The Substitution Reaction of (Chloro)bis(tetraisopropylcyclopentadienyl) Complexes of La, Pr, or Nd with Silylamides

Oliver Schmitt,[a] Gotthelf Wolmershäuser,[a] and Helmut Sitzmann*[a]

Keywords: Lanthanides / Cyclopentadienyl ligands / N ligands / Si ligands

The dimeric complexes $[\{(C_5HR_4)_2Ln(\mu\text{-}Cl)(\mu_3\text{-}Cl)Na(OEt_2)\}_2]$ (**1**) (R = $CHMe_2$, Ln = La, Pr, Nd) eliminate sodium chloride in toluene solution to form the (chloro)bis(cyclopentadienyl) complexes $[(C_5HR_4)_2LnCl]$ (**2**). Crystalline **2**-Nd contains monomeric molecules exhibiting two intramolecular Nd···CH_3 interactions (Nd···C = 3.32 Å) with ring substituents. Reaction of complexes **1** with bis(trimethylsilyl)amides furnishes the tetranuclear complexes $[\{(C_5HR_4)_2Ln(\mu\text{-}Cl)\}_2\{NaN(SiMe_3)_2\}_2]$ (**3**) (R = $CHMe_2$, Ln = La, Pr, Nd), which have been characterized by X-ray crystal structure analyses. In solution the La_2Na_2 complex **3**-La eliminates NaC_5HR_4 (R = $CHMe_2$) to form a mixture of **2**-La and $[(C_5HR_4)La\{N(SiMe_3)_2\}_2]$ (**4**). With less a bulky bis(dimethylsilyl)amide **1**-La yields the substitution product $[(C_5HR_4)_2LaN(SiHMe_2)_2]$ (**5**) (R = $CHMe_2$).

Introduction

Organometallic complexes of the early lanthanides still present a challenge because of the large ionic radii of these elements.[1] The intriguing catalytic properties of cyclopentadienyl complexes of the lanthanides in a variety of C−C, C−H, or C−N bond-formation reactions[2] warrant an investigation of the impact of extremely bulky alkylcyclopentadienyl ligands on these big cations.

The tetraisopropylcyclopentadienyl ligand[3] should be bulky enough to solve problems related to donor solvent or alkali metal salt coordination even for the early lanthanides. We therefore synthesized (chloro)bis(tetraisopropylcyclopentadienyl) complexes of lanthanum, neodymium,[4] and praseodymium (this work) as starting compounds for nucleophilic substitution.

In this paper we report on the behavior of these chloro complexes in nonpolar solvents like toluene, and their reactions with $NaN(SiMe_3)_2$, $KN(SiMe_3)_2$, and $KN(SiHMe_2)_2$.

Results and Discussion

In toluene solution the (chloro)bis(tetraisopropylcyclopentadienyl)lanthanum, -praseodymium, or -neodymium sodium chloride complex $[\{(C_5HR_4)_2Ln(\mu\text{-}Cl)(\mu_3\text{-}Cl)Na(OEt_2)\}_2]$ (**1**) (R = $CHMe_2$; Ln = La, Pr, Nd: **1**-La, **1**-Pr, **1**-Nd) (Scheme 1) eliminates sodium chloride with formation of monomeric $[(C_5HR_4)_2LnCl]$ (**2**: Ln = La, Nd; R = $CHMe_2$). **2**-Nd is the first crystallographically characterized example of a solvent-free, monomeric bis(cyclopentadienyl) halo complex of the lanthanides.

The crystal structure of **2**-Nd (Figure 1, Table 1) shows Nd−C distances within a narrow range from 2.71 to 2.81 Å and an angle of 133.6° between the two ring planes. Two contacts to methyl groups of the ring substituents (C12 and its symmetry-equivalent atom are at an Nd···C distance of 3.32 Å) stabilize the unusually low coordination number of the central atom. The angle C12−Nd−C12′ is 179° and forms a T-shaped arrangement with the Nd−Cl vector located on the crystallographic C_2 axis. Three out of four isopropyl α-carbon atoms are bent out of the ring plane away from the metal center by 0.1−0.3 Å, but the α-carbon atom C11 carrying the methyl C12 atom is bent towards the central atom by 0.02 Å. The isopropyl substituent at C1 of the cyclopentadienyl ring seems to adopt the role of a side chain capable of an additional stabilizing interaction. The tetraisopropylcyclopentadienyl ring in **2**-Nd thus resembles the donor-functionalized cyclopentadienyl ligands in monomeric [(2-methoxyethyl-1-indenyl)$_2$NdCl][5] or [(Me$_2$NCH$_2$CH$_2$C$_5$H$_4$)$_2$NdCl].[6] Similar intramolecular Ln···CH$_3$ interactions have been found for 1,1′,3,3′-tetra(*tert*-butyl)ytterbocene.[7]

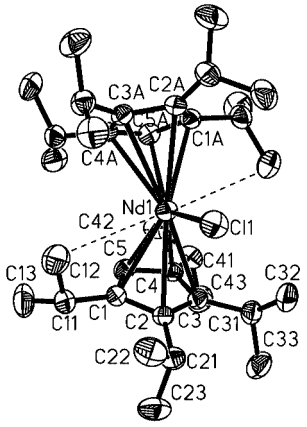

Figure 1. Crystal structure of **2**-Nd; selected bond lengths [Å] and angles [°]: Nd1−Cl1 2.713(1), Nd1−C1 2.724(4), Nd1−C2 2.801(4), Nd1−C3 2.811(4), Nd1−C4 2.782(4), Nd1−C5 2.709(4), Nd1···C12 3.318, Nd1−Cp$_{cent.}$ 2.489, Cp$_{cent.}$−Nd1−Cp$_{cent.}$ 137.3, C12···Nd1···C12a 178.7, Cl1−Nd···C12 90.6; thermal ellipsoids are at the 50% probability level

In toluene solution the (chloro)bis(tetraisopropylcyclopentadienyl)lanthanum, -praseodymium, or -neodymium sodium chloride complexes [{(C$_5$HR$_4$)$_2$Ln}$_2$(μ-Cl)$_2$(μ$_3$-Cl)$_2${Na(OEt$_2$)}$_2$] (**1**-La, **1**-Pr, **1**-Nd) react with sodium bis(trimethylsilyl)amide with formation of the tetranuclear complexes [{(C$_5$HR$_4$)$_2$Ln(μ-Cl)Na(μ-N(SiMe$_3$)$_2$)}$_2$] (**3**), which can be isolated in good yield (Scheme 1) if the reaction is stopped by solvent removal after 45−60 min. If stirring is continued for several hours, reduced yields or oily mixtures of **3** with two follow-up products are obtained. (This clean follow-up reaction of **3** will be discussed shortly.) In the solid state **3** can be stored for months at ambient temperature without noticeable decomposition.

Crystals of **3**-La, **3**-Pr, and **3**-Nd are isotypic and have been crystallographically characterized. Because of the close similarity of the structural parameters only **3**-Nd will be discussed here.

The crystal structure of **3**-Nd (Figure 2, Table 1) shows a four-membered Na_2N_2 ring with one molecule of $[(C_5HR_4)_2NdCl]$ coordinated to each of the two sodium ions via a bridging chloro ligand (Figure 2). The Nd−Cl bond length is 2.683(1) Å in **3**-Nd and the angle between the ring planes is 137.7°. The Na−Cl distance [2.767(2) Å] is shorter than that found in crystalline sodium chloride (2.82 Å).[8] The distance Nd1···C82a is 3.37 Å, and three Nd1···C distances between 3.67 and 3.94 Å are also observed for **3**-Nd. The two NSi_2 planes are not parallel, but twisted by 37.5° relative to each other. Short Na···Si distances [3.216(2)/3.172(2) Å for Si1···Na1 and Si···Na1′] and additional Na···methyl interactions (3.023/2.915 Å for Na···C17 and Na1′···C29) are obviously the reason for this distortion. Similar Na···C distances have been found for the cyclic trimer $[NaN(SiMe_3)_2]_3$ [9] and for the sodate $Na[Na\{N(SiMe_3)_2AlMe_3\}_2]$.[10] Because of this methyl-C···Na interaction in **2**-Nd one of the three N−Si−C angles at Si1 (114.8°, 114.5°, 110.7°) or Si2 (114.8°, 114.9°, 111.1°) is significantly smaller than the others. Moreover, this interaction is strong enough to stop the silyl group rotation even in solution, as can be concluded from ^{1}H and ^{13}C NMR spectra of **3**-La, whose crystal structure shows similar methyl C···Na distances (3.019 and 2.912 Å).

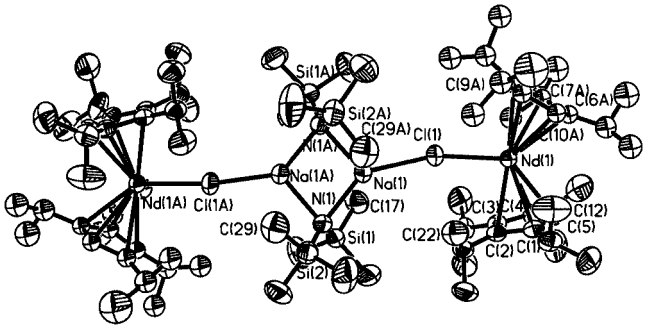

Figure 2. Crystal structure of **3**-Nd. Selected bond lengths [Å] and angles [°]: Nd1−Cl1 2.6832(9), Nd1−C1 2.757(3), Nd1−C2 2.754(3), Nd1−C3 2.766(3), Nd1−C4 2.765(3), Nd1−C5 2.720(3), Nd1−C6a 2.742(7), Nd1−C7a 2.737(7), Nd1−C8a 2.685(8), Nd1−C9a 2.709(7), Nd1−C10a 2.698(7), Nd1−$Cp_{cent.}$ 2.432, Na1···Si1 3.225, Na1···Si2a 3.172, Na1···C29a 2.912, Na1···C17 3.019, Nd1···C82a 3.372, Nd1···C62a 3.673, Nd1···C12 3.759, Nd1···C22 3.938, Cl1−Na1 2.767(2), Na1−N1 2.414(3), Na1−N1a 2.404(3), N1−Si1 1.685(3), N1−Si2 1.689(3), $Cp_{cent.}$−Nd1−$Cp_{cent.}$ 139.4, Nd1−Cl1−Na1 157.04(6), N1−Na1−N1a 101.0(2), Na1−N1−Na1a 78.38(10) thermal ellipsoids are at the 50% probability level

The NMR spectra of **3**-La are well resolved and show one set of resonances for the tetraisopropylcyclopentadienyl ring (cf. ref.[3a] for spectral pattern of C_5HR_4) and two sharp singlets at δ = 0.30 and 0.34 ppm in a 1:2 ratio for the four trimethylsilyl groups. In the ^{13}C NMR spectra two Si*C*H$_3$ signals, with an intensity ratio of 1:2, are observed for **3**-La at δ = 5.3 and 7.0 ppm. NMR spectroscopy at elevated temperatures in order to observe coalescence of the two $SiCH_3$ signals and to determine the activation barrier for $SiMe_3$ rotation was unsuccessful because **3**-La undergoes a clean follow-up reaction with deposition of 1 equiv. of sodium tetraisopropylcyclopentadienide per dimer **3** and formation of two complexes in a 1:1 ratio. One of these complexes is **2**-La, which could be identified by ^{1}H and ^{13}C NMR spectroscopy. The second component, according to the intensity of its NMR signals, contains only one tetraisopropylcyclopentadienyl and two bis(trimethylsilyl)amide ligands according to the formula $[(C_5HR_4)La\{N(SiMe_3)_2\}_2]$ (**4**-La). The observation of only one $SiCH_3$ signal of **4**-La arising from the clean decomposition of **3**-La supports the assignment stated above and rules out the possibility of an unknown impurity causing the 2:1 Si*C*H$_3$ signal pattern found for **3**-La.

In an attempt to generate a possible potassium compound analogous to **3**-Pr, potassium bis(trimethylsilyl)amide was treated with **1**-Pr instead of the sodium salt. Instead of a potassium derivative the sodium compound **3**-Pr was obtained in good yield as before. Under the conditions employed in this work the Ln_2Na_2 complexes **1** are probably not cleaved into fragments of lower nuclearity during the reaction with sodium or potassium bis(trimethylsilyl)amides. The first step could be replacement of the diethyl ether ligand coordinated to each of the sodium cations of **1** with bis(trimethylsilyl)amide anions. Elimination of alkali chloride and rearrangement then furnishes **3** as the isolable product. The attempted rare earth amide formation, a well-known reaction in lanthanide chemistry,[11] has apparently been stopped for steric reasons, and **3** can be regarded as an intermediate in the nucleophilic substitution of chloride by bis(trimethylsilyl)amide.

The composition and geometry of **3** suggests the possible formation of **3** by addition of **2** as a sort of complex ligand to sodium bis(trimethylsilyl)amide. In deuteriobenzene this reaction of **2**-La failed in our hands, however.

Since the bis(trimethylsilyl)amide ligand is obviously too bulky for nucleophilic substitution of the chloro ligand in complexes **1**, we reduced the steric bulk of the nucleophile and used potassium bis(dimethylsilyl)amide for a reaction with **1**-La. The dimer **1**-La reacts with 2 equiv. of $KN(SiHMe_2)_2$ in toluene at room temperature to form the monomeric substitution product $[(C_5HR_4)_2LaN(SiHMe_2)_2]$ (**5**) in good yield (Scheme 1).

The ^{1}H NMR spectra of **5** show the signals of two tetraisopropylcyclopentadienyl ligands, one doublet corresponding to the 12 methyl protons of two dimethylsilyl groups and one signal for the two Si*H* protons, which are coupled to the six protons of two adjacent methyl groups and to the lanthanum central atom. The coupling partner of each signal has been assigned by ^{1}H,{^{1}H}-COSY NMR spectroscopy. The spectroscopic features of the amide ligand of **5** resemble those observed very recently for the bis(dimethylsilyl)amido ligand of *ansa*-metallocene derivatives of lanthanum. Complex **5** shows a $^1J_{Si,H}$ coupling constant of 157 Hz, close to the value of 150 Hz found for $[Me_2Si(C_5Me_4)_2LaN(SiHMe_2)_2]$ indicating a β-agostic interaction of the Si−H bond with the central atom.[12]

Conclusion

The sodium chloride adducts [{$(C_5HR_4)_2Ln(\mu\text{-}Cl)(\mu_3\text{-}Cl)Na(OEt_2)\}_2$] (**1**) (R = $CHMe_2$, Ln = La, Pr, Nd) undergo facile diethyl ether and sodium chloride elimination in nonpolar solvents. [$(C_5HR_4)_2NdCl$] (R = $CHMe_2$) (**2**-Nd) is the first crystallographically characterized bis(cyclopentadienyl)lanthanide halo complex, which crystallizes as a monomeric molecule without additional salt or heteroatom coordination. The tetraisopropylcyclopentadienyl ligand in this example provides not only steric saturation, but also offers electronic stabilization.

With bis(trimethylsilyl)amides the sodium site is attacked rather than the lanthanide cation of complexes **1** because the large cyclopentadienyl ligands around the lanthanide cation prevent the approach of this bulky nucleophile. The complex [{$(C_5HR_4)_2Ln(\mu\text{-}Cl)(Na)\mu\text{-}N(SiMe_3)_2\}_2$] (**3**) resembles a reactive intermediate of the nucleophilic substitution in nonpolar solvents as it consists of the "nucleophile" [a dimeric sodium bis(trimethylsilyl)amide core] coordinated to its designated reaction partner {a neutral [$(C_5HR_4)_2LnCl$] complex}. Two sodium chloride ion-pairs serve as a spacer between the $[(C_5HR_4)_2Ln]^+$ cations and the $[N(SiMe_3)_2]^-$ anions and steric bulk prevents salt elimination and formation of the anticipated substitution product. Instead of chloride substitution slow elimination of sodium tetraisopropylcyclopentadienide occurs and a mixture of **2** and **4** is formed. The driving force for this reaction appears to be the formation of the two Ln−N bonds of [$(C_5HR_4)Ln\{N(SiMe_3)_2\}_2$] (**4**) along with elimination of 1 equiv. of sodium chloride during this step.

With the less bulky bis(dimethylsilyl)amide the substitution reaction proceeds as usual to furnish [$(C_5HR_4)_2LnN(SiHMe_2)_2$] (**5**).

Experimental Section

General: All synthetic operations were performed under dry nitrogen in a glove box (MBraun). Tetrahydrofuran, hexane, and petroleum ether (boiling range 40−60 °C) were distilled from potassium metal, heptane and toluene from sodium metal, and pentane from a sodium/potassium alloy. NMR spectra were recorded with a Bruker AC 200 spectrometer. Chemical shifts are given in ppm and refer to the appropriate solvent signals. Mass spectra were recorded with a Finnigan MAT 90 mass spectrometer. Elemental analyses were performed with a Perkin−Elmer Elemental Analyzer 240 or 400. **1**-La, **1**-Nd[4] and sodium tetraisopropylcyclopentadienide[3d] were prepared according to published procedures.

1-Pr: A suspension of $PrCl_3$ (1.900 g, 7.6 mmol) in THF (100 mL) was stirred at ambient temperature for 30 min, then a solution of sodium tetraisopropylcyclopentadienide (4.040 g, 15.7 mmol) in THF (50 mL) was added dropwise. The mixture was stirred at room temperature for 1 h and then at reflux temperature for 13 h. The solvent was removed in vacuo and the remaining solid was extracted with two 30-mL portions of diethyl ether. After centrifugation, the orange-yellow diethyl ether extract was concentrated and stored at −35 °C to yield 2.394 g (3.1 mmol, 41%) of yellow platelets of **1**-Pr. $C_{38}H_{68}Cl_2NaOPr$ (775.77): calcd. C 58.83, H 8.83; found C 58.50, H 9.12. MS (70 eV, EI): *m/z* (%) = 642.0 (6.7) $[(C_5HR_4)_2PrCl]^+$, 607.1 (2.5) $[(C_5HR_4)_2Pr]^+$, 408.9 (100) $[(C_5HR_4)PrCl]^+$.

2-La: A solution of sodium tetraisopropylcyclopentadienide (0.512 g, 2 mmol) in tetrahydrofuran (10 mL) was added to $LaCl_3(THF)_2$ (0.390 g, 1.0 mmol) in 10 mL of tetrahydrofuran and the mixture stirred at 70 °C for 2 d. Removal of the solvent in vacuo, extraction of the residue with two 25-mL portions of hexane/toluene (3:1), centrifugation, and concentration left a foam, which slowly solidified upon storage under inert gas at ambient temperature to yield 0.280 g (0.44 mmol, 44%) of **2**-La. $C_{34}H_{58}ClLa$ (641.20): calcd. C 63.69, H 9.12; found C 60.04, H 8.16. ^{1}H NMR (200 MHz, 298 K, C_6D_6): δ = 6.18 (s, 2 H, ring-C*H*), 3.34 ("sept", 4 H, C*H*Me_2), 3.08 ("sept", 4 H, C*H*Me_2), 1.51 (d, $^3J_{H,H}$ = 7.2 Hz, 12 H, CH_3), 1.39 (d, $^3J_{H,H}$ = 6.8 Hz, 12 H, CH_3), 1.24 (d, $^3J_{H,H}$ = 7.2 Hz, 12 H, CH_3), 1.08 (d, $^3J_{H,H}$ = 6.7 Hz, 12 H, CH_3) ppm. ^{13}C NMR (50 MHz, 298 K, C_6D_6): δ = 135.5 (s, 8 C, ring-*C*$CHMe_2$), 135.0 (s, 4 C, ring-*C*$CHMe_2$), 134.5 (s, 4 C, ring-*C*$CHMe_2$), 106.1 (d, $^1J_{C,H}$ = 160 Hz, 4 C, ring-*C*H), 27.44 (d, 8 C, *C*HMe_2, *), 27.42 (d, 4 C, *C*HMe_2, *), 26.4 (q, 4 C, *C*H_3, *), 25.0 (q, 4 C, *C*H_3, *), 23.6 (q, 4 C, *C*H_3, *), 23.3 (q, 4 C, *C*H_3, *) ppm. *: Coupling constants not resolved because of signal superimposition.

2-Nd: A suspension of **1**-Nd (1.878 g, 1.2 mmol) in toluene (10 mL) was stirred at −35 °C for 1 h and at 0 °C for 17 h, then the solvents were evaporated to dryness. The green, foam-like solid was extracted with pentane (15 mL), subjected to centrifugation and concentrated to about 3 mL. Storage at −35 °C gave a green, crystalline precipitate within two weeks. A fraction of well-shaped, blue-green crystals suitable for X-ray crystallography was obtained when the mother liquor was allowed to slowly concentrate at room temperature. Combined yield 1.107 g (1.7 mmol, 71%). $C_{34}H_{58}ClNd$ (646.16): calcd. C 63.16, H 9.04; found C 62.29, H 9.02.

3-La: A solution of sodium bis(trimethylsilyl)amide (0.120 g, 0.65 mmol) in toluene (10 mL) was added to a magnetically stirred suspension of **1**-La (0.501 g, 0.32 mmol) in toluene (12 mL). Stirring was continued for 45 min, then a small amount of a gelatinous residue was separated by centrifugation and the solvents were evaporated to yield a faintly yellow, crystalline solid. The solid product was extracted with hexanes (10 mL) and traces of a colorless precipitate were removed by centrifugation. Drying in vacuo yielded 0.372 g (0.23 mmol, 70%) of faintly yellow, crystalline product. $C_{80}H_{152}Cl_2N_2Na_2La_2Si_4$ (1649.16): calcd. C 59.27, H 9.45, N 1.73; found C 57.32, H 8.81, N 1.55. ^{1}H NMR (200 MHz, 298 K, C_6D_6): δ = 6.18 (s, 2 H, ring-C*H*), 3.34 (sept, 8 H, C*H*Me_2), 3.05 (sept, 8 H, C*H*Me_2), 1.50 (d, $^3J_{H,H}$ = 7.3 Hz, 24 H, CH_3), 1.38 (d, $^3J_{H,H}$ = 6.8 Hz, 24 H, CH_3), 1.25 (d, $^3J_{H,H}$ = 7.1 Hz, 24 H, CH_3), 1.07 (d, $^3J_{H,H}$ = 6.6 Hz, 24 H, CH_3), 0.34 (s, 24 H, SiCH_3), 0.30 (s, 12 H, SiCH_3) ppm. ^{13}C NMR (50 MHz, 298 K, C_6D_6): δ = 135.5 (s, 8 C, ring-*C*$CHMe_2$), 134.7(s, 8 C, ring-*C*$CHMe_2$), 106.4 (d, $^1J_{C,H}$ = 160 Hz, 4 C, ring-*C*H), 27.44 (d, 8 C, *C*HMe_2, *), 27.42 (d, 8 C, *C*HMe_2, *), 26.5 (q, 8 C, *C*H_3, *), 25.0 (q, 8 C, *C*H_3, *), 23.6 (q, 8 C, *C*H_3, *), 23.3 (q, 8 C, *C*H_3, *), 7.0 (q, $^1J_{C,H}$ = 116 Hz, 8 C, Si*C*H_3), 5.3 (q, $^1J_{C,H}$ = 117 Hz, 4 C, Si*C*H_3) ppm. *: Coupling constants not resolved because of signal superimposition. MS (70 eV, EI): *m/z* (%) = 639.3 (5) $[(C_5HR_4)_2LaCl]^+$, 604.4 (9) $[(C_5HR_4)_2La]^+$, 531.4 (29) $[(C_5HR_4)LaN(SiMe_3)_2]^+$, 458.5 (36) $[(C_5HR_4)_2LaNSiMe_3]^+$, 406.5 (79) $[(C_5HR_4)LaCl]^+$, 233.9 (24) $[C_5H_2R_4]^+$, 145.9 (100) $[Si_2Me_6]^+$.

3-Nd: A solution of sodium bis(trimethylsilyl)amide (0.122 g, 0.66 mmol) in toluene (5 mL) was added to a magnetically stirred

suspension of **1**-Nd (0.513 g, 0.33 mmol) in toluene (20 mL). The suspended material dissolved initially, but after about 40 min a barely visible turbidity was observed. Stirring was discontinued after 45 min, then a small amount of a sticky residue was separated by centrifugation. The solvents were evaporated and the solid product was washed with hexanes (15 mL). Drying in vacuo yielded 0.375 g (0.23 mmol, 69%) green, microcrystalline solid. The green hexane washings produced green crystals on slow concentration. $C_{80}H_{152}Cl_2N_2Na_2Nd_2Si_4$ (1659.82): calcd. C 57.89, H 9.23, N 1.69; found C 57.78, H 9.31, N 1.56. MS (70 eV, EI): *m/z* (%) = 609.2 (5) $[(C_5HR_4)_2Nd]^+$, 412.0 (11) $[(C_5HR_4)NdCl]^+$, 234.2 (84) $[C_5H_2R_4]^+$, 191.1 (100) $[C_{14}H_{22}]^+$, 146.0 (91) $[Si_2Me_6]^+$.

3-Pr: From **1**-Pr (0.500 g; 0.31 mmol) and $KN(SiMe_3)_2$ (0.130 g; 0.65 mmol), 0.390 g (0.24 mmol, 77%) of the light yellow, crystalline praseodymium complex were obtained by the same procedure. Single crystals were grown from hexane at room temperature by slow concentration. $C_{80}H_{152}Cl_2N_2Na_2Pr_2Si_4$ (1653.16): calcd. C 58.12, H 9.27, N 1.69; found C 58.06, H, 9.05, N 1.68.

4-La as a 1:1 Mixture with 2-La: A solution of sodium bis(trimethylsilyl)amide (0.118 g, 0.64 mmol) in toluene (3 mL) was added slowly to a solution of **1**-La (0.504 g, 0.32 mmol) in toluene (15 mL) at room temperature. The mixture was stirred at room temperature for 12 h. Centrifugation and evaporation of the solvents gave 0.320 g of an oily mixture of equivalent amounts of **2**-La and **4**-La (75%), which could not be separated. ^{1}H NMR for **4**-La (200 MHz, 298 K, C_6D_6): δ = 6.07 (s, 1 H, ring-C*H*), 3.08 ("sept", 4 H, C*H*Me$_2$), 1.50 (d, $^3J_{H,H}$ = 7.3 Hz, 6 H, CH_3), 1.49 (d, $^3J_{H,H}$ = 6.8 Hz, 6 H, CH_3), 1.23 (d, $^3J_{H,H}$ = 7.0 Hz, 6 H, CH_3), 1.14 (d, $^3J_{H,H}$ = 6.7 Hz, 6 H, CH_3), 0.30 (s, 36 H, SiCH_3) ppm. ^{13}C NMR (50 MHz, 298 K, C_6D_6): δ = 136.6 (s, 2 C, ring-*C*CHMe$_2$), 133.0 (s, 2 C, ring-*C*CHMe$_2$), 108.7 (d, $^1J_{C,H}$ = 159 Hz, 1 C, ring-*C*H), 27.6 (d, 2 C, *C*HMe$_2$, *), 27.1 (q, 2 C, *C*H$_3$, *), 27.0 (d, 2 C, *C*HMe$_2$, *), 25.3 (q, 2 C, *C*H$_3$, *), 25.0 (q, 2 C, *C*H$_3$, *), 24.6 (q, 2 C, *C*H$_3$, *), 5.3 (q, $^1J_{C,H}$ = 117 Hz, 12 C, Si*C*H$_3$) ppm. *: Coupling constants not resolved because of signal superimposition.

5-La: At room temperature a solution of $KN(SiHMe_2)_2$ (0.077 g; 0.45 mmol) in toluene (4 mL) was added dropwise with stirring to a solution of **1**-La (0.351 g; 0.225 mmol) in toluene (5 mL). A white precipitate formed and stirring was continued for 36 h. After centrifugation, the solvents were evaporated to dryness yielding an off-white, crystalline residue, which was redissolved in hexane (3 mL). Evaporation of the solvent, extraction with pentane (3 mL) and slow concentration of the solution gave 0.221 g (0.30 mmol, 67%) of faintly yellow crystals. $C_{38}H_{72}NLaSi_2$ (730.08): calcd. C 61.84, H 9.83, N 1.90; found C 60.17, H 9.90, N 1.86. ^{1}H NMR (200 MHz, 298 K, C_6D_6): δ = 6.33 (s, 2 H, ring-C*H*), 4.57 (m, $^1J_{Si,H}$ = 157 Hz, 2 H, Si*H*Me$_2$) 3.27 ("sept", 4 H, C*H*Me$_2$), 3.15 ("sept", 4 H, C*H*Me$_2$), 1.51 (d, $^3J_{H,H}$ = 7.2 Hz, 12 H, CH_3), 1.50 (d, $^3J_{H,H}$ = 6.8 Hz, 12 H, CH_3), 1.28 (d, $^3J_{H,H}$ = 7.0 Hz, 12 H, CH_3), 1.18 (d, $^3J_{H,H}$ = 6.7 Hz, 24 H, CH_3), 0.40 (d, $^3J_{H,H}$ = 2.8 Hz, 12 H, SiCH_3) ppm. ^{13}C NMR (50 MHz, 298 K, C_6D_6): δ = 133.3 (s, 4 C, ring-*C*CHMe$_2$), 133.2 (s, 4 C, ring-*C*CHMe$_2$), 106.6 (d, $^1J_{C,H}$ = 159 Hz, 2 C, ring-*C*H), 27.8 (d, 4 C, *C*HMe$_2$, *), 27.3 (d, 4 C, *C*HMe$_2$, *), 26.9 (q, 4 C, *C*H$_3$, *), 25.4 (q, 4 C, *C*H$_3$, *), 24.8 (q, 4 C, *C*H$_3$, *), 24.1 (q, 4 C, *C*H$_3$, *), 4.3 (q, $^1J_{C,H}$ = 118 Hz, 4 C, Si*C*H$_3$) ppm. * Coupling constants not determined due to signal superimposition, assignment confirmed by DEPT experiments.

X-ray Crystallography: Crystallographic data for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-171977 (**2**-Nd), -171978 (**3**-Nd), -171979 (**3**-Pr) amd -171980 (**3**-La). Copies of the data can be obtained free of charge on applicaton to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk]. A Stoe IPDS and Mo-K_α radiation were used for all structure determinations reported here.

The First Structurally Characterized Aluminum Squaraine Complex: $L_2(AlMe_2)_4 \cdot 2THF \cdot 2$toluene [L = Bis(2,6-diisopropylanilino)squaraine]

Junfeng Rong,[a] Ying Peng,[a] Herbert W. Roesky,*[a] Jiyang Li,[a] Denis Vidovic,[a] and Jörg Magull[a]

Dedicated to Professor Helmut Schwarz on the occasion of his 60th birthday

Keywords: Aluminum / Squaraine / N ligands / O ligands / X-ray diffraction

Bis(2,6-diisopropylanilino)squaraine (**1**) was prepared by condensation of squaric acid and 2,6-diisopropylaniline. Treatment of **1** with trimethylaluminum affords a novel dimeric aluminum squaraine complex: $L_2(AlMe_2)_4 \cdot 2THF \cdot 2$toluene [L = bis(2,6-diisopropylanilino)squaraine] (**2**), which was characterized by X-ray diffraction.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Squaraines are a class of 1,3-derivatives of squaric acid in which the substituents are amines or highly electron-donating aromatic or heterocyclic groups.[1] Their electronic structure and rich chemistry have been the subject of considerable discussion.[2] Several of them show fluorescence[3] or form self-organized films,[4] which imply their application as photosensitive films, organic solar cells, optical recording, and non-linear optical materials.[5] However, research on the organometallic chemistry of squaraines seems to be neglected. In fact, the versatility of squaraines implies that this class of compounds are ideal ligands. Only a few diamino derivatives of squaric acid have been structurally characterized.[2b,2c,6] No complex of aluminum with squaraines as ligand has been isolated and structurally characterized so far. We became interested in employing diaminosquaraines as ligands with the aim of studying their novel structure and property. Herein, we report on the first aluminum complex with the squaraine ligand.

Results and Discussion

Diamino derivatives of squaric acid can be synthesized as main products through the condensation of squaric acid with amines.[7] The ligand, bis(2,6-diisopropylanilino)squaraine (**1**) was prepared by a modified approach of refluxing squaric acid and 2,6-diisopropylaniline in ethanol with a few drops of formic acid as catalyst, as outlined in Scheme 1. The IR spectrum of **1** shows a strong absorption at 1598 cm^{-1} attributed to the squaraine carbonyl group.[2g] The 1,3-derivative of **1** is formed preferentially in this condensation reaction instead of the 1,2-species.[7b−7e] A sharp band at 3151 cm^{-1} is attributed to N−H stretching vibrations,[7b,7c] and a band at 2870 cm^{-1} to $\nu(N^+H)$.[7c] Ligand **1** is an air-stable solid which decomposes above 380 °C. The EI mass spectrum gives the molecular ion peak at $m/z = 432$ and the base peak at $[M^+ - C_3H_7]$. The composition of **1** is further supported by the ^1H and ^{13}C NMR spectra. However, an unambiguously structural assignment can only be made by an X-ray analysis. So far, we have not been able to grow suitable single crystals of **1**.

Bis(2,6-diisopropylanilino)squaraine (**1**) is sparingly soluble in most organic solvents. The reaction between trimethylaluminum and a suspension of **1** in THF was carried out at −78 °C. The acidic hydrogen of **1** is very active towards the CH_3 groups of trimethylaluminum. A clear yellow solution of **2** was readily formed upon warming to room temperature (Scheme 1). Complex **2** is much more soluble than **1** in organic solvents.

Compound **2** crystallizes in the triclinic space group $P\bar{1}$. An overview and numbering scheme is shown in Figure 1. The aluminum squaraine complex **2** turns out to be an interesting dimer with two different coordination modes for Al atoms. Two squaraine moieties are linked together by two $AlMe_2$ units, forming a ten-membered $C_4Al_2N_2O_2$ ring. Two THF molecules coordinate to the Al atoms of the two exocyclic $AlMe_2$ units by O−Al coordinative bonds, whereas the two exocyclic $AlMe_2$ units are linked to the O atoms of the squaraines by Al−O covalent bonds. In the ten-membered $C_4Al_2N_2O_2$ ring each Al atom is surrounded by the O atom, N atom and two Me groups. The N(2) atom adopts an sp^2 electron distribution and the Al−N bonds are

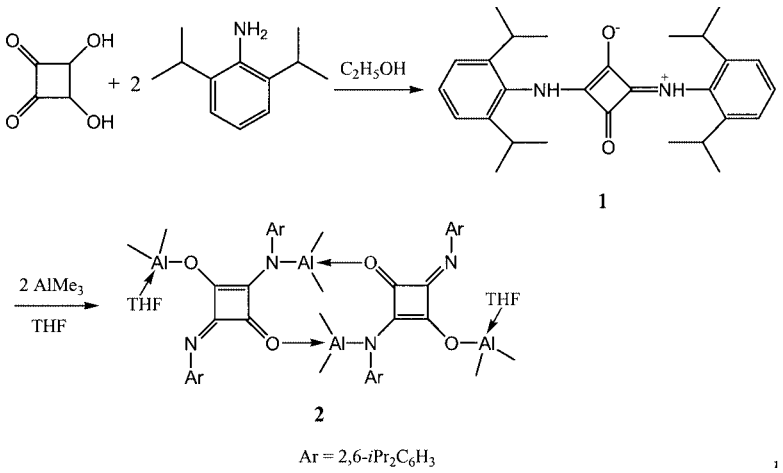

Scheme 1

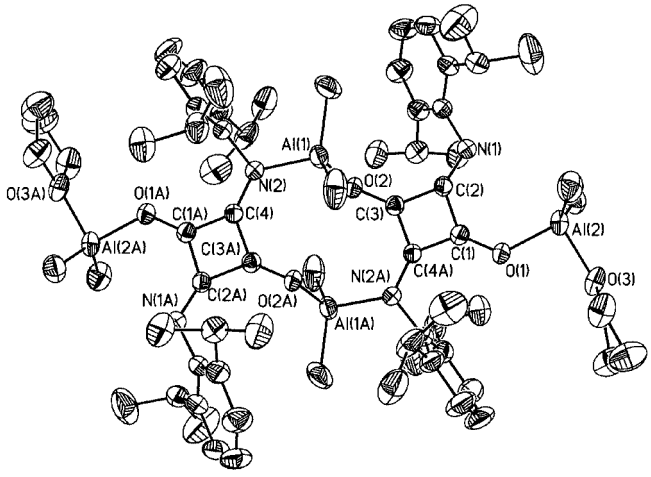

Figure 1. Molecular structure of $L_2(AlMe_2)_4$·2THF·2toluene [L = bis(2,6-diisopropylanilino)squaraine] (**2**) in the crystal (40% probability thermal ellipsoids); toluene molecules and hydrogen atoms are omitted for clarity; selected bond lengths (Å) and angles (deg.): C(1)−C(2) 1.471(3), C(2)−C(3) 1.483(3), C(1)−C(4A) 1.428(3), C(3)−C(4A) 1.446(3), C(1)−O(1) 1.279(2), C(3)−O(2) 1.267(3), C(2)−N(1) 1.281(3), N(2)−C(4) 1.335(3), Al(1)−O(2) 1.835(2), Al(2)−O(1) 1.823(2), Al(1)−N(2) 1.916(2); O(2)−Al(1)−N(2) 102.80(8), C(1)−O(1)−Al(2) 127.97(13), C(3)−O(2)−Al(1) 131.16(14), C(2)−N(1)−C(11) 119.82(18), C(4)−N(2)−Al(1) 125.16(14), C(1)−C(2)−C(3) 85.80(15), C(4A)−C(3)−C(2) 91.80(17)

covalent in nature, with a typical bond length of 1.916(2) Å. The average bond angle around N is 119.5°. The lone pairs on the O atoms coordinate to the Al atom by forming an Al−O coordinative bond. This may account for the formation of a dimer of the complex instead of a monomer, since the bond character of the O and N of the same squaraine ligand is different, and Al is more oxophilic. The two Al atoms within the ring adopt a typical tetrahedral geometry with an average bond angle of 109.3° at Al.

There are some noticeable differences in the structure of the squaraine ligands in complex **2** compared to those reported previously.[2b,2c,6] The C(2)−N(1) bond length of 1.281(3) Å is typical of a C=N double bond (1.273 Å in CH_2=NH[8]). Apparently, N(1) is sp^2 hybridized with a C(2)−N(1)−C(11) bond angle of 119.82(2)°. The C(4)−N(2) bond length of 1.335(3) Å is longer than a double bond but much shorter than a single bond (1.472 Å[9]). The C(1)−O(1) bond length of 1.279(2) Å is also much shorter than a single bond (1.426 Å[9]). These bonding characteristics can be explained by the p-π conjugation of the lone pairs on O(1) and N(2) and the carbon p orbital.[10] Like previously reported squaraines, the C atoms in the four-membered ring in **2** are all sp^2 hybridized.[2b] Delocalization of the electrons is believed to exist, and this accounts for the longer C(1)−C(4A) double bond [1.428(3) Å]. The C(1)−C(2) [1.471(3) Å], C(3)−C(4A) [1.446(3) Å], and C(2)−C(3) bond lengths [1.483(3) Å] are in the range of a C−C single bond (1.466 Å).[2b] This C-C bonding character of **2** is different from that of the reported bis(dimethylamino)squaraine[6] and dipiperidinosquaraine[2b] in which the C-C bond lengths are almost equal. This may stem from the formation of the organometallic complex of the squaraine.

In summary, bis(2,6-diisopropylanilino)squaraine shows many novel characters when it is adopted as a ligand for an aluminum complex. The rich chemistry of this ligand and its corresponding organometallic complexes have prompted us to carry out further investigation.

Experimental Section

Preparation of Complex 1: 2,6-Diisopropylaniline (9.8 mL, 52 mmol) was added to a suspension of squaric acid (2.80 g, 25 mmol) in ethanol (80 mL) at room temperature. After several minutes a few drops of formic acid were added to the suspension to form a clear colorless solution. The resulting solution was refluxed for 2 days to give a pale-yellow solution. The volatiles were then removed in vacuo to give **1** as a pale-yellow powder. Yield: 4.24 g (40%). Mp: 380 °C (decomp.). EI-MS: *m/z* (%) = 432 (38) [M^+], 417 (48) [$M^+ - CH_3$], 389 (100) [$M^+ - C_3H_7$]. ^{1}H NMR (200 MHz, [D_8]THF): δ = 1.16 (d, 12 H, CHMe_2), 1.25 (d, 12 H, CHMe_2), 3.19 (sept, 4 H, C*H*Me_2), 7.11 (m, 6 H, Ar*H*), 10.30 (s, 1 H, N*H*) ppm; N^+H was not observed. ^{13}C NMR (125.77 MHz, [D_8]THF): δ = 25.06, 25.54 (CHMe_2), 30.33 (*C*HMe_2), 67.22,

The experiments below were performed using standard Schlenk techniques or in a glove box under a purified nitrogen atmosphere. Solvents were dried according to standard methods and freshly distilled prior to use.

Preparation of Complex 2: $AlMe_3$ (1.5 mL, 2 M solution in heptane, approx. 2 equiv.) was added to a suspension of **1** (0.70 g, 1.6 mmol) in THF (20 mL) at −78 °C. The suspension was warmed slowly to room temperature and stirred overnight to give a clear yellow solution. All the volatiles were removed in vacuo and the residue was recrystallized from THF/toluene (1:1) at 0 °C to give pale-yellow crystals of **2**. Yield: (0.68 g, 60%). Mp: 190 °C (decomp.). EI-MS: *m/z* (%) only small fragments. ^1H NMR (200 MHz, $CDCl_3$): δ = −1.51 (s, 12 H, Al-*Me*), −0.79 (s, 12 H, Al-*Me*), 1.07−1.17 (m, 48 H, CH*Me*$_2$), 1.85 (s, 8 H, *THF*), 2.94 (sept, 4 H, C*H*Me_2), 3.03 (sept, 4 H, C*H*Me_2), 3.75 (s, 8 H, *THF*) ppm. ^{13}C NMR (125.77 MHz, $CDCl_3$): δ = −10.24, −9.06 (Al-*Me*), 23.62, 24.02, 24.40, 24.50, 24.61, 24.81, 25.01, 25.10, 25.72, 25.75, 26.45 (CH*Me*$_2$), 29.30, 29.37 (*C*HMe_2), 25.16, 69.71 (*THF*), 77.72, 77.98, 78.18, 78.23 (*squaraine carbon*), 124.36, 124.65, 124.76, 124.94, 127.39, 128.07, 138.32, 140.50, 143.29, 144.95, 169.19 (*Ar*) ppm. IR (Nujol mull): $\tilde{\nu}$ = 1594 cm^{-1} (squaraine carbonyl). $C_{86}H_{124}Al_4N_4O_6$ (1417.81): calcd. C 72.85, H 8.82, N 3.95; found C 71.31, H 8.62, N 3.95.

X-ray Crystallographic Study of 2·2toluene: Crystal dimensions 0.30 × 0.20 × 0.15 mm^3, $C_{86}H_{124}Al_4N_4O_6$, M_r = 1417.81, triclinic, space group $P\bar{1}$, a = 10.3468(12) Å, b = 15.0508(17) Å, c = 15.6447(16) Å, α = 114.243(8)°, β = 99.359(9)°, γ = 96.321(9)°, V = 2149.1(4) $Å^3$, Z = 1, $\rho_{calcd.}$ = 1.095 $Mg·m^{-3}$, F(000) = 768, 1.58 < θ < 24.77°; of 22118 reflections collected, 7304(R_{int} = 0.0812) were independent. A Bulky Chelating Diamidoaluminum Monohydride − Synthesis, Structure and Reactions with Me_3SnF and Heavy Group 16 Elements

Hongping Zhu,[a] Jianfang Chai,[a] Herbert W. Roesky,*[a] Mathias Noltemeyer,[a] Hans-Georg Schmidt,[a] Denis Vidovic,[a] and Jörg Magull[a]

Dedicated to Professor Helmut Werner on the occasion of his 70th birthday

Keywords: Aluminum / Hydride / Chalcogens / Fluorine

The bulky chelating diamidoaluminum monohydride $[ArN(CH_2)_3NAr]AlH(NMe_3)$ (Ar = 2,6-*i*$Pr_2C_6H_3$; **1**) was prepared in excellent yield from the reaction of the diamine $ArNH(CH_2)_3HNAr$ with a small excess of $AlH_3{\cdot}NMe_3$ in toluene. Subsequent fluorination of **1** with Me_3SnF resulted in the formation of the aluminum monofluoride $[ArN(CH_2)_3NAr]AlF(NMe_3)$ (**2**). Reaction of **1** with elemental E (E = S, Se and Te) proceeded in toluene with heating to yield the aluminum chalcogenides $\{[ArNH(CH_2)_3NAr]Al(\mu\text{-}E)\}_2$ [E = S (**3**), Se (**4**), and Te (**5**)]. The structures of complexes **1**, **2** and **4** have been determined by X-ray diffraction analyses. Compounds **1** and **2** are well-separated monomers with a central aluminum atom in a tetrahedral environment. The diamide ligand $[ArN(CH_2)_3NAr]^{2-}$ chelates the Al atom to form a distorted six-membered AlN_2C_3 ring which features a boat conformation for **1** and a flattened chair conformation for **2**. Compound **4**, however, is a dimer with a central Al_2Se_2 core bearing an ideal four-membered planar ring and two six-membered AlN_2C_3 rings, both displaying a boat conformation. The latter two rings are arranged perpendicularly to the Al_2Se_2 core in a *trans* configuration. The IR spectra and ^1H NMR spectroscopic data of compounds **3**–**5** suggest that the migration of the hydrogen from selenium to one of the nitrogens at the diamide ligand is involved in the course of the reaction.

Introduction

Studies of aluminum hydrides have received considerable attention due to their scientific importance and numerous applications.[1] In recent years, much work has been devoted to aluminum hydrides of low aggregation, especially the monomeric forms. The synthesis of monomeric aluminum hydrides helps us to understand the reaction chemistry of surface-bound AlH_n groups formed during thin-film growth from organoaluminum sources.[2] Moreover, aluminum hydrides of low aggregation can be very effective precursors for preparing aluminum chalcogenides.[3] However, reactions involving aluminum hydrides of low aggregation with chalcogen or organochalcogenides have been reported to a lesser extent. Raston et al.[4] have investigated the reaction of the trimethylamine adduct of alane $Me_3N{\cdot}AlH_3$ with chalcogen or organochalcogenides. Power et al.[5] have reported one example of the reaction of an aluminum dihydride with an organochalcogenide and our group has discussed the reaction of a series of aluminum dihydrides with chalcogen,[3,6] where the isolation and structural characterization of some novel compounds {such as $LAl(SeH)_2$, $LAl(SeH)Se(SeH)AlL$,[3] $LAl(SH)_2$ [6a] [L = N(Ar)C(Me)-CHC(Me)N(Ar), Ar = 2,6-*i*$Pr_2C_6H_3$); $(RAlE)_2$ (R = 2,4,6-*t*$Bu_3C_6H_2$, E = S;[5] R = $N(SiMe_3)C(Ph)C(SiMe_3)_2$,[6b] 2,6-$(Et_2NCH_2)_2C_6H_3$, 2-$Et_2NCH_2$-6-$MeC_6H_3$;[6c] E = Se, Te], *trans*-$[\{Me_3N(H)Al(\mu\text{-}E)\}_2]$ (E = Se, Te),[4b] *trans*-$[\{Me_3N(PhTe)Al(\mu\text{-}Se)\}_2]$;[4c] $[(\eta^1\text{-}3,5\text{-}t\text{Bu}_2\text{pz}(\mu\text{-Al})H]_2E$ (E = S, Se, Te);[6d] $Me_3NAl(ER)_3$ (E = Se, R = Et, Ph, CH_2Ph; E = Te, R = Ph)[4a] and $Al_4Se_5(H)_2(NMe_3)_4$ [4c]} showed a rich chemistry. Although further reaction of the dimeric chalcogenidoalane, *trans*-$[\{Me_3N(H)Al(\mu\text{-}E)\}_2]$ (E = Se, Te) with chalcogen or organochalcogenides has been investigated,[4b] studies of the reaction of bulky, monomeric aluminum monohydrides with chalcogens, which might generate the corresponding monomeric Al-EH moieties, have not been reported so far. Therefore we became interested in finding a sufficiently bulky ligand to synthesize an intramolecularly stabilized aluminum monohydride, and further studies on its reactivity with the fluorinating agent Me_3SnF and heavy group 16 elements.

The divalent bulky chelating diamide ligand $[ArN(CH_2)_3NAr]^{2-}$ (Ar = 2,6-*i*$Pr_2C_6H_3$) is increasingly being used as a ligand[7] due to its special steric and electronic properties that help to control effectively the geometry at the metal center. Known complexes containing this ligand include main group metal (Li, K, Al) and transition metal (Ti, Zr, Y, Lu) derivatives.[7−11] The only reported alumi-

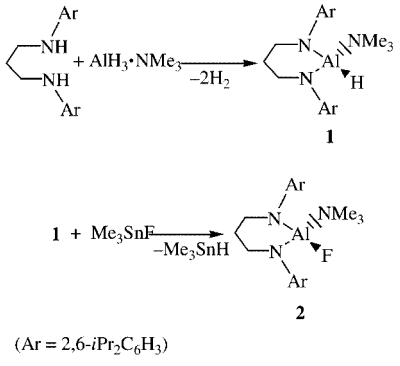
num complexes are a series of compounds containing alkyl and aryl groups [ArN(CH$_2$)$_3$NAr]AlR (R = Me, *i*Bu, C$_6$F$_5$).[11] Herein we report on the synthesis and characterization of the bulky chelating diamidoaluminum monohydride [ArN(CH$_2$)$_3$NAr]AlH(NMe$_3$) (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$; **1**). The metathesis of **1** with Me$_3$SnF to give the monofluoride [ArN(CH$_2$)$_3$NAr]AlF(NMe$_3$) (**2**) and the reaction with heavy group 16 elements to afford the dimeric aluminum chalcogenides {[ArNH(CH$_2$)$_3$NAr]Al(μ-E)}$_2$ [E = S (**3**), Se (**4**), and Te (**5**)] are also described.

Results and Discussion

Syntheses and Characterization of [ArN(CH$_2$)$_3$NAr]AlH(NMe$_3$) (1) and [ArN(CH$_2$)$_3$NAr]AlF(NMe$_3$) (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) (2)

The synthesis of aluminum hydrides has been reported in a number of publications.[12] The use of AlH$_3$·NMe$_3$ as a precursor to react with *N*-substituted diamine, diimine and analogues containing N-H groups or E(SiMe$_3$)$_2$ (E = P, As) with elimination of H$_2$ or HSiMe$_3$ has been shown to be a facile route to aluminum hydrides of low aggregation.[3,13] Reaction of the diamine [ArNH(CH$_2$)$_3$HNAr] with a small excess of AlH$_3$·NMe$_3$ in toluene under heating (80 °C) affords the intramolecularly stabilized diamidoaluminum monohydride [ArN(CH$_2$)$_3$NAr]AlH(NMe$_3$) (**1**) in excellent yield. Subsequent fluorination of **1** with Me$_3$SnF either at room temperature or at high temperature (80 °C) results in the formation of the aluminum monofluoride [ArN(CH$_2$)$_3$NAr]AlF(NMe$_3$) (**2**; Scheme 1).



Scheme 1

Complexes **1** and **2** were characterized by NMR, MS (EI) and IR spectroscopy, and elemental analyses. The presence of the hydride in **1** is evident from the IR spectrum. The broad IR band at 1799 cm^{-1} can be assigned to the Al−H stretching absorption.[14] In the IR spectrum of **2**, this absorption disappears, indicating that compound **1** is completely fluorinated. The ^{19}F NMR spectrum of **2** exhibits one singlet resonance (δ = −175.4 ppm), which is similar to the terminal Al−F resonance in a closely related series of compounds {ArN[Si(R)Me$_2$]AlF$_2$·THF: Ar = 2,6-*i*Pr$_2$C$_6$H$_3$, R = Me, δ = −178.1; R = *i*Pr, δ = −177.0 ppm; R = *t*Bu, δ = −175.1 ppm; Ar = 2,6-Me$_2$C$_6$H$_3$, R = *t*Bu, δ = −175.0 ppm; R = 2,4,6-Me$_3$C$_6$H$_2$, δ = −175.9 ppm}.[15] In the ^{1}H NMR spectra of **1** and **2** the presence of complex resonances for the backbone protons of the diamide ligand [two isopropyl methine (C*H*Me$_2$), four isopropyl methyl (CH*Me$_2$*), two methene (N*CH$_2$*) and two methene (NCH$_2$*CH$_2$*) resonances] is consistent with a pseudotetrahedral geometry and C_s symmetry at aluminium. Similar resonances are observed in compounds [M{ArN(CH$_2$)$_3$NAr}(η-C$_5$H$_5$)Cl] (M = Zr, Y; Ar = 2,6-*i*Pr$_2$C$_6$H$_3$).[7,9] The resonance for the Al−H proton is not seen, which is typical for amidoaluminum hydride species.[13b] Substitution of Al−H in **1** by Al−F has a stronger effect on the chemical shift of the NMe$_3$ group (**1**: δ = 1.66 ppm; **2**: δ = 1.75 ppm), while a smaller effect is observed for the backbone protons of the ligand. The MS (EI) spectrum shows the molecular ion of [M$^+$ − NMe$_3$] for **1**, and [M$^+$] and [M$^+$ − NMe$_3$] for **2** and the single-crystal X-ray structural determinations of **1** and **2** confirm the composition of [ArN(CH$_2$)$_3$NAr]AlR(NMe$_3$) (R = H, **1**; F, **2**), where the former contains half a molecule of *n*-hexane per molecule of complex **1** in the asymmetric unit.

Compounds **1** and **2** are well-separated monomers both of which contain a central aluminum atom in a distorted tetrahedral environment (Figures 1 and 2). Selected bond lengths and angles are listed in Table 1. The terminal Al−H bond length (1.52 Å) is closer to those in compounds (2,4,6-*t*Bu$_3$C$_6$H$_2$)$_2$AlH[16] [1.53(4) Å] and [HAl(NMe$_2$)$_3$]$^-$[17] [1.52(2) Å], but shorter than those in AlH(Cl)-[*t*BuNCH$_2$CH$_2$N(*t*Bu)H][13a] (1.60 Å), Al$_2$(μ-NEt$_2$)$_2$-[N(*i*Pr)$_2$]$_2$H$_2$ [18] (1.67 Å) and (2,4,6-*t*Bu$_3$C$_6$H$_2$)Al(H)Cl·THF[19] [1.73(5) Å]. The terminal Al−F separation [1.678(1) Å] is in the range of 1.657−1.681 Å

observed in $[(Me_3Si)_3CAlF_2]_3$ [20] and somewhat longer than those in $[\{(2,6\text{-}i\text{Pr}_2C_6H_3)N(SiMe_3)AlF_2\}_3]$[15] (1.634−1.642 Å) and AlF_3 [21] (1.63 Å), as determined by electron diffraction. The diamide ligand chelates the Al atom to form an AlN_2C_3 six-membered non-planar ring, in which Al(1) and C(2) occupy the head positions with distances to the quasi-plane N(1)−N(2)−C(3)−C(1) (mean deviation Δ = 0.0716 Å) of 0.1034 and 0.6852 Å in **1** and the plane N(1)−N(2)−C(3)−C(1) (Δ = 0.0316 Å) of −0.0109 and 0.6730 Å in **2**. It is obvious that the former displays a boat conformation and the latter a flattened chair conformation, and this can be explained in terms of the strain imposed by the Ar group. The F atom has a stronger electron-attracting tendency than the H atom, which generates different charge distributions at the central Al atom of **1** and **2**. This gives rise to the small difference in the $Al-N_{diamide}$ bond length between **1** and **2** (average 1.824, **1**; 1.807 Å, **2**), as well as the $Al\text{-}N_{NMe_3}$ bond length [2.024(2), **1**; 2.000(2) Å, **2**] and the N(1)−Al(1)−N(2) chelating angle [106.52(6)°, **1**; 107.45(7)°, **2**]. The $Al-N_{diamide}$ distances in **1** and **2** can be compared with the terminal Al−N(amide) distances in $CH_2(CH_2CMe_2)_2NAlH_2{\cdot}NMe_3$ [13h] [1.838(2) Å], AlH(Cl)[*t*BuNCH$_2$CH$_2$N(*t*Bu)H][13a] [1.80(1) Å] and $\{Al(\mu\text{-}H)[N(CMe_2CH_2)_2CH_2]_2\}_2$ [22] [1.836(3) Å], and are longer than the $Al-N_{diamide}$ bond lengths in the three-coordinate aluminum compound [ArN(CH$_2$)$_3$NAr]AlMe[11] [1.760(3), 1.766(3) Å]. The $Al-N_{NMe_3}$ distances in **1** and **2** are as expected.[13h,23,24]

Syntheses of $\{[ArNH(CH_2)_3NAr]Al(\mu\text{-}E)\}_2$ [E = S (3), Se (4) and Te (5)] and X-ray Structural Analysis of Compound 4

The successful fluorination of **1** using Me_3SnF is indicative of its reactivity despite the steric hindrance of the bulky ligand. Treatment of **1** with equivalent amounts of sulfur, selenium or tellurium proceeded in toluene at elevated temperature to afford the solvated aluminum sulfide **3** as light yellow crystals, the selenide **4** as yellow crystals and the telluride **5** as green-yellow crystals. The former two compounds were obtained in good yield and the latter in moderate yield [Equation (1)].

$$2[ArN(CH_2)_3NAr]AlH(NMe_3) + 2E \rightarrow \{[ArNH(CH_2)_3NAr]Al(\mu\text{-}E)\}_2 + 2NMe_3 \quad (1)$$

E = S (**3**), 80 °C, 12 h
= Se (**4**), reflux, 12 h
= Te (**5**), reflux, 120 h

Compounds **3**−**5** are air and moisture sensitive and soluble in hot toluene and benzene, while poorly soluble in THF, $CHCl_3$ and *n*-hexane. They were characterized by IR and NMR spectroscopy and MS (EI) spectrometry, as well as by elemental analyses. The MS (EI) spectra of **3**−**5** show the dimeric molecular ion with the correct isotope pattern and their ^{1}H NMR spectra show the very similar characters of the ligand, including the resonances of solvent toluene protons. The doublets in the range of δ = 1.10−1.25 ppm, one septet centered at ca. δ = 3.38 ppm and a multiplet at δ = 7.02−7.10 ppm correspond to the protons of the 2,6-*i*Pr$_2$C$_6$H$_3$ group. One broad singlet at ca. δ = 1.36 ppm can be assigned to the NH resonance,[13a,13c] with a satisfactory integral intensity indicating two protons, and two areas of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

unresolved multiplet resonances centered at ca. δ = 1.78 and 3.00 ppm arising from the six non-equivalent methylene protons, with the latter probably coming from the overlapping proton resonances of the two amido NCH_2 and two amine HNCH_2 groups. The IR spectra exhibit the NH absorption in the $\nu_{N\text{-}H}$ region[13a,13b] (**3**: 3190; **4**: 3187; **5**: 3185 cm^{-1}). All these data indicate that compounds **3**, **4** and **5** have the same structure corresponding to the formula $\{[ArNH(CH_2)_3NAr]Al(\mu\text{-}E)\}_2$.

The reaction of aluminum dihydride with selenium has been reported by our group,[3,6b,6c] where the formation of a dimeric compound might proceed through an Al−SeH intermediate. In a similar way the reaction of the aluminum monohydride **1** with selenium might involve the formation of intermediate $[ArN(CH_2)_3NAr]Al(SeH)(NMe_3)$, which dimerizes to produce $\{[ArN(CH_2)_3NAr]Al(\mu\text{-}SeH)\}_2$ with elimination of gaseous NMe_3. However, with reference to the related Al-SeH compounds $LAl(SeH)_2$ and LAl(SeH)Se(SeH)AlL [L = N(Ar)C(Me)CHC(Me)N(Ar), Ar = 2,6-iPr$_2$C$_6$H$_3$],[25] no absorptions in the range of 2000−2500 cm^{-1} in the IR spectrum are observed to indicate the formation of an Al-SeH moiety. This suggests that the dimer $\{[ArN(CH_2)_3NAr]Al(\mu\text{-}SeH)\}_2$ is not stable under heating and the hydrogen atom attached to the selenium atom migrates quickly to one of the nitrogen atoms of the diamide ligand to afford stable compound **4**. The most likely mecha-

nism is given in Scheme 2. The formation of compounds **3** and **5** is probably similar to that of **4**.

A suitable single crystal of compound **4** was measured by X-ray diffraction. The structure analysis of compound **4** shows a dimeric species containing two molecules of toluene. Unfortunately, the quality of the crystal structure did not allow the location of the hydrogen atoms on the nitrogen atoms. Nevertheless, the presence of NH groups was established by IR and ^{1}H NMR spectroscopy. The molecular structure is shown in Figure 3, and selected bond lengths and angles are listed in Table 1. The Al(1)−N(1) [1.932(11) Å] and Al(1)−N(2) [1.916(11) Å] bond lengths are midway between the Al−N_{amine} and Al−N_{amido} bond lengths observed in AlH(Cl)[*t*BuNCH$_2$CH$_2$N(*t*Bu)H][13a] [Al−N(1) (amine): 2.00(1) Å; Al−N(2) (amido): 1.80(1) Å], and are longer than those Al−N distances found in Al[*t*BuNCH$_2$CH$_2$N(*t*Bu)][*t*BuNCH$_2$CH$_2$NH(*t*Bu)],[13b] where the NH hydrogen atom is disordered over all four nitrogen centers [1.850(5), 1.870(5) Å], and much longer than Al−N_{amido} distances in **1** [1.820(1), 1.828(1) Å] and **2** [1.804(2), 1.810(2) Å]. However, compared to AlH(Cl)[*t*BuNCH$_2$CH$_2$N(*t*Bu)H],[13a] where a remarkable difference (0.20 Å) between Al−N(1) (amine) and Al−N(2) (amido) distances was observed, the very slight difference (0.016 Å) between Al(1)−N(1) and Al(1)−N(2) in **4** may imply the disorder of the two hydrogen atoms over the sides of all four nitrogen centers. Moreover, the similar coordination environments and approximately planar coordination geometries at N(1) and N(2) [at N(1), Al(1)−N(1)−C(1) 119.6(8)°, Al(1)−N(1)−C(16) 126.4(8)°, C(1)−N(1)−C(16) 113.2(9)°; at N(2), Al(1)−N(2)−C(3) 121.1(9)°, Al(1)−N(2)−C(4) 130.1(7)°, C(3)−N(2)−C(4) 108.0(9)°, (C−N−Al, C) = 359.2°] do not allow us to distinguish between the amine nitrogen and the amido nitrogen centers. In summary, it is assumed that the almost equal possibility of the hydrogen migration from the selenium atom to any nitrogen atom at the diamide ligand is included in the course of the reaction.

The Al_2Se_2 core exhibits an ideal planar ring (least-square deviation Δ of 0.0005) with an Al(1)−Se(1) distance of 2.339(1) Å, an Al(1)−Se(1A) distance of 2.381(1) Å and an Al(1)−Se(1)−Al(1A) bond angle of 78.56(5)°, which are as expected for Al_2Se_2 core compounds,[4a,4b,6b,6c] while the Al(1)−Se(1) and Al(1)−Se(1A) distances differ by ca. 0.042 Å probably due to the steric effects of the backbone ligand on the Al_2Se_2 ring. The ligand chelates the Al atom to fuse two six-membered AlN_2C_3 rings, which are arranged in *trans* positions on each side of the Al_2Se_2 core. The two AlN_2C_3 rings both display a boat conformation with Al(1) and Al(1A) at the bow and C(2) and C(2A) at the stern, respectively, and are arranged almost perpendicularly to the Al_2Se_2 ring (the dihedral angle between the ring (Al_2Se_2) and the N(1)−N(2)−C(3)−C(1) plane (Δ = 0.0238 Å) being 90.5°).

In summary we have shown that the [ArNCH$_2$CH$_2$NAr]$^{2-}$ ligand forms a stable chelate with the aluminium hydride. The hydride functionally can be replaced by a fluorine atom or substituted by a chalcogen (S, Se, Te) under migration of the hydrogen to an adjacent nitrogen of the chelating ring. The latter reaction does not yield an aluminium chalcogen double bond system but rather a four-membered ring of composition Al_2E_2 (E = S, Se, Te).

Experimental Section

General: All operations were carried out under purified nitrogen atmosphere using Schlenk techniques. Solvents were purified and dried by distillation over sodium under nitrogen prior to use. Elemental sulfur, selenium and tellurium were purchased from Aldrich and used as received. ArNH(CH$_2$)$_3$HNAr (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$),[7] AlH$_3$·NMe$_3$ [26]and Me$_3$SnF[27] were prepared according to the literature.

^{1}H (200.13 MHz), ^{19}F (188.29 MHz) and ^{77}Se NMR (500 MHz) spectra were recorded on a Bruker AM 200 or a Bruker AM 250 spectrometer and the chemical shifts were externally referenced to SiMe$_4$ for ^{1}H nuclei, C$_6$F$_6$ for ^{19}F and Me$_2$Se for ^{77}Se. (In this paper the chemical shift for ^{19}F NMR spectroscopy was adjusted to the scale where CFCl$_3$ is used as external reference). The IR spectra were measured on a Bio-Rad Digilab FTS-7 spectrometer. EI (70 eV) mass spectra were measured on a Finnigan MAT 8230 or a Varian MAT CH5 instrument. Elemental analyses were performed by the Analytisches Labor des Instituts für Anorganische Chemie der Universität Göttingen. Melting points were measured in sealed glass tubes and were not corrected.

[ArN(CH$_2$)$_3$NAr]AlH(NMe$_3$) (1): A solution of ArNH(CH$_2$)$_3$HNAr (4.03 g, 10.24 mmol) (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) in toluene (20 mL) was added to a solution of AlH$_3$·NMe$_3$ (1.18 g, 13.24 mmol) in toluene (30 mL). While stirring, gas evolution was observed. The mixture was slowly heated to 80 °C and stirred for 5 h. All volatiles were removed in vacuo and the residue was extracted with *n*-hexane. After filtration through Celite, the extract was evaporated to dryness to afford [ArN(CH$_2$)$_3$NAr]AlH(NMe$_3$) as a white solid (4.41 g, 90%). X-ray quality crystals were grown from *n*-hexane. M.p. 196−197 °C. ^{1}H NMR (200.13 MHz, C$_6$D$_6$): δ = 1.22, 1.37, 1.47, 1.66 (d, 24 H, CH*Me$_2$*), 1.66 (s, 9 H, N*Me$_3$*), 2.10, 3.00 (m, 2 H, NCH$_2$*CH$_2$*), 3.25−3.45 (m, 4 H, N*CH$_2$*), 3.63, 4.25 (sept, 4 H, *CH*Me$_2$), 7.10−7.16 (m, 6 H, Ar) ppm. MS (EI): *m*/*z* = 420 [M$^+$ − NMe$_3$]. IR (KBr, Nujol mull): ν$_{Al-H}$ = 1799 cm^{-1}(br. sh.). C$_{33}$H$_{57}$AlN$_3$ (522.02) (**1**·1/2 *n*-hexane): calcd. C 75.93, H 11.00, N 8.05; found C 75.44, H 10.64, N 8.26.

[ArN(CH$_2$)$_3$NAr]AlF(NMe$_3$) (2). Method 1: A suspension of **1** (1.44 g, 3 mmol) and Me$_3$SnF (0.55 g, 3 mmol) in toluene (30 mL) was heated to 80 °C and stirred for 12 h. After filtration, the filtrate was concentrated to ca. 10 mL in vacuo and kept at 4 °C for 48 h to afford colorless block-shaped crystals of **2** (1.20 g, 80%). M.p. 220−222 °C. ^{1}H NMR (200.13 MHz, C$_6$D$_6$): δ = 1.22, 1.35, 1.47, 1.71 (d, 24 H, CH*Me$_2$*), 1.75 (s, 9 H, N*Me$_3$*), 2.00, 3.00 (m, 2 H, NCH$_2$*CH$_2$*), 3.27, 3.40 (m, 4 H, N*CH$_2$*), 3.64, 4.29 (sept, 4 H, *CH*Me$_2$), 7.10−7.32 (m, 6 H, Ar) ppm. ^{19}F NMR (188.29 MHz, C$_6$D$_6$): δ = −12.4 (adjusted value, −175.4) ppm. MS (EI): *m*/*z* = 497 [M$^+$], 438 [M$^+$ − NMe$_3$]. C$_{30}$H$_{49}$AlFN$_3$ (497.72): calcd. C 72.40, H 9.92, N 8.44; found C 72.31, H 9.71, N 8.28.

Method 2: A suspension of **1** (1.44 g, 3 mmol) and Me$_3$SnF (0.55 g, 3 mmol) in toluene (30 mL) was stirred for 4 days at room temperature until Me$_3$SnF was almost consumed. After filtration, the filtrate was concentrated to ca. 10 mL in vacuo and kept at 4 °C for a week to afford colorless crystals. All spectroscopic data confirmed the same compound as that obtained from method 1.

{[ArNH(CH$_2$)$_3$NAr]Al(μ-S)}$_2$ (3): A suspension of **1** (1.48 g, 3 mmol) and elemental S (0.096 g, 3 mmol) in toluene (30 mL) was heated to 80 °C and stirred for 12 h. After filtration, the orange-red filtrate was concentrated to ca. 10 mL and kept at 4 °C for 48 h to afford light yellow crystals of **3**·toluene (1.00 g, 67%). M.p. 278−279 °C (> 250 °C, decomp.). ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.17, 1.22 (d, 48 H, CHMe_2), 1.36 (s, 2 H, NH), 1.78 (m, 4 H, NCH$_2$$CH_2$), 2.1 (s, 3 H, MePh), 3.00 (t, 8 H, NCH_2), 3.38 (sept, 8 H, CHMe$_2$), 6.96−7.04 (m, 5 H, MePh), 7.02−7.10 (m, 12 H, Ar) ppm. MS (EI): m/z = 904 [M$^+$]. IR (KBr Nujol mull): $\tilde{\nu}_{N\text{-}H}$ = 3190 cm^{-1}. $C_{61}H_{90}Al_2N_4S_2$ (996.8) (**3**·toluene): calcd. C 73.50, H 9.10, N 5.62; found C 73.25, H 8.90, N 5.07.

{[ArNH(CH$_2$)$_3$NAr]Al(μ-Se)}$_2$ (4): A suspension of **1** (1.44 g, 3 mmol) and elemental Se powder (0.24 g, 3 mmol) in toluene (30 mL) was refluxed for 12 h until almost all the selenium was consumed. In the course of hot filtration, yellowish crystals grew from the orange filtrate, and these were collected by filtration. (0.10 g). The mother liquor was concentrated to ca. 10 mL and kept at 4 °C for 24 h to afford another crop of yellowish crystals of **4**·2 toluene (1.00 g). Total yield: 1.10 g (62%). M.p. 291 °C (> 259 °C, decomp.). ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.17, 1.22 (d, 48 H, CHMe_2), 1.36 (s, 2 H, NH), 1.78 (m, 4 H, NCH$_2$$CH_2$), 2.1 (s, 6 H, MePh), 3.00 (t, 8 H, NCH_2), 3.38 (sept, 8 H, CHMe$_2$), 6.94−7.04 (m, 10 H, MePh), 7.02−7.10 (m, 12 H, Ar) ppm. ^{77}Se NMR (500 MHz, C_6D_6, $CDCl_3$, or C_7D_8): no resonances were observed. MS (EI): m/z = 998 [M$^+$]. IR (KBr Nujol mull): $\tilde{\nu}_{N\text{-}H}$ = 3187 cm^{-1}. $C_{68}H_{98}Al_2N_4Se_2$ (1182.9) (**4**·2 toluene): calcd. C 69.04, H 8.35, N 4.74; found C 68.79, H 8.22, N 4.63.

{[ArNH(CH$_2$)$_3$NAr]Al(μ-Te)}$_2$ (5): A suspension of **1** (1.44 g, 3 mmol) and elemental Te powder (0.39 g, 3 mmol) in toluene (40 mL) was refluxed for 5 days and a small amount of unreacted Te powder still remained. After filtration, the green-yellow filtrate was concentrated to ca. 10 mL and *n*-hexane (5 mL) was added. The solution was kept at 4 °C for 24 h to afford green-yellow crystals of **5**·toluene (0.85 g, 48%). M.p. 320 °C (decomp.). ^{1}H NMR (200.13 MHz, C_6D_6): δ = 1.17, 1.22 (d, 48 H, -CHMe_2), 1.35 (s, 2 H, NH), 1.75 (m, 4 H, NCH$_2$$CH_2$), 2.1 (s, 3 H, MePh), 3.00 (t, 8 H, NCH_2), 3.37 (sept, 8 H, CHMe$_2$), 6.94−7.04 (m, 5 H, MePh), 7.02−7.10 (m, 12 H, Ar) ppm. MS (EI): m/z = 1096 [M$^+$]. IR (KBr Nujol mull): $\tilde{\nu}_{N\text{-}H}$ = 3185 cm^{-1}. $C_{61}H_{90}Al_2N_4Te_2$ (1188.1) (**5**·toluene): calcd. C 61.67, H 7.63, N 4.71; found C 61.72, H 7.61, N 4.76.

X-ray Structural Determinations and Refinements for 1, 2 and 4: The crystallographic data for compounds **1** and **2** were collected on a Stoe−Siemens−Huber four-circle diffractometer coupled to a Siemens CCD area-detector and for **4** on a Stoe IPDS II-array detector system. In both cases graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) was used. All structures were solved by direct methods (SHELXS-96)[28] and refined against F^2 using SHELXL-97.[29] In **1** and **2**, all non-hydrogen atoms were refined anisotropically and hydrogen atoms were included using the riding model with U_{iso} tied to the U_{iso} of the parent atoms, except for the Al−H hydrogen atom in **1**, which was located by difference Fourier synthesis and refined isotropically. In **4** the non-hydrogen atoms in the dimeric structure were refined anisotropically while those in the two solvent molecules were refined isotropically. Treatment of hydrogen atoms was the same as those in **1** and **2**, except for the two NH hydrogen atoms, which could not be located. A summary of cell parameters, data collections, and structure solutions is given in Table 2.

CCDC-207050 (**1**), -207051 (**2**), and -207052 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12,

Partially Fluorinated Rare Earth Metal Complexes

Ana Mirela Neculai,[a] Dante Neculai,[a] Grigori B. Nikiforov,[a] Herbert W. Roesky,*[a] Christine Schlicker,[a] Regine Herbst-Irmer,[a] Jörg Magull,[a] and Mathias Noltemeyer[a]

Keywords: Lanthanides / Fluorides / Tin / N donor ligands

The reaction of $LScBr_2$ (**1**), LYI_2 (**3**), $LHoI_2$ (**4**), or $LErI_2$ (**5**) [L = *N*,*N*′′-(1,3-dimethyl-1,3-propanediylidene)bis(*N*′,*N*′-diethyl-1,2-ethanediamine)] with Me_3SnF was investigated. Treatment of **1** with Me_3SnF results in the formation of $(Me_3BrSn\text{-}\mu\text{-}F)_2LSc$ (**2**) while compounds **3**–**5** give $[LSnMe_2][Me_3SnI_2]$ (**6**) as the only product that could be isolated and characterized. Metathesis reactions of **1** with $AgSO_3CF_3$ led to $LSc(SO_3CF_3)_2$ (**7**). Compounds **1**, **2**, **6** and **7** were characterized by single-crystal X-ray structural analysis.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The rapid development in the chemistry of the rare earth metals has resulted in the synthesis of a plethora of original compounds with various types of ligands, along with the widely exploited cyclopentadienyl substituents. Previous published work from our group concerning β-diketiminato derivatives of these elements includes new information about derivatives of scandium,[1] praseodymium,[2] samarium,[3] terbium,[4] holmium, erbium,[5] and ytterbium[3] with the ligand *N*,*N*′′-(1,3-dimethyl-1,3-propanediylidene)-bis(*N*′,*N*′-diethyl-1,2-ethanediamine) $\{[N(CH_2CH_2NEt_2)C(Me)]_2CH\}^-$, abbreviated as L. These complexes are ideal candidates for use in a less-exploited research area of these metals, namely that of dihalo compounds as promising precursors for catalytically active species. However, we faced problems with metathesis reactions for the preparation of other derivatives when the chloro or bromo compounds were treated with alkyllithium or Grignard reagents, due to a number of side reactions. The pursuit of the complexes resulting from this kind of disubstitution reaction in which dihalo derivatives of rare-earth metals are involved[4] prompted us to study the fluorine-containing systems. More specifically, examples are known where trimethyltin fluoride is used as an effective fluorinating agent for the preparation of *d* and *f* transition metal complexes from chloride congeners.[6−8] However, reactions between other complexes and Me_3SnF are less well known. An interesting example is the oxidation of $[Sm(C_5H_4tBu)_2(THF)_2]$ with Me_3SnF for the preparation of $[(C_5H_4tBu)_2Sm(\mu\text{-}F)]_3$,[9] or the reaction of $CpTiF_3$ and $ZnMe_2$ in the presence of Me_3SnF.[10] In general, since lanthanide-fluorine bonds are very strong (124−135 kcal/mol for trivalent Eu, Yb, Er, Ho and Sm),[11] the metathesis reaction of lanthanide complexes containing Cl, Br, I, SCN or Me ligands with trimethyltin fluoride under mild conditions seemed feasible.

Besides the fluorine ion, another candidate for a successful metathesis is the quite well-known electron-withdrawing triflate group due to the oxophilic character of the rare earth metals.[12] Until now heteroleptic triflate compounds of lanthanides have been obtained using the $Ln(OTf)_3$ (Ln = lanthanide, OTf = triflate) as a starting material.[13] The synthesis of such complexes by substitution of other ligands at the coordination sphere of a metal that already contains an "ancillary" ligand (e.g. halogen) was not explored. In comparison to the homoleptic triflate derivatives, which are widely used as reusable catalysts,[14] it was expected that the heteroleptic compounds should suffer from a decrease of the Lewis acidity but still be advantageous in catalysis due to their high solubility in organic solvents.[15]

Herein, we analyze the results of the reactions of the dibromo derivative of scandium and the diiodo derivatives of yttrium, holmium, and erbium of composition $LLnX_2$ [L = *N*,*N*′′-(1,3-dimethyl-1,3-propanediylidene)bis(*N*′,*N*′-diethyl-1,2-ethanediamine); Ln = Sc, Y, Ho, Er; X = Br, I] with trimethyltin fluoride. To the best of our knowledge reactions of trimethyltin fluoride with lanthanide diiodide complexes have not been explored before in non-aqueous solvents. We also report the metathesis reaction of $LScBr_2$ and $Ag(SO_3CF_3)$ with formation of monomeric $LSc(SO_3CF_3)_2$. The precursor $LScBr_2$ will be discussed in relationship to the fluorine-containing complexes.

Results and Discussion

The precursor $LScBr_2$ (**1**) was synthesized in a similar manner as the previously reported rare earth metal com-

plexes with the same ligand from the lithium salt and scandium tribromide in toluene.[1,2] The X-ray structural analysis reveals the same type of coordination as the chloride congener (Figure 1, Table 1).[1]

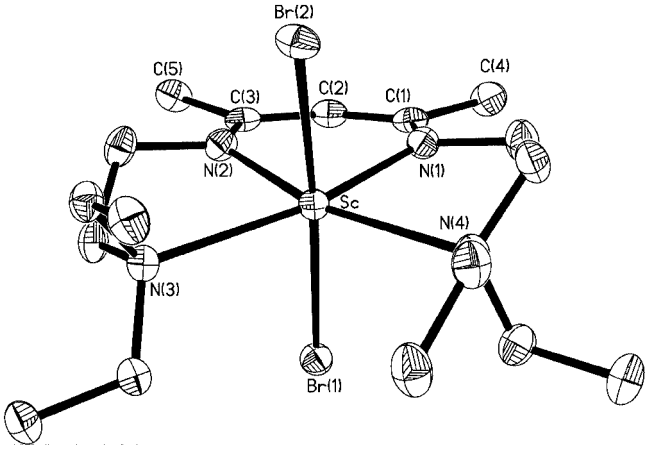

Figure 1. Molecular structure of **1**; thermal ellipsoids are drawn at the 50% probability level

Table 1. Selected bond lengths (Å) and angles (°) for **1**

C(1)−C(2)	1.394(3)	N(2)−Sc(1)−N(1)	85.21(6)
N(1)−C(1)	1.339(2)	N(1)−Sc(1)−N(4)	76.26(5)
Sc(1)−N(1)	2.155(1)	N(2)−Sc(1)−N(3)	79.44(5)
Sc(1)−N(2)	2.133(1)	N(4)−Sc(1)−N(3)	119.09(5)
Sc(1)−N(3)	2.541(1)	Br(1)−Sc(1)−Br(2)	172.274(1)
Sc(1)−N(4)	2.447(2)		
Sc(1)−Br(1)	2.610(1)		
Sc(1)−Br(2)	2.629(1)		

The reaction of $LScBr_2$ (**1**) with Me_3SnF in a 1:2 molar ratio [Equation (1)] led to compound **2** that comprises the anticipated difluorinated scandium derivative but bridged by fluorine to two Me_3SnBr molecules. The reaction of $LScCl_2$ with two equivalents of Me_3SnF gave the chloro analogue **2′** [Equation (2)].

$$\underset{\mathbf{1}}{LScBr_2} + 2\,Me_3SnF \xrightarrow[\text{room temp.}]{\text{toluene}} \underset{\mathbf{2}}{(Me_3BrSn\text{-}\mu\text{-}F)_2LSc} \quad (1)$$

$$LScCl_2 + 2\,Me_3SnF \xrightarrow[\text{room temp.}]{\text{toluene}} \underset{\mathbf{2'}}{(Me_3ClSn\text{-}\mu\text{-}F)_2LSc} \quad (2)$$

Crystals of **2** are extremely sensitive once the mother liquor is removed and they are rapidly decomposed within minutes. After that the substance cannot be dissolved again in toluene or any other solvent, indicating that decomposition and formation of insoluble fluorides has probably occurred. Therefore discussion of its structure will be based only on the X-ray analysis. Complex **2** crystallises in two phases (triclinic **2a** and monoclinic **2b**). The two phases differ only slightly in their bond lengths and angles. In the monoclinic phase **2a** the molecule lies on a twofold axis resulting in a completely planar arrangement of Sc within the β-diketiminato NCCCN plane, while deviation of the scandium atom from the same plane is 0.49 Å in **2a**. The major difference between **2a** and **2b** is found in the F−Sc−F angle [162.2 (**2a**) and 171.2° (**2b**)]. In the following discussion we will refer only to the triclinic phase due to the slightly better results of the refinement. At first glance the structure shows a trinuclear non-linear compound where the scandium atom has a pseudooctahedral geometry and the pentacoordinate tin is trigonal bipyramidal (F−Sn−Br av. 177.1°; Figure 2).

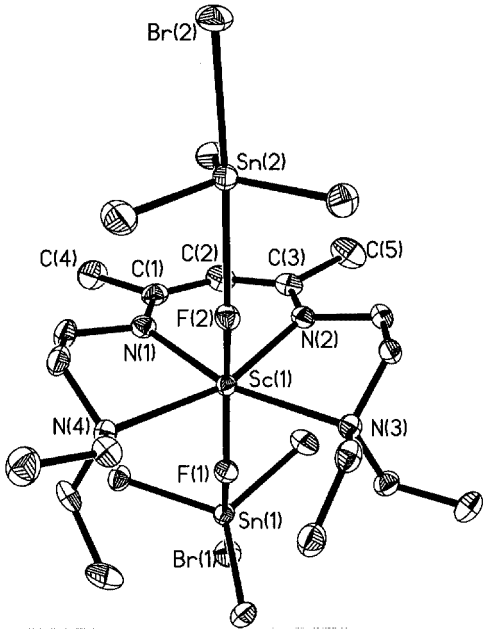

Figure 2. Molecular structure of **2a**; thermal ellipsoids are drawn at the 50% probability level

Scandium is σ-bonded to the β-diketiminato backbone similar to the dibromo derivative (distance from scandium to the backbone plane 0.49 Å). The analogous distances for **1** and **2** indicate that this kind of bonding is caused by the coordination of the metal to all four nitrogen atoms (eight-electron donor) of the ligand. Consequently the β-diketiminato backbone is acting as a four-electron donor.[16] The Sc−F bond lengths are similar to those reported in the literature (1.97 Å and 1.99 Å for **2a** and av. 2.03 Å for Cp_2ScF).[17] The Sn−F bond length (2.42 and 2.46 Å) is of the same order as the longest Sn−F distance in polymeric Me_3SnF,[18] which has the same pentacoordination. The Sc−F−Sn bond angle averages to 148.6°. A comparable intermediate was observed in the fluorination of a zirconium derivative[8a] with Me_3SnF. However, in the scandium case we cannot argue that **2** is an intermediate in the fluorination process although under electron impact conditions fragments corresponding to $LScF^+$ (359) and Me_3Sn^+ (165) are observed. Although compound **2** is quite unstable, we were not able to isolate the monomeric fluoride. Our results are in agreement with those found for the metathesis of $LScCl_2$ with Me_3SnF.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

An X-ray structural analysis of **2′** established the connectivity of the structure but this cannot be discussed in any detail due to the poor quality of the crystals. A qualitative view reveals that **2′** has the same skeletal arrangement as **2b**, with the bromine bridges being replaced by chlorine. In **2** the Me_3Sn units are coordinated in a similar manner to those reported for a zirconium compound (Table 2).[8a]

Table 2. Selected bond lengths (Å) and angles (°) for **2a**

F(1)−Sn(1)	2.419(3)	F(2)−Sn(2)−Br(2)	176.72(6)
F(2)−Sn(2)	2.455(5)		

The variation of the rare earth metal from scandium to yttrium, holmium and erbium, and of the halide from bromine to iodine led to an entirely different behaviour of the complexes $LLnX_2$ [Ln = Y (**3**), Ho (**4**), Er (**5**)] in the reaction with Me_3SnF (1:2). Independent of whether the reaction was carried out in toluene or THF, the isolated product is the same in all three cases, namely $[LSnMe_2][Me_3SnI_2]$ (**6**). Obviously a complete substitution of the rare earth metal with tin has occurred. A solid yellow residue remained which contains non-stoichiometric amounts of Ln, C, H, F, I and N.

$$LLnI_2 + 2\,Me_3SnF \xrightarrow[\text{B. 1. THF, room temp.}]{\text{A. toluene, room temp.}} [LSnMe_2][Me_3SnI_2]$$
$$\text{2. pentane, -}Me_3SnI \qquad \textbf{6}$$
$$\text{3. toluene}$$

Scheme 1. Reaction of $LLnI_2$ with Me_3SnF (Ln = Y, Ho, Er)

Crystalline **6** (Figure 3, Table 3) consists of well-separated cations and anions and crystallizes with one molecule of toluene. In the cation of **6** the β-diketiminato ligand coordinates to the tin(IV) center through three nitrogen atoms, less than in other lanthanide compounds with this ligand but similar to a reported aluminum complex.[1−5,19,20] The Sn(2) atom has a coordination number of five that can be regarded as being distorted trigonal bipyramidal with N(1) and N(4) axial and C(71), C(72), Sn(2) and N(2) coplanar [the angle N(1)−Sn(2)−N(4) is 163.5(3)°].

Table 3. Selected bond lengths (Å) and angles (°) for **6**

C(1)−C(2)	1.413(16)	N(2)−Sn(2)−N(1)	87.3(4)
N(1)−C(1)	1.337(15)	N(1)−Sn(2)−N(4)	163.5(3)
N(2)−C(3)	1.349(16)	C(71)−Sn(2)−N(4)	94.5(4)
C(2)−C(3)	1.344(15)	C(72)−Sn(2)−C(71)	126.4(5)
Sn(2)−N(2)	2.095(9)	N(2)−Sn(2)−C(71)	115.2(4)
Sn(2)−N(1)	2.161(10)	C(61)−Sn(1)−C(62)	116.4(7)
Sn(2)−N(4)	2.381(10)	C(61)−Sn(1)−I(1)	92.0(4)
Sn(2)−C(72)	2.126(11)	I(1)−Sn(1)−I(2)	177.32(4)
Sn(2)−C(71)	2.138(11)		
Sn(1)−C(61)	2.125(15)		
Sn(1)−I(1)	2.997(14)		
Sn(1)−I(2)	3.044(14)		

Cationic tin(IV) complexes are known with N-donor ligands and a number of those have been structurally characterized.[21] In the cationic part of **6**, the Sn(2)−N bond lengths of the pendant arm are longer than those of the backbone, similar to the corresponding distances in related compounds[1−5,19,20] and in **1** and **2** [Sn(2)−N(1) 2.161, Sn(2)−N(2) 2.095, Sn(2)−N(4) 2.381 Å]. The difference between the C−C and C−N bond lengths in the NCCCN unit is greater than in **1** or **2** and other complexes with the same ligand. This may indicate the alternation of single and double bonds in the bonding pattern of the metal to the nitrogen atoms. However, the difference between Sn(2)−N(1) and Sn(2)−N(2) is just greater than the three esd's limit consistent with N(2) as an amido nitrogen and N(1) as part of a C=N unit. The Sn(2)−N bond lengths are

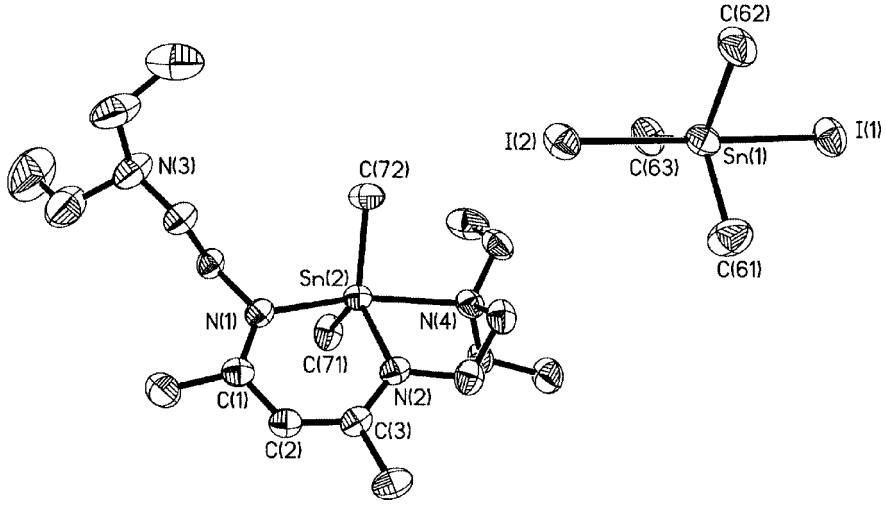

Figure 3. Molecular structure of **6**; thermal ellipsoids are drawn at the 50% probability level

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

similar to those found in the literature for β-diketiminato complexes of Sn^{4+}, such as $LSnMe_2Cl$ (Sn−N 2.110, 2.112 Å)[22a] and $LSnI_3$ (Sn−N 2.163, 2.176 Å; L = β-diketiminato ligand).[22b] The NCCCN backbone of the β-diketiminato ligand remains essentially planar (the deviation from planarity is 0.024 Å) with the tin atom 0.604 Å above the plane. The nitrogen atoms of the pendant arm lie out of the NCCCN plane with N(3) 1.43 Å below and N(4) 1.07 Å above the plane. The Sn(1)−I and Sn−Me bond lengths are similar to those found for Sn^{4+} complexes.[23]

In the anion the Sn(1) atom also has a five coordinate trigonal bipyramidal environment with I(1) and I(2) axial and C(61), C(62), Sn(1) and C(63) coplanar.

The unexpected composition of $[LSnMe_2][Me_3SnI_2]$ that resulted from the X-ray analysis is consistent with the data from mass spectrometry and elemental analysis. The EI mass spectrum of **6** exhibits the $[MeSnI_2^+]$ and $[Me_2SnI_2^+]$ ions and fragments of the β-diketiminato ligand, while in the FAB mass spectrum of **6** the $[LSnMe_2^-]$ ion and fragments of $[LSnMe_2][Me_3SnI_2]$ are observed. In the ^1H NMR spectrum of **6** a set of broad and overlapping resonances is observed.

Obviously, the slight variation of the properties of the metals in complexes $LLnX_2$ between scandium and yttrium as well as the presence of iodine instead of bromine resulted in a different complex. A possible explanation for this behaviour may be due to the formation of very strong Y−F (and Ho−F and Er−F) bonds that leads to complete elimination of the ligand from the coordination sphere of the starting material and migration to the tin atom in complex **6**. The analytical data of the insoluble residues indicate the formation of very impure polymeric fluorides.

As far as the iodine precursors are concerned, the preparation of the holmium and erbium complexes was already reported.[5] The yttrium compound was obtained from the potassium salt of the ligand and yttrium triiodide. LYI_2 was characterized by ^1H, and ^{13}C NMR spectroscopy, mass spectrometry and elemental analysis and is, to the best of our knowledge, the first β-diketiminatoyttrium complex.[24]

Extending our investigation to other fluorine-containing ligands, reaction of the dibromoderivate $LScBr_2$ with $AgSO_3CF_3$ occurs, as expected, with substitution of both bromine atoms due to the oxophilic character of scandium and the thermodynamically favored formation of AgBr [Equation (3)].

$$\underset{\mathbf{1}}{LScBr_2} + 2\,Ag(SO_3CF_3) \xrightarrow[\text{room temp.}]{\text{toluene}} \underset{\mathbf{7}}{LSc(SO_3CF_3)_2} + 2\,AgBr\downarrow \quad (3)$$

Compound **7** is a yellow solid very soluble in aromatic solvents, diethyl ether and THF. The Lewis acidity of scandium is lower than in $Sc(SO_3CF_3)_3$ as a consequence of the substitution of one triflate ligand by the nitrogen-containing ligand L. Moreover, the two triflate ligands increase the electronic density on the scandium atom in **7** in comparison to **1**, documented by the substantial upfield shift of the scandium resonance in the ^{45}Sc NMR spectrum (δ = 335.8 ppm in **1** to 185.0 ppm in **7**).

The crystal structure analysis (Figure 4) reveals that the scandium atom in **7** is hexacoordinated with a pseudooctahedral geometry and the two triflate ligands are arranged in the apical positions [O(3)−Sc−O(1) 170.8° compared to Br(1)−Sc(1)−Br(2) 172.3° of **1**].

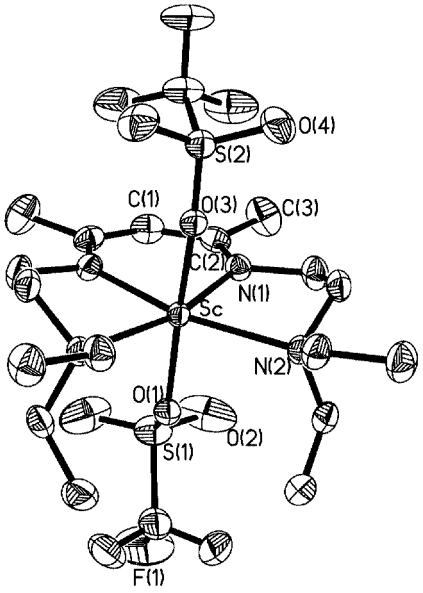

Figure 4. Molecular structure of **7**; thermal ellipsoids are drawn at the 50% probability level

For steric reasons, the triflate groups are not coordinated to scandium in a chelating fashion; they bind in a monodentate fashion through oxygen[13c,25] (Table 4). The NCCCN atoms of the β-diketiminato backbone as well as the nitrogen atoms of the ligand arms are almost coplanar. The distance from Sc to the NCCCN plane (0.28 Å) indicates a σ-bond interaction between scandium and the β-diketiminato ligand (in **1** the corresponding distance is 0.42 Å).[16]

Table 4. Selected bond lengths (Å) and angles (°) for **7** (symmetry transformations used to generate equivalent atoms #1 x, $-y + 1/2$, z)

C(1)−C(2)	1.393(2)	O(1)−Sc−O(3)	170.88(7)
N(1)−Sc	2.126(2)	N(1)−Sc−N(1)#1	85.38(8)
N(2)−Sc	2.378(1)	N(1)−Sc−N(2)	79.66(5)
O(1)−Sc	2.126(2)	N(2)#1−Sc−N(2)	115.12(7)
O(3)−Sc	2.108(2)		

A comparison of the bond lengths and angles of **1**, **2** and **7** showed that within the β-diketiminato frame these units are hardly influenced by the different substituents on scandium (see Tables 1, 2, and 4).

Conclusion

Herein we report some progress in the investigation of the reactivity of complexes of scandium, yttrium, holmium

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and erbium containing the β-diketiminato ligand L. On the basis of the hard-soft acid-base principle it is expected that rare earth metals should form very stable bonds with fluorine. Taking into account also the successful use of Me_3SnF as a fluorinating reagent, we considered that the chances of obtaining compounds of type $LLnF_2$ were realistic. However, reactions of Me_3SnF with $LScBr_2$ (**1**), LYI_2 (**3**), $LHoI_2$ (**4**), and $LErI_2$ (**5**), respectively, led to the isolation of compounds $(Me_3BrSn\text{-}\mu\text{-}F)_2LSc$ (**2**) and $[LSnMe_2][Me_3SnI_2]$ (**6**). The latter species was formed independently of the rare earth metal diiodide used as a starting material (LYI_2, $LHoI_2$, $LErI_2$) by substitution of the metal. Based on the yield of **6** we cannot argue that the fluorine derivatives of the rare earth metals were not formed but it is likely that, as in the case of compound **2**, it aggregates with formation of an insoluble product.

In view of the failure of the metathesis reaction of the scandium derivatives with the usual organometallic reagents we have reacted **1** with $AgSO_3CF_3$ to yield compound **7**.

Experimental Section

General Experimental Procedures: All operations involving air- and moisture-sensitive compounds were performed using standard Schlenk-line and dry-box techniques under purified dinitrogen atmosphere. Hexane and dichloromethane were dried from appropriate drying agents — Na/K alloy (hexane) and CaH_2 (dichloromethane) — and distilled under dinitrogen prior to use. $CDCl_3$, [D_8]THF and C_6D_6 were dried from appropriate drying agents (CaH_2 and Na/K alloy respectively) and degassed. Literature methods for the preparation of the starting materials are cited within the text. $AgSO_3CF_3$ was purchased from Aldrich and used without purification. ^1H, ^{19}F, and ^{45}Sc NMR spectra were recorded on a Bruker AM 200 instrument. Mass spectra were recorded on a Finnigan MAT 8230 instrument, and elemental analyses were carried out at the Analytical Laboratories of the Institute of Inorganic Chemistry at the University of Göttingen. Melting points were determined in sealed capillary tubes under dinitrogen and are uncorrected. IR spectra were recorded using a Perkin−Elmer Bio-Rad Digilab FTS-7.

Preparation of $LScBr_2$ (1): Toluene (30 mL) was added to LLi (2.90 g, 9.6 mmol) obtained in situ following the procedure described previously.[2] This mixture was added dropwise to a suspension of $ScBr_3$ (2.76 g, 9.7 mmol) in toluene (25 mL) in a Schlenk flask. Then, the reaction mixture was refluxed overnight. The suspension was filtered hot, the solvent removed and the crude product washed with pentane (50 mL) to yield 4.35 g (86.6%) of $LScBr_2$. Large colorless crystals were obtained upon cooling the mother liquor to −26 °C. $C_{17}H_{35}Br_2N_4Sc$ (500.3): calcd. C 40.58, H 7.30, N 10.90; found C 40.81, H 7.05, N 11.20. ^1H NMR (200.13 MHz, TMS, 300 K, C_6D_6): δ = 4.82 (s, 1 H, C*H*), 3.08 [m, 16 H, NCH_2CH_2N(CH_2)$_2$], 1.55 (s, 6 H, CHCCH_3), 0.82 (t, 12 H, CH_2CH_3) ppm. ^{13}C NMR (125.75 MHz, TMS, 300 K, C_6D_6): δ = 165.3 (*C*CHC), 100.5 (*C*H), 54.7 (CNCH_2), 47.8 (NCH_2CH_2), 30.1 (CH_2NCH_2), 22.3 (CHC*C*H_3), 8.9 (NCH_2*C*H_3) ppm. ^{45}Sc NMR (121.49 MHz, referenced to $[Sc(H_2O)_6]^{3+}$ in D_2O, 300 K, C_6D_6): δ = 335.87 ppm. M.p. 131−136 °C. EI-MS: *m*/*z* (%) = 500 (10) [M^+], 414 (100) [$M^+ - C_5H_{12}N$].

Preparation of 2 and 2′: A mixture of **1** (0.50 g, 0.98 mmol) or $LScCl_2$ (0.51 g, 0.98 mmol)[1] and Me_3SnF[26] (0.35 g, 1.96 mmol) in a Schlenk flask in toluene (50 mL) was stirred for 1 day until all the Me_3SnF dissolved. The resulting solution was concentrated under reduced pressure and kept at −26 °C. After 3 days crystals of **2** and **2′** were obtained. Cold filtration afforded 0.43 g of **2** (yield 51%) or 0.45 g of **2′** (yield 66%). Attempts to redissolve the resulting products in $CDCl_3$ or C_6D_6 for characterizing **2** and **2′** by NMR spectroscopy failed as the compounds decomposed rapidly once they were taken out of the solution.

2: EI-MS: *m*/*z* (%) = 359 (15) [$LScF^+$], 165 (5) [Me_3Sn^+], 86 (100) [$C_5H_{12}N^+$].

2′: EI-MS: *m*/*z* (%) = 359 (20) [$LScF^+$], 165 (5) [Me_3Sn^+], 86 (100) [$C_5H_{12}N^+$].

Preparation of 3: LK (0.60 g, 1.8 mmol) was obtained in situ by refluxing LH (0.53 g, 1.8 mmol) with KH (0.10 g, 2.5 mmol) in toluene (30 mL) and filtering off the excess KH. The resulting solution was added dropwise to a suspension of YI_3 (0.8 g, 1.8 mmol) in toluene (25 mL) in a 100 mL Schlenk flask. Then, the reaction mixture was refluxed for 1 day. The suspension was filtered hot, the solvent removed and the crude product was washed with pentane (50 mL) then dried in vacuo. Yield: 8.08 g (70.4%). $C_{17}H_{35}I_2N_4Y$ (638.2): calcd. C 31.99, H 5.53, N 8.78; found C 32.20, H 5.40, N 8.56. ^1H NMR (200.13 MHz, 300 K, C_6D_6): δ = 4.80 (s, 1 H, C*H*), 3.10 [m, 16 H, NCH_2CH_2N(CH_2)$_2$], 1.55 (s, 6 H, CHCCH_3), 0.78 (t, 12 H, CH_2CH_3) ppm. ^{13}C NMR (125.75 MHz, 300 K, C_6D_6): δ = 166.3 (*C*CH*C*), 101.0 (*C*H), 55.1 (CNCH_2), 46.9 (NCH_2CH_2), 30.1 (CH_2NCH_2), 22.9 (CHC*C*H_3), 8.4 (NCH_2*C*H_3) ppm. M.p. 150−155 °C. EI-MS: *m*/*z* (%) = 511 (5) [$M^+ - I$], 86 (100) [$C_5H_{12}N^+$].

Preparation of 6. A: A mixture of **3** (1.15 g, 1.8 mmol) and Me_3SnF[26] (0.64 g, 3.5 mmol) in toluene (50 mL) in a Schlenk flask was stirred for 1 day then the turbid yellow solution was filtered. The resulting solution was concentrated under reduced pressure and kept at −26 °C. After one week crystals of **6** were obtained (0.94 g, 34%).

B: Me_3SnF (0.64 g, 3.5 mmol) and THF (40 mL) were added to LYI_2 (**3**; 1.15 g, 1.8 mmol), $LHoI_2$ (**4**; 1.28 g, 1.8 mmol) or $LErI_2$ (**5**; 1.29 g, 1.8 mmol). After stirring for 1 h all the Me_3SnF had dissolved. After the reaction was complete the THF was removed in vacuo, and the residue washed with two portions (20 mL) of pentane. The solid residue was extracted with toluene (60 mL) and the toluene solution concentrated to approximately 10 mL. After standing overnight colorless crystals suitable for X-ray analysis were formed, which were separated by filtration. Another crop of crystals of **6** was obtained by washing the residue with toluene. Yield 0.83 g, 30% (for **3**), 0.75 g, 22% (for **4** and **5**). The concentration of the toluene solution of **6** should proceed slowly, otherwise two liquid layers are formed and no crystallization is observed. $C_{22}H_{50}I_2N_4Sn_2$ (861.9): calcd. C 30.66, H 5.86, N 6.50; found C 30.01, H 5.55, N 6.10. ^1H NMR (200.13 MHz, TMS, 300 K, C_6D_6): δ = 0.29 [s, 6 H, Sn(CH_3)$_2$], 0.57 [s, 9 H, Sn(CH_3)$_3$], 1.00 (t, 12 H, CH_2CH_3), 1.91 (s, 6 H, CCH_3), 2.63 [m, 12 H, CH_2N(CH_2CH$_3$)$_2$], 3.31 (m, 4 H, NCH_2CH$_2$NEt$_2$), 4.61(s, 1 H, *CH*) ppm. M.p. 222−224 °C. EI-MS: *m*/*z* (%) = 403 (2) [$Me_2SnI_2^+$], 388 (2) [$MeSnI_2^+$], 273 (6) [Me_2SnI^+], 247 (4) [SnI^+], 210 (30) [$L^+ - NC_5H_{12}$], 86 (100) [$C_5H_{12}N^+$]. EI-FAB: *m*/*z* (%) = 849 (1) [$(LSnMe_2)(Me_2SnI_2)^-$], 721 (2) [$(LSnMe_2)(Me_2SnI)^-$], 445 (8) [$LSnMe_2^-$], 297 (100) [L^-]. IR (Nujol): $\tilde{\nu}$ = 1619 cm^{-1} (w), 1659 (w), 1572 (m), 1409 (w), 1289 (w), 1261 (vs), 1205 (w), 1168 (w), 1153 (w), 1095 (vs), 1029 (vs), 967 (w), 928 (w), 873 (w), 799 (vs), 728 (m), 699 (w), 668(w), 636 (w), 534 (m), 467 (m).

Preparation of 7: A mixture of **1** (0.50 g, 0.98 mmol) and $AgSO_3CF_3$ (0.11 g, 1.96 mmol) in toluene (35 mL) in a 50 mL Schlenk flask was stirred for 2 days. The suspension was filtered. The resulting clear solution was concentrated under reduced pressure to obtain yellow crystals of **7**, which were collected by filtration and washed with pentane (10 mL). Yield 0.31 g (68%) $C_{17}H_{35}F_6N_4O_6S_2Sc$ (614.6): calcd. C 35.74, H 5.52, N 8.77; found C 35.2, H 5.57, N 8.63. ^{1}H NMR (200.13 MHz, TMS, 300 K, C_6D_6): δ = 4.72 (s, 1 H, *CH*), 3.03 (t, J = 6.28 Hz, 4 H, N*CH*$_2$CH$_2$NEt$_2$), 2.82 (q, J = 6.47 Hz, 4 H, N*CH*$_2$CH$_3$), 2.64 (t, J = 6.24 Hz, 4 H, NCH$_2$*CH*$_2$NEt$_2$) 2.47 (m, J = 6.48 Hz, 4 H, N*CH*$_2$CH$_3$) 1.59 (s, 6 H, CHC*CH*$_3$), 0.66 (t, J = 7.16 Hz, 12 H, CH$_2$*CH*$_3$) ppm. ^{13}C NMR (125.75 MHz, TMS, 300 K, C_6D_6): δ = 165.3 (*C*CH*C*), 100.5 (*C*H), 54.7 (CN*C*H$_2$), 47.8 (NCH$_2$*C*H$_2$), 30.1 (CH$_2$N*C*H$_2$), 22.3 (CHC*C*H$_3$), 8.9 (NCH$_2$*C*H$_3$) ppm. ^{19}F NMR (188 MHz, C_6F_6 as external reference, 300 K, C_6D_6): δ = 85.01 ppm. ^{45}Sc NMR (121.49 MHz, referenced to $[Sc(H_2O)_6]^{3+}$ in D_2O, 300 K, C_6D_6): δ = 185.06 ppm. M.p. 95 °C. EI-MS: m/z (%) = 638 (74) [M$^+$], 552 (36) [M$^+$ − $C_5H_{12}N$], 489 (100) [M$^+$ − CF_3SO_3].

X-ray Crystallography: Crystal structure data were collected on a Stoe Image Plate IPDS II-system (**1**, **7**) or on a Stoe−Siemens−Huber four-circle diffractometer equipped with a Bruker AXS CCD detector (**2**, **6**). All structures were solved by direct methods (SHELXS-97)[27] and refined against F^2 using SHELXL-97.[27] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using the riding model with U_{iso} tied to U_{iso} of the parent atoms. Crystal data collection details, and the solution and refinement procedures are summarized in Table 5.

CCDC-175025 (**1**), -199568 (**2a**), -199569 (**2b**), -203966 (**6**), and -199567 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Monoarylated Fluoromesitylpalladium Complexes

Camino Bartolomé,[a] Pablo Espinet,*[a] Jose M. Martín-Alvarez,[a] and Fernando Villafañe[a]

Keywords: Palladium / Fluorinated ligands / Ligand substitution / Bulky ligands / Steric hindrance

Monoarylated complexes [PdCl(Fmes)(L-L)] [Fmes = 2,4,6-tris(trifluoromethyl)phenyl or fluoromesityl] and *trans*-[PdCl(Fmes)L_2] have been obtained by arylation of [$PdCl_2$(L-L)] (L-L = tmeda) or *trans*-[$PdCl_2L_2$] (L = SMe_2), by splitting the bridging chloro ligands in [Pd(μ-Cl)(Fmes)(NCMe)]$_2$ {L-L = 4,4′-Me_2bipy, biquinolyl (2,2′-biquinoline), OPPhPy$_2$-*N*,*N*′, (OH)(CH_3)CPy$_2$-*N*,*N*′, dppe, pte [1,2-bis(phenylthio)-ethane]; L = 4-pic}, or by substitution of the diolefin in [PdCl(Fmes)(COD)] (L = *t*BuNC). A 1:1 ratio of [Pd(μ-Cl)(Fmes)(NCMe)]$_2$ and monodentate ligands affords [PdCl(Fmes)(NCMe)L] (L = 2,6-lut, 3,5-lut, PPh_3), whereas a 1:1 mixture of [{PdCl(Fmes)(NCMe)}$_2$(μ-dppe)] and [PdCl(Fmes)(dppe)] is obtained with dppe under mild conditions. The precursor [Pd(μ-Cl)(Fmes)(NCMe)]$_2$ is generated by boiling under reflux [PdCl(Fmes)(COD)] in MeCN, and has been used to obtain various binuclear monoarylated complexes [Pd(Fmes)(μ-X)L]$_2$ [X = Br, L = MeCN, P(*o*-Tol)$_3$; X = Cl, L = CO, 4-pic, 3,5-lut, P(*o*-Tol)$_3$]. Other [Pd(Fmes)(μ-X)L]$_2$ complexes have been obtained from *trans*-[PdCl(Fmes)(SMe_2)$_2$] (X = Cl, L = tht, SMe_2, PPh_3) and from K[Pd_4(Fmes)$_4I_5$] [X = I, L = P(*o*-Tol)$_3$]. Despite the steric hindrance imposed by the Fmes ligand (*ortho* effect), the ligand-substitution reactions are suggestive of associative mechanisms.

Introduction

The high steric demand of the 2,4,6-tris(trifluoromethyl)-phenyl (nonafluoromesityl or Fmes) group, an interesting ligand for main-group[1,2] and transition metals,[3] hinders rotation around the M−Fmes bonds, restricts rotation of other ancillary ligands on the same metal center, and shows a high degree of axial protection in square-planar complexes (*ortho* effect).[4]

Like other such ligands Fmes can stabilize species that are otherwise difficult to obtain. Thus, its coordination to palladium has resulted in an unprecedented self-assembled pyramidal tetrametallic complex with a halide apex in the [Pd_4(Fmes)$_4X_5$]$^-$ (X = Cl, Br, I), and has lead to the formation of neutral aquo complexes, and to a new halocarbon ligand that acts as a chelate.[5] Weak M···F interactions, invoked in many other complexes,[1−3] are deemed absent in our fluoromesitylpalladium(II) complexes based on analysis of a number of solid-state structures.[4,5]

The Fmes group's bulk makes its coordination by arylation difficult. In fact, our initial results on the coordination of Fmes in palladium(II) complexes indicate that arylation depends greatly on the size of the ancillary ligands in the parent complex.[4] Therefore, ligand substitution of monoarylated complexes accessible by arylation may widen the range of monoarylated species available. Here we describe the synthesis and characterization of several monoarylated Fmes palladium(II) complexes, with monodentate or bidentate ligands, as well as binuclear monoarylated complexes.

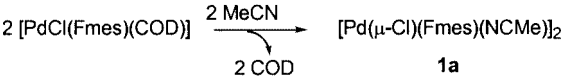
Results and Discussion

The synthesis and structural characterization of the parent complex [Pd(μ-Cl)(Fmes)(NCMe)]$_2$ is described first, followed by discussion of the four types of complexes prepared, i.e. [PdCl(Fmes)(L-L)], [PdCl(Fmes)L_2], [PdCl(Fmes)(NCMe)L], and [Pd(Fmes)(μ-X)L]$_2$.

Synthesis and Characterization of [Pd(μ-Cl)(Fmes)(NCMe)]$_2$

Refluxing [PdCl(Fmes)(COD)][4] in MeCN the dimeric complex [Pd(μ-Cl)(Fmes)(NCMe)]$_2$ (**1a**) was formed, which could be isolated as a yellow solid [Equation (1)].



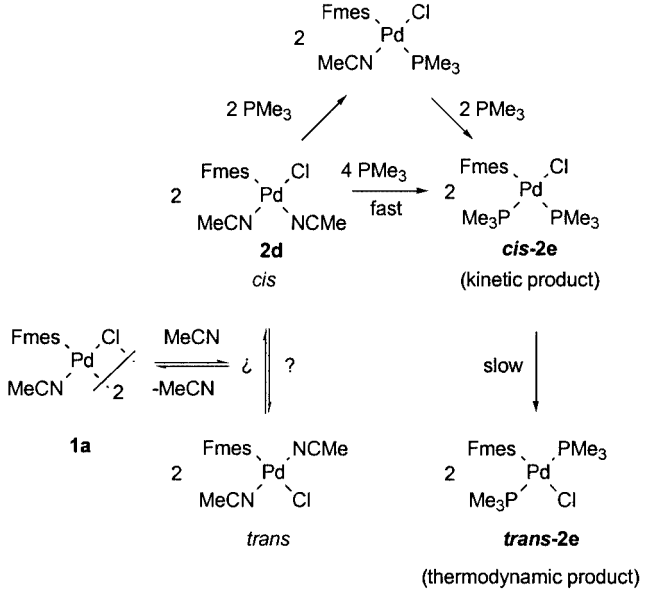
(1)

The ^{1}H and ^{19}F NMR spectra of **1a** show the presence of *cis* and *trans* isomers in solution (Scheme 1). The ^{19}F NMR spectrum in $CDCl_3$ at room temperature has two singlets (ca. 75:25 ratio) corresponding to the *para*-CF_3 groups of each isomer. The *ortho*-CF_3 groups' signals in $CDCl_3$ are coincident, and only one singlet is observed, but two sing-

lets are clearly distinguished in the spectrum recorded in [D_6]acetone. Addition of acetone to a solution of **1a** in $CDCl_3$ produces a progressive increase of the less intense resonance, indicating that it corresponds to the polar *cis* isomer, which is expected to be favored in more polar solvents.[6]

Scheme 1. The *trans* and *cis* isomers of complexes [Pd(μ-Cl)(Fmes)L]$_2$ (**1**)

When **1a** was dissolved in MeCN the initial yellow solution became nearly colorless and only one singlet for the *ortho*-CF_3 and one singlet for the *para*-CF_3 were detected by ^{19}F NMR spectroscopy. This indicates that MeCN has split the chloro bridges, giving rise to only one isomer (either *cis* or *trans*), or to a fast exchange between the two possible isomers (Scheme 2). The solid monomer could not be isolated due to its marked tendency to regenerate **1a**, releasing the MeCN ligand *trans* to the Fmes group,[7] which has a high *trans* influence.[8] The ^{19}F NMR spectrum of **1a** in $CDCl_3$ is hardly affected by the addition of MeCN (**1a**/MeCN, 1:2), and the monomer concentration is high only in the presence of a high excess of acetonitrile in solution.

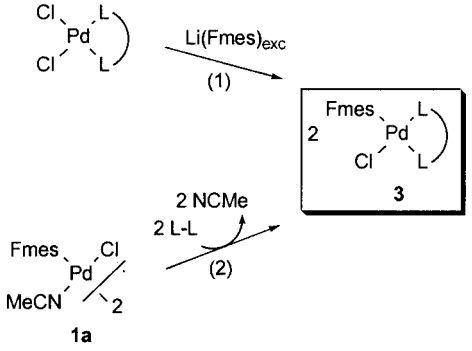


Scheme 2. Complexes detected in solutions of **1a** with MeCN and PMe_3

To understand the reaction behavior of the monomer, PMe_3 was added to a solution of **1a** in MeCN. Instantaneous formation of *cis*-[PdCl(Fmes)(PMe_3)$_2$] (*cis*-**2e**) was observed when two equivalents of PMe_3 per palladium were added, suggesting an associative substitution on *cis*-**2d** promoted by the high *trans* effect of the Fmes ligand.[9] The solution of *cis*-**2e** then isomerizes to the thermodynamic product *trans*-**2e**, according to the general antisymbiotic effect,[10] or to a high *transphobia* between the phosphane and the Fmes group.[11] The geometry of *cis*- or *trans*-**2e** is readily deduced by looking for P−F coupling between the coordinated phosphorus atom and the *ortho*-CF_3 groups. As reported for [PdCl(Fmes)(PPh_3)$_2$],[4] P−F coupling is observed when Fmes and a phosphane are coordinated *cis*, but not when these groups are coordinated *trans*.

Synthesis of [PdCl(Fmes)(L-L)]

Complexes [PdCl(Fmes)(L-L)] (**3**) were synthesized by two methods (Scheme 3): (1) arylation of the dichloro complex with Li(Fmes); or (2) bridge splitting and concomitant substitution of MeCN in **1a** by a bidentate ligand as chelate. The first method successfully furnished [PdCl(Fmes)(tmeda)] (**3a**), as we have reported for other monoarylated complexes containing bidentate chelating ligands.[4] Different neutral bidentate ligands L-L cleaved the chloro bridges and replaced MeCN from **1a** to give [PdCl(Fmes)(L-L)] (L-L= 4,4′-Me_2bipy, **3b**; biquinolyl, **3c**; OPPhPy$_2$-*N*,*N*′, **3d**; (OH)(CH_3)CPy$_2$-*N*,*N*′, **3e**; pte, **3f**; dppe, **3g**). All processes were carried out at room temperature, but to obtain [PdCl(Fmes)(dppe)] (**3g**), refluxing in toluene was needed, as milder conditions lead to a mixture of **3g** and [(μ-dppe){PdCl(Fmes)(NCMe)}$_2$] (**4d**).



Scheme 3. Synthesis of [PdCl(Fmes)(L-L)] complexes **3**; (1) tmeda, **3a**. (2) 4,4′-Me_2bipy, **3b**; biquinolyl (2,2′-biquinoline), **3c**; OPPhPy$_2$-*N*,*N*′, **3d**; (OH)(CH_3)CPy$_2$-*N*,*N*′, **3e**; pte [1,2-bis(phenylthio)ethane], **3f**; dppe, **3g**

The ^{19}F NMR spectrum of **3g** in $CDCl_3$ shows one doublet for the *ortho*-CF_3 due to coupling with the phosphorus atom *cis* to the Fmes ($J_{P,F}$ = 5.5 Hz). The $^{31}P\{^1H\}$ NMR spectrum displays two signals, a doublet of septuplets for the phosphorus atom *cis* to the Fmes group, and a doublet for the phosphorus atoms *trans* to Fmes ($J_{P,P}$ = 23.2 Hz). Coupling between the hydrogen atoms of the Fmes group and the phosphorus atom *trans* to the Fmes ($^4J_{P,H}$ = 1 Hz) is observed in the ^1H NMR spectrum.

The ^1H NMR spectra of complexes **3** show the nonequivalence of the two halves of the bidentate ligands, confirming their coordination as a chelate with two different ligands in the other positions of the square plane. The chemical shifts detected for the H^6 of the pyridyl groups in **3b**, **3c**, **3d** and **3e** are very sensitive to the ligand coordinated *cis*. Thus, those *cis* to the chloro ligand appear at lower field than for the free ligand,[12] whereas anisotropic shielding produces an upfield shift of the H^6 signals *cis* to the Fmes ring.

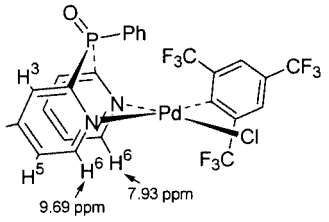
Two conformers may be proposed for **3d**, depending on whether the oxygen atom (*endo*-O) or the phenyl group (*endo*-Ph) of the $OPPhPy_2$ ligand takes the *endo* position in the boat-like metallacycle described by the chelating ligand. An *endo*-Ph conformation (Scheme 4) has been found for solid $[Pd(C_6F_5)Br(OPPhPy_2\text{-}N,N')]$,[13] which is consistent with the clear upfield chemical shift here of one of the *ortho*-CF_3 groups in the ^{19}F NMR spectrum.



Scheme 4. Proposed conformation for $[PdCl(Fmes)(OPPhPy_2\text{-}N,N')]$ (**3d**)

Two similar conformers, (*endo*-OH) or (*endo*-Me), are possible for **3e**. A single-crystal X-ray analysis of **3e** was therefore undertaken to establish this point and other structural features. A perspective view of the molecular structure of **3e** is given in Figure 1, and selected bond lengths and angles are listed in Table 1. The square-planar geometry of Pd is distorted towards tetrahedral to some extent, as the N(1) atom is 0.196(7) Å above the plane described by the C(21), Pd(1) and Cl(1) atoms, and N(2) is 0.307(7) Å below this plane. The C−C−C angle at the *ipso* carbon is significantly less than 120° [ca. 114.4(6)°], due to the electronic effects of the electropositive metal and electronegative CF_3 substituents at these positions.[14] The fluoromesityl ligand adopts the expected coordination, essentially perpendicular to the coordination plane. The Pd···F_3C-*ortho* distances in **3e** [the shortest, Pd(1)···F(291), is 2.914(11) Å] are longer than those found in bisarylated "$Pd(Fmes)_2$" complexes. Bonding M···F interactions can be discounted in a coordinatively saturated metallic center because such contacts should involve a high energy orbital of the palladium atom as an acceptor of electronic density. Therefore, the crowding in **3e** is deemed responsible for the short nonbonding Pd···F contacts, as in other cases previously analyzed.[4]

The conformer found has the methyl group of the $(OH)(CH_3)CPy_2$ ligand oriented toward the axial position of the coordination plane (Figure 1). The hydrogen atom of the alcohol group was located in a difference Fourier map and refined;[15] it is involved in O−H···Cl intermolecular contacts. The O(1F)−Cl(1A) and H(6F)−Cl(1A) distances are 3.251(9) and 2.306(9) Å respectively, whereas the O(1F)−H(6F)−Cl(1A) angle is 165.4(8)°. The H−Cl distance is within the usual range for H−Cl hydrogen bonds,[16] suggesting that the conformation of the chelating ligand in **3e** helps to stabilize this conformer in the solid state. In solution the intermolecular hydrogen contacts probably break down and the spectroscopic evidence available does not allow us to ascertain whether the conformation of the chelating ligand found in the solid state is retained in the solution.

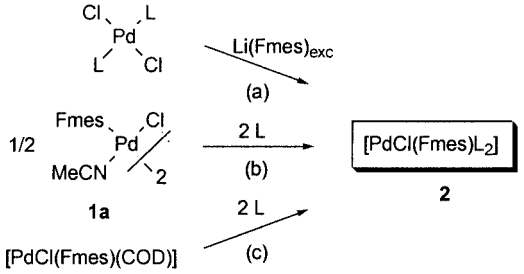
Synthesis of $[PdCl(Fmes)L_2]$

Scheme 5 shows three different ways to synthesize $[PdCl(Fmes)L_2]$ complexes: (1) by arylation of $[PdCl_2L_2]$ with Li(Fmes); (2) by bridge splitting and substitution of MeCN in **1a** by two equivalents of monodentate ligand; and (3) by substitution of the COD ligand in [PdCl(Fmes)-(COD)].[4]



Scheme 5. Synthesis of $[PdCl(Fmes)L_2]$ (**2**). (a) L = SMe_2, **2a**. (b) L = 4-pic, **2b**. (c) L = *t*BuNC, **2c**

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The complex *trans*-[PdCl(Fmes)(SMe_2)$_2$] (**2a**) was obtained by the same procedure previously described for *trans*-[PdCl(Fmes)(tht)$_2$] (tht = tetrahydrothiophene),[4] i.e. arylation of *trans*-[$PdCl_2(SMe_2)_2$] with Li(Fmes), which also gave [Pd(μ-Cl)(Fmes)(SMe_2)]$_2$ (**1h**) and *trans*-[Pd(Fmes)$_2$(SMe_2)$_2$] as by-products. The latter can be synthesized selectively by the method reported for *trans*-[Pd(Fmes)$_2$(tht)$_2$].[4]

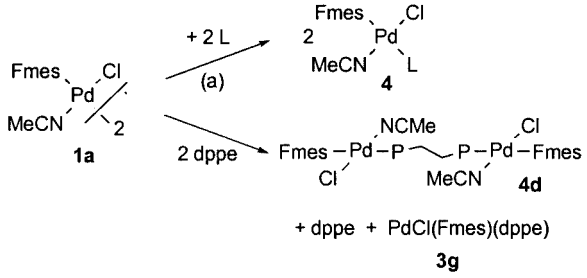
Treatment of **1a** with 4-pic leads to *cis*-[PdCl(Fmes)(4-pic)$_2$] (**2b**), as shown by the nonequivalence of both 4-pic ligands in the ^{1}H NMR spectrum. The solid must be isolated rapidly from its solution, otherwise a mixture with the *trans* isomer and [Pd(μ-Cl)(Fmes)(4-pic)]$_2$ (**1d**) is obtained.

The reaction of [PdCl(Fmes)(COD)] with two equivalents of *t*BuNC per palladium in refluxing acetone lead to *trans*-[PdCl(Fmes)(CN*t*Bu)$_2$] (**2c**), as evidenced by the equivalence of the two CN*t*Bu ligands in the ^{1}H NMR spectrum. Under milder conditions a mixture of the *cis* and *trans* isomers is obtained. All attempts to isolate the pure *cis* isomer were unsuccessful.

These results suggest that the *cis* isomers are the kinetic products formed initially by associative substitution of acetonitrile or COD, the reactions being controlled by the higher *trans* effect of Fmes. Whenever a *cis*-[PdCl(Fmes)L$_2$] is isolated (**2b**) or detected (*cis*-**2c**, or *cis*-**2e**) it readily isomerizes in solution to the thermodynamic product, i.e. the corresponding *trans* isomer, since Fmes is the ligand with the higher *trans* influence.[10] The *cis* to *trans* isomerization seems more favored for *cis*-**2c** than for **2b**. In fact, the isomerization of *cis*-**2c** occurs even in the solid state, because the CN*t*Bu (C-donor ligand) *trans* to Fmes is more destabilized than 4-pic (N-donor ligand). Details for these isomerizations are provided in the Exp. Sect.

Synthesis of [PdCl(Fmes)(NCMe)L]

Complexes [PdCl(Fmes)(NCMe)L] (**4**) were obtained from **1a** (Scheme 6).

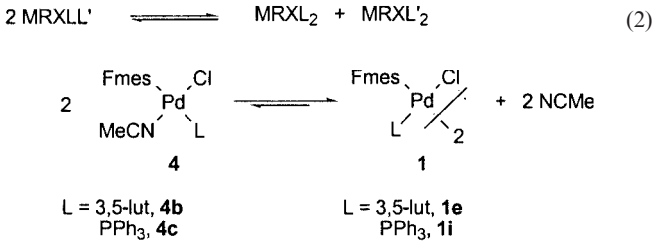


Scheme 6. Synthesis of [PdCl(Fmes)(NCMe)L] (**4**): a) L = 2,6-lut, **4a**; 3,5-lut, **4b**; PPh_3, **4c**

Treatment of **1a** with N- or P-donor ligands (1:1 ratio) in dichloromethane at room temperature leads to [PdCl(Fmes)(NCMe)L] (L = 2,6-lut, **4a**; 3,5-lut, **4b**; PPh_3, **4c**). The reaction with dppe (1:1 ratio) affords a mixture of [(μ-dppe){PdCl(Fmes)(NCMe)}$_2$] (**4d**), [PdCl(Fmes)(dppe)] (**3g**), and free dppe. The dimetallic complex **4d** is scarcely soluble in dichloromethane, which allows its separation from **3g**, which in turn can be isolated pure after free dppe is extracted with Et_2O. The formation of the kinetic product **4d** is a plausible result of the high *trans* effect of Fmes. Nevertheless, under thermodynamic conditions (in refluxing toluene), only **3g** is formed (Scheme 3).

The *trans* to Fmes coordination of the incoming ligand was confirmed by NMR spectroscopic data of the complexes containing phosphanes **4c** and **4d**, since the signals corresponding to the *ortho*-CF_3 and to the phosphorus atoms are singlets. The same geometry is expected for the complexes containing N-donor ligands, but NMR spectroscopic data do not give unequivocal support in this case. The solid IR spectra of all these complexes fit well a relative *cis* arrangement of the Fmes and chloro ligands, since the Pd−Cl stretching wavenumbers are consistently higher than those for unambiguously *trans*-[PdCl(Fmes)L$_2$] complexes.

Halogenoaryl complexes containing two different neutral ligands coordinated to the metal center, such as **4**, are not common and their disproportionation to two symmetric molecules seems to be favored [Equation (2)].[17] Although such disproportionation has not been observed for our complexes **4**, they are not indefinitely stable in solution and slowly lose MeCN to yield [Pd(Fmes)(μ-X)L]$_2$ (**1**) (Scheme 7). Details for the formation of complexes **4** in solution are provided in the Exp. Sect.



Scheme 7. Evolution of **4b** and **4c** in $CDCl_3$ solution

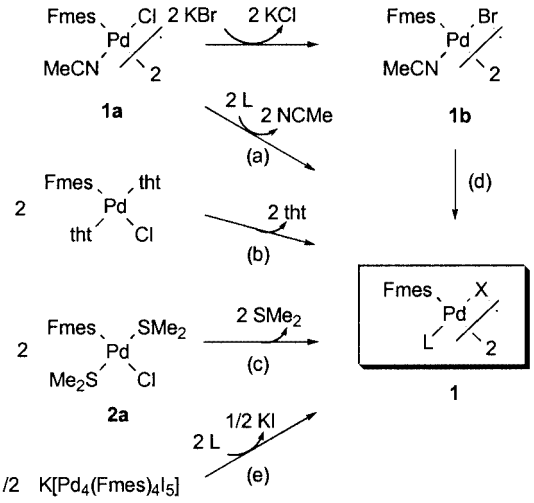
The destabilizing effect associated with the high "*trans-phobia*" between the phosphane and the Fmes group may help in the evolution of **4c** to **1i**.[11] Moreover, the process is entropically favored. The behavior of the complexes with N-donor ligands is remarkable: While **4a** is stable in solution, the $CDCl_3$ solutions of **4b** at room temperature are always in equilibrium with **1e**, revealing a lower tendency to give the dimer than for phosphanes. Solid **4b** is assumed to be pure, since the ^{19}F NMR spectrum of a sample dissolved at −60 °C in $CDCl_3$ showed no signals of **1e**. The different behavior of **4a** and **4b** in solution is explained upon considering that the *cis* disposition of the two bulky groups Fmes and 2,6-lut (both with *ortho* substituents) needed to form the corresponding dimer is highly destabilized.

Synthesis of [Pd(Fmes)(μ-X)L]$_2$

The syntheses of [Pd(Fmes)(μ-X)L]$_2$ (**1**) are depicted in Scheme 8. The main route to [Pd(Fmes)(μ-Cl)L]$_2$ [L = CO, **1c**; 4-pic, **1d**; 3,5-lut, **1e**; P(*o*-Tol)$_3$, **1f**] was the addition of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

neutral monodentate ligands L (Pd/L, 1:1) to solutions of **1a**. For **1c**, carbon monoxide was bubbled through the solution until a white solid precipitated. Boiling under reflux in toluene was needed to obtain **1d** and **1e**, otherwise the monometallic complexes *cis*-[PdCl(Fmes)(4-pic)$_2$] (**2b**) and [PdCl(Fmes)(NCMe)(3,5-lut)] (**4b**) were obtained as shown.



Scheme 8. Synthesis of [Pd(Fmes)(μ-X)L]$_2$ (**1**); (a) L = CO, **1c**; 4-pic, **1d**; 3,5-lut, **1e**, P(*o*-Tol)$_3$, **1f**. (b) L = tht, **1g**. (c) L = SMe$_2$, **1h**; PPh$_3$, **1i**. (d) L = P(*o*-Tol)$_3$, **1j**. (e) L = P(*o*-Tol)$_3$, **1k**

Conversely, boiling under reflux **2a** or [PdCl(Fmes)(tht)$_2$] in toluene affords [Pd(μ-Cl)(Fmes)(SMe$_2$)]$_2$ (**1h**) or [Pd(μ-Cl)(Fmes)(tht)]$_2$ (**1g**) respectively. With PPh$_3$, [Pd(μ-Cl)(Fmes)(PPh$_3$)]$_2$ (**1i**) was obtained. The latter was not selectively obtained using **1a** as starting material, as this process gives a mixture of **1i** and **4c**.

Bromo-bridged dimers can be obtained from **1a**. For instance, reaction of **1a** with KBr in MeCN yields [Pd(μ-Br)(Fmes)(NCMe)]$_2$ (**1b**), which reacts with P(*o*-Tol)$_3$ in toluene to give [Pd(μ-Br)(Fmes){P(*o*-Tol)$_3$}]$_2$ (**1j**). The similar iodo-bridged dimer [Pd(Fmes)(μ-I){P(*o*-Tol)$_3$}]$_2$ (**1k**) has been obtained by treating K[Pd$_4$(Fmes)$_4$I$_5$] with P(*o*-Tol)$_3$.[5a]

As described above for **1a**, two isomers are present in the solutions of these binuclear complexes (Scheme 1). The *trans* isomer is always the major one, but the exact *cis*:*trans* ratio in the solutions of complexes **1** seems to depend on the size of the monodentate ligand coordinated to the metal center: The bulkier the ligand, the higher the *trans*:*cis* ratio (for example, 95:5 for **1i**, L = PPh$_3$; 72:28 for **1c**, L = CO). Spectroscopic details are provided in the Exp. Sect.

All the spectroscopic and analytical data of complexes **1** confirm the geometry proposed, except for binuclear complexes with P(*o*-Tol)$_3$ (**1f**, **1j**, **1k**), where broad signals in their NMR spectra and the lack of P−F coupling prevented an unambiguous assignment. Therefore, an X-ray crystal structure analysis was carried out, revealing that the disposition of the phosphanes is *trans*. A perspective view of the molecular structure of **1j** is given in Figure 2 and selected distances and angles are listed in Table 2.

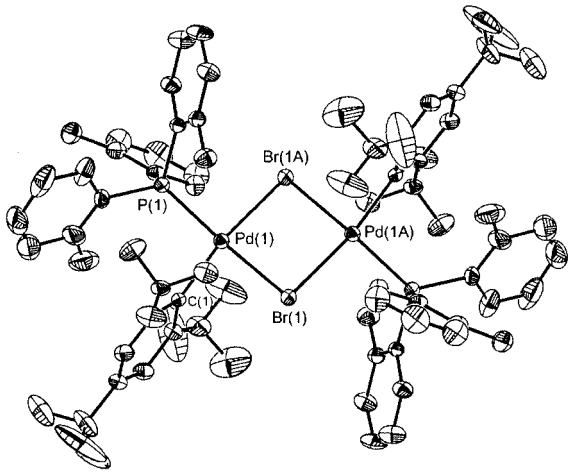


Figure 2. Molecular structure of **1j** showing the atom numbering scheme; the ellipsoids are drawn at 30% probability level

Table 2. Selected bond lengths [Å] and angles [°] for **1j**

Pd(1)−C(1)	2.036(8)	Pd(1)−P(1)	2.328(3)
C(1)−Pd(1)−P(1)	97.8(2)	P(1)−Pd(1)−Br(1)	176.48(7)
C(1)−Pd(1)−Br(1)	85.2(2)	C(1)−Pd(1)−Br(1A)	170.3(2)
Pd(1)−Br(1)	2.5119(13)	Pd(1)−Br(1A)	2.5438(13)
P(1)−Pd(1)−Br(1A)	90.51(7)	Pd(1)−Br(1)−Pd(1A)	93.35(5)
Br(1)−Pd(1)−Br(1A)	86.65(5)	C(2)−C(1)−C(6)	114.9(7)

The two palladium atoms are essentially square planar with minor distortions. Although the fluoromesityl ligand deviates by only 5.7° with respect to the perpendicular to the coordination plane, this keeps them away from the bulky phosphane, thus diminishing the steric hindrance. As usual, the C−C−C angle at the *ipso* carbon atom is less than 120° [ca. 115.0(7)°].[14] The Pd(1)−Br(1) distance at 2.5116(13) Å is smaller than Pd(1)−Br(1A) [2.5437(12) Å], and suggests a higher *trans* influence of the fluoromesityl group compared to the phosphane, as found for other aryl or alkyl phosphane complexes with bromo[18] or chloro bridges.[19]

The shortest Pd···F$_3$C-*ortho* distance found in **1j** [2.807(14) Å] is slightly longer than those found in bisarylated "Pd(Fmes)$_2$" complexes, but shorter than that in **3e**. Again this suggests that this distance is related to the degree of crowding in the fluoromesitylpalladium complexes, rather to bonding interactions.[4]

P(*o*-Tol)$_3$ has an *exo*$_2$ conformation in which an *o*-methyl group is oriented away from the metal. This reduces the rotation of the M−P−C$_{ipso}$ plane, thus also reducing the phosphane cone angle by ca. 35°.[20]

The P(1)−Pd(1)−C(1) angle is 97.8(2)°, instead of the ideal 90°, presumably due to steric constraints. The absence of a P−F coupling in the spectra of **1j** might be related to of this angle. In fact, $J_{P\text{-}F}$ is 4.6 Hz in **1i** (X = Cl, L = PPh$_3$). The involvement of increasingly bulky ligands in the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sequence **1i** < **1j** would consistently open the X−Pd−P angle and decrease the P−F coupling.[21]

The broad signals in the NMR spectra of **1f**, **1j** and **1k** may be due to three different dynamic processes:[18,22] (1) *cis*−*trans* exchange, similar to that of the other binuclear complexes synthesized here (Scheme 1); (2) slow rotation of the Pd−P bond; (3) the so-called "two-flip mechanism" consisting of a slow rotation of the P-C_{ipso} bond which exchanges the *exo*$_2$ and *exo*$_3$ conformers.[23] The ^{19}F NMR spectra of **1f**, **1j** and **1k** show broad signals corresponding to the *ortho*-CF_3 groups. When X = Cl (**1f**) the two *ortho*-CF_3 give rise to only one broad signal at room temperature, whereas two broad signals are displayed by the *ortho*-CF_3 when X is Br (**1j**) or I (**1k**), showing their nonequivalence at room temperature. At lower temperatures many species are observed, since the three possible dynamic processes are restricted, and different conformations of the possible isomers become discernible. The main species for each complex might be assigned to the stable conformer found in the solid state structure of **1j**, but the minor species cannot be assigned only from the spectroscopic data because of the many possible rotamers.

Conclusion

Various [PdXRL_2] complexes with the bulky Fmes group can be obtained, many via ligand substitution processes under mild conditions. This suggests that a single Fmes group does not give a high degree of axial protection, probably because the group can tilt, making associative ligand substitutions kinetically accessible. The results of the ligand-substitution reactions are consistent with a high *trans* effect of the Fmes group. Thus, the kinetic product (where the incoming ligand coordinates *trans* to the Fmes) is first formed. Subsequent isomerization or evolution to the expected thermodynamic product (if only electronic factors were considered) does not always take place. In fact the stability of both isomers depends on electronic (antisymbiotic effect), steric, and entropic factors. Complexes containing two bulky ligands with *ortho* substituents mutually *cis* seem much disfavored, while mutually *trans* substituents can be tolerated.

Experimental Section

General Remarks: All reactions were carried out under dry N_2. Solvents were purified according to standard procedures.[24] 1,3,5-$C_6H_3(CF_3)_3$ (FmesH) was purchased from Fluorochem and used as received. Li(Fmes) was prepared as described in the literature,[25] and used immediately in situ without further purification. The compounds *trans*-[$PdCl_2(tht)_2$], *trans*-[$PdCl_2(SMe_2)_2$],[26] [$PdCl_2$-(tmeda)],[27] $OPPhPy_2$,[28] and $(OH)(CH_3)CPy_2$,[29] were prepared according to literature procedures.

Infrared spectra were recorded with a Perkin−Elmer 883 apparatus as Nujol mulls between polyethylene films from 4000 to 200 cm^{-1}. NMR spectra were recorded with Bruker AC-300 or ARX-300 instruments and are referred to TMS, 85% H_3PO_4, or $CFCl_3$. Elemental analyses were performed with a Perkin−Elmer 2400B microanalyzer.

[Pd(μ-Cl)(Fmes)(NCMe)]$_2$ (1a): [PdCl(Fmes)(COD)][4] (1.090 g, 2 mmol) was boiled under reflux in acetonitrile and monitored by ^{19}F NMR until the starting material disappeared (24 h). The yellow solution thus obtained was filtered through dry Celite, the solvents were pumped off and a yellow solid obtained that was washed with *n*-hexane and vacuum dried to yield 0.850 g (89%) of product. IR: $\tilde{\nu}$ = 2335 m, 2309 w, 1618 s, 1574 m, 1308 vs, 1286 vs, 1265 vs, 1189 vs, 913 vs, 1088 s, 1021 s, 914 s, 955 m, 836 m, 584 vw (br), 574 w, 438 w, 373 vw, 334 vw (sh), 323 w, 302 vw, 277 w cm^{-1}. ^{1}H NMR: δ = 7.79 [s, $C_6H_2(CF_3)_3$, 2 H, *trans*], 7.69 [s, $C_6H_2(CF_3)_3$, 2 H, *cis*], 2.17 (s, NCCH_3, 3 H, *cis*), 2.13 (s, NCCH_3, 3 H, *trans*), (*trans*/*cis*, 77:23) ppm. ^{19}F NMR: δ = −58.65 (s, *ortho*-CF_3, 6 F, *cis* and *trans*), −63.15 (s, *para*-CF_3, 3 F, *trans*), −63.29 (s, *para*-CF_3, 3 F, *cis*), (*trans*/*cis*, 77:23) ppm. $C_{22}H_{10}Cl_2F_{18}N_2Pd_2$ (928.0): calcd. C 28.47, H 1.09, N 3.02; found C 28.26, H 1.15, N 2.81.

[Pd(μ-Br)(Fmes)(NCMe)]$_2$ (1b): KBr (0.173 g, 1.45 mmol) was added to a solution of **1a** (0.135 g, 0.145 mmol) in acetonitrile (30 mL) and stirred for 1 h at room temperature. Then the solvent was removed in vacuo and the resultant yellow residue extracted with dichloromethane (30 mL), filtered, washed with *n*-hexane (3 × 10 mL) and dried to yield 0.128 g (87%) of **1b**. IR: $\tilde{\nu}$ = 2335 m, 2309 w, 1836 vw, 1646 vw, 1619 s, 1575 m, 1300 vs, 1283 vs, 1231 m, 1191 vs, 1122 vs, 1084 s, 1025 s, 954 vw, 913 s, 854 m, 835 s, 683 s, 667 w, 581 vw, 564 vw, 472 w, 438 m, 305 w, 227 w, 218 w cm^{-1}. ^{1}H NMR: δ = 7.81 [s, $C_6H_2(CF_3)_3$, 2 H, *cis*], 7.73 [s, $C_6H_2(CF_3)_3$, 2 H, *trans*], 2.18 (s, NCCH_3, 3 H, *trans*), 2.14 (s, NCCH_3, 3 H, *cis*), (*cis*/*trans*, 72:28) ppm.In the presence of MeCN, **1b** undergoes a process similar to that depicted for **1a** in Scheme 2, giving rise to different NMR signals. ^{19}F NMR: δ = −58.30 (s, *ortho*-CF_3, 6 F, *cis*), −58.31 (s, *ortho*-CF_3, 6 F, *trans*), −62.12 (s, *para*-CF_3, 3 F, *cis*), −63.26 (s, *para*-CF_3, 3 F, *trans*), (*cis*/*trans*, 72:28) ppm. ^{19}F NMR (CH_3CN/[D_6]Me_2CO): δ = −57.18 (s, *ortho*-CF_3, 6 F), −62.14 (s, *para*-CF_3, 3 F) ppm. $C_{22}H_{10}Br_2F_{18}N_2Pd_2$ (1016.9): calcd. C 25.98, H 0.99, N 2.76; found C 26.19, H 1.06, N 2.89.

[Pd(μ-Cl)(Fmes)(CO)]$_2$ (1c): Carbon monoxide was bubbled through a solution of **1a** (0.696 g, 0.75 mmol) in toluene (30 mL) at room temperature for 10 h with stirring. The resultant white solid was decanted and washed with toluene (3 × 5 mL), yielding 0.498 g (74%) of **1c**. IR: $\tilde{\nu}$ = 2149 vs, 2102 w, 1622 s, 1583 m, 1301 vs, 1283 vs, 1269 vs, 1208 vs, 1190 vs, 1130 s, 1091 s, 1023 s, 919 s, 855 m, 839 m, 749 s, 695 m, 683 m, 672 w, 585 vw, 477 m, 436 w, 395 vw, 369 vw, 301 w, 282 m cm^{-1}. ^{1}H NMR: δ = 8.00 [s, $C_6H_2(CF_3)_3$, 2 H, *trans*], 7.90 [s, $C_6H_2(CF_3)_3$, 2 H, *cis*], (*trans*/*cis*, 72:28) ppm. ^{19}F NMR: δ = −59.31 (s, *ortho*-CF_3, 6 F, *trans*), −59.35 (s, *ortho*-CF_3, 6 F, *cis*), −63.39 (s, *para*-CF_3, 3 F, *trans*), −63.53 (s, *para*-CF_3, 3 F, *cis*), (*trans*/*cis*, 72:28) ppm. $C_{20}H_4Cl_2F_{18}O_2Pd_2$ (901.9): calcd. C 26.63, H 0.45; found C 26.57, H 0.69.

[Pd(μ-Cl)(Fmes)(4-pic)]$_2$ (1d): 4-Pic (10 μL, 0.096 mg, 0.1 mmol) was added to a yellow solution of **1a** (0.046 g, 0.05 mmol) in acetone (10 mL) and boiled under reflux for 3 h. The volatiles were then pumped off and the resultant yellow solid was dissolved in dichloromethane; *n*-hexane was then added and the mixture was concentrated and cooled to −20 °C. The yellow crystals thus obtained were decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried to yield 0.041 g (79%) of product. IR: $\tilde{\nu}$ = 2343 vw (br), 2019 vw (br), 1618 m, 1572 w, 1507 w, 1298 s, 1281 vs, 1191 vs, 1126 vs, 1085 m, 1070 m, 1027 m, 911 m, 854 w, 835 w, 572 w, 696

[Pd(μ-Cl)(Fmes)(SMe$_2$)]$_2$ (1h): Compound **2a** (0.110 g, 0.2 mmol) was dissolved in toluene (10 mL) and the resultant solution was boiled under reflux. After 8 h the solution became yellow. It was then filtered through dry Celite, and hexane was added to the filtrate, which was concentrated and cooled to −20 °C. The yellow crystals thus obtained were decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried to yield 0.079 g (81%) of product. IR: ṽ = 1621 m, 1568 w, 1621 m, 1569 w, 1297 s, 1277 vs, 1192 vs, 1180 s, 1135 vs, 1115 vs, 1087 s, 1027 m, 950 w, 914 m, 880 vw, 851 m, 830 m, 805 vw, 754 m, 692 m, 682 s, 520 s, 462 w, 437 w, 310 vw cm^{-1}. ^1H NMR: δ = 7.85 [s, $C_6H_2(CF_3)_3$, 2 H, *trans*], 7.75 [s, $C_6H_2(CF_3)_3$, 2 H, *cis*], 2.23 [s, $S(CH_3)_2$, 6 H, *trans*], 2.17 [s, $S(CH_3)_2$, 6 H, *cis*], (*trans*/*cis*, 86:14) ppm. ^{19}F NMR: δ = −58.99 (s, *ortho*-CF_3, 6 F, *trans*), −59.10 (s, *ortho*-CF_3, 6 F, *cis*), −63.19 (s, *para*-CF_3, 3 F, *trans*), −63.32 (s, *para*-CF_3, 3 F, *cis*), (*trans*/*cis*, 86:14) ppm. $C_{22}H_{16}Cl_2F_{18}Pd_2S_2$ (970.2): calcd. C 27.24, H 1.66; found C 27.43, H 1.78.

[Pd(μ-Cl)(Fmes)(PPh$_3$)]$_2$ (1i): PPh_3 (0.052 g, 0.2 mmol) was added to a yellow solution of **2a** (0.110 g, 0.2 mmol) in toluene (20 mL) and boiled under reflux for 24 h. The volatiles were then pumped off to afford a yellow solid that was dissolved in dichloromethane; *n*-hexane was then added and the mixture concentrated and cooled to −20 °C. The yellow crystals thus obtained were decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried to furnish 0.065 g (47%) of **1i**. IR: ṽ = 1619 s, 1588 w, 1574 m, 1297 vs, 1277 vs, 1186 vs, 1143 vs (br), 1097 s, 1082 s, 1024 s, 1000 m, 972 w, 912 s, 855 m, 833 m, 747 s, 693 vs, 667 w, 532 vs, 509 s, 499 s, 469 w, 450 w, 436 w, 283 w, 277 w cm^{-1}. $^{31}P\{^1H\}$ NMR: δ = 27.3 (m, *trans*) (*cis* isomer signal not observed) ppm. ^1H NMR: δ = 7.44 [s, $C_6H_2(CF_3)_3$, 4 H, *trans*], 8.2−6.2 (br., C_6H_5, 30 H) (*cis* isomer signals not observed) ppm. ^{19}F NMR: δ = −57.74 (d, $J_{P,F}$ = 4.6 Hz, *ortho*-CF_3, 12 F, *trans*), −57.93 (d, $J_{P,F}$ = 5.0 Hz, *ortho*-CF_3, 12 F, *cis*), −63.33 (s, *para*-CF_3, 6 F, *trans*), −63.40 (s, *para*-CF_3, 6 F, *cis*), (*trans*/*cis*, 95:5) ppm. $C_{54}H_{34}Cl_2F_{18}P_2Pd_2$ (1370.5): calcd. C 47.33, H 2.50; found C 47.48, H 2.70.

[Pd(μ-Br)(Fmes){P(*o*-Tol)$_3$}]$_2$ (1j): P(*o*-Tol)$_3$ (0.018 g, 0.06 mmol) was added to a solution of **1b** (0.031 g, 0.03 mmol) in toluene (10 mL) and the solution was stirred at room temperature for 8 h. The volatiles were then pumped off to give a deep-yellow oil that was crystallized from dichloromethane/hexane under an inert atmosphere. The yellow crystals thus obtained were decanted, washed with cold hexane (2 × 5 mL) and vacuum dried to yield 0.020 g (43%) of **1j**. IR: ṽ = 1617 m, 1591 w, 1568 w, 1280 vs, 1261 s, 1161 vs, 1152 vs, 1084 s (br), 1019 s, 910 m, 855 w, 805 s, 754 s, 694 w, 683 m, 564 w, 536 w, 516 vw, 482 m, 469 m cm^{-1}. ^1H NMR: δ = 7.50 [br., $C_6H_2(CF_3)_3$, *cis* and *trans*], 7.5−6.5 [br., C_6H_4, P(*o*-Tol)$_3$], 3.5−1.5 [br., CH_3, P(*o*-Tol)$_3$] ppm. ^{19}F NMR: δ = −53.93 (br., *ortho*-CF_3), −57.44 (br., *ortho*-CF_3), −63.20 (s, *para*-CF_3, *trans*), −62.56 (s, *para*-CF_3, 6 F, *cis*) (*cis*/*trans*, 90:10) ppm. $^{31}P\{^1H\}$: δ = 21.8 (s) ppm. $C_{60}H_{46}Br_2F_{18}P_2Pd_2$ (1543.5): calcd. ***trans*-[PdCl(Fmes)(SMe$_2$)$_2$] (2a):** *trans*-[$PdCl_2(SMe_2)_2$] (0.603 g, 2 mmol) was added to a freshly prepared solution of Li(Fmes) (4.26 mmol) in Et_2O (40 mL). The reaction mixture was then maintained at 40 °C for 24 h, after which two drops of water were added to hydrolyze the excess of organolithium reagent. The volatiles were then pumped off, and the residue extracted with toluene and then filtered through silica gel. This solution afforded, after evaporation and crystallization, a mixture of **1h** and [$Pd(Fmes)_2(SMe_2)_2$].[30] The rest of the residue was extracted with dichloromethane and filtered through silica gel. The solvent was then evaporated and the resultant yellow residue was recrystallized from dichloromethane/hexane at −20 °C giving pale yellow crystals of **2a** that were decanted, washed with hexane and vacuum-dried. Yield 0.529 g (48%). IR: ṽ = 1621 s, 1572 m, 1287 vs (sh), 1262 vs, 1188 vs (sh), 1132 vs, 1085 s, 1035 s, 1026 s, 995 m, 980 s, 915 s, 853 m, 835 m, 754 m, 695 m, 684 m, 668 w, 468 w, 439 w, 377 vw, 358 vw, 306 vw, 285 w cm^{-1}. ^{1}H NMR: δ = 7.90 [s, $C_6H_2(CF_3)_3$, 2 H], 2.24 [s, S(CH_3)$_2$, 12 H] ppm. ^{19}F NMR: δ = −60.81 (s, *ortho*-CF_3, 6 F), −63.18 (s, *para*-CF_3, 3 F) ppm. $C_{13}H_{14}ClF_9PdS_2$ (547.2): calcd. C 28.53, H 2.58; found C 28.69, H 2.49.

***cis*-[PdCl(Fmes)(4-pic)$_2$] (2b):** 4-Pic (43 μL, 0.041 g, 0.44 mmol) was added to a yellow solution of **1a** (0.093 g, 0.1 mmol) in dichloromethane (10 mL) and stirred at room temperature for 15 min. Then *n*-hexane was added to the resultant colorless solution, and this was then concentrated and cooled to −20 °C. The white solid thus obtained was decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried, yielding 0.045 g (37%) of **2b**. IR: ṽ = 1617 s, 1569 w, 1504 m, 1298 vs, 1278 vs (br), 1214 m, 1195 vs (sh), 1126 vs (sh), 1083 s, 1071 s, 1040 m, 1028 m, 938 w, 914 m, 871 vw, 852 w, 834 m, 815 w, 753 w, 695 w, 683 s, 667 vw, 550 vw, 498 m, 470 vw, 436 vw, 329 w cm^{-1}. ^{1}H NMR: δ = 8.42 [d, *J* = 6.0 Hz, $NC_5H_4(CH_3)$, 2 H], 8.13 [d, *J* = 6.0 Hz, $NC_5H_4(CH_3)$, 2 H], 7.76 [s, $C_6H_2(CF_3)_3$, 2 H], 7.14 [d, *J* = 5.6 Hz, $NC_5H_4(CH_3)$, 2 H], 7.02 [d, *J* = 5.6 Hz, $NC_5H_4(CH_3)$, 2 H], 2.36 [s, $NC_5H_4(CH_3)$, 3 H], 2.31 [s, $NC_5H_4(CH_3)$, 3 H] ppm. ^{19}F NMR: δ = −58.89 (s, *ortho*-CF_3, 6 F), −63.13 (s, *para*-CF_3, 3 F) ppm. $C_{21}H_{16}ClF_9N_2Pd$ (609.2): calcd. C 41.40, H 2.65, N 4.60; found C 41.23, H 2.59, N 4.43. A solution of pure *cis*-**2b** maintained at 50 °C in $CDCl_3$ solution showed, with time, the following *cis*-**2b**/**1d**/*trans*-**2b** ratios by ^{19}F NMR: after 24 h, 20:12:68; after 48 h: 9:10:81; after 5 days: 5:9:86.

