysed oxygenations with hydrogen peroxide or air dramatically.[38] Addition of PTSA (only 2 equivalents) considerably increases the rate, and the induction period is eliminated (curve 2; see Figure 4). If 4 equivalents of PCA are added

Table 4. Oxidation of 2-methylcyclohexanone (**8**) to 6-oxoheptanoic acid (Scheme 2)

Entry[a]	Catalyst	[PTSA]/[V]	Conversion (%)[b]	Yield (%)[c]

11	HPA-3[e]	0	99	97

[a] Conditions: vanadium complex, 0.076 mmol; 2-methylcyclohexanone, 7.6 mmol; methanol, 5 mL; dioxygen, 0.1 Mpa; reaction temperature 60 °C; reaction time 24 h. [b] See corresponding footnotes to Table 3. [c] See corresponding footnotes to Table 3. [d] The catalytic species was prepared by the reaction between CF_3SO_3H and $[VO(acac)_2]$ (ratio 1.1) in methanol at 60 °C during 8 h. [e] Reaction in water; reaction time 8 h.

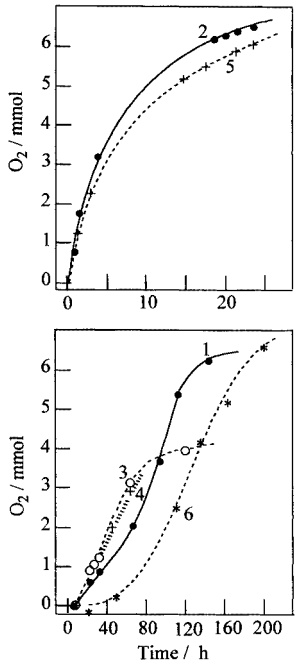

Figure 4. Consumption of O_2 in reaction of 2-methylcyclohexanone (7.6 mmol) in MeCN (total volume of reaction solution 6 mL), catalysed by $[nBu_4N]VO_3$ (0.076 mmol) at 63 °C without additives (curve 1) and with PTSA (0.155 mmol) (2), CH_3COOH (0.32 mmol) (3), PCA (0.306 mmol) (4), PTSA (0.155 mmol) + PCA (0.306 mmol) (5), and pyridine (0.755 mmol) (6)

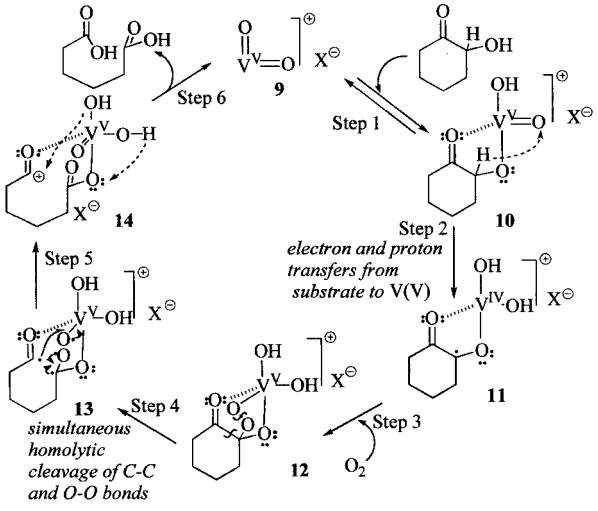
to the same mixture the oxidation proceeds at practically the same rate (curve 5). It may thus be concluded that acids accelerate the oxidation of **8**, the rate of this reaction rising significantly on going from weak acids to strong ones. When pyridine is added, there is a long induction period (curve 6; see Figure 4), a reduced initial rate and a reduction in the yield of keto acid ($\leq 15\%$).

A study of immobilised $[VO_2]^+/[VO]^{2+}$ on several perfluorinated supports with highly acidic and noncoordinating groups such as $-SO_3^-H^+$ has been presented.[11] This system produces highly selective C−C bond cleavage and low-leaching catalysts; mononuclear vanadium(V/IV) moieties are the most likely active species interacting with SO_3^- groups.[11,47]

On the Mechanism of the Oxidative Cleavage of C−C Bonds

On the basis of our results and others in the literature we propose a mechanism as depicted in Scheme 3 for C−C bond cleavage of 2-hydroxycyclohexanone. This scheme represents a formally closed catalytic cycle, although it is likely that other steps occur and that the equilibria are more complex. The reaction begins with the formation of a catalytically active oxovanadium(V) species **9**, depicted as $[VO_2]^+X^-$, this species containing additional ligands such as coordinated water or organic solvent. Species **9** coordinates to the α-ketol monoanion through its hydroxy oxygen to produce complex **10**. One-electron and proton transfers from the carbon atom to the vanadium moieties give rise to the formation of complex **11**. Naturally, the proton transfer occurs not intramolecularly as schematically depicted as step 2, but through deprotonation and protonation with participation of the solvent, substrate or water (the latter is present at relatively low concentrations in all reaction solutions). The one-electron transfer from the electron-rich organic moiety to the V^V-oxo part of the complex produces species **11**, which contains the organic part of the complex σ, *n*-coordinated to V^{IV}. There is an unpaired electron on the organic ligand, and one of the mesomeric forms of **11** would be a carbon-centred radical. In the presence of molecular oxygen species, **11** would react rapidly with O_2. Indeed, it is well known[48] that carbon-centred radicals add to oxygen molecules in a very fast reaction (Scheme 3).



Scheme 3

$$R^{\cdot} + O_2 \rightarrow ROO^{\cdot}$$

It is reasonable to assume that the peroxyl radical formed after addition of O_2 to the carbon atom in **11** would add to the V^{IV} ion of the same complex to form V^V peroxo derivative **12**. In this step, radical ROO· oxidises V^{IV} to V^V. An example of the direct formation of a vanadium(V) peroxo complex in the reaction between a vanadyl(IV) complex and molecular oxygen was recently described.[49]

$$2\,[V^{IV}(=O)(OH)]^+ + O_2 \leftrightarrows [V^V(=O)_2]^+ + [V^V(=O)(O_2)]^+ + H_2O$$

Vanadium(IV) oxo complexes can also be reoxidised by the usual four-electron overall oxidation process shown below.

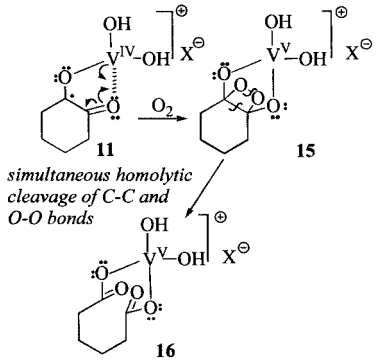
$$4\,[V^{IV}(=O)]^{2+} + 2\,H_2O + O_2 \leftrightarrows 4\,[V^V(=O)_2]^+ + 4\,H^+$$

Vanadium(V) oxo and peroxo complexes have been reported to hydroxylate aromatic compounds in the presence of acids or/and under light irradiation.[50,51] The mechanism of this oxidation appears to include an electron-transfer step.

Vanadium(V) peroxo complexes are unstable and can decompose by homolytic fission of O−O bonds.[52,53] In our case, we propose that homolytic C−C bond cleavage in **12** occurs simultaneously, possibly through a six-membered transition state. Structure **13** represents one of the species on the reaction coordinate for this electron redistribution. As a result we obtain structure **14** with an acylium cation, which could explain the formation of adipaldehyde and lactones.[45] Addition of hydroxy anion (or methoxy anion when methanol is used as a solvent) gives rise to the formation of adipic acid (or its methyl ester) in Step 6. The hydroxy anion from the V^V species in Scheme 3 is used only conventionally to close the catalytic cycle.

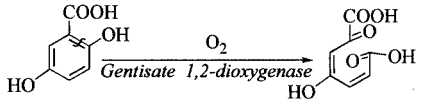
An alternative is that in the interaction between **11** and O_2 the latter adds to the two carbon atoms to produce an endoperoxide species **15** (Scheme 4). It can be seen that this process is also accompanied by the oxidation of V^{IV} to V^V. The simultaneous fission of C−C and O−O bonds in **15** gives adipic acid directly coordinated to vanadium(V) (**16**).

A similar mechanism has previously been proposed for oxidative C−C bond cleavage in acetylacetonate ligand coordinated to palladium(II) to afford acetate.[48,54] In this case the reaction proceeds smoothly at room temperature under irradiation by visible light. Another ligand, *ortho*-metallated azobenzene, coordinated to Pd^{II} plays the role of an "antenna", absorbing light energy necessary for electron transfer from the acac ligand to the palladium centre. It



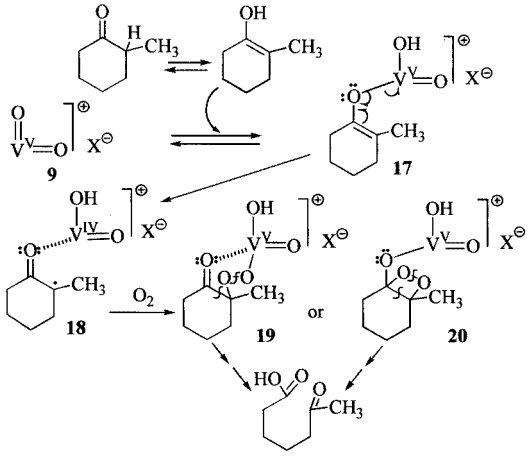
Scheme 4

should be noted that such a mechanism is related to that of C−C bond cleavage in substituted phenols and catechols under the action of O_2 and catalysed by non-heme iron dioxygenase enzymes.[48,55] For example, gentisate 1,2-dioxygenase induces the ring cleavage shown in Scheme 5, and so the oxidative systems described in this paper can be regarded as models of dioxygenases.



Scheme 5

For the oxidation of 2-methylcyclohexanone, direct σ-coordination of the substrate with vanadium-containing catalytically active species is unlikely. However (see above), this compound could react in the enol form, since addition of weak or, especially, strong acids (see Figure 4) dramatically accelerates the oxidation. The reaction starts with the coordination of the enol species to produce species **17** (Scheme 6). Subsequent electron transfer and dioxygen addition give rise to species **19** or/and **20**. After the cleavage of the C−C and O−O bonds, 6-oxoheptanoic acid is formed.



Scheme 6

Conclusion

Despite the advantage of the use of air or dioxygen as the oxidant, there are relatively few known methods that use homogeneous catalysts under very mild conditions. It has been demonstrated here that C−C bond cleavage can be performed efficiently in the presence of dioxygen with simple vanadium-containing precursors or catalysts. Novel anionic vanadium(V) complexes $[n\mathrm{Bu_4N}][\{Ph_3SiO\}_2VO_2]$ (**4a**) and $[n\mathrm{Bu_4N}]_2[\{Ph_2SiO_2VO_2\}_2]$ (**5a**) have been synthesised and used as models of catalytic homogeneous systems in order to generate $[VO_2]^+$ moieties.

Comparison of the activities of substituted heteropolyacids $H_{3+n}[PMo_{12-n}V_nO_{40}]\cdot aq.$, HPA-*n*, with these pervanadyl precursors and other vanadyl complexes with different substrates has caused us to refine our previous mechanism involving mononuclear vanadium(IV) and (V) oxo species and substrate coordination to these $[VO_2]^+$ species.[3] HPA-*n* species are practical and highly efficient reagents for vanadium-based catalysts because their counterions are H_3O^+; they are reversible oxidants, capable of undergoing repeated cycles of reduction and of re-oxidation with dioxygen. Moreover, they can readily be formed from inexpensive reagents: V_2O_5, MoO_3, H_3PO_4 and H_2O_2.[7] We believe that these results can help understanding of systems based on the $[VO_2]^+/[VO]^{2+}$ couple or on modified HPA-*n* species for *linear alkane and cyclohexane oxidation under study in our group*. These systems also give oxygenated intermediates (keto acids, α,ω-diacids, alcohols, ketones, *etc*.) and will be further developed.

Experimental Section

Synthesis

$[n\mathrm{Bu_4N}][\{Ph_3SiO\}_2VO_2]$ (4a): $[n\mathrm{Bu_4N}]VO_3$ [56] (0.68 g; 2 mmol) in ethanol (5 mL) was added to a solution of Ph_3SiOH (1.1 g; 4 mmol) in the same solvent (10 mL). After addition of aqueous ammonia (1.25 M; 3.2 mL), the solution was slowly stirred for 45 min. The white precipitate was isolated by filtration, and then washed with diethyl ether and dried over P_4O_{10} (yield 50−70%). $C_{52}H_{66}NO_4Si_2V$ (876.22): calcd. C 71.28, H 7.59, N 1.60, Si 6.41, V 5.81; found C 71.47, H 7.55, N 1.63, Si 5.58, V 5.40. The structure shows disorder of the tetrabutylammonium cations, but the tetraphenylphosphonium salt gave crystals suitable for an X-ray diffraction study.

$[Ph_4P][\{Ph_3SiO\}_2VO_2]$ (4b): This salt was prepared by dissolving **4a** (0.90 g; 1 mmol) in methanol (10 mL). The complex anion was then precipitated by slow addition of an aqueous solution (10 mL) of PPh_4Cl (0.42 g; 1 mmol). The white solid was isolated by filtration, washed with diethyl ether and then dried in air (yield 95%). $C_{60}H_{50}O_4PSi_2V$ (973.15): calcd. C 74.05, H 5.18, P 3.18, Si 5.77, V 5.23; found C 73.52, H 5.07, P 2.35, Si 5.40, V 5.09.

$[n\mathrm{Bu_4N}]_2[\{Ph_2SiO_2VO_2\}_2]$ (5a): $[n\mathrm{Bu_4N}]VO_3$ [56] (1.36 g; 4 mmol) in ethanol (10 mL) was added to a solution of $Ph_2Si(OH)_2$ (0.86 g; 4 mmol) in the same solvent (10 mL). After 45 min the white precipitate was filtered off, washed with diethyl ether and then dried over P_4O_{10} (yield 50−75%). $C_{56}H_{92}N_2O_8Si_2V_2$ (1079.42): calcd. C 62.31, H 8.59, N 2.59, Si 5.20, V 9.44; found C 62.29, H 8.76, N 2.61, Si 5.30, V 9.38.

"$H_6[PMo_9V_3O_{40}]\cdot 11H_2O$": The heteropolyacids "HPA-3" were prepared by described procedures.[7] $PMo_9V_3O_{51}H_{28}$ (1891.45): calcd. P 1.64, Mo 45.65; V 8.08; found P 1.70, Mo 45.50, V 7.75. Solid HPA-*n* species and their aqueous solutions are multicomponent systems: they contain several polyanions, positional isomers of these, $[VO_2]^+$ and often traces of V^{IV}. The identification is supported by solutions prepared with $2 \leqslant n \leqslant 10$ (see refs.[5,7,47]). Incomplete Keggin species or lacunary HPA-*n* are also formed and only equilibrium exchange-average resonances are observed.

Structure Determinations

Single crystals of **4b** and **5a** were grown from solutions in methanol at room temperature.

$[Ph_4P][\{Ph_3SiO\}_2VO_2]$ (4b): $C_{60}H_{50}O_4PSi_2V$, M_r = 973.14, monoclinic, space group $P2_1/n$ (no. 14); a = 2233.7(4), b = 1118.5(3), c = 2268.2(7) pm, β = 118.59(2)°, V = 4.976 (2) nm^3, Z = 4, $\rho_{calcd.}$ = 1.30 Mg·m^{-3}, $F(000)$ = 2034, λ = 71.069 pm, T = 293 K, μ (Mo-K_α) = 0.317 mm^{-1}, crystal dimensions 0.2 × 0.3 × 0.5 mm^3, $2 \leq 2\theta \leq 50°$, 9487 measured reflections, 8729 were unique; 614 parameters refined in full-matrix, R_1 = 0.046 with 3730 reflections [$I > 3\sigma(I)$], wR_2 = 0.054, $w \neq 1$ [weighting scheme of the form $w = w'[1-(||F_o| - |F_c||) / 6\sigma(Fo))^2]^2$ with $w' = 1/\Sigma_r A_r T_r(X)$ with coefficients 3.55, −0.579 and 2.62 for a Chebyshev series for which X = Fc/Fc(max)].[57] Min./max. residual electron density − 250/320 e nm^{-3}.

$[n Bu_4N]_2[\{Ph_2SiO_2VO_2\}_2]$ (5a): $C_{56}H_{92}N_2O_8Si_2V_2$, M_r = 1079.42, monoclinic, space group $P2_1/n$ (no.14); a = 1207.2(2), b = 1567.8(2), c = 1778.6(2) pm, β = 114.28(1)°, V = 3.068 (2) nm^3, Z = 2, $\rho_{calcd.}$ = 1.17 Mg·m^{-3}, $F(000)$ = 1167, λ = 71.069 pm, T = 293 K, μ (Mo-K_α) = 0.379 mm^{-1}, crystal dimensions 0.1 × 0.3 × 0.4 mm^3, $2 \leq 2\theta \leq 50°$, 5896 measured reflections, 5388 were unique; 317 parameters refined in full-matrix, R_1 = 0.047 with 2386 reflections [$I > 3\sigma(I)$], wR_2 = 0.056, $w \neq 1$ (weighting scheme of the form $w = w'\{1-[(||F_o| - |F_c||)/6\sigma(Fo)]^2\}^2$ with w' = 1/$\Sigma_r A_r T_r(X)$ with coefficients 3.16, 0.109 and 2.29 for a Chebyshev series for which X = Fc/Fc(max)).[57] Min./max. residual electron density −290/300 e nm^{-3}. The data were collected on a Enraf−Nonius CAD4 four-circle diffractometer (ω-2θ scans). All measurements were made at room temperature; two standard reflections showed no significant variation in intensity. Corrections were made for Lorentzian and polarisation effects; an extinction correction was also applied;[58] an empirical absorption correction on the basis of Ψ scan data was introduced. The structures were solved by direct methods (SHELX-86 program)[59] and subsequent Fourier difference techniques. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were found on difference Fourier maps; their positions were not refined and they were given one overall isotropic thermal parameter. Refinements were carried out by minimising the function $\Sigma w(|F_o| - |F_c|)^2$, where F_o and F_c are the observed and calculated structure factors (program CRYSTALS).[60]

CCDC-167421 (**4b**) and CCDC-167420 (**5a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

General

The solvents were purified by standard procedures and distilled under nitrogen.[62] Triphenyl silanol, Ph_3SiOH and diphenylsilanediol $Ph_2Si(OH)_2$ are commercial products; they were purified by fractional crystallisation. 2-Hydroxycyclohexanone (**6**), (1*S*, 2*S*, 5*S*)-2-hydroxypinane-3-one (**7a**), its (1*R*,2*R*,5*R*) enantiomer **7b**, and 2-methylcyclohexanone (**8**), were better than 99% pure by GC and NMR analysis; they were used without further purification. ^{1}H and ^{13}C NMR spectra were recorded at ambient temperature, on a Fourier transform apparatus (Bruker WP200), using $CDCl_3$ as solvent.

The ^{31}P NMR spectra were recorded with 10 mm o.d. tubes on a Bruker WM 250 apparatus operating at 101.2 MHz. From these NMR measurements it was found that the HPA-*n* precursors ($n \geq 2$) are not pure heteropolyacids: they contains a certain fraction of HPA-1, HPA-2, −3 and −4 with several isomers and excess H_3PO_4. We were unable to prepare a 99% pure isomer.

Raman spectra were recorded at room temperature with a Jobin−Yvon U1000 spectrometer with a resolution of 4 cm^{-1}. Solid samples of the complexes were mounted on a disk rotating at about 1000 rpm in order to avoid decomposition and/or photoreduction by the laser beam (excitation line, 514.5 nm of an Ar^+ laser; source power 30−50 mW; scanning time ca. 2 h). Solutions (0.1 M) of the mononuclear complex **4a** were studied. IR spectra (resolution: 2 cm^{-1}) were measured in a Fourier transform apparatus (Bruker Vector 22) in Nujol suspension either between two caesium bromide plates or in KBr pellets. Elemental analyses (C, H, N, Si, V) were carried out at the Service Central d'Analyses CNRS, Lyon.

Oxidation of 6, 7a or b, or 8 by Dioxygen in the Presence of a Vanadium Precursor

Typical experiments were performed in an all-glass reactor vessel (40 mL) attached to a vacuum line, with a manometer and a gas inlet. This was charged with the vanadium precursor (0.076 mmol V), the solvent (5 mL) and the substrate (ca. 7.6 mmol), and the mixture was stirred magnetically under O_2 for 24 h at 60 °C. Dioxygen uptake was determined by use of a gas burette system. The mixture was cooled and analysed by GC (OV 1701). An aliquot portion (usually 1 mL) including a standard (methyl heptanoate or naphthalene) was esterified by addition of ethereal diazomethane to the crude mixture or after removal of the vanadium on active charcoal (GC-MS experiments). Products were identified by GC-MS.

The GC-MS analyses were performed on a TRACE GC 2000 gas chromatograph (50 m capillary column) interfaced with a mass selective detector (RTX5-MS). ^{1}H and ^{13}C NMR spectra and MS (70 eV or CI, NH_3) data correspond to our previous findings[45] or to literature references.

Acknowledgments

G. B. Shul'pin expresses his gratitude to the Pierre and Marie Curie University in Paris for an Invited Professorship. We thank Dr. J. S. Lomas for constructive discussions and for correcting the manuscript.

Template Synthesis of Chiral Vicinal Diphosphinites as Their Pt^{II} and Pd^{II} Complexes

Paola Bergamini,*[a] Valerio Bertolasi,[a] Michela Cattabriga,[a] Valeria Ferretti,[a] Urania Loprieno,[a] Nicoletta Mantovani,[a] and Lorenza Marvelli[a]

Keywords: Template synthesis / Ligand design / P ligands / Platinum / Palladium

The metal-templated synthesis of a few examples of vicinal diphenylphosphinites is accomplished when the corresponding vicinal diols react with the diphenylchlorophosphane complexes *cis*-$[MCl_2(PPh_2Cl)_2]$ (M = Pt, Pd) in anhydrous THF. This process is proposed as a new synthetic route for Pt^{II} and Pd^{II} complexes of the new ligands 1,2-bis(diphenylphosphinito)butane, 2,3-bis(diphenylphosphinito)butane, and 2,3-bis(diphenylphosphinito)diisopropyl-L-tartrate, containing seven-membered chelate rings including stereogenic carbons. The new chiral phosphane-phosphinite (*R*)-3-(diphenylphosphanyl)-2-(diphenylphosphinito)propanol has also been obtained as a Pt^{II} six-membered chelate. The X-ray crystal structure of some of the described complexes and NMR evidence of the possibility of removing the ligands from the metal are reported.

Introduction

Chiral diphosphinites are a well-documented alternative to chiral diphosphanes as ligands for metal ions to give metal complexes that can be exploited in various processes with the double function of catalysts and asymmetry inductors.[1] Particular attention has been given to vicinal diphosphinites whose coordination gives a seven-membered chelate ring similar in size to the successful DIOP-Rh system.[2]

Several examples of chiral diphosphinites obtained by the functionalization of diols belonging to the natural chiral pool have been reported.[3] In particular Rajan-Babu et al. have described asymmetric diphosphinites obtained by the functionalization of sugars and have shown that it is possible to drive some enantioselective hydrogenations to one product or to the other depending on the hydroxy groups selected for the transformation into phosphinites.[4]

Despite the interest of diphosphinites for catalysis, the synthesis of those deriving from low-weight vicinal diols has not been described, with the sole exception of bis(diphenylphosphinite)ethane,[5] observed in 1999 in solution but not isolated.

The apparent lack of attention paid to the simplest vicinal diphosphinites could be due to the known moisture and oxygen sensitivity[6] reported for some members of this group of ligands, which makes their use in catalysis not very convenient and their synthesis quite puzzling.

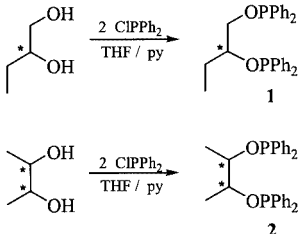
In fact our attempts to prepare 1,2- and 2,3-bis(diphenylphosphinite)butane by the classical route (Scheme 1) − reaction of the corresponding diols with PPh_2Cl − gave **1** and **2** as impure products in low yield.



Scheme 1

Nevertheless, when we succeeded in obtaining a few square-planar Pt^{II} and Pd^{II} complexes from crude **1** and **2**, we noticed that the stability of such molecules is greatly enhanced by the coordination. We therefore reasoned that it should be possible to design a general alternative synthetic route for diphenylphosphinites where they could be built inside the coordination sphere of metal ions (metal template synthesis).

In this paper we compare two synthetic pathways to platinum and palladium dichloride complexes of **1** and **2**: in the first one **1** and **2** are prepared in solution as free ligands and then coordinated to the metal by substitution of COD in $[MCl_2(1,5\text{-COD})]$ (M = Pt, Pd); in the second, the reaction of the diphenylchlorophosphane complexes *cis*-$[MCl_2(PPh_2Cl)_2]$ (**3a**, M = Pt; **3b**, M = Pd) with 1,2- or 2,3-butanediol leads to the same complexes in a shorter time and with higher yield and purity.

This "metal-template" synthesis can be extended to more functionalised ligands, and we also report NMR evidence of the possibility of removing these ligands from the metal exploiting the sequestrating action of CN^- on Pt and Pd.

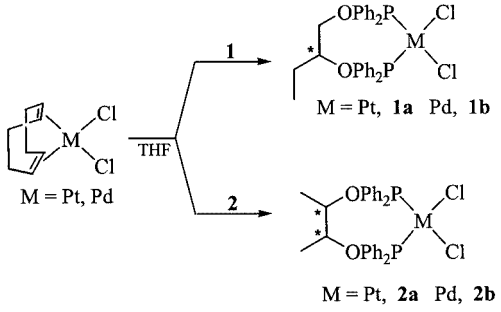
Results and Discussion

Generation of the Diphosphinites 1 and 2 in Solution and Their Coordination to Pt and Pd

The diphosphinites **1** and **2** can be obtained from the reaction of 1,2- and 2,3-butanediol[7] respectively with two equivalents of PPh_2Cl in THF or pyridine (see Exp. Sect.). The reactions were followed by ^{31}P NMR spectroscopy and it was observed that, in both cases, PPh_2Cl (δ = 82.5 ppm) is completely consumed in about 60 min to give the required product (two singlets at δ = 115.7 and 111.5 ppm for **1** and one singlet at δ = 112.2 ppm for **2**) together with a few phosphorus-containing side products.

The major drawback of this direct preparation of **1** and **2** is that impure products were obtained even under carefully controlled conditions. The ^{31}P NMR spectrum of the reaction mixture showed the presence of side products generated both by phosphorus oxidation and by PPh_2Cl decomposition due probably to traces of water contained in the reacting liquid diols.

All attempts to improve the purity of **1** and **2** obtained by this route using chromatographic techniques led to further decomposition. The instability of free phosphinites has been observed before.[6] Nevertheless, the addition of $[MCl_2(1,5\text{-COD})]$ (M = Pt, Pd) to a THF solution containing crude **1** or **2** leads to the precipitation of their platinum (**1a** and **2a**) and palladium (**1b** and **2b**) dichloride complexes in pure form (Scheme 2).



Scheme 2

The ^{31}P NMR spectrum of **1a** shows two doublets with satellites at δ = 90.2 and 89.3 ppm indicating that each phosphorus is coupled to platinum ($^1J_{P,Pt}$ = 4045 and 3994 Hz, typical values for phosphorus *trans* to chloride[8]) and to the other phosphorus ($^2J_{P,P}$ = 12 Hz). The corresponding palladium complex **1b** also shows a doublet of doublets at δ = 119.1 and 118.4 ppm ($^2J_{P,P}$ = 35.7 Hz).

Both **2a** and **2b** show a singlet (with satellites for **2a**, $^1J_{P,Pt}$ = 4021 Hz) in the ^{31}P NMR spectrum due to the equivalence of the two phosphorus atoms in these complexes.

While **1** and **2** undergo rapid decomposition in solution in the presence of traces of oxygen and/or water, solutions of **1a**, **1b**, **2a**, or **2b** in pure chloroform or in $CHCl_3$/acetone do not show any sign of decomposition (by ^{31}P NMR spectroscopy) even in the presence of oxygen and/or water after five days: these observations indicate that coordination to Pt^{II} or Pd^{II} dramatically reduces the susceptibility of phosphinites to oxidation and hydrolysis.

Template Synthesis of 1 and 2

In an attempt to design a more convenient route to diphosphinites we considered that, because the major reason for the interest in these compounds is the use of their complexes with metal ions in catalysis, it should be advantageous to produce them inside the coordination sphere of metal ions of catalytic value, thus obtaining the metal complexes directly. Pt^{II} and Pd^{II} complexes appeared to be convenient models for this synthetic approach. The metal-templated synthesis we carried out is described in Scheme 3.

Treatment of $[MCl_2(1,5\text{-COD})]$ (M = Pt, Pd) with two equivalents of PPh_2Cl in carefully dried THF gives *cis*-$[MCl_2(PPh_2Cl)_2]$ **3a** (M = Pt) and **3b** (M = Pd), which have been described before.[9]

We found that the coordinated chlorophosphane in **3a** and **3b** is still able to react with hydroxy groups. In fact, the reaction of **3a** or **3b** with 1,2- or 2,3-butanediol gave **1a**, **1b**, **2a**, and **2b** which precipitated as pure products in high yields, with elimination of HCl in solution.

Complexes **1a** and **2b** gave crystals suitable for an X-ray crystal-structure determination.

X-ray Crystal Structures of 1a and 2b

ORTEP[10] views of the structure of **1a** and **2b** are shown in Figures 1 and 2, respectively. Selected bond lengths and angles are reported in Table 1. Both complexes present a slightly distorted square-planar geometry, with the metal centre bonded to two chlorides and to two phosphorus atoms belonging to the diphosphinite ligand. The coordination of **1** or **2** to the metal leads to the formation of a seven-membered ring with a boat conformation. The nature of the metallic centre does not significantly affect the bond angles and lengths in the coordination sphere.

A few examples of X-ray crystal structures of diphosphinito complexes have been reported before. For example, both *fac*-$[ReBr(CO)_3(L{-}L)]$ and *fac*-$[ReH(CO)_3(L{-}L)]$ [L−L = 1,2-bis(diphenylphosphinito)ethane] contain seven-membered $ReP_2O_2C_2$ rings with a twisted chair conformation.[5]

Removal of 1 from Its Pt and Pd Complexes

The sequestrating action of cyanide for platinum(II) is well-known.[11] When **1a** was dissolved in $CDCl_3$ and treated with 4.5 equiv. of soluble $(Bu_4N)CN$, the ^{31}P NMR spectrum showed that, in the first step, both the platinum-coordinated chlorides are replaced by cyanide within 5−10 minutes. Further observations show that the diphosphinite **1** is progressively replaced by cyanide and after 30−40 mi-

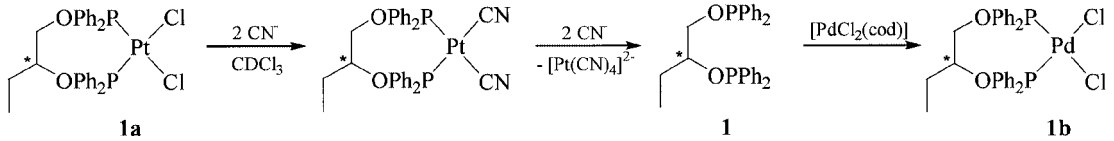
P1−Pt−P2	93.22(3)	P1−Pd−P2	92.92(2)

nutes the free ligand **1** is the only phosphorus-containing product.

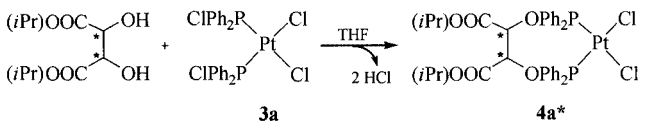
The addition of a small quantity of $[PdCl_2(1,5\text{-COD})]$ to this solution gives the immediate formation of **1b** (Scheme 4), indicating that the shift of **1** from platinum to palladium can be obtained by the addition of cyanide. An analogous experiment showed that the reverse process of ligand transfer from palladium (**1b**) to platinum is also easily achievable.

Template Synthesis of the New Diphosphinite 4 on Platinum

In an attempt to extend the applicability of our template synthesis of phosphinites to more functionalised ligands, we tried the addition of (+)-diisopropyl L-tartrate to the intermediate $[Pt(PPh_2Cl)_2Cl_2]$ (**3a**) preformed in situ in THF. After 18 hours the formation of the optically active complex **4a*** was complete (Scheme 5).



Scheme 4



3a **4a***

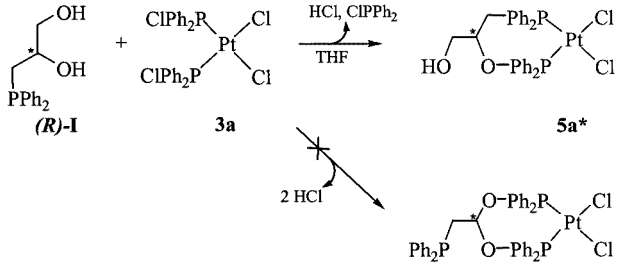
Scheme 5

This complex was isolated and fully characterised (see Exp. Sect.). The ^{31}P NMR spectrum shows a singlet for the two equivalent phosphorus atoms at $\delta = 94.7$ ppm, in the typical downfield range of diphenylphosphinites, with satellites due to the Pt coupling ($^1J_{P,Pt} = 4003$ Hz).

The optical rotation of **4a*** was measured in $CHCl_3$ ($[\alpha]_D^{25} = -10.6$ ($c = 0.5$, $CHCl_3$). This result confirms the expectation that optically active complexes are obtained when a diol bearing a stereogenic carbon is used in an optically active form, due to the fact that the diol reaction with **3a** or **3b** does not involve the chiral carbon.

Template Synthesis of the New Phosphane-phosphinite-ol 5 on Platinum

The optically active phosphane-diol (*R*)-**I** (Scheme 6) can be obtained in two steps from the commercial precursor (*R*)-2,2-dimethyl-1,3-dioxolane-4-methanol *p*-toluenesulfonate through a known procedure.[12]



Scheme 6

When (*R*)-**I** is added to a solution of $[Pt(PPh_2Cl)_2Cl_2]$ (**3a**) its phosphinic group replaces the less nucleophilic PPh_2Cl and the *C(2)*hydroxy group reacts with the remaining coordinated PPh_2Cl (Scheme 6). The driving force of this process is probably the formation of a thermodynamically stable six-membered chelate ring. Complex **5a*** is recovered as the only platinum-containing species.

The identity of **5a***, determined by elemental and spectroscopic analysis, was confirmed by X-ray crystal structure (see below) and its optical rotation was measured (see Exp. Sect.). The ^{31}P NMR spectrum of **5a*** shows two doublets with satellites, one at $\delta = 84.7$ ppm, typical of a coordinate phosphinite, while the coordinated phosphinic P resonates at $\delta = -0.4$ ppm: each phosphorus is coupled to platinum ($^1J_{P,Pt} = 3858$ and 3482 Hz, respectively) and to the other phosphorus ($^2J_{P,P} = 17.7$ Hz).

It is noteworthy that **5a*** contains the new ligand (*R*)-3-(diphenylphosphanyl)-2-(diphenylphosphinito)propanol (**5**), whose direct synthesis would not be possible without protection of the *C(3)*-hydroxy group. Not many examples of phosphane-phosphinites have been reported,[13] and **5** is a rare example of this class of ligand with *C*-chirality.

It should also be noted that the reaction of **3a** with both the OH groups of (*R*)-**I** would give a potentially tridentate phosphane-diphosphinite ligand acting in only a bidentate manner; no evidence of this process was observed.

The deplatinization of **5a*** with CN^- in solution ($CDCl_3$) allowed the observation of a ^{31}P NMR spectrum consistent with that expected for the free ligand **5** – a doublet at $\delta = 111$ ppm, typical for a $ROPPh_2$ group, and a second doublet in the phosphinic range ($\delta = -23$ ppm), each coupled to the other with a $^4J_{P,P}$ coupling constant of 7 Hz.

X-ray Crystal Structure of 5a*

The recrystallisation of **5a*** from CH_2Cl_2 and diethyl ether gave crystals whose X-ray structure is shown in Figure 3. Selected bond lengths and angles are given in Table 2.

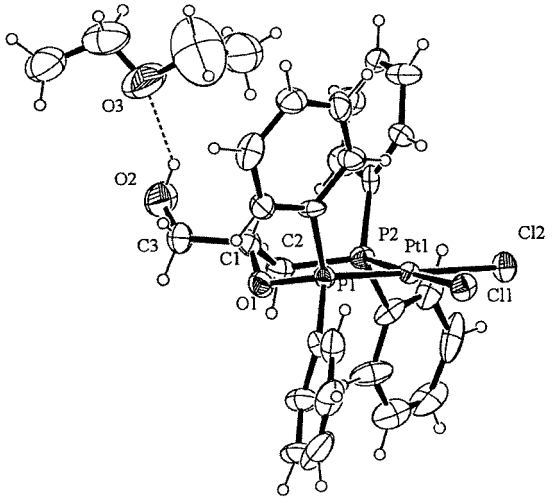


Figure 3. ORTEP[10] view of complex **5a*** linked by hydrogen bonds to a solvent molecule of diethyl ether showing the thermal ellipsoids at the 40% probability level.

Table 2. Selected bond lengths [Å] and angles [°] for compound **5a***

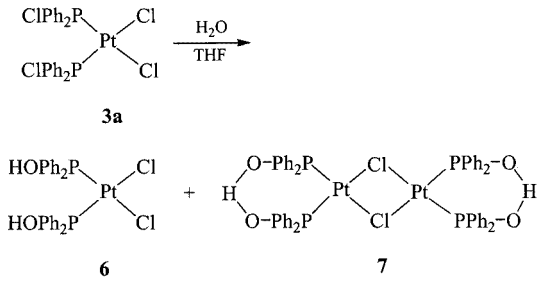
5a*			
Pt1–Cl1	2.352(4)	Cl1–Pt1–Cl2	89.3(1)
Pt1–Cl2	2.364(5)	Cl1–Pt1–P1	87.4(2)
Pt1–P1	2.209(5)	Cl1–Pt1–P2	177.1(2)
Pt1–P2	2.239(5)	Cl2–Pt1–P1	176.6(2)
P1–O1	1.60(1)	Cl2–Pt1–P2	88.0(2)
P2–C2	1.81(2)	P1–Pt1–P2	95.2(1)
C1–O1	1.44(2)		
C1–C2	1.49(2)		
C1–C3	1.52(2)		
C3–O2	1.38(2)		
Hydrogen bond			
O2–H2	0.82		
O3···H2	2.10		
O2···O3	2.78(2)		
O2–H2···O3	140		

The complex displays a slightly distorted square-planar geometry. The Pt1−P1−P2−C1−C2−O1 six-membered ring assumes a half-chair conformation with the C1 atom in the *R* configuration, as determined by the Flack parameter [−0.02(4)] calculated after the least-square refinement. The molecular packing forms channels which include molecules of diethyl ether linked by means of an O2−H···O3 hydrogen bond [O2···O3 = 2.78(2) Å] to the hydroxyl group of the complex.

Hydrolysis of 3a and 3b

The above-described synthesis of diphenylphosphinites on Pt or Pd must be carried out in water-free conditions as we observed that, in the presence of even small quantities of water, competitive hydrolysis of the intermediate complexes **3a** and **3b** prevents the formation of the diphosphinite complexes.

We found that the addition of water to a THF solution of **3a** (Scheme 7) produces a mixture of complex [$PtCl_2(PPh_2OH)_2$] (**6**; δ = 71.1 ppm, $^1J_{P,Pt}$ = 4065 Hz) and of another species, **7**, whose ^{31}P NMR spectrum shows a singlet with satellites at δ = 50.5 ppm ($^1J_{P,Pt}$ = 4090 Hz).



Scheme 7

Recrystallisation of the mixture from THF and diethyl ether gave crystals of **7**, which has been identified before[9] on the basis of its NMR spectroscopic data. The X-ray crystal structure (Figure 4) showed that **7** is the dimeric neutral species [Pt(μ-Cl)($Ph_2POHOPPh_2$)]$_2$ with bridging chloride ligands and terminal PPh_2OH and PPh_2O moieties connected by hydrogen bonds. Although the hydrolysis of **3a** has been studied in detail in the past,[9] the structure of **7** has not been reported before.

In a similar way, the presence of water converts the palladium species **3b** into another species whose ^{31}P NMR spectrum is a singlet at δ = 78.1 ppm, coincident with the signal reported for the palladium analogue of **7** [Pd(μ-Cl)($Ph_2POHOPPh_2$)]$_2$.[9c]

X-ray Crystal Structure of 7

Crystals of **7** were obtained from THF and diethyl ether and its X-ray structure is shown in Figure 4. Selected bond lengths and angles are given in Table 3.

The complex is essentially planar and displays a C_s symmetry. The molecule is characterized by two strong hydrogen bonds O1−H···O2 and O4−H···O3 with very short

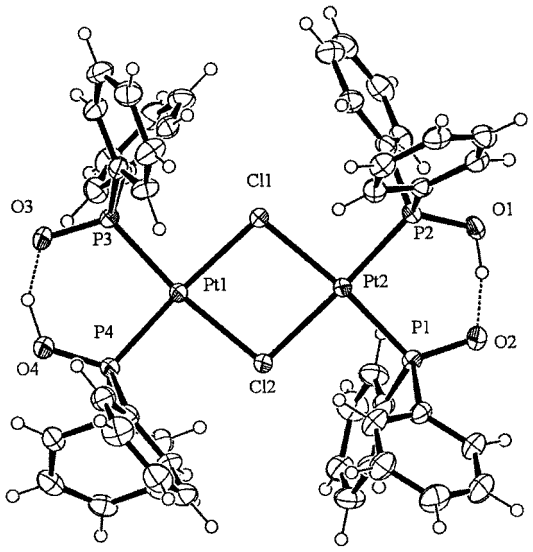


Figure 4. ORTEP[10] view of complex **7** showing the thermal ellipsoids at the 40% probability level

O1···O2	2.415(6)	O3···O4	2.404(5)
O1−H···O2	165(5)	O4−H···O3	149(5)

O···O distances [O1···O2 = 2.415(6) Å and O4···O3 = 2.404(5) Å]. They belong to the $(O-H\cdots O)^-$ class of negative-charge-assisted H-bonds [(−)CAHB][14] where the negative charge is shared between two oxygens. Accordingly, all the P−O bonds are of similar lengths [in the range 1.540(4)−1.550(4) Å], and are significantly longer than the P=O distances [1.48−1.50 Å][15] between phosphorus and neutral oxygen.

Conclusions

The experiments described in this paper show that vicinal diphosphinites can be obtained in the metal-chelate sta-

bilised form, starting from the corresponding 1,2-diols, whose stereochemistry is retained in the process.

We are now investigating the possibility to extend this preparative method to asymmetric complexes of other metals (e.g. Rh or Ru) and of other groups of ligands (e.g. amidophosphane-phosphinites and aminophosphane-phosphinites[16]) relevant to asymmetric catalysis.

Experimental Section

All reactions and manipulations were routinely performed under a dry nitrogen atmosphere by using standard Schlenk-tube techniques. Tetrahydrofuran was doubly distilled from over $LiAlH_4$, while diethyl ether was purified by distillation from over sodium/benzophenone. Dichloromethane and methanol were purified by distillation from calcium hydride. Pyridine was distilled and stored over KOH. $CDCl_3$, used as solvent for the NMR spectra, was dried over molecular sieves (4 Å). PPh_2Cl (d = 1.23 g·mL^{-1}) was purified just prior to use by distillation under nitrogen. All the other solvents and chemicals were reagent grade and, unless otherwise stated, were used as received from commercial suppliers. Infrared spectra were obtained in CsI, using a Nicolet 510 P FT-IR (4000−200 cm^{-1}) spectrometer. ^{1}H and ^{31}P NMR spectra (always ^{1}H decoupled) were recorded on Bruker AC200 spectrometers operating at 200.13 MHz (^{1}H) and 81.01 MHz (^{31}P). Peak positions are given in ppm relative to tetramethylsilane (^{1}H) and to external 85% H_3PO_4 (^{31}P). Elemental analyses (C, H, N) were performed using a Carlo Erba model 1106 elemental analyser. Optical rotations were obtained on a Perkin−Elmer 241 at 25 °C.

Literature methods were used for the preparation of [$PtCl_2$(1,5-COD)][17] and [$PdCl_2$(1,5-COD)].[18]

The diol *R*-**I** was prepared in two steps from commercial *p*-toluenesulfonate of (*R*)-2,2-dimethyl-1,3-dioxolane-4-methanol by the reported procedure.[12]

Synthesis of Pt and Pd Complexes of Ligands 1 and 2

Synthesis of 1a. Method a: A THF (5 mL) solution of 1,2-butanediol (117 mg, 1.3 mmol) was prepared in a Schlenk flask equipped with a dropping funnel and cooled to 0 °C (ice bath). The dropping funnel was charged with THF (5 mL), PPh_2Cl (0.57 mL, 3.2 mmol), pyridine (3 mL), and the mixture was added dropwise to the diol solution whilst stirring. After the addition of a few drops, white pyridinium chloride started to precipitate. After the end of the addition, the reaction mixture was kept stirring at 0 °C for an hour, then the white solid was filtered off under nitrogen on celite, giving a colourless solution whose ^{31}P NMR analysis showed the presence of a main species consistent with **1** [^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): P_a 115.7(s), P_b 111.5 (s) ppm] together with small amount of other unidentified species.
The volume of this solution was reduced to 20 mL by addition of THF and solid [$PtCl_2$(1,5-COD)] (500 mg, 1.3 mmol) was added at room temperature. The reaction mixture was stirred for 1 h at room temperature; during this period the product precipitated as a white solid, which was then filtered and washed with diethyl ether (390 mg, 41%).

Method b: A solution of PPh_2Cl (100 μL, 0.56 mmol) in 5 mL of THF was added dropwise whilst stirring to a solution of [$PtCl_2$(1,5-COD)] (100 mg, 0.27 mmol) in THF (10 mL) placed in a Schlenk flask at room temperature. The immediate formation of the dichlorophosphane complex **3a** was unambiguously confirmed by ^{31}P NMR spectroscopy (δ = 73.4 ppm, $^1J_{PPt}$ = 4069 Hz[9]). The addition of 1,2-butanediol (24 μL, 0.27 mmol) gave a colourless mixture, and within 10 minutes **1a** began to separate as a white microcrystalline precipitate. Slow addition of diethyl ether completed the precipitation. The solid product was filtered off, washed with diethyl ether, and dried under vacuum (130 mg, 67%). $C_{28}H_{28}Cl_2O_2P_2Pt$: calcd. C 46.4, H 3.9%; found C 46.6, H 4.0%. IR: ν_a(Pt−Cl) 317; ν_s(Pt−Cl) 293 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 0.7 (t, $^3J_{H,H}$ = 7 Hz, 3 H, -C*H*$_3$), 1.7−1.4 (m, 2 H, -C*H*$_2$Me), 3.8−4.2 (m, 2 H, -C*H*$_2$OP), 4.4 (m, 1 H, -C*H*OP), 7.0−8.0 (m, 20 H, Ph) ppm. ^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): δ = P_a 90.2 (d, $^1J_{PtP}$ = 4045 Hz,), P_b 89.3 (d, $^1J_{PtP}$ = 3994 Hz) ppm, $^2J_{PaPb}$ = 12 Hz.
Recrystallization of the crude product from dichloromethane/ethanol gave crystals suitable for an X-ray diffraction study.

Synthesis of 2a. Method a: A solution of ligand **2** was prepared from 2,3-butanediol (117 mg, 1.3 mmol), following the method described above for **1**. The ^{31}P NMR analysis showed the presence of a signal consistent with **2** [^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): δ =112.2 (s) ppm].
[$PtCl_2$(1,5-COD)] (500 mg, 1.3 mmol) was added to this solution and the procedure described above for **1a** (method a) was followed. The workup gave **2a** as white crystals. (352 mg, 38%).

Method b: Complex **2a** was obtained as a white solid (137 mg, 70%) following the procedure described above for **1a** (method b), based on 100 mg of [$PtCl_2$(1,5-COD)] (0.27 mmol) and replacing 1,2-butanediol with 2,3-butanediol. $C_{28}H_{28}Cl_2O_2P_2Pt$: calcd. C 46.38, H 3.89%; found C 46.43, H 3.90%. IR: ν_a(Pt−Cl) 321; ν_s(Pt−Cl) 295 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 1.2 (d, $^3J_{H,H}$ = 6.1 Hz, 6 H, -C*H*$_3$), 4.6 (m, 2 H, -C*H*OP), δ = 7.0−8.0 (m, 20 H, Ph) ppm. ^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): δ = 90.4 ppm (s, $^1J_{PtP}$ = 4021 Hz).

Synthesis of 1b. Method a: The diphosphinite **1** was generated in THF (20 mL) from 1,2-butanediol (153 mg, 1.7 mmol), PPh_2Cl (0.64 mL, 3.5 mmol), and pyridine (3 mL) as described above for **1a**. Solid [$PdCl_2$(1,5-COD)] (495 mg, 1.7 mmol) was then added at room temperature with vigorous stirring. Within a few minutes, **1b** precipitated as a yellow solid. The crude product was filtered and washed with diethyl ether (572 mg, 53%). Recrystallization from dichloromethane/ethanol gave yellow crystals.

Method b: The intermediate complex **3b** was prepared in situ by adding a solution of PPh_2Cl (314 μL, 1.75 mmol) in 5 mL of THF dropwise to a second solution of [$PdCl_2$(1,5-COD)] (250 mg, 0.87 mmol) in THF (20 mL). When the complete formation of **3b** was confirmed by ^{31}P NMR spectroscopy (δ = 96 ppm), 1,2-butanediol (81 mg, 0.9 mmol) was added to give a pale yellow mixture. Within a few minutes **1b** began to precipitate as a yellow solid. Slow addition of diethyl ether completed the precipitation. The solid product was filtered off, washed with diethyl ether, and dried under vacuum. (409 mg, 74%). $C_{28}H_{28}Cl_2O_2P_2Pd$: calcd. C 52.85, H 4.44%; found C 53.02, H 4.58%. IR: ν_a(Pd−Cl) 315; ν_s(Pd−Cl) 290 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 0.7 (t, $^3J_{H,H}$ = 6.1 Hz, 3 H, -C*H*$_3$), 1.7 (m, 2 H, -C*H*$_2$Me,), 4.1 (m, 2 H, -C*H*$_2$OP); 4.4 (m, 1 H, -C*H*OP), 7.0−8.0 (m, 20 H, Ph) ppm. ^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): δ = P_a 119.1 (d), P_b 118.4 (d) ppm, $^2J_{PaPb}$ = 35.7 Hz.

Synthesis of 2b. Method a: Complex **2b** was prepared as a yellow crystalline solid (227 mg, 51%) from [$PdCl_2$(1,5-COD)] (200 mg, 0.7 mmol) and a solution where ligand **2** was generated from 2,3-butandiol (72 mg, 0.8 mmol) following the procedure described above for **1b**.

Method b: Complex **2b** was obtained also following the procedure described above for **1b** (method b), using 2,3-butanediol. Yield 74%. $C_{28}H_{28}Cl_2O_2P_2Pd$: calcd. C 52.85, H 4.44%; found C 52.31, H 4.57%. IR: ν_a(Pd−Cl) 311; ν_s(Pd−Cl) 299 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 1.2 (d, $^3J_{H,H}$ = 6.1 Hz, 6 H, -CH_3), 4.5 (m, 2 H, -C*H*OP), 7.3−8.0 (m, 20 H, Ph) ppm. ^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): δ = 118.5 (s) ppm.

Template Synthesis of Other Diphosphinites on Pt^{II}

Synthesis of 4a*: The intermediate complex $[PtCl_2(PPh_2Cl)_2]$ (**3a**; 1.1 mmol) was formed in THF and checked by NMR spectroscopy as described for the previous reactions.
(+)-Diisopropyl L-tartrate (232 μL, 1.1 mmol) dissolved in THF (5 mL) was then added to the reaction mixture. After 18 h the complete formation of **4a*** was detected by ^{31}P NMR spectroscopy. This solution was reduced to a volume of 5 mL and the product was precipitated with *n*-pentane, washed with the same solvent and dried under vacuum (716 mg, 75%). $C_{34}H_{36}Cl_2O_6P_2Pt$: calcd. C 47.00, H 4.15%; found C 47.30, H 4.10%. IR: ν(CO) 1745; ν_a(Pt−Cl) 302; ν_s(Pt−Cl) 292 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 1.1 (dd, $^3J_{H,H}$ = 6 Hz, 12 H, -OCH(CH_3)$_2$], 4.7 (septet, $^3J_{H,H}$ = 6 Hz, 2H, −OC*H*(CH_3)$_2$], 5.2 (m, 2 H, -C*H*OP), 7.2−8.0 (m, 20 H, Ph) ppm. ^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): δ = 94.7 (s, $^1J_{PtP}$ = 4003 Hz) ppm. $[\alpha]_D^{25}$ = −10.6 (*c* = 0.5, $CHCl_3$).

Synthesis of Complex 5a*: The intermediate complex $[PtCl_2(PPh_2Cl)_2]$ (**3a**; 0.77 mmol) was formed in THF and checked by NMR spectroscopy as described for the previous reactions. A solution of the phosphane-diol *R*-**I** (200 mg 0.77 mmol) in 5 mL of THF was then added to the reaction mixture and within 10 minutes a white solid began to precipitate. The addition of diethyl ether completed the precipitation of **5a***, which was filtered off, washed with diethyl ether and dried under vacuum. (404 mg, 74%). $C_{27}H_{26}Cl_2O_2P_2Pt{\cdot}C_2H_{10}O$: calcd. C 47.48, H 4.59%; found C 47.55, H 4.68%. IR: ν(OH) 3450; ν_a(Pt−Cl) 306; ν_s(Pt−Cl) 291 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ = 1.2 (t, 6 H,), 2.6 (m, 2 H, -CH_2P), 3.5 (m, 7 H, OH + Et_2O + CH_2OH), 3.9 (m, 1 H, -C*H*OP), 7.5 (m, 20 H, Ph) ppm. ^{31}P NMR (81.01 MHz, $CDCl_3$, 25 °C): δ = P_a 84.7 (d, $^1J_{PtP}$ = 3858 Hz,), P_b −0.4 (d, $^1J_{PtP}$ = 3482 Hz) ppm, $^2J_{PaPb}$ = 17.7 Hz. $[\alpha]_D^{25}$ = +40.0 (*c* = 0.25, $CHCl_3$).

NMR Experiments

Hydrolysis of 3a and 3b: A solution of PPh_2Cl (300 μL, 1.67 mmol) in dry THF (20 mL) was added dropwise in 15 min to a second solution of $[PtCl_2(1,5\text{-COD})]$ (308 mg, 0.82 mmol) in 30 mL of THF containing 30 μL of water. The mixture was stirred at room temperature. The ^{31}P NMR analysis of an aliquot after two hours showed the formation of **3a** and **6** [δ = 71.1 ppm (s, $^1J_{PtP}$ = 4065 Hz)] in an approximate 1:1 ratio, which increased with time. After 18 h, the signal of **3a** had disappeared and **6** and **7** [δ = 50.5 ppm/s, $^1J_{PtP}$ = 4090 Hz)] were observed in a 2:1 ratio.
At this point, a reduction of the solution volume and the slow addition of diethyl ether induced the separation of a small amount of white crystals whose X-ray structure was determined.

In a similar way, when water (2 equiv.) was added to the palladium complex **3b**, generated in THF from PPh_2Cl (150 μL, 0.83 mmol) and $[PdCl_2(1,5\text{-COD})]$ (117 mg, 0.41 mmol), the ^{31}P NMR showed a mixture of species, the most abundant of which was represented by a singlet at δ = 78.1 ppm {$[Pd(\mu\text{-}Cl)(Ph_2POHOPPh_2)]_2$[9c]}.

Removal and Transfer of Ligand 1

$(Bu_4N)CN$ (4.5 equiv.; 33 mg, 0.121 mmol) was added to a $CDCl_3$ solution (0.8 mL) of **1a** (15 mg, 0.027 mmol) in a 5-mm screw-cap NMR tube. The progress of the reaction was monitored by ^{31}P NMR spectroscopy: within the time necessary for NMR acquisition the substitution of both the chlorides in **1a** with two cyanides was completed (P_a δ = 100.9 ppm, d, $^1J_{PPt}$ = 2815 Hz and P_b δ = 99.5 ppm, d, $^1J_{PPt}$ = 2834, $^2J_{PP}$ 19.6 Hz). The following decomposition of this dicyanide derivative into $[Pt(CN)_4]^{2-}$ and free ligand **1** occurred in about 30 minutes as denoted by the observation of the signals of **1** [δ = P_a 115.7 (s), P_b 111.5 (s) ppm] exclusively.
At this point, the addition of $[PdCl_2(COD)]$ (8.5 mg, 0.03 mmol) to the same NMR tube showed the immediate appearance of the signals of **1b**.

An analogous multi-step transmetallation process was performed by addition of an excess of solid $(Bu_4N)CN$ to a solution of the palladium complex **1b** (15 mg, 0.02 mmol) in 0.8 mL of $CDCl_3$, followed by $[PtCl_2(1,5\text{-COD})]$ (11 mg, 0.03 mmol). The final ^{31}P NMR spectrum showed the phosphinito-platinum complex **1a** to be the only phosphorus-containing species.

Removal of Ligand 5 from Platinum Complex 5a*

A sample of complex **5a*** (10 mg, 0.014 mmol) was dissolved in $CDCl_3$ and a ^{31}P NMR spectrum recorded. Solid $(Bu_4N)CN$ was progressively added to this solution. After the first addition of two equivalents (7.5 mg), a ^{31}P NMR spectrum consistent with the cyanide analogue of complex **5a*** was detected (dd, δ = 92 and −4.4 ppm, $^1J_{PPt}$ = 2716 and $^1J_{PPt}$ = 2398 Hz respectively, $^2J_{PP}$ = 25.6 Hz). Further addition of a large excess of $(Bu_4N)CN$ (5 equiv., 20 mg) produced the appearance of a new pattern showing two coupled doublets (δ = 111 and −23 ppm, $^4J_{PP}$ = 7 Hz), as expected for the phosphane-phosphinite-ol **5**.

X-ray Crystal Structure of 1a, 2b, 5a*, and 7: The crystal data were collected using a Nonius Kappa CCD diffractometer with graphite monochromatized Mo-K_α radiation and corrected for Lorentz, polarization and absorption (SORTAV)[19] effects. The structures were solved by direct and Fourier methods (SIR92)[20] and refined on F^2 (SHELXL-97)[21] using full-matrix least-squares with all non-H atoms anisotropic and hydrogen atoms at calculated positions, riding on their carrier atoms.

1a: $C_{28}H_{28}Cl_2O_2P_2Pt$, *M* = 724.43, *T* = 295 K, monoclinic, space group $P2_1/n$, *a* = 8.9098(2), *b* = 17.8502(4), *c* = 18.1605(4) Å, β = 103.749(1)°, *U* = 2805.5(1) Å^3, *Z* = 4, D_c = 1.715 g·cm^{-3}, μ = 53.269 cm^{-1}. Collected reflections = 18446 (θ ≤ 30°), unique reflections = 8130, R_{int} = 0.031, observed reflections = 6311 [$I \geq 2\sigma(I)$]. Final *R* (observed reflections) = 0.0335, R_w (all reflections) = 0.0659.

2b: $C_{28}H_{28}Cl_2O_2P_2Pd$, *M* = 635.74, *T* = 295 K, monoclinic, space group $P2_1/n$, *a* = 9.2571(2), *b* = 15.4091(3), *c* = 19.7280(4) Å, β = 90.248(1)°, *U* = 2814.0(1) Å^3, *Z* = 4, D_c = 1.501 g·cm^{-3}, μ = 9.865 cm^{-1}. Collected reflections = 18078 (θ ≤ 30°), unique reflections = 8135, R_{int} = 0.036, observed reflections = 6188 [$I \geq 2\sigma(I)$]. Final *R* (observed reflections) = 0.0347, R_w (all reflections) = 0.0845.

5a*: $C_{27}H_{26}Cl_2O_2P_2Pt{\cdot}C_4H_{10}O$, *M* = 784.53, *T* = 295 K, orthorhombic, space group $P2_12_12_1$, *a* = 8.0995(1), *b* = 18.0184(3), *c* = 21.9803(4) Å, *U* = 3207.8(1) Å^3, *Z* = 4, D_c = 1.624 g·cm^{-3}, μ = 46.702 cm^{-1}. Collected reflections = 16288 (θ ≤ 27°), unique reflections = 4850, R_{int} = 0.049, observed reflections = 4057 [$I \geq 2\sigma(I)$]. Flack parameter[22] = −0.02(4). Final *R* (observed reflections) = 0.0428, R_w (all reflections) = 0.1102.

7: $C_{48}H_{42}Cl_2O_4P_4Pt_2$, *M* = 1267.78, *T* = 150 K, triclinic, space group $P\bar{1}$, *a* = 11.9217(2), *b* = 13.3152(2), *c* = 16.1860(4) Å, α = 94.6411(7), β = 99.4177(7), γ = 115.3400(7)°, *U* = 2257.78(8) Å^3,

$Z = 2$, $D_c = 1.865\ g{\cdot}cm^{-3}$, $\mu = 64.935\ cm^{-1}$. Collected reflections = 28569 ($\theta \leq 28°$), unique reflections = 10307, R_{int} = 0.056, observed reflections = 8727 [$I \geq 2\sigma(I)$]. Both the hydrogens forming intramolecular hydrogen bonds O1−H···O2 and O4−H···O3 were refined isotropically. Final R (observed reflections) = 0.0362, R_w (all reflections) = 0.0928.

Di- and Trivalent Ytterbium Complexes Containing Linked Amino- and Amidocyclopentadienyl Ligands

Alexander T. Trifonov,[a] Thomas P. Spaniol,[a] and Jun Okuda*[a]

Keywords: Ytterbium / Chelates / Metallocenes / Cyclopentadienyl ligands

Reactions of the aminocyclopentadienes $(C_5Me_4H)SiMe_2NHR$ (R = Et, allyl, *n*Pr, *t*Bu) with $[YbI_2(THF)_2]$ in the presence of two equivalents of potassium 1,2-diphenylethenide in THF at room temperature gave the diamagnetic half-sandwich complexes $[Yb(\eta^5\text{-}C_5Me_4SiMe_2NHR)L_n(\mu\text{-}I)]_2$ (L = THF, *n* = 2, L = DME, *n* = 1). The *tert*-butylamido derivative $[Yb(\eta^5\text{-}C_5Me_4SiMe_2NHtBu)(THF)_2(\mu\text{-}I)]_2$ was characterized by X-ray structural analysis as a dinuclear complex containing a nonchelating aminocyclopentadienyl ligand. Deprotonation of the aminocyclopentadiene $(C_5H_4tBu)SiMe_2NHtBu$ with two equivalents of potassium 1,2-diphenylethenide in THF, followed by reaction with $[YbI_2(THF)_2]$ at 60 °C, gave the trivalent ytterbium ate complex $[K(DME)][Yb\{(\eta^5{:}\eta^1\text{-}C_5H_3tBu\text{-}3)SiMe_2NtBu\}_2]$. A single crystal X-ray diffraction study of this complex shows polymeric chains consisting of trivalent ytterbocene units with two chelating amidocyclopentadienyl ligands coordinated to potassium ions. Metalation of the aminoindene $(C_9H_7)SiMe_2NHtBu$ under the same conditions and treatment with $[YbI_2(THF)_2]$ in THF at ambient temperature resulted in the formation of the divalent ytterbocene complex $[Yb\{\eta^5\text{-}(1\text{-}C_9H_6)SiMe_2NHtBu\}_2(THF)_2]$. The reaction of ytterbium naphthalenide $[Yb(C_{10}H_8)(THF)_2]$ with one equivalent of $(C_9H_7)SiMe_2NHtBu$ afforded the bis(indenyl) compound which was isolated as its 2,2′-bipyridyl adduct $[Yb\{\eta^5\text{-}(1\text{-}C_9H_6)SiMe_2NHtBu\}_2(bipy)]$. It was shown by single-crystal structural analysis to exhibit a bent metallocene structure with noncoordinating amino side-chains. The reaction of $(C_5Me_4H)CH_2SiMe_2NHtBu$, which contains a longer CH_2SiMe_2 bridge, with $[Yb(C_{10}H_8)(THF)_2]$ gave the complex $[Li_{0.5}][Yb(\mu\text{-}\eta^5{:}\eta^1\text{-}C_5Me_4CH_2SiMe_2NtBu)(THF)_2(\mu\text{-}I)_{0.5}]$. Single crystal X-ray structure analysis revealed the presence of polymeric chains consisting of dinuclear iodo-bridged $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4CH_2SiMe_2NtBu)]$ units with a chelating linked amidocyclopentadienyl ligand, intermolecularly bridged by lithium ions. The lithium ions are bonded in an η^5-manner to both units, forming a lithocene structure. When $YbCl_3$ was reacted with $Li_2[(C_5H_3tBu\text{-}3)SiMe_2NCH_2CH_2X]$ (X = NMe_2, OMe), heterobimetallic complexes $Li[Yb\{(\eta^5{:}\eta^1\text{-}C_5H_3tBu\text{-}3)SiMe_2NCH_2CH_2X\}_2]$ with a helical metallocene structure were isolated. The single crystal structure analysis of one of the three possible diastereomers of $Li\{Yb[(\eta^5{:}\eta^1\text{-}C_5H_3tBu\text{-}3)SiMe_2NCH_2CH_2NMe_2]_2\}$, viz. the thermodynamically stable (*R*,*R*)/(*S*,*S*) epimer was performed. When $YbCl_3$ was reacted with one equivalent of $Li_2[(C_5H_3tBu\text{-}3)SiMe_2NCH_2CH_2NMe_2]$ and reduced "in situ" with one equivalent of sodium 1,2-diphenylethenide in THF, the ytterbium(II) metallocene complex $[Li(THF)]_2[Yb\{(\eta^5\text{-}C_5H_3tBu\text{-}3)\text{-}SiMe_2NH(CH_2CH_2NMe_2)\}_2(\mu\text{-}Cl)_2]$ was isolated, which exhibits a structure with the two amino functions coordinating to the lithium ions and the chloro ligands bridging both the lithium and ytterbium centers.

Introduction

In contrast to the organometallic chemistry of divalent samarium,[1] that of divalent ytterbium is less developed.[2] In the context of developing lanthanide complexes supported by a linked amidocyclopentadienyl ligand,[3] we have started to explore the synthetic access to complexes of divalent ytterbium. Ytterbium(II) is diamagnetic, thus amenable to NMR spectroscopy, and its large ionic radius (1.02 Å, coordination number 6[4]) should allow coordination of the $SiMe_2$-linked amidocyclopentadienyl ligand for the larger lanthanides.[5] The tendency of divalent ytterbium complexes to undergo facile ligand-exchange reactions in solution to form homoleptic derivatives[6] makes linked amidocyclopentadienyl ligands an attractive ligand system that provides access to half-sandwich-type ytterbium(II) derivatives.[2c] We describe here our attempts at coordinating a linked amidocyclopentadienyl ligand to a divalent ytterbium center. During the course of our work, Hou et al. have independently reported the synthesis of linked anilidocyclopentadienyl lanthanide(II) complexes $[Ln(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NPh)(THF)_n]$ (Ln = Sm, Yb, *n* = 0−3) and $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NPh)(THF)]_2$ by the amine elimination reaction of $[Ln\{N(SiMe_3)_2\}_2(THF)_2]$ and $(C_5Me_4H)SiMe_2NHPh$.[7]

Results and Discussion

In order to prepare complexes of divalent ytterbium containing a linked amidocyclopentadienyl ligand, the meta-

thesis of the dilithium derivatives $Li_2(C_5Me_4SiMe_2NtBu)$ and $Li_2[(C_5H_3tBu\text{-}3)SiMe_2NCH_2CH_2NMe_2]$ with $[YbI_2(THF)_2]$ in THF or toluene was first explored, but no tractable products could be isolated. Moreover, all attempts to prepare dipotassium derivatives of the ligand system,[8] for example by exchange reaction of the dilithium derivatives with two equivalents of KO*t*Bu in hexane or toluene, were also unsuccessful. The complete double metalation of the aminocyclopentadienes $(C_5Me_4H)SiMe_2NHR$ (R = Et, allyl, *n*Pr, *t*Bu) was achieved by reaction with two equivalents of potassium 1,2-diphenylethenide in THF at room temperature, as indicated by the disappearance of the characteristic color of the radical anion $[PhCHCHPh]^{\cdot -}$ upon addition of the aminocyclopentadiene. When these "in-situ" prepared dipotassium derivatives were reacted with $[YbI_2(THF)_2]$ in THF, the half-sandwich iodide complexes $[Yb(\eta^5\text{-}C_5Me_4SiMe_2NHR)L_n(\mu\text{-}I)]_2$ (**1**, R = *t*Bu, L = THF, *n* = 2; **2**, R = *n*Pr, L = THF, *n* = 2; **3,** R = Et, L = DME, *n* = 1; **4,** R = allyl, L = DME, *n* = 1) were obtained in good yields as yellow to orange crystals, after filtration and recrystallization from THF/hexane or DME.

The diamagnetic[9] complexes **1**–**4** are soluble in THF, DME, and pyridine, but insoluble in aliphatic and aromatic hydrocarbons. Bright-yellow crystals of **1** suitable for X-ray diffraction analysis were obtained by cooling a concentrated THF/hexane solution to 0 °C. An ORTEP diagram of the structure of **1** is shown in Figure 1. The crystal and structure refinement data are compiled in Table 1. The crystal structure determination revealed **1** to be a centrosymmetric iodo-bridged dimer with *trans*-disposed aminocyclopentadienyl ligands, similar to the structure adopted by its pentamethylcyclopentadienyl analogue $[Yb(\eta^5\text{-}C_5Me_5)(THF)_2(\mu\text{-}I)]_2$.[10] Each ytterbium center is coordinated to an η^5-cyclopentadienyl ring, two bridging iodides and two THF ligands. The pendant amino groups are not coordinated. The value of the Yb-Cp_{Cent} distance in **1** [2.412(6) Å]

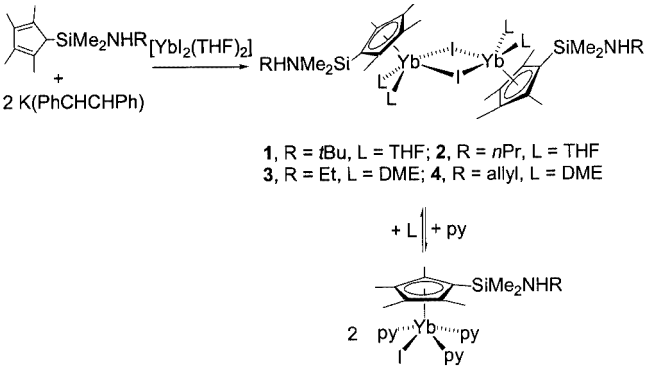
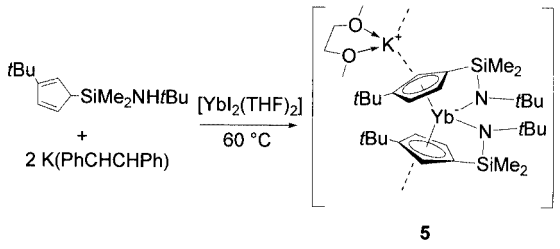
is very close to that previously observed for the related complex $[Yb(\eta^5\text{-}C_5Me_5)(THF)_2(\mu\text{-}I)]_2$,[10] but somewhat shorter than the comparable distance in the mononuclear complex $[Yb\{\eta^5{:}\eta^1\text{-}C_5H_3(CH_2CH_2NMe_2)_2\}I(THF)_2]$.[11] The Yb−O bond lengths fall into the range normally observed for derivatives of divalent ytterbium.[12] Significant differences in the Yb−I and Yb−I′ bond lengths have been found for **1** [3.0985(5) and 3.3008(5) Å respectively]. The shorter Yb−I distance is similar to the values previously observed for related dimeric Yb^{II} complexes,[10,13] but the Yb−I′ distance appears to be very long. The I−Yb−I′ bond angle in **1** is significantly smaller than that in the C_5Me_5 analogue.[10] The structures of (cyclopentadienyl)-iodo complexes of divalent ytterbium are known to be influenced by the nature of both the η^5-bonded carbocyclic ligands and the Lewis base: some of them are dimeric $\{[Yb(\eta^5\text{-}C_5Me_5)L_2(\mu\text{-}I)]_2$ (L = THF, DME)[10]$\}$, while others are monomeric in the solid state ($[Yb(\eta^5\text{-}C_9H_7)I(DME)]$,[6a] $[Yb\{\eta^5{:}\eta^1\text{-}C_5H_3(CH_2CH_2NMe_2)_2\}I(THF)_2]$[11]).

The ^1H and ^{13}C NMR spectra of **1**−**4** in [D$_5$]pyridine at room temperature indicate complete dissociation of the THF or DME molecules, as their signals appear at the positions of the free ligands. All signals of the aminocyclopentadienyl ligands give rise to two sets of signals. The nearly constant intensity ratio for all pairs of signals of a given complex varies with the amino substituent: for **1** the signals are of approximately equal intensities, while for the complexes **2**−**4** the ratios are in the range of 1:2.0−2.6. This finding can be explained by the partial dissociation of the dimeric complex $[Yb(\eta^5\text{-}C_5Me_4SiMe_2NHR)L_2(\mu\text{-}I)]_2$ in pyridine into mononuclear species $[Yb(\eta^5\text{-}C_5Me_4SiMe_2NHR)I(py)_3]$ (Scheme 1). This behavior is in agreement with the unsymmetric structure of the Yb_2I_2 core in the crystal structure of **1**. Absorption bands in the region of 3370−3390 cm^{-1} in the IR spectra of the complexes **1**−**4** indicate the presence of NH groups. Since *trans*-stilbene has been isolated from the reaction mixtures in almost quantitative yield, THF can regarded as the only source for the proton abstraction.



Scheme 1

Temperature was found to have an important influence on the above-mentioned complexation reaction, giving different types of products (Scheme 2). When the aminocyclopentadiene $(C_5H_4tBu)SiMe_2NHtBu$ was deprotonated with two equivalents of potassium 1,2-diphenylethenide in THF and then reacted with $[YbI_2(THF)_2]$ at 60 °C, an ate complex of trivalent ytterbium $[K(DME)][Yb\{(\eta^5{:}\eta^1\text{-}C_5H_3tBu\text{-}3)SiMe_2NtBu\}_2]$ (**5**) was obtained as orange, paramagnetic crystals after recrystallization from DME. The absence of any absorption bands for the NH group in the IR spectrum of **5** indicates coordination of the amido group to the ytterbium atom.



Scheme 2

Orange crystals of **5** suitable for X-ray diffraction analysis were obtained by slow diffusion of hexane into the DME solution at room temperature. An ORTEP diagram of the structure is shown in Figure 2. The compound crystallizes in a polymeric chain structure; crystal structure and refinement data are compiled in Table 1. X-ray diffraction study of **5** shows a polymeric chain consisting of anionic ytterbium(III) metallocene units bridged by $[K(DME)]^+$ ions. The Yb^{III} center is coordinated to two chelating amidocyclopentadienyl ligands to form an anionic metallocene unit with both pendant amido groups coordinated to the ytterbium. The thermodynamically favored (*R*,*R*)/(*S*,*S*) diastereomer is observed. The Yb−C bond lengths in **5** are remarkably scattered [2.571(7) for Yb−C(1) to 2.963(8) Å for Yb−C(3)]. The bond lengths Yb−C(1), Yb−C(2),

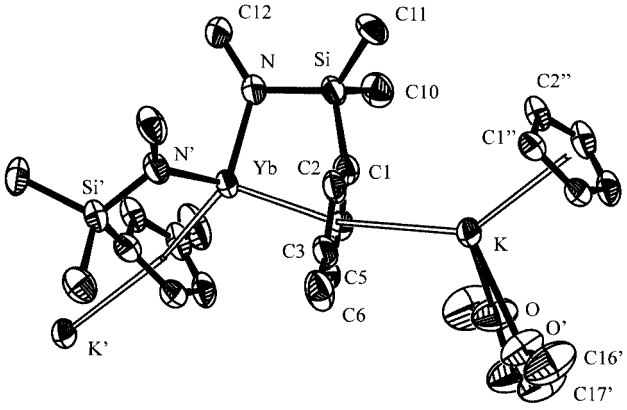


Figure 2. ORTEP drawing and numbering scheme of the molecular structure of **5** with thermal ellipsoids drawn at the 30% probability level; hydrogen atoms as well as the methyl carbon atoms of the *t*Bu groups are omitted for the sake of clarity; selected bond lengths (Å) and bond angles (°): Yb−N 2.237(6), Yb−N′ 2.237(6), Yb−C1 2.571(7), Yb−C5 2.673(7), Yb−C2 2.689(8), Yb−C4 2.908(7), Yb−C3 2.963(8), K−O 2.766(6), K−O′ 2.766(6), K−C1 3.083(7), K−C2 3.062(8), K−C3 3.148(7), K−C5 3.183(7), K−C4 3.225(8), C1−C5 1.39(1), C1−C2 1.42(1), C2−C3 1.40(1), C3−C4 1.38(1), C4−C5 1.40(1); N−Yb−N′ 106.6(3), Cp_{cent1}−Yb−Cp_{cent2} 114.5(3)

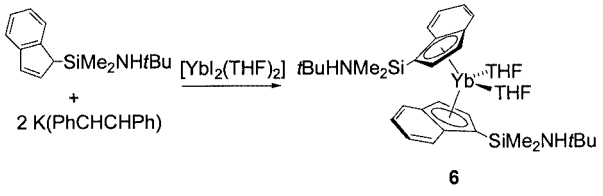
Yb−C(5) are slightly longer than those in the Yb^{III} complex $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N\textit{t}Bu)(THF)(\mu\text{-}H)]_2$ [3c] and are similar to the values of Yb−C bonds in other bis(cyclopentadienyl)ytterbium(III) complexes.[14] The Yb−C(3) and Yb−C(4) distances are extremely long indicating a significant ring slippage toward η^3-bonding. Such an approach to η^3-coordination is well documented for fluorenyl complexes of the lanthanides.[15] This bonding situation can be explained by the strain resulting from the repulsion of the bulky *t*Bu groups in the cyclopentadienyl ring and those of the amido group. The $Cp_{Cent1}-Yb-Cp_{Cent2}$ bond angle in **5** [114(1)°] is smaller than the values previously described for bis(cyclopentadienyl) complexes of trivalent ytterbium, which normally fall into the range 127−143°.[14,16] The Yb−N distance in **5** is very close to that previously reported for $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2N\textit{t}Bu)(THF)(\mu\text{-}H)]_2$ [3c] and is similar to values observed for the Yb^{II} complexes $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NPh)(THF)]_n$ and $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NPh)(THF)]_2$,[7a] accounting for the difference of ionic radii of Yb^{II} and Yb^{III}.[4] The potassium ion is coordinated to one molecule of DME. The potassium-ring distances are in the range of 3.083(7)−3.225(8) Å and are slightly longer than those reported for $[K(py)_2](C_5Me_5)$[17a] and $K[C_5H_4(SiMe_3)]$.[17b] This finding may indicate a more pronounced ionic interaction of the potassium ions with the metallocene ate units. The oxidation of Yb^{II} to Yb^{III} at elevated temperature cannot be satisfactorily explained at this time. We believe, however, that the stability of the bis(chelate) is higher for the monoanionic Yb^{III} species than for the dianionic Yb^{II} complex.

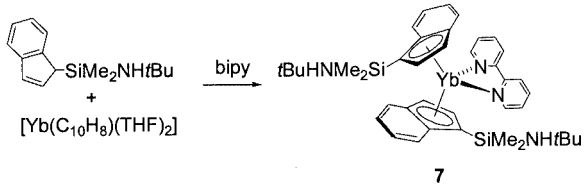
Metalation of the aminoindene $(C_9H_7)SiMe_2N\textit{H}tBu$ under the same conditions and treatment with $[YbI_2(THF)_2]$ in THF at ambient temperature resulted in the Yb^{II} compound $[Yb\{\eta^5\text{-}(1\text{-}C_9H_6)SiMe_2N\textit{H}tBu\}_2(THF)_2]$ (**6**; Scheme 3). Complex **6** was isolated as highly sensitive ruby-red crystals, soluble in THF, DME and aromatic hydrocarbons but insoluble in hexane.



Scheme 3

In the ^1H NMR spectrum of **6** in $[D_6]$benzene the methyl protons of the $SiMe_2$ groups appear as two singlets. The signals in each pair are of equal intensities and the ratio of intensities of the couples is 3:2. The *t*Bu protons are recorded as two singlets in the same ratio as the sets of the $SiMe_2$ protons. All indenyl protons are inequivalent due to the planar chirality, giving rise to six signals. The fact that signals corresponding to the THF molecules are somewhat broadened and high-field shifted (δ = 1.25 and 3.05 ppm for β- and α-CH_2) confirms their coordination to the ytterbium atom in benzene solution. The ^1H and ^{13}C NMR spectra of **6** apparently reflect the presence of rotational isomers in solution, as has previously been reported for the indenyl-derived ytterbocenes $[Yb\{\eta^5\text{-}(C_9H_6\text{-}1\text{-}SiHR_2\text{-}2\text{-}R')\}_2(L)_2]$ (R = Me, Ph, R′ = donor ligand).[18]

Ytterbium naphthalenide $[Yb(C_{10}H_8)(THF)_2]$[19a] has been shown to be a convenient precursor for the synthesis of various types of both di- and trivalent organoytterbium compounds.[19] The reactions of $[Yb(C_{10}H_8)(THF)_2]$ with aminocyclopentadienes $(C_5Me_4H)SiMe_2NHR$ (R = Me, Et, allyl, *n*Pr, *i*Pr, *t*Bu) and $(C_5H_5\textit{t}Bu)SiMe_2N\textit{H}tBu$ in THF or DME at room temperature result in the isolation of yellow-orange powders (Scheme 4). These compounds are diamagnetic, corresponding to the Yb^{II} oxidation state; ^1H, ^{13}C NMR and IR spectra show the presence of the aminocyclopentadiene ligands in deprotonated form. However microanalysis failed to give reproducible data and all attempts to obtain samples suitable for X-ray crystal structure analysis failed. Reaction of one equivalent of $(C_9H_7)SiMe_2N\textit{H}tBu$ with $[Yb(C_{10}H_8)(THF)_2]$ resulted in the ytterbocene $[Yb\{\eta^5\text{-}(1\text{-}C_9H_6)SiMe_2N\textit{H}tBu\}_2(THF)_2]$ which was isolated in crystalline form as a complex with 2,2′-bipyridyl $[Yb\{\eta^5\text{-}(1\text{-}C_9H_6)SiMe_2N\textit{H}tBu\}_2(bipy)]$ (**7**). Complex **7** is soluble in THF, DME and pyridine, sparingly soluble in toluene and insoluble in hexane.



Scheme 4

Black crystals suitable for X-ray diffraction analysis were obtained by slow evaporation of a THF/toluene/hexane solution at room temperature. An ORTEP diagram of the structure of **7** is shown in Figure 3. The crystal and structure refinement data are compiled in Table 1. Single-crystal structural analysis shows that complex **7** adopts a bent metallocene structure with noncoordinating amino side chains and one coordinated 2,2′-bipyridyl ligand. The average value of the Yb−C bond lengths is 2.72 Å. The $Yb-Ind_{Cent}$ bond lengths are 2.440(8) and 2.449(11) Å, and are similar to values for other bis(indenyl) complexes of divalent ytterbium.[20] The bond angle $Ind_{cent}-Yb-Ind_{cent}$ in **7** is slightly larger [132(1)°] than those in complexes $[Yb(\eta^5\text{-}C_9H_7)_2(THF)_2]$ [128.6[20a] and 129.31(5)[20b]] probably due to a lower steric strain resulting from the coordination of a planar 2,2′-bipyridyl ligand instead of two THF molecules. The Yb−N distances [2.454(3) and 2.476(4) Å] are close to those reported for the complex $[YbI(bipy)_2(DME)_2]$.[21]

In the ^1H NMR spectra of **7** in $[D_8]$THF the protons of the $SiMe_2$ groups give rise to four singlets of equal intensity, the *t*Bu protons are recorded as two singlets (1:1 ratio) and the indenyl protons appear as a complex set of six multiplets of different intensities (12 protons together). The bipyridyl protons are observed as a set of eight significantly broadened signals of different intensities.[22] This is probably due to the exchange of bipyridyl by THF within the

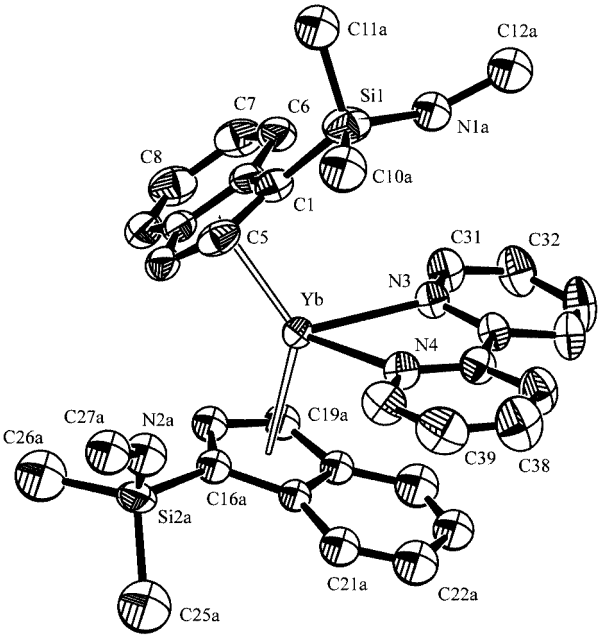


Figure 3. ORTEP drawing and numbering scheme of the molecular structure of **7** with thermal ellipsoids drawn at the 30% probability level; hydrogen atoms as well as the methyl carbon atoms of the *t*Bu groups are omitted for the sake of clarity; for the distorted groups, only one of the two split positions are shown; selected bond lengths (Å) and bond angles (°): Yb-Ind_{cent} 2.440(8), 2.45(1), Yb−C1 2.760(4), Yb−C2 2.755(4), Y−C3 2.722(4), Y−C4 2.680(4), Y−C5 2.695(4), Y−C16A 2.71(1), Y−C17A 2.77(1), Y−C18A 2.79(1), Y−C19A 2.69(1), Y−C20A 2.69(1), Yb−N3 2.454(3), Yb−N4 2.476(4); Ind_{cent}−Yb−Ind_{cent} 132.1(3), N3−Yb−N4 66.1(1)

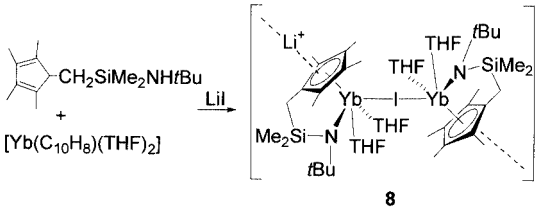
coordination sphere of ytterbium. The ^1H and ^{13}C NMR spectra of **7** display nonequivalence of the indenyl ligands as a consequence of either chirality or the presence of two rotational isomers in the [D_8]THF solution.

The reaction of $(C_5Me_4H)CH_2SiMe_2NHtBu$[23] with $[Yb(C_{10}H_8)(THF)_2]$ was carried out in THF. Cooling of the THF/hexane mixture at 0 °C produced yellow crystals of the composition $[Li_{0.5}][Yb(\mu\text{-}\eta^5{:}\eta^1\text{-}C_5Me_4CH_2SiMe_2N tBu)(THF)_2(\mu\text{-}I)_{0.5}]$ (**8**; Scheme 5). $[Yb(C_{10}H_8)(THF)_2]$ has been shown to contain an admixture of LiI,[19] and the reaction in the presence of LiI gave complex **8**. It is soluble in THF and DME and insoluble in aromatic and aliphatic hydrocarbons. In the ^1H NMR spectrum of **8** in [D_5]pyridine the protons of the $SiMe_2$, *t*Bu, and CH_2 groups appear as singlets, and the methyl groups of the C_5Me_4 ring give rise to two singlets. The chemical shifts of the signals of the α- and β-methylene protons of THF



Scheme 5

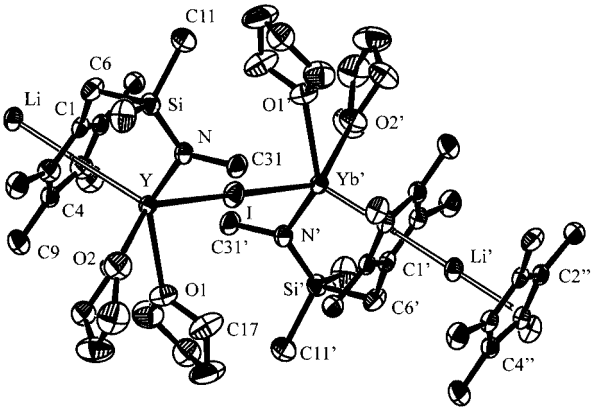


Figure 4. ORTEP drawing and numbering scheme of the molecular structure of **8** with thermal ellipsoids drawn at the 30% probability level; hydrogen atoms as well as the methyl carbon atoms of the *t*Bu groups are omitted for the sake of clarity; selected bond lengths (Å) and bond angles (°): Yb−Cp_{cent} 2.45(3), Yb−C1 2.697(3), Yb−C2 2.713(3), Yb−C3 2.770(3), Yb−C4 2.775(3), Yb−C5 2.740(3), Yb−N 2.356(3), Yb−O1 2.559(3), Yb−O2 2.545(3), Yb−I 3.295(1), Li−C1 2.292(3), Li−C2 2.275(3), Li−C3 2.255(3), Li−C4 2.251(4), Li−C5 2.265(3); Cp_{cent}−Yb−I 106.1(1), Cp_{cent}−Yb−N 104.4(1), Cp_{cent}−Yb−O1 118.8(1), Cp_{cent}−Yb−O2 104.8(1)

molecules and their well-resolved structure indicate THF dissociation in pyridine solution.

Yellow crystals suitable for X-ray diffraction analysis were obtained by recrystallization of **8** from a THF/hexane mixture at 0 °C. An ORTEP diagram of the structure of **8** is shown in Figure 4. The compound crystallizes in a polymeric chain structure; crystal and structure refinement data are compiled in Table 2. Complex **8** exhibits the unusual

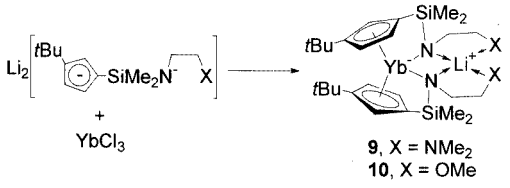
structure of an "inverted" sandwich complex. The Yb^{II} ion is coordinated to the linked amidocyclopentadienyl group, the bridging iodo, and two THF ligands, giving a distorted square-pyramidal coordination geometry. The iodine atom bridges two ytterbium atoms of the neighboring molecules, while the lithium ions connect the cyclopentadienyl ligands, forming zigzag chains. Both the ytterbium and lithium ions are symmetrically η^5-bonded to the tetramethylcyclopentadienyl ligand. The average Yb−C bond length in **9** is slightly longer than those in complexes $[Yb(\eta^5\text{-}C_5Me_5)I(L)_n]_2$ [10] and $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NPh)(THF)]_2$.[7a] The Li−C contacts are similar to those found in lithium complexes of substituted η^5-cyclopentadienyls.[24] The Yb−N bond length in **8** [2.356(3) Å] is close to that in $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2NPh)(THF)]_2$.[7a] The Yb−I bond length [3.295(1) Å] is slightly longer than the value reported for the monomeric complex $[Yb\{\eta^5{:}\eta^1{:}\eta^1\text{-}C_5H_3(CH_2CH_2NMe_2)_2\}I(THF)_2]$[11] and significantly longer than that in the dimeric complexes $[Yb(\eta^5\text{-}C_5Me_5)I(L)_n]_2$ [10] and $[Yb\{C(SiMe_3)_3\}I(OEt_2)]_2$.[13]

Recently we have shown that reactions of yttrium and lutetium chlorides with dilithium derivatives of tridentate amidocyclopentadienyl ligands result in the formation of chiral lanthanocene complexes with a unique heterobimetallic core.[25] Ytterbium trichloride reacted with $Li_2[(C_5H_3t\text{Bu-}3)SiMe_2NCH_2CH_2X]$ (X = NMe_2, OMe) in THF or DME regardless of the reagent ratio, solvent, and the isolation method, to give heterobimetallic complexes $Li[Yb\{\eta^5{:}\eta^1\text{-}C_5H_3t\text{Bu-}3)SiMe_2NCH_2CH_2X\}_2]$ (X = NMe_2, **9**; OMe, **10**) with a helical metallocene structure (Scheme 6). Complexes **9** and **10** are soluble in THF, DME and toluene and have been characterized by IR spectroscopy as well as microanalysis.



Scheme 6

Yellow crystals of **9** suitable for X-ray diffraction analysis were obtained by recrystallization from toluene at −30 °C. An ORTEP diagram of the structure of **9** is shown in Figure 5. The crystal and structure refinement data are compiled in Table 2. The single crystal structure analysis of one of the three possible diastereomers of **9**, viz. the thermodynamically stable (*R*,*R*) or (*S*,*S*) epimer, was performed and confirmed the bent metallocene structure with C_2-symmetry, similar to that described for a related yttrium complex.[25a] The *t*Bu substituents on the two cyclopentadienyl ligands are oriented *trans* to each other. The ytterbium atom is coordinated by two linked amidocyclopentadienyl ligands, forming a distorted tetrahedral coordination environment. The average value of Yb−C distances is similar to those in bis(cyclopentadienyl) derivatives of trivalent ytterbium,[16] and slightly longer than that in complex

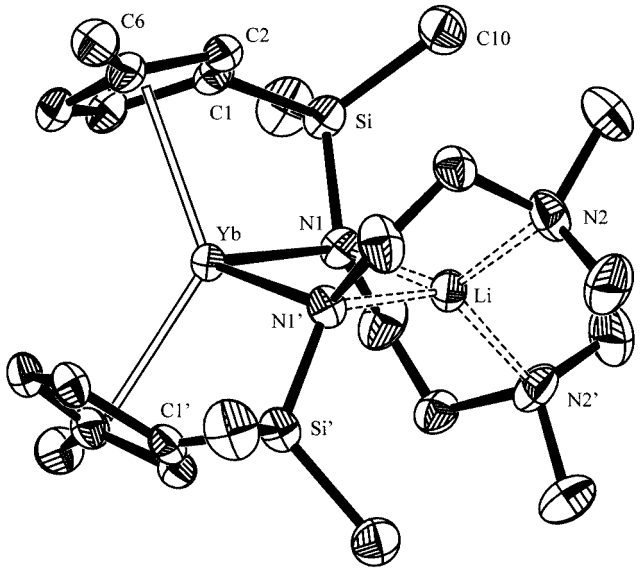


Figure 5. ORTEP drawing and numbering scheme of the molecular structure of **9** with thermal ellipsoids drawn at the 30% probability level; hydrogen atoms as well as the methyl carbon atoms of the *t*Bu groups are omitted for the sake of clarity; selected bond lengths (Å) and bond angles (°): Yb−N1 2.279(3), Yb−C1 2.535(4), Yb−C2 2.672(4), Yb−C3 2.818(4), Yb−C4 2.713(4), Yb−C5 2.548(4), Li−N1 2.193(7), Li−N2 2.124(7); Cp_{cent}−Yb−Cp_{cent} 127.8(1), N1−Yb−N1′ 92.1(2), Li−N1−Yb 85.6(2), N2−Li−N2′ 111.6(5), N1−Li−N2 89.3(2)

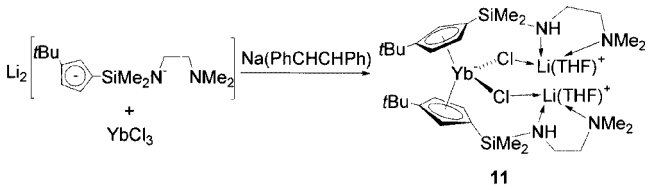
$[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2Nt\text{Bu})(THF)(\mu\text{-}H)]_2$.[3c] The scattering of Yb−C bond lengths [2.534(4)−2.818(4) Å] is somewhat higher than those in complexes (*R*,*R*)-, (*R*,*S*)-$Li[Y\{(\eta^5{:}\eta^1\text{-}C_5H_3t\text{Bu-}3)SiMe_2NCH_2CH_2NMe_2\}_2]$[25a] and $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2Nt\text{Bu})(THF)(\mu\text{-}H)]_2$.[3c] The Yb−C bond lengths distal to the silicon bridge [C(3), C(4)] are longer than the distances for the proximal carbon atoms [C(1), C(2), C(5)]. The Yb−N bond length [2.279(3) Å] is substantially longer than that in $[Yb(\eta^5{:}\eta^1\text{-}C_5Me_4SiMe_2Nt\text{Bu})(THF)(\mu\text{-}H)]_2$,[3c] while the Li−N bond lengths are similar to the corresponding values in related yttrium complexes.[25a] The Cp_{cent}−Yb−Cp_{cent} bond angle (127.8(1)°] in **9** is slightly less than the Cp_{cent}−Y−Cp_{cent} bond angle in (*R*,*R*)-$Li[Y(\eta^5{:}\eta^1\text{-}C_5H_3t\text{Bu-}3)SiMe_2NCH_2CH_2NMe_2]_2$.[25]

Reduction of **9** and **10** with potassium metal or sodium 1,2-diphenylethenide gave a mixture of inseparable products, while reduction of $YbCl_3$ and $Li_2[(C_5H_3t\text{Bu-}3)SiMe_2NCH_2CH_2NMe_2]$ (1:1 molar ratio) prepared "in situ" with one equivalent of sodium 1,2-diphenylethenide in THF resulted in an ate complex of divalent ytterbium $[Li(THF)]_2[Yb\{(\eta^5\text{-}C_5H_3t\text{Bu-}3)SiMe_2N(H)CH_2CH_2NMe_2\}_2(\mu\text{-}Cl)_2]$ (**11**), isolated as bright-red crystals in 46% yield. (Scheme 7).

Complex **11** is soluble in THF and pyridine, sparingly soluble in toluene and in hexane. According to NMR spectroscopy **11** was found to be diamagnetic, indicating the divalency of the ytterbium atom. The ^1H NMR and IR spectroscopic data of **11** suggest the presence of protonated amino groups. This indicates that reduction of the Yb^{III} species by sodium 1,2-diphenylethenide occurs together



11

Scheme 7

with protonation of the amido groups. THF molecules seem the most likely source for proton abstraction because *trans*-stilbene was isolated from the reaction mixture in nearly quantitative yield. In the ^{1}H NMR spectrum of **11** in [D_8]toluene at 20 °C, the methyl protons on the silicon atom are observed as two singlets, while the protons of both methylene groups of the CH_2CH_2 bridge appear as broad signals. The protons of the *t*Bu and dimethylamino groups also give rise to two singlets. The significantly broadened signals of both α- and β-methylene protons of THF are shifted to higher field than those of free THF. At −60 °C the ^{1}H NMR spectrum shows four singlets for the protons of the $SiMe_2$ groups. The signal of the methylene group $SiNC\mathit{H}_2$ splits into two singlets, and the methylene protons of the $C\mathit{H}_2NMe_2$ group appear as four broad multiplets. Despite the poor crystal quality, a preliminary X-ray crystal structure determination confirmed the connectivity in **11**.[26] Furthermore, the divalent oxidation state of the ytterbium atom could be inferred from the Yb−C distances, ranging from 2.70(2) Å to 2.87(2) Å [Yb−C(Cp)$_{av.}$= 2.78 Å]. In the trivalent ytterbium metallocene **9**, the corresponding values range from 2.535(4) Å to 2.814(4) [Yb−C(Cp)$_{av.}$= 2.657 Å]. The Yb−Cl distances in **11** were found to be 2.753(5) Å and 2.774(6) Å. The unusual bent metallocene structure includes a pseudo-tetrahedrally coordinated Yb^{II} center, bonded to two η^5-*tert*-butylcyclopentadienyl rings and two chloro ligands. Each of the amino functions coordinates a [Li(THF)]$^+$ moiety which is linked to the ytterbium center via a bridging chloride ligand.

Conclusion

The attempts to prepare divalent ytterbium complexes with an $SiMe_2$-linked amidocyclopentadienyl ligand by metathesis of their dipotassium salts with [$YbI_2(THF)_2$] in THF or DME resulted in the formation of dimeric iodo (**1**−**4**) or metallocene-type (**6**) complexes with noncoordinating amino groups. Forcing conditions allow coordination of the amino functions, but the resulting Yb^{III} metallocene ate complexes **5** contain oxidized ytterbium centers. Treatment of the naphthalene ytterbium complex with amino-substituted indene or reduction of the Yb^{III} ate complexes gave the metallocene complexes **7** and **11**. The ligand $(C_5Me_4CH_2SiMe_2N\mathit{t}Bu)^{2-}$ allowed the isolation of the Yb^{II} ate complex **8** which contains a chelating linked amidocyclopentadienyl ligand. Our results are in contrast to the smooth complexation of the anilido ligand $(C_5Me_4SiMe_2NPh)^{2-}$ at divalent ytterbium centers as reported by Hou et al.[7] The coordination of the amidocyclopentadienyl ligands at the large divalent ytterbium center apparently requires electron-withdrawing amido substituents, whereas the sterically bulky *tert*-butyl group appears to severely hinder the chelation reaction.

Experimental Section

General: All experiments were performed under argon using standard Schlenk or glove-box techniques. Solvents were purified, dried, and condensed in vacuo prior to use. ^{1}H, ^{13}C, and ^{29}Si NMR: Bruker DRX 400; all spectra were obtained at 25 °C. Elemental analyses: Microanalytical laboratory of this department.

[Yb(η^5-$C_5Me_4SiMe_2NH\mathit{t}Bu$)(THF)$_2$(μ-I)]$_2$ (1): A solution of $(C_5Me_4H)SiMe_2NH\mathit{t}Bu$ (0.298 g, 1.19 mmol) in THF (5 mL) was added at room temperature to a solution of potassium 1,2-diphenylethenide, prepared in situ from *trans*-stilbene (0.430 g, 2.38 mmol) and potassium (0.093 g, 2.38 mmol) in THF (35 mL). The reaction mixture was stirred for 3 h, then slowly treated with [$YbI_2(THF)_2$] (0.679 g, 1.19 mmol) at room temperature with vigorous stirring. The reaction mixture was left stirring overnight. The brownish-yellow reaction mixture was filtered, THF was evaporated in vacuo, and the dark-yellow residue was heated at 60 °C in vacuo for 3 h to sublime off stilbene. The solid residue was recrystallized from the THF/hexane mixture at 0 °C. The mother liquor was decanted from the bright-yellow crystals which were dried in vacuo to afford 0.620 g (76%) of **1**. ^{1}H NMR ([D_5]pyridine): δ = 0.34, 0.62 (s, 2 × 6 H, $SiCH_3$), 0.71, 1.15 (s, 2 × 1 H, NH), 1.17, 1.32 [s, 2 × 9 H, $C(CH_3)_3$], 1.61 (m, 2 × 8 H, β-CH_2, THF), 1.92, 2.07, 2.12, 2.21 [s, 4 × 6 H, $C_5(CH_3)_4$], 3.65 (m, 2 × 8 H, α-CH_2, THF) ppm. ^{13}C{^{1}H} NMR ([D_5]pyridine): δ = 7.3, 7.7 (Si$\mathit{C}H_3$), 12.4, 12.8 (ring $\mathit{C}H_3$), 15.9, 16.3 (ring $\mathit{C}H_3$), 26.8 (β-CH_2, THF), 34.8, 35.1 [$C(\mathit{C}H_3)_3$], 51.0 [$\mathit{C}(CH_3)_3$, 68.9 (α-CH_2, THF), 106.2 (ring C attached to $SiMe_2$), 122.3, 126.1 (ring C) ppm. IR (KBr): $\tilde{\nu}$ = 3382 w, 2964 s, 2921 s, 2858 s, 1622 m, 1592 m, 1443 m, 1379 m, 1256 s, 1216 m, 1043 s, 984 m, 832 s, 800 s, 644 m cm^{-1}. $C_{46}H_{88}I_2N_2O_4Si_2Yb_2$ (1387.2): calcd. C 39.82, H 6.34, N 2.02; found C 39.39, H 6.47, N 2.30.

[Yb(η^5-$C_5Me_4SiMe_2NHCH_2CH_2CH_3$)(THF)$_2$(μ-I)]$_2$ (2): A solution of $(C_5Me_4H)SiMe_2NHCH_2CH_2CH_3$ (0.322 g, 1.36 mmol) in THF (5 mL) was added at room temperature to a solution of potassium 1,2-diphenylethenide, prepared in situ from *trans*-stilbene (0.489 g, 2.72 mmol) and potassium (0.106 g, 2.72 mmol) in THF (35 mL). The reaction mixture was stirred for 3 h, then slowly treated with [$YbI_2(THF)_2$] (0.780 g, 1.36 mmol) at room temperature with vigorous stirring. The reaction mixture was left stirring overnight. The brownish-yellow reaction mixture was filtered, THF was evaporated in vacuo, and the dark-yellow residue was heated at 60 °C in vacuo for 3 h to sublime off stilbene. The solid residue was recrystallized from DME at 0 °C. The mother liquor was decanted from the yellow crystals which were dried in vacuo to afford 0.670 g (79%) of **2**. ^{1}H NMR ([D_5]pyridine): δ = 0.41, 0.52 (s, 2 × 6 H, $SiCH_3$), 0.78, 1.17 (m, 2 × 1 H, NH), 0.95 (m, 2 × 3 H, $NCH_2CH_2C\mathit{H}_3$), 1.50 (m, 2 × 2 H, $NCH_2C\mathit{H}_2CH_3$), 1.62 (s, 2 × 8 H, β-CH_2, THF), 2.03, 2.06, 2.18, 2.24 (s, 4 × 6 H, $C_5(CH_3)_4$], 2.88 (m, 2 × 2 H, $NC\mathit{H}_2$), 3.65 (s, 2 × 8 H, α-CH_2, THF) ppm. ^{13}C{^{1}H} NMR ([D_5]pyridine): δ = 3.4, 3.9 (Si$\mathit{C}H_3$), 12.4, 12.7 (ring $\mathit{C}H_3$), 15.2, 15.6 (ring $\mathit{C}H_3$), 26.5 (β-CH_2, THF), 28.9 ($CH_2CH_2\mathit{C}H_3$), 45.4 ($CH_2\mathit{C}H_2CH_3$), 46.4 ($\mathit{C}H_2CH_2CH_3$), 68.5 (α-CH_2, THF), 106.4 (ring C attached to $SiMe_2$), 118.1, 121.0 (ring

C) ppm. IR (KBr): $\tilde{\nu}$ = 3378 w, 2969 s, 2918 s, 2860 s, 1642 m, 1582 m, 1449 m, 1379 m, 1250 s, 1116 m, 1043 s, 984 m, 832 s, 810 s, 646m cm^{-1}. $C_{44}H_{84}I_2N_2O_4Si_2Yb_2$ (1360.6): calcd. C 38.84, H 6.17, N 2.05; found C 38.99, H 6.11, N 2.49.

[Yb(η^5-$C_5Me_4SiMe_2NHCH_2CH_3$)(DME)(μ-I)]$_2$ (3): A solution of $(C_5Me_4H)SiMe_2NHCH_2CH_3$ (0.412 g, 1.84 mmol) in THF (5 mL) was added at room temperature to a solution of potassium 1,2-diphenylethenide, prepared in situ from *trans*-stilbene (0.665 g, 3.69 mmol) and potassium (0.144 g, 3.69 mmol) in THF (30 mL). The reaction mixture was stirred for 3 h, then slowly treated with $[YbI_2(THF)_2]$ (1.050 g, 1.83 mmol) at room temperature with vigorous stirring. The reaction mixture was left stirring overnight. The resulting dark-orange reaction mixture was filtered, THF was evaporated in vacuo, and the brown residue was heated at 60 °C in vacuo for 2 h to sublime off stilbene. The solid residue was recrystallized from DME/hexane mixture at 0 °C. The mother liquor was decanted from the orange crystals which were dried in vacuo to afford 0.640 g (59%) of **3**. ^{1}H NMR ([D$_5$]pyridine): δ = 0.40, 0.52 (s, 2 × 6 H, $SiCH_3$), 0.92, 1.07 (m, 2 × 1 H, NH), 1.19 (m, 2 × 3 H, NCH_2CH_3), 2.01, 2.03, 2.08, 2.16 [s, 4 × 6 H, $C_5(CH_3)_4$], 2.94 (m, 2 × 2 H, NCH_2CH_3) 3.26 (s, 2 × 6 H, OCH_3, DME), 3.49 (s, 2 × 4 H, OCH_2CH_2O, DME) ppm. ^{13}C{^{1}H} NMR ([D$_5$]pyridine): δ = 4.5, 4.9 ($SiCH_3$), 11.2, 11.7 (ring CH_3), 14.9, 15.3 (ring CH_3), 35.0, 35.6 (NCH_2CH_3), 48.1, 48.9 (NCH_2), 59.8 (OCH_3, DME), 73.3 (OCH_2, DME), 107.3 (ring C attached to $SiMe_2$), 124.2, 128.7 (ring C) ppm. IR (KBr): $\tilde{\nu}$ = 3383 w, 2963 s, 2916 s, 2860 s, 1449 m, 1385 m, 1319 m, 1249 s, 1104 s, 1058 s, 1020 s, 981 m, 917 m, 825 s, 789 s, 698 m, 636w cm^{-1}. $C_{34}H_{68}I_2N_2O_4Si_2Yb_2$ (1224.5): calcd. C 33.34, H 5.55, N 2.28; found C 33.71, H 5.21, N 2.27.

[Yb(η^5-$C_5Me_4SiMe_2NHCH_2CH{=}CH_2$)(DME)(μ-I)]$_2$ (4): A solution of $(C_5Me_4H)SiMe_2NHCH_2CH{=}CH_2$ (0.300 g, 1.27 mmol) in THF (5 mL) was added at room temperature to a solution of potassium 1,2-diphenylethenide, prepared in situ from *trans*-stilbene (0.457 g, 2.53 mmol) and potassium (0.099 g, 2.54 mmol) in THF (30 mL). The reaction mixture was stirred for 3 h, then slowly treated with $[YbI_2(THF)_2]$ (0.720 g, 1.26 mmol) at room temperature with vigorous stirring. The reaction mixture was left stirring overnight. The brownish-red reaction mixture was filtered, THF was evaporated in vacuo, and the brown residue was heated at 60 °C in vacuo for 2 h to sublime off stilbene. The solid residue was recrystallized from DME/hexane mixture at 0 °C. The mother liquor was decanted from the orange crystals which were dried in vacuo to afford 0.500 g (66%) of **4**. ^{1}H NMR ([D$_5$]pyridine): δ = 0.39, 0.54 (s, 2 × 6 H, $SiCH_3$), 1.10, 1.60 (br. s, 2 × 2 H, NH), 2.01, 2.05, 2.23, 2.32 [s, 4 × 6 H, $C_5(CH_3)_4$], 3.31 (s, 2 × 6 H, OCH_3, DME), 3.49 (s, 2 × 4 H, OCH_2CH_2O, DME), 3.54, 3.56 (m, 2 × 2 H, NCH_2CH), 5.08, 5.29 (m, 2 × 2 H, $CH{=}CH_2$), 6.04−6.11 (m, 2 × 1 H, $CH_2CH{=}CH_2$) ppm. ^{13}C{^{1}H} NMR ([D$_5$]pyridine): δ = 3.4, 3.9 ($SiCH_3$), 12.3, 12.6 (ring CH_3), 15.2, 15.4 (ring CH_3), 46.2, 46.9 (NCH_2), 59.3 (OCH_3, DME), 72.8 (OCH_2, DME), 106.4, 110.2 (ring C attached to $SiMe_2$), 113.5, 114.7 ($CH{=}CH_2$), 121.3, 123.7 (ring C), 141.8, 142.9 ($CH{=}CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3384 w, 2984 s, 2914 s, 2857 s, 1634 m, 1574 m, 1450 m, 1252 s, 1045 s, 986 m, 950 m, 832 s, 798 s, 695 m, 645m cm^{-1}. $C_{36}H_{68}I_2N_2O_2Si_2Yb_2$ (1248.5): calcd. C 34.63, H 5.48, N 2.30; found C 34.56, H 5.67, N 2.38.

[K(DME)][Yb{(η^5:η^1-C_5H_3*t*Bu-3)$SiMe_2N$*t*Bu}$_2$] (5): A solution of $(C_5H_4$*t*Bu)$SiMe_2NH$*t*Bu (0.700 g, 2.78 mmol) in THF (5 mL) was added to a solution of potassium 1,2-diphenylethenide, prepared in situ from *trans*-stilbene (1.000 g, 5.55 mmol) and potassium (0.216 g, 5.55 mmol) in THF (30 mL) at room temperature and stirred for 3 h. $[YbI_2(THF)_2]$ (1.580 g, 2.78 mmol) was slowly added at room temperature with vigorous stirring. The reaction mixture was stirred for 3 h at room temperature and at 60 °C for 6 h. The dark orange solution was filtered, THF was evaporated in vacuo, and the brown residue was heated to 60 °C in vacuo for 2 h to remove stilbene (by sublimation). The residue was redissolved in 20 mL of DME and recrystallized by slow condensation of hexane into the DME solution at room temperature. The mother liquor was decanted from the orange crystals which were washed with hexane and dried in vacuo to give 0.850 g (77%) of **5**. IR (KBr): $\tilde{\nu}$ = 2970 s, 2902 s, 2869 s, 1460 m, 1358 m, 1257 s, 1158 s, 1097 s, 1010 s, 838 s, 723 m, 525 m, 433m cm^{-1}. $C_{34}H_{64}KN_2O_2Si_2Yb$ (801.2): calcd. C 50.97, H 7.98, N 3.49; found C 51.24, H 8.03, N 3.68.

[Yb{η^5-(1-C_9H_6)$SiMe_2NH$*t*Bu}$_2$(THF)$_2$] (6): A solution of $(C_9H_7)SiMe_2NH$*t*Bu (0.500 g, 2.04 mmol) in THF (5 mL) was added at room temperature to a solution of potassium 1,2-diphenylethenide, prepared in situ from *trans*-stilbene (0.730 g, 4.05 mmol) and potassium (0.159 g, 4.06 mmol) in THF (30 mL). The reaction mixture was stirred for 3 h, then slowly treated with $[YbI_2(THF)_2]$ (1.160 g, 2.03 mmol) at room temperature with vigorous stirring. The reaction mixture was left stirring overnight. The dark red reaction mixture was filtered, THF was evaporated in vacuo, and the brown residue was heated to 60 °C in vacuo for 4 h (to sublime off stilbene). The solid residue was recrystallized from toluene at −30 °C. The mother liquor was decanted from the red crystals which were dried in vacuo to afford 0.370 g (46%) of **6**. ^{1}H NMR ([D$_6$]benzene): δ = 0.28, 0.39, 0.73, 0.86 (s, 4 × 3 H, $SiCH_3$), 0.81, 1.00 (br. s, 2 × 1 H, NH), 1.12, 1.16 [s, 2 × 9 H, $C(CH_3)_3$], 1.25 (br. s, 2 × 4 H, β-CH_2 THF), 3.05 (br. s, 2 × 4 H, α-CH_2 THF), 6.37, 6.81, 7.04, 7.40, 7.70, 7.88 (m, 2 × 6 H, C_9H_6) ppm. ^{13}C{^{1}H} NMR (101 MHz, [D$_8$]THF): δ = 1.2 ($SiCH_3$), 23.3 (β-CH_2, THF), 31.1 [$C(CH_3)_3$], 47.1 [$C(CH_3)_3$], 65.2 (α-CH_2, THF), 95.2 (ring C attached to $SiMe_2$), 100.2, 114.9, 115.7, 117.8, 120.6, 124.8, 129.3, 132.6 (C_9H_6) ppm. IR (Nujol): $\tilde{\nu}$ = 3382 w, 1322 m, 1222 s, 1154 m, 1025 s, 966 w, 839 s, 764 s, 717 s, 642 w cm^{-1}. $C_{38}H_{60}N_2O_2Si_2Yb$ (806.1): calcd. C 56.61, H 7.58, N 3.47; found C 55.80, H 6.97, N 3.08.

[Yb{η^5-(1-C_9H_6)$SiMe_2NH$*t*Bu}$_2$(bipy)] (7): A solution of $(C_9H_7)SiMe_2NH$*t*Bu (0.548 g, 2.23 mmol) in THF (5 mL) was added to a suspension of $[Yb(C_{10}H_8)(THF)_2]$ (1.000 g, 2.24 mmol) in THF (35 mL) at room temperature with vigorous stirring and the reaction mixture was left standing overnight. The solution was filtered and THF was evaporated in vacuo. The brown residue was washed with hexane to remove naphthalene and redissolved in THF (20 mL). A solution of 2,2′-bipyridyl (0.690 g, 4.48 mmol) in toluene (5 mL) and hexane (3 mL) was added. Slow evaporation of the solvents at room temperature resulted in the precipitation of black crystals. The mother liquor was decanted and the crystals were washed with cold hexane and dried in vacuo to give 0.610 g (67%) of **7**. ^{1}H NMR ([D$_8$]THF): δ = 0.11, 0.21, 0.53, 0.55 (s, 4 × 3 H, $SiCH_3$), 0.62, 1.21 (br. s, 2 × 1 H, NH), 0.92, 1.09 [s, 2 × 9 H, $C(CH_3)_3$], 5.93, 6.36, 6.43, 6.61, 6.95, 7.15 (m, together 12 H, C_9H_6), 7.84, 7.90, 8.02, 8.19, 8.24, 8.39, 8.43, 8.59 (br. s, together 8 H, bipy) ppm. ^{13}C{^{1}H} NMR ([D$_8$]THF): δ = 2.2, 2.6, 2.9, 3.0 ($SiCH_3$), 32.8, 33.0 [$C(CH_3)_3$], 48.6, 48.9 [$C(CH_3)_3$], 97.7, 98.3 (C-1, C_9H_6), 101.8, 102.3 (C-3, C_9H_6), 116.5, 116.7, 117.0, 117.3 (C-6, C-7, C_9H_6), 120, 120.3 (C-5, C_9H_6), 121.6, 121.9 (C-8, C_9H_6), 124.1, 124.6 (C-2, C_9H_6), 129.6, 130.2 (C-4, C_9H_6), 132.2, 135.5 (C-9, C_9H_6), 128.2 (bipy), 136.1 (bipy), 138.0 (bipy), 148.1 (bipy), 153.7 (bipy) ppm. IR (KBr): $\tilde{\nu}$ = 3384 w, 3065 m, 2962 s, 1582 m, 1455 m, 1378 m, 1226 m, 1019 s, 849 m, 759 s, 716 m, 621 w, 450 w cm^{-1}. $C_{40}H_{52}N_4Si_2Yb$ (818.1): calcd. C 58.72, H 6.41, N 6.84; found C 58.80, H 6.39, N 7.63.

[$Li_{0.5}$][Yb(μ−$η^5$: $η^1$-$C_5Me_4CH_2SiMe_2NtBu$)$(THF)_2$(μ-I)$_{0.5}$] (8): A solution of $(C_5Me_4H)CH_2SiMe_2NHtBu$ (0.667 g, 2.51 mmol) in THF (5 mL) was added to a suspension of $[Yb(C_{10}H_8)(THF)_2]$ (1.120 g, 2.51 mmol) in THF (25 mL) at room temperature and the reaction mixture was stirred for 8 h. The brown reaction mixture was filtered, THF was evaporated in vacuo, and the residue extracted with hexane (2 × 20 mL) to remove naphthalene. The resulting solid was recrystallized from a THF/hexane mixture at 0 °C. The mother liquor was decanted and the yellow crystals were dried in vacuo to yield 0.310 g (19%) of **8**. ^{1}H NMR ([D_5]pyridine): δ = 0.73 (s, 6 H, $SiCH_3$), 1.52 [s, 9 H, $C(CH_3)_3$], 1.60 (m, 8 H, β-CH_2, THF), 1.73, 2.10 [s, 6 H, $C_5(CH_3)_4$], 2.37 (s, 2 H, CH_2), 3.64 (m, 8 H, α-CH_2, THF) ppm. $^{13}C\{^1H\}$ NMR ([D_5]pyridine): δ = 10.6 ($SiCH_3$), 12.4, 12.9 (ring CH_3), 20.6 (CH_2), 26.5 (β-CH_2, THF), 36.0 [$C(CH_3)_3$], 54.3 [$C(CH_3)_3$], 68.5 (α-CH_2, THF), 109.7, 109.9 (ring C), 137.2 (ring C attached to CH_2) ppm. IR (KBr): $\tilde{\nu}$ = 2927 s, 2854 s, 1461 m, 1377 m, 1236 w, 1187 w, 1058 s, 1022 m, 987 m, 832 m, 733 w cm^{-1}. $C_{24}H_{45}I_{0.5}Li_{0.5}NO_2SiYb$ (647.7): calcd. C 44.51, H 7.00, N 2.16; found C 44.86, H 7.75, N 2.26.

Li[Yb{(η^5:η^1-C_5H_3tBu-3)$SiMe_2NCH_2CH_2NMe_2$}$_2$] (9): Solid $Li_2(C_5H_3tBuSiMe_2NCH_2CH_2NMe_2)$ (0.670 g, 2.41 mmol) was slowly added at room temperature to a suspension of $YbCl_3$ (0.670 g, 2.40 mmol) in THF (50 mL) with vigorous stirring and the reaction mixture was stirred for a further 18 h. The resulting orange solution was filtered, THF was removed in vacuo, and the crude product was extracted with toluene (2 × 20 mL). LiCl was filtered off and the volume of the solution was reduced to 10 mL. After crystallization at −30 °C for 48 h, the mother liquor was decanted off from the yellow crystals which were dried in vacuo at room temperature to afford 0.530 g (62%) of **9**. IR (KBr): $\tilde{\nu}$ = 2995 s, 2826 m, 2783 m, 1458 m, 1360 m, 1244 s, 1176 m, 1094 s, 1020 s, 952 m, 800 s, 653 w cm^{-1}. $C_{30}H_{56}LiN_4Si_2Yb$ (708.9): calcd. C 50.85, H 7.90, N 7.90; found C 50.34, H 7.76, N 8.11.

Li{Yb[(η^5:η^1-C_5H_3tBu-3)$SiMe_2NCH_2CH_2OMe$]$_2$} (10): Solid $Li_2(C_5H_3tBuSiMe_2NCH_2CH_2OMe)$ (1.150 g, 4.33 mmol) was slowly added at room temperature to a suspension of $YbCl_3$ (1.170 g, 4.34 mmol) in DME (40 mL) under vigorous stirring and the reaction mixture was left stirring overnight. The yellow solution was filtered and the volume of the filtrate was then reduced to 10 mL. After crystallization at 0 °C for 3 days, the mother liquor was decanted from the yellow crystals which were dried in vacuo at room temperature to afford 1.010 g (71%) of **10** as yellow crystals. IR (KBr): $\tilde{\nu}$ = 2949 s, 2898 m, 2819 m, 1459 m, 1359 m, 1239 s, 1176 m, 1075 s, 935 m, 819 s, 763 s, 719 s, 571 m, 426 w cm^{-1}. $C_{28}H_{50}LiN_2O_2Si_2Yb$ (682.4): calcd. C 49.28, H 7.32, N 4.10; found C 48.88, H 7.24, N 4.23.

[Li(THF)]$_2$[Yb{(η^5-C_5H_3tBu-3)$SiMe_2NHCH_2CH_2NMe_2$}$_2$(μ-Cl)$_2$] (11): Solid $Li_2(C_5H_3tBuSiMe_2NCH_2CH_2NMe_2)$ (0.878 g, 3.15 mmol) was slowly added at room temperature to a suspension of $YbCl_3$ (0.882 g, 3.15 mmol) in THF (40 mL) under vigorous stirring and the reaction mixture was stirred overnight. The resulting orange solution was cooled to 0 °C and treated with a solution of sodium 1,2-diphenylethenide, prepared from *trans*-stilbene (0.567 g, 3.15 mmol) and sodium (0.072 g, 3.15 mmol) in THF (30 mL). The reaction mixture was allowed to warm to room temperature and stirred overnight. After filtration, THF was removed in vacuo and the resulting crude product was recrystallized from THF/hexane at −30 °C. The bright red crystals were dried in vacuo to give 1.350 g (46%) of **11**. ^{1}H NMR ([D_8]toluene): δ = 0.11, 0.48 (s, 6 H, $SiCH_3$), 0.87, 1.75 (m, 1 H, NH), 1.48 (br. s, 8 H, β-CH_2, THF), 1.53 (br. s, 4 H, $SiNCH_2CH_2N$), 1.64 [s, 18 H, $C(CH_3)_3$], 1.97 [s, 6 H, $N(CH_3)_2$], 2.29 (br. s, 4 H, NCH_2CH_2N), 3.60 (br. s, 8 H, α-CH_2, THF), 6.06, 6.13, 6.72 (s, 2 H, ring H) ppm. $^{13}C\{^1H\}$ NMR ([D_8]toluene): δ = −2.1, 1.5 ($SiCH_3$), 25.3 (β-CH_2, THF), 31.9 [$C(CH_3)_3$],32.6 [$C(CH_3)_3$, 38.8 [$N(CH_3)_2$], 44.4 ($SiNCH_2$), 61.8 (CH_2NMe_2), 67.3 (α-CH_2, THF), 109.2 (ring C attached to $SiMe_2$), 113.8, 113.1 (ring C), 137.1 (ring C attached to *tBu*) ppm. IR (KBr): $\tilde{\nu}$ = 3380 w, 3050 w, 2960 s, 2826 m, 2783 m, 1458 m, 1360 m, 1240 s, 1176 m, 1050 s, 1090 s, 1024 s, 962 m, 800 s cm^{-1}. $C_{38}H_{74}Cl_2Li_2N_4O_2Si_2Yb$ (933.0): calcd. C 48.91, H 7.93, N 6.00; found C 48.39, H 8.27, Yb 6.42.

X-ray Structure Determination of 1, 5, 7, 8, and 9: The crystal and structure refinement data are listed in Table 1 and 2. Data for **1**, **5**, **8** and **9** were collected on an Enraf−Nonius CAD-4 diffractometer (graphite monochromator, Mo-K_α radiation, λ = 0.71073 Å). Data corrections were carried out using the program WINGX[27a] in the program system WinGX.[27b] Data for **7** were collected on a Bruker AXS diffractometer with area detector. Data correction was carried out using the program system SAINT.[27c] All structures were solved by direct methods using SHELXS-86[27d] and difference Fourier syntheses. All independent reflections were used in the refinement against all F_o^2 data using the program SHELXL-97.[27e] All non-hydrogen atoms were refined with anisotropic thermal parameters; the hydrogen atoms were included in calculated positions. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-195744 (**1**), CCDC-195745 (**5**), CCDC-195746 (**7**), CCDC-195747 (**8**), and CCDC-195748 (**9**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Vinylogue Mono- and Bimetallic Cationic Sesquifulvalene and Monohydro Sesquifulvalene Complexes for Second Harmonic Generation

Timo Meyer-Friedrichsen,[a,b] Hans Wong,[a,c] Marc H. Prosenc,[a] and Jürgen Heck*[a]

Dedicated to Prof. Dr. Dieter Fenske on the occasion of his 60th birthday

Keywords: Sesquifulvalene / Ruthenium / X-ray structure determination / Hyper-Rayleigh Scattering (HRS) / Second harmonic generation (SHG)

The donor-acceptor complexes with a vinylogue monohydro sesquifulvalene and sesquifulvalene backbone of the type $[(\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^6\text{-}C_7H_7)\}ML](PF_6)_n$ [n = 0: ML = none (**1**), $Cr(CO)_3$ (**2**); n = 1: ML = $Ru(\eta^5\text{-}C_5H_5)$ (**3a**), $Ru(\eta^5\text{-}C_5Me_5)$ (**3b**)] and $[(\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^7\text{-}C_7H_6)\}ML](PF_6)_n$ [n = 1: ML = none (**4**), $Cr(CO)_3$ (**5**); n = 2: ML = $Ru(\eta^5\text{-}C_5H_5)$ (**6a**), $Ru(\eta^5\text{-}C_5Me_5)$ (**6b**)], respectively, have been synthesised, and spectroscopically and structurally characterised. A charge-shift correlation was carried out by means of ^1H NMR spectroscopic studies and an increased ground-state donor-acceptor interaction in the order **5** < **6b** < **4** < **6a** was found. The corresponding donor-acceptor interaction in **3a** and **3b** varies by an insignificant amount. Hyper-Rayleigh scattering (HRS) was applied to determine the first hyperpolarisability β of the mono- and dicationic complexes **3a**–**6b**. The β values obtained for the cationic sesquifulvalene complexes **4**–**6b** are among the largest ever measured for ruthenocenyl containing complexes due to a strong resonance enhancement: the sesquifulvalene complexes **4**–**6a**, **6b** show first hyperpolarisabilities which range between 360 and 700×10^{-30} esu, whereas β for the monohydrosesquifulvalene complexes are considerably lower (75 and 162×10^{-30} esu). For the latter complexes the first hyperpolarisability doubles on going from $Ru(\eta^5\text{-}C_5Me_5)$ (**3b**) to $Ru(\eta^5\text{-}C_5H_5)$ (**3a**) in the acceptor unit.

Introduction

In our studies on mono- and dinuclear sesquifulvalene-type complexes[1] directed to nonlinear optical (NLO) properties of organometallic complexes[2] we have found that cationic ferrocenyl based sesquifulvalene complexes often reveal fluorescence[1c–1e] due to two-photon absorption (TPF)[3] in the hyper-Rayleigh scattering (HRS) experiments, with 1064 nm as the fundamental wavelength. Ruthenocenyl containing sesquifulvalene derivatives are different in that they do not show any TPF in comparable HRS studies, which allows for a reliable determination of the first hyperpolarisability β, a measure of the molecular capability for second harmonic generation (SHG).[2] In order to obtain a better understanding of the donor-acceptor interaction in sesquifulvalene-type complexes, directed to NLO properties, we investigated the ruthenocenyl based conegeners in more detail.[4,5] In this work we focussed our interest on the vinylogue sesquifulvalene complexes (**I**) varying the electron-withdrawing force of the tropylium moiety as the electron acceptor (Figure 1). In addition, the cationic monohydro sesquifulvalene complexes **II** are synthesized and investigated, since the coordinated π-bonding system of

the cationic acceptor moiety is assumed to be electronically coupled to the ruthenocenyl donor. For both types of complexes the bonding situation can be described in two mesomeric forms, which differ between a bisaromatic (**I**, **A**) and cross-conjugated form (**I**, **B**) and an aromatic-homoaromatic (**II**, **A**) and cross-conjugated-dienyl (**II**, **B**) form, respectively.

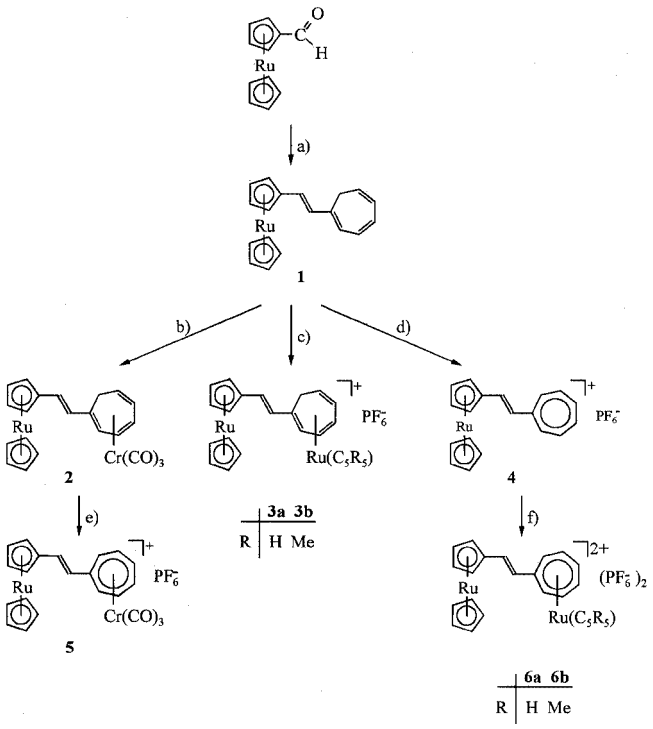
Former investigations on the archetype sesquifulvalene complexes[4,5a] illustrate an increasing SHG effect by reinforced donor-acceptor interaction in the electronic ground state, which is shown by means of NMR spectroscopic data as well as structural data. In terms of a valence bond picture a growing donor-acceptor interaction may be described as an increasing contribution of the cross-conjugated mesomeric form (**B**) to the electronic ground state (Figure 1).

The extension of our NLO studies on organometallic dipolar cationic donor-acceptor complexes to monohydro sesquifulvalene complexes was motivated by the concept that a transition from a homoaromatic to a conjugated-dienyl form (**II**) demands less energy than the loss of aromaticity as shown for the mesomeric forms of **I**. Additionally, mono cationic η^6-cycloheptatriene complexes are expected to be more stable than the corresponding dicationic η^7-cycloheptatrienylium complexes, due to the less electrophilic nature.

Results and Discussion

Synthesis: The cationic dinuclear vinylogue sesquifulvalene and monohydro sesquifulvalene complexes are readily prepared by starting with a Wittig−Horner−Wadsworth−Emmons (WHWE) reaction of the (cyclohepta-1,3,5-trienyl-1-methyl)diethylphosphonate[1d] with *n*BuLi, and formyl ruthenocene[6] (Scheme 1, see a), yielding the mononuclear, monohydro sesquifulvalene complex **1**. The coordination of the neutral unit $Cr(CO)_3$ (Scheme 1, see b) and the cationic half-sandwich moiety $Ru(\eta^5\text{-}C_5R_5)$ (Scheme 1, see c) to the cycloheptatriene ring yields the uncharged and charged dinuclear monohydro sesquifulvalene complexes **2** [ML = $Cr(CO)_3$] and **3** [ML = $Ru(\eta^5\text{-}C_5H_5)$: **3a**; ML = $Ru(\eta^5\text{-}C_5Me_5)$: **3b**], respectively. Hydride abstraction with $[Ph_3C]PF_6$ transforms **1** into the monocationic sesquifulvalene-type complex **4** (Scheme 1, see d), whereas the corresponding reaction with **2** leads to the monocationic, dinuclear sesquifulvalene complex **5** [ML = $Cr(CO)_3$] (Scheme 1, see e). The dicationic complexes **6** [ML = $Ru(\eta^5\text{-}C_5H_5)$: **6a**; ML = $Ru(\eta^5\text{-}C_5Me_5)$: **6b**] are achieved by addition of $[Ru(\eta^5\text{-}C_5R_5)(MeCN)_3]^+$ (R = H, Me) (Scheme 1, see f) to **4**.

The cationic products are complexes that are orange (**3a, 3b**) to dark-red in colour (**4−6a**, **6b**), indicating an increased electronic interaction in the cationic state compared to the neutral monohydro sesquifulvalene starting complex **1,** which has light yellow crystals. The monocationic and dicationic complexes are very soluble in CH_2Cl_2 and $MeNO_2$, respectively. Solutions of **1**, **2**, **3a**, **3b**, **6a** and **6b** are moderately inert in air, whereas **4** and **5** are sensitive to moisture.



Scheme 1. Synthesis of the mono- and dinuclear monohydro sesquifulvalene and sesquifulvalene type complexes **3a** − **6b**: a) THF; *n*BuLi. $C_7H_7CH_2P(O)(OEt)_2$; b) THF, $Cr(CO)_3(EtCN)_3$; c) CH_2Cl_2, $[Ru(\eta^5\text{-}C_5R_5)(MeCN)_3]PF_6$ (R = H, Me); d) CH_2Cl_2, $[CPh_3]PF_6$; f) CH_2Cl_2 $[Ru(\eta^5\text{-}C_5R_5)(MeCN)_3]PF_6$ (R = H, Me).

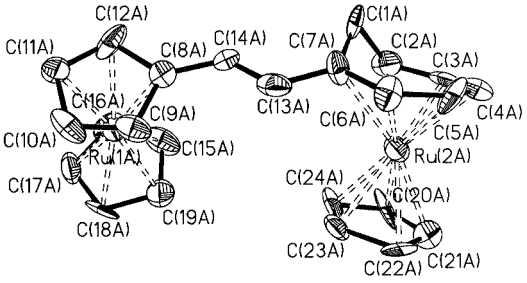


Figure 2. Molecular structure of $[(\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^6\text{-}C_7H_7)\}Ru(\eta^5\text{-}C_5H_5)]PF_6$ (**3a**) (50% ellipsoids, only one of the two independent complex cations is shown, the hydrogen atoms and the counterion are omitted for clarity).

X-ray Structure Determination: Suitable crystals for X-ray structure analysis were obtained by gas phase diffusion of Et_2O in concentrated solutions of the complexes in CH_2Cl_2 (**3a**, **3b**) and $MeNO_2$ (**6a**). Complex **3a** crystallises as twins. However, the twinning law could not be determined and thus reflexes had to be excluded by hand with F(obsd.) ≥ 4 F(calcd.) mostly from the *hk*3, *hk*6, etc. planes. In addition a superstructure was found, in which the *a*-axis was tripled resulting in six independent molecules per asymmetric unit. We circumvented the superstructure problem by solving and refining the structure by standard methods using the smaller unit cell. The dinuclear, monocationic monohydro sesquifulvalene complex **3a** crystallises in the monoclinic space group $P2_1/c$, whereas the pentamethylated derivative **3b** crystallises in a triclinic space group $P\bar{1}$. For

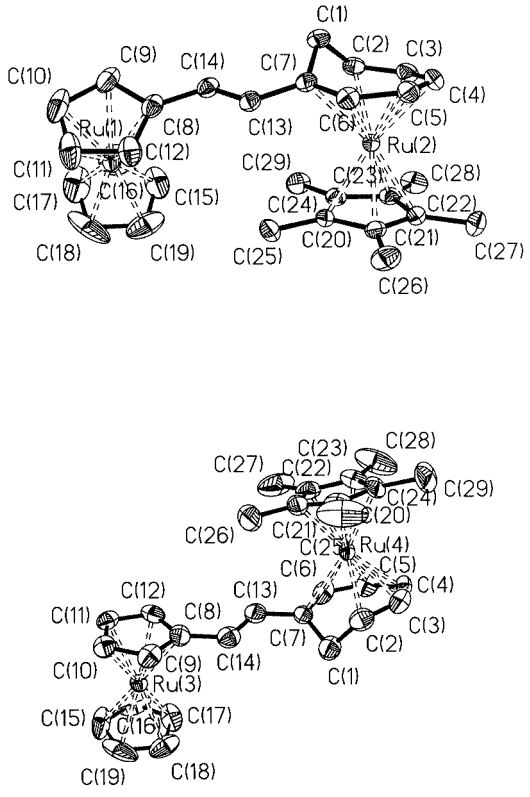

Figure 3. Molecular structures of $[\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^6\text{-}C_7H_7)\}Ru(\eta^5\text{-}C_5Me_5)]PF_6$ (**3b**). The *cisoid* (top) and *transoid* (bottom) conformers are shown (50% ellipsoids, the hydrogen atoms, the solvent molecules and counterions are omitted for clarity).

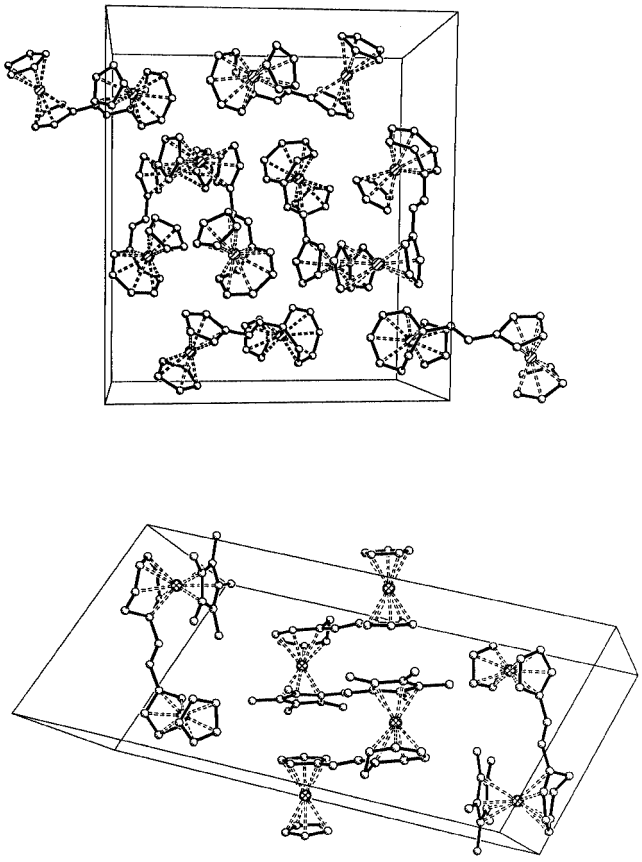

Figure 4. Unit cells of **3a** (top) and **3b** (bottom), illustrating the pairwise arrangements of the two planar chiral enantiomers in pairs (the counterions and solvent molecules are omitted for clarity).

both compounds two independent molecules within the asymmetric unit are found (Figure 2, Figure 3). Since **3a** and **3b** are planar-chiral compounds due to the coordination of the cycloheptatriene ring to a metal centre and its monosubstitution in the proximal position with respect to the sp^3 carbon atom C1, the single crystals are racemic mixtures of both enantiomers. Additionally, for **3b** the solvent molecules $MeNO_2$ and CH_2Cl_2 co-crystallise in a ratio of 2:1. The cations of **3a** and **3b** posses an *E*-configuration, and the sp^3 carbon atom C1 of the seven-membered ring occupies a *trans*-position relative to the hydrogen atom of the neighbouring CH group of the vinyl bridge, which is sterically less demanding. Whereas the monohydro sesquifulvalene cations of **3a** only adopt a *cisoid* conformation in the crystal, the cations of **3b** are packed in a *transoid* and in a *cisoid* conformation (Figure 2, Figure 3, Figure 4). The *transoid* conformation is unprecedented, since all known expanded sesquifulvalene complexes crystallise in a *cisoid* conformation[1] in contrast to the archetype dinuclear sesquifulvalene complexes with directly linked five- and seven-membered rings, which only demonstrate a *transoid* conformation due to steric repulsion.[1a−1c,5a] The *cisoid* complexes of **3a** and **3b** demonstrate a relatively large tilt angle of 47 and 38.1°, respectively, between the best plane of the substituted five-membered ring of the donor moiety and the best plane of the cycloheptatriene ligand defined by the carbon atoms C2−C7; the corresponding tilt angle in the *transoid* conformation only amounts to 20.8°.

The bond lengths and angles of the ruthenocenyl donor moiety are quite similar to those of other ruthenocene derivatives.[6,7]

The cycloheptatriene ligand of the acceptor terminus in **3a** and **3b** adopts a flat boat conformation with a steep bow for the endocyclic methylene group that deflects about 60° from the best plane defined by C2−C7. Similar structural features are known from other cycloheptatriene complexes although with corresponding angles below 50°.[8] The bridging unit C7−C13−C14−C8 does not show any significant deviation from expected bond lengths of sp^2-sp^2 carbon-carbon single and double bonds, indicating only a subtle charge delocalisation in the crystalline state. It is concluded from the bond elongation of more than 10 pm between Ru2 and C7, that a weak donor-acceptor charge equilisation still occurs. This bond elongation indicates electronic communication between the electron donating and accepting termini, which has been found in archetype sesquifulvalene complexes.[1e,5a] Thus, by means of structural data, the electronic ground state of the monohydro sesquifulvalene complexes **3a** and **3b** in the solid state is properly described by the mesomeric form **II**, **A** in Figure 1.

The X-ray structure analysis of the dinuclear dicationic vinylogue sesquifulvalene complex **6a** rendered more diffi-

culties due to a disorder in the vinylene bridge (Figure 5), which is commonly observed in vinylogue sesquifulvalene complexes.[1a,1c,1d,9] The best structural solution was obtained by assuming two different molecules in the ratio 3:1. To separate the atoms of the sesquifulvalene ligand restrictions were necessary, which do not allow a more detailed discussion. Nevertheless, the short carbon-carbon bond C13−C14 [132.1(7) pm] differs distinctly from the carbon-carbon bond C8−C14 [145.3(6) pm) and C7−C13 [144.9(6) p], clearly indicating a carbon-carbon double and single bond, respectively.

The structure data of the cyclopentadienyl-ruthenium moieties in **6a** greatly resemble the data of other CpRu units in Ru sandwich compounds (vide supra and ref.[7]). It is worthwhile noting that − as for **3a** and **3b** − the bond length between the Ru2 atom and the bridge-head carbon atom C7 is elongated by more than 10 pm compared with the other Ru−C bond lengths of the $Ru(\eta^7\text{-}C_7H_6)$ moiety.

Spectroscopic Studies: Considering the two different mesomeric forms depicted in Figure 1, it becomes evident that an increasing contribution of the mesomeric form **B** to the ground state of the complexes under study results in a decrease of the bond order of the carbon-carbon bond C13−C14. Hence, spectroscopic properties based on the C,C bond order should be sensitive probes for the examination of the donor-acceptor interaction.[10]

One indicative probe for the C13−C14 bond order is the energy of the C,C stretching vibration of the carbon-carbon bond C13−C14,[10] which differs only marginally for the cycloheptatriene derivatives but the decrease is more pronounced for the tropylium congeners in the order **5** > **6b** > **4** > **6a** (Table 3). Although the energy of the C,C stretching vibration is still representative of a C=C bond, a distinct charge delocalisation can be stated for the electronic ground state of **6a,** in particular, the amount of which can be taken as a measure of the donor-acceptor interaction. From the energy of the stretching mode of the C,C double bond one can conclude that the donor-acceptor interaction is weakest for **1**−**3** and **5**, and strongest for **6a**, in this series.

This result is in excellent agreement with the NMR spectroscopic data. One NMR probe for the C13−C14 bond order is the *trans* ^{1}H-^{1}H coupling constant of the bridging vinyl group.[10−12] For a real carbon-carbon double bond a *trans*-$^3J(H_\alpha - H_\beta)$ coupling constant of about 16 Hz is expected according to weak donor-acceptor interaction. With increasing charge delocalisation the C13−C14 bond order decreases and hence the ^{1}H-^{1}H coupling constant too;[10] a C,C single bond causes coupling constants of about at least

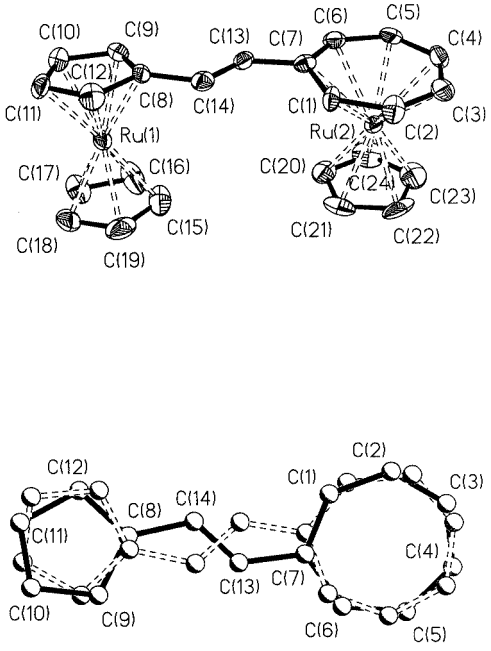

Figure 5. Molecular structure of $[\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^7\text{-}C_7H_6)\}Ru(\eta^5\text{-}C_5H_5)](PF_6)_2$ (**6a**) (50% ellipsoids, the hydrogen atoms and counterions are omitted for clarity). The drawing at the bottom demonstrates the disorder of the vinylogue sesquifulvalene ligand.

10 Hz. Whereas for the neutral and monocationic monohydro sesquifulvalene complexes **1**, **2**, **3a**, **3b** the $^3J(H_\alpha-H_\beta)$ only varies between 15.8 and 15.6 Hz, indicating a more or less unchanged carbon-carbon double bond, the corresponding coupling constants of the vinylogue sesquifulvalene complexes decrease from 16 Hz for **5** to 15.4 Hz for **4** and **6b** and drops to 13.4 Hz for **6a** (Table 3).

Another NMR probe for donor-acceptor interactions in cationic NLO chromophores under study is the charge-shift correlation of Ru sandwich complexes. A linear dependence between the shift of the cyclopentadienyl proton signals and the charge per sandwich complex in $[(\eta^5\text{-}C_5H_5)Ru(\eta^n\text{-}C_nH_n)]^{m+}$ ($n = 5$, $m = 0$; $n = 6$, $m = 1$; $n = 7$, $m = 2$) is found, which allows the calculation of the actual charge for a sandwich complex containing a $(\eta^5\text{-}C_5H_5)Ru$ unit, when the shift of the signal of the cyclopentadienyl protons is known.[5a,5b] The singlet of the unsubstituted cyclopentadienyl ligand of the metallocene donor and of the $Ru(\eta^5\text{-}C_5H_5)$ unit of the acceptor is taken as the monitoring signal. The corresponding NMR shifts are listed in Table 3, and clearly indicate an increasing positive charge on the metallocene terminus in the order **5** < **6b** < **4** < **6a** for the tropylium derivatives. For **6a** a positive charge of +0.61 is calculated for the ruthenocenyl donor in the ground state which is in good harmony with the diminishing positive charge on the acceptor to +1.44 with respect to the positive charge of +2.0 in $[(\eta^5\text{-}C_5H_5)Ru(\eta^5\text{-}C_7H_7)]^{2+}$ (Table 3). It is worth noting for the studies concerning the $^1H_\alpha$-$^1H_\beta$ coupling constants that the change of the donor-acceptor interaction in this series of complexes is the largest on going from complex **6b** (or, **5**) to **6a**, which is in agreement with the IR spectroscopic studies.

[a] **3a** crystallises with two different molecules (A and B) within the unit cell. In this table only the data for one molecule (A) is given (see Figure 2). The corresponding data for molecule B are equal to A within the margin of error.

UV/Vis spectroscopic studies were performed with solutions of different polarity such as dichloromethane and nitromethane, to elucidate solvatochromism which gives an indication of the dipole change $\Delta\mu$ between the ground and the excited state,[13] and is thus relevant for the static first hyperpolarisability β_0 according to the two-level approximation.[14]

The electronic excitation spectra of the vinylogue sesquifulvalene complexes **4**−**6a**, **6b** exhibit two intense absorption bands in the visible or near UV region (Figure 6, Table 4). As outlined earlier for metallocene containing donor-acceptor complexes,[1e,5a,12] the high-energy absorption band is assigned to a donor(ligand)−acceptor charge-transfer (D_L-A CT) transition whereas the low energy band is caused by a donor(metal)-acceptor charge-transfer (D_M-A CT) transition. In accordance with other cationic sesquifulvalene donor-acceptor complexes the energy of the D_M-A CT transitions increase when the acceptor unit A changes in the order $(C_7H_6)^+ < [(\eta^7\text{-}C_7H_6)Ru(\eta^5\text{-}C_5H_5)]^{2+} < [(\eta^7\text{-}C_7H_6)Ru(\eta^5\text{-}C_5Me_5)]^{2+} < [(\eta^7\text{-}C_7H_6)Cr(CO)_3]^+$ [1e,5] The

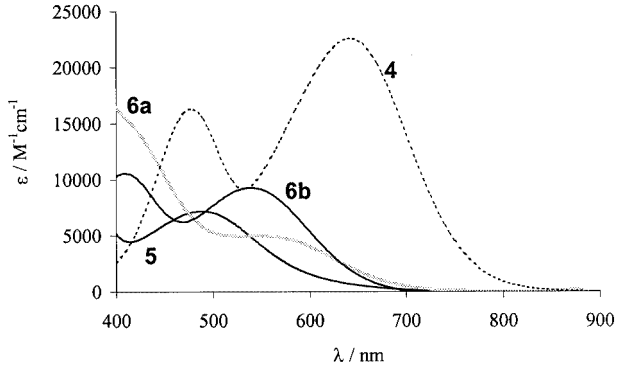

Figure 6. UV/Vis spectra of the vinylogue sesquifulvalene complexes $[(\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^7\text{-}C_7H_6)\}ML](PF_6)_n$ [n = 1, ML = none (**4**), $Cr(CO)_3$ (**5**); n = 2, ML = $Ru(\eta^5\text{-}C_5R_5)$, R = H (**6a**), Me (**6b**)] obtained from $MeNO_2$ solutions.

extraordinary low-energy shift of the D_M-A CT band of the mononuclear complex **4** compared with the dinuclear species may be explained by the formation of additional molecular orbitals (MO) upon coordination of a metal-ligand fragment to the tropylium unit, thus forming occupied bonding MOs which would be lower in energy, and empty anti-bonding MOs which would be higher in energy compared with the orbitals of the initially uncoordinated tropylium moiety.

The monohydro sesquifulvalene complexes **3a** and **3b** only reveal one intense absorption band with a λ_{max} between 400 and 430 nm (Figure 7). Since the energetically lower lying absorption bands in metallocene containing donor-acceptor complexes are generally explained as a D_M-A CT transition, the low-lying absorption band for **3a** (λ_{max} = 423 nm) and **3b** (λ_{max} = 424 nm) is also assigned to a D_M-A CT transition.

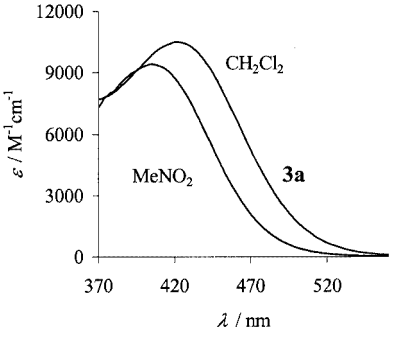

Figure 7. UV/Vis spectra of the vinylogue monohydro sesquifulvalene complex $[(\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^6\text{-}C_7H_7)\}Ru(\eta^5\text{-}C_5H_5)]PF_6$ (**3a**) obtained from CH_2Cl_2 and $MeNO_2$ solutions indicating the hypsochromic shift of λ_{max} by increasing solvent polarity.

All of the above mentioned absorption bands undergo considerable negative solvatochromism i.e. hypsochromic shift, with increasing solvent polarity indicating a more localized positive charge in the ground state than in the excited state, or even an inversion of the polarity upon excitation. The extent of the solvatochromism of both of the absorption bands for **4**−**6a**, **6b** is comparable, indicating a similar change in polarity for both of the CT transitions. Therefore, both CT transitions should contribute considerably to the first hyperpolarisability. The situation is different for **3a** and **3b,** which only reveal one absorption band close to the second harmonic generation. The cut off of the absorption bands around 500 nm warrants a reliable calculation of β_0 for **3a** and **3b**.

NLO Measurements: The low-lying excited states of the sesquifulvalene complexes under study, their facile polarisability as indicated by their strong solvatochromism, and the assignment of the HOMOs and LUMOs to the donor and acceptor orbitals, respectively, make these types of complexes very promising for the second harmonic generation. The cationic nature of the sesquifulvalene complexes requires the hyper-Rayleigh scattering (HRS)[15] as the only method for determining the first hyperpolarisability β, which can be regarded as the molecular capability of doubling the frequency of incoming light. However, a draw-back of the HRS method may be fluorescence due to two-photon absorption.[16−18] Since the realisation of the problem of multiphoton absorption induced fluorescence concerning the determination of the first hyperpolarisability, several techniques have been investigated to overcome this problem. These include long wavelength measurements,[10,19,20] time resolved HRS[19] measurement of the two-photon fluorescence spectrum to abstract the fluorescence contribution to the HRS signal,[21] and, just recently, a high-frequency demodulating technique to suppress the multiphoton fluorescence contribution to the HRS signal.[16] A "low cost" check for the two-photon fluorescence was recently described,[1d,1e] and uses bandpass filters with peak transmittance at different wavelengths, which are introduced in front of the photomultiplier of the HRS set-up. The broad fluorescence signal, which yields the emission maximum at λ/2 of the fundamental wavelength, is easily discerned from the narrow second harmonic signal at λ/2.

In the course of this study no fluorescence was observed (Figure 8). Therefore, for all dipolar mono- and dicationic complexes under study the first hyperpolarisability β was determined by means of HRS (Table 4).

Since the wavelengths of the absorption bands are in close proximity to the wavelength of the SHG signal, the obtained β values are strongly resonance enhanced and are therefore corrected by the dispersion term of the two-level model.[14] It has to be emphasised that the β_0 values for **4**, **5**, **6a** and **6b** are not very reliable, since only the low-energy D_M-A CT transition was taken into account for calculating β_0; the high energy D_L-A CT transition will also contribute to the first hyperpolarisability as indicated by the strong solvatochromism of both CT transitions. However, it is worth noting that the first hyperpolarisability for **4** decreases by almost a factor of two on going from a $MeNO_2$ solution to the less polar CH_2Cl_2 solution, although λ_{max} of the D_L-A CT transition is shifted closer to λ(SHG) for CH_2Cl_2 solutions than for $MeNO_2$ solutions. The opposite is true for the D_M-A CT transition. This behaviour points to larger contributions of the D_M-A CT transition to the β values than the D_L-A CT transition.

The HRS-determined first hyperpolarisability of the vinylogue mono- and dicationic sesquifulvalene complexes **4**, **5**, **6a**, and **6b** (Table 4) belong to the largest values ever obtained for ruthenocenyl containing dipolar NLO chromophores,[24] in particular, when the relatively small molecular mass is taken into account, which is often used as a figure of merit. However, it has to be realized that the first hyperpolarisabilities are strongly resonance enhanced by different contributions of D_L-A CT and D_M-A CT transitions. Therefore, no correlation between the β values of **4**, **5**, **6a** and **6b** and their ground-state donor-acceptor interaction as demonstrated by IR- and NMR spectroscopy, can be stated, although the strongest SHG effect may be expected for **6a** taking into account the ground state donor-acceptor interaction. This can only be proven when λ(SHG) is beyond the cut-off of λ(D_M-A CT).

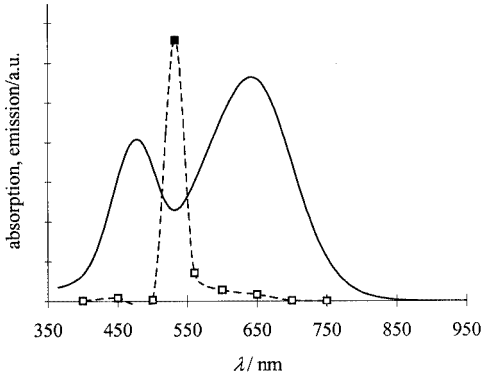

Figure 8. Representative UV/Vis absorption spectrum for vinylogue sesquifulvalene complexes $[(\eta^5\text{-}C_5H_5)Ru\{\mu\text{-}(\eta^5\text{-}C_5H_4)C_2H_2(\eta^7\text{-}C_7H_6)\}ML]PF_6$ (ML: = none: **4**) obtained from CH_2Cl_2 solution (solid line) and the corresponding scattered spectrum obtained from HRS studies (dotted line) indicating only the SHG signal (a.u. = arbitrary units)

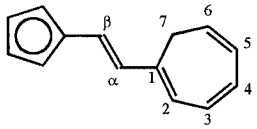
In contrast the cut-off of the absorption band of the D_M-A CT transition of **3a** and **3b** is below λ(SHG), and thus allows a reliable determination of the first hyperpolarisability β, which doubles on going from **3b** (ML = Ru(η^5-C_5Me_5); β = 75 × 10^{-30} esu) to **3a** (ML = Ru(η^5-C_5H_5); β = 162 × 10^{-30}esu). This also holds for the β_0 values, since λ_{max} of **3a** and **3b** is almost identical, and is in excellent agreement with the findings from archetype dinuclear sesquifulvalene complexes which also demonstrate a doubling or almost doubling of β and β_0 values when the metal-ligand fragment on the acceptor site is changed from Ru(η^5-C_5Me_5) to Ru(η^5-C_5H_5).[4,5a] The reason for the lack of correlation between the ground-state spectroscopic data and the SHG effect for **3a** and **3b** remains unclear for the time being, and may reflect that the nature of the ground state *and* the excited state determine the SHG effect.

Conclusion

In contrast to ferrocenyl derivatives of vinylogue sesquifulvalene complexes the ruthenocenyl congeners do not show fluorescence, which can be caused by a two photon absorption in HRS experiments with a fundamental wavelength of 1064 nm.[1d,1e] The obtained β values are the highest ever measured for ruthenocenyl containing donor-acceptor NLO chromophores and in particular when they are correlated to the molecular mass of corresponding complexes. However, these β values are strongly resonance enhanced by an energetically low-lying D_M-A CT transition and an energetically higher lying D_L-A CT transition. The different contributions to the resonance enhancement prevent a rationalisation of the NLO property, i.e. the capability of frequency doubling by electronic ground state properties. This is for example the bond order in the olefinic linker between the donor and the acceptor, which can be characterised by the energy of the C=C stretching mode in IR-spectroscopy and $^3J(^1H\text{-}^1H)$ coupling constants between the protons of this double bond. The situation changes for the monohydro sesquifulvalene complexes, which reveal one electronic absorption band with λ_{max} considerably smaller than λ(SHG) and a cut off at about 500 nm. Reliable values for the first hyperpolarisability β have been determined and thus reasonable β_0 values can be calculated. These data confirm the results obtained for dinuclear archetype sesquifulvalene complexes: the first hyperpolarisability is roughly doubled on going from [Ru(η^5-C_5Me_5)]$^+$ to [Ru(η^5-C_5H_5)]$^+$ complex fragments on the acceptor site.

Experimental Section

Manipulations were carried out under a dry nitrogen atmosphere using standard Schlenk techniques. Solvents were saturated with nitrogen, and diethyl ether (Et_2O), tetrahydrofuran (THF), *n*-hexane and toluene were freshly distilled from the appropriate alkali metal or metal alloy. Dichloromethane (CH_2Cl_2) and nitromethane ($MeNO_2$) were dried over calcium hydride. NMR: Varian Gemini 200 BB; Bruker AM 360; measured at 295 K rel. TMS. UV/Vis: Perkin−Elmer Model 554. IR: KBr pills, FT-IR, Perkin−Elmer Model 325. MS: Finnigan MAT 311 A (EI-MS). Elemental analyses: CHN−O-Rapid (Zentrale Elementanalytik, Fachbereich Chemie, Universität Hamburg), Fa. Heraeus. Tropylium hexafluorophosphate (**7**),[25] formyl ruthenocene,[6] triphenylcarbenium hexafluorophosphate/tetrafluoroborate,[26] (tricarbonyl)(trispropionitrile)chromium(0),[27] (trisacetonitrile)(η^5-cyclopentadienyl)-ruthenium(II) hexafluorophosphate,[28] (trisacetonitrile)(η^5-pentamethylcyclopentadienyl)ruthenium(II) hexafluorophosphate,[29] (cyloheptа-1,3,5-trienyl-1-methyl)diethylphosphonate[1d] were synthesised according to literature procedures.



***E*-(1-Ruthenocenyl)(2-cyclohepta-1′,3′,5′-trien-1′-yl)ethene (1), Method A:** A solution of Li*n*Bu in hexane (0.73 mL, 1.6 M in *n*-hexane) was added to a stirred solution of (cyclohepta-1,3,5-trien-1-ylmethyl)(diethyl)phosphonate (270 mg, 1.1 mmol) in THF (20 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature. After 30 min of stirring at ambient temperature the reaction mixture was cooled to −78 °C, and formyl ruthenocene (250 mg, 0.96 mmol) dissolved in THF (10 mL) was added dropwise. After warming to room temperature the solvent was evaporated to dryness. The residue was extracted with *n*-hexane and purified by column chromatography (SiO_2, *n*-hexane/Et_2O, 1:1). Isolation of the yellow band yielded 300 mg (90%) of **1** as a light yellow crystalline powder.

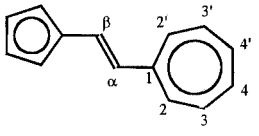
Method B (phase-transfer catalysis): A mixture of an aqueous solution of sodium hydroxide (50%, 30 mL), benzene (30 mL), a catalytic amount of [*n*Bu$_4$N]Br (32 mg, 0.1 mmol), formyl ruthenocene (310 mg, 1.2 mmol) and (cyclohepta-1,3,5-trien-1-yl-methyl)(diethyl)phosphonate (420 mg, 1.7 mmol) was stirred under reflux for 16 h. The progress of the reaction was monitored by TLC. The reaction mixture was extracted by Et_2O, the organic layer dried with $MgSO_4$ and, subsequently, evaporated to dryness. The isolation of the product occurred as described for Method A. Yield (**1**): 198 mg (48%). ^{1}H NMR ($CDCl_3$): δ = 2.60 (d, *J* = 7.2 Hz, 2 H, H-7), 4.52 (s, 5 H, C_5H_5), 4.59 (t, *J* = 1.8 Hz, 2 H, C_5H_4), 4.81 (t, *J* = 1.8 Hz, 2 H, C_5H_4), 5.41 (m, 1 H, H-6), 6.13 (d, *J* = 4.8 Hz, 1 H, H-2), 6.21 (dd, *J* = 9.2, 5.0 Hz, 1 H, H-5), 6.41 (d, *J* = 15.8 Hz, 1 H, CH=C*H*), 6.53 (d, *J* = 15.8 Hz, 1 H, C*H*=CH), 6.54 (m, 2 H, H-3, H-4), ppm. MS(EI): *m/z* (%) = 260 (67) [M$^+$ − 88], 232(100) [$C_{10}H_{10}Ru^+$], 167 (56) [C_5H_5Ru]. $C_{19}H_{18}Ru$ (347.4): calcd. C 65.69, H 5.22; found C 65.52, H 5.55.

***E*-(1-Ruthenocenyl-2-[(tricarbonyl)(η^6-cyclohepta-1′,3′,5′-trien-1′-yl)chromium]ethene (2):** A solution of **1** (90 mg, 0.26 mmol) and $Cr(CO)_3(EtCN)_3$ (78 mg, 0.26 mmol) in THF (20 mL) was stirred overnight at room temperature. The reaction solvent was evaporated in vacuo and the residue extracted with toluene. The toluene extract was filtered and product **2** was precipitated after addition of hexane and cooling to −18 °C. Yield (**2**): 110 mg (88.5%) of a red-violet microcrystalline material. ^{1}H NMR (C_6D_6): δ = 1.07 (m, 1 H, H-7$_{exo}$), 2.62 (m, 2 H, H-7$_{endo}$, H-6), 4.21 (d, *J* = 7.0 Hz, 1 H, H-2), 4.41 (t, *J* = 7.2 Hz, 1 H, H-5), 4.57 (s, 5 H, C_5H_5), 4.67 (s, 2 H, C_5H_4), 4.79 (s, 2 H, C_5H_4), 5.05 (t, *J* = 7.7 Hz, 1 H, H-3), 5.19 (t, *J* = 7.4 Hz, 1 H, H-4), 5.86 (d, *J* = 15.8 Hz, 1 H, CH=C*H*), 6.21 (d, *J* = 15.6 Hz, 1 H, C*H*=CH) ppm. ^{13}C NMR (C_6D_6): δ = 23.0 (C-7), 53.2 (C-6), 68.7 (C_5H_4), 70.7 (C_5H_4), 72.0 (C_5H_5),

75.9 [$C_q(C_5H_4)$], 86.9 (C-1), 96.2 (C-3), 97.5 (C-4), 98.8 (C-2), 100.4 (C-5), 127.5 (C=C), 127.6 (C=C), 232.3 (CO) ppm. IR (KBr): $\tilde{\nu}$ = 1950 (ν_{CO}), 1898 (ν_{CO}), 1883 (ν_{CO}), 1849 (ν_{CO}), 1618 ($\nu_{C=C}$). UV/Vis (CH_2Cl_2): λ_{max} (ε) = 436 (7320), 560 (sh) (1160) nm ($M^{-1}\cdot cm^{-1}$). MS (EI): *m/z* (%) = 484 (10) [M^+], 400 (60) [M^+ − 3CO], 347 (100) [M^+ − H-Cr(CO)$_3$. $C_{22}H_{18}O_3CrRu$ (483.5): C 54.66, H 3.75; found C 54.40, H 3.72.

[*E*-(1-Ruthenocenyl-2-{(η^5-cyclopentadienyl)(η^6-cyclohepta-1′,3′,5′-trien-1′-yl)ruthenium}ethene] Hexafluorophosphate (3a): A solution of **1** (171 mg, 0.49 mmol) and [(η^5-C_5H_5)Ru(MeCN)$_3$]PF_6 (213 mg, 0.49 mmol) in CH_2Cl_2 (20 mL) was stirred at ambient temperature. The progress of the reaction was monitored by TLC. When **1** could not be detected any longer (after three days), the product **3a** was precipitated by addition of Et_2O. A recrystallisation was performed by redissolution of crude **3a** and precipitation by slow gas phase diffusion of Et_2O. Yield (**3a**): 170 mg (53%) of orange-coloured microcrystalline material. ^{1}H NMR (CD_3NO_2): δ = 1.28 (dd, *J* = 13.7, 4.9 Hz, 1 H, H-7$_{exo}$), 3.46 (dd, *J* = 13.7, 9.4 Hz, 1 H, H-7$_{endo}$), 4.15 (m, 1 H, H-6), 4.16 (s, 5 H, C_5H_5), 4.75 (t, *J* = 1.8 Hz, C_5H_4), 4.93 (m, 1 H, C_5H_4), 5.07 (m, 1 H, C_5H_4), 5.35 (s, 5 H, C_5H_5), 5.67 (m, 2 H, H-4, H-5), 6.40 (d, *J* = 15.9 Hz, 1 H, H$_\beta$), 6.51 (m, 2 H, H-2, H-3), 6.87 (d, *J* = 15.9 Hz, 1 H, H$_\alpha$) ppm. ^{13}C NMR (CD_3NO_2): δ = 22.6 (C-7), 30.0 (C-6), 56.6 (C-1), 69.8 (C_5H_4), 71.9 (C_5H_4), 72.9 (C_5H_5) 73.0 (C_5H_4), 73.1 (C_5H_4), 85.3 (C_5H_5), 87.2 [$C_q(C_5H_4)$], 89.0, 91.1 (C-4, C-5), 93.8, 95.8 (C-2, C-3), 126.9 (C_β), 135.2 (C_α) ppm. IR (KBr): $\tilde{\nu}$ = 3115, 3058, 2991, 1624 ($\nu_{C=C}$), 1506, 1416, 1101, 834 ($\nu_{P\text{-}F}$), 557 cm^{-1}. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 423 (10490) nm ($M^{-1}cm^{-1}$), (CH_3NO_2): λ_{max} (ε) = 404 (9410) nm ($M^{-1}cm^{-1}$). $C_{24}H_{23}F_6PRu_2$ (658.6): C 43.77, H 3.52; found C 43.16, H 3.68.

[*E*-(1-Ruthenocenyl-2-{(η^5-pentamethylcyclopentadienyl)(η^6-cyclohepta-1′,3′,5′-trien-1′-yl)ruthenium(II)}ethene] Hexafluorophosphate (3b): A solution of **1** (120 mg, 0.35 mmol) and [η^5-C_5Me_5)Ru(MeCN)$_3$]PF_6 (227 mg, 0.35 mmol) in CH_2Cl_2 (15 mL) was stirred at ambient temperature. The reaction and workup procedure were analogous to that of the synthesis of **3a**. Yield (**3b**): 125 mg (49%) orange-coloured prisms. ^{1}H NMR (CD_3NO_2): δ = 1.24 (dd, *J* = 12.8, 3.5 Hz, 1 H, H-7$_{exo}$) 1.88 (s, 15 H, C_5Me_5), 3.40 (m, 2 H, H-6, H-7$_{endo}$), 4.66 (s, 5 H, C_5H_5), 4.76 (m, 2 H, C_5H_4), 4.93 (m, 1 H, C_5H_4), 5.07 (m, 1 H, C_5H_4), 5.11 (m, 1 H, H-5), 5.18 (dd, *J* = 4.3, 2.6 Hz, 1 H, H-4), 6.18 (m, 2 H, H-2, H-3), 6.25 (d, *J* = 15.8 Hz, 1 H, H$_\beta$), 6.89 (d, *J* = 15.8 Hz, 1 H, H$_\alpha$) ppm. ^{13}C NMR (CD_3NO_2): δ = 10.2 (C_5Me_5), 23.6 (C-7), 35.7 (C-6), 57.8 (C-1), 69.6 (C_5H_4), 71.7 (C_5H_4), 72.5 (C_5H_5), 72.7 (C_5H_4), 72.8 (C_5H_4), 88.2 [$C_q(C_5H_4)$], 94.2 (C-4), 94.7 (C-2 or C-3), 95.4 (C-5), 97.6 (C-2 or C-3), 99.4 (C_5Me_5), 126.8 (C_β), 136.0 (C_α) ppm. IR (KBr): $\tilde{\nu}$ = 2913, 2860, 1619 ($\nu_{C=C}$), 1381, 838 ($\nu_{P\text{-}F}$). UV/Vis (CH_2Cl_2): λ_{max} (ε) = 424 (11460) nm ($M^{-1}\cdot cm^{-1}$), (CH_3NO_2): λ_{max} (ε) 409 (10225) nm ($M^{-1}\cdot cm^{-1}$). ($C_{29}H_{33}PF_6Ru_2$)1/2(CH_2Cl_2)1/2(CH_3NO_2) (801.7): C 44.95, H 4.46, N 0.87; found C 44.62, H 4.39, N 1.07.



[*E*-1-Ruthenocenyl-2-(cycloheptatrienylium-1′-yl)ethene] Hexafluorophosphate (4): A solution of [Ph_3C]PF_6 (538 mg, 1.38 mmol) in CH_2Cl_2 (10 mL) was added to a stirred solution of **1** (480 mg, 1.38 mmol) in CH_2Cl_2 (20 mL). After stirring for 30 min the product **4** was precipitated by dilution with Et_2O. Recrystallisation was performed by gas phase diffusion of Et_2O into a concentrated CH_2Cl_2 solution of **4**. Yield: 0.52 g (77%) of a blue-violet crystalline powder. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 4.78 (s, 5 H, C_5H_5), 5.24 (s, 4 H, C_5H_4), 6.78 (d, *J* = 15 Hz, 1 H, H$_\beta$), 8.18 (d, *J* = 15 Hz, 1 H, H$_\alpha$,), 8.04−8.23 (m, 4 H, C_7H_6), 8.30−8.35 (d, 2 H, C_7H_6) ppm. ^{13}C NMR (50 MHz, CD_3NO_2): δ = 73.5 (C_5H_4), 74.8 (C_5H_4), 77.7 (C_5H_4), 125.0 (C_β), 147.6 (C_7H_6), 148.6 (C_7H_6), 149.3 (C_7H_6), 152.3 C_α), ppm UV/Vis (CH_2Cl_2): λ_{max} (ε) = 480 (16270), 640 (22560) nm (M^{-1} cm^{-1}); (CH_3NO_2): λ_{max} (ε) = 470 (12040), 600 (16430) nm (M^{-1} cm^{-1}). MS (FAB): *m/z* (%) = 347 (78%) [M^+ − PF_6]. $C_{19}H_{17}F_6PRu$ (492.0): C 46.34, H 3.48; found C 45.86, H 3.74.

[*E*-1-Ruthenocenyl-2-{(tricarbonyl)(η^7-cycloheptatrienylium-1-yl)-chromium}ethene] Hexafluorophosphate (5): A solution of [Ph_3C]PF_6 (90 mg, 0.23 mmol) in CH_2Cl_2 (10 mL) was added to a solution of **2** (110 mg, 0.23 mmol) in CH_2Cl_2 (20 mL) at 0 °C. After stirring for 30 min the reaction solution was diluted by addition of Et_2O. The precipitation was filtered off and recrystallised by a gas-phase diffusion of Et_2O into a concentrated solution of **5** in $MeNO_2$. Yield (**5**): 70 mg (48.5%) dark red needles. ^{1}H NMR (CD_3NO_2): δ = 4.65 (s, 5 H, C_5H_5), 4.88 (s, 2 H, C_5H_4), 5.13 (s, 2 H, C_5H_4), 6.48 (d, *J* = 9.3 Hz, 2 H, H-2,2′), 6.52 (m, 2 H, H-4,4′),6.80 (m, 2 H, H-3,3′),6.81 (d, *J* = 16.0 Hz, 1 H, H$_\beta$), 7.63 (d, *J* = 16.0 Hz, 1 H, H$_\alpha$) ppm. ^{13}C NMR (CD_3NO_2): δ = 71. 8 (C_5H_4), 73.3 (C_5H_5), 74.3 (C_5H_4), 85.6 [$C_q(C_5H_4)$], 100.4 (C-2,2′),104.7 (C-4,4′),106.0 (C-3,3′),121.5 (C_β), 126.8 (C-1), 142.7 (C_α), 223.4 (CO) ppm. [*E*-1-Ruthenocenyl-2-{(η^5-cyclopentadienyl)(η^7-cyclohepta-trienylium-1′-yl)ruthenium(II)}ethene] Bishexafluorophosphate (6a): A solution of **4** (340 mg, 0.7 mmol) and [(η^5-C_5H_5)Ru(MeCN)$_3$]PF_6 (300 mg, 0.7 mmol) in CH_2Cl_2 (40 mL) was stirred overnight at ambient temperature. The precipitated product was filtered off, washed with CH_2Cl_2 and recrystallised from $MeNO_2$/Et_2O. Yield (**6a**): 470 mg (84%) red crystals. ^{1}H NMR (CD_3NO_2): δ = 5.11 (s, 5 H, C_5H_5), 5.38 (t, *J* = 1.8 Hz, 2 H, C_5H_4), 5.83 (t, *J* = 1.8 Hz, 2 H, C_5H_4), 5.86 (s, 5 H, C_5H_5), 5.92 (d, *J* = 13.4 Hz, 1 H, H$_\beta$), 6.09 (d, *J* = 9.2 Hz, 2 H, H-2,2′), 6.47 (m, 2 H, H-3,3′), 7.21 (dd, *J* = 5.4, 2.6 Hz, 2 H, H-4,4′), 7.55 (d, *J* = 13.4 Hz, 1 H, H$_\alpha$) ppm. ^{13}C NMR (CD_3NO_2): δ = 70.5 (C-2,2′), 79.6 (C_5H_4), 81.9 (C_5H_5), 87.2 (C_5H_4), 88.2 (C_5H_5), 96.5 [$C_q(C_5H_4)$], 97.5 (C-3,3′), 99.7 (C-4,4′), 117.4 (C_α), 121.6 (C_β), 138.1 (C-1) ppm. IR (KBr): $\tilde{\nu}$ = 3121, 1599 ($\nu_{C=C}$), 1541, 1493, 1418, 835 ($\nu_{P\text{-}F}$). UV/Vis (CH_2Cl_2): λ_{max} (ε) = 400, 600 (sh) nm, (CH_3NO_2): λ_{max} (ε) = 400 (10760), 560 (4975) nm ($M^{-1}\cdot cm^{-1}$). $C_{24}H_{22}Ru_2P_2F_{12}$ (802.5): C 35.92, H 2.76; found C 35.45, H 2.86.

[*E*-1-Ruthenocenyl-2-{η^5-pentamethylcyclopentadienyl)(η^7-cycloheptatrienylium-1′-yl)ruthenium(II)}ethene] Bishexafluorophosphate (6b): The synthesis of **6b** was performed strictly analogously to **6a**. Quantities used: **4** (50 mg, 0.1 mmol), [(η^5-C_5Me_5)Ru(MeCN)$_3$]PF_6 (51 mg, 0.1 mmol), CH_2Cl_2 (10 mL). Yield (**6b**): 64 mg (73%) dark red needles.- ^{1}H NMR (CD_3NO_2): δ = 2.13 (s, 15 H, C_5Me_5), 4.75 (s, 5 H, C_5H_5), 5.05 (t, *J* = 1.7 Hz, 2 H, C_5H_4), 5.24 (t, *J* = 1.7 Hz, 2 H, C_5H_4), 6.77 (d, *J* = 15.4 Hz, 1 H, H$_\beta$), 7.20 (m, 2 H, H-3,3′), 7.23 (d, *J* = 8.6 Hz, 2 H, H-2,2′), 7.33 (dd, *J* = 5.5, 3.6 Hz, 2 H, H-4,4′), 7.98 (d, *J* = 15.4 Hz, 1 H, H$_\alpha$), ppm. ^{13}C NMR (CD_3NO_2): δ = 10.7 (C_5Me_5), 72.7 (C_5H_4), 73.9 (C_5H_5), 76.0 (C_5H_4), 86.1 [$C_q(C_5H_4)$], 99.1 (C-2,2′), 104.9 (C-3,3′), 105.5 (C-4,4′), 110.3 (C_5Me_5), 116.7 (C_β), 128.6 (C-1), 152.6 (C_α) ppm. IR (KBr): $\tilde{\nu}$ = 3071, 1609 ($\nu_{C=C}$), 1539, 1418, 839 ($\nu_{P\text{-}F}$). UV/Vis (CH_2Cl_2): λ_{max}

(ε) = 438, 594 nm, (CH_3NO_2): λ_{max} (ε) = 409 (10580), 541 (9280) nm ($M^{-1}\cdot cm^{-1}$); ($C_{29}H_{32}Ru_2P_2F_{12}$) 2/3 ($CH_3NO_2$) (914.7): C 38.92, H 3.75, N 1.02 found C 39.29, H 3.75, N 1.48.

X-ray Structure Determination: Crystals suitable for an X-ray structure determination were obtained by gas phase diffusion of Et_2O into a CH_2Cl_2 solution of **3a**, **3b** and into an $MeNO_2$ solution of **6a.** Complex **3b** crystallised with CH_2Cl_2 and $MeNO_2$ molecules. During the isolation of the crystalline product of **3b** it was dissolved once in $MeNO_2$, which may explain the co-crystallisation of $MeNO_2$ molecules. The data were collected with a four-circle diffractometer (**3b**, and **6a**: Hilger and Watts, Mo-K_α; **3a**: Siemens aix, Mo-K_α). All structures were resolved by direct methods (SHELXS-86).[30] Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-93, SHELXL-97).[31,32] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined by the riding-model method with fixed isotropic thermal parameter related by a factor of 1.2 to the value of the equivalent isotropic parameter of their carrier atoms. Weights are optimised in the final refinement cycles.

CCDC-195475 (**3a**) CCCDC-195474 (**3b**) and CCDC-195453 (**6a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

HRS Measurements of the First Hyperpolarisabilities: Hyper-Rayleigh scattering measurements were performed with a pulsed Nd:YAG laser at a wavelength of λ = 1064 nm. For the experimental setup see ref.[15b] Solutions of the complexes in CH_2Cl_2 and $MeNO_2$ with concentrations in the range of 10^{-4} to 10^{-6} M were used with *p*-nitroaniline as a reference [$\beta(CH_2Cl_2) = 21.6 \times 10^{-30}$ esu,[22] $\beta(MeNO_2) = 34.6 \times 10^{-30}$ esu].[23] Fluorescence checks were made by replacing the interference filter in front of the photomultiplier tube with filters that have transmittances at 400, 450, 500, 560, 600 and 700 nm.[4]

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (DFG, HE 1309/3), by the European Community (COST D4/003/94, TMR FMRX-CT98−0166) and by the Fonds der Chemischen Industrie. We thank the DEGUSSA AG for a donation of $RuCl_3$ and Sartorius GmbH for a donation of microfilters.

[5] [5a] T. Meyer-Friedrichsen, M. H. Prosenc, J. Heck, manuscript in preparation. [5b] The ^1H NMR signals of the Ru(η^5-C_5H_5) units are found at δ = 4.56 [Ru(η^5-C_5H_5)$_2$], 5.45 [Ru(η^5-C_5H_5)](η^6-C_6H_6)PF_6 and 6.37 {[Ru(η^5-C_5H_5)](η^7-C_7H_7)PF_6}$_2$ ppm (200 MHz, CD_3NO_2, rel. TMS). These shifts demonstrate a linear correlation with the charge of the corresponding complex cation, which obeys the equation δ[Ru(η^5-C_5H_5)] = 0.905 × *m* + 4.56 (*m* = charge of the sandwich complex; correlation coefficient *r* = 1.000); by means of this equation the actual charges of the donor and/or acceptor moieties of the complexes under study can be calculated from the shift of the Cp signal of the Ru(η^5-C_5H_5) unit.

Macrocyclic, Dinuclear Zinc(II)-Directed Self-Assembly with Pyridine, 2,2′-Bipyridine and 2-Methylquinoline: μ^2-OH Bridging Bi-Macrocyclic Complexes and Hydrogen-Bond-Supported Donor-Acceptor Complexes

Wei Huang,[a] Shaohua Gou,*[a] Huifen Qian,[b] Dahua Hu,[a] Suchada Chantrapromma,[c] Hoong-Kun Fun,[c] and Qingjin Meng[a]

Keywords: N,O ligands / Macrocycles / Zinc / Self-assembly / Structure elucidation / Hydrogen bonds

Two macrocyclic dinuclear zinc(II) complexes (**1a** and **1b**) have been self-assembled in the presence of pyridine and 2,2′-bipyridine, respectively, to form μ^2-OH-bridged bimacrocycles with a Zn_4O_4 cavity through coordination bonding. The X-ray structural analysis reveals that both compounds {**2a**: $[Zn_4L^a{}_2(OH)_2]_2(ClO_4)_2$; **2b**: $[Zn_4L^b{}_2(OH)_2]_2(ClO_4)_2$} have an open-mouthed sandwich-like structure with π–π interactions between parts of two phenyl rings to strengthen two hydroxyl groups connecting the metal atoms in the same direction of the macrocycle. Furthermore, nonclassical C–H···Cl intermolecular interactions have been observed in the crystal of **2b**. In addition, the reaction of **1a** with quinoline derivatives has yielded novel hydrogen-bond-supported donor-acceptor complexes {**3a**: $[Zn_2L^a(H_2O)_2(C_{10}H_9N)_2](ClO_4)_2$}. The crystallographic study of the complex containing 2-methylquinoline indicates that two 2-methylquinoline molecules are linked to two coordinating water molecules above and below the macrocyclic framework through O–H···N hydrogen bonds. The 2-methylquinoline plane interacts in a face-to-face fashion with the phenyl ring of adjacent macrocyclic frameworks, forming an ordered arrangement where one macrocycle and two 2-methylquinolines are arrayed alternately with almost the same separation. The interplanar distance mentioned before is ca. 3.6 Å.

Introduction

Metal-directed self-assembly has been actively investigated in recent years because such a phenomenon offers a new and effective way for the construction of organized structures. The known application of this category of self-assembly is mainly focused on the combination of naked or decorated mononuclear metal species with well-designed organic ligands, leading to the production of metal-ligand frameworks with specific structural topologies.[1] Self-assembly involving dinuclear macrocyclic components has rarely been reported[2] since the first homodinuclear macrocyclic complexes were synthesized by template condensation in the early 1970s and a subsequent systematic study of their modeling of metallobiosites.[3]

The coordination behavior of the metal atoms in these complexes plays a key role in controlling the assembly pattern: metal ions with a defined coordination geometry (e.g. square planar, tetrahedral, pyramidal, and octahedral configurations) have to be specifically chosen and/or deliberately modified as building blocks to realize the anticipated assembly; the effect of noncovalent interactions such as hydrogen bonding, aromatic π−π stacking and charge-transfer interactions should also be taken into account.[4]

We recently reported two infinite molecular ladder polymers composed of a macrocyclic component (**1**) (Scheme 1) with 4,4′-bipyridine, in which two adjacent zinc(II) ions, pre-positioned in the macrocyclic backbone, have been linked by 4,4′-bipyridine ligands via coordinating bonds, together with the change of the coordination configuration of the metal atom from a five-coordinate pyramid to a six-coordinate octahedron (Scheme 2, a).[5] To further study the effect of the dinuclear zinc(II) macrocyclic component in self-assembly, some other mono- and bifunctional aromatic ligands have been utilized instead of 4,4′-bipyridine with the expectation of obtaining a novel type of supramolecular compounds or coordination polymers with special structural topologies. When 4-aminopyridine or pyridine-4-carboxylic acid is allowed to react with **1**, molecular ladder elements are obtained (Scheme 2, b and c).[6] We report here two kinds of new complexes obtained by the reaction of macrocyclic component **1** with pyridine, 2,2′-pyridine and quinoline derivatives. Unlike the reaction with 4,4′-bipyrid-

ine (1-D molecular ladder polymers bridged by M−N coordinating bonds), sandwich-like structures (**2**) are formed where **1** moieties are connected by two μ^2-OH groups via bridging zinc atoms in the presence of pyridine or 2,2′-bipyridine ligands (Scheme 2, c). When a quinoline derivative is involved, an infinite one-dimensional hydrogen-bond-supported donor-acceptor polymer is obtained where no coordinating interaction exists between layers (Scheme 2, d).

Results and Discussion

Preparations and Characterization

The syntheses of **2a** and **2b** and **3a** and **3b** are shown in Schemes 3 and 4, respectively. The preparation is a simple one-step reaction that gives the products in high yields. In the process of preparing **2**, however, we were surprised to find that irrespective of whether pyridine or 2,2′-pyridine was used, the same products were obtained (spectral characterization and microanalyses). It seems that pyridine and 2,2′-pyridine serve as bases in the formation of **2a** and **2b**, and that these bases are necessary to assist hydrolysis at the zinc(II) cations, which acts as a Lewis acid under the conditions of the experiments.

3a, 3b

Scheme 4. Synthesis of compounds **3a** and **3b**

Related infrared and mass spectroscopic data of all compounds indicate the existence of macrocyclic skeletons together with perchlorate anions. In addition, strong broad bands for the O−H stretching vibration of the bridging hydroxyl groups are observed at 3512 cm^{-1} for **2a** and 3533 cm^{-1} for **2b**. The hydrogen atoms belonging to the macrocyclic rings are also observed in the ^1H NMR spectra of **2a** and **2b**, although the nature of the self-assembly products can only be clearly determined from the ^1H NMR spectra of **3a** and **3b**, which demonstrate the presence of hydrogen atoms linking to quinoline rings apart from the macrocycle. However, this routine spectroscopic analysis could not provide the detailed information necessary to determine the structures of the products here.

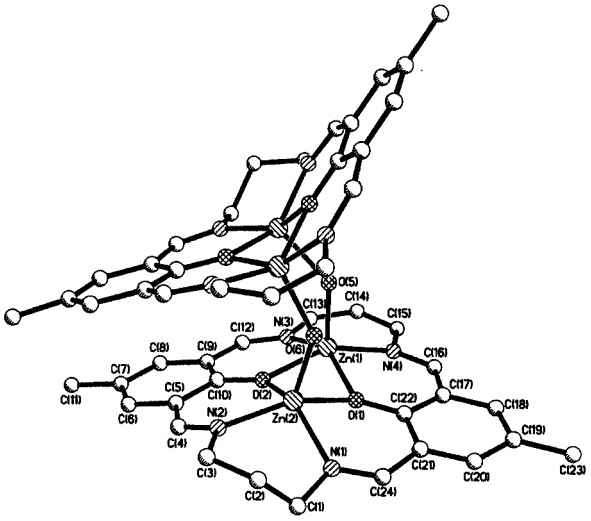
Structural Description of $\{[Zn_4L^a{}_2(OH)_2]_2(ClO_4)_2(H_2O)_2\cdot CH_3OH\}$ (2a) and $\{[Zn_4L^b{}_2(OH)_2](ClO_4)_2(H_2O)_2C_2H_5OH\}$ (2b)

The X-ray structural analysis of **2a** and **2b** shows that both compounds have a unique open-mouthed sandwich-like structure consisting of two macrocyclic covers with two bridging OH groups in the middle (Figure 1). There are two crystallographically independent $[Zn_4L^a{}_2(OH)_2]^{2+}$ (see Scheme 1) ions per asymmetric unit in **2a** with one methanol, two water molecules, and four perchlorate anions noncoordinating. The structure of **2b** has only one crystallographically independent $[Zn_4L^b{}_2(OH)_2]^{2+}$ moiety in the asymmetric cell; one ethanol, two water molecules as well as two perchlorate anions are free from coordination and located in the lattice. The change of the substituted functional group leads to a modification of the crystal system and space group from monoclinic ($P2_1/c$) in **2a** to triclinic

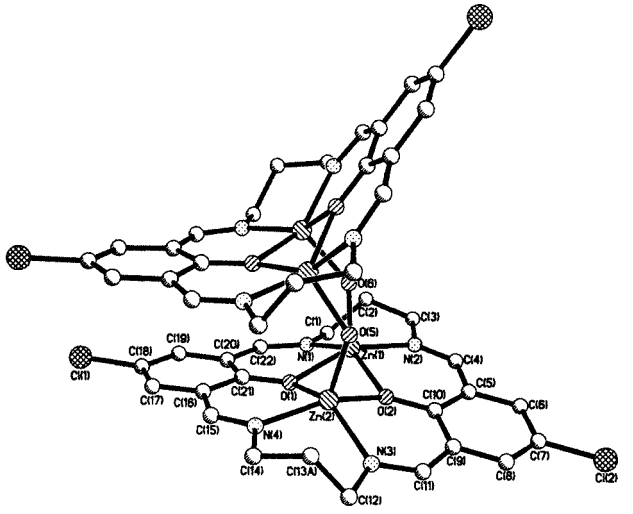
($P\bar{1}$) in **2b**. In complexes **2a** and **2b**, all metal atoms have similar pyramidal configurations where each zinc(II) atom is situated slightly above the base plane composed of two imine nitrogen atoms and two phenolic oxygen atoms, with the axial position occupied by one OH group. Each macrocyclic framework is folded to fit the requirement of two Zn−OH−Zn bond angles [**2a**: 133.6(3)°, 137.8(3)°; **2b**: 133.3(3)°, 141.8(3)°]. In each subunit of one molecule, one part of one ring is nearly parallel to its counterpart in the other one (with a dihedral angle of 9.1° in **2a** and 0.2° in **2b**), while the other parts of the two rings are bent in the opposite position to a certain degree (with a dihedral angle of 42.8° in **2a** and 56.5° in **2b**). The geometric data of the two compounds with respect to the hydroxyl groups are given in Table 1; the average Zn−O (bridging OH) distances are 1.946 Å for **2a** and 1.933 Å for **2b**.

Although the two compounds have similar molecular structures, they have different packing in their crystals (Figure 2) because of the different substituted groups in their macrocyclic backbones. In **2a** there seems to be no intermolecular interactions, whereas in the crystal structure of **2b**, two adjacent chlorine atoms on benzene rings of two different macrocyclic frameworks and their α-positioned hydrogen atoms in phenyl rings are involved in nonclassical C−H···Cl intermolecular interactions in an end-to-end fashion. Thus a 1-D chain structure is formed with the assistance of eight-membered ring structures containing two C−H···Cl H-bonds. There have been a few reports on C−H···X hydrogen bonds in organic and organometallic compounds (where X can be covalently bound atoms or anions),[7] but whether chlorine atoms can be H-bonding acceptors or not is still controversial.[8] Alhough the existence of C−H···Cl hydrogen bonds is questioned, a statistical survey on more than one hundred crystal structures containing structural patterns similar to that in **2b** showed that this kind of intermolecular interaction is not uncommon, and molecular orbital calculations on the energetics of this structural pattern supported the qualitative observation as well.[9] The length of the C−H···Cl intermolecular interactions in our compound agrees well with those reported previously, except that the intermolecular Cl···Cl distances are slightly longer.[10] Thus it is proposed that the different packing in **2a** and **2b** arises from the different substituted groups on the phenyl rings.

It is interesting to observe that each structure shows a rectangular Zn_4 array containing a rigid Zn_4O_4 cavity in both compounds (Figure 3). This arrangement is similar to that reported by Asato et. al in which a tetranuclear zinc(II) complex was synthesized by a template condensation.[11] The related geometric data are listed in Table 2. The cavity is so small that neither solvent molecules nor perchlorate anions can be hosted. In contrast to the situation with 4,4′-bipyridine, pyridine ligands could not be bound to the zinc(II) atoms on the macrocyclic platform to yield a six-coordinate geometry via π−π interactions of the pyridine rings. The reason for this may be that single Zn−N(pyridine) bonds would be freely rotating and therefore they could not be fixed onto the macrocycle due to the spatial repulsion.



2a



2b

Figure 1. Ball-and-stick representation of the structures of complex cations from **2a** and **2b**; only one of the two tetranuclear clusters from **2a** is shown as they are very similar

This means that monofunctional aromatic ligands cannot take the place of the 4,4′-bipyridine ligands, which are framed with the assistance of the macrocyclic skeleton. It is likely that the absence of 2,2′-bipyridine from the macrocyclic framework is also due to the steric hindrance between aromatic rings. Therefore, in the above two cases, small-sized hydroxyl groups from the solution function as bridges to link two macrocyclic species by coordinating to zinc(II) atoms. Regarding the five-coordinate geometry of zinc(II) atoms in **2**, our prior and current research[2,12] indicates that five-coordinate configuration is preferred if linear monofunctional or bifunctional nonaromatic ligands are used. However, unlike **2**, these nonaromatic ligands will occupy the axial position of the pyramid around the two zinc(II)

atoms in a *trans* position of the macrocycle to decrease steric repulsion. It should be noted that there is a π−π interaction between parts of two rings in **2**; this is believed to strengthen two hydroxyl groups connecting the metal atoms in the same direction of the macrocycle.

Structural Description of $\{[Zn_2L^a(H_2O)_2(C_{10}H_9N)_2](ClO_4)_2\}$ (3a)

A single crystal X-ray diffraction study confirmed that the coordination geometry about the two metal atoms in compound **3a** is the same as that in **1**, with two water molecules occupying two apical positions at the opposite side of the macrocyclic plane like **3b** (Figure 4), although the position of the substituted methyl group is different in **3a** and **3b**. There are two crystallographically independent half molecules $[Zn_2L^a(H_2O)_2(C_{10}H_9N)]^{2+}$ in the asymmetric unit, each half molecule being related to another half by a centre of symmetry, giving a total of two molecules in the unit cell. The main bond lengths and angles of complex **3a** are given in Table 3. The zinc(II) atom is situated slightly above the N_2O_2 plane and each metal may be considered as distorted square pyramidal. It has also been clearly observed that two nitrogen atoms from two 2-methylquinoline molecules are linked to two coordinating water molecules above and below the macrocyclic framework, through hydrogen bonds. The resulting two N···H−O hydrogen bonds are the same with N···H, H−O, and N···O lengths of 1.865 Å, 0.809 Å, and 2.663 Å, respectively, and an N···H−O angle of 169.13°. It is very interesting to note that two hydrogen-bonded quinoline rings are found in an almost parallel position to the phenyl ring in the macrocyclic plane (with a dihedral angle of 6.3°). Moreover, they lie in a face-to-face fashion with the adjacent macrocyclic frameworks on their other side. The two quinoline rings situated between two macrocycles are strictly coplanar to each other (with a di-

hedral angle of 0.0°), forming an ordered arrangement where one macrocycle and two 2-methylquinolines are alternately arrayed (Figure 5). The separations between the macrocyclic and quinoline rings are all about 3.6 Å. It is proposed that π−π interactions are present between quinoline and phenyl species in the macrocyclic skeleton, where the electron-rich quinoline moiety (uncoordinated) acts as a donor and the electron-poor phenyl species (owing to the coordination of the macrocyclic ligand) as acceptors. It is suggested that both the π−π interactions and the H-bonding interactions dominate such a stacking structure.

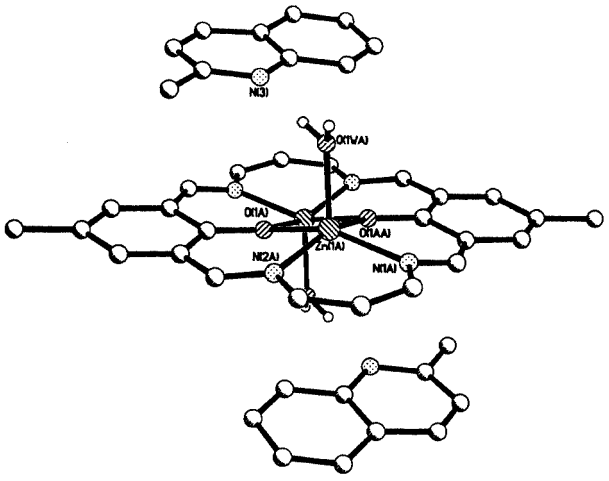

Figure 4. Ball-and-stick representation of the structure of one of the centrosymmetric complex cations from **3a**; only one of the two dinuclear clusters is shown as they are very similar

Our previous studies show that the coordinating water molecules on two sides of the macrocyclic framework can be replaced by a ligand if linear inorganic ligands or organic alkyl ligands are allowed to react with **1**.[12] However, based on the results of **2**, monofunctional aromatic ligands such as pyridine cannot be bonded to the metal atom of **1** at the vertical direction only by one-end coordination bonding, nor can the bidentate chelating ligand 2,2′-bipyridine. This may arise from the spatial repulsion between the macrocycle and the aromatic ring. Such a repulsion could be overcome, however, to permit coordination if extra forces are introduced such as hydrogen bonding or π−π interactions to support the system.[5,6] While in compound **3a** 2-methylquinoline cannot be coordinated directly to the zinc(II) atoms because of its further steric repulsion, it instead adopts a parallel way of interacting with its neighboring macrocyclic plane via π−π forces while, at the same time, forming a hydrogen bond with one macrocyclic unit. The electron transfer from the conjugated system of the macrocycle to the central zinc(II) atom upon coordination assists in forming this kind of arrangement. To the best of our knowledge, **3a** and **3b** are unprecedented examples where a macrocyclic dinuclear metal component serves as an acceptor to produce donor-acceptor compounds sustained by hydrogen bonds.

In recent years, progress in the study of the aggregation of molecular building blocks by self-assembly has risen dramatically, and several studies indicate that the results of self-assembly and the topology of metal-ligand frameworks are mainly upon the application of specific center metal atoms and well-built organic ligands.[13] In our series of experiments, the effect of the coordination geometry of the zinc atom in **1** has been investigated. Based on these and previous results, it is suggested that the coordination behavior of

the metal atom plays an important role in the assembly pattern of **1** with aromatic building blocks.

Experimental Section

Materials and General Methods: The perchlorate salts of **1a** and **1b** were prepared in the same manner as reported previously.[12] All other solvents and chemicals were of analytical grade and used without further purification.

Elemental analyses were measured with a Perkin−Elmer 1400C analyser. Infrared spectra (4000−400 cm^{-1}) were recorded on a Nicolet FT-IR 170X spectrophotometer. ^1H NMR spectra were obtained on a Bruker 500 MHz NMR spectrometer. Electrospray ionization (ES) mass spectra were performed in CH_3CN/CH_3OH on a Finnigan MAT SSQ 710 mass spectrometer in a scan range 300−1200 amu.

Caution! *Although no problem was encountered in all our experiments, transition metal perchlorates are potentially explosive and should be handled in small quantities.*

Preparation

2a: Pyridine (0.08 g, 1 mmol) was added to a solution of **1a** perchlorate (0.37 g, 0.5 mmol) in ethanol (30 cm^3). The solution was refluxed for 1 h, and then cooled to room temperature. Yellow crystal products were obtained, which were washed with a small amount of ethanol and dried in a vacuum. Yield 0.29 g (87%); Elemental analyses: $[C_{48}H_{52}N_8O_4Zn_4(OH)_2](ClO_4)_2(C_2H_5OH)(H_2O)_2$ (M = 1381.53): calcd. C 44.04, H 4.58, N 8.22; found C 44.16, H 4.81, N 8.21%. IR (KBr): $\tilde{\nu}$ [cm^{-1}]: 3512 s (O−H), 1641 s (C=N), 1088 vs and 623 s (ClO_4^-). ES-MS: m/z = 632 $[(Zn_2C_{24}H_{26}N_4O_2)(ClO_4)]^+$ (100%). ^1H NMR (500 MHz, D_2O, 25 °C, TMS) [ppm]: δ = 2.15 (m, 8 H, CH_2), 2.30 (s, 12 H, CH_3), 4.05 (t, 16 H, CH_2), 7.44 (s, 8 H, phenyl), 8.36 (s, 8 H, HC=N).

2b: This preparation is similar to that of **2a**, except that **1b** perchlorate (0.37 g, 0.5 mmol) and 2,2′-bipyridine (0.16 g, 1 mmol) were used. Yield 0.29 g (84%); Elemental analyses: $[C_{44}H_{40}N_8O_4Cl_4Zn_4(OH)_2](ClO_4)_2(C_2H_5OH)(H_2O)_2$ (M = 1463.20): calcd. C 37.76, H 3.58, N 7.66; found C 37.51, H 3.36, N 7.43%. IR (KBr): $\tilde{\nu}$ [cm^{-1}]: 3533 s (O−H), 1643 s (C=N), 1083 vs and 623 s (ClO_4^-). ES-MS: m/z = 337 $\{[(Zn_2C_{22}H_{20}Cl_2N_4O_2)(HClO_4)]^{2+}\}/2$ (100%). ^1H NMR (500 MHz, D_2O, 25 °C, TMS) [ppm]: δ = 2.16 (m, 8 H, CH_2), 4.05 (t, 16 H, CH_2), 7.64 (s, 8 H, phenyl), 8.36 (s, 8 H, HC=N).

3a: 2-Methylquinoline (0.14 g, 1 mmol) was added to an ethanol solution (30 cm^3) of **1a** perchlorate (0.37 g, 0.5 mmol). The solution was refluxed for 1 h and then cooled to room temperature. The yellow precipitate was filtered, washed with a small amount of ethanol, and dried in vacuum. Yield 0.45 g (88%); Elemental analyses: $[C_{24}H_{26}N_4O_2Zn_2(H_2O)_2(C_{10}H_9N)_2](ClO_4)_2$ (M = 1054.56): calcd. C 50.11, H 4.59, N 7.97; found C 50.28, H 4.64, N 7.86%. IR (KBr): $\tilde{\nu}$ [cm^{-1}]: 3377 s (O−H), 1640 s (C=N), 1087 vs and 625 s (ClO_4^-). ES-MS: m/z = 591 $[ZnNaHLClO_4]^+$ (100%). ^1H NMR (500 MHz, D_2O, 25 °C, TMS) [ppm]: δ = 2.26 (m, 4 H, CH_2), 2.43(s, 6 H, CH_3), 2.89 (s, 6 H, CH_3 of quinoline ring), 4.14 (t, 8 H, CH_2), 7.57 (s, 4 H, phenyl), 7.68−8.12 (m, 8 H, quinoline ring), 8.48 (s, 4 H, HC=N), 8.55 (m, 4 H, quinoline ring).

3b: The preparation is analogous to **3a** except that that 8-methylquinoline (0.14 g, 1 mmol) was employed. Yield: 0.46 g (90%). Elemental analyses: $[C_{24}H_{26}N_4O_2Zn_2(H_2O)_2(C_{10}H_9N)_2](ClO_4)_2$ (M = 1054.56): calcd. C 50.11, H 4.59, N 7.97; found: C 50.44, H 4.73, N 8.21. IR (KBr): $\tilde{\nu}$ [cm^{-1}]: 3375 s (O−H), 1641 (C=N), 1087 vs and 624 s (ClO_4^-). Es-ms: m/z = 591 $[ZnNaHLClO_4]^+$ (100). ^1H NMR (500 MHz, D_2O, 25 °C, TMS) [ppm]: δ = 2.25 (m, 4 H, CH_2), 2.41 (s, 6 H, CH_3), 2.84 (s, 6 H, CH_3 of quinoline ring), 4.16 (t, 8 H, CH_2), 7.55 (s, 4 H, phenyl), 7.65−8.10 (m, 8 H, quinoline ring), 8.46 (s, 4 H, HC=N), 8.55 (m, 4 H, quinoline ring).