***trans*-[PdCl(Fmes)(CN*t*Bu)$_2$] (2c):** *t*BuNC (23 μL, 0.017 g, 0.2 mmol) was added to a solution of [PdCl(Fmes)(COD)][4] (0.053 g, 0.1 mmol) in acetone (10 mL), and the mixture was boiled under reflux for 3 h. The solution was then filtered through dry Celite and concentrated; *n*-hexane was subsequently added and the solution cooled to −20 °C. The colorless crystals thus obtained were decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried to yield 0.035 g (59%) of **2c**. IR: ṽ = 2221 s, 1618 m, 1571 m, 1400 w, 1299 vs, 1279 vs, 1236 m, 1196 s, 1033 s (sh), 1085 m, 1043 mw, 1024 m, 934 vw, 922 m, 852 m, 835 m, 753 m, 693 m, 683 vs, 672 w, 580 vw, 534 m, 468 m, 451 w, 438 m, 291 vw cm^{-1}. ^{1}H NMR: δ = 7.91 [s, $C_6H_2(CF_3)_3$, 2 H], 1.33 (s, CNC_4H_9, 18 H) ppm. ^{19}F NMR: δ = −61.31 (s, *ortho*-CF_3, 6 F), −63.06 (s, *para*-CF_3, 3 F) ppm. $C_{19}H_{20}ClF_9N_2Pd$: calcd. C 38.73, H 3.42, N 4.75; found C 38.75, H 3.27, N 4.74. For the same reaction in CH_2Cl_2 at −50 °C, the ^{19}F NMR spectrum of a $CDCl_3$ solution of the crude product obtained after removing immediately the volatiles in vacuo, maintaining the low temperature, showed a mixture of *cis*-**2c** (72%) and *trans*-**2c** (28%). The ^{19}F NMR spectrum of the same sample after 15 h at room temperature showed 31% of *cis*-**2c** and 69% *trans*-**2c**. This crude product was stored as a solid at room temperature and, after several weeks, the ^{19}F NMR of a $CDCl_3$ solution showed only signals due to *trans*-**2c**.

***cis*-[Pd(Fmes)Cl(NCMe)$_2$] (2d):** This complex cannot be isolated pure because it loses MeCN. It was characterized by ^{19}F NMR in CH_3CN solution: ^{19}F NMR (CH_3CN/[D_6]Me_2CO): δ = −57.63 (s, *ortho*-CF_3, 6 F), −62.17 (s, *para*-CF_3, 3 F) ppm.

***cis*-[PdCl(Fmes)(PMe$_3$)$_2$] (*cis*-2e):** This complex was detected upon addition of PMe_3 to a solution of **1a** in acetonitrile (PMe_3/**1a**, 2:1) by ^{19}F NMR (CH_3CN/[D_6]Me_2CO): δ = −58.44 (d, $J_{P,F}$ = 6.0 Hz, *ortho*-CF_3, 6 F), −62.13 (s, *para*-CF_3, 3 F) ppm. ^{31}P{^{1}H} NMR (CH_3CN/[D_6]Me_2CO): δ = −6.7 (d sept, $J_{P,P}$ = 36.0, $J_{P,F}$ = 6.0 Hz), −15.9 (d, $J_{P,P}$ = 36.0 Hz) ppm.

***trans*-[PdCl(Fmes)(PMe$_3$)$_2$] (*trans*-2e):** This was detected in similar fashion to *cis*-**2e**.^{19}F NMR (CH_3CN/[D_6]Me_2CO): δ = −61.41 (t, $J_{P,F}$ = 6.0 Hz, *ortho*-CF_3, 6 F), −62.19 (s, *para*-CF_3, 3 F) ppm. ^{31}P{^{1}H} NMR (CH_3CN/[D_6]Me_2CO): δ = −11.2 (sept, $J_{P,F}$ = 6.0 Hz). [PdCl(Fmes)(dppe)] (3g): The ligand dppe (0.040 g, 0.1 mmol) was added to a solution of **1a** (0.047 g, 0.05 mmol) in toluene (10 mL). The solution was then boiled under reflux for 2 h, after which the volatiles were pumped off and the resultant white residue was dissolved in dichloromethane filtered through dry Celite. Hexane (10 mL) was then added to the filtrate, which was concentrated and cooled to −20 °C. The thus obtained colorless crystals were decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried to yield 0.052 g (63%) of **3g**. IR: $\tilde{\nu}$ = 1618 m, 1569 vw, 1438 m, 1298 s, 1279 vs, 1261 s, 1186 vs, 1130 vs (sh), 1106 s, 1079 m, 1021 w, 1000 vw, 925 vw, 890 w, 852 vw, 826 w, 745 s, 706 s, 692 s, 666 w, 530 m, 498 m, 481 w, 439 vw, 329 vw, 298 vw cm^{-1}. ^{1}H NMR: δ = 8.00 (m, C_6H_5, *para*-H, 4 H), 7.60 [d, $J_{P_{trans}H_{Fmes}}$ = 1.0 Hz, $C_6H_2(CF_3)_3$, 2 H], 7.51 (m, C_6H_5, 6 H), 7.37 (m, C_6H_5, 2 H), 7.18 (m, C_6H_5, 8 H), 2.58 (m, CH_2, 2 H), 2.15 (m, CH_2, 2 H) ppm. ^{19}F NMR: δ = −58.29 (d, $J_{P,F}$ = 5.5 Hz, *ortho*-CF_3, 6 F), −63.12 (s, *para*-CF_3, 3 F) ppm. ^{31}P{^{1}H} NMR: δ = 52.9 (d sept., $J_{P,P}$ = 23.2, $J_{P,F}$ = 5.5 Hz, P_{cis} of dppe), 39.67 (d, $J_{P,P}$ = 23.2 Hz, P_{trans} of dppe) ppm. $C_{35}H_{26}ClF_9P_2Pd$ (821.4): calcd. C 51.18, H 3.19; found C 51.03, H 3.29.

[PdCl(Fmes)(2,6-lut)(NCMe)] (4a): 2,6-Lut (25 μL, 0.023 g, 0.22 mmol) was added to a yellow solution of **1a** (0.093 g, 0.1 mmol) in dichloromethane (10 mL) and stirred for 5 h at room temperature to give a colorless solution, to which *n*-hexane was added. This solution was then concentrated and cooled to −20 °C to give a white solid that was washed with *n*-hexane (3 × 5 mL) and vacuum dried to yield 0.094 g (82%) of **4a**. IR: $\tilde{\nu}$ = 2343 m, 2303 w, 1616 m, 1583 m, 1571 m, 1300 vs, 1288 vs, 1264 vs, 1180 vs (br), 1119 vs (br), 1095 m, 1029 m, 915 s, 854 m, 837 m, 781 s, 757 m, 695 m, 684 s, 668 vw, 577 vw, 470 vw, 438 w, 374 w, 340 w cm^{-1}. ^{1}H NMR: δ = 7.84 [s, $C_6H_2(CF_3)_3$, 2 H], 7.56 [t, $J_H{}^3{}_H{}^4$ = 7.7 Hz, $NC_5H_3(CH_3)_2$, H^4, 1 H], 7.11 [d, $J_H{}^3{}_H{}^4$ = 7.7 Hz, $NC_5H_3(CH_3)_2$, H^3, 2 H], 3.29 [s, $NC_5H_3(CH_3)_2$, 6 H], 2.08 (s, CH_3CN, 3 H) ppm. ^{19}F NMR: δ = −58.22 (s, *ortho*-CF_3, 6 F), −63.06 (s, *para*-CF_3, 3 F) ppm. $C_{18}H_{14}ClF_9N_2Pd$ (571.2): calcd. C 37.85, H 2.47, N 4.90; found C 37.97, H 2.54, N 4.70.

[PdCl(Fmes)(3,5-lut)(NCMe)] (4b): 3,5-Lut (25 μL, 0.023 g, 0.22 mmol) was added to a yellow solution of **1a** (0.093 g, 0.1 mmol) in dichloromethane (10 mL) and stirred for 15 min at room temperature to give a colorless solution. Then *n*-hexane was added and the solution was concentrated and cooled to −20 °C. The colorless crystals thus obtained were decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried to yield 0.060 g (53%) of **4b**. IR: $\tilde{\nu}$ = 2329 w, 2303 w, 1618 m, 1599 w, 1572 w, 1304 vs, 1292 vs, 1263 s, 1184 vs, 1157 s, 1143 s, 1117 vs, 1084 m, 1032 w, 913 m, 865 w, 856 vw, 835 w, 774 w, 755 w, 700 m, 684 m, 667 vw, 471 vw, 439 vw, 344 vw cm^{-1}. ^{1}H NMR: δ = 8.35 [s, $NC_5H_3(CH_3)_2$, H^2, 2 H], 7.80 [s, $C_6H_2(CF_3)_3$, 2 H], 7.42 [s, $NC_5H_3(CH_3)_2$, H^4, 1 H], 2.35 [s, $NC_5H_3(CH_3)_2$, 6 H], 2.14 (s, CH_3CN, 3 H) ppm. ^{19}F NMR: δ = −58.48 (s, *ortho*-CF_3, 6 F), −63.04 (s, *para*-CF_3, 3 F) ppm.

$C_{18}H_{14}ClF_9N_2Pd$ (571.2): calcd. C 37.85, H 2.47, N 4.91; found C 37.62, H 2.31, N 4.72. A $CDCl_3$ solution of **4b** maintained at −20 °C for 5 days showed a **4b/1e** ratio of 81:19 by ^{19}F NMR spectroscopy. In a separate experiment, a $CDCl_3$ solution of **4b** maintained at room temperature during 24 h showed a **4b/1e** ratio of 60:40 by ^{19}F NMR spectroscopy.

[PdCl(Fmes)(NCMe)(PPh$_3$)] (4c): PPh_3 (0.058 g, 0.22 mmol) was added to a yellow solution of **1a** (0.093 g, 0.1 mmol) in dichloromethane (10 mL) and stirred at room temperature for 8 h to give a colorless solution, to which *n*-hexane was added. The resultant solution was then concentrated and cooled to −20 °C. The colorless crystals thus obtained were decanted, washed with *n*-hexane (3 × 5 mL) and vacuum dried to yield 0.060 g (52%) of **4c**·CH_2Cl_2. IR: $\tilde{\nu}$ = 2329 m, 2322 w, 1616 s, 1570 m, 1300 vs, 1286 vs, 1261 vs, 1186 vs (br), 1121 vs (br), 1099 s, 1082 s, 1024 s, 1000 m, 913 s, 852 m, 834 m, 695 vs, 684 s, 668 w, 529 s, 512 s, 494 m, 456 w, 436 w, 330 w cm^{-1}. ^1H NMR: δ = 7.85 [d, $J_{P,H}$ = 2.4 Hz, $C_6H_2(CF_3)_3$, 2 H], 7.76 (m, *ortho*-H, C_6H_5, 6 H), 7.46 (m, *meta*-H and *para*-H, C_6H_5, 9 H), 1.59 (d, $J_{P,H}$ = 1.3 Hz, CH_3CN, 3 H) ppm. ^{19}F NMR: δ = −58.40 (s, *ortho*-CF_3, 6 F), −62.98 (s, *para*-CF_3, 3 F) ppm. $^{31}P\{^1H\}$ NMR: δ = 17.6 (s) ppm. $C_{30}H_{22}Cl_3F_9NPd$ (780.3): calcd. C 44.42, H 2.73, N 1.72; found C 44.25, H 2.77, N 1.76. A $CDCl_3$ solution of **4c** maintained at room temperature for 2 days showed a **4c/1i** ratio of 58:42 by ^{19}F NMR spectroscopy.

[(μ-dppe){PdCl(Fmes)(NCMe)}$_2$] (4d): The ligand dppe (0.080 g, 0.2 mmol) was added to a yellow solution of **1a** (0.093 g, 0.1 mmol) in dichloromethane (10 mL) and stirred at room temperature for 12 h. The white solid so-formed was decanted, washed with diethyl ether (3 × 5 mL) and vacuum dried to yield 0.079 g (59%) of **4d**. IR: $\tilde{\nu}$ = 2331 w, 2304 vw, 1616 s, 1569 m, 1339 m, 1299 vs, 1278 vs, 1186 vs, 1126 vs, 1082 s, 1023 m, 1001 m, 977 vw, 913 s, 852 m, 835 m, 772 vw, 746 s, 705 s, 692 s, 682 s, 535 w, 520 s, 492 m, 450 m, 437 w, 350 w, 302 w cm^{-1}. ^1H NMR ([D$_6$]Me$_2$CO): δ = 8.2−7.7 (m, C_6H_5, 20 H), 7.94 [d, $J_{P,H}$ = 1.0 Hz, $C_6H_2(CF_3)_3$, 4 H], 3.26 (m, CH_2, 4 H), 1.93 (s, CH_3CN, 6 H) ppm. ^{19}F NMR ([D$_6$]Me$_2$CO): δ = −56.99 (s, *ortho*-CF_3, 6 F), −61.91 (s, *para*-CF_3, 3 F) ppm. $^{31}P\{^1H\}$ NMR ([D$_6$]Me$_2$CO): δ = 18.1 (s) ppm. $C_{48}H_{34}Cl_2F_{18}N_2P_2Pd_2$ (1326.4): calcd. C 43.46, H 2.58, N 2.11; found C 43.73, H 2.66, N 1.97. The filtrate was dried and the white solid thus obtained was washed with diethyl ether (3 × 5 mL) and vacuum dried to furnish 0.047 g of **3g** (29%).

X-ray Crystallographic Study: Suitable crystals of **1j** and **3e** were grown by slow diffusion of a concentrated dichloromethane (for **1j**) or acetone (for **3e**) solution of the complex into *n*-hexane at −20 °C. X-ray measurements were made using a Bruker SMART CCD area-detector diffractometer with Mo-K_α radiation (λ = 0.71073 Å).[31] Intensities were integrated from several series of exposures,[32] each exposure covering 0.3° in ω, the total data set being a hemisphere. Absorption corrections were applied, based on multiple and symmetry-equivalent measurements.[33] The structure was solved by direct methods and refined by least-squares on weighted F^2 values for all reflections (Table 3).[34] All non-hydrogen atoms were assigned anisotropic displacement parameters and refined without positional constraints. Hydrogen atoms were constrained to ideal geometries and refined with fixed isotropic displacement parameters except for the hydrogen of the alcohol group in **3e**, which was located in a difference Fourier map and refined. Refinement proceeded smoothly to give the residuals shown in Table 3. Complex neutral-atom scattering factors were used.[35]

CCDC-192421 (**1j**) and -192420 (**3e**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union

[7] For R = C_6F_5, the monomer *cis*-[PdBr(C_6F_5)($NCMe)_2$] is isolated as a solid and the dimer has not been obtained: A. C. Albéniz, P. Espinet, C. Foces-Foces, R. H. Cano, *Organometallics* **1990**, *9*, 1079. This suggests that the *trans* effect of Fmes is higher than that of C_6F_5, which implies that Fmes is a stronger σ-donor than C_6F_5.

[8] K. F. Purcell, J. C. Kotz, *Inorganic Chemistry*, 1st ed., W. B. Saunders C. **1977**, Cap. 13, page 694.

[9] Fmes is a soft σ-donor ligand with a high *trans* influence, which facilitates the release of the leaving ligand in an associative ligand substitution, i.e. the high *trans* influence of Fmes induces a high *trans* effect by destabilizing the fundamental state. Probably, some π-acceptor contribution in the five-coordinate transition state will further increase the *trans* effect of Fmes.

Synthesis, Structure and Chemical Transformations of Ethynylgermatranes

Edmunds Lukevics,[a] Pavel Arsenyan,*[a] Sergey Belyakov,[a] and Olga Pudova[a]

Keywords: Cobalt / Germanium / Germatrane / X-ray diffraction / Alkynes

Ethynylgermatranes have been prepared from monosubstituted acetylenes by a three-step synthesis without isolation of the hydrolytically unstable intermediate chlorogermanes and ethoxygermanes. Boiling an equimolar mixture of tetrachlorogermane Cl_4Ge, acetylene RC≡CH and triethylamine in hexane leads to germylation of the C_{sp}–H bond and the formation of ethynyl-substituted trichlorogermanes. Subsequent alkoxylation of chlorogermanes by ethanol in the presence of triethylamine affords triethoxygermanes that then take part in transalkoxylation with triethanolamine to give ethynylgermatranes. The molecular structures of all ethynylgermatranes and the hexacarbonyldicobalt complex of 1-heptynylgermatrane have been determined by X-ray crystallography.

Introduction

Derivatives of pentacoordinate germanium are the subject of considerable current research activity, particularly germatranes that contain an intramolecular N→Ge bond.[1−4] Investigations have focused on the relationship between the transannular N→Ge bond length and such factors as the character of the substituent at the germanium atom, the atrane skeleton structure, as well as crystal packing (crystal density, *Z* of unit cell, etc). However, the scope of their synthesis is limited. The few reported examples of ethynylgermatranes (unsubstituted ethynylgermatrane, 1-octynylgermatrane, and phenylethynylgermatranes)[5−8] were obtained by the "stannyl" method, by treating ethynyltrichlorogermanes $RC{\equiv}CGeCl_3$ with the tris(trialkylstannyl) ether of triethanolamine or by addition of triethanolamine to $RC{\equiv}CGeCl_3$ in the presence of triethylamine; phenylethynylgermatrane has also been prepared by the reaction of bromogermatrane with lithium phenylacetylenide.[5] The C≡C triple bond in ethynylgermatranes should allow various chemical transformations; however, only the bromination of phenylethynylgermatrane by NBS and bromine has been studied.[5] To the best of our knowledge, only the molecular structures of 1-phenylethynylgermatrane, and its chloroform solvate, and 4-fluorophenylethynylgermatrane have been determined by X-ray crystallography.[5,6,8] In this paper we focus on the synthesis of ethynylgermatranes via germylation of monosubstituted acetylenes by tetrachlorogermane in the presence of an organic base. Various chemical transformations of the acetylene fragment have been carried out, including complexation with octacarbonyldicobalt, [2+3] dipolar cycloaddition, and electrophilic substitution. The molecular structures of all synthesized ethynylgermatranes as well as of the hexacarbonyldicobalt complex of 1-heptynylgermatrane are also reported.

Results and Discussion

The ethynylgermatranes **4a**−**d** were prepared from monosubstituted acetylenes **1a**−**d** by a three-step synthesis without isolation of the hydrolytically unstable intermediate chlorogermanes **2a**−**d** and ethoxygermanes **3a**−**d**. Boiling an equimolar mixture of tetrachlorogermane $GeCl_4$, acetylene RC≡CH and triethylamine in hexane[9,10] leads to germylation of the C_{sp}−H bond and formation of ethynyl-substituted trichlorogermanes **2a**−**d**. Subsequent alkoxylation of chlorogermanes by ethanol in the presence of triethylamine affords triethoxygermanes **3a**−**d** which are then involved in transalkoxylation with triethanolamine to give ethynylgermatranes **4a**−**d** (Scheme 1). The yield of germatranes **4a**−**d** depends on the structure of the substituent R. The highest yield was observed for (trimethylsilyl)ethynylgermatrane (**4d**) (85%); with 1-heptynylgermatrane (**4a**) and (1-cyclohex-1-enyl)ethynylgermatrane (**4b**) the yields were 48 and 55%, respectively. The lowest yield was for 3-methoxypropyn-1-ylgermatrane (**4c**) (12%). Our attempts to prepare germatrane from methyl propiolate failed, since tetrachlorogermane acts as a Lewis acid in the reaction with HC≡CCOOMe to form 1,3,5-tris(methoxycarbonyl)benzene by [2+2+2] cycloaddition (Scheme 2).

As with other acetylene derivatives,[11−14] 1-heptynylgermatrane (**4a**) easily reacts with octacarbonyldicobalt in hexane (20 min at −5 °C). The hexacarbonyldicobalt complex of 1-heptynylgermatrane **5**, isolated in almost quantitative yield (93%) (Scheme 1), is stable in the solid state but com-

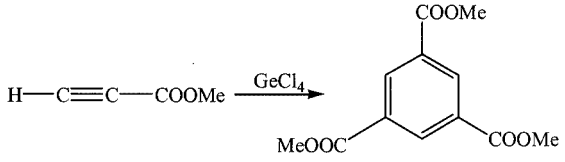

Scheme 2. [2+2+2] Cyclization of methyl propiolate in the presence of tetrachlorogermane

pletely decomposes in organic solvents (even in nonpolar ones such as hexane or benzene) after 2−3 h.

[2+3] Dipolar cycloaddition of acetonitrile oxide to the C≡C triple bonds of heptynylgermatrane (**4a**) and (trimethylsilyl)ethynylgermatrane (**4d**) has been investigated. Acetonitrile oxide, prepared in situ by the Mukaiyama−Hoshito method,[15] reacts with **4d** regioselectively to give only one of the two possible regioisomeric products, i.e. 5-germatranylisoxazole (**6**) in 75% yield. Conversely, for **4a** only a trace amount of the isoxazole derivative was detected by GC-mass spectrometry (Scheme 1).

The reaction of **4d** with NCS and NBS in DMF proceeds with cleavage of the Ge−C bond and formation of chloro- and bromogermatranes **7** (X = Cl, Br).[16] Our attempts to desilylate **4d** by different desilylation agents (Bu_4NF/Et_2O, K_2CO_3/MeOH, Amberlyst 15/THF, TsOH/MeOH) failed to cleave the Si−C bond, and so the initial germatrane **4d** was recovered.

The structures of the germatranes were confirmed by ^1H and ^{13}C NMR spectroscopy (Table 1). The ^1H spectra of

all germatrane derivatives (**4**–**6**) are characterized by two triplets of CH_2N (δ = 2.84–2.90 ppm) and CH_2O (δ = 3.81–3.85 ppm) groups. The signals of carbon atoms in the atrane fragment are in the δ = 51.3–52.6 and 56.4–57.6 ppm regions of the ^{13}C NMR spectra, and the signals of carbonyl-ligand carbon atoms in **5** are shifted to low field (δ = 201.0 and 206.7 ppm). As reported previously,[17] complexation of the C≡C triple bond does not strongly affect the carbon atoms' chemical shifts.

Molecular Structures of the Germatranes

Molecular structure data have been reported for more than 60 germatranes and their structural analogues.[2,18] However, only three of these structures contain an ethynylgermatrane fragment (phenylethynylgermatrane, and its $CHCl_3$ solvate, and 4-fluorophenylethynyl analogue[5,6,8]). These compounds are characterized by transannular N→Ge distances of 2.178, 2.160, and 2.175 Å, respectively, which are short in comparison with those in other alkyl-, alkenyl-, and arylgermatranes (2.20–2.24 Å). To further investigate the influence of various acetylene substituents RC≡C on the transannular N→Ge bond length the molecular structures of ethynylgermatranes **4a**–**d** and of the hexacarbonyldicobalt complex **5** have been determined by X-ray crystallography.

The germanium atom of germatranes **4a**–**d** and **5** has the typical atrane trigonal-bipyramidal geometry with nitrogen and carbon atoms in apical positions and three equatorial oxygen atoms. The axial nitrogen atom is pyramidalized so that its lone pair points towards the germanium atom. Selected bond lengths and angles are presented in Table 2. The transannular N→Ge bond length in ethynylgermatranes **4** varies between 2.202(3) Å (for the disordered germatrane **4a**) and 2.115 Å [for 3-methoxypropyn-1-ylgermatrane, (**4c**)]. The last value is one of the shortest distances detected for germatranes with Ge–C bonds. The shorter intramolecular bond length of 2.108 Å was found only for trifluoromethylgermatrane.[19] The Ge–C bonds in germatranes **4** lie between 1.905 and 1.962 Å. The longest Ge–C

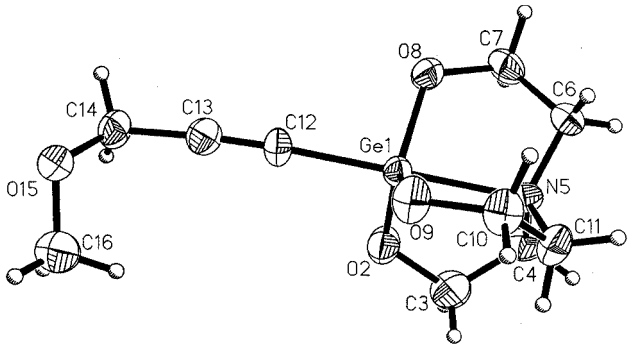

Figure 1. Molecular structure of 3-methoxypropyn-1-ylgermatrane (**4c**)

distance is observed in 3-methoxypropyn-1-ylgermatrane (**4c**) (Figure 1). This indicates that the decrease of the N→Ge bond in the fragment N→Ge–C is accompanied by elongation of the Ge–C bond.

The unit cell of germatrane **4a** contains two independent molecules; one of which is strongly disordered due to the pentyl substituent. Disorder is also observed in the crystal structure of the cyclohexenylethynyl derivative **4b**. The usual disorder for the atrane system occurs for C-4, C-6, and C-11 atoms. Carbon atom C-17 in the six-membered cycle is also disordered. The occupation *g* factor for disordered atoms is 0.5.

Crystals of (trimethylsilyl)ethynylgermatrane (**4d**) were obtained as a solvate with toluene. To prevent toluene evaporating rapidly from the crystal surface, which would destroy the mono crystal of **4d** within 1 h, the X-ray analysis was carried out under an epoxide glue film. The unit cell contains four molecules of germatrane **4d** and two of toluene.

Cobalt complex **5** (Figure 2) crystallized from light petroleum as scarlet prisms. The six-coordinate cobalt atoms have a pseudotetrahedral polyhedron. The Co–Co bond distance is 2.487(1) Å. The dihedral angle between planes C-12, C-13, Co-1 and C-12, C-13, Co-2 is 84.7(1)°. Molecules of complex **5** are in special positions: atoms Ge-1,

N-5, C-12, C-13, C-14, C-15, C-16, C-17 lie in crystallographic plane *m*. However, the molecules are not symmetrical; therefore, disorder occurs in the crystal structure. The occupation *g* factor for disordered atoms is 0.5. According to the literature data, complex **5** is the first example of a cluster structure containing a germatranyl fragment.

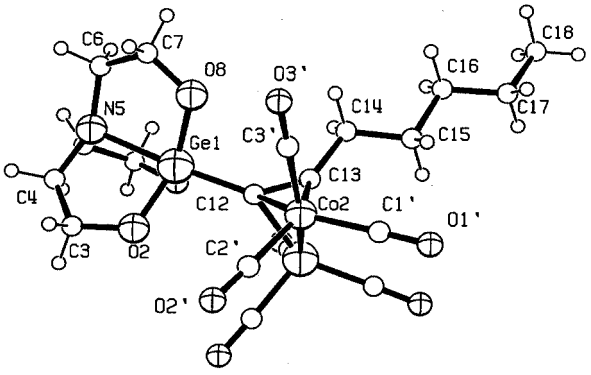

Figure 2. Molecular structure of the hexacarbonyldicobalt complex of 1-heptynylgermatrane (**5**)

Conclusions

Ethynylgermatranes have been prepared from monosubstituted acetylenes by a three-step synthesis from initial acetylenes RC≡CH. With methyl propiolate, tetrachlorogermane acts as Lewis acid to form 1,3,5-tri(methoxycarbonyl)benzene by [2+2+2] cycloaddition. 1-Heptynylgermatrane easily reacts with octacarbonyldicobalt in hexane, almost quantitatively, yielding the hexacarbonyldicobalt complex. The reaction of trimethylsilylethynylgermatrane with NCS and NBS in DMF proceeds with cleavage of the Ge−C bond and formation of chloro- and bromogermatranes. The transannular N→Ge bond lengths (2.115−2.202 Å) of the germatranes are strongly influenced by the RC≡C substituent, with 3-methoxypropyn-1-ylgermatrane having the shortest bond (2.115 Å).

Experimental Section

Instrumental: ^{1}H and ^{13}C NMR spectra were recorded with a Varian Mercury 200 spectrometer at 200.06 and 50.31 MHz, respectively, at 303 K. The chemical shifts are given relative to TMS from the solvent impurity ($CHCl_3$ in $CDCl_3$) signal (δ_H = 7.25 ppm). Mass spectra were recorded with a Hewlett Packard apparatus (70 eV). The melting points were determined with a "Digital melting point analyser" (Fisher) and are uncorrected. 1-Heptyne, 1-ethynylcyclohexene, methyl 2-propynyl ether, trimethylsilylacetylene, triethanolamine and octacarbonyldicobalt [$Co_2(CO)_8$] were purchased from Aldrich.

General Method for Synthesis of Ethynylgermatranes (4a−d): A solution of tetrachlorogermane (4.28 g, 0.02 mol) in dry hexane (10 mL) was added dropwise to a mixture of acetylene **1** (0.02 mol) and triethylamine (0.022 mol) in dry hexane (50 mL). The reaction mixture was boiled under reflux for 2 h and filtered from triethylamine hydrochloride. A mixture of ethanol (0.07 mol) and triethylamine (0.07 mol) was added to the filtrate. The resultant triethylamine hydrochloride precipitate was filtered off after stirring for 2 h at room temperature. The filtrate was then added to a solution of triethanolamine (0.02 mol) in hexane (10 mL). The transalkoxylation reaction was exothermic. After cooling to room temperature the resultant ethynylgermatrane (**4**) precipitate was filtered off and recrystallized from toluene. The products were obtained as white crystalline solids.

For X-ray analysis crystals of germatranes **4a−d** were grown from toluene. Crystals of the hexacarbonyldicobalt complex were obtained by rapid crystallization from dry light petroleum. The crystal structures were solved by direct methods[20−22] and refined with the help of computer programs.[23,24] The main crystallographic data of the germatranes are given in Table 3.

1-Heptynylgermatrane (4a): Yield: 3.02 g (48%). M.p. 89 °C. MS: m/z = 315 [M^+]. $C_{13}H_{23}GeNO_3$ (313.94): calcd. C 49.74, H 7.38, N 4.46; found C 49.51, H 7.30, N 4.45.

(1-Cyclohex-1-enyl)ethynylgermatrane (4b): Yield: 3.56 g (55%). M.p. 211−212 °C. MS: m/z = 325 [M^+]. $C_{14}H_{21}GeNO_3$ (323.93): calcd. C 51.91, H 6.53, N 4.32; found C 51.83, H 6.58, N 4.36.

(3-Methoxypropyn-1-yl)germatrane (4c): Yield: 0.69 g (12%). M.p. 193−194 °C. MS: m/z = 289 [M^+]. $C_{10}H_{17}GeNO_4$ (287.86): calcd. C 41.73, H 5.95, N 4.86; found C 41.77, H 5.99, N 4.84.

(Trimethylsilyl)ethynylgermatrane (4d): Yield: 5.44 g (86%). M.p. 237 °C. MS: m/z = 317 [M^+]. ^{29}Si NMR ($CDCl_3$): δ = −18.6 ppm. $C_{11}H_{21}GeNO_3Si$ (315.98): calcd. C 41.81, H 6.70, N 4.43; found C 41.76, H 6.63, N 4.44.

Hexacarbonyldicobalt Complex of 1-Heptynylgermatrane (5): A solution of octacarbonyldicobalt (0.342 g, 1 mmol) in hexane (10 mL) was added to a solution of 1-heptynylgermatrane (**4a**, 0.314 g, 1 mmol) in hexane (10 mL) at −5 °C. The reaction mixture was stirred 20 min, then hexane was removed and the crude product obtained was purified on silica gel using CH_2Cl_2 as eluent (R_f = 0.55). Yield: 0.56 g (93%). M.p. 102−104 °C. $C_{19}H_{23}Co_2GeNO_9$ (599.46): calcd. C 38.07, H 3.87, N 2.34; found C 38.06, H 3.79, N 2.29.

3-Methyl-4-trimethylsilyl-5-germatranylisoxazole (6): Nitroethane (0.005 mol) and triethylamine (two drops) in dry benzene (20 mL) were added dropwise to a mixture of trimethylsilylethynylgermatrane **4d** (1.58 g, 0.005 mol) and phenylisocyanate (0.01 mol). The mixture was heated for 5 h at 70−80 °C. After cooling to room temperature, diphenylurea was filtered off, the solvent evaporated, and the resultant residue purified on silica gel using dichloromethane as eluent (R_f = 0.45). Yield 1.39 g (75%). M.p. 115 °C. MS: m/z = 374 [M^+]. ^{29}Si NMR ($CDCl_3$): δ = −6.4 ppm. $C_{13}H_{24}GeN_2O_4Si$ (373.04): calcd. C 41.86, H 6.48, N 7.51; found C 41.81, H 6.50, N 7.54.

Method for Synthesis of 1,3,5-Tris(methoxycarbonyl)benzene: A solution of tetrachlorogermane (4.28 g, 0.02 mol) in dry hexane (10 mL) was added dropwise to a mixture of methylpropiolate (1.68 g, 0.02 mol) and triethylamine (2.22 g, 0.022 mol) in dry hexane (50 mL). The reaction mixture was refluxed for 2 h and filtered from triethylamine hydrochloride. The crude product was purified on silica using hexane as eluent. Yield: 52%. The structure was confirmed by MS-GC and ^{1}H NMR spectroscopy.

Reaction of (Trimethylsilyl)ethynylgermatrane with NCS and NBS: NCS or NBS (1 mmol) was added portion-wise, during 1 h at room temperature, to a solution of **4d** (0.315 g, 1 mmol) in DMF (10 mL). After the usual workup the crude product **7** was purified by flash chromatography using ethyl acetate/hexane (5:1) as eluent. Yield: 87−90%.

Relativistic Density Functional Study of the Dinuclear Uranyl Complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ in Its Crystalline Environment

Florian Schlosser,[a] Sven Krüger,[a] and Notker Rösch*[a]

Keywords: Actinides / Uranium / Hydrogen bonds / Relativistic density functional calculations

The hexavalent dinuclear uranyl dichloride complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ was studied computationally with an all-electron scalar relativistic density functional method. This suggested hydrolysis product of uranyl in the presence of chlorine ions is one of the few polynuclear uranyl species for which a crystal structure is known. The calculated gas-phase structure is similar to the experimental crystal geometry; any major deviations are due to hydrogen bonds in the crystal. If the eight strongest hydrogen bonds are included in a model of the complex's crystalline environment, the calculated structure improves significantly. Based on this model, the hydrogen bond lengths and angles were determined, indicating that they are moderate and strong with an average binding energy of 39 kJ/mol. These computational results corroborate earlier suggestions based on experimental results concerning the location and strength of the hydrogen bonds. In addition, a valuable reference for relativistic quantum chemical methods is provided by the gas-phase results.

Introduction

The dinuclear complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ (**1**) has been discussed as a polynuclear species in the initial phase of uranyl hydrolysis in the presence of chlorine ions.[1,2] While structural information about such polynuclear actinide complexes is rare, data are available from EXAFS studies that refer directly to the species in solution or from a crystal structure determination if a crystal can be grown from solution.[3−5] X-ray scattering data of a solution[1] and a crystal structure[2] determined for **1** from hydrolyzed solutions of $UO_3{\cdot}HCl{\cdot}2H_2O$ indicate the presence of the dimeric unit $(UO_2)_2(\mu_2\text{-}OH)_2^{2+}$, which has also been reported in other crystal structures.[3−5] This moiety seems to be an important structural element of dinuclear uranium species in the solid state and in solution.

Recent developments in quantum chemistry[6−12] have rendered relativistic electronic structure calculations feasible for larger compounds of very heavy elements such as the actinides and have, therefore, opened up a computational route to many of their properties. Electronic correlation as well as relativistic effects substantially affect the electronic structure of heavy-element compounds, and therefore have to be accounted for in a correct description of such systems.[13] In addition, the large number of electrons of these elements demands an efficient computational method, so that one is not restricted to small or highly symmetric model species. This renders methods based on density functional (DF) theory very attractive.

Our first goal was to describe the gas-phase structure of the title complex **1** using an appropriate all-electron scalar relativistic DF approach[7,14] that combines a geometry optimization using a local-density approximation (LDA) of the exchange-correlation functional and an energy evaluation using a generalized-gradient approximation (GGA, see Computational Details). In a second step, we modeled the packing effects in the crystal structure of **1** and compared this model with available experimental data.[2] Because **1** is neutral, long-range Coulomb interactions between the different units in the crystal should not be crucial; rather, one expects that hydrogen bonds comprise the main crystal packing effects.[2] Therefore, we chose a model approach which neglects the Madelung field. To the best of our knowledge, this work is the first attempt to model crystal packing effects of a dinuclear actinide species in a quantum chemistry investigation. Even with its simplifications, this model study represents a major challenge to the scalar relativistic DF method applied.

In the next section, we describe details of the crystal structure and present the models chosen to describe complex **1**. We then discuss results for geometry and energetics of **1** and details of the calculated hydrogen bonds, and compare the different models with experimental data. Finally, we provide computational details.

Crystal Structure and Models

Crystals of the diuranyl hydroxide dichloride complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ (**1**) are monoclinic with a unit cell containing four formula units and belong to space group $P2_1/n$ (no. 14).[2] Complex **1** consists of two linear uranyl groups linked by two OH bridges, with the bridging oxygen centers denoted O_b. Both uranium centers are also surrounded by one chlorine and two further oxygen centers O_s and O_a due to coordinating aqua ligands. The index s designates O centers of aqua ligands located *syn* relative to a Cl ligand, while the index a refers to O centers of aqua ligands located *anti*, i.e. at the same uranium center, but on the side opposite to Cl (Figure 1). The two chlorine atoms, one at each U center, are *trans*-coordinated. Overall each U center is locally coordinated as a pentagonal bipyramid, which is typical for uranyl moieties.[15] The central unit $(UO_2)_2(\mu_2\text{-}OH)_2^{2+}$ is also present in the dinuclear hydrolysis product $[(UO_2)_2(\mu_2\text{-}OH)_2(H_2O)_6]^{2+}$ where the chlorine atoms are replaced by aqua ligands.[1] Although both OH and O bridges may be possible in the diuranyl species[16] previous studies[14] confirmed the presence of OH bridges at acidic pH in the initial stage of hydrolysis.

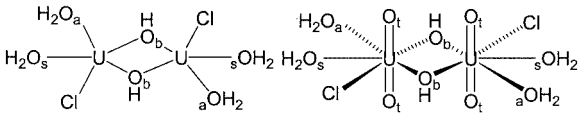

Figure 1. Schematic structure of the dinuclear complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ (**1**): top view (left) and side-view (right); the terminal oxygen atoms of the uranyl units are not shown in the top view

Naturally, X-ray scattering data of the crystal structure do not provide explicit information about the positions of the hydrogen atoms. However, based on typical distances and angles found in the crystal structure, Åberg predicted three types of H bonds, X−H···Y, between adjacent complexes **1** (Figure 2).[2] The four strongest, i.e. shortest, bonds (A, B), extending in the *b* direction of the crystal, are assumed to exist between an oxygen center of an OH bridge and an oxygen center of an *anti*-coordinated aqua ligand, $O_b\cdots H-O_a$ (A) and $O_a-H\cdots O_b$ (B). (Frontier groups of an adjacent complex **1** are designated in *italics*.) Åberg predicted eight additional H bonds oriented mainly in the *c* direction.[2] Each of the first four H bonds (C, D) involves the same water oxygen center as H bond B and a chlorine center, $O_a-H\cdots Cl$ (C) and $Cl\cdots H-O_a$ (D); the second four H bonds (E, F) involve a bridging oxygen atom and a terminal uranyl oxygen atom, $O_t\cdots H-O_b$ (E) and $O_b-H\cdots O_t$ (F) (Figure 2). From a comparison of the corresponding X···Y distances with typical values for H bonds[17] and the van der Waals radii of the corresponding atoms,[18] we expect the bond strengths to decrease from (A, B) to (C, D) to (E, F).[2]

To determine the structure of complex **1**, we applied two models with C_i symmetry: M1 − a model of the gas-phase structure, and, to account for packing effects of the crystal,

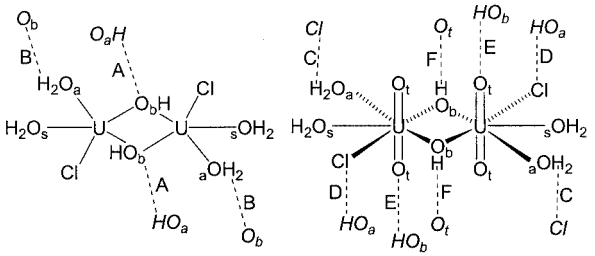

Figure 2. Schematic structure of the dinuclear complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ (**1**), including the proposed H bonds A, B, C, D, E, and F in the crystal; see text; top view (left) and side-view (right); terminal oxygen atoms of the uranyl units are not shown in the top view; *italics* indicate frontier groups of neighboring complexes **1** in the crystal

M2 − a model including important features of the crystalline environment.

The C_i symmetry of M1 does not constrain any degree of freedom for a geometry optimization of **1**. The experimental crystal structure shows slight deviations from C_i symmetry because the local inversion symmetry of **1** is broken by the arrangement of the neighboring complexes: equivalent bond lengths scatter on average by 0.02 Å.[2] In addition, the crystal structure reveals that complex **1** exhibits approximately C_{2h} symmetry if H atoms are ommited.[2] Thus, to reduce the computational effort, we also used a model M0 with overall C_{2h} symmetry to generate a starting geometry for M1. In model M0, the OH bridges are coplanar with the $U-O_b-U-O_b$ plane and the coordinated water molecules are oriented symmetrically to this plane; these restrictions are released in model M1. To investigate the effect of the crystal hydrogen bonds on the gas-phase structure of model M1 we constructed model M2. Here, we place the gas-phase complex obtained with model M1 into a model of its crystalline environment and investigate the relaxation of the complex due to the H bonds. Comparing the optimized structure of model M2 with the crystal structure, we can check if the model environment can reproduce the main effects of crystal packing.

To model the effect of H bonds with neighboring complexes in the crystal, we represented neighboring complexes **1** by those frontier groups involved in the H bonds discussed above (Figure 2). To keep model M2 neutral, we chose H_2O and HCl molecules as the corresponding counterparts. Only the heavy atoms (O, Cl) of these model groups were placed at fixed positions derived from the experimental crystal structure.[2] Thus, the optimizations represent a relaxation of **1** in the fixed framework of heavy frontier atoms of the surrounding species in the molecular crystal. The locations of the hydrogen centers of the model groups (hence also the orientations of the H bonds) were fully optimized, subject to inversion symmetry constraint. The Mulliken charges of the corresponding centers of O (−0.62 e) in H_2O and Cl (−0.24 e) in HCl are close to those of the corresponding atoms of **1** as calculated with reference model M1, namely −0.54 e for O_a and −0.34 e for Cl. Therefore, the chemical environment of **1** in model M2 should be sufficiently similar to that of the crystal.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Our initial, simple model of the environment accounted only for the strongest H bonds (A, B); as expected, this yielded improved distances and angles of atoms directly connected to the simulated bridges but the localized formation of these selected H bonds distorts other parts of the complex. Therefore, in model M2 we included both (A, B) and (C, D) H bonds, still applying C_i symmetry, so as to model the eight strongest out of twelve H bonds assumed to be present in the crystal. Neglect of the weak E and F bridges is supported by the good agreement of the UO_t distances with experiment in all our models, indicating only small effects of these H bonds on the strong UO_t bonds. Rotation of the complex **1** inside the "matrix" set up by the H bonds of the environment would result in further H bonds to the frontier groups of neighboring complexes; to prevent such artifacts, we constrained the equatorial ligand atoms of the uranyl groups in a plane, in agreement with the experimental crystal structure. This approximation was checked by examining the structure's relaxation (model M2′, see below), which led to changes in bond lengths of **1** of < 0.02 Å. Therefore, the following discussion will focus on model M2.

Results and Discussion

Geometry

Table 1 summarizes the calculated structures of the three models studied and compares these results with experiment. First, we shall discuss the gas-phase reference model M1. The central dimeric unit $(UO_2)_2(OH)_2^{2+}$ consists of two slightly different ($\Delta = 0.07$ Å) bonds $U-O_b$ of the bridging hydroxy groups between the uranyl units. The OH moieties show a longer bond $U-O_b$ (2.39 Å) to the uranyl where H_2O is their neighboring ligand and a shorter bond $U-O_b'$ (2.32 Å) close to a neighboring Cl ligand (Figure 1). The O_b-H bonds are bent 66.6° out of the central $U-O_b-U-O_b$ plane. The uranyl moieties of M1 are almost linear (176.7°), very close to the linear structure of a uranyl ion UO_2^{2+}. The terminal oxygen−uranium distances $U-O_t$ are significantly longer than in the corresponding gas-phase calculations of the bare uranyl ion UO_2^{2+} ($\Delta = 0.08$ Å) and even slightly longer than calculated for the solvated uranyl ion $[UO_2(H_2O)_5]^{2+}$ ($\Delta = 0.03$ Å).[19] Such bond elongation is due to increasing competition with other, equatorial ligands at the U center which bind more strongly than water (OH, Cl). For the gas-phase structure of the analogous dinuclear complex $(UO_2)_2(OH)_2(H_2O)_6^{2+}$, almost equal $U-O_t$ distances ($\Delta = -0.01$ Å) and an increased bending of the uranyl moieties (168.0°) have been calculated.[14]

The $U-O_a$, $U-O_s$ and U−Cl bonds are bent out of the $U-O_b-U-O_b$ plane by 15.9°, 0.9° and 6.2°, respectively. Therefore, the pentagonal-bipyramidal coordination of the U centers, which is typical of monomeric complexes,[15] is slightly distorted. The bonds to the aqua ligands $U-O_a$ and $U-O_s$ (2.49 Å) are slightly longer than uranium−water distances in mononuclear $UO_2(H_2O)_5^{2+}$ (2.42 Å) and dinuclear[14] species $(UO_2)_2(OH)_2(H_2O)_6^{2+}$ (2.46 Å) due to an increasing number of more strongly binding ligands. Also, the U−Cl distance (2.63 Å) indicates strong ligand bonding because it is relatively short compared to computational results for $[UO_2Cl_4]^{2-}$ where the U−Cl distances are elongated due to the competition of four strong bonds (2.68 Å). This latter result is in good agreement with EXAFS data for this complex in solution (2.67 Å)[20] while DF GGA calculations yield longer bonds, from 2.73 to 2.81 Å.[8]

As there are no experimental data for the gas phase, we compared the results of model M1 with X-ray data in solution, to obtain initial indications of solvation and crystal packing effects on geometry. Åberg has investigated solutions of hydrolyzed uranyl(VI) chloride with constant [U] (3 M) but varying OH/U ratio, i.e. the average number of OH groups per U atom (0−1.11).[1] We choose the ratio 1.11 for comparison, in agreement with the assumed structure of **1** that exhibits two U centers linked by two OH bridges. The experimental results correspond to the assumed pentagonal coordination, including one U−Cl bond [$n_r = 0.8(1)$ for

Table 1. Structure parameters (distances in Å, angles in °) of models M0 (C_{2h}), M1 (C_i), and M2 (C_i) of complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ (**1**) in the gas phase (M0, M1) and in a model of the crystalline environment (M2); also shown are experimental values and deviations ΔMn ($n = 0, 1, 2$) of calculated quantities from the crystal structure; the last line provides the types of H bonds that directly affect the corresponding distances and angles (for the designations, see Figure 2 and text)

U−Cl, where n_r is the number of corresponding bonds per U atom) and four U−O bonds [n_r = 4.3(2)], i.e. two bonds to bridging hydroxy moieties and two bonds to coordinated water molecules (Figure 1). The latter four uranium−oxygen bonds U−O_b, U−O_b', U−O_a, and U−O_s from the first hydration sphere could not be separated by experiment[1] so that only an average distance is available (2.40 Å, Table 1).

The U−O_t distance of model M1 agrees reasonably well with the solution data (Δ = 0.03 Å), indicating minimal solvation effects on the strong U−O_t bond. The U−O_t distance found in solution (1.76 Å) is short compared with other experimental data for UO_2^{2+} in solution (1.76−1.78 Å);[20,21] in fact, one would expect a longer U−O_t bond in M1 because four aqua ligands of a completely solvated uranyl complex are replaced by stronger bound ligands, namely by two Cl ligands and two OH bridges. The polar U−Cl bond, however, is notably shorter than in solution (Δ = −0.26 Å) and may be elongated by screening effects and possible H bonds in solution. The calculated average distance (2.42 Å) of all equatorial U−O bonds is only 0.02 Å longer than the experimental value. The bridging bonds U−O_b and U−O_b' are significantly shorter than the bonds U−O_a and U−O_s (Δ ≈ −0.14 Å); indicating increased bond strengths of the linking bridges.

Before judging the gas-phase model M1 against the crystal data, we briefly compare the available experimental solution and crystal structure data. Overall, they are similar, with a tendency to longer bonds in the crystal, except for the U−Cl distance. This may be because the H bonds in solution are more flexible and dynamically changing than the localized crystal H bonds; thus, the corresponding bonds are weakened and lengthened in a more pronounced fashion. The average U−O distance in the crystal is 0.01 Å longer than in solution. The U−U and U−Cl distances though are noticeably different from solution, with Δ = 0.10 Å and −0.14 Å, respectively, indicative of a weakening of the bridging bonds due to H bonds in the crystal (A and F in Figure 2). Invoking bond order conservation at the two uranyl moieties, this weakening would lengthen the U−U distance and strengthen the other equatorial bonds, including the U−Cl bond.

Model M1 is in relatively good agreement with the crystal structure, particularly considering the experimental uncertainties. Only slight deviations are found for the U−O_b (Δ = −0.01 Å) and U−O_b' (Δ = −0.02 Å) distances; also, the correct order of these two distances is reproduced (U−O_b > U−O_b'). However, the U−U distance, which does not represent an actual bond (3.80 Å), is strongly underestimated (Δ = −0.14 Å), yielding a more compact complex than the crystal structure; this is probably due to the stronger bridging bonds. The bonds to the aqua ligands U−O_a and U−O_s are almost equal in model M1, with a slightly longer distance U−O_a (Δ = 0.01 Å), whereas the crystal U−O_s bond is significantly longer, by 0.11 Å. The distance U−O_a (Δ = 0.10 Å) is too long compared to experiment whereas that of U−O_s (Δ = −0.01 Å) agrees very well. This may be traced to the effects of the H bonds involved, i.e. A, B, C, and D for U−O_a whereas the U−O_s bond length is unaffected by any of the postulated H bonds (Figure 2). The underestimation of the U−Cl distance (−0.12 Å) can be rationalized with the missing weakening effects due to H bonds C and D. The linearity of the uranyl moieties is very well reproduced (Δ = −1.5°) and deviations of other characteristic angles are small, 3−5° (Table 1).

Before turning to the computational results for model M2, where H bonds are taken into account, we briefly discuss results obtained with the highly symmetric gas-phase model M0 of C_{2h} symmetry. Model M0 shows surprisingly good overall agreement with M1 (Table 1); as expected, the main differences are with the OH bridges which are not bent due to symmetry restrictions. In addition, the order of the two distances U−O_b and U−O_b' is reversed (U−O_b < U−O_b'). The reduction in U−O_b (Δ = −0.14 Å compared to model M1) gives a shorter U−U distance (Δ = −0.02 Å) and a weakening of the U−Cl bond (Δ = 0.07 Å) due to the stronger bridging bonds. Although the U−O_t bonds are only very slightly elongated (Δ = 0.005 Å), the uranyl units are more strongly bent, 169° compared to 177° in M1, whereas deviations of other angles range from 1 to 9°.

In model M2, the H bonds A, B, C, and D were simulated to account for the crystalline environment (Figure 3). Consequently, compared to model M1, most bonds are elongated. All bond lengths except U−O_b are improved in comparison to model M1 (Table 1), with deviations Δ from experiment ranging from less than 0.01 Å up to 0.09 Å; even the U−U distance is distinctly elongated (Δ = −0.07 Å). Agreement with experimental data for U−O_a (Δ = 0.03 Å) and U−Cl (Δ = −0.09 Å) is notably improved whereas the distance U−O_s (|Δ| < 0.01 Å) is hardly affected because O_s is not involved in an H bond. Unlike model M1, the correct ordering of the lengths of the two types of aqua ligand bonds U−O_a and U−O_s is reproduced (U−O_a < U−O_s). The calculated H bond Cl···H−O_a (D) is distinctly longer than the experimental bond (see below), which reduces the effect on the corresponding U−Cl bond; this may explain the relatively strong deviation from experiment calculated for the U−Cl distance (Δ = −0.09 Å). The effect of the H bonds A on the O_b atoms is significant: the distance U−O_b (Δ = −0.05 Å) changes by 0.04 Å, the bending angle of the O_b−H bond is reduced from 66.6° in model

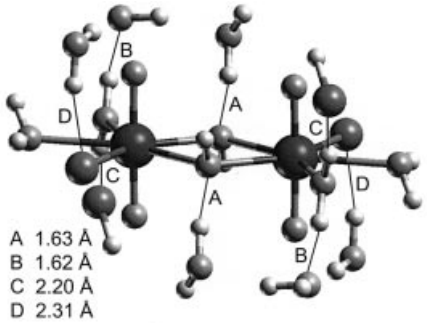

Figure 3. Optimized structure of the dinuclear complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ (**1**), including simulated H bonds A, B, C, and D (model M2); also shown are calculated H···Y distances [Å]

M1 to 52.9°; the distance U−O_b' is less affected and changes by 0.025 Å. Both the angle O_t−U−O_t ($\Delta = -3°$) and the remaining angles ($\Delta = 1-5°$) agree well with experiment, with deviations of the same order as in model M1.

We also find very good agreement for the strong U−O_t bonds ($\Delta < 0.01$ Å), in fact for all models M0, M1 and M2. Thus, the postulated H bonds E and F seem to affect the uranyl bonding only weakly. This corroborates our decision to neglect these weak bonds in model M2. From previous results for similar systems,[14] the expected accuracy of about ±0.02 Å for bond lengths was not reached in model M2 for the U−O_b, U−O_a, and U−Cl bonds; however, inclusion of the most important H bonds in model M2 distinctly improved the results compared to model M1. Note that the crystal structure differs slightly from the C_i symmetry assumed for the computational models, resulting in a scattering of the experimental distances by up to ±0.04 Å; this is of the same order as experimental uncertainties (0.01−0.03 Å, Table 1). Thus, for most bonds, the remaining deviations are within experimental uncertainty, but may also partly be caused by the applied symmetry restriction and the lack of H bonds E and F in model M2.

The crystal structure provides limited information on H bonds, but from model M2 we can locate the hydrogen atoms involved and the angles of the simulated H bonds (Table 2, Figure 3). The calculated H bonds A ($\Delta = -0.02$ Å) and C ($\Delta = 0.04$ Å) are in good agreement with the X···Y distances found in the crystal; this is noteworthy as H bonds are not described with high accuracy with a local-density approximation of the exchange-correlation functional (see $\Delta = 0.07$ Å for the H bonds B and D).[22] The calculated Cl···O_a distance of bridge D is too long, which seems to indicate a weaker H bond in model M2 than expected from the crystal structure. As a consequence, the calculated U−Cl bond is less destabilized and too short (see above). The agreement of both chemical bond lengths and X···Y distances of H bonds, calculated for model M2, with the corresponding data of the crystal structure confirms that the relaxation of the gas-phase structure of complex **1** (M1) is properly described in the simulated crystalline environment of model M2.

Our computational results for H bonds can also be compared to typical data[17] for H···Y distances and X−H···Y angles (Table 2). Such comparison allows us to classify the H bonds A and B as relatively strong, both resulting in almost linear bonds with O_a−H···O_b angles of 173° (Table 2). For the H bonds C and D typical weak-to-moderate bonds are indicated, with elongated distances and O_a−H···Cl angles of 171 and 156°, respectively. Charge exchange from individual H bonds to the corresponding acceptor atoms in the complex is small; the total electronic charge donation of all eight H bonds is ca. 0.4 e compared to the gas-phase model M1. According to a Mulliken population analysis, there is a slight charge donation to centers O_b (0.04 e) and Cl (0.03 e) from the H bonds A and D and also from H bonds B and C to both H atoms in H_2O_a (0.03 and 0.06 e, respectively). The calculated charge donation of ca. 0.4 e is a deficiency of our model because the molecular crystal contains neutral units of **1**. A net donation of electron charge should usually result in an elongation of bonds. However, compared to experiment, the deviations of calculated bond lengths in model M2 are the same size as found for the dinuclear species $(UO_2)_2(OH)_2(H_2O)_6^{2+}$.[14] Thus, we are confident that potential artifacts due to a net charge of complex **1** are small.

In the additional models M2′ and M2′′ we also investigated relaxation effects of complex **1** that occur on removing the constraint that all equatorial ligand atoms of the uranyl moieties be confined to one plane (see above). As the crystal structure provides no evidence for H bonds to *syn*-aqua ligands, there is no predefined orientation of the corresponding hydrogen atoms, in contrast to those of the *anti*-aqua ligands (Figure 2). Therefore, while maintaining overall C_i symmetry during relaxation of the constraint, two isomers are possible. In the first model (M2′), the hydrogen atoms of the *syn*-aqua ligands are oriented as in model M2 (Figure 3); in the second model (M2′′), these ligands are rotated by about 180° around the U−O_s bond.

Table 3 gives the geometries of the two structures M2′ and M2′′ compared with that of model M2. At first sight, the structures of the three models are very similar. Deviations between the three models are generally < 0.02 Å for distances and < 3° for angles. The most prominent geo-

M2′′	3.880	2.337	2.363	2.411	2.486	2.668	12
Exp.[a]	3.94(0)	2.40(2)	2.34(2)	2.39(2)	2.50(3)	2.75(1)	

[a] Ref.[2], crystal structure (average values with respect to the assumed C_i symmetry; maximum scattering of 0.04 Å for distances and 1.7° for angles).

metrical difference relates to the U−O_b and U−O_b′ distances. Model M2′ agrees very well with model M2, concerning both length of the two bridges and their ordering (U−O_b > U−O_b′). A major improvement compared to experiment is the shortening of U−O_a by 0.02 Å (Table 3). Conversely, in model M2′′, U−O_b decreases by 0.02 Å whereas U−O_b′ increases by 0.02 Å compared to model M2; therefore the ordering of the two bridges disagrees with experiment: U−O_b < U−O_b′. Thus, also taking into account small energy disadvantages of ΔE = 12 and 19 kJ/mol over M2 and M2′, respectively, we rule out model M2′′ (Table 3).

Although model M2′ is calculated to be slightly more stable than M2 (by 7 kJ/mol; Table 3), the H bond structure favors M2 over M2′. In model M2′, the X···Y distances of the weak-to-moderate bonds C (Δ = 0.21 Å) and D (Δ = 0.19 Å) are significantly longer than in experiment; they are also overestimated in model M2 (C: Δ = 0.04 Å; D: Δ = 0.07 Å), but to a considerably smaller extent. The X···Y distances of the strong H bonds (A: Δ = −0.02 Å; B: Δ = −0.04 Å) remain similar to model M2 (see above), and the angles X−H···Y are only slightly affected, with changes below 2°. Yet, the structural relaxation of model M2′, where the equatorial ligands bend slightly out of the equatorial plane, results in notable changes in H bond lengths and removes the good agreement of the H bond network calculated for model M2 with the crystal structure.

In summary, we favor model M2 and M2′, and exclude model M2′′ based on structure and energy arguments. M2 and M2′ are very similar if one considers the internal structure of **1**. We note that the H bonds of model M2′ fit the experiment less well. These bonds are rather flexible and thus they change strongly with small geometry alterations of the central complex. Nevertheless the differences between models M2 and M2′ should not be over-interpreted, keeping in mind the approximate modeling of the crystalline environment of **1**.

Energetics

To compare the relative energies of our models, we chose the low symmetry gas-phase model M1 (C_i symmetry) as reference. Model M0, where out-of-plane bending of the OH bridges is prevented by the imposed C_{2h} symmetry, is 47 kJ/mol less stable. Contrary to this relatively small energy change, model M2 is 315 kJ/mol more stable due to the simulated eight H bonds. This calculated stabilization energy was based on the reaction **1** (M1) + 6 H_2O + 2 HCl → **1**·6H_2O·2HCl (M2). With respect to the eight H bonds formed, this energy translates into an average binding energy of 39 kJ/mol per H bond, which falls in the range 20−70 kJ/mol that is typical for moderately strong H bonds,[17] thus corroborating the previously discussed structural evidence concerning their strength.

To estimate the strengths of individual H bonds, we removed the corresponding frontier groups from model M2 and considered the model reaction **1** (M2) → **1** (M2 − 2 X) + 2 X where X = H_2O for the H bonds A, B, and D and X = HCl for H bond C. No structure relaxation was allowed. The energies of the H bonds A, B, C, and D thus estimated are 84, 113, 14, and 27 kJ/mol, respectively (Table 2). These calculated energies confirm the previous classification of the H bonds based on structural evidence: H bonds A and B, with average binding energies of about 99 kJ/mol, represent typical strong H bonds (60−170 kJ/mol)[17] whereas H bonds C and D are significantly weaker, with average binding energies of about 21 kJ/mol. Together with the good overall agreement of the detailed geometry of model M2 with the crystal structure, these energy results confirm that the simulated H bonds represent the main crystal packing effects.

Conclusion

A scalar relativistic density functional method as implemented in the parallel code PARAGAUSS was employed to study the structure of the hexavalent dinuclear uranyl chloride complex $[(UO_2)_2(\mu_2\text{-}OH)_2Cl_2(H_2O)_4]$ (**1**) in the gas phase as well as in its crystalline environment. A local-density approximation of the exchange-correlation functional was used for the geometry optimization; energies were determined with a generalized-gradient approximation (see below).

We applied different models to describe both the gas-phase structure and packing effects in the molecular crystal. The gas-phase reference model agrees reasonably well with the experimental structure; major deviations are due to the neglect of H bonds of the crystal environment. Notable deviations occur for U−O distances of an aqua ligand (too long by 0.10 Å) and U−Cl bonds (too short by 0.12 Å). We also found surprisingly good agreement for an initial high-symmetry model which enforced coplanarity of the OH bridges.

We described H bonds in the crystal environment via model H_2O and HCl moieties that mimic the effect of frontier groups of neighboring complexes **1**. In this model, the calculated structure is significantly improved. Average deviations from experiment are reduced from 0.04 to 0.03 Å for bond lengths (maximum deviation 0.09 Å for U−Cl) and from 3.5 to 2.6° for angles (maximum deviation 5°). One

can imagine a still further improved model that includes all postulated H bonds.

Based on this model, the lengths and angles of the hydrogen bonds were determined, indicating moderate and strong H bonds with an average binding energy of 39 kJ/mol. These computational results corroborate earlier suggestions, based on experimental results, concerning the location and strength of H bonds. The good agreement of both geometry and H bonds with the crystal structure confirms the correct orientation of the complex in the simulated crystalline environment and justifies our model approach.

Computational Details

Scalar relativistic all-electron calculations were carried out by the LCGTO-FF-DF method[23] (linear combination of Gaussian-type orbitals fitting function density functional) as implemented in the parallel code PARAGAUSS.[24,25] The relativistic density functional method applied is based on the second-order Douglas-Kroll-Hess (DKH) approach[26,27] to the Dirac-Kohn-Sham problem.[7,28] Besides the standard scalar relativistic variant, a two-component version is available that includes spin-orbit interaction self-consistently.[29] Due to the closed-shell electronic structure of the U^{VI} species examined we refrained from including spin-orbit interaction.

We employed two exchange-correlation functionals: the local-density approximation (LDA) in the parameterization of Vosko, Wilk, and Nusair (VWN),[30] and the gradient-corrected functional (generalized gradient approximation, GGA) suggested by Becke and Perdew (BP).[31,32] Structures were optimized at the LDA level, invoking a quasi-Newton algorithm and analytical forces.[33,34] The LDA often yields more accurate results for molecular geometries, whereas gradient-corrected functionals perform better for binding energies.[35,36] Therefore, we applied the BP functional self-consistently to calculate binding energies at the structures optimized with the VWN functional.

The Kohn-Sham orbitals were represented by flexible Gaussian-type basis sets, contracted in a generalized fashion using atomic eigenvectors. For U, we used a basis set of the size (24*s*, 19*p*, 16*d*, 11*f*),[37] contracted to [10*s*, 7*p*, 7*d*, 4*f*]. The light atoms (Cl, O, H) were described by standard basis sets:[38] (12*s*, 9*p*, 1*d*) → [6*s*, 5*p*, 1*d*] for Cl, (9*s*, 5*p*, 1*d*) → [5*s*, 4*p*, 1*d*] for O, and (6*s*, 1*p*) → [4*s*, 1*p*] for H. To evaluate the classical Coulomb contribution to the electron-electron interaction in the LCGTO-FF-DF method, the electron density is represented with the help of an auxiliary basis set.[23] The exponents of the corresponding *s*- and r^2-type fitting functions were generated from the orbital basis by a standard procedure;[23] in addition, we chose *p*-, *d*- and *f*-type "polarization exponents" as geometric series with a factor 2.5, starting with 0.1, 0.2 and 0.3 for *p*-, *d*- and *f*-type exponents, respectively. Thus, for U, the auxiliary charge density basis set was of the size (24*s*, 9r^2, 5*p*, 5*d*, 5*f*); the auxiliary basis sets for Cl, O, and H were (12*s*, 9r^2, 5*p*, 5*d*), (9*s*, 5r^2, 5*p*, 5*d*), and (6*s*, 1r^2, 5*p*), respectively. Recently, we checked the quality of the auxiliary basis sets for uranyl; comparison with other DF calculations confirmed the accuracy of the current FF approach for actinide complexes.[39]

In the geometry optimizations, the total energy and elements of the density matrix were required to converge to 10^{-8} au; for the largest component of the displacement gradient vector and the update step length, the convergence criteria were set to 10^{-6} au. For model M1, the grid[40] for the numeric integration of the exchange-correlation functional consisted of about 26200, 16000, 10000, and 8900 points for U, Cl, O, and H centers, respectively.

Previous studies of various hexavalent actinide compounds,[39] including the dinuclear uranium species $[(UO_2)_2(OH)_2(H_2O)_x]^{2+}$ and $[(UO_2)_2O_2(H_2O)_x]$ (x = 0, 2, 4, 6),[14] showed that the computational strategy just described yields very satisfactory results. The LDA (VWN) functional provided accurate bond lengths and vibrational frequencies. Results obtained with uncontracted and contracted basis sets agreed rather well; for the dinuclear species[14] bond lengths differed by at most 0.002 Å, angles by at most 0.2° and binding energies by at most 2 kJ/mol; for mononuclear compounds,[39] deviations of distances were less than 0.0006 Å.

Palladium(II) Complexes Containing a Pyridinyliminophosphorane Ligand

Hung-Ren Wu,[a] Yi-Hung Liu,[a] Shie-Ming Peng,[a] and Shiuh-Tzung Liu*[a]

Keywords: N ligands / Polymerization / Palladium

A series of new pyridinyliminophosphorane bidentate ligands with different steric environments [(2-C_6H_4N)PPh_2=NAr (**NPN**)] and their methylpalladium complexes [PdClMe(**NPN**)] were prepared. From the crystal structure analysis it is evident that the alkyl ligands are always *trans* to the pyridinyl nitrogen donor, revealing a σ-donating ability of the iminophosphorane. However, the two Pd–Cl bonds in [$PdCl_2$(**NPN**)] are essentially the same length. Cationic palladium complexes catalyzed the copolymerization of norbornene/ethylene as well as CO/norbornene.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

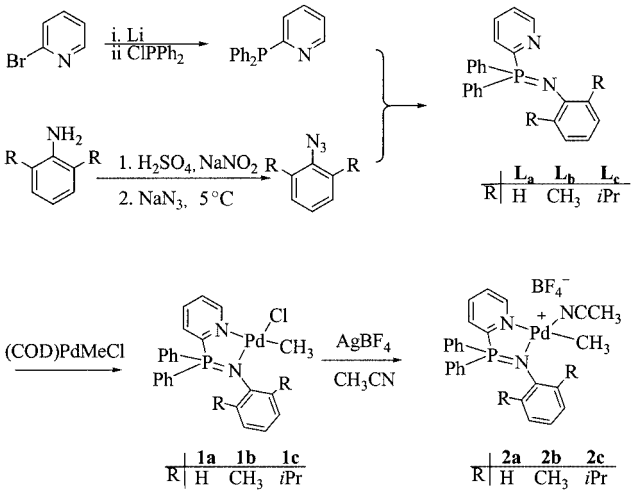
Introduction

Since the discovery of highly active diiminopalladium complexes for the polymerization of olefins under mild conditions by Brookhart's group,[1] the design of new ligands to fine-tune the activity of catalysts has received much attention.[2] It is documented that the steric bulkiness around the active metal center favors chain propagation, leading to higher molecular-weight and branched polymers.[1,2] Another attractive feature in this area is the possibility of employing late transition metal complexes, containing heterodonor systems, since the olefin insertion into the M−C bond can be governed by the electronic properties of donor atoms.[2] Presumably due to the reactivity of iminophosphoranes toward moisture[3] and carbonyl groups,[4] the use of this kind of donor in catalytic polymerization is less-well explored.[5] Recently, Stephan and Collins' groups have reported independently that early transition metal complexes with phosphinimide ligands can catalyze the polymerization of ethylene.[6,7] While the coordination studies involving iminophosphorane toward late transition metal complexes are well-examined,[4c,8−12] we would like to contribute our efforts in this area by investigating the behavior of palladium complexes with a series of bidentate pyridinyliminophosphorane ligands as well as their catalytic polymerization activity toward olefins.

Results and Discussion

Preparation of Complexes

The ligands (**L_a**−**L_c**) were prepared in high yield by the Staudinger reaction of 2-diphenylphosphanylpyridine with the corresponding aryl azide under anhydrous conditions (Scheme 1). Substitution reactions of [PdClMe(COD)] with pyridine-iminophosphorane (**NPN**) in dichloromethane at room temperature readily led to the formation of bidentate palladium complexes (**1a**−**c**), which were treated with $AgBF_4$ to yield the corresponding cationic species (**2a**−**c**; Scheme 1). All the palladium complexes were isolated as solids and were stable in solution under a nitrogen atmosphere.



Scheme 1. Preparation of ligands and palladium complexes

In the NMR spectra of the ligands **L_a**−**L_c** and of the palladium complexes **1a**−**2c**, differences between the substituents on the benzene rings were observed. The ^1H, ^{13}C and ^{31}P NMR resonances of these related species are quite similar as shown in Table 1, and are consistent with the expected structure. It can also be seen that the ^{31}P NMR spec-

tra for **1a−2c** show only one signal for each complex, indicating that one single stereoisomer was formed upon complexation. Fortunately, the detailed structures of **1b**, **1c** and **2a** were further confirmed by a crystal structure analysis, which showed clearly the stereo relationship of the donors around the palladium center.

Single crystals suitable for the analysis of the complexes **1b**, **1c** and **2a·CH$_2$Cl$_2$** were obtained by slow evaporation of dichloromethane/diethyl ether solutions. The crystal data of these complexes are collected in Table 2. ORTEP plots of **1b**, **1c** and **2a·CH$_2$Cl$_2$** are depicted in Figures 1−3, respectively, and selected bond lengths and angles are summarized in Table 3. All the palladium complexes are square planar with slight distortions, particularly for the angle N(1)−Pd−N(2) (ca. 84°). In all instances, the methyl group is located *trans* to the pyridinyl-nitrogen and the Pd−C distances are in the range 2.000−2.114 Å, which are typical palladium-methyl carbon lengths.[13] Examination of

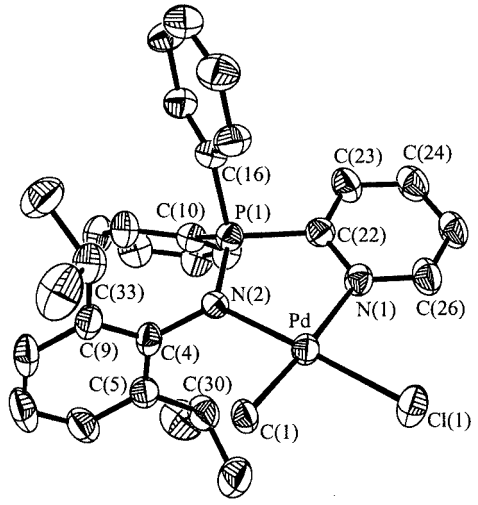

Figure 2. Molecular structure of **1c**

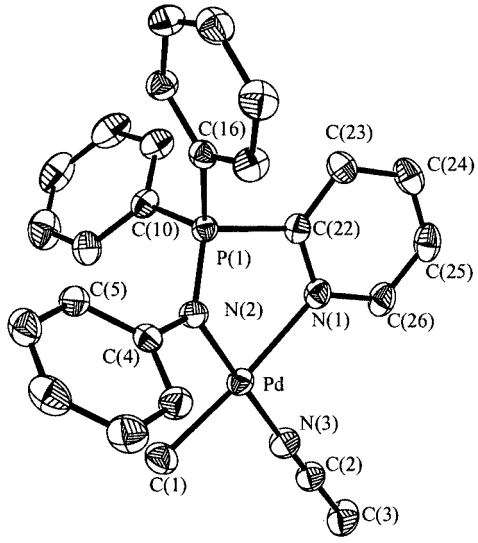

Figure 3. ORTEP drawing of **2a**

Pd−N(2)−C(4), Pd−N(2)−P(1) and P(1)−N(2)−C(4) reveals that the N(2) center is trigonal planar, indicating an sp^2 hybridization of the nitrogen atom. All other bond lengths and bond angles lie within the usual range even in the case of **1c**, with the bulky substituents on the aryl ring. However, the dihedral angles of N(1)−C(22)−P(1)−N(2) and the orientation of the imine [N(2)] aryl ring relative to the chelating ring appear to be the major differences among these crystal structures.

The small dihedral angles of N(1)−C(22)−P(1)−N(2) for **1c** [6.1(6)°] imply an almost planar geometry for this bidentate ligand, whereas a larger deviation of this angle from planar geometry in both **2a** and **1b** [**2a:** 26.9(3)°; **1b:** 28.3(3)°] is observed. In fact, the chelating ring in **1c** lies in a plane with a slight deviation of N(2) by ca. 0.12 Å, based on the calculated plane defined by P(1)−C(22)−N(1)−Pd. The dihedral angle between the chelating ring and the imino [N(2)] aryl ring for **1c** is 82.6(2)°, showing that the isopropyl groups on the aryl ring readily force this ring to lie almost perpendicular to the chelating ring in order to relieve the steric interaction between the ring substituents and the coordinated ligands.

A simple comparison of a few methylpalladium chloride complexes is summarized in Scheme 2. Several differences between these structures are: (1) the Pd−Cl bond *trans* to the phosphane donor is slightly longer than the bonds *trans* to the nitrogen donors. (2) The Pd−C bond of **1c** is longer by ca. 0.1 Å than the bonds in [PdClMe(**P~N**)]and [PdClMe(**N~N**)]. (3) The bite angle decreases in the order: **1c** < [PdClMe(**P~N**)] < [PdClMe(**N~N**)]. The shorter length of Pd−N(2) in **1c** indicates a stronger coordination of the nitrogen donor to palladium, thus showing that the iminophosphorane functionality remains intact. Indeed, the palladium complexes **1a**−**c** are fairly stable towards air or even moisture. In NMR investigations, complexes **2a**−**c** remain unchanged for several days in the presence of water with trace amounts of coordinating acetonitrile replaced by water molecules. It is known that the iminophosphorane moiety undergoes P−N bond cleavage with water,[3] but such activity is readily hindered by the chelation upon complexation, which is quite similar to that reported by Réau in palladium complexes containing 1,2-bis(triphenylphosphinimino)cyclohexane.[8]

Insertion of Carbon Monoxide and Ethylene

The insertion of carbon monoxide into the Pd−C bond of compounds **2a**−**c** was studied (Scheme 3). A dichloromethane solution of the individual complex was bubbled with CO and monitored by ^{31}P NMR spectroscopy. All three complexes, **2a**−**c**, underwent insertion to yield the corresponding acyl complexes and the insertion rate followed the order of the less steric environments (**2a** > **2b** > **2c**), as evidenced by NMR spectroscopy. The resulting acyl complexes **3b** and **3c** were isolated in stable solid form, whereas the inserted product **3a** readily decomposed in the absence of a carbon monoxide atmosphere. Selected spectroscopic data are summarized in Table 4. The presence of the ^{13}C chemical shift at $\delta = 220$ ppm and the infrared stretching frequency around 1700 cm^{-1} clearly demonstrate the formation of the acetyl group.

Subsequent insertion of ethylene into the Pd-acyl bond of **3b**−**c** can be achieved by bubbling ethylene gas through a dichloromethane solution of the respective palladium complex. The inserted products **4b**−**c** were obtained as air-stable yellow solids and the spectroscopic data (Table 4) clearly support the structure proposed. The carbonyl stretching frequency in the range of 1600−1630 cm^{-1} for **4b**−**c** suggests that the formation of the five-membered (C,O) chelate ring provides extra stability for these complexes.[13]

Complex [$PdCl_2(L_b)$]

In order to find out the difference in the *trans* influence between pyridinyl and iminophosphorane nitrogen, the palladium dichloride complex [$PdCl_2(\mathbf{L_b})$] (**5**) was prepared by

simple substitution of $[PdCl_2(CH_3CN)_2]$ with an equimolar amount of $\mathbf{L_b}$. The complex was readily purified by recrystallization and the crystal structure was determined. Figure 4 shows a perspective view of the complex whose selected bond lengths and bond angles are summarized in Table 3. As expected, complex **5** shows a square-planar coordination geometry around the metal center, with the N(1)−Pd−N(2) angle deviating slightly from 90° because of the constraint imposed by the chelating ring. No major deviation was observed in the bond lengths and angles with respect to **1b**, **1c** and **2a**. The lengths of both Pd−Cl bonds are essentially identical. However, the Pd−N(1) lengths in **1b**, **1c** and **2a** which is *trans* to the carbon donors, lie in the range of 2.16−2.17 Å, whereas the Pd−N(1) distance in **5** is shorter by about 0.1 Å. This variation is due to the stronger *trans* influence of carbon versus chloride ligands. From this structural analysis, both nitrogen donors (pyridinyl and iminophosphorane) have a similar *trans* influence. However, the pyridinyl-nitrogen donor appears to be somewhat stronger due to the alkyl ligands being *trans* to the nitrogen ligand in complexes **1** and **2**.

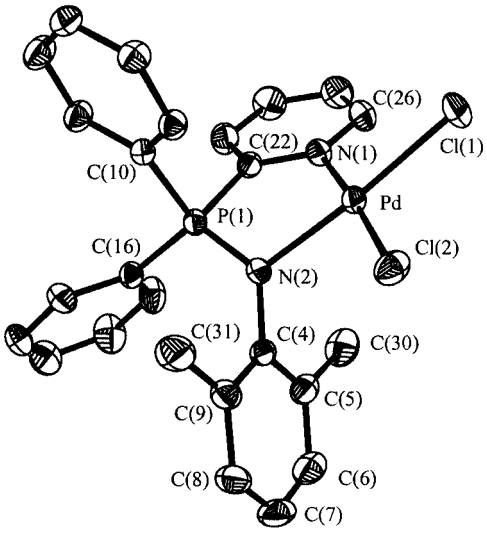

Figure 4. Molecular structure of palladium dichloride complex **5**

Copolymerization

The catalytic activity of the cationic palladium complexes **2a**−**c** was examined. Unlike the corresponding diiminopalladium complexes,[1] this series of complexes were not good catalysts for the polymerization of ethylene. Nevertheless, complex **2b** was found to catalyze the copolymerization of carbon monoxide and norbornene (Table 5). Both the chemical shift in the ^{13}C NMR spectrum and the infrared stretching frequency of the carbonyl group (δ = 211 ppm and 1713 cm^{-1} respectively) clearly demonstrate the formation of the copolymer. As shown in Table 5, the olefin concentration does not have any effect on either the molecular weight or the yield. However, a higher pressure of carbon monoxide led to the precipitation of palladium black out of solution and to lower molecular weight copolymers. In terms of solvent effect, both a coordinating solvent such as acetonitrile (entry 6) and a non-polar solvent (entry 8) provide poor conversions. By comparing the catalysts (entries 1, 7 and 9), complex **2b** appears to be much more active than either **2a** or **2c**. The lower activity of **2c** is presumably due to the steric hindrance of the ligand, whereas in the case of **2a** it is due to the lower stability of the inserted intermediates as illustrated in the previous section. In terms of the catalytic copolymerization of CO/norbornene, complex **2b** shows a similar activity to that of [PdMe(**P~N**)(CH_3CN)]BF_4.[13a]

Table 5. Results of copolymerization of CO and norbornene[a]

Entry	CO(psi)	M_N	PDI	Yield	TOF[b]
1	14.7	5746	1.50	311 mg	24
2	200	3288	1.93	204 mg	16
3	14.7	5137	1.37	251 mg	19
4	200	2352	1.51	254 mg	20
5	50	2373	1.43	216 mg	17
6[c]	14.7	2902	1.58	125 mg	10
7[d]	14.7	2485	1.63	187 mg	14
8[e]	150	–[f]	–	76 mg	5.9
9[g]	14.7	1976	1.61	173 mg	13

[a] Catalyst: **2b** (30 mg), norbornene (5 g), 24 h, in CH_2Cl_2 (20 mL) at 30 °C except where noted; norbornene (10 g) was used in entries 3 and 4. [b] $g{\cdot}mol^{-1}{\cdot}h^{-1}$ [c] In CH_2Cl_2/CH_3CN = 4:1. [d] **2a** as the catalyst. [e] In toluene. [f] M_N was not determined due to its poor solubility in organic solvent. [g] **2c** as the catalyst.

In addition to the copolymerization of CO/norbornene, this series of complexes can also copolymerize ethylene and norbornene. In a typical reaction, **2b** (30 mg) was added to norbornene and ethylene (500 psi) in toluene (20 mL) at 30 °C and after 24 hours, 1.4 g of copolymer was produced. The results are summarized in Table 6. The appropriate reaction conditions for this polymerization appear in entry 4 with the ratio of norbornene to ethylene being 55:45. The mol percentage of the incorporated norbornene units was determined by the glass transition point (T_g) method developed by Ruchatz and Fink.[14] Among these catalysts (entries 4−6), complex **2b** appears to be the one with the highest activity. On the other hand, the phosphanylimine palladium complex [PdMe(CH_3CN)(**P~N**)]BF_4 does not show this kind of activity.

Table 6. Results of copolymerization of ethylene/norbornene[a]

Entry	norbornene	Time (h)	M_N	PDI	Yield (mg)	N%[b]	T_g (°C)	TOF[c]
1	2.5	24	31000	1.41	1431	54.2	141.8	110
2[d]	5.0	48	20000	1.75	1114	61.9	130.2	43
3	5.0	48	34000	1.61	2378	49.8	144.3	92
4	5.0	24	35000	1.59	1772	55.5	126.6	137
5[e]	5.0	24	3600	1.87	538	64.0	154.5	45
6[f]	5.0	24	2900	1.44	108	59.7	122.4	8

[a] Ethylene/Norbornene (5 g) with **2b** (30 mg) as catalyst in toluene (20 mL) at 30 °C unless noted. [b] N%: mol percent of norbornene (by T_g method). [c] $g{\cdot}mol^{-1}{\cdot}h^{-1}$ [d] Reaction temperature at 50 °C. [e] **2a** as the catalyst. [f] **2c** as the catalyst.

In summary, a series of pyridinyliminophosphorane ligands with different steric influences was prepared and their methylpalladium complexes appear to be stable toward moisture. As for the reactivity toward insertion of CO and ethylene, complexes **2b**−**c** with a sterically hindered environment can stabilize the inserted intermediates, but not **2a**. As for catalysis, complex **2b** is a good candidate for the coplymerization of CO/norbornene and ethylene/norbornene.

Experimental Section

General Information: NMR spectra were recorded in $CDCl_3$ or [D_6]acetone on either a Bruker AC-E 200 or AM-300 spectrometer. Chemical shifts are given in parts per million relative to $SiMe_4$ for ^1H and ^{13}C NMR, and 85% H_3PO_4 for ^{31}P NMR spectroscopy. Due to the complication of the aromatic region, chemical shifts of non-aromatic carbons are reported. Infrared spectra were measured on a Nicolet Magna-IR 550 spectrometer (Series-II) as KBr pellets, unless otherwise noted. Gel permeation chromatography (GPC) data were obtained from a Waters Model 590 liquid chromatograph installed with a Lab Alliance RI 2000 detector using THF as eluent at room temperature and the polystyrene calibration curve for analyses. Differential scanning calorimetric (DSC) measurement was carried out on a TA 2920 system.

All reaction, manipulation and purification steps were performed under a dry nitrogen atmosphere. Tetrahydrofuran was distilled under nitrogen from sodium benzophenone ketyl. Dichloromethane and acetonitrile were dried with CaH_2 and distilled under nitrogen. Other chemicals and solvents were of analytical grade and were used as received unless otherwise stated. 2-Diphenylphosphanylpyridine was prepared by reacting lithium diphenylphosphide with 2-bromopyridine.[15] Phenyl azide and 2,6-dialkylphenyl azide were obtained by the diazotization of the corresponding aniline followed by the substitution of azide anion.[16]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

General Procedure for the Preparation of Ligands L_a–L_c: 2-Diphenylphosphanylpyridine (0.5 g, 1.9 mmol) and dichloromethane (15 mL) were placed in a degassed round-bottomed flask. A solution of aryl azide (1.9 mmol) was transferred into the above flask under nitrogen. Nitrogen gas was generated immediately and the resulting mixture was stirred for 2.5 h. After concentration, the desired ligands were obtained as moisture-sensitive, viscous liquids.

Ligand L_a: (0.65 g, 96%), ^{1}H NMR ($CDCl_3$): δ = 8.78 (d, J = 4.6 Hz, 1 H, py-H_6), 8.34 (dd, J = 7.1, 6.1 Hz, 1 H, py-H_4), 7.99–7.94 (m, 4 H, Ar-H), 7.78–7.76 (m, 1 H, py-H), 7.51–7.35 (m, 7 H, Ar-H, py-H), 7.07 (dd, J = 9.0, 8.4 Hz, 2 H, Ar-H), 6.90 (d, J = 8.4 Hz, 2 H, Ar-H), 6.71 (t, J = 9.0 Hz, 1 H, Ar-H) ppm. ^{13}C NMR: δ = 155.2 (d, $J_{C,P}$ = 130.0 Hz), 150.2 (d, $J_{C,P}$ = 19.1 Hz), 140.0, 136.2 (d, $J_{C,P}$ = 9.0 Hz), 133.0 (d, $J_{C,P}$ = 9.3 Hz), 131.7 (d, $J_{C,P}$ = 2.7 Hz), 130.8, 129.3 (d, $J_{C,P}$ = 19.8 Hz), 128.7, 128.5 (d, $J_{C,P}$ = 11.9 Hz), 125.1 (d, $J_{C,P}$ = 3.0 Hz), 123.4 (d, $J_{C,P}$ = 18.2 Hz), 117.4 ppm. ^{31}P NMR: δ = 14.8 ppm. HRMS (EI): calcd. for $C_{23}H_{19}N_2P$ m/z = 354.1286; found: 354.1277. $C_{23}H_{19}N_2P$ (354.38): calcd. C 77.95, H 5.40; found C 77.59, H 5.38.

Ligand L_b: (0.68 g, 93%), ^{1}H NMR ($CDCl_3$): δ = 8.75 (d, J = 4.8 Hz, 1 H, py-H_6), 8.38 (dd, J = 7.0, 6.2 Hz, 1 H, py-H_4), 7.80–7.75 (m, 5 H, Ar-H), 7.50–7.48 (m, 2 H, py-H), 7.43–7.36 (m, 5 H, Ar-H), 6.95–6.93 (d, J = 7.0 Hz, 2 H, Ar-H), 6.68 (t, J = 7.0 Hz, 1 H, Ar-H), 2.07 (s, 6 H, Ar-CH_3) ppm. ^{13}C NMR: δ = 157.2 (d, $J_{C,P}$ = 133.8 Hz), 149.8 (d, $J_{C,P}$ = 20.1 Hz), 146.6, 136.1 (d, $J_{C,P}$ = 8.9 Hz), 132.8 (d, $J_{C,P}$ = 6.4 Hz), 132.5 (d, $J_{C,P}$ = 9.2 Hz), 131.3 (d, $J_{C,P}$ = 2.3 Hz), 128.2 (d, $J_{C,P}$ = 12.0 Hz), 127.8, 128.5, 124.8, 123.3, 119.0, 21.4 ppm. ^{31}P NMR: δ = 16.5 ppm. HRMS calcd. for $C_{25}H_{23}N_2P$ m/z = 382.1599; found 382.1596. $C_{25}H_{23}N_2P$ (382.44): calcd. C 78.51, H 6.06; found C 78.22, H 5.79.

Ligand L_c: (0.91 g, 91%), ^{1}H NMR ($CDCl_3$): δ = 8.84 (d, J = 4.0 Hz, 1 H, py-H_6), 7.59–7.41 (m, 7 H, py-H, Ar-H), 7.24–7.17 (m, 6 H, py-H, Ar-H), 7.09–6.98 (m, 3 H, Ar-H), 3.40–3.33 (m, 2 H, -CH-), 1.41 (d, J = 6.9 Hz, 6 H, -CH_3), 1.09 (d, J = 6.7 Hz, 6 H, -CH_3) ppm. ^{13}C NMR: δ = 156.8 (d, $J_{C,P}$ = 132.3 Hz), 150.1 (d, $J_{C,P}$ = 20.0 Hz), 143.2 (d, $J_{C,P}$ = 4.9 Hz), 140.4, 136.2 (d, $J_{C,P}$ = 8.9 Hz), 134.4, 132.7 (d, $J_{C,P}$ = 9.1 Hz), 128.4 (d, $J_{C,P}$ = 11.9 Hz), 127.1, 125.1, 124.2, 123.2, 118.8, 29.0 (-CH-), 23.8 (-CH_3), 22.7 (-CH_3) ppm. ^{31}P NMR: δ = 15.6 ppm. HRMS calcd. for $C_{29}H_{31}N_2P$ m/z = 438.2225; found 438.2233. $C_{29}H_{31}N_2P$ (438.54): calcd. C 79.42, H 7.12; found C 79.02, H 6.89.

General Procedure for the Preparation of [L_XPdClMe] (1a–c): A mixture of [PdClMe(COD)] (0.5 g, 1.89 mmol) with an equimolar amount of ligand in dichloromethane (5 mL) was stirred at room temperature under a nitrogen atmosphere. After stirring for 3 h, the solvents were evaporated and the remaining material was dissolved in dichloromethane. Pre-dried diethyl ether was slowly added to the above solution to precipitate the desired complexes as yellow solids.

Complex 1a: (0.71 g, 74%). M.p. 180–196 °C (dec). ^{1}H NMR ($CDCl_3$): δ = 9.39 (d, J = 4.5 Hz, 1 H, py-H_6), 7.84–7.81 (m, 1 H, py-H), 7.76–7.64 (m, 6 H, py-H, Ar-H), 7.57–7.51 (m, 5 H, Ar-H), 7.36 (m, 1 H, py-H), 6.99–6.93 (m, 4 H, Ar-H), 6.80–6.76 (m, 1 H, Ar-H), 0.77 (s, 3 H, Pd-CH_3) ppm. ^{13}C NMR: δ = 153.8 (d, $J_{C,P}$ = 143.9 Hz), 151.0 (d, $J_{C,P}$ = 12.8 Hz), 145.9, 137.4 (d, $J_{C,P}$ = 10.2 Hz), 133.7 133.3, (d, $J_{C,P}$ = 10.3 Hz), 129.3 (d, $J_{C,P}$ = 11.2 Hz), 128.0, 127.2 (d, $J_{C,P}$ = 9.8 Hz), 126.9, 125.2, (d, $J_{C,P}$ = 9.2 Hz), 121.8, −3.0 (s, Pd-CH_3) ppm. ^{31}P NMR: δ = 26.56 ppm. $C_{24}H_{22}ClN_2PPd$ (511.29): calcd. General Procedure for the Synthesis of [L_XPd(COMe)(CH_3CN)]BF_4: Carbon monoxide was bubbled through an acetonitrile solution of [L_XPdMe(CH_3CN)]BF_4 (0.9 mmol) for 20 min. The resulting mixture was passed through celite and the filtrate was concentrated. The crude product was dissolved in dichloromethane and diethyl ether was added to precipitate the desired insertion products as yellow solids. These complexes readily decomposed due to decarbonylation.

Complex 5: A mixture of 2,6-dimethylphenyl azide (0.223 g) and 2-diphenylphosphanylpyridine (0.4 g) was placed in a degassed flask. Dichloromethane (25 mL) was introduced into the flask with a syringe under nitrogen atmosphere. The resulting mixture was stirred at room temperature for 2.5 h. [$PdCl_2$(COD)] (0.31 g) in dichloromethane was added to the above solution. The reaction mixture turned yellow immediately. After concentration to a small volume, diethyl ether was slowly added and the desired product precipitated. The latter was then re-crystallized from diethyl ether/dichloromethane to provide **5** as a yellow solid (765 mg, 90%). ^{1}H NMR ($CDCl_3$): δ = 8.74 (d, J = 4.4 Hz, 1 H, py-H_6), 8.38 (m, 1 H, Py-H_4), 7.84- 7.78 (m, 5 H, Ar-*H*), 7.64−7.62 (m, 2 H, py-H), 7.51−7.46 (m, 5 H, Ar-H), 6.91−6.88 (t, J = 7.4 Hz, 1 H), 6.81 (d, J = 7.4 Hz, 2 H), 2.15 (s, 6 H, -CH_3) ppm. ^{31}P NMR: δ = 28.42 ppm. HRFABMS: Calcd for $C_{25}H_{23}{}^{35}Cl_2N_2PPd$: m/z = 558.0011; found 558.0018. $C_{25}H_{23}Cl_2N_2PPd$ (559.76): calcd. C 53.64, H 4.14, N 5.00; found C 53.29, H 3.78, N 4.89.

Copolymerization of CO/Norbornene: The catalysts and norbornene were placed into a stainless-steel autoclave (100 mL) and dissolved in the solvent (20 mL). The reaction mixture was then pressurized with a mixture of CO and stirred at 30 °C. The reaction was stopped after the specified time and the resulting white solid was filtered and washed with 5 N HCl followed by water and acetone. The Results are listed in Table 5.

Copolymerization of Ethylene/Norbornene: The procedures for this coplymerization are similar to the ones of the copolymerization of CO/norbornene, except that ethylene is replaced by CO. The results are summarized in Table 6.

X-ray Crystallographic Study: Crystals suitable for X-ray determination were obtained for **1b**, **1c**, **2a**·CH_2Cl_2, and **5** by slow diffusion of diethyl ether into a dichloromethane solution at room temperature. The cell parameters were determined on a Siemens SMART CCD diffractometer. The crystal data for complexes **1b**, **1c**, **2a**·CH_2Cl_2 and **5** are listed in Table 2 and their ORTEP plots are shown in Figures 1−4 respectively (labels of phenyl groups are omitted for clear view).

CCDC-210737 (**1b**), -210739 (**1c**), -210738 (**2a**·CH_2Cl_2) and -210740 (**5**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge

Geometrical and Linkage Isomers of $[OsCl_2(dmso)_4]$ − The Complete Picture

Enzo Alessio,*[a] Barbara Serli,[a] Ennio Zangrando,[a] Mario Calligaris,[a] and Natalia S. Panina[b][‡]

Keywords: Density functional calculations / Dimethyl sulfoxide / Isomerizations / Osmium

The isomerisation between the three known isomers of the $[OsCl_2(dmso)_4]$ complex — *trans*-$[OsCl_2(dmso\text{-}S)_4]$ (**1**), *cis,fac*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ (**2**), and *cis*-$[OsCl_2(dmso\text{-}S)_4]$ (**3**) — has been investigated by NMR spectroscopy, X-ray crystallographic analysis, and DFT calculations. We show that the two dmso-linkage isomers **2** and **3** equilibrate slowly at room temperature in solutions of both dimethyl sulfoxide (DMSO) and light-protected chloroform. Although crystals of **2** precipitate from DMSO solutions, crystals of **3** were obtained from chloroform solutions. Compound **2** isomerises to **1** after exposure to sunlight, while **1** transforms into **2** in hot DMSO solution. The molecular energies were calculated by DFT methods, which show that in the gas phase there are small differences in the total energies (E_t), with **1** exhibiting the lowest energy, in contrast with its low population in solution. This result indicates that the stability of each isomer in solution is not simply determined by E_t, but that the solvent plays an important role. In fact, quantum chemical calculations for the isomerisation process **1** → **2** show a marked increase in the equilibrium constant with increasing the solvent polarity. The calculation of the metal–dmso binding energies, in combination with the X-ray data, shows a significantly higher strength of Os–S bonds with respect to Ru–S bonds, which explains the different behaviour of otherwise analogous osmium–dmso and ruthenium–dmso complexes.

Introduction

Neutral ruthenium(II) halide dimethyl sulfoxide complexes are widely used precursors in inorganic synthesis.[1] In addition, these complexes have anti-tumour[2] and radiosensitising[3] properties, as well as catalytic activity.[4]

Dimethyl sulfoxide (dmso) is an ambidentate ligand that can bind to metal centres either through the sulfur (dmso-*S*) or through the oxygen atom (dmso-*O*). The binding mode of dmso at the RuX_2 centre (X = Cl, Br) has been a matter of interest and debate since the characterisation of *cis,fac*-$[RuX_2(dmso\text{-}S)_3(dmso\text{-}O)]$ and the corresponding thermodynamically less stable geometrical/linkage isomers, *trans*-$[RuX_2(dmso\text{-}S)_4]$.[5−7] The structural and spectroscopic data for these four neutral species, together with those concerning the dinuclear compound $[Ru_2Cl_4(dmso\text{-}S)_5]$,[8] and the charged species [Y][*fac*-$RuCl_3(dmso\text{-}S)_3$] (Y = NH_2Me_2 or RR′NHOH),[9] [*fac*-$RuCl(dmso\text{-}O)_2(dmso\text{-}S)_3][BF_4]$,[10] and [*fac*-$Ru(dmso\text{-}O)_3(dmso\text{-}S)_3][BF_4]_2$,[10,11] have suggested that dmso prefers to bind to Ru^{II} through the sulfur atom for electronic reasons, and that the facial geometry of three dmso-*S* ligands seems to be a particularly stable binding motif. However, coordination of dmso through the sulfur atom is sterically more demanding, compared to coordination through the oxygen atom, and apparently the *fac*-$[Ru(dmso\text{-}S)_3]$ fragment allows coordination of further dmso ligands only through their oxygen atoms for steric reasons.[12] We have also shown that replacement of one dmso-*S* unit by a strongly π-accepting ligand, such as CO or NO, induces the S-to-O-linkage isomerisation of one or more of the remaining dmso units.[13,14] This behaviour was expected since dmso-*S* is a moderate π-acceptor ligand and, thus, it binds preferentially *trans* to pure σ donor ligands; when strong π-acceptors are present in the metal coordination sphere, dmso prefers to bind through its oxygen atom to avoid competition for π electrons.

The synthesis of *cis,fac*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ and of *trans*-$[OsCl_2(dmso\text{-}S)_4]$,[15] together with the X-ray crystallographic characterisation of *trans*-$[OsBr_2(dmso\text{-}S)_4]$,[16] were in perfect agreement with the previous reports on the analogous ruthenium species and suggested that Os^{II} behaves essentially as does Ru^{II}. This seemingly well-defined belief was shaken, however, in 1998 by McDonagh et al. who reported the X-ray structural characterisation of the unprecedented all-S-bonded isomer *cis*-$[OsCl_2(dmso\text{-}S)_4]$,[17] which showed that the two metal ions can behave quite differently.

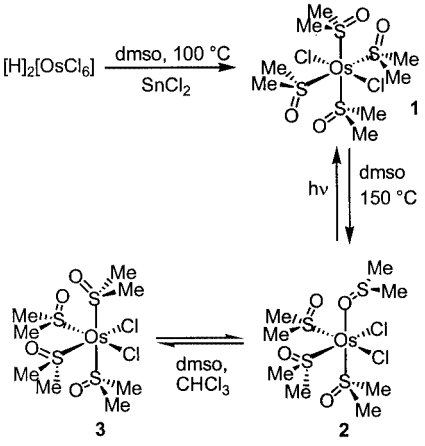
Here we report the results of a combined structural, spectroscopic and computational investigation of the three $[OsCl_2(dmso)_4]$ isomers that we undertook with the aim of gaining a better understanding of the system.

Results and Discussion

Solution Behaviour

The complex *trans*-$[OsCl_2(dmso\text{-}S)_4]$ (**1**) was prepared, as described by Antonov et al.,[15] by treatment of $H_2[OsCl_6]$ with $SnCl_2$ in DMSO at 100 °C (Scheme 1); complex **1** spontaneously precipitates from the hot reaction mixture. This compound was structurally and spectroscopically characterised by McDonagh et al.[17] We found, by NMR spectroscopy, that this isomer is quite stable in $CDCl_3$ solution at ambient temperature: the intensity of the resonance at $\delta = 3.44$ ppm, which accounts for the four equivalent dmso-S ligands, decreased very slowly over a period of days and the signal for free DMSO at $\delta = 2.62$ ppm increased correspondingly. No new resonance for coordinated dmso appeared as a consequence of dmso-*S* hydrolysis from **1**. A similar behaviour was found also in D_2O ($\delta = 3.47$ ppm for dmso-*S*). In contrast, the corresponding Ru^{II} isomer, which presumably binds dmso-*S* more weakly (see below), releases one dmso unit immediately upon dissolution in $CDCl_3$ and two *cis* dmso units upon dissolution in D_2O.[7a]



Scheme 1

As described by Antonov et al.,[15] when the above reaction was performed at higher temperature (150 °C), complete dissolution of the *trans* isomer **1** occurred and a white precipitate (**2**) formed from the DMSO solution after cooling to room temperature and addition of acetone (Scheme 1). The spectroscopic signature of this compound,[15] reported also by McDonagh et al.,[17] is typical of *cis*,*fac*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ (**2**); the presence of O-bonded dmso in **2** was established unequivocally by both NMR and IR spectroscopy. We monitored the isomerisation from **1** to **2** in hot DMSO by visible spectroscopy: at 90 °C the absorption band at 360 nm of the yellow isomer *trans*-$[OsCl_2(dmso\text{-}S)_4]$ (**1**) is completely replaced by that of the colourless *cis* isomer **2** (absorption maximum at 294 nm) within 8 h, with a clear isosbestic point at 282 nm. Recrystallisation of **2** from hot DMSO, followed by addition of acetone, yielded crystals of the same isomer, whose structure was determined by X-ray crystallography (see below). However, as described by McDonagh et al.,[17] crystallisation of **2** at room temperature from chloroform/diethyl ether mixtures yielded crystals that were found by X-ray crystallography to correspond to the all-S-bonded isomer, *cis*-$[OsCl_2(dmso\text{-}S)_4]$ (**3**). Thus, an isomerisation from **2** to **3** must occur in the chloroform solution, while this transformation was not observed in a DMSO solution (Scheme 1).

We found that two sets of resonances are present initially in the ^1H NMR spectrum of **2** in $CDCl_3$ (crystals from the batch used for the X-ray analysis): the major set contains four singlets of equal intensity and corresponds to **2** (dmso-*S* at $\delta = 3.57$, 3.54, and 3.43 ppm; dmso-*O* at $\delta = 2.76$ ppm), while the minor set contains only two equally intense singlets in the region of S-bonded dmso ($\delta = 3.66$ and 3.50 ppm) and corresponds to **3**. The signals of **2** are gradually replaced by those of **3**; equilibrium between the two isomers is reached after ca. 8 d at room temperature (light-protected solution); for longer observation periods (16 d) a very small signal for **1** was also apparent. The equilibrium concentrations of the three isomers correspond to ca. 66% of **3**, 33% of **2**, and less than 1% of **1**. The isomerisation is accompanied by partial hydrolysis of dmso (at equilibrium free DMSO accounts for 5% of the total DMSO) and by the growth of a new minor singlet in the region of S-bonded dmso at $\delta = 3.56$ ppm, which was not assigned. These results confirm the observations of McDonagh et al.[17] A similar behaviour was found to occur also in deuterated DMSO solution ($\delta = 3.41$, 3.38, 3.25, and 2.74 ppm for **2**; $\delta = 3.56$ and 3.40 ppm for **3**); in this case, however, the isomerisation of **2** into **3** could not be followed over a long period of time because of the concomitant exchange of coordinated dmso with the deuterated solvent that led to gradual disappearance of the signals. Thus, in both chloroform and DMSO solution, *cis*,*fac*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ (**2**) appears to be slightly thermodynamically less stable than *cis*-$[OsCl_2(dmso\text{-}S)_4]$ (**3**) and an equilibrium between the two isomers is established. While crystals of **2** were obtained from DMSO solutions, crystals of **3** were obtained from chloroform solutions.

Finally, as in the case of the corresponding Ru^{II} compounds,[7a] we found that exposure of **2** in solution to sunlight led to its isomerisation to the *trans* isomer **1**. This process was followed by visible spectroscopy in DMSO solution and by NMR spectroscopy in $CDCl_3$ solution.

X-ray Crystal Structure of *cis*,*fac*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ (2)

The results of the crystal structure determination show that *cis*,*fac*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ (**2**) (Figure 1) is isostructural with one of the three polymorphs (**F3**) isolated for the ruthenium analogue, *cis*,*fac*-$[RuCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$.[7a] The molecular geometry of this form differs from that detected in its other monoclinic (**F1**)[5] and orthorhom-

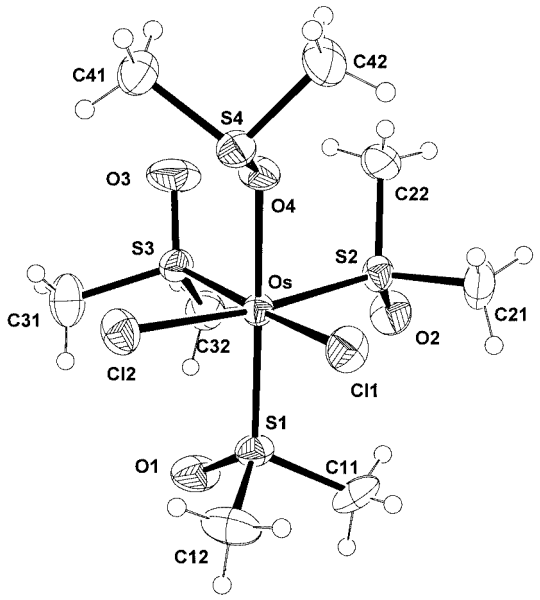

Figure 1. Molecular structure of the compound *cis,fac*-[$OsCl_2$(dmso-*S*)$_3$(dmso-*O*)] (**2**) (thermal ellipsoids drawn at a 40% probability level) with atom numbering scheme

bic (**F2**)[18] crystals, essentially by the different conformation assumed by the dmso-*S* groups upon rotation about the Ru−S bonds.[7a] Infrared spectra have shown that **F2** is the thermodynamically less stable rotamer, which transforms slowly in the solid state into **F3**, in agreement with Molecular Mechanics calculations suggesting that **F3** has the lowest molecular strain energy.[9b] The minimum-strain-energy structure is characterised by a skewed arrangement of the O and S planes of the three dmso-*S* groups (dihedral angle, $\alpha = 25.8°$) and by a *trans*−*trans* conformation of the dmso-*O* group (torsion angle Ru−O−S−C, ψ_1, in the range $-167° < \psi_1 < -90°$).[19] Owing to the similarities between the Os and Ru complexes, the experimental values of $\alpha = 24.2°$ and $\psi_1 = -121.5°$ in the osmium complex **2** suggest that the present molecular structure, found in the solid state, corresponds to the most stable rotamer for this isomer.

Comparison of the Os−S bond lengths in **2** (Table 1) with those of its isomers, *trans*-[$OsCl_2$(dmso-*S*)$_4$] (**1**) (Table 2)[20] and *cis*-[$OsCl_2$(dmso-*S*)$_4$] (**3**) (Table 3),[17] shows a lengthening of the Os−S bond lengths *trans* to S, with respect to those *trans* to Cl or O, as generally observed in metal (e.g., Ru, Rh, Pd, and Pt) sulfoxide complexes.[12,21] However, in **3** the Os−S distances, *trans* to S, are ca. 0.014 Å longer than those in **1**, probably because of stronger steric interactions. The steric demand of the four dmso-*S* groups in **3** is also indicated by the fact that the axial *trans* dmso-*S* groups are pushed away from the *cis* dmso-*S* groups, towards the less-bulky chloride ligands [av. S−Os−S angle, 93(2)°; av. Cl−Os−S angle, 87(2)°]. Similarly, in the equatorial plane, the S−Os−S and Cl−Os−Cl bond angles are 91.60(4)° and 85.42(4)°, respectively. In **1**, the bond angles between the *cis* ligands are restricted to 90°, with the four dmso-*S* groups strictly "interlocked", so that their oxygen atoms lie between the two methyl groups of the adjacent ligand. This arrangement suggests a marked reduction in flexibility on going from **2** and **3** to **1**. The greatest flexibility is to be expected in **2**, because the S→O isomerisation of one of the two *trans* dmso groups leads to a greater degree of rotational freedom.[22]

Finally, the Os−Cl and Os−O bond lengths in **2** are ca. 0.010 and 0.025 Å longer , respectively, than the corresponding distances in the Ru derivative, which is in agreement with the slightly larger covalent radius for the osmium atom. In contrast, we note that the Os−S distances are ca. 0.008 Å shorter than the corresponding Ru−S distances,

Table 1. Observed and calculated selected bond lengths [Å] and angles [°] for *cis,fac*-[$OsCl_2$(dmso-*S*)$_3$(dmso-*O*)] (**2**)

suggesting a strengthening of the metal-to-sulfur bonds in the osmium(II) complexes.

Gas-Phase Structures of the $[OsCl_2(dmso)_4]$ Isomers 1−3

Selected bond lengths and angles calculated for the three isomers **1**, **2**, and **3** are reported in Tables 1−3, respectively, together with the experimental values. Inspection of the tables shows a good agreement between experimental and calculated bond lengths, making allowance for an average systematic 2.3% overestimate of the calculated bond lengths. On the other hand, bond angles show both positive and negative deviations, with an average difference of −0.07°.

The calculated Mulliken atomic charges in the isomers of $[OsCl_2(dmso\text{-}S)_4]$ (Table 4) show that the highest dmso-to-O electron density transfers take place for the isomers with all-S-coordinated dmso ligands, **1** and **3**. In accordance with these effects, we observe the lowest electronic energy contribution (E_e, Table 5) to the total molecular energy (E_t) for **1** and **3**. Interestingly, for the isomer **3**, *cis*-$[OsCl_2(dmso\text{-}S)_4]$, we found the highest nuclear repulsion energy contributions (E_n), which likely reflects the steric repulsion effects.

Table 5. Total molecular energy (E_t) with its electronic (E_e) and nuclear repulsion (E_n) energy components for the three isomers of $[OsCl_2(dmso)_4]$, scaled with respect to isomer **1**

Isomer	E_e (a.u.)	E_n (a.u.)	E_t (a.u.)

2 *cis*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$	40.66623	−40.65683	0.00940
3 *cis*-$[OsCl_2(dmso\text{-}S)_4]$	−14.07069	14.07620	0.00551

Molecular Energies and Isomer Equilibration

The calculated molecular energies of 0.0, 24.7, and 14.4 kJ·mol^{-1}, for **1**, **2**, and **3**, respectively (Table 6), show that in the gas phase the isomer **1**, *trans*-$[OsCl_2(dmso\text{-}S)_4]$, exhibits the lowest energy. The molecular energy differences [$\Delta E_1 = E(\mathbf{2}) - E(\mathbf{1}) = 24.7$ kJ·mol^{-1}, $\Delta E_2 = E(\mathbf{3}) - E(\mathbf{2}) = -10.3$ kJ·mol^{-1}, $\Delta E_3 = E(\mathbf{3}) - E(\mathbf{1}) = 14.4$ kJ·mol^{-1}] are relatively small, yet they are indicative of a preference, in the isolated molecules, for all-S-bonded arrangements (**1** and **3**). On the other hand, a comparison with the experimental population ratios (**1/2/3** = 1:33:66) suggests that, in solution, solvent interactions lower the molecular energies of **2** and **3** with respect to **1**. In fact, the calculated values of ΔE_1 and ΔE_3 in $CHCl_3$ solution are 0.7 and 5.1 kJ·mol^{-1}, respectively, and −9.8 and 0.8 kJ·mol^{-1}, respectively, in DMSO (Table 7). Interestingly, the stabilisation of **2** and **3** relative to **1** increases with the increase in solvent polarity (from $CHCl_3$ to DMSO), paralleling the increase of the solvation energy, E_s (Table 7). The effect is particularly evident for **2**. We have to consider, however, that the equilibrium constant (K) between each pair of isomers is related to its free energy difference, according to the relationship $\ln K = -\Delta G/RT$, with $\Delta G = \Delta H - T\cdot\Delta S$. The term ΔE is only a part of ΔH, as shown by the equation $\Delta H = \Delta E + \Delta ZPE + \Delta H' + R\cdot T$, where ΔZPE is the difference in the zero-point vibration energy, and $\Delta H' = \Delta E_{vib} + \Delta E_{rot} + \Delta E_{trans}$ is the difference between the sums of the vibration, free rotation and translation energy contributions. In the present case, these additional terms can play an important role because of the small ΔE values. The values of ΔZPE, $\Delta H'$, and ΔS were calculated from the normal mode frequencies of the compounds, in the gas phase, on the basis

Table 4. Mulliken atomic electron charges, q [e], in the three isomers of $[OsCl_2(dmso)_4]$

Isomer	$q(Cl_1)$	$q(Cl_2)$	q(dmso-S_1)	q(dmso-S_2)	q(dmso-S_3)	q(dmso) [a]	q(Os)
1	−0.45	−0.45	0.45	0.45	0.45	0.45 ($-S_4$)	−0.90
2	−0.44	−0.44	0.30	0.39	0.39	0.24 (−O)	−0.44
3	−0.43	−0.43	0.47	0.40	0.40	0.47 ($-S_4$)	−0.88

of the DFT force field. From the data in Table 6 we obtained, for the isomerisation process **1** → **2**, ΔZPE = −7.6 kJ·mol^{-1}, $\Delta H'$ = 3.1 kJ·mol^{-1}, and ΔS = 35.3 J·mol^{-1}·K^{-1}, so that ΔG(298 K) = 9.7 kJ·mol^{-1} and K = 2.0·10^{-2}. For the isomerisation process **2** → **3**: ΔZPE = 7.3 kJ·mol^{-1}, $\Delta H'$ = −3.5 kJ·mol^{-1}, ΔS = −33.3 J·mol^{-1}·K^{-1}, ΔG(298 K) = 3.4 kJ·mol^{-1}, K = 2.5·10^{-1}; for the isomerisation process **1** → **3**: ΔZPE = −0.3 kJ·mol^{-1}, $\Delta H'$ = −0.4 kJ·mol^{-1}, ΔS = 2.0 J·mol^{-1}·K^{-1}, ΔG(298 K) = 13.1 kJ·mol^{-1}, K = 5.0·10^{-3}. The trend in the values of ΔS is consistent with that expected from the variation of the conformational entropy of each isomer pair. The highest value is calculated for the process **1** → **2**. In fact, in **2** there is the maximum degree of rotational freedom, while in **1** this rotation is strongly restricted because the four dmso-*S* groups are "blocked' in the equatorial plane (see the X-ray structure section above).

Table 6. Total molecular energy, E_t (kJ·mol^{-1}), in the gas phase, for the three isomers of [$OsCl_2$(dmso)$_4$], scaled with respect to isomer **1**. The zero-point vibration energy (ZPE, kJ·mol^{-1}), the sum of the vibration, free rotation, and translation energy contributions (H', kJ·mol^{-1}), and the entropy value (S, J·mol^{-1}), are also reported

Isomer		E_t (gas)	ZPE	H'	S
1	*trans*-$OsCl_2$(dmso-*S*)$_4$	0.0	877.0	77.6	731.8
2	*cis*-$OsCl_2$(dmso-*S*)$_3$(dmso-*O*)	24.7	869.4	80.7	767.1
3	*cis*-$OsCl_2$(dmso-*S*)$_4$	14.4	876.7	77.2	733.8

The above calculated equilibrium constants, however, which show a prevalence of isomer **1**, are not consistent with the experimental data (**1**/**2**/**3** = 1:33:66). Accounting for the solvation energy, E_s($CHCl_3$) (Table 7), in the calculations for the process **1** → **2**, leads to a lower value of ΔG(298 K) (−14.3 kJ·mol^{-1}), and a corresponding increase in the equilibrium constant to 3.2·10^2. In DMSO solution, because of the greater solvation energy, E_s(dmso) (Table 7), ΔG(298 K) = −24.8 kJ·mol^{-1}, with a further increase of the equilibrium constant (K = 2.2·10^4). For the process **2** → **3**, the corresponding values are ΔG(298 K) = 18.1 kJ·mol^{-1} and K = 6.6·10^{-4} in $CHCl_3$; in DMSO, ΔG(298 K) = 24.3 kJ·mol^{-1} and K = 5.4·10^{-5}. Thus, the calculations show that formation of isomers **2** and **3** is largely preferred, in chloroform and DMSO solutions, with respect to that of **1**. Complex **2** should prevail over **3**, however, for both entropy and solvent effects. In fact, to evaluate the equilibrium constants correctly, the terms ΔZPE, $\Delta H'$, and ΔS should be derived from the normal mode frequencies of the compounds calculated in solution, rather than in gas phase, which is a calculation that is somewhat problematic at present.

The different behaviour of the ruthenium analogue of **2**, *cis*-[$RuCl_2$(dmso-*S*)$_3$(dmso-*O*)], which does not isomerise to *cis*-[$RuCl_2$(dmso-*S*)$_4$], is likely related to the weaker metal−S bonds in the Ru complexes. In fact, the Os−S bond lengths are, on average, ca. 0.008 Å shorter than the corresponding Ru−S bond lengths. Furthermore, previous DFT calculations have shown that *cis*-[$RuCl_2$(dmso-*S*)$_4$] exhibits a molecular energy that is 56 kJ·mol^{-1} higher than that of *cis*-[$RuCl_2$(dmso-*S*)$_3$(dmso-*O*)],[24] while our present calculations show that in the corresponding Os derivatives this energy is 10.3 kJ·mol^{-1} lower.

The increased strength of the Os−S bonds relative to the Ru−S bonds, which is suggested by the trend of the bond lengths, is supported by the DFT calculations of the M−dmso binding energies, BE,[23] in the *cis*-MCl_2(dmso-*S*)$_3$(dmso-*O*) complexes, M = Ru and Os (Table 8). We note that all of the binding energies are higher in the Os derivative, but the energy differences are significantly larger for the M−S bonds [BE^S(Os) − BE^S(Ru) = 32.2 and 40.7 kJ·mol^{-1}, for dmso-*S*-*trans*-to-Cl and dmso-*S*-*trans*-to-O, respectively) than for the M−O bonds [BE^O(Os) − BE^O(Ru) = 11.6 kJ·mol^{-1}, for dmso-*O*-trans-to-S). Interestingly, in both the Ru and Os complexes, BE^S(dmso-*S*-*trans*-to-O) is larger than BE^S(dmso-*S*-*trans*-to-Cl), in agreement with the observed M−S1 distances (Os, 2.246 Å; Ru,[7a] 2.245 Å), which are significantly shorter than values of M−S2 and M−S3 (Figure 1) (Os, av. 2.270 Å; Ru,[7a] av. 2.279 Å).

Table 8. M−dmso binding energies, BE (kJ·mol^{-1}), for *cis*-[MCl_2(dmso-*S*)$_3$(dmso-*O*)]

M	dmso-*S* (*trans*-Cl)	dmso-*S* (*trans*-*O*)	dmso-*O* (*trans*-*S*)
Os	166.8	213.4	137.1
Ru	134.6	172.7	125.5

Conclusions

We have shown by NMR spectroscopy that at room temperature, both in light-protected $CDCl_3$ and [D_6]DMSO solutions, *cis*,*fac*-[$OsCl_2$(dmso-*S*)$_3$(dmso-O)] (**2**) equilibrates slowly with its linkage isomer, *cis*-[$OsCl_2$(dmso-*S*)$_4$] (**3**). For very long observation times in chloroform solution (16 d),

Table 7. Total molecular energy, E_t (kJ·mol^{-1}), in gas phase and in chloroform and DMSO solutions, for the three isomers of [$OsCl_2$(dmso)$_4$], scaled with respect to isomer **1**. The solvation energies of $CHCl_3$ and DMSO, E_s (kJ·mol^{-1}), are also reported

Isomer		E_t (gas)	E_t ($CHCl_3$)	E_s ($CHCl_3$)	E_t (DMSO)	E_s (DMSO)
1	*trans*-[$OsCl_2$(dmso-*S*)$_4$]	0.0	0.0	−63.6	0.0	−68.7
2	*cis*-[$OsCl_2$(dmso-*S*)$_3$(dmso-*O*)]	24.7	0.7	−87.6	−9.8	−103.2
3	*cis*-[$OsCl_2$(dmso-*S*)$_4$]	14.4	5.1	−72.9	0.8	−82.3

a small amount of *trans*-$[OsCl_2(dmso\text{-}S)_4]$ (**1**) is also formed, with the equilibrium population ratio of **1/2/3** = 1:33:66. Crystals of **2** were obtained from DMSO solutions, while crystals of **3** were obtained from chloroform solutions, most likely because of solubility effects. As previously found for the well-known ruthenium analogues, **2** isomerises to **1** upon exposure of its solution to sunlight. On the other hand, the ruthenium analogue of **3** has never been observed. We attribute such behaviour to the greater preference of osmium(II) for S-bonding, as shown by the trend of the metal−sulfur bond lengths and the calculated metal−dmso binding energies. The molecular energies, calculated in gas phase by the DFT B3LYP method, show small differences between the three osmium isomers, with the lowest energy being exhibited by **1**, whereas, in solution, this isomer is only a minor product. Quantum chemical calculations show that the solvent plays an important role in determining the isomer stability in solution, together with conformational entropy effects. In fact, when taking into account both of these factors, the populations of **2** and **3** largely exceed that of **1**. A quantitative analysis of the isomer distribution is limited by the possibility of calculating the normal mode frequencies only in the gas phase.

Experimental Section

The complexes *trans*-$[OsCl_2(dmso\text{-}S)_4]$ (**1**) and *cis*,*fac*-$[OsCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ (**2**) were prepared as described by Antonov et al.[15]

Materials: Chemicals, including $H_2OsCl_6{\cdot}6H_2O$ and deuterated solvents, were purchased from Aldrich and used as received. Electronic absorption spectra were recorded in quartz cells with a Jasco UV/Vis V500 spectrophotometer equipped with a Peltier thermostatic unit. Infrared spectra (KBr) were obtained on a Perkin−Elmer 2000 NIR FT-Raman spectrometer. ^1H and $^{13}C\{^1H\}$ NMR spectra were collected at room temperature at 400 and 100.5 MHz, respectively, on a Jeol Eclipse 400 FT spectrometer, with 2,2-dimethyl-2,2-silapentane-5-sulfonate (DSS) as an internal standard for D_2O solutions and the residual non-deuterated solvent signals as references for spectra in $[D_6]$DMSO (δ = 2.50 ppm) and $CDCl_3$ (δ = 7.26 ppm).

Crystallography: Data collection was carried out on a Nonius DIP-1030H system, equipped with graphite monochromator and Mo-K_α radiation (λ = 0.71073 Å). A total of 30 frames were collected, each with a rotation of 6° about , exposure time of 20 min, detector positioned at 80 mm from the crystal. Cell refinement and data reduction were carried out using the programs Mosflm and Scala.[25] The crystals were found to be isomorphous with those of the ruthenium analogue.[7a] The structure was solved, however, by conventional Fourier methods, using SHELXS-97,[26] to avoid any bias toward any of the possible rotational isomers.[7] Anisotropic refinement was carried out by the full-matrix least-squares method based on F^2 using SHELXL-97.[26] All calculations were performed using the WinGX system, Ver 1.64.03.[27] Crystal data and details of the refinement are listed in Table 9. Bond lengths and angles are given in Table 1.

CCDC-205611 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

DFT Calculations: The calculations of the electronic structures of the osmium complexes were carried out by means of the DFT B3LYP method with a 6-31G(d,p) basis for main group elements, and with the HW effective core potential (ncore = 60) for the Os atom,[28] using the GAMESS-2001 program set.[29] Solvation energies of the compounds in chloroform solutions were calculated on the basis of the polarised continuum model.[30] Starting coordinates for the geometry optimisation were derived from the X-ray structures. The terms Δ*ZPE*, Δ*H′*, and Δ*S*, used to evaluate the values of Δ*G*, were calculated from the normal-mode frequencies of the compounds, in the gas phase, on the basis of the DFT force field.[29]

Atom and dmso-group charges for the three isomers of $OsCl_2(dmso)_4$ are reported in Table 4. The scaled total molecular energies, with their electronic and nuclear repulsion components, are listed in Table 5. The scaled total molecular energies in the gas phase, together with zero-point vibration energies, the sum of the vibration, free rotation, and translation energy contributions, and entropy values, are reported in Table 6. A comparison of the molecular energies, in the gas phase and in chloroform and DMSO solutions, are given in Table 7, together with the $CHCl_3$ and DMSO solvation energies. Table 8 gives the binding energies of dmso to Os and Ru in the *cis*-$[MCl_2(dmso\text{-}S)_3(dmso\text{-}O)]$ complexes.

Polynuclear Nickel(II) Complexes: Preparation and Magnetic Properties of Ni^{II}_4, Ni^{II}_5, and Ni^{II}_6 Species with Ligands containing O∩X∩O (X = S, Se or N) Donor Atoms

Tapan K. Paine,[a] Eva Rentschler,[a] Thomas Weyhermüller,[a] and Phalguni Chaudhuri*[a]

Keywords: Magnetic properties / Nickel / Selenium / Sulfur / Tripodal ligands

A family of bisphenol-containing ligands with XO_2 donor atoms, where X = S, Se, or N, yields $[Ni^{II}]_4$ (**1**) and (**2**), $[Ni^{II}]_5$ (**3**), and $[Ni^{II}]_6$ (**4**) complexes. Complex **2**, **3**, and **4** have been structurally characterised by X-ray diffraction. The compounds were characterised spectroscopically and by variable-temperature (2–295 K), variable-field (1, 4, and 7 T) magnetic susceptibility measurements. Analysis of the magnetic data shows predominant ferromagnetic interactions between the nickel centres (S_{Ni} = 1) indicating "high-spin" ground states for **1**, **2**, and **3**, whereas complex **4** shows antiferromagnetic interactions. A plot of *J* vs. Ni–O–Ni angles for all structurally characterised Ni_4O_4 cubane cores, including **2**, irrespective of their symmetry, shows a large variation of *J* values within a small range of Ni–O–Ni angles. A simple two-*J* model was found to be adequate to describe the magnetic properties of the hexanuclear complex, **4**.

Introduction

There are several intriguing features associated with polynuclear transition metal complexes. Firstly, these complexes can have unusual electronic properties and may serve as sources of fundamental information about exchange coupling in multinuclear assemblies. A second general reason to study polynuclear metal complexes is that they may be building blocks for molecularly based magnetic materials. In another field of coordination chemistry, polynuclear complexes are important for the advancement of bioinorganic chemistry, both in their roles in advancing understanding of the chemistry of metallobiomolecules[1] and in the production of useful new biomimetic and bioinspired reactions. The magnetic molecular assemblies are therefore of interest for research areas as different as biochemistry and molecular magnetism.[2] These potential applications and issues have sparked and fuelled the interest of coordination chemists in synthesising molecules with large numbers of unpaired electrons in ground states. Consequently, the search for ligands capable of giving rise to molecules of high nuclearity is an important theme in modern coordination chemistry.

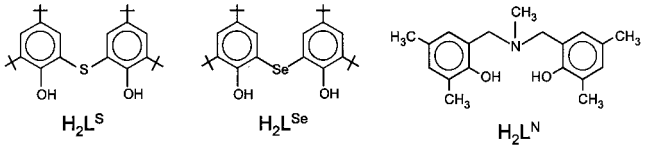
We have been exploring the feasibility of using phenol-containing ligands[3–6] to influence the nuclearity and topology of metal complexes. Since nickel(II) is known to have a large single-ion zero-field splitting and often gives rise to ferromagnetic coupling, we have especially focussed our attention on polynuclear nickel(II) complexes[7] with the aim of obtaining "high spin" species. Although polynuclear nickel(II) complexes containing up to four metal ions are not rare,[8–9] assemblies with five,[10] six,[11] and more[12] nickel(II) ions still remain a matter of curiosity. In this paper we report on the extension of our studies with the ligands containing the donor atoms (O, X, O), where X = S, Se, or N, and include the preparation and magnetochemical characterisation of

$[Ni^{II}_4L^S_2(\mu_3\text{-}OMe)_4(MeOH)_4(MeCN)_2]$ (**1**),
$[Ni^{II}_4L^{Se}_2(\mu_3\text{-}OMe)_4(MeOH)_4(MeCN)_2]$ (**2**),
$[Ni^{II}_5L^N_4(\mu_3\text{-}OH)_2(\mu_2\text{-}OH_2)_2(EtOH)_2]$ (**3**),

and

$[Ni^{II}_6L^N_4(\mu_2\text{-}OHMe)(\mu_3\text{-}OMe)_2(\mu_3\text{-}OH)_2(MeOH)_2(MeCN)_2]$ (**4**),

where H_2L^S is 2,2′-thiobis(4,6-di-*tert*-butylphenol), H_2L^{Se} is 2,2′-selenobis(4,6-di-*tert*-butylphenol), and H_2L^N is methylamino-*N*,*N*-bis(2-methylene-4,6-dimethylphenol).



H_2L^S H_2L^{Se} H_2L^N

Results and Discussion

Depending on the solvents and the bases used during the preparations, complexes **1**–**4** were isolated in good yields (Scheme 1). The sulfur- and selenium-containing ligands, H_2L^S and H_2L^{Se}, reacted with $NiCl_2{\cdot}6H_2O$ at room tem-

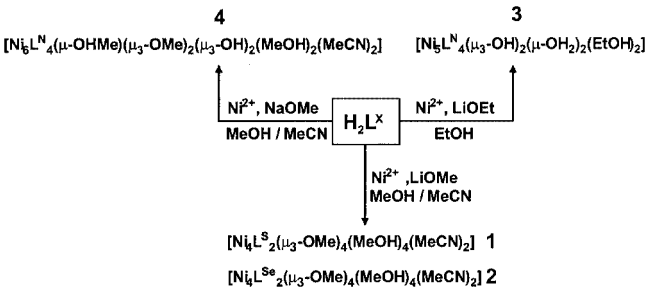

Scheme 1

perature in a solvent mixture (5:1) of methanol and acetonitrile containing $LiOCH_3$ as the base to deprotonate the phenolic −OH groups, from which complexes **1** and **2**, respectively, were isolated. On the other hand, treatment of the nitrogen-containing ligand H_2L^N with $NiCl_2{\cdot}6H_2O$ in ethanol in the presence of the base $LiOC_2H_5$ resulted in a yellow-green microcrystalline solid, which on subsequent recrystallisation from a solvent mixture (1:2) of CH_2Cl_2 and C_2H_5OH yielded pure pentanuclear material **3** in a good isolated yield of 75%. The incorporation of OH^- and H_2O in **3** presumably implies the involvement of water from the starting material. Interestingly, the isolation of the green **4**, a Ni^{II}_6 species, from a solvent mixture of methanol and acetonitrile was particularly sensitive to the use of dry solvents, although the starting material was a hydrated metal salt. This indicates that complex **4** appears in the reaction mixture only at water concentrations considerably lower than present in the case of complex **3**, and hence the absence of water as ligands in the final product **4**. That the isolated complexes **1**−**4** are thermodynamic products is shown by the reactions' insensitivity to the ligand/Ni^{II} ratios, which vary between 2:1 to 0.5:1.

Selected IR data for complexes **1**−**4** are given in the Exp. Sect. The sharp ν(OH) band around 3400 cm^{-1} for the free ligands is replaced by a broad band, indicating that the phenol character of the ligand has been lost on complexation. There are several strong bands in the 2960−2820 cm^{-1} region, due to the ν(C−H) stretchings of the *tert*-butyl groups. The weak bands in the 2300−2250 cm^{-1} region correspond to the ν(CN) vibrations of the CH_3CN molecule. The strong sharp band at 1047 cm^{-1} for both **1** and **2** is attributed to the ν(OCH_3) group of the bridging methoxide ligand.[19] The corresponding band at 1057 cm^{-1} for **4** appears as a medium band. The other ν(C−H), ν(C=C), and ν(C−O) vibrations are found in the normal ranges for these types of linkages.

Mass spectrometry in the EI and ESI mode has not proved to be a useful analytical tool for characterisation of the polynuclear Ni^{II} complexes **1**−**4**, presumably due to their decomposition at the temperatures applied in mass spectrometry.

Single-Crystal X-ray Diffraction Studies

The analytical, spectroscopic and magnetic data for **1** and **2** showed their isostructural characters, so X-ray analysis only of **2** was undertaken, to remove the doubts regarding connectivity.

Molecular Structure of 2

The crystal structure of **2** is shown in Figure 1, with selected bond lengths and angles provided in Table 1. The solid-state structure of **2**·3.5MeCN·0.5MeOH contains discrete

tetrameric molecules of formula $[Ni_4L^{Se}_2(\mu_3\text{-}OMe)_4(MeOH)_4(MeCN)_2]$, based on a Ni_4O_4 cubane-type unit and consisting of two interpenetrating tetrahedra: one of four nickel atoms and one of four μ_3-oxygen atoms originating from bridging methoxide groups. Each Ni^{II} is in a distorted octahedral environment and bound to three μ_3-OCH_3 ligands. For Ni(1) and Ni(2), two facially coordinated $O^{\cap}Se^{\cap}O$ donor sets of the deprotonated ligands $[L^{Se}]^{2-}$ complete the sixfold coordination. Each Ni(3) and Ni(4) is coordinated to three bridging methoxide oxygens and two terminal MeOH ligands. The sixth coordination site in each nickel centre is occupied by a N-atom of a terminal MeCN molecule. Although it was not possible to locate all the hydrogen atoms in the structure, the intramolecular contacts between the oxygen atoms of the methanol molecules and the oxygen atoms of the phenolate groups of the ancillary $[L^{Se}]^{2-}$ ligand − of ca. 2.70 Å [O(1)···O(63) 2.674 Å; O(2)···O(62) 2.718 Å; O(3)···O(60) 2.702 Å; O(4)···O(61) 2.720 Å] − can be interpreted as hydrogen bonds. The intramolecular hydrogen bonds have the effect of lowering the effective symmetry of the $[Ni_4(OMe)_4]$-core from T_d *to* D_{2d}.

A similar pattern of intramolecular hydrogen bonding and structural distortions have also been observed in other alkoxide cubane complexes containing Ni^{II} and bound alcohol. The Ni−O−Ni angles in **2** vary between 95.9(1) and 101.5(1)°. The Ni···Ni distances on different cubic faces are also different, the shortest being Ni(3)···Ni(2) 3.046(2) Å and the longest Ni(1)···Ni(2) 3.217(2) Å. Average Ni−O bond lengths of 2.045 Å (phenolate) and 2.075 Å (methoxide) lie well within the range of reported[4,8] values for the corresponding bond lengths of the tetranuclear cubane-like Ni^{II}. All phenyl rings of the ligands are planar and retain their aromaticity after complexation. No substantial differences in bond lengths and angles are found between the two crystallographically independent molecules.

Molecular Structure of 3

The molecular structure of **3** is shown in Figure 2. Selected interatomic distances and bond angles are listed in Table 2. The solid-state structure of $\mathbf{3}\cdot 0.75CH_2Cl_2$ contains discrete pentanuclear molecules of formula $[Ni_5L^N_4(\mu_3\text{-}OH)_2(\mu_2\text{-}OH_2)_2(EtOH)_2]$. The structure can be regarded as a corner-shared dicubane, in which one of the corners of each cubane is missing. The pentanuclear assembly is composed of a $Ni_2-Ni-Ni_2$ array; there is a virtually twofold axis passing through the central Ni(3). There are two different types of peripheral Ni atoms: the five-coordinate Ni(2) and Ni(5) with a NO_4 square-pyramidal environment and the six-coordinate Ni(1) and Ni(4) in a distorted octahedral NO_5 environment. The peripheral metal atoms, Ni(1), Ni(2), Ni(4), and Ni(5), are bound equatorially to the deprotonated ancillary ligand $[L^N]^{2-}$. Two μ_3-hydroxide ions [O(100) for Ni(2) and O(200) for Ni(5)] act as the axial donor atoms of the square pyramids. That the donor atoms O(101) and O(201) are constituents of water molecules is discernible from the Ni−O bond lengths. Furthermore, the hydrogen atoms of the water molecules and of hydroxy groups were located from a difference map and are shown as circles of arbitrary radii in Figure 2. Two ethanol molecules, O(300) and O(400), are bound as terminal ions to Ni(1) and Ni(4), respectively, *trans* to the μ_2-OH_2 ligands.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

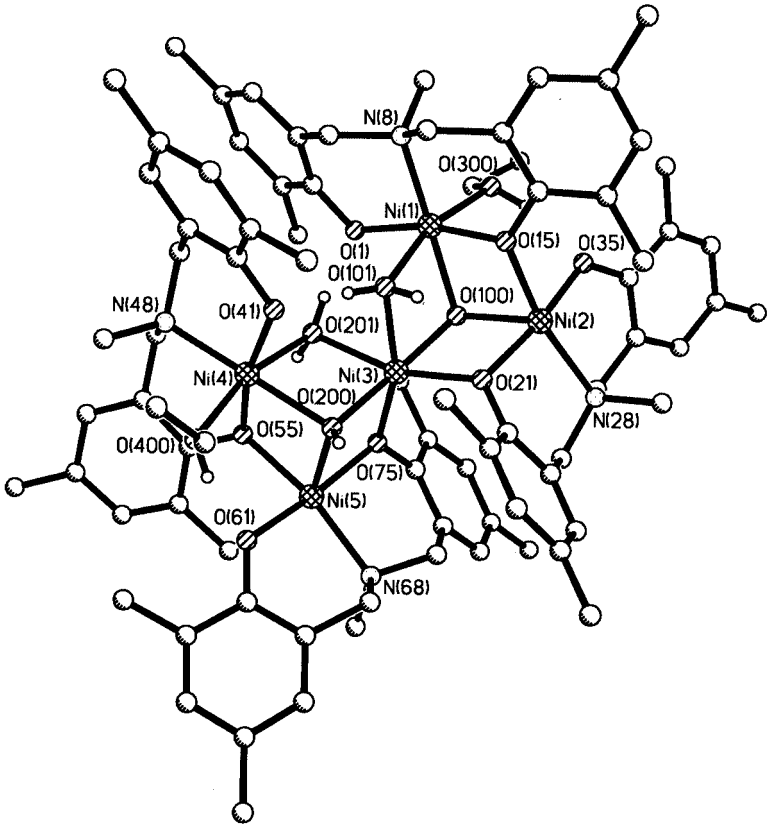

Figure 2. ORTEP representation of $[Ni_5L^N_4(\mu_3\text{-}OH)_2(\mu_2\text{-}OH_2)_2(EtOH)_2]$ (**3**)

The hydrogen atoms on the OH_2 and EtOH ligands enter into hydrogen bonding with the phenolate oxygens O(1), O(41), O(35) and O(61), with O(1)···O(201) 2.459 Å, O(41)···O(101) 2.448 Å, O(61)···O(400) 2.563 Å, and O(35)···O(300) 2.590 Å distances, thus presumably making the cluster unsusceptible to disruption. The central Ni(3) is six-coordinate, with oxygen donor atoms only. The long Ni···Ni distances (Table 2) exclude the possibility that the exchange coupling between the paramagnetic centres is transmitted directly through space. All Ni−O and Ni−N bond lengths are in conformity with the nickel ions in +II oxidation state.

Molecular Structure of 4

X-ray analysis reveals that **4** contains a Ni_6 unit and is best written as $[Ni_6L^N_4(\mu_2\text{-}OHMe)(\mu_3\text{-}OMe)_2(\mu_3\text{-}OH)_2(MeOH)_2(MeCN)_2]$, as shown in Figure 3(a). Figure 3(b) highlights the central hexanuclear core with the atom connectivity in the coordination sphere. Selected metrical parameters are given in Table 3. The structure of the Ni_6-cluster can be regarded as a face-shared distorted dicubane in which one of the corners of each cubane is missing. There is a twofold crystallographic axis passing through an oxygen atom (O60) of the bridging μ_2-methanol molecule. The nickel centres Ni(1) and Ni(1)# are five-coordinate, whereas Ni(2), Ni(3) and their symmetry related nickel centres are six-coordinate. Five-coordinated nickel centres possess square-pyramidal NO_4 geometries, with O(70) of the μ_3-OMe group as the axial ligand, whereas the six-coordinate nickel centres have NO_5 environments. The ancillary ligand $[L^N]^{2-}$, O(15), N(8) and O(1), together with the phenolate oxygen O(70) (which is a μ_2-bridging ligand) from a second ligand $[L^N]^{2-}$, form the equatorial plane for the five-coordinate Ni(1). The six-coordinate Ni(2) is bound to two μ_3-OH (O10 and O60), one μ_3-OMe (O70), one μ_2-OHMe (O60), one μ_2-phenolate (O1) and an acetonitrile (N50) ligand. On the other hand, Ni(3) is triply coordinated to the ligand $[L^N]^{2-}$ along with its monocoordination to a methanol (O80), a μ_3-hydroxide and a μ_3-methoxide group.

Magnetic Susceptibility Studies

Magnetic susceptibility data for polycrystalline samples of complexes **1**−**4** were collected in the 2−290 K temperature range in an applied magnetic field of 1 T to characterise the nature and magnitude of the exchange interaction propagated by the bridging ligands. We use the Heisenberg spin-Hamiltonian in the form $\hat{H} = -2J\,\hat{S}_A\cdot\hat{S}_B$ for an isotropic exchange coupling with $S_{Ni} = 1$ for **1**−**4**. The experimentally measured magnetic data were simulated by use of a least-squares fitting computer program[13] with a full-matrix diagonalisation of exchange coupling, Zeeman splitting, and axial single-ion zero-field interactions (DS^2_z), if necessary. The susceptibility data were corrected for diamagnetism (Pascal corrections). No temperature-independent paramagnetism (TIP) or paramagnetic impurities (PI) were used for the simulations. The experimental data are displayed in Figure 4 as the effective magnetic moment (μ_{eff})

versus temperature (T). The solid lines in the figure represent the simulations.

The magnetic moment μ_{eff}/molecule for **1** and **2** of 6.54 μ_B ($\chi_M{\cdot}T$ = 5.332 $cm^3{\cdot}K{\cdot}mol^{-1}$) and 6.52 μ_B ($\chi_M{\cdot}T$ = 5.233 $cm^3{\cdot}K{\cdot}mol^{-1}$), respectively, at 290 K increases monotonically with decreasing temperature, reaching a maximum at 20 K with μ_{eff} = 7.54 μ_B ($\chi_M{\cdot}T$ = 7.115 $cm^3{\cdot}K{\cdot}mol^{-1}$) for **1** and μ_{eff} = 7.15 μ_B ($\chi_M{\cdot}T$ = 6.444 $cm^3{\cdot}K{\cdot}mol^{-1}$) for **2**. Below 20 K, μ_{eff} starts to decrease, reaching a value of 6.01 μ_B ($\chi_M{\cdot}T$ = 4.60 $cm^3{\cdot}K{\cdot}mol^{-1}$) for **1** and 4.68 μ_B ($\chi_M{\cdot}T$ = 3.525 $cm^3{\cdot}K{\cdot}mol^{-1}$) for **2** at 2 K (Figure 4); it is clear that the magnetic properties of **1** and **2** are dominated by a ferromagnetic exchange interaction between four $^3A_2$ nickel(II) ions as propagated by bridging methoxides. The structural parameters of **2** strongly suggest a lower symmetry than T_d (idealised D_{2d}) for the molecule. We have assumed the same symmetry for **1**.

The most important parameter in the magnetostructural correlation of the Ni_4O_4 cubane cores has been reported in the literature[4,9i,9h,9l,9p] to be the averaged Ni−O−Ni angle of a cubane face. In accordance with the three averaged Ni−O−Ni angles of 96.2°, 97.2°, and 101.3° observed for **2**, a three-J model based on the diagram shown in Scheme 2 was used to analyse the magnetic data for **1** and **2**.

Very good fits were obtained by use of this model, the best fit parameter sets being J_1 = +2.39 cm^{-1}, J_2 = −5.77 cm^{-1}, J_3 = +6.9 cm^{-1}, g = 2.27 for **1** and J_1 = +1.05 cm^{-1}, J_2 = −4.1 cm^{-1}, J_3 = +5.5 cm^{-1}, g = 2.25 for **2**. No zero-field splitting parameter D, TIP, or PI was needed to obtain the good quality of fit shown in Figure 4 as solid lines. The differences and natures of the signs of the exchange parameters are in full agreement with the Ni−O−Ni angle correlation and support the three-J model used, which takes account of the reduced symmetry of the cubane core observed in the X-ray structure of **2**. These results for **1** and **2** thus predict a switch from ferromagnetic to antiferromagnetic coupling only for Ni−O−Ni angles above ca. 98°, as also observed by us earlier.[4] We have also plotted the observed J values for **2** and other structurally characterised $[Ni_4(OR)_4]^{4+}$ cubanes against average Ni−O−Ni angles (Figure 5 and Table 4). The solid line in Figure 5, shown only as a guide for the eyes, allows us to see that the antiferromagnetic interactions ($-J$) fall fairly well on the correlated line with respect to Ni−O−Ni angles. In contrast, the positive J values scatter appreciably.

The magnetic data indicate that **1** and **2** have complicated, low-lying magnetic structures with non-diamagnetic ground states smaller than the spin state S_t = 4 expected for a ferromagnetically coupled tetranuclear nickel(II) species (S_{Ni} = 1). We have performed magnetisation measurements at applied magnetic fields of 1, 4, and 7 T and collected most of the magnetisation data in the 2−10 K temperature range (26 data point) and only 7 data points in the 12.3−260.0 K range, which are shown in Figure 6 as plots of M/Ngβ vs. βH/kT for **1** and **2**. It is clear from Figure 6 that the saturated magnetisation value reaches a value of approximately 3.45 for **1** and 3.10 for **2** in the 2.0−2.8 K temperature range at the highest field of 7 T. Noteworthy is

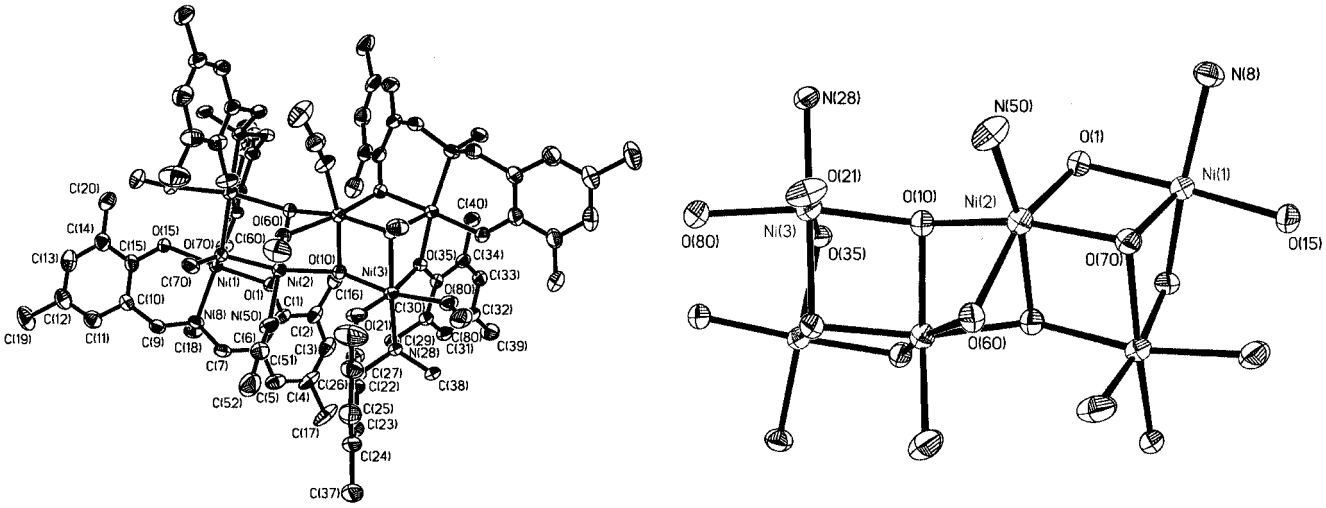

Figure 3. (a) Molecular structure of $[Ni_6L^N{}_4(\mu_2\text{-OHMe})(\mu_3\text{-OMe})_2(\mu_3\text{-OH})_2(MeOH)_2(MeCN)_2]$ (**4**); (b) a view of **4** highlighting the coordination spheres of the hexanuclear nickel core

a downward tendency of magnetisation at low temperatures and low fields, presumably due to the population of the lower component of the multiplet split in the magnetic fields.

The nature of the field dependence of the susceptibility in the present system is extreme. The first-order Zeeman splitting of the ground state $S = 4$ results in nine separate energy levels. Thus, in the absence of zero-field splittings, the energy span of the ground state is $8g\beta H$, so that at 1 T the ground state Zeeman levels span several wave numbers. It is not possible to calculate the ground state in the form of an S_t value; S is not a good quantum number to describe the ground state, but rather M_S. However, the magnetic analysis of **1** and **2** unambiguously demonstrates the overall ferromagnetic nature of the exchange interactions yielding "high-spin" ground states of $S_t > 3.0$.

The plot of μ_{eff} vs. T (Figure 4) for **3** shows the exchange coupling within the pentanuclear Ni^{II} complex to be predominantly ferromagnetic in nature. The effective magnetic moment μ_{eff} shows a maximum value of 8.52 μ_B ($\chi_M{\cdot}T$ = 9.079 $cm^3{\cdot}K{\cdot}mol^{-1}$) at 15 K and then decreases with decreasing temperature, reaching a value of 7.98 μ_B ($\chi_M{\cdot}T$ = 7.96 $cm^3{\cdot}K{\cdot}mol^{-1}$) at 5 K. The maximum μ_{eff} value of 8.52 μ_B clearly shows that both the five- and the six-coordinate nickel centres present in **3** are paramagnetic with $S_{Ni} = 1$. The maximum value of 8.52 μ_B is significantly smaller than the spin-only value of 10.95 μ_B expected for five ferromagnetically coupled Ni^{II} ions. The data were fitted by use of a two-J model based on the model shown in Scheme 3, as two different ranges of Ni−O−Ni angles of 94−96° and 100−103° prevail in **3**.

The spin-Hamiltonian used is

$$\hat{H} = -2J(\hat{S}_1{\cdot}\hat{S}_2 + \hat{S}_2{\cdot}\hat{S}_3 + \hat{S}_4{\cdot}\hat{S}_5 + \hat{S}_3{\cdot}\hat{S}_5) - 2J'(\hat{S}_1{\cdot}\hat{S}_3 + \hat{S}_3{\cdot}\hat{S}_4).$$

The best fit obtained with the parameter set $J' = +6.5$ cm^{-1}, $J = -0.24$ cm^{-1}, $g = 2.32$ is shown as a solid line in Figure 4. No zero-field splitting parameter D, TIP or PI was used to obtain the good quality of fit shown in Figure 4, suggesting that any zero-field splitting effects are small. As the value of J is very small, we checked its influence on the quality of the simulation by keeping $J = 0$ (fixed). The good quality of the simulation shown in Figure 4 could not be reproduced, indicating the importance, albeit very small, of J for the fit procedure. The spin ladder calculated by the evaluated exchange parameters exhibits clearly that the energy separation between low-lying states is very small (< 1 cm^{-1}), yielding an intermixing of the two states with $S_t = 4$ and $S_t = 5$. This is also corroborated with the magnetisation measurements at 1, 4, and 7 T, shown in Figure 6. The saturation behaviour observed at 7 T with a magnetisation value of ca. 4.5 unambiguously shows the dominant nature of the ferromagnetic coupling within the pentanuclear cluster, the nature of which is a mixture of $S_t = 4$ and $S_t = 5$ states.

Variable-temperature magnetic data for **4** (Figure 4) exhibit a steady decrease of μ_{eff} from 7.65 μ_B ($\chi_M{\cdot}T$ = 7.308 $cm^3{\cdot}K{\cdot}mol^{-1}$) at 290 K to 2.90 μ_B ($\chi_M{\cdot}T$ = 1.047 $cm^3{\cdot}K{\cdot}mol^{-1}$) at 2 K, which is indicative of an overall antiferromagnetic interaction within the hexanuclear nickel(II) complex **4**. That all five- and six-coordinate nickel(II) centres are paramagnetic with $S_{Ni} = 1$ is clearly attested to by the observed magnetic moment of μ_{eff} = 7.65 μ_B at 290 K. In accordance with the structural parameters, a three-J model, shown in Scheme 4, can be envisaged for the analysis of magnetic data.

The data were initially fit by use of g (fixed), J, J', and J'', which yielded a good fit (not shown) with $J = -1.16$ cm^{-1}, $J' = -9.11$ cm^{-1}, $J'' = -6.13$ cm^{-1}, $g = 2.269$ (fixed). To avoid overparametrisation, we did not use the zero-field splitting parameter D for the simulations. The above solution was discarded, as the Ni−O−Ni angles related to J'' are smaller than 90° and a small ferromagnetic coupling could be expected for the path. This suggested that a better fitting model should be used, so we again fitted the

data with use of three different exchange parameters, but with the following constraints: g, J, and J' free for reiteration but J'' fixed between zero and a small positive value of +2.0. The quality of fit became poor, but the exchange values vary negligibly between −1.79 and −1.95 cm^{-1} for J and between −9.0 and −8.93 cm^{-1} for J', indicating that although J'' has some influence on the quality of fit, J and J' are nearly independent of J''. We therefore started another simulation, making all four parameters free to move. The quality of fit increased dramatically, yielding the following parameters: $g = 2.295$, $J = -1.15$ cm^{-1}, $J' = -9.87$ cm^{-1}, and $J'' = -9.66$ cm^{-1}. As the evaluated values for J' and J'' are nearly the same, we carried out the magnetic analysis with the constraint $J' = J''$ (i.e., a two-J model to reduce the number of fit parameters). A very good fit obtained with the parameter set $g = 2.295$, $J = -1.12$ cm^{-1} and $J' = J'' = -9.77$ cm^{-1} is shown as a solid line in Figure 4. We note that the sign of the exchange parameter J'' is not in line with the commonly accepted Ni−O−Ni angle correlation; this might be due to three different competitive exchange couplings operating on Ni(2) and Ni(2)* making the correlation more complex. Irrespective of that, the two-J model suitably describes the magnetic properties of complex **4**, which does not possess a well separated ground state of $S_t = 0$, as would be expected for an antiferromagnetically coupled hexanuclear Ni^{II} complex; the excited state of $S_t = 1$ is energetically very close to the ground state, and so a non-zero magnetic moment is observed even at 2 K. This is also corroborated by the variable-temperature magnetisation curves at 1, 4, and 7 T (Figure 6).

Concluding Remarks

The tridentate bisphenol ligands used in this work give rise to polynuclear nickel(II) complexes of different nuclearity: four, five or six, depending on the heterodonor atoms such as S, Se, or N. The S- and Se-containing ligands H_2L^S and H_2L^{Se} coordinate facially with five-membered chelation to a metal centre, whereas the N-containing ligand H_2L^N forms six-membered chelate rings and, presumably as a consequence of the ring size, the ligand H_2L^N coordinates meridionally. This different geometrical coordination mode seems to yield tetranuclear complexes with H_2L^S and H_2L^{Se}, but H_2L^N results in penta- and hexanuclear complexes. Thus, our starting goal of preparing polynuclear complexes with ferromagnetic exchange coupling has been partly achieved, although the hexanuclear nickel(II) complex does not belong to the class of molecules with large spin ground states.

Complexes **1** and **2** exhibit overall ferromagnetic interactions, producing ground states with "large spins". The *J* values obtained here are similar to those found for other $[Ni_4(\mu_3\text{-}OR)_4]^{4+}$ cubanes reported in the literature[9] (Table 4). The coupling between the nickel(II) ions is very close to the crossover point between antiferromagnetic and ferromagnetic coupling. In all cases, bond angles of less than ca. 98° produce ferromagnetic coupling, whilst those that are larger give rise to antiferromagnetic coupling. This correlation is similar to that in the bridged Cu−O−Cu systems,[14] in which ferromagnetic pathways of the form[15] $e_g \perp O \perp e_g$ are found to be most effective for Cu−O−Cu angles smaller than 97.5°.

Complex **2** contains the low-symmetry cubane core $[Ni_4(\mu_3\text{-methoxide})_4]^{4+}$ with differing Ni···Ni distances and Ni−O−Ni angles, resulting in three types of Ni_2O_2 faces. The observation of three discrete exchange parameters for **2** is consistent with the lower symmetry of the cubane; the symmetry of **2** is lower than that in the majority of the nickel-cubanes reported in the literature. Figure 5 shows a plot of *J* vs. Ni−O−Ni angles for all structurally characterised Ni_4O_4 cubane cores, irrespective of their symmetry; it exhibits a large variation of *J* values within a small span of Ni−O−Ni angles (90−103°). This figure also indicates that

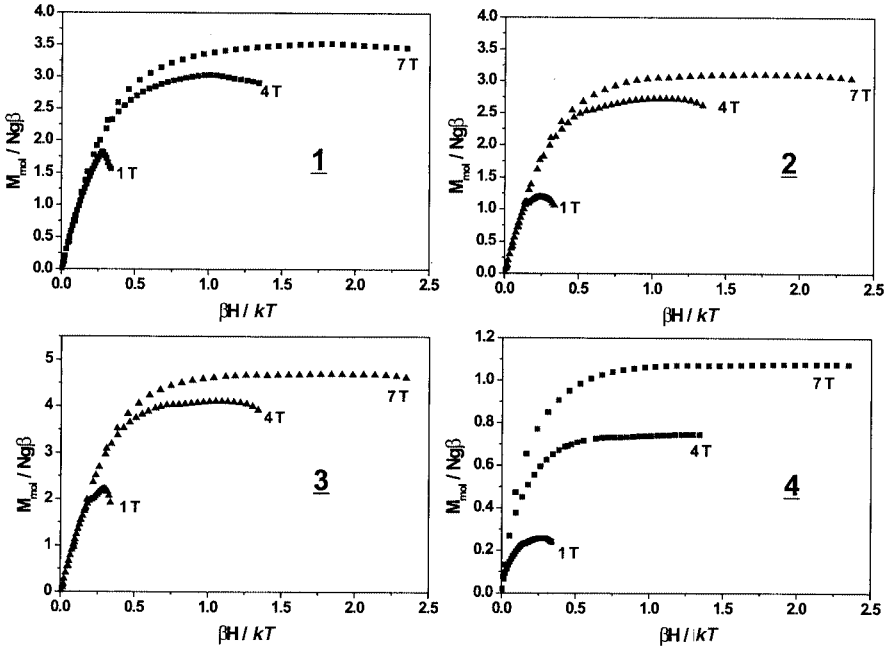

Figure 6. The field-dependent magnetisations of **1**−**4** as a function of temperature

the symmetry of the cubane core has a profound effect on the magnetostructural correlation. In particular, the scattering of the positive J values is noteworthy. This is not surprising in view of the high tolerance attached in general to the positive J values (ferromagnetic interactions) evaluated through simulation of the susceptibility data. The syn-

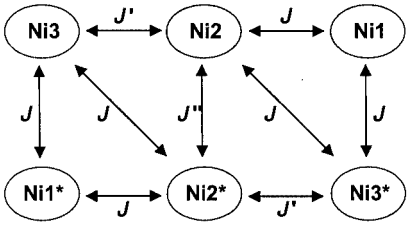

Scheme 4

thesis of more such distorted cubane-type Ni^{II} complexes would therefore be warranted in order to resolve this problem of magnetostructural correlation.

In the literature, there are only two examples of pentanuclear Ni^{II} complexes in which all five metal centres are paramagnetic with $S_{Ni} = 1$. The first example, $[Ni_5(en)_4(\mu_3\text{-}OH)_2(NO_2)_8]$,[10g] reported as early as 1981, contains a planar, pentameric arrangement of nickel(II) ions, linked by bridging hydroxide and nitrite ligands; unfortunately no magnetic data were reported. In the second example,[10a] four six-coordinate Ni^{II} ions are arranged at the apices of a tetrahedron with the fifth nickel at the centre; the compound is antiferromagnetically coupled with an admixed ground state of $S_t = 0, 1$. *Complex* **3** *constitutes the first example of a pentanuclear* Ni^{II} *complex exhibiting ferromagnetic interactions with an intermixed ground state of* $S_t = 5.0$ *and 4.0.* Pentanuclear nickel(II) complexes with five $S_{Ni} = 1$ centres still belong to the rare examples of coordination complexes.

An apparently trivial modification of the reaction, use of a mixed solvent medium, resulted in the isolation of complex **4**, a hexanuclear Ni^{II} complex, under reaction conditions otherwise the same as those used for complex **3**. The amount of water present in the reaction mixture is decisive for the isolation of complex **4**. The central nickel centres, Ni(2) and Ni(2)#, are primarily devoid of coordination to the ancillary ligand $[L^N]^{2-}$. In complex **4**, and also in **3**, the ligand $[L^N]^{2-}$ also for the first time shows the bridging functionality through one of its phenolate oxygens. The magnetic studies exhibiting predominantly antiferromagnetic exchange between the metal centres are disappointing in view of the original expectation of large-spin ground states. A simple two-*J* model shows good agreement with experimentally ascertained low-temperature magnetic data. The sign of an exchange coupling parameter J'' (-9.77 cm^{-1}) cannot be correlated with the corresponding Ni−O−Ni angles, which are appreciably smaller than 90°.

Experimental Section

Materials and Physical Measurements: Commercial grade chemicals were used for synthetic purposes, and solvents were distilled and dried before use. Fourier transform infrared spectroscopy on KBr pellets was performed on a Perkin−Elmer 2000 FT-IR instrument. Solution electronic spectra were measured on a Perkin−Elmer Lambda 19 spectrophotometer. Mass spectra were recorded either in the EI or the ESI (in CH_2Cl_2) modes with a Finnigan MAT 95 or 8200 spectrometer. Magnetic susceptibilities of the polycrystalline samples were recorded on a SQUID magnetometer (MPMS, Quantum Design) in the 2−290 K temperature range, with an applied field of 1 T. Diamagnetic contributions were estimated for each compound by use of Pascal's constants.

X-ray Crystallographic Data Collection and Refinement of the Structures: Single crystals of **2**, **3**, and **4** were coated with perfluoropolyether, picked up with glass fibres, and mounted on a Nonius Kappa-CCD diffractometer equipped with a cryogenic nitrogen cold stream operating at 100(2) K. Graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) was used. Intensity data were corrected for Lorentz and polarisation effects. The intensity data set of **2** and **3**, were corrected for absorption by use of the program Gaussian face-indexed, whereas that of **4** was not corrected. The Siemens SHELXTL software package (G. M. Sheldrick, Universität Göttingen) was used for solution, refinement, and depiction of the structure, and neutral atom scattering factors of the program were used. All structures were solved and refined by direct methods and difference Fourier techniques. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters. Details of the data collection and structure refinements are summarised in Table 5.

CCDC-204445 (**2**), -204446 (**3**), and -204447 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Ligand Synthesis: The ligands H_2L^S [16] and H_2L^N [3,17] were synthesised by the published procedures. The ligand H_2L^{Se} was synthesised by a modification of the method described in the literature.[18]

2,2′-Selenobis(4,6-di-*tert*-butylphenol) (H_2L^{Se}): A suspension of 2,4-di-*tert*-butylphenol (61.89 g, 0.3 mol) and SeO_2 (11.1 g, 0.1 mol) in conc. HCl (55 mL) was heated at 80 °C with constant stirring for 2 h. The mixture was then cooled, extracted with $CHCl_3$ (3×100 mL), washed with brine solution (2×50 mL) and then with water (100 mL), dried with Na_2SO_4 and concentrated in vacuo. The crude brown product was then recrystallised from heptane and MeOH (1:1) to obtain a pure white compound. Yield: 18.5 g (25%). Melting Point: 141 °C. $C_{28}H_{42}SeO_2$ (489.6 g/mol): calcd. C 68.69, H 8.65; found C, 68.7, H 8.7%. ^{1}H NMR ($CDCl_3$): δ = 1.20 (s, 18 H); 1.38 (s, 18 H); 6.25 (s, OH, 2 H); 7.24 (m, 4 H) ppm. ^{13}C NMR ($CDCl_3$): δ = 29.5 (s, *tert*-butyl); 31.6 (s, *tert*-butyl); 34.3 (s, *tert*-butyl); 35.2 (s, *tert*-butyl); 117.0 (s), 125.4 (s); 129.6 (s); 135.7 (s); 143.3 (s), and 151.6 (s) ppm. MS (EI): The desired molecular ion ($M^+ = 490$) was observed in the ratio calculated for the naturally abundant isotope mixture of Se-74, 76, 77, 80, and 82.

General Method of Synthesis for Complexes 1 and 2: The ligand (1 mmol) was dissolved in a mixture of MeOH (12.5 mL) and

MeCN (2.5 mL). LiOMe (1 M methanolic solution, 2 mL, 2 mmol) was added, and the solution was stirred for 5 min. $NiCl_2\cdot 6H_2O$ (0.24 g, 1 mol) was added to that yellow solution, and the resulting green solution was stirred for 5 min and then kept for slow evaporation of solvent under air. A green crystalline compound separated overnight.

$[Ni_4L^{S}_2(\mu\text{-}OMe)_4(MeOH)_4(MeCN)_2]$ (1): Yield: 0.42 g (58%). $C_{68}H_{114}S_2O_{12}Ni_4N_2$ (1450.54): calcd. C 56.31, H 7.92, S 4.42, N 1.93, Ni 16.18; found C 55.7, H 7.9, S 4.3, N 2.0, Ni 15.7%. IR: $\tilde{\nu}$ = 3423 cm^{-1} (br), 2957−2818 (s), 2315−2253, 1432 (s), 1298 (s), 1047 (s), 829, 731.

$[Ni_4L^{Se}_2(\mu\text{-}OMe)_4(MeOH)_4(MeCN)_2]$ (2): Yield: 0.34 g (44%). $C_{68}H_{114}Se_2O_{12}Ni_4N_2$ (1544.34): calcd. C 52.89, H 7.44, Ni 15.20; found C 49.6, H 7.3, Ni 14.9%. IR: $\tilde{\nu}$ = 3404 cm^{-1} (br), 2954−2821 (s), 2315−2253, 1429 (s), 12989 (s), 1047 (s), 828, 724.

$[Ni_5L^{N}_4(\mu_3\text{-}OH)_2(\mu\text{-}H_2O)_2(EtOH)_2]\cdot 0.75CH_2Cl_2$ (3): The ligand (1 mmol, 0.30 g) was dissolved in EtOH (15 mL). LiOEt (1 M methanolic solution, 2 mL, 2 mmol) was added, and the solution was stirred for 5 min. $NiCl_2\cdot 6H_2O$ (0.24 g, 1 mol) was added to the yellow solution, and the resulting light green solution was stirred under air. The separated yellowish green microcrystalline compound was filtered and dried. X-ray-quality crystals were grown from a solvent mixture (1:2) of CH_2Cl_2 and EtOH. Yield: 0.32 g (75%). $C_{80}H_{140}N_4O_{14}Ni_5\cdot 0.75CH_2Cl_2$ (1708.96): calcd. C 56.75, H 6.58, N 3.28, Ni 17.17; found C 56.9, H 6.7, N 3.2, Ni 17.4. IR: $\tilde{\nu}$ = 3510 cm^{-1} (br), 2915 (s), 1477 (s), 1263 (s), 1162, 801, 648, 451.

$[Ni_6L^{N}_4(\mu\text{-}MeOH)(\mu_3\text{-}OMe)_2(\mu_3\text{-}OH)_2(MeOH)_2(MeCN)_2]$ (4): The ligand (0.5 mmol, 0.15 g) was treated with NaOMe (2 mL, 0.5 M methanolic solution) in a solvent mixture of MeCN (3 mL) and MeOH (15 mL). $NiCl_2\cdot 6H_2O$ (0.12 g, 0.5 mmol) was added, and the light green solution was kept at room temperature. A green crystalline complex separated out overnight. Yield: 0.11 g (49%). $C_{85}H_{118}N_6O_{15}Ni_6$ (1816.04): calcd. C 56.22, H 6.55, N 4.63, Ni 19.39; found C 53.3, H 6.3, N 3.9, Ni 19.2. IR: $\tilde{\nu}$ = 3448 cm^{-1} (br), 2918 (s), 1475 (s), 1266 (s), 1057, 802, 453.

Mononuclear Rhodium(I) Complexes with Chelating *N*-Heterocyclic Carbene Ligands − Catalytic Activity for Intramolecular Hydroamination

Suzanne Burling,[a] Leslie D. Field,*[a] Hsiu L. Li,[a] Barbara A. Messerle,[b] and Peter Turner[a]

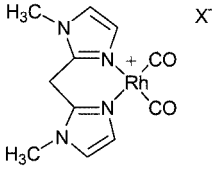
Keywords: Rhodium / Carbene ligands / Homogeneous catalysis / Hydroamination

The mononuclear cationic Rh^I complexes $[Rh(cod)(mdd)]^+X^-$ and $[Rh(CO)_2(mdd)]^+X^-$ (X = BPh_4, PF_6) containing the chelating bidentate *N*-heterocyclic carbene ligand 1,1′-methylene-3,3′-dimethyldiimidazoline-2,2′-diylidene (mdd) have been synthesised and spectroscopically characterised. The complexes $[Rh(cod)(mdd)]^+BPh_4^-$ and $[Rh(CO)_2(mdd)]^+PF_6^-$ have also been characterised by X-ray crystallography. The dicarbonyl complexes catalyse the intramolecular hydroamination of 4-pentyn-1-amine to 2-methyl-1-pyrroline.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

In 1991, Arduengo[1] synthesised and characterised the first crystalline carbene 1,3-di-1-adamantylimidazol-2-ylidene. Since then, there has been a resurgence of interest in metal complexes containing *N*-heterocyclic carbene ligands, fuelled by reports of their ability to increase catalyst activity in a range of catalytic reactions.[2,3] Our interest in Rh complexes with chelating *N*-heterocyclic carbene ligands stemmed from the synthesis of a successful hydroamination catalyst[4] $[Rh(bim)(CO)_2]^+BPh_4^-$ **1** [bim = bis(*N*-methylimidazol-2-yl)methane]; a carbene analogue might influence the catalytic activity.



X = BPh_4 **1**
PF_6 **6**

Reactions of Rh^I precursors such as $[RhCl(cod)]_2$ or $[Rh(OEt)(cod)]_2$ (cod = 1,5-cyclooctadiene) with bidentate *N*-heterocyclic carbenes (or their precursor imidazolium halide salts) have produced dinuclear complexes where two rhodium metals are bridged by the bidentate carbene ligand.[5,6] These reactions are probably driven by the inherent insolubility of the dinuclear products. Similar reactions in the presence of OAc^- and I^- gave the mononuclear complexes, although the rhodium metal was oxidised from Rh^I to Rh^{III} [7] and the mechanism for this oxidation is as yet unknown.

In this paper, we report the successful synthesis and characterisation of mononuclear Rh^I complexes with chelating bidentate *N*-heterocyclic carbene ligands and initial studies into their activity as hydroamination catalysts.

Results and Discussion

The mononuclear Rh^I complexes were synthesised using a modification of the sodium ethoxide method introduced by Köcher et al.[6] (Scheme 1). $[RhCl(cod)]_2$ was treated with NaOEt and the product $[Rh(OEt)(cod)]_2$ was washed with methanol to remove residual chloride. The halide-free $[Rh(OEt)(cod)]_2$ was reacted with 1,1′-methylene-3,3′-dimethyldiimidazolium bis(tetraphenylborate) to form predominantly the mononuclear Rh carbene complex $[Rh(cod)(mdd)]^+BPh_4^-$ (**2**; mdd = 1,1′-methylene-3,3′-dimethyldiimidazoline-2,2′-diylidene). The removal of all

halide from the reaction mixture is the simple and effective key to the formation of the mononuclear complex rather than the dinuclear complex containing bridging mdd ligands. The reaction, however, was complicated by the formation of an off-white, sparingly soluble by-product which was difficult to remove. The by-product was identified as the zwitterionic compound [Rh(cod)(η^6-PhBPh$_3$)] by the four IR bands at 1478, 1458, 1426 and 1395 cm^{-1} characteristic of coordinated tetraphenylborate.[8] Complex **2** was isolated as a microanalytically pure compound after careful recrystallisation from acetone. Further reaction of **2** with carbon monoxide gas formed the Rh dicarbonyl complex [Rh(CO)$_2$(mdd)]$^+$BPh$_4^-$ (**3**). The hexafluorophosphate analogues [Rh(cod)(mdd)]$^+$PF$_6^-$ (**4**) and [Rh(CO)$_2$(mdd)]$^+$PF$_6^-$ (**5**) were synthesised in similar reactions. In the synthesis of complex **4**, it is essential to use halide-free [Rh(OEt)(cod)]$_2$ to avoid the formation of the dinuclear complex.

The ^{1}H NMR spectra of the cod complexes **2** and **4** show two separate resonances for the backbone methylene protons with a geminal splitting of 13.0 Hz, whilst the dicarbonyl complexes **3** and **5** show only a singlet for the corresponding protons. The magnetic inequivalence of the methylene protons in the cod complexes probably arises from rigidity of the non-planar metallacyclic ring imposed by the steric bulk of the cod ligand, whereas the methylene protons in the dicarbonyl complexes are more fluxional and exchange rapidly on the NMR timescale. The ^{13}C{^{1}H} NMR spectra for cod complexes **2** and **4** show the carbene resonances at δ = 181 ppm with $^1J_{Rh,C}$ in the range 52−53 Hz. The cod resonances also exhibit coupling to Rh with coupling constant values of about 8 Hz. The carbene resonances for dicarbonyl complexes **3** and **5** appear at δ = 174 ppm with $^1J_{Rh,Carbene}$ of about 45 Hz, whilst the carbonyl carbons appear at δ = 189 ppm with $^1J_{Rh,CO}$ of 57 Hz. The assignment of the carbonyl resonances was confirmed when solutions of the complexes were placed under an atmosphere of ^{13}C-labelled CO gas. There is exchange between bound and free CO and the carbonyl resonances increase in intensity relative to all resonances. The value of $^1J_{Rh,CO}$ (57 Hz) is somewhat smaller than that for the corresponding bim complexes and other related bidentate nitrogen-donor complexes where the one-bond coupling is typically in the range 66−69 Hz.[4,9] Two strong IR stretches for ν(CO) were observed for complexes **3** and **5** at 2071−2076 and 2014−2017 cm^{-1}, consistent with the *cis* geometry of the complexes.

X-ray Crystallography

A single-crystal X-ray diffraction analysis of an orange tabular section excised under a polarising microscope from a contact twinned crystal mass (grown from a concentrated [D$_6$]acetone solution at 300 K), confirmed the structure of [Rh(cod)(mdd)]$^+$BPh$_4^-$ (**2**). An ORTEP[10,11] depiction of the cation is shown in Figure 1 and selected bond lengths and angles are listed in Table 1. The structure was modelled as a pseudo-centrosymmetric structure, with $P2_1/m$ symmetry broken by a lack of mirror symmetry in the cyclooctadiene ligand. The complex molecule is bisected by a (pseudo) mirror plane, with the Rh metal and methylene carbon C(12) located in that plane. The six-membered metallacyclic ring as defined by Rh(1), C(9), N(1), C(12), N(1*) and C(9*) is boat-like with Rh and methylene carbon deviations from the boat plane of 0.94 Å and 0.58 Å, respectively. The Rh-carbene bond length [2.025(3) Å] agrees well with that found in non-chelated Rh(cod)(carbene) complexes such as [RhCl(cod)(diy)] and [Rh(cod)(diy)$_2$]Cl (diy = 1,3-dimethylimidazoline-2-ylidene) [2.023(2)−2.059(8) Å].[5,12] The Rh-cod distances [2.171(6)−2.244(6) Å] are also similar to the corresponding distances in [RhCl(cod)(diy)] and [Rh(cod)(diy)$_2$]Cl [2.095(2)−2.205(2) Å].

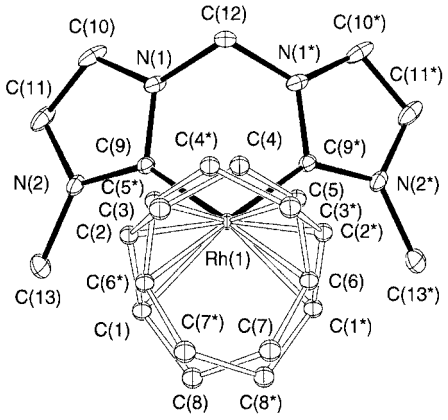

Figure 1. An ORTEP[10,11] depiction of the cation of [Rh(cod)(mdd)]$^+$BPh$_4^-$ (**2**) showing 20% displacement ellipsoids and cod ligand disorder about a (pseudo) mirror plane (see main text and Exp. Sect.); atoms labelled with an asterisk are generated from the unique sites by x, 3/2 − y, z

Single crystal X-ray diffraction analysis of an orange columnar-like crystal (grown from a methanol/diethyl ether solution) confirmed the structure of [Rh(CO)$_2$(mdd)]$^+$PF$_6^-$ (**5**). An ORTEP[10,11] depiction of the cation is shown in Figure 2 and selected bond lengths and angles are listed in Table 1. The asymmetric unit in the crystal structure of complex **5** contains the complex molecule and its hexafluorophosphate counterion, both of which are bisected by a mirror plane passing through Rh(1), C(5), P(1), F(3) and F(4). The complex has a boat-like metallacyclic ring as defined by Rh(1), C(2), N(1), C(5), N(1*) and C(2*) with Rh and methylene carbon deviations from the boat plane of 0.88 Å and 0.59 Å respectively. The Rh-carbene bond length [2.062(2) Å] is similar to that reported for [Rh(CO)(diy)$_2$Cl][13] [2.049(4) Å and 2.047(4) Å]. The Rh-carbonyl bond length [1.892(2) Å] is marginally longer than those in analogous Rh complexes with N-donor bidentate ligands [1.79(1)−1.868(7) Å].[9]

Hydroamination Catalysts

Cationic Rh^{I} complexes with chelating N-donor ligands are known to catalyse intramolecular hydroamination of aminoalkynes,[4] amino alcohols and amino carboxylic acids.[14] At a catalyst loading of 1.5%, both complexes

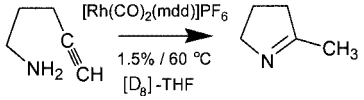
$[Rh(CO)_2(mdd)]^+BPh_4^-$ (**3**) and $[Rh(CO)_2(mdd)]^+PF_6^-$ (**5**) catalyse the cyclisation of 4-pentyn-1-amine to 2-methyl-1-pyrroline (76% and 85% conversion, respectively, in 16 hours at 60 °C in $[D_8]$THF solution). Turnover rates[15] at 50% conversion of 6 h^{-1} and 10 h^{-1} were calculated for complexes **3** and **5** respectively (Scheme 2). The reaction rate for complex **3** was slower than that observed for the analogous bisimidazolylmethane complex $[Rh(bim)(CO)_2]^+BPh_4^-$ (**1**) (Figure 3), where conversion was complete after 12 hours (turnover rate 17 h^{-1}). In contrast, the reaction rate for complex **5** was significantly faster than that observed for $[Rh(bim)(CO)_2]^+PF_6^-$ (**6**) where the conversion was only 49% complete after 16 hours (turnover rate 2 h^{-1}) at the same catalyst loading under the same reaction conditions. Complex **6** is the PF_6^- analogue of **1**. The synthesis of **6** is analogous to that reported for the synthesis of **1**.[4]

In comparing the two carbene complexes, the PF_6^- complex **5** has a higher turnover rate for the conversion of 4-



Scheme 2

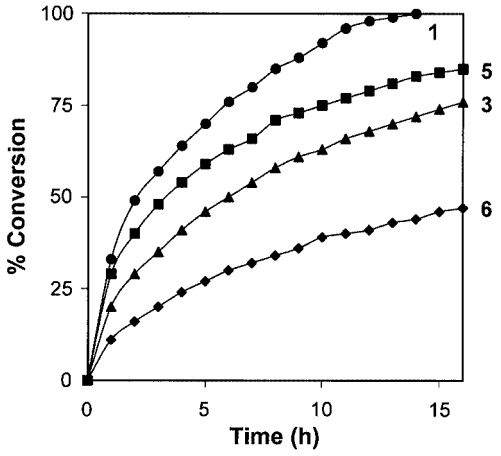


Figure 3. Comparative reaction rates for the metal-catalysed cyclisation of 4-pentyn-1-amine to 2-methyl-1-pyrroline using $[Rh(CO)_2(mdd)]^+BPh_4^-$ **3** (▲), $[Rh(CO)_2(mdd)]^+PF_6^-$ **5** (■), $[Rh(bim)(CO)_2]^+PF_6^-$ **6** (◆), and $[Rh(bim)(CO)_2]^+BPh_4^-$ **1** (●); catalyst loading 1.5% at 60 °C in $[D_8]$THF solution

pentyn-1-amine to 2-methyl-1-pyrroline than the corresponding BPh_4^- complex **3**. The dependence of the turnover rate on the counterion has also been noted previously with related catalysts and this could be the result of significant ion pairing in solution.

Conclusions

A synthetic route to mononuclear Rh^I complexes containing the bidentate bis-carbene ligand 1,1′-methylene-3,3′-dimethyldiimidazoline-2,2′-diylidene (mdd) has been developed. The complexes are robust and two Rh complexes containing the mdd ligand have been structurally characterised. Both complexes show the presence of a boat-like six-membered metallacycle containing two metal-carbon bonds. $[Rh(mdd)(CO)_2]^+$ is catalytically active for the intramolecular cyclisation of aminoalkynes and the turnover rate is similar to $[Rh(bim)(CO)_2]^+$ and other related catalysts for this conversion. Reaction conditions for this conversion are as yet unoptimised and these results demonstrate the future potential of rhodium carbenes in a range of catalytic applications.

Experimental Section

All manipulations of metal complexes and air-sensitive reagents were carried out using standard Schlenk or vacuum techniques or in a Vacuum Atmospheres nitrogen-filled drybox. $RhCl_3 \cdot H_2O$ was purchased from Strem and used as received. $[RhCl(cod)]_2$ was prepared by the literature method.[16] 1,1′-Methylene-3,3′-dimethyldiimidazolium dibromide was synthesised by a modification of the literature procedure for the analogous diiodide salt.[17] All bulk compressed gases were obtained from BOC Gases. Nitrogen (> 99.5%) and carbon monoxide (> 99.5%) were used as supplied without further purification.

Tetrahydrofuran and diethyl ether were stored over sodium wire and distilled under nitrogen from sodium benzophenone ketyl. Methanol was distilled from magnesium methoxide under nitrogen. Acetone was distilled from calcium sulfate under nitrogen. Deuterated solvents for NMR purposes were obtained from Merck and Cambridge Isotopes. Solvents were dried over suitable drying agents, degassed using three consecutive freeze-pump-thaw cycles and vacuum distilled immediately prior to use.

Microanalyses were carried out at the Campbell Microanalytical Laboratory, University of Otago, New Zealand. Electrospray mass spectra were recorded on a Finnigan LCQ mass spectrometer. Infra-red spectra were obtained using a Perkin−Elmer 1600 Series F.T.I.R. spectrometer as KBr discs.

NMR spectra were recorded on Bruker Avance DPX 300 or DRX 400 spectrometers at 300 K. ^1H and ^{13}C NMR chemical shifts (δ/ppm) were referenced to internal solvent resonances. ^{31}P NMR chemical shifts were referenced to external neat trimethyl phosphite, taken to be at δ = 140.85 ppm. ^{19}F NMR chemical shifts were externally referenced to neat hexafluorobenzene, taken to be at δ = −163 ppm.

Synthesis of $[mddH_2]^{2+}$ $2BPh_4^-$: Sodium tetraphenylborate (2.0 g, 5.9 mmol) was added to a solution of 1,1′-methylene-3,3′-dimethyldiimidazolium dibromide (1.0 g, 3.0 mmol) in water (20 mL). The white precipitate formed was isolated by filtration and dried in vacuo overnight. 1,1′-Methylene-3,3′-dimethyldiimidazolium bis(tetraphenylborate) was recrystallised from acetone/diethyl ether as a white solid (1.4 g, 58%), m.p. 218 °C (dec). $C_{57}H_{54}B_2N_4$ (816.69): calcd. C 83.8, H 6.7, N 6.9; found C 83.7, H 6.8, N 6.9. ^1H NMR ([D$_6$]acetone, 400 MHz): δ = 8.75 (s, 2 H, NCHN), 7.75 (d, $^3J_{H,H}$ = 1.6 Hz, 2 H, NCH), 7.53 (d, $^3J_{H,H}$ = 1.6 Hz, 2 H, NCH), 7.48 (m, 16 H, *o*-H), 6.93 (t, $^3J_{H,H}$ = 7.3 Hz, 16 H, *m*-H), 6.77 (t, $^3J_{H,H}$ = 7.3 Hz, 8 H, *p*-H), 6.50 (s, 2 H, NCH_2), 3.81 (s, 6 H, NCH_3) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 101 MHz): δ = 164.9 (q, $^1J_{C,B}$ = 49.3 Hz, *ipso*-C), 138.4 (NCHN), 136.9 (*o*-C), 126.1 (*m*-C), 126.0 (NCH), 122.9 (NCH), 122.3 (*p*-C), 59.8 (NCH_2), 37.1 (NCH_3) ppm.

Synthesis of $[mddH_2]^{2+}$ $2PF_6^-$: A solution of 1,1′-methylene-3,3′-dimethyldiimidazolium dibromide (2.6 g, 7.7 mmol) in water (15 mL) was added to a solution of potassium hexafluorophosphate (2.9 g, 15 mmol) in water (50 mL). The precipitate was isolated by filtration, washed with diethyl ether and dried in vacuo overnight to give 1,1′-methylene-3,3′-dimethyldiimidazolium bis(hexafluorophosphate) as a white solid (2.8 g, 77%), m.p. 200 °C. $C_9H_{14}F_{12}N_4P_2$ (468.24): calcd. C 23.1, H 3.0, N 12.0; found C 23.1, H 3.2, N 11.7. ^1H NMR ([D$_6$]acetone, 300 MHz): δ = 9.37 (s, 2 H, NCHN), 8.05 (s, 2 H, NCH), 7.84 (s, 2 H, NCH), 7.02 (s, 2 H, NCH_2), 4.10 (s, 6 H, NCH_3) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 75 MHz): δ = 139.1 (NCHN), 126.0 (NCH), 123.2 (NCH), 60.1 (NCH_2), 37.2 (NCH_3) ppm. ^{19}F NMR ([D$_6$]acetone, 282 MHz): δ = −70.9 (d, $^1J_{P,F}$ = 708 Hz) ppm. ^{31}P NMR ([D$_6$]acetone, 121 MHz): δ = −146.4 (sep, $^1J_{P,F}$ = 708 Hz). Note: Spectroscopic data (^1H and ^{31}P NMR) for this compound have been reported,[18] although no microanalytical data were included.

Synthesis of $[Rh(OEt)(cod)]_2$: $[RhCl(cod)]_2$ (100 mg, 0.20 mmol) in methanol (0.6 mL) was treated with NaOEt (0.44 mL of 1 M methanol solution, 0.44 mmol) under nitrogen. After stirring for 30 min, the yellow suspension was filtered. The yellow solid obtained was washed with methanol and dried. $[Rh(cod)(OEt)]_2$ (102 mg, 98%) was used directly without further purification.

Synthesis of $[Rh(cod)(mdd)]^+$ BPh_4^- (2): Sodium ethoxide (0.40 mL of 1 M methanol solution, 0.40 mmol) and 1,1′-methylene-3,3′-dimethyldiimidazolium bis(tetraphenylborate) (290 mg, 0.36 mmol) were added to a suspension of $[Rh(cod)(OEt)]_2$ (92 mg, 0.18 mmol) in methanol (1 mL). The reaction mixture was heated at reflux for 15 minutes and then stirred at room temperature overnight, during which time the pale-yellow suspension changed to an orange suspension. The resulting precipitate was filtered and washed with methanol. (Cyclooctadiene)(1,1′-methylene-3,3′-dimethyldiimidazoline-2,2′-diylidene)rhodium(I) tetraphenylborate was recrystallised from acetone as an orange crystalline solid (159 mg, 63%), m.p. 188 °C (dec). $C_{41}H_{44}BN_4Rh$ (706.52): calcd. C 69.7, H 6.3, N 7.9; found C 69.5, H 6.5, N 8.0. ^1H NMR ([D$_6$]acetone, 400 MHz): δ = 7.45 (d, $^3J_{H,H}$ = 1.8 Hz, 2 H, NCH), 7.34 (m, 8 H, *o*-H), 7.15 (d, $^3J_{H,H}$ = 1.8 Hz, 2 H, NCH), 6.92 (t, $^3J_{H,H}$ = 7.3 Hz, 8 H, *m*-H), 6.77 (t, $^3J_{H,H}$ = 7.3 Hz, 4 H, *p*-H), 6.59 (d, $^2J_{H,H}$ = 13.0 Hz, 1 H, NCH_2), 6.26 (d, $^2J_{H,H}$ = 13.0 Hz, 1 H, NCH_2), 5.05 [m, 2 H, CH(cod)], 4.87 [m, 2 H, CH(cod)], 3.84 (s, 6 H, NCH_3), 2.54 [m, 2 H, CH_2(cod)], 2.4−2.1 [m, 6 H, CH_2(cod)] ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 101 MHz): δ = 181.1 (d, $^1J_{Rh,C}$ = 52.7 Hz, NCN), 164.9 (q, $^1J_{C,B}$ = 49.6 Hz, *ipso*-C), 137.0 (*o*-C), 126.0 (*m*-C), 123.4 (NCH), 122.3 (*p*-C), 121.8 (NCH), 92.0 [d, $^1J_{Rh,C}$ = 7.8 Hz, CH(cod)], 87.8 [d, $^1J_{Rh,C}$ = 7.8 Hz, CH(cod)], 64.1 (NCH_2), 38.0 (NCH_3), 31.2 [CH_2(cod)], 31.0 [CH_2(cod)] ppm. MS (ES+, CH_3CN): *m/z* (%) = 387 (45) $[Rh(cod)(mdd)]^+$, 361 (25) $[Rh(mdd)(CH_3CN)_2]^+$, 320 (100) $[Rh(mdd)(CH_3CN)]^+$, 279 (35) $[Rh(mdd)]^+$.

Synthesis of $[Rh(CO)_2(mdd)]^+$ BPh_4^- (3): $[Rh(cod)(mdd)]^+BPh_4^-$ (**2**; 50 mg, 71 μmol) was suspended in methanol (1 mL). The mixture was degassed using three freeze-pump-thaw cycles, flushed with carbon monoxide gas and stirred at room temperature overnight, during which time the orange suspension became a yellow suspension. The precipitate was isolated by filtration and washed with diethyl ether producing dicarbonyl(1,1′-methylene-3,3′-dimethyldiimidazoline-2,2′-diylidene)rhodium(I) tetraphenylborate as a yellow solid (41 mg, 88%), m.p. 170 °C (dec). $C_{35}H_{32}BN_4O_2Rh$ (654.36): calcd. C 64.2, H 4.9, N 8.6; found C 64.2, H 4.7, N 8.7. ^1H NMR ([D$_6$]acetone, 400 MHz): δ = 7.56 (d, $^3J_{H,H}$ = 1.8 Hz, 2 H, NCH), 7.35 (m, 9 H, NCH and *o*-H), 6.91 (t, $^3J_{H,H}$ = 7.3 Hz, 8 H, *m*-H), 6.77 (t, $^3J_{H,H}$ = 7.3 Hz, 4 H, *p*-H), 6.21 (s, 2 H, NCH_2), 3.93 (s, 6 H, NCH_3) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]acetone, 101 MHz): δ = 189.0 (d, $^1J_{Rh,C}$ = 57.0 Hz, CO), 173.6 (d, $^1J_{Rh,C}$ = 45.2 Hz, NCN), 164.9 (q, $^1J_{C,B}$ = 49.3 Hz, *ipso*-C), 137.0 (*o*-C), 126.0 (*m*-C), 124.1 (NCH), 123.2 (NCH), 122.2 (*p*-C), 63.8 (NCH_2), 38.9 (NCH_3) ppm. MS (ES+, CH_3CN): *m/z* (%) = 361 (18) $[Rh(mdd)(CH_3CN)_2]^+$, 335 (26) $[Rh(CO)_2(mdd)]^+$, 320 (100) $[Rh(mdd)(CH_3CN)]^+$, 279 (53) $[Rh(mdd)]^+$. IR: $\tilde{\nu}$ = 2071s (νCO), 2014s (νCO) cm^{-1}.

Synthesis of $[Rh(cod)(mdd)]^+$ PF_6^- (4): Sodium ethoxide (0.45 mL of 1 M methanol solution, 0.45 mmol) and 1,1′-methylene-3,3′-

sequent computations were carried out with the teXsan[20] and WinGX[21] graphical user interfaces. A Gaussian absorption correction was applied to the data.[19,22] The structures were solved by direct methods with SIR97[23] and extended and refined with SHELXL-97.[24] In general the non-hydrogen atoms were modelled with anisotropic displacement parameters, and a riding-atom model with group displacement parameters was used for the hydrogen atoms. The crystal structure of complex **2** was modelled as a disordered (pseudo)centrosymmetric structure in $P2_1/m$ (no. 11). An alternative model in $P2_1$ (no. 4) had significantly higher residuals at convergence [$R1(F) = 0.0591$ and $wR2(F^2) = 0.1656$], and high levels of correlation requiring extensive geometry and displacement restraints. The Flack parameter[25] in $P2_1$ refined to 0.49(8) suggesting either an inversion twin or a centrosymmetric structure. The disordered centrosymmetric model was adopted as the better model for the crystal structure. The asymmetric unit in $P2_1/m$ contains a complex molecule bisected by a (pseudo) mirror plane, with the metal ion and C(12) atoms located in that plane. A tetraphenylborate counterion also resides on a mirror plane, with the B(1), C(14), C(15), C(16), C(17), C(18), C(19), C(20) and C(23) atoms located in the mirror plane. Two of the phenyl residues of the counterion have orientational disorder about the boron to quaternary carbon axis. The $P2_1/m$ symmetry is broken by a lack of mirror symmetry in the cyclooctadiene ligand, which is disordered about the mirror plane. The fully occupied non-hydrogen sites were modelled with anisotropic displacement parameters, and isotropic displacement parameters were used for the partially occupied non-hydrogen sites and for the fully occupied boron site. The site occupancies were refined, and then fixed and rounded to the first decimal place.

CCDC-186563 (**2**) and -186564 (**5**) contain the supplementary crystallographic data for this paper. Synthesis, Kinetic Study and Molecular Orbital Investigation of Cadmium(II), Mercury(II) and Lead(II) Complexes with the Mixed Pendant-Arm Macrocyclic Ligand 1,7-Bis(carboxymethyl)-4,10-bis(1-methylimidazol-2-ylmethyl)-1,4,7,10-tetraazacyclododecane

Massimo Di Vaira,[a] Fabrizio Mani,[a] Stefano Seniori Costantini,[a] Piero Stoppioni,*[a] and Alberto Vacca[a]

Keywords: Macrocyclic ligands / Cadmium / Lead / Mercury / Conformational equilibrium / Density functional calculations

The neutral $[ML^6]\cdot 3H_2O$ complexes (M = Cd^{II}, Hg^{II} and Pb^{II}) formed with the potentially octadentate ligand 1,7-bis(carboxymethyl)-4,10-bis(1-methylimidazol-2-ylmethyl)-1,4,7,10-tetraazacyclododecane (H_2L^6) in its anionic deprotonated form, which bears two pairs of different dangling groups in *trans* positions on the cyclen skeleton, have been synthesized. Their low-temperature limiting NMR spectra (^1H and ^{13}C) in D_2O show that both the dangling groups and the ethylenic moieties of the macrocycle ring are in a fixed conformation in all complexes at 273 K. These conditions are relaxed at higher temperatures, yielding a dynamic behaviour that proceeds through both ring inversion and rearrangement of the pendant arms. The kinetic parameters for ring inversion have been obtained from the temperature-dependent ^{13}C NMR spectra. Cd: k(298 K) = 236 s^{-1}; $\Delta H^{\ddagger}$ = 72.9 ± 0.6 kJ·mol^{-1}; $\Delta S^{\ddagger}$ = 45 ± 2 J K^{-1}·mol^{-1}; Hg: k(298 K) = 292 s^{-1}; $\Delta H^{\ddagger}$ = 68 ± 3 kJ·mol^{-1}; $\Delta S^{\ddagger}$ = 29 ± 10 J K^{-1}·mol^{-1}; Pb: k(298 K) = 122 s^{-1}; $\Delta H^{\ddagger}$ = 65 ± 2 kJ·mol^{-1}; $\Delta S^{\ddagger}$ = 14 ± 5 J K^{-1}·mol^{-1}. In the absence of experimental structure determinations, some insight into the geometries has been obtained by quantum-mechanical calculations.

Introduction

Considerable attention has been addressed to metal complexes of 1,4,7,10-tetraazacyclododecane (cyclen) bearing pendant arms.[1−6] Depending on the number of substituent groups on the macrocyclic framework, as well as on the requirements of the metal ions employed, the substituted cyclen ligands easily adapt to coordination numbers six[7−9] seven[10] or eight,[11−13] and thus they might coordinate mono-, di- and trivalent metal ions. Complexes with these ligands exhibit notable thermodynamic stability and kinetic inertia and, consequently, they have important applications in, for example,[14] (i) the design of luminescent chelates for immunoassays,[6,15,16] (ii) use of Gd-containing contrast agents in diagnostic medicine[17,18] and (iii) labelling and specific cleavage of DNA and RNA.[19−21]

Representative examples of such ligands include the 1,4,7,10-tetraazacyclododecane-tetraacetic acid (H_4DOTA), which can provide anionic donors on the dangling groups, and molecules bearing four neutral donors on the arms of functionalized tetraazacyclododecane (Scheme 1).[7,22−26] Crystal data of the complexes have revealed that the four nitrogen atoms of the macrocycle and the four donors from the dangling groups are arranged in two parallel squares that are tilted by an angle denoted as α (Scheme 2). The coordination geometry can range from a regular antiprism (α = 45°) to a prism (α = 0°). Neither limiting case has been observed so far, and most known geometries cluster around two values: α = 40° and 15° (A and B, respectively, in Scheme 2).[7,26−32]

We have synthesized potentially octadentate ligands based on tetraazacyclododecane bearing, on the pendant arms, either four pyrazoles, L^5,[33] or two pairs of different groups in *trans* positions, namely two methylimidazoles and two carboxy groups, H_2L^6 [9] (Scheme 3). The solid manganese and cadmium complexes with L^5 have nearly prismatic structures,[34,35] a geometry that is preferred in solution by some lanthanide complexes with L^6.[36] Generally, the eight donors of the octadentate ligands L^1−L^6 are also considered to be bound to the metal ion in solution, a notable exception being the seven-coordinate magnesium complex with 1,4,7,10-tetrakis(2-methoxyethyl)-1,4,7,10-tetraazacyclododecane (L^4), which has the oxygen of a pendant arm uncoordinated.[10] Most of the complexes undergo dynamic behaviour in solution, which has been rationalized in terms of an exchange process between two enantiomers,[29,30] at

rates within the ^{13}C NMR timescale. In this paper we report both on the synthesis of complexes formed by the "mixed" H_2L^6 ligand (Scheme 3) in the anionic form with different size metal ions (Cd^{II}, Hg^{II} and Pb^{II}) and on their dynamic behaviour in solution by using variable-temperature ^1H and ^{13}C NMR spectroscopy. As repeated attempts to obtain suitable crystals of the compounds for X-ray investigations failed, quantum mechanical calculations were undertaken to obtain information on their geometry and bonding.

Results and Discussion

Syntheses of the Metal Complexes

The cadmium derivative was prepared by direct reaction of cadmium carbonate with the ligand H_2L^6, dissolved in water. The mercury and lead derivatives were prepared in water by reacting the acetate of the metal with the ligand and then neutralizing the resulting solution with Na_2CO_3. The complexes obtained after workup crystallize with three water molecules, $[ML^6]\cdot 3H_2O$, and are very soluble in polar solvents (water, methanol and ethanol). As expected for such compounds, they are stable in solution for weeks in the pH range 5−10.[37]

NMR Spectra of the Complexes

The $^{13}C\{^1H\}$ spectrum of the cadmium complex at 273 K exhibits eleven peaks which, on the basis of data for lanthanide complexes with the same ligand, are assigned as δ = 177.7 ppm to the carboxylate functionalities, δ = 145.8, 125.6 and 122.5 ppm to the carbon atoms of the imidazole rings, δ = 57.4 and 48.4 ppm to the methylenic carbon atoms of the acetate and of the imidazole arms, respectively, δ = 51.8, 50.9, 48.4 and 48.1 ppm to the ethylenic carbons of the tetraazamacrocycle, and δ = 32.0 ppm to the methyl carbon of imidazole. The signals of two equivalent carbons of the macrocycle and of the two carbons of the imidazole CH_2 bridges have the same shift (δ = 48.4 ppm) and yield a resonance of comparatively higher intensity. The C^2 carbon of imidazole couples with the metal ($^2J^{13}_{C\text{-}}{}^{111}_{Cd}$ = 13.1 Hz), which does not change in the range of temperatures investigated. On increasing the temperature the four signals due to the macrocycle broaden, collapse, and then merge (Figure 1) to afford, at 358 K, two resonances at δ = 50.3 and 49.7 ppm; the signals due to the other carbon atoms remain narrow, undergoing small drifts. The proton NMR spectrum of the cadmium derivative shows thirteen resonances at 273 K (see the Exp. Sect.) which have been assigned with the aid of a 2D COSY experiment. The imidazole protons appear as a pair of doublets at low field and those of the methyl group yield a singlet at δ = 3.28 ppm. The protons of the CH_2COO^- moiety yield two doublets (δ = 3.69 and 3.34 ppm; J = 15 Hz). The CH_2 bridging the macrocycle and the imidazole yields a doublet (δ = 2.56 ppm; J = 16 Hz) and a resonance (δ = 2.28 ppm) which overlaps with those of the macrocycle. Such resonances, also seen, with minor changes, for diamagnetic lanthanide complexes with L^6,[36] are typical of two non-equivalent AB

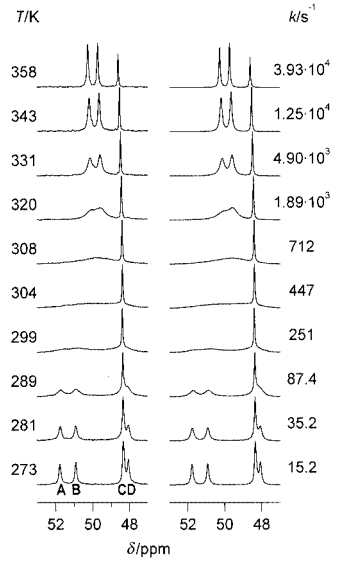

Figure 1. $^{13}C\{^1H\}$ spectra of the macrocyclic carbons of the [CdL^6] complex at different temperatures (left) compared with spectra calculated by line-shape analysis (right). The simulation has been performed by assuming an ABCD → CDAB exchange mechanism

systems.[38,39] The ethylenic moieties of the macrocycle present four triplets at δ = 3.01, 2.91, 2.67 and 2.37 ppm (coupling constants ca. 12.0 Hz), overlapping doublets centered at δ = 2.28 ppm and two doublets at δ = 2.05 and 1.86 ppm (coupling constant ca. 12.0 Hz). The chemical shifts of the resonances around δ = 2.7 and 2.1 ppm, and the multiplicity and coupling constants, are typical of two nonequivalent ABCD systems exhibiting large geminal and axial couplings, with small equatorial couplings. Such systems parallel those observed at low temperature for the ethylenic groups of lanthanum(III) and lutetium(III) complexes with L^6;[36] furthermore, each ABCD system is similar to that exhibited by diamagnetic lanthanide complexes with DOTA.[38,39] By increasing the temperature the three resonances due to the protons of methylimidazole remain narrow, undergoing a low-field shift; all the other resonances broaden, collapse, and then merge to afford a spectrum which exhibits, at 358 K, narrow signals at δ = 4.46 and 3.37 ppm for the CH_2 of the dangling groups and two unresolved resonances centered at δ = 3.54 and 3.25 ppm, due to the ethylenic moieties of the macrocycle.

The mercury and lead derivatives yield ^1H and ^{13}C NMR spectra at low temperature which parallel that of the cadmium complex; the shift of each signal is marginally affected by the nature of the metal (see the Exp. Sect.), which induces partial overlapping of some resonances so that they may appear as complex multiplets. The coupling constant between the C^2 imidazole carbon atom and mercury ($^2J^{13}_{C\text{-}^{199}Hg}$ = 54 Hz) does not change in the range of temperatures investigated. However, for no obvious reason, a similar coupling is not observed in the [PbL^6] spectrum (nor with the [PbL^1]$^+$ complex cation[7]), possibly due to either a low intensity or a small coupling constant for the ^{207}Pb satellites.[7] Both the ^{13}C and ^1H spectra of the mercury and lead complexes change with increasing temperature, as found for the cadmium derivative. At the highest temperature (Hg, 346 K, Pb 353 K) they exhibit two signals for the macrocycle (Hg, δ = 49.2 and 48.8 ppm; Pb, 49.8 and 49.7 ppm) in the ^{13}C spectra; in the proton spectra they exhibit narrow signals (Hg, δ = 4.37 and 3.27 ppm; Pb, δ = 4.50 and 3.70 ppm) for the CH_2 of the dangling groups and two unresolved resonances (Hg, δ = 3.45 and 3.20 ppm; Pb, δ = 3.55 and 3.45 ppm) due to the ethylenic moieties.

Similarities between the NMR spectroscopic data for the present cadmium, mercury and lead derivatives at the low exchange limit and the spectra of other metal complexes with L^5 and L^6, which either possess a nearly prismatic geometry in the solid state[34,35] or have been assigned that geometry in solution,[36] suggest that the same conformation should also be assigned to the present [ML^6] species. This view is supported by the quantum mechanical calculations (see below). Conversely, the variable temperature NMR experiments reveal that the conformational equilibria are thermally activated. Interconversion processes between the conformational isomers may occur via (a) simple rearrangement ("rotation") of the pendant arms (A → B or C → D, in Scheme 2), (b) macrocycle ring inversion (A → C or B → D) or (c) combinations of both types of motion,[40,53] which may afford interconversion between enantiomers. The coupling detected between the Cd or Hg atom and one imidazole carbon over the whole temperature range, which is consistent with previous results for lanthanide analogues,[36] suggests that the rearrangements occur without detachment of the pendant arms (but see below, computational results for Hg species). The above interconversion processes, particularly process (b), involve changes in the magnetic environment of the macrocycle carbon atoms, which may be characterized by a four-site line-shape analysis. Typical experimental and calculated ^{13}C NMR spectra for the cadmium complex are displayed in Figure 1. The temperature dependence of the rate constants, fitted according to the Eyring equation, yielded the parameters: Cd, k(298 K) = 236 s^{-1}, $\Delta H^{\ddagger}$ = 72.9 ± 0.6 kJ·mol^{-1}, $\Delta S^{\ddagger}$ = 45 ± 2 J^{-1}·mol^{-1}; Hg, k(298 K) = 292 s^{-1}, $\Delta H^{\ddagger}$ = 68 ± 3 kJ·mol^{-1}, $\Delta S^{\ddagger}$ = 29 ± 10 J K^{-1}·mol^{-1} and Pb, k(298 K) = 122 s^{-1}, $\Delta H^{\ddagger}$ = 65 ± 2 kJ·mol^{-1}, $\Delta S^{\ddagger}$ = 14 ± 5 J K^{-1}·mol^{-1} (details are given with the Supporting Information, see also the footnote on the first page article). The kinetic parameters for compounds with the L^1−L^4 or DOTA ligands are affected by the nature of the donor atoms on the dangling groups and by the metal, or the solvent,[7,10,41] and are higher for complexes with anionic donors on the arms. The kinetic parameters of the present [ML^6] compounds compare best with those of lanthanum complexes formed with DOTA[38] or L^6,[36] being significantly larger than those of compounds with four neutral donors on the arms. This may be due to the presence of two anionic donors on L^6 and, in part, to the nature of the metal atoms. Line shape analysis of the ^{13}C NMR peaks due to the macrocycle carbon atoms provides direct kinetic information on the macrocycle ring inversion, rather than on rotation of the arms. However, the ^1H NMR spectra show that both ring inversion and arm rotation occur sim-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ultaneously in the temperature range studied, as indicated by the loss of rigidity of all of the NCH_2CH_2N, NCH_2COO^- and NCH_2MeIz moieties with increasing temperature. The rate constants for the above processes (a) and (b) were not measured by ^1H NMR spectroscopic data due to the complexity of the exchanging system. However, as both processes occur in the same temperature range their rate constants should be similar, so that all types of interconversions may take place.

Quantum-Mechanical Calculations

For the [ML^6] systems considered here, calculations on gas-phase models yielded two low-energy conformers, with closely spaced energies ($\leq$ 13 kJ·mol^{-1} energy differences). Their geometries broadly correspond to the idealized coordination types of Scheme 2, but precisely defined geometrical parameters (detailed below) are needed for the following discussion. The upper/lower arrangements of Scheme 2 will be, respectively, denoted by *ap* and *iap*, for "*a*nti*p*rismatic" and "*i*nverted *a*nti*p*rismatic ", as previously used to describe the analogous coordination modes in the related DOTA systems.[40,53] The cadmium conformers will, accordingly, be denoted Cd*ap* and Cd*iap*, and so on. Optimized geometries for the two Cd conformers are shown in Figure 2, and selected geometrical parameters, as well as energy differences between the low-energy conformers of each metal system, are given in Table 1.

The two fundamental geometries may be identified unambiguously by the signs of the torsion angles of the ethylenic chains of the macrocycle, τ_1 and τ_2 in Table 1, and those of the dangling groups, τ_3 and τ_4. The signs are all negative for an "idealized *iap*" conformer, such as Cd*iap* in Figure 2 (they would be all positive for its enantiomer), whereas the signs are opposite in pairs, τ_1 and τ_2 with respect to τ_3 and τ_4, for a "pure *ap*" conformer, such as Cd*ap*. These sign distributions, however, do not match the present Pb and Hg models, due to inconsistent τ_4 signs (Table 1). Therefore, the *ap*/*iap* assignments for the latter systems were based solely on consideration of the τ_{1-3} signs. Indeed, unlike the present Cd and the previous lanthanide models,[53] the angle (β in Table 1) by which the plane of the imidazole group is bent away from the line connecting the metal and the heterocycle N donor (N_{im} hereafter; the macrocycle nitrogens are collectively labelled N_{mac}) is exceedingly large for the two lowest energy conformers of both the Pb and the Hg systems. The lowest energy, Pb*iap* and Hg*iap*, conformers are shown in Figure 3 and more representations are shown in the Supporting Information. These arrangements suggest weaker interactions between the Pb or Hg atom and the "neutral" dangling groups than those between the metal and the charged carboxylates. This is particularly evident for the Hg species, where the imidazole groups lie at considerable distances from the metal (Table 1). The difference under discussion between the Pb and the Cd (or the lanthanide[53]) models may be ascribed to the smaller charge/radius ratio of the former cation and to the strain imposed

Table 1. Values of selected geometrical parameters and energy differences between conformers for the [ML^6] model systems

Model system[a]	Cd*iap*	Cd*ap*	Pb*iap*	Pb*ap*	Hg*iap*	Hg*ap*
Relative energy[b]	0	9.29	0	12.29	0	13.43

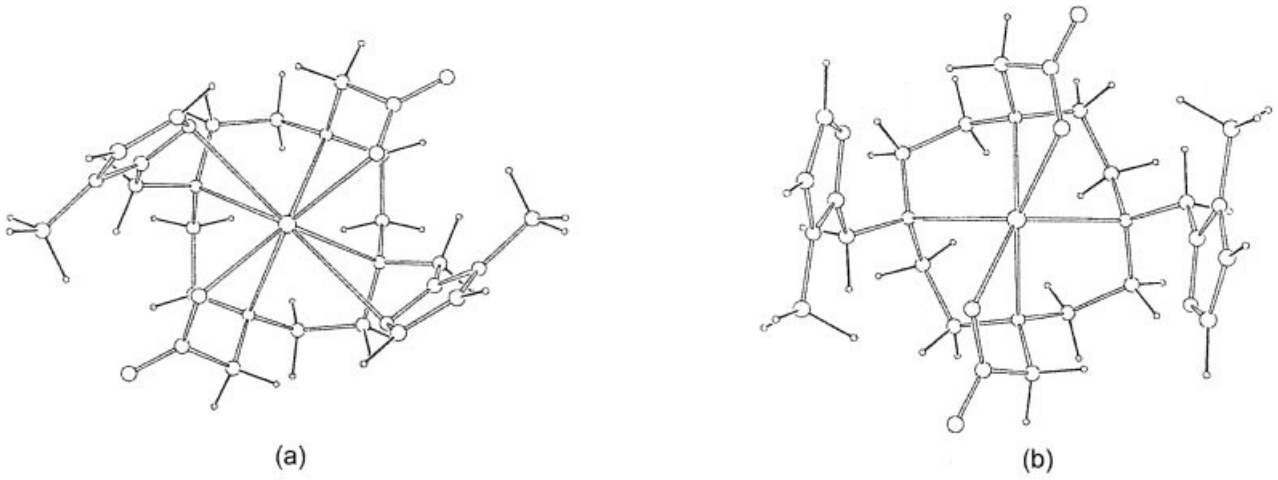

Figure 3. Geometries of the (a) Pb*iap* and (b) Hg*iap* conformers

on the chains by the overall longer metal−donor atom distances in the Pb species − factors that are obviously interrelated to some extent. The Hg conformers are peculiar, as most of their metal−donor distances are significantly shorter than those of Pb (the Hg−N_{mac} and Hg−O bond lengths are close to those of the Cd models), except for the very long Hg−N_{im} interactions (Table 1). The latter distances, which presumably affect the τ_4 values for the Hg models, may be traced to the specific electronic requirements of the Hg^{2+} cation. Indeed, the metal-based part of the HOMO for the Hg conformers has a stereochemically active d-orbital component, whereas the metal contribution to the HOMO of the Pb models has predominantly s (spherical) character; plots of sections of these electron densities are given with the Supporting Information.

Unfortunately, no experimental structure is available for detailed comparison. X-ray structures of Pb complexes formed by pyrazole-functionalized macrocycles revealed appreciable displacements of the metal atom from the planes of coordinating pyrazoles.[42] Previous computational experience with related systems[53] suggests that the overall geometrical features should be reproduced with reasonable accuracy, although individual metal−donor atom distances may be significantly in error. It may be appropriate to note here that the calculations with the SDD metal functions for the Cd systems, referred to in the Exp. Sect., yielded metal−donor atom distances that deviate by 0.012 Å (mean of absolute differences) from those obtained with the LANL2DZ metal functions (Table 1); conversely, for the less tightly bound Pb systems the considerably larger 0.070 Å mean for the absolute difference values was found, the SDD distances being consistently longer than those listed in Table 1. An indirect, but useful, test of the present procedures involves optimizing the geometries of two complex cations that are related to the present compounds and have known structures, namely the Cd[35] and Na[43] derivatives of tetraazacyclododecane functionalized with four pyrazole groups, $[CdL^5]^{2+}$ and $[NaL^5]^{+}$ in the notation of Scheme 3. These optimizations, starting from moderately idealized (C_4 symmetry constraint) but otherwise unbiased geometries [identical (enantiomeric) starting geometries for the two model systems, with parameters borrowed from parts of the present *ap*/*iap* Cd systems], and run at the same level as the present calculations, yielded results in reasonable agreement with experiment (details and graphic representations are shown in the Supporting Information), except for the Cd−N_{mac} distances, which were calculated to be as much as 0.18 Å too long. Such a discrepancy, mostly due to mispositioning of the metal cation between the two planes of donor atoms, was not unexpected for compounds of this type,[53] but should not affect too adversely other geometrical features; in particular, all computed τs are within 2° of the experimental ones. The offset of the metal atom from the heterocycle plane is 0.04 Å for the Cd model (experimental mean value: 0.51 Å) and 0.82 Å for the Na one (experimental, 1.19 Å). Good agreement cannot be expected for the latter quantity, which is very sensitive to the smallest geometrical changes, but the results seem to exclude a computational bias toward bent arrangements of the heterocycle planes, such as those found for the present Pb and Hg models. The increasing metal offset from the heterocycle plane with increasing metal size, from the Cd to the Na test model, found both experimentally and computationally, suggests that the metal−donor distance may be responsible for the predicted arrangements of the Pb and Hg models.

The calculated energy ordering consistently yielded the *iap*-type conformer as slightly more stable than the *ap* one, in agreement with the NMR results. The energy separations (Table 1) indicate that thermally activated interconversion processes between conformers may take place. Although the agreement is gratifying, the definitive assessment of such subtle features is probably beyond these calculations on gas-phase models but, limited to such models, the computed energy orderings may be trusted as merely conformational rearrangements are considered. However, the complexity of such systems may preclude the unequivocal identification of specific factors that determine such energy preferences. In fact a third conformer was found for both the Pb and Hg systems, at slightly higher energy than that of the *ap*-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

species. Interestingly, the third conformer is characterized in both cases by shorter $M-N_{im}$ but longer $M-N_{mac}$ distances than the other conformers (details are in the Supporting Information, where the third species is denoted as *ap′* or *iap′*), and features better oriented imidazole groups for coordination to the metal. All four τ signs of these *ap′*/*iap′* species conform to the expected sign distributions for the "pure" *ap* or *iap* types, at variance with results for the lower-energy Pb or Hg conformers (Table 1). Therefore, the attainment of such more regular geometries with these metals seems to involve an energy cost.

As a partial attempt to verify whether solution conditions might affect the arrangement of the dangling groups, reaction field model calculations were undertaken according to Onsager's approach,[54,55] which is based on a spherical solvent cavity and induced-dipole interactions; more explicit treatment of the solvent was difficult due to the size of the systems. Optimizations were performed with a slightly smaller basis than that used for gas-phase calculations (see the Exp. Sect., level B) and were followed by single-point energy calculations at level A. No important changes in geometries were recorded with respect to the vacuum results, and the energy ordering of the conformers was preserved. There were small contractions (< 1%) in the $M-N_{mac}$ and M−O distances and elongations (generally < 2%) of the $M-N_{im}$ distances, except that the loose $M\cdots N_{im}$ interactions of the Hg models (Table 1) decreased by < 1%. The different trends for changes in coordinative bond lengths for the two types of dangling groups might be related to the different overall negative charges localized on them. The torsion angles of the dangling groups were more affected than the metal−donor distances, but with qualitative retention of the arrangements found for the gas-phase models. Parameter values and more details are in Tables S4−S5 of the Supporting Information.

The calculated ^{13}C NMR chemical shifts broadly reproduce the experimental δ values, but are not particularly informative (Table S7). However, the calculated δ's for some carbon atoms of the pendant arms (Table 2), which appear to be sensitive to the *iap* vs. *ap* geometry differences, support the assignment of the *iap* conformer geometry to the species in solution at low temperatures. In particular, there is comparatively better agreement between experimental and calculated δ's for the *iap*-conformer carbon atoms of the acetate arms (those more tightly coordinating), irrespective of the metal atom. The computed δ value for the other arm's methylene carbon moderately favours the *iap* geometry for the Cd derivative, but is inconclusive for both Pb and Hg species. On the one hand, the GIAO calculations do not clarify the arrangement of the imidazole-bearing arms in the Hg complex; on the other hand, they suggest that signals due to those arms' carbon atoms may be insensitive to the geometrical differences predicted between the Hg and the other models.

Table 2. Comparison of computed and experimental ^{13}C NMR shifts[a]

	[CdL^6]			[PbL^6]			[HgL^6]		
	iap	*exp*	*ap*	*iap*	*exp*	*ap*	*iap*	*exp*	*ap*
C6	178.4	177.7	183.8	183.2	178.2	185.3	180.8	176.6	183.4
C5	56.6	57.4	63.1	59.5	54.7	62.9	56.3	56.6	59.7
C7	45.7	48.4	52.6	44.5	49.2	53.8	43.5	47.5	52.9

[a] Shifts (ppm) are calculated from the isotropic shielding tensor value of the Me_4Si carbon (computational level C, see the Exp. Sect.). Atomic labels are as in Figure 2.

Conclusions

Metal−C2 coupling has, perhaps surprisingly, been detected in the NMR spectra of the Cd and Hg derivatives, but not in that of [PbL^6]; however, such discrepancies are not unusual and are not easily rationalized.[7] One might invoke effects of the distinctive HOMO composition of [HgL^6] and/or effects (in the context of a ^3J, rather than ^2J coupling constant) of the shorter $Cd-N_{mac}$ and $Hg-N_{mac}$ distances compared to $Pb-N_{mac}$.

The bonding picture in these compounds set forth by the calculations, featuring two dangling groups less and less strongly bound to the metal, on going from the Cd to the Pb and the Hg derivatives appears to disagree with the similarities in their NMR properties, as well as with the similarities between their NMR behaviour and that of the L^6 lanthanide derivatives,[36] or even of DOTA complexes.[30,38] However, as may be inferred from a previous theoretical investigation,[53] the energetics of the interconversion processes between conformers may not be greatly affected by the presence of two loosely coordinating arms, as long as the other two arms are strongly bound to the metal.

Experimental Section

General Remarks: Commercial solvents were dried from appropriate drying agents just before use according to standard procedures. NMR spectra were obtained with a Varian Gemini g300bb spectrometer, equipped with variable temperature unit, operating at 300 MHz (^1H) and 75.46 MHz (^{13}C). Positive chemical shifts are to high frequency relative to Me_4Si. The variable temperature accessories were checked against methyl alcohol and ethylene glycol. CD_3OH was used as an internal reference for the ^{13}C spectra of the lead derivative. The spectra of the cadmium and mercury derivatives are referred to the CH_3 of the imidazole, whose signal is not affected by the nature of the metal. The $^{13}C\{^1H\}$ NMR spectra of the compounds in the range δ = 55−47 ppm were analyzed with the program CAHOS,[44] which can perform a line-shape fitting by simultaneous refinement of several spectral parameters. Elemental analyses were performed by the Microanalytical Laboratory of the Department of Chemistry of the University of Florence. The ligand H_2L^6 was prepared according to the published procedure.[36] Anhydrous cadmium carbonate (Aldrich), mercuric acetate (Acros) and lead acetate trihydrate (Carlo Erba) were used as received.

Synthesis of [CdL^6]·3H$_2$O: Neat $CdCO_3$ (43 mg, 0.25 mmol) was added to a solution of the ligand $H_2L^6\cdot 2H_2O$ (128 mg, 0.25 mmol) in H_2O (15 cm^3) and the resulting suspension warmed (ca. 60 °C) for 2 h; the remaining solid was eliminated by centrifugation and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the solvent was removed in a desiccator under vacuum at room temperature. The resultant complex was recrystallized from CH_3CN and toluene; yield 65%. ^1H NMR (D_2O, 273 K, C_M = $9.2\cdot10^{-2}$, pD = 7.3): δ = 6.69 (d, J = 1.2 Hz, 2 H, H imidazole), 6.42 (d, J = 1.2 Hz, 2 H, H imidazole), 3.69 (d, J = 15.4 Hz, 2 H, CH_2 acetate), 3.34 (d, J = 15.3 Hz, 2 H, CH_2 acetate), 3.28 (s, 6 H, CH_3 imidazole), 3.01 (t, J = 11.9 Hz, 2 H, CH_2 macrocycle), 2.91 (t, J = 12.0 Hz, 2 H, CH_2 macrocycle), 2.67 (t, J = 12.5 Hz, 2 H, CH_2 macrocycle), 2.56 (d, J = 16.5 Hz, 2 H, CH_2 imidazole), 2.37 (t, J = 12.8 Hz, 2 H, CH_2 macrocycle), 2.28 (m, 6 H, CH_2 imidazole and CH_2 macrocycle), 2.05 (d, J = 12.9 Hz, 2 H, CH_2 macrocycle) and 1.86 (d, J = 12.9 Hz, 2 H, CH_2 macrocycle) ppm. $^{13}C\{^1H\}$ NMR: δ = 177.7 (COO^-), 145.8 (d, $^2J^{13}_{C\text{-}^{111}Cd}$ = 13.1 Hz, C^2 imidazole), 125.6, 122.5 (C^4, C^5 imidazole), 57.4 (CH_2COO^-), 51.8, 50.9, 48.4, 48.1 (CH_2 macrocycle), 48.4 (CH_2 imidazole) and 32.0 (CH_3 imidazole) ppm. $C_{22}H_{40}CdN_8O_7$ (641.0): calcd. C 41.2, H 6.3, N 17.5; found C 40.9, H 6.3, N 17.3.

Synthesis of $[ML^6]\cdot3H_2O$ (M = Hg, Pb): $Hg(CH_3COO)_2$ (0.25 mmol) dissolved in water (5 cm^3) was added to $H_2L^6\cdot2H_2O$ (0.25 mmol) in water (8 cm^3); the solution was then gently warmed (ca. 40 °C) for 5 h. After cooling, the pH was adjusted to 7.3 by adding Na_2CO_3 dissolved in water. The solvent was then removed at room temperature in a desiccator under vacuum and the obtained solid was recrystallized from CH_3CN and toluene; yield 60%. The lead derivative was obtained by the same procedure by adding $Pb(CH_3COO)_2\cdot3H_2O$ dissolved in water to a water solution of the ligand; yield 65%. $C_{22}H_{40}HgN_8O_7$ (729.2): calcd. C 36.2, H 5.5, N 15.4; found C 36.4, H 5.4; N. 14.6. ^1H NMR (D_2O, 273 K, c_M = $8.5\cdot10^{-2}$, pD = 7.3): δ = 6.76 (d, J = 1.3 Hz, 2 H, H imidazole), 6.44 (d, J = 1.2 Hz, 2 H, H imidazole), 3.73 (d, J = 15.6 Hz, 2 H, CH_2 acetate), 3.45 (d, J = 15.6 Hz, 2 H, CH_2 acetate), 3.29 (s, 6 H, CH_3 imidazole), 2.85 (m, 6 H, CH_2 macrocycle), 2.40 (m, 10 H, CH_2 imidazole and CH_2 macrocycle), 2.10 (d, J = 12.6 Hz, 2 H, CH_2 macrocycle) and 1.90 (d, J = 12.6 Hz, 2 H, CH_2 macrocycle) ppm. $^{13}C\{^1H\}$ NMR (D_2O, 273 K, c_M = $8.5\cdot10^{-2}$, pD = 7.3): δ = 176.6 (COO^-), 145.1 (d, $^2J^{13}_{C\text{-}^{199}Hg}$ = 54.5 Hz, C^2 imidazole), 125.6, 122.7 (C^4, C^5 imidazole), 56.6 (CH_2COO^-), 50.9, 50.6, 48.3, 47.5 (CH_2 macrocycle), 47.5 (CH_2 imidazole) and 32.0 (CH_3 imidazole) ppm.

$C_{22}H_{40}N_8O_7Pb$ (735.8): calcd. C 35.9, H 5.5, N 15.2; found C 36.0, H 5.4; N. 15.0. ^1H (D_2O, 273 K, c_M = $8.8\cdot10^{-2}$, pD = 7.2): δ = 6.74 (d, J = 1.3 Hz, 2 H, H imidazole), 6.50 (d, J = 1.3 Hz, 2 H, H imidazole), 3.98 (d, J = 15.6 Hz, 2 H, CH_2 acetate), 3.82 (d, J = 15.8 Hz, 2 H, CH_2 acetate), 3.27 (s, 6 H, CH_3 imidazole), 3.07 (m, 10 H, CH_2 macrocycle), 2.74 (t, J = 13.0 Hz, 2 H, CH_2 macrocycle), 2.48 (m, 6 H, CH_2 imidazole and CH_2 macrocycle) and 2.34 (d, J = 12.0 Hz, 2 H, CH_2 macrocycle) ppm. $^{13}C\{^1H\}$ (D_2O, 273 K, c_M = $8.8\cdot10^{-2}$, pD = 7.2): δ = 178.2 (COO^-), 145.4 (C^2 imidazole), 124.4, 123.1 (C^4, C^5 imidazole), 57.4 (CH_2COO^-), 53.3, 52.3, 49.9, 49.4 (CH_2 macrocycle), 49.2 (CH_2 imidazole) and 32.1 (CH_3 imidazole) ppm.

Computational Procedures: Calculations on the neutral $[ML^6]$ model systems (M = Cd, Pb, Hg) were performed with the GAUSSIAN 98 suite of programs,[45] generally using the hybrid HF-DFT B3LYP method.[46–48] Unless specified differently, the 6-311G(d) basis set was used for all non-metal atoms.[45,49] For the Cd and Pb atoms the LANL2DZ valence and effective core potential functions,[50] as well as their SDD counterparts,[51,52] were used for comparison purposes (only results from the former set of calculations are reported in some detail). For Hg the SDD functions were initially used and the lengthy calculations were not repeated with the alternative functions as no detailed comparisons were sought between systems formed with the different metal atoms. For brevity, the computational level B3LYP/6−311G(d) with LANL2DZ (Cd, Pb) or SDD (Hg) functions will be referred to as "level A". Geometry optimizations on gas phase models were performed with the C_2 symmetry restraint, all atoms being included. Initial geometries were from the previously investigated lanthanide analogs[53] or were applied by cross assignments, e.g. starting a Pb-model optimization from an optimized Hg-model geometry, and so on. The nature of stationary points as true minima was checked by frequency calculations, and unscaled ZPE corrections were applied to the energy values. To mimic conditions in solution, calculations (without vibrational analysis) were undertaken according to Onsager's reaction field (SCRF) approach,[54,55] at the B3LYP/6-311G(d)//B3LYP/6-31G(d) level (level B), with the above LANL2DZ/SDD metal functions. NMR shielding tensors were obtained by GIAO[56] [HF/6-311G(d) calculations on the vacuum-optimized geometries computational level C: HF/6-311G(d)//B3LYP/6-311G(d), with metal functions as above], chemical shifts for carbon atoms being calculated with respect to the 194.51 isotropic shielding tensor obtained for the Me_4Si carbon, at the same level C. For graphics, Molden[57] and ORTEP[58,59] were employed.

Metal Complexes of a Novel Achiral Symmetric Pentadentate Ligand – Crystal Structures of Monohelical Zinc(II) and Cadmium(II) Complexes

Rosa Pedrido,[a] Manuel R. Bermejo,*[a] Ana M. García-Deibe,[a] Ana M. González-Noya,[a] Marcelino Maneiro,[a] and Miguel Vázquez[a]

Keywords: Supramolecular chemistry / Helical structures / Schiff bases / Electrochemistry

By both electrochemical synthesis and a traditional chemical procedure the interaction of the pentadentate ligand 2,6-bis{1-[2-(tosylamino)phenylimino]ethyl}pyridine (H_2DAPATs), with Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Cd^{II} gives rise to neutral mononuclear complexes that have been characterised by elemental analyses, FAB mass spectrometry, IR, ^{1}H and COSY NMR spectroscopy and magnetic measurements, where appropriate. Recrystallisation of the zinc complex obtained electrochemically yielded single crystals of [Zn(DAPATs)] (**1**), while recrystallisation of cadmium complexes obtained by both techniques afforded the same structure, [Cd(DAPATs)(H_2O)] (**2**). Both **1** and **2** are monohelical single-stranded compounds with different coordination geometries. In the zinc complex, the metal ion assumes a distorted trigonal-bipyramidal geometry involving the N_5 atoms of the dianionic ligand. For cadmium complexes the metal ion is in a distorted pentagonal-pyramidal environment, as the result of coordination to the N_5 ligand donor set and an additional water molecule.

Introduction

Helical complexes are an active research area in supramolecular chemistry.[1–5] Nevertheless, predicting the outcome of a self-assembly process is still difficult and dependent upon numerous factors, such as the nature of the metal (coordination numbers and stereochemical preferences), the structure of the ligand, the existence of weak non-covalent interactions, etc.

Most ligands employed in the synthesis of helicates are predominantly benzimidazole,[6] catechole[7] or polypyridine types,[8] and they usually imply long and complicated synthetic routes. More recently, readily prepared Schiff-base ligands have been used to obtain helical species.[9,10]

In recent years part of our research program has focused on using pentadentate hydrazone ligands derived from 2,6-diacetylpyridine to produce helical compounds.[10–12] Previous works have demonstrated that such ligands react with metal chlorides to yield complexes containing the non-deprotonated ligand, while complexes with the bis(deprotonated) ligand could be obtained with metal acetates.[13,14] We have recently found that pentadentate ligands incorporating a rigid spacer such as pyridine yield dinuclear helical complexes for Ni[10,11] and Cu[15] and non-helical mononuclear complexes for Mn,[10,11] Co[10] and Cd[12] by electrochemical synthesis.

We have also shown that introducing bulky tosyl groups in Schiff-base ligands with different spacers is very useful in obtaining mono- and dihelical species.[16]

We then wanted to check the effect of the simultaneous presence of a bulky group, such as tosyl, and a rigid spacer, like pyridine, in a pentadentate Schiff-base ligand. Therefore, we have designed the novel pentadentate N_5 ligand 2,6-bis{1-[2-(tosylamino)phenylimino]ethyl}pyridine (H_2DAPATs).

The interaction of H_2DAPATs with Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Cd^{II} using electrochemical and chemical procedures was investigated and the results obtained are described herein.

Results and Discussion

Synthesis of the Ligand

The Schiff base H_2DAPATs has been prepared according to a two-step synthetic route (Scheme 1) with an overall yield of 50%. The first step involves the *N*-tosylation of 1,2-diaminobenzene[17] (**I**), to obtain 2-(tosylamino)aniline (**II**). Treatment of **II** with 2,6-diacetylpyridine in a 1:2 stoichiometric ratio in ethanol under reflux yields the N_5 Schiff-base ligand H_2DAPATs.

The deep yellow powdery solid formed was satisfactorily characterised by elemental analysis, FAB mass spec-

trometry, IR and ^{1}H and COSY NMR spectroscopy (Tables 1, 2 and 6).

Synthesis of the Complexes

A series of neutral complexes were obtained by electrochemical oxidation of the corresponding metal anode in the presence of the ligand.[18] The electrochemical efficiency of the cell was close to 0.5 mol·F^{-1}, which is compatible with the following reaction scheme:

Cathode: $H_2DAPATs + 2\ e^- \rightarrow H_2\ (g) + DAPATs^{2-}$

Anode: $DAPATs^{2-} + M \rightarrow M(DAPATs) + 2\ e^-$

This synthetic procedure allowed us to obtain neutral complexes of the type M(DAPATs)$(H_2O)_n$ with high purity and in very good yield.

These metal compounds were also obtained by a traditional chemical procedure, in which a solution of the ligand was refluxed in the presence of a metal(II) acetate. As the characterisation patterns of these complexes are similar to those obtained by electrochemical synthesis we shall discuss only the latter ones.

Elemental analyses (Table 1) show that metal ions react with the ligand in a molar ratio of 1:1 to afford solvated complexes of the bis(deprotonated) ligand $DAPATs^{2-}$. These neutral complexes are either insoluble or sparingly soluble in water and common organic solvents, but soluble in polar coordinating organic solvents such us DMSO, DMF and pyridine. The powdery complexes appear to be stable both in the solid state and in solution, and all of them melt above 300 °C without decomposition.

X-ray Studies

The crystal structures of complexes [Zn(DAPATs)] (**1**) and [Cd(DAPATs)(H_2O)] (**2**) are shown in Figures 1, 2 and 3. Selected bond lengths and angles are given in Tables 4 and 5. The complexes are considered together here in order to comment on their structural similarities and differences.

They consist of discrete neutral molecules of [Zn(DAPATs)] (**1**) and [Cd(DAPATs)(H_2O)] (**2**), the ligand being bis(deprotonated), $DAPATs^{2-}$. In complex **1** all five nitrogen donor atoms of the ligand (two imine, two amide and one pyridine nitrogen atoms) bind to the same zinc ion. No additional ligands are coordinated to the zinc ion, resulting in a coordination number of five and a distorted bipyramidal-trigonal geometry. In this complex the Schiff-base li-

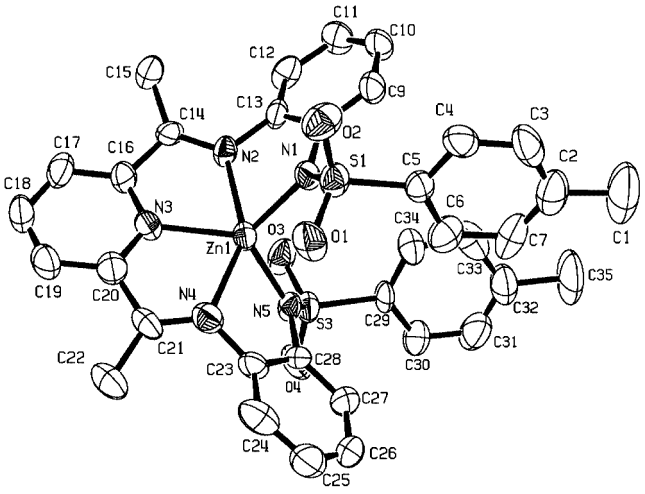

Figure 1. ORTEP view of the crystal structure of [Zn(DAPATs)] (**1**); ellipsoids are drawn at 50% of probability; hydrogen atoms have been omitted for clarity

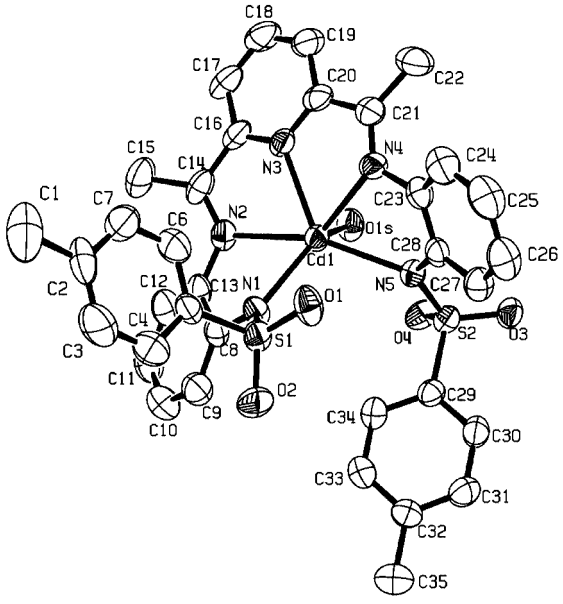

Figure 2. ORTEP view of the crystal structure of [Cd(DAPATs)-(H_2O)] (**2**); ellipsoids are drawn at 50% of probability; hydrogen atoms have been omitted for clarity

gand fulfills all the stereochemical requirements of the metal, and subsequently it can be considered a saturated compound.[4]

However, **2** is an unsaturated compound because the cadmium ion is coordinated to the same five nitrogen donor atoms of the bis(deprotonated) ligand but also needs one additional water molecule, leading to a coordination number of six and to a distorted pentagonal-pyramidal geometry.

This geometry is unusual for cadmium complexes derived from pentadentate Schiff-base ligands because, to the best of our knowledge, only one such cadmium complex with this type of geometry has been previously reported.[12] In addition, helicity in cadmium compounds is uncommon – only two monohelical cadmium complexes with Schiff-base ligands have been reported.[12,19]

For complex **1** the $Zn-N_{imine}$ distances [Zn(1)–N(2) 2.160(6) Å, Zn(1)–N(4) 2.172(7) Å] are of the order of those found for the unique monohelical zinc complex reported with similar geometry,[20] $[Zn(SpyNpy_2)]^{2+}$. The distance $Zn-N_{pyridine}$ [Zn(1)–N(3) 2.102(7) Å] is shorter than those found for penta-[21] or heptacoordinated[13,22] com-

plexes with pentadentate ligands containing $Zn-N_{pyridine}$ bonds.

For complex **2** all Cd−N distances are significantly longer than the corresponding Zn−N distances, and in both complexes $M-N_{imine}$ are longer than $M-N_{amide}$. In addition, the $Cd-N_{pyridine}$ bond [Cd(1)−N(3) 2.350(5) Å] is shorter than that of the distorted pyramidal-pentagonal cadmium complex with the pentadentate Schiff base H_4daps[12] [2.403(6) Å], but longer than those found in octahedral complexes with quite similar Schiff-base ligands (ranging from 2.310 to 2.346 Å).[23−26]

The distance Cd−O(1s) [2.377(4) Å] is of the order of those found for similar cadmium complexes.[12]

The remaining distances for both compounds are in the usual range for complexes derived from Schiff-base ligands containing tosyl groups[16,27,28] and do not merit further analysis.

The four bond angles N−Zn−N formed by the four chelate rings are close to 75°. The fifth one, N(5)−Zn(1)−N(1), is 108.9(3)°. These values explain the distorted trigonal-bipyramidal geometry adopted in **1**. In complex **2** the distortion from the ideal geometry is clearly shown by the angles between water, cadmium and the donor set of the ligand (Table 5). Four of the five angles subtended at Cd by adjacent equatorial atoms are slightly smaller than those of an ideal pentagonal-pyramidal arrangement, being close to 70°, while the fifth, N(1)−Cd(1)−N(5) is 105.33(16)°. Moreover three bond angles O(1s)−Cd(1)−N are in the range 81−84° while the other two are in the range 101−125°, reinforcing the highly distorted pyramidal-pentagonal geometry adopted by **2**.

The bond angles C(5)−S(1)−N(1) and C(29)−S(3)−N(5) are quite similar for the zinc complex [108.2(4) and 108.7(4)°, respectively]; both tosyl groups adopt a similar conformation (Figure 3). Nevertheless, in the cadmium complex these angles, C(5)−S(1)−N(1) and C(29)−S(2)−N(5), are slightly different [107.0(3) and 111.1(2)°, respectively], causing an *anti* orientation of the tosyl groups to reduce the steric hindrance.

Why do zinc and cadmium complexes show different coordination numbers and geometries? We suggest that two factors could be responsible:

i. Steric hindrance of the bulky tosyl groups.

The pentadentate dianionic ligand, $DAPATs^{2-}$, is wrapped around the metal ions to afford a helical arrangement in both complexes. This screwed disposition of the ligand seems to be clearly favoured by the two terminal bulky tosyl groups. The steric hindrance these groups induce appears to provoke a twisting of the Schiff base to minimise the sterically unfavourable interactions.

Therefore, a rigid spacer such as pyridine, containing a donor atom, and the torsion around the C=N bonds will allow the imine nitrogen atoms to be quite close (ca. 4.2 Å for **1** and 4.4 Å for **2**) and coordinate to the same metal centre. This permits the five nitrogen atoms to bind to the same metal centre, leading to the isolation of mononuclear single-stranded helical complexes.

ii. Closeness of the tosyl oxygen atoms to the metal centre.

For **1**, one oxygen atom of each tosyl group, O(1) and O(3), seems to weakly interact with the metal ion [distances O(1)···Zn(1) 3.052 Å and O(3)···Zn(1) 3.092 Å]. These Zn···O distances are too long to be true coordinated bonds, but could be considered as secondary intramolecular interactions that could be responsible for the distorted trigonal-bipyramidal disposition around the metal centre, instead of the usual bipyramidal-pentagonal or pyramidal-pentagonal geometries, because these oxygen atoms avoid coordinating additional donor ligands in the apical positions.

In complex **2** the bigger cadmium ion leads to longer metal−donor distances, in general, and in $Cd-O_{tosyl}$ especially. Thus, only one oxygen atom of one tosyl group, O(1) could weakly interact with the cadmium ion [distance

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Cd(1)···O(1) 3.126 Å], while in the other tosyl group both oxygen atoms are too far to interact with the cadmium ion [Cd(1)···O(4) 3.540 Å, Cd(1)···O(3) 4.749 Å]. Such a situation affords an easy entrance and binding for a new additional ligand such as water, increasing the coordination number to six.

Thus, the different monohelical dispositions of these two complexes can be attributed to the tosyl groups, which show different spatial orientations (Figure 3). In the zinc complex the angle between the benzene rings of the tosyl groups is 11.75°. This nearly parallel orientation for the terminal tosyl aromatic rings is unusual for complexes with Schiff-base ligands containing these bulky groups. It can be explained by the lack of superposition of the tosyl groups, which avoid the unfavourable steric interactions.

In the cadmium complex the angle between the benzene rings is 47.60°, yielding a spatial conformation quite similar to that of other monohelical complexes derived from tetradentate Schiff bases containing tosyl groups.[16]

The $DAPATs^{2-}$ thread forms four five-membered chelate rings around the metal centres. The angles between adjacent calculated chelate planes (36.65 and 37.76° for **1**; 29.48 and 26.10° for **2**) confirm the different twisting degree of the ligand for both complexes. The smaller degree of twisting for the cadmium complex is also confirmed by the angles formed between the benzylidene rings (63.45° for **1** and 37.21° for **2**).

If the tosyl groups are not considered, we can clearly observe that the wrapping angle is less than 360°, and slightly higher for the zinc complex than for the cadmium (287° for **1** and 274° for **2**). All these considerations agree with the ionic radius of the metals, as expected. The size of the cadmium ion forces the N_5 donor set of the ligand to deviate from planarity when it surrounds this metal, resulting a smaller twisting degree.

[Zn(DAPATs)] crystallises in the achiral space group $P\bar{1}$ and [Cd(DAPATs)(H_2O)] in $P(2)1/c$, so that both right- (*P*) and left-handed (*M*) helixes[4] can be simultaneously observed (in 50% yields) in their unit cells. Helicates obtained from ligands not containing chiral groups usually crystallise as racemic mixtures and self-recognition is not a very common process.

Finally, no face-to-face π-stacking interactions between the terminal tosyl aromatic rings can be identified in either complex.

FAB Mass and IR Spectra

All the FAB mass spectra show peaks due to the fragments $[M(DAPATs)]^+$, indicating ligand coordination to the metal centres (Table 1). No additional peaks appear, suggesting that the complexes are mononuclear.

The IR spectra of the complexes (Table 2) show a strong band between 1621 and 1656 cm^{-1} attributable to ν(C=N). This band appears 6 cm^{-1} shifted to lower energy from that in cobalt and copper complexes. With manganese, iron, nickel, zinc and cadmium complexes the ν(C=N) band is shifted to higher wavenumbers (7−29 cm^{-1}), indicating a slight shift of charge towards the CN group on coordination. However, the $\nu(C-N)_{py}$ stretching frequency is not shifted for manganese and iron complexes and is slightly shifted to lower energy (6−10 cm^{-1}) for the other compounds. This behaviour is compatible with the participation of both imine and amide nitrogen atoms in the coordination to the metal centres. Additionally, two bands in the ranges 1335−1381 and 1130−1167 cm^{-1} are assigned to the asymmetric and symmetric vibration modes of SO_2 groups, respectively.[29,30]

Furthermore, no bands around 3270 cm^{-1} are seen, indicating the deprotonation of the NH groups, and therefore the dianionic character of the ligand.

Finally, the ν(O−H) bands around 3400 cm^{-1} agree with the hydrate nature of these complexes.

Magnetic Characterisation

Magnetic measurements were performed at room temperature for all paramagnetic complexes. Their magnetic moments are close to those expected for magnetically dilute M^{II} ions, confirming the oxidation state II for the central atom and, therefore, that the ligands are dianionic.

^{1}H NMR Spectroscopy

The ^{1}H NMR spectra of the zinc and cadmium complexes were recorded in [D_6]DMSO at room temperature and CD_3CN at low temperatures (273 and 233 K). Selected ^{1}H NMR data are shown in Table 6. The room-temperature spectra were totally assigned by COSY experiments. The spectra do not show significant changes with temperature, being quite similar to those recorded at room temperature. All spectra show a single set of signals that could be completely assigned. This seems to indicate a single species in

Table 6. Selected ^{1}H NMR spectroscopic data for the ligand H_2DAPATs and its diamagnetic complexes (in ppm)

Compound	H1	H2	H3	H4	H5	H6	H7	H8	H9	H10	H11

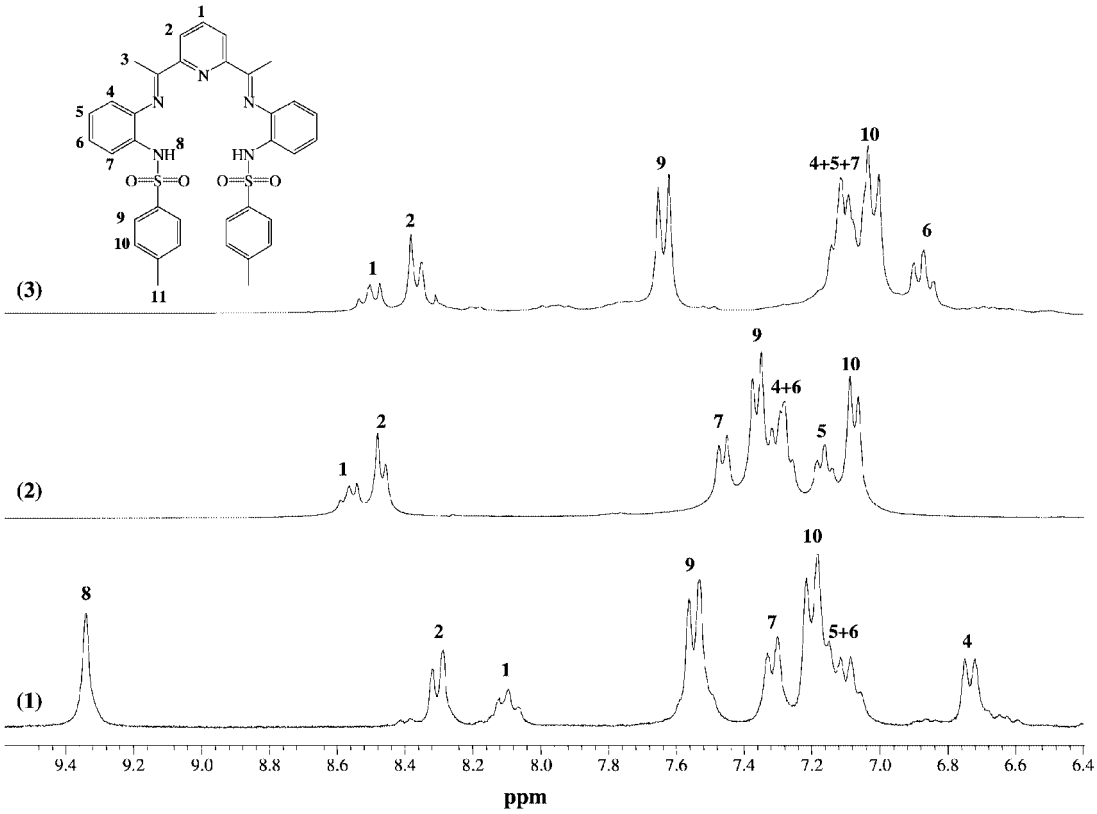

Figure 4. ^{1}H NMR spectra in [D_6]DMSO at room temperature for: (1) H_2DAPATs, (2) Zn(DAPATs)(H_2O)$_2$ and (3) Cd(DAPATs)(H_2O)

solution. Comparison of the ^{1}H NMR spectrum of the free ligand with those of the complexes (Figure 4) shows some interesting aspects:

– The NH (H8) protons present in the free ligand disappear for both complexes, in agreement with the bis(deprotonation) of the ligand.

– The aromatic proton signals of the pyridine ring are shifted downfield, and the displacements are higher for the zinc complex. The spectra show that complexation through the $N_{pyridine}$ atom affects the environments of the H1 and H2 atoms, and these signals appear with their positions exchanged with respect to the free ligand.

– The aromatic proton signals of the tosyl groups also shift on complexation, but the displacements differ for the zinc and cadmium complexes. For the zinc complex the H9 and H10 signals are shifted upfield, whilst in the cadmium compound the H10 signal is shifted upfield and the H9 signal is shifted downfield. This could be attributed to an interaction between the tosyl groups and the metal centres, as the solid-state X-ray structures of **1** and **2** seem to confirm.

– The aromatic proton signals of the benzylidene rings also appear to show different behaviour on complexation. In the zinc complex the H5 signal moves its position slightly while the H4, H6 and H7 signals are shifted downfield, with the H4 and H6 signals overlapped. With the cadmium complex the H4, H5 and H7 signals are completely overlapped. The H5 signal does not show significant changes in its position, while the H6 and H7 signals are shifted upfield and the H4 signal is strongly shifted downfield.

– Finally, in both complexes the methyl proton signals corresponding to tosyl and acetyl groups are shifted slightly downfield.

Comparison of the ^{1}H NMR spectra of zinc and cadmium complexes suggests that the tosyl groups adopt different spatial orientations in each complex, as the X-ray structures confirm, because of the size of the metal ions and their different geometrical preferences.

From the characterisation techniques employed in this work, some general points can be made. All complexes seem to be mononuclear, as FAB mass spectrometry suggests. The magnetic studies, the similar IR patterns and X-ray results agree with the coordination of the N_5 donor set of the ligand to the metal centres. In addition ^{1}H NMR studies, and other data, indicate that the solid-state structures of **1** and **2** are retained in solution.

Conclusion

The novel potentially dianionic and pentadentate Schiff-base ligand H_2DAPATs readily stabilises neutral mononuclear complexes of Mn^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Cd^{II} formed by either an electrochemical method or a traditional chemical procedure. The electrosynthesis is both simpler and shorter.

The rigid spacer in this ligand, such as pyridine, and the bulky terminal groups, such as tosyl, favour the formation of monohelical single-stranded compounds.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

It thus seems that careful design of the ligand is useful in controlling the selective formation of monohelical complexes.

Experimental Section

General: Elemental analyses were performed with a Carlo Erba EA 1108 analyser. NMR spectra were recorded with Bruker DPX-250 and AMX-500 spectrometers with [D_6]DMSO (296 K) and CD_3CN (273 and 233 K) as solvents. Infrared spectra were registered as KBr pellets with a Bio-Rad FTS 135 spectrophotometer in the range 4000−600 cm^{-1}. Fast atom bombardment (FAB) mass spectra were obtained with a Kratos MS-50 mass spectrometer, employing Xe atoms at 70 keV in *m*-nitrobenzyl alcohol as matrix. Room-temperature magnetic susceptibilities were measured using a Digital Measurement system MSB-MKI, calibrated by using tetrakis(isothiocyanato)cobaltate(II).

Syntheses: All solvents, 2,6-diacetylpyridine, 1,2-diaminobenzene, tosyl chloride and M^{II} acetates are commercially available and were used without further purification. Metals (Ega Chemie) were used as ca. 2 × 2 cm^2 plates and were cleaned of oxides in dilute hydrochloric acid prior to electrolysis. 2-(Tosylamino)aniline was prepared and characterised according to a method previously reported[17] (Scheme 1).

Ligand Synthesis: H_2DAPATs has been prepared by condensation of 2,6-diacetylpyridine (2 g, 12.3 mmol) with 2-(tosylamino)aniline (6.4 g, 24.6 mmol) in ethanol (250 cm^3). The solution was heated under reflux over a 5-h period, concentrated with a Dean−Stark trap to ca. 30 mL and cooled during 12 h (4 °C). The yellow precipitate that then formed was collected by filtration and purified by Soxhlet extraction (with EtOH as solvent) over a period of 12 h. The resulting solid was finally washed with diethyl ether (3 × 10 mL) and dried in vacuo.

Metal Complexes Syntheses: All complexes have been obtained by two methods: an electrochemical synthesis[18] and a traditional chemical procedure.

Electrochemical Synthesis: A warm acetone suspension of H_2DAPATs, containing tetramethylammonium perchlorate (about 10 mg) as supporting electrolyte, was electrolysed using a platinum wire as the cathode and a metal plate as anode. The cell can be summarised as: Pt(−) | H_2DAPATs + MeCOMe | M(+), where M = Mn, Fe, Co, Ni, Cu, Zn and Cd. The synthesis is typified by the preparation of Zn(DAPATs)(H_2O)$_2$: A suspension of the ligand H_2DAPATs (0.2 g, 0.46 mmol) in warm acetone (80 mL), containing tetramethylammonium perchlorate (10 mg), and using a zinc plate as anode, was electrolysed for 2.5 h using a current of 10 mA. ***Caution:*** *Although no problems have been encountered in our experiments, all perchlorate compounds are potentially explosive, and should be handled in small quantities and with great care!* The resulting orange solid was washed with diethyl ether and dried in vacuo. Slow diffusion of diethyl ether into a dichloromethane/acetone solution of Zn(DAPATs)(H_2O)$_2$ yielded orange crystals of [Zn(DAPATs)] (**1**) suitable for X-ray diffraction studies. The other complexes were obtained by the same method, using the appropriate metal anode. Orange prismatic crystals of [Cd(DAPATs)(H_2O)] (**2**), suitable for single X-ray diffraction studies, were obtained by slow concentration of acetone solutions containing Cd(DAPATs)(H_2O).

Chemical Synthesis: Complexes were obtained by refluxing the ligand and the appropriate metal(II) acetate hydrate in ethanol. A typical preparation is outlined below.

Cd(DAPATs)(H_2O): A mixture of H_2DAPATs (0.2 g, 0.31 mmol) and $Cd(C_2H_3O_2)_2\cdot 2H_2O$ (0.08 g, 0.31 mmol) in ethanol (60 mL) was refluxed for 3 h to afford a black suspension. Filtration followed by washing with diethyl ether and drying in vacuo yielded an orange powdery solid. Recrystallisation of Cd(DAPATs)(H_2O) complex in DMSO yielded [Cd(DAPATs)(H_2O)] (**2**).

X-ray Crystallographic Studies: Crystals of **1** and **2**, suitable for X-ray diffraction studies, were grown as described above. Data were collected with a Smart CCD-1000 Bruker diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) from a fine focus sealed tube source. The structures were solved by direct methods[31] and DIRDIF-99.2 for Windows and finally refined by full-matrix least squares based on F^2. An empirical absorption correction was applied using SADABS.[32] All non-hydrogen atoms were anisotropically refined, and all hydrogen atoms were included in the model at geometrically calculated positions. CCDC-203518 (**1**) and -203519 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Transition metals / Fullerenes / Electrochemistry / Optical activity

This paper reports on several new optically active organometallic [60]fullerene complexes that contain a chiral (+)-DIOP or (–)-DIOP ligand [DIOP = 2,3-*O*,*O*′-isopropylidene-2,3-dihydroxy-1,4-bis(diphenylphosphanyl)butane]. The Mo/W complexes *mer*-[(η^2-C_{60})M(CO)$_3${(–)-DIOP}] (**1**, M = Mo; **2**, M = W) and *mer*-[(η^2-C_{60})M(CO)$_3${(+)-DIOP}] (**3**, M = Mo; **4**, M = W) were synthesized by a photochemical reaction of a mixture of [M(CO)$_6$], (–)-DIOP or (+)-DIOP and C_{60} in chlorobenzene in 42–51% yields, whereas the Pd/Pt complexes [(η^2-C_{60})M{(–)-DIOP}] (**5**, M = Pd; **6**, M = Pt) were prepared by a thermal reaction of C_{60} with [M(PPh$_3$)$_4$], followed by in situ treatment of the intermediate [(η^2-C_{60})M(PPh$_3$)$_2$] with (–)-DIOP, in toluene in > 90% yields. All the new complexes **1**–**6** were fully characterized by elemental analysis, ^{1}H (^{31}P, ^{13}C) NMR, IR, UV/Vis and circular dichroism (CD) spectroscopy. The structure of [(η^2-C_{60})Pt{(–)-DIOP}] (**6**) was further confirmed by X-ray diffraction techniques. The electrochemical properties of complexes **1**, **2**, **5** and **6** were studied in dichloromethane solution. Complexes **1** and **2** display the reversible, four-membered, one-electron reduction sequence typical of fullerene ligands, as well as the reversible (in the cyclic voltammetric time scale) one-electron oxidation of the outer metal fragment. Complexes **5** and **6** are less stable to the same electron transfer processes. EPR measurements suggest that in the different electrogenerated monoanions, the added electrons enter the LUMO orbitals partially contributed by the metal fragment. In addition, they confirm that the instability of the reduction intermediates is due to the release of free C_{60}.

Introduction

The organotransition metal derivatives of C_{60} have drawn great attention[1] since the discovery of C_{60}[2] and its synthesis in macroscopic amounts.[3] The first example of such derivatives, namely (η^2-C_{60})Pt(PPh$_3$)$_2$, was reported in 1991 by Fagan and co-workers.[4] Although a great number of such derivatives have so far appeared in the literature,[5−8] very few organotransition metal C_{60} derivatives containing chiral ligands are known to be reported.[9,10] We have been interested in the synthesis, structural characterization and properties of organotransition metal fullerene complexes.[11] In view of the theoretical and practical significance of such complexes, we recently initiated a study on optically active organometallic C_{60} complexes. This paper describes the synthesis and spectroscopic characterization of the new optically active complexes *mer*-[(η^2-C_{60})M(CO)$_3${(−)-DIOP}] (**1**, M = Mo; **2**, M = W), *mer*-[(η^2-C_{60})M(CO)$_3${(+)-DIOP}] (**3**, M = Mo; **4**, M = W) and [(η^2-C_{60})M{(−)-DIOP}] (**5**, M = Pd; **6**, M = Pt), the crystal structure of **6** and the electrochemical properties of **1**, **2**, **5** and **6**.

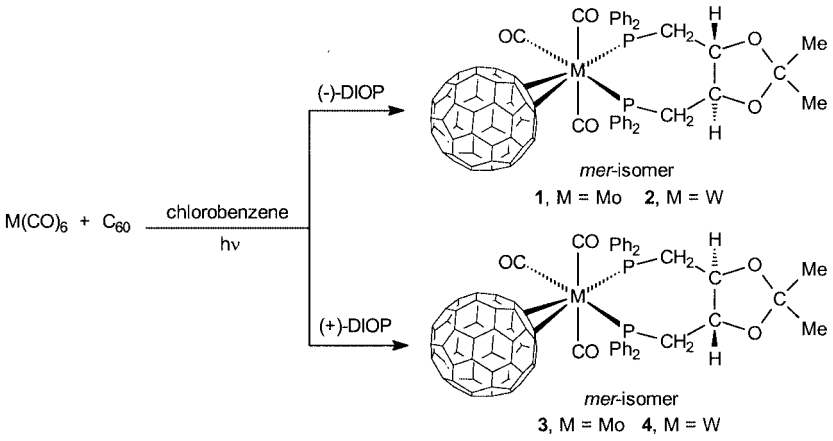
Results and Discussion

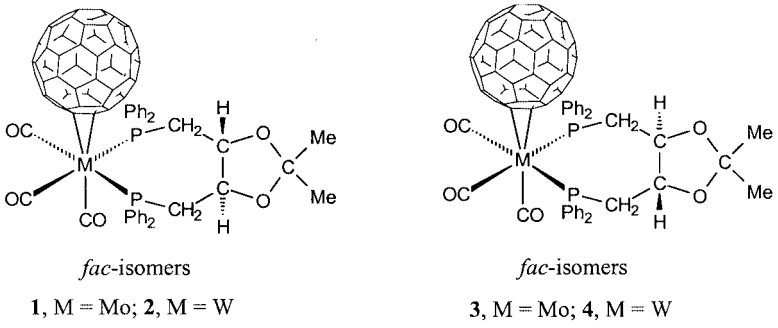
Synthesis and Characterization of *mer*-[(η^2-C_{60})M(CO)$_3$-{(−)-DIOP}] (1, M = Mo; 2, M = W) and *mer*-[(η^2-C_{60})M(CO)$_3${(+)-DIOP}] (3, M = Mo; 4, M = W)

Irradiation of [M(CO)$_6$] (M = Mo, W), in the presence of an equimolar quantity of C_{60} and (−)-DIOP or (+)-DIOP in chlorobenzene, with a UV 450-W mercury vapor lamp at ambient temperature, resulted in the formation of complexes **1**−**4** in 42−51% yields, as shown in Scheme 1.

Complexes **1**−**4** as the *mer* isomers obtained from the above "one-pot" reactions might be regarded as being produced by the reaction of M(CO)$_6$ with one of the chiral



Scheme 1



Scheme 2

diphosphane ligands (±)-DIOP, with subsequent substitution of one equatorial CO ligand from the intermediate complex [M(CO)$_4${(−)-DIOP}] or [M(CO)$_4${(+)-DIOP}] by the C_{60} ligand.

Complexes **1**−**4** are new and have been characterized by elemental analyses, ^{1}H (^{31}P, ^{13}C) NMR, UV/Vis, IR, FAB-MS and CD spectroscopy. The combustion analyses agree with their chemical formulas, and the FAB-MS spectra clearly show the molecular ion M^+ or [M^+ + 1 − 3 H] peaks. Theoretically, **1**−**4** each may have two possible isomers, namely the *fac* and the *mer* isomer. The *mer* isomers are shown in Scheme 1, and the *fac* isomers for **1**−**4** are shown in Scheme 2. However, the ^{31}P NMR spectra of **1**−**4** have indicated that they exist as the *mer* isomers. In the ^{31}P NMR spectra of **1**−**4**, two signals are present, which is consistent with the fact that *mer* isomers have two different P atoms, one *cis* to the C_{60} ligand, and the other *trans* to it (*fac* isomers have two identical P atoms, both *cis* to the C_{60} ligand). The two ^{31}P NMR signals are doublets; the doublets for the Mo complexes **1** and **3** appear at δ ≈ 20 and 15 ppm, with $J_{P\text{-}P}$ = 30−32 Hz, and the doublets for the W complexes **2** and **4** appear at δ ≈ −4 and −5 ppm, with $J_{P\text{-}P}$ ≈ 21 Hz. This can be seen from the two representative spectra of **3** and **4** (Figure 1). It is worth noting that the ^{31}P chemical shifts of complexes containing a DIOP ligand, such as **1**−**4**, usually lie at a higher field than the corre-

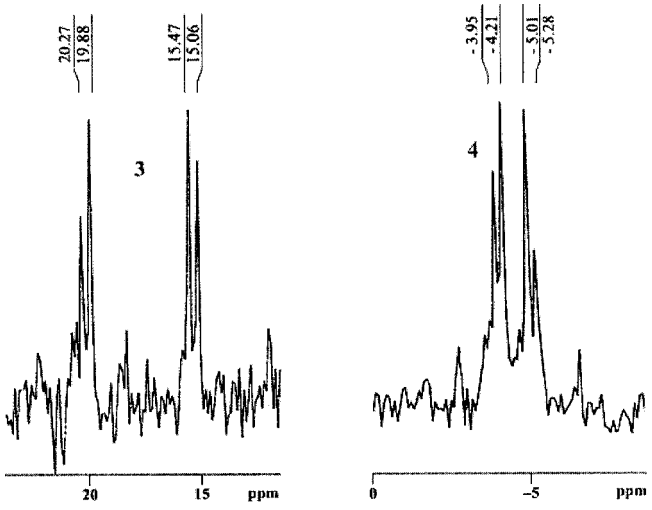


Figure 1. ^{31}P NMR spectra of **3** and **4**

sponding complexes containing a dppe ligand {such as *mer*-[$Mo(CO)_3$(dppe)(η^2-C_{60})] and *mer*-[$W(CO)_3$(dppe)(η^2-C_{60})]: δ_P = 62.64/54.21 ppm and 41.48/38.11 ppm, respectively} or a dppb ligand {such as *mer*-[$Mo(CO)_3$(dppb)(η^2-C_{60})] and *mer*-[$W(CO)_3$(dppb)(η^2-C_{60})]: δ_P = 66.18/55.66 ppm and 49.50/43.49 ppm, respectively}. This is because δ_P of the free ligand DIOP (δ = −23.5 ppm)[12] lies at a much higher field than those of the free ligands dppe (δ = 12.5 ppm)[13] and dppb (δ = −13.41 ppm, determined by us, since no reported δ_P value is available).

The ^{1}H NMR spectra of **1**−**4** are much more complicated than those of the free ligands (−)-DIOP and (+)-DIOP. The spectra of the free ligands show a sharp singlet assigned to the two methyl groups. This singlet appears as two singlets in the spectra of their complexes. The two broad peaks in the spectra of the free DIOP ligands, assigned to the two H atoms bonded to the chiral carbon atoms, appear as two apparent triplets and two apparent quadruplets in the spectra of their complexes. Further, in the spectra of the free ligands, the multiplet assigned to the two CH_2 groups, appears as two multiplets in the spectra of their complexes. Obviously, such ^{1}H NMR spectroscopic changes are consistent with the chelation of the DIOP ligands in the *mer*-isomers of **1**−**4**.

In the ^{13}C NMR spectra of **1**−**4**, the saturated, ketal and phenyl ring carbon atoms of the DIOP ligands lie in the ranges δ = 17−27, 103−109 and 123−136 ppm, respectively. In addition, the C_{60} ligands in **1**−**4** display resonance signals in the ranges δ = 136−163 ppm for the 58 sp^2 carbon atoms, and δ = 73−80 ppm for their 2 sp^3 carbon atoms. This is consistent with known η^2-C_{60} transition metal complexes, such as [$Rh(NO)(PPh_3)_2$(η^2-C_{60})][14] and [$Fe(CO)_4$(η^2-C_{60})].[15] The ^{13}C NMR spectrum of the sp^2 and sp^3 carbon atoms of the C_{60} core in **2** is shown in Figure 2. As seen in Figure 2, there are 20 signals in the δ = 164−140 ppm region, which can be assigned to the 58 carbon atoms of the C_{60} core.[14,15] Another ^{13}C NMR signal at δ = 78.81 ppm can be assigned to the two sp^3 carbon atoms of the C_{60} core that is directly linked to the W atom.[14,15] Among the 20 signals, two signals at δ = 163.43 and 162.78 ppm are assigned to the four carbon atoms in close proximity to the carbon atoms linked to the W atom. Nine signals at δ = 147.09, 145.40, 145.05, 144.44, 144.35, 142.59, 142.49, 142.01 and 141.77 ppm can each be assigned to four carbon atoms and the other eleven signals at δ = 163.43, 162.78, 146.27, 145.28, 144.86, 143.87, 143.77, 143.64, 142.92, 141.33 and 140.03 ppm can each be assigned to two carbon atoms. Similarly, in the ^{13}C NMR spectrum of the C_{60} core, **1** displays 25 signals in the region δ = 163.42−140.95 ppm and one signal at δ = 80.01 ppm, **3** shows 19 signals in the region δ = 163.03−140.56 ppm and one signal at δ = 78.72 ppm, and **4** exhibits 22 signals in the region δ = 158.21−136.55 ppm and one signal at δ = 73.60 ppm.

The IR spectra of **1**−**4** show four characteristic absorption bands for the C_{60} core[16] in the range 1434−525 cm^{-1}, as well as three strong bands in the range 2002−1870 cm^{-1}, which can be assigned to the terminal carbonyl groups.[17] The simplicity of the carbonyl bands provides further evidence that complexes **1**−**4** consist of only one isomer (since a mixture of *fac*/*mer* isomers would exhibit more active carbonyl absorption bands).[18]

In the UV/Vis spectra of **1**−**4**, there are five absorbance bands in the range 200−610 nm. This is typical of a free C_{60} ligand that has been complexed by a transition metal moiety.[19] The largest changes in the UV/Vis spectra occur in the visible region relative to that of free C_{60}. A new weak and broad band appears at ca. 430 nm in the spectra of complexes **1**−**4**. This peak is responsible for the color change in the reaction mixture, from purple C_{60} to dark green for the corresponding complexes. In addition, the new band suggests that the C_{60} ligands are coordinated to Mo and W atoms via an η^2-coordination mode in **1**−**4**.[20]

CD spectroscopy is an important method for the characterization of chiral compounds. The CD spectra of **1**−**4** are shown in Figures 3 and 4, respectively. As can be seen in Figure 3, **1** shows the negative and positive Cotton effects at 293 (−), 326 (+), 401 (−), 451 (−) and 540 (+) nm, and **2** displays similar Cotton effects at 288 (−), 324 (+), 399 (−), 449 (−) and 537 (+) nm.

Interestingly, the CD spectra of **3** and **4** (Figure 4) appear to be the mirror images of **1** and **2**, respectively. For example, **3** shows Cotton effects at 293 (+), 326(−), 402 (+), 450 (+), and 538 (−) nm, whereas **1** shows Cotton effects at 293 (−), 326(+), 401 (−), 451 (−) and 540 (+) nm. This is consistent with the behavior of chiral compounds with the ligands (+)-DIOP and (−)-DIOP. In addition, it is worth noting that the main Cotton effects of **3** and **4**, con-

taining a (+)-DIOP ligand, are very similar to those of (η^2-C_{60})Pt{(+)-DIOP} and (η^2-C_{60})Pd{(+)-DIOP}.[21]

Electrochemistry of Complexes 1 and 2 and Complementary EPR Measurements

Figure 5 shows the cyclic voltammetric behavior of the W complex **2** in dichloromethane solution at −20 °C.

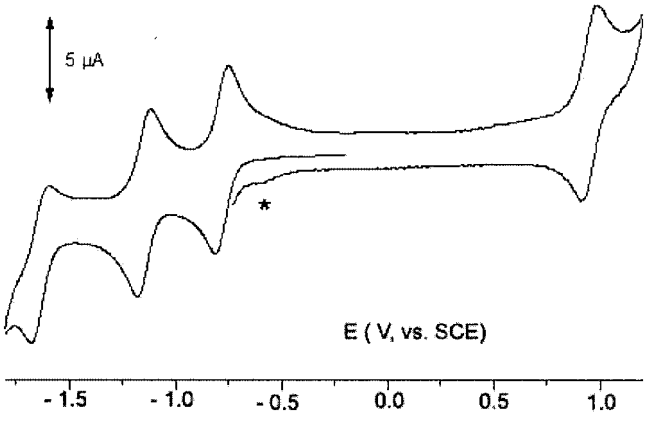

Figure 5. Cyclic voltammogram on a platinum electrode of a CH_2Cl_2 solution of **2** (0.4×10^{-3} mol·dm^{-3}); scan rate 0.2 V·s^{-1}; $T = -20$ °C; the starred peak indicates the appearance of identified by-products (see text)

Three sequential reductions appear that have features indicating chemical (i_{pa}/i_{pc} constantly equal to 1, independently from scan rate) and electrochemical (ΔE_p in the range from 58 to 70 mV with scan rate varying from 0.02 V·s^{-1} to 0.5 V·s^{-1}) reversibility. An oxidation process also occurs that shows reversibility.

In confirmation with the suggested fullerene-centered nature of the cathodic processes and their chemical reversibility, controlled potential coulometry of the first reduction step ($E_w = -0.9$ V) indicates one electron per molecule. The resulting solution displays a cyclic voltammetric profile that resembles the original one.

The anodic process is straightforwardly assigned as a one-electron process that is centered on the exohedral metal fragment. In spite of its features, which show chemical reversibility, it can be seen that in the back-scan a minor starred-peak appears at potential values coincident with the first reduction process of the free fullerene. This suggests that the monocation $[\mathbf{2}]^+$ is not indefinitely stable. At ambient temperature, the voltammetric patterns remain substantially unaltered.

The formal electrode potentials of the multiple redox changes are presented in Table 1.

As commonly seen for metallofullerenes,[22] the reduction processes are shifted towards more negative potential values, indicating that the appended metal fragment is electron-donating towards the fullerene. In the present case, these values are shifted by about 0.20 V with respect to the free fullerene.

In previous papers we have proved, by EPR spectroscopy, that the LUMO orbitals of exohedral metallofullerenes are in part contributed by the d orbitals of the metal ion itself.[23] Here, we have studied the nature of the electrogenerated paramagnetic anion radical $[\mathbf{2}]^-$ by X-band EPR spectroscopy. Figure 6 shows the spectrum recorded under glassy conditions ($T = 100$ K), relative to that of $[C_{60}]^-$.

The broad lineshape of $[\mathbf{2}]^-$ can be suitably interpreted assuming an $S = 1/2$ electron spin Hamiltonian with axial resolution either in the first or second derivative modes. The EPR features suggest that the paramagnetic species possesses significant metallic character [$g_i > g_{electron} = 2.0023$; $\Delta g = 0.083(5)$]. No evidence for a_{aniso} hyperfine (hpf) splittings of the ^{183}W nucleus (^{183}W: I nuclear spin = 1/2; natural abundance = 14.4%) has been obtained, probably as a consequence of either the broad lineshape, which masks the low intensity satellite peaks of the ^{183}W isotope, or the partial metallic character.[23] Moreover, no ^{31}P (^{31}P: $I = 1/2$; natural abundance = 100%) superhyperfine (shpf) splittings are detectable in the second derivative mode, suggesting that the unpaired electron is mainly delocalized in a SOMO basically constituted by the C_{60} and metal d atomic orbitals.

When the temperature at the glassy-fluid transition phase is raised, the anisotropic features of $[\mathbf{2}]^-$ disappear and the fluid solution becomes EPR-silent. However, rapid refreezing quantitatively restores the original glassy spectrum. This indicates the stability of the metal complex species under different experimental conditions. The absence of the absorption peaks under fluid solution conditions is not un-

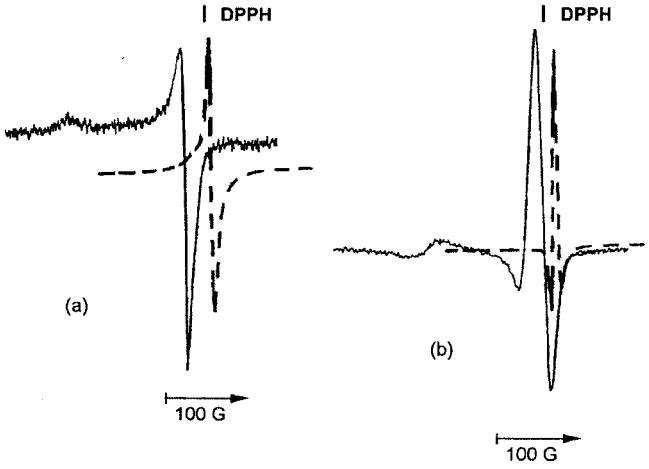

Figure 6. Low-temperature (T = 105 K) X-band EPR spectra of the electrogenerated anions [**2**]$^-$ (——) and [C_{60}]$^-$ (− −) in CH_2Cl_2 solution; (a) first derivative; (b) second derivative

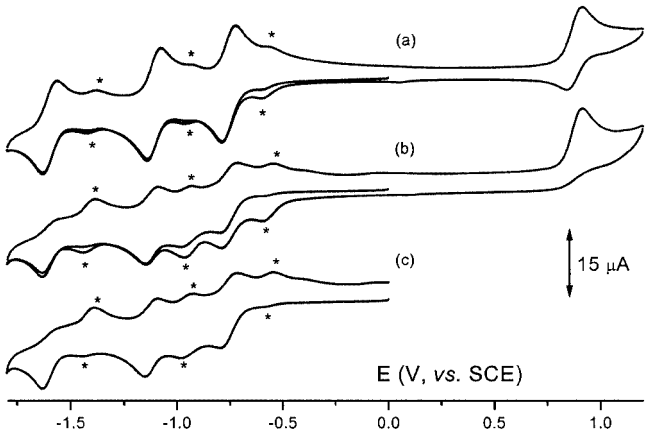

Figure 7. Cyclic voltammograms on a platinum electrode of a CH_2Cl_2 solution of **1** (0.7×10^{-3} mol·dm^{-3}); (a) T = −20 °C; (b, c) T = +20 °C; scan rate 0.2 V·s^{-1}; starred peaks indicate the appearance of identified by-products (see text)

expected in view of the increasing inter-/intramolecular dynamics induced by temperature. This in turn reflects the significant decrease in the ESR times.[24]

The X-band EPR parameters obtained by simulation procedures[25] are presented in Table 2.

Table 2. Low-temperature (100 K) X-band EPR parameters of the electrogenerated anions [2]$^-$ and [C_{60}]$^-$ in CH_2Cl_2 solution (g_i: ± *0.005)*

Anion	$g_\parallel$	$g_\perp$	$<g>$[a]	g_{iso}
[**2**]$^-$	2.093	2.010	2.034	−
[C_{60}]$^-$	2.006[b]	2.006[b]	2.006[b]	2.001[c]

[a] $<g> = (g_\parallel + 2g_\perp)/3$. [b] Averaged values. [c] T = 230 K.

The redox activity of the molybdenum analogue **1** is illustrated in Figure 7.

At low temperatures (T = −20 °C), **1** exhibits a voltammogram that is similar to that of **2** (Figure 7, a). In fact, apart from minor traces of free C_{60} initially present in solution, three fullerene-centered reductions also appear that have features indicative of chemical and electrochemical reversibility. In this case, however, the molybdenum-centered oxidation is partially chemically reversible (i_{pc}/i_{pa} = 0.4 at 0.1 V·s^{-1}). The fact that the instability of [**1**]$^+$ is due to the relatively fast release of the fullerene subunit can clearly be seen from the voltammogram in Figure 7 (b), which has been recorded at ambient temperature. Increasing amounts of the free fullerene are evident in the backscan, indicated as starred reduction processes. However, it should be noted that the monoanions [**1**]$^{-/2-/3-}$ are unstable at increasing temperatures, such that the fast release of free C_{60} occurs after traversing the respective peaks (Figure 7, c). The pertinent formal electrode potentials are given in Table 1.

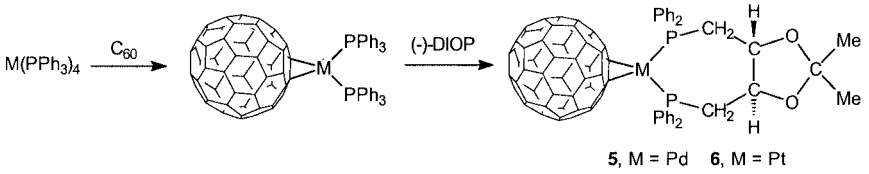
Synthesis and Characterization of [(η^2-C_{60})M{(−)-DIOP}] (5, M = Pd; 6, M = Pt)

The toluene solution of the intermediate complex [(η^2-C_{60})Pd(PPh_3)$_2$] or [(η^2-C_{60})Pt(PPh_3)$_2$], formed from C_{60} and [Pd(PPh_3)$_4$] or [Pt(PPh_3)$_4$], reacted in situ with an excess amount of (−)-DIOP, through a ligand exchange process between PPh_3 and DIOP, to give **5** and **6**, as shown in Scheme 3.

Complexes **5** and **6** were isolated, as their toluene solvates **5**·PhMe and **6**·PhMe in > 90% yields, by layering the reaction mixtures with hexane.

Compounds **5** and **6** were fully characterized by elemental analysis, ^{1}H, ^{31}P NMR, IR and UV/Vis spectroscopy. The ^{31}P NMR spectrum of **5** displays a singlet at δ = 9.28 ppm assigned to its two identical P atoms, and that of **6** exhibits a singlet at δ = 11.13 ppm, along with two satellite singlets due to the ^{195}Pt-^{31}P coupling, assigned to its two identical P atoms. The Pt-P coupling constant (3749 Hz) for **6** is almost the same as that for [(η^2-C_{60})Pt{(+)-DIOP}] (3751 Hz).[10] The ^{1}H NMR spectra of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 3

5 and **6** indicate the presence of the (−)-DIOP ligand and toluene as the solvent molecule.

Compared with the UV/Vis spectrum of free C_{60}, the UV/Vis spectra of **5** and **6** display a new band at ca. 295 nm in the ultraviolet region, and a new band at 440 nm in the visible region. The former band can be attributed to the presence of phenyl groups in **5** and **6**, and the latter to the η^2-coordinating mode of C_{60} [20] with Pd and Pt, in **5** and **6**, respectively. The IR spectra of **5** and **6** show four absorption bands at 527, 576, 1184 and 1428 cm^{-1}, characteristic of the C_{60} core.

Interestingly, similar to the Mo/W complexes **1**−**4**, the CD spectra of **5** and **6**, as shown in Figure 8, display multiple Cotton effects at 298 (+), 325 (−), 366 (−) and 453 (+) nm for **5**, and 291 (+), 324 (−), 363 (−) and 450 (+) nm for **6**. The CD spectra of **5** and **6** are the mirror images of their enantiomers with (+)-DIOP in the region 280−600 nm.[21]

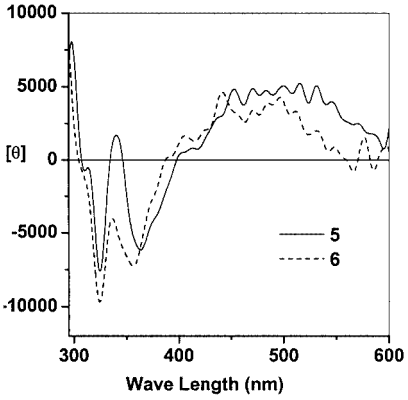


Figure 8. CD spectra of complexes **5** and **6** in toluene

Single Crystal Molecular Structure of 6

The structure of **6** has been unambiguously confirmed by X-ray diffraction methods. The molecular structure of **6** and its cell packing are demonstrated in Figures 9 and 10, respectively. As seen intuitively from Figure 9, complex **6** consists of a (4*R*,5*R*)-DIOP [i.e. (−)-DIOP] ligand chelated to platinum atom Pt(1) through its two phosphorous atoms P(1) and P(2), and a C_{60} ligand coordinated to Pt(1) through its C(1) and C(2) atoms in an η^2-fashion. The C(1)−C(2) bond length is 1.502(11) Å, similar to that of a normal C−C single bond, which suggests that C(1) and C(2) are σ-coordinated rather than π-coordinated to form a metallacyclopropane ring with the Pt(1) atom. The zerovalent platinum atom Pt(1) is at the center of a tetragon

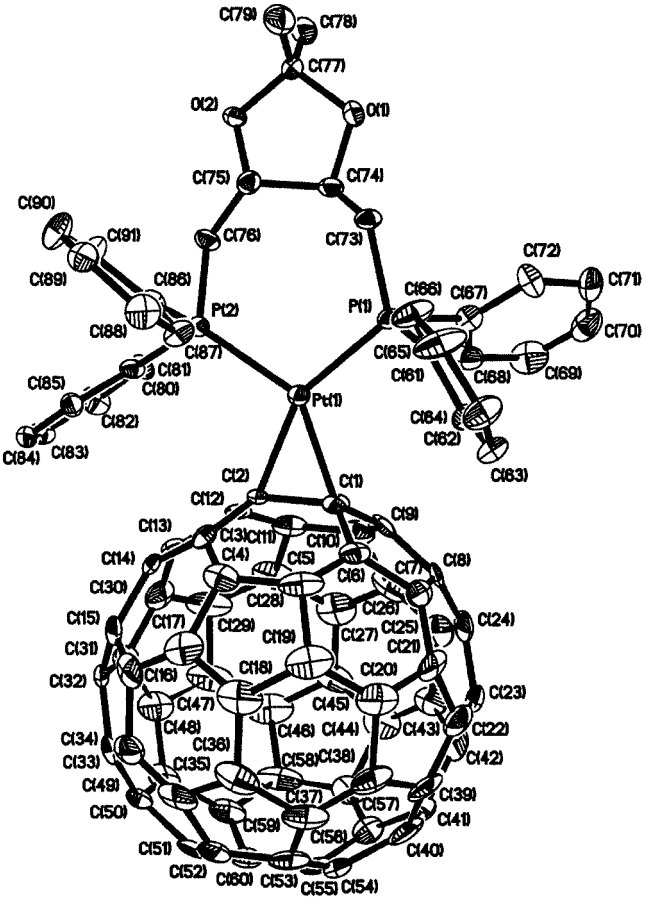

Figure 9. Structural drawing of **6** with ellipsoids drawn at the 30% probability

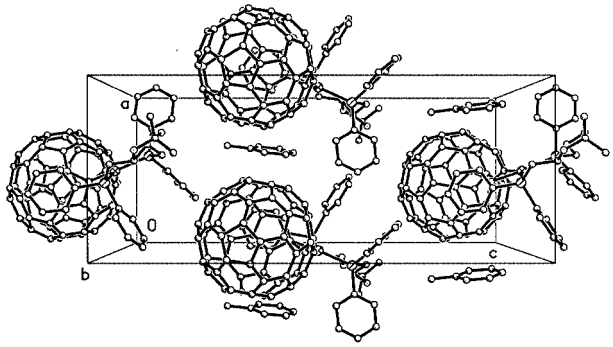

Figure 10. Molecular arrangement in a unit cell of **6**

constituted by the atoms C(1), C(2), P(1) and P(2), and all five atoms are coplanar with a mean deviation of only 0.014 Å. In addition, it is worth noting that the C_{60} ligand in **6** is slightly distorted from the perfect sphere. The two coordin-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ating carbon atoms C(1) and C(2) are pulled out of the spherical surface by about 0.2 Å, and the distance from C(1) and C(2) to the C_{60} center (ca. 3.72 Å) is much longer than the distance from each of the other carbon atoms to the C_{60} center (3.49−3.56 Å). As a matter of fact, such a structure is typical of some diphosphane-chelated C_{60} transition metal complexes. Table 3 shows some geometric parameters of the crystal structures of **6** and its enantiomer (η^2-C_{60})Pt{(+)-DIOP}.[10] Obviously, the geometric parameters of these two platinum complexes are very similar to each other.

Table 3. Comparison of the crystal structures of **6** and its analogue with (+)-DIOP

	6	(η^2-C_{60})Pt{(+)-DIOP}
Bond length between the two coordinating carbon atoms [Å]	1.502(11)	1.51(2)
Pt−C bond length [Å]	2.107(7)	2.09(2)
	2.135(7)	2.12(2)
Pt−P bond length [Å]	2.252(2)	2.262(4)
	2.281(2)	2.279(4)
C−Pt−C bond angle [°]	41.5(3)	42.0(4)
P−Pt−P bond angle [°]	105.41(7)	109.47(13)
C−Pt−P bond angle [°]	101.2(2)	104.2(4)
	111.8(2)	104.4(4)

As seen in Figure 10, each crystal cell contains four molecules of **6** and four molecules of toluene. The closest distance between the solvent molecule toluene and the C_{60} moiety in **6** is 3.6 Å. This indicates that there are no evident interactions between them.

Electrochemistry of Complexes 5 and 6 and Complementary EPR Measurements

As exemplified in Figure 11 which refers to the Pt complex **6**, derivatives [(η^2-C_{60})M{(−)-DIOP}] exhibit a reduced redox activity compared with that of [(η^2-C_{60})M(CO)$_3${(−)-DIOP}].

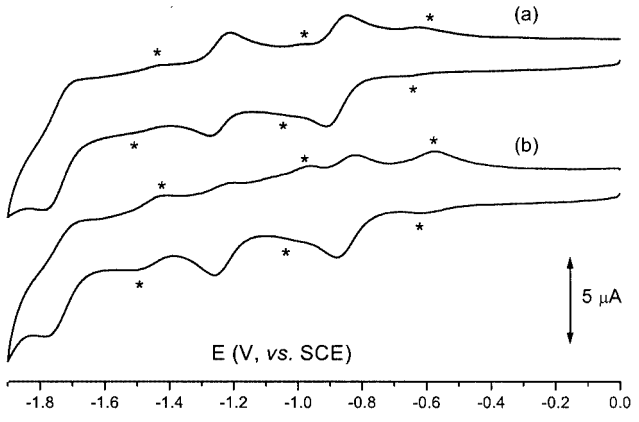

Figure 11. Cyclic voltammograms on a platinum electrode of a CH_2Cl_2 solution of **6** (0.7×10^{-3} mol·dm^{-3}); (a) $T = -20$ °C; (b) $T = +20$ °C; scan rate 0.2 V s^{-1}; starred peaks indicate the appearance of identified by-products (see text)

Complexes **5** and **6** display two fullerene-centered sequential reductions. The reduction processes show significant chemical reversibility, only at low temperatures. At ambient temperature, fast release of free C_{60} occurs on reduction. A third cathodic process is present at very negative potential values, which, based on the relative peak-height, most likely involves the metal fragment.[23] Further, these complexes show an anodic process (not shown in figure) that is completely irreversible (or, quick C_{60} release take places) at low temperatures. The formal electrode potentials are presented in Table 4.

It should be noted that the Pd/Pt fragment is slightly more electron-donating than the Mo/W unit, such that the negative shift in the redox potentials is about 0.25 V with respect to the free fullerene.

In agreement with the electrochemical findings, the liquid-nitrogen X-band EPR spectra of the electrogenerated [**5**]$^-$ monoanion show the undoubted presence of [C_{60}]$^-$ (Figure 12).

As a matter of fact, two different paramagnetic species, partially overlapped in the high-field region, are detected. The narrow, high-field (starred) signal is due to the [C_{60}]$^-$ monoanion, while the low-field signal is attributed to the parallel region of the axial absorption of [**5**]$^-$, the relevant broad parallel region is shifted at lower field. The metallofullerene anion exhibits significant metallic character [$g_i > g_{electron} = 2.0023$; $\Delta g = 0.090(5)$]. There is no evidence for a_{aniso} hpf splittings of the ^{105}Pd nucleus (^{105}Pd: I nuclear spin = 5/2; natural abundance = 22.2%), as well as no ^{31}P shpf splittings. When the temperature at the glassy-fluid transition is raised, the anisotropic features of [**5**]$^-$ disappear, while the isotropic signal of the [C_{60}]$^-$ monoanion is maintained. Rapidly refreezing the fluid solution quantitatively restores the original glassy spectrum of the complex. The X-band EPR parameters are given in Table 5.

In spite of the apparent high stability of the Pt anion [**6**]$^-$ in the cyclic voltammetric time scale, exhaustive electrolysis at the first cathodic process of **6** affords a solution which, through EPR spectroscopy, only shows the signal for [C_{60}]$^-$.

Experimental Section

General: All reactions were carried out under highly purified nitrogen using standard Schlenk or vacuum-line techniques. Chlorobenzene was dried by distillation from P_2O_5 and subsequently from CaH_2 under nitrogen. Toluene, THF, pentane and hexane were distilled under nitrogen from sodium/benzophenone ketyl. All solvents were degassed by bubbling a stream of nitrogen through them for at least 15 min before use. C_{60} (99.9%), (−)-DIOP and (+)-DIOP were of commercial grade and used as received. [$Pd(PPh_3)_4$][26] and [$Pt(PPh_3)_4$][27] were prepared according to literature procedures. Preparative thin-layer chromatography (TLC) and column chromatography were performed on glass plates coated with silica gel (10−40 μm, 20 cm × 25 cm × 0.25 cm) and glass columns packed with silica gel (200−300 mesh, 30 cm × 2.5 cm), respectively. Melting points were determined with a Yanaco MP-500 melting point apparatus. Elemental analyses and FAB-MS were performed with

an Elementar Vario EL analyzer and a Zabspec spectrometer, respectively. IR and UV/Vis spectra were recorded with a Bio-Rad FTS-135 and a Shimadzu UV-2401/PC spectrophotometer, respectively. ^{1}H NMR, ^{31}P NMR and ^{13}C NMR spectra were obtained either with a Bruker AC-P200 or a UNITY-PLUS 400 spectrometer. The CD spectra and the specific rotatory powers were determined with a JASCO 715 spectrapolarimeter and a Perkin−Elmer 241-MC polarimeter, respectively. Materials and apparatus for electrochemistry and joint EPR spectroscopy have been described elsewhere.[23] Potential values are referred to the saturated calomel electrode (SCE). Under the present experimental conditions, the one-electron oxidation of ferrocene occurs at +0.36 V.

Preparation of *mer*-[(η^2-C_{60})Mo(CO)$_3${(−)-DIOP}] (1): A 100-mL photoreactor equipped with an N_2 inlet tube and a serum cap was charged with C_{60} (0.072 g, 0.10 mmol), (−)-DIOP (0.050 g, 0.10 mmol), [Mo(CO)$_6$] (0.026 g, 0.10 mmol) and chlorobenzene (50 mL). The mixture was sonicated until all C_{60} was dissolved. The photoreactor containing the resulting purple solution was evacuated to a pressure of ca. 0.1 Torr, and was irradiated by a water-cooled UV 450-W mercury vapor lamp for 3 h to afford a dark green solution. The resulting solution was concentrated in vacuo, and the residue was separated by column chromatography using toluene/light petroleum ether (2:1, v/v) as the eluent under anaerobic conditions. From the second chlorophyll-green band, 0.059 g (42%) of **1** as a dark green solid was obtained. M.p. 300 °C (dec.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.35 (s, 3 H, CH_3), 1.46 (s, 3 H, CH_3), 1.60−1.88 (m, 2 H, CH_2), 2.35 (q, J = 8 Hz, 0.5 H, OCH), 3.01 (t, J = 13.2 Hz, 0.5 H, OCH), 3.26 (t, J = 13.2 Hz, 0.5 H, OCH), 3.62−3.78 (m, 2 H, CH_2), 4.93 (q, J = 8 Hz, 0.5 H, OCH), 7.10−8.00 (m, 20 H, 4 C_6H_5) ppm. ^{31}P NMR (80.96 MHz, $CDCl_3$): δ = 20.05 (d, 1 P), 15.26 (d, $J_{P\text{-}P}$ = 29.6 Hz, 1 P) ppm. ^{13}C{^{1}H} NMR (100.6 MHz, C_6D_6): δ = 211.17 (CO), 210.48 (CO), 163.42 (2 C), 162.76 (2 C), 147.59 (2 C), 147.54 (2 C), 146.63 (2 C), 146.04 (2 C), 145.93 (2 C), 145.82 (2 C), 145.67 (4 C), 145.11 (4 C), 145.04 (4 C), 144.76 (2 C), 144.70 (2 C), 144.59 (2 C), 144.05 (2 C), 143.69 (2 C), 143.62 (2 C), 143.38 (4 C), 142.97 (2 C), 142.89 (2 C), 142.75 (2 C), 142.67 (2 C), 142.30 (2 C), 141.10 (2 C), 140.95 (2 C), 80.01 (2 C) (C_{60} resonance), 135.2, 134.65, 134.45, 134.34, 133.09, 132.99, 131.62, 131.44, 131.02, 130.91, 130.81, 130.28, 129.73, 129.64, 129.51, 129.42 (4 C_6H_5P, resonance), 109.28 (−OCO−), 27.47 (CHO), 27.39 (CH_2), 23.07 (CH_3) ppm. [(η²-C_{60})Pd{(−)-DIOP}] (5): A three-necked flask equipped with a magnetic stirrer bar, a rubber septum and a nitrogen inlet tube was charged with C_{60} (0.018 g, 0.025 mmol) and 8 mL of toluene. The mixture was stirred until the solids were dissolved. When [Pd(PPh$_3$)$_4$] (0.029 g, 0.025 mmol) was added, the solution turned dark green immediately. After (−)-DIOP (0.025 g, 0.050 mmol) was added, the solution was stirred for 10 min. 20 mL of hexane was then carefully layered on the reaction mixture. The flask was left to stand for 1 d without disturbing and tiny black needles precipitated. After the precipitate was filtered, washed with pentane and dried in vacuo, 0.030 g (91%) of **5**·$C_6H_5CH_3$ was obtained. M.p. > 300 °C (dec.). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.38 (s, 6 H, 2CH_3), 2.34 (s, 3 H, PhCH_3), 2.58−2.76 (m, 2 H, 2OCH), 3.30−4.24 (m, 4 H, 2CH_2), 7.16−7.94 (m, 25 H, 5 C_6H_5) ppm. ^{31}P NMR (200 MHz, $CDCl_3$): δ = 9.28 (s, 2 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 3061 (w), 3018 (w), 2983 (w), 2933 (w), 2910 (w), 2879 (w), 2860 (w), 1571 (w), 1480 (w), 1459 (w), 1433 (s), 1370 (m), 1252 (m), 1218 (m), 1183 (m), 1159(m), 1099 (m), 1055 (s), 978 (m), 885 (m), 832 (m), 749 (s, sh), 735 (s), 692 (s), 577 (m), 527 (s), 507 (s) cm^{-1}. UV/Vis (toluene): λ_{max} (log ε) = 288.5 (4.57), 294.5 (4.58), 334.5 (4.54), 447.0 (3.97) nm. $C_{98}H_{40}O_2P_2Pd$ (1417.76): calcd. C 83.02, H 2.84; found C 83.12, H 3.08.

[(η²-C_{60})Pt{(−)-DIOP}] (6): The synthesis was similar to that of **5**, except that [Pt(PPh$_3$)$_4$] (0.031 g, 0.025 mmol) was used instead of [Pd(PPh$_3$)]. 0.036 g (96%) of **6**·$C_6H_5CH_3$ as tiny black needles was obtained. M.p. > 300 °C (dec.). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.37 (s, 6 H, 2 CH_3), 2.33 (s, 3 H, PhCH_3), 2.60−2.82 (m, 2 H, 2 OCH), 3.58−4.20 (m, 4 H, 2 CH_2), 7.10−8.04 (m, 25 H, 5 C_6H_5) ppm. ^{31}P NMR (200 MHz, $CDCl_3$): δ = 11.13 (s, $J_{Pt\text{-}P}$ = 3749 Hz, 2 P) ppm. IR (KBr disk): $\tilde{\nu}$ = 3057 (w), 3022 (w), 2983 (w), 2941 (w), 2910 (w), 2879 (w), 2860 (w), 1571 (w), 1478 (w), 1458 (w), 1434 (m), 1372 (w), 1332 (w), 1251 (m), 1218 (m), 1183 (m), 1160 (m), 1102 (m), 1057 (s), 979 (m), 884 (m), 832 (m), 784 (m), 745 (s, sh), 734 (s), 692 (s), 576 (m), 527 (s), 508 (s) cm^{-1}. UV/Vis (toluene): λ_{max} (log ε) = 288.5 (4.59), 295.0 (4.59), 334.5 (4.51), 438.5 (4.11) nm. $C_{98}H_{40}O_2P_2Pt$ (1506.42): calcd. C 78.14, H, 2.68. found C 78.40, H 2.67.

Crystal Structure Determination of 6: Single crystals of **6** suitable for X-ray diffraction analysis were obtained by slow diffusion of hexane into the toluene solution of **6** at ambient temperature. A crystal of **6** was glued to a glass fiber and mounted on a Bruker SMART-1000 automated diffractometer. Data were collected at room temperature, using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) in the ω-2θ scanning mode. Absorption correction was performed using the SADABS method. The structure was solved by direct methods using the SHELXS-97 program[28] and refined by full-matrix least-squares techniques (SHELXL-97)[29] on F^2. Hydrogen atoms were located by using the geometric method. The crystal data and structural refinement details are listed in Table 6. The calculations were performed using the TEXSAN crystallographic software package of Molecular Structure Corporation. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-199653. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK [Fax: (internat.) + 44-1223/336033; E-mail: deposit@ccdc.cam.ac.uk or www:http://www.ccdc.cam.ac.uk].

Syntheses, Structures and Theoretical Investigations of $1\lambda^4,3\lambda^4,5\lambda^4$-Trithia-2,4,6,8,9-pentaazabicyclo[3.3.1]nona-1(9),2,3,5,7-pentaenes

Carsten Knapp,[a] Enno Lork,[a] Tobias Borrmann,[b] Wolf-Dieter Stohrer,[b] and Rüdiger Mews*[a]

Keywords: Sulfur / Nitrogen / Fluorine / Solid-state structures / Quantum chemistry

The syntheses of the title compounds RCN_5S_3 with electron-withdrawing aryl substituents [R = 2-FC_6H_4 (**1m**), 4-FC_6H_4 (**1n**), 2,6-$F_2C_6H_3$ (**1o**), C_6F_5 (**1p**), 4-NCC_6H_4 (**1q**) and Cl_3C (**1r**)] are described. The X-ray structures of **1n**, **1o**, **1q** and **1r**, together with those of $Me_2NCN_5S_3$ (**1b**) and 4-$CH_3C_6H_4CN_5S_3$ (**1f**), are reported. The experimentally determined dependence of the bond lengths on the substituents R within the bicyclic system RCN_5S_3 is well-reflected in the results of the theoretical calculations (RHF, MP2, B3LYP). The bonding model developed shows that acceptor substituents do not influence bonding within the bicycle. In the solid state, two fundamentally different primary interactions of the RCN_5S_3 molecules are observed; "stacking" and "dimerisation", which can be rationalised by electrostatic interactions between the CN_5S_3 units. However, secondary effects – the interactions between the R substituents – may be even more dominant.

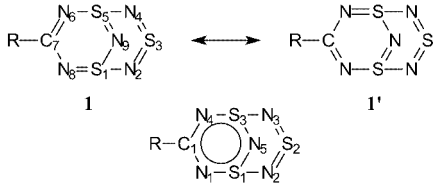
Introduction

The bicyclic carbon-sulfur-nitrogen heterocycles, $1\lambda^4,3\lambda^4,5\lambda^4$-trithia-2,4,6,8,9-pentaazabicyclo[3.3.1]nona-1(9),2,3,5,7-pentaenes **1** (Scheme 1), are multifunctional sulfur-nitrogen systems with a versatile chemistry.

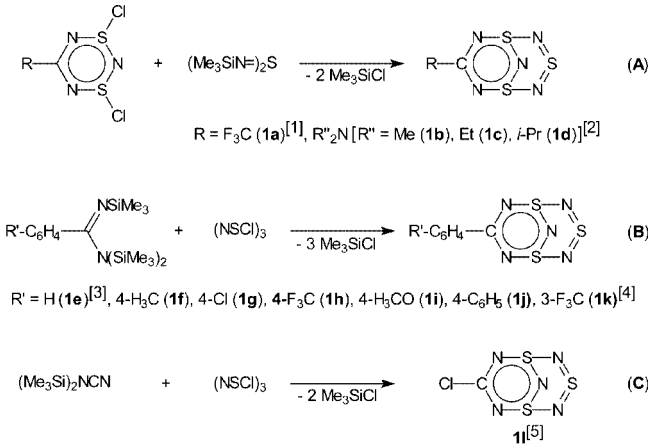


1 **1'**

R = X_3C [X = F (**1a**), Cl (**1r**)]
= R''_2N [R'' = Me (**1b**), Et (**1c**), *i*-Pr (**1d**)]
= $R'C_6H_4$ [R' = H (**1e**), 4-H_3C (**1f**), 4-Cl (**1g**), **4**-F_3C (**1h**), 4-H_3CO (**1i**), 4-C_6H_5 (**1j**), 3-F_3C (**1k**), 4-NC (**1q**)]
= Ar_F [Ar_F = 2-FC_6H_4 (**1m**), 4-FC_6H_4 (**1n**), 2,6-$F_2C_6H_3$ (**1o**), C_6F_5 (**1p**)]
= Cl (**1l**)

Scheme 1. Note: The numbering in the top left represents the IUPAC numbering scheme, the scheme below is that used consistently in this article

They are accessible via two different routes, either from the reaction of 1,3-dichloro-1,3-dithiatriazines $(RCN)(NSCl)_2$ with $Me_3SiNSNSiMe_3$ (dithiatriazine route A; Scheme 2), or from $(NSCl)_3$ and tris(trimethylsilyl)amidines $RC(NSiMe_3)[N(SiMe_3)_2]$ (amidine route B).



Scheme 2

The preparation of the chloro derivative, described by route C,[5] is difficult to reproduce, but the compound is also accessible via route A from $(ClCN)(NSCl)_2$.[6] Attempts to prepare the corresponding fluoro derivative from $(FCN)(NSCl)_2$ resulted in a very unstable product.[6]

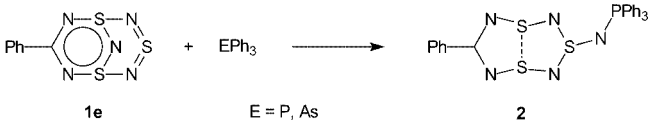
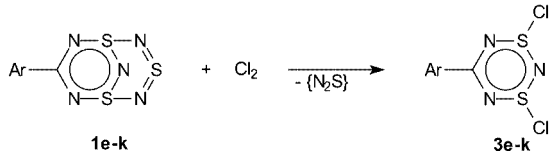
To date, the chemistry of these systems has not been well investigated. Based on MNDO calculations,[7] it has been proposed that the coordination chemistry of compounds **1** is varied. From the large number of chemically non-equivalent donor and acceptor sites in **1**, many interesting and not readily predictable reaction possibilities are expected. To date, only the F_3C derivative **1a** has been introduced as a ligand. $[Ni(F_3CCN_5S_3)_2(OSO)_2(FAsF_5)_2]$ and $[Ag(F_3CCN_5S_3)(\mu\text{-}F_3CCN_5S_3)]_2(AsF_6)_2$ have been isolated and characterised by X-ray crystallography.[7] The bicyclic system undergoes nucleophilic attack with EPh_3 (E = P, As), and **1e** is transformed into the monocyclic eight-membered imino derivatives **2** (Scheme 3),[8] with weak transannular S−S bonds.



Scheme 3

Under the conditions of both thermolysis and photolysis,[9] it was recently found that the bicyclic sulfur-nitrogen heterocycles **1** afford the corresponding 1,2,3,5-dithiadiazolyl radicals, which are of high interest.[10]

The dependence of the reactivity on the substituent R is documented in the reaction of **1a** and **1e**−**k** with elemental chlorine. The aryl derivatives **1e**−**k** are readily degraded to dithiatriazines **3e**−**k** (Scheme 4),[3,4] while the trifluoromethyl derivative **1a** is not attacked under similar conditions.[11,12]



Scheme 4

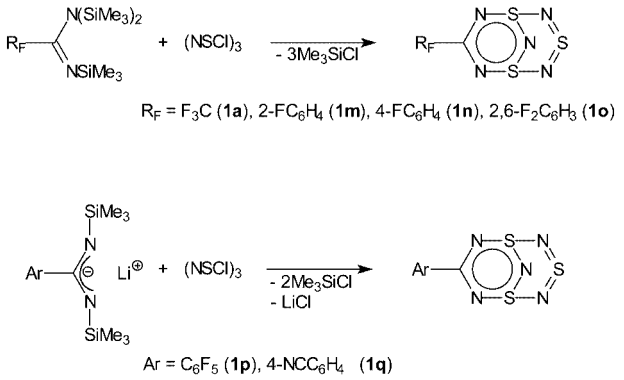
From the structural and theoretical investigations we endeavoured to explain the different stabilities. Furthermore, these theoretical investigations should allow us to predict the reactivities and the properties of **1**, based on the nature of the substituent.

The X-ray structures of **1a**,[1] **1d**,[3,13] **1e**[14] and **1l**[5] have been described previously. A preliminary theoretical discussion of the bonding properties based on MNDO calculations was reported earlier by our group.[1] In this paper, the synthesis of compounds with electron-withdrawing substituents [RCN_5S_3: R = 2-FC_6H_4 (**1m**), 4-FC_6H_4 (**1n**), 2,6-$F_2C_6H_3$ (**1o**), C_6F_5 (**1p**), 4-NCC_6H_4 (**1q**) and Cl_3C (**1r**)], for which an increased stability is expected, are reported. The X-ray structures of selected compounds (**1b**, **1f**, **1n**, **1o**, **1q** and **1r**) have been determined. The experimental results are compared with the results of the theoretical calculations.

Results and Discussion

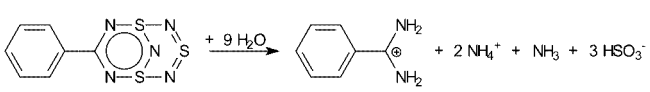
Syntheses of $1\lambda^4,3\lambda^4,5\lambda^4$-trithia-2,4,6,8,9-pentaazabicyclo-[3.3.1]nona-1(9),2,3,5,7-pentaenes

As expected, the bicyclic sulfur nitrogen systems **1m**−**1o** with partially fluorinated aryl substituents are readily prepared by the amidine route B from silylated amidines and trithiazyl trichloride. This route can also be used for the preparation of the trifluoromethyl-substituted derivative **1a** (Scheme 5). Thus, **1a** is more-readily accessible than previously reported.[1] It is not possible to use route B for the preparation of derivatives with stronger electron-withdrawing aryl groups (e.g. C_6F_5, 4-NCC_6H_4), since the corresponding *N*,*N*,*N*′-tris(trimethylsilyl)amidines cannot be prepared by silylation of lithium *N*,*N*′-bis(trimethylsilyl)amidines with Me_3SiCl. Their reactivity is greatly reduced due to the electron-withdrawing groups.[15,16] In this case, the corresponding lithium *N*,*N*′-bis(trimethylsilyl)amidines are directly reacted with $(NSCl)_3$ in diethyl ether. Under these conditions, **1p** and **1q** are also formed, but in lower yields. The compounds were obtained in a pure crystalline state by recrystallisation from acetonitrile.



Scheme 5

Compounds **1** can be stored at room temperature in an inert atmosphere and do not decompose. The bicyclic sulfur nitrogen framework undergoes chemical, photochemical or thermal decomposition (partial or complete). In moist air, most of the bicycles are transformed into a white solid within a few hours or days. Even $PhCN_5S_3$, described in the literature as air-stable,[3] will slowly decompose under these conditions. Complete hydrolysis occurs according to Scheme 6:

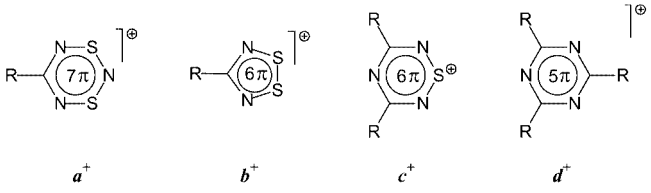


Scheme 6

The products from the direct complete hydrolysis in moist CH_2Cl_2, detected by mass spectrometry (FAB) and chemical analysis, are the corresponding amidinium ions and the NH_4^+, sulfate and thiosulfate ions; only small amounts of the sulfite ion are detected.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The results of the mass spectrometric analysis of the pure bicyclic systems depend on the ionisation method applied. With ionisation by EI, molecular ions are mostly detected, but with low intensity. The peak representing the fragment $[M - N_3S]^+$ is always present. This corresponds to the stable 1,2,3,5-dithiadiazolylium cation b^+ (Scheme 7) The more gentle FI method also allows for the detection of molecular ions. Furthermore, the direct degradation products a^+ and b^+ are observed, together with the ions (c^+, d^+) formed by recombination of the fragments.