Crystallography

Single crystals of all compounds suitable for X-ray diffraction measurements were grown from their ethanol/methanol solutions. The molecular structure of **3b** has been reported elsewhere where only 8-methylquinoline was used to assemble **1a**.[14] Because crystals of **2a**, **2b**, and **3a** are very unstable in the absence of their mother liquors, their single-crystal samples were covered in glue before measurements. Reflection data for three crystals were measured by a Bruker SMART 1K CCD diffractometer system at 293(2) K by using graphite monochromated Mo-K_α radiation (λ =

0.71073 Å). The data were collected by using SMART and reduced with the program SAINT.[15] Empirical absorption correction was done by using the SADABS program.[16] All structures were solved by direct methods and refined by least-squares method on F^2_{obs} with the SHELXTL-PC software package.[17] All non-H atoms, except the oxygen atoms from two perchlorate ions and solvent molecules in **2b**, were refined anisotropically. The hydrogen atom positions were fixed geometrically and allowed to ride on the attached atoms. One middle carbon atom of the 1,3-diaminopropane in one macrocyclic unit in **2b** was found to be disordered over two sites, with an occupancy of 0.48(3) and 0.52(3) for C-13. Crystal data and structural refinement for three compounds are listed in Table 4.

CCDC-140749 (**2a**), -140750 (**2b**), and -157365 (**3a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Photophysical Properties of Hybrid Metal Complexes Containing both 2,2′-Bipyridine and 2,2′:6′,2′′-Terpyridine Units

Anthony Harriman,*[a] Muriel Hissler,[b] Abderrahim Khatyr,[b] and Raymond Ziessel[b]

Keywords: Luminescence / Photophysics / Molecular electronics / Energy transfer

Stepwise cross-coupling reactions between functionalized metallo synthons and bipyridine- or terpyridine-based building blocks afford novel photoactive, hybrid complexes bearing multiple chromophores that function separately or cooperatively according to the nature of the coordinated metal cations.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Many (polypyridine)ruthenium(II) complexes possess photophysical and electrochemical properties suitable for the putative construction of luminescent sensors and/or photoactive molecular-scale devices.[1−3] A large number of mono- and multinuclear complexes are now known, notably built around 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen), or 2,2′:6′,2′′-terpyridine (terpy) ligands, and have been used for various applications.[4−6] The terpy-based ligands are especially useful for the design of linear multicomponent systems but, because of its very short-lived triplet excited state, the parent $[Ru(terpy)_2]^{2+}$ complex has found little use in photoactive devices.[7] Different strategies have been devised[8] for prolonging the triplet lifetime of $[Ru(terpy)_2]^{2+}$, and dinuclear derivatives have been identified that exhibit reasonable emission yields in deoxygenated solution at 20 °C.[9,10] The most successful approach for prolonging the triplet lifetime of $[Ru(terpy)_2]^{2+}$ involves direct attachment of an alkynylene group at the 4′-position of the coordinated terpy ligand.[11] We now show that this strategy can be used to generate hybrid metal complexes containing Ru(terpy) and Ru(bpy) metallo terminals linked by a single ethynylene group. The resultant dinuclear complex exhibits photophysical properties suggestive of a highly delocalized triplet state.

Results and Discussion

The target complex **RBTR**, together with appropriate reference complexes **RBT** and **RTB**, could not be prepared from the free **BT** ligand[12] by conventional synthetic protocols, but was accessible by iterative Sonogashira-type coupling reactions starting from the relevant metallo synthon, as shown in Figure 1. These cross-coupling reactions proceed smoothly under mild conditions in the presence of a catalytic amount of $[Pd(PPh_3)_4]$ and acetonitrile. It is noteworthy that **RBTR** could be constructed either from the **RTB** or **RBT** precursors, while the mixed **RBTO** species was only obtained from the **RBT** metallo synthon. Interestingly, during the first step (a), when the leaving group (Br) is grafted onto the ruthenium complex the rate of the cross-coupling reaction is significantly enhanced due to the pronounced electron-withdrawing effect of the metal center. However, no major difference in reactivity was observed during cross-coupling of the ethynylene-grafted Ru(bpy) complex with either the bromo- or triflate-substituted terpy fragments (step c). The tripartite complex **RBTZ** was prepared from **RBT** using a slight excess of zinc(II) perchlorate. All compounds were isolated by column chromatography and characterized by FT-IR, ES mass, ^1H and ^{13}C NMR spectra, and elemental analyses. These compounds are stable and reasonably soluble in polar organic solvents. All compounds were studied as their hexafluorophosphate salts in deoxygenated acetonitrile and the chemical structures are depicted in Figure 1.

The photophysical properties recorded for the mononuclear reference compounds were as expected for ethynylene-substituted (polypyridine)ruthenium(II) complexes (Table 1). In particular, each compound shows a pronounced metal-to-ligand charge-transfer (MLCT) absorption transition (λ_{max}) in the region 450−500 nm, for which the molar absorption coefficient (ε_{MLCT}) at the band maximum is reminiscent of related mononuclear com-

Figure 1. plexes.[13,14] Luminescence is readily detected at 20 °C and, by reference to other (polypyridine)ruthenium(II) complexes,[7] can be assigned to emission from the (nominally) triplet excited MLCT state. Luminescence maxima (λ_{lum}), quantum yields (Φ_{lum}), and lifetimes (τ_{lum}) are similar to those recorded earlier for ethynylene-substituted complexes formed from bpy or terpy ligands in deoxygenated acetonitrile. In all cases, the corrected luminescence excitation spectrum agrees well with the absorption spectrum recorded over the range 250−600 nm and emission decay profiles are well described by a mono-exponential fit.

There are two important points to note from these experimental data. First, emission from the Ru(bpy) unit is much more pronounced and longer-lived than that from the corresponding Ru(terpy) fragment. Such behavior is normal and has been attributed to mixing between MLCT triplet and metal-centered states that promotes nonradiative deactivation in Ru(terpy) systems.[15] Second, the luminescence maximum found for the Ru(terpy) unit is red-shifted by ca. 30 nm with respect to that of the Ru(bpy) fragment, suggesting that the latter possesses the higher triplet energy. In fact, the individual luminescence profiles are readily analyzed in terms of a spectral curve-fitting routine[15] that permits accurate calculation of the triplet energies (E_T). This analysis confirms that the triplet state associated with the Ru(terpy) unit lies at lower energy (Table 1) but indicates that the energy gap between these two triplets is rather small ($\Delta E_T = 1100\ cm^{-1} \approx 5\ k_BT$). The same analysis allows calculation of the reorganization energy (λ_T) that accompanies deactivation of the MLCT triplet state and the Huang−Rhys factor (*S*). It can be seen that both values are substantially higher for **RBT** than for **RTB**, indicating that the former undergoes a more significant geometry change upon excitation to the triplet state.[7]

Table 1. Photophysical properties recorded for the various metal complexes in deoxygenated acetonitrile at 20 °C

Property	**RBT**	**RTB**	**RBTO**[a]	**RBTZ**	**RBTR**
λ_{MLCT} [nm][b]	461	490	505	475	506
ε_{MLCT} [$M^{-1}\cdot cm^{-1}$][c]	14,400	24,900	13,900	25,100	35,200
λ_{LUM} [nm][d]	650	680	735	670	705
τ_{LUM} [ns][e]	710	75	380	1,080	350
Φ_{LUM}[e]	0.046	0.001	0.0100	0.060	0.006
E_T [cm^{-1}][f]	16,500	15,400	14,670	16,300	15,320
λ_T [cm^{-1}][f]	1,250	850	1,000	1,450	1,180
S[f]	0.95	0.60	0.70	0.98	0.85

[a] Photophysical properties refer to the osmium-based chromophore. [b] ±2 nm. [c] ±5%. [d] ±5 nm. [e] ±8%. [f] Derived from spectral curve fitting analyses.

Photophysical properties recorded for the corresponding Os(terpy) fragment in the **RBTO** complex are also given in Table 1 and indicate that the triplet state localized on this chromophore lies at significantly lower energy. These measurements were made following laser excitation at 646 nm, where only the Os(terpy) fragment absorbs. The derived values appear to be in reasonable agreement with measurements made for related Os(terpy)-based systems except that the triplet lifetime is rather long. This is probably due to extended electron delocalization at the triplet level.

In fact, the mixed-metal hybrid complex **RBTO** displays a clear indication of intramolecular triplet energy transfer. Thus, the emission spectrum recorded in deoxygenated acetonitrile at 20 °C is characteristic of emission from an Os(terpy) fragment,[16] the peak being at 735 nm, and is independent of excitation wavelength. The corrected excitation spectrum is in excellent agreement with the absorption spectrum recorded across the entire visible range. There is no obvious emission from the Ru(bpy) fragment following excitation around 460 nm, where the latter is the dominant chromophore, and the emission decay profile, recorded after excitation with a 10-ns laser pulse at 460 nm, follows first-order kinetics at all wavelengths. The average triplet lifetime recorded for the Os(terpy) fragment following laser excitation at 460 nm is 410±25 ns, which is similar to that recorded after direct excitation of the Os(terpy) fragment at 646 nm ($\tau_T = 380\pm20$ ns). There is a reasonable thermodynamic driving force for intramolecular energy transfer from the Ru(bpy) unit to the appended Os(terpy) fragment ($\Delta E_T = 1830\ cm^{-1}$).

Excitation of **RBTO** with a sub-ps laser pulse at 460 nm causes a biphasic bleaching of the Os(terpy) chromophore at 500 nm (Figure 2). Approximately 40% of this bleaching occurs within the laser pulse and can be attributed to direct absorption by the Os(terpy) fragment. The remainder bleaches on a time scale of several tens of ps, corresponding to a first-order process of $7\pm2\times10^{10}$ s^{-1}, which is assigned to intramolecular triplet energy transfer from the Ru(bpy) unit. This rate is similar to those observed for other ethynylene-bridged Ru−Os systems.[16]

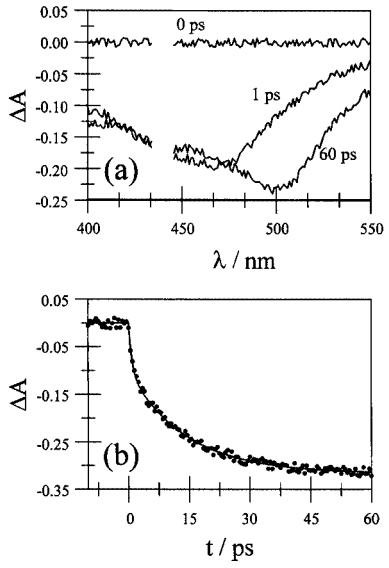

Figure 2. (a) Differential transient absorption spectra recorded at various delay times for **RBTO** in deoxygenated acetonitrile at 20 °C; the excitation source was a sub-ps laser pulse at 460 nm; (b) kinetic trace recorded at 500 nm for the experiment described in (a) above; the solid points refer to the experimental data while the line drawn through the points corresponds to a fit to a two-exponential growth process having time constants of 0.8 (38%) and 14 (62%) ps, respectively

It is normal practice to consider that intramolecular triplet energy transfer in such systems might occur by either the Dexter electron-exchange[17] or the Förster dipole-dipole[18] mechanisms, or by a combination of both processes. Using spectroscopic data collected for **RBT** and the Os(terpy) fragment present in **RBTO**, the Förster spectral overlap integral (J_F) for energy transfer along the molecular axis in **RBTO** was calculated[18] to be 2.8×10^{-14} $mmol^{-1}$ cm^6. Using this latter value in conjunction with the photophysical properties recorded for **RBT**, the rate constant for dipole-dipole energy transfer in **RBTO** is calculated to be ca. 10^8 s^{-1}, for random orientations of the two terminals. Although fast, this rate is well below the experimental value. As such, we conclude that the dominant mechanism for triplet energy transfer in **RBTO** involves through-bond electron exchange.

Assuming energy transfer occurs by electron exchange and that the Franck−Condon factor ($FC = 1.5\times10^{-4}$ cm) can be determined[15] from emission spectra recorded for the relevant subunits, it is possible to calculate the electronic coupling matrix element (V_{DA}) for this system by application of the Fermi−Golden rule[19] [Equation (1)]. The derived value ($V_{DA} = 6$ cm^{-1}) is in keeping with earlier observations.[20] These findings can be used to argue that the mixed-metal hybrid complex **RBTO** comprises two separate chromophores and that, in terms of photophysics, it can be regarded as a closely-spaced molecular dyad. The long triplet lifetime found for the Os(terpy) fragment might indicate that the ethynylene group possesses increased electron density at the MLCT triplet level.

$$k_D = \frac{2\pi}{\hbar}|V_{DA}|^2 FC \quad (1)$$

The photophysical properties of the tripartite complex **RBTZ** (Table 1) can be understood in terms of the coordinated zinc(II) cation extending the degree of electron delocalization over the bridging ligand. Thus, binding of zinc(II) cations to the vacant terpy ligand will lower the LUMO energy of the bridging ligand.[20] This has the effect of increasing blending between orbitals on the bpy and terpy ligands, thereby favoring electron delocalization at the triplet level. The effect is apparent from the red-shifted absorption and emission spectra and from the prolonged triplet lifetime found for **RBTZ** relative to **RBT**. There is a slight decrease in triplet energy (E_T) but a more substantial increase in the reorganization energy (λ_T). The latter effect is characteristic of increased electron delocalization.[7]

Understanding the photophysical properties of the dinuclear hybrid complex **RBTR** is more demanding and it is unclear if this system behaves as two closely coupled but separate units or as a single giant supermolecule. The absorption spectrum (Figure 3) contains indications of MLCT transitions associated with both Ru(bpy) ($\lambda_{MLCT} \approx 450$ nm) and Ru(terpy) ($\lambda_{MLCT} \approx 500$ nm) fragments, together with ligand-centered transitions around 300 nm. This spectrum is in reasonable agreement with a superposition of spectra recorded for **RBT** and **RTB**.[21] The emission spectrum recorded at 20 °C, which is centered around 705 nm, differs markedly from that recorded for a 1:1 molar mixture of **RBT** and **RTB** (Figure 3). This spectrum is independent of excitation wavelength, the corrected excitation spectrum agrees well with the absorption spectrum recorded across the entire visible region, and the emission decay profile follows exponential kinetics, regardless of excitation or detection wavelengths, following excitation with a 10-ns laser pulse. The average emission lifetime in deoxygenated acetonitrile is 350 ns while the luminescence quantum yield is 0.006. These values, except for the triplet lifetime, are more in keeping with **RTB** than **RBT** (Table 1).

The emission spectrum recorded for **RBTR** at room temperature was analyzed[15] as above to give a value for the triplet energy (E_T) that is closely similar to that derived for **RTB** (Table 1). The hybrid compound, however, gave an increased reorganization energy (λ_T) and a larger Huang−Rhys factor (S) than that found for the relevant mononuclear complex **RTB**. In fact, these derived values lie between those observed for **RBT** and **RTB**. Given the small triplet energy gap between these latter two complexes, the

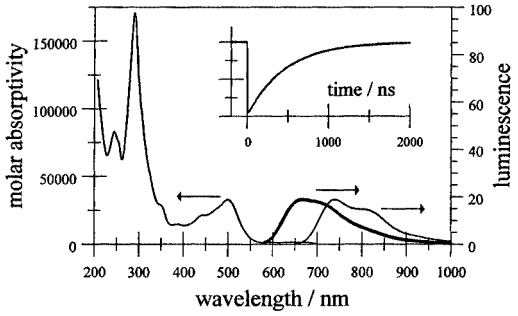

Figure 3. Absorption and emission spectra recorded for **RBTR** in deoxygenated acetonitrile at 20 °C; also shown (solid curve) is the emission spectrum recorded for a 1:1 molar mixture of **RBT** and **RTB** under identical conditions; the excitation wavelength for emission studies was 480 nm; the insert shows the luminescence decay profile recorded at 700 nm

emission spectrum recorded for **RBTR** might be considered to comprise an equilibrium mixture of the two triplets associated with the mononuclear terminal complexes. Taking ΔE_T to be 1100 cm^{-1}, the equilibrium mixture of triplet states would be completely dominated (i.e. 99.6%) by the triplet associated with **RTB**. Allowing for the difference in emission quantum yields found for these terminals, it can be concluded that the luminescence spectrum of the hybrid complex would contain a major contribution (i.e. 85%) from **RTB** and a minor portion (i.e. 15%) from **RBT**. Spectral analysis shows that this is not the case and, instead, the emission spectrum appears to be that of a single chromophore. It is also evident that the decay kinetics recorded at all wavelengths are best fitted by a single-exponential analysis. There is no rapidly decaying component in the kinetic traces; based on the spectral parameters derived for **RBT** and **RTB**, and taking V_{DA} to be 6 cm^{-1}, we would expect triplet energy transfer from **RBT** to **RTB** to occur on a time scale of ca. 30 ps. There is no obvious indication of intramolecular triplet energy transfer on this time scale; the inference being that **RBTR** behaves as a single giant emitter.

A similar conclusion is reached from analysis of the transient absorption spectrum recorded after laser excitation of **RBTR** at 460 nm (Figure 4). Thus, the differential absorption spectrum recorded for **RBTR** in deoxygenated acetonitrile differs markedly from those recorded for the reference compounds under identical conditions. There is strong absorption in the near IR region and bleaching in the MLCT region, especially around where the Ru(terpy) subunit is expected to absorb. This latter observation indicates that the triplet state is primarily of MLCT character and is not a π,π^* state localized on the polytopic ligand. The near-IR differential absorption bands appear as two distinct peaks. Whilst the lower-energy peak centered around 900 nm has some resemblance to the near-IR peak seen for **RTB** the higher-energy peak centered around 650 nm is not apparent in the spectra recorded for either **RTB** or **RBT** (Figure 5). The signal decays by first-order kinetics, with an averaged lifetime of 350±15 ns, at all monitoring wavelengths. Examination of the spectrum on very short time scales indicates that the signal evolves over a few ps but does not undergo any obvious changes in profile that might be consistent with intramolecular triplet energy transfer from **RBT** to **RTB** units. Again, the conclusion is that, at the triplet level, **RBTR** behaves more like a single chromophore than a closely-coupled admixture of two discrete MLCT triplet states.

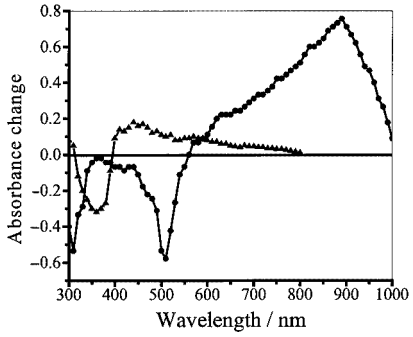

Figure 5. Transient absorption spectra recorded for **RBT** (black triangle) and **RTB** (black circle) in deoxygenated acetonitrile solution following excitation with a 10-ns laser pulse at 460 nm

Conclusion

In summary, the hybrid **BT** ligand introduced here can give rise to several distinct triplet states upon coordination of a metal cation. Either chelate can be capped with a suitable metallo fragment to produce **RBT** or **RTB**, where the lowest-energy, triplet excited state is of MLCT character and is localized on the capped terminal. Coordinating zinc(II) cations to the vacant terpy-based terminal in **RBT** gives rise to the tripartite, mixed-metal complex **RBTZ**, where the triplet state is of MLCT character but is more extensively delocalized than in **RBT**. The mixed-metal complex **RBTO** displays rapid intramolecular triplet energy transfer and the lowest-energy triplet is clearly localized on the Os(terpy) unit. For **RBTR**, the two terminals are of comparable energy, both in terms of redox chemistry and excitation energies, and it appears that the lowest-energy triplet excited state is extensively delocalized.

Experimental Section

Synthesis of RTB: Acetonitrile (4 mL), diisopropylamine (1.5 mL), and $[Pd(PPh_3)_4]$ (6 mol %, 0.008 g, 0.006 mmol) − a catalyst precursor − were added consecutively to a stirred solution containing $[Ru(terpy)(4'\text{-ethynyl-terpy})](PF_6)_2$[22] (0.080 g, 0.090 mmol) and 5-bromo-bpy[23] (0.022 g, 0.090 mmol) in Ar-degassed benzene (10 mL). After heating at 90 °C for 4 d, KPF_6 (0.034 g, 0.18 mmol) was added and the solvent removed under vacuum. The deep-red material was washed with water under centrifugation and the resultant solid was purified by flash chromatography on silica gel, first with a mixture of acetonitrile/water (0−10%) as eluent and secondly with a mixture of acetonitrile/water (0−10%) having a gradient of a saturated aqueous solution of KNO_3 as eluent. Metathesis of the anion was ensured using an excess of KPF_6 in an acetone/water mixture. The solid sample was collected, washed with diethyl ether and dried under vacuum. Yield 0.046 (48%). ^{1}H NMR ([D$_6$]acetone): δ = 9.11−9.01 ppm (m, 3 lines, 4 H), 8.91 (t, ^3J = 7.3 Hz, 4 H), 8.69 (s, 1 H), 8.53 (t, ^3J = 7.9 Hz, 3 H), 8.18 (d, ^3J = 12.8 Hz, 1 H), 8.04 (q, ^3J = 14.0 Hz, 4 H, ^3J = 7.1 Hz), 7.77 (d, ^3J = 5.4 Hz, 2 H), 7.65 (d, ^3J = 5.2 Hz, 2 H), 7.31 (q, ^3J = 6.1 Hz, 4 H), 6.98 (d, ^3J = 7.0 Hz, 1 H), 6.43 (d, ^3J = 12.8 Hz, 1 H), 6.89 (d, ^3J = 7.0 Hz, 1 H). ES-MS (acetone): *m*/*z* = 890.6 [M − PF_6, calcd. 890.8], 372.6 [(M − 2 PF_6)/2, calcd. 372.9]. $C_{42}H_{28}F_{12}N_8P_2Ru$ (1035.74): calcd. C 48.71, H 2.72, 10.82; found C 48.56, H 2.42, N 10.51.

Selected Data for RBTR: ES/MS (acetone): *m*/*z* = 724.9 [(M − 2 PF_6)/2, calcd. 724.6], 434.9 [(M − 3 PF_6)/3, calcd. 434.7], 290.0 [(M − 4 PF_6)/4, calcd. 289.8]. $C_{62}H_{44}F_{24}N_{12}P_4Ru_2{\cdot}CH_3CN$ (1739.12 + 41.05): calcd. C 43.18, H 2.66, 10.23; found C 43.26, H 2.72, N 10.38.

Selected Data for RBTO: ES/MS (acetone): *m*/*z* = 769.5 [(M − 2 PF_6)/2, calcd. 769.2], 464.5 [(M − 3 PF_6)/3, calcd. 464.4], 312.5 [(M − 4 PF_6)/4, calcd. 312.1]. $C_{62}H_{44}F_{24}N_{12}OsP_4Ru$ (1828.24): calcd. C 40.73, H 2.43, 9.19; found C 40.42, H 2.17, N 9.00.

Photophysical Studies Absorption spectra were recorded with a Hitachi U3310 spectrophotometer and emission was monitored with a Hitachi F4500 spectrophotometer. All emission spectra were fully corrected using a correction curve compiled by reference to a standard lamp. Luminescence lifetimes were measured with a Spex tau-3 time-resolved emission spectrometer. All luminescence studies were made at 20 °C using deoxygenated acetonitrile solutions. Transient absorption studies were made by laser flash photolysis using a frequency-doubled Nd-YAG laser as pump for a coumarin dye laser emitting at 460 nm. For direct excitation into the Os(terpy) chromophore at 646 nm the frequency-doubled output from the Nd-YAG laser was Raman shifted with ethanol. In each case, the pulse width was either 10 ns or 25 ps according to the needs of the experiment. Improved time resolution was achieved with a mode-locked, Nd-YAG pumped dye laser operating with Rhodamine 6G (FWHM = 350 fs). Output from the dye laser was focussed into water and the excitation pulse was isolated with a narrow-bandpass filter centered at 460 nm.

Dynamic Behavior of an *N*-Metalated β-Enaminoimine Complex − Preparation of *N*-Phosphanylenamine and β-Enaminoimine Derivatives

Alexandrine Maraval,[a] Krzysztof Owsianik,[b] Damien Arquier,[a] Alain Igau,*[a] Yannick Coppel,[a] Bruno Donnadieu,[a] Maria Zablocka,[b] and Jean-Pierre Majoral*[a]

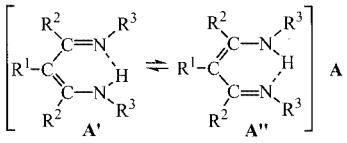
Keywords: N ligands / NMR spectroscopy / Imines / Zirconium / Metallocenes / Transmetalation

Variable-temperature NMR spectroscopy of the β-enaminoimine complex **2** showed a dynamic process which was attributed to an internal fluxional aldimido *N*-zirconated π-linear/σ-bent structure. Such an internal rearrangement has been previously proposed to occur in these systems but never observed. We have prepared a variety of (*N*-phosphanyl-β-enamino)imine ligands using the hydrozirconation/transmetalation reaction of malonodinitrile compounds $RCH(CN)_2$ (R = H, PPh_2). In addition to their potential uses in coordination chemistry, these systems are good tools for the study of intramolecular hydrogen bonding. The X-ray crystal structure of **14** at 180 K shows an unsymmetrical system with the N(H) proton localized on one of the two chelating nitrogen atoms, consistent with the existence in solution of a low barrier proton transfer process with a double-well potential.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

β-Enaminoimine derivatives have been intensively studied as members of the family of polymethine merocyanines, a fundamental group of organic dyes with a wide variety of uses. [1] Related compounds of the type **A**, also called β-diimine systems, described as "formal" six-membered rings with a chelating μ^2-H proton bridged to the nitrogen atoms, have been successfully used as ligands in coordination chemistry.[2]



Recently, we described the synthesis of the β-enaminoimine compound **2**, with a transition metal fragment bonded to the nitrogen atoms (**A**: $R^1 = R^2 = H$, $R^3 = ZrCp_2Cl$).[3] In addition to the dynamic NMR behaviour of the *N*-zirconated β-enaminoimine **2**, we present herein the preparation of *N*-phosphanylenamine derivatives and describe the formation of unsymmetrical (*N*-phosphanyl-β-enamino)imine compounds according to a hydrozirconation/transmetalation reaction sequence. We also report an X-ray crystal structure of a β-enaminoimine compound containing an unsymmetrical intramolecular hydrogen bond.

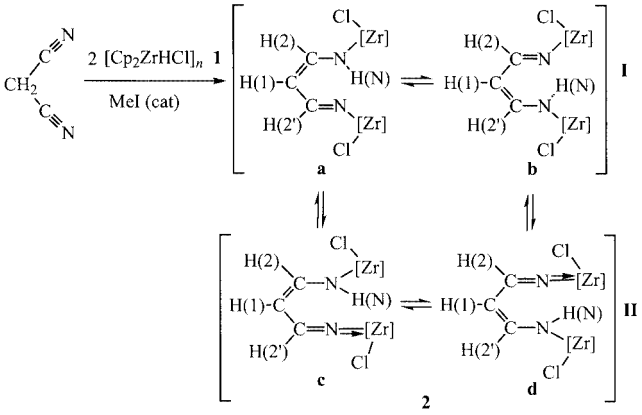
Results

The *N*-metalated β-enaminoimine compound **2** was prepared by the addition of 2 equiv. of **1** to malonodinitrile in the presence of a catalytic amount of MeI (Scheme 1).[3]



Scheme 1. Description of the different conformers of the (*N*-zircona-β-enamino)imine derivative **2** at 193 K; [Zr] = $ZrCp_2$

At 293 K, 1D ^{1}H and ^{13}C NMR spectra show only one set of signals for the two CH(2/2′)−N aldimine groups, indicative of a process that rapidly interconverts the hydrogen atoms H(2) and H(2′) on the NMR time scale. An excitation-sculpted singly selective 1D TOCSY (Figure 1)[4] allows the assignment of the signal of the H(N) proton bridged by the two nitrogen atoms of the β-enaminoimine skeleton at δ = 7.10 ppm.[5]. It was clear from this experiment that the H(N) proton was involved in an exchange having a rate in the intermediate range on the NMR time scale. The NMR spectra exhibit two singlets for the Cp groups at δ = 6.35 and 6.53 ppm (^{1}H NMR, 10 H each) and δ = 116.6 and 114.5 ppm (^{13}C NMR). Lowering of the temperature from 293 to 193 K leads to a splitting of the H(N) and H(2/2′) protons, suggesting the presence of at least two conformers (Figure 1).

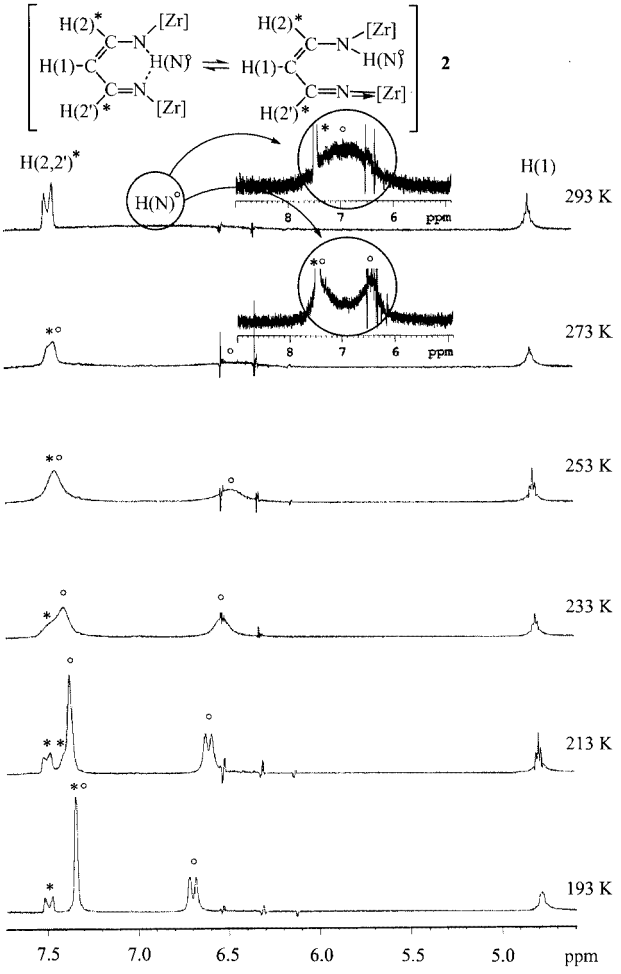


Figure 1. 1D selective TOCSY of **2** at variable temperature with excitation of H(1) (the corresponding symmetric Lewis structures are omitted for clarity); mixing time = 60 ms; [Zr] = $ZrCp_2Cl$

At 193 K the ^{1}H NMR spectrum of the CH(2/2′)−N−H(N) moiety of one of the two conformers shows a doublet of doublets at δ = 7.49 ppm [H(2/2′)] and a doublet at δ = 6.70 ppm [H(N)], with coupling constants of $^3J_{H(2/2')\text{-}H(1)}$ = 5.5 Hz and $^3J_{H(2/2')\text{-}H(N)}$ = 13.0 Hz. The ^{13}C NMR spectrum displays a peak at δ = 157.6 ppm, assigned to the aldimine carbon atom CH(2/2′). Signals due to the H(2/2′) and H(N) protons of the other conformer accidentally overlap (^{1}H at 193 K: δ = 7.34 ppm), and the outer lines of the doublets are thus no longer visible. Consequently, it was not possible to determine the different coupling constants. The ^{13}C NMR spectrum exhibits a peak at δ = 158.4 ppm [CH(2/2′)−N group]. Note that the methine CH(1) group resonances [δ = 4.78 ppm − broad peak (^{1}H); δ = 93.7 ppm (^{13}C)] and the Cp signals of **I** and **II** cannot be differentiated. The NMR spectroscopic assignments have been unambiguously confirmed by 2D NMR experiments at 193 K (gs-DQFCOSY, gs-HMQC). Note that line broadening was observed for the Cp groups, but no splitting of the signals was detected on decreasing the temperature. Exchange between the two conformers **I** and **II** was definitively established by 1D GROESY experiments (Scheme 1, Figure 2).[8]

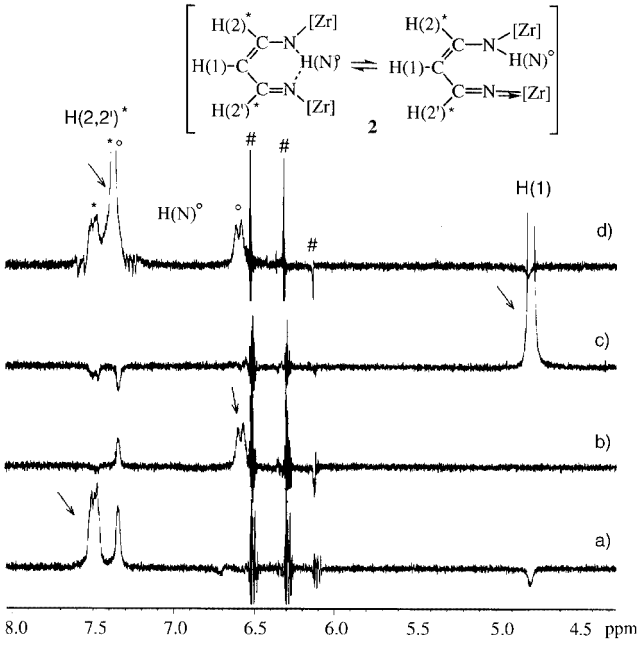

Figure 2. 1D GROESY of **2** at 193 K (the corresponding symmetric Lewis structures are omitted for clarity) with selective excitation of the site indicated by the arrow →; mixing time = 200 ms; lines denoted by # are residual signals of the Cp protons; [Zr] = $ZrCp_2Cl$

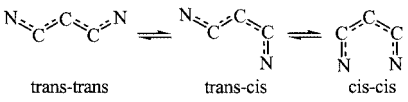
The 1D GROESY spectrum obtained on irradiation of the H(2/2′) protons of the conformer with δ = 7.49 ppm displays an exchange peak with the H(2/2′) protons of the other conformer (δ = 7.34 ppm) and an ROE enhancement (spatial proximity) with H(1) (Figure 2, a). Irradiation of the H(N) proton of the conformer with δ = 6.70 ppm gives only a positive exchange peak with the H(N) protons of the other conformer (δ = 7.34 ppm) (Figure 2, b). Finally, irradiation of the H(1) protons only gives rise to ROE enhancements with the H(2/2′) protons of conformers **I** and **II** (Figure 2, c). The GROESY spectrum obtained on irradiation of the signal at δ = 7.34 ppm follows from the experiments a), b), and c) in Figure 2 and definitively demonstrated the overlapping H(2/2′) and N(H) protons for one

conformer: in addition to an ROE enhancement with H(1), an exchange peak with the H(2/2′) protons (δ = 7.49 ppm) and with the N(H) proton (δ = 6.70 ppm) of the other conformer is also observed. The chemical shift equivalence of the H(2) and H(2′) protons in **I** and **II** is accommodated by a rapid tautomeric conversion of **a** and **b** for **I** and **c** and **d** for **II**. From the results of the dynamic NMR spectra, **2** appears to behave as a rather unconventional β-enaminoimine system. At low temperature, it is likely that we have been able to "freeze out" a dynamic process involving a fluxional structure from which each form identified is in a fast tautomeric equilibrium, namely **a** and **b** for **I** and **c** and **d** for **II**.

Discussion

The bis(*N*-zirconated) β-enaminoimine complex **2** contains the vinamidine moiety N−C−C−C−N and an *N*-metalated alkylideneamido arrangement, two types of substructures which may undergo fluxional processes.

It has been reported that β-enaminoimine derivatives with N−C−C−C−N core atoms may exist in three different configurations: "*trans-trans*", "*trans-cis*", and "*cis-cis*" [Equation (1)]. The tautomeric and conformational equilibria of these products have been found to be substituent-, solvent-, and temperature-dependent.[9]



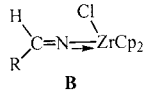
(1)

In CD_2Cl_2 at 193 K, the coupling constant of $^3J_{H(2/2')\text{-}H(1)}$ = 5.5 Hz observed for one of the conformers indicates the presence of the *cis-cis* form.[10] At 293 K the time-averaged $^3J_{H(2/2')\text{-}H(1)}$ coupling constant of 5.7 Hz implies that the second conformer exhibits the same *cis-cis* configuration for the vinamidine moiety. Moreover, the same ^{13}C NMR chemical shift observed for the CH(1) methine group indicates that the geometry around this carbon atom is retained in **I** and **II**.[11] Finally, the ROE enhancement observed for the H(1) and H(2/2′) protons of one of the conformers confirms the proximity of these protons. These NMR spectroscopic data establish conformers **I** and **II** as having a *cis-cis* configuration. Therefore, the dynamic NMR behavior observed for the *N*-zirconated β-enaminoimine complex **2** does not involve the core atoms of the β-enaminoimine system; the *cis-cis* rigidity about the N−C−C−C−N skeleton is maintained throughout the observed fluxional process.

Starting from the Lewis structure **I** for **2** (Scheme 1), two intramolecular dynamic processes may be proposed to rationalize the results of the low-temperature NMR spectra : i) rotation of the $ZrCp_2Cl$ fragments about the Zr−N bond and/or ii) a fluxional π-linear/σ-bent process involving the *N*-metalated alkylideneamido moieties in the plane containing the β-enaminoimine system −N(H)−$(CH)_2$−CH=N−.

Simple close-contact calculations carried out on complex **2**[12] revealed severe intramolecular nonbonded contacts between the Cp ring hydrogen atoms of the two metal fragments and between the Cp ring hydrogen atoms and the hydrogen atom of the H−C−N moiety of the β-iminoenamine skeleton. Because of these steric constraints, the magnitude of the rotation of the $ZrCp_2Cl$ fragments about the Zr−N bonds is limited, and therefore only a restricted rotation is observed for **2**. In metallocene complexes, restricted rotation about the bond between a metal ion and a planar amido/ketimide nitrogen atom is assumed to have a very low activation barrier; to the best of our knowledge no restricted rotation processes in such complexes has been "frozen out" by variable-temperature NMR experiments.[13,14c]

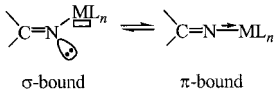
16-Electron d^0 group-4 metallocene complexes of the type Cp_2MRR' (M = Ti, Zr, Hf) have one vacant orbital available for conjugative interaction with lone pairs or π-systems at adjacent σ-bonded ligands R, R′.[15] Even though Cp_2M-N π-interactions are not maximized in group-4 amido[13] and ketimide[14] metallocene complexes, π-overlap between the LUMO of the metal fragment and the nitrogen lone pair has been commonly observed. Erker and co-workers have reported that aldimido [RCH=N−$ZrCp_2Cl$] complexes have a substantial Zr−N π-character. This was unambiguously demonstrated by an X-ray structure analysis of **B** (R = Ph), which showed a nearly linear Zr−N=CHPh unit (Zr−N−C 170.5(5)°].[15a,15b] In solution, the linear heteroallene-type structural unit in **B** (R = Ph) is of high stereochemical persistence and rigidity, and the geometric isomerization (*E*)/(*Z*) could be effected neither thermally nor photochemically. Moreover, the hydrozirconation of nitriles using the Schwartz reagent $[Cp_2ZrHCl]_n$ led to the corresponding zirconocene ketimide complexes with a *syn* stereochemistry; the metal-bound chlorine atom and the hydrogen atom of the aldimine function are positioned *syn* to the linear Zr−N−C moiety.



B

It is likely that, at room temperature, we are observing the results of the two rapid dynamic processes which involve: i) restricted rotation about the Zr−N bonds and ii) the σ-bound (**I**) and π-bound-like (**II**) *N*-zirconated conformers of the β-enaminoimine compound **2** (Scheme 1). Consistent with the studies reported in the literature, the two sets of Cp resonances observed for **2** at room temperature may be the result of restricted rotation about the Zr−N bonds, with a molecular geometry which places the chlorine atoms of the zirconocene fragments Cp_2ZrCl *syn* to the hydrogen atom of the HCN subunits. It is reasonable to propose that lowering of the temperature has the effect of "freezing out" the *N*-σ-bent-zirconated β-enaminoimine form **I** and linearising the Zr−N=C units to form the heteroallene system **II** (Scheme 1).[16] This internal fluxional *N*-zirconated π-linear/σ-bent structure [Equation (2)] was previously proposed to occur in these systems but until now

it has not been observed in coordinatively unsaturated *N*-metalated alkylideneamido complexes.

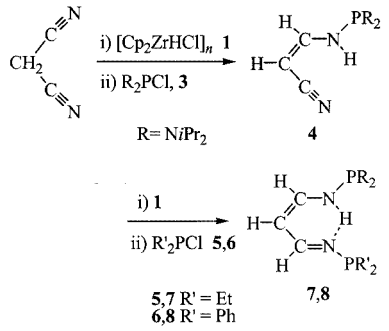


(2)

On the basis of variable-temperature ^{1}H NMR experiments, the activation barrier of the observed dynamic process attributed to the transition between bent (**I**) and linear (**II**) conformers in **2** has been calculated as $\Delta G^{\ddagger} = 13$ kcal/mol.[17]

Preparation of *N*-Phosphanylenamine and (*N*-Phosphanyl-β-enamino)imine Ligands

The next step in the preparation of β-enaminoimine ligands starting from malonodinitrile was to probe the monohydrozirconation/transmetalation reaction process. Treatment of $CH_2(CN)_2$ with 1 equiv. of the Schwartz reagent $[Cp_2Zr(H)Cl]_n$ (**1**), followed by addition of $(i\mathrm{Pr}_2N)_2PCl$ (**3**) led to the formation of the *N*-phosphanylenamine compound **4** in 66% isolated yield (Scheme 2).

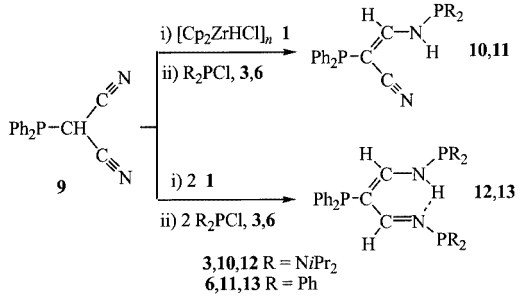


Scheme 2. Selective monohydrozirconation/transmetalation reactions of malonodinitrile and the β-nitriloeneamine compound **4**

This compound was identified by its spectroscopic properties which included strong absorptions in the IR spectrum at 1600 and 2194 cm^{-1} assigned to the C=N and C≡N stretches, respectively. The ^{31}P NMR spectrum of **4** displays a singlet at δ = 87.1 ppm. In addition to signals due to the isopropyl group, ^{1}H and ^{13}C NMR spectra display signals in the region expected for a CH= vinylic group geminal to an electron-withdrawing group [δ = 3.74 (^{1}H) and 66.1 (^{13}C) ppm] and a CH−N< enamine fragment [δ = 6.53 (^{1}H) and 150.8 (^{13}C) ppm]. The broad signal at δ = 5.30 ppm in the ^{1}H NMR is typical of an NH secondary amine. The NMR spectroscopic data establish **4** as an (*N*-phosphanyl-β-enamino)nitrile. Another hydrozirconation/transmetalation reaction on the enamine compound **4** using **1** and R′$_2$PCl [R′ = Et (**5**), Ph (**6**)] gave the expected unsymmetrical (*N*-phosphanyl-β-enamino)imine derivatives **7** and **8**, respectively (Scheme 2). IR spectra indicate the disappearance of the ν(C≡N) band in **4** and the appearance of an absorption in the region expected for the C=N functionality in β-enaminoimine systems [ν(C≡N): 1625 cm^{-1} (**7**), 1621 cm^{-1} (**8**)]. The ^{31}P NMR spectra of **7** and **8** display two singlets at δ = 53.3, 87.1 (**7**) ppm and 64.8, 89.3 (**8**) ppm. Signals in both ^{1}H and ^{13}C NMR spectra are consistent with CH=N aldimine groups [**7**: δ = 7.62 (^{1}H, overlapped) ppm, δ = 156.1, 159.8 (^{13}C) ppm; **8**: δ = 7.39, 7.91 (^{1}H) ppm, δ = 150.5, 164.5 (^{13}C) ppm] and the central methine CH fragments [**7**: δ = 4.87 (^{1}H) and δ = 97.6 (^{13}C) ppm; **8**: δ = 4.89 (^{1}H) and δ = 97.8 (^{13}C) ppm] in the β-diimine derivatives **7** and **8**. The ^{13}C NMR chemical shifts of the central methine CH fragments and the upfield shift of the broad NH signal [δ = 5.30 (**4**), 10.54 (**7**), 10.84 (**8**) ppm] in the ^{1}H NMR spectra establish **7** and **8** as having a *cis-cis* configuration, with a hydrogen-bonded chelate form in a β-diimine compound.

It is noteworthy that hydrozirconation of succinonitrile and glutaronitrile using **1** (1 and 2 equiv.) followed by an exchange reaction with Ph_2PX (X = Cl, Br, CN) led to the formation of insoluble polymeric products.

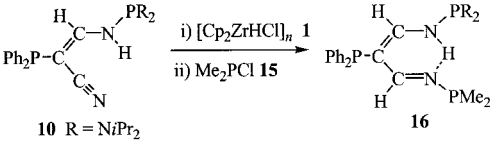
Under the same experimental conditions as those used for $CH_2(CN)_2$, the phosphanylmalononitrile **9** undergoes the same "one pot" mono- and dihydrozirconation/transmetalation reaction sequence(Scheme 3). Addition of 1 equiv. of **1** to **9** followed by addition of a stoichiometric amount of R_2PCl (**3**, **6**) to the resulting mixture affords the corresponding *N*-phosphanylenamine compounds **10** and **11**, respectively (Scheme 3).



Scheme 3. Mono-and dihydrozirconation/transmetalation reactions of the phosphanylmalonodinitrile compound **9**

The IR spectra of **10** and **11** display both C=N and C≡N stretches. The parent ion peak $[M + 1]^+$ detected in the mass spectrum of **11** is in agreement with the general formula $[C_3H_2N_2(PPh_2)_2]$. The ^{31}P NMR spectra of **10** and **11** display two singlets at δ = 8.0, 85.2 and δ = −1.6, 55.1 ppm, respectively. ^{1}H and ^{13}C NMR spectra exhibit (besides the chemical shifts corresponding to the protons and carbon atoms of the phosphanyl substituents) signals in the region expected for a CH−N< enamine fragment [**10**: δ = 7.58 (^{1}H) and δ = 159.1 (^{13}C) ppm; **11**: δ = 7.75 (^{1}H) and δ = 163.7 (^{13}C) ppm]. The broad signal at δ = 5.90 (**10**) and 8.18 (**11**) ppm in the ^{1}H NMR spectra corresponds to the NH secondary amine. The NMR spectroscopic data establish an (*N*-phosphanyl-β-enamino)nitrile skeleton in **10** and **11**.

Reaction of **9** with 2 equiv. of **1** and addition of 2 equiv. of R_2PCl (**3**, **6**) allowed isolation of the corresponding *N*-phosphanyl-β-diimines **12** and **13**, respectively (Scheme 3). The parent ion $[M + 1]^+$ detected in the mass spectrum of **13** was in agreement with the general formula $[C_3H_3N_2(PPh_2)_3]$. Infrared spectra show absorptions at 1633 cm^{-1} (**12**) and 1635 cm^{-1} (**13**) assigned to the C=N stretch of the enaminoimine fragment. In addition to signals corresponding to the phosphanyl substituents, ^1H and ^{13}C NMR spectra of **12** and **13** show the presence of the β-diimine NC(H)CC(H)N skeleton. The chemical shifts in both ^1H [δ = 7.90 (**12**) and 8.35 (**13**) ppm] and ^{13}C [δ = 161.3 (**12**) and 166.9 (**13**) ppm] NMR spectra are consistent with the CH=N aldimine and with the central methine PC fragments the signals of which appear at δ = 99.9 (**12**) and 103.4 (**13**) ppm in the ^{13}C NMR spectrum, respectively. The NMR spectroscopic data (^{13}P, ^1H, and ^{13}C) indicate symmetric ligand environments, which is consistent with a rapid tautomeric interconversion. Addition of **1** to the (*N*-phosphanyl-β-enamino)nitrile **10**, followed by a substitution reaction with Me_2PCl (**15**), gave the corresponding unsymmetrical β-enaminoimine derivative **16** in 84% yield (Scheme 4).



Scheme 4. Monohydrozirconation/transmetalation reactions of the phosphanyl-β-nitriloeneamine compound **10**

The ^{31}P NMR spectrum of **16** displays three singlets at δ = −4.6 (PPh), 40.6 (PMe), and 86.3 ($PNiPr_2$) ppm. Both CH=N aldimine groups exhibit characteristic NMR signals at δ = 7.91 and 8.29 (^1H) ppm and δ = 160.7 and 166.5 (^{13}C) ppm. The ^{13}C NMR chemical shift of the central methine CP fragment (δ = 100.5 ppm) and the upfield shift of the broad NH signal in the ^1H NMR spectrum (δ = 11.39 ppm) establish **16** as having a "*cis-cis*" configuration, with a hydrogen-bonded chelate form in a β-enaminoimine compound.

X-ray Crystal Structure of 14

To confirm the spectroscopic assignments and to have a better insight into the molecular structure of the (*N*-phosphanyl-β-enamino)imine species prepared, an X-ray diffraction study was carried out on the phosphane sulfide product **14** obtained after addition of elemental sulfur to **13** (Figure 3, Table 1).

The crystal structure of **14**, recorded at 180 K, shows discrete molecular units which do not display the C_{2v} symmetry previously observed in compound **A** [$R^1 = R^2 = H$, $R^3 = P(S)Ph_2$].[3,18] All atoms in **14** except those of the phenyl groups and the sulfur atoms S1 and S3 lie in the same plane with a maximum deviation of 0.0046 Å. The

presence of the N1−H1···N2 intramolecular hydrogen bond, with an N···N distance of 2.66 Å[19] and an N−H···N angle of 137°, may be responsible for the planarity of the system, together with some degree of charge delocalization. The C2−N1 [1.351(6) Å] and C3−N2 [1.298(6) Å] distances are close to the values reported for C=C−NH− and $C(sp^2)$−C=N− fragments respectively, and are representative of single and double bond lengths in such systems.[20,21] The thiophosphoryl groups $-P(S)Ph_2$ in **14** showed the expected typical structural parameters.[22]

The X-ray data recorded at 180 K showed that the β-enaminoimine compound **14** possesses an unsymmetrical intramolecular hydrogen H(N) bond with two different nitrogen chelating atoms, N1 and N2, in the solid state. However, in solution it behaves as a symmetric compound, consistent with the occurrence of a very fast tautomeric proton

exchange equilibrium. These observations can be rationalized if it is assumed that **14** possesses a low-barrier hydrogen bond with a double-well potential. This is in agreement with the mechanism of proton transfer in malonaldehyde recently proposed by Silvi and co-workers,[23] involving a two-step reaction with a concerted charge transfer from one bond to another within the planar framework of the aldehyde. This description may also be applied to the analogous β-enaminoimine systems.[24]

Conclusion

In conclusion, we have demonstrated that the bis(*N*-zirconated) β-enaminoimine system **2** shows a dynamic NMR behavior which may be reasonably attributed to a σ-bent/π-linear fluxional structure. Complex **2** is the ideal synthon to prepare unsymmetrical β-enaminoimine derivatives following the hydrozirconation/transmetalation reaction sequence. Starting with the phosphanylmalononitrile $Ph_2P-CH(CN)_2$ and using an identical reaction process, (*N*-phosphanyl-β-enamino)imine derivatives have been prepared and characterized. These compounds will be further investigated as ligands in coordination complexes.

The X-ray crystal structure of **14** at 180 K shows an unsymmetrical system, with the N(H) proton localized on one of the two chelating nitrogen atoms. This solid-state structural analysis is consistent with the existence in solution of a rapidly interconverting pair of tautomers[25] with a low-barrier proton transfer process corresponding to a double-well potential. The β-enaminoimine compounds described in this paper represent a good model for the study of intramolecular hydrogen bonding.

Experimental Section

General Remarks: All manipulations were performed under argon in a vacuum line using standard Schlenk techniques. Solvents were freshly distilled from dark purple solutions of sodium/benzophenone ketyl (THF and toluene), lithium aluminum hydride (pentane), or CaH_2 (CH_2Cl_2). Deuterated NMR solvents were treated with $LiAlH_4$ ([D_8]toluene, C_6D_6, [D_8]THF) and CaH_2 (CD_2Cl_2), distilled, and stored under argon. Nuclear magnetic resonance (NMR) spectra were recorded at 25 °C with Bruker AMX-400, AM-250, AC-200, and AC-80 Fourier transform spectrometers. Chemical shifts are given downfield relative to Me_4Si (^1H, ^{13}C) or H_3PO_4 (^{31}P), respectively. ^{13}C NMR assignments were confirmed by inverse gradient δ^1H-$\delta^{13}C\{^{13}C,^{31}P\}$ HMQC and ^{31}P-^1H NMR experiments. Elemental and mass spectral analyses (obtained using a Nermag R10-10H) were performed by the analytical service of the Laboratoire de Chimie de Coordination (LCC) of the CNRS. $(i\mathrm{Pr}_2\mathrm{N})_2\mathrm{PCl}$[26] and $[Cp_2Zr(H)Cl]_n$[27] were prepared according to literature procedures. Ph_2PCl (Aldrich), Me_2PCl (Strem), Et_2PCl (Strem), MeI (Aldrich), and $CH_2(CN)_2$ (Aldrich) were purchased and used without further purification.

Preparation of 2: A solution of $CH_2(CN)_2$ (0.100 g, 1.514 mmol) in CH_2Cl_2 (5 mL) was added to a suspension of $[Cp_2Zr(H)Cl]_n$ (0.781 g, 3.028 mmol) in CH_2Cl_2 (3 mL) at −30 °C. The reaction mixture was stirred for 30 min at room temperature and then cooled to −50 °C, at which temperature MeI (0.188 μL, 3028 mmol) in CH_2Cl_2 (5 mL) was slowly added. The solution was then stirred for an additional 2 h at room temperature. Removal of the solvent in vacuo gave **2** as an orange solid. ^1H and ^{13}C NMR recorded at 293 K: ^1H NMR (CD_2Cl_2): δ = 4.84 (br, 1 H, CH), 6.35 (s, 10 H, Cp), 6.53 (s, 10 H, Cp), 7.10 (br., 1 H, NH), 7.48 (dd, $J_{H(2)-H(1)}$ = 5.8, $J_{H(2)-H(N)}$ = 12.6 Hz, CHN) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 97.9 (s, CH), 114.5, 116.6 (s, Cp), 157.6 (s, CHN) ppm. ^1H and ^{13}C NMR of conformers **I** and **II** recorded at 193 K: ^1H NMR (CD_2Cl_2): δ = 4.78 (br, 1 H, CH), 6.30 (s, 10 H, Cp), 6.52 (s, 10 H, Cp), 6.70 [d, $J_{H(2)-H(N)}$ = 13.0 Hz, NH), 7.49 (dd, $J_{H(2)-H(1)}$ = 5.5, $J_{H(2)-H(N)}$ = 13.0 Hz, CHN) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 97.9 (s, CH), 114.8, 117.0 (s, Cp), 157.6 (s, CHN) ppm. ^1H NMR (CD_2Cl_2): δ = 4.78 (br, 1 H, CH), 6.30 (s, 10 H, Cp), 6.52 (s, 10 H, Cp), 7.34 (br, CHN and NH) ppm. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 97.9 (s, CH), 114.8, 117.0 (s, Cp), 158.4 (s, CHN) ppm.

Preparation of 4: A suspension of $[Cp_2ZrHCl]_n$ (0.600 g, 2.327 mmol) in CH_2Cl_2 (3 mL) was added to a solution of malonodinitrile (2.327 mmol, 0.154 g) in CH_2Cl_2 (10 mL) at −40 °C. and the reaction mixture was allowed to warm slowly to room temperature. As soon as the reaction mixture turned clear, $(i\mathrm{Pr}_2\mathrm{N})_2\mathrm{PCl}$ (0.619 mg, 2.327 mmol) in CH_2Cl_2 (2 mL) was added and the solution was stirred for 1 h at room temperature. Removal of the solvent in vacuo gave a yellow solid residue which was extracted with cold pentane (10 mL). After filtration, the volatiles were evaporated and **4** was obtained as a yellow powder. Yield: 66% (457 mg). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 87.1 (s) ppm. ^1H NMR (C_6D_6): δ = 1.03 (d, $^3J_{H,H}$ = 6.7 Hz, 24 H, CH_3), 3.24 (d sept, $^3J_{H,H}$ = 6.7, $^3J_{HP}$ = 11.8 Hz, 4 H, $CHCH_3$), 3.74 (d, $^3J_{H,H}$ = 8.1 Hz, 1 H, CHCN), 5.30 (br. d, $^3J_{H,H}$ = 15.0 Hz, 1 H, NH), 6.53 (ddd, $^3J_{HP}$ = $^3J_{H,H}$ = 8.1, $^3J_{H,H}$ = 15.0 Hz, 1 H, CHNH) ppm. ^{13}C NMR (C_6D_6): δ = 24.0 (d, $^3J_{PC}$ = 7.2 Hz, CH_3), 24.6 (d, $^3J_{PC}$ = 7.2 Hz, CH_3), 45.9 (d, $^2J_{PC}$ = 12.8 Hz, $CHCH_3$), 66.1 (d, $^2J_{PC}$ = 7.5 Hz, CHCN), 118.8 (s, CN), 150.8 (d, $^2J_{PC}$ = 27.7 Hz, CHNH) ppm. FT-IR (KBr): $\tilde{\nu}$ = 1600 (C=N), 2194 (C≡N) cm^{-1}. $C_{15}H_{31}N_4P$ (298.47): calcd. C 60.36, H 10.47, N 18.77; found C 60.48, H 10.28, N 18.56.

Typical Procedure for the Synthesis of Compounds 7 and 8: Compound **4** (0.215 g, 0.721 mmol) in CH_2Cl_2 (2 mL) was added to a suspension of $[Cp_2ZrHCl]_n$ (0.186 g, 0.721 mmol) in CH_2Cl_2 (2 mL) at −40 °C. The resulting mixture was stirred and allowed to warm slowly to room temperature. As soon as the solution turned clear, Et_2PCl (0.90 mg, 0.721 mmol) in CH_2Cl_2 (1 mL) was added. The mixture was stirred for 15 min at room temperature and then concentrated to dryness. The volatiles were removed to give **7** as an orange powder. Yield: 78% (218 mg). **7**: $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 64.8 (s, PEt_2), 89.3 (s, $PN\mathrm{i}Pr_2$) ppm. ^1H NMR (C_6D_6): δ = 0.99 (t, $^3J_{H,H}$ = 7.6 Hz, 3 H, CH_2CH_3), 1.05 (t, $^3J_{H,H}$ = 7.6 Hz, 3 H, CH_2CH_3), 1.16 (d, $^3J_{H,H}$ = 6.7 Hz, 12 H, $CHCH_3$), 1.19 (d, $^3J_{H,H}$ = 6.7 Hz, 12 H, $CHCH_3$), 3.50 (d sept, $^3J_{H,H}$ = 6.7, $^3J_{HP}$ = 11.0 Hz, 4 H, $CHCH_3$), 4.87 (dd, $^3J_{H,H}$ = $^3J_{H,H}$ = 5.9 Hz, 1 H, CH), 7.55−7.74 (m, 2 H, CHN), 10.54 (br. m, 1 H, NH) ppm. ^{13}C NMR (C_6D_6): δ = 9.5 (d, $^2J_{PC}$ = 14.5 Hz, CH_2CH_3), 24.6 (d, $^3J_{PC}$ = 7.5 Hz, $CHCH_3$), 24.8 (d, $^3J_{PC}$ = 7.5 Hz, $CHCH_3$), 25.0 (d, $^2J_{PC}$ = 12.3 Hz, CH_2CH_3), 46.3 (d, $^2J_{PC}$ = 12.5 Hz, $CHCH_3$), 97.6 (dd, $^3J_{PC}$ = $^3J_{PC}$ = 13.6 Hz, CH), 156.1 (d, $^2J_{PC}$ = 37.3 Hz, $CHNPN\mathrm{i}Pr$), 159.8 (d, $^2J_{PC}$ = 27.4 Hz, CHNPEt) ppm. Preparation of 9: $CH_2(CN)_2$ (0.480 g, 0.076 mmol) in THF (5 mL) was added slowly to a solution of LDA (0.779 g, 0.0726 mmol) in THF (25 mL) at 0 °C. The mixture was stirred at 0 °C for 1 h, then Ph_2PCl (1.600 g, 0.076 mmol) in THF (5 mL) was added dropwise. The mixture was slowly warmed to room temperature over 1 h, filtered, and the solvent was evaporated. The resulting solid residue was washed with Et_2O (2 × 20 mL). The volatiles were removed in a vacuum line over 5 h at 80 °C to give **9** as a yellow-brown solid.Yield: 95% (1.514 g). M.p. 83−84 °C. $^{31}P\{^1H\}$ NMR ([D_8]THF): δ = −5.9 ppm. ^1H NMR ([D_8]THF): δ = 7.18−7.50 (m, 10 H, Ph) ppm. ^{13}C NMR ([D_8]THF): δ = 7.9 (d, $^1J_{C,P}$ = 5.8 Hz, PC), 127.4 (s, *p*-Ph), 127.9 (d, $^3J_{C,P}$ = 6.2 Hz, *m*-Ph), 128.4 (d, $^2J_{C,P}$ = 21.1 Hz, CN), 132.5 (d, $^2J_{C,P}$ = 19.4 Hz, *o*-Ph), 142.2 (d, $^1J_{C,P}$ = 11.2 Hz, *i*-Ph) ppm. FT-IR (KBr): $\tilde{\nu}$ = 2189 (C≡N) cm^{-1}.

Preparation of 10: A solution of **9** (0.262 g, 1.046 mmol) in THF (2 mL) was added to a suspension of $[Cp_2ZrHCl]_n$ (0.270 g, 1.046 mmol) in THF (2 mL) at −40 °C. The resulting mixture was stirred and allowed to warm slowly to room temperature. As soon as the reaction mixture turned clear, $(iPr_2N)_2PCl$ (0.278 mg, 1.046 mmol) in THF (2 mL) was added. The solution was stirred for 30 min at room temperature and the solvent was then removed. The resulting solid residue was extracted with pentane (20 mL) and filtered. The volatiles were removed and **10** was obtained as a yellow-orange solid. Yield: 55% (277 mg). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −8.0 (PPh_2), 85.2 ($PNiPr_2$) ppm. ^1H NMR (C_6D_6): δ = 1.01 (d, $^3J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 1.05 (d, $^3J_{H,H}$ = 6.7 Hz, 12 H, CH_3), 3.23 (d sept, $^3J_{H,H}$ = 6.7, $^3J_{HP}$ = 11.6 Hz, 4 H, *C*HCH_3), 5.95 (br. dd, $^3J_{H,H}$ = 2.0, $^3J_{HP}$ = 15.6 Hz, 1 H, NH), 7.00−7.28 (m, 5 H, Ph), 7.58 (ddd, $^3J_{H,H}$ = 7.1, $^3J_{HP(PPh2)}$ = 15.6, $^3J_{HP(PNiPr)}$ = 9.5 Hz, 1 H, C*H*NH), 7.65−7.77 (m, 5 H, Ph) ppm. ^{13}C NMR (C_6D_6): δ = 24.4 (d, $^3J_{PC}$ = 8.2 Hz, CH_3), 24.7 (d, $^3J_{PC}$ = 8.2 Hz, CH_3), 46.2 (d, $^2J_{PC}$ = 12.3 Hz, *C*HCH_3), 76.3 (dd, $^1J_{PC}$ = 16.0, $^3J_{PC}$ = 5.8 Hz, PC), 129.2 (s, *p*-Ph), 129.3 (s, *m*-Ph), 133.5 (d, $^1J_{C,P}$ = 20.0 Hz, *o*-Ph), 139.0 (d, $^1J_{C,P}$ = 5.8 Hz, *i*-Ph), 159.1 (dd, $^2J_{C,P}$ = 21.1, $^2J_{C,P}$ = 67.3 Hz, PCCH) ppm. FT-IR (KBr): $\tilde{\nu}$ = 1619 (C=N), 2195 (C≡N) cm^{-1}. $C_{27}H_{40}N_4P_2$ (482.65): calcd. C 67.19, H 8.35, N 11.61; found C 67.35, H 8.12, N 11.45.

Preparation of 11: A solution of **9** (340 mg, 1.356 mmol) in THF (2 mL) was added to a suspension of $[Cp_2ZrHCl]_n$ (250 mg, 1.356 mmol) in THF (2 mL) at −40 °C. The resulting mixture was stirred and allowed to warm slowly to room temperature. As soon as the solution turned clear (ca. 20 min), Ph_2PCl (300 mg, 1.356 mmol) in THF (2 mL) was added. The resulting mixture was stirred at room temperature for 30 min and then concentrated to dryness. The solid residue was extracted with CH_2Cl_2/pentane (1:5, 20 mL) and filtered. The volatiles were removed to give **11** as a white solid. Yield: 66% (391 mg). M.p. 155−156 °C. $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −1.6 ($CPPh_2$), 55.1 ($NPPh_2$) ppm. ^1H NMR (C_6D_6): δ = 7.28−7.65 (m, 20 H, Ph), 7.75 (ddd, $^3J_{H,H}$ = 14.5, $^3J_{HP(NPPh2)}$ = 10.3, $^3J_{HP(C,PPh2)}$ = 9.5 Hz, 1 H, C*H*NH), 8.18 (dd, $^3J_{H,H}$ = 4.0, $^2J_{Hp}$ = 14.5 Hz, 1 H, NH) ppm. ^{13}C NMR (C_6D_6): δ = 80.0 (dd, $^1J_{C,P}$ = 17.6, $^3J_{C,P}$ = 10.4 Hz, PC), 118.4 (d, $^2J_{C,P}$ = 5.0 Hz, CN), 130.3 (d, $^3J_{C,P}$ = 6.9 Hz, *m*-Ph), 130.6 (d, $^3J_{C,P}$ = 6.9 Hz, *m*-Ph), 131.6 (s, *p*-Ph), 133.6 (d, $^2J_{C,P}$ = 19.9 Hz, *o*-Ph), 134.6 (d, $^2J_{C,P}$ = 19.9 Hz, *o*-Ph), 139.9 (d, $^1J_{C,P}$ = 16.1 Hz, *i*-Ph), 140.1 (d, $^1J_{C,P}$ = 16.2 Hz, *i*-Ph), 163.7 (dd, $^2J_{C,P(C,PPh2)}$ = 70.0, $^2J_{C,P(NPPh)}$ = 37.5 Hz, *C*HNP) ppm. FT-IR (KBr): $\tilde{\nu}$ = 1642 (C=N), 2202 (C≡N) cm^{-1}. MS (DCI/CH_4): *m*/*z* = 437 $[M + H]^+$. $C_{27}H_{22}N_2P_2$ (436.45): calcd. C 74.30, H 5.08, N 6.42; found C 74.45, H 4.94, N 6.32.

Typical Procedure for the Synthesis of Compounds 12 and 13: A solution of **9** (0.270 g, 1.078 mmol) in THF (2 mL) was added to a suspension of $[Cp_2ZrHCl]_n$ (0.556 g, 2.156 mmol) in THF (3 mL) at −40 °C. The resulting mixture was stirred and slowly warmed to room temperature. As soon as the reaction mixture turned clear (ca. 30 min), $(iPr_2N)_2PCl$ (0.574 mg, 2.156 mmol) in THF (2 mL) was added. After stirring for 4 h, the solution was concentrated to dryness. The resulting solid residue was extracted with CH_2Cl_2/pentane (1:4, 30 mL) and filtered. The volatiles were evaporated to give **16** as a yellow solid. Yield 67% (516 mg).

Data for 12: $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −1.8 (PPh_2), 86.2 ($PNiPr_2$) ppm. ^1H NMR (C_6D_6): δ = 1.02 (d, $^3J_{H,H}$ = 6.6 Hz, 24 H, CH_3), 1.21 (d, $^3J_{H,H}$ = 6.6 Hz, 24 H, CH_3), 3.54 (dsept, $^3J_{H,H}$ = 6.6, $^3J_{HP}$ = 12.3 Hz, 8 H, C*H*CH_3), 6.90−7.58 (m, 10 H, Ph), 7.90 (ddd, $^3J_{H,H}$ = 7.3, $^3J_{HP(PPh)}$ = 7.3, $^3J_{HP(PniPr)}$ = 18.0 Hz, 2 H, C*H*NH), 10.35 (br. m, 1 H, NH) ppm. ^{13}C NMR (C_6D_6): δ = 24.4 (d, $^3J_{C,P}$ = 7.0 Hz, CH_3), 24.8 (d, $^3J_{C,P}$ = 7.0 Hz, CH_3), 47.9 (d, $^2J_{PC}$ = 13.1 Hz, $CHCH_3$), 99.9 (dd, $^1J_{PC}$ = $^3J_{PC}$ = 9.3 Hz, PC), 128.1 (s, *p*-Ph), 128.7 (d, $^3J_{C,P}$ = 5.5 Hz, *m*-Ph), 133.0 (d, $^2J_{C,P}$ = 17.6 Hz, *o*-Ph), 141.0 (d, $^1J_{C,P}$ = 11.4 Hz, *i*-Ph), 161.3 (dd, $^2J_{C,P(PPh2)}$ = 36.1, $^2J_{HP(PNiPr)}$ = 20.6 Hz, CHNP) ppm. Preparation of 14: Treatment of **13** (362 mg, 0.581 mmol) in CH_2Cl_2 (8 mL) with an excess of sulfur at room temperature for 12 h afforded **14**, which was purified by column chromatography (silica gel, pentane/ethyl acetate, 1:4, R_f = 0.49). The product crystallized from toluene as colorless crystals. Yield: 81% (338 mg). M.p. 185−186 °C. $^{31}P\{^1H\}$ NMR (400 MHz, 233 K, [D_8]toluene): δ = 43.5 [CP(S)Ph_2], 63.2 [NP(S)Ph_2] ppm. ^1H NMR (400 MHz, 233 K, [D_8]toluene): δ = 7.46−8.04 (m, 30 H, Ph), 9.59 (ddd, $^3J_{H,H}$ = 5.8, $^3J_{HP(NPPh)}$ = 8.5, $^3J_{HP(C,PPh)}$ = 23.5 Hz, 2 H, C*H*NH), 13.59 (tt, $^3J_{H,H}$ = 5.8, $^2J_{HP(NPPh)}$ = 5.0 Hz, 1 H, NH) ppm. ^{13}C NMR (C_6D_6): δ = 102.8 (dt, $^1J_{C,P(C,PPh)}$ = 97.1, $^3J_{C,P(NPPh)}$ = 14.0 Hz, PC), 128.7 (d, $^3J_{C,P}$ = 13.8 Hz, *m*-Ph), 129.3 (s, *p*-Ph), 131.0 (d, $^2J_{C,P}$ = 11.5 Hz, *o*-Ph), 134.4 (d, $^1J_{C,P}$ = 96.0 Hz, *i*-Ph), 164.4 (d, $^2J_{C,P}$ = 19.7 Hz, *C*HNP) ppm. FT-IR (KBr): $\tilde{\nu}$(C=N) 1596 cm^{-1}. MS (DCI/CH_4): *m*/*z* = 719 [M + H]$^+$. $C_{39}H_{33}N_2P_3S_3$ (718.65): calcd. C 65.18, H 4.63, N 3.90; found C 65.05, H 4.45, N 3.79.

Preparation of 16: A solution of **10** (0.351 g, 0.729 mmol) in CH_2Cl_2 (2 mL) was added to a suspension of $[Cp_2ZrHCl]_n$ (0.556 g, 2.156 mmol) in CH_2Cl_2 (2 mL) at −40 °C. The resulting mixture was stirred and slowly warmed to room temperature. As soon as the reaction mixture turned clear (ca. 20 min), Me_2PCl (0.070 g, 0.729 mmol) in CH_2Cl_2 (2 mL) was added. After stirring for 15 min, the solution was concentrated to dryness. The resulting solid residue was extracted with pentane (30 mL) and filtered. The volatiles were removed to give **16** as a yellow solid. Yield: 84% (0.334 g). $^{31}P\{^1H\}$ NMR (C_6D_6): δ = −4.6 (PPh_2), 40.6 (PMe_2), 86.3 (PN*i*Pr_2) ppm. ^1H NMR (C_6D_6): δ = 1.06 (d, $^2J_{H,H}$ = 4.5 Hz, 6 H, PCH_3), 1.09 (d, $^3J_{H,H}$ = 6.5 Hz, 12 H, CH_3), 1.14 (d, $^3J_{H,H}$ = 6.5 Hz, 12 H, CH_3), 3.41 (dsept, $^3J_{H,H}$ = 6.5, $^3J_{HP}$ = 11.3 Hz, 4 H, C*H*CH_3), 6.86−7.72 (m, 10 H, Ph), 7.91 (m, 1 H, C*H*NPN*i*Pr), 8.29 (m, 1 H, C*H*NPMe), 11.39 (br. m, 1 H, NH) ppm. ^{13}C NMR (C_6D_6): δ = 18.9 (d, $^1J_{C,P}$ = 17.0 Hz, CH_3), 24.6 (d, $^3J_{C,P}$ = 8.4 Hz, CH_3), 24.7 (d, $^3J_{C,P}$ = 8.4 Hz, CH_3), 46.4 (d, $^2J_{C,P}$ = 12.8 Hz, *C*HCH_3), 100.5 (d, $^3J_{C,P}$ = 9.2 Hz, PC), 129.1 (s, *p*-Ph), 129.2 (d, $^3J_{C,P}$ = 8.0 Hz, *m*-Ph), 133.2 (d, $^2J_{C,P}$ = 17.6 Hz, *o*-Ph), 140.7 (d, $^1J_{C,P}$ = 10.9 Hz, *i*-Ph), 160.7 (dd, $^2J_{C,P(PPh2)}$ = 34.6, $^2J_{C,P(PNiPr)}$ = 28.8 Hz, CHNPN*i*Pr), 166.5 (dd, $^2J_{C,P(PPh)}$ = 35.0, $^2J_{C,P(PMe)}$ = 18.9 Hz, CHNPMe) ppm. FT-IR (KBr): $\tilde{\nu}$ = 1593 (C=N) cm^{-1}. $C_{29}H_{47}N_4P_3$ (544.71): calcd. C 63.94, H 8.70, N 10.28; found C 63.92, H 8.56, N 10.35.

X-ray Analysis of 14: Single crystals of **14** were obtained from toluene. Data (Table 2) were collected at 180 K with an IPDS STOE diffractometer equipped with an Oxford Cryosystems Cryostream Cooler Device using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). The final unit cell parameters were obtained by means of a least-squares refinement performed on a set of 5000 strong reflections. No significant intensity fluctuations were observed during the data collection, indicating crystal decay was minimal. The structure was solved by Direct Methods using SIR92,[28] and refined by means of least-squares procedures on F^2 using SHELXL-97.[29] Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[30] All hydrogen atoms were located in a difference Fourier map, and, with the exception of H(N), were refined using a riding model with an isotropic thermal parameter fixed at 20% greater than those of the carbon atoms to which they are connected. H(N), the hydrogen atom connected to N(1), was refined isotropically. All non-hydrogen atoms were refined anisotropically, and the weighting scheme $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$, was used in the last cycles of refinement. Molecular graphics were produced using ZORTEP,[31] with non-hydrogen atoms drawn at the 50% probability level. CCDC-196233 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

[12] Simple close-contact calculations were carried out on complex **2** (**I**) using standard $Cp_2Zr(Cl)$ fragment parameters and the β-enaminoimine skeleton $-N(H)-(CH)_2-CH=N-$ from the X-ray crystal structure of **1**. The Cambridge Structural Database was used to determine the mean Zr−N bond lengths in amido (2.15 Å) and ketimide (2.04 Å) zirconocene complexes (note that from the CSD, group-4 metallocene amido complexes exhibit a planar nitrogen atom with a Cp_2M-N-C angle from 135 to 150° and zirconocene ketimide complexes contain C−N−Zr angle values from 164 to 178°). On varying the C−N−Zr angle value from 120 to 180° in **2** (**I**), rotation around the Zr−N bond revealed that: i) van der Waals contacts between Cp ring hydrogen atoms and the hydrogen atom of the H−C=N fragment are observed up to a C−N−Zr angle value of 150°, ii) van der Waals contacts between the Cp ring hydrogen atoms of the two Cp_2ClZr metal moieties are not observed for a C−N−Zr angle lower than 130° in the amido and ketimide subunits. For a good discussion of orbital constraints and symmetry requirements of the bent metallocene derivatives, see: J. W. Lauher, R. Hoffmann, *J. Am. Chem. Soc.* **1976**, *98*, 1729.

[16] Alternative structures for **2** which involve the formation of dimers, trimers, or oligomers with the zirconated metal fragment cannot be totally ruled out, but it is highly unlikely as it will prevent any fluxional process within the alkylideneamido subunit.

[17] Rate constants were derived from band-shape analysis using the software MEXICO (available from A. D. Bain, Department of Chemistry, McMaster University, Hamilton, Ontario, Canada). NMR parameters were optimized to match the simulated and the experimental data. Activation parameters were determined by a standard Eyring analysis.

[18] The X-ray crystallographic investigation of **A** [$R^1 = R^2 = H$, $R^3 = P(S)Ph_2$] at 293 K revealed two "half-hydrogen" atoms in the N···N region of the molecule, similar to what might be obtained by the superposition of one half molecule of **A′** on one half molecule of **A′′**.

[19] The observed nitrogen−nitrogen separation [N1−N2 = 2.657(6) Å] is smaller than the sum of the nitrogen van der Waals radii (3.10 Å); see: A. Bondi, *J. Chem. Phys.* **1964**, *68*, 441. R. C. Weast, *Handbook of Chemistry and Physics*, CRC, Boca Raton, FL, **1974**.

Syntheses and Crystal Structures of Copper and Silver Complexes with New Imine Ligands − Air-Stable, Photoluminescent Cu^IN_4 Chromophores

Goutam Kumar Patra[a] and Israel Goldberg*[a]

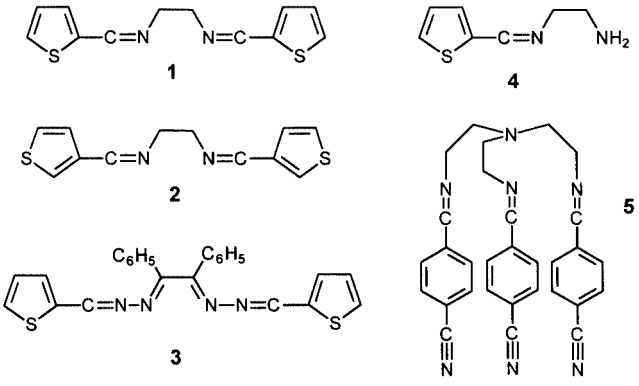
Keywords: N ligands / Copper / Silver / Luminescence / Electrochemistry

A series of new imine ligands [**1** ($C_{12}H_{12}N_2S_2$), **2** ($C_{12}H_{12}N_2S_2$), **3** ($C_{24}H_{18}N_4S_2$), and **5** ($C_{30}H_{27}N_7$)] have been synthesized (**1** and **2** are structural isomers). Cu^I and Ag^I complexes of the nonconjugated dithiophene-diimine ligands **1**, **2** and the tripodal imine-amine ligand **5** have also been prepared and thoroughly characterized by spectroscopic techniques as well as by X-ray diffraction. In cyclic voltammetry at a glassy carbon milli electrode in anhydrous dichloromethane under dry N_2, the corresponding Cu^I complexes [**6** ($2C_{12}H_{12}N_2S_2{\cdot}CuClO_4$), **7** ($2C_{12}H_{12}N_2S_2{\cdot}CuClO_4$), and **12** ($C_{30}H_{27}N_7{\cdot}CuClO_4$)] show quasi-reversible $Cu^{II/I}$ couples with high redox potentials (1.001 V for **6**, 0.958 V for **7**, and 0.692 V for **12**, vs. Ag/AgCl). This indicates that the π-acid ligands **1**, **2**, and **5** preferentially stabilize copper(I) over copper(II). The Cu^IN_4 chromophores in the complexes **6**, **7**, and **12** display photoluminescence in dichloromethane at room temperature. The related silver complexes of the same three ligands **10** ($2C_{12}H_{12}N_2S_2{\cdot}AgClO_4$), **11** ($2C_{12}H_{12}N_2S_2{\cdot}AgClO_4$), and **13** [$C_{30}H_{27}N_7{\cdot}Ag(CH_3CN)ClO_4$] reveal similar structural features but lack specific photophysical properties.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Metal complexes of N-donor ligands are of considerable current interest because they catalyze many organic transformations,[1] including the cyclization of 1,2-allene derivatives,[2] the asymmetric cyclization reaction of isocyanoacetic acid or isocyanomethyl toluenesulfonate with aldehydes,[3] asymmetric intramolecular carbene C−H insertion reactions[4] and the enantioselective addition of allyltin reagents to aldehydes.[5,6] Further interest is in photoluminescent complexes of copper(I). The photophysics of compounds derived from 1,10-phenanthroline species, which contain the Cu^IN_4 chromophore, is well established.[7−9] However, materials based on other ligands with N-donor atoms are less abundant in the literature.[10−12] In this context we have synthesized a series of new nonconjugated diimine and imine-amine nitrogen donor ligands (**1**−**5**) and attempted the formulation and thorough spectral and structural characterization of their complexes with Cu^I, as well as with the related Ag^I ion. The linear ligands **1**−**4** also contain peripheral thiophene substituents, which may have some unique effect on the photophysical properties of the anticipated Cu^IN_4 chromophores, depending on the proximity of the sulfur atoms (although they are considered to be weak nucleophiles) to the complexation site. Another variant of this study involves transition metal complexes with tetradentate tripodal Schiff-base ligands, due to their diverse structural and physical properties, as well as their possible application as magnetic imaging agents and models of metalloenzymes such as superoxide dismutases.[13,14] Correspondingly, Cu^I and Ag^I complexes with the tripodal ligand **5** were prepared and characterized. The Cu^I complex of **5** is also photoluminescent.



Herein we report the detailed structures and preliminary photophysical properties of three new Cu^IN_4 chromophores derived from ligands **1**, **2**, and **5**; chemical spectral and structural data are provided for the Ag^I complexes of these ligands as well. The bulky ligand **3** does not form stable complexes with these metal ions, while the asymmetric ligand **4** yields a stable structure only with divalent copper ions.

Results and Discussion

Synthesis and Structure

Compounds **1** and **2** were synthesized by condensing ethylenediamine with 2-thiophenecarboxaldehyde or 3-thiophenecarboxaldehyde, respectively. These compounds are flexible about the central C−C bond. A 1:2 condensation reaction of benzil dihydrazone with 2-thiophenecarboxaldehyde yields a bulkier ligand **3**, which is considerably more rigid. The molecular structures of **2** and **3** are shown in Figure 1. Ligand **2** is located in the crystal on an axis of twofold rotational symmetry, the torsion angle about the central C−C bond that connects the two equivalent parts of the molecule being 70.6(3)°. The inner nitrogen atoms are exposed to the surrounding species, and provide excellent sites for metal ion binding. The N−C−C−N torsion angle about the central bond in **3** is 49.6(2)°. The nitrogen atoms are involved in partly delocalized π-electron systems

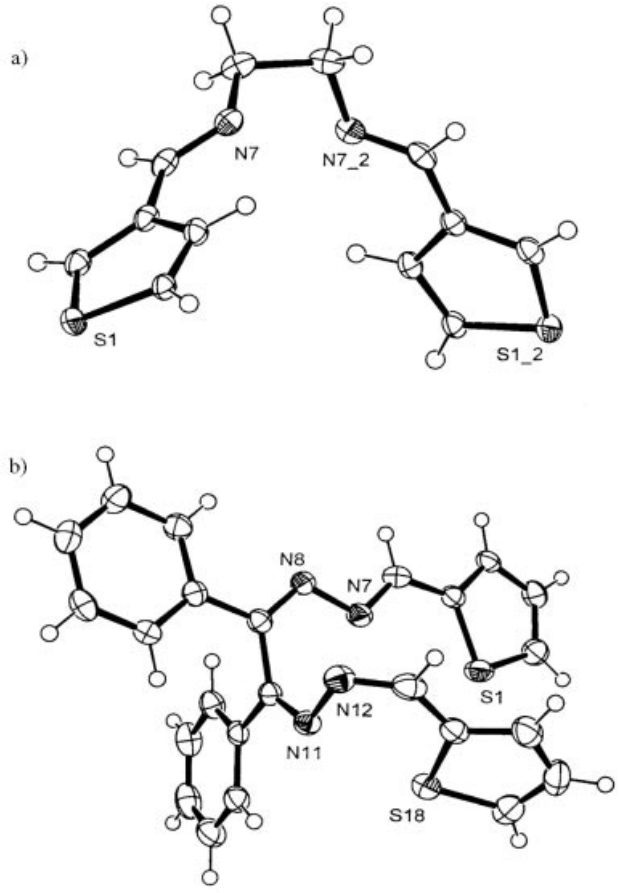

Figure 1. Molecular structures of (a) ligand **2** (located on a twofold symmetry axis), and (b) ligand **3**; the heteroatoms are indicated by darkened circles and are labeled; 50% probability thermal ellipsoids at 110 K are shown

(one part of the molecule is nearly planar; Figure 1), and therefore are less-effective donor sites for complex formation.

In this work we have been able to synthesize and crystallize stable Cu^I and Ag^I complexes of **1** and **2**, but no metal ion complexes of **3** could be obtained. The copper(I) derivatives were prepared by treating ligands **1** and **2** with $[Cu(CH_3CN)_4]ClO_4$ in anhydrous methanol under argon in a 1:2 metal/ligand ratio. The resulting bright orange-yellow solids $[Cu(\mathbf{1})_2](ClO_4)$ (**6**) and $[Cu(\mathbf{2})_2](ClO_4)$ (**7**) are extremely stable in air both in the solid state and in solution (CH_3OH and CH_2Cl_2). The observed structures of the cat-

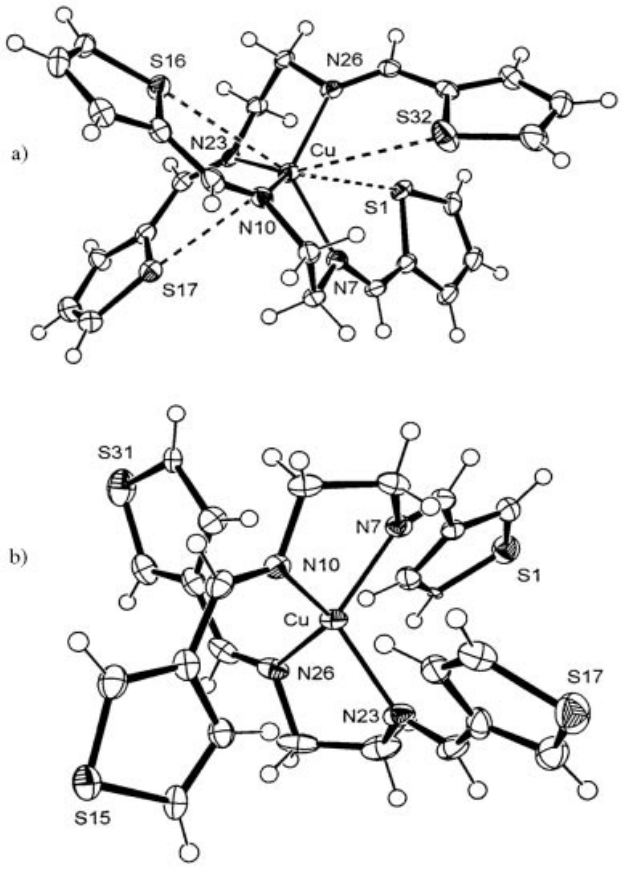

Figure 2. Complexes of Cu^I with (a) ligand **1**, and (b) ligand **2**; note in (a) the additional attractive interactions of the metal ion with the inward turning sulfur sites (dotted lines); in this and the following structural illustration the counterions and solvent moieties are omitted for clarity

ionic species in **6** and **7** are illustrated in Figure 2. The high propensity of the copper ion to form tetrahedrally structured complexes determines the 1:2 stoichiometry of the metal/ligand reaction. In **6** and **7** the Cu−N bond lengths within the Cu^IN_4 chromophore are in the range 2.004−2.111(2) and 2.039−2.071(3) Å, respectively. However, in **6** all the S-atom sites of the 2-thiophene substituents are oriented towards, and weakly interact with, the central metal ion; the corresponding Cu···S distances range from 3.24 to 3.60 Å (Figure 2, a). Such interactions are not possible in the 3-thiophene derivative **7**. As a result the thiophene rings in this structure (as well as in the related complexes described below) tend to exhibit twofold orientational disorder about the C−C bond through which they are connected to the central part of the ligand. The Cu^IN_4 moieties are distorted tetrahedra with two N−Cu−N

angles near 85° (which involve nitrogen atoms from the same ligand) and four N−Cu−N angles greater than 115° (for N atoms of the two different ligands).

The corresponding $[Cu(\mathbf{1})_2](ClO_4)_2$ complex with divalent copper, of a deep-green color, is stable in CH_3OH or CH_3CN only for a few minutes, and could not be characterized. An alternative reaction of **1** with $Cu(CF_3SO_3)_2$ yielded a somewhat more stable product, $[Cu(\mathbf{1})_2](CF_3SO_3)_2$ (**8**), which is stable in air, and in solution in CH_3OH or CH_3CN, for about 2−3 h. However, upon slow recrystallization from the solution mixture the ligand framework in **8** is partially hydrolyzed, transforming after about 8 h to a different species of composition $[Cu(\mathbf{4})_2](CF_3SO_3)_2$ (**9**) characterized by a light pink color.[15] In situ partial hydrolysis of a diimine ligand within the coordination sphere of copper is rare. No stable complexes of ligand **2** with Cu^{II} ions could be obtained under similar experimental conditions. The structure of the $[Cu(\mathbf{4})_2]^{2+}$ cation in **9** is depicted in Figure 3. It shows a nearly square-planar complex with the metal ion located on a center of inversion, with Cu−N distances of 1.997(2) and 2.038(2) Å and N−Cu−N bond angles between the *cis*-related nitrogen sites of 83.40(6)° within the ligand and 96.60(6)° between the two ligands.

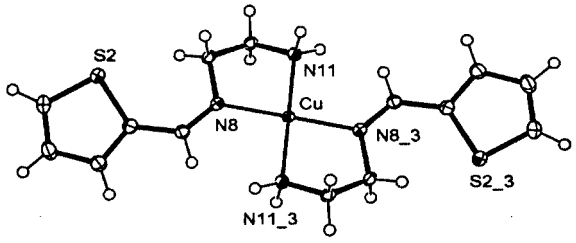

Figure 3. Molecular structure of the square-planar complex **9** of Cu^{II}, the metal ion being located in the crystal on a crystallographic center of inversion

The structures of the respective Ag^I complexes of **1** and **2** {$[Ag(\mathbf{1})_2](ClO_4)$ (**10**) and $[Ag(\mathbf{2})_2](ClO_4)$ (**11**)} are shown in Figure 4. They were prepared readily by treating the ligands with $Ag(ClO_4)$ at room temperature. These two 1:2 metal/ligand complexes are stable in the solid state for about two weeks, and in solution (MeOH or MeCN) for at least 12 h. Their structures have a distorted tetrahedral geometry similar to that observed for the corresponding copper(I) derivatives.

The coordination parameters are: (a) in **10**, Ag−N bond lengths of 2.293−2.298(3) Å, N−Ag−N bond angles within the same ligand of nearly 76°, and involving two different ligands greater than 120°; (b) in **11**, the corresponding values are 2.273−2.353(3) Å, 76−77° and greater than 118°, respectively. In **10**, the silver ions are also approached, in a convergent manner, by the four thiophene S-sites at an Ag···S distance range of 3.22−3.37 Å. The latter may represent additional weakly attractive interactions between the metal ion and the ligand species.

Ligand **5** is a 1:3 condensate of tris(2-aminoethyl)amine (tren) and 4-cyanobenzaldehyde. It contains an amino nitrogen atom, as well as three imino N-donors, and may act

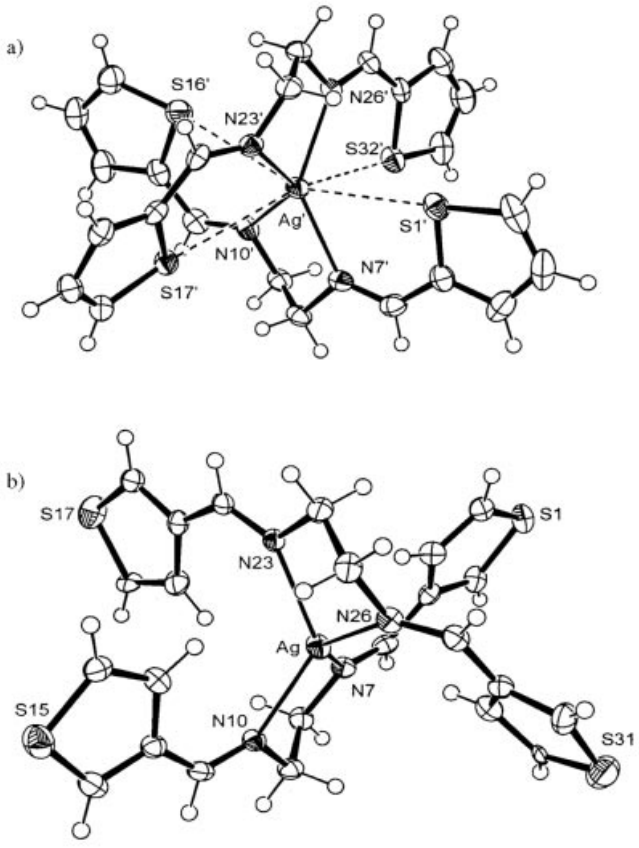

Figure 4. Structures of complexes of Ag^I with (a) ligand **1**, and (b) ligand **2**; note in (a) the additional attractive interactions of the metal ion with the inward turning sulfur sites (dotted lines), as in the corresponding Cu^I complex shown in Figure 2a

as a tetradentate ligand of adjustable conformation. Correspondingly, in complexation reactions with Cu^I and Ag^I one molecule of **5** should function as two molecules of **1** or **2**. The yellow-reddish Cu^I complex $[Cu(\mathbf{5})](ClO_4)$ (**12**) was obtained by treating **5** with $[Cu(CH_3CN)_4]ClO_4$ in equimolar proportions in methanol under argon. Complex **12** is also fairly stable in air, both in the solid state and in solution. A similar reaction of **5** with $Ag(ClO_4)$ in acetonitrile at room temperature yielded $[Ag(\mathbf{5})(CH_3CN)](ClO_4)$ (**13**). The molecular structures of the two complexes are illustrated in Figure 5.

Indeed, complex **12** has a tripodal structure with the Cu^I cation trapped inside the ligand by internal coordination to the four N-donor sites. The Cu−N(imino) distances are within the range 2.000−2.008(2) Å, while the Cu−N(amino) bond length is 2.206(2) Å. The geometry of the Cu^IN_4 moiety in this structure resembles a trigonal pyramid with the amino nitrogen atom at its apex. The Cu^IN_4 chromophore with a trigonal-pyramidal geometry around the metal ion is not common.[16] The N(imino)−Cu−N(amino) bond angles are constrained by the proximity of the two nitrogen sites to low values within the range 84.6−85.3(1)°, while the geometrically less constrained N(imino)−Cu−N(imino) bond angles in the base of the pyramid are characterized by larger values of be-

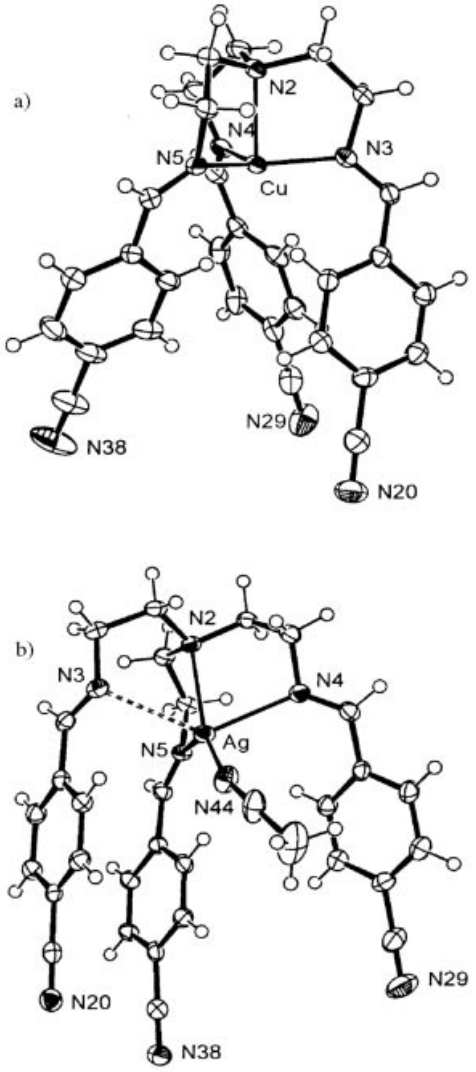

Figure 5. Structures of the tripodal complexes of ligand **5** with (a) Cu^I and (b) Ag^I; the Cu^IN_4 moiety in (a) is characterized by a trigonal-pyramidal geometry; the coordination geometry around the silver ion in (b) is affected by the additional coordinated acetonitrile ligand

tween 116.6 and 121.4(1)°. The geometry of the corresponding silver complex **13** is disrupted by coordination of one acetonitrile ligand which coordinates to the metal ion with an Ag−N distance of 2.211(3) Å. The latter also coordinates strongly to three N-atom donor sites of the ligand at 2.315−2.461(2) Å, and more weakly to the fourth (imino) nitrogen at 2.763(2) Å.

IR and NMR Characterization

Ligands **1** and **2** exhibit strong IR absorption bands at 1635 and 1641 cm^{-1}, respectively, for the ν(C=N) stretching vibration. On coordination with Cu^I this band shifts to much lower energies (1611 and 1614 cm^{-1} for **6** and **7**, respectively). In case of the Ag^I complexes **10** and **11**, however, this band appears at 1631 and 1640 cm^{-1}, respectively. For the ligand **5** and its Cu^I and Ag^I complexes, **12** and **13**, this ν(C=N) stretching vibration appears at 1642, 1635, and 1633 cm^{-1}, respectively, and the ν(C≡N) stretching vibrations appear at 2221, 2228, and 2226 cm^{-1}, respectively. Complexes **6**, **7**, **10**, **11**, **12**, and **13** give characteristic well-resolved bands around 1088, 1080, 1085, 1081, 1090, and 1091 cm^{-1}, respectively, for the noncoordinated ν(ClO_4^-) vibrations.[17]

The ^1H and ^{13}C NMR spectra of the ligands **1**, **2**, and **5** in $CDCl_3$ consist of sharp and well-resolved signals for each of the organic groupings present. The Cu^I and Ag^I complexes **6**, **7** and **10**, **11** show almost the same pattern as the ligand in their ^1H NMR spectra in $(CD_3)_2SO$. While the ^1H NMR spectrum of **13** shows the same pattern as that of the ligand, the ^1H NMR spectrum of **12** shows different chemical shifts. In case of the ligand **5** and its Ag^I complex **13** all the phenylic protons appear at the same position (δ = 7.67 ppm for ligand **5** and δ = 7.93 ppm for the Ag^I complex **13**) but for the Cu^I complex **12** they appear at two different positions (δ = 8.07 and 7.46 ppm). In the EI mass spectra ligands **1** and **2** show exactly the same type of fragmentation pattern.

Electrochemistry

The redox behavior of the Cu^I complexes **6**, **7**, and **12** has been examined by cyclic voltammetry in dichloromethane at a glassy carbon working electrode under dry N_2 (Figure 6). Quasi-reversible oxidative voltammograms attributed to the $Cu^{II/I}$ couple were observed with half-wave potential ($E_{1/2}$) values of 1.001, 0.958 and 0.692 V vs. Ag/AgCl, 1 M KCl for **6**, **7**, and **12**, respectively. The couple is more reversible in the case of **6** and **7** than for **12**. The peak-to-peak (ΔE_p) separation values for this couple are 190, 205, and 310 mV for **6**, **7**, and **12**, respectively, at a scan rate of 50 $mV \cdot s^{-1}$ and these values increase when the scan rate is increased. The higher potential of this couple in **6** and **7** than in **12** indicates that the Cu^I complexes **6** and **7** are more stable than **12**; this has been observed experimentally: a dichloromethane solution of **6** or **7** is stable in air

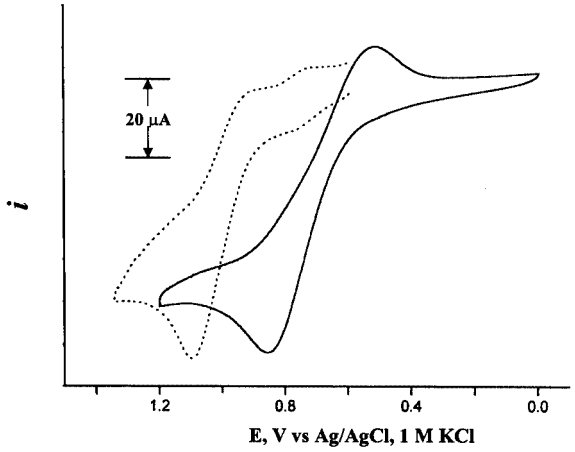

Figure 6. Cyclic voltammograms of **6** (broken line) and **12** (full line) [approximately 10^{-3} M in dichloromethane, 0.2 M Bu_4NClO_4] at a glassy carbon electrode, scan rate 50 $mV \cdot s^{-1}$

for at least 10 d, whereas a solution of **12** is stable only for about 3−4 d. The $Cu^{II/I}$ potential in the $Cu^{I}N_4$ chromophore increases with the π-acidity of the ligand and the extent of tetrahedral distortion in the corresponding copper(II) species.[18] The π-acidity of ligands **1** and **2** is larger than that of **5**. In this context, it should be mentioned that, to the best of our knowledge, the highest potential for the $Cu^{II/I}$ couple so far reported in a $Cu^{I}N_4$ chromophore is 1.55 V vs. SCE.[8]

UV/Vis and Photophysical Data

There is a difference in the absorption spectra of the ligands **1** and **2** in dichloromethane. While ligand **1** shows two charge-transfer bands at 284 and 261 nm with intensities (ε) of 24975 and 28160 $M^{-1}cm^{-1}$, respectively, ligand **2** shows only one charge-transfer band at 250 nm (ε = 31 945). These intra-ligand charge-transfer bands appear at 282 and 266 nm for the Cu^{I} complex **6** and at 254 nm for **7**. In addition to these bands, **6** shows two metal-to-ligand charge-transfer (MLCT) bands at 415 (ε = 2480) and 345 nm (ε = 8785). These two MLCT bands appear at 410 (ε = 2405) and 347 nm (ε = 7250) for complex **7**. The deep green color of copper(II) complexes of the ligand **1** and pale pink color of the copper(II) complex of ligand **4** are due to the d-d transition band at 613 nm (ε = 215) and 587 nm (ε = 150), respectively. Ligand **5** shows an intra-ligand charge-transfer band at 255 nm (ε = 38 120) in dichloromethane. This band appears at 251 nm (ε = 30 730) for its copper(I) complex **12** and at 248 nm (ε = 26 500, in CH_3CN) for its silver(I) complex **13**. The copper(I) complex shows an MLCT band at 379 nm (ε = 2526).

Ligands **1**, **2**, and **5** are not photoluminescent in dichloromethane. Upon excitation at 350 nm (MLCT envelope) in dichloromethane at room temperature both complexes **6** and **7** yield a single, structureless, broad emission band with maxima at 445 and 456 nm, respectively, with quantum yields (φ) of $2.9\cdot10^{-4}$ and $7.2\cdot10^{-5}$ (against quinine sulfate[19] in 0.1 N H_2SO_4; Figure 7), respectively. In complex **6** all the four S-atoms are directed towards the metal ion, so the metal coordination sphere is sterically more hindered. This may be the reason for the larger quantum yield (φ) of **6** than **7**. The chemical nature, the size and the position of the substituents in the ligand can affect the geometry of the excited state, which influences the emission properties.[9] It has been found for 2,9-disubstituted phenanthroline derivatives that the Cu^{I} geometry is stabilized by enforcing a tetrahedral geometry that inhibits the flattened square-planar coordination geometry in the Cu^{II} state formed upon excitation.[20]

On excitation at 380 nm (MLCT band), complex **12** exhibits a single structureless broad emission band with a maximum at 505 nm and a quantum yield (φ) of $5.8\cdot10^{-5}$ (against quinine sulfate[19] in 0.1 N H_2SO_4; Figure 7). The photophysical properties of the $Cu^{I}N_4$ chromophore have been analysed mainly for complexes of Cu^{I} with derivatives of 1,10-phenanthroline.[9] These complexes are of the bis-type in which all the nitrogen donor atoms are essentially of the same type. Complex **12** is only the second known example of a photoluminescent $Cu^{I}N_4$ chromophore where the nitrogen donor atoms are of the imino as well as the amino type, and come from the same ligand. The only photoluminescent $Cu^{I}N_4$ chromophore of this type known so far has been reported recently.[12]

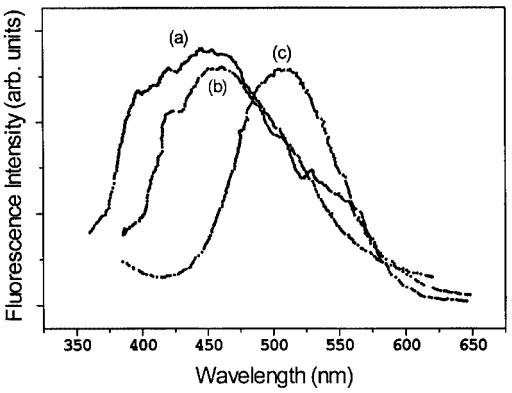

Figure 7. Emission spectra of (a) **6**, (b) **7**, and (c) **12** at room temperature in dichloromethane; excitation wavelength is 350 nm for **6** and **7**, 380 nm for **12**; absorbances for **6**, **7**, and **12** are 0.68, 0.73, and 0.80, respectively

Conclusions

In a search for new metal ion complexes with interesting features, we have synthesized a series of copper(I) and silver(I) compounds with targeted diimine and tripodal ligands, and examined their structural, photophysical, and electrochemical properties. The copper(I) complexes are of particular interest here, as they reveal a more unique photophysical behavior. The emission quantum yield (φ) of complex **6** at room temperature in dichloromethane was found to be four to five times larger than that of complexes **7** and **12**. The $Cu^{II/I}$ redox potential values of all three compounds are rather high, indicating that the copper(I) state is much more stable than the corresponding copper(II) state.

Experimental Section

General Procedures: The complex $[Cu(CH_3CN)_4]ClO_4$ was synthesized by a reported procedure.[21] All other reagents were procured commercially. Copper was estimated gravimetrically as CuSCN. Microanalyses were performed with Perkin−Elmer 2400II elemental analyzer and CE instruments. Melting points were determined by an electrothermal IA9000 series digital melting point apparatus and are uncorrected. IR spectra (KBr disc) were recorded with a Nicolet Magna-IR spectrophotometer (Series II), UV/Vis spectra with a Shimadzu UV-160A spectrophotometer, ^1H and ^{13}C NMR spectra with a Bruker DPX200 spectrometer and EI (electron impact) mass spectra with a VG Autospec M-250 instrument. Cyclic voltammetry was performed at room temperature at a planar glassy carbon milli electrode using μ-Autolab II with GPES software, version 4.8.5 (EcoChemie, The Netherlands) in purified and anhydrous dichloromethane under dry nitrogen with a conventional three-electrode configuration. Under the experimental condi-

tions employed here, the ferrocene/ferrocenium couple appears at 0.42 V vs. Ag/AgCl in 1 M KCl with a ΔE_p of 110 mV at a scan rate of 50 mV·s^{-1} (Figure 6). The photophysical studies were performed in air with a Shimadzu RF-540 spectrofluorophotometer.

Ligand 1: Distilled ethylenediamine (1 mL, 15 mmol) and freshly distilled 2-thiophenecarboxaldehyde (2.80 mL, 30 mmol) were refluxed in 60 mL of anhydrous methanol for 6 h. On evaporating the solvent a light yellow solid was obtained, which on recrystallization from *n*-hexane gave colorless needles suitable for X-ray analysis. Yield: 2.98 g (80%); m.p. 91−93 °C. $C_{12}H_{12}N_2S_2$ (248.36): calcd. C 58.01, H 4.87, N 11.28, S 25.83; found C 58.05, H 4.83, N 11.32, S 25.87. EI-MS: *m*/*z* (%) = 248.1 (20) [M$^+$], 124 (55) [M$^+$/2]. FTIR (KBr): $\tilde{\nu}$ = 507 (m), 577 (m), 648 (w), 715 (vs), 792 (vs), 841 (s), 860 (s), 955 (s), 1051 (s, split), 1192 (m), 1235 (vs), 1284 (s), 1326 (m), 1430 (s), 1635(vs), 2848 (wb), 2908 (wb), 3099 (s) cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 8.35 (s, 2 H), 7.35 (d, *J* = 4 Hz, 2 H), 7.27 (d, *J* = 4 Hz, 2 H), 7.04 (dd, *J* = 2 and 4 Hz, 2 H), 3.91 (s, methylene, 4 H) ppm. ^{13}C NMR (200 MHz, $CDCl_3$, TMS): δ = 155.96, 142.27 (quaternary), 130.46, 128.70, 127.27, 60.92 ppm. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 284 (24975), 261 nm (28160 M^{-1}·cm^{-1}).

Ligand 2: This compound was prepared by following a similar procedure starting with distilled ethylenediamine (1 mL, 15 mmol) and freshly distilled 3-thiophenecarboxaldehyde (2.63 mL 30 mmol) to obtain shiny white crystals, suitable for X-ray analysis. Yield: 2.66 g (71%); m.p. 97 °C. $C_{12}H_{12}N_2S_2$ (248.36): calcd. C 58.01, H 4.87, N 11.28, S 25.83; found C 58.08, H 4.91, N 11.27, S 25.90. EI-MS: *m*/*z* (%) = 248.1 [M$^+$] (20), 124 [M$^+$/2] (55). FTIR (KBr): $\tilde{\nu}$ = 575 (m), 625 (s), 717 (m), 789 (vs), 828 (s), 878 (m), 902 (m), 1021 (vs), 1070 (m), 1160 (s, split), 1240 (vs), 1291 (s), 1346 (w), 1354 (m), 1426 (m), 1458 (s), 1641 (vs), 2844 (wb), 3049 (m, split), 3091 (s) cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 8.28 (s, 2 H), 7.57 (d, *J* = 4 Hz, 2 H), 7.51 (d, *J* = 4 Hz, 2 H), 7.30 (dd, *J* = 2 and 4 Hz, 2 H), 3.90 (s, methylene, 4 H) ppm. ^{13}C NMR (200 MHz, $CDCl_3$, TMS): δ = 156.98, 140.32 (quaternary), 128.44, 126.30, 125.66, 61.57 ppm. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 250 nm (31945 M^{-1}·cm^{-1}).

Ligand 3: Benzil dihydrazone (1.87 g, 7.85 mmol), synthesized by a reported procedure,[22] was dissolved in 50 mL of anhydrous methanol. To this solution, freshly distilled 2-thiophenecarboxaldehyde (1.47 mL, 15.70 mmol) was added. The resulting yellowish mixture was refluxed for 6 h, maintaining dry conditions. Then it was slowly cooled to room temperature to yield a yellowish crystalline solid, which was filtered off and dried in air. Crystals suitable for X-ray analysis were obtained by slow concentration of an acetonitrile solution. Yield 2.15 g (64%); m.p. 159−160 °C. $C_{24}H_{18}N_4S_2$ (426.54): calcd. C 67.56, H 4.26, N 13.14, S 15.05; found C 67.58, H 4.29, N 13.19, S 14.99. FTIR (KBr): $\tilde{\nu}$ = 525(m), 596 (m), 610 (m), 685 (vs), 712 (vs), 764 (vs, split), 835 (w), 919 (m), 1050 (s), 1074 (m), 1175 (m), 1212 (s), 1237 (m, split), 1299 (w), 1326 (m), 1424 (vs), 1445 (s), 1490 (s), 1605 (vs), 2840 (wb), 2917 (w), 3105(s) cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 8.65 (s, 2 H), 8.05−7.99 (m, 6 H), 7.97−7.90 (m, 6 H), 7.30 (d, 2 H), 7.10 (d, 2 H), 6.96 (dd, 2 H) ppm. ^{13}C NMR (200 MHz, $CDCl_3$, TMS): δ = 164.86 (quaternary), 162.40 (quaternary), 155.65, 148.31, 139.22 (quaternary), 134.19, 133.50, 131.75, 128.80, 127.22 ppm. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 328 (35 600), 276 (28 690), 257 nm (26845 M^{-1}·cm^{-1}). EI-MS: *m*/*z* (%) = 426.1 [M$^+$] (15).

[Cu(1)$_2$]ClO$_4$ (6): Solid $[Cu(CH_3CN)_4]ClO_4$ (0.165 g, 0.5 mmol) was added to 30 mL of an anhydrous, degassed methanol solution of **1** (0.25 g, 1 mmol) under argon, and stirred for 1 h maintaining dry conditions. An orange-yellow compound precipitated. This was filtered off, washed with 2 mL of methanol and dried in vacuo over fused $CaCl_2$. Yield: 0.18 g (55%). Single crystals were grown by diffusion of *n*-hexane into a concentrated dichloromethane solution of the complex. $C_{24}H_{24}ClCuN_4O_4S_4$ (659.70): calcd. C 43.67, H 3.67, Cu 9.63, N 8.49, S 19.45; found C 43.62, H 3.73, Cu 9.69, N 8.46, S 19.49. FTIR (KBr): $\tilde{\nu}$ = 625 (m), 641 (w), 722 (m, split), 853 (w), 1088 (vs), 1108 (vs), 1187 (m), 1234 (s), 1288 (s), 1321 (m), 1435 (s), 1611 (vs), 2850 (wb), 2910 (m), 3099 (s) cm^{-1}. ^{1}H NMR [200 MHz, $(CD_3)_2SO$, TMS]: δ = 8.68 (s, 4 H), 7.52 (d, *J* = 4 Hz, 4 H), 7.27 (d, *J* = 4 Hz, 4 H), 7.05 (dd, *J* = 2 and 4 Hz, 4 H), 4.17 (s, methylene, 8 H) ppm. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 415 sh (2480), 345 sh (8785), 282 (22080), 266 nm (31250 M^{-1}·cm^{-1}).

[Cu(2)$_2$]ClO$_4$ (7): This complex was prepared similarly by treating $[Cu(CH_3CN)_4]ClO_4$ (0.165 g, 0.5 mmol) with **2** (0.25 g, 1 mmol) in 50 mL of anhydrous methanol under argon. Yield: 0.16 g (48%). Single crystals were grown by direct diffusion of *n*-hexane into a dichloromethane solution of the complex. $C_{24}H_{24}ClCuN_4O_4S_4$ (659.70): calcd. C 43.67, H 3.67, Cu 9.63, N 8.49, S 19.45; found C 43.69, H 3.74, Cu 9.74, N 8.44, S 19.47. FTIR (KBr): $\tilde{\nu}$ = 628 (m), 722 (m, split), 787 (m), 832 (s), 910 (w), 1080 (vs), 1105 (vs), 1161 (m), 1236 (m), 1326 (w), 1371 (w), 1462 (s), 1614 (vs), 3096 (s) cm^{-1}. ^{1}H NMR [200 MHz, $(CD_3)_2SO$, TMS]: δ = 8.42 (s, 4 H), 7.76 (br., 4 H), 7.55 (br., 4 H), 7.05 (br. 4 H), 4.08 (s, methylene, 8 H) ppm. UV/Vis (CH_3OH): λ_{max} (ε) = 410 sh (2405), 347 sh (7250), 254 nm (34320 M^{-1}·cm^{-1}).

[Cu(1)$_2$](CF$_3$SO$_3$)$_2$ (8): Ligand **1** (0.25 g, 1 mmol) was dissolved in 20 mL of acetonitrile. To this colorless solution 5 mL of an acetonitrile solution of $Cu(CF_3SO_3)_2$ (0.18 g, 0.5 mmol) was added dropwise with constant stirring. The solution turned bottle green. Diethyl ether was then added dropwise to this solution until precipitation occurred. The reaction mixture was kept in a refrigerator for 10 min. The green precipitate was then filtered off, washed with diethyl ether, and dried in air. Yield: 0.44 g (51%). $C_{26}H_{24}CuF_6N_4O_6S_6$ (858.12): calcd. C 36.36, H 2.82, Cu 7.40, N 6.53, S 22.42; found C 36.41, H 2.85, Cu 7.47, N 6.49, S 22.48. FTIR (KBr): $\tilde{\nu}$ = 528 (w), 535 (m), 641 (s), 736 (s), 867 (m), 1118 (m), 1211 (m), 1268 (vs, split), 1338 (m), 1418 (s), 1621 (vs), 2912 (wb), 3095 (m) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 613 (215), 287 (34225), 264 nm (35075 M^{-1}·cm^{-1}).

[Cu(4)$_2$](CF$_3$SO$_3$)$_2$ (9): Complex **8** (0.43 g, 0.5 mmol) was dissolved in 15 mL of acetonitrile. To this solution 10 mL of diethyl ether was added. This green solution was kept in the refrigerator for 8 h. Light pink colored crystals, suitable for X-ray analysis were deposited. These were filtered and dried in vacuo over fused $CaCl_2$. Yield: 0.095 g (28%). $C_{16}H_{20}CuF_6N_4O_6S_4$ (670.14): calcd. C 28.66, H 3.01, Cu 9.48, N 8.36, S 19.14; found C 28.72, H 2.95, Cu 9.43, N 8.42, S 19.18. FTIR (KBr): $\tilde{\nu}$ = 515 (m), 576 (m), 635 (s), 755 (m), 1042 (vs, split), 1112 (m), 1170 (vs), 1265 (vs, split), 1486 (m), 1625 (vs), 2895 (w), 3305 (vb) cm^{-1}. UV/Vis (CH_3CN): λ_{max} (ε) = 587 (150), 281 (28470), 269 nm (28750 M^{-1}·cm^{-1}).

[Ag(1)$_2$](ClO$_4$) (10): Ligand **1** (0.25 g, 1 mmol) was dissolved in 15 mL of methanol. To this solution 5 mL of a methanol solution of $AgClO_4$ (0.105 g, 0.5 mmol) was added dropwise with constant stirring, causing an off-white solid to precipitate. It was kept in air for 1 h, then filtered off, washed with 2 mL of methanol and dried in vacuo over fused $CaCl_2$. Yield: 0.19 g (54%). Single crystals suitable for X-ray analysis were grown by slow concentration of an acetonitrile solution. The compound crystallizes with half a molecule of the acetonitrile solvent. $C_{24}H_{24}AgClN_4O_4S_4$ (704.03): calcd. C 40.92, H 3.44, N 7.96, S 18.22; found C 40.95, H 3.39, N 10.89,

S 18.26. FTIR (KBr): $\tilde{\nu}$ = 505 (m), 581 (w), 623 (s), 715 (vs), 842 (s), 951 (m), 1085 (vs, split), 1217 (m), 1285 (m), 1326 (w), 1430 (s), 1459 (m), 1631 (vs), 2861 (wb), 3100 (m) cm^{-1}. ^1H NMR [200 MHz, $(CD_3)_2SO$, TMS]: δ = 8.83 (s, 4 H), 7.74 (d, J = 4 Hz, 4 H), 7.61 (d, J = 4 Hz, 4 H), 7.14 (dd, J = 2 and 4 Hz, 4 H), 4.06 (s, methylene, 8 H) ppm. UV/Vis (CH_3CN): λ_{max} (ε) = 281 (28385), 260 nm (32155 $M^{-1}\cdot cm^{-1}$).

[Ag(2)$_2$](ClO$_4$) (11): Silver perchlorate (0.105 g, 0.5 mmol) was added to a solution of **2** (0.25 g, 1 mmol) in 20 mL of methanol. The reaction mixture was stirred at room temperature for 1 h. A light yellow compound precipitated. This was filtered off, washed with a few drops of methanol and dried in vacuo over fused $CaCl_2$. Yield: 0.16 g (46%). Single crystals suitable for X-ray analysis were grown by slow evaporation of the methanol solution of the complex. $C_{24}H_{24}AgClN_4O_4S_4$ (704.03): calcd. C 40.92, H 3.44, N 7.96, S 18.22; found C 40.97, H 3.48, N 7.91, S 18.28. FTIR (KBr): $\tilde{\nu}$ = 579 (w), 625 (vs), 715 (w), 790 (vs), 867 (m, split), 951 (m), 1081 (vs, split), 1237 (m), 1291 (s), 1346 (m), 1407 (m), 1457 (s), 1522 (m), 1640 (vs), 2843 (wb), 2904 (w), 3098 (m) cm^{-1}. ^1H NMR [200 MHz, $(CD_3)_2SO$, TMS]: δ = 8.68 (s, 4 H), 8.15 (d, J = 4 Hz, 4 H), 7.73 (d, J = 4 Hz, 4 H), 7.63 (dd, J = 2 and 4 Hz, 4 H), 3.94 (s, methylene, 8 H) ppm. UV/Vis (CH_3CN): λ_{max} (ε) = 248 nm (37535 $M^{-1}\cdot cm^{-1}$).

Ligand 5: 4-Cyanobenzaldehyde (3.93 g, 30 mmol) was dissolved in 150 mL of anhydrous methanol. To this solution distilled tris(2-aminoethyl)amine (1.5 mL, 10 mmol) was added dropwise. The re-

[a] Molecules are located on symmetry axes of twofold rotation. [b] The crystallographic asymmetric unit contains two independent moieties of the complex. [c] The metal complex is located on centers of inversion.

action mixture was refluxed for 8 h maintaining dry conditions. Then, it was transferred into a beaker and left in the air overnight. A yellowish solid precipitated. This was filtered off, washed with 5 mL of methanol, dried in the air, and then recrystallized from acetonitrile. Yield: 3.2 g (66%); m.p. 135−137 °C. $C_{30}H_{27}N_7$ (485.27): calcd. C 74.19, H 5.61, N 20.20; found C 74.26, H 5.66, N 20.14. EI-MS: *m/z* (%) = 486.2 [MH^+] (30). FTIR (KBr): $\tilde{\nu}$ = 553 (s), 646 (m), 834 (vs), 927 (m), 1023 (m), 1067 (vs), 1158 (w), 1221 (w), 1287 (m), 1375 (s), 1440 (m), 1503 (m), 1642 (vs), 2221 (vs), 2841 (wb), 3428 (vb) cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$, TMS): δ = 8.19 (s, 3 H), 7.67 (m, 12 H), 3.74 (t, methylene, 6 H), 2.97 (t, methylene, 6 H) ppm. ^{13}C NMR (200 MHz, $CDCl_3$, TMS): δ = 159.73, 139.86 (quaternary), 132.31, 128.26, 118.30 (quaternary), 113.79 (quaternary), 60.08, 55.20 ppm. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 255 nm (38120 $M^{-1}\cdot cm^{-1}$).

[Cu(5)]ClO_4 (12): Complex **5** (0.243 g, 0.5 mmol) was dissolved in 35 mL of anhydrous methanol by warming. Argon was purged through the solution and it was then cooled to room temperature. After 15 min, solid [$Cu(CH_3CN)_4$]ClO_4 (0.165 g, 0.50 mmol) was added to the degassed methanol solution. The reaction mixture was stirred at room temperature under argon for 1 h, maintaining dry conditions. A reddish yellow compound precipitated. This was filtered off, washed with 2 mL of methanol, and dried in vacuo over fused $CaCl_2$. Yield: 0.148 g (46%). Single crystals were grown by direct diffusion of diethyl ether into a concentrated acetonitrile solution of the complex. The compound crystallizes with one molecule of acetonitrile and half a molecule of diethyl ether. $C_{30}H_{27}ClCuN_7O_4$ (648.58): calcd. C 55.53, H 4.20, Cu 9.80, N 15.11; found C 55.61, H 4.25, Cu 9.91, N 15.08. FTIR (KBr): $\tilde{\nu}$ = 556 (s), 624 (s), 829 (s), 890 (m), 1090 (vs, split), 1286 (m), 1390 (w), 1460 (m), 1635 (vs), 2228 (vs), 2858 (wb), 3449 (vb) cm^{-1}. ^1H NMR [200 MHz, $(CD_3)_2SO$, TMS]: δ = 8.75 (s, 3 H), 8.07 (d, 6 H), 7.46 (d, 6 H), 3.88 (s, methylene, 6 H), 3.12 (s, methylene, 6 H) ppm. UV/Vis (CH_2Cl_2): λ_{max} (ε) = 379 (2526), 251 nm (30730 $M^{-1}\cdot cm^{-1}$).

[Ag(5)(CH_3CN)]ClO_4 (13): Silver perchlorate (0.105 g, 0.5 mmol) was added to a solution of **5** (0.243 g, 0.5 mmol) in 25 mL of acetonitrile. The reaction mixture was stirred at room temperature for 1 h and was then kept in a refrigerator for 24 h. Large colorless blocks, which were suitable for X-ray analysis, separated. They were filtered off, washed with a few drops of methanol, and dried in vacuo over fused $CaCl_2$. Yield 0.155 g (42%). One molecule of the acetonitrile solvent was found coordinated to the silver ion (another noncoordinated acetonitrile was found included in the lattice with partial occupancy). $C_{32}H_{30}AgClN_8O_4$ (733.79): calcd. C 52.34 H 4.12, N 15.27; found C 52.60, H 4.10, N 15.32. FTIR (KBr): $\tilde{\nu}$ = 552 (s), 623 (s), 833 (s), 927 (m), 972 (w), 1091 (vs, split), 1220 (w), 1288 (m), 1374 (m), 1505 (m), 1563 (w), 1633 (vs), 2226 (vs), 2842 (wb), 3442 (vb) cm^{-1}. ^1H NMR [200 MHz, $(CD_3)_2SO$, TMS]: δ = 8.61 (s, 3 H), 7.93 (m, 12 H), 3.81 (br., methylene, 6 H), 2.98 (br., methylene, 6 H), 2.07 (s, 3 H) ppm. UV/Vis (CH_3CN): λ_{max} (ε) = 248 nm (26500 $M^{-1}\cdot cm^{-1}$). ***Caution:*** Perchlorates are potentially explosive and should not be prepared and stored in large amounts.

Crystallography: The diffraction measurements were carried out with a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.7107 Å). Crystalline samples of the analyzed compounds were covered with a thin layer of light oil and freeze-cooled to 110 K in order to minimize solvent escape (if present), structural disorder (particularly of the anions) and thermal motion effects, and to increase the precision of the results. The crystal and experimental data for all the compounds are summarized in Table 1. The structures were solved by direct (SHELXS-86, SIR-92, SIR-97)[23,24] and Patterson methods (DIRDIF-96),[25] and refined by full-matrix least squares on F^2 (SHELXL-97).[26] Intensity data of the silver-containing structures were corrected for absorption effects. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located in idealized positions, and were refined using a riding model with fixed thermal parameters [U_{ij} = 1.2·U_{ij}(eq.) of the atom to which they are bonded]. CCDC-188495 to -188503 for compounds **2**, **3**, **6**, **7**, **9**, **10**, **11**, **12**, and **13**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

The Reactivity of an Iron(II)/Iron(III) System with Polyamine Ligands in Ethanol: An Electrochemical Study

Víctor M. Ugalde-Saldivar,[a] Martha E. Sosa-Torres,[a] and Ignacio González*[b]

Keywords: Iron / N ligands / Electrochemistry / Oxidative dehydrogenation / Disproportionation

The pentadentate ligand picdien [L_A; 1,9-bis(2′-pyridyl)-2,5,8-triazanonane)] and $[Fe(DMSO)_6](NO_3)_3$ produce the hexacoordinate coordination compound $[FeL'_B]^{2+}$ after reaction in ethanol. This compound shows a change in the oxidation state of Fe^{III} to Fe^{II} as well as an increase in the denticity of the starting ligand L_A. The new ligand L'_B {1,9-bis(2′-pyridyl)-5-[(ethoxy-2′-pyridyl)methyl]-2,5,8-triazanon-1-ene} has an imine carbon–nitrogen double bond. This study provides evidence for the nature of the intermediate species during the formation of $[FeL'_B](BPh_4)_2$. A systematic study was performed based on the evolution of the voltammograms observed after the addition of ligand (L_A, L_B) or base (LiOEt) to Fe^{III}, Fe^{II} solutions or stoichiometric metal-ligand mixtures (L_B is L'_B without the imine group). The stability of FeL_A^{3+} and FeL_A^{2+} species in acidic media and under nitrogen atmosphere was confirmed. The reactivity of FeL_B^{3+} and FeL_A^{3+} systems was found to be very similar, and the reduction products were found to be Fe^{II} species with simultaneous ligand oxidation, which, in both cases, produces an imine double bond, giving rise to an intramolecular redox reaction. The following disproportionation equation describes the general form of this process: $2\,FeL^{3+} \leftrightharpoons FeL^{2+} + FeL'^{2+} + 2\,H^+$. The oxidation was verified by the double bond formation in L_A and L_B giving rise to L'_A and L'_B as can be seen in the general equation: $R^1–CH_2–NH–R^2 \leftrightharpoons R^1–CH=N–R^2 + 2\,H^+ + 2e^-$. The disproportionation reaction for FeL_A^{3+} and FeL_B^{3+} species depends on the acidity level of the media: this reaction cannot be verified in acidic media, while neutral and slightly basic media favour formation of the Fe^{II} species with L'_A and L'_B.

Introduction

Oxidative dehydrogenation reactions of alcohols and amines are of great interest in biochemistry (e.g., alcohol dehydrogenase enzymes, galactose oxidase, amine oxidase) as well as in systems related to the protein degradation that contributes to aging. In addition, this type of reaction is of great importance in combustion cell operation. The nature of the products obtained in these reactions and the rates of their formation may vary depending on the reaction conditions, and are particularly strongly influenced by the presence of metallic ions. In the above-mentioned biochemical processes, the Zn^{II} is present in the active site of alcohol dehydrogenase enzyme, whereas Cu^{II} is found in galactose oxidase[1] and amine oxidase.[2] The Fe^{II} of metal-catalyzed oxidation (MCO) systems contributes to enzyme deterioration through dehydrogenation.[3] Amine oxidation may give rise to different products (including nitriles, nitro species and carbonylic compounds formed by insertion of highly reactive imine species formed during oxidation). The oxidation of amines and alcohols coordinated to metallic centers leads to quantitative formation of dehydrogenated products.[4] The nature of the metallic center plays a dominant role since the route followed by imine formation depends on it. Metallic ions available in high oxidation states govern the formation of compounds through radicals in a concerted two-electron reaction, with subsequent loss of two protons, as in the reaction of compounds of Ru^{II} [5–7] and Os^{II} [8,9] with ethylenediamine. When the metallic ion cannot reach high oxidation states, the reaction takes place only in the presence of strong oxidants, as in the reactions with compounds of Ni^{II} [10,11] and Cu^{II}.[12]

In the particular case of iron, most oxidation products of amines and coordinated polyamines are coordination compounds containing imines, and in some cases the final product is stable.[13] There are very few reports on this kind of compounds in which the ligand not only oxidizes, but also increases its size during the process of final compound formation.[14] Despite vast numbers of reports on electrochemical characterization in oxidative dehydrogenation reactions of coordination compounds with polyamines, almost none of them prove the stability of the coordination compounds formed during dissolution.[15,16]

(1a)

Reports on Fe^{III} systems with polyamine ligands published by Morgenstern−Baradau et al.,[13] provide proof of an Fe^{III} system with a tripyridine ligand (TPAA) in which an internal redox reaction proceeds between the metallic ion and the ligand. However, the evidence reported to prove this process is the synthesis of three compounds: two Fe^{II} compounds with TPAA (reduced ligand) and one Fe^{II} compound with $(py)_3$tren (TPAA-oxidized ligand). The compounds were obtained by different procedures from previously isolated starting materials. The evidence presented in the study of possible intermediates formed during the reaction, whether in dissolved or solid form, was inconclusive and in others papers their presence is demonstrated using analytical techniques.[17,18] Few publications address iron(III) and iron(II) compounds with the particular case of pentadentate ligands. The high reactivity of iron(III) in this system produces oxidation reactions between the metallic ion and the coordinated ligand. An interesting example of this reactivity occurs between iron(III) and the ligand L_A {L_A=1,9-bis(2′-pyridyl)-2,5,8-triazanonane)}, in ethanol. When they are mixed in stoichiometric quantities, a reaction occurs whose final product is a coordination compound with a new hexadentate ligand (L'_B). A previous work describes synthesis of the compound in detail and the crystal structure of the final product.[14] An explanation for the unexpected formation of this compound is shown in the following reaction. In the general reaction [Equation (1a)], an electron exchange occurs between Fe^{III} and L_A to stabilize an iron(II) compound, and a new ligand (L'_B), which, besides having a double bond, (oxidation product) includes an additional pyridine ring forming a potentially hexadentate compound $[FeL'_B](BPh_4)_2$. In this work we describe the key steps of the redox reaction and analyze the electrochemical properties of the species formed in solution during this process.

The following equation summarizes the synthesis of the iron(II) compounds using the ligand L_A in the reaction conditions described (ethanol, 70 °C, N_2).

$$Fe^{III} + L_A \leftrightarrows Fe^{II}L'_B \quad (1b)$$

With:
L_A = 1,9-bis(2′-pyridyl)-2,5,8-triazanonane
L_B = 1,9-bis(2′-pyridyl)-5-[(ethoxy)(2′′-pyridyl)methyl]-2,5,8-triazanonane
L'_B = 1,9-bis(2′-pyridyl)-5-[(ethoxy)(2′′-pyridyl)methyl]-2,5,8-triazanon-1-ene

In the proposed reaction [Equation (1)], clarification of the final product of the redox process between the metallic ion and the ligand can be achieved using electrochemical techniques. The characteristics of the intermediates formed in the iron(III)-L_A reaction demand a complete study of dissolved species supported by electrochemical techniques. We performed a systematic evaluation using cyclic voltammetry to elucidate the complicated steps occurring during development of the global reaction described in Equation (1b).

Results and Discussion

Because the reaction in Equation (1) is so complex, it is difficult to perform a direct electrochemical study of the reaction mixture. We therefore proposed electrochemical characterization of the following mixtures: a) L_A·3HCl and $[Fe(DMSO)_6](NO_3)_3$, b) equimolar mixtures of L_A·3HCl and $[Fe(DMSO)_6](NO_3)_3$ and L_A·3HCl and $FeCl_2$, c) neutralization of a stoichiometric mixture of L_A·3HCl with $[Fe(DMSO)_6](NO_3)_3$, d) an equimolar mixture of L_B and $FeCl_2$, and e) an equimolar mixture of L_B and $[Fe(DMSO)_6](NO_3)_3$.

A half-wave potential ($E_{1/2}$) of 0.504 V vs. AgCl/Ag was obtained from the voltammogram of a ferrocene solution, and this was considered the reference system in all the voltammograms discussed below, according to IUPAC convention.[19]

a) Electrochemistry of a Mixture of L_A·3HCl and $[Fe(DMSO)_6](NO_3)_3$

L_A·3HCl (15.73 μmol) was dissolved in 5 mL of electrolyte support (0.1 M LiCl in ethanol) and the voltammograms were obtained at 100 mV·s^{-1} in the potential interval established by the electroactivity domain. Figure 1 (see a) shows a typical voltammogram for L_A·3HCl (3.145×10^{-3} M) obtained on a platinum electrode. When the potential scan was initiated in the negative direction, L_A·3HCl presented three well-defined reduction signals (I_C, II_C and III_C), and when the potential scan was reversed, three less-defined oxidation signals (I_A, II_A and III_A). When the potential scan was reversed after each cathodic peak, the corresponding anodic peak was well defined (not shown). We

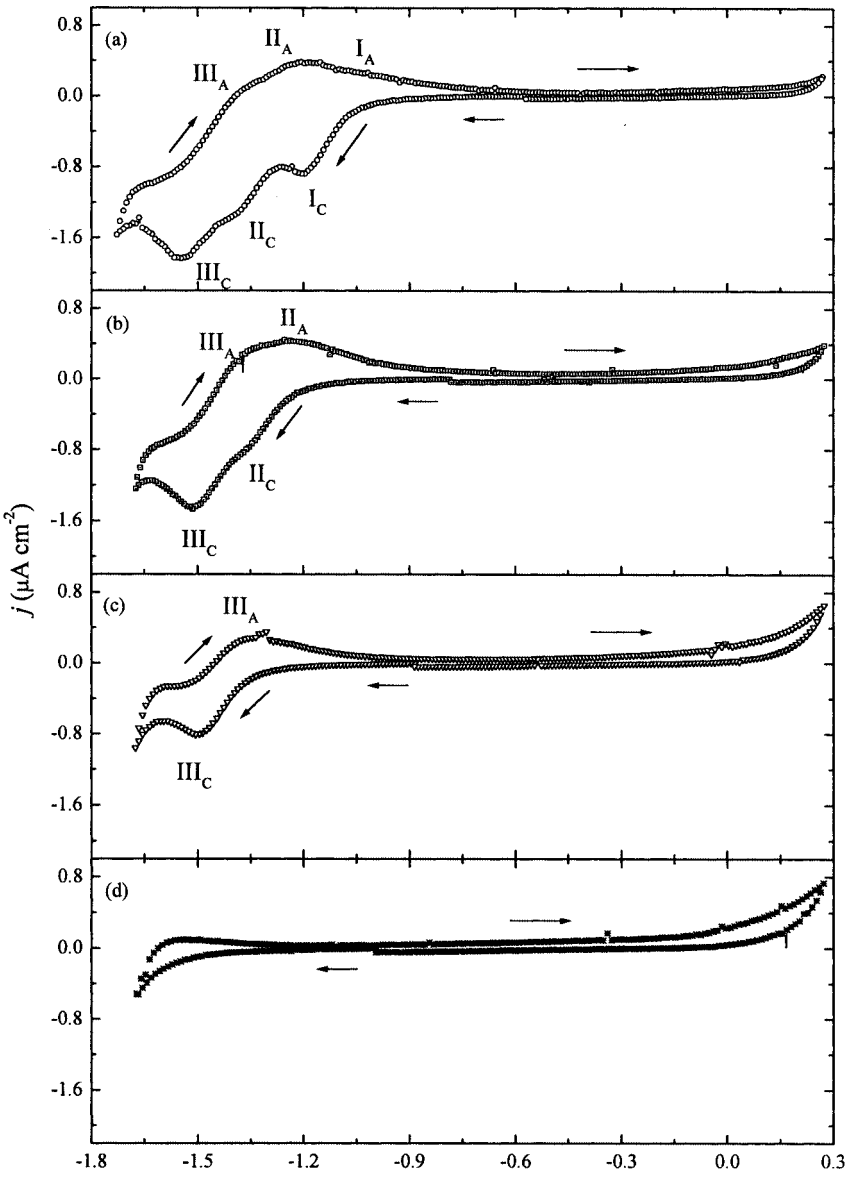

Figure 1. Typical cyclic voltammograms obtained for 15.73 μmol L_A·3HCl in 5 mL of ethanolic 0.1 M LiCl solution at 100 mV s^{-1} on a Pt electrode; the potential scan was initiated in the negative direction from $E_{j=0}$; the voltammograms were obtained after the addition of different quantities of lithium ethoxide: (a) −o− 0.0; (b) −□−15.72; (c) −▽− 31.45 and (d) −■− 47.17 μmol

propose as a preliminary hypothesis that the reductions are due to protons from the hydrochlorides located at the secondary amines of the ligand. To test this, we gradually added aliquots of a 0.524 M solution of LiOEt to 5 mL of a 3.145×10^{-3} M solution of L_A·3HCl. Figure 1 shows the voltammograms obtained when the potential scan was initiated in the negative direction for the L_A·3HCl solution and following several additions of LiEtO.

With the first additions of the LiEtO (15 and 30 μL, 15.72 and 31.45 μmol), the signal I_C decreased until it disappeared. The calculated equivalents added in 30 μL (15.72 μmol) coincide with neutralization of the first acid equivalent in the ligand (Figure 1, b). This observation was repeated for signals II_C and III_C with aliquot volumes of 60 and 90 μL (31.45 and 47.17 μmol), respectively (Figure 1, c and d, respectively). After the intensity of the cathodic peaks had diminished, the corresponding anodic peak was better defined (see Figure 1, c). Thus, we effectively proved that the signals observed correspond to the acidic protons of the ligand. We can thereby explain each of the reductions observed based on the following general electrochemical reaction:

$$H_nL_A^{3+} + e^- \leftrightarrows 1/2\ H_{2(g)} + H_{n-1}L_A^{2+} \quad \text{for } 1 \le n \le 3 \tag{2}$$

This equation confirms that the reduction signals are related to the acidic protons attached to the ligand. In addition, Figure 1 establishes that the neutral ligand is not elec-

troactive as testified by the absence of signals in the voltammogram corresponding to the addition of 90 μL (Figure 1, d). Equation (2) summarizes the different chemical and electrochemical steps and also the different chemical nature of the involved species [i.e. $H_{2(g)}$], and thus is not a reversible process. The difference of the anodic and cathodic peak potential and anodic−cathodic peak current ratio for each peak supports this fact.

An electrochemical study of a 10^{-3} M solution of iron(III) salt $[Fe(DMSO)_6](NO_3)_3$, used for synthesizing the final compound, was performed. A typical voltammogram of a reversible system was obtained, with one cathodic and anodic peak observed (not shown). We analyzed the half-sum of the peak potentials $[(Ep_C + Ep_A)/2]$ as a function of the logarithm of the scan rate (log v_B), observing a constant behavior, in this way the half-wave potential of Fe^{III}/Fe^{II} ($E_{1/2} = -0.546$ V vs. Fc^+/Fc) was obtained. The predominant Fe^{III} species in solution undergoes an electrochemical reaction as shown in the following equation:

$$Fe^{III} + 1e^- \leftrightharpoons Fe^{II}\ (E_{1/2} = -0.546\ \text{V vs. } Fc^+/Fc) \quad (3)$$

b) Electrochemistry of an Equimolecular Mixture of L_A·3HCl and $[Fe(DMSO)_6](NO_3)_3$ and L_A·3HCl and $FeCl_2$

Based on the independent assignment of signals detected for the ligand and iron(III) salt, we proceeded with an electrochemical study with an equimolar mixture of L_A·3HCl and $[Fe(DMSO)_6](NO_3)_3$ (5 μmol) at a concentration of 10^{-3} M in 5 mL of electrolyte support. Voltammograms were obtained initiating the potential scan in the positive direction and then in the negative direction while maintaining the same experimental conditions as for the previous experiments. Figure 2, curve a shows a voltammogram obtained for this solution when the potential scan was initiated in the positive direction; in the direct scan no oxidation signal was observed. In the reversed scan two reduction signals were observed (I''_C, II''_C) with cathodic peak potentials (Ep_C) of −0.540 and −1.126 V vs. Fc^+/Fc, respectively. The value of the current of the peak associated with I''_C is approximately one third that for II''_C. When the negative switching potential was reached ($E_{-\lambda} = -1.725$ V vs. Fc^+/Fc) and the potential scan was performed in the reverse direction, two oxidation signals were observed (II''_A, I''_A) with potential anodic peak values (Ep_A) of −0.913 and −0.401 V vs. Fc^+/Fc, respectively.

The signals I''_C and I''_A appear in the potential zone near the half-wave potential of the Fe^{III}/Fe^{II} system and for this reason we studied the half sum of the peak potentials $(Ep_C + Ep_A)/2$ as a function of the logarithm of the scan rate (log v_B). We observed a constant behavior for the $(Ep_C + Ep_A)/2$ value with $E_{1/2} = -0.470$ V vs. Fc^+/Fc. In this case, ΔEp_{A-C} (0.138 V) and the voltammetry function show a similar behavior to that of the Fe^{III}/Fe^{II} system.

The information obtained from the Fe^{III}/Fe^{II} system in the absence and presence of ligand L_A establishes that the kinetic electron-transfer behavior for both cases is similar, therefore the difference in $E_{1/2}$ is attributable to the formation of the Fe^{III} complex with L_A. Comparison of the voltammograms of the ligand alone (Figure 1, a) and in the presence of Fe^{III} (Figure 2, a) substantiate this assumption, since three initial reduction signals for the ligand are not observed. The initial complexing reaction could explain the formation of the proposed complex according to the following equation:

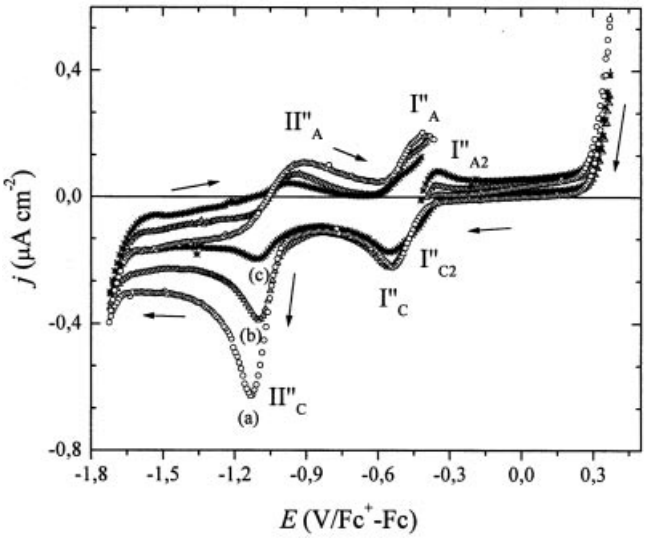

Figure 2. Typical cyclic voltammograms obtained for an equimolar mixture of L_A·3HCl and $[Fe(DMSO)_6](NO_3)_3$ (10^{-3} M) in ethanolic 0.1 M LiCl solution on a Pt electrode at 100 mV s^{-1}; the scan potential was initiated in the positive direction from $E_{j=0}$; the voltammograms were obtained after the addition of different quantities of lithium ethoxide: (a) −o− 0.0; (b) −Δ− 6.0 and (c) −■− 12.0 μmol

$$Fe^{3+} + H_3L_A^{3+} \leftrightharpoons FeL_A^{3+} + 3\,H^+ \quad (4)$$

According to Equation (4), these signals indicate formation of the coordination compound between Fe^{III} and L_A as formation of the FeL_A^{3+} compound increases the acidity of the protons localized in the ligand, producing a strong acid in solution with a concentration three times that of the compound, explaining the appearance of peak II''_C in Figure 2 (a). The new species in solution (FeL_A^{3+}) undergoes an electrochemical reduction reaction (I''_C) described by the following equation:

$$FeL_A^{3+} + 1e^- \leftrightharpoons FeL_A^{2+}$$
$$E_{1/2} = -0.470\ \text{V vs. } Fc^+/Fc \quad (5)$$

As a consequence, the electrochemical reaction for signal II''_C occurs according to the following equation:

$$H^+ + e^- \leftrightharpoons 1/2\ H_{2(g)}$$
$$E_{1/2} = -1.020\ \text{V vs. } Fc^+/Fc \quad (6)$$

The proton reduction [Equation (6)] is not reversible under the experimental conditions considered here despite the fact that it is not associated to L_A ligand. The voltammetric parameters of peak $II''_C-II''_A$ support this conclusion.

Although we still have to confirm that the species formed at the electrode following the reduction is the compound FeL_A^{2+}, we can determine that the difference in half-wave potentials for the Fe^{III}/Fe^{II} system in the absence and presence of L_A is 0.076 V. The shift toward more positive potentials is probably due to the fact that the complex of L_A with Fe^{II} has a greater stability constant than with Fe^{III}. This effect in the Fe^{III}/Fe^{II} system has been described previously when varying the ligand π acceptor and analyzing the effects on $E_{1/2}$ in different compounds.[20] A shift in the half-wave potential for this system can explain whether this is the effect of the ligand in the compound. The presence of strong π-acceptors in the ligand (two pyridine rings) allows the central metal ion to resist a greater electron density due to the cooperative effect of this type of ligand. Therefore, we expect coordination compounds with lower oxidation states to have greater formation constants (K_f). According to the Nernst law, we can predict a new half-wave potential for a system in which both species of the redox pair form stable coordination compounds [Equation (7)]

$$FeL_A^{3+} + 1e^- \cdots FeL_A^{2+}$$

$$E'_{1/2} = E^\circ_{1/2} - 0.058 \log\left[\frac{K_f^{Fe^{III}L_A}}{K_f^{Fe^{II}L_A}}\right] \quad (7)$$

Where $E^\circ_{1/2}$ corresponds to the conditional half-wave potential for the Fe^{III}/Fe^{II} redox pair in 0.1 M lithium chloride and in the absence of the ligand (L_A). Thus the values of $E_{1/2}$ for Fe^{III}/Fe^{II} and FeL_A^{III}/FeL_A^{II} allow us to determine the following equation.

$$\frac{K_f^{Fe^{III}L_A}}{K_f^{Fe^{II}L_A}} = 10^{0.95}$$

Under our experimental conditions (room temperature, ethanol, N_2 atmosphere), the compound FeL_A^{3+} is stable in solution. Nevertheless, the different methods used in attempting to separate out the solid product were unsuccessful.

Equation (5) proposes that the complex FeL_A^{2+} generated electrochemically is stable in solution and, therefore, it is important to use a mixture of L_A·3HCl with an Fe^{II} salt in this study in order to corroborate the presence of this complex.

As electrochemical proof of the formation of the FeL_A^{2+} complex, voltammograms were performed on a solution containing an equimolar mixture of $FeCl_2$ and L_A·3HCl (10^{-3} M; voltammograms not shown). As in Figure 2, curve a, we observed the same number of signals with very similar peak potentials; this confirms the stability of the FeL_A^{2+} species in solution. This conclusion is very important since there are no reports of coordination compounds of Fe^{III} and Fe^{II} with L_A and this could represent a feasible alternative for studying such compounds. The chemical structure of this compound (availability at the sixth position) lets us consider this redox pair for use in catalytic processes in homogeneous phase.

c) Electrochemistry of the Neutralization of an Equimolar mixture of L_A·3HCl with $[Fe(DMSO)_6](NO_3)_3$

During the synthesis reaction, L_A·3HCl is neutralized. We therefore performed a group of experiments with 5 mL of an equimolar metal-ligand mixture at 10^{-3} M (5 μmol) to which was added successive quantities of a 0.10 M LiOEt solution. Figure 2 shows the voltammograms for the initial mixture and after adding 60 and 120 μL (6 and 12 μmol) of LiOEt; in all cases the scan potential was initiated in the positive direction. When the base is added to the solution, the intensity of the reduction signals I''_C and II''_C decreases with increasing amounts of added base, with a greater decrease for the signal II''_C (Figure 2, b and c). We also observe an oxidation signal (I''_{A2}) corresponding to the formation of a new species in solution with an anodic peak potential of −0.351 V vs. Fc^+/Fc. The current values for some signals change as the quantity of added base increases. The oxidation signal I''_{A2} increases while the signals $I''_C-I''_A$, corresponding to the FeL_A^{3+}/FeL_A^{2+} pair, decrease. The changes in the current values for signal II''_C are explained by consumption of the H^+ species during neutralization. The peak-potential value of signal I''_{A2} is more positive than for the FeL_A^{3+}/FeL_A^{2+} system, and for this reason the new signal I''_{A2} suggests formation of a new iron complex with a more positive redox potential under the new acidic conditions. The voltammogram obtained in the absence of added LiEtO shows no oxidation signals of Fe^{II} in the potential interval −0.35 to 1.00 V vs. Fc^+/Fc (Figure 2, a), confirming that only Fe^{III} is present initially in solution as the species FeL_A^{3+}.

Since the study was carried out under an inert atmosphere in the absence of oxygen and only the compounds FeL_A^{3+} and LiCl in ethanol were present in solution, we propose that the ligand L_A is responsible for the reduction via an intramolecular redox reaction. The formation of imines (oxidation) in coordination compounds with this type of ligand has been described in the literature, with a subsequent reduction of the different metal ions, for example cobalt,[21] copper,[17] iron,[13,15,22] nickel,[10,23−27] osmium,[8,9,28−31] platinum[32] and ruthenium.[5−7,16,33−45] To explain this global process we must consider the following:

a) Oxidation of the ligand is a process requiring two electrons. The following equation expresses the general form of the reaction:

$$R^1-CH_2-NH-R^2 \leftrightarrows R^1-CH=N-R^2 + 2\,H^+ + 2e^-$$
$$L_A \leftrightarrows L'_A + 2H^+ + 2e^- \quad (8)$$

b) The reduction of the Fe^{III} species is a single-electron process described by the reaction below:

$$Fe^{III} + 1e^- \leftrightarrows Fe^{II} \quad (9)$$

c) The reaction explaining the overall neutralization process must consider that the FeL_A^{3+} species contains the oxidant (Fe^{III}) and the reductant (L_A). The stoichiometry of the reaction is 2:1 (Fe^{III}:L_A) such that the general form of the intramolecular redox reaction can be represented by the following equation:

$$2\ FeL_A^{3+} \leftrightarrows FeL_A^{2+} + FeL'_A{}^{2+} + 2\ H^+ \quad (10)$$

The above equation describes a disproportionation reaction that is similar to that reported previously,[46,47] and justifies the observed changes, demonstrating that the equilibrium shifts to favour formation of the Fe^{II} species as the H^+ concentration decreases (neutralization). It also explains the transformation of the Fe^{III} species to give rise to two new Fe^{II} species. To confirm this mechanism, we added a slight excess of LiOEt (18 μmol) relative to the initial H^+ concentration (15 μmol) and performed voltammograms under the same conditions as before. The initial scan of the voltammogram obtained in the negative direction (Figure 3, a) shows no reduction signals in the interval −0.40 to −1.00 V vs. Fc^+/Fc. The inverse scan shows only two signals, one for oxidation I''_{A2} and the other for reduction I''_{C2}. The absence of reduction signals in the initial scan confirms the hypothesis proposed in Equation (10) for the quantitative transformation of the initial FeL_A^{3+}. When the voltammogram is performed initiating the potential scan in the positive direction (not shown), two signals were also observed

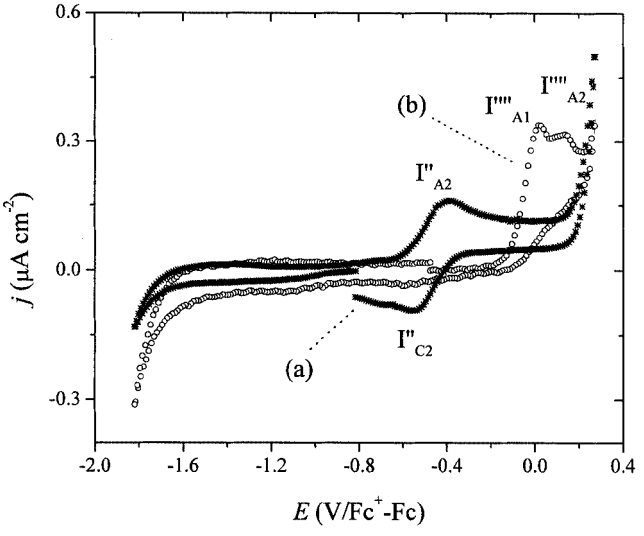

Figure 3. Typical cyclic voltammograms obtained in 5 mL of ethanolic 0.1 M LiCl solution on a Pt electrode at 100 mV s^{-1}; the voltammograms were obtained when the scan potential was initiated from $E_{j=0}$ for different solutions: (a) −■− a mixture of 5 μmol of L_A·3HCl, 5 μmol of $[Fe(DMSO)_6](NO_3)_3$ and 18 μmol of LiEtO (the scan potential was initiated in the negative direction), and (b) −o− 10^{-3} M of $[FeL'_B](BPh_4)_2$ (the scan potential was initiated in the positive direction)

(I''_{A2}, I''_{C2}) as in Figure 3 (a). A comparison of Figure 3 (a) and Figure 2, curve b−c, demonstrates that, under these conditions, only the Fe^{II} complex is present in solution.

We can therefore conclude that the decrease in the intensity of signal II''_C is due to neutralization of the protons formed as products of the complexation reaction. The simultaneous disappearance of the Fe^{III} reduction signal and the appearance of oxidation signals prove that the compound FeL_A^{3+} is chemically transformed into two new Fe^{II} species through a redox process in solution. The redox pair responsible for signals I''_A and I''_C is FeL_A^{3+}/FeL_A^{2+}, and the electrochemical process is described by Equation (5). The signals I''_{A2} and I''_{C2} are explained by the formation of the new species, $FeL'_A{}^{2+}$, through the electrochemical oxidation process described in the following equation:

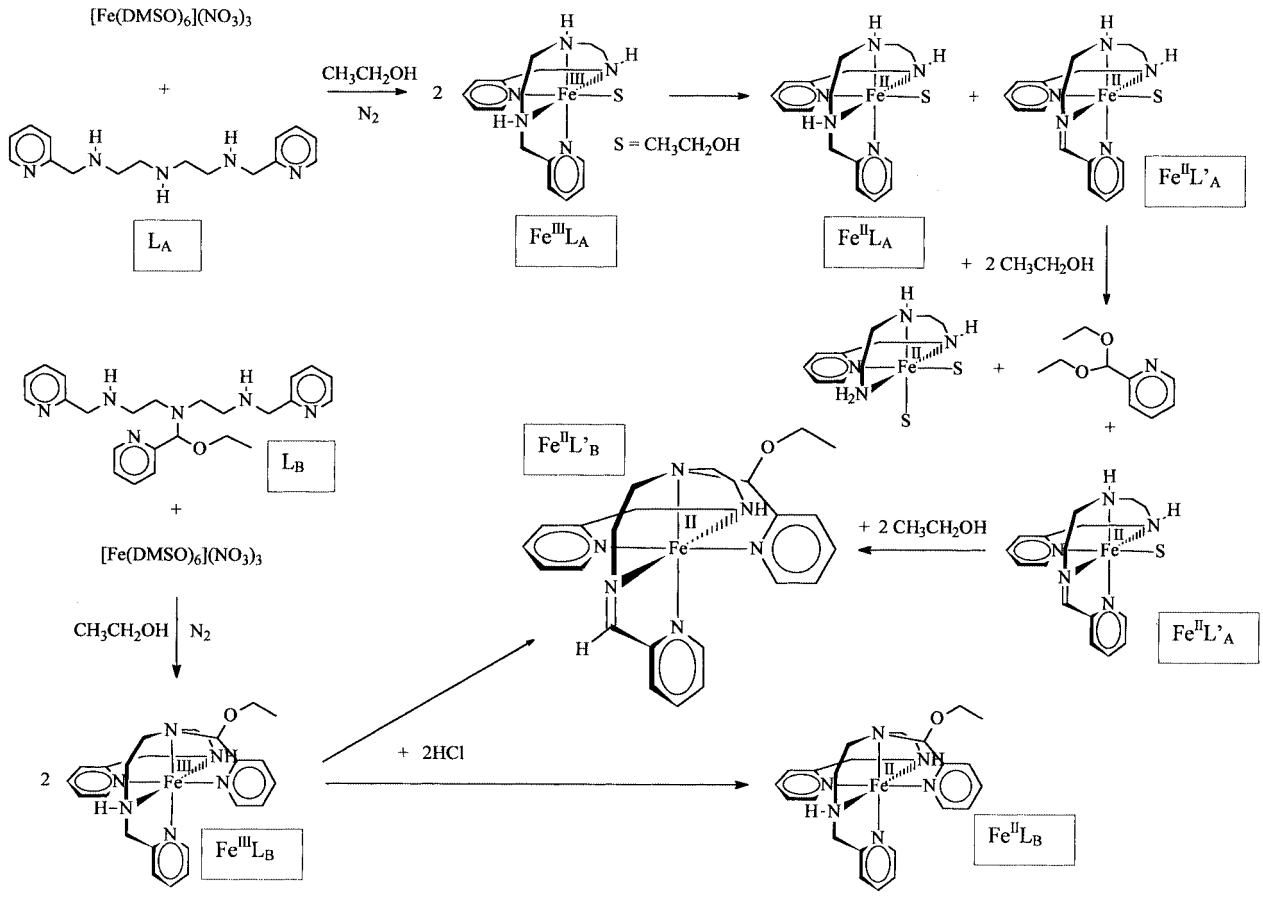
$$FeL'_A{}^{2+} \leftrightarrows FeL'_A{}^{3+} + 1e^-\ E_{1/2} = -0.365\ \text{V vs. } Fc^+/Fc \quad (11)$$

In the new species, $FeL'_A{}^{2+}$, L'_A represents oxidized picdien (containing an imine group). According to Equation (5) and (11), the half-wave potential for the redox pairs resulting from the disproportionation are very close in value. This explains the breadth of the signal and the observation of a single peak for both species FeL_A^{2+} and $FeL'_A{}^{2+}$ in the voltammogram of Figure 3 (a).

Thereby, the increase in half-wave potential observed for the final product $FeL'_A{}^{2+}$ results principally from an increase in the π-acceptor character of the new ligand (L'_A), giving a conjugated double bond π system between the imine and the pyridine ring. We thus conclude that FeL_A^{3+} is the precursor to $FeL'_A{}^{2+}$ produced by a disproportionation reaction [Equation (10)], favoured at neutral and slightly alkaline pH where the compound $FeL'_A{}^{2+}$ is thermodynamically favored.

To prove that $FeL'_A{}^{2+}$ indeed corresponds to the coordination compound of $FeL'_B{}^{2+}$ (L'_B = oxidized form of ligand L_B), we performed an additional experiment. Figure 3, curve b shows the voltammogram of 5 μmol of $[FeL'_B](BPh_4)_2$ dissolved in 5 mL of electrolyte support; $[FeL'_B](BPh_4)_2$ is the final product isolated in the original synthesis. When the potential scan was initiated in the positive direction, two irreversible oxidation signals, I''''_{A1} and I''''_{A2}, appeared with peak-potential values of 0.075 and 0.158 V vs. Fc^+/Fc, respectively. There is a huge difference between this voltammogram and the one obtained for the neutralized mixture of Fe^{III}-L_A (Figure 3, a), establishing that the $FeL'_A{}^{3+}/FeL'_A{}^{2+}$ system is far from being the final product isolated in the $[FeL'_B](BPh_4)_2$ synthesis process and should be considered an intermediate under the general reaction [Equation (1)].

The end product of the synthesis displays a very different electrochemical behaviour and the voltammograms of the neutralized mixture evolve a wide variety of signals over time which are extremely difficult to explain. Therefore, we used an analogous system to complement our studies in the hope of reproducing this electrochemical behaviour. We proceeded to characterize the Fe^{III}/Fe^{II} system electrochemically with a ligand similar in characteristics to that obtained as the major product of the reaction, in this case ligand L_B, (see Scheme 1).



Scheme 1

Synthesis of the ligand L_B begins with formation of the ketal of 2-pyridinecarboxylaldehide in situ followed by addition of the neutral ligand L_A in ethanol to form the compound L_B. This synthetic strategy shows that L_B has a similar reactivity with Fe^{III} as that discussed up to now for Fe^{III} and L_A. We describe the details of these experiments below. Unlike the previous experiments with $L_A \cdot 3HCl$, the new ligand L_B was used in its neutral form.

d) Electrochemistry of an Equimolar Mixture of L_B and $FeCl_2$

We performed a cyclic voltammetric study using 5 mL of a 3×10^{-3} M $FeCl_2$ solution (15 μmol) in electrolyte support to which 250 μL of a 0.06 M L_B (15 μmol) solution was added. The cyclic voltammogram (not shown) obtained when the potential scan was initiated in the positive direction showed a reversible redox system with $E_{1/2} = -0.409$ V vs. Fc^+/Fc. Voltammograms for the mixture were performed initiating the potential scan in the negative direction; none of the voltammograms show a reduction signal for any Fe^{III}-containing species at the start of recording (−0.500 to −1.100 V). In this case the reversible redox system is assigned to the complex FeL_B^{2+} formed in solution. The new species in solution follows the electrochemical reaction described below:

$$FeL'_B{}^{2+} \leftrightharpoons FeL'_B{}^{3+} + 1e^- \quad (12)$$
$$E_{1/2} = -0.409 \text{ V vs. } Fc^+/Fc$$

The FeL_B^{2+} species is stable under the experimental conditions and no change in the oxidation state of the initial Fe^{II} species in solution is observed. The half-wave potential difference between the Fe^{III}/Fe^{II} and FeL_B^{3+}/FeL_B^{2+} systems produces a value of 0.121 V, with the FeL_B^{3+}/FeL_B^{2+} system potential shifting toward more positive values. Nonetheless, the electrochemical behavior of the new system does not explain the signals observed for the compound $[FeL_B](BPh_4)_2$ (Figura 3, b), and for this reason we carried out further experiments with L_B and Fe^{III}.

e) Electrochemistry of an Equimolar Mixture of $[Fe(DMSO)_6](NO_3)_3$ and L_B

The electrochemical study was carried out with an equimolar mixture of $[Fe(DMSO)_6](NO_3)_3$ and L_B (5 mmol) in 5 mL of electrolyte support. Voltammograms were obtained beginning the potential scan in the negative direction (Figure 4, a) and then in the positive direction (Figure 4, b). The signals assigned to the system FeL_B^{3+}/FeL_B^{2+}, ($I'_{A3}-I'_{C3}$) present a half-wave potential of −0.428 V vs. Fc^+/Fc.

When the potential scan is initiated in the positive direction (Figure 4, b), unlike the previous recording, an oxidation signal, I'_{A3}, was observed indicating the presence of an

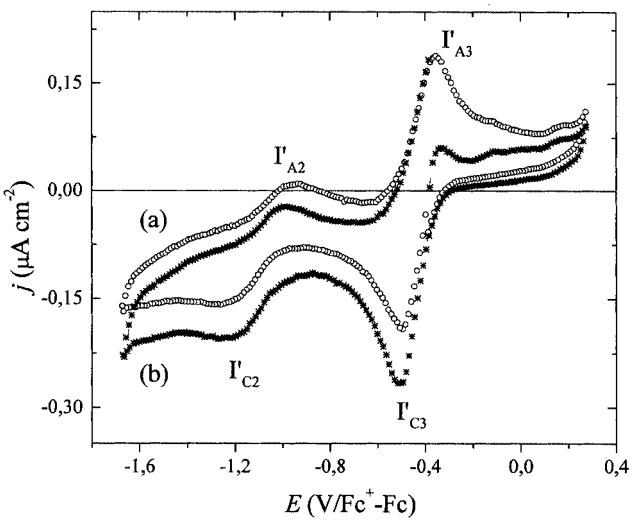


Figure 4. Typical cyclic voltammograms obtained for a fresh equimolar mixture of $[Fe(DMSO)_6](NO_3)_3$ and L_B, (10^{-3} M) in ethanolic 0.1 M LiCl solution on a Pt electrode at 100 mV s^{-1}; the potential was initiated from $E_{j=0}$ in different directions: (a) −o− negative direction and (b) −■− positive direction.

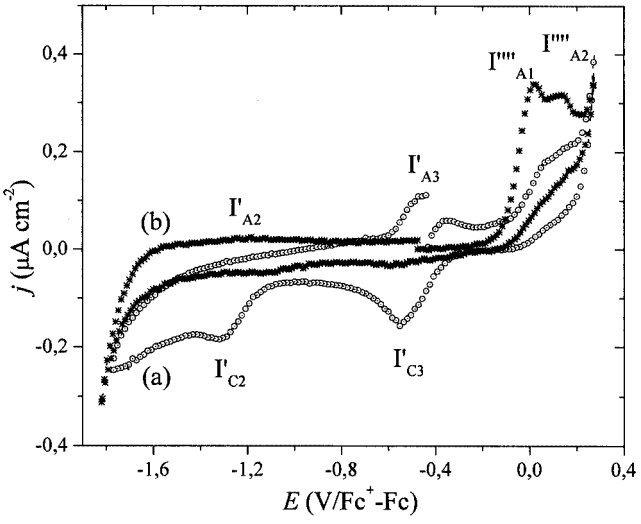

Figure 5. Typical cyclic voltammograms obtained in ethanolic 0.1 M LiCl solution on a Pt electrode at 100 mV s^{-1}; the scan potential was initiated in the positive direction from $E_{j=0}$; the voltammograms were obtained for different solutions: (a) −o− mixture of L_B and $[Fe(DMSO)_6](NO_3)_3$ (10^{-3} M each one), 12 h further mixing and (b) −■− 10^{-3} M $[FeL'_B][B(Ph)_4]_2$

Fe^{II} species in solution. In addition, a reduction signal (I'_{C2}) was present at a peak potential of −1.246 V, with its corresponding oxidation signal I'_{A2} at −0.976 V. The presence of an Fe^{II} species is more obvious (signal I'_{A3}). Although it is not clearly observed, we propose the existence of additional oxidation signals within the −0.10 to 0.2 V potential interval.

These observations and the proposal of Equation (10) suggest that the FeL_B^{3+} species undergoes a similar disproportionation reaction as the FeL_A^{3+} species, involving an oxidation of the ligand L_B with a simultaneous reduction of Fe^{III} to Fe^{II}. The equation below describes this disproportionation.

$$2FeL_B^{3+} \leftrightharpoons FeL_B^{2+} + FeL'_B{}^{2+} + 2H^+ \quad (13)$$

In this case L_B' represents the oxidized ligand (imine), and the species H^+, appearing as a product of the reaction, explains the reduction signal (I'_{C2}) at −1.246 V. A decrease of the Fe^{III} reduction signal along with the presence of oxidation signals demonstrates that the compound FeL_B^{3+} is chemically transformed into two new Fe^{II} species by a redox process in solution. The electrochemical reaction for the redox pair FeL_B^{3+}/FeL_B^{2+} occurs according to Equation (12).

For the Fe^{III}-L_B system, the variation in the concentration of species in solution over time determines the evolution of the voltammograms. To study these variations, an electrochemical study was performed 12 hours after preparing the mixture, initiating the potential scan in the positive direction (Figure 5, a). The recording shows the oxidation signal I'_{A3} and two new oxidation signals, I''''_{A1} and I''''_{A2}, at peak-potential values of 0.075 and 0.158 V vs. Fc^+/Fc (Figure 5, a). When the cycle was complete, the signals described coincided with those described previously in Figure 4. The reduction signal I'_{C2} at −1.246 V increased its current over time while the signal corresponding to the FeL_B^{3+}/FeL_B^{2+} system decreased. These observations confirm the reaction proposed in Equation (13) and, in this particular case, the products of the disproportionation reaction have very different electrochemical properties. It is therefore possible to distinguish the two Fe^{II} species formed. For the FeL_B^{2+} species, the half-wave potential is −0.428 V vs. Fc^+/Fc. The signals with Ep_A = 0.075 and Ep_A = 0.158 V vs. Fc^+/Fc are assigned to the $FeL'_B{}^{2+}$ species. To prove this, this voltammogram was compared with the one shown in Figure 3 (b), where the signals assigned to the complex ion $FeL'_B{}^{2+}$ (Figure 5, b) coincide sufficiently well with the peak-potential values of the isolated product $[FeL'_B](BPh_4)_2$.

We have thus shown that the reactivity of ligands L_A and L_B in the presence of Fe^{II} and Fe^{III} is very similar, and that for Fe^{III} an intramolecular reaction occurs involving a redox process in solution between the ligand and the metal. Scheme 1 shows the key steps proposed for the formation of $[FeL'_B](BPh_4)_2$ based on the stability of the species demonstrated in this work.

Conclusions

A systematic study based on evolution of voltammograms following addition of ligand (L_A, L_B) or base (LiOEt) to solutions containing Fe^{III}, Fe^{II} or stoichiometric metal-ligand mixtures was performed. This study provides evidence for the nature of the intermediate species in the process of formation of $[FeL'_B](BPh_4)_2$. An intramolecular redox process between Fe^{III} and the ligand is demonstrated when the cyclic voltammograms are initiated in the null current potential and by comparing voltammograms when the po-

tential scan is initiated in both positive and negative directions.

The stability of the FeL_A^{3+} and FeL_A^{2+} species in acidic media and under nitrogen atmosphere was confirmed. Since no prior evidence exists of solid state compounds existing with the complex ions mentioned here, the electrochemical technique used herein to demonstrate their existence and stability is fundamental.

The reactivity of the systems FeL_B^{3+} and FeL_A^{3+} was shown to be very similar and the products of the reduction are Fe^{II} species with simultaneous oxidation of the ligand, which, in both cases, produces the formation of an imine double bond, giving rise to an intramolecular redox reaction. The following equation describes the general form of this process.

$$2\ FeL^{3+} \leftrightarrows FeL^{2+} + FeL'^{2+} + 2\ H^+$$

The oxidation is verified by formation of the double bond in L_A and L_B giving rise to L_A' and L_B' as explained by the general equation below.

$$R^1{-}CH_2{-}NH{-}R^2 \leftrightarrows R^1{-}CH{=}N{-}R^2 + 2\ H^+ + 2\ e^-$$

The reduction revealed by the change in oxidation state from Fe^{III} to Fe^{II} due to a single-electron process establishes the proportion of metal to ligand at 2:1 to complete the exchange and thus justify the presence of two different Fe^{II} species. For L_B the compounds identified show very different electrochemical behaviors.

The disproportionation reaction depends on the acidity level of the reaction medium. When this medium is acidic, the disproportionation of the FeL_A^{2+} and FeL_B^{2+} species cannot be verified, while neutral and slightly basic media favor formation of the Fe^{II} species with L'_A and L'_B.

Experimental Section

Synthesis of $[FeL'_B](BPh_4)_2$

The reaction was carried out as described in a previous paper.[14] 20% product yield. $C_{72}H_{70}B_2FeN_6O$: calcd. C 77.71, H 6.34, N 7.55; found C 77.21, H 6.55, N 7.39.

Synthesis of Ligand L_B: This reaction was carried out by mixing three equivalents of lithium hydroxide in ethanol with one equivalent of the ligand trihydrochloride ($L_A{\cdot}3HCl$). After neutralization, one equivalent of 2-pyridylcarboxaldehyde was added while maintaining the reaction mixture temperature at 60−70 °C for one hour. Thin-layer chromatography was performed for the mixture, eluting with methanol/chloroform/hexane (1:5:3), to verify that the aldehyde had reacted completely.

Electrochemistry: 0.10 M LiCl dissolved in absolute ethanol was used as electrolyte support in the electrochemical studies. A Pt disc (0.0314 cm^2) was used as the working electrode, a Pt wire as the auxiliary electrode and $KCl_{(sat)}/AgCl_{(S)}/Ag$ was used as the reference electrode. The working electrode (Pt) was polished with alumina assuring the absence of surface residues. All voltammograms were initiated from the null current potential ($E_{j=0}$) and the scan was initiated in both positive and negative potential directions. In order to report the potentials used according to IUPAC convention,[19] voltammograms were obtained for approximately 10^{-3} M ferrocene (Fc) in electrolyte support. For the working conditions, the electroactive domain was between −1.726 and 0.274 V vs. Fc^+/Fc.

Synthesis, X-ray Studies and Magnetic Properties of Dinuclear Ni^{II} and Cu^{II} Complexes Bridged by the Azo-2,2′-bipyridine Ligand

Cristian S. Campos-Fernández,[a] José R. Galán-Mascarós,*[b] Bradley W. Smucker,[a] and Kim R. Dunbar*[a]

Keywords: Magnetic properties / Azo compounds / Nickel / Copper

Two new paramagnetic transition metal complexes that contain the bridging ligand azo-2,2′-bipyridine (abpy) have been prepared and characterized by X-ray crystallography and magnetic susceptibility measurements. The compound $[Ni_2(\mu\text{-abpy})(CH_3CN)_2(NO_3)_4]\cdot 2CH_3CN$ (**1**·2CH_3CN) crystallizes in the triclinic space group $P\bar{1}$ with a = 8.290(5) Å, b = 8.343(5) Å, c = 11.180(5) Å, α = 105.36(3)°, β = 94.39(3)°, γ = 107.56(3)°, V = 700.5(7) Å^3 and Z = 1. The related salt $[Cu_2(\mu\text{-abpy})(CH_3CN)_8][BF_4]_4$ (**2**) crystallizes in the triclinic space group $P\bar{1}$ with a = 10.240(2) Å, b = 10.597(2) Å, c = 10.712(2) Å, α = 64.23(3)°, β = 78.21(3)°, γ = 78.57(3)°, V = 1026.7(3) Å^3 and Z = 1. Solutions of **2** eventually produce the polymeric Cu^I compound $\{[Cu(\mu\text{-abpy})][BF_4]\}_\infty$ (**3**) which was also crystallographically characterized: monoclinic space group $P2_1/n$, with a = 9.295(2) Å, b = 9.541(2) Å, c = 13.486(3) Å, β = 91.58(3)°, V = 1195.5(4) Å^3 and Z = 4. The magnetic properties of these dinuclear paramagnetic complexes have been studied in detail, and have provided an opportunity for probing the ability of this ligand to mediate magnetic exchange interactions between paramagnetic metal centers. Compound **1** exhibits antiferromagnetic exchange interactions (J = −7.5 cm^{-1}) whereas the magnetic interactions in compound **2** were found to be negligible.

Introduction

The redox and spin-state properties of transition metal complexes render them attractive candidates for applications in many areas including molecular electronics, information recording, and catalysis.[1−3] One approach for the preparation of metal compounds with enhanced properties is to use organic ligands that engage in π-interactions with metal ions. In our quest for such ligands to use in assemblies of paramagnetic metal ions, we recently prepared families of transition metal complexes based on the nitrogen heterocyclic ligands 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine (bptz)[4,5] and 1,4,5,8,9,11-hexaazatriphenylene (HAT).[6] By controlling parameters such as the identity of the anions in reactions of metal cations with bptz, for example, we have demonstrated that one can deliberately prepare different cyclic oligomers, such as molecular squares[4,6] or molecular pentagons.[5] Despite the interesting supramolecular aspects of this work, our main goal, namely to induce magnetic interactions between the paramagnetic metal ions in these molecules, was not achieved. This is primarily due to the fact that the bptz and HAT bridging ligands position the metal centers at greater distances than is reasonable for the observation of strong magnetic coupling. In considering this problem, we turned to the azo-2,2′-bypyridine (abpy) ligand (Figure 1) which offers several obvious advantages over the previous ligands, one of which is the fact that it is possible to prepare the one-electron reduction species $abpy^{-\cdot}$ to use as a radical bridging ligand. It is well-known that the use of a paramagnetic bridge is advantageous for improving magnetic superexchange between metal centers,[7−19] but we reasoned that even the diamagnetic neutral form of abpy may allow for magnetic interactions due to the short distances between metal ions afforded by the azo bridging group. Monomeric and dimeric complexes of this ligand with 3d metals have been reported,[20] although their magnetic properties have only been briefly described for several monomeric complexes and for the dimers $[(\mu\text{-abpy})Co_2Cl_4]$ and $[(\mu\text{-abpy})Co_2(hfacac)_4]$ [hfacac = bis(hexafluoroacetylacetonate)].[21,22] We postulated that the shorter path could give rise to stronger magnetic interactions between spin carriers than the previously mentioned polynitrogen ligands, which require a four-atom separation between metals. There is, in fact, evidence that the abpy ligand allows for electronic communication between metals,[23−25] as illustrated by the redox behavior of the compound [(bpy)Ru(μ-abpy)Ru-

(bpy)][PF_6]$_4$ which exhibits a comproportionation constant K_c of more than 10^8. This value corresponds to a class III delocalized system on the Robin and Day scale.[26]

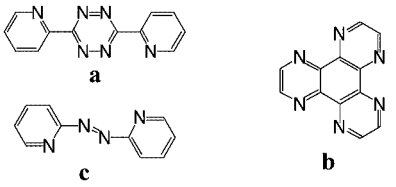

Figure 1. Scheme of the polynitrogen ligands: (a) 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine (bptz); (b) 1,4,5,8,9,11-hexaazatriphenylene (HAT); (c) azo-2,2′-bipyridine (abpy)

With all the aforementioned premises in mind, we embarked on a study of the nature of azo-2,2′-bypyridine (abpy) as a bridge between magnetic ions of the first row transition metals. Three compounds were isolated and characterized in this work, namely two magnetic dinuclear compounds of Ni^{II} and Cu^{II}, and a diamagnetic Cu^{I} polymer.

Results and Discussion

Syntheses

The reactions between Ni^{II} and Cu^{II} ions with abpy proceed instantaneously in acetonitrile to afford the products [Ni_2(abpy)(CH_3CN)$_2$(NO_3)$_4$] (**1**) and [Cu_2(abpy)(CH_3CN)$_8$][BF_4]$_4$ (**2**) in good yields. In marked contrast to previous reports, which concluded that a large activation barrier exists for the coordination of a second metal center after the first metal is bound,[17] the formation of the dinuclear species is facile in these cases. Crystals of [Ni_2(abpy)(CH_3CN)$_2$(NO_3)$_4$] were obtained by slow vapor-diffusion of diethyl ether into the reaction mixture, whereas crystals of [Cu_2(abpy)(CH_3CN)$_8$][BF_4]$_4$ (**2**) were obtained by saturating the solution with diethyl ether and chilling it to −10 °C. The Cu^{II} compound [Cu_2(abpy)(CH_3CN)$_8$][BF_4]$_4$ (**2**) eventually decomposes to the Cu^{I} polymer {[Cu(abpy)][BF_4]$_2$}$_\infty$ (**3**) over a period of several months in toluene/acetonitrile. The identity of the reducing agent is unknown.

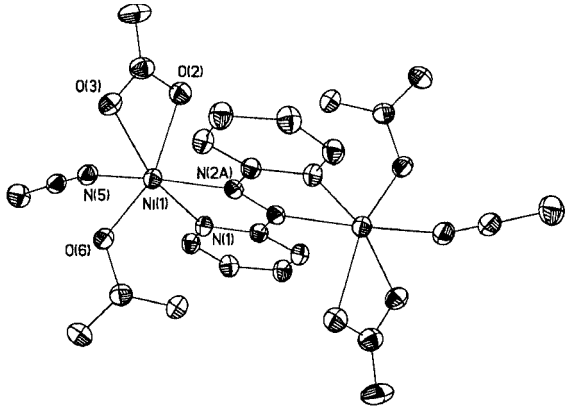

Figure 2. Thermal ellipsoid diagram (50% probability) for the dimer [Ni_2(abpy)(CH_3CN)$_2$(NO_3)$_4$] (**1**)

Electrochemical Studies

The cyclic voltammogram of **1** in acetonitrile exhibits two oxidation features at $E_{p,a}$ = +0.62V and $E_{p,a}$ = +0.4V, with no associated return waves. In addition, there are three reversible reductions located at $E_{1/2}$ = −0.10 V, $E_{1/2}$ = −0.4 V and at $E_{1/2}$ = −0.9 V. The dinuclear Cu^{II} compound **2** also exhibits a rich electrochemistry with an irreversible oxidation located at $E_{p,a}$ = +1.10 V, a reversible oxidation at $E_{1/2}$ = +0.65 V, and two reversible reductions at $E_{1/2}$ = +0.40 V and $E_{1/2}$ = 0.0 V. The fact that these reductions occur at positive potentials vs. Ag/AgCl explains why the formation of **3** is so facile.

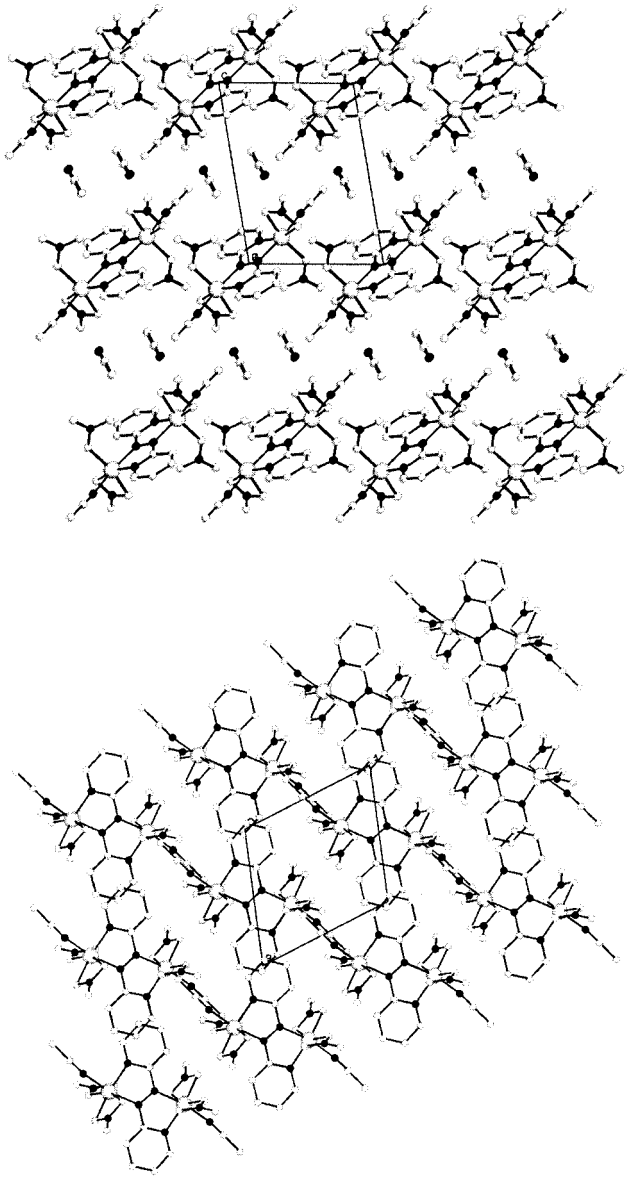

Figure 3. Projection of the packing diagram for [Ni_2(abpy)(CH_3CN)$_2$(NO_3)$_4$]·2CH_3CN (**1**·2CH_3CN) on the *ac* plane (top) and on the *bc* plane (bottom)

X-ray Crystallographic Studies

[Ni$_2$(abpy)(CH$_3$CN)$_2$(NO$_3$)$_4$]·2CH$_3$CN (1)

Crystals of [Ni$_2$(abpy)(CH$_3$CN)$_2$(NO$_3$)$_4$]·2CH$_3$CN (**1**·2CH$_3$CN) contain Ni^{II} ions in a distorted octahedral geometry (Figure 2). Each Ni center is coordinated to two [NO$_3$]$^-$ ligands — one of which acts as a bidentate ligand — as well as to an acetonitrile molecule and the bridging abpy ligand. The distortion from perfect octahedral geometry is most likely a consequence of the small bite angle of the chelating nitrate anion, which leads to an acute O−Ni−O angle of 61.43(8)° and Ni−O distances of 2.125(2) and 2.105(2) Å. The shortest Ni−L bond is with the monodentate nitrate ligand [1.990(2) Å]. The Ni−N distance to the acetonitrile ligand is 2.044(2) Å, which is essentially the same as the distance in the homoleptic solvated cation [Ni(CH$_3$CN)$_6$]$^{2+}$. The Ni−N(azo) interaction is the longest of the three Ni−N interactions [Ni(1)−N(2) = 2.121 (2) Å]. The angles within the coordination sphere also provide some helpful insight into the distortion of the ligand environment of this compound. The angle between the pyridyl and the acetonitrile ligand is close to the ideal value for an octahedron [N(5)−Ni(1)−N(1) = 93.80(2)°]. The binding angle of abpy [N(1)−Ni(1)−N(2) = 76.45(9)°] is very close to the values observed for bptz in [Ni$_2$(bptz)(CH$_3$CN)$_8$][ClO$_4$]$_4$,[4] which contains a bridging interaction involving N atoms from a pyridyl nitrogen and the tetrazine ring to give an N−Ni−N angle of 78.10 (3)°. The two Ni atoms are 4.942 Å apart, which is much shorter than the corresponding distance of 6.904 Å in [Ni$_2$(bptz)(CH$_3$CN)$_8$][ClO$_4$]$_4$. An important feature to note in the structure of **1** is the elongation of the N=N bond in the bridging abpy ligand by 0.025 Å [N(2)−N(2#) = 1.271(4) Å) relative to the corresponding distance in free abpy (1.246 Å).[27] This lengthening is indicative of π back-donation from the Ni^{II} centers into the empty π* (abpy) orbitals. This effect has been noted for a complex of abpy with Cu^I as well.[27]

In terms of intermolecular interactions, the Ni$_2$ molecules form pseudo-tetragonal layers in the *ab* plane, with solvent molecules occupying the interstices (Figure 3). There are no short contacts between the molecules, with the Ni···Ni intermolecular contacts being greater than 6 Å.

[Cu$_2$(abpy)(CH$_3$CN)$_8$][BF$_4$]$_4$ (2)

The structure of [Cu$_2$(abpy)(CH$_3$CN)$_8$][BF$_4$]$_4$ (**2**) contains the tetracationic Cu$_2$ unit, [Cu$_2$(abpy)(CH$_3$CN)$_8$]$^{4+}$, since the Cu^{II} centers are coordinated only by neutral ligands. The Cu^{II} centers exhibit a typical axial Jahn−Teller distortion, with the elongated axis oriented along the azo and acetonitrile interactions [azo: Cu(1)−N(1) 2.401(4) Å and CH$_3$CN: Cu(1)−N(12) 2.313(5) Å] (Figure 4). The other four coordination sites are filled by three acetonitrile molecules at an average Cu(1)−N distance of 2.01(5) Å, and the pyridyl ring [Cu(1)−N(2) 2.040(5) Å]. The L−Cu−L angles are distorted from the ideal octahedral values, with N(1)−Cu(1)−N(13) and N(1)−Cu(1)−N(2) being 107.0(2)° and 71.5(2)°, respectively. As noted for the Ni analogue, the longer N=N distance in the azo group [1.277 (1) Å] is indicative of π back-donation. The Cu^{II} centers are separated by a distance of 5.408 Å, which is longer that the corresponding value in the Ni^{II} compound; this situation is a consequence of the Jahn−Teller distortion.

In the Cu^{II} structure, the 3D arrangement is best described as consisting of mixed anion-cation layers in the *ab* plane separated by [BF$_4$]$^-$ anions (Figure 5). In this structure, the presence of the anions increases the intermolecular distances, with all Cu···Cu intermolecular distances being longer than 8 Å.

{[Cu(abpy)][BF$_4$]}$_\infty$ (3)

The Cu^I species,{[Cu(abpy)][BF$_4$]}$_\infty$ (**3**) is a 1-D polymer consisting of Cu^I ions connected along the *a* axis (Figure 6). The Cu^I centers exhibit a distorted tetrahedral geometry

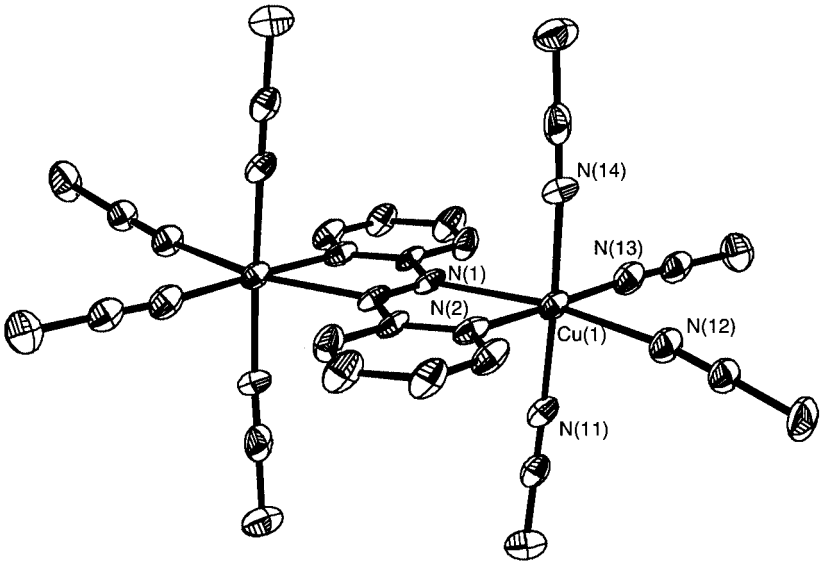

Figure 4. Thermal ellipsoid diagram (50% probability) for the dimer [Cu$_2$(abpy)(CH$_3$CN)$_8$]$^{4+}$ (**2**)

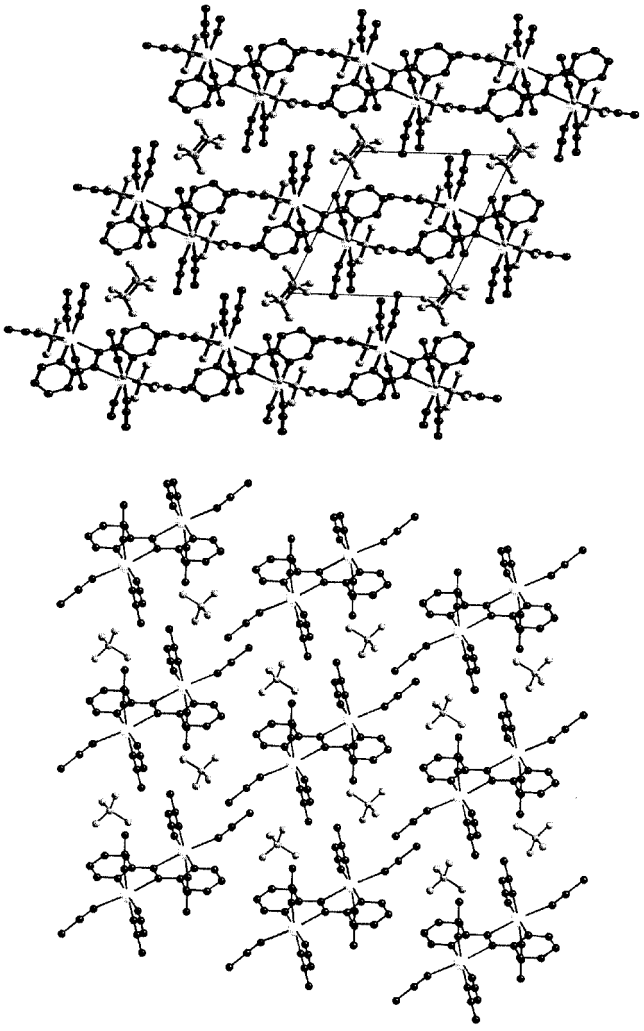

Figure 5. Projection of the packing diagram for $[Cu_2(abpy)(CH_3CN)_8][BF_4]_4$ (**2**) on the *bc* plane (top) and of the structure of one of the layers (bottom)

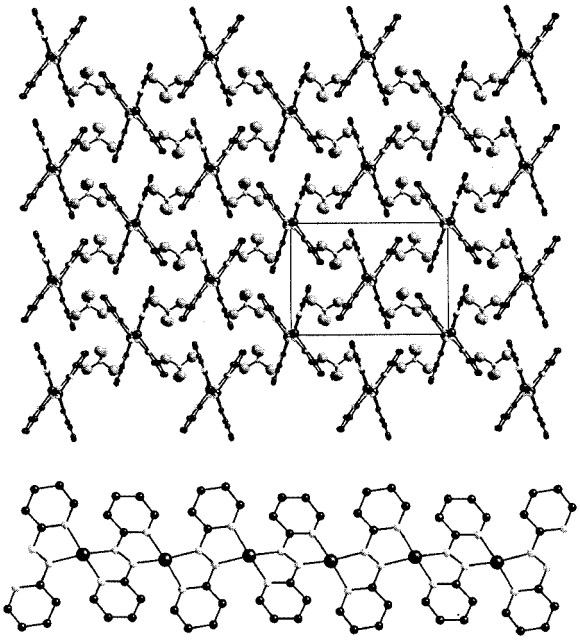

Figure 6. Projection of the packing diagram for $\{[Cu(abpy)][BF_4]\}_\infty$ (**3**) on the *bc* plane (top) and of the structure of one of the chains perpendicular to the *bc* plane (bottom)

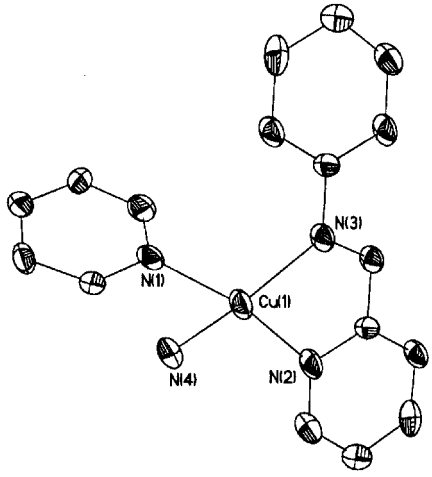

Figure 7. Thermal ellipsoid diagram (50% probability) for the monomeric building block of the $\{[Cu(abpy)]\}_\infty$ chain

(Figure 7), with the main distortions being observed due to the bite angles of the abpy ligand: N(1)−Cu(1)−N(4) = 77.7 (3)°, and N(2)−Cu(1)−N(3) = 79.4 (3)°. These angles are far from the ideal 109.5° for a tetrahedral geometry. The N(3)−N(3#) distance of 1.29(2) Å indicates that the azo group is obviously involved in appreciable π back-donation from the Cu^I, as expected for an electron-rich d^{10} center. The N=N distance is 0.054 Å longer in this compound than in free abpy, which is nearly twice the lengthening noted for the Ni^{II} and Cu^{II} complexes. The 1-D chains pack in a pseudo-hexagonal arrangement, with the counterions occupying the interstices afforded by the packing of the chains (Figure 6).

Magnetic Properties

Magnetic susceptibility measurements were performed on $[Ni_2(abpy)(CH_3CN)_2(NO_3)_4]$ (**1**) and $[Cu_2(abpy)(CH_3CN)_8][BF_4]_4$ (**2**) at 1000 G. Compound **1** shows a $\chi_m T$ value at room temperature (2.17 emu·K·mol^{-1}) that is close to the expected spin-only value for two magnetically dilute Ni centers. The $\chi_m T$ value remains constant down to 200 K (Figure 8), and then shows a steady decrease which is indicative of the presence of antiferromagnetic interactions between the $S = 1$ Ni^{II} centers. The χ versus T graph depicted in Figure 9 shows a broad maximum at 18 K which is an obvious indication that the azo bridging ligand promotes antiferromagnetic interactions. This magnetic behavior was analyzed with an isotropic model for a Ni^{II} dimer. From the Hamiltonian: $H = -2J\,(S1 \cdot S2)$ where $S1 = S2 = S_{Ni} = 1$, a simple expression of χ_m was derived, to which an additional paramagnetic contribution was added [Equation (1)].

The best fit to the experimental data was obtained for $g = 2.03$ and $J = -7.5$ cm^{-1}. The paramagnetic term ($C = 0.075$) accounts for about 4% of monomer impurity in the sample.

$$\chi_m = \frac{3g^2\,(2e^{2J/T}+10e^{6J/T})}{8T(1+3e^{2J/T}+5e^{6J/T})} + \frac{C}{T} \quad (1)$$

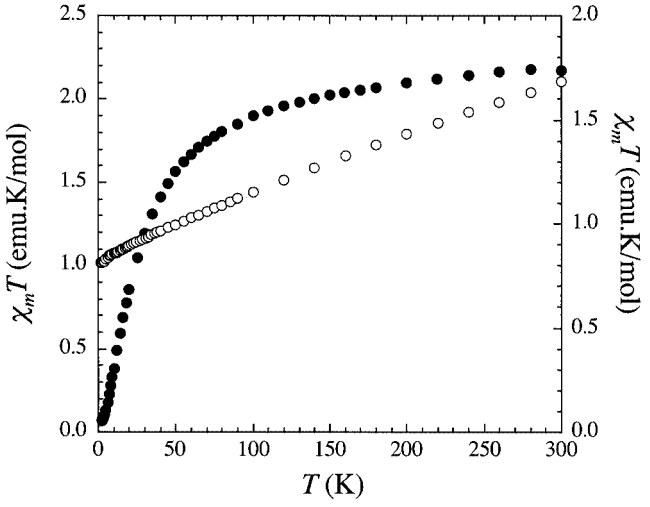

Figure 8. Plot of the $\chi_m T$ product vs. T for $[Ni_2(abpy)(CH_3CN)_2(NO_3)_4]\cdot 2CH_3CN$ (**1**, full circles) and $[Cu_2(abpy)(CH_3CN)_8][BF_4]_4$ (**2**, empty circles)

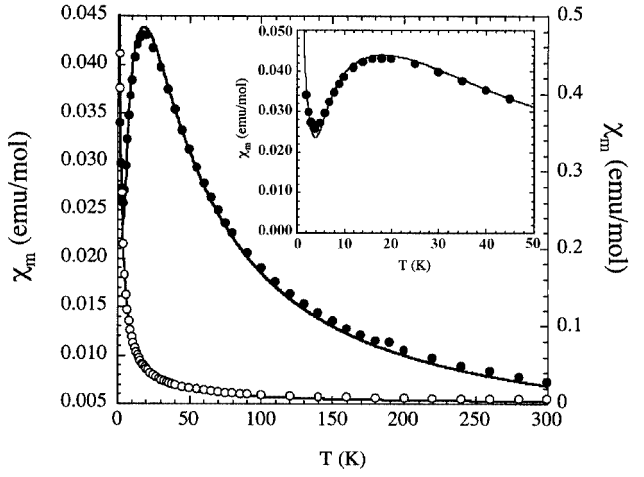

Figure 9. Plot of χ_m vs. T for $[Ni_2(abpy)(CH_3CN)_2(NO_3)_4]\cdot 2CH_3CN$ (**1**, full circles) and $[Cu_2(abpy)(CH_3CN)_8][BF_4]_4$ (**2**, empty circles); the corresponding lines represent the best fit obtained in each case

Compound **2** exhibits a $\chi_m T$ value (Figure 8) of 1.6 emu·K·mol^{-1} at room temperature, as compared to the expected spin-only value of 0.75 emu·K·mol^{-1} (for $g = 2$). The $\chi_m T$ plot gradually decreases with temperature and reaches a minimum value of 0.81 emu·K·mol^{-1} at 1.8 K. This behavior suggests the presence of a TIP (temperature-independent paramagnetism). The absence of a maximum in χ_m indicates that the magnetic interaction through the abpy ligand is small in this case. Indeed, the χ_m versus T graph (Figure 9) shows a typical exponential paramagnetic behavior. The data were fitted to a model for a Cu^{II} dimer, analogous to the one used for the Ni case, including a TIP contribution instead of a paramagnetic impurity contribution. From the expression derived for the susceptibility [Equation (2)], the fitting led to values of $g = 2.09$ and $J = -0.05$ cm^{-1}, and a TIP of 4×10^{-3} emu·mol^{-1}. These results support the conclusion that the interaction is essentially negligible in the Cu^{II} compound.

$$\chi_m = \frac{3g^2(2e^{2J/T})}{8T(1+3e^{2J/T})} + \chi_{TIP} \quad (2)$$

The fact that the magnetic interaction between Cu^{II} centers through the abpy ligand is much weaker than the corresponding interaction between Ni^{II} centers can be rationalized on the basis of geometrical considerations of the magnetic orbitals involved in the interaction, in addition to the longer distance between metal centers, when compared to the one observed for the Ni dimer. The X-ray studies reveal that the Cu^{II} centers exhibit a Jahn−Teller distortion of the axial elongation type along the N atoms of the azo group. The magnetic orbital therefore is $d_{x^2-y^2}$ which is orthogonal to the azo interaction. One would expect that superexchange through the pyridine ring and across the azo group to the adjacent pyridine ring would be very poor. Conversely, in the case of the Ni_2 compound both e_g orbitals are singly-occupied and there is no Jahn−Teller distortion. The improved overlap of the magnetic orbitals on the Ni^{II} ions with the N atoms of the bridging abpy ligand would be expected to lead to improved magnetic superexchange; this is corroborated by the magnetic measurements.

Conclusion

Two new paramagnetic dinuclear molecules were prepared by the reaction of Ni^{II} and Cu^{II} ions with the azo-2,2′-bypyridine (abpy) ligand. The compounds $[Ni_2(abpy)(CH_3CN)_2(NO_3)_4]$ and $[Cu_2(abpy)(CH_3CN)_8][BF_4]_4$ were fully characterized by X-ray crystallography, electrochemistry, electronic spectroscopy and magnetic susceptibility. The abpy ligand acts as a bridge between paramagnetic Ni^{II} and Cu^{II} centers in both cases and promotes antiferromagnetic interactions between the $S = 1$ Ni^{II} centers but does not provide a good pathway for superexchange in the $S = 1/2$ Cu^{II} dinuclear molecule. The different magnetic behavior can be explained by the fact that the Cu^{II} compound exhibits a Jahn−Teller distortion that leads to poor overlap of the magnetic orbitals through the bridging ligand.

The magnetic results allow for consideration of whether superexchange will be efficient through the abpy ligand. The antiferromagnetic exchange observed in the Ni^{II} compound is of the same order of magnitude found for ligands such as oxalate[28,29] and 2,2′-bipyrimidine.[30,31] On the ba-

sis of this study, we conclude that the abpy ligand will be useful for the design of a range of magnetically interesting molecules and materials.

Experimental Section

General Remarks: All operations were performed under a nitrogen atmosphere using standard Schlenk-line techniques, unless otherwise indicated. Solvents were distilled prior to use from the appropriate drying agents. Acetonitrile was distilled from over 3 Å molecular sieves, whereas toluene and diethyl ether were distilled from over a Na/K amalgam. The reagent $Ni(NO_3)_2{\cdot}6H_2O$ was purchased from Aldrich and used without further purification. The compound $[Cu(CH_3CN)_4][BF_4]_2$ was synthesized according to published methods.[32] IR spectra were measured as Nujol mulls between KBr plates on a Nicolet 740 FT-IR spectrometer. Magnetic susceptibility measurements were performed in the range of 2−300 K with a Quantum Design SQUID magnetometer MPMS-XL. All measurements were performed on polycrystalline samples. Data were corrected for diamagnetic contributions calculated from Pascal constants.[33] The cyclic voltammetric studies were performed on a CH Instruments Electrochemical Analyzer in acetonitrile containing 0.1 M tetra-*n*-butylammonium hexafluorophosphate ([TBA][PF_6]) as the supporting electrolyte. The working electrode was a BAS Pt disk electrode, the reference electrode was Ag/AgCl and the counter electrode was a Pt wire. The Cp_2Fe/Cp_2Fe^+ couple occurs at +0.52 V vs. Ag/AgCl under the same experimental conditions.

$[Ni_2(abpy)(CH_3CN)_2(NO_3)_4]$ (1): A sample of $Ni(NO_3)_2{\cdot}6H_2O$ (100 mg, 0.34 mmol) was dissolved in 30 mL of acetonitrile to give a pale green solution which was stirred until the entire solid had dissolved, after which time abpy (32 mg, 0.17 mmol) was added. The resulting intensely green solution was stirred for 4 additional hours and then concentrated to 10 mL. Slow vapor diffusion of diethyl ether into the reaction solution afforded dark green crystals within 6 days. Yield = 80 mg (75%). IR (KBr): $\tilde{\nu}$ = 2724 cm^{-1} (w), 1620 (w), 1147 (w), 1039 (w), 1022 (w), 801 (w), 722 (w). UV/Vis (acetonitrile, $c = 9.8 \times 10^{-6}$ M): λ = 344 nm [$\varepsilon = 1.8 \times 10^4$ L(mol·cm)$^{-1}$].