Scheme 7

Chlorine cleaves the NSN bridge of the aryl-substituted bicyclic systems, forming the 1,3-dichloro-1,3,2,4,6-dithiatriazines.[3,4] In contrast to the aryl derivatives, the trifluoromethyl derivative $F_3CCN_5S_3$ (**1a**) is astonishingly stable and does not react with elemental chlorine or with SO_2Cl_2.[4,11,12] Attempts to obtain the corresponding dithiatriazines by degradation reactions of **1a** with Br_2 or $(CF_3)_2NO$ also failed.[12] To date, no explanation for the unexpected stability could be given. In contrast to **1a**, the partially and fully fluorinated aryl derivatives **1o** and **1p** also react with chlorine in CCl_4 (the reaction occurs within a few minutes) to give the corresponding 1,3-dichloro-1,3,2,4,6-dithiatriazines. An obvious dependence of the rate of chlorination on the substituents at the aryl groups has been noted for electron-withdrawing groups (**1g**, **1h**) vs. electron-donating groups (**1f**, **1i**).[4]

Some years ago investigations on the thermal decomposition of $PhCN_5S_3$ (**1e**) in acetonitrile solution were undertaken; only benzonitrile and S_4N_4 were identified as the decomposition products.[17] More recent investigations of the thermolysis of **1e** in squalane by ESR spectroscopy have shown that the radicals b˙ and c˙ are formed as the decomposition products, in accord with the results of the mass spectrometric investigations mentioned before. Both radicals are known from the literature and can be prepared by straightforward methods.[18]

Structure Investigations

Single crystals of RCN_5S_3 [R = Me_2N (**1b**), 4-$CH_3C_6H_4$ (**1f**), 4-FC_6H_4 (**1n**), 2,6-$F_2C_6H_3$ (**1o**), 4-NCC_6H_4 (**1q**), and Cl_3C (**1r**)] were obtained by crystallisation from acetonitrile at −40 °C. They crystallise in the triclinic space group $P\bar{1}$ with the exception of $Cl_3CCN_5S_3$ (**1r**), which crystallises in the monoclinic space group $P2_1/n$ with one molecule of acetonitrile in the asymmetric unit. Crystal data and details of the structure determinations are given in Table 1. Figure 1 shows the structures and the numbering scheme of **1o** and **1q** as representative examples. In these bicycles, the different substituents only have a slight effect on the bond lengths. The C1−N1 bond lengths (131.8−135.3 pm), the N1−S1 bond lengths (158.3−164.0 pm) and the S1−N5 bond lengths (162.6−163.4 pm) lie in the range between that of single and double bonds, while the S1−N2 bonds (172.3−174.8 pm) might be considered as single bonds and the N2−S2 bonds (154.0−155.2 pm) as double bonds. In line with the mesomeric structures (Scheme 1), the bicyclic

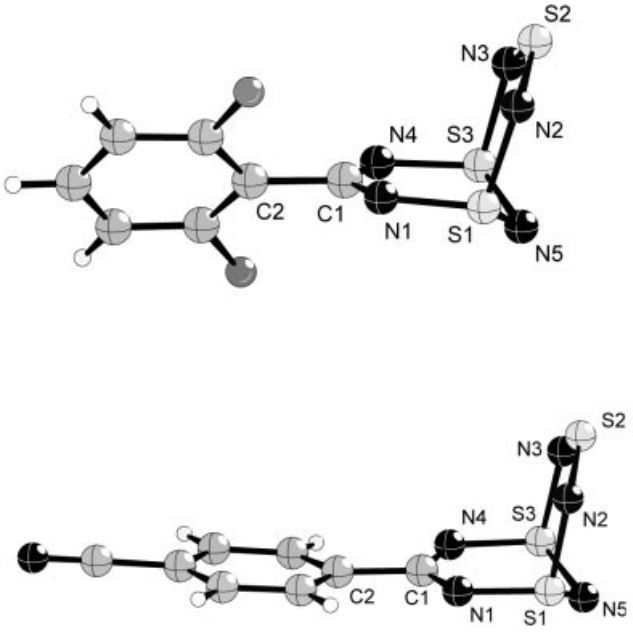

Figure 1. Crystal structures and numbering scheme of **1o** and **1q**

framework is best described as a dithiatriazine bridged by a sulfur diimide group.

Closer examination of the bonding parameters shows the effect of the substituents. The ten bicycles described in Table 2 can be divided into three groups. Strong donors or strong acceptors bonded directly to the bicycles each form one group. The third group consists of all aryl-substituted bicycles, the bond lengths of which are independent of the substituents at the aryl ring (they are equal within the range of standard deviations).

The difference between the three different groups is particularly apparent in the C1−N1 and the N1−S1 bond lengths. The C1−N1 bond length is increased by approximately 2 pm by electron-donating substituents (R = Me_2N), and shortened by approximately 1.5 pm by electron-accepting substituents (R = CF_3), relative to the weakly interacting phenyl group. The neighbouring N1−S1 bonds show the reverse effect. The effects on the other bonds in the system, except on the S1−N2 bond, are within experimental error. Directly bonded amino groups significantly increase this bond length when compared with the directly bonded electron-withdrawing groups and the aryl substituents.

The change in the C1−N1 bond lengths is accompanied by a change in the NCN angle: 127−128° for compounds with donor substituents, around 130° for the aryl derivatives, and up to 134−135° for the acceptor-substituted bicycles.

In the aryl derivatives the twist angle τ between the aromatic phenyl ring and the plane of the five atoms (C1, N1, N4, S1, S3) in the heterocycle is 26−29° for **1e**, **1f** and **1n**, i.e. the 6π-aromatic and the delocalised sulfur-nitrogen systems are not coplanar. However, in **1q**, which has a strongly electron-accepting nitrile group in the *para* position, the two rings are virtually coplanar (τ = 5.2°). However, this does not lead to an apparent shortening of the exocyclic C−C1 bond. In **1o**, the phenyl ring is 50.1° out of the plane formed by the five atoms of the heterocycle, because of the repulsive interactions between the fluorine atoms in the *ortho*-positions and the nitrogen atoms N1 and N4.

Solid-State Packing

In the crystal, the packing of the molecules varies. Two completely different arrangements of the bicycles are observed that can be described as "stacking" or "dimerisation". Stacking is found for the bicycles with R = Cl (**1l**), F_3C (**1a**) and 4-NCC_6H_4 (**1q**); a related structure is shown

by (**1d**; R = *i*Pr$_2$N). The sulfur-nitrogen rings fit into one another like stacked crates. Most of the aryl-substituted bicycles [R = 4-H$_3$CC$_6$H$_4$ (**1f**), 4-FC$_6$H$_4$ (**1n**), 2,6-F$_2$C$_6$H$_3$ (**1o**)] and the dimethylamino derivative (**1b**) form centrosymmetric dimers. The structure of Cl$_3$CCN$_5$S$_3$ (**1r**), which crystallises with one equivalent of acetonitrile, is different and cannot be assigned to either of these two types.

The stacking of the bicycles is represented by **1q** in Figure 2. Each heterocycle has one $N^{\delta-}\cdots S^{\delta+}$ and one $N^{\delta-}\cdots C^{\delta+}$ interaction with the molecule above. The $N^{\delta-}\cdots S^{\delta+}$ interacting distance between the bridging nitrogen atom and the sulfur atom of the diimide bridge is around 300−310 pm (**1q** 299.2, **1l** 304.5, **1a** 311.8 pm), depending on the substituent at the bicycle, and thereby lies within the sum of the van der Waals radii (335 pm). The $N^{\delta-}\cdots S^{\delta+}$ distance in **1d** is significantly longer (327.4 pm), which can be attributed to the repulsive steric effect of the large isopropylamino groups. The same effect is also observed for the $N^{\delta-}\cdots C^{\delta+}$ distance between the bridging nitrogen atom and the carbon atom of the heterocycle. This distance is more than 100 pm longer for **1d** (438.8 pm) than for the other three bicycles (around 315 pm). This is barely within the sum of the van der Waals radii (320−325 pm). The average distance between the planes through the parallel phenyl rings is approximately 350 pm for **1q**.

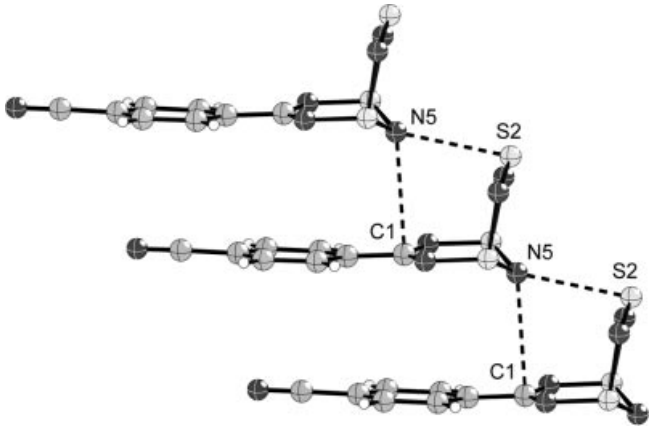

Figure 2. Stacking of **1q** in the crystal

In this case, "dimerisation" implies that two molecules are arranged with their heterocyclic heads facing each other (represented in Figure 3). The second molecule is rotated by 180° with respect to the first, so that two $N^{\delta-}\cdots S^{\delta+}$ interactions can be formed. The shortest distances between the molecules, independent of the substituent, is around 295 pm (**1o** 291.5−**11n** 296.4 pm), and is thus shorter than the sum of the van der Waals radii (335 pm).

Figures 4−6 present crystal packing diagrams that show the different arrangements of the bicycles in the crystal. Figure 4 shows details of the crystal lattice of **1q**, which is representative of the stacking arrangement. The structures of **1n** (Figure 5) and **1e** (Figure 6) show that the arrangement in the crystal is dependent on the substituents at the bicycles. The partially fluorinated aryl substituents form additional weak H-F interactions with neighbouring molecules. For example, in **1n** (Figure 5), this leads to a head-head/tail-tail arrangement of the molecules, thus forming a chain. The offset parallel chains form layers. In the phenyl derivative (**1e**), an arrangement (Figure 6) which resembles a fishbone pattern is observed.

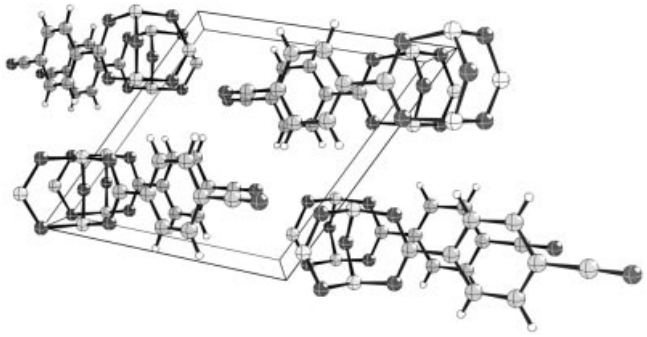

Figure 4. Crystal packing diagram of **1q**

Theoretical Calculations

Theoretical investigations were undertaken with the goal of finding explanations for the different stabilities of this bicyclic system with respect to the substituents, and for the different arrangements in the solid state. In Table 3, experimental bond lengths and bond angles for **1a** (R = CF$_3$), **1q** (R = 4-NCC$_6$H$_4$), **1e** (R = C$_6$H$_5$) and **1b** (R = Me$_2$N), representative examples for the different types of structures, are compared with the results of the RHF, MP2 and B3LYP calculations. As discussed previously, this bicyclic system is best described as a six-membered dithiatriazine with two sulfur atoms bridged by a sulfur diimide group. The experimental bond lengths within the dithiatriazine fragment are in reasonable agreement with all three methods, the best fit is found with the RHF calculations. The S1−N2 distances between the sulfur of the dithiatriazine fragment and the sulfur diimide group, obtained by the RHF method, are slightly shorter than those determined experimentally. The

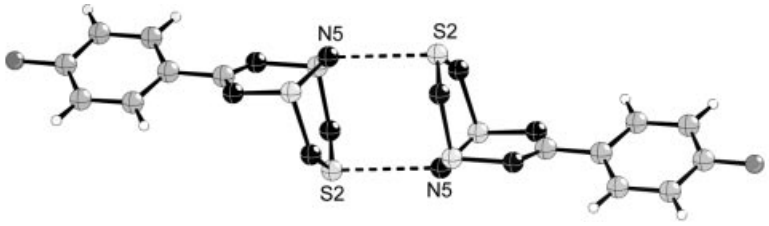

Figure 3. Centrosymmetric Dimer of **1n**

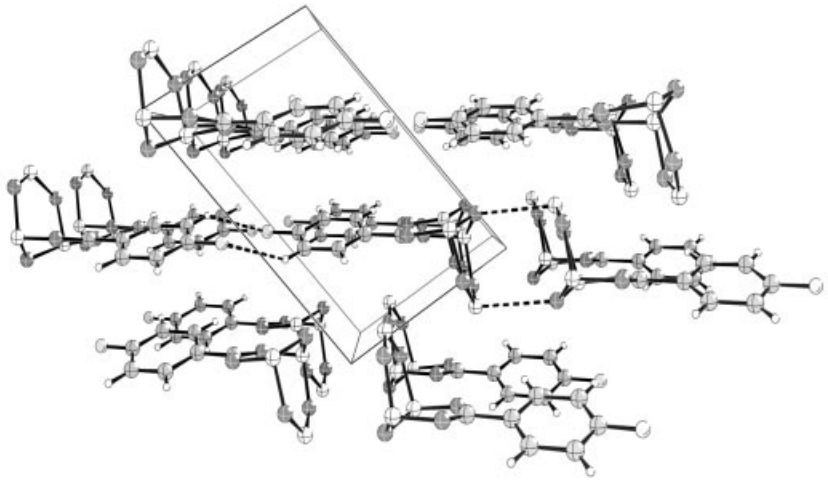

Figure 5. Crystal packing diagram of **1n**

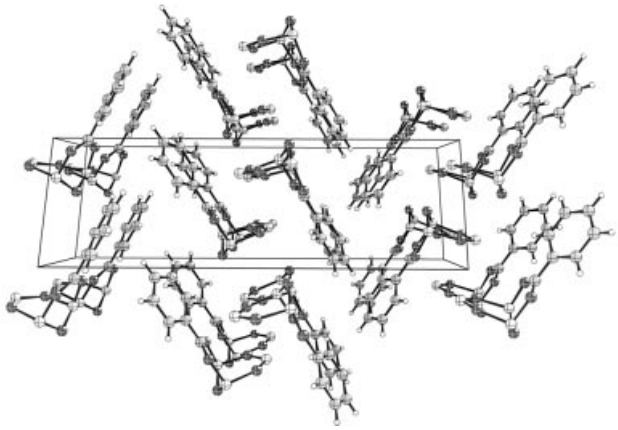

Figure 6. Crystal packing diagram of **1e**

distances resulting from the MP2 and B3LYP calculations are much larger. Similar results were obtained for the axial S−F distances in the related difluorodithiatriazines $RCN_3S_2F_2$ (R = F, CF_3). The RHF calculated distances are shorter and the MP2 and B3LYP calculated distances are much longer than those determined experimentally. The distances within the dithiatriazine are also well-reflected by all three methods.[19] The S2−N2 distances in the sulfurdiimide groups in **1**, calculated by the MP2 method, show the largest deviations (too long). Once again, the RHF calculated bond lengths are too short and those calculated by the B3LYP method are too long. Similar results have recently been obtained from the calculations of the molecular geometries of thioaminyl radicals.[20]

On the other hand, inspection of Table 3 shows that the experimentally determined influence of the different substituents on the bond lengths and on the NCN bond angle

is quite well-reflected by all three methods. Compared with the CF_3 derivative **1a**, C1−N1 increases by 1−1.5 pm in the aryl derivatives **1q**, **1e**, and to 2.5−3 pm in the Me_2N compound **1b**; S1−N1 decreases by 1−1.5 pm in **1q**, **1e** and to 2.8−3.4 pm in **1b**. S1−N5 and the diimide bond N2−S2 are not affected. According to the experiments, a marginal lengthening of the axial S1−N2 bond is observed when going from **1b** to **1q** and **1e**, the calculations show a slightly larger effect. A stronger influence on the lengthening of this bond is shown by experiment and by the calculations for **1b**, but this difference can hardly account for the different stabilities of **1q**, **1e**, **1b** compared with **1a**. The larger increase in the NCN angle in **1b** relative to **1q**, **1e** is also shown by experiment and by calculations.

The influence of the substituents can already be explained in terms of the (extended) frontier orbital model. The energetically highest occupied donor orbitals of the substituents interact with the energetically lowest unoccupied acceptor orbital of the bicycles with the same symmetry, as shown in Figure 7. By this, the *a priori* empty (unoccupied) acceptor orbital with antibonding character in the CN and bonding character in the SN region is partly populated, thus explaining the lengthening of the C−N and the shortening of the S−N bonds. These results are in perfect agreement with our MNDO calculations reported earlier.[1]

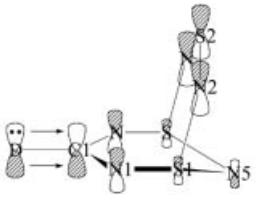

Figure 7. Interaction of the energetically highest occupied orbitals of the donor D with the energetically lowest unoccupied acceptor orbital with the same symmetry

Compared to the experimentally yet unknown hydrogen derivative included in the calculations in Table 3, acceptor substituents have no effect on the bond lengths. This is because the energetically highest occupied orbital in the bicycle with the appropriate symmetry is too low in energy for significant interaction with an empty acceptor orbital. The analysis of the orbitals with different model acceptors also confirms this. The acceptor orbital only shows negligible mixing with other orbitals. This also explains why the phenyl group acts as a donor only.

Another aim of the quantum chemical calculations was to find an explanation for the different crystallisation pattern: "stacking" and "dimerisation", and how this is dependent upon the substituents R.

The Mulliken and NBO charges (Table 4) for the atoms S2 and N5 at which the dimerisation occurs show virtually no dependency on the group R, therefore no correlation between the crystallisation pattern and the type of substituent can be observed. However, when we consider the MEP (mapped electrostatic potential),[21] which has also been utilised recently to rationalise the solid state packing of other SN systems,[22] a different picture is obtained. In Figure 8, representative examples for stacking (R = CF_3, Figure 8a) and dimerisation (R = NMe_2, Figure 8b) are shown. Positive electrostatic potential (ESP; blue) and negative ESP (red) fit perfectly together in the dimer of **1b** (R = NMe_2). For R = CF_3, the ESP's at S2 and N5 are not very pronounced. Furthermore, the negative potentials of N5 and C3 are lower than in the NMe_2 derivative, therefore "stacking" is less hindered by repulsive interactions.

Table 4. Calculated Mulliken and NBO charges (RHF/6−311G*) of **1a**, **1b**, **1e**, and **1q**

Conclusions

Several new aryl 1λ⁴,3λ⁴,5λ⁴-trithia-2,4,6,8,9-pentaazabicyclo[3.3.1]nona-1(9),2,3,5,7-pentaenes RCN_5S_3 were prepared by the amidine route from $(NSCl)_3$ and $ArC(NSiMe_3)N(SiMe_3)_2$. When the persilylated amidines cannot be obtained from lithium-amidinates $RC(NSiMe_3)_2Li$ (R = C_6F_5, 4-NCC_6H_4) and Me_3SiCl, due to the decreased nucleophilicity of the amidinate, the amidinates can be used di-

rectly as starting materials. Contrary to our expectations, the introduction of electron-withdrawing aryl groups does not increase the stability of the RCN_5S_3 system.

The results of X-ray structure investigations and the theoretical calculations are in good agreement. The influence of the substituents on bonding is readily understood from the extended frontier orbital model. Compared with the parent hydrogen derivative, acceptor substituents have no effect, since the -CN_5S_3 HOMO of appropriate symmetry is too low in energy for significant interaction. The interaction of the donor orbitals with the LUMO of appropriate symmetry will increase the C−N bond lengths and decrease the lengths of the adjacent S−N bonds because the antibonding and bonding character in these regions is increased. The influence on the other bonds is only marginal because of the nonbonding character of the LUMO in these regions. The calculations show a slight increase of the S1−N2 bond lengths when going from electron-withdrawing to aryl to amino-substituted bicycles. The experimentally observed significant lengthening of the S1−N2 bond in the amino derivatives is not reflected by the calculations.

No explanation can be given for the unusual stability of the CF_3 derivative from the structural data and the theoretical calculations (the chemistry of the CCl_3 derivative was not investigated). From the large negative charges at the nitrogen centres (Table 4), the RCN_5S_3 derivatives are expected to act as multifunctional donor ligands. When going from CF_3 to aryl to Me_2N, only the positive charges at C1 and the negative charges at N2 increase, the charges at the other centres are not affected. Therefore, *a priori* the ligand properties should not be dependent on the substituents R.

In the solid state, two fundamentally different packing patterns are observed for RCN_5S_3, stacking of the RCN_5S_3 molecules and face-to-face dimerisation of the N_3S_3 subunits of the $-CN_5S_3$ bicycle. The dependence of the packing pattern on the substituents is difficult to predict. Primary electrostatic interactions are responsible for the different packing as shown by the MEP in Figure 8, but they might be dominated by steric requirements of the substituents R and by interactions between the substituents.

Experimental Section

Materials and Methods: All manipulations of air-sensitive materials were performed under an inert atmosphere of dry nitrogen, with the absence of oxygen and moisture. The fluorinated *N,N,N′*-tris-(trimethylsilyl)amidines {R = F_3C,[15] R = 4-FC_6H_4, 2-FC_6H_4, 2,6-$F_2C_6H_3$[16]}, $[(C_6F_5C(NSiMe_3)_2Li]_2{\cdot}OEt_2$,[16] $[(Me_3Si)_2NLi{\cdot}OEt_2]_2$,[23] $Cl_3CCN(NSCl)_2$,[24] $Me_3SiNSNSiMe_3$,[25] RCN_5S_3 [R = 4-$H_3CC_6H_4$, 4-$C_6H_5C_6H_4$,[4] R = Me_2N[2]] and trithiazyltrichloride $(NSCl)_3$[26] were prepared according to published procedures. Terephthalonitrile is a commercial compound. The solvents were carefully dried and distilled prior to use. NMR spectra were recorded on Bruker DPX 200 (^1H, ^{19}F) and on Bruker AM 360 NB (^{13}C) spectrometers in [D_1]chloroform. Chemical shifts are given with respect to Me_4Si. Infrared analyses were acquired as thin Kel-F and Nujol films (with KBr cells), using a Perkin−Elmer Paragon 500 FT-IR instrument. Mass spectra were measured on a Finnigan MAT 8200, using the field ionisation (FI) technique. The high-resolution mass spectra were obtained by using the peak matching method (chemical ionisation neg.). Melting points were obtained on a Gallenkamp melting point apparatus and are uncorrected.

Preparation of $F_3CCN_5S_3$ (1a): $F_3CC(NSiMe_3)[N(SiMe_3)_2]$ (13.7 g, 42 mmol) in 50 mL of dichloromethane was added dropwise to trithiazyl trichloride (10.0 g, 41 mmol) in 100 mL of dichloromethane at 0 °C. The solution became dark red. The solvent and all volatile products were removed and the remaining residue was dissolved in 100 mL of acetonitrile and the solution was filtered. On storage at −40 °C, yellow crystals were obtained (6.35 g, 26 mmol, 63% yield). The spectroscopic data are in accordance with literature data.[1] MS-FI: *m/z* = 247 (100) [M^+]. MS-HR: found 246.92615, calcd. 246.92679.

Preparation of 2-$FC_6H_4CN_5S_3$ (1m): 2-$FC_6H_4C(NSiMe_3)[N(SiMe_3)_2]$ (14.5 g, 41 mmol) in 100 mL of acetonitrile was added dropwise to trithiazyl trichloride (10.0 g, 41 mmol) in 100 mL of acetonitrile. The solution became dark red and a precipitate formed. The solvent and all volatile products were removed and the remaining residue was dissolved in 150 mL of boiling acetonitrile and the solution was filtered. On cooling to room temperature, yellow crystals were obtained (7.7 g, 28 mmol, 69% yield), m.p. 111 °C. ^1H NMR: δ = −7.16 ppm (ddd, $^3J_{H,F}$ = 11.3, $^3J_{H,H}$ = 8.3, $^4J_{H,H}$ = 1.0 Hz, 1 H, *m*-C_6H_4F), 7.25 (td, $^3J_{H,H}$ = 7.5, $^4J_{H,H}$ = 1.0 Hz, 1 H, *m*-C_6H_4F), 7.50 (dddd, $^3J_{H,H}$ = 8.3, $^3J_{H,H}$ = 7.5, $^4J_{H,F}$ = 4.8, $^4J_{H,H}$ = 2.0 Hz, 1 H, *p*-C_6H_4F), 7.91 (td, $^3J_{H,H}$ = 7.5, $^4J_{H,F}$ = 7.5, $^4J_{H,H}$ = 2.0 Hz, 1 H, *o*-C_6H_4F ppm. $^{13}C\{^1H\}$ NMR: δ = 117.1 (d, $^2J_{C,F}$ = 22 Hz, *m*-C_6H_4F), 124.1 (s, *m*-C_6H_4F), 125.4 (d, $^2J_{C,F}$ = 8 Hz, *ipso*-C_6H_4F), 130.8 (s, *o*-C_6H_4F), 133.6 (d, $^3J_{C,F}$ = 8 Hz, *p*-C_6H_4F), 161.1 (d, $^1J_{C,F}$ = 259 Hz, *o*-C_6H_4F), 165.6 (d, $^3J_{C,F}$ = 4 Hz, NCN) ppm. ^{19}F NMR: δ = −113.3 (ddd, $^3J_{F,H}$ = 11.3, $^4J_{F,H}$ = 7.5, $J_{F,H}$ = 4.8, 1F) ppm. IR: $\tilde{\nu}$ = 1508 w, 1485 m, 1451 m, 1410 m, 1342 s, 1263 w, 1226 m, 1154 m, 1101 m, 996 s, 927 m, 843 w, 822 w, 770 s, 745 s, 721 s, 685 w, 670 m, 574 s, 551 m, 504 s, 476 m cm^{-1}. MS-FI: *m/z* = 273 (48) [M^+]. MS-HR: found 272.96192, calcd. 272.96130.

Preparation of 4-$FC_6H_4CN_5S_3$ (1n): The procedure follows that of **1m**. 4-$FC_6H_4C(NSiMe_3)[N(SiMe_3)_2]$ (14.5 g, 41 mmol) was reacted with trithiazyl trichloride (10.0 g, 41 mmol). After recrystallisation from CH_3CN, **1n** (7.8 g, 29 mmol, 71% yield) was obtained as orange crystals, m.p. 132 °C. ^1H NMR: δ = 7.07−7.19 (m, 2 H, C_6H_4F), 8.18−8.28 (m, 2 H, C_6H_4F) ppm. $^{13}C\{^1H\}$ NMR: δ = 115.5 (d, $^2J_{C,F}$ = 21 Hz, *m*-C_6H_4F), 129.9 (d, $^3J_{C,F}$ = 9 Hz, *o*-C_6H_4F), 132.4 (d, $^4J_{C,F}$ = 2 Hz, *ipso*-C_6H_4F), 164.6 (s, NCN), 166.1 (d, $^1J_{C,F}$ = 237 Hz, *p*-C_6H_4F) ppm. ^{19}F NMR: δ = −107.2 (tt, $^3J_{F,H}$ = 8.3, $^4J_{F,H}$ = 5.5 Hz, 1F) ppm. IR: $\tilde{\nu}$ = 2932 w, 1594 m, 1503 m, 1422 s, 1360 m, 1339 s, 1296 w, 1225 m, 1152 m, 1093 w, 997 s, 967 sh, 926 w, 849 m, 829 w, 814 m, 776 s, 750 s, 718 s, 688 w, 668 m, 629 w, 597 w, 573 s, 516 w, 490 s, 480 m cm^{-1}. MS-FI: *m/z* = 273 (100) [M^+]. MS-HR: found 272.96244, calcd. 272.96130.

Preparation of 2,6-$F_2C_6H_3CN_5S_3$ (1o): 2,6-$F_2C_6H_3C(NSiMe_3)[N(SiMe_3)_2]$ (9.3 g, 25 mmol) was reacted with trithiazyl trichloride (6.1 g, 25 mmol). After recrystallisation from boiling acetonitrile and storage at −40 °C, **1o** (4.9 g, 17 mmol, 68% yield) was obtained as yellow-brown crystals, m.p. 104 °C. ^1H NMR: δ = 6.92−7.04 (m, 2 H, *m*-$C_6F_2H_3$), 7.32−7.43 (m, 1 H, *p*-$C_6F_2H_3$) ppm. $^{13}C\{^1H\}$ NMR: δ = 111.9 (dd, $^2J_{C,F}$ = 23, $^4J_{C,F}$ = 2 Hz, *m*-$C_6F_2H_3$), 111.9 (t, $^2J_{C,F}$ = 13 Hz, *ipso*-$C_6F_2H_3$), 131.8 (t, $^3J_{C,F}$ = 10 Hz, *p*-$C_6F_2H_3$), 159.8 (dd, $^1J_{C,F}$ = 254, $^3J_{C,F}$ = 6 Hz, *o*-$C_6F_2H_3$), 163.5

(s, NCN) ppm. ^{19}F NMR: δ = −114.9 (dd, $^3J_{F,H}$ = 7.8, $^4J_{F,H}$ = 6.2 Hz, 2F) ppm. IR: ṽ = 2926 w, 1622 m, 1591 m, 1566 w, 1472 m, 1344 s, 1238 m, 1148 m, 1011 s, 966 sh, 929 w, 818 w, 792 m, 776 m, 752 s, 630 m, 690 w, 670 m, 576 s, 523 w, 503 sh, 489 s, 467 m cm^{-1}. MS-FI: *m/z* = 291 (45) [M$^+$]. MS-HR: found 290.95194, calcd. 290.95187.

Preparation of $C_6F_5CN_5S_3$ (1p): $[C_6F_5C(NSiMe_3)_2Li]_2{\cdot}OEt_2$ (7.1 g, 18 mmol) in 50 mL of diethyl ether was added dropwise to trithiazyl trichloride (4.6 g, 19 mmol) in 50 mL of diethyl ether. The solution became dark red. The solvent and all volatile products were removed and the remaining residue was dissolved in 100 mL of acetonitrile and the solution was filtered. On storage at −40 °C, yellow-brown crystals were obtained (2.4 g, 7 mmol, 39% yield), m.p. 97 °C. ^{13}C{^{1}H} NMR: δ = 115.0 (t, $^2J_{C,F}$ = 17 Hz, *ipso*-C_6F_5), 138.7 (dm, $^1J_{C,F}$ = 253 Hz, *o*-C_6F_5), 143.2 (dm, $^1J_{C,F}$ = 253 Hz, *p*-C_6F_5), 145.2 (dm, $^1J_{C,F}$ = 247 Hz, *m*-C_6F_5), 162.1 (s, NCN) ppm. ^{19}F NMR: δ = −145.5 (dddd, $^3J_{FF}$ = −21.8, $^4J_{FF}$ = −4.7, $^4J_{FF}$ = 3.2, $^5J_{FF}$ = 8.0 Hz, 2F, *o*-F), −154.9 (tt, $^3J_{FF}$ = −20.2, $^4J_{FF}$ = 3.2, 1F, *p*-F), −164.3 (dddd, $^3J_{FF}$ = −21.8, $^3J_{FF}$ = −20.2, $^4J_{FF}$ = −0.8, $^5J_{FF}$ = 8.0 Hz, 2F, *m*-F) ppm. IR: ṽ = 1656 w, 1524 m,. 1504 s, 1427 sh, 1402 s, 1360 s, 1278 m, 1200 s, 1171 m, 1151 m, 1126 s, 1040 w, 1016 w, 986 m, 972 s, 901 m, 812 m, 761 sh, 722 s, 703 sh, 656 w, 626 w, 598 w, 570 w, 555 w, 531 m, 504 m, 473 m cm^{-1}. MS-FI: *m/z* = 345 (26) [M$^+$]. MS-HR: found 344.92149, calcd. 344.92361.

Preparation of 4-$NCC_6H_4CN_5S_3$ (1q): A solution of lithium bis(trimethylsilyl)amide (3.9 g, 16 mmol) and terephthalonitrile (2.1 g, 16 mmol) in 150 mL of diethyl ether was added dropwise to trithiazyl trichloride (4.4 g) in 50 mL of diethyl ether at 0 °C. The solution became brown. The solvent and all volatile products were removed and the remaining residue was dissolved in 100 mL of dichloromethane and the solution was filtered. On storage at −40 °C, orange crystals were obtained (1.4 g, 5 mmol, 31% yield), m.p. 158 °C. ^{1}H NMR: δ = 7.75 (ddd, $^3J_{H,H}$ = 8.3, $^4J_{H,H}$ = 2.0, $^5J_{H,H}$ = 1.5 Hz, 2 H, C_6H_4), 8.33 (ddd,$^3J_{H,H}$ = 8.3, $^4J_{H,H}$ = 2.0, $^5J_{H,H}$ = 1.5 Hz, 2 H, C_6H_4) ppm. ^{13}C{^{1}H} NMR: δ = 116.9 (s, *p*-C_6H_4), 119.0 (s, NC), 128.9 (s, *o*-C_6H_4), 133.0 (s, *m*-C_6H_4), 141.2 (s, *ipso*-C_6H_4), 165.4 (s, NCN) ppm. IR: ṽ = 2226 m, 1413 m, 1366 m, 1334 m, 1299 m, 1188 w, 1148 m, 1110 w, 1035 w, 1009 sh, 975 s, 921 w, 858 m, 836 w, 785 w, 768 sh, 750 m, 722 s, 692 m, 666 s, 642 sh, 561 m, 541 s, 506 m, 490 w, 467 m cm^{-1}. MS-FI: *m/z* = 280 (12) [M$^+$], 206 ($NCC_6H_4CN_2S_2^+$, 100). MS-HR: found 279.96632, calcd. 279.96597.

Preparation of $Cl_3CCN_5S_3$ (1r): $Me_3SiNSNSiMe_3$ (0.8 mL, 0.7 g, 3.5 mmol) in 10 mL of carbon tetrachloride was added dropwise to $Cl_3CCN(NSCl)_2$ (0.85 g, 2.7 mmol) in 25 mL of carbon tetrachloride. After standing overnight, the solvent and all volatile products were removed and the remaining residue was dissolved in a small amount of acetonitrile and the solution was filtered. On storage at −40 °C and after drying under vacuum, yellow crystals of **1r**·CH_3CN (0.55 g, 1.9 mmol, 68% yield) were obtained, m.p. 102 °C. ^{13}C NMR: δ = 97.3 (s, CCl_3), 168.4 (s, NCN) ppm. IR: ṽ = 1545 w, 1503 w, 1467 w, 1430 s, 1400 sh, 1362 m, 1292 s, 1265 sh, 1211 sh, 1202 m, 1171 w, 1151 m, 1127 w, 1028 m, 1004 sh, 987 m, 972 m, 946 sh, 916 sh, 872 sh, 862 m, 801 m, 758 m, 739 sh, 722 s, 702 w, 692 m, 660 m, 639 w, 567 m, 559 m, 506 s, 402 m cm^{-1}. MS-FI: *m/z* = 295 (58) [M$^+$]. MS-HR: found 294.83877, calcd. 294.83813.

Crystallographic Analysis

The single-crystal X-ray structure determinations were performed on a Siemens P4 diffractometer using Mo-K_α (0.71073 Å) radiation with a graphite monochromator. The crystals were mounted using Kel-F oil onto a thin glass fibre. Details of the data collection and refinement are given in Table 1. The programs SHELX-97[27] and DIAMOND[28] were used. The structures were solved by direct methods (SHELXS).[27] Subsequent least-squares refinement (SHELXL 97−2)[27] located the positions of the remaining atoms in the electron density maps. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions using a riding model and refined isotropically in blocks.

CCDC-205700 (**1b**) -205701 (**1f**) -205702 (**1n**) -205703 (**1r**) -205704 (**1o**) and -205705 (**1q**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Quantum Chemical Calculations: All *ab initio* calculations were performed with the GAUSSIAN′98 program package.[29] The mapped electrostatic potential (MEP) representations are made with MOLEKEL.[21]

Keywords: Titanium / Density functional calculations / Nitrogen heterocycles / Voltammetry / O ligands

Twenty 4-acyl-5-pyrazolonato (Q) titanium derivatives of varied nuclearity have been synthesized from $Ti(OR)_4$ or $TiCl_4$ and characterized with spectroscopic methods (IR, NMR, ESI-MS). While Ti–(β-diketonato) cleavage is not seen in isolated solids, Ti–O(alkoxy) (or Ti–Cl) bonds cleave upon hydrolysis, leading to several structural forms, including oligomers. Ionic Q species with no Ti, i.e., obtained after Ti–Q cleavage, are seen for some Ti–Q derivatives by ESI-MS, which also indicates a varied nuclearity for a given species, e.g., the isolated polynuclear $[Q_2Ti\text{-}\mu\text{-}O]_n$ has several "*n*" values. Mononuclear Ti complexes are obtained under rigorous anhydrous conditions. The *cis* structures of the mononuclear species $(Q^T)_2Ti(OCH_3)_2$, Q^T = 3-methyl-4-(neopentylcarbonyl)-1-phenylpyrazol-5-onato have been analyzed with DFT methods. A *trans* influence is a major driving force that accounts for several sets of Ti–O bonds. One of the *cis* stereoisomers is 56 kcal/mol higher in energy than the other two. In contrast, all $(Q^T)_2TiCl_2$ *cis* isomers show similar energies. Voltammetry of the mononuclear species $(Q^T)_2Ti(OnPr)_2$ and the antitumor tetranuclear compound $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$, ($Q^B$ = 4-benzoyl-3-methyl-1-phenylpyrazol-5-onato) indicate that the Ti^{IV} is less prone to reduction to Ti^{III} in the latter (Ep_c for the Ti^{IV}/Ti^{III} couple is –1.71 V and –1.46 V versus Fc^+/Fc, respectively). Potential antitumor compounds having a Ti/Q ratio of 1:1 do not disproportionate, unlike the equivalent acetylacetonato derivatives, and are water-soluble.

Introduction

Titanium tetraalkoxides react with β-diketones to give products formulated as (β-diketonato)$Ti(OR)_3$ and (β-diketonato)$_2Ti(OR)_2$.[1,2] For $(bzac)_2Ti(OEt)_2$, bzac = benzoylacetonato, an equilibrium mixture of the three possible octahedral *cis* stereoisomers is seen in CH_3CN/H_2O solution.[3] Qualitatively, the *cis* configurations are more strained but are preferred due to electronic effects caused by $p_\pi - d_\pi$ (t_{2g}) bonding of the β-diketonato ligand.[4,5] $[(acac)_2TiO]_2$, acac = acetylacetonato, consists of a cyclic dimer with titanium centers linked by oxygen atoms.[5]

Other stable polynuclear oxo-bridged species have been isolated as Ti is a hard acid that forms strong metal–oxygen bonds. For example, hydrolysis of $(\eta^5\text{-}C_5H_5)_2TiCl_2$ and $(\eta^5\text{-}C_5H_5)TiCl_3$ yields the two related oxo-bridged titanium dimers $[(\eta^5\text{-}C_5H_5)_2TiCl]_2O$ and $[(\eta^5\text{-}C_5H_5)TiCl_2]_2O$, respectively.[6–8]

The success of cisplatin,[11,12] *cis*-$(NH_3)_2PtCl_2$, has prompted studies of metal-based antitumor compounds[9,10] with other metal derivatives.[13–15] The (β-diketonato)titanium species mentioned above, $(bzac)_2Ti(OEt)_2$ (Figure 1), known as budotitane,[16] was the first non-Pt metal compound to reach clinical trials.[17] It undergoes stereoisomer interconversion[3] and a theoretical[18] study shows a calcu-

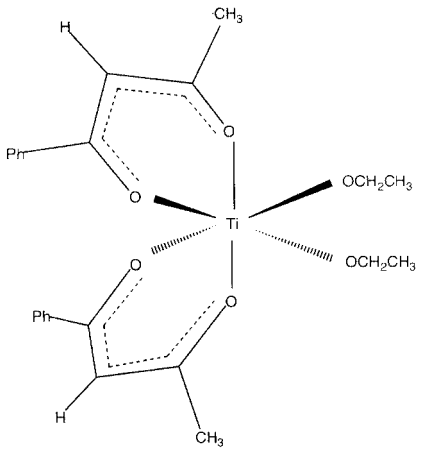

Figure 1. Isomer of budotitane, $(bzac)_2Ti(OCH_2CH_3)_2$; bzac = benzoylacetonato

lated isomer distribution that agrees with ^1H NMR spectroscopic data.

Budotitane was selected for development on the basis of structure-activity studies in which metal atom, β-diketonato substituents, and leaving groups (ethoxy in budotitane) were modified.[3] The ethoxy derivative gave the best pharmacological formulation (a limiting feature in budotitane) because hydrolysis is reduced when ethanol is added to it. These studies showed that asymmetric β-diketonates induce higher activity.[3] This structural feature is fulfilled by 4-acyl-5-pyrazolones, a sub-class of asymmetric β-diketones having a fused pyrazole ring and three useful positions for substitution (Figure 2).

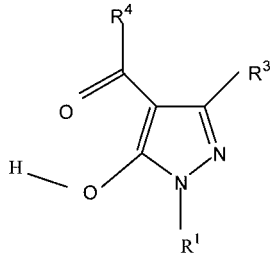

Figure 2. 4-Acyl-5-pyrazolones (keto-enol form), HQ

Recently, one such derivative, *cyclo*-tetrakis[bis(4-benzoyl-3-methyl-1-phenylpyrazolon-5-ato)(μ-oxo)titanium(IV)], $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$, has demonstrated potent and selective antitumor activity in vitro and in vivo, with an increased life span (T/C ≈ 300%), in the TA-3 mouse mammary adenocarcinoma[19] (Figure 3).

Ti−O(ethoxy) bonds in budotitane tend to hydrolyze, yielding Ti−OH derivatives. Subsequently, condensation of two Ti−OH units from different molecules produce a Ti−O−Ti linkage while releasing a molecule of water.[3] Ti−(β-diketonato) bond hydrolysis also occurs in budotitane and the system evolves towards polynuclear compounds that ultimately yield harmless titanium dioxide. While letting $TiCl_4$ react to obtain $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$ a similar hydrolytic process for the Ti−Cl bonds is seen, but without hydrolysis of the Ti−(β-diketonato) bonds.[19] This is important for the antitumor activity of Ti derivatives. In fact, budotitane and titanocene dichloride,[20] Cp_2TiCl_2 (an antitumor compound currently in clinical phase II trials),[21] are characterized by rapid hydrolysis of ethoxy and Cl^-, respectively, in comparison with a much slower hydrolysis of bzac and Cp. This slow hydrolysis was recently suggested to be a key property for biological activity in antitumor Ti compounds.[22,23] Following our interest in antitumor inorganic compounds[19,22−24] we report here the synthesis of novel Ti−(4-acyl-5-pyrazolonato) compounds with several degrees of polymerization (Table 1). Since recent results[25] show that, in addition to Ti^{IV} complexes, Ti^{III} species may also display antitumor activity (a property also shown by Pt^{II} and Pt^{IV} species),[26] we also describe the redox behavior of one mononuclear and one tetranuclear Ti−(β-diketonato) compound. Structural features are analyzed with Density Functional Theory (DFT) methods. Electrospray ionization mass spectrometry (ESI-MS) is a powerful tool with which to study charged species in the gas phase[27,28] and has been successfully applied to address

biochemical questions[29] and the speciation of inorganic complexes of various metals, including Ti.[30,31] We also describe here an ESI-MS study.

Results and Discussion

Synthesis and Spectroscopic Characterization

Polynuclear (oxo)titanium β-diketonates **1**−**8** (Table 2) have been obtained by treating TiX_4 (X = Cl or OR; R = Me, Et, *n*Bu, or *n*Pr) with 4-acyl-5-pyrazolones (HQ) in alcoholic solvent in the presence of KOH [see Equation (1) for tetranuclear species **1**]. KCl is removed after centrifugation of the suspension containing a soluble Ti-Q derivative. Insoluble Ti-Q products are separated from KCl after dissolution in CH_2Cl_2. Alternatively, **1**−**8** can be obtained in refluxing benzene (without addition of base) with an excess of Q ligands.

Table 2. Synthesized compounds

1	$[(Q^B)_2Ti(\mu\text{-}O)]_4$	**11**	$(Q^T)_2Ti(O\textit{n}Pr)_2$
2	$[(Q^T)_2Ti(O)(H_2O)]_n$	**12**	$(Q^T)_2Ti(O\textit{n}Bu)_2(H_2O)$
3	$[(Q^A)_2Ti(O)(H_2O)]_n$	**13**	$[(Q^A)Ti(OH)_3(H_2O)]_n$
4	$[(Q^N)_2Ti(O)(H_2O)]_n$	**14**	$[(Q^C)Ti(OH)_3]_n$
5	$[(Q^C)_2Ti(O)(H_2O)_2]_n$	**15**	$[(Q^B)Ti(OH)_2(O\textit{n}Pr)](H_2O)$
6	$[(Q^L)_2Ti(O)(H_2O)_2]_n$	**16**	$[(Q^B)Ti(OH)_2(O\textit{n}Bu)](H_2O)$
7	$[(Q^E)_2Ti(O)(H_2O)]_n$	**17**	$[(Q^L)Ti(O)(OH)]_n$
8	$[(Q^P)_2Ti(O)(H_2O)]_n$	**18**	$[(Q^E)Ti(O)(OH)]_n$
9	$(Q^B)_2Ti(O\textit{n}Pr)_2$	**19**	$(Q^B)_2TiCl_2$
10	$(Q^T)_2Ti(OMe)_2$	**20**	$(Q^T)_2TiCl_2$

X-ray data for **1** show a tetranuclear structure,[19] which agrees with the measured molecular weight of 2200 (the expected value for the tetranuclear arrangement is 2473.9). This technique suggests a mixture of di- and other polynuclear species for **4**, that is $[(Q^N)_2Ti(O)(OH_2)]_n$ (n = 2.8). In a related study of budotitane, after dissolution in CH_3CN/H_2O the species $[(bzac)_2Ti(O)]_n$ with n = 2.4 is formed.[3]

Compounds **1**−**8** are generally soluble in chlorohydrocarbons, acetonitrile, and DMSO, insoluble in ethers and alcohols, and are very stable in the air at room temperature. Compound **3**, however, is insoluble in CH_2Cl_2 and $CHCl_3$ due, probably, to the formation of bridges between different metal centers via hypervalent oxygen atoms of the OMe group.

$$8\ HQ + 16\ KOH + 4\ TiCl_4 \rightarrow [Q_2Ti(\mu\text{-}O)]_4 + 16\ KCl + 12\ H_2O \quad (1)$$

Complexes $Q_2Ti(OR)_2$ **9**−**12** have been prepared in excellent yields by treating stoichiometric amounts of the β-diketone and the titanium alkoxide in refluxing benzene according to Equation (2). These complexes are soluble in DMSO, CH_2Cl_2, and $CHCl_3$, acetonitrile and nitrobenzene, slightly soluble in benzene and acetone, and nearly insoluble in diethyl ether, water, and saturated hydrocarbons. In $CHCl_3$ they seem to hydrolyze to a large extent as several signals were found for each group of protons. Molecular weight measurements in solution further confirmed this hypothesis; the ratio between experimental and calculated molecular weights for compounds **9** and **11** being 0.62 and 0.53, respectively. Ionic species are excluded on the basis of conductivity data.

$$Ti(OR)_4 + 2\ HQ \rightarrow Q_2Ti(OR)_2 + 2\ ROH \quad (2)$$

The reaction between $Ti(OR)_4$ and HQ in a 1:1 ratio, in the presence of KOH, gave the hydroxy derivatives **13**−**16**. In addition, TiO_2 was obtained as a sub-product, probably from $Ti(OR)_4$. Compounds **13**−**16** are generally very soluble in water and behave as sol-gel precursors, a property observed in other Ti−(β-diketones) used as "modifiers" in sol-gel processing.[32] The literature is somewhat ambiguous about the structures and behavior of such species present in solution. The partially hydrolyzed hydroxy(oxo) complexes **17** and **18** are also water-soluble.

As already mentioned, compound **1** is a potent and selective cytotoxic agent that is water-insoluble and, therefore, is formulated as a liposome for pharmacological use.[19] Compounds **13**−**18** (Ti/Q = 1:1), however, are water-soluble and are thus interesting candidates for simpler formulation. They do not disproportionate, in contrast to acac-related derivatives,[33] and they resemble related Ti−Cp antitumor compounds.

$TiCl_4{\cdot}2THF$ reacts with HQ^B and HQ^T in methanol, in the presence of an equimolar amount of NaOMe, to give the mononuclear Q_2TiCl_2 complexes **19**−**20** in good yields [Equation (3)], under rigorous anhydrous conditions.

$$TiCl_4{\cdot}2THF + 2\ HQ + 2\ NaOMe \rightarrow Q_2TiCl_2 + 2\ NaCl + 2\ MeOH + 2\ THF \quad (3)$$

Therefore, reaction in basic (KOH) alcohol solution yields polynuclear products **1**−**2** whereas replacing KOH with NaOMe, under anhydrous conditions, furnishes the corresponding mononuclear compounds **19**−**20**. However, mononuclear species are more simply obtained in benzene, where hydrolysis is hindered.

Conductance data in the ionizing solvents acetone, DMSO or nitrobenzene show that complexes **1**−**20** are non-electrolytes.

Compounds **1**−**8** can be also obtained by hydrolysis of bis(4-acyl-5-pyrazolonato)dialkoxytitanium(IV) or bis(4-acyl-5-pyrazolonato)dichlorotitanium(IV). With excess β-diketone some titanium alkoxides are converted into (oxo)titanium β-diketonates. Compounds **9**−**11** also appear to hydrolyze, in solution, more rapidly than **19**−**20**.

Nujol mull IR spectra of the oxo complexes contain bands in the chelating carbonyl stretching region 1600−1300 cm^{-1}; similar frequencies are observed for other metal 4-acyl-5-pyrazolonato derivatives.[34−41] No bands were observed in the 1600−1750 cm^{-1} region, where ketonic carbonyl modes are expected for the pyrazolonato keto form. Therefore, both carbonyl groups are coordinated

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

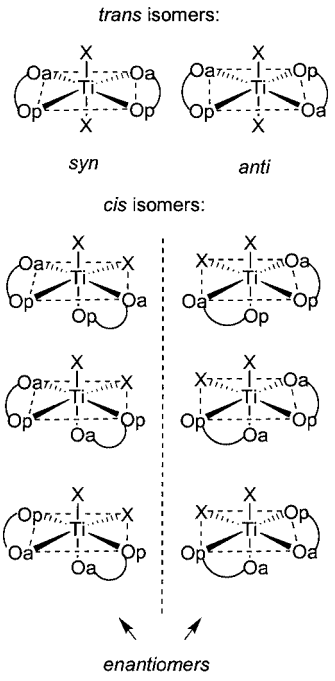

Figure 4. Possible Q_2TiX_2 stereoisomers; Oa = O(acyl), Op = O(pyrazolonato), X = Cl, OEt, O*n*Pr, O*i*Pr, or O*n*Bu; the three pairs of *cis* stereoisomers are ordered as CIS3, CIS2, and CIS1 as defined in the text

to the Ti atom. Broad bands in the 500−400 cm^{-1} region and some strong absorption in the 400−300 cm^{-1} region are associated with Ti−O bonds.[5,33−43]

Six-coordinate titanium derivatives can theoretically exist in solution as a mixture of several *cis* and *trans* isomers (Figure 4). However, for related dialkoxy- and dihalobis(acetylacetonato)titanium(IV) derivatives, steric interactions influence the relative stabilities of the isomers and *cis* forms are strongly preferred.[18,42] In particular, the low-temperature ^1H NMR spectrum of budotitane exhibits four signals for the different methyl groups due to the three *cis* isomers. Our own ^1H NMR variable-temperature experiment on compounds **9** and **11** revealed only one signal (also at 273 K) for each equivalent proton of the propoxy groups and two signals having the same integrals for the methyl group of Q^B and Q^T. This can be assigned to the equatorial and axial methyl groups of the CIS2 isomer (Figure 4) − that is only one *cis* conformer is detected under such experimental conditions. It is worth noting that 20 min after dissolution of **9** and **11** in $CHCl_3$, *n*PrOH formation was observed, i.e., hydrolysis of the Ti−O*n*Pr bond occurred. Hydrolysis is fast at high temperatures and complete 48 h after dissolution. It is also reversible as the addition of *i*PrOH or *n*PrOH to the NMR solutions showed signals due to (TiO*i*Pr)- and (TiO*n*Pr)-containing species. In contrast, derivative **10** was immediately hydrolyzed in solution, as indicated by ten signals, due to OMe groups at room temperature, seen 10 min after dissolution.

The spectrum of the monomer species $(Q^B)_2TiCl_2$ **19** carried out in non-anhydrous deuterated benzene (98%) and recorded at least 1 h after dissolution of the sample, showed some multiplets at 283 and 353 K, analogous to those in the spectrum of **1**, i.e., the mononuclear $(Q^B)_2TiCl_2$ hydrolyzed and became a polynuclear species. The same spectrum was obtained after adding H_2O (0.01 mL) to a deuterated anhydrous benzene (99.9%) solution of **19**. This shows faster hydrolysis since the spectrum was taken after 15 min.

Hydrolysis is avoided by not adding water and working under N_2 to avoid air humidity in deuterated anhydrous benzene (99.9%). This additional variable-temperature ^1H NMR of **19** shows a single sharp resonance for the methyl protons at 353 K. At 313 K line broadening is observed and the methyl resonance begins to split into two peaks. At 303 K further splitting of these peaks gives a total of four signals. The same multiplicity was found at 283 K. This sequence of increasing peaks as the temperature decreases is assigned to the four non-equivalent methyl groups of the three diastereoisomers.[18] The line broadening could be due to a rapid isomerization process. Broadening of the multiplets obscures the fine structure due to spin coupling of *ortho*, *meta*, and *para* protons.

The same experiment in $CDCl_3$ shows hydrolysis, as indicated by more than 15 lines at 218 K for the methyl groups of Q^B. Addition of MeOH to the NMR solution of **19** generates a signal at $\delta = 4.70$ ppm due to an OMe group coordinated to Ti after formation of a Ti(OMe)-containing species.

The extraordinarily high number of signals detected for each equivalent group of protons in the ^1H spectra of derivatives **1**−**3** suggests the formation of several different nuclearities (like mono-, di-, trititanium species, etc.), in solution, and perhaps even dissociation of the pyrazolonato ligands. The latter is, probably, a reversible dynamic feature, as elemental analyses of the isolated products **1**−**3** show a Ti/Q ratio of 1:2, indicating no Ti−Q cleavage in the solid. We further describe these features below.

Electrospray

Positive electrospray mass spectra of complexes **1**−**2**, **5**−**7**, **15**−**16**, **18**−**20** (the most relevant data are reported in the Exp. Sect.) indicate that, in solution, these derivatives undergo loss of the anionic pyrazolonato ligands which immediately interact with proton, sodium and/or potassium ions, yielding 1−6 polynuclear monocharged species such as $[NaH(Q)]^+$, $[NaK(Q)]^+$, $[Na_3(Q)_2]^+$, $[Na_2K(Q)_2]^+$, $[NaK_2(Q)_2]^+$, $[Na_3H(Q)_3]^+$, $[Na_2KH(Q)_3]^+$, $[NaK_2H(Q)_3]^+$, $[Na_4H(Q)_4]^+$, $[Na_3KH(Q)_4]^+$, $[Na_2K_2H(Q)_4]^+$, $[Na_4KH_2(Q)_6]^+$, $[Na_3K_2H_2(Q)_6]^+$. In general, protonated species are more abundant than Na, K, or mixed Na/K compounds. The population of polynuclear species increases as trinuclear > hexanuclear > higher isomers whereas acetonitrile derivatives containing H, Na, and K are far less abundant. Na and K adducts are common in ESI-MS spectra[44] because the O-donors immediately interact and aggregate with the small quantities of Na and K that are always present in H_2O solvent.

The aggregation behavior is strongly dependent on the ligands. For some systems, aggregation of Ti and Q is seen significantly in acetonitrile even at 10^{-3} M, and aggregates

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

containing Na^+, K^+, or H^+ dominate significantly over larger adducts. Relevant peaks present in the spectra of **1** are due to the interaction of tetranuclear species with Na^+, K^+, or H^+. The most abundant Ti-containing species are the trinuclear ions $[H(Q^B)_6Ti_3O_3]^+$, $[NaTi_3(Q^B)_6O_3]^+$, and $[KTi_3(Q^B)_6O_3]^+$. For derivative **2** additional signals due to the dinuclear species $[H(Q^T)_4Ti_2O_2]^+$, $[Na(Q^T)_4Ti_2O_2]^+$, and $[K(Q^T)_4Ti_2O_2]^+$ are present. The isotopic distribution of these species agrees with the calculated composition.

The absence of ions containing MeCN indicates that there is no binding between the solvent and Ti.

The ESI-MS spectrum of **6**, recorded in the negative detection mode, is dramatically improved and simpler. It shows four main peaks, assigned to the tri- $\{[Na_3(Q)_4]^-\}$, di- $\{[Na_2(Q)_3]^-\}$, and mono-Na anions $\{[Na(Q)_2]^-\}$, and the free anionic ligand $[Q]^-$.

Since only charged species are transferred from solution to the gas phase, quantitative ESI-MS results do not represent the real relative distribution of species in solution. The strong association of Na and K cations and protons to the Q ligands concurs with an X-ray structure of an Rh^I derivative that has 4-acyl-5-pyrazolonato as a counteranion.[45]

The ESI-MS spectra clearly indicate different nuclearities within polymeric species, in agreement with the high number of NMR signals for the methyl group in **1**−**3**.

As shown in the Exp. Sect., Ti-Q compounds are isolated as mono-, tetra-, and polynuclear species, whereas the synthesis of budotitane derivatives yields only mononuclear species. However, in a biological environment for antitumor therapy, budotitane undergoes extensive hydrolysis, first on the Ti−O(ethoxy) bonds and later on the Ti−bzac moiety, to eventually yield titanium dioxide.[3] In other words, for mononuclear $(bzac)_2Ti(OEt)_2$ all of the Ti substituents, ethoxy and benzoylacetonato, are cleaved, whereas in (4-acyl-5-pyrazolonato)titanium synthesis it is the alkoxy (or Cl) bonds that cleave. Although the ESI-MS spectra suggest that the Ti−Q bonds are labile, the different environments in each case may explain such differences, as shown in the literature.[46−48]

Structural Features Obtained with DFT

As we could not obtain crystals suitable for X-ray diffraction studies, we calculated the minimum energy geometry using DFT (Density Functional Theory) theoretical methods. As shown in Figure 4 a mononuclear species can have three *cis* stereoisomer conformers, we name them CIS1, CIS2, and CIS3. For $(Q^T)_2Ti(OMe)_2$, CIS3 has the lowest energy and selected geometrical parameters are shown in Table 3. This CIS3 conformer shows both O(methoxy) groups opposite to O(pyrazolonato) atoms. A *trans* influence is seen for the two pairs of opposite bonds (Ti−O3 = 1.801 Å, Ti−O1 = 2.084 Å, and Ti−O4 = 1.816 Å, Ti−O51 = 2.046 Å) where the shorter Ti−O(methoxy) bond is opposite the longer Ti−O(pyrazolonato) bond. Completing the coordination sphere are two opposing

[a] Y3 and Y4 are: O associated to methoxy groups in $(Q^T)_2Ti(OCH_3)_2$ and $(Q^B)_2Ti(OCH_3)_2$; Cl in $(Q^T)_2TiCl_2$; $Q^{[B]}$ = 4-benzoyl-3-methyl-1-phenylpyrazolon-5-ato, Q^T = 3-methyl-4-neopentylcarbonyl-1-phenylpyrazolon-5-ato. In the corresponding columns for the polynuclear compounds Ti−O(oxo) bonds are shown. [b] O1 and O2 belong to the 1st β-diketonato chelate; O51 and O52 belong to the 2nd β-diketonato chelate. [c] Energy: CIS1 has the lowest energy, followed by CIS3 (2 kcal/mol) and CIS2 (2.2 kcal/mol) for $(Q^T)_2TiCl_2$. [d] Energy: CIS1 has the lowest energy, followed by CIS2 (0.3 kcal/mol) and CIS3 (2.8 kcal/mol) for $(Q^B)_2Ti(OCH_3)_2$. [e] Energy: CIS3 has the lowest energy, followed by CIS2 (0.7 kcal/mol) and CIS1 (56 kcal/mol) for $(Q^T)_2Ti(OCH_3)_2$. [f] This parameter is O3−Ti−O4. [g] These parameters are Ti−O3−Ti and Ti−O4−Ti. [h] $[(Q^B)_2Ti(\mu\text{-}O)]_4$ has an inversion center that makes two Ti units equivalent to the other two.[19] Ti conformation is similar to CIS1. [i] $[L_2Ti(\mu\text{-}O)]_4$ has a twofold axis passing on two Ti atoms; L = 2,2,6,6-tetramethylheptane-3,5-dionato.[50] [j] The 2nd Ti unit is crystallographically related by an inversion center; L′ = acetylacetonato.[5]

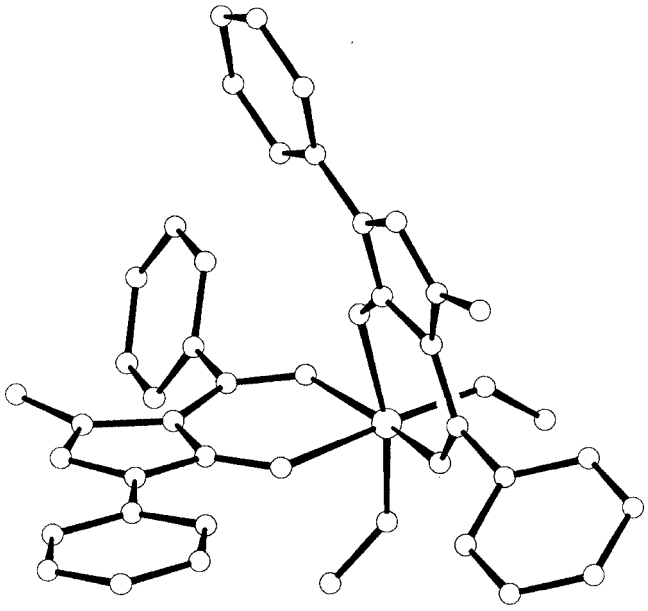

Figure 6. CIS3 DFT structure of $(Q^B)_2Ti(OCH_3)_2$

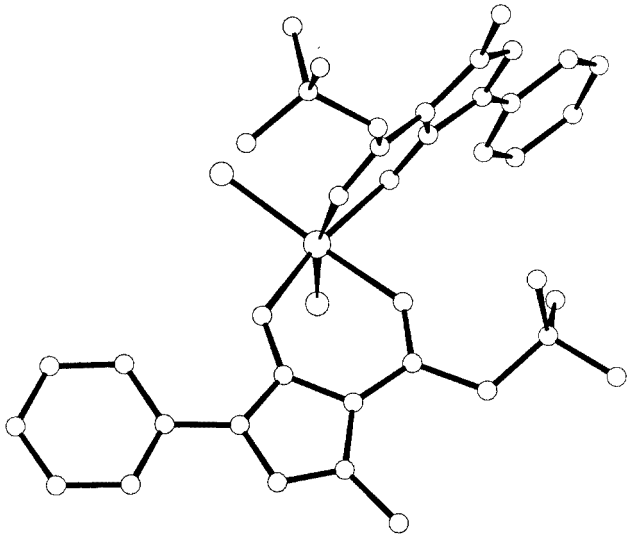

Figure 7. CIS1 DFT structure of $(Q^T)_2TiCl_2$

O(acyl) atoms; here there is no dominant *trans* influence and both Ti−O(acyl) bonds are equal (Ti−O2 = 1.994 Å, Ti−O52 = 1.992 Å).

X-ray structures of Sn-Q derivatives[34−41] show coplanarity between the pyrazole and its attached phenyl due to extended intraligand conjugation. CIS3 agrees with this experimental feature as the torsion angles C5−N1−C7−C8 and C55−N51−C57−C58 are 5.9 and −1.0° (Figure 5). Other DFT conformers studied here also show this feature.

The CIS2 conformer of $(Q^T)_2Ti(OMe)_2$ is 0.7 kcal/mol higher in energy than CIS3, whereas the CIS1 isomer shows markedly higher energy (56 kcal/mol).

We studied $(Q^B)_2Ti(OMe)_2$ and analyzed the role of the R^4 group in these complexes. In contrast with $(Q^T)_2Ti(OMe)_2$ the three *cis* conformers of $(Q^B)_2Ti(OMe)_2$ have similar energies. Thus, the CIS1 conformer shows the lowest energy followed by CIS2 (0.3 kcal/mol) and CIS3 (2.8 kcal/mol). The marked difference between the CIS1 conformers of $(Q^B)_2Ti(OMe)_2$ and $(Q^T)_2Ti(OMe)_2$ may be ascribed to the bulkiness of the neopentyl R^4 group in the latter compared with Ph in the former.

Although the CIS3 conformer of $(Q^B)_2Ti(OCH_3)_2$ (Figure 6) shows the same *trans* influence seen in $(Q^T)_2Ti(OCH_3)_2$ (both shown in Table 3), the former has slightly shorter Ti−O(methoxy) and longer Ti−O(acyl) bonds. This difference is probably related to the lower basicity of the O(acyl) atom attached to an R^4 group that is electron-withdrawing (Ph), in comparison with the more basic neopentyl group in $(Q^T)_2Ti(OCH_3)_2$. Therefore, the shortening of the Ti−O(methoxy) bond in $(Q^B)_2Ti(OCH_3)_2$ seems to arise from the weak O(acyl) basicity.

The role of leaving groups can be analyzed by comparing $(Q^T)_2Ti(OMe)_2$ and $(Q^T)_2TiCl_2$. The three *cis* conformers of the latter have similar energies; the lowest energy being CIS1 (Figure 7) followed by CIS2 (2 kcal/mol, Figure 8) and CIS3 (2.2 kcal/mol, Figure 9). Therefore, the CIS1 conformer of the Cl derivative is not as strained as that of $(Q^T)_2Ti(OCH_3)_2$. This may be associated with a longer Ti−Cl bond compared with Ti−O(methoxy). A lengthening of the Ti−Cl bond is expected due to the longer covalent radius of Cl (0.99 Å) compared to that of O (0.73 Å).[49] However, this difference (0.26 Å) is largely overcome by calculated values of about 0.42 Å (Table 3). The very short Ti−O(methoxy) bonds in $(Q^T)_2Ti(CH_3O)_2$ and $(Q^B)_2Ti(CH_3O)_2$ probably possess partial double bond character that is missing in Ti−Cl bonds. Consequently, stronger Ti−chelate bonds are induced in $(Q^T)_2TiCl_2$; see Ti−O(chelate) bonds for CIS3 isomers of $(Q^T)_2Ti(CH_3O)_2$ and $(Q^B)_2Ti(CH_3O)_2$ in Table 3.

Further agreement between our DFT calculated structures and data from diffraction studies is seen as the O(methoxy) atoms form the shortest Ti−O bonds in CIS1,

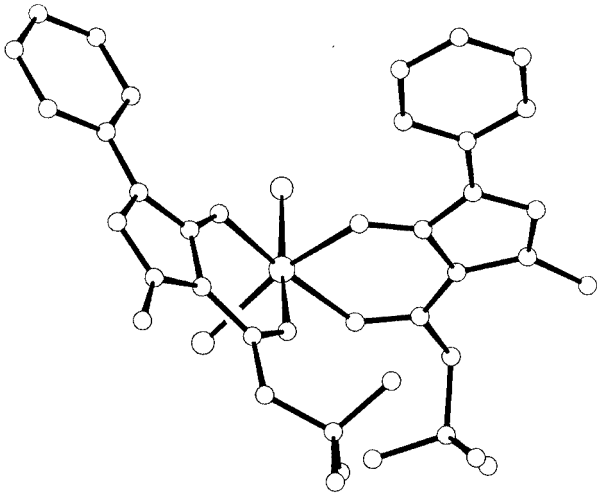

Figure 8. CIS2 DFT structure of $(Q^T)_2TiCl_2$

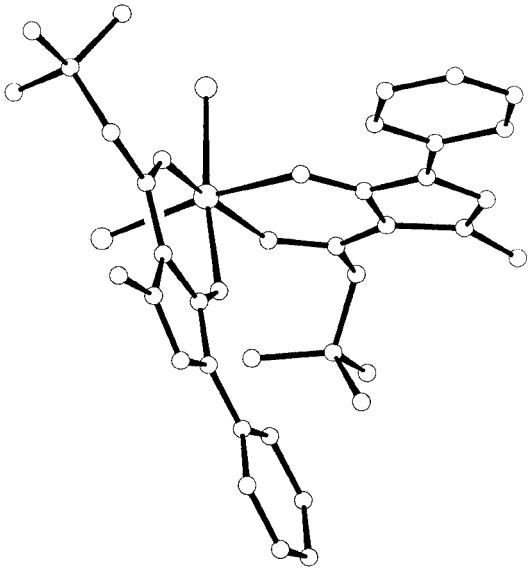

Figure 9. CIS3 DFT structure of $(Q^T)_2TiCl_2$

CIS2, and CIS3, similar to the O(oxo) atoms in the polynuclear Ti−(β-diketonates) $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$,[19] $[L_2Ti\text{-}\mu\text{-}O]_4$ (L = 2,2,6,6-tetramethylheptane-3,5-dionato)[50] and $[(acac)_2Ti\text{-}\mu\text{-}O]_2$,[5] i.e., Ti−O(β-diketonato) bonds are longer.

In conclusion, the *trans* influence determines the structural features in titanium 4-acyl-5-pyrazolonates. O(oxo) in $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$ and O(methoxy) in $Q_2Ti(OCH_3)_2$ are strong donors to Ti, resulting in the shortest Ti−O bonds and weakening their opposite Ti−O bonds in the coordination sphere.

Voltammetry

Because antitumor platinum and gold compounds exist in two metal oxidation states, Pt^{II} [11,12] and Pt^{IV} [26] and Au^{I} and Au^{III},[51−52] respectively, a redox reaction may play a role in the cytotoxic mechanism of metal derivatives. This has been demonstrated for the antitumor drug bleomycin, which forms a bleomycin−Fe^{II}−O_2 species that undergoes $Fe^{II} \rightarrow Fe^{III}$ oxidation before performing DNA cleavage.[53]

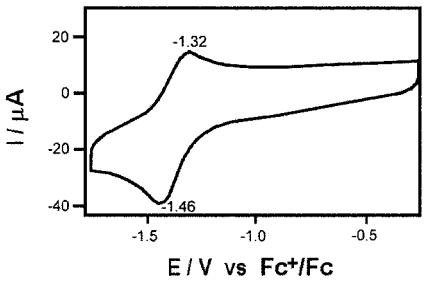

Figure 10. Voltammogram of the antitumor compound $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$(**1**)

Protein Ti-bound transferrin, believed to play a key role in the antitumor mechanism of Ti^{IV} titanocene dichloride, can also be obtained from Ti^{III} citrate.[25]

We have examined the redox behavior of Ti in the tetranuclear antitumor compound $[Q^B)_2Ti\text{-}\mu\text{-}O]_4$ (**1**) and the mononuclear species $(Q^T)_2Ti(O\textit{n}Pr)_2$ (**11**). The results, referred to Fc^+/Fc, for $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$ show a cyclic voltammogram in the cathodic region with a reversible redox couple, assigned to Ti^{IV}/Ti^{III}, with $Ep_c = -1.46$ V (Figure 10), whereas the same process for $(Q^T)_2Ti(O\textit{n}Pr)_2$ has −1.71 V (voltammogram not shown). Therefore, in the tetranuclear species all four Ti atoms undergo the same process and are indistinguishable. In addition, the Ti atom has a greater tendency to be reduced to Ti^{III} in the tetranuclear species than in the mononuclear one. In the related titanium β-diketonato compound $(Cp)_2Ti^{III}(acac)$,[54] the Ti^{IV}/Ti^{III} couple was $Ep_c = -0.85$ V (referred to Fc^+/Fc). Although comparison with the present work is difficult because of markedly different experimental conditions, it seems that the Ep_c value is highly ligand sensitive.

An initial stage in the voltammetric reduction of the mononuclear species $(Q^T)_2Ti(OCH_2CH_2CH_3)_2$ was also studied using DFT methods. Since the CIS3 stereochemistry of $(Q^T)_2Ti(OCH_3)_2$ and $(Q^B)_2Ti(OCH_3)_2$ show low energies, this conformation was expected to be favored for $(Q^T)_2Ti(OCH_2CH_2CH_3)_2$. After convergence, the anionic species $[(Q^T)_2Ti(OCH_2CH_2CH_3)_2]^-$ generally agrees with the structural trends shown by the methoxy derivatives mentioned above. However, the Ti−O*n*Pr bonds (1.840, 1.868 Å) are longer than the equivalent Ti−O(methoxy) bonds in $(Q^T)_2Ti(OCH_3)_2$ (1.801, 1.816 Å) and $(Q^B)_2Ti(OCH_3)_2$ (1.797, 1.801 Å); this seems reasonable as a leaving O*n*Pr group would induce a neutral, more stable $(Q^T)_2Ti^{III}(OCH_2CH_2CH_3)$ species.

Although Ti^{III} tends to oxidize to Ti^{IV}, the voltammetry experiment indicates a lower tendency for Ti^{IV} in the tetranuclear species $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$ and suggests a redox stability for polymeric forms stemming from $[(Q^B)_2Ti^{III}X_2]^-$ units. Such anionic forms can be water-soluble and thus improve their pharmacological formulation by avoiding the use of liposomes such as in the tetranuclear species $[(Q^B)_2Ti^{IV}\text{-}\mu\text{-}O]_4$. Biological results for the antitumor water-soluble Ti agents will be reported in a separate publication.

Conclusion

A rich variety of (4-acyl-5-pyrazolonato)titanium(IV) compounds, with several nuclearities, is observed due to hydrolysis during synthesis. Avoiding moisture prevents polymerization and discriminates between mono- or polynuclear compounds. Spectroscopic data (NMR, ESI-MS) and molecular weight analysis describe the polymerization features. Isolated compounds do not show Ti−Q cleavage, in contrast with classical Ti−(β-diketones). The ESI-MS results indicate mild Ti−Q cleavage compared with the fast breaking of Ti−Cl (or Ti−alkoxy). These features may enhance antitumor properties as the two most investigated antitumor titanium compounds, budotitane, and titanocene dichloride, show fast hydrolysis for Ti−O(ethoxy) (or Ti−Cl) and slow hydrolysis for Ti−(β-diketonato) (or Ti−Cp) bonds. Ti-Q (1:1) derivatives possess novel water solubility, which is useful for antitumor drug formulation. Quantum mechanical calculations on mononuclear $Q_2Ti(OCH_3)_2$ species show (a) three different sets of Ti−O bonds and a strong *trans* influence; (b) no preference for a unique *cis* isomer, although one of the three *cis* conformers has a markedly higher energy for one compound with a bulky substituent. Voltammetry data on a mono- and a tetranuclear species show a lower tendency towards reduction to Ti^{III} in the latter.

Experimental Section

General: The Ti precursors were obtained from Aldrich and used without further purification. 1-Phenyl-3-R^3-4-R^4-(C=O)-pyrazol-5-ones HQ (Figure 2) were prepared according to the literature. Samples for microanalysis were dried in vacuo to constant weight (20 °C, about 0.1 Torr). Molecular weight (M.W.) determinations were performed at 40 °C with a Knauer KNA0280 vapour pressure osmometer calibrated with benzil. The solvent was Baker Analysed Spectrophotometric grade chloroform. The results were reproducible to ±2%. Elemental analyses (C,H,N) were performed inhouse with a Fisons Instruments 1108 CHNS-O Elemental Analyser. IR spectra were recorded from 4000 to 100 cm^{-1} with a Perkin−Elmer System 2000 FT-IR instrument. ^1H NMR spectra were recorded with a VXR-300 Varian spectrometer. Melting points were determined with an IA 8100 Electrothermal instrument. The positive and negative electrospray mass spectra were obtained with a Series 1100 MSI detector HP spectrometer, using an acetonitrile mobile phase. Solutions (3 mg/mL) for electrospray ionization mass spectrometry (ESI-MS) were prepared using reagent grade acetone or acetonitrile. For the ESI-MS data, mass and intensities were compared to those calculated using IsoPro Isotopic Abundance Simulator, version 2.1.[55] Peaks containing silver(I) ions are identified as the center of an isotopic cluster.

Synthesis and Spectroscopic Characterization

$[(Q^B)_2Ti(\mu\text{-}O)]_4$ (1): Compound **1** was prepared by treating $TiCl_4$ with HQ^B [56] (1:2 ratio) under reflux in basic (KOH, 1:1 regarding HQ^B) ethanol (10 mL). A yellow precipitate formed which was then dissolved in CH_2Cl_2 to remove KCl. After filtration, the solution was concentrated and the residue recrystallized from ethyl acetate/*n*-hexane under aerobic conditions, m.p. 195 °C (dec.). Yield 0.525 g (85%) for $TiCl_4$ (0.190 g) and of Q^B (0.556 g). F.W. = 2473.9 (a tetranuclear compound shown by X-ray diffraction[19]). M.W. ($CHCl_3$) = 2200 (0.5 10^{-2} M) (r = 0.89). $C_{34}H_{26}N_4O_5Ti$: calcd. C 66.03, H 4.24, N 9.06; found C 65.92, H 4.33, N 8.86. ^1H NMR ($CDCl_3$, 300 MHz, 293 K, ppm): δ = 1.3 m, 1.4 m, 1.6 m, 1.7 m (br) (6 H, 3-CH_3), 6.2 br, 6.5 br, 6.7 br, 7.0 br, 7.5 br, 8.0 br (20 H, C_6H_5). ^1H NMR ($CDCl_3$, 300 MHz, 324 K, ppm): δ = 1.3−1.8 (15 s, 6 H, 3-CH_3), 6.2 m, 6.3 m, 6.4 m, 6.6 m, 7.1 m, 7.2 m, 7.4 m, 7.6 m, 7.9 m, 8.0 m (20 H, C_6H_5). ^1H NMR ($CDCl_3$, 300 MHz, 218 K, ppm): 1.0−2.1 (25 s, 6 H, 3-CH_3), 6.0 m, 6.2 m, 6.3 m, 6.4 m, 6.6 m, 7.1 m, 7.2 m, 7.4 m, 7.6 m, 7.9 m, 8.0 m, 8.2 m, 8.8 d, 9.05 d br (20 H, C_6H_5). IR (Nujol mull, cm^{-1}): ṽ = 1606 s, 1580 s, 1568 s, 1531 s (C···O, C···C and C···N), 554 m, 518 m, 504 m, 460 s, 448 vs, 410 sh, 398 s, 357 s (Ti−O). ESI-MS (MeCN) (+): *m*/*z* (%) = 301 (95) $[Na(HQ^B)]^+$, 924 (60) $[Na_4(Q^B)_3]^+$, 940 (95) $[Na_3K(Q^B)_3]^+$, 956 (60) $[Na_2K_2(Q^B)_3]^+$, 1856 (30) $[Ti_3(Q^B)_6O_3H]^+$, 1877 (30) $[NaTi_3(Q^B)_6O_3]^+$, 1894 (45) $[KTi_3(Q^B)_6O_3]^+$, 2497 (15) $[NaTi_4(Q^B)_8O_4]^+$. Alternatively, compound **1** can be obtained by treating $TiCl_4$ (1 mmol) with HQ^B (2 mmol) in CH_2Cl_2 in the presence of excess of KOH, or by direct reaction of $Ti(OR)_4$ (1 mmol, R= Me, Et or Bu) with HQ^B (at least 4 mmol).

$[(Q^T)_2Ti(O)(H_2O)]_n$ (2): Compound **2** was prepared by treating $Ti(OEt)_4$ with HQ^T [57] (1:4 ratio) under reflux in basic (KOH) ethanol. After 2 d, the solution was concentrated under vacuum and diethyl ether was then added. A yellow precipitate formed which was identified as compound **2**; yield 0.541 g (85%), m.p. 299−302 °C. For a monomeric unit F.W. is 636.56. $C_{32}H_{38}N_5O_6Ti$: calcd. C 61.54, H 6.46, N 8.97; found C 61.78, H 6.65, N 8.98. ^1H NMR ($CDCl_3$, 300 MHz, 293 K, ppm): δ = 1.0−1.6 (18 s, 22 H, CH_3 + CH_2), 2.4 (br m, 6 H 3-CH_3), 7.2 (br, 4 H, C_6H_5), 7.4 (br m, 2 H, C_6H_5), 7.8−8.1 (br m, 4 H, C_6H_5), 2.75 (s br, 2 H, H_2O). IR (Nujol mull, cm^{-1}): ṽ = 3176 (CH), 1602 s, 1595 sh, 1574 s, 1527 s (C···O, C···C, and C···N), 506 m, 474 s, 455 s, 411 w, 381 w, 363 w, 332 w, 287 m (Ti−O). ESI-MS (MeCN) (+): *m*/*z* (%) = 295 (95) $[Na(HQ^T)]^+$, 611 (15) $[Na_3(Q^T)_2]^+$, 629 (58) $[Na_2K(Q^T)_2]^+$, 645 (8) $[NaK_2(Q^T)_2]^+$, 1235 (30) $[Ti_2(Q^T)_4O_2H]^+$, 1257 (10) $[Ti_2(Q^T)_4O_2Na]^+$, 1274 (10) $[Ti_2(Q^T)_4O_2K]^+$, 1819 (10) $[Ti_3(Q^T)_6O_3H]^+$, 1842 (100) $[Ti_3(Q^T)_6O_3Na]^+$, 1858 (15) $[Ti_3(Q^T)_6O_3K]^+$.

$[(Q^A)_2Ti(O)(H_2O)]_n$ (3): Compound **3** was obtained by the reaction of $Ti(O\textit{n}Pr)_4$ with HQ^A [58] (1:2 ratio) in *n*PrOH, in the presence of KOH (4:1 ratio regarding Ti). The reaction mixture was stirred for 3 d. The resultant clear solution was then concentrated and the residue washed with diethyl ether and shown to be compound **3**; yield 0.566 g (81%), pale yellow, m.p. 235−238 °C. For a monomeric unit F.W. is 698.57. $C_{36}H_{34}N_4O_8Ti$: calcd. C 60.51, H 4.80, N 7.84; found C 60.32, H 5.0, N 7.51. ^1H NMR (D_2O, 200 MHz, 293 K, ppm): δ = 2.16 (s, 6 H, 3-CH_3), 3.78 (s, 6 H, OCH_3), 6.90 d, 4 H, C_6H_5), 7.19 (t, 2 H, C_6H_5), 7.23 (t, 4 H, C_6H_5), 7.5 (d, 4 H, C_6H_5), 7.58 (d, 4 H, C_6H_5). IR (Nujol mull, cm^{-1}): ṽ = 1603 s br, 1530 s br (C···O, C···C, and C···N), 598 s, 536 s br, 510 s, 442 m, 432 m, 422 sh, 388 w, 368 w, 325 m, 284 w.

$[(Q^N)_2Ti(O)(H_2O)]_n$ (4): The yellow compound **4** was obtained as for **3**, using HQ^N,[58] in 54% yield (0.402 g); m.p. 334 °C (dec.). For a monomeric unit F.W. is 744.52. M.W. ($CHCl_3$) = 2100 (2.1 10^{-2} M) (r = 2.82) $C_{34}H_{28}N_6O_{11}Ti$: calcd. C 54.85, H 3.79, N 11.29; found C 54.54, H 3.52, N 11.16. ^1H NMR (D_2O, 200 MHz, 293 K, ppm): δ = 2.19 (s, 6 H, 3-CH_3), 7.19 (t, 2 H, C_6H_5), 7.31 (t, 4 H, C_6H_5), 7.39 (d, 4 H, C_6H_5), 7.63 (d, 4 H, C_6H_5), 8.18 (d, 4 H, C_6H_5). IR (Nujol mull, cm^{-1}): ṽ = 3200 br (OH) 1632 s br, 1592 s, 1500 sh br (C···O, C···C, and C···N), 566 w, 510 m, 448 m, 397 w, 376 w, 325 w, 303 w, 290 w, 279 w, 253 w, 247 w.

Theoretical Calculations: The structural features of Q_2TiX_2 compounds were analyzed as follows. Starting coordinates were obtained from the X-ray molecular structure of the tetranuclear compound[19] $[(Q^B)_2Ti\text{-}\mu\text{-}O]_4$; three $(Q^B)_2TiO$ units were eliminated and the two former O(oxo) atoms were converted into two OH groups by adding two H atoms. Calculations on this mononuclear molecule, $(Q^B)_2Ti(OH)_2$, were preformed with the Mulliken program[60] package using an IBM/SP2 supercomputer. The MB3LYPDFT (Density Functional Theory)[61] method was used and the basis set was 6-31G*. For the titanium atom an ECP approximation[62−70] was applied, as implemented within MULLIKEN, using a double zeta basis. The starting structure was very far from that of the energy minimum reached because of the strain in the original tetranuclear molecule,[19] where *trans* O−Ti−O bond angles were as low as 163°, *cis* O(oxo)−Ti−O(oxo) bond angles were about 100° and Ti−O(oxo)−Ti bond angles were as wide as 154° − very far from the regular angle subtended at an oxygen atom. Consequently, the minimization process took about 45 d. After convergence, the H atoms in the two OH groups were replaced by methyl groups, and the two Ph groups (R^4) were replaced by neopentyl groups. This conformer, *cis*-$[(Q^T)_2Ti(OCH_3)_2]$, named CIS1, was minimized with the Accelrys program Cerius 2.4.6, subroutine DMol3,[71] using an Octane SGI computer. Standard local density was the VWN[72] functional and full geometric optimization was performed using a double numeric basis set with polarization functions (DNP)[73] on all atoms. The two other feasible *cis* isomers were analyzed after modifying the Q^T positions accordingly, and energy-minimized; these two conformers are named CIS2 and CIS3. The structure of $(Q^B)_2Ti(OH)_2$, converged with MULLIKEN, was also minimized with DMol3 and gave the same structural parameters in the coordination sphere. A related process was performed to study (a) $(Q^T)_2TiCl_2$ conformers, i.e., replacement of methoxy groups by Cl atoms in $(Q^T)_2Ti(OCH_3)_2$; (b) $(Q^B)_2Ti(OCH_3)_2$ replacing neopentyl groups by Ph groups in $(Q^T)_2Ti(OCH_3)_2$; (c) the anion $[(Q^T)_2Ti(OCH_2CH_2CH_3)_2]^-$, whose coordinates were obtained from $(Q^T)_2Ti(OCH_3)_2$ by replacing a H with a CH_2CH_3 group in each methoxy group.

Voltammetry: Electrochemical measurements were performed in a conventional three-compartment cell with three electrodes. The working electrode was vitreous carbon, the counter electrode was a platinum wire, and the reference electrode was saturated calomel. Ferrocene was used as an internal reference potential. The complex concentration was $1\cdot10^{-3}$ M, the solvent was *N*,*N*-dimethylformamide (Merck), used without further purification, and the support electrolyte was $1\cdot10^{-1}$ M tetraethylammonium perchlorate. The cyclic voltammograms were recorded with a PAR173 potentiostate/galvanostate coupled to a PAR175 universal potential programmer and a Graphtec WX4301 XY recorder.

Synthesis, Structure and Reactivity of New Late Transition Metal Complexes Bearing Diphosphane Ligands Derived from Bis(pyrazol-1-yl)methane

Antonio Otero,*[a] Fernando Carrillo-Hermosilla,*[a] Pilar Terreros,[b] Teresa Expósito,[a] Sergio Rojas,[b] Juan Fernández-Baeza,[a] Antonio Antiñolo,[a] and Isabel López-Solera[a]

Keywords: Nitrogen heterocycles / Phosphanes / Palladium / Platinum / Rhodium / Iridium / Hydrogenation

Modification of the multistep synthesis of the previously described bis[5-(diphenylphosphanyl)pyrazol-1-yl)]methane (bppzm, **1**) produces the novel diphosphane (diphenylphosphanyl)-[5-(diphenylphosphanyl)pyrazol-1-yl](pyrazol-1-yl)-methane (p4m, **2**). Treatment of this ligand with $[MCl_2(PhCN)_2]$ (M = Pd, Pt) or $[M(COD)(THF)_2]BF_4$ (M = Rh, Ir) produces $[MCl_2(p4m)]$ (M = Pd **3**, Pt **4**) or $[M(COD)(p4m)]BF_4$ (M = Rh **5**, Ir **6**) complexes, which chelate in a *P*,*P*-bidentate fashion. Sulfidation of bppzm and p4m produces the disulfidophosphanes $bppzmS_2$ (**7**) and $p4mS_2$ (**8**). Treatment of **7** and **8** with $[PdCl_2(PhCN)_2]$ produces $[PdCl_2(bppzmS_2)]$ (**9**) and $[PdCl_2(pmS_2)]$ (**10**), respectively, in which ligands **7** and **8** act in an *N*,*N*-bidentate chelate fashion. In contrast, ligand **8** reacts with $[Rh(COD)(THF)_2]BF_4$ to produce $[Rh(COD)(p4mS_2)]BF_4$, where ligand **7** acts in a dynamic *S*,*S*-chelate fashion. The activity of some of these complexes in the catalytic hydrogenation of olefins is reported and the single-crystal X-ray structures of **4**, **8**, and **9** have been obtained.

Introduction

The synthesis of polydentate phosphanes is a continuously developing field because these ligands are expected to allow greater control over the coordination sphere of a metal.[1] Increasing interest in the use of polyfunctional ligands has focused the attention of researchers on phosphanes with groups bearing nitrogen donors. Phosphorus-nitrogen hemilabile ligands are particularly useful in catalytic processes because one part of the ligand is capable of partially dissociating from the chelate form, thus allowing a substrate to coordinate to the metal centre and undergo some transformation.[2] With these precedents in mind, we have previously prepared and characterized[3] several poly(pyrazol-1-yl)methane derivatives bearing phosphane groups on the pyrazole rings, for example bis[5-(diphenylphosphanyl)-pyrazol-1-yl]methane (bppzm) (**1**). The coordinative capacity of the bppzm ligand was investigated with the metal centres niobium, palladium and platinum. In the first case, *N*,*N*-six-membered metallacyclic species were isolated. However, square-planar species with a *P*,*P*-eight-membered metallacycle were found for the late metals (see Figure 1), confirming the hard-hard, soft-soft acid-base principle.

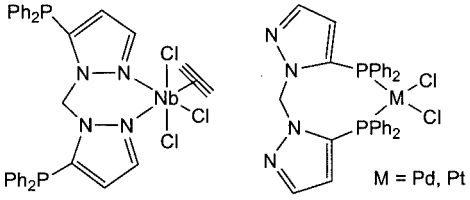

Figure 1. Complexes with the bppzm ligand

Research into the related phosphane sulfide ligands has been much less extensive.[4] Several complexes of late transition metals, namely platinum group metals, have been described with a variety of tertiary phosphane sulfides. The X-ray data suggest that $R_3P{=}S$ groups bind to the metal as simple σ-donors through the *p*-electrons of the sulfur atom, with no evidence of π-bonding between the metal *d* electrons and the empty orbitals of sulfur. This situation gives rise to weaker metal-ligand bonding than with the related phosphane ligands.

In order to extend these studies we sought to develop new functionalised bis(pyrazol-1-yl)methanes and to prepare and characterise new metal complexes formed by these ligands. Furthermore, we present here a modification of the synthesis of **1** to obtain a new chiral diphosphane. The influence of sulfidation of this new diphosphane and the previously described bppzm ligand on their coordination behaviour was also studied. One of the resulting complexes

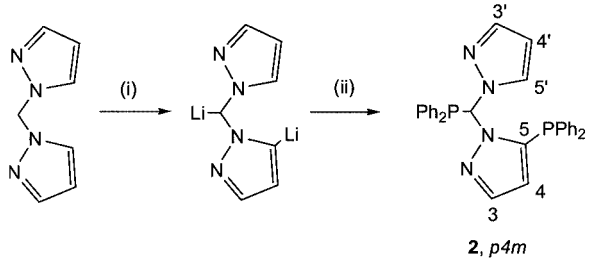
was found to be active in the hydrogenation of simple olefins.

Results and Discussion

We have previously described the synthesis of bis[5-(diphenylphosphanyl)pyrazol-1-yl)]methane (**1**),[3] which was prepared by reaction of bis(pyrazol-1-yl)methane (bpzm) and *n*BuLi at low temperature, followed by the addition of PPh_2Cl and warming. In many cases a minor by-product was observed in these reactions, although this was easily removed by crystallization from CH_2Cl_2/Et_2O.

The minor product has now been isolated and identified as a new asymmetric diphosphane. In an attempt to improve the yield of this new and interesting compound, the previously described synthetic procedure was modified by the addition of a slight excess of first *n*BuLi and then PPh_2Cl at room temperature, followed by recrystallization of the product from CH_2Cl_2 (Scheme 1). Similar behaviour[5] was also observed upon the modification of bis(pyrazol-1-yl)methane with MeI or $PhCH_2Br$.

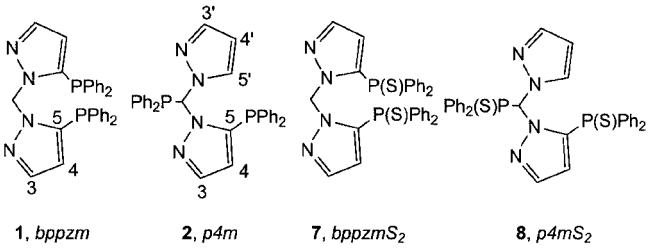


Scheme 1. (i) 2.5 *n*BuLi, THF, room temp., 30 min; (ii) 2 PPh_2Cl, THF, room temp., 16 h

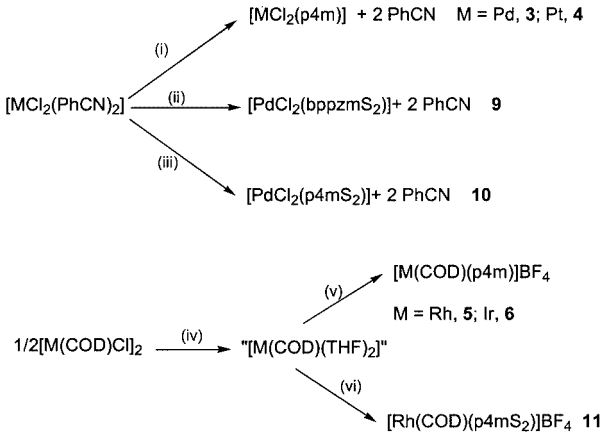
This new ligand, (diphenylphosphanyl)-[5-(diphenylphosphanyl)pyrazol-1-yl](pyrazol-1-yl)methane (**2**) (p4m), can be obtained from the reaction mixture with good purity as a light brown solid (see Exp. Sect.). In this procedure compound **1** is formed as the by-product.

The ^1H NMR spectrum of **2** shows two sets of two doublets assigned to H^3 and H^4 of the two pyrazole rings, with the more shielded peak corresponding to H^4. These data indicate that the two rings are not equivalent. The signal due to the bridging CH group appears as a doublet of doublets due to coupling with the two phosphorus atoms. The $J_{H,P}$ coupling constants are similar to those found for analogous compounds described by us.[3] The ^{13}C NMR spectrum confirms the asymmetry around the CH group, which gives rise to a doublet of doublets due to coupling with phosphorus atoms. Finally, the $^{31}P\{^1H\}$ NMR spectrum exhibits two singlets at $\delta = -30.99$ and -60.94 ppm for the inequivalent phosphorus atoms.

Ligand **2** (Scheme 2) is of considerable interest on two counts; firstly due to its chiral nature and secondly because it can provide different coordination modes than compound **1**. In fact, versatile ligand **2** would form six-membered *P*,*P*-, six-membered *N*,*N*- or seven-membered *N*,*P*-chelating complexes. Chiral chelating ligands that, when complexed to a metal such as rhodium, allow homogeneous hydrogenation to proceed in an enantioselective fashion to yield chiral products are of great interest and have been the focus of many reviews.[6] Compound **2** was used in the complexation of some late transition metal fragments, namely $[MCl_2(PhCN)_2]$ (M = Pd, Pt) and $[M(COD)(THF)_2]BF_4$ (M = Rh, Ir; COD = cyclooctadiene), in order to test its coordination capacity as a chelating agent (Scheme 3).



Scheme 2. Ligands **1**, **2**, **7** and **8**



Scheme 3. (i) p4m, CH_2Cl_2, room temp., 5 h; (ii) $bppzmS_2$, CH_2Cl_2, room temp., 16 h; (iii) $p4mS_2$, CH_2Cl_2, room temp., 16 h; (iv) $AgBF_4$, THF, room temp., 30 min; (v) p4m, THF, 203 K to room temp., 3 h; (vi) $p4mS_2$, THF, 203 K to room temp., 3 h

The complexes were isolated as crystalline solids in good yields (see Exp. Sect.). Complexes **3**, **4** and **5** are very stable under an inert atmosphere but complex **6** slowly decomposes in solution.

The ^1H NMR spectra of **3**, **4**, **5** and **6** show two sets of resonances for the H^3 and H^4 protons of the pyrazolyl rings. In addition, the H^5 proton of the unsubstituted ring appears as a broad singlet. The ^{13}C NMR spectra actually exhibit the signal for the methyne carbon atom and this appears as a doublet due to coupling with the neighbouring phosphorus atom. The asymmetry of these molecules is also reflected in the COD region of the spectra. For example, the diene ligand shows two broad peaks for the =CH carbons. The $^{31}P\{^1H\}$ NMR spectra show two broad peaks for complexes **3** and **6** and these are at significantly lower fields than the corresponding peaks for the free ligand **2**, suggest-

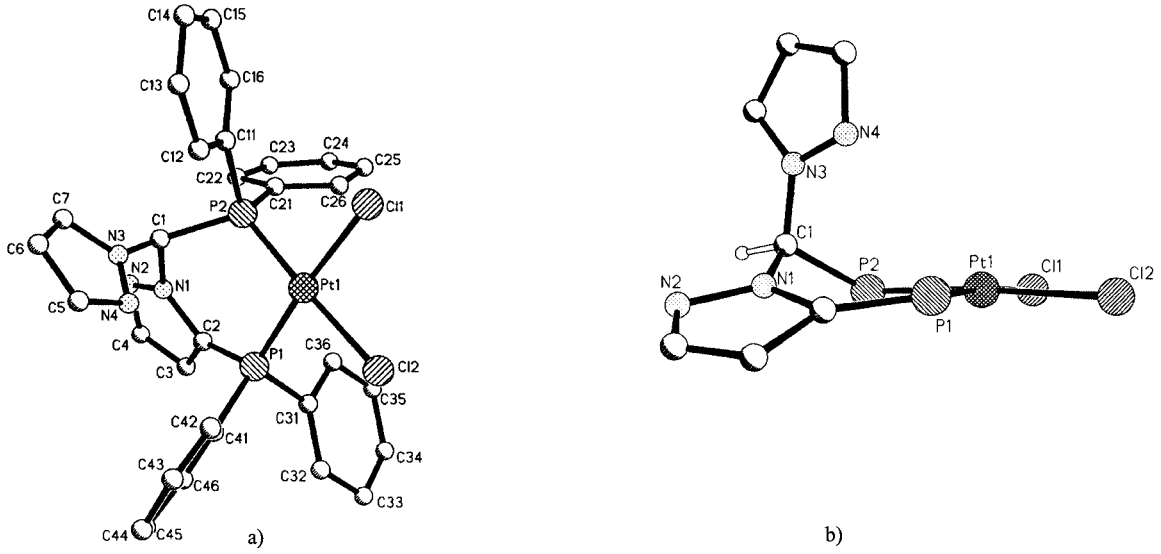

Figure 2. a) Molecular structure and atom-labelling scheme for compound 4; b) conformation of the six-membered chelate ring

ing that in these complexes a coordination of the p4m ligand takes place in a *P,P*-mode. Complex **5** also exhibits lower field signals but, in this case, the peaks appear as two doublets of doublets due to coupling between the two *cis* phosphorus atoms ($^2J_{P,P}$ = 39 Hz), through the metal, and also due to coupling with the rhodium atom ($^1J_{P,Rh}$ = 115 Hz). Complex **4** shows two doublets ($^2J_{P,P}$ = 16 Hz) at lower fields than the corresponding signals in the free ligand and these doublets are flanked by two ^{195}Pt satellites ($^1J_{Pt,P}$ = 1870 and 1791 Hz, respectively).

A crystal structure analysis of complex **4** was carried out in order to confirm the proposed coordination for these complexes. The molecular structure and atomic numbering scheme is shown in Figure 2. Selected bond lengths and angles for **4** are given in Table 1.

Pt(1)−P(1)−C(2)	115(1)

The structure consists of discrete monomeric molecules separated by van der Waals distances. The platinum centre is bound to four atoms (Figure 2b) — the two phosphorus atoms from the p4m group and the two chlorine atoms — in a quasi-planar coordination. The Cl1, Cl2, P1 and P2 atoms are co-planar and Pt1 is displaced from this plane by −0.057(6) Å. The six-membered chelate ring exists in a half-boat conformation with C1 −0.96(4) Å and N1 −0.36(5) Å out of the plane defined by Pt1, P1, P2 and C2. The Pt−P and Pt−Cl distances are in reasonable agreement with the values published for related structures.[3]

In contrast to the well-known use of diphosphanes as chelating ligands, the coordination chemistry of phosphane sulfide derivatives toward platinum group metals is much less extensively studied.[7]

The sulfide derivatives (**7** and **8**) of compounds **1** and **2** (Scheme 2), respectively, were obtained by reaction with an excess of elemental sulfur (see Exp. Sect.).

In the ^{1}H NMR spectrum of **7** the signals due to the methylene protons are shifted to lower field than the precursor ligand **1**. In a similar way to **1**, compound **7** gives rise to a single set of signals for H^3 and H^4 in the ^{1}H NMR spectrum as well as the corresponding C3, C4 and C5 carbon atoms in the ^{13}C NMR spectrum. This observation confirms the equivalence of the two pyrazole rings. Sulfidation of the phosphorus atoms produces a singlet at δ = 3.22 ppm in the ^{31}P{^{1}H} NMR spectrum, at higher field than those found for the more simple diphosphane sulfides such as $dppmS_2$ (δ = 35.4 ppm),[7d] and shifted to lower field than the value found for the original diphosphane ligand **1**. A similar effect was observed in the ^{31}P{^{1}H} NMR spectrum of **8**, which exhibits two singlets at δ = 25.57 and 3.62 ppm. The ^{1}H NMR signal for the proton on the methyne bridge of compound **8** is also shifted to lower field than for **2**. The ^{1}H and ^{13}C NMR spectra of **8** confirm the non-equivalence of the pyrazole rings, with two sets of signals observed for the proton and carbon atoms of the pyrazole rings. The IR spectra of compounds **7** and **8** show characteristic[7d] broad ν(P=S) bands at 658 cm^{-1} and 633 cm^{-1}, respectively.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The molecular structure of **8** was confirmed by X-ray crystallography. The molecular structure and atomic numbering scheme are shown in Figure 3. Selected bond lengths and angles for **8** are given in Table 2.

C(1)−P(2)−C(41)	106.9(1)
C(31)−P(2)−C(41)	106.6(1)

Each phosphorus atom shows a distorted tetrahedral coordination. The P−S distances of 1.955(1) and 1.939(1) Å indicate a double bond between P and S. The angle between the planes of the pyrazolyl rings is 112.5(1)°.

In order to study the behaviour of these new compounds as ligands in comparison to their phosphorus precursors **1** and **2**, we explored the reactivity of the sulfide derivatives **7** and **8** towards Pd and Rh metal centres. In these cases, we expect the possibility of an *S*,*S*-, *N*,*N*- or *N*,*S*-chelating coordination. Unfortunately, attempts to prepare analogous compounds of Pt or Ir were unsuccessful.

Addition of a stoichiometric amount of **7** to a dichloromethane solution of $[PdCl_2(PhCN)_2]$ led to the formation of complex **9** as a very insoluble solid (Scheme 3). The ^1H NMR spectrum of **9** exhibits two broad singlets for H^3 and H^4, which indicates the equivalence of the two pyrazole rings. A particularly interesting result was found on examining the $^{31}P\{^1H\}$ NMR spectrum of **9**. In this case, a singlet for two equivalent phosphorus atoms appears at δ = 4.80 ppm, which is close to the value of δ = 3.22 ppm found in the free ligand. This result seems to indicate that coordination of the phosphorus atoms to the palladium centre does not take place and hence that the ligand behaves as an *N*,*N*-donor in this complex. The IR spectrum confirms this coordination mode, with a ν(P=S) band at 660 cm^{-1}, similar to the value found in the free ligand. The position of the P=S band in the IR spectrum of previously reported sulfur-coordinated complexes is shifted 20−50 cm^{-1} to lower energy relative to the corresponding band in the uncomplexed ligands.[8]

Similar Pd^{II} complexes incorporating bis(pyrazol-1-yl)methane ligands with *N*,*N*-coordination have been prepared previously[9] with the aim of studying the electronic and steric effects of these ligands on the dynamic structure and reactivity of the corresponding complexes. In some cases, cationic derivatives were used as ethylene polymerization catalysts.

The analogous complex $[PdCl_2(bppzm)]$ shows a dynamic behaviour in solution that involves a boat-to-boat inversion.[3] For this reason, we carried out a variable-temperature NMR study in order to elucidate the possible dynamic behaviour of **9**. In the $^1H\{^{31}P\}$ NMR spectrum, the signal for the CH_2 group appears as a broad singlet at δ = 7.09 ppm at room temperature. At 228 K, however, this peak disappears in the baseline but, unfortunately, a slow exchange limit could not be observed.

The molecular structure of **9** was confirmed by X-ray crystallography. The molecular structure and atomic numbering scheme is shown in Figure 4. Selected bond lengths and angles for **9** are given in Table 3.

The structure consists of discrete monomeric molecules separated by van der Waals distances. There are two molecules per asymmetric unit. The palladium atom is bound to four atoms (Figure 4b) — the two nitrogens from the $bppzmS_2$ group and the two chlorine atoms — in a square-planar coordination. The six-membered chelate ring exists in a boat conformation with C4 and Pd1 out of the plane defined by N1, N2, N3 and N4 [C4: 0.656(7) and −0.638(7) Å for molecules 1 and 2, respectively; Pd1: 0.624(7) and −0.606(7) Å for molecules 1 and 2, respectively]. The Pd−N and Pd−Cl distances are in good agreement with the previously published values.[9] The angle between the planes of the pyrazolyl rings is 47.6(2)° and 47.5(2)° for molecules 1 and 2, respectively. The angles between the N1−N2−N3−N4 and N1−Pd1−N3 planes [154.5(2)° and 155.3(2)° for molecules 1 and 2, respectively] and N1−N2−N3−N4 and N2−C4−N4 planes [128.5(2)° and 129.8(2)° for molecules 1 and 2, respectively] are similar[3] to that in the complex $[PdCl_2(bppzm)]$, in which steric interactions are not appreciable.

It is worth noting that $[PdCl_2(bppzm)]$, which was reported previously by us,[3] shows a *P*,*P*-eight-membered metallacycle in preference to a less-open *N*,*N*-six-membered

S(2)−P(2)−C(7)	112.0(2)	115.2(2)

system. This behaviour can be explained if one considers the stable soft-soft interactions between Pd^{II} and P atoms. In contrast, in complex **9** a stable *N*,*N*-six-membered chelate is preferred to the soft-soft Pd−S bonds in a ten-membered metallacycle.

The behaviour of sulfur-containing ligand **8** towards $[PdCl_2(PhCN)_2]$ was investigated in order to explore the existence of *N*,*N*-six-membered or *S*,*S*-eight-membered complexation. The reaction of **4** and $[PdCl_2(PhCN)_2]$ was performed in CH_2Cl_2 (see Scheme 3) and afforded $[PdCl_2(p4mS_2)]$ (**10**) as a very insoluble solid.

The ^1H NMR spectrum of **10** shows evidence for the non-equivalence of the pyrazole rings. The signal for the proton of the methyne group appears as a doublet at δ = 9.61 ppm due to coupling with the nearest phosphorus atom. The $^{31}P\{^1H\}$ NMR spectrum of **10** shows two singlets at δ = 26.11 and 5.70 ppm, which are closer to those of the free ligand (δ = 25.57 and 3.62 ppm). The IR spectrum confirms an *N*,*N*-coordination on the basis of the ν(P=S) absorption at 630 cm^{-1} for complex **10** — a value similar to that found in the free ligand.

Finally, reaction of **8** and the solvate moiety $[Rh(COD)(THF)_2]BF_4$ in THF afforded $[Rh(COD)(p4mS_2)]BF_4$ (**11**) as a very insoluble brown solid (see Scheme 3). This complex was prepared in order to study the influence of sulfur on the reactivity of complex **11** in comparison with the analogous complex **5** (see below).

The $^{31}P\{^1H\}$ NMR spectrum of complex **11** contains two peaks near to those of the free ligand **8**. The peak at δ = 20.64 ppm appears as a very broad multiplet, indicating that some interaction with rhodium is present and that the molecule shows a dynamic behaviour in solution. This situation was confirmed by performing a variable temperature $^{31}P\{^1H\}$ NMR study. At low temperature (213 K), the process can be frozen out and the broad peak gives rise to a pseudo-triplet at δ = 18.76 ppm (J = 9 Hz), probably due to coupling with the rhodium and the second phosphorus. On the other hand, a sharp peak at δ = 21.52 ppm was observed at 333 K. A temperature-dependent coordination/decoordination process involving one of the $P(S)Ph_2$ groups was proposed as being responsible for these changes. Additionally, the IR spectrum shows a ν(P=S) absorption at 556 cm^{-1}, which indicates an *S*,*S*-coordination mode.

Hydrogenation of Olefins

Complex **5**, which contains the ligand p4m, is an active hydrogenation catalyst for cyclohexene and 1-heptene (Table 4).

The reactions were conducted under different conditions of pressure, reaction time, solvent, and in the presence/absence of additives. In CH_2Cl_2, a conversion of 26% for cyclohexene was obtained after ca. 20 h. at 10 bar and 353 K. A similar conversion (21%) was obtained in MeOH. In contrast, addition of a small amount of KOH to the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 4. Results of the catalysis experiments; reaction conditions: catalyst 0.03 mmol; substrate 3 mmol; solvent 30 mL; KOH 0.04 mmol

Complex	Substrate	Solvent	Additive	Time(h)	Temp.(K)	Pressure(bar)	Conversion (%)
5	cyclohexene	CH_2Cl_2		20	298	1	7.7
5	cyclohexene	CH_2Cl_2		20	353	10	26
5	cyclohexene	MeOH		20	353	10	21
5	cyclohexene	MeOH	KOH	1	353	10	33
5	1-heptene	MeOH	KOH	1	353	10	50

latter reaction mixture produced the highest conversion observed (33%) in only 1 h. The activity is similar to those found for other rhodium derivatives of multidentate heterocyclic ligands, of the type $[Rh(diene)(OPPy_2R)]BF_4$,[2j] under very analogous conditions. As expected, complex **5** is a better catalyst for the hydrogenation of 1-heptene, giving a conversion of 50% in 1 h. The iridium derivative **6**, probably due to its lack of stability in solution, and the rhodium complex **11**, probably due to the presence of sulfur[10] in the coordination sphere and the low solubility of this complex, did not show any catalytic activity at all, in comparison to the analogous phosphane complex **5.**

These results suggest the possibility of testing the activity and enantioselectivity of chiral complex **5** in the hydrogenation of prochiral substrates. Experiments to obtain pure enantiomers of ligand **2** are currently underway.

Conclusion

The preparation of a new chiral functionalised phosphorus-containing bis(pyrazol-1-yl)methane compound, p4m, has been carried out by modification of a previously described procedure. The coordination modes of this compound were studied towards the metal centres palladium, platinum, rhodium and iridium to produce *P*,*P*-six-membered metallacycles. Sulfidation of the previously described bppzm and the new p4m ligands produces the corresponding sulfidodiphosphanes. The compounds $p4mS_2$ and $bppzmS_2$ coordinate a palladium centre in an *N*,*N*-six-membered metallacycle and reaction of $p4mS_2$ with $[Rh(COD)(THF)_2]^+$ produces an *S*,*S*-dynamic coordination of the ligand.

Finally, complex $[Rh(COD)(p4m)]BF_4$ showed a moderate activity in the catalytic hydrogenation of simple olefins.

Experimental Section

All reactions were carried out using Schlenk-tube techniques under an atmosphere of dry nitrogen. Solvents were distilled from appropriate drying agents and degassed before use. ^1H,^{13}C and ^{31}P NMR spectra were obtained on a 300 Unity Varian spectrometer. Assignment of the signals was achieved by means of DEPT, NOE difference and two-dimensional NMR experiments, acquired using standard Varian-FT software. IR spectra were obtained in the region 500−4000 cm^{-1} using a Nicolet Magna FT-IR 550 spectrophotometer. $[MCl_2(PhCN)_2]$ (M = Pd, Pt) and bis(pyrazol-1-yl)-methane were prepared as reported previously.[11,12] $[RhCl(COD)]_2$ and $[IrCl(COD)]_2$ were purchased from Aldrich and used as received

(5-Diphenylphosphanylpyrazol-1-yl)(diphenylphosphanyl)-(pyrazol-1-yl)methane (p4m) (2): A solution of bpzm (3 g, 20 mmol) in dry THF (150 mL) in a 250 mL Schlenk tube was cooled to 203 K. A 1.6 M solution of *n*BuLi (31.3 mL, 50 mmol) in hexane was added and the solution was allowed to reach room temperature slowly. PPh_2Cl (7.27 mL, 41 mmol) was added and the reaction mixture was stirred for 16 h. The suspension was filtered and the solvent removed under vacuum. The resulting red oil was washed with hexane and the residue extracted with CH_2Cl_2. The solvent was removed and the resulting orange oil was washed with Et_2O. A pale-brown solid was obtained and was recrystallized from CH_2Cl_2. Yield 90%. $C_{31}H_{26}N_4P_2$ (516.5): calcd. C 72.08, H 5.07, N 10.85%; found C 72.20, H 5.09, N 10.49. ^1H NMR (300 MHz, $CDCl_3$, 293 K): δ = 7.87 (d, $^3J_{H,H}$ = 2.5 Hz, 1 H, H3′), 7.81 (dd, $^2J_{H,P}$ = 6.0, $^4J_{H,P}$ = 3.0 Hz, 1 H, CH), 7.58 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H3), 7.37−7.05 (m, 20 H, Ph), 7.24 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H5′), 6.08 (dd, $^3J_{H,H}$ = 2.0, $^3J_{H,H}$ = 2.5 Hz, 1 H, H4′), 5.87 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$, 293 K): δ = 141.05 (d, $^1J_{C,P}$ = 12.0 Hz, C5), 140.83 (d, $^3J_{C,P}$ = 3.5 Hz, C3), 139.53 (d, $^3J_{C,P}$ = 1.5 Hz C5′), 135.20−128.10 (Ph), 128.94 (s, C3′), 114.54 (d, $^2J_{C,P}$ = 2.0 Hz, C4), 107.16 (s, C4′), 73.48 (dd, $^1J_{C,P}$ = 14.0, $^3J_{C,P}$ = 5.0 Hz, CH) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, H_3PO_4 as reference): δ = −30.99 (s, PPh_2), −60.94 (s, PPh_2) ppm.

[$PdCl_2$(p4m)] (3): An equimolar quantity of p4m (0.402 g, 0.78 mmol) was added to a CH_2Cl_2 (50 mL) solution of $[PdCl_2(PhCN)_2]$ (0.300 g, 0.78 mmol). The solution was stirred for 5 h at room temperature. The solvent was removed in vacuo and the resulting pale orange solid was washed with cold CH_2Cl_2 and dried in vacuo. Yield 85%. $C_{31}H_{26}Cl_2N_4P_2Pd$ (693.8): calcd. C 53.66, H 3.78, N 8.07; found C 53.89, H 3.79, N 8.01. ^1H NMR (300 MHz, CD_2Cl_2, 293 K): δ = 7.67 (d, $^2J_{H,P}$ = 3.0 Hz, 1 H, CH), 7.65−7.26 (m, 20 H, Ph), 7.24 (br. s, 1 H, H5′), 7.13 (br. s, 1 H, H3′), 6.98 (br. s, 1 H, H3), 6.17 (br. s, 1 H, H4′), 5.92 (br. s, 1 H, H4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, CD_2Cl_2, 293 K): δ = 142.21 (s, C3′), 140.08 (d, $^1J_{C,P}$ = 13.1 Hz, C5), 136.00−128.00 (Ph), 130.80 (s, C5′), 129.80 (d, $^3J_{C,P}$ = 11.0 Hz, C3), 118.75 (d, $^2J_{C,P}$ = 7.4 Hz, C4), 107.17 (s, C4′), 68.75 (d, $^1J_{C,P}$ = 48.6 Hz, CH) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, CD_2Cl_2, H_3PO_4 as reference): δ = −18.36 (s, PPh_2), 15.06 (s, PPh_2) ppm.

[$PtCl_2$(p4m)] (4): The synthetic procedure was the same as for complex 2, using $[PtCl_2(PhCN)_2]$ (0.300 g, 0.64 mmol) and p4m (0.330 g, 0.64 mmol), to give complex **4** as a white solid. Yield 90%. Crystals for X-ray diffraction were grown from a cooled saturated solution in CH_2Cl_2. $C_{31}H_{26}Cl_2N_4P_2Pt{\cdot}4CH_2Cl_2$ (1116.1): calcd. C 37.46, H 3.05, N 4.99; found C 37.50, H 3.06, N 5.02. ^1H NMR (300 MHz, CD_2Cl_2, 293 K): δ = 7.82 (d, $^2J_{H,P}$ = 3.0 Hz, 1 H, CH), 7.59−7.26 (m, 20 H, Ph), 7.24 (br. s, 1 H, H5′), 7.06 (br. s, 1 H, H3′), 6.83 (br. s, 1 H, H3), 6.16 (br. s, 1 H, H4′), 5.80 (br. s, 1 H,

H4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, CD_2Cl_2, 293 K): δ = 141.02 (s, C3′), 139.50 (d, $^1J_{C,P}$ = 11.1 Hz, C5), 136.00−128.00 (Ph), 130.71 (s, C5′), 129.65 (d, $^3J_{C,P}$ = 11.0 Hz, C3), 118.48 (d, $^2J_{C,P}$ = 8.0 Hz, C4), 106.71 (s, C4′), 67.28 (d, $^1J_{C,P}$ = 54.3 Hz, CH) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, CD_2Cl_2, H_3PO_4 as reference): δ = −34.94 (t of d, $^1J_{P,Pt}$ = 1797, $^2J_{P,P}$ = 16.0 Hz, PPh_2), −3.03 (t of d, $^1J_{P,Pt}$ = 1870, $^2J_{P,P}$ = 16.0 Hz, PPh_2) ppm.

[Rh(COD)(p4m)]BF_4 (5): An equimolar quantity of $AgBF_4$ (0.078 g, 0.40 mmol) was added to a THF (10 mL) solution of $[Rh(COD)Cl]_2$ (0.100 g, 0.20 mmol). The solution was stirred for 30 min at room temperature. The precipitated AgCl was filtered off and the filtrate was cooled to 203 K. A cooled solution of p4m (0.103 g, 0.40 mmol) in THF (10 mL) was then added slowly. The reaction was allowed to reach room temperature slowly over 3 h. The solvent was removed in vacuo and the resulting yellow solid was extracted with THF. Concentration of the solution afforded complex 5 as a bright yellow microcrystalline solid. Yield 75%. $C_{39}H_{38}BF_4N_4P_2Rh$ (814.4): calcd. C 57.51, H 4.67, N 6.88; found C 57.60, H 4.80, N 6.76. ^1H NMR (300 MHz, $CDCl_3$, 293 K): δ = 8.25 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H5′), 8.11 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H3′), 7.62−7.20 (m, 20 H, Ph), 7.59 (d, $^2J_{H,P}$ = 3.0 Hz, 1 H, CH), 7.43 (br. s, 1 H, H3), 6.82 (dd, $^3J_{H,H}$ = 2.0, $^3J_{H,H}$ = 2.0 Hz, 1 H, H4′), 5.99 (br. s, 1 H, H4), 4.17, 3.89 (m, 2 H, 2 H, CH, COD), 2.02, 2.33, 2.59, 2.99 (m, 2 H, 2 H, 2 H, 2 H, CH_2, COD) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$, 293 K): δ = 144.08 (s, C3′), 140.63 (d, $^3J_{C,P}$ = 10.0 Hz, C3), 138.00−128.00 (Ph), 133.53 (d, $^3J_{C,P}$ = 2.0 Hz, C5′), 132.11 (d, $^1J_{C,P}$ = 15.0 Hz, C5), 116.94 (d, $^2J_{C,P}$ = 6.0 Hz, C4), 112.03 (s, C4′), 86.15 (dd, $^2J_{C,P}$ = 13.0, $^1J_{C,Rh}$ = 14.0 Hz, CH, COD), 84.16 (dd, $^2J_{C,P}$ = 10.0, $^1J_{C,Rh}$ = 10.0 Hz, CH, COD), 72.60 (d, $^1J_{C,P}$ = 60.3 Hz, CH), 35.93 (s, CH_2, COD), 28.54 (s, CH_2, COD) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, H_3PO_4 as reference): δ = 27.40 (dd, $^1J_{P,Rh}$ = 115.0, $^2J_{P,P}$ = 39.0 Hz, PPh_2), 21.10 (dd, $^1J_{P,Rh}$ = 115.0, $^2J_{P,P}$ = 39.0 Hz, PPh_2) ppm.

[Ir(COD)(p4m)]BF_4 (6): The synthetic procedure was the same as for complex **5**, using $[Ir(COD)Cl]_2$ (0.100 g, 0.15 mmol) and p4m (0.077 g, 0.30 mmol), to give complex **6** as a pale orange solid. Yield 55%. $C_{39}H_{38}BF_4IrN_4P_2$ (903.7): calcd. C 51.83, H 4.24, N 6.20; found C 51.95, H 4.30, N 6.26. ^1H NMR (300 MHz, $CDCl_3$, 293 K): δ = 8.43 (br. s, 1 H, H5′), 7.70 (d, $^2J_{H,P}$ = 3.0 Hz, 1 H, CH), 7.60−7.20 (m, 20 H, Ph), 7.40 (d, $^2J_{H,P}$ = 2.0 Hz, 1 H, H3), 7.31 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H3′), 6.45 (br. s, 1 H, H4′), 6.01 (br. s, 1 H, H4), 3.80, 3.42 (m, 2 H, 2 H, CH, COD), 1.42, 2.45 (m, 4 H, 4 H, CH_2, COD) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$, 293 K): δ = 142.43 (C3′), 139.59 (d, $^3J_{C,P}$ = 10.0 Hz, C3), 134.48 (d, $^1J_{C,P}$ = 13.0 Hz, C5), 133.10 (C5′), 128−134 (Ph), 117.00 (d, $^2J_{C,P}$ = 4.0 Hz, C4), 111.83 (C4′), 72.90 (d, $^1J_{C,P}$ = 39.2 Hz, CH), 69.12 (d, $^2J_{C,P}$ = 10.0 Hz, CH, COD), 69.09 (d, $^2J_{C,P}$ = 10.0 Hz, CH, COD), 67.45 (d, $^2J_{C,P}$ = 10.0 Hz, CH, COD), 67.43 (d, $^2J_{C,P}$ = 10.0 Hz, CH, COD), 36.22 (CH_2, COD), 36.18 (CH_2, COD), 30.42 (CH_2, COD) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, H_3PO_4 as reference): δ = −44.26 (br. s, PPh_2), 9.36 (br. s, PPh_2) ppm.

Bis(5-diphenylphosphanylpyrazol-1-yl)methane Disulfide (bppzmS_2) (7): An excess of elemental sulfur S_8 (0.640 g, 2.50 mmol) was added to a CH_2Cl_2 (50 mL) solution of bppzm (1.000 g, 2.00 mmol). The reaction mixture was stirred for 48 h at room temperature. The solvent was removed in vacuo and the resultant solid was washed with CS_2 (100 mL). The residue was washed with Et_2O and recrystallized from CH_2Cl_2/Et_2O to afford compound 7 as a pale brown solid. Yield 95%. $C_{31}H_{26}N_4P_2S_2$ (580.6): calcd. C 64.13, H 4.48, N 9.65; found C 64.17, H 4.55, N 9.75. ^1H NMR (300 MHz, $CDCl_3$, 293 K): δ = 7.76−7.40 (m, 20 H, Ph), 7.28 (d, $^3J_{H,H}$ = 1.5 Hz, H3), 7.06 (br. s, 2 H, CH_2), 5.91 (d, $^3J_{H,H}$ = 1.5 Hz, H4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$, 293 K): δ = 138.60 (d, $^3J_{C,P}$ = 14.0 Hz, C3), 138.72 (d, $^1J_{C,P}$ = 38.0 Hz, C5), 132.15−128.42 (Ph), 116.57 (d, $^2J_{C,P}$ = 15.0 Hz, C4), 63.74 (s, CH_2) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, H_3PO_4 as reference): δ = 3.22 [s, $P(S)Ph_2$] ppm. IR (KBr): $\tilde{\nu}$ = 658 cm^{-1} (s) [ν(P=S)].

(5-Diphenylphosphanylpyrazol-1-yl)(diphenylphosphanyl)-(pyrazol-1-yl)methane Disulfide (p4mS_2) (8): The synthetic procedure was the same as for compound **7**, using p4m (1.000 g, 3.88 mmol) and sulfur (1.250 g, 4.85 mmol), to give compound **8** as a pale orange solid. Yield 90%. The crystals for X-ray diffraction were grown from CH_2Cl_2/hexane. $C_{31}H_{26}N_4P_2S_2$ (580.6): calcd. C 64.13, H 4.48, N 9.65; found C 64.02, H 4.62, N 9.45. ^1H NMR (300 MHz, $CDCl_3$, 293 K): δ = 9.35 (d, $^2J_{H,P}$ = 6.8 Hz, 1 H, CH), 8.20−7.15 (m, 20 H, Ph), 7.83 (d, $^3J_{H,H}$ = 2 Hz, 1 H, H3′), 7.45 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H5′), 6.94 (d, $^3J_{H,H}$ = 2.3 Hz, 1 H, H3), 5.96 (dd, $^3J_{H,H}$ = 2.3, $^3J_{H,H}$ = 2.0 Hz, 1 H, H4′), 5.84 (d, $^3J_{H,H}$ = 2.3 Hz, 1 H, H4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$, 293 K): δ = 139.58 (d, $^1J_{C,P}$ = 14.0 Hz, C5), 139.59 (s, C5′), 139.37 (d, $^3J_{C,P}$ = 2.0 Hz, C3), 136.60−127.80 (Ph), 130.32 (s, C3′), 116.73 (dd, $^2J_{C,P}$ = 14.4, $^4J_{C,P}$ = 10.0 Hz, C4), 105.96 (d, $^4J_{C,P}$ = 9.0 Hz, C4′), 72.40 (d, $^1J_{C,P}$ = 65.0 Hz, CH) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, H_3PO_4 as reference): δ = 25.57 [s, $P(S)Ph_2$], 3.62 [s, $P(S)Ph_2$] ppm. IR (KBr): $\tilde{\nu}$ = 633 cm^{-1} (s) [ν(P=S)].

[$PdCl_2$(bppzmS_2)] (9): An equimolar quantity of bppzmS_2 (0.452 g, 0.78 mmol) was added to a CH_2Cl_2 (50 mL) solution of $[PdCl_2(PhCN)_2]$ (0.300 g, 0.78 mmol). The solution was stirred for 16 h at room temperature. The solvent was removed in vacuo and the residue was washed with Et_2O to give an orange solid. Yield 85%. The crystals for X-ray diffraction were grown from a cooled saturated solution in CH_2Cl_2. $C_{31}H_{26}Cl_2N_4P_2PdS_2{\cdot}3.5CH_2Cl_2$ (1055.2): calcd. C 46.45, H 3.81, N 6.47; found C 46.50, H 3.84, N 6.49. ^1H NMR (300 MHz, $CDCl_3$, 293 K): δ = 8.27 (br. s, H3), 7.70−7.54 (m, 20 H, Ph), 7.09 (br. s, 2 H, CH_2), 5.99 (m, H4) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$, 293 K): δ = 143.62 (d, $^1J_{C,P}$ = 27.0 Hz, C5), 138.85 (d, $^3J_{C,P}$ = 14.0 Hz, C3), 133.35−128.69 (Ph), 117.35 (d, $^2J_{C,P}$ = 14.6 Hz, C4), 63.48 (s, CH_2) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, H_3PO_4 as reference): δ = 4.80 [s, $P(S)Ph_2$] ppm. IR (KBr): $\tilde{\nu}$ = 660 cm^{-1} (s) [ν(P=S)].

[$PdCl_2$(p4mS_2)] (10): The synthetic procedure was the same as for compound **9**, using $[PdCl_2(PhCN)_2]$ (0.300 g, 0.78 mmol) and p4mS_2 (0.452 g, 0.78 mmol), to give compound **10** as an orange solid. Yield 90%. $C_{31}H_{26}Cl_2N_4P_2PdS_2$ (757.9): calcd. C 49.12, H 3.46, N 7.39; found C 49.22, H 3.50, N 7.43. ^1H NMR (300 MHz, CD_2Cl_2, 293 K): δ = 9.61 (d, $^2J_{H,P}$ = 7.0 Hz, 1 H, CH), 8.35 (m, 1 H, H5′), 8.02 (m, 1 H, H3′), 7.83−7.49 (m, 20 H, Ph), 7.45 (m, 1 H, H3), 6.15 (m, 1 H, H4), 6.13 (m, 1 H, H4′) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, CD_2Cl_2, H_3PO_4 as reference): δ = 26.10 [s, $P(S)Ph_2$], 5.70 [s, $P(S)Ph_2$] ppm. IR (KBr): $\tilde{\nu}$ = 630 cm^{-1} (s) [ν(P=S)].

[Rh(COD)(p4mS_2)]BF_4 (11): An equimolar quantity of $AgBF_4$ (0.078 g, 0.40 mmol) was added to a THF (10 mL) solution of $[Rh(COD)Cl]_2$ (0.100 g, 0.20 mmol). The solution was stirred for 30 min at room temperature. The precipitated AgCl was filtered off and the filtrate was cooled to 203 K. A cooled solution of p4mS_2 (0.232 g, 0.40 mmol) in THF (10 mL) was then added slowly. The reaction was allowed to reach room temperature slowly over 3 h. The solvent was removed in vacuo and the resulting brown solid was extracted with THF. The solution was concentrated and cooled to give complex **11** as a brown microcrystalline solid. Yield 65%. $C_{39}H_{38}BF_4N_4P_2RhS_2$ (878.5): calcd. C 53.32, H 4.36, N 6.38; found

C 53.40, H 4.42, N 6.45. ^{1}H NMR (300 MHz, $CDCl_3$, 293 K): δ = 9.67 (d, $^2J_{H,P}$ = 7.0 Hz, 1 H, CH), 8.42 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H3), 8.20−7.10 (m, 20 H, Ph), 7.24 (d, $^3J_{H,H}$ = 2 Hz, 1 H, H3′), 6.72 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, H5′), 6.51 (d, $^3J_{H,H}$ = 2.2 Hz, 1 H, H4), 6.04 (dd, $^3J_{H,H}$ = 2.0, $^3J_{H,H}$ = 2.0 Hz, 1 H, H4′), 4.32−4.17 (m, 4 H, CH, COD), 2.75−2.54 (m, 8 H, CH_2, COD), 2.02−1.82 (m, 8 H, CH_2, COD) ppm. ^{13}C{^{1}H} NMR (75 MHz, $CDCl_3$, 293 K): δ = 143.25 (d, $^3J_{C,P}$ = 13.0 Hz, C3), 141.19 (s, C3′), 134.00−128.00 (Ph), 134.10 (d, $^1J_{C,P}$ = 12.0 Hz, C5), 133.07 (s, C5′), 118.60 (d, $^2J_{C,P}$ = 13.0 Hz, C4), 107.01 (s, C4′), 79.46 (m, CH, COD), 77.01 (m, CH, COD), 69.00 (d, $^1J_{C,P}$ = 40.1 Hz, CH), 31.35 (m, CH_2, COD), 29.65 (m, CH_2, COD) ppm. ^{31}P{^{1}H} NMR (121 MHz, $CDCl_3$, H_3PO_4 as reference): δ = 20.64 [bs, P(S)Ph_2], 4.42 [s, P(S)Ph_2] ppm. IR (KBr): $\tilde{\nu}$ = 556 (s) [ν(P=S)].

X-ray Crystallographic Study: Crystals obtained for complex **4** decomposed quickly with the loss of CH_2Cl_2, even when the data collection was performed at low temperature. We attempted this study with several crystals but data collection could not be completed. Given the importance of this structure, it was solved despite the aforementioned problems. Intensity data for complexes **4**, **8** and **9** were collected on a NONIUS-MACH3 diffractometer equipped with a graphite monochromator (Mo-K_α radiation, λ = 0.71073 Å) using the ω/2θ scan technique. The final unit-cell parameters were determined from 25 well-centered reflections and refined by the least-squares method. The space group was determined from the systematic absences and this was vindicated by the success of the subsequent solutions and refinements. Two standard reflections were measured every 60 minutes as an orientation and intensity control; significant intensity decay was not observed for compounds **8** and **9**. However, compound **4** showed an intensity decay of 56% at the end of the process. The structures were solved by direct methods using SHELXS[13] and refined on F^2 by full-matrix least-squares (SHELXL-97).[14] The CH_2Cl_2 solvate molecule could be located in complexes **4** and **9**. All non-hydrogen atoms were refined with anisotropic thermal parameters in complexes **8** and **9**. The hydrogen atoms were included in their calculated positions and were refined with an overall isotropic temperature factor using a riding model. Weights were optimized in the final cycles. Crystallographic data are given in Table 5. CCDC-207627 (**4**), -207628 (**8**) and -207629 (**9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Catalytic Activity: Hydrogenation reactions were carried out in a 100 mL stainless steel autoclave (Magnedrive Autoclave Engineers). The autoclave was evacuated for 2 h before a solution containing the catalyst and substrate was introduced by suction. Hydrogen was then introduced and the mixture was warmed to the reaction temperature. The pressure in the autoclave was monitored using a transducer. Samples were analysed by gas chromatography on a Hewlett Packard HP 6890 chromatograph equipped with an FID detector and 30 m × 0.032 mm HP-Innovax column.

Synthesis, Properties, and Reactions of Trinuclear Macrocyclic Nickel(II) and Nickel(I) Complexes: Electrocatalytic Reduction of CO_2 by Nickel(II) Complex

Eun Young Lee,[a] Daewon Hong,[a] Han Woong Park,[a] and Myunghyun Paik Suh*[a]

Keywords: Nickel / Macrocyclic compounds / Carbon dioxide / Electroreduction / Multinuclear complex

The trinuclear Ni^{II} complex of trismacrocyclic ligand **1**, $[Ni_3(\mathbf{1})](ClO_4)_6$, where **1** is 8,8′,8"-(2,2′,2"-nitrilotriethyl)-tris(1,3,6,8,10,13,15-heptaazatricyclo[11.3.1.1^{3,15}]octadecane), has been synthesized by template condensation reactions and shown to have poor axial binding ability. Cyclic voltammetry of the complex shows a three-electron reversible reduction at −1.59 V and an irreversible oxidation at +1.25 V vs. Ag/Ag^+ (0.01 M). Differential pulse voltammetry and Osteryoung square-wave voltammetry indicate that the three Ni^{II} ions are electrochemically independent. A single crystal was obtained as $[Ni_3(\mathbf{1})](ClO_4)_3{\cdot}Cl_3{\cdot}10H_2O$ and its X-ray structure was determined. When $[Ni_3(\mathbf{1})](ClO_4)_6$ was reduced to a Ni^I species by reaction with Na(Hg) in MeCN, $[Ni_3(\mathbf{1})](ClO_4)_3$ was isolated. $[Ni_3(\mathbf{1})](ClO_4)_6$ shows catalytic activity for the electrochemical reduction of CO_2 to CO in $MeCN/H_2O$ (9:1, v/v), as revealed by cyclic voltammetry and controlled-potential coulometry. The catalytic efficiency of $[Ni_3(\mathbf{1})]^{6+}$ is lower than that of $[Ni(cyclam)]^{2+}$. It gives a greater $i_p(CO_2)/i_p(N_2)$ value but produces less CO per nickel center (**3**: 8-methyl-1,3,6,8,10,13,15-heptaaza-tricyclo-[11.3.1.1^{3,15}]octadecane) compared with monometallic $[Ni(\mathbf{3})]^{2+}$.

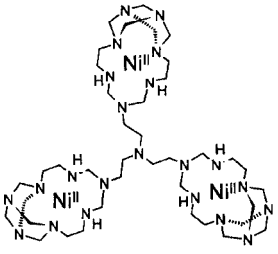
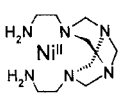
Introduction

Multinuclear macrocyclic complexes can be interesting multi-electron redox catalysts and may act as models for polynuclear metalloenzymes. The synthesis and design of electrocatalyses to reduce abundant and inexpensive CO_2 may be important in lessening the greenhouse effect and in developing new sources of fuels.[1−3] CO_2 reduction may provide various products: carbon monoxide or formic acid, formaldehyde, methanol, and methane, by two-, four-, six-, and eight-electron reduction reactions, respectively. The high activation energy of CO_2 reduction at a platinum electrode, requiring a more negative potential than −2.24 V vs. SCE, is due to the high energy intermediate CO_2^- [4] but can be lowered by using catalysts. Some transition metal complexes with macrocyclic ligands − both mononuclear[5−19] and dinuclear[20−21] complexes − exhibit catalytic effects on the electrochemical reduction of CO_2 to CO or formate, shifting the CO_2 reduction potential by ca. +0.5 V. To obtain reduction products involving more than two electrons, multimetallic catalysts should be employed.

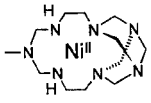
Here we report the synthesis of trinuclear Ni^{II} and Ni^I complexes of the trismacrocyclic ligand 8,8′,8"-(2,2′,2"-nitrilotriethyl)-tris(1,3,6,8,10,13,15-heptaaza-tricyclo-[11.3.1.1^{3,15}]octadecane) (**1**). We also report their electrocatalytic activity for CO_2 reduction compared with the mononuclear $[Ni(\mathbf{3})]^{2+}$ complex.



$[Ni_3(\mathbf{1})]^{6+}$



$[Ni(\mathbf{2})]^{2+}$



$[Ni(\mathbf{3})]^{2+}$

Results and Discussion

Synthesis and Properties of $[Ni_3(1)](ClO_4)_6$

The trinuclear trismacrocyclic complex $[Ni_3(\mathbf{1})](ClO_4)_6$ was synthesized by the template condensation of $[Ni(\mathbf{2})]^{2+}$ with tris(2-aminoethyl)amine and formaldehyde as described in Equation (1). Template condensation reactions involving amines and formaldehyde have provided various types of macrocyclic complexes that cannot be obtained in the absence of metal ions.[22−29] However, multinuclear macrocyclic complexes containing more than three metal ions are still very rare.[30]

$$3\,[Ni(\mathbf{2})]^{2+} + 6\,CH_2O + (H_2NCH_2CH_2)_3N \rightarrow [Ni_3(\mathbf{1})]^{6+} \quad (1)$$

Although the reaction of Equation (1) seems to be entropically unfavorable, it provides the trismacrocyclic complex in ca. 50% yield. The amount of water present significantly affects the yield of $[Ni_3(\mathbf{1})](ClO_4)_6$, and the complex $[Ni_3(\mathbf{1})](ClO_4)_6$ was synthesized in MeOH/H_2O (2:1, v/v). When water was absent, the starting complex did not dissolve into the solution and provided a poor yield.

$[Ni_3(\mathbf{1})](ClO_4)_6$ is soluble in MeCN, $MeNO_2$, DMSO, and hot water, but insoluble in MeOH and diethyl ether. The ^{13}C NMR spectrum (Figure 1) is consistent with the structure of trismacrocyclic ligand **1**. The molar conductance for $[Ni_3(\mathbf{1})](ClO_4)_6$, measured in $MeNO_2$ at 25 °C, depends on the concentration of the complex; 214 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ for a 1.13×10^{-3} M solution and 393 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ for a 5.16×10^{-5} M solution. In MeCN, the molar conductances are 439 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ at 2.77×10^{-4} M and 684 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ at 1.66×10^{-5} M. A plot of molar conductance in $MeNO_2$ at various concentrations is given in Figure S1 in the Supporting Information. Extrapolation of this plot to 0 M gives 434−491 $\Omega^{-1}\cdot cm^2\cdot mol^{-1}$ for a highly diluted $MeNO_2$ solution. The highly charged (+6) cation seems to form ion-pairs even in 10^{-5} M solutions. The electronic spectrum of $[Ni_3(\mathbf{1})](ClO_4)_6$ shows a maximum absorption at 439 nm with an extinction coefficient of 273 $cm^{-1}\cdot M^{-1}$ in $MeNO_2$. The λ_{max} value of $[Ni_3(\mathbf{1})](ClO_4)_6$ is similar to that of monometallic $[Ni(\mathbf{3})](ClO_4)_2$ (438 nm)[23] but its molar absorptivity is almost three times greater than that (83 $cm^{-1}\cdot M^{-1}$) due to the existence of three Ni^{II} chromophores. The spectrum depends slightly on the solvent used. The complex does not coordinate ligands such as NCS^-, Cl^-, pyridine, NH_3, and NO_3^- at the axial site in the noncoordinating solvent $MeNO_2$, as evidenced by the UV/Vis spectra. Upon addition of CN^-, however, the solution changed from yellow to pink and then the demetallation of Ni^{II} ions took place within a few minutes.

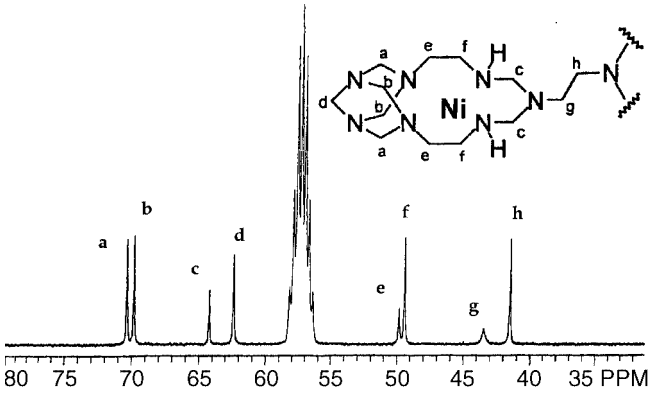

Figure 1. ^{13}C NMR spectrum of $[Ni_3(\mathbf{1})](ClO_4)_6$ in [D_3]nitromethane

Crystal Structure of $[Ni_3(\mathbf{1})](ClO_4)_3\cdot Cl_3\cdot 10H_2O$

We could not obtain single crystals of $[Ni_3(\mathbf{1})](ClO_4)_6$ by recrystallization from any solvent system. However, we acquired single crystals of $[Ni_3(\mathbf{1})](ClO_4)_3\cdot Cl_3\cdot 10H_2O$ by mixing $[Ni_3(\mathbf{1})](ClO_4)_6$ and NaCl in a hot solvent mixture of

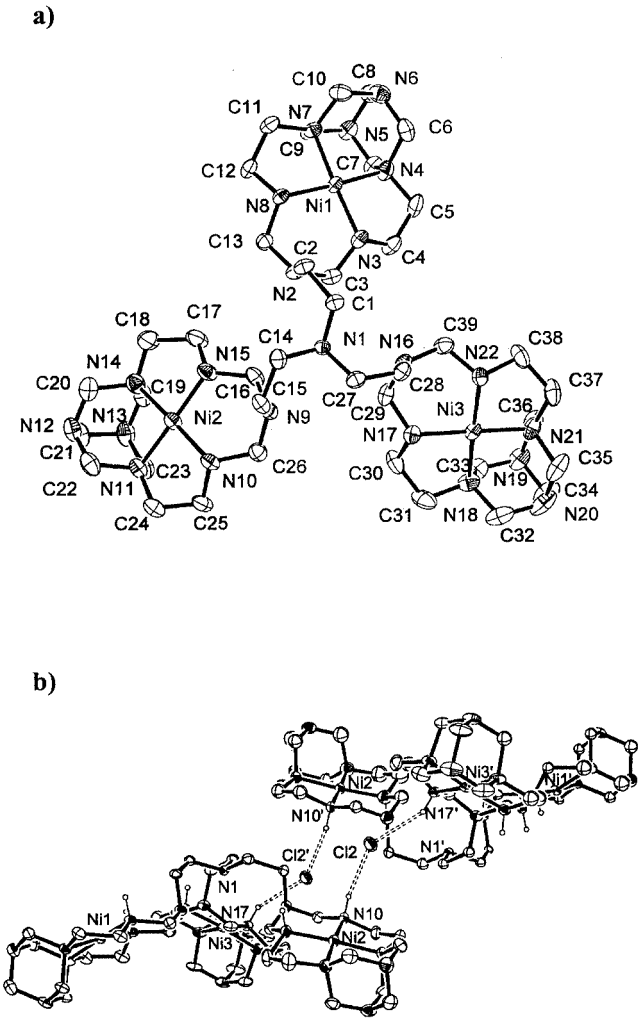

Figure 2. ORTEP views of the cation of $[Ni_3(\mathbf{1})](ClO_4)_3\cdot(Cl)_3\cdot 10H_2O$ with atomic numbering scheme: top view (a) and side view showing hydrogen bonded dimer (b); the atoms in (a) and (b) are represented by 20% probable thermal ellipsoids. Atoms marked ′ are generated by symmetry operations: $1-x$, $-1-y$, $-z$. Hydrogen bonds are indicated as dashed lines.

MeCN, MeOH, and H_2O. An ORTEP view of the cation in $[Ni_3(\mathbf{1})](ClO_4)_3\cdot Cl_3\cdot 10H_2O$ is presented in Figure 2a. The three Ni^{II} macrocycles are linked by a tren group to form a bowl-shaped molecule. Three Ni^{II} ions in the molecule are almost at the corners of a triangle. The Ni1···Ni2, Ni2···Ni3, and Ni3···Ni1 distances are 9.062(3), 9.420(2), and 8.983(2) Å, respectively. The Ni1···Ni2···Ni3, Ni2···Ni3···Ni1, and Ni3···Ni1···Ni2 angles are 58.12(2), 58.94(2), and 62.94(1)°, respectively. The central tertiary nitrogen (N1) of the tren unit is 2.624(5) Å above the triangular plane made by the Ni1, Ni2, and Ni3 atoms. The dihedral angles between the square-coordination planes involving Ni1 and Ni2, Ni2 and Ni3, and Ni3 and Ni1 are 51.15(16), 49.53(22), and 46.42(18)°, respectively. There are three ClO_4^- and three Cl^- anions per trismacrocyclic complex. The ClO_4^- anions are found at the open hollow part of the bowl, and Cl^- anions and water molecules are out of the bowls. A Cl^- anion (Cl2) connects two molecules through hydrogen bonds with the secondary amines of the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

macrocycle, involving N10 and N17 [Cl2···N10 3.204 Å, Cl2···H−N10 169.7°, Cl2···N17(1−x, −1−y, −z) 3.248 Å, Cl2···H−N17(1 − x, −1 − y, −z) 147.4°], as shown in Figure 2b.

In each macrocycle, the Ni^{II} ion exhibits square-planar coordination geometry, being coordinated with two secondary and two tertiary nitrogen atoms of the ligand. The Ni^{II} ions are displaced from their square-coordination planes by 0.057(3), 0.032(3), and 0.049(3) Å, respectively, showing a slight square-pyramidal distortion. The average Ni−N bond length is 1.927(2) Å, which falls in the range (1.86−1.94 Å) normally observed for square-planar Ni^{II} complexes.[23] In general, *N*-methylation of the secondary nitrogen donors of the macrocyclic complex decreases the ligand-field strength and increases the Ni−N distances.[23,31] However, the present complex shows no significant differences in the Ni−N distances for the secondary and tertiary amines. The local environment of every Ni^{II} ion possesses a pseudo-mirror plane that is perpendicular to the square coordination plane. The average N−C distances and average C−*N*−C angles involving coordinated tertiary nitrogens (N4, N7, N11, N14, N18, N21) are 1.504(3) Å and 109.2(1)°. The average N−C distances and average C−*N*−C angles involving uncoordinated tertiary nitrogens (N5, N6, N12, N13, N19, N20) are 1.451(3) Å and 110.4(1)°, indicating the contribution of sp^2 hybridization.[22−27]

Electrochemical Behavior of $[Ni_3(1)](ClO_4)_6$

The cyclic voltammogram of an MeCN solution of $[Ni_3(\mathbf{1})](ClO_4)_6$ shows a reversible reduction peak at −1.59 V and an irreversible oxidation peak at +1.25 V vs. Ag/Ag^+(0.01 M) (Table 1), which are very similar to those (−1.61 V and +1.10 V, respectively) for the monocyclic $[Ni(\mathbf{3})]^{2+}$ complex.[22,23] Bulk electrolysis at −1.8 V vs. Ag/Ag^+ (0.01 M) indicated n = 3.16 for the Ni^{II}/Ni^{I} reduction. The differential pulse and Osteryoung square-wave voltammograms show only one peak at −1.59 V vs. Ag/Ag^+ (0.01 M), indicating that the three Ni^{II} ions in the complex are electrochemically independent and that reduction of the three Ni^{II} centers takes place simultaneously.

Synthesis of Ni^{I} Complex

Numerous Ni^{I} azamacrocyclic complexes have been reported[32−50] but few have been isolated from solution. The trinuclear Ni^{I} complex $[Ni_3(\mathbf{1})](ClO_4)_3$ was prepared by reducing the Ni^{II} complex with Na(Hg) in MeCN under an N_2 atmosphere. The Ni^{I} complex was isolated together with the impurity $NaClO_4$, which was hardly removed by recrystallization, and so the analysis data for the Ni^{I} complex are relatively poor. The electronic absorption spectrum of the Ni^{I} complex (Table 1) shows maximum absorptions at 524 nm and 319 nm. These λ_{max} are similar to those of $[Ni(\mathbf{3})]^+$, whose X-ray structure displays the square-planar geometry around the Ni^{I} ion.[41] For Ni^{I} complexes λ_{max} is often shifted ca. 100 nm to longer wavelengths, with extinction coefficients increasing by ca. 5−10 times, compared with those of the corresponding Ni^{II} complexes.[26,41,43] The complex $[Ni^{I}_3(\mathbf{1})](ClO_4)_3$ (powder sample) shows an anisotropic axial EPR spectrum with g values of $g_\perp$ = 2.069 and g_{II} = 2.247 (Figure 3), indicating that the Ni^{I} ions have a square-planar coordination geometry with an unpaired electron in the d $d_{x^2-y^2}$ orbital.[23] The g values are similar to those of the Ni^{I} complex of **3**.[23,41]

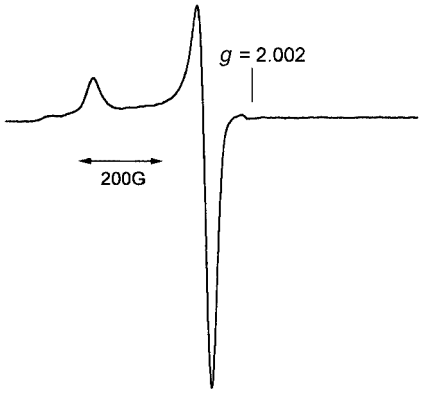

Figure 3. EPR powder spectrum of $[Ni^{I}_3(\mathbf{1})](ClO_4)_3$ at room temperature.

The Ni^{I} complex $[Ni_3(\mathbf{1})](ClO_4)_3$ is very sensitive to air and moisture. For example, a red-purple MeCN solution of the Ni^{I} complex exposed to air turned yellow, the color of

Ni^{II} complex, in less than 15 min. When CO_2 gas was bubbled through an MeCN solution, the change to yellow was abrupt, $[Ni_3(\mathbf{1})](ClO_4)_6$ was isolated from solution, and CO gas was detected in the head space of the reaction vessel.

Electrochemical Reduction of CO_2 Catalyzed by $[Ni_3(1)]^{6+}$

Some Ni^{II} tetraaza macrocyclic complexes have shown catalytic activity in the electroreduction of CO_2.[5−21] In particular, $[Ni(cyclam)]^{2+}$ is an efficient and selective catalyst on a Hg electrode in water.[5] Ni^{II} systems that can be easily reduced to Ni^{I} species are efficient electrocatalysts for reducing CO_2.[14] Since the complex $[Ni_3(\mathbf{1})]^{6+}$ exhibits a much more anodic Ni^{II}/Ni^{I} reduction potential than $[Ni(cyclam)]^{2+}$, and its trinuclear Ni^{I} species is stable enough to be isolated, we expected that $[Ni_3(\mathbf{1})]^{6+}$ would catalyze the electroreduction of CO_2, which we then investigated by cyclic voltammetry and controlled potential coulometry. In a typical cyclic voltammetric experiment, a solution of trinuclear Ni^{II} complex (2.0 mM) was prepared in a MeCN/H_2O (9:1, v/v) solution containing 0.1 M $NaClO_4$. Under N_2 atmosphere, the cyclic voltammogram of $[Ni_3(\mathbf{1})](ClO_4)_6$ showed a reversible Ni^{II}/Ni^{I} reduction peak at $E_{1/2} = -1.39$ V ($E_{cathode} = -1.44$ V and $E_{anode} = -1.35$ V) vs. SCE. When the complex solution was saturated with CO_2, the current intensity at −1.44 V increased ca. three times compared with that measured under N_2, and the anodic peak at −1.35 V disappeared (Figure 4). This indicates that the complex acts as a catalyst for the electrochemical reduction of CO_2.[51] The results of the same experiment with the mononuclear Ni^{II} complexes of cyclam and **3** are summarized in Table 2. In the cyclic voltammetry, the peak current (i_p) measured under N_2 can be described as $i_p = (2.69 \times 10^5)n^{3/2}AD_o^{1/2}v^{1/2}C_o^*$.[51] The diffusion coefficients (D_o) of $[Ni_3(\mathbf{1})]^{6+}$ and $[Ni(\mathbf{3})]^{2+}$, measured in MeCN/H_2O (9:1, v/v) by rotating disk electrode, are 1.8×10^{-5} and 8.8×10^{-5} $cm^2\,s^{-1}$, respectively. Theoretically, when the concentrations of the complexes are the same, $i_p(N_2)$ of $[Ni_3(\mathbf{1})]^{6+}$ should be 2.35 times greater than that of $[Ni(\mathbf{3})]^{2+}$. The ratio of $i_p(N_2)$ of $[Ni_3(\mathbf{1})]^{6+}$ versus that of $[Ni(\mathbf{3})]^{2+}$ is 2.1−2.3 (Table 2). Although all catalysts showed peak potentials at −1.44 to −1.49 V vs. SCE in the presence of CO_2, the trinuclear Ni^{II} complex of **1** showed a much greater catalytic current than the monometallic complex of **3**. To exclude the effect of n and D_o values on the catalytic efficiencies, the ratio of peak current measured under CO_2 vs. that measured under N_2, $i_p(CO_2)/i_p(N_2)$, was compared (Table 2). The $i_p(CO_2)/i_p(N_2)$ for $[Ni_3(\mathbf{1})]^{6+}$ is ca. 3 while those of $[Ni(\mathbf{3})]^{2+}$ and $[Ni(cyclam)]^{2+}$ are 2 and 5, respectively. This indicates that $[Ni_3(\mathbf{1})]^{6+}$ is a better catalyst than $[Ni(\mathbf{3})]^{2+}$ in terms of the catalytic current although it is not a better catalyst than $[Ni(cyclam)]^{2+}$.

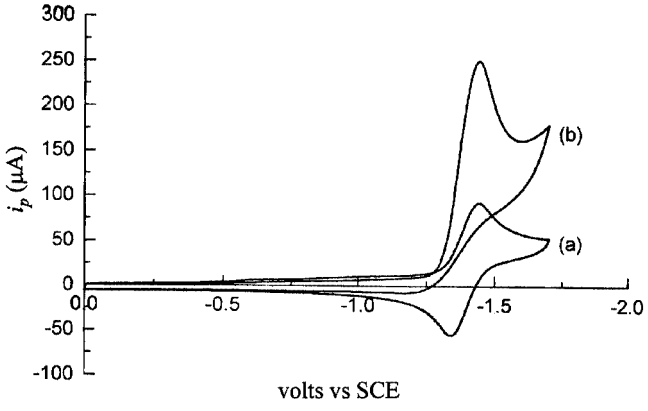

Figure 4. Cyclic voltammogram of $[Ni_3(\mathbf{1})](ClO_4)_6$ at a glassy carbon electrode in MeCN/H_2O (9:1, v/v) measured under N_2 (a) and under CO_2 (b). Volts vs. SCE; concentration of complex, 2.0 mM; electrolyte, 0.1 M $NaClO_4$; scan rate, 100 mV s^{-1}.

The solvent system as well as the electrode material dramatically affects the catalytic peak current. For example, that of $[Ni(cyclam)]^{2+}$ (10^{-3} M) increased ca. 50 times under CO_2 with H_2O as solvent and a Hg dropping mercury electrode.[5] However, here it increased by only ca. 5 times in MeCN/H_2O (9:1, v/v) at a glassy carbon electrode. In the present study, experiments could not be performed in 100% water because of the low solubility of the Ni^{II} complexes of **1** and **3** in water. In MeCN without added water, a catalytic current was not observed under CO_2 both with $[Ni_3(\mathbf{1})]^{6+}$ and $[Ni(\mathbf{3})]^{2+}$ complexes, probably due to the lack of a proton source. Protons are needed in CO_2 reduction according to Equation (2).

$$2\,Ni^{I} + 2\,H^{+} + CO_2 \rightarrow 2\,Ni^{II} + CO + H_2O \quad (2)$$

The concentration of the catalyst also affects catalytic activity and turnover number. This was especially so for a Hg electrode, where the active catalyst is a species adsorbed on the electrode, and saturation of catalytic activity occurred

at 5×10^{-6}–2×10^{-3} M of catalyst.[12,52] To see if catalytic saturation took place under the present experimental conditions, $i_p(CO_2)$ was measured at various concentrations of $[Ni_3(\mathbf{1})]^{6+}$ (1.0×10^{-4}–2.0×10^{-3} M). The results obtained for a Hg electrode are summarized in Table 3, and those for a glassy carbon electrode are presented in Figure 5. For both electrode materials, saturation of catalytic activity was not observed in the concentration range employed.