$[Cu_2(abpy)(CH_3CN)_8][BF_4]_4$ (2): A sample of $[Cu(CH_3CN)_4][BF_4]_2$ (100 mg, 0.249 mmol) was dissolved in 20 mL of acetonitrile and treated with abpy (22 mg, 0.124 mmol). A color change from blue to pale green quickly ensued. The reaction mixture was stirred overnight, concentrated and treated with diethyl ether to the point of saturation. Light green platelet crystals of **2** were obtained by placing the solution in the freezer at −4 °C for a week. Yield = 82 mg (80%). IR (KBr): $\tilde{\nu}$ = 2724 cm^{-1} (w), 2296 (w), 2323 (w), 1589 (w), 1261 (w), 1229 (w), 1027 (br,s), 805 (w), 722 (w). UV/Vis (acetonitrile, $c = 8.0 \times 10^{-6}$ M): λ = 351 nm [$\varepsilon = 2.7 \times 10^4$ L(mol·cm)$^{-1}$], 230 [$\varepsilon = 1.98 \times 10^4$ L(mol·cm)$^{-1}$].

$\{[Cu(abpy)][BF_4]\}_\infty$ (3): A solution of **2** in acetonitrile layered with toluene produced dark green needle-like crystals of **3** after a period of one month.

X-ray Crystallographic Study: The X-ray data sets were collected on a SMART 1 K area detector diffractometer equipped with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). The frames were integrated with the Siemens SAINT[34] software package and the data were corrected for absorption using the SADABS program.[35] The structures were solved using the direct-methods programs SHELXS-97 (**1** and **3**),[36] and SIR97 (**2**). Crystal parameters and basic information pertaining to data collection and refinement are summarized in Table 1.

A dark green prismatic crystal of **1** was secured on the tip of a glass fiber with Dow Corning silicone grease and placed in a cold N_2(g) stream at 110 (2) K. A total of 8160 reflections were collected of which 3252 were unique. The final refinement cycle was based on 2815 reflections with $F_0 > 2\sigma(F_0)$ ($R1$ = 0.0416 and $wR2$ = 0.1054).

A light green platelet of **2** was secured on the tip of a glass fiber with Dow Corning silicone grease and placed in a N_2(g) stream at 110 (2)K. The data collection involved a total of 7358 reflections of which 3484 were unique. The final refinement cycle was based

on 2887 reflections with $F_0 > 4\sigma(F_0)$ that were used to fit 309 parameters which led to $R1 = 0.0662$ and $wR2 = 0.1688$. The goodness-of-fit index is 1.021, and the highest peak in the final difference map is 1.195 $e^-\cdot Å^3$.

A green needle-like crystal of **3** was covered with Paratone oil, secured on the tip of a glass fiber with Dow Corning silicone grease, and placed under a N_2(g) stream at 110 (2)K. A total of 11151 reflections were collected of which 2040 were unique. The final refinement cycle was based on 1096 reflections with $F_0 > 4\sigma(F_0)$ that were used to fit 181 parameters which led to $R1 = 0.0833$ and $wR2 = 0.2028$. The goodness-of-fit index is 0.973, and the highest peak in the final difference map is 1.765 $e^-\cdot Å^3$.

CCDC 183947 (**1**), -183948 (**2**) and -183949 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of (η^3-Allyl)bromodicarbonylbis(pyrazole)molybdenum(II) and Reactivity towards [Au(acac)PPh_3]: Structure and Dynamic Behavior of the Monometallic Pyrazole and Heterometallic Pyrazolate Complexes

Paloma Paredes,[a] Daniel Miguel,[a] and Fernando Villafañe*[a]

Keywords: Molybdenum / Gold / Heterometallic complexes / N ligands / Fluxionality

The reactions of [Mo(η^3-allyl)Br$(CO)_2(NCMe)_2$] and two equivalents of Hpz (pyrazole) or Hdmpz (3,5-dimethylpyrazole) lead to [Mo(η^3-allyl)Br$(CO)_2(Hpz)_2$] or [Mo(η^3-allyl)Br$(CO)_2(Hdmpz)_2$]. The Hpz and Hdmpz ligands are coordinated *cis* and *trans* with respect to the allyl group in the solid state, whereas in their solutions a slow trigonal twist process is detected. These complexes react with Tl(acac) giving [Mo(acac)(η^3-allyl)$(CO)_2$(Hpz)] and [Mo(acac)(η^3-allyl)$(CO)_2$(Hdmpz)], which also undergo a slow trigonal twist process in solution. The latter complex may also be obtained by the reaction of equimolar amounts of [Mo(η^3-allyl)Br$(CO)_2(Hdmpz)_2$] and [Au(acac)PPh_3], giving [Au$BrPPh_3$] as a by product. The reaction of these molybdenum acac complexes with [Au(acac)PPh_3] give rise to the heterobimetallic bridging pyrazolate complexes [Mo(acac)(η^3-allyl)$(CO)_2$(μ-pz)AuPPh_3] and [Mo(acac)(η^3-allyl)$(CO)_2$(μ-dmpz)AuPPh_3]. The solid state structure of the latter, which is also obtained from [Mo(η^3-allyl)Br$(CO)_2(Hdmpz)_2$] and two equivalents of [Au(acac)PPh_3], with [Au$BrPPh_3$] as a by product, reveals the coordination of the bridging dimethylpyrazolate ligand *trans* to the allyl group. Two different dynamic processes which are slowed down at low temperatures are detected in solution for each heterobimetallic complex: trigonal twist for the pyrazolate bridging complex, and hindered rotation of the Mo–N bond for the more hindered dimethylpyrazolate complex.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Pyrazolate ligands are commonly used as bridging ligands since they allow for the study of the bimetallic moiety, holding both metals in close proximity but at the same time being flexible enough to adopt different geometries with a wide variety of metals.[1] The interest of these studies embraces different fields, such as the physical properties and the biological activity of new complexes, or their unusual chemical behavior and catalytic activity.[2]

The bridging pyrazolate heterobimetallic complexes are of special interest, and may be obtained by deprotonation of a terminal pyrazole complex when a second metallic substrate is present. This strategy allows the systematic synthesis of heterobimetallic systems, as has been successively used by different groups, mainly with middle and late transition elements.[3] Herein we report on the synthesis of molybdenum(II) complexes containing two terminal pyrazoles coordinated in a *cis* manner. We also present the first results of the use of these compounds as precursors for heterobimetallic systems: deprotonation of the pyrazole ligands, and further coordination to a late transition metal would lead to the synthesis of early-late bimetallic complexes. These are particularly interesting in the field of heterobimetallic systems, as the clear differences between both metals enhance the synergism responsible for their improved activity.[4]

Results and Discussion

Synthesis and Characterization of [MoBr(η^3-allyl)$(CO)_2(Hpz)_2$] and [MoBr(η^3-allyl)$(CO)_2(Hdmpz)_2$]

The reactions of [MoBr(η^3-allyl)$(CO)_2(NCMe)_2$] with a two-fold excess of pyrazole (Hpz) or dimethylpyrazole (Hdmpz) in dichloromethane are instantaneous at room temperature affording [MoBr(η^3-allyl)$(CO)_2(Hpz)_2$] (**1a**) and [MoBr(η^3-allyl)$(CO)_2(Hdmpz)_2$] (**1b**), respectively, isolated as yellow crystalline solids.

There are two possible geometries for these complexes, as depicted in Figure 1. They are pseudo-octahedral if the η^3-allyl ligand is considered as occupying one coordination po-

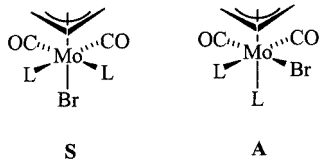

Figure 1. Two possible structures for complexes [MoBr(η^3-allyl)$(CO)_2L_2$]

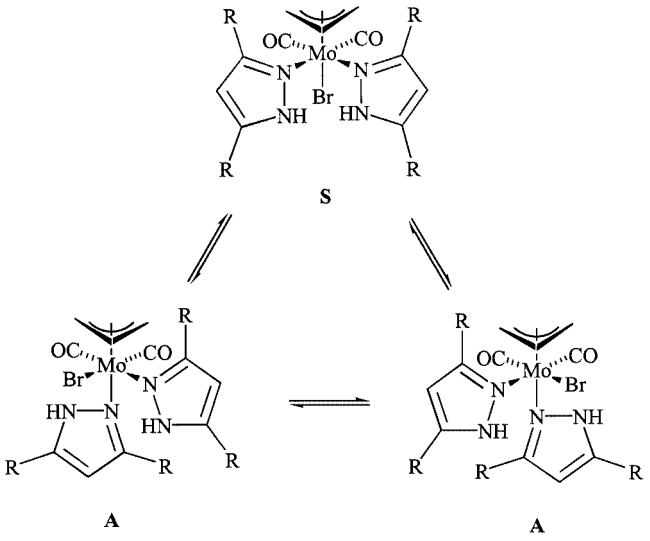
[a] Departamento de Química Inorgánica, Facultad de Ciencias, Universidad de Valladolid, 47005 Valladolid, Spain

sition, having its terminal atoms oriented over the carbonyl groups, as has been demonstrated to be the most energetically favorable arrangement.[5] The two possible geometries are: **S** or symmetric, where the pyrazoles are coordinated in the *equatorial* positions, *trans* to the carbonyls; and **A** or asymmetric, where one of the pyrazoles is coordinated *trans* to the allyl group, in the *axial* position (Figure 1).

The NMR spectra provide very useful information for identifying the geometry of the complex, since both pyrazoles and both methylenes of the allyl group are equivalent in the symmetric isomer **S**, but inequivalent in the asymmetric isomer **A**. The latter is the only isomer detected in the ^1H and $^{13}C\{^1H\}$ NMR spectra of **1a** and **1b** at room temperature. However, some of the signals in the ^1H NMR spectra are broad, which might be a consequence of a slow exchange process before the coalescence.

These complexes $[MoX(\eta^3\text{-allyl})(CO)_2L_2]$ (X = halide or pseudo halide, L_2 = two monodentate ligands or a bidentate ligand) usually display a nondissociative trigonal twist process in which there is an intramolecular rotation of the XL_2 triangular face,[6] which would lead to the equilibrium depicted in Scheme 1. The isomers involved in this equilibrium are the symmetric **S** and both enantiomers of the asymmetric **A**. Therefore, if this exchange process is fast enough, a symmetric average spectrum should be observed.



Scheme 1. Trigonal twist process observed for **1a** (R = H) and **1b** (R = CH_3)

Other dynamic processes in solution have been detected for these types of complexes, such as the $\eta^3-\eta^1-\eta^3$ rearrangement of the allyl,[7] or the recently described "pivoted double switch" process, where the *axial* ligand remains in the same position, while the bromo and the other ligand *trans* to the carbonyls switch between both *equatorial* positions.[8] The $\eta^3-\eta^1-\eta^3$ rearrangement of the allyl would render the H^{anti} and H^{syn} equivalent, giving an A_4X pattern for the allyl group in the ^1H NMR spectra. On the other hand, the "pivoted double switch" mechanism would never render both pyrazole ligands equivalent, since the pyrazole in the *axial* position would not exchange with the other pyrazole.

A variable temperature ^1H NMR spectroscopic study was carried out in order to understand the exact nature of the process in solution that leads to the broadening of the signals observed in the ^1H NMR spectra at room temperature for **1a** and **1b**.

The ^1H NMR spectrum of **1a** at 333 K shows signals due to a symmetric dynamic situation where both pyrazoles are equivalent, thus confirming the trigonal twist exchange process which is very slow at room temperature. On the other hand, a symmetric situation appears when the ^1H NMR spectrum of **1b** is recorded at 353 K in C_6D_6, as some of the signals of the different Hdmpz groups coincide, as well as those of different halves of the allyl group (see Exp. Sect.). Hence, the same trigonal twist exchange process is proposed for **1b**, but is slower than that of **1a**. This is in accordance with the higher steric requirements of Hdmpz compared with Hpz.

The allyl protons H^{anti} and H^{syn} always remain inequivalent, and the pyrazole ligands are equivalent when the processes are fast, which leads to both the $\eta^3-\eta^1-\eta^3$ rearrangement of the allyl and the "pivoted double switch" process being discarded.

Only the asymmetric isomer is detected in the ^1H NMR spectra of both complexes at low temperatures, indicating that the equilibrium occurs between the two asymmetric enantiomers **A** depicted in Scheme 1. The symmetric isomers **S** are not observed for any of the two complexes, which suggests that they are energetically very unfavorable.

The ^1H NMR spectra recorded at low temperatures display sharp signals. The H^4 signals in **1a** are pseudo quadruplets, due to coupling with the rest of pyrazolic protons including the pyrrolic proton, as was confirmed from selective homodecoupling experiments. Therefore, the broadness observed at room temperature might then also be due to a rapid prototropic exchange involving the pyrrolic proton, which is common in pyrazole complexes.[9] The homodecoupling experiments carried out on **1a** at low temperature allowed us to unequivocally assign the signals of the pyrazolic hydrogens. However, this assignment cannot be extended to the rest of the complexes described here, since the chemical shifts of the hydrogens or methyl groups in positions 3 and 5 seem to be affected by different factors, which are difficult to evaluate: whether the hydrogen (or methyl) group at position 3 resonates at a higher field than at position 5 or vice versa may vary in the same family of complexes,[3g] or even depend on the solvent used.[10] Therefore, the assignment proposed for the rest of the complexes in the Experim. Section may be considered as tentative.

The IR spectra of both complexes show two bands in the C−O stretching region in solution, although more bands are detected in the solid state. This is a common feature in carbonyl complexes and is attributed to the lower symmetry of the molecule in the crystal compared to the isolated molecule in solution. The C−O frequencies are slightly higher for **1a** than for **1b** when the IR is recorded in solution. This is to be expected considering that Hdmpz is a better donor

than Hpz, and is also observed for the rest of the complexes described in this work. However, the C−O frequencies of **1a** in the solid state are appreciably lower than those of **1b** (see Exp. Sect.). This has no immediate explanation, as the rest of the analytical and spectroscopic data are in accordance with the proposed geometries. Thus, we decided to carry out an X-ray study of both complexes in order to also obtain crystallographic data, and thus to determine whether this could shed some light on these anomalous frequencies.

The structures are shown in Figure 2 and relevant distances and angles are collected in Table 1. As indicated above, the molybdenum atoms are pseudo-octahedrally coordinated, assuming that the allyl groups occupy one site. The two carbonyls and the allyl group show the expected orientation, already described.[5,11] As evidenced by Table 1, the distances and angles are very similar in both complexes, and similar to those found in the previously reported structure of a bromodicarbonylmolybdenum(II) complex with pyrazole and phenylallyl.[12] It should be noted that one of the pyrazole ligands is coordinated *trans* to the allyl group in all three structures (asymmetric isomer **A** in Scheme 1), opposite to what is usually found in complexes of the type [MoX(η^3-allyl)$(CO)_2L_2$] (X = halide or pseudo halide, L_2 = nitrogen donor ligand), where the nitrogen donor ligands are always *trans* to the carbonyl groups (**S** isomer).[11]

The Mo−C and C−O distances in the structures of **1a** and **1b** follow the expected sequence: those *trans* to the bromo ligand [C(1)−O(1)] are similar in both structures, whereas those *trans* to the pyrazoles are slightly different: C(2)−O(2) distance in **1a** is 1.132(3) Å vs. 1.160(5) Å in **1b**. This indicates that the C−O bond is stronger in **1a**, inferring that Hdmpz is a better donor than Hpz, as predicted. However, this result is difficult to rationalize with the frequencies observed from the solid-state IR spectra, which point to the opposite, since they are lower for **1a**. This feature might be explained considering lattice effects, since different space groups are detected for each molecular packing, and this should affect the C−O frequencies. This frequency anomaly might also be explained considering the short intermolecular distances where the oxygen atoms of the carbonyl groups are involved, as is discussed below.

The pyrrolic hydrogens in the structures of these two complexes are involved both in both intramolecular and in-

termolecular hydrogen bonds. The intramolecular hydrogen bonds affect the bromine atoms: 2.51 and 2.62 Å are found in **1a**, and 2.51 and 2.74 Å in **1b**, for Br(1)···H(4) and Br(1)···H(2), respectively. These distances are typical of weak hydrogen bonds,[13] and are always shorter those between the bromine atom and the pyrrolic hydrogen in the *equatorial* position. Similar hydrogen bond lengths have been found for other bromo complexes containing pyrazoles.[14]

The intermolecular hydrogen bonds involving the pyrrolic atoms clearly differ in both complexes: in **1a**, the acceptor atoms are the oxygens of the carbonyls giving distances expected for weak hydrogen bonds [H(2)···O(1) 2.75 Å, H(4)···O(2) 2.39 Å],[13] whereas no intermolecular interaction is observed for the pyrrolic hydrogens of **1b**. As indicated above, either the lattice effects or this feature (or both) might be responsible for the observed decrease in the C−O stretching frequencies in the solid IR for **1a**, since this interaction is only detected in this complex.

Acac Complexes

Once the two precursors needed to obtain heterobimetallic complexes had been synthesized, we decided to explore their reactivity towards different bases in order to deprotonate the pyrazoles and then react this pyrazolate complex with a second metal fragment. However, the treatment of either **1a** or **1b** with K_2CO_3, NEt_3, NaH, or KOH gave unchanged starting material or mixtures of unidentifiable products after forcing the conditions. This can be easily be explained in terms of the fact that these bases may act as nucleophiles, and the attack of nucleophiles on coordinated η^3-allyl groups is well-known. For [MoX(η^3-allyl)$(CO)_2L_2$] complexes, these reactions do not always afford the expected olefin,[15] but may lead to the substitution of the coordinated halogen by the nucleophile,[16] or even to decomposition.[17]

An alternative way of obtaining heterobimetallic complexes was the use of a base already coordinated to the metal fragment that was to be introduced. This fragment could immediately trap the pyrazolate formed by coordination to the second metal fragment. Thus, [Au(acac)PPh_3] was used, since the acetylacetonate could act as a base. Other acac complexes have previously been used for this purpose.[3a−3c]

The reaction of **1b** with a two-fold excess of [Au(acac)PPh_3] occurs at room temperature for 1 h in THF, and allows for the isolation of [Mo(acac)(η^3-allyl)$(CO)_2$(μ-dmpz)$AuPPh_3$] (**3b**) after separating [$AuBrPPh_3$] as a white solid by crystallization [Equation (1)]:

[MoBr(η^3-allyl)$(CO)_2$(Hdmpz)$_2$] (**1b**) + 2 [Au(acac)PPh_3] → [Mo(acac)(η^3-allyl)$(CO)_2$(μ-dmpz)$AuPPh_3$] (**3b**) + [$AuBrPPh_3$] + Hdmpz + Hacac (1)

As inferred from Equation (1), one equivalent of acac acts as a ligand, substituting one dimethylpyrazole and the bromo ligands, whereas the second acts as a base, removing the pyrrolic hydrogen and coordinating the pyrazolate ligand to the liberated "$AuPPh_3$" fragment. This sequence should coincide with the path followed by the reaction, since the products detected when the reaction was repeated using equimolar amounts of the reactants were [Mo(acac)(η^3-allyl)$(CO)_2$(Hdmpz)] (**2b**) and [$AuBrPPh_3$] [Equation (2)].

[MoBr(η^3-allyl)$(CO)_2$(Hdmpz)$_2$] (**1b**) + [Au(acac)PPh_3] → [Mo(acac)(η^3-allyl)$(CO)_2$(Hdmpz)] (**2b**) + [$AuBrPPh_3$] + Hdmpz (2)

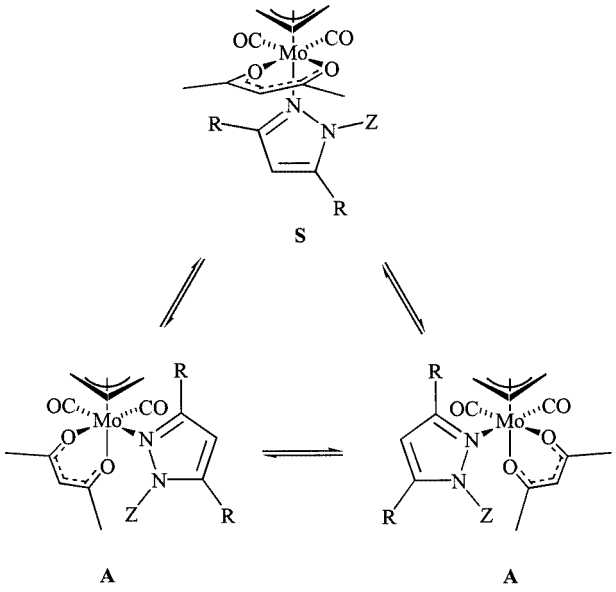
This result led us to propose a more logical synthetic path in order to obtain these two new complexes: (a) the substitution of the bromo and pyrazole ligands by acetylacetonate was carried out with Tl(acac) instead of [Au(acac)PPh_3], and (b) this gold complex was used for the deprotonation of the remaining pyrazole and formation of the heterobimetallic complexes.

The reaction of Tl(acac) with equimolar amounts of **1a** or **1b** in dichloromethane at room temperature yielded, after separating TlBr as a precipitate, [Mo(acac)(η^3-allyl)$(CO)_2$(Hpz)] (**2a**) or [Mo(acac)(η^3-allyl)$(CO)_2$(Hdmpz)] (**2b**). The second equivalent of Hpz or Hdmpz liberated in the reaction remained in the mother liquor.

The allyl and acac signals in the ^{1}H NMR spectra of **2a** and **2b** at room temperature are indicative of a symmetric situation with respect to the plane that bisects the allyl and contains the metal atom. However some signals are broad, as occurred for complexes **1**, what is indicative of a dynamic process in solution. The ^{1}H NMR spectra at lower temperatures show signals of two isomers: one symmetric and one asymmetric, the ratio of the latter increasing as the temperature decreases. This is again in accordance with a trigonal twist process between the possible stereoisomers shown in Scheme 2. Contrarily to complexes **1**, the symmetric isomers **S** are detected in the solutions of complexes **2** (their ratio being higher as the temperature rises) which is indicative of their higher stability in this case.[18] The signals for both isomers are clearly differentiated in the $^{13}C\{^1H\}$ NMR spectra at 233 K of **2a** and **2b**.

The IR spectra of complexes **2a** and **2b** show two absorptions in the C−O stretching region, those of **2a** being slightly higher, as should be expected given the lower neat donor character of Hpz compared with Hdmpz. Another interesting feature is the N−H stretching bands, which show an important decrease for **2a**: 3159 cm^{-1}, vs. ca. 3300 cm^{-1} for **1a** and **1b**, or 3396 cm^{-1} for **2b**. In addition to this low frequency, the N−H stretching absorption observed for **2a** is very broad, which suggests that this hydrogen bond is stronger than those in complexes **1** and **2a**, which show sharp absorptions. These two factors point to a moderate hydrogen bond in **2a**, whereas those detected in the other complexes herein may be considered to be weak, as indicated above.[12,19]

Once acac has been incorporated to the molecules, they may be deprotonated to obtain the pyrazolate bridging het-



Scheme 2. Trigonal twist process observed for **2a** (R = H, Z = H), **2b** (R = CH_3, Z = H), and **3a** (R = H, Z = $AuPPh_3$).

erobimetallic complexes. The reactions of **2a** or **2b** with the equimolar amounts of [Au(acac)PPh_3] occur in 5 minutes at room temperature and in THF as the solvent, to give [Mo(acac)(η^3-allyl)$(CO)_2$(μ-pz)$AuPPh_3$] (**3a**) and [Mo(acac)(η^3-allyl)$(CO)_2$(μ-dmpz)$AuPPh_3$] (**3b**) as orange crystalline solids.

The IR spectra of **3a** and **3b** show two C−O absorptions, their frequencies being once again slightly higher for the Hpz complex, and no N−H bands are detected. Their ^{1}H NMR spectra at room temperature show allyl and acac signals indicative of a symmetric situation respect to the plane which bisects the allyl and contains the metal atom. The $^{31}P\{^1H\}$ NMR spectra show only one singlet at room temperature, whereas no $^{13}C\{^1H\}$ NMR spectra could be recorded due to the low solubility of the complexes. In this case, **3a** and **3b** showed different behavior when the variable temperature NMR spectroscopic study was carried out.

The behavior of **3a** at lower temperatures is similar to that described above for **2a**, since two isomers are detected, symmetric and asymmetric, although this time the ratio of the latter increases as the temperature decreases. This is observed both in the ^{1}H and $^{31}P\{^1H\}$ NMR spectra at low temperatures, and supports again a trigonal twist process between isomer **S** and the two enantiomers of isomer **A**, as shown in Scheme 2.

On the other hand, the $^{31}P\{^1H\}$ NMR spectra of **3b** at 213 K displays six singlets, one of them clearly more intense than the others. The ^{1}H NMR spectra at low temperature also show a major isomer with inequivalent halves for the acac and allyl ligands, and a mixture of minor isomers, although not all their signals could be completely interpreted due to their low ratio.

An X-ray diffractometric study was carried out in order to identify which isomer crystallizes. The result of this determination is shown in Figure 3, whereas Table 2 contains the more relevant distances and angles. The usual pseudo-octahedral geometry of (η^3-allyl)molybdenum complexes is found, with the open face of the allyl moiety oriented over the carbonyls. The acac ligands occupy the *equatorial* positions, whereas the *axial* position is occupied by the dimethylpyrazolate, which bridges the molybdenum and the gold atoms. The plane defined by the bridging pyrazole and the gold atom lies nearly perpendicular [91.4(1)°] to the plane defined by Mo, N(2), and the central atoms of the allyl and acac ligands [C(9) and C(5), respectively], which bisects the molybdenum complex.

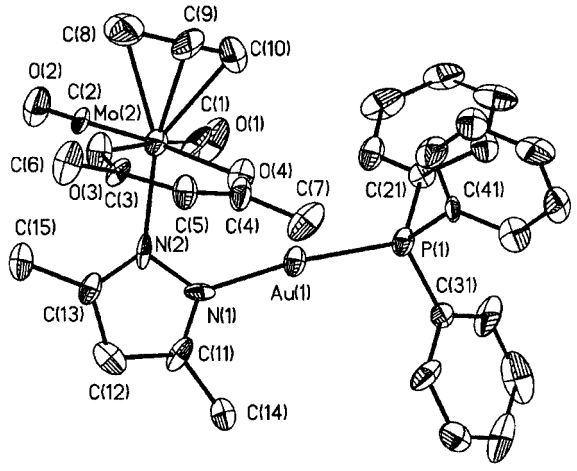


Figure 3. Perspective view of [Mo(acac)(η^3-allyl)$(CO)_2$(μ-dmpz)$AuPPh_3$] (**3b**) showing the atom numbering (the hydrogen atoms have been omitted for clarity)

The distances and angles of the "Mo(acac)(η^3-allyl)$(CO)_2$" moiety are very similar to those found in the structure of the complex [Mo(acac)(η^3-allyl)$(CO)_2$(py)],[20] where the acac also occupies the *equatorial* positions. The Au−N and Au−P distances [1.976(18) and 2.20(5) Å] are in the lower range of those previously reported for phosphanepyrazolylgold complexes [2.06(2) and 2.231(5)−2.334(5) Å, respectively].[21] The P−Au−N angle [171.9(6)°] is also in the lower limit with respect to those previously described [174.3(4)−178.0(5)°].[21]

Once the isomer in the solid state had been identified, the next step was to assign its signals in the NMR spectra. Therefore, the crystals were mixed with frozen $CDCl_3$ at 195 K, and the NMR spectra were recorded immediately after the solvent melted at 213 K. The ^{1}H and $^{31}P\{^1H\}$ NMR spectra show signals that correspond to the above mentioned major isomer. Small signals due to the minor isomers appear and increase as the solution is maintained at low temperature, until finally the same spectra as that described above, obtained when the solution was prepared at room temperature, is observed.

Hence, the isomer detected in the solid state is that labeled **S** in Scheme 2, but the $AuPPh_3$ moiety makes the plane bisecting the acac and the allyl ligands no longer a symmetry plane. This explains why its ^{1}H NMR spectrum shows inequivalent halves for the acac and allyl ligands, and suggests that the rotation of the Mo−N bond has been

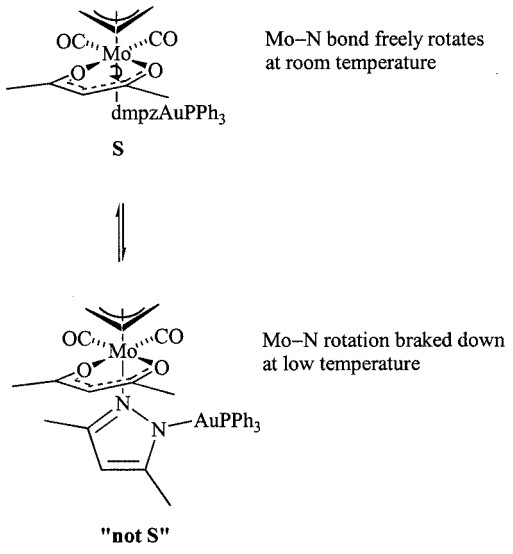
stopped at low temperature. In complexes **2a**, **2b**, and **3a**, (Scheme 2) the Mo−N bonds rotate freely even at 213 K, as both halves of allyl and acac ligands are equivalent in the symmetric isomer **S**, opposite to what is observed for **3b**. Although the presence of isomers such as **A** in Scheme 2 cannot be completely ruled out, the isomers detected in the NMR spectra of **3b** should be different rotamers, the Mo−N bond rotation being slow at low temperature but fast at room temperature (Scheme 3).

Therefore, rotation of the Mo−N bond, which is only detected for **3b**, is fast for the rest of the complexes described herein. As **3b** contains bulkier substituents, this leads to the conclusion that the trigonal twist rearrangement is more energetically demanding. This is easily foreseeable considering that the scrambling of coordination sites should be more difficult to achieve than a bond rotation. In **3b**, both the presence of the methyl groups in the dimethylpyrazolate and its coordination to the $AuPPh_3$ fragment cooperate to brake the rotation of the Mo−N bond, which is too fast to be detected when only one of these factors (either in **2b** or **3a**) is absent. Thus the addition of these two factors allow the "molecular brake" to be obtained.



Scheme 3. Hindered rotation of the Mo−N bond observed for **3b**

Experimental Section

General Remarks: All manipulations were performed under a N_2 atmosphere following conventional Schlenk techniques. Filtrations were carried out on dry Celite under N_2. Solvents were purified according to standard procedures.[22] [Mo(η^3-allyl)Br$(CO)_2$-$(NCMe)_2$],[23] Tl(acac),[24] and [Au(acac)PPh_3][24] were obtained as described previously. All other reagents were obtained from the usual commercial suppliers, and used as received. Infrared spectra were recorded on Perkin−Elmer 1720X or RX I FT-IR apparatus on KBr pellets from 4000 to 400 cm^{-1}. NMR spectra were recorded on Bruker AC-300 or ARX-300 instruments in $CDCl_3$, at room temperature unless otherwise stated. NMR spectra are referred to the internal residual solvent peak for ^1H and $^{13}C\{^1H\}$ NMR or to external 85% aqueous H_3PO_4 for $^{31}P\{^1H\}$ NMR spectra. Assignment of the $^{13}C\{^1H\}$ NMR spectroscopic data was supported by DEPT experiments and relative intensities of the resonance signals. Elemental analyses were performed on a Perkin−Elmer 2400B microanalyzer.

[Mo(η^3-allyl)Br$(CO)_2(Hpz)_2$] (1a): [Mo(η^3-allyl)Br$(CO)_2(NCMe)_2$] (0.550 g, 1.5 mmol) was added to a solution of Hpz (0.205 g, 3 mmol) in CH_2Cl_2 (30 mL). The solution was stirred at room temperature for 5 min and hexane was added (ca. 30 mL). Concentration of the solution in vacuo and cooling to −20 °C gave a yellow microcrystalline solid, which was decanted, washed with hexane (3 × 3 mL approximately), and dried in vacuo, yielding 0.589 g (96%). IR (THF): $\tilde{\nu}$ = 1945 cm^{-1} vs, 1846 vs. IR (KBr): $\tilde{\nu}$ = 3304 cm^{-1} m, 3146 w, 3130 w, 1926 s, 1911 s, 1815 vs, 1654 vw, 1637 vw, 1466 w, 1404 vw, 1352 w, 1257 vw, 1158 vw, 1127 w, 1047 m, 911 vw, 792 w, 778 m, 719 vw, 675 vw, 602 vw, 590 vw, 502 vw. ^1H NMR (333 K, 300 MHz): 1.47 ppm (br., 2 H, H^{anti}), 3.50 (br., 2 H, H^{syn}), 4.04 (m, 1 H, H^c allyl), 6.33 (br., 2 H, H^4 Hpz), 7.39 (s, 2 H, H^3 Hpz), 7.70 (br., 1 H, H^5 Hpz), 8.10 (br., 1 H, H^5 Hpz), 11.75 (br., 2 H, *H*N). ^1H NMR (room temp., 300 MHz): 1.29 ppm (d, J = 9.2 Hz, 1 H, H^{anti}), 1.63 (d, J = 10.0 Hz, 1 H, H^{anti}), 3.19 (br., 1 H, H^{syn}), 3.84 (br., 1 H, H^{syn}), 4.03 (m, 1 H, H^c allyl), 6.25 (s, 1 H, H^4 Hpz), 6.43 (s, 1 H, H^4 Hpz), 7.40 (s, 2 H, H^3 Hpz), 7.57 (s, 1 H, H^5 Hpz), 8.37 (s, 1 H, H^5 Hpz), 11.61 (br., 1 H, *H*N), 11.78 (br., 1 H, *H*N) ppm. ^1H NMR (253 K, 300 MHz): 1.28 ppm (d, J = 9.4 Hz, 1 H, H^{anti}), 1.62 (d, J = 9.9 Hz, 1 H, H^{anti}), 3.19 (dd,

J = 6.4, 3.5 Hz, 1 H, H^{syn}), 3.82 (dd, J = 5.9, 3.5 Hz, 1 H, H^{syn}), 4.02 (m, 1 H, H^{c} allyl), 6.25 (q, J = 2.2 Hz, 1 H, H^{4} Hpz), 6.43 (q, J = 2.2 Hz, 1 H, H^{4} Hpz), 7.41 (s, 2 H, H^{3} Hpz), 7.54 (t, J = 1.8 Hz, 1 H, H^{5} Hpz), 8.39 (t, J = 1.8 Hz, 1 H, H^{5} Hpz), 11.52 (br., 1 H, HN), 11.74 (br., 1 H, HN). $^{13}C\{^{1}H\}$ NMR (room temp., 75.78 MHz): 57.5 ppm (s, CH$_2$), 63.6 (s, CH$_2$), 73.2 (s, CH allyl), 107.1 (s, C^{4}H Hpz), 107.5 (s, C^{4}H Hpz), 129.1 (s, $C^{3,5}$H Hpz), 129.2 (s, $C^{3,5}$H Hpz), 142.7 (s, $C^{5,3}$H Hpz), 144.8 (s, $C^{5,3}$H Hpz), 224.2 (s, CO), 225.1 (s, CO). $C_{11}H_{13}BrMoN_4O_2$: calcd. C 32.30, H 3.20, N 13.70; found C 32.65, H 3.08, N 13.70.

[Mo(η^3-allyl)Br(CO)$_2$(Hdmpz)$_2$] (1b): [Mo(η^3-allyl)Br(CO)$_2$(NCMe)$_2$] (0.147 g, 0.4 mmol) was added to a solution of Hdmpz (0.077 g, 0.8 mmol) in CH_2Cl_2 (15 mL). The solution was stirred at room temperature for 5 min, the volatiles were removed in vacuo, and the yellow residue was extracted with Et_2O (ca. 20 mL) and filtered. Hexane was added (ca. 20 mL) and the solution was concentrated and cooled to −20 °C, giving a yellow-orange microcrystalline solid, which was decanted, washed with hexane (3 × 3 mL approximately), and dried in vacuo, yielding 0.146 g (78%). IR (THF): $\tilde{\nu}$ = 1942 cm^{-1} vs, 1843 vs. IR (KBr): $\tilde{\nu}$ = 3294 cm^{-1}s, 3069 vw, 2994 vw, 2927 vw, 1948 s, 1930 s, 1854 vs, 1654 vw, 1636 vw, 1570 m, 1467 w, 1419 w, 1373 w, 1283 w, 1155 w, 1024 w, 799 w, 654 w, 572 vw, 512 vw, 474 vw. ^{1}H NMR (353 K, C_6D_6, 300 MHz): 1.44 ppm (br., 6 H, CH_3 Hdmpz + 2 H, H^{anti}), 2.12 (br., 3 H, CH_3 Hdmpz), 2.87 (br., 3 H, CH_3 Hdmpz), 4.20 (br., 2 H, H^{syn}), 4.32 (m, 1 H, H^{c} allyl), 5.35 (s, 2 H, H^{4} Hdmpz), 11.4 (br., 2 H, HN). ^{1}H NMR (room temp., 300 MHz): 1.25 ppm (d, J = 9.4 Hz, 1 H, H^{anti}), 1.51 (d, J = 9.9 Hz, 1 H, H^{anti}), 2.04 (s, 3 H, CH_3 Hdmpz), 2.05 (s, 3 H, CH_3 Hdmpz), 2.25 (s, 3 H, CH_3 Hdmpz), 2.95 (m partially hidden by the following signal, 1 H, H^{syn}), 2.97 (s, 3 H, CH_3 Hdmpz), 3.96 (m, 1 H, H^{syn}), 4.12 (m, 1 H, H^{c} allyl), 5.78 (s, 1 H, H^{4} Hdmpz), 5.93 (s, 1 H, H^{4} Hdmpz), 10.25 (br., 1 H, HN), 11.25 (br., 1 H, HN). ^{1}H NMR (243 K, 300 MHz): 1.26 ppm (d, J = 9.5 Hz, 1 H, H^{anti}), 1.47 (d, J = 9.8 Hz, 1 H, H^{anti}), 2.00 (s, 3 H, CH_3 Hdmpz), 2.03 (s, 3 H, CH_3 Hdmpz), 2.25 (s, 3 H, CH_3 Hdmpz), 2.91 (dd, J = 6.2, 3.3 Hz, 1 H, H^{syn}), 2.98 (s, 3 H, CH_3 Hdmpz), 3.95 (dd, J = 6.3, 3.3 Hz, 1 H, H^{syn}), 4.08 (m, 1 H, H^{c} allyl), 5.78 (s, 1 H, H^{4} Hdmpz), 5.94 (s, 1 H, H^{4} Hdmpz), 10.06 (br., 1 H, HN), 11.12 (br., 1 H, HN). $^{13}C\{^{1}H\}$ NMR (room temp., 75.78 MHz): 10.7 ppm (s, CH$_3$ Hdmpz), 10.9 (s, CH$_3$ Hdmpz), 14.1 (s, CH$_3$ Hdmpz), 15.7 (s, CH$_3$ Hdmpz), 58.8 (s, CH$_2$), 64.2 (s, CH$_2$), 75.4 (s, CH allyl), 106.5 (s, C^{4}H Hdmpz), 106.7 (s, C^{4}H Hdmpz), 139.9 (s, $C^{3,5}$ Hdmpz), 140.6 (s, $C^{3,5}$ Hdmpz), 152.2 (s, $C^{5,3}$ Hdmpz), 155.9 (s, $C^{5,3}$ Hdmpz), 224.5 (s, CO), 226.3 (s, CO). $C_{15}H_{21}BrMoN_4O_2$: calcd. approximately), and dried in vacuo, yielding 0.073 g (43%). IR (THF): $\tilde{\nu}$ = 1924 cm^{-1} vs, 1825 vs. IR (KBr): $\tilde{\nu}$ = 3055 cm^{-1} w, 2990 w, 2914 w, 1913 vs, 1816 vs, 1585 s, 1521 s, 1482 w, 1437 m, 1393 m, 1374 m, 1264 w, 1184 vw, 1136 vw, 1102 m, 1020 w, 998 vw, 934 vw, 749 w, 712 w, 694 m, 545 m, 508 m. ^{1}H NMR (room temp., 300 MHz): 1.39 ppm (br., 2 H, H^{anti}), 1.60 (s, 6 H, CH_3 acac), 2.37 (s, 6 H, CH_3 dmpz), 3.27 (br., 1 H, H^c allyl), 3.38 (br., 2 H, H^{syn}), 4.80 (br., 1 H, CH acac), 5.88 (br., 1 H, H^4 dmpz), 7.52 (br., 10 H, C_6H_5,), 7.71 (br., 5 H, C_6H_5). ^{1}H NMR (213 K, 300 MHz, Major isomer): 1.37 ppm (d, J = 9.2 Hz, 1 H, H^{anti}), 1.44 (d, J = 8.9 Hz, 1 H, H^{anti}), 1.53 (s, 3 H, CH_3 acac), 1.69 (s, 3 H, CH_3 acac), 2.38 (s, 3 H, CH_3 dmpz), 2.40 (s, 3 H, CH_3 dmpz), 3.19 (m, 1 H, H^c allyl), 3.29 (br., 1 H, H^{syn}), 3.43 (br., 1 H, H^{syn}), 4.81 (s, 1 H, CH acac), 5.93 (s, 1 H, H^4 dmpz), 7.32 (m, 10 H, C_6H_5), 7.67 (m, 5 H, C_6H_5). Ratio major isomer/minor isomers = 1:0.3. ^{31}P{^{1}H} NMR (room temp., 121.49 MHz): 31.40 ppm (s, PPh$_3$). ^{31}P{^{1}H} NMR (213 K, 121.49 MHz): 30.4 (s, PPh$_3$, minor isomer), 30.6 (s, PPh$_3$, minor isomer), 31.0 (s, PPh$_3$, major isomer), 31.6 (s, PPh$_3$, minor isomer), 32.4 (s, PPh$_3$, minor isomer), 43.3 (s, PPh$_3$, minor isomer). The ^{1}H and ^{31}P{^{1}H} NMR spectra recorded at 213 K of a sample obtained immediately after mixing the solid complex and frozen $CDCl_3$ at −78 °C showed only signals of the major isomer. $C_{33}H_{34}AuMoN_2O_4P$: calcd. C 46.82, H 4.05, N 3.31; found C 46.45, H 3.85, N 3.05.

X-ray Crystallographic Study of 1a, 1b, and 3b: Crystals were grown by slow diffusion of hexane into concentrated solutions of the complexes in CH_2Cl_2 at −20 °C. Relevant crystallographic details are given in Table 3. A crystal was attached to a glass fiber and transferred to a Bruker AXS SMART 1000 diffractometer with graphite monochromatized Mo-K_α X-radiation and a CCD area detector. A hemisphere of the reciprocal space was collected up to 2θ = 48.6°. Raw frame data were integrated with the SAINT program.[26] The structure was solved by direct methods with SHELXTL.[27] A semi-empirical absorption correction was applied with the program SADABS.[28] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were set in calculated positions and refined as riding atoms, with a common thermal parameter. All calculations and graphics were made with SHELXTL. CCDC-189498 (**1a**), −189499 (**1b**), and −189500 (**3b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis, Crystal Structure and Magneto-Structural Correlation of an Unusual Thiocyanato-Bridged Nickel(II) Compound, $[Ni(\mu\text{-}NCS)(dpt)(NCS)]_2$-$[Ni(\mu\text{-}NCS)(dpt)(NCS)]_4$ [dpt = bis(3-aminopropyl)amine]

Tapas Kumar Maji,[a] Golam Mostafa,[b] Juan M. Clemente-Juan,[c] Joan Ribas,*[d] Francesc Lloret,[c] Ken-ichi Okamoto,[e] and Nirmalendu Ray Chaudhuri*[a]

Keywords: Nickel / Bridging ligands / S ligands / Magnetic properties / N ligands

Reaction of $Ni(ClO_4)_2 \cdot 6H_2O$ with bis(3-aminopropyl)amine (dpt) and ammonium thiocyanate produces the novel thiocyanato-bridged nickel(II) compound $[Ni(\mu\text{-}NCS)(dpt)(NCS)]_2[Ni(\mu\text{-}NCS)(dpt)(NCS)]_4$, which has been structurally characterised. The structure determination reveals that there are two different molecules in the crystal lattice; one is dinuclear and other is tetranuclear. Low-temperature magnetic measurements show that there are ferro- as well as antiferromagnetic interactions. The ferromagnetic interaction arises from the dinuclear part and the doubly bridged part of the tetranuclear unit; the antiferromagnetic interaction occurs between singly bridged nickel centres in the tetranuclear unit.

Introduction

In the last few years there has been a considerable amount work dedicated to the design and elaboration of polymetallic molecular systems with extended structures and electronic properties, mainly molecular-based magnets and inorganic materials.[1−5] The precondition for synthesising these type of materials is that the metal ions should have an unpaired electron and should be assembled in a molecule containing a bridging moiety that can propagate this electron between the paramagnetic metal centres. The pseudohalogens are very versatile ligands for making such a bridge. Amongst them, the versatility of the azido ligand as a superexchange pathway in polynuclear complexes of Cu^{II}, Ni^{II} and Mn^{II} has been well explored.[6−11] In contrast, thiocyanato-bridged polynuclear systems are not common.[12−15] Curtis et al.[16] have reported the synthesis of $[NiL(NCS)_2]$ [L = bis(2-aminoethyl)amine (dien) or bis(2-aminopropyl)amine (dpt)] and have proposed structures with one bridging thiocyanate and one N-bonded terminal thiocyanate in the *cis* position on the basis of IR spectroscopy. Vicente et al.,[12,14] however, have reported the structures and magnetic properties of two polymeric complexes, $[Ni(\mu\text{-}NCS)(L)(NCS)]_n$ [L = bis(2-aminoethyl)methylamine (medien) or bis(3-aminopropyl)methylamine (medpt)] and have observed noticeable differences in the structures upon increasing the chain length of the triamine.

Recently, our group has also reported[17−19] some novel thiocyanato-bridged nickel(II) complexes and noticed some remarkable phenomena, such as that the chain length of the linear chain triamine, the alkyl group substitution on the donor atom of the triamine and the method of preparation play a very important role when synthesising complexes with different nuclearities. Starting with $Ni(NCS)_2$ in methanol, dien gives a dimeric structure whereas aepn [(2-aminoethyl)(3-aminopropyl)amine] yields a polymeric structure.[17] On the other hand, the reaction of medpt with $Ni(NCS)_2$ in methanol gives two dimeric fragments in the unit cell,[18] while the reaction between $Ni(ClO_4)_2 \cdot 6H_2O$ and NH_4NCS generates a 1D polymeric complex.[14]

The present paper reports the synthesis, X-ray structure analysis and magneto-structural correlation of a novel thiocyanato-bridged nickel(II) compound $[Ni(\mu\text{-}NCS)(dpt)(NCS)]_2[Ni(\mu\text{-}NCS)(dpt)(NCS)]_4$. The structure determination reveals that this is a rare type of thiocyanato-bridged

compound containing two different molecules in the crystal lattice: one is dinuclear and other is tetranuclear. Linear chain tetranuclear nickel(II) octahedral compounds are scarce in the literature.[20−21] Low-temperature magnetic measurements show that there are ferro- as well as antiferromagnetic interactions. The ferromagnetic interaction arises from the dinuclear part and the doubly bridged part of the tetranuclear unit; the antiferromagnetic interaction occurs between singly bridged nickel centres in the tetranuclear unit. To the best our knowledge this is the first report of a thiocyanato-bridged nickel(II) compound where ferro- as well as antiferromagnetic interactions are observed.

Results and Discussion

IR Spectroscopy

The compound shows two bands with medium intensity at $\tilde{\nu}$ = 3240, 3300 cm^{-1} corresponding to ν(N−H) and at $\tilde{\nu}$ = 2880, 2925 cm^{-1} assigned to the ν(C−H) stretching vibration of the triamine ligand. The occurrence of two strong peaks at 2080 and 2110 cm^{-1} in the IR spectrum, corresponding to ν(CN) stretching vibrations, suggests the presence of a bridging as well as a terminal linkage of the thiocyanate ligand. The higher frequency correlates to the bridging thiocyanate group whereas the lower frequency is assigned to a terminally bound thiocyanate ligand.[22]

Description of the Structure

The structure determination of the title complex reveals that there are two crystallographically independent molecules in the unit cell. One part of the complex is a dimer and other part is a tetramer (Figure 1). In the dimeric fragment two nickel atoms (Ni1 and its symmetry related counterpart) are bridged by two thiocyanate ligands in an end-to-end fashion; the other two thiocyanate groups exist as terminal ligands. The coordination polyhedron around the Ni1 atom in the dimeric fragment is best described as a distorted octahedron with an N_5S donor set. The three nitrogen atoms (N7, N8 and N9) from the triamine dpt ligand and one nitrogen atom (N1*; * =1 − *x*, 1 − *y*, 1 − *z*) from one of the bridging thiocyanate groups define the equatorial plane for Ni1 atom. The equatorial Ni1−N bond lengths are in the range 2.059(5)−2.114(4) Å (Table 1). The axial position is occupied by S1 [Ni1−S1, 2.577(2) Å] and N2 [Ni1−N2, 2.106(4) Å] from the bridging and terminal thiocyanate ligand, respectively. The Ni1 atom deviates from the mean plane by 0.008(2) Å and the maximum deviation of any equatorial atom (N1*) from the mean plane is 0.011(2) Å.

In the tetrameric part, the asymmetric unit comprises two nickel atoms (Ni2 and Ni3) with different coordination environments. The geometry around the Ni2 centre in the tetrameric part is distorted octahedral with an NiN_6 chromophore. The Ni2 atom is linked to Ni3 centre by only one bridging thiocyanate ligand. The other two terminal thiocy-

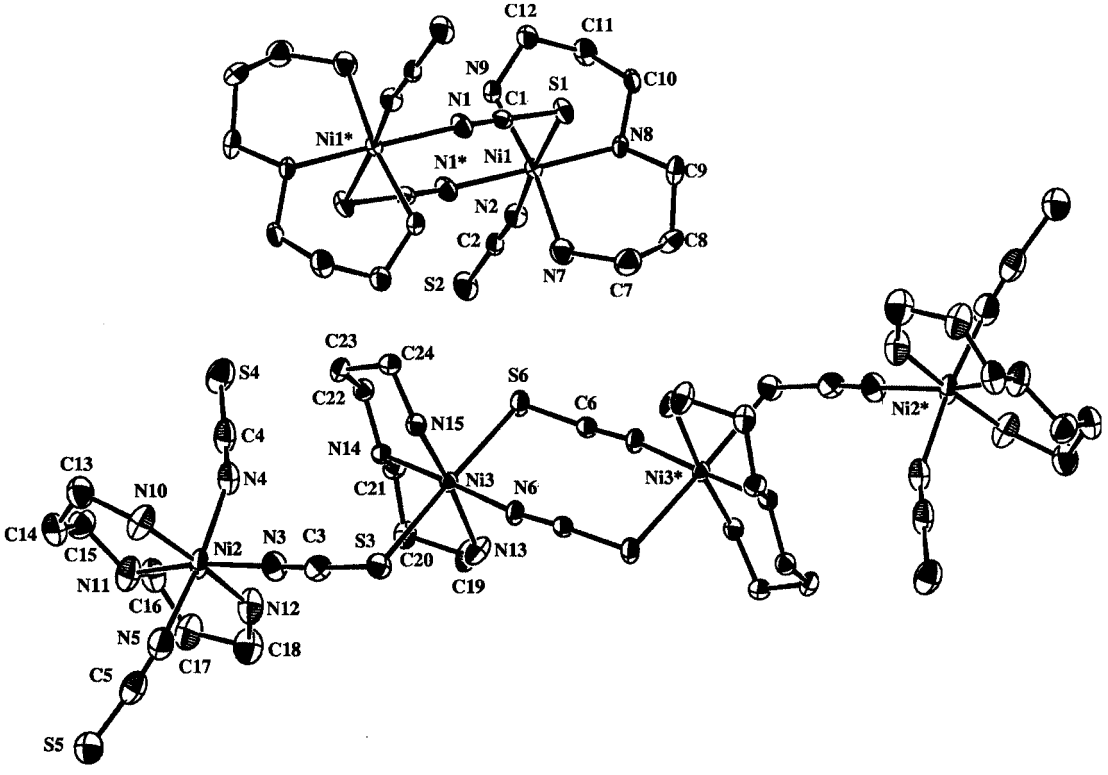

Figure 1. ZORTEP plot with atom labelling scheme of $[Ni(\mu_{N,S}\text{-NCS})(dpt)(NCS)]_2[Ni(\mu_{N,S}\text{-NCS})(dpt)(NCS)]_4$ (thermal ellipsoids are drawn at 50% probability for all non-hydrogen atoms)

[a] Symmetry code: i = 1 − x, 1 − y, 1 − z; ii = 3 − x, 2 − y, 1 − z.

anate groups are attached in a *cis* position to each other. The two nitrogen atoms (N4 and N5) [Ni2−N4, 2.133(6) Å; Ni2−N5, 2.078(7) Å] from the two pendent thiocyanate groups and other two nitrogen atoms (N10, N12) [Ni2−N10, 2.075(7) Å; Ni2−N12, 2.022(7) Å] (Table 1) form the equatorial plane around Ni2. One nitrogen atom (N3) [Ni2−N3, 2.082(5) Å] of the singly bridging thiocyanate ligand and a second nitrogen atom (N11) [Ni2−N11, 2.291(7) Å] of the triamine are in a *trans* axial position around Ni2. The maximum deviation of Ni2 from the mean plane formed by the four equatorial nitrogen atoms is 0.077(3) Å and the maximum deviation of any equatorial atom (N10) from the mean plane is 0.011(3) Å. In the case of Ni3 all the ligated thiocyanate groups are involved in bridging: two of them are attached to its symmetry related counterpart Ni3* and the other to Ni2. The coordination environment around Ni3 is pseudo-octahedral with an NiN_4S_2 chromophore. The two sulfur atoms (S6, S3) [Ni3−S6, 2.522(2) Å; Ni3−S3, 2.667(2) Å] from thiocyanate groups and N13 and N15 [Ni3−N13, 2.027(5) Å; Ni3−N15, 2.062(4) Å] (Table 1) from the triamine ligand define the equatorial plane around Ni3. The *trans* axial sites are occupied by N14 and N6 [Ni3−N14, 2.117(4) Å; Ni3−N6, 2.086(4) Å] of the triamine ligand and the bridging thiocyanate group, respectively. The maximum deviation of Ni3 from the mean plane formed by the four equatorial atoms is 0.088(2) Å and the maximum deviation of any equatorial atom (S3) from the mean plane is 0.005(2) Å.

The Ni−S−C, Ni−N−C and N−C−S angles in the bridge are 102.2(2)−104.5(3) Å, 157.0(4)−176.5(5) Å and 176.0(6)−178.2(5) Å, respectively. The Ni−N−C angle in the nonbridging thiocyanate group is 155.8(9)−166.9(5) Å. The Ni···Ni separation in the dimeric fragment is 5.736(9) Å and in the tetrameric fragment Ni2···Ni3 and Ni3···Ni3* are 5.998(2) and 5.682(3) Å, respectively. Weak intra- and intermolecular H-bonding (Table 2) results in a 1D supramolecular network lying on the *ab* plane (Figure 2). These H-bonding interactions are responsible for the overall conformation and stability of the crystal lattice.

Table 2. Hydrogen bonding interactions (Å,°) for [Ni(μ-NCS)(dpt)(NCS)]$_2$[Ni(μ-NCS)(dpt)(NCS)]$_4$

D−H···A[a]	D−H	H···A	D···A	D−H···A
N7−H7A···S6^{i}	0.90	2.865	3.696(6)	154.25
N15−H15A···S2^{ii}	0.90	2.711	3.500(6)	146.90

[a] Symmetry code: (i) =2 − x, 1 − y, 1 − z; (ii) = 3 − x, 1 − y, 1 − z.

Magnetic Measurements

Taking into account that there are two independent molecular entities — one dinuclear and the other tetranuclear — a plot of the magnetic data in the 200−2 K range is shown in Figure 3 as $\chi_M T$ vs. T for a molecular weight corresponding to six nickel(II) atoms. At 200 K, the $\chi_M T$ value is equal to 7.047 cm^3·mol^{-1}·K, a value that would be expected for six isolated nickel(II) ions with local S = 1 spins. $\chi_M T$ increases smoothly as T is lowered, reaching a maximum value of 7.35 cm^3·mol^{-1}·K at 22 K. From this temperature down to 2 K there is a clear and abrupt decrease of $\chi_M T$, reaching a minimum of 3.9147 cm^3·mol^{-1}·K at 2 K. These features are indicative of global weak ferromagnetic interactions between nickel(II) ions in the dinuclear and/or in the tetranuclear species present in the crystal, followed by a contribution of zero-field splitting, D, and antiferromagnetic coupling between the dinuclear and tetranuclear systems. Variable-temperature susceptibility data for a dinuclear moiety could be analysed using the isotropic Ginsberg [23] model from the Hamiltonian

$$H = -2JS_1S_2 - D(S_{1z}^2 + S_{2z}^2) - g\beta H(S_1 + S_2) - z'J'S\{S\}$$

where J is the intradimer exchange parameter, D the single-ion zero-field splitting and $z'J'$ the quantity for effective interdimer exchange; it is assumed that $g_x = g_y = g_z = g$. As previously indicated by Ginsberg, the parameters D and $z'J'$ are very strongly correlated with each other, but are

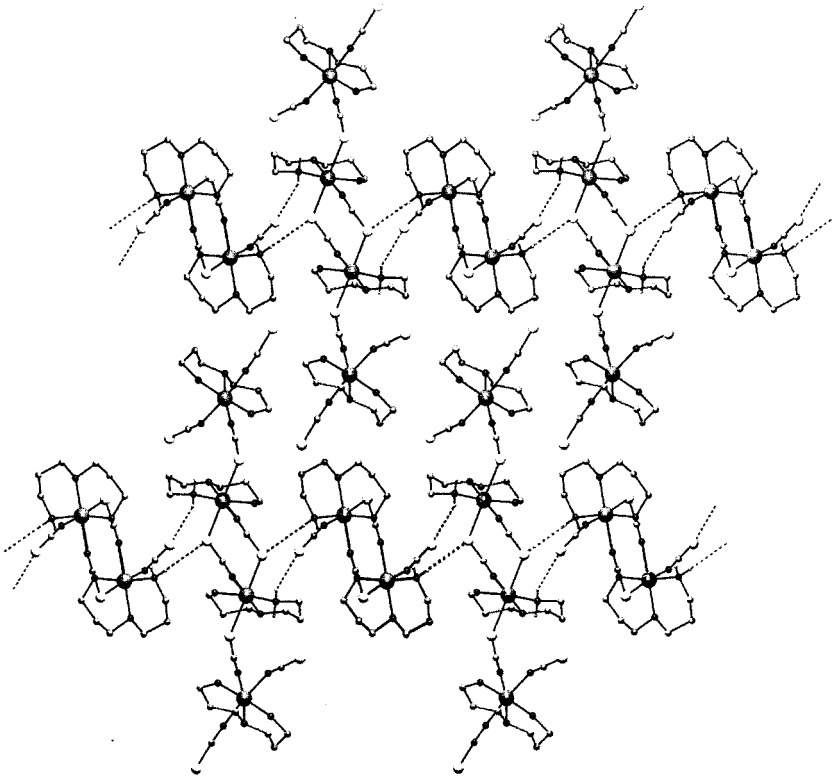

Figure 2. View of infinite one-dimensional H-bonded polymeric network of $[Ni(\mu_{N,S}\text{-}NCS)(dpt)(NCS)]_2[Ni(\mu_{N,S}\text{-}NCS)(dpt)(NCS)]_4$ (for clarity only relevant hydrogen atoms are shown)

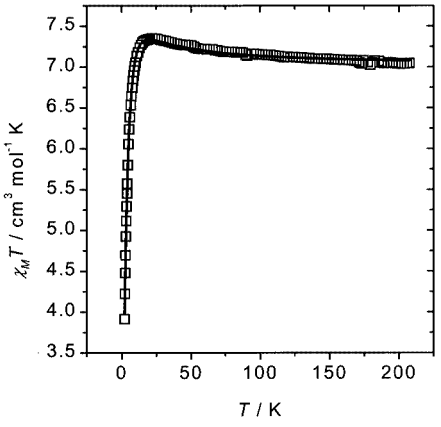

Figure 3. $\chi_M T$ vs. T plot for $[Ni(\mu_{N,S}\text{-}NCS)(dpt)(NCS)]_2[Ni(\mu_{N,S}\text{-}NCS)(dpt)(NCS)]_4$ [considering a molecular weight of 1836.58 corresponding to six nickel(II) centres]; the solid line corresponds to the best fit

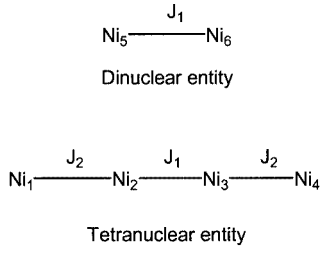
The spin-Hamiltonian for all these tetranuclear nickel(II) complexes can easily be solved applying Kambe's method,[29] although for the linear systems a full diagonalization method is required and, seemingly, has never used for this kind of complex. The topological spin-scheme for this system is represented in Scheme 1.



Scheme 1

only weakly correlated with g and J, therefore it is impossible to calculate D and $z'J'$ values accurately. Unfortunately, there is no mathematical expression which allows a fit of the tetranuclear part. The tetranuclear nickel(II) complexes reported in the literature are either planar, rhomboidal, cubanes or have square (cyclic) cores;[24−27] one zig-zag tetranuclear nickel(II) complex is known where two terminal nickel(II) atoms are in a square-planar geometry and thus show a diamagnetic behaviour.[28]

In this scheme, taking into account the structure, we assume that the coupling constants between the nickel(II) ions in the dinuclear entity (Ni1−Ni1*) and the central part (Ni3−Ni3*) of the tetranuclear entity (J_1) are the same. In both these cases, the two nickel(II) ions are linked by two thiocyanate bridges, although the terminal nickel(II) ions are linked to the central ones by only a thiocyanate bridge in the tetranuclear entity. Following this scheme, the ther-

mal variation of the $\chi_M T$ product was analysed using the following anisotropic Hamiltonian:

$$H = -2J_1(S_2S_3 + S_5S_6) - 2J_2(S_1S_2 + S_3S_4) + D(S_{1z}^2 + S_{2z}^2 + S_{3z}^2 + S_{4z}^2 + S_{5z}^2 + S_{6z}^2)$$

This Hamiltonian takes into account the interactions of one tetramer unit and one dimer unit at the same time. In order to remove the over-parametrization we have assumed some simplifications. Firstly, both exchange pathways through two end-to-end thiocyanate bridging ligands are associated to the same parameter, J_1, and secondly all single-ion parameters are identical (all single-ion anisotropies, D_i, are equal and collinear and all nickel(II) atoms have the same isotropic g value).

Evaluation of the susceptibility curve was performed with the MAGPACK programs package.[30−31] This efficient computing program allows the solution of the full spin-Hamiltonian by a numerical procedure and the calculation of the magnetic properties of spin clusters of arbitrary nuclearity, topology and anisotropy. Least-squares fitting of the magnetic data was accomplished with an adapted version of the function-minimization program MINUIT.[32] Using this conditions the best set of parameters is the following: $J_1 = +2.73$ cm^{-1}, $J_2 = -1.27$ cm^{-1}, $D = 3.12$ cm^{-1} and $g = 2.16$ ($R = 3.1 \times 10^{-3}$).

Magneto-Structural Correlations

The number of nickel(II) complexes with one or two bridging thiocyanate ligands is very limited. The magnetic data and the main structural parameters of these complexes, along with the title complex, are gathered in Tables 3 and 4. The J values found for the two systems with double end-to-end bridging thiocyanate ligand agree perfectly with those reported in the literature for the same kind of linkage. As can be seen from Table 3 the structural parameters are also very similar. However, the single thiocyanate bridging ligand in the tetrameric entity causes an antiferromagnetic coupling, while the other three complexes reported so far are ferromagnetically coupled. Comparing Tables 3 and 4 it is easy to realize that when there are two bridging thiocyanate ligands, J is always positive and greater than the values reported when there is only one thiocyanate ligand. On the other hand, the Ni−S−C and Ni−N−C angles are very different in the tetrameric entity from the other three complexes (Table 4). It has been postulated that these angles are the most important features for the character of the exchange coupling constant;[33] the Ni2−N3−S3−Ni3 torsion angle is −4.8°. It has been reported that, with the very similar OCN^- ligand, the effect of this torsion angle is similar to that reported for the azido bridging ligand: the maximum of the antiferromagnetic component corresponds to a torsion of 180° (or 0°), with a value close to zero for $J_{antiferro}$ (accidental orthogonality) for a torsion angle of 90°.[33] According to this idea, it is not surprising to find that other metal complexes with end-to-end bridging thiocyanate ligands show antiferromagnetic coupling. The $2J$ value for a dinuclear copper(II) complex is −148.2 cm^{-1},[34] and for some similar manganese(II) complexes the J values are −0.15 cm^{-1} and −2.5 cm^{-1}.[35−36]

New efforts are necessary for synthesising new complexes with this kind of structure in order to analyze their magnetic properties. This goal will not be easy, though, because there is a spontaneous tendency for four nickel(II) ions to give cubane-like or square-planar complexes.[24−27]

Experimental Section

Materials: High purity (98%) bis(3-aminopropyl)amine (dpt) was purchased from Aldrich Chemical Company Inc. and used as received. All other chemicals used were of AR grade.

Physical Measurements: Elemental analysis (C, H and N) was performed using a Perkin−Elmer 240C elemental analyser. IR spectra (4000−400 cm^{-1}) were taken using Nicolet Magna-IR 750 spectrometer series-II. Variable temperature (2−208 K) magnetic susceptibility measurements on polycrystalline sample was carried out with a Quantum Design SQUID magnetometer. Diamagnetic corrections of the constituent atoms were estimated from Pascal's constants.

Synthesis of [Ni(μ-NCS)(dpt)(NCS)]$_2$[Ni(μ-NCS)(dpt)(NCS)]$_4$: A methanolic solution (5 mL) of dpt (1 mmol) was added to an aqueous solution (15 mL) of $Ni(ClO_4)_2·6H_2O$ (1 mmol). Solid NH_4SCN (2 mmol) was then added slowly with constant stirring. The resulting solution was kept in a $CaCl_2$ desiccator and after a few days a blue crystalline complex separated out. This was dissolved in ethanol and filtered and the filtrate was kept in an open atmosphere. After some days blue single crystals suitable for X-ray diffraction were obtained. Yield ca. 80%. $C_8H_{17}N_5NiS_2$ (306.1): calcd. C 31.40, N 22.89, H 5.56, Ni 19.18; found C 31.40, N 22.88, H 5.54, Ni 19.20. IR: ν(NH_2), 3240, 3300 cm^{-1}; ν(CH_2), 2880, 2925 cm^{-1}; ν(CN), 2080, 2120 cm^{-1}.

Reaction Scheme:

$6Ni(ClO_4)_2·6H_2O + 12NH_4SCN + 6dpt = [Ni(μ\text{-}NCS)(dpt)(NCS)]_2[Ni(μ\text{-}NCS)(dpt)(NCS)]_4 + 12NH_4ClO_4 + 36H_2O$

Crystal-Data Collection and Refinement: A suitable single crystal of the title complex was mounted on a Rigaku AFC 7 diffractometer. The unit cell parameters and crystal orientation matrix were determined by least square refinement of 25 accurately centred reflections. Intensity data were collected in the ω-2θ scan mode using graphite-monochromated Mo-$K_α$ radiation. The crystal and instrument stabilities were monitored with a set of three standard reflections measured at a regular interval; in all cases no significant variations were found. The intensity data were corrected for Lorentz and polarisation effects[37] and an empirical absorption correction based on ψ-scans (T_{min}/T_{max} 0.678/0.968) was also employed. A total of 5865 reflections ($2.1 < θ < 27.5°$) were measured and all of them were assumed observed applying the condition $I > 2σ(I)$. The structure was solved by a Patterson synthesis and followed by successive Fourier and difference-Fourier syntheses. Full-matrix least-squares refinements on F^2 were carried out using SHELXL-97, with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were included in fixed calculated positions. At convergence the final residuals were $R = 0.045$; $wR = 0.122$. The final difference Fourier map showed a maximum and minimum peak height of 0.54 e·Å^{-3} and −0.39 e·Å^{-3} respectively, with no chemical significance. Complex neutral atom scattering factors[38] were used throughout. All calculations were carried out using the SHELXS-86,[39] SHELXL-97,[40] PLATON 99[41] and ZORTEP[42] programs. Crystal data are summarised in Table 5. Selected bond lengths and angles are listed in Table 1. Possible hydrogen bonds are displayed in Table 2.

COVER PICTURE

The cover picture shows the arrangement of the 3-D $[Hg_7As_4]^{4+}$ host framework and the AgI_3^{2-} guest anions in a novel supramolecular architecture $[Hg_7As_4](AgI_3)_2$, self-assembled from a heterogeneous system at high temperature. Although the host–guest interaction is weak, it governs both the geometry of the host framework (mercury atoms, blue; arsenic atoms, pink) and guest anions (silver atoms, red; iodine atoms, violet) and the positioning of the guest in the framework cavities. A mutual adjustment of the host and guests results is the unusual off-plane geometry of the AgI_3^{2-} anion. Details are discussed in the article of A. V. Shevelkov et al. on p. 1053 ff.

Glasses with Medical Applications

María Vallet-Regí,*[a] C. Victoria Ragel,[a] and Antonio J. Salinas[a]

Keywords: Glasses / Materials science / Organic-inorganic hybrid composites / Metallic coatings / Textural properties

Bioactive glasses react chemically with the body fluids. The reaction product is an apatite, which, with the intervention of biological drivers, assists the generation of bone matrix and bone growth. The main application of these bioactive glasses in the clinical field is the filling of osseous cavities, manufacture of small parts for middle ear bone replacement and maxilofacial reconstruction and dental applications. Thanks to advances in related medical technologies, bioactive glasses are now undergoing a new stage of development, resulting in different mechanical properties, drug delivery capabilities, bioactive coating of metallic implants, protein and/or cell activation for tissue regeneration and tissue engineering, and are also finding use in biomimetics, nanotechnology, production of hybrid organic-inorganic materials and as bioactivity accelerators of mineral apatites or as bioactivity inductors of magnetic materials for hyperthermia treatment of osseous tumours.

1. Introduction

The discovery of the first *bioactive* ceramic took place 30 years ago, and since then has given rise to new strategies in the use of artificial materials in clinical bone repairs and replacement. The bioactive ceramics spontaneously bond to and integrate with living bone in the body without fibrous tissue forming around them. It was Hench et al.[1,2] who first introduced the idea of firmly bonding bone with synthetic materials through the chemical reactions that take place on a glass surface when it is implanted into a living body. Such an original line of thinking focussed attention on silica-based glasses, with the amorphous structure of silica glass, and on the chemical reactions that occurred on the surfaces of such materials. Bioglass® [1] and the subsequent family of bioactive glasses are now regarded, from the point of view of their application, as the earliest expression of all bioactive ceramics.

The characteristic amorphous quality of these glasses is generally a product of the structure of silicate glass, usually defined by [SiO_4] tetrahedra. These geometrical figures are linked together at all corners. While crystallised silica shows a uniform arrangement of these tetrahedra, as could be expected of any crystalline material (Figure 1, a), this is not

María Vallet-Regí (left, top) was born in Las Palmas, Spain, in 1946. She studied Chemistry at the Universidad Complutense de Madrid (UCM) and received her PhD at the same University in 1974. She is full professor of Inorganic Chemistry and Head of the Department of Inorganic Chemistry and Bioinorganic at the Faculty of Pharmacy (UCM). Her current research field is solid state chemistry, covering aspects of synthesis, characterisation and reactivity in oxides and bioceramics.

C. Victoria Ragel (right) was born in Madrid, Spain, in 1957. She studied Pharmacy at the Universidad Complutense de Madrid (UCM) and received her PhD at the same University in 1984. She was associate professor at the Department of Inorganic Chemistry and Bioinorganic at the Faculty of Pharmacy (UCM). In the last years, her research fields were the synthesis, characterisation and study of the properties of bioceramics, particularly bioactive sol-gel glasses to be included in drug release systems and biphasic materials. She passed away on June 1, 2002.

Antonio J. Salinas (left, bottom) was born in Madrid, Spain, in 1957. He studied Chemistry at the Universidad Complutense de Madrid (UCM) and received his PhD at the same University in 1992. He is associate professor at the Department of Inorganic Chemistry and Bioinorganic of the Faculty of Pharmacy (UCM). His current research field is the synthesis and characterisation of bioactive ceramics: gel glasses and glass ceramics, to be used in the osseous defects treatment.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

the case in silica glass. A common feature of both the crystalline − i.e., quartz − and the amorphous structures is that each oxygen ion links two tetrahedra, although forming a more open arrangement in the case of amorphous silica (Figure 1, b). Such a rather open structure facilitates the inclusion of cations referred to as network modifiers, and this feature allows a wide range of silica glasses to be obtained.

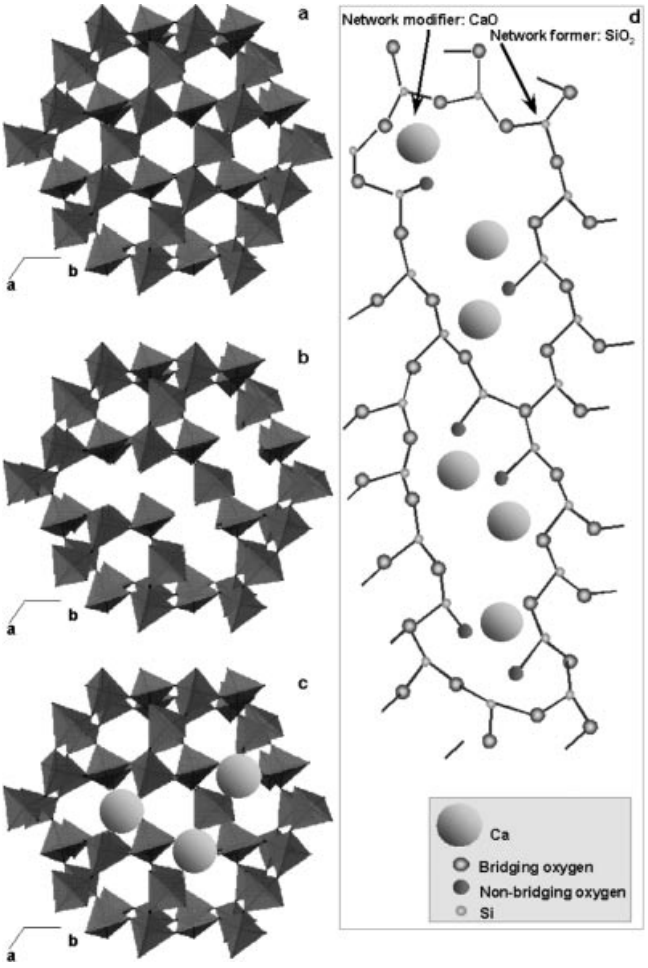

Figure 1. (a) Crystallised silica, (b) amorphous silica, (c) silica glass, (d) glassy network in two dimensions

The presence of cations such as Na^+, K^+ and Ca^{2+} (Figure 1, c) in the glass causes a discontinuity of the glassy network through the disruption of some Si−O−Si bonds. As a consequence, non-bridging oxygen is released. Figure 1, part d schematically depicts a glassy network in two dimensions. The network modifier in this case is an MO-type oxide, CaO, while the network former is SiO_2. Some Si atoms are bonded to other Si atoms through bridging oxygen, while others are coordinated through a non-bridging oxygen to the network of modifying ions. The purpose of the *network formers* is to build Si−O−Si bonds, while the *network modifiers* are there to break a proportion of those bonds, thus allowing the melt to solidify with a high degree of disorder. Its presence provides lower melting temperatures and viscosity values, reducing the economic costs of glass production, while ensuring a high degree of disorder.

This disordered structure, enhanced by the presence of network modifiers, gives rise to the high reactivity of these glasses in aqueous environments. This high reactivity is the main advantage of their application in periodontal repair and bone augmentation, as the reaction products obtained from these types of glasses and physiological fluids result in the crystallisation of the apatite-like phase, similar to the inorganic component of bones in vertebrate species.[3−9]

Bioactive glasses, from their beginnings in the 1970s, have reached a significant level of development, resulting since their discovery in the publication of several reviews on ceramics for medical applications, studying various aspects of their evolution.[11−18] This microreview reflects the more relevant results of our research in bioactive glasses.

2. Bioactive Glasses

Early bioactive glasses were prepared by the classic quenching of melts comprising SiO_2 and P_2O_5 as network formers and CaO and Na_2O as network modifiers.[1] This was the route followed for more than two decades in the synthesis of bioactive glasses.[3,19−24] In the early 1990s, sol-gel processing was introduced for the synthesis of bioactive glasses;[25] Figure 2 shows a scheme illustrating the main stages of the melting and sol-gel processes. The sol-gel route allows glasses of higher purity and homogeneity to be obtained, and the ranges of their compositions and textural properties to be expanded. In addition, all the steps in this route are carried out at temperatures notably lower than those required to obtain glasses by the melting method. It was therefore no longer necessary to include components intended to decrease the melting temperature (i.e., Na_2O), and the first bioactive gel glasses in the SiO_2·CaO·P_2O_5 system were obtained.

Our research group used the sol-gel route for preparation of bioactive glasses not only in the ternary SiO_2·CaO·P_2O_5 system,[26−43] but also in the quaternary SiO_2·CaO·P_2O_5·MgO[26,28,31,32,44] and the binary SiO_2·CaO[30,35,37,41−43,45−48] systems (see Table 1).

The addition of MgO to obtain quaternary gel glasses was performed in an attempt to improve the mechanical features of the glasses. The magnesium should be regarded as a network modifier, just as calcium, but it has different chemical behaviour and so substantial variations in the glass properties would be expected. Thus, Kokubo et al.[49] described the bioactive Apatite−Wollastonite glass-ceramic, based on an SiO_2·CaO·P_2O_5·MgO melt glass, with mechanical properties appreciably better than those of glasses.

The sol-gel method allows the ternary system to be simplified, P_2O_5 to be eliminated, and binary SiO_2·CaO bioglasses of a wide compositional range to be obtained. The objective of these studies was to determine the role of phosphorus in the gel glasses' bioactivity. This binary system can also help to understand the mechanism of bioactivity,

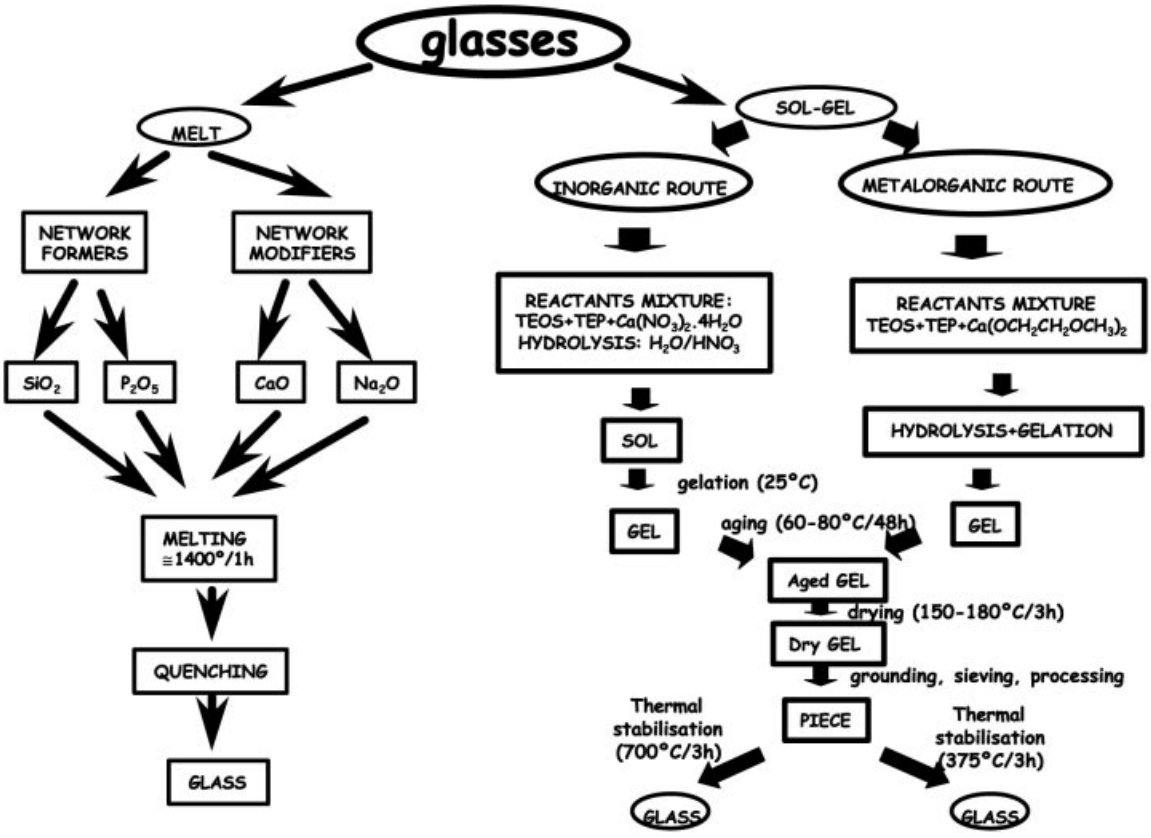

Figure 2. Diagram of the main stages in the melting and sol-gel processes (inorganic and metalorganic routes) to obtain bioactive glasses

since the phosphorus required for the apatite-like layer formation could now only originate from the assay solution.

In all cases, the syntheses of glasses were carried out by hydrolysis and polycondensation in the glass of stoichiometric amounts of the oxide precursors: tetraethyl orthosilicate (TEOS), triethyl phosphate (TEP), magnesium nitrate hexahydrate and calcium nitrate tetrahydrate (*inorganic route*) or calcium methoxyethoxide (*metalorganic route*),[39] by the scheme shown in Figure 2.

In the *inorganic route*, HNO_3 (2 N) was used to catalyse the TEOS and TEP hydrolyses, the (HNO_3 + H_2O/TEOS + TEP) molar ratio being constant and equal to 8. Reactants were added consecutively after 1-h intervals, with continuous stirring. The solution (*sol*) was poured into Teflon® containers, which were closed and kept at room temperature until gelation (*gel*) was reached (2−5 d depending on the *sol* composition). Ageing was achieved by a thermal treatment (70 °C/55 h) and the drying of the gel at 150 °C/72 h, after replacement of the container lid with another one with a small hole, allowing the gasses to leak. The dried gel was ground and sieved, and the 63−32 μm fractions were selected. Disks (13 mm diameter, 2 mm in height), were conformed by uniaxial (50 MPa) and isostatic (150 MPa) pressures on 0.5 g of dried gel powders. Nitrate elimination and material stabilisation was carried out at 700 °C/3 h, the temperature being determined by thermogravimetric analysis of the dried gels.

On the other hand, in view of the excellent bioactivity of the obtained gel glasses, we considered that their application field could be expanded through the preparation of new mixed materials, in which these glasses would be the bioactivity-inducing elements. We have thus obtained: (i) bioactive systems for controlled release of anti-inflammatory drugs and antibiotics, avoiding problems derived from implantation as bone substitutes, (ii) magnetic bioactive materials, for the treatment of osseous tumours by hyperthermia, and (iii) calcium phosphate based materials with improved kinetics for the formation of new apatite, thanks to the presence of the bioactive glass.

Finally, gel glasses have been used to prepare metallic substrate coatings (of Ti6Al4V) by dip-coating. These coatings allow the good mechanical properties of metals to be combined with the bioactivity of sol-gel glasses.

3. Ternary Compositions: SiO_2·CaO·P_2O_5 System

3.1 Characterisation of Glasses

Analyses of the compositions of gel glass by X-ray fluorescence (XRF) and energy dispersive X-ray spectroscopy (EDS) showed good agreement with the nominal compositions[26−43] (Table 1).

X-ray diffraction (XRD) characterisation confirmed the amorphous character of all the materials, but in some cases a diffuse maximum was observed at $2\theta \approx 32°$. This could

50S50C	50	50	–	–	[48]

be attributable to the more intense reflection of an apatite-like phase that could start to crystallise in the amorphous glass matrix.

The obtained Fourier-transform infrared (FTIR) spectra show bands attributable to the Si–O stretching vibrations (ν_a: ca. 1085 cm^{-1}; ν_s: ca. 802 cm^{-1}) and Si–O–Si bending vibrations (ca. 472 cm^{-1}). In addition, two low-intensity bands are registered at about 602 and 568 cm^{-1} and could be attributable to stretching vibrations of phosphate groups.

Characterisation by scanning electron microscopy (SEM) indicates that pieces of the glasses are made up of particle aggregates with a wide size distribution (ca. $1-25 \times 10^3$ nm) and with sharp edges, allowing numerous voids between them.

The textural properties (porosity and specific surface) were also determined,[32–34,38,42] by N_2 adsorption and intrusion mercury porosimetry. Figure 3 (see a) shows the nitrogen adsorption isotherms for the ternary, 60S, 65S, 75S and 80S gel glasses.[38] The inset shows the BET surface and mesoporous volume values obtained by this technique.

All the nitrogen adsorption isotherms can be identified as type IV isotherms with slight differences in the hysteresis loop.[50] Samples with SiO_2 contents under 70 mol % have an H1 type hysteresis loop in the mesoporous region (3–50 nm), characteristic of cylindrical pores with both sides open, with some narrow parts. In contrast, glasses with SiO_2 contents higher than 70 mol % present hysteresis loops of H2 type associated with inkbottle-like pores with variable size and narrow necks.

Figure 3, part b shows the pore volume as a function of the pore diameter in the macropore region (2×10^5 to 50 nm) obtained by mercury intrusion. The inset shows macropore diameter vs. SiO_2 content. As observed, the pore volume in this region increases when the SiO_2 content in the glasses decreases.

These results indicate that the textures of the sol-gel glasses in this system are determined by the relative amounts of the glass components. For the same contents in P_2O_5 (4 mol %), higher CaO percentages, and consequently lower SiO_2 contents, yield higher mesopore volumes. Simultaneously, pore diameter increases, whereas the surface area decreases. These results were explained by taking into account that increases in calcium content in the SiO_2 network increase the number of nonbonding oxygen atoms. A proportion of the micropores is therefore substituted by mesopores, producing a decrease in the specific surface.

It was observed that variations in the pore morphology parallel their modifications in volume and diameter. An increase in the pore size and volume joins the "inkbottle" pores together, producing cylindrical pores. A model presenting the transition in the pore morphology is depicted schematically in Figure 3, part c.

For constant CaO contents (25 mol %), however, the surface area increases and the pore diameter and volume decrease with increasing P_2O_5 content.[42] This was explained by considering that P_2O_5 bonds to calcium, decreasing the amount of this element that can interact with the silica network. An increase in the P_2O_5 content in the glass thus produces effects similar to those of a decrease in the CaO content (increasing the SiO_2 percentage).

Another point studied was the influence of the CaO precursor on the features of the sol-gel glasses obtained. With this as the objective, a glass composition was prepared from two different precursors (Figure 2): calcium nitrate tetrahydrate (*inorganic route*, 76S glass) and calcium methoxyethoxide (*metalorganic route*, 76SA glass).[39] 76SA has the following differences from 76S: it (i) was obtained in monolithic form, (ii) presented a lower pore volume (0.13 $cm^3 \times g^{-1}$ vs. 0.72 $cm^3 \times g^{-1}$ of 76S, obtained by Hg intrusion), and (iii) showed only one maximum (at 180 nm) in the pore size distribution, while 76S glass showed a bimodal distribution with maxima at 820 nm and 6 nm. Variations in texture can be explained by the porosity generated in the thermal treatment required for nitrate elimination in the synthesis of the 76S glass. This different textural properties give rise to different in vitro behaviour in the two glasses, as explained in the next section.

3.2 In Vitro Bioactivity Studies

There is a well-established relationship between the ability of a given material to form bonds with living tissues and its ability to grow an apatite-like layer when soaked in fluids mimicking human plasma, and so in vitro assays are pop-

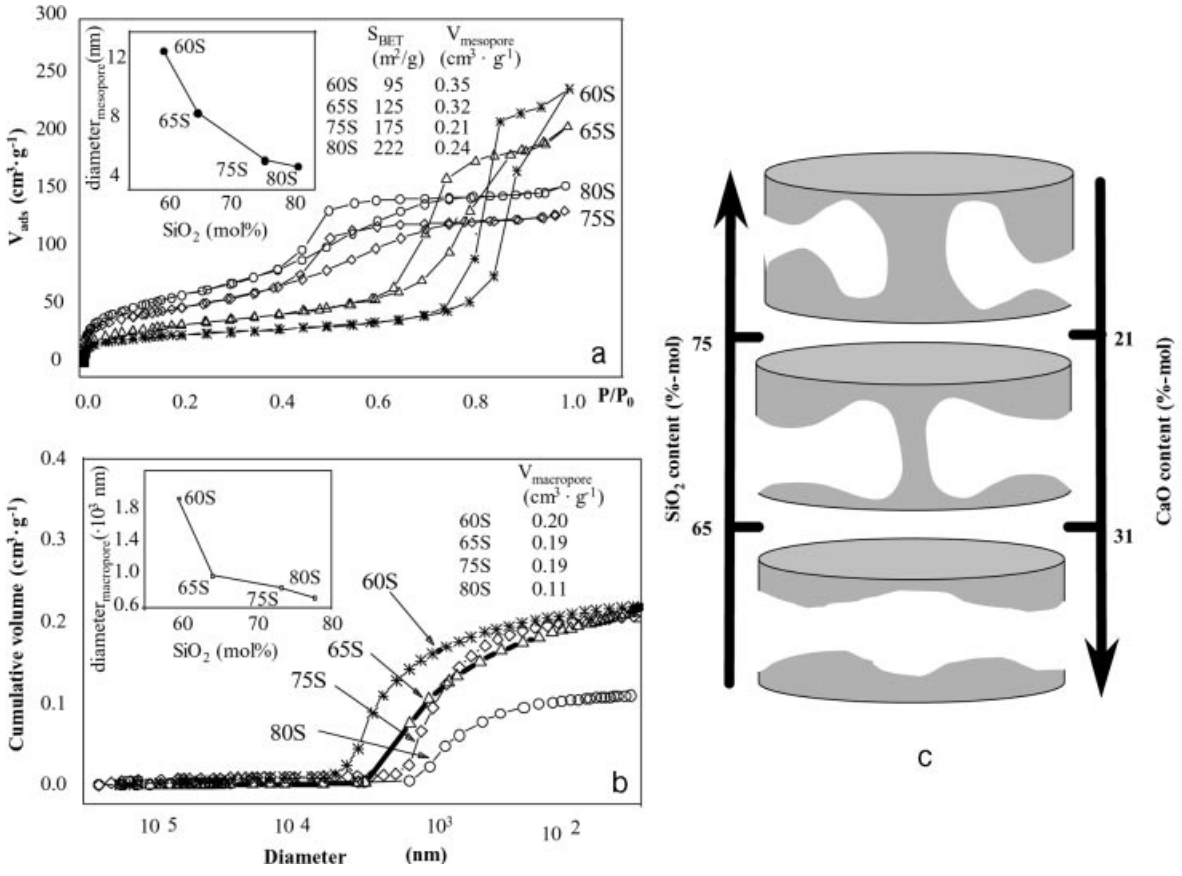

Figure 3. (a) N_2 adsorption isotherms of several $SiO_2 \cdot CaO \cdot P_2O_5$ sol-gel glasses; the inset shows the mesopore diameter versus SiO_2 content; BET surface and mesopore volume data are also included; (b) volume of intrusion Hg as a function of pore diameter; the inset shows the macropore diameter versus SiO_2 content; the macropore volume data are included; (c) model of the transition in the mesopore morphology as a function of the composition of the gel glasses

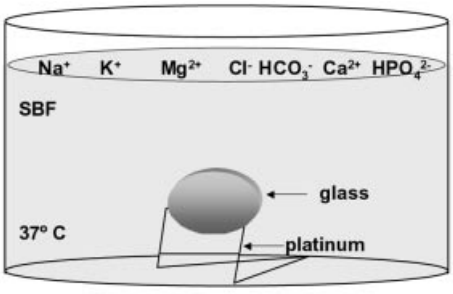
ular tools in the study of bioactivity of new candidate implant materials. In most of our research we have used the simulated body fluid (SBF) proposed by Kokubo et al.[7] SBF is an acellular, aqueous solution with an ionic composition that closely resembles that of human plasma, buffered to physiological pH (7.25−7.40) at 37 °C with a mixture of HCl/tris(hydroxymethyl)aminomethane. Figure 4 compares the ionic compositions of SBF and human blood plasma. Since this fluid contains Ca^{2+} and HPO_4^{2-} ions, it can be used to assess the in vitro bioactivity of a wide range of materials.

During the in vitro assays, the glass disks are soaked in SBF for time periods ranging from 1 h to 2 weeks. To homogenise our studies, to avoid effects due to volumetric differences, the relationship between the geometric areas of pieces and the volumes of solutions was 0.075 cm^{-1} in all cases. Disks are kept in a vertical position in a platinum scaffold (Figure 4). After the assays, pieces are washed with water and acetone and dried in air. Microorganism contamination of samples is avoided by performing all the manipulations inside a laminar flux cabinet and by filtering the SBF with a 0.22 μm Millipore® system.

In vitro bioactivity of glasses is evaluated by monitoring changes in pH and Ca^{II}, Si^{IV} and P^{V} concentrations in solution and by analysing the apatite layer formation on the surface of the pieces by XRD, FTIR, SEM-EDS, transmission electron microscopy (TEM) and electron diffraction (ED).



Ionic composition of SBF and Human Blood Plasma (mM)

	Na^+	K^+	Mg^{2+}	Ca^{2+}	Cl^-	HCO_3^-	HPO_4^{2-}	SO_4^{2-}
SBF	142.0	5.0	1.5	2.5	147.8	4.2	1.0	0.5
plasma	142.0	5.0	1.5	2.5	103.0	27.0	1.0	0.5

Figure 4. Schematic depiction of the in vitro bioactivity test; ion concentrations in SBF and in human blood plasma are also indicated

In general terms, as soaking time increases there is an increase in pH and in the Ca^{II} and Si^{IV} concentrations in SBF, whereas the P^{V} concentration in SBF decreases simultaneously. These effects are more pronounced in the first 12

h of assay and decrease after that. These variations agree with an exchange taking place between Ca^{2+} ions of the glass and H_3O^+ of the solution. This exchange favours the formation of Si−OH in the glass surface and increases the Ca^{2+} supersaturation in solution, inducing nucleation and crystallisation of apatite (Figure 5).

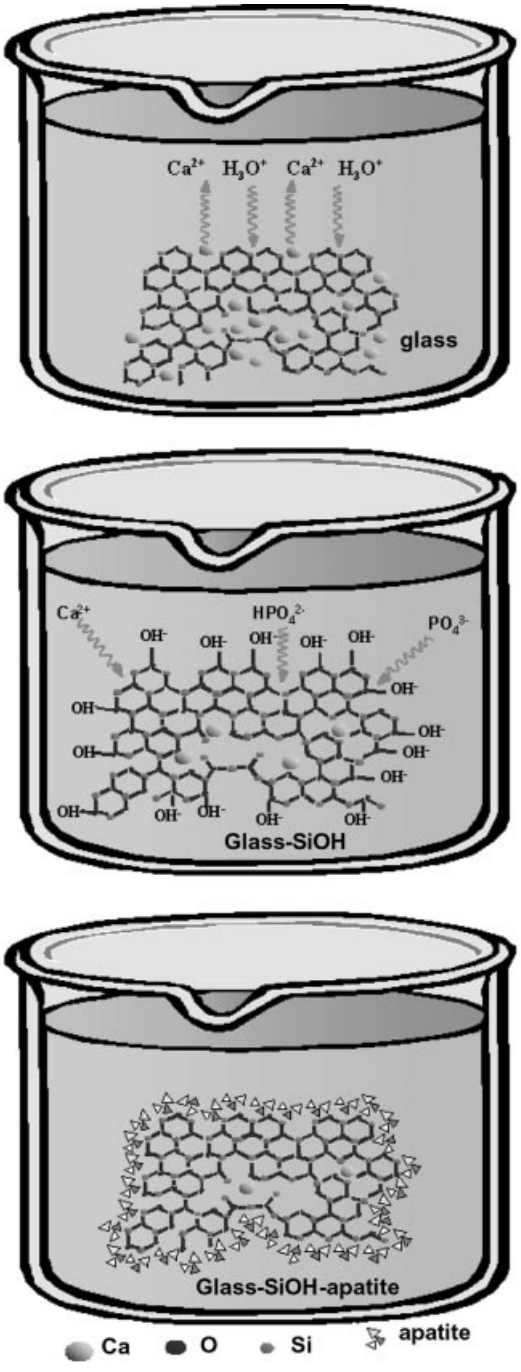


Figure 5. Depiction of the apatite formation mechanism as a function of the reactivity of bioactive glasses when in contact with physiological fluids, under in vitro conditions

Figure 6, part a shows the XRD diagrams of 60S glass before and after soaking for different periods in SBF. As the soaking time increases, diffraction maxima attributable to the more intense reflections of an apatite-like phase are registered. The intensities of these maxima increase with the immersion time as the apatite crystal size increases.

Figure 6, part b depicts FTIR spectra of 58S glass before and after soaking in SBF for different time periods. As the immersion time increases, the spectra develop bands attributable to the phosphate and carbonate groups, the intensities of these bands increasing with the soaking time. The presence of such bands shows that the material formed on the glass surface is hydroxycarbonate apatite (HCA), similar to biological apatites.[51,52]

SEM studies indicate that during the early soaking stages the glasses are totally coated by a layer of spheres of a diameter between 1 and 20×10^3 nm, identified by FTIR and EDS as amorphous calcium phosphate. For soaking times longer than 3−4 d, it was observed that the spheres were composed of numerous elongated particles (Figure 6, c). The times required for these processes varied with the gel glass composition but, in general, were lower for ternary gel glasses with high CaO contents.

The particles forming the spheres are made up of numerous crystalline aggregates, as confirmed by TEM (Figure 6, d). The correspondent ED diagram shows rings and diffraction maxima attributable to the more intense reflections of an apatite-like layer (Figure 6, e).[30] In addition, EDS analysis shows that the layer formed on 80S17C glass after 7 d in SBF is made up only of Ca, P and O (Figure 6, f).

The thickness of the newly formed layer can be studied by SEM, by cutting the pieces after the in vitro assays and applying the procedure shown in Figure 7. The EDS spectrum of the bulk glass (Figure 7, c) agrees with its nominal composition, whereas higher Ca and P concentrations and a lower Si content are detected in the layer, the thickness of which varies with glass composition and soaking time in SBF. For 55S glass, a thickness of 2×10^3 nm is measured after 15 h and increases up to a maximum value of 10×10^3 nm after 5 d of assay. In addition, the Ca/P molar ratio in the newly formed layer ranged between 1.4 and 1.7, within the common limit values for biological apatites.[53,54]

3.3 Texture − In Vitro Bioactivity Relationship in Sol-Gel Glasses

The formation of an Si-rich layer and a calcium phosphate layer on bioactive glasses is a well-established fact.[55−59] Figure 5 outlines the essential steps in the mechanism of formation of an apatite-like layer. The process takes place through the free surface of the glass, so those factors responsible for an increase in the specific surface of the initial glass also support an acceleration of the kinetics of this mechanism of chemical reactivity in bioactive glasses. This was in fact one of the main reasons to search for additional synthesis routes to these glasses, trying to enhance the specific surface and porosity of the final product.[60−64] The Si-rich layer is clearly seen on the bulk glass, and the calcium phosphate is seen as a light uppermost layer on the Si-rich gel.

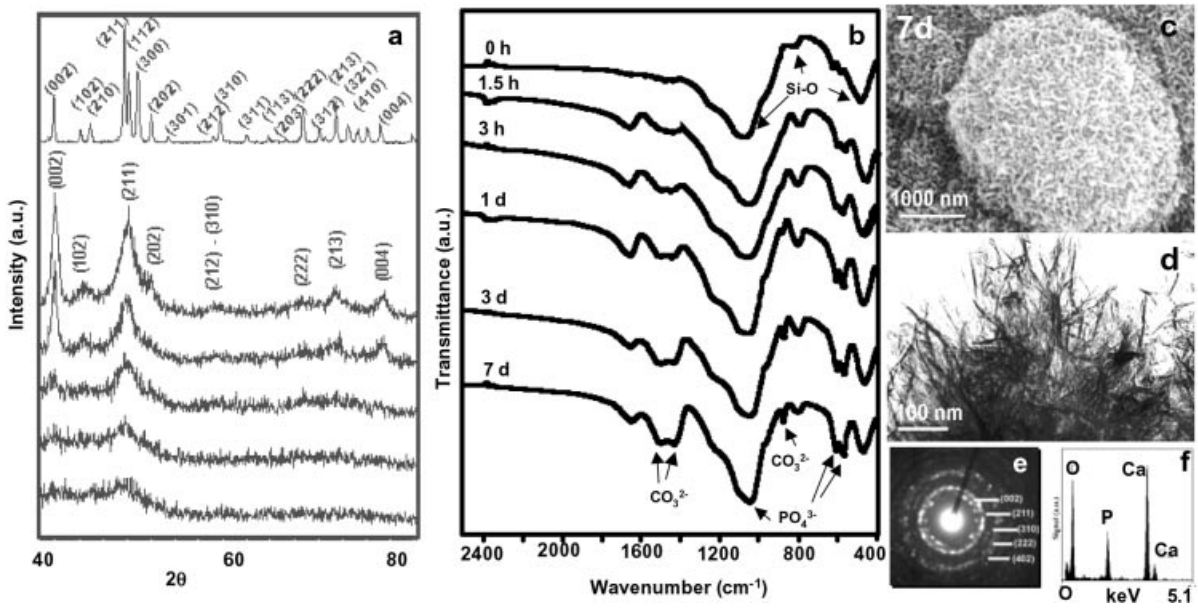

Figure 6. (a) XRD patterns of 70S before and after soaking different periods of time in SBF; an XRD pattern of hydroxyapatite is included as a reference; (b) FTIR spectra of 58S before and after soaking in SBF; (c) SEM micrographs; (d) TEM micrograph; (e) ED pattern, and (f) EDS spectra of 80S17C after a 7-d assay in SBF

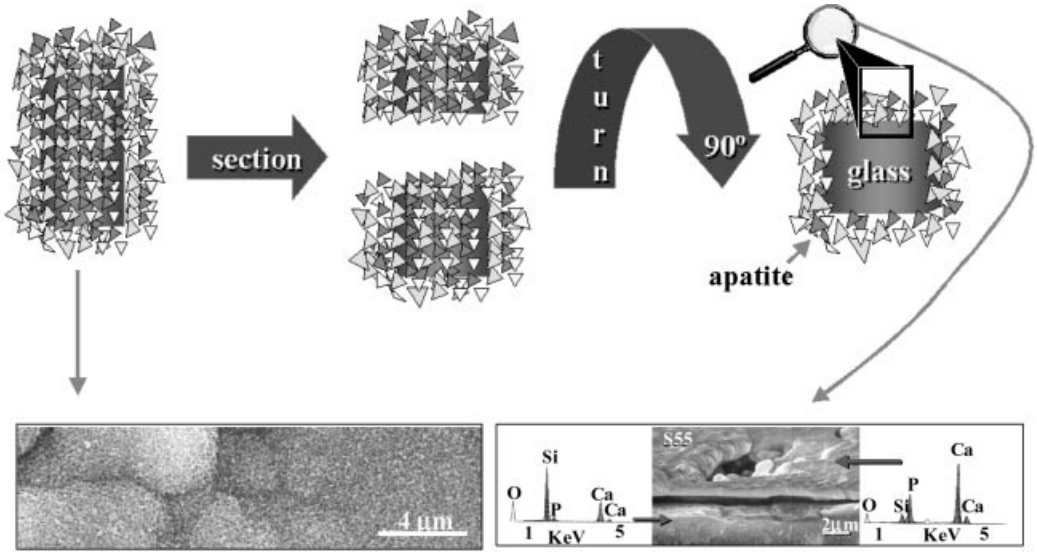

Figure 7. Schematic depiction of the sample treatment used to study the layer thickness by SEM-EDS; an SEM micrograph of 55S glass surface after 7 d soaking and SEM micrograph and EDS spectra of the inside of the glass and on the layer are also shown

High porosity in sol-gel glasses favours the formation of the apatite-like layer, since it facilitates rapid and massive release of Ca^{2+} ions from the glass into the solution. This release increases the Ca^{2+} saturation and pH in the medium, and induces silanol group (Si−OH) formation in the glass surface according to the following Equation:

$$2\ (Si{-}O)^{2-}\ Ca^{2+} + 2\ H_2O \rightarrow 2\ Si{-}OH + Ca^{2+} + 2\ OH^-$$

The formation of the silicon-rich layer is almost instantaneous, and it is covered within minutes by an amorphous phosphate layer, which in 2 or 3 d crystallises with an apatite structure. These processes also produce additional porosity, which facilitates the diffusion of more Ca^{2+} ions into the medium and the formation of new silanol groups. There are, however, other factors contributing to these reactions. CaO acts as network modifier, inducing instability in the system by provoking stress in the glassy network. Thus, generally speaking, a higher CaO content in the glass implies faster formation kinetics of the apatite phase.

The presence of CaO is also associated with a larger porosity of the glass, more so when introduced in the form of an inorganic salt such as $Ca(NO_3)_2$. In this context, a study on the differences between glasses in which CaO was included either as calcium alkoxide (76SA) or as calcium nitrate (76S) indicated that glasses obtained by the latter

method are more porous and less homogeneous.[39,65] In vitro studies of glasses indicate that both are bioactive. However, because of their better textural and structural properties, the layers formed on 76SA glass are thicker, more compact and more homogeneous.

3.4 Quantification of Bioactivity in SiO_2 Glasses

We have proposed a method to quantify and predict the bioactivity of silicate glasses;[40] it relates the SiO_2 network degradation with the factors that cause the formation of silanol groups on the glasses surface. As mentioned, these factors are mainly *composition* (amount of network modifiers: CaO, Na_2O, ...) and *textural* properties (surface area and porosity).

Preliminary studies show that the energy of activation (E_a) for the diffusion of $Si(OH)_4$, the soluble form of SiO_2, is closely related to the in vitro bioactivity of the studied glasses.[43] For melt and sol-gel silica glasses with in vitro bioactivity, it was observed that E_a for $Si(OH)_4$ diffusion after 6 h of assay is lower than 0.35 eV.

3.5 Sol-Gel Glasses Biocompatibility

The biocompatibility of these ternary sol-gel glasses was studied by means of osteoblast cell cultures.[41] It was observed that these materials allow and favour osseous cell growth.

In vivo studies involving the implantation of glass pieces in rabbit femur for time periods between 1 and 12 weeks were also performed;[66] the implants present excellent biocompatibility and osseous integration.

4. Quaternary Compositions: SiO_2·CaO·MgO·P_2O_5 System

As already indicated, the inclusion of certain quantities of MgO as a network modifier in the melt glass compositions can improve their mechanical properties. For that reason we performed the synthesis and an in vitro bioactivity study of sol-gel glasses of the SiO_2·MgO·P_2O_5 and SiO_2·CaO·MgO·P_2O_5 systems.

None of the compositions obtained in the SiO_2·MgO·P_2O_5 system show in vitro bioactivity. In the surface of SiO_2·CaO·MgO·P_2O_5 glasses, however, a phosphate-rich layer was formed after soaking in SBF at 37 °C.[26,28,31,32,44] In vitro studies show that the rate of formation of the new layer decreases with increasing magnesium content in glasses. Moreover, a whitlokite-like phase [β-$Ca_3(PO_4)_2$] was detected in the layer as well as the apatite, together with a noticeable increase in the layer thickness, reaching 20×10^3 nm for 80S7M glass.

In order to explain this decrease in the kinetics of layer formation in quaternary glasses, their textural properties were studied.[32,44] Increases in the MgO content were found to increase the surface area and pore volume, whereas the pore sizes remained almost constant. These differences are not sufficient to justify the strong inhibitory effect of MgO in the crystallisation and growth of apatite, since the opposite effect (that is, an increase in the apatite layer growth for larger surface areas) was observed in bioactive ternary SiO_2·CaO·P_2O_5 glasses.

Because of this, the surfaces of quaternary glasses were analysed by TEM-EDS. The study shows that the glasses are chemically heterogeneous at nanometric scales and that

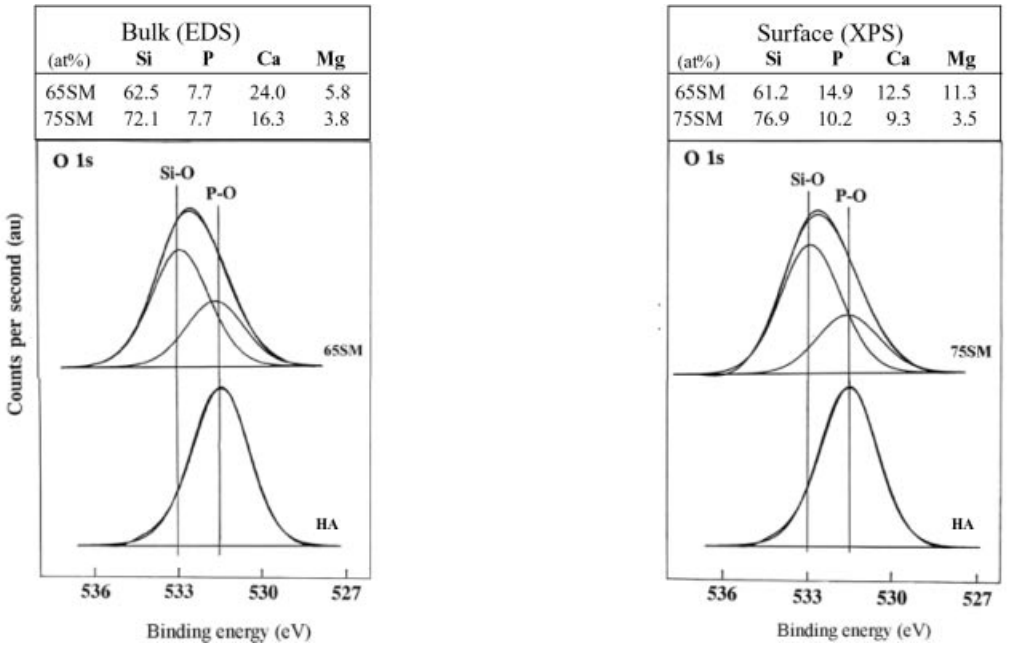

Figure 8. XPS spectra of oxygen 1s of the quaternary 65SM and 75SM glasses; hydroxyapatite spectra are included as reference; bulk (EDS) and surface (XPS) compositions of the glasses are also included

magnesium is always attached to Ca, P and Si, whereas pure calcium phosphate crystals were not detected. Therefore, Mg seems to inhibit the formation of calcium phosphate microdomains. These microdomains would eventually act as preferred centres for apatite crystallisation in Mg-free glasses, as they would offer a minimum interfacial energy for nucleation.[32]

To gain a deeper knowledge of the glass surface, a surface analysis technique, such as X-ray Photoelectron Spectroscopy (XPS), is needed. These studies show that the glasses' surfaces are richer in phosphorus and magnesium and poorer in calcium than the interiors (Figure 8).[32] Figure 8 shows the XPS spectra of O1s for 65SM and 75SM, together with that of hydroxyapatite (HA), included as a reference. The spectra of glasses can be deconvoluted into two components at 531.3 eV (P−O in HA) and 533.1 eV (Si−O).

Results from EDS-TEM and XPS studies suggest the existence of calcium-magnesium phosphate microdomains on the surface of quaternary glasses. Since the amount of calcium phosphate domains drastically decreased when MgO was included, this was regarded as the primary factor producing the bioactivity decrease in quaternary glasses containing magnesium.

5. Binary Compositions: SiO_2·CaO System

As already mentioned, addition of MgO to the SiO_2·CaO·P_2O_5 system modifies the textural properties and decreases the bioactivity of sol-gel glasses, while simultaneously increasing the complexity of the system. We therefore conjectured that the exclusion of a component of the ternary system, such as P_2O_5, might help understanding of the bioactivity mechanism in glasses, if the resultant glass was bioactive.

There are literature reports of bioactivity for SiO_2·CaO melt glasses with maximum SiO_2 contents of 65 mol %[67] (higher silica contents would produce phase separation by this synthesis method).

Our group has synthesised CaO·SiO_2 glasses with SiO_2 contents between 50 and 90 mol % by the sol-gel method.[42,45,48] In vitro bioactivity studies in all cases show the formation of an apatite-like layer. These results indicate that the presence of P_2O_5 in glasses of this system is not essential to ensure bioactivity, even at very high SiO_2 contents.

As with the ternary system, it was observed that the rate of formation of the new layer increases with the CaO content in the glasses.[30] In addition, in glasses with high CaO contents (40 and 50 mol %), calcite ($CaCO_3$) was also detected in the layer together with the apatite.

To understand the role of P_2O_5 in the glasses' bioactivity, the behaviour of an 80% SiO_2/20% CaO glass in SBF was compared with that of a ternary glass with identical silica content and 3% of P_2O_5.[30] Moreover, silicate glasses with identical CaO contents (25 mol %) and P_2O_5 contents of 0, 2.5 and 5 mol % were compared.[42]

The obtained results allow the conclusion that the presence of phosphorus retards the initial reactivity of glasses, defined as the time required for the initial formation of the amorphous calcium phosphate. Once some nuclei are formed, however, the growth of apatite crystals in the new layer is quicker and affords larger crystals when there is a small amount of P_2O_5 in the glass composition.

6. Procedures for the In Vitro Bioactivity Studies

During the in vitro studies described above, the assay solution was not renewed and so the ions released from the glass remain in the container. This method is termed *static* or *integral*. When materials with high reactivity in aqueous solutions are studied, however, ionic analysis of the solutions shows huge ionic concentration variations during the assay. As a result, some authors have proposed the so-called *differential* method,[5,6] in which the solution is renewed at predetermined intervals. For sol-gel glasses, our studies have shown that solution substitution should be at intervals so short that sample manipulations would affect the apatite formation process. For that reason, also to simulate the continuous flux of body fluids at the implant surface, we have proposed a new *dynamic* or *continuous* in vitro procedure, in which SBF is continuously renewed with the aid of a peristaltic pump. Figure 9 shows the scheme of the device used for *dynamic* in vitro assays.

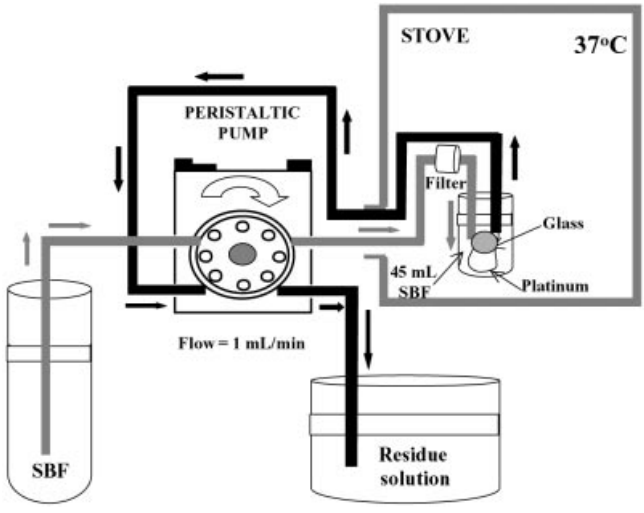

Figure 9. Representation of the dynamic procedure used for in vitro tests in SBF; a peristaltic pump continuously exchanges the assay solution to model the continuous flow of body fluids at the implant surface

This procedure was used for a bioactivity study of several glasses, results being compared with those obtained in *static* mode.[37,47] The use of a *dynamic* procedure allows complete bioactivity assays to be performed while keeping ionic concentration and pH almost equal to those of plasma. Fig-

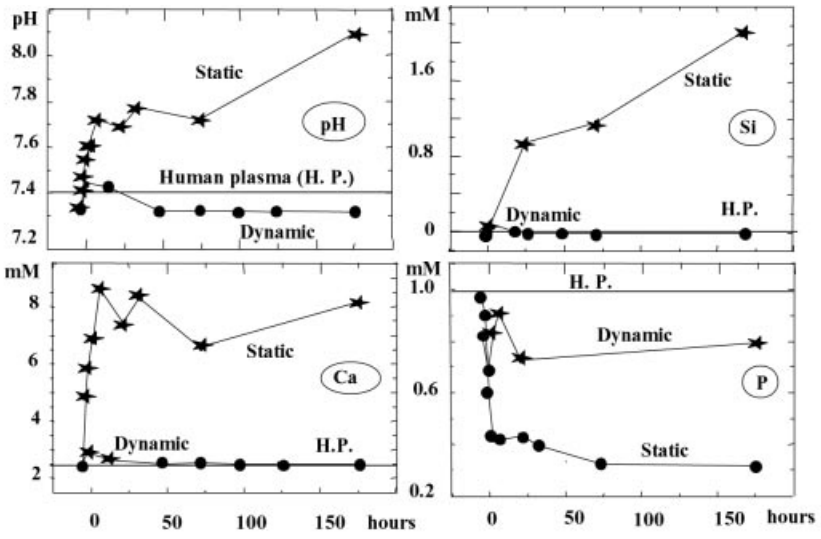

Figure 10. Variation of pH and Ca^{II}, P^{V} and Si^{IV} concentrations with soaking time in solution for 80S20C by use of static and dynamic in vitro procedures; the horizontal line in the figures indicates the values in human plasma

Table 2. Comparison between the two procedures used for in vitro studies of 80S20C and 80S17C sol-gel glasses

		Static	Dynamic
	SBF	Variations in solution after 7 d	
pH	7.30	8	7.30
Ca^{II} [mM]	2.5	8.5	2.5
P^{V} [mM]	1.0	0.3	0.8
Si^{IV} [mM]	0	2.1	0
		Variations in the layer	
Amorphous calcium phosphate		early formation	later formation
Apatite crystallisation		smaller crystals	bigger crystals
Layer composition		detected silicon	no silicon
Ca/P molar ratio		1.6	1.2

ure 10 shows variations with immersion time of Ca^{II}, P^{V}, Si^{IV} and pH in solution for 80S20C glass under *static* and *dynamic* conditions. Differences in solution composition, mainly pH, produced variations in the formation of calcium- and phosphorus-rich layers, shown schematically in Table 2. In *dynamic* mode, the amorphous phosphate layer was detected only after longer soaking times, but the size of the apatite crystals formed later is larger than in *static* mode. Regarding the layer composition, in contrast with static conditions, no traces of silicon were detected in *dynamic* mode and the Ca/P ratio was considerably lower (Figure 11, a). These differences were explained by the mechanism shown in Figure 11, b. The lower pH in *dynamic* mode (7.3) increases the HPO_4^{2-} ion concentration in solution compared with the static conditions under which the pH is close to 8. In this sense, use of the *dynamic* mode would favour the formation of calcium-deficient apatite, which might coexist with other calcium phosphates of lower Ca/P molar ratio.

7. Sol-Gel Glasses: Components of Mixed Materials

The excellent bioactivity of sol-gel glasses (SGGs) makes them potential candidates for osseous tissue regeneration. These glasses could be the optimal complement in systems for release of therapeutic action substances, such as antibiotics or anti-inflammatory agents, able to mitigate the problems originating from the material implantation.

The combination of these bioactive glasses with magnetic materials may also be an option for treatment of osseous tissues affected by tumours, since it should be possible to obtain bioactive and magnetic pieces capable of regenerating the bone, and to apply hyperthermia treatment. Moreover, the bioactive glass/hydroxyapatite (HA) combination can accelerate the bioactive response of HA. We have developed several SGG-polymer-drug, SGG-magnetic component and SGG-HA mixed materials, described below.

7.1 Sol-Gel Glass-Polymer-Drug

The study of systems for controlled release of drugs began with the synthesis of ceramic-polymer-drug materials including anti-inflammatory and antibiotic drugs.[68−73] In vitro studies showed that the release of the drug depends on its solubility and the piece matrix's porosity and capability to absorb liquid.

If a bioactive SSG is used as inorganic component in these systems,[74−77] a controlled release system, simultaneously bioactive, is produced. In this way, the osseous integration is improved and the drug release is favoured, due to the ionic interchange between the glass and medium.

On the other hand, the release of gentamicin from SSG implants was studied under in vivo conditions.[66] Gentamicin levels found in the organs analysed indicate that these

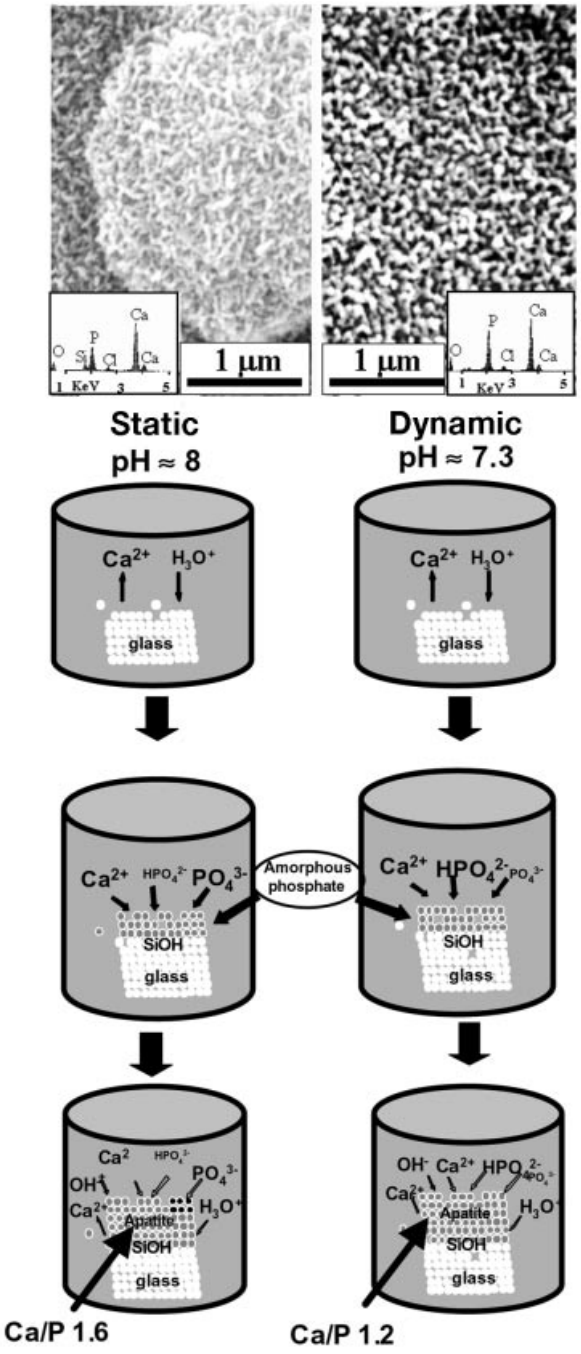

Figure 11. SEM micrographs and EDS patterns of 80S20C after 7 d soaking with use of static and dynamic in vitro bioactivity procedures and the proposed model to explain the different Ca/P molar ratio values obtained by EDS in the newly formed layer

implants are useful as drug release systems in bone during the 12 weeks of study.

7.2 Sol-Gel Glass-Magnetic Glass-Ceramic

The sensitivity of cancer cells to high temperatures was discovered 70 years ago, and the possibility of treating tumours by controlled heating has been studied since then. Nowadays, such therapy is termed *hyperthermia*. Among the techniques for application of this therapy, those of *interstitial hyperthermia* produce heat with the aid of devices directly implanted in the affected area. These devices can be magnetic materials, which will generate heat in an external alternating field, due to hysteresis losses or parasite currents. Heat is restricted to the desired volume without affecting the surrounding tissues.

Among those materials that have been proposed as *thermoseeds* in *interstitial hyperthermia*, magnetic glass-ceramics (MGCs) are interesting alternatives for the substitution and filling of osseous tissues exhibiting tumours.[78−82]

In our group we have studied the possibility of combining MGCs with bioactive glasses, synthesising biphasic materials presenting both properties. We have obtained several materials with varying proportions of the two components. Our studies showed that SGGs produce increases in the macro- and mesoporosity of the system, as well as higher reactivity in simulated body fluids, conferring high bioactivity on these biphasic materials.[83−84] However, the presence of SGGs seems partially to inhibit the incorporation of iron in the crystalline phases of the glass-ceramic, consequently decreasing the magnetic behaviour.[84]

7.3 Sol-Gel Glass-Hydroxyapatite

Hydroxyapatite (HA) is a highly suitable material for bone substitutions because it is not cytotoxic, presents excellent biocompatibility with living tissues, and is the material most similar to the mineral component of bone. However, the bioactivity of HA ceramics is lower than that of bioactive glasses.[85]

Our group has prepared and characterised SGG/HA biphasic materials offering more rapid kinetics of new apatite formation than pure HA.[86−88]

Figure 12 shows surface micrographs of 70S, HA and biphasic 70S/HA before and after soaking in SBF for different periods of time. As can be observed, the glass is coated by a layer of spheres after 7 d in SBF whereas the HA surface is not modified even after 45 d of immersion. Moreover, the biphasic 70S/HA is bioactive after only 12 h.

In addition, cross-sections of the biphasic materials before and after soaking for 3, 7 and 14 d in SBF were studied by SEM-EDS. The silicon content decreases from the inner part (ca. 30 μm) to the border, whereas Ca and P contents increase. The small amount of Si in the limit with the apatite-like layer obtained after 3 d of immersion is related to the lower thickness of this layer relative to those obtained after 7 or 14 d of treatment.

To visualise the newly formed layer better, Figure 13 shows the SEM micrographs, at different magnification, of the biphasic material surface after 7 d in SBF, as well as a cross section. The EDS spectrum of the new layer is also included. A layer thickness of approximately 3×10^3 nm and the absence of silicon in the new formed layer are observed.

8. Sol-Gel Glasses Coatings

Ceramic coatings of metallic pieces used as implants are of great interest because they combine the good mechanical

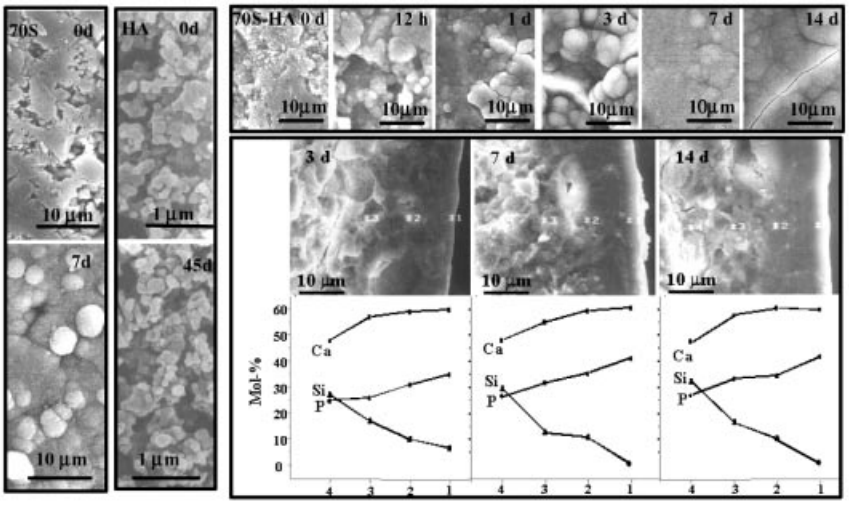

Figure 12. SEM micrographs of 70S glass, hydroxyapatite and 70S-HA biphasic material surfaces after SBF soaking several times; Ca, Si and P contents as a function of depth obtained by EDS in the transversal sections of biphasic material after SBF soaking for 3, 7 and 14 d are also included

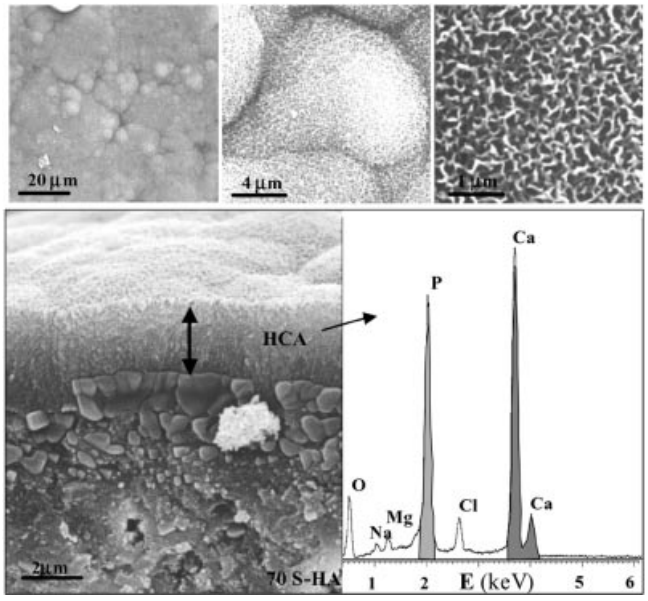

Figure 13. SEM micrographs of surface and a cross section of 70S-HA biphasic material after 7 d soaking; the EDS spectrum of the newly formed apatite layer is also included

properties of metals with the excellent biocompatibility and, in some cases, bioactivity of ceramics. At the same time, the metallic surface is protected from the biological medium, reducing corrosion and the release of ionic metals into the medium.

Sol-gel processing is ideal for the preparation of films by *dip-coating*. This method requires simple equipment and soft thermal treatments, and − its main advantage − allows a high degree of control over the microstructure and composition of the film, highly pure and homogeneous coatings being obtainable. *Dip-coating* technology is based on the capability of *sols* to form films on substrates introduced into them and extracted at a known rate. Many parameters affect the microstructure and thickness of the films, although the extraction velocity of substrate and the *sol* viscosity are strong limiting parameters. The extraction velocity must be lower than or equal to the gelling rate of the film in order to avoid flocculation processes and to maximise the adhesion to substrate.

Our group has prepared SiO_2·CaO system sol-gel coatings on metallic Ti6Al4V prostheses by *dip-coating*.[89] The characteristics of the method allow the porosity and thickness of coatings to be controlled by varying the properties of the starting solution. Figure 14 shows SEM and atomic force microscopy (AFM) micrographs of 80% SiO_2/20% CaO sol-gel coatings on a Ti6Al4V substrate.

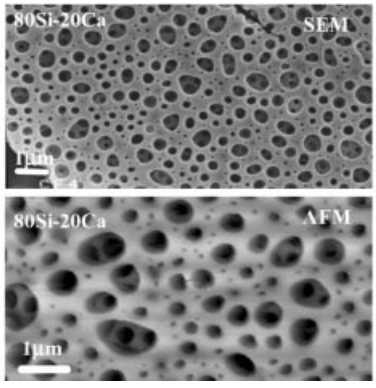

Figure 14. SEM and AFM micrographs of sol-gel glass coatings (80S20C glass) on metallic Ti6Al4V substrates

9. Future Expectations in Bioactive Glasses

From the advances in related medical technologies, bioactive materials appear to be entering a new stage of development in which they will have to be skilfully designed to exhibit a variety of new functions. These new functions include different mechanical properties, drug delivery capabil-

ity, the capability to activate proteins and/or cells for tissue regeneration and tissue engineering, biomimetics, nanotechnology, etc. Namely, there is significant increase in requirements for novel bioactive materials with different functions. To design a novel bioactive material successfully, the mechanism of bone-like apatite formation on the current bioactive materials should be specifically addressed and established.

Sol-gel glasses, as fibres or high-porosity monoliths, are good candidates with which to obtain biocompatible scaffolds for tissue engineering while maintaining mechanical properties during the resorption process. Growth factors (bone, platelet-derived, basic fibroblast) and polypeptides for their release can be included in the scaffolds.

On the other hand, the potential design of combinations of bioactive glasses and apatites could give very satisfactory results in terms of acceleration of the bioactivity of the apatites, which, due both to their composition and structure, are the ceramics most similar to the mineral component of the bone.

The new expectations on the field of hybrid organic/inorganic materials represent another route for future applications of bioactive glasses.

Acknowledgments

We would like to express our deepest gratitude to all our coworkers and friends who have contributed with their effort and thinking to these studies over the years. Financial support by the Spanish CICYT (MAT99-0466 and MAT01-1445-C02-01) is gratefully acknowledged.

First Star-Like Oligophenylene Molecules Containing a Dinuclear Organometallic Core

Frédéric Chérioux,*[a] Bruno Therrien,[a] and Georg Süss-Fink[a]

Dedicated to Professeur Bernard Laude on the occasion of his 65th birthday

Keywords: Rhodium / Ruthenium / Oligomerization / Oligophenylene

The cationic complexes $Ru_2[(p\text{-}MeC_6H_4iPr)_2(p\text{-}SC_6H_4Br)_3]^+$ and $Rh_2[(C_5Me_5)_2(p\text{-}SC_6H_4Br)_3]^+$ are available in quantitative yields from the reaction of $p\text{-}HSC_6H_4Br$ with $[Ru(p\text{-}MeC_6H_4iPr)Cl_2]_2$ and $[Rh(C_5Me_5)Cl_2]_2$ respectively. These complexes are found to undergo triple Suzuki coupling with oligophenylene boronic acids to give $[Ru_2(p\text{-}MeC_6H_4iPr)_2\{p\text{-}S\text{-}(C_6H_4)_n\text{-}C_6H_5\}_3]^+$ and $[Rh_2(C_5Me_5)_2\{p\text{-}S\text{-}(C_6H_4)_n\text{-}C_6H_5\}_3]^+$ respectively. The star-like trisbromo complexes are potential precursors for the insertion of dinuclear organometallic entities into the main chain of conjugated molecules.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

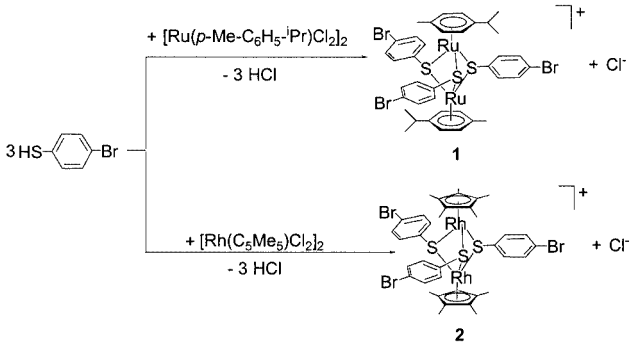
Introduction

During the two past decades there has been a growing interest in the field of conjugated molecules containing metal centers because of their electronic, nonlinear optical, magnetic and catalytic properties,[1−3] and more recently for the development of sensors.[4,5] It is quite impossible to be exhaustive because of the plethora of new compounds synthesized in all these fields of research, but, to the best of our knowledge, all relevant molecules are built around mononuclear building blocks coordinated by different types of organic ligand such as metallocenes, salens, dithiolenes or "nitrogen bridges" (terpyridines, bipyridines or porphyrins). These types of molecules are the most common in the literature because of their extraordinary ability to develop supramolecular structures.[1,6] However, the challenge remains to develop versatile and selective strategies with a view to creating new molecular designs and new bridging ligands.

Star-shaped molecules can lead to a strong enhancement of the physical properties — such as nonlinear optical susceptibilities[7,8] or electronic conductivities − in hyperbranched conjugated polymers.[9] Moreover, there is a large interest in conjugated oligomers for their intrinsic physical properties[10,11] as because they are model compounds for the study of the corresponding conductive polymers.[12] In this paper, we report the first example of dinuclear organometallic species in star-like conjugated molecules with sulfur connectivities of the type $[Ru_2(p\text{-}MeC_6H_4iPr)_2(p\text{-}SC_6H_4Br)_3]^+$ and $[Rh_2(C_5Me_5)_2(p\text{-}SC_6H_4Br)_3]^+$ and the increase of their conjugation length by Suzuki coupling reactions with oligophenylene boronic acids.

Results and Discussion

In accordance with our previous studies,[13] the dinuclear dichloro complexes $[Ru(p\text{-}MeC_6H_4iPr)Cl_2]_2$ and $[Rh(C_5Me_5)Cl_2]_2$ are found to react in ethanol with *p*-bromothiophenol to give the cationic complexes $[Ru_2(p\text{-}MeC_6H_4iPr)_2(p\text{-}SC_6H_4Br)_3]^+$ (**1**) and $[Rh_2(C_5Me_5)_2(p\text{-}SC_6H_4Br)_3]^+$ (**2**), respectively, which can be isolated in quantitative yield as the chloride salts (Scheme 1).



Scheme 1. Synthesis of star-like trisbromo complexes **1** and **2**

Both cations **1** and **2** are unambiguously characterized by their MS, IR, ^1H and ^{13}C NMR spectroscopic data as well as by satisfactory elemental analysis data of the chloride salts. These cationic complexes are readily soluble as their chloride salts in alcohols, acetone and chlorinated

solvents. Their molecular structures were confirmed by a single-crystal X-ray structure analysis of [**1**]Cl and [**2**]Cl. The cations were found to consist of a closed trigonal bipyramid M_2S_3 framework (M = Ru or Rh), with each ruthenium or rhodium atom being coordinated to an η^6-Me-C_6H_4*i*Pr or an η^5-C_5Me_5 ligand, respectively, and each sulfur atom carrying a *p*-bromophenyl group. The molecular structures of **1** and **2** are shown in Figure 1.

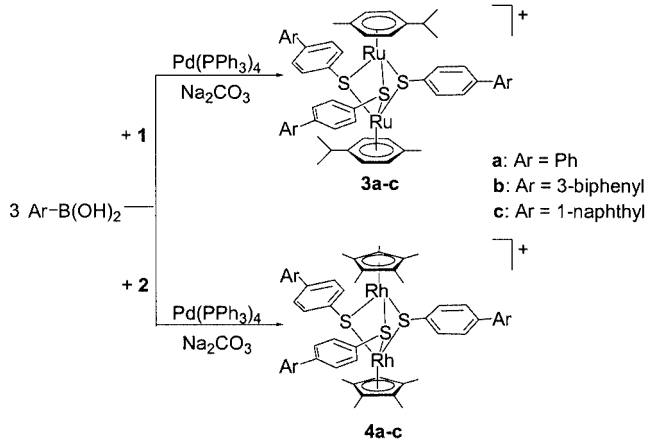
Figure 1. Molecular structure of [**1**]Cl and [**2**]Cl; the chloride ion, solvent molecules, and H atoms have been omitted for clarity; displacement ellipsoids are drawn at the 50% probability level; selected bond lengths (Å) and angles(°): [**1**]Cl Ru(1)−S(1) 2.392(2), Ru(1)−S(2) 2.4192(19), Ru(1)−S(3) 2.385(2), Ru(2)−S(1) 2.411(2), Ru(2)−S(2) 2.3989(19), Ru(2)−S(3) 2.402(2), Ru(1)−Ru(2) 3.3532(8); Ru(1)−S(1)−Ru(2) 88.56(7), Ru(1)−S(2)−Ru(2) 88.20(6), Ru(1)−S(3)−Ru(2) 88.92(8); [**2**]Cl Rh(1)−S(1) 2.3882(16), Rh(1)−S(2) 2.4145(17), Rh(1)−S(3) 2.3937(16), Rh(2)−S(1) 2.4112(17), Rh(2)−S(2) 2.3817(15), Rh(2)−S(3) 2.4059(16), Rh(1)−Rh(2) 3.2254(7); Rh(1)−S(1)−Rh(2) 84.45(5), Rh(1)−S(2)−Rh(2) 84.52(5), Rh(1)−S(3)−Rh(2) 84.44(5)

The bromo-ended star-shaped arrangement adopted by these complexes is very interesting as these compounds represent conductive organometallic nodes. The intramolecular charge transfer (ICT) between the organometallic moieties and the *p*-bromophenyl groups can be shown by the NMR spectroscopy. An important shielding of the arene (Cp* or *p*-MeC_6H_4*i*Pr) attached to the metal centers is observed in the NMR spectra, whereas a large deshielding of the signals of the *p*-bromophenyl groups is observed in the corresponding NMR spectra (see Exp. Sect.). This phenomenon is larger in the case of ruthenium-based complexes than in the rhodium derivatives. This is proof of the ICT between the *p*-bromophenyl group and the arene moieties through the sulfur bridges and the metal centers in cations **1** and **2**. The bromo sites at the periphery can lead to the insertion of original conductive nodes in the main chain of conjugated oligomers by organometallic cross-coupling Suzuki reactions[14] with appropriate boronic acid derivatives.

Cations **1** and **2** are found to react with boronic acids (a: phenylboronic acid; b: 3-biphenylboronic acid; c: 1-naphthylboronic acid) in ethanol with $Pd^0(PPh_3)_4$ as catalyst to give the star-shaped conjugated oligomers **3** and **4**, respectively, with yields ranging from 75 to 85% (See Scheme 2). We observed only the formation of the trisubstituted compounds.



Scheme 2. Synthesis of star-shaped conjugated complexes **3** and **4**

Cations **3** and **4** were characterized by their MS and spectroscopic data (IR, ^1H and ^{13}C NMR) as well as by satisfactory elemental analysis data of the chloride salts. These cationic complexes are very soluble in alcohols, acetone and chlorinated solvents but not in water. The molecular structure of **4a** was confirmed by a single-crystal X-ray structure analysis of the PF_6 salt. The cation maintains the closed trigonal bipyramid M_2S_3 framework of its precursor **2**, as shown in Figure 2.

Consequently, the insertion of star-shaped dinuclear organometallic nodes into the main chain of a conjugated polymer during their growth is possible via Suzuki cross coupling reactions. These cations can be considered as star-shaped conductive reticulating agents for conjugated oligomers or polymers like 1,3,5-tribromobenzene and its derivatives[9,15]

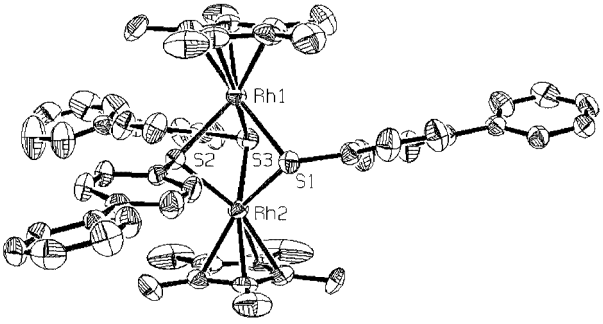


Figure 2. Molecular structure of [**4a**]PF_6; hexafluorophosphate, solvent molecules, and H atoms have been omitted for clarity; displacement ellipsoids are drawn at the 50% probability level; selected bond lengths (Å) and angles(°): Rh(1)−S(1) 2.4113(15), Rh(1)−S(2) 2.4006(15), Rh(1)−S(3) 2.4064(15), Rh(2)−S(1) 2.3835(14), Rh(2)−S(2) 2.3840(14), Rh(2)−S(3) 2.4121(17), Rh(1)−Rh(2) 3.2124(6); Rh(1)−S(1)−Rh(2) 84.13(5), Rh(1)−S(2)−Rh(2) 84.35(5), Rh(1)−S(3)−Rh(2) 83.63(5)

Conclusion

In conclusion, we report here the first synthesis of star-shaped dinuclear organometallic entities, based on a closed trigonal bipyramid M_2S_3 framework (M = Ru or Rh). We have demonstrated that these frameworks are conductive nodes that ensure the electronic connectivity of the *p*-bromophenyl group and the arene moieties through the three sulfur bridges and the two metal centers. Cations **1** and **2** react with oligophenylene boronic acid derivatives to give original star-shaped dinuclear organometallic complexes possessing three oligophenylene moieties. The electrochemical behavior, the electronic and optical properties of these conjugated star-shaped oligomers, as well as their insertion into the main chain of conductive polymers, are currently being investigated.

Experimental Section

General Remarks: All reactions were carried out under nitrogen, by using standard Schlenk techniques. Solvents were degassed prior to use. The dinuclear dichloro complexes $[Ru(p\text{-}MeC_6H_4iPr)Cl_2]_2$ and $[Rh(C_5Me_5)Cl_2]_2$ were synthesized by previously described methods.[16−18] All other reagents were purchased (Acros) and used as received. NMR spectra were recorded with a Varian Gemini 200 BB instrument and referenced to the signals of the residual protons in the deuterated solvents and TMS. The mass spectra were recorded at the University of Fribourg (Switzerland) by Prof. Titus Jenny. Microanalyses were carried out by the Laboratory of Pharmaceutical Chemistry, University of Geneva (Switzerland).

General Method for the Preparation of 1 and 2: The dinuclear dichloro complex $[Ru(p\text{-}MeC_6H_4iPr)Cl_2]_2$ (60 mg, 0.1 mmol) or $[Rh(C_5Me_5)Cl_2]_2$ (62 mg, 0.1 mmol) was refluxed in technical grade ethanol (25 mL). When the complex had completely dissolved, a solution of *p*-bromothiophenol (95 mg, 0.5 mmol) in 5 mL of ethanol was added dropwise to the hot solution. The resulting mixture was refluxed in ethanol for 3 hours. After cooling to 20 °C, the red solution was filtered through Celite, and the solvent was removed under reduced pressure. The oil obtained was purified by column chromatography (silica gel, dichloromethane/ethanol 5:1; r_f close to 0.8). Cations **1** and **2** were isolated in the form of their chloride salts, after evaporation of the solvent, as red-orange powders in quantitative yields.

$[Ru_2(p\text{-}Me\text{-}C_6H_4\text{-}iPr)_2(p\text{-}SC_6H_4Br)_3]^+$ (1): Yield: 107 mg; quantitative. ^{1}H NMR (200 MHz, $CDCl_3$, 21 °C): δ = 0.82 [d, $^3J_{H,H}$ = 7.0 Hz, 6 H, $(CH_3)_2CH$], 0.92 [d, $^3J_{H,H}$ = 7.0 Hz, 6 H, $(CH_3)_2CH$], 1.64 (s, 6 H, CH_3), 1.97 (sept, $^3J_{H,H}$ = 7.0 Hz, 2 H, $(CH_3)_2CH$), 5.23 (d, $^3J_{H,H}$ = 6.2 Hz, 2 H, C*H*-Ar), 5.26 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, C*H*-Ar), 5.32 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, C*H*-Ar), 5.60 (d, $^3J_{H,H}$= 6.2 Hz, 2 H, C*H*-Ar), 7.54 (d, $^3J_{H,H}$ = 8.8 Hz, 6 H, C*H*-Ar), 7.86 (d, $^3J_{H,H}$ = 8.8 Hz, 6 H, C*H*-Ar) ppm. ^{13}C NMR (50 MHz, $CDCl_3$, 21 °C): δ = 18.09 (*C*H_3), 22.12 [(*C*H_3)$_2$CH], 22.94 [(*C*H_3)$_2$CH], 30.00 [$(CH_3)_2CH$], 84.12 (Ru-*C*-Ar), 85.50 (Ru-*C*-Ar), 85.96 (Ru-*C*-Ar), 100.29 (Ru-*C*-Ar), 108.00 (Ru-*C*-Ar), 123.01 (*C*-Br), 132.60 (*C*-Ar), 134.61 (*C*-Ar), 137.16 (*C*-S) ppm. MS (ESI): *m*/*z* = 1036 [M^+]. $C_{38}H_{40}Br_3ClRu_2S_3$ (1070.23): calcd. C 42.65, H 3.77; found C 42.39, H 4.02.

$[Rh_2(C_5Me_5)_2(p\text{-}SC_6H_4Br)_3]^+$ (2): Yield: 107 mg; quantitative. ^{1}H NMR (200 MHz, $CDCl_3$, 21 °C): δ = 1.37 (s, 30 H, CH_3), 7.49 (d, $^3J_{H,H}$ = 8.4 Hz, 6 H, C*H*-Ar), 7.66 (d, $^3J_{H,H}$ = 8.4 Hz, 6 H, C*H*-Ar) ppm. ^{13}C NMR (50 MHz, $CDCl_3$, 21 °C): δ = 8.99 (*C*H_3), 98.51 (d, $^2J_{Rh,C}$ = 6.8 Hz; Rh-*C*-Ar), 123.74 (*C*-Br), 131.77 (*C*-Ar), 132.31 (*C*-Ar), 134.88 (*C*-S) ppm. MS (ESI): *m*/*z*: 1040 [M^+]. $C_{38}H_{42}Br_3ClRh_2S_3$ (1075.91): calcd. C 42.30, H 4.20; found C 42.18, H 4.33.

General Method for the Preparation of 3 and 4: The trisbromo dinuclear complex $[Ru_2(p\text{-}MeC_6H_4iPr)_2(p\text{-}SC_6H_4Br)_3]Cl$ (107 mg, 0.1 mmol) or $[Rh_2(C_5Me_5)_2(p\text{-}SC_6H_4Br)_3]Cl$ (108 mg, 0.1 mmol) and boronic acid derivatives C_6H_5-$B(OH)_2$ (**a**; 40 mg, 0.33 mmol), $C_{12}H_9$-$B(OH)_2$ (**b**; 65 mg, 0.33 mmol), and $C_{10}H_7$-$B(OH)_2$ (**c**; 57 mg, 0.33 mmol), were dissolved in technical grade ethanol. Then, an aqueous solution of Na_2CO_3 (1 mL, 2 N), and $Pd(PPh_3)_4$ catalyst (0.01 mmol, 11 mg) was added. The resulting mixture was refluxed in ethanol for 48 hours. After cooling to 20 °C, the red solution was filtered through Celite and the solvent was removed under reduced pressure. The oil obtained was purified by column chromatography (silica gel, dichloromethane/ethanol 10:1; r_f close to 0.8). Cations **3** and **4** were isolated in the form of their chloride salts, after evaporation of the solvent, as red-orange powders.

$[Ru_2(p\text{-}MeC_6H_4iPr)_2(p\text{-}SC_6H_4C_6H_5)_3]^+$ (3a): Yield: 90 mg; 85%. ^{1}H NMR (200 MHz, $CDCl_3$, 21 °C): δ = 0.81 [d, $^3J_{H,H}$ = 7.0 Hz, 6 H, $(CH_3)_2CH$], 0.92 [d, $^3J_{H,H}$ = 7.0 Hz, 6 H, $(CH_3)_2CH$], 1.70 (s, 6 H, CH_3), 2.03 (sept, $^3J_{H,H}$ = 7.0 Hz, 2 H, $(CH_3)_2CH$), 5.21 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, C*H*-Ar), 5.29 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, C*H*-Ar), 5.33 (d, $^3J_{H,H}$ = 5.9 Hz, 2 H, C*H*-Ar), 5.58 (d, $^3J_{H,H}$= 5.9 Hz, 2 H, C*H*-Ar), 7.40−7.54 (m, 9 H, C*H*-Ar), 7.68 (d, 12 H, $^3J_{H,H}$ = 8.4 Hz, C*H*-Ar), 8.05 (d, $^3J_{H,H}$ = 8.4 Hz, 6 H, C*H*-Ar) ppm. ^{13}C NMR (50 MHz, $CDCl_3$, 21 °C): δ = 18.14 (*C*H_3), 22.22 [(*C*H_3)$_2$CH], 22.90 [(*C*H_3)$_2$CH], 30.90 [$(CH_3)_2CH$], 84.14 (Ru-*C*-Ar), 85.08 (Ru-*C*-Ar), 85.58 (Ru-*C*-Ar), 85.66 (Ru-*C*-Ar), 100.31 (Ru-*C*-Ar), 107.55 (Ru-*C*-Ar), 127.19 (*C*-Ar), 127.91 (*C*-Ar), 129.28 (*C*-Ar), 133.43 (*C*-Ar), 137.24 (*C*-Ar), 140.04 (*C*-Ar), 141.31 (*C*-S) ppm. Nitric Oxide Reduction by Heme-Thiolate Enzymes (P450nor): A Reevaluation of the Mechanism

Radu Silaghi-Dumitrescu[a]

Keywords: Nitrogen oxides / Enzymes / Heme proteins / Density functional calculations / Bioinorganic chemistry

The details of the heme-thiolate nitric oxide reductase (P450nor) catalytic mechanism are still controversial. One theory, supported by computational results [D. L. Harris, *Int. J. Quantum Chem.* **2002**, *88*, 183–200], assumes two sequential one-electron transfers from NAD(P)H to an initial $[FeNO]^6$ complex. The $[FeNO]^8$ species thus formed would react with NO, eventually liberating the unstable $ONNO^{2-}$ anion (most probably in its protonated form), which decomposes to N_2O and water. However, more recent experimental results [A. Daiber et al., *J. Inorg. Biochem.* **2002**, *88*, 343–352] suggest the first committed step of the mechanism to be direct hydride transfer from NAD(P)H to $[FeNO]^6$, presumably resulting in an iron-bound HNO unit, $[Fe\text{-}(H)NO]^8$, that would be readily protonated to $[Fe\text{-}(H)NOH]^8$. Subsequent NO addition would yield the unstable HO-N(H)-N=O, which would dissociate from the heme and decompose to H_2O and N_2O. Here, the DFT geometry optimization of all previously proposed reaction intermediates is reported. The first step of the mechanism is predicted to be hydride transfer to $[FeNO]^6$, to produce $[FeNOH]^8$ or $[Fe\text{-}N(H)O]^8$. Subsequent addition of NO to $[Fe\text{-}NOH]^8$ (but not to $[Fe\text{-}N(H)O]^8$ or $[Fe\text{-}N(H)OH]^8$) is predicted to lead to immediate liberation of $HN_2O_2^-$, without any stable intermediates. Contrary to what would be predicted according to the "thiolate push effect" dogma, the *thiolate ligand at the heme active site is shown to obstruct NO reduction*, rather than facilitate it. It is in fact shown that replacement of the thiolate by a neutral nitrogen ligand (i.e., lysine, as found in the active site of cytochrome c nitrite reductase, an enzyme that can reduce NO) clearly favors, from a thermodynamic point of view, NO reduction at the heme site.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The active site of fungal nitric oxide reductases (enzymes that belong to the superfamily of cytochromes P450, and are commonly referred to as P450nor) consists of a solvent-exposed, cysteinate-ligated heme.[1,2] The widely accepted mechanism of P450nor[3–9] (Figure 1) involves binding of NO to the ferric form of the active site heme, followed by reduction of this $[FeNO]^6$ complex by NAD(P)H. Subsequent attack of a second molecule of NO leads to formation of a nitrogen-nitrogen bond and liberation of the very stable N_2O. Besides the starting $[FeNO]^6$ species, only one intermediate, absorbing at 444 nm, has been experimentally observed.[3]

The details of the P450nor mechanism, and in particular the identity of the 444 nm intermediate, are still controversial. One theory[5] (top half, Figure 1), supported by recent computational results,[9] assumes two sequential one-electron transfers from NAD(P)H to the initial $[FeNO]^6$ complex. The $[FeNO]^8$ species thus formed would constitute the 444-nm intermediate, and would react with NO, eventually liberating the unstable $ONNO^{2-}$ anion (most probably in its protonated form), which decomposes to N_2O and water. However, more recent experimental results[8] support a theory originally put forth by Averill,[11] suggesting the first committed step of the mechanism to be direct hydride transfer from NAD(P)H to the nitrogen atom of $[FeNO]^6$, resulting in an iron-bound HNO unit, $[Fe\text{-}(H)NO]^8$, that would undergo protonation to $[Fe\text{-}(H)NOH]^8$ (444-nm intermediate). Subsequent NO addition would yield the unstable HO-N(H)-N=O, which would dissociate from the heme and decompose to H_2O and N_2O. The present study reports DFT geometry optimization results on the putative reaction intermediates implied by the P450nor mechanisms proposed so far. These results not only provide a reasonable account of the P450nor mechanism, but also provide a basis for better understanding key notions in hemoproteins, such as "the thiolate push effect". Implications for other nitric oxide-reducing proteins (such as cytochrome c nitrite reductase) are also noted.

Results and Discussion

Geometry optimization results are shown in Table 1 and Table 2. Some of the models ($[FeNO]^{6,7,8}$) have already been

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

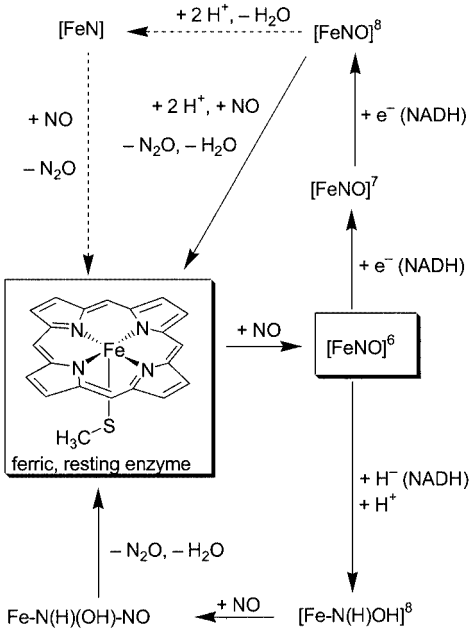

Figure 1. The two previously proposed mechanisms for P450nor (top half: supported by calculations,[9] bottom half: supported by experimental data[10]); species unambiguously known to be involved in the catalytic cycle are highlighted; species in the top and bottom right corners, respectively, have been proposed to constitute the experimentally-observed 444-nm intermediate;[9,10] an alternative pathway, based on partial DFT results, is marked with dashed arrows;[9] the Enemark−Feltham notation is used for iron-nitrosyl species $[FeNO]^n$, as well as for their protonated counterparts such as $[Fe\text{-}(H)NOH]^n$ (with the hydrogens counted as protons when summing up the electrons, "*n*", in the Enemark−Feltham formalism)

characterized elsewhere,[4,6,9,12] and are therefore not discussed in any detail here. It should be noted, however, that the predicted optimum geometries and spin states are in agreement with previously published data. Results on small molecules (i.e., NO, HNO, N_2O, H_2O, etc.), that would be useful as references when discussing overall energetics of the mechanism, are supplied as Supporting Information (see footnote on the first page of this article).

Regarding the first committed step of the P450nor mechanism, reduction of the $[FeNO]^6$ complex by NADH, two theories have been put forward to date.[9,11] Previous DFT results[9] have been used to support the idea that two electrons would be sequentially delivered to the active-site $[FeNO]^6$ complex by NADH in an outer-sphere mechanism, to generate $[FeNO]^8$ (which would be the experimentally observed 444-nm intermediate). According to this hypothesis, any one-electron reducing agent with a redox potential equal to or lower than that of NADH should yield the same $[FeNO]^8$ intermediate upon reaction with the $[FeNO]^6$ at the P450nor active site. Yet, this is known not to be the case: dithionite (redox potential lower than that of NADH by about 100 mV) can only reduce the active site $[FeNO]^6$ to $[FeNO]^7$.[3] Daiber et al.[8] have pointed out this shortcoming of the one-electron theory, and have instead shown kinetic isotope effects, using deuterium-substituted NADH, thereby concluding that hydride transfer from NADH to the nitrogen atom of $[FeNO]^6$ is the key step of the mechanism. The 444-nm intermediate would thus be $[Fe\text{-}N(H)OH]^8$, with the second proton provided by solvent and/or the protein matrix. These authors[8] were also able to generate the 444-nm intermediate by chemical reduction of $[FeNO]^6$ with borohydride, or by addition of pulse radiolysis-generated $NHOH^{\cdot}$ radicals to the ferric (resting) form of the active site heme. However, no evidence exists so far as to why a strong reducing agent like dithionite is not able to generate a $[FeNO]^8$ (protonated or not) species at the P450nor active site.

The energies listed in Table 1 suggest that a mechanism implying two sequential one-electron transfer steps for the reduction of $[FeNO]^6$ to $[FeNO]^7$ to $[FeNO]^8$ would be energetically unfeasible. That is, a $[FeNO]^7$ species would be generated as an intermediate, that is more than 200 kJ/mol more stable than the end-product $[FeNO]^8$, and some 150 kJ/mol more stable than $[FeNO]^6$. Thus, with one-electron reducing agents (such as dithionite) the P450nor site remains trapped in a $[FeNO]^7$ form that is too stable to be catalytically useful. By contrast, with a two-electron donor, such as NADH, reduction proceeds from $[FeNO]^6$ *directly*

Table 1. Results (energies in kJ/mol, distances in Å) for relevant P450nor models

Model	Energy	Fe−S	Fe−N	N−O	N−N	N−H/O−H	Fe−N−O
$[FeNO]^6$, $S = 0$	−7404902	2.30	1.67	1.18	–	–	163°[a]

to the (protonated or not) $[FeNO]^8$ stage. This observation also identifies the reason why the P450nor active site is solvent-exposed and allows NADH access to the heme,[2] unlike in any other member of the P450 protein[13] family. Thus, all other members of the P450 protein family have a heme active site buried inside the protein, and electrons are supplied to this heme by NADH in an indirect, outer-sphere, long-range manner, via flavin moieties, *in two sequential one-electron steps*.[13] Unlike P450nor, these other P450 proteins do not exhibit any nitric oxide reductase activity. Thus, the ability to perform the two-electron oxidation of NO at a heme-thiolate active site seems to depend on the possibility of performing the two-electron reduction *in a single step*.

Cytochrome c nitrite reductase (ccNirR) contains a heme at the active site, which can reduce NO to ammonia (with NO being, in fact, an intermediate product of nitrite reduction).[10] The electrons for this reduction are supplied by five neighboring heme units within the protein. Nitric oxide reduction by ccNiR may be deemed as unexpected, since no hydride donor appears to be required and the active site heme is actually not ligated by a thiolate, but by a lysine side-chain. Indeed, thiolate ligands are commonly believed to exert a certain "thiolate push effect" that would enable heme actives site to accomplish key reactions such as dioxygen activation or NO reduction. How can ccNiR perform the same chemistry as P450nor in the absence of a hydride donor *and* of a thiolate ligand? A simple answer is provided by calculations (cf. Table 3) on $[FeNO]^{6,7,8}$ models where the thiolate ligand was replaced by a methylamine unit to mimmick the ccNiR active-site heme. Unlike in P450nor, the ccNiR $[FeNO]^8$ complex is predicted to be more stable

than Fe[NO]^7. We propose this to be the reason why in ccNiR there is no need for a two-electron (hydride) donor. As shown in Table 3, the same situation as in the ccNiR models occurs if the axial ligand trans to NO is omitted altogether. A general observation may then be that nitrogenous heme axial ligands (such as lysine, and, most likely, histidine) favor easier reduction of NO (*thermodynamically speaking*) than anionic ligands such as thiolate. This raises an intriguing question: could the same type of argument ("thiolate obstruction") hold true for other heme enzymes, such as oxygen-activating (heme-thiolate) and oxygen-binding (heme-histidine) enzymes? The data in Table 1−4 clearly confirm that the "thiolate push effect" is a reality in the [FeNO]^{6,7,8} systems examined here. Indeed, in thiolate-ligated systems the electron density on the NO moiety is consistently higher (both charge-wise and spin-wise) than in their non-thiolate counterparts (Table 4). Nevertheless, the differences are not large enough (especially at the level of Fe−N and N−O distances) to warrant the assumption that this "push effect" significantly weakens the respective bonds to the extent that they would be easier to cleave.

With the one-electron theory now ruled out in P450nor by both DFT and experimental results, it follows that the first committed step in the P450nor mechanism can only be hydride transfer from NADH to [FeNO]^6, yielding [FeN(H)O]^8. Table 1 shows that the [Fe-N(H)O]^8 isomer is in fact more stable than its oxygen-protonated counterpart [FeNOH]^8. It is entirely conceivable that an [Fe-N(H)O]^8 species undergoes further protonation to [Fe-N(H)OH]^8 (presumably as a concerted process upon hydride addition), and Table 1 shows that such protonation would result in significant energetical stabilization. The active site has previously been shown to contain appropriate proton donors.[6] Thus, at this stage the Daiber mechanism has the full support of computational results, in that the [Fe-N(H)OH]^8 species appears the most likely candidate for the 444-nm intermediate.

The next step in the mechanism would then be addition of a second molecule of NO to the [Fe-N(H)OH]^8 intermediate, to form a nitrogen-nitrogen bond. Regardless of the exact mechanism of this step (see ref.[8]), this Fe-N(H)(OH)-NO complex would then decay to yield ferric heme, N_2O and H_2O, a process likely to occur by internal rearrangements of the $H_2N_2O_2$ moiety. Indeed, we found that geometry optimization of a putative $S = 5/2$ Fe-N(H)(OH)-NO model resulted in "cleavage" of the Fe−N bond, without an apparent energy barrier, leading to liberation of H_2N_2O. However, for $S = 1/2$ and $S = 3/2$ states of the same model, the Fe−N bond remained unperturbed and the N−N bond was "broken". Thus, Fe-N(H)(OH)-NO should not be conceived as a reaction intermediate, but rather as a transition state, with the observation that a spin crossover ($S = 1/2$ to $S = 5/2$) must occur in order for the interaction of the $S = 0$ [FeNHOH]^8 with $S = 1/2$ NO to be productive. However, for Fe-N(H)(OH)-NO models, $S = 1/2$ and $S = 3/2$ potential energy surfaces were more than 100 kJ/mol below $S = 5/2$, suggesting that, should the $S = 5/2$ pathway ever be active, it would have to be due to assistance from the protein matrix and/or solvent.[14] By contrast, if one assumes the 444-nm intermediate to be [FeNOH]^8 or even [FeNO]^8, addition of a second molecule of NO would result in formation of a strong nitrogen-nitrogen bond (cf. Table 1) and a significant weakening of the Fe−N bond, so that liberation of $HN_2O_2^-$ or (with further assistance from the protein) $H_2N_2O_2$, are entirely feasible reaction pathways. We note that in models where iron-nitrogen *and* nitrogen-nitrogen bonds exist, both electrons originating from NAD(P)H are located on the newly formed $N_2O_2H_x$ ($x = 1,2$) moiety, which is only loosely coordinated to Fe and is therefore likely to be readily displaced by solvent. Finally, it should be noted that attempts to dock an NADH molecule onto the P450nor active site using the Dock module of the Sybyl software package have consistently yielded conformations that would be appropriate for hydride transfer towards the oxygen — but not nitrogen — atom of the [FeNO]^6 unit. Thus, the above results suggest that [Fe-NOH]^8 and not its N-protonated versions is the productive intermediate that reacts with the second NO molecule. This conflict between theory and the Averill/Daiber mechanism may conceivably be solved by invoking active-site dynamics and solvation, which would then provide the extra energy required for the spin transition in the {[FeN(H)OH]^8-NO} system, to render the [FeN(H)OH]^8 + NO interaction productive.

Conclusion

A detailed account of the P450nor mechanism has been provided via geometry optimization of all possible reaction intermediates. The experimentally observed 444-nm intermediate is proposed to be a [FeNOH]^8 species, with [FeN(H)O]^8 or [FeN(H)OH]^8 not entirely ruled out as productive intermediates for reacting with the second NO molecule. Contrary to what would be predicted according to the "thiolate push" dogma, the *thiolate ligand in P450nor is shown to obstruct NO reduction*, rather than facilitate it. It is in fact shown that replacement of the thiolate with a neutral nitrogenous ligand (i.e., lysine, as found in the active site of cytochrome c nitrite reductase, an enzyme that can reduce NO) clearly facilitates (from a thermodynamic point of view) NO reduction at the heme site.

Experimental Section

Geometries of all models were optimized in the Spartan 02 (Windows)[15] package at the University of Georgia, on a Windows 2000-operated Pentium 4 PC (1.7 GHz, 1024 MB RAM). The UBP86 functional, which uses the gradient-corrected exchange functional proposed by Becke (1988) and the correlation functional by Perdew (1986), and the 6-31G** basis set were used as implemented in Spartan.[15] For the SCF calculations, a fine grid was used and the convergence criteria were set to 10^{-6} (for the root-mean square of electron density) and 10^{-8} (energy). For geometry optimization, convergence criteria were set to 0.001 au (maximum gradient criterion) and 0.0003 (maximum displacement criterion). Reported charges and spin densities were derived from NBO popu-

lation analyses. Energy differences between models of different sizes are fairly large, and therefore overall trends and relative energies are unlikely to be modified upon applying theoretically sophisticated and time-consuming corrections such as BSSE. Such corrections were therefore omitted from the present work.

All models were subjected to full geometry optimization, without any geometry or symmetry constraints. All models reported in Table 1 and 2 consisted of an unsubstituted heme coordinated axially by a methylthiolate unit (i.e., the species named "ferric, resting enzyme" in Figure 1), while the sixth coordination position was occupied by various ligands (see Table 1). All results reported in Table 1 for $[FeNO]^{6,7,8}$ models were obtained for end-on (monodentate) coordination, since $[FeNO]^6$ and $[FeNO]^7$ have already been characterized experimentally as being end-on complexes; a detailed theoretical treatment of $[FeNO]^{6,7,8}$ can be found elsewhere.[9] Attempts to model $[FeNO]^8$ as *bidentate* led to a *monodentate* geometry for the $S = 0$ state, and to a true bidentate geometry for $S = 1$ (details of this bidentate geometry are only listed as Supplementary Information; its energy was significantly higher than that of its monodentate isomer). Models reported in Table 3 and 4 consisted of an unsubstituted heme-coordinated NO, while the other axial coordination position was either empty, or occupied by a methylamine unit (see Table 2). Low-spin states ($S = 0$, 1/2) were chosen, for reasons detailed in ref.[10]

Synthesis, Crystal and Electronic Structure of $[Hg_7As_4](AgI_3)_2$, a Novel Supramolecular Complex with the Off-Plane AgI_3^{2-} Guest Anion

Andrei V. Olenev,[a] Alexei I. Baranov,[b] Olga S. Oleneva,[a] Ivan I. Vorontsov,[c] Mikhail Yu. Antipin,[c] and Andrei V. Shevelkov*[a]

Keywords: Supramolecular chemistry / Inorganic chemistry / Mercury / Silver / Host-guest interactions

A novel supramolecular inorganic complex $[Hg_7As_4](AgI_3)_2$ has been prepared and its crystal structure determined. It crystallizes in the cubic system (space group $Pa\bar{3}$) with the unit cell parameter a = 13.138(1) Å and Z = 4. The crystal structure comprises a three-dimensional positively charged host framework $[Hg_7As_4]^{4+}$ with AgI_3^{2-} guest anions trapped in each cavity of the framework. The guest anion shows an unusual off-plane geometry (C_{3v} symmetry), with a large, anisotropic thermal displacement parameter for the silver atom, which lowers significantly upon cooling from 293 down to 120 K. A study of the electronic structure shows that, although the host-guest interaction is weak and diffuse, it governs both the geometry of the guest anion and its positioning within the framework cavities.

Introduction

Supramolecular architectures with three-dimensional (3D) host frameworks possess a huge variety of crystal structures. A number of supramolecular complexes in which the positively charged 3D host substructures are built from linear mercury and tetrahedral pnicogen atoms have been reported over the past few years.[1−4] The combination of linear and tetrahedral units in the host substructure, together with the possibility of forming homonuclear bonds, provides a rich structural diversity of such complexes. Indeed, the crystal chemistry of the compounds under consideration ranges from phosphorus and arsenic analogues of the Millon phases[1] to a group of symmetric complexes with $[Hg_6Z_4]^{4+}$ host frameworks.[2] The positive charge of the host framework in these compounds is compensated by the halometallate anions of different shape and size that reside in the host framework cavities. Due to large separations between the host and guest moieties their interactions are limited to weak electrostatic forces.

It is well known that the guest moieties usually serve as templates during the formation of supramolecular complexes.[5] Host frameworks, in turn, may influence the geometry of the guests. Hence, the formation of a supramolecular architecture is often achieved by a mutual adjustment of the host and guest substructures. Examples of such an adjustment were shown in our previous work where we reported a family of new supramolecular complexes[4] in which the SnX_3^- (X = Cl, Br, I) guests are encapsulated in the cavities of the Hg−Z (Z = P, As, Sb) host framework. Evidently, the formation of a supramolecular complex is facilitated by a certain "crystallographic flexibility" of the guest, or, in general, by the possibility that the atoms of the guest moiety have different coordination (and oxidation) numbers. For silver, for example, the generic formula of the halometallate anions can be written as $AgX_n^{(n-1)-}$ ($2 \leq n \leq 4$; X = Cl, Br, I). Examining the possibility of the formation of supramolecular assemblies with $AgX_n^{(n-1)-}$ guest anions, we unexpectedly discovered a novel complex $[Hg_7As_4](AgI_3)_2$ in which an unusual off-plane AgI_3^{2-}anion resides in the cavities of a Hg−As cationic framework.

Here we report on the synthesis and crystal structure of $[Hg_7As_4](AgI_3)_2$. The host-guest interactions in the title compound, which lead to the observed off-plane geometry of the guest AgI_3^{2-} anion, are also discussed on the basis of the ab initio molecular structure and extended Hückel band-structure calculations.

Results

$[Hg_7As_4](AgI_3)_2$ was prepared from a stoichiometric mixture of mercury(II) iodide, arsenic, silver powder, and liquid mercury by a two-step ampoule synthesis (see Exp. Sect. for details). The sample formed as a dark-brown polycrystalline powder. The compound is air- and moisture-stable, and it melts incongruently at 675 K.

For the structure investigation a suitable single crystal was selected from a sample prepared from a nonstoichiometric mixture of starting reagents as described in the Exp. Sect. The crystal structure of the new compound was determined by single-crystal X-ray diffraction methods at ambient temperature (Table 3). Analysis of the systematic absences in the data set revealed one possible space group $Pa\bar{3}$ (no. 205). The positions of the mercury, iodine, arsenic, and silver atoms were localized by direct methods (SHELXS 97[6]). It should be noted that the electron-density peak assigned to the silver atom position was the lowest one. Refinement of the crystal structure (SHELXL 97[6]) showed that the silver atom has a large thermal displacement parameter. Nevertheless, the refinement of the occupancy of the silver atom position confirmed this position to be fully occupied. Final anisotropic refinement led to quite acceptable R values ($R1 = 3.9\%$ $wR2 = 8.4\%$). However, it also revealed that the silver atom has a strongly prolate thermal ellipsoid, which could possibly indicate that the silver position is split. In order to check if this was the case, a low-temperature (120 K) X-ray structure investigation was carried out. The analysis of the diffraction frames showed the absence of superstructural reflections and confirmed the space group to be the same as that determined during the ambient-temperature diffraction experiment. The crystal structure was successfully refined ($R1 = 4.2\%$, $wR2 = 9.1\%$) with the atomic positions determined in the room-temperature experiment (Table 1). The thermal displacement parameters of all atoms, and especially of the silver atom (Table 1), lowered significantly. No electron-density peaks were observed near the position of the silver atom, which could be assigned to the split position of the silver.

Table 1. Atomic positions for $[Hg_7As_4](AgI_3)_2$ at 293 K and equivalent displacement parameters for the compound at 293 and 120 K

Atom	Wykoff	*x/a*	*y/b*	*z/c*	U_{eq} [Å^2][a] 293 K	120 K
Hg(1)	24d	0.2122(1)	0.4165(1)	0.4521(1)	0.0341(3)	0.0159(2)

[a] U_{eq} is defined as one third of the trace of the orthogonalized U_{ij} *tensor.*

Atomic parameters and selected interatomic distances and bond angles for $[Hg_7As_4](AgI_3)_2$ are listed in Tables 1 and 2, respectively. The crystal structure of the title compound (Figure 1) is composed of a positively charged $[Hg_7As_4]^{4+}$ host framework and AgI_3^{2-} guest anions encapsulated in the closed cavities of the host. The guest and host moieties are not connected by covalent bonds [d_{min}(Hg−I) = 3.31 Å], which is typical for supramolecular assemblies.

The host framework (Figure 1) is built from nearly linear-coordinated mercury and tetrahedrally coordinated arsenic

Table 2. Selected interatomic distances and bond angles for $[Hg_7As_4](AgI_3)_2$ at 293 K

Distances [Å]	
As(1)−As(1)	2.405(6)
As(1)−Hg(1)	2.510(1) ×3
As(2)−Hg(1)	2.500(1) ×3
As(2)−Hg(2)	2.497(3)
Ag−I	2.711(1) ×3
Hg(1)−I	3.307(1)

Hg(1)−I	3.573(1)
Hg(1)−I	3.575(1)
Angles [°]	
Hg(1)−As(1)−Hg(1)	113.00(6) ×3
As(1)−As(1)−Hg(1)	105.66(7) ×3
Hg(2)−As(2)−Hg(1)	105.84(7) ×3
Hg(1)−As(2)−Hg(1)	112.85(6) ×3
As(2)−Hg(1)−As(1)	166.94(9)
As(2)−Hg(2)−As(2)	180.00(6)
I−Ag−I	117.53(7) ×3

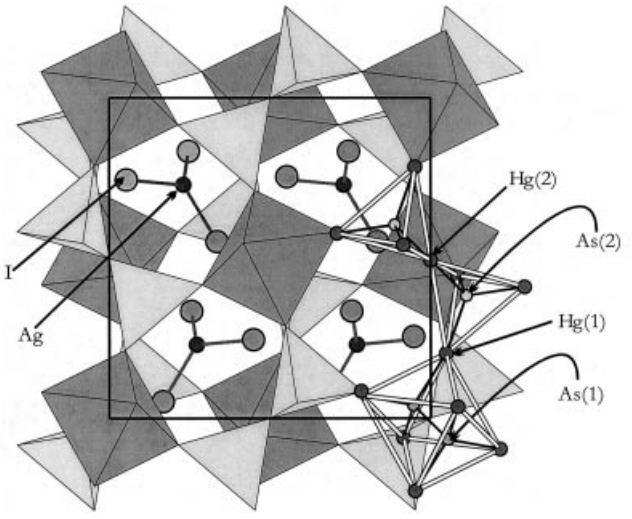

Figure 1. A view of the crystal structure of $[Hg_7As_4](AgI_3)_2$

atoms. There are two positions of the mercury atoms, Hg(1) and Hg(2), each of which is surrounded by two arsenic atoms. The additional neighbors of the Hg(2) atom lie 3.95 Å apart from it, and the As−Hg(2)−As angle appears to be 180°. In contrast with that, four iodine atoms of the guest anion serve as distant neighbors for the Hg(1) atom, the Hg−I separations being 3.31−3.56 Å. Thus, four iodine atoms of the guest complete the coordination sphere of the Hg(1) atom as a distorted octahedron, and, as a result, the As−Hg(1)−As angle (166.9°) departs from the ideal linear value.

The nearest neighbors of two crystallographically independent arsenic atoms are different (Figure 1). The As(1) atoms are joined into As_2^{4-} dumbbells and each As(1) atom is connected to one arsenic and three Hg(1) atoms. Six Hg(1) atoms surround the As(1)−As(1) dumbbell forming

an $Hg(1)_6As(1)_2$ octahedral building block. The As(2) atom has a tetrahedral arrangement of three Hg(1) and one Hg(2) atom. Two $As(2)Hg(1)_3Hg(2)$ tetrahedra share a common Hg(2) vertex forming an Hg_7As_2 bitetrahedral group. The Hg_7As_2 and Hg_6As_2 building blocks all share the Hg(1) vertices to form a 3D $[Hg_7As_4]^{4+}$ host framework. The As−As (2.41 Å) and As−Hg (2.50−2.51 Å) distances within the framework are in good agreement with the values found in the literature for numerous mercury pnictide halides.[1−4]

The $[Hg_7As_4]^{4+}$ host framework has eight cavities of equal size per unit cell. To compensate for the positive charge of the host, the AgI_3^{2-} guest anions occupy each cavity. The guest anion departs significantly from the expected configuration, which would be a regular triangle with an in-plane silver atom (D_{3h} symmetry). All the Ag−I separations in the anion are the same (2.71 Å), while the I−Ag−I angle (117.5°) indicates that the silver atom does not reside in the plane of three iodine atoms. It lies 0.41 Å apart from the ligand plane, therefore the actual symmetry of the guest anion is C_{3v}.

The equilibrium geometry of the AgI_3^{2-} anion was calculated at different levels of theory (RHF and DFT). All calculations exploiting different basis sets and correlation potentials resulted in the expected planar triangle geometry (D_{3h} symmetry), with the Ag−I distances ranging from 2.93 to 3.01 Å depending on the type of calculation. Then, the positions of the three iodine atoms were frozen according to their positions in the crystal structure, while the position of the silver atom was optimized. Such calculations at the RHF level with the MP2 correction resulted in the C_{3v} geometry of the anion with an off-plane shift of the silver atom of 0.36 Å and three equidistant Ag−I contacts of 2.69 Å.

The band-structure calculations (at the EH level, Figure 2) showed that the bands below the Fermi level are composed of p-orbitals of I and As, s-orbitals of Hg, and d-orbitals of Ag. Analysis of the overlap population revealed the existence of strong covalent Hg−As and As−As bonding within the host framework and Ag−I bonding in the guest anion, whereas the host-guest Hg−I interaction is weak. A detailed analysis of the molecular orbitals of the AgI_3^{2-} anion revealed two sets of MOs corresponding to the Ag−I interaction, d(Ag)−p(I) bonding (between −14.5 and −12.3 eV) and d(Ag)−p(I) antibonding (between −12.3 eV and E_F). Both sets contain σ- and π-orbitals whose energies are only slightly sensitive to the small deviation of the anion geometry from D_{3h} towards C_{3v} symmetry.

Discussion

The structure of the host framework of the title complex is similar to the structure of the hosts found in two earlier reported supramolecular architectures $[Hg_7As_4I_3]SnI_3$ and $[Hg_7P_4Br_3]SnBr_3$.[4] The main building blocks of the host frameworks of these two complexes are Hg_6Z_2 octahedra and Hg_7Z_2 bitetrahedal groups, their connection being the same as in the title compound. The main difference is that in the tin-containing complexes additional halogen atoms lie quite close to the mercury atoms thus modifying the host frameworks. The formulae of such frameworks can be written as $[Hg_7As_4I_3]^+$ and $[Hg_7P_4Br_3]^+$, respectively. They have two cavities of different size per formula unit and one guest anion − SnI_3^- or $SnBr_3^-$ − per formula unit is enough to compensate for the positive charge of the host framework These guest anions reside only in the larger cavities of the framework. In $[Hg_7As_4](AgI_3)_2$ the formal charge of the framework is +4, and all cavities in it have the same size. The electroneutrality of the complex is achieved by encapsulating the AgI_3^{2-} in each cavity of the host.

As was already mentioned, the geometry of the AgI_3^{2-} anion deviates considerably from the expected D_{3h} triangle. It is reasonable to compare the observed configuration of the guest anion with the geometry of AgX_3^{2-} (X = Cl, Br, I) anions in the literature. Analysis of the literature data surprisingly shows that there are only a small number of structurally characterized complexes that contain AgX_3^{2-}anions. The $AgCl_3^{2-}$ and $AgBr_3^{2-}$ anions have been isolated as their (dibenzo-18-crown-6)potassium and -rubidium salts.[7] In these two compounds the AgX_3^{2-} anions are regular (D_{3h} symmetry).

To the best of our knowledge there is only one known complex − $[PPh_3Me]_2[AgI_3]$[8] − that contains discrete AgI_3^{2-} anions. The triangular AgI_3^{2-} anion in it is reported to be only slightly distorted. The distance between the Ag atom and the ligand plane is only 0.04 Å. However, all three Ag−I distances in it are not equal and lie in the range 2.74−2.76 Å, thus lowering the symmetry of the anion from D_{3h} to effectively C_s.

The silver atom in the guest anion has a large thermal vibration amplitude in the direction perpendicular to the ligand plane. This indicate that the compound might undergo phase transformation (decomposition) at a relatively low temperature, or that the silver atom is distributed over two close crystallographic positions. However, neither the first nor the second supposition was proved to be the case.

The complex under investigation is stable up to 675 K, and the low-temperature X-ray diffraction experiment, as mentioned previously, unambiguously confirmed that the position of the silver atom is not split.

The off-plane construction of the AgI_3^{2-} guest anion, as well as the large thermal displacement parameter of the silver atom, deserve more discussion. It is clear from the results of the electronic structure calculations that the interaction of the host framework and guest anions is not strong and is predominantly of an electrostatic nature. Although the orbitals of As, Hg, Ag, and I apparently mix in the region below the Fermi level (from −10.8 to −14.5 eV), the overlap population analysis indicates that the Hg−I orbital interaction, which is responsible for the host-guest bonding, is weak and diffuse (Figure 2). On the contrary, bonding within the host and guest moieties is strongly covalent, and, consequently, the title compound can be formulated as pseudo-ionic: $[Hg_7As_4^{4+}](AgI_3^{2-})_2$. Each AgI_3^{2-} guest anion experiences the influence of 12 positively charged Hg(1) atoms of the host framework through distant Hg−I contacts (Figure 3). The Hg−I separations lying in the range of 3.31−3.58 Å are typical for a "secondary" Hg−I interaction. Analysis of the literature data[9] shows that the Hg−I separations in the 2+4 pseudo-octahedral array of mercury fall into two ranges: 2.62−2.64 Å for two collinear covalent Hg−I bonds, and 3.37−3.51 Å for four distant contacts. It is plausible to conclude that the positions of the iodine atoms in the title complex are governed by the arrangement of the positively charged mercury atoms of the rigid covalent framework. This leaves a limited space for the silver atom, forcing the latter to move from the ideal position at the center of the iodine triangle along its threefold axis. It should be noted that the observed 0.41 Å off-plane shift of Ag and the Ag−I distances of 2.72 Å are in very good agreement with the values calculated using a model with frozen iodine positions. Thus, the increase of the host anion energy due to the off-plane displacement of Ag is compensated for by the decrease of the energy of interaction between the host framework and the distorted AgI_3^{2-} guest anion. Furthermore, the off-plane shift of Ag is favored by an absence of neighbors along the threefold axis, the nearest, As(2), lying 3.66 Å apart. The absence of near neighbors in the direction of the threefold axis can also explain the large amplitude of the thermal vibrations along this axis, which lowers upon cooling (Figure 4).

Experimental Section

Synthesis: A stoichiometric mixture of mercury(II) iodide, arsenic, silver powder, and liquid mercury (all > 99.99%; 0.5 g) was heated for 2 d at 775 K in a vacuum-sealed silica tube. Then, the ampoule was cooled down to 575 K and heated for further 2 d. A comparison of the diffraction pattern of the sample [STADI-P (STOE), Cu-$K_{\alpha 1}$ radiation] with the theoretical pattern calculated on the basis of the data obtained during the structure refinement revealed that the sample was almost phase-pure and had only a slight admixture of arsenic and Hg_2I_2.

Crystal Growth: Single crystals of the title compound were obtained by annealing a mixture of starting materials (3:4:2:3 molar ratio, total weight approx. 0.5 g) in a vacuum-sealed silica tube (60 mm length, 6 mm inner diameter) for 5 d at 675 K, and then cooling it down to ambient temperature at a rate of 30 K/h.

Crystal Structure Determination: For the ambient temperature experiment, a suitable single crystal of the reported compound was mounted on a CAD-4 (Nonius) goniometer head. The cubic unit-cell parameter was refined based on 24 well-centered reflections. The data collection parameters are listed in Table 3. A semiempirical absorption correction was introduced based on azimuthal scans of six reflections with χ angles close to 90°. The structure was solved by direct methods (SHELXS-97)[6] and refined anisotropically by a full-matrix least-squares method on F^2 (SHELXL-97)[6] to $R_1 = 0.0393$ and $wR_2 = 0.0839$. Final $\Delta\rho(xyz)$ synthesis revealed no chemically significant electron-density peaks. For the low-temperature structural investigations on the same single crystal, a data set was collected with a Bruker SMART 1000 CCD diffractometer at 120 K (Table 3). The absorption correction was applied by a standard routine (SADABS[10]). The crystal structure was refined (SHELXL-97,[6] anisotropic full-matrix least-squares

refinement on F^2, $R1 = 0.0419$, $wR2 = 0.0905$) using the starting atomic positions determined in the previous experiment. Further details of the crystal structure determination may be obtained from Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-391131 and -391132.

Thermal Properties: A small quartz ampoule was completely filled with compound (approx. 0.2 g). The ampoule was evacuated and sealed. The differential thermal analysis curve was recorded with a modified PRT-1000m device at a 10 °C/min heating/cooling rate.

Calculational Details

Band Structure Calculations: Extended Hückel calculations of the band structure were performed with the YAeHMOP[11] program package utilizing the built-in atomic parameters. A mesh of 41 k-points taken within the irreducible wedge of the Brillouin zone was used.

Molecular Calculations: RHF (including MP2[12] correlation correction) and DFT (BLYP, VWN, and B3LYP[13] exchange-correlation potentials) calculations were performed using the GAMESS-US[14] program. The SBKJC effective core potentials were applied to all atoms and the SBKJC basis set[15] implemented in GAMESS was used. The starting geometry of the AgI_3^{2-} anion was taken from the crystal structure refinement. Geometry optimizations were performed by the quasi-Newton algorithm implemented in GAMESS.

Structural Investigation of the Thermal Decomposition of Ammonium Heptamolybdate by in situ XAFS and XRD

Julia Wienold,[a] Rolf E. Jentoft,[a] and Thorsten Ressler*[a]

Keywords: X-ray absorption spectroscopy / X-ray diffraction / Molybdenum / Polyoxometalates

The decomposition of ammonium heptamolybdate (AHM, $(NH_4)_6Mo_7O_{24}\times4H_2O$) was studied in situ by X-ray diffraction and X-ray absorption spectroscopy, as well as by thermal analysis (TG/DTA). Decomposition conditions such as reactant atmospheres, (20% oxygen, 5% propene, 5% hydrogen, pure helium, and static air), heating rates, and gas flow rates were varied to investigate their influence on the decomposition process. The results obtained show that the reaction pathway is affected by the partial pressures of the gas-phase decomposition products. The partial pressures of the decomposition products, water and ammonia, at a given temperature, is influenced mainly by the reactant gas flow rate and the heating rate. Lowering the partial pressures of ammonia and water inhibits the crystallization of the intermediate ammonium tetramolybdate (ATM), and promotes the formation of the intermediate hexagonal MoO_3. The decomposition pathway under low gas phase product partial pressure is: (i) AHM; (ii) (ca. 335 K) X-ray amorphous phase; (iii) (ca. 520 K) hexagonal MoO_3; (iv) (ca. 650 K) the products, which depend on the reactant atmosphere, are mixtures of highly disordered Mo_4O_{11}, and/or α-MoO_3. Under different conditions the decomposition pathway is: (i) AHM; (ii) (ca. 350 K) X-ray amorphous phase; (iii) (ca. 470 K) ATM; (iv) (ca. 570 K) hexagonal MoO_3 + α-MoO_3; (ca. 650 K) α-MoO_3. Under a hydrogen containing atmosphere, a peculiar decomposition pathway is observed: an intermediate MoO_3 with an unusual texture is formed prior to the reduction to MoO_2 and the consecutive formation of orthorhombic Mo_4O_{11}.

Introduction

Numerous authors have investigated the thermal decomposition of ammonium heptamolybdate tetrahydrate [$(NH_4)_6Mo_7O_{24}\times4H_2O$, AHM] using several techniques.[1−24] The decomposition pathway of AHM has been the subject of most studies.[2−13,19,23,24] Thermogravimetric analysis [TGA] and/or differential thermal analysis [DTA],[2−12,19,24] infrared spectroscopy [IR],[6,9,12] and X-ray diffraction [XRD][3−7,9,10] have been used to identify the intermediates and final products. Other studies have compared the decomposition of AHM with that of compounds with similar composition.[8,18−21] The decomposition of AHM was also investigated with respect to the effect of varying decomposition conditions. The influence of dopants, such as vanadium,[14] cobalt,[15] and alkali metal ions,[16] the influence of supports,[17,19,22] and the influence of reactant atmosphere has also been investigated.[1,23] In most studies, flowing or static air was used, the exceptions being the studies by Yong (1990)[13], Thomazeau (2000),[22] and the thermo-Raman study by Murugan (2001),[23] which were carried out under H_2, Ar, and N_2 and O_2, respectively. The TG study by Hegedüs (1957),[1] was carried out under a variety of different atmospheres.

In Table 1, the results of several representative studies are summarized. For comparison, the total amounts of molybdenum and oxygen, reported in the formulas from the literature, were normalized to five molybdenum atoms for the first step (this phase is mostly reported as pentamolybdate), and eight molybdenum atoms for the second step (this phase is mostly reported as octamolybdate). Normalization was done without changing the stoichiometry and is valid since the reported stoichiometric formulae were all based on chemical analyses and not on structural analyses. Although four decomposition stages can be distinguished, as indicated in Table 1, not all the authors observed all stages, and the temperatures of the decomposition steps vary. The first step takes place at temperatures of about 370 K (335−400 K), affording $(NH_4)_4Mo_5O_{17}$ as an intermediate. At about 470 K (430−510 K), the second decomposition step takes place, and the intermediate formed is reported to be $(NH_4)_4Mo_8O_{26}$, with the exception of study 7. In studies 4, 5, and 6, the formation of hexagonal intermediates ($MoO_3 \times xH_2O \times yNH_3$) at about 520 K (510−545 K) is reported as the third step. The final step in all the studies is the formation of α-MoO_3 (orthorhombic), with the corresponding temperatures varying from 540 K to 630 K. In two studies, 4 and 6, this step is preceded by the formation of a hydrous MoO_3 species.

Table 1. Results of the study of AHM decomposition from selected publications

No.	Publication	Conditions; method			
		Decomposition scheme			
1	Ma et al., 1963	Static air; 7 K/min; TG/DTA, ex situ XRD characterization			
		400 K → $(NH_4)_4Mo_5O_{17;}$	510 K → $(NH_4)_4Mo_8O_{26}$		630 K → α-MoO_3
2	Schwing-Weill, 1967	No information on atmosphere and flow rate; 0.25 K/min; TG, ex situ XRD characterization and chemical analysis			
		370 K → $(NH_4)_4Mo_5O_{18;}$	460 K → $(NH_4)_4Mo_8O_{26}$		575 K → α-MoO_3
3	Louisy et al., 1970	static air; 0.25 K/min / TG/DTA, ex situ XRD characterization			
		350 K → $(NH_4)_4Mo_5O_{17}$	430 K → $(NH_4)_4Mo_8O_{26}$	525 K → dodecamolybdate	540 K → α-MoO_3
4	Kiss et al., 1970	Air; 277 ml/min; 5 and 10 K/ min; TG/DTA, in situ IR analysis of gaseous products, ex situ XRD and IR characterization			
		370 K → $(NH_4)_4$*$Mo_5O_{17;}$	(430 K → pseudo octamolybdate) 480 K → $(NH_4)_4Mo_8O_{26}$	530 K→$(NH_4)_2O$*$Mo_{14}O_{42}$(hex.) 545 K→$(NH_4)_2O$*$Mo_{22}O_{66}$(hex.)	550 K → MoO_3*× H_2O 570 K → α-MoO_3
5	Isa et al., 1981	static air 3 K/min; TG/DTA, in situ XRD analysis			
		335 K → decomposition starts	445 K → $(NH_4)_4Mo_8O_{26}$ + hex. MoO_3	525 K→ hex. MoO_3	630 K → α-MoO_3
6	Hanafi et al., 1980	No information on atmosphere and flow rate; 1.25 K/min; TG, ex situ XRD and IR characterization			
		370 K → $(NH_4)_4Mo_5O_{17;}$	480 K °C → $(NH_4)_4Mo_8O_{26}$	510 K→$(NH_4)_2O$*$Mo_{12}O_{36}$(hex.) 530 K→$(NH_4)_2O$*$Mo_{22}O_{66}$(hex.)	550 K → MoO_3*× H_2O 580 K → α-MoO_3
7	Said et al., 1994	Dry air; 40 ml/min; 10 K min; TG/DTA, ex situ XRD and IR characterization			
		395 K → $(NH_4)_{2.86}Mo_5O_{16,43}$*$1.43H_2O$	490 K → $(NH_4)_{2.28}Mo_8O_{25,14}$*$2.28H_2O$		575 K → α-MoO_3

In study 5, all the phases formed during the decomposition are identified in situ. This is the only study in which this is observed. In all the other studies, with the exception of study 6 where at least some intermediates are identified in situ, the characterization and identification of the intermediates and products were performed ex situ, and are based on chemical and XRD powder pattern analyses. The considerable variation in the reported decomposition step temperatures may be due to experimental conditions, i.e. different heating rates. The reasons for the differences in the observed phases and the wide temperature range for the formation of the final phase are not obvious. The results of study 5 are unique in that the first decomposition step is not observed at all, and after the second step at 445 K, two phases were reported, namely $(NH_4)_4Mo_8O_{26}$ and hexagonal MoO_3. In summary, although the decomposition process has already been studied to some extent, no description of the sequence of events that can explain the spread in materials and conditions of this key reaction in the production of molybdate heterogeneous catalysts exists.

An overview of the molybdenum-oxygen polyhedra found in the structures of the reported intermediates and products is presented in Figure 1. The structure of AHM is composed of monomers of seven distorted, edge-sharing, molybdenum-oxygen octahedra (Figure 1, A) [ICSD 4153]. The intermediate formed in the first step has been identified as $(NH_4)_4Mo_5O_{17}$, ammonium pentamolybdate, in several studies. Powder lines calculated from single crystal data of $(NH_4)_8Mo_{10}O_{34}$ [ICSD 67325] match the powder lines reported for this material [ICDD 21−971 and 26−77], and hence this intermediate can be identified as ammonium decamolybdate. This structure is composed of monomers of eight distorted, edge-sharing, molybdenum-oxygen octahedra and two distorted molybdenum-oxygen tetrahedra, which are linked to the cluster through bridging oxygen atoms. The resulting polyhedron is shown in Figure 1, B. The second intermediate, with the stoichiometry $(NH_4)_4Mo_8O_{26}$, can be identified as ammonium tetramolybdate, by comparing the literature powder lines [ICDD 18−117] with the powder diffraction data calculated from single crystal data of $(NH_4)_2Mo_4O_{13}$ [ICSD 68562]. In this structure, the distorted, edge-sharing, molybdenum-oxygen octahedra form one-dimensional oligomers, i.e. chains, as seen in Figure 1, C. The last intermediate is reported to be hexagonal. In studies 4 and 6, two phases with different stoichiometry, occurring successively and at nearly the same temperature (530/545 K), are reported. The powder patterns given for these phases are very similar and can be simulated with one single crystal data set with slightly varied lattice constants. The corresponding phase is $(NH_3)(MoO_3)_3$ [ICSD 62163], which can be understood as a hexagonal MoO_3 with NH_3 intercalated in the lattice. This phase is built from a three-dimensional network of distorted, edge and corner-sharing, molybdenum-oxygen octahedra that form six-fold channels in the structure, see Figure 1 (see D). The structure of the final product, α-MoO_3 (orthorhombic), is shown in Figure 1 (see E) [ICSD 35076], and is built from planes which are made from edge- and corner-sharing, distorted molybdenum-oxygen octahedra. A row of corner sharing, distorted molybdenum-oxygen octahedra, as indicated in Figure 1, constitute the structural unit in both hexagonal and α-MoO_3.

Our particular interest in the decomposition of AHM is because of its use as a precursor in the production of mol-

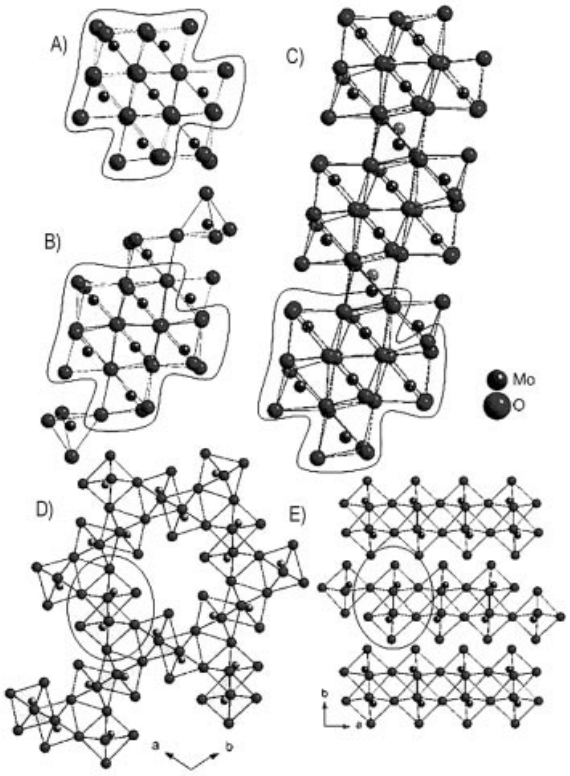

Figure 1. Schematic structural representation of potential intermediates in the decomposition of ammonium heptamolybdate: A, monomer of ammonium heptamolybdate; B, monomer of ammonium decamolybdate, C, sequence of the one-dimensional oligomer of ammonium tetramolybdate; D, hexagonal MoO_3 projected along the *c* axis; E, α-MoO_3 projected along the *c* axis. Only the molybdenum and oxygen atoms of the structures are shown. Ammonia and water are omitted. The structural units encircled in the monomers A and B and in the oligomer C are similar in all three phases. The structural units in hexagonal MoO_3 and α-MoO_3, encircled, indicate the rows of edge-shared octahedra, which are the same in the two structures

ybdenum trioxide (MoO_3) and partially reduced molybdenum oxide (MoO_{3-x}) catalysts. These oxides are suitable model systems[25] for the more complex mixed-oxide systems (molybdenum oxide with different additional components, for example Bi, W, V, Cu), which are used extensively as partial oxidation catalysts for light alkenes.[26] The catalytic activity of these materials depends on their properties,[27] i.e. their real structure (number and type of defects), their composition, and their particle sizes; which, in turn, will depend on the treatment of the precursor. Therefore, in order to learn how to control the textural and chemical properties of the resulting binary oxide, studies on the influence of different treatment parameters on the decomposition process, such as the composition of the gas phase or the heating rate, are required, together with a detailed analysis of the short- and long-range structure evolution.

In this work the decomposition of AHM is studied using in situ XRD and in situ X-ray absorption spectroscopy (XAS). The use of these two complementary methods allows us to follow the evolution of the short- and long-range structures of the phases formed. XRD is used to identify the phases and to reveal their crystallinity on a long-range order scale. The information gathered by XRD is used as a starting point for the analysis of the local structure by XAS. In addition, amorphous phases, which cannot be characterized by XRD, can be analyzed by XAS. The decomposition products in the gas phase are simultaneously analyzed by mass spectrometry. Additionally, the onset temperatures for the decomposition steps are obtained by TG/DTA coupled with evolved gas analysis (EGA) by mass spectrometry. Further, the influence of different atmospheres, such as pure helium, helium and oxygen, hydrogen, or propene, on the formation of intermediates and products is examined. In addition, the influence of the heating rate and the gas phase flow rate on the decomposition process is also investigated. The atmospheres are chosen to have oxidative, reductive, inert, and catalytically relevant reaction environments.

Results

Characterization of Ammonium Heptamolybdate

In Figure 2, the experimental diffraction pattern of ammonium heptamolybdate [$(NH_4)_6Mo_7O_{24}\times4H_2O$, AHM] in the range from 7 to 60° 2θ is shown, together with both the XRD powder pattern simulation employing single crystal data [ICSD 4153] (a = 8.393(1), b = 36.170(4), c = 10.472(1) Å, β = 116.0(0)°] and the difference between the experimental and simulated patterns. The refinement of the lattice parameters was performed with the software PowderCell 2.3. For the peak profile, the Pseudo-Voigt2 function was used and the full width at half maximum (FWHM) was taken as FWHM = $f(U,V,W)$, where only W was fitted and U = V = 0. The R_p value of the fit was 13.73. The resulting lattice constants are: a = 8.395(7), b = 36.204(3), c = 10.4765 Å, β = 115.884°. The good agreement between the experimental data and the single crystal data, the relatively small R_p value, and the fact that all the peaks in the experimental pattern of AHM were accounted for, indicate that the sample is pure and that the stoichiometry according to the structural formula is valid. The latter is also confirmed by the good agreement between the calculated and the measured weight loss for the decomposition of AHM in O_2/He with α-MoO_3 as the final product. In Figure 3, the IR absorption spectrum of AHM is shown. It is very similar to those previously reported for AHM and related compounds.[9,23,39,40] An assignment of the absorption bands is given in Table 2. For H_2O and NH_4^+, hydrogen bridging to the terminal oxygen of the Mo−O octahedra can be assumed from the structural data of AHM, whereas $O_{H2O}-O_{Molybdenum}$ = 2.72 Å and $N_{NH_4^+}-O_{Molybdenum}$ = 2.86 Å (stretching modes of H_2O at approximately 3400 cm^{-1} and of NH_4^+ at approximately 3100 cm^{-1}). The bending mode at 1640 cm^{-1} for H_2O refers to the free H_2O molecule. The bands below 1000 cm^{-1} are all assigned to the Mo−O modes, with the exception of the H_2O vibration mode at 636 cm^{-1}.

TG/DTA

Figure 4 shows the progression of the TG curve, together with the DTA signal and the MS signals for $m/z = 18$ (assigned to H_2O) and $m/z = 15$ (assigned to NH), during the decomposition of AHM in 20% oxygen with a heating rate of 5 K/min. Four decomposition steps at 320, 460, 530, and 635 K, characterize the evolution of the weight loss, with a continuous weight loss between the first and the third decomposition steps. The change in the slope of the TG curve, corresponding to the second decomposition step at 460 K, is small and can only be observed in the first derivative of the curve. The weight loss after the third decomposition step at 530 K amounts to 17.22%, and after the fourth step at 635 K, to 18.61%. The latter value is in agreement with the calculated weight loss of 18.48%, if α-MoO_3 is assumed to be the decomposition product of the starting material $(NH_4)_6Mo_7O_{24}\times4H_2O$. During the first decomposition step, two endothermic DTA signals can be distinguished. The third decomposition step also shows endothermic character, while the second and fourth steps are exothermic. With the exception of the first step, which

begins with the evolution of water only, all steps are accompanied by the evolution of water and ammonia. The TG curve and the corresponding DTA signals for the decomposition of AHM in pure helium are almost identical to those obtained for the decomposition under a 20% O_2 atmosphere at the same heating rate of 5 K/min. The only difference is the slightly greater total weight loss of 18.95% after the last decomposition step at 635 K, instead of 18.61%.

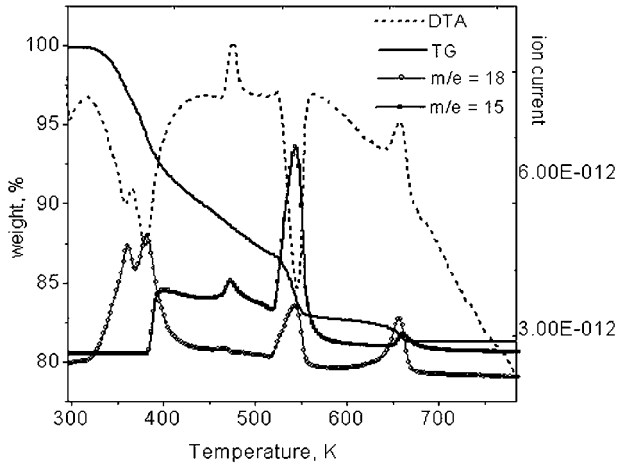

Figure 4. Evolution of the weight loss during decomposition of ground AHM in 20% oxygen in helium, together with MS signals for H_2O and NH_2^- and DTA signal (no axis inscription for the DTA signal). Heating rate: 5 K/min, flow rate: 100 mL/min

The influence of the different heating rates on the TG curve is shown in Figure 5. Lowering the heating rate from 5 K/min to 0.5 K/min does not affect the overall shape of the TG curve, however, the decomposition steps occur at lower temperatures and the weight loss prior to the third decomposition step increases. When the heating rate is increased from 5 K/min to 15 K/min, the overall shape of the TG curve changes. At this heating rate (15 K/min), the second decomposition step is accompanied by a visible change in the slope of the TG curve, resulting in a discernible stage. The total weight loss before the third decomposition step is less at the higher heating rate, and after the third decomposition step the weight loss increases from 17.22% to 18.03%. The total weight loss after the last step remains unchanged. All the decomposition steps take place at higher temperatures, except for the last step.

The influence of the heating rate and the gas flow on the TG curve is shown in Figure 6. A similar effect is observed on changing from a flowing to a static gas phase, as is seen on increasing the heating rate, i.e. lower weight loss at a given temperature and more distinct steps. A combination of accelerating the heating rate and a static gas phase results in a TG with four distinct decomposition steps, each resulting in a distinct stage. The corresponding weight loss for the steps is 6.63, 11.21, 18.03, and 18.6%. The weight

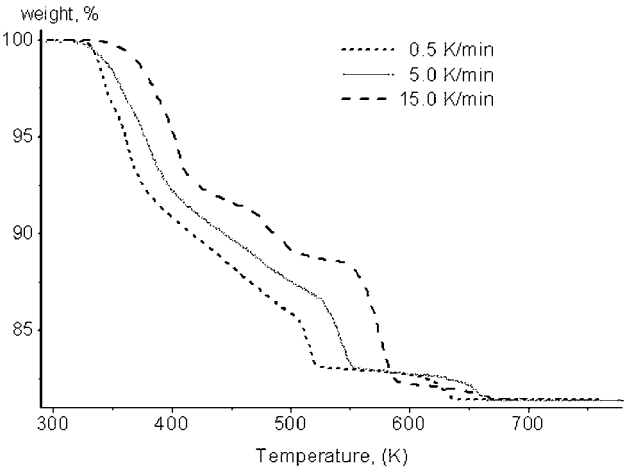

Figure 5. Comparison of the weight loss during decomposition of AHM in 20% oxygen in helium, flow rate 50 mL/min, with heating rates of 0.5, 5, and 15 K/min

loss for the first step is in excellent agreement with the calculated weight loss for the decomposition of AHM into ammonium decamolybdate (6.68%), and the second step corresponds to the formation of ammonium tetramolybdate with a weight loss of 11.09%.

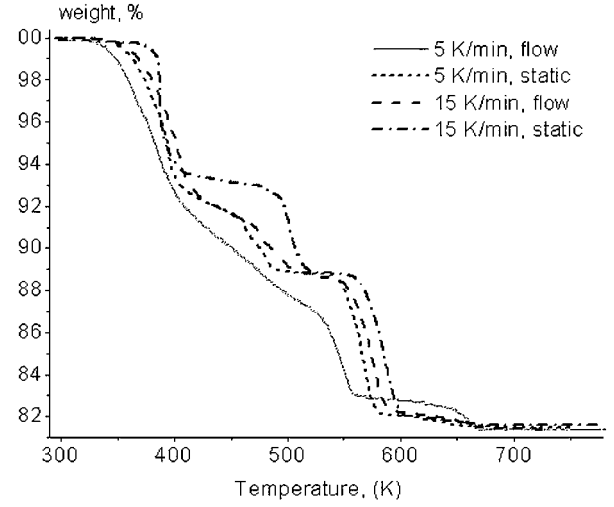

Figure 6. Comparison of the weight loss during decomposition of AHM in 20% oxygen in helium, flow rate 50 mL/min, with heating rates 5 and 15 K/min, and during decomposition of AHM in static air with heating rates of 5 and 15 K/min

The DTA signals in Figure 7 indicate that the exothermic character of the second decomposition step in Figure 4 is changed to an endothermic signal as the decomposition step becomes more pronounced due to the more rapid heating and static conditions as described above. Similarly, the exothermic signal of the last decomposition step becomes less distinct or is missing.

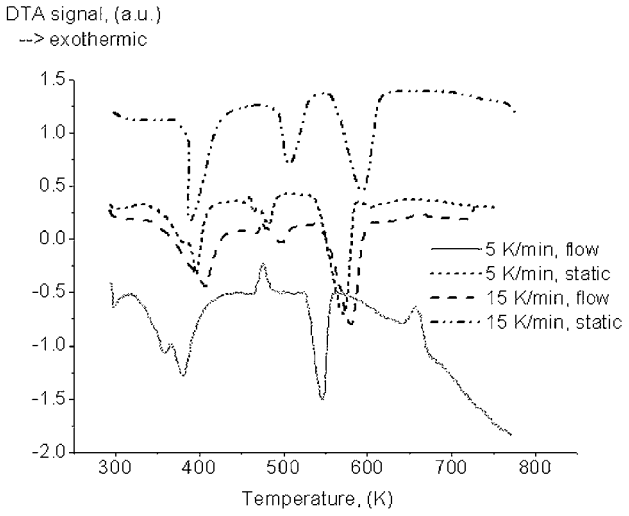

Figure 7. Comparison of the DTA signals, which belong to the TG curves shown in Figure 6. The DTA signals of the decomposition of AHM, 50 mL/min, 20% oxygen in helium, 0.5 K/min, are not shown, due to their weakness

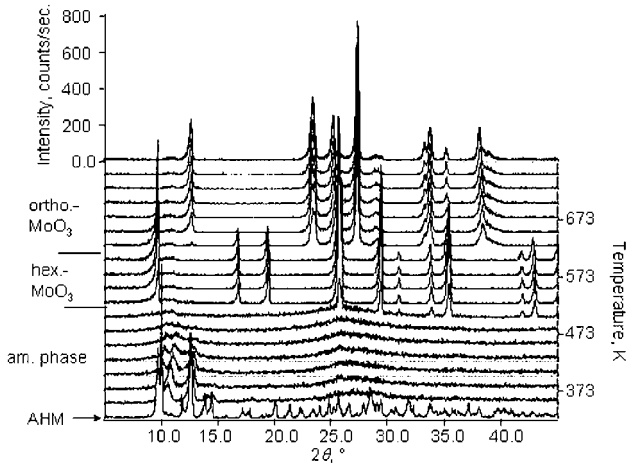

Figure 8. Evolution of the X-ray diffraction pattern during decomposition of AHM in 20% oxygen in helium. room temp. 770 K; effective heating rate: 0.1 K/min, Temperature held every 25 K for measurement; flow rate: 100 mL/min. The phases formed are indicated in the figure

In situ XRD and in situ XAS

Decomposition in 20% Oxygen

Figure 8 shows the evolution of the diffraction patterns during the decomposition of ground AHM in 20% oxygen with an effective heating rate of 0.1 K/min. Three distinct steps are visible in the diffraction patterns. In the first pattern at 320 K, changes from the expected pattern of AHM at room temperature are already observed, indicating that the decomposition has started. The patterns up to 420 K show a rapid decrease in crystallinity, and at 420 K show an X-ray amorphous phase. At 520 K, the formation of a new phase is observed which is identified as hexagonal $[H(_2O/NH_3)](MoO_3)_3$ [ICSD 62163], see Figure 1 (see D, denoted as hexagonal MoO_3 in the following). The splitting of the diffraction peak at approximately 25.7° 2θ with increasing temperature, can be explained by an expansion along the *a* and *b* axes. At 600 K, the hexagonal MoO_3 is transformed into α-MoO_3 [ICSD 35076]. Refinement of the lattice parameter of α-MoO_3 at 770 K affords a = 3.98(5) Å [3.96 Å], b = 14.222(3) Å [13.855 Å], c = 3.69(1) Å [3.69 Å] (the values in brackets are the initial values from the single crystal data [ICSD 35076] at room temperature). The variation of the lattice parameters indicates an anisotropic thermal expansion, which has also been reported by Kierkegard (1964).[33] The XRD investigations in 20% oxygen were performed with both, long and short ranges of 2θ in the XRD measurements, i.e. with effective heating rates of 0.1 K/min and 1 K/min. No differences are observed in the phases formed and the corresponding temperatures with the different effective heating rates.

Figure 9 (see A) shows the in situ XRD patterns obtained during the decomposition of AHM in 20% oxygen and with an effective heating rate of 1 K/min (short range of 2θ). The evolution of the radial-distribution-function {[FT(χ(*k*))],

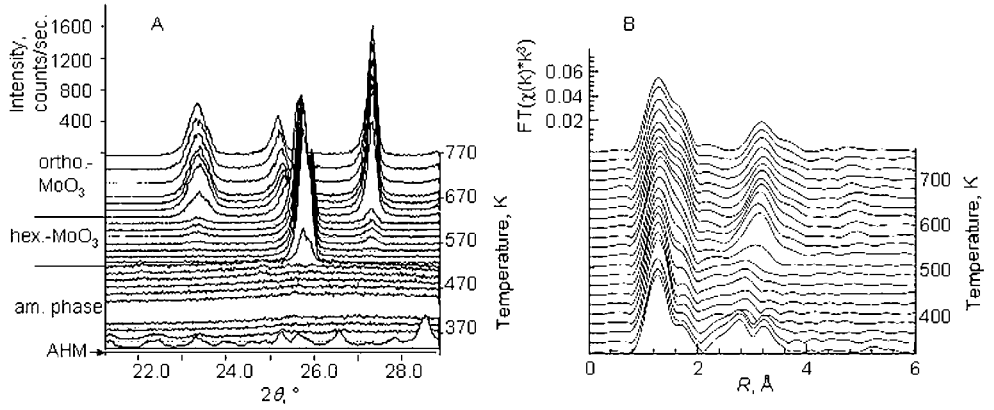

Figure 9. **A**: Evolution of the X-ray diffraction pattern during decomposition of AHM in 20% oxygen in helium. room temp. 770 K; effective heating rate: 1 K/min, Temperature held every 25 K for measurement; flow rate: 100 mL/min. **B**: Evolution of the radial distribution function (RDF) during decomposition of AHM in 20% oxygen in helium. Heating rate: 5 K/min, flow rate: 40 mL/min. The phases formed are indicated in the figure

RDF} from the corresponding in situ XAS experiment is presented in Figure 9 (see B). At the start of the decomposition process, the RDF corresponds to that of AHM. At about 345 K, the RDF exhibits a pronounced decrease in amplitude of the shells above 2 Å, indicating a loss of structural order. A comparison of the RDFs obtained between 450 K and 550 K and the RDF of crystalline ATM (the experimental RDF of ATM at 500 K is displayed in Figure 10) shows an agreement in the nodes and a comparable shape of the curve, and despite some small differences in the amplitudes, indicates a similar short-range order. At 520 K, a distinct change in the RDF occurs, corresponding to the phase change observed from the XRD data. However, in contrast to the XRD data, the RDF at about 600 K does not indicate the formation of a new phase. Despite the lack of changes in the RDF at 600 K, the simultaneously obtained MS data reveal the evolution of water and ammonia at 600 K, hence indicating a decomposition step. Although the hexagonal MoO_3 and the α-MoO_3 possess different long-range structures (see Figure 1, D and E), the pair distribution functions of the two phases within 6 Å are very similar, as is expected for phases which share the same structural features, as indicated in Figure 1. An overview of the bond lengths and coordination numbers of the two phases is given in Table 3. XAFS refinements on the RDFs between 520 K and 770 K, employing paths calculated with the FEFF7 code for either one of the two phases, result in similar distances (±0.05 Å). In Figure 11, the experimental RDF at 670 K is shown, together with a refinement using phases and amplitudes calculated for α-MoO_3.

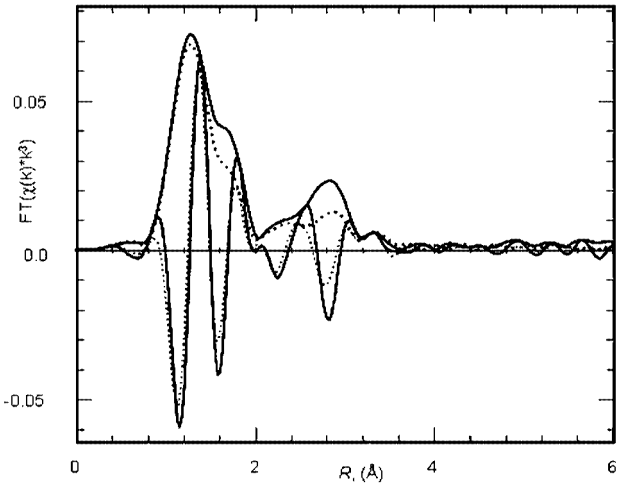

Figure 10. Comparison of the radial distribution function measured at 500 K during the decomposition in 20% oxygen (—) and the radial distribution function of ATM (· · · · ·)

Decomposition in Pure Helium

In Figure 12, A, diffraction patterns measured during the decomposition of AHM in pure helium with an effective heating rate of 1 K/min are presented. Figure 12, B shows the RDFs obtained from XAS measurements during the decomposition of AHM in pure helium. The evolution of the diffraction patterns for temperatures up to 600 K is similar to that observed for the decomposition of AHM in 20% oxygen. At temperatures above 600 K, the pattern of α-MoO_3 begins to show broad shoulders that can be identified as poorly crystallized Mo_4O_{11} (both monoclinic and orthorhombic). Mo_4O_{11} crystallizes with increasing temperature, without a decrease in the absolute intensity of α-MoO_3. The ratio between the monoclinic and orthorhombic Mo_4O_{11} phases changes from about 1:1 to 3:1 during crystallization. At 620 K, the evolution of the RDF during the decomposition of AHM in pure helium with a heating rate of 5 K/min exhibits a phase change, in contrast to the decomposition of AHM in 20% oxygen. The RDF of the phase formed at 620 K remains unchanged on further heating, i.e. there is no change in the short-range order with increasing temperature, in contrast to the changes in the long-range order observed with XRD. The evolution of the edge-shift with temperature, corresponding to the evolution

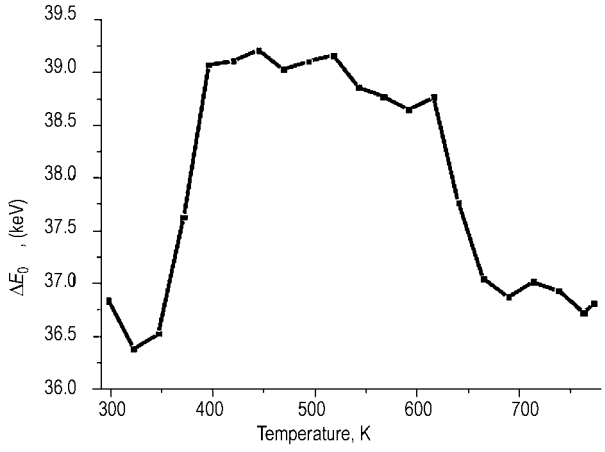

Figure 13. Evolution of the edge-shift with temperature from in situ XAS data of the decomposition of AHM in helium

of the radial distribution functions in Figure 12, B, is shown in Figure 13.

Decomposition in 5% Propene

The evolution of the diffraction patterns measured during the decomposition of AHM in 5% propene in helium with an effective heating rate of 1 K/min is shown in Figure 14, A. The corresponding RDFs are presented in Figure 14, B. For temperatures up to 600 K, the evolution of diffraction patterns is similar to that observed for the decomposition of AHM in pure helium or in 20% oxygen. At 620 K, poorly ordered orthorhombic and monoclinic Mo_4O_{11} is formed as intermediates. Subsequently, these phases are reduced to MoO_2, and at 700 K, the reduction to MoO_2 is complete. MoO_2 remains unchanged on further heating. In order to characterize the Mo_4O_{11} formed, this phase was isolated in situ, by stopping the flow of propene at the temperature of its formation, thus preventing further reduction to MoO_2. The evolution of the diffraction pat-

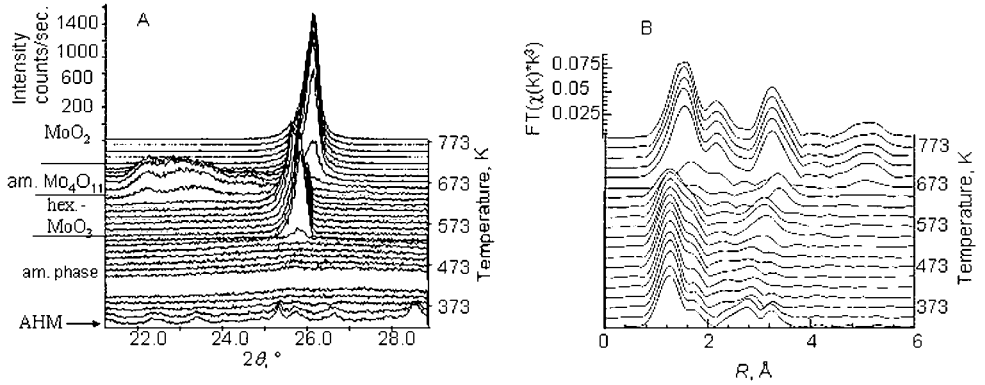

Figure 14. **A**: Evolution of the X-ray diffraction pattern during decomposition of AHM in 5% propene in helium. room temp. 770 K; temperature held every 25 K for measurement; effective heating rate: 1 K/min, flow rate: 100 mL/min. B. Evolution of the RDF during decomposition of AHM in 5% propene in helium. Heating rate: 5 K/min, flow rate: 40 mL/min. The phases formed are indicated

terns in the temperature range from 700 K to 770 K shows progressive crystallization of Mo_4O_{11}. A small amount of α-MoO_3 is also detected, and its absolute intensity remains constant with increasing temperature. The ratio between monoclinic and orthorhombic Mo_4O_{11} changes from about 1:2 to 1:1 during crystallization.

The evolution of the RDF during decomposition in 5% propene is similar to that during the decomposition in helium up to ca. 600 K. At 620 K, the RDF during the decomposition in 5% propene indicates a phase change. The phase formed is rapidly transformed into MoO_2, and can be identified at 645 K. The MoO_2 is identified by simulation of the RDF with an extended fine structure calculated from single crystal data.

Decomposition in Hydrogen

Figure 15, A shows the evolution of the diffraction patterns measured during the decomposition of AHM in 5% hydrogen with an effective heating rate of 1 K/min. Up to 520 K, the evolution of the diffraction patterns is similar to those described above. At 520 K, α-MoO_3 is obtained, in contrast to the decomposition processes in oxygen, helium, or propene where hexagonal MoO_3 is detected at 520 K. The α-MoO_3 formed possesses a strong preferred orientation which can be described as platelets with a (110) basal plane, according to the model of March.[34] This is different from the common (010) texture effects for α-MoO_3. The reduction of this phase to MoO_2 begins at 655 K, and at 745 K, the formation of Mo_4O_{11} is detected. Under these condition only the orthorhombic phase of Mo_4O_{11} is observed.

Evolution of the RDF of AHM during decomposition in 20% hydrogen is shown in Figure 15, B. The evolution of the RDF up to 620 K is similar to that in helium, and to that in 20% oxygen in helium. At about 600 K, the RDF of α-MoO_3 and/or hexagonal MoO_3 can be identified by comparison of the experimental RDF with a theoretical RDF of α-MoO_3. From 620 K to 770 K, the RDF changes continuously, corresponding to the formation of MoO_2.

Decomposition in Static Air

In Figure 16, the evolution of the diffraction patterns (1 K/min) and the RDFs measured during the decomposition of AHM in static air (5 K/min) are shown. Analysis of the XRD data shows that after the formation of an X-ray amorphous phase, ammonium tetramolybdate {ATM, $(NH_4)_2Mo_4O_{13}$, [ICSD 68562]} crystallizes at about 450 K. At 550 K, ATM decomposes into hexagonal MoO_3 and α-MoO_3. At 600 K, hexagonal MoO_3 transforms into α-MoO_3.

The evolution of the RDFs of AHM during decomposition in static air is similar to that during the decomposition in 20% O_2 (Figure 9, B). The formation of either hexagonal or α-MoO_3 can be seen at 640 K, instead of 620 K as in the decomposition in 20% O_2. During decomposition, the temperatures corresponding to the transformation of ATM to α-MoO_3/hexagonal MoO_3 in static air obtained from the XRD analysis are different from those obtained from the evolution of the RDFs (550 and 640 K, respectively). These differences may be attributed to a combination of the differences in the heating rates (1 or 5 K/min for XRD or XAS, respectively), and the differences in the reactor volume, which, under static conditions, may affect the gas phase composition.

Discussion

The experiments presented were performed to elucidate a reaction scheme for the decomposition of ammonium heptamolybdate, AHM, and to determine the effect of the gas phase composition, heating rate, and gas phase flow rate on the decomposition pathway. The emphasis herein was to obtain phase sequences from a phenomenological analysis of in situ experiments under controlled and comparable conditions. The results show that the decomposition scheme and the products formed are strongly influenced by the composition of the gas atmosphere in which the decomposition process takes place. Both the type of gas feed to the system, and the degree to which gas phase products are removed during the decomposition are important. These dependencies, hitherto not systematically recognized, and the knowledge of the sequence of phases formed during the various paths of decomposition explain the differences in the results which have been reported in the literature, and described in the introduction of this paper.

The TG/DTA experiments reveal that the pathway of the decomposition, i.e. the number of decomposition stages (Figures 4, 5, and 6) and the exothermicity or endothermicity of the step (DTA, Figure 7), depend on the heating rate and the gas flow rate. These observations suggest that all the reaction steps for the formation of α-MoO_3 from AHM are kinetically controlled. The extrinsic control variables, i.e. the processes at the gas-solid interface, including the transport of molecules and energy, are important for the reaction sequences. The intrinsic parameters, such as non-stoichiometry or morphology of the precursor, are not ruled out as additional control variables, however, these parameters were not investigated here.

The decomposition can be controlled, by the gas flow rate and the heating rate, to proceed through two phenomenologically different decomposition pathways: one with an extended region of continuous weight loss after the first decomposition step, denoted as Pathway 1; or alternatively through four distinct decomposition stages, denoted as Pathway 2 (Figures 4−6). Intermediate pathways in which the first and second decomposition stages are not pronounced can also be observed. Both pathways are characterized by DTA signals, and by the MS signals of water and ammonia, which indicate a decomposition process that occurs in four steps.

The heating rate and the gas flow rate affect the decomposition process in a similar manner, as indicated by the TG curves. The common parameter which influences the decomposition process is the partial pressure of the gas phase decomposition products, water and ammonia. The temperature at which decomposition occurs is dependent on the partial pressures of the gas phase products, which in turn is dependent on the heating rate and/or gas flow rate. The partial pressures of the gas phase products determine their availability for interaction with the solid. Decreasing the heating rate or increasing the gas flow rate reduces the partial pressure of ammonia and water and allows the decomposition to proceed at lower temperatures without the formation of distinct stages. Conversely, increasing the heating rate and/or decreasing the reactant gas flow rate increases the partial pressure of ammonia and water in the gas phase, stabilizes intermediate phases, and hence results in distinct stages. Under these conditions the decomposition progresses with distinct steps and stages. A similar correlation between the decomposition pathway and the interaction of the gas phase decomposition products with the base material has also been discussed by Maciejewski et al. (2000) for the decomposition of cobalt oxalate dihydrate.[35] They found that the primary gas- and solid-phase products reacted in secondary gas-solid and gas-gas reactions. Similarly, we suggest that the crystallization processes of the molecular structures of the intermediates after the first and second decomposition step, ammonium decamolybdate (possibly X-ray amorphous phase A), and ammonium tetramolybdate, may require water and/or ammonia as ligands. The crystallization of these intermediates results in the process of polycondensation (the formation of hexagonal MoO_3 and/or α-MoO_3) occurring at higher temperatures. The formation of hexagonal MoO_3 decreases with the formation of crystalline ATM, and thus appears to be induced by the low partial pressure of gaseous water and ammonia.

The kinetic reaction control discussed above would suggest that the effect of reactant gas composition on the decomposition pathway be studied at low heating rates, conditions under which product gases are purged and gas phase diffusion limitations are minimized. Such conditions allow analysis of the decomposition by structurally sensitive in situ XRD and in situ EXAFS experiments. Figure 5 indic-

ates that no qualitative changes are introduced into the sequence of events at low heating rates. Differences in the onset temperatures of the phase changes observed can be expected (≈ 20 K), because of the different heating rates.

From in situ XRD and XAS measurements, the sequence of phase transformations corresponding to the decomposition steps was elucidated. Decomposition in flowing reactants (20% oxygen, (Figure 9), pure helium, (Figure 10), and in 5% propene, (Figure 11), all proceed by a reaction scheme denoted as Pathway 1 (effective heating rate of 1 K/min for XRD and 5 K/min for XAS). The XAS data for the decomposition in oxygen suggest that the X-ray amorphous phase, present after the second decomposition step, is similar to ATM. On the basis of the XAS data, the X-ray amorphous phase has to be divided into two categories, X-ray amorphous phase A, formed after the first decomposition step at ca. 340 K, and X-ray amorphous phase B, formed after the second decomposition step at ca. 470 K. The relatively low barrier for the transition between the two amorphous phases explains the continuous weight loss observed in the TG curves (Figure 4). The sequence of phases formed is (i) AHM, as the starting phase, (ii) X-ray amorphous phase A, at ca. 340 K, (iii) X-ray amorphous phase B (ATM) at 470 K, (iv) amorphous phase B is transformed into hexagonal MoO_3 at 520 K, and (v) final products, which differ according to the reducing potential of the gas phase [α-MoO_3 (O_2), Mo_4O_{11} (He), or MoO_2 (propene)].

Pathway 1:

$$\text{AHM} \xrightarrow{340\ \text{K}} \text{X-ray amorphous phase A} \xrightarrow{470\ \text{K}} \text{B(ATM)} \xrightarrow{520\ \text{K}} \text{hex.}MoO_3 \xrightarrow{635\ \text{K}} \text{products}$$

The temperatures given for the decomposition steps should be considered only as reference points. They are a function of, not only the atmosphere, but also the heating rate and the gas flow rate.

The decomposition of AHM in 20% oxygen results in α-MoO_3, decomposition in helium results in α-MoO_3 and highly disordered Mo_4O_{11}, which recrystallizes with increasing temperature, and decomposition in 5% propene results in highly disordered Mo_4O_{11}, which is eventually reduced to MoO_2. The formation of highly dispersed Mo_4O_{11}, together with α-MoO_3 in the final step of the decomposition in helium is confirmed by the in situ XAS data (RDFs), which shows no change in the short-range structure with increasing temperature. The evolution of the corresponding edge-shift (Figure 13) reveals that the reduction takes place mainly during the decomposition of hexagonal MoO_3. A slight increase in the reduction with temperature is then observed, which is due to the mobility of lattice oxygen in this temperature region.[41] The changes observed by XRD after the decomposition of hexagonal MoO_3 are mainly due to recrystallization of Mo_4O_{11} with increasing temperature, and the formation of Mo_4O_{11} from MoO_3 and MoO_2.[29] The apparent oxidation during the decomposition of AHM at approximately 370 K (Figure 13) corresponds to the loss of NH_3 and H_2O during the formation of the amorphous phases (A+B), and thus oxidation of the remaining molybdenum oxide clusters. The Mo-*K* edge-shift observed during the decomposition in helium is representative for all decomposition conditions studied. However, under an oxidizing atmosphere (20% O_2 in helium), no reduction occurs during the decomposition of hexagonal MoO_3.

For the decomposition of AHM in a hydrogen containing atmosphere (Figure 15), Pathway 1 has to be modified. The XRD results indicate that the first decomposition step in hydrogen proceeds according to Pathway 1. The third decomposition step, however, yields MoO_3 with an unusual texture, instead of hexagonal MoO_3. With increasing temperature, α-MoO_3 is subsequently reduced to MoO_2.

The decomposition of AHM under static conditions follows a reaction scheme denoted as Pathway 2: (i) AHM, (ii) X-ray amorphous phase A, ca. 370 K, (iii) ATM is formed at ca. 500 K, followed by (iv) α-MoO_3 and hexagonal MoO_3, ca. 600 K, and (v) the decomposition of hexagonal MoO_3 to α-MoO_3 at 635 K. Since the influence of the heating rate may be more pronounced in a static atmosphere, larger differences were observed in the onset temperatures of the phase changes detected by in situ XRD and in situ XAS.

Pathway 2:

$$\text{AHM} \xrightarrow{370\ \text{K}} \text{X-ray amorphous phase A} \xrightarrow{500\ \text{K}} \text{ATM} \xrightarrow{635\ \text{K}} \alpha\text{-}MoO_3$$
$$\xrightarrow{600\ \text{K}} \text{hex.} + \alpha\text{-}MoO_3$$

Structural Relationships Between Intermediates and Products

Following the given sequence of phases, the transformation from the cluster structure of AHM to the three-dimensional MoO_3 structure can be described as a polycondensation. In the structural sequences of the two monomers, hepta- and decamolybdate, and the one-dimensional oligomer, tetramolybdate, the structural unit of 6 Mo-O octahedra is preserved, as indicated in Figure 1. In the tetramolybdate, however, the octahedra in this 6 membered unit are tilted (Figure 1, C). Nevertheless, for structural rearrangement between these 3 phases, considerable mass transport has to be assumed. For the transition from the heptamolybdate to the decamolybdate, a complete rearrangement of the clusters is required. In the decamolybdate and in the tetramolybdate, the clusters, and thus the Mo-O octahedra, are all uniquely oriented, neglecting the slight tilt in the tetramolybdate. This unique orientation of the octahedra is retained in hexagonal and α-MoO_3. The density of the phases hepta-, deca-, and tetramolybdate are 2.46, 2.84, and 3.32 g/cm^3, respectively (not including NH_3 and H_2O molecules).

The water and ammonia ligands in AHM play an important role in the transformation process. In the AHM structure, all the NH_4^+ and H_2O ligands differ in their coordination to the molybdenum-oxygen clusters (some bridging,

some singly coordinated). However, since the loss of NH_4^+ is not stoichiometric from one phase to another and since the structural relationships between the phases are not obvious, it is difficult to deduce which of the ligand molecules is being removed during the individual transformation steps.

The polymers, α-MoO_3 and hexagonal MoO_3, possess no readily visible structural relationships with the monomers and the oligomer, and thus a reconstructive phase transformation has to be assumed. Hexagonal and α-MoO_3 can be described as two different arrangements of the same structural subunits. These subunits are chains of edge-sharing distorted Mo-O octahedra, which are orientated along the *c* axis in both structures, as indicated in Figure 1. In α-MoO_3, these chains are connected along the *a* axis via edge-sharing of the octahedra, forming a layer structure. In hexagonal MoO_3, the chains are arranged around a three-fold axis via edge-sharing of the octahedra, forming a three-dimensional network. The resulting density of α-MoO_3, 4.7 g/cm^3, is higher than that of hexagonal MoO_3, 3.97 g/cm^3, calculated for the structures (not including NH_3 and H_2O molecules).

The X-ray amorphous phase A in Pathway 1 and 2 could not be identified with the data available. Isothermal decomposition of AHM over extended periods of time (up to eight days) produced only amorphous phases or phase mixtures unsuitable for the identification of the X-ray amorphous phase A. With respect to the observation of ammonium decamolybdate in the literature, besides the role of the ammonia and water ligands in the kinetic inhibition of the formation of sufficiently crystalline ammonium decamolybdate, two structural features may hinder the formation of crystalline decamolybdate. The first is the necessary rearrangement of the clusters in a way that all Mo−O octahedra exhibit the same orientation, as described above. Secondly, in ammonium decamolybdate, two out of ten molybdenum atoms are coordinated by oxygen in a four-fold manner, rather than in a six-fold manner. The rearrangement of the Mo-O octahedra is observed in the formation of crystalline ATM, hexagonal MoO_3 and α-MoO_3. However, molybdenum is not coordinated by oxygen in a four-fold manner in any of the crystalline phases detected.

A Unifying Decomposition Scheme

A schematic representation of decomposition Pathways 1 and 2 is shown in Figure 17. In comparison with the results reported in the literature (Table 1), Pathway 2 is in good agreement with the in situ study 6. A few differences should be noted. They are the formation of ATM, together with the formation of hexagonal MoO_3 at approximately 445 K, and only hexagonal MoO_3 is detected without α-MoO_3during the third decomposition stage. These differences may be due to the limited 2θ range used for the XRD analysis in study 5. No ammonium decamolybdate is observed in study 5, which is in agreement with the study presented here. If an intermediate pathway between Pathway 1 and Pathway 2 is achieved (depending on the experimental conditions), only a small amount of crystalline ammonium decamolybdate may be formed. The agreement of the results of study 6 with those of this work indicates significant differences between the phases identified from in situ and ex situ experiments.

Considerable differences can be seen between this work and the other studies included in Table 1, which were primarily performed ex situ. With the exception of study 8, the other studies also identified ammonium tetramolybdate in the second decomposition stage, albeit in this study it is also found in an amorphous form under conditions which favors Pathway 1. Hexagonal MoO_3 formed during step three of Pathway 2 has only been reported in studies 5, 6, and 7. However, in study 5, hexagonal MoO_3 was prepared ex situ , from aqueous solution, in order to verify the results of the phase analysis of the third decomposition stage. Hexagonal MoO_3 is reported in the literature[35−38] to be metastable, which may be a reason that it is not detected in some ex situ studies. So far we have not succeeded in preparing hexagonal MoO_3 by decomposition of AHM under controlled conditions. Only mixtures of hexagonal and α-MoO_3 were obtained. Furthermore, the temperatures given for the formation of α-MoO_3 in studies 2, 3, 4, and 8 actu-

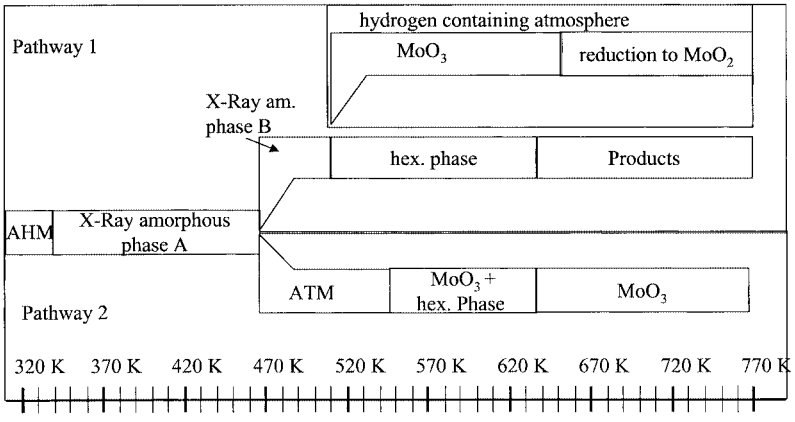

Figure 17. Schematic representation of the different pathways of the decomposition of AHM

ally correspond to step three in Pathway 2, where a mixture of hexagonal and α-MoO_3 is obtained.

With respect to the use of AHM as a catalyst precursor in the production of molybdenum oxide (MoO_{3-x}) based catalysts, the results show that it is possible, not only to control the reduction state but also the phase composition of the products. Apparently, this control can be most efficiently exerted at temperatures below ca. 520 K, where the molecular precursors persist with water as a spacer and ammonia as a counterion. In the temperature range from 610 K to 650 K, where molybdenum oxide catalysts exhibit the onset of catalytic activity, and hence are employed in the partial oxidation reactions of alkenes, the decomposition product obtained consists of partially reduced MoO_3 and mixtures of different oxides, rather than pure and defect-free MoO_3. In addition, this temperature range coincides with the onset of sufficient oxygen mobility in the molybdenum oxide lattice, a prerequisite for partial oxidation activity. This is in agreement with our previous results, that under partial oxidation reaction conditions, "MoO_3" corresponds to a partially reduced molybdenum oxide phase, probably with a considerable amount of shear-type defects in the regular structure. (For more detailed information see ref.[41] and references therein.)

This study demonstrates that control of the decomposition of AHM is possible. It is clear that the heating rate and reactant gas flow rate are coupled under the conditions investigated here. These parameters both function through their ability to affect the partial pressure of the gas phase decomposition products, which in turn control the decomposition path. This result indicates that it may be possible to direct the decomposition with a more complete control of the gas phase composition. Specifically, this control my be accomplished by purging with mixtures of product and/or reactant gases, with rates sufficient to minimize gas phase diffusion limitations and to allow only differential changes in the gas composition over the solid. This type of control could additionally be used to decouple the H_2O and NH_3 partial pressures, which are otherwise intrinsically coupled by the stoichiometry of the decomposition reactions.

Conclusion

The influence of the reactant atmosphere, and the heating rate and the gas flow rate on the decomposition of AHM has been shown. The results indicate that the decomposition scheme is sensitive to changes that affect the partial pressures of the gas phase decomposition products. In fact, differences in the gas phase product partial pressures, due perhaps to different flow rates, heating ramps, or experimental setups, are adequate to explain the differences in the results reported in the literature. The response of the system to changes in the gas phase decomposition product partial pressures is mainly important for the formation of hexagonal MoO_3, which depends on the preceding crystallization of ATM. Depending on the gas phase composition, two different Pathways can be distinguished:

Pathway 1 (low concentration of gaseous decomposition species at a given temperature)

(i) AHM; (ii) (≈ 335 K) X-ray amorphous phase A, (iii) (≈ 470 K) X-ray amorphous phase B (amorphous ATM), (iv) (≈ 520 K) hexagonal MoO_3; (v) (≈ 650 K) products (as a function of atmosphere, α-MoO_3, Mo_4O_{11}, or MoO_2).

Pathway 2 (high concentration of gaseous decomposition species at a given temperature)

(i) AHM, (ii) (≈ 350 K) X-ray amorphous phase A; (iii) (≈ 470 K) ATM.

(iv) (≈ 570 K) hexagonal MoO_3 + α-MoO_3; (v) (≈ 650 K) α-MoO_3.

Experimental Section

Ammonium Heptamolybdate Tetrahydrate: Ammonium heptamolybdate tetrahydrate, AHM, $(NH_4)_4Mo_7O_{24}\times 4\ H_2O$, was used as purchased (Aldrich, Analysis: total metallic impurities < 200 ppm). Phase purity and crystalline structure were verified by XRD and found to agree well with the simulated XRD powder patterns generated from single crystal data [ICSD 4153]. IR spectra of AHM were recorded with a FT-IR (Perkin−Elmer 2000), using the KBr disc technique. Chemical purity was confirmed by X-ray fluorescent analysis, which showed that there were no detectable impurities.

X-ray Diffraction: In situ XRD studies were performed with a Stoe STADI-P diffractometer (Ge secondary monochromator, Cu K_α radiation, Bragg−Brentano geometry), which is equipped with a Bühler HDK S1 high temperature cell (400 mL). Analysis of the gas phase was performed with a quadrupole mass spectrometer, QMS 200 (Pfeiffer), using a selective mass scan mode (≈ 12 s per scan). Measurements were performed in the temperature range from 300 K to 770 K, employing 2θ ranges of either 21.25−28.75° (short-range) or 5−45° (long-range). The shorter 2θ range was used to obtain more dynamic information, the longer 2θ range was sufficient for identification of the different phases. The short-range was selected in a 2θ region containing diffraction peaks of adequate intensities of all potential phases. With a heating rate of 5 K/min, diffractograms were recorded every 25 K for the long 2θ range, or every 15 K for the short 2θ range, resulting in effective heating rates of about 1 K/min or 0.1 K/min, respectively. The total gas flow rate was set to 100 mL/min. The concentrations of reactant gases in helium were 20% for oxygen, 5% for hydrogen, and 5% for propene. 30 mg of sample were suspended with acetone on the sample holder. A detailed description of the XRD set up can be found in Günter (2001).[28]

XRD studies of the ex situ samples were performed with a Stoe STADI-P diffractometer (Ge primary monochromator, Cu-K_α radiation, Debye−Scherrer geometry) equipped with a position sensitive detector.

Analysis of diffraction patterns was conducted using PowderCell for Windows, Version 2.3, and Stoe WinXPOW, Version 1.03. The ICDD (International center for diffraction data, former JC,PDS) database and the ICSD (Inorganic crystal structure database) were used for phase analysis.

X-ray Absorption Spectroscopy: In situ XAS measurements were performed in a flow reactor with a volume of ca. 4 mL, used in transmission geometry. Measurements were performed in a temperature range from 300 K to 770 K, with a heating rate of 5 K/·min.

The acquisition time was 4.5 minutes per spectrum, resulting in a temperature resolution of 22.5 K. Total flow rates of gases was set to 20 mL/min. Analysis of the gas phase was performed with a quadrupole mass spectrometer, QMS 200 (Pfeiffer), with a time resolution of ca. 12 s per scan using a selected mass scan mode. The AHM was mixed with boron-nitride (7 mg of AHM, 30 mg of BN) and pressed with a force of 1 ton into self-supporting pellets with a diameter of 5 mm. The resulting edge jump at the Mo-*K*-edge averages $\Delta\mu_x \approx 2$. For details of the experimental set up, see Ressler (2000).[29]

XAS measurements were performed at the Mo-*K* edge (19.999 keV) at the Hamburger Synchrotronstrahlungslabor, HASYLAB, beamline X1. The storage ring operated at 3.6 GeV with injection currents of 150 mA. A Si(311) double crystal monochromator was used.

Data analysis of the XAS spectra was performed using the software WinXAS 2.1.[30] The spectra were energy calibrated with respect to a molybdenum foil reference spectrum. Background subtraction and normalization were done using first order polynomials to fit the pre-edge and EXAFS region. Spectra were converted to k space using an E_0 defined as the second inflection point in the Mo-*K* edge. Atomic absorption, μ_0, fitting was performed using a cubic spline with 7 nodes and was optimized by minimization of peaks at low (< 1 Å) R value in the Fourier transformed $\chi(k)$.

Refinement of the local structure was performed in *R* space using the FEFF7 code[31] for calculation of amplitudes and phases for clusters with a radius of 6 Å around the absorber atom. The clusters were calculated from single crystal data of hexagonal and α-MoO_3 using the software Atoms.[32] All single scattering paths were considered, as well as multiple scattering paths with weights greater than 5% and a maximum of 4 legs. Fits were carried out in a range of ca. 0.4−3.9 Å, which resulted in 12 single scattering paths (SS) and 19 multiple-scattering paths (MS) for α-MoO_3 and hexagonal MoO_3. The number of free running parameters used during fitting was restricted to 19, well below the maximum of 28 allowed by the Nyquist theorem for the data range used. The free running parameters were (i) one Debye temperature for molybdenum and one for oxygen, (ii) one E_0 each for molybdenum and oxygen, (iii) - the distances of all SS paths, constrained to a maximum shift of ±0.1 Å, (iv) one third cumulant expansion factor for molybdenum and oxygen each and (v) the overall damping factor S_0.

TG/DTA: Weight loss measurements and differential thermal analysis (TG/DTA) were performed with a Seiko Instruments SSC/5200 (Pt-Rh 13% thermocouple). Measurements in 20% oxygen in helium and with a flow rate of 50 mL/min were carried out at heating rates of 0.5, 5, and 15 K/min. Three different flow rates 100 mL/min, 50 mL/min and no flow (static air), were examined with an atmosphere of 20% oxygen in helium and with a heating rate of 5 K/min. Additionally, a measurement in pure helium with a heating rate of 5 K/min and a flow rate of 50 mL/min was performed. Gas phase analyses were performed by using a Pfeiffer QMS 200 mass spectrometer.

Acknowledgments

We acknowledge the Hamburger Synchrotronstrahlungslabor HASYLAB for providing beam-time for this work. T. Ressler thanks the Deutsche Forschungsgemeinschaft "DFG" for financial support (Habilitationsstipendium). The authors are grateful to Prof. R. Schlögl for extended discussions and continuous support.

3-Metalla-1,2-dioxolanes and Their Reactivity

Monique Krom,[a] Theo P. J. Peters,[a] Ruud G. E. Coumans,[a] Timo J. J. Sciarone,[a] Johan Hoogboom,[a] Sandra I. ter Beek,[a] Paul P. J. Schlebos,[a] Jan M. M. Smits,[a] René de Gelder,[a] and Anton W. Gal*[a]

Keywords: Formylmethyl complexes / Metallacycles / N ligands / Oxygenations / Rhodium

The ethene complexes $[M^{I}(CH_2CH_2)]^+$ (M = Ir, Rh) can be oxygenated by molecular oxygen or air in the solid state, to form isolable unsubstituted 3-metalla-1,2-dioxolanes $[M^{III}(CH_2CH_2OO\text{-}\kappa^2C^1,O^2)]^+$. Such selectivity could not be achieved in solution. The stereoselectivity of the oxygenation process is highly dependent on the ligand, the metal and the counterion used. Oxygenation of $[(tpa)M(CH_2CH_2)]PF_6$ {tpa = tri(2-pyridylmethyl)amine; **4**PF_6, **7**PF_6} results in the formation of two isomeric 3-metalladioxolanes, whereas oxygenation of $[(tpa)M(CH_2CH_2)]BPh_4$ (**4**BPh_4, **7**BPh_4) only yields one isomer. Furthermore, oxygenation of [(Metpa)-$Rh(CH_2CH_2)]PF_6$ {**14**PF_6, Metpa = [(6-methyl-2-pyridyl)methyl]bis(2-pyridylmethyl)amine} proved to be much slower than that of $[(tpa)Rh(CH_2CH_2)]PF_6$ (**7**PF_6). The *solid* propene complex $[(tpa)Rh(CH_2CHCH_3)]BPh_4$ (**23**BPh_4) loses propene on reaction with molecular oxygen, and selectively forms the peroxo complex $[(tpa)Rh(\eta^2\text{-}O_2)]BPh_4$ (**24**BPh_4). The obtained 3-metalla-1,2-dioxolanes rearrange, both in the solid state and in solution, to formylmethyl hydroxy complexes on exposure to photons or protons. The isomeric 3-rhoda-1,2-dioxolanes $[(tpa)Rh(CH_2CH_2OO\text{-}\kappa^2C^1,O^2)]^+$ **8a**$^+$ and **8b**$^+$ differ in reactivity. On exposure of a solution of **8a**PF_6/**8b**PF_6 to glass-filtered daylight, isomer **8b**$^+$ rearranges to form the formylmethyl hydroxy complex **9b**$^+$. This rearrangement is three times faster than the rearrangement of **8a**$^+$ to **9a**$^+$. The iridadioxolanes are much more reactive than the corresponding rhodadioxolanes, whereas the iridium formylmethyl hydroxy complexes are less reactive than the corresponding rhodium formylmethyl hydroxy complexes. The tpa formylmethyl hydroxy complexes react reversibly with carbon dioxide to form formylmethyl hydrogen carbonate complexes.

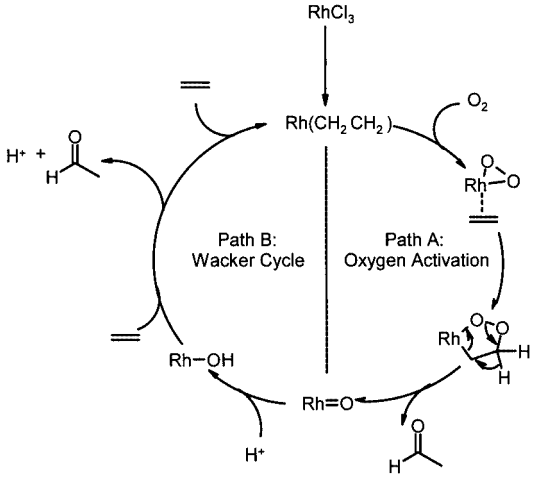
Introduction

Transition metal catalyzed oxidation of olefins is one of the most important methods of converting these readily available and cheap starting materials into useful chemicals. For economical and environmental reasons, molecular oxygen or air are the most interesting oxidants. However, not much is known about the mechanisms involved in transition metal catalyzed olefin oxidations. In an attempt to investigate the validity of some of the earlier proposed mechanisms, we have investigated the oxygenation of rhodium and iridium ethene complexes by air.

3-Metalla-1,2-dioxolanes (κ^2-C^1,O^2-2-peroxyethyl metal complexes, see Structure) have been proposed as intermediates in the catalytic oxygenation of olefins by group VI and VIII metals.[1] These reactions include epoxidation[1d–1f] and oxidation to ketones.[1a–1c] Mimoun et al. have proposed that the rhodium-catalyzed olefin oxidation proceeds via a peroxo ethene complex. Insertion of ethene into the rhodium dioxygen bond then results in the formation of a 3-rhoda-1,2-dioxolane complex, which subsequently decomposes to acetaldehyde and a rhodium oxo complex (Scheme 1).[1a]



Scheme 1. Mechanism proposed by Mimoun for the rhodium catalyzed oxidation of ethene to acetaldehyde[1a]

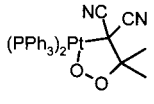
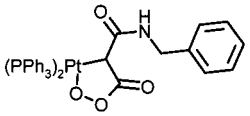
Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

In the molybdenum catalyzed oxidation of olefins, Mimoun proposed that decomposition of 3-molybdena-1,2-dioxolanes results in the formation of a molybdenum oxo complex and ethylene oxide.[1e][1f] However, calculations by Frenking et al. have indicated that this would lead to the formation of acetaldehyde instead of ethylene oxide.[2]

3-Metalla-1,2-dioxolanes containing an *unsubstituted* 3-metalla-1,2-dioxolane fragment [M(κ^2C^1,O^2-CH_2CH_2OO-)] have not been reported before. However, tri- and tetra-substituted 3-platina-1,2-dioxolanes, with substituents that prevent β-hydrogen transfer, have been obtained from the reaction of [$(PPh_3)_2Pt(\eta^2$-$O_2)$] with electron-deficient olefins, and have been structurally characterized (**1** and **2**).[3] These *substituted* platinadioxolanes cannot be used as models for the further study of proposed metalladioxolane intermediates.



1



2

We now report on the synthesis of *unsubstituted* 3-metalla-1,2-dioxolanes, through the oxidation of rhodium and iridium ethene complexes by air or molecular oxygen. Oxidation by molecular oxygen was sometimes necessary due to the reactivity of the oxidation products towards water or carbon dioxide from the air. Rearrangement of the 3-metalla-1,2-dioxolanes to formylmethyl hydroxy complexes is also reported. Part of this work has been communicated previously.[4]

Results and Discussion

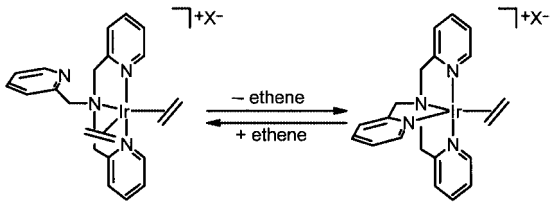
Synthesis of Ethene Complexes

Rhodium tpa Complexes

The complexes [(tpa)Rh(CH_2CH_2)]BPh_4 {**7**BPh_4, tpa = tris(2-pyridylmethyl)amine} and [(Metpa)Rh(CH_2CH_2)]-PF_6 {**14**PF_6, Metpa = [(6-methyl-2-pyridyl)methyl]bis(2-pyridylmethyl)amine} were synthesized according to a literature procedure. $NaBPh_4$ and KPF_6 were used to precipitate **7**BPh_4 and **14**PF_6, respectively.[5]

Iridium tpa Complexes

Bis(ethene) complexes **3**BPh_4 and **3**PF_6 were synthesized from in situ generated $IrCl(C_2H_4)_4$, tpa, and $NaBPh_4$ or KPF_6, respectively. Whereas a mono-ethene complex ($\mathbf{7}^+$) is formed for rhodium, a bis(ethene) complex is initially obtained for iridium, probably due to the better π-back-donating ability of iridium. However, an ethene molecule is easily lost from the bis(ethene) complex; when N_2 is bubbled through a solution containing $\mathbf{3}^+$, the mono-ethene complex $\mathbf{4}^+$ is obtained (Scheme 2). This reaction is reversible; when ethene is bubbled through a solution containing $\mathbf{4}^+$, the bis(ethene) complex $\mathbf{3}^+$ is obtained.



$\mathbf{3}^+$ $\mathbf{4}^+$

Scheme 2. Reactivity of bis(ethene) complex **3**PF_6 and mono-ethene complex **4**PF_6

The structure of complex $\mathbf{3}^+$, as determined by X-ray diffraction, is shown in Figure 1. The complex has a trigonal bipyramidal conformation and contains the tpa ligand in a meridional tridentate coordination mode. This coordination mode has not been observed before for bis(olefin) metal complexes stabilized by bpa-type ligands {bpa = bis(2-pyridylmethyl)amine}; in such complexes the bpa-type tridentate nitrogen donor ligand usually adopts a facial coordination mode.[6,7] The ^1H NMR spectrum of $\mathbf{3}^+$ at room temperature shows four triplets and its ^{13}C NMR spectrum shows four singlets for the ethene fragments, indicating that the fragments are not rotating, probably due to steric hindrance.

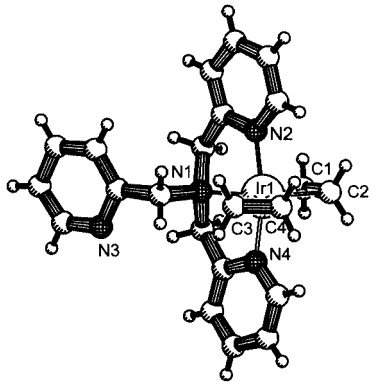


Figure 1. X-ray structure of bis(ethene) complex $\mathbf{3}^+$

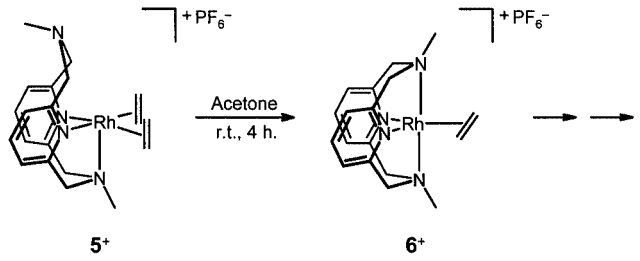
Rhodium N_4Me_2 Complexes

To test the influence of the nitrogen donor ligand on the reactivity of the ethene complexes, bis(ethene) complex $\mathbf{5}^+$ (Scheme 3) was synthesized as the PF_6-salt from [{$(ethene)_2RhCl$}$_2$], N_4Me_2 and KPF_6. Complex $\mathbf{5}^+$ contains the rigid macrocyclic N_4 ligand, *N*,*N*′-dimethyl-2,11-diaza[3,3](2,6)pyridinophane[8] (N_4Me_2). As mentioned earlier, reaction of tpa with $IrCl(C_2H_4)_4$ initially gives a bis(ethene) complex, which easily and reversibly loses one ethene molecule. The same reaction with [{$(C_2H_4)_2RhCl$}$_2$] only produces the mono-ethene complex $\mathbf{7}^+$, even when carried out at low temperature. Rhodium apparently does not bind the second ethene molecule as strongly as iridium. Therefore, the initial formation of the bis(ethene) complex **5**PF_6 with N_4Me_2 was surprising. However, **5**PF_6 also loses an ethene molecule easily (see below). The synthesis of **5**PF_6 is discussed in more detail in the supporting information.



Scheme 3. Loss of ethene from bis(ethene) complex $\mathbf{5}PF_6$

The ^1H NMR and ^{13}C NMR resonances of the vinylic groups of $\mathbf{5}^+$ are broad at room temperature, which indicates the rotation of the ethene fragments. At −60 °C this rotation is frozen, resulting in an ABCD-pattern in the ^1H NMR spectrum. X-ray quality crystals of $\mathbf{5}PF_6$ were obtained by crystallization from acetone/diethyl ether (v/v = 1:3) over a period of nine days at −70 °C. The X-ray structure of the cation $\mathbf{5}^+$ is shown in Figure 2. This is the first reported X-ray structure of a bis(ethene) rhodium complex stabilized by three nitrogen donors.

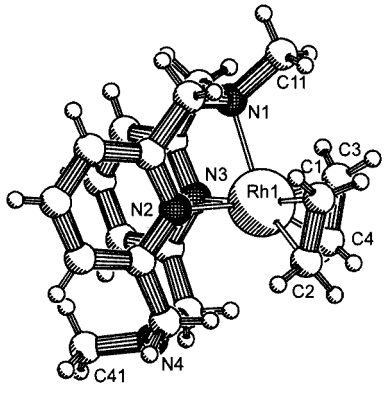


Figure 2. X-ray structure of bis(ethene) complex $\mathbf{5}^+$

Cation $\mathbf{5}^+$ has a pseudo square pyramidal geometry with the amine occupying the apical position, and the N_4Me_2 ligand in a tridentate coordination mode. Three complexes in which this coordination mode is found for N_4Me_2 (or an analogous ligand) have been reported earlier,[9] but usually this ligand adopts a tetradentate coordination mode.[10] In complex $\mathbf{5}^+$, as well as in the earlier reported κ^3-N_4Me_2 complexes,[9] the N_4Me_2 ligand adopts a *syn* (chair-boat) conformation. The X-ray structure of $\mathbf{5}^+$ is discussed in more detail in the supporting information.

Mono-ethene complex $\mathbf{6}PF_6$ is easily obtained by allowing $\mathbf{5}PF_6$ to stand in acetone solution under a nitrogen atmosphere at room temperature for approximately four hours (Scheme 3). This is not a reversible reaction; bubbling ethene through a solution of $\mathbf{6}PF_6$, or exposure of such a solution to an ethene atmosphere does not lead to the formation of $\mathbf{5}PF_6$. The rate and selectivity of the conversion of $\mathbf{5}^+$ to $\mathbf{6}^+$ are highly dependent on the counterion used. Formation of $\mathbf{6}^+$ is slower and more selective if PF_6^- is used as the counterion, instead of BPh_4^-. Furthermore, irrespective of the counterion, the selectivity is higher in acetone than in acetonitrile.

Since a square planar $[(\kappa^3\text{-}N_4Me_2)Rh(C_2H_4)]^+$ structure is not possible for complex $\mathbf{6}^+$ due to the rigidity of the N_4Me_2 ligand, we propose that the ligand has a κ^4-coordination mode, similar to tpa in $\mathbf{7}^+$.[5] Another indication for tetradentate coordination is the fact that the signals for the NMe groups in the ^1H NMR and ^{13}C NMR spectra are at approximately the same chemical shifts [$\delta(^1H)$ = 2.15 ppm, $\delta(^{13}C)$ = 49.8 ppm] as the signals for the coordinated NMe group in $\mathbf{5}^+$ [$\delta(^1H)$ = 2.25 ppm, $\delta(^{13}C)$ = 52.6 ppm].

Complex $\mathbf{6}PF_6$ is not stable in solution at room temperature, and decomposes within hours to a mixture of unidentified products. Thus, the formation of $\mathbf{6}PF_6$ is always accompanied by some decomposition, and analytically pure samples of it and its oxidation products (see below) could not be obtained.

Formation of 3-Metalla-1,2-dioxolanes from Ethene Complexes

Rhodium tpa Complexes

Oxidation of $\mathbf{7}BPh_4$ by air at room temperature *in solution* (acetone, acetonitrile, dichloromethane) results in the dissociation of ethene and the formation of a mixture of unidentified products. In marked contrast, exposure of *solid* $\mathbf{7}BPh_4$ to air for two days results in the formation of 3-rhoda-1,2-dioxolane $\mathbf{8a}BPh_4$ (Scheme 4).[11] A small amount of the hydroperoxy hydroxy complex $\mathbf{25}BPh_4$ is also formed (see below).

The ESI-MS spectrum of $\mathbf{8a}BPh_4$ shows a base peak at m/z = 453, corresponding to $[(tpa)Rh(CH_2CH_2) + O_2]^+$. The ^1H NMR spectrum shows the presence of a $Rh-CH_2-CH_2$ group. The $^3J(H_\alpha,H_\beta)$ coupling constant for this group (6.1 Hz, Table 1) suggests that it is part of a five-membered ring: the coupling constant is intermediate in magnitude between that observed in the four-membered 2-rhodaoxetane ring in $\mathbf{12b}^+$ and the six-membered ring in the rhodium 2-(acetimidoyloxy)ethyl complex $\mathbf{13b}^{2+}$ (Scheme 5).[5]

Crystals of $\mathbf{8a}BPh_4$ suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into a 1,2-dichloroethane/acetonitrile solution. The unit cell contains two crystallographically independent units, which are almost mirror images. The structure of one of the units is shown in Figure 3. The five-membered ring has an envelope conformation. The puckering of the 3-rhoda-1,2-dioxolane ring is virtually the same as in the 3-platina-1,2-dioxolane ring of **1**.[3a],[12] The average O1−O2 distance [1.500(17) Å] is normal compared with the O−O distances in **1** [1.482(15) Å][3a] and other M−O−O-C compounds (1.40−1.52 Å);[13] the average O2−C2 distance [1.443(10) Å] is also similar to that in **1** [1.407(19) Å] and other M−O−O-C compounds (1.40−1.47 Å).[14]

The nature of the counterion largely influences the selectivity of this solid-gas oxygenation reaction. On changing the counterion of $\mathbf{7}^+$ from BPh_4^- to PF_6^-, a 1:1 mixture of

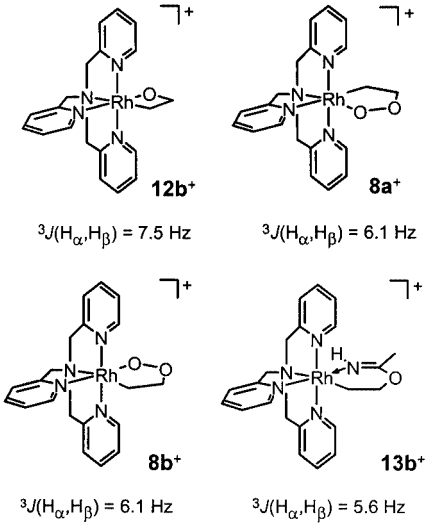

Scheme 5. Typical $^3J(H_\alpha,H_\beta)$ for $Rh-CH_2-CH_2$ fragments in four-membered (**12b**$^+$), five-membered (**8a**$^+$, **8b**$^+$), and six-membered (**13b**$^{2+}$) rings

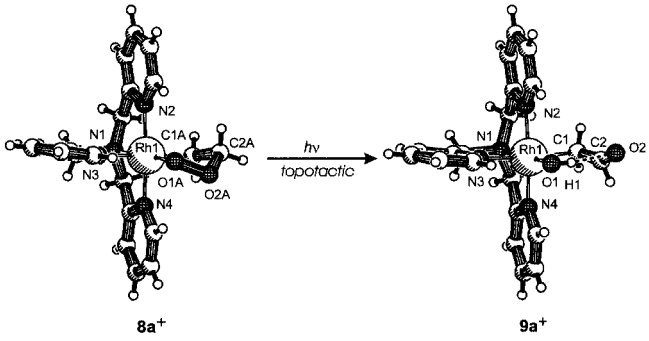

Figure 3. X-ray structures of 3-rhoda-1,2-dioxolane **8a**$^+$ and rhodium formylmethyl hydroxy complex **9a**$^+$

8aPF_6 and a new complex **8b**PF_6 is obtained after exposure to air for two days.[11] The ESI-MS and ^{1}H NMR spectra of the mixture of **8a**PF_6 and **8b**PF_6 in CD_3CN indicate that **8b**$^+$ is the isomeric 3-rhoda-1,2-dioxolane in Scheme 4. The C_α resonances in the ^{13}C NMR spectrum are at δ = 35.0 and δ = 44.8 ppm for **8a**$^+$ and **8b**$^+$, respectively, reflecting the stronger donor capacity of a pyridine versus an amine group (Table 2). The same trend is observed for **9a**$^+$/**9b**$^+$, **10a**$^+$/**10b**$^+$, and **11a**$^+$/**11b**$^+$, which are discussed below.

The NOE contacts in **8a**$^+$ and **8b**$^+$ are consistent with their proposed structures: isomer **8a**$^+$ shows NOE contacts between $Rh-CH_2-CH_2-$ and one proton each of the two equivalent $Rh-N_{amine}-CH_2-$ groups, and between $Rh-CH_2-CH_2-$ and the two equivalent py-H6 atoms; isomer **8b**$^+$ shows NOE contacts between $Rh-CH_2-CH_2-$ and all three py-H6 atoms, and between $Rh-CH_2-CH_2-$ and the two equivalent py-H6 atoms.

Possibly, the different packing in (microcrystalline) **7**BPh_4 and **7**PF_6 leads to the different accessibility of cation **7**$^+$ to O_2. Remarkably, oxidation of **7**$^+$ by hydrogen peroxide only leads to the formation of 2-rhodaoxetane **12b**$^+$ (N_{amine}, *C trans*) (Scheme 5).[5] Thus far, a 2-rhodaoxetane, **12a**$^+$ (N_{amine}, *O trans*), has not been observed.

Besides the influence of the counterion, small ligand changes also have a large effect on the reactivity of *solid* rhodium-ethene complexes towards air. Substitution of one

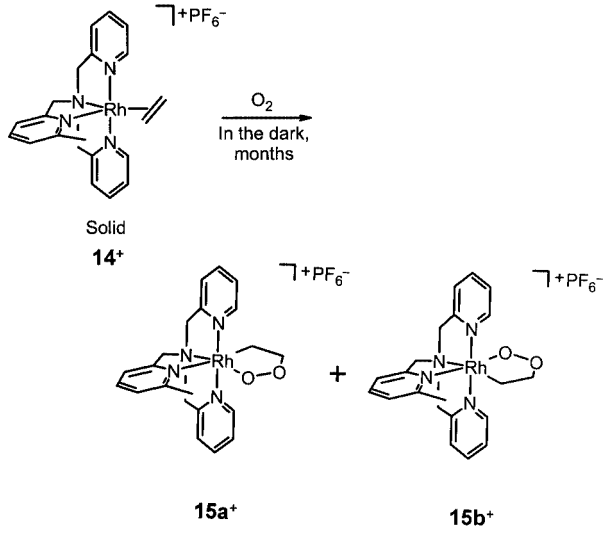
Py-H6 of tpa for a methyl group, for example, leads to a large decrease in the reaction rate. According to the ^1H NMR spectrum (Scheme 6), exposure of *solid* **14**PF_6 to pure molecular oxygen for *7 months* results in approximately 45% conversion into a 2:1 mixture of **15a**$^+$ and **15b**$^+$ (the remainder being starting material). Exposure of *solid* **14**BPh_4 to pure molecular oxygen for a similar period of time also results in the formation of a mixture of **15a**$^+$ and **15b**$^+$. This was unexpected since exposure of the analogous complex **7**BPh_4 only results in the formation of isomer **8a**$^+$. Again, different packing in **7**BPh_4 and **14**BPh_4 might be responsible for this difference in selectivity.



Scheme 6. Oxygenation of rhodium ethene complex **14**PF_6

Iridium tpa Complexes

Exposure of a *solution* of **4**BPh_4 to air leads to a mixture of unidentified products, whereas exposure of *solid* **4**BPh_4 to air leads to the formation of 3-irida-1,2-dioxolane **10a**BPh_4 (Scheme 4). Exposure of *solid* **4**PF_6 to air results in the formation of a mixture of the isomeric iridadioxolanes **10a**PF_6 and **10b**PF_6, in an approximate ratio of 2:5 (Scheme 4). Powder X-ray diffraction spectra of **4**PF_6 and **7**PF_6 show that these complexes are isomorphous, which indicates that the different ratios in which the isomeric 3-rhoda- and 3-iridadioxolanes are formed do not stem from the different packing of the starting materials.

ESI-MS spectra of **10a**BPh_4 and **10a**PF_6/**10b**PF_6 could not be obtained because of the instability of these complexes in solution at room temperature (see below). The ^1H NMR spectra show two triplets for the $Ir-CH_2-CH_2-$ fragment, with $^3J(H_\alpha,H_\beta)$ = 6.2 and 6.7 Hz for **10a**$^+$ and **10b**$^+$, respectively. This indicates that the fragments are part of five-membered rings (Table 1, Scheme 5). The ^1H NMR signals for Ir*C*H_2- and for $-CH_2O-$ were assigned by analogy with the 3-rhoda-1,2-dioxolanes (Table 1).

Rhodium N_4Me_2 Complexes

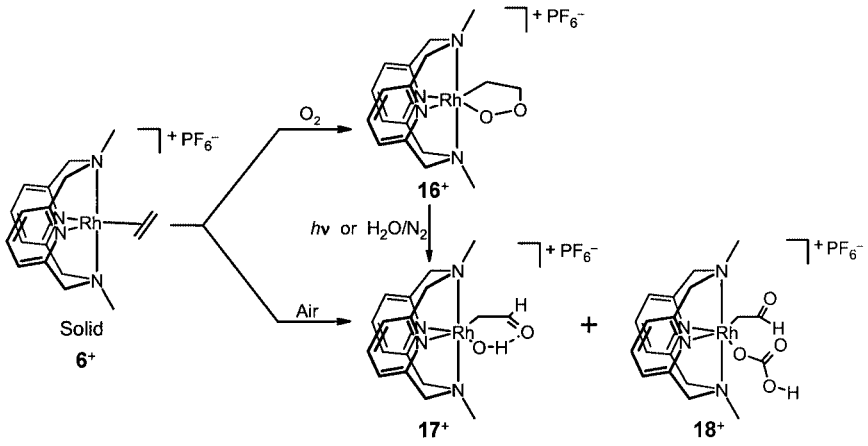
On reaction of *solid* **6**PF_6 with dioxygen (instead of air; see below), at room temperature in the dark, **16**PF_6 was formed within a few days.[11] The ^1H NMR spectrum of **16**PF_6 shows two double triplets at δ = 2.94 ppm and at δ = 3.70 ppm, indicating the presence of a $RhCH_2CH_2X$ fragment (Table 1). A coupling constant of $^3J_{H,H}$ = 6.5 Hz for these signals indicates that a five-membered ring is formed (Table 1). The ESI-MS spectrum shows a base peak at m/z = 431, which is in accordance with the formation of 3-rhodadioxolane **16**$^+$ (Scheme 7). All attempts to obtain X-ray quality crystals of **16**$^+$ failed, partly because of its instability in solution.

Rearrangement of 3-Metalla-1,2-dioxolanes to Formylmethyl Hydroxy Complexes

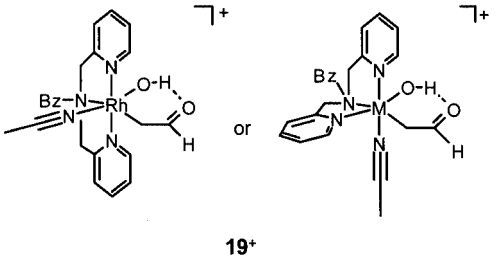
Rhodium tpa Complexes

Exposure of microcrystalline **8a**BPh_4 to glass-filtered daylight under N_2 results in the selective conversion into the corresponding rhodium formylmethyl hydroxy complex **9a**BPh_4, in several weeks (Scheme 4). Similarly, exposure of a solution of **8a**BPh_4 in CD_3CN to the glass-filtered light of a high-pressure mercury lamp at −30 °C results in the conversion into **9a**BPh_4. Monitoring of this reaction by ^1H NMR indicates that an optimum yield of 90% **9a**BPh_4 is obtained after 90 minutes of illumination (see Supporting Information).

The ESI-MS spectrum of **9a**$^+$ is similar to that of **8a**$^+$, with the exception of a peak at m/z = 435, which corresponds to the loss of water from the parent cation. Such loss of water in the gas-phase has been observed earlier for the transient formylmethyl hydroxy complex [(MeCN)(Bzbpa-κ^3)Rh(CH_2CHO-κ^1)(OH)]BPh_4 (**19**BPh_4), which is the only other formylmethyl hydroxy complex reported thus far,[15,16] although several other formylmethyl complexes have been reported.[17]



Scheme 7. Formation and rearrangement of rhodadioxolane **16**PF_6 and subsequent reaction with CO_2

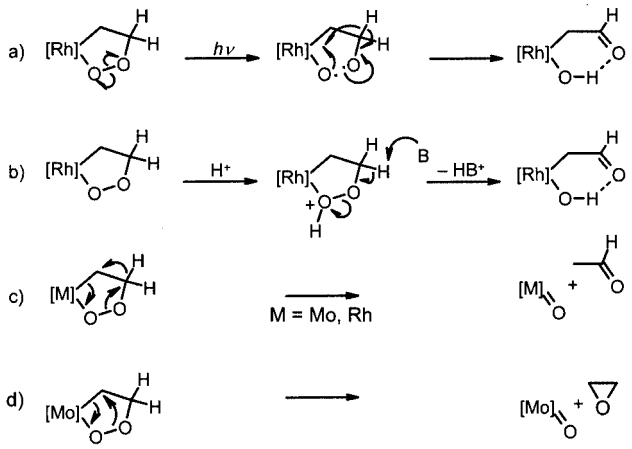


The ^1H NMR and ^{13}C NMR spectra of **9a**BPh_4 show signals typical of a metal-bound formylmethyl group, similar to those found in **19**BPh_4 (Tables 1 and 2).[16] Complex $\mathbf{9a}^+$ shows a strong IR absorption at 1655 cm^{-1}, in accordance with the presence of a carbonyl group.

After repeated attempts to obtain X-ray quality crystals of **9a**BPh_4 had failed, an attempt was made to photochemically convert a single crystal of **8a**BPh_4 to a single crystal of **9a**BPh_4. The crystal that had been used for the X-ray structure determination of **8a**BPh_4 was exposed to glass-filtered daylight for one week and its crystal structure was re-determined. It was found that $\mathbf{8a}^+$ had been fully converted into $\mathbf{9a}^+$ leaving the crystal packing virtually unchanged (a "topotactic" transformation).[18]

The crystal structure of $\mathbf{9a}^+$ shows that the hydroxy group forms a hydrogen-bond with the formyl fragment, thus forming a puckered six-membered ring (Figure 3). The bridging hydrogen (H1) was refined at an O1−H1 distance of 0.80(5) Å [Rh−O1−H1 = 99(4)°] and a H1−O2 distance of 1.92(5) Å [O1−H1−O2 = 168(5)°]. The puckering of the six-membered ring results from the rotation of the formyl fragment around the C1−C2 bond [torsion angle Rh−C1−C2−O2 = −72(3)°]. The crystal structure of $\mathbf{9a}^+$ is discussed in more detail in the supporting information.

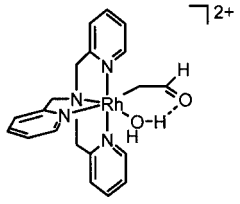
We propose that the photochemical rearrangement of $\mathbf{8a}^+$ to $\mathbf{9a}^+$ involves photolysis of the O−O bond, followed by abstraction of a β-hydrogen atom from $-CH_2-CH_2-O^{\cdot}$ by $-O^{\cdot}$ (Scheme 8, a). In the solid state, the puckering of the 3-rhoda-1,2-dioxolane ring positions a β-hydrogen in close proximity of the O1 atom (Figure 3). Therefore, this reaction would not be hindered by the constraints of the lattice. The mechanism, shown in Scheme 8 (see a), is supported by preliminary DFT calculations.[19]



Scheme 8. Proposed mechanisms for rearrangement of 3-metalla-1,2-dioxolanes: a) photochemically, to a formylmethyl hydroxy complex b) proton assisted, to a formylmethyl hydroxy complex c) directly, to an oxo complex species and acetaldehyde[1a,2] and d) directly, to an oxo complex and ethylene oxide[1f]

Analogous to microcrystalline 3-rhoda-1,2-dioxolane **8a**BPh_4, the microcrystalline mixture of the isomeric 3-rhoda-1,2-dioxolanes **8a**PF_6 and **8b**PF_6 (**8a**PF_6/**8b**PF_6) rearranges photochemically to a mixture of the isomeric formylmethyl hydroxy complexes **9a**PF_6 and **9b**PF_6 (**9a**PF_6/**9b**PF_6; Scheme 4). However, **8a**BPh_4 and **8a**PF_6/**8b**PF_6 react differently when exposed to a N_2 atmosphere saturated with H_2O; complex **8a**BPh_4 proved to be stable, whereas **8a**PF_6/**8b**PF_6 rearranges to **9a**PF_6/**9b**PF_6. Since **8a**PF_6/**8b**PF_6 is stable under dry N_2, this reactivity must have been triggered by the presence of H_2O. Since there is no obvious mechanism by which H_2O would directly cause O−O bond breaking in the rhodadioxolane, we considered the possibility that a trace of acid (possibly generated from hydrolysis of a small amount of PF_6^- to $PF_2O_2^-$ and HF) catalyzes the conversion. To investigate proton-assisted ring opening in solution, 0.1 equivalent of the noncoordinating acid $[H(OEt_2)_2]B[C_6H_3(CF_3)_2]_4$ ($HBAr^F_4$) was added to a solu-

tion of **8a**BPh_4 in CD_3CN. In a typical experiment, the ^1H NMR spectrum shows that **8a**$^+$ is converted into the formylmethyl hydroxy complex **8a**$^+$ (87%) within 10 minutes, and a small amount (8%) of the formylmethyl aqua complex **20a**$^{2+}$ (i.e. protonated **9a**$^+$) is also formed.[20] Likewise, addition of 1.1 equivalent of $HBAr^F_4$ to a solution of **8a**BPh_4 results in the formation of **20a**$^{2+}$ in approximately 85% yield within 10 minutes.[20] In the latter case, any **9a**$^+$ formed is apparently directly protonated. This protonation results in a downfield shift of the Rh−CH_2−CHO and Rh−CH_2−C*H*O ^1H NMR signals from δ = 2.69 to δ = 3.05 ppm and from δ = 9.26 to δ = 9.51 ppm, respectively. The base-peak in the ESI-MS spectrum of the obtained solution has the correct isotope distribution pattern and *m*/*z* value (227) for **20a**$^{2+}$. As demonstrated by its formylmethyl ^1H NMR signals, a trace of **20a**$^{2+}$ is also formed in the conversion of *solid* **8a**PF_6/**8b**PF_6 to **9a**PF_6/**9b**PF_6 under N_2 saturated with H_2O. This supports our hypothesis of an acid-catalyzed ring opening.



20a^{2+}

A possible mechanism for the acid-catalyzed ring opening is shown in Scheme 8, b. Protonation of **8a**$^+$ at O_α induces heterolytic splitting of the O−O bond, followed by the deprotonation at C_β by an external base and the formation of a carbonyl double bond. This mechanism was supported by preliminary DFT calculations.[19]

The isomeric 3-rhodadioxolanes **8a**$^+$ and **8b**$^+$ clearly differ in their photoreactivity: on exposure of a CD_3CN solution of **8a**$^+$ and **8b**$^+$ to glass-filtered daylight at room temperature, the relative intensities of the ^1H NMR 2-peroxyethyl signals show that the initial reaction rate of **8b**$^+$ is three times faster than that of **8a**$^+$ (Figure 4).

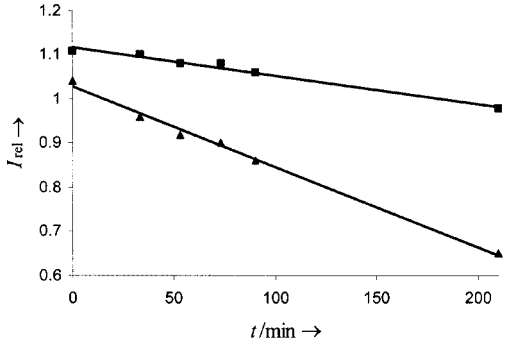


Figure 4. Relative intensities of the 2-peroxyethyl ^1H NMR signals of **8a**$^+$ (■) and **8b**$^+$ (▲) on exposure to glass-filtered daylight

Formylmethyl hydroxy complexes **9a**$^+$ and **9b**$^+$ decompose to a mixture of unidentified products in solution at room temperature on prolonged exposure to light.

Iridium tpa Complexes

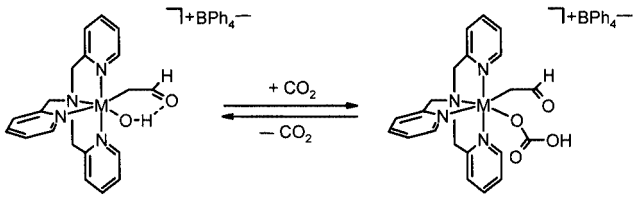
Both **10a**$^+$ and **10b**$^+$ rearrange to iridium formylmethyl hydroxy complexes (**11a**$^+$ and **11b**$^+$) on exposure to light. The ESI-MS spectra of **11a**BPh_4 and **11a**PF_6/**11b**PF_6 show the expected base peak at *m*/*z* = 543. For **11a**BPh_4, the daughter ion spectrum from this base peak shows a peak at *m*/*z* = 525, corresponding to the loss of water.

There is a large difference in reactivity between the 3-rhodadioxolanes and the 3-iridadioxolanes: 3-iridadioxolanes rearrange to form formylmethyl hydroxy complexes in solution at room temperature, whereas 3-rhodadioxolanes need to be exposed to light or protons before rearrangement can take place. It is possible that the iridadioxolanes are more sensitive to traces of adventitious acid, e.g. on glass surfaces, than the rhodadioxolanes. Another possibility is that for iridium, water is already a strong enough acid to induce the conversion. Finally, an alternative conversion mechanism, not requiring any acid, may be possible for iridium.

The iridium formylmethyl hydroxy complexes **11a**$^+$ and **11b**$^+$ are stable in CH_3CN solution at room temperature when exposed to light, whereas the rhodium analogues decompose under these conditions.

Rhodium N_4Me_2 Complexes

Both in the presence and absence of visible light, the *solid* mono-ethene complex **6**PF_6 reacts with air, within a few days at room temperature, to form a mixture of two formylmethyl complexes in an approximate ratio of 5:1, according to the ^1H NMR spectrum in CD_3CN. The ESI-MS spectrum of the mixture in CH_3CN shows a base peak at *m*/*z* = 431, in accordance with the presence of the formylmethyl hydroxy complex **17**$^+$, and a peak at *m*/*z* = 475, corresponding to the formylmethyl hydrogen carbonate complex **18**$^+$. Water present in the air probably induces an acid-catalyzed rearrangement of the initially formed dioxolane to a formylmethyl hydroxy complex. Although rearrangement on exposure to a nitrogen atmosphere saturated with water had been observed earlier for the tpa complexes (see above), rearrangement on exposure to air was not observed. Furthermore, the resulting formylmethyl hydroxy complex reacts with carbon dioxide from the air, forming **18**$^+$. This has not been observed for the tpa complexes either. However, exposure of **9a**BPh_4 or **11a**BPh_4 to a CO_2 atmosphere leads to the full conversion into the formylmethyl hydrogen carbonate complexes **21a**BPh_4 and **22a**BPh_4, respectively (Scheme 9). On removal of the CO_2 atmosphere, CO_2 is released and the formylmethyl hydroxy complexes **9a**BPh_4 or **11a**BPh_4 are regenerated. Formation of rhodium and iridium hydrogen carbonate complexes from metal hydroxy complexes and CO_2, and vice versa have been reported before.[21]



Scheme 9. Reversible reaction of formylmethyl hydroxy complexes $\mathbf{9a}^+$ and $\mathbf{11a}^+$ with CO_2

Exposure of *solid* $\mathbf{16}PF_6$ (obtained from $\mathbf{6}PF_6$ and dioxygen; see above) to visible light and N_2 leads to the conversion into $\mathbf{17}PF_6$, as shown by the ESI-MS, ^1H NMR and ^{13}C NMR spectra in CD_3CN (Tables 1 and 2). Exposure of $\mathbf{16}PF_6$ to water vapour/N_2 also leads to the formation of $\mathbf{17}PF_6$, probably due to the PF_6^- counterion (see above).

Oxidation of a Rhodium Propene Complex to a Peroxo Complex and Its Reactivity towards Water

As mentioned earlier, exposure of *solid* $\mathbf{7}BPh_4$ to air not only produces 3-rhoda-1,2-dioxolane $\mathbf{8a}BPh_4$, but also a small amount of the hydroperoxy hydroxy complex $\mathbf{25}BPh_4$. Exposure of *solid* $\mathbf{7}BPh_4$ to pure dioxygen, however, leads to the formation of $\mathbf{8a}BPh_4$ and a small amount of the peroxo complex $\mathbf{24}BPh_4$. This peroxo complex can be obtained more efficiently by the oxidation of *solid* $[(tpa)Rh(CH_2CHCH_3)]BPh_4$ ($\mathbf{23}BPh_4$) with molecular oxygen (Scheme 10).

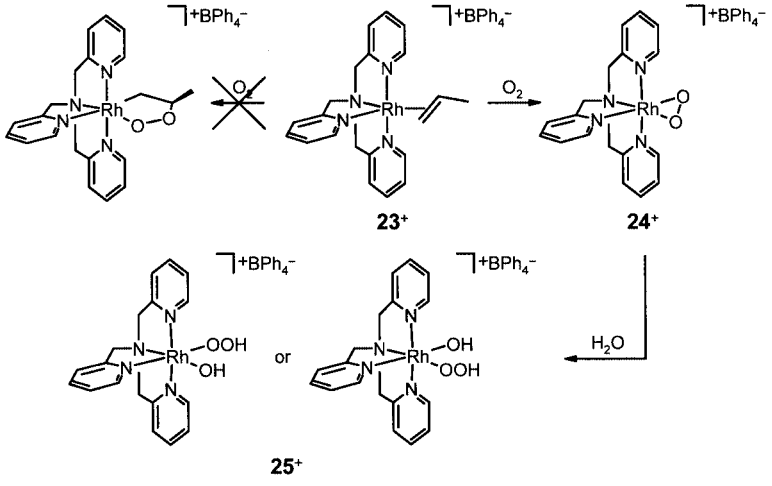
Complex $\mathbf{23}BPh_4$ was synthesized from $[\{(ethene)_2RhCl\}_2]$, propene, tpa, and $NaBPh_4$. It is the first reported rhodium propene complex stabilized by a tetradentate nitrogen donor ligand. Propene coordinates less strongly to the rhodium center than ethene, resulting in an easier loss of olefin from the complex and the quantitative formation of $\mathbf{24}BPh_4$ on oxidation with molecular oxygen. Oxidation with air results in a mixture of unidentified products. The reason for this is still unclear. Possibly, further reactions of $\mathbf{24}BPh_4$ with water (see below), and subsequently with CO_2 occur. The ^1H NMR and ^{13}C NMR spectra of $\mathbf{24}BPh_4$ only show signals for the (coordinated) tpa ligand. The ESI-MS spectrum of $\mathbf{24}BPh_4$ shows a base peak at $m/z = 425$, corresponding to $[(tpa)Rh + O_2]^+$, and the loss of O_2 from the parent cation.[22]

Exposure of complex $\mathbf{24}BPh_4$ to a nitrogen atmosphere saturated with water leads to the complete conversion into $\mathbf{25}BPh_4$. The ^1H NMR and ^{13}C NMR spectra of $\mathbf{25}BPh_4$ again only show signals for the (coordinated) tpa ligand. The ESI-MS spectrum shows a base peak at $m/z = 443$, corresponding to $\mathbf{25}^+$, and the loss of H_2O, HO_2, and H_2O_3 from the parent cation. Complex $\mathbf{25}BPh_4$ is the first rhodium hydroperoxy hydroxy complex reported, but other metal hydroperoxy hydroxy complexes have been reported earlier.[23] Analytically pure samples of $\mathbf{24}BPh_4$ and $\mathbf{25}BPh_4$ were not obtained, due to their instability in solution at room temperature. Since the decomposition of $\mathbf{25}BPh_4$ is a problem in solution at −30 °C as well, no ^{13}C NMR spectroscopic data were obtained for this complex.

Conclusions

We have achieved selective oxidation of $[M]^I$(ethene) (M = Rh, Ir) complexes by air or dioxygen to form isolable 3-metalla-1,2-dioxolanes for the first time. Remarkably selective dioxygenation was only achieved for ethene complexes embedded in a crystalline matrix. The reasons for this difference between solid phase reactivity and solution phase reactivity have not yet been elucidated. However, our results clearly indicate that solid-gas reactions should be considered as a useful alternative to conventional solution phase chemistry, not only under heterogeneous conditions (high pressures and temperatures), but also at room temperature and atmospheric pressure.

Small changes have a large effect on the reactivity of the ethene complexes. The dioxygenation of $\mathbf{14}PF_6$ is much slower than of $\mathbf{7}PF_6$. Using a completely different N_4-ligand (N_4Me_2) results in a higher reactivity of not only the ethene

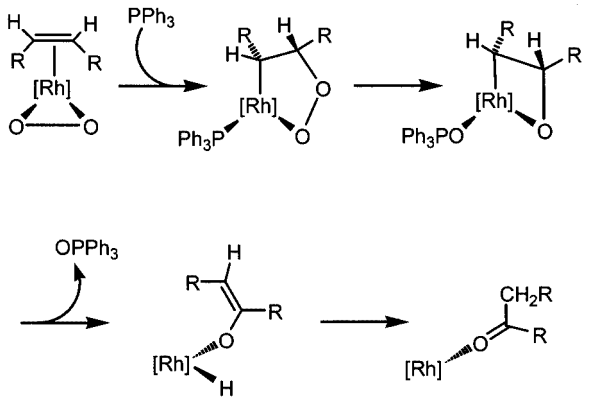


Scheme 10. Reaction of propene complex $\mathbf{23}BPh_4$ with dioxygen

complex, but also of the 3-rhodadioxolane and the formylmethyl hydroxy complex. More interestingly, even the counterion affects the oxidation chemistry; oxygenation of **7**PF_6 results in the formation of two isomeric 3-rhodadioxolanes, whereas oxygenation of **7**BPh_4 only yields one isomer. Thus, it appears that for these solid-gas reactions, new opportunities for reaction tuning exist.

The observed rearrangement of 3-metalla-1,2-dioxolanes to formylmethyl hydroxy complexes is in marked contrast with the rearrangements proposed earlier for 3-metalla-1,2-dioxolanes i.e. direct rearrangement to a metal oxo complex and acetaldehyde, or to a metal oxo complex and ethylene oxide.[1f] However, the formylmethyl complexes may still be intermediates in the formation of acetaldehyde and a rhodium oxo or hydroxy complex.

In the 1980's Read et al. proposed that 3-rhodadioxolanes are intermediates in the co-oxygenation of terminal or cyclic olefins and triphenylphosphane, to ketones and triphenylphosphane oxide (Scheme 11).[1b] The 3-rhodadioxolane is converted into a 2-rhodaoxetane via the transfer of an O atom to triphenylphosphane. The triphenylphosphane oxide stabilized 2-rhodaoxetane then successively loses triphenylphosphane oxide and a ketone. Our findings do not support such a mechanism. 3-Rhoda-1,2-dioxolane **8a**BPh_4 does not react with triphenylphosphane, and the formation of 2-rhodaoxetanes from 3-rhoda-1,2-dioxolanes have not been observed.



Scheme 11. Mechanism proposed by Read for rhodium catalyzed co-oxygenation of olefins and triphenylphosphane to ketones and triphenylphosphane oxide[1b]

Both Mimoun and Read proposed the formation of 3-rhoda-1,2-dioxolanes from rhodium peroxo ethene complexes.[1a,1b] We have not observed such peroxo ethene intermediates in the formation of 3-rhoda-1,2-dioxolanes. Our group has isolated iridium peroxo ethene complexes, generated through the reaction of iridium ethene complexes with dioxygen in solution, however, these complexes are quite stable and the formation of 3-irida-1,2-dioxolanes is not observed from these complexes.[6c]

Experimental Section

General Methods: All procedures were performed under a nitrogen atmosphere using standard Schlenk techniques, unless indicated otherwise. The solvents (p.a.) were deoxygenated by bubbling through a stream of nitrogen.

NMR experiments were carried out on Bruker DPX200, Bruker AC300, Bruker WM400, and Bruker AM-500. Solvent shift references for ^1H NMR are: CD_2Cl_2 $\delta(^1H)$ = 5.31 ppm, CD_3CN $\delta(^1H)$ = 1.94 ppm and [D_6]acetone $\delta(^1H)$ = 2.05 ppm. Solvent shift references for ^{13}C NMR are: CD_3CN $\delta(^{13}C)$ = 118.1 ppm and [D_6]acetone $\delta(^{13}C)$ = 206.18 ppm. Abbreviations used are: s = singlet, d = doublet, dd = double doublet, t = triplet, dt = double triplet, q = quadruplet, qq = quadruplet of quadruplets, m = multiplet, dm = double multiplet, br. = broad. Mass spectra (ESI) were recorded on a Finnigan MAT 900S and a Finnigan TSQ 7000 mass spectrometer. Elemental analyses (C, H N) were carried out on an Hanau Elementar-Analyzer CHN-O-Rapid. Infrared spectra were measured on a Perkin−Elmer 1720X spectrometer.

Compounds [{$(CH_2CH_2)_2RhCl$}$_2$],[24] tpa,[25] Metpa,[26] [(Metpa)$Rh(CH_2CH_2)$]BPh_4/PF_6,[5] [(tpa)$Rh(CH_2CH_2)$]BPh_4/PF_6,[5] N_4Me_2,[27] [{$(C_8H_{14})IrCl$}$_2$],[28] and $[H(OEt_2)_2]B[C_6H_3(CF_3)_2]_4$ ($HBAr^F_4$)[29] were prepared according to literature procedures. All other chemicals were obtained commercially and were used without further purification.

X-ray Diffraction: Crystals of **3**PF_6 suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into an acetonitrile solution. Crystals of **5**PF_6 were obtained by crystallization from acetone/diethyl ether (v/v = 1:3) over a period of nine days at −70 °C. Crystals of **8a**BPh_4 were obtained through slow diffusion of diethyl ether into a 1,2-dichloroethane/acetonitrile solution. A crystal of **9a**BPh_4 was obtained by exposure of a crystal of **8a**BPh_4 to glass-filtered daylight for one week.

X-ray diffraction data for **3**PF_6 and **5**PF_6 were collected at 208(2) K on an Enraf−Nonius CAD4 diffractometer, using graphite monochromatized Mo-K_α radiation (λ = 0.71073 Å) and Cu-$K\alpha$ radiation (λ = 1.54184 Å), respectively. X-ray diffraction data for **8a**BPh_4 and **9a**BPh_4 were collected at 150(2) K on a Nonius KappaCCD diffractometer with rotating anode, using graphite monochromatized Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by the PATTY[30] option of the DIRDIF[31] program system. All non-hydrogen atoms were refined with anisotropic temperature factors. The bridging hydrogen atom of the formyl fragment in **9a**BPh_4 was taken from a difference Fourier map and was freely refined. All other hydrogen atoms were placed at calculated positions and were refined isotropically in riding mode. Subsequently, for **5**PF_6, the hydrogen atoms were freely refined. Selected bond lengths and angles are shown in Tables 3 and 4. Other relevant crystal data are summarized in Table 5. Drawings were generated with the program PLATON.[32]

3PF_6**:** Geometrical calculations (PLATON, Spek 1995)[33] revealed neither unusual geometric features, nor unusual short intermolecular contacts. The calculations revealed no higher symmetry and no solvent accessible areas.

5PF_6**:** There is a disordered solvent molecule present in the crystal structure. Calculations (PLATON, Spek,1995)[33] showed a void of 95 Å^3, containing 31 electrons, at 0.0032, 0.466, 0.842. Based on the synthetic route, the electron density most probably represents one acetone molecule (C_3H_6O, 32 electrons). The SQUEEZE pro-

cedure was applied to account for the electron density of the solvent molecule.

8aBPh$_4$: The five-membered dioxolane ring has the envelope form and occurs in two conformations. As expected there is considerable positional overlap for some of the atoms (C1A and C1B, C2A and C2B, O1A and O1B). Therefore, some geometrical constraints had to be applied: the two conformations were 'SAMEd' and the anisotropic thermal displacement parameters were tied. Calculations (PLATON, Spek 1995)[33] showed two distinct voids, one of 229 Å^3, containing 68 electrons, around a two-fold axis (position 4e, 0, *y*, 1/4; $y = -0.036$), and one of 152 Å^3, containing 44 electrons, around an inversion center (position 4b: 1/2, 0, 0). Based on the synthetic route and evidence from NMR spectroscopy, it is assumed that these electron densities represent one molecule of diethyl ether ($C_4H_{10}O$, 42 electrons) plus one molecule of acetonitrile (CH_3CN, 22 electrons) in the first void (64 electrons, 28.5 Å^3/atom), and one molecule of dichloroethane ($C_2H_4Cl_2$, 50 electrons) in the second void (30.2 Å^3/atom). It was not possible to assign any physically meaningful parameters to the electron densities found in the difference fourier map. Therefore the SQUEEZE procedure was applied to account for these electron densities.

9aBPh$_4$: Hydrogen atom H1 was clearly visually observed in a difference fourier map and its position was subsequently determined automatically. Its positional and thermal parameters were refined freely and this refinement proved to be stable. The position of H1 is well outside the regions influenced by the SQUEEZE procedure described later on.

From the anisotropic thermal displacement parameters for C2 and O2 it is clear that these atoms show a large positional disorder. Although it is possible to use several partially occupied positions for these atoms, no physically reasonable models result from these parameters, at least not any better than the model presented here. Splitting up these atoms serves no other purpose but to lower the *R*-value. The calculated hydrogen positions on C2 are therefore merely indications of possible positions.

Calculations (PLATON, Spek 1995)[33] showed two distinct voids, one of 239 Å^3, containing 58 electrons, around a two-fold axis (position 4e, 0, *y*, 1/4; $y = -0.041$), and one of 152 Å^3, containing 39 electrons, around an inversion center (position 4b: 1/2, 0, 0). Based on the synthetic route and evidence from NMR spectroscopy, it is assumed that these electron densities possibly represent one molecule of diethyl ether ($C_4H_{10}O$, 42 electrons) plus one molecule of acetonitrile (CH_3CN, 22 electrons) in the first void (64 electrons, 29.9 Å^3/non-hydrogen atom), and one molecule of dichloroethane ($C_2H_4Cl_2$, 50 electrons) in the second void (38.0 Å^3/non-hydrogen atom). These assumptions are in accordance with the earlier crystal structure determination of the original crystal of **8a**BPh$_4$ before its exposure to glass-filtered daylight, and account for the calculated physical molecular properties as reported in this paper.

It was not possible to assign any physically meaningful parameters to the electron densities found in the difference fourier map. Therefore, the SQUEEZE procedure was applied to account for these electron densities.

CCDC-187013 (**3**PF$_6$), CCDC-187012 (**5**PF$_6$), CCDC-157414 (**8a**BPh$_4$), and CCDC-170096 (**9a**BPh$_4$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis

Bis(ethene)[*N*-(2-pyridylmethyl)-*N*,*N*-bis(2-pyridylmethyl-κ*N*)amine-κ*N*]iridium(I) Hexafluorophosphate (3PF$_6$): Ethene was bubbled through a solution of $[(C_8H_{14})_2IrCl]_2$ (325 mg, 0.36 mmol) in MeOH (13 mL) until a clear solution was obtained. Under an ethene atmosphere, tpa (216 mg, 0.74 mmol) was added and the reaction mixture was stirred for 10 minutes. KPF_6 (167 mg, 0.91 mmol) was then added under an ethene atmosphere, and after stirring for 1 hour, the solution was cooled to −78 °C. The cold suspension was filtered under a nitrogen atmosphere and the white

Bis(ethene)[*N*-(2-pyridylmethyl)-*N*,*N*-bis(2-pyridylmethyl-κ*N*)amine-κ*N*]iridium(I) Tetraphenylborate (3BPh_4): Complex **3**BPh_4 was obtained by the same procedure as **3**PF_6, using $NaBPh_4$ instead of KPF_6.

(Ethene)[*N*,*N*,*N*-tris(2-pyridylmethyl-κ*N*)amine-κ*N*]-iridium(I) Hexafluorophosphate (4PF_6): Complex **4**PF_6 was synthesized according to the same procedure as bis(ethene) complex **3**PF_6, but nitrogen was bubbled through the MeOH solution before the addition of KPF_6. Complex **4**PF_6 was obtained as a yellow/orange powder. Yield: 83%. ^{1}H NMR (200 MHz, CD_3CN, 300 K): δ = 9.19 (d, $^3J_{H,H}$ = 5.2 Hz, 1 H, Py_a-H6), 8.28 (d, $^3J_{H,H}$ = 5.3 Hz, 2 H, Py_b-H6), 7.64 (t, $^3J_{H,H}$ = 7.8 Hz, 3 H, Py-H4), 7.21 (m, 4 H, Py-H3 and Py_a-H5), 7.05 (t, $^3J_{H,H}$ = 6.6 Hz, 2 H, Py_b-H5), 5.11 (d[AB], $^2J_{H,H}$ = 15.3 Hz, 2 H, NCH_2Py_b), 4.83 (d[AB], $^2J_{H,H}$ =

15.3 Hz, 2 H, NCH_2Py$_b$), 4.69 (s, 2 H, NCH_2Py$_a$), 1.28 (m, 4 H, CH_2CH_2) ppm; ^{13}C{^{1}H} NMR (75 MHz, CD_3CN, 300 K): δ = 165.5 (Py$_b$-C2), 161.1 (Py$_a$-C2), 152.4 (Py$_a$-C6), 151.4 (Py$_b$-C6), 137.8 (Py$_a$-C4), 136.3 (Py$_b$-C4), 125.8 (Py$_b$-C3/5), 124.6 (Py$_a$-C3/5), 123.4 (Py$_b$-C3/5), 122.3 (Py$_a$-C3/5), 71.6 (NCH$_2$Py$_b$), 65.9 (NCH$_2$Py$_a$), 4.3 (CH$_2$CH$_2$), 4.1 (CH$_2$$CH_2$) ppm. ESI-MS (THF): 511 [M − PF$_6$]$^+$, 483 [M − CH$_2$CH$_2$ − PF$_6$]$^+$; elemental analysis for **4**PF$_6$ ($C_{20}H_{22}F_6IrN_4P$; 655.61): calcd. C 36.64, H 3.38, N 8.55; found C 36.63, H 3.44, N 8.66 %.

(Ethene)[*N*,*N*,*N*-tris(2-pyridylmethyl-κ*N*)amine-κ*N*]-iridium(I) Tetraphenylborate (4BPh$_4$): Complex **4**BPh$_4$ was obtained by the same procedure as **4**PF$_6$, using NaBPh$_4$ instead of KPF$_6$.

Bis(ethene){3,11-dimethyl-3,11,17,18-tetraazatricyclo-[11.3.1.1^{5,9}]octadeca-1(17),5(18),6,8,13,15-hexaene-κ^4*N*^{1},*N*^{2},*N*^{3}} rhodium(I) Hexafluorophosphate (5PF$_6$): [Rh(μ-Cl)(C$_2$H$_4$)$_2$]$_2$ (100 mg, 0.26 mmol) was added to a suspension of NaHCO$_3$ (100 mg, 1.2 mmol) in methanol (5 mL) at −20 °C. The reaction mixture was stirred for 15 minutes, after which N_4Me_2 (138 mg, 0.51 mmol) was added. After stirring for 5 minutes at −20 °C, the reaction mixture was cooled to −78 °C and stirred for 30 minutes. Undissolved material was removed by filtration. A solution of KPF$_6$ (100 mg, 0.54 mmol) in methanol (1 mL) was then added to the filtrate at −78 °C, causing the precipitation of a light yellow solid. After stirring for 1 hour, the solid was collected by filtration. Additional KPF$_6$ (60 mg, 0.33 mmol) was added to the filtrate. The solution was warmed to room temperature for two minutes, after which it was cooled to −78 °C again. This produced a second batch of solid, which was collected by filtration after stirring for 15 minutes. The combined solids were washed with methanol and dried under vacuum. Yield: 245 mg (83%). ^{1}H NMR (500 MHz, [D$_6$]acetone, 203 K): δ = 7.73 (t, $^3J_{H,H}$ = 7.8 Hz, 2 H, Py-H4), 7.37 (d, $^3J_{H,H}$ = 7.5 Hz, 2 H, Py-H3/5), 7.28 (d, $^3J_{H,H}$ = 7.8 Hz, 2 H, Py-H3/5), 6.06 (d[AB], $^2J_{H,H}$ = 14.1 Hz, 2 H, NCH_2Py), 5.17 (d[AB], $^2J_{H,H}$ = 16.7 Hz, 2 H, NCH_2Py), 4.51 (d[AB], $^2J_{H,H}$ = 16.9 Hz, 2 H, NCH_2Py), 4.46 (d[AB], $^2J_{H,H}$ = 14.1 Hz, 2 H, NCH_2Py), 3.84 (s, 3 H, NCH_3), 3.22 (m, 2 H, CH_2CH_2), 2.92 (br.t, $^3J_{H,H}$ = 10.3 Hz, 2 H, CH_2CH_2), 2.53 (br.t, $^3J_{H,H}$ = 10.9 Hz, 2 H, CH_2CH_2), 2.25 (s, 3 H, NCH_3), 1.72 (m, 2 H, CH_2CH_2) ppm; ^{13}C{^{1}H} NMR (100 MHz, [D$_6$]acetone, 243 K): δ = 160.0 (Py-C2/6), 158.1 (Py-C2/6), 138.4 (Py-C4), 126.3 (Py-C3/5), 121.9 (Py-C3/5), 68.1 (NCH$_2$Py), 65.4 (NCH$_2$Py), 57.7 (br., CH$_2$$CH_2$), 52.6 (N$CH_3$), 46.6 (br., CH$_2$$CH_2$), 37.7 (N$CH_3$) ppm. ESI-MS ($CH_3CN$): 427 [M − PF$_6$]$^+$, 399 [M − (CH$_2CH_2$) − PF$_6$]$^+$.

(Ethene){3,11-dimethyl-3,11,17,18-tetraazatri-cyclo[11.3.1.1^{5,9}]octadeca-1(17),5(18),6,8,13,15-hexaene-κ^4*N*^{1},*N*^{2},*N*^{3},*N*^{4}}rhodium(I) Hexafluorophosphate (6PF$_6$): After stirring **5**PF$_6$ (245 mg, 0.43 mmol) in [D$_6$]acetone (10 mL) for 4 hours, diethyl ether (40 mL) was added. A red solid precipitated and was collected by filtration and washed with diethyl ether. The obtained brick-red solid was isolated by filtration, washed with diethyl ether and dried in vacuo. Yield 112 mg (48%). ^{1}H NMR (200 MHz, CD_3CN, 298 K): δ = 7.62 (t, $^3J_{H,H}$ = 7.9 Hz, 2 H, Py-H4), 7.11 (d, $^3J_{H,H}$ = 7.8 Hz, 4 H, Py-H3 and Py-H5), 4.01 (d[AB], $^2J_{H,H}$ = 15.1 Hz, 4 H, NCH_2Py), 3.82 (d[AB], $^2J_{H,H}$ = 15.0 Hz, 4 H, NCH_2Py), 2.54 (d, $^2J_{H,Rh}$ = 2.4 Hz, 4 H, CH_2CH_2), 2.15 (d, $^3J_{H,Rh}$ = 1.3 Hz, 6 H, NCH_3) ppm; ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone, 297 K): δ = 155.4 (Py-C2 and Py-C6), 136.6 (Py-C4), 121.3 (Py-C3 and Py-C5), 76.1 (NCH$_2$Py), 49.8 (NCH$_3$), 24.8 (d, $J_{C,Rh}$ = 18 Hz, CH$_2$$CH_2$) ppm. Chelate Complexes of Functionalized Cycloheptatrienyl Ligands: Molybdenum Complexes with Linked Cycloheptatrienyl-Phosphane Ligands and Their Use in Catalytic Carbon−Carbon Bond Formation

Matthias Tamm,*[a][‡] Bernd Dreßel,[a][‡] Thomas Lügger,[a] Roland Fröhlich,[b] and Stefan Grimme[b]

Keywords: Alkyne ligands / C−C coupling / Cycloheptatrienyl ligands / Density functional calculations / Hydride ligands

The synthesis of *P*-functionalized molybdenum chelate complexes incorporating the linked cycloheptatrienyl-phosphane ligand [2-(diisopropylphosphanyl)phenyl]cycloheptatrienyl (*o*-*i*Pr_2P–C_6H_4–C_7H_6) is described. From the ligand precursor [2-(cyclohepta-2,4,6-trienyl)phenyl]diisopropylphosphane (**1**) the paramagnetic 17-electron dibromide [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)$MoBr_2$(*P–Mo*)] (**2**) can readily be obtained. This is a versatile starting material for the preparation of cycloheptatrienyl molybdenum hydrides [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)Mo(η^2-BH_4)(*P–Mo*)] (**3**) and [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)Mo(PPh_3)-H(*P–Mo*)] (**4**). Treatment of **3** with dimethylanilinium tetraphenylborate ([$PhNMe_2H$][BPh_4]) allows the production of the cationic 14-electron complex fragment [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)Mo(*P–Mo*)]$^+$ (**13**), which can be stabilized in the presence of suitable ligands L. The complexes [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)MoL_2(*P–Mo*)]BPh_4 [L = dimethylphenyl isocyanide, (**5**)BPh_4; L_2 = η^4-2,5-norbornadiene, (**6**)BPh_4; L_2 = η^2-phenylacetylene, (**7**)BPh_4; L_2 = η^2-*tert*-butylacetylene, (**8**)BPh_4] can thus be isolated in good yields. The alkyne complex (**7**)BPh_4 can be used as a single-source catalyst for the oligomerization of phenylacetylene, affording a mixture of triphenylbenzenes and linear oligomers. Quantum chemical calculations reveal an intimate relationship between the catalytically active 14-electron complex fragment [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)Mo(*P–Mo*)]$^+$ (**13**) and *hypothetical* isoelectronic and isolobal complexes of the type [(*o*-*i*$Pr_2PC_6H_4$-η^5-C_5H_4)M(*P–M*)]$^+$ (M = Ru, **14**; M = Os, **15**), indicating that cycloheptatrienyl molybdenum systems might in general be a suitable replacement for cyclopentadienyl ruthenium and osmium catalysts.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Ruthenium half-sandwich complexes of the type [(η-C_5R_5)Ru(PR'_3)$_2$Cl] (R = H, Me; R′ = alkyl, aryl) are among the most important starting materials in organotransition metal chemistry and have played key roles in the stabilization of highly reactive species such as vinylidenes and allenylidenes by metal coordination.[1] In addition, extensive studies have shown that these complexes are particularly useful for effective ruthenium-catalyzed C−C bond formation.[2] The actual active catalyst system in this process is generated by splitting off of the halide and one phosphane ligand, resulting in the formation of the doubly coordinatively unsaturated complex fragment [(η-C_5R_5)Ru(PR'_3)]$^+$ (**I**), which allows various organic substrates to be brought together and coupled in its coordination sphere.[2,3] The similarity between the isoelectronic and isolobal fragments [(η-C_5R_5)Ru] and [(η-C_7H_7)Mo] prompted us to pursue a general study on the possibility of replacing the frequently used ruthenium catalysts by the analogous but much cheaper molybdenum systems. Consequently, similar chemical and physical properties may be expected in complexes possessing an identical set of co-ligands upon substitution of the [(η-C_5R_5)Ru] unit by [(η-C_7H_7)Mo] unit.[4,5]

Our goal of introducing cycloheptatrienyl molybdenum complexes into homogeneous catalysis is based on the concept of donor functionalization, extremely successful in cyclopentadienyl chemistry in particular,[6−9] and we have already been able to synthesize complexes with novel cycloheptatrienyl ligands bearing pendant O-, N-, S- and P-donor groups capable of coordinating to a transition metal center in a chelating η^7:η^1-fashion.[10,11] Complexes with linked cycloheptatrienyl-phosphane ligands seemed to be particularly well suited for applications in catalytic C−C coupling reactions, and so we have started to prepare precursor complexes that should allow us to obtain coordin-

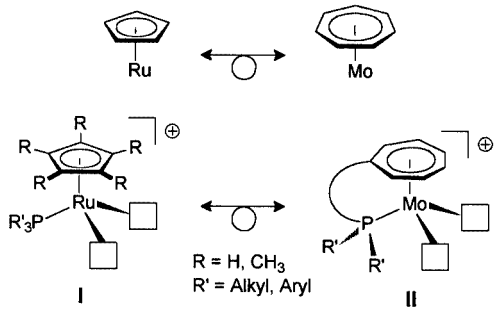
atively unsaturated molybdenum complex fragments of type **II** (Scheme 1).[12] In this contribution we present the syntheses of tetrahydroborate complexes of type [(*o*-$R_2PC_6H_4$-η^7-C_7H_6)Mo(η^2-BH_4)(*P*-*Mo*)] (R = *i*Pr, Ph), from which the cationic 14-electron complex fragments [(*o*-$R_2PC_6H_4$-η^7-C_7H_6)Mo(*P*-*Mo*)]$^+$ can be generated and stabilized in the presence of suitable co-ligands.



Scheme 1. Isolobal relationship between cyclopentadienyl ruthenium and cycloheptatrienyl molybdenum complex fragments

Results and Discussion

Preparation and Reactions of Molybdenum Hydride Complexes

We have recently reported on the preparation of a cycloheptatriene with a diphenylphosphanyl donor group, and were able to demonstrate that the resulting paramagnetic 17-electron complexes of the type [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)MoX_2(*P*-*Mo*)] (X = Br, CH_2SiMe_3) can be used in the ring-opening metathesis polymerization of norbornene.[11] In order to render the donor moiety more sterically demanding and electron-rich, we aimed at replacement of the phenyl substituents with isopropyl groups, and the corresponding ligand precursor [2-(cyclohepta-2,4,6-trienyl)-phenyl]diisopropylphosphane (**1**) used in this contribution was prepared by addition of 2-(diisopropylphosphanyl)-phenyllithium to the tropylium cation $C_7H_7^+$. A three-step synthesis starting from the air-sensitive **1** and $Mo(CO)_6$ affords the 17-electron dibromo complex **2** (Scheme 2). Full details of the preparation of **1** and **2**, together with the spectroscopic and structural properties of all reaction intermediates, will be presented elsewhere.[13]

Reduction of paramagnetic **2** can be achieved by use of $NaBH_4$ in ethanol solution, resulting in the formation of the tetrahydroborate complex **3** (Scheme 2). In contrast, Suzuki and co-workers have shown that the corresponding treatment of isoelectronic ruthenium(III) complexes of the type [(η-C_5Me_5)Ru(PR_3)Cl_2] (R = Ph, *i*Pr, *cyclo*-C_6H_{11}) does indeed also give tetrahydroborate complexes [(η-C_5Me_5)Ru(PR_3)(η^2-BH_4)], but that these undergo immediate ethanolysis under these conditions to yield the trihydrides [(η-C_5Me_5)Ru(PR_3)H_3].[14] In our hands, **2** could not be converted into a trihydride complex and remained perfectly stable toward hydrolysis even in wet ethanol solution. The molecular structure of **3** is shown in Figure 1 (top), and selected bond lengths and angles are listed in Table 1.

The positions of all hydrogen atoms were refinable, indicating that the BH_4 anion is coordinated to the molybdenum atom through two three-center, two-electron bonds, thereby simultaneously blocking two coordination sites. This bidentate M(μ^2-H_2BH_2) ligation represents the most common mode of bonding in tetrahydroborate transition metal complexes.[15] In addition, it is possible to establish the angles between the centroid of the cycloheptatrienyl ring, the C_7 carbon atoms, and the adjacent hydrogen atoms, to reveal a significant out-of-plane displacement for the C_7 ring hydrogen atoms. The average bending is about 9° toward the molybdenum center, such deviation having previously been attributed to a reorientation of the large seven-membered ring for a better metal overlap.[4,16]

As described above, **3** remained perfectly stable in ethanol solution. In the presence of Lewis bases such as PPh_3, however, rapid ethanolysis and cleavage of the BH_4 ligand can be achieved, and formation of the monohydride complex **4** is observed together with evolution of dihydrogen. The reaction can be followed by ^{31}P NMR spectroscopy, which reveals two doublets at 74.5 and 53.7 ppm for the two different phosphorus nuclei in **4** ($^2J_{P,P}$ = 31 Hz) together with the singlet at δ = 67.9 ppm for complex **3**. Pure hydrides such as **4** can also be efficiently prepared directly from the dibromide **2** by use of various hydride sources in the presence of Lewis bases. Consequently, treatment of **2** with sodium hydride in the presence of PPh_3 affords **4** in good yield. In **4**, the pseudotetrahedrally coordinated molybdenum center has four different ligands, and so the complex is obtained as a racemic mixture of two enantiomers. As this representative of so-called "chiral-at-metal" half-sandwich compounds[17−19] is configurationally stable, the diastereotopic cycloheptatrienyl hydrogen atoms give rise to six different ^1H NMR resonances between 3.8 and 5.5 ppm. This portion of the 600 MHz spectrum is shown in Figure 2. Correspondingly, seven ^{13}C NMR resonances are observed for the C_7H_6 carbon atoms, together with six resonances for the phenylene bridge and six resonances for the diastereotopic isopropyl groups. The hydride resonance in **4** is observed as a doublet of doublets at −2.88 ppm with 62 and 41 Hz couplings to the two different phosphorus nuclei (Figure 2). Recrystallization of **4** from hexane afforded single crystals suitable for structure determination by X-ray diffraction; the molecular structure is shown in Figure 1 (bottom). The position of the Mo−H hydrogen atom could be refined to reveal a molybdenum hydrogen

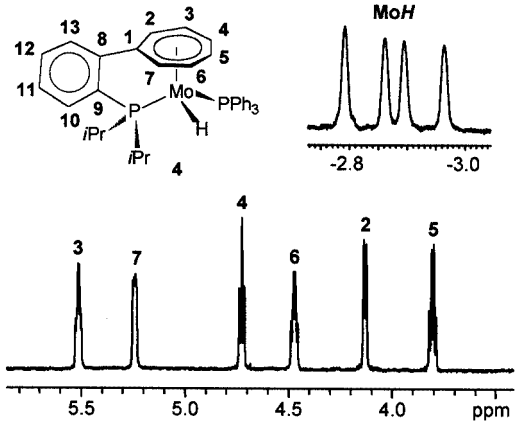

Figure 2. Selected parts of the ^{1}H NMR spectrum (600 MHz, [D_8]toluene) of **4**

bond length of 1.69(2) Å. As would be expected, this distance is slightly shorter than the Mo−H distances of 1.88(2) and 1.96(2) Å in **3**.

Compound **4** is a rare example of a cycloheptatrienyl transition metal hydride, and to the best of our knowledge, [(η^7-C_7H_7)Mo(dppe)H] represents the only previously reported closely related example,[20] apart from a series of tungsten complexes of the type [(η^7-C_7H_7)W(PR_3)(CO)H] (R = OMe, O*i*Pr, Ph).[21] Furthermore, chiral hydrides such as **4** might − in view of the extensive chemistry of related cyclopentadienyl iron, ruthenium, and osmium hydrides − be interesting starting materials for hydrometalation or hydrogenation reactions.[22] For instance, protonation of the hydride ligand in **4** might result in the formation of a cationic dihydrogen complex [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)Mo(PPh_3)(H_2)(*P*-*Mo*)]$^+$, from which the 14-electron complex fragment [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)Mo(*P*-*Mo*)]$^+$ could be generated by splitting of the phosphane and the dihydrogen ligands. To our disappointment, however, decomposition was mainly observed upon treatment of **4** with HBF_4·Et_2O.

More conveniently, the tetrahydroborate **3** proved to be an ideal starting material for the generation of our target 14-electron complex by cleavage of the boranate ligand. In fact, this unit can be made available by treatment of **3** with dimethylanilinium (DMA^+) salts, widely used as mild acids in metallocene chemistry.[23] Treatment of **3** with [$HNMe_2Ph$][BPh_4] proceeds with evolution of dihydrogen, and the formation of stable cationic adducts is observed in THF and acetonitrile solutions. The bis(acetonitrile) complex can even be isolated in crystalline form. The two available coordination sites can be blocked irreversibly by addition of more strongly coordinating ligands. If the protonolysis is carried out in the presence of 2,6-dimethylphenyl isocyanide (XyNC), for instance, the stable diisocyanide complex (**5**)BPh_4 is obtained. The CN stretching frequencies of 2099 and 2066 cm^{-1} show that the cationic [(*o*-*i*$Pr_2PC_6H_4$-η^7-C_7H_6)Mo(*P*-*Mo*)]$^+$ unit has a relatively strong electron-releasing capability, although significantly stronger metal-to-ligand backbonding is observed in, for instance, *trans*-diisocyanide molybdenum(0) complexes containing only additional phosphane ligands.[24,25] Accordingly, the molecular structure of the cation in (**5**)BPh_4·C_5H_{12} (Figure 3, top) has longer Mo-C bond lengths [2.076(5) and 2.078(5) Å] to the isocyanide carbon atoms, together with slightly shorter C≡N bond lengths [1.164(5) and 1.165(6) Å], in comparison with the values found for the centrosymmetric structure of *trans*-[$Mo(dppe)_2(CNPh)_2$] [2.031(6) and 1.171(6) Å].[25] Only slight deviation from linearity is observed for the Mo-C−N and C−N−C bond angles in **5** (168.7(5) − 174.6(5)°).

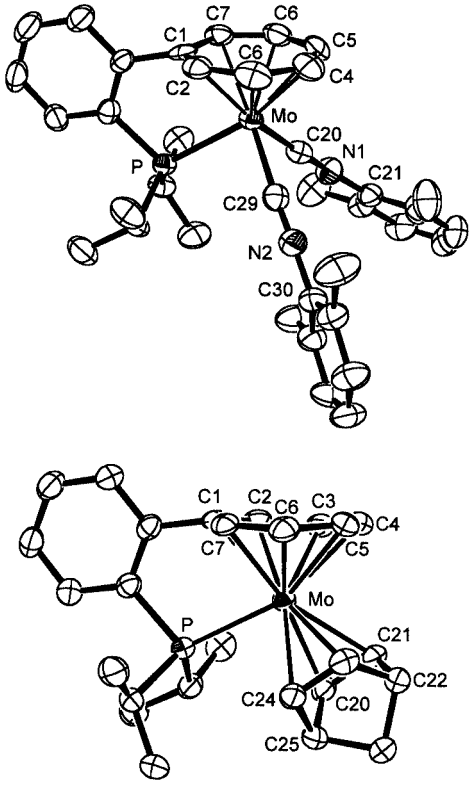

Figure 3. ORTEP drawings of the cations in (**5**)BPh_4·C_5H_{12} (top) and (**6**)BPh_4·CH_2Cl_2 (bottom) with thermal ellipsoids drawn at 50% probability

In a similar fashion, treatment of **3** with [$HNMe_2Ph$][BPh_4] in the presence of norbornadiene gives the diolefin complex (**6**)BPh_4, which is also a versatile starting material for further ligand substitution reactions. Treatment of (**6**)BPh_4 with XyNC thus results in the quantitative formation of (**5**)BPh_4. The norbornadiene complex was also characterizable by X-ray diffraction analysis, and the molecular structure of the cation in (**6**)BPh_4·CH_2Cl_2 is shown in Figure 3 (bottom). Although the structural parameters about the molybdenum centers again fall in the expected ranges (Table 1),[11] the norbornadiene ligand seems to cause some steric congestion at the metal center, and so an elongated Mo−P bond length of 2.5863(10) Å together with a slight puckering of the seven-membered ring can be observed with the longest molybdenum-carbon bonds to C4 and C5, which are adjacent to the diolefin ligand. A similar observation has been made in the related ruthenium complex [(η-C_5Me_5)Ru(PPh_3)(η^4-NBD)]ClO_4.[26]

Preparation of Molybdenum Alkyne Complexes

Cyclopentadienyl ruthenium complexes are extensively used for C−C bond formation through the employment of terminal alkynes, which can either be oligomerized or coupled with various other substrates such as allyl alcohols or alkenes.[2,3] We have consequently studied the cleavage of the tetrahydroborate ligand in the presence of phenyl- and *tert*-butylacetylene, resulting in the formation of crystalline (**7**)BPh_4 and (**8**)BPh_4. Both complexes contain η^2-coordinated alkyne ligands, which stabilize both available coordination sites with their π-electrons and must therefore act as four-electron donors. This fact is easily deduced from their ^{1}H NMR spectra, which exhibit characteristic resonances at low field for the acetylenic *H*C-hydrogen atoms.[27] These resonances appear as doublets at δ = 10.41 ppm ($^3J_{H,P}$ = 29.4 Hz) for **7** and at δ = 10.03 ppm, ($^3J_{H,P}$ = 33.0 Hz) for **8**. A similar downfield shift is observed in the ^{13}C NMR spectra for the acetylenic carbon atoms. For the phenylacetylene complex **7**, these resonances are found as doublets at δ = 178.5 ppm ($^2J_{C,P}$ = 28.4 Hz, ≡CH) and at δ = 173.2 ppm ($^2J_{C,P}$ = 4.5 Hz, ≡CPh). Surprisingly, the order of these resonances is reversed for the *tert*-butylacetylene complex **8**, its ^{13}C NMR spectrum exhibiting a broad singlet at δ = 191.2 ppm (≡C*t*Bu) and a doublet at 177.8 ppm ($^2J_{C,P}$ = 30.1 Hz, ≡CH).

In addition, the molecular structure of the cation **7** (Figure 4, top) shows the structural parameters for the alkyne ligand, with an elongated C≡C (C14−C15) bond length of 1.291(4) Å, together with a small C≡C−C(Ph) (C14−C15−C16) angle of 136.5(3)°, which are clearly indicative of a four-electron donor alkyne ligand.[27] The geometry around the molybdenum atom can be interpreted as a two-legged piano stool with the acetylenic C14−C15 carbon bond and the Mo−P axis in the same plane, and the P-Mo-C14−C15 torsion angle is 173.7°. The acetylenic phenyl and the *ortho*-phenylene rings are also almost coplanar (interplanar angle of 16.7°), so the complex can be regarded as being essentially C_s-symmetric if the two isopropyl groups are neglected. The molybdenum distances to the ring carbon atoms range from 2.221(3) Å (Mo-C3) to 2.373(3) Å (Mo-C1), indicating a fairly significant deviation from planarity (Table 1), and the mean and maximum deviations from the least-squares plane (C1−C7) are 0.075 and −0.108 Å (for C3), respectively. Nevertheless, these structural parameters are still strongly indicative of an η^7-coordinated cycloheptatrienyl ligand. We are not aware of any related ruthenium complex containing an η^2-bonded alkyne ligand. Very recently, however, the molecular structure of a related osmium complex [(η-C_5H_5)Os(η^2-HC≡CCPh_2OH)(P*i*Pr_3)]PF_6 containing a coordinated propargyl alcohol has been reported.[28] Comparison of the bond lengths and angles with those in **7** demonstrates that cycloheptatrienyl molybdenum complexes are also strongly related to cyclopentadienyl osmium systems, with which they exist in a diagonal relationship.

For purposes of comparison, we also studied the possibility of synthesizing the corresponding tetrahydroborate complex **9** containing the linked cycloheptatrienyl-phosphane ligand with a diphenylphosphanyl donor group, the synthesis and coordination chemistry of which have been reported before.[11] Treatment of [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)$MoBr_2$-(*P*−*Mo*)] with $NaBH_4$ in EtOH does indeed result in the formation of **9**, which could be isolated in relatively low yield as a green, air-sensitive solid. The crude product was only characterized by ^{1}H and ^{31}P NMR spectroscopy and was used without further purification for the preparation of the alkyne complex (**10**)BPh_4. Thus, treatment of **9** with [$HNMe_2$Ph][BPh_4] in the presence of phenylacetylene afforded (**10**)BPh_4 as a stable, crystalline compound (Scheme 3). Single crystals of (**10**)BPh_4·3THF could be obtained by recrystallization from THF/hexane solution, and Figure 4 (bottom) shows an ORTEP presentation of the cation **10**. The alkyne ligand in **10** seems to be somewhat more weakly coordinated than in **7**, as it has a slightly shorter C≡C bond length [1.279(5) vs. 1.292(4) Å], together with a slightly larger C≡C−C(Ph) angle [138.4(3) vs. 136.5(3)°]. The overall geometry, though, is similar to that observed for **7** (Table 1), although the phenylacetylene ligand deviates more strongly from a perfectly C_s-symmetric conformation, as indicated by the torsion angle of 169.8° between the P-Mo-C26−C27 atoms and by the interplanar angle of 26.6° between the least-squares planes containing the acetylenic phenyl and phenylene carbon atoms. From the difficulties encountered in particular with the synthesis of the tetrahydroborate derivative **9**, we were able to ascertain that in our hands the more sterically demanding diisopropylphosphane donor seems to be superior to its diphenylphosphane analogue. We have generally observed increased stability upon replacement of the phenyl groups with isopropyl groups, and so both our experimental work and our catalytic studies have mainly focused on, and

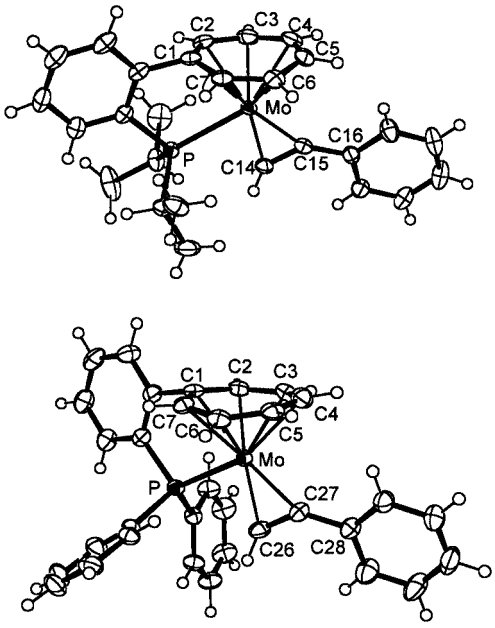

Figure 4. ORTEP drawings of the cations in (**7**)BPh_4 (top) and (**10**)BPh_4·C_6H_{14} (bottom) with thermal ellipsoids drawn at 50% probability

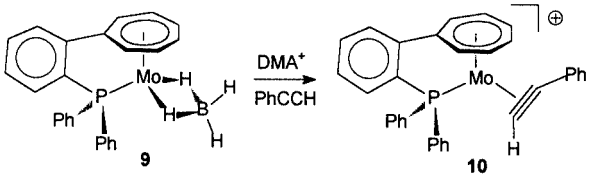
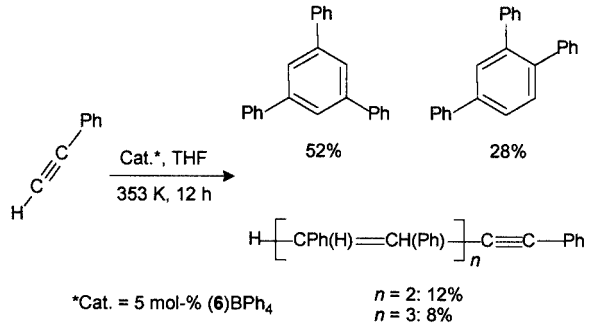
mainly will continue to focus on, the use of complexes containing the [2-(diisopropylphosphanyl)phenyl]cycloheptatrienyl ligand.



Scheme 3. DMA^+ = dimethylanilinium $(PhNMe_2\ H)^+$

Catalytic Study

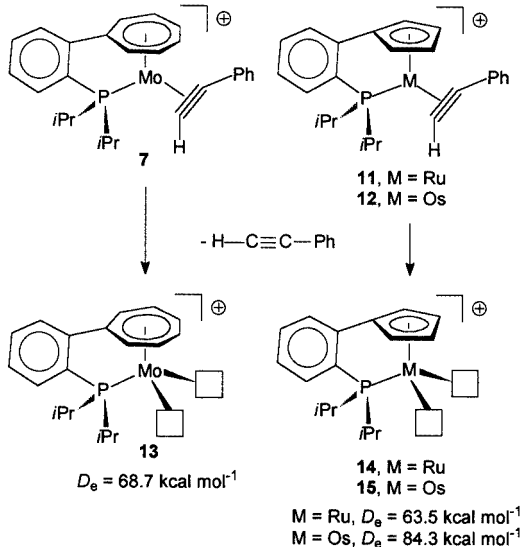
Alkyne complexes such as **7**, **8**, and **10** could be intermediates in the catalytic coupling of acetylenes at cationic molybdenum complex fragments of type II (Scheme 1).[2,3] We have therefore studied the use of (**7**)BPh_4 (5 mol %) as a catalyst for the oligomerization of phenylacetylene[29] in THF solution at 80 °C. Our preliminary results indicate that this system is indeed efficient at catalyzing the above reaction, affording a product mixture of cyclotrimers (80%) and linear oligomers (20%). Surprisingly, cyclotrimerization to give 1,3,5-triphenylbenzene (52%, unambiguously characterized by X-ray diffraction analysis)[30] and 1,2,4-triphenylbenzene (28%) is predominantly observed, in addition to the formation of a linear dimer (12%) and a linear trimer (8%) (Scheme 4). This result contrasts with the reaction involving ruthenium catalysts, in which linear dimers and trimers are formed almost exclusively.[3b,3e,3f] Further work will be directed toward the elucidation of the oligomerization mechanism[31] effective with our novel molybdenum catalyst system. Thus, (**7**)BPh_4 and our related alkyne complexes represent ideal starting materials for further controlled stoichiometric transformations, which will hopefully allow additional possible intermediates in the catalytic cycle to be identified.



Scheme 4. Catalytic oligomerization of phenylacetylene

Theoretical Study

To study the (C_7H_7)Mo-(C_5R_5)M-relationship (M = Ru, Os) by theoretical methods, we chose the molybdenum phenylacetylene complex **7** for comparison with the *hypothetical* cyclopentadienyl ruthenium and osmium complexes **11** and **12**, each containing an identical diisopropylphosphanylphenyl substituent (Scheme 5). The structures of all three cationic complexes were optimized by DFT methods employing the BP86 functional (Figure 5). The alkyne conformations in all three complexes are very similar and are in agreement with the expected nearly C_s-symmetric geometry about the metal centers. The phenylacetylene ligand in each complex exhibits the expected lengthening of the C≡C



Scheme 5. Alkyne bond dissociation energies (D_e) of phenylacetylene complexes

bond length, together with a small C≡C−C(Ph) angle (Table 2). For the molybdenum complex **7**, the computed optimized geometry is in excellent agreement with the structure determined by X-ray diffraction analysis (Table 2, Figure 3), and the puckering of the seven-membered ring is also accurately reproduced. This deviation from planarity is significantly less pronounced in **11** and **12**, the structural data of which are very similar and in excellent agreement with the experimentally measured and calculated geometric parameters of unbridged cyclopentadienyl osmium alkyne complexes.[28]

Scheme 5 shows the theoretically predicted alkyne bond dissociation energies (D_e) of **7**, **11**, and **12**, calculated as the energy difference between the alkyne complex on one hand, and the *unoptimized* complex fragments **13** −**15** and the phenylacetylene ligand at its optimized geometry on the other (vertical D_e). The predicted D_e for the molybdenum complex **7** (68.7 kcal·mol^{-1}) takes an intermediate position between the values calculated for the Ru (D_e = 63.5 kcal·mol^{-1}) and Os systems (D_e = 84.3 kcal·mol^{-1}). Comparative calculations employing the popular B3LYP hybrid functional result in D_e values approximately 10 kcal·mol^{-1} lower, but the differences between the three complexes are very similar. Figure 6 shows a representation of the frontier orbitals in the unoptimized 14-electron complexes **13** −**15** formed by splitting of the phenylacetylene ligand.

In each complex, the symmetry properties of the two lowest unoccupied molecular orbitals (LUMOs), which are essentially vacant d-orbitals, match those of the occupied $\pi_{\|}$ and $\pi_{\perp}$ orbitals of an alkyne ligand. Consequently, this can act as a four-electron donor, providing 18-electron complexes.[27,28,32] Comparison of the energies and shapes of the relevant frontier orbitals reveals the close resemblance between **13**, **14**, and **15** and confirms the intimate relationship between the isoelectronic and isolobal [(η-C_7H_7)Mo] and [(η-C_5R_5)M] fragments (M = Ru, Os).

Conclusion

In summary, we present a new method for the generation and stabilization of coordinatively unsaturated cycloheptatrienyl molybdenum complexes, which can be used for catalytic alkyne-alkyne coupling reactions. These results indicate that cycloheptatrienyl complexes can indeed be potentially useful for applications in homogeneous transition metal catalysis, the goal of these studies being the develop-

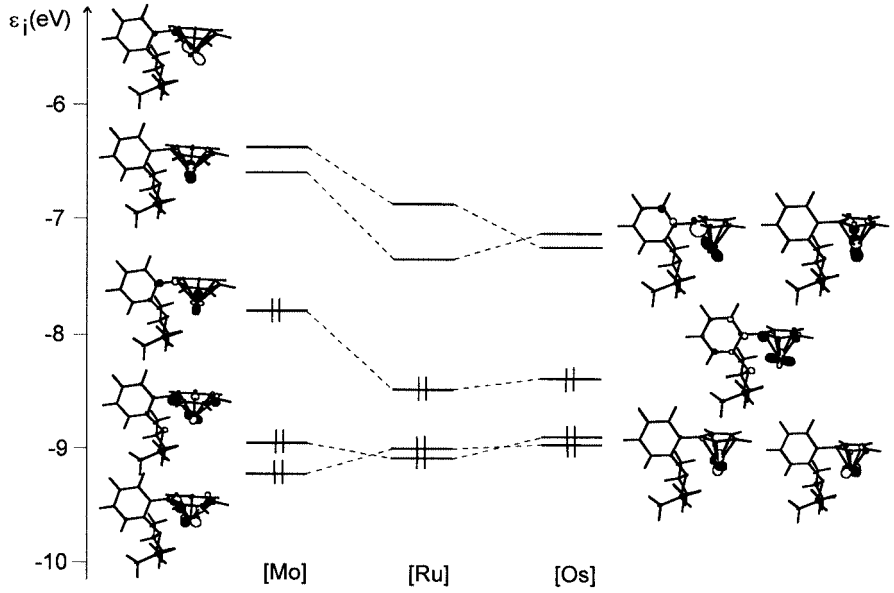

Figure 6. Frontier orbitals of the 14-electron complexes **13** [M = Mo], **14** [M = Ru], and **15** [M = Os]

ment of novel effective catalyst systems that should allow the precious metal ruthenium (and also osmium) to be substituted with the much cheaper molybdenum. This work is part of our general goal to extend the chemistry of cycloheptatrienyl complexes and to raise their level of significance in comparison with those of cyclopentadienyl and benzene complexes.

Experimental Section

General: All operations were performed under an atmosphere of dry argon by Schlenk and vacuum techniques. Solvents were dried by standard methods and distilled prior to use.

Dimethylanilinium tetrafluoroborate was prepared by published procedures.[33] Full details of the preparation of **1** and **2**, together with the spectroscopic and structural properties of all reaction intermediates, will be presented elsewhere.[13] Elemental analyses (C, H N) were performed on a Heraeus CHNS-Rapid elemental analyzer. EI and ESI mass spectra were recorded on a Varian MAT 212 or on a Micromass Quattro LCZ mass spectrometer, respectively. ^{1}H and ^{13}C NMR spectra were measured on Bruker AC 200, Bruker AMX 400, or Varian U 600 spectrometers with the solvent as internal standard, whereas ^{31}P NMR measurements were run on a Bruker AC 200 spectrometer with aqueous H_3PO_4 (85%) as an external reference. IR spectra were recorded on a Bruker Vector 22 instrument. The assignment of all ^{1}H and ^{13}C NMR resonances was supported by two-dimensional NMR spectroscopy (COSY and NOE experiments). For the atomic numbering schemes used in the Exp. Sect., see Figure 2.

[(*o*-*i*Pr$_2$PC$_6$H$_4$-η^7-C$_7$H$_6$)Mo(η^2-BH$_4$)(*Mo*−*P*)] (3): A solution of **2** (500 mg, 0.93 mmol) in ethanol was treated at 0 °C with $NaBH_4$ (250 mg, 6.52 mmol) and stirred for 3 h at ambient temperature. The solvent was removed in vacuo, and the residue was extracted with diethyl ether/hexane (1:1). After evaporation of the solvent, **3** could be isolated as a light green compound. Purification by recrystallization from diethyl ether/hexane was possible, affording green crystals of **3**. Yield: 342 mg (91%). ^{1}H NMR ([D$_8$]toluene, 600 MHz): δ = 7.56 (dm, 1 H, C_6H_4), 7.31 (tm, 1 H, C_6H_4), 7.19 (m, 2 H, C_6H_4), 5.48 (m, 2 H, C_7H_6), 4.49 (m, 4 H, C_7H_6), 1.86 (sept, 1 H, *i*Pr: CH), 1.84 (sept, 1 H, *i*Pr: CH), 0.72 (dd, 6 H, *i*Pr: CH_3), 0.64 (dd, 6 H, *i*Pr: CH_3), −5.72 (br. s, 4 H, BH_4) ppm. ^{13}C NMR ([D$_8$]toluene, 150.9 MHz): δ = 155.2 (d, $^2J_{C,P}$ = 24.8 Hz, C-8), 138.7 (d, $^1J_{C,P}$ = 33.8 Hz, C-9), 130.2 (br. s, C_6H_4), 129.6 (br. s, C_6H_4), 114.2 (d, $^3J_{C,P}$ = 2.6 Hz, C-1), 90.3 (d, $^2J_{C,P}$ = 5.4 Hz, C_7H_6), 85.8 (d, $^2J_{C,P}$ = 2.0 Hz, C_7H_6), 76.6 (s, C_7H_6), 25.0 (d, $^1J_{C,P}$ = 17.2 Hz, *i*Pr: CH), 19.1 (d, $^2J_{C,P}$ = 7.0 Hz, *i*Pr: CH_3), 19.0 (d, $^2J_{C,P}$ = 1.5 Hz, *i*Pr: CH_3) ppm. ^{31}P NMR ([D$_8$]toluene, 81 MHz): δ = 68.0 ppm. MS (EI): *m*/*z* (%) = 394 (100) [M]$^+$, 379 (80) [M$^+$ − BH_4]. $C_{19}H_{28}BMoP$ (394.1): calcd. C 57.90, H 7.16; found C 57.65, H 6.77.

[(*o*-*i*Pr$_2$PC$_6$H$_4$-η^7-C$_7$H$_6$)Mo(PPh$_3$)H(*Mo*−*P*)] (4): A solution of **2** (1.184 g, 2.20 mmol) and PPh_3 (576 mg, 2.20 mmol) in THF was treated with NaH (421 mg, 17.54 mmol) and stirred for 12 h. The reaction mixture was filtered, and the solvent was removed by evaporation. The crude product was recrystallized from hexane to afford **4** as a brown crystalline solid. Yield: 848 mg (60%). ^{1}H NMR ([D$_8$]toluene, 600 MHz): δ = 7.74 (t, 3 H, PPh_3), 7.52 (dm, 1 H, C_6H_4), 7.32 (m, 6 H, PPh_3), 7.16 (m, 1 H, C_6H_4), 7.05 (m, 1 H, C_6H_4), 7.04 (m, 6 H, PPh_3), 6.98 (t, 1 H, C_6H_4), 5.57 (m, 1 H, C_7H_6), 5.29 (m, 1 H, C_7H_6), 4.78 (t, 1 H, C_7H_6), 4.52 (q, 1 H, C_7H_6), 4.18 (d, 1 H, C_7H_6), 3.86 (q, 1 H, C_7H_6), 2.10 (m, 1 H, *i*Pr: CH), 1.09 (d sept, 1 H, *i*Pr: CH), 0.86 (m, 6 H, *i*Pr: CH_3), 0.81 (dd, 3 H, *i*Pr: CH_3), 0.68 (dd, 3 H, *i*Pr: CH_3), −2.82 (dd, 1 H, MoH) ppm. ^{13}C NMR ([D$_8$]toluene, 150.9 MHz): δ = 154.0 (d, $^2J_{C,P}$ = 25.8 Hz, C-8), 141.4 (d, $^1J_{C,P}$ = 28.7 Hz, *ipso*-C_6H_5), 140.5 (d, $^1J_{C,P}$ = 28.3 Hz, C-9), 134.2 (d, $^3J_{C,P}$ = 11.0 Hz, *o*-PPh_3), 134.0 (d, $^2J_{C,P}$ = 19.9 Hz, *m*-PPh_3), 129.1 (m, C-10), 128.3 (d, $^3J_{C,P}$ = 1.9 Hz, C-11), 127.2 (d, $J_{C,P}$ = 8.5 Hz, *p*-PPh_3), 126.9 (d, $^3J_{C,P}$ = 7.7 Hz, C-13), 126.7 (d, $J_{C,P}$ = 4.1 Hz, C-12), 105.4 (t, $^2J_{C,P}$ = 2.0 Hz, C-1), 88.3 (d, $^2J_{C,P}$ = 1.5 Hz, C-7), 87.9 (d, $^2J_{C,P}$ = 3.1 Hz, C-5), 87.9 (s, C-6), 85.9 (d, $^2J_{C,P}$ = 5.1 Hz, C-4), 84.6 (dd, $^2J_{C,P}$ = 8.3 Hz, C-2), 80.6 (s, C-3), 26.5 (d, $^1J_{C,P}$ = 21.4 Hz, *i*Pr: CH), 25.7 (dd, $^1J_{C,P}$ = 14.4 Hz, *i*Pr: CH), 19.9 (d, $^2J_{C,P}$ = 27.2 Hz, *i*Pr: CH_3), 18.9 (d, $^2J_{C,P}$ = 3.7 Hz, *i*Pr: CH_3), 18.7 (d, $^2J_{C,P}$ = 6.3 Hz, *i*Pr: CH_3), 17.4 (d, $^2J_{C,P}$ = 3.7 Hz, *i*Pr: CH_3) ppm. ^{31}P NMR ([D$_8$]toluene, 81 MHz): δ = 74.5 (d, $^2J_{P,P}$ = 31.0 Hz, P*i*Pr$_2$), 53.7 (d, $^2J_{P,P}$ = 31.0 Hz, PPh_3) ppm. MS (EI): *m*/*z* (%) = 642 (100) [M]$^+$. $C_{19}H_{28}BMoP$ (642.7): calcd. C 69.14, H 6.27; found C 70.45, H 6.51.

[(*o*-*i*Pr$_2$PC$_6$H$_4$-η^7-C$_7$H$_6$)Mo(XyNC)$_2$(*Mo*−*P*)]BPh$_4$ (5)BPh$_4$: A solution of **3** (250 mg, 0.63 mmol) in THF (50 mL) was treated at room temperature with [HNMe$_2$Ph][BPh_4] (355 mg, 0.76 mmol). After addition of an excess of 2,6-dimethylphenyl isocyanide, the reaction mixture was subsequently stirred at ambient temperature for 12 h. After evaporation of the solvent, the residue was extracted with a small amount of dichloromethane and added dropwise to rapidly stirred diethyl ether. Purification by recrystallization from dichloromethane/diethyl ether at 0 °C was possible, affording air-stable, brown crystals. Yield: 472 mg (78%). ^{1}H NMR (CD_2Cl_2, 600 MHz): δ = 7.81 (dm, 1 H, C_6H_4), 7.68 (tm, 1 H, C_6H_4), 7.64 (m, 2 H, C_6H_4), 7.41 (br. m, 8 H, *o*-BPh_4), 7.28 (t, 2 H, *p*-$C_6H_3Me_2$), 7.22 (d, 4 H, *m*-$C_6H_3Me_2$), 7.08 (t, 8 H, *m*-BPh_4), 6.93 (t, 4 H, *p*-BPh_4), 5.50 (m, 4 H, C_7H_6), 5.04 (dd, 2 H, C_7H_6), 2.55 (m, 2 H, *i*Pr: CH), 2.44 (s, 12 H, *o*-CH_3), 1.21 (dd, 6 H, *i*Pr: CH_3), 1.11 (dd, 6 H, *i*Pr: CH_3) ppm. ^{13}C NMR (CD_2Cl_2, 150.9 MHz): δ = 177.8 (d, $^2J_{C,P}$ = 16.6 Hz, CNR), 164.4 (q, $^1J_{C,B}$ = 49.4 Hz, *ipso*-BPh_4), 150.2 (d, $^2J_{C,P}$ = 25.9 Hz, C-8), 137.8 (d, $^1J_{C,P}$ = 35.9 Hz, C-9), 136.3 (s, *o*-BPh_4), 134.8 (s, *o*-$C_6H_3Me_2$), 131.6 (d, $J_{C,P}$ = 2.6 Hz, C_6H_4), 130.7 (s, C_6H_4), 129.5 (s, *p*-$C_6H_3Me_2$), 129.4 (d, $J_{C,P}$ = 5.1 Hz, C_6H_4), 128.7 (s, *m*-$C_6H_3Me_2$), 127.5 (d, $J_{C,P}$ = 9.3 Hz, C_6H_4), 127.3 (s, *ipso*-$C_6H_3Me_2$), 125.9 (q, $^3J_{C,B}$ = 2.6 Hz, *m*-BPh_4), 122.0 (s, *p*-BPh_4), 118.0 (d, $^3J_{C,P}$ = 2.5 Hz, C-1), 92.9 (s, C_7H_6), 91.1 (d, $^2J_{C,P}$ = 3.9 Hz, C_7H_6), 91.0 (s, C_7H_6), 26.2 (d, $^1J_{C,P}$ = 21.1 Hz, *i*Pr: CH), 19.2 (s, $C_6H_3\mathit{Me}_2$), 18.6 (d, $^2J_{C,P}$ = 5.1 Hz, *i*Pr: CH_3), 18.1 (s, *i*Pr: CH_3) ppm. ^{31}P NMR (CD_2Cl_2, 81 MHz): δ = 75.7 ppm. [(*o*-Ph$_2$PC$_6$H$_4$-η^7-C$_7$H$_6$)Mo(η^2-BH$_4$)(*Mo*−*P*)] (9): A solution of [(*o*-$Ph_2PC_6H_4$-η^7-C_7H_6)$MoBr_2$(*Mo*−*P*)] (500 mg, 0.72 mmol) in ethanol was treated at 0 °C with $NaBH_4$ (250 mg, 6.52 mmol) and stirred for 1 h at ambient temperature. The solvent was removed by evaporation, and the residue was extracted with diethyl ether/hexane (1:1). After evaporation of the solvent, **9** was isolated as a light green compound. Purification by recrystallization from diethyl ether/hexane was possible, affording green crystals of **9**. Yield: 165 mg (36%). ^{1}H NMR ([D$_6$]benzene, 200 MHz): δ = 7.34 (m, 1 H, C_6H_4), 7.12−7.00 (m, 2 H, C_6H_4), 6.86−6.72 (m, 6 H, C_6H_4 + C_6H_5), 6.65 (m, 5 H, C_6H_4+C_6H_5), 5.12 (dd, 2 H, C_7H_6), 4.40 (dd, 2 H, C_7H_6), 4.18 (tm, 2 H, C_7H_6), −5.56 (br. s, 4 H, BH_4) ppm. ^{31}P NMR ([D$_6$]benzene, 81 MHz): δ = 52.6 ppm.

[(*o*-Ph$_2$PC$_6$H$_4$-η^7-C$_7$H$_6$)Mo(η^2-HCCPh)(*Mo*−*P*)]BPh$_4$ (10)BPh$_4$: Compound (**10**)BPh_4 could be prepared in a manner similar to that described for (**5**)BPh_4, by treatment of a solution of **9** (165 mg, 0.36 mmol) in THF with $[HNMe_2Ph][BPh_4]$ (188 mg, 0.43 mmol), followed by the addition of large excess of phenylacetylene. Yield: 186 mg (60%). ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 10.08 (d, $^3J_{H,P}$ = 34.2 Hz, 1 H, C≡CH), 7.86−7.41 (br. m, 14 H, C_6H_4 + PC_6H_5), 7.31 (br. m, 8 H, *o*-BPh_4), 6.98 (br. t, 8 H, *m*-BPh_4), 6.83 (br. t, 4 H, *p*-BPh_4), 5.86 (m, 2 H, C_7H_6), 5.60 (m, 2 H, C_7H_6), 5.25 (m, 2 H, C_7H_6) ppm.^{31}P NMR ([D$_6$]benzene, 81 MHz): δ = 95.1 ppm.

Catalytic Study: A solution of phenylacetylene (0.2 mL, 3.03 mmol) in THF (10 mL) was treated with (**7**)BPh_4 (128 mg, 0.16 mmol, 5 mol %), and the reaction mixture was stirred at 80 °C for 12 h. The solvent was evaporated, and the residue was transferred to a chromatography column (SiO_2, 4% H_2O). Elution with hexane afforded a yellow oil (245 mg, 65%). GC/MS studies revealed that the mixture contained a linear dimer (12%, *m*/*z* = 204, presumably one regioisomer of diphenyl-1,3-butenyne), 1,3,5-triphenylbenzene (52%, *m*/*z* = 306), a linear trimer (8%, *m*/*z* = 306, presumably one regioisomer of triphenylhex-1-yne-3,5-diene) and 1,2,4-triphenylbenzene (28%, *m*/*z* = 306). Crystals of 1,3,5-triphenylbenzene were isolated from the mixture and characterized by X-ray diffraction analysis.[30] Subjection of these crystals to a GC/MS study confirmed the formation of 1,3,5-triphenylbenzene as the main product.

X-ray Crystallography:[34] Data sets were collected at −75 °C [for **4** and (**5**)BPh_4] with an Enraf−Nonius KappaCCD or at −120 °C [for **3**, (**6**)BPh_4, (**7**)BPh_4, and (**10**)BPh_4] with a Bruker AXS APEX diffractometer, both equipped with a rotating anode and both using Mo-K_α radiation (λ = 0.71073 Å). Empirical absorption correction with SORTAV[35] [for **4** and (**5**)BPh_4] or SADABS[36] [for **3**, (**6**)BPh_4, (**7**)BPh_4, and (**10**)BPh_4] was applied to the raw data. Structure solution in all cases with SHELXS[37] and refinement with SHELXL[38] with anisotropic thermal parameters for all atoms. Hydrogen atoms were added to the structure models on calculated positions and were refined as riding atoms [**4**, (**5**)BPh_4] or are unrefined (for (**10**)BPh_4). Hydrogen atoms for **3**, (**6**)BPh_4, and (**7**)BPh_4 were located in the difference Fourier map and were refined with isotropic thermal parameters. ORTEP[39] was used for all drawings. Additional crystallographic data are listed in Table 3.

Computational Details: All quantum chemical calculations were performed with the TURBOMOLE suite of programs.[40] The phenylacetylene complexes have been fully optimized at the density functional (DFT) level employing the BP86 functional[41] and Gaussian AO basis sets of valence-triple-ξ quality including polarization functions (TZVP, C:[5s3p1d], H:[3s1p], P:[5s4p1d]).[42] For the metals the quasi-relativistic pseudo potentials of the Stuttgart group with a 28 (Mo, Ru) and 60 (Os) electron core, respectively, are used.[43] The corresponding optimized AO basis sets (Mo, Ru: [5s3p3d1f], Os: [6s3p3d1f]) have been taken from the TURBOMOLE library.[44] The calculated dissociation energies have been obtained by freezing the metal fragment without the phenylacetylene ligand in the optimized geometry of the complex (vertical D_e). Comparative calculations have also been performed with the popular B3LYP hybrid functional.[45]

Modes of Reactivity of Cyclic Diynes: Probing the *syn*/*anti* Selectivity of Tetrathiacycloalkadiynes and Mono(alkyne)cobalt Complexes

Christoph Benisch,[a] Daniel B. Werz,[a] Rolf Gleiter,*[a] Frank Rominger,[a] and Thomas Oeser[a]

Keywords: Alkynes / Cobalt / Cyclobutadiene complexes / *syn-anti* selectivity

Cyclic tetrathiaalkadiynes in which two 1,4-dithiaalkyne units are connected with alkane bridges of length *n* and *m* [**A(*m*.*n*)**] were treated with [η^2-bis(*tert*-butylsulfonyl)acetylene]carbonyl(η^5-cyclopentadienyl)cobalt(I) (**8a**) and several substituted analogues (**8b**–**8e**) in order to probe the reactivity of electron-rich cyclic diynes. Both mono- [**B(*m*.*n*)**] and bis(cyclobutadiene) [**C(*m*.*n*)**] complexes were isolated as products of these reactions and the *anti*/*syn* ratio of **C(*m*.*n*)** was determined. For *m*, *n* < 4 the *syn* isomers dominate and this is attributed to the configuration of the intermediate metallacycle which is correlated with the conformations of the rings in the mono(cyclobutadiene) products **B(*m*.*n*)**. This analysis was corroborated by X-ray structural investigations of the products.

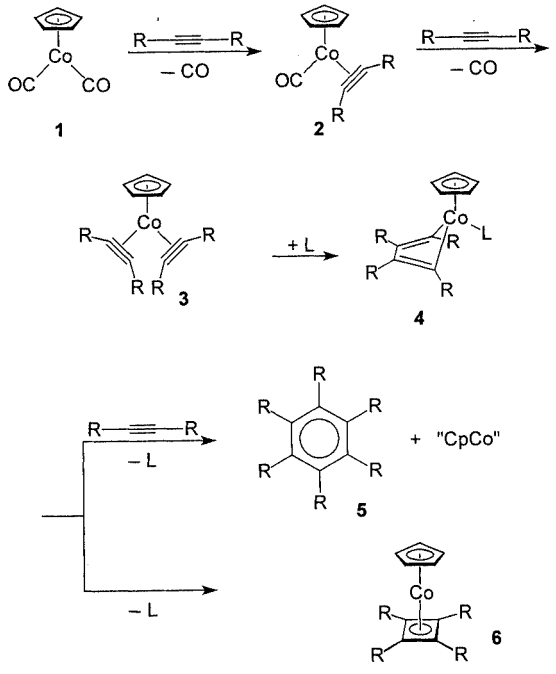
Introduction

Dicarbonyl(η^5-cyclopentadienyl)cobalt [$CpCo(CO)_2$] (**1**) is a very convenient and efficient reagent for the di- and trimerisation of alkynes.[1] Two different mechanisms have been proposed for this reaction. One involves (alkyne)dicobalt complexes[2] whereas the other assumes that the reaction occurs on one CpCo fragment only.[3–5] The latter seems to be preferred at low temperatures whereas polynuclear complexes may play a role at higher temperatures.[2] The mechanism involving only one $CpCoL_2$ unit, in which the ligands are replaced successively by the alkyne to yield a 16-electron metallacycle which is converted to an 18-electron species **4** by an additional ligand L, is outlined briefly in Scheme 1.

The fact that derivatives of **2** and **4** have been isolated at room temperature[6–9] and that the alkynes react either to cyclobutadiene (**6**)[10] or to aromatic species (**5**)[4] support this mechanism.

Recently, we found a mild and efficient procedure to isolate congeners of **2** by treating **1** with bis(*tert*-butylsulfonyl)-acetylene (BTSA, **7**).[7] The resulting complex **8** reacts under very mild conditions with electron-rich alkynes to yield the cyclobutadiene complexes **9**. The reactions with dithiaalkynes (R = SR′ in Scheme 2) were especially efficient.[11]

In view of the complex mechanism of cyclobutadiene formation (Scheme 1) it is of general interest to test the reactivity of electron-rich cyclic diynes with the electrophile **8**, and to see if there is any preference for one of the two possible products (*syn* or *anti*). For cyclic tetrathiadiynes **A(*m*.*n*)** the anticipated products **B(*m*.*n*)R**, and *syn*- and *anti*-**C(*m*.*n*)R** are shown in Scheme 3.



Scheme 1

Results

We used the recently prepared cyclic tetrathiadiynes **A(2.2)** to **A(5.5)**[12] and [η^2-bis(*tert*-butylsulfonyl)acetylene]-

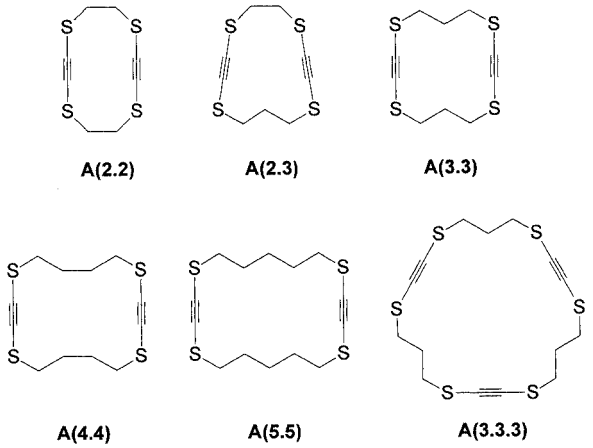

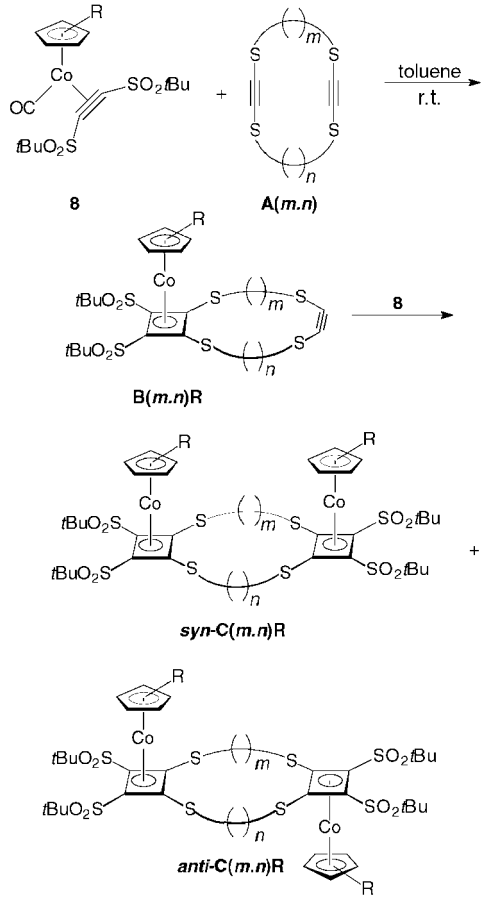

Scheme 3

carbonyl(η^5-cyclopentadienyl)cobalt(I) (**8a**) and several analogues **8b**−**8e** substituted at the Cp ring[7] as starting materials.

The cyclic tetrathiadiynes **A(*m.n*)** were treated with **8a**−**8e** in 1:1 and 2:1 ratios at room temperature in toluene as solvent to give the 1:1 and 2:1 cyclobutadienes. The yields of the products **B(*m.n*)R** and **C(*m.n*)R** are reported in Table 1.

Because the solubility of the cyclobutadiene complexes decreases with reduced ring size we treated cycles **A(2.2)** and **A(2.3)** with **8c** only. The $SiMe_3$ substituent in the products ensured reasonable solubilities. The yields listed in Table 1 were obtained as follows: The reaction was monitored by thin layer chromatography, and as soon as no monoalkyne complex was present or no further reaction could be detected, we removed the solvent in vacuo and separated the products by column chromatography. In the case of **A(5.5)** the *syn*/*anti* ratio was determined by NMR spectroscopy since the stereoisomers could not be separated.

When the reaction was carried out such that **8**/**A** = 1:1, good yields of **B(*m.n*)R** were obtained (30−60%), whereas the yields of the 2:1 products were low. A closer look (Table 2) at the distributions of the *anti*/*syn*-**C(*m.n*)** product ratios shows a considerable variation.

In the case of the twelve-membered ring system **A(2.2)**, the *syn* isomer of **C(2.2)SiMe$_3$** was formed predominantly in about 13% yield. For **A(2.3)** and **A(3.3)** the *syn* isomers dominated, whereas for **A(4.4)** the *anti* isomer of **C(4.4)R** was preferred. Only when both triple bonds were separated by pentamethylene chains [**A(5.5)**] was the *anti*/*syn* ratio of the product [**C(5.5)**] found to be 1. These results reveal that thermodynamic factors are not important for the *anti*/*syn* selectivity observed, because the *anti*-**C(*m.n*)R** isomers should be more stable than the *syn* isomers due to steric reasons. We believe that it is the conformation of the large ring of the monosubstituted product **B(*m.n*)R** which primarily influences the *anti*/*syn* ratio of **C(*m.n*)R**. The *anti*/*syn* selectivity in the reactions of **A(3.3)** and **A(4.4)** with **8a**−**8c** (Table 3) allows estimation of the influence of the substituents on the Cp ring. The *anti*/*syn* ratio of the products **C(3.3)** and **C(4.4)** remains essentially constant for **C(3.3)R** and increases in the case of **C(4.4)R** with increasing size of R.

Reaction of triyne **A(3.3.3)** with a large excess of **8c** gave the trinuclear cobalt complexes *anti*-**C(3.3.3)SiMe$_3$** and all-*syn*-**C(3.3.3)SiMe$_3$** in 56 and 13% yield, respectively. In the former, two of the three cobalt centres are above the plane of the ring, whereas in the latter, all three cobalt atoms are on the same side.

Table 1. Yields of the products **B(*m.n*)R** and **C(*m.n*)R** as a function of the ratio of starting materials [**8**: **A(*m.n*)**]

X-ray Investigations

Isolation of single crystals of mono- and disubstitution products of the 12-, 13-, 14- and 16-membered rings **A(2.2)**, **A(2.3)**, **A(3.3)** and **A(4.4)** allowed a detailed study of their molecular structures using X-ray techniques. The molecular structures of **B(2.2)SiMe$_3$** and *syn*-**C(2.2)SiMe$_3$** are shown in Figure 1.

As can be seen from the conformation of the 12-membered ring of the monoadduct, the triple bond is situated relatively close (472 pm) to the cyclobutadiene (Cb) ring. The distances between the metal atom and the centres of the Cp ring and the Cb ring are 167 and 168 pm, respectively. Owing to the sizeable $SiMe_3$ substituent, the Cp and Cb rings are not parallel but are tilted by 8.3°. It is interesting to note that the torsion angle between the CH_2-S bonds at the triple bond of **B(2.2)SiMe$_3$** is 93.0°. In *syn*-**C(2.2)SiMe$_3$** (Figure 1) the two Cb rings are separated by 538 pm and 645 pm, corresponding to an angle between the two Cb planes of 42.7°.

The structure of **B(2.3)SiMe$_3$** in the crystal (Figure 2) shows that the 13-membered ring is more remote from the Cb ring (556 pm) and also from the $CpSiMe_3$ group. The interplanar angle between the Cp and Cb rings (4.1°) is smaller than in **B(2.2)SiMe$_3$**.

The X-ray structure of the *anti*-**C(2.3)SiMe$_3$** isomer is also shown in Figure 2. In this structure, both Cb rings are tilted towards each other by 62.0°.

The X-ray analysis of single crystals of **B(3.3)SiMe$_3$** revealed two molecules as asymmetric unit. The quality of the data was somewhat marginal and, while the distances and angles must therefore be viewed with caution, only the conformation of the 14-membered ring could be elucidated (Figure 3).

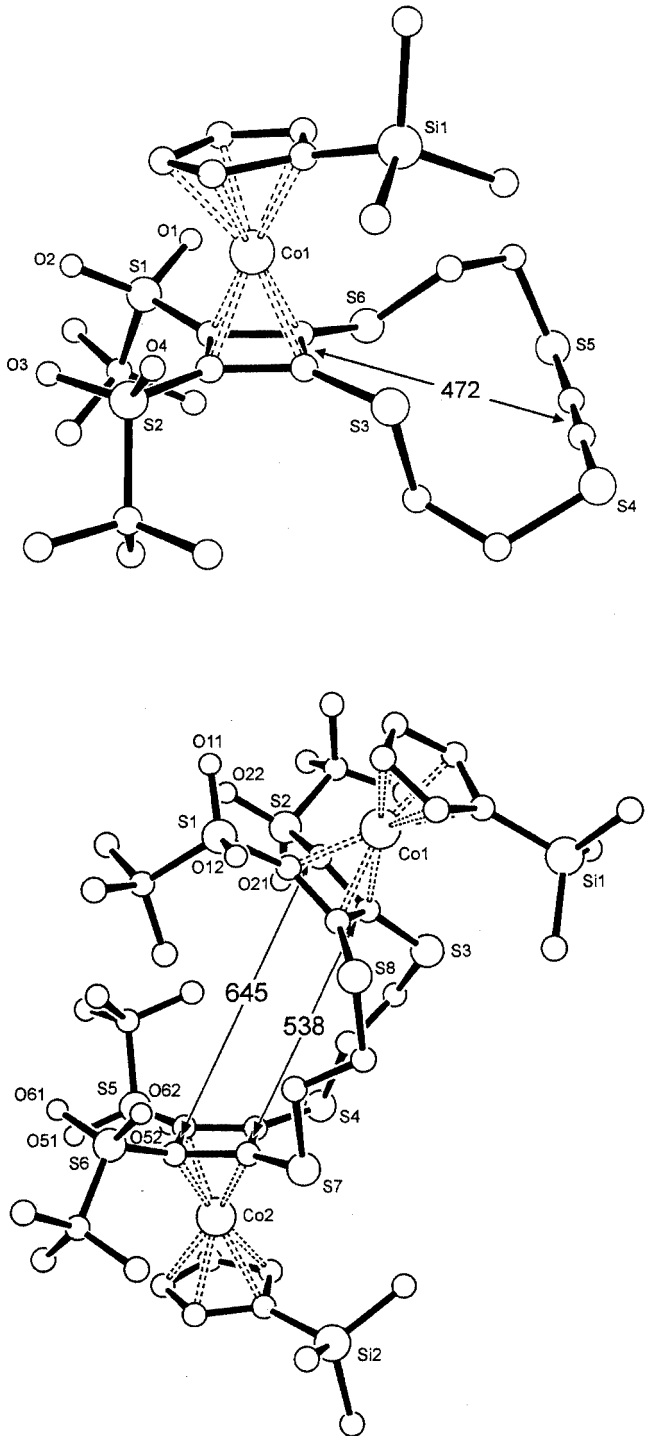

Figure 1. Molecular structures of **B(2.2)SiMe$_3$** and *syn*-**C(2.2)SiMe$_3$**; distances between the π-units defined by the arrows are given

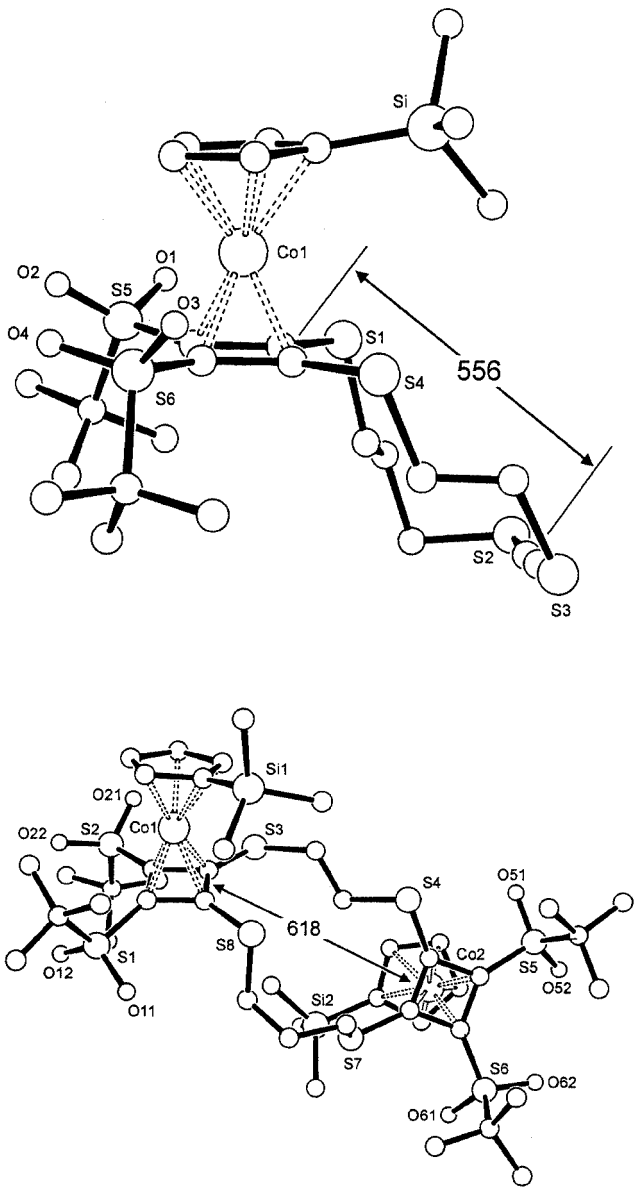

Figure 2. Molecular structures of **B(2.3)SiMe$_3$** and *anti*-**C(2.3)SiMe$_3$**; distances between the π-units defined by the arrows are given

The quality of the structure of *syn*-**C(3.3)SiMe$_3$** (R_w = 0.147) is similar to that of **B(3.3)SiMe$_3$**, and therefore a structural diagram has not been included. However, it can be deduced that the conformation of *syn*-**C(3.3)SiMe$_3$** is similar to that of *anti*-**C(2.3)SiMe$_3$** insofar as the planes of the two cyclobutadiene rings are twisted by about 72°. All *tert*-butylsulfonyl groups are bent away from the $SiMe_3CpCo$ moieties. Figure 3 also shows the structure of *anti*-**C(3.3)SiMe$_3$** in the crystal. As in the *syn* isomer the two Cb rings are twisted, but the twist angle is 54° (calculated as "torsion angle" between the two nearest Cb bonds of both rings), less than in the *syn* isomer. The distance between the cyclobutadiene rings in the *anti* isomer (685 pm) is larger than that found in *syn*-**C(3.3)SiMe$_3$** (661 pm). Both *tert*-butylsulfonyl moieties are bent away from the $SiMe_3CpCo$ fragment.

The triple bond in **B(4.4)CH$_3$** (Figure 4) is relatively far remote from the cyclobutadiene ring (705 pm) and is nearly in plane with the cyclobutadiene ring. The large ring adopts an armchair conformation. In both *syn*- and *anti*-**C(4.4)CH$_3$** (Figure 4) a chair-like conformation of the central ring is maintained. A comparison of the structures of

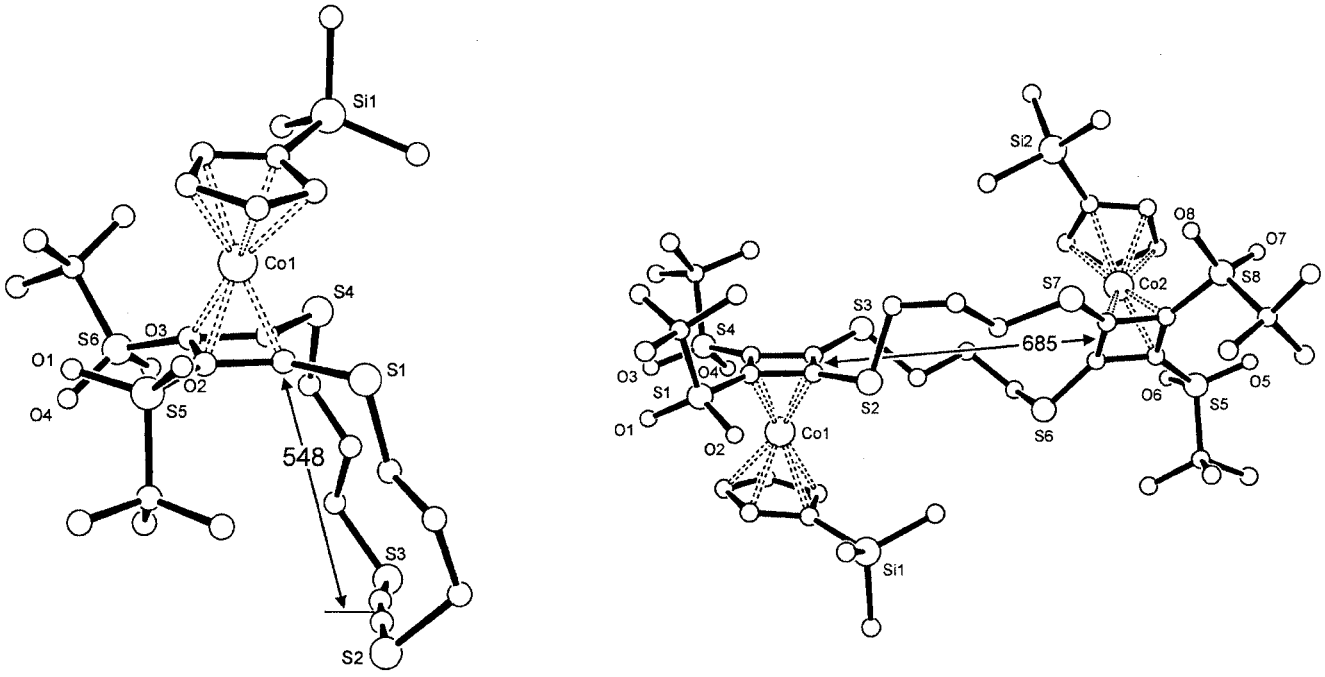

Figure 3. Molecular structures of **B(3.3)SiMe$_3$** (only one of both independent molecules is shown) and *anti*-**C(3.3)SiMe$_3$**; distances between the π-units defined by the arrows are given

B(4.4)CH$_3$ and **C(4.4)CH$_3$** shows an increase in the distance between the former triple bonds [779 pm in *syn*-**C(4.4)CH$_3$**]. The "torsion angle" between the two nearest bonds of both cyclobutadiene units is 3.8°. All four *tert*-butylsulfonyl groups point away from the MeCpCo moieties. In *anti*-**C(4.4)CH$_3$** the central ring adopts a chair-like conformation. A crystallographic inversion center is found and consequently both cyclobutadiene rings are parallel to each other. As anticipated, the distance between both cyclobutadiene units (776 pm) is larger than in **B(4.4)CH$_3$**. The distance between the cobalt atoms is larger in the *anti* isomer (1080 pm) than in the *syn* isomer (1024 pm). The CpMe unit adopts a conformation which places the CH_3 group mostly between the SO_2 groups. Such a conformation has previously never been encountered for bulky $SiMe_3$ substituents.

Table 4 gives a comparison of the transannular distances *d* between the π units of **A(*m.n*)**, **B(*m.n*)R** and **C(*m.n*)R**, as well as the torsional angles α between the unsaturated bonds as defined in Figure 5. This shows that the transannular distance *d* between the triple bonds in **A(*m.n*)** is increased in the complexes. This increase is anticipated because it is due to the rehybridisation of the sp centres into sp^2 centres. Thus, the former C(sp)−C(sp)−S angles are reduced from 180 to about 120°. There are small torsion angles α between the triple bonds and the cyclobutadiene rings in the **B(*m.n*)R** complexes. It is interesting to note that the chair conformation of the 14-membered ring of **A(3.3)** is changed to a twisted conformation in both *syn*- and *anti*-**C(3.3)SiMe$_3$**, with α = 66.4 and 54.2°, respectively. The opposite is found in the case of the 16-membered ring of **A(4.4)**. Here the twisted conformation (α = 58.7°) is transformed into an armchair and a chair conformation, respectively, with small torsion angles. Figure 6 shows the molecular structure of the trinuclear cobalt complex all-*syn*-**C(3.3.3)SiMe$_3$**.

Discussion

The rationalisation of our results is difficult since the system contains a number of unknowns. As outlined in Scheme 1 the metal-supported cyclobutadiene formation follows a sequence of several steps. A further complication arises from the unknown minimum energy conformation of the medium-sized ring in **B(*m.n*)** in solution. In order to rationalise the outcome of our experiments we assume that the transition state which determines the stereochemistry of the products is close in energy and structure to the intermediate metallacycle (e.g. **4** in Scheme 1) and rather different to the cyclobutadiene product. We furthermore assume that the barrier to ring inversion in the metallacycles is in the order of 5 kcal/mol.[8] Steric effects should therefore be important in determining the *syn*/*anti* ratios.

In order to discuss the reaction mechanism, two conformations of **B(*m.n*)**, **D1** and **D2** (Figure 7) must be considered. In **D1** the triple bond is situated on the same level with the cyclobutadiene system, whereas in **D2** it is placed below the cyclobutadiene ring. Which of the two geometries is favoured depends mainly on the conformations of the methylene chains and, to a minor extent, on the substituents at the Cp ring. The methylene chains favour a zig-zag arrangement, as demonstrated for several cyclic diynes[13] and especially for cyclic tetrathiadiynes[11] and tetrathiaenynes.[14] In these ring systems a staggered conformation is achieved.

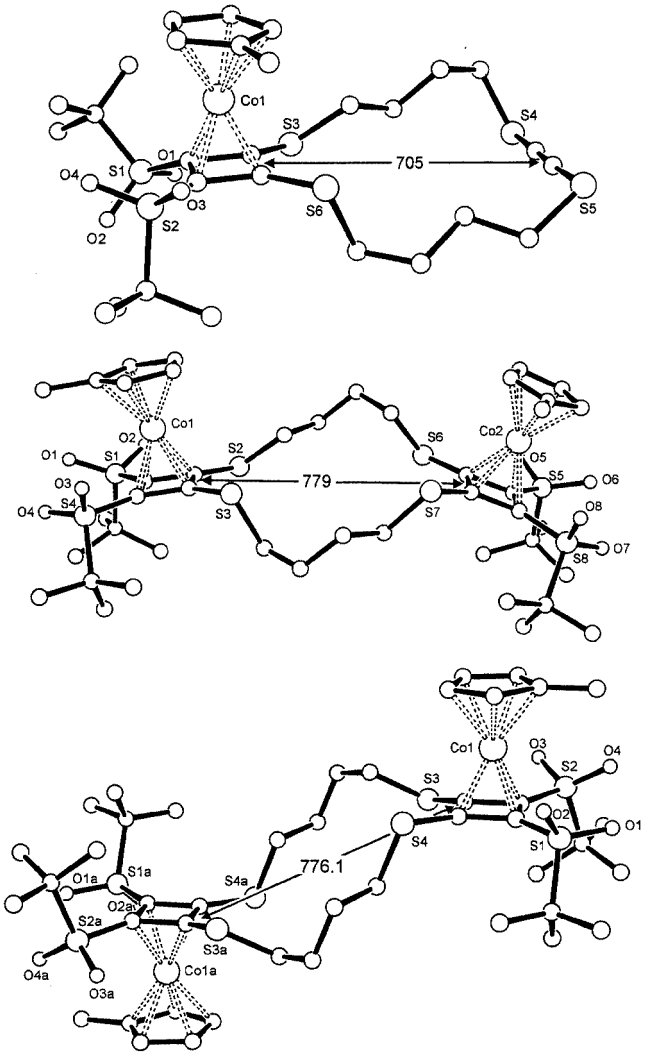

Figure 4. Molecular structures of **B(4.4)Me** (top), *syn*-**C(4.4)Me** (centre) and *anti*-**C(4.4)Me** (bottom); distances between the π-units defined by the arrows are given

Table 4. Transannular distances *d* [pm] and torsional angles α [°] for **A(*m*.*n*)**, **B(*m*.*n*)R** and **C(*m*.*n*)R** ($m = 2-4$, $n = 2-4$) as defined in Figure 5

m	*n*	R		**A(*m*.*n*)**	**B(*m*.*n*)R**	**C(*m*.*n*)R** *syn*	*anti*
2	2	$SiMe_3$	*d*	356	472	539	–
			α	0.0	5.8	20.9	–
2	3	$SiMe_3$	*d*	405	556	–	61.8
			α	13.9	3.3	–	59.1
3	3	$SiMe_3$	*d*	545	548/561	661/652	685
			α	0.0	9.6/10.6	66.4/89.7	54.2
4	4	Me	*d*	535	705	779	776
			α	58.7	1.6	3.8	0.0

The two conformations **D1** and **D2** yield two intermediates **E1** and **E2** (Figure 7). In **E1** the repulsion between the two Cp rings is minimised. Reaction via **E1** should lead to the *anti* isomer, whereas **E2** will give the *syn* isomer. The close distance between the triple bond and the cyclobutadiene ring (472 pm) and the bulky $SiMe_3$ substituent in **B(2.2)SiMe$_3$** should clearly favour **E1** even when the triple bond and cyclobutadiene ring are situated at the same level (Figure 1). The strong preference for *syn*-**C(2.2)SiMe$_3$** (Tables 1 and 2) can be rationalised by assuming that the energy difference between the conformation shown in Figure 1 and one close to that found for **B(2.3)SiMe$_3$** (Figure 2) should be small. This assumption is supported by X-ray studies of (*Z*)-1,4,7,10-tetrathiacyclododeca-2-en-8-yne (**9**).[14] The conformation of **9** is given in Figure 8 and resembles that of the enyne fragment of **B(2.3)SiMe$_3$**. In this conformation the triple bond is rather close to the *tert*-butyl groups, and therefore the metallacycle with the CpCo fragment on the *syn* side should be favoured. The same holds for **B(2.3)SiMe$_3$** and **B(3.3)SiMe$_3$**. Owing to the stair-like arrangement of double and triple bonds, and the close proximity of the *tert*-butyl groups and the triple bond, a *syn* product should be favoured as indicated in Table 2. The results summarised in Table 3 suggest that, for the reaction of **B(3.3)R** with **8a**–**8c**, a transition state similar to **E2** should be preferred, whereas in the reaction of **B(4.4)R** with **8a**–**8c**, a geometry closely related to **E1** should be favoured. These conclusions are in agreement with the structures of **B(3.3)SiMe$_3$** and **B(4.4)SiMe$_3$** in the crystal.

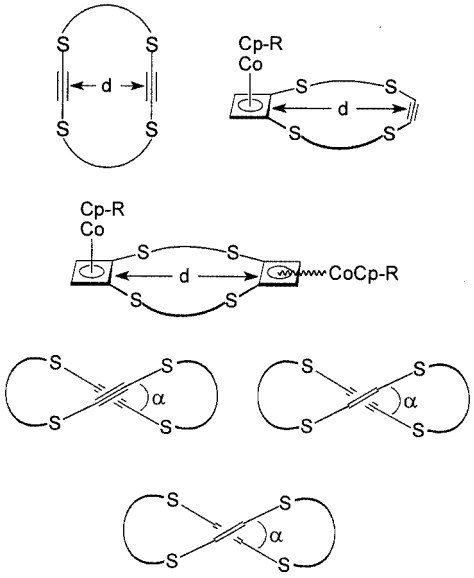

Figure 5. Definition of *d* and α for the values listed in Table 4

Conclusions

In the beginning of our investigations we raised the question of the *syn*/*anti* selectivity in the twofold cyclobutadiene formation in nonconjugated cyclic diynes. We have been able to determine the *syn*/*anti* ratio in the reaction of the medium-sized rings **A(*m*.*n*)** ($n = 2-4$ and $m = 2-4$) by using highly reactive nucleophilic tetrathiaalkadiynes and strongly electrophilic mono(alkyne)cobalt complexes. No selectivity was observed for larger rings ($m, n > 4$). For smaller rings, *syn* selectivity was preferred for **A(2.2)**, **A(2.3)**

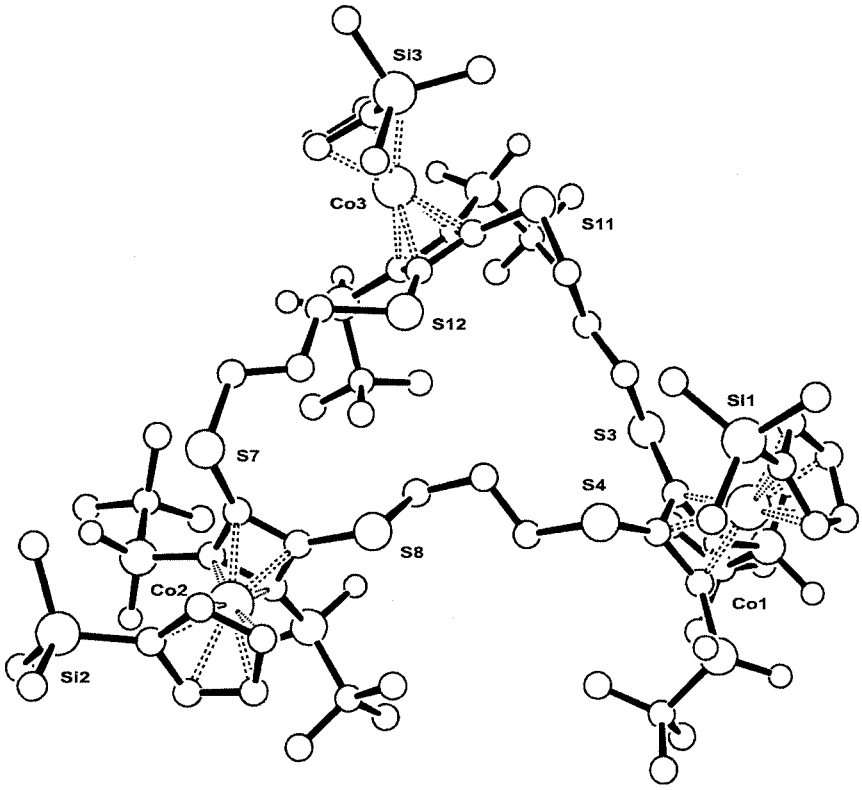

Figure 6. Molecular structure of all-*syn*-**C(3.3.3)SiMe$_3$**

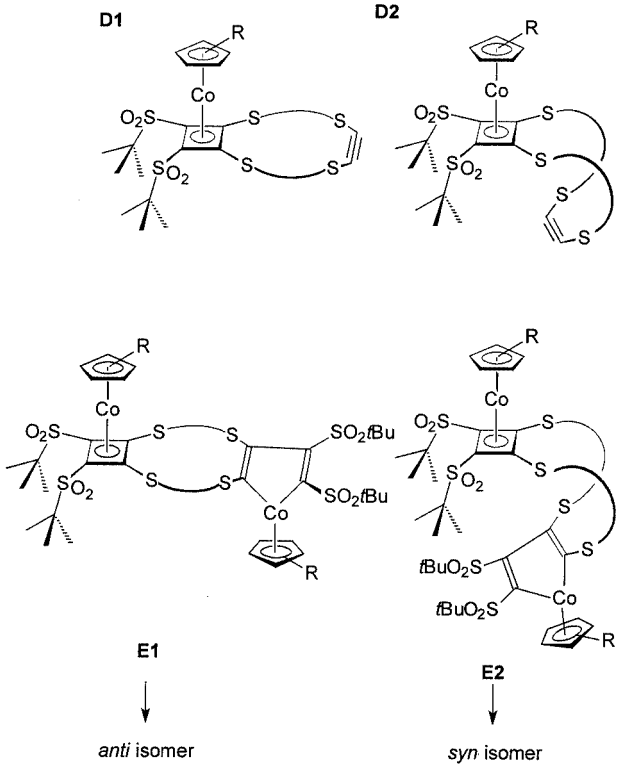

Figure 7. Possible conformations, **D1** and **D2**, of the 1:1 products **B(*m.n*)R** (top); resulting intermediates, **E1** and **E2**, from the reactions of **D1** and **D2** with **8a**−**8e**

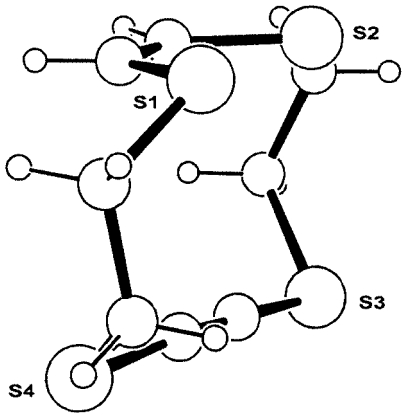

Figure 8. The conformation of (*Z*)-1,4,7,10-tetrathiacyclododeca-2-en-8-yne (**9**) in the crystal that resembles that of the enyne fragment of **B(2.3)SiMe$_3$**

and **A(3.3)**, whereas for **A(4.4)** *anti* selectivity prevails. Our X-ray investigations on the mono- and disubstituted complexes revealed that the selectivity is mainly determined by the conformation of the medium-sized chain. For short chains (m, $n < 4$) we found that the ring with the dithiaalkyne unit in **B(*m.n*)** is bent away from the CpCo moiety. This conformation favours the formation of the second metallacycle *syn* to the CpCo-stabilised cyclobutadiene complex. These studies suggest that a stepwise synthesis of cyclic oligomers[15] should be possible if the chain length between the triple bonds is small. For pure hydrocarbons the chain length should be below six CH_2 groups.

Experimental Section

General Methods: Moisture- and oxygen-sensitive reactions were conducted in oven-dried glassware under argon. Toluene was dried with sodium/benzophenone and distilled under argon before use. Petroleum ether and diethyl ether were distilled before use. Melting points are uncorrected. Materials used for column chromatography: Silica gel 60 (Machery−Nagel). ^{1}H and ^{13}C NMR: Bruker AS 200 (^{1}H at 200 MHz and ^{13}C at 50.33 MHz), Bruker Avance 300 (^{1}H at 300 MHz and ^{13}C at 75.47 MHz), Bruker Avance 500 (^{1}H at 500 MHz and ^{13}C at 125.77 MHz) using the solvent as internal standard. The signals were assigned by NMR correlation techniques. IR: Bruker Vector 22 FT-IR. MS: Low resolution: ZAB-2F; high resolution: JEOL JMS-700. Elemental analyses were carried out by the Mikroanalytisches Laboratorium der Universität Heidelberg. Complexes **8a**−**8e**[7] and the tetrathiacyclodiynes **A(2.2)** to **A(5.5)**[12] were prepared according to literature methods.

General Procedure for the Preparation of the Cyclobutadiene Complexes: The mono(alkyne)cobalt complex was dissolved in toluene (150 mL) and the tetrathiacycloalkadiyne was added in one portion. The reaction mixture was stirred at room temperature. After completion of the reaction, the solvent was removed by rotary evaporation and the products were isolated by column chromatography (SiO_2; diethyl ether/petroleum ether, 1:1 → 2:1 → 5:1 → dichloromethane/methanol, 30:1).

Reaction of A(2.2) with [CpSiMe$_3$Co(CO)(BTSA)] (8c). Reaction A: 8c (134 mg, 0.27 mmol) and **A(2.2)** (70 mg, 0.30 mmol). Yield: 77 mg (41%) of **B(2.2)SiMe$_3$** and 15 mg (5%) of *syn*-**C(2.2)SiMe$_3$**. **Reaction B: 8c** (324 mg, 0.66 mmol) and **A(2.2)** (70 mg, 0.30 mmol). Yield: 126 mg (60%) of **B(2.2)SiMe$_3$** and 46 mg (13%) of *syn*-**C(2.2)SiMe$_3$**.

B(2.2)SiMe$_3$: Yellow solid, m.p. 186 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 0.36 [s, 9 H, $Si(CH_3)_3$], 1.45 [s, 18 H, $C(CH_3)_3$], 2.97/3.60 (m, 8 H, SCH_2), 5.32/5.68 (pt, 4 H, CpH) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = −0.4 [$Si(CH_3)_3$], 24.7 [$C(CH_3)_3$], 33.1/34.1 (SCH_2), 61.6 [$C(CH_3)_3$], 78.3 [*C*(Cb)SO_2tBu], 81.6 [*C*(Cb)S], 87.3 (≡C), 88.5/90.1 [*C*(Cp)H], 93.7 [*C*(Cp)$SiMe_3$] ppm. Reaction of A(3.3.3) with [CpSiMe$_3$Co(CO)(BTSA)] (8c). Synthesis of A(3.3.3): A suspension of lithium acetylide in THF and a solution of 1,3-dithiocyanatopropane in THF were added simultaneously at −40 °C to THF (1 L) over a period of 4 h. After complete addition, the reaction mixture was allowed to warm to room temperature overnight. The solvent was removed by rotary evaporation and polymers and salts were removed by flash filtration [SiO_2; 3% NEt_3(v/v), toluene]. After removal of the solvent, the product was isolated by column chromatography [SiO_2; 3% NEt_3 (v/v), *n*-hexane/toluene, 3:1]. Starting material: Dilithium acetylide, prepared from *n*BuLi (60 mmol) in THF (250 mL) and 1,3-dithiocyanatopropane (4.51 g, 28.5 mmol) in THF (250 mL). Yield: 107 mg (3%) of **A(3.3.3)**.

A(3.3.3): Colourless solid, m.p. 100 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.24 (quint, 6 H, SCH_2CH_2), 2.81 (t, ^3J = 7.1 Hz, 12 H, SCH_2) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = 28.5 (SCH_2CH_2), 34.4 (SCH_2), 86.2 (C≡) ppm. IR (KBr): $\tilde{\nu}$ = 2929 cm^{-1}, 2058, 1437. MS (EI+): 390 [M^+], 204, 88. HRMS (EI+): [M^+] $C_{15}H_{18}S_6$: calcd. 389.9733; found 389.9725. $C_{15}H_{18}S_6$ (390.7): calcd. C 46.11, H 4.64, S 49.25; found C 46.22, H 4.70, S 48.99.

Starting material: **A(3.3.3)** (60 mg, 0.15 mmol) and **8c** (453 mg, 0.92 mmol). Yield: 154 mg (56%) of *anti*-**C(3.3.3)SiMe$_3$**, 36 mg (13%) of *all-syn*-**C(3.3.3)SiMe$_3$**.

***anti*-C(3.3.3)SiMe$_3$:** Yellow solid, m.p. 103 °C (dec.). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.29 [s, 9 H, $Si(CH_3)_3$], 0.32 [s, 18 H, $Si(CH_3)_3$], 1.47 [s, 48 H, $C(CH_3)_3$], 1.99 (m, 6 H, $CH_2CH_2CH_2$), 3.03 (m, 12 H, SCH_2), 5.19/5.73 (pt, 12 H, CpH) ppm. ^{13}C NMR (75 MHz, $CDCl_3$): δ = −0.2 [$Si(CH_3)_3$], 24.7 [$C(CH_3)_3$], 29.5 ($CH_2CH_2CH_2$), 29.6 ($CH_2CH_2CH_2$), 36.1 (SCH_2), 36.1 (SCH_2), 36.3 (SCH_2), 61.8 [$C(CH_3)_3$], 61.8 [$C(CH_3)_3$], 61.9 [$C(CH_3)_3$], 76.4 [C(Cb)SO_2tBu], 76.5 [C(Cb)SO_2tBu], 76.6 [C(Cb)SO_2tBu], 82.9 [C(Cb)SCH_2], 83.6 [C(Cb)SCH_2], 83.6 [C(Cb)SCH_2], 88.5/88.6/88.6/89.6/89.8/90.3 [C(Cp)H], 93.7/93.9 [C(Cp)$SiMe_3$] ppm. X-ray Diffraction Analyses: Reflections were collected using Nonius CAD4, Bruker Smart CCD and Bruker APEX diffractometers (Mo-K_α radiation, graphite monochromator). Intensities were corrected for Lorentz and polarisation effects. Numerical (face indexing) or empirical absorption corrections were applied using SADABS.[16] The structures were solved by direct methods. The structural parameters of the non-hydrogen atoms were refined anisotropically according to a full-matrix least-squares technique (F^2). Hydrogen atom positions were calculated according to stereochemical aspects. In **B(2.3)SiMe$_3$** the *tert*-butyl groups (6:4) and the thiaalkyne side chain (7:3) were disordered. In *syn*-**C(2.2)SiMe$_3$** one ethano moiety was disordered (1:1:1). In *syn*-**C(3.3)SiMe$_3$** two methylene units were disordered (3:1). The minor positions were refined isotropically. Structure solution and refinement were carried out using the SHELXTL software package.[16] Tables 5 and 6 contain the crystallographic data, details of the data collection and the refinement procedure. ORTEP drawings were obtained using ORTEP-3 for Windows.[17] CCDC-193187 to -193198 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mono- and Dimetallic Cyano Complexes with {Mo(η^3-allyl)$(CO)_2$(N−N)} Fragments

Julio Pérez,*[a] Eva Hevia,[a] Lucía Riera,[a] Víctor Riera,[a] Santiago García-Granda,[a] Esther García-Rodríguez,[b] and Daniel Miguel[c]

Keywords: Allylic compounds / Cyanides / Heterometallic compounds / Molybdenum / Manganese / Rhenium

Treatment of [MoCl(η^3-allyl)$(CO)_2$(phen)] with NaCN in CH_2Cl_2/MeOH afforded [Mo(CN)(η^3-allyl)$(CO)_2$(phen)] [allyl = C_3H_5 (**1a**); 2-MeC_3H_4 (**1b**)] as the sole products (no products of cyanide attack on the allyl group were detected). Treatment of **1a**,**b** with [Mo(OTf)(η^3-C_3H_5)$(CO)_2$(phen)] and $NaBAr'_4$ in CH_2Cl_2 yielded the compounds [{Mo(η^3-allyl)$(CO)_2$(phen)}(μ-CN){Mo(η^3-C_3H_5)$(CO)_2$(phen)}]BAr'_4 (**2a**,**b**). Analogous treatment of **1a** with *fac*-[M(OTf)$(CO)_3$(bipy)] (M = Mn, Re) and $NaBAr'_4$ resulted in the synthesis of [{Mo(η^3-C_3H_5)$(CO)_2$(phen)}(μ-CN){M$(CO)_3$(bipy)}]BAr'_4 (**3**, **4**), in which the C and N atoms of the cyano bridge are bonded to Mo and M (M = Mn, Re), respectively. The linkage isomer of **4** (C and N atoms of the cyano group bonded to Re and Mo, respectively) (**6**) was prepared by treatment of [Re(CN)$(CO)_3$(bipy)] (**5**) with [Mo(OTf)(η^3-C_3H_5)$(CO)_2$(phen)] and $NaBAr'_4$. Compounds **1a**, **2b**, **3**, and **6** were characterized by X-ray diffraction.

Introduction

Monometallic complexes with terminal cyano ligands can act as metalloligands toward a second metal fragment through the uncoordinated nitrogen atom of the cyano group, affording dimetallic complexes with CN bridges,[1−6] simpler models of the supramolecular and solid-state entities in which cyano groups act as links between metal atoms.

We have recently found that pseudooctahedral [MoX(η^3-allyl)$(CO)_2$(N−N)] (N−N = 2,2′- bipyridine, bipy; 1,10-phenanthroline, phen) complexes react with organolithium or organomagnesium reagents and with sodium alkoxides to afford new alkyl,[7] alkynyl,[8] and alkoxo[9] complexes by selective halide substitution. A similar reactivity pattern would provide access to the previously unknown [Mo(CN)(η^3-allyl)$(CO)_2$(N−N)] complexes. Attractive features of the known [MoX(η^3-allyl)$(CO)_2$(N−N)] compounds are their ease of preparation[10] and the robustness of the {Mo(η^3-allyl)$(CO)_2$(N−N)} fragment[11] that directs the reactivity towards the remaining coordination position.[7−9] This paper summarizes the results of our study on the reactivity of [MoX(η^3-allyl)$(CO)_2$(N−N)] complexes towards cyanide, as well as the behavior of the resulting cyano complexes as ligands.

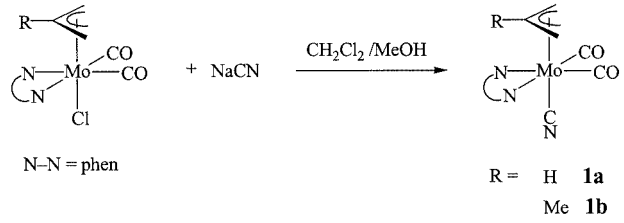
Results and Discussion

Treatment of [MoCl(η^3-C_3H_5)$(CO)_2$(phen)][12] with excess sodium cyanide in CH_2Cl_2/MeOH resulted in the formation of [Mo(CN)(η^3-C_3H_5)$(CO)_2$(phen)] (**1a**) as the only product, as depicted in Scheme 1. Employment of methanol as co-solvent was needed to provide sufficient solubility for the sodium cyanide. The product **1a** was easily separated from the excess sodium cyanide and the sodium chloride by-product by extraction into pure CH_2Cl_2, followed by filtration and crystallization.



Scheme 1

The IR spectrum of **1a** shows, in addition to the two strong bands corresponding to the *cis*-Mo$(CO)_2$ fragment, a weak band indicative of the presence of a cyano group.[1,2] Its ν_{CN} value (2113 cm^{-1}) is higher than that of the free cyanide anion (2080 cm^{-1}), as is typically found for C-

bound cyano ligands in transition metal complexes.[13] The ^{1}H NMR spectrum of **1a** reveals the presence of a molecular mirror plane (four signals for the phen ligand), and a symmetric, static η^3-allyl group. The methallyl complex [Mo(CN)(η^3-2-MeC_3H_4)(CO)$_2$(phen)] (**1b**) was prepared in a similar manner. Its spectroscopic features are also indicative of a geometry like that of **1a**, and so the structures shown in Scheme 1 are assumed. The low solubility of **1a**,**b** in organic solvents precluded the observation of significant ^{13}C NMR spectroscopic data, but the structure of **1a** was determined by single-crystal X-ray diffraction. A view of the molecule is displayed in Figure 1, and selected distances and angles are given in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] for [Mo(CN)(η^3-C_3H_5)(CO)$_2$(phen)] (**1a**)

Mo(1)−C(1)	1.966(7)	Mo(1)−N(1)	2.243(5)
Mo(1)−C(2)	1.959(9)	Mo(1)−N(2)	2.255(5)
Mo(1)−C(4)	2.329(7)	C(1)−O(1)	1.140(7)
Mo(1)−C(5)	2.229(7)	C(2)−O(2)	1.155(8)
Mo(1)−C(6)	2.325(7)	C(3)−N(3)	1.103(8)
Mo(1)−C(3)	2.188(8)		
C(1)−Mo(1)−C(2)	79.0(3)	C(2)−Mo(1)−C(3)	89.0(2)
N(1)−Mo(1)−N(2)	73.65(17)	C(3)−Mo(1)−N(1)	81.5(2)
C(1)−Mo(1)−N(1)	169.8(2)	C(3)−Mo(1)−N(2)	81.09(19)
C(2)−Mo(1)−N(2)	169.6(2)	N(3)−C(3)−Mo(1)	178.3(6)
C(1)−Mo(1)−C(3)	88.4(2)		

The molecule is isostructural with previously known [MoX(η^3-allyl)(CO)$_2$(N−N)] compounds.[14] It can thus be described, if the η^3-allyl group is regarded as occupying one coordination position, as pseudooctahedral: the molybdenum atom is surrounded by the two carbonyl groups, the cyano group, the η^3-allyl group, and the two nitrogen atoms of the phenanthroline ligand. The two CO groups are mutually *cis*, and each is *trans* to a phen nitrogen atom. The cyano and allyl groups are therefore mutually *trans*. The C(3)−N(3) [1.103(8) Å] and N(3)−C(3)−Mo(1) [178.3(6) °] values are typical for M−C−N groupings,[1,2] and the Mo(1)−C(3) distance [2.188(8) Å] is similar to Mo-C(alkynyl) distances recently found in isostructural complexes.[8,15]

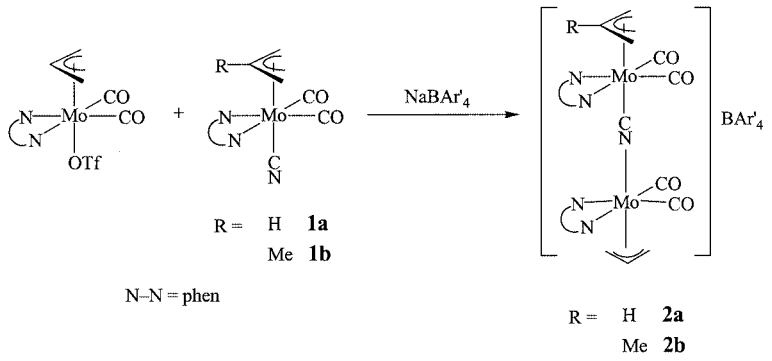
This structure concurs with the static structure in solution as deduced from the spectroscopic data (see above). In fact, X-ray diffraction does not allow clear differentiation between carbonyl and cyano groups, and so the spectroscopic data constitute the stronger evidence of their relative positions (two *cis*-carbonyl ligands related by a mirror plane). The cyano complexes **1a**,**b** are obtained in good yield, and no products resulting from cyanide anion attack on the allyl group could be detected. It is worth noting that, in general, attack on the allyl moiety is preferred for stabilized, soft nucleophiles, whereas hard ones preferentially attack the metal atom.[16,17] For [MoX(η^3-allyl)(CO)$_2$(L−L)] complexes in particular, stabilized carbanions − such as those resulting from deprotonation of dialkyl malonates − attack the allyl ligand.[18] In contrast, we have found here that the soft cyanide anion attacks the metal atom.