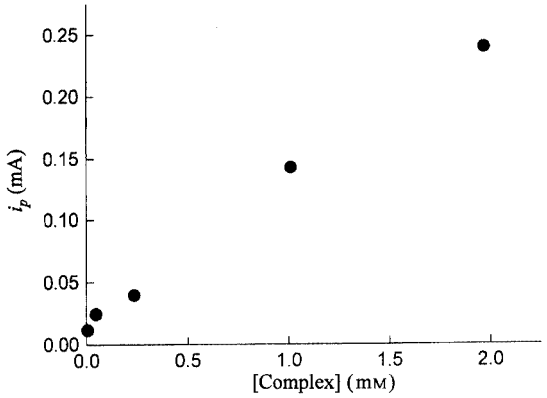

Figure 5. Effect of $[Ni_3(\mathbf{1})](ClO_4)_6$ concentration on the intensity of the catalytic wave for CO_2 electroreduction. Measured in MeCN/H_2O (9:1, v/v) with 0.1 M $NaClO_4$; glassy carbon electrode; scan rate, 100 mV s^{-1}.

It has been reported that the electrode material affects the electrocatalytic reduction of CO_2. For example, $[Ni^I(cyclam)]^+$ adsorbed on Hg is a better catalyst than that on a glassy carbon electrode.[52] For $[Ni_3(\mathbf{1})]^{6+}$ complex (2.0 mM), however, $i_p(CO_2)/i_p(N_2)$ measured on a glassy carbon electrode is 3.04 (Table 2) and that measured on the controlled growth mercury electrode is 2.12 (Table 3). This indicates that electrode-adsorption is less important for the present trinuclear catalyst.

Controlled potential coulometric experiments were carried out with CO_2-saturated MeCN/H_2O (9:1, v/v) solutions in the presence of $[Ni_3(\mathbf{1})]^{6+}$ and $[Ni(\mathbf{3})]^{2+}$ using a mercury pool electrode. The CO_2 reduction products were analyzed by GC both for gas and solution samples. Interestingly, CO was the only product, and other reduction products, including formate and H_2, were not detected. The amount of CO evolved depends on the applied voltage (Figure 6), with higher voltages producing more CO. In addition, CO production started to saturate within 0.5 h (Figure 7) and, therefore, the CO evolved after 30 min at the applied potential of −1.6 V vs. SCE was measured for various Ni^{II} catalysts (Table 4). The relative electrocatalytic efficiencies of the complexes, in terms of CO production per mol of catalyst, almost parallel the order of $i_p(CO_2)/i_p(N_2)$; $[Ni(cyclam)]^{2+} > [Ni_3(\mathbf{1})]^{6+} > [Ni(\mathbf{3})]^{2+}$ (Table 2). However, when the number of nickel centers is considered, $[Ni_3(\mathbf{1})]^{6+}$ is not as good as the monometallic complexes, $[Ni(cyclam)]^{2+}$ and $[Ni(\mathbf{3})]^{2+}$. $[Ni_2(biscyclam)]^{4+}$ produced only ca. half of the amount of CO gas or $HCOO^-$ per nickel center in DMF compared with that produced by the monometallic catalyst $[Ni(cyclam)]^{2+}$.[20] This is because an electrode(Hg)-adsorbed species was important in this electrocatalytic reaction, and only one metal center of $[Ni_2(biscyclam)]^{4+}$ was directly involved in each reaction cycle. The larger surface area of $[Ni_2(biscyclam)]^{4+}$ led to a smaller superficial surface density than that of $[Ni(cyclam)]^{2+}$, resulting in a poorer catalytic efficiency. For the present study, the TON value of $[Ni_3(\mathbf{1})]^{6+}$ (2.6) is slightly less than that of $[Ni(\mathbf{3})]^{2+}$ (3.9) (Table 4).

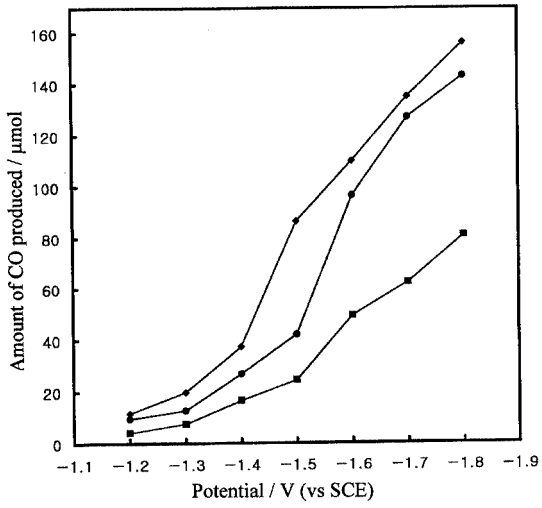

Figure 6. Effect of applied potential on CO production in the electrocatalytic reduction of CO_2. $[Ni_3(\mathbf{1})](ClO_4)_6$ (●); $[Ni(\mathbf{3})](ClO_4)_2$ (■); $[Ni(cyclam)](ClO_4)_2$, (◆). Volts vs. SCE; measured in 0.1 M $NaClO_4$ in MeCN/H_2O (9:1, v/v); electrolysis time, 30 min; 20 °C; CO_2 pressure, 1 atm; working electrode, Hg pool; concentration of catalyst, 1.0 mM.

The catalytic activity of the Ni^{II} complexes of **1** and **3** might be attributed to their ready reduction to Ni^I species. In CO_2 reduction catalyzed by cobalt macrocyclic complexes, the CO_2 adduct of the reduced complex was proposed as an intermediate, and a five-coordinate cobalt(I)–CO_2 was isolated from the reaction.[53–54] Hydrogen bonding between the coordinated CO_2 and the N–H of the macrocycle was important in stabilizing this ad-

Table 4. CO production from the electrochemical reduction of CO_2 catalyzed by Ni^{II} complexes[a][b]

catalyst	applied potential volts vs. SCE	conc. of catalyst	CO produced in 0.5 h (μmol)	Turnovers[c] per 0.5 h at 20 °C	current efficiency (%)
$[Ni_3(\mathbf{1})]^{6+}$	−1.6	1.0 mM	96.5	2.6	96.2
$[Ni(\mathbf{3})]^{2+}$	−1.6	1.0 mM	49.2	3.9	95.3
$[Ni(cyclam)]^{2+}$	−1.6	1.0 mM	110	8.4	98.7

[a] Measured in MeCN/H_2O (9:1, v/v) with 0.1 M $NaClO_4$; 25 mL of solution with 25 μmol of complex; concentration of complex, 1.0×10^{-3} M; electrolysis time, 0.5 h. [b] Measured at 20 °C and 1 atm; working electrode, Hg pool. [c] Number corresponds to twice the number of mol of CO produced in 0.5 h per mol of nickel center.

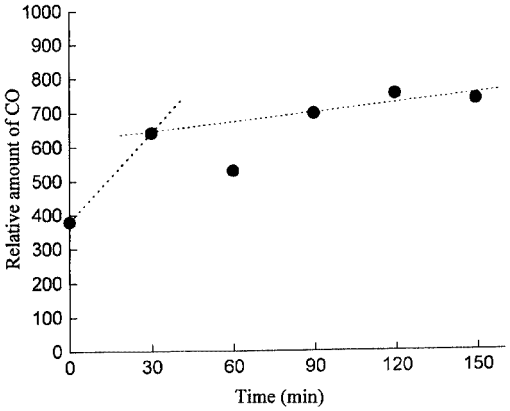

Figure 7. Relative amount of CO vs. MeCN detected by GC during the electroreduction of CO_2 catalyzed by $[Ni_3(\mathbf{1})](ClO_4)_6$; *t*, electrolysis time; applied potential, −1.6 V vs. SCE; glassy carbon electrode; data at $t = 0$ min is CO contained in the background CO_2 gas that is saturated with MeCN vapor

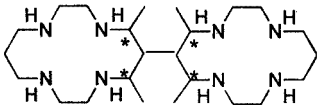
duct.[20] In the present study, it may be assumed that the Ni^{I} species binds CO_2 in the transition state, even though Ni^{II} species have poor coordinating ability. The secondary amines in the macrocycle **1** might promote the formation of the CO_2 adducts. It has been reported that the Ni^{II} complex of bismacrocyclic ligand **4** is highly active and selective catalyst for the photochemical reduction of CO_2[55] although the Ni^{II} species has poor binding ability for the solvent water molecule, similarly to $[Ni_3(\mathbf{1})]^{6+}$.



4

Conclusion

The trinuclear Ni^{II} complex $[Ni_3(\mathbf{1})]^{6+}$, in which three macrocyclic complexes are linked by a flexible tren bridge, was prepared and its X-ray structure was determined. The three Ni^{II} centers in $[Ni_3(\mathbf{1})]^{6+}$ are electrochemically independent and are easily reduced to Ni^{I} by reaction with Na(Hg) in MeCN. The complex $[Ni_3(\mathbf{1})](ClO_4)_6$ shows catalytic activity for the electrochemical reduction of CO_2 to CO in MeCN/H_2O (9:1, v/v), exhibiting a greater catalytic current than monometallic $[Ni(\mathbf{3})]^{2+}$ but producing less CO gas per nickel center. The catalytic efficiencies of $[Ni_3(\mathbf{1})]^{6+}$ and $[Ni(\mathbf{3})]^{2+}$, in terms of $i_p(CO_2)/i_p(N_2)$ and turnover number, are lower than that of $[Ni(cyclam)]^{2+}$.

Experimental Section

Reagents: All chemicals and solvents used in the syntheses were reagent grade and used without further purification. For the synthesis of Ni^{I} complex and the physicochemical measurements, reagents and solvents were purified according to the literature procedure[56] and deaerated prior to use. $[Ni(\mathbf{2})](ClO_4)_2$ and $[Ni(\mathbf{3})](ClO_4)_2$ were prepared and recrystallized according to the methods previously reported.[22] N_2 and CO_2 gases were deaerated and dried by passing through a BASF column and then a $CaCl_2$ column.

Measurements: IR spectra were recorded with a Bruker IFS48 FT IR spectrophotometer. Conductance was measured by a SUNTEX SC-170 conductivity meter. Electronic absorption spectra were obtained on a Beckman DU68 UV/Vis spectrophotometer equipped with an electronic temperature controller. ^{13}C NMR spectra were recorded on a Gemini-300 FT NMR spectrometer. EPR spectra were obtained on a Bruker ER 200E spectrometer. Elemental analyses (EA) were performed by the analytical laboratory of Seoul National University and by The Korea Basic Science Center, Seoul. Electrochemical experiments were performed on a BAS 100B/W electrochemical analyzer. Cyclic voltammetry, differential pulse voltammetry, and Osteryoung square-wave voltammetry were carried out in MeCN containing 0.1 M $(n\text{Bu})_4NPF_6$. The working electrode was a glassy carbon, the auxiliary electrode was a coiled platinum wire, and the reference electrode was Ag/Ag^+ (0.01 M in MeCN). The electrochemical reduction of the Ni^{II} complex to Ni^{I} was performed by controlled potential coulometry, carried out at −1.8 V vs. Ag/Ag^+ (0.01 M) in an MeCN solution of 0.1 M $(n\text{Bu})_4NPF_6$ under a N_2 atmosphere until the end current became 1% of the initial value.

Synthesis

Caution! *Perchlorate salts of metal complexes are potentially explosive and should be handled with care.*

$[Ni_3(\mathbf{1})](ClO_4)_6$: Tris(2-aminoethyl)amine (96%, 0.34 g, 2.2 mmol) and triethylamine (4.0 mL, 29 mmol) were added to a solution of $[Ni(\mathbf{2})](ClO_4)_2$ (3.05 g, 6.5 mmol) dissolved in hot MeOH/H_2O (2:1, v/v, 120 mL). The mixture was then heated at reflux. Excess 37% formaldehyde (3.76 mL, 50 mmol) mixed with MeOH (5 mL) was introduced dropwise over 1 hour and the solution was heated at reflux for an additional 2 h, during which time a yellow precipitate formed. The precipitate was filtered off from the hot solution and was washed with MeOH and dried in vacuo. It was then purified

by recrystallization from H_2O/MeOH (1:1, v/v). The compound was not obtained as single crystals in any solvent. Yield: ca. 50% (5.31 g). $C_{39}H_{84}Cl_6N_{22}Ni_3O_{24}$ (1634.1): calcd. C 28.67, H 5.18, N 18.86; found C 29.29, H 5.30, N 18.87. UV/Vis: λ_{max} (ε) = 439 nm (251 cm^{-1} M^{-1}) in MeCN; 439 nm (273 cm^{-1} M^{-1}) in $MeNO_2$. IR (Nujol mull): $\tilde{\nu}$ = 3207 cm^{-1} (ν_{N-H}), 1100 cm^{-1} (br., ν_{Cl-O}). ^{13}C NMR ([D$_3$]nitromethane): δ = 41.5, 43.4, 49.4, 49.8, 62.4, 64.2, 69.8, 70.3 ppm.

Preparation of Single Crystals of $[Ni_3(1)](ClO_4)_3{\cdot}Cl_3{\cdot}10H_2O$: $[Ni_3(\mathbf{1})](ClO_4)_6$ (0.143 g) and NaCl (0.2 g) was added to a mixture of MeCN (6 mL), MeOH (6 mL), and H_2O (0.5 mL). The solution was then heated until the complex went into the solution. The resultant yellow solution was filtered while hot, and the filtrate was allowed to stand at room temperature until orange crystals formed, which were then filtered off, washed with mother liquor, and dried in air. $C_{39}H_{104}Cl_6N_{22}Ni_3O_{22}$ (1622.2): calcd. C 28.88, H 6.46, N 19.00; found C 28.17, H 6.29, N 18.69.

$[Ni^I{}_3(1)](ClO_4)_3$: The synthesis, experiments with, and manipulation of the Ni^I compound should be conducted under strict exclusion of air by using Schlenk lines since the compound is air-sensitive. **Method 1.** $[Ni_3(\mathbf{1})](ClO_4)_6$ (1.0 g, 0.6 mmol) was stirred with 5% Na(Hg) (3 g, 6.5 mmol) in MeCN (50 mL) for 20 min as the yellow complex slowly went into a red-purple solution. The solution was filtered, concentrated to one-third of the initial volume, and then allowed to stand in a refrigerator under strict exclusion of air until a red precipitate formed. The precipitate was then filtered off, washed with MeCN, and dried in vacuo. Yield: 70% (0.56 g). $C_{39}H_{84}Cl_3N_{22}Ni_3O_{12}$ (1335.7): calcd. C 35.07, H 6.34, N 23.07; found C 32.01, H 5.42, N 20.85. **Method 2.** $[Ni_3(\mathbf{1})](ClO_4)_3$ can be prepared in solution by bulk electrolysis of $[Ni_3(\mathbf{1})](ClO_4)_6$. A solution of $[Ni_3(\mathbf{1})](ClO_4)_6$ (1.0×10^{-3} M) was prepared in MeCN containing 0.1 M $(n\text{Bu})_4NPF_6$. A current was passed through the solution at -1.8 V vs. Ag/Ag$^+$ (0.01 M) for ca. 3 h until the intensity of end current became 1% of the initial value. The solution, which became reddish purple, was then frozen and its EPR spectrum was measured.

Electrochemical Reduction of CO_2: The electrochemical reduction of CO_2 was measured by cyclic voltammetry and controlled-potential coulometry. Cyclic voltammetry was performed on MeCN/H_2O (9:1, v/v) solutions of Ni^{II} complex (2.0 mM) containing 0.1 M $(n\text{Bu})_4NPF_6$ by using a glassy carbon or a controlled growth mercury electrode. Measurements were made with the solutions saturated with N_2 and then with CO_2. Controlled-potential coulometric experiments were performed at 20 °C by using a Hg pool as working electrode and a platinum plate as auxiliary electrode with a solution (25 mL) containing 1.0 mM of the Ni^{II} complex in a gas-tight electrolysis cell (internal gas volume; 32 mL). After CO_2 gas was bubbled through the solution for 30 min, a fixed potential (voltage range: -1.2 to -1.6 V vs. SCE) was applied for 30 min. The gas products were analyzed with a Hewlett−Packard 5890 Gas Chromatograph with a thermal conductivity detector. A Porapak Q column (8′ × 1/8″, 80−100 mesh) and He carrier gas were used for CO analysis. Molecular sieves, 13X column (7′ × 1/8″, 60−80 mesh), and N_2 gas were used for H_2 analysis. The CO (or H_2) peak was identified by comparing its retention time with that of standard CO (or H_2) gas. The CO was quantified by using a prepared standardization curve; the average of the three repeated experiments was obtained. Turnover frequencies were calculated as twice the number of mol of CO produced in 30 min per mol of electrocatalyst.

X-ray Crystallographic Study for $[Ni_3C_{39}H_{84}N_{22}](ClO_4)_3{\cdot}Cl_3{\cdot}10H_2O$: $C_{39}H_{104}Cl_6N_{22}Ni_3O_{22}$, M_r = 1622.27 g/mol^{-1}, a = 15.969(5) Å, b = 16.148(5) Å, c = 16.722(5) Å, α = 105.051(5)°, β = 114.812(5)°, γ = 94.227(5)°, V = 3697(2) Å^3, Z = 2, $d_{calcd.}$ = 1.457 g/cm^{-3}, triclinic, space group $P\bar{1}$ (No.2), μ = 1.052 mm^{-1}, $F(000)$ = 1708, T = 298 K. An orange rod-shaped single crystal (0.20 × 0.25 × 0.50 mm) was mounted on an Enraf Nonius Kappa CCD diffractometer. Data were collected with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) through use of the ω-2θ scan technique. Preliminary orientation matrices and unit cell parameters were obtained from the peaks of the first ten frames and then refined using the whole data set. Frames were integrated and corrected for Lorentz and polarization effects using *DENZO*.[57] The scaling and global refinement of crystal parameters were performed by *SCALEPACK*.[57] No absorption correction was made. Of 16696 reflections measured in the range $2.68 < 2\theta < 55.22$, 9361 were assumed to be observed [$I > 2\sigma(I)$]. The crystal structures were solved by direct methods[58] and refined by full-matrix least-squares refinement using the *SHELXL-97* computer program.[59] The positions of all non-hydrogen atoms were refined with anisotropic displacement factors, except for oxygen atoms with severe thermal disorder: three from ClO_4^- anions (O4, O9, O10) and eight from water (OW2, OW3, OW5, OW6, OW7, OW8, OW9, OW10). All hydrogen atoms were allowed to ride on their bonded atoms with values of 1.2× those of the bonded atoms. Convergence of the 783 variable parameters by full-matrix, least-squares refinement on F^2 reaches R_1 = 0.0918 [$I > 2\sigma(I)$] and wR_2= 0.2554 with a goodness-of-fit of 1.061. ORTEP drawings were made with ORTEP-3 for windows.[60] Crystallographic data are summarized in Table S1, and selected bond lengths and angles are provided in Table S2, of the Supporting Information.

CCDC-194395 contains the supplementary crystallographic data for this paper. Large-Scale Synthesis of High Quality Trigonal Selenium Nanowires

Changhua An,[a,b] Kaibin Tang,*[a,b] Xianming Liu,[b] and Yitai Qian[a,b]

Keywords: Nanostructures / Semiconductors / Selenium

A direct and simple one-step hydrothermal reaction route has been developed for the synthesis of high quality trigonal selenium (t-Se) nanowires at 110 °C, with $(NH_4)_2S_2O_3$ and Na_2SeO_3 as starting materials in the presence of the surfactant sodium dodecyl sulfate (SDS). The diameter of the trigonal selenium nanowires can be tuned by carefully adjusting the initial feedstock concentration. The unusual chain like structure of the target material plays a key role in determining the final morphologies of the products. Several factors, such as initial concentration of the feedstock, the presence of surfactant, and the temperature which influences the quality of the t-Se nanowires, have been investigated. The optical properties of the t-Se nanowires with different diameters were examined by means of UV/Vis absorbance spectroscopy at room temperature. The investigation revealed that the absorbance peak for the t-Se nanowires with diameters of 20–40 nm shifts to the blue, relative to those for bulk t-Se nanowires (374 nm) and nanowires with diameters of 50–130 nm (306 nm).

Introduction

Nanoscale one-dimensional (1D) materials, such as nanotubes, nanowires and nanorods, have stimulated great interest due to their importance in basic scientific research and potential technological applications.[1−3] Moreover, new synthetic methods for the synthesis of semiconductor 1D nanostructures, such as nanowires or quantum wires, and their potential use in applications ranging from integrated circuit interconnectors to functional electronic and optical devices, have recently been investigated.[4−7] Besides significant technological advances due to their unique electrical, optical, and mechanical properties, nanowires can provide a material system to experimentally test fundamental quantum mechanical concepts.

For many applications, nanowires must be crystalline and largely defect free, with diameters in the range of 10−100 nm and lengths that greatly exceed their diameters. Many semiconductor nanowires, including Si, Ge, GaN, GaAs, InP etc., have been explored using various methods, such as laser ablation, arc-discharge, vapor phase transport processes, chemical vapor deposition and template-based routes.[8−12] On the other hand, chemical approaches (so called bottom-up techniques) may provide a more promising technique for the preparation of 1D nanostructure materials, in terms of versatility and potential for large-scale production, than conventional methods. Recently, there has been a strong trend towards the application of solution synthesis techniques for the preparation of 1D materials.[13−16] The hydrothermal method is one of the promising solution synthesis routes for the exploration of novel materials, due to the relatively mild conditions required, the one-step synthetic procedure, and the fact that the particle size can be controlled.[17] We have selectively prepared semiconducting famatinite (Cu_3SbS_4) nanofibers and tetradrite ($Cu_{12}Sb_4S_{13}$) nanoflakes via the mild solution synthesis route.[18]

Selenium is an important group VI semiconductor, which has found applications in rectifiers, solar cells, photographic exposure meters, and xerography. It is also used in the glass industry to eliminate bubbles and remove undesirable tints produced by iron.[19] In addition, selenium also has a high reactivity towards numerous chemicals that can potentially be exploited to convert selenium into other functional materials such as CdSe, ZnSe, Ag_2Se etc.[20] It is reasonable to assume that the availability of 1D selenium nanowires will introduce new types of applications or enhance the performance of currently existing devices, as a result of size restriction. The acicular and filament single crystals of selenium were studied 40 years ago.[21,22] Recently, Xia and coworkers have exploited sonochemical irradiation, and self-seeding solution-phase processes for the preparation of trigonal selenium nanowires.[23,24] Zhang et al. prepared α-monoclinic selenium nanowires via the decomposition of selenodiglutathiones.[25] Abdelouas and co-workers have also attempted to employ a reduction reaction route using cytochrome c_3 for the synthesis of monoclinic Se

nanowires.[26] More recently, Xie et al. reported a laser ablation method for the preparation of trigonal selenium nanorods at different temperatures.[27]

In this paper, we have designed a low-temperature hydrothermal synthesis route for the direct production of high quality crystalline trigonal selenium nanowires, using $(NH_4)_2S_2O_3$ and Na_2SeO_3 as starting materials in the presence of the surfactant sodium dodecyl sulfate (SDS). The initial concentration of feedstock solution is a key factor which influences the quality of the as-synthesized nanowires. The high yields of the products, without using complex apparatus, and the low reaction temperature employed, means that this simple method has good prospects for use in related future applications. The hydrothermal synthesis of t-Se nanowires is associated with the following chemical reaction.

$$(NH_4)_2S_2O_3 + Na_2SeO_3 \xrightarrow[110^{o}\,C]{SDS} Se + (NH_4)_2SO_3 + Na_2SO_3$$

In this process, the low solubility of selenium in water at 110 °C may be the driving force for this reaction to go to completion.

Results and Discussion

The obtained samples were weighed; the yields of the products were about 95%, based on the amount of Na_2SeO_3. Figure 1 (A) shows a typical XRD pattern of the sample prepared using 0.2 M feedstock in the presence of SDS at 110 °C for 18 h. All of the strong and sharp reflection peaks can readily be indexed to a single phase of trigonal-structured selenium (space group $P3_121$ (152) with infinite, helical chains of selenium atoms packed parallel to each other along the *c*-axis), with cell parameters a = 0.4364 nm and c = 0.4949 nm. These values are in agreement with the values reported in the literature (JCPDS Cards No. 73−0465). The product formed is further confirmed by XPS and Raman spectroscopy. Figure 1 (B) shows the XPS of the as-synthesized product. The binding energy at 54.8 eV, corresponding to Se3d, is the characteristic peak for elemental selenium.[28] Figure 1 (C) presents the Raman spectrum of the sample. The resonance peak at 237 cm^{-1} is a characteristic signature of trigonal selenium, which can be assigned to the vibration of the Se helical chain.[23] In comparison, the characteristic Raman peaks for monoclinic selenium and α-Se are at 256 cm^{-1} and 264 cm^{-1}, respectively.[29] These results, obtained from XRD, XPS and Raman spectroscopy, indicate that phase-pure t-Se is successfully produced via the present one-step synthetic route.

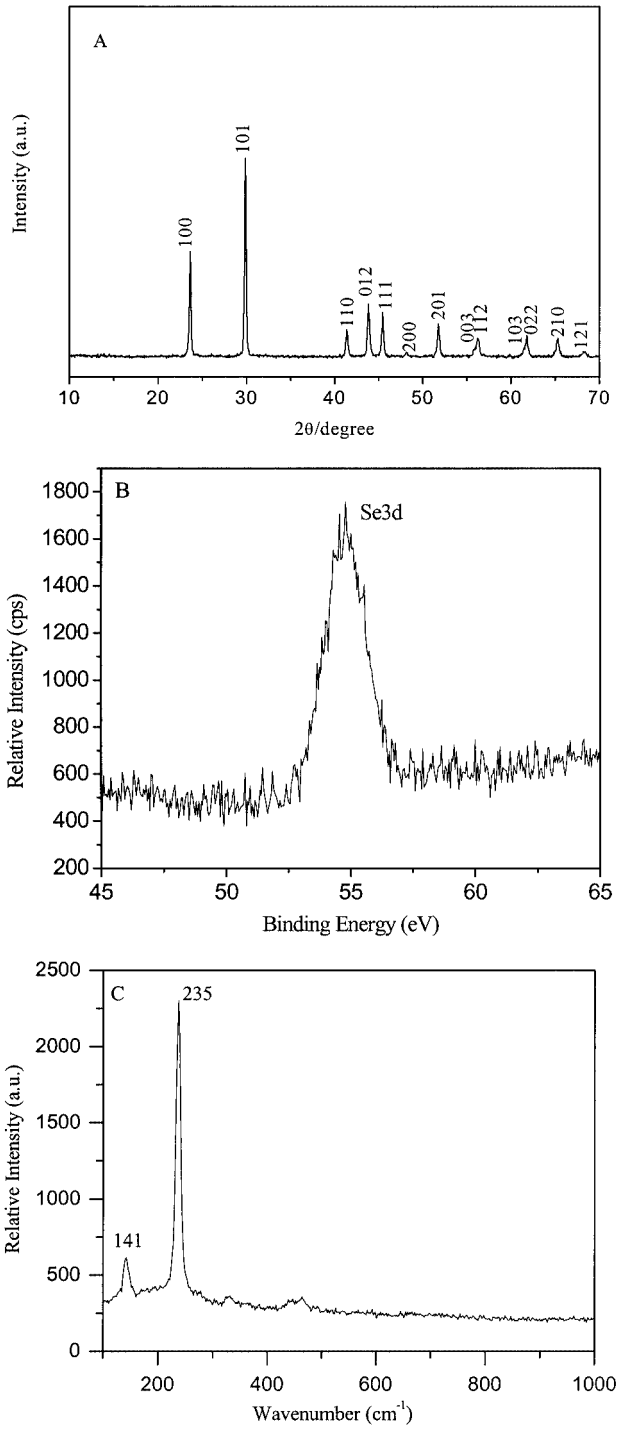

Figure 1. (A) Typical XRD pattern of the sample with 0.2 M feedstock solution in the presence of SDS; (B) XPS spectrum of the same sample as used in A; (C) Raman spectrum of the same sample as used in A

Figure 2 (A−C) provide SEM and TEM images of the same product as that presented in Figure 1. These images clearly show that the sample obtained is composed of a large number of nanowires, with a high aspect ratio (length/diameter). The uniformity in lateral dimension, the level of perfection, and the copiousness in quantity, show a good growth environment for the selenium nanowires in our system. Their lengths range from several micrometers to tens of micrometers, and their diameters are 20−40 nm, which is in agreement with that of micelles formed by SDS in aqueous solution.[30] The aspect ratio of the nanowires is in the range of several hundreds, which may be a useful feature in related applications. The inset of Figure 2 (C) shows the

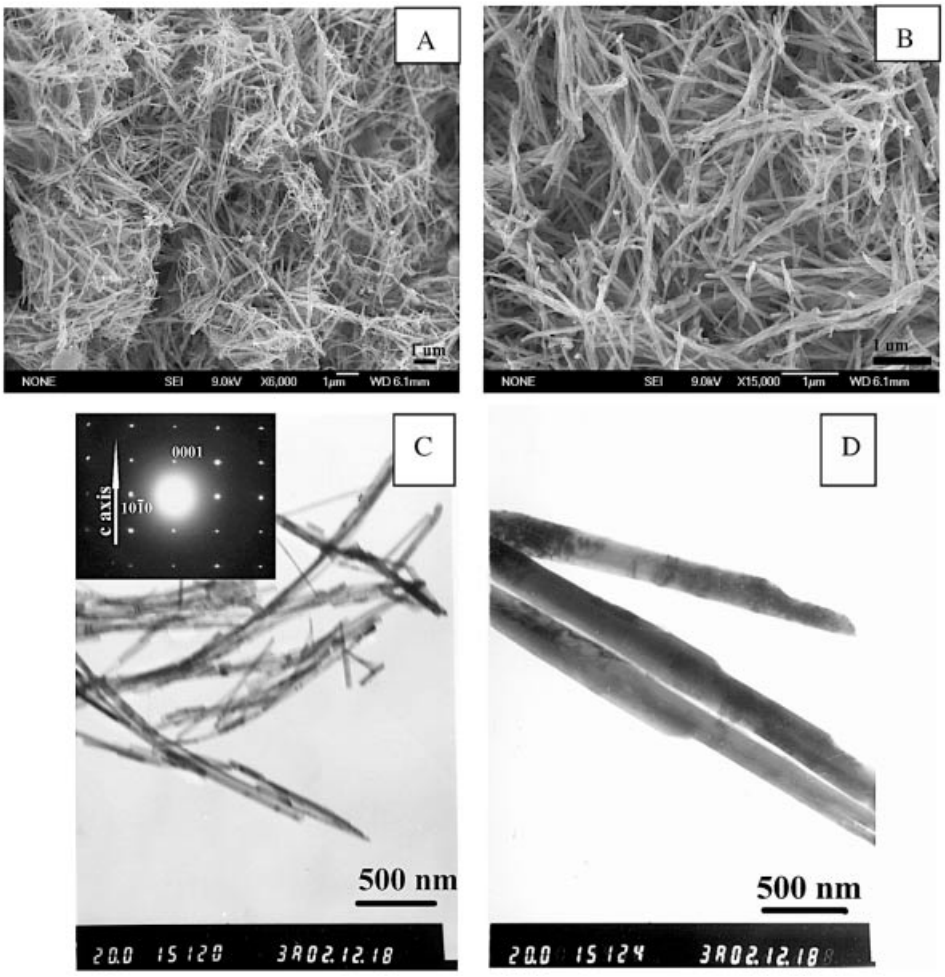

Figure 2. (A−B) Low and high magnification of the SEM images of the t-Se nanowires with 0.2 M feedstock solution in the presence of SDS; (C) TEM image of the same sample as presented in Figure 1A and ED pattern from a single nanowire (inset); (D) TEM image of the sample prepared with 0.1 M feedstock solution in the presence of SDS

selected-area electron diffraction (SAED) pattern obtained from a single nanowire, and exhibits the single-crystalline nature of nanowires. The two-fold rotational symmetry associated with this pattern indicates that these t-Se nanowires had predominately grown along the [001] direction (*c*-axis), with the helical chains of the Se atoms parallel to the longitudinal axis.[31] We have also carried out extensive investigations on more individual nanowires using ED, the results of which demonstrate that the as-synthesized sample is single-crystalline.

Selenium nanowires with larger diameters can be obtained when the initial concentration of the feedstock is reduced. Figure 2 (D) is a TEM image of the sample prepared with 0.1 M feedstock solution, whilst keeping the other conditions identical to those in the synthesis of the sample presented in Figure 1. It can be seen that the diameter (50−300 nm) of this product is much larger than that of the product synthesized at high initial concentrations. The length of the nanostructures is in the range of 2−5 μm. The corresponding aspect ratio ranges from 40 to 100. The experimental results demonstrate that the lateral dimensions of the products are strongly dependent on the initial concentrations of the feedstock. Such a dependence can be employed to control the lateral dimensions of the nanowires in the range of 20−300 nm. There have been some similar reports that show that increasing the initial concentration of reagents will favor the formation of 1D nanostructures with a high aspect ratio. Alivisatos and co-workers have systematically studied the conditions for the shape-controlled growth of CdSe nanocrystals in a mixed hexylphosphonic acid (HPA) and trioctylphosphane oxide (TOPO) surfactant system. Their results indicated that as the monomer concentration is increased, the average aspect ratio of the CdSe nanorods increase rapidly.[32] Whilst preparing Te nanorods in a sodium dodecyl benzenesulfate (NaDDBS) surfactant system, Liu et al.[33] also found that on increasing the initial concentration of $(NH_4)_2TeS_4$, the diameter of the 1D nanostructures decrease, and the nanowires will favorably be formed when a high concentration of $(NH_4)_2TeS_4$ is used. The observed phenomena in our experiments can be explained according to the previous reports.[32] At a given temperature, the high reagent concentration can provide enough selenium nuclei seeds, with a relatively narrow size distribution as the starting point. The

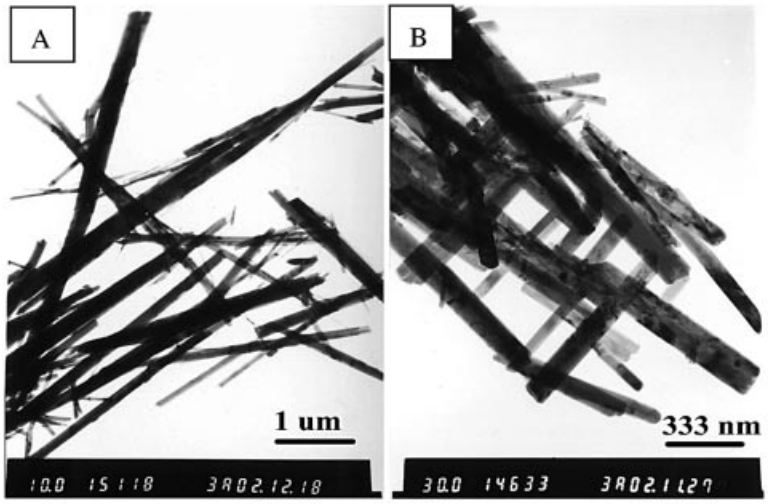

Figure 3. TEM images of the products obtained with different initial concentrations of feedstock solution in the absence of SDS (A) 0.2 M (B) 0.1 M

growth of the particles will be along the unique *c*-axis of t-Se, and finally results in high quality nanowires.

In contrast, we also prepared samples in the absence of surfactant, whilst keeping the other conditions constant. As shown in Figure 3, the TEM image of the sample synthesized using 0.2 M feedstock without using the surfactant displays uniform nanorods with diameters of 50−120 nm and lengths of up to 5 μm. When the concentration is decreased to 0.1 M, the diameters of the obtained sample are found to be 35−130 nm with lengths of about 2 μm [Figure 3 (B)]. The concentration-dependence of the diameter in the absence of surfactant is much less pronounced than that in the presence of surfactant. Hence, the surfactant is an important factor for the formation of high quality t-Se nanowires.

UV/Vis absorbance spectroscopy was used to characterize the samples. Figure 4 (A−C) shows the absorbance spectra of the obtained trigonal selenium nanowires with mean diameters of 20−40 nm, 50−120 nm and bulk t-Se, respectively. The results show that the absorbance peak for the t-Se nanowires with diameters of 20−40 nm (285 nm) is shifted to the blue, relative to those of the nanowires with diameters of 50−130 nm (306 nm) and bulk t-Se nanowires (374 nm). This shift can be attributed to the smaller diameters and larger aspect ratios of the nanowires.[34,35] Moreover, it should be noted that there is a large blue shift for both nanowires relative to that for the reported Se nanoparticles (620 nm).[19] As already known, different preparation methods have important effects on material microstructure and physical properties.[36] We believe that the optical properties of t-Se nanoparticles might be associated with its morphology and size. Thus, different optical characteristics are seen for t-Se nanowires and nanoparticles. Of course, our present understanding of the optical mechanism of crystalline t-Se nanoparticles is still limited, and more in-depth studies are underway.

Using the soft solution process, one-dimensional trigonal selenium nanostructures (nanowires or nanorods) have successfully been obtained, regardless of whether surfactants are used. In this solution-solid transformation, the morphology of the final product is determined mainly by the anisotropic nature of the target material. In other words, the 1D characteristic of the infinite, helical chains of selenium in the trigonal phase provides a natural template to define and guide the growth along one particular axis (*c*-axis). However, SDS and a relatively high initial concentration of feedstock solution are important factors for the formation of high quality trigonal selenium nanowires. The surfactant may act as a "size-tunable" reagent for the formation of selenium nanowires. A similar observation was reported for the preparation of γ-Al_2O_3 nanofibers with poly(ethylene oxide) as the surfactant.[37] We have also investigated the effect of temperature on the formation of t-Se nanowires. When the temperature is below 100 °C, the reaction is very slow and does not go to completion, and the yield is very low. When the temperature is above 130 °C, the size of the products is larger. Figure 5 shows a TEM image of the sample obtained at 150 °C using 0.2 M feedstock solution in the presence of SDS. It can be seen that the diameter of the rod-like crystal is up to 500 nm. This phenomena can be attributed to deterioration with increase in hydrothermal temperature. Therefore, 110 °C was chosen as the optimum temperature for the hydrothermal synthesis of t-Se nanowires.

Conclusion

A simple and convenient hydrothermal reaction route has been developed for the synthesis of high quality trigonal selenium nanowires in the presence of SDS. Several factors such as initial concentration of the feedstock, the presence of surfactant, and the temperature which influences the quality of the t-Se nanowires have been investigated. The unusual anisotropic structure of trigonal selenium provides a natural template to determine the morphology of the final products. The present route may be extended to the direct

synthesis of 1D selenides. Moreover, the as-synthesized selenium nanowires may be useful in providing templates for the formation of 1D nanostructures of many technologically important materials, by reacting with other chemicals. The related studies are in progress and will be reported later.

Experimental Section

All chemical reagents in this work, such as $NH_4S_2O_3$, Na_2SeO_3 and sodium dodecyl sulfate (SDS), were of A.R. grade and purchased from Shanghai Chemical Company, China. They were used as received without further purification.

Preparation of High Quality t-Se Nanowires

In a typical procedure, equivalent molar amounts of $(NH_4)_2S_2O_3$ and Na_2SeO_3 (10 mmol) were added to an aqueous solution (50 mL) of SDS (0.325 g). The solution was stirred for approximately 20 min until the solids had completely dissolved, and a 0.2 M homogeneous solution was formed. The solution was then transferred to a Teflon-lined autoclave (capacity of 60 mL). The autoclave was sealed and heated at 110 °C for 16−18 h, after which the autoclave was allowed to cool to room temperature naturally over a period of about 5 h. The resulting precipitate was rinsed with distilled water and absolute alcohol several times. After drying in vacuo at 40 °C for 4 h, the orange-red powders were collected for characterization.

For comparison, we prepared samples in the absence of surfactant whilst keeping the other conditions identical to those used in the preparation of high quality t-Se nanowires. Moreover, studies on the effect of initial concentrations (0.2 M, and 0.1 M) of feedstock solution on the resulting products were also carried out. The detailed experimental conditions were also similar to those used in the synthesis of high quality t-Se nanowires, with the exception that the initial feedstock concentrations were varied.

Sample Characterization

The phase composition and structure of the as-synthesized products were examined by X-ray powder diffraction (XRD), operating on a Japan Dmax-γA X-ray diffractometer with graphite-monochromated Cu-K_α radiation (λ = 1.54178 Å). X-ray photoelectron spectra (XPS) were recorded on a VGESCALAB MKII X-ray photoelectron spectrometer, using non-monochromated Mg-K_α radiation as the excitation source. The Raman spectra were recorded on a Jobin Yvon HR800 (Horiba group), using 514.5 nm as the excitation line. The morphology and particle size of the final

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

products were determined by scanning electron microscopy (SEM), using a JEOL-6700F scanning electron microanalyzer, and Transmission electron microscopy (TEM), using a Hitachi H-800 transmission electron microscope with a tungsten filament and an accelerating voltage of 200 KV. Room temperature absorbance spectra were recorded on a Shimadzu UV/Vis absorbance diode array spectrometer, using 1 cm quartz cuvettes. The samples were prepared by dispersing t-Se nanowires in absolute alcohol.

COVER PICTURE

The cover picture shows an Li_2N_2 unit which is prevented by the bulk of the aryl substituents from stacking with another to form a cubic cluster. The diethyl ether solvent traps this fragment of a molecule which, in the absence of diethyl ether, precipitates as a powder, possibly by lateral association of Li_2N_2 rings to form an infinite ladder in a manner first suggested by Ronald Snaith, whose memory is honoured in this special edition of EurJIC. Details are presented in the article by F. Mair et al. on p. 3464 ff.

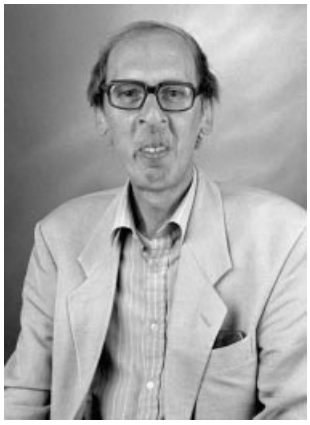
Ron Snaith (1947−2000), Inspirational Alkchemist and Altruist



This volume is dedicated to the memory of Dr Ron Snaith, the highly respected and much-loved scientist, teacher, researcher and raconteur, whose sudden and tragic death on the first day of this millennium, January 1st 2000, shocked his family and friends throughout the world. His passing deprived his widow Jane, son Tom, and daughter Katie of a loving, adored husband and father, and the chemical community at large of a remarkably influential pioneering researcher, writer and speaker. He was an unforgettable character, regarded with great affection by all who came to know him, particularly those who had had the privilege to have been taught by him. It is a measure of the high esteem in which he and his chemistry are held that, three years after his death, an international meeting, the third in a series he founded, concerned with alkali and alkaline earth metal chemistry (ALKCHEM 3, Würzburg, Germany 28/9/03−2/10/03) should be dedicated to his memory, and that so many fellow chemists should have contributed papers to this special memorial volume.

Ron was born in Kingston-upon-Hull, Yorkshire, in 1947. Fiercely proud of the county of his birth, he showed its legendary grit, determination and spirit in all he did. A born communicator, and blessed with a sympathetic character that allowed him to see the world from others' viewpoints, he was able to turn a feeling for the pithy phrase, a gently sardonic sense of humour, and a capacity for self-mockery to excellent effect in his interactions with others, consistently instilling wit and good humour daily into their lives. In this increasingly egocentric world, he was remarkably altruistic, putting the needs of others ahead of his own, particularly the needs of those least able to help themselves. His concern for the underdog, the underprivileged, permeated his thoughts and actions.

His route into a research career in chemistry was unorthodox. Whilst studying for his BSc in chemistry at Durham University from 1965−1968, he originally intended, on graduating, to become a teacher at secondary school level (pupils aged 11−18), preferably working with pupils who were disabled. His interest in his chosen subject was, however, fired by lectures from Professor Geoffrey Coates, the charismatic pioneering organometallic chemist who headed the Department of Chemistry at Durham from 1953−1968. Subsequently, having gained a richly deserved first class honours degree in 1968, Ron stayed on at Durham (1968−1971) to secure a science Ph.D. to ensure he had some leverage later when he embarked on his career. As Coates moved in 1968 to Laramie, Ron worked for his PhD with Ken Wade, then a lecturer at Durham (formally Ron's research supervisor, Ken was soon to find himself learning more from Ron than vice versa). Having completed his PhD in 1971, Ron spent a year training as a teacher, still in Durham, before going on to teach chemistry very successfully for the next seven years at Durham Johnston Comprehensive School, putting his subject across with inspirational flair and insight, creating a generation of young enthusiasts who went on to study the subject at university and then make their own careers in chemistry. His former pupils at Johnston School (originally founded, as a technical school, by the first professor of chemistry at Durham University, J F W Johnston FRS) include some distinguished figures in UK chemistry today such as David Parker FRS, who now heads the Chemistry Department at Durham (for the second time) and Paul Attfield, chair of material science at the University of Edinburgh. It is no surprise that Ron's talent as a born teacher was recognised at Johnston School from his arrival there, and he rose rapidly to head his department.

It was from Durham Johnston School that Ron was head-hunted, in 1979, by Professor Peter Perkins, then head of inorganic chemistry at the University of Strathclyde, in Glasgow. Perkins was seeking a charismatic teacher, one able to communicate with and interest students who were required to study the subject in their first year at university but who might not go on to study the subject in depth as specialists. Ron proved so adept at this, making chemistry not only intelligible but also genuinely interesting, indeed fascinating, that he soon became a rising star in the Department of Pure and Applied Chemistry at Strathclyde. It was there that he started the researches into aspects of lithium chemistry that were soon to establish him as a leading authority on s-block chemistry.

The reputation he acquired at Strathclyde, however, prompted another university, this time Cambridge, to head-hunt him, and he moved to a lectureship there in 1986, subsequently being promoted to a Readership in Main Group Chemistry in 1998. His growing stature at Cambridge prompted many invitations for him to move again, to chairs elsewhere in the UK or abroad, but these came during a period in which another move would have been inconvenient for family reasons, and anyway he found

 DOI: 10.1002/ejic.200300559 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

his departmental and college work at Cambridge too fulfilling to succumb to any of these tempting invitations, for which scores of students who passed through the Chemistry Department and/or St John's College during the nineties will be most grateful. The outside world is aware of Ron's scientific work at Cambridge through his publications. His staff colleagues in the chemistry department and in St John's College will be aware of the enormous amount of work he did, whether as a brilliant lecturer and sympathetic teacher in a world-class department, as an acutely conscientious and fair admissions tutor and patient undergraduate supervisor in a historic college, or as a committee man and helper always prepared to lend a hand with many duties.

Although Ron acquired a well-deserved reputation as a chemist, his knowledge of and lectures on Egyptology probably brought him into contact with a wider public in the UK, and certainly deserve a mention here. His long-standing interest in ancient civilisations flourished through a friendship with Professor Tom Thacker, Head of Middle Eastern and Oriental Studies at Durham in the sixties and seventies. From his graduate student days, Ron soon became skilled at the specialist applied chemical techniques needed for the safe cleaning of priceless but corroded artifacts made centuries or millennia earlier. Indeed, at one time he came near to carrying out postdoctoral research in restoration work on items in the Oriental Museum at Durham. Later in his career he was in great demand on the lecture circuit on the subject of Egyptian Mummies, on which he spoke with consummate authority and brilliant wit and humour, tuning his raconteur's discourse on the subject with unerring skill to the background and interests of his audience, reducing his captivated listeners (whether schoolchildren, undergraduates, enthusiasts for the advancement of science, or members of women's institutes) to helpless laughter as he entertained them with hilarious tales about Isis, Osiris, assorted other gods and their bizarrely scattered vital parts, yet still imparting a feeling for ancient civilisations, hieroglyphics, early alchemy, and the technicalities of mummification.

As a researcher in chemistry, Ron was a thoroughly reliable experimentalist, bravely prepared to tackle systems that were so acutely air-and moisture-sensitive as to discourage others from attempting to work with them. Like his experimental work, his written or oral presentations of his work were also always meticulously well prepared, and conveyed clearly the insight and implications his results generated. He could turn his hand to preparative, spectroscopic, structural or bonding problems with equal facility, and thought laterally, making connections others had not spotted, highlighting the common characteristics of seemingly disparate species.

His early Ph.D. work on ketimino derivatives $(R_2C{=}N)_xM$, $(RC{=}N)_xMX_y$, $(R_2C{=}N)_xMLi$, etc, of such elements M as boron, aluminium and silicon, established and consolidated the link between the structures of such systems, particularly their CNM bond angles, and the number of electrons (1 or 3) the ligand provided for bonding terminally to a metal or metalloid, deduced from "sporting" methods such as IR or NMR spectroscopy if X-ray evidence was unavailable as was often the case in those days. He showed, in early examples of the method, how the state of aggregation of his products could be controlled by use of judiciously chosen bulky substituents, and was thereby responsible for preparing the first set of monomeric ketiminoboranes R_2CNBR_2, isoelectronic with allenes R_2CCCR_2, that contained linear CNB skeletons. His syntheses of these compounds entailed the use of *N*-lithio-ketimines, $R_2C{=}NLi$, as reagents, though their structures were not then known. He was later to solve their structures at Strathclyde, and show their importance in elucidating structural patterns in lithium chemistry. Also in the course of this work on ketiminates, he generated systems exhibiting significant C-H···M interactions like those found earlier by Erwin Weiss in his classic studies on lithium alkyls. Interestingly, it was to be some years before these types of interaction were detected in transition metal systems, hailed as novel, and dubbed "agostic".

In his career, Ron spent no time on conventional postdoctoral studies. However, he found time during his doctoral, teacher-training, and school-teaching years to read widely in boron cluster chemistry, on which he also became an authority and wrote a number of reviews that were well received. He later developed new methods of deducing the enthalpies of formation of such systems, initially using classical bond length-bond energy arguments but later adapting for this purpose the bond index concept developed by David Armstrong and Peter Perkins at Strathclyde. Also with David Armstrong, Ron carried out ab initio MO calculations on borane cluster systems long before such calculations became as routinely possible as they are now.

However, it is for his lithium chemistry, notably his elucidation of the patterns that permeate the structural chemistry of lithium, that he is best known. His inspired use of amino and ketimino ligands, R_2N and $R_2C{=}N$, allowed him to exploit and probe both electronic and substituent bulk effects. The twofold symmetry of these ligands, and the complementarity of the orientations of their alkyl groups (in the plane of the nitrogen lone pairs in the latter case, out of that plane in the former case) led to either laddering or stacking of the $(LiN)_n$ rings (n = commonly 2 or 3). Through Ron's ingenuity and vision, what began modestly as an esoteric study of lithium amides and lithium ketimides was transformed into ring-stacking and ring-laddering principles that could be applied with equal relevance and rigour to the structures of lithium organoelement compounds in general, including alkoxides, alkyls, aryls, alkynyls, enolates, halides and phosphides, and to the heavier alkali metal congeners. Developed through a series of key papers, these ideas were later expounded by Ron in a seminal review article on "structures of organonitrogen-lithium compounds: recent patterns and perspectives in organolithium chemistry" (*Adv. Inorg. Chem.* **1991**, *37*, 47−142), which was co-written with Karina Gregory and Paul von Ragué Schleyer (with whom

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Ron teamed up to probe the nature of the bonding in his lithium-nitrogen systems). How fitting that Ron, a son of a builder, should become an expert in the design and construction of molecular architectures.

Ron went on to show that the structural principles applicable to salts of electropositive metals with organic anions are also equally applicable to salts of the same metals with inorganic anions. This led him to develop the ''ammonium salt route'' for the synthesis of a series of novel Lewis base-captured molecular fragments of common inorganic salts. One of his great strengths was in recognising the significance of a single result, and designing a comprehensive project around it. His discovery that water and lithium, long regarded as incompatible in organolithium chemistry, can indeed coexist in an organic compound (derived from 2-mercaptobenzoxazole) is a case in point, which led him to an in-depth investigation of aqua and other protic ligand complexes of alkali and alkaline earth metal organic compounds.

Having devoted much of his career to solving and rationalising the structures of lithium reagents, Ron later turned to documenting the mechanisms by which lithio reagents operate in organic syntheses. The results were published in a string of definitive papers detailing the identities and the solid-state and (more importantly) solution structures of lithium-based intermediates isolated during the courses of several key organic syntheses, not only providing benchmarks by which such reactions can be understood, but also underlining the comprehensive, interdisciplinary nature of modern chemistry, where pooling the resources of organic, inorganic, organometallic and mechanistic investigations is necessary if we are to understand the subtleties and complexities of what initially may appear straightforward reactions between the monomeric species by which reagents are so commonly, and misleadingly, represented in equations.

Sadly, the death of Ron in his prime means that this particularly promising line of work was taken less far than he had planned. Bereft of his unique approach and originality, it will not be developed in the way he himself would have taken it. However, as a superb teacher and source of inspiration to generations of graduate students and postdoctoral co-workers, he has ensured that his ideas and philosophy will live on. Ron's own publications ensure that his very substantial contribution to science remains available to us. He has also bequeathed to academia many former students and co-workers who have themselves gone on to highly successful research careers, including Matt Davidson (Bath), Rob Davies (Imperial College, London), Rab Mulvey (Strathclyde), Andy Wheatley and Dom Wright (both Cambridge). They themselves have won a clutch of prestigious Royal Society of Chemistry Awards (Meldola/Harrison Memorial/Main Group Element Medals and Prizes). He also had a major influence on the academic careers of two former postdoctoral associates (Frank Mair, UMIST and Dietmar Stalke, Würzburg). This legacy to research chemistry is all the more remarkable given that Ron always deliberately restricted the size of his research group to a select small number.

Ron himself won the RSC Award for Main Group Element Chemistry in 1996, an award which undoubtedly would have been followed by many more awards had he survived to pursue a normal length career. Characteristically, throughout his life, he was always self-effacingly concerned to see that others gained the recognition he did not seek for himself, a true altruist. Inspirational in chemistry and in how to live one's life, Ron had a generosity of spirit and infectious good humour that enriched and transformed the lives of all who knew him, and will live long in their memories.

Throughout his career, Ron was given immense and unstinting support by Jane, whom he had met when they were both students at Durham (she herself took a PhD in engineering science). She and Tom (who followed in his father's footsteps to take a first in chemistry at Durham in 2000 before turning to law) and Katie (close to completing her studies for a Master's degree in criminology) were a source of great pride and joy to Ron, who appreciated their tolerance of his not infrequent preoccupation with chemistry. We, and the chemical community at large, share their loss, in his prime, of this highly talented, kind, considerate, lovable man.

Bryan, J. Halfpenny, E. A. Petch, K. Wade, *J. Organomet. Chem.* **1983**, *249*, Cl−C5.

[11] Crystal and Molecular Structures of the Lithioketimine, $[Li(N=CtBu_2)]_6$, and Lithioguanidine, $[LiN=C(NMe_2)_2]_6$: Electron-Deficient Bridging of Li_3 Triangles by Methyleneamino-Nitrogen Atoms: W. Clegg, R. Snaith, H. M. M. Shearer, K. Wade, G. Whitehead, *J. Chem. Soc., Dalton Trans.* **1983**, 1309−1317.

[12] Crystal Structures of $[Ph_2C=NLi.NC_5H_5]_4$ and $[ClLi{\cdot}O=P(NMe_2)_3]_4$: Discrete Tetrameric Pseudo-cubane Clusters with Bridging of Li_3 Triangles by Nitrogen and by Chlorine Atoms: D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1984**, 79−80.

[13] Crystal Structure of $\{Li[O=P(NMe_2)_3]_4\}^+{\cdot}\{Li[N=CPh_2]_6{\cdot}O=P(NMe_2)_3\}^-$: A Lithium 'Ate Complex, with a Pentanuclear Li_5 Clustered-Anion, having Both μ_2 Edge and μ_3 Face Nitrogen to Lithium Bonding: D. Barr, W. Clegg, R. B. Mulvey, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1984**, 226−227.

[14] Trimeric Dibenzylamidolithium and its Dimeric Diethyl Ether and Hexamethylphosphoramide Complexes: Structural and Theoretical Studies of Reactive Organonitrogen-Lithium Oligomers: D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1984**, 285−287.

[15] Evidence for CH···Li Interactions in the Solid-State Structure of Dibenzylamidolithium, and in Solutions of it and its Complexes: Coloured Species due to Benzyl → Lithium Charge Transfer: D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1984**, 287−289.

[16] The Isolation and Crystal Structure of $[Ph(2\text{-}Pyr)NLi]{\cdot}[O=P(NMe_2)_3]{\cdot}[Ph(2\text{-}Pyr)NH]$: A Model Monomeric Organonitrogen-Lithium Species Containing Coordination of Lithium by both an Anchimeric Pyridyl N-Atom and by a Potentially Reactive Amine Ligand: D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1984**, 469−470.

[17] The Structural Isomers of $\{[Ph(2\text{-}Pyr)NLi]{\cdot}[O=P(NMe_2)_3]\}_2$: Dimeric Species with Alternative $(LiN)_2$ and $(LiO)_2$ Rings, the latter involving Unprecedented Neutral Bridging Oxygen Ligands: D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1984**, 700−701.

[18] The Isolation and Crystal Structure of $\{Li(H_2O)_2[O=P(NMe_2)_3]\}_2^{2+}{\cdot}2Cl^-$: a $(LiO)_2$ Ring Compound with Bridging Neutral Oxygen (HMPA) Ligands: D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1984**, 974−975.

[19] Crystal and Solution Structures of $\{tBu_2C=NLi{\cdot}O=P(NMe_2)_3\}_n$: D. Barr, W. Clegg, R. E. Mulvey, D. Reed, R. Snaith, *Angew. Chem. Int. Ed. Engl.* **1985**, *24*, 328−329.

[20] Amination Reactions of Alkoxy-amidolithium Compounds: an *Ab Initio* S.C.F. M.O, Model involving an (N−O)-Lithium-bridged Intermediate: D. R. Armstrong, R. Snaith, G. T. Walker, *J. Chem. Soc., Chem. Commun.* **1985**, 789−791.

[21] Cluster Bonding and Energetics of the Borane Anions, $B_nH_n^{2-}$ (n = 5−12): a Comparative Study using Bond Length/Bond Enthalpy Relationships, MO Bond Index Calculations: C. E. Housecroft, R. Snaith, K. Moss, R. E. Mulvey, M. E. O'Neill, K. Wade, *Polyhedron* **1985**, *4*, 1875−1881.

[22] High-Field Lithium-7 Nuclear Magnetic Resonance Spectroscopic and Cryoscopic Relative Molecular Mass Studies on Solutions of Amido- and Imidolithium Compounds: D. Reed, D. Barr, R. E. Mulvey, R. Snaith, *J. Chem. Soc., Dalton Trans.* **1986**, 557−564.

[23] The Isolation of a Highly Arene-Soluble Alkali Metal Tetrafluoroborate Complex, $LiBF_4{\cdot}4HMPA$: Evidence for Strong Li···F Interactions in Solution: D. Barr, K. B. Hutton, J. H. Morris, D. Reed, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1986**, 127−129.

[24] Bonding Implications of Interatomic Distances and Ligand Orientations in the Iminolithium Hexamers $\{LiN=C(Ph)tBu\}_6$ and $\{LiN=C(Ph)NMe_2\}_6$: a Stacked-Ring Approach to these and Related Oligomeric Organolithium Systems: D. Barr, R. Snaith, W. Clegg, R. E. Mulvey, K. Wade, *J. Chem. Soc., Chem. Commun.* **1986**, 295−297.

[25] Bond Indices, Enthalpies, and Relative Stabilities of Real and Hypothetical Closo-Clusters $B_nH_n^{c-}$ (n = 5−12; c = 0, 2 or 4) as Revealed by the MO Bond Index Method: R. Snaith, R. E. Mulvey, M. E. O'Neill, K. Wade, *Polyhedron* **1986**, *5*, 1437−1447.

[26] The Laddering Principle in Lithium Amide Chemistry: the Crystal and Molecular Structure of the Pyrrolididolithium Adduct $[H_2C(CH_2)_3NLi]_3{\cdot}MeN(CH_2CH_2NMe_2)_2$: D. R. Armstrong, D. Barr, W. Clegg, R. E. Mulvey, D. Reed, R. Snaith, K. Wade, *J. Chem. Soc., Chem. Commun.* **1986**, 869−870.

[27] Variable Temperature and Concentration ^1H and ^7Li NMR Studies of Solutions of Hexameric Iminolithium Compounds, $(R^1R^2C=NLi)_6$: D. Barr, R. Snaith, R. E. Mulvey, K. Wade, D. Reed, *Magn. Reson. Chem.* **1986**, *24*, 713−717.

[28] Crystal Structure of NaI·diglyme: an Unprecedented Bridging Role for Diglyme: R. E. Mulvey, W. Clegg, D. Barr, R. Snaith, *Polyhedron* **1986**, *5*, 2109−2111.

[29] The Synthesis and X-ray Structural Characterisation of the First Mixed Alkali Metal Organonitrogen Molecular Cluster $LiNa_3{\cdot}[O=P(NMe_2)_3]_3{\cdot}[N=C(NMe_2)_2]_4$: W. Clegg, R. E. Mulvey, R. Snaith, G. E. Toogood, K. Wade, *J. Chem. Soc., Chem. Commun.* **1986**, 1740−1742.

[30] The Ring-Stacking Principle in Organolithium Chemistry: its Development through the Isolation and Crystal Structures of Hexameric Iminolithium Clusters $(RR'C=NLi)_6$, (R′ = Ph, R = *t*Bu or Me_2N; R = R′ = *t*Bu or Me_2N): D. Barr, R. Snaith, W. Clegg, R. E. Mulvey, K. Wade, *J. Chem. Soc., Dalton Trans.* **1987**, 1071−1081.

[31] X-ray Crystallographic- and Solution-Studies of the PMDETA and TMEDA Adducts of Lithium Diphenylphosphide: R. E. Mulvey, K. Wade, D. R. Armstrong, G. T. Walker, R. Snaith, W. Clegg, D. Reed, *Polyhedron* **1987**, *6*, 987−993.

[32] The Syntheses and Crystal Structures of Two Iminolithium Adducts: $(Ph_2C=NLi{\cdot}Pyridine)_4$, a Tetrameric Pseudo-cubane Formed by Stacking Two $(LiN)_2$ four-membered Rings, and $(tBu_2C=NLi{\cdot}HMPA)_2$, a Dimer Prevented Sterically from Stacking: D. Barr, R. Snaith, W. Clegg, R. E. Mulvey, K. Wade, *J. Chem. Soc., Dalton Trans.* **1987**, 2141−2147.

[33] Three Model Structural Types in Lithium Amide Chemistry: the Crystal and Molecular Structures of Dimeric $(PhMeNLi{\cdot}TMEDA)_2$ and Monomeric PhNaphthylNLi·PMDETA, and of $(PhNapthylNLi{\cdot}TMEDA)_2$, a "Loose Dimer": D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1987**, 716−718.

[34] Isolation and Solution Structures of $\{PhCH_2NLiCH_2CH_2NMe_2\}_n$ and of the Totally Rigid Dilithium Compound $\{o\text{-}LiC_6H_4CH_2NLiCH_2CH_2NMe_2\}_n$: Evidence for Li···*o*HC Interactions: D. Barr, R. Snaith, D. S. Wright, R. E. Mulvey, K. Jeffrey, D. Reed, *J. Organomet. Chem.* **1987**, *325*, C1−C6.

[35] Structure and Bonding of the Tris(diphenylmethyleneamino)aluminium Dimer, $[Al(N=CPh_2)_3]_2$: Relative Strengths of Bridging and Terminal Al−X Bonds in Systems $X_2Al(\mu\text{-}X)_2A1X_2$: S. J. Bryan, W. Clegg, R. Snaith, K. Wade, E. H. Wong, *J. Chem. Soc., Chem. Commun.* **1987**, 1223−1224.

[36] Reactions of Ammonium Salts with BuLi and with LiH: New Routes to Fully Anhydrous Inorganic Lithium Compounds: D. Barr, R. Snaith, D. S. Wright, R. E. Mulvey, K. Wade, *J. Am. Chem. Soc.* **1987**, *109*, 7891−7893.

[37] Synthesis, and Crystal and Solution Structures of the 1:1 TMEDA Complex of Lithium Thiocyanate, $(LiSCN{\cdot}TMEDA)_n$: a Polymeric Solid with Li^+ Ions Linked by Bifunctional Linear SCN^- Ligands: D. Barr, M. J. Doyle, R. E. Mulvey, P. R. Raithby, R. Snaith, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1988**, 145−147.

[38] A Li_8 Cluster of Three Edge-connected Li_4 Tetrahedra Held by Li−N, and Li···C, and Li···Li Interactions: Crystal Structure of $(o\text{-}LiC_6H_4CH_2NLiCH_2CH_2NMe_2)_4$, and Detection of

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Metal···Metal Coupling within it by ^{7}Li COSY NMR Spectroscopy: D. Barr, W. Clegg, S. M. Hodgson, R. E. Mulvey, D. Reed, R. Snaith, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1988**, 367−369.

[39] Syntheses and Solid-state Structures of Trimeric Dibenzylamidolithium and its Diethyl Ether and Hexamethylphosphoramide Complexes: an Explanation of these Structures and Evidence for Li···HC Interactions in both Solid and Solution Phases: D. R. Armstrong, R. E. Mulvey, G. T. Walker, D. Barr, R. Snaith, W. Clegg, D. Reed, *J. Chem. Soc., Dalton Trans.* **1988**, 617−628.

[40] Characterisation of the bis(Pyridine) Complex of the Butyllithium-Pyridine Adduct, 2-Bu(C_5H_5N)Li·(C_5H_5N)$_2$; its Decomposition to 2-Butylpyridine via a Dihydropyridine: D. Barr, R. Snaith, R. E. Mulvey, D. Reed, *Polyhedron* **1988**, *7*, 665−668.

[41] Oligomeric Iminolithium and Amidolithium Compounds: Comments on Previously Reported Theoretical Calculations and Experimentally Determined Structures: W. Clegg, R. Snaith, K. Wade, *Inorg. Chem.* **1988**, *27*, 3861−3862.

[42] MOBI Calculations on Selected Organolithium and Lithium 'Ate Species: Evidence for Li···HC Three-centre Interactions: D. Barr, R. Snaith, R. E. Mulvey, P. G. Perkins, *Polyhedron* **1988**, *7*, 2119−2128.

[43] Isolation, Characterisation, and Solution Structures of the Bis(Pyridine) Complex of the *n*-Butyllithium-Pyridine Adduct, *n*Bu(C_5H_5N)Li·(C_5H_5N)$_2$, its Mode of Decomposition, and *Ab Initio* Calculations on Model Systems: D. R. Armstrong, R. E. Mulvey, D. Barr, R. Snaith, D. Reed, *J. Organomet. Chem.* **1988**, *350*, 191−205.

[44] Evidence for a Radical-forming Process during the Reaction of Solid NH_4SCN with *n*BuLi and HMPA in Toluene: Crystal Structure of the Product, (LiNCS·2HMPA)$_2$: D. Barr, M. J. Doyle, S. R. Drake, P. R. Raithby, R. Snaith, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1988**, 1415−1417.

[45] Reaction of Solid NaH with Solid NH_4SCN in HMPA/Toluene: an E.S.R. Spectroscopic Investigation, and Crystal Structures of the Two Products of the Reaction, {(NaNCS·HMPA)$_2$}$_\infty$ and (NaNCS·2HMPA)$_2$: D. Barr, M. J. Doyle, S. R. Drake, P. R. Raithby, R. Snaith, D. S. Wright, *Polyhedron* **1989**, *8*, 215−218.

[46] Ladder Structures in Lithium Amide Chemistry: Syntheses, Solid-state, and Solution Structures of Donor-deficient Lithium Pyrrolidide Complexes, {[$H_2C(CH_2)_3NLi$]$_3$·PMDETA}$_2$ and {[$H_2C(CH_2)_3NLi$]$_2$·TMEDA}$_2$, and *Ab Initio* Calculations Probing Ring vs Ladder vs Stack Structural Preferences: D. R. Armstrong, D. Barr, W. Clegg, S. M. Hodgson, R. E. Mulvey, D. Reed, R. Snaith, D. S. Wright, *J. Am. Chem. Soc.* **1989**, *111*, 4719−4727.

[47] Dilithiation of *N*,*N*′-Diphenylthiourea, PhNHC(=S)HNPh: The Unexpected Structure of the Product, [PhNLiC(=NPh)SLi·2HMPA]$_2$, and Supporting *Ab Initio* MO Calculations on Model Systems: D. R. Armstrong, R. E. Mulvey, D. Barr, R. Snaith, D. S. Wright, W. Clegg, S. M. Hodgson, *J. Organomet. Chem.* **1989**, *362*, Cl−C4.

[48] A K_3-Containing Trigonal Bipyramidal Cluster: Synthesis of (KSCN)$_3$·5HMPA by Reaction of Solid NH_4SCN with Solid K or KH in Toluene/HMPA, and its Crystal Structure Revealing a Triangle of Three K^+ Ions Linked by Three Equatorial μ_2-HMPA Ligands and Bicapped by Two μ_3-HMPA Ligands: D. Barr, M. J. Doyle, S. R. Drake, P. R. Raithby, R. Snaith, D. S. Wright, *Inorg. Chem.* **1989**, *28*, 1767−1768.

[49] A Unique Lithium Halide Complex, {(LiBr)$_2$·3HMPA·Toluene}: Synthesis from Reaction of Solid NH_4Br with *n*BuLi in HMPA/Toluene Media, Crystal Structure showing Two Li−Br Units Linked by Three μ_2-HMPA Ligands, and Detection of ^{7}Li···^{31}P Coupling in Solutions of the Complex: D. Barr, M. J. Doyle, P. R. Raithby, R. Snaith, D. S. Wright, R. B. Mulvey, D. Reed, *J. Chem. Soc., Chem. Commun.* **1989**, 318−319.

[50] Synthesis and Crystal Structure of the Mixed Alkali-Metal Imide Compound $Li_{3.7}Na_{2.3}${N=C(Ph)*t*Bu}$_6$: Three (Metal-Nitrogen)$_2$ Ring Dimers in a Triple-Layered Stack: D. Barr, W. Clegg, R. E. Mulvey, R. Snaith, D. Reed, *J. Chem. Soc., Chem. Commun.* **1989**, 57−58.

[51] Two Monomeric, Octahedral Complexes of Alkaline Earth Metal Salts; Syntheses, Physical Characteristics, and Crystal Structures of SrI_2·4HMPA and Sr(NCS)$_2$·4HMPA: D. Barr, A. T. Brooker, M. J. Doyle, S. R. Drake, P. R. Raithby, R. Snaith, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1989**, 893−395.

[52] A New Coordinating Chiral Lithium Amide: J. F. Stoddart, D. J. Berrisford, R. Snaith, D. Barr, R. V. H. Jones, D. J. Williams, A. M. Z. Slawin, *Angew. Chem. Int. Ed. Engl.* **1989**, *28*, 1044−1047.

[53] [$H_2C(CH_2)_5NLi$]$_6$, The First Cyclised Lithium Amide Ladder: Synthesis and Structure of Hexamethyleneimidolithium: R. Snaith, D. Barr, D. S. Wright, W. Clegg, S. M. Hodgson, G. R. Lamming, A. J. Scott, R. E. Mulvey, *Angew. Chem. Int. Ed. Engl.* **1989**, *28*, 1241−1243.

[54] Unusual Routes to Complexes of Binary Alkali Metal−Nonmetal Compounds: Preparations and Crystal and Solution Structures of Li_2S_6·(TMEDA)$_2$ and Synthetic Extensions of the Routes: A. J. Banister, D. Barr, A. T. Brooker, W. Clegg, M. J. Cunnington, M. J. Doyle, S. R. Drake, W. R. Gill, K. Manning, P. R. Raithby, R. Snaith, K. Wade, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1990**, 105−107.

[55] The Ammonium Salt Route to Oligomeric Lanthanum Salt Complexes: Synthesis and X-ray Crystal Structure of La(NCS)$_3$·4HMPA: D. Barr, A. T. Brooker, M. J. Doyle, S. R. Drake, P. R. Raithby, R. Snaith, D. S. Wright, *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 285−287.

[56] [PhLiNCH_2CH_2NLiPh]·3HMPA, a Monomeric Dilithiumethylenediamide Complex with N_2Li_2 Double Bridging: Synthesis, Crystal Structure, and Model MO Calculations: D. R. Armstrong, D. Barr, A. T. Brooker, W. Clegg, K. Gregory, S. M. Hodgson, R. Snaith, D. S. Wright, *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 410−411.

[57] The First Lithiated Organic Compound containing Water as a Ligand: Synthesis and Crystal Structure of 2-Mercaptobenzoxazoyl(tetramethylethylenediamine)lithium Monohydrate, C_6H_4OC(···S)···NLi·(TMEDA)·H_2O, a Model Acid-Base Intermediate: D. Barr, P. R. Raithby, P. v. R. Schleyer, R. Snaith, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1990**, 643−645.

[58] Aggregation of Aza Crown Ethers by Metallation: Synthesis and Crystal Structure of 1-Lithio-1,7-diaza-12-crown-4; The First Lithiated Crown Ether: D. Barr, D. J. Berrisford, L. Méndez, A. M. Z. Slawin, R. Snaith, J. F. Stoddart, D. J. Williams, D. S. Wright, *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 82−84.

[59] Lithiations of Mercaptoamines Containing =NC(=S)NH−, −NHC(=S)S−, and −NHC(=S)NH− Units: Syntheses, Crystal Structures, and Model MO Calculations: D. R. Armstrong, R. E. Mulvey, D. Barr, R. W. Porter, P. R. Raithby, T. R. E. Simpson, R. Snaith, D. S. Wright, K. Gregory, P. Mikulcik, *J. Chem. Soc., Dalton Trans.* **1991**, 765−776.

[60] The Stabilisation of Water as a Ligand in Lithiated Organic Compounds: Inter- and Intra-Molecular Hydrogen Bonding in the Crystal Structures of [C_6H_4OC(···S)···NLi·HMPA·H_2O]$_2$ and [C_6H_4OC(···S)···NLi·HMPA]$_2$·H_2O: D. R. Armstrong, D. Barr, P. R. Raithby, P. v. R. Schleyer, R. Snaith, D. S. Wright, *Inorg. Chim. Acta* **1991**, *185*, 163−167.

[61] Alkaline Earth Metal Complexes Containing Deprotonated Organic Acids and Water: Preparation, Structures and a New Synthetic Strategy: P. Mikulcik, P. R. Raithby, R. Snaith, D. S. Wright, *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 428−430.

[62] Mixed-Anion Aggregates of Metalated Organics: Preparation and Crystal Structure of the Mixed-Anion Tetramer (PhO$^-$Li$^+$·HMPA)$_3$·(μ_3-HMPA·Li$^+$)·NCS$^-$: P. R. Raithby, D. Reed, R. Snaith, D. S. Wright, *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1011−1013.

[63] Capturing Platinum(II) Chloride Using a Side-arm Donating Calcium Complex: Synthesis and Structure of $[(HMPA)_3Ca(\mu_2\text{-}Cl)_3Ca(HMPA)_3]^+\cdot\{Pt[C_6H_4OC(\cdots S)\cdots N]_4\cdot CaCl]$: M. G. Davidson, P. R. Raithby, R. Snaith, D. Stalke, D. S. Wright, *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1643−1650.

[64] Dilithiation of a Primary Amine: Synthesis and Crystal Structure of a Paramagnetic Li_{20} Aggregate $(NaphthylNLi_9)_{10}\cdot(Et_2O)_6\cdot(Et_2O)$: D. R. Armstrong, D. Barr, W. Clegg, S. R. Drake, R. J. Singer, R. Snaith, D. Stalke, D. S. Wright, *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1707−1709.

[65] Synthesis, Structure, MO Calculational Investigations of a Highly Stable, Hydrogen-bonded Primary Amine:Phosphane Oxide Adduct, 2-aminobenzothiazole:HMPA; a Possible Model to Explain the Carcinogenicity of HMPA: D. R. Armstrong, S. Bennett, M. G. Davidson, R. Snaith, D. Stalke, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1992**, 262−264.

[66] The First Calcium-Mercury Co-Complex: Synthesis and Crystal Structure: M. G. Davidson, S. C. Llewellyn, M.-I. Lopez-Solera, P. R. Raithby, R. Snaith, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1992**, 573−575.

[67] Metal-mediated Conversion of a 5-Aminothiatriazole into a 5-Mercaptotetrazolyl Ligand by Reaction with a Solid Metal Hydroxide: Synthesis and Crystal Structure of $[NaphthylNN{=}NN\cdots C(\cdots S)]_2Ba\cdot 3HMPA$: F. A. Banbury, M. G. Davidson, A. Martin, P. R. Raithby, R. Snaith, K. L. Verhorevoort, D. S. Wright, *J. Chem. Soc., Chem. Commun.* **1992**, 1152−1154.

[68] Lithiation and Dethiacarbonylation of a Hetcrocyclic Thioamide $C_6H_4OC(=S)NH$ by Reaction with Solid Li_2S in the Presence of HMPA: Synthesis and Crystal Structure of $[C_6H_4OC(=S)NLi\cdot HMPA]_2\cdot C_6H_4(OH)NH_2$: F. A. Banbury, M. G. Davidson, P. R. Raithby, R. Snaith, D. Stalke, *J. Chem. Soc., Chem. Commun.* **1992**, 1492−1494.

[69] Investigations on a 1:1 Adduct of 2-Aminobenzothiazole and DMPU: Subtle Variations in Hydrogen-Bond Acceptors Cause Spectacular Supramolecular Differences: D. R. Armstrong, M. G. Davidson, A. Martin, P. R. Raithby, R. Snaith, D. Stalke, *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 1634−1636.

[70] A Thiouracil-Ca^{2+} Complex Which Captures $PtCl_2$: Synthesis and Crystal Structure of $[(thiouracilyl)_2Ca\cdot 2DMSO\cdot H_2O]_2$, Containing Two Tautomeric Forms of the Thiouracilyl Anion: F. A. Banbury, M. G. Davidson, A. J. Edwards, M.-I. Lopez-Solera, P. R. Raithby, R. Snaith, D. Stalke, D. S. Wright, *Inorg. Chim. Acta* **1993**, *203*, 93−95.

[71] Metalations of 1-Aminonaphthalene with $AlMe_3$ and with $ZnEt_2$: Syntheses and Crystal Structures of Cyclobutane-like $[Me_2AlNHnaphthyl]_2$ and Cyclohexane-like $[EtZnNHnaphthyl\cdot THF]_3$: M. G. Davidson, D. Elilio, S. L. Less, A. Martin, P. R. Raithby, R. Snaith, D. S. Wright, *Organometallics* **1993**, *12*, 1−3.

[72] General Equations for Determining Equilibrium Constants and Thermodynamic Data from Solution Molecular Mass Measurements: M. G. Davidson, R. Snaith, D. Stalke, D. S. Wright, *J. Org. Chem.* **1993**, *58*, 2810−2816.

[73] A New Bonding Mode for the Thiocyanate Ligand: Structure of the $[LiNCS\cdot Me_2N(CH_2)_3NMe_2]_2$ Dimer with Asymmetric NCS-Bridge Bonding: D. R. Armstrong, A. H. Khandelwal, P. R. Raithby, R. Snaith, D. Stalke, D. S. Wright, *Inorg. Chem.* **1993**, *32*, 2132−2136.

[74] Dilithiation of Aromatic Diamines Leads to Self Recognition of Monomeric Units and Assembly of "Adamantanoid" Metal Cores: The Synthesis and Structural Characterisation of the Dimeric Lithium Amide Complexes $\{[MeOCH_2CH_2N(Li)C_6H_4]_2O\}_2$ and $\{[Me_2NCH_2CH_2N(Li)C_6H_4]_2O\}_2$: I. Cragg-Hine, M. G. Davidson, O. Kocian, F. S. Mair, E. Pohl, P. R. Raithby, R. Snaith, N. Spencer, J. F. Stoddart, *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1182−1184.

[75] Monometallation of a Di(aminoaryl)ether Induces a Smiles Rearrangement Leading to a Sodium Aryloxide Complex: the Synthesis and Crystal Structure of $[(MeOCH_2CH_2)(C_6H_4NHCH_2OMe)NC_6H_4ONa]_2$: I. Cragg-Hine, M. G. Davidson, O. Kocian, T. Kottke, F. S. Mair, R. Snaith, J. F. Stoddart, *J. Chem. Soc., Chem. Commun.* **1993**, 1355−1357.

[76] The First Structurally Characterised Early Main Group Metal Diaza-allyl Complex: Synthesis and Crystal Structure of $LiCPh(NPh)_2\cdot$PMDETA: I. Cragg-Hine, M. G. Davidson, F. S. Mair, P. R. Raithby, R. Snaith, *J. Chem. Soc., Dalton Trans.* **1993**, 2423−2424.

[77] An Unusual Co_2-Containing Anion: Synthesis and Structure of $[(OxS)Ca\cdot 4HMPA]^+\cdot[(OxS)Co\cdot\mu\text{-}(OxS)_3\cdot CoCl]^-$ $[OxS^- = C_6H_4O\cdot(C\cdots S)\cdots N^-$; $HMPA = O{=}P(NMe_2)_3]$: M. G. Davidson, M. Gerloch, S. C. Llewellyn, P. R. Raithby, R. Snaith, *J. Chem. Soc., Chem. Commun.* **1993**, 1363−1364.

[78] Structure of Bis(pentamethyldiethylenetriamine)disodium Hexasulfide: S. Besser, R. Herbst-Irmer, D. Stalke, A. T. Brooker, R. Snaith, D. S. Wright, *Acta Crystallogr., Sect. C* **1993**, *49*, 1482−1483.

[79] Synthesis and Structure of a Sixteen-Membered $Al_4(NCO)_4$ Ring Compound: C. M. Bird, C. Breheny, M. G. Davidson, A. J. Edwards, S. C. Llewellyn, P. R. Raithby, R. Snaith, *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1433−1484.

[80] The First Lithiated Cyanamide Structure; Synthesis of $(PhNCNLi\cdot HMPA)_n$ by Extrusion of N_2 and S from 5-Phenylamino-1,2,3,4-thiatriazole $PhNHC{=}NN{=}NS$ using Various Lithium Reagents and HMPA: D. R. Armstrong, F. A. Banbury, I. Cragg-Hine, M. G. Davidson, F. S. Mair, E. Pohl, P. R. Raithby, R. Snaith, *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1769−1771.

[81] On Enantioselective Deprotonation: Synthesis and Crystal Structure of a Chiral Amidolithium Tetrahydrofuran Complex: A. J. Edwards, S. Hockey, F. S. Mair, P. R. Raithby, R. Snaith, N. S. Simpkins, *J. Org. Chem.* **1993**, *58*, 6942−6943.

[82] Thermal Decomposition of Lithium Amides: A Matrix Isolation Investigation: R. Withnall, I. R. Dunkin, R. Snaith, *J. Chem. Soc., Perkin Trans. 2* **1994**, 1973−1977.

[83] η^3- and η^6-Bridging Cations in the Pentamethyldiethylenetriamine-Solvated Complexes of Benzylpotassium and Benzylrubidium: an X-ray, NMR and MO Study: D. Hoffmann, W. Bauer, F. Hampel, N. J. R. van Eikema Hommes, P. v. R. Schleyer, P. Otto, U. Pieper, D. Stalke, R. Snaith, D. S. Wright, *J. Am. Chem. Soc.* **1994**, *116*, 528−536.

[84] The First Structurally Characterised Sodium Primary Amide Complex: Synthesis and Crystal Structure of $2\text{-}PhOC_6H_4NHNa\cdot NMe[(CH_2)_2NMe_2]_2$: I. Cragg-Hine, M. G. Davidson, A. J. Edwards, P. R. Raithby, R. Snaith, *J. Chem. Soc., Dalton Trans.* **1994**, 2901−2902.

[85] Synthesis and Crystal Structure of a 1D-sodium Coordination Polymer: $[NaL^4(PMDETA)]_\infty$: R. W. Saalfrank, O. Struck, M. G. Davidson, R. Snaith, *Chem. Ber.* **1994**, *127*, 2489−2492.

[86] Self-Assembly in the Metallation of Bis(aminoaryl)Ethers: O. Kocian, N. Spencer, J. F. Stoddart, I. Cragg-Hine, M. G. Davidson, F. S. Mair, P. R. Raithby, R. Snaith, T. Kottke, E. Poll, *Tetrahedron* **1995**, *51*, 579−590.

[87] The First Solid-State Structure of a Mixed-Anion ROLi/LiOH Compound: $(t\text{BuOLi})_{10}\cdot(LiOH)_6$: C. Lambert, F. Hampel, P. v. R. Schleyer, M. G. Davidson, R. Snaith, *J. Organomet. Chem.* **1995**, *487*, 139−141.

[88] Aggregation of Metallated Organics by Hydrogen Bonding: Synthesis and Crystal Structures of 2-Aminophenoxy-aluminium and Salen-aluminium Ligand-separated Ion Pairs: M. G. Davidson, C. Lambert, M.-I. Lopez-Solera, P. R. Raithby, R. Snaith, *Inorg. Chem.* **1995**, *34*, 3765−3779.

[89] The Occurrence of Both Amide and Thiolate Forms of the 2-Mercaptobenzoxazolyl Anion ($C_7H_4ONS^-$) in the Same Molecule: Synthesis and Crystal Structure of $C_7H_4ONSNa[(\mu\text{-}OP(NMe_2)_3]_3NaC_7H_4ONS$: F. A. Banbury, M. G. Davidson, P. R. Raithby, D. Stalke, R. Snaith, *J. Chem. Soc., Dalton Trans.* **1995**, 3139−3142.

[90] Synthetic, Structural, Spectroscopic and Calculational Studies of a Lithium β-Diketinimate Complex: F. S. Mair, D. Scully, A. J. Edwards, P. R. Raithby, R. Snaith, *Polyhedron* **1995**, *14*, 2397−2401.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

[91] An Investigation of the Lithium Species Present during the CO_2-Protected/Directed α-Lithiation and Subsequent α-Substitution of Heterocyclic Amines: S. C. Ball, I. Cragg-Hine, M. G. Davidson, R. P. Davies, A. J. Edwards, M.-I. Lopez-Solera, P. R. Raithby, R. Snaith, *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 921−923.

[92] The First Dilithiated Salen Complexes: Chiral $(SalenLi_2{\cdot}HMPA)_2$ and Deliberate Partial Hydrolysis to give $(SalenLi_2)_3{\cdot}Li_2O{\cdot}(TMEDA)_2{\cdot}H_2O$: S. C. Ball, I. Cragg-Hine, M. G. Davidson, R. P. Davies, M.-I. Lopez-Solera, P. R. Raithby, D. Reed, R. Snaith, E. M. Vogl, *J. Chem. Soc., Chem. Commun.* **1995**, 2147−2149.

[93] The Isolation and Structure of a Highly Stable, Metallation-Resistant and Multiply Hydrogen-Bonded Sulfonylamide-Phosphane Oxide Adduct, $PhSO_2CH_2C(=O)NH_2{\cdot}O=P(NMe_2)_3$: I. Cragg-Hine, M. G. Davidson, A. J. Edwards, E. Lamb, P. R. Raithby, R. Snaith, *Chem. Commun.* **1996**, 153−154.

[94] A Stable Methyl Phosphane Oxide-Lithium Amide Complex: a Structural, MO Calculational Investigation of the Mechanism of Proton Abstraction by Alkali Metal Reagents: D. R. Armstrong, M. G. Davidson, R. P. Davies, H. J. Mitchell, R. M. Oakley, P. R. Raithby, R. Snaith, S. Warren, *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 1942−1944.

[95] The Mechanisms of Dilithiation Reactions in Organic Syntheses: a Case Study Based on the Syntheses of Ketene Dithioacetals: S. C. Ball, I. Cragg-Hine, M. G. Davidson, R. P. Davies, P. R. Raithby, R. Snaith, *Chem. Commun.* **1996**, 1581−1582.

[96] Structural Models for Lithium Intermediates During Carboxamide-Directed Metallations: M. G. Davidson, R. P. Davies, P. R. Raithby, R. Snaith, *Chem. Commun.* **1996**, 1695−1696.

[97] A Likely Intermediate During the CO_2-Induced Activation of 2-Alkylindoles Towards Electrophilic Substitution: Structure of a Unique Tetramer Formed by Joining Two Boat-shaped $(LiOCO)_2$ Rings: R. P. Davies, P. R. Raithby, R. Snaith, *Organometallics* **1996**, *15*, 4355−4356.

[98] Role of Bifunctional N/S Bridging in the Association of Metals; Syntheses and Structures of Heterobimetallic $[(Ph_3P_2)CuL_2Li(THF)_2]{\cdot}$thf and Tetrameric $[CuL(PPh_3)]_4$ (L= 1,3-benzoxazoline-2-thionate): M. A. Beswick, C. Brasse, M. A. Halcrow, P. R. Raithby, C. A. Russell, A. Steiner, R. Snaith, D. S. Wright, *J. Chem. Soc., Dalton Trans.* **1996**, 3793−3797.

[99] An Experimental, MO Calculational Study of the Stereoselective Horner−Wittig Reaction with Phosphane Oxides: Control of Stereoselectivity by Lithium: D. R. Armstrong, D. Barr, M. G. Davidson, G. Hutton, P. O'Brien, R. Snaith, S. Warren, *J. Organomet. Chem.* **1997**, *529*, 29−33.

[100] Lithiated Amidines: Syntheses and Structural Characterisations: J. Barker, D. Barr, N. D. R. Barnett, W. Clegg, I. Cragg-Hine, M. G. Davidson, R. P. Davies, S. M. Hodgson, J. A. K. Howard, M. Kilner, C. W. Lehmann, M.-I. Lopez-Solera, R. E. Mulvey, P. R. Raithby, R. Snaith, *J. Chem. Soc., Dalton Trans.* **1997**, 951−955.

[101] A Unique Li_{12}-Aggregate Containing Both $-NL_2$ and −CHLi~NLi Units: S. C. Ball, J. Cobb, R. P. Davies, P. R. Raithby, G. P. Shields, R. Snaith, *J. Organomet. Chem.* **1997**, *534*, 241−245.

[102] The Remarkable Product of Using a Large Excess of *n*-Butyllithium to Lithiate a Simple Amine: $(Ph_2NLi){\cdot}[[Ph(C_6H_4Li)NLi]_2{\cdot}(nBuLi)_2{\cdot}(Et_2O)_4$: R. P. Davies, P. R. Raithby, R. Snaith, *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 1215−1217.

[103] Inhibition of the Cyclotrimerisation of Benzonitrile: Structure of a New Tetrameric α-Amino Lithium Imide Demonstrating *Intra*-Monomer Stabilisation of the Metal Centres: R. P. Davies, P. R. Raithby, G. P. Shields, R. Snaith, A. E. H. Wheatley, *Organometallics* **1997**, *16*, 2223−2225.

[104] The First Lithiated Phosphane Oxide with Li−C Bonds: Synthesis and Structure of $[Ph_2P(O)CHLiC(H)MeEt]_4$: J. E. Davies, R. P. Davies, L. Dunbar, P. R. Raithby, M. G. Russell, R. Snaith, S. Warren, A. E. H. Wheatley, *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 2334−2335.

[105] The Synthesis and Novel Structure of the First Crystallographically Characterised Chiral α-Amino Lithium Alkoxide: J. E. Davies, P. R. Raithby, R. Snaith, A. E. H. Wheatley, *Chem. Commun.* **1997**, 1721−1722.

[106] Reaction of an Alkynyllithium Reagent with Boron Trifluoride: the Structure of a Likely Intermediate in Alkynyl Anion Chemistry: J. E. Davies, P. R. Raithby, R. Snaith, A. E. H. Wheatley, *Chem. Commun.* **1997**, 1797−1798.

[107] Lithiations of Phosphane Oxides: D. R. Armstrong, R. P. Davies, L. Dunbar, P. R. Raithby, R. Snaith, A. E. H. Wheatley, *Phosphorus, Sulfur, and Silicon* **1997**, *124−125*, 51−62.

[108] A Structural and Theoretical Study of the Mono-Lithiation of Hydroxylamines: D. R. Armstrong, W. Clegg, S. M. Hodgson, R. Snaith, A. E. H. Wheatley, *J. Organomet. Chem.* **1998**, *550*, 233−240.

[109] The Mechanism of Lithiation and Nitrile Insertion Reactions of β-Methylazines: Evidence from the Structure of $3\text{-}C_5H_4NCH{=}C(Ph)N(H)C(Ph){=}NLi{\cdot}PMDETA$, S. C. Ball: R. P. Davies, P. R. Raithby, G. P. Shields, R. Snaith, *J. Organomet. Chem.* **1998**, *550*, 457−461.

[110] The First Solid-State Structure of a Simple Lithiated Diazomethane with C−Li Bonds: $\{[Me_3SiC(Li)N_2]_2{\cdot}3THF\}_\infty$: N. Feeder, M. A. Hendy, P. R. Raithby, R. Snaith, A. E. H. Wheatley, *Eur. J. Org. Chem.* **1998**, 861−864.

[111] First Structurally Characterised Lithium Hexafluorophosphate Complexes with Acyclic Lewis Bases: Ion-separated $[Li_2(HMPA)_5]^{2+}{\cdot}2(PF_6^-)$ and Ion-contacted $[(PMDETA)LiPF_6]_2$: D. R. Armstrong, A. H. Khandelwal, L. C. Kerr, S. Peasey, P. R. Raithby, G. P. Shields, R. Snaith, D. S. Wright, *Chem. Commun.* **1998**, 1011−1012.

[112] The First Structural Studies on Trithiocyanuric Acid: the Solid-State Structures of its HMPA Adduct and its Monolithiated HMPA Complex: W. Clegg, J. E. Davies, M. R. J. Elsegood, E. Lamb, J. J. Longridge, J. M. Rawson, R. Snaith, A. E. H. Wheatley, *Inorg. Chem. Commun.* **1998**, *1*, 58−60.

[113] Reaction of *ortho*-Methylbenzonitrile with Lithium Trimethylethylenediamide: Assembly and Crystal Structure of a Primary Isoquinolinoamidolithium-Secondary Amine Complex: N. Feeder, R. Snaith, A. E. H. Wheatley, *Eur. J. Inorg. Chem.* **1998**, 879−883.

[114] The Synthesis and Solid-state and Solution Structures of an Unprecedented Mixed Chiral α-Amino Lithium Alkoxide-Lithium Alkoxide Aggregate: Evidence for Intermolecular LiH Transfer: W. Clegg, S. T. Liddle, R. Snaith, A. E. H. Wheatley, *New J. Chem.* **1998**, *22*, 1323−1326.

[115] Dynamic Processes in Organolithium Chemistry: Tetrameric and "Open" Tetrameric Chiral α-Amino Lithium Alkoxides: D. R. Armstrong, J. E. Davies, R. P. Davies, P. R. Raithby, R. Snaith, A. E. H. Wheatley, *New J. Chem.* **1999**, *23*, 35−41.

[116] Towards an Understanding of the Conjugate Addition of Organolithium Reagents to α,β-Unsaturated Ketones: the Isolation and Solid-State Structure of a Monomeric Lithium Aluminate with Very Short Agostic Li···HC Interactions: W. Clegg, E. Lamb, S. T. Liddle, R. Snaith, A. E. H. Wheatley, *J. Organomet. Chem.* **1999**, *573*, 305−312.

[117] Hexameric Chiral α-Amino Lithium Alkoxides: a Solid-state and Theoretical Structural Investigation: D. R. Armstrong, R. P. Davies, P. R. Raithby, R. Snaith, A. E. H. Wheatley, *New J. Chem.* **1999**, *23*, 499−507.

[118] Lithiated Organophosphorus Enamines: A New Synthetic Approach and the First Crystal Structures: W. Clegg, R. P. Davies, L. Dunbar, N. Feeder, S. T. Liddle, R. E. Mulvey, R. Snaith, A. E. H. Wheatley, *Chem. Commun.* **1999**, 1401−1402.

[119] The First Molecular Main Group Metal Species Containing Interstitial Hydride: W. Clegg, R. P. Davies, S. T. Liddle, D. J. Linton, P. R. Raithby, R. Snaith, A. E. H. Wheatley, *Angew. Chem. Int. Ed.* **1999**, *38*, 3367−3370.

[120] Structural studies of the chiral lithium amides $[\{PhC(H)Me\}_2NLi]$ and $[PhCH_2\{PhC(H)Me\}NLi{\cdot}THF]$ de-

Patents

[146] (a) Alkali Metal Salt Complexes Synthesised by the Ammonium Salt Route. Preliminary Patent filed by Associated Octel Co. Ltd., Ellesmere Port, U.K. Inventors named, R. Snaith, D. S. Wright. (b) European Patent No. 88309913.7, **1987**, R. Snaith, D. S. Wright.

[147] (a) Alkaline-Earth, Lanthanide, and Transition Metal Salt Complexes Synthesised by the Ammonium Salt Route. Preliminary Patent filed by the Associated Octel Co. Ltd., Ellesmere Port, U.K. Inventors named, A. T. Brooker, S. R. Drake, R. Snaith, D. S. Wright. (b) European Patent No. 8915531.1, 1989. A. T. Brooker, S. R. Drake, R. Snaith, D. S. Wright.

[148] (a) Alkali Metal Salt Complexes Synthesised by the Metal/Non-Metal *In Situ* Route. Preliminary Patent filed by the Associated Octel Co. Ltd., Ellesmere Port, U.K. Inventors named, A. T. Brooker, S. R. Drake, R. Snaith, D. S. Wright. (b) European Patent No. 8911600.8, 1989. A. T. Brooker, S. R. Drake, R. Snaith, D. S. Wright.

[149] Method for the Preparation of Aquo and other Small Protic Lewis Base Complexes of Metal Salts of Organic Acids. Preliminary Patent filed by Associated Octel Co. Ltd., Ellesmere Port, U.K. Inventors named, M. G. Davidson, R. Snaith, D. S. Wright. Filed 1991.

Toroidal Main Group Macrocycles: New Opportunities for Cation and Anion Coordination

Emma L. Doyle,[a] Lucía Riera,[a] and Dominic S. Wright*[a]

Dedicated to the memory of Dr. Ron Snaith

Keywords: Coordination chemistry / Macrocycles / Main group elements / Synthesis

Inorganic macrocycles, possessing molecular frameworks composed entirely of elements other than carbon, are rare. Even rarer are species analogous to classical organic macrocycles (like crown ethers) that possess the potential ability to coordinate metal ions within their cavities. Recent studies reveal an emerging structural class of valence-isoelectronic main-group ligands of general formula $[\{E(\mu\text{-}E'R)\}_2Y]_n^{x-}$, which possess fascinating coordination characteristics. Such species can coordinate metal ions within their cavities (using the donor centres Y and E′), their peripheral donor centres (E′) (in an *exo* fashion) and are also capable of coordinating anions (where Y = N–H). This short review highlights the recent synthetic and structural studies of these unusual ligand systems and pinpoints potential future areas of development.

Introduction

Classical macrocyclic ligands based essentially on carbon backbones (such as crown ethers, calixarenes and cyclophanes) have a central role in modern coordination chemistry.[1] Modification of the donor or acceptor atoms (or groups) within these arrangements has provided an ever-growing class of ligand arrangements which are capable of coordinating cations,[2] anions or neutral guest molecules.[3] In contrast, "inorganic" counterparts whose frameworks are constructed from elements other than carbon are still relatively rare, and their coordination behaviour has been little studied. There are a number of obvious reasons for this situation. Firstly and perhaps most importantly, owing to the greater range of available orbitals and hybridisation states, a far more diverse range of bonding connectivities

[a] Chemistry Department, University of Cambridge
Lensfield Road, Cambridge CB2 1EW, U.K.

Emma L. Doyle was born in Chatham, Kent in England in 1977. She obtained her BA (Hons) in Natural Sciences in 1999 and an MSc in Chemistry in 2000 from Cambridge University. She is currently pursuing her Ph.D. at Cambridge University under the supervision of Dr. Dominic S. Wright where she is studying cyclodiphosph(III)azane chemistry. Her research interests include the study of phosphorus−nitrogen based macrocycles and the future prospects of these for host−guest and Lewis base coordination. Particular interest is in the potential selectivity of anion coordination.

Lucía Riera was born in Zaragoza, Spain in 1974. She obtained her first degree in 1997 at the University of Oviedo and completed her M.Sc. (Tesina) in Oviedo in 1998. Her Ph.D. was undertaken in Oviedo under the supervision of Julio Antonio Peréz Martínez and was obtained in 2002. She joined the Wright group in October of that year and is currently funded by an E.U. fellowship.

Dominic S. Wright obtained his first degree in Pure and Applied Chemistry at the University of Strathclyde (1982−1986). He then studied for his Ph.D. alkali metal salt complexes under the supervision of the late Dr. Ron Snaith at Cambridge University (1986−1989). After a period as a Research Fellowship at Gonville and Cauis College, Cambridge (1989−1991), he became a lecturer in Inorganic Chemistry at Cambridge. He was promoted to Reader in Inorganic Chemistry in October 2002. Dr. Wright has published extensively in the area of main-group and transition-metal chemistry, specialising in the development of new p-block element ligand systems, the chemistry of p-block cyclopentadienyl anions and the chemistry of main-group and transition-metal imido and phosphide complexes.

MICROREVIEWS: This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

and geometries are characteristic of elements after the first period of the periodic table. An associated feature is the availability of various oxidation states. These factors make rational design of cyclic systems complicated and often limit the applications of synthetic stategies. A second factor is the commonly lower thermodynamic stability and polar nature of bonds to these elements, leading to thermodynamically less robust and/or kinetically more labile ligand arrangements.

Of the few inorganic macrocycles so far investigated the most common type are acceptors (or Lewis acids), particularly those based on electropositive metals.[4−6] An example of this class recently reported are the so-called "inverse-crowns" investigated by Mulvey and co-workers.[4] These macrocyclic, (mainly) alkali or alkaline earth metal amides have been shown to be capable of coordinating various inorganic and organic anions within their cavities. The complex $[(tmp)_6Na_4Mg_2(C_6H_3CH_3)]$ (**1**) (Figure 1) is a particularly interesting example that illustrates a fascinating feature of inverse crowns, the ability to stabilise and direct the formation of highly unusual organic anions (in this case a 2,5-deprotonated $[C_5H_4CH_3]^{2-}$ dianion). Conceptually related mercury(II) metallacarborands investigated earlier by Hawthorne and co-workers are examples of rigid ligand frameworks of this type, which are capable of anion-selective behaviour (an example of which is shown in Figure 2).[5]

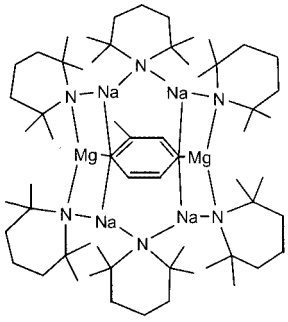

Figure 1. Structure of the inverse crown $[(tmp)_6Na_4Mg_2(C_6H_3CH_3)]$ (**1**), with coordination of a 2,5-deprotonated toluene at the center of the cavity

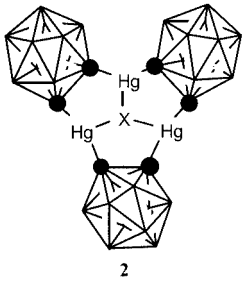

Figure 2. Structure of a trimeric mercury(II) metallacarborand coordinating a halide ion (X) within the cavity

Far rarer than Lewis acidic inorganic arrangements are macrocycles which (like crown ethers) are potentially capable of cation coordination. Examples of this type include organophosphorus macrocycles, such as the octamer $[1,2\text{-}C_6H_4P_2]_8$, composed of a 16-membered ring of P atoms, and the tetrameric anion $[1,2\text{-}C_6H_4P_2]_4^{4-}$.[7] In addition, a few macrocyclic cyclophosph(v)azanes, such as $[(Me_2N)_2PN]_6$, are also known.[8] Our interest in the area of inorganic macrocycles has derived from a general interest in inorganic donor ligands based on p-block element/nitrogen and phosphorus frameworks.[9,10] This short review aims to highlight an emerging class of structurally related, valence-isoelectronic p-block macrocycles of general formulae $[\{E(\mu\text{-}E'R)\}_2Y]^{x-}$ (Figure 3), in which dimeric $\{E(\mu\text{-}E'R)\}_2$ ring units are bridged into neutral or anionic cyclic arrangements via heteroatomic groups or atoms (Y).

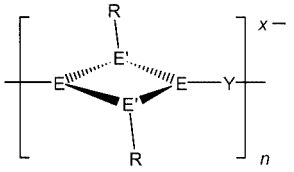

Figure 3. Structural arrangement of the macrocycles

An early indication of the existence of this structural class of macrocycles was provided by the seminal work of Scherer et al., who showed that the phosph(III)azane $[\{P(\mu\text{-}N\mathit{i}Pr)\}_2N\mathit{i}Pr]_2$ (**3**) is obtained by the thermolysis reaction of $[ClP(\mu\text{-}N\mathit{i}Pr)_2PN(\mathit{i}Pr)(SiMe_3)]$ (Scheme 1).[11] More recently, it has been shown that the similar dimeric macrocycle $[\{P(\mu\text{-}N\mathit{t}Bu)\}_2N\mathit{t}Bu]_2$ (**4**) can be obtained by the reaction of the symmetric dimer $[ClP(\mu\text{-}N\mathit{t}Bu)]_2$ with $[\mathit{t}BuNP(\mu\text{-}N\mathit{t}Bu)]_2^{2-}$ (Scheme 2).[12] A. D. Norman and co-workers were the first to suggest that smaller chain and cyclic arrangements of this kind may represent homologues of a broader family of compounds.[13] However, prior to our studies cyclic arrangements had been restricted to dimeric macrocycles of group-15 elements only.

Higher Homologues of Group 15

Our interest in macrocyclic species of this type came about by the chance discovery that the deprotonation reaction of the lithium tris(amidostannate) $[Sn(HNma)_3Li{\cdot}2thf]$ (H_2Nma = 2-methoxyaniline) (**5**) with $Sb(NMe_2)_3$ gives the hexameric macrocycle $[\{Sb(\mu\text{-}Nma)\}_2(\mu\text{-}Nma)]_6$ (**6**), rather than the anticipated heterometallic cage $[Sb(\mu\text{-}Nma)_3Sn]Li$ (**7**).[14] This reaction presumably occurs by elimination of $[Sn(NMe_2)_3Li]$ as a "leaving group" (Scheme 3).[15] Interestingly, **6** can also be obtained by the transmetallation reaction of the $[Sb(Nma)_3]^{3-}$ trianion with $SbCl_3$, a process which can be seen as an inorganic example of masked functionality (Scheme 4).[16]

The solid-state structure of **6** (Figure 4) has an all-*trans* arrangement of the dimer units and a macrocyclic cavity of ca. 13.8 Å (measured between opposite Sb^{III} centers). This was the first example of a higher oligomer of this type for

group 15. More recently, N. C. Norman and co-workers showed that the similar hexameric macrocycle $[\{Sb(\mu\text{-}NPh)\}_2(\mu\text{-}NPh)]_6$ (**8**) can be readily prepared by the reaction of $SbCl_3$ with PhHLi.[17] The observation of hexameric ring units for both **6** and **8**, rather than dimeric macrocycles like **3** and **4**, gives a fundamental clue to the factors directing ring sizes of the homologues $[\{E(\mu\text{-}NR)\}_2NR]_n$.

In considering the formation of higher homologues of the type $[\{E(\mu\text{-}NR)\}_2NR]_n$ (with $n > 2$, like **7** and **8**), a number of factors need to be considered. Perhaps the most important factor influencing the size of macrocycle obtained is the steric demands of the organic substituents (R). The steric influence of the dimer-bridging NR groups is likely to be most critical in this respect. As depicted in Figure 5, for dimeric ($n = 2$) macrocycles the disposition of dimer-bridging NR groups *exo* to the cavity will minimise steric congestion. This dimeric structure is likely to be observed for R groups with moderately large steric demands (as is the case with **3** and **4**). However, in order to sustain the *exo* orientation of these groups for higher homologues ($n > 2$) some or all of the $[P(\mu\text{-}NR)]_2$ units will have to adopt *trans* orientations. This situation is likely to lead to increased ring strain for intermediately sized macrocycles. As the size of the macrocycle increases increased preference for *trans* conformations of the ring units is expected in order to minimise ring strain and at the same time prevent unfavourable *endo* orientation of the dimer-bridging NR groups. These simple considerations therefore suggest that macrocycles of the type $[\{E(\mu\text{-}NR)\}_2NR]_n$ are most likely to occur for $n = 2$ and for larger ring units, where an all-*trans* conformation of the dimeric ring units matches the geometric constraints (as presumably occurs for the hexameric macrocycles **6** and **8**).

A significantly different set of circumstances occurs where the dimer-bridging NR groups have very low steric demands. Now a *cis* configuration of the dimeric ring units can be sustained even for rings beyond $n = 2$. Such occurs

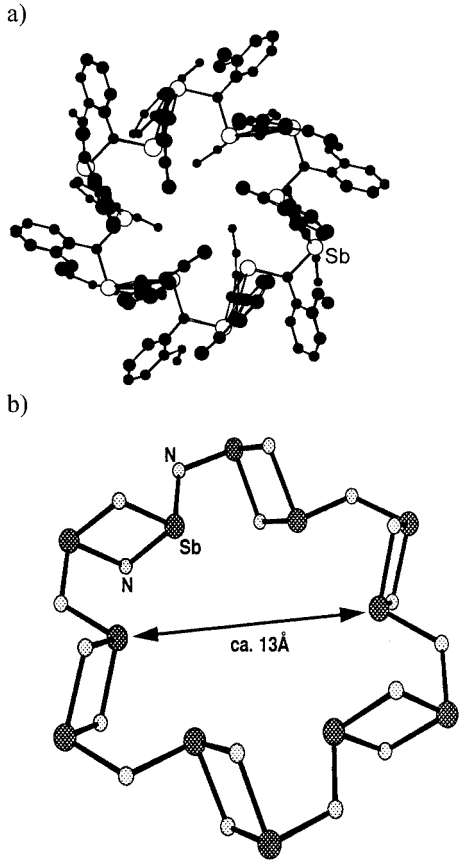

Figure 4. a) Structure of the hexamer **6**; b) core arrangement with ma groups removed

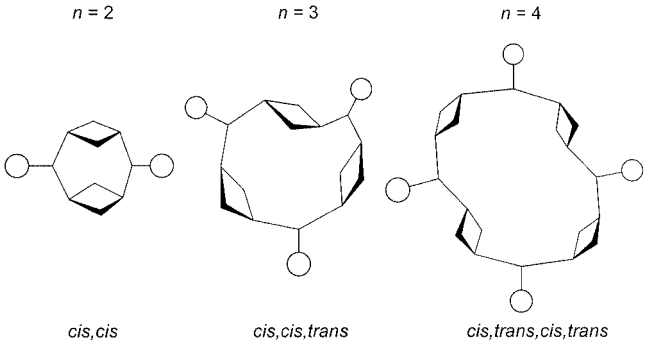

Figure 5. The transition from *cis* to *trans* conformations in macrocycles with increasing *n*

in the case of the tetrameric macrocycle $[\{P(\mu\text{-}NtBu)\}_2NH]_4$ (**9**) (Figure 6), obtained in almost quantitative yield (95−100%) from the condensation reaction of the symmetric dimers $[ClP(\mu\text{-}NtBu)]_2$ (**10**) and $[H_2NP(\mu\text{-}NtBu)]_2$ (**11**) in the presence of Et_3N (Scheme 5).[18] The *cis* conformations of the dimer ring constituents of **9** mean that the four N−H protons are now directed *endo* to the cavity, with the twelve P···P−N units defining the macrocyclic ring being almost in one plane. The transannular N···N separation between opposite pairs of N centers within the cavity of **9** differ by only ca. 0.05 Å, with the size of the cavity being ca. 5.22 Å. Presumably, the formation of a tetrameric macrocycle is a further consequence of the low steric demands of the dimer-bridging N−H groups of **9**, allowing aggegation to occur beyond simple dimers like **3** and **4.** The arrangement of **9** is reminiscent of organic ligands such as tetraazacyclotetradecanes (i.e., based on $[CH_2CH_2NH]_4$). However, the latter have significantly smaller cavities (range 4.07−4.29 Å).[19]

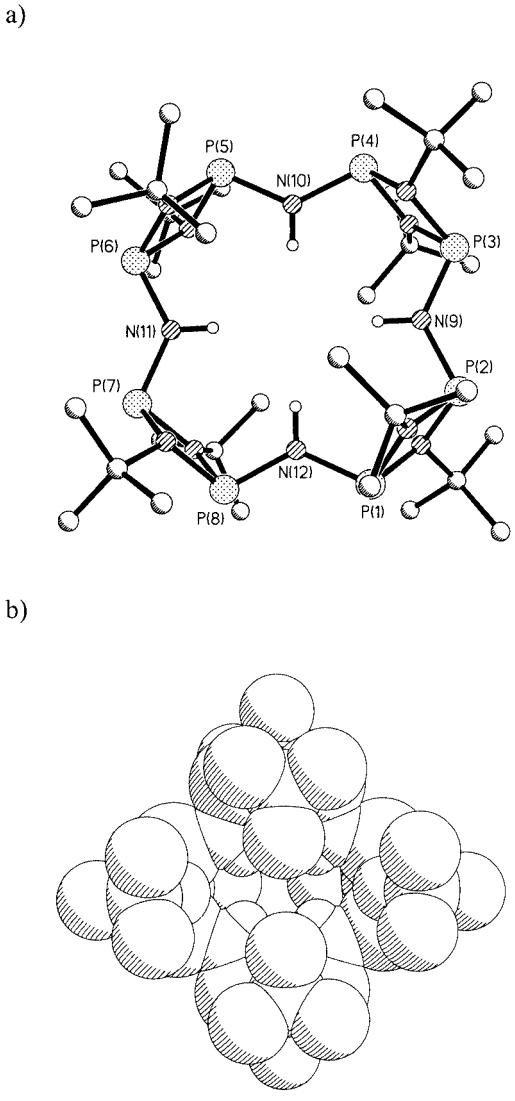

Figure 6. a) Structure of the tetramer **9**; b) space-filling diagram of **9** showing the crowding of the core

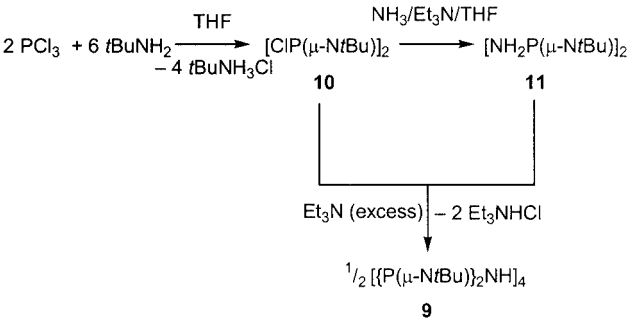

Scheme 5

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

An important kinetic feature involved in the formation of **9** is "pre-organisation" of the dimer precursors **10** and **11**. The latter have both been shown to adopt *cis* conformations of the Cl and NH_2 substituents in the solid state and solution.[20,21] Indeed, in the case of **11** this *cis* conformation results in cyclisation of the dimers in the solid state via N−H···N hydrogen bonding.[20] Pre-organisation is primarily responsible for the near quantitative formation of the macrocyclic arrangement of **9**, rather than of polymeric alternatives. This is a rare (if not unprecedented) example of pre-organisation for an inorganic system. A further aspect of the mechanism by which **9** is formed is indicated by the formation of minor amounts of the host−guest complex $[\{P(\mu\text{-}NtBu)\}_2NH]_5$·HCl (**12·HCl**) along with **9** in the condensation reaction of **10** and **11** (Figure 7).[20] Like **9**, the dimer units of **12·HCl** adopt *cis* conformations, with the complex being composed of the pentameric macrocyclic ring $[\{P(\mu\text{-}NtBu)\}_2NH]_5$ (**12**) coordinating an HCl unit at the centre of the cavity via five N−H···Cl hydrogen bonds to all of the dimer-bridging N−H groups (N···Cl mean 3.6 Å, H···Cl 2.57−2.66 Å). The arrangement of the five N−H groups towards the centre of the macrocyclic unit creates a cavity of ca. 6.8 Å in diameter (measured with respect to the N atoms of the ring). The structure of **12·HCl** is similar to host−guest adducts of sapphyrins (expanded porphyrins),[22] in particular the pentapyrrole−HF complex $[\{3\text{-Me-4-Et-pyrNH}\}_5(CH_2)_4\cdot F][PF_6]$ (pyrN = pyrrole) which contains a similar arrangement of five N−H groups surrounding a central F^- anion.[22c] However, the core sizes in these complexes are significantly smaller than that in **12** (at ca. 5.5 Å in the pentaporphyrins, with respect to the five N centres[22]).

The isolation of **12·HCl** indicates that, in addition to pre-organisation, the formation of **9** may also rely on templating by Cl^- ions in the reaction. Extensive in situ ^{31}P NMR spectroscopic studies of the reactions of the dimers **10** and **11** under various conditions show that **9** and **12·HCl** are not in dynamic equilibrium with each other.[20] The most likely mechanism by which **9** and **12·HCl** are formed is by a divergent pathway like that shown in Scheme 6. The growing chain effectively competes with Et_3N as the Brønsted base in this reaction, so that N−H···Cl hydrogen bonding templates cyclisation. The pivitol intermediate **I[4]** can either eliminate HCl in the presence of Et_3N to form **9** or react with another molecule of **11** to give **12·HCl**. It is noteworthy in this regard that the formation of a pentameric macrocycle would be impossible by a simple, stepwise condensation pathway involving **9** and **10**, for which only macrocycles containing an even number of ring units (*n*) could be obtained.

A further discovery made during these ^{31}P NMR spectroscopic investigations is that the formation of the pentamer **12** can be biased by addition of excess lithium halide salts.[20] The high concentration of halide ions present presumably supresses the elimination of HX involved in the formation of **9**. The ability for the halide ions to template the formation of **12** is in the order $I^- > Br^- > Cl^-$. In the case of LiI, only the host−guest complex **12·HI** is generated

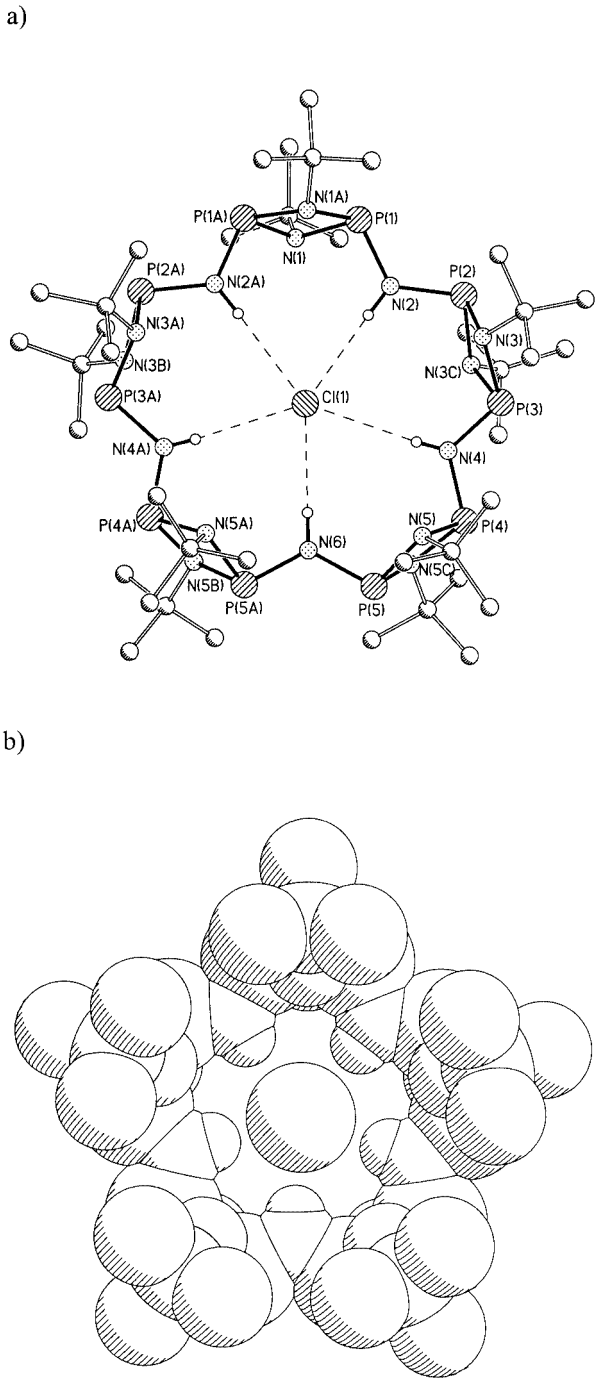

Figure 7. a) Structure of host−guest complex **12·HCl**; b) space-filling diagram of the molecule

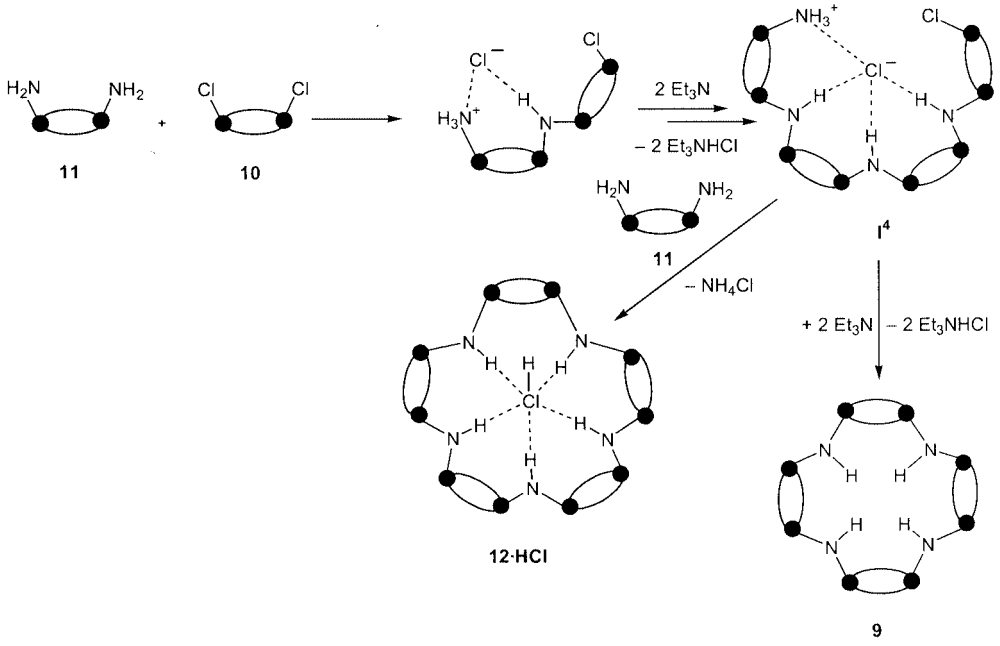
(without **9**). This observation is broadly consistent with the size of the macrocyclic cavity of **12** (ca. 6.8 Å), which appears to be better suited to coordination of I^- (typical N···I 3.46 Å) than Cl^- (typical N···Cl 3.00−3.20 Å).[23]

At first sight, it might be expected that the presence of *cis* subunits within macrocycles of the type $[\{P(\mu\text{-}NR)\}_2NH]_n$ would limit the ring size obtainable, since beyond a particular point addition of further units would result in unfavourable ring strain. However, the formation of the tetrameric

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

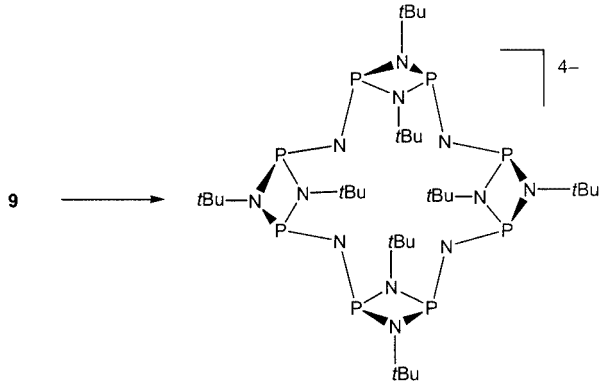


Scheme 6

and pentameric arrangements of **9** and **12** provides direct evidence that the dimeric [{P(μ-N*t*Bu)}$_2$NH] constituents of these macrocycles are in fact highly flexible. Relatively small changes in the endocyclic P−N−P and N−P−N angles within the [{P(μ-N*t*Bu)}$_2$NH] units, in the exocyclic N(*t*Bu)−P−NH angles, and in the puckering of the P_2N_2 ring units result in a significantly different bite distance (α) between adjacent N(−H) atoms within the tetramer **9** (mean 3.7 Å) compared to the pentamer **12** (mean 4.0 Å). For macrocycles like **9** and **12**, it can be shown that Equation (1) gives the relationship between the radius of the cavity (*r*) (expressed with respect to the N atoms), the number of [{P(μ-NR)}$_2$(NH)] units (*n*) and the bite distance (α). The effect of the increase in the bite distance in going from **9** to **12** (of 0.3 Å) therefore accounts for a ca. 0.2 Å increase in the size of the cavity (compared to the cavity size which would be present if the bite distance remained the same as in **9**).

$$r^2 = \frac{\alpha^2}{2(1 - \cos 2\pi/n)} \quad (1)$$

The ability of these macrocycles to coordinate anions within their cavities is witnessed in the structure of **12·HCl**. However, a more obvious potential property of macrocycles of this type is the coordination of metal cations. The attempted deprotonation of the tetramer **9** with various main-group reagents has so far failed to generate the desired tetraanion [{P(μ-N*t*Bu)}$_2$N]$_4^{4-}$ (Scheme 7).[24] In the case of s-block organometallic reagents (including MeLi, *t*BuLi and *n*BuLi), no reactions are observed. It can be noted that the dimer [*t*BuNHP(μ-N*t*Bu)]$_2$ (**13**) is fully deprotonated by *n*BuLi in toluene or THF.[12,25] Thus, the apparently low acidity of the N−H protons of **9** appears to stem from the extreme steric hindrance due to the *t*Bu groups, which fully shield the cavity to the approach of the base (Figure 6, b). With more forcing conditions, decomposition of the macrocyclic structure can arise. For example, the reaction of **9** with $PhCH_2K$ gives [*t*BuNHP(μ-N*t*Bu)]$_2$ (**13**) and/or [(*t*BuN)$_2$PK]$_\infty$ (**14**) as the only P-containing products (depending on the stoichiometry used).[24]



Scheme 7

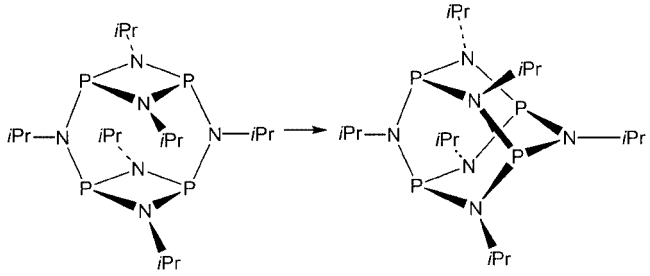
Nonetheless, macrocyclic anions can be generated by alternative synthetic approaches. For example, the reaction of the dimer [Me_2NSb(μ-NCy)]$_2$ (**15**) with "active" $LiNH_2$ (generated in situ from NH_3 and *n*BuLi) gives [{Sb(μ-NCy)}$_3$(Li·THF)$_3$(LiN=NH)] (**16**).[26] Remarkably, the trimeric [({Sb(μ-NCy)}$_2$N)$_3$]$^{3-}$ trianion of **16** is produced by double-deprotonation of the NH_2^- anion (according to Scheme 8). The unexpected presence of an N=NH$^-$ anion in this arrangement has been confirmed by IR and ^{15}N NMR spectroscopic studies. The X-ray crystallographic study of **16** shows that it contains a cone-shaped [({Sb(μ-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

NCy)}$_2$N)$_3$]$^{3-}$ trianion, which is reminiscent of the arrangement of coordinated or uncoordinated calixarenes (Figure 8).[1] This trianion coordinates one Li^+ cation within the macrocyclic cavity, using the anionic μ-N centres. The remaining four, symmetry-related Li^+ cations reside above the macrocyclic cavity and are coordinated by the anionic μ-N and neutral NCy centres. The $N{=}NH^-$ anion then caps the structure, along the virtual C_3 axis of the cage.

Macrocyclic and Adamantane Alternatives

In a previous study Scherer et al. had shown that the dimeric macrocycle [{P(μ-N*i*Pr)}$_2$N*i*Pr]$_2$ (**3**) reverts to adamantane alternative [P$_4$(μ$_3$-N*i*Pr)$_6$] (**17**) on prolonged heating in the solid state (Scheme 9).[11] In contrast, a more recent study of the related macrocycle [{P(μ-N*t*Bu)}$_2$N*t*Bu]$_2$ (**4**) showed that this species does not rearrange into the adamantane under similar conditions.[22b] These limited studies

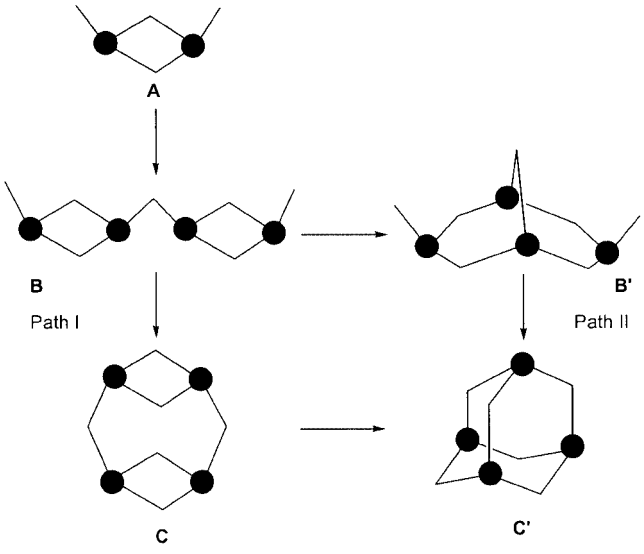


iPr
N
P
iPr
iPr
iPr

ring constituents maximise the space available. On the other hand, the six-membered ring constituents of the adamantane arrangement will result in an inherent increase in steric congestion, and such an arrangement is likely only to be formed where sterically less demanding sustituents are present. Although the mechanism by which **3** is converted into **17** is not known, as noted in Scheme 8 the rearrangement can be described by a facile "twist" of one of the (iPrN)P_2 units.

A recent study of the synthesis of the dimer [ClP(μ-Npy)]$_2$ (py = 2-pyridyl) (**18**) indicates the potential generality of this twist process in this area.[27] Attempts to prepare **18** from pyNHLi and PCl_3 in the presence of Et_3N give **18** together with the nonaphosphazane [$ClP_4(Npy)_5$] (**19**). Low-temperature ^{31}P NMR spectroscopic studies reveal that the reaction of **18** with pyNHLi/Et_3N gives **19**. The likely intermediate in this reaction is [{ClP(μ-Npy)P}$_2$(μ-Npy)] (**20**), the chain isomer of **19** which can also be detected prior to rearrangement (Scheme 10). DFT calculations on the rearrangement of the model chain species [{ClP(μ-NR)P}$_2$(μ-NR)] into the nonaphosphazanes [$ClP_4(NR)_5$] (R = H, Me) show that the thermodynamics of this reaction are dependent on the steric demands of the R group. The rearrangement being most favourable for least sterically demanding substituents.

This result gives a key insight into the relationship between various imidophosphazane frameworks that have been characterised previously. The relationship between these frameworks can be represented mechanistically in Scheme 11. It appears that there are two possible modes of reaction of imidophosphazane dimers **A**: Path I (leading to macrocyclic arrangements) or Path II (leading to adamantane arrangements). The twist process observed in the conversion of **20** into **19** is pivotal in the selection of the two alternative arrangements. As is the case in the rearrangement of the dimeric macrocycle [{P(μ-NiPr)}$_2$NiPr]$_2$ (**3**) into the adamantane [$P_4(\mu_3$-NiPr$)_6$] (**17**),[11] the steric demands of the R group is the decisive factor governing which Path (I or II) will be followed. The rearrangement of the chain isomer **B** into the nonaphosphazane **B′** is only favoured where sterically less demanding substituents are present, since otherwise the steric congestion would be too great within the six-membered ring units of the latter. Closure of **B′** with a further P center results in the adamantane structure **C**. In the case of sterically more demanding R groups, the dimeric ring units of **B** will be sustained on steric grounds. Closure with a further P center will lead to the macrocyclic isomer **C**.



Scheme 11

Whether the importance of steric factors in the formation of macrocyclic and adamantane alternatives will limit the range of organic substituents that can be introduced into larger macrocycles of the type [{P(μ-NR)}$_2$(NH)]$_n$ is not yet known. However, a recent study indicates one potential way by which the undesired adamantane pathway may be avoided. Coordination of CuCl to the P centers of the dimer [ClP(μ-Npy)]$_2$ (**18**) before cyclisation with H_2O in the presence of pyridine gives [{P(μ-Npy)}$_2$(μ-O)]$_2${CuCl(pyridine)$_2$}$_4$ (**21**) (Figure 9), containing a dimeric macrocyclic core arrangement.[24] The potential to revert to the apparently thermodynamically more stable adamantane arrangement in this case is avoided by the increased steric demands of the *P*-coordinated metal fragments. This also has the effect of limiting the ring size of the macrocycle generated to a dimer. The structure of **21** reveals an additional property of this type of ligand arrangement not previously observed, their ability to employ the soft P centers in the coordination of metals at the periphery of the macrocycles.

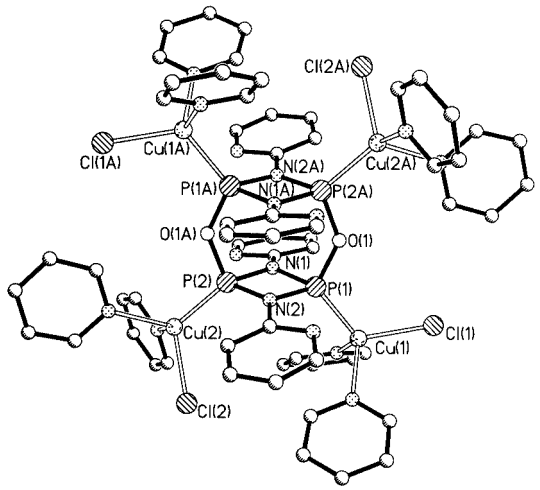

Figure 9. Structure of **21**

Valence-Isoelectronic Macrocycles Containing Other p-Block Elements

The applications of isoelectronic principles in the rationalisation and prediction of structure and bonding are long established in the area of main-group chemistry. Recently, these ideas have formed the basis of reviews concerning p-block element−N ligand systems.[28] In the context of the class of the macrocycles which the current review concerns, it can be seen that replacement of the P centers of a dimeric macrocycle of the type $[\{P(\mu\text{-}E'R)\}_2(\mu\text{-}E'R)]_2$ (E′= N or P, like **3** and **4** discussed in the previous section) with a +2 oxidation-state group-14 metal center (E) or with an organo group-13 metal fragment (R−E; E = group-13 element) would give valence-isoelectronic tetraanions of the type $[\{E(\mu\text{-}E'R)\}_2(\mu\text{-}E'R)]_2^{4-}$ and $[\{R'E(\mu\text{-}E'R)\}_2(\mu\text{-}E'R)]_2^{4-}$, respectively (Figure 10).

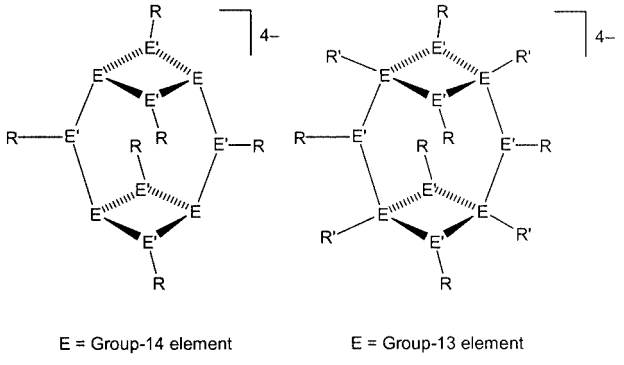

Figure 10. Valence-isoelectronic group-13 and -14 dimers

In practice the formation of isoelectronic anions of this type is not simple and different synthetic strategies have to be employed to those used in the related P−N systems. One earlier synthetic approach which we employed is the "templating" reaction of cubanes such as $[Sn(NtBu)]_4$ (**22**)[29] and $[MeAl(NMes)]_4$ (**23**)[30] with CyPHLi (Schemes 12 and 13, respectively). These reactions involve replacement of all four of the imido (RN^{2-}) ligands of the **22** and **23** with organophosphide groups (RP^{2-}). It can be noted that the related reactions with metallated primary amines (RNHLi) do not produce related macrocyclic frameworks.[29] More recently, however, we have found that group-14 frameworks of this type can be obtained in a more straightforward manner by the direct reactions of $Sn(NMe_2)_2$ with RPHLi (R= *t*Bu, Cy) (Scheme 14).[31] This strategy is restricted to aliphatic phosphides and to Li as the metal, as extensive coupling of the RP groups occurs in reactions involving aromatic phosphides or with aliphatic phosphides of the heavier alkali metals.[32] For example, the analogous reaction of MesPHLi with $Sn(NMe_2)_2$ in the presence of the Lewis base ligand TMEDA (= $Me_2NCH_2CH_2NMe_2$) gives $[\{Sn(\mu\text{-}PMes)\}_2(PMesPMes)](Li{\cdot}TMEDA)_2$ (**24**) (Mes= 2,4,6-$Me_3C_6H_3$), containing an $[Sn(\mu\text{-}PMes)\}_2(PMesPMes)]^{2-}$ dianion in which two of the MesP groups have coupled to form a $[MesPPMes]^{2-}$ unit (Scheme 15).[31]

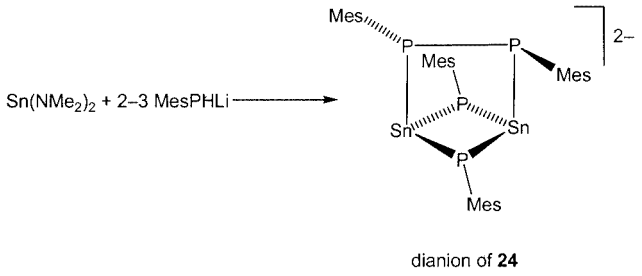

Scheme 15

of this type. The $[\{Sn(\mu\text{-}PtBu)\}_2(\mu\text{-}PtBu)]_2^{4-}$ of **25** coordinates the four Li^+ cations using both the μ-P*t*Bu groups within the dimeric ring units and those bridging the dimer units together. This coordination mode is the same as that seen for the three of the Li^+ cations by the $[(\{Sb(\mu\text{-}NCy)\}_2N)_3]^{3-}$ trianion of **16** (discussed above).[26]

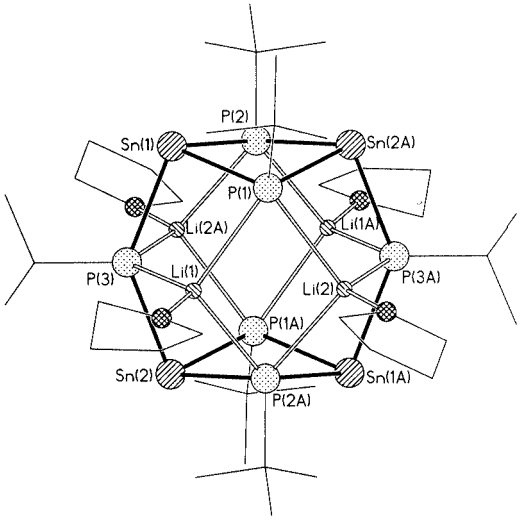

Figure 11. Structure of **25**

Future Prospects

This review has highlighted recent developments in this area. However, there is clearly much more to be done in extending the range of macrocycles available, both for group-15 systems and their valence-isoelectronic analogues, and in understanding and utilising the factors affecting the ring size of these species in general. Studies to date have pinpointed three distinctive coordination characteristics of this new class of macrocyclic ligands: the ability to coordinate metal ions within the cavity (in the case of deprotonated species), coordination of anions within the cavity (in the case of macrocycles having *endo* N−H functionality) and metal ions outside the cavity (using, for example, P centres within the macrocyclic backbone). Future studies will investigate these coordination patterns particularly with a view to (i) the synthesis of mixed-metal complexes, by utilising a combination of cavity and peripheral metal coordination, and (ii) the templating of macrocycles using anion coordination.

The Directed Lithiation of Benzenoid Aromatic Systems

Andrew E. H. Wheatley[a]

Dedicated to the memory of Ron Snaith. An inspirational teacher and a great friend

Keywords: Aromaticity / Directing group / Lithium / Solid-state structure / Solution structure

Directed metallation using organolithium bases is one of the best ways of regiospecifically elaborating aromatic systems and their substituents. For benzenoid arenes, deprotonation occurs at the ortho, lateral or peri positions. The reasons for each type of reaction will be considered in the context of the propensities of different directing groups for complex formation with the incoming organolithium base, acidification of the reactive site(s) and post-reaction stabilisation of the metal ion(s). Discussion will concentrate on structural investigations, for the most part by single-crystal X-ray diffraction and/or by multinuclear NMR spectroscopy. Theoretical studies will also be incorporated.

Introduction

Directed metallation using Group 1 organometallic bases in general, and organolithium substrates in particular, represents one of the most selective ways of regiospecifically elaborating benzenoid aromatic rings and substituents thereon, with deprotonation generally taking one of three forms: ortho, lateral or peri (Figure 1). The synthetic applications of the first of these have formed the basis for several review articles.[1] Orthometallation occurs both because the directing group can raise the acidity of the ortho hydrogen and also because the incoming organometallic substrate closely approaches this position. It is in the context of this reactivity that, for example, the recent total syntheses of phomactin, narciclasine, and analogues of meridine and atpenin B have been achieved.[2] The elaboration of aromatic substituents by means of directed lateral lithiation, that is metallation of, for example, alkyl groups located ortho to a directing group,[3] has facilitated the preparation of many polycyclic products, including corydalic acid methyl ester and fredericamycin.[4] Selectivity for ortho- vs. lateral lithiation is poorly understood, though kinetic, thermodynamic and steric effects all seem to play a role. Stereochemical aspects of the formation and reaction of laterally lithiated amides have been investigated,[5] with enantio-[6] and atroposelective lateral lithiations[7] having been published. Less

Dr. Andrew Wheatley graduated from the University of Kent and did his Ph.D. (University of Cambridge, 1995−1998) for the late Dr. Ron Snaith after which he became a Research Fellow at Gonville & Caius College (1998−2002). In 1999 he was awarded the Harrison Memorial Medal by the Royal Society of Chemistry and in 2000 he was made a University Assistant Lecturer at Cambridge. In 2002 he became a Fellow of Fitzwilliam College and he was made University Lecturer in 2003. He has published extensively in the field of Main Group organometallic chemistry. He specialises in the elucidation of organolithium reaction intermediates and the development of alkali metal 'ate complexes and Main Group metal interstitial hydrides.

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

commonly employed as a synthetic tool, the perimetallation of arenes occurs not because of directing group acidification of this position (*cf.* orthometallation) but because the incoming organometallic substrate closely approaches it.

The manifold synthetic applications that have been developed in light of the reactivities discussed above have recently been the subject of comprehensive review.[8] Nevertheless, it is remarkable that little is known of the organometallic products of metallation reactions involving demonstrably useful directing groups. The success of such synthetic protocols, involving metallation in general and lithiation specifically, have been interpreted in terms of promotion of the "complex-induced proximity effect",[9] with kinetic isotope effect evidence suggesting that rate-determining deprotonation of the arene proceeds in the wake of the formation of an equilibrating substrate-organometallic complex.[10]

The aim of the present article is to amalgamate the reported structural data for the products of the directed deprotonation of benzenoid aromatic systems by organolithium substrates. "Complex bases" have been used to occasion the derivatization of aromatic substrates as heterometallic Li-Group 1,[11] Li-Cu,[12] Li-Zn[13] and other Li-(d-block)[14] salts. However, only homometallic lithium derivatives will be considered by the present article since it is with these compounds that the synthetic utility of alkali metallated arenes lays.[8] The three main parts of the text will each deal with a different deprotonation position and, thereafter, the article is sub-divided firstly into solution studies and, secondly, into solid-state structural studies. Each of these two sub-sections will be ordered, with homoaromatics preceding heteroaromatics and with further categorisation occurring by directing group. Discussion of both solution and solid-state studies will be augmented by that of theoretical investigations where appropriate.

Orthometallation

Since the seminal studies that established the ability of substituted aromatic systems to undergo regioselective reaction[15] many synthetic procedures have been developed that utilise ortholithiation,[1a] and extensive studies have been undertaken into the relative directing abilities of a wide variety of substituents, many of which contain heteroatoms.[16] It is acknowledged that the best directors of orthometallation—and also the most versatile—are the so-called "N+O class" amide-type functional groups such as secondary and tertiary amides, carbamates and oxazolines.[1a] Other powerful (though less synthetically useful) orthodirecting groups include "S+O class" sulfones, sulfonamines[17] and *tert*-butyl sulfoxides.[18] Less potent are "O class" (e.g. ether) and "N class" (e.g. amine) substituents.[8] Halogens ("X class") are of importance, though prone to undergo halogen-metal exchange.[19]

The orthometallation of electron-deficient benzenoid heterocycles has been utilised synthetically,[8] though competition between deprotonation of and addition to the ring has been noted.[20] In the context of heterocyclic arenes, by far the most commonly employed systems are those of pyridyl derivatives. In spite of this, there are no reported structural characterisations of pyridines that have undergone alkali metallation at the ortho position.