We aimed to explore the potential of the cyano complexes **1a**,**b** as ligands. We recently found that triflate abstraction from [Mo(OTf)(η^3-allyl)(CO)$_2$(phen)] can be smoothly effected by use of NaBAr′$_4$[19] [Ar′ = 3,5-bis(trifluoromethyl)phenyl] in CH_2Cl_2.[20] We thus treated equimolar amounts of this triflato complex, **1a**,**b**, and NaBAr′$_4$, in each case obtaining a single product, the IR ν_{CN} band of which showed the shift to higher wavenumber values expected for a change in the coordination mode of the cyano group from terminal to bridge (ν_{CN}: 2129 cm^{-1} for **2a** and 2132 cm^{-1} for **2b**) (Scheme 2).[1,2]

These compounds, partly due to the presence of the BAr′$_4$ anion, displayed high solubility in dichloromethane, allowing the acquisition of their ^{13}C NMR spectra. The most characteristic features are the weak signals at δ = 169.8 ppm (**2a**) and δ = 169.9 ppm (**2b**), attributable to the CN groups. Red crystals of **2a** could be obtained from CH_2Cl_2/hexane mixtures, but an attempt to determine its structure by X-ray diffraction was complicated by the severe disorder affecting one of the allyl groups. The analogous dimetallic compound **2b** did not suffer from this problem, and its structure could be determined with acceptable accuracy (see Figure 2 for a view of the cation, Tables 2 and 5 for selected geometrical data). The cation of **2b** consists of two {Mo(η^3-allyl)(CO)$_2$(N−N)} fragments, isostructural with that of **1a**, bridged by a CN group in linear fashion [Mo(1)−C(1)−N(1) = 176.2(8)°, C(1)−N(1)−Mo(2) = 179.4(8)°].

The bond between the cyano group and a second metal fragment is therefore formed without disruption of the Mo−CN bond. In contrast, the alkynyl group (for which similarities with CN as a ligand have been noted)[21] is transferred from {Mo(η^3-allyl)(CO)$_2$(N−N)} to other metal fragments.[15] Since the two metal fragments of **2b** are distinguishable, and only one species is present both in solution and in the crystal, the complex is stable with respect to CN $\rightleftarrows$ NC isomerization of the bridge.

We wanted to evaluate the ability of the new monometallic cyanomolybdenum complexes to act as ligands towards



Scheme 2

different metal centers. Treatment of the triflato complex [Re(OTf)$(CO)_3$(bipy)] with the salt NaBAr′$_4$ in the presence of neutral, two-electron ligands has recently been used to synthesize [Re(L)$(CO)_3$(bipy)]BAr′$_4$ compounds.[22] Similarly, [Mo(CN)(η³-C_3H_5)$(CO)_2$(phen)] (**1a**) reacted with [M(OTf)$(CO)_3$(bipy)] (M = Mn, Re)[23] and NaBAr′$_4$ to afford the dimetallic compounds **3** and **4**, respectively, as presented in Scheme 3.

The new compounds **3** and **4** could be isolated as solids by filtration, followed by crystallization (see Exp. Sect.). The simultaneous presence of the molybdenum and the manganese or rhenium fragments was indicated by the appearance of both the bipy and phen signals in a 1:1 ratio in the ^{1}H NMR spectra. Accordingly, the IR spectra of **3** and **4**, in their ν(CO) regions, show two bands of similar intensity, attributed to the *cis*-Mo$(CO)_2$ moiety, and bands similar to those of cationic *fac*-[M$(CO)_3$(bipy)(L)]⁺ (M = Mn, Re) complexes. For the rhenium compound **4** the latter bands are some 10 cm^{-1} lower than those of [Re$(CO)_3$(bipy)(NCR)]BAr′$_4$ (R = Me, Ph),[22] indicating that the cyano complex is a stronger donor than nitriles. On the other hand, the frequencies corresponding to the *cis*-Mo$(CO)_2$ fragment are little shifted with respect to those of the monometallic precursor. Thus, coordination of the cyano nitrogen atom to the rhenium atom modifies the electron density at the molybdenum center only a little. The presence of the bridging cyano group is shown by the weak C−N stretches in the IR spectra (2145 cm^{-1} for **3**, 2140 cm^{-1} for **4**), and by the low-intensity signals in the ^{13}C NMR spectra (δ = 166.6 and 163.8 ppm for **3** and **4**, respectively). The close similarity between these ^{13}C NMR chemical shifts and those of the homodimetallic compounds **2a**,**b** is consistent with coordination of the cyano bridge to the molybdenum atom through the carbon atom in compounds **3** and **4** (see below for carbon coordination to a rhenium atom). Crystals of **3** suitable for structural determination by X-ray diffraction were obtained, and the results are presented in Figure 3, Tables 3 and 5. These results confirm the [{Mo(η³-C_3H_5)$(CO)_2$(phen)}(μ-CN){Mn$(CO)_3$(bipy)}]BAr′$_4$ formulation for **3**.

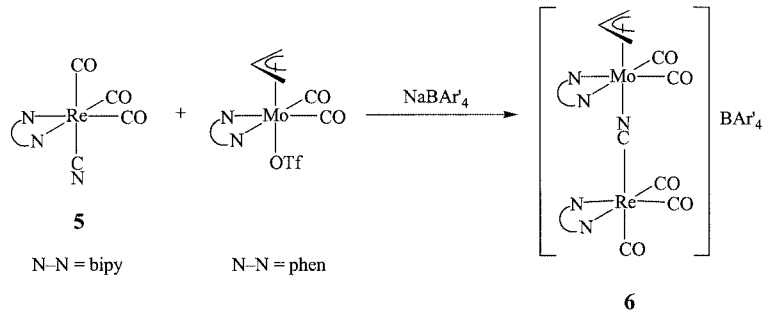
Given the asymmetric nature of the cyano bridge (i.e., one metal atom is bound to a carbon and the other to a nitrogen atom), heterodimetallic cyano-bridged complexes such as **3** and **4** have linkage isomers. For complexes **3** and **4**, those isomers would feature Mo−N and M−C (M = Mn or Re) bonds. As recently pointed out, linkage isomers of cyano-bridged dimetallic complexes have been isolated in only a few instances.[24] This prompted us to attempt the synthesis of the linkage isomers of **3** and **4**. The Mo/Mn complex proved to be labile in solution, and attempts to isolate it by crystallization afforded crystals of the dimolybdenum compound **2a**. Therefore, only the Mo/Re complex is discussed.

The first step, just as in the synthesis of **3** and **4**, was to prepare the mononuclear cyano complexes. [Re(CN)$(CO)_3$(bipy)] had previously been synthesized by heating [ReCl$(CO)_3$(bipy)] at reflux with a 100-fold molar excess of sodium cyanide in water or an ethanol/water mixture and subsequent extraction with dichloromethane.[25,26]

We have found that [Re(CN)$(CO)_3$(bipy)] (**5**) can be conveniently prepared by treatment of the labile triflato complex [Re(OTf)$(CO)_3$(bipy)] with tetraethylammonium cyanide. The reaction takes place in dichloromethane within 2 h at room temperature when 1.2 equiv. of [Et_4N]CN is used, and the IR spectrum of the resulting solution shows only the bands of [Re(CN)$(CO)_3$(bipy)] (**5**). The coordinated cyano group appears as a weak signal at δ = 156.1 ppm in the ^{13}C NMR spectrum. However, the isolated material (see Exp. Sect.) was contaminated with [Et_4N]CN, as indicated by the ^{1}H NMR spectrum. Since purification of this mononuclear complex proved difficult, the crude material was employed for the synthesis of the targeted dimetallic compound. Thus, by the methodology used for the synthesis of **2**, [Re(CN)$(CO)_3$(bipy)] (**5**) was added to the filtered solution obtained from the reaction between [Mo(η^3-allyl)(OTf)$(CO)_2$(phen)] and NaBAr′$_4$ in CH_2Cl_2.

The formation of the dimetallic compound [{Mo(η^3-allyl)$(CO)_2$(phen)}(μ-NC){Re$(CO)_3$(bipy)}]BAr′$_4$ (**6**), depicted in Scheme 4, was instantaneous, as indicated by IR monitoring, and the product could be purified and isolated by crystallization and characterized by spectroscopy and single-crystal X-ray diffraction. The cyano ligand of **6** gives rise to a signal at δ = 155.1 ppm in the ^{13}C NMR spectrum. This value, very close to that found for the mononuclear complex **5**, strongly supports C-coordination to Re in **6** (see above for the chemical shifts values found for the C−Mo isomer). The results of the structural determination of the



Scheme 4

cation are displayed in Figure 4, Tables 4 and 5. The cationic complex consists of a cyano bridge N-bonded to the molybdenum of an {Mo(η³-allyl)(CO)₂(phen)} fragment, and C-bonded to the rhenium atom of a {Re(CO)₃(bipy)} fragment.

N(2)−Re(1)−N(3)	74.9(2)		

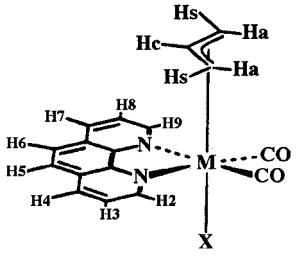
As in the isomer **4**, the IR spectrum of **6** shows sets of bands attributable to *cis*-{Mo(CO)₂} and *fac*-{Re(CO)₃}, together with a weak ν_{CN} absorption at a higher frequency (2143 cm^{-1}) than that of the starting monometallic cyano complex (2122 cm^{-1}).

Conclusion

In summary, [Mo(CN)(η³-allyl)(CO)₂(phen)] complexes were easily synthesized and employed as building blocks for the preparation of cationic homo- and heterodimetallic cyano-bridged complexes by treatment with neutral triflato complexes in the presence of the salt NaBAr′₄ as triflate abstractor. This strategy was extended to prepare the two linkage isomers of [{Mo(η³-allyl)(CO)₂(phen)}(μ-NC){Re(CO)₃(bipy)}]BAr′₄.

Experimental Section

General Remarks: All manipulations were carried out under nitrogen by standard Schlenk techniques. Solvents were distilled from freshly wired Na (hexanes) or CaH_2 (CH_2Cl_2 and MeOH) prior to use. CD_2Cl_2 was degassed by three freeze-pump-thaw cycles, dried with molecular sieves (4 Å), and stored in the dark in a Young tube. Elemental analyses were obtained with a Perkin−Elmer 240-B microanalyzer. The IR and NMR spectra were recorded with Perkin−Elmer FT 1720-X and Bruker AC 200 or AC 300 spectrometers, respectively. [MoCl(η³-C_3H_5)(CO)₂(phen)],[12] [MoCl(η³-C_3H_4-2-Me)(CO)₂(phen)],[27] [Mo(OTf)(η³-C_3H_5)(CO)₂(phen)],[20] [M(OTf)(CO)₃(bipy)] (M = Mn, Re),[23] and NaBAr′₄ [19] were prepared according to literature procedures. All other chemicals were used as received from commercial sources. H_s and H_a designate the *syn*- and *anti*-H atoms, respectively, of the allyl and methallyl ligands; H_c is the central H atom of the allyl ligand. The atom-labeling scheme for the allyl, 1,10- phenanthroline, and BAr′₄ groups is shown below.



[Mo(CN)(η³-C_3H_5)(CO)₂(phen)] (1a): NaCN (0.013 g, 0.294 mmol) was added to a solution of [MoCl(η³-C_3H_5)(CO)₂(phen)] (0.100 g, 0.245 mmol) in a mixture of CH_2Cl_2 (20 mL) and MeOH (3 mL), and the mixture was stirred for 2 h at room temperature. The red solution obtained was concentrated in vacuo, and the residue was

redissolved in CH_2Cl_2 and filtered through Celite. The volatiles were removed in vacuo, and the residue was washed with hexane (3 × 10 mL). Slow diffusion of hexane into a solution of [Mo(CN)(η^3-C_3H_5)(CO)$_2$(phen)] (**1a**) in CH_2Cl_2 (15 mL) at room temperature produced red crystals of **1a**. A single crystal obtained in this way was used for the X-ray analysis. Yield: 0.088 g, 90%. $C_{18}H_{13}MoN_3O_2$ (399.26): calcd. C 54.15, H 3.28, N 10.52; found C 54.11, H 3.07, N 10.15. IR (CH_2Cl_2): $\tilde{\nu}$ = 2113 ($\nu_{C\equiv N}$), 1952, 1868 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 9.06 (dd, $J_{2,3\text{-H}} = J_{9,8\text{-H}}$ = 5.0, $J_{2,4\text{-H}} = J_{7,9\text{-H}}$ = 1.5 Hz, 2 H, 2,9-H), 8.52 (dd, $J_{H4,3} = J_{H7,8}$ = 8.3 Hz, 2 H, 4,7-H), 7.98 (s, 2 H, 5,6-H), 7.81 (dd, 2 H, 3,8-H), 3.35 (d, $J_{Hs,c}$ = 6.5, 2 H, H_s), 3.01 (m, 1 H, H_c), 1.83 (d, $J_{Ha,c}$ = 9.8 Hz, 2 H, H_a) ppm.

[Mo(CN)(η^3-2-MeC_3H_4)(CO)$_2$(phen)] (1b): The procedure was similar to that described above for the preparation of **1a**, starting from [MoCl(η^3-2-MeC_3H_4)(CO)$_2$(phen)] (0.100 g, 0.237 mmol) and NaCN (0.014 g, 0.284 mmol). Yield: 0.090 g, 92%. $C_{19}H_{15}MoN_3O_2$ (413.28): calcd. C 55.22, H 3.66, N 10.17; found C 55.01, H 3.34, N 10.38. IR (CH_2Cl_2): $\tilde{\nu}$ = 2112 ($\nu_{C\equiv N}$), 1950, 1870 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 9.02 (dd, $J_{2,3\text{-H}} = J_{9,8\text{-H}}$ = 5.0, $J_{2,4\text{-H}} = J_{7,9\text{-H}}$ = 1.3, 2 H, 2,9-H), 8.53 (dd, $J_{4,3\text{-H}} = J_{7,8\text{-H}}$ = 8.2 Hz, 2 H, 4,7-H), 8.00 (s, 2 H, 5,6-H), 7.83 (dd, 2 H, 3,8-H), 3.10 (s, 2 H, H_s), 1.81 (s, 2 H, H_a), 0.59 [s, 3 H, η^3-C_3H_4(CH_3)] ppm.

[{Mo(η^3-C_3H_5)(CO)$_2$(phen)}$_2$(μ-CN)]BAr′$_4$ (2a): NaBAr′$_4$ (0.093 g, 0.105 mmol) was added to a solution of [Mo(OTf)(η^3-C_3H_5)(CO)$_2$(phen)] (0.055 g, 0.105 mmol) in CH_2Cl_2 (20 mL), and the resulting slurry was stirred for 15 min. The solution was filtered by cannula into a solution of [Mo(CN)(η^3-C_3H_5)(CO)$_2$(phen)] (**1a**, 0.038 g, 0.105 mmol) in CH_2Cl_2 (15 mL) and the deep red solution obtained was stirred for 2 h. The solution was then concentrated in vacuo to a volume of 5 mL, and slow diffusion of hexane at room temperature gave red crystals of **2a**. Yield: 0.110 g, 71%. $C_{67}H_{38}BF_{24}Mo_2N_5O_4$ (1635.73): calcd. C 49.20, H 2.34, N 4.28; found C 48.93, H 2.38, N 4.34. IR (CH_2Cl_2): $\tilde{\nu}$ = 2129 ($\nu_{C\equiv N}$), 1958, 1878 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 8.75, 8.59, 8.46, 7.96, 7.95 and 7.68 (m, 16 H, 2 × phen), 7.78 (m, 8 H, C_o-H), 7.58 (m, 4 H, C_p-H), 3.27 (d, $J_{Hs,c}$ = 6.4 Hz, 2 H, H_s), 3.19 (d, $J_{Hs,c}$ = 6.4 Hz, 2 H, H_s), 2.87 (m, 2 H, H_c), 1.75 (d, $J_{Ha,c}$ = 9.5 Hz, 2 H, H_a), 1.45 (d, $J_{Ha,c}$ = 9.4 Hz, 2 H, H_a) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 223.7 and 223.2 (CO), 169.8 (CN), 152.3, 152.1, 144.7, 138.6, 138.3 and 130.3 (phen), 162.1 (q, J = 49.8 Hz, C_i), 135.2 (C_o), 129.3 (q, J = 31.4 Hz, C_m), 124.9 (q, J = 272.4 Hz, CF_3), 117.9 (C_p), 79.0 (C-2 of η^3-C_3H_5), 60.2 (C-1 and C-3 of η^3-C_3H_5), 57.8 (C-1 and C-3 of η^3-C_3H_5) ppm.

[{Mo(η^3-C_3H_4-Me-2)(CO)$_2$(phen)}(μ-CN){Mo(η^3-C_3H_5)(CO)$_2$-(phen)}]BAr′$_4$ (2b): The procedure was similar to that described above for the preparation of **2a**, starting from [Mo(CN)(η^3-2-MeC_3H_4)(CO)$_2$(phen)] (**1b**, 0.047 g, 0.115 mmol), [Mo(OTf)(η^3-C_3H_5)(CO)$_2$(phen)] (0.060 g, 0.115 mmol) and NaBAr′$_4$ (0.102 g, 0.115 mmol) to give complex **2b**. Yield: 0.143 g, 79%. $C_{68}H_{40}BF_{24}Mo_2N_5O_4$ (1649.75): calcd. C 49.51, H 2.44, N 4.24; found C 49.17, H 2.38, N 4.01. IR (CH_2Cl_2): $\tilde{\nu}$ = 2132 ($\nu_{C\equiv N}$), 1959, 1878 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 8.73, 8.54, 8.47, 7.98 and 7.68 (m, 16 H, 2 × phen), 7.74 (m, 8 H, C_o-H), 7.56 (m, 4 H, C_p-H), 3.17 (d, $J_{Hs,c}$ = 6.5 Hz, 2 H, H_s), 3.01 (s, 2 H, H_s), 2.99 (d, $J_{Hs,c}$ = 6.7 Hz, 2 H, H_s),1.70 (s, 2 H, H_a), 1.68 (d, $J_{Ha,c}$ = 9.2 Hz, 2 H, H_a), 1.42 (d, $J_{Ha,c}$ = 9.3 Hz, 2 H, H_a), 0.42 [s, 3 H, C_3H_4(CH_3)] ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 223.7 and 223.6 (CO), 169.9 (CN), 152.1, 151.9, 144.8, 138.7, 138.1, 130.5, 127.8, 127.7, 125.4, 125.3, 125.2 and 119.5 (2 × phen), 162.1 (q, J = 49.4 Hz, C_i), 135.1 (C_o), 129.2 (q, J = 34.2 Hz, C_m), 124.9 (q, J = 272.4 Hz, CF_3), 117.8 (C_p), 88.9, 73.6, 71.4, 58.3, 58.1 and 57.7 [C-1, C-2 and C-3 of η^3-C_3H_5 and η^3-C_3H_4(CH_3)], 17.6 [η^3- C_3H_4(CH_3)] ppm.

[{Mo(η^3-C_3H_5)(CO)$_2$(phen)}(μ-CN){Mn(CO)$_3$(bipy)}]BAr′$_4$ (3): NaBAr′$_4$ (0.099 g, 0.112 mmol) was added to a solution of [Mn(OTf)(CO)$_3$(bipy)] (0.050 g, 0.112 mmol) in CH_2Cl_2 (15 mL)

and the resulting solution was stirred for 15 min at room temperature. The color of the solution turned from yellow to orange. The solution was filtered by cannula into a solution of [Mo(CN)(η³-C_3H_5)(CO)$_2$(phen)] (**1a**, 0.045 g, 0.112 mmol) in CH_2Cl_2 (15 mL) and the color of the solution turned bright red. The resulting solution was concentrated in vacuo to a volume of 5 mL, and slow diffusion of hexane at −20 °C gave dark orange crystals of **3**. A single crystal obtained in this way was used for the X-ray analysis. Yield: 0.105 g, 62%. $C_{63}H_{33}BF_{24}MnMoN_5O_5$ (1557.64): calcd. C 48.58, H 2.13, N 4.50; found C 48.78, H 1.98, N 4.85. [Re(CN)(CO)$_3$(bipy)] (5): NEt_4CN (0.016 g, 0.104 mmol) was added to a solution of [Re(OTf)(CO)$_3$(bipy)] (0.050 g, 0.087 mmol) in CH_2Cl_2 (20 mL), the mixture was stirred for 2 h at room temperature, and the color of the solution turned from yellow to orange. The volatiles were removed in vacuo and the residue was washed with Et_2O (3 × 15 mL). IR (CH_2Cl_2): $\tilde{\nu}$ = 2122 ($\nu_{C\equiv N}$), 2023, 1920 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 9.02, 8.36, 8.14 and 7.56 (2 H each, bipy), 3.24 (q, J = 7.1 Hz, CH_2, Et_4N), 1.31 (t, J = 7.1 Hz, CH_3, Et_4N) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 196.1 and 191.2 (CO), 156.1 (CN), 153.6, 143.1, 139.7, 127.7 and 124.1 (bipy), 53.86 (CH_2, Et_4N), 7.11 (CH_3, Et_4N) ppm.

[{Mo(η³-C_3H_5)(CO)$_2$(phen)}(μ-NC){Re(CO)$_3$(bipy)}]BAr′$_4$ (6): NaBAr′$_4$ (0.093 g, 0.105 mmol) was added to a solution of [Mo(OTf)(η³-C_3H_5)(CO)$_2$(phen)] (0.055 g, 0.105 mmol) in CH_2Cl_2 (20 mL), and the resulting slurry was stirred for 15 min. The solution was filtered by cannula into a solution of [Re(CN)(CO)$_3$(bipy)] (**5**, 0.047 g, 0.105 mmol) in CH_2Cl_2 (15 mL), and the deep red solution obtained was stirred for 2 h. The solution was then concentrated in vacuo to a volume of 5 mL, and slow diffusion of hexane at room temperature gave red crystals of **6**. Yield: 0.151 g, 87%. $C_{60}H_{28}BF_{24}MoN_5O_5Re$ (1647.84): calcd. C 43.73, H 1.71, N 4.25; found C 43.61, H 2.03, N 4.17. IR (CH_2Cl_2): $\tilde{\nu}$ = 2143 ($\nu_{C\equiv N}$), 2030, 1947, 1926, 1875 (ν_{CO}) cm^{-1}. ^{1}H NMR (CD_2Cl_2): δ = 8.89, 8.49, 8.15, 8.06 and 7.37 (m, 32 H, bipy, phen and BAr′$_4$), 3.26 (d, $J_{Hs,c}$ = 6.0 Hz, 2 H, H_s), 2.70 (m, 1 H, H_c), 1.51 (d, $J_{Ha,c}$ = 9.3 Hz, 2 H, H_a) ppm. ^{13}C{^{1}H} NMR (CD_2Cl_2): δ = 225.75 and 224.15 (2 CO, Mo−CO), 193.61 (2 CO, Re−CO) 191.78 (1 CO, Re−CO), 162.49 (q, J = 49.9 Hz, C_i), 155.67 (CN), 155.66, 153.35, 152.35, 139.95, 138.98 (bipy and phen), 135.20 (C_o), 130.48, 130.40 (bipy and phen), 129.27 (q, J = 31.9 Hz, C_m), 127.92, 127.86, 126.79 (bipy and phen), 124.38 (q, J = 272.3 Hz, CF_3), 119.57 (phen), 117.91 (C_p), 73.87 (C-1 and C-3 of η³-C_3H_5), 59.9 (C-2 of η³-C_3H_5) ppm.

X−ray Crystallographic Study:[28] The crystal of **1a** was measured with a Nonius CAD4 diffractometer. Profile analysis was performed on all reflections.[29,30] Symmetry-equivalent and other redundant reflections were averaged, and drift, Lorentz, and polarization corrections were applied. The structure was solved by Patterson methods with DIRDIF-96.[31] Isotropic least-squares refinement was carried out on F^2 by use of SHELXL-97.[32] An empirical absorption correction was applied at this stage, by use of XABS2.[33] All atoms were located by Fourier synthesis. During the final stages of the refinement, all positional parameters and the anisotropic temperature factors of all the non-H atoms were refined with SHELXL-97.[31] The atoms were isotropically refined. Plots were made with the EUCLID package.[34] Geometrical calculations were performed with PARST.[35] Data in common for compounds **2b**, **3**, and **6**: Bruker AXS SMART 1000 CCD diffractometer, φ and ω scans, Mo-K_α radiation (λ = 0.71073 Å), graphite monochromator, T = 295 K. Raw frame data integrated by use of the SAINT[36] program. Structures were solved by direct methods with SHELXTL,[37] semiempirical absorption correction with SADABS.[38] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were set in calculated positions and refined as riding atoms, with a common thermal parameter. All calculations were performed with SHELXTL.

Charge-Transfer Mechanisms between Gold Clusters

Viktoria Torma,[a] Olivia Vidoni,[a] Ulrich Simon,[b] and Günter Schmid*[a]

Keywords: Gold / Cluster compounds / Charge transfer / Activation energy / Conductivity

Electron-transfer processes in complex chemistry are usually described by Taube's "outer sphere" and "inner sphere" mechanisms. A behaviour related to these electron-transfer mechanisms in complex chemistry can be observed for charge-transfer transport between ligand protected Au_{55} nanoclusters. A linear dependence between cluster-cluster distance and activation energy for electron transfer is observed if a noncovalent linkage exists; this interaction is independent of the distance in covalently linked clusters. Instead, the activation energy depends on the electronic nature of the linking molecules. The dithiols 1,5-dithionaphthaline (**1**), 4,4′-thiobis(benzenethiol) (**2**), and 2,8-dithio-6-hydroxypurine (**3**) have been used as bifunctional covalent linkers either in their monomeric form (**2**) or, in the presence of air, dimerized via S–S bonds (**1**, **2**, **3**), causing an increase in the distance between the clusters and leading to the cluster networks **4**–**7**. Noncovalent cluster networks are formed either by pellets of clusters with monodentate ligands in **8** and **11**, linked only by van der Waals forces, or by using bifunctional spacers that interact with the clusters by ion attractions (**9**, **10**).

A study of the activation energies clearly indicates that in the case of noncovalently organized nanoparticles only the cluster spacing is of relevance, even if conjugated π-systems like in **10** are used. This behaviour corresponds to an outer-sphere mechanism. On the contrary, for covalently linked clusters the distances between them does not play a visible role. The activation energies all lie below those of the noncovalent examples, and a relation between cluster-cluster distance and activation energy is not obvious. In those cases the relationship suggests an inner-sphere mechanism where the transport properties of the spacer play a decisive role.

These findings possibly help to explain contradictory reports on the conductivity behaviour of organic molecules.

Introduction

The study of the electric properties of nanosized materials is a rapidly emerging field of great fundamental and practical interest owing to their potential as building blocks in future nanoelectronic devices. Much of the recent work is therefore driven by prospective applications in nanoelectronics, nonlinear optics, sensors etc. The charge-transfer properties of individual particles,[1−3] monolayers,[4−6] multilayers,[7,8] as well as of three-dimensional structures[9−11] have been investigated. Generally, it was found that the electrical conductivity depends on the size of the particles[12] and on the distance between them.[13] Whereas particles with diameters larger than about 2 nm were suggested to be used for the fabrication of nanowires to connect electrical circuit elements,[14] particles smaller than 2 nm are promising candidates for room-temperature single electron transistors[15] since the rate-limiting step of the electron-transfer process is the charging of the particles. Therefore, charge transport is connected with a relatively high activation energy.

In order to vary the activation energy for electron transfer between nanoparticles many different ligand molecules or interconnecting spacers have been applied. Among these are thiols and dithiols,[7,16−18] dicyanides,[5] phosphanes,[9,10,15] and other molecules with or without conjugated π-systems.[5,19] There is, however, no agreement among different authors whether and/or in which way the chemical nature of the spacers influences the conduction properties of the nanoparticle arrangement[4,5] or not.[13,15,20] It has been shown that the resistance of an adsorbed monolayer on a surface, measured by STM, depends on the nature of the end groups of the adsorbed molecules.[21] This effect was interpreted by the conduction through the highest occupied molecular orbitals (HOMOs) or the lowest unoccupied states (LUMOs).

On the other hand we found that the activation energy for charge transport in three-dimensional cluster arrangements depends simply on the cluster spacing rather than on the chemical nature of the molecules between them.[22] This is reflected by an almost linear dependence of the activation energy on the cluster spacing that is observed provided that

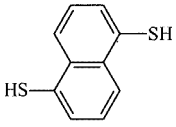
the cluster linkage results from ionic coupling instead of a covalent linkage. A simple approach based on the Landauer formula, which allows a first-order estimate of the resistance of the linking molecules, leads to the conclusion that the charge transport between clusters via organic molecules (ligands/spacers) involves tunnelling rather than propagation.[20]

Results and Discussion

In this paper we report on the synthesis and electrical characterisation of different types of covalently crosslinked Au_{55} clusters in order to compare the charge-transfer properties with those of previously described noncovalently organized systems. For that purpose we used three different dithiols, since sulfur−gold bonds are of a strongly covalent character and dithiol-protected clusters can be three-dimensionally linked through direct Au-dithiol-Au bonds or S−S bonds formed by smooth oxidation of the second SH groups.

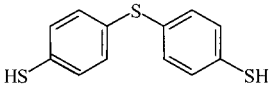
As dithiols we used

1,5-dithionaphthaline (DNP)



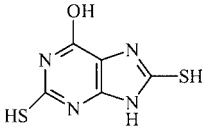
1

4,4'-thiobis(benzenethiol (TBBT)



2

and 2,8-thio-6-hydroxypurine (purine)



3

The process aimed is illustrated schematically in Figure 1.

The formation of the dithiol-stabilized gold clusters results from ligand-transfer reactions and has been performed previously with various other thiol ligands.[7,23,24] As shown in Figure 1, the first step should represent the formation of individual thiol-stabilized clusters (A) which have not been isolated. Afterwards, two further reactions can take place: in the absence of air, the terminal thiols can interact directly with other clusters (B) (due to the high steric hindrance, this exchange can need several weeks), whereas in the presence of air, fast oxidation of the free SH groups to S−S disulfide bridges occurs, crosslinking the clusters (C). This process can be followed by the formation of brown precipitates, consisting of three-dimensionally linked cluster-dithiol hybrid materials, and residual colourless solutions.

Under a nitrogen atmosphere, well-ordered arrangements of Au_{55} clusters, directly linked by the spacer molecule **2**

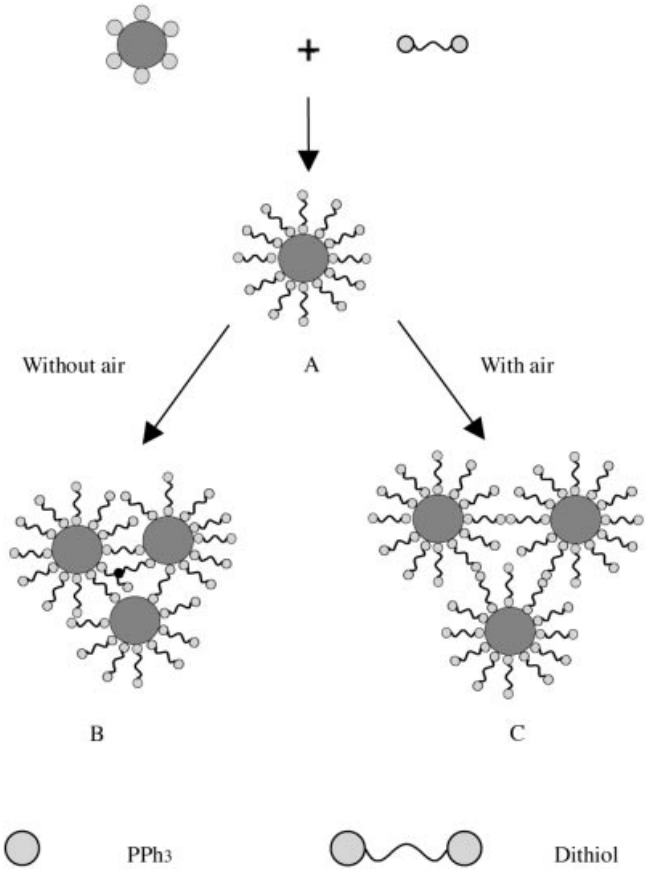


Figure 1. Schematic representation of the cross-linkage of Au_{55} clusters with dithiols (A); without air, aggregates of type B are formed, whereas in the presence of air aggregates C, with S−S bridges, result

through formation of Au−S bonds, were observed (**4**, Figure 2, top). In air, various assemblies of clusters were formed (**6**, Figure 2, middle). These clusters do not adopt a specific ordering, but a regular average distance of 2.3 nm between two adjacent particles attests to the presence of a disulfide bridge. In contrast to **4**, which took about two weeks to form and precipitate, the formation of **6** was finished after two hours so no higher organization is possible. This lack of organisation can be explained by the fact that the spacer molecules used are long and flexible enough to fold during the experiments modifying the inter-particle distance. The number of spacer molecules present around one Au_{55} cluster depends on the ligands used. Because of the nature of the product (insoluble polymer), the elemental analysis does not allow the determination of the exact stoichiometry of the compounds, but only an estimation concerning the number of linkers present around each cluster. The results are the following:

entity 4: $Au_{55}[TBBT]_{22/2}$; entity 5: $Au_{55}[purine]_{16}$; entity 6: $Au_{55}[TBBT]_{14}$; entity 7: $Au_{55}[DNP]_{18}$.

As a blank, one drop of a solution of gold clusters was deposited onto a TEM grid (Figure 2, bottom). In this case, no special kind of organisation of the gold particles was observed. For the electrical measurements the washed and

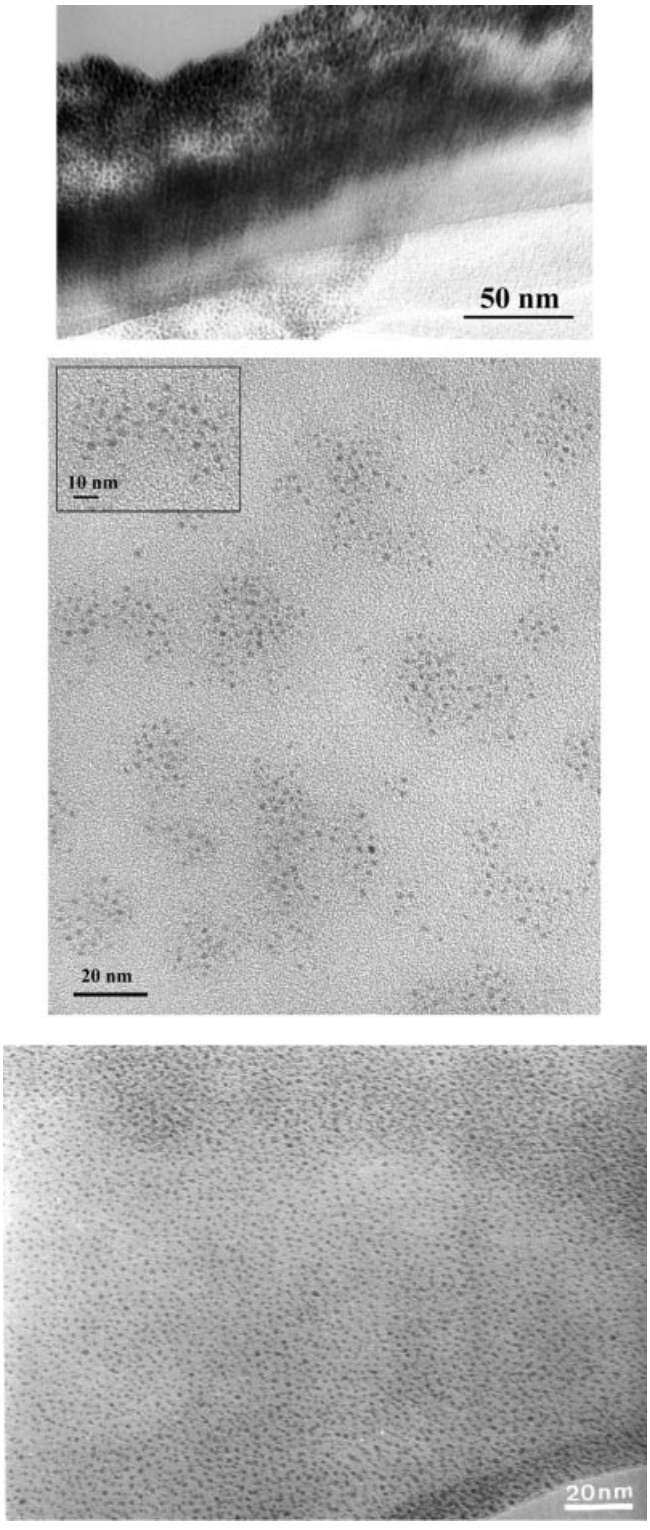

Figure 2. (top): TEM image of an ordered arrangement of $[Au_{55}Cl_6(PPh_3)_{12}]$ clusters linked by the spacer molecule **2** without oxygen (sample **4**); (middle): TEM image of $[Au_{55}Cl_6(PPh_3)_{12}]$ clusters linked by the spacer molecules **2** in the presence of air (sample **6**); the insert shows the magnified aggregate below; (bottom): TEM image of nonlinked $[Au_{55}Cl_6(PPh_3)_{12}]$ clusters

carefully dried precipitates were pressed into pellets and contacted on the top and bottom with silver paint. The activation energies were determined by temperature-dependent conductivity measurements. The temperature dependence shows simply activated behaviour for a temperature range between 200 K and 300 K. In this temperature range the charge transport is due to thermally activated electron exchange between neighbouring clusters. The corresponding activation energy E_a i.e. the charging energy of the particles in the three-dimensional arrangement, is determined by the respective particle size and spacing. Thus, E_a represents the charge disproportionation energy, which needs to be overcome to create mobile charge carriers.[25] Below 200 K a transition from nearest neighbour exchange to variable range exchange is observed, leading to a temperature dependent activation energy. In these experiments E_a was determined between 200 K and 300 K by a regression line fit. Figure 3 contains the experimental curves of the investigated samples and Table 1 summarises these data together with the calculated cluster distances. In addition, the corresponding data for the non-covalently crosslinked clusters of our previous investigations[15,25,26] are included for comparison.

Figure 4 illustrates the data of Table 1. As already mentioned, in the case of noncovalently crosslinked Au_{55} clusters there is a linear relation (correlation coefficient: 0.992) between cluster-cluster distances and activation energies, indicating that only the distance between the nanoparticles determines the energy of the hopping processes. The chemical nature of the linking molecules obviously plays a minor role. This can be understood due to the fact that there is no direct electronic interaction between the clusters via either the stabilizing ligand molecules in a close packing in samples **8** and **11** (van der Waals attraction), or the crosslinking spacer molecules in **9** and **10** (ionic attraction between spacer and functional groups and outer ligand sphere). This is most visible in the case of the spacer in sample **10**, which comprises a conjugated π-system along its backbone and from which a molecular conducting behaviour might be expected. Instead, E_a also depends on its length, implying that propagation along the π-system is blocked by the ionic interconnection between spacer and ligand.

On the contrary, the dithiol spacers link the clusters directly by covalent bonds. The activation energies are characteristically lower and do not depend linearly on the cluster spacing. Although a direct relation between the molecule length, electron density, symmetry etc. and E_a could not be established, it is obvious that the chemical nature of these molecules, which differ considerably among each other, essentially affect the transition probability for electrons between the clusters. This suggests an electron-transport mechanism, where bonding and/or antibonding molecular orbitals of the linking molecules are involved in the conductivity process.

In a first-order approximation the difference between directly (covalent) and nondirectly (van der Waals, ionic) linked clusters can be compared with the mechanisms of classical redox processes, which have been divided into "outer sphere" and "inner sphere" mechanisms.[27–31] The inner-sphere mechanism of electron transfer is characterised

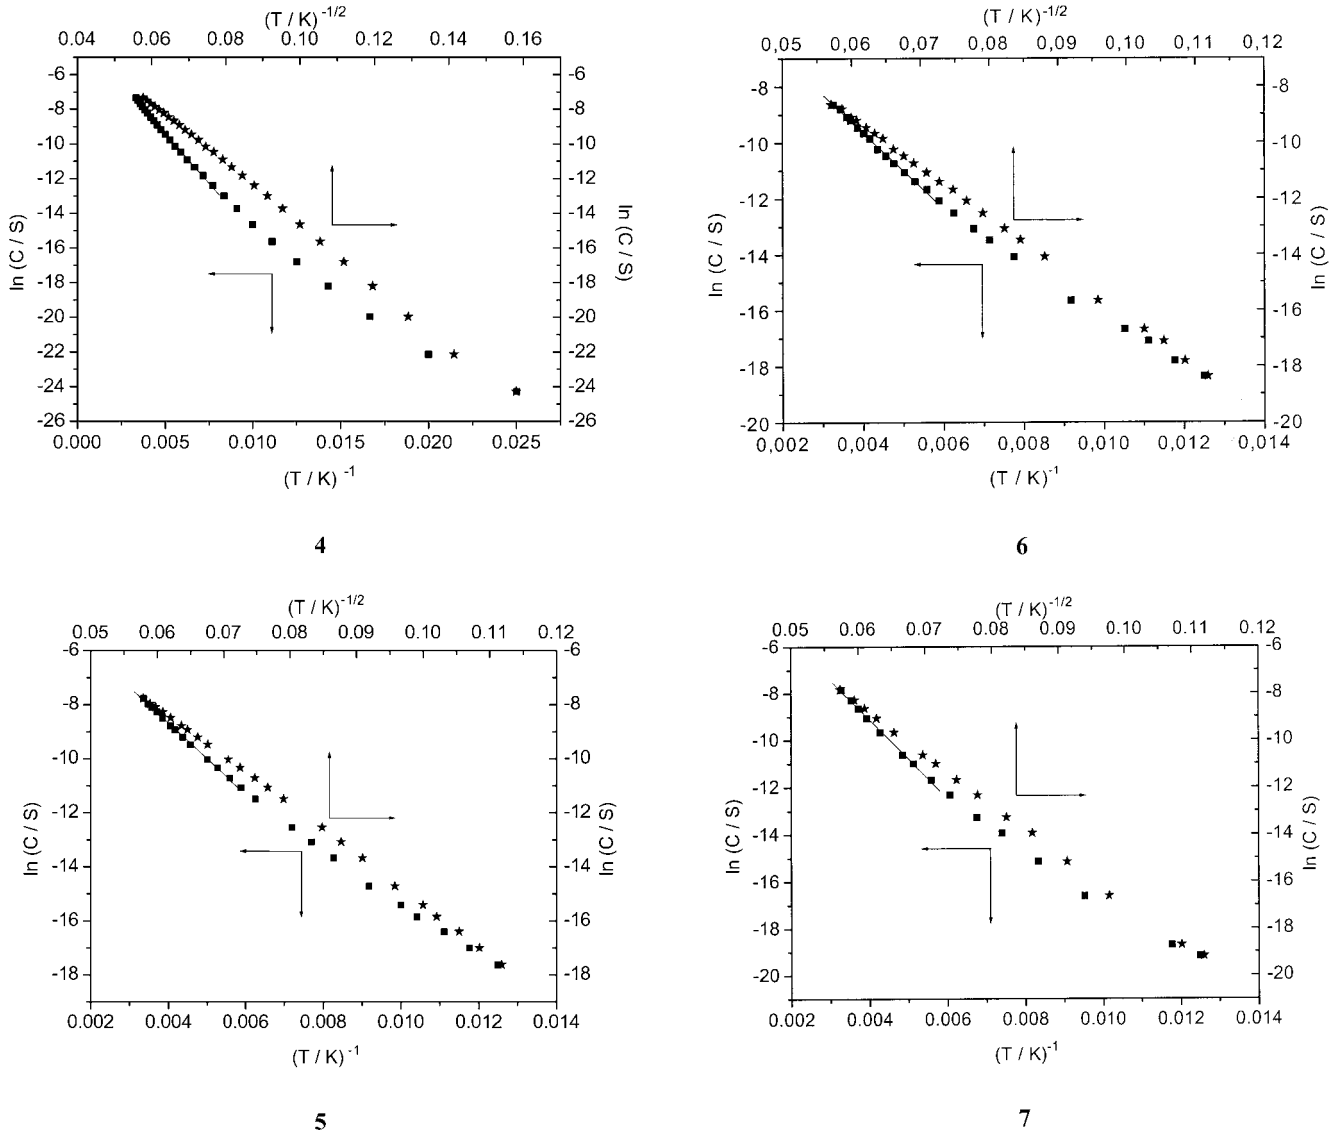

Figure 3. Experimental curves (temperature versus conductance) of **4**, **5**, **6**, and **7**

by the participation of a bridging ligand between the oxidizing and the reducing metal ion. In the outer-sphere process the coordinated metal ions simply touch each other via their coordination spheres, and the electron transfer has to occur through the ligand shell and probably involves a deformation of the coordination spheres. Electron transfer between clusters can indeed be compared with those redox processes. The initial step for the creation of free charge carriers is the charge disproportionation of two initially neutral clusters in the immediate vicinity. Thus, charged cluster pairs represent both reduced and oxidized species, and E_a corresponds to the inverse of the electron-transfer rate, which is essentially higher in redox pairs with direct coupling (inner-sphere mechanism).

Conclusion

We have shown that electron-transfer processes between Au_{55} clusters can occur in two different ways: compared with classical inner-sphere redox processes, noncovalently linking molecules simply act as spacers, independent of their chemical nature, and require activation energies that correspond only to their length. Covalently cluster-linking

Table 1. Activation energies and cluster-cluster distances of the covalently and the non-covalently organized systems

Linking System		Distance [nm][a]	E_a [eV]
Covalently Linked			
	**4**	1.1	0.095
	**5**	1.6	0.11
	**6**	2.3	0.12
	**7**	1.5	0.14
Noncovalently Linked			
Linking System		Distance [nm][a]	E_a [eV]
	**8**	0.7	0.16
	**9**	1.9	0.2
	**10**	2.8	0.23
	**11**	3.1	0.26

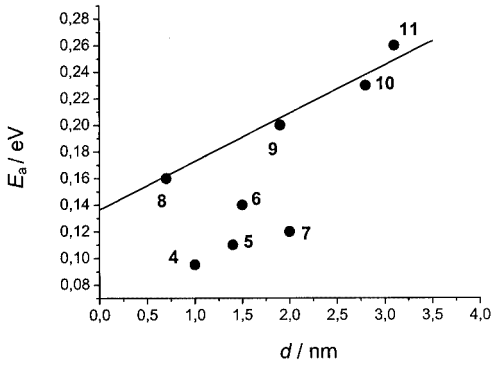

Figure 4. Activation energies versus cluster-cluster distances of the covalently (**4**−**7**) and the noncovalently (**8**−**11**) organized systems

species, possessing delocalised π-electrons, enable inter-cluster electron transfers by lower activation energies, depending on the electronic situation in the molecule, not only on their lateral extension. These results give a new insight into the charge-transport mechanism between nanoparticles, and long and controversial questions concerning the nature of this transport − whether it involves propagation via the organic molecules or whether it predominantly involves tunnelling − can now be considered as at least partially to be answered.

Experimental Section

General: 4,4′-Thiobis(benzenethiol) (**2**) and 2,8-dimercapto-6-hydroxypurine (**3**) were purchased from Aldrich (98% purity) and from Avocado (98% purity), respectively. 1,5-Dithionaphthalene (**1**) was synthesised from 1,5-naphthalenedisulfonic acid sodium salt hydrate (Aldrich, 95% purity) following described synthetic procedures.[32,33] $[Au_{55}Cl_6(PPh_3)_{12}]$ was synthesised as described previously.[34] Transmission electron microscopy was performed with a Philips CM 2000 FEG at 200 kV, the electrical measurements were done with a Keithley 6517 ElectroMeter and a Keitheley 2400 SourceMeter in a CryVac cooling system under N_2.

4: A solution of **2** (53 mg, $2.1\cdot10^{-4}$ mol) was added dropwise under a nitrogen atmosphere to a stirred solution of $[Au_{55}(PPh_3)_{12}Cl_6]$ (100 mg, $7\cdot10^{-6}$ mol) in dichloromethane (300 mL). After three weeks, the black precipitate isolated from a colourless solution by filtration was washed carefully several times with CH_2Cl_2 and dried under reduced pressure. Yield 52 mg; Au 58.7, S 11.2.

5, 6, 7: All experiments were performed using the same procedure. Only the solvents were modified, depending on the solubility of the linker: Et_2O for **1**, CH_2Cl_2 for **2**, and DMF for **3**. In a typical experiment, 100 mL of a solution of **1**, **2**, **3** ($2\cdot10^{-4}$ mol) was added dropwise to a stirred dichloromethane solution (300 mL) of $[Au_{55}Cl_6(PPh_3)_{12}]$ (100 mg, $7\cdot10^{-6}$ Mole) under an atmosphere of nitrogen. After addition the reaction was continued for ca. 12 h under an atmosphere of air, leading to a brown precipitate, which was isolated by filtration from the colourless solution. After careful washing with CH_2Cl_2 and the corresponding linker solvent the products (**5**, **6**, **7**) were dried under reduced pressure and used for the electrical measurements.

Product 5: Yield 66 mg; Au 63.6, S 6.17.

Product 6: Yield 78 mg; Au 65.7, S 8.18.

Product 7: Yield 53 mg; Au 65.0, S 6.76.

Monohelical Complexes of a Novel Asymmetric N_4 Schiff Base: Unfamiliar Tetrahedral Environments of Manganese(II) and Iron(II) Helicates

Miguel Vázquez,[a] Manuel R. Bermejo,*[a] Matilde Fondo,[a] Ana M. García-Deibe,[a] Jesús Sanmartín,[a] Rosa Pedrido,[a] Lorenzo Sorace,[b] and Dante Gatteschi[b]

Keywords: Electrochemistry / Helical structures / Schiff bases / Transition metals

The electrochemical reaction of the bis-bidentate H_2ABATs Schiff base [H_2ABATs = *N*,*N*′-bis(2-tosylaminobenzylidene)-2-aminobenzylamine] with manganese, iron, cobalt, nickel, copper, zinc and cadmium was investigated. The reaction cell yields products of empirical formula M(ABATs). X-ray diffraction studies show that [Mn(ABATs)]·0.75H_2O (**1**), [Fe(ABATs)]·0.75H_2O (**2**), [Ni(ABATs)]·0.75H_2O (**3**), [Cu(ABATs)]·0.5H_2O (**4**) and [Zn(ABATs)]·0.75H_2O (**5**) are mononuclear distorted tetrahedral helical complexes in the solid state. Complexes **1** and **2** confirm the ability of this type of ligand to dictate the geometry around the metal centre, as is shown by the unfamiliar tetrahedral environments of manganese(II) and iron(II) ions in complexation with the Schiff bases.

Introduction

Molecular architectures featuring helical arrangements of multidentate ligands around one or more metal centres are one of the goals of supramolecular chemistry.[1−4] In this search, many studies have been performed in order to develop synthetic procedures for new multidentate ligands exhibiting the potential to give bridged polynuclear species.[5−11] Among the various ligand systems capable of promoting self-assembly of mononuclear and/or polynuclear helical coordination complexes, careful design of imine-based ligands[12−20] demonstrates that this can be an inexpensive approach to supramolecular chemistry. These ligands have the advantage of being easily modified, allowing changes in the features (length, flexibility, donor ability) of the spacer, the position of the donor atoms and the presence of different groups that can give rise to intermolecular interactions and/or induce torsion of the ligand. A systematic study of the factors affecting the isolation of helical complexes can therefore be done by changing just one of the variables.

We have recently prepared some bis-bidentate Schiff bases containing bulky tosyl groups and different spacers.[21−22] These ligands yield mononuclear and/or dinuclear helicates, depending on the flexibility and/or the length of the spacer, as well as on the nature of the metal atom. In fact, a Schiff base with a flexible propylene spacer separating the *N*-imine donors can give rise to complexes of different nuclearity, depending on the metal ion.

Regardless of the mono- or dinuclear nature of the helix, all complexes prepared with this kind of Schiff base show coordination numbers of four for the metal centres. It therefore seems that the stereochemical preferences of the metal do not play a fundamental role in the nuclearity of the complex in this case study. Until now, however, neither manganese(II) nor iron(II) complexes of this type had been crystallographically characterised, these metals having special preference for an octahedral coordination. To the best of our knowledge, in fact, no tetrahedral Schiff-base complexes with these metal atoms have been structurally characterised.

In an attempt to determine whether the presence of the tosyl groups can always dictate the geometry around the metal centre, and to examine the influence of the flexibility of the spacer on the nuclearity of the helix, the new H_2ABTs ligand (Scheme 1), with a semi-rigid benzylidene group (three carbon atoms) between the two imine moieties, was prepared. The interaction of H_2ABATs with manganese, iron, cobalt, nickel, copper, zinc and cadmium in an electrochemical cell was investigated and the results achieved are described.

Results and Discussion

Synthesis of the Ligand

The Schiff base H_2ABATs was prepared by conventional condensation between 2-tosylaminobenzaldehyde and 2-aminobenzylamine. The yellow solid showed a satisfactory

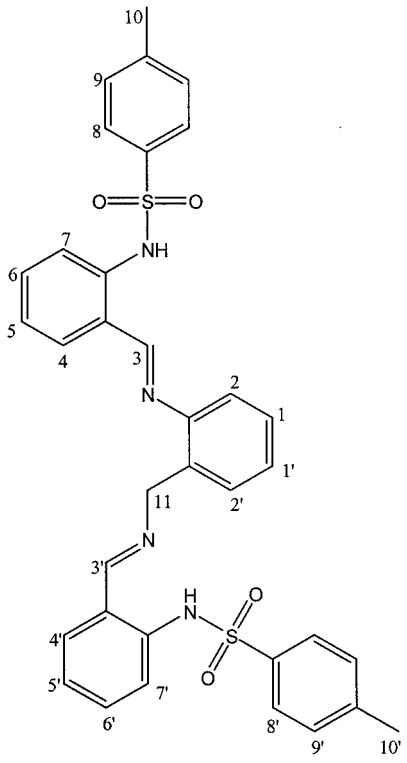

Scheme 1. H_2ABATs

elemental analysis and was further characterised by IR and ^{1}H NMR spectroscopy and FAB mass spectrometry.

Electrochemical Synthesis of the Complexes

All the complexes were prepared by a previously described electrochemical method.[21]

Elemental analyses show that all metals employed here react with the ligand in a 1:1 molar ratio to afford complexes of the bis-deprotonated $[ABATs]^{2-}$ with high purity. All these neutral metal complexes are obtained in good yields and appear to be stable both in the solid state and in solution. It therefore seems that although an inert atmosphere is necessary for the isolation of pure manganese(II) and iron(II) complexes, these compounds are air-stable once formed.

X-ray Studies

The crystal structures of $[Mn(ABATs)]\cdot 0.75H_2O$ (**1**), $[Fe(ABATs)]\cdot 0.75H_2O$ (**2**), $[Ni(ABATs)]\cdot 0.75H_2O$ (**3**), $[Cu(ABATs)]\cdot 0.5H_2O$ (**4**) and $[Zn(ABATs)]\cdot 0.75H_2O$ (**5**) were solved as detailed below.

The five complexes are isomorphous and isostructural, and so only the ORTEP diagram of **1** is shown in Figure 1. Experimental details are recorded in Table 1 and the main bond distances and angles in Table 2.

Metal-Ion Geometry

All the complexes consist of mononuclear compounds with water as solvate. In each case the ligand uses its four nitrogen atoms (two imine and two amide) to link to the metal atom. In addition, one oxygen atom of each tosyl group interacts weakly with the metal centre (Table 2). These distances are too long to be regarded as true coordinated bonds, and are better described as secondary intramolecular interactions. The metal centre is therefore in a tetracoordinated environment, with the tosyl groups playing an important role in the adopted coordination number. However, it is noteworthy that the higher preference for an octa-

hedral geometry is displayed in the shorter M···O_{tosyl} distance.

The dihedral angle θ between the two MNN terminal planes (ca. 62.3° for **1**, 62.6° for **2**, 65.3° for **3**, 55.9 for **4** and 64.9° for **5**) shows that the metal ion displays a tetrahedral geometry with a square-planar distortion (θ = 0° for square-planar geometry and θ = 90° for tetrahedral geometry). The value of θ for **4** indicates that the geometry around the copper atom could in fact be viewed as intermediate between tetrahedral and square-planar. This geometry is quite unfamiliar for manganese(II) and iron(II) Schiff-base complexes, which display clear stereochemical preferences for octahedral environments, and even for Ni^{II}, which also prefers octahedral or square-planar rather than tetrahedral geometries. To the best of our knowledge, no manganese Schiff-base complexes with this geometry have been described previously, and just one iron(II) tetrahedral complex of a bidentate Schiff base (FeL_2) has recently been characterised.[23] Nevertheless, it should be noted that this complex was prepared in non-polar, non-coordinating solvents under an inert atmosphere. In our case the iron centre maintains its tetrahedral environment despite the presence of water in the solvent and trapped in the unit cell, which demonstrates the ability of this type of ligand to predetermine the coordination polyhedron. It therefore seems that the steric hindrance induced by the tosyl groups, in conjunction with the second order interactions of the metal with the tosyl oxygen atoms, prevent any other donor from coordinating to the metal ion.

In addition, it must be pointed out that Zn and Ni form dinuclear complexes with H_2PTs [*N*,*N*′-bis(2-tosylaminobenzylidene)-1,3-diaminopropane],[21] while they afford mononuclear compounds with H_2ABATs. The related H_2PTs ligand, like H_2ABATs, contains three carbon atoms

between the imine moieties. However, the spacer in H_2PTs is an aliphatic chain and this emphasises the role of the spacer flexibility in the nuclearity of the helix.

The M−N (M = Ni, Cu, Zn) distances are typical of tetracoordinate tetrahedral complexes,[21−22] but are shorter than those found for octahedral complexes with similar ligands,[24] reflecting the lower coordination number. The $M-N_{imine}$ (M−N2 and M−N3) distances decrease monotonically from **1** to **4** and increase for **5**, following the trend (**1** ≈ **2** > **5** > **3** > **4**) of the ionic radii. The $M-N_{amide}$ (M−N1 and M−N4) distances show the same pattern.

The wide range of angles observed around the metal centres, varying between ca. 87° and 143.2°, compares fairly well with those previously reported for this kind of complex and reflects the severe distortion from the ideal tetrahedral geometry.

Chelate Rings and Helical Coiling

The ligand forms three chelate rings around the central metal atom. The two terminal six-membered rings are reasonably planar while the central six-membered ring is less so, as would be expected, due to the presence of one sp^3 carbon atom. The loss of planarity between the N_{imine} atoms is also shown by the N(2)C(15)C(16)C(21) torsion angles, which range from −58.7(5)° for **3** to 63.0(4)° for **2**, showing the strain of the ligand. The central N(2)C(15)C(16)C(21)N(3) chelate ring forms angles of ca. 46° and 27° for **1**−**3** and **5** and of ca. 41° and 23° for **4** with N(1)C(8)C(13)C(14)N(2) and N(3)C(22)C(23)C(28)N(4), respectively. These angles show the screwing of this thread, which affords monohelical single-stranded molecules. The twisting of the ligand can be attributed to an attempt by the additional peripheral tosyl groups to minimise the steric hindrance, being orientated in different directions, as shown in Figure 2.

The extent of helical coiling in these chiral complexes can be described in terms of the ligand wrapping angle. However, the value of this angle, and of the helical pitch of the thread, can change significantly depending on different considerations, such as the actual helix top-ends or the helical axis declination, so only qualitative aspects are considered.

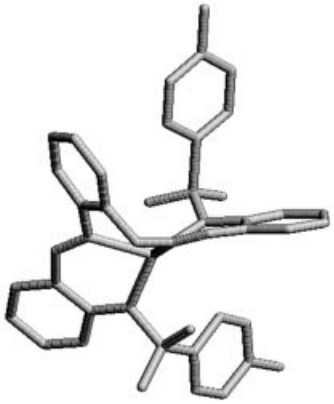

Figure 2. Stick view of **1**, showing the wrapping of the ligand

It can clearly be observed (Figure 2) that, if only the donor atoms are taken into account, the wrapping angle is always shorter than 360°. Nevertheless, if the tosyl groups are included, the ligand wraps slightly more than once. In that sense, the S···S distances could be taken as a close value for the pitch, being ca. 5.0 Å for **1**, 4.98 Å for **2**, 4.88 Å for **3**, 4.74 Å for **4** and 4.99 Å for **5**. These distances show that the shortest pitch corresponds to **4**, which is in agreement with its more distorted (tetrahedral towards square-planar) geometry.

Finally, the space group and the analysis of the crystal data indicate the formation of a racemic mixture, with both *P* and *M* enantiomers present in the unit cell with 50% yield for all the complexes.

IR Spectra

The IR spectra of the free ligand and complexes show two bands at ca. 1605 and 1630 cm^{-1}, in agreement with the presence of two inequivalent imine groups. Both ν(C=N) bands are shifted to higher wavenumber values (1−15 cm^{-1}) with respect to the free ligand for most of the complexes. In addition, all complexes show a negative shift of ν(C−N) relative to free H_2ABATs. This suggests the coordination of the ligand to the metal centre through the imine and amide nitrogen atoms. In addition, two bands in the ranges 1250−1261 cm^{-1} and 1127−1138 cm^{-1} are attributable to the asymmetric and symmetric vibration modes of the SO_2 group, respectively.[25−26] Finally, no bands above 2500 cm^{-1} were detected for any of the complexes, indicating the deprotonation of the NH groups and, therefore, the dianionic character of the ligand.

Magnetic Studies

The magnetic moments of all the paramagnetic complexes were recorded in the solid state between 2 and 280 K. In agreement with the observed long distances between magnetic centres (ca. 9.5 Å), and with the absence of any efficient exchange pathway, the temperature dependence of the magnetic susceptibilities between 2 and 280 K for all the complexes shows deviation from Curie behaviour only at low temperature, with the exception of the Ni^{II} complex for which, due to the expected partially unquenched orbital contribution, a deviation is observed below 50 K (Figure 3). The values of the magnetic moment, obtained by the Curie−Weiss fit of $1/\chi$ vs. *T* plots (Table 3), are very close to those expected for magnetically diluted tetrahedral M^{II} ions, with *g* values that, except for Mn^{II}, differ greatly from that of the free electron.[27] This provides confirmation of the oxidation state +II for the metal centre, indicating the deprotonation of the Schiff-base ligand, and the achieved high-spin configuration for [Mn(ABATs)] and [Fe(ABATs)], as would be expected. The EPR spectra essentially confirm this picture; indeed, a typical tetrahedral Cu^{II} spectrum is observed for the complex [Cu(ABATs)], which yielded *g* values $g_{\|}$ = 2.185 $g_{\perp}$ = 2.095 with an average *g* value of 2.125, in good agreement with the magnetic moment observed at room temperature. On the other hand, the EPR

spectrum of the Mn^{II} derivative, recorded at low temperature, clearly shows a fine structure deriving from a non-negligible zero field splitting (ZFS) of the $S = 5/2$ multiplet (Figure 4). Finally, no EPR spectra are observed for the Fe^{II} and Co^{II} derivatives: the absence of a spectrum for the former is in agreement with the expected large ZFS and integer spin state that usually make tetrahedral high-spin Fe^{II} complexes silent at EPR X-band frequencies.[28] The non-observation of an EPR spectrum for the Co^{II} derivative, a Kramers ion, could be attributable to fast relaxation.[29]

Thus, in view of the formulations of the complexes and their magnetic moments, it seems quite reasonable to propose a tetrahedral environment around the metal atoms for all the paramagnetic complexes, as the crystal structures of **1** to **5** confirm.

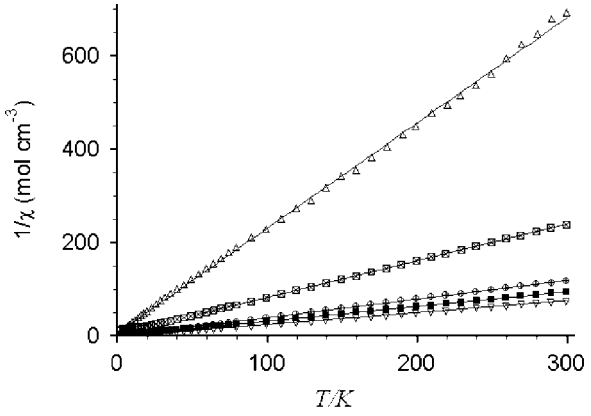

Figure 3. Curie−Weiss plots for paramagnetic complexes; Δ Cu derivative, □ Ni derivative, ○ Co derivative, ■ Fe derivative and ▽ Mn derivative

Table 3. Value of the Curie constant for the complexes

Complex	C ($cm^3 \cdot K \cdot mol^{-1}$)
Mn(ABATs)	3.88
Fe(ABATs)	3.17
Co(ABATs)	2.5
Ni(ABATs)	1.28
Cu(ABATs)	0.44

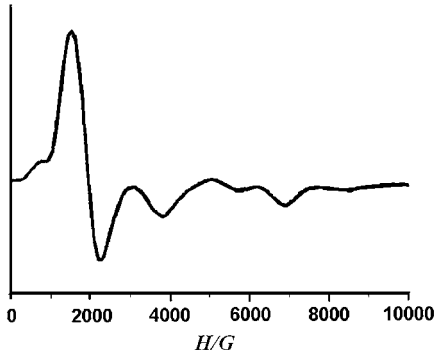

Figure 4. EPR band spectrum (at 9.225 GHz) of Mn(ABATs) recorded at 4.2 K

FAB Mass Spectra

FAB mass spectra of all the complexes show peaks due to $[M(ABATs)]^+$ fragments (M = Mn, Fe, Co, Ni, Cu, Zn or Cd), corroborating the coordination of the ligand to the metal. However, no peaks attributable to $[ML]_2^+$ fragments could be detected for any of the complexes, suggesting mononuclear natures in solution for all of them.

NMR Studies

The ^1H NMR spectra of H_2ABATs, [Zn(ABATs)] and [Cd(ABATs)] were recorded in [D_6]DMSO as solvent. The spectra show two sets of aromatic signals in a 1:1 ratio, indicating that the two arms are not magnetically equivalent. The assignments of the signals were based on COSY and NOESY experiments, as well as on previous results.[21−22]

The comparison of the free ligand spectrum with those of the complexes allows some conclusions to be drawn:

1. The NH protons present in the free ligand disappear in the spectra of the complexes, in agreement with bis-deprotonation of the Schiff base.
2. The imine hydrogen atoms (3-H and 3′-H) show a shift to lower field for the zinc complex, while 3-H is shifted to higher field in the cadmium complex, indicating that the coordination of the imine groups to the metal centre induces opposite shielding effects on these hydrogen atoms. This situation was also found for zinc and cadmium complexes with ligands containing an aliphatic spacer.[21b]

The imine protons of the cadmium complex are flanked by satellites arising from spin-spin coupling to $^{111/113}$Cd, suggesting that the complex is kinetically inert on the NMR timescale.

3. The methylene protons (11-H) are magnetically equivalent in the free ligand and appear as a singlet at δ = 5.08 ppm. However, the room-temperature spectrum of the zinc complex contains a well resolved AB doublet of doublets for the 11-H protons. The AB pattern for the methylene hydrogen atoms implies that the strong coordination of the hard imine nitrogen to the zinc atom abolishes the erstwhile enantiotopic nature of these protons to make them diastereotopic. This observation can be interpreted in terms of a helical conformation of the new complex, making it chiral. It therefore seems that the zinc complex in solution maintains the structure found in solid state.

The spectrum of the cadmium complex at room temperature shows just one broad signal at $\delta = 4.97$ ppm for the 11-H protons. This could indicate that the complex is not chiral or that a fast interconversion of enantiomers of the chiral single helicate takes place in solution.

Finally, it should be noted that just one diastereoisomer exists in solution for both complexes, as no additional peaks indicative of a second species could be detected.

Conclusions

The electrochemical interaction of manganese, iron, cobalt, nickel, copper, zinc and cadmium with the bis-bidentate H_2ABATs Schiff base yields mononuclear [M^{II}(ABATs)] complexes. The bulky tosyl groups induce torsion in the ligand, giving rise to monohelical, single-stranded, tetrahedral compounds. This geometry is quite unusual for manganese(II) and iron(II) with Schiff bases. In fact, to the best of our knowledge, there are no previous crystallographically characterised examples of this type of complex obtained from non-anhydrous solvents. This demonstrates the ability of this type of ligand to dictate the coordination number in spite of the geometrical preferences of the metal.

Finally, this work further contributes to make the role of the flexibility of the spacer in the nuclearity of the helix evident: nickel and zinc double-helical compounds have previously been reported for a related ligand (H_2PTs) with a flexible propylene spacer (three aliphatic carbon atoms between imine-N atoms), while the semi-rigid benzylidene spacer in H_2ABATs (three carbon atoms, two aromatic and one aliphatic, between imine-N atoms) only allows the isolation of monohelical complexes.

Experimental Section

General: Elemental analyses were performed on a Carlo Erba EA 1108 analyser. Infrared spectra were recorded as KBr pellets on a Bio-Rad FTS 175 spectrophotometer in the 4000−600 cm^{-1} range. NMR spectra were recorded on a Bruker AMX 500 spectrometer in [D_6]DMSO as solvent. Fast atom bombardment (FAB) mass spectra were performed on a Kratos MS-50 mass spectrometer, employing Xe atoms at 70 keV in *m*-nitrobenzyl alcohol as matrix. EPR spectra were recorded on a Varian ESR9 spectrometer working at the X-band frequency (9.225 GHz) equipped with a ^{4}He continuous flow cryostat for low temperature measurements. Magnetic measurements were performed between 2 and 280 K with a Cryogenics Squid S600 magnetometer with applied field of 1 T. The data were corrected for sample holder contribution and diamagnetism of the sample by the use of Pascal constants.

Synthesis: All the starting materials were purchased from Aldrich and used without further purification. 2-Tosylaminobenzaldehyde was prepared and characterised according to the literature.[30−31]

Ligand Preparation: 2-Aminobenzylamine (1.13 g, 9.1 mmol) was added to a solution of 2-tosylaminobenzaldehyde (5.0 g, 18.2 mmol) in chloroform (150 mL), and the mixture was heated to reflux. The volume of the solution was reduced to ca. 50 mL over a 4 h period with the aid of a Dean−Stark trap, and the mixture was then allowed to cool. The resultant yellow solution was concentrated to ca. 10 mL. The solid that precipitated was collected by filtration, washed with diethyl ether (4 mL) and dried in vacuo. Yield: 5.20 g (90%); m.p. 187 °C. $C_{35}H_{32}N_4O_4S_2$ (636): calcd. C 66.0, H 5.1, N 8.8, S 10.1; found C 66.1, H 5.1, N 8.7, S 10.2. IR (KBr): $\tilde{\nu}$ = 1628, 1605 [s, ν(C=N)], 1339 [s, ν(C−N)], 1285, 1165 [s, ν(SO_2)] cm^{-1}. FAB-MS: *m*/*z* = 637.3 [H_3L^+]. ^{1}H NMR (500 MHz, [D_6]DMSO): δ = 2.09 (s, 3 H, 10′-H), 2.22 (s, 3 H, 10-H), 5.09 (s, 2 H, 11-H), 6.95−7.0 (m, 4 $H_{arom.}$), 7.10−7.13 (m, 4 $H_{arom.}$), 7.38−7.53 (m, 9 $H_{arom.}$), 7.67 (d, 2 H, 8-H), 7.76 (d, 1 H, 4-H), 8.65 (s, 1 H, 3′-H), 8.88 (s, 1 H, 3-H), 12.82 (s, 1 H, NH), 12.94 (s, 1 H, NH) ppm.

Synthesis of the Complexes: All the complexes were obtained by an electrochemical procedure. The cell can be summarised as: Pt(−)|H_2ABATs + MeCN|M(+), where M stands for the metal. The synthesis can be typified by the preparation of Cu(ABATs). A suspension of the ligand (0.2 g, 0.32 mmol) in acetonitrile (80 mL), containing tetramethylammonium perchlorate (10 mg), was electrolysed with a current of 10 mA for 3.4 h. Concentration of the resultant solution to a third of its initial volume yielded a yellow-brown solid that was washed with diethyl ether and dried under vacuum. Recrystallisation of the bulk sample by diffusion of diethyl ether into an acetonitrile solution, produced dark-green crystals of [Cu(ABATs)]·0.5H_2O (**4**).

CAUTION: Perchlorate salts are potentially explosive and should therefore be handled with the appropriate care.

The synthetic procedure is the same for all the metals except for manganese and iron. These two compounds were prepared in a closed cell under an argon atmosphere. Prismatic crystals of [Mn(ABATs)]·0.75H_2O (**1**, orange brown), [Fe(ABATs)]·0.75H_2O (**2**, brown), [Ni(ABATs)]·0.75H_2O (**3**, brown), [Cu(ABATs)]·0.5H_2O (**4**, dark green) and [Zn(ABATs)]·0.75H_2O (**5**, yellow) were obtained by slow evaporation of a saturated acetonitrile solution in air. No crystals suitable for X-ray studies could be obtained for [Co(ABATs)] or [Cd(ABATs)].

[Mn(ABATs)]: Dark red solid. Yield 0.17 g (78%). $C_{35}H_{30}MnN_4O_4S_2$ (688.9): calcd. C 60.9, H 4.3, N 8.1, S 9.3; found C 60.9, H 4.4, N 8.2, S 9.3. IR (KBr): $\tilde{\nu}$ = 1632, 1605 [s, ν(C=N)], 1281 [s, ν(C−N)], 1250, 1127 [s, ν(SO_2)] cm^{-1}. FAB-MS: *m*/*z* = 690.2 [MnL]$^+$. μ (280 K) = 5.6 BM.

[Fe(ABATs)]: Red solid. Yield 0.15 g (70%). $C_{35}H_{30}FeN_4O_4S_2$ (689.5): calcd. C 60.9, H 4.3, N 8.1, S 9.3; found C 60.8, H 4.5, N 8.1, S 9.2. IR (KBr): $\tilde{\nu}$ = 1636, 1606 [s, ν(C=N)], 1290 [s, ν(C−N)], 1255, 1136 [s, ν(SO_2)] cm^{-1}. FAB-MS: *m*/*z* = 691.1 [FeL]$^+$. μ (280 K) = 5.0 BM.

[Co(ABATs)]: Dark red solid. Yield 0.17 g (81%). $C_{35}H_{30}CoN_4O_4S_2$ (692.9): calcd. C 60.6, H 4.3, N 8.1, S 9.2; found C 60.7, H 4.4, N 8.0, S 9.2. IR (KBr): $\tilde{\nu}$ = 1632, 1605 [s, ν(C=N)], 1285 [s, ν(C−N)], 1258, 1134 [s, ν(SO_2)], cm^{-1}. FAB-MS: *m*/*z* = 694.1 [CoL]$^+$. μ (280 K) = 4.3 BM.

[Ni(ABATs)]: Dark green solid. Yield 0.15 g (72%). $C_{35}H_{30}N_4NiO_4S_2$ (692.7): calcd. C 60.6, H 4.3, N 8.1, S 9.2; found C 60.6, H 4.4, N 8.2, S 9.0. IR (KBr): $\tilde{\nu}$ = 1640, 1605 [s, ν(C=N)], 1285 [s, ν(C−N)], 1254, 1138 [s, ν(SO_2)] cm^{-1}. FAB-MS: *m*/*z* = 693.1 [NiL]$^+$. μ (280 K) = 2.7 BM.

[Cu(ABATs)]: Dark green solid. Yield 0.15 g (69%). $C_{35}H_{30}CuN_4O_4S_2$ (697.5): calcd. C 60.2, H 4.3, N 8.0, S 9.2; found C 60.1, H 4.3, N 8.0, S 9.0. IR (KBr): $\tilde{\nu}$ = 1636, 1605 [s, ν(C=N)],

1285 [s, ν(C−N)], 1258, 1138 [s, ν(SO_2)], cm^{-1}. FAB-MS: *m*/*z* = 698.2 $[CuL]^+$. μ (280 K) = 2.1 BM.

[Zn(ABATs)]: Yellow solid. Yield 0.17 g (80%). $C_{35}H_{30}N_4O_4S_2Zn$ (699.4): calcd. C 60.0, H 4.3, N 8.0, S 9.1; found C 60.1, H 4.3, N 8.1, S 9.2. IR (KBr): $\tilde{\nu}$ = 1643, 1615 [s, ν(C=N)], 1296 [s, ν(C−N)], 1261, 1138 [s, ν(SO_2)], cm^{-1}. FAB-MS: *m*/*z* = 699.1 $[ZnL]^+$. ^1H NMR (500 MHz, [D_6]DMSO): δ = 2.22 (s, 3 H, 10′-H), 2.35 (s, 3 H, 10-H), 4.72 (d, 1 H, 11-H), 5.44 (d, 1 H, 11-H), 6.95−7.03 (m, 3 H, 2 × 9′-H + 6′-H), 7.26−7.38 (m, 7 H, 2 × 9-H + 7-H + 7′-H + 6-H + 5-H + 4′-H + 2′-H), 7.44−7.73 (m, 6 H, 2 × 8′-H + 7-H + 2-H + 1-H + 1′-H), 7.81(d, 1 H, 4-H), 7.90 (d, 2 H, 8-H), 8.75 (s, 1 H, 3′-H), 8.92 (s, 1 H, 3-H) ppm.

[Cd(ABATs)]: Pale yellow solid. Yield 0.19 g (83%). $C_{35}H_{30}CdN_4O_4S_2$ (746.4): calcd. C 56.2, H 4.0, N 7.5, S 8.6; found C 56.2, H 3.9, N 7.5, S 8.7. IR (KBr): $\tilde{\nu}$ = 1636, 1613 [s, ν(C=N)], 1289 [s, ν(C=N)], 1258, 1127 [s, ν(SO_2)] cm^{-1}. FAB-MS: *m*/*z* = 749.1 $[CdL]^+$. ^1H NMR (500 MHz, [D_6]DMSO): δ = 2.26 (s, 3 H, 10′-H), 2.28 (s, 3 H, 10-H), 4.97 (br., 2 H, 2 × 11-H), 6.75 (t, 1 H, 5′-H), 6.97 (t, 1 H, 5-H), 7.08−7.16 (m, 6 H, 2 × 9-H + 2 × 9′-H + 6′-H + 7′-H), 7.25 (t, 1 H, 6-H), 7.33−7.36 (m, 2 H, 4′-H + 2′-H), 7.41−7.50 (m, 4 H, 7-H + 2-H + 1-H + 1′H), 7.67 (d, 1 H, 4-H), 7.74 (d, 2 H, 8′H), 7.82 (d, 2 H, 8-H), 8.68 (s, 1 H, 3′-H), 8.70 (s, 1 H, 3-H) ppm.

Crystallographic Measurements: Crystals of **1** to **5** suitable for X-ray diffraction studies were obtained as described previously. Data were collected on a Siemens SMART CCD diffractometer for **1**, **2**, **4** and **5** and on a Siemens P4 diffractometer for **3**, with graphite monochromatised Mo-K_α radiation (λ = 0.71073 Å), at room temperature. The structures were solved by direct methods and refined by full-matrix, least-squares based on F^2 with the SHELX-97 program package.[32] Absorption corrections were carried out semiempirically from equivalents by use of the Sadabs program.[33] All non-hydrogen atoms were refined anisotropically, except for some of those corresponding to solvated water molecules (**2−4**), which are disordered over two different positions (0.5 and 0.25 occupancies sites) for **1−3** and **5**. Hydrogens bonded to carbon atoms were included in the model at geometrically calculated positions and refined with a riding model. Only some H atoms corresponding to solvated water molecules could be located, fixed and given isotropic displacement parameters of 0.1 $Å^2$.

CCDC-190797−190801 (**1−5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Mono- and Bis-Guanosine Adducts of Platinum Complexes with Carrier Ligands Having In-Plane Steric Bulk: The Case of 1,10-Phenanthroline and 2,9-Dimethyl-1,10-phenanthroline

Nicola Margiotta,[a] Paride Papadia,[a] Francesco P. Fanizzi,[b,c] and Giovanni Natile*[a]

Keywords: Platinum / Nucleobases / Antitumour agents / Atropisomerism / NMR spectroscopy

The steric hindrance generated by carrier ligands, in particular in *cis*-Pt$\mathbf{A}_2\mathbf{G}_2$ adducts ($\mathbf{A}_2$ = diamine, **G** = guanine derivative), has often been used to slow down rotation about the platinum-guanine bonds, thus allowing the characterisation of different conformers and the analysis of the interactions that are involved in the stabilisation of cisplatin adducts with DNA. In a previous study concerning 1,10-phenanthroline and 2,9-dimethyl-1,10-phenanthroline (phen and Me_2phen, respectively), the Me_2phen ligand was reported to form an unusual bis-guanosine derivative with a *trans* disposition of the nucleobases and monodentate Me_2phen. The present investigation has demonstrated that phen and Me_2phen, like other bidentate ligands, allow formation of both mono- and bis-guanosine derivatives, the latter having the usual *cis* configuration. In both the phen and Me_2phen carrier ligands the rigidity of the phenanthroline skeleton is able to hinder rotation of the guanosine base(s) about the Pt–N(7) bond(s) and render the interconversion between rotamers slow on the NMR timescale even at 350 K (the highest temperature explored). However there are noticeable differences between the two ligands. As a consequence of the increased in-plane steric bulk of Me_2phen: (i) the H(8) chemical shifts within the *HH* (*Head-to-Head*) conformer and between the *HT* (*Head-to-Tail*) conformers become closer, (ii) the average H(8) chemical shift of the *HT* conformers is at higher field and that of the *HH* form at lower field, and (iii) the *HT* rotamers become even more favoured than the *HH* rotamer. Observation (ii) is in agreement with the *HT* rotamers preferring the "6-in" conformation, which brings the six-membered rings of the guanines closer to one another and is also in agreement with the phen ligand allowing a greater canting of the guanine bases than Me_2phen. Moreover, free chloride ion readily displaces the coordinated guanosines, particularly in solvents of lower dielectric constants than water.

Introduction

Despite undesirable side effects, cisplatin {*cis*-$[PtCl_2(NH_3)_2]$} remains one of the most widely used drugs in the treatment of several tumours.[1,2] There is general consensus that nuclear DNA is the main target of cisplatin and that 1,2-intrastrand cross-links between adjacent purines are responsible for the anticancer activity of the drug.[3]

A huge number of models of the 1,2-intrastrand cross-link have been investigated.[4,5] In particular, carrier ligands able to introduce steric hindrance in the coordination sphere of platinum and to slow down dynamic motions about the platinum-ligand bonds have proven to be very informative.[6−12] By slowing down the rotation of the nucleobases about the Pt−N(7) bonds different rotamers, with *HT* (*Head-to-Tail*) and *HH* (*Head-to-Head*) conformations, have been identified.[13,14]

In principle 1,10-phenanthroline (phen) and, even better, 2,9-Me_2-1,10-phenanthroline (Me_2phen, neocuproine) could be used to introduce steric bulk in the coordination plane (Figure 1). 1,10-Phenanthrolines, differently from

other chelating diamines, have a very rigid structure and the lone pairs on the nitrogen atoms are convergent and hence ideally oriented for complexation to a metal centre.[15] Because of these distinctive properties, 1,10-phenanthrolines have found biological application as complexing agents of metal ions (removal of essential metal can lead to inactivation of cellular proteins and enzymes) and as bacteriostatic, fungistatic, antihelmintic, tuberculostatic, antispermatozoal, and antifibrilatory agents.[16,17] Moreover, some phenanthrolines are endowed with antitumour activity against sarcomas in mice and inhibit formation of carcinomas in rats.[18,19]

In a recent study the reaction of guanosine with phen-Pt^{II} and Me_2phen-Pt^{II} substrates was investigated.[20] The results were interpreted as being due to formation of bis-guanosine adducts of formula *cis*-[Pt(*N*,*N*-phen)$(Guo)_2]^{2+}$ and *trans*-[PtCl(*N*-Me_2phen)$(Guo)_2]^{+}$. The presence of two H(8) resonances in *cis*-[Pt(*N*,*N*-phen)$(Guo)_2]^{2+}$ was interpreted as formation of two rotamers: one *HH* and one *HT*. However the *HH* rotamer should have inequivalent G moieties and therefore should give two H(8) signals of equal intensities. Moreover, two *HT* rotamers are possible (Λ*HT* and Δ*HT*), each of which should have equivalent G's, but the H(8) chemical shifts should be different for the two *HT* rotamers. In the second case examined (Me_2phen complex) the structure was essentially deduced from the observation of two signals in the methyl region with an intensity ratio of ca. 1:1. This was interpreted as being due to the presence of a *trans*-[PtCl(*N*-Me_2phen$)(Guo)_2]^{+}$ complex, with monocoordinated Me_2phen undergoing slow exchange of the donor atoms. The latter result was rather unusual since, in all complexes previously investigated by us and containing monocoordinated Me_2phen, the diamine undergoes fast exchange between the two nitrogens at room temperature.[21−23] The discrepancy between the newly reported data and those reported in the literature for analogous systems prompted us to reinvestigate the reaction of guanosine with platinum substrates containing phen and Me_2phen as carrier ligands.

Results and Discussion

Stereochemistry of *cis*-PtA_2G_2 Adducts

Previous reports have demonstrated that the 1,2-intrastrand cross-links formed by cisplatin with double-strand oligonucleotides have the guanines in a *Head-to-Head* (*HH*) conformation with both H(8)'s on the same side of the platinum coordination plane (Figure 2).[24−26] The phosphodiester linkage and the GC Watson−Crick base pairing of the vicinal guanosines are supposed to constrain such adducts in the *HH* conformation. In the case of cisplatin adducts with two guanine bases untethered by a phosphodiester linkage, the *Head-to-Tail* (*HT*) conformation is by far the most favoured at equilibrium, although the *HH* conformer should account for 50% on a statistical basis.[27]

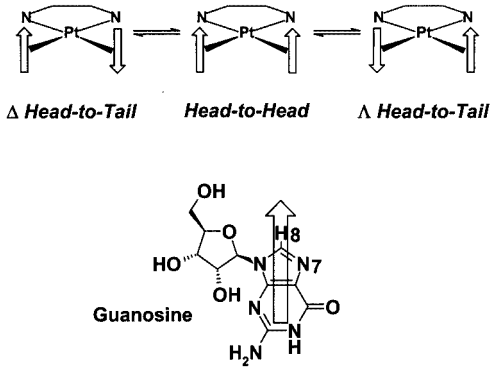

Figure 2. Schematic representation of *HH* and *HT* rotamers; arrows represent guanosines having H(8) coincident with the pointed end

Rotation about the Pt−**G**(N7) bonds in *cis*-PtA_2G_2 adducts [$\mathbf{A_2}$ = two monodentate or one bidentate amine ligand, **G** = N(7)-bound guanine base], interconverts *HH* and *HT* rotamers (Figure 2). When A_2 is a nonbulky ligand, the rotation about the Pt−**G**(N7) bonds is fast on the NMR timescale and only one set of NMR signals, which is an average of several conformations, is observed. In contrast, when A_2 is bulky, the rotation is restricted by steric interactions between the rotating guanines and the A_2 ligand(s) and different sets of signals are observed in the NMR spectra. In this respect the signals of the **G**(H8) protons are particularly informative. The number of H(8) signals detectable in solution for each *cis*-PtA_2G_2 conformer depends upon the symmetry of the A_2 carrier ligand and of the substituents at N(9) of the **G** residues. For carrier ligands of C_2, or higher, symmetry and asymmetric N(9) substituents the two **G**'s are equivalent within each *HT* conformer (Δ-*HT* and Λ-*HT*), and inequivalent within the *HH* conformer.

Complexes with Me_2phen (1 and 2)

[Pt(Me₂phen)(Guo)₂]Cl₂ (1)

The procedure used for the preparation of [Pt(Me_2phen)-$(Guo)_2]Cl_2$ (**1** in Figure 3) was different from that reported by Clement et al.[20] Instead of performing the reaction in water at high temperature (80 °C, 24 h) we carried out the reaction at room temperature (so reducing the risk of decomposition) in chloroform/methanol since the starting substrate [$PtCl_2$(Me_2phen)] is soluble in chloroform and guanosine is soluble in methanol. The desired product was formed in a shorter time (2 h) and with higher yield (90%) than reported in reference 20 (60% yield).

The ^{1}H NMR spectrum of complex **1**, in D_2O and pH* = 2.90 (the asterisk denotes pH values uncorrected for the effect of deuterium on the glass electrode), is reported in Figure 4 (a small amount of free guanosine was added to the sample for comparison). Two strong signals of unequal intensity (at δ = 8.51 and 8.52 ppm, intensity ratio 1:1.25) and two much weaker signals of equal intensities (at δ = 9.00 and 9.01 ppm) are observed in the region of H(8). The

downfield shift of the H(8) resonances relative to that for free guanosine (δ = 7.87 ppm at pH* = 2.90) is a clear indication that the nucleobases are coordinated to platinum through N(7).[28] This was further confirmed by pH titration experiments (Figure S1 in the Supporting Information, see also the footnote on the first page of this article). The two strong and more-shielded signals of unequal intensities are assigned to the *HT* rotamers (Δ-*HT* and Λ-*HT*), while the two weak and less-shielded signals of equal intensities

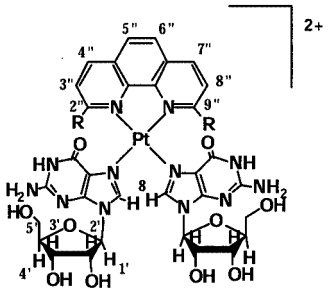

Figure 3. Schematic drawing and numbering schemes for compounds **1**–**4**

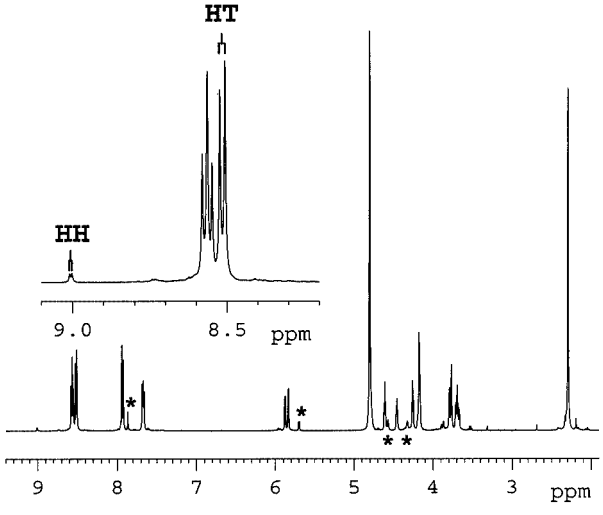

Figure 4. ^{1}H NMR spectrum of complex **1** in D_2O (pH* = 2.90, T = 298 K); the asterisks mark the signals of free guanosine added to the sample for comparison; the H(8) signals of the *HH* and *HT* rotamers are also labelled

are assigned to the *HH* conformer. Literature data indicate that the *HT* orientation can be stabilised with respect to the *HH* orientation in *cis*-Pt$\mathbf{A}_2\mathbf{G}_2$ adducts because of a better dipole-dipole interaction between the two guanine residues.

Three singlets at δ = 2.29, 2.32, and 2.33 ppm (intensity ratios 36:1:1) are observed for the methyl protons. Therefore, a large upfield shift (ca. 1 ppm) is experienced by these methyls upon substitution of the two chlorides by two guanosine molecules (for [$PtCl_2$(Me_2phen)] the Me chemical shift is at δ = 3.12 ppm in CD_3OD). The most intense signal, at δ = 2.29 ppm, is assigned to the two *HT* conformers, which therefore give coincident signals for the methyls in positions 2′′ and 9′′ of the phenanthroline moiety (see Figure 3 for the numbering scheme). The less-intense signals at δ = 2.32 and 2.33 ppm of 1:1 intensities are assigned to the *HH* conformer (for which the two methyls of Me_2phen are expected to be inequivalent). The chemical shifts of the phenanthroline Me's are influenced mostly by the shielding effect of the *cis*-coordinated nucleobase, while the effect of the chiral ribose, which should be responsible for the difference in chemical shift between *HT* rotamers and within the *HH* rotamer, is practically negligible.

The pattern of the methyl protons (1 ppm upfield shift) clearly indicates that Me_2phen is biscoordinated to platinum and the other two coordination positions are occupied by guanosine molecules. This complex composition is also supported by the absence of the typical Pt−Cl stretching frequency,[29] which is found in the IR spectrum of the precursor complex [$PtCl_2$(Me_2phen)] at 341 cm^{-1}.

The complete ^{1}H NMR analysis of the [Pt(Me_2phen)($Guo)_2$]$^{2+}$ complex with the assignments of all proton signals pertinent to the various rotamers is given in Table 1. The aliphatic region of a gradient-enhanced COSY spectrum showing the sequential assignment of the resonance peaks of the ribose protons is reported in Figure S2 (Supporting Information).

An interesting observation from the NOESY experiment is the presence of strong cross-peaks between H(8) and the sugar proton H(1′) for both *HT* rotamers (Figure S3). The presence of a cross-peak between H(8) of the guanine and the anomeric proton H(1′) is an indication that there is a *syn* contribution to the conformation of the nucleoside (the conformation is *anti* in natural B-DNA).[30−33] This result was also confirmed by a ROESY experiment (Figure S4) showing cross-peaks between the H(8) proton of the guanine and the sugar protons H(1′), H(2′) and H(3′). The ratio between the volumes of cross-peaks H(8)/H(1′) and H(8)/H(2′) is 2.1 and 1.8 for the two *HT* conformers, thus confirming the partial *syn* character of the nucleosides in these adducts. The 4.8 Hz value of the $^3J_{H1',H2'}$ coupling constant observed for the *HT* rotamers suggests a higher percentage of *S* puckering of the ribose rings (S/N sugar pucker ratio of ca. 54:46). None of the above NOE's was observed for the *HH* rotamer because of its low concentration in solution.

^{1}H NMR spectra were also recorded at higher temperatures in order to detect possible interconversion between the *HH* and the *HT* conformers. Under the experimental

conditions used (solvent D_2O, pH* = 3.5), only a slight broadening of the resonance peaks was observed upon raising the temperature to 353 K (Figure S5). Complex **1** proved to be stable at high temperature for quite a long time as indicated by the similarity between the initial spectrum and that recorded at 298 K after a long stay at 353 K. The slow interconversion between rotamers, on the NMR timescale, was also confirmed by the absence of EXSY cross-peaks between the H(8) signals of the three rotamers in the NOESY-EXSY experiment (Figure S3).

Effect of Chloride Ions on the Ligand Exchange in Complex 1: Formation of [PtCl(Me$_2$phen)(Guo)]Cl (2)

It is well documented that in *cis*-Pt**A$_2$G$_2$** species the nucleobases are strongly bound to the platinum centre[34] and their displacement requires the use of strong nucleophiles such as CN^- or sulfur donor ligands. For example, the displacement of guanine from *cis*-$[Pt(NH_3)_2(Guanine)_2]^{2+}$ by thiourea has been calculated from ^{13}C NMR spectroscopic data to have a rate constant of 1.5×10^{-5} M^{-1} s^{-1} at 316 K.[35,36] Only in the case of strong *trans*-labilizing ligands, such as phosphanes, has the ready displacement of a coordinated guanosine by chloride been observed.[37]

The situation appears to be different when a solvent with a lower dielectric constant than water is used.[38] For instance $[Pt(Me_2phen)(Guo)_2]Cl_2$ dissolved in CD_3OD gave rise to a dissociation equilibrium in which two new species were formed, one of which was easily recognised as free guanosine. The second species shows two signals in the region of H(8) (δ = 8.79 and 8.73 ppm) and three singlets (δ = 3.27, 2.27, and 2.26 ppm, relative intensities 2:1:1) in the region of the methyl protons. Moreover, integration of the aromatic protons shows that only one molecule of guanosine is present per molecule of neocuproine. Therefore the new complex can be formulated as [PtCl(Me$_2$phen)(Guo)]Cl with a bidentate Me$_2$phen, one chloride, and one guanosine in the coordination sphere of platinum. Such a complex is expected to have inequivalent Me's with one Me (the one *cis* to the guanosine) more shielded than the other. The presence of two signals for H(8) and two signals at high field for the Me's (δ = 2.27 and 2.26 ppm) is indicative of the presence of two conformers stemming from restricted rotation of the guanosine about the Pt−N(7) bond (as observed for compound **1**). The two conformers are made diastereomeric by the presence of the asymmetric ribose. A noteworthy observation is that the average H(8) chemical shifts of the mono-guanosine derivative (δ = 8.76 ppm), which is not influenced by the magnetic anisotropy of a *cis*-**G**, falls right in between the average H(8) chemical shifts of the *HT* and *HH* rotamers of the bis-guanosine derivative. (δ = 8.51 and 9.01 ppm, respectively). Although some caution is needed since the overall charge of the complex (+1 and +2 for compounds **2** and **1**, respectively) and the set of donor atoms are different in the two cases, it nevertheless appears that, with respect to the monoadduct, in the bis-guanosine derivative the H(8)'s are shielded by the *cis* **G** in the *HT* rotamer and are deshielded by the *cis* **G** in the *HH* rotamer.

The same complex, [PtCl(Me$_2$phen)(Guo)]Cl (**2**), was prepared independently and fully characterised by ele-

mental analysis and ^{1}H NMR spectroscopy (the ^{1}H NMR spectrum in CD_3OD is reported in Figure S6). The complete assignment of the ^{1}H NMR chemical shifts for the two conformers of compound **2** is reported in Table 1. NOESY cross-peaks were observed (Figure S7) between the guanosine H(8)'s and the sugar protons H(1′) and H(2′). The H(8)−H(1′) cross-peaks indicate that the nucleoside conformation has a partial *syn* character, while the value of 4.4 Hz for the $^3J_{H1',H2'}$ coupling indicates a higher percentage of N-pucker for the ribose (S/N of ca. 49:51).

^{1}H NMR spectra were recorded at different temperatures in order to investigate the effect of the temperature upon the rate of interconversion between conformers in compound **2**. Unfortunately the monosubstituted guanosine derivative started to decompose at temperatures slightly above 50 °C. This shows that the attempt by Clement and co-workers[20] to prepare the bis-guanosine derivative of Me_2phen from a reaction in H_2O at 80 °C is probably not the most appropriate.

The dependence of the dissociation equilibrium of **1** in methanol [Equation (1)] upon the Cl^- concentration was confirmed by addition of KCl (three times the stoichiometric amount) to a solution of **1** in CD_3OD (NMR tube).

$$[Pt(Me_2phen)(Guo)_2]^{2+} + Cl^- \rightleftharpoons [PtCl(Me_2Phen)(Guo)_2]^+ + Guo \quad (1)$$

The molar ratio **1**:**2** changed from 3:1 to 2:1, supporting the involvement of the chloride ion in the equilibrium of displacement of one guanosine from complex **1**.

The observation of the displacement of a guanosine derivative by a chloride ion in a different solution environment (the phenomenon was not observed in water) could be relevant to the biochemistry of this type of substrates in lipophilic environments.

Complexes with phen (3 and 4)

[Pt(phen)(Guo)$_2$](NO$_3$)$_2$ (3)

Because of the low solubility of the starting dichloro complex [$PtCl_2$(phen)], this substrate was first converted into the solvato species $[Pt(phen)(DMF)_2]^{2+}$ by reaction with a stoichiometric amount of $AgNO_3$ in DMF and then allowed to react, at room temperature, with a stoichiometric amount of guanosine (ratio 1:2) to give [Pt(phen)-$(Guo)_2](NO_3)_2$. Once more our experimental conditions were different from those used by Clement and co-workers (starting material [$PtCl_2$(phen)] and reaction performed in water at 65 °C for three days).

The ^{1}H NMR spectrum of complex **3** in D_2O at pH* 3.0 is reported in Figure 5 (a small amount of free guanosine was added to the sample for comparison) and the complete assignment of the NMR spectroscopic data is reported in Table 1. Four peaks are observed in the H(8) region: two signals are much more intense and rather shielded (δ = 8.80 and 8.75 ppm, relative intensities 1.1:1) and two signals are very weak, rather deshielded, and of equal intensities (δ = 8.91 and 8.86 ppm). The two strong signals with different intensities were assigned to the two *HT* rotamers, each one having equivalent H(8) protons, while the two weaker signals were assigned to the *HH* conformer with inequivalent H(8)'s.

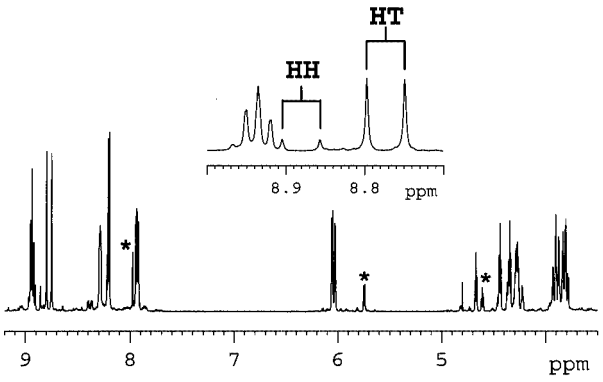

Figure 5. ^{1}H NMR spectrum of complex **3** in D_2O (pH* = 3.00, 298 K); the asterisks mark the peaks of free guanosine added to the sample for comparison; the H(8) peaks of the *HH* and *HT* rotamers are also labelled

The chemical shifts of the H(8) protons are indicative of N(7) coordination of the guanosine ligands. This type of coordination was also confirmed by a pH titration experiment.

A COSY experiment (Figure S8) allowed the assignment of all resonances (Table 1). A comparison of the 2D maps obtained in the ^{1}H-^{13}C HSQC experiments performed on complexes **3** and **1** (Figure 6) indicates that, differently from Clement's assignment,[20] the less-shielded signal (δ = 8.94 ppm) belongs to protons 4"/7′′ and the more-shielded signal (δ = 8.27 ppm) to protons 2"/9′′. It is likely that the aromatic ring current of the *cis*-coordinated guanosines is responsible for the shielding of protons 2"/9′′ (a similar effect has already been observed for methyls 2"/9′′ in the analogous complex **1**). Further support for our assignment of the aromatic protons comes from the presence of a ROESY cross-peak (C in Figure 7) between protons 5"/6′′ (δ = 8.21 ppm) and the less-shielded signal here assigned to protons 4"/7′′ (δ = 8.94 ppm). Significant ROESY cross-peaks are also observed between H(8) and H(2"/9") and between H(8) and H(1′) for the two *HT* rotamers (cross-peaks **B** and E, respectively). Similarly to the case of complexes **1** and **2**, the latter cross-peak gives an indication that the base/sugar conformation has some *syn* character. The ratios between the integrals of the ROESY cross-peaks H(8)−H(1′) and H(8)−H(2′) are equal to 2.17 and 1.63 for the two *HT* rotamers, respectively, suggesting a high percentage of S-pucker for the ribose. Such a pucker was also confirmed by the value of the $^3J_{H1'-H2'}$ coupling constant (4.9 Hz, which corresponds to an S/N ratio of ca. 55:45).

The effect of temperature on the rate of interconversion between *HT* and *HH* conformers was also investigated. The ^{1}H NMR spectrum of a sample of **3** in D_2O at pH* 3.50 and 355 K shows only a slight broadening of the peaks of the aromatic protons (Figure S9) with respect to the spectrum at 295 K, indicating that, even at the highest temperature explored, the rate of interconversion between rota-

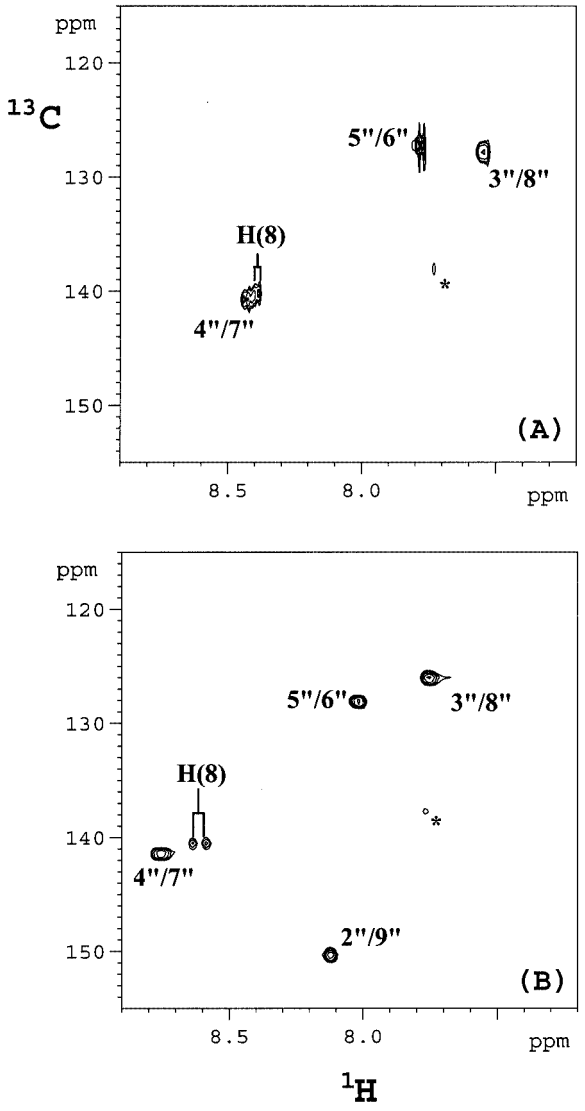

Figure 6. ^{1}H-^{13}C HSQC contour map of complex **1** (A) and complex **3** (B) in D_2O (pH* 2.90 and 3.00 for **1** and **3**, respectively; T = 298 K for both experiments); the asterisks mark the peaks of free guanosine added to the samples for comparison

mers is slow on the NMR timescale. Therefore the steric hindrance of the protons in positions 2′′ and 9′′ of phen is sufficient to prevent the free rotation of the guanosines about the Pt−N(7) bonds.

The analogy between the behaviour of **3** and that of **1** was quite unexpected since protons 2"/9′′ were not believed to inhibit the rotation around the Pt−N(7) bond to the same extent as the methyls 2"/9′′ of Me_2phen.

[PtCl(phen)(Guo)](NO$_3$) (4)

For the preparation of [PtCl(phen)(Guo)](NO_3) (**4**) the starting [$PtCl_2$(phen)] was first treated with one equivalent of $AgNO_3$ in DMF and then with one equivalent of guanosine. A small amount of complex **3** was always formed as a by-product in this reaction.

Similarly to the case of complex **2**, two sharp H(8) signals (at δ = 8.86 and 8.81 ppm, ratio 1.2:1) indicate the presence

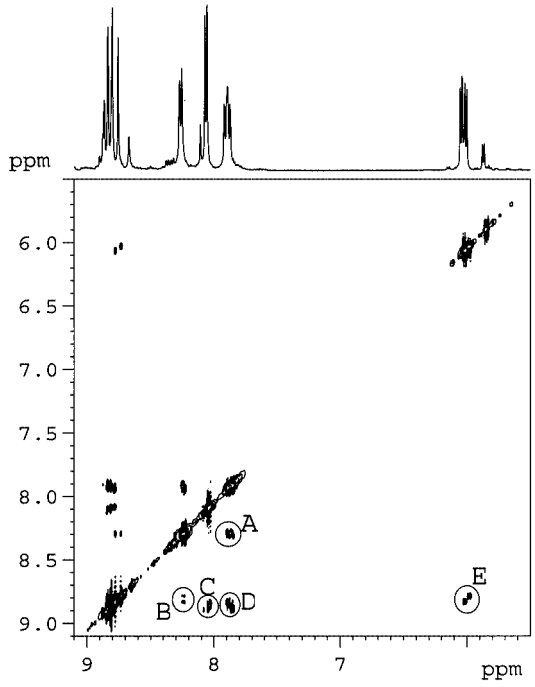

Figure 7. 2D-ROESY contour map of complex **3** in D_2O; the labelled cross-peaks are in antiphase with respect to the diagonal and represent intraresidual spatial couplings between protons of the *HT* rotamers: H(3"/8")−H(2"/9"), A; H(2"/9")−H(8), B; H(5"/6")−H(4"/7"), C; H(3"/8")−H(4"/7"), D; H(8)−H(1′), E

of two conformers in slow interconversion on the NMR timescale (Figure S10). The assignment of the ^{1}H NMR signals was facilitated by a COSY experiment (Figure 8) and is reported in Table 1. One *ortho* proton of phen is less shielded (δ = 9.72 ppm) and is assigned to the proton *cis* to the chlorine ligand (2′′ in Figure 3), since a similar chemical shift was observed for the *ortho* protons in the starting [$PtCl_2$(phen)] complex (δ = 9.80 ppm in [D_7]DMF). In con-

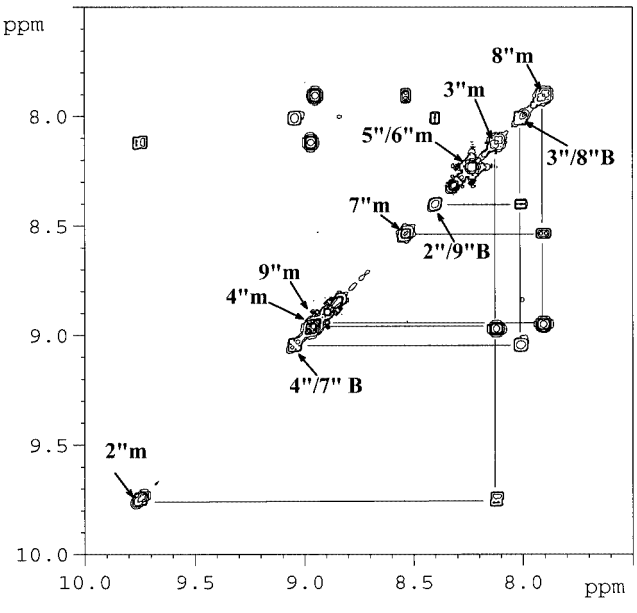

Figure 8. 2D-COSY contour map of complex **4** (resonances labelled m); resonances labelled B belong to complex **3**

trast, the *ortho* proton 9′′ undergoes an upfield shift of ca. 1 ppm which appears to be typical for an *ortho* proton *cis* to a guanine base. A similar upfield shift was observed for the *ortho* methyl(s) of Me_2phen *cis* to a guanine base.

The presence of two conformers indicates that there is also restricted rotation about the Pt−N(7) bond in the case of the monoadduct, and that the in-plane steric hindrance of the *ortho* protons of phen is sufficient to inhibit the free rotation of a *cis* guanosine.

The partial *syn* character of the guanosine conformation was also revealed by a ROESY experiment for compound **4**. The value of the $^3J_{H1',H2'}$ coupling (4.3 Hz) corresponds to an S/N pucker ratio of ca. 48:52.

As for Me_2phen and for phen the monoadduct has a slightly higher percentage of N pucker than the bis adduct and the average chemical shift of the H(8) protons falls in between the average H(8) chemical shifts of the *HH* and *HT* rotamers of the bis adduct.

Comparison between Me_2phen and Phen Derivatives

The differences in chemical shift between the H(8) signals of the two *HT* rotamers and between the two H(8) signals of the single *HH* rotamer observed in compounds **1** and **3** are very small ($\leq$ 0.05 ppm) when compared to those observed in similar compounds with C_2-symmetrical ligands having a strong asymmetry with respect to the coordination plane. These latter ligands were named Chirality Controlling Chelates, **CCC**, since they are able to favour one *HT* rotamer over the other and to induce a difference in the H(8) chemical shift between *HT* rotamers of the order of 0.2−0.4 ppm and a difference in chemical shift between the two guanines of the *HH* rotamer of the order of 0.8−1.1 ppm.[39−41]

The large dispersion of the H(8) signals within the *HH* conformer and between the two *HT* conformers observed in the platinum compounds with **CCC** ligands is mostly determined by the ability of these ligands to induce a preferential canting (either right- or left-handed) to the nucleobases. For a given direction of canting one *HT* rotamer will have the H(8) protons leaning towards the *cis* amine and deshielded while the second *HT* rotamer will have the H(8) protons leaning towards the *cis*-**G** and shielded. The two forms have been termed "6-in" and "6-out" since the former has the six-membered rings of the guanines closer to one another and the latter further apart. The *HH* rotamer will have one "6-in" and one "6-out" guanine, the former guanine will have a deshielded signal and the latter a shielded H(8) signal. Differently from **CCC** ligands, the phenanthroline ligands are perfectly symmetrical with respect to the coordination plane and cannot induce preferential canting of the nucleobases. Therefore the average canting could either be zero for all rotamers or, in the case of *HT* rotamers, be driven by the rotamer chirality. We will see (following section) that the latter is the case here. However there is no question that in **1** and **3** the differences between *HT* rotamers and between the two guanines of the *HH* conformer are determined entirely by the chiral ribose substituent, and are small.

There are some significant differences in chemical shifts between **3** and **1**. First, the chemical shift difference between the H(8) signals of the two *HT* rotamers and between the two H(8) signals of the single *HH* form is ca. 0.05 ppm in **3** and ca. 0.01 ppm in **1**. Second, the average H(8) chemical shift of the *HT* rotamers is at lower field in compound **3** than in compound **1** (δ = 0.26 ppm). Finally, the average H(8) chemical shift of the *HH* rotamer is at higher field in compound **3** than in **1** (δ = 0.12 ppm). All these features can be explained by assuming that, because of the smaller steric hindrance of the *ortho* substituents, the two guanosines have significantly greater wagging freedom in the case of phen than in the case of Me_2phen.

Therefore, with reference to the first point, the effect of the ribose in rendering the guanine bases within the *HH* rotamer and between the two *HT* rotamers magnetically inequivalent will be greater in **3** than in **1**.

With reference to the second point, the smaller shielding of the H(8) protons in the HT rotamers of **3** than in **1** is in agreement with the *HT* rotamers preferring the "6-in" conformation and the phen ligand allowing a greater canting of the guanine bases. The "6-in" conformation moves the six-membered ring of each guanine towards the *cis* **G** while the H(8) proton is moved towards the *cis* amine; it follows, therefore, that the more canted the bases are, the more deshielded the H(8) protons. The latter observation can be taken as proof that in the absence of other factors, such as the preferential canting imposed by **CCC** ligands, the canting of the bases is driven by the chirality of the *HT* conformer. The Δ-*HT* conformer induces an R canting and the Λ-*HT* conformer an L canting so that in both cases the six-membered rings move closer to each other and give a better internucleoside interaction. The canting direction [right-handed (R) or left-handed (L)] is defined by the chirality of two screw lines, one passing through the N(7) atoms of the two coordinated guanines and the other passing through H(8) and bisecting the given guanine.

With reference to the third point, we have to consider that in the *HH* rotamer the guanine with the "6-out" orientation is generally more canted and has a more-shielded H(8) signal than the guanine with the "6-in" orientation. Moreover, in the case of canting neutral phen ligands each guanine oscillates between the "6-in" and "6-out" conformations leading to an average H(8) signal which is similar for the two guanines. However, since the phen ligand allows for a more canted "6-out" conformation, the average H(8) chemical shift of the *HH* rotamer will be at higher field in compound **3** (δ = 0.12 ppm) than in compound **1**, in which the guanosines are more constrained to an orthogonal position.

Conclusions

This investigation has shown that phen and Me_2phen behave like other bidentate ligands, allowing the formation of platinum complexes in which one or both of the remaining two coordination positions can host guanosine ligands.

The features of the mono- and bis-guanosine adducts are strongly influenced by the special stereochemistry of the phen and Me_2phen ligands. First, both the Me_2phen and the phen carrier ligands are able to hinder rotation of the guanosine bases about the Pt−N(7) bonds so that the interconversion between rotamers becomes slow on the NMR timescale. Such a result was rather unexpected for phen. It is likely that the rigidity of the phenanthroline skeleton amplifies the steric impediment created by the small *ortho*-hydrogen atoms and restricts the free rotation of the *cis* guanosine ligand.

An interesting result of this investigation is that, by increasing the in-plane steric bulk of the carrier ligand (Me's instead of H's in positions 2/9 of the phenanthroline), the degree of wagging of the guanosine ligands is reduced and, in the case of Me_2phen, these ligands are forced to be more strictly orthogonal to the coordination plane. As a consequence: (i) the H(8) chemical shifts within the *HH* conformer and between *HT* conformers become more similar ($\Delta\delta$ of 0.01 ppm in the Me_2phen system as compared to 0.05 ppm in the case of phen), (ii) the H(8) protons of the *HT* conformers are more shielded ($\Delta\delta$ of 0.26 ppm), (iii) the H(8) protons of the *HH* rotamer are less shielded ($\Delta\delta$ of 0.12 ppm), and (iv) the *HT*/*HH* ratio is greater (ca. 18 and 8 in Me_2phen and phen, respectively).

Another result of this investigation is that in all the reported compounds the guanosine conformation appears to have some *syn* character.

Finally, the different behaviour of compound **1** in water and methanol solutions indicates that the solvent can play an important role in the stabilisation of cationic platinum adducts with purine bases when coordinating anions, such as Cl^-, are also present in solution.

Experimental Section

Physical Measurements: Elemental analyses were performed using a Carlo Erba Elemental Analyzer mod. 1106 instrument. IR Spectra were recorded on a Perkin−Elmer Spectrum One spectrometer using KBr as solid support for pellets. ^{1}H NMR spectra were recorded on a DPX 300 MHz WB Avance Bruker instrument. Chemical shifts are referenced to TMS using the residual protic peak of the solvent as internal reference (δ = 4.80 ppm for D_2O and δ = 3.30 ppm for CD_3OD). ^{1}H NMR experiments at different temperatures were performed using the heating control unit of the spectrometer. 2D ^{1}H NMR experiments were performed on a DRX 500 MHz WB Avance Bruker Instrument.

A Crison Micro-pH meter Model 2002 equipped with a Crison micro-combination electrode (9 mm diameter) and calibrated with Crison standard buffer solutions at pH 4.00 and 7.02 was used for all pH measurements. The pH readings for D_2O solutions are indicated as pH* values and are uncorrected for the effect of deuterium on glass electrodes.

Calculations of pK_a Values: The pH titration curves were fitted to the Henderson−Hasselbach equation using the program Kaleidagraph 3.0 for Macintosh.[42]

Starting Materials: Commercial reagent-grade chemicals, 2,9-Me_2-1,10-phenanthroline (Me_2phen, neocuproine), 1,10-phenanthroline (phen), guanosine (Guo), dimethyl sulfoxide (DMSO) and dimethylformamide (DMF) were used without further purification. $[PtCl_2(DMSO)_2]$ was prepared from an aqueous solution of K_2PtCl_4 and DMSO.[43] $[PtCl_2(Me_2phen)]$ was prepared by previously reported procedures.[21]

Preparation of Complexes

$[PtCl_2(phen)]$: A suspension of $[PtCl_2(DMSO)_2]$ (359 mg, 0.85 mmol) in methanol (100 mL) was treated with 1,10-phenanthroline (170 mg, 0.85 mmol). After stirring for one day, the newly formed precipitate was collected by filtration of the reaction mixture. The filtrate was concentrated to half its volume by evaporation of the solvent under reduced pressure and kept at room temperature for a few more days while another crop of yellow precipitate was formed. The combined solid fractions were washed with methanol and dried under vacuum to give 367 mg of product (97% yield based on starting platinum complex). $C_{12}H_8Cl_2N_2Pt$ (446.2): calcd. C 22.9, H 1.3, N 4.5; found C 22.6, H 1.3, N 4.4.

$[Pt(Me_2phen)(Guo)_2]Cl_2$ (1): $[PtCl_2(Me_2phen)]$ (250 mg, 0.53 mmol) was dissolved in methanol/chloroform (150 mL; 2:1, v/v) and a solution of guanosine in methanol (299 mg, 1.06 mmol, in 100 mL of solvent) was added dropwise to the resulting solution. The reaction mixture was stirred for two hours at room temperature and then taken to dryness by evaporation of the solvents under vacuum. The solid residue was treated with water (10 mL) and the mixture stirred overnight. The water solution was then filtered and taken to dryness by evaporation of the solvent under vacuum. The yellow residue proved to be pure $[Pt(Me_2phen)(Guo)_2]Cl_2$ (496 mg, 90% yield). $C_{34}H_{38}Cl_2N_{12}O_{10}Pt$ (1040.7): calcd. C 39.2, H 3.7, N 16.2; found C 39.8, H 3.5, N 16.8.

$[PtCl(Me_2phen)(Guo)]Cl$ (2): $[PtCl_2(Me_2phen)]$ (100 mg, 0.21 mmol) was dissolved in methanol/chloroform (80 mL; 2:1, v/v) and a stoichiometric amount (1:1 molar ratio) of guanosine dissolved in methanol (119 mg, 0.1 mmol, in 50 mL of solvent) was added dropwise to the resulting solution. The reaction mixture was stirred for two hours at room temperature and then concentrated under vacuum to 50 mL. Addition of diethyl ether induced the precipitation of a yellow product which was separated by filtration of the reaction mixture, washed with diethyl ether, and dried under vacuum to give 135 mg of product (85% yield). $C_{24}H_{25}Cl_2N_7O_5Pt$ (757.5): calcd. C 38.1, H 3.3, N 12.9; found C 37.8, H 3.1, N 12.7.

$[Pt(phen)(Guo)_2](NO_3)_2$ (3): $[PtCl_2(phen)]$ (200 mg, 0.56 mmol) was dissolved in DMF (70 mL) and treated with $AgNO_3$ (190 mg, 1.12 mmol) previously dissolved in the minimum amount of water. The solution was left stirring in the dark for 12 hours and a white precipitate of AgCl formed. The reaction mixture containing the solvato species $[Pt(DMF)_2(phen)]^{2+}$ was filtered through celite and treated with guanosine (317 mg, 1.12 mmol) previously dissolved in the minimum amount of DMF. This mixture was stirred for 5 hours at room temperature and then treated with diethyl ether to induce the formation of a yellow precipitate. The solid product was separated by filtration of the mother liquor, washed with several aliquots of diethyl ether and dried under vacuum to give 477 mg of product (80% yield). $C_{32}H_{34}N_{14}O_{16}Pt$ (1065.8): calcd. C 36.1, H 3.2, N 18.4; found C 36.6, H 3.3, N 18.2.

$[PtCl(phen)(Guo)](NO_3)$ (4): The procedure used for the preparation of $[PtCl(phen)(Guo)](NO_3)$ was similar to that used for compound **3** with the only difference being that only one equivalent of $AgNO_3$ and guanosine were added per mol of platinum substrate. In addition to compound **4** some compound **3** was also formed as

side-product, this prevented the characterisation of **4** by elemental analysis.

Structural Variations and Formation Constants of First-Row Transition Metal Complexes of Biologically Active Aroylhydrazones

Claire M. Armstrong,[a] Paul V. Bernhardt,*[a] Piao Chin,[a] and Des R. Richardson[b]

Keywords: Hydrazones / Structure elucidation / Transition metals / N ligands

Iron chelators of the 2-pyridinecarbaldehyde isonicotinoylhydrazone (HPCIH) class show high potential for the treatment of iron overload diseases. In the present study, selected first-row transition metal (from Mn to Zn) complexes with HPCIH and 2-pyridinecarbaldehyde (4′-aminobenzoyl)hydrazone (HPCAH) were synthesised and characterised. Crystallography reveals that HPCAH exclusively forms bis complexes with divalent transition metals, with each ligand coordinating meridionally through its pyridine-N, imine-N and carbonyl-O atoms, forming distorted octahedral *cis*-MN_4O_2 complexes. Complexes of HPCIH were more varied and unpredictable, with metal/ligand ratios of 1:1, 1:2, 2:2 and 3:2 obtained with different metal ions. The isonicotinoyl ring N-atom in HPCIH was found to be an effective ligand, and this resulted in the varied metal/ligand ratios observed. The formation constants of divalent metal complexes with HPCIH were determined by potentiometric titrations and the values obtained were consistent with similar tridentate ligands and with the Irving–Williams order.

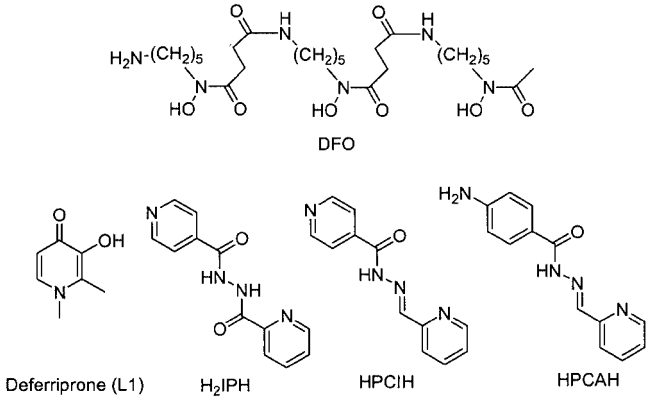
Introduction

In recent years the search for an orally effective drug for iron (Fe) overload diseases has gained increasing attention.[1−3] The motivating factors behind this interest are that the chelator in current clinical use, desferrioxamine B (DFO, see Scheme 1),[4] is expensive, is found to cause serious side effects in some patients, and is orally ineffective. In fact, DFO requires frequent and long periods of subcutaneous infusion leading to poor patient compliance.[5,6]



Scheme 1

An orally active alternative drug, deferiprone (also known as L1, see Scheme 1), was developed and extensively tested in the 1980s and 1990s,[7,8] but was found to result in myelotoxicity, liver fibrosis and have limited ability to reduce hepatic Fe levels.[9−11] Indeed, the use of this chelator remains controversial.[12] However, recent studies have shown more promise,[13−15] particularly when DFO is combined with Deferiprone.[16,17] Lipophilic Fe chelators have also been proposed for the treatment of other Fe-loading diseases such as the severe neurological disease Friedreich's ataxia.[18] If successful, this strategy will provide a new therapeutic application for these compounds.[18,19]

Our research program revolves around the design and synthesis of ligands that exhibit high Fe chelation efficacy and are potentially orally effective. We have designed and patented a novel class of ligands based on 2-pyridinecarbaldehyde isonicotinoylhydrazone (HPCIH, see Scheme 1), that have shown great promise in vitro, demonstrating a high Fe chelation efficacy.[20−22] Moreover, these chelators show very low toxicity in vitro in cultured cells and the compounds are simple and economical to prepare by a Schiff-base condensation reaction.[19−23]

Interestingly, and unexpectedly, the parent chelator of this class, HPCIH, has been shown to be oxidized by Fe^{III} to the diacylhydrazine, *N*-(isonicotinoyl)-*N*′-(picolinoyl)hydrazine (H_2IPH; see Scheme 1).[23] In contrast, in the absence of Fe^{III}, the parent hydrazone is not oxidized in aerobic aqueous solution.[23] To examine whether the diacylhydrazine H_2IPH could be responsible for the biological ef-

fects of PCIH, their Fe chelation efficacy was compared. Unlike its parent hydrazone, the diacylhydrazine showed little Fe chelation activity, probably because the latter ligand was charged at physiological pH (pH = 7.4), hindering its access across membranes to cellular Fe pools.[23] In contrast, the IPH-Fe complex was charge-neutral, which would permit passage through cell membranes. These data allow a model of Fe chelation for this compound to be proposed: the parent aroylhydrazone (HPCIH) diffuses through cell membranes to bind Fe and is subsequently oxidized to the IPH-Fe complex, which then diffuses from the cell.[23] However, other diacylhydrazine ligands showed much higher activity, probably because they had a neutral charge.[23]

As part of our continuing research into the properties of this class of ligand we have investigated their coordination chemistry with divalent metal ions of the first transition series (Mn to Zn). This was relevant to our work as many of these metal ions are biologically important. From this class of chelators, HPCIH itself was examined as it represented the parent compound of these potential drugs and our earlier studies demonstrated that it possessed interesting properties.[23] For comparison, another member of this group has been assessed in parallel, namely, 2-pyridinecarbaldehyde (4-aminobenzoyl)hydrazone (HPCAH, Scheme 1), which does not bear a potentially bridging N-donor atom. The role of this latter ligating atom in HPCIH was important to assess as it could play a role in the chelation of some transition metal ions and result in different complexes to those found for HPCAH.

We were also interested to assess whether the unprecedented Fe-catalysed oxidation of HPCIH to its diacylhydrazine analogue H_2IPH discovered in our previous investigation[23] could be observed in HPCAH, or in the presence of other metal ions. The results obtained in this study are important for understanding the biological activity of HPCIH and its analogues, especially in terms of their affinity towards other biologically important divalent metal ions that can act as competitors against Fe in vivo.

Results and Discussion

Synthesis and Spectroscopic Properties

Upon reaction of 1 equiv. of the divalent metal ion (chloride salt), 2.5 equiv. of the ligand, and 2 equiv. of Et_3N in methanol, divalent complexes of the general formula ML_2 (M = Mn, Ni, Cu and Zn; L = $PCIH^-$ and $PCAH^-$) were obtained. The 2 equiv. of Et_3N accept protons released from the amide functional group upon complexation. The use of a suitable base was found to be important to afford good yields of the bis(complex), as the same experiments conducted without base gave poor yields or no product at all.

If the same synthesis is applied to the Fe^{II} and Co^{II} analogues, mixtures of products were obtained comprising varying ratios of metal and ligand. The synthesis in MeCN was straightforward by comparison. The Fe^{II} and Co^{II} complexes yield solid-state spin-only magnetic moments of 4.87 and 4.59 B.M., respectively, which are both indicative of high-spin d^6 and d^7 electronic ground states in pseudo-octahedral coordination environments.

In addition to the formation of ML_2 complexes, HPCIH exhibited a variety of other metal/ligand stoichiometries. Complexes of (H)PCIH with metal/ligand ratios of 1:1, 2:2 and 3:2 were obtained, although not with the HPCAH analogue, despite the application of similar conditions. This behaviour may be attributed to the presence of the unhindered N-donor on the isonicotinoyl ring of HPCIH. As seen from crystal structures of the three unusual complexes to be discussed later, the participation of the isonicotinoyl nitrogen atom in coordination evidently changes the way the complexes are formed. By contrast, the free amino group on HPCAH is an ineffective ligand as a result of conjugation of the N-atom lone pair with the aromatic ring.

The free ligand amide N−H (ca. 3450 cm^{-1}) and C=O (ca. 1650 cm^{-1}) stretching vibrations[24,25] are not observed in the IR spectra of the divalent $[M(PCAH)_2]$ and $[M(PCIH)_2]$ complexes. However, the complexes exhibit a strong absorption band at ca. 1600 cm^{-1} not observed in the free ligands, which is due to the conjugated C=N−N=C−O^- moiety.[26] Thus, in each ML_2 complex, the deprotonated ligands are predominantly in the enolate resonance form (Figure 1). The trivalent complex $[Co(PCAH)_2]Cl$ exhibits an IR spectrum essentially the same as the divalent bis complexes. By contrast, the IR spectrum of $[Zn(HPCIH)]SO_4$, where the amide N-atom is not deprotonated, exhibits both the amide N−H and C=O vibration bands (3422, 1684 and 1653 cm^{-1}) and the 1600 cm^{-1} peak characteristic of the deprotonated ligand is absent.

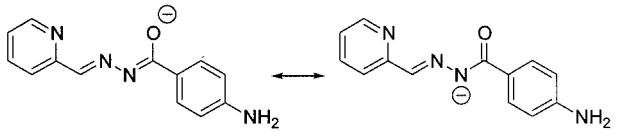

Figure 1. Line drawing of enol and keto resonance forms of $PCAH^-$

The ^{1}H NMR spectrum of $[Co(PCAH)_2]Cl$ shows that both ligands are deprotonated, with the amide-H being absent from the spectrum. In the ^{13}C NMR spectrum, the signals of the carbonyl and imine carbon atoms are shifted downfield by ca. 20 ppm, as expected when this ligand is coordinated through the imine-N and amide-O. Similar results were obtained with the $[Co(PCIH)_2]^+$ analogue.

The electronic spectra of the ML_2 complexes of $PCIH^-$ and $PCAH^-$ in methanol are very similar, and are dominated by intense ligand-based transitions in the near UV region (Table 1). However, the Ni^{II} complexes display weak maxima at ca. 840 nm while complexes of Cu^{II} exhibit maxima at ca. 690 nm, which are both due to d-d transitions. All bis(complexes) show one intense band at ca. 360 nm and one or two less-intense absorptions in the range 240−300 nm. In general, the ligand-based transitions for the (H)PCAH complexes are at lower energy than those for (H)PCIH complexes. Similar red-shifted maxima have been

observed for similar Mn, Fe and Cu complexes when the substituent on the ligand becomes more strongly electron-donating.[27−33] In the electronic spectrum of [Co(PCAH)$_2$]Cl, the intense absorption at ca. 360 nm observed in the other bis(complexes) is shifted significantly to a lower energy at 427 nm (Table 1). This suggests that this electronic transition is of ligand-to-metal charge-transfer origin, with the lower energy reflecting the greater ease of reduction of the trivalent metal ion than the other divalent analogues.

Description of Crystal Structures

HPCAH

The crystal structure of HPCAH·H$_2$O (Table 2) has been determined and a view of the molecule is shown in Figure 2. The bond lengths and angles (Table 3) are as expected for a compound of this type and agree with the other ligands belonging to the HPCIH series.[21] Of note is the C7−O1 bond length, which is typical of a double bond, and the N2−N3 bond, which has a bond order intermediate between a single and a double bond.

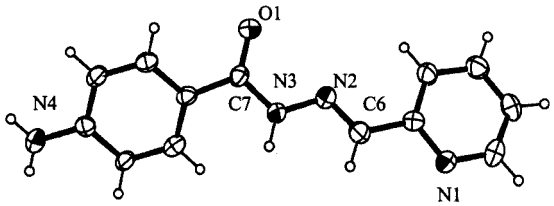

Figure 2. View of HPCAH structure (30% probability ellipsoids)

[M(PCAH)$_2$]·H$_2$O (M = Mn, Ni, Cu and Zn)

The molecular structure of Mn(PCAH)$_2$ is shown in Figure 3. Structures of the Ni^{II}, Cu^{II} and Zn^{II} analogues are very similar and are not shown. Selected bond lengths and angles are listed in Table 3. Each metal ion has a *cis*-N$_4$O$_2$ coordination sphere, where the two deprotonated ligands bind meridionally through their pyridine-N, imine-N and carbonyl-O atoms. The coordinated ligands from two five-membered chelate rings, imposing large distortions on the ideally octahedral coordination angles. The *trans*-N2A−M−N2B angles are close to 180°, whereas the *trans*-N1A(B)−M−O1A(B) angles defined by each meridionally coordinated ligand deviate markedly from linearity; this distortion is greatest for the largest metal ions in the series (Mn^{II} and Zn^{II}). Distortion of the *cis* coordination angles defined by the five-membered chelate rings also increases with metal ion size. The M−N(pyridine), M−N(imine) and M−O bond lengths observed here are within the range reported for other similar complexes of divalent metal ions.[32−36] The variations in C−C, C−N, C−O and N−N bond lengths and angles across the [M(PCAH)$_2$] series are very small, as expected. In general, the average M−N2A(B) distances are significantly shorter than the M−N1A(B) distances, which can be attributed to greater π-back-bonding in the M−N(imine) bond than in the M−N(pyridine)

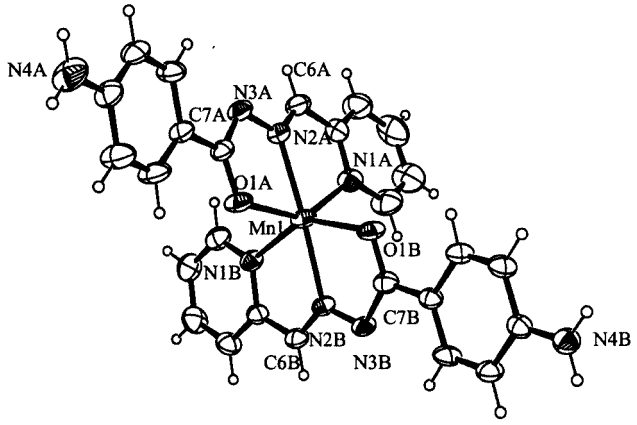

Figure 3. View of the $[Mn(PCAH)_2]$ molecule (30% probability ellipsoids)

bond[36,37] and also to the steric requirements of the meridionally coordinated ligand.

Although the C6A(B)−N2A(B) and N2A(B)−N3A(B) bond lengths are unaffected by complexation [ca. 1.27 and 1.37 Å in the complexes compared with 1.265(7) and 1.365(6) Å in the free ligand, respectively], the C7A(B)−O1A(B) bond lengthens significantly (by ca. 0.04 Å); variations in the C7A(B)−N3A(B) bond upon complexation are less pronounced. Overall, these observations are consistent with the enolate resonance form of the ligand (Figure 1) being dominant in the deprotonated coordinated ligand, and this is supported by the IR spectroscopic data.[36,38−45]

HPCIH Complexes

Crystal data and selected bond lengths and angles of the various HPCIH complexes are given in Tables 4 and 5 respectively. The molecular structure of $[Cu(PCIH)_2]$ is shown in Figure 4. The four (Cu, Ni and both Co) bis(complexes) of HPCIH share common structural characteristics with the ML_2 complexes of $PCAH^-$ described above. All metal ions have *cis*-N_4O_2 coordination spheres, where each of the two ligands binds the metal ion meridionally via the pyridine-N, imine-N and carbonyl-O atoms. In most cases the bond lengths in the $[M(PCIH)_2]$ complexes (Table 5) are similar to those found in $PCAH^-$ analogues (Table 3). This implies that the coordinated HPCIH ligand also exists predominantly in the enolate resonance form with the conjugated C=N−N=C−O^- moiety, agreeing with the IR spectra.

Two Co^{III} complexes of HPCIH were isolated, shown in Figures 5 and 6. $[Co(HPCIH)(PCIH)](NO_3)_2$ exhibits a structure (Figure 5) similar to the Cu^{II} and Ni^{II} bis(complexes), except that one of the ligands is protonated at its isonicotinoyl N-atom; i.e., the protonated ligand is present in a zwitterionic (pyridinium/amidate) form. The other cobalt complex of HPCIH consists of two cobalt ions: an octahedral Co^{III} coordinated within the expected N_4O_2 donor set and a tetrahedral Co^{II} ion coordinated to three chloride ions and the nitrogen atom of the isonicotinoyl ring (Figure 6, Table 6). Since a 1:2 ratio of Co/HPCIH was used in the synthesis, the formation of this complex may be attributed to the strong tendency for the free isonicotinoyl nitrogen atom to coordinate.

The fact that DMSO is an effective ligand, together with the presence of residual chloride ions and the strongly coordinating isonicotinoyl nitrogen atom, are compounding reasons that lead to the isolation of $[\{MnCl_2(DMSO)(HPCIH)\}_2Mn(DMSO)_2Cl_2]$, as an unusual M_3L_2 complex (Figure 7, Table 6). The bridging Mn (Mn1), at a centre of symmetry, bears no chelate rings, so all *cis* coordination angles are close to 90°. The coordination

sphere comprises two DMSO ligands, two chloride ions and two isonicotinoyl residues. The symmetry-related Mn ions (Mn2 and Mn2′) are each coordinated in a tridentate fashion to an HPCIH ligand. It is interesting to note that the two chloride ions on the central Mn1 are *trans* oriented, whereas on Mn2 the chloride ions are *cis*. A large distortion from octahedral geometry is imposed by the tridentate coordinated HPCIH ligand on the ideally linear N1−Mn−O1 bond angle, which is contracted to 138.1(2)°. No substantial C7−O1 bond lengthening or C7−N3 bond shortening is observed in the complex relative to free ligand. The amide N3 atom is not deprotonated, thus preventing the formation of enolate ion and the conjugated C=N−N=C−O$^-$ moiety.

In the case of [Zn(HPCIH)SO_4], the participation of the isonicotinoyl nitrogen atom and sulfate anions in coordination led to a surprising result (Figure 8). The N_2O-tridentate HPCIH is again bonded to Zn^{II} meridionally in addition to an isonicotinoyl nitrogen atom *trans* to the imine nitrogen atom. These ZnN_3O moieties are arranged in parallel planes, with bridging sulfate anions occupying the sites perpendicular to this plane. The result is a three-dimensional coordination polymer. This mode of coordination is in contrast to the other complexes reported herein, which

are discrete molecules. While the *trans*-O2−Zn−O3′ and -N2−Zn−N4′ bonds are almost linear, the *trans*-N1−Zn−O1 bond is bent to 149.3(2)°. The C7−O1 and C7−N3 bond lengths in this complex are similar to those in the free ligand. The fact that the hydrazone remains protonated in this complex results in these bonds retaining their double bond character in the absence of the electron delocalisation seen in the complexed deprotonated ligands.

Overall, it can be concluded that the active participation of the isonicotinoyl nitrogen of HPCIH in bonding has led to a much more varied and unpredictable coordination chemistry.

EPR Spectroscopy of Copper(II) Complexes

The Jahn−Teller distortions observed in most six-coordinate Cu^{II} complexes[46] are revealed in the crystal structure of [Cu(PCIH)$_2$], where the *trans*-Cu−N1B and -Cu−O1B bonds are exceptionally long [2.301(4) and 2.328(3) Å, respectively] compared to the other four coordination bonds (Table 5). However, this distortion is not apparent in the structure of [Cu(PCAH)$_2$]·H_2O (Table 3). EPR spectroscopy was employed to resolve this issue. [Cu(PCIH)$_2$] and [Cu(PCAH)$_2$] exhibit identical EPR spectra (Figure 9) and these could be simulated with identical, axially symmetric spin Hamiltonian parameters ($g_{\|}$ = 2.262, $g_{\perp}$ = 2.09, $A_{\|}$ = 122 *G* and $A_{\perp}$ = 25 G). These parameters are consistent with a tetragonally elongated d^9 complex in a $d_{x^2-y^2}$ ground state ($g_{\|} > g_{\perp}$ and $A_{\|} > A_{\perp}$) with significant distortion of the in-plane *cis* coordinate angles away from 90° ($A_{\|} <<$ 200 G). Note that the broad feature around 3300 G ($g \approx$ 2) is due to an impurity in the EPR spectrometer cavity, and so the experimental and simulated spectra are obviously different in this region. The EPR results indicate that the copper ions are in the same electronic environment in both [Cu(PCIH)$_2$] and [Cu(PCAH)$_2$] despite their apparent structural differences. That is, the bond lengths found in [Cu(PCIH)$_2$] are representative of the true tetragonally elongated structures of both [Cu(PCIH)$_2$] and [Cu(PCAH)$_2$], whereas the geometry defined by the crystal structure of [Cu(PCAH)$_2$] is a weighted average of two tetragonally elongated forms, and thus apparently (but not really) tetragonally compressed.

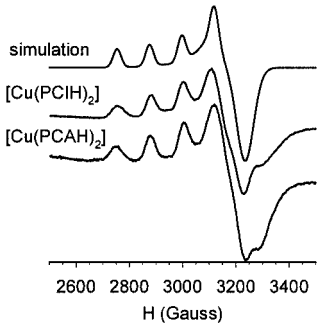

Figure 9. Experimental X-band (9.303 GHz) EPR spectra of [Cu(PCAH)$_2$] (bottom) and [Cu(PCIH)$_2$] (centre): conditions: 1 mM complex in DMF/H_2O (1:2), 77 K; the simulated spectrum is shown at the top (see text for simulation parameters); broad, high-field resonances ($g \approx 2$) in experimental spectra are due to cavity impurities

Ligand Oxidation

One interesting observation while preparing the Co-HPCIH complexes was that the HPCIH ligand is not oxidised when the redox-active Co^{II} is oxidised to Co^{III} by dissolved atmospheric oxygen in the solution during complex formation. This is in contrast to our earlier report of the oxidation of HPCIH to the diacylhydrazine *N*-(isonicotinoyl)-*N*′-(picolinoyl)hydrazone (H_2IPH) while trying to prepare the Fe^{III} complex of HPCIH.[23] We successfully duplicated the preparation of the trivalent complex [Fe(HIPH)(IPH)] from Fe^{II} salts and HPCIH as starting materials, but as yet have been unable to isolate the trivalent [Fe(PCIH)$_2$]$^+$ complex. We believe that the ligand oxidation is not a straightforward process. Indeed, it probably involves Fe^{III}, water and O_2 in the mechanism, since a similar oxidation is not observed with Co^{II} and Co^{III}, or any other transition metals investigated in this report. Nevertheless, the divalent [FeL_2] (L = PCIH and PCAH) complexes have been synthesised and the [Fe(PCIH)$_2$] complex formation constants have been demonstrated by potentiometric titration (see below). So far our work on HPCAH has not shown any evidence of ligand oxidation in the presence of either Fe^{II} or Fe^{III}. This adds another dimension to the ligand oxidation phenomenon such that oxidation seems to be peculiar to HPCIH. We are currently working toward an understanding of this oxidation mechanism.

Formation Constants

The formation constants of the bis(complexes) of HPCIH with divalent first-row transition metals from manganese to zinc have been determined. The results are shown in Table 7. The values obtained are similar to those obtained with similar tridentate ligands and consistent with the Irving−Williams order.[47] The exceptionally low log K_2 value ($ML + L \rightleftarrows ML_2$) of Cu^{II} at 7.42 is expected, since

the addition of a second ligand forces the Cu^{II} centre into a strained tetragonally elongated six-coordinate configuration evident from the crystal structure (Table 5) and EPR spectrum (Figure 9) of $[Cu(PCIH)_2]$, where the rigid meridionally coordinated second ligand must span the elongated axis of the coordination sphere.

Table 7. Formation constants of complexes of (H)PCIH with divalent first row transition metals

	Mn^{II}	Fe^{II}	Co^{II}	Ni^{II}	Cu^{II}	Zn^{II}
$\log K_1$ (ML)	4.71(3)	7.02(3)	7.67(5)	9.27(4)	10.83(8)	7.41(7)
$\log\beta_2$ (ML_2)	9.20(3)	13.37(2)	14.42(5)	16.97(4)	18.25(9)	13.85(7)

A typical speciation plot, such as that for the Ni^{II} complex shown in Figure 10, illustrates the transition from free metal ions to bis(complexes) as pH increases. At lower pH, the monoligand complex is the prevailing species, with $[Ni(PCIH)]^+$ beginning to form at pH = 2.5 (while $[Cu(PCIH)]^+$ begins to form at pH = 1.5). As the pH increases, bis(complexes) begin to form, eventually becoming the only species at pH = 7 and beyond. The Mn^{II} complex is the exception due to the closeness of log K_1 ($M + L \rightleftarrows ML$) and log K_2 ($ML + L \rightleftarrows ML_2$) values (4.71 and 4.49, respectively). $[Mn(PCIH)]^+$ only begins to form at pH = 5 while $[Mn(PCIH)_2]$ begins to form at pH = 7. Both species coexist in equilibrium through to pH = 12. Thus, the isolation of $[\{MnCl_2(DMSO)(HPCIH)\}_2Mn(DMSO)_2Cl_2]$ can be further rationalised by considering the formation constants, which illustrate that the formation of $[Mn(PCIH)_2]$ is least favourable of all ML_2 metal complexes in this series.

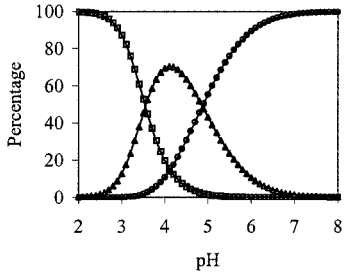

Figure 10. pH speciation plot for Ni^{II} complexes of HPCIH; key: squares: free Ni^{2+} ions; triangles: $[Ni(PCIH)]^+$; circles: $[Ni(PCIH)_2]$

Biological Activity

The Fe chelation efficacy of the HPCIH analogues is now established.[19−21] An important question concerns the physiologically relevant form of these chelators and their complexes upon encountering intracellular Fe and other competing metal ions. The HPCIH analogues form divalent Fe complexes even in the presence of oxygen. This is in contrast with other biologically active Fe chelators such as DFO, which spontaneously oxidises Fe^{II} to its trivalent state under aerobic conditions.

Given the reactivity of the Fe^{III} complex of $PCIH^-$ and the ready formation of the divalent complex in our synthetic studies,[23] it appears that the trivalent complexes of the HPCIH analogues will not be the major species in vivo, and the biological activity of the chelators may be attributed to their ability to act as intracellular Fe^{II} chelators rather than Fe^{III} chelators. The formation constants of HPCIH with Fe^{II} are not particularly high (Table 7) and there is nothing to suggest that the ligands are selective for divalent Fe over any of the other metal ions. In fact, at face value, the ligands should form more stable divalent complexes with Cu and Zn which are also present in biological fluids. However, intracellular Fe is present in much higher concentrations than other transition metals, and this will naturally influence the outcome under physiological conditions.

It is well known that charge neutrality and lipophilicity are desirable features in facilitating passage across cell membranes and thus enhancing Fe mobilisation activity. It is pertinent that the divalent complexes of HPCIH are charge-neutral, so the metal-free chelators may enter the cell in a charge-neutral form and the Fe complexes also may leave the cell in a charge-neutral form. A similar charge neutrality has been sought in tribasic ligands such as DFO and tris-L1 in complexes with trivalent Fe. Although the FeL_2 (L = PCIH, PCAH) complexes may be oxidised to their trivalent forms with mild oxidants, they are highly reactive and would be unlikely to survive in vivo. Furthermore, they would necessarily carry a positive charge, which may inhibit their exit from the cell.

An alternative, but less likely, hypothesis to explain the pronounced Fe mobilisation activity of these chelators is that ligand dehydrogenation of the unstable trivalent Fe complexes of the HPCIH (hydrazone) analogues occurs generating the corresponding hydrazine (H_2IPH) complex within the cell, by analogy with observations of the chemistry of these complexes on a preparative scale.[23] At this point, we prefer the former argument, as the hydrazine analogue of HPCIH (H_2IPH) exhibits very poor Fe mobilisation activity,[23] and its biological role in the activity of the HPCIH analogues is doubtful. Even though the formation constants of bis(complexes) of HPCAH with divalent first-row transition metals have not been determined, we would expect their values to exhibit the same trend and order of magnitude as those of HPCIH due to the similarities of the two ligands. In fact, the crystallographic and spectroscopic data reported herein show that the local coordination environments of the $[M(PCIH)_2]$ and $[M(PCAH)_2]$ complexes are indistinguishable. The main feature that distinguishes the HPCIH analogues in terms of their biological activity appears to be their lipophilicity, which affects their ability to cross the cell membrane and gain access to intracellular Fe pools.

Conclusion

Divalent first-row transition metals (Mn, Fe, Co, Ni, Cu and Zn) readily form similar bis(complexes) with HPCAH as shown by spectroscopy and X-ray crystallography. How-

ever, complexes of HPCIH are less predictable, forming complexes of various metal/ligand ratios. Such behaviour is attributed to the active participation of the unhindered isonicotinoyl nitrogen atom in bonding. In the case of the trinuclear complex $[\{MnCl_2(DMSO)(HPCIH)\}_2Mn(DMSO)_2Cl_2]$, the low formation constant of $[Mn(PCIH)_2]$ coupled with competition from ligands like DMSO and chloride, as well as participation of the isonicotinoyl nitrogen atom in coordinate bonding, led to the formation of this unique compound. From the IR spectra and crystal data, it is evident that the deprotonated hydrazone ligands exist predominantly in the enolate resonance form. Oxidation of HPCIH and HPCAH in the presence of divalent metal ions was not observed in this study, which further strengthens our belief that the unique participation of Fe^{III} and oxygen is the key to this unprecedented oxidation of HPCIH to H_2IPH. On the other hand, formation constants of the divalent metal complexes of HPCIH show that the affinity of this ligand for Fe^{II} is not particularly great, although the chelator is successful in mobilising iron as shown by our cell culture experiments.[23] Other factors such as the greater bioavailability of Fe or, less likely, the intracellular oxidation of HPCIH to H_2IPH could be the answer and further studies are being undertaken to ascertain these unresolved questions.

Experimental Section

Materials: The chemicals and solvents used in this work were of analytical grade, available commercially, and were used without further purification.

Physical Measurements: Solution UV/Vis spectra were measured with a Perkin−Elmer Lambda 40 spectrophotometer. Infrared spectra were measured with a Perkin−Elmer 1600 series instrument, with compounds being dispersed as KBr discs. ^1H NMR spectra were obtained with a Bruker AC200F spectrometer using TMS as the internal standard. Electron paramagnetic resonance (EPR) spectra were recorded at 77 K with a Bruker ER200D spectrometer at X-band frequency (9.303 GHz). Samples were made up as 1 mM solutions in a DMF/water (1:2) mixture. Spectra were simulated with the program EPR50F.[48] Potentiometric titrations were performed under nitrogen at 298 K with a Metrohm E665 Dosimat autotitrator equipped with a 5-mL burette. The titrant was 0.1 M Et_4NOH standardised with HCl. Solutions of pure ligands (1 mM) were used in the titrations for the determination of protonation constants. The chelators were prepared in $HClO_4$ (6 mM) and Et_4NClO_4 (0.1 M) as supporting electrolyte to maintain a constant ionic strength throughout the titration. Solutions of transition metal ions plus ligands used in the titration for the determination of metal complex formation constants contained transition metal ions as the perchlorate salt (0.5 mM), ligand (1.25 mM) (calculated at a 1:2 metal ion/ligand ratio, with 25% excess ligand added), $HClO_4$ (6−12 mM) and Et_4NClO_4 (0.1 M). Care was taken to pre-purge all solutions with nitrogen so as to prevent complications from redox reactions. Milli-Q water was used to make up the transition metal salt solutions, which were also pre-purged with nitrogen before dissolution. The solution potential was measured using an Orion 720A pH meter and an Ionode IJ44 intermediate junction pH electrode. The electrode was calibrated by strong acid-strong base titration prior to every potentiometric titration of the ligands or complexes. Data obtained were fitted to the Nernst equation and the pK_a values or formation constants were determined using the program SuperQuad.[49] In each case, a minimum of four titrations was performed in the range $2 < pH < 12$.

Ligand Syntheses: HPCIH and HPCAH were synthesised by a Schiff-base condensation between 2-pyridinecarbaldehyde and the respective acid hydrazides as described previously.[20,21,50] Slow concentration of an aqueous methanol (1:1) solution of HPCAH afforded crystals suitable for X-ray work.

HPCIH·2H$_2$O: $C_{12}H_{14}N_4O_3$ (262.2): calcd. C 54.96, H 5.38, N 21.36; found C 55.10, H 5.34, N 21.55. Complex Syntheses

Bulk Syntheses of [M(PCIH)$_2$] and [M(PCAH)$_2$] Complexes (M = Mn, Ni, Cu and Zn): The ligand (HPCIH or HPCAH; 2.5 mmol) was dissolved in 30 mL of methanol. The chloride salt of the respective metal (1 mmol) was added to the solution, followed by triethylamine (Et_3N; 2 mmol). The mixture was gently refluxed for 3 h and then concentrated to approximately one third of the original volume. The resulting precipitate was collected by vacuum filtration and washed with distilled water. Complexes ML_2 of Mn^{II}, Ni^{II} and Cu^{II} were all brown in colour, while the Zn^{II} complexes were bright yellow. Yields of the first crops of compound were 20−40%. Further crops were obtained from concentration of the filtrates.

Bulk Syntheses of [M(PCIH)$_2$] and [M(PCAH)$_2$] Complexes (M = Fe and Co): The ligand (HPCIH or HPCAH; 4 mmol) was dissolved in 50 mL of MeCN. Triethylamine (30 mmol) was added, followed by the perchlorate salt of the respective metal (1.6 mmol). The mixture was gently refluxed for 3 h and then concentrated to approximately one third of the original volume. The resulting precipitate was collected by vacuum filtration and washed with MeOH and then with distilled water. The Fe^{II} complexes were green and the Co^{II} complexes were deep purple. Yields of the first crops of compound were 75−80%.

[Mn(PCIH)$_2$]·H$_2$O: $C_{24}H_{20}MnN_8O_3$ (524.4): calcd. C 55.07, H 3.85, N 21.41; found C 54.97, H 3.42, N 21.38. IR: $\tilde{\nu}_{max}$ = 3070 w, 3023 w, 1607 s, 1591 s, 1568 s, 1497 vs, 1487 vs, 1460 vs, 1358 vs, 1308 s, 1150 s, 1068 vs, 782 w, 755 s and 699 s cm^{-1}.

[Fe(PCIH)$_2$]·0.5H$_2$O: $C_{24}H_{10}FeN_8O_{2.5}$ (515.3): calcd. C 55.94, H 3.72, N 21.74; found C 55.42, H 3.44, N 21.79. IR: $\tilde{\nu}_{max}$ = 3072 w, 3021 w, 1601 s, 1566 s, 1498 vs, 1482 vs, 1456 vs, 1362 vs, 1344 vs, 1308 s, 1151 s, 1063 vs, 784 w, 754 s and 700 s cm^{-1}.

[Co(PCIH)$_2$]: $C_{24}H_{18}CoN_8O_2$ (509.4): calcd. C 56.59, H 3.56, N 22.00; found C 56.67, H 3.53, N 22.03. IR: $\tilde{\nu}_{max}$ = 3014 w, 1604 s, 1567 s, 1484 vs, 1457 vs, 1359 vs, 1308 s, 1149 s, 1072 vs, 785 w, 755 s and 700 s cm^{-1}.

[Ni(PCIH)$_2$]·3H$_2$O: $C_{24}H_{24}N_8NiO_5$ (563.2): calcd. C 51.18, H 4.30, N 19.90; found C 51.57, H 3.82, N 19.78. IR: $\tilde{\nu}_{max}$ = 1609 vs, 1567 s, 1488 vs, 1460 vs, 1357 vs, 1153 s, 1312 s, 1153 s, 1078 vs, 784 w, 758 s and 701 s cm^{-1}.

[Cu(PCIH)$_2$]: $C_{24}H_{18}CuN_8O_2$ (514.0): calcd. C 56.08, H 3.53, N 21.80; found C 55.84, H 3.51, N 21.61. IR: $\tilde{\nu}_{max}$ = 3068 w, 3020 w, 1603 s, 1586 s, 1570 vs, 1519 vs, 1486 vs, 1458 vs, 1364 vs, 1351 vs, 1339 vs, 1306 vs, 1151 s, 1064 vs, 784 s, 754 s and 700 s cm^{-1}.

[Zn(PCIH)$_2$]·0.5H$_2$O: $C_{24}H_{19}N_8O_{2.5}Zn$ (524.9): calcd. C 54.92, H 3.65, N 21.35; found C 55.22, H 3.45, N 21.63. IR: $\tilde{\nu}_{max}$ = 3072 w, 3020 w, 1609 w, 1591 s, 1569 s, 1500 vs, 1486 vs, 1462 vs, 1355 vs, 1307 s, 1149 s, 1073 s, 784 s, 756 s and 700 s cm^{-1}.

[Mn(PCAH)$_2$]·H$_2$O: $C_{26}H_{24}MnN_8O_3$ (551.4): calcd. C 56.63, H 4.39, N 20.32; found C 56.42, H 4.41, N 19.99. IR $\tilde{\nu}_{max}$ = 3354 s, 3210 s, 2677 w, 1624 s, 1599 vs, 1551 w, 1484 s, 1456 s, 1421 s, 1354 vs, 1291 vs, 1174 vs, 1146 vs, 1102 s, 1070 vs, 914 w, 851 w, 767 s, 678 w, 637 s and 503 w cm^{-1}.

[Fe(PCAH)$_2$]·2.5H$_2$O: $C_{26}H_{27}N_8O_{4.5}Fe$ (579.4): calcd. C 53.90, H 4.70, N 19.34; found C 54.08, H 4.26, N 19.34. IR: $\tilde{\nu}_{max}$ = 3332 s, 3214 s, 1632 s, 1604 vs, 1560 w, 1472 s, 1448 s, 1411 s, 1363 vs, 1289 vs, 1175 vs, 1150 vs, 1110 s, 1068 vs, 846 w, 761 s, 681 w and 506 w cm^{-1}.

[Co(PCAH)$_2$]·H$_2$O: $C_{26}H_{24}$ Co N_8O_3 (555.5): calcd. C 56.22, H 4.35, N 20.17; found C 55.90, H 4.46, N 19.97. IR: $\tilde{\nu}_{max}$ = 3344 s, 3214 s, 1628 s, 1598 vs, 1548 w, 1482 s, 1456 s, 1420 s, 1354 vs, 1289 vs, 1175 vs, 1147 vs, 1105 s, 1079 vs, 847 w, 765 s, 679 w and 504 w cm^{-1}.

[Ni(PCAH)$_2$]·H$_2$O: $C_{26}H_{24}N_8NiO_3$ (555.3): calcd. C 56.24, H 4.36, N 20.18; found C 56.23, H 4.45, N 19.76. IR: $\tilde{\nu}_{max}$ = 3336 s, 3218 s, 1628 s, 1599 vs, 1552 w, 1485 vs, 1458 s, 1424 s, 1353 vs, 1339 vs, 1288 vs, 1174 vs, 1147 vs, 1107 s, 1083 vs, 847 w, 767 s, 679 w, 642 w and 504 w cm^{-1}.

[Cu(PCAH)$_2$]·H$_2$O: $C_{26}H_{24}CuN_8O_3$ (560.1): calcd. C 55.76, H 4.32, N 20.01; found C 55.61, H 4.40, N 19.63. IR: $\tilde{\nu}_{max}$ = 3329 s, 3212 s, 1628 w, 1598 vs, 1551 w, 1522 w, 1483 s, 1459 s, 1424 w, 1354 vs, 1337 vs, 1289 vs, 1174 vs, 1148 vs, 1104 s, 1075 s, 846 w, 766 s, 681 w, 622 w, and 505 w cm^{-1}.

[Zn(PCAH)$_2$]·H$_2$O: $C_{26}H_{24}N_8O_3Zn$ (561.9): calcd. C 55.58, H 4.30, N 19.94; found C 55.39, H 4.36, N 19.67. IR: $\tilde{\nu}_{max}$ = 3347 s, 3216 w, 1628 w, 1600 vs, 1553 w, 1521 w, 1487 s, 1460 s, 1426 w, 1354 vs, 1338 vs, 1289 vs, 1174 vs, 1147 vs, 1104 s, 1081 s, 851 w, 768 s, 680 w, 640 w and 504 w cm^{-1}. ^{1}H NMR ([D$_6$]DMSO): δ = 5.60 (s, 2 H), 6.50 (d, 2 H), 7.28 (m, 1 H), 7.64 (d, 1 H), 7.80 (d, 2 H), 7.91 (m, 2 H) and 8.55 (s, 1 H) ppm.

Crystals of [M(PCAH)$_2$]·H$_2$O (M = Mn, Ni, Cu, Zn) and [Cu(PCIH)$_2$]: The perchlorate salt of the respective metal (14 μmol) and the ligand (35 μmol; 1:2.5 ratio) were dissolved in 6 mL of MeCN/toluene (3:2) and 40 μL of Et_3N was added to the solution. The solutions were allowed to concentrate slowly and crystals suitable for X-ray work were formed. IR spectra of the crystals were found to be identical to the spectra of their respective counterparts in the bulk syntheses. Crystals of [Ni(PCIH)$_2$]·2H$_2$O were obtained from vapour diffusion of 2-propanol into a concentrated DMSO solution of the complex.

Trivalent and Oligomeric Complexes

[Co(PCIH)$_2$][CoCl$_3$]·2H$_2$O: HPCIH (0.5 g, 2 mmol) was dissolved in methanol (50 mL). $CoCl_2$·6H$_2$O (0.26 g, 1 mmol) was added to the solution and the mixture was refluxed for 16 h. Dichloromethane vapour diffusion into the concentrated reaction mixture afforded red-brown crystals suitable for X-ray work. Further crops were obtained from diethyl ether vapour diffusion into a concentrated methanolic solution of the solid. Total yield was 21%. $C_{24}H_{22}Cl_3Co_2N_8O_4$ (710.1): calcd. C 40.56, H 3.12, N 15.73; found C 40.45, H 3.02, N 15.87. IR: $\tilde{\nu}_{max}$ = 1618 s, 1484 vs, 1446 vs, 1380 vs, 1341 s, 1209 s, 1151 s, 1077 s, 848 w, 727 s and 606 s cm^{-1}.

[Co(HPCIH)(PCIH)](NO$_3$)$_2$·H$_2$O·0.5CH$_3$OH: HPCIH (0.5 g, 2 mmol) was dissolved in 50 mL of methanol. Co(NO$_3$)$_2$·6H$_2$O (0.32 g, 1.1 mmol) was added to the solution and the mixture gently refluxed for 16 h. A precipitate of the product formed on cooling and was collected and washed with diethyl ether. Diethyl ether vapour diffusion into a concentrated methanolic solution of the mother liquor afforded crystals suitable for X-ray work. More crystals were obtained from slow concentration of the mother liquor. Total yield was 16%. $C_{24.5}H_{23}CoN_{10}O_{9.5}$ (668.5): calcd. C 44.02, H 3.47, N 20.95; found C 44.10, H 3.40, N 21.07. IR: $\tilde{\nu}_{max}$ = 1636 s, 1540 s, 1483 s, 1448 vs, 1383 vs, 1208 s, 1148 s, 1078 s, 1000 w, 928 w, 844 w, 750 s, 716 s, 682 w and 607 w cm^{-1}.

[Co(HPCIH)$_2$](NO$_3$)$_3$·2H$_2$O: HPCIH (1.0 g, 4 mmol) was dissolved in 50 mL of methanol. Co(NO$_3$)$_2$·6H$_2$O (0.55 g, 2 mmol) was added to the solution and the mixture gently refluxed for 48 h. A precipitate of the product formed on cooling and was collected and washed with diethyl ether. Total yield was 81%. $C_{24}H_{26}CoN_{11}O_{13}$ (733.5): calcd. C 39.30, H 3.30, N 21.01; found C 39.36, H 2.94, N 21.02. IR: $\tilde{\nu}_{max}$ = 3063 s, 2526br, 1636 s, 1527 s, 1482 s, 1448 vs, 1384 vs, 1300 s, 1213 s, 1151 s, 1077 s, 1006 w, 930 w, 826 w, 749 s, 716 s, 682 w and 600 w cm^{-1}.

[Co(PCIH)$_2$]NO$_3$·2H$_2$O: Addition of 2 equiv. of Et_3N to an aqueous solution of [Co(HPCIH)$_2$](NO$_3$)$_3$·2H$_2$O resulted in immediate precipitation of the product, which was collected and washed with diethyl ether. Total yield was 75%. $C_{24}H_{22}CoN_9O_7$ (607.4): calcd. C 47.46, H 3.65, N 20.75; found C 47.52, H 3.42, N 20.73. IR: $\tilde{\nu}_{max}$ =1610 s, 1567 w, 1483 s, 1443 vs, 1384 vs, 1340 s, 1209 s, 1150 s, 1079 s, 927 w, 840 w, 780 w, 750 w, 713 s, and 607 w cm^{-1}.

[Co(PCAH)$_2$]Cl·4H$_2$O: HPCAH (0.5 g, 2 mmol) was dissolved in 50 mL of methanol. $CoCl_2$·6H$_2$O (0.23 g, 1 mmol) was added to the solution and the mixture was gently refluxed for 16 h. A red precipitate of the product formed on cooling. The solution was concentrated to approximately one third of the original volume and the precipitate collected and washed with cold methanol and then with distilled water. Total yield was 48%. $C_{26}H_{30}ClCoN_8O_6$ (645.0): calcd. C 48.42, H 4.69, N 17.37; found C 48.04, H 4.34, N 17.05. IR: $\tilde{\nu}_{max}$ = 3328 s, 3207 w, 1624 w, 1601 vs, 1559 w, 1522 w, 1479 s, 1451 s, 1374 vs, 1287 s, 1215 w, 1174 vs, 1148 s, 1079 s, 843 w, 758 w, 682 w, 636 w and 511 w cm^{-1}. ^{1}H NMR ([D$_6$]DMSO): δ = 6.14 (s, 2 H), 6.47 (d, 2 H), 7.39 (t, 1 H), 7.64 (d, 2 H), 7.85 (d, 1 H), 8.07 (m, 2 H) and 9.39 (s, 1 H). ^{13}C NMR ([D$_6$]DMSO): δ = 112.8, 116.2, 126.4, 127.7, 131.4, 141.8, 148.6, 151.6, 153.8, 160.7 and 184.0 ppm.

[{MnCl$_2$(DMSO)(HPCIH)}$_2$Mn(DMSO)$_2$Cl$_2$]: The preparation of [Mn(PCIH)$_2$] (described above) occasionally resulted in a product contaminated with small amounts of $MnCl_2$ as a co-precipitate. Dissolution of this crude compound in DMSO followed by vapour diffusion of 2-propanol into the mixture afforded yellow crystals suitable for X-ray work. [{MnCl$_2$(DMSO)(HPCIH)}$_2$Mn-

$(DMSO)_2Cl_2$]. $C_{32}H_{44}Cl_6Mn_3N_8O_6S_4$ (1142.5): calcd. C 33.64, H 3.88, N 9.81; found C 33.59, H 3.80, N 9.76.

[Zn(HPCIH)SO_4]·3.5H_2O: HPCIH (0.5 g, 2 mmol) was dissolved in 15 mL of methanol. Then $ZnSO_4·7H_2O$ (0.28 g, 1 mmol) was added to the solution and the mixture gently refluxed for 18 h. The mixture was cooled and a yellow precipitate of the product was collected and washed with diethyl ether. A small amount of the product was dissolved in minimum amount of acetonitrile/toluene (1:1) mixture. Slow concentration of the solution yielded crystals suitable for X-ray work. Total yield was 20%. $C_{12}H_{17}N_4O_{8.5}SZn$ (450.7): calcd. C 31.98, H 3.80, N 12.43; found C 32.10, H 3.60, N 12.37. IR: $\tilde{\nu}_{max}$ = 1684 vs, 1653 vs, 1575 vs, 1551 vs, 1472 s, 1433 s, 1406 s, 1361 s, 1298 vs, 1147 s, 1071 s, 926 s, 846 s, 781 s, 750 s and 686 vs cm^{-1}.

Crystallography: Cell constants were determined by a least-squares fit to the setting parameters of 25 independent reflections measured with an Enraf−Nonius CAD4 four-circle diffractometer employing graphite-monochromated Mo-K_α radiation. Data reduction, absorption correction (ψ-scans) and all calculations were performed with the WINGX suite of programs.[51] Structures were solved by direct methods for HPCAH, [Mn(PCAH)$_2$], [Ni(PCAH)$_2$], [Cu(PCAH)$_2$], [Zn(PCAH)$_2$] and [Cu(PCIH)$_2$] and Patterson methods for [Ni(PCIH)$_2$], [Co^{III}(PCIH)$_2$$Co^{II}Cl_3$] and [$Co^{III}$(HPCIH)(PCIH)]$NO_3$ with SHELXS,[52−54] and with SIR92 for [{$MnCl_2$(DMSO)(HPCIH)}$_2$Mn(DMSO)$_2$$Cl_2$] and [Zn(HPCIH)]$SO_4$.[55] Structures were refined by full-matrix least-squares analysis with SHELXL-97.[56] All non-H atoms were refined with anisotropic thermal parameters. Aryl and amino H-atoms were included at estimated positions whereas amide H-atoms (if any) were first located from difference maps then restrained in a similar manner to that employed for the remaining H-atoms. Crystal data appear in Tables 2 and 4 and selected bond lengths and angles are presented in Tables 3, Table 5 and 6. The atomic nomenclature is defined in Figures 2−8 and drawn with programs PLATON[57] and ORTEP-3.[58] CCDC-182551 to -182561 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

P. C. thanks the Department of Chemistry, University of Queensland for a departmental scholarship. P. V. B. acknowledges financial support from the University of Queensland. D. R. thanks the National Health and Medical Research Council for grant and fellowship support. We also thank Mr. K. Thurecht for assistance with the EPR spectral measurements.

New Rhenium(I) and Rhenium(II) Species Assembled by Stereospecific Azopyridine Chelation

Suman Sengupta,[a] Indranil Chakraborty,[a] and Animesh Chakravorty*[a,b]

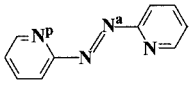
Keywords: Rhenium / N ligands / Chelates / Back-bonding / Isomer specificity

The spontaneous reaction of $[ReO(OEt)I_2(PPh_3)_2]$ with 2,2′-azobipyridine (L) in acetonitrile, and of $[ReOCl_3(PPh_3)_2]$ with L in toluene, proceeds stereospecifically furnishing the green tris-chelate $[Re^{I}L_3]I$ (**1**) and the red bis-chelate $[Re^{II}Cl_2L_2]$ (**2**), respectively. A structure determination reveals that the coordination geometry of **1** is facial and that of **2** is *cis*(Cl,Cl)-*trans*(N^p,N^p)-*cis*(N^a,N^a) (N^p is a pyridine nitrogen and N^a is an azo nitrogen). The isomer preference is exclusive in both cases and no other isomer has been observed. The average N–N distance in both compounds is about 1.35 Å, signifying the presence of strong d(Re)-π*(azo) back-bonding which plays a crucial role in controlling isomer specificity. The bis-chelate **2** is a one-electron paramagnet and displays a six-line EPR spectrum in fluid solution with g = 2.080 and A = 320 G. The ^{1}H NMR spectrum of diamagnetic **1** is consistent with the facial geometry. In acetonitrile solution **1** displays an Re^{II}/Re^{I} couple and **2** an Re^{III}/Re^{II} couple, the reduction potentials being 0.60 and 0.50V vs. SCE respectively. The violet-coloured imide complex $[Re^{V}Cl_3(NC_6H_4Cl\text{-}p)L]$ (**3**) is also reported; it displays an Re^{VI}/Re^{V} redox wave at 1.33 V vs. SCE. The stabilization of the lower rhenium oxidation states in **1** and **2** is consistent with the decrease of metal reduction potential with progressive L chelation.

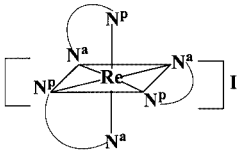
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

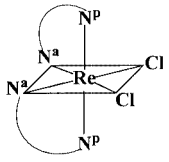
In the design of potential radiopharmaceuticals based on rhenium the higher oxidation states of the metal (especially +5) have commonly been employed, although lower states like +1 and +2 are now receiving increasing attention.[1,2] This has prompted us to investigate the synthesis and characterization of new rhenium(I) and rhenium(II) species. Herein we report the unprecedented rhenium coordination types $Re^{I}N_6$ and $Re^{II}Cl_2N_4$ in the form of **1** and **2**, respectively, assembled by 2,2′-azobipyridine (L) chelation. The compounds occur exclusively in a single geometrical form: facial in the case of **1** and *cis*(Cl,Cl)-*trans*(N^p,N^p)-*cis*-(N^a,N^a) in the case of **2**.



L



1



2

Results and Discussion

The reaction of $[ReO(OEt)I_2(PPh_3)_2]$ with excess L in boiling acetonitrile afforded the green tris-complex $[ReL_3]I$ (**1**). On the other hand a 1:2.5 mixture of $[ReOCl_3(PPh_3)_2]$ and L reacted in boiling toluene furnishing red coloured $[ReCl_2L_2]$ (**2**). The latter displays two Re−Cl stretches ($\tilde{\nu}$ = 320, 330 cm^{-1}) in the IR spectrum corresponding to the *cis*-$ReCl_2$ moiety and is paramagnetic (1.95 μB; t_{2g}^5, S = 1/2) displaying a six-line EPR spectrum (^{185}Re and ^{187}Re: I = 5/2)[3] in dichloromethane solution (300 K) with g = 2.080 and A = 320 G. The ^{1}H NMR spectrum of diamagnetic (t_{2g}^6) **1** is consistent with a facial geometry in which the three chelate rings are equivalent in solution.

The geometries of **1** and **2** have been authenticated by an X-ray structure determination. Molecular views are shown in Figure 1 and 2.

Careful chromatographic workup during the syntheses did not reveal the presence of the meridional isomer of **1** or of any of the other theoretically possible isomers (*cis-cis-cis, trans-cis-cis, cis-cis-trans*, and *trans-trans-trans*) of **2**. Bond length data provide a clue to this geometrical specifi-

city. The average Re−N^a and Re−N^p lengths are 1.98 and 2.11 Å in **1** and 2.00 and 2.06 Å in **2**. The average N−N length in both compounds is about 0.1 Å longer than the uncoordinated azo length (1.25 Å).[4] These data clearly underline the presence of strong d(Re)-π*(azo) back-bonding in **1** and **2**. In osmium(II) bis-chelates[5,6] of azoheterocyclic ligands related to L, the N−N length is shorter by about 0.04 Å than that in **2**, signifying the π-basicity order $Re^{II} > Os^{II}$.

The *cis* (as opposed to *trans*) disposition of the two N^a donor sites ensures lack of competition between them for the same metal d-orbitals, thus maximizing back-bonding. In facial $[ReL_3]^+$ three *cis* ReN^a pairs are present, representing a model situation for back-bonding. This geometry is, however, more crowded (aryl groups pendant from the same face) than the unobserved meridional form which has only two *cis* ReN^a pairs. It is proposed that the stronger back-bonding more than offsets the steric disadvantage of the facial geometry which alone becomes observable. As a π-base rhenium(I) is superior to isoelectronic osmium(II) and this has a dramatic geometrical consequence. Osmium(II) tris-chelates of 2-arylazopyridines (pendant pyridine ring of L replaced by, for example, phenyl) occur primarily in the meridional form.[5]

In the case of $[ReCl_2L_2]$ the *cis-trans-cis* form is sterically more favourable than the other two possible but unobserved isomers — *cis-cis-cis* and *trans-cis-cis* — with a *cis* ReN^a pair. In the case of azoheterocyclic bis-chelates of $M^{II}X_2$ (M = Ru,[7] Os;[5,6] X = Cl, Br) isomers have been isolated and these undergo spontaneous thermal conversion into the stable *cis-trans-cis* form.[8] The stability is more critically poised for $[ReCl_2L_2]$, which occurs only in the *cis-trans-cis* form **2**.

A comment on the redox stabilization of rhenium oxidation states by L is in order here. In acetonitrile solution the nearly reversible (peak-to-peak separation 70−80 mV)

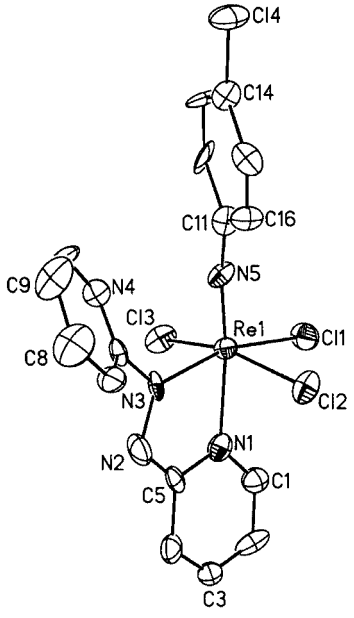

Figure 3. Perspective view and atom labeling scheme of $[ReCl_3(NC_6H_4Cl\text{-}p)L]$; all non-hydrogen atoms are represented by 30% thermal probability ellipsoids (hydrogen atoms are omitted for clarity) selected bond lengths [Å]: Re1−N5 1.72(2), Re1−N1 2.18(3), Re1−N3 2.00(2), Re1−Cl1 2.354(9), Re1−Cl2 2.386(9), Re1−Cl3 2.335(9), N2−N3 1.30(4)

cyclic voltammetric metal redox couples Re^{II}/Re^{I} in **1** and Re^{III}/Re^{II} in **2** have $E_{1/2}$ values of 0.60 and 0.50 V versus SCE respectively. No other metal redox couples are observed in the accessible potential window. On the other hand the rhenium(V) state has been realized in the violet-coloured imide complex $[ReCl_3(NC_6H_4Cl\text{-}p)L]$ (**3**; Figure 3) synthesized by reacting $[ReOCl_3(PPh_3)_2]$ with L in 1:1.5 ratio in the presence of excess $p\text{-}ClC_6H_4NH_2$.

It displays a single metal redox couple Re^{VI}/Re^{V} having an $E_{1/2}$ of 1.33V. Evidently the $E_{1/2}$ of a given Re^{n+1}/Re^{n} couple increases dramatically as the number of L chelate rings increase. The variation of this number along with coligand control provides an excellent handle for stabilizing various oxidation states of rhenium under ambient conditions. Monochelation stabilizes rhenium(V) as has also been documented for related azoheterocyclic ligands.[9,10] Tris- and bis-chelation are now shown to make the mono- and divalent states accessible in the form of **1** and **2**, respectively.

Conclusion

So far rhenium(I) compounds have been primarily known to involve[11,12] carbon monoxide, isocyanide and tertiary phosphane coordination. On the other hand, authentic mononuclear rhenium(II) compounds generally incorporate[11,13] nitrosyl/thionitrosyl and phosphane binding, with a few exceptions.[1,14] The $[ReL_3]I$ and $[ReCl_2L_2]$ chelates add a new dimension to compound types that can span the +1 and +2 oxidation states of rhenium.

Experimental Section

General: $[ReOCl_3(PPh_3)_2]$,[15] $[ReO(OEt)I_2(PPh_3)_2]$,[16] and 2,2′-azobipyridine[4] were prepared by reported methods. For electrochemical work HPLC-grade acetonitrile was used. All other chemical and solvents were of reagent grade and were used as received. Spectral measurements were made with the following equipment: IR (KBr disk), Perkin−Elmer 783 IR spectrometer; X-band EPR, Varian E-109C spectrometer. ^1H NMR, Bruker 300 MHz FT spectrometer (the proton numbering scheme used is the same as in crystallography and the assignments are based on chemical shifts, coupling constants and previous work[5]). The magnetic susceptibility was measured on a PAR 155 vibrating-sample magnetometer. Electrochemical measurements were performed under a nitrogen atmosphere using a PAR 370−4 electrochemistry system with platinum working electrode.[17] The supporting electrolyte was tetraethylammonium perchlorate (TEAP), and the potentials are referenced to the saturated calomel electrode (SCE) without junction correction.

Complex 1: L (107 mg, 0.582 mmol) was added to a solution of $[ReO(OEt)I_2(PPh_3)_2]$ (100 mg, 0.097 mmol) in acetonitrile (15 mL). The resulting mixture was heated to reflux for 3 h, affording a brownish green solution. The solvent was then removed under reduced pressure. The mass thus obtained was dissolved in a minimum amount of dichloromethane and subjected to chromatography on a silica gel column (20 × 1 cm, 60−120 mesh). A deep-green band was eluted out with a toluene/acetonitrile (1:1) mixture. Removal of solvent from the eluate gave $[ReL_3]I$ (**1**) in pure form. It was finally dried under vacuo over fused calcium chloride {**1:** 51 mg, 60% yield based on $[ReO(OEt)I_2(PPh_3)_2]$}. ^1H NMR (300 MHz, $CDCl_3$, 298 K): δ = 8.12 (d, J = 3.7 Hz, H1), 7.85 (complex multiplet, H2), 7.85 (complex multiplet, H3), 8.00 (d, J = 6.0, H4), 6.99 (d, J = 6.0, H7), 7.47 (t, J = 6.0, H8), 7.59 (t, J = 8.7, H9), 7.20 (d, J = 5.6, H10)

Complex 2: L (55.3 mg, 0.300 mmol) was added to a suspension of $[ReOCl_3(PPh_3)_2]$ (100 mg, 0.120 mmol) in toluene (25 mL). The resulting mixture was refluxed for 20 min affording a reddish solution. The solvent was then quickly removed under reduced pressure and the solid mass thus obtained was dissolved in a small amount of dichloromethane and subjected to chromatography in the same manner as mentioned above. A reddish orange band was eluted out with a toluene/acetonitrile (25:2) mixture. Solvent removal under reduced pressure afforded $[ReCl_2L_2]$ (**2**) in pure form which was dried under vacuo over fused calcium chloride {**2:** 49 mg, 65% yield based on $[ReOCl_3(PPh_3)_2]$}.

Complex 3: L (33 mg, 0.180 mmol) and *p*-chloroaniline (76 mg, 0.600 mmol) were added to a suspension of $[ReOCl_3(PPh_3)_2]$ (100 mg, 0.120 mmol) in toluene (25 mL). The mixture was heated to reflux for 2.5 h, affording a violet solution. The solvent was then removed under reduced pressure, and the mass thus obtained was subjected to chromatographic workup as before. Excess amine ($p\text{-}ClC_6H_4NH_2$) was eluted with toluene. A violet band was eluted with a toluene/acetonitrile (25:1) mixture. Solvent removal from the eluate under reduced pressure afforded $[ReCl_3(NC_6H_4Cl\text{-}p)L]$ (**3**) as a dark solid {**3:** 43 mg, 60% yield based on $[ReOCl_3(PPh_3)_2]$}.

Crystal Structure Determination: Single crystals of complexes **1**, **2** and **3** were grown by slow diffusion of hexane into dichloromethane solutions of the respective compounds. Data were collected on a Nicolet R3m/V four-circle diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) by the ω-scan technique in the range $3° \le 2\theta \le 47°$ for complexes **1** and **3** and $3° \le 2\theta \le 50°$ for **2**. All data were corrected for Lorentz-polarization and absorption.[18] The metal atoms were located from Patterson maps and the rest of the non-hydrogen atoms emerged from successive Fourier syntheses. The structures were then refined by a full-matrix least-squares procedure on F^2. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were included in calculated positions. Calculations were performed using the SHELXTL™ V 5.03 Program package.[19] In the structure of **3** there are two very similar but crystallographically independent molecules in the asymmetric unit. Figure 3 refers to molecule 1.

Crystal Data for 1: $C_{30}H_{24}IN_{12}Re$, monoclinic, *C*2/*c* (no. 15) a = 22.914(5), b = 13.236(3), c = 21.722(4) Å, β = 110.61(3)°, V = 6166(2) Å^3, Z = 8, Mo-K_α (λ = 0.71073 Å), 4589 unique reflections (R_{int} = 0.0360). Final residuals R_1 = 0.0391 and wR_2 = 0.0826 [$I > 2\sigma(I)$], 403 parameters.

Crystal Data for 2: $C_{20}H_{16}Cl_2N_8Re$, orthorhombic, *Pbcn* (no. 60), a = 19.190(9), b = 15.431(9), c = 15.062(14) Å, V = 4460(5) Å^3, Z = 8, Mo-K_α (λ = 0.71073 Å), 3937 unique reflections (R_{int} = 0.0338). Final residuals R_1 = 0.0603 and wR_2 = 0.1356 [$I > 2\sigma(I)$], 280 parameters.

Crystal Data for 3: $C_{16}H_{13}Cl_3N_5Re$, triclinic, $P\bar{1}$ (no. 2), a = 13.379(5), b = 13.652(5), c = 13.992(6) Å, α = 61.90(3), β = 65.44(3), γ = 66.12(3)°, V = 1980(1) Å^3, Z = 4, Mo-K_α (λ = 0.71073 Å), 5815 unique reflections (R_{int} = 0.0368). Final residuals R_1 = 0.0981 and wR_2 = 0.2232 [$I > 2\sigma(I)$], 464 parameters.

CCDC-192908 (**1**), -192909 (**2**) and -192910 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12,

Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44−1223/336−033; E-mail: deposit@ccdc.cam.ac.uk].

[Bis(oxazolinyl)pyrrole]palladium Complexes as Catalysts in Heck- and Suzuki-Type C−C Coupling Reactions

Clément Mazet[a] and Lutz H. Gade*[a]

Keywords: Catalysis / Helical structures / N ligands / Palladium / Suzuki reaction / Heck reaction

The two bis(oxazoline)pyrrole ligand precursors 2,5-bis(4,4′-dimethyl-4,5-dihydrooxazol-2-yl)pyrrole ("dmoxpH", **2**) and 2,5-bis(4,4′-dimethyl-4,5-dihydrooxazol-2-yl)-3,4-diethylpyrrole ("Et_2dmoxpH", **5**) have been synthesised and metallated by treatment with *n*-butyllithium at −78 °C in diethyl ether. Treatment of the lithium pyrrolide with 1.1 mol-equiv. of [$PdCl_2$(COD)] gave the corresponding helical dinuclear palladium complexes [Pd_2Cl_2(dmoxp)$_2$] (**6**) and [Pd_2Cl_2(Et_2dmoxp)$_2$] (**7**). In both complexes the tridentate bis(oxazolinyl)pyrrolide ligands bridge the two metal centres, with one of the oxazoline rings and the charged pyrrolide being coordinated to the one Pd centre while the second oxazoline ring is twisted relative to the pyrrolide unit and coordinates to the second palladium atom. Complexes **6** and **7** were found to be precursors for active catalysts for Heck coupling reactions of styrene and ethyl acrylate, with turnover numbers of over 9000 for the former, as well as for disubstituted alkenes such as methyl crotonate and methyl cinnamate. Complex **6** was found to be a very active catalyst for Suzuki coupling reactions of activated and deactivated bromoarenes.

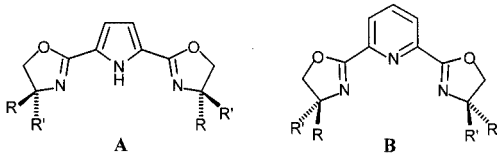
Introduction

In recent years, nitrogen donor ligands have increasingly been employed as ancillary ligands in molecular catalysis.[1] This is due to the great variety of synthetic strategies available. Nitrogen-based catalysts may generate catalytically active complexes complementary to the known phosphane-based systems. Oxazolines and their derivatives have been intensely studied in a wide range of applications, particularly in asymmetric catalysis.[2,3]



A

B

We recently began to develop the coordination chemistry of a new class of potentially tridentate, monoanionic N-donor ligands based on the combination of two oxazoline rings and a central pyrrole unit (**A**).[4] This class of compounds may be viewed as precursors to monoanionic analogues of the well-established family of pybox ligands (**B**), which have found widespread application in asymmetric catalysis in recent years.[5] The monoanionic charge of the deprotonated molecule and the more open structure of this derivative of the five-membered pyrrole ring in comparison with the ligands containing a central pyridine unit would be expected to result in somewhat different complex structures in comparison to pybox complexes. In a preliminary study of their coordination chemistry we discovered that the arrangement of its three N-donor atoms does not permit meridional tris(coordination) to a single metal centre.[4] This gives rise to dinuclear complexes that dissociate in solution only at higher temperatures.[6]

In this paper we report the synthesis of two achiral type **A** bis(oxazolinyl)pyrroles, one of which is alkyl-substituted in the 3- and 4-positions of the pyrrole ring, and the synthesis of two helical dinuclear palladium complexes. The principle focus was to assess their suitability as precursors for efficient catalytic C−C coupling reactions. To this end, a series of Heck and Suzuki coupling reactions were carried out as benchmark reactions in order to test these novel molecular systems.

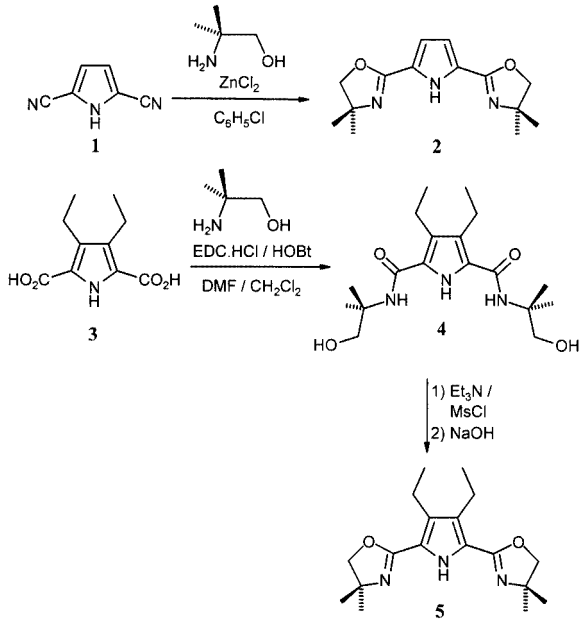
Results and Discussion

Synthesis of the Two Ligand Precursors 2,5-Bis[2-(4,4′-dimethyl-4,5-dihydrooxazolyl)]pyrrole ("dmoxpH", 2) and 2,5-Bis[2-(4,4′-dimethyl-4,5-dihydrooxazolyl)]-3,4-diethylpyrrole ("Et_2dmoxpH", 5)

As a starting material in the synthesis of 2,5-bis(4,4′-dimethyl-4,5-dihydrooxazol-2-yl)pyrrole ("dmoxpH", **2**) we chose pyrrole-2,5-dicarbonitrile (**1**), for which we had previously developed an efficient synthetic route.[6] Its cyclisation with two mol-equiv. of 2-amino-2-methyl-1-propanol was

[a] Laboratoire de Chimie Organométallique et de Catalyse, CNRS UMR 7513, Institut Le Bel, Université Louis Pasteur, 4, rue Blaise Pascal, 67070 Strasbourg, France

carried out by the method reported by Witte and Bolm.[7] Heating at reflux in chlorobenzene in the presence of 0.5 mol-equiv. of activated $ZnCl_2$ for 12 h gave crude **2**, which was purified by flash chromatography to give a cream-coloured solid. The formulation of compound **2** was confirmed by elemental analysis and mass spectrometry, while its ^1H, ^{13}C NMR and infrared spectra were consistent with the structure depicted in Scheme 1.

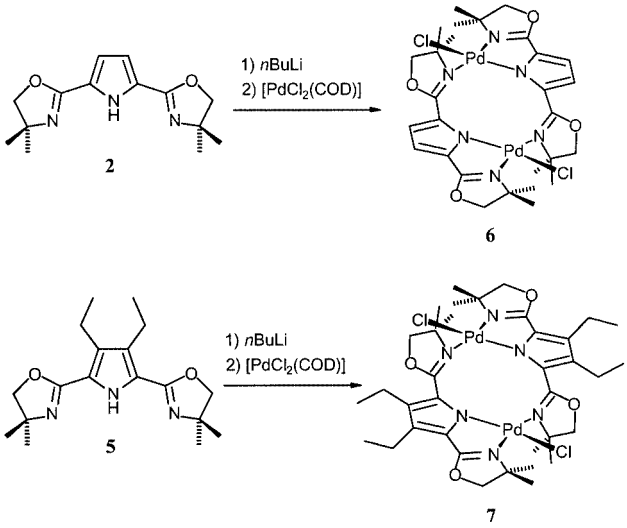


Scheme 1. Synthesis of the two bis(oxazolinyl)pyrroles **2** and **5**

The 3,4-diethylpyrrole analogue of **2**, 2,5-bis(4,4′-dimethyl-4,5-dihydrooxazol-2-yl)-3,4-diethylpyrrole ("Et_2dmoxpH", **5**) was synthesised in two steps, starting from the known 3,4-diethylpyrrole-2,5-dicarboxylic acid (**3**).[8] This has frequently been used as a starting material in porphyrin synthesis, and several efficient preparative procedures have been published in recent years.[9] The purpose behind the replacement of the central pyrrole ring by a diethylpyrrole unit was the variation of the donor capacity of the pyrrolide ligand, an approach previously pursued in oligopyrrole (notably porphyrin) chemistry.[9] In the first reaction step the dicarboxylic acid **3** was treated with 2.5 mol-equiv. of the amino alcohol in the presence of the well-established amide coupling reagent *N*′-[3-(dimethylamino)propyl]-*N*-ethylcarbodiimide (EDC·HCl) and 1-hydroxybenzotriazole (HOBt) (Scheme 1).[10] The diamide **4** was dimesylated and then cyclized in the presence of an excess of NaOH in methanol. After workup, the target compound **5** was obtained as a pale yellow oil, which was characterised by elemental analysis, mass spectrometry and infrared and ^1H and ^{13}C NMR spectroscopy.

Synthesis and Structural Characterisation of the Helical Dinuclear Palladium Complexes $[Pd_2Cl_2(dmoxp)_2]$ (6) and $[Pd_2Cl_2(Et_2dmoxp)_2]$ (7)

Deprotonation of the pyrrole rings in dmoxpH (**2**) and Et_2dmoxpH (**5**) with *n*-butyllithium at −78 °C in diethyl ether and subsequent stirring of the lithium pyrrolide with 1.1 mol-equiv. of $[PdCl_2(COD)]$ gave the corresponding palladium complexes $[Pd_2Cl_2(dmoxp)_2]$ (**6**) and $[Pd_2Cl_2(Et_2dmoxp)_2]$ (**7**) after chromatographic workup (Scheme 2).



Scheme 2. Synthesis of the helical dinuclear palladium complexes $[Pd_2Cl_2(dmoxp)_2]$ (**6**) and $[Pd_2Cl_2(Et_2dmoxp)_2]$ (**7**)

In order to establish their molecular structures, X-ray diffraction studies of both complexes **6** and **7** were carried out. Two views of their very similar molecular structures are depicted in Figures 1 and 2, together with the principal bond lengths and interbond angles.

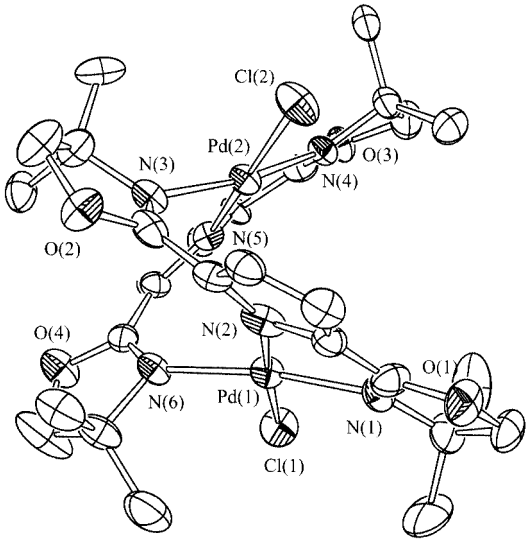


Figure 1. Molecular structure of the palladium complex $[Pd_2Cl_2(dmoxp)_2]$ (**6**); selected bond lengths [Å] and angles [°]: Pd(1)−N(1) 2.052(8), Pd(1)−N(2) 2.039(8), Pd(1)−N(6) 2.036(8), Pd(1)−Cl(1) 2.296(3), Pd(2)−Cl(2) 2.287(3), Pd(2)−N(3) 2.043(8), Pd(2)−N(4) 2.025(7), Pd(2)−N(5) 2.039(8); N(2)−Pd(1)−N(6) 97.7(3), N(1)−Pd(1)−N(2) 79.8(3), Cl(1)−Pd(1)−N(1) 96.5(2), N(3)−Pd(2)−N(5) 97.7(3), N(4)−Pd(2)−N(5) 79.9(3), N(2)−C(28)−C(8)−N(3) 29.3(5), N(5)−C(19)−C(22)−N(6) 26.4(5)

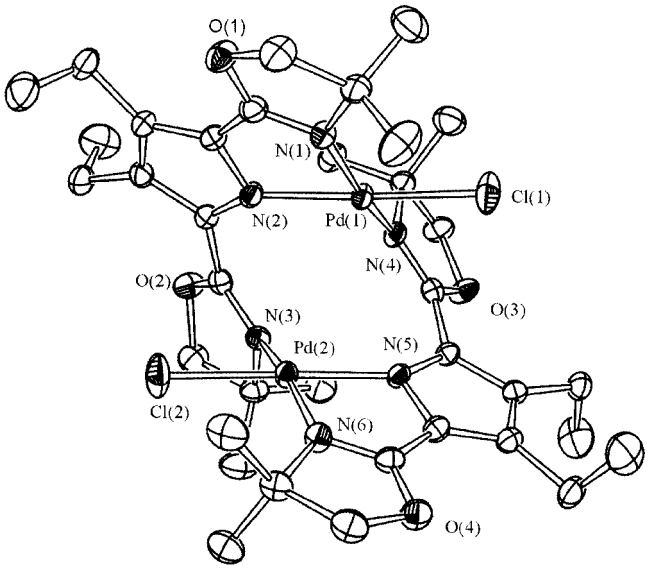

Figure 2. Molecular structure of the palladium complex $[Pd_2Cl_2(Et_2dmoxp)_2]$ (**7**); selected bond lengths [Å] and angles [°]: Pd(1)−N(1) 2.031(2), Pd(2)−N(3) 2.043(2), Pd(1)−Cl(1) 2.2922(7), Pd(1)−N(2) 2.036(2), Pd(2)−N(5) 2.031(2), Pd(2)−Cl(2) 2.0311(7), Pd(1)−N(4) 2.035(2), Pd(2)−N(6) 2.036(2); N(1)−Pd(1)−Cl(1) 94.94(6), N(6)−Pd(2)−Cl(2) 95.75(6), N(1)−Pd(1)−N(2) 80.01(8), N(3)−Pd(2)−N(5) 94.48(8), N(2)−Pd(1)−N(4) 96.80(8), N(5)−Pd(2)−N(6) 79.86(8), N(2)−C(7)−C(14)−N(3) 21.4(5), N(4)−C(21)−C(24)−N(5) 28.3(5)

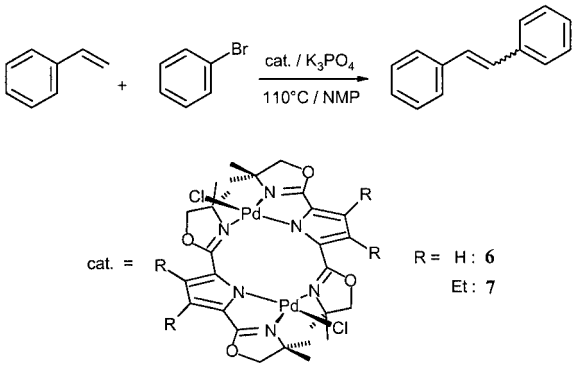
Both compounds **6** and **7** are dinuclear complexes in which the tridentate bis(oxazolinyl)pyrolide ligands bridge the two metal centres. Whereas one of the oxazoline rings and the charged pyrrolide are coordinated to the one Pd centre, adopting an almost coplanar arrangement, the second oxazoline ring is twisted relative to the pyrrolide unit [**6**: 26.4 and 29.3°; **7**: 21.4 and 28.3°] and coordinates to the second palladium atom. The coordination geometry at each metal centre is distorted square-planar, with the chloro ligand disposed *trans* to the pyrrolide. Although neither of the complexes **6** and **7** possesses exact crystallographic symmetry, both have an approximate twofold molecular symmetry axis relating the {Pd(ligand)Cl} fragments. Overall, the two bis(oxazolinyl)pyrrolide ligands are wrapped around the two metal centres to give helical arrangements,[11] with Pd−Pd distances of 3.389 and 3.426 Å for **6** and **7**, respectively. It is interesting to note that complex **6** crystallised in the polar space group *C*2 as a conglomerate of (*P*)- and (*M*)-helical enantiomers, although we were unable to separate them mechanically. For the solution of the crystal structure of **6** we selected by chance a crystal containing the (*M*) enantiomer, which is depicted in Figure 1.

The dimerisation of both **6** and **7** to give the helical dinuclear complexes implies the loss of all local symmetry elements at the metal centres. Only the two tridentate ligands as a whole are related by a twofold rotational axis. This loss in local symmetry is reflected in the signal patterns of the ^1H and ^{13}C NMR spectra of both compounds, in which all the ^1H and ^{13}C nuclei in the individual ligands are chemically inequivalent. Consistent with this reduced symmetry with respect to the ligand precursors **2** and **5** is the observation of two vibrational C=N bands for the two inequivalent oxazoline rings at 1632 and 1608 cm^{-1} for **6** and at 1622 and 1600 cm^{-1} for **7**.

Heck Coupling Reactions with Mono- and 1,2-Disubstituted Alkenes, Catalysed by $[Pd_2Cl_2(dmoxp)_2]$ (6) and $[Pd_2Cl_2(Et_2dmoxp)_2]$ (7)

Originally, Pd-catalysed Heck and Suzuki coupling reactions were based almost entirely on phosphane or phosphane-derived systems.[12] In recent years, however, a whole range of alternative ligand systems for this reaction has been successfully tested. These include *N*-heterocyclic carbenes,[13,14] N-, O- and S-containing palladacycles,[15,16] cyclometallated imines[17] and diazabutadienes[18] which act as mono- or polydentate ancillary ligands.

We tested the activities of compounds **6** and **7** in Heck coupling reactions. In an initial study, the reaction conditions (solvent, base, reaction temperature) were optimised for the reference reaction between bromobenzene and styrene, in the presence of 0.1 mol % of the catalyst precursor (Scheme 3). The best results were obtained at 110 °C in *N*-methylpyrrolidone with K_3PO_4 as a base, and these reaction conditions were chosen for all subsequent catalytic runs. It should be pointed out that the palladium catalysts were stable under these conditions throughout the conversions. Precipitation of "Pd-black", potentially due to the degradation of the molecular catalysts, was not observed in any case. The results of a comparative study with $[Pd_2Cl_2(dmoxp)_2]$ (**6**) and $[Pd_2Cl_2(Et_2dmoxp)_2]$ (**7**) are depicted in Table 1.



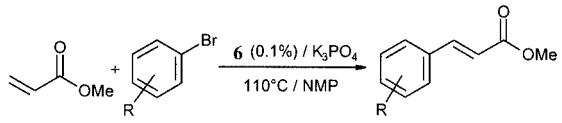
Scheme 3. Application of the palladium complexes $[Pd_2Cl_2(dmoxp)_2]$ (**6**) and $[Pd_2Cl_2(Et_2dmoxp)_2]$ (**7**) in the Heck reaction between bromobenzene and styrene

Table 1. Comparative study of the catalytic activities of catalysts **6** and **7** in the Heck reaction between bromobenzene and styrene

Entry	Catalyst	Cat./Sub.	Time	Conv. [(*Z*) + (*E*)]	T.O.N.
1	6	10^{-3}	3 d	97.1%	971
2	7	10^{-3}	3 d	96.6%	966
3	6	10^{-4}	3 d	87.3%	8730
4	7	10^{-4}	3 d	85.4%	8540
5	6	$5{\cdot}10^{-5}$	4 d	47.4%	9480
6	7	$5{\cdot}10^{-5}$	4 d	43.2%	8640

In general, there does not seem to be a significant difference in the catalytic performances of complexes **6** and **7**. A minimum catalyst/substrate ratio of $5 \cdot 10^{-5}$ was employed, and this, after 4 d reaction time at 110 °C, gave degrees of conversion to the product stilbene of 47 and 43%, respectively. The electronic effect expected from the introduction of the ethyl substituent on the pyrrolide ring[9] is not reflected in a modulation of the catalytic activity. It should be noted, though, that the turnover numbers of 9480 and 8640 place these catalysts among the most efficient systems containing exclusively nitrogen donor ligands.[19,20]

The results of the coupling of methyl acrylate with several substituted bromobenzene derivatives catalysed by compound **6** (Scheme 4) is shown in Table 2. The degree of conversion after a reaction time of 3 d was high and the stereoselectivity in favour of the (*E*) isomers essentially quantitative. In none of the cases did we observe traces of the geminally disubstituted coupling product.[21] No activity was observed for derivatives of chlorobenzene for the coupling either of styrene or of methyl acrylate.

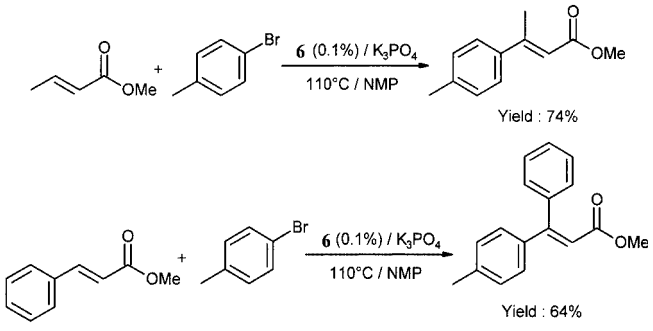


Scheme 4. Coupling of methyl acrylate with substituted bromobenzene derivatives

Table 2. Results of the Heck reactions between methyl methacrylate and substituted bromobenzene derivatives, catalysed by **6**

Entry	R	Time	Conversion	(*E*)/(*Z*)
1	2-Me	3 d	77%	100:0
2	4-Me	3 d	97%	100:0
3	4-OMe	3 d	85%	99:1

The use of the Heck coupling reaction for the synthesis of trisubstituted alkenes has received much less attention than the standard conversions affording disubstituted C=C double bonds.[20,22,23] We therefore carried out several tests to investigate the activity of **6** towards (*E*)-1,2-disubstituted alkenes. With a catalyst loading of 0.1 mol %, the reactions of methyl crotonate and methyl cinnamate with 4-bromotoluene gave the corresponding trisubstituted olefins after a reaction time of 7 d (Scheme 5).