Solution Studies

The ^{13}C NMR spectrum of 2,4,6-tri-*tert*-butylphenyllithium (**1**) in THF has been studied in some detail, with electric quadrupole relaxation of ^{7}Li incurring the partial averaging of $^{1}J(^{13}C,^{7}Li)$ while metal-carbon bond exchange has been reported between ^{6}Li enriched isotopomeric monomers.[21] In a similar vein, mesityllithium has been probed as a PMDETA complex (**2**), with data suggesting an asymmetric structure in which the metal is chiral at low temperature.[21]

The ortholithiation of anisole by *n*BuLi has been extensively studied by NMR spectroscopy.[22] Low temperature ^{1}H and ^{13}C NMR spectroscopy suggests that upon the addition of organolithium substrate a tetramer of the complex *n*BuLi·MeOPh (**3**) forms with the introduction of TMEDA causing its replacement by dimers of *n*BuLi·TMEDA (**4**). The spectroscopic benefits of ^{6}Li enrichment having been previously demonstrated,[23] the conversion of **3** to **4** has been corroborated by $^{6}Li,^{1}H$ HOESY and it has been suggested that orthometallation only proceeds in the presence of (more reactive) **4**.[22] This interpretation of the metallation of anisole, depending on the conversion of **4** to $(n\text{BuLi})_2$·TMEDA·MeOPh (**5**), has also been scrutinised theoretically with MNDO calculations suggesting that the orthodirecting functionality stabilises the transition state during deprotonation.[24] More recently, the reactivity of 1-methoxynaphthalene towards various organolithium substrates has been probed.[25] Whereas it has been previously noted that 1-methoxynaphthalene reacts with a 1:1 mixture of *n*BuLi and TMEDA to give an almost uniquely orthometallated product **6**, regioselectivity has proved less easy to control if an excess of Lewis base is present.[26] Accordingly, ^{1}H, ^{13}C and $^{6}Li,^{1}H$ HOESY spectra suggest that in the absence of a donor a 1-methoxynaphthalene-(*n*BuLi) complex **7** forms initially, whereas in the presence of TMEDA such complexation is precluded. The observation that ortholithiation nevertheless results from the employment of *n*BuLi/TMEDA, when taken in conjunction with the detection of an isotope effect (in $[D_8]$THF) whereby the exchange of hydrogen at the ortho position by deuterium incurs a slower lithiation process, suggests kinetic control. This view is reinforced by the observation that at elevated temperatures, the ortholithiated complex slowly converts into the corresponding perimetallate **8**.[25]

The ability of a [2-(dimethylamino)]-containing substituent to exhibit chelation control[27] during an orthometallation reaction has been demonstrated by the structural elucidation of $[Me_2NN(Me)]C_6H_4Li\cdot{}^{1}/_{2}$TMEDA (**9**)[28] and 2-(dimethylaminomethyl)phenyllithium (**10**)[29] in various media. The asymmetric solid-state structure of **9** (see below) is based on a $(CLi)_2$ metallacyclic core, the integrity of

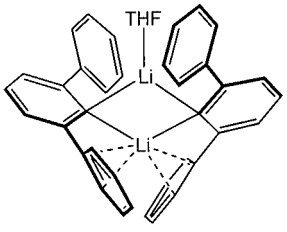
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which in [D_6]benzene is suggested by the observation of a septet [$^1J(^{13}C,^7Li)$ = 20 Hz] for the metallated carbon centre by ^{13}C NMR spectroscopy at room temperature.[28] While it is known that **10** takes the form of a chelated tetramer in hydrocarbon solution[30] it had been formerly suggested that the introduction of etherate solvent not only incurred separation into dimers[31] but also disrupted internal coordination.[32] However, more recent work using the doubly labelled ($^6Li,^{15}N$) compound, indicates that three interconverting isomeric and fully chelated dimers are retained in the presence of THF, and that internal coordination is not depleted even upon treatment with HMPA.[29]

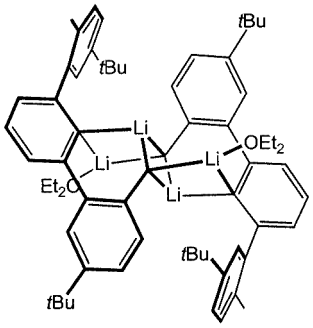
The ability of lithium itself to direct subsequent metallation has applications in the lateral deprotonation of aromatics (see below) but is also revealed in the context of ortholithiation by the reaction of 2-lithio-1-phenylpyrrole (**11**), a solid-state dimer,[32] with *n*BuLi.[33] $^6Li,^1H$ HOESY suggests that in [D_8]THF/TMEDA a co-complex forms in which the ortho position of the benzenoid ring may be agostically activated.[32] In a like vein, *trans*-1-lithio-1,2-diphenylhex-1-ene (**12**) undergoes orthometallation of the 2-phenyl substituent upon treatment with *n*BuLi. In the same way as for **11**, $^6Li,^1H$ HOESY points to activation of the position of ultimate dilithiation.[34] Low temperature ^1H and ^{13}C NMR spectroscopy suggests that the dissolution of (*n*Bu)[C_6H_4(Li·TMEDA)-2]C=C(Li·TMEDA)Ph (**13**) in [D_8]THF yields a mixture of essentially unaltered **13** and a pseudo-cubic dimer of (*n*Bu)[C_6H_4(Li·[D_8]THF)-2]C=C(Li·[D_8]THF)Ph (**14**).[34] $^6Li,^6Li$ COSY with fixed delays reveals scalar coupling between the two chemically inequivalent metal locations in this last species[35] and interchange of the metal centres between **13** and **14** has been demonstrated by $^6Li,^6Li$ EXSY.[36]

Solid-State Studies

Several straightforward examples of substituted phenyllithium compounds have been fully characterised, both in their pure forms and as complexes with Lewis bases. Dilithiated biphenyl has been characterised as the TMEDA solvate μ_2-biphenyl-C2,C2, C2′,C2′-bis(lithium-TMEDA) (**15**).[37] Concerning polysubstituted arenes, various dimers of unsolvated 2,6-$R_2C_6H_3Li$ are known. Whereas for R = mesityl (**16**)[38] the structure is based on a normal $(CLi)_2$ core, for the more sterically congested ligand in which R = 2,6-(*i*Pr)$_2C_6H_4$ (**17**) dimerisation occurs by the η^6-interaction of one R group on each ligand with the metal component of an adjacent monomer.[39] Solvated analogues exhibit even more diverse behaviour; 2,6-$(C_{10}H_7)_2C_6H_3Li$·2THF (**18**),[40] 2,6-$Ph_2C_6H_3Li$·2OEt_2 (**19**),[41] 2,6-[4-(*t*Bu)C_6H_4]$_2C_6H_3Li$·2OEt_2 (**20**),[42] 2,6-(4-$MeOC_6H_4)_2C_6H_3Li$·2OEt_2 (**21**) (wherein the methoxy groups are passive with respect to the metal),[43] 2,6-[2,4,6-(*i*Pr)$_3C_6H_2$]C_6H_3Li·L (L = OEt_2 **22**,[44] η^6-C_6H_6 **23**[39]) and 2,4,6-$Ph_3C_6H_2Li$·2OEt_2 (**24**)[45] are monomers in the solid state while 2,4,6-(*i*Pr)$_3C_6H_2Li$·OEt_2 (**25**)[46] and 2,4,6-$Me_3C_6H_2Li$·2THF (**26**)[47] form differently solvated dimers. The complex 2,4,6-$Ph_3C_6H_2Li$·$^1/_2$THF (**27**) is unusual by virtue of its asymmetry. While both metal ions in its dimeric structure straddle the formal charge centres, one is mono-THF solvated and the other is bis(η^2-Ph) supported.[40] In a like vein, the dimer of 2,6-$Ph_2C_6H_3Li$·$^1/_2$THF, **28**, reveals Lewis base stabilisation of one metal centre and the η^2-interaction of two phenyl rings with the other.[40] Whereas the simple monolithiate **21** is formed by lithium-halogen exchange with the corresponding iodide,[19] application of *excess* *n*BuLi to the related substrate 2,6-[2-Me-4-(*t*Bu)C_6H_3]$_2$-C_6H_3I has yielded the dilithium complex 2-[2-CH_2Li-4-(*t*Bu)C_6H_3]-6-[2-Me-4-(*t*Bu)C_6H_3]C_6H_3Li·OEt_2 (**29**).[42] As part of the same study, a 1:1 co-complex (**30**) between *t*BuLi and 2,6-[2,4,6-(*i*Pr)$_3C_6H_2$]$_2C_6H_3Li$ (*cf.* **22**, **23**) has been reported to incorporate a $(CLi)_2$ core.[42] As already mentioned, **21** reveals coordinatively inactive methoxy substituents.[43] However, in the THF-solvated co-complex (**31**) between lithium iodide and 2,6-bis(2-methoxyphenyl)phenyllithium each metal centre is singly MeO-bonded.[48] Just as the tetramer of 2,4,6-tris(isopropyl)phenyllithium, **32**, reveals η^6-support of the metal centres[39] so the butyllithium-phenyllithium complex *n*BuLi·[2,4,6-(*t*Bu)$_3C_6H_2Li$] (**33**) exhibits a dimeric solid-state structure by virtue of there being η^6-links between the component monomers.[38] Lastly, as previously pointed out the extensively conjugated system *trans*-1-lithio-1,2-diphenylhex-1-ene (**12**) has been reported to react with one equivalent of *n*BuLi at the 2-phenyl substituent to give **13**.[34] This last complex reveals a solid-state structure similar to that of μ_2-biphenyl-C2,C2, C2′,C2′-bis-(lithium-TMEDA) **15**.[37]



(28)$_2$



(29)$_2$

The potential for passivity on the part of MeO groups towards lithium has already been alluded to in the context of the diethyl ether solvate **21**.[43] However, the lithiation of anisoles is more commonly known to proceed at the position ortho to this weak "O class" director, with internal Li−O stabilisation of the metal occurring. While solution

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

studies into such processes have already been discussed (see above), several examples of chelated lithioalkoxyarenes have been characterised in the solid state. The metallation of anisole itself using *n*BuLi has long been known to yield a tetramer of the simple orthometallate 2-$MeOC_6H_4Li$ (**34**),[49] with the methylcyclopropane solvate 2-$MeOC_6H_4Li{\cdot}OCH_2CHMe$ (**35**) having a similar structure[50] and 2-$MeOC_6H_4Li{\cdot}{}^1/_8$TMEDA (**36**) revealing pairs of tetramers that are TMEDA bridged.[51] While the simplest poly(methoxy) example of such species is a dimer of 2,6-(dimethoxy)phenyllithium (**37**), in which each metal is supported by interaction with both charge centres and one oxygen atom on each ligand,[52] more extensive (tetrameric) aggregation of **37** has also been reported.[53] Meanwhile, increasing the steric demands of alkoxy groups [in 2,6-di-(*tert*-butoxy)phenyllithium (**38**)] has been noted to incur the formation of a rare cyclic trimer based on a $(CLi)_3$ core.[54]

Remaining with chalcogen-based directing groups, polymeric chains based on $(CLi)_2$-centred dimers of 2-(tBu)$SC_6H_4Li{\cdot}{}^1/_2$TMEDA (**39**) have been noted to form by virtue of the ability of TMEDA to adopt a dimer-bridging motif.[55] Biphenyl sulfide has been shown to undergo dimetallation in TMEDA (in a manner analogous to that revealed by biphenyl, *cf.* **15**)[37] to yield μ_2-biphenyl sulfide-C2,C2′,C2′-bis(lithium-TMEDA) (**40**).[56] In the context of "S+O class" directing agents, 3-fluorophenyl(phenyl)sulfone has been shown to undergo lithiation on the fluorinated ring between the two substituents to afford 3-FC_6H_3(Li·PMDETA-2)SO_2Ph (**41**).[57] Of the two possible coordinating substituents, it is the SO_2 moiety that dominates, with one of its two oxygen centres interacting with the metal [Li−O = 2.170(8) Å; Li···F = 3.672(7) Å]. Nevertheless, in spite of the lack of Li−F coordination, the arene-fluorine distance is, at 1.389(5) Å, longer than normal. This has been interpreted in terms of the observation that **41** eliminates LiF at +60 °C.[57] The dilithiated sulfone 2-[$(Me_3Si)_2C$(Li·OEt_2)SO_2]$C_6H_4Li{\cdot}OEt_2$ (**42**) has been reported, wherein both O-directed ortholithiation (the solid-state structure reveals Li−C_{ortho} and Li−O coordination) and deprotonation of the sulfone α-carbon are seen.[58] Reaction of racemic EtS(=O)(Ph)=NMe with *n*BuLi/TMEDA in the presence of a trace oxide source[59] yields the heterochiral mixed α-mono- and α,orthodilithiated sulfoximine [MeCHLiS(=O)(Ph)=NMe]$_2$·[MeCHLiS(=O)(C_6H_4Li-2)=NMe]$_2$·Li_2O·3TMEDA (**43**),[60] the solid-state structure of which reveals chiral resolution. Consequently, the aggregate is composed of two (*S*)-configured α-metallated sulfoximine monoanions and two (*R*)-configured α,orthometallated dianions. At the structure core, and interacting with six of the eight metal centres present, is a rogue oxide dianion (thought to arise from LiOH contamination of the organolithium reagent). The α-Li centre in the monolithiated moiety interacts with neither the oxygen nor the nitrogen centres in the same unit but sits *gauche* with respect to these atoms and bonds, instead, to TMEDA and the O-centre of a dianionic sulfoximine unit (Figure 2a). Each of these dianions interact with both metal counterions *via* their deprotonated ortho positions — the corresponding

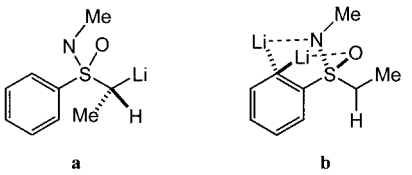


Figure 2. a) Li^+ in the monolithiated component of **40** bonds to TMEDA and the O-centre of a dianionic sulfoximine unit and, b) the α-C lone pair in the dianion adopts a *gauche* conformation with respect to nitrogen and arene[60]

two metals being stabilised by intramolecular N,O-coordination. The α-C lone pair in the dianion adopts a *gauche* conformation with respect to both nitrogen and deprotonated arene (Figure 2b).[61]

The solution structures incurred by the action of the purely "N class" directing group in 2-(dimethylaminomethyl)-phenyllithium (**10**) have already been discussed[29] in the context of retention of the pseudo-cubic tetramer noted in the solid state.[30a] The substrate 3,5-dimethyl(dimethylaminomethyl)benzene has been shown to undergo orthodirected metallation upon treatment with *n*BuLi/OEt_2. The result is a dimer of 2-Me_2NCH_2−4,6-$Me_2C_6H_2Li{\cdot}{}^1/_2OEt_2$ (**44**), an asymmetric species in which one metal centre in a $(CLi)_2$ core is supported by two amine N-donors while the other metal is mono(diethyl ether) solvated (*cf.* **28**). This species is thermally unstable with respect to the formation of (2-Me_2NCH_2−4,6-$Me_2C_6H_2Li$)·(Me_2NCH_2−3,5-$Me_2C_6H_3$) (**45**).[28] As part of the same study, the TMEDA-solvated structural analogue of **44** has been obtained using trimethylhydrazine directors. Whereas *n*BuLi/OEt_2 fails to

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

effect lithiation of $Me_2NN(Me)Ph$, the use of *n*BuLi/TMEDA affords the asymmetric complex **9**, which is known to retain its solid-state structure in hydrocarbon solution (see above).[28] Extensive crystallographic work has been done on bis(amine) compounds of the type 2,6-$(R_2NCHR')_2C_6H_nR''_{3-n}Li$. For $n = 3$, the pure ortholithiates 2,6-bis(*N*,*N*-diethylaminomethyl)phenyllithium (**46**)[61] and 2,6-bis[1′-(dimethylaminoethyl)]phenyllithium (**47**)[62] have both been shown to adopt dimeric structures in the solid state. The 1:1 co-complex of 2,6-bis[1′-(dimethylaminopropyl)]phenyllithium with *n*BuLi **48** is based on a more complicated $(CLi)_4$ ladder, in which the *n*-butyl ions reside in the ladder middle while the ortho deprotonated aromatic systems both intercept laddering and straddle ladder edges.[62] The compound 2,3,5,6-$(Me_2NCH_2)_4C_6HLi$ (i.e., $n = 1$) (**49**) exists as a dimer in which each metal in the core $(CLi)_2$ ring is supported by the 2- and 6-aminomethyl groups in either ligand, the remaining substituents being coordinatively inactive.[63] In a related vein, 2-Me_2N-6-$Me_2NCH_2C_6H_3Li$ (**50**) reveals a dimer incorporating both four- and five-membered chelate rings,[64] whereas 2,6-$(Me_2N)_2C_6H_3Li$ (**51**) is a $(CLi)_3$-based trimer incorporating only four-membered C_2NLi chelate rings.[65] Just as (O-directed) 2,6-di-(*tert*-butoxy)phenyllithium (**38**)[54] and (N-directed) **51** are unusual by virtue of the fact that they exist as cyclic trimers in the solid state, in 2-(*t*Bu)O-6-$Me_2NC_6H_3Li$ (**52**) trimerisation is noted to result from the employment of both N- and O-directing groups.[66] In contrast to the intramolecular N-stabilisation revealed by **50** and **51**, 2-[(4-methylpiperazinyl)phenyl-C,N]lithium-THF (**53**) exhibits a dimeric structure based on an eight-membered $(C_2NLi)_2$ core by virtue of intermolecular stabilisation of the metal ions by piperazinyl α-nitrogen atoms.[67] The investigation of orthometallated compounds incorporating polyfunctional substituents has been extended to cover the solid-state structure of 2-(dimethylaminoethoxy)phenyllithium (**54**)[68]and also that of 2-[*N*-alkyl(*N*′,*N*′-diethylaminoethyl)aminomethyl]phenyllithium (alkyl = methyl **55**,[69] ethyl **56**[70]). The use of α-aminolithium alkoxides[71] has allowed the regiospecific metallation of arylaldehydes. Hence, in situ protection of variously substituted benzaldehydes and heterocyclic arylaldehydes[72] has been reported[71,73] by reaction with lithium dialkylamides, and has been followed by ring lithiation, affording a convenient one-pot route to orthosubstituted arylaldehydes. In a comparable area, **54** exhibits a tetrameric structure in the solid state. Unusually, for such an aggregation state, a straightforward pseudo-cubane does not result. Instead, two boat-shaped eight-membered $(C_2OLi)_2$ rings are found to be stacked with one being inverted and twisted by approximately 90° to the other. In a manner analogous to *N*,*N*,*N*′-trialkylethylenediamine-substituted aromatics,[70] the 2-(dimethylaminoethoxy)phenyl anion acts as an N,O-chelating ligand in **54** such that each metal is rendered four-coordinate by the action of nitrogen.[68] Compounds **55** and **56** have revealed a $(CLi)_2$-based dimer with both donor centres on each side-chain chelating a given metal centre.[69,70] A related co-complex has been reported; that of 2,6-bis[*N*-methyl(*N*′,*N*′-dimethylaminoethyl-)aminomethyl]phenyllithium with BrLi (**57**) is centred on a four-membered $CBrLi_2$-ring.[74] The polyfunctional ligand *N*-(2-phenoxyphenyl)-*N*-(trimethylsilyl)amine has been used to afford a variety of structural motifs upon dilithiation.[75] As such, simple deprotonation in DME to give, for example, N,O-chelated 2-$PhOC_6H_4N(Li{\cdot}DME)SiMe_3$ (**58**), can be followed by reaction with further *n*BuLi in the presence of different Lewis bases to give the dimer of diglyme-bridged 2-$(C_6H_4Li\text{-}2')OC_6H_4N(Li{\cdot}OEt_2)SiMe_3{\cdot}{}^1/_2$-$O(CH_2CH_2OMe)_2$ (**59**), the dimer of 2-$(C_6H_4Li\text{-}2')OC_6H_4N(Li{\cdot}DME)SiMe_3$ (**60**) or *n*BuLi-containing co-complex *n*BuLi·2-$(C_6H_4Li\text{-}2')OC_6H_4N(Li{\cdot}OEt_2)SiMe_3$ (**61**).[76] Attempts to react dilithiates such as **59** or **60** with $LaCl_3$ in Et_2O have serendipitously afforded a decalithium cluster that comprises two units of formulation EtOLi·[2-$(C_6H_4Li\text{-}2')OC_6H_4N(Li{\cdot}OEt_2)SiMe_3]_2$ (**62**).[76] The dilithiation of *N*-phenylcarbazole in TMEDA gives μ_2-*N*-phenylcarbazole-C1,C1, C2′,C2′-bis(lithium-TMEDA) (**63**)[56] (*cf.* **15**[37] and **40**[56]). Whereas previous studies into the propagation of reactions between organolithium substrates and amines have typically utilised an excess of amine and so generated species of the type $R_2NLi{\cdot}HNR_2$,[77] a recent probe has investigated the reaction of *n*BuLi with Ph_2NH using as much as a sixfold excess of organolithium substrate. Such work has afforded the remarkable (*n*BuLi)-containing (mixed anion)-dianion co-complex $(n\text{BuLi})_2{\cdot}[Ph(C_6H_4Li\text{-}2)NLi{\cdot}OEt_2]_2{\cdot}Ph_2NLi$ (**64**).[78] The structure of **64** incorporates three connected units. The first two are $(CLi)_2$-based $(n\text{BuLi}{\cdot}OEt_2)_2$ and a dimer of dilithiated $Ph(C_6H_4Li\text{-}2)NLi{\cdot}OEt_2$. The four negative charge centres of the latter fragment interact with the third component of the structure; a single Ph_2NLi molecule.[78]

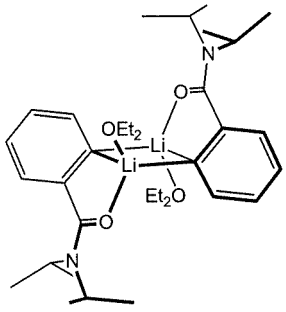
Remaining with the nitrogen-based chelation of metal centres, two common ligand types have been found to exhibit a predilection for stabilising lithium cations; those that contain separate "N class" and "O class" directing groups and those that feature "N+O class" directors. In the context of the first of these, compounds **52** and **59**−**62** have already been discussed.[66−76] Concerning the latter, mixed "N+O class", it has already been mentioned that about the best and most versatile orthodirecting substituents of all are those incorporating amide-type groups in general[1a] and tertiary amides specifically.[16a] In spite of this utility it is only recently that the propensity of even the simple amides $(i\text{Pr})_2\text{NC(O)Ar}$ (Ar = Ph, $C_{10}H_7$) for directing lithiation has been adequately explained with reference to the known sterically induced amide-arene twist-angle.[79] While it is well documented that this angle has a bearing on the rate of lithiation,[79a] even these two relatively rigid and nearly perpendicular amides undergo efficient orthometallation.[79b][80] Accordingly, treatment of $(i\text{Pr})_2\text{NC(O)Ph/OEt}_2$ with *t*BuLi yields crystalline $(i\text{Pr})_2\text{NC(O)C}_6\text{H}_4(\text{Li}\cdot\text{OEt}_2)$-2 (**65**) with X-ray diffraction revealing a $(\text{CLi})_2$-centred dimer in which the core is stabilised by the O-centres of OEt_2 and of the amide carbonyl functionalities (amide-arene twist-angle of 47°). A similar structural motif is noted for $(i\text{Pr})_2\text{NC(O)C}_{10}\text{H}_6(\text{Li}\cdot\text{THF})$-2 (**66**; twist-angle 65°), which is obtained from the 1:1 reaction of $(i\text{Pr})_2\text{NC(O)C}_{10}\text{H}_7$ with *t*BuLi in THF.[81] More complicated is the behaviour of 2-ethyl-*N*,*N*-diisopropylbenzamide with respect to *t*BuLi. Recent crystallographic results suggest that ortho- and lateral lithiation are in strongly solvent-dependent competition, with the formation of $(i\text{Pr})_2\text{NC(O)-2-Et-C}_6\text{H}_3\text{Li}\cdot\text{THF}$ (**67**) − a dimer in the solid state − and $(i\text{Pr})_2\text{NC(O)C}_6\text{H}_4\text{CH(Li}\cdot\text{PMDETA)Me-2}$ (**68**; see below) being made possible by the employment of different reaction media.[82]



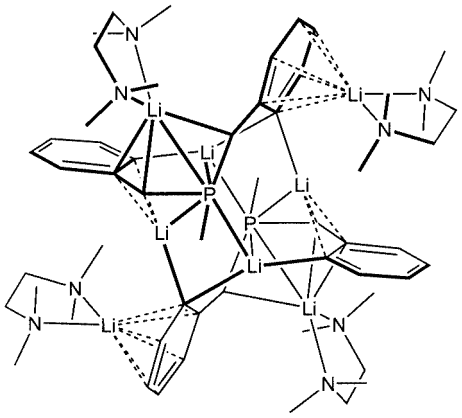
$(\mathbf{65})_2$

Unsurprisingly, 2-(*P*,*P*-dimethylphosphanylmethyl)phenyllithium-OEt_2 (**69**)[83] and 2,6-bis(*P*,*P*-dimethylphosphanylmethyl)phenyllithium (**70**)[84] reveal solid-state dimers related to that of internally coordinated "N class"-controlled **46**.[61] Triphenylphosphane also undergoes efficient "P class" orthodirected metallation in the presence of *n*BuLi/OEt_2. However, while 2-$\text{Ph}_2\text{PC}_6\text{H}_4(\text{Li}\cdot\text{OEt}_2)$-2 (**71**) is a dimer in the solid state, its structure contrasts with that of **69** insofar as it fails to demonstrate Li−P bonding.[85] Bis(2-bromobenzyl)methylphosphane undergoes lithiation of both aromatic benzylic positions in the presence

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of TMEDA. This is of note in the context of the recently reported ring-activating properties of lithium substituents themselves.[86] Hence, bis(orthometallation) of the phosphane proceeds, upon treatment with *n*BuLi and via a lithium-halogen exchange mechanism,[19] to give MeP[$CH_2(C_6H_4Li$-2)]$_2$·2TMEDA (**72**). However, the monolithiation of each benzyl α-carbon centre in **72** occurs readily upon the subsequent introduction of *n*BuLi/TMEDA. The product (**73**) is a dimer in the solid state with four metal ions adopting a near planar equilateral rhombus, the edges of which are bridged both by as many deprotonated ortho carbon centres and two phosphane Group 15 donors. Peripheral to this core, four TMEDA-chelated metal ions are positioned: two are η^4-bonded to ligand phosphorus and benzyl centres and one ipso carbon centre while two more are each η^6-stabilised by the two remaining aromatic rings.[87]

A single crystallographic example of "P+N class" ortho-directed lithiation has been reported. Whereas reaction of the iminophosphorane (2-$C_5H_4N)_3P{=}NSiMe_3$ with MeLi proceeds via nucleophilic attack on the phosphorus, the same is not true of $Ph_3P{=}NSiMe_3$. In this latter case, the direction of ortholithiation affords an asymmetric dimer of $Me_3SiN{=}PPh_2C_6H_4Li{\cdot}{}^1/_2OEt_2$ (**74**) (*cf.* **44**).[28] The solid-state structure of **74** reveals that the orthometallated iminophosphorane anions N,C_{ortho}-chelate one of the two metal centres.[88]



$(\mathbf{73})_2$

Whereas an example in which "S+O class" direction supersedes "X class" direction of an ortholithiation process has already been discussed (*cf.* **41**)[57] it is, nonetheless, the case that the fluorine-based direction of orthometallation has been reported in synthetic contexts[26b] and, in rare instances, in the solid state. As part of an investigation into the magnitude of carbon-fluorine bond extension upon ortholithiation both 1,2,3,4-tetrafluorobenzene and (from it) the benzyne precursor (2,3,4,5-tetrafluoro)phenyllithium-tris(THF) (**75**) have been prepared. Complex **75** is a monomer in the solid state wherein external solvation of the metal obviates the need for lithium-fluorine interaction. However, at 3.448(4) Å Li···F_{ortho} is less than in **41**,[57] and this is consistent with the observation that **75** undergoes LiF elimination at temperatures as low as −40 °C.[89] Conversely, in spite of the inclusion of coordinating diethyl ether, metal-fluorine interactions are noted in the dimer of (2,4,6-trifluoromethyl)phenyllithium-OEt_2 (**76**).[90] In this case each metal centre is in part stabilised by two fluorine atoms on ortho-CF_3 groups.

Lateral Metallation

Lateral or benzylic metallation results from the ability of a directing group situated ortho to a given lateral group to both coordinate an organometallic substrate and withdraw electrons from the lateral group in question. The result is that ortho- and lateral metallation are competitive processes that result from the presence of the same classes of directing group.[3] The promotion of lateral metallation by a directing group is emphasised by the observation that whereas toluene can be laterally metallated by *n*BuLi/TMEDA,[91] 2-(dimethylaminomethyl)toluene affects the same reaction much more rapidly on treatment with *n*BuLi/OEt_2.[27][92]

Solution Studies

Fluorenyllithium (FlLi; **77**) has been studied with a view to understanding whether it exists as a contact ion pair (CIP) or a solvent-separated ion pair (SSIP). SSIP and CIP solid-state structures have been reported for fluorenyl derivative $Fl^-(Li^+{\cdot}4THF)$ (**78**)[93] and the related complex FlLi·2N$(CH_2CH_2)_3CH$ (**79**),[94] respectively (see below). It has been noted that **77** affords SSIPs in THF solution at low temperature.[93] This view has been reinforced by ^{6}Li,^{1}H HOESY. Data suggest that **78** dissolves in [D_8]THF to give mostly SSIPs at low temperature but a higher proportion of CIPs in which the metal η^5-interacts with the central Cp ring at elevated temperatures.[95] In contrast, analysis of a [D_{10}]diethyl ether solution of **78** reveals that in this inferior solvent a CIP structure in which the metal is η^1-bonded to fluorenyl-C9 is preferred.[95]

The lateral direction of metallation by a lithium aryloxide moiety has been noted in 2,6-$(CH_2Li)_2C_6H_3OLi$·TMEDA (**80**).[96] The solid-state structure (see below) reveals a tetramer, the solution integrity of which is implied (in hydrocarbon media at room temperature) by the ^{1}H NMR spectroscopic discrimination of aromatic 3- and 5-positions and the observation of three different metal environments in the ^{7}Li NMR spectrum. At elevated temperatures and in [D_8]THF symmetry about the Ar−O axis is implied spectroscopically.[96]

Whereas the ortho-directing capacities of 2-(dimethylaminomethyl) fragments have already been discussed,[29] their ability to incur lateral deprotonation has been probed by NMR spectroscopic study of the co-complex *n*BuLi·[2,6-$(Me_2NCH_2)_2$−3,5-$Me_2C_6HCHLiR$]. (R = H **81**,[97] $SiMe_3$ **82**, *t*Bu **83**, 4-toloyl **84**[98]). At low temperature, a ^{6}Li-enriched sample of **81** reveals two signals, with ^{6}Li,^{6}Li INADEQUATE spectroscopy[99] affording a homonuclear scalar coupling and suggesting retention of the tetranuclear co-complex noted in the solid state (see below).[100] Unambigu-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ous assignment of the two ^{6}Li resonances is enabled by ^{6}Li,^{13}C HMQC spectroscopy[35c] on the basis that the metal ions bonded to *two* butyl anions show the higher intensity ^{6}Li,$^{13}C_\alpha$ correlation; assignment of these ^{6}Li resonances also allows interpretation of the ^{15}N and ^{6}Li,^{15}N HMQC[101] NMR spectra (natural abundance with respect to ^{15}N). Accordingly, 1:1:1 triplets observed in the first of these experiments are attributable to ^{6}Li,^{15}N interactions.[29] For **81**−**84**, reaction of 1,3-bis(dimethylaminomethyl)-2,4,6-trimethylarene with *n*BuLi has yielded a 2:2 mixed butyllithium-aryllithium cluster. However, whereas that noted for **81** is pseudo-cubic, the use of **82** gives a ladder structure (see below). NMR spectroscopy and cryoscopic relative molecular mass measurements combine to suggest that **81** retains its pseudo-cubane structure in hydrocarbon solution. Hence, at low temperatures (< −10 °C) the ^{1}H NMR spectrum of **81** reveals four signals for the two NMe_2 functions, two signals for the two ArMe groups, two AB multiplets for the two CH_2N units and an ArH singlet. Such diastereotopicity of the dimethylaminomethyl moieties suggests the absence of a symmetry plane through ipso and para positions perpendicular to the arene. Such a symmetry element is, however, manifest above room temperature, where a single AB pattern, two NMe signals and one ArMe singlet are seen. If the sample is heated to above +100 °C then the AB pattern and NMe peaks coalesce into single lines. In conjunction with the ^{6}Li NMR spectrum, which reveals a single peak, these data suggest rapid scrambling of the four organic anions.[97] For **82**, ^{1}H NMR spectroscopy points — through the observation of two AB patterns for the NCH_2 groups — to asymmetric interaction of the benzylic anion with two Li^+ ions (see below) and to the static nature of Li−N interactions at and below room temperature. However, a rapid fluxional process involving the dissociation/association of these bonds is evidently manifest at higher temperatures, with one singlet and one AB pattern observed for the two NMe_2 and NCH_2 groups, respectively.[98] In solution, both **83** and **84** appear to be close structural analogues of **82**.[98]

The establishment that lateral metallation occurs under the influence of a tertiary amide directing group has recently been probed both theoretically and in the solid state (see below).[102] This follows on from formative studies, which established that enantiomerically pure α-stanyllated anilides undergo tin-lithium exchange and electrophilic workup with retention and inversion of configuration, respectively.[103] Thus, 2-ethyl-*N*,*N*-diisopropyl-1-naphthamide has been metallated using *s*-BuLi to give a pair of configurationally stable diastereomeric *syn* atropisomers of $(i\text{Pr})_2NC(O)C_{10}H_6CHLiMe$-2 (**85a**). Reaction of **85a** with Bu_3SnCl yields the corresponding *syn* and *anti* stannylated atropisomers in the kinetic ratio 89:11, with subsequent heating establishing a 4:96 equilibrium.[104] While lithiation of the thermodynamic *anti* stannylated atropisomer yields *syn*-**85a**, the *syn* stannylated atropisomer itself lithiates to give a 60:40 *syn*:*anti* (**85a**:**85b**) mixture. ^{1}H NMR studies have corroborated the non-stereospecific nature of each of these two reaction steps, revealing the existence of non-interconverting *syn* and *anti* stannylated diastereoisomers in THF at −40 °C.[104] In contrast, the dissolution of preformed $(i\text{Pr})_2NC(O)C_{10}H_6CH(Li{\cdot}3THF)Me$-2 (**86**; see below) in [D_8]THF appears to yield (by ^{1}H NMR spectroscopy) one dominant solution species, with the observation of two diastereotopic *i*Pr groups at −25 °C pointing to slow rotation about the amide C−N bond below room temperature. Two diastereotopic *i*Pr moieties are also noted at −25 °C in [D_8]-toluene, as are signals attributable to the deprotonated α-CH group. However, at −48 °C in [D_8]-toluene all ^{1}H NMR resonances split into two in a 60:40 ratio, suggesting that diastereoisomers interconvert very much faster, with NMR spectroscopy showing rapid exchange in solution above this temperature.[102]

Metallation of the tertiary phosphane $MeP(C_6H_4CH_2NMe_2{-}2)_2$ using *t*BuLi yields a dimer of the benzyllithium product $MeP(C_6H_4CH_2NMe_2{-}2)$-$(C_6H_4CHLiNMe_2{-}2)_2$ (**87**) that exhibits novel dynamics in [D_8]toluene solution.[105] In spite of this it is apparent that the main features of the solid-state structure are retained at 203 K. However, ^{31}P and ^{7}Li NMR spectroscopy reveal that at elevated temperatures each metal can be associated with either phosphorus atom in the dimeric structure, but not with both simultaneously.

Solid-State Studies

Several solid-state structures have been published in which metallation has been laterally directed by the acidifying (delocalising) action of a 1-aryl substituent. In this context, the biphenyl derivatives 2-($CH_2Li{\cdot}$PMDETA)-6-$MeC_6H_3(C_6H_3Me_2{-}2,6)$ (**88**)[106] and (the dimer of) 2-(CHRLi·TMEDA)C_6H_4 (R = H **89**, $SiMe_3$ **90**)[107] have been characterised. Moreover, the structure of 2,2′-bis(TMEDA)lithiomethyl-1,1′-binaphthyl (**91**) has also been reported.[106] Just as ortholithiation has been noted in aromatic alkenes (*cf.* **13**),[34] so the 1,3-dialkyl lateral direction of metallation has been noted in the α-deprotonation of styrene. Hence, simple dimers of $2,6\text{-}Me_2C_6H_3C(Li{\cdot}L)=CH_2$ [L = OEt_2 **92**, MeO(*t*Bu) **93**] have been reported.[108] Whereas both SSIP and CIP structures have been noted for fluorenyllithium complex **78** upon dissolution in Lewis base media,[95] X-ray crystallography has established an ion-separated structure in the solid state.[93] Meanwhile, the related species **79** has been found to be a CIP with η^3-stabilisation of the metal via the 1-, 9- and 10-fluorenyl positions.[94] More recently, two lithium complexes have been generated from the substituted fluorenyl ligand 9-(dimethylaminoethyl)fluorenyl (Fl^N). In either case deprotonation at the 9-position is accompanied by internal amine-coordination, the presence of etherate solvent also supporting the metal. In $Fl^NLi{\cdot}OEt_2$ (**94**) the metal exhibits η^5-interaction with the anion, while this is reduced to η^2-bonding in $Fl^NLi{\cdot}2THF$ (**95**).[109]

In contrast to **92** and **93**, where external solvation combined with the lack of directing group donor sites to obviate the possibility of clear metal-directing group interaction, a single example of a (2-methoxy)-stabilised aromatic allene has been reported. In $2\text{-}MeOC_6H_4C(Li{\cdot}OEt_2)=C=CPh_2$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(**96**) the metal forms part of a five-membered ring incorporating both the methoxy oxygen atom and the site of formal deprotonation.[110] Whereas a methoxy directing-group is itself passive to direct metallation, the other common "O class" director hydroxyl is, of course, itself susceptible to deprotonation. As such, this latter group will only act as a director of subsequent reaction in its phenoxide form and in the presence of excess metal. Sterically congested 2-methyl-6-(*tert*-butyl)phenol undergoes just such a reaction to give a hexalithium aggregate of 2-CH_2Li-6-(*t*Bu)C_6H_3OLi·$Me_2N(CH_2)_2N(Me)CH_2$Li·TMEDA (**97**). This complex contains a laterally lithiated aromatic system and both deprotonated and unchanged TMEDA.[111] Dimerisation of **97** occurs *via* the formation of an $(OLi)_2$ ring, each metal component of which is also supported by interaction with $ArCH_2^-$ (that is, chelated by the aryl dianion) and NCH_2^-. An investigation of "superbase" structural chemistry[112] has led to the deprotonation of 2,6-dimethylphenol in the presence of TMEDA and the unexpected formation of a dodecalithium tetramer of 2,6-$(CH_2Li)_2C_6H_3$OLi·TMEDA (**80**) wherein the lack of steric congestion [relative to that noted for 2-methyl-6-(*tert*-butyl)phenol] combines with the introduction of a second acidic methyl substituent on each aromatic ring to allow the generation of organic trianions.[96] The tetramer core is defined by an elongated eight-membered $(OLi)_4$ boat-shaped ring, at either end of which reside Li^+·TMEDA units. Such a structure contains three unique metal environments; an observation consistent with solution studies (see above).[96]

The lateral directing capacity of "N class" substituents such as R_2N- and $R_2N(CH_2)_n$- have been the subject of investigation. As already discussed, extensive solution studies have been carried out on the various lateral lithiates obtained utilising the directing abilities of 2,6-bis(dimethylaminomethyl) substituents. As part of these studies, the (*n*-butyllithium)-containing co-complexes *n*BuLi·[2,6-$(Me_2NCH_2)_2$−3,5-$Me_2C_6HCHLiR$] (R = H **81**,[97] $SiMe_3$ **82**, *t*Bu **83**, 4-toloyl **84**[98]) have been prepared and fully characterised. The solid-state structure of **81** reveals a $(CLi)_4$ pseudo-cubic dimer of dimers with each metal centre being supported by a single dimethylaminomethyl donor centre.[97] Attempts to overcome pseudo-cubane formation have revolved around the introduction of a non-hydrogen α-substituent, with R = trimethylsilyl affording **82**. The solid-state structure of **82** reveals a $(CLi)_4$ ladder, at either end of which resides an asymmetrically bonded benzylic anion.[98] The straightforward lithium salt 2-Me_2N-

$Me_3Si(TMEDA{\cdot}Li)CHC_6H_4$ (**98**) is a solid state monomer incorporating N-centre chelation of the metal, with transmetallation yielding the potassium congener as a precursor to the bis(benzyl)strontium species.[113] Moreover, the higher Group 15 analogue $2\text{-}Ph_2P\text{-}Me_3Si(TMEDA{\cdot}Li)CHC_6H_4$ (**99**) has been reported.[114] Nitrogen and phosphorus donor centres can, of course, act in tandem and, as such, the previously discussed benzyllithium dimer of $MeP(C_6H_4CH_2NMe_2{-}2))C_6H_4CHLiNMe_2{-}2)_2$ (**87**) reveals both intra- and intermolecular direction of lithiation in the solid state. Whereas one metal centre is η^2-bonded by both the benzylic carbon with which it is formally associated and the adjacent α-nitrogen, the second metal ion shows no intramolecular N-stabilisation. It instead exhibits a weak intermolecular interaction with a benzylic carbon centre. Both alkali metal ions are intermolecularly chelated by P- and N-donors.[105]

Concerning "N+O class" directing agents, the competitive formation of $(i\text{Pr})_2NC(O)\text{-}2\text{-}Et\text{-}C_6H_3Li{\cdot}THF$ (**67**) and $(i\text{Pr})_2NC(O)C_6H_4CH(Li{\cdot}PMDETA)Me\text{-}2$ (**68**) has already been alluded to.[82] This latter compound is structurally analogous to the product of reaction between 2-ethyl-*N*,*N*-diisopropyl-1-naphthamide and *t*BuLi in toluene/THF. Crystallography reveals that $(i\text{Pr})_2NC(O)C_{10}H_6CH(Li{\cdot}3THF)Me\text{-}2$ (**86**) is monomeric in the solid state, there being no Li−C interaction and the metal instead being entirely oxygen-supported.[102] Calculations (at the 6-311G**/B3LYP level) on $(i\text{Pr})_2NC(O)C_{10}H_6CH(Li{\cdot}3OMe_2)Me\text{-}2$ corroborate the stability of the crystallographically characterised tris(solvate) and suggest that cleavage of the $Li{-}C_\alpha$ interaction occurs in order to allow coordination of the third solvent molecule. In consequence, the calculated enthalpy of complexation for the introduction of this donor molecule is largely negated.[102]

Whereas the absence of structural data on ortholithiated pyridines has already been mentioned, 2-[bis(trimethylsilyl)methyl]pyridine is known to undergo lateral deprotonation. It is now several years since the solid-state structure of the dimeric product was first revealed.[115] Recently, however, this species has been revisited, with a topological analysis of single crystal neutron diffraction data being combined with DFT calculations to reveal that in the dimer of $2\text{-}(Me_3Si)_2CLiC_5H_4N$ (**100**) delocalisation of the C−Li bonding electrons over the agostic alkyl group controls the geometry of the Si−C−Li bond angle.[116] Just as ortho- and lateral deprotonation represent competing reactions in the case of 2-[bis(trimethylsilyl)methyl]pyridine, the lithiation of 2,6-disubstituted analogues has led to the elucidation of both the monolithiate $[2\text{-}Me\text{-}6\text{-}CH_2LiC_5H_4N]_2$ (**101**)[117] and the monomeric dilithiate $2,6\text{-}[Me_3SiCH(Li{\cdot}TMEDA)]_2C_5H_4N$ (**102**).[118] In this last complex the aromatic dianion acts as a η^2-donor to each of the two metal ions, utilising its formal charge centres and pyridyl nitrogen to do this. More complicated is the mixed anion-dianion product of reaction between 2-hydroxy-6-methylpyridine and *n*BuLi. Deprotonation is effected not only at the hydroxy position in all ligands within the cluster, but also at the orthomethyl group in four of these ligands, making the product $(2\text{-}OLi\text{-}6\text{-}CH_2LiC_5H_3N)_4{\cdot}(2\text{-}OLi\text{-}6\text{-}MeC_5H_3N)_6{\cdot}9THF$ (**103**).[119]

Perimetallation

Contrary to ortho- and lateral metallation, perimetallation occurs in the absence of electron-withdrawing properties in the directing group. Instead, whereas evidence exists (see above) for the kinetic nature of deprotonation at the ortho position, a perimetallated salt represents the thermodynamic product of reaction between organolithium and substituted arene.

Solution Studies

The THF-solvated and perilithiated derivative of 1-(dimethylamino)naphthalene has been probed by low-temperature ^{13}C NMR spectroscopy, with both the observed $^1J(^{13}C,^7Li)$ coupling constant of 20.5 Hz and the sevenfold multiplicity of the peri carbon resonance suggesting that 1-(dimethylamino)-8-naphthyllithium·THF (**104**) is dimeric in $[D_8]THF$ at −90 °C.[120]

In light of formative MNDO studies,[121] the perimetallation of 1-naphthol in THF to give $LiOC_{10}H_6Li\text{-}8{\cdot}THF$ (**105**) has been studied both as a function of the *n*BuLi:1-naphthol ratio and (for reaction in a 4:1 ratio) as a function of temperature. Moreover, $^6Li,^1H$ HOESY[122] has revealed the presence of a strong correlation for the peri hydrogen and has thus established the intermediacy of a mixed aggregate in the deprotonation of 1-naphthol.[123] Whereas the ortholithiation of 1-methoxynaphthalene by *n*BuLi/TMEDA (to give **6**) has already been alluded to effect per-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

imetallation. Moreover, the isotope effect suggestive of kinetic control in the former reaction is not observed in the latter case, pointing to perimetallated product **8** representing the thermodynamic one.[25]

The ability of lithium itself to direct perimetallation has been investigated in the context of the dilithiation of naphthalene. $^{6}Li,^{1}H$ HOESY[122] and one-dimensional $^{6}Li\{^{1}H\}$ spectroscopy[36b] have been employed to probe the 1:1 complex between 1-naphthyllithium and TMEDA (**106**) with data suggesting chelation of the metals in a dimeric aggregate. Treatment of **106** with *n*BuLi has long been known to effect the formation of 1,8-$Li_2C_{10}H_6$ (**107**),[124] with $^{6}Li,^{1}H$ HOESY more recently revealing a cross-peak involving the peri hydrogen atom prior to reaction and suggesting activation of this position.[122]

Solid-State Studies

Little structural work has been done on perimetallated systems in the solid state. The simple dimers of 1-(dimethylamino)-8-naphthyllithium·THF (**105**) and 1-methoxy-8-naphthyllithium·THF (**108**) obtained from the reaction of *n*BuLi with "N class" and "O class" directors 1-(dimethylamino)naphthalene[120] and 1-methoxynaphthalene,[120,125] respectively, have been crystallographically characterised. In each case the metal components of a core $(C_{peri}Li)_2$ ring are supported by reaction-directing amine or methoxy heteroatoms and, for **105**, this renders the structure analogous to that noted in Lewis base solution (see above). The core-naphthyl twist-angle of 63° in the crystal structure of **105** is decreased to 38° in that of **108**. If the inferior Lewis base OEt_2 is used in place of THF then the twist-angle is reduced further, such that dimeric 1-(dimethylamino)-8-naphthyllithium·OEt_2 (**109**) reveals an 11° twist.[69,126] This trend is backed up by semi-empirical (PM3) calculations.[120]

Conclusions

Directed metallation using Group 1 organometallic bases in general and organolithium substrates in particular has been shown to be of great efficacy in regiospecifically elaborating benzenoid rings (ortho-, perimetallation) and their substituents (lateral metallation). While the manifold synthetic applications of this chemistry have been extensively reviewed[1,3,8] the structural parameters surrounding lithiated species of types salient to such processes have been discussed here.

Of interest in interpreting the ability of directing groups to interact with incoming organolithium substrates are the structural elucidation of several species that incorporate either *tert*- (*cf.* **30**)[42] or *n*BuLi. The latter have taken the form of both organolithium-organic complexes (*cf.* **3**, **4**, **7**)[22,23,25] that represent precursors to directed reaction and mixed-anion organolithium co-complexes (*cf.* **33**, **48**, **61**, **64**, **81**–**84**).[38,62,75,78,97,98] This latter class of aggregates pose interesting questions about the nature of multilithiation processes.[78]

In the context of straightforward monolithiates many of the compounds discussed reveal structural characteristics normal to the field of organolithium chemistry. However, the inclusion of various mono- (e.g. "O class" or "N class") or polyheteroatom (e.g. "N+O class") directing groups has had significant effects in several cases. The ability of various electron-rich directors to interact with metals at ortho, lateral and peri sites is richly demonstrated and has been shown to effect observed chemistries in synthetically important transformations such as tertiary amide directed metallation.[81–82] Less predictable are polymetallated species. Nevertheless, fundamentally similar chelation-control processes to those noted in monolithiates dictate their structures. Overall, the synthetic utility of directed metallation is well established and promises to facilitate the development of new methodologies and total syntheses in the future. Central to the understanding of these processes is the understanding of organolithium complexes of the types discussed here.

Synthesis and Structure of a Monomeric Chiral Lithium Dialkylaluminium Amide Derived from Schöllkopf's Bis-lactim Ether and α-(Methylbenzyl)benzylamine

Philip C. Andrews,*[a] Melissa Maguire,[a] and Esteban Pombo-Villar[b]

Dedicated to the memory of Ron Snaith in recognition of his great contribution to lithium chemistry

Keywords: Lithium / Aluminium / Chirality / Amides / Structure elucidation

Crystals of a monomeric lithium dialkylaluminium amide containing two different chiral amide moieties have been isolated from the reaction of lithiated Schöllkopf's bis-lactim ether complexed by pmdta with the diethylaluminium amide of (*S*)-α-(methylbenzyl)benzylamine, with single crystal X-ray diffraction revealing a migration of the Li cation in the aluminate from its initial position on the pyrazine ring of the lactim ether precursor.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Lithium aluminates can show significantly different reactivity and selectivity when compared to that of their constituent parts — the nucleophilic alkyllithium or lithium hydride and the organoaluminium species — the reactivity of the latter being dominated primarily by its Lewis acidic properties.[1a−1c] By analogy, lithium dialkylaluminium amides have the potential to play a similar role, although synthetic activity has largely focused on the amidohydroaluminates.[2a,2b] However, some interest in their solid-state structures has developed since they fall within an important broader group of main-group heterobimetallic complexes containing group 1 metals, a family of complexes whose reactivity and selectivity is only gradually coming to be understood and exploited.[3a−3e] The lithium dialkylaluminium amide complexes that have been structurally characterised to date are comprised primarily of (N_2MM') rings,[4a−4d] the two metals not surprisingly being bridged by the N_{amido} atoms, for example $[Me_2Al(Bn_2N)_2]Li\cdot(THF)$],[5] although further association into a ladder-type structure[6] and bridging through Me groups has also been observed.[7]

Recently, we have been interested in two related areas dealing with the structural chemistry of chiral lithium amide bases which are important in the synthesis of biologically active compounds. The first area is the alkali-metal complexes of α-(methylbenzyl)benzylamine,[8a−8c] which have become prominent in β-amino acid and β-lactam syntheses,[9a−9d] and we have been extending our studies to the reactions of this and similar chiral amines with group 13 organometallic compounds. The second area concerns the lithium complexes of Schöllkopf's bis-lactim ether, 1-lithio-3,6-diethoxy-2-isopropyl-1,2-dihydropyrazine,[10a−10c] and we recently reported the structure of the complex coordinated by the tridentate donor pmdta, (*R*)-**1**, represented in Figure 1.[11]

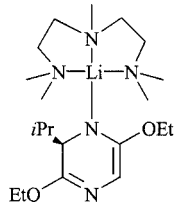

Figure 1. Lithiated Schöllkopf's bis-lactim ether, (*R*)-**1**, coordinated by pmdta

In bringing these two "precursor" areas together we have now synthesised and structurally characterised, by single-crystal X-ray diffraction, the first lithium dialkylaluminium amide, **2**, which is both monomeric in the solid state and comprised of two completely different chiral amide bases.

Results and discussion

Prompted by extensive studies on the formation of aluminium amides from dibenzylamine[12] we found that the thermal elimination of EtH from the reaction of Et_3Al and

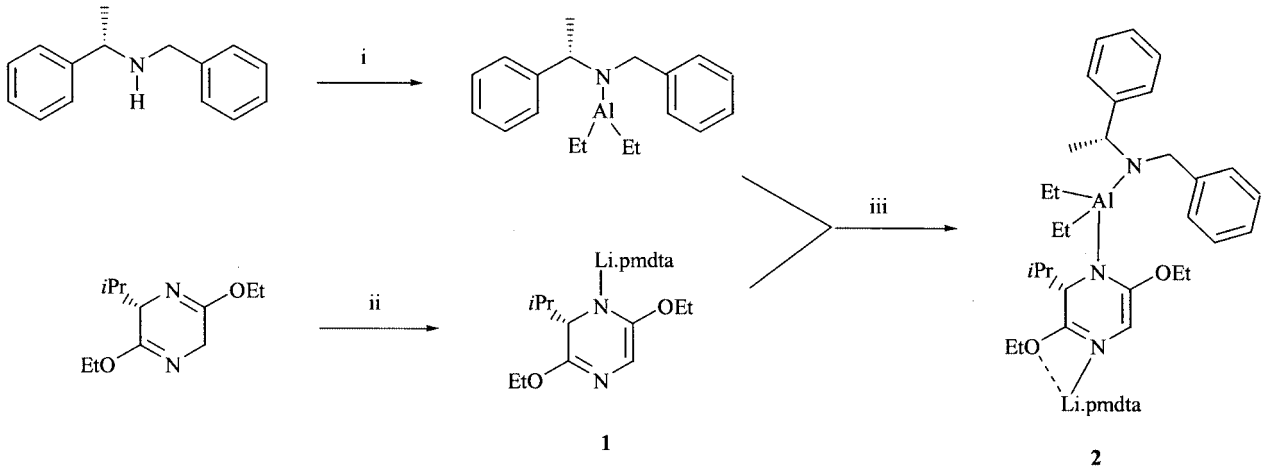

Scheme 1. Reaction conditions; i. Et_3Al, toluene, 120 °C, 4−6 h; ii. *n*BuLi, pmdta, toluene, −30 °C to room temp.; iii toluene, −30 °C to room temp.

(*S*)-α-(methylbenzyl)benzylamine occurs on heating to 120 °C (Scheme 1), although no crystalline product has yet been obtained from this reaction. This may be influenced by the fact that EtH elimination does not appear to occur quantitatively.

Following an analogous procedure to that described for the synthesis of $[Me_2Al(Bn_2N)_2]Li\cdot(py)]$,[13] a toluene solution of the lithiated Schöllkopf's bis-lactim ether, (*S*)-**1**, was added to a toluene solution of the aluminium amide generated in situ. A deep orange coloured solution was formed from which a low yield of orange crystals were isolated after approximately one week at −25 °C. By this time the solution had become dark red.

A second crop of crystals was then extracted after refrigeration at 4 °C over several days. However, the collective yield was still not high (32%) and no further solid product was obtained even at lower temperatures, with a dark red oil being observed to have formed. The crystals melt to a deep red between 142−144 °C and, as would be expected, are highly sensitive to atmospheric moisture and oxygen. Elemental analysis, multi-dimensional NMR studies, and single crystal X-ray diffraction identified the crystals as the chiral heterobimetallic species **2** (Figure 2).

Complex **2** crystallises in the orthorhombic space group $P2_12_12_1$ with four molecules in the unit cell. Although the crystal quality was not exceptionally high, leading to a large amount of weak intensities and high R_{int} value, the structural solution was of sufficient quality to allow us to assign definitive atom connectivities. The first striking feature of the structure comes directly from a comparison with the parent lithiated bis-lactim ether **1**. As can be seen, the Li cation, with its accompanying pmdta molecule, migrates from one N in the pyrazine ring in **1** to the opposite one in **2** as the lithium aluminate is formed. The Li(1)−O(2) bond at 2.543(11) Å would be considered long, however, an analysis of the bond angles at the sp^2 pyrazine nitrogen attached to Li reveals a high degree of asymmetry [Li(1)−N(3)−C(22) 108.7(5)°, Li(1)−N(3)−C(21)

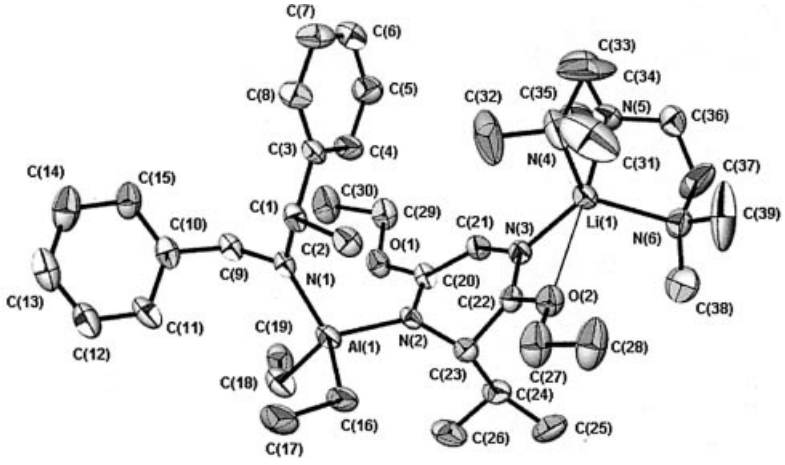

Figure 2. Molecular structure of (*S,S*)-**2**; thermal ellipsoids shown at 50% probability; all H atoms omitted for clarity; selected bond length (Å) and angles (°); Li(1)−N(3) 2.014(12), Li(1)−N(4) 2.117(14), Li(1)−N(5) 2.127(13), Li(1)−O(2) 2.543(11), Al(1)−N(1) 1.860(5), Al(1)−N(2) 1.939(5), C(21)−N(3) 1.423(8), C(22)−N(3) 1.265(7), N(2)−C(23) 1.449(7) N(2)−C(20) 1.352(7); Al(1)−N(2)−C(23) 122.0(4), Al(1)−N(2)−C(20) 126.4(4), Li(1)−N(3)−C(22) 108.7(5), Li(1)−N(3)−C(21) 136.2(5), C(21)−N(3)−C(22) 114.1(5), C(20)−N(2)−C(23) 111.5(5), N(2)−C(23)−C(22) 105.2(5)

136.4(5)°] with the Li cation clearly associating itself preferentially with the C=N bond [C(21)−N(3) 1.423(8) Å, C(22)−N(3) 1.265(7) Å] and the ethoxy O atom. The Li−N_{amido} distance in **2** of 2.014(12) Å is only marginally longer than that in **1** [1.965(3) Å] and is typical of four-coordinate Li complexed by pmdta. Not unexpectedly there are two significantly different Al−N bond lengths. They are 1.860(5) Å and 1.939(5) Å for Al(1)−N(1, 2) respectively indicating that the tetravalent Al center is bound more tightly to the α-(methylbenzyl)benzylamido group than to the pyrazine ring. Though there are no direct structural comparisons available for **2** since all analogous compounds contain bridging N rather than terminal, the Al(1)−N(1) distance is nevertheless similar to those commonly found in complexes with a dialkylaluminium dibenzylamido moiety in which Al is four coordinate (e.g. 1.982 Å in $[Bn_2NAlMe_2]_2$),[14] while the bond from Al(1)−N(2) is longer than that commonly found {e.g. 1.934(2) Å in $[Me_2Al(Bn_2N)_2]Li\cdot(py)$]}.[13] This is undoubtedly to relieve steric interactions between the Al centre and the pyrazine ring and is compensated for by the shorter Al(1)−N(1) bond.

It is hard to reason the migration of the Li^+ solely on steric grounds, i.e. avoidance of the *i*Pr group, since the presence of the two Et and the α-(methylbenzyl)benzylamido groups on the Al centre amounts to a substantial degree of steric bulk, most likely equivalent to that offered by pmdta on the Li cation. However, it is notable that in both **1** and **2** the metals locate themselves on the side of the pyrazine ring opposite the *i*Pr group, and, indeed, in **2** both Li and Al are located on the same side of the slightly buckled ring. If we assume the precursor to the aluminate is an intermediate containing a mixed-metal aggregate structured around the formation of a (Li-*N*-Al-N) four-membered ring then the steric strain could easily influence the cleavage of the Li^+-N^- bond and separation of the pmdta-bound Li cation. We had speculated when reporting the solution studies on (*R*)-**1** that, even without any additional chemical factors, a relocation of the Li cation was possible though our evidence was circumstantial.[11] As such, several co-incident factors may effect the migration of the lithium ion and aluminate formation: the possibility of solvent-separated ion pairs in **1** facilitated by the ethoxy groups, the sterically assisted weakening and ultimate cleavage of the Li^+-N^- bond, and the greater electrophilicity of Al^{3+} over that of Li^+. The Li cation then satisfies its coordinative demands by bonding with the available electron density associated with the N=C bond and the OEt group.

It is important to note that it would not be possible to form complex **2** by the alternate route which would involve swapping the metals on the constituent components, principally because the pmdta complex of α-(methylbenzyl)-benzylamidolithium undergoes facile transformation to an aza-allyl complex at low temperature.[8c] However, this could indicate one possibility for the gradual presence of the red oil in the reaction mixture if an electronic rearrangement in solution occurs which allows for the formation of (*S*)-[{Ph(Me)CH}($PhCH_2$)NLi·(pmdeta)] and its subsequent decomposition.

From this structural study there is no doubt that **1**, **2** and any Lewis base (L) complexes of α-(methylbenzyl)benzylamidolithium, $[\{PhC(Me)H\}(PhCH_2)NLi\cdot(L)_k]_n$, would behave very differently to each other in synthetic procedures, an aspect which needs to be further explored.

Experimental Section

Crystallographic Data for (*S,S*)-2: $C_{35}H_{68}AlLiN_6O_2$, M = 686.91, T = 123 K, orthorhombic $P2_12_12_1$, a = 14.300(3), b = 16.848(3), c = 17.659(4) Å, V = 4254.5(15) Å^3, D_c = 1.072 g·cm^{-3}, Z = 4; $F(000)$ = 1504, $\mu_{Mo\text{-}K\alpha}$ = 0.85 cm^{-1}, $2\theta_{max}$ = 56.6°, N_{tot} = 43347, N = 10455 [R(int) = 0.2173], N_o = 5801, final R, R_w = 0.076, 0.17 [$I > 2\sigma(I)$], GooF 0.938. Crystals were coated in oil, mounted on a fibre,[15] and data collected on an Enraf−Nonius KappaCCD at 123 K with Mo-K_α radiation (λ = 0.71073Å). The structure was solved by direct methods (SHELXS-97)[16] and refined by full-matrix least-squares on F^2 using the X-Seed interface.[17] All H atoms were placed in calculated positions (C−H 0.95 Å) and included in the final least-squares refinement. All other atoms were located and refined anisotropically. The absolute stereochemistry could not be accurately determined since the Flack parameter was indeterminate and the final assignment was based on a knowledge of the starting materials.

CCDC-197094 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis of (*S,S*)-2: Et_3Al (5 mmol, 5 mL of a 1 M solution in hexanes) was added to a toluene solution of (*S*)- α-(methylbenzyl)-benzylamine (5 mmol, 1.05 mL) and heated to 120 °C for 6 h. On cooling to room temperature this was then added to a chilled (−30 °C) equimolar toluene solution of (*S*)-**1**, prepared by the method previously described for (*R*)-**1**.[11] The reaction mixture was allowed to warm slowly to room temperature and stirred overnight before being placed in the freezer at −25 °C. After approximately one week a moderate crop of yellow crystals were obtained. These were isolated and washed with cold toluene. A further crop of crystals were obtained after a further duration at 4 °C. These were analytically identical to the first crop. Yield 32% (1.1 g), m.p. 142−144 °C (decomp. to dark red melt). ^{1}H NMR (300 MHz, 25 °C, [D_6]benzene): δ = 7.79 (d, 2 H, *o*), 7.73 (d, 2 H, *o*), 7.34 (m, 4 H, *m*), 7.15 (m, 2 H, *p*), 4.84 (s, 1 H, C=C*H*), 4.68 (d, 1 H, PhCH_2), 4.47 [q, 3 H, Ph(Me)C*H*), 4.40 (d, 1 H, *i*Pr-C*H*), 4.06 (d, 1 H, PhCH_2), 3.95 (q, 2 H, CH_2O···Li), 3.66 (q, 2 H, CH_2O), 2.45 (m, 1 H, Me_2CH), 1.87 (m, 6 H, $AlCH_2CH_3$), 1.80 (br., 3 H, PhC(*Me*)H], 1.79, 1.71, 1.65, 1.58 (br., 4 × s, 23 H, pmdta), 1.39 (d, 3 H, Me_2CH), 1.00 (d, 3 H, Me_2CH), 0.68 (m, 4 H, $AlCH_2CH_3$) ppm. ^{13}C NMR (75.5 MHz, 25 °C, [D_6]benzene): δ = 158.1 (*q*C), 148.1 (*q*C), 147.5 (*q*C), 128.0 (*o*CH), 127.5 (*m*CH), 123.9 (*p*CH), 123.8 (*p*CH), 81.5 (N-*C*=C), 61.7 (C=*C*-O), 61.0 (CH_2O), 58.0 [Ph*C*(Me)], 56.4 (CH_2O), 54.6 (CH_2N), 52.7 ($PhCH_2$), 51.9 (MeN), 43.8 (Me_2N), 25.4 (Me_2C), 24.5 (Me_2C), 18.4 (CH_3), 14.0 (CH_3), 11.1 (CH_2Al) ppm. $C_{35}H_{68}AlLiN_6O_2$ (638.9): calcd. Synthesis and Structure of $[\{(THF)_2Li\}_3Me_2Al\{(PhNH)_2(PhN)_4P_3N_3\}]$, the First Mixed-Metal Phosphazenate Complex

Frederic Rivals[a] and Alexander Steiner*[a]

In memory of Ron Snaith

Keywords: Phosphazenes / Phosphazenates / Aluminium / Lithium / Heterometallic complexes

Reaction of the trilithium phosphazenate $[\{(THF)_2Li\}_3\{(PhNH)_3(PhN)_3P_3N_3\}]$ with one equivalent of trimethylaluminium yields the first mixed-metal phosphazenate complex $[\{(THF)_2Li\}_3Me_2Al\{(PhNH)_2(PhN)_4P_3N_3\}]$. X-ray structure analysis showed that the Me_2Al group is accommodated in an N(exo)–P–N(exo) chelation site of the phosphazenate ligand. Two lithium ions reside in N(ring)–P–N(exo) sites, while the third lithium ion interacts with the ligand solely via an N(ring) atom. NMR spectroscopic data obtained from THF solution indicate a fluxional behaviour of the lithium ions, which oscillate between mono- and bidentate coordination sites.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Multianionic ligand systems containing extended arrays of coordination sites often enable the accommodation of well-defined and kinetically stable multinuclear metal ion and mixed-metal ion arrangements. Prominent examples are multianionic calixarinates[1] and calixpyrrolates[2] comprising cyclic structures of repeating monoanionic phenolate and pyrrolate units, respectively. Recently, we introduced phosphazenates as multianionic ligands. They are assembled from repeating tridentate dianionic $[-N{=}P(NR)_2-]^{2-}$ units and facilitate the accommodation of large numbers of metal ions around the ligand backbone in a variety of bi- and tridentate coordination sites.[3] The highly selective sequential deprotonation patterns of the multiprotic phosphazene precursors enable the synthesis of well-defined partially metallated phosphazenate complexes. For example, threefold deprotonation of the hexaprotic phosphazene $(PhNH)_6P_3N_3$ (**1**) by *n*BuLi occurs in a *cis*-fashion yielding the monomeric trilithium phosphazenate $[\{(THF)_2Li\}_3\{(PhNH)_3(PhN)_3P_3N_3\}]$ (**2**), which hosts three lithium ions in alternating N(ring)−P−N(exo) chelation sites on one face of the central phosphazenate ring.[4] The other face of the ring is equipped with three protonated N(exo) functions. Organoaluminium compounds were also applied as metallating agents. Trimethylaluminium fully deprotonates $(CyNH)_6P_3N_3$ to give the monomeric pentanuclear organoaluminium complex $[(THFMeAl)(Me_2Al)_4\{(CyN)_6P_3N_3\}]$ (**3**). All five Al atoms in **3** occupy bidentate chelation sites.[5] Threefold deprotonation generates the trinuclear complex $[(Me_2Al)_3\{(CyNH)_3(CyN)_3P_3N_3\}]$.[3a] The characteristic sequential metallation pattern leading to multinuclear metal phosphazenates is an ideal platform for the preparation of mixed-metal complexes by subsequent treatment of multiprotic phosphazenes with different metallating agents. Herein, we discuss further metallation of the trilithium complex **2** with Me_3Al. This reaction yields the complex $[\{(THF)_2Li\}_3Me_2Al\{(PhNH)_2(PhN)_4P_3N_3\}]$ (**4**), the first example of a mixed-metal phosphazenate.

Results and Discussion

The trilithium phosphazenate **2** reacts with one equivalent of trimethylaluminium in THF as indicated by the appearance of a doublet at $\delta = 3.7$ ppm and a triplet at $\delta = 7.9$ ppm, with an intensity ration of 2:1, in the ^{31}P NMR spectrum. The reaction product was crystallised from THF solution and an X-ray structure analysis showed the formation of the monomeric complex $[\{(THF)_2Li\}_3Me_2Al\{(PhNH)_2(PhN)_4P_3N_3\}]$ (**4**; Figure 1). In addition, the crystal lattice contains two non-bonded THF molecules per formula unit. The crystal structure reveals that one NH group of **2** has been deprotonated by Me_3Al, with evolution of methane (Scheme 1). One exocyclic N−P−N unit chelates the resulting Me_2Al group by forming a planar four-membered PN_2Al ring system. Both N−Al bonds are of equal length (selected bond lengths and angles are listed in Table 1). The chelation of an Me_2Al group in an exocyclic N−P−N site of a phosphazenate ligand also occurs in the solid-state structure of the pentaalu-

minium phosphazenate **3**.[5] The two lithium ions Li2 and Li3 reside in the N(ring)−P−N(exo) sites of **4**, while Li1 is interacting with the ligand solely via an N(ring) atom. In addition, each lithium ion is coordinated by two THF molecules. This results in a trigonal planar coordination at Li1 and distorted tetrahedral environments at Li2 and Li3. The Li−N(ring) distance at Li1 is shorter than the Li−N distances of Li2 and Li3, reflecting the low coordination number of Li1. Within the bidentate chelates Li−N(exo) bonds are slightly shorter than Li−N(ring) bonds. The coordination of Li2 and Li3 is similar to that of the lithium ions in the C_3 symmetrical precursor complex **2**.[4] In **4** there are no interactions between the Al-coordinated N(exo) centres and the lithium ions, presumably due to the strong acceptor behaviour of the aluminium atom. This reduces the number of N-donor sites available for Li coordination. As a result, the ligand provides only a monodentate interaction to one of the lithium ions.

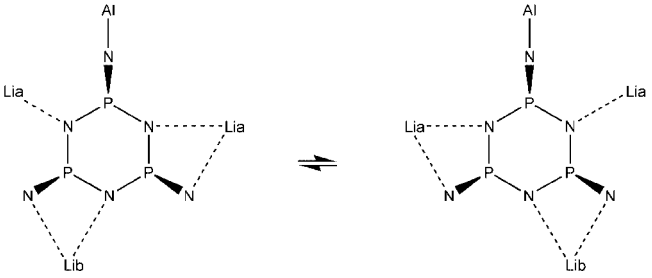
The central P_3N_3 ring in **4** adopts a half-chair conformation. The ring atom N2 deviates by 0.43 Å from the planar arrangement of the other five ring atoms. The P−N(ring) bond lengths are similar throughout the ring, ranging from 1.605(3) to 1.622(3) Å. Conversely, the P−N(exo) bond lengths have a broader range: short P−N(exo) bonds are found at lithiated N(exo) positions [P−N(Li) 1.593(3), 1.595(3) Å], while P−N(exo) bonds within the chelate coordinating Al1 are of intermediate length [P−N(Al) 1.659(3), 1.666(3) Å] and P−N(exo) bonds associated with NH functions are relatively long [P−N(H) 1.701(3), 1.709(3) Å]. Equally short P−N(Li)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bonds and long P−N(H) bonds were observed in **2**, but somewhat shorter P−N(H) bonds were found in the hexaprotic phosphazene **1**.[6] Interestingly, the average P−N bond length of the four P−N bonds surrounding one phosphorus atom is almost the same for all three P atoms (av. P−N at P1: 1.638, at P2: 1.635 and at P3: 1.631 Å). This cooperative "seesaw" effect suggests that the P−N bond orders within each PN_4 tetrahedron vary, but the overall sum of P−N bond orders around each P atom is finely balanced. A similar effect has been observed for the S−N bonds in iminosulfonate complexes.[7] The shortness of the P−N(Li) bonds indicates delocalisation of the negative charge from the P−N(Li) onto the P−N(ring) bond and a mainly ionic character of the N−Li interactions. This extra amount of negative charge around the PN_4 tetrahedra is compensated by an elongation of the P−N(H) bond. On the other hand the N−Al bonds in **4** are covalent, as indicated by P−N(Al) bonds of intermediate lengths. The range of exocyclic N−P−N angles mirrors the flexibility of the phosphazenate ligand towards metal coordination. The N−P−N angle of the exocyclic chelate hosting the aluminium centre is very sharp [89.9(2)°] compared to the other two exocyclic N−P−N angles [111.0(2), 111.8(2)°]. The N−P−N angles within the ring are similar and range from 113.3(2)° to 114.2(2)°. The two N(ring)−P−N(exo) angles of lithium binding chelates are identical [102.6(2), 102.7(2)°], but not as acute as that of the Al binding site.

A variety of complexes containing both lithium and aluminium centres have been described,[8] although the accommodation of three Li and one Al centre around one ligand system has not been reported so far. The coordination modes exhibited in **4** are closely related to those of other ligands containing N−P−N chelates.[3a] Several metal complexes have been described featuring four-membered PN_2M ring systems where M is either Li[9] or Al.[10] Monodentate coordination of N-donor ligands towards tricoordinate lithium ions in monomeric complexes, like Li1 in **4**, is usually achieved by bulky ligands with sterically demanding substituents.[11] On the contrary, the phosphazenate ligand **4** gains its steric demand by accommodating a larger number of metal ions rather than providing bidentate chelation sites.

In contrast to the solid-state structure, which contains three chemically different phosphorus nuclei, the ^{31}P NMR spectrum of a solution of complex **4** in THF exhibits an AX_2 system. Variable-temperature NMR studies were hampered by the low solubility of **4** in THF at low temperatures. However, NMR spectroscopic data obtained from measurements at room temperature suggest a fluctuating behaviour of the lithium ions in solution, as illustrated in Scheme 2. The three lithium ions oscillate in a concerted manner around the three N(ring) and the two lithiated N(exo) sites. The two chemically equivalent lithium ions, Li^a, oscillate between a bidentate N(ring)−P−N(exo) chelate and the monodentate N(ring) site, whilst Li^b oscillates between two neighbouring N(ring)−P−N(exo) sites. This mechanism is backed up by the ^7Li NMR spectrum, which consists of two signals at δ = 2.83 and 3.40 ppm displaying an intensity



Scheme 2. Proposed mechanism of fluctuation of lithium ions within complex **4** in THF solution (for clarity, only P, Al, Li and coordinating N atoms are shown)

ratio of 2:1. Also, four sets of chemically distinct phenyl groups are evident from the ^{13}C NMR spectrum, reflecting the mirror symmetry of the fluctuating structure. These four sets consist of: (i) the two PhNH groups, (ii) the two PhNLi groups, (iii) the PhNAl group at the "NH face" of the phosphazenate ring, and (iv) the PhNAl group at the "NLi face" of the ring. The ^1H NMR spectrum exhibits one singlet at δ = −0.89 ppm for the Me_2Al, unit indicating the chemical equivalence of both methyl groups, and one signal at δ = 6.21 ppm for the two NH groups.

Further metallation of the phosphazenate ligand in **4** appears possible, since it holds two potentially acidic NH functions. The stepwise addition of excess Me_3Al to **2** was monitored by ^{31}P NMR spectroscopy (Figure 2). The familiar AX_2 pattern of **4** emerges upon addition of one equivalent Me_3Al. After further addition of Me_3Al several other species appear, exhibiting either an AX_2 or AXY pattern, indicating the presence of either two or three distinct phosphorus nuclei. So far, we have been unsuccessful in isolating mixed Li-Al complexes showing higher metallation grades than **4**. Moreover, complex **4** proved to be a rather stable member of a possible series of mixed Li-Al phosphazenates, since higher metallated species slowly degrade in THF solu-

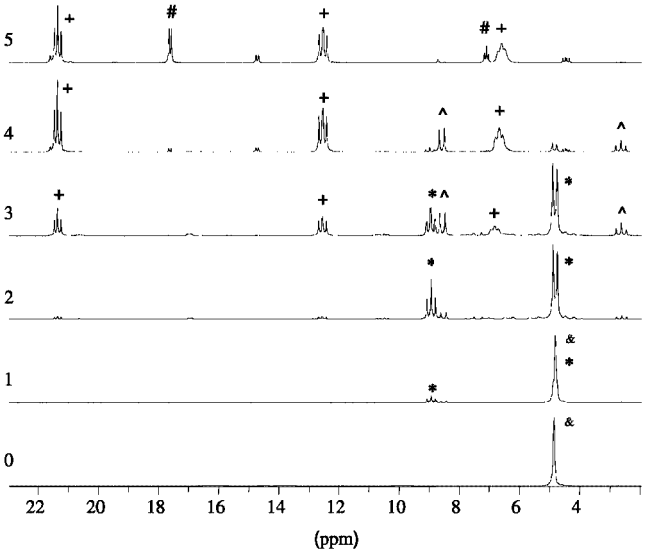


Figure 2. ^{31}P NMR spectrum of stepwise reaction of **2** with *n* equivalents of Me_3Al in THF at room temperature; & represents complex **2** and * complex **4**; +, ^ and # indicate further metalated species

tion to give **4**. The fluctuating behaviour of lithium ions could be a stabilising factor for **4**.

In summary, we have presented the first phosphazenate complex that accommodates a mixed-metal array. The synthesis of the mixed Li-Al complex was achieved by successive deprotonation of a hexaprotic phosphazene with *n*BuLi and Me_3Al. It looks as if a variety of other stable mixed-metal species can be generated by exploiting the selective metalation pattern of multiprotic phosphazenes. Metal ions and organometallic fragments occupy specific coordination sites around the phosphazenate core. The ligand provides both rigid metal chelation and allows a fluctuating behaviour of the metal ions within the ligand sphere. This concept could lead to tailor-made, mixed-metal complexes for homogeneous catalysis.

Experimental Section

All synthetic procedures were carried out under a dry N_2 atmosphere. Compounds **1**[6] and **2**[4] were prepared according to literature methods. Organometallic reagents were applied as standard solutions: *n*BuLi (1.6 M in hexane) and Me_3Al (2 M in hexane).

Synthesis of 4: *n*BuLi (0.85 mL, 1.35 mmol) was added at −78 °C to a solution of **1** (300 mg, 0.45 mmol) in 20 mL of THF. After stirring for one hour at room temperature, Me_3Al (0.22 mL, 0.45 mmol) was added dropwise and the solution was stirred overnight at room temperature. Subsequently the reaction solution was filtered and the volume of the filtrate reduced by half in vacuo. Single crystals were obtained after three days. In the absence of mother liquor the crystals degrade to give a white powder. Yield 215 mg (73%). ^{1}H NMR (300 MHz, [D$_8$]THF SiMe$_4$): δ = −0.87 (s, 3 H, AlC*H*$_3$), 6.21 (br., 2 H, N*H*), 6.98−6.51 (m, 30 H, Ph) ppm. ^{7}Li NMR [97.16 MHz, THF, $(CD_3)_2CO$, LiCl in D_2O ext.] δ = 2.83 (2 Li), 3.40 (Li) ppm. $^{13}C\{^1H\}$ NMR (75.46 MHz, [D$_8$]THF, SiMe$_4$): δ = −9.94 (Me_2Al), 113.6, 114.7, 115.3, 116.7 (*ortho*), 117.4, 120.0, 120.1, 120.2 (*para*), 127.6, 127.7, 127.8 128.1, (*meta*), 143.8, 148.5, 148.7, 153.1 (*C*N) ppm. ^{31}P NMR (101.25 MHz, [D$_8$]THF, 85% H_3PO_4 in D_2O ext.): δ = 3.7 (t, $^2J_{P,P}$ = 21.8 Hz, 1 P), 7.9 (d, $^2J_{P,P}$ = 21.8 Hz, 2 P) ppm. IR (nujol): $\tilde{\nu}$ = 3380.5 (N−H), 1588.2, 1335.3, 1300.2, 1242.5, 1109.2 (P−N), 1073.5, 1030.9, 1005.9, 891.9, 860.8, 797.2, 748.6, 692 cm^{-1}. $C_{62}H_{86}AlLi_3N_9O_6P_3$ (1193.62): calcd. C 62.4, H 7.26, N 10.6; found C 62.0, H 7.01, N 11.1.

Crystal data for **4**·2THF were recorded on a Stoe-IPDS diffractometer using Mo-K_α radiation (λ = 0.71073 Å), T = 200 K. The structure was solved by direct methods and refined by full-matrix least-squares against F^2 using all data (SHELX-97). $C_{70}H_{102}AlLi_3N_9O_8P_3$: M = 1338.32, triclinic, $P\bar{1}$, a = 12.431(2), b = 14.467(2), c = 23.663(4) Å, α = 91.97(2)°, β = 101.62(2)°, γ = 114.46(2)°, V = 3760.9(9) Å^3, Z = 2, D_c = 1.182, μ(Mo-K_α) = 0.147, number of reflections: 23726 (total), 11018 (unique), R_{int} = 0.057, R_1 [$I > 2\sigma(I)$] = 0.057, wR_2 (all data) = 0.160. One THF molecule bonded to Li3 and the two non-bonded lithium ions are disordered over two positions and were refined using similar distance and similar U restraints. Non-hydrogen atoms were refined anisotropically, except for the disordered positions, which were treated isotropically. H-atoms were placed geometrically in accordance with the hybridisation of their parent atoms.

CCDC-208395 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Cooperative THF Ring-Opening by $B(C_6F_5)_3$ and a Tellurium Diimide Dimer

Tristram Chivers*[a] and Gabriele Schatte[a]

Dedicated to the memory of Professor Ron Snaith

Keywords: N ligands / Ring opening / Lewis acids / Boron / Tellurium

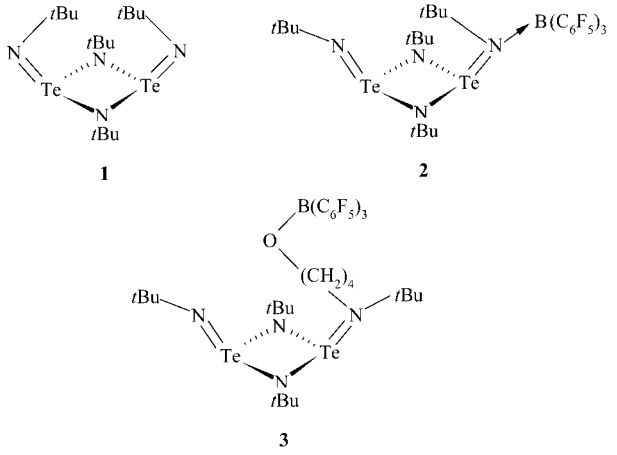
The tellurium diimide dimer [*t*BuNTe(μ-N*t*Bu)$_2$TeN*t*Bu] (**1**) and $B(C_6F_5)_3$ form a 1:1 adduct which instigates THF ring-opening to give [*t*BuNTe(μ-N*t*Bu)$_2$TeN(*t*Bu)$(CH_2)_4OB(C_6F_5)_3$] (**3**) quantitatively; complex **3** is also formed rapidly when **1** is added to a THF solution of $B(C_6F_5)_3$.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

The perfluorinated borane $B(C_6F_5)_3$ was first reported in 1963.[1] During the past decade this strong Lewis acid has attracted wide attention as a co-catalyst for olefin polymerization.[2] While early work established that $B(C_6F_5)_3$ forms 1:1 adducts with NH_3 and NMe_3,[1] more recent studies with nitrogen bases have included cyano derivatives,[3] imidazole,[4] pyridines,[5] amines,[6] and the anions CN^- [7] and NH_2^-.[8] As part of our studies of the Lewis base behaviour of the tellurium diimide dimer *t*BuNTe(μ-N*t*Bu)$_2$TeN*t*Bu (**1**),[9] we have investigated the reaction of this bidentate ligand with $B(C_6F_5)_3$. We report here the formation of the 1:1 adduct **2**, which engenders rapid THF ring-opening to produce [*t*BuNTe(μ-N*t*Bu)$_2$TeN(*t*Bu)$(CH_2)_4OB(C_6F_5)_3$] (**3**). Complex **2** is also generated when **1** is added to a THF solution of $B(C_6F_5)_3$. Although various transition-metal and uranium complexes promote THF ring-opening,[10] main-group element Lewis acids are rarely involved[11,12] and, to the best of our knowledge, this is the first example involving $B(C_6F_5)_3$.

The reaction of **1** with $B(C_6F_5)_3$ in a 1:1 molar ratio in *n*-pentane at 23 °C produced the adduct **2** as a moisture-sensitive yellow-orange adduct in almost quantitative yield. The same reaction with a 1:2 molar ratio affords an equimolar mixture of **2** and $B(C_6F_5)_3$. The ^{11}B NMR chemical shift of **2** ($\delta = -6.1$ ppm) is consistent with the formation of a four-coordinate boron complex [cf. $\delta^{11}_B = 59.5$ ppm for $B(C_6F_5)_3$ in CD_2Cl_2].

An X-ray structural determination of **2**, on crystals obtained from a saturated CH_2Cl_2 solution at −20 °C, confirmed the formation of a 1:1 adduct and revealed a *cis*(*endo*, *exo*) arrangement of the exocyclic N*t*Bu groups



(Figure 1).[13] This conformation is also found in **1**·HCl, whereas a *cis*(*endo*, *endo*) arrangement is observed for **1** in the solid state.[14] Pertinent bond lengths and bond angles for **2** are given in the caption to Figure 1. Coordination of **1** to $B(C_6F_5)_3$ lengthens one of the exocyclic Te−N bonds involving the coordinated nitrogen by ca. 0.10 Å, whereas the other exocyclic Te−N bond is unchanged. Concomitantly, the endocyclic Te−N bond lengths involving the tellurium atom connected to the three-coordinate nitrogen are elongated by ca. 0.04 Å. The Te_2N_2 ring is puckered, with a torsion angle N(2)−Te(1)−N(1)−Te(2) of −21.17(11)°, and the geometry at the bridging N atoms is distinctly non-planar $\Sigma\angle N(1) = 344.8°$ and $\Sigma\angle N(2) = 341.3°$. The B−N bond length of 1.632(4) Å in **2** is identical to that in $(C_6F_5)_3B{\cdot}NH_2tBu$.[15] As indicated in Figure 1 the tellurium atom Te(1) engages in weak Te···F interactions [3.136(2) and 3.112(2) Å; sum of van der Waals radii is 3.53 Å[16]] with one of the *ortho*-fluorine atoms of two C_6F_5 groups. Similar intramolecular M···F contacts have been observed in transition-metal complexes.[17]

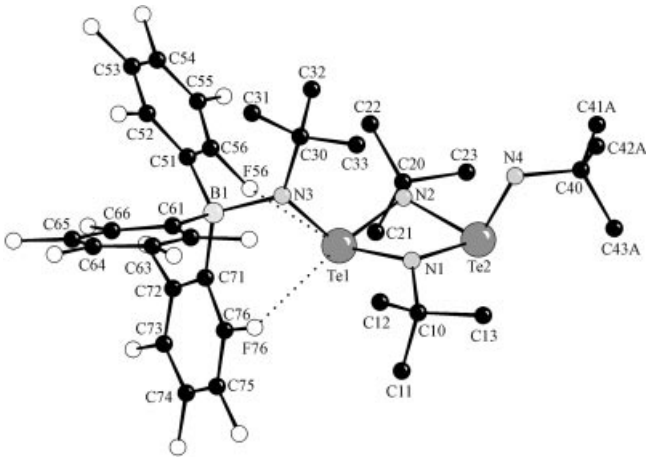

Figure 1. X-ray structure of **2** showing the weak intramolecular Te···F interactions; selected bond lengths (Å) and bond angles (deg): Te(1)−N(1) 2.035(2), Te(1)−N(2) 2.040(2), Te(1)−N(3) 1.970 (2), Te(2)−N(1) 2.061(3), Te(2)−N(2) 2.081(2), Te(2)−N(4) 1.875(3), B(1)−N(3) 1.632(4)

Surprisingly, an attempt to recrystallize **2** from THF/*n*-pentane (1:1) produced X-ray quality orange-yellow needles, within 20 min at 23 °C, of a complex identified as **3** by CHN analysis, multinuclear NMR spectroscopy and an X-ray structural analysis. The ^1H and ^{13}C NMR spectra of **3** in [D_8]THF show the characteristic ($CH_2CH_2CH_2CH_2O$) resonances of a ring-opened THF molecule[10d,11] in addition to resonances corresponding to the N*t*Bu groups. In the ^1H NMR spectrum two of these resonances are almost isochronous (δ = 1.479 and 1.477 ppm) and have a relative intensity corresponding to 27 H compared to 9 H for the third resonance at δ = 1.503 ppm. In the ^{13}C NMR spectrum three environments are readily distinguishable because of their well-separated chemical shifts. The ^{11}B NMR chemical shift of this product in [D_8]THF is δ = −3.6 ppm. Collectively, the NMR spectroscopic data suggest that complex **2** promotes THF ring-opening to give the adduct **3**, which is isolated in essentially quantitative yield. Subsequently, it was shown that **3** can also be obtained in high yield by addition of a THF solution of **1** to a solution of $B(C_6F_5)_3$ in THF at 23 °C.

X-ray crystallography[18] confirmed the molecular structure of **3** (Figure 2), with the ring-opened THF molecule linked to boron through the oxygen atom and to one of the terminal N*t*Bu groups via a carbon atom. In contrast to **2**, the $(CH_2)_4OB(C_6F_5)_3$ substituent occupies an *endo* position with respect to the Te_2N_2 ring while both terminal N*t*Bu groups are in *exo* configurations. The trends in Te−N bond lengths in **3** compared to those in **1**[14] are similar to, but less pronounced than, those described above for **2**. An interesting feature of the solid-state structure of **3** is the intermolecular Te···F interactions of 2.991(2) and 3.275(2) Å (Figure 2) that produce molecular strands parallel to the *b* axis. These strands are separated by THF solvent molecules. The shorter contact involves Te(1), which has a larger formal positive charge than Te(2) (Scheme 1). The Te_2N_2 ring in **3**, with a torsion angle of 14.0(1)°, is less puckered than that of **1** and **2**, and the geometry at the bridging nitrogen atoms is closer to planarity [$\Sigma\angle$N(1) = 352.3° and $\Sigma\angle$N(2) = 356.8°]. The B−O bond length in **3** is 1.444(5) Å {cf. 1.480(11) Å in the anion $[HOB(C_6F_5)_3]^-$}.[19]

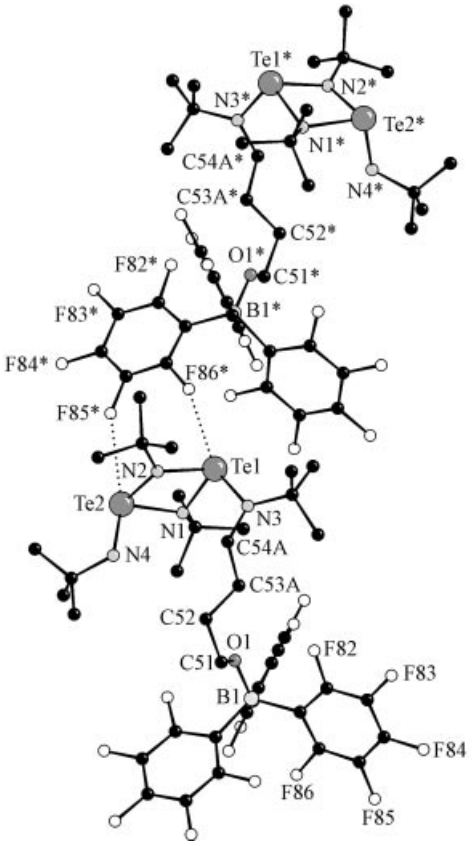

Figure 2. X-ray structure of **3** showing the weak intermolecular Te···F interactions; selected bond lengths (Å) and bond angles (deg): Te(1)−N(1) 2.020(3), Te(1)−N(2) 2.012(3), Te(1)−N(3) 1.922 (3), Te(2)−N(1) 2.036(3), Te(2)−N(2) 2.053(3), Te(2)−N(4) 1.905(3), B(1)−O(1) 1.444(5); the THF molecule in the lattice is not shown

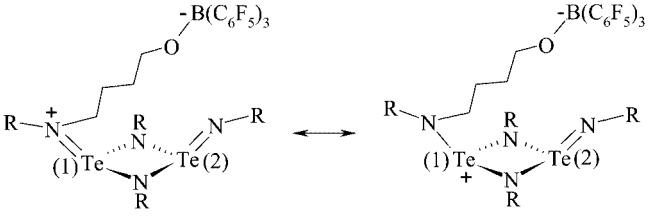

Scheme 1

The NMR spectra for **3** in [D_8]THF at 23 °C indicate that the Te···F contacts are not maintained in solution. Thus, the ^{19}F NMR spectrum shows only one set of resonances at δ = 131.3, 163.8 and 166.7 ppm, corresponding to the *ortho*, *para* and *meta* fluorine atoms, respectively, of the three C_6F_5 groups. By contrast, the complex NMR spectra for **2** in CD_2Cl_2 at 23 °C indicate intramolecular Te···F interactions. Thus, the ^{19}F NMR spectrum exhibits multiple resonances in each of the regions characteristic of *ortho*,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

meta and *para*-fluorines of a C_6F_5 group. The ^{13}C NMR spectrum of **2** is especially difficult to assign due to numerous overlapping doublets. The ^1H NMR spectrum of **2** exhibits four equally intense singlets that are consistent with the inequivalence of the bridging N*t*Bu groups as well as the terminal N*t*Bu groups. Variable-temperature NMR studies indicated the presence of conformational isomers, but the spectra could not be unequivocally assigned.

The strong Lewis acid $B(C_6F_5)_3$ forms a complex with THF.[20] Over a few hours at room temperature, the THF is polymerized by $B(C_6F_5)_3$, as reported for some other Lewis acids, for example $AlCl_3$.[21] The addition of **1** to a freshly prepared solution of $B(C_6F_5)_3$ in THF preempts this polymerization and, instead, generates the ring-opened complex **3**. By analogy with transition-metal systems,[10] it is proposed that coordination of the THF oxygen atom to the electrophilic boron centre polarizes the C−O bond so that the α-carbon atom is susceptible to nucleophilic attack. As a result, and in contrast to the THF ring-opening mode observed for $PPh_3/TeBr_4$,[12] the carbon atom of the THF fragment is bonded to the nucleophilic centre in **3**.

Experimental Section

2: A solution of $B(C_6F_5)_3$ (0.285 g, 0.556 mmol) in *n*-pentane (20 mL) was added to an orange-red solution of sublimed [*t*BuNTe(μ-N*t*Bu)$_2$TeN*t*Bu][19] (0.300 g, 0.556 mmol) in *n*-pentane (20 mL) at −78 °C. After 3.5 h at 23 °C the solvent was removed from the reaction mixture under vacuum to give analytically pure [*t*BuNTe(μ-N*t*Bu)$_2$TeN(*t*Bu)B$(C_6F_5)_3$] (0.546 g, 0.519 mmol, 93%) as a yellow-orange solid. $C_{34}H_{36}BF_{15}N_4Te_2$ (1051.68): calcd. C 38.83, H 3.45, N 5.33; found C 38.13, H 3.24, N 4.93. All NMR spectroscopic data were recorded in CD_2Cl_2 solution at 23 °C. ^1H NMR: δ = 1.617 (s, 9 H, *t*Bu), 1.589 (s, 9 H, *t*Bu), 1.501 (s, 9 H, *t*Bu), 1.426 (s, 9 H, *t*Bu) ppm. ^{11}B NMR: δ = −6.06 (s) ppm. ^{19}F NMR: δ = −116.10 (m, *ortho*), −124.30 (m, *ortho*), −130.10 (m, *ortho*), −130.50 (m, *ortho*), −130.90 (m, *ortho*), −157.24 (m, *para*), −159.60 (m, *para*), −161.65 (m, *para*), −161.90 (m, *meta*), −164.56 (m, *meta*), −166.42 (m, *meta*), −166.88 (m, *meta*) ppm. ^{125}Te NMR: δ = 1552.9 (s) ppm.

3: A solution of **1** (0.300 g, 0.556 mmol) in THF (10 mL) was added to a solution of $B(C_6F_5)_3$ (0.285 g, 0.556 mmol) in THF (10 mL) at −78 °C. After 2 h at 23 °C the solvent was removed under vacuum to give **3**·THF (0.533 g, 0.474 mmol, 85%) as an orange solid. Analytical and spectroscopic data were obtained for crystals of **3**·THF obtained from the attempted recrystallization of **2** from THF/*n*-pentane (1:1). $C_{42}H_{52}BF_{15}N_4O_2Te_2$ (1195.89): calcd. C 42.18, H 4.38, N 4.68; found C 42.11, H 4.21, N 4.61. All NMR spectroscopic data were recorded in [D_8]THF at 23 °C. ^1H NMR: δ = 4.02 (t, 2 H, CH_2-CH_2-CH_2-CH_2-O), 3.61 (4 H, THF, CH_2-CH_2-O), 3.17 (t, 2 H, CH_2-CH_2-CH_2-CH_2-O), 1.96 (q, 2 H, CH_2-CH_2-CH_2-CH_2-O), 1.77 (4 H, THF, CH_2-CH_2-O), 1.59 (q, 2 H, CH_2-CH_2-CH_2-CH_2-O), 1.50 (s, 9 H, *t*Bu), 1.479 and 1.477 (both s, 27 H, *t*Bu) ppm. ^{11}B NMR: δ = −3.64 (s) ppm. ^{13}C NMR: δ = 149.09 [d, $^1J_{C,F}$ = 235.0 Hz, *ortho*], 138.91 [d, $^1J_{C,F}$ = 245.9 Hz, *para*], 137.20 [d, $^1J_{C,F}$ = 249.1 Hz, *meta*], 126.64 (br, *ipso*), 68.27 (THF, CH_2-CH_2-O), 66.44 (CMe_3), 64.03 (CH_2-CH_2-CH_2-CH_2-O), 63.23 (CMe_3), 60.23 (CMe_3), 44.83 (CH_2-CH_2-CH_2-CH_2-O), 36.83 (CMe_3), 35.75 (CMe_3), 34.32 (CH_2-CH_2-CH_2-CH_2-O), 32.79 (CMe_3), 30.85 (CH_2-CH_2-CH_2-CH_2-O), 26.43 (THF, CH_2-CH_2-O) ppm. ^{19}F NMR: δ = −131.34 (m, *ortho*), −163.84 (m, *para*), −166.71 (m, *meta*) ppm. ^{125}Te NMR: δ = 1395.7 (s) ppm.

X-ray data were collected on a Nonius Kappa CCD diffractometer using Mo-K_α radiation (λ = 0.71073 Å) at 173 K. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions and not refined.

Organomagnesium Phosphanide "Grignard" Analogues − Synthesis, Structural Characterisation and Solution Behaviour of $[BuMg\{P(CH[SiMe_3]_2)(C_6H_3\text{-}2\text{-}OMe\text{-}3R)\}]_2$ [R = H, Me]

Keywords: Magnesium / P ligands / Grignard reaction / Rearrangement

The reaction between either one or two equivalents of the secondary phosphane $\{(Me_3Si)_2CH\}PH(C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}R')$ [R′ = H (**1a**), Me (**1b**)] and Bu_2Mg yields the heteroleptic complexes $[BuMg\{P[CH(SiMe_3)_2](C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}R')\}]_2$ [R′ = H (**2a**), Me (**2b**)], irrespective of the ratio of **1** to Bu_2Mg. X-ray crystallography shows that **2a** and **2b** crystallise as dimers containing a central Mg_2P_2 core. Dissolution of either **2a** or **2b** in THF results in complex degradation and formation of the tertiary phosphanes $\{(Me_3Si)_2CH\}P(Me)(C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}R')$ and unidentified magnesium-containing products.

Introduction

Although the synthesis of the parent calcium phosphanide $Ca(PH_2)_2$, by metallation of PH_3 with calcium in liquid ammonia, was reported as early as 1942,[1] little progress was made in the synthesis of other alkaline earth metal phosphanides until 1987, when Raston and co-workers reported that the reaction between *n*Bu*s*BuMg and $PhPH_2$ in the presence of tmeda gave the adduct [(tmeda)$Mg(PHPh)_2$] in good yield (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine).[2] However, the last two decades have seen growing interest in such species, with Westerhausen and co-workers making a particularly important contribution to this area.[3,4] With few exceptions, crystallographically characterised alkaline-earth metal phosphanides are limited to complexes containing phosphanide ligands in which the donor phosphorus atom is directly bonded to a silyl substituent. Such species typically crystallise as solvated monomers, symmetrical or unsymmetrical dimers, or linear trimers. We recently reported the synthesis, structural characterisation and dynamic behaviour of a homologous series of mononuclear alkaline-earth metal phosphanides without a direct Si−P bond.[5] We now describe the synthesis and structural characterisation of two related, heteroleptic organomagnesium phosphanide "Grignard analogues" and their behaviour in solution.

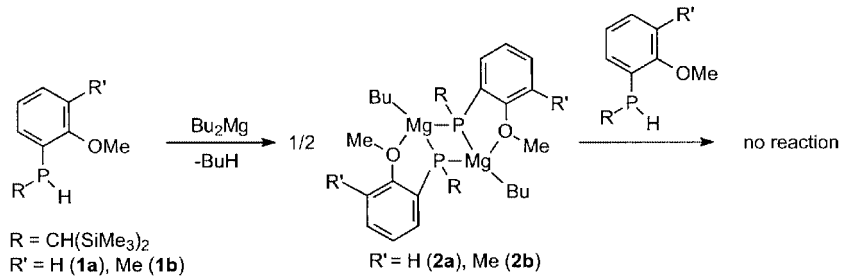
Results and Discussion

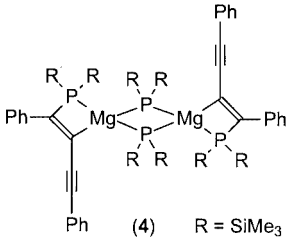
The reaction between Bu_2Mg and one equivalent of the secondary phosphanes $\{(Me_3Si)_2CH\}PH(C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}R')$ [R′ = H (**1a**), Me (**1b**)][6] gives the heteroleptic dimeric organomagnesium phosphanides $[BuMg\{P[CH(SiMe_3)_2](C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}R')\}]_2$ [R′ = H (**2a**), Me (**2b**)] in good yields (Scheme 1).

Unexpectedly, when Bu_2Mg was reacted with *two* equivalents of **1** under the same conditions only **2** and one equivalent of unchanged **1** were recovered. This is in marked contrast to the reaction between Bu_2Mg and two equivalents of the related secondary phosphane $\{(Me_3Si)_2CH\}PH(C_6H_4\text{-}2\text{-}CH_2NMe_2)$, which proceeds cleanly to give the bis(phosphanide) $[Mg\{P[CH(SiMe_3)_2](C_6H_4\text{-}2\text{-}CH_2NMe_2)\}_2]$ (**3**) in essentially quantitative yield.[5] The reason for this mono-substitution is, as yet, unclear, although it is possible that the five-membered chelate ring in **2** engenders greater steric hindrance at the metal centre than the six-membered chelate ring present in **3**, disfavouring substitution of the second Bu group.

Compounds **2a** and **2b** are unusual examples of "Grignard analogues", RMgX, in which the halide X has been replaced by a phosphanide ligand. Although there are several examples of amide analogues of these species, $RMg(NR_2)$,[7] to the best of our knowledge there has been only one previous report of an organomagnesium phosphanide $RMg(PR_2)$: Westerhausen and co-workers found that the reaction between $Mg\{P(SiMe_3)_2\}_2$ and diphenylbutadiyne in toluene gave an unusual organomagnesium phosphanide addition product (**4**).[8]



Scheme 1



Compounds **2a** and **2b** are initially precipitated as colourless solids from reactions conducted in light petroleum and freshly prepared samples of either compound may be recrystallised from cold (6 °C) diethyl ether as colourless blocks suitable for X-ray crystallography. Compounds **2a** and **2b** are insoluble in hydrocarbon solvents such as light petroleum, benzene or toluene, but dissolve readily in THF to give deep yellow solutions. However, dissolution in donor solvents is accompanied by decomposition (see below), preventing satisfactory characterisation of these compounds by NMR spectroscopy.

The crystals of compounds **2a** and **2b** studied by X-ray diffraction differ both in the substitution of the aromatic ring and in the nature of the butyl group. This latter effect is a consequence of the mixture of isomers present in the commercially sourced Bu_2Mg used in their synthesis. Compounds **2a** and **2b** have very similar molecular structures but they do not form isomorphous crystals; the molecule of **2a** has crystallographic inversion symmetry, but **2b** occupies a general position in its crystal structure. The molecular structures of **2a** and **2b** are shown in Figure 1 and details of bond lengths and angles are given in Table 1. Both compounds crystallise as dimers in which each Mg centre is bound by the P and O atoms of a chelating phosphanide ligand, forming five-membered chelate rings with bite angles of 80.76(4)° (**2a**) and 81.13(9) and 81.23(9)° (**2b**). The P atoms of the ligands further bridge the two Mg centres, forming a planar, parallelogram-shaped Mg_2P_2 core with Mg−P−Mg angles of 97.16(2)° (**2a**) and 95.83(5)° (two crystallographically independent but equal values in **2b**). The two, essentially planar, chelate rings adopt a *transoid* conformation, generating a pseudo-ladder arrangement; the dihedral angles between the Mg_2P_2 core and the chelate rings in the two compounds are 80.8° (**2a**) and 81.8 and 82.9° (**2b**).

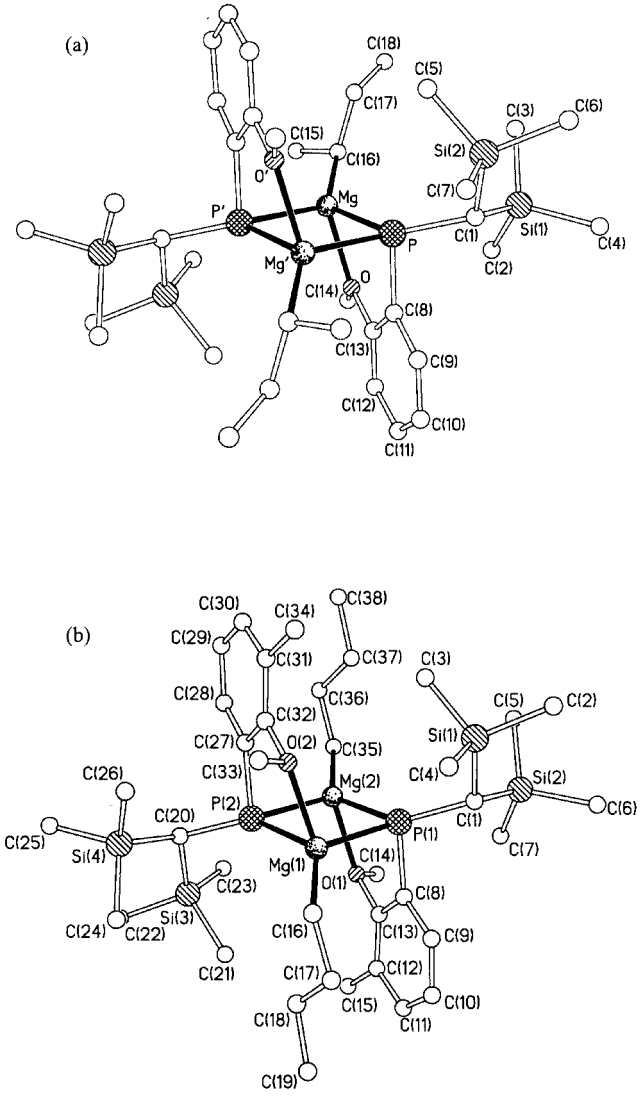


Figure 1. Molecular structures of (a) **2a** and (b) **2b**; H atoms omitted for clarity

In both **2a** and **2b** the phosphorus atoms bridge the two Mg centres in a slightly unsymmetrical fashion; the Mg−P distances in **2a** are 2.5760(8) and 2.5978(8) Å, whilst in **2b** they are 2.5765(17)/2.5730(16) Å [Mg(1)−P(2)/

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

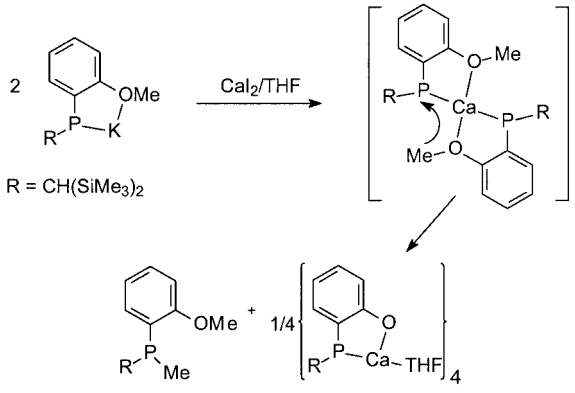
Mg(2)−P(1)] and 2.6138(16)/2.6105(17) Å [Mg(1)−P(1)/Mg(2)−P(2)]. These distances compare with Mg−P distances of 2.592(5) and 2.587(5) Å in [(tmeda)Mg(PHPh)$_2$],[2] 2.5031(6) Å in [(THF)$_2$Mg{P(SiMe$_3$)$_2$}$_2$],[4b] and 2.5555(11) and 2.5557(11) Å in **3**.[5] The Mg−C distances of 2.127(2) Å (**2a**) and 2.141(5) and 2.136(5) Å (**2b**) are similar to Mg−C distances in typical diorganomagnesium or Grignard-type compounds; for example, the Mg−C distance in {(1,4-dioxane)MgEt$_2$}$_n$ is 2.142(2) Å.[9]

The ^{31}P{^{1}H} NMR spectra of **2a** and **2b** in [D$_8$]THF recorded shortly after sample preparation show rapid decomposition at room temperature, preventing precise characterisation of these compounds by NMR spectroscopy. A ^{31}P{^{1}H} NMR spectrum of a solution of **2a** in [D$_8$]THF obtained immediately after sample preparation (Figure 2) exhibits two main peaks at δ = −107.0 (**A**) and −103.1 ppm (**B**), both signals arising from magnesium phosphanide species. After one hour peak **A** has decreased markedly in intensity and new signals have appeared at δ = −104.4 and −31.8 ppm (**C** and **D**, respectively). Peak **C** is likely to be due to a magnesium phosphanide species, whereas peak **D** is consistent with the presence of a tertiary phosphane. After a period of 36 hours peaks **A** and **B** have almost disappeared, leaving only peaks **C** and **D** with significant intensity (Figure 2). The ^{1}H NMR spectra of **2a** in [D$_8$]THF solution recorded at several intervals over a period of 24 hours are very complicated, with numerous peaks due to SiMe$_3$, aromatic and OMe protons; however, a clear doublet at δ = 1.43 ppm (J_{PH} = 6.4 Hz) is visible in the later spectra, consistent with the presence of a PMe group.

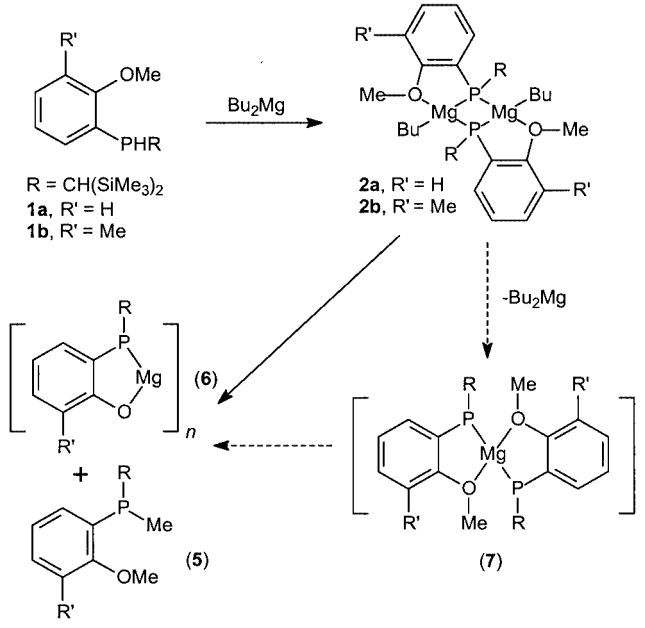
We recently reported that the metathesis reaction between [{(Me$_3$Si)$_2$CH}(C$_6$H$_4$-2-OMe)P]K and CaI$_2$ in THF yields the novel alkoxophosphanide cluster complex [{([Me$_3$Si]$_2$CH)(C$_6$H$_4$-2-O)P}Ca(THF)]$_4$·4THF via an unusual ligand degradation reaction, involving rapid migration of a methyl group from the oxygen atom of one phosphanide ligand to the phosphorus atom of another (Scheme 2).[10] This process yields the tertiary phosphane {(Me$_3$Si)$_2$CH}P(Me)(C$_6$H$_4$-2-OMe) (**5a**) as the sole phosphorus-containing side product [this phosphane has a ^{31}P chemical shift of δ = −31.8 ppm and a ^{1}H chemical shift of δ = 1.41 ppm (d, J_{PH} = 6.1 Hz) due to the PMe group].



Scheme 2

Thus, the ^{31}P and ^{1}H NMR spectra of **2a** are consistent with rapid complex degradation upon dissolution in [D$_8$]THF and formation of a new magnesium phosphanide species and the tertiary phosphane **5a** (peak **D**). Unfortunately, in spite of repeated attempts, it was not possible to separate the new magnesium phosphanide species from the tertiary phosphane **5a** for further characterisation; in contrast to **2a**, this new species appears to be highly soluble, even in the extremely poor solvent hexamethyldisiloxane. Compound **2b** displays similar behaviour to **2a** in THF solution. NMR spectra recorded shortly after sample preparation suggest the presence of two magnesium phosphanide species and the corresponding tertiary phosphane {(Me$_3$Si)$_2$CH}P(Me)(C$_6$H$_3$-2-OMe-3-Me) (**5b**). After several hours compound **2b** appears to have completely degraded to a new magnesium phosphanide and **5b**.

We therefore propose that in THF solution compounds **2a** and **2b** undergo a ligand degradation reaction, possibly forming a magnesium alkoxophosphanide complex of the form [{[(Me$_3$Si)$_2$CH](C$_6$H$_3$-2-O-3-R′)P}Mg(THF)$_n$]$_m$ (**6**; R′ = H, Me) and the corresponding tertiary phosphane **5**. This process may occur via the Grignard-type compounds **2**, or else these compounds may be subject to a Schlenk-type equilibrium in solution, generating the homoleptic phosphanides [{[(Me$_3$Si)$_2$CH](C$_6$H$_3$-2-OMe-3-R′)P}$_2$Mg] (**7**) and one equivalent of Bu$_2$Mg (Scheme 3). The homoleptic compound **7** may then undergo a methyl migration reaction analogous to that observed in the formation of [{[(Me$_3$Si)$_2$CH](C$_6$H$_4$-2-O)P}Ca(THF)]$_4$·4THF to give the alkoxophosphanide complex **6**.



Scheme 3

At present the available evidence does not allow these two reaction pathways to be distinguished. However, if such a Schlenk-type equilibrium were slow on the NMR time scale, this may account for the two magnesium phosphanide

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

species present in initially prepared samples of **2a**, peaks **A** and **B** perhaps arising from the Grignard analogue **2a** and the homoleptic bis(phosphanide) **7a**.

Experimental Section

General Comments: All manipulations were carried out using standard Schlenk techniques under an atmosphere of dry nitrogen. Diethyl ether and light petroleum (b.p. 40−60 °C) were distilled from sodium/potassium alloy under an atmosphere of dry nitrogen and were stored over a potassium film. Bu_2Mg was obtained from Aldrich as a 1.0 M solution of a mixture of isomers in heptanes. The compounds $\{(Me_3Si)_2CH\}PH(C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}R')$ (R′ = H, Me) were prepared by a previously published procedure.[6] All other compounds were obtained from commercial sources and were used as supplied.

Due to the poor solubility of **2a** and **2b** in non-donor solvents and their rapid degradation in THF, satisfactory NMR spectroscopic data could not be obtained. The constitutions of compounds **2a** and **2b** were confirmed by elemental analyses and X-ray crystallography. Elemental analyses for **2a** and **2b** were obtained by the Elemental Analysis Service of London Metropolitan University, UK.

Preparation of $[BuMg\{P[CH(SiMe_3)_2](C_6H_4\text{-}2\text{-}OMe)\}]_2$ (2a): Bu_2Mg (4.33 mL, 4.33 mmol) was added to a solution of $\{(Me_3Si)_2CH\}PH\{C_6H_4\text{-}2\text{-}OMe\}$ (1.29 g, 4.33 mmol) in light petroleum (10 mL) and the solution was stirred for 16 h. The colourless precipitate was isolated by filtration and dissolved in diethyl ether (10 mL). The resulting solution was concentrated and cooled to −30 °C for 48 h, yielding colourless blocks of **2a**. Yield 0.94 g, 57%. $C_{36}H_{70}Mg_2O_2P_2Si_4$ (757.84): calcd. C 57.05, H 9.31; found C 56.93, H 9.20.

Preparation of $[BuMg\{P[CH(SiMe_3)_2](C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}Me)\}]_2$ (2b): Bu_2Mg (1.70 mL, 1.70 mmol) was added to a solution of $\{(Me_3Si)_2CH\}PH\{C_6H_3\text{-}2\text{-}OMe\text{-}3\text{-}Me\}$ (0.53 g, 1.70 mmol) in light petroleum (10 mL). The solution was stirred for 16 h and the resulting colourless precipitate was isolated by filtration. The solid was dissolved in diethyl ether, concentrated and cooled to −30 °C for 60 h, to yield **2b** as colourless blocks. Yield 0.41 g, 61%. $C_{38}H_{74}Mg_2O_2P_2Si_4$ (785.89): calcd. C 58.07, H 9.49; found C 57.94, H 9.43.

Crystal Structure Determination of 2a and 2b: All measurements were made at 150 K on a Bruker AXS SMART CCD diffractometer using graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å) and narrow (0.3° in ω) frame exposures. Cell parameters were refined from the observed positions of all strong reflections in each data set. The structures were solved by direct methods and refined on F^2 values for all unique data. Table 2 gives further details. All non-hydrogen atoms were refined anisotropically, and H atoms were constrained with a riding model; U(H) was set at 1.2 (1.5 for methyl groups) times U_{eq} for the parent atom. Programs were Bruker AXS SMART (control) and SAINT (integration), and SHELXTL for structure solution, refinement, and molecular graphics.[11] CCDC-207042 (**2a**) and -207043 (**2b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Sodiated β-Diphosphonate Carbanions: Characterization of the Tetrameric Cubane and the Hexameric Ladder Complexes $[\{(i\text{PrO})_2\text{P(O)}\}_2\text{CHNa}]_4$ and $[\{(\text{EtO})_2\text{P(O)}\}_2\text{CHNa}]_6$

Roger Nassar,[a] Alicia M. Beatty,[a] and Kenneth W. Henderson*[a]

In memory of the late Dr. Ron Snaith, an independent thinker and spirit

Keywords: Alkali metals / Sodium / Cage compounds / Chelates / O Ligands

Reaction of the methylene diphosphonates $[(\text{RO})_2\text{P(O)}]_2\text{CH}_2$, where R = *i*Pr or Et, with the metalating reagents NaH, *n*BuNa or the superbasic mixture *t*BuONa/*n*BuLi leads to monodeprotonation, and formation of the complexes $[\{(i\text{PrO})_2\text{P(O)}\}_2\text{CHNa}]_4$ (**1**) and $[\{(\text{EtO})_2\text{P(O)}\}_2\text{CHNa}]_6$ (**2**). Single-crystal X-ray diffraction studies revealed that **1** is tetrameric in the solid state, with a central Na_4O_4 cubane core. Each metal in **1** is rendered pentacoordinate by binding to three μ_3-O phosphoryl bridges within the cubane, a chelating phosphoryl unit, and also a single *i*PrO group. In contrast, the structure of **2** is hexameric, and is composed of an unusual six-rung Na_6O_6 ladder core. Three distinct sodium environments as well as μ_1-, μ_2- and μ_3-O phosphoryl units are present within the ladder framework. No Na–C interactions are present in either **1** or **2**. All of the six-membered NaOPCPO chelate rings display localized P=O double bonds and partial multiple bonding on the P–C–P linkages (mean P–O: 1.49 Å, and mean P–C: 1.69 Å). Ab initio molecular orbital calculations (HF/6–31G*) on model complexes indicate that the hexameric arrangement found for **2** is thermodynamically more stable than the cubane structure of **1**, in the absence of steric effects.

Introduction

Metallated β-diphosphonates, $[\{(\text{RO})_2\text{P(O)}\}_2\text{CH}]^-\ \text{M}^+$, have been receiving continuous attention since their first reported synthesis and subsequent usage in 1953 by Kosolapoff.[1] The presence of two stabilizing groups adjacent to a methylene unit of the parent neutral diphosphonate allows straightforward access to the carbanion by deprotonation using a variety of bases. In turn, these carbanions have proven highly useful in the formation of new carbon-carbon bonds, in particular via alkylation and also Horner−Wadsworth−Emmons-type reactions.[2−4] Interest in β-diphosphonates has resulted from their potent biological activity,[5] and they have found applications as agrochemicals,[6] and in medicinal chemistry.[7] In addition, they are used in several industrial processes including as detergents,[8] sequestrates[9] and as fixing agents in photography.[10]

From a coordination chemistry perspective, there are clear parallels between β-diphosphonates and the widely studied β-diketonates,[11] β-enaminoketonates[12] and β-diketiminates,[13] as metal binding ligands (Figure 1). However, relatively few solid-state studies of metallated β-diphosphonates have been reported, and these have generally been limited to transition metal complexes.[14,15] This is somewhat surprising considering that the vast majority of the reaction chemistry involving these ligands has been developed using their alkali metal salts as reactive intermediates.

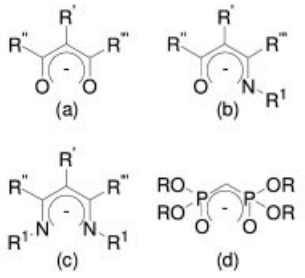

Figure 1. Generalized (a) β-diketonato, (b) β-enaminoketonato, (c) β-diketiminato, and (d) β-diphosphonato ligand frameworks

Of particular relevance to this study is the finding that the nature of the alkoxyl sidearms can strongly influence the reactivity of the β-diphosphonates.[3a] For example, whereas the tetraisopropyl esters react to give almost quantitative yields of *C*-alkylated esters, the methyl and ethyl esters give very low yields (>20%) under similar conditions.

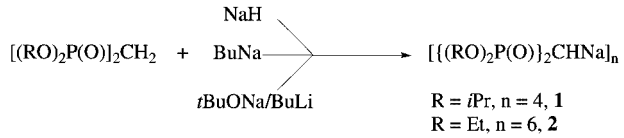
E-mail: khenders@nd.edu

Moreover, the rates of alkylation are higher and less side products are formed when the larger alkoxy groups are used in these reactions. Such large and unexpected discrepancies between apparently very similar types of ligands still remains to be fully explained.[3b] In an effort to shed light on some of these issues we wish to report the single-crystal X-ray diffraction studies of the two sodium β-diphosphonate complexes $[\{(RO)_2P(O)\}_2CHNa]_n$, where R = *i*Pr and *n* = 4 (**1**) and where R = Et and *n* = 6 (**2**).

Results and Discussion

Synthetic and Solid-State Studies

Three alternative metalating reagents, NaH, *n*BuNa and *t*BuONa/*n*BuLi,[16] were reacted with hexane solutions of the parent phosphonates $[(RO)_2P(O)]_2CH_2$ [R = *i*Pr (**3**), Et (**4**)] in stoichiometries varying from 1:1 to 3.5:1 (Scheme 1). In all instances, the only crystalline material precipitated from the resulting solutions (or filtrates) was the monosodiated complex **1** or **2**, as determined by NMR spectroscopy. Previous spectroscopic studies of both **1** and **2** have been reported and will not be elaborated upon here.[3b,15] Single crystals suitable for X-ray diffraction were prepared for both complexes and their structures elucidated.



Scheme 1

The core of cage complex **1** is composed of four sodium and four oxygen centers arranged in an approximate cubane structure (Figure 2 and 3). In addition to the three Na−O contacts associated with the Na_4O_4 unit, each metal binds to one chelating phosphoryl group and also to a single *i*PrO group, rendering the sodium centers pentacoordinate. Hence, within **1**, each phosphonate forms five Na−O bonds and bridges between three different metal centers. Tetra-

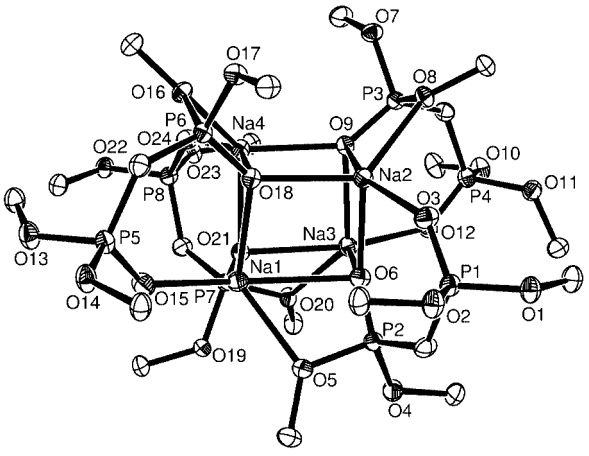


Figure 2. Molecular structure of $[\{(iPrO)_2P(O)\}_2CHNa]_4$, **1**, with hydrogen atoms and methyl groups removed for clarity

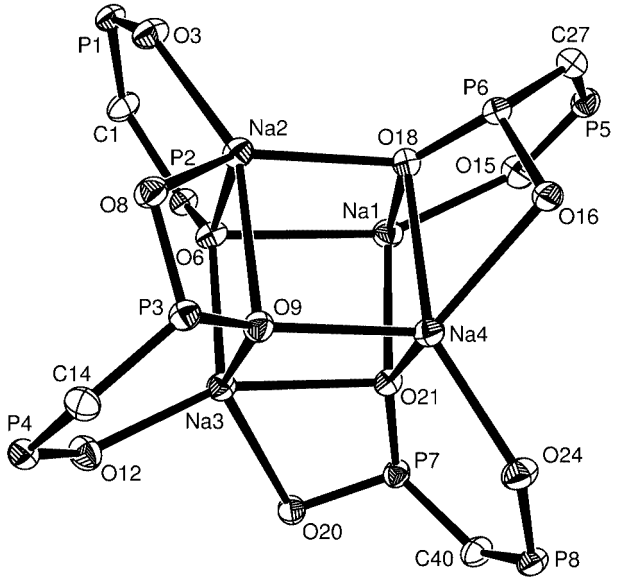

Figure 3. Core of the molecular structure of **1**, showing only the atoms involved with binding to the metal centers

meric cubane aggregates are comparatively common for sodium complexes, in particular when alkoxy or aryloxy ligands are employed.[17] The closest structural analog to **1** is the complex $[4\text{-Me-2,6-}(Me_2NCH_2)_2C_6H_2ONa]_4$, in which the "pincer phenolate" ligands coordinate to three sodium centers of a Na_4O_4 cubane.[18] However, the phenolate possesses approximate D_2 symmetry, whereas **1** is rendered closer to C_2 symmetry due to the "secondary" chelation of the *i*PrO groups.

There are no significant interactions present between the carbanionic carbons and the sodium centers, with all Na−C distances greater than 3.8 Å (see Table 1 for a list of pertinent bond lengths and angles). This bonding arrangement is commonly found for alkali metal complexes of α-stabilized carbanions, where the highly electropositive cations preferentially bind to the electronegative groups of the anion.[19,20] In fact, the phosphoryl unit has proved to be an excellent bridge for group 1 metals even when present as part of a neutral ligand.[21] For example, the crystal structure of the dimeric lithium chloride complex $[\{(iPrO)_2P(O)\}_2CH_2{\cdot}LiCl]_2$ contains a central Li_2O_2 ring and terminal chloride anions.[22]

Complex **2** was the focus of an early ^1H NMR spectroscopic study by Cotton in 1962.[15a] As part of these investigations cryoscopic measurements indicated that **2** is hexameric in benzene solution. However, at that time he did not speculate on the structure of the complex. Our X-ray diffraction studies of **2** confirm that it is indeed hexameric in the solid state and that it adopts a highly unusual centrosymmetric six-rung ladder framework (Figure 4 and 5, and Table 2). Each sodium is bound to five oxygen centers, however, three distinct metal and ligand environments are present within the structure. The three different types of sodium centers present can be related to their position within the ladder framework, i.e. rung-one, rung-two or rung-three. The three crystallographically unique phosphonate li-

gands within **2** can be distinguished by the number of Na−O contacts they make and the number of metals they bind to, i.e. (i) four Na−O contacts, and bridging two metals [terminal ligand carrying P(5) and P(6)]; (ii) four Na−O contacts, and bridging three metals [central ligand carrying P(1) and P(2)]; and (iii) seven Na−O contacts, and bridging five metals [central ligand carrying P(3) and P(4)]. The remarkable coordination flexibility of the β-diphosphonate ligands found within **1** and **2** is illustrated in Figure 6.

The coordination modes labeled (a), (b) and (d) in Figure 6 have not previously been observed for either neutral or anionic complexes of β-diphosphonates.[14] In fact, to the best of our knowledge, there are no reported examples of ester phosphonates that utilize an attached alkoxy unit as a

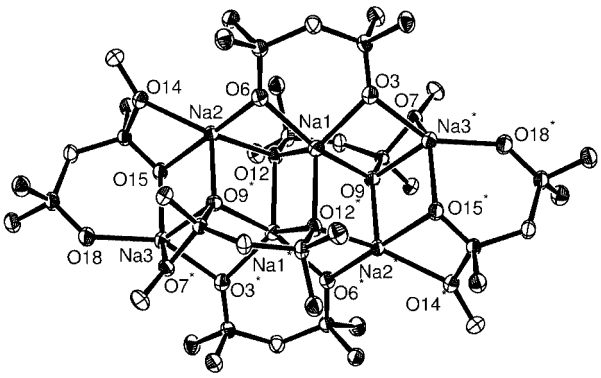

Figure 4. Molecular structure of $[\{(EtO)_2P(O)\}_2CHNa]_6$, **2**, with hydrogen atoms and ethyl groups (except for the α-Cs of the ethoxy groups involved in metal binding) removed for clarity

ligating site to a metal center.[23] However, simple chelation by the phosphoryl units and also binding mode (c) in Figure 6 have previously been found for several transition metal and lanthanide complexes of β-diphosphonates.[14,24,25]

Although hexameric aggregates for sodium complexes have previously been characterized,[26] the six-rung ladder arrangement found in **2** is unusual. Most commonly, sodium hexamers adopt either double-stacked trimeric[27] or triple-stacked dimeric[28] structures (Figure 7). The closest structural analog to **2** is the imidophosphate complex $[\{(PhO)_2P(O)\}_2NNa]_6$, which has a similar Na_6O_6 ladder core but has only very long range interactions between the metals and the phenoxy groups (>2.8 Å).[29] A simple six-rung ladder aggregate of a group 1 complex has also been characterized, the lithium phosphane $[(Me_3Si)_2PLi]_6$.[30] Most commonly, four-rung (association of two dimers) or polymeric ladders are formed for these metal complexes.[31] The seminal work of Snaith and others in developing the ring-laddering and ring-stacking principles has been essential to our understanding of such systems.[32,33]

Looking in detail at the key geometric parameters within the cages **1** and **2**, the Na−O bond lengths vary over a

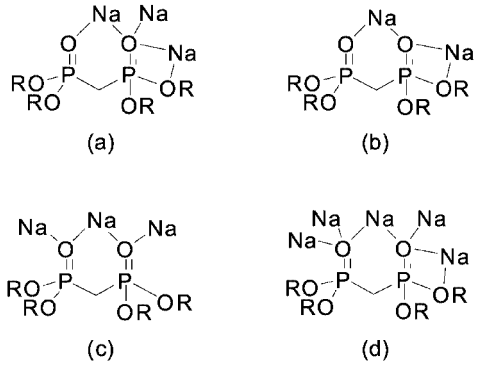

Figure 6. The different bonding modes found for the ligands in **1** (a), and **2** (b-d)

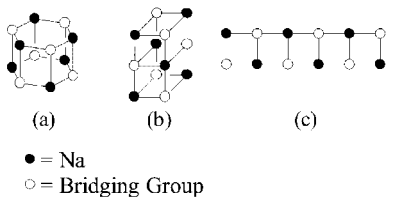

Figure 7. Hexameric aggregation states of sodium complexes: (a) double-stacked trimeric, (b) triple-stacked dimeric, (c) six-rung ladder

relatively wide range, from 2.202(1) to 2.623(1) Å. The shortest Na−O distances are associated with the chelating phosphoryl units, which ligate to a single sodium center [mean 2.220 Å in **1** and Na(3)−O(18): 2.225(2) Å in **2**]. Within the cubane framework of **1** each metal has two relatively short Na−O contacts (mean 2.312 Å) and a third longer contact (mean 2.518 Å) along the edges of the cube containing the chelating *i*PrO groups. The Na−O distance involving the *i*PrO groups lies in between these values at 2.400 Å (mean). A similar pattern is observed in **2**, where the Na−O distances lengthen, as expected, as the number of metals bridged by the phosphoryl increases (μ_1 to μ_3). The exceptions are the phosphoryl to sodium bonds Na(2)−O(15) at 2.450(2) and Na(3)−O(9*) at 2.451(2) Å, which are longer than expected. These elongated bonds are again associated with the four-membered NaOPO rings formed by the chelating OEt groups. Hence, the alkoxy-to-metal interactions in both **1** and **2** are relatively strong, and in fact the structures are significantly distorted in order to accommodated this mode of bonding.

The P=O distances lie in a relatively narrow range from 1.480(1) to 1.504(1) Å (mean 1.491 Å) over the two complexes, with the bonds lengthening as the number of metals bridged increases, i.e. μ_1, μ_2 and μ_3. These distances correspond well with those of previously characterized transition metal complexes of neutral β-diphosphonates,[14a,14b] and are consistent with localized P=O double bonds. The P−C distances in **1** and **2** range between 1.679(2) and 1.705(2) Å (mean 1.692 Å), and are substantially shorter than single P−C bonds in neutral β-diphosphonates (approximately 1.79 Å).[14] The shorter P−C bonds are associated with phosphoryl units that are involved in bridging multiple sodium centers. However, for the set of symmetrically bound ligands in **2** the P−C distances are identical, i.e. where P(1)−C(1) and P(2)−C(1) are both 1.694(2) Å. For comparison, the P−C distances in the ylides $Ph_3P{=}CH_2$ and mesitylP=CPh_2 are 1.67 and 1.69 Å respectively.[34] Overall, the bonding within the ligand backbone is best described as localized double bonding for the P=O units and delocalized partial multiple bonding over the P−C−P fragment.

It is also worth noting that although there are four different modes of ligation found for the β-diphosphonates in **1** and **2** (Figure 6), all the ligands contain synperiplanar phosphoryl units that chelate a metal center. It has previously been speculated that the reactivity differences between the anions of **3** and **4** may be due to the steric bulk of the isopropyl groups prohibiting coplanarity of the phosphoryl and carbanion groups.[3a] However, the six-membered OPCPONa chelate rings in both complexes are all similarly non-planar, with the range of the rms deviations from the planes being between 0.077 and 0.277 Å (mean 0.117). Again, these results are in agreement with the mostly localized bonding model described above.

Ab Initio Calculations

In an effort to determine the relative stabilities of the tetrameric and hexameric aggregations states found for **1** and **2** a set of ab initio calculations performed at the HF/

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

6−31G* level were undertaken on model systems.[35,36] The tetramethoxy complexes $[\{(MeO)_2P(O)\}_2CHNa]_4$ (**I**) and $[\{(MeO)_2P(O)\}_2CHNa]_6$ (**II**) were geometry optimized using the relevant crystal structure data for **1** and **2** as starting positions. The geometries of the calculated and experimentally determined structures are in excellent agreement, with differences of less than 0.01 Å (mean) for the bonds involving the metals. The key finding from these calculations was that the hexamer is more stable than the tetramer by 12.08 kcal mol^{-1} according to Equation (1) (or by 2.01 kcal mol^{-1} on a per-monomer basis).

$$3/2\ [\{(MeO)_2P(O)\}_2CHNa]_4 \xrightarrow{-12.08\ kcal\ mol^{-1}} [\{(MeO)_2P(O)\}_2CHNa]_6 \quad (1)$$

Considering that all the metals are pentacoordinate, and in the absence of any significant steric effects, the stability of the aggregates is most likely related to differences in the types of metal-to-ligand interactions present. In **I** each metal binds to four phosphoryl oxygen centers and a single *i*PrO group. Two of the metals in **II** also have this bonding pattern but the third metal bonds solely to five phosphoryl units. The increased coulombic component resulting from this bonding mode may, in turn, favor the formation of the hexamer. Furthermore, formation of the more open ladder framework will result in a decrease in ring strain compared with the cubane but without necessitating a reduction in the coordination number at the metals.

Conclusions

The main findings from this work are: (i) complexes **1** and **2** are the first examples of simple alkali metal derivatives of β-diphosphonates to be crystallographically characterized, and were found to form tetrameric cubane and hexameric ladder structures respectively, (ii) the β-diphosphonate ligands display four distinct ligation modes, three of which have not been described previously, (iii) the bonding within the β-diphosphonate backbones in both complexes are similar, and are composed of localized P=O double bonds and partial delocalization of the charge over the P−C−P units, and (iv) the hexameric six-rung ladder structure has been determined by calculations to be thermodynamically preferred over the tetrameric cubane structure for the model complexes **I** and **II**.

In summary, formation of the cubane **1** is most likely a consequence of the increased steric encumbrance of the attached alkoxy sidearms precluding the multiple bridging ligand environments required for construction of the hexameric framework found for **2**. Nevertheless, each individual β-diphosphonate ligand within **1** and **2** still adopts relatively similar local geometries, with synperiplanar phosphoryl units. Finally, in view of the different aggregation states found for **1** and **2**, it is unsurprising that there are differences in the reactivity of the β-diphosphonates. While it is true that the smaller tetrameric aggregate **1** has increased reactivity compared to the larger hexameric **2**, it may be too simplistic to attribute the reactivity differences solely to aggregate size.[37] Rather, the ability of the electrophile to approach the carbanion has to be considered. Also, the increased strain within the cubane compared to the ladder may lead to an attenuation in its reactivity.[38]

Experimental Section

General Procedures: All manipulations were carried out under a protective dinitrogen atmosphere using standard Schlenk techniques.[39] All glassware was flame-dried under vacuum before use. Hexane was purified by passage through copper-based catalyst and molecular sieves columns (Innovative Technology). The sodium hydride was supplied by Alfa Aesar as an oil dispersion, and was washed with dry hexane prior to use. The sodium butoxide was used as supplied by Acros Organics. *n*BuLi was purchased from Aldrich as a 1.6 M solution in hexane and was standardized by titration with salicylaldehyde phenylhydrazone directly before use.[40] Butylsodium (*n*BuNa) was prepared according to modified literature procedures and stored in an argon-filled glove box before use.[41] The phosphonate ligands $[(RO)_2P(O)]_2CH_2$ (R = *i*Pr, Et), **1** and **2**, were supplied by Lancaster and were purified by distillation from over calcium hydride and stored over 4 Å molecular sieves.

Although reactions using stoichiometries ranging between 1:1 and 3.5:1 of the three metalating reagents — NaH, *n*BuNa and *t*BuONa/*n*BuLi — and the parent phosphonates **3** and **4** were conducted, the only single crystals gleaned were the monodeprotonated complexes **1** or **2**. It has been reported previously that these ligands undergo cleavage in the presence of excess base and at elevated temperatures.[3g] Complexes **1** and **2** could be prepared in a rational manner as described below.

Synthesis of 1 and 2: The parent phosphonate (**3** or **4**, 10 mmol) was dissolved in 5 mL of hexane and the solution cooled to 0 °C. *n*BuNa (10 mmol) was added to the reaction mixture via a solids addition tube over several minutes, and the resulting mixture was slowly warmed to room temperature. The mixture was heated gently, filtered and the filtrate was stored at −45 °C. After one day, small colorless blocks of the complexes **1** or **2** were precipitated. Formation of **1** and **2** was confirmed by their ^1H and ^{13}C NMR spectra, which were in agreement with previously published data.[3b,15a]

1: Yield = 52%. ^1H NMR (300 MHz, [D$_5$]pyridine, 25 °C): δ = 1.05 (t, $^2J_{H,P}$ = 6.3 Hz, 1 H, PCH), 1.33 (d, $^3J_{H,H}$ = 6.0 Hz, 12 H, CH_3), 1.37 (d, $^3J_{H,H}$ = 6.0 Hz, 12 H, CH_3), 4.80 (m, 4 H, CH) ppm. $^{13}C\{^1H\}$ NMR (300 MHz, [D$_5$]pyridine, 25 °C): δ = 12.8 (t, $^1J_{C,P}$ = 213.4 Hz, CP), 24.7 (t, $J_{C,P}$ = 4.5 Hz, CH_3), 24.9 (t, $J_{C,P}$ = 4.5 Hz, CH_3), 67.7 (s, CH) ppm.

2: Yield = 46%. ^1H NMR (300 MHz, [D$_5$]pyridine, 25 °C): δ = 1.13 (t, $^2J_{H,P}$ = 6.4 Hz, 1 H, PCH), 1.28 (t, $^3J_{H,H}$ = 7.0 Hz, 12 H, CH_3), 4.16 (m, 8 H, CH_2) ppm. $^{13}C\{^1H\}$ NMR (300 MHz, [D$_5$]pyridine, 25 °C): δ = 10.2 (t, $^1J_{C,P}$ = 217.1 Hz, CP), 17.1 (t, $J_{C,P}$ = 3.7 Hz, CH_3), 60.4 (s, CH_2) ppm.

X-ray Structure Determination: Table 3 contains details of the data collection. In both cases the crystalline sample was placed in inert oil, mounted on a glass pin, and transferred to the cold N_2 gas stream of the diffractometer. Crystal data were collected and integrated using a Bruker Apex system, with graphite monochromated Mo-K_α (λ = 0.71073 Å) radiation at 100 K. The structures were

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

solved by direct methods using SHELXS-97 and refined using SHELXL-97.[42] Non-hydrogen atoms were found by successive full-matrix least-squares refinement on F^2 and refined with anisotropic thermal parameters. All hydrogen atoms were placed at idealized positions and a riding model was applied, with fixed thermal parameters [uij = 1.2*U*ij(eq) for the atom to which they are bonded]. The asymmetric unit contains one tetrameric cage for **1** and one half of a hexameric cage for **2**.

CCDC-209651 (**1**) and -209652 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1233/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: The Gaussian 98 series of programs were used for the calculations.[35] No symmetry constraints were imposed and the molecules were allowed to freely optimize at the HF/6−31G* level using the relevant crystal structure data for **1** and **2** as starting geometries.[36] Frequency analysis was used to ensure that true minima were located. The total energies for **I** and **II** are 5958.4381 and 8937.6764 Hartrees respectively.

The First Structurally Characterized Diorganoaluminate

Colin Eaborn,[a] Ian B. Gorrell,[b] Peter B. Hitchcock,[a] and J. David Smith*[a]

Dedicated to the memory of our friend and colleague Ron Snaith

Keywords: Aluminum / Silicon / Hydride ligands / Lithium

The first structurally characterized dialkylaluminate $[\{Li(THF)\}(Al\textit{t}Bu\{C(SiMe_3)_3\}H_2)]_2$ (**3**) is dimeric in the solid state with $[Li(THF)]^+$ and $[Al\textit{t}Bu\{C(SiMe_3)_3\}H_2]^-$ fragments linked by Li···H–Al bridges.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Dialkylaluminates − compounds containing the $[AlR_2H_2]^-$ fragment − have been known as useful intermediates in syntheses for nearly 50 years.[1] The $NaAlEt_4$-$NaAlH_4$ phase diagram shows that sodium diethylaluminate is a thermodynamically stable species,[2] and both this and sodium dimethylaluminate are commercially available reducing agents.[3] Several routes to dialkylaluminates have been reported but evidence for individual species has been confined to elemental analysis (R = Me,[4−6] Et,[2,4,5,7,8] *n*Pr,[4] *i*Bu [4,5,9]), IR spectroscopy[6,8,10] and ^{27}Al NMR spectroscopy.[11] Dialkylaluminates are sometimes obtained from reaction mixtures that might be expected to yield monoalkylaluminates. For example, attempts to make sodium ethylaluminate $Na[AlEtH_3]$ give $Na[AlEt_2H_2]$ and $Na[AlH_4]$, suggesting that any initially formed $Na[AlEtH_3]$ rearranges as shown in Equation (1) (R = Et).

$$2Na[AlH_3R] \rightarrow Na[AlH_2R_2] + Na[AlH_4] \quad (1)$$

Diorganoaluminates are much less well characterized than the corresponding dialkoxo- and diaryloxoaluminates, which contain the ions $[Al(OR)_2H_2]^-$,[12,13] or aluminates containing the ions $[Al(ER_2)_2H_2]^-$ (E = N, P or As).[14,15] As far as we are aware, no diorganoaluminate has previously been structurally characterized, though the $[AlR_2H_2]^-$ fragment has been identified in titanium[16] and rhenium[17] hydride complexes and an aluminacarborane.[18]

In a footnote to a paper describing the alkylaluminate $[\{Li(THF)_2\}\{Al\{C(SiMe_2Ph)_3\}H_3\}]_2$ (**1a**), we mentioned briefly the di-*tert*-butylaluminate $Li[Al\textit{t}Bu_2H_2]\cdot 2THF$ (**2**).[19] This was obtained from the reaction of $LiAlH_4$ with one equivalent of Li*t*Bu, indicating that any initially formed $Li[Al\textit{t}BuH_3]$ either reacted more rapidly than $LiAlH_4$ with Li*t*Bu, or rearranged according to Equation (1) (R = *t*Bu). Treatment of $LiAlH_4$ with LiR (R = $C_6H_2\textit{i}Pr_3$-2,4,6) followed by $SiMe_3Cl$ gave AlR_2H, again suggesting that a diarylaluminate intermediate was formed from the monoaryl species.[20]

We have not been able to obtain crystals of **2** suitable for an X-ray structure determination, but we report the synthesis of the related compound $[\{Li(THF)\}(Al\textit{t}Bu\{C(SiMe_3)_3\}H_2)]_2$ (**3**) and its crystal structure. The iodide $Al\textit{t}Bu_2I\cdot THF$ (**4**) and the compounds $Li(TMEN)_n[Al\textit{t}Bu_2H_2]$ (n = 2, **5**; n = 1, **6**; TMEN = tetramethylethylenediamine), are also described.

Results and Discussion

Treatment of $Li[AlH_4]$ with $LiC(SiMe_3)_3(THF)_2$ or $LiC(SiMe_2Ph)_3(THF)$ gave the alkylaluminates **1b** and **1a**, in each of which one of the four hydride ligands has been replaced by a bulky organic group. Treatment of $Li[AlH_4]$ with the smaller Li*t*Bu led to the replacement of two hydride ligands and the formation of a dialkylaluminate **2**. The formation of a di- rather than a mono-substituted aluminate appears, therefore, to depend on the size of the attacking lithium derivative. We surmised that the reaction between **1b** and Li*t*Bu might yield the dialkylaluminate **3**, and this proved to be the case. Compound **3** was isolated in good yield as an air- and moisture-sensitive solid.

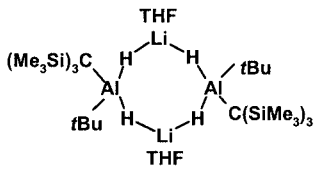
1a R = Ph, **1b** R = Me
1c R = NMe_2

$Li[AltBu_2H_2].2THF$



2 **3**

The molecular structure is shown in Figure 1 and selected bond lengths and angles in Table 1. The molecules of **3** are dimeric with a twofold axis through O2Li2···Li1O1. As in the organoaluminates **1a**[19] and **1c**,[21] the arylaluminates $Li[Al\{C_6H_2R_3\text{-}2,4,6\}H_3]$ with R = Ph (**1d**) or *t*Bu (**1e**),[22] the aryloxyaluminate $[Li(Et_2O)_2][Al\{OC_6H_3tBu_2\text{-}2,6\}H_3]$,[12] the bis(trimethylsilyl)amido derivatives $[Li(Et_2O)_2][Al\{N(SiMe_3)_2\}H_3]$[15] and $[Li(Et_2O)_2][Al\{PhNN(SiMe_3)_2\}H_3]$,[23] and the tetrahydoaluminates $[LiL\{AlH_4\}]_2$ {L = HN(*t*Bu)CH(*t*Bu)CH=N*t*Bu,[24] HN(*t*Bu)CH(*t*Bu)CH_2N(H)*t*Bu,[25] or TMEN[26]}, the cationic lithium and anionic aluminum fragments are held together by hydride bridges to give an eight-membered puckered $Li_2Al_2H_4$ ring. However, the conformation of this ring differs from those in the previously described compounds. In these the rings are in a chair conformation **I** with the aluminum atoms bent away from the almost planar Li_2H_4 array so that the large organic groups R on the periphery of the molecule point outwards. In **3** the $Li_2Al_2H_4$ ring adopts a skew-boat configuration **II** in which the atoms H1a′ and H1b lie above and H1a and H1b′ lie below the plane containing the Li, Al and O atoms; the larger ligands R are *trans* with respect to the ring. We cannot at present say whether the conformation is determined by other than crystal packing forces. In contrast to **1a**, there are no problems with crystallographic disorder.

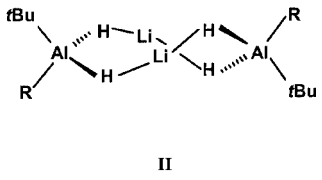
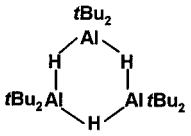
I



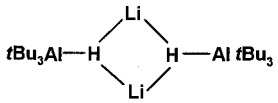
II

The distances from aluminum to the central carbon atoms of the *t*Bu [2.043(2) Å] and $C(SiMe_3)_3$ groups [2.041(2) Å] are the same within the experimental uncertainty and identical to those in **1a** [2.046(4) Å]. Similar distances [2.001(2) to 2.081(4) Å] are found in the *tert*-butylaluminium compounds $(AltBu_2H)_3$ (**7**) and $Li[AltBu_3H]$ (**8**).[27] The Li−H bond lengths are greater than the Al−H bond lengths and cover a wider range, indicating that the ionic formulation $[Li(THF)][AltBu\{C(SiMe_3)_3\}H_2]$ accurately describes the structure. The experimental uncertainties in the mean Al−H and Li−H distances are considerably greater than those in the exocyclic Al−C bonds, but the endocyclic bonds in **3** [Al−H 1.57(3) and Li−H 1.80(3) Å] are not significantly different from the bridging bonds in **1a** [1.62(4) and 1.93(4) Å, respectively], other compounds containing $Li_2Al_2H_4$rings,[12,15,22−26] or **8** [1.68(3) and 1.92(3) Å].[27] The increased crowding from the replacement of an exocyclic hydrogen in **1b** by a *tert*-butyl group to give **3** results in the displacement of one molecule of coordinated THF. The conformations of the bulky groups attached to aluminum are such that the crowding at Li1 is different from that at Li2; the mean planes of the attached THF molecules are orthogonal and the H−Li−H angles [114(2)° at Li1 and 141(2) at Li2] are significantly different. The C−Al−C angle [130.23(10)°] in **3** is considerably wider and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



7



8

the H−Al−H angle within the ring [101(1)°] narrower than the tetrahedral value.

The NMR spectra of **3** at 298 K are consistent with the structure found in the solid state but, as we have not collected data over a range of temperatures, we cannot comment on whether isomeric species are obtained under different conditions. The ^{27}Al resonance (δ = 137 ppm) is at higher frequencies than those in **1a** and **1b** (δ = 113−115); similar shifts (δ = 132−141) have been reported in **2**[19] and other diorganoaluminates.[11]

The organoaluminates **1a**−**1e** are versatile starting materials for the synthesis of a range of organoaluminum derivatives bearing bulky groups,[20,28,29] since the Al−H bonds are considerably more reactive than the more protected Al−C bonds towards a variety of reagents. The reactions of the diorganoaluminates **2** and **3** can be expected to lead to a similar range of products containing AlR_2 or AlRR′ fragments, in which R and R′ are bulky or fairly bulky organic groups. We report two preliminary results here.

Treatment of **2** with iodomethane gave a good yield of Al*t*Bu$_2$I·THF (**4**) as an air- and moisture-sensitive solid [Equation (2)]. Although di-*tert*-butylaluminum fluoride, chloride,[30] bromide[31] and hydride[27] have been described we cannot find any previous report of the iodide.

$$\underset{\mathbf{2}}{\text{Li[Al}t\text{Bu}_2\text{H}_2\text{].2THF}} + \text{MeI} \longrightarrow \underset{\mathbf{4}}{\text{Al}t\text{Bu}_2\text{I.THF}} + \text{CH}_4 + \text{LiH} \qquad (2)$$

$$\underset{\mathbf{1e}}{[\{\text{Li(THF)}_2\}\{\text{AlRH}_3\}]_2} + 2\text{MeI} \longrightarrow (\text{AlRH}_2)_2 + 2\text{CH}_4 + 2\text{LiI} + 4\text{THF} \qquad (3)$$

$$\text{R} = \text{C}_6\text{H}_2\,t\text{Bu}_3\text{-2,4,6}$$

The reaction of **3** with iodomethane gave a complex mixture but reaction of the compound [{Li(THF)$_2$}{AlH$_3${C$_6$H$_2$*t*Bu$_3$-2,4,6}}]$_2$ (**1e**) gave [AlH$_2$C$_6$H$_2$-*t*Bu$_3$-2,4,6]$_2$ and LiI cleanly [Equation (3)].[29] These results can be attributed to effects of steric hindrance to attack at bonds in the eight-membered $Li_2Al_2H_4$ rings. In **2** the two *t*Bu groups attached to aluminum are not large enough to prevent coordination of the iodine of MeI and consequent reaction at Al−H bonds. In **1d**, however, coordination of iodine at aluminum is inhibited by the bulky aryl group so that the iodomethane attacks at Li−H rather than Al−H bonds. In **3** the rates of attack by MeI at Al−H and Li−H bonds appear to be similar so that a complex mixture of products is formed. The fact that the aluminum iodide rather than the hydride is isolated in reaction (2) indicates that under the conditions that we employed LiH is an ineffective reagent for reduction of Al*t*Bu$_2$I.

Reaction of **2** with an excess of TMEN gave a colorless solid that was shown by chemical analysis and NMR spectroscopy to be [Li(TMEN)$_2$][Al*t*Bu$_2$H$_2$] (**5**). One equivalent of TMEN was lost when the compound was sublimed at 120 °C in a way that is reminiscent of the behavior of [Li(TMEN)$_2$][AlH$_4$]. This was shown to crystallize in an extended ionic lattice, but the species obtained after loss of one mol of TMEN was [{Li(TMEN)}{(μ-H)$_2$AlH$_2$}]$_2$, which formed a lattice of dimeric ion pairs having Li···H−Al bridges like those in **3**.[26] With the elucidation of the structure of **3**, examples of compounds containing each of the species [AlR$_n$H$_{4-n}$]$^-$ with n = 0−4 (R = alkyl or aryl) are now known. However, when n = 1−3, the group R varies from compound to compound[19,21,22,27,31,32] so that it is not possible at this stage to draw meaningful conclusions about trends in bond lengths and angles.

Experimental Section

Air and moisture were excluded by Schlenk-tube techniques with Ar as blanket gas. All glassware was flame-dried immediately before use and solvents were carefully dried by standard methods. NMR spectra were recorded at 300.13 (^{1}H), 75.43 (^{13}C), 194.5 (^{7}Li), 130.4 (^{27}Al) or 99.36 MHz (^{29}Si) and chemical shifts are given relative to SiMe$_4$, aqueous LiCl or Al(NO$_3$)$_3$. IR spectra are for Nujol mulls.

The compound [Li(THF)$_2$][AlH$_2$*t*Bu$_2$] (**2**) has been made previously.[19]

[{Li(THF)}(Al*t*Bu{C(SiMe$_3$)$_3$}H$_2$)]$_2$ (3): A solution of Li*t*Bu (0.97 mmol) in pentane (0.6 mL) was added dropwise to a stirred solution of **1b** (0.40 g, 0.97 mmol) in toluene (20 mL) at room temperature. The mixture was stirred for 15 h, then the white precipitate was filtered off, solvent was removed from the filtrate and the residue was recrystallised from benzene to give **3** as a white air- and moisture-sensitive solid (0.28 g, yield 74%), m.p. 160 °C. C$_{18}$H$_{46}$AlLiOSi$_3$ (396.7): calcd. C 54.4, H 11.7; found C 53.3, H 11.4. IR: $\tilde{\nu}_{max}$ = 1731m, 1612br, (Al−H), 1253s, 1205w, 1168w, 1043m, 1008w, 855s, 782w, 670m cm^{-1}. ^{1}H NMR (C$_6$D$_6$, 298 K): δ = 0.48 (s, 27 H, SiMe$_3$), 1.23 (m, 4 H, THF), 1.39 (s, 9 H, *t*Bu), ca. 2.9 (br. s, 2 H, AlH), 3.42 (m, 4 H, THF) ppm. ^{7}Li NMR: δ = −0.37 ppm. ^{13}C NMR: δ = −2.9 (CSi$_3$), 5.8 ($^1J_{SiC}$ = 50 Hz, SiMe$_3$), 25.1 (THF), 34.6 (*t*Bu), 68.9 (THF) ppm. ^{27}Al NMR: δ = 137 ppm ($\Delta\nu_{1/2}$ = 3 kHz). ^{29}Si NMR: δ = −3.9 ppm.

Reaction of 2 with MeI: Iodomethane (0.20 g, 3.2 mmol) was added dropwise to a stirred solution of **2** (0.70 g, 2.4 mmol) in toluene (25 mL) at room temperature. After 15 h the solvent was pumped from the white suspension and the residue was extracted with heptane (25 mL). The extract was filtered and the filtrate reduced to ca. 10 mL in volume to give Al*t*Bu$_2$I.THF (**4**) as a white crystalline solid, m.p. 46 °C, which was filtered off and dried (0.64 g, 79%). C$_{12}$H$_{26}$AlIO (340.2): calcd. C 42.4, H 7.6; found C 42.4, H 7.7. IR: $\tilde{\nu}$ = 1359s, 1301w, 1252m, 1177m, 1044s, 1004s, 923m, 854m, 812s, 683m cm^{-1}. ^{1}H NMR (C$_6$D$_6$, 298 K): δ = 0.94 (m, 4 H, THF), 1.20 (s, 18 H, CMe$_3$), 3.63 (m, 4 H, THF) ppm. ^{13}C NMR: δ = 17.4 (CMe$_3$), 24.8 (THF), 30.5 (CMe$_3$), 74.8 (THF) ppm. ^{27}Al NMR: δ = 158 ppm ($\Delta\nu_{1/2}$ = 3.4 kHz). MS: *m*/*z* = 268 (69) [M − THF], 211 (100) [M − THF − *t*Bu], 169 (90), 154 (70).

[Li(TMEN)$_2$][Al*t*Bu$_2$H$_2$] (5) and [Li(TMEN)][Al*t*Bu$_2$H$_2$] (6): TMEN (4.5 mL, 29.8 mmol) was added to a stirred solution of **2** (2.20 g,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

7.5 mmol) in toluene (30 mL) at room temperature. After 30 min the solvent was removed until the solution became cloudy, then the mixture was cooled to give colorless air-sensitive crystals of **5** (2.40 g, 84%). $C_{20}H_{52}AlLiN_4$ (382.6): calcd. C 62.8, H 13.7, N 14.6; found C 62.2, H 13.3, N 13.5. IR: $\tilde{\nu}_{max}$ = 1651vs, br (Al−H), 1361s, 1291s, 1251m, 1187m, 1166m, 1132s, 1103m, 1070m, 1036s, 1018s, 1003sh, 948s, 811m, 788m, 750m cm^{-1}. ^1H NMR (C_6D_6, 298 K): δ = 1.48 (s, 18 H, *t*Bu), 1.95 (s, 8 H) and 1.99(s, 24 H) (TMEN) ppm. ^7Li NMR: δ = 0.37 ppm. ^{13}C NMR: δ = 15.0 (CMe_3), 32.3 (CMe_3), 45.9 and 75.4 (TMEN) ppm. ^{27}Al NMR: δ = 152 ppm ($\Delta\nu_{1/2}$ 1.37 kHz).

With the same experimental procedure, the reaction between **2** (1.65 g, 5.6 mmol) and TMEN (0.85 mL, 5.6 mmol) gave colorless crystals of **6** (1.32 g, 89%), m.p. 140 °C. $C_{14}H_{36}AlLiN_4$ (294.4): calcd. C 63.1, H 13.6, N 10.5; found C 62.5, H 13.0, N, 10.5. IR: $\tilde{\nu}_{max}$ 1740s, 1633s, br (Al−H), 1358s, 1291s, 1250m, 1208w, 1180sh, 1160s, 1130s, 1101m, 1069m, 1035s, 1021s, 1002m, 974s, 811w cm^{-1}. ^1H NMR: δ = 1.44 (s, 18 H, *t*Bu), 1.66 (s, 4 H) and 1.94 (s, 12 H, TMEN) ca. 2.7 (vb s, 2 H, AlH) ppm. ^7Li NMR: δ = 0.26 ppm. ^{13}C NMR: δ = 15.8 and 32.3 (*t*Bu), 45.9 and 56.8 (TMEN) ppm. ^{27}Al NMR: δ = 151 ppm ($\Delta\nu_{1/2}$ 1.57 kHz). Compound **6** was also obtained by sublimation of **5** at 120 °C/0.01 Torr.

Crystal Data for Compound 3: $C_{36}H_{92}Al_2Li_2O_2Si_6$: M = 793.5; T = 173(2) K; orthorhombic, $C222_1$ (no. 20); a = 15.705(4), b = 19.977(6), c = 17.089(5) Å; U = 5361(3) Å^3; Z = 4; μ = 0.21 mm^{-1}. Data from 9405 reflections, 4721 unique [R(int) = 0.038], were collected on an Enraf−Nonius CAD4 diffractometer by use of Mo-K_α radiation and full-matrix least-squares refinement was by use of SHELXL-97 programs. All non-H atoms were isotropic, the hydrogen atoms attached to Al were refined freely, and the others were refined in riding mode to give $R1$ = 0.034, $wR2$ = 0.080 [$I > 2\sigma(I)$] and $R1$ = 0.041, $wR2$ = 0.083 (all data).
CCDC-208982 contains the supplementary crystallographic data for this paper. Monomeric Magnesium and Calcium Complexes Containing the Bidentate, Dianionic 1,2-Bis[(2,6-diisopropylphenyl)imino]acenaphthene Ligand

Igor L. Fedushkin,*[a] Alexandra A. Skatova,[a] Valentina A. Chudakova,[a] Georgy K. Fukin,[a] Sebastian Dechert,[b] and Herbert Schumann*[b]

Dedicated to Prof. Irina P. Beletskaya on occasion of her anniversary

Keywords: Magnesium / Calcium / N ligands / Anions / Dianions

The reduction of 1,2-bis[(2,6-diisopropylphenyl)imino]-acenaphthene (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN) with metallic magnesium or calcium in THF affords the monomeric complexes (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_3$ (**1**) and (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)-Ca(THF)$_4$·(THF)$_{1/2}$ (**2**). The crystallisation of **1** and **2** from benzene causes the removal of one of the coordinated THF molecules, yielding (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_2$·(C$_6$H$_6$)$_{1/2}$ (**3a**) and (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Ca(THF)$_3$ (**4**). Repeated recrystallisation of **1** from benzene gives (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_2$·(C$_6$H$_6$)$_2$ (**3b**). Although the crystals of **3a** and **3b** differ in colour and in their crystallographic parameters, their molecular dimensions are very similar. Recrystallisation of **1** from pyridine produces (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(py)$_3$·(py)$_2$ (**5**). Complexes **1**–**5** have been characterised by elemental analysis, UV, IR and ^{1}H NMR spectroscopy, as well as by single-crystal X-ray diffraction.

Introduction

The first reports on the preparation of bis(arylimino)acenaphthenes (Ar-BIAN) were published in the late sixties.[1] However, the complex chemistry of these ligands was not explored before the early nineties, when van Asselt and Elsevier reported in a series of papers on the synthesis and application of Ar-BIAN complexes.[2] In the last decade, Ar-BIAN complexes of the transition metals, mainly of the late transition metals, have been studied extensively[3−7] due to the wide range of their applications, for example in the catalytic hydrogenation of alkynes,[3] C−C[4] and C−Sn[5] bond formation, and especially in olefin polymerisation.[6] While metal complexes containing radical-anionic or -dianionic ligands generated by reduction of 2,2′-bipyridyl[8] or of diimines like 1,4-diaza-1,3-dienes (DAD)[9] are well-known, investigations concerning Ar-BIAN were unknown until now. However, it is to be supposed that Ar-BIAN will be easily reduced forming not only radical-monoanions or -dianions, but also radical-trianions or even -tetraanions, since these ligands can be considered as hybrids of naphthalene and diazadienes, components which either can be reduced to radical-anions and -dianions (Scheme 1). Thus, several metal complexes with DAD[9f−9i] or naphthalene[10] dianions have been previously reported. According to the reduction potentials of acenaphthylene (−1.63 V),[11] 1,4-di-*tert*-butyl-1,4-diaza-1,3-diene (−1.82 V),[12] and naphthalene (−2.6 V),[11] the alkali metals lithium, sodium, or potassium, possessing reduction potentials of −3.05, −2.71, or −2.92 V,[13] respectively, should be suitable for the reduction of Ar-BIAN ligands. Actually, we were able to synthesise and to determine the structures

of the sodium salts of the mono-, di-, tri- and tetraanions of Ar-BIAN.[14]

In this paper, we report on the products obtained by the reduction of 2,6-*i*$Pr_2C_6H_3$-BIAN with metallic magnesium and calcium. In this context the successful synthesis of heteroleptic magnesium β-diketiminato complexes,[15] homoleptic alkaline-earth bis-β-diketiminates,[16] and alkaline-earth metal complexes containing diazadiene ligands[17–19] should be mentioned.

Results and Discussion

(2,6-*i*$Pr_2C_6H_3$-BIAN)$Mg(THF)_3$ (1) and (2,6-*i*$Pr_2C_6H_3$-BIAN)$Ca(THF)_4\cdot(THF)_{1/2}$ (2)

The reduction of 2,6-*i*$Pr_2C_6H_3$-BIAN by activated metallic magnesium or calcium in THF affords the complexes (2,6-*i*$Pr_2C_6H_3$-BIAN)$Mg(THF)_3$ (**1**) and (2,6-*i*$Pr_2C_6H_3$-BIAN)$Ca(THF)_4\cdot(THF)_{1/2}$ (**2**), each in high yield.