Scheme 5. Heck reactions giving trisubstituted alkenes

The most remarkable aspect of these conversions is the complete stereoselectivity in the positioning of the entering aryl group in the reaction products. The configuration was established by NOESY experiments, NOEs between the α-olefin proton and the *ortho*-protons of the tolyl group providing the key assignment. It was not possible to detect any other stereoisomer even in trace quantities by GC, GCMS or by NMR spectroscopy. The exclusive formation of the (*E*) stereoisomers may be explained by the stereospecificity of the migratory insertion step resulting in the coupling of the olefin and the Pd-bonded aryl group and of the subsequent β-elimination step (Scheme 6).

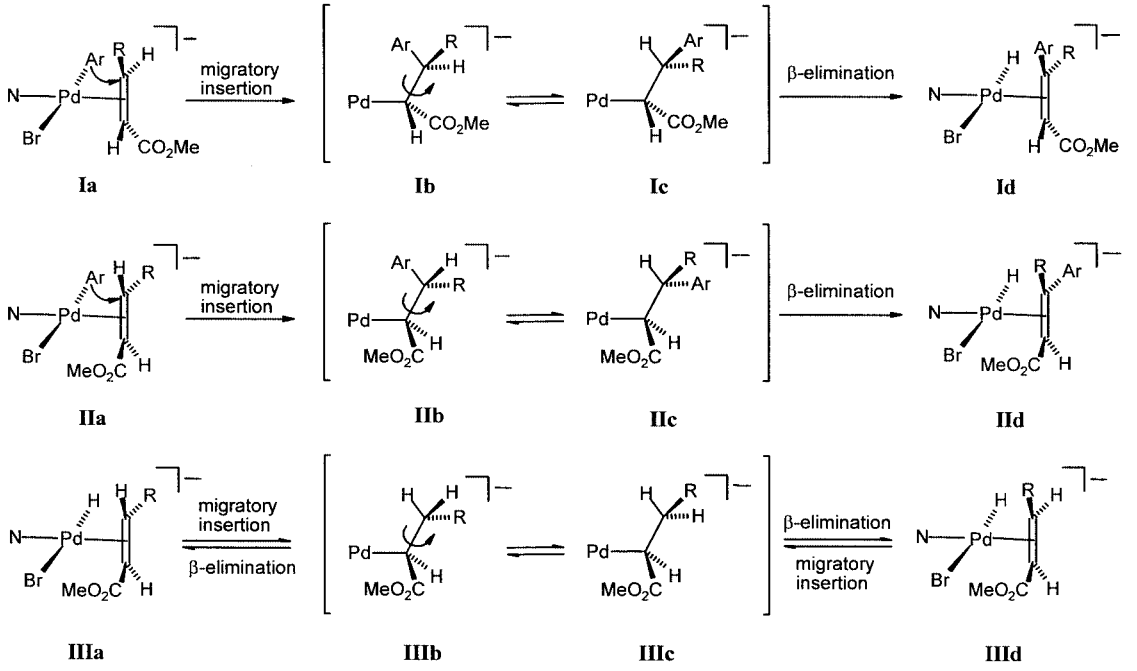
We have shown in a previous study that these dissociate in solution at temperatures above 70 °C,[6] and it is within this thermodynamic regime that their catalytic activities in Heck and Suzuki C−C coupling reactions have been observed. We therefore only consider monomeric species in the following mechanistic discussion. The *endo* approach of the aryl group in the intermediates **Ia** and **IIa** stereospecifically generates the alkyl complexes **Ib** and **IIb**, in which rotation around a C−C bond gives access to a conformation (**Ic** and **IIc**, respectively) in which the β-H is oriented towards the metal centre and from which β-elimination occurs. This gives the intermediates **Id** and **IId**, both of which liberate exclusively the (*E*) isomer.

Buchwald et al. have previously found a high degree of stereoselectivity in non-phosphane/palladium-catalysed Heck reactions of 1,2-substituted α,β-unsaturated carboxyl esters.[20] They also pointed out that the generally accepted mechanism of the catalytic Heck coupling implied a stereospecific reaction sequence as detailed above. The deviations from ideal stereoselection were interpreted as being due to an isomerisation of the configuration at the C=C double bond after the Heck coupling step. For the two cases described above we were unable to establish such an post-Heck equilibration, which may be due to the short lifetime of the hydridopalladium intermediate after decoordination of the product olefin. In fact, such a hydrido species may play a role either before or after the Heck reaction:

a) It may in principle coordinate the disubstituted alkene starting material (**IIIa** in Scheme 6), which is isomerised to the (*Z*)-1,2-disubstituted alkene in a sequence of migratory insertion and β-elimination (liberated from **IIId** in Scheme 6).

b) Alternatively, given a sufficient lifetime of the hydridopalladium complex, the reaction products liberated from **Id** and **IId** may recoordinate to the metal centre, and the migratory insertion into the Pd−H bond may then take place in part with a reversed regioselectivity (migration of the H atom to the C atom adjacent to the carboxyl function). A subsequent β-elimination from such an intermediate may indeed give the other isomer and, since all steps are reversible, the product distribution may be under thermodynamic control.

The fact that no isomerisation is observed in the case at hand even after the considerable reaction time of 7 d, necessary because of the low catalyst loadings of 0.1 mol %, indicates the short lifetime of the hydridopalladium species.

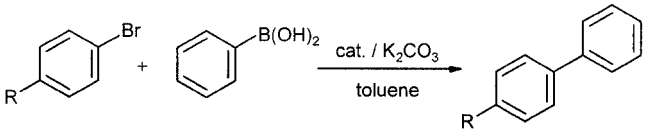


Scheme 6. Mechanistic scheme representing the stereospecific migratory insertion-β-elimination sequence in the Heck reaction involving 1,2-disubstituted alkenes

This may in part be due to the proximity of the relatively basic oxazoline functions attached to the pivotal pyrrolide ligand.

Suzuki Coupling Reactions Catalysed by $[Pd_2Cl_2(dmoxp)_2]$ (6)

Compound **6** was found to be a highly active catalyst for the Suzuki-type coupling of phenylboronic acid with aryl bromides at relatively moderate temperatures (Table 3). In the general procedure a catalyst/substrate ratio of 10^{-4} was used and the aryl bromide and phenylboronic acid were stirred at 70 °C in toluene in the presence of K_2CO_3 as auxiliary base.



Scheme 7. Suzuki coupling between bromobenzene derivatives and phenylboronic acid

As observed for the Heck-type coupling reactions discussed above, catalyst **6** was found to be highly stable under Suzuki coupling conditions, and no palladium-black was formed during the reaction. The catalytic reaction was monitored by GC MS, and 100% conversion was obtained with both activated and deactivated bromides after 1−6 h. A decrease in the catalyst/substrate ratio to 10^{-5} still gave an 82% isolated yield of 4-bromoacetophenone and 54% of 4-methoxyacetophenone after 4 h, corresponding to turnover numbers of 82000 and 54000, respectively. In contrast to the reactivity towards aryl bromides, the catalyst proved to possess only very low activity towards the aryl chlorides, the reaction effectively stopping after a few cycles at 110 °C. As in the case of the Heck coupling reactions discussed in the previous section, the use of the diethyl-substituted derivative $[Pd_2Cl_2(Et_2dmoxp)_2]$ (**7**) gave essentially identical results in the catalytic conversions.

Table 3. Results of the Suzuki reactions between phenylboronic acid and substituted bromobenzene derivatives, catalysed by **6**

Entry	R	Product	Time	Cat./Sub.	Temp.	Yield	T.O.N.
1	H		2 h	10^{-4}	70 °C	97 %	9700
2	CH_3		2 h	10^{-4}	70 °C	89 %	8900
3	$C(O)CH_3$		1 h	10^{-4}	70 °C	92 %	9200
4	$C(O)OCH_3$		4 h	10^{-4}	70° C	95 %	9500
5	OCH_3		6 h	10^{-4}	70 °C	88 %	8800
6	$C(O)OCH_3$		4 h	10^{-5}	110 °C	82 %	**82000**
7	OCH_3		4 h	10^{-5}	110 °C	54 %	**54000**

Conclusions

Through the charging and deformation of the well-established pybox ligand **B** systems by replacement of the central pyridine unit by a formally charged pyrrolide ring, the more open "pyrrbox" ligands **A** have been obtained. The specific arrangement of the three nitrogen donor functions in these has given rise to helical dinuclear complexes if coordinated

to palladium(II). Whereas their activity is lower than those found for some Pd complexes bearing phosphane or N-heterocyclic arene ligands, they are nevertheless among the most active catalysts containing exclusively nitrogen-donor ligands. The observation of the high stereoselectivity in the Heck reactions with 1,2-disubstituted alkenes described in this work is remarkable and has initiated a more systematic investigation into this aspect, currently underway in our laboratory.

Experimental Section

General: Solvents were dried by standard procedures and saturated with nitrogen. Solids were separated from suspensions by centrifugation, thus avoiding filtration procedures, with a Hettich Rotina 48 centrifuge equipped with a specifically designed Schlenk tube rotor (Hettich Zentrifugen, Tuttlingen, Germany).[24] Optical rotations were recorded with a thermostated Perkin−Elmer Otopol III instrument in a 1.0-dm cell. The ^1H and ^{13}C NMR spectra were recorded with Bruker AC 300 (^1H 300 MHz; $^{13}C\{^1H\}$ 75 MHz), Bruker AM 400 (^1H 400 MHz; $^{13}C\{^1H\}$ 100 MHz), and Bruker ARX 500 (^1H 500 MHz; $^{13}C\{^1H\}$ 125 MHz) spectrometers. Infrared spectra were recorded with a Perkin−Elmer 1600 FT-IR spectrometer. EI mass spectra were recorded with a Shimadzu QP5050-GC/MS system. The elemental analyses were carried out by the Service Commun de Microanalyse de l'Université Louis Pasteur at Strasbourg. Pyrrole-2,5-dicarbonitrile,[6] 3,4-diethylpyrrole-2,5-dicarboxylic acid[8] and $[PdCl_2(1,5\text{-}COD)]$[25] were prepared by published procedures. All other chemicals used as starting materials were obtained commercially and used as received without further purification.

Preparation of 2,5-Bis(4,4′-dimethyl-4,5-dihydrooxazol-2-yl)pyrrole ("dmoxpH", 2): $ZnCl_2$ (1.164 g, 8.54 mmol, 0.5 equiv.) was melted under vacuum and then cooled under nitrogen for 15 min. A slurry of pyrrole-2,5-dicarbonitrile (2 g, 17.6 mmol) and 2-amino-2-methyl-1-propanol (4.263 g, 47.82 mmol, 2.8 equiv.) in chlorobenzene (25 mL) was added, and the mixture was heated at reflux for 24 h. The solvent was removed in vacuo and the orange-brown residue was chromatographed on silica gel (hexanes/EtOAc, 1:1); R_f = 0.43, yielding 4.263 g of an off-white solid (yield 72%). ^1H NMR (300 MHz. $CDCl_3$): δ = 11.40 (br. s, 1 H, NH_{pyrr}), 6.71 (s, 2 H, $H_{3/4,pyrr}$), 4.05 (s, 4 H, $CH_{2,oxa}$), 1.34 (s, 12 H, $CH_{3,oxa}$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz. $CDCl_3$): δ = 155.6 ($C{=}N_{oxa}$), 123.0 (C-2/5$_{pyrr}$), 112.9 (C-3/4$_{pyrr}$), 79.0 ($CH_{2,oxa}$), 67.4 ($C_{quat,oxa}$), 28.2 ($CH_{3,oxa}$) ppm. IR (KBr): $\tilde{\nu}$ = 3436 (s), 2969 (m), 1660 (s), 1612 (m), 1499 (s), 1404 (m), 702 (m) cm^{-1}. MS (EI, 70 eV): *m*/*z* = 261 $[M]^+$, 246 $[M - CH_3]^+$, 174 $[M - CH_3 - (CH_3)_2CCH_2O]^+$. $C_{14}H_{19}N_3O_2$ (261.15): calcd. C 64.35, H 7.33, N 16.08; found C 63.89, H 7.25 N 15.99.

Preparation of Compound 4: A mixture of 3,4-diethylpyrrole-2,5-dicarboxylic acid (4.1 g, 19.4 mmol), amino alcohol (5.191 g, 58.2 mmol), EDC·HCl (11.164 g, 58.2 mmol), and HOBt (7.870 g, 58.2 mmol) in 75 mL of CH_2Cl_2 and 75 mL of DMF was stirred under nitrogen at room temperature for 48 h. The reaction mixture was poured into a saturated NH_4Cl/CH_2Cl_2 solution, and the aqueous layer was extracted with CH_2Cl_2. The combined organic layers were washed with 1 N HCl, water, saturated $NaHCO_3$ and brine, and then dried with anhydrous Na_2SO_4. After removal of the solvent, the product was isolated as a pale yellow oil (5.2 g, 14.7 mol, 77% yield). ^1H NMR (300 MHz, $CDCl_3$): δ = 10.4 (br. s, 1 H, NH_{pyrr}), 6.39 (s, 2 H, NH), 3.61 (s, 4 H, CH_2), 2.64 (q, 4 H, $CH_{2,pyrr}$), 1.38 (s, 12 H, CH_3), 1.20 (t, 6 H, $CH_{3,oxa}$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 162.1 (C-3/4$_{pyrr}$), 128.1 (C=O or C-2/5$_{pyrr}$), 123.9 (C-2/5$_{pyrr}$ or C=O), 69.9 (CH_2), 56.2 [*C*$(CH_3)_2$], 24.8 (CH_3), 17.9 ($CH_{2,pyrr}$), 15.8 ($CH_{3,pyrr}$) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 3423 (m), 2971 (s), 2253 (s), 1634 (s), 1516 (s), 1469 (s), 1301 (s), 1062 (m), 651 (s) cm^{-1}. $C_{18}H_{31}N_3O_4$ (353.23): calcd. C 61.17, H 8.84, N 11.89; found C 61.24, H 8.67 N 11.74.

Preparation of 2,5-Bis(4,4′-dimethyl-4,5-dihydrooxazol-2-yl)-3,4-diethylpyrrole ("Et$_2$dmoxpH", 5): MsCl (1.18 mL, 15.2 mmol) was slowly added to an ice-cold solution of **3** (2.440 g, 6.9 mmol) and Et_3N (3.30 mL, 30.4 mmol) in 20 mL of dichloromethane. The mixture was allowed to warm to room temperature and was then stirred for 1 h. After washing with water (5 mL), the organic phase was dried with Na_2SO_4, and the volatiles were removed in vacuo to give a yellow oil, which was used in the next step without purification. The bis(mesylated) compound was treated with KOH (0.4 g, 7.1 mmol) in 25 mL of an MeOH/H_2O mixture (5:1). The reaction mixture was stirred at room temperature for 3 d, then washed with water and dried with Na_2SO_4. The solvents were removed to give the ligand precursor as a pale yellow oil in 73% yield (1.6 g). ^1H NMR (300 MHz, $CDCl_3$): δ = 9.6 (br. s, 1 H, NH_{pyrr}), 4.24 (s, 4 H, $CH_{2,oxa}$), 2.70 (q, 4 H, $CH_{2,pyrr}$), 1.32 (s, 12 H, CH_3), 1.15 (t, 6 H, $CH_{3,oxa}$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 156.6 ($C{=}N_{oxa}$), 130.1 (C-2/5$_{pyrr}$), 118.6 (C-3/4$_{pyrr}$), 79.0 ($CH_{2,oxa}$), 66.9 [*C*$(CH_3)_2$], 28.2 (CH_3), 17.7 ($CH_{2,pyrr}$), 15.8 ($CH_{3,pyrr}$) ppm. IR ($CHCl_3$): $\tilde{\nu}$ = 3437 (m), 2969 (s), 1640 (s), 1461 (m), 1353 (m), 1305 (m), 1197 (m), 651 (s) cm^{-1}. MS (EI, 70 eV): *m*/*z* = 317 $[M]^+$, 302 $[M - CH_3]^+$, 160 $[M - 2\,CH_2CH_3]^+$. $C_{18}H_{27}N_3O_2$ (317.21): calcd. C 68.11, H 8.57, N 13.24; found C 68.02, H 8.52 N 13.15.

General Procedure for the Preparation of the Palladium Complexes [Pd$_2$Cl$_2$(dmoxp)$_2$] (6) and [Pd$_2$Cl$_2$(Et$_2$dmoxp)$_2$] (7): A solution of *n*BuLi (1.6 M) in hexanes (3.59 mL) was added to a diethyl ether (50 mL) solution of the bis(oxazolinyl)pyrrole (5.74 mmol), which was cooled to −78 °C. The reaction mixture was stirred for 15 min and then allowed to warm to room temperature. After an additional hour, a suspension of dichlorobis(1,5-cyclooctadiene)palladium (1.639 g; 5.74 mmol) in diethyl ether (20 mL) was added and the resulting mixture was stirred for 12 h at room temperature. The reaction mixture was then filtered and the resulting orange oil was purified by flash chromatography (silica gel, hexanes/EtOAc, 1:1) to give **6** (and **7**) as orange, air-stable solids.

[Pd$_2$Cl$_2$(dmoxp)$_2$] (6): Yield: 42%. R_f = 0.56. ^1H NMR (300 MHz, $CDCl_3$): δ = 6.64 (br. d, 2 H, 3/4-H_{pyrr}), 4.38 (d, 1 H, $CH_{2,oxa}$), 4.24 (t, 2 H, $CH_{2,oxa}$), 4.17 (d, 1 H, $CH_{2,oxa}$), 1.92 (s, 3 H, $CH_{3,oxa}$), 1.57 (s, 3 H, $CH_{3,oxa}$), 1.43 (s, 3 H, $CH_{3,oxa}$), 1.15 (s, 3 H, $CH_{3,oxa}$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$): δ = 167.8 ($C{=}N_{oxa}$), 164.9 ($C{=}N_{oxa}$), 133.1 (C-2/5$_{pyrr}$), 131.9 (C-5/2$_{pyrr}$), 117.1 (C-3/4$_{pyrr}$), 112.2 (C-3/4$_{pyrr}$), 83.2 ($CH_{2,oxa}$), 80.0 ($CH_{2,oxa}$), 67.9 [*C*$(CH_3)_2$], 65.9 [*C*$(CH_3)_2$], 30.4 ($CH_{3,oxa}$), 27.8 ($CH_{3,oxa}$), 27.5 ($CH_{3,oxa}$), 26.7 ($CH_{3,oxa}$) ppm. IR (KBr): $\tilde{\nu}$ = 2964, 1632, 1608, 1521, 1376, 721, 362 cm^{-1}. $C_{28}H_{38}Cl_2N_6O_5Pd_2$ (822.36): calcd. C 41.81, H 4.51; found C 41.95, H 4.73.

[Pd$_2$Cl$_2$(Et$_2$dmoxp)$_2$] (7): Yield 30%. R_f = 0.47. ^1H NMR (500 MHz, C_6D_6): δ = 3.72 (m, 3 H, $CH_{2,oxa}$), 3.52 (d, $^3J_{H,H}$ = 8.3 Hz, 1 H, $CH_{2,oxa}$), 2.92 (m, 1 H, $CH_{2,pyrr}$), 2.79 (m, 2 H, $CH_{2,pyrr}$), 2.68 (m, 1 H, $CH_{2,pyrr}$), 1.77 (s, 3 H, $CH_{3,oxa}$), 1.53 (s, 3 H, $CH_{3,oxa}$), 1.41(m, 6 H, $CH_{3,oxa}$ and $CH_{3,pyrr}$), 1.32 (t, $^3J_{H,H}$ = 8 Hz, 3 H, $CH_{3,pyrr}$), 1.04 (s, 3 H, $CH_{3,oxa}$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, C_6D_6): δ = 168.3 ($C{=}N_{oxa}$), 165.5 ($C{=}N_{oxa}$), 133.0 (C-2/5$_{pyrr}$), 131.1 (C-3/4$_{pyrr}$), 130.0 (C-3/4$_{pyrr}$), 128.4 (C-3/4$_{pyrr}$), 83.2

($CH_{2,oxa}$), 80.0 ($CH_{2,oxa}$), 67.4 [$C(CH_3)_2$], 65.2 [$C(CH_3)_2$], 31.0 ($CH_{3,oxa}$), 27.6 ($CH_{3,oxa}$), 27.4 ($CH_{3,oxa}$), 26.6 ($CH_{3,oxa}$), 18.8 ($CH_{2,pyrr}$), 17.9 ($CH_{2,pyrr}$), 17.3 ($CH_{3,pyrr}$), 17.2 ($CH_{3,pyrr}$) ppm. IR (KBr): $\tilde{\nu}$ = 2965 (m), 1622 (s), 1600 (s), 1519 (m), 1406 (s), 1189 (s), 1151 (s), 965 (m), 742 (m), 349 (w) cm^{-1}. $C_{36}H_{52}Cl_2N_6O_5Pd_2$ (914.15): calcd. C 47.17, H 5.72; found C 47.21, H 5.56.

General Procedure for the Heck Coupling Reactions: The aryl bromide (1.1 mmol), the olefinic substrate (1.0 mmol, 6.0 mmol in the case of methyl acrylate) and K_3PO_4 (1.1 mmol) were dissolved in 3 mL of dry NMP. The catalyst (or a solution of the catalyst) was then added the reaction mixture was purged three times with nitrogen and heated to 110 °C. The reaction was monitored by GCMS analysis until the generation of the product olefin had ceased. The (*Z*)/(*E*) ratio and the degree of conversion were determined by GC analysis.

General Procedure for the Heck Coupling Reactions with 1,2-Disubstituted Alkenes: The aryl bromide (1.1 mmol), the olefin (1.0 mmol) and K_3PO_4 (1.1 mmol) were dissolved in 3 mL of dry NMP. The catalyst (0.1%) was then added and the reaction mixture was purged three times with nitrogen and heated to 110 °C. When the reaction was complete, as determined by GCMS analysis, the reaction mixture was allowed to cool to room temperature, diluted with diethyl ether and washed three times with water. The organic layer was dried with $MgSO_4$ and concentrated in vacuo to give the crude product. Purification by flash chromatography (hexane 100%, then hexanes/EtOAc, 1:1) afforded the analytically pure alkene product.

General Procedure for the Suzuki Cross-Coupling Reactions: The arylboronic acid and K_2CO_3 (2 equiv.) were placed in a Schlenk tube equipped with a stirring bar. Three nitrogen/vacuum cycles were performed before addition of dry toluene (5 mL), the aryl bromide (1.1 equiv.) and the palladium catalyst (or a solution of the palladium catalyst). The reaction was performed at the temperature indicated in Table 3. On completion of the reaction, the mixture was diluted with Et_2O, filtered through a pad of Celite, washed three times with water, concentrated and purified by column chromatography or recrystallisation. All the products were characterised by standard spectroscopic and analytical methods. Their spectroscopic data are in agreement with those found in the literature.[26]

X-ray Crystallographic Study of 6 and 7: Suitable crystals of the complexes **6** and **7** were obtained by layering concentrated solutions of the compounds in dichloromethane with *n*-hexane and allowing slow diffusion at room temperature. The crystal data were collected at −100 °C with a Nonius Kappa CCD diffractometer and transferred to a DEC Alpha workstation; for all subsequent calculations the Nonius OpenMoleN package was used.[27] The structures were solved by direct methods with absorption corrections being part of the scaling procedure of the data reductions. After refinement of the heavy atoms, difference Fourier maps revealed the maxima of residual electron density close to the positions expected for the hydrogen atoms; they were introduced as fixed contributors in the structure factor calculations with fixed coordinates (C−H: 0.95 Å) and isotropic temperature factors [B(H) = 1.3 B_{equiv}(C) Å^2] but not refined. Full least-squares refinements on F^2. A final difference map revealed no significant maxima of electron density. The scattering factor coefficients and the anomalous dispersion coefficients were taken from ref.[28] Crystal data and experimental details for the crystals of compounds **6** and **7** are given in Table 4. CCDC-173019 (**6**) and -194957 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

The Synthesis and Structure of P−C−P Bridged Ferrocene

Igor Shevchenko,*[a] Dmitrii Shakhnin,[a] Hongming Zhang,[b] Michael Lattman,[b] and Gerd-Volker Röschenthaler[c]

Keywords: Sandwich complexes / Phosphane ligands / Asymmetry / Bridging ligands

The reaction of dilithioferrocene **12** with methylene-bis(dialkylaminochlorophosphanes) **13a,b** (**a** = CH_3, **b** = C_2H_5) leads to the formation of compounds **14a,b** in which the two cyclopentadiene rings are bridged by a P–C–P chain. Because of the cyclic structure, *cis*- and *trans*-isomerism is expected. The *cis*- and *trans*-isomers of the sulfur derivative **16b** have been separated by column chromatography.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Phosphane-substituted ferrocene derivatives have been intensively investigated in the last two decades. Particular attention was paid to the study of non-racemic ferrocene derivatives, as they have found wide application as ligands for catalysts of numerous asymmetric reactions. The chemistry of chiral ferrocene derivatives has been extensively reviewed up to 1997.[1−3]

The main method of synthesis of non-racemic ferrocene derivatives is based on the lithiation of *N*,*N*-dimethyl-1-ferrocenylethylamine (**1**; Scheme 1) followed by the addition of chlorophosphane **2**. This reaction can result in the formation of either the monophosphane **4** or the diphosphane derivative **5**.

The presence of the asymmetric substituent R* (*N*,*N*-dimethyl-1-ethylamine) at one of the rings brings about selective lithiation of the ring.

The bridging of dilithioferrocene **3** with methylene-bis(dichlorophosphane) **6** should give rise to isomerism caused by different positions of the substituents R at the phosphorus atom. Taking into account that one of the ferrocene rings bears the substituent R*, four isomers **7**−**10** are possible. These ligands may be useful in the design of asymmetric catalysts.

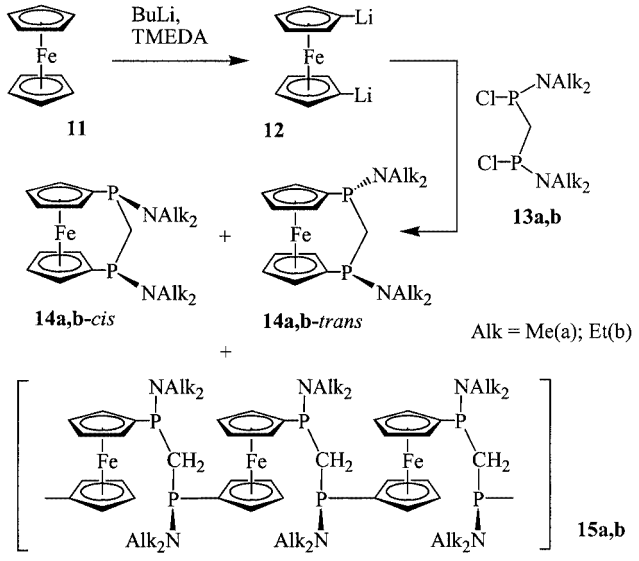
Results and Discussion

To the best of our knowledge, there are no examples in which two cyclopentadiene rings are bridged by a diphosphane unit. P-B bridged species are known[4] and a P-bridged derivative has also been reported.[5] In addition, there have been several P−N−P-bridged ferrocenes reported where the bridge is part of a cyclic triphosphazene.[6−9] For the first step of the proposed ap-

proach we have chosen a simple model, namely bridging of the unsubstituted ferrocene **11** with methylene-bis(dialkylaminochlorophosphanes) **13a,b** (**a** = CH_3, **b** = C_2H_5; Scheme 2). The dialkylamino-substituted chlorophosphanes **13a,b** are easier to synthesise than other methylene-bis(chlorophosphanes).



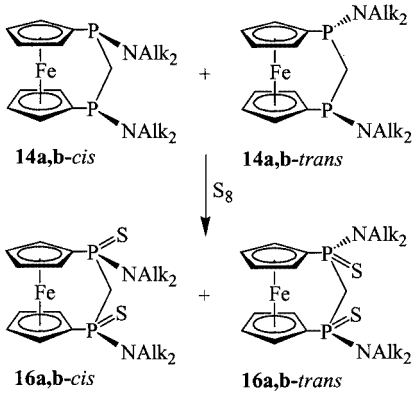
Scheme 2

The lithiation of both rings of the ferrocene **11** proceeds easily with *n*BuLi at room temperature, in the presence of TMEDA.[10] The dilithium derivative **12** crystallizes from the reaction mixture as a complex with TMEDA and can be isolated as dark-red crystals. This compound was immediately used for the reaction with **13a,b** in a solution of THF. The *cis*- and *trans*-isomers of the reaction products **14a,b** possess different spectral characteristics and show separate singlets in their ^{31}P NMR spectra. The presence of the two reaction centers in each starting compound led to the formation of oligomeric/polymeric by products. In their ^{31}P NMR spectra these compounds display broad signals with chemical shifts close to that of the respective monomers. Dilution of the reaction mixture and lowering of the temperature reduced the formation of these by products.

Both isomers were formed in approximately equal proportions (*cis*:*trans* = 45:55), and do not interconvert at room temperature. The differences in physical characteristics allowed the isomers to be separated. Unlike **14a,b-*trans***, the **14a,b-*cis*** isomers possess a more compact structure and crystallize more readily from the reaction mixture. The isolation of the pure *trans*-isomers in this manner was not possible as they crystallized together with the remaining *cis*-isomer. Unfortunately the purification of the **14a,b-*trans*** isomers by column chromatography was not possible either, as the P−N bond in trivalent phosphorus compounds is rather sensitive to moisture.

Compounds in which a plane of symmetry divides the P−P or P−C−P system into two equal parts display signals of substituents at the phosphorus atoms in the NMR spectra as an $AX_nA'X'_n$ spin system. Thus, PH- or PC-coupling may appear, not as doublets, but as pseudo-triplets. Recently, for example, we have noted this to be the case for carbodiphosphoranes.[11] ^{13}C NMR spectroscopic studies of **14a,b-*cis*** isomers revealed that the carbon atoms of the ferrocene cyclopentadienyl rings also appear as pseudo-triplets.

Compounds **14a**,**b** easily react with sulfur to give the sulfur derivatives **16a**,**b** quantitatively (Scheme 3). They are not sensitive to moisture and oxygen and can be used for the separation of *cis*- and *trans*-isomers by column chromatography. For separation purposes, the diethylamino derivative **16b** was chosen, as it is more soluble than **16a**.



Scheme 3

The detailed structure of compounds **14b-*cis*** (Figure 1), **16b-*cis*** (Figure 2) and **16b-*trans*** (Figure 3) have been determined by X-ray analysis. Selected bond lengths and angles are collected in Table 1. Both *cis* molecules have very similar Fe−Cp carbon distances with a spread of only 3 pm. The *trans* molecule shows a slightly greater spread of distances (5 pm). In all three derivatives, the Cp rings are planar with no carbon atom more than 0.5(5) pm from its mean plane. The Cp rings in each molecule are almost coplanar with "tilt" angles of 5.07(3)°, 2.9(3)°, and 3.1(5)° for **14b-*cis***, **16b-*cis*** and **16b-*trans***, respectively. In addition, one of the phosphorus atoms in each molecule lies somewhat more out of the Cp plane than does the other, with deviations from the mean Cp planes being P(1): 13(1), 3(1), 3(1) pm, and P(2): 6(1), 11(1), 17(1) pm for **14b-*cis***, **16b-*cis*** and **16b-*trans***, respectively. One important structural feature is the degree to which the Cp rings are staggered or eclipsed, since there is a variation in these molecules despite the fact that the rings are bridged by a P−C−P unit in each case. The C(11)-ring centroid-ring centroid-C(16) torsion angles are 3.0°, −7.6°, and −17.3°, for **14b-*cis***, **16b-*cis*** and **16b-*trans***, respectively. Thus, these molecules adopt more of an eclipsed, rather than a staggered, conformation; however, **16b-*trans*** is essentially halfway between the eclipsed and staggered geometries. These structures can be compared with the known Si−O−Si bridged ferrocenes $O(R_2SiCp)_2Fe$ (R = Me, Ph),[12] as well as the P−N−P phosphazene-bridged ferrocenes mentioned above.[6−9] All are similar in

structure with a slight trend towards increasing torsion angles (i.e., eclipsed to staggered) in the order P−N−P, P−C−P, Si−O−Si. This tendency may simply be due to crystal packing forces.[13]

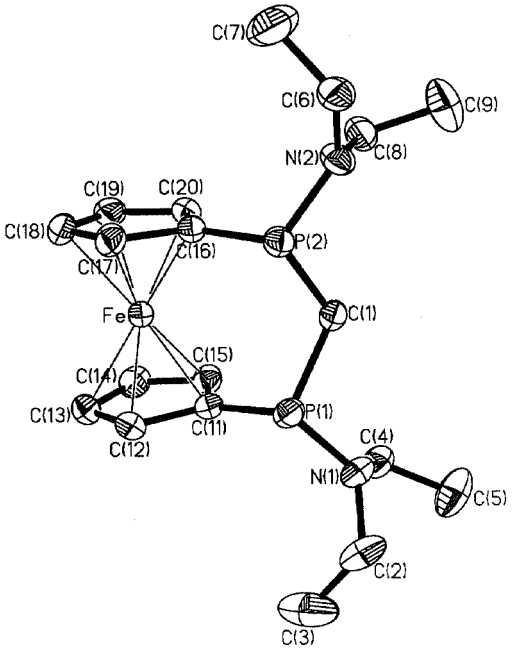


Figure 1. Perspective view and labeling scheme for the molecule **14b-*cis***

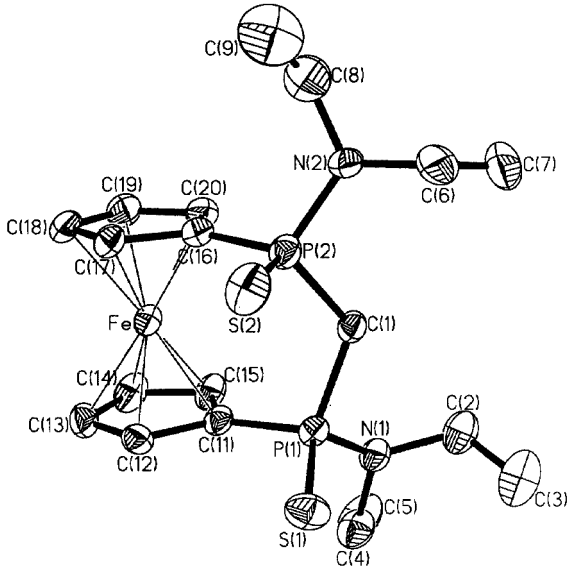

Figure 2. Perspective view and labeling scheme for the molecule **16b-*cis***

Finally, the P−C−P angle in these derivatives shows a large variation from the ideal tetrahedral angle of 107.9(1)° in **14b-*cis*** to 122.7(4)° in **16b-*trans***. Large variations in P−C−P-containing molecules have been observed before[14] and illustrate the ability of this unit to accommodate various geometrical constraints.

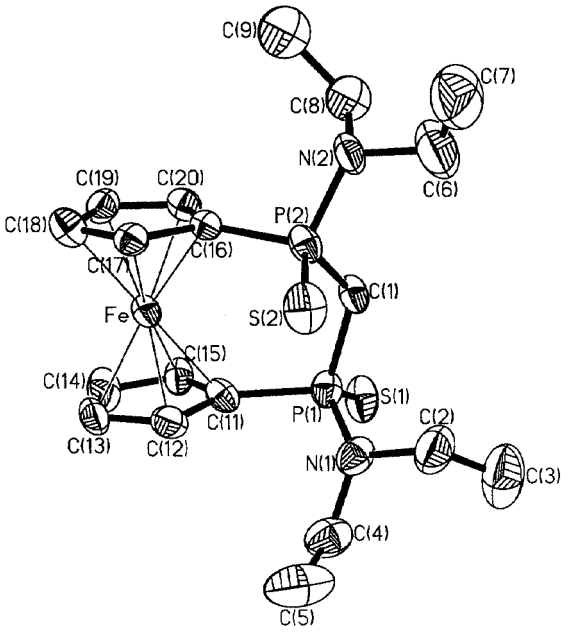

Figure 3. Perspective view and labeling scheme for the molecule **16b-*trans***

Experimental Section

General Remarks: All operations were performed under nitrogen in a dry box. The solvents were dried by the usual procedures. The NMR spectra were recorded with JEOL FX-90Q, Bruker DPX 200 and Bruker AMX 360 spectrometers. The ^{1}H and ^{13}C chemical shifts were referenced to tetramethylsilane (TMS). The ^{31}P chemical shifts were referenced to 85% aqueous orthophosphoric acid as an external standard. As usual, high frequency shifts are given positive signs. The digital resolutions were 0.25 Hz, 0.5 Hz and 1.25 Hz for the ^{1}H, ^{13}C and ^{31}P NMR spectra, respectively. Compounds **13a,b** were obtained from methylenebis(dichlorophosphane)[15] and *N*,*N*-dimethyl- or *N*,*N*-diethyltrimethylsilylamine in petroleum ether at 0 °C and isolated in 60% yield by distillation [b.p. 77−78 °C (**13a**), 108−110 °C (**13b**); 0.04 Torr].

Compound 12: Ferrocene (710 mg, 3.81 mmol) was dissolved in diethyl ether (12 mL) in a closed flask at 40 °C and, after cooling to room temperature, the solution obtained was added to a mixture of TMEDA (1.155 g; 9.96 mmol) and *n*BuLi (9.5 mmol of 1.6 M solution in hexane) in diethyl ether (6 mL). After 16 h the reaction mixture was decanted from the precipitated red crystals of **12** which were quickly dried under a stream of dry nitrogen (yield 1.180 g, 2.74 mmol, 72%) and immediately dissolved in THF (20 mL).

Compound 14a-*cis*: A freshly obtained solution of **12** (1.180 g, 2.74 mmol) in THF (20 mL) (see above) was cooled to −80 °C and a solution of **13a** (644 mg, 2.74 mmol) in THF (10 mL) was added to it in portions while stirring, keeping the temperature constant. The mixture was stirred at −80 °C for 20 min, then slowly warmed to −15 °C and left at this temperature overnight. The solvents were then evaporated in vacuo and the dry residue was extracted with petroleum ether (70−100 °C, 3 × 10 mL, boiling each portion for 1 min). The solvents were evaporated from the combined extracts in vacuo, the residue was re-extracted with boiling petroleum ether (70−100 °C, 5 mL) and the solution obtained was left at −15 °C. After 16 h, 130 mg of **14a-*cis*** contaminated with **14a-*trans*** was isol-

ated. The pure *cis*-isomer was obtained after recrystallization from dichloromethane/hexane at −15 °C. Yield 80 mg, (8.4%). M.p. 217−218 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.27 (dt, $^2J_{H,H}$ = 11.4, $^2J_{P,H}$ = 2.6 Hz, 1 H, P-CH_2-P), 4.18 (pseudo t, $^3J_{P,H}$ = 5.6 Hz, 12 H, NCH_3), 5.22 (dt, $^2J_{H,H}$ = 11.4, $^2J_{P,H}$ = 4.4 Hz, 1 H, P-CH_2-P), 5.67−5.81 [m, 2 H, Fe(Cpd$_2$)], 5.87−6.04 [m, 4 H, Fe(Cpd$_2$)], 6.09−6.24 [m, 2 H, Fe(Cpd$_2$)] ppm. ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 32.4 (t, $^1J_{P,C}$ = 17.56 Hz, 1 C, P-*C*-P), 41.6 (pseudo t, $^2J_{P,C}$ = 6.7 Hz, 4 C, NCH_3), 69.9 [pseudo t, $^2J_{P,C}$ = 5.8 Hz, 2 C, Fe(Cpd$_2$)], 70.1 [pseudo t, $^2J_{P,C}$ = 2.9 Hz, 2 C, Fe(Cpd$_2$)], 71.9 [s, 4 C, Fe(Cpd$_2$)], 77.1 [pseudo t, $^1J_{P,C}$ = 24.4 Hz, 2 C, Fe(Cpd$_2$)] ppm. ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 42.3 (s, 2 P, *P*-C-*P*) ppm. $C_{15}H_{22}FeN_2P_2$ (348.15): calcd. C 51.75, H 6.37; found C 50.78, H 6.27.

Compound 14b-*cis*: A freshly obtained solution of **12** (1.180 g, 2.74 mmol) in THF (20 mL) (see above) was cooled to −80 °C and a solution of **13b** (798 mg, 2.74 mmol) in THF (10 mL) was added to it in portions while stirring, keeping the temperature constant. The mixture was stirred at −80 °C for 20 min, then slowly warmed to −15 °C and left at this temperature overnight. The solvents were then evaporated in vacuo and the dry residue was extracted with hexane (5 × 15 mL, boiling each portion for 1 min). The combined extracts were evaporated in vacuo and the residue was dissolved in hexane (3 mL) at boiling and left at −15 °C for 48 h. Recrystallization was not needed as the *cis*:*trans* ratio was 98:2. Yield 234 mg, (21%). M.p. 113−116 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 0.98 (t, $^3J_{H,H}$ = 7.0 Hz, 12 H, NCH_2CH_3), 1.62 (dt, $^2J_{H,H}$ = 11.4, $^2J_{P,H}$ = 2.6 Hz, 1 H, P-CH_2-P), 2.8−3.3 (m, 8 H, NCH_2CH_3), 3.83

(dt, $^2J_{H,H}$ = 11.4, $^2J_{P,H}$ = 4.1 Hz, 1 H, P-CH_2-P), 4.1−4.2 [m, 2 H, Fe(Cpd_2)], 4.3−4.4 [m, 4 H, Fe(Cpd_2)], 4.5−4.7 [m, 2 H, Fe(Cpd_2)] ppm. ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 14.5 (pseudo t, $^3J_{P,C}$ = 2.0 Hz, 4 C, NCH_2CH_3), 35.5 (t, $^1J_{P,C}$ = 17.6 Hz, 1 C, P-*C*-P), 43.9 (pseudo t, $^2J_{P,C}$ = 6.8 Hz, 4 C, NCH_2CH_3), 69.3 [pseudo t, $^2J_{P,C}$ = 5.9 Hz, 2 C, Fe(Cpd_2)], 69.5 [pseudo t, $^2J_{P,C}$ = 3.0 Hz, 2 C, Fe(Cpd_2)], 71.4 [s, 2 C, Fe(Cpd_2)], 76.2 [pseudo t, $^1J_{P,C}$ = 25.4 Hz, 2 C, Fe(Cpd_2)], 81.0 [pseudo t, $^3J_{P,C}$ = 12.6 Hz, 2 C, Fe(Cpd_2)] ppm. ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 37.0 (s, 2 P, *P*-C-*P*) ppm. $C_{19}H_{30}FeN_2P_2$ (404.26): calcd. C 56.45, H 7.48, N 6.93; found C 55.86, H 7.48, N 6.74.

Compounds 16a,b-*cis*: Sulfur (20 mg, 0.63 mmol) was added to a solution of **14a-*cis*** or **14b-*cis*** (0.12 mmol) in dichloromethane (0.5 mL) and the reaction mixture was stirred at room temperature for 2 h. According to NMR spectroscopic data the reaction proceeds quantitatively. The reaction solution was diluted with hexane until it became turbid and left at −15 °C overnight. The crystalline product that formed was separated and dried in vacuo. Yield after crystallization 46−50%.

16a-*cis*: M.p. 230 °C (dec.). ^{1}H NMR (90 MHz, $CDCl_3$): δ = 2.47 (d, $^3J_{PH}$ = 15.5 Hz, 12 H, NCH_3), 3.36 (t, $^2J_{P,H}$ = 15.5 Hz, 1 H, P-CH_2-P), 3.38 (t, $^2J_{P,H}$ = 17.0 Hz, 1 H, P-CH_2-P), 4.38−4.54 [m, 4 H, Fe(Cpd_2)], 4.50−4.64 [m, 2 H, Fe(Cpd_2)], 5.01−5.17 [m, 2 H, Fe(Cpd_2)] ppm. ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 37.2 (s, 4 C, NCH_3), 44.2 (t, $^1J_{P,C}$ = 73.1 Hz, 1 C, P-*C*-P), 69.9−70.6 [m, 4 C, Fe(Cpd_2)], 71.8−72.7 [m, 2 C, Fe(Cpd_2)], 73.2−74.0 [m, 2 C, Fe(Cpd_2)], 77.3−78.3 [m, $^2J_{P,C}$ = 17.6 Hz, 2 C, Fe(Cpd_2)] ppm. ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 66.6 (s, 2 P, *P*-C-*P*) ppm. $C_{15}H_{22}FeN_2P_2S_2$ (412.27): calcd. C 43.70, H 5.38, N 6.80; found C 43.61, H 5.23, N 7.24.

16b-*cis*: M.p. 175−180 °C (dec.). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.06 (t, $^3J_{H,H}$ = 7.0 Hz, 12 H, NCH_2CH_3), 2.87−3.10 (m, 8 H, NCH_2CH_3), 3.20 (dt, $^2J_{H,H}$ = 13.8, $^2J_{P,H}$ = 17.1 Hz, 1 H, P-CH_2-P), 3.40 (q, $^2J_{H,H}$ = 13.8, $^2J_{P,H}$ = 13.8 Hz, 1 H, P-CH_2-P), 4.37−4.46 [m, 4 H, Fe(Cpd_2)], 4.47−4.55 [m, 2 H, Fe(Cpd_2)], 5.04−5.12 [m, 2 H, Fe(Cpd_2)] ppm. ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 14.5 (m, 4 C, NCH_2CH_3), 40.90 (m, 4 C, NCH_2CH_3), 44.32 (t, $^1J_{P,C}$ = 71.2 Hz, 1 C, P-*C*-P), 69.45−70.15 [m, 4 C, Fe(Cpd_2)], 71.65−72.38 [m, 2 C, Fe(Cpd_2)], 72.80−73.45 [m, 2 C, Fe(Cpd_2)], 77.65−78.55 [m, $^2J_{P,C}$ = 17.6 Hz, 2 C, Fe(Cpd_2)] ppm. ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 60.0 [s, 2 P, *P*-C-*P*) ppm. $C_{19}H_{30}FeN_2P_2S_2$ (468.38): calcd. C 48.72, H 6.46; found C 47.86, H 6.48.

Compound 16b-*trans*: An excess of sulfur (300 mg) was added to the mother liquor left after crystallization of **14b-*cis***, which contained about 970 mg of dissolved compounds (*cis*:*trans* = 15:85) (see above) and the mixture was stirred vigorously at room temperature for 12 h. The reaction mixture was dried in vacuo, dissolved in a minimum amount of dichloromethane and passed through a column with silica gel (45 g) using dichloromethane (about 1200 mL) as solvent. Fractions with R_f = 0.65 yielded 200 mg of **16b-*trans***. (R_f **16b-*cis*** = 0.45). M.p. 128−129 °C (dec.). ^{1}H NMR (90 MHz, $CDCl_3$): δ = 1.06 (t, $^3J_{H,H}$ = 7.1 Hz, 12 H, NCH_2CH_3), 2.91−3.40 (m, 8 H, NCH_2CH_3), 3.61 (t, $^2J_{P,H}$ = 14.6 Hz, 2 H, P-CH_2-P), 4.27−4.44 [m, 2 H, Fe(Cpd_2)], 4.44−4.60 [m, 2 H, Fe(Cpd_2)], 4.78−4.92 [m, 2 H, Fe(Cpd_2)], 4.92−5.07 [m, 2 H, Fe(Cpd_2)] ppm. ^{13}C NMR (22.5 MHz, $CDCl_3$): δ = 13.8 (pseudo t, $^3J_{P,C}$ = 2.4 Hz, 4 C, NCH_2CH_3), 40.3 (pseudo t, $^2J_{P,C}$ = 1.5 Hz, 4 C, NCH_2CH_3), 47.3 (t, $^1J_{P,C}$ = 61.4 Hz, 1 C, P-*C*-P), 71.9 [t, $^3J_{P,C}$ = 6.0 Hz, 4 C, Fe(Cpd_2)], 73.9 [t, $^2J_{P,C}$ = 4.8 Hz, 2 C, Fe(Cpd_2)], 74.8 [t, $^2J_{P,C}$ = 4.8 Hz, 2 C, Fe(Cpd_2)], 78.2 [m, $^2J_{P,C}$ = 8.3 Hz, 2 C, Fe(Cpd_2)] ppm. ^{31}P NMR (36.2 MHz, $CDCl_3$): δ = 62.2 (s, 2 P, *P*-C-*P*) ppm. $C_{19}H_{30}FeN_2P_2S_2$ (468.38): calcd. C 48.72, H 6.46; found C 48.16, H 6.41.

X-ray Crystallographic Study: Crystals of complexes **14b-*cis*, 16b-*cis*,** and **16b-*trans*** are all orange in color. The diffraction data of the three structures were collected on a Bruker P4 diffractometer. Diffraction data for **14b-*cis*** were collected at room temperature, while data for **16b-*cis*** and **16b-*trans*** were collected at −45 °C. The pertinent crystallographic data and conditions for data collection are summarized in Table 2. The data were corrected for Lorentz and polarization effects. ψ-Scan absorption studies were carried out

Hydrothermal Synthesis and Characterisation of Two Novel Large-Pore Framework Vanadium Silicates

Paula Brandão,[a] Anabela Valente,[a] Andreas Philippou,[b] Artur Ferreira,[c] Michael W. Anderson,[b] and João Rocha*[a]

Keywords: Microporous materials / Silicates / Vanadium / Catalysis / Hydrothermal synthesis

Two new large-pore sodium vanadium silicates, denoted AM-15 and AM-17 (Aveiro-Manchester, structures number 15 and 17) with framework composition $Na_6Si_{14}V_4O_{39}$ and $Na_4CaSi_{10}V_2O_{27}$, respectively, are reported. Electron paramagnetic resonance (EPR), Fourier transform infrared (FTIR) and diffuse reflectance ultraviolet-visible (DR UV/Vis) spectroscopy reveal that as-prepared AM-15 contains both V^{IV} and V^{V} in a square pyramidal and tetrahedral coordination, respectively, while AM-17 contains predominantly octahedral V^{IV}. The thermal stability of AM-15 in air is modest (ca. 380 °C), while AM-17 is stable up to 450 °C. The acid-base and redox properties of AM-17 have been assessed by the conversion of isopropanol and ethanol oxidation, respectively.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Microporous vanadium silicates are a new class of materials with potential for applications as selective heterogeneous catalysts for acid-catalysed and oxidation reactions.[1−3] In such systems, catalyst deactivation is a major issue, associated with reduced thermal stability and leaching phenomena.[4] As a result, much research has been carried out in order to prepare vanadium silicates with improved catalytic behaviour.[5−14]

In 1997 we reported the first example of a large-pore vanadium silicate containing stoichiometric amounts of hexacoordinate vanadium (Si/V = 5).[15] This material, dubbed AM-6, is a structural analogue of titanium silicate ETS-10, where titanium has been fully replaced by vanadium. ETS-10 has a framework consisting of "TiO_2" rods, which run in two orthogonal directions and are surrounded by tetrahedral silicate units. The pore structure consists of twelve-, seven-, five- and three-membered rings and has a three-dimensional channel system whose minimum diameter is defined by twelve-membered ring apertures.[16] Jacobson and co-workers reported two novel small-pore vanadium silicates $K_2(VO)(Si_4O_{10})\cdot H_2O$ (VSH-1) and $Cs_2(VO)(Si_6O_{14})\cdot 3H_2O$ (VSH-2), whose structures are closely related to the structures of cavansite and pentagonite.[17] Cavansite and pentagonite, dimorphs of the mineral $Ca(VO)(Si_4O_{10})\cdot 4H_2O$, are small-pore materials containing V^{IV} in a square-pyramidal coordination.[18,19] The framework of cavansite is formed by silicate layers of four- and eight-membered rings of tetrahedra connected vertically by V^{IV} cations. Calcium cations and water molecules reside in the channels formed by the eight-membered rings and between the SiO_2 layers. Cavansite has channels running parallel to the *c* direction with a free diameter of only 3.3 Å in the hydrated state. Recently, the same authors reported on a series of novel vanadium silicates with open-framework and microporous structures with general formula $A_r[(VO)_s(Si_2O_5)_p(SiO_2)_q]\cdot tH_2O$, where A is Na, K, Rb, Cs, or a combination of these metals.[20] Two other large-pore vanadium silicates, AM-13 and AM-14 with Si/V molar ratios of 4 and 10, respectively, have also been reported.[21] In the as-prepared samples, both V^{IV} and V^{V} occur simultaneously in different coordination environments. Like AM-6, AM-14 contains essentially hexacoordinate V^{IV}, while in AM-13 V^{IV} may be in a square-pyramidal coordination. The preparation of these two materials depends strongly on variables such as gel pH, cations present, time and temperature.[22] AM-13 requires a pH between 10.6 and 11.0 whereas AM-14 is obtained in the pH range 10.3−10.5. The AM-13 gel contains 60% Na and 40% Ca, whereas AM-14 crystallises in the presence of Na cations. Here we wish to report the synthesis and characterisation of two novel large-pore vanadium silicates, AM-15 and AM-17.

Results and Discussion

Powder XRD

The powder XRD patterns of AM-15 and AM-17 are shown in Figure 1 with the corresponding d-spacings and intensities listed in Table 1 and 2, respectively. The AM-15 cell is monoclinic with $a = 29.612$, $b = 17.892$, $c = 11.400$ Å, $\beta = 97.39°$ (volume 5990 Å^3). The most probable space group is $P2_1/n$ (no.14). The AM-17 cell is orthorhombic with $a = 37.712$, $b = 26.973$, $c = 16.456$ Å, (volume 16740 Å^3). The most probable space group is *Pba*2 (no. 32).

SEM and EDAX

SEM images of the AM-15 samples (Figure 2) reveal that the crystals consist of thin plates with a particle size of ca. 5 μm. EDAX analysis of different AM-15 crystals shows a similar molar composition: Si/V = 3.7, Na/V = 1.5. No other phases rich in silicon or vanadium were detected. Assuming that all vanadium is present as V^{IV} (which is probably not entirely correct, see below) the ideal formula of dehydrated AM-15 is $Na_6Si_{14}V_4O_{39}$. AM-17 crystals consist of plates with a size of ca. 1−2 μm, with the following molar ratios: Si/V = 4.4, Na/Ca = 2.9, Na/V = 1.0. The ideal formula of AM-17 is $Na_6Ca_2Si_{24}V_6O_{65}$, where all vanadium is assumed to be present as V^{IV}.

Thermal Analysis

The thermal stability of AM-15 and AM-17 was investigated using TGA/DSC in air, and variable temperature (25−650 °C) in-situ powder XRD in air and in vacuo. The AM-15 and AM-17 total mass loss between 30 and 600 °C is ca. 12.0% and 9.8%, respectively. DSC exhibits exothermic peaks centred at 380 °C (AM-15) and 450 °C (AM-17) probably due to the collapse of the crystalline structure (Figure 3). When calcined in vacuo, both materials retain their structural integrity up to about 600 °C (not shown). Upon calcination in air at temperatures of ca. 400 °C the structure of AM-15 collapses, while AM-17 is stable until ca. 450 °C (Figure 4).

Adsorption Measurements

Nitrogen adsorption isotherms are of type I, with a slight upward distortion (Figure 5), suggesting that microporosity (pore width < 2 nm, according to IUPAC) is associated with significant external surface area. These vanadium silicates have similar specific surface areas (330−380 m^2/g) and micropore volumes (0.1−0.13 cm^3/g; Table 3). A narrow pore-size distribution with median pore width of 8 and 7.3 Å is obtained for AM-15 and AM-17, respectively. Both materials adsorb benzene, *m*-xylene and mesitylene and the sorption capacities (taken at $p/p_0 \approx 0.4$) decrease with increasing size of the diffusing molecule (molecular dimension in brackets): benzene (6.8 Å) > *m*-xylene (7.4 Å) > mesitylene (8.4 Å; Table 4). The above results suggest that AM-15 and AM-17 have large accessible pores with a width of 7−8 Å.

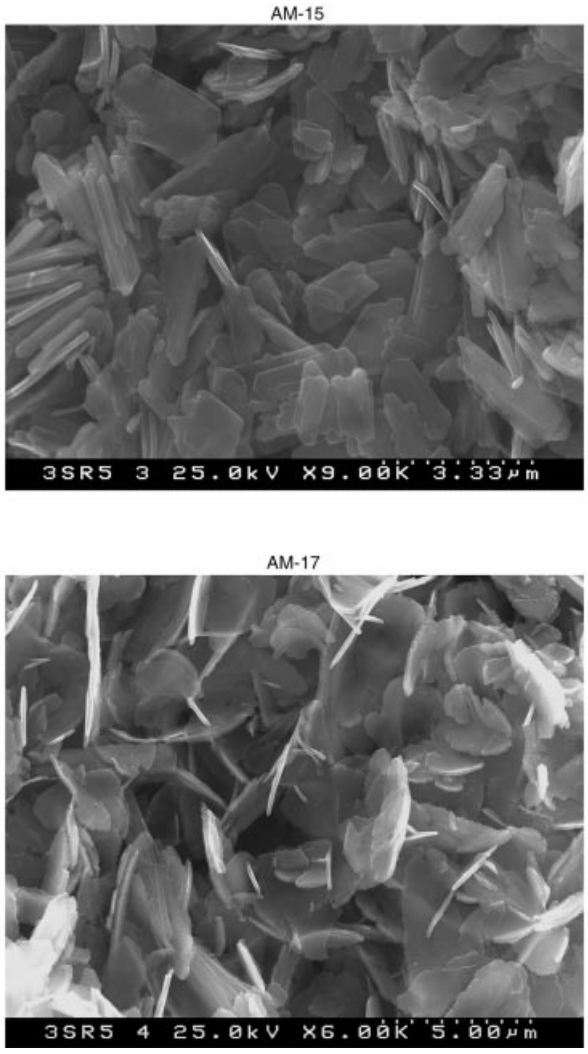

Figure 2. SEM images of AM-15 and AM-17

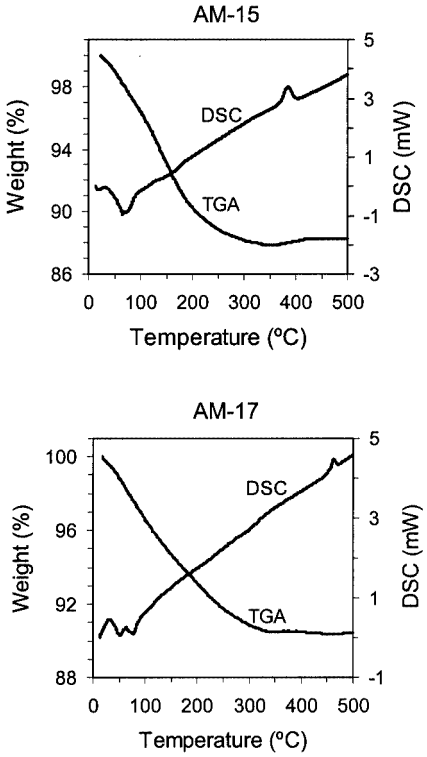

Figure 3. TGA and DSC curves of AM-15 and AM-17, recorded in air

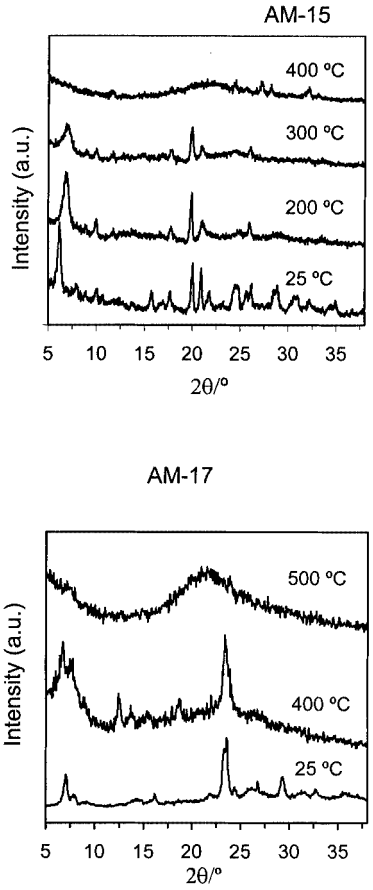

Figure 4. Powder XRD patterns of AM-15 and AM-17, recorded in situ at different temperatures in air

Electron Paramagnetic Resonance

The oxidation state of vanadium atoms in as-synthesised AM-15 and AM-17 was studied by EPR spectroscopy at room temperature. The spectra of AM-15 and AM-17 display a broad signal centred at $g = 2.357$ and 2.415, respectively (Figure 6). No hyperfine structure is observed, indicating the presence of (nonisolated) V^{IV} dipolar-coupled to other V^{IV} ions.

Fourier Transform Infrared Spectroscopy

FTIR spectra of AM-15, AM-17 and, for comparison, AM-6 and crystalline V_2O_5 (Aldrich) are shown in Figure 7. Since the characteristic FTIR bands at $\tilde{\nu} = 838$ and 605 cm^{-1} are not observed, the presence of crystalline V_2O_5 in AM-15 and AM-17 is ruled out. The band at $\tilde{\nu} = 872$ cm^{-1} in the spectrum of AM-6 is ascribed to V^{IV} in an octahedral coordination. The IR absorption spectrum of AM-17 shows a small band at $\tilde{\nu} = 887$ cm^{-1} which, by comparison with

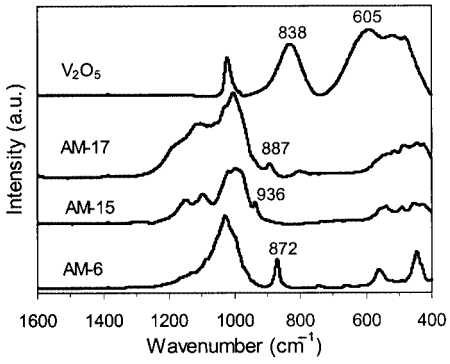

Figure 7. FTIR absorption spectra of AM-15, AM-17, AM-6 and V_2O_5

AM-6, is assigned to hexacoordinate V^{IV}. The AM-15 band at $\tilde{\nu} = 936\ cm^{-1}$ indicates the presence of V=O bonds, which usually give bands in the region $\tilde{\nu} = 900-1000\ cm^{-1}$.[23] No band is observed in the range of octahedral V^{IV}.

Diffuse-Reflectance UV/Visible Spectroscopy

Additional structural information on vanadium coordination may be obtained by DR UV/Vis spectroscopy. AM-6 is used as a DR UV/Vis reference compound, since it contains hexacoordinate V^{IV}. All samples exhibit broad bands at about 600, 435, and 220−270 nm (Figure 8). Charge transfer (CT) associated with O to V^{IV} electron transfer occurs in the range 220−270 nm.[10,24] The bands at 600 and 435 nm are assigned to V^{IV} d-d transitions and are responsible for the green colour of the solids. These observations suggest that both vanadium silicates contain V^{IV}. However, AM-15 gives a band at 340 nm, which is absent from the AM-6 and AM-17 spectra. In general, the spectra of materials containing V^{V} ions exhibit CT absorption bands in the region 280−340 nm.[9,25] Therefore, the AM-15 UV band observed in this region may be ascribed to the presence of tetrahedral V^{V}. Combining the DR UV/Vis and FTIR evidence, we propose that in AM-15 V^{IV} and V^{V} may be in a square pyramidal and tetrahedral coordination, respectively, while AM-17 contains essentially hexacoordinate V^{IV}.

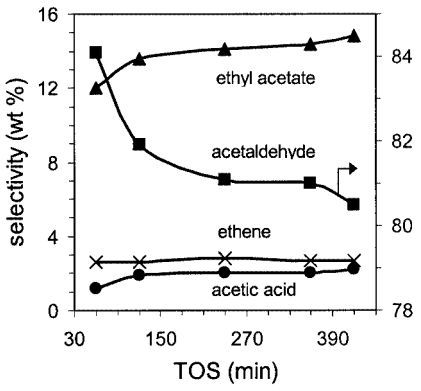

Figure 9. Effect of TOS on the products distribution of ethanol oxidation (T = 300 °C; WHSV = 0.4 h^{-1}), over AM-17

Catalytic Tests

Given the modest thermal stability of AM-15 the catalytic reactions in the gas phase were carried out over AM-17.

Isopropanol Conversion

A preliminary characterisation of the acid-base properties of AM-17 was performed by means of 2-propanol conversion, a probe reaction which is tailored for both acidity and basicity.[26] AM-17 yields mainly acetone, resulting from base-catalysed dehydrogenation of 2-propanol, whereas propene, formed by acid-catalysed dehydration, was produced in smaller amounts (Table 5). These results point to the basic character of AM-17.

Ethanol Oxidation

The oxidation activity of AM-17 was studied using the oxidation of ethanol with air as a model reaction.[27] The catalytic results obtained at 300 °C are shown in Table 5. AM-17 yields mainly acetaldehyde (84.1% selectivity at 23.7% conversion) and ethyl acetate (12% selectivity), along with minor amounts of ethene and acetic acid. Acetaldehyde is formed in the dehydrogenation process. As seen in Figure 9, long times on stream (TOS) favour the formation of ethyl acetate at the expense of acetaldehyde. The consecutive reaction of acetaldehyde with ethanol and oxygen produces ethyl acetate.[28,29] AM-17 possesses little dehydration activity in this process, evidenced by the formation of minor amounts of ethene (2.3% selectivity). After the catalytic tests, AM-17 was characterised by powder XRD, and the results show 21% crystallinity loss. The above results indicate that AM-17 is a basic solid with potential in redox catalysis.

Acetic acid	–	1.2

[a] $T_{reaction}$ = 350 °C; TOS = 60 min; WHSV = 2 h^{-1}; carrier gas: argon. [b] $T_{reaction}$ = 300 °C; TOS = 60 min; WHSV = 0.4 h^{-1}; carrier gas: air.

Conclusions

Two novel large-pore sodium vanadium silicates, AM-15 and AM-17, with approximate framework compositions $Na_6Si_{14}V_4O_{39}$ and $Na_6Ca_2Si_{24}V_6O_{65}$, respectively, have been prepared hydrothermally. Spectroscopic techniques suggest that as-synthesised AM-15 contains both square pyramidal V^{IV} and tetrahedral V^{V}, whereas V^{IV} in AM-17 assumes octahedral coordination. The latter is an interesting catalyst for dehydrogenation reactions.

Experimental Section

Synthesis: The synthesis of AM-15 and AM-17 was carried out in Teflon-lined autoclaves under static hydrothermal conditions.

Synthesis of AM-15. An alkaline solution was made by mixing 5.08 g of sodium silicate solution (Na_2O 8 wt%, SiO_2 27 wt%, Merck), 8.27 g of H_2O and 0.55 g of NaOH (Merck). A second solution was made by mixing 7.61 g of H_2O with 1.02 g of $VOSO_4 \cdot 5H_2O$ (Merck). These two solutions were combined and stirred thoroughly.

Synthesis of AM-17. An alkaline solution was made by mixing 5.01 g of sodium silicate solution (Merck), 10.35 g of H_2O, and 0.10 g of $Ca(OH)_2$ (Aldrich). A second solution was made by mixing 5.53 g of H_2O with 1.00 g of $VOSO_4 \cdot 5H_2O$ (Merck). The AM-15 gel with a composition $6.7Na_2O{:}11.4SiO_2{:}V_2O_5{:}441H_2O$, and the AM-17 gel with a composition $3.3Na_2O{:}0.7CaO{:}11.3SiO_2{:}V_2O_5{:}441H_2O$, were autoclaved for three days at 230 °C. The crystalline powders were filtered off, washed and dried at room temperature.

Catalytic Tests: The catalytic reactions were carried out at atmospheric pressure in a fixed-bed stainless-steel reactor (height = 16 cm, internal diameter = 0.5 cm), which was charged with 50 mg

of catalyst. Prior to reaction, the catalyst was activated at 350 °C in a flow of argon (10 mL/min) for 2-propanol conversion or in a flow of air (2 mL/min) for ethanol oxidation. The reactant was fed using a syringe pump and mixed with the flowing gas before entering the reactor tube. The products were analysed by gas chromatography with a 30-metre long capillary column (DP1 fused silica phase) and an FID (flame ionisation detector).

Techniques: Powder XRD data were collected on an X'Pert MPD Philips diffractometer (CuK_α X-radiation) with a curved graphite monochromator, a fixed divergence slit (0.5°, irradiated length 10.00 mm), a progressive receiving slit (slit's height 0.2 mm) and a flat-plate sample holder, in a Bragg−Brentano para-focusing optics configuration. Intensity data were collected by the step counting method, step 0.02°, time 120 (AM-17) and 64 s (AM-15) in the 2θ range 3−40°. X-ray diffraction pattern auto-indexing was performed with DICVOL[30] from the resolved first 22 lines and checked with the Chekcell package.[31]

SEM images were recorded on a Hitachi S-4100 Field Emission Gun tungsten filament working with a voltage of 25000 V. Chemical composition was determined by energy dispersive analysis of X-rays (EDAX). TGA and DSC curves were measured with TGA-50 and DSC Shimadzu analysers. Samples were heated under air with a rate of 2 °C/min. Variable temperature in situ powder XRD was carried out using an Anton Parr high-temperature chamber with a 10 °C/min heating rate. Nitrogen adsorption measurements were performed using a Micromeritics ASAP 2010 V1.01 B automatic instrument at 77 K. Pore-size distributions were determined using the density functional theory (DFT) Plus Software for data files generated from the ASAP instrument. Adsorption of benzene, *m*-xylene and mesitylene was measured at 298 K using a gravimetric adsorption apparatus equipped with a CI electronic MK2−M5 microbalance and an Edwards Barocel pressure sensor. Before measurements, the samples were outgassed overnight at 573 K. EPR spectra were obtained at room temperature on a Bruker ESP 300E spectrometer, operating at 9.53 GHz. The g-values were obtained by reference to standard diphenylpicrylhydrazine (DPPH, $g = 2.0037$). FTIR spectra were recorded in absorbance mode on a Mattson Mod 7000 spectrophotometer, as KBr pellets, in the range 400−4000 cm^{-1}. The pellets were prepared by sample dispersion (0.2 mg) in a KBr matrix (150 mg) and pressed. The spectra were typically an average of 64 scans with 4 cm^{-1} resolution. DR UV/Vis was performed on a Jasco V-560 PC spectrometer using $BaSO_4$ as the reference material.

Introduction

In the past decade, transition metal complex polymers in which a ligand bridges two or more metal centers have received increasing attention due to the potential applications of their physical and/or chemical properties.[1] It is well-known that pyrazine and RCO_2^- can act as excellent bridging ligands for the syntheses of such compounds.[2] Most compounds, however, have either chain-like structures or two-dimensional layer-like structures.[3] For three-dimensional coordination frameworks, it is often difficult to predict the structures and obtain single crystals for X-ray structural analysis. Recently, we have chosen pyrazine and malonate as ligands and attempted to explore the synthetic strategies and structural features. In this paper, the syntheses and structural characterization of two new complexes with 3-D coordination frameworks, $[Cu_2(C_3H_2O_4)_2(C_4H_4N_2)]\cdot 2H_2O$ (**1**) and $[Zn_2(OH_2)_2(C_3H_2O_4)_2(C_4H_4N_2)]$ (**2**), are reported. The magnetic behavior and temperature dependence of the electric conductivity of complex **1** are also described.

Results and Discussion

Blue crystalline blocks of **1** were obtained from the reaction of $Cu(C_3H_2O_4)\cdot 2H_2O$, malonic acid and pyrazine, and its structure determined by a single crystal X-ray diffraction study. An ORTEP diagram of **1** is shown in Figure 1 with selected bond distances and angles listed in Table 1. The crystal structure reveals that the copper(II) ion is pentacoordinate with four oxygen atoms from three malonate ligands and a nitrogen atom from the pyrazine ligand. The coordination geometry of the Cu^{II} ion can be described as square-based pyramidal, the square plane being defined by O(1), O(3), O(4), and N(1) with an average Cu−O bond length of 1.950 Å. The Cu−N distance is 2.045(3) Å, while the Cu−O(2) distance is slightly longer at 2.252 Å. The Cu^{II} center and the four atoms forming the base are displaced from the least-squares plane by −0.0338, +0.0346, −0.0343, +0.0334, and +0.1151 Å respectively, while the capping atom O(2) is 2.3553 Å away from the corresponding least-squares plane. As described in previous reports,[4] each malonate ligand has two different coordination modes both of which are seen in compound **1**. In the first mode, each malonate acts as a bridge for three Cu^{II} ions, whilst in the second mode each malonate forms a six-membered chelate ring with one Cu^{II} ion in a boat-type configuration. As shown in Figure 2, four Cu^{II} ions are bridged by malonate ligands forming a square 4.848×4.848 Å in size which is slightly bigger than that previously reported.[4] Such square arrangements are then linked by four pyrazines forming a two-dimensional network, leaving a much bigger square (11.685×11.685 Å) in the same plane. Finally, the two-dimensional network is further linked into a three-dimensional structure via malonate ligands (Figure 3). Interestingly, the interstices of the structure are filled with water molecules.

Colorless rhombohedral crystals of **2** were obtained by a similar method to those of **1**. The molecular structure has been determined by a single crystal X-ray diffraction study and an ORTEP diagram of the structure is shown in Figure 4. Selected distances and angles are listed in Table 2. The crystal structure reveals that each Zn^{II} ion is six-coordinate and the coordination geometry of the Zn^{II} centers is octahedral. Each Zn^{II} ion is chelated by two oxygen atoms from one malonate, two oxygen atoms from two neighbor-

O(5), and N(1) and the deviations of those atoms and the Zn^{II} center from this plane are −0.0045, +0.0046, −0.0049, +0.0047, and −0.1077 Å, respectively, while the axial atoms O(1) and O(4) are −2.1704 and +1.9738 Å away from the corresponding least-squares plane. As in compound **1**, the malonate in complex **2** displays similar coordination modes. As shown in Figure 5, the two-dimensional layer that can be seen is formed in the following way: Zn^{II} ions are first coordinated by malonate ligands to form a chain along the *x*-axis, such chains are then linked by pyrazine units along the *y*-axis to form a wall-like layer. Finally, these layers are

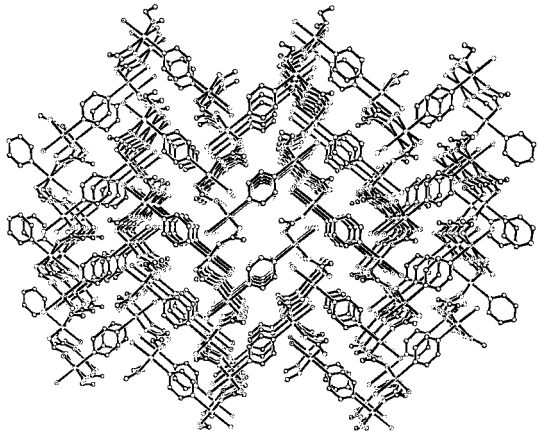

Figure 6. Network structure for complex **2** viewed along the *z*-axis

linked by malonate ligands to form a three-dimensional network possessing polygonal channels (Figure 6).

The magnetic susceptibility of a powder sample of compound **1** was measured using a Quantum Design SQUID magnetometer on the MPMS-7 system with a 10000Qe magnetic field in the temperature range of 5.0−300 K. Its magnetic behavior is highlighted by plots of $\chi_M T$ vs. T and

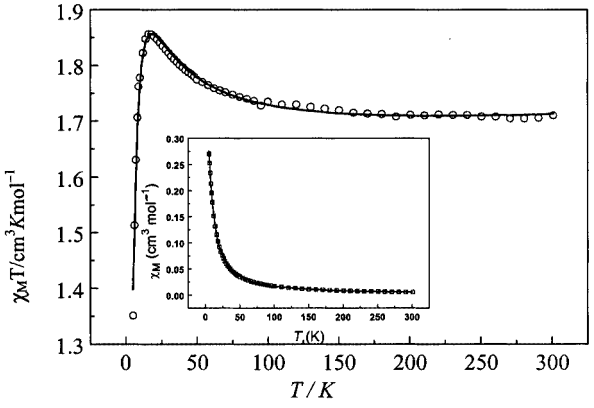

Figure 7. Plots of the experimental temperature dependence of $\chi_M T$ and χ_M for **1**

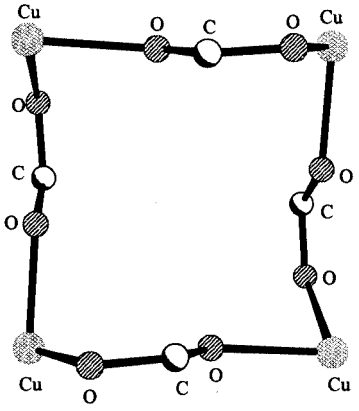

Figure 8. The magnetic exchange path of Cu−O−C(R)−O′−Cu′ in the tetranuclear "Cu_4" mini-square

χ_M vs. T as shown in Figure 7. The temperature dependence of χ^{-1} is in good agreement with the Curie−Weiss law with C = 0.42(1) cm^3·K·mol^{-1} and Θ = 1.51(1) K, indicating that overall, complex **1** displays ferromagnetic behavior. As the temperature decreases, the $\chi_M T$ values increase gradually from 1.71 cm^3·K·mol^{-1} at 300 K, reaching 1.856 cm^3·K·mol^{-1} at 16 K, and then drop rapidly to 1.351 cm^3·K·mol^{-1} at 5 K. On the basis of the geometrical structure, the magnetic exchange involves a Cu−O−C(R)−O′−Cu′ superexchange path through *syn-anti* bridging binary carboxylate groups in the tetranuclear "Cu_4" mini-square (Figure 8) and a Cu−L−Cu (L = pyrazine) interaction between the "Cu_4" clusters. Using the Van Vleck equation results in Equations (1) and (2) for χ_M' and χ_M.

$$\chi_M' = \frac{2Ng^2\beta^2}{kT} \times \frac{e^{2x} + 2e^{4x} + 5e^{6x}}{1 + 3e^{2x} + 7e^{4x} + 5e^{6x}}, \text{ where } x = J/k \quad (1)$$

$$\chi_M = \frac{\chi_M'}{1 - \frac{2zj\chi_M'}{Ng^2\beta^2}} + \text{TIP} \quad (2)$$

J is the exchange constant for Cu−O−C(R)−O′−Cu′. j and z are the exchange constant for Cu−L−Cu and the number of nearest neighbors respectively. TIP is temperature-independent paramagnetism. A good agreement of $R = 8.55\cdot10^{-5}$ [$R = [(\chi_M T)_{obs} - (\chi_M T)_{cal}]^2/(\chi_M T)^2_{obs}$] is obtained with $J = 5.62(3)$ cm^{-1}, $j = -0.284$ cm^{-1} [for $zj = -1.138(8)$cm^{-1}, $z = 4$, $g = 2.092(4)$, $TIP = 0.00015(3)$]. These results indicate that there is ferromagnetic exchange between Cu^{II} through the *syn-anti* [Cu−O−C(R)−O′−Cu′] bridge, and the whole [Cu−O−C(R)−O′−Cu′]$_n$ chain skeleton is non-planar. This is consistent with the results of the magnetic properties of the compounds [Cu$_4$(DZB)$_3$(DZBH)(NO$_3$)-(H$_2$O)]·2H$_2$O[5] and [CuL(H$_2$O)]$_n$[6] reported previously. The exchange interaction between the Cu^{II} centers through pyrazine is more complicated. When the dihedral angle between the pyrazine plane and the coordination plane of Cu^{II} in the reported complex [Cu(NO$_3$)(pyz)]$_x$,[7] is around 50°, the antiferromagnetic exchange interaction parameter j is about -7.4 cm^{-1}. The corresponding dihedral angle in compound **1** is about 65.3°, and the exchange constant $j = -0.2845$, indicating the antiferromagnetic exchange between Cu^{II} through pyrazine is very weak.

It is worthwhile noting that the g value of 2.092(4) mentioned above corresponds well with the results from the EPR measurements at room temperature and at liquid nitrogen temperature ($g = 2.152$ and 2.155, respectively).

In recent years, polymeric unconventional semiconductors have been of much interest.[8] Consequently, we were prompted to investigate the temperature dependence of the electrical conductivity of **1**. Measurements were been carried out using a small pressed disc of the powdered sample on a ZL5-LCR conductometer, giving conductivity values from $2.500\cdot10^{-5}$ S·cm^{-1} to $7.095\cdot10^{-5}$ S·cm^{-1} as the temperature was increased from 298 K to 353 K (Figure 9). These results indicate that complex **1** belongs to the class of semiconductors[9] and this might be mainly due to the interesting structural feature of the copper(II) being linked by aromatic pyrazine and RCOO$^-$ (possessing delocalized π bonding[10]) units.

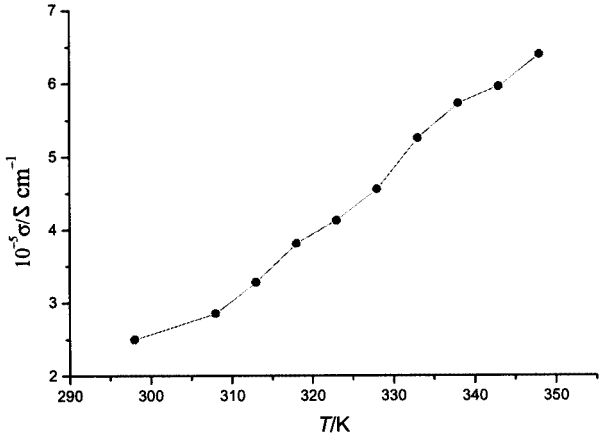

Figure 9. Temperature-dependent electrical conductivity of **1**

Crystalline samples of **1** and **2** were heated from 30 °C to 830 °C. For **1,** TGA showed that the first weight loss, estimated at about 8.15%, occurred between 80 °C and 110 °C which is consistent with the loss of two H$_2$O molecules (calcd. 8.05% for **1)**. The other ligands in **1** (pyrazine and malonate) were lost gradually from 215 °C. In **2**, the loss of two coordinated water molecules and other ligands occurred from 195 °C.

Experimental Section

Syntheses

Preparation of Complex 1: 1) A solution of basic cupric carbonate [CuCO$_3$·Cu(OH)$_2$·xH$_2$O, ca. 0.05 mol] and malonic acid (0.1 mol) in H$_2$O (200 mL) was heated to reflux for 10 minutes and then filtered. The filtrate was concentrated to approximately 10 mL and filtered again. The resultant precipitates from the filtrations were then dried. 2) To a solution of the dry precipitates (0.2 g) in H$_2$O (30 mL), was added, dropwise, a solution of pyrazine (0.08 g, 2 mmol) in EtOH (15 mL). The solution was filtered and then evaporated slowly in air. Blue crystalline blocks were obtained after several hours. Yield 0.29 g. Analysis: found C 26.88, H 2.57, N 6.30, Cu 28.34; calcd. C, 26.85, H 2.70, N 6.26, Cu 28.41%. IR (KBr, cm^{-1}): ν(OH) 3431−3587, ν(−C−H, =C−H) 3053−3132, δ(OH) 1647, ν(COO) 1558~1429, ν(Cu−O, Cu−N) 228−482.

Preparation of Complex 2: 1) A solution of zinc carbonate (0.1 mol) and malonic acid (0.1 mol) in H$_2$O (200 mL) was heated to reflux for 10 minutes and then filtered. The filtrate was concentrated to ca. 10 mL and filtered again. The resultant precipitates were then dried. 2) To a solution of the above dry precipitates (0.2 g) in H$_2$O (30 mL) was added, dropwise, a solution of pyrazine (0.08 g, 2 mmol) in EtOH (15 mL). The solution was filtered and the filtrate was sealed in flask. Colorless rhombohedral crystals were obtained after several days. Yield 0.26 g. Analysis: found C 26.68, H 2.18, N 6.10; Zn, 29.10; calcd. C, 26.63, H 2.23, N 6.21; Zn, 29.00%. IR (KBr, cm^{-1}): ν(OH) 3248, ν(−C−H, =C−H) 3053−3122, δ(OH) 1626, ν(COO) 1574~1417, ν(Zn−O, Zn−N) 239−463.

X-ray Crystallography

Crystal Data for 1: Crystal dimensions 0.26 × 0.10 × 0.06 mm, Cu$_2$C$_{10}$H$_{12}$N$_2$O$_{10}$, $M = 447.30$, tetragonal, space group P-42(1)c, $a = 12.6075(4)$, $c = 9.1944(4)$ Å, $V = 1461.44(9)$ Å^3, $Z = 4$, $D_{calcd.} = 2.033$ g·cm^{-3},μ(Mo-K_α) = 2.969 mm^{-1}, $T = 293(2)$ K. The data were collected on a Siemens SMART CCD diffractometer over the range $2.28 < \theta < 25.04°$. 4349 Reflections were collected of which 1291 were considered to be observed [$I > 2\sigma(I)$]. The structure solution by Patterson methods and full-matrix least-squares refinement were carried out using the SHELXL-97 software package[11] with anisotropic thermal parameters for all skeleton non-hydrogen atoms. All non-hydrogen atoms were refined anisotropically, whilst hydrogen atoms of dissociated water were placed in calculated positions and not refined. It should be pointed out that the U(eq) values for C(1) and C(2) are relatively large and could not be improved with an alternative data set from another crystal. The final agreement factors are R [$I > 2\sigma(I)$] = 0.0279, $R_w = 0.0719$ and GOF = 1.059.

Crystal Data for 2: Crystal dimensions 0.46 × 0.24 × 0.06 mm, Zn$_2$C$_{10}$H$_{12}$N$_2$O$_{10}$. $M = 450.99$, monoclinic, space group $P2_1/n$, $a = 6.9659(5)$, $b = 14.3405(9)$, $c = 7.4477(5)$ Å, β = 92.179(2)°, $V = 743.45(9)$ Å^3, $Z = 2$, $D_{calcd.} = 2.014$ g·cm^{-3}, μ(Mo-K_α) = 3.284

mm^{-1}, $T = 293(2)$ K. Data were collected on a Siemens SMART CCD diffractometer over the range $2.84 < \theta < 25.01°$. 2428 reflections were collected of which 1117 were considered observed [$I > 2\sigma(I)$]. The structure solution by direct methods and the full-matrix least-squares refinement were carried out using the SHELXL-97 software package[11] with anisotropic thermal parameters for all skeleton non-hydrogen atoms. All non-hydrogen atoms were refined anisotropically, whilst hydrogen atoms of coordinated water molecules were placed in calculated positions and not refined. The final agreement factors are R [$I > 2\sigma(I)$] = 0.0350, R_w = 0.0943 and GOF = 1.053.

CCDC-184200 and CCDC-184201 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Solid-State Adducts between C_{60} and Decamethylferrocene

Aldo Arrais,[a] Eliano Diana,[a] Roberto Gobetto,[a] Marco Milanesio,[b] Davide Viterbo,[b] and Pier Luigi Stanghellini*[b]

Keywords: Donor-acceptor systems / Fullerenes / Infrared spectroscopy / Raman spectroscopy / Sandwich complexes

Co-deposition from concentrated solutions of C_{60} and $Fe[C_5(CH_3)_5]_2$ affords two solid products in different yields. The major product **1**, in the form of regular shaped crystals, has been investigated by X-ray diffraction, ^{13}C CPMAS NMR and vibrational spectroscopy, which showed it to be a co-crystalline adduct of C_{60} and $Fe[C_5(CH_3)_5]_2$ with no significant electron charge transfer between the two building blocks. The minor product **2**, in the form of an amorphous powder, has been investigated by vibrational techniques. Both IR and Raman spectra are consistent with a solid structure in which electron transfer between the two units appears to be possible.

Introduction

Interesting chemical and physical properties indicate fullerene C_{60} to be a useful building block for the preparation of new materials with particular electronic and magnetic properties.[1−4] C_{60} behaves as a mild electron acceptor, capable of incorporating up to six electrons in the cage[5−8] and of forming salts with several inorganic and organic cations.[9] The most fascinating example of these species are the alkali metal salts M_nC_{60}, which show superconductivity properties at quite high temperatures.[10−11]

On the other hand, C_{60} can form molecular adducts with several organic and organometallic electron donors D,[12−22] giving rise to molecular charge-transfer (CT) complexes $D_n(C_{60})$. Presumably, there is no neat distinction between ionic complexes and CT molecular complexes, in that the formally neutral systems probably imply some electron transfer from the donors to C_{60} through π-stacking interactions, particularly favourable when the donor exhibits a largely delocalised π-structure. It might be expected that even a fractional electron transfer should change the spectroscopic (vibrational and magnetic) properties of both the donor and the C_{60} acceptor. Spectroscopic data on C_{60} and its anions are available in the literature, and while they usually indicate that the effect of the charge on the cage is not very evident, careful study can allow their extents to be estimated.[23−27] A clear example is given by the ionic salt $[TDAE]^+[C_{60}]^-$ [TDAE = tetrakis(dimethylamino)ethylene]: the transfer of one electron from TDAE to C_{60} has been associated with subtle modification of the Raman spectrum of C_{60} itself.[28] A parallel opportunity is offered by changes in the spectroscopic properties of the donor molecule as a consequence of electron transfer.[29]

On the basis of our knowledge of the metallocene complexes and their cations, primarily ferrocene (Fc) and decamethylferrocene (*Fc),[30,31] we performed the reaction between C_{60} and *Fc, and the products have been characterised by vibrational and NMR spectroscopy and, when possible, by X-ray diffraction methods. The results, also in comparison with the spectroscopic data concerning the well-known $C_{60}(Fc)_2$,[14] form the object of this paper.

Results and Discussion

Adduct 1

Description of the Structure

The main features of the crystal structure of the adduct **1** are illustrated in Figures 1 and 2. The C_{60} molecule sits with the centre of the "ball" on a crystallographic inversion centre. There are two different types of *Fc molecules: one (molecule A with Fe1 atom) in a general position and one (molecule B with Fe2 atom) with the iron atom sitting on a crystallographic inversion centre. Both rings of molecule A (Figure 1) face two pentagons of the fullerene, in an almost staggered way, and without relevant side shift. On the other hand, molecules B form unconnected layers between the layers of $C_{60}[*Fc_2(A)]$ complexes (Figure 2). In these last layers, each fullerene molecule is surrounded by four

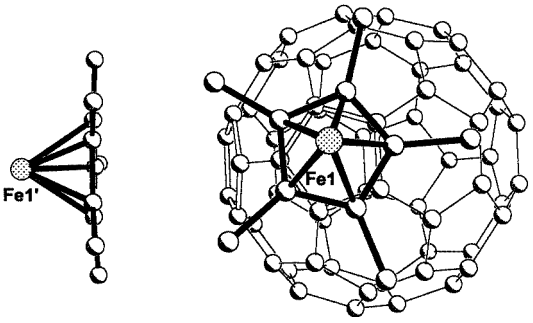

Figure 1. The two different staggered facings of the two *Cp moieties linked to Fe1 and Fe1′ (molecule A) with the five-membered rings of fullerene

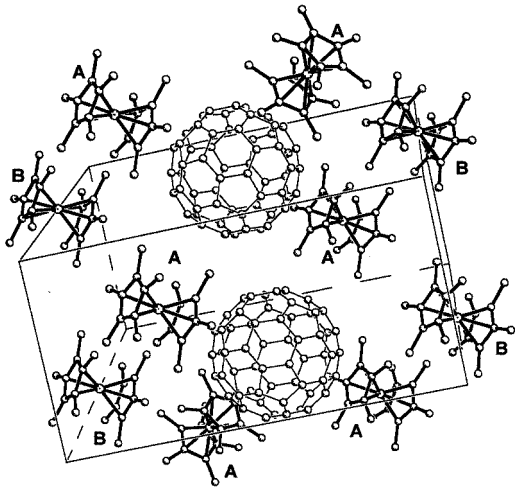

Figure 2. Crystal packing of adduct **1**, showing both the interacting (A) and the non-interacting (B) *Fc molecules in the unit cell

*Fc(A) molecules. The facing of the two rings of molecule A is rather different: one is almost parallel to the pentagon of the C_{60} ring [dihedral angle 4.7(8)°], with a centre-to-centre distance of 3.26(1) Å, while the other is tilted by 14.0(8)°, with a centre-to-centre distance of 3.35(1) Å. The values of the centre-to-centre distances are typical of π interactions between aromatic molecules and are in keeping with the interplane distance of 3.35 Å in graphite. The facing is stabilised by a number of weak C−H···π interactions between methyl hydrogen atoms and fullerene six-membered rings. The shortest distances are found for hydrogen atoms linked to C17 [distance from H to the centre of the ring: 2.94(3) Å] and to C18 [distance from H to the centre of the ring: 2.80(3) Å], belonging to the cyclopentadienyl ring most tilted with respect to the fullerene pentagon. This may suggest that the tilting allows better anchoring of the ring to C_{60}, hindering its free rotation as a sort of a wedge. All other "H-to-ring" distances are greater than 3.0 Å.

The geometry of the fullerene molecule shows the usual bimodal distribution of the C−C distances: the average hexagon−hexagon bond is 1.39(1) Å, while the average hexagon−pentagon bond is 1.45(1) Å. The distances between the centre of the ball and the 30 independent carbon atoms vary from 3.53(1) to 3.56(1) Å. An analysis of the distances between the centre of the ball and the 30 independent carbon atoms does not indicate any systematic deformation, such as is found in the ionic structure of decamethylnickelocenium fulleride.[22]

The crystal structure of **1** is quite different from that of the $C_{60}Fc_2$ adduct,[14] in which only one ring of the single ferrocene molecule faces (with a sideways slipping of 0.8 Å) a fullerene pentagon in an almost eclipsed way.

In order to carry out a more accurate comparison of the *Fc molecules in **1** with the same molecule alone, we also redetermined the crystal structure of *Fc, at 150 K. However, the resulting resolved structure did not substantially differ from that reported by Freyberg et al.,[32] which was carried out at room temperature. The molecule has a C_{2h} crystallographic site symmetry with the iron atom sitting on an inversion centre, and so the two cyclopentadienyl rings must be exactly staggered. The three independent Fe−C, C−C, and C−CH_3 distances and the C−C−C angles differ by less than 3σ and their average values are reported in Table 1. With respect to the plane through the five-membered rings, the methyl carbon atoms are slightly (about 0.06 Å) displaced in the direction away from the central Fe atom. In all the methyl groups, two hydrogen atoms point towards the Fe and are relatively close to the cyclopentadienyl plane, while the third H sticks out of the plane away from the Fe. This pattern was also found in a series of $Fe(Me_4RCp)_2$ derivatives.[33,34]

The two different *Fc molecules in compound **1** are somewhat less regular than in *Fc alone; nevertheless, average values of selected distances and angles are very similar in the two structures. Table 1 summarises the most significant distance and angle values for A and B in **1**, in comparison with those in *Fc. The disposition of the methyl groups

Table 1. Main geometrical parameters of the *Fc moiety from the crystal structure of adduct **1**, in comparison with *Fc alone

	Adduct **1** − molecule A			Adduct **1** − molecule B			*Fc
Distance [Å]	Minimum	Maximum	Average	Minimum	Maximum	Average	Average
Fe−C	2.038(6)	2.068(6)	2.053(6)	2.035(7)	2.063(7)	2.047(7)	2.053(2)
C−C	1.417(9)	1.437(9)	1.428(9)	1.397(10)	1.440(10)	1.416(10)	1.430(3)
C−CH_3	1.489(9)	1.519(9)	1.508(9)	1.477(10)	1.529(10)	1.509(11)	1.500(3)
Angle [°]							
C−C−C	107.3(6)	109.0(6)	108.0(6)	105.5(7)	109.2(7)	108.0(7)	108.0(2)

is similar to that found in *Fc alone, and their deviations from the cyclopentadienyl plane are also of the same order of magnitude and in the same direction.

Solid-State ^{13}C NMR

The ^{13}C CPMAS spectrum of **1** shows the presence of five resonances, at δ = 142.1, 79.9, 79.3, 78.8, and 10.8 ppm. The low-field resonance falls in the range typical of the C_{60} peak. The fact that all 60 carbon atoms are equivalent indicates that rapid isotropic motion of C_{60} on the NMR timescale is occurring in the solid at room temperature.[35−36] This result is apparently in conflict with the X-ray data, which allow complete refinement of the fullerene structure, but one should consider the different measurement temperatures and the different timescales involved in X-ray and NMR analyses.[37] Unfortunately, further attempts to observe the static ^{13}C CPMAS spectrum at low temperature were precluded by the low signal/noise ratio, probably due to the increasing of relaxation times with decreasing temperature.

The three resonances in the range δ = 70−80 ppm can readily be assigned to the cyclopentadienyl carbon atoms. Bearing in mind that inequivalences in the solid state can arise from the crystal packing, these data are in full agreement with the solid-state structure, which shows the presence of three different environments for the *Cp rings. The single resonance found for each *Cp ligand in the ^{13}C CPMAS spectrum is an indication that the rings are in a fast rearrangement process in the solid state. As previously shown in the case of *Fc,[38] the dynamic process corresponds to a rotation of the *Cp rings in the planes perpendicular to their C_5 coordination axes. Finally, the resonance at higher field appears as a broad signal due to partial overlapping of the slightly different methyl ligands.

Vibrational Spectra

The infrared and Raman features of adduct **1** are nearly coincident with those of the two separated components, as Figures 3 and 4 clearly show. Table 2 reports the frequency values and the assignments. In particular, neither the different crystallographic position of the *Fc molecules, nor the different orientations of the *Cp rings strongly affect the vibrational behaviour.

Adduct 2

The adduct **2** was always obtained only in trace amounts, as a faint light brown powder accompanying the crystals of adduct **1**. Any attempt to recrystallise the powder failed: the result was the recovery of the starting components. The only reliable experimental data that we were able to obtain are the infrared and Raman spectra in the solid state. Although the vibrational patterns of *Fc and C_{60} would not be expected to change greatly as a consequence of electron transfer,[39] a careful examination finds significant differences. First of all, the ν(CH) pattern is significantly shifted towards higher frequency by ca. 6−8 cm^{-1} and it is surprisingly similar to that of the adduct [*Fc][TCNE] (TCNE = tetracyanoethylene), for which an ionic structure is proposed.[40] In a recent study on the spectra of permethylated metallocene complexes we proposed the shift of the ν(CH) modes as a measure of the positive charge on the metallocene unit.[31] In order to allow a quantitative estimate of this effect, we compared the frequency of the most intense Raman band in this region, which ranges from 2894 and 2895 cm^{-1} for *Fc and adduct **1** to 2904 cm^{-1} for adduct **2**, to 2919 cm^{-1} for the TCNE adduct, and up to 2926 cm^{-1} for the PF_6^- salt. The same trend is shown by the $\delta(CH_3)$ symmetric mode, the frequency of which (1384 cm^{-1}) is close to those in $[*Fc]^+[TCNE]^-$ (1386 cm^{-1}) and $[*Fc]^+[PF_6]^-$ (av. 1385 cm^{-1}) and significantly different from those of *Fc (av. 1375 cm^{-1}) and adduct **1** (av. 1372 cm^{-1}).

Even more interesting is the Raman pattern between 1600 and 1350 cm^{-1}. This includes some $\delta(CH_3)$ and ν(CC)

modes of *Fc and the highest frequency modes − $H_g(8)$, $H_g(7)$, and $A_g(2)$ − of C_{60}. In Figure 5 the Raman spectrum of adduct **2** is compared with those of *Fc and C_{60}: the difference in the frequency and in the shape of the bands is clearly evident. More informative data can be obtained by a deconvolution of the spectral pattern between 1550 and 1350 cm^{-1}. Figure 6 shows the experimentally measured spectrum and the fitted curve obtained as a sum of five mixed Lorentzian/Gaussian curves centred at 1475, 1451, 1423, 1384, and 1367 cm^{-1}. The good quality of the matching between the experimentally measured and the fitted curve is shown by the value of the correlation coefficient (0.99857). The band at 1451 cm^{-1} is attributable to the $A_g(2)$ mode of C_{60} (the others are *Fc modes). The $H_g(8)$ mode appears at 1562 cm^{-1}.[41] These modes show significant low-energy shifts of 12 and 16 cm^{-1} for H_g and A_g, respectively. Other C_{60} modes show similar shifts: such as A_g, from 495 to 486 cm^{-1}, and H_g, from 271 to 249 cm^{-1}. In addition, the bands of adduct **2** are clearly broadened with respect to those of C_{60} [e.g., the full width at half maximum (fwhm) of the $A_g(2)$ mode is ca. 22 cm^{-1} for adduct **2** and ca. 6 cm^{-1} for C_{60} alone]. Both effects have been already reported for the compound C_{60}/TDAE and ascribed to electron-transfer from TDAE to C_{60}.[28] All the vibrational data and assignments are listed in Table 3.

A Comparison with Fc_2C_{60} Adduct

The molecular structure of this adduct was described almost ten years ago.[14] The crystal packing of the Fc molecules is simpler than that shown in adduct **1**. Only one Fc molecule in a general crystallographic position is present

and only one Cp ring faces one of the C_{60} pentagons. We explored its spectroscopic features further.

The ^{13}C CPMAS spectrum is consistent with the crystal structure. Two peaks of equal intensity at $\delta = 71.09$ and 72.20 ppm are attributable to the cyclopentadienyl carbon atoms. The splitting of the expected unique peak is consistent with the different environments of the two rings, due to the proximity of one ring to the C_{60} cage. A resonance at $\delta = 144.43$ ppm is attributable to the C_{60} carbon atoms. The narrowness of the peak and the absence of spinning side bands confirm the high mobility of the fullerene molecule at room temperature.

At very first sight, the infrared and Raman spectra appear as a simple superpositions of the spectra of the single components, but careful inspection reveals that some spectral features differ significantly, in that the bands show small frequency shifts or changes in their relative intensities. This is particularly evident in the 3200−3000 cm^{-1}, 900−800 cm^{-1}, and 500−300 cm^{-1} regions, which are typical of the ν(CH), γ(CH), and Fe−ring stretching modes. Not surprisingly, they belong to the vibrations that, more than the others, are involved in possible interactions between the Cp rings and fullerene. See, for instance, Figure 7, which shows the spectra of Fc and Fc_2C_{60} in the low-wavenumber region. The intensity and the frequency of the infrared and Raman features corresponding to the skeletal motion of the Fc unit in the Fc_2C_{60} adduct are significantly different from those of Fc alone, presumably reflecting the

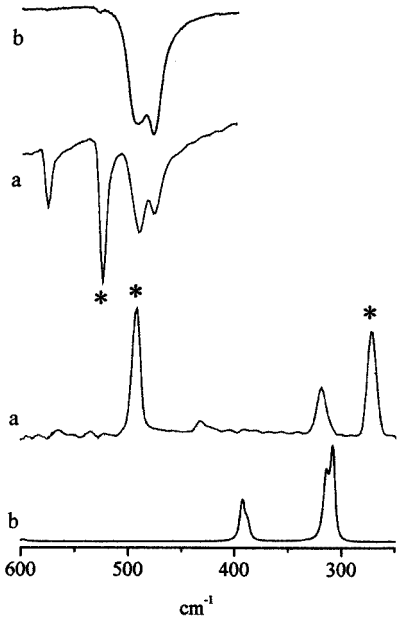

Figure 7. Infrared (top curves, KBr disk) and Raman (bottom curves, crystals) spectra of Fc_2C_{60} adduct (a) and Fc (b); the bands marked with * correspond to C_{60} modes

interaction of one Cp ring with C_{60}. On the other hand, the bands of the C_{60} component also show small but significant changes with respect to those of the free C_{60}. Thus, the Raman feature at 493 cm^{-1}, the totally symmetric A_g breathing mode of the cage,[42,43] which can be expected to interact with the sym. Cp−Fe−Cp stretching, is clearly shifted (2.5 cm^{-1}). In addition, the band at 1464 cm^{-1}, regarded as a measure of electron transfer from the donor metallocene to C_{60}, shows a small (4 cm^{-1}) low-energy shift. Other figures (Figures S1 and S2), illustrating selected regions of the spectra, and a table (Table S1), listing the frequency data and assignment, are included as Supporting Information (see also footnote on the first page of this article).

Conclusion

The formation of co-crystals of organic and organometallic species with fullerene molecules is governed both by structural and by electronic aspects: a curved surface of co-blocks[44] allows a better fit in the formation of a solid-state complex structure, and the interaction of the electron acceptor C_{60} with good electron-donating systems is thermodynamically favoured. Nevertheless, the fullerene species exhibit behaviour determined by the aromatic character of its bonds and, like planar aromatic molecules, are able to enter into intermolecular interactions through the π electron density, without net electron transfer between the C_{60} and a donor molecule. For example, the C_{60} benzene solvate[45] can be viewed as a co-crystal between C_{60} and C_6H_6. The benzene rings are parallel to the surface of the C_{60} and lie over the (6,6) bond, where the electron density is most localized. Similarly, the facing of the pentagonal ring of C_{60} with the five-carbon ring of the permethylated

ferrocene may suggest an interaction between the HOMO of the *Fc and the LUMO of C_{60}.

While **1** is undoubtedly a molecular adduct, the vibrational data suggest that the minor product **2** has an ionic structure, similar to those of Cp^*_2Mn/C_{60}, Cp^*_2Ni/C_{60}, and bis(toluene)$_2$Cr/C_{60}.[46] In the absence of any other experimental support, we are confident that the vibrational behaviour is a strong indicator of the charge transfer between the donor and the acceptor molecules, as it has been demonstrated for C_{60}[28] and *Fc[31], separately linked to other species. In this light, the spectra also suggest a small degree of electron transfer from Fc to C_{60} in the Fc_2C_{60} molecular adduct.

Experimental Section

Reactants and Solvents: All manipulations were performed by standard Schlenk techniques under an inert gas. C_{60} was purchased from Hoechst and used without further purification. *Fc (Aldrich) was purified by sublimation. The solvents were distilled from sodium (benzene and toluene) or P_4O_{10} (1,2-dichlorobenzene) and then stored under argon.

Synthesis of Adducts of *Fc and C_{60}: The preparation of intermolecular adducts of C_{60} is influenced by the starting material's low solubility. Solvents able to dissolve both *Fc and C_{60} significantly are benzene, toluene, and 1,2-dichlorobenzene. Any attempted co-crystallisation in these solvents by changing the stoichiometric ratio between *Fc and C_{60} always gave the same results: well-shaped, black crystals of adduct **1**, mixed with a small amount of light brown powder identified as the adduct **2**. In a typical preparation, C_{60} (50 mg, 0.069 mmol) was dissolved in benzene (35 mL) in a Schlenk tube and mixed with *Fc (45 mg, 0.14 mmol), previously dissolved in a few drops of benzene. The solution was slowly concentrated under an inert gas in a dry-box. After concentration, a thin layer of light brown dust mixed with black, lustrous crystals had deposited on the wall of the tube. The excess of deposited *Fc was removed by sublimation. The two compounds were mechanically separated from the solid mixture. Shiny black crystals of adduct **1** suitable for X-ray analysis were obtained by recrystallization of a 1,2-dichlorobenzene solution of the crude product at −30 °C.

X-ray Crystal Structure Analyses: Crystallographic data and details of data collection and refinement for adduct **1** and *Fc[47] are given in Table 4. Both sets of data collection were carried out with a four-circle automatic diffractometer at 150 K. Structure solutions were obtained by direct methods and refinements by full-matrix, least squares on F^2 (non-H atoms with anisotropic displacement parameters, H atoms geometrically positioned and treated as riding atoms). The computer programs used were: XSCANS[48] for data collection, SIR92[49] for structure solution, SHELXL-97[50] for structure refinement and MOLDRAW[51] and XP[52] for graphic analysis.

NMR Spectra: The ^{13}C CPMAS spectrum was acquired with a Jeol GSE-270 spectrometer operating at 67.8 MHz. The MAS rotor was spun with air at ca. 5.2 kHz, the contact time was 3.5 ms and the recycle delay 10 s. The Hartmann−Hann condition was optimised with hexamethylbenzene. ^{13}C chemical shifts are given in ppm from external tetramethylsilane reference.

Infrared Spectra: The infrared spectra were collected with a Bruker Equinox 55 FT-IR spectrophotometer, with a resolution of 2 cm^{-1} and an average 64 scans.

Table 4. Crystal data and structure refinement parameters for adduct **1** and *Fc

Compound	Adduct **1**	*Fc
Empirical formula	$(C_{120}H_{90}Fe_3)/2$	$C_{20}H_{30}Fe$
Formula mass	849.74	326.29

R indices [$I > 2\sigma(I)$]	$R1 = 0.0621$, $wR2 = 0.1194$	$R1 = 0.0470$, $wR2 = 0.1006$
R indices (all data)	$R1 = 0.1543$, $wR2 = 0.1647$	$R1 = 0.0841$, $wR2 = 0.1159$
Largest diff. peak and hole [e·Å^{-3}]	0.439, −0.436	0.590, −0.715
Weight (calculated)	$w = 1/[\sigma^2(\|F_0\|^2) + (gP)^2 + qP]$, $P = (\|F_0\|^2 + 2\|F_c\|^2)/3$	
	$g = 0.054$, $q = 3.352$	$g = 0.049$, $q = 1.030$

Raman Spectra: The Raman spectra were collected with a Bruker RFS 100 FT Raman spectrophotometer, by use of NIR laser radiation at 1064 nm and a Ge diode (laser power 100 mW, res. 4 cm^{-1}). To minimize decomposition of the sample, the complexes were sealed in capillary glass tubes under nitrogen. Adduct **2**, which shows a significant fluorescence background, required low laser power (30 mW) and an average of 2000 scans, obtained by a sequence of several scan-packets (50−100 scans each) to give a good spectrum.

Synthesis, Structure, and Characterization of $[RAl(\mu\text{-}NHEt)(\mu\text{-}NEt)_2Si(NHEt)]_2$ (R = Me, Et)

Stefan Kaskel,*[a] Christian W. Lehmann,[a] Gerald Chaplais,[a] Klaus Schlichte,[a] and Meik Khanna[a]

Keywords: Aluminium / Nitrogen / Precursor development / Silicon

The reaction between tetrakis(ethylamino)silane, $Si(NHEt)_4$ (**1**) and trialkylaluminium compounds AlR_3 [R = Me (**2**), R = Et (**3**)] results in partial deprotonation of **1** and subsequent formation of a new dimeric alumosilazane in high yield. Single-crystal X-ray analyses reveal the structure of two new four-membered ring compounds $[RAl(\mu\text{-}NHEt)(\mu\text{-}NEt)_2Si(NHEt)]_2$ [R = Me (**4**), R = Et (**5**)]. They are isostructural and crystallize in the triclinic space group $P\bar{1}$ (No. 2) with a = 8.3052(8) Å, b = 9.8323(9) Å, c = 10.324(1) Å, α = 115.498(4)°, β = 97.684(4)°, γ = 94.382(4)° (**4**) and a = 8.2319(3) Å, b = 9.3748(5) Å, c = 10.8221(6) Å, α = 107.035(2)°, β = 104.435(2)°, γ = 94.375(2)° (**5**). The alternating edge- and corner-sharing SiN_4- and $AlCN_3$-tetrahedra represent a new structural motif with μ-NHEt and μ-NEt groups in one double bridge. The compounds were further characterized by elemental analysis, mass spectrometry, and NMR and IR spectroscopy.

Introduction

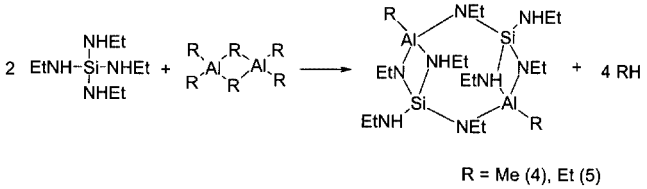
The design of new oxygen-free molecular precursors is crucial for the development of new nitride ceramics, porous non-oxide materials, and nanocomposites. Our interest is in the development of such precursors for the manufacture of porous non-oxide materials and gels, especially for catalytic applications in solid base catalysis.[1–4] For the synthesis of three-dimensional zeolitic frameworks such as nitridosilicates, molecular alumosilazanes may be suitable.[5,6] However, the known and well characterized triaminosilanes that form cage-type compounds in the reaction with $AlMe_3$ or $LiAlMe_4$ are expensive and require several synthesis steps.[7] We have therefore explored the reactions between AlR_3 and silanes such as $Si(NHEt)_4$, which on one hand is accessible in high yield from a one-step reaction between aminoethane and tetrachlorosilane,[8] and on the other hand is known to be transformable into $Si(NH)_2$ under mild conditions.[9] An important feature in comparison with other silane precursors is the absence of Si–C bonds. Si–C bonds are extremely stable, and so their cleavage and conversion into imides or nitrides under ammonothermal conditions requires high temperatures.

AlH_3 is known to form polymers of a wide compositional range in its reaction with $Si(NHMe)_4$. These are suitable precursors for the design of Si_3N_4/AlN nanocomposites.[10] Surprisingly, we found that AlR_3 (R = Me, Et) and $Si(NHEt)_4$ do not form polymers. Instead, molecular, crystalline compounds of the type $[RAl(\mu\text{-}NHEt)(\mu\text{-}NEt)_2Si(NHEt)]_2$ (R = Me, Et) with a fixed Al:Si ratio of 1:1 are obtained. They each have a cyclic four-membered ring structure, with bridging and terminal ethylamino ligands, and form through deprotonation of two ethylamino groups per $Si(NHEt)_4$. We report below on the preparation of the two isostructural compounds $[RAl(\mu\text{-}NHEt)(\mu\text{-}NEt)_2Si(NHEt)]_2$ (R = Me, Et) and on their structural and spectroscopic characterization by single-crystal X-ray analysis and spectroscopic methods.

Results and Discussion

Synthesis and Spectra

The compounds $[RAl(\mu\text{-}NHEt)(\mu\text{-}NEt)_2Si(NHEt)]_2$ [R = Me (**4**), R = Et (**5**)] are directly prepared by dropwise addition of trimethylaluminium ($AlMe_3$) or triethylaluminium ($AlEt_3$) to tetrakis(ethylamino)silane, $Si(NHEt)_4$ (**1**) (Scheme 1). The synthesis may be carried out either with or without solvent. If $AlEt_3$ is added slowly to the pure silane without solvent dilution the generation of gas bubbles is rather vigorous and the reaction vessel should be cooled.



Scheme 1

[a] Max-Planck-Institut für Kohlenforschung

After several minutes, ethane formation begins to slow down. The product is obtained after twelve hours, in the form of transparent crystals. Without the use of solvent dilution, in fact, the vessel is completely filled with white, crystalline product.

The reaction may also be carried out in pentane solution. In that case the solvent is removed in vacuo after twelve hours reaction time and the product is obtained as a white, crystalline solid.

Both compounds were characterized by mass spectrometry, IR and NMR spectroscopic studies, elemental analysis, and single-crystal X-ray diffraction.

The EI mass spectrum of **4** shows the molecular ion peak [M^+] at m/z = 488 (19%) and a signal due to the [$M^+ - CH_3$] fragment at m/z = 473 (100%). The EI mass spectrum of **5** does not show the molecular ion peak, but a signal due to the [$M^+ - C_2H_5$] fragment is seen at m/z = 487 (100%). The molecular ion peak [$M^+ + H$] of **5** at m/z = 517 (35%) is only recorded if chemical ionization (isobutane) is used.

The ^{1}H NMR spectrum of **4** shows broad signals at δ = 2.88−3.14 and 1.06−1.40, due to the methylene and methyl protons in the amino ethane groups. The protons of the methyl groups bound to the aluminium center appear as a singlet (δ = −0.20 ppm). At 300 K the signals due to the methylene protons appear as two broad, overlapping peaks, whereas the methyl protons appear as three broad peaks. At lower temperatures (243 K, [D_8]toluene), on the other hand, the methyl protons are resolved as four triplets, two of which are separated (δ = 1.30 and 1.18 ppm) while two overlap with each other (δ = 1.09 and 1.04 ppm). The signals at δ = 2.88−3.14 appear at 243 K as a complicated structure of overlapping multiplets.

The ^{1}H NMR spectrum of **5** is very similar to that of **4**, but the broadening of the signals at 300 K is less pronounced. The methylene protons in the vicinity of the aluminium atom appear at δ = 0.37 ppm.

The temperature-dependent linewidth in the proton NMR spectra indicates inter- or intramolecular exchange of terminal and bridging groups on the NMR timescale in solution (benzene, toluene).

The molecular compounds each show two distinct absorptions in the IR spectrum, at 3413 (**4**) [3410 (**5**)] and 3262 (**4**) [3254 (**5**)] cm^{-1}. These are attributable to the N−H stretching frequency of the terminal ethylamino group, similar to that in Si(NHEt)$_4$ (3414 cm^{-1}), and the N−H stretching frequency of the μ-NHEt groups in the double bridge (Scheme 1).

The simultaneous presence of alkyl groups bound to aluminium and residual acidic protons in the aminoethane ligands is similar to the situation seen in an incomplete condensation reaction between a primary amine and an alkylaluminium compound and is not uncommon,[6] subsequent formation of alane-amine adducts, aminoalanes, and poly(*N*-alkylimino)alanes typically being observed in such reactions.[11] For **4** and **5**, further intramolecular condensation is difficult to achieve without complete rearrangement of the molecular structure, so further condensation of the terminal ethylamino and alkyl groups would probably result in polymerization. Obviously, this polymerization does not take place at room temperature because several alkyl groups are pointing outwards, acting as a protective shell for the cluster and hindering further polymerization.

X-ray Structures of [MeAl(μ-NHEt)(μ-NEt)$_2$Si(NHEt)]$_2$ (4) and [EtAl(μ-NHEt)(μ-NEt)$_2$Si(NHEt)]$_2$ (5)

Single-crystal X-ray structure determinations carried out at 100 K show that compounds **4** and **5** both crystallize in the $P\bar{1}$ space group, with one cagelike molecule per unit cell, situated on an inversion center. The basic structural motif in **4** and **5** is a heterocyclic eight-membered ring composed of alternating Al and Si atoms with interspersed N(Et) groups (Figure 1). Two additional NHEt groups, each bridging one pair of Si-Al atoms, produce a formally tricyclic ring system. The tetrahedral coordination of the Si and Al atoms is completed with an additional EtNH group for silicon and alkyl groups for aluminium, to give an overall neutral molecule. The cage is therefore made up of two pairs of edge-sharing $AlCN_3$ and SiN_4 tetrahedra linked through the corners to form a four-membered cycle (Figure 2). Two crystallographically and chemically different EtN groups can be distinguished. Both are μ_2-bridging ligands between Al and Si centers, but one has a common corner (top and bottom in Figure 2) of two tetrahedral units whereas the other is part of a common edge of two tetrahedra. The two μ_2-ligands forming a common edge of two tetrahedra are termed a "double-bridge" below.

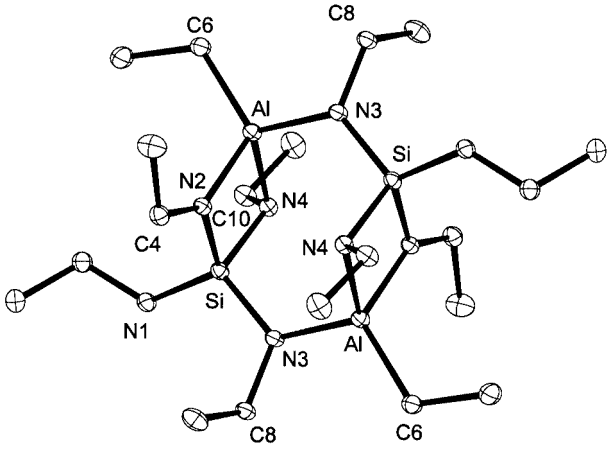

Figure 1. Crystal structure of **5** (hydrogen atoms are omitted for clarity); selected bond length [Å] and angles [°] are given in Table 1

The deviation of the coordination from an ideal tetrahedron (Figures 1 and 3, Table 1) is noticeable for the aluminium center, since the double bridges give rise to compression of one of the tetrahedron angles (N2−Al−N4) to only 80.4(1)°, whereas all other angles except for one (N3−Al−N4: 107.6(1)°] are expanded (113.5−119.4°). The Al−C6 bond length is 1.971(2) Å in **5** and 1.967(4) Å in **4,** close to Al−C distances typically observed in organoaluminium compounds (LiAlEt$_4$: d(Al−C) = 2.023 Å[12]). The Al−N bond lengths to the bridging EtN nitrogens [Al−N2: 1.849(2), Al−N3: 1.851(2) Å in **5**; 1.858(3) and 1.856(3) Å

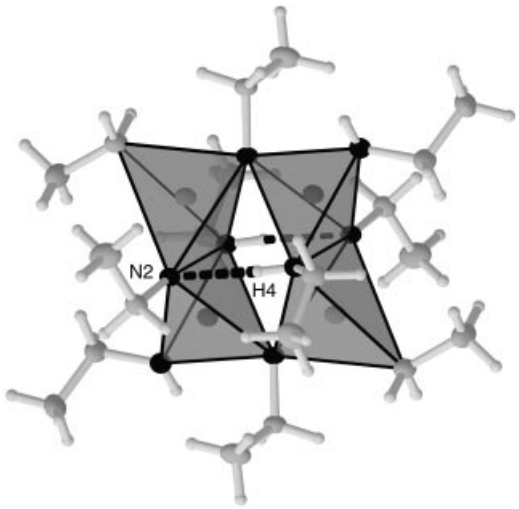

Figure 2. Polyhedral representation of **5**; the proton in position H4 was located in the Fourier map and refined without constraints; the dashed line indicates a secondary interaction between EtNH and EtN groups in neighboring double bridges

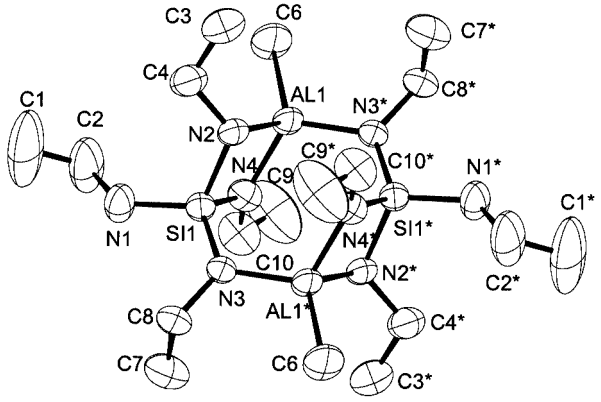

Figure 3. Molecular structure of **4**

Si−N4−Al	90.0(1)		
C10−N4−Al	121.1(1)		

in **4**] are significantly shorter than the bond to the EtNH ligand [Al−N4: 2.006(2) Å in **5**, 1.992(3) Å in **4**].

For silicon, compression of the tetrahedral environment along the double bridge is less severe [N2−Si−N4: 89.6(1)°] and the other N−Si−N angles are between 110 and 114°, with one exception [N2−Si−N3: 118.3(1)°]. As in the $AlCN_3$ tetrahedron, the Si−N bond length to the μ_2-bridging EtNH group is longer [Si−N4: 1.833(2) Å (**5**); 1.826(3) Å (**4**)] than the other Si−N bonds [1.699(2)−1.704(2) Å].

An interesting feature is that only 50% of the original EtNH groups are deprotonated. Bridging EtN groups are clearly different from the bridging EtNH ligands in geometry. In the former, the nitrogen atoms (N2 and N3) show a distorted trigonal planar coordination [C4−N2−Si: 125.3(1)°, C4−N2−Al: 134.9(1)°, Si−N2−Al: 99.9(1)°, sum: 360.1°; C8−N3−Si: 119.7(1)°, C8−N3−Al: 118.2(1)°, Si−N3−Al: 119.8(1)° sum: 357.7° (359.7° for **4**)] whereas in the latter N4 has a pseudotetrahedral arrangement of non-hydrogen atoms [C10−N4−Si: 118.3(1)°, Si−N4−Al: 90.0(1)°, C10−N4−Al: 121.1(1)°, sum: 329.4° (332.2° for **4**)].

The simultaneous presence of bridging EtNH and EtN groups is a unique structural feature of the new cluster. The proton H4, attached to N4, was located in the difference Fourier map and refined without constraints to give an N4−H4 distance of 0.80(2) Å. Interestingly, the distance between H4 and the non-covalently bonded N2 in the neighboring double bridge is only 2.49(2) Å (Figure 2, dashed line), so a secondary interaction between the EtNH and the EtN ligand in the neighboring double bridge is probably the reason for the unusual structural motif. The H4 location is also ideal for an intramolecular exchange of the proton from the EtNH to the EtN ligand, which is unprecedented and would explain some of the broadening in the NMR spectra.

The position of the proton in the terminal EtNH group attached to silicon was also located in the course of the structural refinement.

Although differentiation between aluminium and silicon and location of the hydrogen position are not trivial, the assignment of positions is evident from the synthesis and the geometrical considerations outlined above. The good solubilities of **4** and **5** in non-polar solvents such as pentane are also in agreement with the overall zero charge on the molecule deduced from the structural analysis, especially since the ethyl groups point outwards from the cluster to provide an overall hydrophobic shell. Hydrophobic interactions between those groups therefore also largely determine the lattice energy and packing of the clusters in the crystal structure.

Overall, the structures of the new compounds are a remarkable new element in alane chemistry. Tetrameric iminoalanes commonly possess cubane-type skeletons.[11] However, for an Al_2Si_2 skeleton the cubane structure, for reasons of charge-matching, would not only require one unusual terminal EtN ligand ($[RAl(\mu_3\text{-}NEt)_2Si(NEt)]_2$) but would also produce neighboring aluminium tetrahedra, obviously less favorable than alternating silicon and aluminium tetrahedra. Interestingly, the latter can be seen as a molecular analogy of Löwenstein's rule, which states that the Al:Si

ratio in zeolites can never exceed 1.0 because Al−O−Al linkages are avoided.[13]

Conclusion

We have shown that heterocyclic precursors containing aluminium and silicon in a fixed ratio of 1:1 are accessible as crystalline compounds in high yield. They represent pre-organized structural building units for the assembly of tetrahedral framework materials such as nitrido zeolites. Preliminary investigations in our group show that they are suitable precursors for the generation of porous aluminium silicon imide materials with high accessible surface area by use of ammonothermal transamination in supercritical ammonia.

Experimental Section

Synthesis of 4 and 5: All operations were performed either in a glove box (Argon, $O_2 < 1$ ppm, $H_2O < 1$ ppm) or with use of a vacuum line and dry solvents. Tetrakis(ethylamino)silane was obtained from aminoethane and silicon chloride (9:1) and purified by distillation in vacuo (99.7%, GC).[8]

Typically, AlR_3 (5 mmol) was added dropwise at room temperature either to a stirred solution of $Si(NHEt)_4$ (5 mmol, 1 g) in pentane or to pure $Si(NHEt)_4$. The liquid mixture was stirred at room temperature for 12 hours. For reactions carried out in the absence of solvent the vessel was completely filled with white, crystalline product after 12 h. For reactions carried out in pentane, the solvent was removed in vacuo and a solid product was obtained [yield: 98%, 1.198 g (**4**), 100%, 1.292 g (**5**)].

Compound 4: $C_{18}H_{50}Al_2N_8Si_2$ (488.80) Calcd. C 44.23, H: 10.31, N 22.93, Al 11.04, Si 11.49; found C 44.15, H 10.19, N 23.11, Al 11.15, Si 11.81. MS(EI): *m/z* (%) = 488 (19) [M^+], 473 (100) [$M^+ - CH_3$]. ^{1}H NMR (300 MHz, 300 K, [D_6]benzene, ppm): δ = −0.20 (s, 6 H, $AlCH_3$), 1.06−1.40 (m, 24 H, N-CH_2−CH_3), 2.88−3.14 (m, 16 H, N-CH_2−CH_3). Structure and Reactivity Studies on Dinuclear Copper Complexes of the Ligand α,α′-Bis{bis[1-(1′-methyl-2′-benzimidazolyl)methyl]amino}-*m*-xylene

Giuseppe Battaini,[a] Luigi Casella,*[a] Michele Gullotti,[b] Enrico Monzani,[a] Giorgio Nardin,[c] Angelo Perotti,[a] Lucio Randaccio,[c] Laura Santagostini,[b] Frank W. Heinemann,[d] and Siegfried Schindler[d]

Keywords: Bioinorganic chemistry / Copper / Dioxygen activation / Enzyme models

The ligand α,α′-bis{bis[1-(1′-methyl-2′-benzimidazolyl)-methyl]amino}-*m*-xylene (L-55) forms the complexes $[Cu^{I}_2$(L-55)$(MeCN)_2](PF_6)_2$ (**1**) and $[Cu^{II}_2$(L-55)$(OMe)_2][ClO_4]_2$ (**2**), in which an extremely weak axial amine interaction is imposed by the small five-membered benzimidazole chelating ring units. This structural feature has been characterized by X-ray crystal structure determination. In **1**, the Cu^{I} centers are three-coordinate with ligation from two benzimidazolyl and one acetonitrile N-donors, in a slightly distorted trigonal arrangement. In **2**, each Cu^{II} center has a distorted square-planar geometry and coordinates to the benzimidazolyl N atoms and the bridging methoxy groups in the basal positions, with a much weaker interaction with the tertiary amine N in an apical position. These structural features affect the reactivities of the copper(I)– and copper(II)–L-55 complexes toward dioxygen and hydrogen peroxide, respectively. $[Cu^{I}_2$(L-55)$(MeCN)_2]^{2+}$ does not produce a stable peroxo complex, but undergoes an irreversible oxidation to copper(II) species, while $[Cu^{II}_2$(L-55)$(H_2O)_2]^{4+}$ reacts slowly with hydrogen peroxide to undergo regiospecific hydroxylation of the ligand at one benzylic carbon atom, which causes decomposition of the complex. $[Cu_2$(L-55)$(H_2O)_2]^{4+}$ is easily converted into its bis(μ-hydroxo) adduct $[Cu_2$(L-55)$(OH)_2]^{2+}$. This pH-driven equilibrium was monitored by paramagnetic ^1H NMR spectroscopy, and the solution magnetic properties of the complexes were determined by the Evans susceptibility method.

Introduction

The interactions between synthetic copper complexes and dioxygen have become increasingly important in the last decade,[1−4] in connection with the enzymatic reactions catalyzed by copper enzymes,[5−9] particularly tyrosinase, and potential applications in catalytic transformations of organic substrates.[10,11] In the best characterized systems, the μ-η^2:η^2-peroxodicopper(II) or bis(μ-oxo)dicopper(III) complexes have been found to be able to effect C−H bond cleavage of the ligand[12−18] or an exogenous substrate[19,20] with insertion of an oxygen atom. In other dinuclear copper systems the putative copper−dioxygen intermediate could not be characterized, due to high reactivity even at low temperature.[21−26] The first and most intensely studied example of a tyrosinase model, $[Cu_2$(*m*-XYLpy$_2$)$]^{2+}$,[12,13,27−29] performs ligand arene hydroxylation, to produce a μ-hydroxo-μ-phenoxodicopper(II) species, through the peroxo complex derived from the reaction with dioxygen. In the same system, xylyl ligand hydroxylation can also be achieved by treatment of the dinuclear Cu^{II} complex $[Cu_2$(*m*-XYLpy$_2$)$]^{4+}$ with hydrogen peroxide.[30] The monooxygenase reaction by Cu^{I} and dioxygen is not observed when the pyridine rings in the chelating arms of the *m*-xylyl-containing ligand are replaced by other nitrogen heterocycles such as imidazoles or benzimidazoles.[23,31−34] However, the dicopper(I) complex $[Cu_2$(L-66)$]^{2+}$, in which the ligand L-66 contains *N*-methylbenzimidazole rather than pyridine rings,[32] forms a peroxodicopper(II) complex capable of hydroxylating an exogenous phenol.[19] In addition, when $[Cu_2$(L-66)$]^{4+}$ is treated with hydrogen peroxide, the resulting hydroperoxodicopper(II) complexes effect double hydroxylation of the xylyl aromatic ring, to produce a hydroquinone complex.[34] In this paper we report structure and reactivity studies on the dicopper(I) and dicopper(II) complexes of the ligand L-55 (L-55 = α,α′-bis{bis[1-(1′-methyl-2′-benzimidazolyl)-

methyl]amino}-*m*-xylene, Scheme 1),[35] which is related both to L-66, containing longer chains on the benzimidazolyl arms connected to the diamino-*m*-xylene unit, and to EBA, where a more flexible carbon chain replacing the *m*-xylyl unit[26] (Scheme 1). The synthesis and spectroscopic characterization of the copper(I) and copper(II) complexes of L-55 in solution have been reported before.[33,35] The X-ray crystal structure investigation of the $[Cu^{I}_2(L\text{-}55)(MeCN)_2](PF_6)_2$ (**1**) and $[Cu^{II}_2(L\text{-}55)(OMe)_2][ClO_4]_2$ (**2**) complexes reported here shows an extremely weak Cu−amine axial interaction, constrained by the small five-membered chelating ring units. This structural feature strongly affects the properties of the resulting copper complexes, particularly the reactivity patterns of the reduced and oxidized forms of the L-55 complexes towards dioxygen and hydrogen peroxide, respectively.

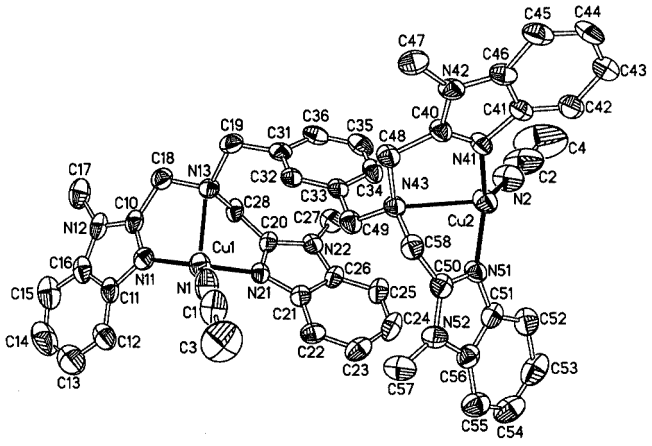

Figure 1. ORTEP[37] diagram of the cation **1** with the atom numbering labels

Results and Discussion

X-ray Structure of $[Cu^{I}_2(L\text{-}55)(MeCN)_2](PF_6)_2$ (1)

The structure of **1** consists of discrete $[Cu^{I}_2(L\text{-}55)(MeCN)_2]^{2+}$ cations and PF_6^- anions. An ORTEP view of the cation, including the labelling scheme, is shown in Figure 1. The two crystallographically independent Cu^{I} centers are three-coordinate with ligation from two benzimidazolyl N-donors and one acetonitrile N-donor, in a slightly distorted trigonal arrangement. The Cu−NCMe distances are slightly shorter than the other two. A long contact to the tertiary amino nitrogen donor [Cu1−N13, 2.602(5) Å, and Cu2−N43, 2.707(5) Å] is observed, the $N(sp^3)$ lone pair pointing approximately towards the copper ion; this may be indicative of a weak bonding interaction. The geometry around Cu is similar to the coordination around one copper(I) ion in a dinuclear complex derived from the ligand 1,3-bis[bis(2-pyridylmethy1)amino]benzene, although the Cu−N distance here is shorter [2.39(2) Å].[36] The geometry of **1** differs significantly from that found in the $[Cu^{I}_2(m\text{-}XYLpy_2)]^{2+}$ cation,[27] in which *m*-$XYLpy_2$ = $[(2\text{-}pyCH_2CH_2)_2N{-}CH_2C_6H_4CH_2{-}N(2\text{-}pyCH_2CH_2)_2]$. In the latter, in fact, each Cu^{I} achieves tricoordination through ligation of two pyridyl donors at short distances, slightly more than 1.90 Å, and the $N(sp^3)$ amino donor at a long distance, around 2.2 Å. Furthermore, the planar arrangement of the N donors around the copper ions is dramatically distorted from ideal trigonal geometry towards a T-shaped geometry with an angle of about 150° between the two Cu−benzimidazolyl distances.

The differences observed in the Cu^{I} coordination in the two cations may mainly be ascribed to the presence in $[Cu^{I}_2(L\text{-}55)(MeCN)_2]^{2+}$ of a methylene group bridging the $N(sp^3)$ atom to the benzimidazole residues. This does not allow ring-closure at a suitable Cu−$N(sp^3)$ coordination distance, as occurs in $[Cu^{I}_2(m\text{-}XYLpy_2)]^{2+}$, in which $N(sp^3)$ and the pyridyl moieties are joined by ethylene bridges. Consequently, the coordinatively unsaturated Cu^{I} center binds an acetonitrile molecule, so the two Cu^{I} ions in the two kinds of cations have dramatically different coor-

dinations and possibly different electronic configurations. Crystal data and structure refinement are given in Table 1. Complete tables of atomic parameters and bond lengths and angles are deposited with the CCDC.

X-ray Structure of $[Cu^{II}_2(L\text{-}55)(OMe)_2][ClO_4]_2\cdot 1.25MeOH$ (2)

The crystals consist of dinuclear $[Cu^{II}_2(L\text{-}55)(OMe)_2]^{2+}$ cations and two ClO_4^- anions. These crystals spontaneously formed from a methanolic solution of the bis(μ-hydroxo)-bridged complex $[Cu_2(L\text{-}55)(OH)_2][ClO_4]_2$. Crystal data and structure refinement are shown in Table 1, and an ORTEP drawing, together with the atom numbering scheme of the cation, is shown in Figure 2.[37] The cation has an approximate mirror symmetry, the mirror plane containing the two bridging OMe, C40, and C43 atoms. The structure of the cation is similar to that of $[Cu_2(EBA)(OH)_2]^{2+}$, in which the ligand has a flexible spacer of six methylene carbon atoms instead of the five carbon atoms of the L-55 ligand. Each Cu has a highly distorted square-pyramidal geometry and coordinates to the tertiary amine in the apical position and the two sp^2-N atoms of the tridentate arm in two *cis* basal positions. The other two equatorial positions are occupied by the bridging methoxy groups. (Figure 2). In spite of the different spacer, the overall geometries of the $N_5Cu_2O_2N_5$ moieties are very similar in L-55 and EBA derivatives, as are the coordination geometries about the metal ions. These are compared in Table 2, together with the length of the spacer (N5···N10) and the intermetallic distances.

The basal donors of Cu1 and Cu2 are coplanar within 0.013 and 0.005 Å, respectively, and the displacements of Cu1 and Cu2 out of their respective mean planes toward the apical N donor are 0.114(4) and 0.149(4) Å, respectively. The two N_2O_2 basal planes make a dihedral angle (β) of 19.1(2)°, very similar to that observed in the EBA derivative

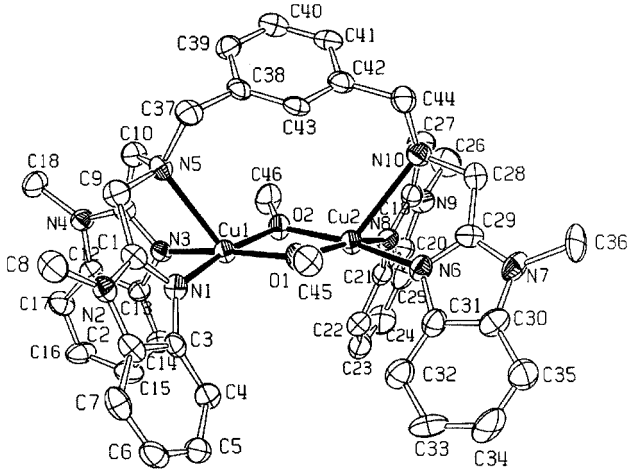

Figure 2. ORTEP[37] representation of the crystal structure of the cation **2**

[β = 20.0(2)°]. The geometry of the cation of **2** differs significantly from that reported for $[Cu_2L_3(OMe)_2]^{2+}$ [L_3 = (2-py$(CH_2CH_2)_2$N$(CH_2)_3$N(2-pyCH_2CH_2py)$_2$],[38] which has a crystallographic mirror symmetry, the L_3 ligand having aminobis(2-CH_2CH_2-pyridyl) arms [instead of aminobis(2-CH_2-benzimidazolyl)ones] and a trimethylene spacer. The Cu coordination in the latter cation is less distorted than that in the cation of **2**, with a small shortening of the apical Cu−N distance of about 0.2 Å, and a small, but significant, lengthening of the basal distances of about 0.03 Å (Table 2). Correspondingly, the N(sp^3)−N(sp^3) distance is more than 1 Å shorter than that in the L-55 and EBA analogues. This is due to the large difference in the spacer length (Table 2) and to N(sp^3)$(CH_2)_n$N(sp^3) arms, as previously suggested.[26] Notwithstanding, the geometries of the CuO_2Cu moieties are similar in the three dinuclear cations (Table 2). However, the *m*-xylyl plane in the cation of **2** is not parallel

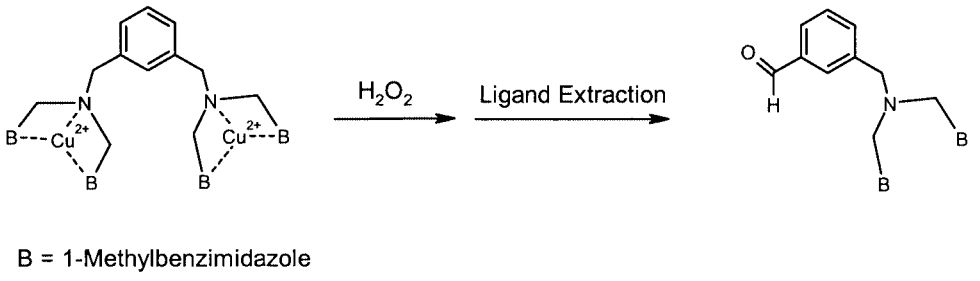
Reactivity of L-55 Complexes: Cu^I_2 vs. O_2 and Cu^{II}_2 vs. H_2O_2

The reactivity of the Cu^I complex $[Cu_2(L\text{-}55)(CH_3CN)_2]^{2+}$ toward dioxygen has been tested in different solvents and at various temperatures. When solutions of the complex are oxygenated at −85 °C in acetone, −90 °C in CH_2Cl_2, or −95 °C in THF, a moderately intense band near 350 nm (CT, $\varepsilon \approx 6000\ M^{-1}\cdot cm^{-1}$) and a weaker band at 500 nm (d-d envelope, $\varepsilon \approx 200\ M^{-1}\cdot cm^{-1}$) rapidly develop. In neither case can the reaction be reversed by application of vacuum/argon purge cycles, even upon mildly warming the solution. The UV band is bleached by the addition of a small excess of acid at low temperature, and no trace of hydrogen peroxide could be detected by peroxidase assay[19] after quenching of the reactions. Therefore, on reaction with dioxygen, $[Cu_2(L\text{-}55)(CH_3CN)_2]^{2+}$ does not produce a stable peroxo complex, but undergoes an irreversible oxidation to copper(II) species. Furthermore, application of the low-temperature stopped-flow method, a technique that has proved extremely useful for the spectroscopic detection of "copper−dioxygen adducts",[28,39] did not allow the observation of a peroxo intermediate complex. The spectral characteristics of the formed species are different from those of L-55 (hydroxo)dicopper(II) complexes that we have reported previously.[35] However, these oxygenated solutions are highly sensitive to moisture, and their UV/Vis spectra change quickly upon exposure to air, producing LMCT bands at 300 nm ($\varepsilon \approx 4300\ M^{-1}\cdot cm^{-1}$) and 335 nm ($\varepsilon \approx 3500\ M^{-1}\cdot cm^{-1}$), which testify to the formation of the previously characterized bis(hydroxo)dicopper(II) adduct.[35] The spectroscopic data and the sensitivity to water suggest that the low-temperature oxygenation of **1** affords a μ-oxodicopper(II) complex, which may be formed in a fast reaction as the Cu_2O_2 intermediate reacts with excess Cu^I [Equation (1)].

$$Cu^I\cdots Cu^I + O_2 \rightarrow [Cu_2O_2] + Cu^I\cdots Cu^I \rightarrow 2\,Cu^{II}-O-Cu^{II} + H_2O \rightarrow 2\,Cu^{II}-(OH)_2-Cu^{II} \quad (1)$$



Scheme 2

The positions of the LMCT bands developing during the low-temperature experiments do, in fact, agree with those reported for other μ-oxodicopper(II) complexes.[40,41] The oxygenation behavior of $[Cu_2(EBA)]^{2+}$, in which the copper coordination set is identical to that of $[Cu_2(L\text{-}55)(CH_3CN)_2]^{2+}$, is also similar.[26] The extreme electrophilicity of the putative oxygen intermediate $[Cu_2O_2]$ is not unexpected in view of the structural features of **1** and **2**, in which essentially only two poorly basic benzimidazole nitrogen donors of the ligand are coordinated to the copper ions (Figures 1 and 2). With $[Cu_2(L\text{-}66)]^{2+}$, in contrast, a stable and reversible dioxygen complex is formed at low temperature.[19] In this case, the larger size and flexibility of the chelate rings allows the ligand to bind each Cu^I with three nitrogen donors and the copper(I) centers to attain a more regular tetrahedral geometry. This is confirmed by the electrochemical data, which show that the ligand L-66 stabilizes the copper(I) state more than L-55 or EBA.[26,35] Furthermore, the ligand flexibility more easily supports the structural reorganization involved in the Cu^{II}/Cu^I redox exchange.[35]

The reactivity of $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$ toward hydrogen peroxide was also investigated. A tenfold excess of H_2O_2, after 12 h reaction time at room temperature, produced a regiospecific hydroxylation of the ligand at one benzylic carbon atom, followed by decomposition of the complex, in 50% yield (Scheme 2). Isolation of the oxidized ligand showed the presence of an aldehyde group, with a characteristic ^1H NMR peak at $\delta \approx 10$ ppm. The loss of a chelating arm of the ligand was confirmed by ESI-MS analysis (see Exp. Sect.). It is interesting to note that in the related complex $[Cu_2(L\text{-}66)]^{4+}$,[34] and also in $[Cu_2(m\text{-}Xylpy_2)]^{4+}$,[30] hydrogen peroxide effects ligand hydroxylation at the central xylyl residue. Therefore, the coordination environment of Cu^{II} centers, and in particular the five- or six-membered chelate ring size, plays a major role in effecting the hydroxylation reaction and in controlling the regiochemistry of C−H attack. Oxidative cleavage at the benzylic carbon atom, with production of an aromatic aldehyde, has previously been observed in the oxygenation of the Cu^I complexes $[Cu(PhCH_2Py)_2]^+$ [41] and $[Cu_2(m\text{-}Xyl^{i\text{Pr}4})]^{2+}$.[42]

Ligand Protonation and Stability Constants of Copper(II)−L-55 Complexes

The protonation and Cu^{2+} complex-forming equilibria of the ligand L-55 were investigated potentiometrically in a mixture of acetonitrile/water (4:1, v/v). We were able to monitor five protonation steps for L-55 and to determine their cumulative logβ values as 8.04 (0.2), 14.94 (0.2), 19.85 (0.3), 23.98 (0.1), 25.85 (0.3). The ligand easily and simultaneously incorporates two copper(II) ions according to the equilibrium in Equation (2).

$$2\,Cu^{2+} + \text{L-55} \rightleftarrows [Cu_2(\text{L-55})]^{4+} \quad \log\beta_{120} = 20.62\,(0.1) \tag{2}$$

The stability constant of this complex is similar to that of the corresponding dinuclear Cu^{II} complex derived from L-66 ($\log\beta_{120} = 19.89$[34]), while that of the $[Cu_2(EBA)]^{4+}$ complex is much larger ($\log\beta_{120} = 37.68$[26]), indicating that the longer and flexible carbon chain of EBA enables the repulsion between the positively charged cationic centers to be reduced.

With increasing pH, the two copper ions, each containing coordinated water molecules, undergo stepwise deprotonation of coordinated water molecules, as shown in the species distribution diagram in Figure 3, according to the equilibria in Equation (3) and (4) which occur with pK_a values of 6.93 and 6.25, respectively.

$$[Cu_2(\text{L-55})(H_2O)_2]^{4+} \rightleftarrows [Cu_2(\text{L-55})(H_2O)(OH)]^{3+} + H^+ \tag{3}$$

$$[Cu_2(\text{L-55})(H_2O)(OH)]^{3+} \rightleftarrows [Cu_2(\text{L-55})(OH)_2]^{2+} + H^+ \tag{4}$$

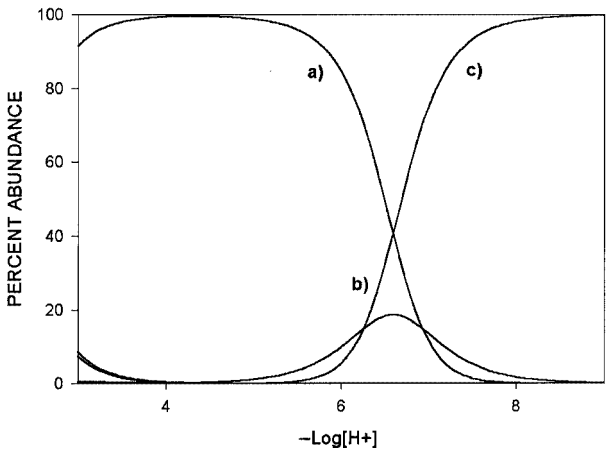


Figure 3. Species distribution in the 2Cu/L-55 system as a function of pH in acetonitrile/water solution: a) $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$; b) $[Cu_2(L\text{-}55)(H_2O)(OH)]^{3+}$; c) $[Cu_2(L\text{-}55)(OH)_2]^{2+}$

Both pK_a values are rather low and consistent with the formation of a bis(μ-hydroxo)dicopper(II) species. It may be noted that the second deprotonation occurs with lower pK_a values, even though the charge decreases after the first step. This behavior is not surprising. As is suggested by the X-ray crystal structure of $[Cu_2(L\text{-}55)(OMe)_2][ClO_4]_2$ (**2**), formation of the bis(μ-hydroxo) bridge probably drives proton dissociation, accounting for pK_{a2} < pK_{a1}. Therefore, as we have previously noted,[26] the monohydroxo species that forms after the first deprotonation step preorganizes the complex and facilitates the formation of the dibridged complex containing the ring-closed $Cu_2(OH)_2$ core. Deprotonation of coordinated water in the related complex $[Cu_2(EBA)(OH)_2]^{4+}$ follows the same trend (pK_{a2} < pKa1), but both pK_a values are larger.[26] This indicates that the *m*-xylyl residue of L-55 more readily favors the adoption of the folded conformation, stabilizing the bis(μ-hydroxo) bridge with respect to the long aliphatic chain of EBA.

NMR Studies on Copper(II)−L55 Complexes

The pH-driven equilibrium between $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$ (**3**) and its bis(μ-hydroxo) adduct **4** reported above can conveniently be monitored by ^{1}H NMR spectroscopy. The ^{1}H NMR spectrum of **3** in DMSO solution shows typical paramagnetic behavior, with broad signals (Figure 4a) resulting from the presence of only weakly coupled metal centers. The unresolved and broad peaks are spread between δ = 30 and −3 ppm, and increasing temperature shifts the downfield resonances towards the diamagnetic region, obeying Curie behavior, as shown in Figure 5a. In agreement with the above interpretation, the μ_{eff}/Cu was 1.27 μ_B, confirming the existence of a moderate interaction between the copper centers. This interaction is probably mediated by bridging water molecule(s) between the dicopper(II) centers. The addition of 2 equiv. of OH^- to the DMSO solution of **3** completely changes the NMR spectral shape. Formation of the bis(μ-hydroxo) bridge in **4** strongly increases the ex-

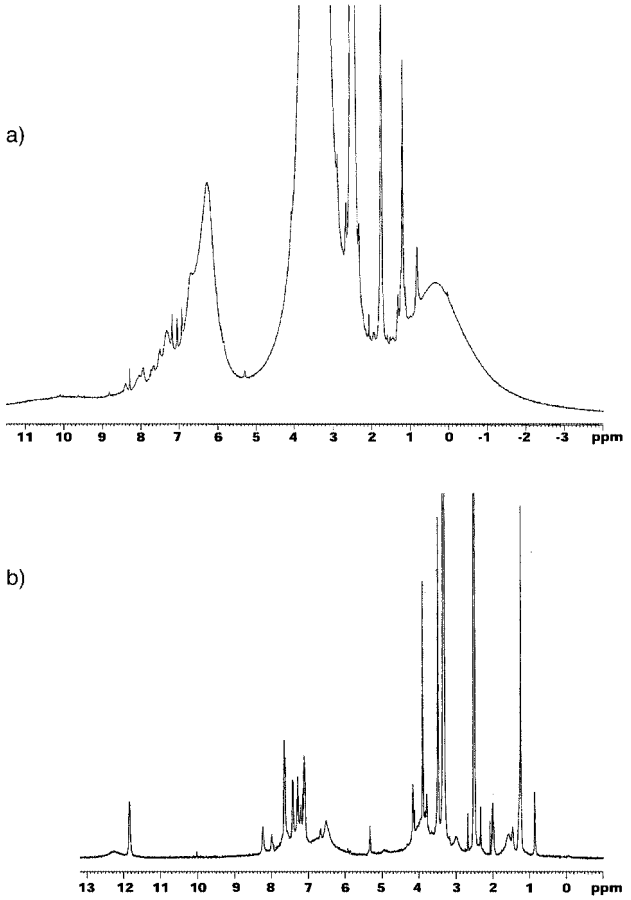

Figure 4. Diamagnetic regions of the ^{1}H NMR (δ values, ppm) spectra of $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$ and $[Cu_2(L\text{-}55)(OH)_2]^{2+}$ in DMSO solutions (1.5 mM) at 25 °C

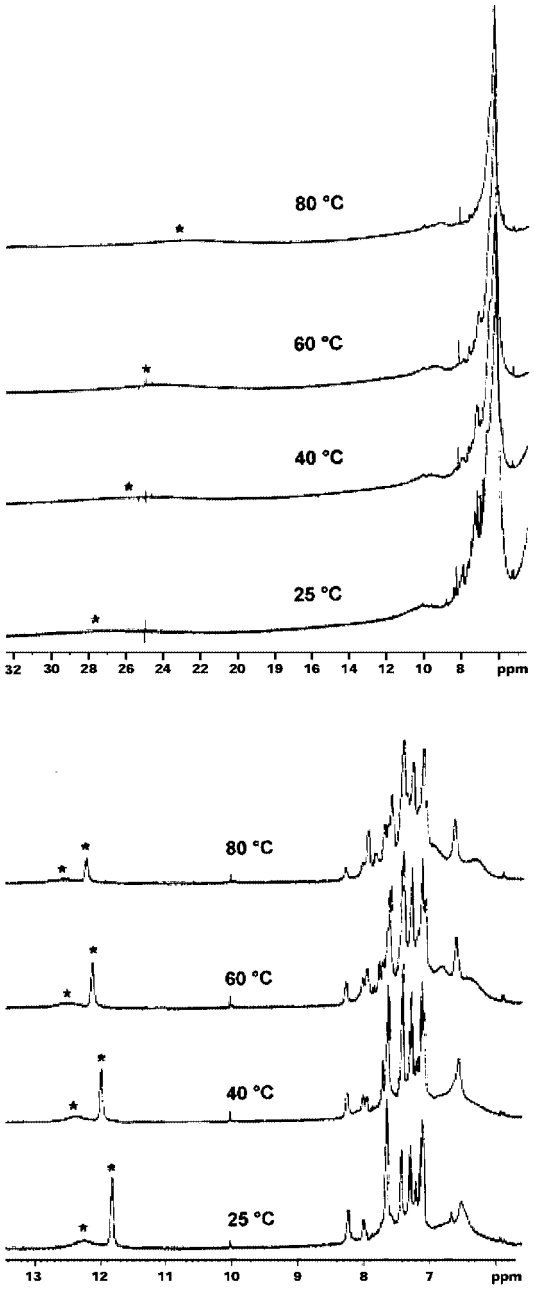

Figure 5. Upfield shifted resonances of a) $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$ and b) $[Cu_2(L\text{-}55)(OH)_2]^{2+}$; ^{1}H NMR spectra were recorded in DMSO at different temperatures

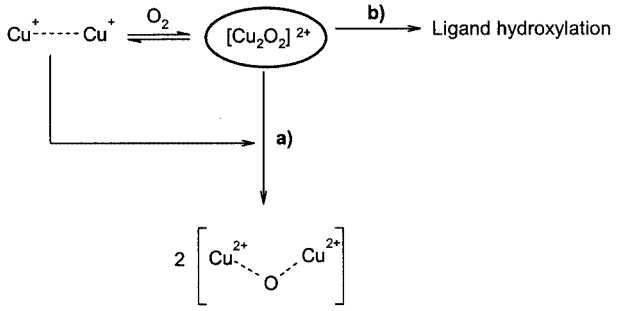
change interaction between the metal centers. The compound gives a diamagnetic-type NMR spectrum in which broadening of the peaks is reduced dramatically (Figure 4b), and the signals are detected only between $\delta = 0$ and 14 ppm. The temperature dependence of these signals was studied over the temperature range between 25 and 80 °C. As shown in Figure 5b, the downfield resonances clearly shift away from the diamagnetic region as the temperature increases, obeying anti-Curie law behavior. The magnetic properties of **4** in solution were confirmed by the Evans susceptibility method. At 25 °C, μ_{eff}/Cu was reduced to 0.47 μ_B, indicating a strong exchange coupling between the copper(II) centers. In the bridged bis(μ-hydroxo)dicopper(II) complexes the exchange interaction between the electron spins of the metal ions affects both the relaxation and the paramagnetic shift properties.[43,44] Hence, ^{1}H NMR spectroscopy strongly confirms the double-bridged structure of $[Cu_2(L\text{-}55)(OH)_2]^{2+}$ in solution, which should be clearly similar to those reported for **2** and $[Cu_2(EBA)(OH)_2]^{2+}$.[26] It can be noted that this coordination arrangement for $[Cu_2(L\text{-}55)(OH)_2]^{2+}$ was previously postulated on the basis of UV/Vis titration data.[35]

Conclusion

The reaction between $[Cu^I_2(L\text{-}55)(MeCN)_2]^{2+}$ and dioxygen produces $[Cu^{II}_2(L\text{-}55)(OH)_2]^{2+}$ through the formation of a species that we formulate as the μ-oxo-bridged complex $[Cu^{II}_2(L\text{-}55)O]^{2+}$, on the basis of its spectral properties and reaction with water. With $[Cu^I_2(L\text{-}66)]^{2+}$, in contrast, the isolation and characterization of the $[Cu_2(L\text{-}66)O_2]^{2+}$ peroxo complex at low temperatures was possible.[19] On raising the temperature, this peroxo complex also undergoes a similar irreversible oxidation (Scheme 3, a). However, when $[Cu^I_2(m\text{-}Xylpy_2)]^{2+}$ reacts with O_2, the resulting Cu_2O_2 complex effects a hydroxylation of the aromatic ring (Scheme 3b), giving a five-coordinate μ-phenoxo,μ-hydroxo-bridged dicopper(II) complex.[27] Structural results for compounds **1** and **2**, in comparison with those for the corresponding *m*-Xylpy$_2$ complexes, suggest that the different behavior of the Cu^I species toward dioxygen should be principally related to the different structural environments of the Cu^I ions, in spite of the apparently favorable orientation of the xylyl ring. Although the structure of the starting Cu^I compound is not known, the Cu^I−EBA complex should behave like the L-55 derivative, as suggested by the long Cu···N(amine) distance found in Cu^{II}−EBA,[26] close to that found for **2**. The reactivity of the putative dioxygen intermediates involved in the reaction pathways of L-55 and EBA complexes (Scheme 3a) are strictly related to their structural features. The absent or weak axial interaction offered by the amine group of the ligands increases the electrophilic reactivity of the $[Cu_2O_2]^{2+}$ moiety. Even at low temperature, as soon as the $[Cu_2(L\text{-}55)O_2]^{2+}$ or $[Cu_2(EBA)O_2]^{2+}$ complexes form, they probably react rapidly with excess Cu^I species present in solution (Scheme 3a), producing their corresponding μ-oxodicopper(II) complexes.



Scheme 3

The reactivity of the Cu^{II} complexes with hydrogen peroxide also elicits important differences in the behavior of L-55 vs. L-66 or *m*-Xylpy$_2$ complexes. In the last two cases, in fact, formation of a hydroperoxo intermediate results in hydroxylation of the central *m*-xylyl ring.[30,34] With $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$ a similar reaction through a putative μ-hydroperoxodicopper(II) complex seems possible, judging from the crystal structure of **2**, but the observed hydroxylation is much slower and occurs at the benzylic position. To clarify these differences, our current efforts are directed to the characterization of the so far elusive hydroperoxo intermediate formed by $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$.

Experimental Section

General: All reagents were purchased from commercial sources and were used as received unless otherwise noted. The ligand L-55 and the corresponding dinuclear copper(I) and copper(II) complexes studied here were prepared by published procedures.[33,35] NMR spectra were recorded with a Bruker Avance 400 spectrometer. Optical spectra were measured with HP 8452A and 8453 diode array spectrophotometers. Electrospray ionization MS spectra were acquired with a Finnigan MAT system equipped with an ion trap detector. Solutions were introduced into the electrospray source by syringe pump at 10 μL·min^{-1}. The ESI source was operated at 3.5 kV, the capillary temperature was set at 180 °C, and its voltage at 10 V; the experiments were performed in positive ion mode.

Single-Crystal X-ray Structure Determination of 1: Crystals of **1** were obtained by diffusion of diethyl ether into a solution of **1** in acetonitrile under an inert gas. Single crystals were coated with polyfluoropolyalkyl ether oil and mounted on a glass fiber. Data were collected with a Siemens P4 diffractometer. Lorentz and polarization corrections were applied. The structures were solved by direct methods and refined on F^2 by full-matrix, least-squares techniques.[45] Non-hydrogen atoms were refined with anisotropic thermal parameters. The PF_6^- anions are partly situated on inversion centers and disordered; they were refined by use of SIMU restraints. All hydrogen atoms are positioned geometrically. No hydrogen atoms were included in the description of three not very well defined acetonitrile solvate molecules.

Single-Crystal X-ray Structure Determination of 2: The crystals used in the X-ray analysis were grown by slow concentration of a methanol solution of $[Cu_2(L\text{-}55)(OH)_2][ClO_4]_2$. For data collection, a crystal of 0.6 × 0.4 × 0.4 mm, sealed in a glass capillary tube, in the presence of mother liquor, was used. The diffraction data were

collected at room temperature with an Enraf−Nonius CAD4 four-circle automated diffractometer with graphite-monochromated Mo-K_α radiation. Accurate unit cell parameters and orientation matrix were determined by least-squares refinement of the setting angles of 25 well-centered reflections in the range $22° < 2\theta < 30°$. Reflections were collected in the ω/2θ-scan mode. No decay was observed throughout the data collection. Correction for Lorentz polarization and scan absorption was applied. A total of 9476 (9449 independent) reflections were collected, 4424 of which having $I > 2\sigma(I)$. Unit cell parameters are a = 10.462(4), b = 13.226(4), c = 20.149(7) Å, α= 78.08(3), β= 89.18(3), and γ = 80.07(2)° for the triclinic $P\bar{1}$ space group, V = 2686.4(16) Å^3, Z = 2, M_w = 1135.9 and $D_{calcd.}$ = 1.404 Mg/m^3. The structure was solved by conventional Patterson and Fourier methods and refined by least-squares methods.[46,47] All the non-H atoms were treated anisotropically, except those of the solvent methanol, and the H atom contribution was held constant in the final refinement of 653 parameters. The final R index was 0.086 (Rw = 0.196) for reflections with $I > 2\sigma(I)$. Crystal collection and refinement data are given in Table 1. Complete tables of atomic parameters and bond lengths and angles are deposited with the CCDC. CCDC-198231 (**2**) and -198232 (**1**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Low-Temperature Spectroscopy: Low-temperature spectra (−80 °C and below) recorded during the reaction between $[Cu_2(L\text{-}55)(CH_3CN)_2]^{2+}$ and dioxygen were obtained with a custom-designed immersible fiber-optic quartz probe (Hellma) fitted to a Schlenk vessel and connected with an HP 8452A diode array spectrophotometer. Experiments were performed by bubbling chilled dioxygen into ca. 1.5 mM solutions of the complexes, formed in situ by mixing stoichiometric amounts of ligand and copper(I) BArF salt {BArF = $[\{3,5\text{-}(CF_3)_2C_6H_3\}_4B]^-$} in the appropriate solvent.[40,48]

Potentiometric Determinations: Potentiometric determination of L-55 in the absence and in the presence of copper(II) ions were performed with an apparatus and by methods described elsewhere[49] in 50 mL of an acetonitrile/water mixture (80:20, v/v) made up to 0.1 M in ionic strength with $NaClO_4$ at 298 K. The electrodes were dipped in the above solvent mixture for more than 1 h before standardization of the system, which was also made as described previously.[49] The HYPER-QUAD program was used to process the data to calculate both the protonation and stability constant.[50]

Solution Susceptibility Measurements: The susceptibility of the sample was measured by the modified Evans method.[51,52] A coaxial NMR tube was used with *tert*-butyl alcohol as an internal reference. The solution of the paramagnetic species (5 mM, DMSO) of which the susceptibility was to be determined was introduced into the inner narrow-bore tube, while the solvent containing the reference compound (4%, v/v) was placed into the outer tube. The paramagnetic solution also contained the reference compound, in an identical amount. The methyl proton signals of *tert*-butyl alcohol were recorded and the separation of the two signals ($\Delta\nu$) was monitored and regarded as the paramagnetic shift. Mass susceptibility (χ_p) is correlated to the above measured $\Delta\nu$ as given in Equation (5) where c is the concentration of the solution (mol/L), M the molecular weight of the complex, ν_0 the operating rf of the spectrometer, and χ_0 the susceptibility of pure solvent.

$$\chi_p = \chi_0 + \frac{3000 \cdot \Delta\nu}{4\pi\nu_0 cM} \quad (5)$$

Molar susceptibility (χ_M) can then be calculated after the usual correction.[53] The magnetic moment in solution (μ_{eff}) was obtained from the same shift data as reported in the literature.[54] The reliability of our measurement method was tested with $CuSO_4 \cdot 5H_2O$ as paramagnetic standard. The χ_p, χ_M, μ_{eff} values for this compound agreed perfectly with those previously calculated and available in the literature.[51,52]

Isolation of the Hydroxylated Ligand: The complex $[Cu_2(L\text{-}55)(H_2O)_2]^{4+}$ (100 mg, 0.07 mmol) was dissolved in a mixture of MeOH/phosphate buffer (50 mM, pH = 7, 8:2, v/v), and a concd. aqueous solution of hydrogen peroxide (0.7 mmol) was added. The solution was allowed to react for 12 h whilst stirring at room temperature. It was then concentrated under reduced pressure and chromatographed on a Sephadex LH-20 column (1.5 × 40 cm). The resulting fraction was collected, and the solvent volume was reduced by rotary evaporation and added to 100 mL of a mixture of concentrated ammonia/CH_2Cl_2 (1:1, v/v). The aqueous layer was separated and further extracted with cold CH_2Cl_2 (50 mL, 3 times). The organic extracts were combined, washed with water, and dried with $MgSO_4$. The final organic mixture was purified by silica gel column, by eluting with a mixture of CH_2Cl_2/MeOH (9:1, v/v) to which an increasing amount of concentrated NEt_3, from 1 to 15%, was added. The fraction containing the product was collected by spectrophotometric monitoring of the UV absorptions of the benzimidazole ring (284, 276, 254 nm) in the eluate, and after evaporation of the solvent afforded a light yellow, unstable oil (overall yield 50%). ^{1}H NMR ($CDCl_3$): δ = 9.8 (s, 1 H, HCO), δ = 7.6 (m, 8 H, Bz + Xy), 4.1 (t, 4 H, CH_2), 3.9 (s, 2 H, CH_2-Xy), 3.6 (s, 6 H, CH_3-Bz) ppm. ESI-MS: m/z = 424.4 $[L + H]^+$.

Novel Adducts of the Anticancer Drug Oxaliplatin with Glutathione and Redox Reactions with Glutathione Disulfide

Sarah Fakih,[a] Vivienne P. Munk,[a] Michelle A. Shipman,[a] Piedad del Socorro Murdoch,[a] John A. Parkinson,[a] and Peter J. Sadler*[a]

Keywords: Antitumour agents / Platinum / S ligands / Peptides / Redox chemistry

Reactions of [Pt(*rac*-1,2-DACH)Cl_2], [Pt(1*R*,2*R*-DACH)Cl_2] and the anticancer drug oxaliplatin with the tripeptide glutathione and glutathione disulfide have been studied by HPLC, ESI-MS and NMR methods. The same two major products are formed in each reaction: a thiolate-bridged dimer and a novel thiolate-bridged dinuclear macrochelate containing a nine-membered chelate ring. Redox reactions of Pt^{II} anticancer drugs with biological disulfides are of potential importance to their mechanism of action.

Introduction

cis-Diamminedichloroplatinum(II) or cisplatin (**1**) has been used as an anticancer drug since it entered clinical trials in the 1970s.[1] Its effectiveness against ovarian and testicular cancers is well established, and it has also been used to improve the response rate of head, neck and lung tumours.[2] Although one of the most effective anticancer drugs known to date, cisplatin possesses inherent disadvantages, namely limited solubility and extreme side-effects, including nausea, vomiting and nephrotoxicity.[3] Furthermore, many tumours have displayed a natural resistance to cisplatin while others develop resistance during treatment.[4] Thus, the use of the drug is limited to a narrow class of tumours. The occurrence of such adverse side-effects has been addressed by the introduction of hyperhydration therapies and serotonin antagonists.[5] Concurrently, there has been a major effort in the production of alternative drugs, which display all of the activity of cisplatin but with fewer side-effects.[6] A large library of platinum complexes has been synthesised and their antitumour activity examined, resulting in the determination of structure-activity relationships.

The nature of the amine has a pronounced effect on the activity observed. Preclinical studies of platinum complexes containing diaminocyclohexane (DACH) have demonstrated activity against cisplatin-resistant cell lines.[7] The drug (1*R*,2*R*)-diaminocyclohexaneoxalatoplatinum(II), oxaliplatin (**2**), has recently been approved for use in the treatment of colorectal and ovarian cancers in Europe, Asia and South America.[8,9] In the clinical trials of oxaliplatin, the drug was highly active in solid tumour types, and particularly effective against advanced colorectal cancer when administered with 5′-fluorouracil.[5,10] Oxaliplatin shows no nephrotoxicity or myeloid toxicity. However, the dose-limiting toxicity is governed by peripheral sensory neuropathy.[11] Evidence also exists that cisplatin analogues containing the bulky, nonpolar ligand DACH, such as oxaliplatin, do not elicit resistance in mismatch repair-deficient cells.[12] Thus, oxaliplatin may be able to overcome tumour resistance caused by loss of mismatch repair. Studies have shown that [Pt(1,2-DACH)Cl_2] is nearly twice as cytotoxic to HT-29 cells as oxaliplatin, although cellular uptake of oxaliplatin is considerably higher.[11]

Although cellular DNA is the ultimate target for platinum anticancer drugs,[13−15] many other biomolecules can also interact with platinum drugs, especially thiols and thioethers. Such biomolecules could either aid the transport of the drug or, equally, hinder transport by effectively capturing it, thereby preventing it from ever reaching its intended target site.

The thiol-containing tripeptide glutathione (γ-L-Glu-L-Cys-Gly, GSH, **3**) is present in most cells in millimolar concentrations (0.5−10 mM).[16,17] Intracellular interactions between glutathione and cisplatin have previously been found to be deactivating, and cisplatin-resistant tumour cells often contain elevated levels of glutathione.[18,19] There is strong evidence that GS-X pumps can facilitate the active transport of Pt drugs from the cell.[20] Interestingly, however, the strong affinity of sulfur for platinum complexes has led to the coadministration of platinum drugs with glutathione as a chemoprotectant.[21,22] The toxic side-effects are reduced due to reversal or prevention of Pt-S adducts in proteins, while the antitumour activity of cisplatin remains un-

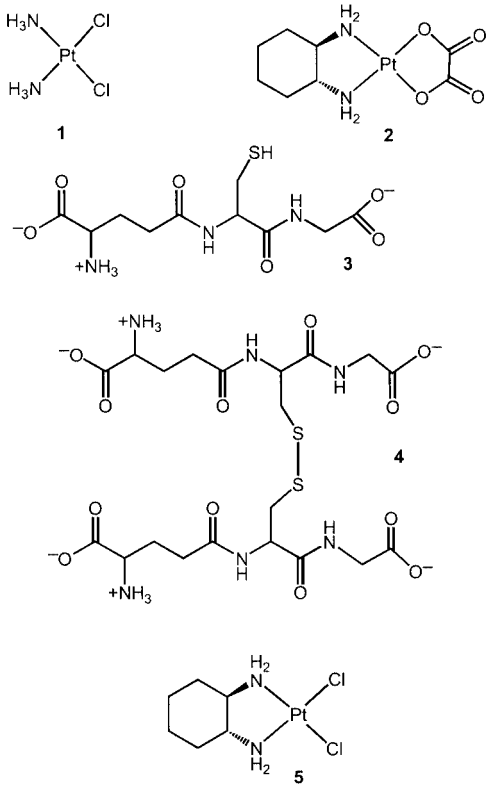
affected.[23] Platinum-sulfur adducts might constitute drug reservoirs from which the platinum could later be transferred onto the target DNA.[17] Could this provide an alternative pathway to the direct attack of the drug (or its aqua adducts) on DNA? Such a question has provided the stimulus for a number of studies into reactions between platinum drugs and potential sulfur nucleophiles.[24−28]

The major product from the reaction of cysteine derivatives with *cis*-diam(m)ineplatinum(II) complexes is thought to be the bridged dimer $[(am)_2Pt(\mu_2\text{-}SR)_2Pt(am)_2]$, where "am" is am(m)ine or one half of a diamine. However, these bridged complexes are unlikely to be reactive towards DNA bases, although the ammine complexes can slowly release ammonia.[29,30] Reactions carried out with [PtCl(dien)]Cl and methionine (Met) or methylated glutathione (GSMe)[26,27] and 5′ GMP have indicated that the platinum−sulfur adducts $[Pt(dien)(Met\text{-}S)]^{2+}$ and $[Pt(dien)(GSMe\text{-}S)]^{2+}$ are formed initially with subsequent intermolecular displacement of the thioether in the Pt−S adducts by 5′ GMP-N7. Interestingly, this displacement of guanine-N7 has been observed only with thioether adducts and not for reactions with thiolate complexes.[30] The biotransformation products of oxaliplatin have been investigated in patients with gastrointestinal cancers and there is evidence of nucleophilic substitution of the oxalate leaving group, with mono- and dichlorinated DACH-platin and glutathione-DACH-platin adducts being present as metabolites in the blood plasma and urine.[31]

In work reported here, we have isolated and characterised new products formed from reactions of either GSH or GSSG (GSH disulfide, **4**) with oxaliplatin, and (1*R*,2*R*)-diaminocyclohexanedichloroplatinum(II), [Pt(1*R*,2*R*-DACH)-Cl_2], **5**. These reactions have been carried out under physiological conditions, and for each complex a glutathione-bridged dinuclear platinum(II) macrochelate has been isolated. This is a potentially reactive species and could play a role in the mechanism of action of platinum anticancer drugs.



Results

Reactions of [Pt(1,2-DACH)Cl_2] with GSH and GSSG

UV/Vis Measurements

The time-courses of reactions between [Pt(*rac*-1,2-DACH)Cl_2] with GSH or GSSG at 310 K were studied using UV/Vis spectroscopy. Two molar equivalents of GSH or GSSG (10 μL, 20 mM, pH 7) were added to a solution of [Pt(*rac*-1,2-DACH)Cl_2] (1 mL, 100 μM). Typical spectra are shown in Figure 1. In both experiments a major new absorption band was observed at 220 nm which increased in intensity with time over a period of ca. 24 h. Interestingly, the reaction with GSH was only slightly faster than that with GSSG [see also Figure 8(b)].

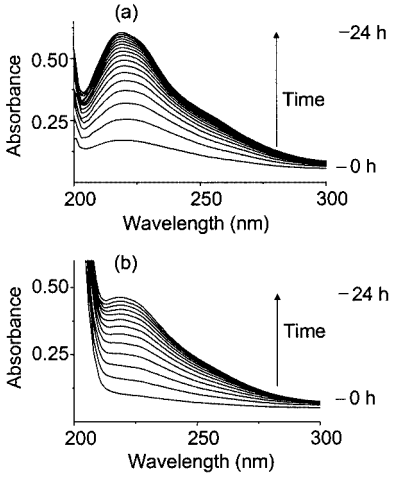


Figure 1. The change in absorbance with time for reactions of [Pt(*rac*-1,2-DACH)Cl_2] with two molar equivalents of (a) GSH, or (b) GSSG in aqueous solution (pH 7); measurements were taken at 310 K at regular hourly intervals for the first 24 hours of the reaction

HPLC Measurements

HPLC techniques were used to isolate two major products (labelled **A** and **B** in Figure 2) which formed during six-day incubations at 310 K of [Pt(*rac*-1,2-DACH)Cl_2] (2 mL, 100 μM) with two molar equivalents of GSH or GSSG (20 μL, 20 mM) initially at pH 7. Small amounts of unchanged GSH and GSSG were still present in the reaction mixture after six days. The major product peaks eluted at 20.6 min (peak **A**) and 21.6 min (peak **B**) using a gradient of acetonitrile (0−30% over 25 min) in water, with 0.1% trifluoroacetic acid as an ion pairing agent. Other minor peaks were also observed in the chromatogram, but these peaks were not isolated or identified.

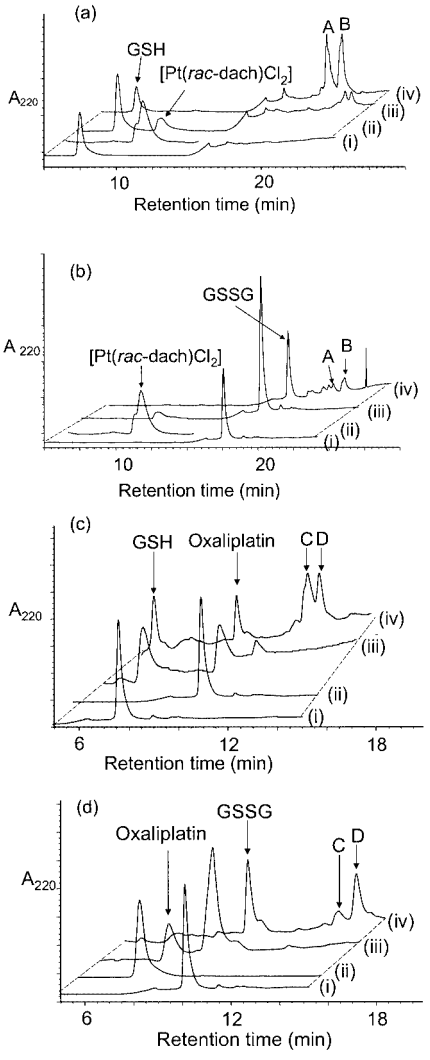

Figure 2. HPLC chromatograms (C_{18} reverse phase column eluted with a CH_3CN/H_2O gradient containing 0.1% of the ion pairing agent, monitored at 220 nm) for reactions of [Pt(*rac*-1,2-DACH)Cl_2] with two molar equivalents of either (a) GSH, or (b) GSSG (310 K, initially at pH 7), and oxaliplatin with two molar equivalents of either (c) GSH, or (d) GSSG (310 K, initially at pH 7); labels for chromatograms: (i) GSH or GSSG alone, (ii) [Pt(*rac*-1,2-DACH)Cl_2] or oxaliplatin alone (iii) after 5 min of reaction and (iv) after six days of reaction; baseline drifts in the chromatograms are observed due to a change in the refraction index of the solvent

Using the same acetonitrile gradient, the reaction of [Pt(*rac*-1,2-DACH)Cl_2] (2 mL, 100 μM) with two molar equivalents of GSH (20 μL, 20 mM, pH 7) at 310 K was monitored at hourly intervals for 24 h. The resulting chromatograms are shown in Figure S1 in the Supporting Information. The chromatograms show that the peaks for the starting materials decrease and the intensities of the product peaks **A** and **B** increase with time. No intermediates were observed during the course of the reaction. The reaction was complete after ca. 24 h, at which point the peaks due to the starting materials, 8.1 min (GSH) and 8.9 min ([Pt(*rac*-1,2-DACH)Cl_2]), have almost disappeared and the peaks for the products, 19.1 min (**A**) and 22.1 min (**B**), reach maximum intensity.

Reactions of [Pt(*rac*-1,2-DACH)Cl_2] with increasing GSH concentrations (1, 2, 4, 8 and 10 molar equivalents) were investigated by HPLC using a different acetonitrile gradient (4−20% over 30 min). The resulting chromatograms are shown in Figure 3. With this acetonitrile gradient the peaks that represent the major products, peaks **A** and **B**, do not appear as the single peaks previously seen in Figure 2, but as a series of split peaks. This difference can be attributed to changes in the HPLC elution conditions and the possible presence of isomers. The chromatograms clearly indicate a steady increase in the area of the peaks for product **A** (ca. 14 min) with increasing concentrations of GSH, while the intensities of the peaks for product **B** (ca. 18 min) decrease with increasing GSH concentrations. The areas of the peaks for products **A** and **B** are approximately equal at a 2:1 molar ratio of GSH to [Pt(*rac*-1,2-DACH)Cl_2].

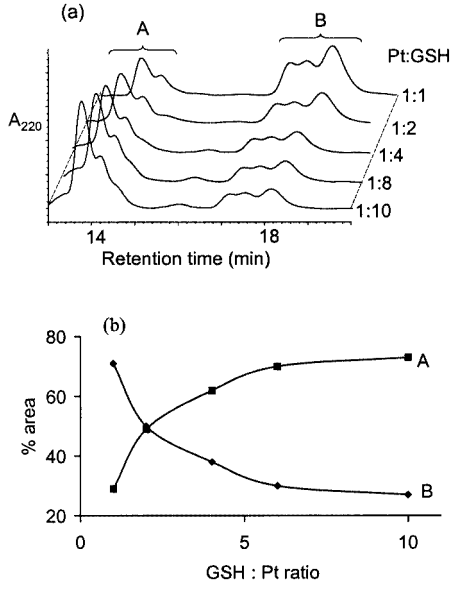

Figure 3. (a) Effect of variation of the molar ratio of [Pt(*rac*-1,2-DACH)Cl_2]:GSH on the intensities of the groups of peaks **A** and **B** in the HPLC chromatogram from reactions incubated at 310 K for 6 days; (b) variation of the intensities of peaks **A** and **B** with Pt:GSH molar ratio

To investigate the possibility that the split peaks observed in the HPLC chromatograms shown in Figure 3 are due to the presence of isomers, an analogous reaction of GSH (20 μL, 20 mM, pH 7) with enantiomerically pure [Pt(1*R*,2*R*-DACH)Cl_2] (2 mL, 100 μM) was carried out at 310 K. The resulting HPLC chromatogram, obtained using a 4−20% acetonitrile gradient over 30 min, is shown in Figure 4, together with the HPLC trace of products from the reaction of [Pt(*rac*-1,2-DACH)Cl_2] and GSH for comparison. The chromatogram for the reaction products of the enantiomerically pure platinum complex contains two single peaks in a ratio of ca. 1:2. The overall ratio of peak areas **A**:**B** is similar for reactions of the racemic and enantiomerically pure DACH complexes. The small change in HPLC retention times can be attributed to slight differences in the HPLC elution conditions.

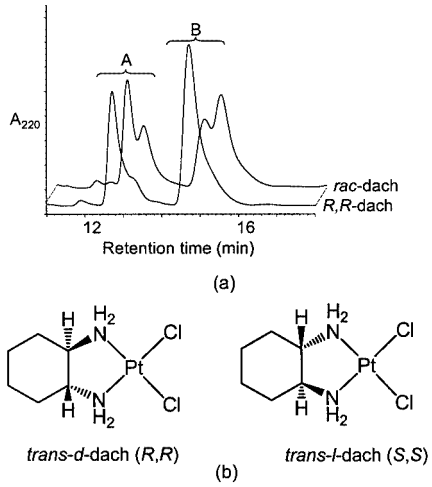

Figure 4. (a) HPLC chromatograms for products formed at 310 K from the reaction of [Pt(*rac*-1,2-DACH)Cl_2] or [Pt(1*R*,2*R*-1,2-DACH)Cl_2] with two molar equivalents of GSH in aqueous solution (initially at pH 7); HPLC elution conditions are slightly different from those in Figures 2 and 3, accounting for slight variations in the retention times; (b) structures of the two optical isomers of [Pt(1,2-DACH)Cl_2], [Pt(1*R*,2*R*-DACH)Cl_2] and [Pt(1*S*,2*S*-DACH)Cl_2]

The absorption coefficients of the separated products **A** (ε = 32,000 $M^{-1}cm^{-1}$) and **B** (ε = 34,000 $M^{-1}cm^{-1}$) at 220 nm were determined by freeze-drying the collected peaks, redissolution in water, measurement of their absorption spectra and determination of the platinum concentration in the same solution by ICP-AES.

Since GSH in cells is likely to be present in high molar excess over the platinum complex, an analogous reaction of [Pt(1*R*,2*R*-DACH)Cl_2] and a 100-fold molar excess of GSH was also monitored by HPLC. Two product peaks were formed in this reaction, and their identities (peaks **A** and **B**) were confirmed by ESI-MS (see below).

ESI-MS Measurements

The positive ion ESI-MS data of the reaction mixtures of [Pt(*rac*-1,2-DACH)Cl_2] with GSSG or GSH revealed the presence of peaks for two major products at *m*/*z* = 462 and *m*/*z* = 615 for both of the reactions (Figure S2 in the Supporting Information). The only other observed peaks are attributable to small amounts of the starting materials. Peaks **A** and **B** were separated by HPLC, and ESI-MS measurements of the collected fractions indicated that each peak consists of a single product. The observed ESI-MS spectrum for each of these products is shown in Figure 5. Both peaks show a cluster of ions characteristic of the isotopic distributions of Pt and N. The most abundant molecular ion obtained from collected peak **A** has a molecular ion [M^{2+}] at *m*/*z* = 615. Isotope modelling suggested that peak **A** corresponds to the molecular formula of $[Pt_2C_{32}H_{58}N_{10}O_{12}S_2]^{2+}$, assignable to an *S*-bridged dimer [Figure 6(a)]. The fraction associated with peak **B** [Figure 5(b)] has a molecular ion [M^{2+}] at *m*/*z* = 462, and isotope modelling suggested a molecular formula

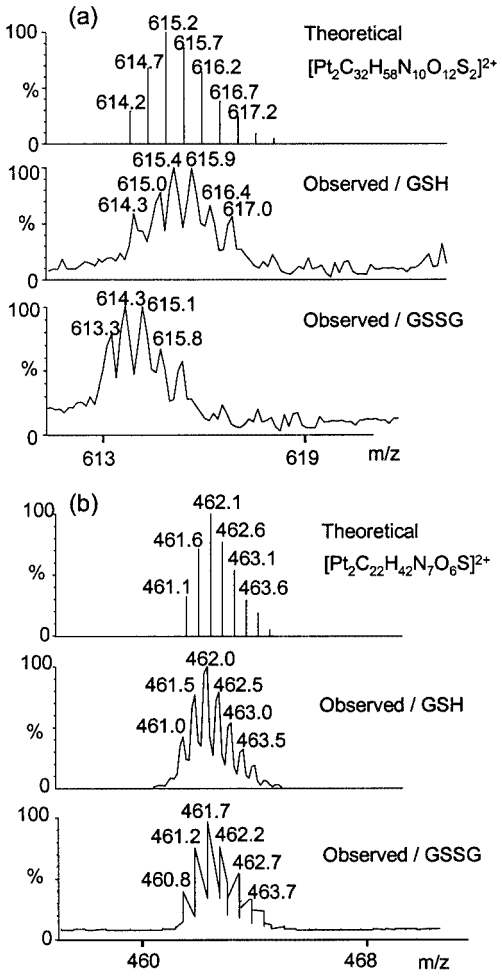

Figure 5. Positive ion ESI-MS spectra for HPLC peaks (a) **A** and (b) **B** separated from the reaction of [Pt(*rac*-1,2-DACH)Cl_2] with two molar equivalents of GSH or GSSG (310 K, initially at pH 7, six days); the HPLC conditions for the separation of these species are the same as in Figure 2; the HPLC peaks were collected, concentrated by lyophilisation and redissolved in acetonitrile/water, 1:1, for ESI-MS measurements; the observed and theoretical isotope patterns of the proposed structures for each peak are shown; the full ESI-MS spectrum is shown in Figure S2 in the Supporting Information

$[Pt_2C_{22}H_{42}N_7O_6S]^{2+}$, assignable to a glutathione-bridged macrochelate [Figure 6(b)].

NMR Analysis

1D ^1H and 2D ^1H DQFCOSY, NOESY, TOCSY and ROESY NMR experiments were carried out on a ca. 1.3 mM solution of product **B** in 90% H_2O/10% D_2O, pH 4. Specific assignments were determined for most of the ^1H NMR resonances based on the 2D TOCSY NMR spectroscopic data (Figure 7): Gly-N*H* (δ = 7.90 ppm) couples to two doublets of doublets at δ = 4.10 ppm (Gly−Hα^a) and δ = 3.61 ppm (Gly−Hα^b). Cys−Hα (δ = 5.02 ppm) couples to Cys−Hβ^b (δ = 2.79 ppm) but not to its geminal partner Cys−Hβ^a (δ = 2.66 ppm). Both of these signals are clearly visible in the 1D ^1H NMR spectrum (Figure S3 in the Supporting Information, which also shows the atom labelling scheme). A spin system consisting of six resonances was

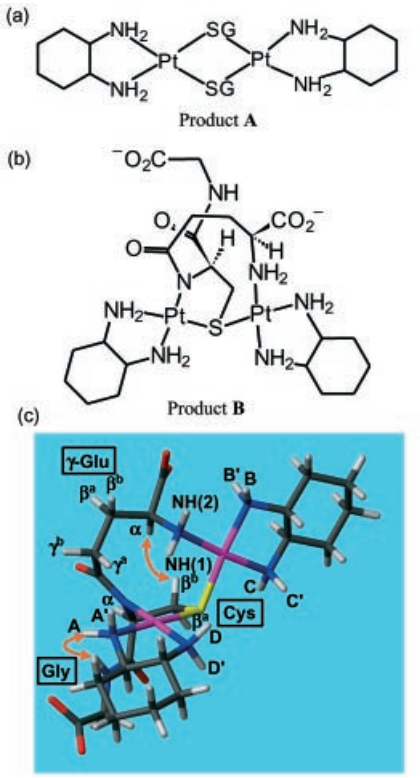

Figure 6. Proposed structures for the products of the reactions of [Pt(*rac*-DACH)Cl_2] with GSH or GSSG, which give rise to HPLC peaks (a) **A**, and (b) **B**; (c) capped-stick representation of the structure of the product corresponding to HPLC peak **B** formed between GSH with [Pt(1*R*,2*R*-DACH)Cl_2], as determined by ^{1}H NMR spectroscopy; two key structural ^{1}H-^{1}H rOes are shown by double-headed arrows; of the N*H* signals, the highest frequency resonance is that of NH(1) of γ-Glu; the space-filled representation explains how this shift may arise since the proton sits above one of the platinum centres (see contents entry); this proton therefore experiences a larger deshielding effect compared to all other N*H* protons in the molecule

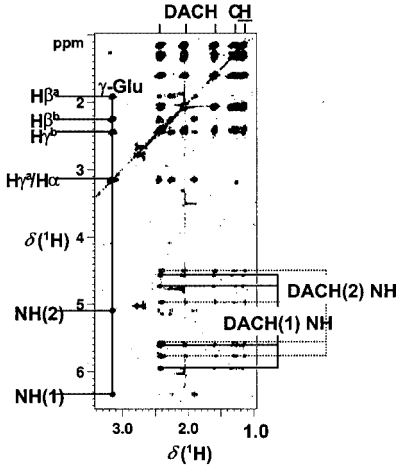

Figure 7. Section of the 600 MHz ^{1}H 2D TOCSY NMR spectroscopic data for peak **B** formed between GSH with [Pt(1*R*,2*R*-DACH)Cl_2], showing assignments for γ-Glu and DACH ligand resonances; despite several overlaps between DACH C*H* protons, it is still possible to distinguish two independent spin systems from the DACH N*H* resonances; resonance assignments are summarised in Table 1

assigned to γ-Glu: $\delta_{NH(1)}$ = 6.33 ppm; $\delta_{NH(2)}$ = 5.10 ppm; $\delta_{H\alpha}$ = 3.15 ppm; $\delta_{H\beta}{}^{b}$ = 2.25 ppm; $\delta_{H\beta}{}^{a}$ = 1.91 ppm; $\delta_{H\gamma}{}^{a}$ = 3.25 ppm; $\delta_{H\gamma}{}^{b}$ = 2.40 ppm. In addition, two complete spin systems are visible for two independent DACH units (Figure 7). Stereospecific assignments for the ring protons were not made due to resonance overlap. The NMR signal assignments are given in Table 1.

Table 1. ^{1}H NMR resonance assignments for the 2:1 macrochelate (peak **B**) formed between [Pt(1*R*,2*R*-DACH)Cl_2] and GSH; for proton labelling see Figures 6(c) and Figure S3 in the Supporting Information

		δ (NH)				
{Pt-DACH}		5.95 (A), 4.56 (A′) 5.62 (D), 4.75 (D′)			5.78 (C), 4.96 (C′) 5.57 (B), 4.50 (B′)	
H_2-SG	δ (NH)	δ (Hα)	δ (Hβ^a)	δ (Hβ^b)	δ (Hβγ^a)	δ (Hβγ^b)
Gly	7.90	4.10[a], 3.61[b]				
Cys	– [a]	5.02	2.66[b]	2.79[c]		
γ-Glu	6.33 (NH1), 5.10 (NH2)	3.15	1.91	2.25	3.16	2.40

[a] The NH signal is absent, consistent with the N of Cys being bound directly to one of the two platinum metal centres. [b] $^3J_{H,H}$ = 0, $^2J_{H,H}$ = 14 Hz. [c] $^3J_{H,H}$ = 6.4, $^2J_{H,H}$ = 14 Hz.

A molecular model of product **B** was constructed as a glutathione-bridged macrochelate molecule, $[Pt_2C_{22}H_{42}N_7O_6S]^{2+}$, which accounts for three specific observed rOes: Gly-N*H* shows an rOe to the NH proton A of DACH(1); Cys-Hβ^b shows an rOe to γ-Glu−Hα; γ-Glu−Hγ^a shows an rOe to the NH proton A′ of DACH(1). The energy-minimised model incorporating these constraints is shown in Figure 6(c).

pH Considerations

No buffers were used in these investigations, since buffer ions (e.g. phosphate) are potential ligands for Pt^{II}. The pH of each solution was regularly monitored during the course of each reaction. The pH of the glutathione and glutathione disulfide solutions was adjusted to 7 prior to addition of the platinum complex solution. Following addition of the platinum complex, the pH of the reaction mixture dropped within ca. 4 h to a value of between 4.5 and 5. The ^{1}H NMR spectra of products **A** and **B** show little change over the pH range 2.8−8.7, and therefore these species appear to be stable over a wide pH range.

Reactions of Oxaliplatin with GSH and GSSG

UV/Vis Measurements

The reaction between oxaliplatin (1 mL, 100 μM) and GSH (10 μL, 20 mM, pH 7) at 310 K gives rise to a new absorption band at 220 nm, which increases in intensity over a period of 48 h (Figure 8). The reaction between oxaliplatin and GSSG, which was monitored over 96 hours, is also slow and gives rise to a similar new absorption band. In comparison with the similar reactions of [Pt(*rac*-1,2-

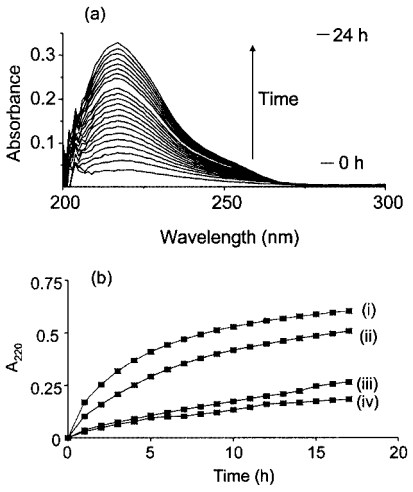

Figure 8. (a) The change in absorbance with time for reactions of oxaliplatin with two molar equivalents of GSH (initially at pH 7) in aqueous solution; measurements were taken at 310 K at regular hourly intervals for the first 24 hours of the reaction; (b) comparison of the changes in absorbance at 220 nm with time for reactions of [Pt(*rac*-1,2-DACH)Cl_2] or oxaliplatin with two molar equivalents of GSH or GSSG; labels for graphs: (i) [Pt(*rac*-1,2-DACH)Cl_2]/GSH, (ii) [Pt(*rac*-1,2-DACH)Cl_2]/GSSG, (iii) oxaliplatin/GSH and (iv) oxaliplatin/GSSG

DACH)Cl_2], those of oxaliplatin are approximately three times slower [Figure 8(b)].

HPLC Measurements

The HPLC chromatograms for reaction mixtures of oxaliplatin (2 mL, 100 μM) with two molar equivalents of GSH or GSSG (20 μL, 20 mM, pH 7, 310 K) using a 4−20% acetonitrile gradient over 30 min are shown in Figure 2(c) and (d). Peaks for two major products which elute at 14.8 min (**C**) and 15.5 min (**D**) appear in both chromatograms and increase in intensity over a period of 48 h, whilst the peaks corresponding to the reactants decrease in intensity. Small amounts of the starting materials were still present in the reaction mixtures after five days. Some minor peaks for unidentified products were also observed. For the GSH reactions, the relative areas of peaks **C** and **D** are similar, whereas for GSSG, peak **D** is more intense than peak **C**. A timecourse study (Figure S1 in the Supporting Information) showed that this preference for formation of product **D** was similar throughout the 0−24 h period that the reaction was studied.

ESI-MS Measurements

HPLC peaks **C** and **D** were collected for reactions between oxaliplatin and GSH or GSSG, and analysed by ESI-MS (Figure 9). Each peak corresponds to only one major product, with molecular ions at m/z = 615 (**C**) and m/z = 462 (**D**). Isotope modelling of the data showed that peak **C** was assignable to the molecular formula $[Pt_2C_{32}H_{58}N_{10}O_{12}S_2]^{2+}$ [the S-bridged dimer shown in Figure 6(a)] and peak **D** assignable to the formula $[Pt_2C_{22}H_{42}N_7O_6S]^{2+}$ [the glutathione-bridged macrochelate shown in Figure 6(b)]. These data are consistent with the

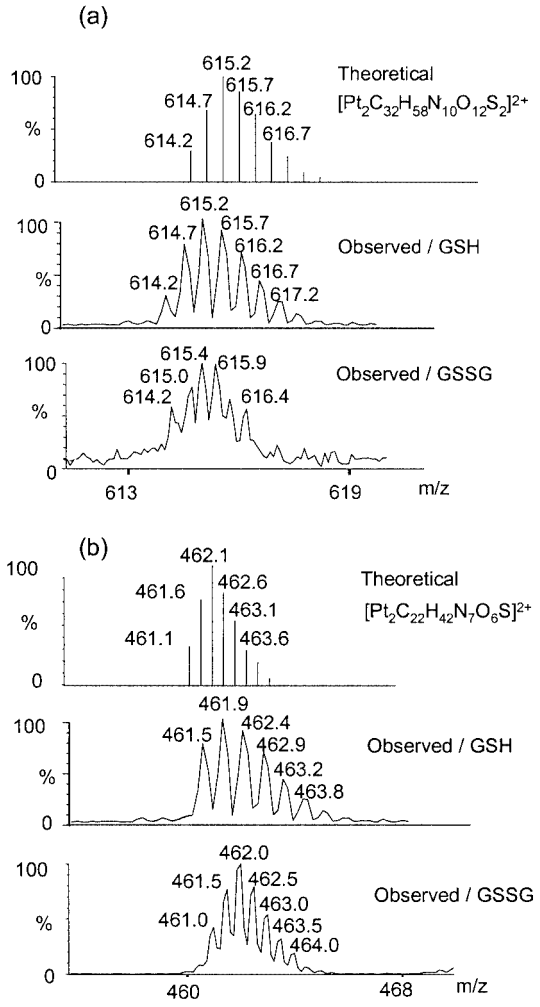

Figure 9. Positive ion ESI-MS spectra obtained from HPLC peaks (a) **C**, and (b) **D**, products from the reaction of oxaliplatin with two molar equivalents of GSH (310 K, initially at pH 7, six days), separated and collected using the elution conditions shown in Figure 2, and concentrated by lyophilisation; the observed and theoretical isotope patterns for the proposed structures are shown

products giving rise to peaks **C** and **D** from the oxaliplatin reactions being identical to those of peaks **A** and **B**, respectively, from the reactions of [Pt(1,2-DACH)Cl_2].

Discussion

Although cisplatin is an effective anticancer drug, a major clinical problem is the development of resistance.[4] Early on it was discovered that diaminocyclohexane (DACH) platinum(II) complexes are non-cross resistant with cisplatin and this has led to the clinical approval of one such DACH derivative, [Pt(1*R*,2*R*-DACH)(oxalate)] (oxaliplatin), for the treatment of metastatic colorectal cancer.[8,32] For [Pt(DACH)Cl_2] complexes containing the *trans*-DACH geometrical isomer, the *R*,*R* diastereomer is more active than *S*,*S*, and both are more active than the meso (*R*,*S*) adduct.[33] Since thiols such as the tripeptide glutathione (GSH), present in cells at concentrations of

0.5−10 mM,[16] can play a major role in cellular resistance mechanisms, there is a need to elucidate reactions between Pt-DACH anticancer complexes and glutathione.

In the only previous study (as far as we are aware) of such reactions, two products from the reaction of [Pt(1,2-DACH)Cl_2] and GSH were separated by HPLC.[34] They were found to be 1:1 (Pt:GSH) adducts, but were not further characterised. In this work we have studied reactions of both GSH and its oxidised form GSSG with both racemic (1*R*,2*R*/1*S*,2*S*) and enantiomerically pure [Pt(1*R*,2*R*-DACH)Cl_2], as well as the drug oxaliplatin. The time dependence of the reactions was followed by both UV/Vis spectroscopy and by HPLC. Remarkably, reactions of both GSH and GSSG gave rise to a similar broad band at ca. 220 nm (Figures 1 and 8), assignable to a thiolate-to-platinum charge-transfer band ($\varepsilon > 30{,}000\ M^{-1}cm^{-1}$). Reactions with GSSG were more than three times slower than with GSH. HPLC studies showed that reactions of [Pt(*rac*-1,2-DACH)Cl_2] with both GSH and GSSG gave rise to the same two major products [**A** and **B**, Figure 2(a) and (b)], which were identified by ESI-MS as 2(Pt):2(GSH) (**A**) and 2(Pt):1(GSH) (**B**) adducts.

Displacement of oxalate from oxaliplatin by GSH (or GSSG) leads to products **C** and **D**, which are identical to products **A** and **B** from reactions of the dichloro complex, from which the chloro ligands are displaced. Reactions of oxaliplatin with GSH and GSSG were much slower than those of [Pt(1,2-DACH)Cl_2]. This is not surprising in view of the presence of chelated oxalate in oxaliplatin.

Remarkably, therefore, GSSG undergoes redox reactions with platinum(II) complexes, leading to cleavage of the disulfide bond and formation of Pt^{II}-GSH adducts. Such redox chemistry of platinum(II) anticancer drugs has received relatively little previous attention. Lempers et al. have suggested that cleavage of GSSG by $[Pt(dien)Cl]^+$ involves H_2O as the reducing agent[16] and Fazlur-Rahman and Verkade have detected initial binding of GSSG to $[Pt(dien)]^{2+}$.[35] Ohta et al. have reported that *trans*-$[PtCl_2(NH_3)_2]$ can cleave disulfide bonds in human serum albumin,[36] and they also found that GSH reacts with cisplatin 17 times faster than with GSSG, and six times faster with the monoaqua adducts.[37] Further work is needed to elucidate the mechanism of such redox reactions.

The resolution of the reverse-phase HPLC chromatograms is very sensitive to the elution conditions (solvent gradient and temperature), but under certain conditions diastereomeric products were separable for reactions of the racemic complex. On the basis of ESI-MS and NMR spectroscopic data, product **A** can be identified as a thiolate-bridged dimer [Figure 6(a)] and product **B** as a novel dinuclear glutathione-bridged macrochelate [Figure 6(b)]. Evidence for the latter structure was provided by comparing 1D ^1H NMR, 2D [^1H, ^1H] TOCSY and NOESY data with those for products from similar reactions of the ethylenediamine complex [Pt(en)Cl_2], for which a comprehensive NMR study was possible with the use of ^{15}N-labelled en.[38] ^{15}N-DACH was not available for the present study.

In particular, similarities in the chemical shifts of the peptide ^1H NMR resonances and between the chemical shifts of the N*H* resonances of the diamine ligand are notable (Figures S3−S5 in the Supporting Information). A large doublet with a broadened base at $\delta = 6.33$ ppm, assignable to γ-Glu NH(1), is evidence for the presence of an unsymmetrical *bis* adduct. Differential couplings are consistent with torsion angles Cys−(Hβ^a−Cβ−Cα−Hα) = 90° and Cys−(Hβ^b−Cβ−Cα−Hα) = 30°; no signal was detected for Cys−N*H*, consistent with formation of a Cys−N(S) chelate ring. The macrochelate **B** contains a five-membered N,S chelate ring formed by the deprotonated amide N and S of the cysteine residue of GSH, and a nine-membered macrochelate ring formed by coordination of the γ-Glu α-amino group to the second Pt(DACH) unit.

Although the S-bridged dimer **A** is likely to be a stable end product, the macrochelate **B** is expected to be more reactive. Since we found that **B** is still formed even in the presence of a large excess of GSH (as would be the case inside cells), further studies of this species may well have physiological significance. Protonation of the Cys−N would produce a reactive coordination site, and the pH on the surface of DNA may be as low as 5;[39] however, complex **B** appeared to be stable down to pH 2.8.

Conclusions

Previous studies of the mechanism of action of platinum anticancer drugs have mostly been centred on the nature of hydrolysis reactions that activate chloro complexes, and reactions with DNA bases that lead to structural changes such as DNA bending. Whilst it is well recognised that platinum(IV) anticancer drugs are readily reduced in physiological media giving active platinum(II) products,[40] and that Pt^{II} can react with amides and imides to form mixed-valence "platinum blues",[41] little attention has been given to redox reactions of platinum(II) drugs with disulfides. We have shown here that reactions of the drug oxaliplatin with glutathione disulfide are only slightly slower than analogous reactions with the reduced form of glutathione. Remarkably, reactions of oxaliplatin with glutathione and glutathione disulfide lead to the same major products, both platinum(II) adducts of glutathione. Clearly, oxaliplatin can induce reductive cleavage of the disulfide bond of glutathione disulfide. Since platinum is still in oxidation state +2 in the products, the electrons must be supplied by another component of the reaction, probably water. The formation of the unusual macrochelate **B**, even in the presence of excess glutathione, could potentially be of biological importance.

Experimental Section

Materials: Potassium oxalate, *rac*-1,2-DACH and (1*R*,2*R*)-DACH were purchased from Aldrich. Potassium tetrachloroplatinate(II) was provided by Johnson Matthey. Enantomerically pure [Pt(1*R*,2*R*-DACH)Cl_2], [Pt(*rac*-1,2-DACH)Cl_2] and oxaliplatin

were prepared using previously described procedures.[42−45] Glutathione (GSH) was purchased from Acros and glutathione disulfide (GSSG) from Sigma.