(2,6-*i*$Pr_2C_6H_3$-BIAN) + M $\xrightarrow{\text{THF}}$ (2,6-*i*$Pr_2C_6H_3$-BIAN)$M(THF)_n\cdot(THF)_x$

1, 2

1 M = Mg, $n = 3$, $x = 0$

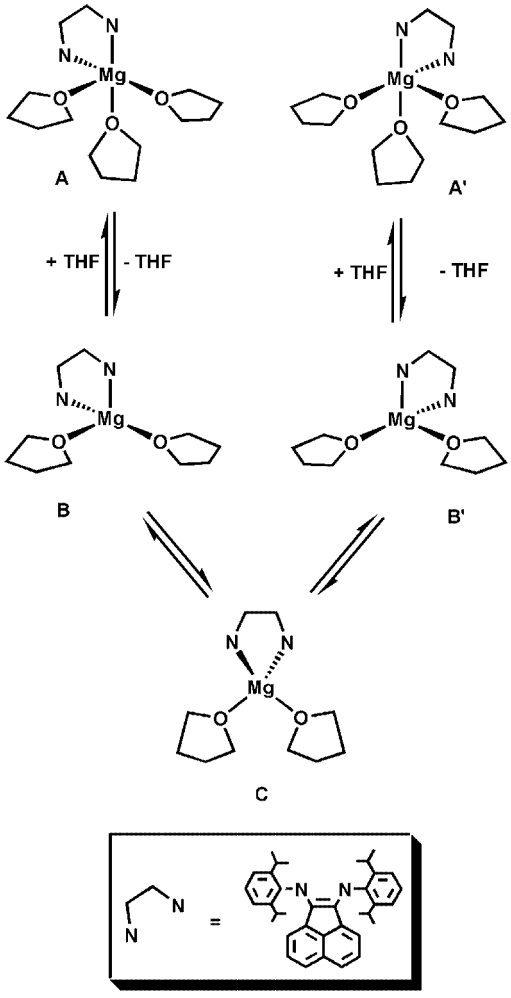
2 M = Ca, $n = 4$, $x = 1/2$

The reactions require the use of an excess of the respective metal, the activation of the metal shavings or granules, and a short reflux of the reaction mixture. The activation of the metals can be achieved by the addition of CH_2I_2 or CH_3I. The presence of the diiodides in a molar amount similar to that of the ligand causes the intermediate formation of the mixed ligand complexes (2,6-*i*$Pr_2C_6H_3$-BIAN)$MI(THF)_n\cdot(THF)_x$ (M = Mg, Ca), which, however, on refluxing the reaction mixtures react with the respective metal being present in excess to give **1** or **2**. In our experiments, we used CH_2I_2 to activate the metals. The formation of species in which the metals are coordinated to two 2,6-*i*$Pr_2C_6H_3$-BIAN radical anions has not been observed. The preferential formation of **1** and **2** is confirmed by the fact that the isolated complexes do not react further with the free ligand in THF. Nevertheless, it is to be expected that such complexes will be formed under changed conditions and, very recently, we successfully synthesised and characterised the solvent-free homoleptic complexes (2,6-*i*$Pr_2C_6H_3$-BIAN)$_2$M (M = Mg, Ca).[20] Complex **2** can also be prepared by reacting K_2(2,6-*i*$Pr_2C_6H_3$-BIAN) in situ with CaI_2 in THF or by reduction of 2,6-*i*$Pr_2C_6H_3$-BIAN with calcium naphthalenide, $(C_{10}H_8)Ca(THF)_2$, but its synthesis starting from pure calcium metal proved to be the most convenient method for laboratory use.

At the temperature of refluxing THF, the reaction mixtures show a green (**1**) or green-brown colour (**2**) and the time at which the colour of the mixtures does not become more intense can be considered as the end of the reactions. On cooling the mixtures below 0 °C, their colour turns to red-brown.

Both compounds crystallise from concentrated THF solutions as block-like, deep-red crystals, which are highly sensitive towards oxygen and water. In addition to the 2,6-*i*$Pr_2C_6H_3$-BIAN ligand, THF molecules complete the coordination sphere of the metal atoms. Owing to the difference in the ionic radii of the cations, three THF molecules are coordinated to the Mg^{II} cation in **1** and four THF molecules to the Ca^{II} cation in **2**.

In the ^{1}H NMR spectrum of **1**, the methyl protons of the four isopropyl groups give rise to two doublets centred at δ = 1.16 and 1.03 ppm due to the restricted rotation of the 2,6-*i*$Pr_2C_6H_3$ groups and the methine protons appear as a septet at δ = 3.85 ppm. All the aromatic protons appear as a broad signal at δ = 4.5 to 8.0 ppm with only four peaks, one of them showing a spin-spin coupling structure (doublet at δ = 6.81 ppm). The broadening of these signals may be explained by a dynamic process in the coordination sphere of the metal associated with an equilibrium between complex molecules with three or two coordinated THF ligands (Scheme 2). The assumption of such a dynamic process seems to be justified by the molecular structure of **1**, which shows that one of the three Mg-O_{THF} bonds is significantly longer than the other two (see Figure 2).



Scheme 2

The IR spectra of the complexes **1** and **2** confirm the dianionic character of the 2,6-*i*$Pr_2C_6H_3$-BIAN ligand. The strongest absorptions in the IR spectrum of the free ligand are the C=N stretching vibrations at 1671, 1652, and 1642 cm^{-1}.[7a,7b] In the Cu^I complex [(2,6-*i*$Pr_2C_6H_3$-BIAN)-$CuBr]_2$ in which the 2,6-*i*$Pr_2C_6H_3$-BIAN ligand acts as a neutral bidentate ligand, the corresponding absorptions are shifted only slightly to lower wavenumbers (1669 and 1633 cm^{-1}),[7a,7b] whereas these vibrations are totally absent in the spectra of **1** and **2** which show the C-N stretching vibration at ca. 1300 cm^{-1} (broad band) as the most intensive absorption associated with the 2,6-*i*$Pr_2C_6H_3$-BIAN ligand.

(2,6-*i*$Pr_2C_6H_3$-BIAN)$Mg(THF)_2\cdot(C_6H_6)_n$ [$n = 0.5$ (**3a**), $n = 2$ (**3b**)] and (2,6-*i*$Pr_2C_6H_3$-BIAN)$Ca(THF)_3$ (**4**)

The starting point of our research on magnesium and calcium Ar-BIAN complexes was the preparation of coordinatively unsaturated, highly reactive complexes. In the case of the coordinatively saturated complexes **1** and **2**, this corresponds to the elimination of coordinated THF ligands. Several methods are known to eliminate coordinated solvent molecules from metal complexes, including the sublimation of the compounds in high vacuum or the distillation of solutions of the compounds in non-coordinating media. Since initial attempts to eliminate THF molecules from **1** or **2** by heating the complexes in vacuo up to 180 °C failed, we used the "wet" method. Crude **1** and **2**, dried in vacuo, were dissolved in benzene forming green solutions which were heated to 60−80 °C. Cooling of these solutions to ambient temperature resulted in the separation of khaki-coloured cubic crystals when starting from **1** or of red prismatic crystals when starting from **2**. The ratio of the THF protons to the methyl protons of the 2,6-*i*$Pr_2C_6H_3$-BIAN ligand, estimated by integration of the respective ^1H NMR signals, indicates that both **1** and **2** lost one THF ligand in the course of this dissolution-crystallisation procedure, thus changing into (2,6-*i*$Pr_2C_6H_3$-BIAN)$Mg(THF)_2\cdot(C_6H_6)_{1/2}$ (**3a**) and (2,6-*i*$Pr_2C_6H_3$-BIAN)$Ca(THF)_3$ (**4**). In the case of **1**, the repetition of this procedure again leads to a different complex, the emerald-green, rhombic crystals of (2,6-*i*$Pr_2C_6H_3$-BIAN)$Mg(THF)_2\cdot(C_6H_6)_2$ (**3b**). Complex **3b** differs from **3a** only in the number of C_6H_6 lattice molecules. Surprisingly, crystallisation of **3b** from benzene again affords crystals of different colour and shape: thin, square, deep-brown coloured plates (**3c**). The NMR spectrum of **3c** is almost identical to that of **3b** and indicates the presence of two THF molecules coordinated to the magnesium. Unfortunately, the crystals of **3c** were not suitable for X-ray diffraction. However, based on the data of the crystal structures of **3a** and **3b**, one can suggest that **3c** differs from **3a** and **3b** only with regard to its crystal packing.

Since the molecular structures of **3a** and **3b** differ only with respect to their dihedral angles between the N(1)−Mg−N(2) and N(1)−C(1)−C(2)−N(2) planes, being, as expected, rather small in both cases, [6.7° (**3a**), 14.6° (**3b**)], one can suggest that the different colours of their crystals may be a result of the difference in ligand-to-metal charge transfer. Alternatively, the difference in colour may be attributed to differences in the mutual arrangement of the complex molecules and the lattice benzene molecules and thus to differences in the kind of charge transfer between them. The question as to why **3a**, **3b** and **3c** never jointly crystallise in one and the same crop and what forces determine the kind of crystal growth cannot yet be answered. The repeated crystallisation of **4** from benzene did not cause any change in the complex.

The dissolution of **1** in hot pyridine (60 to 70 °C) results in a replacement of the THF ligands by pyridine ligands and formation of (2,6-*i*$Pr_2C_6H_3$-BIAN)$Mg(py)_3\cdot(py)_2$ (**5**), which separates as black prismatic crystals on cooling the concentrated pyridine solution to ambient temperatures.

Molecular Structures of 1, 2, 3a, 3b, 4, and 5

Prior to the detailed discussion of each structure, some general remarks on the structure of the complexes should be made:

a) The 2,6-*i*$Pr_2C_6H_3$-BIAN molecule acts as a rigid, chelating ligand. Probably due to the bulkiness of the 2,6-*i*$Pr_2C_6H_3$ groups, the complexes crystallise from different solvents as monomers. The metal atoms deviate to a varying degree from the 1,2-diimonoacenaphthene plane, forming dihedral angles of 5.7° (**1**), 10.3° (**2**), 6.7° (**3a**), 14.6° (**3b**), 11.1° (**4**), and 12.3° (**5**) (Figure 1). These dihedral angles are somewhat larger than those in the magnesium DAD complexes [RN(Ph)CC(Ph)NR]$Mg(DME)_2$ (3.0°, R = Ph; 5.0°, R = *p*-MeC_6H_4), but much smaller than those in the analogous calcium complex (40.0°, R = *p*-MeC_6H_4).[18]

b) The two-electron reduction of the diimine moiety causes a reorganization of the bonds from Ar-N=C(R)-(R)C=N-Ar to $[(Ar)N\text{-}(R)C{=}C(R)\text{-}N(Ar)]^{2-}$. Thus, the dianionic nature of the 2,6-*i*$Pr_2C_6H_3$-BIAN ligand in the complexes **1** to **5** must be apparent from a shortening of the C(1)−C(2) bond and an elongation of the N(1)−C(1) and N(2)−C(2) bonds compared to the respective bond lengths in metal complexes containing the ligand in the neutral form. Actually, the C(1)−C(2) bonds in **1**−**5**, ranging from 1.389 to 1.409 Å, are shorter than those in (2,6-*i*$Pr_2C_6H_3$-BIAN)$CuCl_2$(AcOH) (1.500 Å)[7a] and [(2,6-*i*$Pr_2C_6H_3$-BIAN)$CuBr]_2$ (1.517 Å),[7b] and the N(1)−C(1) and N(2)−C(2) bonds in **1**−**5** (1.378 to 1.402 Å) are longer than those in the above $CuCl_2$ (av. 1.287 Å)[7a] and CuBr complexes (1.285 Å).[7b]

c) Another general feature of the molecular structure of complexes **1**−**5** is the fact that one of the solvent ligands fits into the pocket formed by two isopropyl groups, one of each *N*-phenyl moiety (Figure 1). The angles between the diiminoacenaphthene moiety, the metal atom, and the donor atom of the ligand located in this pocket range from 92 to 116°. A similar situation has been observed in the complex (2,6-*i*$Pr_2C_6H_3$-BIAN)$CuCl_2$(AcOH)[7a] in which the acetic acid molecule occupies the vertex of a square pyramid (O−Cu−N 95.4 and 94.6°) and two N and two Cl atoms form the square plane.

The molecular structures of **1**, **2**, **3a**, **4**, and **5** are depicted in Figures 2−6, respectively (the figure of the molecular

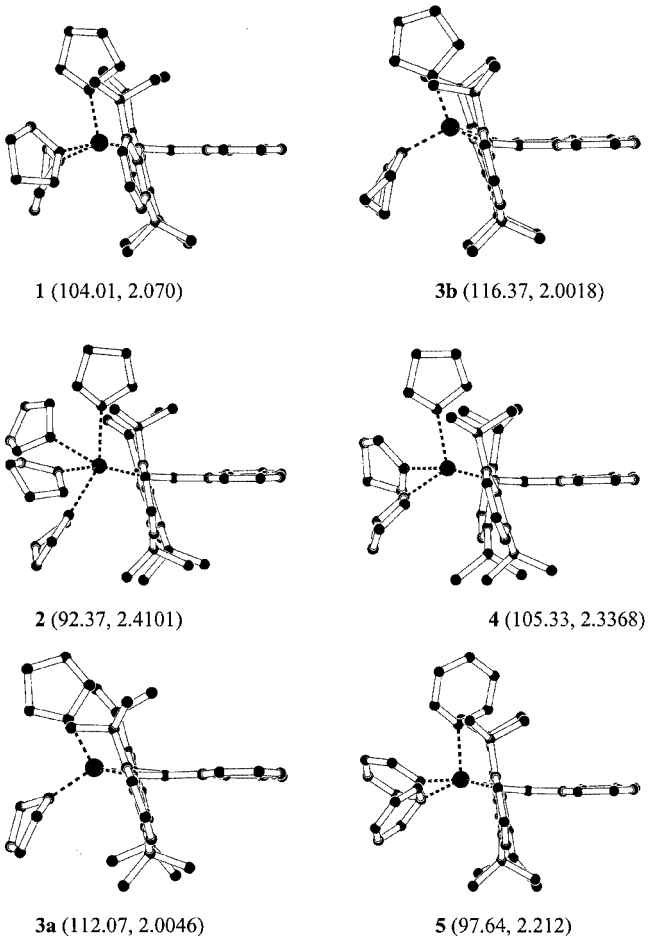

Figure 1. View of the molecules **1**−**5** along the acenaphthylene plane; the angles (deg) between the plane formed by the acenaphthene moiety, the metal, and the solvent donor atom, which is located between two isopropyl groups of the N bonded aryls, are given in parentheses along with the respective M−O(THF) and M−N(pyridine) distances (Å)

structure of **3b** is omitted since it is almost identical to that of **3a**). The crystal data collection and structure refinement data for **1**, **2**, **3a**, **3b**, **4**, and **5** are listed in Tables 1 and 2, selected bond lengths and bond angles of the molecules of these complexes are listed in Table 3 and 4. A comparison of the main bond lengths and angles in **1**−**5** is given in Figure 7.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_3$ (1): Assuming that in **1** the ligand arrangement around the Mg atom is that of a square pyramid, the basal plane, made up by the atoms N(1), N(2), O(2), and O(3), is strongly distorted towards a rhombus because the Mg−O(3) bond (2.224 Å) is significantly longer than the Mg−O(1) (2.070 Å) and the Mg−O(2) bonds (2.084 Å) and the Mg−N(2) bond (2.105 Å) is longer than the Mg−N(1) bond (2.045 Å). Furthermore, the longer Mg−O(3) bond and the longer Mg−N(2) bond are in opposite positions relative to the magnesium atom. Thus, the atoms N(2) and O(3) match much better with the axial positions of a trigonal bipyramid, the equatorial plane of which is formed by the atoms N(1), O(1) and O(2) (Figure 2). The sum of the angles (359.3°) between the Mg atom and the equatorial atoms corresponds almost exactly with the ideal value of 360°, thus indicating the absence of an umbrella-like distortion of the trigonal bipyramid. Owing to the higher rigidity of the 2,6-*i*Pr$_2$C$_6$H$_3$-BIAN ligand compared to the β-diketiminate ligand, the bite angle N(1)−Mg−N(2) in **1** (84.8°) is smaller than that of the β-diketiminate ligand in (2,6-*i*PrC$_6$H$_3$NCMe)$_2$CHMg(R)(THF) (98.8° for R = O-*t*Bu, 92.8° for R = N-*i*Pr$_2$).[15e]

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Ca(THF)$_4$·(THF)$_{1/2}$ (2): Due to the larger ionic radius of Ca^{2+} compared to Mg^{2+} (1.00 and 0.72 Å, respectively, for six-coordinate ions[22]), the calcium atom is coordinated by four THF molecules which, along with the bidentate 2,6-*i*Pr$_2$C$_6$H$_3$-BIAN ligand, surround the calcium atom in a distorted octahedral fashion (Figure 3). One of the four Ca−O(THF) bonds is longer [Ca−O(4) 2.619 Å] than the other three which are in a fairly narrow range (2.410−2.458 Å). In contrast to the Mg−N bonds in **1**, the two Ca−N bonds (2.396 and 2.382 Å) are almost of the same length, but, as expected, longer by about 0.3 Å. The distorted octahedron is made up by O(4) and N(1) in the axial positions and O(1), O(2), O(3), and N(2) forming the equatorial plane. This distortion is caused by both the crowding around the calcium atom and the small bite angle N(1)−Ca−N(2) (75.8°), this angle being the smallest among complexes **1**−**5**.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_2$·(C$_6$H$_6$)$_{1/2}$ (3a) and (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_2$·(C$_6$H$_6$)$_2$ (3b): Despite the different crystallographic parameters, the different crystal packing and the difference in the number of the lattice solvent molecules, **3a** and **3b** exhibit almost the same molecular structure, showing a distorted tetrahedral ligand arrangement around the central Mg atom. For this reason only the structure of **3a** is depicted (Figure 4) and discussed. The two Mg−O bonds and the two Mg−N bonds do not differ markedly in length [Mg−O(1) 2.005, Mg−O(2) 1.999 Å; Mg−N(1) 1.994, Mg−N(2) 2.004 Å]. The Mg−N bonds are notably shorter than those in **1**, and, as a consequence, the bite angle N(1)−Mg−N(2) in **3a** (90.7°) is larger than in **1** (84.8°). Although the sum of the angles N(1)−Mg−N(2), N(1)−Mg−O(2) and N(2)−Mg−O(2) of 332.7° approaches the value of 328.5° for an ideal tetrahedral MgN_2O_2 moiety, a considerable distortion of the tetrahedron is apparent from the bite angle (90.7°) and the angle O(1)−Mg−O(2) (96.2°), both of which deviate significantly from the ideal value of 109.5°.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Ca(THF)$_3$ (4): Except for the fact that all bonds in **4** are longer than the respective bonds in **1**, the molecular structures of **1** and **4** (Figure 5) are very similar and correspond to a trigonal bipyramid. Similar to **1**, the two Ca−N bonds differ in their length [Ca−N(1) 2.290 Å, Ca−N(2) 2.345 Å] and one of the Ca−O(THF) bonds, the Ca−O(3) bond (2.445 Å), is considerably longer than the other two, which in turn are essentially equal in length [Ca−O(1) 2.337 Å, Ca−O(2) 2.338 Å]. Thus, O(3) and N(2) are the apical atoms of the trigonal bipyramid and the equatorial plane is formed by the atoms N(1), O(1), and O(2). Also, the sum of the basal bond angles N(1)−Ca−O(1), N(1)−Ca−O(2) and O(1)−Ca−O(2)

(359.8°) coincides with that of **1** (359.3°) and corresponds with the ideal value of 360°. Because of the longer Ca−N bonds compared to the Mg−N bonds in **1**, the bite angle N(1)−M−N(2) in **4** (M = Ca; 77.0°) is smaller than in **1** (M = Mg; 84.8°). A closer look at the structures of **1** and **4** establishes that the molecules are enantiomorphic (see

[a] For **1** and **5** L(1), L(2), L(3) are O(1), O(2), O(3) and N(3), N(4), N(5), respectively; for **3a** and **3b** L(1) and L(2) are O(1) and O(2).

Figure 7). One can suggest that in solutions of the compounds, the structures may interconvert by splitting off and recoordinating a THF ligand, thus forming four-coordinate species B and B′ as intermediates (Scheme 2). We propose such a process in order to explain the broadened aryl signals in the ^{1}H NMR spectrum of **1** (see below).

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(py)$_3$·(py)$_2$ (5): The structure of complex **5** (Figure 6) corresponds with the trigonal-bipyramidal structures of the five-coordinate complexes **1** and **4** except that the axial and equatorial positions in **5** are not as pronounced as in **1** and **4**. The axial positions of N(1) and N(5) are apparent from the angle N(1)−Mg−N(5) of 168.3°, but the distances of N(1) and N(5) to the magnesium atom [Mg−N(1) 2.103 Å, Mg−N(5) 2.271 Å] do not differ all that much from those of the other three N−Mg distances [Mg−N(2) 2.071, Mg−N(3) 2.198 Å, Mg−N(4) 2.212 Å]. The sum of the bond angles between the Mg atom and N(2), N(3), and N(4) is exactly 360°, thus indicating that the Mg atom lies perfectly in the equatorial plane of the bipyramid. The bite angle N(1)−Mg−N(2) (84.9°) can be considered to be equal to that in complex **1** (84.8°). A closer inspection of the crystal structure of **5** shows that one of the CH_3 groups of the 2,6-*i*Pr$_2$C$_6$H$_3$-BIAN ligand is turned towards the magnesium atom, but keeps away from the metal by ≥ 3 Å (Figure 8). In the case of complex **1** this contact is less evident due to the overcrowding around the magnesium atom arising from the shorter Mg−O distances and the non-flat shape of the THF ligands.

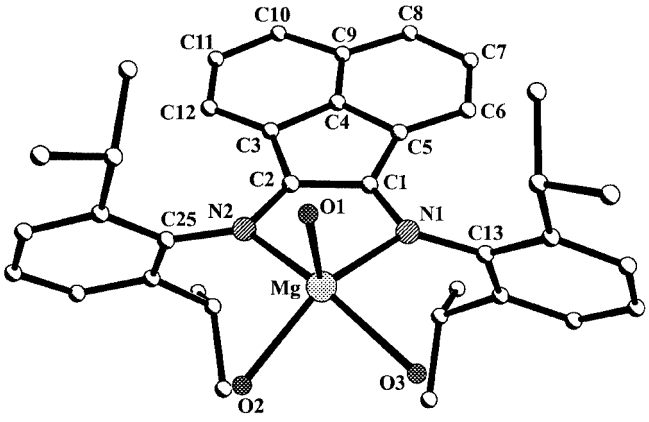

Figure 2. PLATON plot[21] of the molecular structure and the numbering scheme of **1**; all hydrogens and the carbon atoms of the THF ligands have been omitted

NMR Studies on Solutions of 1 and 5: The solution behaviour of the five-coordinate complexes **1** in [D$_8$]THF and **5** in [D$_5$]pyridine is rather different. The broadening of the aromatic signals in the ^{1}H NMR spectrum of **1** (see Figure 9a) can be explained by a dynamic process in the metal coordination sphere connected with a change in the coordination number of the magnesium atom from five to four (Scheme 2). Similar processes have been observed for THF

solutions of the β-diketiminato complexes (2,6-iPrC$_6$H$_3$NCMe)$_2$CHMgR (R = N-iPr$_2$, O-tBu).[15e] The change in the coordination number of the magnesium effects the electronic properties of the planar diiminoacenaphthene system and explains the broadening of its proton

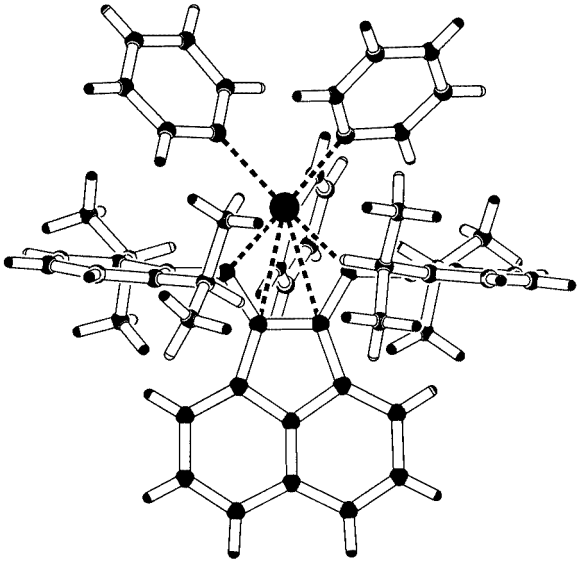

Figure 8. View of **5**, emphasising the tendency of one CH_3 group to interact with the Mg atom

signals. Since the 2,6-*i*$Pr_2C_6H_3$ groups are attached in an almost orthogonal fashion to the five-membered metallacycle C_2N_2Mg [due to the restricted rotation around the C(*ipso*)−N bond] the electronic changes at the metal do not influence the 2,6-*i*$Pr_2C_6H_3$ groups substantially, thus causing a normal shape of the isopropyl methyl and the isopropyl methine signals (two doublets and a septet, respectively). On going from THF to benzene as the solvent, the NMR spectrum of **1** does not change significantly. At this point it should be noted that the ^{1}H NMR spectrum of (2,6-*i*PrC_6H_3-BIAN)$Mg(THF)_2\cdot(C_6H_6)_{1/2}$ (**3a**) (Figure 9b), containing four-coordinate magnesium, does not indicate the formation of a three-coordinate species by splitting off of one of the two THF ligands.

The ^{1}H NMR spectrum of **5** in [D_5]pyridine (Figure 9c) exhibits four isopropyl methyl signals of different intensity at δ = 1.26 (bs), 1.19 (d), 1.13 (d), and 0.86 ppm (bs), two of which are significantly broadened. The isopropyl methine proton signal centred at δ = 3.84 ppm (spt) corresponds to the two methyl doublets at δ = 1.19 and 1.13 ppm, whereas the chemical shift of the methine proton signal corresponding to the two broadened isopropyl methyl signals is

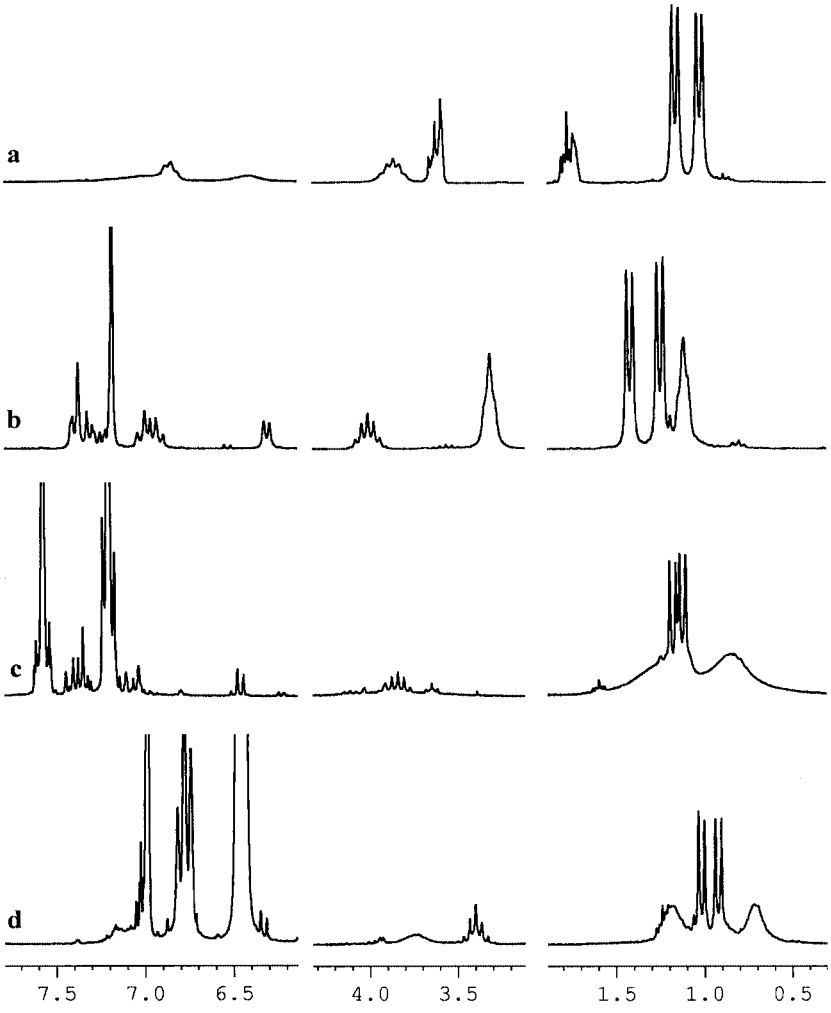

Figure 9. ^{1}H NMR spectra (200 MHz) of **1** in [D_8]THF (a) and C_6D_6 (b) and of **5** in [D_5]pyridine (c) and C_6D_6 (d)

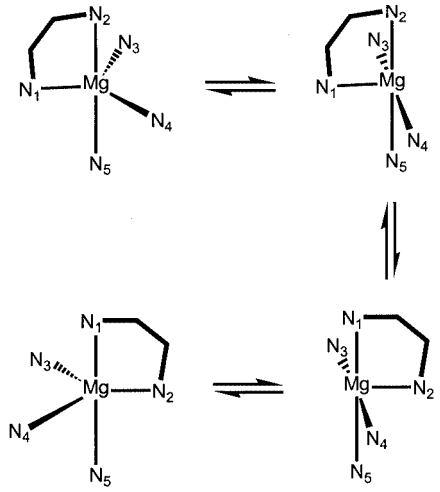
 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

impossible to ascertain because of its extreme broadening. However, in the ^{1}H NMR spectrum of **5** in C_6D_6 (Figure 9d), the two methine proton signals corresponding to the four isopropyl methyl proton signals at δ = 1.38 (bs), 1.21 (d), 1.12 (d), and 0.91 ppm (bs) can be located at δ = 3.93 (bs) and 3.59 ppm (spt). In this case, the four methyl signals are approximately of equal intensity, whereas in the spectrum of **5** recorded in pyridine (Figure 9c), the broadened methyl signals are more intense. For comparison, in the ^{1}H NMR spectrum of the free 2,6-*i*Pr$_2$C$_6$H$_3$-BIAN ligand in [D$_5$]pyridine three signals represent the isopropyl protons, two doublets at δ = 1.27 (12 H) and 1.07 ppm (12 H) for the methyl protons and a septet at δ = 3.24 ppm (4 H) for the methine protons. The difference in the integrals of the four methyl signals in the spectra of **5** in [D$_5$]pyridine and in C_6D_6 evidently indicates the presence of two different species in both solutions. When using pyridine as the solvent for **5**, the removal of one of the three pyridine ligands from the magnesium atom, and thus the formation of a four-coordinate species, as discussed in the case of complex **1** for a THF ligand (see Scheme 2), should be considerably suppressed. Furthermore, the Mg−N(py) bonds are stronger than the Mg−O(THF) bonds due to the higher donor strength of pyridine compared to THF (33.1 and 20.0, correspondingly vs. $SbCl_5$).[23] Therefore, we suggest that besides the dynamic dissociation-recoordination process connected with a change in the coordination number of the magnesium atom, a second process (slow on the NMR time scale) will take place in solutions of **5** in pyridine, as well as in benzene, consisting of a distortion of the coordination sphere of the metal without a change of its coordination number. In the case of **5**, the well-known Berry pseudorotation[24,25] of five-coordinate complexes cannot serve as an explanation because of the constraints imposed by the chelating ring system and the molecular structure of **5**, which is best described as a distorted trigonal bipyramid and not as a square pyramid. We therefore suppose that in solutions of **5**, a distortion of the trigonal bipyramid occurs, in the course of which the nitrogen atoms N(1) and N(2) change their positions from axial to equatorial and vice versa (Scheme 3). A weak interaction between the Mg atom and the CH_3 groups may play some role in this process.



Scheme 3

Conclusion

We have synthesised and characterised magnesium and calcium complexes with the dianionic 1,2-bis[(2,6-diisopropylphenyl)imino]acenaphthene ligand. The sterically demanding substituents at both nitrogen atoms cause the formation of monomeric species. In the near future, we intend to investigate the reactivity of these complexes towards different organic substrates, such as ketones, organic halides and unsaturated organic compounds in order to find out whether these magnesium and calcium complexes may serve as one- and two-electron reductants. Preliminary studies have shown that the reactions of complex **1** with $Ph_2C{=}O$ or Me_3SiCl afford a pinacone coupling product or a product formed by the two-electron oxidative addition of Me_3SiCl to the complex, respectively.

Experimental Section

General Remarks: All manipulations were carried out under vacuum in Schlenk tubes. Tetrahydrofuran and benzene were distilled from sodium/benzophenone. Pyridine was distilled and further treated with small amounts of sodium and then condensed in vacuo immediately prior to use. The deuterated solvents [D$_8$]THF, C_6D_6, and [D$_5$]pyridine (Aldrich) were dried at ambient temperature over sodium/benzophenone (THF, benzene) or sodium (pyridine) and, just prior to use, condensed under vacuum into the NMR tubes containing the compounds. Melting points were measured in sealed capillaries. 1,2-Bis[(2,6-diisopropylphenyl)imino]acenaphthene (2,6-*i*Pr$_2$C$_6$H$_3$-BIAN) was prepared according to the published procedure.[7a] The excess of Mg and Ca left after the preparation of **1** and **2** was used without further activation by CH_2I_2 for the repeated synthesis of these complexes. The IR spectra were recorded on a Specord M80 spectrometer and the UV/Vis spectra on a Specord M80. The ^{1}H and ^{13}C{^{1}H} NMR spectra were recorded on a Bruker DPX-200 NMR spectrometer (^{1}H, 200 MHz; ^{13}C, 50.32 MHz). Chemical shifts are reported in ppm relative to the ^{1}H and ^{13}C{^{1}H}- residues of the deuterated solvents.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_3$ (1): Magnesium shavings (2.4 g, 100 mmol) and CH_2I_2 (0.8 g, 2.98 mmol) were placed in a Schlenk-like ampoule (ca. 100 mL volume) equipped with a Teflon stopcock. After evacuation of the ampoule (10^{-1} Torr within ca. 1 min), THF (40 mL) was added by condensation and the mixture was stirred for 2 h. The $MgI_2(THF)_n$ formed was decanted together with the solvent and the residual metal was washed three times with THF (40 mL). A suspension of 2,6-*i*Pr$_2$C$_6$H$_3$-BIAN (0.5 g, 1.0 mmol) in THF (30 mL) was then added to the activated magnesium metal and the mixture was refluxed. In the course of about 10 min reflux, the reaction mixture turned deep green. The solution was then cooled to ambient temperature and decanted from the excess of magnesium. Crude **1** (0.69 g, 93%) was obtained as a deep-red crystalline solid on removal of the volatiles from the solution in vacuo. Recrystallisation of **1** from THF (15 mL) yielded large block-like crystals (0.27 g, 37%) and further **1** (0.31 g, 42%)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was obtained by concentration of the mother liquor. M.p. 176 °C (decomp.). ^{1}H NMR ([D$_8$]THF, 20 °C): δ = 8.0−4.5 (br. m, 12 H, C$_{arom}$), 3.85 (spt, 4 H, C*H*Me$_2$), 3.61 [m, 8 H, α-C*H*$_2$(THF)], 3.58 [s, 8 H, α-C*H*$_2$(THF)], 1.76 [m, 4 H, β-C*H*$_2$(THF)], 1.73 [s, 4 H, β-C*H*$_2$(THF)], 1.16 [d, ^3J = 8.0 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.03 [d, ^3J = 6.0 Hz, 12 H, CH(C*H*$_3$)$_2$]. IR (Nujol): $\tilde{\nu}$ = 1580 s, 1410 s, 1315 vs, 1250 s, 1170 m, 1105 w, 1020 s, 910 m, 875 s, 800 m, 760 vs, 615 m cm^{-1}. UV/Vis (THF, 20 °C): λ_{max} = 822, 370 nm. $C_{48}H_{64}MgN_2O_3$ (741.32): calcd. C 77.77, H 8.70, Mg 3.28; found C 77.02, H 8.13, Mg 3.26.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Ca(THF)$_4$·(THF)$_{1/2}$ (2): Calcium metal granules (5.5 g, 137 mmol) were activated by CH_2I_2 (0.8 g, 2.98 mmol) as described for **1**. The activated Ca was treated with 2,6-*i*Pr$_2$C$_6$H$_3$-BIAN (0.5 g, 1.0 mmol) in THF (30 mL) and the mixture was stirred under reflux for 1 h. After cooling the mixture to ambient temperature, the solution was decanted from the excess of Ca metal. Evaporation of the solvent in vacuo afforded 0.75 g (85%) of crude **2** as deep-red crystals. Analytically pure, black coloured **2** was isolated by concentration of the decanted solution under reflux to 15 mL and cooling of the concentrate to ambient temperature. M.p. >160 °C (decomp.). ^{1}H NMR ([D$_8$]THF, 20 °C): δ = 8.0−5.0 (br. m, 12 H, C$_{arom}$), 3.9 (br. m, 4 H, C*H*Me$_2$), 3.63 (m, 8 H, α-C*H*$_2$(THF)], 3.60 [s, 8 H, α-C*H*$_2$(THF)], 1.78 [m, 8 H, β-C*H*$_2$(THF)], 1.75 [s, 8 H, β-C*H*$_2$(THF)], 1.18 [s, 24 H, CH(C*H*$_3$)$_2$]. IR (Nujol): $\tilde{\nu}$ = 1585 s, 1405 s, 1310 vs, 1250 s, 1170 m, 1100 w, 1020 m, 1010 m, 910 m, 870 s, 800 m, 760 vs, 620 m cm^{-1}. $C_{52}H_{72}CaN_2O_4(C_4H_8O)_{1/2}$ (865.25): calcd. C 74.96, H 8.85, Ca 4.63; found C 74.13, H 8.47, Ca 4.41.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_2$·(C$_6$H$_6$)$_{1/2}$ (3a): Complex **1** (0.69 g, 0.93 mmol) dried in vacuo for 1 h, was dissolved in benzene (20 mL) and the solution was heated to 70−80 °C. The volume of the green benzene solution was than reduced to 10 mL by evaporation in vacuo at 70 °C. After cooling the solution to ambient temperature khaki-green crystals of **3a** (0.31 g, 47%) separated within 24 h. M.p. > 260 °C. ^{1}H NMR (C$_6$D$_6$, 20 °C): δ = 7.38−7.20 (m, 6 H, C$_{arom}$), 7.02−6.87 (m, 4 H, C$_{arom}$), 6.29 (d, ^3J = 8.0 Hz, 2 H), 3.99 (spt, 4 H, C*H*Me$_2$), 3.30 [s, 8 H, α-C*H*$_2$(THF)], 1.41 [d, ^3J = 6.0 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.23 [d, 12 H, ^3J = 6.0 Hz, CH(C*H*$_3$)$_2$], 1.08 [s, 4 H, β-C*H*$_2$(THF)]. IR (Nujol): $\tilde{\nu}$ = 1605 w, 1575 s, 1415 vs, 1300 vs, 1250 s, 1170 m, 1100 w, 1020 s, 910 m, 905 s, 870 s, 800 m, 760 vs, 680 s, 615 m cm^{-1}. UV/Vis (C$_6$H$_6$, 20 °C): λ_{max} = 750, 370 nm. $C_{44}H_{56}MgN_2O_2(C_6H_6)_{1/2}$ (708.27): calcd. C 79.70, H 8.40, Mg 3.43; found C 78.61, H 7.48, Mg 3.29.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(THF)$_2$·(C$_6$H$_6$)$_2$ (3b): Complex **1** (0.65 g, 0.87 mmol) was heated in vacuo to 80 °C for 10 min. The solid was then dissolved in hot benzene (20 mL) and after its dissolution the solvent was evaporated in vacuo. The remaining solid was redissolved in hot benzene (20 mL), followed by evaporation of the solvent. The residue was crystallised from benzene (10 mL) at ambient temperature affording 0.25 g (34%) of **3b** as thin emerald-green crystals. M.p. ca. 180 °C (decomp.). ^{1}H NMR (C$_6$D$_6$, 20 °C): δ = 7.38−7.20 (m, 6 H, C$_{arom}$), 7.02−6.87 (m, 4 H, C$_{arom}$), 6.29 (d, ^3J = 8.0 Hz, 2 H), 3.99 (spt, 4 H, C*H*Me$_2$), 3.30 [s, 8 H, α-C*H*$_2$(THF)], 1.41 [d, ^3J = 6.0 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.23 [d, ^3J = 6.0 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.08 [s, 4 H, β-C*H*$_2$(THF)] ppm. IR (Nujol): $\tilde{\nu}$ = 1580 s, 1415 vs, 1300 vs, 1250 s, 1170 m, 1100 w, 1020 s, 910 m, 905 s, 870 s, 800 m, 760 vs, 680 vs, 615 m cm^{-1}. UV/Vis (C$_6$H$_6$, 20 °C): λ_{max} = 750, 370 nm. $C_{44}H_{56}MgN_2O_2(C_6H_6)_2$ (825.43): calcd. C 81.48, H 8.30, Mg 2.94; found C 81.67, H 7.88, Mg 2.62.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Ca(THF)$_3$ (4): Crude **2** (0.7 g, 0.81 mmol) was dried in vacuo at ambient temperature for 10 min and was then dissolved in hot benzene (15 mL; 60−80 °C). Cooling the benzene solution to ambient temperature caused the precipitation of **4** as deep red-brown crystals within 36 h (0.38 g, 63%). M.p. 178 °C (decomp.). ^{1}H NMR (C$_6$D$_6$, 20 °C): δ = 7.38−7.21 (m, 6 H, C$_{arom}$), 6.99−6.88 (m, 4 H, C$_{arom}$), 6.35 (d, ^3J = 6.0 Hz, 2 H), 3.98 (spt, 4 H, C*H*Me$_2$), 3.39 [s, 12 H, α-C*H*$_2$(THF)], 1.41 [d, ^3J = 6.4 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.32 [d, ^3J = 6.6 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.17 [s, 4 H, β-C*H*$_2$(THF)]. IR (Nujol): $\tilde{\nu}$ = 1580 s, 1550 w, 1400 vs, 1320 vs, 1220 s, 1170 m, 1100 w, 1020 s, 910 s, 870 s, 850 s, 800 s, 755 vs, 680 w, 610 m cm^{-1}. $C_{48}H_{64}CaN_2O_3$ (757.09): calcd. C 76.15, H 8.52, Ca 5.29; found C 75.94, H 8.13, Ca 4.89.

(2,6-*i*Pr$_2$C$_6$H$_3$-BIAN)Mg(py)$_3$·(py)$_2$ (5): Crude **1** (0.65 g, 0.87 mmol) was dissolved in pyridine (30 mL) and the solution was heated to 60 °C. The brown solution formed was concentrated to 10 mL by evaporation of the solvent in vacuo. After one day, black crystals of **5** (0.56 g, 69%) had precipitated. M.p. 171 °C (decomp). ^{1}H NMR (C$_6$D$_6$, 20 °C): δ = 3.93 [s, 4 H, C*H*(CH$_3$)$_2$], 3.59 [spt, ^3J = 6.0 Hz, 4 H, C*H*(CH$_3$)$_2$], 1.38 [br. s, 12 H, CH(C*H*$_3$)$_2$], 1.21 [d, ^3J = 6.6 Hz, 12 H, CH(C*H*$_3$)$_2$], 1.12 [d, ^3J = 6.8 Hz, 12 H, CH(C*H*$_3$)$_2$], 0.91 [br. s, 12 H, CH(C*H*$_3$)$_2$] ppm; the signals of the aromatic protons are broadened and covered by the pyridine resonances. IR (Nujol): $\tilde{\nu}$ = 1600 m, 1580 vs, 1485 m, 1310 vs, 1250 s, 1210 m, 1170 s, 1100 w, 1070 m, 1040 m, 990 w, 910 s, 890 w, 800 m, 750 vs, 705 vs cm^{-1}. $C_{51}H_{55}MgN_5(C_5H_5N)_2$ (920.51): calcd. C 79.59, H 7.12, Mg 2.64; found C 78.94, H 6.82, Mg 2.63.

Single-Crystal X-ray Structure Determination of 1−5: The crystal data and details of data collection are given in Table 1 and 2. The data for **1**, **2**, **5**, and **3a**, **3b**, **4** were collected on a SMART CCD and a SMART APEX diffractometer, respectively (graphite-monochromated Mo-K_α radiation, ω- and ψ-scan technique, λ= 0.71073 Å). The structures were solved by direct methods using SHELXS-97[26] and were refined on F^2 using all reflections with SHELXL-97.[27] All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 Å^2. Absolute structure parameters were determined according to the method of Flack[28] with SHELXL-97.[27] For **1**, the determination of the correct absolute structure was not possible. SADABS[29] was used to perform area-detector scaling and absorption corrections. The geometrical aspects of the structures were analysed with the PLATON program.[21]

CCDC-206142 (**1**) -206143 (**2**) -206144 (**3a**) -206145 (**3b**) -206146 (**4**) and -206147 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

Solvent-Free and TMEDA-Solvated Mixed Alkali Metal-Magnesium Tris-diisopropylamides

Eva Hevia,[a] Fiona R. Kenley,[a] Alan R. Kennedy,[a] Robert E. Mulvey,*[a] and René B. Rowlings[a]

Dedicated to the memory of Ron Snaith

Keywords: Alkali metals / N ligands / Heterometallic complexes / Potassium / Magnesium

A trio of heterobimetallic tris-diisopropylamides, the solvent-free potassium-magnesium amide [{KMg(N*i*Pr$_2$)$_3$}$_\infty$], its TMEDA solvate [KMg(N*i*Pr$_2$)$_3$·TMEDA] and the sodium congener [NaMg(N*i*Pr$_2$)$_3$·TMEDA] has been synthesised by mixing the appropriate metal alkyl reagents with three molar equivalents of diisopropylamine in a hydrocarbon medium, to which, in the last two cases, TMEDA is added. All three amides have been successfully crystallographically characterised by X-ray diffraction studies. Representing the first pure *s*-block mixed-metal diisopropylamide free of solvent molecules or other stabilising anionic co-ligands, the first compound adopts an infinite spiral chain of ···K-(μ-N)$_2$-Mg-N··· links, the metal-N framework of which is supported by agostic K···C intra-dinuclear and inter-dinuclear contacts. The dinuclear tris-amido motif is maintained in both TMEDA complexes, the metal-N cores of which are essentially isostructural, but the presence of the chelating diamine blocks the propagating terminal site on the alkali metal and so gives rise to discrete molecular structures.

Introduction

Generally dispensed in the form of its lithium compound, the sterically demanding diisopropylamido ligand (*i*Pr$_2$N$^-$, DA; with lithium, LDA) has long commanded a high-ranking position in synthesis on account of its good (kinetic) basicity and poor nucleophilicity. These complementary properties combine to make LDA the shelf reagent of choice in a legion of proton abstraction applications (especially with weakly acidic organic compounds).[1] When planning a synthesis it would be a tactical error to view LDA as simply a convenient source of DA, as the presence of the lithium counterion imparts (or affects) certain characteristics of the amide [including, for example, aggregation state/s; extent and nature of solvation; polarity and strength of the metal-N bond; hybridisation of the anionic N centre; solubility; thermal stability; susceptibility to β-hydride elimination from the Me$_2$C(H)- branches], which can have a profound effect on the outcome and rate of a reaction with a substrate.[2] Though patterns can be discerned and rationalised in certain systems, in general metal effects in metal-mediated reactions can be a minefield of complexity, which can only be safely trodden through by assessing the influence of each metal on an individual basis.[3] It follows that changing the metal supporting the DA ligand from lithium to another metal can bring about significant differences in the reactivity/selectivity and kinetics of the amido functionality. This is one reason for synthesising new metal complexes of DA. We have an additional incentive for pursuing such a goal. The DA ligand has played a major role in advancing our work in *s*-block metal synergy and "inverse crown" chemistry. So called because of their inverse topological relationship to conventional crown ether complexes, inverse crowns are poly-mixed-metal amide cationic ring compounds with anionic centres.[4] DA has served as the metal atom linking unit in inverse crowns with alkoxo [{MMg(DA)$_2$OR}$_2$] (M = Li, R = *n*Oct; M = Na, R = *n*Bu or *n*Oct),[5] hydrido [Na$_2$Mg$_2$(DA)$_4$(H)$_2$·(toluene)$_2$][6] or ferrocenetetrayl [Na$_4$Mg$_4$(DA)$_8${Fe(C$_5$H$_3$)$_2$}] cores,[7] where it performs a μ$_2$ bonding role. The "super" inverse crown structure of [{NaMg(DA)(O)·(THF)}$_6$][8] also has μ$_2$-DA ligands in the sodium amide appendages to the hexameric (MgO)$_6$ cage. Common to the synthesis of each of these species is a synergic tris-amide of general formula [MMg(DA)$_3$], though hitherto no structural information has been available on these inverse crown precursors. Here we report the first isolated and crystallographically characterised such tris-diisopropylamides in the solvent-free, mixed potassium-magnesium polymer [{KMg(DA)$_3$}$_\infty$] **1**, its diamine-solvated analogue [KMg(DA)$_3$·TMEDA] **2**, and for comparison the mixed sodium-magnesium solvate [NaMg(DA)$_3$·TMEDA] **3** [where TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine,

[a] Department of Pure and Applied Chemistry, University of Strathclyde,
Glasgow, G1 1XL, U.K.

$Me_2N(CH_2)_2NMe_2$]. A survey of the literature also reveals that the significance of **1** goes beyond its relevance to inverse crown chemistry as, to the best of our knowledge, it represents the first pure *s*-block heterobimetallic diisopropylamide, pure in the sense that it is free of stabilising anionic co-ligands or neutral solvent ligands. Such a pure form is also unknown in homometallic systems if one discounts the crystal structure of LDA itself, as this was determined from a sample which contained small, non-stoichiometric quantities of TMEDA and the parent amine DAH.

Results and Discussion

The new compounds **1**−**3** were prepared by the same mixed-metallation strategy [Equation (1)]: metal alkyl reagents are stirred together in a hydrocarbon medium, before the introduction of the required quantity of DAH to convert all of the alkyl substituents to gaseous alkane (or to an arene in the case of the benzyl substituents), leaving the desired heterobimetallic amide mixture in solution. The preparation of **1** from *n*-butylpotassium is not straightforward. While crystals of **1** can be grown reproducibly in low yields, they are invariably accompanied by variable amounts of an oily residue and a black waxy solid, the characterisation of which was not pursued. This decomposition is almost certainly triggered by β-hydride elimination from *n*-butylpotassium in the main (prior to the alkane generation stage) and possibly from DA ligands — it has been reported previously that homometallic $Mg(DA)_2$ suffers a thermally induced hydride elimination from one of its β-C atoms, in a process which can be subsequently exploited to reduce aldehydes or ketones to alcohols.[9] Heating the reaction solution of **1** above ambient temperature proves particularly detrimental, leading to more black waxy solid residue. Switching to benzylpotassium seems to produce a cleaner reaction, though the yield of **1**, whilst better, does not improve vastly. When toluene is added as a co-solvent the reaction solution can even tolerate reflux conditions using this resonance-stabilised reagent, however, under such conditions the reaction follows a different course, generating hydride ions, which ultimately end up in the new inverse crown species $[K_2Mg_2(DA)_4(H)_2\cdot(toluene)_2]$, as discussed in the following paper in this issue.[10] To complete the formation of both **2** and **3**, TMEDA is added in an additional step. While in comparison to that for **1** it is a more routine task to crystallise these TMEDA complexes (by cooling the resulting solutions to −28 °C) it is not easy to collect all of the crystalline product/s by vacuum filtration. This is because the crystals of both **2** and **3** readily dissolve in hexane/heptane solution at ambient temperature, hence the isolation procedure is best carried out at subambient temperature (even then, a large proportion of the crystalline material is visibly lost). Such exceptionally good solubility in hydrocarbon media pointed to a synergic effect with both metal atoms intimately involved in the crystalline structures (as confirmed later by the X-ray crystallographic studies, vide infra), as on their own NaDA/KDA exhibit little or no solubility in hexane/heptane and their solvated offspring $[(NaDA\cdot TMEDA)_2]$[11] and $[(KDA\cdot TMEDA)_2]$[12] only limited solubility. The solubilising effect of mixing alkali metal and magnesium compounds in certain systems has also been noted in alkoxide chemistry.[13] As expected, the synergic influence has no bearing on the air instability of **1**−**3** as all are highly sensitive to moisture and oxygen.

$$RM + Bu_2Mg + 3iPr_2NH \rightarrow \text{“}MMg(NPr^i_2)_3\text{”} + 2BuH + RH \quad (1)$$

Solvent-free **1** dissolves in arene solvents allowing a ^1H NMR spectrum to be recorded in [D_6]benzene solution. At room temperature a single type of amide *i*Pr group [$(CH_3)_2CH$ septet at δ = 3.38 ppm; $(CH_3)_2CH$ doublet at δ = 1.27 ppm] is revealed. This is consistent with either chemically distinct amide ligands undergoing a fast exchange process or chemically equivalent ligands. With respect to the crystal structure, the former scenario could involve the exchanging of bridging and terminal groups within a “$K(\mu\text{-}DA)_2MgDA$” molecule, while the latter scenario could be envisioned as a discrete $[Mg(DA)_3]^-$ “ate” with the K^+ counterion sequestered by π-binding arene solvent ligands (alkali metal π-arene interactions, which have been observed in several inverse crown complexes, are believed to be of fundamental structural importance to a wide range of materials).[14,15] In both these scenarios the agostic $K\cdots C(H)(CH_3)_2$/$K\cdots C(H_3)C(H)(CH_3)$ intermolecular interactions extending the molecular structure in the solid state would be absent in solution. The corresponding spectrum of **3** also reveals a single type of amido *i*Pr group, but the chemical shifts of the $CH(CH_3)_2$ septet (δ = 3.50 ppm) and the $CH(CH_3)_2$ doublet (δ = 1.38 ppm) show a modest yet significant move to higher frequency compared to those in **1** (by 0.12 and 0.11 ppm respectively) suggesting that a $[Mg(DA)_3]^-$ “ate” anion is not common to both species. These chemical shifts in **3** also differ from those in homometallic $[(NaDA\cdot TMEDA)_2]$[11] (corresponding values δ = 3.66 and 1.26 ppm) where the DA ligand bridging is exclusively to Na^+ centres. In $[(NaDA\cdot TMEDA)_2]$ it was reasoned that TMEDA is not bound to the Na^+ centres in [D_6]benzene solution at room temperature on account of the relative positioning of the TMEDA resonances [CH_2CH_2N at δ = 2.13 ppm; $(CH_3)_2N$ at δ = 2.08 ppm]; when TMEDA is ligated to the metal the situation is reversed. Significantly, the latter case, and at notably lower chemical shift values [$(CH_3)_2N$ at δ = 1.81 ppm; CH_2CH_2N at δ = 1.72 ppm], is observed for **3**, indicative of metal-bound TMEDA ligands. This evidence points to the molecular structure within the crystal (vide infra) being retained in solution. Strong support for this viewpoint was gained from a variable temperature study in [D_8]toluene solution. At room temperature two broad resonances are observed for the $(CH_3)_2CH$ and $(CH_3)_2CH$ hydrogen atoms at δ = 3.43 and 1.31 ppm, respectively. However, on cooling the solution to −30 °C, the former resonance separates into two distinct ones at δ = 3.77 and 3.38 ppm in a 1:2 inte-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gration ratio. These resonances can be confidently assigned to terminal and bridging DA groups, respectively, and thus it can be concluded that these groups undergo a rapid dynamic equilibration at room temperature in the manner of that seen in classic dimeric structures such as $[(A1Me_3)_2]$.[16] The ^1H (and ^{13}C) NMR spectra of the potassium analogue **2** show enough similarity to those of **3** to suggest that it too retains its crystalline molecular structure in arene solution. Thus in deutero-toluene solution the $(CH_3)_2CH$ and $(CH_3)_2CH$ resonances of **2** shift by only 0.03 and 0.02 ppm respectively (to lower frequency) than those in **3** and the corresponding ^{13}C resonances differ by only 0.6 and 0.2 ppm (shifted to higher and lower frequency respectively) than those in **3**. A slight anomaly seemingly exists when considering the ^1H resonances associated with TMEDA: the order of the CH_2 and Me_2N resonances (at $\delta = 1.91$ and 1.89 ppm respectively) is reversed compared to that for **3** (corresponding values $\delta = 1.76$ and 1.84 ppm). However, the limited chemical shift range of all the signals involved (covering a mere 0.15 ppm), and, more importantly, the substantial margin between these and those of free TMEDA (i.e., CH_2, $\delta = 2.32$ ppm; Me_2N $\delta = 2.11$ ppm) would appear to refute any notion that the TMEDA is not attached to the K^+ centre in **2**.

Figure 1 shows the asymmetric unit of the crystal structure of **1**, while Figure 2 captures a view of a section of the infinite, one-dimensional arrangement. Its primary feature is the familiar tris-amido motif, here consisting of a [K(μ-$N)_2$Mg] ring (strictly planar) with an additional amide N "terminus" on the Mg centre. Connected by the N terminus on one interacting with the K centre of the other, two such tris-amido motifs make up the asymmetric units, which interconnect through similar K−N linkages to generate an infinite spiral chain. All the intermolecular tris-amido connection points are reinforced by agostic K···C interactions. Table 1 records the principal bond lengths and bond angles for **1**. A noteworthy observation is the lack of distinction in the Mg−N bond lengths. The notional terminal ones (Mg1−N3; Mg2−N6) display a mean length (2.046 Å) longer, not shorter, than that of the bridging type (2.037 Å), but by a mere 0.009 Å. This reflects the fact that the former DA ligands are not actually terminal but bridging (through intermolecular contacts between tris-amido units). A similar lack of distinction is found for the K−N bond lengths (mean: intramolecular bridges, 2.9351 Å; intermolecular bridges, 2.9297 Å). Thus with the intramolecular and intermolecular bridging having approximately equal weighting, the bonding can therefore be best described as genuinely supramolecular (polymeric) in nature, as opposed to that of a single tris-amido molecule with weak extended forces. An army of short, agostic K···C contacts involving both methyne and methyl groups helps to strengthen the K-(μ-$N)_2$-Mg-N framework. Disorder in two of the *i*Pr branches (those labelled C16/17/18 and C34/35/36) precludes discussion of bond lengths involving them, though they almost certainly make as important a contribution as those now mentioned. For both K atoms, the shortest of these contacts involve intramolecularly bound methyne groups [K1···C8, 3.126(2) Å; K2···C23, 3.135(3) Å]. The closest such intermolecular contacts are again to methyne C atoms [K1···C32, 3.420(2) Å; K2···C14, 3.288(2) Å]. Other K···C contacts range from 3.138(2)−3.516(3) Å for K1 and 3.167(2)−3.506(3) Å for K2. Though hydrogen atoms were not independently refined in this study, it can be assumed from the short K···C contact distances that the K atoms also lie in close proximity to CH_3 and/or CH hydrogen atoms. This may have some bearing on the propensity of **1** to undergo β-hydride elimination.[10] Turning to bond angles, the Mg atoms display distorted trigonal planar geometries. To make the bridge within the [K(μ-$N)_2$Mg] ring, the endocyclic N−Mg−N bond angle must compress (mean value, 112.78°). A concomitant widening occurs at the exocyclic N−Mg−N positions (mean value, 123.58°), but not symmetrically as one bond angle (mean, 125.72°) is significantly more obtuse than the other (mean, 121.43°). The coordination geometry of the K centres is less well-defined in keeping with its softer, Lewis acidic character (compared to that of Mg). With respect to N atoms, the K atoms are trigonal pyramidal (sum of bond angles: 352.64° for K1; 356.08° for K2) with two obtuse (mean, 141.87°) and one acute (mean, 70.61° belonging to the [K(μ-$N)_2$Mg] ring) N−K−N bond angles, but including the close K···C contacts the coordination number of the alkali metal could be considered as high as twelve.

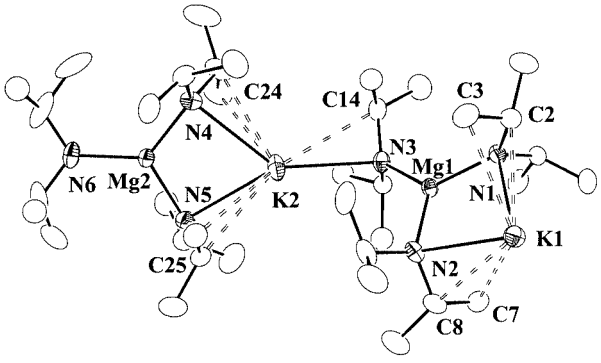

Figure 1. Asymmetric unit of the molecular structure of **1** with agostic contacts shown as broken lines; hydrogen atoms are omitted for clarity

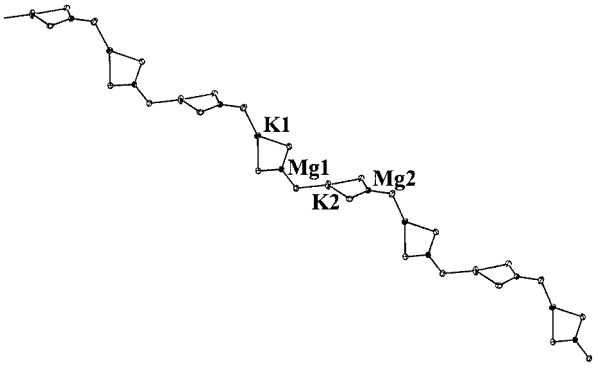

Figure 2. A section of the extended structure of **1**

The tris-amido motif also dominates the structure of **2** though now it is contained within a discrete molecular arrangement (Figure 3). This modification is due to the introduction of the didentate, chelating TMEDA ligand. By completing a distorted tetrahedral coordination sphere around K^+, the TMEDA ligation kills the need for any intermolecular K−N interactions. Table 2 records the principal bond lengths and bond angles for **2**. The distorted trigonal planar Mg coordination sphere is marked by long Mg-(μ-N) (mean length, 2.0418 Å) and short terminal Mg−N bonds [length, 1.9722(13) Å], in line with coordination number differences (i.e., 3 for N1; 4 for N2/N3). Only the latter bond shows a significant shortening compared to those in **1**, reflecting its genuine terminal nature. Adding to the asymmetry of the essentially planar $[K(\mu\text{-}N)_2Mg]$ trapezoidal ring, there is one long and one short K-(μ-N) bond (difference in length, 0.054 Å). These bonds clearly represent the weak points of the tris-amido motif given that their Mg-(μ-N) counterparts are on average 0.848 Å shorter. A comparison with the series of potassium hexamethyldisilazide $[(Me_3Si)_2N^-$; HMDS] complexes $[\{K(ar)_2\}^+\{Mg(HMDS)_3\}^-]$[17] (ar = benzene, toluene or *para*-xylene) shows that it is possible to completely cleave the large alkali metal from its tris-amido magnesiate partner (severing all K−N linkages, but retaining agostic K···C connections) by introducing π-binding arene ligands. It is significant that the K atoms in **2** ignored the toluene solvent molecules generated in the reaction by protonation of benzylpotassium. This is because TMEDA fulfils the donor responsibility in **2**, and effectively at that going on the lengths of the dative K−N bonds (mean, 2.8759 Å) which, unusually, are of the same magnitude (mean, 2.8899 Å) as their anion-containing K-(μ-N) comrades. In the aforementioned homometallic relative $[(KDA{\cdot}TMEDA)_2]$,[12] the K−N "anionic" bonds are significantly shorter than their dative counterparts (mean values, 2.771 and 2.886 Å respectively). Worthy of comment is the marked variation between the length of the shortest K−N (from DA) bond in this homodimer [2.706(2) Å] and that of the corresponding shortest bond in heterodimeric **2** [K−N2, 2.8630(13) Å]: this emphasises the profound proximal effect that the introduction of a Mg atom can exert on the dimensions of an identical K coordinative environment (here involving four N atoms, two from DA and two from TMEDA). The presence of TMEDA in **2** also lessens the need for reinforcement K···C agostic bonding. This is manifested in fewer K···C contacts and much longer contact distances than those previously discussed for **1**. There are only three such contacts below 4 Å in length: the shortest is to the methyl C17 at 3.277 Å, the next shortest is to the methyne C10 at 3.303 Å, and the remaining contact is to the methyl C11 at 3.475 Å. There are no intermolecular K···C contacts present, in keeping with the monomeric (dinuclear) constitution of the structure.

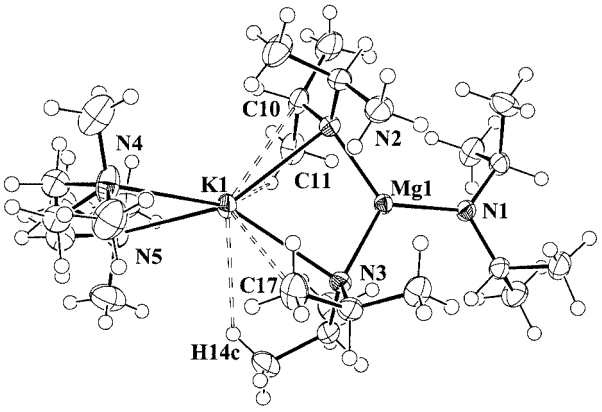

Figure 3. Molecular structure of **2** with agostic contacts shown as broken lines

Table 2. Selected bond lengths (Å) and bond angles (°) for $[KMg(NiPr_2)_3(TMEDA)]$ (**2**)

Bond lengths (Å)		Bond angles (°)	
Mg(1)−N(1)	1.9722(13)	N(4)−K(1)−N(2)	131.82(4)
Mg(1)−N(2)	2.0381(13)	N(2)−K(1)−N(5)	132.33(4)
Mg(1)−N(3)	2.0454(13)	N(4)−K(1)−N(3)	139.84(4)
K(1)−N(2)	2.8630(13)	N(2)−K(1)−N(3)	72.60(3)

K(1)···C(11)	3.475(2)	Mg(1)−N(2)−K(1)	86.96(4)
K(1)···C(17)	3.303(2)	Mg(1)−N(3)−K(1)	131.82(4)

Since the metal-N core of the molecular structure of the sodium congener **3** (Figure 4) is essentially isostructural to that of **2**, it merits only a brief discussion. Table 3 records the principal bond lengths and bond angles for **3**. There is a marginally greater deviation in the bridging and terminal Mg−N (from DA) bond lengths [2.0613 Å (mean) and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1.9679(13) Å, respectively] than that in **2**. Comparison with the dimensions of the homodimeric structure of $[(NaDA{\cdot}TMEDA)_2]$,[11] where the mean Na−N (from DA) bond length is 2.447 Å, reveals again the strong bonding power of the proximate Mg atom in **3** as it draws the amido N bridges away from the Na atom to elongate the Na−N bonds (mean length, 2.5313 Å). To compensate the Na atom in **3** for this loss in valency, there is a concomitant strengthening of the dative bonding to TMEDA as reflected by short Na−N bonds (mean length, 2.5504 Å; *cf.* 2.6195 Å in the homodimer). Within the Na-$(\mu\text{-}N)_2$-Mg trapezoidal ring, the obtuse bond angle is at Mg [110.44(5)°] and the acute one is at the larger Na centre [83.94(4)°], with a mean angle at N of 82.72°. Switching to the yet larger K centre in **2**, as expected, exacerbates this trapezoidal distortion to give corresponding values of 113.87(6)°, 72.60(3)°, and 86.17° respectively. Finally it should be noted that there are no Na···C agostic interactions in **3**, with the shortest such contact being 3.239 Å.

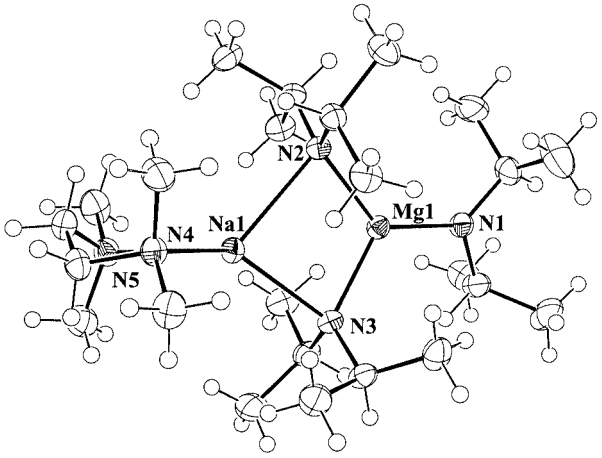

Figure 4. Molecular structure of **3**

Table 3. Selected bond lengths (Å) and bond angles (°) for $[NaMg(N\textit{i}Pr_2)_3(TMEDA)]$ (**3**)

		Mg(1)−N(2)−Na(1)	83.49(4)

Structural differences in the solid state, if maintained in solution, can influence the reaction chemistry of the DA anion given the close correlation that exists between structure and reactivity. A brief survey of a selection of previously determined *s*-block metal-based DA structures (see Figure 5) is therefore warranted to enable the novelty of the structures of **1**−**3** to be put into perspective. Pure crystalline LDA exists as a helical polymer (**A**) with near linear NLiN segments, eight of which constitute a turn of the helix.[18] More relevant to the solution phase, the solvated derivative $[(LDA{\cdot}THF)_2]$ (**B**) exhibits a planar $(LiN)_2$ dimeric ring, the Li corners of which carry monodentate THF ligands.[19] A similar discrete four-membered ring structure (**B**) is observed in both the aforementioned $[(NaDA{\cdot}TMEDA)_2]$[11] and $[(KDA{\cdot}TMEDA)_2]$,[12] though the wider exocyclic coordination arcs offered by the larger alkali metals allows for the chelation of didentate TMEDA ligands. Combining LDA with the same diamine molecule in $[\{(LDA{\cdot}TMEDA)_2\}_\infty]$[20] again generates a $(LiN)_2$ dimeric ring, but the reduced space about the Li centres forces the TMEDA ligands into bridging (non-chelating) roles to create an infinite chain of linked dimers (**C**). It may be significant from a reactivity standpoint that the exclusively bridging mode of the DA ligands in all of the last four structures discussed contrasts with the combination of bridging and terminal modes encountered in both **2** and **3** (and possibly in **1** depending on its fragmentation process in solution). The opportunity for **1**−**3** to dissociate in the form of a complex "ate" anion $[Mg(DA)_3]^-$, which is unavailable to the homometallic compositions, may also cause them to react differently towards protic substrates. To the best of our knowledge, this tris-DA coordination about Mg is unique to the structures of **1**−**3** though it is known with other metals both discretely, for example with A1 in neutral monomeric $[A1(DA)_3]$ (**D**),[21] or linked into the common dimeric motif as with Mn in $[\{Mn(DA)_2\}_2]$ (**E**).[22] On the other hand bis-DA coordination of Mg is well-known when auxiliary ligands are present to fill the remaining sites: it is only rarely observed in homomagnesium structures such as the mixed alkynyl/DA dimer $[\{Mg(DA)(C{\equiv}CPh){\cdot}THF\}_2]$ (**E**),[23] where the linearity of the alkynyl ligand allows for a tetrahedral Mg coordination, but is much more common in heterometallic examples, and these can exhibit three (trigonal planar), or more usually, four (tetrahedral) Mg coordination depending on the steric characteristics of the ligand sets, as illustrated by the alkide $[Me_2A1(DA)_2MgMe]$ (**G**)[24] and the amidinate $[Me_2A1(DA)_2Mg\{\textit{t}BuNC(Me)N\textit{t}Bu\}]$ (**H**)[25] respectively. While mixed aluminium-magnesium complexes of this type are commonplace, in general, the range of heterometallic magnesium-containing DA-based crystal structures is rather limited. Extending the search to other related amide ligands reveals a far higher number of hits of "ate" complexes with the general formula $[Mg(amide)_3]^-$. HMDS complexes of this type are particularly commonplace as exemplified by the aforementioned π-arene series $[\{K(ar)_2\}^+\ \{Mg(HMDS)_3\}^-]$.[17] The recent report of the trimetallic lithium-potassium-(bis)magnesium N-metallated/N,C-dimetallated amide $[Li_2K_2Mg_4\{\textit{t}Bu(Me_3Si)N\}_4\{\textit{t}Bu[Me_2(H_2C)Si]N\}_4]$,[26] an inverse crown molecule with an atomless cavity, suggests there is every possibility that the rich structural variety found within the s-block chemistry of the DA ligand is far from exhausted.

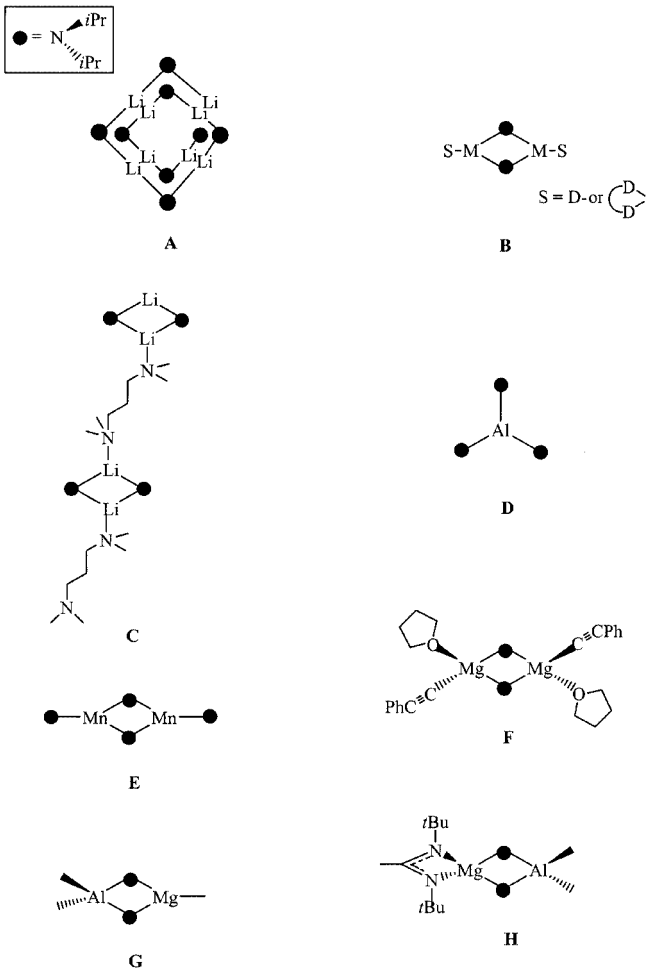

Figure 5. Selected structures in the *s*-block chemistry of the DA ligand and related structures

Experimental Section

General: All reactions were performed under a protective argon atmosphere using standard Schlenk techniques. Hexane was dried by heating to reflux over sodium benzophenone ketyl and distilled under nitrogen prior to use. Diisopropylamine was dried by heating to reflux over calcium hydride and stored over 4 Å molecular sieves. *n*,*s*-Dibutylmagnesium was purchased from Aldrich Chemicals as a 1 M solution in heptane and standardised immediately prior to use using salicylaldehyde phenylhydrazone.[27] Benzylpotassium,[28] butylpotassium[29] and butylsodium[30] were prepared according to the literature methods. Melting points were determined in sealed argon-filled capillary tubes and are uncorrected. NMR experiments were carried out on a Bruker DPX 400 MHz spectrometer, operating at 400.13 MHz for ^{1}H and 100.62 MHz for ^{13}C.

[{KMg(DA)$_3$}$_\infty$] (1): (From butylpotassium) A 1:1:3 stoichiometric mixture of *n*BuK (0.4 g, 5 mmol)/*n*,*s*-Bu_2Mg (5 mL of a 1 M solution in heptane, 5 mmol)/*i*Pr_2NH (2.1 mL, 15 mmol) in hexane (15 mL) was stirred at ambient temperature overnight. This resulted in the formation of a brown oily solution with a trace amount of a black waxy solid. The solid was removed by filtering the mixture through Celite. The filtrate was reduced in volume in vacuo, then placed in the freezer at −28 °C. Overnight this solution deposited a crop of colourless crystals of **1** (yield 0.49 g, 27%). M.p. 96−98 °C (decomposes to brown oil). Satisfactory microanalyses could not be obtained due to samples losing weight rapidly on the balance.^{1}H NMR ([D$_6$]benzene solution; 25 °C): δ = 3.38 (sep., 1 H, Me_2CH), 1.27 (d, 6 H, Me_2CH).
(From benzylpotassium) Benzylpotassium (0.65 g, 5 mmol) was suspended in hexane (20 mL). *n*,*s*-Bu_2Mg (5 mL of a 1 M solution in heptane, 5 mmol) and *i*Pr_2NH (2.1 mL, 15 mmol) were then added. The reaction mixture was stirred for 12 hours at ambient temperature. The resulting cloudy red mixture was filtered through Celite and the filtrate was concentrated by removing some solvent in vacuo. Freezer cooling of the solution at −28 °C afforded a crop of colourless crystals of **1** (yield 0.62 g, 34%). Characterisation as above but in addition: ^{1}H NMR ([D$_8$]toluene solution; 25 °C): δ = 3.30 (sep., 1 H, Me_2CH), 1.21 (d, 6 H, Me_2CH) ppm. ^{13}C NMR ([D$_8$]toluene solution; 25 °C): δ = 49.7 (Me_2CH), 27.92 (Me_2CH) ppm.

[KMg(DA)$_3$·TMEDA] (2): Benzylpotassium (0.65 g, 5 mmol) was suspended in hexane (20 mL). *n*,*s*-Bu_2Mg (5 mL of a 1 M solution in heptane, 5 mmol) and *i*Pr_2NH (2.1 mL, 15 mmol) were then introduced. The resulting red solution was stirred for 30 minutes after which time TMEDA (0.75 mL, 5 mmol) was added. After stirring for a further 60 minutes, the solution was concentrated by removing some solvent in vacuo. Freezer cooling of the remaining solution at −28 °C produced a crop of colourless crystals of **2**. These were partially covered by a red oil which hindered the isolation of the pure crystalline material and precluded a meaningful determination of its yield. Satisfactory microanalyses could not be obtained due to contamination by the red oily coating. ^{1}H NMR ([D$_8$]toluene solution; 25 °C): δ = 3.40 [m (broad), 6 H, Me_2CH], 1.91 (s, 4 H, CH_2, TMEDA), 1.89 (s, 12 H, CH_3, TMEDA), 1.29 [d (broad), 36 H, Me_2CH] ppm. ^{13}C NMR ([D$_8$]toluene solution; 25 °C): δ = 57.2 (CH_2, TMEDA), 49.8 (Me_2CH), 45.4 (CH_3, TMEDA), 27.9 (Me_2CH) ppm.

[NaMg(DA)$_3$·TMEDA] (3): *n*BuNa (0.4 g, 5 mmol) was suspended in hexane (10 mL) and placed in an ultrasonic bath for 10 minutes. *n*,*s*-Bu_2Mg (5 mL of a 1 M solution in heptane, 5 mmol) was introduced slowly to give a brown gum, which dissolved upon the addition of *i*Pr_2NH (2.1 mL, 15 mmol). The resulting pale yellow solution was stirred for 20 minutes at which time TMEDA (0.75 mL, 5 mmol) was added. Turning cloudier, the solution was stirred for a further 20 minutes, filtered through Celite, reduced in volume in vacuo, and left to cool in the freezer at −28 °C. After several days a crop of colourless crystals of **3** was obtained (isolated yield 0.51 g, 22% − the bulk of the crystalline product redissolved during the isolation procedure). M.p. 103−105 °C. Satisfactory microanalyses (C,H,N) were obtained. ^{1}H NMR ([D$_6$]benzene solution; 25 °C): δ = 3.50 (sep., 6 H, Me_2CH), 1.81 (s, 12 H, CH_3, TMEDA), 1.72 (s, 4 H, CH_2, TMEDA), 1.38 (d, 36 H, Me_2CH) ppm. ^{1}H NMR ([D$_8$]toluene solution; 25 °C): δ = 3.43 [m (broad), 6 H, Me_2CH], 1.84 (s, 12 H, CH_3,TMEDA), 1.76 (s, 4 H, CH_2, TMEDA), 1.31 [d (broad), 36 H, Me_2CH] ppm. ^{1}H NMR ([D$_8$]toluene solution; −30 °C): δ = 3.77 [s (broad), 2 H, Me_2CH], 3.38 [s (broad), 4 H, Me_2CH, μ-DA] 1.75 [s, 12 H, CH_3, TMEDA], 1.60 [d, 4 H, CH_2, TMEDA], 1.27[s (broad), 36 H, Me_2CH] ppm. ^{13}C NMR ([D$_8$]toluene solution; 25 °C): δ = 57.4 (CH_2, TMEDA), 49.2 (Me_2CH), 46.2 (CH_3, TMEDA), 28.1 (Me_2CH) ppm.

X-ray Structure Determinations: Measurements were made on a Nonius Kappa CCD diffractometer at 123 K with Mo-K_α radiation (λ = 0.71073 Å). Structures were refined on F^2 using all reflections with the Shelxl-97 program. All non-H atoms were treated anisotropically except for the disordered components in **1** and **2**. H atoms were not refined except for those involved in agostic interac-

Keywords: Potassium / Magnesium / N ligands / Hydride ligands / Density functional calculations

Reaction of benzylpotassium, *n*,*s*-dibutylmagnesium and diisopropylamine in boiling toluene produces a rare example of a molecular magnesium hydride with a Mg-$(\mu\text{-}H)_2$-Mg double bridge, in $[K_2Mg_2(NiPr_2)_4(\mu\text{-}H)_2\cdot(toluene)_2]$ (**1**). In an effort to rationalise the formation of **1**, a series of DFT calculations were performed. This report of **1** establishes the first isostructural pair of Na and K complexes solvated by toluene to be reported in the Cambridge Crystallographic Database. In comparison with its previously reported Na analogue, **2**, the metal-arene centroid distances are considerably *shorter* (by 0.159 Å) in the new complex reported here. It was found that a hydrocarbon solution of **1** is capable of reducing benzophenone to benzhydrol in moderate yields (74%).

Introduction

Main group metal hydrides, in particular those containing aluminium are widely utilised by the synthetic chemist as highly efficient reducing agents.[1] Commercially available reagents such as lithium aluminium hydride, lithium tri-*tert*-butoxyaluminohydride and Red-Al® [sodium bis(2-methoxyethyoxy)aluminium hydride] can effect the reduction of many polarised organic functional groups easily and efficiently. The structural chemistry of molecules containing an Al−H−Al linkage is also well developed.[2] However, unlike their aluminium counterparts, magnesium hydrides have thus far not been the subject of intensive research. To the best of our knowledge, only one genuine molecular magnesium hydride, which contains a Mg−H−Mg bridge, has been prepared and crystallographically characterised[3] (see below). Synthetically, it has been shown that magnesium hydride-containing species (such as RMgH, ROMgH or R_2NMgH; where R = Me, Et, *i*Pr or C_5H_5 for the alkylmagnesium hydrides and R = Me, *i*Pr, *t*Bu, *t*$BuCH_2$, $PhCH_2CH_2$, Ph, Ph_3C, 2,6-$Me_2C_6H_3$, 2,6-$iPr_2C_6H_3$ or 2,6-tBu_2-4-MeC_6H_2 for the alkoxy or aryloxymagnesium hydrides and R = Et, *i*Pr, *n*Bu or Ph for the dialkyl or diarylaminomagnesium hydrides) are useful in effecting reductive transformations.[4] Unsolvated magnesium bis(diisopropylamide)[5] is also capable of converting aldehydes/ketones to alcohols and converting nitro compounds to amines via hydride transfer from the carbon positioned beta to the magnesium centre.

Herein we report the synthesis and structural analysis of $[K_2Mg_2(NiPr_2)_4(\mu\text{-}H)_2\cdot(toluene)_2]$ (**1**). Complex **1** represents the first structurally characterised potassium-containing heterobimetallic diisopropylamide and only the second molecular magnesium hydrido species which contains an Mg−H−Mg bridge, the first being the Na analogue of **1**, $[Na_2Mg_2(NiPr_2)_4(\mu\text{-}H)_2\cdot(toluene)_2]$ (**2**). This complex was reported in a recent communication.[3] Here we provide further details of the structure of **2**. Complex **1** is only the second example of a crystallographically characterised potassium diisopropylamide, the first example being the simple dimeric, TMEDA solvate $[(KNiPr_2\cdot TMEDA)_2]$ (**3**).[6] Recent work in our laboratory has focused on the synergistic chemistry of combining an alkali metal amide with its magnesium (or zinc) bis(amide) analogue. The major consequence of these studies thus far has been the development of a series of heterobimetallic macrocyclic amide complexes that have become known collectively as "inverse crowns."[7] A subset of the inverse crowns (IC) are the inverse crown ethers (ICE). This non-precise nomenclature was chosen because the ICE complexes show an inverse topological relationship to conventional crown ether complexes — the Lewis acidic metal sites and Lewis basic oxygen centres are mutually interchanged. IC complexes are distinguished

[a] Department of Pure and Applied Chemistry, University of Strathclyde,
Glasgow, G1 1XL, UK

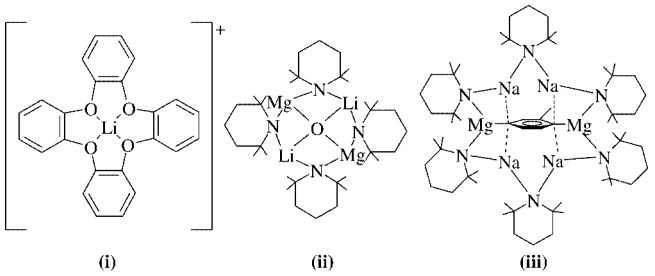

Figure 1. Examples of a conventional crown ether complex (i), an inverse crown ether (ii)[8] and an "oxygen-free" inverse crown complex (iii)[9]

from ICE complexes by the fact that the former do not contain any oxygen-containing anions (Figure 1).

As well as forming complexes with aesthetically pleasing crystal structures, a special chemistry that is otherwise irreproducible has been uncovered using these synergistic metal amide bases. Employing "$NaMg(NiPr_2)_3$", the tris(amido) species prepared from the in situ reaction of BuNa, Bu_2Mg and $HNiPr_2$ in a 1:1:3 molar ratio, the unprecedented 1,1′,3,3′-tetrametallation of ferrocene was accomplished.[10] Returning to **1**, this molecule is the most recent addition to the inverse crown family. Although essentially isostructural with its sodium analogue, in the potassium variant, the alkali metal exhibits stronger coordination to the arene molecule, indicated by the fact that the mean arene-M (where M = Na or K) length is *shorter* for the K analogue. Alkali metal-π interactions have recently been the subject of considerable research.[11] The importance of these interactions has been realised in zeolite-supported processes,[12] in the interaction of alkali metal cations with aromatic side chains of proteins,[13] and in the selectivity of superbases,[14] via the coordination of an arene molecule to a group 1 metal centre.

Results and Discussion

Preparation and Spectra

Complex **1** was prepared by heating a 1:1:3 mixture of benzylpotassium, *n*,*s*-dibutylmagnesium and diisopropylamine, in a toluene/heptane medium. This synthesis marks a significant departure from that of most of the other members of the inverse crown family prepared to date[15] — a M*n*Bu (where M = Li, Na or K) reagent has not been utilised in the preparation. The synthesis of **1** was initially attempted using *n*-butylpotassium; however, on the addition of amine to the heterobimetallic alkyl mixture, a significant quantity of an insoluble, black solid was obtained. The formation of this impurity can be attributed to the fact that *n*-butylpotassium is not thermally stable being readily susceptible to β-hydride elimination. Ironically, a similar decomposition pathway is vital to the formation of **1** (vide infra), but at this early stage in the synthetic procedure, it appears to be highly detrimental. On changing the potassiating reagent from butyl- to benzyl- (i.e. ruling out β-hydride elimination as a potential decomposition pathway) the reaction proceeded in a seemingly more controlled manner, resulting in the observation of a discernible colour change without the precipitation of an undesired solid by-product. Although less reactive than its butyl counterpart, the activity of benzylpotassium is adequate for our needs, and this easily prepared reagent will undoubtedly be utilised by our group in various reactions in the future. Interestingly, if the heterobimetallic amide mixture is not subjected to intense heating, complex **1** is not formed — instead the unsolvated tris(amido) species $KMg(NiPr_2)_3$ is produced. Details of the preparation and structural analysis of this complex and two other related compounds can be found in the preceding paper in this issue.[16]

The by-product of amine deprotonation by benzylpotassium is toluene and since the bulk of the reaction medium is composed of this solvent, the by-product does not have a disadvantageous effect on the reaction. Indeed, toluene is actually incorporated into the molecular structure of **1**. The shielding of the potassium and magnesium centres by the isopropyl groups and the former by toluene molecules results in the entire molecule being highly lipophilic.[17] As a consequence the complex is highly hydrocarbon soluble, explaining why the isolated yield of the crystals of **1** was relatively low.

Table 1 contains the ^1H NMR spectroscopic data for **1** along with those of **2** for comparison. The chemical shifts for the potassium analogue **1** are systematically at a higher frequency than those for the sodium variant **2**, although the differences are rather small. The hydride shift in both complexes is similar indicating that changing the alkali metal has little effect on the Mg−H−Mg bridge. This supports our interpretation that there is essentially no K−H bonding in **1** (see below). Unfortunately, the relative chemical shifts of the complexed toluene molecules in **1** and **2** cannot be directly compared. For **1** the acquired spectrum in C_6D_6 clearly shows that the correct stoichiometric amount of toluene is present, consistent with that in the crystal structure; however, for **2** in the same solvent virtually no toluene can be observed, meaning that the vast majority of the toluene is lost on isolation. When **2** is dissolved in $C_6D_5CD_3$, two distinct methyl resonances are observed. These are attributed to uncomplexed toluene (δ = 2.09 ppm) and toluene which has been incorporated into the structure of **1** (δ = 2.11 ppm).

X-ray Crystallography

The molecular structure of **1** (Figure 2) is essentially isostructural with its sodium analogue **2**. Listed in Table 2 are the key structural dimensions of **1**, alongside those of **2** for comparison.

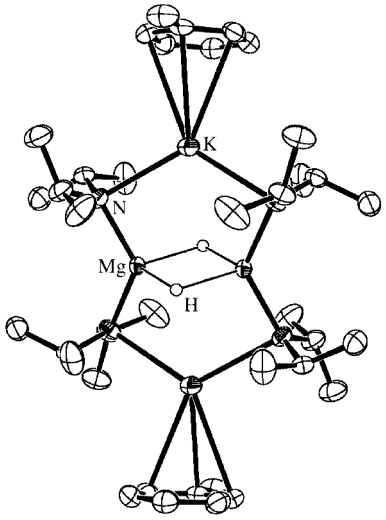

Figure 2. Molecular structure of **1**

Table 2. Key structural dimensions of **1** and **2**

Selected bonds and bond angles	Bond lengths (Å) and bond angles (°) M = K (**1**)	M = Na (**2**)
M1−N1	2.7754(16)	2.4807(18)
Mg1−N1	2.0595(15)	2.0651(18)
M···H	2.96(3)	2.68(3)
Mg1−H1	1.94(2)	1.89(2)
Mg···Mg	2.9437(14)	2.8921(19)
M-*ipso*-C	3.107(3)	3.157(4)
M-*ortho*-C	3.1840(19)	3.275(3)
M-*meta*-C	3.339(2)	3.531(3)
M-*para*-C	3.422(3)	3.663(4)
M-centroid	2.955	3.114
N−M−N	119.55(6)	132.08(10)
N−Mg−N	126.55(9)	133.16(11)
Mg−H−Mg	98.7(14)	100(2)

The eight-membered metal-amide ring of **1** is chair-shaped. As for **2**, the N−Mg−N···N−Mg−N "chair-seat" is strictly planar, whilst the "head-" and "foot-rest" positions (signified by N−K−N in **1**) are tilted at an angle of 154.70(11)° compared to 153.5(2)° in **2** (Figure 3). At this juncture it is important to mention that the bridging hydride ions were independently refined. The Mg−H bond length in **1** is the same within experimental error as that in **2**. These dimensions resemble those of the Mg−H bonds present in a selection of other heterobimetallic hydride complexes: $[\{(C_5Me_5)_2Ti(\mu\text{-}H)_2\}_2Mg]$,[18] (mean, 1.88 Å); $[\{(C_5HMe_4)_2Ti(\mu\text{-}H)_2Mg(THF)(\mu\text{-}Cl)\}_2]$,[19] (mean, 1.91 Å); and $[(\{Me_2Si(C_5Me_4)_2\}Zr\{\eta^2\text{-}C_2H_4\}H)_2Mg]$,[20] (mean, 1.82 Å). The magnesium atoms in **1** are forced into a highly distorted tetrahedral coordination environment [the angles around the magnesium centres range from 104.1(9) to 126.55(9)°; mean, 115.57°].

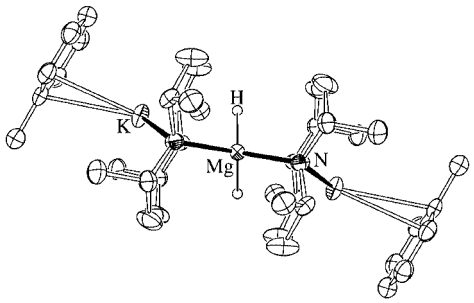

Figure 3. Alternative view of the molecular structure of **1** highlighting the planar "seat" and tilted "head-" and "foot-rest" arrangements

The closest K···H contact in **1** is 2.96(3) Å. This value can be compared with those in [K(*fac*-$RuH_3\{Cy_2P(CH_2)_4PCy_2\}\{CO\}$)$KBHsBu_3$],[17] [mean, 2.63 Å; range, 2.44(6)−2.82(5) Å], and in $[\{(C_5Me_5)Sm(\mu\text{-}H)_2\}_6\{(\mu\text{-}H)K(THF)_2\}_3]$,[21] [2.58(4) and 2.89(7) Å]. Unlike **1**, these complexes exhibit both short and long K···H contacts. The short contacts are significantly shorter than those found in **1**; however, the longer contacts, especially those in the latter complex, are similar to those in **1**. Therefore it appears that the K···H contacts in **1** appear to be too long to be considered significant.

The K−N bond length in **1** [2.7754(16) Å] is of the same order as those in the aforementioned TMEDA solvate **3** (mean, 2.7715 Å). The K centres in each form two bonds to diisopropylamido bridges, therefore it can be assumed that the TMEDA chelation and toluene π-interactions stabilise the respective molecules to a similar extent. To elaborate, the K coordination sphere in **1** is completed by an η^3 (*ipso* and two equivalent *ortho* C atoms) π-interaction to a toluene molecule [bond lengths: K−C_{ipso}, 3.107(3) Å; K−C_{ortho}, 3.1840(19) Å; all other K···C separations are 3.339(2) Å or longer]. There are no agostic bonds evident in the molecule, presumably as a consequence of the strong K-arene interactions which are present. Arguably the most interesting feature of the dimensions is that the K−C_{ipso} bond lengths are approximately 0.05 Å *shorter* than the corresponding Na−C_{ipso} bonds in **2**. Also, the K−C_{ortho} bonds are approximately 0.09 Å shorter than their Na counterparts in **2**, seemingly contrary to the fact that the ionic radius of K (1.52 Å) is larger than that of Na (1.16 Å).[22] These short metal-carbon contacts may help to explain some anomalies in the chemical analysis of **1** and **2**. Firstly, the elemental analysis results for **2** were found to be extremely variable — this was attributed to the rapid loss of toluene upon isolation of the inverse crown. In contrast, the elemental analysis results for **1** were reproducible and accurate, possibly as a reflection of the stronger complexation of the toluene to the larger alkali metal. Secondly, the ^1H NMR spectroscopic studies of **1** and **2** in C_6D_6 seem to confirm this assertion, namely that the spectra indicate

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that for the sodium analogue **2**, there is much less toluene present than expected in comparison from the stoichiometry in the crystal structure, whereas for **1**, the spectrum indicates that no toluene had been lost during the isolation procedure.

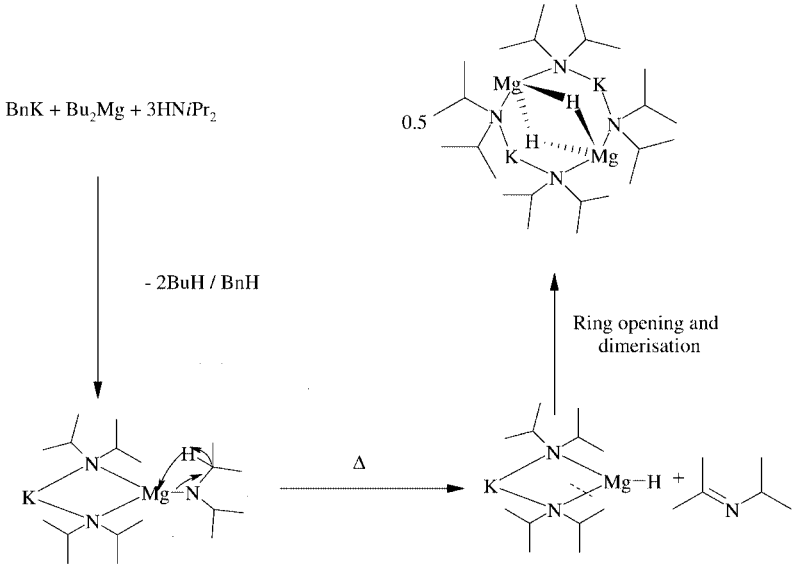
To determine whether or not this apparently surprising anomaly in the M-arene distances has been observed previously, a search of the Cambridge Crystallographic Database[23] was conducted. This search uncovered no examples of an isostructural pair of Na and K toluene solvated species that could be used as a direct comparison to **1** and **2**. However, it revealed five complexes[3,24] that contain a sodium atom solvated by a neutral toluene molecule — as opposed to a benzyl fragment — and there are fourteen examples[11c,24a,25] of complexes that contain a potassium atom solvated by a toluene molecule. Examples of such Na−toluene(centroid) distances found in the search are 2.664[24a] and 2.746 Å[24b] for the hexameric thiolate $[(NaSSiPh_3)_6 \cdot (toluene)_2]$ and the monomeric aluminate $[NaAl(SiMe_3)_4 \cdot (toluene)_2]$, respectively. These are 0.368−0.450 Å shorter than the Na−toluene(centroid) distances found for **2**. In the former complex two of the six sodium centres interact strongly with a molecule of toluene, whilst in the latter complex the Na cation is sandwiched between two arene molecules rendering it separate from its aluminate anion. The range of K−toluene(centroid) distances is 2.936[25d]−3.128[25f] Å. It is therefore evident that the K−toluene(centroid) distance in **1** is representative of those for the other complexes, whilst the Na−toluene(centroid) distance in **2** is much longer (and by implication weaker) than previously observed.

The N−K−N endocyclic bond angle in **1** [119.55(6)°] compares to that of 100.54(5)° in **3**, and the N−Na−N angles of 132.08(10)° in **2**. Therefore on changing from Na to K there is a significant narrowing of the N−M−N angle. The consequence of this narrowing, coupled with the longer K−N bonds, creates a greater N···N separation of 4.796 Å compared to 4.534 Å in **2**, resulting in the K atom being pushed out further from the core of the structure. Concomitantly, a wider separation of the diisopropylamido groups occurs to give a larger coordination arc, which allows for a closer approach of the toluene molecule compared to that in **2**. The N−Mg−N bond angles in **1** are also less obtuse than those in **2** [126.55(9)° vs. 133.169(11)°].

Returning to the point made earlier, the formation of **1** and **2** can be explained by a β-hydride elimination process (Scheme 1). Thus, on heating a solution of the heterobimetallic tris(amide) species to reflux, it is proposed that hydride elimination could take place from an amido group to yield a hydrido intermediate and a molar equivalent of imine [*i*Pr-N=C(Me)$_2$]. The resultant relaxation in steric crowding about the magnesium centre would then allow dimerisation to take place. To ascertain whether the process proposed is a realistic possibility, a series of ab initio MO calculations were performed. The findings of this theoretical study are discussed in the next subsection.

DFT Calculations

As described previously, complex **1** was prepared by reacting a 1:1:3 mixture of benzylpotassium and dibutylmagnesium with diisopropylamine, and then boiling in toluene. Although the reaction was carried out in situ, according to the proposed mechanism it can be thought of as proceeding in five stages. Stage I involves the formation of the monometallic amides, which is accompanied by butane and toluene generation. Stage II involves the formation of the single tris(amide) species from its two component monometallic amides. Stage III involves the β-hydride elimination from a diisopropylamide group and transfer of the hydride ion to the magnesium centre with concomitant elimination of imine. Stage IV involves ring opening and dimerisation to give the eight-membered inverse crown ring. The final stage,



Scheme 1. Proposed reaction pathway for the preparation of **1**; for clarity, the solvating toluene molecules in the final product have been omitted

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stage V, involves the completion of the K coordination sphere by the docking of a toluene solvent molecule.

Relevant starting molecules, intermediates and final products (Figure 4) were initially modelled[26] at the Hartree−Fock (HF) level, using the 6−31G(d)[27−31] basis set and subjected to a frequency analysis. Using the HF-optimised structures, the geometry of molecules were then refined at the DFT[32] level, using the B3LYP[33,34] method and the 6−311G(d, p)[35,36] basis set. The geometrical values reported here are taken exclusively from the DFT calculations while the energy values[37] are the DFT results modified by the scaled (0.91) zero point energy correction abstracted from the corresponding HF calculation. All the molecules have C_1 symmetry except for **11** (C_{2h}) and **1a** (C_i).

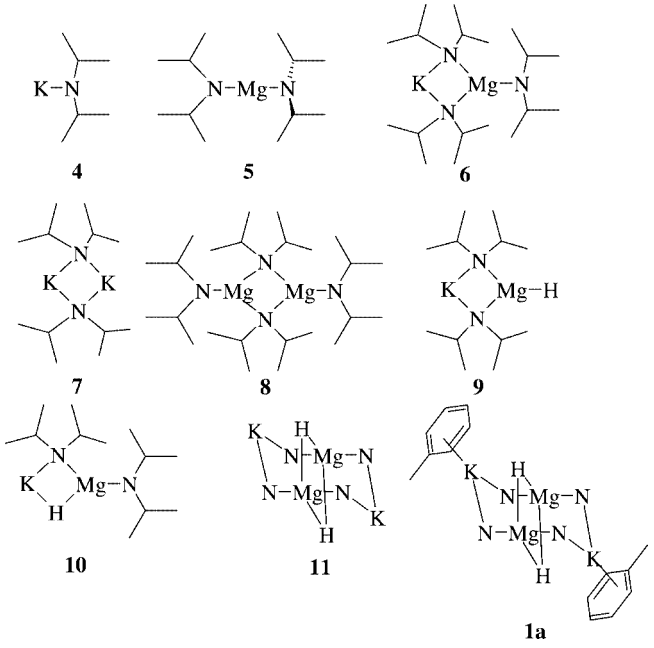


Figure 4. Schematic diagram of **1a** (modelled version of the experimental complex **1**) and other key complexes which were modelled by DFT calculations

In Stage I, KN*i*Pr$_2$ (**4**) and Mg(N*i*Pr$_2$)$_2$ (**5**) are assumed to be the initial products along with toluene and butane [Equations (1) and (2)]. To aid calculational simplicity, the metallo products were modelled as monomers. For the potassium amide **4** the K−N bond length was found to be 2.438 Å and the N centre was distorted trigonal planar with KNC angles of 123.0° and a CNC angle of 114°. For the magnesium amide **5** the Mg−N bond length is 1.935 Å, whilst the diisopropylamide ligands lie essentially perpendicular to each other. The N−Mg−N bond angle is near-perfect linear (179.6°). The combined calculated energy for the formation of the monometallic amides from the monomeric alkyl reagents was found to be −44.0 kcal mol^{-1}. The formation of **4** is a much less exothermic process than the formation of **5**. This can be partially attributed to the fact that for the formation of **4**, only one new metal-N bond is being formed whereas for **5**, two new metal-N bonds are formed. However, even if the energy of formation value for the latter process [Equation (2)] is halved, to account for the formation of only one new metal-N bond, the energy derived from the monoamination of Bu$_2$Mg (19.8 kcal mol^{-1}) is significantly higher than for the amination of BnK (4.4 kcal mol^{-1}). Intuitively, it would be expected that an alkylpotassium reagent would react more exothermally than an alkylmagnesium; however, in the case of the BnK model, the K centre is stabilised by coordination to the π-system of the benzyl fragment.

$$\mathrm{BnK} + \mathrm{HN}i\mathrm{Pr}_2 \rightarrow \mathbf{4} + \mathrm{BnH}\ (\Delta E_f = -4.4\ \mathrm{kcal\ mol^{-1}}) \quad (1)$$

$$\mathrm{Bu_2Mg} + 2\mathrm{HN}i\mathrm{Pr}_2 \rightarrow \mathbf{5} + 2\mathrm{BuH}\ (\Delta E_f = -39.6\ \mathrm{kcal\ mol^{-1}}) \quad (2)$$

In Stage II, the mixed metal tris(amido) species **6** is formed [Equation (3)]. Largely as a consequence of forming two new (one K−N and one Mg−N) bonds, **6** was calculated to be 26.5 kcal mol^{-1} more stable than its monometallic components. The optimised structure indicates asymmetric K−N bonds (2.690 and 2.737 Å) whilst the Mg−N$_{bridging}$ bonds are more uniform in length (2.097 and 2.100 Å). As expected from coordination number considerations, the Mg−N$_{terminal}$ bond length is shorter and calculated to be 2.000 Å. A general elongation of approximately 0.2 Å is observed in all of the M−N$_{bridging}$ bonds in comparison with the terminal ones in the respective monometallic species. Another possibility at this stage would be the formation of the monometallic dimers **7** and **8** [Equation (4) and (5) respectively]. The energies for the formation of **7** and **8** are −34.2 kcal mol^{-1} and −19.3 kcal mol^{-1} respectively. The energy of formation of **6** is intermediate between these two values, hence either outcome could be considered as a viable possibility.

$$\mathbf{4} + \mathbf{5} \rightarrow \mathbf{6}\ (\Delta E_f = -26.5\ \mathrm{kcal\ mol^{-1}}) \quad (3)$$

$$\mathbf{4} + \mathbf{4} \rightarrow \mathbf{7}\ (\Delta E_f = -34.2\ \mathrm{kcal\ mol^{-1}}) \quad (4)$$

$$\mathbf{5} + \mathbf{5} \rightarrow \mathbf{8}\ (\Delta E_f = -19.3\ \mathrm{kcal\ mol^{-1}}) \quad (5)$$

In Stage III, a hydride anion is transferred from a β-carbon of a diisopropylamide unit to the magnesium centre with the elimination of the imine *i*Pr-N=C(Me)$_2$, which, as previously noted, was detected in the experimental study. Two possible pathways for this elimination have been investigated, one where the hydride elimination occurs via a terminal amide group, giving **9** [Equation (6)], and one where the hydride elimination occurs via a bridging amide group, giving **10** [Equation (7)]. In an effort to determine which pathway hydride transfer favours, the optimised geometries of both intermediates were calculated. Since a C−H and a Mg−N bond are broken while a Mg−H and a C−N bond are formed, it would be expected that the reaction would be endothermic. This was indeed found to be the case [this

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

is in agreement with the experimental work, as **1** can only be prepared if the tris(amido) intermediate **6** is heated strongly] with the formation of **9** having a calculated energy of +13.1 kcal mol^{-1}, while the corresponding value for **10** is +13.8 kcal mol^{-1} (i.e. +0.7 kcal mol^{-1} higher in energy). Hence, hydride transfer is most likely to occur via the terminal amide. As a further comparison, it was observed that the β-hydride elimination reaction from the terminal amide of magnesium bis(diisopropylamide) (**5**) — a known experimentally observed process[5] [Equation (8)] — was found to be considerably higher in energy (+22.4 kcal mol^{-1}).[38] Therefore it appears that on synergistically combining the two metal amides, β-hydride elimination occurs more readily for either **9** or **10** than for when the diisopropylamide moiety resides on the Mg centre in the monometallic Mg(N*i*Pr$_2$)$_2$. Intermediate **9** has a greater degree of symmetry than **6**, due to the absence of the terminal, sterically demanding diisopropylamido group. Focusing on the planar, four-membered [Mg-(μ-N)$_2$-K] ring in **9**, the Mg−N bonds span 2.087 Å, whilst the K−N bond lengths are symmetrical (unlike those previously mentioned for **6**) and have a length of 2.714 Å. The former bonds are slightly shorter, whilst the latter are longer than the calculated values in **6** due to the presence of the terminal Mg−H bond (length, 1.743 Å).

6 → **9** + *i*Pr-N=C(Me)$_2$ (ΔE_f = +13.1 kcal mol^{-1}) (6)

6 → **10** + *i*Pr-N=C(Me)$_2$ (ΔE_f = +13.8 kcal mol^{-1}) (7)

5 → *i*Pr$_2$NMgH + *i*Pr-N=C(Me)$_2$ (ΔE_f = +22.4 kcal mol^{-1}) (8)

In Stage IV, it has been assumed that two equivalents of **9** (since the formation of **9** was slightly preferred over **10**) combine to produce the dimeric inverse crown **11** [Equation (9)]. The calculated energy of dimerisation is −35.3 kcal mol^{-1}. This can be rationalised in terms of the formation of new Mg−H bonds and also in the formation of a less sterically demanding larger eight-membered ring.

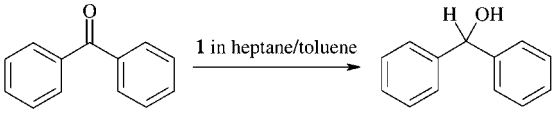
9 + **9** → **11** (ΔE_f = −35.3 kcal mol^{-1}) (9)

In Stage V, one toluene molecule coordinates to each K centre and, as expected, this process is exothermic resulting in the calculated structure corresponding to **1a** [Equation (10)]. The data from the calculated structure were found to closely resemble the crystal data. For instance, the K−N bonds from the X-ray crystallographic data were found to be 2.7754(16) Å whilst the theoretical value is 2.777 Å. Good agreement was also found in the Mg−N bond lengths [2.0595(15) Å vs. theoretical value of 2.103 Å), the N−K−N bond angle [119.55(6)° vs. theoretical value of 122.30°] and the N−Mg−N bond angle [126.55(9)° vs. theoretical value of 128.40°]. As expected the docking of the toluene molecules is exothermic (−1.45 kcal mol^{-1} per coordinating toluene molecule). However, the energy gain calculated by this study is much lower than would have been predicted considering the strength of the K-arene interaction which is evident from the crystal data. This is related to the substantial difference between the K-arene bond lengths for the calculated structure and those found experimentally [shortest K···C$_{tol}$ approach 3.730 Å vs. 3.107(3) Å from the X-ray data].

11 + 2 PhCH$_3$ → **1a** (ΔE_f = −2.9 kcal mol^{-1}) (10)

Reduction of Benzophenone

Preliminary studies have shown that a heptane/toluene solution of **1** has the ability to act as a reducing agent. As mentioned previously, Sanchez and Scott[5] report that, like **1**, Mg(N*i*Pr$_2$)$_2$ can reduce benzophenone to benzhydrol [Equation (11)].



(11)

A 1:4 molar ratio of benzophenone to an in situ solution of **1** was chosen, in accordance with the work of Ashby et al.[4] On work up of the reaction mixture using standard protocols, a ^{1}H NMR spectrum of the crude product was obtained. The spectrum indicated that, as well as the reduction product benzhydrol, some unchanged benzophenone was present (26% by NMR spectroscopy). The spectrum of the crude product also indicated the presence of the imine *i*Pr-N=C(Me)$_2$ produced as a secondary product of the β-hydride elimination. The yield of benzhydrol (74%) is similar to that obtained using monometallic Mg(N*i*Pr$_2$)$_2$ [5] as the reducing agent (73%).

To provide further evidence that the reduction is taking place as a consequence of β-hydride elimination, 2,2,6,6-tetramethylpiperidide (TMP) — an amide in which it is impossible for β-hydride elimination to take place — was utilised instead of diisopropylamide. Previously, BuK, Bu$_2$Mg and TMPH in a 1:1:3 mixture in toluene has been used to prepare the hexapotassium-hexamagnesium twenty-four membered inverse crown [K$_6$Mg$_6$(TMP)$_{12}$(C$_6$H$_4$CH$_3$)$_6$], where the 6+ charge of the "host" heterobimetallic cationic ring is balanced by the encapsulation of six monodeprotonated "guest" arene molecules.[39] For the experiment outlined here, BuK was exchanged for BnK. The reaction was carried out in an analogous fashion to that shown for the benzophenone reduction using **1** in the Exp. Sect. As for the reaction reported earlier, a dramatic colour change occurred upon addition of the ketone. Similarly, when quenched with water, a white suspension of NaOH and Mg(OH)$_2$ was produced. After work up, a ^{1}H NMR spectrum of the crude reaction mixture was obtained. While this spectrum contained a large number of resonances it was

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

clear that benzhydrol was not present although some unchanged benzophenone remianed. As found in the study by Sanchez and Scott,[5] it proved impossible to identify the other products present, presumably due to their intractable polymeric nature. This evidence coupled with both the X-ray data and the detection of *i*Pr-N=C(Me)$_2$ by ^{1}H NMR spectroscopy, unequivocally proves that the reduction must be taking place as a consequence of a β-hydride elimination pathway.

Experimental Section

The synthesis of **1** was carried out under a protective atmosphere of argon using standard Schlenk techniques. Hexane and toluene were dried by heating to reflux over sodium benzophenone ketyl and distilled under nitrogen prior to use. Diisopropylamine was dried by heating to reflux over calcium hydride, distilled under nitrogen and stored over 4 Å molecular sieve. *n*,*s*-Dibutylmagnesium in the form of a 1 M solution in heptane was purchased from Aldrich Chemicals and standardised immediately prior to use using salicylaldehyde phenylhydrazone.[40] Benzylpotassium was prepared according to literature methods.[41] Benzophenone was used as received from Aldrich Chemicals. The melting point was determined in a sealed argon-filled capillary tube and is uncorrected. NMR spectroscopic experiments were carried out on a Bruker DPX 400 MHz spectrometer.

[K$_2$Mg$_2$(N*i*Pr$_2$)$_4$(μ-H)$_2$.(toluene)$_2$] (1): A flame-dried, argon-filled Schlenk tube was charged with benzylpotassium (0.65 g, 5 mmol). This orange/red solid was subsequently suspended in toluene (10 mL). *n*,*s*-Dibutylmagnesium in heptane (5 mL, 5 mmol) was added, followed by diisopropylamine (2.1 mL, 15 mmol) to give an orange solution. The solution was heated to reflux for 35 minutes and an orange to red colour change was observed. The solution was then concentrated by removal of some solvent in vacuo and then placed in a freezer operating at −28 °C. After 48 hours, colourless needle-like crystals were deposited from the solution. Due to their high solubility, the crystals proved difficult to isolate in high yields (first batch = 0.26 g, 15%). m.p. >280 °C. $C_{38}H_{74}K_2Mg_2N_4$ (713.8): calcd. C 63.9, H 10.4, N 7.8; found C 64.7, H 10.3, N 7.6. ^{1}H NMR (400.13 MHz, C_6D_6, 300 K): δ = 1.29 [d, 48 H, CH(C*H*$_3$)$_2$], 2.11 (s, 6 H, C_6H_5C*H*$_3$), 3.35 [sept, 8 H, C*H*(CH$_3$)$_2$], 3.78 (s, 2 H, Mg*H*), 6.94 (d, 4 H, *o*-tol), 7.05 (t, 2 H, *p*-tol), 7.15 (m, 4 H, *m*-tol) ppm. ^{13}C NMR (100.62 MHz, C_6D_6, 300 K): δ = 21.75 (C_6H_5*C*H$_3$), 27.29 [CH(*C*H$_3$)$_2$], 49.50 [*C*H(CH$_3$)$_2$], 126.03 (*p*-tol), 129.67 (*o*-tol), 138.00 (*ipso*-tol) ppm. The *m*-tol resonance is obscured by the solvent C_6D_6 resonance at δ = 128 ppm.

X-ray Crystal Structure Determination of 1: The X-ray structural analysis was carried out at 123 K on a Nonius Kappa CCD diffractometer (Mo-K_α, λ = 0.71073 Å, graphite monochromator, standard techniques). Crystal data: $C_{38}H_{74}K_2Mg_2N_4$, mol. wt. 713.83, orthorhombic, space group *Pnnm*, *a* = 9.9080(2) Å, *b* = 12.5553(3) Å, *c* = 17.4310(4) Å, *U* = 2168.38(8) Å^3, *Z* = 2, D_c = 1.093 g cm^{-3}. A total of 5567 reflections were collected out to θ_{max} = 29.16°, of which 3018 were unique (R_{int} = 0.0204). The structure was solved by direct methods and refined by full-matrix least-squares on F^2 with all non-H atoms anisotropic and using SHELX-97.[42] The bridging hydride H-atoms were refined isotropically but all other H-atoms were placed in calculated positions. Final *R* values: *R*1 = 0.0508, *wR*2 = 0.1422, GOF = 1.043.

CCDC-213617 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Reduction of Benzophenone: A flame-dried, argon-filled Schlenk tube was charged with benzylpotassium (0.65 g, 5 mmol). This orange/red solid was subsequently suspended in toluene (10 mL). *n*,*s*-Dibutylmagnesium in heptane (5 mL, 5 mmol) was added, followed by diisopropylamine (2.1 mL, 15 mmol) to give an orange solution. The solution was heated to reflux for 35 minutes and an orange to red colour change was observed. Benzophenone (0.2275 g, 1.25 mmol) was added, immediately producing a deep purple coloured oil. This mixture was allowed to stir for thirty minutes before being quenched with distilled water (5 mL). The resulting white suspension was washed with three aliquots of diethyl ether (10 mL). The organic phase was dried over anhydrous $MgSO_4$. All volatiles were removed in vacuo and the reduction product — benzhydrol, Ph_2CHOH — was recrystallised from petroleum ether 60−80 (0.11 g, 48% not optimised: yield obtained from NMR analysis relative to recovered benzophenone was 74%). The purity of the product was confirmed by ^{1}H NMR spectroscopy. ^{1}H NMR (400.13 MHz, $CDCl_3$, 300 K): δ = 2.20 (d, 1 H, O*H*), 5.87 (d, 1 H, C*H*), 7.25−7.41 (overlapping multiplets, 10 H, Ph) ppm. As well as obtaining the yield with respect to benzophenone from the ^{1}H NMR spectrum of the crude product, the presence of *i*Pr-N=C(Me)$_2$, the by-product from the formation of **1**,[43] was also noted: δ = 1.12 (d, 6 H, C*H*$_3$), 1.85 (s, 3 H, *H*$_3$C′-C=N), 1.99 (s, 3 H, *H*$_3$C-C=N), 3.62 (sept, 1 H, C*H*) ppm.

A Solid-State, Solution, and Theoretical Structural Study of Kinetic and Thermodynamic Lithiated Derivatives of a Simple Diazomethane and Their Reactivities Towards Aryl Isothiocyanates

(Trimethylsilyl)diazomethane (**1-H**) reacts with *n*BuLi in THF at elevated temperature to afford (previously reported) **1-Li·$^3/_2$THF**. However, reaction in hexane/TMEDA at low temperature affords instead the *N*-lithiate $Me_3SiCNNLi$·TMEDA (**9**), which is a novel "open" pseudo-cubic tetramer in the solid state. Variable-temperature NMR spectroscopy suggests that *N*-metallated **9**, apparently the kinetic product of the reaction, irreversibly rearranges at high temperature in solution to give the thermodynamically preferred *C*-lithiated isomer. These observations, supported by DFT calculations, influence our understanding of the reactivity of lithiated diazomethanes towards aryl isothiocyanates, suggesting as they do that previously observed product selectivity in these reactions is critically dependent on temperature control exercised during the process.

Introduction

(Trimethylsilyl)diazomethane (**1-H**), a safe and stable analogue of diazomethane, has many applications in, for example, Arndt−Eistert syntheses,[1] the homologation of ketones[2] and aldehydes,[3] cycloaddition reactions,[4] and the methyl esterification of carboxylic acids.[5] Moreover, the chemistry of its lithiated derivative (**1-Li**) has also been extensively studied due to its synthetic utility. This derives from its combination of reactivity (greater than that of **1-H**) and safety (relative to diazomethane).[6] In consequence, **1-Li** has found ready use in the preparation of substituted triazoles[7] and tetrazoles,[8] the syntheses of aldehydes from ketones,[9] Colvin rearrangements[10] and the formation of synthetically useful[11] silyl ketenes.[12] These last species react with phosphorus ylides and so afford a simple route to silyl allenes.[13] In this context, central to the synthesis[13] of the disubstituted silyl ketene **3**, is the formation, by the sequential treatment of **1-H** with *n*-butyllithium and carbon monoxide, of a lithium ynolate **2**. This latter species is considered to result from the insertion[14] of CO into the proposed C−Li bond in **1-Li**, whereupon N_2 is eliminated (Scheme 1), the addition of triethylsilyl trifluoromethanesulfonate (Et_3SiOTf) and subsequent work-up affording **3**.

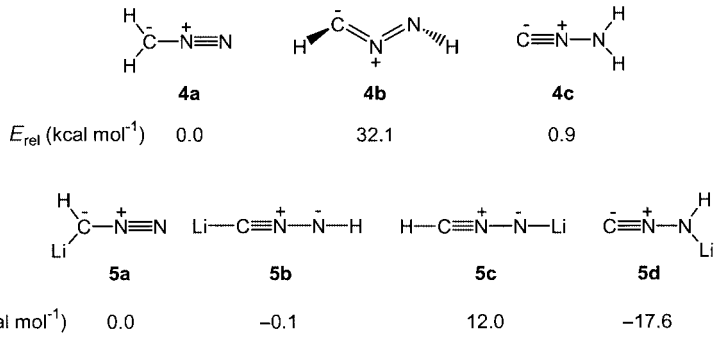

Figure 1. Possible isomers of **1-H**[15] (and their relative energies)[17] and **1-Li** (and their relative energies, 1 kcal = 4.184 kJ)

The chemistry of metallated (mono-substituted) diazomethane has been previously investigated[15] (Figure 1) with results indicating that deprotonation/reprotonation of diazomethane **4a** affords the *less* stable CH_2N_2 *N*-isocyanoamine isomer **4c**, which undergoes base-induced reversion to **4a**. The other possible non-cyclic CH_2N_2 isomer (nitrile imine **4b**) has not been detected experimentally. The structures and energies of the CH_2N_2 isomers **4a**−**c**, as well as those of their lithiated derivatives, **5a**−**d**, have recently been modelled theoretically.[16,17] From these calculations it was suggested that while N-protonation of **5d** would give **4c**, C-protonation of **5a** would yield **4a**. Further, consistent with experiment, theory pointed to the most stable **1-H** isomer (**4a**) being obtainable, in the presence of base, from energetically less favourable **4c** (Scheme 2). This is in spite of the suggestion, based on calculation, that **5a** (precursor to **4a**) is less stable than **5d**; in other words that the reaction is thermodynamically controlled by the stability of the final protonated product. In contrast to the parent diazomethane structures discussed above, calculations[17] have shown that for the lithiated mono-substituted (trimethylsilyl)diazomethanes **1-Li** and **6** (Figure 2), the *N*-metallated nitrile imine isomer was slightly more stable than the *C*-lithiate. However, previous attempts to isolate and crystallographically characterise **6** have resulted only in the isolation and structural elucidation of {hexakis[lithio(trimethylsilyl)-diazomethane]·bis[lithio{4,5-bis(trimethylsilyl)triazole}]·heptakis(diethyl ether)} [(**7**)$_2$·OEt_2; Figure 3].[17] This species is composed both of **6** and lithiotriazole **8**, this last component evidently being formed by the reaction of **6** with **1-H**.

Suggestions[12,18] that the reactivity of lithiated **1-H** is solvent dependent have been borne of the observation that whereas it reacts with RNCS (R = alkyl, aryl) in OEt_2 to afford 2-amino-1,3,4-thiadiazole (**13**), in THF thio-1,2,3-triazoles **10**−**12** result (Scheme 3).[18b] However, such differing behaviour has not hitherto been explained in detail and this has led us to attempt the isolation and structural characterisation of *pure* lithiated (trimethylsilyl)diazomethane (cf. **7**) in order to clarify which of the proposed model structures, *C*- or *N*-lithiated, better describes the true structure of lithiated **1-H**. In this context, we report here on the observation of both kinetic [giving $Me_3SiCNNLi$·TMEDA, **9**] and thermodynamic [giving **1-Li·$^3/_2$THF**] metallation. The latter observation has led to the isolation and structural characterisation of an intermediate in the synthesis of disubstituted silyl ketene **3** (Scheme 1). Finally, we report here on the reactions of lithiodiazomethanes with different isothiocyanates with a view to understanding the relationship between the site of lithiation in the substrate and the structure of the final cyclised product.

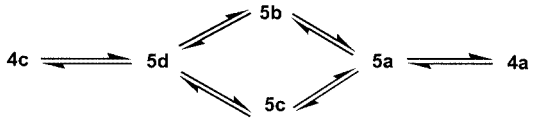
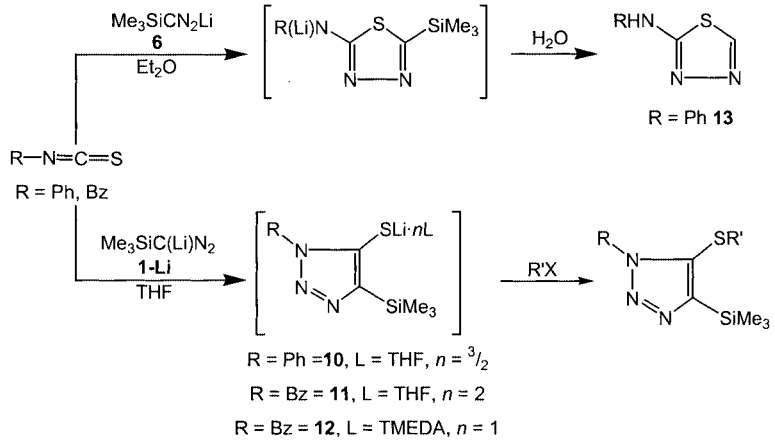


Scheme 2. Equilibria in the interconversion of diazomethane isomers

Results and Discussion

Solid-State and Theoretical Studies on 1-Li·$^3/_2$THF and 9

The reaction of **1-H** with *n*BuLi in THF yielded large yellow crystals of pure lithiated (trimethylsilyl)diazomethane $^1/_2$[{$Me_3SiC(Li)N_2$}$_2$·3THF] (**1-Li·$^3/_2$THF**), the solid-state structure of which we have previously reported.[19] X-



Scheme 3. Proposed pathways for the reaction of different **1-Li** isomers with RNCS (R = Ph, Bz)[12,18]

ray crystallography has shown **1-Li·$^3/_2$THF** to be a polymer based on a repeating tetramer unit (Figure 4), consisting of two (*mono*-THF) complexed lithiodiazomethane molecules and two (*bis*-THF) complexed ones i.e. $\{[Me_3SiC(Li{\cdot}THF)N_2]{\cdot}[Me_3SiC(Li{\cdot}2THF)N_2]\}_2$. This revelation of two types of lithiodiazomethane molecule in the solid-state structure of **1-Li·$^3/_2$THF** is consistent with the observation of two sets of C=N=N stretching modes by IR spectroscopy (ν_{sym} = 2149, 2116 cm^{-1} and ν_{asym} = 2092, 2052 cm^{-1}) which collapse to a single set upon hydrolysis to **1-H**. The ambiguity surrounding the preferred site of lithiation in **1-H** that results from the contrasting structures noted for **1-Li·$^3/_2$THF** and **7** made it desirable to theoretically probe the relative stabilities and geometries of both *N*- and *C*-lithiates. DFT calculations[20] based on a variety of models were undertaken (B3LYP[21]/6-311G**[22]). Energetic results for $XCN_2Li{\cdot}nL$ (X = H_3Si, Me_3Si; n = 0, 1, 2; L = OEt_2, THF) are summarised in Table 1 with selected calculated geometrical parameters in Table E1 (see Electronic Supporting Information; see footnote on the first page of this article).

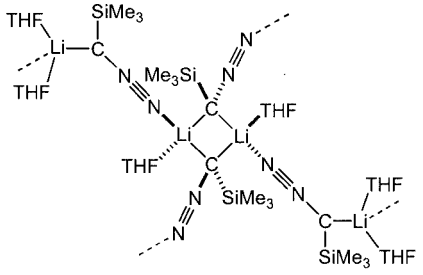


Figure 4. The molecular structure of polymeric **1-Li·$^3/_2$THF**

Overall, calculations reported here on lithiodiazomethanes and their complexes suggest that, while *N*-metallation is thermodynamically preferred, *C*-metallation becomes increasingly favourable in the presence of strongly coordinating media. For unsolvated diazomethanes XCN_2Li (X = H_3Si, Me_3Si) *C*-lithiation is 2.5 kcal·mol^{-1} (**I**; 1 kcal = 4.184 kJ) more energetic than *N*-lithiation (**II**) for X = H_3Si (Table 1 and Figure 5) while for X = Me_3Si the computed preference for *N*- (**IV**) over *C*-metallation (**III**) is 4.0 kcal·mol^{-1}, illustrating the electron-donating nature of the methyl groups over hydrogen atoms yet still suggesting a fine energetic balance between the differently metallated, unsolvated monomers. Calculated molecular geometries show little dependence upon X. Whereas *C*-lithiates **I** and **III** both show relatively long C−N (1.283 and 1.282 Å, respectively) and short N−N (1.141 and 1.144 Å, respectively) bonds, the opposite is true of *N*-lithiates **II** and **IV** (C−N = 1.195 Å in both, N−N = 1.201 and 1.205 Å, respectively). The structural feature most significantly dependent on X is the Si−C bond length. This increases significantly from a mean of 1.798 Å to one of 1.817 Å on replacing H atoms with Me groups−presumably reflecting both the increased steric requirements of the trimethylsilyl group and its aforementioned inductive effect. The metallo−organic bonds show no significant variation with X. Hence, while the C−Li bonds are 1.906 Å in both **I** and **III**, the N−Li ones in **II** and **IV** are 1.697 and 1.692 Å, respectively.

The extension of calculations to the simple mono-solvated, monomeric lithiates $Me_3SiCN_2Li{\cdot}L$ (L = OEt_2, THF) shows that, irrespective of the choice of L, the *C*-lithiates (**V**, **VII**) are higher in energy than the *N*-lithiates (**VI**, **VIII**; Table 1 and Figure 5). All of the resultant structure types are significantly more stable than either **III** or **IV** by virtue of Lewis base coordination [$\Delta E_{Complexation}$ (ΔE_C) = −21.5 (**V**), −22.9 (**VII**), −21.5 (**VI**), −22.7 (**VIII**) kcal·mol^{-1}]. Of note (see below) for both types of L, *C*-lithiated models show more negative ΔE_C values than their *N*-lithiated counterparts. Moreover, for both *C*- and *N*-lithiates, both the magnitude of and differences between ΔE_C values are enhanced for coordination of the stronger Lewis base (THF). Thus, $-\Delta E_C$(**V**) = $-\Delta E_C$(**VI**) and $-\Delta E_C$(**VII**) > $-\Delta E_C$(**VIII**), $-\Delta E_C$(**VII**) > $-\Delta E_C$(**V**) and $-\Delta E_C$(**VIII**) > $-\Delta E_C$(**VI**) and, whereas for *mono*-OEt_2 solvation **VI** is preferred to **V** by 4.0 kcal·mol^{-1}, for *mono*-THF solvation **VII** is 3.8 kcal·mol^{-1} more stable than **VIII**. This implies that *N*-metallation is less strongly favoured over *C*-metal-

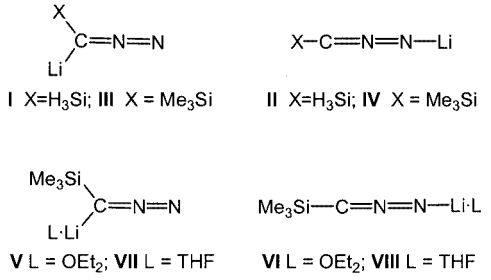

Figure 5. Theoretically modelled structures of the simple *C*- (**I**, **III**) and *N*-lithiated (**II**, **IV**) diazomethanes XCN_2Li (X = H_3Si, Me_3Si) and **III**·L and **IV**·L complexes (**V**−**VIII**; L = OEt_2, THF)

lation as external solvation increases; an important inference given the previously reported reactivities of lithiated (trimethylsilyl)diazomethanes in different Lewis base media.[12,18] Differences in the calculated energies of the variously coordinated *mono*-solvates do not, however, translate into significant differences in bonding parameters. Slight changes are noticeable relative to unsolvated **III** and **IV** on the inclusion of Lewis base and this is most apparent in increments to C−Li lengths (to, 1.959 and 1.956 Å for **V** and **VII**, respectively, cf. 1.906 Å in **III**) and N−Li distances (to, 1.735 and 1.732 Å for **VI** and **VIII**, respectively, cf. 1.692 Å in **IV**).

Calculations on $Me_3SiCN_2Li{\cdot}2$ L (L = OEt_2, THF; Table 1 and Figure 6) reinforce the view that, irrespective of the choice of L, the preference for *N*- over *C*-lithiation is diminished as external solvation of the metal is introduced. The resultant structure types (**IX**−**XII**) are all significantly more stable than models **V**−**VIII** [ΔE_C = −33.7 (**IX**), −40.1 (**XI**), −32.6 (**X**), −38.7 (**XII**) kcal·mol^{-1}]. As for **V**−**VIII**, ΔE_C is most negative for solvation by THF while the predilection for *N*-metallation is minimised in this medium [$Me_3SiC(Li{\cdot}2THF)N_2$ (**XI**) is only 2.6 kcal·mol^{-1} less stable than $Me_3SiCN_2Li{\cdot}2THF$ (**XII**)]. The addition of a second Lewis base molecule causes the further extension of C−Li (to, 2.055 and 2.038 Å for **IX** and **XI**, respectively) and N−Li bonds (to 1.801 Å for both of **X** and **XII**).

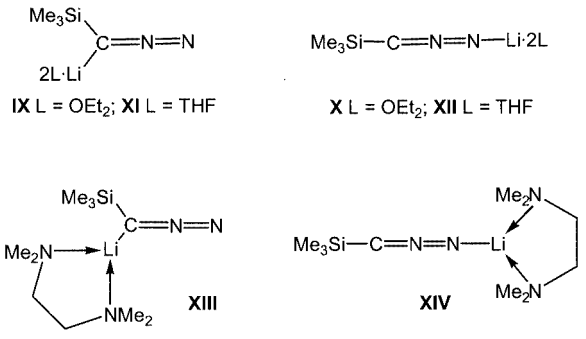

Figure 6. Modelled structures of monomeric **III**·2L and **IV**·2L complexes **IX**−**XII**; L = OEt_2, THF) and **III**·L and **IV**·L (L = TMEDA)

While the gas phase calculations do not account for the aggregation behaviour either of **1-Li·$^3/_2$THF** or of **7** it is nonetheless apparent that some useful correlations exist between theory and experiment. Table E1 (Supp. Inf.) indicates close carbon−nitrogen and the nitrogen−nitrogen bond length agreement both between **1-Li·$^3/_2$THF** and **I** (Figure 5) and between **7** and **II**. Clearly, in **1-Li·$^3/_2$THF** the carbon−nitrogen bond (mean 1.326 Å) is longer than a double one and the nitrogen−nitrogen bond (1.182 Å) is shorter than a double one.[23] Furthermore in **7**, the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

carbon−nitrogen bond (mean 1.202 Å) is longer than a triple one and the nitrogen−nitrogen bond (1.208 Å) is slightly longer than a double one.

Previously reported calculations on H_3SiCN_2Li [6-31G(d)/MP2] have suggested (in the light of structurally characterising **7**) an energetic preference of 1.4 kcal·mol^{-1} for the *N*- over the *C*-lithiate.[17] However, calculations presented here clearly suggest that any such preference is eroded by the introduction of external solvation. This leads us to the view that in the presence of excess donor (either solvent or, by aggregation, other molecules of lithiated **1-H**) the *C*-metallated product represents the thermodynamic product of lithiation whereas the *N*-metallate reveals kinetic control. Consistent with this is the fact that, whereas **1-Li·$^3/_2$THF** is afforded after having heated the reaction mixture to reflux (approx. 65 °C), **7** results from a process in which the temperature never exceeds −25 °C.

In order to further probe the question of thermodynamic versus kinetic control in the metallation of **1-H** and also in an attempt to obtain pure lithiated derivatives based on oligo- rather than complex polymeric structures, we have effected the crystallisation of lithiated (trimethylsilyl)diazomethanes from polydentate Lewis bases. The best results have been obtained by the reaction of **1-H** with *n*BuLi in TMEDA (= *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) at low temperature (< −25 °C). This process achieves yellow crystals of a single isolable product and these analyse as Me_3SiCN_2Li·TMEDA (**9**). Not only does ^{1}H NMR spectroscopy support the 1:1 TMEDA/lithiate ratio but it also, by displaying just a single trimethylsilyl resonance, suggests the adoption of a single aggregation state, symmetrical species in solution. In line with the kinetic control exercised during the reaction, the solid-state structure of **9** reveals a tetramer (Table 2 and Figures 7 and 8) consisting of *N*-lithiated (trimethylsilyl)diazomethane molecules arranged as an "open" pseudo-cubane. Unusually, stabilisation of the metal centres by TMEDA takes two distinct forms with both *mono*- and *bi*dentate coordination modes being observed. Notably, such a structure is incompatible with the symmetry suggested by NMR spectroscopy, suggesting that the structure is either rapidly fluxional and/or significantly deaggregated in solution (see below).

While Li(1), Li(2), and Li(4) are each coordinated by three diazomethane terminal N-centres, Li(3) is coordinated by just two; there being no interaction with N(1) [Li(3)···N(1) = 2.839(9) Å]. *Bis*-coordination by the two TMEDA molecules that exhibit bidentate behaviour renders Li(3) and Li(4) four and five coordinate, respectively. The remaining two Li^+ ions are tetra-coordinate, each being *mono complexed* by one N-centre of a monodentate TMEDA molecule. Thus the aggregate can be viewed as a dimer of dimeric pairs [each one based on a $(NLi)_2$ ring, i.e. Li(3)N(5)Li(4)N(7) and Li(1)N(1)Li(2)N(3)] whereby each one is defined by the characteristic behaviour of its TMEDA components (Figure 8). Nevertheless, the combination of pseudo-cubane opening and differences in the coordinative modes adopted by TMEDA incurs significant variations in core Li−N interactions (Table 2). Perhaps most significantly, and presumably symptomatic of the predilection of lithium for forming four bonds,[24] pentacoordinate Li(4) forms long[25] interactions both with bidentate TMEDA [mean Li(4)−N = 2.264 Å] and with three deprotonated diazomethane monomers [mean Li(4)−N = 2.204

Å]. The remaining TMEDA-chelated metal shows similar, though less pronounced, lengthening of Li−N(TMEDA) bonds [Li(3)−N(13) and Li(3)−N(14) = 2.208(9) and 2.146(8) Å, respectively] but rather stronger bonds to the cluster core [mean Li(3)−N = 2.035 Å]. It may be the case that the discrepancy between these two Li−N(TMEDA) interactions has its origins in the orientation of the Lewis base since the shorter of the two interactions is associated with N(14), which can presumably closely approach Li(3) by virtue of diminished steric interactions with the N(1)-containing diazomethane unit−a result of the extended Li(3)···N(1) distance. A further consequence of bond-cleavage in the aggregate core is that N(1) becomes unique among the terminal diazomethane N-centres in that it stabilises just two metal ions [mean Li−N(1) = 2.001 Å]. Finally, shorter than the Li−N(TMEDA) bonds previously noted for the *bis*-coordinating Lewis base molecules are those in which the TMEDA acts only as a monodentate donor [mean Li−N = 2.079 Å]. A comparison of the solid-state structural parameters observed for **9** with those noted in **7** reveals that both C−N (mean 1.206 and 1.202 Å respectively for **9** and **7**) and N−N (mean 1.214 and 1.208 Å) bond lengths correlate well but differ significantly from those in *C*-lithiated **1-Li·$^3/_2$THF**.[19]

Coincidentally, the only other known example of an "open" $(LiN)_4$ pseudo-cubane in which a single core bond is absent is **7**. However, bond cleavage in **7** derives from the mixed-anion nature of the cluster, with one vertex of the [otherwise lithio(trimethylsilyl)diazomethane-based] cube being defined by the deprotonated N-centre in the triazole ring, the neighbouring ring-nitrogen inserting into a cubane edge. The only other discrete, related "open" pseudo-cubanes reported are the $(LiO)_4$-based structures $(PhOLi{\cdot}THF)_4{\cdot}PhOH$ (wherein a single core interaction is absent),[26] $[2\text{-}MeOC_6H_4C(H)(OLi)NMe(CH_2)_2NMe_2]_4$[27] and $[PhC(O)N(Ph)Li{\cdot}THF]{\cdot}[PhC(O)N(Ph)Zn(t\text{Bu})_2\text{-}Li{\cdot}THF]$[28] (in each of which two eclipsed core bonds are absent). This latter mode of separation is also noted in polymeric $(BrLi{\cdot}THF)_\infty$.[29] The remaining rare feature of $(\mathbf{9})_4$ in the solid state is highlighted by $Cl_6Li_6{\cdot}2TMEDA{\cdot}{}^4/_2TMEDA$.[30] Here variations in the mode of external solvation by TMEDA allow four of the six Lewis base molecules associated with each hexamer to bridge between aggregates affording a three-dimensional network. Contrastingly, in $(\mathbf{9})_4$, Li(1) and Li(2) are each stabilised by just one TMEDA N-centre [N(9), N(11)]; these donors being strictly monodentate with neither N(10) nor N(12) bridging to adjacent aggregates.

Complex **9** (like **7**) results from the employment of kinetic control during the reaction and this, perhaps, overshadows the true aim of employing TMEDA here. Nevertheless, the solid-state structure of **9** affords us the first glance of a discrete molecular lithiodiazomethane [cf. $(\mathbf{1\text{-}Li\cdot{}^3/_2THF})_\infty$] which incorporates no other by-products (cf. **7**) and a theoretical probe has been undertaken [B3LYP/6-311G**;[21,22] Figure 6 and Table 1 and Table E2 (Supp. Inf.)].[20−22] The stabilities of $Me_3SiC(Li{\cdot}TMEDA)N_2$ (**XIII**) and $Me_3SiCN_2Li{\cdot}TMEDA$ (**XIV**) are significantly enhanced by the coordination of TMEDA [ΔE_C = −35.1 (**XIII**), −32.8 (**XIV**) kcal·mol^{-1}] relative to unsolvated **III** and **IV**. In line with earlier calculations reported here (see above) $-\Delta E_C$(**XIII**) > $-\Delta E_C$(**XIV**), pointing again to the chances of *C*-metallation being enhanced by external solvation. Whilst *C*-lithiate **XIII** is still less stable than *N*-lithiated analogue **XIV** the introduction of TMEDA has almost completely negated the energy difference (1.7 kcal·mol^{-1}). The structural parameters in diazomethane anions in **9** correlate well with those of computed **XIV**. Notably, in **9** (as in **7**) the carbon−nitrogen and the nitrogen−nitrogen bond lengths are very similar (in contrast to those in *C*-lithiated **1-Li·$^3/_2$THF**, wherein the carbon−nitrogen distance was significantly greater than the nitrogen−nitrogen one).

Solution Studies on 1-Li·$^3/_2$THF and 9

The observation of **1-Li·$^3/_2$THF** and **9** demonstrates the viability of both *C*- and *N*-lithiated derivatives of **1-H** in the solid state. However, the details of their syntheses suggest that the regiospecificity of metallation is critically dependant on reaction conditions. This observation made it desirable to elucidate the structures of species obtained on dissolution of both **1-Li·$^3/_2$THF** and **9** and to probe the possible interconversion between *N*- and *C*-lithiates. Cryoscopic relative molecular mass (CRMM) measurements[31] on **1-Li·$^3/_2$THF** in benzene show both that the complex deaggregates significantly in non-donor solution and that the molecular mass (M_r) and aggregation state (n) remain essentially constant at 177 ± 10 and n = 0.77 ± 0.04, respectively [assuming n = 1 for $Me_3SiC(Li)N_2{\cdot}{}^3/_2THF$, M_r = 228] over a wide concentration range ($4.55{\cdot}10^{-3}$ to $3.20{\cdot}10^{-2}$ mol·dm^{-3}, Table E3, Supp. Inf.). This may signify the polymer (M_r = 912) breaking down (the chain-linking Li−N bonds cleaving) such that $[Me_3SiC(Li{\cdot}THF)N_2]_2$ dimers (M_r = 384) and $Me_3SiC(Li{\cdot}2THF)N_2$ monomers (M_r = 264) result. Dimerisation of these monomers, concomitant with the evolution of THF molecules yields fundamental *mono*-THF solvated dimers in solution (M_r = 228). Deaggregation of — and/or loss of THF from — these species can then explain the observed M_r. For **9**, CRMM measurements suggest significant deaggregation of the tetramer. Over the concentration range $4.80{\cdot}10^{-2}$ to $2.60{\cdot}10^{-1}$ mol·dm^{-3} (Table E4, Supp. Inf.) M_r increases from 425 ± 5 (n = 1.80 ± 2 assuming n = 1 for $Me_3SiCN_2Li{\cdot}TMEDA$) to 494 ± 3 (n = 2.14 ± 2). This points to substantial dislocation of the tetramer (M_r = 945) to give $(Me_3SiCN_2Li{\cdot}TMEDA)_2$ (M_r = 473), with limited dissociation of dimers and/or de-coordination of TMEDA occurring at lower concentrations. Data indicates some tetramer retention at higher concentrations.

Variable-temperature ^{1}H NMR spectra of **9** in $[D_8]$PhMe (Figure 9) reveal broadening of the TMEDA peaks and downfield movement of the Me_3Si signal as the temperature is reduced. By −25 °C new sets of Me_3Si and (both) TMEDA resonances develop, suggesting the evolution of a second species and, as the temperature is further reduced, these new signals become dominant. Such behaviour is consistent with the aggregation of $(Me_3SiCN_2Li{\cdot}TMEDA)_2$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(see above) to give tetramers at low temperature and, as such, these spectral changes are thermally reversible. If, instead, this sample is heated above room temperature the Me_3Si singlet (δ = 0.28 ppm at 35 °C) is replaced by a second one (δ = 0.34 ppm at 52 °C; both signals are present in the range 45−51 °C) suggesting a significant change in the lithiodiazomethane molecule whereby kinetically favoured *N*-lithiate **9** rearranges to the (thermodynamic) *C*-lithiate in situ. This view is supported by the observation that subsequent cooling of the sample to room temperature fails to incur any further significant changes in the appearance of the spectrum, suggesting that this thermal rearrangement is irreversible.

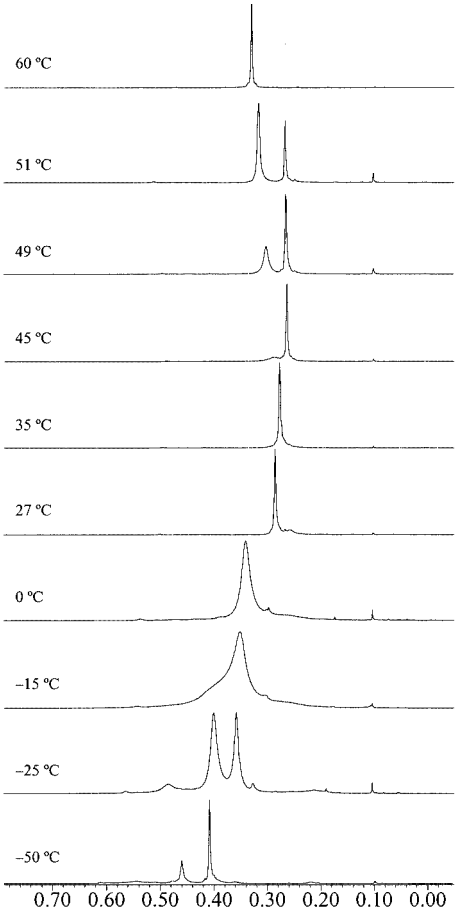

Figure 9. ^{1}H NMR spectroscopic data for the Me_3Si group in **9** in [D_8]PhMe over the range 60 °C to −50 °C

The room temperature ^{13}C NMR spectrum of **9** in [D_8]PhMe (Figure 10) shows a dominant Me_3Si signal at δ = 2.2 and a significantly smaller one at δ = −0.8. (This latter signal may represent a small amount of the sample converting slowly to the thermodynamic isomer at room temperature.) Cooling the sample to −30 °C (below the temperature at which ^{1}H NMR spectroscopy showed the effects of aggregation, see above) causes both the main Me_3Si and the TMEDA CH_2-peak to split into two. (The trace signal tentatively attributed to Me_3Si in the *C*-lithiate at room temperature is not observed at this lower temperature. However, at −30 °C all peaks are noticeably broader and it seems reasonable that this already weak resonance becomes difficult to detect.) If the same sample is heated to +95 °C it is found that the Me_3Si resonance (dominant at room temperature) is completely replaced by one at high field (δ = −0.7 ppm, cf. the weak δ = −0.8 ppm signal at room temperature). In the same way as for ^{1}H NMR spectroscopic data, this encourages the view that whereas the dominant species both at and below room temperature is the *N*-lithiate, it is converted into the *C*-metallated isomer at higher temperature. While the signal for the C=N carbon centre does not move in a manner that might be expected for such a rearrangement, it should be noted that the ^{13}C NMR spectra of both (*C*-lithiated) **1-Li·$^3/_2$THF** and (*N*-lithiated) **9** (in [D_6]DMSO at room temperature) show extremely similar chemical shifts for this carbon nucleus.

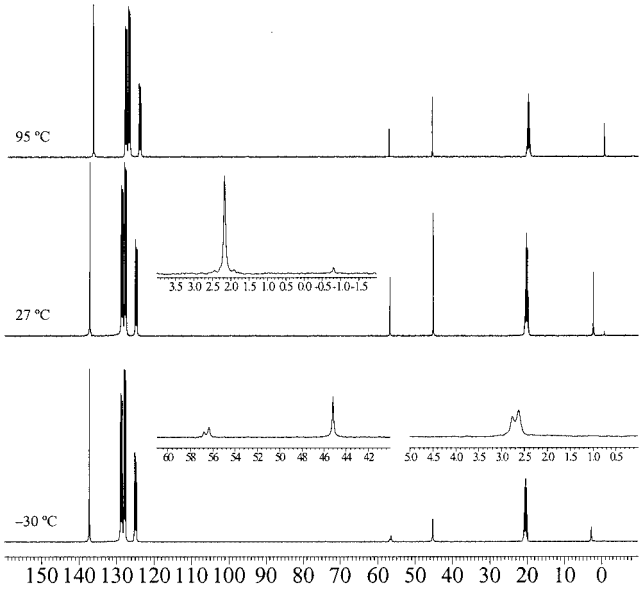

Figure 10. ^{13}C NMR spectroscopic data for **9** in [D_8]PhMe over the range 95 °C to −30 °C

Variable-temperature ^{7}Li NMR spectra (Figure 11) reinforce the information gained from ^{1}H and ^{13}C NMR spectroscopy. The single resonance observed at δ = −1.59 ppm at room temperature broadens as the temperature is lowered until at −20 °C it splits into two separate signals, consistent with the dimer-tetramer system implicated by cryoscopy. If the temperature is reduced still further this new peak becomes the dominant one. As the sample is heated to above room temperature a significant alteration in the position of the sole lithium signal can be seen. Consistent with the ^{1}H NMR spectra, this latter thermal change is irreversible.

The observation of both **1-Li·$^3/_2$THF** and **9** suggests a complicated chemistry for lithiated diazoalkanes and (in tandem with calculations) challenges previous assertions that **1-H** is necessarily preferentially *N*- rather than *C*-lithiated. Rather, calculations now suggest metallation of the carbon centre in the presence of excess donor. Indeed, further synthetic work, culminating in the isolation and structural characterisation of *N*-lithiated **9** suggests that the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

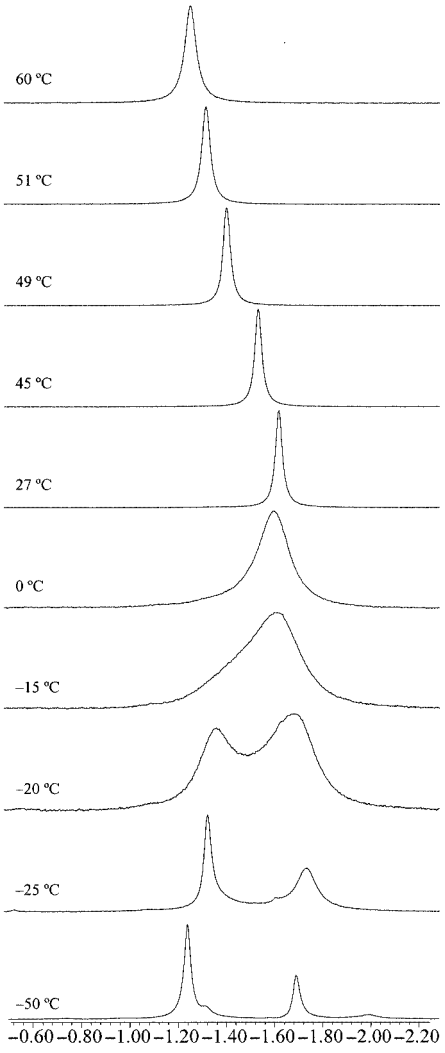

Figure 11. ^{7}Li NMR spectroscopic data for **9** in [D_8]PhMe over the range 60 °C to −50 °C

regiospecificity of metallation is temperature dependant. Clearly, such variability in the behaviour of **1-H** towards organolithium species has consequences for our understanding of the reactions undergone by the subsequently formed lithiate, and this has led us to probe the details of representative processes.

Reactions of Lithio(trimethylsilyl)diazomethane with Aryl Isothiocyanates

i) Treatment of 1-H with *n*BuLi and RNCS in THF: Syntheses of 10 (R = Ph) and 11 (R = PhCH$_2$ = Bz)

Reaction of lithio(trimethylsilyl)diazomethane with phenyl isothiocyanate (PhNCS)[18] in THF affords a product that analyses as PhNNNC(Me_3Si)C(SLi·$^3/_2$THF) **10** (Scheme 3). This shows a 1:1 Ph/Me_3Si ratio by ^{1}H NMR spectroscopy − consistent with expectation for the intended cyclised product. That ring-formation has occurred is also suggested by ^{13}C NMR spectroscopy, which reveals peaks for the sp^2 ring-carbons. However, the failure of **10** to afford crystals suitable for an unambiguous structure determination led to the replacement of phenyl isothiocyanate with its benzylic analogue (BzNCS).

Employment of BzNCS in the above reaction sequence yields a crystalline material that analyses as *S*-lithio-1-benzyl 4-trimethylsilyl-5-thio-1,2,3-triazole [BzNNNC(Me_3Si)C(SLi·2THF)], **11**. X-ray crystallography affords the first full characterisation of a lithiated thio-1,2,3-triazole (Figure 12 and Table 3; the asymmetric unit incorporates two crystallographically independent but structurally similar molecules of **11** of which a representative one is discussed). The species is rendered polymeric in the solid state through the coordination of lithium by, for example, N(3) [Li−N = 2.050(9) Å] in the almost planar (internal angles sum to 540.1°), aromatic triazole ring. The anion is formally metallated at sulfur and, at 2.460(8) Å, Li(1)−S(1) is consistent with metal-sulfur distances reported for lithium-containing thiolates,[32] thioimidates,[32j,33] and thioureas.[34] The only other solid-state structures to incorporate an alkali metallated 1,2,3-triazole ring are those of lithiated[35] and potassiated[36] benzotriazole (the triazole ring being pre-formed in both cases). In **7** a triazole ring is incorporated as a neutral adduct.[17a] The observation of a triazole ring in **11** has ramifications for our interpretation of the cyclisation process by which lithiodiazomethanes and RNCS combine to give 1-substituted 5-alkylthio-1,2,3-triazoles suggesting, as it does, the action of *C*-lithio(trimethylsilyl)diazomethane in THF solution (Scheme 4).

ii) Treatment of 1-H with *n*BuLi and RNCS in OEt$_2$: Syntheses of 12 (R = Bz) and 13 (R = Ph)

According to previous reports, the sequential combination of **1-H** with *n*BuLi and BzNCS in OEt$_2$ affords, via a postulated lithio-2-benzylamino-5-trimethylsilyl-1,3,4-thiadiazole intermediate, 2-amino-1,3,4-thiadiazoles with redirection of the reaction being attributed to an ambiguous

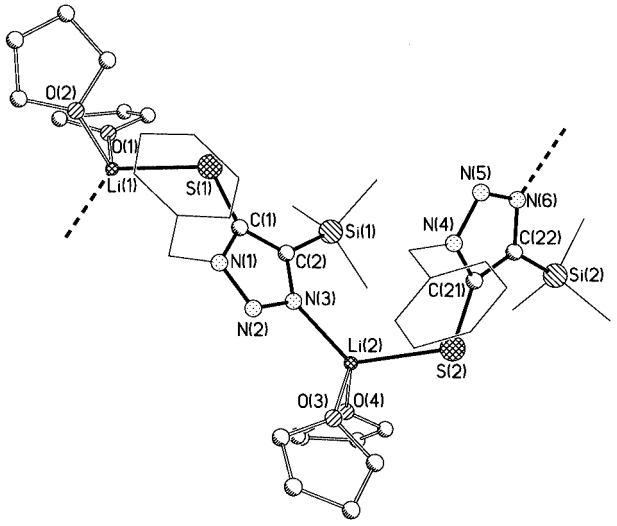

Figure 12. The solid state structure of polymeric **11**, showing the association of two crystallographically independent monomer units via *N*-stabilisation of the metal; for clarity hydrogen atoms have been omitted

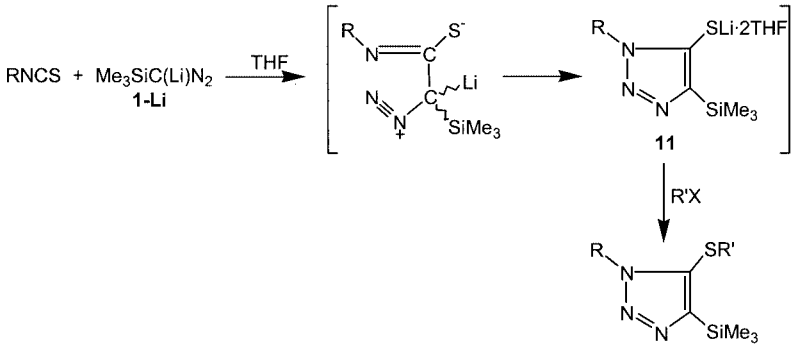
solvent effect.[1] However, we report here that (for R = Bz) such a reaction, if followed by reflux and the addition of TMEDA affords *S*-lithio-1-benzyl 4-trimethylsilyl-5-thio-1,2,3-triazole, BzNNNC(Me_3Si)C(SLi·TMEDA) (**12**) as the only isolable product. In the solid state **12** is dimeric (Figure 13) and consists of two (mono-TMEDA) complexed metallo-1-benzyl-5-thio-4-trimethylsilyl-1,2,3-triazole molecules. Akin to **11**, **12** is an *S*-lithiate [Li−S = 2.422(6) Å], with metal centre stabilisation [Li(1)−N(3) = 2.053(6) Å] incurring dimerisation. The two planar triazole systems show aromatic character (Table 4) and, as such, are essentially similar to those in **11** notwithstanding that the N−N distances in the triazole component of **12** are consistent with greater localisation of electron density [viz. C(4)−N(1), N(1)−N(2), N(2)−N(3) in **11** and C(1)−N(1), N(1)−N(3), N(2)−N(3) in **12**]. Dimerisation of **12** results in these triazole systems being linked by (and participating in) a hitherto unknown type of 10-membered $(NNCSLi)_2$ heterocycle.