Instrumental Methods: High pressure liquid chromatography (HPLC) was carried out on a Hewlett Packard 1100 system with UV detection. For all analytical separations, a RP C18 column (250 × 4.6 mm, 100 Å, 5 μM, Hichrom) with UV detection at 220 nm, eluting with 0−50% acetonitrile gradients over varying time intervals with 0.1% trifluoroacetic acid as an ion-pairing agent. ESI-MS positive ion electrospray mass spectrometry (ESI-MS) was performed using a Platform-II mass spectrometer (Micromass, Manchester, UK). A Corning 240 pH meter equipped with an Aldrich microcombination electrode standardised with Aldrich buffers at pH 4, 7 and 10 was used to make pH measurements. Electronic absorption spectra were recorded over a range of 800 to 200 nm at 310 K on a Perkin−Elmer Lambda-16 spectrometer using a cell with a path length of 1 cm. ICP-AES determination of platinum concentrations was carried out using a Thermo Jarrell Ash *IRIS* ICP-AES, calibrated with 0−100 ppm standards purchased from BDH.

NMR spectroscopic data were acquired using a Varian ^{UNITY}*INOVA* 600 NMR spectrometer equipped with a z-field gradient triple resonance NMR probe and operating at a ^{1}H resonance frequency of 599.841 MHz. A sample of the 2:1 adduct between [Pt(1*R*,2*R*-DACH)Cl$_2$] and GSH (1.3 mM, 90% H_2O/10% D_2O, pH = 4, separated by HPLC) was used for the acquisition of all NMR spectroscopic data. 1D ^{1}H NMR spectroscopic data sets were typically acquired under the following conditions: frequency width 7 kHz, acquisition time 2.34 s, number of data points 32 *k*, relaxation delay 2 s, number of transients 128, pulse angle 90°. Homonuclear ^{1}H 2D NOESY (τ_m = 150 and 500 ms), TOCSY (τ_m = 70 ms), DQFCOSY and ROESY (τ_m = 120 ms) NMR spectroscopic data sets were typically acquired over a 5 kHz frequency width in both ω2 and ω1 for which 32 transients were acquired into 2 k complex data points (acquisition time 205 ms) for each of 2 × 400 hypercomplex t_1 increments. For all data accumulation, solvent suppression was achieved using either WET[46] or excitation sculpting.[47] The sample temperature was maintained at 298 K throughout data acquisition. Data were converted (Xwin-NMR version 2.0, Bruker, U.K. Ltd.) and processed using suitable apodization functions. Referencing of all data was made internally to the methyl singlet of TSP at δ = 0 ppm. A model for [{Pt(1*R*,2*R*-DACH)}$_2$(μ$_2$-*S*G)] was constructed on the basis of the structure calculated for [Pt(en)$_2$(μ$_2$-*S*G)][38] using Sybyl (version 6.3, Tripos Inc.). The presence of an rOe in the NMR spectroscopic data was used to define upper (3.5 Å) and lower (2.5 Å) distance bounds between associated protons in the molecule. Distance range force constants, k_{NOE}, were set to 20 kcal·mol^{-1} Å^{-2} for each distance restraint. A single torsion angle restraint was also incorporated (γ-Glu−(Hα−Cα−Cβ−Hβ^a); θ_{tor} = 90°, k_{tor} = 0.01 kcal·mol^{-1} deg^{-2}). Energy minimization of the model was carried out with repeated conjugate gradient steps until the structure was stable.

Reactions of [Pt(1,2-DACH)Cl$_2$] and Oxaliplatin with Glutathione (GSH) or Glutathione Disulfide (GSSG): The pH of GSH or GSSG solutions (20 mM) was adjusted to 7 with NaOH. [Pt(1,2-DACH)Cl$_2$] or oxaliplatin (100 μM, 2 mL) was added to an aliquot of GSH or GSSG (20 μL, 2 mol equiv.), and the reaction mixture was incubated at 310 K for 24 h ([Pt(1,2-DACH)Cl$_2$]) or 48 h (oxaliplatin). The pH of the reaction was monitored at regular intervals. Analytical separation of the products was carried out by HPLC methods as described above.

Acknowledgments

We thank the BBSRC, EPSRC and Wellcome Trust (Edinburgh Protein Interaction Centre) for their support for this work. We also thank members of EC COST D8/D20 for stimulating discussions.

Synthesis, Reactivity, Crystal Structures and Catalytic Activity of New Chelating Bisimidazolium-Carbene Complexes of Rh

Macarena Poyatos,[a] Elena Mas-Marzá,[a] José A. Mata,[a] Mercedes Sanaú,[b] and Eduardo Peris*[a]

Keywords: Heterocycles / Carbenes / Rhodium / Homogeneous catalysis

A series of new bridging, chelating and pincer *N*-heterocyclic carbenes of Rh^{I} and Rh^{III} have been obtained under mild conditions. The compounds have been fully characterised and their crystal structures determined. The chelate-pincer coordination of the ligands means that the stability of these compounds is significantly greater than other carbene complexes of Rh. The compounds have been tested in catalytic reactions such as hydrogen transfer from alcohols to ketones, and hydrosilylation of terminal olefins and alkynes; they show a high activity for both processes.

Introduction

The number of synthetic applications of homogeneous catalysts has increased enormously during the last three decades. Highly active and selective catalysts have been prepared to activate a large variety of bonds, thus providing efficient methods to obtain new products with important industrial and pharmaceutical applications. However, homogeneous catalysts are far from being widely used in industrial processes, mainly due to their low chemical and thermal stability and to their low potential to provide recyclable systems. With this in mind, recent research in this area has focused mainly on the search for new methods for the synthesis of stable, effective and recyclable catalysts, since this would combine both economic and environmental benefits.

Homogeneous organometallic catalysis has long depended on phosphane ligands.[1,2] Despite their effectiveness in controlling reactivity and selectivity, phosphane catalysts require air-free handling to prevent the oxidation of the ligand and are subject to P−C activation at elevated temperatures.[3] As an alternative to the use of phosphanes, *N*-heterocyclic carbenes are currently being used in the design of new homogeneous catalysts.[4] The chemical versatility of these compounds and their easy access provide methods to obtain ligands with tunable steric and electronic properties. The precursor imidazolium salts are often easier to obtain than phosphanes, but their coordination to the metal often requires harsh preactivation conditions, in most cases needing the addition of strong bases such as *n*BuLi.[5,6] Once bound to the metal, however, monodentate carbenes are often reactive and undergo decomposition processes that can reduce the catalytic efficiency at high temperatures.

In order to improve the stability of the carbene-imidazolium compounds we[7−10] and others,[6,11−17] have reported a series of compounds whose stability is entropically improved by the chelate effect. In this sense, a series of bis-chelate and pincer-bis-carbene compounds have been reported, providing catalysts which resist higher temperatures than other classical homogeneous catalysts.

Most of the tridentate pincer CNC bis-carbene ligands reported so far are Pd-based and have been used in catalytic C-C bond formation reactions (Heck, Suzuki, Sonogashira).[9,10,15] Due to the high thermal stability of these catalysts, traditionally inert bonds such as C−Cl are readily activated providing the highest turnover numbers reported to date in the Heck C−C coupling.[9] Pincer CNC ligands have also allowed the preparation of recyclable heterogeneous catalysts which have also been effectively used in the Heck C−C coupling reaction.[18]

Despite their obvious potential applications, the use of bis-carbene chelate or pincer ligands with other metals is limited to a few papers reporting Rh[7] and Ru[13] complexes whose catalytic applications were envisaged.

Based on our previous findings, we now report the synthesis and reactivity of a series of CNC-bis-carbene complexes of Rh^{I} and Rh^{III}. The crystal structures of several of the reported compounds are described. We also report the

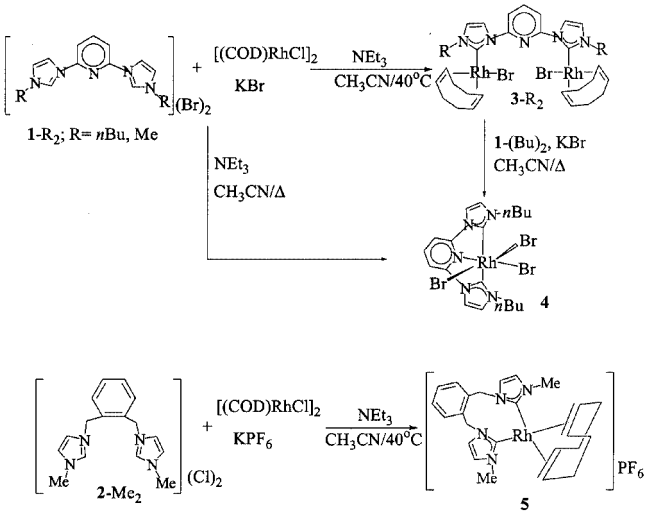
catalytic applications of our compounds toward the hydrosilylation of terminal olefins and alkynes, and hydrogen transfer between alcohols and ketones.

Results and Discussion

Synthesis and Reactivity of the Compounds

In order to obtain the new Rh compounds, we used the ligand precursors **1**-R_2 [9] (R = Me, Bu) and **2**-Me_2. The preactivation of the ligand (deprotonation) was performed with NEt_3, since we have previously found that this base affords good results under mild reaction conditions. As metal complex we used $[RhCl(COD)]_2$.

Scheme 1 shows the general method for the synthesis of complexes **3**, **4** and **5**. The reaction of $[RhCl(COD)]_2$ with **1**-R_2 allowed the synthesis, in high yield, of two different compounds, depending on the reaction conditions used. Under inert conditions, using a Rh/**1**-R_2 molar ratio of 1:1, compound **3** was obtained (65−80% yield). The complex **3**-Bu_2 was recently obtained and fully characterized in our group,[19] and **3**-Me_2 has very similar spectroscopic features[19] allowing for the obvious differences derived from changing the two Bu wingtips by two methyl groups. The more relevant NMR spectroscopic features arise from the fact that the twofold symmetry of the ligand is maintained upon coordination, and that the ^{13}C NMR spectrum of the complex shows Rh−C coupling ($^1J_{Rh,C}$ = 49.2 Hz, δ = 184.8 ppm), which confirms that metallation of the ligand has occurred.



Scheme 1

The synthesis of **4** can proceed both from $[RhCl(COD)]_2$ and from **3** (Scheme 1). The mechanism of this reaction is not well understood, but it looks as if the oxidation of the starting Rh^I complex is the first step in the reaction, which is why aerating the initial CH_3CN solution increases the reaction yields. In fact, when the reaction is carried out under a completely inert atmosphere, much lower yields are obtained, and most of the starting $[RhCl(COD)]_2$ complex is recovered, together with the Rh^I complex **3**, which can be considered as a reaction intermediate in the synthesis of **4**. KBr is added to the reaction medium in order to favour the formation of the perbrominated complex, although in most occasions mixtures of the Cl and Br complexes were still obtained. In the absence of KBr, mixtures of [Rh(CNC-Bu_2)Br_3] and *trans*-[Rh(CNC-Bu_2)Br_2Cl] were obtained, which we could not separate by conventional methods (i.e. column chromatography, crystallization, etc.).

The ^1H NMR spectrum of **4** shows the typical pattern of the bis-carbene ligand coordinated in the pincer form, very similar to that of related Pd complexes.[9,10] In the ^{13}C NMR spectrum, the carbene signal is observed as a doublet at δ = 177.5 ppm with a coupling constant that is diagnostic for Rh binding ($^1J_{Rh,C}$ = 33.7 Hz).

In order to confirm that **3** is in fact a reaction intermediate in the synthesis of **4**, we reacted **3**-Bu_2 with an equimolar amount of **1**-Bu_2 in refluxing CH_3CN, with the formation of **4** in almost quantitative yield (Scheme 1). We still do not have a satisfactory explanation for the oxidation step from **3**-Bu_2 to **4**, although we have observed that aerated solvents provide better yields. A possible explanation for this process may be the oxidation of traces of Br^- to Br_2 by dioxygen, with the subsequent oxidative addition of Br_2 to **3**. Further studies on this matter are being carried out in more detail.

All attempts to coordinate **1**-Bu_2 and **1**-Me_2 to Rh^I in the pincer form were unsuccessful. Although all these attempts were with $[RhCl(COD)]_2$, we believe that any other Rh^I starting compound would have given us similar results. Reduction of the corresponding Rh^{III} species was unsuccessful, with decomposition of the compound and the formation of unknown species.

We also wanted to see whether a chelating bis-carbene coordination to Rh^I was possible, since all attempts made so far have resulted in the oxidation to Rh^{III}, both in the results that we now present and in our previous work.[7] With this aim in mind, we tried to coordinate the ligand precursor **2**-Me_2, made from direct reaction of dichloro-*o*-xylene and methylimidazole. The reaction of **2**-Me_2 with $[RhCl(COD)]_2$ in CH_3CN in the presence of NEt_3 yielded compound **5** in high yield (85%). The synthesis of **5** occurs without the formation of any Rh^{III} species, which could support the idea that prior oxidation of the halide (in this case Cl^- to Cl_2 obviously would be not possible) by air is needed for the oxidation of Rh^I to Rh^{III}. Evidence for the chelate coordination of the bis-carbene ligand comes again from NMR spectroscopy, which shows that the imidazole rings are symmetry related. The metallation of the ligand is confirmed by the presence of a doublet (δ = 180.8 ppm; $^2J_{Rh,C}$ = 52.6 Hz) in the ^{13}C NMR spectrum. The coordination sphere of the rhodium atom is completed by the presence of a molecule of 1,5-COD.

The molecular structures of **3**-Me_2, **4** and **5** were unambiguously confirmed by single crystal X-ray diffraction.

The molecular structure of **3**-Me_2 (Figure 1) is virtually identical to that of complex **3**-Bu_2 which we have published previously.[19] The compound consists of a dirhodium struc-

ture bridged by 2,6-bis(1-methyl imidazolylidene-3-yl)pyridine, with the nitrogen atom of the pyridine unbound. The geometry about each rhodium atom is pseudo-square-planar, with Rh−C_{imid} distances of 1.948(11) and 2.029(11) Å suggesting that these bonds have a major σ contribution with very little back-donation.

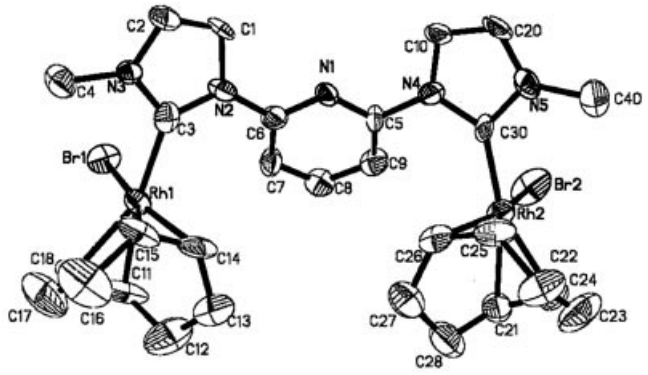


Figure 1. ORTEP diagram of **3**-Me_2 with 50% probability ellipsoids; hydrogen atoms omitted for clarity; selected bond lengths (Å) and angles (°): Rh(1)−C(3) 2.029(11), Rh(1)−C(15) 2.095(12), Rh(1)−C(14) 2.105(12), Rh(1)−C(11) 2.200(12), Rh(1)−C(18) 2.220 (11), Rh(1)−Br(1) 2.5172(17), Rh(2)−C(30) 1.948(11), Rh(2)−C(26) 2.101(11), Rh(2)−C(25) 2.157(12), Rh(2)−C(22) 2.189(11), Rh(2)−C(21) 2.216(11), Rh(2)−Br(2) 2.5169(18); C(3)−Rh(1)−Br(1) 87.7(3), C(30)−Rh(2)−Br(2) 90.2(3)

Figure 2 shows the molecular structure of complex **4**. The crystal contains a mixture of [Rh(CNC-Bu_2)Br_3] and *trans*-[Rh(CNC-Bu_2)Br_2Cl], and was refined with a 50% occupancy for each. The molecular structure shows the Rh atom in a distorted octahedral coordination, with a pincer-ligand bite angle of 79.9°. The imidazole and pyridine rings are virtually coplanar, and the two butyl groups point out of these planes. The Rh−C bond length (2.05 Å) is slightly longer than that obtained for a similar *cis*-chelate rhodium(III) bis-carbene reported in our group (1.99 Å),[7] due to the mutual trans influence.

The molecular diagram of **5** is shown in Figure 3. The structure shows the Rh atom in a distorted square-planar coordination with a chelate bite angle of 90.55°. The Rh−C bond lengths of 2.03 and 2.05 Å are similar to those of compound **3**, implying that the Rh−C bond has a major σ contribution. To the best of our knowledge, this is the first Rh^I chelate-bis-carbene complex reported so far.

Catalytic Hydrosilylation

Hydrosilylation of multiple bonds represents a useful class of catalytic processes for the functionalization of organic molecules. Vinylsilanes, which are widely used intermediates for organic synthesis, can be efficiently prepared by transition-metal-catalyzed addition of silanes to alkynes. Most of the recent efforts in the study of catalytic hydrosilylation concern the design of new and efficient catalysts that enable the preparation of both (*Z*)- and (*E*)-alkenylsilanes independently.[20−25] For this reason, the number of reports regarding mechanistic studies in order to rationalize the factors affecting the selectivity of this reaction have increased over the last few years.[20,22,25−27] In view of the compounds that we report in this paper, we thought that catalytic hydrosilylation could be a good test of the catalytic potential of these new complexes. Our Rh^I complexes (**3**-Me_2, **3**-Bu_2 and **5**) display all the structural and chemical requirements for this catalytical system, and could throw some light onto the reaction process.

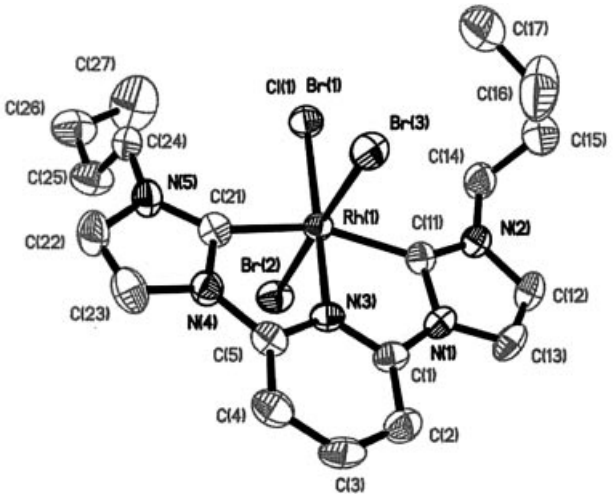

Figure 2. ORTEP diagram of **4** with 50% probability ellipsoids; hydrogen atoms omitted for clarity; selected bond lengths (Å) and angles (°): Rh(1)−N(3) 1.969(4), Rh(1)−C(21) 2.045(5), Rh(1)−C(11) 2.055(5), Rh(1)−Br(1) 2.4382(12), Rh(1)−Br(3) 2.4922(12); N(3)−Rh(1)−C(27) 78.7(2), N(3)−Rh(1)−C(11) 78.9(2)

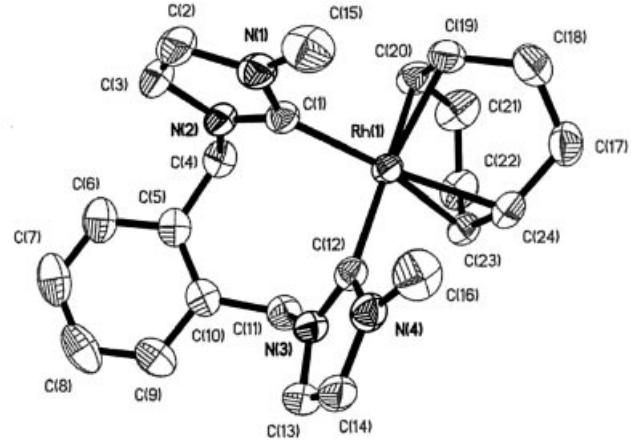

Figure 3. ORTEP diagram of **5** with 50% probability ellipsoids; hydrogen atoms omitted for clarity; selected bond lengths (Å) and angles (°): Rh(1)−C(12) 2.027(3), Rh(1)−C(1) 2.050(3), Rh(1)−C(23) 2.193(3), Rh(1)−C(19) 2.199(3), Rh(1)−C(24) 2.222(3), Rh(1)−C(20) 2.225(3); C(12)−Rh(1)−C(1) 90.55(11), C(19)−Rh(1)−C(24) 80.57(12), C(23)−Rh(1)−C(20) 80.95(12)

Table 1 shows the catalytic results for the hydrosilylation of several terminal alkynes with $HSi(OEt)_3$ and $HSiMe_2Ph$. All the reactions were carried out without any special need for inert conditions, since the catalysts used proved to be fairly stable under oxygen-containing atmospheres, even at high temperatures. The reactions were carried out in $CDCl_3$ at 60 °C, with 1 mol % catalyst. For all the reactions studied, all the catalysts used give a mixture of the β-(*E*),

[a] 0.077 mmol of alkyne, 0.085 mmol of silane. and 1% mol catalyst used in $CDCl_3$. T = 60 °C. Yields determined by ^1H NMR spectroscopy.

β-(*Z*) and α-isomers, although the β-(*E*) isomer is preferred in all cases where the process is carried out for long reaction times (72 h). In most metal-catalyzed hydrosilylations, the regioselectivity is affected by factors such as types of alkynes and silanes, catalyst, solvent or temperature. However, it has been reported that cationic Rh complexes catalyze the hydrosilylation of alkynes to give the β-(*E*)-vinylsilanes as the major products, while neutral Rh complexes show a higher preference to yield the β-(*Z*) ones.[20,28−30] Since initially we did not see this tendency for the neutral complexes, we decided to follow the reaction more carefully, and study how the isomer ratio evolves with time (Figure 4).

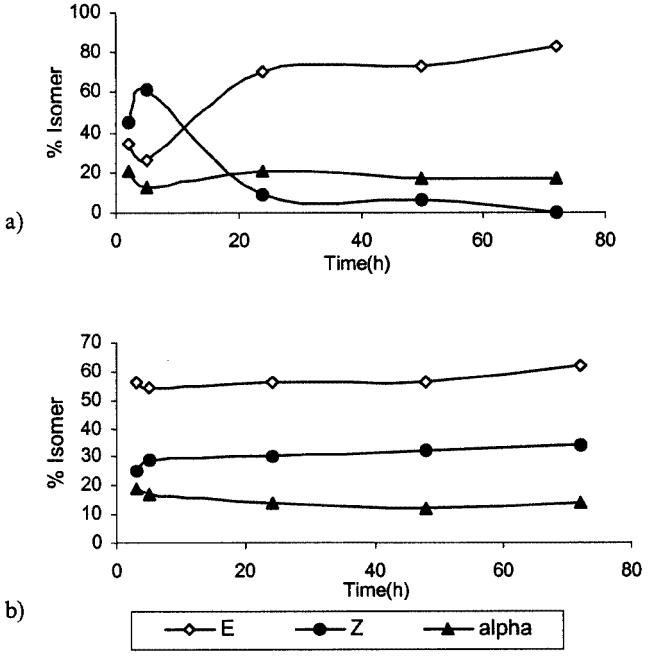

Figure 4. Reaction profiles for the hydrosilylation reactions of phenylacetylene by using **3**-Me_2 (1 mol % ratio) with: (a) $HSiMe_2Ph$, and (b) $HSi(OEt)_3$; percentage of isomer relative to molar fraction ($E + Z + \alpha = 100$)

As seen from Figure 4a, the reaction of phenylacetylene with $HSiMe_2Ph$ using **3**-Me_2 as catalyst starts by showing a higher preference for the β-(*Z*) isomer. As the reaction proceeds, there is a conversion from the (*Z*)- to the (*E*)-isomer, until total conversion into the (*E*)-isomer is achieved. A similar behavior is observed for the *n*BuC≡CH/$HSiMe_2Ph$ system with both neutral catalysts. These results confirm that the rate of isomerization of the initially preferred (*Z*)-isomer to the thermodynamically more stable (*E*)-isomer competes with the hydrosilylation process. The fact that no (*Z*)-vinylsilane is observed at the end of the reaction probably implies that the isomerization occurs via a reversible addition of the (*Z*) product in the last step of the reaction mechanism rather than a change in the selectivity of the catalyst due to a modification of its nature during the reaction.[20,27] When $HSi(OEt)_3$ is used, there is a clear preference for the (*E*)-isomer from the start of the reaction, and no (*Z*)-(*E*) conversion is observed with time (Figure 4b).

For the cationic catalyst **5**, the tendency to produce the (*E*)-vinylsilane isomer is observed from the beginning of the reaction. A higher selectivity for the (*E*)-isomer is obtained when $HSiMe_2Ph$ is used instead of $HSi(OEt)_3$.

These results are in agreement with other reports on rhodium-catalyzed alkyne-hydrosilylation reactions, in which a mixture of isomers is always obtained.[31] $[Rh(nbd)(dppe)_2]PF_6$ gives no β-(*Z*) isomer, although some α-isomer is formed.[22]

The relative efficiencies of these Rh complexes as olefin hydrosilylation catalysts were compared by means of a standard reaction of styrene with $HSi(OEt)_3$ and $HSiMe_2Ph$ (Table 2). No induction periods were observed, and the formation of the silylated compounds proceeded without detectable by-products by NMR spectroscopy. As seen from the results shown in Table 2, there is a predominant tendency to yield the linear (terminal) phenethyl isomer. The cationic complex **5** has a better ability to yield the mentioned isomer, displaying higher selectivities.

It is difficult to determine whether the neutral dimetallic precatalysts **3**-Me_2 and **3**-Bu_2 remain dimetallic under the reaction conditions of the hydrosilylation process. In fact, we cannot exclude that the compounds evolve to a stable Rh^{III} species with the chelate carbene bound and a Rh^{I} compound without carbene, which could be the true cata-

Table 2. Hydrosilylation of styrene

Entry[a]	$HSiR_3$	Catalyst	Time (h)	Linear/ branched	Yield (%)

lytic species. However, according to our previous results on the hydroformylation of olefins,[19] we have observed that **3**-Me_2 and **3**-Bu_2 do not decompose to mononuclear species under the harsh conditions required for hydroformylation, thus suggesting that the complexes may maintain their dinuclear nature under the much milder conditions used in hydrosilylation.

Catalytic Hydrogen Transfer

The pseudo-octahedral Rh^{III} complex fulfills the electronic and structural requirements to catalyze the hydrogenation of the C=O groups of ketones via hydrogen transfer from *i*PrOH/KOH. The reactions are slow at room temperature, but proceed at very good rates at 80 °C. Again, the high stability of **4** allowed us to run all the reactions under non-inert conditions, with solvents used as purchased and in the absence of any precautions concerning the presence of air or moisture. As seen from the data shown in Table 3, the hydrogenation rates of the aromatic ketones are significantly higher than those shown for the aliphatic ones. The catalytic activity of this compound is similar to that reported by us for another Rh^{III} bis-carbene complex,[7] although in that case aliphatic ketones were hydrogenated faster than the aromatic ones.

In order to check whether incubation of the catalyst is important for this system we studied the reaction profiles of the hydrogen transfer to the three ketones used. As seen in Figure 5, the reaction profile is a sigmoid curve for the acetophenone case, indicating that a preactivation period of 3−4 h is necessary only for this substrate. This result is also observable for the reaction performed with 6×10^{-3} mol % catalyst (not shown in Figure 5). We still do not have a satisfactory explanation for this observation, although further studies are being carried out.

Transfer hydrogenation to alkenes failed with our catalyst, which in fact allows chemoselective reduction of C=O bonds in conjugated enones.

Table 3. Selected results for catalytic hydrogenation transfer of ketones with **4** as catalyst

Entry[a]	Substrate	Time (h)	Catalyst (mol %)	TON	TOF

Conclusion

We have obtained new bis-carbene complexes of Rh^{I} and Rh^{III}, and complex **4** is the first CNC-pincer complex of Rh described to date. The synthetic methods that we have described provide high yields under mild conditions, and establish a new method of activating bis-imidazolium salts in order to perform their coordination to metal complexes. The complexes obtained have been tested in the catalytic hydrosilylation of alkynes and olefins, and in the hydrogen transfer from alcohols to ketones; they show high catalytic activity. All in all, we have shown that a new family of Rh bis-carbene complexes can be easily obtained, providing a new and versatile class of catalysts whose properties deserve to be exploited.

Experimental Section

General Remarks: NMR spectra were recorded on Varian Innova 300 MHz and 500 MHz spectrometers, with $CDCl_3$ or [D_6]DMSO as solvents. The ligand precursors **1**-R_2 [7] (R = Me, *n*Bu) and the complex **3**-Bu_2 [19] were prepared according to literature methods. All other reagents are commercially available and were used as received.

Synthesis of [*o*-(CH_3-imid-CH_2)$_2$Ph](Cl)$_2$ (2): A mixture of α,α′-dichloro-*o*-xylene (2 g, 11.2 mmol) and *N*-methylimidazole (1.93 mL, 22.4 mmol) was heated at 150 °C for 12 h. The resulting solid was then washed with CH_2Cl_2 and filtered, yielding pure **2** (95%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 9.61 (s, 2 H, NC*H*N), 7.92 (s, 2 H, imid), 7.84 (s, 2 H imid), 7.48 (2 H, Ph), 7.38 (2 H, Ph), 5.82 (s, 4 H, CH_2), 3.92 (s, 6 H, CH_3) ppm. $C_{16}H_{20}Cl_2N_4$

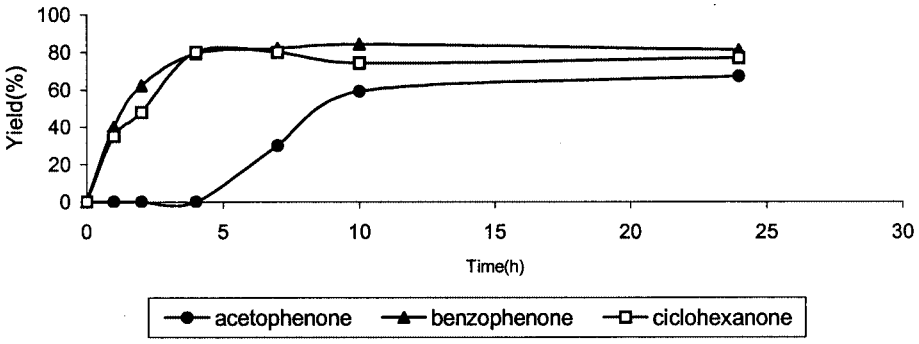

Figure 5. Reaction profile for the hydrogen-transfer reaction; 80 °C and 0.06 mol % catalyst (**4**)

(339.0): calcd. C 56.6, H 5.89, N 16.52; found C 56.2, H 5.67, N 16.87.

Synthesis of [(COD)RhBr]$_2$(μ-CNC-Me$_2$) (3-Me$_2$) and [(COD)RhBr]$_2$(μ-CNC-Bu$_2$) (3-Bu$_2$): A mixture of [RhCl(COD)]$_2$ (200 mg, 0.41 mmol), **1**-Me$_2$ (327 mg, 0.82 mmol), KBr (300 mg) and NEt$_3$ (0.5 mL, 3.5 mmol) was heated at 45 °C for 12 h in CH_3CN. The reaction mixture was filtered and the solvent was eliminated under vacuum. The resulting solid was redissolved in CH_2Cl_2 and the solution was transferred to a chromatography column. Elution with CH_2Cl_2 separated a minor yellow band that contained [RhCl(COD)]$_2$. Further elution with a gradient of CH_2Cl_2/acetone (10:1) allowed the separation of a major yellow band that contained **3**-Me$_2$ (yield 80%). $C_{29}H_{37}Br_2N_5Rh_2$ (820.9): calcd. C 42.42, H 4.51, N 8.53; found C 42.1, H 4.49, N 8.59.

[(COD)RhBr]$_2$(CNC-Me$_2$), (3-Me$_2$): ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 10.05 (d, $^2J_{H,H}$ = 8.1 Hz, pyridine-*H*), 8.28 (t, $^2J_{H,H}$ = 8.0 Hz, pyridine-*H*), 7.80 (imidazole-H), 6.99 (imidazole-*H*), 4.21 (s, 6 H, NCH_3) ppm. ^{13}C NMR ([D$_6$]DMSO, 300 MHz): δ = 184.8 (d, $^2J_{Rh-C}$ = 49.2 Hz, N*C*N), 149.8 (C_{ipso}), 139.7 (C_{ortho}), 123.1 (im-C), 123 (C_{meta}), 116.2 (im-C), 98.8, 97.5, 70.2 (COD), 39.6 (CH_3), 29.8, 29.3 (COD) ppm.

Synthesis of Rh(CNC-Bu$_2$)Br$_3$ (4): A mixture of [RhCl(COD)]$_2$ (200 mg, 0.41 mmol), **1**-Bu$_2$ (400 mg, 0.82 mmol), KBr (300 mg) and NEt$_3$ (0.5 mL, 3.6 mmol) was refluxed in 10 mL of CH_3CN for 12 h. During this time the solvent was aerated several times by bubbling a steam of air through the reaction medium. The reaction mixture was filtered and the solvent of the filtrate was removed under vacuum. The crude solid was redissolved in CH_2Cl_2 and the solution was transferred to a column chromatography. Elution with CH_2Cl_2 separated a minor yellow band that contained [RhCl(COD)]$_2$. Further elution with a gradient of CH_2Cl_2/acetone (10:1) afforded the separation of an orange band containing **4** (yield 53%). Complex **4** can also be obtained from **3** as follows: a mixture of **3**-Bu$_2$ (100 mg, 0.12 mmol), **1**-Bu$_2$ (59 mg, 0.12 mmol), KBr (100 mg) and NEt$_3$ (150 μL) was refluxed in CH_3CN for 5 h. After this time the workup was similar to that described above (yield 62%).

Rh(CNC-Bu$_2$)Br$_3$ (4): ^{1}H NMR ([D$_6$]DMSO, 300 MHz): δ = 8.54 (d, $^3J_{H,H}$ = 1.5 Hz, 2 H, imidazole−*H*), 8.39 (t, $^3J_{H,H}$ = 7.8 Hz, 1 H, pyridine−*H*), 8.04 (d, $^3J_{H,H}$ = 8.1 Hz, 2 H, pyridine−*H*), 7.77 (d, $^3J_{H,H}$ = 1.5 Hz, 2 H, imidazole−*H*), 4.77 (t, 4 H, N*C*H_2CH$_2$CH$_2$CH$_3$), 2.48 (quintet, 4 H, NCH$_2$*C*H_2CH$_2$CH$_3$), 1.89 (sextet, 4 H, NCH$_2$CH$_2$*C*H_2CH$_3$), 0.88 (t, 6 H, NCH$_2$CH$_2$CH$_2$*C*H_3) ppm. ^{13}C NMR ([D$_6$]DMSO, 300 MHz): δ = 177.5 (d, $^1J_{Rh,C}$ = 33.7 Hz, N*C*N), 152.5 (C_{ipso}), 144.51 (C_{ortho}), 124.97 (im-C), 118.54 (C_{meta}), 108.44 (im-C), 50.39 (*C*H$_2$CH$_2$CH$_2$CH$_3$), 33.70 (CH$_2$*C*H$_2$CH$_2$CH$_3$), 20.02 (CH$_2$CH$_2$*C*H$_2$CH$_3$), 14.68 (CH$_2$CH$_2$CH$_2$*C*H$_3$) ppm. $C_{19}H_{25}Br_{2.5}Cl_{0.5}N_5Rh$ (643.85): calcd. C 35.42, H 3.88, N 10.87; found C 35.42, H 4.11, N 10.07.

Synthesis of [Rh(COD)(C∧C)]PF$_6$ (5): A mixture of [RhCl(COD)]$_2$ (200 mg, 0.41 mmol), **2**-Me$_2$ (275 mg, 0.82 mmol), KCl (400 mg) and NEt$_3$ (0.5 mL, 3.5 mmol) was heated at 45 °C for 12 h in CH_3CN. The reaction mixture was filtered and washed with CH_2Cl_2, and the solvent was then eliminated under vacuum. The crude solid was redissolved in CH_2Cl_2 and the solution was transferred to a chromatography column. Elution with CH_2Cl_2 separated a minor yellow band that contained [RhCl(COD)]$_2$. The solution was eluted with a gradient of CH_2Cl_2/acetone/KPF_6 allowing the separation of a major yellow band that contained **5** (yield 85%).

[Rh(COD)(C∧C)]PF$_6$ (5): ^{1}H NMR ($CDCl_3$, 300 MHz): δ = 7.84 (m, 2 H, phenylene-*H*), 7.55 (d, 2 H, imidazole-*H*), 7.40 (m, 2 H, phenylene-H), 7.19 (d, imidazole-*H*), 6.48 (d, 2 H, NCH_2), 5.12 (d, 2 H, NCH$_2$) ppm. ^{13}C NMR ([D$_6$]DMSO, 300 MHz): δ = 180.8 (d, $^2J_{Rh,C}$ = 52.6 Hz, N*C*N), 136.4 (C_{ortho}, phenylene), 132.4 (C, phenylene), 129.7 (C, phenylene), 124.3 (im-C), 121.9 (im-C), 90.2, 88.9 (COD), 51.3 (CH_2), 39.2 (CH_3), 31.0 (COD) ppm. $C_{24}H_{30}F_6N_4PRh$ (621.9): calcd. C 46.32, H 4.82, N 9.02; found C 46.7, H 4.73, N 8.82.

Hydrosilylation of 1-Alkynes and Olefins with Silanes. General Procedure: In a 5 mm NMR tube, *n*BuC≡CH or PhC≡CH (0.077 mmol), silane [HSi(OEt)$_3$ or HSiMe$_2$Ph, 0.085 mmol] and a catalytic amount of **3**-Me$_2$, **3**-Bu$_2$ or **5** (1 mol %, 7.7×10^{-5} mmol) were dissolved in $CDCl_3$ (0.5 mL). The mixture was kept at 60 °C by immersion in a hot oil bath. The progress of the reaction was monitored by ^{1}H NMR spectroscopy, according to the data of the products obtained from the literature.[28,30]

Hydrogen-Transfer Catalysis: A mixture of the ketone (2 mmol), KOH (10 mL, 0.2 M in *i*PrOH) and a suspension of **4** (0.06% or 0.006% mol vs. substrate) in CH_2Cl_2 was heated to reflux. After the desired reaction times, aliquots were extracted from the reaction vessel and added to an NMR tube containing 0.5 mL of $CDCl_3$. Yields were determined by ^{1}H NMR spectroscopy.

X-ray Diffraction Studies: Single crystals of **3**-Me$_2$, **4** and **5** were mounted on a glass fiber in a random orientation. Crystal data are summarized in Table 4. Data collection was performed at room temperature on a Siemens Smart CCD diffractometer using graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) with a nominal crystal-to-detector distance of 4.0 cm. A hemisphere of data was collected based on three ω-scan runs (starting with ω = −28°) at φ values of 0°, 90° and 180° with the detector at 2θ = 28°. After each of these runs, frames (606, 435 and 230) were collected at 0.3° intervals and 30 s per frame. Space group assignment was based on systematic absences, E statistics and successful refinement of the structures. The structures were solved by direct methods with the aid of successive difference Fourier maps and were refined using the SHELXTL 5.1 software package.[32] All non-hydrogen were refined anisotropically. Hydrogen atoms were assigned to ideal positions and refined using a riding model. Details of the data collection, cell dimensions and structure refinement are given in Table 4. The diffraction frames were integrated using the SAINT[33] package and corrected for absorption with SADABS.[34]

Crystal Structure of Bis[acetone-1-naphthoylhydrazinato(−1)]copper(II) and Investigations of Intermolecular Interactions

Zoran D. Tomić,[a] Vukadin M. Leovac,[b] Srdjan V. Pokorni,[c] Dieter Zobel,[d] and Snežana D. Zarić*[c]

Keywords: Pi interactions / Stacking interactions / Copper / Chelates

In the crystal structure of the bis(acetone-1-naphthoylhydrazinato)copper(II) complex there are interactions of neighbouring molecules via naphthyl groups; the naphthyl group of one molecule interacts with the copper centre and CH_3 group of another molecule. The geometry of the crystal structure and dispositions of charges in the naphthyl and chelate rings indicate that there are stacking interactions between the aromatic ring and, not only the copper atom, but also the whole chelate ring.

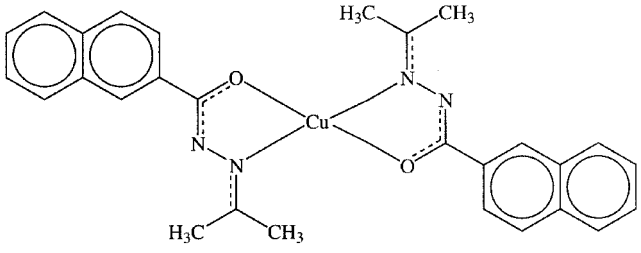
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

In the past decades, investigations of non-covalent forces involving aromatic rings, such as weak hydrogen bonds, π-π interactions, and cation-π interactions, have attracted considerable interest.[1−12] Extended ab initio calculations on the orientation of two benzene molecules have shown that T-shaped and slipped-parallel orientations are more stable than a parallel orientation. It has also been shown that long range interactions such as electrostatic and dispersion interactions are a major source of attraction and that they are responsible for the directionality of the interactions.[13,14]

Noncovalent interactions of aromatic rings in transition metal complexes have been investigated by searching databases of crystal structures,[15−19] by quantum chemical calculations[18−22] and by spectroscopic methods.[23] These interactions play a role in crystal engineering,[11,12,16] and in the stability of metal complexes[10,18,23] and metalloproteins,[17] and it was proposed that these interactions can play a role in the mechanism of enzymatic reactions.[17]

Here we report on a crystal structure of the bis(acetone-1-naphthoylhydrazinato)copper(II) complex (complex I) and the study of a special type of noncovalent interaction between an aromatic ring and a transition metal complex.



Complex I

In transition metal complexes with square planar and square pyramidal geometries, there are possibilities for noncovalent interactions that involve a metal atom. Noncovalent interactions of carbon atoms with the Cu^{II} metal ion have been noticed in our previously published crystal structure of aqua(4-methyl-1-naphth-1-yl-2,3-diaza-1,3,5-heptatriene-1,6-diolato-*N*,*O*,*O*,′)copper(II),[24] (complex II) and in other crystal structures of copper(II) complexes.[25−27] Small magnetic interactions transmitted through the interaction between the metal ion and the aromatic ring were recently identified and evaluated by EPR measurements in the crystal structure of the L-(tryptophylglycinato)copper(II) complex.[28]

Complex II

For the newly synthesised complex I, a square-planar geometry was anticipated since there is a tendency for bis(chelate) Cu^{II} complexes to adopt such geometries.[29] Due to the absence of hydrogens on the nitrogen and oxygen atoms, the hydrogen bonding potential of this complex is diminished. Thus, it was anticipated that intermolecular contacts of the complex molecules would primarily be determined by the interactions involving aromatic rings. Indeed, in the crystal structure a naphthyl ring is involved in some kind of stacking interaction with a coordination plane of the other molecule.

Results and Discussion

Crystal Structure

The structure is built up of isolated units with a copper ion located at the centre of symmetry. Two molecules of the acetone-1-naphthoylhydrazinato ligand are coordinated through the O and terminal N atoms arranged in a distorted square-planar geometry resulting in a *trans* disposition of these ligands (Figure 1). The Cu−N and Cu−O bond lengths are 2.032(3) and 1.904(2) Å, respectively, while the bite angle of the chelate ring, N5−Cu1−O2 is 80.31°.

The bond lengths in the chelate ring indicate a delocalisation of electrons in the O2−C3−N4 fragment [C3−O2 1.299(3), C3−N4 1.299(3) Å] and the presence of a localised double bond N5−C16 [1.298(4) Å]. These naphthalene fragments are nearly planar and are twisted with respect to the chelate ring about the C3−C6 bond, the dihedral angle between the mean planes of the naphthalene and chelate rings being 16.20(7)°.

Intermolecular interactions between the outer six-membered ring and the Cu atom link the molecules into an infinite one-dimensional chain along the A axis (Figure 2). The Cu···centroid distance is 3.89 Å, while the distance of the Cu atom to the nearest C atom of the naphthyl ring is 3.185(3) Å. The dihedral angle between the mean planes of the chelate and the aromatic ring involved in the Cu···ring interaction is 16.35°. The second nearest C atom is at a distance of 3.529(4) Å. These arrangements are also associated with C−H···π interactions between the methyl hydrogen atom H(17C) and the inner six-membered ring of the neighbouring molecule (H···centroid 2.80 Å, C−H···centroid angle 132.20°). The corresponding distance from the ring centroid to the projection of the H atom position on the plane of the ring is 0.33 Å. This is in accordance with the preference of the hydrogen bond involved in the X−H··· π interaction to be directed towards the centre of the phenyl ring.[30] Adjacent chains are linked by van der Waals forces and weak C−H···π interactions of the methyl hydrogen atom H18C with the outer six-membered ring (H···centroid 3.01 Å, C−H···centroid angle 160.25°) to form sheets across the *ab* plane. The H···centroid distance

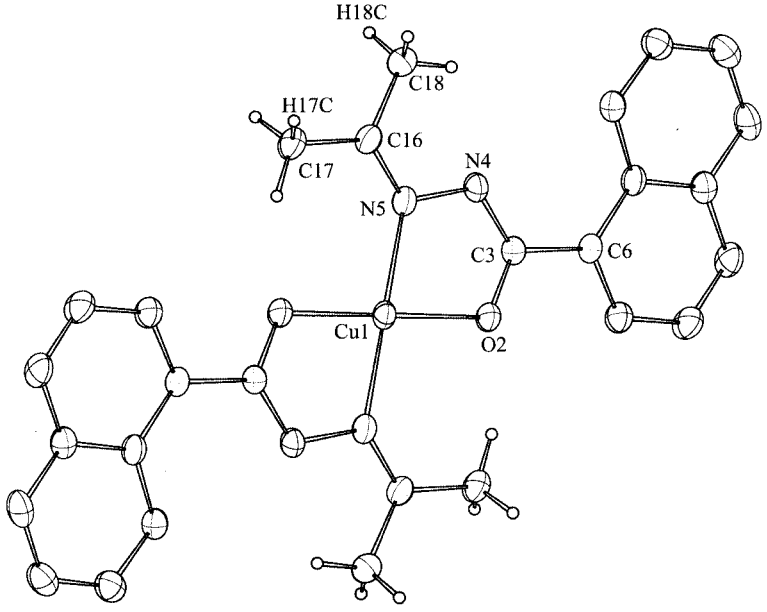

Figure 1. ORTEP[38] view (50% probability ellipsoids) of complex I showing the atom labelling

is slightly larger than the sum of the van der Waals radii of 3.05 Å.[31] However it was shown[32] that, besides the H···acceptor distance, the directional properties of the corresponding fragment must be considered, bearing in mind the tendency of the X−H···acceptor fragment to form a linear angle. The nearest intra- and inter-chain Cu···Cu separation is 6.261(5) and 8.474(7) Å, respectively.

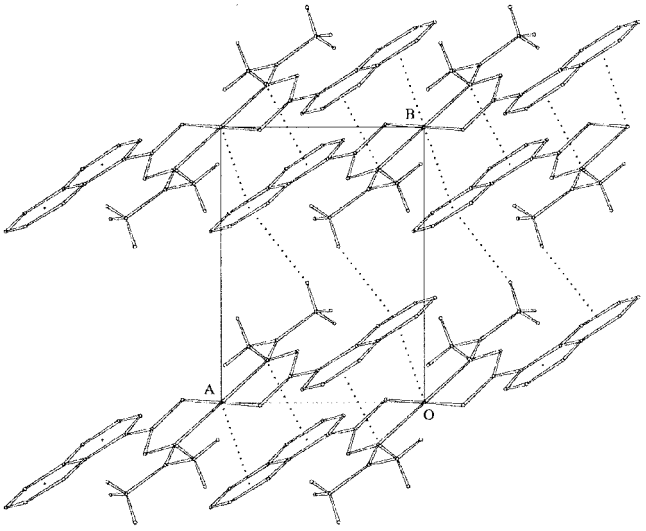

Figure 2. Arrangement of molecules into chains along the a axis and interchain contacts (dotted lines: C−H···π, and Cu···centroid)

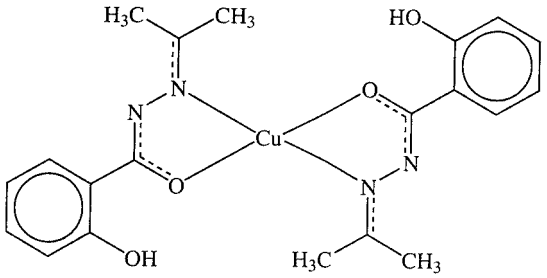
We noticed that intermolecular forces in this crystal structure are similar to the forces reported in the previously published crystal structure of compound II.[24] In that structure, the molecules in the unit cell form chains with alternating O−H···π and Cu-naphthalene interactions. This arrangement is associated with a distance of 3.52/3.68 Å for the Cu···centroid of the six-membered ring, and a Cu···C distance of 3.116/3.061 Å.

A comparison of the two crystal structures shows that in both crystals a chain formation is achieved via X−H···π and Cu···phenyl contacts, associated with the distance of the Cu-centroid of the six-membered ring, in the range of 3.5−3.9 Å. The six-membered ring in both crystal structures is in a slipped-parallel position with respect to the chelate ring.

It is also interesting to compare the structure of complex I with the crystal structure of bis(*N*-isopropylidene-*N*′-salicyloylhydrazinato)copper(II) (complex III).[33] Although the ligands are very similar, the OH group on the aromatic ring in complex III has a large influence on the intermolecular interactions. Oxygen atoms have a large affinity to interact with Cu^{II} ions, hence in this crystal structure there is a Cu−O interaction (Cu···O distance of 2.764 Å), and no interaction of the Cu^{II} atom with the aromatic ring.



Complex III

Chelate Ring−Aromatic Ring Contacts

Chelate rings with delocalised bonds are considered to be similar to aromatic rings.[19,34] We assume that the slipped-parallel orientation in the structures of complexes I and II is a result of the balance of interacting forces, similar to that for two benzene molecules, for which the slipped-parallel orientation is very stable.[13] The slipped-parallel orientation can also been found in crystal structures of metal complexes, as can the usual π-interaction for aromatic nitrogen-containing ligands.[15] Since it is known that electrostatic interactions are important for interactions between aromatic rings,[13] we calculated the charges for complex I. Some atoms of the chelate ring are partially positively charged [Cu (0.6), C3 (0.3)], while some atoms are partially negatively charged [O2 (−0.6), N4 (−0.3), N5 (−0.3)]. The geometry of the crystal structure shows that the partially positively charged atoms of the chelate ring (Cu and C) have the shortest distance to the partially negatively (−0.07) charged carbons of the aromatic ring (C1···C14 3.185 Å, C12···C3 3.393 Å), whereas the nitrogen atoms from the chelate ring have the shortest distance to the partially positively (0.07) charged hydrogen atom (N4···H13 2.942, N5···H13 2.975 Å) (Figure 3).

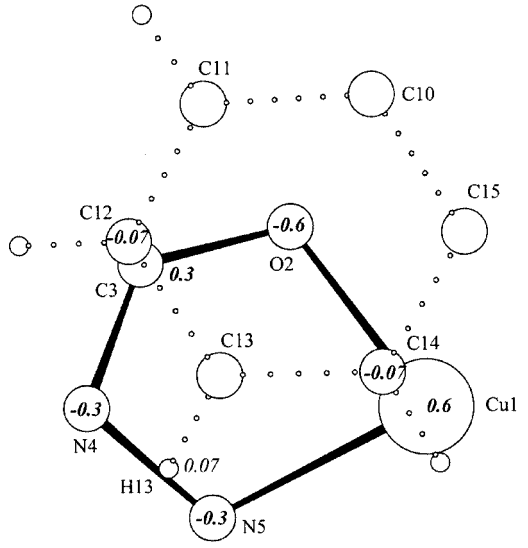


Figure 3. Interaction of the chelate ring and aromatic ring in complex I showing partial atomic charges; orientation is in the direction normal to the chelate mean plane; the aromatic ring is represented by dots

It should be mentioned that in the crystal structure of complex III[33] there is no slipped-parallel orientation of the chelate and phenyl ring; however, inspection of the crystal packing showed that the shortest distances between atoms from two molecules are the distances between partially positively charged atoms and partially negatively charged atoms (Cu···O 2.764 Å, N1···C7 3.354 Å).

Conclusion

In the crystal structure of bis(acetone-1-naphthoylhydrazinato)copper(II) the intermolecular distances between the copper and aromatic carbons indicates that interactions may occur. A mutual slipped-parallel orientation of the chelate and the aromatic ring, similar to the stable orientation of two benzene molecules, suggests that these interactions involve not only the copper atom but also the whole chelate ring. This assumption is supported by analysis of the distances in the crystal structure connected with the partial atomic charges on the aromatic ring and the chelate ring. This indicates that a modification of the chelate ring could modify the interaction of the aromatic ring with the Cu^{II} atom, in square-planar copper(II) complexes.

Experimental Section

Preparation

A synthesis of the title compound has been reported[35] although crystals of the product were not suitable for X-ray diffraction analysis. In the modified procedure the compound was unexpectedly obtained from a reaction of an acetone/ethyl alcohol (1:1) solution of acetone-1-naphthoylhydrazone and a methyl alcohol solution of $Cu(NO_3)_2{\cdot}3H_2O$ and NH_4NCS (molar ratio 1:1:2, respectively). After precipitation of CuNCS, the solution was filtered, allowed to stand and after a few days, crystals of the title complex suitable for X-ray diffraction were obtained.

X-ray Crystallography

Crystal data for $C_{28}H_{26}CuN_4O_2$: M = 514.07, monoclinic space group $P2_1/c$, a = 6.261(5) Å, b = 8.474(5) Å, c = 21.830(5) Å, β = 90.110(5)°, V = 1158.2(12) Å^3, D_c = 1.474 mg/m^3, λ (Mo-K_α radiation) = 0.71073 Å, F_{000} = 534. Diffraction data were measured on a Stoe 4-circle diffractometer with graphite monochromator, using ω/2θ scans. Lattice parameters were determined from 43 reflections in the range $15 < 2\theta < 30$. 5866 reflections were measured ($\theta < 28$), of which 2786 were independent. The data were corrected for Lorentz and polarisation factors, but not for absorption. The structure was solved by direct methods using SIR92 [36] and refined by applying a full-matrix least-squares method based on F^2, including all reflections. All non-hydrogen atoms were refined anisotropically using SHELXL-97.[37] Hydrogen atoms were included at calculated positions and allowed to ride on their parent atoms. The refinement converged at R = 0.051, and wR = 0.1453 for 2068 reflections satisfying the condition $I > 2\sigma(I)$, (wR = 0.1565 for all reflections). The maximum and minimum residual electron densities in the final ΔF map were 0.797 and −0.521 e/Å^3, respectively. The structure diagram was generated using ORTEP 3[38] and geometrical analysis was performed using PLATON-99.[39] All calculations were done using WinGX as an integrated system for all the crystallographic programs.[40]

CCDC-183111contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details

Quantum chemical calculations of partial charges were performed on a model system built from the crystal structure, using the B3LYP[41,42] method and LACVP** basis set. Calculations were done with the Jaguar 4.1 program.[43]

The First Structurally Characterized Trinuclear Dipicolinato Manganese Complex and its Conversion into a Mononuclear Species by Ligand Substitution

Chengbing Ma,[a] Changneng Chen,[a] Qiutian Liu,*[a] Daizheng Liao,[b] and Licun Li[b]

Keywords: Manganese / N ligands / Cluster compounds

The novel complex $[Mn_3(pdc)_3(bpy)_3(H_2O)_2]$ (**1**) (H_2pdc = 2,6-pyridinedicarboxylic acid, also known as 2,6-dipicolinic acid; bpy = 2,2′-bipyridine), has been obtained from the reaction of polymeric $[MnK_2(pdc)_2(H_2O)_7]_n$ (**2**) with bpy, and is the first example of a structurally characterized, trinuclear Mn complex incorporating dipicolinato ligands. All the Mn^{II} centers are seven-coordinate in severely distorted pentagonal-bipyramidal geometries. The conversion of **1** to mononuclear $[Mn(pdc)(bpy)(Him)_2]$ (**3**) (Him = imidazole), which is the first seven-coordinate Mn complex with a Him ligand, has also been achieved by substitution of the labile ligand in **1** by Him.

Introduction

Much attention has been paid to the design and synthesis of transition metal complexes incorporating 2,6-dipicolinic acid due to the versatile bidentate, tridentate, or bridging coordination modes of the ligand,[1] its diverse biological activity and its capacity to stabilize unusual oxidation states,[2] as well as its application to diverse areas of technology.[3] Up to now, the control of product architecture has been elusive and remains a major challenge of modern chemistry.[4] Only one example of a trinuclear 2,6-dipicolinate complex is known in the literature,[5] although many examples of mononuclear and dinuclear dipicolinates, as well as complexes with chain structures, have been reported.[6] Manganese complexes of 2,6-dipicolinates are nevertheless rare.[7] Recently, we obtained a Mn/K polymer, $[MnK_2(pdc)_2(H_2O)_7]_n$, from a reaction system containing Mn^{2+}, H_2pdc, and alkali metal hydrate as a member of the family $[MnK_2(pdc)_2(H_2O)_7]_n$ (M = Mn, Co, Zn etc.).[8] Here we report the reaction of the Mn/K polymer with bpy, from which the first example of a dipicolinato, trinuclear Mn complex, $[Mn_3(pdc)_3(bpy)_3(H_2O)_2]$ (**1**), was obtained. Further study of the reaction leads to the mononuclear complex $[Mn(pdc)(bpy)(Him)_2]$ (**3**) with three different ligands within the coordination sphere.

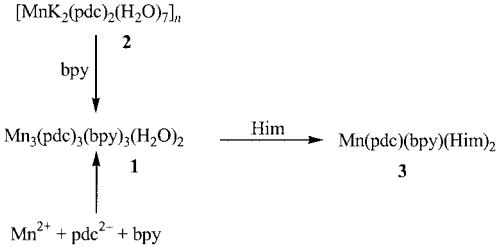
Results and Discussion

Dipicolinates commonly ligate to transition metals by either carboxylate bridges between metal centers, to form polymeric complexes, or tridentate (O,N,O′) chelation to one metal ion.[9] With the intention of preparing pdc-coordinated oligomers as model compounds for Mn-containing enzymes,[10] the bpy ligand, which strongly favours bidentate coordination, was used to cleave the carboxylate bridges of **2**, and a trinuclear cluster (**1**·9H_2O) was successfully isolated as single crystals. Complex **1** can also be obtained directly from a reaction mixture containing Mn^{2+}, pdc^{2-}, and bpy. However, the excess pdc^{2-} used in this direct synthesis gives rise to the formation of impurities and does not allow the formation of good quality single crystals. Upon reaction of **1** with an excess of imidazole (Him) in DMF/H_2O, substitution of H_2O by Him occurs and the trinuclear **1** decomposes, resulting in mononuclear **3**. Related reactions are compiled in Scheme 1.

Single-crystal X-ray analysis revealed **1** to be a discrete trimanganese cluster. As shown in Figure 1, all Mn atoms



Scheme 1. Preparation of **1** and its decomposition to produce **3**

are seven-coordinate, although two types of inequivalent Mn atoms are observed. Both bpy and pdc^{2-} ligands chelate to each Mn center in bi- and tridentate mode (N,N′ and O,N,O′) respectively, while one additional terminal water molecule binds to Mn1 and Mn2, giving the same coordination sphere for the Mn1 and Mn2 sites. In addition to bpy and pdc^{2-} chelation, Mn3 is bidentately coordinated by a carboxylate group of the pdc^{2-} ligand bound to the central Mn2 atom. Interestingly, the three pdc^{2-} ligands exhibit diverse coordination modes. The pdc^{2-} bridges between the Mn ions are also different from each other: double μ-O bridges occur between Mn1 and Mn2 and both carboxylate (μ-OCO) and μ-O bridges exist between Mn2 and Mn3. Consequently, each of the three metals possesses a highly asymmetrical coordination environment, forming a pentagonal bipyramidal geometry around each Mn^{II} center. The intracluster Mn···Mn separations were found to be 3.739(2) Å for Mn1···Mn2, and 4.607(2) Å for Mn2···Mn3; the difference of 0.86 Å in Mn···Mn separation in a single structure is rather rare.[11] Complex **1** is the first dipicolinato trimanganese complex, although a similar triiron dipicolinate [{Fe(pdc)(Hpdc)}$_2$Fe(H$_2$O)$_4$] has been reported.[5] High spin d^5 compounds can be expected to adopt geometries dictated by electrostatic effects, and many seven-coordinate Fe^{III} compounds are known.[12] Seven-coordinate Mn^{II} complexes are often observed with a quinquedentate ligand such as 15-crown-5,[13] which serves to define a pentagonal plane on the equator and leaves two axial positions open for further coordination to give a regular pentagonal bipyramid. However, the coordination sphere in **1** is severely distorted (Table 1) because the two planar ligands (bpy and pdc^{2-}) do not coexist in the equatorial plane and, therefore, large steric strain results between the ligands. On the other hand, linear connection between the metal centers and ligand distortion offer the possibility of further reaction with certain reagents, such as imidazole, to give mononuclear,

three ligands is evidently favorable to stabilize the structure and promotes the conversion of trinuclear **1** into mononuclear **3**.

The room-temperature magnetic moment measured for **3** (μ_{eff} = 10.3 B.M.) is close to that expected for the spin-only value of 10.24 B.M. for three uncoupled S = 5/2 sites. The effective magnetic moment remains essentially constant with decreasing temperature, but μ_{eff} decreases rapidly below 40 K, exhibiting a characteristic antiferromagnetic interaction between the neighboring Mn^{II} ions. A model containing a linear Mn_3 system was used for fitting the experimental magnetic data by invoking an exchange pathway through the carboxylate bridges, in which the magnetic exchange constant (J) between Mn2 and Mn1 (or Mn3) is assumed to be equal, for simplification, and the interaction between Mn1 and Mn3 is omitted. The spin-spin coupling

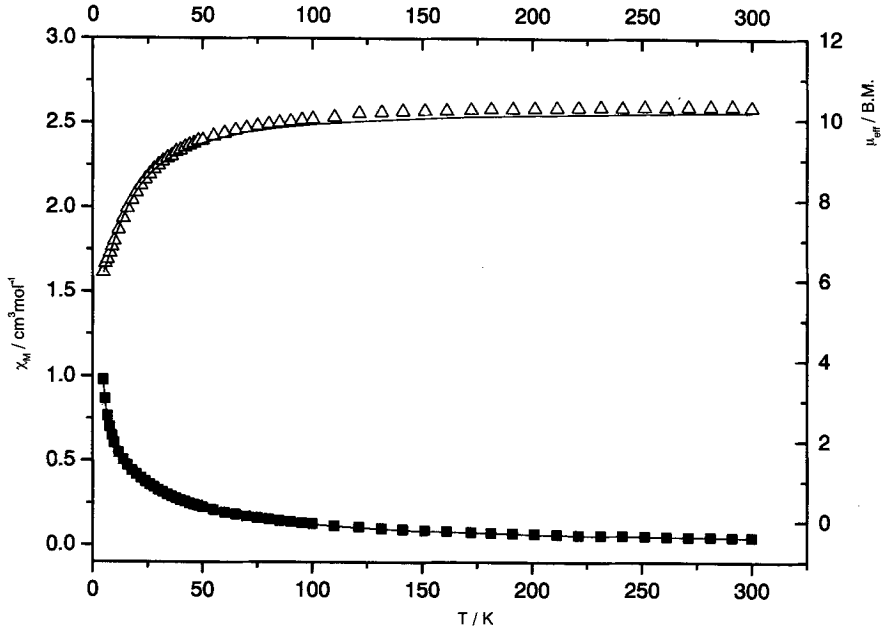

Figure 3. Experimental susceptibilities (χ_M, marked as square) and effective magnetic moment (μ_{eff}, marked as triangle) as functions of temperature for **1**; the solid lines represent the calculated values

Hamiltonian appropriate for describing the magnetic exchange interaction of the model is presented in Equation (1).

$$\hat{H} = -2J(\hat{S}_1\hat{S}_2 + \hat{S}_2\hat{S}_3)$$

$$\chi_M = \frac{Ng^2\beta^2}{3kT}\left[\frac{A}{B}\right]$$

$$A = 2040e^{-32x} + 1860e^{-17x} + 858e^{-4x} + 495e^{7x} + 252e^{16x} + 105e^{23x} + 1365e^{-27x} + 858e^{-14x} + 495e^{-3x} + 252e^{6x} + 105e^{13x} + 30e^{18x} + 858e^{-22x} + 492e^{-11x} + 252e^{-2x} + 105e^{5x} + 30e^{10x} + 3e^{13x} + 252e^{-8x} + 105e^{-x} + 30e^{4x} + 252e^{-12x} + 105e^{-5x} + 30 + 105e^{-7x}$$

$$B = 32e^{-32x} + 48e^{-17x} + 24e^{-4x} + 24e^{7x} + 16e^{16x} + 12e^{23x} + 28e^{-27x} + 24e^{-14x} + 20e^{-3x} + 16e^{6x} + 12e^{13x} + 8e^{18x} + 24e^{-22x} + 20e^{-11x} + 16e^{-2x} + 12e^{5x} + 8e^{10x} + 4e^{13x} + 16e^{-8x} + 12e^{-x} + 8e^{4x} + 16e^{-12x} + 12e^{-5x} + 8 + 12e^{-7x}$$

$$x = \frac{-J}{kT} \qquad (1)$$

The best fitting curves are depicted in Figure 3 for **1**. The best fitting parameters are $J = -0.81$ cm^{-1}, $g = 2.02$, and $R = [(\chi_M)_{obsd.} - (\chi_M)_{calcd.}]^2/(\chi_M)^2_{obsd.}] = 1.84 \times 10^{-4}$, showing weak antiferromagnetic exchange interactions between the metal atoms.

Conclusion

This work has described the synthesis and structure of a novel trinuclear Mn complex **1** derived from a polymeric Mn/K precursor **2**, as well as the conversion of **1** into a mononuclear species, **3**, which represents a preliminary result in the control of product nuclearity by ligand exchange or substitution. The control of product architecture is yet to be explored.

Experimental Section

General: All manipulations were performed under aerobic conditions with materials as received. Polymeric $[MnK_2(pdc)_2(H_2O)_7]_n$ was prepared from the reaction of dipicolinic acid and KOH with $Mn(OAc)_2{\cdot}4H_2O$.[8] The IR spectra were recorded on a Bio-Rad FTS-40 Model spectrophotometer. The variable-temperature susceptibilities were measured on a Model CF-1 superconducting extraction sample magnetometer with a crystalline sample kept in a capsule between 5 and 300 K. Diamagnetic corrections were made with Pascal's constants. Elemental analyses were performed by a Vario EL Elemental Analyzer.

$[Mn_3(pdc)_3(bpy)_3(H_2O)_2]{\cdot}9H_2O$ ($1{\cdot}9H_2O$): 2,2′-Bipyridine (0.32 g, 2 mmol) in 10 mL of EtOH was added to a solution of $[MnK_2(pdc)_2(H_2O)_7]_n$ (1.18 g, 2 mmol) in 5 mL of H_2O with continuous stirring. The mixture was refluxed for six days, producing large plate-like crystals of $1{\cdot}9H_2O$. Yield: 0.39 g (44%). $C_{51}H_{55}Mn_3N_9O_{23}$ (1326.86): calcd. C 46.17, H 4.18, N 9.50, Mn 12.42; found C 46.11, H 4.15, N 9.54, Mn 12.47. IR (KBr pellet): $\tilde{\nu}$ = 3396 (br. s), 1645 (m), 1616 (s), 1603 (s), 1579 (s), 1566 (s), 1493 (w), 1475 (m), 1439 (s), 1375 (s), 1363 (s), 1317 (w), 1277 (m), 1246 (w), 1186 (m), 1161 (w), 1119 (w), 1076 (m), 1063 (w), 1043 (w), 1016 (s), 962 (w), 916 (m), 862 (w), 837 (w), 773 (s), 762 (s), 737 (m), 698 (m), 661 (m), 625 (w), 530 (w), 432 (m), 413 cm^{-1} (w).

$[Mn(pdc)(bpy)(Him)_2]{\cdot}H_2O$ ($3{\cdot}H_2O$): Imidazole (0.68 g, 10 mmol) was added to a solution of $1{\cdot}9H_2O$ (1.33 g, 1 mmol) dissolved in 20 mL of H_2O/DMF (1:4, v/v). The mixture was refluxed for two hours and was then filtered. The filtrate was left in a desiccator with $CaCl_2$ for six days to produce yellow crystals of $3{\cdot}H_2O$. Yield: 0.86 g (54%). $C_{23}H_{21}MnN_7O_5$ (530.41): calcd. C 52.08, H 3.99, N 18.49, Mn 10.36; found C 52.02, H 3.97, N 18.44, Mn 10.42. IR (KBr pellet): $\tilde{\nu}$ = 3492 (s), 3379 (br. s), 3107 (m), 3045 (w), 2846 (m), 2611 (w), 1622 (s), 1587 (m), 1531 (m), 1437 (s), 1377 (s), 1327 (w), 1279 (m), 1244 (w), 1184 (m), 1159 (w), 1136 (m), 1101 (m), 1065 (s), 1011 (m), 935 (m), 904 (w), 843 (m), 804 (w), 768 (s), 725 (s), 698 (m), 661 (s), 642 (w), 623 (m), 521 (w), 415 cm^{-1} (w).

X-ray Crystallography: Data were collected at 293 K on a Siemens SMART CCD diffractometer for $1{\cdot}9H_2O$ and $3{\cdot}H_2O$ with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) using the ω-scan mode, and were corrected with the SADABS program. Structure solutions were made with the SHELXTL program.[14] The structures were solved by direct methods. All non-hydrogen atoms were refined anisotropically with three exceptions: O20, O21 and O22 of the solvate water molecules in $1{\cdot}9H_2O$ are disordered over two positions with occupancies of 0.5 each.

Crystal Data for $1{\cdot}9H_2O$: $C_{51}H_{55}Mn_3N_9O_{23}$, M_r = 1326.86, monoclinic, space group $P2_1/n$, a = 21.2089(3), b = 10.0559(2), c = 28.1400(1) Å, β = 108.017(1)°, V = 5707.26(1) Å^3, Z = 4, $D_{calcd.}$ = 1.544 g/cm^3, $F(000)$ = 2732, μ = 0.743 mm^{-1}. R = 0.0754 and Rw = 0.1683 for 5979 observed reflections with $I > 2\sigma(I)$.

Crystal Data for $3{\cdot}H_2O$: $C_{23}H_{21}MnN_7O_5$, M_r = 530.41, monoclinic, space group $P2_1/n$, a = 8.1309(1), b = 16.9103(5), c = 17.3252(5) Å, β = 102.017(2)°, V = 2329.94(1) Å^3, Z = 4, D_c = 1.512 g/cm^3, $F(000)$ = 1092, μ = 0.618 mm^{-1}. R = 0.0698 and Rw = 0.1956 for 2766 observed reflections with $I > 2\sigma(I)$.

CCDC-188829 (**$1{\cdot}9H_2O$**) and -188830 (**$3{\cdot}H_2O$**) contain the supplementary crystallographic data for $1{\cdot}9H_2O$ and $3{\cdot}H_2O$. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat. +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Coordination Chemistry of Nitrile and Amino Pendant Arm Derivatives of [9]aneN$_2$S and [9]aneNS$_2$ with Pd^{II} and Cu^{II}

Massimiliano Arca,[a] Alexander J. Blake,[b] Vito Lippolis,*[a] Daniela R. Montesu,[a] Jonathan McMaster,[b] Lorenzo Tei,[a,b] and Martin Schröder*[b]

Keywords: Macrocycles / Palladium / Copper / N ligands / S ligands

Palladium(II) and copper(II) complexes [Pd(**L^1**)Cl$_2$], [Pd(**L^3**)Cl$_2$], [Cu(**L^1**)Cl$_2$], [Cu(**L^3**)Cl$_2$], [Pd(**L^2**)][BF$_4$]$_2$, [Pd(**L^4**)Cl]BF$_4$, [Cu(**L^2**)][NO$_3$]$_2$ and [Cu(**L^4**)Cl]PF$_6$ of the nitrile (**L^1** and **L^3**) and amino (**L^2** and **L^4**) pendant arm derivatives of 1-thia-4,7-diazacyclononane ([9]aneN$_2$S) and 7-aza-1,4-dithiacyclononane ([9]aneNS$_2$) have been prepared and fully characterised. In each case, a square-pyramidal coordination sphere is observed at both metal ions with either one or two Cl$^-$ anions completing the donor set. The tridentate nine-membered macrocyclic moiety adopts a [333] conformation in all the complexes obtained. The five-membered chelate rings involving the donor atoms of the basal plane adopt a *gauche* configuration with very similar degrees of puckering. The "innocent" nitrile pendant arms in **L^1** and **L^3** do not bind to the metal ions, but still appear to influence the binding of the tridentate macrocyclic frameworks via the tertiary amine sites.

Introduction

1,4,7-Triazacyclononane ([9]aneN$_3$) and 1,4,7-trithiacyclononane ([9]aneS$_3$; Scheme 1) have been extensively studied, and afford bis(sandwich) octahedral complexes in which the ligands bind to the metal centre in a facial manner; [9]aneN$_3$ has been used mainly to complex 3d transition metal ions[1,2] whereas the trithia analogue, [9]aneS$_3$, because of the soft nature of its donor atoms, has also been considered for complexation with 4d and 5d transition metal ions.[3] Thus, a range of complexes of noble metal ions having uncommon oxidation states have been synthesised.[3] The two related nine-membered ring macrocycles [9]aneN$_2$S (1,4-diaza-7-thiacyclononane) and [9]aneNS$_2$ (1-aza-4,7-dithiacyclononane) are of particular interest since the loss of threefold symmetry and the presence of both hard N- and soft S-donors can potentially have interesting stereochemical consequences and thereby offer specific coordination selectivity. However, their coordination chemistry has not been studied extensively,[4] perhaps in part due to the greater difficulty in preparing these mixed donor macrocycles. In comparison to [9]aneN$_3$,[5] even less attention has been directed to the *N*-functionalisation of [9]aneN$_2$S and [9]aneNS$_2$ by incorporation of pendant arms bearing coordinating donor groups to give potentially tetra- and pentadentate ligands, respectively.[4,6–13] In particular, the coordination chemistry of nitrile and amino pendant arm derivatives of [9]aneN$_2$S and [9]aneNS$_2$ such as **L^1**–**L^4** is unknown, although **L^1** and **L^2** have been described previously as free ligands.[14,15] The ethyl-bridged bis([9]aneNS$_2$), which can also be formally considered as an amino pendant arm derivative of [9]aneNS$_2$, is also known.[13] Interestingly, **L^1** and **L^4** can impose stereorestrictive modes of coordination at metal centres such as Pd^{II} and Cu^{II} by forming potentially four- or five-coordinate complexes possessing unusual and interesting coordination and/or redox properties. Due to their electronic requirements, Pd^{II} and Cu^{II} typically form square-planar and Jahn–Teller distorted octahedral complexes, respectively, and as a result, five-coordinate complexes of these metal ions would represent potential models for intermediates in associative substitution reactions at square-planar d^8 complexes, and in dissociative reactions of hexacoordinate compounds, respectively. Furthermore, five-coordinate metal complexes of coordinatively unsaturated metal centres such as Cu^{II} lead to the possibility of binding and activation of small molecules and therefore represent useful models of enzymatic systems. As a continuation of our studies[4,6–11] of the coordination chemistry of *N*-functionalised pendant arms derivatives of tridentate mixed thia/aza nine-membered macrocycles, we report herein our studies of the complexation of Pd^{II} and Cu^{II} centres with **L^1**, **L^2**, **L^3** and **L^4**.

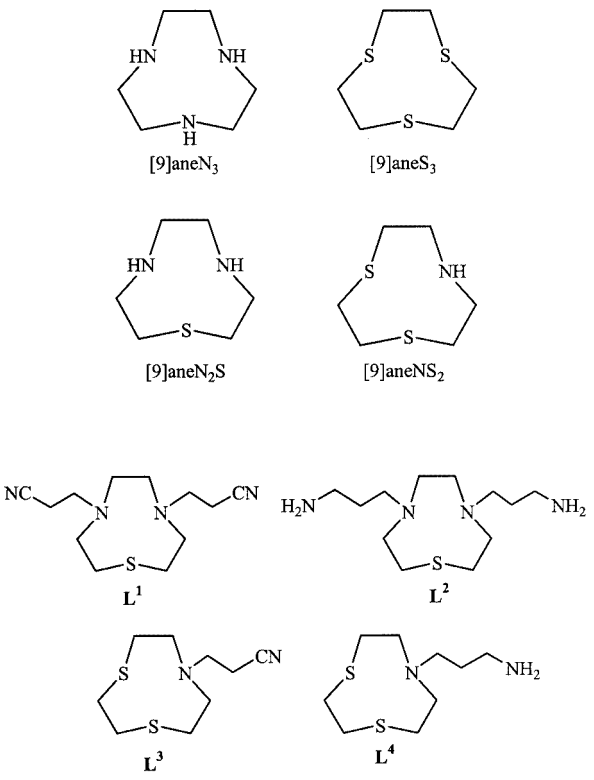

Scheme 1

Results and Discussion

Coordination to Pd^{II}

Reaction of $PdCl_2$ with 1 mol-equiv. of **L^1** in refluxing MeCN for 12 h gave an orange solution. After partial removal of the solvent and filtration through a pad of Celite, dark-red crystals of [Pd(**L^1**)Cl$_2$] were formed upon diffusion of Et_2O vapour into the remaining solution. The X-ray crystal structure of [Pd(**L^1**)Cl$_2$] (Figure 1, top; Table 1) shows a square-planar $NSCl_2$ coordination sphere at Pd^{II} with two mutually *cis*-Cl$^-$ ligands *trans* to N- and S-donors of the [9]aneN$_2$S macrocyclic framework. The remaining N-donor of the [9]aneN$_2$S ring is oriented towards the Pd^{II} centre and lies above the $NSPdCl_2$ coordination plane with a Pd···N(7) distance of 2.638(4) Å. Thus, an overall [NS+N] coordination for the [9]aneN$_2$S framework is observed. The Pd(1)−N(7) vector shows a slight deviation from perpendicularity to the Pd^{II} coordination plane with N(7)−Pd(1)−X angles [X = S(1), N(4), Cl(1) or Cl(2)] ranging from 77.23(12) to 101.23(8)°. The Pd^{II} centre lies only 0.006 Å above the mean $NSCl_2$ coordination plane and the two nitrile-functionalised pendant arms do not bind to the metal centre.

Examples of long-range Pd···N apical interactions in square-based pyramidal complexes of tridentate nine-membered macrocycles are very rare. The complex cations $[Pd([9]aneN_3)_2]^{2+}$ and $[Pd([9]aneN_3)(H[9]aneN_3)]^{3+}$ have square-planar coordination geometries at Pd^{II},[16,17] but with the remaining apical N-centres oriented away from the axial site of the PdN_4 plane at a distance of 3.499(5) Å for centrosymmetric $[Pd([9]aneN_3)_2]^{2+}$,[16] and 2.982(11)−3.079(11) Å for $[Pd([9]aneN_3)(H[9]aneN_3)]^{3+}$.[17]

N(7)−M(1)−Cl(2)	101.23(8)	92.1(2)
Cl(1)−M(1)−Cl(2)	91.79(4)	91.28(11)

Interesting exceptions are represented by the complex cation $[Pd(py_3[9]aneN_3)]^{2+}$ {$py_3[9]aneN_3$ = 1,4,7-tris(2-pyridylmethyl)-1,4,7-triazacyclononane}[2] in which one of the N-donors of the [9]aneN$_3$ framework occupies the apical site [Pd−N$_{ap}$ 2.580 Å] of a square-based pyramidal geometry. A similar geometry is observed in $[Pd(NCMe)_2(Me_3[9]aneN_3)]^{2+}$ in which the apical N-donor of the macrocycle is sited 2.523(8) from the Pd^{II} centre.[18] It is also interesting to compare the coordination modes of [9]aneN$_2$S and **L^1** to Pd^{II}. In the sandwich complexes $[Pd([9]aneN_2S)_2][PF_6]_2$ and $[Pd([9]aneN_2S)_2]Cl_2\cdot H_2O$ each metal centre is bound by four N-donors of the two macrocycles in a square-planar arrangement, with the thioether S-donors showing either long-range apical interactions with the Pd^{II} centre {as in $[Pd([9]aneN_2S)_2][PF_6]_2$} or no interaction at all {as in $[Pd([9]aneN_2S)_2]Cl_2\cdot H_2O$}.[19] A [2N+S] coordination is also observed for the [9]aneN$_2$S units in the trinuclear complex $[Pd_3([9]aneN_2S)_4Cl_2]Cl_4\cdot 2H_2O$,[19] and similar structural features have been observed for Pt^{II} complexes with both [9]aneN$_3$ and [9]aneN$_2$S[1,4,6−11] and for the complex $[Au([9]aneN_2S)Cl_2]^+$.[20] Therefore, the [NS+N] coordination of the [9]aneN$_2$S macrocyclic framework in [Pd(**L^1**)Cl$_2$] is unusual: it may have its origins in either electronic or steric effects which arise from the combination of the two nitrile functionalised pendant arms and the two bound Cl$^-$ ligands. [Pd(**L^1**)Cl$_2$] units interact with each other in the crystal lattice through long-range Cl···S contacts [3.527(2) Å] (Figure 2) to form polymeric chains of [Pd(**L^1**)Cl$_2$] which run along the (010) direction.

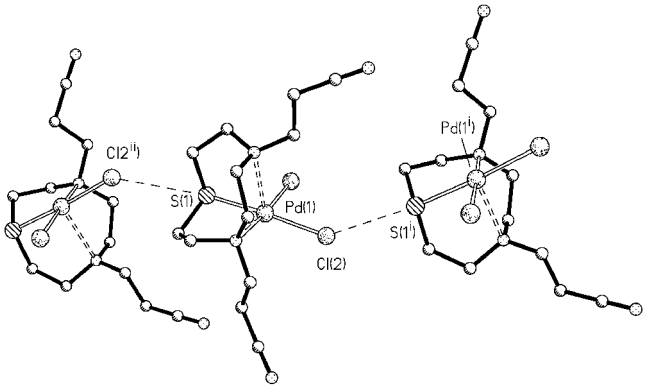

Figure 2. Partial view of the crystal packing in [Pd(**L^1**)Cl$_2$]: Cl(2)···S(1^i) 3.527(2) Å; Pd(1)−Cl(2)−S(1^i) 141.56(5), Pd(1)−S(1)−Cl(2^{ii}) 171.25(5)°; i = 1 − *x*, 1/2 + *y*, 1/2−z; ii = 1 − *x*, −1/2 + *y*, 1/2 − *z*

In order to study the effect that nitrile-functionalised pendant arms can have upon the coordination mode of mixed thia/aza nine-membered macrocyclic derivatives towards Pd^{II}, we treated **L^3** with PdCl$_2$ under the same conditions used for the synthesis of [Pd(**L^1**)Cl$_2$]. The red-orange crystals of [Pd(**L^3**)Cl$_2$] obtained after recrystallisation from DMF/Et$_2$O were analysed by X-ray diffraction. The Pd^{II} centre is bound by the two S-donors of the macrocyclic ring and two Cl$^-$ ligands to form an approximate S$_2$PdCl$_2$ plane (Figure 3, top; Table 2). The remaining tertiary N-atom of the [9]aneNS$_2$ moiety is disposed apically relative to this coordination plane with N(7)−Pd(1)−X angles [X = S(1), S(4), Cl(1) or Cl(2)] ranging from 79.24(5) to 100.94(6)°. The Pd^{II} centre is displaced 0.007 Å out of the S$_2$PdCl$_2$ mean plane in the direction of the apical N-centre. Therefore, as for [Pd(**L^1**)Cl$_2$], the addition of a nitrile pendant arm to the N-centre in [9]aneNS$_2$ leads to the macrocyclic framework adopting an unusual [2S+N] coordination in [Pd(**L^3**)Cl$_2$], with the N-centre occupying the apical position of a "flat" square-pyramidal coordination geometry. In contrast an [NS+S] coordination mode has been observed for [9]aneNS$_2$ in the complex cation $[Pd([9]aneNS_2)_2]^{2+}$ where the Pd^{II} centre is bound to two N- and two S-donors in a square-planar configuration with the remaining two S-atoms interacting apically.[21] Significantly, in the related half-sandwich complex [Pd([9]aneS$_2$O)Cl$_2$], the macrocyclic ligand assumes a facial [2S+O] coordination mode at the metal centre with the oxygen atom lying above the basal S$_2$PdCl$_2$ plane and pointing toward the Pd centre.[22] At this stage it is difficult to conclude whether the observed [NS+N] and [2S+N] coordination modes of **L^1** and **L^3** in [Pd(**L^1**)Cl$_2$] and [Pd(**L^3**)Cl$_2$], respectively, are determined by the steric requirements of the nitrile pendant arms, by electronic effects or by the binding of soft S-donors to soft Pd^{II}. It might be argued that the pendant arms in [Pd(**L^1**)Cl$_2$] and [Pd(**L^3**)Cl$_2$] tend to dispose themselves as far as possible from the Cl$^-$ ligands because of steric requirements. Alternatively, the tertiary nitrogen centres in **L^1** and **L^3** may have a weaker σ-donor character than the analogous secondary N-donors in [9]aneN$_2$S and [9]aneNS$_2$. According to molecular orbital calculations performed by Rossi and Hoffmann for d^8 low-spin metal centres,[23] this would lead to a tendency for the N-donor to lie in the apical position of a square-based pyramidal coordination geometry. However, thioether donors in macrocyclic systems have a limited π-donor/acceptor capacity,[3] and according to calculations performed by Rossi and Hoffmann for a five-coordinate, square-based pyramidal geometry, the disposition and the relative bond strengths of the substituents in the apical and basal positions, as well as the degree of pyramidality, are the result of a delicate balance between σ- and π-substituent effects.[23]

In both [Pd(**L^1**)Cl$_2$] and [Pd(**L^3**)Cl$_2$] the nitrile groups of the pendant arms are directed away from the metal centre. We argued that conversion of nitriles to amine functions would switch the coordination mode at Pd^{II} and restore the more usual [2N+S] and [NS+S] binding of the [9]aneN$_2$S and [9]aneNS$_2$ moieties in **L^2** and **L^4**, respectively. This would be driven by the formation of six-membered chelate rings on coordination of the strongly donating amine pendant arms to Pd^{II}. The reaction of **L^2** with 1 mol-equiv. of $[Pd(CH_3CN)_4](BF_4)_2$ in MeCN/MeOH at room temperature yielded a yellow solid after removal of the solvent. Recrystallisation by diffusion of Et$_2$O into a solution of the complex in MeNO$_2$ afforded pale-yellow crystals which, according to analytical and mass spectrometric data, had the formulation [Pd(**L^2**)][BF$_4$]$_2$. A crystal structure determination confirmed the formation of the cation [Pd(**L^2**)]$^{2+}$ (Figure 4, top; Table 3), with the pentadentate ligand **L^2** impos-

ing a formal [4+1] coordination sphere at the Pd^{II} centre, which is bound by the two tertiary N-donors of the [9]aneN$_2$S ring and the nitrogen atoms of both amino pendant arms forming an approximate PdN$_4$ plane. The S-donor of the macrocyclic ring occupies an apical site of a distorted square-pyramidal geometry with a long-range Pd···S(1) interaction of 3.0865(11) Å. The Pd^{II} centre is displaced 0.07 Å out of the mean plane defined by the atoms N(4), N(7), N(44) and N(74) towards S(1), with the angles S(1)−Pd(1)−N$_{eq}$ ranging from 75.60(9) to 106.72(9)°. Therefore, the introduction of coordinating functionalised pendant arms does indeed switch the [9]aneN$_2$S moiety of **L^2** to adopt a facial [2N+S] donation to Pd^{II} rather than the [NS+N] mode observed for **L^1** in [Pd(**L^1**)Cl$_2$] (see above). The Pd···S(1) distance in [Pd(**L^2**)]$^{2+}$ is consistent with those for long-range Pd···S apical interactions found in other sandwich and half-sandwich Pd^{II} complexes with thia- and mixed thia/aza macrocycles.[3,19−21,24−32] In [Pd(**L^2**)]$^{2+}$ (Figure 4, top) there are one five- and two six-membered chelate rings involving the metal centre. The former adopts a *gauche* conformation with a torsion angle at the C(5)−C(6) bond of 45.7(5)°, while the latter adopt chair forms. The chelate angles range from 86.47(13) [N(4)−Pd(1)−N(7)] to 93.02(14)° [N(4)−Pd(1)−N(44)] and do not suggest any particular structural or steric constraints imposed by the five- and six-membered chelate rings.

Reaction of [Pd(CH$_3$CN)$_4$](BF$_4$)$_2$ with **L^4** affords a brown oil which was treated with 1 mol-equiv. of aqueous NaCl at room temperature to give, after removal of the solvent, a brown solid which could be recrystallised from MeCN/Et$_2$O. The fast-atom bombardment (FAB) mass spectrum of the product exhibited peaks with the correct isotopic distribution for [^{106}PdCl(**L^4**)]$^+$ (*m*/*z* = 362) and for [^{106}Pd(**L^4**)]$^+$ (*m*/*z* = 327). These, together with elemental analytical data, suggest a formulation [Pd(**L^4**)Cl]BF$_4$. An X-ray diffraction study confirmed the formation of the complex cation [Pd(**L^4**)Cl]$^+$ in which a formal [4+1] square-based pyramidal geometry is achieved at the metal centre (Figure 5, top; Table 4). One N- and one S-donor of the macrocyclic framework, the amino group of the pendant arm and one Cl$^-$ ligand are coordinated to the Pd^{II} centre in a square-planar arrangement. The remaining S-donor of [9]aneNS$_2$ shows a long-range apical Pd···S(4) interaction of 2.9278(9) Å, with the metal atom displaced only 0.004 Å out of the N$_2$SCl mean plane towards S(4). Symmetry-related [Pd(**L^4**)Cl]$^+$ complex cations interact with each other to form dimeric units through Pd···Cl contacts of 3.6091(11) Å, while the S-donors in the PdN$_2$SCl coordination plane interact with F$^-$ centres in BF$_4^-$ counter-anions (Figure 6, top).

Significantly, the Pd···S$_{ap}$ interaction in [Pd(**L^4**)Cl]$^+$ is shorter than that observed in the sandwich complex cation [Pd([9]aneNS$_2$)$_2$]$^{2+}$ [3.011(3) Å],[21] even though the overall cationic charge of the former is lower. This demonstrates once again that apical interactions in square-pyramidal Pd^{II} and Pt^{II} complexes are influenced significantly by the electronic nature of the equatorial ligands. As predicted, the binding of **L^2** and **L^4** to Pd^{II} drives the [9]aneN$_2$S and

[9]aneNS$_2$ moieties to bind facially with long-range S-donor apical interactions as opposed to long-range N-donor interactions in the case of $\mathbf{L^1}$ and $\mathbf{L^2}$.

While the macrocyclic ligands in $[Pd([9]aneN_3)_2]^{2+}$,[16] half-sandwich Pd^{II} complexes with [9]aneS$_3$[25] and $[Pt([9]aneS_3)phen]^{2+}$[32] have been shown to be fluxional in solution, no evidence of similar behaviour has yet been reported for mixed thia/aza macrocycles [9]aneN$_2$S and [9]aneNS$_2$ or their derivatives. For $[Pd(py_2[9]aneN_2S)]^{2+}$ it has been shown by NMR spectroscopy that the ligand is nonfluxional in solution, with the axial S-donor believed to maintain a constant position by weak interaction with the Pd^{II} centre.[26] The structures of $[Pd(\mathbf{L^1})Cl_2]$ and $[Pd(\mathbf{L^3})Cl_2]$ clearly demonstrate the possibility for [9]aneN$_2$S, [9]aneNS$_2$ and their derivatives to adopt different facial coordination

modes at low-spin d^8 metal centres. Furthermore, the structure of [Pd([9]aneN$_2$S)$_2$]Cl$_2$·H$_2$O shows that the S-centres do not interact apically with the metal centre[19] and this situation could represent the first step towards a dynamic structure in solution in which the metal atom undergoes a series of inner-sphere substitution reactions with the ligand rotating between [2N+S] and [NS+N] configurations. Although the results herein apply only to situations in the solid state, they confirm the low energy differences between these different possible coordination modes and suggest that fluxional behaviour in solution may be possible for [9]aneN$_2$S and [9]aneNS$_2$ within sandwich and half-sandwich complexes with Pd^{II} and Pt^{II}. Unfortunately, due to the very low solubilities of [Pd(**L**^{1})Cl$_2$] and [Pd(**L**^{3})Cl$_2$] we have not been able to demonstrate this in solution.

Coordination to Cu^{II}

Reaction of **L**^{1} with 1 mol-equiv. of CuCl$_2$·2H$_2$O in MeCN afforded a green solution after 1 h of reflux under N$_2$. Slow concentration of this solution yielded green crystals having the formulation [Cu(**L**^{1})Cl$_2$] according to analytical and mass spectrometric data. A crystal structure determination (Figure 1, bottom; Table 1) shows the metal centre in a distorted square-pyramidal environment, with the basal positions occupied by the two tertiary N-donors of the [9]aneN$_2$S moiety of **L**^{1} and by two Cl$^-$ ligands. The S-donor S(1) of the macrocyclic ring occupies the apical position whereas the nitrile functionalised pendant arms are directed away from the metal centre. The Cu^{II} centre is displaced 0.1145 Å out of the mean plane defined by the atoms N(4), N(7), Cl(1) and Cl(2), in the direction of S(1). The structure of [Cu(**L**^{1})Cl$_2$] is very similar to that reported for the half-sandwich complex [Cu([9]aneN$_2$S)Br$_2$],[33] where the macrocyclic ligand also adopts a facial [2N+S] coordination at the metal centre [Cu−N$_{eq}$ 2.03(1), 2.02(1) Å; Cu−S$_{ap}$ 2.567(3) Å] but with two Br$^-$ ligands at basal positions completing the square-pyramidal geometry. However, the Cu−N$_{eq}$ distances appear significantly longer in the case of [Cu(**L**^{1})Cl$_2$] (Table 1) and this could be due to an increased steric repulsion at the tertiary N-centres in **L**^{1} compared to the secondary N-centres in [9]aneN$_2$S. Cu−S$_{ap}$ bonds longer than those reported for [Cu([9]aneN$_2$S)Br$_2$][33] and [Cu(**L**^{1})Cl$_2$] have been observed for the sandwich complex [Cu([9]aneN$_2$S)$_2$]$^{2+}$ [Cu−N$_{eq}$ 2.027(3), 2.067(3); Cu−S$_{ap}$ 2.707(1) Å] in which the macrocyclic ligand also adopts a facial [2N+S] coordination mode.[34,35] [Cu(**L**^{1})Cl$_2$] provides an interesting contrast to [Pd(**L**^{1})Cl$_2$] in that changing the metal centre from low-spin d^8 to d^9 causes the [9]aneN$_2$S framework of **L**^{1} to pass from the [NS+S] to the [2N+S] facial coordination mode. This is clearly consistent with the preference of Cu^{II} for binding N-donor centres, as also demonstrated by the structure of the sandwich complex [Cu([9]aneN$_2$S)$_2$]$^{2+}$ in which the four N-donors occupy the equatorial sites of a distorted octahedral geometry and the two S-donors occupy the axial positions.[33,34]

In order to investigate the coordinative behaviour of the [9]aneNS$_2$ moiety in **L**^{3} towards Cu^{II}, **L**^{3} was treated with

1 mol-equiv. of $CuCl_2 \cdot 2H_2O$ in MeCN under the same experimental conditions used for the synthesis of $[Cu(\mathbf{L^1})Cl_2]$. Well-shaped crystals of $[Cu(\mathbf{L^3})Cl_2]$ suitable for X-ray diffraction studies were obtained after recrystallisation from DMF/Et_2O. The [2S+N] ligand arrangement in $[Cu(\mathbf{L^3})Cl_2]$ (Figure 3, bottom; Table 2) is very similar to that observed in $[Pd(\mathbf{L^3})Cl_2]$ but contrasts with that observed for $[Cu(\mathbf{L^1})Cl_2]$. In $[Cu(\mathbf{L^3})Cl_2]$ it appears that the preference of Cu^{II} for N-donors is offset by steric effects of the bulky tertiary N-donors which induces the [9]aneNS$_2$ framework to adopt the observed [2S + N] coordination mode. A similar coordination mode is observed in $[Cu([9]aneNS_2)_2]^{2+}$ with the S-donors occupying the equatorial sites of an octahedral geometry [Cu−S_{eq} 2.547(1)−2.539(1) Å] and the N-donors at the axial positions average [Cu−N_{eq} 2.016(4) Å].[36] In this case the average Cu−N_{eq} distance is much shorter and the Cu−S_{eq} are much longer than the corresponding bond lengths observed in $[Cu(\mathbf{L^3})Cl_2]$ suggesting a possible opposite direction of the Jahn−Teller effect in the two complexes. It appears, therefore, that a delicate balance between electronic and steric factors might be responsible for the type of donation of the macrocyclic framework in the square-pyramidal complexes $[M(\mathbf{L^1})Cl_2]$ and $[M(\mathbf{L^3})Cl_2]$ (M = Pd, Cu).

$[Cu(\mathbf{L^3})Cl_2]$ units in the crystal lattice interact with each other via long Cl···Cu contacts to give infinite zigzag chains which run along the *c* axis, with the nitrile-functionalised pendant arms dangling away from the metal centres (Figure 7).

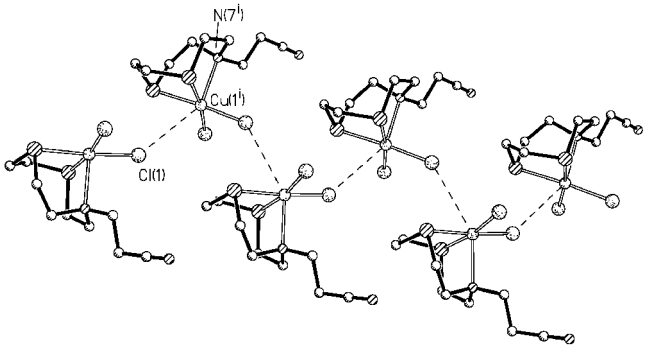

Figure 7. Partial view along the (110) direction of zigzag chains of $[Cu(\mathbf{L^3})Cl_2]$ molecules running along the (001) direction: Cl(1)···Cu(1^{i}) 3.5886(11) Å; Cl(1)···Cu(1^{i})−N(7^{i}) 150.52(10)°; i = 1 − *x*, − *y*, *z* − 1/2

Given that structural data on CuN_4S systems are relatively rare in the literature, we treated $\mathbf{L^2}$ with 1 mol-equiv. of $Cu(NO_3)_2 \cdot 3H_2O$ in MeCN/EtOH at room temperature. A blue colour was immediately formed and the residue obtained after removal of the solvent was repeatedly crystallised from EtOH/Et_2O to give blue blocky crystals having the formulation $[Cu(\mathbf{L^2})][NO_3]_2$.

As observed for $[Pd(\mathbf{L^2})]^{2+}$, the structure of the cation $[Cu(\mathbf{L^2})]^{2+}$ (Figure 4, bottom; Table 3) shows the ligand encapsulating the metal ion in a distorted square-based pyramidal geometry. The basal coordination sites are occupied by the N-atoms of the [9]aneN$_2$S moiety and by the primary amino groups of the pendant arms, with the remaining S-donor of the pentadentate ligand $\mathbf{L^2}$ occupying the apical position. The metal ion is displaced out of the N_4 plane by 0.0965 Å in the direction of the S donor. The Cu−N_{eq} bond lengths [average 2.05(2) Å] are typical for an N_4-donor set arranged in a plane around the Cu^{II} centre, and similar average Cu−N_{eq} bond lengths have been observed for Cu^{II} complexes of amino-functionalised pendant arm derivatives of [9]aneN$_3$ and ethyl-bridged bis([9]aneN$_3$).[37] The Cu−S_{ap} bond length [2.5608(13) Å] is towards the lower end of the range [2.56−2.82 Å] expected for axial Cu−S contacts.[34] The structure of $[Cu(\mathbf{L^2})]^{2+}$ can be compared to those of $[Cu(py_2[9]aneN_2S)]^{2+}$ [Cu−S_{ap} = 2.496(8), Cu−N_{eq} = 2.02(1) Å][38] and [Cu(*b*[10.5.2][19]aneN$_4$S)]$^{2+}$ bicyclo [Cu−S_{ap} = 2.549(2), Cu−N_{eq} = 2.04(1) Å][14] {py$_2$[9]aneN$_2$S = 4,7-bis(2-pyridylmethyl)-1-thia-4,7-diazacyclononane; *b*[10.5.2][19]aneN$_4$S = 15-thia-1,5,8,12-tetraazabicyclo[10.5.2]nonadecane}. These represent the only examples of structurally characterised CuN_4S systems with a square-pyramidal coordination sphere at the metal centre. Py$_2$[9]aneN$_2$S differs from $\mathbf{L^2}$ in that it has pyridyl-functionalised pendant arms, whereas *b*[10.5.2][19]aneN$_4$S can be considered as derived from $\mathbf{L^2}$ by formally joining the primary amino groups of the pendant arms with a $-CH_2CH_2-$ bridge to form a tetraazamacrocycle fused with a [9]aneN$_2$S moiety. In the case of $[Cu(py_2[9]aneN_2S)]^{2+}$, the structural data seem to indicate the presence of significant geometric constraints imposed by the pentadentate ligand py$_2$[9]aneN$_2$S. Indeed, the Cu−S_{ap} bond is particularly short and, although the mean Cu−N_{eq} bond length is similar for all three complexes, the Cu−N_{eq} bonds involving the pyridine donors in $[Cu(py_2[9]aneN_2S)]^{2+}$ are significantly shorter.[14,38] A similar trend in M−S_{ap} and M−N_{eq} distances is observed when comparing $[Pd(\mathbf{L^2})]^{2+}$ with $[Pd(py_2[9]aneN_2S)]^{2+}$.[26] Finally, the rather strained square-pyramidal coordination imposed on Cu^{II} by py$_2$[9]aneN$_2$S is also seen in the strong distortion of the basal plane in $[Cu(py_2[9]aneN_2S)]^{2+}$ where the metal centre suffers by far the greatest displacement (0.22 Å) from the N_4 plane towards the apical S-donor in the three complexes considered.

The ligand $\mathbf{L^4}$ was treated with 1 mol-equiv. of $CuCl_2 \cdot 2H_2O$ in MeOH at room temperature to give a deep blue solution. Addition of excess NH_4PF_6 followed by removal of the solvent gave a blue product, which was recrystallised from MeCN/Et_2O. The fast-atom bombardment (FAB) mass spectrum of this product exhibits peaks with the correct isotopic distribution for $[^{63}Cu(\mathbf{L^4})Cl]^+$ (*m*/*z* = 319) and for $[^{63}Cu(\mathbf{L^4})]^+$ (*m*/*z* = 284), and elemental analytical data suggested a formulation $[Cu(\mathbf{L^4})Cl]PF_6$. A structure determination confirmed the formation of a $[Cu(\mathbf{L^4})Cl]^+$ cation (Figure 5, bottom; Table 4) having structural features very similar to those observed in the analogous Pd^{II} complex $[Pd(\mathbf{L^4}Cl)]^+$. The square-pyramidal coordination geometry in $[Cu(\mathbf{L^4})Cl)]^+$ involves an N_2SCl donor set defining the basal plane and an S-donor at the apical site. The Cu−S_{ap} bond length is 2.5962(11) Å and, as expected, the Cu−N_{eq} distance involving the amino pen-

dant arm group [1.996(3) Å] is shorter than that involving the tertiary N-donor of the macrocyclic ring [2.103(3) Å]. The metal centre is displaced 0.1307 Å out of the mean plane defined by the atoms N(74), N(7), S(1) and Cl(1) in the direction of the apical S-donor S(4). In [Cu(**L^4**)Cl]$^+$, as in [Pd(**L^4**)Cl]$^+$, the coordination of the amino pendant arm to the metal centre with the formation of a six-membered chelate ring has driven the [9]aneNS$_2$ framework to adopt a facial [NS+S] coordination mode in contrast to the [2N+S] binding observed in [Cu(**L^2**)Cl$_2$] and [Pd(**L^2**)Cl$_2$]. [Cu(**L^4**)Cl]$^+$ units are associated in pairs via long-range Cu···Cl contacts and Cl···H hydrogen bonds, giving a Cu···Cu distance of 4.001(1) Å (Figure 6, bottom). Also, pairs of [Cu(**L^4**)Cl]$^+$ cations interact with each other through hydrogen bonds involving the amino pendant arm of the ligand to give ribbons which run along the *a* axis.

Conclusions

The binding of **L^1**−**L^4** to Pd^{II} and Cu^{II} is the same for each pair of complexes (Table 5) except for [M(**L^1**)Cl$_2$] for which both [NS+N] (M = Pd) and [2N + S] (M = Cu) coordination modes are observed. Generally, the amine ligands **L^2** and **L^4** show strong basal coordination of the N-donors of the macrocycle and of the primary amine. This is driven by the excellent binding properties of the primary amine donors and by the inherent stability of the chelate rings thus formed. The apparently "innocent" nitrile pendant arms are found to modulate the binding of the macrocyclic units within complexes of **L^1** and **L^3** and afford rare examples of long-range apical Pd···N$_{ap}$ interactions.

Experimental Section

General: Melting points are uncorrected. Microanalyses were performed by the University of Nottingham School of Chemistry Microanalytical Service. IR spectra were recorded as KBr discs using a Perkin−Elmer 598 spectrometer over the range 400−4000 cm^{-1}. NMR spectra (^{1}H and ^{13}C) were recorded at 298 K with a Bruker DPX300 instrument. UV/Vis spectra were measured in quartz cells using a Perkin−Elmer Lambda 9 spectrophotometer. Reagents and analytical-grade materials were obtained from commercial suppliers and used without further purification. All solvents were dried by conventional methods, freshly distilled and degassed. All reactions of air- and water-sensitive materials were performed in oven-dried glassware under dinitrogen. **L^1**,[14,39,40] **L^2** [14] and **L^3** [39,40] were synthesised according to literature procedures.

Table 5. Summary of coordination modes in Pd^{II} and Cu^{II} complexes of **L^1**−**L^4**

	M = Pd	M = Cu
[M(**L^1**)Cl$_2$]	[NS + N]	[2N + S]
[M(**L^2**)]$^{2+}$	[2N + S]	[2N + S]
[M(**L^3**)Cl$_2$]	[2S + N]	[2S + N]
[M(**L^4**)Cl]$^+$	[NS + S]	[NS + S]

Synthesis of L^4: A mixture of **L^3** (0.879 g, 3.99 × 10^{-3} mol) and BH$_3$·THF (1 M THF solution, 25 mL) was refluxed under N$_2$ for 48 h. The mixture was cooled and water (40 mL) was slowly added to destroy excess BH$_3$. The solvent was removed in vacuo and the solid residue was treated with 2 M HCl (50 mL) under reflux for 2 h. The solvent was removed under reduced pressure and the residue dried in vacuo. The white solid obtained was dissolved in water and the solution passed through an ion-exchange resin (Dowex 1X8-200) to give, after removal of the solvent, a colourless oil (0.585 g, 65% yield). EI$^+$ MS: *m*/*z* = 161 [M$^+$ − CH$_2$CH$_2$S], 147 [M$^+$ − CH$_2$ − CH$_2$CH$_2$S]. ^{1}H NMR (CDCl$_3$, 300 MHz): δ = 1.52 (quint, *J* = 7.23 Hz, 2 H, NCH$_2$*C*H$_2$CH$_2$NH$_2$), 2.43−2.81 (m, 12 H, NC*H*$_2$CH$_2$C*H*$_2$NH$_2$, NC*H*$_2$C*H*$_2$S), 3.06 (s, 4 H, SC*H*$_2$C*H*$_2$S) ppm. ^{13}C NMR (CDCl$_3$, 75.47 MHz): δ = 31.2, 32.6 (*C*H$_2$S*C*H$_2$), 34.2 (NCH$_2$*C*H$_2$CH$_2$NH$_2$), 39.8 (NCH$_2$CH$_2$*C*H$_2$NH$_2$), 54.7 (N*C*H$_2$CH$_2$CH$_2$NH$_2$), 57.7 (N*C*H$_2$CH$_2$S) ppm. IR spectrum (film between KCl discs): ṽ = 3277 br. m, 2911 s, 2800 s, 1627 m, 1572 m, 1461 m, 1405 m, 1305 m, 1144 w, 1111 w, 1022 w, 905 w, 811 w cm^{-1}.

[Pd(L^1)Cl$_2$]: A mixture of **L^1** (30 mg, 0.12 mmol) and PdCl$_2$ (21.08 mg, 0.12 mmol) in MeCN (10 mL) was refluxed overnight under N$_2$. The solvent was partially removed under reduced pressure and the resulting orange solution was filtered. Et$_2$O vapour was allowed to diffuse into the filtrate solution giving 37 mg (72% yield) of dark red microcrystals. Diffraction-quality crystals were obtained by recrystallisation from MeCN/Et$_2$O. M.p. 200−204 °C (dec.).C$_{12}$H$_{20}$Cl$_2$N$_4$PdS (429.68): calcd. C 33.54, H 4.69, N 13.04; found C 33.32, H 4.13, N 12.88. ES$^+$ MS: *m*/*z* = 427; calcd. for [^{106}Pd(**L^1**)Cl$_2$]$^+$ [M$^+$] 428. UV/Vis (MeCN): λ$_{max}$ (ε$_{max}$) = 400 nm (606 dm^3 mol^{-1} cm^{-1}). IR (KBr disc): ṽ = 2926 m, 2875 w, 2823 w, 2242 s, 1478 m, 1456 s, 1412 m, 1356 m, 1286 m, 1236 w, 1207 m, 1187 w, 1126 m, 1094 m, 1008 m, 931 m, 940 w, 908 w, 860 w, 760 m, 586 w cm^{-1}.

[Pd(L^3)Cl$_2$]: A mixture of **L^3** (20 mg, 0.092 mmol) and PdCl$_2$ (16.31 mg, 0.092 mmol) in MeCN (10 mL) was refluxed overnight under N$_2$. The resulting solution was filtered through a pad of Celite and the solvent removed under reduced pressure to give a red-brown residue. Recrystallisation by diffusion of Et$_2$O vapour into a DMF solution of the obtained solid gave red-orange crystals (20 mg, 55% yield). M.p. 260−262 °C (dec.). C$_9$H$_{16}$Cl$_2$N$_2$PdS$_2$ (393.66): calcd. C 27.46, H 4.10, N 7.12; found C 26.98 , H 3.88, N 6.90. FAB MS [3-nitrobenzyl alcohol(3-noba)]: *m*/*z* = 359; calcd. for [^{106}PdCl(**L^3**)]$^+$ [M$^+$] 358. UV/Vis (DMF): λ$_{max}$ (ε$_{max}$) = 410 nm (945 dm^3 mol^{-1} cm^{-1}). IR spectrum (KBr disc): ṽ = 2978 m, 2950 m, 2827 m, 2246 m, 1453 m, 1440 m, 1400 s, 1371 m, 1346 s, 1298 m, 1132 m, 1113 m, 1045 w, 1011 m, 959 m, 926 m, 896 w, 808 w, 736 w, 654 w, 580 w cm^{-1}.

[Pd(L^2)][BF$_4$]$_2$: A mixture of **L^2** (50 mg, 0.1920 mmol) and Pd(CH$_3$CN)$_4$(BF$_4$)$_2$ (85.3 mg, 0.1920 mmol) in MeCN/MeOH (1:1, v/v; 10 mL) was stirred at room temperature for 4 h. The solvent was removed in vacuo to give a yellow solid. Diffusion of Et$_2$O vapour into a solution of the complex in MeNO$_2$ afforded pale yellow crystals (77.5 mg, 75% yield). M.p. 214−216 °C. C$_{12}$H$_{28}$B$_2$F$_8$N$_4$PdS (540.46): calcd. C 26.67, H 5.22, N 10.37; found C 27.09, H 5.53, N 10.77. FAB MS (3-noba): *m*/*z* = 453, 366; calcd. for [^{106}Pd(**L^2**)(BF$_4$)]$^+$ [M$^+$] 454 and [^{106}Pd(**L^2**)]$^+$ [M$^+$] 367. UV/Vis (MeCN): λ$_{max}$ (ε$_{max}$) = 300 (459), 396 nm (60 dm^3 mol^{-1} cm^{-1}). IR (KBr disc): ṽ = 3310 s, 3276 s, 3171 m, 3096 m, 2944 m, 1612 s, 1469 m, 1328 m, 1175 s, 1087 s, 992 s, 771 m, 540 m, 420 w cm^{-1}.

[Pd(L^4)Cl]BF$_4$: A mixture of **L^4** (21 mg, 0.0953 mmol) and Pd(CH$_3$CN)$_4$(BF$_4$)$_2$ (42.33 mg, 0.0953 mmol) in MeCN (5 mL) was

stirred at room temperature for 48 h. The solvent was removed in vacuo to give a brown-orange oil. This oil was dissolved in H_2O (4 mL), NaCl (5.57 mg, 0.095 mmol) was added and the resulting mixture was stirred at room temperature for 24 h. The solvent was removed under reduced pressure to give a brown solid, which was taken up in MeCN. The suspension was filtered off, and Et_2O was allowed to diffuse into the filtrate to give dark red crystals (8.2 mg, 19% yield). M.p. 214−220 °C with decomposition. $C_9H_{20}BClF_4N_2PdS_2$ (449.05): calcd. C 24.07, H 4.49, N 6.24; found C 23.85, H 4.24, N 6.10. FAB MS (3-noba): *m*/*z* = 363, 325; calcd. for $[^{106}PdCl(\mathbf{L^4})]^+$ $[M^+]$ 362 and $[^{106}Pd(\mathbf{L^4})]^+$: $[M^+]$ 327. UV/Vis (MeCN): λ_{max} (ε_{max}) = 350 (464), 452 nm (51 dm^3 mol^{-1} cm^{-1}). IR (KBr disc): $\tilde{\nu}$ = 3422 s, 3289 m, 3189 m, 3133 m, 3089 m, 2955 w, 1589 m, 1444 m, 1400 m, 1289 m, 1200 w, 1072 s, 917 w, 805 w, 733 w, 533 m, 522m cm^{-1}.

[Cu(L^1)Cl$_2$]: A mixture of **L^1** (46.9 mg, 0.18 mmol) and $CuCl_2{\cdot}2H_2O$ (30.12 mg, 0.18 mmol) was refluxed in MeCN (15 mL) for 1 h under N_2. The solvent of the resulting green solution was allowed to evaporate and after 2 d green crystals of the complex were formed (46.4 mg, 65.5% yield). M.p. 128−130 °C. $C_{12}H_{20}Cl_2CuN_4S$ (386.82): calcd. C 37.26, H 5.21, N 14.48; found C 37.50, H 5.29, N 14.46. FAB MS (3-noba): *m*/*z* = 350, 315; calcd. for $[^{63}Cu(\mathbf{L^1})Cl]^+$ $[M^+]$ 351 and $[^{63}Cu(\mathbf{L^1})]^+$ $[M^+]$ 316. UV/Vis (MeCN): λ_{max} (ε_{max}) = 250 (1670), 335 (4912), 419 (1093), 716 nm (39 dm^3 mol^{-1} cm^{-1}). IR (KBr disc): 2940 w, 2905 w, 2880 w, 2840 w, 2220 m, 1480 m, 1440 s, 1410 s, 1400 s, 1350 s, 1300 s, 1270 m, 1230 w, 1210 w, 1120 w, 1080 s, 1060 m, 1045 m, 1030 m, 1010 w, 1000 w, 985 s, 970 m, 960 w, 940 m, 880 w, 730 m, 710 w, 525 w, 475 w, 380 w, 365w cm^{-1}.

[Cu(L^3)Cl$_2$]: A solution of $CuCl_2{\cdot}2H_2O$ (48.4 mg, 0.28 mmol) in MeCN (4 mL) was added to a solution of **L^3** (61.5 mg, 0.28 mmol) in MeCN (4 mL). A green solid was immediately formed and the mixture was stirred at room temperature for 2 h. The solid was filtered off, washed with Et_2O and dried under reduced pressure (67.4 mg, 68% yield). Single crystals suitable for X-ray diffraction studies were grown by diffusion of Et_2O vapour into a DMF solution of the green solid. M.p. 158−160 °C with decomposition. $C_9H_{16}Cl_2CuN_2S_2$ (350.80): calcd. C 30.81, H 4.60, N 7.98; found C 30.84, H 4.73, N 8.26. FAB MS (3-noba): *m*/*z* = 314, 279; calcd. for $[^{63}Cu(\mathbf{L^3})Cl]^+$ $[M^+]$ 315 and $[^{63}Cu(\mathbf{L^3})]^+$ $[M^+]$ 280. UV/Vis (MeCN): λ_{max} (ε_{max}) = 251 (530), 281 (327), 347 (1090), 428 (348), 762 nm (34 dm^3 mol^{-1} cm^{-1}). IR (KBr disc): $\tilde{\nu}$ = 2978 w, 2929 m, 2243 s, 1472 s, 1444 s, 1409 m, 1366 m, 1344 m, 1305 m, 1119 m, 1097 m, 1037 m, 961 m, 906 m, 834 w, 819 w, 756 w, 734 w, 671 w, 634 w, 595 w, 527 w, 445w cm^{-1}.

[Cu(L^2)][NO$_3$]$_2$: A solution of $Cu(NO_3)_2{\cdot}3H_2O$ (49.5 mg, 0.21 mmol) in MeCN (2 mL) was added to a solution of **L^2** (53.3 mg, 0.21 mmol) in MeCN/EtOH (1:1, v/v; 10 mL). A blue colour immediately developed and the mixture was stirred at room temperature for 1 h. The solvent was removed in vacuo and the residue repeatedly crystallised from EtOH/Et_2O to give blue block-like crystals (48.3 mg, 55% yield). M.p. 190−192 °C. $C_{12}H_{28}CuN_6O_6S$ (448.00): calcd. C 32.17, H 6.30, N 18.76; found C 31.95, H 6.10, N 18.45. FAB MS (3-noba): *m*/*z* = 385, 323; calcd. for $[^{63}Cu(\mathbf{L^2})(NO_3)]^+$ $[M^+]$ 386 and $[^{63}Cu(\mathbf{L^2})]^+$ $[M^+]$ 324. UV/Vis (MeOH): λ_{max} (ε_{max}) = 281 (3013), 556 nm (102 dm^3 mol^{-1} cm^{-1}). IR (KBr disc): $\tilde{\nu}$ = 3378 s, 3200 s, 3100 s, 2922 m, 2855 m, 1611 w, 1372 s, 1205 w, 1161 w, 1083 m, 1069 m, 1041 m, 1020 m, 923 w, 864 w, 826 w, 729 w, 688 w, 542w cm^{-1}.

[Cu(L^4)Cl]PF$_6$: A solution of $CuCl_2{\cdot}2H_2O$ (23.18 mg, 0.14 mmol) in MeOH (4 mL) was added to a solution of **L^4** (30 mg, 0.14 mmol) in MeOH (4 mL); an intense blue colour developed immediately and the mixture was stirred at room temperature for 2 h. The solvent was partially removed under reduced pressure and a large excess of NH_4PF_6 in MeOH solution was added. The solvent was completely removed and the residue washed with water to give a blue solid that was dried under reduced pressure (22.3 mg, 35% yield). Single crystals suitable for X-ray diffraction studies were obtained by recrystallisation from MeCN/Et_2O. M.p. 168 °C. $C_9H_{20}ClCuF_6N_2PS_2$ (464.35): calcd. C 23.28, H 4.34, N 6.03; found C 23.15, H 4.25, N 5.88. FAB MS (3-noba): *m*/*z* = 318, 283; calcd. for $[^{63}Cu(\mathbf{L^4})Cl]^+$ $[M^+]$ 319 and $[^{63}Cu(\mathbf{L^4})]^+$ $[M^+]$ 284. UV/Vis (MeCN): λ_{max} (ε_{max}) = 240 (1671), 312 (3996), 624 nm (126 dm^3 mol^{-1} cm^{-1}). IR (KBr disc): $\tilde{\nu}$ = 3291 s, 3214 s, 3140 w, 2959 w,

Crystallography: A summary of the crystal data and refinement details for the compounds is given in Table 6. The crystals were cooled using an Oxford Cryosystems open-flow dinitrogen cryostat.[41] For all the compounds diffraction data were collected with a Stoë Stadi-4 four-circle diffractometer using ω-θ scans. Data were corrected for Lorentz and polarisation effects and absorption corrections were applied using numerical or ψ-scan methods. For [Pd(**L^1**)Cl$_2$], and [Pd(**L^4**)Cl]BF$_4$ and [Cu(**L^2**)][NO$_3$]$_2$ a Patterson synthesis using *SHELXS-97*[42] provided a satisfactory set of starting parameters for the heavier atoms. The other structures were solved by direct methods using either *SIR92*[43] or *SHELXS*[42] and developed through subsequent difference Fourier synthesis.[44] All non-H atoms were refined anisotropically and H atoms were located from difference Fourier synthesis (solvent methyl H atoms) or introduced at calculated positions and thereafter incorporated into a riding model with $U_{iso}(H) = xU_{eq}(C)$ (x = 1.2 for CH_2, 1.5 for CH_3). For [Cu(**L^2**)][NO$_3$]$_2$ the NO_3^- anions were restrained to planarity and to have equal N−O bond lengths. In the case of [Cu(**L^4**)Cl]PF$_6$ the PF_6^- ion was found to be disordered during refinement. The disorder was modelled by a partial occupancy model over two sites for each of the four F atoms in the equatorial plane with occupancy factors of 0.59 and 0.41. The two F atoms in the axial positions could be treated as ordered. All the P−F bond lengths were restrained to have the same value during refinement. CCDC-181045 to -181052 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Intercalation of Poly(Ethylene Oxide) Derivatives into Layered Double Hydroxides

Fabrice Leroux,[a] Pilar Aranda,*[b] Jean-Pierre Besse,[a] and Eduardo Ruiz-Hitzky[b]

Keywords: Layered compounds / Intercalations / Nanostructures

Mono- and bi-functional guest molecules, poly(ethylene glycol)-*n*-alkyl-3-sulfopropyl diether (PEG-AS) and poly(ethylene glycol)dicarboxylic acid (PEG-DC), containing hydrophilic polyoxyethylene (PEO) chains of different ethylene oxide units (EOUs) are incorporated between the layers of $Cu_2Cr(OH)_6Cl{\cdot}nH_2O$ hydrotalcite-type materials. The intercalation compounds are characterized by chemical analysis, adsorption measurements, XRD, SEM, FTIR and ^{13}C CP-MAS spectroscopy. It is found that the polyoxyethylene chain of PEG-DC distorts its helical symmetry when it is intercalated in the LDH galleries. The basal spacing of PEG-AS nanocomposites is independent of the number, *n*, of EOUs in the polymer chain. In addition to changes in the IR bands, ^{13}C CP-MAS spectra are modified with new resonance peaks at more deshielded values. These facts suggest a strong interaction of polyether chains with the LDH inner-surface, with the hydrophobic alkyl tail dangling into the interlamellar space. It is shown that the terminal functionalities dictate the arrangement of the PEO chains.

Introduction

The preparation of hybrid organic-inorganic nanocomposites has generated a lot of interest.[1] Layered materials are well-known to be highly suitable as host matrices for the incorporation of a large variety of organic species, readily accommodating the guest molecules via topotactic reactions. The development of tunable systems synergically enhanced by their two components is topical, the main interest being to obtain desirable properties that are unattainable from only one of the two components. This notion has also been extended to reinforced composites in which the inorganic part is usually finely dispersed or exfoliated within a polymer that supplies the mechanical strength.[2]

Due to their applications in heterogeneous catalysis, a lot of interest has been devoted to layered double hydroxides (LDH), also known as hydrotalcite-like solids, as host materials.[3] $Mg(OH)_2$ brucite material has been used, in which the M^{2+} cations are partially substituted by M^{3+} cations. The substitution creates a positive net charge counterbalanced by the presence of anions located in the interlamellar region. The exchange capacity of LDH materials, defined by the trivalent to divalent cation ratio, is usually two to three times greater than that of cations in smectite clay minerals. This may be considered as a drawback for incorporating a large organic guest, when considering the packing between the layers. Nevertheless, large molecules with variable functionalities lying parallel to the LDH plan have been incorporated, such as DNA[4] or polymers.[5] It was found that the match between the charge density and the monomeric repetition of the LDH layer, viz. the projected area of the anionic function, is of great importance in obtaining complete exchange with large molecules and the ordered nanocomposites of the stiff polymer.[5d]

With regard to the nanocomposites, a lot of attention has been paid to the intercalation of poly(ethylene oxide) (PEO) into different lamellar inorganic frameworks, such as smectites,[6] V_2O_5,[7] MoO_3,[8] and other host lattices,[9] giving hybrid materials with improved properties such as ion-conductivity or mechanical strength. PEO is known to present a flexible helical arrangement[10] that can be distorted to obtain zigzag conformations, depending on its environment and in particular on the presence of alkali-metals or other complexing ions. Besides this application, we were also interested to know how the PEO chain could be accommodated in the LDH gallery. As intercalation in LDH hosts is limited to anionic species, we focussed our attention on two charged polymers (Table 1), one an acid monofunctional, poly(ethylene glycol)alkenylsulfonic acid (PEG-AS) and the other a bifunctional, poly(ethylene glycol)dicarboxylic acid (PEG-DC), presenting an average of 11 or 7 and 12 (OCH_2CH_2) units (EOUs), respectively.

The morphology and flexibility of layered structures are important factors for topotactic reactions. For this reason, the $Cu_2Cr(OH)_6Cl{\cdot}nH_2O$ (noted as [CuCr] host structure) LDH sample, which is presented as corrugated sheets,[11] is

Table 1. Polyethylene oxide compounds used in this work

Polymer	Formula	Characteristics
PEG-DC	$HO_2C(CH_2OCH_2)_nCO_2H$	n ≈ 12; Mw average 600 Dalton
PEG-AS 11	$R(OCH_2CH_2)_nO(CH_2)_3SO_3K$	R = $CH_3(CH_2)_y$, y = 12-14; $n \approx 11$
PEG-AS 7	$R(OCH_2CH_2)_nO(CH_2)_3SO_3K$	R = $CH_3(CH_2)_y$, y = 12-14; $n \approx 7$

taken as the host material. In addition, its acid character will prevent contamination by carbonate anion uptake, thus avoiding competition with polymer incorporation.

In this work we have tried several synthetic procedures to incorporate the two PEO-based polymers indicated above for the preparation of new polymer/LDH nanocomposites. The study of the adsorption and intercalation processes of both polymers between the sheets of the [CuCr] host structure and characterization of the resulting nanocomposites by a combination of technique, such as X-ray diffraction, FTIR and ^{13}C solid state NMR spectroscopy, employed to postulate models for the polymer arrangements. Some results concerning another LDH host solid, ($Zn_2Cr(OH)_6Cl{\cdot}nH_2O$) noted as [ZnCr], will also be discussed.

Results

Polymer Incorporation

A powder X-ray diffraction pattern of [CuCr], typical of hydrotalcite-type material, was refined using an $R\bar{3}m$ space group in rhombohedral symmetry (Figure 1a). The cell parameters **a** and **c** (equal to three times the interlamellar distance) are equal to 0.31 nm and 2.31 nm, respectively, in agreement with previous results.[11]

The uptake of PEG-DC between the LDH layers is confirmed by an expansion of the d-spacing. The intercalation of PEG-DC performed in an aqueous medium for four hours induces an increase of the basal spacing from 0.77 to 3.03 nm (Figure 1b). Longer reaction times (up to three days) give rise to a lower d-spacing of 2.60 nm (Figure 1c). To explain this result it is necessary to suppose that the sample is altered by the progressive action of the solution containing PEG-DC or invoking a reorganization of the polymer chain inside the interlayer space of the LDH. This could be due to a reorganization of the polymer in the LDH galleries. An XRD pattern of the sample synthesized in butanol (BuOH) solution is very similar to the one prepared by direct exchange in an aqueous medium, although a d-spacing of 2.95 nm is obtained (Figure 1d). It is noteworthy that other alternatives such as the guest displacement or templating methods, appear to be unsuccessful in completing the exchange, giving rise to a mixture of an intercalated phase with a d-spacing of about 2.6 nm and to the pristine host material.

In comparison with the pristine host material, the broadness of the diffraction peaks is affected by the polymer incorporation. This broadening indicates the presence of either some turbostatic effects or of a large decrease in the stacking sequence, as usually observed after topotactic reactions. This is even more pronounced after a longer exchange reaction time (Figure 1c). The incorporation of PEG-AS 11, by an exchange reaction, is also visible from the variation of the 2D-periodicity from 0.77 to 3.79 nm (Figure 2a). Since the diffusion of PEG-AS into the LDH gallery may be thermodynamically and/or sterically hindered, the templating method was carried out. During the co-precipitation, the polymer is entrapped between LDH sheets.

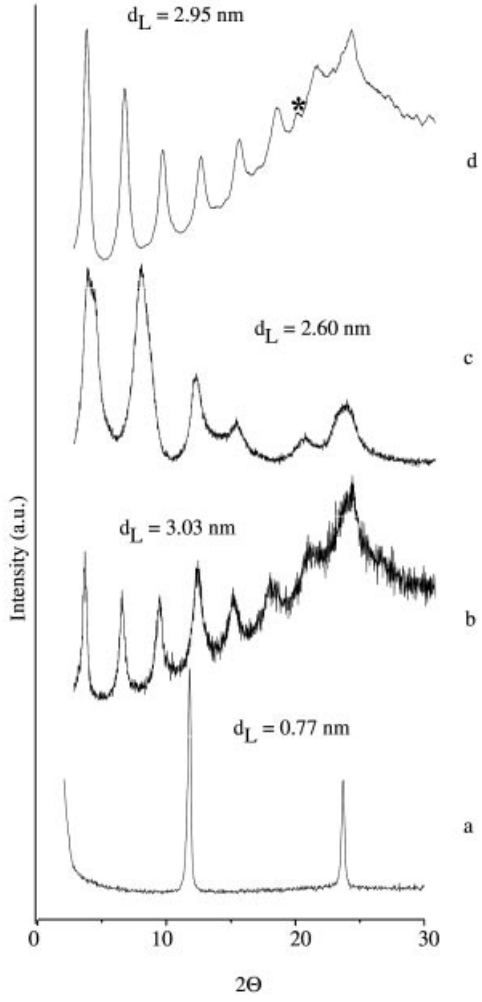

Figure 1. XRD patterns of: a) [CuCr] LDH pristine material, and PEG-DC/LDH nanocomposites obtained after b) 4 hours and c) 3 days of exchange reaction in water, and d) 4 hours of exchange reaction in butanol (* indicates a non-harmonic peak observed at 19.3°, i.e. 0.46 nm)

This is associated with a greater expansion of the d-spacing of up to 4.30 nm (Figure 2b). In Figure 2, the set of the first three harmonics is of different intensity. This is related to the arrangement of the organic molecule within the interlayer space. The polymer organization is then sensitive to the synthetic pathway. Additionally, a broad scattering hump is observed between 20−30° in 2θ, suggesting that a part of the polymer remains associated with the surface of the material. This occurs because the polymer is used in excess and can be adsorbed on the surface during the co-precipitation; the use of less polymer during the formation of $Cu_2Cr(OH)_6Cl{\cdot}nH_2O$ has not been explored.

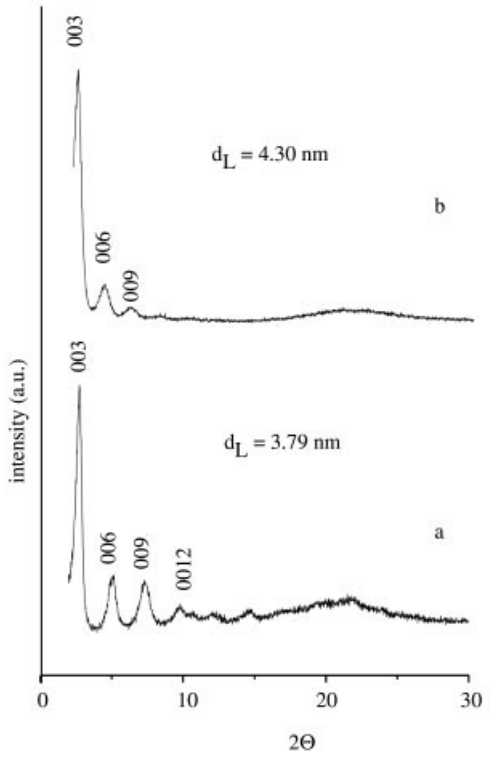

Figure 2. XRD patterns of PEG-AS (11 EOUs)/[CuCr] nanocomposites obtained via: a) exchange reaction in water, and b) co-precipitation

Our findings may be compared with the incorporation of $C_{12}H_{25}(OCH_2CH_2)_mSO_4^-$ surfactant molecules (m = 1, 2, 4) between LDH materials as reported by Kopka et al.[12] The authors noticed that the degree of exchange decreased with the increase of EOUs (90 and 71% of exchange for m = 1 and 4, respectively) reaching a d-spacing of 3.31 nm for m = 4. In our case, this implies a highly constrained environment of PEG-AS 11 between LDH sheets because the d-spacing changes from 3.60 to 3.79 nm for the polymer with 7 and 11 EOUs, respectively.

It is noteworthy that for the exchange reaction, and after repeated centrifugations, the solution still remains a pale green color. This shows the presence of finely dispersed particles. Such behavior must be related to the colloidal properties of PEG-AS that induces the formation of micelles, thus giving rise to the disassembly of the LDH microcrystals. This approach could be an alternative to other exfoliation processes.[13]

The carbon content of the nanocomposites is lower than what was theoretically expected from the complete exchange reaction. The polymer content per formula [$Cu_2Cr(OH)_6$] is found to be in the range of 0.24−0.76 for PEG-AS and 0.53−0.84 for PEG-DC (Table 2). These differences depend strongly on the synthetic approach and may be explained by the limited diffusion of the polymer between the LDH sheets, as reported for the intercalation of cumbersome molecules.[14] The presence of chlorine anions was detected in the material, showing that the host structure encounters a co-intercalation phenomenon. A peculiar arrangement of the EOU units may also induce strong effects (see below).

Polymer Adsorption Measurements

Adsorption isotherms (Figure 3) exhibit features characteristic of the H(2) Langmuir type according to the classification of Giles et al.;[15] this usually occurs when the solute consists of large units such as ionic micelles or polymeric molecules. It shows that both polymers possess a strong affinity for the LDH surface, and are completely adsorbed at a low concentration range. The Langmuir-type process is modeled according to Equation (1),[16] where C_e is the concentration of adsorbate at equilibrium (mmol/L), q_e the amount adsorbed at equilibrium (mmol/g), X_m (mmol/g) the maximum amount of adsorbate that can be adsorbed in a monolayer, and K_e the Langmuir constant related to the energy of adsorption.

$$C_e/q_e = 1/X_mK_e + C_e/X_m \quad (1)$$

The q_e versus C_e curve was fitted according to Equation (1) (inset Figure 3, a and b). The fitting and the correlation parameters for both polymers are indicated in the figure caption. X_m and K_e are equal to 0.48 and 0.37, respectively, for the adsorption process of PEG-DC, and 1.18 and 5.76, respectively, for the PEG-AS with 11 EOUs. The energy of adsorption is much higher for PEG-AS than it is for PEG-DC. This agrees with the stronger acid character of sulfonic versus carboxylic species.

It is interesting to note that the adsorption mechanism could be different for each polymer. In fact, the analysis of the shape of the plateau and the maximum adsorbed amount is quite different for each one. In both cases, the polymer must be strongly reorganized in the interlayer space, as shown by the variations in the adsorbed amount of polymer and d-spacing values.

For PEG-DC the maximum of the adsorbed amount is lower than 0.50 mmol per gram, which corresponds to 0.16 mol per formula. There is no complete ion-exchange even for the most concentrated equilibrium solutions. There is a progressive intercalation as the amount of polymer increases, and the basal spacing of the organic intercalated phase is modified. The maximum adsorption has not been reached and so even for the 0.46 mmol/g material there are

Table 2. Characteristics of PEG-DC/ and PEG-AS/ nanocomposites prepared in this work

Nanocomposites	Method of synthesis	Δd_L (nm)	%C in the solid	Tentative formula[a]
PEG-DC/CuCr	ion-exchange in H_2O	2.55	17.3	$Cu_2Cr(OH)_6 \cdot PEG\text{-}DC_{0.32}Cl_{0.36} \cdot nH_2O$
	ion-exchange in BuOH	2.47	29.5	$Cu_2Cr(OH)_6$ $PEG\text{-}DC_{0.76} \cdot nH_2O$[c]
	co-precipitation	2.12[b]	14.6	$Cu_2Cr(OH)_6$ $PEG\text{-}DC_{0.24}Cl_{0.52} \cdot nH_2O$
PEG-AS/CuCr	ion-exchange of PEG-AS 11 EOUs in H_2O	3.31	30.1	$Cu_2Cr(OH)_6$ $PEG\text{-}AS_{0.53}Cl_{0.47} \cdot nH_2O$
	ion-exchange of PEG-AS 7 EOUs in H_2O	3.12	33.5	$Cu_2Cr(OH)_6$ $PEG\text{-}AS_{0.70}Cl_{0.30} \cdot nH_2O$
	co-precipitation in presence of PEG-AS 11 EOUs	3.82	36.2	$Cu_2Cr(OH)_6$ $PEG\text{-}AS_{0.84}Cl_{0.16} \cdot nH_2O$
PEG-AS/ZnCr	ion-exchange of PEG-AS 11 EOUs in H_2O	3.22	33.1	$Zn_2Cr(OH)_6$ $PEG\text{-}AS_{0.66}Cl_{0.34} \cdot nH_2O$
	ion-exchange of PEG-AS 7 EOUs in H_2O	3.07	32.3	$Zn_2Cr(OH)_6$ $PEG\text{-}AS_{0.65}Cl_{0.35} \cdot nH_2O$

[a] Tentative formula calculated assuming that the anionic polymers are intercalated by replacing Cl^- ions of the pristine $Cu_2Cr(OH)_6Cl \cdot nH_2O$ or $Zn_2Cr(OH)_6Cl \cdot nH_2O$ LDH matrices. [b] Also a phase of pristine LDH is observed. [c] Incorporated amount of PEG-DC exceeds the ion-exchange capacity.

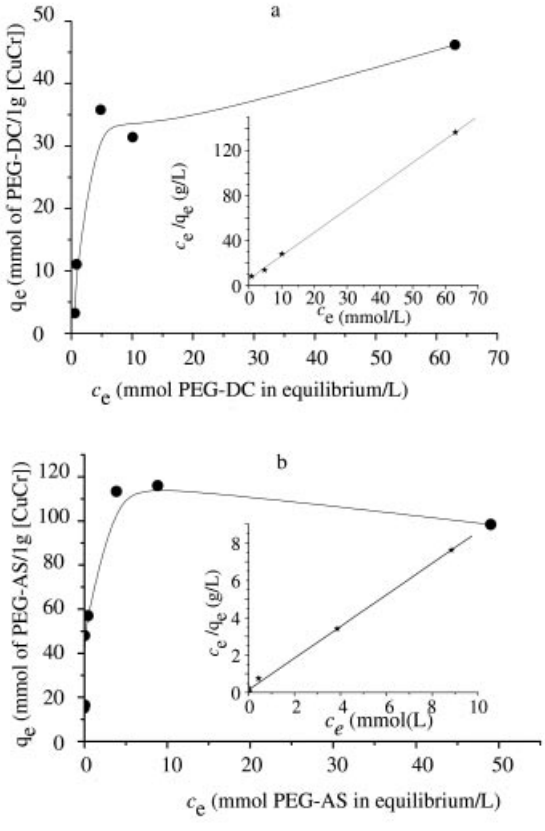

Figure 3. Adsorption isotherm from water solutions of: a) PEG-DC and b) PEG-AS containing 11 EOUs on [CuCr]; the fit is displayed in the inset [according to Equation (1)]: a) $C_e/q_e = 5.55 + 0.0033292\ C_e$ ($R = 0.99968$), b) $C_e/q_e = 0.1468 + 0.00109\ C_e$ ($R = 0.9989$)

still peaks associated with the pristine solid [CuCr]. An incorporation of PEG-DC as high as 0.76 mol per [CuCr] formula unit is reached using BuOH as the solvent (Table 2). Such high polymer content may be explained by the preparation method. The use of BuOH under reflux conditions is known to break up the LDH structure, thus creating an increase in the interface. A part of the polymer must coat the surface of the crystallites.

For the PEG-AS (11 EOUs) there is a maximum in the adsorption close to 120 mmol/g (0.40 mmol per formula unit) for equilibrium concentrations below 20 mmol/L. At higher C_e values, a slight decrease is observed for the adsorbed amount of about 0.35 mol per formula unit. The XRD patterns still exhibit the diffraction peak of pristine [CuCr] LDH material. The formation of an intercalated phase progresses along with an increase in the amount of polymer to the point where the LDH structure starts to dissolve, as illustrated by the large scatter between 20 and 30° in 2θ. A green color indicates that a disassembly of the 2D-host matrix occurs, probably entangled by the polymer. The monofunctional polymer may play the role of a spacer acting at the edge of the crystallites like dodecylsulfate molecules for the LDH delamination.[13a][13b]

FTIR Spectroscopy

IR spectroscopy of the resulting PEO/LDH nanocomposites affords significant information on how the polymer is associated into the 2D host solid. The lattice vibration bands arising from M−O and O−M−O (M= Cu, Cr) bonds are observed in the 400−800 cm^{-1} region and there are no important differences between LDH and the nanocomposites (Figure 4 and 5). In the 1300−1350 cm^{-1} region several vibration bands appear that are related to the wagging vibration of the $-CH_2-O-$ groups, which give crucial information about characteristics of the polyoxyethylene skeleton and its deformation. This is exemplified by the vibration band at 1346 cm^{-1} for PEG-DC (Figure 4), characteristic of $-CH_2-O-$ groups of polyether chains in a helical conformation. The presence of a weak band at 1325

cm^{-1} in the non-intercalated pristine polymer suggests a very slight distortion of the helix. However, for the PEG-DC/LDH nanocomposites the band at higher wavenumber can be shifted towards 1330 cm^{-1} and a new and intense band develops at 1314 cm^{-1}. These facts indicate that the polyoxyethylene chain presents EOUs in a *trans* conformation[10] and therefore the helix is distorted. The degree of distortion depends on the nature of the host-guest matrix interactions. Some of the nanocomposites show planar zigzag conformations of the polymer as is observed for other poly(ethylene oxide) intercalation compounds.[6]

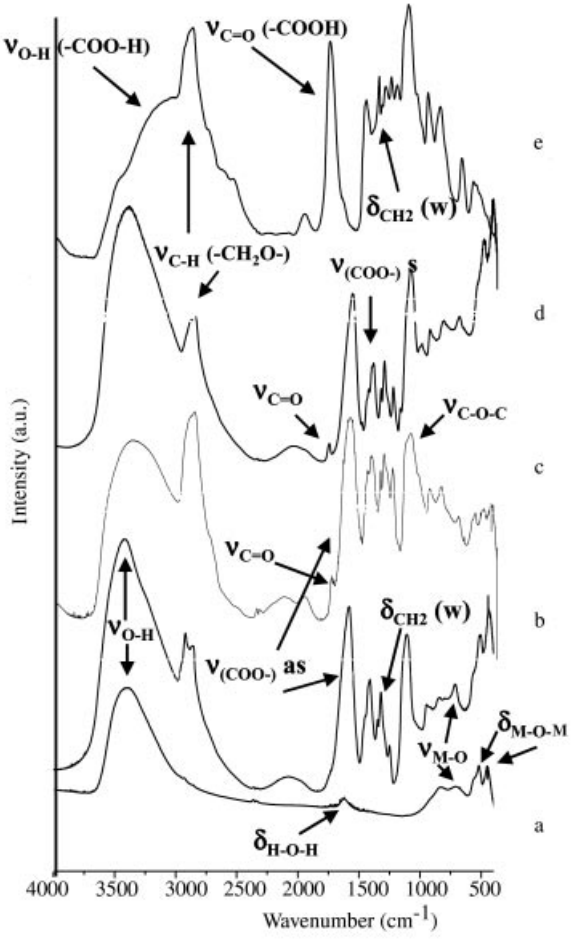

Figure 4. FTIR spectra of: (a) LDH pristine material, and PEG-DC/LDH nanocomposites obtained via b) ion-exchange in water, c) ion-exchange in butanol, d) co-precipitation, and e) pure PEG-DC

The assignment of the different vibration bands is displayed in Table 3. In the case of PEG-DC based nanocomposites, the bands associated with the $\nu_{C=O}$ stretch of the carboxylic groups are split into two at around 1578 cm^{-1} and 1407 cm^{-1}, corresponding to the antisymmetric and symmetric $\nu_{C=O}$ mode of the COO^- groups, respectively, as the acid is intercalated in the anionic form. In spite of this, the spectra of the nanocomposites, prepared by co-precipitation and BuOH under reflux, still show weak bands at around 1770 cm^{-1} and 1240 cm^{-1}, indicating the presence of free acid groups in the polymer associated with the solid.

The $\nu_{O=S=O}$ vibration bands of the SO_3^- group are observed at around the same wavenumber, 1190 and 1040 cm^{-1} for the antisymmetric and symmetric contribution, respectively, for pure PEG-AS and PEG-AS/LDH nanocomposites (Figure 5). The inversion in their relative intensity suggests that the SO_3^- group is in a more symmetric environment for the nanocomposites; this is probably a consequence of the interaction with the hydroxide sheet. For PEG-AS (11 EOUs)/LDH nanocomposites prepared by different synthetic approaches, either in [CuCr] or [ZnCr] LDHs, the striking difference when compared with the pristine polymer or even with the nanocomposites based on PEG-AS of 7 EOUs, is the appearance of two new bands around 1720 and 1570 cm^{-1} (Figure 5). The assignment of these bands is still unclear as there are no appreciable alterations, either in the organic backbone vibration bands or in those corresponding to the inorganic host (Figure 4). The vibration band at around 1720 cm^{-1} is indicative of a carbonyl group, suggesting that the polymer chain can be partially altered by heterolytic oxidation reactions.

^{13}C Solid-State NMR Spectroscopic Study

In order to get more information on the guest/host interaction in the PEG-AS/[CuCr] nanocomposite, ^{13}C solid-state CP MAS spectroscopy experiments were performed (Figure 6). The spectrum of PEG-AS of 11 EOUs exhibits several resonance peaks, with chemical shifts attributed as follows: δ = 72.2 ppm to carbon nuclei in the (-OCH_2CH_2-) ethylene oxide chain, δ = 48.4 ppm for C attached to an SO_3^- group, and several peaks lumped together (shoulder Figure 6a) from δ = 30.2 to δ = 14.4 ppm associated with the different methylene groups, and the terminal CH_3, respectively. The latter contribution is also observed for the LDH derivatives (Figure 6b and c), only the response is broader. For the C linked to the S, an up-field shift is observed up to δ = 42.5 ppm; this shielding may correspond to an electrostatic attraction between the molecule and the sheets of [CuCr] as observed in other systems.[17] The same effect, but much less pronounced, is observed for carbon nuclei in the ethylene chain with a shielding from δ = 72.2 to 71.1 ppm. However, it is interesting to note that the relative carbon nuclei population of the polymer is very different from that of the organic-inorganic phase. Even if the CP experiment does not strictly supply quantitative information, it is obvious that the population relative to carbon in the polyoxyethylene chain has decreased.

Surprisingly, some new peaks at δ = 127.0, 121.9 and 149.8 ppm appear for the nanocomposite that are absent for PEG-AS. These are not spinning side-bands since they are present in the spectra recorded at the two different fields. Such chemical shift values are typical of aromatic or highly deshielded carbons such as carbonyl carbons. It is noteworthy that these down-field contributions are not observed for PEG-DC hybrid materials.

Table 3. IR vibration bands (cm^{-1}) and their assignment for the PEG-DC and PEG-AS polymers and some of their LDH nanocomposites derivatives

PEG-DC	PEG-DC/CuCr ion-exchange	PEG-DC/CuCr co-precipitation	PEG-AS (11 EOUs)	PEG-AS (11 EOUs)/CuCr ion-exchange	PEG-AS (11 EOUs)/CuCr co-precipitation	PEG-AS (11 EOUs)/ZnCr ion-exchange	PEG-AS (7 EOUs)/CuCr ion-exchange	Assignment [a]

[a] Asym: antisymmetric; sym: symmetric; w: wagging; t: twisting; r: rocking. [b] Very broad and strong band centred around 3200 cm^{-1}. [c] Tentative assignation of the bands to vibration modes of C=O functions related to oxidation products of the oxyethylene polymer chain. [d] When two bands are observed the relative intensity of both of them is signalled (m = medium; w = weak).

SEM Observations

SEM pictures of the pristine material and derivative phases are displayed in Figure 7. The starting chloride-exchanged [CuCr] material gives rise to a platelet-like shape, this morphology being characteristic of the applied method of synthesis.[5b] This is found to be different for the PEG-DC nanocomposites, which show a leaf aspect.

For PEG-AS/LDH nanocomposites with either 7 or 11 EOUs, the crystallite surface presents a crumpled shape. The part of the polymer coating the material (see above) must be the origin of the irregularities. Moreover, the polymer chains must be linked to close chunks, giving rise to a large ill-defined piece. In the inset of Figure 7 (see f), the 2D-character is evidenced for these hybrid organic-inorganic phases.

Discussion

To shed some light on the present results, different hypotheses must be considered in order to postulate a model for the intercalated materials. The conformation of the PEO chain is an important factor for the polymer geometry between the layers. PEO presents a repetition of ($-OCH_2CH_2-$) units adopting a helical structure in its crystalline state.[10] Instead of taking the EOU linear size as three methylene groups in a zigzag conformation,[12] a flexible polyoxyethylene chain adopting a helix with either a $9_{1/2}$ or $7_{1/2}$ symmetry must be considered for long PEO chains.[10] The first gives rise to a dimension of 1.95 nm for 9 EOUs, and the second 1.90 nm for 7 EOUs.

By subtracting the LDH layer width of 0.48 nm from the d-spacing, we access the space available to accommodate the polymer between the sheets. For the PEG-DC nanocomposite prepared by ion-exchange, this gives a space of around 2.60 nm (Table 2), which is in agreement with a polyoxyethylene chain in a $9_{1/2}$ helical symmetry (expected value of 2.72 nm considering 12 EOUs instead of 9 in the helical conformation with the size of the two carboxylic groups being 0.12 nm[14]). After a longer reaction time, the gallery size is shortened to 2.17 nm (Figure 1, c), showing that the polyoxyethylene chains are strongly confined and the helix is distorted by chain-chain interactions and/or with OH from the LDH layer or H_2O molecules. This interpretation is supported by the high intensity of the δ_{CH2} (w) vibration band at 1314 cm^{-1} (Table 3).

For the PEG-DC/[CuCr] nanocomposite prepared by an exchange reaction in BuOH, eight well-defined harmonics are observed suggesting that the stacking is good. An additional peak at 19.3° (d = 0.46 nm) is also observed. In the absence of other possible explanations, this was related to a superlattice ($\sqrt{3}$ times the perpendicular distance between [100] planes).[18] Since this material presents an excess of polymer over the ion-exchange capacity determined from the chemical analysis (Table 2), a portion of the organics should be intercalated either in their acid form and/or adsorbed on the surface through interaction with OH groups. The first interpretation is supported by the presence of a

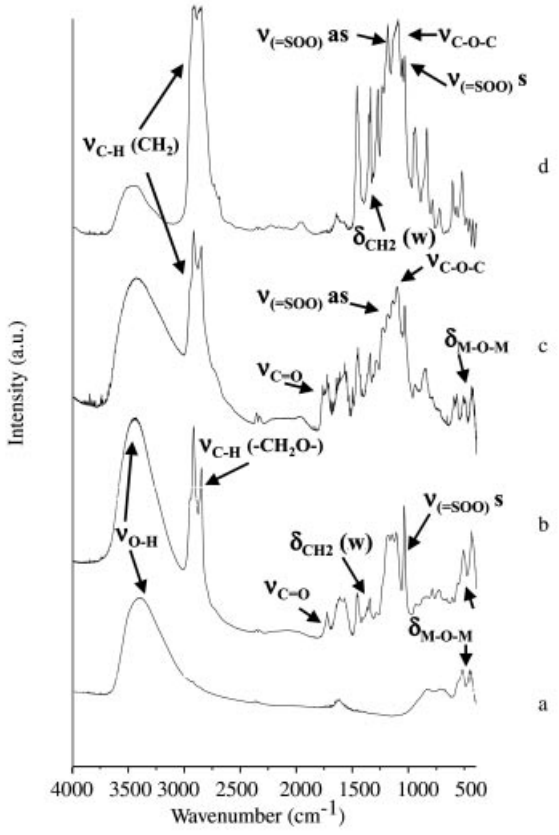

Figure 5. FTIR spectra of: (a) [CuCr] LDH pristine material, and PEG-AS/LDH nanocomposites obtained via b) ion-exchange in water, c) co-precipitation, and d) potassium salt of PEG-AS of 11 EOUs

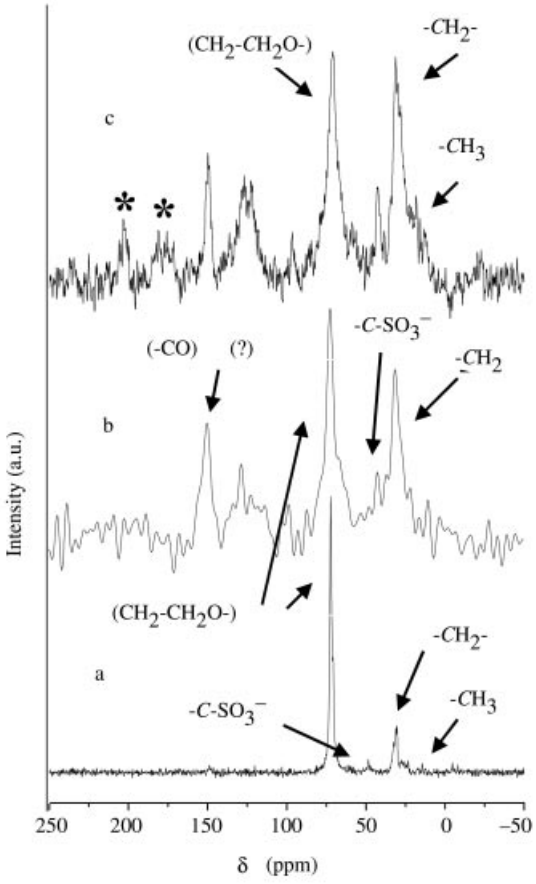

Figure 6. ^{13}C NMR spectra of: (a) the potassium salt of PEG-AS of 11 EOUs, and the PEG-AS/ [CuCr] nanocomposites recorded at (b) 7.04 T (300 MHz), and c) 9.39 T (400 MHz); spinning sidebands are indicated with an asterisk

band at 1742 cm^{-1} (Figure 4, c) assignable to the $\nu_{C=O}$ vibration mode of a free carboxylic group.

Bearing all of the above considerations in mind, we propose a model in which the molecule is intercalated with each of its functional groups interacting with one of the hydroxide surfaces in the interlayer space and with the polyoxyethylene chain being more or less twisted (Figure 8a). This model takes into account the possibility of obtaining nanocomposites with different arrangements of PEG-DC in which the amount of intercalated polymer and its interaction with OH groups of the layer and with H_2O molecules induce distortions in the polyether chain. The vibration bands and switching in intensity of the δ_{CH2} wagging vibration bands for $(-CH_2O-CH_2-)$ groups are affected (Table 2). As for PEO/montmorillonite nanocomposites,[6] the nature of the interlayer space may affect the distortion of the polyoxyethylene chains.

The same approach was taken to unravel the arrangement, between the LDH sheets, of the PEG-AS with 11 EOUs. Using similar calculations for the organic moieties, the size of the polymeric molecule is 4.73 and 5.39 nm, depending on the $9_{1/2}$ or $7_{1/2}$ helical symmetry, respectively. This calculation was made considering the following dimensions from Kopka and co-workers:[12] 0.127 nm per CH_2 group, and 0.30 nm for the $-CH_3$ and 0.18 nm for the $-CH_2SO_3^-$ groups. This appears to be much larger than that of the available space of 3.31 to 3.82 nm, depending on the synthesis (Table 2) of the [CuCr] LDH sheets. It underlines a different arrangement between the two guest molecules. At this point, two hypotheses may be considered: i) the PEG chain is strongly confined, but presents no significant interaction with the LDH layers. In this case, the molecule adopts an angle to the LDH surface, and ii) the PEG chains are close to the LDH layers, and may interact through their hydroxy groups.

The FTIR spectra of PEG-AS/LDH nanocomposites show only a band at around 1345 cm^{-1}, which is assigned to the δ_{CH2} (w) vibration mode of the EOUs in the helical conformation; this is different from that of the PEG-DC/LDH derivatives. However, from ^{13}C CP MAS and FTIR spectroscopy, highly deshielded carbon atoms were observed in these latter nanocomposites compared to the polymer alone. This was also associated with the appearance of a new vibration at 1720 cm^{-1}, and may be interpreted as a strong interaction of some of the EOUs with the LDH sheets. This situation was also observed for other organic surfactants, where ethoxy groups were found to be folded in a "hairpin" conformation and remained in contact with

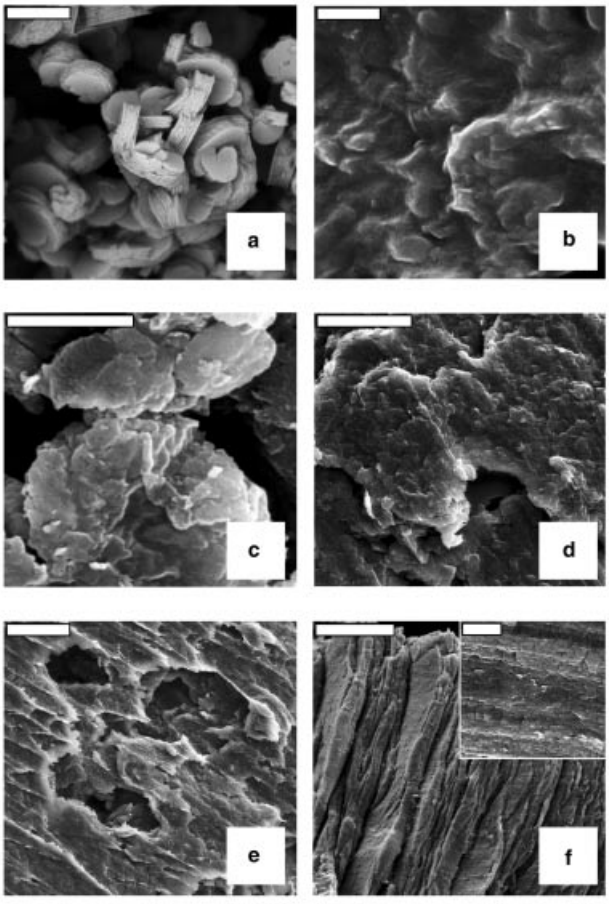

Figure 7. SEM pictures of (a) [CuCr] LDH pristine material; PEG-DC/[CuCr] nanocomposites obtained via (b) ion-exchange in water, (c) co-precipiation, and PEG-AS/[CuCr] nanocomposites of the polymer of 11 EOUs prepared via (d) ion-exchange in water, (e) co-precipitation, and the polymer of 7 EOUs prepared via (f) ion-exchange in water (in inset, the view is perpendicular to the stacking direction). The bar represents 2, 2, 2, 10, 20, 50, 5 (inset) μm, respectively

the LDH surface.[12] However, as PEO and PEO-salt complexes in certain circumstances can easily be oxidized following different mechanisms,[19] giving a complex mixture of primary products including ester, aldehyde, carboxylic acid and formate-end groups, the IR absorption bands observed in the 1500−1900 cm^{-1} region could be attributed to the oxidative degradation of the polymer catalyzed by the host LDH. Thus, for instance, the band at around 1720 cm^{-1} developed from the intercalates of PEG-AS of 11 EOUs (Table 3) could be ascribed to the formation of formate end-functions (-CH_2-O-CHO).

To corroborate this interpretation, PEG-AS of 7 EOUs was intercalated into [CuCr] and [ZnCr] LDH frameworks. These are materials that present the same layer charge density. From the XRD patterns (Figure 9) of nanocomposites derived from the polymer with 11 EOUs intercalated by ion-exchange in the two hosts, the space available for the guest molecule, calculated from the third harmonic position, varies from 3.31 to 3.22 nm for [CuCr] and [ZnCr] derivatives, respectively (Table 2). Thus, PEG-AS may also

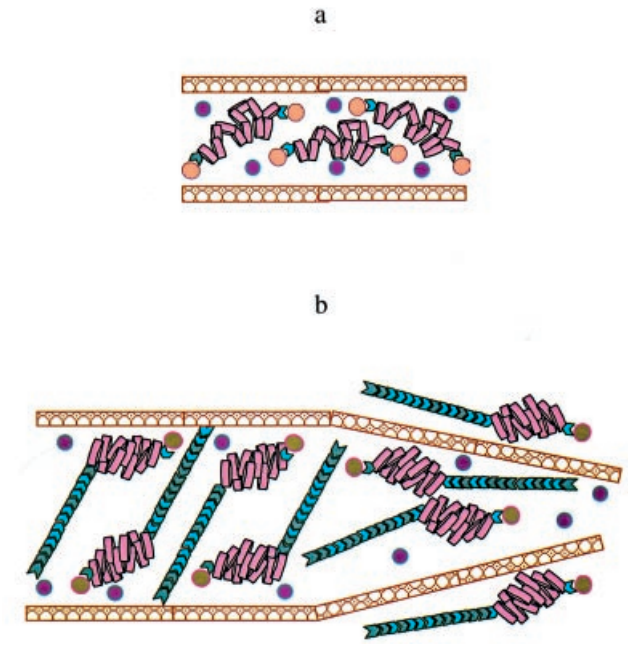

Figure 8. Proposed models for the [CuCr] LDH nanocomposites incorporating (a) PEG-DC and (b) PEG-AS

adopt a highly confined arrangement within the layers of the [ZnCr] LDH structure. For the polymer with 7 EOUs, the situation is slightly modified to 3.12 and 3.07 nm, respectively (Table 2).

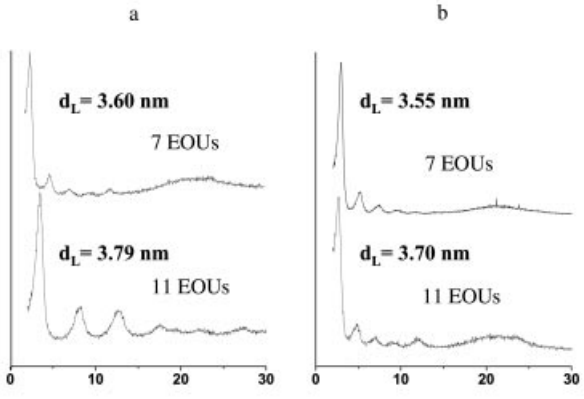

Figure 9. XRD patterns of nanocomposites prepared by ion-exchange reaction of PEG-AS of different EOUs (*n*) with (a) [CuCr] and (b) [ZnCr]; the values of *n* are displayed

The small difference between the variation of basal spacing from 7 to 11 EOUs for the PEG-AS/LDH nanocomposites cannot be explained by the increase in size of the polyoxyethylene chain. This fact proves that the polyoxyethylene chains are not directly contributing to the expansion of the interlayer space available for the molecule. These results are supported by a model in which the polyether chain interacts with the corrugated [CuCr] LDH inner-surface, with the alkyl tails dangling in the interlayer space

(Figure 8b). Qualitatively, this is the same as a polymer literally gluing the inner and outer surface of the matrix, as illustrated by SEM micrographs (Figure 7) and as pointed out by the adsorption measurements, which indirectly give rise to a large surface covered by the mono-functional guest molecule. The existence of such an interaction might also be the cause of a break in the polyether chain that originates, in certain cases, in the presence of carbonyl functions, as deduced from IR and NMR spectroscopic studies and consistent with the observations of other authors.[19]

Conclusion

This paper provides clear evidence of the intercalation of the mono- and bifunctional molecules, PEG-DC and PEG-AS polymers, containing flexible oxyethylene groups between the sheets of LDH [CuCr]. For the macromolecule PEG-DC, the basal spacing of the hybrid phase is small, and has to be explained by assuming a highly distorted helical situation for the polyoxyethylene chain. For PEG-AS, the polymer chain must be in a helical symmetry, although complementary results gathered by FTIR and NMR spectroscopy seem to indicate the presence of additional intricate effects. From these results, we assume that the polyether chain must interact strongly with the LDH layers, giving rise to a distribution of chemical shifts depending on the orientation of the helix with the positively charged layers.

Experimental Section

All the reagents are of analytical grade: $CuCl_2{\cdot}2H_2O$, CuO, $CrCl_3{\cdot}6H_2O$, $ZnCl_2$, NaOH and BuOH are commercial products from Aldrich. Water soluble polymers (Table 1), potassium poly(ethylene glycol) (ca. 7 and 11 ethylene oxide units, EOUs) −[*n*-alkyl(C_{13}−C_{15})− (3-sulfopropyl diether] salt [$R(OCH_2CH_2)_nO(CH_2)_3SO_3$]K, noted as PEG-AS-*n* of 7 or 11 EOUs, respectively], poly(ethylene glycol)dicarboxylic acid [$HO_2C(CH_2OCH_2)_nCO_2$ H, average M_n 600, $n \approx 12$ EOUs − noted as PEG-DC] are available from Aldrich. Deionized water was used for the synthesis and washing procedures.

LDH starting material, [CuCr] of general composition $Cu_2Cr(OH)_6Cl{\cdot}nH_2O$ was prepared by either co-precipitation or salt-oxide methods.[20] For the former, the solutions of transition metal chlorides were slowly added at a controlled pH of 4.9 ($CuCl_2$: 10^{-2} M, $CrCl_3$: 5×10^{-3} M).[20a] For the second preparation, $CrCl_3$ was added to a solution containing CuO that was finely dispersed in water by sonication.[20b] The resulting precipitates were kept overnight in the mother liquor for aging, then separated by three repeated washing/centrifugation cycles and, finally, dried in air at room temperature. In the present study, the second method was preferred, giving rise to more crystalline materials. Co-precipitation was used for the templating reaction (see below). $Zn_2Cr(OH)_6Cl{\cdot}nH_2O$ LDH material, noted as [ZnCr], was prepared by the co-precipitation method at a constant pH of 5.5.

Intercalation of the Polymers

1) Direct exchange was performed as follows: the LDH material (30 mg) was ultrasonicated (5 minutes) in decarbonated water (25 mL) and added to a solution containing the polymer neutralized at pH 7. The amount of dissolved polymer corresponded to two to five times the anionic exchange capacity (AEC) of the LDH material (270 mequiv. per 100 g for [CuCr]). The exchange reaction was performed under nitrogen gas for 3 to 12 h. The resulting powder was centrifuged, washed several times and finally dried at room temperature. In some cases, a mixture of solvents [such as H_2O/MeOH,H_2O/EtOH (1:1)] was used instead of pure water.
2) The method defined as "solvent-assisted preparation", consists of dispersing the LDH sample into butanol. The exchange was then carried out under reflux conditions at 90 °C with vigorous stirring.
3) Co-precipitation is an approach similar to the "templating" method used by Oriaki et al.[5b] for the incorporation of polysulfonated polymers. The hybrid LDH phase was synthesized in the presence of the polymer previously dissolved in aqueous solution (the amount of polymer corresponds to twice the AEC of the solid which, hypothetically, results in the complete formation from the initial salts concentration) on adjusting the pH to 7.0.

The adsorption isotherms were measured by the batch equilibration technique. Thus, a known amount of hydrotalcite-like material (ca. 50 mg) was sonically dispersed in 25 mL of deionized water and then kept in contact with the polymer solution at 25 °C for 24 h. The polymer concentration ranged from 10^{-4} to 5×10^{-2} M. The amount of organic matter adsorbed by the solid, expressed in mmol per gram of LDH (q_e), was determined from HCN elemental microanalyses. The final concentration (C_e, adsorbate concentration at equilibrium after a contact time of 24 hours) was determined by subtracting the quantity of polymer (m) retained by the solid from the total content in the original solution: $C_e = (C_i \times V - q_e \times m)/V$. The adsorption isotherms were obtained by plotting q_e versus C_e (relative error $< 1\%$).

Elemental chemical analysis of the LDH materials was performed using the inductive conduction plasma coupled to atomic emission spectroscopy (ICP/AES) at Center d'Analyse de Vernaison, France. The organic content was determined by conventional HCN chemical analysis (Perkin−Elmer 240C). Materials were characterized by the XRD technique with a D500 Siemens or a Philips 1710 spectrometer, both operating with Cu-K_α radiation. FTIR was performed with a Nicolett 20SXC apparatus employing the KBr dilution technique for solid samples. SEM observations were performed on a SEM-EDX microscope (Zeiss DSM 960) operating at 15.0 kV. ^{13}C solid-state NMR spectroscopy experiments were performed with a 300 Bruker spectrometer at 75.47 MHz, using a 4-mm diameter zirconia rotor and working under magic angle spinning (MAS) condition of 10 kHz. A second spectrometer 400 Bruker (^{13}C Larmor frequency of 100.63 MHz) was also employed. ^{13}C spectra obtained by the proton-enhanced cross-polarization method (CP) were referenced to the carbonyl of the glycine calibrated at $\delta = 176.03$ ppm or tetramethylsilane (TMS).

Acknowledgments

The authors would like to thank Pr. C. Forano for fruitful discussions and Dr. I. Sobrados and Mr. F. Pinto for helpful assistance in the NMR spectroscopic study and SEM characterization, respectively. F. L and P. A. thank the CNRS and CSIC for a French−Spanish cooperation grant (France n°7945, Spain 2000FR0024) and to the CICYT (Spain, MAT2000-1585-C03-01 and MAT2000-1451 projects) for financial support.

COVER PICTURE

The cover picture shows the X-ray structure of [Pd(Et_2timdt)-Br_2] (left; Et_2timdt = diethylimidazolidine-2,4,5-trithione), obtained by treating the symmetrically substituted dithiolene [Pd(Et_2timdt)$_2$] with Br_2 or IBr. This complex has been exploited as a starting material for the synthesis of the new mixed-ligand, push-pull dithiolene [Pd(Et_2timdt)(mnt)] (mnt = maleonitriledithiolate), whose X-ray molecular structure is depicted on the right. Details are discussed in the Short Communication by M. Arca et al. on p. 1291 ff.

Heterodimetallic Chalcogen-Bridged Cubane-Type Clusters of Molybdenum and Tungsten Containing First-Row Transition Metals

Rosa Llusar*[a] and Santiago Uriel[b]

Keywords: Molybdenum / Tungsten / Cluster compounds / Sulfur / Selenium / Heterometallic complexes

Transition metal cluster chalcogenides with cubane-type structures are relevant to our understanding of several industrial and biological catalytic processes. Recent advances in cluster chemistry owe much to the development of rational synthetic approaches, an aspect that is emphasised in this review which focuses on cuboidal clusters of molybdenum and tungsten (M) with $M_2M'_2S_4$ and $M_3M'Q_4$ (Q = S, Se) central units that incorporate a first-row transition metal atom (M′). Special attention has been paid to the non-aqueous chemistry of these compounds. The structural features of these complexes are discussed in relation to their electronic structures within the framework of molecular orbital theory, spectroscopic, magnetic and electrochemical experimental data. Finally, the importance of these clusters in catalysis, nonlinear optics and in the formation of supramolecular adducts is discussed.

Introduction

Transition metal chalcogenide clusters with a cubane-type structure, where the metal and chalcogen atoms occupy adjacent vertices in a cube, are a unique area within cluster chemistry. These compounds are of interest not only because of their contribution to the development of modern chemistry, but also for their potential use as models for various industrial and biological catalytic processes.[1−3] In addition, these complexes have recently been utilised as optical limiters and contrast agents.[4−7]

The first cuboidal cluster to be identified contained the Fe_4S_4 core, a redox-active unit present in the electron-transfer protein ferredoxin. In addition to this homonuclear system, several important metalloenzymes contain heteronuclear transition metal sites. For example, nitrogenase contains the unique Fe-Mo cofactor, which is a major part of the dinitrogen activation system. The characterisation of the Fe-Mo cofactor by X-ray diffraction techniques has

Rosa Llusar was born in Almenara (Spain). She studied chemistry at the University of Valencia (Spain) and received Ph.D. degrees from Valencia University in 1987 and from Texas A&M University (USA) in 1988 under the guidance of Prof. F. Albert Cotton. After working for industry for three years, she spent one year (1992) with Prof. John D. Corbett at the Ames Laboratory (Iowa State University, USA). Since 1993, she has held a position at the University Jaume I of Castelló (Spain) and became Associate Professor of Physical Chemistry in 1995. Her research has focussed on the chemistry of transition metal clusters, especially the relationship between their molecular and electronic structures and their properties.

Santiago Uriel was born in Madrid (Spain). He received his PhD degree in 1992 from Zaragoza University. His doctoral work, under the supervision of Dr. J. Garín, dealt with the synthesis of new (aminomethyl)tetrathiafulvalene derivatives. He then spent three years with Dr. Patrick Batail, first at Laboratoire de Physique the Solides of the University of Paris XI (Orsay) supported by an E. U. Human Capital and Mobility fellowship, and subsequently at the Institut de Matériaux de Nantes as Research Associate at the Centre National de la Recherche Scientifique. He worked on the molecular chemistry of octahedral rhenium clusters and their association within organic-inorganic materials. He joined the research group of Dr. R. Llusar in 1997 at the Jaume I University of Castellón (Spain) supported by Ministerio de Educación y Ciencia and he is currently Profesor Asociado at the Organic Chemistry Department of the University of Zaragoza. His research interests include synthesis, structural chemistry and physical properties of transition metal molecular ions.

MICROREVIEWS: This feature introduces the readers to the authors′ research through a concise overview of the selected topic. Reference to important work from others in the field is included.

shown the presence of a $MoFe_7S_8$ core structure with two partial thiocubane substructures, each of which contains an open Fe_3 face.[8,9] Synthetic efforts to prepare chemical analogues of the cofactor have been extensively reviewed and will not be covered here.[10,11]

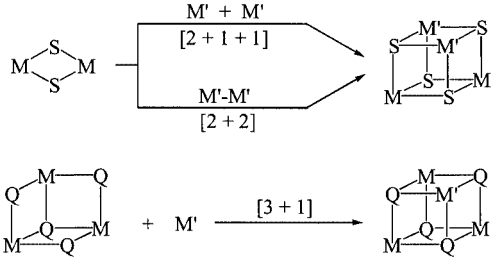
This review is limited to heterodimetallic cuboidal $M_2M'_2$ and M_3M' cluster chalcogenides of molybdenum and tungsten (M) that incorporate a first-row transition metal (M′). Heterodimetallic clusters with $M_2M'_2S_4$ and $M_3M'S_4$ cores (M′ = Ni, Co) are considered as discrete molecular models for substrate binding in the hydrodesulfurisation process (HDS), due to the fact that cobalt and nickel are known to act as promoters of the catalytic activity of the molybdenum sulfide industrial heterogeneous catalysts.[12] Sulfur- or selenium-containing transition metal clusters with MM'_3S_3Br or $M_3M'Se_4$ (M = Mo and W; M′ = Cu and Ag) cubane-like structures are also known to possess strong optical limiting effects.[4,5,13,14] In the past ten years, several review articles have appeared covering the most important aspects of the chemistry of molybdenum and tungsten transition metal chalcogenides.[1,15−19] Special attention has been given to the aqueous chemistry of heterodimetallic molybdenum and tungsten $M_3M'Q_4$ clusters that incorporate a second transition metal atom.[1,15,17,18]

In this work we place our emphasis on the non-aqueous chemistry of these complexes, a field of particular interest to us. In addition, we have included results reported on the $M_2M'_2S_4$ systems for comparative purposes. We have restricted M′ to the first-row transition elements, again motivated by our own research interests. The review is organised as follows. The first section provides a general overview of the synthesis, structure and electron counts of clusters with $M_2M'_2S_4$ and $M_3M'Q_4$ central units. Each subsection is defined based on the nature of the surrounding ligands around the group-6 metal atom. The next section discusses the electronic structure, electrochemistry and magnetism of these $M_2M'_2S_4$ and $M_3M'Q_4$ clusters. The final section deals with some selected properties that we have decided to emphasise, based on their potential applications such as catalysis, nonlinear optics and the capability of these cluster compounds to form supramolecular adducts.

Synthesis, Structure and Electron Counts

The development of the chemistry of transition metal clusters is closely related to the discovery of rational synthetic routes for the preparation of these compounds. In recent years, different strategies have evolved for the synthesis of molecular transition metal sulfide systems. These strategies can be roughly classified into six different categories: (i) spontaneous self-assembly where the structure of the reactant is not preserved in the final product; (ii) fragmentation of clusters of higher nuclearity; (iii) cluster excision from solid-state polymers; (iv) building-block synthesis from lower nuclearity species; (v) transmetallation or replacement of one metal atom by another, and (vi) substitution of peripheral ligands. The first two procedures suffer from the disadvantage that the structures of the products cannot be easily predicted.

The building-block approach has been the most widely used method for the construction of cuboidal heterodimetallic $M_2M'_2S_4$ and $M_3M'Q_4$ (Q = S, Se) cluster complexes. Using this approach, $M_2M'_2S_4$ complexes can be prepared from a dinuclear precursor and two mononuclear complexes according to the so-called [2 + 1 + 1] route, or from two dinuclear compounds according to a strategy designated as [2 + 2]. $M_3M'Q_4$ clusters can be prepared in an analogous fashion by adding a monomeric compound to a triangular metal complex, this method being termed a [3 + 1] synthesis. Scheme 1 gives a graphical representation of these three methods.



Scheme 1. Building-block synthetic methods for heterometallic cubane clusters

Once the heterodimetallic tetrameric unit has been formed, it can undergo different chemical transformations without changing its nuclearity. For example, one of the metal atoms can be substituted for a different metal atom (transmetallation) or the outer ligands can be replaced by other ligands (ligand substitution). In addition, the structure of the cluster core can rearrange in the presence of certain reagents.

The trinuclear and dinuclear precursors have been prepared by a variety of methods such as self-assembly, cluster fragmentation and cluster excision. This last method has represented a major advance in the field because it both allows the synthesis of previously inaccessible compounds and gives significant improvements in the yields of the cluster formation reactions. In this section we will first present details of the synthesis of the dinuclear or trinuclear precursors for each particular group of compounds, and then continue with a general description of the synthesis employed to obtain $M_2M'_2S_4$ and $M_3M'Q_4$ cluster complexes.

Clusters with $M_2M'_2S_4$ Central Units

A simplified representation of the structures of representative compounds with $Mo_2M'_2S_4$ and $W_2M'_2S_4$ cluster units is given in Figure 1. All structures have been drawn to emphasise the familiar thiocubane core and the coordination environments of the metal atoms. No analogous compounds of selenium have yet been reported to our knowledge. A summary of intermetallic distances for some representative cluster compounds within this series is given in Table 1.

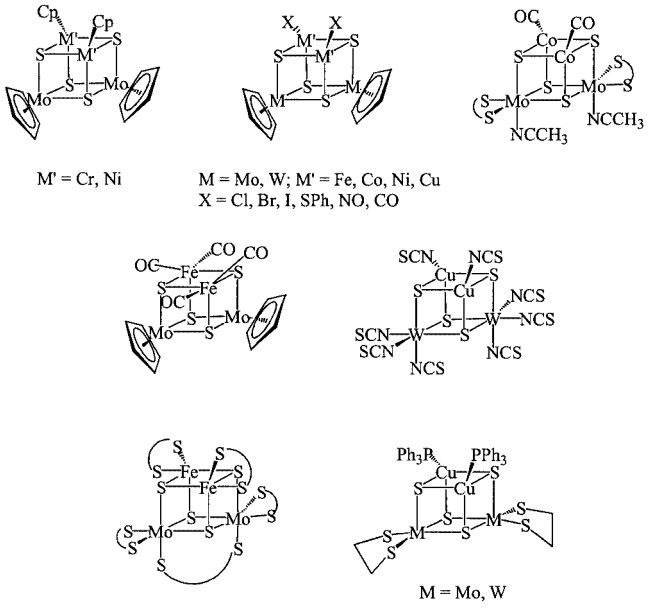


Figure 1. Schematic representations of the different coordination environments in $M_2M'_2S_4$ cubane-type clusters

Dimeric molybdenum and tungsten sulfur-rich complexes with cyclopentadienyl (Cp) and sulfur-containing ligands (dithiocarbamates, 1,2-dimercaptoethane or polysulfides) have been used as precursors for the synthesis of heterometallic $M_2M'_2S_4$ clusters through [2 + 1 + 1] or [2 + 2] building block strategies. These complexes behave as metalloligands towards heterometal atoms by using the lone-pair electrons of the sulfur atoms. The most widely used building block is the M_2S_4 unit, particularly the molybdenum- and tungsten(V) $[M_2S_2(\mu_2\text{-}S)_2]$ isomeric forms. Note however, that the tetrabridged molybdenum(IV) complex $[Mo_2(\mu_2\text{-}S)_2(\mu_2\text{-}SH)_2Cp_2]$ is often used for the synthesis of (cyclopentadienyl)molybdenum derivatives. The heterometal M′ is usually incorporated as a mononuclear or a dinuclear carbonyl complex except in the case of copper, where incorporation has always been accomplished by reaction with copper halides. The coordination environment of the heteroatom depends on the composition of the carbonylmetal compound.

$M_2M'_2S_4$ Clusters with Cyclopentadienyl Ligands

The dinuclear cyclopentadienyl building blocks $[M_2S_4Cp_2]$ are prepared by reaction of the molybdenum(I) or the tungsten(I) dinuclear complex $[MCp^*(CO)_2]_2$ with elemental sulfur in refluxing toluene to produce a mixture of isomers with metal atoms in oxidation states ranging from III to V.[34] The product distribution depends on the reaction conditions. Typical reaction yields for the $[M_2S_4Cp_2]$ dimer are 40% for Mo and 60% for W. In the case of tungsten, the *syn*-$[W_2S_2(\mu_2\text{-}S)_2]$ isomer is obtained in 54% yield, while the molybdenum analogue is produced in only 10% yield. Alternatively, the *trans*-$[Mo_2S_2(\mu_2\text{-}S)_2Cp^*_2]$ isomer can be prepared in 65% yield by treating the hydridomolybdenum complex $[MoCp^*H(CO)_3]$ with elemental sulfur in refluxing THF.[35] The preparation of the widely used $[Mo_2(\mu_2\text{-}S)_2(\mu_2\text{-}SH)_2Cp^{\#}_2]$ precursor is car-

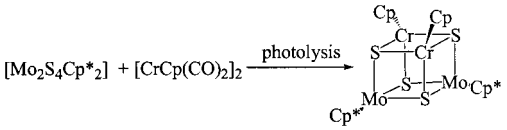
[a] All IR data are referred to the CO or NO stretching frequency in KBr unless otherwise indicated. [b] IR data in CH_3CN solutions.

ried out through reduction of the polymeric phase $\{Mo_2S_xCp^{\#}\}_n$ ($Cp^{\#}$ = Cp, Cp′, Cp*; with Cp′ = methylcyclopentadienyl and Cp* = pentamethylcyclopentadienyl) with an excess of lithium ethylborohydride.[36] This phase is obtained by treating $[MoCp^{\#}(CO)_3]_2$ with elemental sulfur.[35,37] The intermetallic distance in $[Mo_2(\mu_2\text{-}S)_2(\mu_2\text{-}SH)_2Cp^{\#}_2]$ as well as in $[M_2S_2(\mu_2\text{-}S_2)Cp^*_2]$ is consistent with the presence of a metal−metal single bond.

The Mo_2Cr_2 core is formed by photolysis of the carbonylchromium(I) complex $[CrCp(CO)_2]_2$ in the presence of $[Mo_2S_4Cp^*_2]$, which affords the cubane-like diamagnetic cluster $[Mo_2Cr_2S_4Cp^*_2Cp_2]$ in 41% yield according to Equation (1).[38]

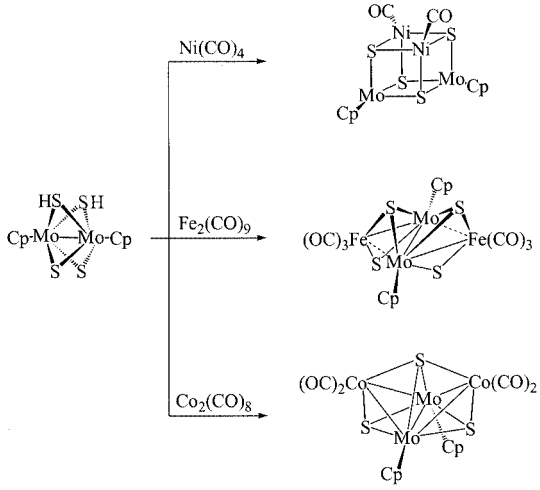


(1)

The equivalent $[Mo_2Cr_2S_4Cp_2Cp^*_2]$ complex has also been prepared by treating a chromium sulfide dimer $[Cr_2(\mu_2,\eta^2\text{-}S_2)(\mu_2,\eta^1\text{-}S_2)(\mu_2\text{-}S)Cp^*_2]$ with the corresponding carbonylmolybdenum compound $[MoCp(CO)_2]_2$. The final oxidation state of both Mo and Cr in the cluster is III and consequently there are 12 metal cluster electrons available for metal−metal bonding. The analogous nickel cluster $[Mo_2Ni_2S_4Cp'_2Cp_2]$ has been synthesised in 15% yield from $[Mo_2(\mu_2\text{-}S)_2(\mu\text{-}SH)_2Cp'_2]$ and $[NiCp(CO)]_2$ in refluxing THF to produce a 22 metal electron cluster, for which the oxidation state assignment $Mo^{III}_2Ni^{II}_2$ has been proposed.[27] Consequently, the reaction implies reduction of the dimolybdenum sulfide (Mo^{IV} to Mo^{III}), with concomitant oxidation of the carbonylnickel compound from Ni^I to Ni^{II}. Although these tetrametallic $Mo_2Cr_2S_4$ and $Mo_2Ni_2S_4$ clusters have not been characterised by X-ray structural analysis, a cubane-type structure has been proposed based on spectroscopic evidence. The complex $[Mo_2(\mu_2\text{-}S)_2(\mu_2\text{-}SH)_2Cp'_2]$ does not react with $[Fe_2Cp_2(CO)_4]$ or $[CoCp(CO)_2]$ under the conditions used for the synthesis of the Mo_2Ni_2 complex.[27]

The hydridosulfides $[Mo_2(\mu_2\text{-}S)_2(\mu_2\text{-}SH)_2Cp^{\#}_2]$ ($Cp^{\#}$ = Cp, Cp′) react rapidly (< 2 h) with $[Ni(CO)_4]$, $[Fe_2(CO)_9]$ and $[Co_2(CO)_8]$ in organic solvents, but only in the case of nickel can $M_2M'_2S_4$ thiocubane clusters be isolated. These have the formula $[Mo_2Ni_2S_4Cp^{\#}_2(CO)_2]$ and are obtained in 25 and 50% yields for Cp and Cp′, respectively, as represented in Scheme 2.[27,36]

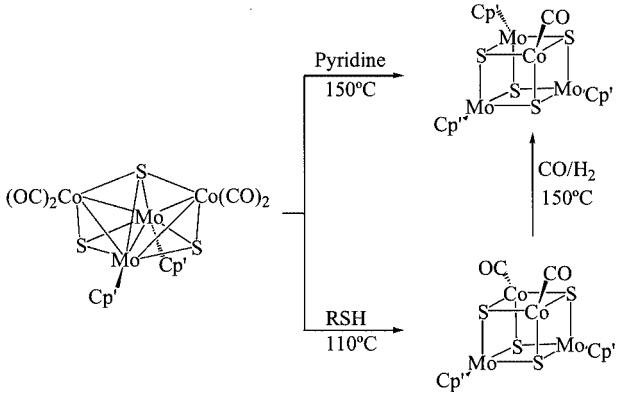
These nickel compounds, also with 22 metal cluster electrons, adopt a cubane-butterfly structure with the Ni atoms placed at the wing tips (Ni···Ni = 2.962 Å) In the case of iron, the complexes $[Mo_2Fe_2(\mu_3\text{-}S)_2(\mu_2\text{-}S)_2Cp^{\#}_2(CO)_6]$ ($Cp^{\#}$ = Cp, Cp′) are obtained. These contain a planar Mo_2Fe_2 core and have the μ_3-S ligands lying on opposite sites of the Mo_2Fe_2 plane. Reaction with the carbonylcobalt compound affords the tetranuclear clusters $[Mo_2Co_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Cp^{\#}_2(CO)_4]$ in 50% yield. These have an $Mo_2Co_2S_3$ core containing a μ_4-S sulfido ligand. The Cp′ derivative



Scheme 2. Reactions of $[Mo_2(\mu_2\text{-}S)_2(\mu_2\text{-}SH)_2Cp_2]$ with carbonylmetal compounds

undergoes thermal decomposition by heating with pyridine at 150 °C to give a trimolybdenum cuboidal cluster $[Mo_3CoS_4Cp'_3(CO)]$ in 15% yield.[24]

The $[Mo_2Co_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Cp'_2(CO)_4]$ complex deserves special attention due to its relevance as a molecular model for hydrodesulfurisation catalysis.[25,39] This $Mo_2Co_2S_3$ cluster compound reacts with a variety of organic thiols RSH (R = *tert*-butyl, isopentyl, phenyl) in near quantitative yield to give the corresponding hydrocarbon and the $[Mo_2Co_2(\mu_3\text{-}S)_4Cp'_2(CO)_2]$ cubane having 20 metal electrons. Treatment of the $Mo_2Co_2S_4$ cluster with a CO/H_2 mixture (1:4) at 150 °C and 13.4×10^5 Pa affords the $[Mo_3CoS_4Cp'_3(CO)]$ complex in 15−30% yield, according to Scheme 3.[24]



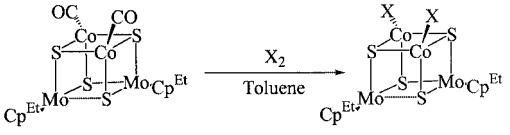
Scheme 3. Rearrangement reactions of the $Mo_2Co_2S_3$ core

An analogue of $[Mo_2Co_2(\mu_3\text{-}S)_4Cp'_2(CO)_2]$ can be obtained in better yields (72%) from the sulfur-rich dinuclear complex $[Mo_2S_4Cp^*_2]$ and $[Co_2(CO)_8]$ in toluene.[40] This procedure can be extended to tungsten to afford the $[W_2Co_2S_4Cp^*_2(CO)_2]$ cubane compound in 51% yield.[22] The $M_2Co_2S_4$ cluster unit in these compounds having 20 metal electrons shows a complete metal tetrahedron with six intermetallic bonds (see Table 1), in contrast to the Ni

complex analogue where only five metal−metal bonds are present. If one neglects the intermetallic bonds, the coordination environment around the heterometal in both the Ni and the Co clusters is nearly tetrahedral.

Reduction of the carbonylcobalt cubane $[Mo_2Co_2S_4Cp^{Et}_2(CO)_2]$ (Cp^{Et} = ethyltetramethylcyclopentadienyl) with sodium amalgam in THF affords the extremely air-sensitive one-electron reduction product which was crystallised as the $[Na(15\text{-crown-}5)_{1.5}]^+$ salt in 44% yield. Alternatively, the analogous Cp′ complex has been prepared by the thermal decomposition of the thiolate adduct $[Mo_2Co_2S_3Cp'_2(CO)_2(SAr)]^-$ (Ar= *p*-tolyl) formed from $[Mo_2Co_2S_3Cp'_2(CO)_4]$ and *p*-toluene thiolate in acetonitrile. The addition of an electron causes an increase of ca. 0.4 Å in the Co−Co bond length with respect to the neutral 20 metal electron cluster, while the Mo−Mo and Mo−Co distances remain practically unchanged.[26] Thus, in a formal sense, changes in the number of metal electrons mainly involve the Co atoms; these are reduced from Co^{2+} to $Co^{1.5+}$.

Oxidation of the heterodimetallic sulfidocobalt cluster $[Mo_2Co_2S_4Cp^{Et}_2(CO)_2]$ with X_2 (X = Cl, Br, I, SPh) causes oxidative substitution of the carbonyl groups by halogens or PhS to give the 18 metal electron clusters $[Mo_2Co_2S_4Cp^{Et}_2X_2]$ in 48−83% yields, as shown in Equation (2).[21,41]

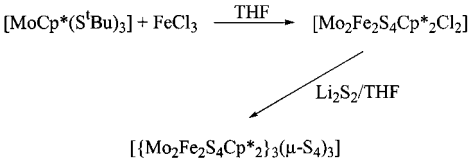


(2)

The $Mo_2Co_2S_4$ core in these 18 electron metal clusters shows a cubane butterfly structure with five metal−metal bonds. The Co···Co distances in these complexes are 2.934(3) and 2.953(3) Å for the iodine and the chlorine derivatives, respectively, and 2.741(1) Å for the thiolato cluster. This last value is very similar to that found for the radical anion $[Na(15\text{-crown-}5)_{1.5}][Mo_2Co_2S_4Cp^{Et}_2(CO)_2]$ [2.735(1) Å] that was associated with a formal Co···Co bond order of 1/2.

A (carbonyl)$Mo_2Fe_2S_4$ cubane-type cluster of formula $[Mo_2Fe_2S_4Cp^*_2(CO)_4]$ has been synthesised from the molybdenum(IV) complex $[Mo_2(\mu_2,\eta^2\text{-}S_2)(\mu_2\text{-}S)_2Cp^*_2]$, by reaction with $[Fe_2(CO)_9]$ in THF at room temperature (33% yield) or by photochemical reaction with $[Fe(CO)_5]$ (10% yield).[30] Two heterodimetallic Mo_2FeS_2 trimers with a trigonal-bipyramidal core are also obtained from this reaction. The $[Mo_2Fe_2S_4Cp^*_2(CO)_4]$ complex possesses 18 metal cluster electrons which agrees with a formal oxidation state assignment of $Mo^{III}_2Fe^{II}_2$. The cubane cluster with 18 metal cluster electrons adopts a butterfly structure and consequently five metal−metal bonds. The coordination sphere around the iron atom consists of three μ_3-S sulfur atoms and two carbonyl groups in a square-pyramidal geometry.

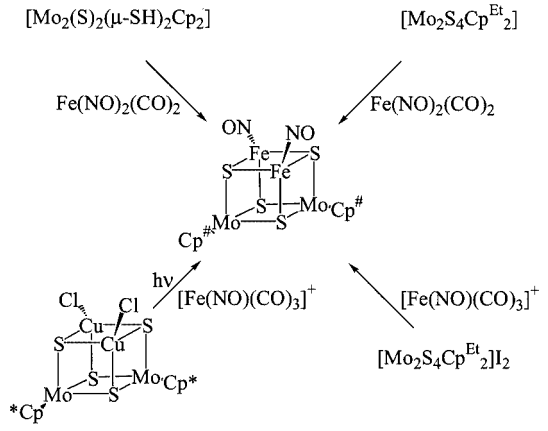
In the case of iron, the cyclopentadienyl halide derivative $[Mo_2Fe_2S_4Cp^*_2Cl_2]$ has been prepared through a self-assembly reaction between the molybdenum(IV) monomer $[MoCp^*(S(tBu)_3)]$ and $FeCl_3$ in THF that unexpectedly gives the cubane cluster $[Mo_2Fe_2S_4Cp^*_2Cl_2]$ in 39% yield.[20] The resulting $[Mo_2Fe_2S_4]$ complex has 16 metal cluster electrons, and in spite of the uncertainty related to the oxidation state definition in cluster compounds, a possible assignment is $Mo^{IV}_3Fe^{II}_2$. The reduction of iron from Fe^{III} to Fe^{II} is considered to occur during the cluster formation reaction, with simultaneous cleavage of the C−S bond. The electron deficiency in this cluster mainly affects the Fe−Fe distance which is ca. 0.09 Å longer than in similar iron complexes having 20 metal electrons, as can be observed in Table 1. Reaction of $[Mo_2Fe_2S_4Cp^*_2Cl_2]$ with Li_2S_2 gives rise to a tricubane cluster where the three $Mo_2Fe_2S_4$ cluster units are linked by three Fe−Fe bonds (2.610 Å) and three $\mu_2,\eta^2\text{-}S^{2-}_4$ ligands, as represented in Equation (3).



(3)

The only example of a heterodimetallic Mo_2Cu_2 cluster with cyclopentadienyl ligands is the $[Mo_2Cu_2S_4Cp^*_2Cl_2]$ complex, prepared by reaction of $[Mo_2S_4Cp^*_2]$ with 2 equiv. of CuCl in acetonitrile. Three different isomeric forms of the dinuclear sulfido starting material have been used, namely $[Mo_2(\mu_2,\eta^2\text{-}S_2)S_2Cp^*_2]$, $[Mo_2(\mu_2,\eta^2\text{-}S_2)(\mu_2\text{-}S)_2Cp^*_2]$, and $[Mo_2(\mu_2\text{-}S)_2S_2Cp^*_2]$, and the best yields (81%) are obtained for the first of these. In all three cases, other trimetallic Mo_2Cu and noncuboidal tetrametallic Mo_2Cu_2 complexes are also obtained as coproducts. The resulting $[Mo_2Cu_2S_4Cp^*_2Cl_2]$ complex having 22 metal electrons has a similar cubane-butterfly structure to the one observed for the 22 electron Mo_2Ni_2 systems.[28]

Finally, several nitrosyl derivatives of the $M_2M'_2S_4$ unit derived from (cyclopentadienyl)group-6 complexes have been prepared with Fe and Co as heterometals. These complexes have the chemical formula $[M_2M'_2S_4Cp^{\#}_2(NO)_2]$ (M = Mo and W and M′ = Fe and Co).[22,42] The clusters $[Mo_2Fe_2S_4Cp^{\#}_2(NO)_2]$ ($Cp^{\#}$ = Cp, Cp^{Et}, Cp*) were synthesised using different Mo/S synthons and two (nitrosyl)Fe complexes as the source of the FeNO vertex, as summarised in Scheme 4. Typical yields for these reaction are ca. 40%. In contrast to the carbonylcobalt findings, the reaction between the (sulfhydryl)molybdenum complex $[Mo_2S_2(SH)_2Cp_2]$ and $[Fe(CO)_2(NO)_2]$ does not lead to the "$Mo_2Fe_2S_3$" cluster, isoelectronic with $[Mo_2Co_2S_3Cp^{Et}_2(CO)_2]$.[22] It is interesting to point out that when the 22 electron cluster $[Mo_2Cu_2S_4Cp^*_2Cl_2]$ is irradiated in the presence of $[Fe(NO)(CO)_3]^+$, the CuCl fragments are replaced by Fe(NO) to afford the 20 metal electron cluster $[Mo_2Fe_2S_4Cp^*_2(NO)_2]$.[28]



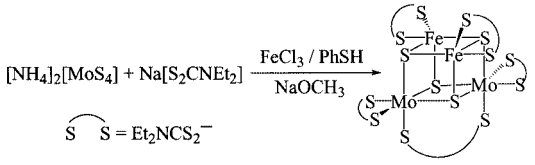
Scheme 4. Synthetic routes to the $[Mo_2Fe_2S_4Cp^{\#}(NO)_2]$ cubane.

The analogous (nitrosyl)W_2Fe_2 complex is obtained by reaction of $[W_2S_4Cp^*_2]$ with $[Fe(NO)_2(CO)_2]$ in refluxing toluene to afford $[W_2Fe_2S_4Cp^*_2(NO)_2]$ in 36% yield. These $[M_2Fe_2S_4Cp^{\#}_2(NO)_2]$ compounds have 20 metal cluster electrons and their structures show six metal−metal bonds and an NO ligand attached to the tetrahedral Fe atom. Similar cluster complexes are obtained for cobalt by treating $[Mo_2S_4Cp^{Et}_2]$, $[W_2S_4Cp^*_2]$ or $[Mo_2(\mu_2\text{-}S)_2(\mu\text{-}SH)_2Cp_2]$ with $[Co(CO)_3(NO)]$ in toluene to afford complexes with formula $[M_2Co_2S_4Cp^{\#}_2(NO)_2]$ in low to moderate (30−50%) yields.[22] The change of iron for cobalt increases the number of metal cluster electrons from 20 to 22. The formal oxidation states of the metal atoms in these clusters are M^{III} and Co^{I} (the nitrosyl ligand is assumed to be NO^+) and consequently, replacement of Fe by Co has the same effect as substitution of a carbonyl by a nitrosyl group. The Co−Co distances of ca. 3.12 Å in the $[M_2Co_2S_4Cp^{\#}_2(NO)_2]$ clusters (see Table 1) are well beyond the typical Co−Co single bond lengths and the metal atoms adopt the butterfly disposition already observed for other 22 metal electron clusters.

$M_2M'_2S_4$ Clusters with Sulfur-Containing Ligands

The number of $M_2M'_2$ clusters with sulfur-containing ligands is more limited than their cyclopentadienyl counterparts. All known examples contain dithiolate or dithiocarbamate as ancillary ligands and metal electron counts between 15 and 20. The main building block fragment used for this chemistry is the *syn*-$[M_2(\mu_2\text{-}S)_2S_2]$ unit, in particular the molybdenum and tungsten dimers $[M_2S_4(dtc)_2]$ (dtc = diethyldithiocarbamate) and $[Et_4N]_2[M_2S_4(edt)_2]$ (edt = 1,2-ethanedithiolate). The *syn* isomers of the molybdenum complexes $[Mo_2(\mu_2\text{-}S)_2S_2(dtc)_2]$ and $[Mo_2(\mu_2\text{-}S)_2S_2(edt)_2]^{2-}$ are prepared in 82 and 75% yield, respectively, by reaction of $[NH_4]_2[Mo_2(S-S)_6]$ with an excess (20−25 equiv.) of Na[dtc] or Na_2[edt] in refluxing methanol.[43] The excess thiolate serves both as the reductant of the disulfide ligand and as a peripheral ligand in the final product. The neccessity for excess thiolate may be obviated by using triphenylphosphane as the reducing agent. A more general route for the synthesis of $[Et_4N]_2[Mo_2(\mu_2\text{-}S)_2S_2(edt)_2]$ has been developed, and this can also be used to prepare the analogous tungsten complex. $[NH_4]_2[MS_4]$ is treated with 1,3-ethanedithiol in DMF, and addition of tetraethylammonium bromide precipitates the $[Et_4N]_2[M_2(\mu_2\text{-}S)_2S_2(edt)_2]$ salt in 63 and 55% yields for Mo and W respectively.[44,45] The tungsten complex $[W_2(\mu_2\text{-}S)_2S_2(dtc)_2]$ can be obtained in 75% yield by treatment of $(Et_4N)_2[W_2(\mu_2\text{-}S)_2S_2(S_4)]$ with sodium diethyldithiocarbamate, triphenylphosphane and NH_4PF_6 in acetonitrile.[45] The sulfur-rich $[W_2(\mu_2\text{-}S)_2S_2(S_4)_2]^{2-}$ anion has also been employed as a building block. This tungsten(V) dimer is obtained in 83% yield by heating $[NH_4]_2[WS_4]$ and elemental sulfur in DMF.[45] It can also be obtained at room temperature by using a reducing agent such as $NH_2NH_2{\cdot}HCl$.[32]

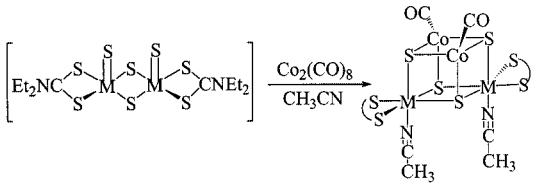
The synthesis of the cubane cluster $[Mo_2Fe_2S_4(S_2CNEt_2)_5]$ in 18% yield has been reported, using a one-pot reaction between $[NH_4]_2[MoS_4]$, $FeCl_3$, Na[dtc], PhSH and $NaOCH_3$ in methanol/DMF solutions, as shown in Equation (4).[29]



(4)

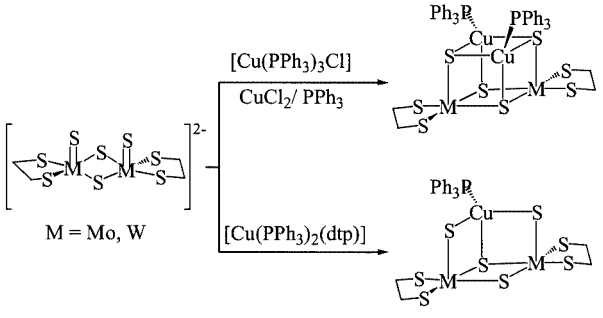
It is very likely that the reducing conditions used in this reaction (PhS^- and $Et_2NCS_2^-$) cause the formation of an intermediate molybdenum(V) dimer with an $M_2(\mu_2\text{-}S)_2S_2$ central core, as found for tungsten. The $Mo_2Fe_2S_4$ cluster skeleton has a cubane-type structure where each metal atom is coordinated by three μ_3-S atoms and two sulfur atoms of the dithiocarbamate chelating terminal ligand. In addition, the fifth $Et_2NCS_2^-$ group acts as a bridging ligand between two Mo atoms, resulting in an octahedral environment for that metal atom. The coordination geometry around the iron atom is an irregular triangular bipyramid. The intermetallic distances within this cluster are listed in Table 1. The Mo−Mo and Mo−Fe bond lengths are consistent with metal−metal single bonds, while the Fe−Fe bond length of 2.784 Å lies outside the single bond range. In consequence there are in total five metal−metal bonds, with the metal atoms defining a butterfly arrangement in which the Mo atoms occupy the hinge positions. The dithiocarbamate bridging ligand causes a shorthening of the Mo−Mo bond length (2.734 Å) in the $[Mo_2Fe_2S_4(S_2CNEt_2)_5]$ cluster, while the other intermetallic Mo−Fe and Fe−Fe bond lengths are similar to those observed in the 16 metal electron cluster $[Mo_2Fe_2S_4Cp^*_2Cl_2]$.

The $Mo_2Co_2S_4$ cluster $[Mo_2Co_2S_4(S_2CNEt_2)_2(CH_3CN)_2(CO)_2]$ having 20 metal cluster electrons has been prepared by reaction of $[Mo_2(\mu_2\text{-}S)_2S_2(dtc)_2]$ with an equimolar amount of $[Co_2(CO)_8]$ in THF or acetonitrile, as represented in Equation (5).[23]



(5)

The analogous tungsten complex is prepared from $[W_2(\mu_2\text{-}S)_2S_2(dtc)_2]$ in acetonitrile.[45] The structure of the parent $[M_2S_4(dtc)_2]$ fragment remains essentially unchanged in the final cluster, where the M_2Co_2 atoms define a tetrahedron. The dinuclear precursor shows no tendency to bind acetonitrile, in contrast to the final cubane product, and thus it appears that the presence of cobalt enhances the affinity for ligands at the molybdenum or tungsten site *trans* to the μ_3-S atom. There are no known examples of $M_2Ni_2S_4$ derivatives with sulfur-containing ligands and examples with copper are restricted to the molybdenum and tungsten $[M_2Cu_2S_4(SCH_2CH_2S)_2(PPh_3)_2]$ complexes. When $[Et_4N]_2[MoS_4(edt)_2]$ reacts with 2 equiv. of $[Cu(PPh_3)_3Cl]$ under an inert gas, the cubane cluster compound $[Mo_2Cu_2S_4(edt)_2(PPh_3)_2]$ is obtained. The isomorphous tungsten compound $[W_2Cu_2S_4(edt)_2(PPh_3)_2]$ was synthesised from $[Et_4N]_2[WS_4(edt)_2]$, $CuCl_2{\cdot}H_2O$ and PPh_3 in CH_2Cl_2/EtOH solution.[31] The coordination sphere around the Mo or W atoms in these complexes consists of three μ_3-S sulfido ligands and two sulfur atoms from the bidentate ligand, arranged in a tetragonal-pyramidal geometry. The four metal atoms adopt a cubane-butterfly structure, as found in the (cyclopentadienyl)M_2Cu_2 derivatives which also have 22 metal cluster electrons.[33] Alternatively, the reaction of $[Et_4N]_2[M_2S_4(edt)_2]$ (M = Mo, W) with $[Cu(PPh_3)_2(dtp)]$ (dtp = $^-S_2P(OCH_2{-}CH_3)_2$, dithiophosphate] in CH_2Cl_2/CH_3CN solution at room temperature gives the incomplete cubane cluster $[Et_4N][M_2CuS_4(edt)_2(PPh_3)]$ (M = Mo, W), as summarised in Scheme 5.[46]



Scheme 5. Incorporation of one or two copper atoms to $(Et_4N)_2[M_2S_2(\mu_2\text{-}S)_2(edt)_2]$

No interconversion between the trinuclear and the tetranuclear species, as has been found in similar systems with noble metals instead of copper, has been reported.[47]

Finally, the air-stable complex $[Et_4N]_4[W_2Cu_2S_4(SCN)_8]$ having 22 metal cluster electrons has been prepared in 45% yield by reacting $[Et_4N]_2[W_2S_4(S_4)_2]$ with CuCl in the presence of KSCN.[32] In contrast to the other complexes described in this section, the tungsten atom is coordinated to the nitrogen atoms of the thiocyanate ligands in a octahedral coordination environment. The thiocyanate ligands attached to the Cu atoms define a tetrahedron. All the reported $M_2Cu_2S_4$ clusters are electron-precise, having 22 metal cluster electrons (see Table 1) and a cuboidal−butterfly arrangement of the metal atoms, where the nonbonding distance corresponds to the Cu···Cu interaction.

Clusters with $M_3M'Q_4$ Central Units

In contrast to the above-reported cuboidal complexes where, with the exception of the $[\{Mo_2Fe_2S_4Cp^*_2\}_3(\mu\text{-}S_4)_3]$ tricubane cluster, only isolated single-cube structures have been found, compounds with $M_3M'Q_4$ central cores exhibit single, edge linked double-cube and corner-shared double-cube structures, as represented in Figure 2. In the case of first-row transition heterometals, only the first two structural types have been encountered to date.

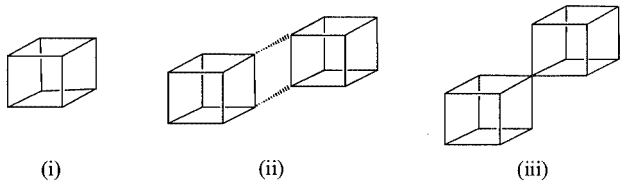


Figure 2. Structural types of $M_3M'Q_4$ aquo cuboidal clusters: (i) single cubane (ii) edge-linked double cubane (iii) corner-shared double cubane

The chemistry of heterodimetallic clusters with $M_3M'Q_4$ cores has been developed predominantly in aqueous media, and major advances have been made in the field of molybdenum clusters, where the heterometals incorporated into the incomplete cuboidal $[Mo_3S_4(H_2O)_9]^{4+}$ aquo ion according to a [3 + 1] synthetic strategy range from group-6 to -15 elements.[18] For tungsten, the number of heterometals incorporated is more restricted, a fact that has been attributed to the greater difficulty in reducing tungsten as compared to molybdenum. Reactivity studies of $[M_3Se_4(H_2O)_9]^{4+}$ complexes towards a second metal are limited to some preliminary results regarding the incorporation of Ni and Pd into the molybdenum selenide aquo ion[48] and Mo insertion into the W_3Se_4 aquo ion.[49] This chemistry has been extensively reviewed in the past year, and for this reason we will only comment on the most relevant aspects regarding the insertion of first-row transition metals into the M_3Q_4 aquo ion. However, we will give a detailed description of the non-aqueous chemistry of these $M_3M'Q_4$ heterodimetallic clusters.[17−19] Figure 3 presents a number of representative $M_3M'Q_4$ clusters that have been

reported, where again the familiar cubane core has been emphasised.

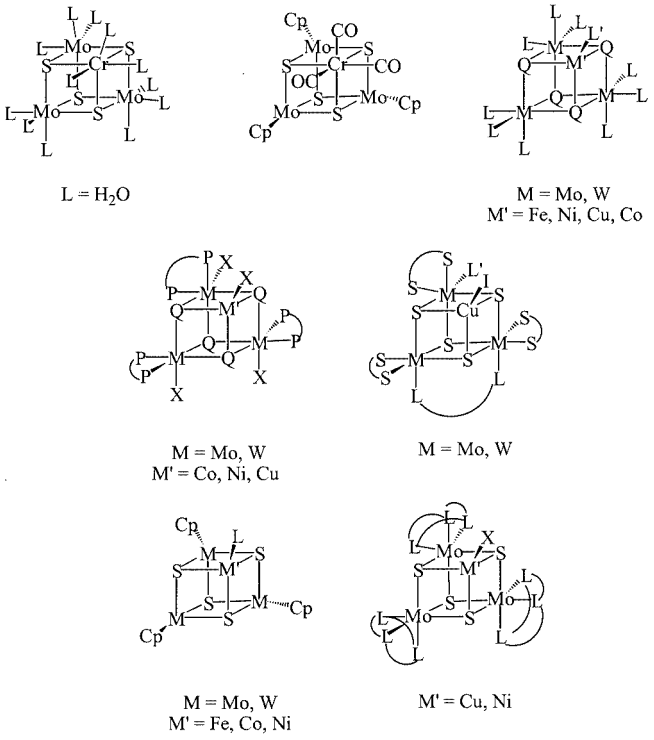

Figure 3. Schematic representations of cubane structures and metal environments of $M_3M'Q_4$ clusters

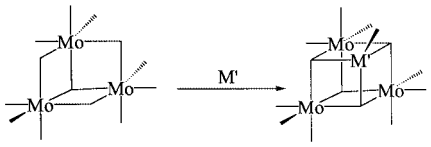
$M_3M'Q_4$ Clusters as Derivatives of the M_3Q_4 Aquo Ion

Since Shibahara's report in 1986 of the reaction of the molybdenum aquo cluster $[Mo_3S_4(H_2O)_9]^{4+}$ with iron metal to give the molybdenum−iron mixed-metal cluster $[Mo_3FeS_4(H_2O)_{10}]^{4+}$, much work has been carried out in the field.[50] The insertion of other metal atoms has been successfully achieved as previously mentioned, and the analogous tungsten and selenium building blocks M_3Q_4 have been prepared.

The synthesis of the green aquo cluster $[Mo_3S_4(H_2O)_9]^{4+}$ has been recently reviewed.[17] This aquo ion was first prepared in low yields (ca. 20%) by two different routes; the self-assembly reaction of $[Mo(CO)_6]$ with anhydrous Na_2S in acetic anhydride[51] and oxidative fragmentation of the tetrametallic $[Mo_4S_4(H_2O)_{12}]^{5+}$ aquo ion in acidic solutions.[52,53] An almost quantitative synthesis of this aquo ion has been developed that involves abstraction of sulfur from the $[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S_2)_3X_6]^{2-}$ (X = Cl, Br) trimer with PPh_3.[54] The analogous selenium cluster $[Mo_3Se_4(H_2O)_9]^{4+}$ has been prepared in a similar manner from the selenium-rich trimer $[PPh_4]_2[Mo_3(\mu_3\text{-}Se)(\mu_2\text{-}Se_2)_3Cl_6]$, which was aquated in acid prior to the diselenide reduction to selenide with PPh_3.[55] The most efficient method for the synthesis of the $[W_3Q_4(H_2O)_9]^{4+}$aquo ions (yields ca. 60−70%) involves treatment of the corresponding $\{W_3Q_7Br_4\}_x$ polymeric phases with hypophosphorous acid in hot HCl.[56,57] Purification of the aquo ions is achieved by cation exchange chromatography. The sulfur-bridged trimers are stable in acidic solution, but the selenium analogues are less stable, giving a deposit of red selenium after a week.[57,58]

First-row transition metal incorporation into the $[Mo_3S_4]^{4+}$ aquo ion has been achieved by treating $[Mo_3S_4(H_2O)_9]^{4+}$ with iron,[50] cobalt,[59] nickel[60] and copper metal[61] (M′) in acidic solution, HCl or *p*-toluenesulfonic acid (Hpts), to afford the corresponding heterodimetallic $[Mo_3M'S_4(H_2O)_{10}]^{4+}$ complexes with 14, 15, 16 and 17 metal cluster electrons for M′ = Fe, Co, Ni and Cu, respectively, as shown in Equation (6).

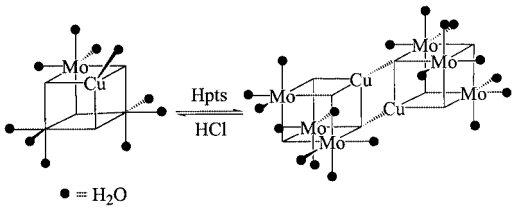


(6)

This synthetic strategy has also been applied to obtain the selenido derivative $[Mo_3NiSe_4(H_2O)_{10}]^{4+}$ [48] or the tungsten-containing cluster sufides $[Mo_{3-x}W_xNiS_4(H_2O)_{10}]^{4+}$ (x = 0−3).[62] Alternatively, the $[Mo_3NiS_4(H_2O)_{10}]^{4+}$ aquo ion has been synthesised by a self-assembly reaction between $[NH_4]_2[MoS_4]$ and nickel metal in HCl solution or by reduction of an Ni^{2+} salt in the presence of $[Mo_3S_4(H_2O)_9]^{4+}$.[63,64] With the exception of the $[Mo_3NiS_4(H_2O)_{10}]^{4+}$ complex, the remaining heterodimetallic aquo ions, especially the cobalt derivative, are very air-sensitive.

The Mo_3Fe and Mo_3Ni aquo ions, having an even number of cluster metal electrons, crystallised from *p*-toluensulfonic acid solutions as isolated single cubes of formula $[Mo_3M'S_4(H_2O)_{10}](pts)_4\cdot 7H_2O$ (pts = *p*-toluenesulfonate), while the analogous Co and Cu heterodimetallic clusters, having an odd number of metal electrons, crystallise under the same conditions as an edge-linked double cuboidal structure formulated as $[\{Mo_3M'S_4(H_2O)_9\}_2](pts)_8\cdot nH_2O$ (M′ = Co, n = 18; M′ = Cu, n = 20). The Co−Co and Cu−Cu bond lengths in these double cubes are 2.498 and 2.426 Å, respectively, corresponding to an M′−M′ single bond. A summary of intermetallic distances for $M_3M'S_4$ cubanes is presented in Table 2.

In contrast to the $[M_2M'_2S_4]$ heterodimetallic complexes, changes in the heterometal within the $[Mo_3M'S_4]^{4+}$ aquo ion series does not produce significant differences in the intermetallic distances that can be correlated with the number of metal cluster electrons. The single-to-double cube dimerisation reaction is reversible in the case of Cu, as shown in Equation (7).[76,77]



(7)

Table 2. Selected bond lengths [Å] for some representative $M_3M'S_4$ cubane-type clusters (standard deviations for averaged values are given in brackets)

Cluster	No. of metal electrons	M−M	M−M′	Ref.
Single cubes:				
$[Mo_3FeS_4(H_2O)_{10}]^{4+}$	14	2.767[7]	2.671[11]	[65]
$[Mo_3FeS_4Cp'_3(SH)]$	14	2.86[2]	2.79[2]	[24]
$[Mo_3CoS_4Cp'_3CO]$	16	2.838[11]	2.745[11]	[24]
$[Mo_3NiS_4(H_2O)_{10}]^{4+}$	16	2.755[10]	2.640[9]	[60]
$[Mo_3NiS_4(H_2O)_9CO]^{4+}$	16	2.744[8]	2.677[7]	[66]
$[\{Mo_3NiS_4Cp'_3\}_2(\mu\text{-}C_4H_8S_2)]^{2+}$	16	2.819[13]	2.71[1]	[67]
$[W_3NiS_4(H_2O)_9(C_2H_4)]^{4+}$	16	2.7137(9)	2.701(2)	[62]
$[W_3NiS_4Cp'_3(PPh_3)]^{+}$	16	2.809[1]	2.733[9]	[68]
$[Mo_3CuS_4(Hnta)_3Cl]^{2-}$	16	2.778(1)	2.838(2)	[69]
$[Mo_3CuS_4(dmpe)_3Cl_4]^{+}$	16	2.782[1]	2.823[8]	[5]
$[W_3CuS_4(dmpe)_3Br_4]^{+}$	16	2.780[2]	2.884[7]	[5]
$[Mo_3CuS_4(dtp)_3(\mu\text{-}OAc)(DMF)I]$	16	2.73[5]	2.85[4]	[70]
$[Mo_3CuS_4(n\text{Pr}_2PS_2)_3(\mu\text{-}n\text{Pr}_2PS_2)(py)I]$	16	2.769[9]	2.857[14]	[71]
$[W_3CuS_4(dtp)_3(\mu\text{-}O_2CCl_3)(CH_3CN)I]$	16	2.73[3]	2.87[5]	[72]
$[Mo_3CuS_4(Et_2NCS_2)_3(\mu\text{-}Et_2NCS_2)(py)I]$	16	2.76[3]	2.849[13]	[73]
$[Mo_3CuS_4(tdci)_3Br]^{3+}$	17	2.832[9]	2.916[12]	[74]
$[Mo_3CuSe_4(dmpe)_3Cl_4]^{+}$	16	2.839[4]	2.839[4]	[75]
Edge-linked double cubes:				
$[\{Mo_3CoS_4(H_2O)_9\}_2]^{8+}$	15	2.744[11]	2.64[2]	[59]
$[\{W_3NiS_4(H_2O)_9\}_2]^{8+}$	16	2.747[7]	2.66[4]	[62]
$[\{Mo_3CuS_4(H_2O)_9\}_2]^{8+}$	17	2.730[7]	2.89[8]	[61]

The $[Mo_2WNi]^{4+}$ aquo ions crystallise as single cuboidal clusters in the same way as the analogous Mo_3Ni complexes. However, further substitution of Mo for W results in the formation of $[\{Mo_nW_{3-n}NiS_4(H_2O)_9\}_2](pts)_8\cdot 20H_2O$ (n = 0, 1) edge-linked double cuboidal structures, with Ni−Ni bond lengths of 2.549 Å for MoW_2Ni and 2.56 Å for the W_3Ni cluster.[62]

In contrast to the reactivity just reported for the incomplete cuboidal molybdenum sulfide versus a first-row transition metal, the $[Mo_3S_4]^{4+}$ aquo ion does not react with chromium metal. Instead, the $[Mo_3CrS_4(H_2O)_{12}]^{4+}$ cluster is prepared by treating $[Mo_3S_4(H_2O)_9]^{4+}$ with $[Cr(H_2O)_6]^{2+}$. This Mo_3Cr cube has only been characterised spectroscopically in solution.[78] The reaction of the $[Mo_3S_4]^{4+}$ aquo ion with Cu^+, or with a Cu^{2+} salt in the presence of sodium borohydride, gives the 16 electron metal cluster $[Mo_3CuS_4(H_2O)_{10}]^{5+}$ in contrast to the 17 electron species obtained by direct reaction between the trimer and the metal.[76] The 16 electron Mo_3Cu clusters are air-stable in HCl due to coordination of Cl^- to the heterometal, but they tend to disproportionate to Cu^{2+}(aq.) and $[Mo_3CuS_4]^{4+}$in noncoordinating acids.[69] The existence of the 16 metal electron $[Mo_3CuS_4]^{5+}$ complex is also detected as the first step of the oxidation reaction of the corresponding 17 metal electron cluster.[76] The transmetallation reaction of $[Mo_3M'S_4(H_2O)_{10}]^{4+}$ (M′ = Fe, Ni) in the presence of a 10 molar excess of a Cu^{2+} salt in 2 M HCl also produces the 16 electron $[Mo_3CuS_4(H_2O)_9Cl]^{3+}$ aquo complex as the major reaction product.[79] When the cluster concentration is increased to ca. 0.1 M, the reaction of $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ with a Cu^{2+} salt under similar conditions instead affords the 17 electron cluster $[Mo_3CuS_4(H_2O)_9Cl]^{4+}$ as the major product (yield = 37%), while the 16 electron cluster is only obtained in 5% yield.[69] Further investigations are required to understand these replacement reactions.

In the same way that chlorine coordination to the heteroatom stabilises the $[Mo_3CuS_4]^{4+}$ cluster core, substitution of the water molecule coordinated to the extremely air-sensitive $[Mo_3CoS_4]^{4+}$ aquo ion affords the more stable $[Mo_3CoS_4(H_2O)_9(CO)]^{4+}$ cluster.[48] The nickel aquo cluster also coordinates CO and ethylene (L) in aqueous or organic solutions to give $[M_3NiS_4(H_2O)_9L]^{4+}$ and $[Mo_3NiSe_4(H_2O)_9L]^{4+}$.[62] Coordination of ethylene is favoured by an increase in the number of tungsten atoms in the cluster core.

The heterodimetallic $[M_3M'S_4]^{4+}$ cluster aquo ions can also be derivatised by substitution of the water molecules coordinated to the group-6 metal by mono-,[65] bi-[80] or tridentate ligands.[60] In some cases, this substitution results in complexes having an enhanced stability, a fact that has allowed the crystallisation and further X-ray characterisation of certain cluster cores. For example, addition of nitrilotriacetate (H_3nta + base) to the $[Mo_3CuS_4(H_2O)_9Cl]^{4+}$ aquo complex allows crystallisation of the single cube $[Mo_3CuS_4(Hnta)_3Cl]^{2-}$ as the K^+ or $[NH_4]^+$ salt.[69] The Mo−Mo and Mo−Cu distances in this 16 metal electron cluster are similar to those observed for the $[\{Mo_3CuS_4(H_2O)_9\}_2](pts)_8\cdot 20H_2O$ double cube with 17 metal electrons per cubane unit. In other cases, derivatisation of the heterodimetallic $[M_3M'S_4]^{4+}$ cluster aquo ions produces unexpected results. For example, reaction of $[Mo_3CuS_4(H_2O)_{10}]^{4+}$ with concentrated ammonia yields the $[\{(NH_3)_6(H_2O)(OH)Mo_3CuS_4(\mu_2\text{-}O)\}_2]Cl_4\cdot 8H_2O$ com-

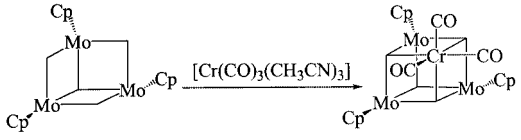
plex in which two cuboidal $[Mo_3CuS_4]^{5+}$ cores are bridged by two oxygen atoms. The oxidant of the cluster core in this reaction remains unidentified.[81]

$M_3M'S_4$ Clusters with Cyclopentadienyl Ligands

$[Mo_3M'S_4Cp_3]^{n+}$ (n = 0, 1) cluster compounds with M′ = Cr, Fe, Co and Ni have been prepared through [3 + 1] building-block synthetic strategies using the $[Mo_3S_4Cp_3]^+$ incomplete cuboidal cluster as the precursor in the case of Cr and Ni, or by rearrangement of tetrametallic cluster species with Mo_2Fe_2 and Mo_2Co_2 units. Of the analogous tungsten complexes, only the nickel derivative $[W_3NiS_4Cp'_3]^+$ has been prepared.

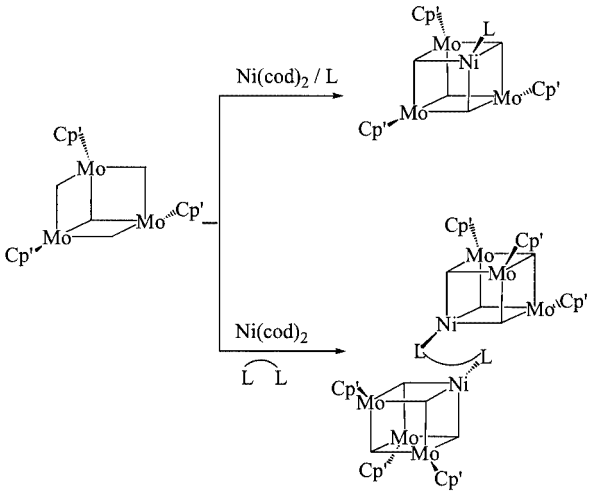
The synthesis of the trinuclear complex $[Mo_3S_4Cp_3][Sn(CH_3)_3Cl_2]$ was first reported in 1971 from the reaction of $[MoCp(CO)_3Cl]$ with $[Sn(CH_3)_3]_2S$ in 1,2-dimethoxyethane in 50% yield.[82] An improved synthetic procedure for this trimer that uses the $[Mo_3S_4]^{4+}$ aquo ion as the starting material has recently been reported. This synthesis can also be used to prepare the analogous tungsten complex. Reaction of the $[M_3S_4(H_2O)_9]^{4+}$ ion (M = Mo or W) with triethyl orthoformate in the presence of a catalytic amount of *p*-toluenesulfonic acid converts the aquo ligands into ethanol ligands which can be further replaced by acetonitrile and tetrahydrofuran. Finally, addition of TlCp or TlCp′ results in formation of the desired $[M_3S_4Cp^{\#}_3](pts)$ ($Cp^{\#}$ = Cp or Cp′) species. Treatment with CH_3CN prior to THF is carried out to ensure removal of traces of $(CH_3CH_2O)_3CH$ and results in an improvement of the final yield. Typical yields for these reactions are 85% for molybdenum and 22% for tungsten.[68,83,84] The reduced $[Mo_3S_4Cp^{\#}_3]$ ($Cp^{\#}$ = Cp, Cp*) species have been synthesised by reaction of $[MoH(CO)_3Cp]$ or $[MoH(CO)_2Cp[P(OC_6H_5)_3]$ with propylene sulfide in THF or by reduction of $[Mo\{S(tBu_3)_3\}Cp^*]$ with sodium amalgam in 88% yield.[85,86]

$[Mo_3S_4Cp_3](pts)$ reacts with $[Cr(CO)_3(CH_3CN)_3]$ in CH_2Cl_2 to produce $[Mo_3CrS_4Cp_3(CO)_3][pts]$ in 64% yield, as represented in Equation (8).[83]



(8)

This Mo_3CrS_4 cluster is stable in air for at least a few days and soluble in common polar organic solvents. This reaction also works for the analogous molybdenum and tungsten carbonylmetal compounds, showing that the [3 + 1] insertion reactions are not restricted to aqueous media. A nickel atom can also be incorporated into the $[Mo_3S_4Cp'_3][pts]$ and $[W_3S_4Cp'_3][pts]$ complexes by treating these trimeric precursors with $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene) to yield the coordinatively unsaturated cubane-like cluster $[M_3NiS_4Cp'_3][pts]$ in high yields.[68,87] The reaction produces an instant colour change from green to dark brown in the case of molybdenum while, for the tungsten complex, the colour change from violet to brown takes approximately 3 h, probably due to solubility problems. Addition of various ligands to the reaction mixture [triphenylphosphane, M = W; dimethyl sulfide, diethyl sulfide, di(*tert*-butyl) sulfide, tetrahydrothiophene, 1,4-dithiane, thiochroman-4-ol, pyridine, quinoline, 4,4′-bipyridine, M = Mo] saturates the vacant Ni coordination site, as represented in Scheme 6.[67]



Scheme 6. Coordination of mono- and bidentate ligands to the $[Mo_3NiS_4Cp'_3]^+$ cluster

The crystal structures of the tungsten derivative $[W_3NiS_4Cp'_3(PPh_3)][pts]$ and the molybdenum derivatives $[\{Mo_3NiS_4Cp'_3\}_2(\mu_2\text{-}C_4H_8S_2)][pts]_2$ and $[\{Mo_3NiS_4Cp'_3\}_2(\mu_2\text{-}(4,4'\text{-bipy})][pts]_2$ have been determined. In the last two examples, the 1,4-dithiane and the 4,4′-bipyridine ligands act as bridges between two cubane units. The intermetallic distances for these M_3Ni complexes having 16 metal electrons are similar to those found for the analogous aquo derivatives (see Table 2). Structural data for the molybdenum complexes, where the Ni atom coordinates a sulfur or a nitrogen atom, do not indicate any activation of the C−S or C−N bond.

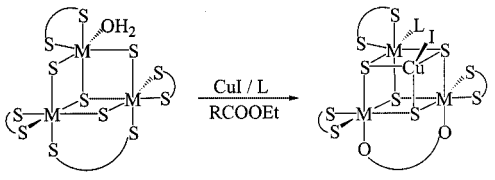
The trimolybdenum cluster $[Mo_3CoS_4Cp'_3(CO)]$ is formed in ca. 15% yield by heating $[Mo_2Co_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Cp'_2(CO)_4]$ in pyridine at 150 °C for 3 h, or by treatment of $[Mo_2Co_2(\mu_3\text{-}S)_4Cp'_2(CO)_2]$ with a CO/H_2 mixture in toluene at 250 °C (15−30% yield), as represented in Scheme 3.[24] The resulting Mo_3Co cluster appears to be a thermodynamic sink for the decomposition of the two Mo_2Co_2 complexes. The intermetallic Mo−Mo and Mo−Co distances in this 16 electron Mo_3Co complex are ca. 0.09 and 0.027 Å longer than the corresponding distances in the 16 electron Mo_3Ni cluster. Finally, the cuboidal $[Mo_3FeS_4Cp'_3(SH)]$ compound is obtained in low yields from the reaction between the butterfly-type cluster $[Mo_2Fe_2(\mu_3\text{-}S)_2Cp'_2(CO)_8]$ and thiophene at 150 °C in a pressure reactor.[24] The Mo−Mo and Mo−Fe distances in this cluster are 0.09 and 0.12 Å longer than the equivalent

distances in the $[Mo_3FeS_4]^{4+}$ aquo cluster which also possesses 14 metal cluster electrons.

$M_3M'S_4$ Clusters with Sulfur-Containing Ligands

In parallel to the development of the aqueous chemistry of the $M_3M'Q_4$ complexes, a non-aqueous chemistry arises from inserting Cu into M_3S_4 units derivatised with dithiophosphates [dtp = $(EtO)_2PS_2^-$]. This was subsequently extended to other sulfur-containing ligands such as dithiocarbamates (dtc = $Et_2NCS_2^-$) and dithiophosphinates ($R_2PS_2^-$). These complexes are always prepared through [3 + 1] synthetic routes. The trimeric molybdenum and tungsten dithiophosphate precursors $[M_3S_4\{(EtO)_2PS_2)_3(\mu_2\text{-}(EtO)_2PS_2\}(H_2O)]$ have been synthesised by reaction of $MoCl_3{\cdot}H_2O$ in ethanol or EtOH/HCl solutions.[88] The water molecule is easily replaced by other ligands such as dimethylformamide and pyridine. The dithiocarbamate and dithiophosphinate derivatives have been prepared by reduction of the disulfido μ_2-S_2 bridging ligand in $[Mo_3(\mu_2\text{-}S_2)_3(\mu_3\text{-}S)(Et_2NCS_2)_3]^+$ and $[Mo_3(\mu_2\text{-}S_2)_3(\mu_3\text{-}S)(R_2PS_2)_3](R_2PS_2)$ (R = Et, *n*Pr) with triphenylphosphane to yield $[Mo_3(\mu_2\text{-}S)_3(\mu_3\text{-}S)(Et_2NCS_2)_3(\mu_2\text{-}Et_2NCS_2)(H_2O)]$ and $[Mo_3(\mu_2\text{-}S)_3(\mu_3\text{-}S)(R_2PS_2)_3(\mu_2\text{-}R_2PS_2)(py)]$, respectively.[89–92] The structures of these trinuclear clusters are similar to other M_3Q_4 trimers, with octahedral metal environments and with the bidentate chelating ligand occupying positions *trans* to the capping and one bridging sulfur atoms. The remaining coordination site is occupied by the sulfur atom of the bridging bidentate ligand for two of the metal atoms, and by a water or pyridine molecule for the remaining metal atom. This ligand arrangement gives rise to chirality.[93]

A series of heterodimetallic complexes with $[M_3CuS_4]^{5+}$ cores and consequently 16 metal cluster electrons has been synthesised by treating $[M_3S_4((EtO)_2PS_2)_3(\mu_2\text{-}(EtO)_2PS_2)(L)]$ (L = H_2O, CH_3CN) with CuI in organic solvents in the presence of various acetates, producing tetranuclear clusters of the general formula $[M_3CuS_4((EtO)_2PS_2)_3(\mu_2\text{-}O_2CR)L]$ (R = CH_3, CF_3, CCl_3; L = DMF, DMSO, py, CH_3CN), as shown in Equation (9).[70,94,95]



(9)

The Mo_3CuS_4 dithiocarbamate and dithiophosphinate complexes $[Mo_3CuS_4(Et_2NCS_2)_3(\mu_2\text{-}Et_2NCS_2)(py)I]$ and $[Mo_3CuS_4(R_2PS_2)_3(\mu_2\text{-}R_2PS_2)(py)I]$ (R = Et, *n*Pr) have also been prepared by reaction of the corresponding trimeric precursors with CuI in pyridine.[71,96,97] The presence of acetate ligands in the reaction media does not cause substitution of the bridging dithiocarbamate or dithiophosphinate, as is observed for the analogous dithiophosphate compound. This ligand environment provides these M_3CuS_4 complexes with great stability towards air oxidation, in contrast to the equivalent aquo complexes.

The structures of several of these derivatives have been determined by single-crystal X-ray diffraction experiments. Intermetallic distances for some representative complexes are listed in Table 2. The coordination environment around the M atoms is pseudooctahedral, as observed for the trinuclear starting materials, although in the case of the dithiophosphate derivatives the bridging μ_2-$(EtO)_2PS_2^-$ ligand has been substituted for a bridging acetate ligand. The pseudotetrahedral Cu atom is coordinated to the iodine atom. The average M−M and M−Cu bond lengths are similar to those reported for the 16 metal electron aquo derivative $[Mo_3CuS_4Cl(Hnta)_3]^{2+}$. However, the presence of a ligand bridging two molybdenum or tungsten atoms causes a shortening of this M−M bond length by ca. 0.08 Å, with concomitant lengthening of the M−Cu bonds by ca. 0.05−0.08 Å. The M−Cu distances are between 0.1 and 0.2 Å longer than the M−M′ (M′ = Co or Ni) bond lengths observed for other 16 metal electron clusters.

$M_3M'S_4$ Clusters with Phosphanes

A series of heterodimetallic clusters of molybdenum and tungsten with $M_3M'Q_4$ (Q = S, Se) units have been reported for M′ = Cu, where the group-6 metal atom is coordinated to different bidentate phosphanes such as dmpe or dppe. Recent work in our group has shown that the procedures employed can also be extended to Co and Ni.[98] The preparation of these tetrametallic species has also been achieved through a [3 + 1] synthetic strategy, using the molecular clusters $[M_3Q_4(diphosphane)_3X_3]^+$ [M = Mo, W; Q = S, Se; X = Cl, Br; diphosphane = 1,2-bis(dimethylphosphanyl)ethane (dmpe), 1,2-bis(diphenylphosphanyl)ethane (dppe)] as starting materials. The excision of polymeric $\{M_3Q_7X_4\}_x$ phases with chalcogen-abstracting ligands such as phosphanes has proved to be a general method for the preparation of M_3Q_4 incomplete cuboidal clusters having phosphanes as ancillary ligands.[54,99–101] The cationic $[M_3S_4(dmpe)_3X_3]^+$ trimers are obtained in high yields (> 90%) by excision of the corresponding $\{M_3S_7X_4\}_x$ polymers with dmpe in refluxing acetonitrile.[102] The analogous dppe derivatives $[M_3S_4(dppe)_3X_3]^+$ are obtained in ca. 75% under similar reaction conditions. This synthetic method can also be extended to selenium, with typical yields of 50−65% for the $[M_3Se_4(dmpe)_3X_3]^+$ complexes and 67−85% for the $[M_3Se_4(dppe)_3X_3]^+$ compounds.[75,98,103,104] Alternatively, the $[M_3S_4(diphosphane)_3X_3]^+$ [diphosphane = dmpe, 1,2-bis(diethylphosphanyl)ethane (depe)] complexes can be obtained in 15−55% yields by treating the metal halides with NaHS in THF/methanol in the presence of an excess of dmpe or depe.[105–107] The synthesis of the (dppe)molybdenum derivatives in approximately 50% yield has been reported from the reaction of the molecular cluster $[Mo_3S_7X_6]^{2-}$ (X = Cl, Br) with dppe in methanol.[54] In addition, the $[M_3Se_4(dppe)_3X_3]^+$ cationic cluster can be obtained by excision of the polymeric precursor in molten

dppe, with an overall reaction yield of 40 and 62% for the Mo and W derivatives, respectively.[108] These $[M_3Q_4(diphosphane)_3X_3]^+$ complexes have one phosphorus atom *trans* to the capping sulfur atom and another *trans* to the bridging sulfur atom, as shown in Figure 4. This arrangement results in chiral complexes with an effective C_3 symmetry. However, the nonstereospecificity of the reaction leads to racemic mixtures.

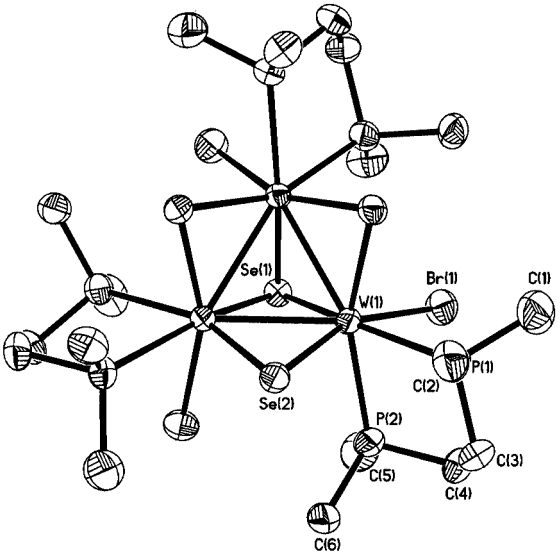


Figure 4. ORTEP representation of the $[W_3Se_4(dmpe)_3Br_3]^+$ cation; only the atoms in the asymmetric unit are labeled

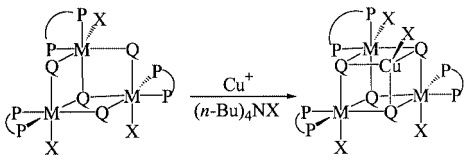
The first attempt to introduce a first-row transition metal atom into an incomplete cuboidal M_3S_4 unit was the reaction between the molybdenum(IV) trimer $[Mo_3S_4Cl_4(PEt_3)_3(MeOH)_2]$ and $[Ni(cod)_2]$ in THF which afforded a pentanuclear $Mo_3Ni_2S_4$ cluster instead of the expected Mo_3Ni cubane. X-ray structural analysis of this pentanuclear sulfido cluster revealed a square-pyramidal core with an Mo_2Ni_2 base, an Mo atom at the vertex, and short intermetallic distances: d(Mo−Mo) = 2.65−2.67 Å, d(Mo−Ni) = 2.50−2.67 Å and d(Ni−Ni) = 2.71 Å. An oxidation state assignment of $Mo_3^{IV}Ni_2^0$ has been proposed based on the XPS spectra, suggesting that Ni incorporation into the Mo trimer occurs without changes in the metal oxidation states.[101]

Cubane-type Mo_3CuQ_4 and W_3CuS_4 clusters have been obtained by reaction of the trimers $[Mo_3Q_4(dmpe)_3X_3][PF_6]$ and $[W_3S_4X_3(dmpe)_3][PF_6]$ in THF with CuX, or with $[Cu(CH_3CN)_4][PF_6]$ in the presence of a tetrabutylammonium halide salt, to give the corresponding $[M_3CuQ_4(dmpe)_3X_4][PF_6]$ heterodimetallic tetramers, according to Equation (10).[5,75]



(10)

The products are air-stable and soluble in common organic solvents such as CH_2Cl_2 and CH_3CN. Typical yields for the reaction range from 40 to 73%. The reaction takes place without overall changes in the oxidation states of the metal atoms, and these M_3CuQ_4 clusters possess 16 electrons for metal−metal bonding. X-ray structural analysis reveals that there is no significant structural rearrangement on going from M_3Q_4 to M_3CuQ_4, and in consequence the resulting heterodimetallic clusters are also chiral, although the product is again obtained as a racemic mixture. Metal−metal distances for some representative complexes are listed in Table 2. The M−M distances do not change significantly between molybdenum and tungsten, while the M−M bonds in the selenido derivatives are ca. 0.06 Å longer than the corresponding distances in the sulfido complexes. The Mo−Cu bonds in the sulfido clusters are 0.04 Å longer than the Mo−Mo distance, while the W−Cu bond is 0.1 Å longer than the W−W distance. This distortion of the tetrametallic unit can be regarded as an elongation along the C_3 axis through Cu, and is less pronounced for the selenido clusters in comparison to the analogous sulfido complexes. The average M−M and M−Cu bond lengths are similar to those reported for other M_3CuQ_4 clusters having an identical metal electron population of 16 e^-.

As previously mentioned, trinuclear $[M_3Q_4(diphosphane)_3X_3]^+$ (diphosphane = dmpe, dppe; X = Cl, Br) complexes can also incorporate atoms of other metals such as nickel or cobalt through reaction of the trimeric cations with $[Ni(cod)_2]$ or $[Co_2(CO)_8]$.[98] Alternatively, an entry to these complexes through the $[Mo_3NiS_4(H_2O)_9Cl]Cl_3$ aquo ion has been proposed. Water substitution takes place by treating the solid aquo ion with dppe in methanol to afford $[Mo_3NiS_4(dppe)_3Cl_4]$ in 43% yield.[80] In contrast to the reactivity observed at the Ni site in the analogous cyclopentadienyl complexes, the Cl ligand attached to the Ni atom cannot be replaced by CO, PMe_3 or PMe_2Ph. On the other hand, electrospray mass spectrometry of the Ni derivatives prepared by direct Ni insertion into the trimer $[M_3S_4(diphosphane)_3X_3]^+$ shows coordination of a solvent molecule to the heteroatom. This solvent molecule can then be substituted for a various N- and S-donor ligands.

$M_3M'S_4$ Clusters with N−O Donor Tripodal Ligands

There is only one example of this type of clusters but it deserves special mention because it is the only case of an Mo_3CuS_4 complex with a simple cubane structure and an odd number of metal cluster electrons (17 e^-). The compound $[Mo_3CuS_4(tdci)_3Br]^{3+}$ [tdci = 1,3,5-trideoxy-1,3,5-tris(dimethylamino)-*cis*-inositol] was prepared in 55% yield by treating the trinuclear precursor $[Mo_3S_4(tdci)_3]^{4+}$ with copper metal in ethanol.[74] This synthetic route contrasts with the other procedure reported in non-aqueous solvents, in that Cu metal is used as starting material instead of a Cu^I halide, and this difference results in a change in the number of cluster metal electrons from 16 to 17. This complex has been structurally characterised and the intermetallic distances are listed in Table 2. The observed Mo−Mo and Mo−Cu distances in $[Mo_3CuS_4(tdci)_3Br]^{3+}$ are longer

than those found in all reported Mo_3CuS_4 complexes having single cube structures and 16 metal electrons.

Electronic Structure, Electrochemistry and Magnetism

$M_2M'_2S_4$ Clusters

The most common ligand arrangement for the $M_2M'_2$ cubane-type clusters results in a pseudooctahedral geometry around the 4d or 5d metal, M, and a pseudotetrahedral coordination environment for the first-row transition metal, M′. Harris et al. have developed a qualitative molecular orbital (MO) scheme for this system.[109] In this model, the metal M "t_{2g}" and the M′ "t_2" orbitals combine to form a set of six bonding and six antibonding orbitals, while the M "e_g" and the M′ "e" orbitals remain nonbonding. This results in a total of ten metal-based MOs; four nonbonding low-lying MOs which are predominately M′ in character and six bonding "t" symmetry MOs of higher energy. Based on this model, a cluster metal electron count of 20 is expected to be necessary for a completely bonding metal $M_2M'_2$ tetrahedron and any metal electrons in excess of this number are expected to occupy antibonding orbitals.

Table 1 lists intermetallic distances together with carbonyl and nitrosyl frequencies for some representative complexes with $Mo_2M'_2S_4$ and $W_2M'_2S_4$ central units. The strongest metal−metal interactions occur between the 4d or 5d metals in these complexes, and the weakest interactions are between the two 3d metals. These clusters can exist with metal electron counts between 16 and 22, although in the case of Cu and Ni only 22 electron systems have been reported to date. In the 20 electron clusters there are nominally six metal−metal bonds, and a bond order of one is assigned to the M′−M′ bond. Differences in bond lengths between the Fe and Co complexes can be ascribed to the slightly larger covalent radius of Fe as compared to Co. All 20 electron clusters are diamagnetic.

The clusters with 16 or 18 metal electrons show a marked increase in the M′−M′ distance. In the 18 e^- systems, eight electrons will occupy the low-lying nonbonding orbitals leaving ten electrons to fill five metal−metal bonding orbitals. Different situations arise depending on the nature of these MOs, which may be highly delocalised over the tetrametallic core or localised between metal pairs. In the $[Mo_2Co_2S_4Cp^{Et}_2X_2]$ (X = halogen) clusters, it appears that the electron density has been removed from the Co−Co bond, resulting in a long nonbonding Co···Co distance. In the thiolato cluster $[Mo_2Co_2S_4Cp^{Et}_2(SPh)_2]$, much less electron density appears to be removed from the Co−Co bond and an apparent bond order near 0.5 results.[21] These differences can be attributed to the differences in electronegativities and π-donor characteristics of the ligands on the Co atoms. These differences evidently affect the degree of localisation/delocalisation of the metal-based MOs involved in Co−Co bonding. In the 16 electron $[Mo_2Fe_2S_4Cp^*_2X_2]$ cluster, the electron density is also preferentially removed from the Fe−Fe bond.[20] The ^{1}H NMR spectrum of this complex in $CDCl_3$ showed a broad singlet at δ = 1.81 ppm, indicating the weak paramagnetic nature of this compound. On the other hand, the ^{1}H NMR spectrum of the 18 e^- $[Mo_2Co_2S_4Cp^{Et}_2X_2]$ (X = I, Br, Cl) complexes showed clear NMR peaks corresponding to those expected for Cp^{Et} ligands on diamagnetic clusters even though these complexes are paramagnetic both in solution and in the solid state. These $[Mo_2Co_2]^{12+}$ halo compounds exhibit complex spin equilibria with thermally accessible S = 1, 2 and 3 spin states and consequently there is no simple explanation for their apparently diamagnetic ^{1}H NMR spectra. In contrast, the analogous thiolate cluster shows simple paramagnetism consistent with an S = 1 spin state, which may simply mean that the S = 2 state is not thermally accessible at the temperature studied since the thiolate ligands are better π-donors than halide ligands. No ^{1}H NMR signal is observed for the $[Mo_2Co_2S_4Cp^{Et}_2(SPh)_2]$ thiolate cluster, as expected for a paramagnetic system. The differences in magnetic behaviour between the halide and thiolate $[Mo_2Co_2]^{12+}$ complexes are not well understood and require further investigation.

The butterfly arrangement observed in the 16 and 18 metal electron clusters is also seen in the 21 and 22 e^- complexes, and the M−M and M−M′ distances correspond to single bonds (see Table 1). The M′−M′ distance in the 22 metal electron complex is nonbonding, suggesting that the HOMO is an M′−M′ σ* antibonding orbital. The Co−Co bond lengths of 2.75 Å found in the 21 e^- clusters are halfway between the fully bonded distance of 2.57 Å found in the 20 electron clusters and the nonbonding distance observed for the 22 electron systems, supporting the M′−M′ antibonding character of the HOMO. This interpretation is also supported by the ESR spectrum of the $[Mo_2Co_2S_4Cp^{Et}_2(CO)_2]^-$ complex which is consistent with the odd electron being delocalised over two Co atoms, each with spin I = 7/2; 13 of the expected 15 lines were observed, with the outer two being too weak.[26] Addition of another electron reduces the M′−M′ bond order to zero, producing diamagnetic complexes.

Qualitative bonding schemes have also been developed for other M_2M_2' cubane sulfido clusters with different metal coordination environments to the ones previously discussed. Changes in the symmetry of the system result in different electron counts for the formation of intermetallic cluster bonds. For example, the Dahl group has developed an MO energy diagram for homometallic $[M_4S_4Cp_4]$ clusters based on the cubic T_d symmetry of the metallic tetrahedron that makes it possible to predict and understand the changes in metal−metal bonding which accompany changes in the number of electrons.[110] The number of metal electrons required for a completely filled set of six M−M bonding orbitals (a_1 + e + t_2) is 12. This bonding scheme is also assumed to be applicable to the relatively rare heterometallic $[M_2M'_2S_4Cp_4]$ clusters. Although there are no structural data on these clusters, spectroscopic evidence suggests that the $[Mo_2Cr_2S_4Cp^*_2Cp_2]$ complex with 12

cluster electrons has a cubane-type structure with presumably a fully bonded metal tetrahedron.[38]

Another combination of metal coordination geometries is found in the $[Mo_2Fe_2Cp_2(CO)_4]$ cluster with a square-pyramidal "$FeS_3(CO)_3$" fragment. Fenske−Hall calculations on this complex predict that a cluster electron count anywhere between 12 and 16 e^- should lead to a completely bonding metal tetrahedron.[111] In the 18 electron $[Mo_2Fe_2Cp_2(CO)_4]$ compound, two electrons will occupy an Fe−Fe antibonding orbital and the long Fe−Fe distances observed in this complex agree with this prediction. On the other hand, the $[Mo_2Fe_2S_4(\mu_2\text{-}S_2CNEt_2)(S_2CNEt_2)_4]$ complex, also with a pentacoordinate iron fragment (albeit trigonal-bipyramidal instead of square-pyramidal) and 15 metal cluster electrons, has a full set of six metal−metal bonds.

Finally, the $[M_2Cu_2S_4(S_2C_2H_4)_2(PPh_3)_2]$ complexes with a pentacoordinate environment for the molybdenum and tungsten atoms that differs from the octahedral coordination found in the remaining $M_2M'_2$ clusters have the same butterfly-cubane geometry found in the octahedrally coordinated Mo and W complexes. Although no qualitative MO energy diagram of this system has been developed, the structural findings also agree with the existence of an antibonding HOMO localised between the two copper atoms, as theoretically predicted for the $M_2M'_2S_4$ cyclopentadienyl derivatives.

A comparison of the IR spectra of the Mo clusters and their W analogues shows that the ν_{CO} or ν_{NO} values are lower for the tungsten clusters in all cases, indicating a higher back-donation for the heavier metal which is effectively more electron-rich. This is consistent with the electrochemical results. Cyclic voltammetry studies show that these systems undergo reversible or quasireversible conversions between the 20, 21 and 22 metal electron species. The reported redox potentials for representative $M_2M'_2$ compounds are listed in Table 3. The tungsten clusters are more difficult to reduce and easier to oxidise than their molybdenum analogues, which is also consistent with the tungsten complexes being more electron-rich.

$M_3M'Q_4$ Clusters

Fenske−Hall MO calculations on $M_3M'S_4$ complexes show the presence of a group of three strongly bonding cluster MOs (1e and $1a_1$), a doubly degenerate M′-based bonding orbital (2e), a group of three weakly antibonding cluster MOs ($2a_1$ and 3e) and three strongly antibonding cluster MOs (4e and $3a_1$).[112] In the clusters having electron counts of 14 and 16 e^-, 12 metal electrons will occupy the cluster bonding orbitals and the weakly antibonding $2a_1$ orbital, and two or four electrons will partially or fully occupy the 3e HOMO. Metal electrons in excess of 16 will occupy strongly antibonding 4e and $3a_1$ cluster MOs.

This MO scheme is supported by magnetic susceptibility measurements on powdered samples of single crystals of $[Mo_3M'S_4(H_2O)_{10}][pts]_4\cdot 7H_2O$ (M′ = Fe, Ni) which give effective moments of 2.78 B.M. at 2.16 K and 3.26 B.M. at 269.95 K for M′ = Fe and 0.11 B.M. at 2.00 K and 1.26 B.M. at 260.7 K for M′ = Ni.[65,113,114] These results are consistent with the presence of two unpaired electrons in the Mo_3Fe 14 metal electron cluster and no unpaired electrons in the Mo_3Ni 16 metal electron cluster. No ESR spectra could be observed for frozen solutions of $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ in 2 M HCl or $HClO_4$ at temperatures down to 4.2 K, in agreement with an S = 1 ground state for this system. The magnetic susceptibility data for $[Mo_3M'S_4(H_2O)_{10}](pts)_4\cdot 7H_2O$ (M′ = Fe, Ni) were analysed using the vector model formalism of Kambe and the

experimental data were fitted to a model with an $Mo^{IV}Mo_2^{III}M'^{II}$ core. The ground state assignment agrees with the experimental results of ^{57}Fe-Mössbauer spectroscopy, where the oxidation state of the iron atom in the Mo_3Fe cluster has been determined to be +2.39. The order of the binding energies of Mo $3d_{3/2}$ and Mo $3d_{5/2}$ for these tetranuclear clusters and their trinuclear Mo_3 precursor have been obtained from X-ray photoelectronic spectra to give the following values: $E(Mo_3)$ = 233.7, 230.7 eV; $E(Mo_3Fe)$ = 233.1, 230.0 eV and $E(Mo_3Ni)$ = 233.3, 230.3 eV. The fact that $E(Mo_3) > E(Mo_3M')$ indicates a real charge transfer from the incorporated metal atom to the Mo_3 trimer, in good agreement with the previous $Mo^{IV}Mo_2^{III}M'^{II}$ metal oxidation state assignment.

A comparison of the bond lengths between the 14 and 16 metal electron M_3M' clusters with single-cube structures (see Table 2) does not show any clear relationship between the intermetallic distances and the number of metal electrons, in contrast to the general findings for $M_2M'_2$ complexes. This fact can be attributed to the highly delocalised nature of the bond in the M_3M' system. On the other hand, significant differences are observed in the metal−metal bond lengths between clusters with identical $Mo_3M'S_4$ cores and the same number of metal electrons, indicating that changes in the donor ability of the outer ligands have important effects on the electronic structure of the cluster.

Fenske−Hall calculations also show that the bonding/antibonding character of the middle group of cluster orbitals ($2a_1$ and 3e) is affected by the relative energies of the M′ and M_3 fragment orbitals.[112] As the M′ fragment orbitals increase in energy relative to the Mo_3 fragment orbitals, they mix more strongly with the unoccupied Mo_3S_4 fragment orbitals and as a result, the middle group of cluster orbitals becomes more bonding (or in this case, less antibonding). The energies of the M′ fragment increase in the order Cu < Ni < Co < Fe and thus the antibonding character of the ($2a_1$ and 3e) orbitals decrease according to the sequence Cu > Ni > Co > Fe. Consequently, the strength of the M−M′ interaction increases in the order Cu < Ni < Co < Fe. This effect is seen in the calculated M−M′ bond orders of 0.561 and 0.432 for $[Mo_3CoS_4Cp'_3(CO)]$ and $[Mo_3NiS_4(H_2O)_9(CO)]^{4+}$, respectively.

Discrete variational (DV) Xα calculations carried out on $[Mo_3M'S_4(H_2O)_{10}]^{4+}$ (M′= Fe, Ni) complexes agree with the general picture of the bond provided by the Fenske−Hall scheme, except that the Xα method gives a HOMO with "a" symmetry for both the Mo_3Fe and the Mo_3Ni complexes.[65] In the case of nickel the HOMO symmetry matches the LUMO of small molecules such as carbon monoxide or ethylene, thus explaining the reactivity of the Mo_3Ni cluster towards these molecules. The absence of reactivity found for the iron complex has been attributed to the lack of symmetry matching between the Mo_3Fe cluster HOMO and the LUMO of these small molecules.

The only compounds with $[M_3M'Q_4]$ cores and 17 metal cluster electrons to have been structurally characterised are those with M = Mo, M′ = Cu and Q = S, and two different structural types, isolated cube and double cubane, have been identified. In all cases, the Mo−Cu distances are longer than those observed for the analogous 16 electron clusters. Extended Hückel MO calculations on isolated Mo_3CuS_4 complexes suggest that the extra electron in the 17 e^- cluster occupies a strongly antibonding Mo−Mo and Mo−Cu orbital, thus explaining the longer Mo−Mo and Mo−Cu distances observed for $[Mo_3CuS_4(tdci)_3Br]^{3+}$ [tdci = *cis*-1,3,5-tris(dimethylamino)inositol].[74,77]

EPR studies on the 17 electron mixed-metal single-cubane cluster $[Mo_3CuS_4(H_2O)_{10}]^{4+}$, generated by decomposition of the double cubane cluster complex $[\{Mo_3CuS_4(H_2O)_9\}_2]^{8+}$, indicate that the complex is paramagnetic with S = 1/2 and the hyperfine splitting is consistent with a metal oxidation state formulation of $Mo_2^{IV}Mo^{III}Cu^{I}$ in which the paramagnetic centre is mainly located on one of the molybdenum atoms. The Mo^{III} site is not fixed at a specific position but moves over the three molybdenum sites at a rate of the order of 10^7 s^{-1}.[77] Extended Hückel MO calculations on the $[Mo_3CuS_4(H_2O)_{10}]^{4+}$ aquo ion agree with a large spin distribution on Mo, as observed experimentally.

The redox properties of these $M_3M'Q_4$ complexes have been investigated by cyclic voltammetry and a list of selected potentials is presented in Table 4.

In general, the M_3M' clusters are easier to reduce than their $M_2M'_2$ counterparts and, with the exception of the $[Mo_3NiS_4(dppe)_3Cl_4]$ complex which has a reversible oxidation wave at 0.2 V (vs. Fc), no oxidation processes have been reported for the M_3M' compounds, in contrast to the rich electrochemical activity found for the $M_2M'_2$ clusters upon oxidation.[80] As found for the $M_2M'_2$ system, the tungsten derivatives are more difficult to reduce than those of molybdenum. An interesting point arises when comparing the electrochemical behaviours of the tetrametallic $M_3M'Q_4$ clusters with those of their trimeric M_3Q_4 precursors. In the case of the Fe or Ni incorporation into the $[Mo_3S_4]^{4+}$ aquo ion, the resulting $[Mo_3M'S_4(H_2O)_{10}]^{4+}$ (M′ = Fe, Ni) complexes are ca. 0.45 V more difficult to reduce than their precursor aquo trimers.[65] These observations suggest a formal oxidation state for the metals of $Mo^{IV}Mo_2^{III}M'^{II}$, in agreement with the Mössbauer and XPS experimental results. The three reduction waves can then be attributed to three monoelectronic processes, namely $Mo^{IV}Mo_2^{III}M'^{II} \rightleftarrows Mo^{IV}Mo_2^{III}M'^{I} \rightleftarrows Mo^{IV}Mo_2^{III}M'^{0} \rightleftarrows Mo_3^{III}M'^{0}$, taking into account that the peak potential for the third reduction of these Mo_3Fe and Mo_3Ni complexes is very close to that for the third reduction of the $[Mo_3S_4]^{4+}$ aquo precursor in which $Mo^{IV}Mo_2^{III}$ is reduced to Mo_3^{III}.

In contrast to the Fe and Ni findings, Cu insertion into the $[M_3Q_4(dmpe)_3X_3]^+$ trimers results in an anodic shift of the redox potential in the sulfides and selenides of both molybdenum and tungsten.[5,75] This fact, together with the $Mo_2^{IV}Mo^{III}Cu^{I}$ oxidation state assignment of the 17 electron $[Mo_3CuS_4]^{4+}$ aquo ion (based on EPR results) and close inspection of the redox potential values for the Mo_3Cu complexes and their Mo_3 precursors (see Table 4), has led us to propose the following reduction mechanism: $Mo_3^{IV}Cu^{I} \rightleftarrows Mo_2^{IV}Mo^{III}Cu^{I} \rightleftarrows Mo^{IV}Mo_2^{III}Cu^{I}$. Note that the potential

values for the second reduction process of the Mo_3Cu complexes are similar to the peak potential of the first bielectronic wave found for the sulfide trimers, where Mo_3^{IV} is reduced to $Mo^{IV}Mo_2^{III}$. They are also similar to the peak potential of the second monoelectronic wave observed in the trinuclear selenides, where $Mo_2^{IV}Mo^{III}$ is reduced to $Mo^{IV}Mo_2^{III}$. A similar mechanism could be tentatively extended to the W_3CuS_4 complexes. In general the selenido clusters are more easily reduced than the analogous sulfides.

Properties and Applications

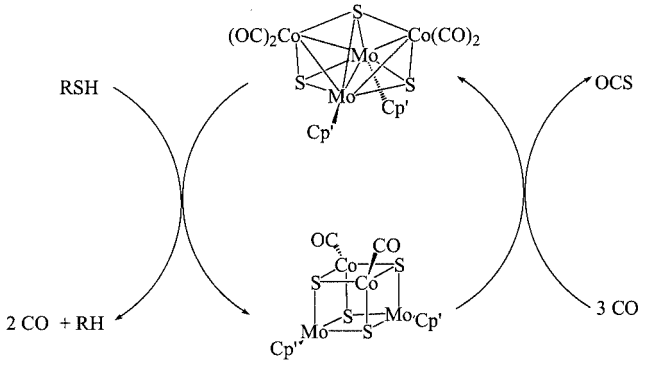
In this last section we highlight some properties of these $M_2M'_2S_4$ and $M_3M'Q_4$ transition metal chalcogenido clusters that make these complexes useful as materials with potential technological applications. We have chosen these properties based on our own interests in catalysis, nonlinear optics and the capability of these complexes to form supramolecular adducts.

Catalysis

The only molecular clusters of the type discussed in this microreview that have proved to resemble the industrial HDS heterogeneous catalyst are the $Mo_2Co_2S_x$ ($x = 3, 4$) complexes. As described in a previous section, $[Mo_2Co_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Cp'_2(CO)_4]$ reacts with thiols at temperatures of several hundred degrees below that used in the HDS of petroleum feed stocks to give the cubane cluster $[Mo_2Co_2S_4Cp'_2(CO)_2]$ in almost quantitative yields together with the corresponding hydrocarbon. No molecular rearrangement or alkene formation is observed in the course of the reaction. This fact, together with the stereospecificity of the reaction, indicates homolytic cleavage of the C−S bond.[25,115] The reaction of $[Mo_2Co_2S_3Cp'_2(CO)_4]$ with the thiolate $MeC_6H_4S^-$ was studied at −60 °C by NMR spectroscopy and it provides the first insight into the mechanism of desulfurisation. Initially, the thiolate ion binds a cobalt atom to form a red adduct. An increase of the temperature to −24 °C causes a transformation of this red adduct to a green compound in which the thiolate bridges the Co−Mo bond. Desulfurisation occurs upon heating this bridged adduct under reflux conditions in deuterated MeCN to produce $[D_1]$toluene (MeC_6H_4D) plus the radical anion $[Mo_2Co_2(\mu_3\text{-}S)_4Cp'_2(CO)_2]^-$, again supporting the idea of homolytic cleavage of the C−S bond.[25]

This $Mo_2Co_2S_3$ cluster also cleaves the C−S bond in thiols by an apparent free radical mechanism. The kinetics of thiol desulfurisation are first-order in both cluster and thiol concentration. When the reaction product $[Mo_2Co_2(\mu_3\text{-}S)_4Cp'_2(CO)_2]$ is heated at 150 °C with CO at 69 atm, a 20% conversion into $[Mo_2Co_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Cp'_2(CO)_4]$ and OCS is obtained. The combination of the sulfur abstraction reaction and the regeneration of $[Mo_2Co_2S_3Cp'_2(CO)_4]$ constitutes a cycle for catalytic carbonyl desulfurisation of organic sulfides, as represented in Scheme 7.[21,25,41,115]

The cluster $[Mo_2Co_2(\mu_3\text{-}S)_4Cp^{Et}_2(CO)_2]$ reacts with good sulfur donors such as thiiranes and thietanes to give the organic hydrocarbons that result from their hydrodesulfurisation, together with an insoluble black solid for which a polymeric structure of $[Mo_2Co_2(\mu_3\text{-}S)_4Cp^{Et}_2]$ cubes linked together by sulfur bridges has been proposed.[116]



Scheme 7. Catalytic desulfurisation cycle of organic sulfides

$[Mo_2Co_2(\mu_3\text{-}S)_4Cp^{Et}_2(SPh)_2]$, obtained by oxidation of the carbonyl starting material cluster, was used to model the sulfur-bridged polymer. When $[Mo_2Co_2(\mu_3\text{-}S)_4Cp^{Et}_2(SPh)_2]$ is treated with H_2 (13.4×10^5 Pa)/CO (13.4×10^5 Pa) at 130 °C, the carbonyl cluster $[Mo_2Co_2(\mu_3\text{-}S)_4Cp^{Et}_2(CO)_2]$ is regenerated and gives PhSSPh as the sole organic product. Furthermore, a catalytic cycle for the conversion of PhSH to PhSSPh with the $Mo_2Co_2S_4$ cluster as catalyst is feasible.[21] It is interesting to point out that these $Mo_2Co_2S_x$ ($x = 3, 4$) clusters are capable of cleaving C−S bonds at temperatures several hundred degrees below that used in the industrial heterogeneous hydrodesulfurisation process, suggesting that C−S bond activation is not the rate-determining step in the industrial process, but rather the removal of sulfur from the surface of the catalyst.

The cluster $[Mo_2Co_2(\mu_3\text{-}S)_2(\mu_4\text{-}S)Cp'_2(CO)_4]$ has been supported on alumina and subjected to temperature-programmed decomposition under hydrogen. The activity and selectivity of this $MoCoS/Al_2O_3$ system for thiophene hydrodesulfurisation are similar to those of conventionally prepared catalysts under similar reaction conditions. Spectroscopic characterisation of the cluster-derived catalyst suggests that the clusters undergo oxidation by the surface upon loss of the organic ligands.[117]

The uptake of CO is often used as a measure of the HDS activity of a heterogeneous catalyst. The fact that several $M_3M'Q_4$ complexes react with CO supports the idea that these clusters may be functional models in homogeneous HDS catalysis.[63] The ability of the heterometal atoms in the $[M_3M'Q_4]^{n+}$ (M′= Fe, Co, Ni, Cu) aquo ions to bind CO has been correlated with the number of metal cluster electrons. The Mo_3CoS_4 and M_3NiQ_4 cubes with 15 and 16 metal electrons react with CO to afford the $[Mo_3CoS_4(H_2O)_9(CO)]^{4+}$, $[Mo_3NiQ_4(H_2O)_9(CO)]^{4+}$ and $[W_3NiS_4(H_2O)_9(CO)]^{4+}$ cationic clusters, which are more stable than their starting aquo ions. In the case of nickel, the presence of chloride ions in the reaction media precludes formation of the carbonyl adduct, and CO is replaced by Cl^- on addition of concentrated HCl to $[M_3NiQ_4(H_2O)_9(CO)]^{4+}$. Coordination of CO to $[Mo_3CoS_4(H_2O)_{10}]^{4+}$ is reversible, and bubbling nitrogen through $[Mo_3CoS_4(H_2O)_9(CO)]^{4+}$ regenerates the starting aquo ion. The $[Mo_3CuS_4(H_2O)_{10}]^{5+}$ cluster, which has the same 16 metal electron count as the Ni complexes, reacts with CO in a different manner to produce the trinuclear $[Mo_3S_4]^{4+}$aquo ion plus $[Cu(CO)]^+$. As observed for the cobalt system, bubbling of nitrogen regenerates the starting aquo cluster. On the other hand, the $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ and $[Mo_3CuS_4(H_2O)_{10}]^{4+}$ clusters, with 14 and 17 metal cluster electrons, respectively, do not react with CO.[48]

The IR spectra of $[M_3NiS_4(H_2O)_9(CO)]^{4+}$ show CO stretching bands at 2077 cm^{-1} for M = Mo and 2045 cm^{-1} for M = W. IR spectra of heterogeneous NiWS catalysts after CO uptake display a CO band at 2090 cm^{-1}, suggesting that there are differences in the chemical environment between the nickel atoms in the NiMS heterogeneous catalyst and in the $[M_3NiS_4(H_2O)_9(CO)]^{4+}$ aquo ions. The structural characterisation of $[Mo_3NiS_4Cp'_3L]^+$ compounds in which the nickel atom is coordinated to organic sulfur- or nitrogen-containing ligands (L), do not indicate any activation of the C−S or C−N bonds, as reported in a previous section. In addition, the reaction between $[Mo_3NiS_4Cp'_3L]^+$ and benzothiophene/quinoline at 30 bar of H_2 and 130 °C does not reveal the formation of any of the expected hydrodesulfurisation or hydrodenitrogenation products.[67] This lack of HDS activity has been attributed to the low electron density on Ni, based on quantum mechanical calculations.[112] However, the limited backbonding to CO, a consequence of the low electron density on the heterometal, is also observed in the industrial MNiS catalysts. Further investigations are needed to understand these observations.

One of the key problems in the hydrodesulfurisation of light oil is the low reactivity of 4-methyldibenzothiophene and 4,6-dimethyldibenzothiophene, since the methyl groups hinder the approach of sulfur to the active sites of the catalyst. In order to overcome this limitation, $[Mo_3S_4(H_2O)_9]^{4+}$ and $[Mo_3NiS_4(H_2O)_9Cl]^{3+}$ have been loaded into zeolites in the hope that the acidic properties of zeolites might be capable of activating the alkyl group(s) in the thiophenic derivatives as the cluster core promotes the desulfurisation reaction. The Mo_3S_4 and Mo_3NiS_4 complexes have been incorporated into zeolites (NaY, HUSY, NaHβ, Na mordenite and KL) by aqueous ion-exchange without destruction of the zeolite structure.[118−120] The trinuclear cluster remains virtually intact after ion exchange. On the other hand, partial decomposition of the NiMo cluster to Ni^{2+} and the Mo_3S_4 trimer has been observed after ion exchange. The HDS activity of benzothiophenone is significantly affected by the zeolite structure and the best results are found for NaY or KL. The catalysts prepared by incorporation of the nickel heterodimetallic cluster were more active in the HDS reaction than those prepared by ion exchange of the Mo_3S_4 cluster with nickel nitrate solutions in the zeolites. The effectiveness of employing the MoNi mixed cluster suggests some similarities between the structure of the active sites and that of the Mo_3Ni heterodimetallic cluster.

Recent work in our group shows that the $[Mo_3CuS_4(dmpe)_3Cl_4]^+$ cationic cluster is a useful catalyst for the cyclopropanation of diazo compounds. The reaction of 1-diazo-5-penten-2-one in dichloromethane solutions un-

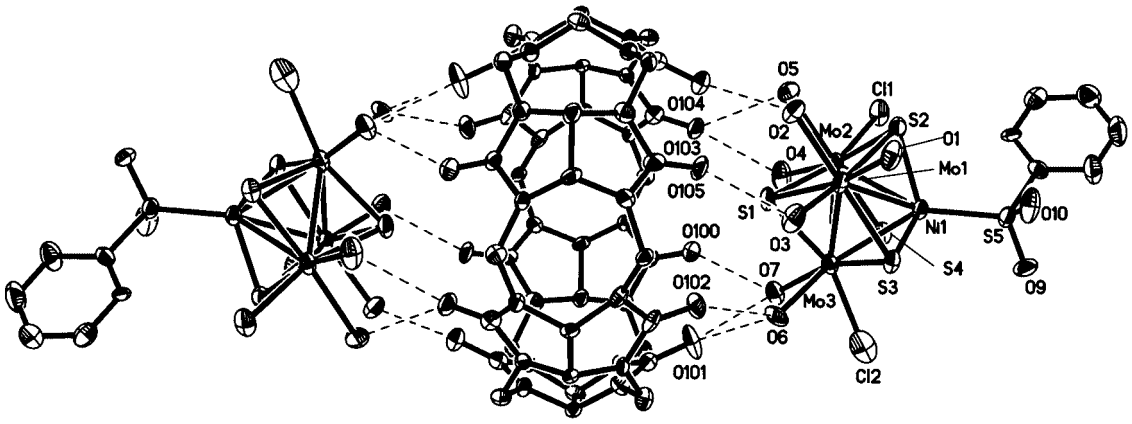


Figure 5. Drawing of the $[\{Mo_3[Ni(PhSO_2)]S_4(H_2O)_{7.83}Cl_{1.17}\}_2(C_{36}H_{36}N_{24}O_{12})]^{3.66+}$ supramolecular adduct with partial atom-numbering scheme

der reflux conditions for 3 d affords the cyclopropanation product bicyclo[3.1.0]pentan-2-one in yields greater than 95%.[121]

Nonlinear Optics

The optical-limiting merit of transition metal clusters has attracted much interest recently because these compounds combine the advantages of the presence of heavy atoms with structural versatility of the coordination environment. The clusters $[M_3CuS_4(dmpe)_3X_4]^+$ (X = Cl, Br) as well as their trinuclear precursors $[M_3Q_4(diphosphane)_3X_3]^+$ (diphosphane = dmpe, dppe) are all efficient optical limiters.[5,108] A large ratio of the effective excited-state cross section (σ_{eff}) to ground-state absorption cross section (σ_0) is one criterion for assessing potential as optical limiters. Values of σ_{eff}/σ_0 for these trinuclear and tetranuclear clusters lie within an order of magnitude (from 1.1 to 12), suggesting a common power-limiting mechanism, possibly purely thermal in origin. The threshold-limiting fluence in these optical limiters decreases on proceeding from the tetranuclear cluster to its trinuclear precursor and from the tungsten-containing to its molybdenum-containing analogue.

Formation of Supramolecular Adducts

The $M_3M'S_4$ aquo ions yield supramolecular compounds on reaction with macrocyclic ligands such as cucurbituril (cuc).[122,123] In cases where M′ is a first-row transition metal, this ligand forms stable compounds with cations such as $[Mo_3NiS_4(H_2O)_7Cl_3]^+$, $[Mo_3NiS_4(H_2O)_8Cl_2]^{2+}$ and $[Mo_3NiS_4(H_2O)_9(PhSO_2)]^{3+}$.[124,125] The typical arrangement (cluster)(cucurbituril)(cluster) is shown in Figure 5 for the latter derivative. The driving force for the crystallisation process is the formation of several complementary hydrogen bonds between the C=O groups and the water molecules coordinated to the cluster, and as a result, addition of cucurbituril is often used as a method to facilitate crystallisation of cuboidal aquo ions.

This entry to supramolecular chemistry also allows the development of host−guest chemistry. This is illustrated by the crystallisation of the supramolecular adduct $\{[Mo_3NiS_4(H_2O)_8Cl_2](pyH^+\subset cuc)\}Cl_3\cdot 14\cdot 5H_2O$ with a pyridinium cation inside the cucurbituril cavity.

A Facile Synthesis of a Push-Pull Mixed-Ligand Pd-Dithiolene Complex Containing the Et_2timdt Ligand (Et_2timdt = Monoreduced Diethylimidazolidine-2,4,5-trithione)

M. Carla Aragoni,[a] Massimiliano Arca,*[a] Carla Denotti,[a] Francesco A. Devillanova,[a] Emanuela Grigiotti,[b] Francesco Isaia,[a] Franco Laschi,[b] Vito Lippolis,[a] Luca Pala,[a] Alexandra M. Z. Slawin,[c] Piero Zanello,[b] and J. Derek Woollins[c]

Keywords: Palladium / Halogenation / S ligands / Density functional calculations / Nonlinear optics

The reaction of the dithiolene [Pd(Et_2timdt)$_2$] (Et_2timdt = formally monoreduced diethylimidazolidine-2,4,5-trithione) with Br_2 or IBr yields the complex [Pd(Et_2timdt)Br_2], a good starting material for the synthesis of novel push-pull mixed-ligand Pd-dithiolenes. The synthesis and characterisation of the unsymmetrical dithiolene [Pd(Et_2timdt)(mnt)] (mnt = maleonitriledithiolato dianion) is also reported.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

In recent years, non-linear optical (NLO) materials have attracted great interest because of their wide range of possible applications in several fields, such as laser technology, telecommunications, data storage, and optical switches.[1] So far, most reports have dealt with inorganic and organometallic compounds with extended delocalized π-systems.[2] Among these, "non-innocent"[3] metal-dithiolenes represent a very promising class of compounds in view of their peculiar electronic structure accompanied by high thermal and photochemical stabilities.[4]

Recently, we have reported a new class of neutral dithiolenes [M(R,R′timdt)$_2$] (M = Ni, Pd, Pt),[5] which shows remarkable stability and an unusually intense NIR absorption at about 1000 nm, whose energy is tunable by changing the metal ion and/or substituents R and R′.[6−9] The intense NIR absorption makes these dithiolenes good candidates as Q-switching and/or mode-locking dyes in the technology of Nd-lasers (such as Nd:YLF and Nd:YAG, emitting at 1053 and 1064 nm, respectively), and for applications in solid-state NIR-photodetectors.[10] These compounds are structurally analogous to the metal dithiolenes that derive from the ligand dmit (dmit = 2-thioxo-1,3-dithiol-4,5-dithiolate), while differing in that NR groups are present instead of endocyclic S atoms in the heterocyclic organic framework of the ligand.[11] However, while [M(R,R′timdt)$_2$] dithiolenes are isolated in the neutral state, [M(dmit)$_2$] complexes have been reported as anions with integer or fractional charges, and have been used as building blocks to prepare materials with interesting conducting properties.[12,13]

DFT calculations have confirmed that the terminal sulfur atoms in the two classes of dithiolenes are differently charged: those in the neutral [M(dmit)$_2$] dithiolenes carry a small positive charge, while those in the neutral [M(R,R′timdt)$_2$] dithiolenes carry a non-negligible negative charge.[8] The donor properties of the latter complexes have been exploited in the reactions with iodine: the interaction of I_2 at the terminal sulfur atoms gives CT adducts bearing linear S−I−I groups.[6,7] The reactions of [Ni(R,R′timdt)$_2$] with Br_2 and IBr generally occur with elimination of the central Ni ion. For example, in the case of the reaction of [Ni(*i*Pr_2timdt)$_2$] with IBr, together with other unidentified by-products, the corresponding 1,3,6,8-tetrasubstituted 4,5,9,10-tetrathiocino-[1,2-*b*:5,6:*b*′]diimidazolyl-2,7-dithione was identified by X-ray diffraction.[14]

Unexpectedly, the reaction between [Pd(Et_2timdt)$_2$] (**1**)[7] and either IBr or Br_2 in molar ratios ranging from 1:1 to 1:20 gave very tiny bronze crystals, with an elemental analysis that corresponds to the formula of [Pd(Et_2timdt)Br_2] (**2**). Although the quality of these crystals was not good enough to obtain reliable structural data (see Exp. Sect.), it is possible to note that on passing from **1** to **2**, the Pd ion maintains a square-planar coordination geometry, which is achieved for **2** by coordination to one Et_2timdt ligand and two bromide ions.

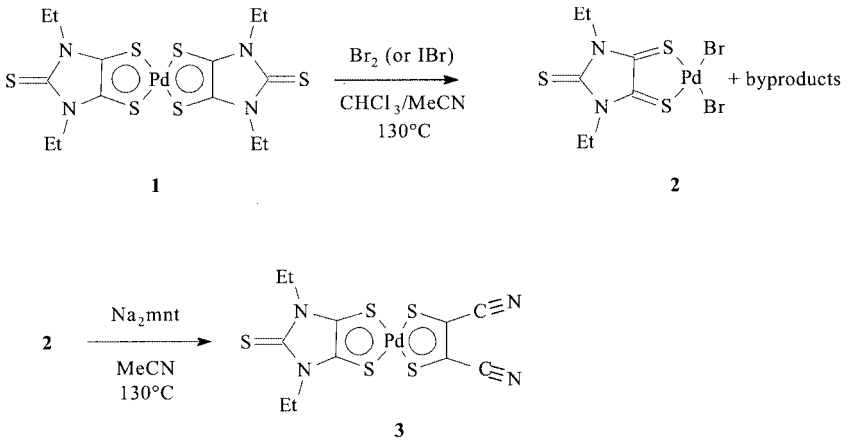

Scheme 1

The reaction of **2** with [Na_2mnt] (mnt = maleonitriledithiolate) in MeCN (Scheme 1) yielded dark crystals, whose X-ray crystal structure determination showed that they consist of the mixed-ligand dithiolene [Pd(Et_2timdt)(mnt)] (**3**; Figure 1).[15] In **3**, the C(1)−C(2) bond length within the Et_2timdt ligand is longer than that found in **1** [1.453(4) and 1.397(9) Å, respectively], while the C(1)−S(1) and C(2)−S(2) distances [corresponding averaged value in **1** 1.689(8) Å][7] are shorter [1.661(3) and 1.655(3) Å, respectively]. On comparing the two C_2S_2Pd metallacycles in **3**, the C−C length in the mnt unit [1.354(4) Å] is shorter than that in the Et_2timdt one, while the C−S distances are longer in the mnt ligand [C(3)−S(3) 1.731(3); C(4)−S(4) 1.734(3) Å]. The structural features in **1**,[7] **3**, and [Pd$(mnt)_2$], [characterised as (perylene)$_2$Pd$(mnt)_2$][16] clearly indicate that the Et_2timdt ligand in **3** shows a remarkable trithione character, while mnt occurs in the dithiolato form.[17]

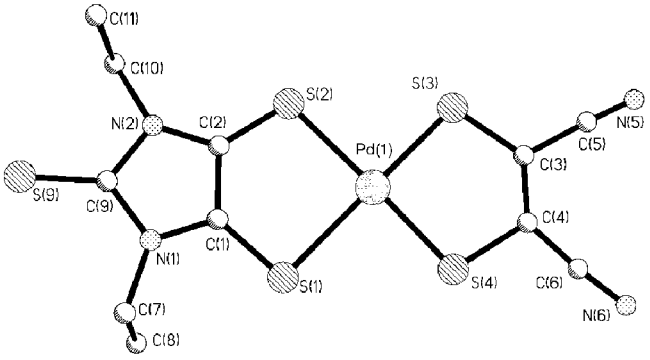

Figure 1. Molecular structure and atom labelling scheme for [Pd(Et_2timdt)(mnt)] (**3**); selected bond lengths (Å) and angles (°): Pd(1)−S(1) 2.3293(8), Pd(1)−S(2) 2.3300(8), Pd(1)−S(3) 2.2633(8), Pd(1)−S(4) 2.2526(8), C(1)−S(1) 1.660(3), C(2)−S(2) 1.655(3), C(3)−S(3) 1.731(3), C(4)−S(4) 1.734(3), C(1)−C(2) 1.453(4), C(3)−C(4) 1.354(4); S(1)−Pd(1)−S(2) 91.02(3), S(3)−Pd(1)−S(4) 90.59(3), S(1)−C(1)−C(2) 124.4(2), S(2)−C(2)−C(1) 124.3(2), S(3)−C(3)−C(4) 122.6(2), S(4)−C(4)−C(3) 122.1(2)

The dithiolato nature of mnt in **3** is also confirmed by its FT-Raman spectrum in the solid state: the C=C stretching vibration of the mnt unit is found at 1485 cm^{-1}, in very good agreement with the value of 1482 cm^{-1} reported for $[Pd(mnt)_2]^{2-}$.[18]

These experimental results are in agreement with a push-pull nature for **3**, also supported by DFT calculations carried out on the corresponding model complex [Pd(H_2timdt)(mnt)] (**4**). In this dithiolene, the HOMO and LUMO are π-type molecular orbitals (Figure 2): while the HOMO is mainly centred on the mnt dithiolato ligand and the terminal sulfur atom of the H_2timdt trithione ligand, the LUMO has a remarkable contribution from the H_2timdt ligand.

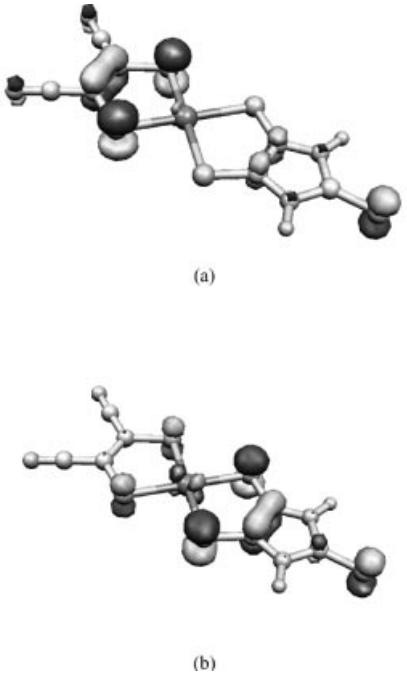

Figure 2. Kohn−Shan HOMO (a) and LUMO (b) calculated for [Pd(H_2timdt)(mnt)] (**4**)

Due to the different nature of the two ligands, a strong intramolecular polarisation can be expected for **3**, as confirmed by its remarkable solvatochromism (the position of the maximum in the NIR spectrum ranges between 920 nm in MeCN and 1060 nm in $CHCl_3$, Figure 3). On the other hand, the NBO[19] charge distribution calculated for **4** [Pd(1) 0.348, S(1,2) 0.055, S(3,4) 0.052, C(1,2) 0.016, C(3,4)

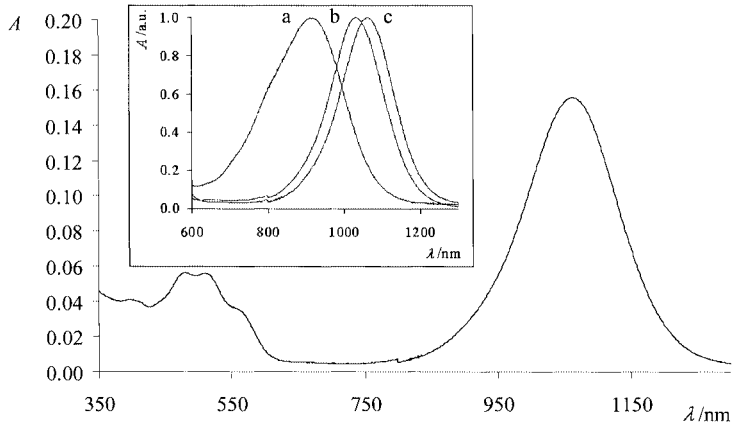

Figure 3. UV/Vis-NIR spectrum of **3** in $CHCl_3$ solution ($1.2 \cdot 10^{-5}$ M); the inset shows the superimposed normalised NIR spectra in MeCN (a), CH_2Cl_2 (b) and $CHCl_3$ (c)

−0.027, N(1,2) −0.583, C(5,6) 0.280, N(5,6) −0.271 e] agrees with a strong intramolecular polarisation. The cyclic voltammetry (Figure 4a) of complex **3** in CH_2Cl_2 shows two consecutive, (coulometrically tested) one-electron reversible reductions [$E^{\circ\prime}_{0/-1} = +0.41$; $E^{\circ\prime}_{-1/-2} = -0.27$ V, vs. SCE]. A one-electron irreversible oxidation (not shown in Figure 3a) is also present close to the solvent discharge ($E_{pa,\ 0/+} = +1.43$ V). On the basis of the nature of the calculated Kohn−Shan HOMO and LUMO, the reduction process should be considered as being centred mainly on the Et_2timdt ligand, while oxidation occurs mostly on the mnt unit.

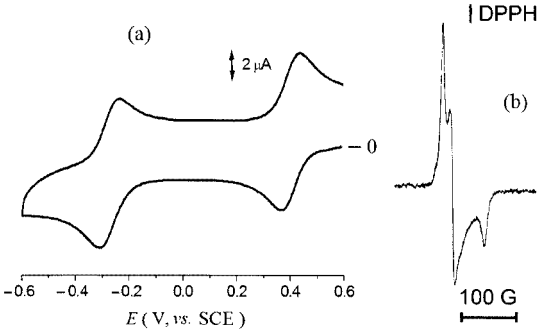

Figure 4. (a) Cyclic voltammogram recorded at a platinum electrode on a CH_2Cl_2 solution of **3** ($0.7 \cdot 10^{-3}$ M); scan rate 0.5 $V \cdot s^{-1}$; (b) X-band EPR spectrum recorded at 100 K on the electrogenerated $[\mathbf{3}]^-$ monoanion

Both the monoanion and the dianion also proved to be stable over the longer time-span of macroelectrolysis. Figure 4b shows the low-temperature EPR spectrum recorded on a CH_2Cl_2 solution of the electrogenerated $[Pd(Et_2timdt)(mnt)]^{\cdot -}$ radical monoanion. The $<g>$ value of the rhombic absorption [$<g> = 1/3(g_l + g_m + g_h) = 2.013$] proved to be appreciably higher than $g_{electron}$ (2.002), confirming that the central palladium atom partly contributes to the LUMO of **3**, even though the low Δg value ($\Delta g = g_l - g_h = 0.048$) agrees with a predominantly ligand-centred reduction process.

In conclusion, by exploring the reactivity of $[M(R,R'timdt)_2]$ towards Br_2 and IBr we have found an alternative method to easily prepare non-centrosymmetric push-pull [M(R,R′timdt)L] dithiolenes (L is a dithiolate ligand) with potential NLO applications.

Experimental Section

Materials and Methods: All solvents and reagents were purchased from Aldrich and used as received. The degree of purity of each compound was checked by elemental and TLC analyses. Elemental analysis, and FT-Raman, and UV/Vis-NIR spectroscopy were carried out as previously reported.[8] Cyclic voltammetry was performed in an anhydrous dichloromethane solution using electrochemical grade $[NBu_4][PF_6]$ as supporting electrolyte in a three-electrode cell containing a platinum working electrode surrounded by a platinum-spiral counter electrode and an aqueous saturated calomel reference electrode (SCE) mounted with a Luggin capillary. A BAS 100 W electrochemical analyser was used as polarising unit. Controlled potential coulometry was performed in an H-shaped cell with anodic and cathodic compartments separated by a sintered-glass disk. The working macroelectrode was a platinum gauze; a mercury pool was used as the counter electrode. All potential values are referred to the SCE (under the present experimental conditions, the one-electron oxidation of ferrocene occurs at $E^{\circ\prime} = +0.39$ V). X-band electron spin resonance (ESR) spectra were recorded with an ER 200 D-SRC Bruker spectrometer operating at a frequency of 9.62 GHz using a HS Bruker rectangular cavity. The operational frequency was controlled with a Hewlett−Packard x 5−32 B wavemeter and the magnetic field was calibrated with a DPPH (diphenylpicrylhydrazyl) free radical as a suitable field marker. The temperature was controlled with a Bruker ER 4111 VT device (±1 K). The g values are referred to DPPH ($g = 2.0036$) used as the external standard reference. The starting dithiolene **1** was synthesised according to the previously described method.[7]

Synthesis of $[Pd(Et_2timdt)Br_2]$ (2): Compound **1** (50 mg, $9.2 \cdot 10^{-5}$ mol) was reacted with an excess of bromine (100 mg, $6.8 \cdot 10^{-4}$ mol) in 30 mL of a mixture of $CHCl_3$ and MeCN (1:2 v/v) for 10 minutes in an Aldrich pressure tube at 130 °C. After cooling, the precipitate was filtered off, washed with light petroleum ether, and dried under vacuum. Yield 27 mg, 60%. M.p. > 250 °C. $C_7H_{10}Br_2N_2PdS_3$ (484.6): calcd. C 17.35, H 2.08, N 5.78, S 19.85; found C 17.48, H

2.03, N 5.76, S 19.91. FT-Raman (1500−50 cm^{-1}; solid state): $\tilde{\nu}$ = 1433 (1.0), 1350 (3.5), 1300 (10.0), 1257 (3.0), 1166 (0.9), 446 (7.5), 425 (2.1) cm^{-1} (relative intensities in parentheses).

Synthesis of [Pd(Et_2timdt)(mnt)] (3): Compound **2** (31 mg, $6.3\cdot10^{-5}$ mol) was reacted with [Na_2mnt] (21 mg, $1.12\cdot10^{-4}$ mol) in 30 mL of MeCN for 30 minutes in an Aldrich pressure tube at 130 °C. After cooling, the precipitate was filtered off, washed with water, and dried under vacuum. Yield 12 mg, 40%. M.p. > 250 °C. $C_{11}H_{10}N_4PdS_5$ (464.9): calcd. C 28.42, H 2.17, N 12.05, S 34.48; found C 28.82, H 2.15, N 11.98, S 33.89. FT-Raman (1500−50 cm^{-1}; solid state): $\tilde{\nu}$ = 1485 (4.7), 1348 (5.2), 1292 (10.0), 1165 (2.7), 1059 (3.3), 530 (4.7), 449 (6.8), 362(8.7), 332 (6.7) cm^{-1} (relative intensities in parentheses).

X-ray Crystal Structure Determination: Data collections were performed on a SMART CCD area detector diffractometer with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data collection was performed at 125 K for **2** and at room temperature for **3**. A full hemisphere of data with 0.3° steps was collected. SADABS corrections were applied. The non-hydrogen atoms were refined anisotropically except for the carbon atoms in **2** (the crystals available for **2** were very thin needles, numerous samples were examined and several types of absorption corrections performed with no improvement in the quality of the collected data or of this refinement); the calculations employed the SHELXTL program system.[20]

X-ray Structure Determination of 2: $C_7H_{10}Br_2N_2PdS_3$, monoclinic, space group $P2_1/n$, a = 13.7244(15) Å, b = 23.829(3) Å, c = 16.4013(17) Å, β = 91.404(2)°, V = 5362.3(10) $Å^3$, Z = 16, D_c = 2.401 Mg/m^3, T = 125 K. R = 0.0525, wR = 1.004 for 7627 observed independent data.

X-ray Structure Determination of 3: $C_{11}H_{10}N_4PdS_5$, monoclinic, space group $P2_1/n$, a = 7.8685(3) Å, b = 14.0557(5) Å, c = 14.9088(6) Å, β = 90.985(1)°, V = 1648.63(11) $Å^3$, Z = 4, D_c = 1.873 Mg/m^3, T = 293 K. R = 0.0210, wR = 0.0459 for 2364 observed independent data.

CCDC-188021 (**2**) and CCDC-188022 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Theoretical Calculations: Hybrid-DFT calculations were performed with the Gaussian 98 package[21] on compounds [Pd(H_2timdt)$_2$], [Pd(H_2timdt)Br_2], and **4**. In all cases both the Becke3LYP[22] and MPW1PW[23] hybrid functionals were used, along with the Schafer et al. basis set[24] for all atoms except Pd, for which the Hay−Wadt LANL2DZ basis set[25] with Effective Core Potentials was preferred. For each molecule, after the geometry optimisation, a normal mode frequency calculation was performed. The experimental structures are in better agreement with those calculated using the MPW1PW functional.

Supporting information: (See Footnote on the first page of this article). Optimized geometries in Cartesian coordinate form and frontier Kohn−Shan orbital energies for complexes [Pd(H_2timdt)$_2$], [Pd(H_2timdt)Br_2] and **4** are available from the authors on request.

[5] R,R′timdt = formally monoreduced disubstituted imidazolidine-2,4,5-trithione. Attention should be paid to the fact that through the paper R,R′timdt is used for both the neutral and the negatively charged ligand, since the assignment of the net charges on the central metal and on the ligands is not straightforward due to the non-innocent nature of the ligands in dithiolenes.[3] Nevertheless, on passing from the neutral trithione ligand to its mono- or dianionic dithiolato species, the C−C and C−S bonds are shortened and lengthened, respectively. Therefore, the experimental structural values of these bond lengths give information on the nature of the ligand in each compound.

Preferential Siting of Iron Atoms in an MFI-type Ferrisilicate Zeolite Framework: An Attempt to Explain Experimental Data with TPA-Silicate Solution Chemistry

Elisabeth Theunissen,[a] Christine E. A. Kirschhock,[a] Sebastien P. B. Kremer,[a] David D. Habermacher,[a] and Johan A. Martens*[a]

Keywords: Zeolites / Transition metals / Iron / X-ray diffraction

In this paper an attempt is made to explain the experimentally observed iron siting in ferrisilicate MFI-type zeolites based on TPA-silicate solution chemistry. A critical molecular step in the formation of Silicalite-1 zeolite is the formation of the precursor, counting 36 T-atoms, by condensation of three pentacyclic dodecamers around a TPA molecule. Incorporation of a tetracyclic undecamer instead of a pentacyclic dodecamer results in a precursor with a missing Si atom at a position that becomes a T_9 or T_{10} site of the orthorhombic unit cell of the MFI-type zeolite. The incorporation of iron at these empty positions of the precursor explains the experimentally observed preferred iron positions. Close examination of the precursor formation mechanism reveals that the iron is incorporated at the same T-atom positions, viz. T_9 and T_{10}, when the precursor is formed from an iron-containing pentacyclic dodecamer.

Introduction

In the field of heterogeneous catalysis, zeolites with the MFI framework topology are important materials.[1] Incorporation of heteroatoms, and particularly of aluminum, iron or titanium in the MFI-type silicate framework, leads to unique acid-base and redox catalytic properties. MFI-type zeolites have been given particular names according to their chemical composition or assignment of the inventors, such as Silicalite-1 for the purely siliceous version,[2] ZSM-5 for the aluminosilicate,[3] TS-1 for the titanosilicalite composition,[4] and Fe-ZSM-5, or Fe-MFI for the iron-containing analogue.[5,6] The ferrisilicate composition has received much attention in the recent literature as it is an effective catalyst for a variety of reactions.[7−11]

MFI zeolites have orthorhombic or monoclinic symmetry, and possess 12 or 24 crystallographically different T-atom sites, respectively. The distribution of the heteroatoms over the framework positions has already been the subject of numerous experimental[12−15] and computational studies.[16−18] The evidence for the occurrence of isomorphous substitution is convincing, and although there is general agreement that the distribution of the heteroatoms over the different T-sites is non-random, the precise location remains uncertain. The kinetic rather than thermodynamic control over the formation of siliceous zeolite phases and over the incorporation of heteroatoms[19,20] complicates the theoretical studies.[16−18]

Recently, structural evidence for preferential iron siting at the T_9 and T_{10} sites of Fe-MFI could be obtained using synchrotron radiation single-crystal X-ray diffraction.[21] Identification of the iron positions was done based on the localization of the sodium counterions in the channels of the MFI structure and comparison of T−O distances in Silicalite-1 and Fe-MFI. In parallel with this development, the initial molecular steps involved in the formation of Silicalite-1 were recently revealed.[22,23] In this paper, we explain how the oligomerization chemistry responsible for the formation of the Silicalite-1 framework can offer an explanation for the experimentally determined iron atom siting.

Discussion

The tetrapropylammonium hydroxide (TPA) directed silica oligomerization sequence, identified by ^{29}Si NMR spectroscopy, involves a bicyclic pentamer (**1**), a pentacyclic octamer (**2**), a tetracyclic undecamer (**3**), and a pentacyclic dodecamer (**4**; Figure 1).[22,23] These polyanions have curved surfaces and are hydrophobic on the inside and hydrophilic on the outside. The propyl arms of the TPA molecule interact favorably with the hydrophobic internal surface. The assembly of three dodecamers around the TPA molecule leads to the formation of the precursor (**5**; Figure 1). The precursor has the same connectivity as in the MFI framework. The T-sites of the MFI framework are

mapped onto a model of the precursor in Figure 2. Aggregation of the precursor in the three directions leads to an MFI framework without missing T-atoms. The pentacyclic dodecamer (**4**) was detected as an intermediate in a polymerization experiment at 0 °C. At room temperature, it is a short-lived species and is quickly transformed into the precursor. The assembly of three pentacyclic dodecamers leads to precursors (**5**) containing 36 T-atoms. When a tetracyclic undecamer (**3**) is incorporated into precursor (**5**) instead of pentacyclic dodecamers (**4**), a T-atom is missing.

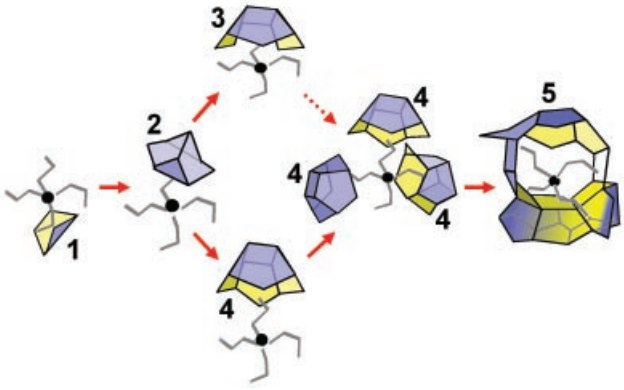

Figure 1. TPA-directed molecular steps involved in the formation of the 36-mer precursor:[22,23] (**1**) pentamer, (**2**) pentacyclic octamer, (**3**) tetracyclic undecamer, (**4**) pentacyclic dodecamer, and (**5**) precursor

In order to determine which T-atoms are missing, a close examination of the tetracyclic undecamer (**3**), pentacyclic dodecamer (**4**) and precursor (**5**) formation mechanism is needed. Incorporation of a tetracyclic undecamer (**3**) into the precursor (**5**) requires opening of the four-ring, which results in an intermediate with a three five-ring sequence, corresponding to the ones occurring in the precursor (**5**). Incorporation of the pentacyclic dodecamers (**4**) needs the opening of two rings, one five-ring and one four-ring. Comparison of the two opened intermediates shows that in the intermediate obtained from the tetracyclic undecamer (**3**), the Q^1-atom is missing. The latter atoms are always positioned in the precursor at positions that become T_9 or T_{10} sites of the orthorhombic MFI framework. They are marked with an asterisk in Figure 2. The T_9 and T_{10} sites represent extremities of the precursor (Figure 2). Incorporation of trivalent iron at these missing T-positions does not interfere with the hydrophobic interactions of the inner surface of the precursor with the TPA molecule. Near the T_9 and T_{10} sites of the precursor, there is ample space for the cation necessary for balancing the framework charge generated by incorporation of a trivalent iron atom as well as for possible non-framework ligands of iron when adopting a higher than fourfold coordination (Figure 2).

The T_9 and T_{10} positions constitute the four-rings in the MFI framework (Figure 2 bottom). Preferential substitution of aluminum in four-membered rings was earlier proposed based on upper substitution limits.[24] For iron incorporation into ferrisilicate MFI, the upper limit according to Szostak et al.[6] corresponds to an Si/Fe atomic ratio of 36, or 2.5 iron atoms per unit cell. When higher iron loadings are attempted, part of the iron is located at non-framework sites.[25] The experimentally observed maximum iron loading of one iron atom per 36 T-atoms suggests the incorporation of one iron atom per precursor. The achievement of higher iron loadings of the MFI zeolite would require the formation of precursors with two irons incorporated. Formation of these precursors is difficult, and coupling with other doubly substituted precursors will be impossible due to the Löwenstein's rule and/or formation of four-rings with double iron substitution. These doubly substituted four-rings are unlikely to form considering the preferred octahedral coordination of iron. This explains the maximum iron loading of one iron per 36 T-atoms.

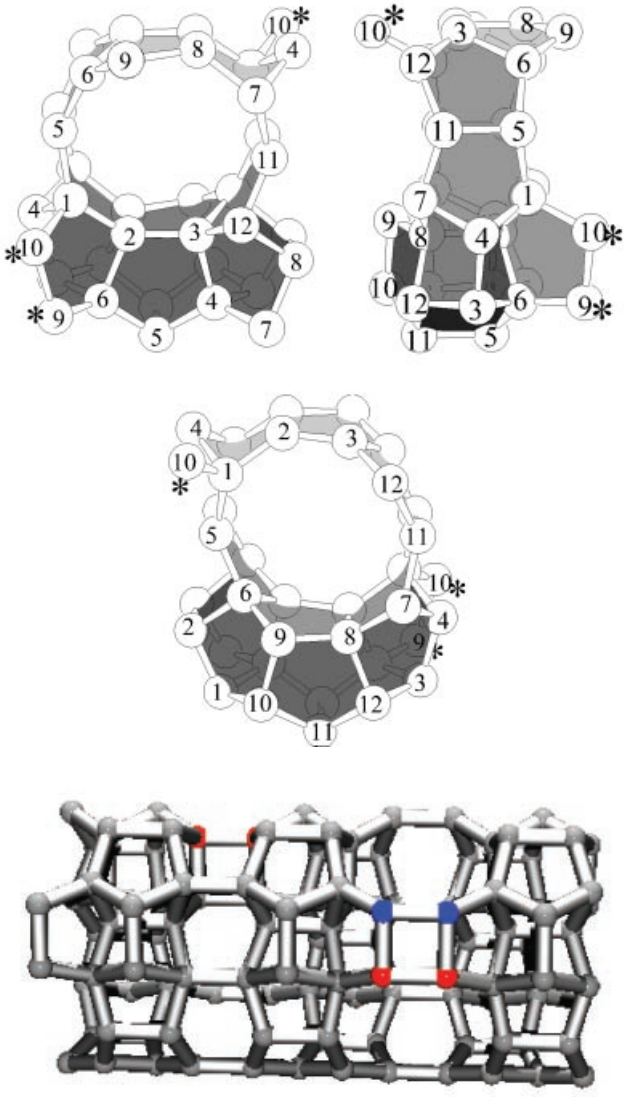

Figure 2. (top) Three views of the precursor model and T-atom numbering; at the T-atoms marked with an asterisk, the Si atom is missing when tetracyclic undecamer (**3**) is incorporated instead of pentacyclic dodecamer (**4**) and Fe^{3+} incorporated; (bottom) coupling of the precursor (**5**) into the MFI framework showing T_9 (blue) and T_{10} (red) sites forming four-rings

If the exclusive pathway for iron incorporation were through occupation of missing T-sites in the precursor (**5**), to obtain this maximum ratio each precursor would have to be defective. It is therefore likely that iron atoms can already be part of pentacyclic dodecamers (**4**). In view of the large atomic radius of iron, these heteroatoms will preferably be at the Q^2-positions of the pentacyclic dodecamers (**4**). Fe^{3+}-containing rings are the least stable, and ring opening preceding the precursor formation will occur in this ring, inevitably resulting in Fe^{3+}-atoms at the T_9 or T_{10} positions of the precursor.

Conclusion

In conclusion, the early molecular steps involved in the TPA-directed formation of Silicalite-1 offer an explanation for the experimentally observed iron location at T_9 and T_{10} [21] sites in the niche of the sinusoidal channel of the MFI-type framework. Examination of the synthesis model reveals that trivalent iron can be incorporated into the pentacyclic undecamer and at T-site vacancies created by the incorporation of tetracyclic undecamers in the precursor. Both incorporation mechanisms result in the same iron siting, viz. T_9 and T_{10}.

Design and Structural Analysis of Metallamacrocycles Based on Zinc Halides and a V-Shaped Bismonodentate Ligand of the Cyclophane Type

Cédric Klein,[a] Ernest Graf,[a] Mir Wais Hosseini,*[a] André De Cian,[a] and Nathalie Kyritsakas[b]

Keywords: Cyclophanes / Pyridine / Zinc / Metallacycles

The ligand **1**, based on the [1,1,1,1]cyclophane skeleton and bearing two pyridine units as monodentate coordination sites on the same face of the backbone, leads, in the presence of ZnX_2 (X = Cl, Br or I) complexes, to three isostructural neutral metallamacrocycles with an M/L ratio of 2:2. All three binuclear complexes have been characterised in the solid state by single-crystal X-ray diffraction. All three metallamacrocycles possess a roof-shaped geometry affording a pocket with a single opening. The latter is occupied by solvent molecules in the solid state. A correlation between the size of the halide and dimensions of the pocket is described.

Introduction

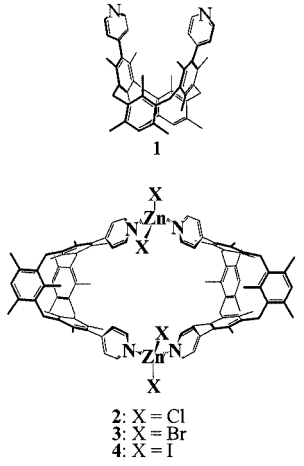
Over the last decade considerable efforts have been invested in the design and synthesis of macro(poly)cyclic structures of the metallamacrocycle type.[1−9] These molecules are based on the interconnection of organic fragments (L) bearing coordination sites and metal centres (M). The topology (macrocyclic, macrobicyclic etc.) and the nuclearity (M/L ratio) of such complexes have been shown to be dependent on both the structural and coordination features of the organic ligand (number of coordination sites, denticity of the coordination units and their spatial arrangement) and on the stereochemical demands of the metal centre (coordination geometry, number of available coordination sites and their disposition within the coordination sphere of the metal).

In a continuation of our investigations on the design and formation of metallamacrocycles,[10−15] we designed the V-shaped ligand **1** and explored its ability to form metallamacrocycles with an imposed 2:2 nuclearity.

We report here the formation of a homologous series of metallamacrocycles based on ZnX_2 (X = Cl, Br, I) and the V-shaped ligand **1**, and their solid state structures.

Results and Discussion

The design of the ligand **1** is based on the [1.1.1.1]metacyclophane skeleton (Scheme 1), which adopts the thermally stable 1,3-alternate conformation.[16] The functionalisation of the two distal aromatic moieties by two pyridine derivatives leads to ligand **1**, for which the two monodentate coordination sites are located on the same face of the backbone. The connection between the cyclophane skeleton and pyridines was achieved through C−C bonds at the *para* position of the pyridine ring.



Scheme 1

Due to the rather rigid nature of the ligand **1** and its V-shaped geometry (angle of 30−40° between the pyridine rings), it appeared interesting to explore the possibility of preparing metallamacrocycles using this ligand. The majority of metallamacrocycles reported to date are based on square-planar protected Pd^{II} and Pt^{II} complexes,[2−4] however, based on the geometry of **1** and the orientation of the two pyridines, metal centres adopting a tetrahedral coordination geometry appeared to be the most interesting ones

for the formation of metallamacrocycles. Thus, three zinc halides (ZnX_2, X = Cl, Br, I) were used. The rationale behind the choice of this type of complex was based on the fact that, taking into account the neutral nature of the ligand **1** and the rather strong biding ability of halides towards Zn^{2+} dication, the combination of **1** and ZnX_2 would lead to neutral metallamacrocycles **2**−**4**. In other words, for a neutral ZnX_2 complex adopting a tetrahedral coordination geometry, two vertices would be occupied by two halides and thus the remaining two coordination positions would be available for coordination to two molecules of **1** through their pyridines. It is perhaps interesting to note that the majority of metallamacrocycles are obtained using *cis*-protected square-planar metal complexes such as diphosphane or ethylenediamine complexes of Pd^{II} and Pt^{II}, whereas in the present case, the connecting metal cation adopts a tetrahedral coordination geometry. This aspect has been recently demonstrated by Braga et al.[7] Furthermore, it was believed that by changing the steric demand of the halogen, one could tailor the geometric features of the metallamacrocycles. Indeed, the increase in the size of the halogen from chloride to bromide and finally to iodide must induce a strong deformation of the tetrahedral Zn complex by increasing the X−Zn−X angle and, consequently, would lead to a decrease in the N−Zn−N angle.

Dealing with the synthesis of metallamacrocycles, an important issue is the control of the nuclearity (Figure 1), i.e. the M/L ratio. Indeed, using rigid and linear organic bismonodentate ligands, depending on the metal cation used, a variety of cyclic compounds such as [2.2]- (Figure 1a), [3.3]- (Figure 1b), [4.4]- (Figure 1c), [5.5]- (Figure 1d) and [6.6]metallamacrocycles (Figure 1e) may be obtained. Based on the angular characteristics of the ligand **1**, we believed that use of ZnX_2 complexes as connecting centres would favour the formation of the [2,2]metallamacrocycle (Figure 1a).

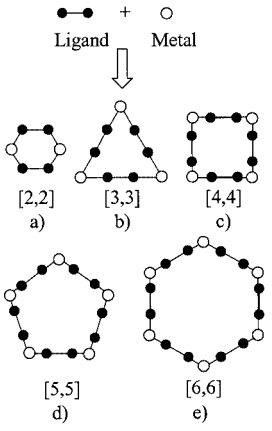

Figure 1. Schematic representation of the formation of metallamacrocycles with different M/L ratio

Metallamacrocycles **2** and **3** were obtained in quantitative yield by mixing the ligand **1** and ZnX_2 (X = Cl or Br) in CH_2Cl_2 at room temperature and then evaporating the solvent. Both binuclear complexes are soluble in $CHCl_3$. They were characterised in solution by ^1H and ^{13}C NMR spectroscopy, and by X-diffraction studies on single crystals in the solid state.

In solution, the ^1H NMR investigations in $CDCl_3$ at 25 °C revealed that the signals corresponding to H atoms belonging to the pyridine units are significantly downfield shifted for both complexes **2** and **3** with respect to the free ligand **1** (Figure 2). Interestingly, addition of an excess of $ZnCl_2$ or $ZnBr_2$ to a solution containing **2** and **3**, respectively, has no effect on the line-widths and chemical shifts of the signals, indicating that the species present in solution are the metallamacrocycles **2** and **3** with a well-defined 2M/2 L ratio.

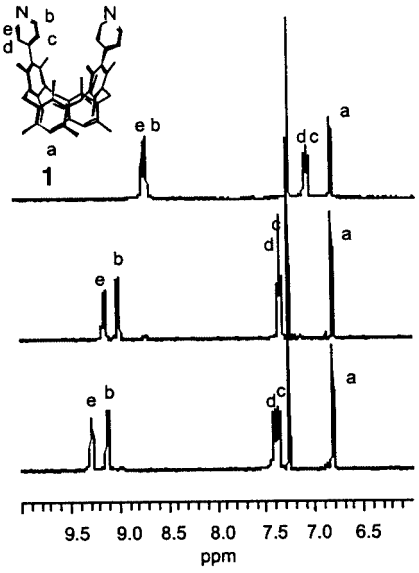

Figure 2. ^1H NMR (300 MHz, $CDCl_3$) studies at room temperature of the free ligand **1** (top) and metallamacrocycles **2** (middle) and **3** (bottom); only signals corresponding to protons belonging to pyridine units are presented

Compound **4**, due to its insolubility in $CHCl_3$, was not characterised in solution under the same conditions but only in the solid state by single-crystal X-ray diffraction.

In the solid state, the X-ray diffraction investigations revealed that, for all three compounds, neutral metallamacrocycles of the [2,2]-type are formed.

In the case of **2** (Figure 3a), the crystal is composed of $(\mathbf{1}\cdot ZnCl_2)_2$, and one ethanol and eight chlorobenzene molecules. The coordination sphere around the metal centre is composed of two Cl^- anions and two N atoms belonging to two pyridine units of two ligands **1**, with Zn−N and Zn−Cl bond lengths in the range 2.03−2.07 Å and 2.19−2.23 Å, respectively. The metal centre adopts a distorted tetrahedral coordination geometry with N−Zn−N and Cl−Zn−Cl angles of 101.3−101.7°, and 122.0−126.0°, respectively. Due to the rigidity of **1** and the tetrahedral geometry around the zinc(II) cation, the metallamacrocycle adopts a roof-type conformation with an average angle between the two main cyclophane axes of 110° and a Zn−Zn separation of 11.37 Å. Due to the peculiar arrangement of the two cyclophane units **1**, a pocket-type cavity possessing a single opening is formed; this is occupied by one chlorobenzene molecule.

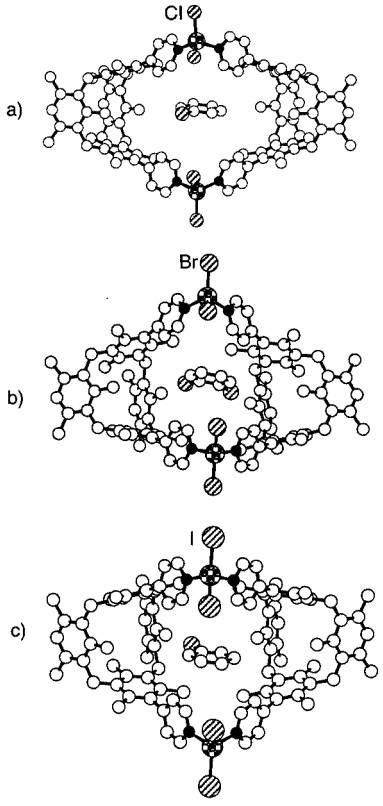

Figure 3. The solid-state structures of the metallamacrocycles **2** (a), **3** (b) and **4** (c); non-included solvent molecules and H atoms are omitted for clarity; see text for bond lengths and angles

In the case of **3** (Figure 3b), the crystal is composed of a $(\mathbf{1}\cdot ZnBr_2)_2$ metallamacrocycle and nine 1,2-dichlorobenzene molecules. Again, the coordination sphere around the metal centre is composed of a set of two Br^- anions and two N atoms with average Zn−N and Zn−Br bond lengths of 2.07 Å and 2.34 Å, respectively. The Zn^{2+} cation adopts a more distorted tetrahedral coordination geometry, with N−Zn−N and Br−Zn−Br angles of 93.7°, and 123.4°, respectively. Once again, the metallamacrocycle **3** adopts a roof-type conformation, as expected, with an average angle between the two main cyclophane axes of 82° and a Zn−Zn separation of 10.92 Å. The pocket-type cavity is occupied by a 1,2-dichlorobenzene molecule.

In the case of **4** (Figure 3c), the crystal is composed of a $(\mathbf{1}\cdot ZnI_2)_2$ metallamacrocycle and three chlorobenzene molecules. The latter were found to be disordered over two positions. Again, the coordination sphere around the metal centre is composed of a set of two I^- anions and two N atoms with average Zn−N and Zn−I bond lengths of 2.07 Å and 2.54 Å, respectively. The Zn^{2+} cation adopts an even more distorted tetrahedral coordination geometry with N−Zn−N and I−Zn−I angles of 92.6° and 121.6°, respectively. Once again, the metallamacrocycle **4** adopts a roof-type conformation, as expected, with an average angle between the two main cyclophane axes of 77.0° and a Zn−Zn separation of 11.21 Å. The pocket-type cavity is occupied by a disordered chlorobenzene molecule.

For all metallamacrocycles **2**−**4**, except for a few van der Waals contacts, no particular host-guest type interactions can be identified.

In $CDCl_3$ solution, no trace of the inclusion complexes of **2** and **3** could be observed by H-H NOESY investigations.

In summary, owing to the rigidity of the V-shaped bismonodentate ligand **1** and the orientation of the pyridine units, three isostructural neutral metallamacrocycles **2**−**4** of the 2M/2 L-type have been obtained in the presence of ZnX_2 (X = Cl, Br or I). All three metallamacrocycles have been characterised in the solid state by single-crystal X-ray diffraction. Due to the geometry of the ligand, the binuclear metallamacrocycles contain a pocket-type cavity possessing a single opening. The dimension of the cavity is determined by the size of the halide. In all three cases, the cavity is occupied by solvent molecules. Using the ligand **1**, the formation of other types of finite metallamacrocycles using other metal centres and the generation of infinite coordination networks are currently under investigations.

Experimental Section

Synthesis of Metallamacrocycles 2−4

General: All commercially available reagents were purchased and used without further purification. ^1H and ^{13}C NMR spectra were recorded on Bruker spectrometers at 400 and 300 MHz and at 50 MHz, respectively. Microanalyses were performed by the Service de Microanalyses de la Fédération de Recherche Chimie, Université Louis Pasteur, Strasbourg.

$(\mathbf{1}\cdot ZnCl_2)_2$ 2: A mixture of ligand **1**[16] (20 mg, 0.029 mmol) and $ZnCl_2$ (3.9 mg, 0.029 mmol) in CH_2Cl_2 (7 mL) was stirred at room temp. for 2 hours. Subsequent evaporation of the solvent gave the pure complex **2** as a white powder in quantitative yield (23 mg). $C_{100}H_{108}Cl_4N_4Zn_2\cdot 0.5CH_2Cl_2$ (1681.1): calcd. C 71.80, H 6.53, N 3.33; found C 71.78, H 6.55, N 3.27.^1H NMR ($CDCl_3$, 300 MHz, 25 °C): δ = 1.19 (s, 12 H, *p*-CH_3), 1.28 (s, 12 H, *p*-CH_3), 1.99 (s, 24 H, *o*-CH_3), 2.34 (s, 24 H, *o*-CH_3), 3.90 et 3.98 (AB, 2d, 16 H, *J* = 17 Hz, Ar-CH_2-Ar), 6.81 (s, 4 H, H-Ar), 7.34 (d, *J* = 5 Hz, 4 H, H-Py), 7.36 (d, *J* = 5 Hz, 4 H, H-Py), 9.00 (d, *J* = 5 Hz, 4 H, H-Py), 9.15 (d, *J* = 5 Hz, 4 H, H-Py) ppm. ^{13}C NMR ($CDCl_3$, 50 MHz, 25 °C): δ = 17.5, 18.1, 19.5, 21.4, 32.2, 126.4, 127.6, 130.1, 130.6, 144.4, 135.4, 136.8, 137.4, 138.2, 148.9, 149.1 ppm.

$(\mathbf{1}\cdot ZnBr_2)_2$ 3: A mixture of ligand **1**[16] (20 mg, 0.029 mmol) and $ZnCl_2$ (6.5 mg, 0.029 mmol) in CH_2Cl_2 (7 mL) was stirred at room temp. for 2 hours. Subsequent evaporation of the solvent gave the pure complex **3** as a white powder in quantitative yield (26 mg). $C_{100}H_{108}Br_4N_4Zn_2\cdot 2CH_2Cl_2$ (1986.3): calcd. C 61.68, H 5.68, N 2.82; found C 61.84, H 5.62, N 2.80. ^1H NMR ($CDCl_3$, 300 MHz, 25 °C): δ = 1.19 (s, 12 H, *p*-CH_3), 1.28 (s, 12 H, *p*-CH_3), 1.98 (s, 24 H, *o*-CH_3), 2.34 (s, 24 H, *o*-CH_3), 3.89 et 3.98 (AB, 2d, 16 H, *J* = 17 Hz, Ar-CH_2-Ar), 6.81 (s, 4 H, H-Ar), 7.37 (d, *J* = 5.5 Hz, 4 H, H-Py), 7.41 (d, *J* = 5.5 Hz, 4 H, H-Py), 9.12 (d, *J* = 5.5 Hz, 4 H, H-Py), 9.29 (d, *J* = 5.5 Hz, 4 H, H-Py) ppm. ^{13}C NMR ($CDCl_3$, 50 MHz, 25°C): δ = 17.5, 18.1, 19.5, 21.3, 32.1, 126.5, 127.8, 130.1, 130.5, 133.4, 135.3, 136.6, 136.9, 137.3, 138.2, 148.9, 149.0, 153.4, 157.1 ppm.

$(\mathbf{1}\cdot ZnI_2)_2$ 4: Due to the insolubility of complex **4** in CH_2Cl_2, this metallamacrocycle was generated directly as crystals in a crystallis-

ing tube upon slow diffusion of an ethanol solution (0.75 mL) of ZnI_2 (5.7 mg, 0.018 mmol) into a chlorobenzene (0.5 mL) solution of ligand **1**[16] (5 mg, 0.0073 mmol).

Crystallisation Conditions

Metallamacrocycles 2 and 3: An EtOH solution (1 mL) of ZnX_2 (4.4 mg for X = Cl, 7.2 mg for X = Br) was added dropwise to a stirred solution (5 mL) of **1** (20 mg, 0.029 mmol) in chlorobenzene (X = Cl) or 1,2-dichlorobenzene (X = Br). After stirring at room temperature for two hours, EtOH (3 mL) was diffused into the solution. Complexes **2** and **3** were obtained as colourless crystals after about a week.

Single crystals of the binuclear metallamacrocycle **4** were obtained as described above.

Crystal Structure Characterisation: X-ray diffraction data collection was carried out on a Kappa CCD diffractometer equipped with an Oxford Cryosystem liquid N_2 device, using graphite-monochromated Mo-K_α radiation. For all structures, diffraction data were corrected for absorption and analysed with the OpenMolen package.[17] All non-H atoms were refined anisotropically.

Crystal Data for 2 ($1{\cdot}ZnCl_2)_2$: Colourless crystals, 173 K, $C_{200}H_{216}Cl_8N_8Zn_4{\cdot}8C_6H_5Cl{\cdot}C_2H_5OH$, M = 4223.66, triclinic, space group $P\bar{1}$, a = 12.4464(2), b = 21.8475(2), c = 22.8606(3) Å, α = 112.173(5)°, β = 90.786(5)°, γ = 92.262(5)°, V = 5749.4(1) Å^3, Z = 1, D_c = 1.22 g cm^{-3}, μ = 0.653 mm^{-1}, 14989 data with $I > 3\sigma(I)$, R = 0.117, Rw = 0.142.

Crystal Data for 3 ($1{\cdot}ZnBr_2)_2$: Colourless crystals, 173 K, $C_{50}H_{52}Br_2N_2Zn{\cdot}4.5C_6H_4Cl_2$, M = 1567.69, monoclinic, space group $C2/c$, a = 36.3141(4), b = 11.4622(1), c = 36.2867(4) Å, β = 107.446(5)°, V = 14409.2(3) Å^3, Z = 8, D_c = 1.45 g cm^{-3}, μ = 1.828 mm^{-1}, 8040 data with $I > 3\sigma(I)$, R = 0.053, Rw = 0.080.

Crystal data for 4 ($1{\cdot}ZnI_2)_2$: Colourless crystals, 173 K, $C_{50}H_{54}I_2N_2Zn{\cdot}3C_6H_5Cl$, M = 1337.84, monoclinic, space group $C2/c$, a = 34.2298(5), b = 11.7252(2), c = 34.6599(7) Å, β = 117.237(5)°, V = 12368.4(6) Å^3, Z = 8, D_c = 1.44 g cm^{-3}, μ = 1.566 mm^{-1}, 8235 data with $I > 3\sigma(I)$, R = 0.078, Rw = 0.091.

CCDC 199799−199801 (**2**−**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

A Novel Open-Framework Gallium Phosphate Containing Two Different Building Units

Daofeng Sun,[a] Rong Cao,*[a] Yanqiong Sun,[a] Wenhua Bi,[a] and Maochun Hong[a]

Keywords: Zeolite analogues / Gallium / Phosphates / Alkali metals / Fluorides

A novel open-framework fluorinated gallium phosphate has been prepared hydrothermally. X-ray diffraction shows each double four-ring (D4R) links four 1D gallium phosphate chains made up of single four-rings (S4R) to form a 3D framework with eight-ring channels where potassium ions reside.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Since the discovery of the family of crystalline aluminophosphates (ALPOs) in 1982,[1] microporous zeolite-like materials have attracted much interest due to their potential applications in, for example, ion-exchangers, catalysts and adsorbents.[2,3] In the past decade, the replacement of Al in ALPOs by Ga has resulted in a large number of gallium phosphates with a wide range of structure types[4,5] because of the ability of gallium to adopt a more variable and expanded coordination environment compared to aluminum. Recently, fluoride ion has been discovered to play a major role in the gallium phosphate system and many fluoride gallium phosphates have been synthesized.[6] Férey and others have prepared a series of fluoride gallium phosphates that show interesting templating effects and structure types. Some of these gallium phosphate materials, such as cloverite,[7] ULM-5,[8] ULM-18[9] and Mu-15,[10] contain a double four-ring unit (D4R), with a fluoride ion occluded at its center. This has resulted in the postulation that the fluoride ion acts as a template for the formation of the D4R species and makes the cuboidal D4R an attractive target because of its rigid 3D shape.[11] In the synthesis of materials containing D4R units, the use of organic amines as structure-directing and charge-compensation agents is very common, but that of alkali metal ions is rare. In this communication, we report a novel gallium phosphate containing fluoride-templating D4R units and potassium ion charge-compensation agents.

In an attempt to prepare new a gallium phosphate material with 1-(2-aminoethyl)piperazine as the structure-directing agent, an open framework fluoride gallium phosphate, $K[(GaPO_4)\{F_{1/4}(GaPO_4)\}_4]$ (**1**), was obtained. This novel material was prepared by a hydrothermal synthesis with KF as a source of fluoride ions. Single-crystal X-ray diffraction indicates that **1** possesses a three-dimensional open framework containing one-dimensional channels along the *c* axis, in which potassium ions reside.

Two crystallographically independent gallium and phosphate centers, Ga(1), P(1) and Ga(2), P(2), which form different second building units (SBUs), are present in the structure. The first SBU is a $Ga_2(PO_4)_2$ single four-ring (S4R; Figure 1, Part I, left) made up of Ga(1) and P(1). The gallium atom is four-coordinate and is linked by corner-sharing PO_4 tetrahedra with an average Ga−O distance of 1.875(4) Å. This distance is slightly longer than that found in complex ULM-16,[5d] in which the $Ga_2(PO_4)_2$ unit links layers to form a 3D open framework. As is well known, the linkage of S4Rs often results in 2D layers containing eight-ring windows, and this phenomenon has been observed for a number of zeolites and zeolite analogues.[12,13] Interestingly, in **1**, a one-dimensional infinite gallium phosphate chain is formed by the linkage of S4Rs, in which the gallium atom and the phosphate tetrahedron alternate (Figure 1, Part I, right).

The second SBU is a double four-ring unit (D4R; Figure 1, Part II) formed by Ga(2) and P(2), similar to that observed in many gallium phosphate molecular sieves.[7−10] A fluoride ion resides in the D4R unit as observed in cloverite[7] and other ULM complexes.[8−10] In this case, the fluoride atoms lie a long distance from the four gallium atoms, with a relatively long contact of 2.459 Å, which is longer than that found in CYCLAM-GaPO (2.286 Å)[14] and illustrates that the fluoride ion less strongly bound in the D4R center. The average Ga−O distance in the D4R unit is 1.865(4) Å, shorter than that in the S4R unit. In previous reports, D4R is usually linked through its corners to other D4R units to give rise to a 2D or 3D ACP topology first reported by Stucky.[15] Surprisingly, in **1**, the D4Rs themselves have no linkage, each D4R links four above mentioned 1D gallium phosphate chains by its four corners with a Ga−O distance of 1.920(4) Å, and a 3D open framework with eight-ring channels (9.657 × 3.763 Å) is formed along the *c* axis, in which the potassium ions reside. As

shown in Figure 2, every two adjacent eight-membered rings are almost perpendicular to each other.

TGA determination shows that complex **1** possesses a high degree of thermal stability and there is no weight loss even upon heating to more than 800 °C, indicating that **1** is thermally more stable than potassium templating gallium phosphatooxalate.[16] After heating a sample of **1** to 800 °C the XRPD pattern remains essentially the same, although slight changes in the strength of some peaks were observed. This result validates the stability of **1** and is in agreement with the structural data.

Experimental Section

Synthesis of 1: Ga_2O_3 (0.023 g, 0.0625 mmol) was dispersed in 16 mL of distilled water by vigorous stirring, and then phosphoric acid (0.5 g, 85% weight aqueous solution) was added. After stirring for 15 minutes, 1-(2-aminoethyl)piperazine (0.1 mL) and KF (0.03 g, 0.5 mmol) were added and stirred to homogeneity. The mixture was sealed in a Teflon-lined stainless autoclave and heated at 160 °C for three days under autogenous pressure, then cooled to room temperature over 8 hours. The resulting product, consisting of colorless prism-like crystals was collected by filtration. Yield: 35%.

X-ray Crystallography: $F_{0.25}Ga_2KO_8P_2$, (**1**), M = 373.23, *tetragonal*, space group $P4_2/n$, a = 13.2322(19), b = 13.2322(19), c = 8.6535(17) Å, U = 1515.2(4) Å^3, T = 293 K, Z = 4, D_c = 1.636 g/cm^3, λ = 0.71073 Å, 1730 unique reflections were used in the calculations. $R1$ = 0.0350 and $wR2$ = 0.1308. The intensity data were collected on a Smart CCD diffractometer with graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation at room temperature in the ω-2θ scan mode. An empirical absorption correction was applied to the data using the SADABS program. The structures were solved by direct methods. All calculations were performed using the SHELXTL program. Crystallographic data for the complex **1** are given in Table 1.

Synthesis, Structures, and Properties of a Series of $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ Cluster Compounds with Different Counterions

Andreas Eichhöfer,*[a] Oliver Hampe,[a] and Martine Blom[a]

Keywords: Cluster compounds / Cadmium / Selenium / X-ray diffraction / UV/Vis spectroscopy / Mass spectrometry

A series of seven single-crystalline ionic CdSe cluster compounds, all possessing the cluster anion $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$, but with different counterions, has been synthesized. The compounds were characterized in the solid state, solution, and gas phases using single-crystal XRD, powder XRD, UV/Vis spectroscopy, and FT mass spectrometry. The results of the crystal structure determination show that the increasing size of the different counterions does not simply lead to an increase in the shortest inter-cluster distance, but rather to changes in the crystal structure. Room-temperature UV/Vis absorption and reflectance spectra of the crystalline powders are virtually identical, proving that the electronic transitions in the energy range probed can be attributed to the cluster anion $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$. The band of the first transition in the solid-state UV/Vis spectra are broadened relative to that in the solution spectra, as it is possibly affected by the collective interactions between the nanoclusters in the three-dimensional crystal lattice. Interestingly, in solution, the position and feature of the lowest-energy transition band changes as the solvent is varied. As FT mass spectrometry gives clear evidence for the existence of the intact $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anion in all these solutions, these shifts can be interpreted in terms of solvatochromic effects.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Recent progress in the syntheses of CdSe cluster molecules has led to the development of a series of homologous compounds, namely $[NPr_4^+]_2[Cd_4(SePh)_6Cl_4]^{2-}$ $[Cd_{10}Se_4(SePh)_{12}(PPr_3)_4]$, $[Cd_{17}Se_4(SePh)_{24}(PPh_2Pr)_4]^{2+}[Cd_8Se(SePh)_{12}Cl_4]^{2-}$, and $[Cd_{32}Se_{14}(SePh)_{36}(PPh_3)_4]$ (Ph = phenyl, Pr = *n*-propyl).[1] As the largest clusters already overlap in size with the smallest nanocrystals, these clusters of semiconductor materials, composed of tens of atoms with bonding resembling that present in the solid state, are interesting molecular models for the investigation of the evolution of properties with size.[2−4] Systematic studies of the size-dependent optical and electronic properties of the CdSe cluster molecules mentioned above show that the onset of the absorption and low-temperature photoluminescence excitation of the clusters systematically shift to the blue in smaller clusters, manifesting the quantum confinement effect well known for larger CdSe nanocrystals. Photo-darkening experiments on the ionic cluster $[Cd_{17}Se_4(SePh)_{24}(PPh_2Pr)_4]^{2+}[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ provide the first evidence for collective interactions between the cluster molecules within the crystalline solids. The results from a recent report by Döllefeld et al. on the absorption and reflectance spectra of $[Cd_{17}S_4(SCH_2CH_2OH)_{26}]$ cluster molecules show that collective interactions in the crystalline state also influence the lowest energy transition bands relative to the those in solution.[5,6]

In the work presented herein, we study the influence of the subsequent change in the type of counterion used in the synthesis of the cluster anion $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ on the properties of the compounds formed in solution and in the solid state. The compounds were characterised using X-ray diffraction on single crystals and crystalline powders, as well as by using different spectroscopic methods such as UV/Vis spectroscopy and electrospray Fourier transform mass spectrometry. The latter has proven to be a powerful tool in identifying charged, large cluster species present in solution.[7]

Results and Discussion

Cluster compounds **1**−**7** have been synthesised according to Scheme 1. Different conditions were optimised for the crystallisation of the different clusters, depending on the type of counterion present.

Structure Determination by Single-Crystal X-ray Diffraction

For all the compounds, crystal structures have been determined by single-crystal X-ray analysis. The molecular structure of the cluster anion $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ is similar for all the compounds studied (Figure 1).[8,9] A central selenium atom Se1 is tetrahedrally surrounded by four "in-

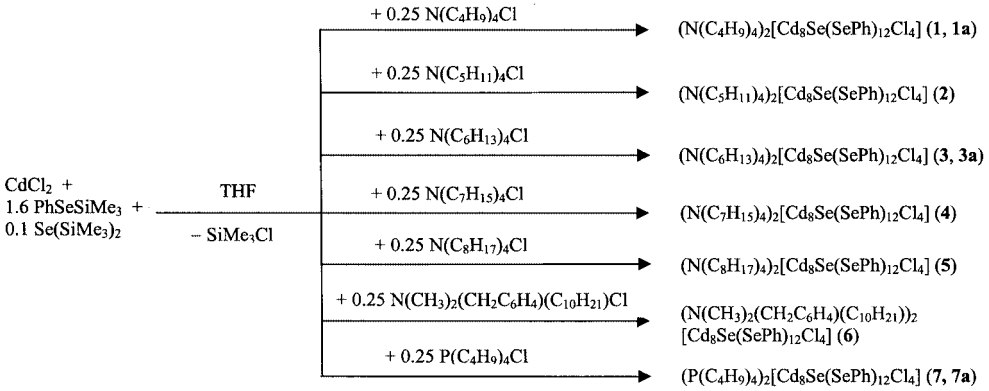

Scheme 1

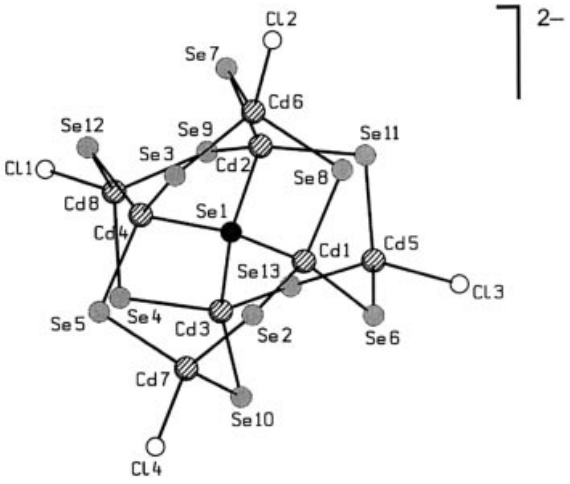

Figure 1. Molecular structure of the cluster anion $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ in **1**–**7**; C and H atoms are omitted for clarity; Se^{2-}: black, μ_2-$SePh^-$: grey, Cd^{2+}: hatched, and Cl^-: open circles

ner" cadmium atoms Cd1 to Cd4. Each of these four inner cadmium atoms is bound, through three μ_2-$SePh^-$ ligands (Se2 to Se13), to one of the four "outer" cadmium atoms Cd5 to Cd8, which also form a tetrahedron. In addition, each of the four outer cadmium atoms is bound to a terminal chloro ligand (Cl1 to Cl4). Each of the eight cadmium atoms has a distorted tetrahedral coordination sphere. The selenium atoms form a distorted icosahedron with the eight cadmium atoms bridging the triangular faces, whereby four of the cadmium atoms lie within, and four outside the icosahedron. The ranges of selected bond lengths are listed in Table 1 and display similar values for **1**–**7**, with the exception of the Cd–Se1 bond length range in **6**. In this compound a THF molecule is located close to Cd1 (Cd1–O2 2.813 Å), which possibly elongates the Cd1–Se1 bond length to a value of 2.672 Å.

The main difference in the structures of **1**–**7** arises as a result of the different crystal packing of the cluster anions and the ammonium or phosphonium cations. An interesting feature is the variation in the cluster–cluster distance in the crystal lattice. In Table 1, the variation of the shortest inter-cluster distances, measured as the distance between the central selenium atoms of the molecules, is shown (**1**: 15.076 Å, **1a**: 14.741 Å, **2**: 15.160 Å, **3**: 14.238 Å, **3a**: 14.995, **4**: 15.320 Å, **5**: 14.086 Å, **6**: 13.947 Å, **7**: 14.020 Å, **7a**: 14.145 Å). For all cluster molecules, the shortest inter-cluster distance varies from 13.95 Å in **6** to 15.32 Å in **4**. The trend in the variation of these distances is also followed by the shortest inter-cluster interactions between the selenium atoms. Interestingly, these values do not show a systematic increase with increasing length of the alkyl chain of the ammonium counterion. Even in **2**, **3a**, and **4**, which crystallise in the same space group with similar packing of the cluster molecules, inter-cluster distances do not systematically increase. In addition, different values for the pairs of similar compounds **1**, **1a** and **3**, **3a** and **7**, **7a** show that the size of the counterion is not the only parameter influencing the inter-cluster distance. The flexibility of the alkyl chains

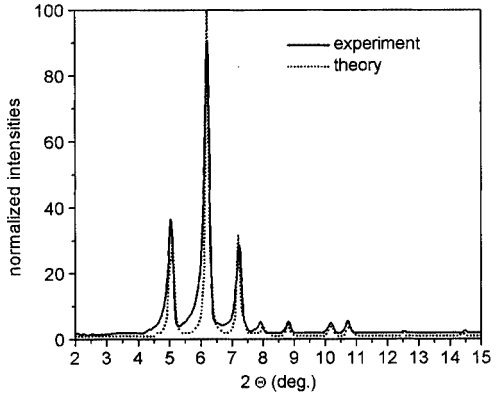
[a] Inter-cluster distances were measured as the distances between the central selenium atoms of the cluster molecules.

allows for the variable arrangements of the cations in the space between the $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anions, which, in addition to the incorporation of a varying number of solvent molecules, leads to the formation of different crystal packings. We found that the crystals incorporate more solvent molecules with increasing length of the alkyl chain of the ammonium cations, and as a result the crystal decomposes faster when separated from the mother liquor. Cations with more rigid and more bulky organic ligands than the "structurally weak" alkyl groups used here could lead to a better spacing of the cluster ions.

Powder X-ray Diffraction

In order to check the purity of the samples with respect to the possibility of the crystallisation of mixtures of different crystalline cluster compounds, as observed for **3**, **3a** and **7**, **7a**, powder X-ray diffraction patterns were measured for all compounds and compared with the calculated peak patterns from the data of the corresponding single-crystal X-ray analysis. The diffraction pattern of **4** (Figure 2, top) displays a good agreement between theory and experiment, however, those for **1**, **1a**, **2**, **3**, **3a**, **5**, **6**, **7**, and **7a** do not match the calculated patterns. Although the powder patterns show intense peaks in the low-angle region, the position of the peaks does not fit and the patterns could not be indexed. However, elemental analyses, UV/Vis spectra, and FT mass spectra (see below) all indicate the existence of the clusters determined by single-crystal X-ray diffraction. The powder patterns display no phase change on cooling from room temperature to 200 K. Determinations of the cell parameters of the single crystals at different temperatures also do not support the occurrence of phase changes, although difficulties do arise from the easy decomposition of the crystals at higher temperatures as a result of the loss of solvent molecules. Therefore, we suggest that the diffraction patterns of the dried crystalline powders show that the cluster molecules still present an order, but with a slight change in the lattice due to the loss of solvent molecules during the drying of the powder samples. In good agreement with this suggestion is the fact that the diffraction patterns of the crystalline powders in the mother liquor perfectly fit those calculated. The change in the curves by subsequent drying of the crystalline powder of **6** is shown in Figure 2 (bottom). The powder patterns of **3**, **3a** and **7**, **7a** measured in this way display peaks of both crystallographic species.



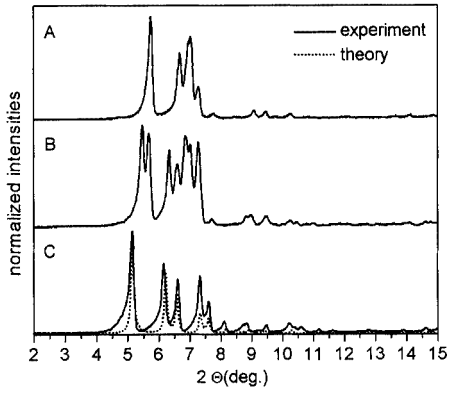


Figure 2. Top: room-temperature powder diffraction patterns of the dried crystalline powders of $[N(C_7H_{15})_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (**4**); bottom: change in room-temperature powder diffraction pattern of $[N(CH_3)_2(CH_2C_6H_4)(C_{10}H_{21})]_2[Cd_8Se(SePh)_{12}Cl_4]$ (**6**) by subsequent drying; A: dried under vacuum (10^{-3} bar); B: dried under nitrogen flow; C: as a suspension in THF (theoretical curve shown as dotted line)

FT Mass Spectrometry

Figure 3 shows a negative ion mass spectrum obtained by spraying a solution of crystalline **1** in 1,2-dichloroethane at a cone voltage of 25 V. It shows four peaks A−D that we identify as double negatively charged species: $[Cd_8Se(SePh)_{11}Cl_5]^{2-}$, $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$, $[Cd_8Se(SePh)_{13}Cl_3]^{2-}$, $[Cd_8Se(SePh)_{14}Cl_2]^{2-}$, respectively. The inset compares the high-resolution mass spectrum of peak B with the simulated isotope distribution pattern of $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$.

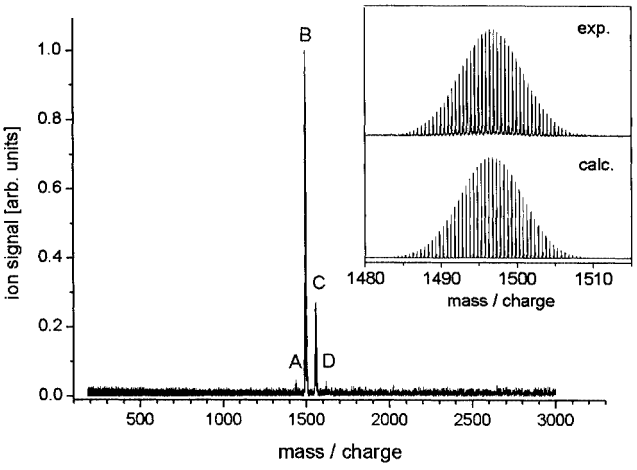

Figure 3. Electrospray FT mass spectrum of $[N(C_4H_9)_4^+]_2[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ (**1**) in negative ion mode; the inset shows the high-resolution peak B ($[Cd_8Se(SePh)_{12}Cl_4]^{2-}$), experiment and simulation

Table 2. Assignment of the observed negative ions in the ESI mass spectra (as shown in Figure 3)

Peak	Ion	*m/z* (exp.)	*m/z* (calcd.)	Rel. intensity
A	$[Cd_8Se(SePh)_{11}Cl_5]^{2-}$	1436.41	1436.24	0.04
B	$[Cd_8Se(SePh)_{12}Cl_4]^{2-}$	1496.41	1496.55	1.00
C	$[Cd_8Se(SePh)_{13}Cl_3]^{2-}$	1556.92	1556.87	0.25
D	$[Cd_8Se(SePh)_{14}Cl_2]^{2-}$	1616.93	1617.18	0.03

The results are summarised in Table 2. It is worth noting that no fragmentation of the cluster ion occurred as long as cone voltages were kept below 30 V. This proves the high stability of these cluster complexes and also strongly suggests that these species are present intact in solution. Mass spectra taken from all seven compounds **1**−**7**, under virtually identical conditions, reveal very similar results, with slight variations in the relative intensities of peaks A−D. The observation of peaks A, C, and D next to the parent ion B is indicative of a ligand exchange process. Ligand exchange reactions were recently observed in electrospray mass spectrometric studies on thiophenolate-capped clusters of CdS, CdSe, and ZnS,[10−12] under conditions where partial fragmentation also takes place. Contrary to these studies, the mass spectra of our selenophenolate-bridged clusters do not show any ion signal due to Cl^- or $SePh^-$.

Given the relative ion intensities observed, the cluster has a tendency to lose Cl^- in favour of $SePh^-$, while keeping the total number of ligands constant. This could indicate that the cluster keeps its original structure as shown in Figure 1. This exchange can be attributed to the fact that $SePh^-$ is a better bridging ligand than Cl^-. However, the observation of $[Cd_8Se(SePh)_{11}Cl_5]^{2-}$ proves that a bridging $SePh^-$ ligand which is replaced by Cl^- potentially leads to a species with halide bridging. As the FT mass spectra show the same peaks when using different solvents, namely THF, acetonitrile, dichloromethane, and 1,2-dichloroethane, we deduce that this ligand exchange is a direct result of intercluster reactions.

Warming and cooling of the solutions of the cluster molecules do not lead to a change in the observed mass spectra or UV/Vis spectra (see next chapter). Mass spectra taken from solutions after one week also do not differ from the original spectra, showing their intrinsic stability.

UV/Vis Spectroscopy

UV/Vis absorption spectra of solutions of **1**−**7** in 1,2-dichloroethane were measured. All compounds display a very similar spectrum, with a maximum at 301 nm and a minimum at 284 nm. Figure 4 shows the absorption spectra of **2** with $\varepsilon = 6.12 \cdot 10^4\ M^{-1}cm^{-1}$ at 301 nm (dashed line). According to these results, it is obvious that the different counterions have virtually no effect on the absorption behaviour of the cluster anions in solution. Solid state reflectance spectra of **1**−**7** were measured directly on the milled crystalline powders or as a mull in oil between two quartz plates inside an integrating sphere (Figure 4). For all compounds, the onset of the absorption shifts slightly to

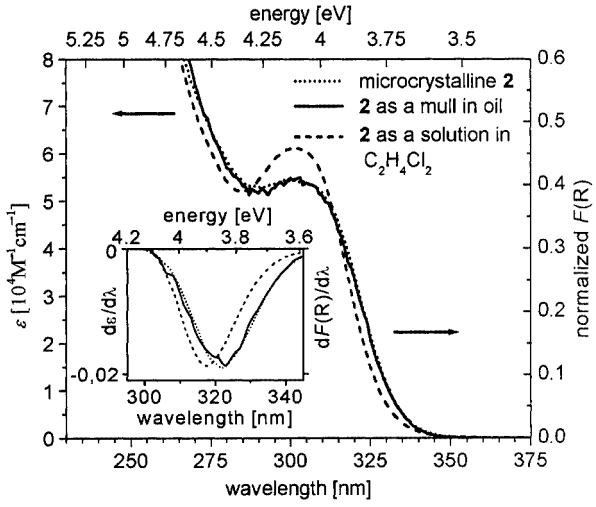

Figure 4. UV/Vis absorption spectrum of $[N(C_5H_{11})_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (**2**) in $C_2H_4Cl_2$ (dashed line) and UV/Vis reflectance spectra of **2** as a mull in mineral oil (straight line) and as a microcrystalline powder (dotted line); the inset shows part of the first derivative spectra

lower energies relative to that in the solution spectra. This is accompanied by a loss of structure, as can be seen from the spectra of **2** in Figure 4. Slight differences in the solid state spectra of **1**−**7** are thought to arise mostly from the quality of the mull, since the concentration and grain sizes cannot be kept constant for all the samples. Therefore, these differences cannot be related to the different spacing of the $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anions in the crystal lattice. Further, the powder X-ray diffraction patterns reveal that the crystals lose solvent molecules on drying, which is accompanied by a change in the packing in the crystal lattice. This leads to the deduction that the different counterions have no distinct influence on the UV/Vis absorption spectra of the $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anion in the solid state as well.

The broadening of the solid state spectra, indicated by a shift of the maximum of the first derivative by about 55 meV to lower energies with respect to the spectra in solution, could result from the effect of the crystal packing and/or of the counterion on the electronic properties in the solid state, as was recently suggested by Döllefeld et al. for crystals of $[Cd_{17}S_4(SCH_2CH_2OH)_{26}]$.[5] They found a shift of the first electronic transition to lower energies by about 150 meV in the reflectance spectra of micron-sized crystals, relative to that in their solution spectra in DMF. They suggest that both the electronic and the dipole−dipole interactions play a role in the complete description of the interactions between semiconductor nanoclusters in crystalline superstructures. Besides the difference in charges, the main difference between the compound $[Cd_{17}S_4(SCH_2CH_2OH)_{26}]$ investigated by Döllefeld et al. and the $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anions in this work is the fact that the former are directly bonded in the crystal lattice to one another by bridging thiolato ligands. The remarkable change in the solid state and solution spectra in this case may arise from

the breaking of the covalent bonds of the bridging thiolato groups by the strongly coordinating solvent DMF. This suggestion is also supported by the fact that the authors can find for thin layers of this cluster deposited from DMF solutions only a broadening of the lowest energy transition in comparison to the spectra of the DMF solutions.[6]

Regarding the $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anions, the use of various solvents, with a range of dielectric constants (ε_r), has a clear effect on the absorption properties of the cluster molecules, as can be seen for **7**, **7a** (Figure 5). The absorption spectra in dichloromethane (ε_r = 8.9) and 1,2-dichloroethane (ε_r = 10.2) are very similar, whereas the first absorption maximum in acetonitrile (ε_r = 37.5) is shifted by about 41 meV to a higher energy. The shape of the first absorption peak in the spectra of **7**, **7a** in THF (ε_r = 7.6) is more featureless and broader than those in the other solution spectra. While the value for the first absorption maximum is similar to that found in acetonitrile, the inflection point (maximum of the first derivative) is similar to that in the two chlorinated solvents. Therefore, the shift of the lowest energy absorption band does not simply follow the change in the permittivity of the medium, but is probably more affected by the different coordination properties of the various solvents. In this context, it can be seen that a THF molecule coordinates one cadmium atom of the $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anion in **6**, leading to a coordination number of five for this metal atom.

FT mass spectrometry clearly shows the existence of the intact $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anion in all solutions. However, the observed ligand exchange reaction of chlorine atoms for phenylselenolato ligands could also have an effect on the UV/Vis absorption spectra, although we cannot rule out that these reactions take place in the electrospraying step. Interestingly, the use of the different solvents, THF, acetonitrile, dichloromethane, and 1,2-dichloroethane, leads to virtually identical products of ligand exchange, with slightly varying intensities in the FT mass spectra.

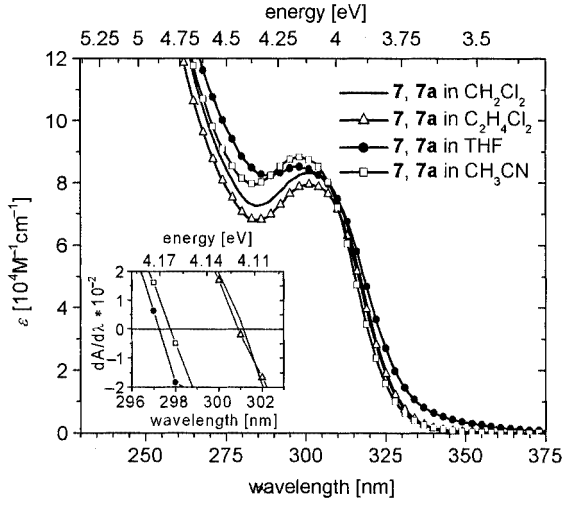

Figure 5. UV/Vis absorption spectra of $[P(C_4H_9)_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (**7**, **7a**) dissolved in different solvents; the inset shows part of the first derivative spectra; values for the relative dielectric constants, ε_r, of the solvents are: 8.9 (CH_2Cl_2), 10.2 ($C_2H_4Cl_2$), 7.6 (THF), 37.5 (CH_3CN)

Conclusions

A series of seven single-crystalline CdSe cluster molecules with the same $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anion has been synthesised by altering the counterion. The cluster molecules were characterised by a detailed analytical investigation, which included single-crystal XRD, powder XRD, UV/Vis spectroscopy, as well as FT mass spectrometry. The results of the crystal structure determination show that the increasing size of the different counterions does not simply lead to an increase in the shortest inter-cluster distances, but rather to changes in the crystal structure. Room-temperature UV/Vis absorption and reflectance spectra of the crystalline powders are virtually identical, proving that the electronic transitions in the energy range probed can be attributed to the cluster anion $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$. The band of the lowest energy transition in the solid-state UV/Vis spectra are broadened relative to that in the solution spectra, as it is possibly affected by the collective interactions between the nanoclusters in the three-dimensional crystal lattice. Interestingly, in solution, the position and feature of the lowest energy transition band changes as the solvent is varied. As FT mass spectrometry gives clear evidence for the existence of the intact $[Cd_8Se(SePh)_{12}Cl_4]^{2-}$ cluster anion in all these solutions, these shifts can be interpreted in terms of solvatochromic effects.

Further studies will focus on the use of other counterions, including higher charged species and more rigid organic ligands, and on the crystallisation of larger ionic cluster molecules that are shown to be stable from simple theoretical calculations.[13] Additional synthetic interest arises from the possibility to form covalently linked two- or three-dimensional networks of these cluster molecules, through reaction of the four reactive Cd−Cl bonds with bifunctional silylated chalcogen compounds, such as $(Me_3Si)Se-R-Se(SiMe_3)$, where R = C_2H_4, C_3H_6, C_4H_8. Interesting collective phenomena based on direct cluster−cluster interactions are to be expected in these compounds.

Experimental Section

Syntheses: Standard Schlenk techniques were employed throughout the syntheses using a double manifold vacuum line with high-purity dry nitrogen. The solvents tetrahydrofuran and diethyl ether were dried with sodium/benzophenone and distilled under nitrogen. Anhydrous $CdCl_2$, as well as ammonium and phosphonium salts, were purchased from Aldrich. $PhSeSiMe_3$ [14] and $Se(SiMe_3)_2$ [15] were prepared according to standard literature procedures.

$[N(n\text{-}C_4H_9)_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (1, 1a): $CdCl_2$ (0.20 g, 1.09 mmol) and $N(n\text{-}C_4H_9)_4Cl$ (0.08 g, 0.27 mmol) were suspended in 130 mL of THF. $PhSeSiMe_3$ (0.33 mL, 1.74 mmol) was then added, and the resulting clear solution stirred overnight. Addition of $Se(SiMe_3)_2$ (0.025 mL, 0.11 mmol) at −40 °C, and warming to room temper-

ature led to the formation of colourless hexagonal plates of **1**, **1a**, with a total yield of 60% after further concentration of the solution. $C_{104}H_{132}Cd_8Cl_4N_2Se_{13}$ (3477.48): calcd. C 35.92, H 3.83, N 0.83; found C 35.93, H 3.98, N 0.88. Suitable crystals for single-crystal XRD were obtained either by layering the concentrated filtered solution with diethyl ether to yield **1**, or by recrystallising the white crystalline powder from THF at −20 °C to give **1a**.

$[N(n\text{-}C_5H_{11})_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (2): $CdCl_2$ (0.24 g, 1.31 mmol) and $N(n\text{-}C_5H_{11})_4Cl$ (0.11 g, 0.33 mmol) were suspended in 70 mL of THF. $PhSeSiMe_3$ (0.40 mL, 2.10 mmol) was then added, and the resulting clear solution was stirred overnight. Addition of $Se(SiMe_3)_2$ (0.029 mL, 0.13 mmol) at −30 °C, and warming to room temperature led to the formation of colourless crystals of **2** with a yield of 74%. **2** can be recrystallised from THF on careful addition of small aliquots of diethyl ether. $C_{112}H_{148}Cd_8Cl_4N_2Se_{13}$ (3589.99): calcd. C 37.47, H 4.16, N 0.78; found C 37.89, H 4.39, N 0.82.

$[N(n\text{-}C_6H_{13})_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (3, 3a): $CdCl_2$ (0.24 g, 1.31 mmol) and $N(n\text{-}C_6H_{13})_4Cl$ (0.13 g, 0.33 mmol) were suspended in 70 mL of THF. $PhSeSiMe_3$ (0.40 mL, 2.10 mmol) was then added, and the resulting clear solution stirred overnight. Addition of $Se(SiMe_3)_2$ (0.029 mL, 0.13 mmol) at −30 °C, and warming to room temperature led to the formation of colourless crystals of **3**, **3a**, with a yield of 62%. Suitable crystals of **3** were obtained directly from the reaction solution at room temperature, while crystals of **3a** were grown at 0 °C. $C_{120}H_{164}Cd_8Cl_4N_2Se_{13}$ (3702.21): calcd. C 38.93, H 4.46, N 0.76; found C 38.72, H 4.48; N 0.85.

$[N(n\text{-}C_7H_{15})_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (4): $CdCl_2$ (0.18 g, 0.98 mmol) and $N(n\text{-}C_7H_{15})_4Cl$ (0.11 g, 0.25 mmol) were suspended in 75 mL of THF. $PhSeSiMe_3$ (0.30 mL, 1.57 mmol) was then added, and the resulting clear solution stirred overnight. Addition of $Se(SiMe_3)_2$ (0.022 mL, 0.098 mmol) at −30 °C, and warming to room temperature led to the formation of a small amount of a precipitate of unknown composition. This was filtered, and on addition of 5 mL of diethyl ether, colourless crystals of **4** were formed with a 68% yield. **4** can be recrystallised from THF on addition of aliquots of diethyl ether. $C_{128}H_{180}Cd_8Cl_4N_2Se_{13}$ (3814.42): calcd. C 40.30, H 4.76, N 0.73; found C 38.98, H 4.76, N 0.63.

$[N(n\text{-}C_8H_{17})_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (5): $CdCl_2$ (0.21 g, 1.15 mmol) and $N(n\text{-}C_8H_{17})_4Cl$ (0.14 g, 0.25 mmol) were suspended in 50 mL of THF. $PhSeSiMe_3$ (0.35 mL, 1.84 mol) was then added, and the resulting clear solution stirred overnight. Addition of $Se(SiMe_3)_2$ (0.026 mL, 0.12 mmol) at −30 °C, and warming to room temperature led to the formation of a clear colourless solution. Concentration to 3 mL led to the formation of thin needles in a white precipitate of unknown composition. This was filtered, and on addition of 8 mL of diethyl ether, colourless crystals of **5** were formed with a 65% yield. **5** can be recrystallised from THF on addition of aliquots of diethyl ether. $C_{136}H_{196}Cd_8Cl_4N_2Se_{13}$ (3926.64): calcd. C 41.60, H 5.03, N 0.71; found C 41.08, H 4.99, N 0.75.

$[N(CH_3)_2(CH_2C_6H_4)(n\text{-}C_{10}H_{21})]_2[Cd_8Se(SePh)_{12}Cl_4]$ (6): $CdCl_2$ (0.17 g, 0.093 mmol) and $N(CH_3)_2(CH_2C_6H_4)(n\text{-}C_{10}H_{21})Cl$ (0.07 g, 0.23 mmol) were suspended in 60 mL of THF. $PhSeSiMe_3$ (0.28 mL, 1.49 mmol) was then added, and the resulting clear solution stirred overnight. Addition of $Se(SiMe_3)_2$ (0.021 mL, 0.093 mmol) at −30 °C, and warming to room temperature led to the formation of colourless crystals of **6**; concentration led to the further precipitation of crystals, yielding 71% of **6**. $C_{110}H_{128}Cd_8Cl_4N_2Se_{13}$ (3545.81): calcd. C 37.26, H 3.64, N 0.79; found C 38.61, H 4.02, N 0.94.

$[P(n\text{-}C_4H_9)_4]_2[Cd_8Se(SePh)_{12}Cl_4]$ (7, 7a): $CdCl_2$ (0.25 g, 1.36 mmol) and $P(n\text{-}C_4H_9)_4Cl$ (0.10 g, 0.34 mmol) were suspended in 150 mL of THF. $PhSeSiMe_3$ (0.42 mL, 2.18 mmol) was then added, and the resulting clear solution stirred overnight. Addition of $Se(SiMe_3)_2$ (0.031 mL, 0.14 mmol) at −30 °C, and warming to room temperature led to the formation of a colourless solution. Colourless crystals of **7**, **7a** were formed after concentration, with a 76% yield. Recrystallisation from THF/diethyl ether also yielded a mixture of crystals of **7** and **7a**. $C_{104}H_{132}Cd_8Cl_4P_2Se_{13}$ (3511.71): calcd. C 35.57, H 3.79 found C 35.58, H 3.94.

Structure Determinations: Crystals suitable for single-crystal X-ray diffraction were obtained directly from the reaction solutions of compounds **2**, **3**, **3a**, **4**, **6**, **7**, and **7a**. In the case of **1a** and **5**, crystals were grown by recrystallisation of the obtained microcrystalline powders. **1** was crystallised by layering of the concentrated reaction solution. Single-crystal X-ray diffraction data were collected using graphite-monochromatised Mo-K_α radiation (λ = 0.71073 Å) with a STOE IPDS (Imaging Plate Diffraction System), equipped with a SCHNEIDER rotating anode. All the structures were solved with the direct methods program SHELXS[16] of the SHELXTL PC suite programs, and they were refined with the use of the full-matrix least-squares program SHELXL.[16] Molecular diagrams were prepared using the program SCHAKAL 97.[17] All Cd, Se, and Cl atoms were refined with anisotropic displacement parameters. In **1a**, **3a**, **5**, **6**, **7**, and **7a**, the N, P, and the C atoms of the SePh rings were also refined anisotropically. The C atoms of the phenyl groups in **1** were refined isotropically as a rigid group. In **6**, the atoms C1 to C6, and in **3**, the atoms C55 to C60 are disordered. The C atoms of the ammonium and phosphonium counterions were all refined isotropically and show some disorder in the case of **3**, **6**, and **7**. In **5**, some of the C atoms of the $N(C_8H_{17})_4^+$ counterions show high thermal parameters due to the flexibility of the long alkyl chain and could only be refined with reduced occupancy. For one octyl chain in **5**, only four carbon atoms could be located in the difference fourier map. These problems probably arise from the fact that the crystals decompose, even at 110 K after 1 d of measurement. THF and Et_2O solvent molecules were mostly refined with half occupancy because of a high degree of disorder and large thermal parameters. The H atoms of the SePh groups were included in the calculated positions for **2**, **3a**, **4**, **7**, and **7a**. X-ray powder diffraction data (XRD) were collected with a STOE STADI P diffractometer (Cu-K_α radiation, germanium monochromator, Debye−Scherrer geometry). The measurements were performed on crystalline powders, dried or in mother liquor, in 0.5 mm sealed glass capillaries. Theoretical powder diffraction patterns for **1**−**7** were calculated on the basis of the atom coordinates obtained from single-crystal X-ray analysis using the program package STOE WinXPOW.[18] Crystal data for each compound are listed in Tables 3 and 4.[19]

UV/Vis Measurements: Absorption spectra of cluster molecules in solution were measured with a Perkin−Elmer Lambda 900 spectrophotometer in quartz cuvettes. Solid state reflectance spectra were measured with a Varian Cary 500 as micron-sized crystalline powders or as nujol mulls between quartz plates inside a Labsphere integrating sphere.

FT-Mass Spectrometry: Mass spectra were measured with a 7-Tesla-APEX II Fourier transform mass spectrometer (Bruker Daltonics) equipped with an electrospray ionisation source (Analytica of Branford). Freshly prepared solutions of compounds **1**−**7** in $C_2H_4Cl_2$ (ca. 0.1 mmol/L) were sprayed employing a syringe infusion pump (Cole-Parmer), at typical rates of 300 μL/h. Neat nitro-

A DFT Study of Tin- and Crown-Ether-Based Host Molecules Capable of Binding Anions and Cations Simultaneously

Ricardo Vivas-Reyes,[a,b] Frank De Proft,[b] Monique Biesemans,[c] Rudolph Willem,[c] and Paul Geerlings*[b]

Keywords: Acidity / Basicity / Crown compounds / Density functional calculations / Host-guest systems / Tin

DFT calculations are reported for a series of tin- and crown-ether-based host compounds {i.e., the trimethyl derivatives [18]-crown-6-$C_6H_3COOSn(CH_3)_3$ and [15]-crown-5-$C_6H_3COOSn(CH_3)_3$} capable of binding cations and anions simultaneously. The B3LYP functional together with the 6-31G* basis set was used for the atoms C, H, N, O, S, Na and K and the 3-21G* basis set for Sn in order to obtain insights into the factors determining the nature of the interactions of these compounds with the neutral molecules acetone and H_2O, the SCN^- anion, and the Na^+ and K^+ cations. The interaction strength pattern with these molecules was explained by the use of a series of reactivity descriptors such as the Fukui function, hardness, local softness, and the MEP (molecular electrostatic potential). In all cases studied in this paper, the complexes with Na^+ were more stable than those with K^+, correlating with the size of the cation and the volume available in the crown ether. Moreover, this finding is also in accordance with the greater hardness of Na^+ relative to K^+, in combination with the hard environment of the crown ether moiety. This region was also analysed by computation of electrostatic potentials, which showed that highly negative values are associated with the inside region of the cavity of the crown, this region thus being amenable to electrophilic attack. The HSAB principle, characterising the reactive sites on the basis of local softness and the Fukui function, provided a firm explanation of the reactivity of the tin atom of the crown ether benzocarboxylate towards SCN^-, acetone and water. The HSAB concept was also successfully used to explain the preference of the tin atoms in both crown ethers to bind with the nitrogen atom rather than the sulfur atom of SCN^-. This result is a confirmation that the tin atoms in the compounds under consideration behave as hard atoms. Overall, these results fit remarkably well with previous experimentally measured NMR spectroscopy data and demonstrate that the interactions of this kind of molecules can be predicted and interpreted by the use of DFT calculations and DFT-based reactivity descriptors, as well as MEP calculations.

1. Introduction

The complexation of host molecules capable of binding an anion and a cation simultaneously is still a relatively unexplored topic in chemistry.[1] Numerous studies, however, have been devoted either to the interactions between cations and preorganised host molecules,[2] or to fixation of anions by neutral molecules containing Lewis acidic metal centres.[3] Studies on interactions between crown ethers and various inorganic and organic cations have spawned wide applications in chemistry, biology, medicine and technology,[4] while the Lewis acidity of the tin atom in, for instance, organotin halides is well documented.[5] Fewer studies have been reported on interactions of Lewis bases with organotin carboxylates,[6] despite widespread interest in their in vitro antitumour activity[7] and their rich structural diversity in the solid state.[8]

We recently reported a novel type of salt complexation by a new class of host molecules, containing both a crown ether susceptible to interaction with the cation and a Lewis acidic tin centre potentially acting as an anion carrier.[9] It was demonstrated that tri-*n*-butyl and triphenyltin derivatives of 4-carboxybenzo-[18]crown-6 or [15]crown-5 are receptors capable of binding M^+SCN^- ion pairs heterotopically. The Lewis acidic complexation of Sn by the thiocyanate anion cooperates with the crown ether complexation by the alkali metal cation and gives rise to a large charge separation, as evidenced by X-ray data in the crystalline state for the triphenyltin derivatives and by NMR spectroscopic data in solution for the tri-*n*-butyltin analogues.

This paper presents a theoretical investigation of the trimethyltin analogues of these compounds {i.e., [18]crown-6-$C_6H_3COOSn(CH_3)_3$ and [15]crown-5-$C_6H_3COOSn(CH_3)_3$,

see Figure 1, the triphenyltin and tributyltin analogues being computationally too time-consuming}, in order to gain more insight into the factors determining the nature of the interactions of these molecules with the SCN^- anion and the Na^+ and K^+ cations. Moreover, as far as the inductive effects of the functional groups attached to the tin atom are concerned, the methyl group lies in between the +I *n*-butyl group and the −I phenyl group, and so also constitutes an optimal choice from that point of view. The studies were performed at a nonempirical ab initio level, still relatively rare for tin-containing compounds,[10] and interpreted by the use of DFT-based descriptors and principles.

Of particular interest in the understanding of chemical reactivity are the so-called response functions of the system to perturbations in the number of electrons or external potential, commonly referred to as atomic or molecular reactivity descriptors.[11−17] These descriptors have a sound basis in density functional theory (DFT).[18] Electronic chemical potential (μ), electronegativity (χ), hardness (η) and softness (*S*) are examples of such reactivity descriptors (for detailed accounts see refs.[18b−18d]). In this work, the basic quantities to be addressed are hardness and softness both at the global (i.e., molecular) and at the local (i.e., atomic sites in molecules) levels. A detailed discussion of these quantities can be found elsewhere.[18−24]

The local properties[18] developed are the Fukui function (FF) and the local softness typically describing the local role of a specific atom within a molecule in the reactivity of the latter.[18]

Fukui function and local softness, which are related to changes in the electron density function $\rho(r)$ with the total number of electrons at constant external potential $[\partial\rho(r)/\partial N]_v$, have been used to determine the site of reactivity of a system.[25] The FF was originally used essentially as an indicator of intramolecular reactivity sequences[26] (regioselectivity), the local softness being involved in intermolecular reactivity sequences. When the HSAB principle is used at a local level, the consideration of local softness turns out to be essential for estimating relative interaction energies of different sites in a molecule towards electrophilic or nucleophilic reagents.

In this study, and also in the context of a series of papers aiming at the description of properties of tin compounds with the aid of DFT reactivity indicators,[27−28] we investigate the use of the FF and the local softness to describe the interactions between the tin atom and the SCN^- anion, as well as neutral molecules such as acetone for which experimental NMR spectroscopic data are available,[9] Pearson's hard and soft acids and bases (HSAB) principle[19−21] being expected to act as the guiding principle.[29,30] When the HSAB principle is applied in a local sense,[31] regioselectivity problems can be addressed on the basis of the idea that soft (or hard) regions of one reaction partner will preferentially interact with soft (or hard) regions of the other partners.[32−34] We are also interested in knowing whether (i) only the cation or the anion is involved in a monotopic interaction, or (ii) both ions are involved in a heterotopic interaction.[1k] If the latter holds, an additional question is whether anions and cations remain electrostatically paired or undergo a charge separation from their initial ion pair.

The molecular electrostatic potential (MEP) is also used to predict the behaviour of the crown ether moiety, because its cavity is expected to be hard, as it is found to interact with hard cations such as Na^+ and K^+.

The MEP[35−37] has indeed been found suitable for the description of electrostatic (i.e., nonorbital-based) interactions, and has been used in recent years to study the structures and reactivities of polyoxometallate cages and, in our group, the $(CH_3Sn)_{12}O_{14}(OH)_6^{2+}$ cationic cluster.[28] The spatial distribution and the values of the MEP can be taken, at least in the case of a fairly hard reagent, as an indicator of where a nucleophilic or electrophilic attack is likely to take place. We used MEP calculations to describe the interactions between the oxygen atoms of the crown ether and Na^+ and K^+ cations.

2. Theory and Computational Details

As a detailed presentation and discussion of the reactivity parameters used in this paper can be found elsewhere,[18,38] only the relevant expressions used for the evaluation of different quantities for the crown ethers [15]crown-5-$C_6H_3COOSn(CH_3)_3$ and [18]crown-6-$C_6H_3COOSn(CH_3)_3$ are given here.

The global hardness (η) and the global softness (*S*) are calculated from Equations (1) and (2), by use of the finite-difference approximation, where *IE* and *EA* are the vertical ionisation energy and electron affinity, respectively.

$$\eta = \frac{IE - EA}{2} \quad (1)$$

$$S = \frac{1}{2\eta} \tag{2}$$

The Fukui function $f(r)$ is defined as the partial derivative of the total electron density at a given point r, $\rho(r)$, with respect to the number of electrons N, at constant external potential $v(r)$ (the potential exerted by the nuclei) determined for the N values considered. Parr and Yang[18,19,25] have proposed an association of different reactivity indices through Equation (3).

$$f(\underline{r}) = \left(\frac{\partial \rho(\underline{r})}{\partial N}\right)_{v(\underline{r})} \tag{3}$$

The expressions used to investigate nucleophilic or electrophilic attack on the system are given by Equation (4) for a nucleophilic attack and Equation (5) in the case of an electrophilic attack.

$$f^{+}(\underline{r}) = \left(\frac{\partial \rho(\underline{r})}{\partial N}\right)^{+}_{v(\underline{r})} \tag{4}$$

$$f^{-}(\underline{r}) = \left(\frac{\partial \rho(\underline{r})}{\partial N}\right)^{-}_{v(\underline{r})} \tag{5}$$

The superscripts + and − refer to right and left derivatives, respectively. In a finite difference approach, $f^{+}(r)$ and $f^{-}(r)$ can be approximated by Equations (6) and (7),[18,25,39] where ρ_N, ρ_{N+1} and ρ_{N-1} are the electron densities of the systems with N, $N + 1$ and $N - 1$ electrons, respectively.

$$f^{+}(\underline{r}) \approx \rho_{N+1}(\underline{r}) - \rho_{N}(\underline{r}) \tag{6}$$

$$f^{-}(\underline{r}) \approx \rho_{N}(\underline{r}) - \rho_{N-1}(\underline{r}) \tag{7}$$

Because of the constraint of a constant external potential, the quantities ρ_{N+1} and ρ_{N-1} are calculated with the same geometry as the N electron system.

The f^{o} function, which governs radical attack, is considered to be the average of $f^{+}(r)$ and $f^{-}(r)$, and can therefore be approximated by Equation (8).

$$f^{o}(\underline{r}) \approx \frac{1}{2}[\rho_{N+1}(\underline{r}) - \rho_{N-1}(\underline{r})] \tag{8}$$

Yang and Mortier[26] have also proposed a condensed version of Equations (6) to (8). The information contained in $f(r)$ in the neighbourhood of a given atom A can be approximated by use of the atomic population N_A, obtained by population analysis on the considered atom.[40] Accordingly, the condensed Fukui function on the atom A, f_A, is obtained as Equations (9) to (11), where $N_A(N)$ stands for the atomic population on atom A in the N electron system.

$$f_A^{+} \approx N_A(N+1) - N_A(N) \tag{9}$$

$$f_A^{-} \approx N_A(N) - N_A(N-1) \tag{10}$$

$$f_A^{o} \approx \frac{1}{2}[N_A(N+1) - q_A(N-1)] \tag{11}$$

According to the relation given in Equation (12) the corresponding condensed local softness parameters can easily be calculated from the condensed Fukui function and the global softness, as in Equation (13).

$$s(\underline{r}) = Sf(\underline{r}) \tag{12}$$

$$s_A^{+} = Sf_A^{+} \tag{13}$$

The MEP,[36,37] $V(r)$, was calculated in the usual way, neglecting polarisation and nuclear rearrangement effects, as described in Equation (14), where the summation runs over all nuclei A with charge Z_A and coordinate R_A.

$$V(\underline{r}) = \sum_A \frac{Z_A}{|\underline{R}_A - \underline{r}|} - \int \frac{\rho(\underline{r}')}{|\underline{r}' - \underline{r}|} d\underline{r}' \tag{14}$$

The first term on the right-hand side of Equation (14) gives the contribution of the nuclei, the second term reflects the effect of the electrons.

In this contribution, the MEP has been computed in a plane containing three oxygen atoms (oxygen O1, O2 and O3; see Figure 1) of the crown ether moiety, for both the [18]crown-6 and the [15]crown-5 systems (see Figures 3 and 4, respectively). The MEP was also calculated on a straight line perpendicular to the plane containing the oxygen atoms used to calculate the MEP contours, starting at 5 Å above and ending 5 Å below the mean crown ether plane, with steps of 0.01 Å.

Structures and energies were calculated with the aid of the Gaussian98[41] program. All geometries were completely optimised at the DFT level with the B3LYP[42−44] functional, with a 6-31G*[45] basis set for H, C, O, Na and K and 3-21G*[45] for Sn.

The geometries of all the complexes between the tin atoms of the crown ether derivatives and the nucleophiles (SCN^{-}, acetone and water) interacting with the tin atom, and the cations (Na^{+} and K^{+}) interacting with the crown ether moiety itself were fully optimised.

3. Results and Discussion

The stabilisation energies resulting from the interactions between [15]crown-5-$C_6H_3COOSn(CH_3)_3$ and [18]crown-6-

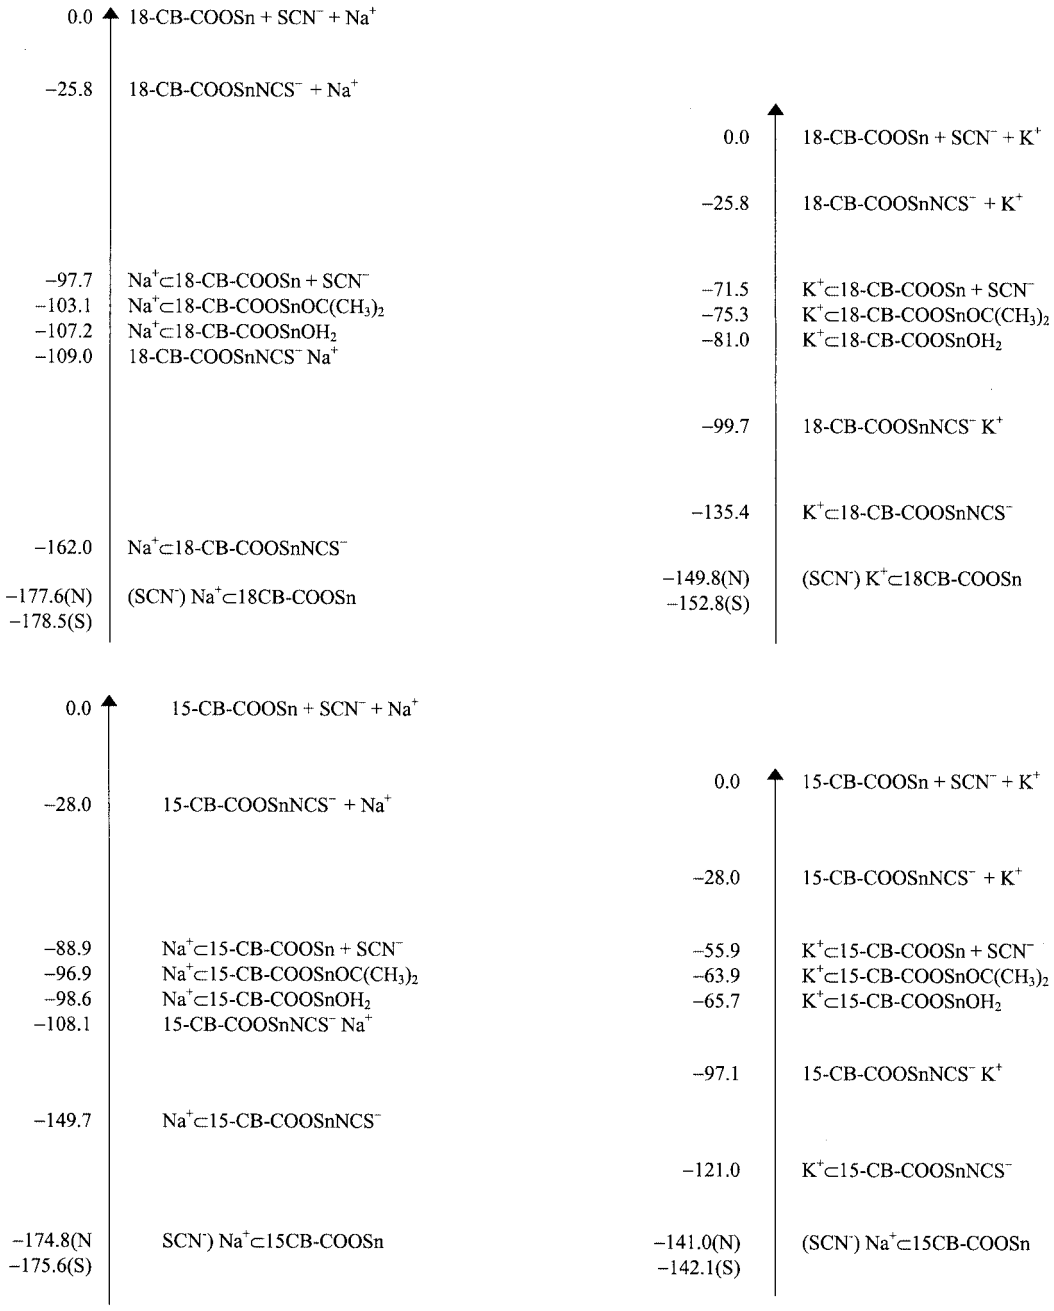

Figure 2. Diagram of stabilisation energies (B3LYP level) for (top left) the [18]crown ether complexes with different nucleophiles and Na^+, (top right) the [18]crown ether complexes with different nucleophiles and K^+, (bottom left) the [15]crown ether complexes with different nucleophiles and Na^+, and (bottom right) the [15]crown ether complexes with different nucleophiles and K^+; the methyl groups on tin are omitted for clarity

$C_6H_3COOSn(CH_3)_3$, nucleophiles either charged or uncharged and of variable softness (SCN^-, acetone and H_2O), and cations (Na^+ and K^+) are shown in Figures 2a−d. The hardness sequence of the above nucleophiles was calculated at the level outlined in the previous section to yield: H_2O (8.42 eV) > acetone (5.91 eV) > SCN^- (4.36 eV). The investigated complexes displayed interactions between a nucleophile and the tin atom on one hand, and on the other hand between the alkali cations and either the crown ether cavity or the nucleophilic sulfur atom of the SCN^- anion.

The stabilisation energies for the complexation of the crown ether tin derivative with SCN^-, H_2O and acetone were calculated both with Na^+ and with K^+ in the crown ether moiety of the molecule. Initially the nucleophiles were positioned at a distance of 2.20 Å from the tin atom and forming an angle of 180° between the attacking atom of the nucleophile (the oxygen atom for water or acetone and the N atom for SCN^-), the tin atom and the oxygen atom of the carboxylate group bound to tin. The final geometry of the complex of acetone and water with Sn was almost ident-

ical for both crown ether tin derivatives, the final distance between the Sn atom and the attacking nucleophilic atom in all cases being between 2.55 and 2.56 Å. The deviations with respect to the original NSnO(7) angle in the X-ray data were only 3.2° and 3.5° for both crown ethers. For the complex with SCN^-, the final distance between the Sn atom and the attacking N atom was 2.10 Å and the deviation in the angle was 3.0°.

This orientation (attacking N and not S) was considered first in view of the crystallographic data,[9] this regioselectivity being further discussed below.

The much smaller Sn−N distances of 2.10 Å − in comparison with the Sn−O distance of 2.55 Å − in the water and acetone complexes suggest a stronger complex (vide infra).

The results of the calculations of the stabilisation energies obtained as a result of the interaction of the SCN^-, H_2O and acetone nucleophiles with the tin atom and the Na^+ or K^+ cations with the crown ether moiety are shown in Figure 2a−d.

The influence of the nature of the cation and the crown ether size is discussed first on the basis of MEP calculations. The MEP contours of the crown ethers (see Figures 3 and 4) show that the crown cavity is associated with negative values of the electrostatic potential while the regions outside the crown ether ring are associated with positive values of the electrostatic potential. This behaviour of the MEP thus straightforwardly explains the positions of the Na^+ and K^+ cations in the crown ether cavity.

In order to find where the minimum (expected to appear in a region with a substantial accumulation of electronic density) was located, we calculated the potential on a straight line over a distance of 10 Å from 5 Å above to 5 Å below the averaged crown ether plane. The results of this calculation can be seen in Figure 5; the minimum was found exactly at the point where the cation should be located and, moreover, a more negative value is associated with the [18]crown-6 ether (−0.1452 a.u.) than for the [15]crown-5 ether (−0.1062 a.u.).

Na^+ complexes are systematically more stable than K^+ complexes, which can be correlated with the larger ionic radius of K^+ (133 pm versus 68 pm for Na^+) taking into account the space available in the crown ether.[46] It is also in accordance with the greater hardness of Na^+ than of K^+, thus interacting more favourably with the hard environment constituted by the ring oxygen atoms of the crown ether moieties. These observations are confirmed by the stabilisation energies calculated for the [18]crown-6 with Na^+ (97.7 kcal·mol^{-1}) and with K^+ (71.5 kcal·mol^{-1}) and for the [15]crown-5 ether, for which the stabilisation energy with Na^+ is 88.9 kcal·mol^{-1} and with K^+ 55.9 kcal·mol^{-1} (see Figure 2). As can be observed, higher stabilisation energies are observed for both cations with the [18]crown ether than with the [15]crown.

The interaction with the cation turns out to be more stabilizing than the interaction with the nucleophile. Note, however, that the interaction energies of SCN^--containing complexes are not additive, with deviations of 38.5 and 38.9

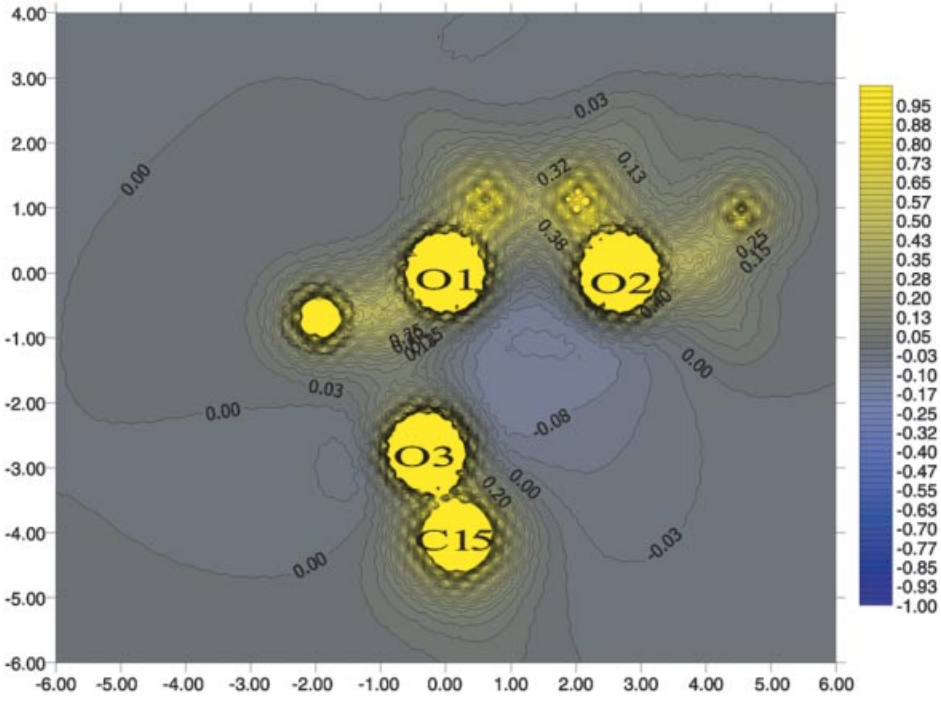

Figure 3. The MEP for the plane containing three of the six oxygen atoms (O1, O2, O3) in the crown ether moiety in [18]crown-6-$C_6H_3COOSn(CH_3)_3$

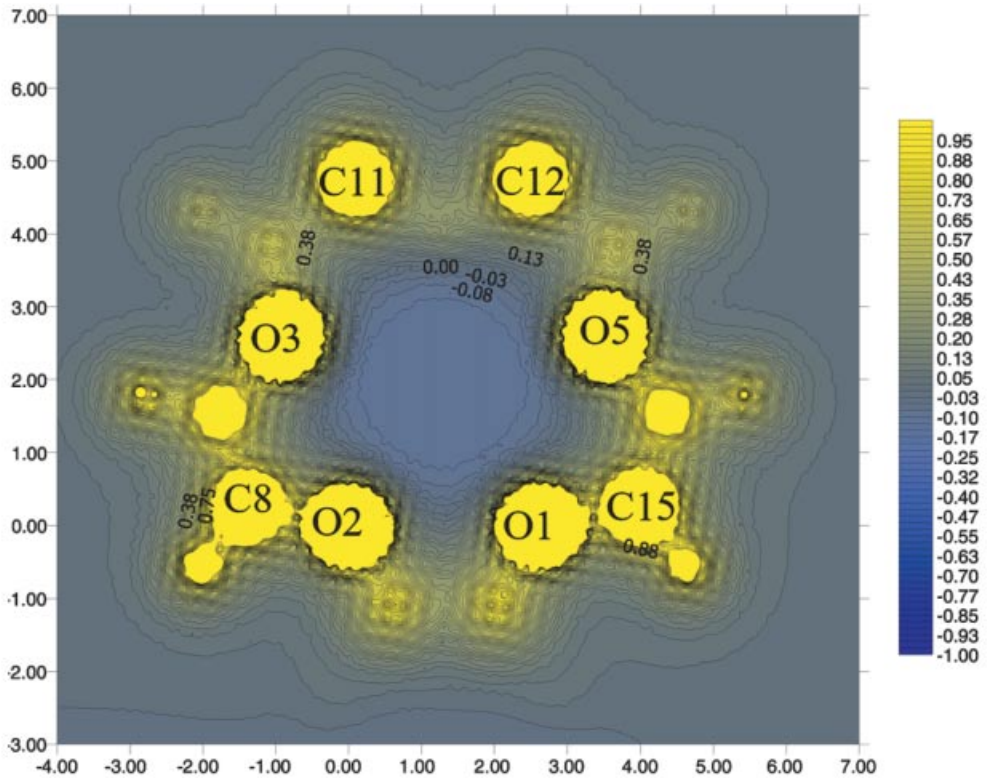

Figure 4. The MEP for the plane containing three of the five oxygen atoms (O1, O2, O3) in the crown ether moiety [15]crown-5-$C_6H_3COOSn(CH_3)_3$

kcal·mol^{-1} for the [18]crown ether with Na^+ and K^+, respectively, and 32.4 and 37.2 for the [15]crown ether with Na^+ and K^+, respectively.

One may note that the complexes formed between the tin atom of the crown benzocarboxylate moiety and SCN^- are always more stable (i.e., display more negative values) than for water and acetone both for the Na^+ and for the K^+ cations, and also both for the [15]crown and for the [18]crown ethers. At first glance, this sequence is in line with the softness sequence $SCN^- >$ acetone $> H_2O$, suggesting that the Sn acts as a soft centre (soft Lewis acid).

In the case of the interaction with SCN^-, however, a problem is posed by the regioselectivity. It is known from previous detailed studies on the Fukui function,[47−49] by the present authors among others, that the S atom is the soft centre. It was indeed shown that the sulfur atom in SCN^- was softer than the nitrogen atom, the values being 0.667 a.u. for the condensed Fukui function f^-_S as compared to 0.342 a.u. for the f^-_N (obtained at the QCISD/aug-cc-pVDZ level by use of Bader's population analysis[50]). These values show the same trend as the values calculated in this work (see Table 1).

Table 1 shows that this result is in fair agreement with our calculations, the sequence of local softness values being $s^-_S(SCN^-) > s^-_O(H_2O) \approx s^-_O(\text{acetone}) > s^-_N(SCN^-)$.

This result is a first indication that the Sn atom in the compounds under consideration behaves as a hard atom, since it preferentially interacts with the harder part of SCN^-. Note that the charge on the tin atom in both compounds is of the order of +1 a.u. (1.001 a.u. for the [18]crown ether and 1.002 a.u. for the [15]crown ether). This relatively high charge may be due to the structure of the crown ether, where the pentacoordination of Sn, resulting in an almost ideal trigonal-bipyramidal structure[9] in which the two electronegative ligands (the carboxylate group and the nitrogen atom of SCN^-) occupy the two apical positions, gives rise to longer bonds with little s character and hence a higher ionic contribution.

The reason that SCN^- as a whole interacts more strongly than acetone or water can then again be traced back to interaction between the Sn moiety and nucleophiles in which charge control (i.e., hard−hard interactions; SCN^- carries a negative charge) dominate. It is found that, in the absence of a net negative charge on the molecule, the oxygen atoms in H_2O and acetone have net charges of 0.72 and 0.40, respectively, making these atoms hard, the sequence being in line with the interaction strength $H_2O >$ acetone. Here we took the net atomic charge as a first indicator of local hardness (see ref.[51] for an in-depth discussion of the problem of finding a well-suited counterpart to local softness).

The hardness of the tin atom has been a point of controversy. From the position of the atom in the Periodic Table, one could conclude that Sn should be relatively soft; indeed, a low value of 3.05 eV is found for the absolute hardness for the isolated atom.[18] In our previous study[36] on the nanocluster $[(RSn)_{12}O_{14}(OH)_6]^{2+}$ (R = CH_3), however, we found a local softness value of 0.0074, of the same order as

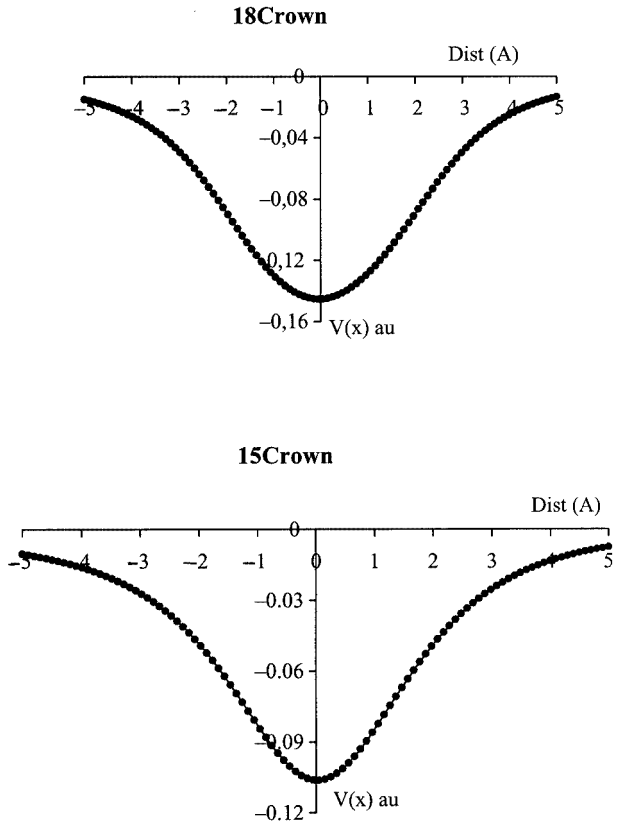

Figure 5. The MEP $V(x)$ (a.u.) for [18]crown-6-$C_6H_3COOSn(CH_3)_3$ and [15]crown-5-$C_6H_3COOSn(CH_3)_3$ along a straight line starting at 5 Å perpendicular to the plane containing the oxygen atoms used in the calculation of the MEP contours (Figures 3 and 4), the intersection point being the Na^+ or K^+ cation position, in steps of 0.01 Å

the value found here (0.0076), indicating in both cases that the oxophilicity of the tin atom makes it a hard centre, preferring to interact with hard molecules. In addition, the well-known tendency of the tin atom to involve intra- and intermolecularly bridging fluorine atoms is in line with the hardness of Sn in tin fluorides.[52]

Confirmation of a preference for N−Sn interaction over S−Sn interaction was found when the possibility of complexation through the S atom of SCN^- was explicitly studied. In these cases the sulfur atom was placed at the same position as the N atom in the other complexes. Geometry optimisation starting from this alternative complexation mode, however, never provided stable complexes. Moreover, complexes of Sn with SCN^- through the N atom have also been reported elsewhere.[53]

We also calculated complexes in which the nucleophile interacted with the tin atom and the Na^+ or K^+ were infinitely remote. For the [18]crown-6 we found that the stabilisation energy is 25.8 kcal·mol^{-1} and for the [15]crown-5 28.0 kcal·mol^{-1}. By comparison with the data above, it appears that the cation alone in the crown ether hole stabilises the molecule more than when only the nucleophiles are interacting with the tin atom. This can be explained by considering that the crown ether moiety is harder than the Sn atom region. A numerical confirmation (e.g., through the MEP) is quite difficult though, as one region is nucleophilic whereas the other part is electrophilic in nature.

We also studied cases in which SCN^- is bound to the tin atom through the N atom, and the sodium and potassium ions are bound to the S atom of SCN^- (the initial distance between the S atom of SCN^- and the sodium and potassium cations being 2.35 and 2.71 Å, respectively). The energies show the same trends as already obtained in the previous calculations, according to which the [18]crown-6 complex was more stable than the [15]crown-5. They are all less stable than when the cation is trapped in the crown ether cavity. As may be expected in view of the very soft nature of the S centre of SCN^-, hard cations interact preferentially with the hard, oxygen-rich crown ether hole.

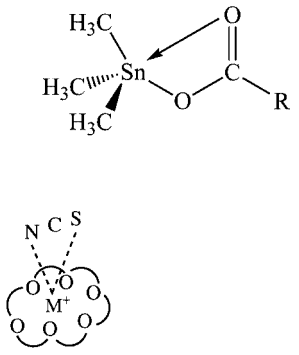
A final set of complexes for the two kinds of trimethyltin crown ether benzocarboxylates was also assessed. In these new cases, SCN^- is directly interacting with the Na^+ or K^+ ions located in the crown ether hole. For these calculations, both possibilities − that the ions could interact with the N or with the S atom of SCN^- − were considered. The SCN^- was placed at a distance of 2.2 Å from the cation, forming an angle of 90° with the cation and oxygen atoms 1 and 2 (see Figure 1). This geometry was used for both tin ether moieties. For each of the two crown ethers and the two cations, the geometry optimisation was started with a binding situation in which the cation was exclusively interacting either with the nitrogen atom or with the sulfur atom. The optimised end geometries appeared to be roughly identical, since, when starting from the N^-Na^+ interaction in the [18]crown ether, optimised $N^-−Na^+$ and $S^-−Na^+$ distances of 2.30 and 4.64 Å were obtained, while when starting from the S^-Na^+ interaction fairly similar optimised distances of 2.33 and 4.21 Å, with very close interaction energies of −177.6 and −178.5 kcal·mol^{-1} respectively, were

Table 1. Calculated hardnesses η [eV], softnesses S [eV^{-1}], condensed Fukui functions f^+ and f^- (atomic units, a.u.) and local softness values s^+ and s^- (a.u. eV^{-1}); atoms to which condensed functions refer are given in parentheses

Molecule	η	S	f^+	f^-	s^+	s^-
[18]Crown-6	4.07	0.246	0.0316 (Sn)		0.00776 (Sn)	
[15]Crown-5	4.04	0.248	0.0309 (Sn)		0.00765 (Sn)	
SCN^-	4.36	0.229		0.264 (N)		0.0299 (N)
				0.620 (S)		0.1420 (S)
Acetone	5.91	0.169		0.365 (O)		0.0619 (O)
H_2O	8.42	0.119		0.662 (O)		0.0786 (O)

calculated. Similar calculations for the [18]crown K^+ complex give 2.71 and 4.56 Å when starting from N^-K^+ and 2.96 and 3.34 Å when starting from S^-K^+, with interaction energies of −149.8 and −152.2 kcal·mol^{-1}, respectively. For the [15]crown ether, optimised N^-Na^+ and S^-Na^+ distances of 2.28 and 4.14 Å were obtained, while when starting from the S^-Na^+ interaction, optimised distances of 2.75 and 3.54 Å, with very close interaction energies of −174.8 and −175.6 kcal·mol^{-1}, respectively, were calculated. Similar calculations for the [15]crown K^+ complex give 2.75 and 3.54 Å when starting from N^-K^+, and 2.95 and 3.28 Å when starting from S^-K^+, with interaction energies of −141.0 and −142.1 kcal·mol^{-1}, respectively. These final geometries show very clearly that wherever the N atom of SCN^- is initially located, the final structure always has the nitrogen atom closer to the cation, although with the nitrogen and sulfur atoms arranged in such a way that a bidentate chelation mode with the cation results.

The final geometries of these complexes always yield a pentacoordinate tin atom, since the carboxylate ligands also bind to Sn in a bidentate mode, the oxygen atom of the carbonyl group expanding its coordination (see Scheme 1).



Scheme 1. Bidentate chelating mode of the carboxylate ligand in triorganotin carboxylates, and of SCN^- with the cation positioned in the crown ether

These complexes are more stable (see values above) than the complexes reported in Figure 2. This stability can be attributed to the simultaneous presence of a chelating bidentate mode of the nucleophiles at the levels of both the tin atom and the alkali cation.

Overall, these results fit remarkably well with previous experimental findings from multinuclear NMR studies[9] from which a mixture of several species was proposed to exist in dynamic equilibrium in acetone solution (Figure 6). No direct evidence for species b and c could be given in the NMR study. In the current ab initio study, the species actually merge into a single one with a bidentate mode for NCS^- with the alkali cation. The reason for the lack of NMR evidence lies in the poor sensitivity of ^{23}Na chemical shifts to coordination changes, the chemical shift difference between completely free Na^+ and Na^+ interacting with six oxygen atoms amounting to only ca. 10 ppm. A supplementary interaction with external SCN^- is therefore hardly able also to influence the ^{23}Na chemical shifts. In the crystalline state, the only species observed is the one with the cation trapped in the crown ether cavity and the anion bound to Sn (i.e., of the species calculated here, the most stable one; after $M^+\subset CBCOOSnNCS^-$, species a). In solution, this coexists with the third most stable species, the one where the cation interacts with the sulfur atom of the anion, itself bound to Sn through the nitrogen atom ($CBCOOSnNCS^-M^+$). In addition, ^{117}Sn NMR chemical shift data reveal that the tin−nitrogen interaction is broken up with increasing temperature, favouring a species in which acetone from the solvent is complexing Sn [$M^+\subset CBCOOSnOC(CH_3)_2$].

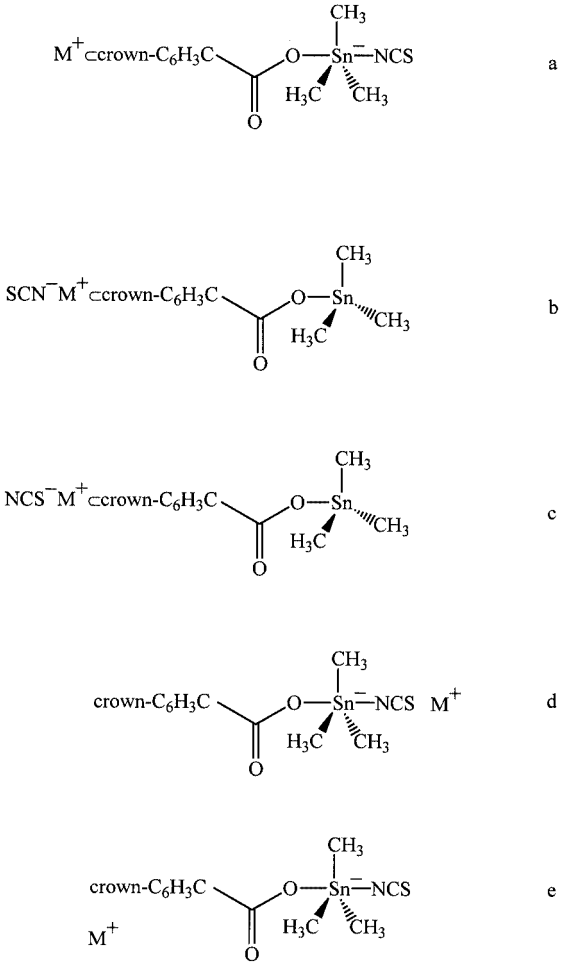


Figure 6. Possible zwitterionic ion pairings

Finally, ^{23}Na NMR spectroscopic data show the existence of an equilibrium between free Na^+ and Na^+ trapped in the crown ether hole, this equilibrium favouring Na^+ trapping much more for the [18]crown ether than for the [15]crown ether, in line with the results of our calculations indicating more stable alkali cation complexation with the former crown ether than with the latter. Interestingly, when the cation interacts with the sulfur atom of the thiocyanate anion complexing Sn through the nitrogen atom or does not interact at all, the stabilisation energy of the complexes are essentially independent of the crown ether sizes, as they actually should be.

These experiments are also in line with the electrostatic attraction between the positive charge of the cation and the negative values of the MEP being more pronounced for the [18]- than for the [15]crown ether ring (see Figure 5).

4. Conclusion

In conclusion, this paper clearly demonstrates that the sites of interactions of the trimethyltin derivatives of [18]crown-6 and [15]crown-5 benzo-4-carboxylates can be predicted by use of DFT-based reactivity descriptors such as the hardness, softness and Fukui function, as well as MEP calculations. The agreement with experimental results is good to excellent, so such calculations both help in interpreting experimental data as well as providing a firm theoretical basis for the different cases of complexation observed.

The HSAB principle, characterising the reactive sites on the basis of local softness, and the Fukui function provide a firm explanation for the reactivity of the tin atom of the crown ether benzocarboxylate towards SCN^-, acetone and water. The HSAB concept was also successfully used to explain the preferences of the tin atoms in both crown ethers for binding with the nitrogen atom of SCN^- rather than with the sulfur atom.

Synthesis and Structure of Two New High Nuclearity Ru/Pt Mixed-Metal Clusters

Brian F. G. Johnson,*[a] Sophie Hermans,[a] and Tetyana Khimyak[a]

Keywords: Cluster compounds / Ruthenium / Platinum / Heterometallic complexes / Bridging ligands

The reaction of the dianion $[Ru_5C(CO)_{14}]^{2-}$ with $[PtCl_2(MeCN)_2]$ in the presence of silica yields $[Ru_5PtC(CO)_{16}]$ (**1**) and the new compound $[PPN]_2[Ru_{10}Pt_2C_2(CO)_{28}]$ (**2**), while, in a related reaction, $[Ru_6C(CO)_{16}]^{2-}$ undergoes addition of $[PtCl_2(MeCN)_2]$ to yield the cluster $[Ru_{12}PtC_2(CO)_{32}(MeCN)_2]$ (**3**). The high nuclearity compounds **2** and **3** have been fully characterized and their structures determined by single crystal X-ray analysis.

Introduction

Our recent success in the preparation of ruthenium-palladium mixed-metal nanoparticles which have been shown to possess high catalytic activity for a number of processes,[1] has led us to consider the possibility of extending our studies to embrace similar systems containing ruthenium and platinum. To this end, we have investigated the possibility of preparing appropriate high nuclearity derivatives based on both the Ru_5C and Ru_6C sub-cores, and which fall in the nanometer scale. In this paper we wish to report the synthesis and complete characterization of two such new high nuclearity clusters based on $[Ru_{10}Pt_2C_2]$ and $[Ru_{12}PtC_2]$ central units, one of which having already been used successfully as a nano-catalyst precursor.[2] These two compounds are reminiscent of the "sandwich" Ru-Pd clusters reported previously, which were obtained by reacting $[Ru_6C(CO)_{16}]^{2-}$ with $[Pd(MeCN)_4]^{2+}$.[3] Our investigations have also led us to a potentially highly valuable method involving the use of silica as a "synthetic" reagent for the stabilization of highly active cationic metal fragments, a process that has already been reported elsewhere,[4] but is extended further here.

Results and Discussion

When the salt $[PPN]_2[Ru_5C(CO)_{14}]$ {$[PPN]^+$ = bis-(triphenylphosphane)iminium cation} was reacted with $[PtCl_2(MeCN)_2]$ in dichloromethane in the presence of silica, the solution darkened immediately. After separation by thin layer chromatography, two compounds were obtained. The first red compound was identified as the known $[Ru_5PtC(CO)_{16}]$ (**1**) on the basis of its mass and IR spectra.[5] The second, brown, compound, isolated in 21% yield, was identified as $[PPN]_2[Ru_{10}Pt_2C_2(CO)_{28}]$ (**2**) on the basis of its mass spectrum, which shows a high intensity peak at m/z = 1104.7 corresponding to half the mass of the anionic $[Ru_{10}Pt_2C_2(CO)_{28}]^{2-}$. A weaker peak at m/z = 2209.4 could be attributed to the same formulation, but only singly charged. The IR spectrum of **2** contains one broad peak at 2026 cm^{-1} corresponding to terminal CO ligands and two weak peaks at 1823 and 1789 cm^{-1} attributable to bridging carbonyls. Compound **2** could also be isolated as its Ph_4P^+ salt, whose crystal structure is reported here. Crystals suitable for X-ray structure determination were obtained by slow diffusion of diethyl ether into a solution of **2** in dichloromethane. Compound **2** crystallises in the monoclinic space group $P2_1/n$ and the molecular structure of the dianion $[Ru_{10}Pt_2C_2(CO)_{28}]^{2-}$ is presented in Figure 1, together with selected bond lengths and angles in Table 1.