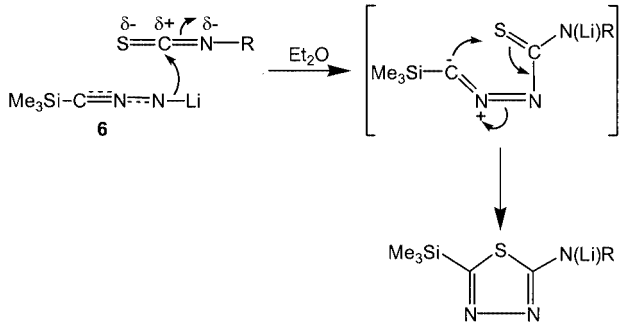
Of mechanistic importance is the observation that **12** is not the expected lithio-2-benzylamino-5-trimethylsilyl-1,3,4-thiadiazole,[1] but rather a lithio-1-benzyl 4-trimethylsilyl-5-thio-1,2,3-triazole. This is, of course, inconsistent with the reaction of *N*-lithio(trimethylsilyl)diazomethane (cf. **9**) with BzNCS but rather suggests that the reactive species in solution is the *C*-lithiate (cf. **1-Li**) instead (Scheme 4). This observation suggests several things. That the reaction is refluxed in the presence of TMEDA prior to the recrystallisation and isolation of **12** agrees with the view that preference for the *N*-lithiate is diminished in the presence of sufficiently strong external donation. Furthermore, the reaction of BzNCS with **1-Li** is apparently not facile. Hence, treatment of the lithiated diazomethane in (relatively poorly donating) OEt_2 with BzNCS at low temperature presumably gives only a slow reaction via the *N*-lithiate. However, heating of the reaction mixture immediately after introducing BzNCS (but *before* the application of TMEDA) affords the lithio-1-benzyl-5-thio-4-trimethylsilyl-1,2,3-triazole, strongly suggesting that the N-isomer has been converted into its C-congener prior to significant reaction hav-



Scheme 4. Proposed mechanism for the formation of **11** from a *C*-lithiated diazomethane precursor[18]

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ing occurred. Notably the synthesis of **12** can be reproduced in THF/TMEDA (with reflux prior to introduction of the bidentate donor) whereas if the literature preparation (no reflux) is closely adhered to then **1-H**, *n*BuLi and PhNCS can be sequentially combined in OEt_2 at 0 °C and worked up to give PhNHCSCHNN **13** in high yield (its formation requiring a lithio-2-phenylamino-1,3,4-thiadiazole precursor). While it has been noted that four types of cyclic system could reasonably result from the reaction of lithiodiazomethanes with aryl isothiocyanates,[37] only two such classes have been reported.[1] Reaction of the *C*-lithiate has been considered (Scheme 4) to require the initial formation of a C−C bond between the diazomethane carbanionic centre and the isothiocyanate carbon atom. However, 2-amino-5-trimethylsilyl-1,3,4-thiadiazole production necessitates that the *N*-lithio(trimethylsilyl)diazomethane molecule forms a N−C bond prior to ring closure by C−S bond formation (Scheme 5).



Scheme 5. Proposed mechanism for the production of lithio-2-amino-5-trimethylsilyl-1,3,4-thiadiazole from an *N*-lithiated diazomethane precursor

Conclusions

This work clearly demonstrates for the first time the viability of both the *C*- and *N*-lithiated isomers of a simple diazomethane both in the solid state (as, **1-Li·$^3/_2$THF** and **9**, respectively) and in solution. X-ray crystallographic characterisations of these two species point to bonding in the two types of molecule being quite different (Figure 14). New calculations corroborate these bonding patterns and also suggest that while the *C*-lithiated isomer of **1-Li** is less stable than its *N*-metallated analogue, the energetic difference between the two decreases with the extent of solvation by progressively stronger donors. Reaction conditions employed in the syntheses of these compounds point to the regiospecificity of metallation being significantly temperature dependent. Thus, *C*- and *N*-metallation result from the exercise of thermodynamic and kinetic control, respectively. Consistent with this is the observation, by variable temperature NMR spectroscopy, of the *irreversible* conversion of *N*- to *C*-lithiate at high temperature, a result that has significant consequences for our view of the reactivity of this lithiodiazomethane with aryl isothiocyanates.

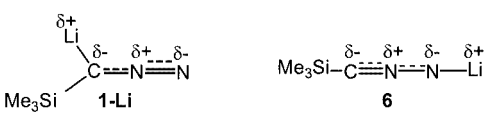


Figure 14. A review of bonding in *C*- and *N*-lithiated isomers of (trimethylsilyl)diazomethane

The solid-state structures of both **1-Li·$^3/_2$THF** and **9** indicate why it is that organic syntheses which involve the elimination of N_2 from diazomethanes require formation of the *C*-lithiate with its weak C−N and strong N=N bond. Finally, such reactivity has been probed and has resulted in the crystallographic characterisation of lithiothiotriazoles **11** and **12**. Details of their syntheses and structures bear out the view that product selectivity in these reactions, rather than being directly solvent dependent, is in fact influenced by temperature.

Experimental Section

General Remarks: All operations were carried out using standard Schlenk techniques. Toluene (freshly distilled from sodium) was added direct to the nitrogen-filled Schlenk tube using standard syringe techniques. NMR spectroscopy: Bruker DPX 250 (250.133 MHz for ^{1}H, 62.533 MHz for ^{13}C), DRX 400 (400.136 MHz for ^{1}H, 100.614 MHz for ^{13}C, 155.508 MHz for ^{7}Li), DRX 500 (500.050 MHz for ^{1}H) at 27 °C unless otherwise stated. For NMR spectroscopy, [D_6]DMSO, [D_8]THF, or [D_8]PhMe as solvents, TMS at 27 °C as external standard (for ^{1}H and ^{13}C) and PhLi in [D_8]PhMe at 27 °C as external standard (for ^{7}Li).

Synthesis of $^1/_2$[{$Me_3SiC(Li)N_2$}$_2$·3THF] (1-Li·$^3/_2$THF): Preparation as previously reported.[19] IR (Nujol): $\tilde{\nu}$ = 2149 cm^{-1} w, 2116 m (C=N=N sym. str.), 2092 m, 2052 m (C=N=N asym. str.), 838 w [$SiMe_n$ (n = 3)[38] str.], after air exposure 2160 w (C=N=N sym. str.), 2116 m (C=N=N asym. str.). ^{1}H NMR (250 MHz, [D_6]DMSO): δ = 3.60 (m, 6 H, THF), 1.76 (m, 6 H, THF), 0.05 (s, 3 H, Me), −0.18 (s, 6 H, Me) ppm. ^{13}C NMR (63 MHz, [D_6]DMSO): δ = 103.9 (C=N), 67.1 (THF), 25.2 (THF), 2.1 (SiMe), 0.4 (SiMe) ppm.

Synthesis of 6(Me_3SiCN_2Li)·2[($Me_3SiC)_2N_3Li$]·7OEt_2 [(7)$_2$·OEt_2]: Based on the literature preparation.[17a] *n*BuLi (2.5 mL, 3.2 M in hexanes, 4 mmol) was added to an OEt_2 (0.5 mL) solution of **1-H** (2 mL, 2 M in hexanes, 4 mmol) at −78 °C. The resultant orange solution was frozen in liquid nitrogen and then kept at −25 °C. Crystals of (**7**)$_2$·OEt_2 were afforded after 2 days at this temperature. The crystal structure of this compound has been reported,[17a] but supporting data has not been given previously. Yield 201 mg (30% based on **1-H**), m.p. 106−110 °C. $C_{68}H_{160}Li_8N_{18}O_7Si_{10}$ (1677): calcd. C 48.66, H 9.61, N 15.02; found C 44.93, H 9.11, N 15.34. IR (Nujol): $\tilde{\nu}$ = 2085 cm^{-1} m, 2066 m (C=N=N sym. str.), 2047 m, 2000 br (C=N=N asym. str.), 1632 m (C=C), 839 m [$SiMe_n$ (n = 3)[38] str.], after air exposure 2066 w (C=N=N sym. str.). ^{1}H NMR (500 MHz, [D_6]DMSO): δ = 3.36 (q, 15 H, OEt_2), 1.07 (t, 22.5 H, OEt_2), 0.18 (s, 36 H, Me), −0.14 (s, 12 H, Me), −0.18 (s, 42 H, Me) ppm. ^{13}C NMR (100 MHz, [D_6]DMSO): δ = 144.2 (C=C), 104.1 (C=N), 65.0 (OEt_2), 15.3 (OEt_2), 2.1 ($SiMe_3$), 0.4 ($SiMe_3$) ppm.

Synthesis of Me_3SiCN_2Li·TMEDA (9): *n*BuLi (2.5 mL, 1.6 M in hexanes, 4 mmol) was added to a TMEDA (0.9 mL, 6 mmol) solu-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion of **1-H** (2 mL, 2 M in hexanes, 4 mmol) at −78 °C. The resultant orange solution was frozen in liquid nitrogen and then kept at −25 °C. Crystals of **9** were afforded after storage for 24 hours at this temperature. Yield 500 mg (53%), m.p. 122−124 °C. $C_{10}H_{25}LiN_4Si$ (236): calcd. C 50.82, H 10.66, N 23.70; found C 50.56, H 10.79, N 23.84. IR (Nujol): $\tilde{\nu}$ = 2129 cm^{-1} w (C=N=N sym. str.), 2042 s (C=N=N asym. str.), 835 m [$SiMe_n$ (n = 3)[38] str.], after air exposure 2171 w (C=N=N sym. str.), 2092 m (C=N=N asym. str.). ^1H NMR (400 MHz, [D_6]DMSO): δ = 2.27 (s, 4 H, CH_2), 2.11 (s, 12 H, NMe), −0.18 (s, 9 H, Me) ppm. ^{13}C NMR (100 MHz, [D_6]DMSO): δ = 104.1 (C=N), 57.0 (TMEDA), 45.6 (TMEDA), 0.3 ($SiMe_3$) ppm.

Synthesis of PhNNNC(Me_3Si)C(SLi·$^3/_2$THF) (10): nBuLi (1.25 mL, 1.6 M in hexanes, 2 mmol) was added to a THF (3.0 mL) solution of **1-H** (1 mL, 2 M in hexanes, 2 mmol) at −78 °C whereupon the solution was treated with phenyl isothiocyanate (PhNCS) (0.24 mL, 2 mmol). The orange precipitate formed on allowing the solution to warm to room temperature was dissolved at reflux and the reaction mixture was then cooled slowly to room temperature. After 1 day needles of PhNNNC(Me_3Si)C(SLi·$^3/_2$THF) (**10**) were deposited. Yield 225 mg (31%), m.p. > 116−118 °C (decomp.). $C_{34}H_{52}Li_2N_6O_3S_2Si_2$ (726): calcd. C 56.17, H 7.21, N 11.56; found C 55.82, H 7.40, N 10.46. IR (Nujol): $\tilde{\nu}$ = 2116 cm^{-1}, 2044, 1600, 1499, 1402, 1378, 839 m [$SiMe_n$ (n = 3)[38] str.], after air exposure 2053, 2028, 1625 br (C=C str.), 1499. ^1H NMR spectroscopy (400 MHz, [D_8]THF): δ = 8.12 (m, 2 H, Ph), 7.30 (m, 2 H, Ph), 7.17 (tt, 1 H, Ph), 3.59 (m, 6 H, THF), 1.75 (m, 6 H, THF), 0.33 (s, 9 H, Me) ppm. ^{13}C NMR (100 MHz, [D_8]THF): δ = 158.7 (C−S), 143.1 (C−Si), 140.7, 129.9, 128.2, 126.5, 126.1, 125.4 (Ph), −0.8 (Me) ppm.

Synthesis of BzNNNC(Me_3Si)C(SLi·2THF) (11): nBuLi (1.25 mL, 1.6 M in hexanes, 2 mmol.) was added to a THF (2.0 mL) solution of **1-H** (1 mL, 2 M in hexanes, 2 mmol) at −78 °C after which the solution was treated with benzyl isothiocyanate (BzNCS) (0.27 mL, 2 mmol). The orange precipitate formed on allowing the solution to warm to room temperature dissolved at reflux. The reaction mixture was then allowed to cool slowly to room temperature whereupon it was stored for 2 days, affording crystals of BzNNNC(Me_3Si)C(SLi·2THF) (**11**). Yield 256 mg (31%), m.p. > 168−170 °C (decomp.). $C_{20}H_{32}LiN_3O_2SSi$ (413): calcd. C 58.08, H 7.80, N 10.16; found C 57.15, H 7.76, N 10.39. IR (Nujol): $\tilde{\nu}$ = 1720 cm^{-1} w, 1403, 1217, 917, 841 [$SiMe_n$ (n = 3)[38] str.], after air exposure 1719 w, 1625 br (C=C stretch). ^1H NMR (400 MHz, [D_8]THF): δ = 7.28 (d, 2 H, Ph), 7.13 (m, 2 H, Ph), 7.08 (tt, 1 H, Ph), 5.35 (s, 2 H, CH_2), 0.29 (s, 9 H, Me) ppm. ^{13}C NMR (100 MHz, [D_8]THF): δ = 160.4 (C−S), 141.5 (C−Si), 140.2, 129.0, 128.5, 127.2 (Ph), 48.8 (CH_2), −0.8 (Me) ppm.

Preparation of BzNNNC(Me_3Si)C(SLi·TMEDA) (12): (a) nBuLi (1.25 mL, 1.6 M in hexanes, 2 mmol) was added to an OEt_2 (2.0 mL) solution of **1-H** (1 mL, 2 M in hexanes, 2 mmol) at −78 °C. BzNCS (0.27 mL, 2 mmol) was then added to the chilled solution, affording a clear yellow solution at room temperature. This was heated to reflux whereupon TMEDA (0.3 mL, 2 mmol) was added. Storage of the resultant solution for 2 days at room temperature afforded crystals of BzNNNC(Me_3Si)C(SLi·TMEDA), **12**.

(b) nBuLi (1.25 mL, 1.6 M in hexanes, 2 mmol) was added to a THF (1.8 mL) solution of **1-H** (1 mL, 2 M in hexanes, 2 mmol) at −78 °C. BzNCS (0.27 mL, 2 mmol) was then added to the chilled solution, affording a yellow precipitate at room temperature. The mixture was heated to reflux and TMEDA (0.3 mL, 2 mmol) was added, providing an orange solution. Storage of the resultant solution for 2 days at room temperature afforded crystals of **12**: Yield 154 mg (20%; route a), 62 mg (8%; route b), m.p. > 163−165 °C (decomp.). $C_{18}H_{32}LiN_5SSi$ (385): calcd. C 56.07, H 8.37, N 18.16; found C 55.99, H 8.94, N 21.43. IR (Nujol, cm^{-1}): $\tilde{\nu}$ = 1735, 1403, 1377, 842 [$SiMe_n$ (n = 3)[38] str.], after air exposure 1734, 1627 br (C=C str.), 1377. ^1H NMR (400 MHz, [D_8]THF): δ = 7.52 (d, 2 H, Ph), 7.17 (m, 2 H, Ph), 7.10 (tt, 1 H, Ph), 5.66 (s, 2 H, CH_2), 2.32 (s, 8 H, TMEDA), 2.17 (s, 24 H, TMEDA), 0.32 (s, 9 H, Me) ppm. ^{13}C NMR (100 MHz, [D_8]THF): δ = 159.9 (C−S), 140.1 (C−Si), 139.7, 128.5, 127.4, 126.0 (Ph), 57.8 (TMEDA) 47.8 (CH_2), 45.3 (TMEDA), −1.6 (Me_3Si) ppm.

Synthesis of PhNHCSCHNN (13): nBuLi (0.75 mL, 1.6 M in hexanes, 1.2 mmol) was added to an OEt_2 (10.0 mL) solution of **1-H** (0.6 mL, 2 M in hexanes, 1.2 mmol) at 0 °C. After stirring for 20 minutes PhNCS (0.12 mL, 1.2 mmol) was added to the chilled solution and the mixture stirred for a further 2 hours at this temperature. The solution was allowed to warm to room temperature and NH_4Cl (20 mL) was added. The resultant mixture was extracted with OEt_2 (2 × 10 mL) washed with water (2 × 10 mL) and dried ($MgSO_4$). Removal of excess solvent afforded **13** as a white powder. Yield 160 mg (75%), m.p. > 170−172 °C (decomp.). $C_8H_7N_3S$ (177): calcd. C 54.22, H 3.98, N 23.71; found C 53.49, H 5.43, N 21.05. IR (Nujol, cm^{-1}): $\tilde{\nu}$ = 3411, 3245 w, 3195 w (N−H str.), 1715, 1597, 1573 (C=N str.). ^1H NMR (400 MHz, [D_6]DMSO): δ = 10.42 (s, 1 H, N−H) 8.90 (s, 1 H, N=C−H), 7.65 (d, 2 H, Ph), 7.32 (m, 2 H, Ph), 7.00 (t, 1 H, Ph), 2.32 (s, 8 H, TMEDA), 2.17 (s, 24 H, TMEDA), 0.32 (s, 9 H, Me) ppm. ^{13}C NMR (100 MHz, [D_6]DMSO): δ = 164.3 (N=C(N)−S), 144.1 (S−C(H)=N), 140.8, 129.1, 121.9, 117.4 (Ph) ppm.

X-ray Crystallography: Data to check the unit cell of (**7**)$_2$·OEt_2 ($C_{68}H_{160}Li_8N_{18}O_7Si_{10}$, monoclinic, space group $C2/m$, a = 23.05, b = 15.77, c = 15.05 Å, β = 101.9°) were collected on a Rigaku R-Axis II imaging plate diffractometer[39] at 200(2)K using graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). This compared with the previously published[17a] unit cell and so the full data were not collected. Data for **9** were collected on a Rigaku R-Axis II imaging plate diffractometer using 45 frames, each frame covering a 4° oscillation with an exposure time of 30 minutes per frame, in each of four orientations. Data for **11** were collected by the ω/2θ method on a Rigaku AFC-7R four circle diffractometer[39] and data for **12** were collected on a Stoe−Siemens four circle diffractometer. All structures were solved by direct methods[40] and subsequent Fourier difference syntheses and refined by full-matrix least-squares[41] on F^2 with anisotropic thermal parameters for Li, N, Si, and most C atoms. A riding model with idealised geometry was employed for H-atom refinement. For **9**, one terminal methyl group of a TMEDA molecule and three of the $SiMe_3$ groups showed positional disorder with respect to the position of the C atoms and were refined isotropically over two different sites with partial occupancies. Crystallographic data for **9**, **11** and **12** are given in Table 5. CCDC-207850 (**9**), -207849 (**11**), and -207848 (**12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Methods: Preliminary geometry optimisation calculations[20] based on XCN_2Li·nL (X = H_3Si, Me_3Si; n = 0, 1, 2; L = OEt_2, THF) were done using the 6-31G* basis set[22] at the HF level. A frequency analysis was performed on the most stable conformation of each structure and the geometry was refined using

DFT methods (B3LYP/6-311G**).[21,22] The structural parameters reported here were taken from the DFT calculations while the electronic energy of the DFT calculation was modified by the scaled (0.91) ZPE correction taken from the HF calculation. Geometries modelled are shown in Figure 5 [XCN_2Li (X= H_3Si, Me_3Si), Me_3SiCN_2Li·L (L = OEt_2, THF)] and Figure 6 [Me_3SiCN_2Li·2 L (L = OEt_2, THF), (Me_3SiCN_2Li·TMEDA)]. The results are summarised in Table 1 and selected computed bonding parameters are given in Tables E1 and E2 (Supporting Information, see footnote on page 1 of this article).

Acknowledgments

We gratefully thank the U. K. EPSRC (R. H., M. A. H.) for financial support and Dr. Neil Feeder for collecting X-ray data for $(\mathbf{7})_2$·OEt_2, **9**, **11**, and **12**.

Heteroaromatic-Substituted Mono- and Bis(triimidosulfonates)

Carola Selinka[a] and Dietmar Stalke*[a]

Dedicated to the memory of Ron Snaith

Keywords: Heterocycles / Lithium / N ligands / S ligands / Sulfur

In this paper we present the syntheses and structures of the metal complexes $[(THF)_2Li\{(NtBu)_3S(C_4H_3NMe)\}]$ (**1**), $[(tmeda)Li\{(NtBu)_3S(C_4H_3S)\}]$ (**2**), $[(tmeda)Li\{(NtBu)_3S(C_4H_3Se)\}]$ (**3**), $[(THF)_4Li_2\{(tBuN)_3S(SC_4H_2)S(NtBu)_3\}]$ (**4a**) and $[(tmeda)_2Li_2\{(tBuN)_3S(SC_4H_2)S(NtBu)_3\}]$ (**4b**). The lithium salts form non-aggregated soluble molecules rather than infinite insoluble solid-state lattices like their oxo analogues. The metals are *N*,*N*-chelated rather than tripodally coordinated. Although the S–N bond to the one pendant spectator *t*BuN group is considerably shorter than in the metal-coordinated *t*BuN groups, conjugation of the S–N bonds to the heteroaromatic rings could not be deduced unambiguously from the experimental structures.

Introduction

Arylsulfonates ($ArSO_2^-$) and arylsulfamides $[ArS(NR)_2^-]$ are used in various fields of modern chemistry. Sulfonic acids (RSO_2OH) and their metal salts (RSO_3M) are versatile catalysts used on a large scale for industrial cyclization and polymerization processes. A catalytic transfer-hydrogenation process is provided by sulfonates.[1] The preparation of inclusion compounds based on lamellar host frameworks constructed from guanidinium and organodisulfonate ions has been reported.[2] With this and the recent progress in isoelectronic replacement of oxygen atoms in simple *p*-block element oxoanions in mind, we aimed to synthesise aryltriimidosulfonates $ArS(NR)_3^-$ with Ar = $MeNC_4H_3$, SC_4H_3 and SeC_4H_3. To envisage oligo- or even polymeric molecules two $S(NR)_3^-$ moieties were linked by a 2,5-disubstituted thiophenyl ring. Thiophenesulfonamides and their alkali metal or non-toxic acid addition salts are useful as insecticides, acaricides and larvicides.[3] Molecules like 5-substituted thiophene-2-sulfonamides are promising drugs that are currently being used as carbonic anhydrase inhibitors for the treatment of glaucoma.[4] This industrial relevance combined with the recent progress in isoelectronic replacement of oxygen atoms in simple *p*-block element oxoanions[5] encouraged us to generate the unprecedented aryltriimidosulfonates $ArS(NR)_3^-$. Substitution of the oxygen atom in the aryloxoanions $ArSiO_3^{3-}$, $ArPO_3^{2-}$, $ArAsO_3^{2-}$, $ArSbO_3^{2-}$, $ArPO_2^{2-}$, $ArSO_2^-$, $ArSeO_3^-$ or $ArTeO_3^-$ by an NR imido group gives the polyimido anions $ArP(NR)_2^{2-}$, $ArS(NR)_2^-$, $ArSi(NR)_3^{3-}$, $ArP(NR)_3^{2-}$ and $ArAs(NR)_2^{2-}$.[6] However, to the best of our knowledge, related species with Sb, Se, Te and S^{VI} have not yet been reported in the literature. By contrast to the simple oxoanions, these species should be soluble because they form contact ion pairs in cage complexes surrounded by a lipophilic layer of organic residues rather than infinite solid-state lattices by multiple oxygen/cation contacts. Furthermore, their redox potential and coordination behaviour is tuneable by variation of the organic substituents.

To date the *S*-alkyl-[7] $[MeS(NR)_2]^-$ and *S*-phenyl diimidosulfinates[8] $[PhS(NR)_2]^-$ and *S*-alkyltriimidosulfonates[9] $[MeS(NR)_3]^-$ have been studied in detail. The CH-acidic organic substituent at the sulfur atom in the first and the latter species can be deprotonated to give dianionic alkylenediimidosulfites[10] and alkylenetriimidosulfates[11] in which the CR_2 group replaces the oxygen or NR group isoelectronically. They can both be rationalized as S^{IV}- and S^{VI}-ylides. Until recently the direct reaction of thiols with chloroamines or, better, bromoamines was the only known synthetic access to *S*-alkyltriimidosulfonates.[12] In this paper we present a new straightforward synthetic route which involves the nucleophilic addition of aryllithiums to the formal S=N double bond of sulfur triimides.[13] Presumably due to the steric crowding in the products, only sterically less-demanding alkyls could be added (e.g. MeLi) to the few structurally known sulfur triimides $[S(NR)_3$, R = *t*Bu, $SiMe_3$).[14] Addition reactions with *n*BuLi and *t*BuLi failed. In principle, the resulting $[MeS(NR)_3]^-$ anion possesses C_{3v} symmetry prompting feasible tripodal cap-shaped metal coordination. While the triimidosulfite[15] $S(NR)_3^{2-}$ and the triimidosulfate[16] $OS(NR)_3^{2-}$ dianions show this

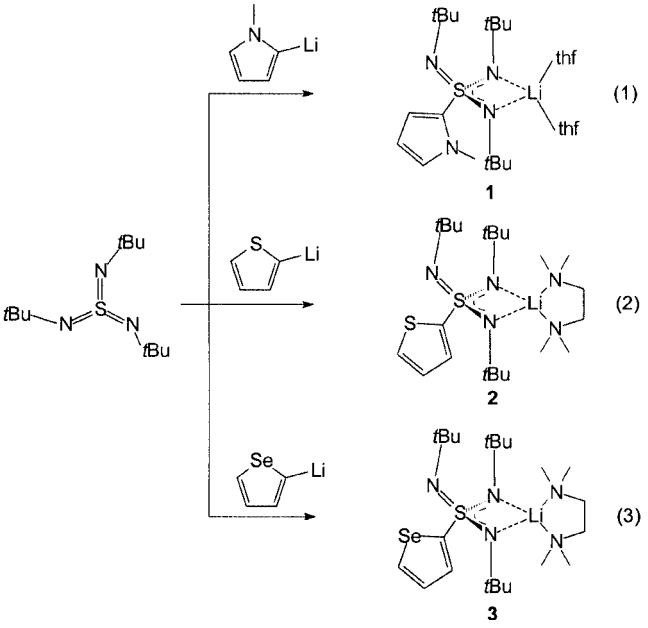
anticipated tripodal behaviour even in mixed-metal complexes,[17] only (*N*,*N*)-SN_2 chelation has been observed for the $[MeS(NR)_3]^-$ monoanion.[18]

In this paper we aimed both to evaluate the reactivity of the sulfur triimide towards organolithium reagents and to introduce an additional coordination site in the S-bound organic substituent. Experimental charge-density investigations of $S(NtBu)_3$ suggested that only flat carbanions are suitable for addition across the polar S−N bond as the reactive surface at $\nabla^2\rho(\mathbf{r}) = 0$ shows holes in the SN_3 plane on the NSN bisectors and maxima above and below the central sulfur atom. Hence, the carbanion needs to approach the electrophilic sulfur along the bisectors and slot in between the *t*BuN groups.[19] Thus we decided to react $S(NtBu)_3$ with lithiated furan, pyrrole, thiophene and selenophene.

Results and Discussion

[Li{(N*t*Bu)$_3$SAr}] Complexes

The aromatic heterocycles were lithiated first with BuLi and then reacted at low temperatures with a stoichiometric amount of the sulfur triimide. Although addition reactions of organolithiums like *n*BuLi and *t*BuLi to $S(NtBu)_3$ failed in the past, presumably because of steric crowding in the sulfonates, methylpyrrolyl-, thiophenyl-, and selenophenyllithium react smoothly to give the related products $[(THF)_2Li\{(NtBu)_3S(C_4H_3NMe)\}]$ (**1**), $[(tmeda)Li\{(NtBu)_3S(C_4H_3S)\}]$ (**2**), and $[(tmeda)Li\{(NtBu)_3S(C_4H_3Se)\}]$ (**3**). Due to the reactivity and thermal instability of 2-lithiofuran all attempts to add it to sulfur triimide failed. Upon addition of $S(NtBu)_3$ to $Li(C_4H_3O)$ the reaction mixture polymerises instantaneously. The organic substituents (C_4H_3NMe), (C_4H_3S) and (C_4H_3Se) bond in the 2-position to the electropositive sulfur while the lithium cation is coordinated to the nitrogen atoms (Scheme 1). This reactivity is not surprising in view of the S^{2+} charge and the sp^3-hybridization of the nitrogen atoms.[20]



Scheme 1. Preparation of $[(THF)_2Li\{(NtBu)_3S(C_4H_3NMe)\}]$ (**1**), $[(tmeda)Li\{(NtBu)_3S(C_4H_3S)\}]$ (**2**), and $[(tmeda)Li\{(NtBu)_3S(C_4H_3Se)\}]$ (**3**)

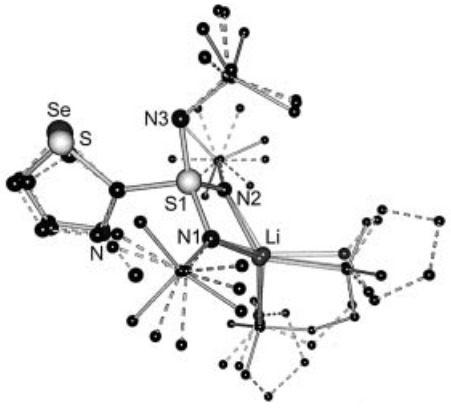


Figure 1. Superposition plot of the solid-state structures of **1**−**3**

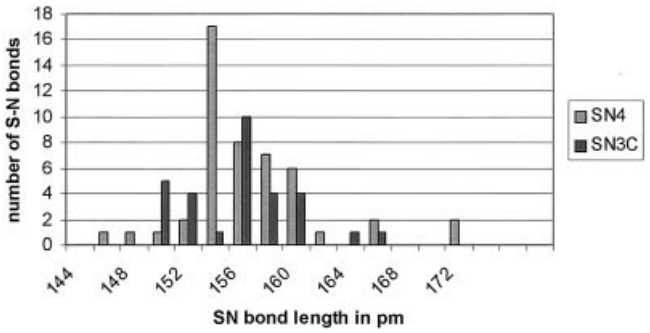
Structures of 1−3

The solid-state structures of the lithium *S*-aryl-tri(*tert*-butyl)triimidosulfonates **1**, **2** and **3** (Figure 1) show that neither tripodal coordination nor additional coordination of the heteroatom in the aromatic five-membered ring to the lithium cations is accomplished. Like in the coordination of $PhS(NSiMe_3)_2^-$ [8] and $PhCCS(NtBu)_3^-$,[18] the ligand coordinates one hemisphere of the metal, leaving the two THF donor molecules coordinated to the other in **1**. In **2** and **3** the tetragonal coordination sphere is completed by one tmeda molecule each. Like the methyl derivatives, these anions coordinate in a bidentate manner with only two nitrogen atoms orientated towards the metal. No further coordination of the third *t*BuN group could be detected. In all three complexes one *tert*-butyl group is turned in the direction of the N_3 face, away from the heteroaromatic group, so one nitrogen atom is blocked from conceivable metal coordination. The methyl group of the heteroaromatic ring in **1** points towards the chelated lithium atom while the sulfur and selenium atoms in the heterocycles of **2** and **3** point towards the pendant *t*BuN group. The negative charge is distributed over both nitrogen atoms of the chelating SN_2 unit, as indicated by the almost ideal planar arrangement of the C1−N1−S1−N2−C5−Li1 moiety (mean deviation from best plane only 4.6 pm for **1**, 8.31 pm for **2** and 8.45 pm for **3**) and the S−N bond lengths, half-way between an S−N single and an S−N double bond [**1**: av. 158.5(6) pm; **2**: av. 157.7(4) pm; **3**: av. 157.91(30) pm]. The nitrogen atoms of the pendant *t*BuN group show significantly shorter S−N distances [**1**: 153.6(3) pm; **2**: 154.3(2) pm; **3**: 154.72(14) pm]. They are similar to the S=N double bonds in $S(NtBu)_2$ (153.2 pm),[21] but notably longer than in $S(NtBu)_3$ (151.5 pm).[14] In general, the S−N bond lengths in **1**, **2** and **3** match the standard range for S^{VI}−N

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



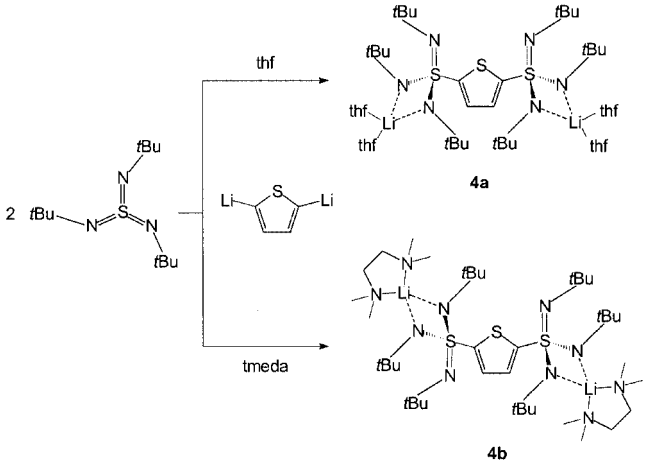
Scheme 2. $S^{VI}-N$ bond lengths from the CCDC (dark: SN_3C compounds; light: SN_4 compounds).

bond lengths found in the CCDC (Scheme 2).[22] The S−N bond lengths of non-coordinating nitrogen atoms are in the range of 150−156 pm, and the S−N bond lengths of coordinating nitrogen atoms are in the range of 156−168 pm. The S−C bond lengths of 179.6(3) pm in **1**, 179.2(3) pm in **2** and 179.29(19) pm in **3** are only marginally longer than a typical S−C(sp^2) single bond of 176 pm.[23] The Li−N bond lengths of about 200 pm match those normally observed in lithium amides.[24] The geometrical features of **1**, **2** and **3** (Table 1) reveal that the mean metric parameters of the $ArS(NtBu)_3^-$ anion (i.e. S−N and S−C-distances, N−S−N and S−N−C-angles, etc.) are almost independent of the nature of the aromatic system. In addition, the delocalisation in the heteroaromatic ring seems not to be perturbed by the metalated $S(NtBu)_3$ moiety.

In all known metal complexes the alkyltriimidosulfonate chelates as a bidentate ligand,[18] although tripodal coordination occurs with the triimidosulfite[13,15] and the oxotriimidosulfate $OS(NtBu)_3^{2-}$.[15] In these dianions, tripodal coordination is facilitated by all the *tert*-butyl groups pointing towards the sulfur atom, leaving the lone pairs of the nitrogen atoms pointing in the opposite direction. A comparison with the tripodal $OS(NtBu)_3^{2-}$ dianion proves that tripodal coordination is primarily caused by the higher negative charge than by steric or electronic effects:[18] for a single negative charge in the triimidosulfonates it is sufficient to be distributed over two nitrogen atoms rather than over all three. To stabilise a double negative charge in the triimidosulfite and the oxotriimidosulfate three S-bound nitrogen atoms are required.

[Li{(N*t*Bu)$_3$S(C$_4$H$_3$S)S{(N*t*Bu)$_3$}Li] Complexes

Thiophene was lithiated twice with BuLi and subsequently reacted with two equivalents of sulfur triimide. Despite the anticipated steric strain in the disubstituted product the reaction works under mild conditions. The non-optimised yields for both complexes were about 65%. Dependant on the donating solvent used in the reaction, two different complexes $[(THF)_4Li_2\{(tBuN)_3S(SC_4H_2)S(NtBu)_3\}]$ (**4a**), and $[(tmeda)_2Li_2\{(tBuN)_3S(SC_4H_2)S(NtBu)_3\}]$, (**4b**) could be obtained (Scheme 3).



Scheme 3. Preparation of $[(THF)_4Li_2\{(tBuN)_3S(SC_4H_2)S(NtBu)_3\}]$ (**4a**), and $[(tmeda)_2Li_2\{(tBuN)_3S(SC_4H_2)S(NtBu)_3\}]$ (**4b**)

Crystal Structures of 4a and 4b

Each central thiophenyl ring is 2,5-disubstituted by a triimidosulfite group coordinated to a single lithium atom. Like in the complexes **1**−**3** only two nitrogen atoms of each (tBuN)$_3$S moiety chelate the metal while the third tBuN group acts as a pendant spectator. The preferred tetragonal coordination of each lithium cation is completed by two THF molecules (**4a**) or one tmeda molecule (**4b**; Figure 2).

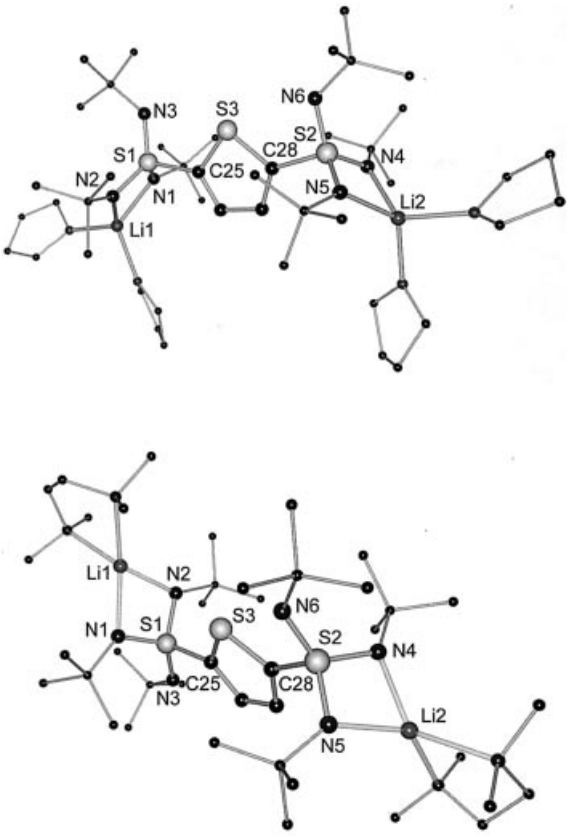

Figure 2. Solid-state structures of [(THF)$_4$Li$_2${(tBuN)$_3$S(SC$_4$H$_2$)S(NtBu)$_3$}] (**4a**; top), and [(tmeda)$_2$Li$_2${(tBuN)$_3$S(SC$_4$H$_2$)S(NtBu)$_3$}] (**4b**; bottom); selected bond lengths [pm] and angles [°] are compiled in Table 2

Although **4a** and **4b** are isostructural they differ in the arrangement of the NtBu groups. In **4a** the uncoordinated NtBu groups are pointing exactly in the same direction toward the thiophene ring sulfur atom S3, while in **4b** they are located opposite to each other like the lithium atoms. The S1−N3 and the S2−N6 bonds of both molecules are in the same plane as the thiophene ring. In addition, the N1−S1−N2 and the N4−S2−N5 bisectors are almost coplanar with the thiophene plane.

The negative charge in the (tBuN)$_3$S sulfonate unit is distributed over both nitrogen atoms of the chelating N−S−N unit [(S−N(av.): **4a** 157.2(5); **4b** 156.7(3) pm], and therefore the S−N bonds are equal to those in the monosubstituted aryltriimidosulfonates **1**−**3**. The S−N bonds of the pendant NtBu group are much shorter than the other S−N bonds [S−N(av.): **4a** 151.4(3); **4b** 153.8(5) pm]. Most remarkably, the S1−N3 bond in **4b** of 149.4(3) pm is the shortest S−N bond ever observed in SN$_3$C moieties (see Scheme 2), possibly due to hyperconjugation[25] to the SC$_4$ thiophenyl perimeter, as it is the only one in-plane and next to a C=C bond in the C$_4$S perimeter. Donation of the electron density via p(N3) → σ*(C25) in the S(NR)$_3^-$ moiety (anionic or negative hyperconjugation[25d]) would result in shortening of the S1−N3 bond and an elongation of the S1−C25 bond. The latter, however, could not be confirmed experimentally. Clearly NBO and NRT analysis are required to elucidate that problem. In [(THF)Li$_2${O$_2$S(NtBu)$_2$}]$_8$·2LiOH·2LiCl [av. S−N: 155.0(4) pm] and [{(THF)Li}$_2${O$_2$S(NtBu)$_2$]·(THF)LiCl}$_2$ [av. S−N: 155.7(2) pm] the S−N bonds are about 6 pm longer.[26] The S−C$_{ipso}$ distances in **4a** and **4b** of 180.1(5) and 178.8(4) pm, respectively, are considerably longer than the S−C bond in [(tmeda)$_2$Li$_2${(CH$_2$)S(NtBu)$_3$}] of 172.5(2) pm (see also Table 2).[11]

Table 2. Selected bond lengths [pm] and angles [°] of [(THF)$_4$Li$_2${(tBuN)$_3$S(SC$_4$H$_2$)S(NtBu)$_3$}] (**4a**), and [(tmeda)$_2$-Li$_2${(tBuN)$_3$S(SC$_4$H$_2$)S(NtBu)$_3$}] (**4b**)

Conclusions from the Structural Comparisons

Comparison of the structures of **1**, **2** and **3** reveals that the geometrical features of the ES(NtBu)$_3^-$ unit (e.g. S−N distances, N−S−N and N−S−C angles) are almost independent of the nature of the heteroaromatic substituent and vice versa. The S or Se atom in the heteroaromatic ring is not involved in lithium coordination. Linkage of two sulfonate units via an S-heteroaromatic ring is possible, but conjugation of the S−N bonds to the SC$_4$ perimeter seems unlikely as the S−C and C−C bonds match the range of the related bond lengths in the parent thiophene. The negative charge in each sulfonate unit is distributed over both

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nitrogen atoms of the chelating N−S−N unit; the third N*t*Bu group remains non-coordinating. Tripodal metal coordination of the SN_3 unit is necessary for a double negative charge in the $S(NR)_3^{2-}$ triimidosulfite and the oxotriimidosulfate $OS(NR)_3^{2-}$, whereas for a single negative charge in $RS(NR)_3^-$ *N*,*N*-chelation seems to be sufficient.

Experimental Section

All manipulations were performed under inert-gas atmosphere of dry N_2 with Schlenk techniques or in an argon glove box. All solvents were dried over Na/K alloy and distilled prior to use. NMR spectroscopic data were obtained on either a Bruker AMX 400 or a Bruker AMX 300 instrument in the FT mode in C_6D_6 solvent. Elemental analyses were performed by the Microanalytisches Labor der Universität Würzburg. $S(NtBu)_3$ was obtained as described previously in ref. 15.

[(THF)$_2$Li{(H$_3$CNC$_4$H$_3$)S(N*t*Bu)$_3$}] (1): A solution of butyllithium in hexane (1.6 M, 2.44 mmol, 1.52 mL) was added dropwise to a solution of *N*-methylpyrrole (2.44 mmol, 0.2 g) in 3.5 mL THF at −78 °C. The reaction mixture was allowed to warm to room temperature and finally refluxed gently for 30 min. *N*,*N*′,*N*′′-Tris(*tert*-butyl)sulfur triimide (2.44 mmol, 0.6 g) was added to the solution and stirred for 12 h. All volatile material was removed under vacuum and the residue was dissolved in 3 mL of hexane and 1 mL of THF. Crystallisation at −36 °C gave colourless crystals. Yield: 0.76 g (65%). ^{1}H NMR (400 MHz, C_6D_6): δ = 1.31 [q, 4 H, (CH_2CH$_2$)$_2$O], 1.44 [s, 18 H, C(CH_3)$_3$], 1.50 [s, 9 H, C(CH_3)$_3$], 3.47 [t, 4 H, (CH$_2$CH_2)$_2$O], 3.52 (s, 3 H, NCH_3), 6.02 (t, 1 H, H2), 6.19 (t, 1 H, H4), 6.83 (q, 1 H, H3) ppm. ^{7}Li (155 MHz, C_6D_6): δ = 0.87 ppm. ^{13}C NMR (100 MHz, C_6D_6): δ = 25.48 [(*C*H$_2$CH$_2$O)$_2$], 30.57 [C(*C*H$_3$)$_3$], 33.11 [C(*C*H$_3$)$_3$], 37.05 (N-*C*H$_3$), 53.83 [*C*(CH$_3$)$_3$], 54.82 [*C*(CH$_3$)$_3$], 68.23 [(CH$_2$*C*H$_2$O)$_2$], 105.76 (C3), 114.91 (C4), 126.00 (C2), 128.28 (C1) ppm. $C_{25}H_{49}LiN_4O_2S$ (476.37): calcd. C 62.99, H 10.36, N 11.75, S 6.73; found C 60.69, H 9.6, N 12.77, S 7.12. Mp.: 60 °C.

[(tmeda)Li{(SC$_4$H$_3$)S(N*t*Bu)$_3$}] (2): Thiophene (5 mmol, 0.42 g) was added slowly to a mixture of tmeda (5 mmol, 0.58 g), 2 mL of diethyl ether and butyllithium in hexane (1.6 M, 5 mmol, 3.125 mL) and stirred for 30 min. A solution of *N*,*N*′,*N*′′-tris(*tert*-butyl)sulfur triimide (4.5 mmol, 1.1 g) in 2 mL of hexane was added to the solution and stirred for 12 h. After the small amount of precipitate was filtered off, 5 mL of hexane and 1.5 mL of THF were added. The solution was stored at +6 °C and after 1 day colourless crystals were obtained. Yield: 1.60 g (70%). ^{1}H NMR (400 MHz, C_6D_6): δ = 1.42 [s, 18 H, C(CH_3)$_3$], 1.74 [s, 9 H, C(CH_3)$_3$], 1.82 (s_{br}, 4 H, Me$_2$NCH_2CH_2NMe$_2$), 1.99 (s, 12 H, *Me*$_2$NCH$_2$CH$_2$N*Me*$_2$), 6.80, 6.95, 7.26 (C$_4$*H*$_3$S) ppm. ^{7}Li (155 MHz, C_6D_6): δ = 0.64 (s) ppm. ^{13}C NMR (100 MHz, C_6D_6): δ = 33.02 [C(*C*H$_3$)$_3$], 33.83 [C(*C*H$_3$)$_3$], 46.72 (*Me*$_2$NCH$_2$CH$_2$N*Me*$_2$), 51.82 [*C*(CH$_3$)$_3$], 56.80 (Me$_2$N*C*H$_2$*C*H$_2$NMe$_2$) ppm. $C_{22}H_{46}LiN_5S_2$ (451.34): calcd. C 58.50, H 10.26, N 15.50, S 14.20; found C 55.63, H 9.45, N 14.11, S 13.01. Mp.: 141 °C.

[(tmeda)Li{(SeC$_4$H$_3$)S(N*t*Bu)$_3$}] (3): A solution of selenophene (3.8 mmol, 0.5 g) in 4.77 mL of hexane was added dropwise to a solution of tmeda (3.8 mmol, 0.45 g) and butyllithium in hexane (1.6 M, 3.8 mmol, 2.4 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred for 1 h. *N*,*N*′,*N*′′-Tris(*tert*-butyl)sulfur triimide (3.8 mmol, 0.94 g) in 1 mL hexane was added at 0 °C. After 12 h stirring at room temperature, the small amount of precipitate was filtered off. Crystallisation from the resulting solution at +6 °C yielded colourless crystals after 1 day. M = g/mol. (yield 1.74 g, 91%). ^{1}H NMR (400 MHz, C_6D_6): δ = 1.45 [s, 18 H, C(CH_3)$_3$], 1.72 (s_{br}, 4 H, Me$_2$NCH_2CH_2NMe$_2$), 1.80 [s, 9 H, C(CH_3)$_3$], 1.97 (s, 12 H, *Me*$_2$NCH$_2$CH$_2$N*Me*$_2$), 7.15 (s_{br}, 1 H, H2), 7.34 (s_{br}, 1 H, H4), 7.66 (dd, 1 H, H3) ppm. ^{7}Li NMR (155.5 MHz, ext. sat. LiCl solution): δ = 0.62 (s) ppm. ^{13}C NMR (100 MHz, C_6D_6): δ = 33.69 [C(*C*H$_3$)$_3$], 33.98 [C(*C*H$_3$)$_3$], 46.71 (*Me*$_2$NCH$_2$CH$_2$N*Me*$_2$), 51.82 [*C*(CH$_3$)$_3$], 53.17 [*C*(CH$_3$)$_3$], 56.75 (Me$_2$N*C*H$_2$*C*H$_2$NMe$_2$), 127.87, 128.11, 128.35, 129.06 (*C*$_4$H$_3$Se) ppm. $C_{22}H_{46}LiN_5SSe$ (499.30): calcd. C 53.00, H 9.30, N 14.05, S 6.43; found C 49.21, H 8.57, N 13.62, S 6.01. Mp.: 134 °C (dec).

[(THF)$_4$Li$_2${(*t*BuN)$_3$S(SC$_4$H$_2$)S(N*t*Bu)$_3$}] (4a): Thiophene (2.08 mmol, 0.18 g) was added slowly to a mixture of tmeda (4.15 mmol, 0.48 g), 2 mL of diethyl ether and butyllithium in hexane (1.6 M, 4.15 mmol, 2.60 mL) and stirred for 30 min. A solution of *N*,*N*′,*N*′′-tris(*tert*-butyl)sulfur triimide (4.15 mmol, 1.0 g) in 1 mL of hexane was added to the solution and stirred for 3 days. The suspension was dissolved by addition of 4 mL of THF and 1 day storage at +6 °C yielded yellow crystals. M = 875.28 g/mol. (yield 1.43 g, 84%). All spectroscopic and analytical data are virtually identical to those of the tmeda derivative **4b**.

[(tmeda)$_2$Li$_2${(*t*BuN)$_3$S(SC$_4$H$_2$)S(N*t*Bu)$_3$}] (4b): Thiophene (2.08 mmol, 0.18 g) was added slowly to a mixture of tmeda (4.15 mmol, 0.48 g), 2 mL of diethyl ether and butyllithium in hexane (1.6 M, 4.15 mmol, 2.60 mL) and stirred for 30 min. A solution of *N*,*N*′,*N*′′-tris(*tert*-butyl)sulfur triimide (4.15 mmol, 1.0 g) in 1 mL of hexane was added to the solution and stirred for 3 days. The white precipitate was filtered off. The clear reaction mixture was stored at +6 °C and after 1 day light-yellow crystals could be obtained. M = g/mol. (yield 1.46 g, 86%). ^{1}H NMR (400.13 MHz, C_6D_6): δ = 1.55 [s, 18 H, C(CH_3)$_3$], 1.77 (s, 4 H, Me$_2$NCH_2CH_2NMe$_2$), 1.83 [s, 9 H, C(CH_3)$_3$], 2.07 (s, 12 H, *Me*$_2$NCH$_2$CH$_2$N*Me*$_2$), 6.95, 7.34 (2s, 2 H, C$_4$*H*$_2$S) ppm. ^{7}Li NMR (155.5 MHz, ext. sat. LiCl solution): δ = 0.70 (s) ppm. ^{13}C NMR (100 MHz, C_6D_6): δ = 33.10 and 33.92 [C(*C*H$_3$)$_3$], 46.58 (*Me*$_2$NCH$_2$CH$_2$N*Me*$_2$), 51.91 [*C*(CH$_3$)$_3$], 53.58 [*C*(CH$_3$)$_3$], 55.03 (Me$_2$N*C*H$_2$*C*H$_2$NMe$_2$), 130.27, 130.69, 133.16, 148.89 (*C*$_4$H$_2$S). $C_{40}H_{88}Li_2N_{10}S_3$ (819.26): calcd. C 58.64, H 10.83, N 17.10, S 11.74; found C 55.33, H 10.42, N 15.54, S 10.98. Mp.: 152 °C (dec).

Crystal Structure Determinations: Crystal data for the structures **1**−**4b** are presented in Table 3. Data for structures were collected on a Bruker Apex CCD diffractometer at low temperature using oil-coated shock-cooled crystals[27] and Mo-K_α radiation (λ = 0.71073 Å). The structures were solved by direct methods using SHELXS 97.[28] The structures were refined by full-matrix least-squares procedures on F^2, using SHELXL 97.[29] All non-hydrogen atoms were refined anisotropically, and a riding model was employed in the refinement of the hydrogen atom positions. Data were corrected for absorption using SADABS2.[30] In complex **2** one disordered tmeda molecule (C20−C22) was refined to a split site occupancy factor of 0.51/0.49. In complex **4a** the disordered THF molecule (O4−C44) was refined to a split site occupancy factor of 0.51/0.32/0.17, and the *tert*-butyl groups to 0.51/0.49 (C2−C4), 0.67/0.33 (C14−C16) and 0.78/0.22 (C22−C24), respectively. In complex **4b** the disordered tmeda molecule (C32−C34) was refined to a split site occupancy factor of 0.67/0.33, and the *tert*-butyl groups to 0.85/0.15 (C5−C8) and 0.69/0.31 (C13−C16), respectively. In all these refinements bond length and similarity restraints were applied.

A Homologous Series of Base-Free Organo(alkaline-earth) Metallocenes: Synthesis and Molecular Structures of [1,2,4-$(SiMe_3)_3C_5H_2]_2$(Ca, Sr, Ba)

Melanie J. Harvey,[a] Keith T. Quisenberry,[a] Timothy P. Hanusa,*[a] and Victor G. Young Jr.[b]

Dedicated to the memory of Professor Ronald Snaith

Keywords: Alkaline-earth metals / Metallocenes / Solid-state structures

Bis[1,2,4-tris(trimethylsilyl)cyclopentadienyl] complexes [1,2,4-$(SiMe_3)_3C_5H_2]_2$Ae [$(Cp^{3Si})_2$Ae; Ae = Ca (**1**), Sr (**2**), Ba (**3**)] are isolated from the 2:1 reaction of K[Cp^{3Si}] and AeI_2 in diethyl ether. Under the same reaction conditions used for the heavier metallocenes, the corresponding $(Cp^{3Si})_2$Be compound was not formed, although calculations suggest that the beryllocene would be sterically feasible. Compound **1** crystallizes as a bent monomer from hexanes (ring centroid–Ca–ring centroid = 166.7°) with two η^5-Cp^{3Si} ligands on the calcium atom [Ca–C(av) = 2.63(2) Å]. Metallocene **2**, the first crystallographically characterized example of an unsolvated strontocene, is also isolated as a bent monomer (159.4°) from hexanes with two η^5-Cp^{3Si} ligands on the strontium atom [Sr–C(av) = 2.819(2) Å]. Compound **3** crystallizes on sublimation as a coordination dimer in which each barium atom is flanked by two η^5-Cp^{3Si} rings [Ba–C(av) = 3.01(2) Å] and one methyl group from a neighboring Cp′ ring; the intermolecular Ba···C(methyl)′ distance is 3.275(6) Å. The amount of bending observed in **1**–**3** and other Group-2 metallocenes varies with the metals, the steric bulk of the cyclopentadienyl ligands, and crystal packing effects, and is not easily predictable.

Introduction

A characteristic feature of nearly all base-free metallocenes of the heavy alkaline-earth (Ca, Sr, Ba) and lanthanide (Sm, Eu, Yb) elements is a distinctly "bent" geometry, with ring centroid−metal−ring centroid angles as small as 131°.[1−8] The non-linear structures are found in both the solid state and the gas phase,[9,10] and their origin is not easily explained on steric or electrostatic grounds alone. One analysis of the bending phenomenon found that a strongly linear correlation existed between metal−ring distances and the ring−metal−ring bending angles in decamethylmetallocenes of the alkaline-earth, lanthanide, and p-block elements;[8] larger metals (with longer M−C distances) were associated with greater bending angles. The distance/bending correlation partially reflects the fact that decamethylmetallocenes with long metal−ring distances can bend proportionally farther back before encountering appreciable van der Waals resistance between the methyl groups (Figure 1).

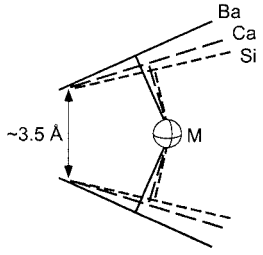

Figure 1. Origin of the strongly linear correlation between metal radius and bending angles in Cp^*_2M (M = Ae, Ln, Group 14) complexes; with longer M−C distances, greater bending is allowed before CH_3···CH_3′ repulsions on the "closed" side of the metallocene prevent further bending

With cyclopentadienyl rings less symmetrical than Cp*, the bending angle/metal radius relationship is less easily modeled. Although it can be expected that metallocenes with bulkier rings, i.e., [(*i*Pr)$_4C_5H]_2$(Ca, Ba), would be less bent than Cp_2M or Cp^*_2M complexes,[11] it is not simple to compare the relative bulkiness of cyclopentadienyl rings when both the number and sizes of the substituents are different. In addition, there are still many gaps within the series of structurally characterized metallocenes containing a particular cyclopentadienyl ligand; in fact, until this re-

port, there were no published crystallographic data for any base-free strontocene.

We have been examining the properties of 1,2,4-tris(trimethylsilyl)cyclopentadiene (HCp^{3Si})[12,13] as a sterically bulky ligand in s-block metal chemistry.[14,15] In conjunction with the previously reported structure of the substituted magnesocene [1,2,4-$(SiMe_3)_3C_5H_2]_2Mg$ [$(Cp^{3Si})_2Mg$],[16] a homologous series of unsolvated Group-2 metallocenes from Mg to Ba has now been synthesized and crystallographically authenticated. Such data provide a means for testing the strength of the M−C bond length/ring bending relationship when the metal radius is varied by nearly a factor of two (for 6-coordination, $r_{Mg^{2+}}$ = 0.72 Å; $r_{Ba^{2+}}$ = 1.35 Å).[17]

Results and Discussion

The bis[tris(trimethylsilyl)cyclopentadienyl]alkaline-earth metallocenes, $(Cp^{3Si})_2Ae$ (Ae = Ca, Sr, Ba), can be isolated from the 2:1 reaction of $K[Cp^{3Si}]$ and AeI_2 in diethyl ether [Equation (1)].

$$2\ K[Cp^{3Si}] + AeI_2 \xrightarrow{Et_2O} (Cp^{3Si})_2Ae + 2\ KI\downarrow \quad (1)$$

Ae = Ca (**1**), Sr (**2**), Ba (**3**)

The metallocenes were characterized with spectroscopic methods and X-ray crystallography, which supported the proposed formulations. The complexes are thermally stable and begin to sublime at temperatures ranging from 125 to 140 °C at between 10^{-5} and 10^{-7} Torr. These complexes must be formed in diethyl ether, since in the presence of even small amounts of THF, the mono(ring) complexes $(Cp^{3Si})AeI(THF)_n$ are isolated as the exclusive products.[15] Once formed, however, the complexes can be recrystallized as base-free metallocenes from THF solution. The hexakis(trimethylsilyl)metallocenes visibly decompose upon exposure to air after only a few seconds, turning from white to dark brown. In contrast, enhanced air stability has been reported for both the octa- and decaisopropylated alkaline-earth metallocenes.[18,19]

The magnesium compound $(Cp^{3Si})_2Mg$ was reported some time ago by Jutzi and co-workers.[16] Of the remaining Group-2 elements, only the radium and beryllium analogues remain unknown. We attempted to synthesize $(Cp^{3Si})_2Be$ with methods similar to those used recently to prepare $(Me_4C_5H)_2Be$ and Cp^*_2Be;[20] viz., the reaction of $BeCl_2$ and $K[Cp^{3Si}]$ in diethyl ether (3 d at room temperature) or in a 1:1 diethyl ether/toluene mixture at reflux for 3 d. The reaction at room temperature yielded only starting materials; the refluxed reaction mixture produced a black residue from which no metallocene was isolated.

Solid State Structures

$(Cp^{3Si})_2Ca$ (1)

A crystal of **1** grown from hexanes was used to determine its structure with X-ray crystallography. A summary of bond lengths and angles for **1** is given in Table 1. An ORTEP is provided in Figure 2.

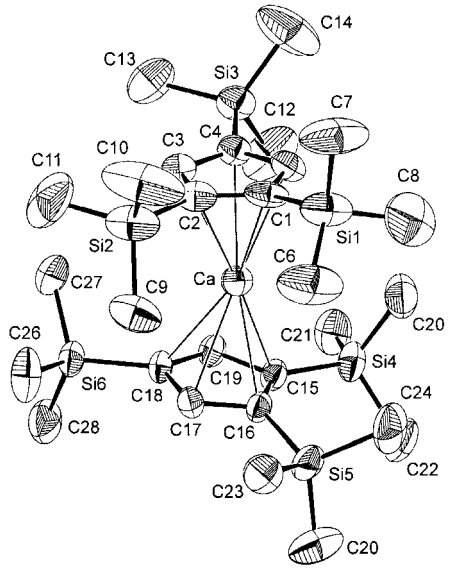

Figure 2. ORTEP of the non-hydrogen atoms of **1**; Ca−C bond lengths [A] to C1, C2, C3, C4, C5, C15, C16, C17, C18, and C19 are 2.619(7), 2.607(7), 2.618(6), 2.665(6), 2.631(6), 2.625(6), 2.618(6), 2.638(6), 2.650(6), and 2.612(6), respectively

The compound exists as a monomeric species with two nearly eclipsed (twist angle of 8°) η^5-Cp^{3Si} ligands framing a Ca core in a bent geometry. The average Ca−C distance

Table 1. Selected bond lengths [Å] and angles [°] for $(Cp^{3Si})_2Ae$ (Ae = Mg, Ca, Sr, Ba)

	Mg (a)[a]	Mg (b)	**1**	**2**	**3**

in **1** is 2.63(2) Å. This distance is within experimental error of the average Ca−C length observed in the other structurally characterized base-free calcocenes, i.e., $(Cp^{4i})_2Ca$,[18] $(Cp^{3i})_2Ca$ {Cp^{ni} = $[(iPr)_nC_5H_{5-n}]$},[21] and Cp^*_2Ca[2] [2.64(1) Å, 2.62(2) Å, and 2.64(2) Å, respectively]. Although the two complexes belong to structurally distinct classes of compounds, the Ca−centroid distance of 2.35 Å in **1** is indistinguishable from the analogous distance in $[(Cp^{3Si})Ca(\mu\text{-}I)(THF)]_2$, which also contains a formally six-coordinate calcium center.[15] The ring centroid−Ca−ring centroid angle of 166.7° is more linear than the analogous angles found in $(Cp^{4i})_2Ca$[18] and Cp^*_2Ca[2] (162.3° and 147.0°, respectively). There is no evidence for excessive steric crowding in the complex, however, as the closest intramolecular methyl···methyl′ contact is at 4.0 Å; this is equal to the sum of the van der Waals radii of two methyl groups.[22] In addition, the greatest silyl group displacement from the cyclopentadienyl ring plane is 8.3°, which is similar to the maximum displacement of 8.7° found in the relatively uncrowded $[(Cp^{3Si})Ca(\mu\text{-}I)(THF)]_2$.[15]

$(Cp^{3Si})_2Sr$ (2)

A crystal of **2** grown from hexanes was used to determine its structure with X-ray crystallography. A summary of bond lengths and angles for **2** is given in Table 1. An ORTEP is provided in Figure 3.

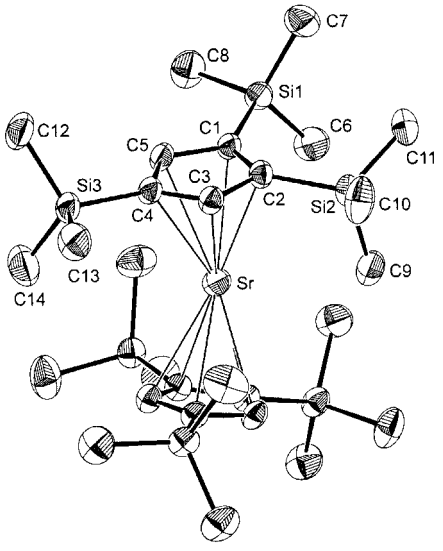

Figure 3. ORTEP of the non-hydrogen atoms of **2**; Sr−C bond lengths [Å] to C1, C2, C3, C4, and C5 are 2.811(4), 2.773(4), 2.784(4), 2.850(4), and 2.841(4), respectively

The compound exists as a monomer in which the strontium atom is coordinated by two partially staggered (twist angle of 18°) Cp^{3Si} rings. The strontium atom resides on a crystallographic C_2 axis, so that only half the molecule is unique. Although no other unsolvated strontocenes exist for direct comparison, useful structural parallels exist with divalent organolanthanide species, as Sm^{2+} and Eu^{2+} have six-coordinate radii (1.17 Å) that are almost identical to that of Sr^{2+} (1.18 Å).[17] The average Sr−C distance of 2.812(9) Å in **2** is similar to the analogous distances observed in Cp^*_2Sm and Cp^*_2Eu [Ln−C = 2.79(1) Å],[1] or $(Cp^{4i})_2Sm$ (Sm−C = 2.79 Å)[23] and $(Cp^{4i})_2Eu$ [Eu−C = 2.782(6) Å].[24] Giving consideration to the difference between the six- vs. seven-coordinate radii of Sr^{2+} (Δ = 0.03 Å), the Sr−ring centroid distance of 2.54 Å in **2** is also equivalent to the 2.57 Å distance found in $(Cp^{3i})_2Sr(THF)$.[25] The ring centroid−Sr−ring centroid angle of 159.4° represents a substantially more linear structure than is found in Cp^*_2Sm and Cp^*_2Eu (140.1° and 140.3°).[1] This is not unexpected, given the increase in steric bulk in going from Cp* to Cp^{3Si} ligands. Even so, the closest interring methyl···methyl contact is at 3.78 Å, which is 95% of the sum of the van der Waals radii of two methyl groups,[22] and as with compound **1**, **2** does not display any significant silyl group displacements from the cyclopentadienyl ring planes (maximum of 7.7°; cf. 8.7° in the dimer $[(Cp^{3Si})Sr(\mu\text{-}I)(THF)_2]_2$.[15]

$(Cp^{3Si})_2Ba$ (3)

A crystal of **3**, grown by sublimation, was used to determine its structure with X-ray crystallography. A summary of bond lengths and angles for **3** is given in Table 1. An ORTEP is provided in Figure 4.

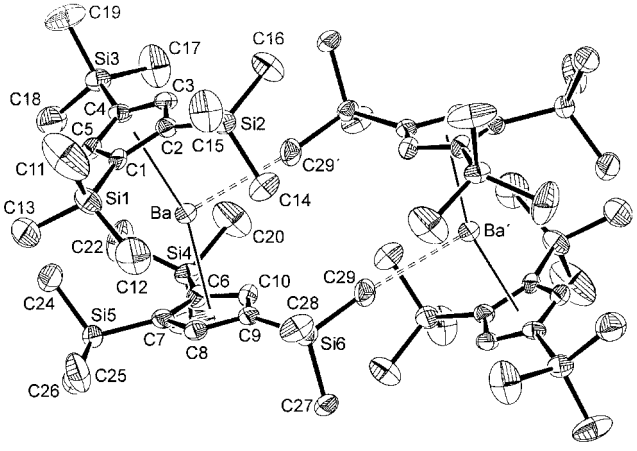

Figure 4. ORTEP of the non-hydrogen atoms of **3**, giving the numbering scheme used in the text; Ba−C bond lengths [Å] to C1, C2, C3, C4, C5, C6, C7, C8, C9, C10, and C29′ are 2.975(5), 2.977(5), 2.988(5), 3.044(5), 3.012(5), 2.981(5), 2.976(5), 3.007(5), 3.076(5), 3.036(5), and 3.275(6), respectively

Unlike the calcium and strontium analogues, **3** crystallizes as a coordination dimer in which each barium atom is surrounded by two nearly eclipsed η^5-1,2,4-tris(trimethylsilyl)cyclopentadienyl rings and one methyl group from a neighboring Cp^{3Si} ring. The average Ba−C(Cp′) distance in **3** of 3.01(2) Å and the Ba−ring centroid distance of 2.75 Å are longer than those observed in the formally six-coordinate $(Cp^{4i})_2Ba$ [2.94(2) Å and 2.68 Å, respectively].[18] The Ba−C distance is similar to that found in the sterically crowded metallocene $[(iPr)_5C_5]_2Ba$ [2.997(4) Å].[19] Based on the additional bridging interaction, however, **3** could be considered a formally seven-coordinate complex; consistent with this, the average Ba−C and Ba−ring centroid dis-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tances are indistinguishable from those observed in the seven-coordinate $\{[(Cp^{3Si})BaI(THF)_2]\cdot C_7H_8\}_\infty$ [3.00(2) and 2.76(1), respectively].[18] The ring centroid−Ba−ring centroid angle of 162.2° in **3** is considerably wider than the angle in either $(Cp^{4i})_2Ba$ (154.2°)[18] or Cp^*_2Ba (131.0°).[2] In contrast, $(Cp^{5i})_2Ba$ is strictly linear with a ring centroid−Ba−ring centroid angle of 180°.[19]

The intermolecular contact between each barium metal center and a methyl group from an adjacent metallocene unit [Ba(1)−C(29′)] is at 3.275(6) Å, a shorter distance than the sum of the van der Waals radius of a methyl group and the ionic radius of seven-coordinate Ba^{2+} (= 3.4 Å). Similar interactions between cyclopentadienyl ring substituents and neighboring metallocenes have been observed in Group-2 and lanthanide metallocene structures. For example, in Cp^*_2Ba, there are two methyl groups with Ba···CH_3′ distances of 3.35 and 3.36 Å.[2] There is a related interaction observed in the polymeric structure of $[\{1,3\text{-}(SiMe_3)_2C_5H_3\}_2Yb]_\infty$,[26] i.e., a close contact is present between the metal and a methyl group of a neighboring metallocene unit at 2.872(7) Å (the radii of seven-coordinate Yb^{2+} and Ba^{2+} differ by 0.30 Å[17]). The europium derivative $[\{1,3\text{-}(SiMe_3)_2C_5H_3\}_2Eu]_\infty$ displays the same type of intermolecular metal···methyl contact at 3.091(6) Å;[26] the difference in Eu^{2+} and Ba^{2+} radii is 0.18 Å, so that the contact distances in the europium and barium structures are equivalent.[17]

The trimethylsilyl group with the bridging interaction in **3** (Si6) is displaced from the cyclopentadienyl ring plane by 0.33 Å (equivalent to 10.3°), which is only slightly more than the maximum displacements observed in **1** and **2**; the next largest displacement in **3** is at 0.26 Å (= 8.1°), involving Si3. The closest intramolecular methyl···methyl′ contact is found between the eclipsed trimethylsilyl groups containing Si2 and Si6 at 3.66 Å (C14···C28).

Relative Orientations of Tris(trimethylsilyl) Rings

The presence of three trimethylsilyl groups on a Cp^{3Si} ring allow for six distinct possible relative orientations of the two rings in a metallocene (with three eclipsed C_5 rings and three staggered rings).[27] Among those possibilities, three different orientations are observed in the $(Cp^{3Si})_2Ae$ series. The magnesium[16] and calcium complexes both adopt the same eclipsed configuration [Figure 5(a)] with twist angles of 1° [for Mg(a)], 5° [for Mg(b)] and 8° [for Ca (**1**)] (Table 1). The analogous germanium complex adopts the same arrangement of silyl groups in the solid state,[27] as does the ferrocene derivative $(Cp^{3Si})_2Fe$.[28] Calculations with $(Cp^{3Si})_2Ge$ demonstrated that this conformation lies in a steric energy minimum.[27] The two rings in $(Cp^{3i})_2Ca$ also adopt the same relative orientation;[21] this seems to be a favored arrangement for 1,2,4-substituted rings in complexes with metal radii ≤ 1.0 Å. The orientation probably reflects a balance between steric repulsions and van der Waals attractive forces in these complexes; with larger metals and greater separation of the rings, steric repulsions between substituents are less energetically costly, and more eclipsing of substituents is possible.

Figure 5. Orientation of the tris(trimethylsilyl)cyclopentadienyl rings in $(Cp^{3Si})_2Ae$ [Ae = Mg, Ca (**1**): (a); Sr (**2**): (b); Ba (**3**): (c)]

The rings in **2** crystallize in a staggered conformation [Figure 5(b)] with a twist angle of 18° between them (Table 1). In contrast, **3** adopts an orientation with two sets of eclipsed trimethylsilyl substituents [Figure 5(c)]; the cyclopentadienyl rings are in correspondingly close alignment (twist angle of 2°). The bending of the metallocene occurs so that the staggered substituents are on the "closed" side of the metallocene. The interaction of the barium metal center with the bridging methyl group takes place from the "open" side.

Degree of Bending in Cp'_2Ae Complexes

Despite the controversy that still surrounds the issue, the bending observed in many base-free main-group and lanthanide metallocenes is probably most readily understood through the use of various polarization models of bonding, although the participation of low-lying d-orbitals has also been proposed.[3,29−31] The amount of possible bending is limited by steric repulsions between the substituent groups, and therefore the bending angle changes not only with the metal radius and polarizability, but also with the bulk of the cyclopentadienyl ligands. Consequently, before the bending observed in metallocenes with differently substituted Cp′ rings can be compared in a meaningful way, possible ring orientations, the existence of coordination oligomers, and distortions from crystal packing all need to be taken into account.

The complexes reported here illustrate the difficulties involved in establishing such metal/bending correlations. For example, the bending angles (ring centroid−metal−ring centroid) of the four known $(Cp^{3Si})_2Ae$ compounds decrease as the metal radii increase from Mg to Sr [i.e., 171.1°, 166.7°, and 159.4° for $(Cp^{3Si})_2Mg$, $(Cp^{3Si})_2Ca$ and $(Cp^{3Si})_2Sr$, respectively] but then increase slightly for barium (162.2°). The break in the trend reflects the change from the mononuclear structures to the dimeric geometry of the barium compound, whose ring bending angle is evidently influenced by the bridging methyl group.

Comparisons of bending angles using metallocenes with only a single type of metal suffer from similar anomalies, although the difficulties may not always be apparent in small sets of compounds. For instance, the bending angles of calcocenes open from Cp^*_2Ca (147.0°) to $(Cp^{4i})_2Ca$ (162.3°) to $(Cp^{3Si})_2Ca$ (166.7°). The order is repeated with barocenes [i.e., Cp^*_2Ba (131°) < $(Cp^{4i})_2Ba$ (154°) < $(Cp^{3Si})_2Ba$ (162.2°)], even though Cp^*_2Ba exists as a coordination polymer and $(Cp^{3Si})_2Ba$ is a coordination dimer in the solid state. Based on the progression in bending angles,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

there might be a temptation to conclude that the Cp^{3Si} ring is effectively more bulky than Cp^{4i}. However, the structure of bis(1,2,4-triisopropylcyclopentadienyl)calcium, $(Cp^{3i})_2Ca$, despite having two fewer isopropyl groups than $(Cp^{4i})_2Ca$, has a wider bending angle (169.7°) than either $(Cp^{4i})_2Ca$ or $(Cp^{3Si})_2Ca$.[32] This counterexample demonstrates that the approach to linearity in the solid state is not solely a function of the number and size of ring substituents, but that packing effects may be involved as well. Great care is needed when proposing the existence of quantitative relationships between steric bulk and bending angles in such conformationally flexible molecules.

The Case of Bulky Beryllocenes

Almost all crystallographically characterized magnesocenes, including Cp_2Mg,[33] $[(t\mathrm{Bu})C_5H_4]_2Mg$,[34] $[(PhCH_3CH)C_5H_4]_2Mg$,[35] and $(Me_4C_5H)_2Mg$[36] have parallel rings. The slight tilting of the rings observed in $(Cp^{3Si})_2Mg$ (7.8°) has been ascribed to the large amount of steric encumbrance around the Mg^{2+} center generated by the two Cp^{3Si} rings.[16] The steric pressure on a beryllocene with Cp^{3Si} rings might be even greater, and could conceivably destabilize the complex through the operation of "steric oversaturation."[37] Although we were not successful in isolating a beryllocene containing two Cp^{3Si} rings, combination DFT/semiempirical (ONIOM) calculations were performed on several possible conformations of $(Cp^{3Si})_2Be$, including η^1/η^1, η^1/η^5, and η^5/η^5, to try to establish the steric feasibility of such a structure.

The η^1/η^1 geometry shown in Figure 6(a) was used as a starting geometry in optimization. The unsubstituted position on the rings was chosen as the site of ligation, both to minimize steric interactions between the rings and from the fact that in $(\eta^5\text{-}C_5Me_4H)(\eta^1\text{-}C_5Me_4H)Be$,[20] the beryllium atom is attached to the unsubstituted carbon atom in the η^1-bonded ring. Nevertheless, during optimization one ring rotated relative to the other, and the structure collapsed to an η^1/η^5 geometry [Figure 6(b)]. The beryllium atom is now attached to a carbon atom bearing a trimethylsilyl group; the Be−C(η^1) distance is 1.781 Å (cf. 1.827 Å in Cp_2Be[38]),

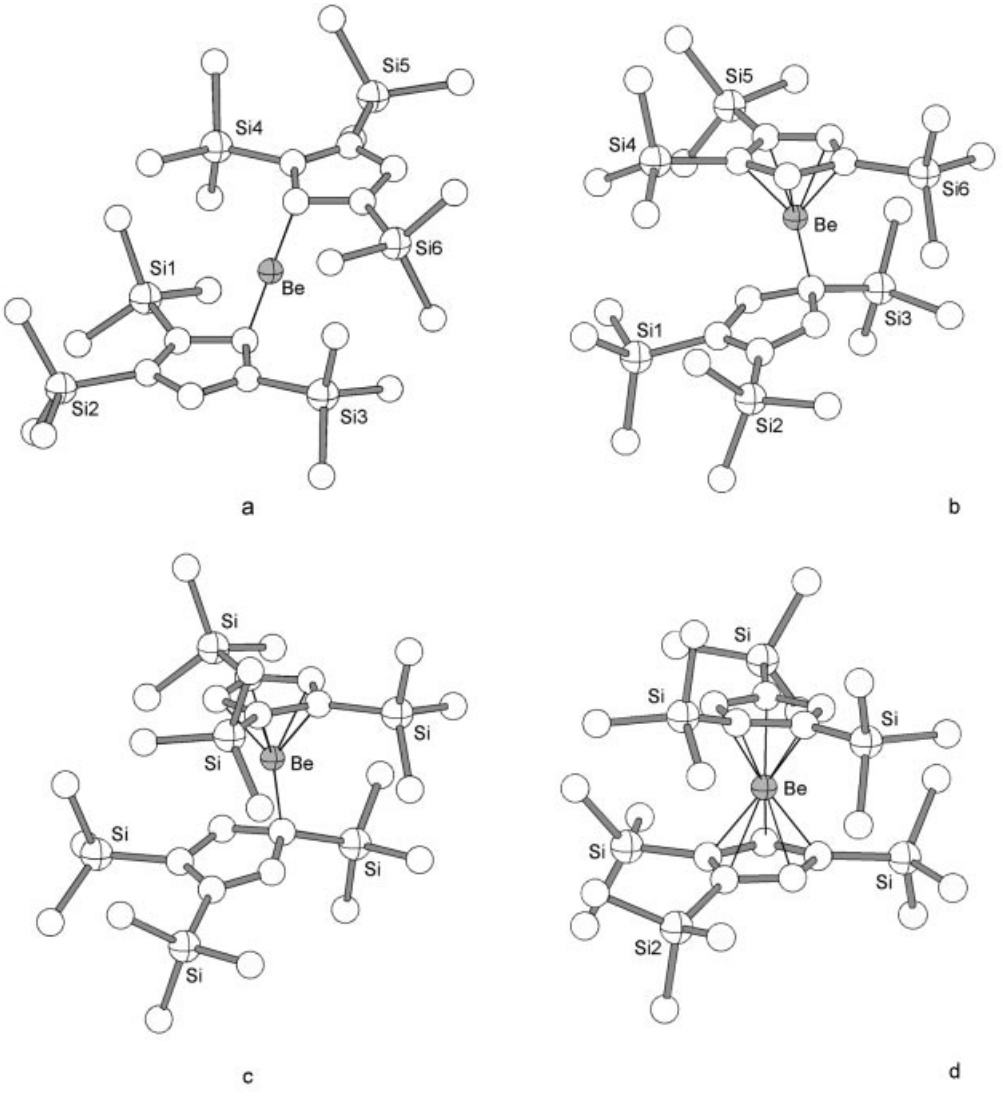

Figure 6. ONIOM-optimized geometries (H atoms omitted) for $(Cp^{3Si})_2Be$

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and Si3 is bent out of the C_5 plane by 1.03 Å (32.8°). Such a rearrangement can be rationalized on electronic grounds, as silicon atoms help stabilize negative charges on adjacent atoms; the bending distortion also serves to increase the negative charge on the carbon atom.[39] The Be−C(η^5) bonds are in the narrow range from 1.901 to 1.934 Å, and average 1.923 Å, nearly matching the average Be−C(η^5-Cp) bond length in the parent molecule (1.93 Å[38]). The structure is a local minimum on the potential energy surface (PES) (no imaginary frequencies), but a similar η^1/η^5 structure can be obtained that is formally related to the first by a ring rotation [Figure 6(c)]. The latter geometry is also a minimum on the PES, and has nearly identical geometric parameters [Be−C(η^1) = 1.780 Å; Be−C(η^5) = 1.921 Å (av)]. Structure (b) in Figure 6 is 1.9 kcal mol^{-1} higher in enthalpy ($\Delta H°$) than structure (c) a difference that is not meaningful at this level of theory. The height of the energy barrier that might separate the two forms, however, is not known.

The stability of an η^5/η^5 configuration was evaluated by starting from an eclipsed conformation similar to that in Figure 5(a). The sandwich geometry was retained during optimization [Figure 6(d)]; a frequency calculation indicated that it was a local minimum (N_{imag} = 0). The angle between the ring planes is 6.9°, and the metallocene is somewhat slipped, with Be−C bonds ranging from 2.04 to 2.14 Å; the latter distance is slightly longer than the maximum distance observed in Cp*$_2$Be (2.11 Å), which is already long compared to the Be−C bond length in the parent molecule.[38] Even so, there are no intermolecular methyl···methyl′ contacts closer than 3.64 Å; the closest analogous contact in Cp*$_2$Be is at 3.63 Å. The η^5/η^5 structure is 3.3 kcal mol^{-1} higher in enthalpy ($\Delta H°$) than structure (c) in Figure 6; the height of the energy barrier that separates the η^1/η^5 and η^5/η^5 forms is not known. In any case, the failure of the reactions designed to produce (Cp^{3Si})$_2$Be (like the initial attempts to form Cp*$_2$Be[40,41]) is probably best ascribed to kinetic difficulties, rather than to fundamental steric limitations on the geometry of the beryllocene.

Conclusion

The 1,2,4-tris(trimethylsilyl)cyclopentadienyl ligand has now been incorporated into unsolvated metallocenes containing metals from magnesium to barium. A balance between steric repulsions and van der Waals attractive forces evidently directs the relative ring orientations. A configuration with a single eclipsed substituent seems to be a favored arrangement in complexes with smaller metals ($r \leq 1.0$ Å); the larger metals adopt arrangements that may be influenced more by intermolecular interactions. With the exception of (Cp^{3Si})$_2$Mg, whose rings are non-parallel owing to high steric pressure within the complex, the other metallocenes are all bent less than their Cp, Cp* or Cp^{4i} counterparts, although the trends are not uniform for all combinations of metals and cyclopentadienyl rings. In addition, three trimethylsilyl substituents do not block access to the metal center as completely as do four isopropyl groups; **3** forms a coordination dimer, for example, whereas (Cp^{4i})$_2$Ba remains rigorously monomeric. Hence the bending angle of a metallocene, although reflecting the steric bulk of the cyclopentadienyl rings, is not a completely reliable indicator of the shielding of the metal center.

Experimental Section

General Remarks: All manipulations were performed with the rigorous exclusion of air and moisture using high vacuum, Schlenk, or drybox techniques. Anhydrous calcium, strontium or barium iodide (Strem Chemicals or Cerac, 95%) were heated under vacuum (150 °C, 10^{-6} Torr) to remove residual amounts of free iodine. K[1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$] was prepared as described previously.[15] Solvents for reactions were distilled under nitrogen from sodium or potassium benzophenone ketyl. NMR solvents were vacuum-distilled from Na/K (22:78) alloy and stored over molecular sieves (4 Å). Proton (^{1}H) and carbon (^{13}C) NMR spectra were obtained with a Bruker NR-300 spectrometer at 300 and 75.5 MHz, respectively, and were referenced to the residual resonances of C_6D_6 (δ = 7.15 and 128.0 ppm) or [D_8]THF (δ = 3.58 and 67.4 ppm). Infrared data were measured with KBr pellets as described previously.[18] Elemental analyses were performed by Desert Analytical Laboratory, Tucson, AZ; the low carbon value found for **1** reflects a not uncommon problem with highly air-sensitive organo(alkaline-earth) compounds.[42]

Synthesis of [1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$]$_2$Ca (1): CaI_2 (0.145 g, 0.49 mmol) and K[1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$] (0.291 g, 0.91 mmol) were added to a flask under nitrogen at room temperature. Diethyl ether (45 mL) was added to the flask, and the reaction mixture was stirred overnight, concentrated to dryness under vacuum, and the residue extracted with hexanes. The extract was filtered, and the filtrate concentrated to an oil that crystallized upon standing, yielding **1** as air-sensitive, colorless crystals (0.100 g, 37%). This material sublimed at 125−140 °C and 10^{-5} Torr to give a white powder (0.093 g, 34%), m.p. 164 °C. $C_{28}H_{58}CaSi_6$ (603.36): calcd. C 55.74, H 9.69; Ca, 6.64; found C 54.41, H 10.20; Ca, 6.70. ^{1}H NMR (C_6D_6, 20 °C): δ = 6.96 (s, 2 H, ring-C*H*), 0.38 [s, 27 H, Si(CH_3)$_3$] ppm. ^{1}H NMR ([D_8]THF, 20 °C): δ = 6.76 (s, 2 H, ring-C*H*), 0.28 [s, 18 H, Si(CH_3)$_3$], 0.17 [s, 9 H, Si(CH_3)$_3$] ppm. ^{13}C NMR (75.5 MHz, C_6D_6, 20 °C): δ = 133.1 (2C, ring-*C*H), 131.7 [ring-*C*Si(CH$_3$)$_3$], 126.5 [ring-*C*Si(CH$_3$)$_3$], 2.0 [Si(*C*H$_3$)$_3$], 1.1 [Si(*C*H$_3$)$_3$]. Selected IR bands (KBr): $\tilde{\nu}$ = 2956 (s), 2904 (m), 1633 (m), 1556 (m), 1250 (vs), 1116 (w), 1016 (m), 977 (m), 833(vs), 526 (w) cm^{-1}. Crystals for X-ray structural analysis were grown by slow concentration of a saturated hexanes solution of **1** at room temperature.

Synthesis of [1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$]$_2$Sr (2): SrI_2 (0.100 g, 0.29 mmol) and K[1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$] (0.176 g, 0.54 mmol) were added to a flask under nitrogen at room temperature. Diethyl ether (55 mL) was added to the flask, and the reaction mixture was stirred overnight, concentrated to dryness, and the residue extracted with hexanes. The extract was filtered, and the filtrate concentrated to an oil that crystallized upon standing, yielding **2** as air-sensitive, colorless crystals (0.125 g, 71%). Analytically pure material was obtained by sublimation at 140−165 °C and 10^{-6} Torr to give a white crystalline solid (71 mg, 40%), m.p. 94−96 °C. $C_{28}H_{58}Si_6Sr$ (650.90): calcd. C 51.67, H 8.98; found C 51.93, H 9.20. ^{1}H NMR (300 MHz, C_6D_6, 20 °C): δ = 6.89 (s, 2 H, ring-C*H*), 0.37 [s, 9 H, Si(CH_3)$_3$],

0.34 [s, 18 H, Si(CH_3)$_3$] ppm. ^{1}H NMR ([D$_8$]THF, 20 °C): δ = 6.69 (s, 2 H, ring-C*H*), 0.27 [s, 18 H, Si(CH_3)$_3$], 0.17 [s, 9 H, Si(CH_3)$_3$] ppm. ^{13}C NMR (75.5 MHz, C_6D_6, 20 °C): δ = 132.4 (2C, ring-*C*H), 130.0 (ring-*C*Si(CH$_3$)$_3$], 125.5 (ring-*C*Si(CH$_3$)$_3$], 1.9 [Si(*C*H$_3$)$_3$], 1.1 [Si(*C*H$_3$)$_3$]. Selected IR bands (KBr): $\tilde{\nu}$ = 2957 (vs, br), 1247 (vs, sh), 1091 (ms), 1005 (ms), 850 (vs, br), 751 (s) cm^{-1}. Crystals for X-ray structural analysis were grown by slow concentrated of a saturated hexanes solution of **2** at room temperature.

Synthesis of [1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$]$_2$Ba (3): BaI_2 (0.455 g, 1.2 mmol) and K[1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$] (0.794 g, 2.5 mmol) were added to a flask under nitrogen at room temperature. Diethyl ether (65 mL) was added to the flask, and the reaction mixture was stirred overnight, concentrated to dryness, and the residue extracted with hexanes. The extract was filtered, and the filtrate concentrated to dryness to yield a beige powder (0.42 g, 50%). The crude product was sublimed at 140 °C and 10^{-7} Torr to give air-sensitive, colorless crystals of **3** (0.206 g, 24%), m.p. 139−140 °C. $C_{28}H_{58}BaSi_6$ (700.61): calcd. C 48.00, H 8.34; found C 47.97, H 8.40. ^{1}H NMR (C_6D_6, 20 °C): δ = 6.78 (s, 2 H, ring-C*H*), 0.35 [s, 18 H, Si(CH_3)$_3$], 0.33 [s, 9 H, Si(CH_3)$_3$] ppm. ^{1}H NMR ([D$_8$]THF, 20 °C): δ = 6.60 (s, 2 H, ring-C*H*), 0.25 [s, 18 H, Si(CH_3)$_3$], 0.17 [s, 9 H, Si(CH_3)$_3$] ppm. ^{13}C NMR (75.5 MHz, C_6D_6, 20 °C): δ = 133.1 (2 C, ring-*C*H), 130.5 (ring-*C*Si(CH$_3$)$_3$], 125.4 (ring-*C*Si(CH$_3$)$_3$], 2.0 [Si(*C*H$_3$)$_3$], 0.9 [Si(*C*H$_3$)$_3$]. Selected IR bands (KBr): $\tilde{\nu}$ = 2955 (s), 2897 (m), 1436 (w), 1250 (s), 1092 (m), 1005 (m), 978 (m), 830 (vs), 752 (m), 689 (w), 629 (w) cm^{-1}. Crystals for X-ray structural analysis were obtained from the sublimation of **3**.

Attempted Syntheses of [1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$]$_2$Be: $BeCl_2$ (0.031 g, 0.39 mmol) and K[1,2,4-(SiMe$_3$)$_3$C$_5$H$_2$] (0.252 g, 0.79 mmol) were added to a flask under nitrogen at room temperature. Diethyl ether (20 mL) was added to the flask, and the reaction mixture was stirred at room temperature for 3 d, concentrated to dryness under vacuum, and the residue extracted with hexanes. ^{1}H NMR analysis of the extract indicated that only starting materials were present. The reaction was repeated in a 1:1 diethyl ether/toluene mixture, which was refluxed under nitrogen for 3 days. A black residue was left at the completion of the reaction, and no metallocene was isolated on workup of the reaction mixture.

X-ray Crystallographic Studies: The crystal structure measurement and refinement data for **1**−**3** are given in Table 2. Measurements on **1** and **2** were performed with a Rigaku AFC6S diffractometer at Vanderbilt University with graphite-monochromated Cu-K_α radiation (λ = 1.54178 Å). A crystal of each compound was sealed in a glass capillary tube. Selected crystal and data collection parameters for the present study are given in Table 2. The space groups were determined from reflection conditions and intensity statistics. Data collection was performed using continuous ω-2θ scans with stationary backgrounds (peak/background counting time = 2:1). The structures were solved by direct methods and Fourier techniques with TEXSAN software. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were inserted in calculated positions based on packing considerations and *d*(C−H) = 0.95 Å. The positions were fixed for the final cycles of refinement. Measurements on **3** were performed on a Siemens SMART system at the X-ray Crystallography Laboratory at the University of Minnesota. A crystal of **3** was attached to a glass fiber, and mounted for data collection at 173(2) K. Data collection and structure solution were conducted at the X-ray Crystallography Laboratory at the University of Minnesota. All calculations were performed using the SHELXTL V5.0 suite of programs. A successful direct-methods solution was calculated which provided most non-hydrogen atoms from the E-map. Several full-matrix least-squares/difference Fourier cycles were performed that located the remainder of the non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in ideal positions and refined as riding atoms with relative isotropic dis-

placement parameters. SAME restraints were applied to the disordered Si(4)/C(20)/C(21)/C(22) group, which was found to be occupied in a 0.53:0.47 ratio. CCDC-210464 (**1**), -210465 (**2**) and -210466 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) + 44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Details: Calculations on $(Cp^{3Si})_2Be$ were performed using the Gaussian 03 W suite of programs.[43] A full geometry optimization using even the relatively modest 6-31G(d,p) basis set would have involved a computationally expensive set of 839 basis functions. An ONIOM calculation[44] was performed instead, using the 6-31G(d,p) basis set on Be, the ten carbon atoms of the cyclopentadienyl rings, and the directly attached atoms (hydrogen or silicon). The semi-empirical PM3 method was used for the 18 methyl groups. The B3PW91 functional, which incorporates Becke's three-parameter exchange functional[45] with the 1991 gradient-corrected correlation functional of Perdew and Wang,[46] was used; this hybrid functional has previously been shown to provide realistic geometries for organometallic species.[47,48] Frequency calculations were used to establish that all optimized geometries were local minima ($N_{imag} = 0$).

Synthesis and Structures of Alkali Metal Amides Derived from the Ligands $[N(SiMe_2Ph)(SiMe_3)]^-$, $[N(tBu)(SiMe_3)]^-$, $[N(Ph)(2\text{-}C_5H_4N)]^-$, and $[N(2\text{-}C_5H_4N)_2]^-$

Floria Antolini,[a] Peter B. Hitchcock,[a] Alexei V. Khvostov,[a] and Michael F. Lappert*[a]

Dedicated to the memory of Ron Snaith

Keywords: Alkali metals / Amides / Synthesis / NMR spectra / X-ray structures

The following crystalline complexes are reported: $[(M\{\mu\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_n$ [the *cis* complex for $n = 1$ and M = Li (**1**); and the *trans* complexes with $n = \infty$ and M = Na (**2**), K (**4**), Rb (**5**), Cs (**6**)], $[(Na\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2(tmeda)]$ (**3**), $[(K\{\mu\text{-}trans\text{-}N(tBu)(SiMe_3)\})_4(\eta\text{-}C_6H_6)_2]$ (**7**), $[(K\{\mu\text{-}trans\text{-}N(Ph)(2\text{-}C_5H_4N)\})_2(\mu'\text{-}thf)_3]_\infty$ (**8**), and $[K\{\mu\text{-}N(2\text{-}C_5H_4N)_2\}]_\infty$ (**9**). Each, except **3**, was obtained by metallation of the appropriate secondary amine with Li*n*Bu (for **1**), MBzl [M = Na (for **2**), K (for **4** and **7**), Rb (for **5**), Cs (for **6**)], or KH (for **8** and **9**); treatment of **2** with an excess of tmeda yielded **3**. Each of **1**–**9** has an unusual, and in some cases unprecedented, molecular structure.

Introduction

Bulky alkali metal amides MNR_2 (especially M = Li and R = *i*Pr or $SiMe_3$, or NR_2 = 2,2,6,6-Me_4-piperidyl) are widely used as proton abstractors in organic synthesis, by virtue of their strong basicity but low carbon-centred nucleophilicity; and as reagents for the synthesis (including enantioselective) of compounds containing C−C bonds.[1−11] In coordination chemistry they are of synthetic interest as (i) ligand-transfer reagents; as substrates for (ii) reactions with protic compounds, thereby eliminating amine and generating new alkali metal compounds, and (iii) insertion of heterocumulenes or α-H-free organic cyanides.[12] They are also of major structural interest.[13−15]

We have a long-standing interest in the chemistry of metal and metalloid amides.[12] Many are prepared from the corresponding metal or metalloid chlorides, or other leaving groups such as triflates, by treatment with an alkali metal amide. Whereas lithium amides are the most readily available, the heavier alkali metal congeners, especially the sodium or potassium compounds, are often to be preferred because of the ease of separation of the target metal amide from the alkali metal halide coproduct.

Our most recent contributions have dealt with the crystalline dimeric dilithium diamide $[Li_2\{(1,3\text{-}CH_2NC_6H_3iPr_2\text{-}2',6')_2C_6H_4\}]_2$ [16] and crystalline polymeric lithium amides $[(Li\{\mu\text{-}N(Ph)R\}\text{-}trans)_2(\mu\text{-tmeda})]_\infty$ (R = $SiMe_3$ or *t*Bu).[17]

Results and Discussion

Synthesis and Characterisation

In a preliminary communication, we described the conversion of $HN(SiMe_2Ph)(SiMe_3)$ into the crystalline lithium (**1**) and sodium (**2**) amides [as well as related chemistry based on $HN(Ph)SiMe_3$].[18] An objective was to compare their structures with those of the metal amides of the better known C_2-symmetric ligand $[N(SiMe_3)_2]^-$. In this paper we report (i) full details of the synthesis and characterisation of **1** and **2**; (ii) extensions to **3**, the crystalline tmeda complex of **2**, and the potassium (**4**), rubidium (**5**) and caesium (**6**) analogues of **1** and **2**; (iii) the synthesis of the potassium salt of another C_1-symmetric trimethylsilylamide $K[N(tBu)(SiMe_3)]$ **7a** and its crystalline benzene adduct **7**; (iv) the preparation of the crystalline potassium 2-pyridylamides $[K\{N(Ph)(2\text{-}C_5H_4N)\}\cdot 11/2thf]_\infty$ (**8**) and $[K\{N(2\text{-}C_5H_4N)_2\}]_\infty$ (**9**); and (v) X-ray structural data on the crystalline compounds **3**−**9** (those of **1** and **2** are in the literature[18]). As for (iv), the crystalline X-ray-characterised tmeda analogue of **8** $[K\{N(Ph)(2\text{-}C_5H_4N)\}(tmeda)]$ has been reported.[19] The first metal complexes of the ligand $[N(2\text{-}C_5H_4N)_2]^-$ to be described were the crystalline $[Cu_3\{N(2\text{-}C_5H_4N)_2\}X_2]\cdot H_2O$ chloride and bromide,[20] and further transition metal analogues have been much studied.[21]

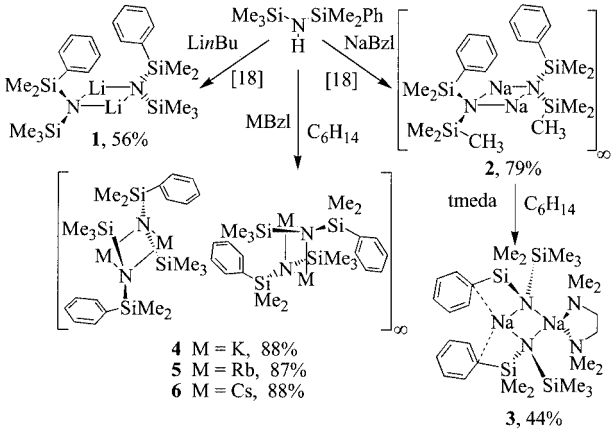


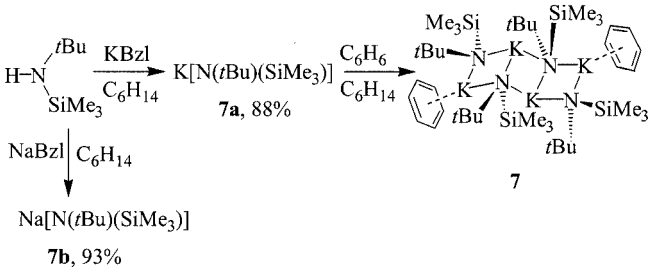
Scheme 1. Synthesis of the crystalline alkali metal phenyldimethylsilyl(trimethylsilyl)amides **1**−**6**; yields of **1**−**3** refer to X-ray quality specimens

The syntheses of the new alkali metal amides $[(M\{\mu\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_n$ [n = 1 with M = Li (**1**); and n = ∞ with M = Na (**2**), K (**3**), Rb (**5**), Cs (**6**)], as well as that of the tmeda adduct **3** of **2**, are shown in Scheme 1. For each of **1**, **2**, **4**, **5**, and **6**, the parent silazane was metallated at −78 °C in hexane (**1**) or pentane, using *n*-butyllithium (**1**) or the appropriate heavier alkali metal benzyl (MBzl). The latter were prepared as solids from M*O*t*Bu (M = Na, K, Rb), Li*n*Bu and toluene in hexane at −78 °C, the precipitated MBzl then thoroughly washed with hexane; CsBzl was obtained by carefully heating Cs in toluene at ca. 60 °C. Complex **3** was made from **2** and an excess of tmeda in hexane at ambient temperature, removal of volatiles and extraction of the residue with benzene; it is surprising that the dinuclear complex **3** contains only a single sodium-bound tmeda ligand.

The alkali metal amides **1**, **2**, **4**, **5** and **6** were found to be more soluble in hydrocarbon solvents than the corresponding compounds having the $[N(SiMe_3)_2]^-$ ligand, possibly in part due to the phenyl substituent assisting in delocalising the negative charge on the nitrogen atom. Each of the compounds **1**−**5** gave satisfactory microanalyses for hydrogen and nitrogen, although values for carbon were invariably low (as we have generally found for silicon-containing compounds, which is attributed to incomplete combustion). The caesium amide **6** proved to be too moisture-sensitive to give reproducible analytical data. Each of **1**−**6** gave satisfactory NMR and EI-mass spectra.

Treatment of trimethylsilyl(*tert*-butyl)amine with benzylpotassium, under identical conditions to those used for the preparation of **4**, yielded the potassium amide **7a** as a powder, which from benzene afforded the crystalline tetranuclear potassium amide as the bis(benzene) adduct **7** (Scheme 2). In a similar fashion, but using benzylsodium, the product was the sparingly hydrocarbon-soluble amorphous sodium amide **7b**, from which X-ray quality crystals were not obtained.

Values for $^{29}Si\{^1H\}$ NMR spectral chemical shifts in $C_6D_5CD_3$ for **1** or C_6D_6 for **2**−**6** and $M[N(SiMe_3)_2]$ (M = Li, Na) at ambient temperature are shown in Table 1.



Scheme 2. Synthesis of the colourless solid sodium (**7b**) and potassium (**7a**) *tert*-butyl(trimethylsilyl)amides and the crystalline benzene adduct (**7**) of **7a**

Addition of *N*-2-pyridylaniline to potassium hydride in THF at ambient temperature yielded, after filtration and concentration of the filtrate, pale-yellow crystals of the corresponding potassium amide **8**, as a triply THF-bridging polymer of a tetranuclear array chain structure. The colourless, polymeric, crystalline bis(2-pyridyl)amidopotassium complex **9**, of layer structure, was obtained similarly, from bis(2-pyridyl)amine and KH in THF (Scheme 3). Each of the amides **8** and **9** was characterised by microanalyses (C, H, N) and ^1H and $^{13}C\{^1H\}$ NMR spectra in $[D_8]$THF, as well as their X-ray structures.

Crystal Structures

The structures of $[Li\{\mu\text{-}cis\text{-}N(SiMe_2Ph)(SiMe_3)\}]_2$ (**1**) and $[(Na\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_\infty$ (**2**) have been published.[18] In summary, **1** is unusual in that it appears to be only the second example of a neutral donor-free binuclear lithium amide,[18] albeit of opposite stereochemistry to that of $[Li\{\mu\text{-}trans\text{-}N(C_6H_3iPr_2\text{-}2,6)(SiMe_3)\}]_2$.[22] The LiNLi′N′ core in the C_2-symmetric **1**, unlike in the latter (which is centrosymmetric), deviates from a planar rhombus, the Li−N bonds ranging from 1.980(3) to 2.019(3) Å, the four atoms alternating above and below the plane by ca. 0.033 Å. The endocyclic angles subtended at the nitrogen atoms (71.75 ± 0.05°) are narrower than those at the lithium atoms (106.6 ± 0.3°), and are similar to those in $[Li\{\mu\text{-}trans\text{-}N(C_6H_3iPr_2\text{-}2,6)(SiMe_3)\}]_2$.[22] Crystalline **2** is a polymer of linked C_2-symmetric, planar dinuclear units, each attached to its neighbour by close Na···C contacts.[18] Neutral donor-free dinuclear sodium amides are, we believe, unprecedented. Each of **1** and **2** has close M···C contacts (see Table 9 below).

The crystalline dinuclear sodium amide − mono-tmeda adduct **3** is unusual in that the two four-coordinate sodium atoms of the central Na1N1Na2N2 core are in different environments: Na1 has an exocyclic chelating tmeda ligand, whereas Na2 has close Na2···C_{ipso} contacts of 2.698 ± 0.006 Å (Figure 1); as a corollary, the endocyclic Na−N bonds are longer for Na1 than Na2 (Table 2) and both are significantly longer than those in **2** (2.420 ± 0.012 Å[18]) or in $[Na\{\mu\text{-}trans\text{-}N(Ph)(SiMe_3)\}(tmeda)]_2$ (av. 2.475 Å[18]), while the endocyclic bond angle at N2 is much wider than that at N1 and their mean is close to that in **2** (102.2 ± 0.7 Å[18]).

Table 1. $^{29}Si\{^1H\}$ NMR spectral chemical shifts (δ) in C_6D_6 at 298 K of $M[N(SiMe_3)_2]$ (M = Li, Na) and of compounds **1**−**7**

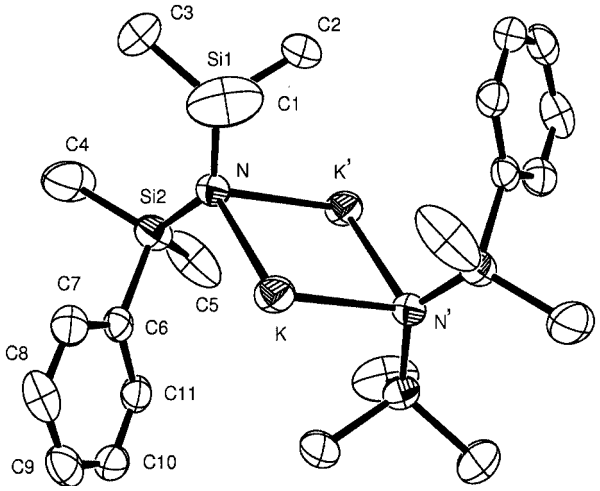

Figure 2. Molecular structure of $[(K\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_\infty$ (**4**), showing one of the dimeric units

Each of the crystalline alkali metal amides bearing the $[N(SiMe_3)(SiMe_2Ph)]^-$ ligand adopts a dinuclear structure. The heavier alkali metal amides $[(M\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_\infty$ (M = K, Rb, Cs) have a very similar crystal architecture. Two molecules are situated in the unit cell, which are orientated in such a way that the cations are stabilised by both intra- and intermolecular interactions with the methyl and/or phenyl substituents (Table 9), responsible for the polymeric aggregation. Descending the group, the $[MN]_2$ central core becomes progressively more rectangular.

X-ray quality crystals of $[(K\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_\infty$ (**4**) were obtained by sublimation at 180 °C and 5×10^{-4} Torr. The molecular structure of one dimeric unit is shown in Figure 2; there are two independent dimers **A** and **B** in the unit cell, each lying on an inversion centre. The phenyl groups in **A** are orthogonal to those in **B**. A list of selected interatomic bond lengths (Å) and angles (°) together with those of a related compound $[K\{\mu\text{-}N(SiMe_3)_2\}]_2$ [23] are in Table 3. The structural parameters describing the internal core $[KN]_2$ in **4** are unexceptional. Comparing **4** with $[K\{\mu\text{-}N(SiMe_3)_2\}]_2$,[23,24] only the Si(1)−N−Si(2) and SiB(1)−NB−SiB(2) [133.49(13) and 132.56(12)° [23]] angles show significant differences.

As shown by a portion of the structure of **4** depicted in Figure 3, close contacts between a potassium atom (say in **B**) and the phenyl ring of the neighbouring unit (say **A**) are present: [K−C(2) 3.512(2), K−C(3) 3.119(2), K−C(4)

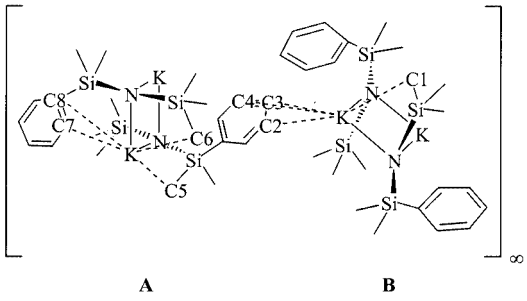

Figure 3. Schematic view of intra- and intermolecular K···C interactions in compound **4**

3.225(2) Å]. The same potassium atom is involved in an intramolecular K-methyl interaction, K−C(1), of 3.231(2) Å. In the other dimer (say **A**) the potassium atom has intramolecular contacts with the phenyl and methyl substituents: [K−C(5) 3.450(2), K−C(6) 3.357(2), K−C(7) 3.587(2) and K−C(8) 3.381(2) Å]. A higher coordination number with increasingly heavier alkali metal complexes is to be expected. The C_2-symmetric analogue $[K\{\mu\text{-}N(SiMe_3)_2\}]_2$ exhibits close intramolecular agostic-type contacts of 3.34 Å,[23] and also, as a referee (but not refs. 23 or 24) has noted, close intermolecular contacts.

Crystals of the rubidium amide **5** were obtained from a saturated toluene solution. There are two independent dimers **A** and **B** in the unit cell, as shown in Figure 4. A list of selected geometrical parameters for a single dimeric unit is shown in Table 4, together with comparative data for $[Rb\{\mu\text{-}N(SiMe_3)_2\}]_2$.[25] Crystalline **5** is similar to **4**, but the coordination sphere at the metal is different; thus the rubidium in the **A** molecule is involved in an η^6-bonding mode with the phenyl substituent of the **B** molecule [Rb−C(1B) 3.716(7), Rb−C(2B) 3.640(8), Rb−C(3B) 3.466(8), Rb−C(4B) 3.339(7), Rb−C(5B) 3.407(7), Rb−C(6B) 3.570(7) Å], as shown schematically in Figure 5.

Crystals of the caesium amide **6** were obtained from a solution in benzene and hexane. As for **4** and **5**, there are two independent dimers **A** and **B** in the unit cell, as shown in Figure 6. A list of selected geometrical parameters for a single dimeric unit is shown in Table 5, together with comparative data for $[Cs\{\mu\text{-}N(SiMe_3)_2\}]_2$ (**C**) and $[Cs\{\mu\text{-}N(SiMe_3)_2\}]_2(\mu'\text{-}\eta^6,\eta^6\text{-}PhMe)]_\infty$ (**D**).[25] The caesium atom in each of **A** and **B** has a different coordination environment, as shown schematically in Figure 7. In **A**, there are two close intra-**A** and three inter-**A/B** Cs···Ph contacts: Cs−C(1) 3.473(2), Cs−C(2) 3.556(2), Cs−C(3) 3.682(2), Cs−C(4) 3.487(2), Cs−C(5) 3.586(2) Å. In **B**, only intra-**B**

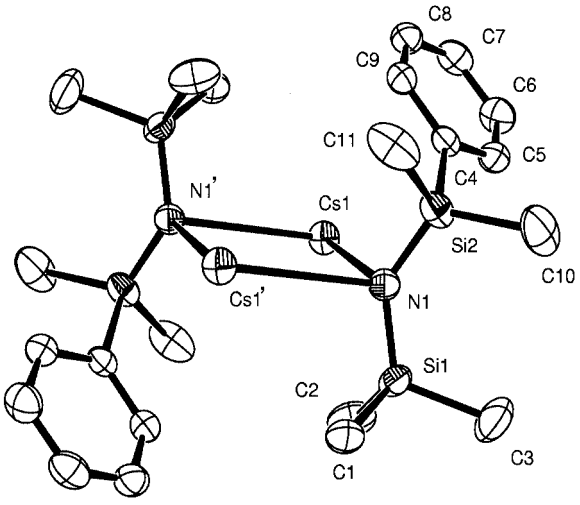

Figure 6. Molecular structure of $[(Cs\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_\infty$ (**6**), showing one of the dimeric units

Cs···Ph contacts are present: Cs−C(8) 3.451(2), Cs−C(9) 3.653(2) Å; but additionally there are two Cs···CH_3 close contacts: Cs−C(7) 3.624(2), Cs−C(6) 3.556(2) Å.

Compound **7** is a centrosymmetric tetramer, comprising a fusion of three rhomboidal planes, arranged in ladder fashion. The conformational order of the ladder in the molecule is *cisoid-transoid* with angles between the planes of 151.21° (Figure 8). The use of benzene as crystallisation solvent, which is η^6-coordinated to each terminal K^+ cation, may have caused the partial rupture of the probable infinite polymeric chain adopted by the solid $[K\{\mu\text{-}N(t\text{Bu})(SiMe_3)\}]_\infty$. We believe that **7** is the first oligomeric potassium amide having a ladder structure. The central rhomboid K2N2 K2′N2′ is flanked by terminal planar K1N1 K2N2 and K1′N1′K2′N2′ rings. The K2 and K2′ ions have three nitrogen atom neighbours and close K2···C3, K2′···C3′ contacts, while K1 and K1′ have two nitrogen neighbours and also are η^6-C_6H_6-bound. Selected bond lengths and angles are listed in Table 6, along with some comparative data for $[K\{\mu\text{-}N(SiMe_3)_2\}]_2$.[23]

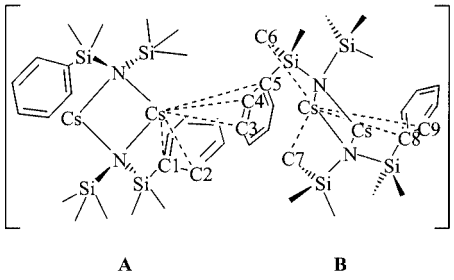

Figure 7. Schematic view of caesium-carbon contacts in a dimeric pair **A** and **B** of $[(Cs\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_\infty$ (**6**)

The crystalline complex $[(K\{\mu\text{-}trans\text{-}N(Ph)(2\text{-}C_5H_4N)\})_2(\mu'\text{-thf})_3]_\infty$ (**8**) has a polymeric chain structure generated by alternation of inversion centres (relating N1 and N1′) and C_2 axes (through O3; Figure 9). Thus, the potassium ions in the chain are connected to one another by alternating bridges of three THF ligands (average K−O bond length, 2.79 Å) and two amido ligands (average K−NPh, 2.81 Å and average K−NC_5H_4, 2.90 Å). A similar [K-(μ-amido)]$_2$ motif is present in $[K\{\mu\text{-}trans\text{-}[N(Ph)(2\text{-}C_5H_4N)]\}(tmeda)]_2$,[19] but the bridging is symmetrical [K−NPh, 2.805(3) Å; K−NC_5H_4-2, 2.841(2) and 2.877(3) Å]; in both this compound [K−N−K′, 73.9(1)° and

N−K−N′, 106.0(1)°] and **8**, the central potassium amido KNK′N′ planar ring has comparable endocyclic bond angles. Similar endocyclic geometric parameters are also found in $[K\{\mu\text{-}trans\text{-}[N(SiMe_3)(2\text{-}C_5H_4N)]\}(12\text{-crown-}4)]_2$ but the K-NSiMe$_3$ distances [2.858(2), 2.912(2) Å] are almost identical to the K−NC$_5$H$_4$-2 distance of 2.853(2) and 2.858(2) Å.[26] An unprecedented feature in the structure of **8** is the presence of the three bridging THF ligands in the M(μ-thf)$_3$M′ moiety; THF-bridging between two metals is well documented, as for M = K.[27−36] Table 7 lists selected geometric parameters for **8**.

Table 7. Selected bond lengths (Å) and angles (°) for **8**

Bond		Angles

K(1)−N(2)	2.908(2)		
K(1)−N(1)′	2.924(2)		

The complex $[K\{\mu\text{-}N(2\text{-}C_5H_4N)_2\}]_\infty$ (**9**) crystallises from THF as a THF-free polymer of layer structure (Figure 10); selected geometric parameters are given in Table 8. Complex **9** differs from each of **1**−**8** in being free from a central cyclic MNM′N′ core. Each potassium ion is in a six-coordinate KN$_6$ environment; for K, four of the nitrogen atoms (N2#1 and N2#2; N2#3 and N2#4) are from μ_2-bridging pyridine atoms on adjacent *cisoid* $[N(C_5H_4N\text{-}2)_2]^-$ ligands, while the other two are from μ_2-amido nitrogen atoms (N1 and N1#5) of another pair of *cisoid* $[N(C_5H_4N\text{-}2)_2]^-$ ligands. Each of the $[N(C_5H_4N\text{-}2)_2]^-$ ligands is thus hexadentate.

Conclusion

The synthesis and structures of the following crystalline alkali metal amides is reported:

1. the homologous series of compounds $[(M\{\mu\text{-}N(SiMe_2Ph)(SiMe_3)\})_2]_n$ [the *cis* complex for $n = 1$ and M = Li (**1**); and the *trans* complexes with $n = \infty$ and M = Na (**2**), K (**4**), Rb (**5**), Cs (**6**)];
2. $[(Na\{\mu\text{-}trans\text{-}N(SiMe_2Ph)(SiMe_3)\})_2(tmeda)]$ (**3**);
3. $[(K\{\mu\text{-}trans\text{-}N(t\text{Bu})(SiMe_3)\})_4(\eta\text{-}C_6H_6)_2]$ (**7**);
4. $[(K\{\mu\text{-}trans\text{-}N(Ph)(2\text{-}C_5H_4N)\})_2(\mu'\text{-thf})_3]_\infty$ (**8**);
5. $[K\{\mu\text{-}N(2\text{-}C_5H_4N)_2\}]_\infty$ (**9**).

Each of **1**−**9** has an unusual, and in some cases unprecedented, molecular structure. Thus **1** is only the second example of a neutral donor-free binuclear lithium amide, while **2** has no antecedents as a neutral donor-free sodium amide. Complex **3** is remarkable in having only one of its two sodium ions bound by a chelating tmeda ligand. Each of the isoleptic amides **4**, **5** and **6** adopts a similar polymeric chain structure made up of a tetranuclear aggregate of two independent dimers **A** and **B**. The centrosymmetric tetranuclear potassium amide **7** is the first potassium amide of ladder structure. The polymeric chain complex **8** provides the first example of a complex in which two metal ions are bridged by three THF ligands. Complex **9**, although crystallised from THF, is a THF-free sheet polymer and is the first X-ray-characterised alkali metal bis(2-pyridyl)amide.

Table 9 provides a summary of the metal coordination environment, as well as M···L contacts, in which L represents a non-nitrogen-centred neutral ligand.

Experimental Section

General Remarks: All manipulations were performed under argon using standard Schlenk techniques. Toluene was dried using sodium. Pentane, benzene and hexane were dried using sodium-potassium alloy; THF was dried and distilled from sodium-benzophenone and stored over a sodium mirror under argon; tmeda (Aldrich) was distilled from CaH_2 prior to use. The NMR spectra were recorded on a Bruker DPX 300 (300.1 MHz for ^1H, 75.5 MHz for ^{13}C and 116.6 MHz for ^7Li) or AMX 500 (49.7 MHz for ^{29}Si) instruments and referenced externally (^7Li, using LiCl; ^{29}Si, using $SiMe_4$) or internally to the residual solvent resonances (chemical shift data in δ). Unless otherwise stated, all NMR spectra were measured at 298 K and other than ^1H were proton-decoupled. Electron impact mass spectra were taken from solid samples using a Kratos MS 80 RF instrument. Melting points were taken in sealed capillaries and are uncorrected. Elemental analyses were determined by Medac Ltd., Brunel University. The amines HN(*t*Bu)SiMe_3 and HN($SiMe_2Ph$)($SiMe_3$) (Aldrich) were dried over KOH and distilled therefrom, while HN(Ph)(2-C_5H_4N) and HN(2-$C_5H_4N)_2$ (Aldrich) were used without purification.

$[Li\{\mu\text{-}cis\text{-}N(SiMe_2Ph)(SiMe_3)\}]_2$ (1): L*i*nBu (6 mL of a 1.6 mol·dm^{-3} solution in hexane, 9.60 mmol) was added dropwise to a cooled (−70 °C) and stirred solution of HN($SiMe_2Ph$)($SiMe_3$) (2.13 g, 9.53 mmol) in pentane (35 mL) over a period of 15 min. The reaction mixture was warmed to room temperature and stirred

for 12 h. The mixture was filtered and the filtrate was concentrated and stored at −25 °C for two days yielding tiny white crystals. Recrystallisation from hexane afforded colourless crystals of **1** (1.22 g, 56%), m.p. 60−65 °C. $C_{22}H_{40}Li_2N_2Si_4$ (458.8): calcd. C 57.6, H 8.79, N 6.10; found C 56.6, H 8.30, N 5.81. ^{1}H NMR ($C_6D_5CD_3$): δ = 0.02 (s, 9 H, $SiMe_3$), 0.27 (s, 6 H, $SiMe_2Ph$), 7.07−7.17 (m, 1 H, *p*-H), 7.20−7.25 (t, $^3J_{H,H}$ = 6.4 Hz, 2 H), 7.45 (dd, $^3J_{H,H}$ = 6.4, $^4J_{H,H}$ = 1.4 Hz, 2 H) ppm. ^{13}C NMR ($C_6D_5CD_3$): δ = 3.5 ($SiMe_3$), 4.7 ($SiMe_2Ph$), 129.7, 129.9, 133.2, 143.8 (*ipso*-C) ppm. ^{29}Si NMR ($C_6D_5CD_3$): δ = −13.9, −10.6 ppm. ^{7}Li NMR ($C_6D_5CD_3$): δ = −2.0 ppm. MS (*M* denotes the monomer): *m*/*z* (%) = 271 (10) [M_2 − $SiMe_2Ph$ −3Me − Li]$^+$, 208 (100) [$SiMe_2Ph$ + $SiMe_3$]$^+$, 192 (57) [271 − $SiMe_3$ − Li + H]$^+$.

[(Na{μ-*trans*-N($SiMe_2Ph$)($SiMe_3$)})$_2$]$_\infty$ (2): Benzylsodium (0.43 g, 3.80 mmol) was added in small portions to a cooled (−78 °C) and stirred solution of HN($SiMe_2Ph$)($SiMe_3$) (0.963 mL, 3.74 mmol) in hexane (50 mL). The reaction mixture was warmed to room temperature and stirred for 12 h. The volatiles were removed at 35 °C/10^{-2} Torr for 30 min. The residue was washed with hexane to yield compound **2** as a white fluffy powder (0.72 g, 79%). $C_{22}H_{40}N_2Na_2Si_4$ (491.0): calcd. C 53.8, H 8.21, N 5.71; found C 52.5, H 8.28, N 5.49%. Recrystallisation from benzene after 1 day at 15 °C afforded colourless plates of **2** (0.57 g, 62%), m.p. 130−133 °C. ^{1}H NMR (C_6D_6): δ = 0.05 (s, 9 H, $SiMe_3$), 0.31 (s, 6 H, $SiMe_2Ph$), 7.14−7.23 (m, 3 H), 7.50 (d, $^3J_{H,H}$ = 7.7 Hz, 2 H) ppm. ^{13}C NMR (C_6D_6): δ = 5.1 ($SiMe_3$), 6.9 ($SiMe_2Ph$), 128.5 (*p*-C), 128.8, 132.7, 148.7 (*ipso*-C) ppm. ^{29}Si NMR (C_6D_6): δ = −18.1, −13.2 ppm. MS (*M* denotes the monomer): *m*/*z* (%) = 342 (50) [M_2 − $PhSiMe_3$ +2H]$^+$, 270 (55) [Na_2M +2H]$^+$, 192 (100) [M − Na]$^+$, 135 (70) [$SiPhMe_2$]$^+$.

[(Na{μ-*trans*-N($SiMe_2Ph$)($SiMe_3$)})$_2$(tmeda)] (3): Addition of tmeda (0.57 mL, 3.75 mmol) to a milky suspension of Na[N($SiMe_2Ph$)($SiMe_3$)] (0.46 g, 1.87 mmol) in hexane (40 mL) immediately gave a colourless mixture, which was stirred for 2 h at room temperature, then filtered. The volatiles were removed at 25 °C/10^{-2} Torr for 30 min. The residue was extracted with benzene (20 mL) and the extract was concentrated (to ca. 1 mL); hexane (10 mL) was added. Storage at −25 °C for two weeks yielded compound **3** (0.52 g, 44%) as transparent crystals, m.p. 55−60 °C. $C_{28}H_{56}N_4Na_2Si_4$ (607.1): calcd. C 55.4, H 9.30, N 9.22; found C 54.1, H 9.32, N 8.95. ^{1}H NMR (C_6D_6): δ = 0.23 (s, 9 H, $SiMe_3$), 0.47 (s, 6 H, $SiMe_2$), 1.52 (s, 4 H, CH_2, tmeda), 1.62 (s, 12 H, Me, tmeda), 7.23 (m, 3 H, *p*-H and *m*-H), 7.66 (d, $^3J_{H,H}$ = 7.77, $^4J_{H,H}$ = 1.37 Hz, 2 H, *o*-H) ppm. ^{13}C NMR (C_6D_6): δ = 5.3 ($SiMe_3$), 7.1 ($SiMe_2Ph$), 45.3 (CH_3, tmeda), 56.6 (CH_2, tmeda), 132.95, 128.1, 128.6 (Ph), 149.8 (*ipso*-C) ppm. ^{29}Si NMR (C_6D_6): δ = −20.9 ($SiMe_3$), −16.6 ($SiMe_2Ph$) ppm. MS (*M* denotes the monomer of **3**): *m*/*z* (%) = 530 (8) [M_2 − Ph]$^+$, 500 (13) [M_2 − Ph − 2Me]$^+$, 475 (63) [M_2 − $SiMe_2Ph$ − 3H]$^+$, 459 (80) [M_2-2$SiMe_3$]$^+$, 399 (35) [M_2 − amine − Me]$^+$, 230 (100) [*M* − tmeda − Me]$^+$, 208 (95) [*M* − tmeda − Na − Me]$^+$, 192 (82) [208 − Me]$^+$, 58 (100) [1/2 tmeda]$^+$.

[(K{μ-*trans*-N($SiMe_2Ph$)($SiMe_3$)})$_2$]$_\infty$ (4): Benzylpotassium (1.0 g, 7.68 mmol) was added in small portions to a cooled (−78 °C) and stirred solution of HN($SiMe_2Ph$)($SiMe_3$) (2.1 mL, 8.06 mmol) in hexane (60 mL). The reaction mixture was allowed to warm up to room temperature and stirred for 12 h. The volatiles were removed at 35 °C/10^{-2} Torr for 30 min. The residue was washed with hexane (4 × 15 mL) to yield compound **4** (1.76 g, 88%) as a white fluffy powder, m.p. 131−135 °C. $C_{22}H_{40}K_2N_2Si_4$ (532.1): calcd. C 50.5, H 7.71, N 5.35; found C 48.7, H 7.81, N 5.35. Sublimation at 180 °C/5 × 10^{-4} Torr afforded a few X-ray quality crystals. ^{1}H NMR (C_6D_6): δ = 0.12 (s, 9 H, $SiMe_3$), 0.28 (s, 6 H, $SiMe_2Ph$), 7.18 (dd, $^3J_{H,H}$ = 1.50, $^4J_{H,H}$ = 1.37 Hz, 2 H), 7.23 (d, $^3J_{H,H}$ = 7.23 Hz, 2 H), 7.55 (dd, $^3J_{H,H}$ = 7.51, $^4J_{H,H}$ = 1.35 Hz, 2 H) ppm. ^{13}C NMR (C_6D_6): δ = 5.6 ($SiMe_3$), 7.2 ($SiMe_2Ph$), 127.8, 128.3, 133.1 (Ph) ppm. ^{29}Si NMR (C_6D_6): δ = −24.0, −19.5 ppm. MS (*M* denotes the monomer): *m*/*z* (%) = 270 (22) [M_2 − $SiMe_2Ph$ − $SiMe_3$-3Me + H]$^+$), 208 (100) [$SiMe_3$ + $SiMe_2Ph$]$^+$, 194 (72) [208 − Me + H]$^+$.

[(Rb{μ-*trans*-N($SiMe_2Ph$)($SiMe_3$)})$_2$]$_\infty$ (5): Benzylrubidium (0.23 g, 1.30 mmol) was added in small portions to a cooled (−78 °C) and stirred solution of HN($SiMe_2Ph$)($SiMe_3$) (0.35 mL, 1.36 mmol) in hexane (25 mL). The reaction mixture was allowed to warm up to room temperature and stirred for 12 h. The volatiles were removed at 25 °C/10^{-2} Torr for 30 min. The residue was washed with hexane (4 × 5 mL) to yield compound **5** (0.35 g, 87%) as a grey fluffy powder. $C_{22}H_{40}N_2Rb_2Si_4$ (615.9): calcd. C 42.9, H 6.55, N 4.55; found C 39.8, H 6.59, N 4.49. Compound **5** was extracted into hot toluene (10 mL) and the extract was filtered; the filtrate was concentrated and stored at 15 °C for 12 h to afford tiny transparent crystals, m.p. 150−152 °C. ^{1}H NMR ($C_6D_5CD_3$): δ = 0.03 (s, 9 H, $SiMe_3$), 0.22 (s, 6 H, $SiMe_2Ph$), 7.12 (m, 3 H, *p*-H and *m*-H), 7.49 (dd, $^3J_{H,H}$ = 7.84, $^4J_{H,H}$ = 1.46 Hz, 2 H) ppm. ^{13}C NMR ($C_6D_5CD_3$): δ = 5.4 ($SiMe_3$), 7.2 ($SiMe_2$), 127.6, 128.2, 133.2 (Ph) ppm. C of 2-C_5H_4N), 135.95 (*4*-*C* of 2-C_5H_4N), 114.1 (*5*-*C* of 2-C_5H_4N), 109.45 (*3*-*C* of 2-C_5H_4N) ppm.

X-ray Crystallographic Study: Diffraction data for compounds **3**−**9** were collected on an Enraf−Nonius Kappa-CCD diffractometer using monochromated Mo-K_α radiation (λ = 0.71073 Å). Crystals were directly mounted on the diffractometer under a stream of cold nitrogen gas. For compound **7**, the [N(*t*Bu)$SiMe_3$] groups are predominantly as shown in Figure 5 but with a small occupancy having the *t*Bu and $SiMe_3$ groups reversed; the disorder is 0.75:0.25 for the N1 group and 0.87:0.13 for the N2 group; the disorder was not resolved and hence the dimensions within these groups are unreliable. The structures were refined on all F^2 using SHELXL 97.[37] Further details are given in Table 10.

Hypersilyl-Substituted Complexes of Group 1 and 2 Metals: Syntheses, Structures and Use in Styrene Polymerisation

Florian Feil[a] and Sjoerd Harder*[a]

In memory of Professor Ron Snaith

Keywords: Alkali metals / Alkaline earth metals / Si ligands / Polymerization

Alkali and alkaline-earth metal complexes with sterically demanding hypersilyl-substituted cyclopentadienyl or fluorenyl ligands [hSi-Cp or hSi-Flu; hSi = $(Me_3Si)_3Si$] were prepared. The crystal structures of $[Li(hSi\text{-}Flu)(THF)_2]$, [K(hSi-Flu)(THF)], $[Ca(hSi\text{-}Flu)_2(THF)_2]$, $[Sr(hSi\text{-}Flu)_2(THF)_2]$ and $[Ca(hSi\text{-}Cp)_2(THF)]$ were determined. All structures show the enormous steric bulk of the hypersilyl substituent, which either results in a reduction in the number of solvent molecules in the coordination sphere of the metal or in a distortion of the ligand-metal interaction. Heteroleptic calcium and strontium complexes with a benzyl ligand (2-Me_2N-α-Me_3Si-benzyl) and a sterically demanding hSi-Flu ligand were prepared and used as initiators in the polymerization of styrene. The polymers produced with the heteroleptic benzylcalcium initiator are enriched in syndiotactic sequences, although they show the same tacticities as polymers obtained with benzylcalcium initiators containing the less bulky Me_3Si-Flu ligand. Introduction of the bulky hypersilyl group in heteroleptic benzylstrontium initiators resulted in a slight increase of the syndiotacticity of the polymers.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

We recently introduced novel heteroleptic benzylcalcium complexes (e.g. **1**)[1] as initiators for the living anionic polymerization of styrene. The polymers obtained show a high degree of syndiotacticity.[2] Syndioselective chain growth arises from a chain-end controlled insertion mechanism (**2**) in which communication between the chiral chain-end and the chiral carbon of a coordinated styrene monomer is responsible for stereocontrol. The 9-Me_3Si-fluorenyl group in **1** is a spectator ligand, i.e. it fills one side of the coordination sphere around calcium and is passive during the polymerization. We are currently studying the influence of the spectator ligand on the syndioselectivity in styrene polymerization.

A highly sterically demanding spectator ligand, like 9-hypersilyl-fluorenyl [9-$(Me_3Si)_3Si$-fluorenyl), would confine the remaining coordination sphere around calcium and decrease the distance between the chiral centers in the polymerization active species **3**. This might lead to a more efficient communication between chain-end and monomer, thus improving stereocontrol.

3

Here we describe the syntheses and structures of hypersilyl-substituted fluorenyl and cyclopentadienyl complexes of alkali and alkaline-earth metals. Also, the syntheses and applications in styrene polymerization of heteroleptic benzylcalcium and -strontium complexes containing the hypersilyl-substituted ligands are described.

Results and Discussion

Direct lithiation of 9-hypersilyl-fluorene (hSi-FluH) with *n*BuLi in THF gave the lithium complex 9-hypersilyl-fluorenyllithium Li(hSi-Flu) in quantitative yield. Recrystallization of the crude product yielded bright-red, plate-like crystals with the composition [Li(hSi-Flu)(THF)$_2$]. The monomeric lithium complex (Figure 1) contains a Li^+ ion with a nearly planar trigonal coordination sphere: the sum of the valence angles between O1, O2 and ring$_{center}$ is 357.2°. The Li^+ ion is bonded over the five-membered ring of the hSi-Flu ligand and, despite the steric bulk of the hypersilyl group, is situated slightly closer to the carbon attached to Si. This situation has also been observed in Me_3Si-fluorenyl complexes of the alkaline-earth metals[1,3] and is likely attributed to the higher charge-density at the silyl-substituted carbon. A space-filling model of Li(hSi-Flu) (Figure 1b) shows the extraordinary steric bulk of the hypersilyl substituent. This substituent is efficiently shielding a large part of the metal's coordination sphere, although no indication of agostic $SiCH_3\cdots Li^+$ interactions is found (the shortest C···Li distance observed is 3.975 Å).

The number of THF ligands attached to Li^+ is another measure of the steric bulk of the hSi-Flu anion. The *ansa*-lithocene anion $[Me_2Si(Flu)_2Li]^-$ also crystallizes with two THF ligands bonded to Li^+.[4] Likewise, a fluorenyllithium complex with a pendant chelating $CH_2CH_2NMe_2$ arm in the 9-position crystallizes with two THF ligands at the Li^+ ion.[5] Therefore, the steric demand of the hSi-Flu$^-$ ligand is similar to that of 9-$(Me_2NCH_2CH_2)$Flu$^-$ or to that of the dianionic *ansa*-ligand $Me_2Si(Flu)_2{}^{2-}$.

Reaction of 9-hypersilyl-fluorene with the superbase mixture *n*BuLi/KOCMe(Et)$_2$ yielded 9-hypersilyl-fluorenylpotassium K(hSi-Flu) in 85% isolated yield. Recrystallization of the raw product from a benzene/THF mixture gave orange needle-like crystals with the composition [K(hSi-Flu)(THF)(C_6H_6)]. The K(hSi-Flu) units form a polymer chain (Figure 2) in which the K^+ ions are sandwiched between the six-membered rings of neighbouring hSi-Flu anions. The large hypersilyl substituents of neighbouring hSi-Flu anions point in opposite directions. The THF ligands complete the planar trigonal coordination of the K^+ ions (the sum of the valence angles between O and the aryl ring centers is 359.4°). Vacant sites in the coordination sphere of K^+ are shielded by the bulk of the hypersilyl groups. Short $Si-CH_3\cdots K^+$ contacts (Figure 2) point to weak agostic interactions. The benzene solvent fills channels between the chains; there is no interaction between benzene and K^+. A similar chain structure was observed

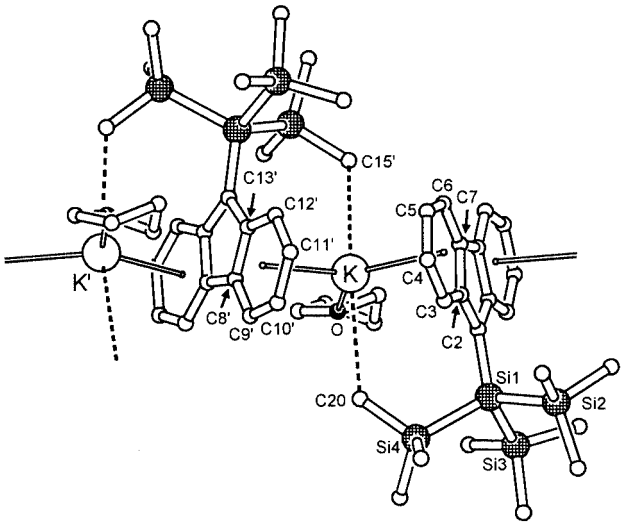

Figure 2. The crystal structure of {K(hSi-Flu)(THF)}$_\infty$ (hydrogens omitted for clarity); C−K bond lengths (Å) for atoms in the ring C2, C3, C4, C5, C6, C7 are respectively 3.053(4), 3.258(6), 3.391(8), 3.385(7), 3.210(6) and 3.015(4), ring$_{center}$−K = 2.903(3) Å; C−K bond lengths (Å) in the ring C8′, C9′, C10′, C11′, C12′, C13′ are respectively 3.114(4), 3.209(6), 3.240(7), 3.187(7), 3.117(6) and 3.072(4), ring$_{center}$−K 2.829(3) Å; O−K 1.919(4) Å; weak agostic $Si-CH_3\cdots K^+$ interactions: C15′···K 3.80(1) Å and C20···K 3.40(1) Å

for K(9-*t*Bu-Flu),[6] which crystallizes with two, instead of one, THF ligands coordinated to K^+, again showing the steric bulk of the hypersilyl substituent.

Reaction of two equivalents of K(hSi-Flu) with CaI_2 in THF gave bis[9-hypersilyl-fluorenyl]calcium, Ca(hSi-Flu)$_2$. Recrystallization of the crude product from hot benzene yielded red, needle-like crystals with the composition [Ca(hSi-Flu)$_2$(THF)$_2$(C_6H_6)]. The crystal structure of this monomeric calcium complex is shown in Figure 3. One of the hSi-Flu$^-$ ligands binds the Ca^{2+} ion in an η^5 fashion with Ca−C bond lengths in the narrow range of 2.722(4)−2.785(4) Å. The second hSi-Flu$^-$ ligand binds to Ca^{2+} only with the outer edge of the fluorenyl ring. This is a rather unusual and hitherto unseen bonding mode for a fluorenyl ligand in a non-polymeric coordination complex. The enormous bulk of the hypersilyl group apparently blocks η^5 coordination of a second hSi-Flu ligand. Also, the shallow potential energy surface of the fluorenyl anion allows easy migration of the metal cations.[7] The structure of [Ca(hSi-Flu)$_2$(THF)$_2$] can be interpreted as an intermediate on the pathway for formation of the solvent-separated ion-pair (ssip) [hSi-FluCa$^+$·(THF)$_3$] [hSi-Flu$^-$]. Structures of the first ssip's with calcium have been reported only recently: the structure of [Cp*Ca$^+$·(O=PPh$_3$)$_3$][I$^-$][8] and the structure of a complete ssip [Me_3Si-Flu$^-$]$_2$ [C_6H_6]$_2$ [Ca^{2+}·(THF)$_6$], which was described with the "metal-in-a-box" model.[9]

The analogous Sr complex, Sr(hSi-Flu)$_2$, was obtained by reacting two equivalents of hSi-FluK with SrI_2 in THF. Recrystallization from hot hexane yielded dark-red crystals with the composition [Sr(hSi-Flu)$_2$(THF)$_2$]. The crystal structure of [Sr(hSi-Flu)$_2$(THF)$_2$] (Figure 4) is similar to that of its Ca analogue. One of the hSi-Flu$^-$ ligands is coordinated through the five-membered ring, whereas the other ligand coordinates through the aryl part of the fluorenyl ring. Despite the larger radius of Sr^{2+} (Ca: 0.99 Å, Sr 1.12 Å), a second coordination through the five-membered ring is still not possible on the basis of steric congestion. However, the larger Sr^{2+} ion allows a more extended aryl-metal interaction than in the Ca complex.

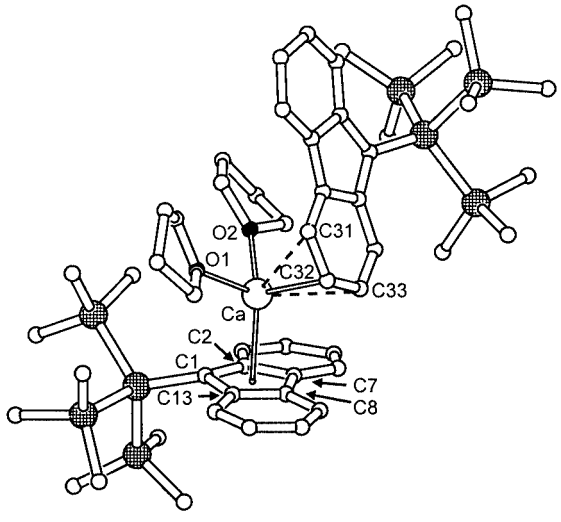

Figure 3. The crystal structure of [Ca(hSi-Flu)$_2$(THF)$_2$] (hydrogens omitted for clarity); C−Ca bond lengths (Å) for atoms in the ring C1, C2, C7, C8, C13 are respectively 2.748(4), 2.785(4), 2.766(4), 2.735(4) and 2.722(4), ring$_{center}$−Ca = 2.462(2) Å; Ca−O1 2.296(3), Ca−O2 2.376(4), Ca−C31 2.993(4), Ca−C32 2.662(4), Ca−C33 2.833(4)

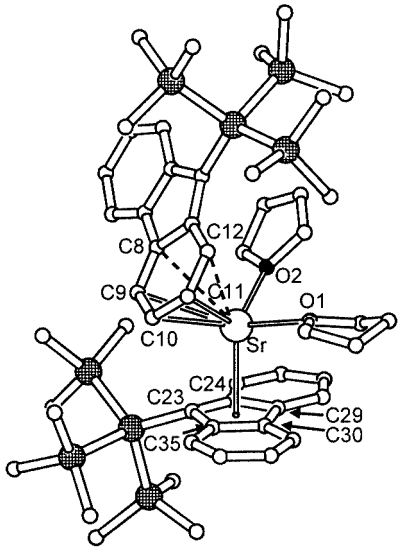

Figure 4. The crystal structure of [Sr(hSi-Flu)$_2$(THF)$_2$] (hydrogens omitted for clarity); C−Sr bond lengths (Å) for atoms in the ring C23, C24, C29, C30, C35 are respectively 2.913(3), 2.891(3), 2.852(3), 2.863(3) and 2.876(3), ring$_{center}$−Sr = 2.606(2) Å; Sr−C8 3.095(3), Sr−C9 2.927(4), Sr−C10 2.853(4), Sr−C11 2.929(4), Sr−C12 3.099(3), Sr−O1 2.466(3), Sr−O2 2.551(2)

The various crystal structures of alkali and alkaline-earth metal complexes with the hSi-Flu ligand show the enormous steric bulk of the hypersilyl substituent. The $(Me_3Si)_3Si$ substituents all display normal Si−Si and Si−C bond lengths, as well as expected tetrahedral Si−Si−Si, Si−Si−C and C−Si−C angles. This means that steric stress is relieved rather by deformation of the metal coordination sphere than by deformation of the hypersilyl substituent. It should be mentioned, however, that whereas the $(Me_3Si)_3Si$ geometry itself is practically undisturbed, the (Flu)C−Si bond is slightly elongated: bond lengths in the complexes reported here vary from 1.864(4) to 1.885(3) Å. In comparison, a typical (sp^2)C−Si bond length is tabulated as 1.84(1) Å[10] and the (Flu)C−Si bond length in **1** is 1.851(2) Å.[1] A similar situation was observed in the sterically congested $(Me_3Si)_3Si$-fluorene itself: the (Flu)C−Si bond of 1.947(4) Å[11] is significantly longer than an average (sp^3)C−Si bond [1.865(8) Å].[10] All structures reported here also show a similar rotation of the $(Me_3Si)_3Si$ substituent with respect to the fluorenyl plane: typically, one of the Me_3Si groups eclipses the plane of the fluorenyl ring, whereas the other two are in gauche positions. Especially noteworthy are the geometries of the (η^5)hSi-Flu ligands in the complexes [Ca(hSi-Flu)$_2$(THF)$_2$] and [Sr(hSi-Flu)$_2$(THF)$_2$]. The fluorenyl rings show deviations from planarity, with the aryl

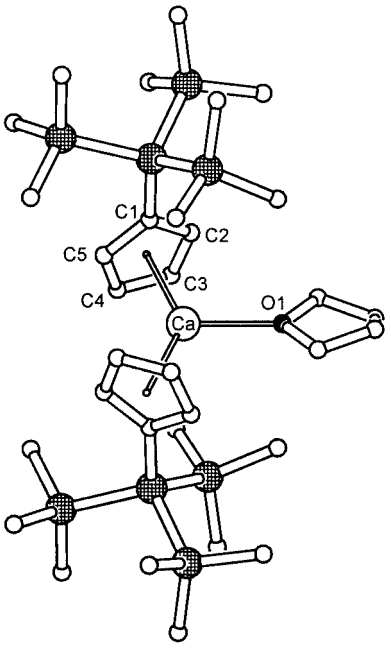

Figure 5. The crystal structure of [Ca(hSi-Cp)$_2$(THF)] (hydrogens omitted for clarity; crystallographic C_2 axis through Ca−O); C−Ca bond lengths (Å) for atoms in the ring C1, C2, C3, C4, C5 are respectively 2.667(3), 2.655(3), 2.657(3), 2.649(3) and 2.649(3), ring$_{center}$−Ca = 2.371(2) Å; Ca−O1 2.381(3)

parts being slightly bent away from the metal. More importantly, the $(Me_3Si)_3Si$ substituents are bent out of the C_5 plane away from the metal [Ca: 16.1(2)° and 13.9(2)°; Sr: 20.2(2) and 10.3(2)°]. Out-of-plane bending of silyl substituents costs only half the energy of that of alkyl substituents[4] and maximizes the Coulomb attraction between Flu^- and M^{2+}.[12] We attribute these deviations also partly to steric stress between the hypersilyl substituent and the rest of the structure.

In order to evaluate the effect of a large hypersilyl substituent in a Cp ring, we also prepared Ca(hSi-Cp)$_2$ from K(hSi-Cp) and CaI_2. The compound crystallized from a hexane/THF mixture in the form of colourless plates with the composition [Ca(hSi-Cp)$_2$(THF)]. The crystal structure (Figure 5) shows a C_2-symmetric sandwich complex with a perfectly trigonal planar coordination at Ca.

The hSi-Cp ligands coordinate to the Ca^{2+} ion in an η^5 fashion with Ca−C bond lengths in the narrow range of 2.649(3) to 2.667(3) Å. Steric stress is avoided by the orientation of the two hypersilyl substituents in different directions rather than by a distortion of the Cp-Ca coordination. The two sterically demanding hSi-Cp ligands leave room for coordination of only one THF ligand [all other monosubstituted calcocenes, Ca(RCp)$_2$, possess two THF ligands]. The steric bulk of the hSi-Cp ligand can be compared to that of 1,3-$(Me_3Si)_2$Cp or *i*Pr$(Me)_4$Cp, which both form calcocenes with only one THF ligand.[13,14]

The heteroleptic alkaline-earth metal complexes containing the hypersilyl-substituted ligands are of particular interest as initiators in stereoselective styrene polymerization.[1] These initiators were prepared by mixing the homoleptic bis-fluorenyl and bis-cyclopentadienyl complexes of Ca (or Sr) with a polymerization-active homoleptic dibenzylcalcium (or strontium) complex.

Reaction of [Ca(hSi-Flu)$_2$(THF)$_2$] with [Ca(DMAT)$_2$(THF)$_2$] in C_6D_6 [Equation (1)] resulted in the quantitative formation of the heteroleptic calcium complex [Ca(DMAT)(hSi-Flu)(THF)$_x$] with x = 1 or 2. The heteroleptic nature of the newly formed complex is clear from NOE's observed between protons of the hSi-Flu ligand and protons of the DMAT ligand. Low temperature NMR spectra (0 °C) of the heteroleptic complex show unique signals for all fluorenyl protons, which are diastereotopic due to the chirality of the benzylic carbon [$\Delta G^{\ddagger}$(20 °C) = 15.3 kcal

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mol^{-1}]. Fast exchange proceeds either by inversion of the chiral benzyl carbon or by a dissociation/association process of the hSi-Flu$^-$ ligand. It is unclear how many THF molecules coordinate at the Ca^{2+} ion. Evaporation of the solvent and drying of the complex under vacuum (0.01 Torr) at 60 °C yielded the complex [Ca(DMAT)(hSi-Flu)(THF)]. The NMR spectra of [Ca(DMAT)(hSi-Flu)(THF)] redissolved in C_6D_6 also display signals originating from small amounts of the homoleptic precursors ($K \approx 20$). This means that the Schlenk equilibrium is dependent on the Ca/THF ratio.

Reaction of the homoleptic complexes [Ca(hSi-Cp)$_2$(THF)] and [Ca(DMAT)$_2$(THF)$_2$] in C_6D_6 [Equation (2)] resulted in a mixture of both a homoleptic and a heteroleptic calcium complex ($K \approx 3$). In this case no strong preference for the formation of the heteroleptic complex was found. The use of fluorenyl ligands seems therefore to be essential in directing the Schlenk equilibrium to the heteroleptic side. This might originate from the steric stress observed in the crystal structure of homoleptic [Ca(hSi-Flu)$_2$(THF)$_2$], making this particular homoleptic species energetically unfavourable. Steric stress is less severe in homoleptic [Ca(hSi-Cp)$_2$(THF)]: the Cp-Ca coordination observed for both hSi-Cp ligands is not distorted from an ideal η^5 geometry.

Reaction of the homoleptic complexes [Sr(hSi-Flu)$_2$(THF)$_2$] and [Sr(DMAT)$_2$(THF)$_2$] in C_6D_6 [Equation (1)] resulted in the formation of the heteroleptic strontium complex as the major product. Only traces of the homoleptic compounds were detected ($K \approx 800$). Evaporation of the solvent and drying of the complex under vacuum (0.01 Torr) at 60 °C yielded the complex [Sr(hSi-Flu)(DMAT)(THF)]. The Schlenk equilibrium for this compound dissolved in C_6D_6 is similar as above ($K \approx 800$). The heteroleptic complex shows NOE's between the two different ligands. Also, at lower temperatures diastereotopic fluorenyl signals were observed [$\Delta G^{\ddagger}$(5 °C) = 14.2 kcal mol^{-1}].

Styrene polymerizations with a mixture of [Ca(hSi-Flu)$_2$(THF)$_2$] and [Ca(DMAT)$_2$(THF)$_2$], i.e. with the pure heteroleptic compound, were carried out. ^{13}C NMR analyses of the polymers obtained show that there is no significant improvement in the syndiotacticity when compared with polymers obtained by polymerization with **1** (r = 92%, rr = 85%).[2] However, it was found that, under the same reaction conditions, the chain lengths of the polymers obtained with the more bulky hypersilyl-substituted initiator are only 10% of those of polymers obtained with initiator **1**. Apparently, the chain-growth step for the hypersilyl-substituted species **3** is significantly slower than that for the less bulky active species **2**. It should be mentioned that a discussion on the relation of polymer tacticity and spectator ligand is hampered by the possible existence of small quantities of homoleptic polymerylcalcium species which might influence the overall stereoselectivity of monomer insertion.

Styrene polymerization with a mixture of [Sr(hSi-Flu)$_2$(THF)$_2$] and [Sr(DMAT)$_2$(THF)$_2$], i.e. with a predominantly heteroleptic compound, were carried out. ^{13}C NMR analyses of the polymers obtained show that there is a slight improvement in syndiotacticity when compared with polymers obtained by polymerization with a mixture of [Sr(Me$_3$Si-Flu)$_2$(THF)] and [Sr(DMAT)$_2$(THF)$_2$].[15] The syndiotacticity of the polymers is, however, lower than that of polymers obtained with analogous Ca initiators and no estimation of r and rr J-ades could be made. The use of the bulky hSi-Flu ligand in Sr initiators also resulted in short chain lengths, indicative of a sluggish chain growth.

Conclusion

Homoleptic hypersilyl-substituted cyclopentadienyl and fluorenyl complexes of alkali and alkaline-earth metals are readily accessible in crystalline purity. All crystal structures of these compounds show the enormous bulk of the hypersilyl substituent, which either limits the number of THF ligands coordinated at the metal center or distorts the metal-anion coordination geometry. The homoleptic [M(hSi-Flu)$_2$(THF)$_2$] complexes of Ca and Sr, both show structures in which one of the hSi-Flu$^-$ ligands is only weakly bound through the edge of the aryl ring. These compounds are intermediates on the reaction path to the solvent-separated ion-pair [hSi-FluM$^+$(THF)$_3$] [hSi-Flu$^-$].

Heteroleptic benzylcalcium and -strontium complexes with hSi-Flu spectator ligands were generated by ligand exchange between the homoleptic compounds. The Schlenk equilibrium for the fluorenyl complexes lies largely towards the heteroleptic side. Exchange of the fluorenyl group for a cyclopentadienyl group resulted in mixtures of homo- and heteroleptic complexes.

Styrene polymerization with benzylcalcium initiators containing the sterically demanding hSi-Flu spectator ligand gave predominantly syndiotactic polymers (r = 92%, rr = 85%). However, no improvement was observed in comparison with polymers obtained with **1**, i.e. with Me$_3$Si-Flu as a spectator ligand. Only in the case of benzylstrontium initiators containing the hSi-Flu spectator ligand was a slight improvement in the syndiotacticity of the obtained polymer observed. In all cases the large hypersilyl substituent retarded the chain growth step.

Experimental Section

General Remarks: All experiments were carried out under argon using dry solvents and Schlenk techniques. The following compounds were prepared according to literature procedures: 9-tris(trimethylsilyl)silylfluorene,[11] bis(2-dimethylamino-α-Me$_3$Si-benzyl)-bis(tetrahydrofuran)calcium[16] and bis(2-dimethylamino-α-Me$_3$Si-benzyl)bis(tetrahydrofuran)strontium.[17] NMR spectra were recorded on Bruker AC250 (250 MHz) and Bruker DRX600 (600 MHz) machines.

Polymerizations of styrene were performed in a thermostatted 100 mL stainless-steel reactor at normal pressure. Polymerizations were either carried out in a 1 M styrene solution (90 mL cyclohexane and 11.5 mL styrene at 50 °C) or in pure styrene (at 20 °C).

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Styrene was freshly distilled from CaH_2 and kept over dry aloxperls. A solution of the initiator (0.1 mmol of active benzyl anion) in 1.0 mL of benzene/cyclohexane was added via a port. After a polymerization time of 30 minutes the mixture was quenched with oxygen-free methanol. The tacticity of the polymer was checked by analyzing the ^{13}C NMR signal (solvent: [D_2]tetrachloroethane) for the C_{ipso} phenyl ring carbon.[2]

[Li(hSi-Flu)(THF)$_2$]: *n*-Butyllithium (1.6 M in hexane, 1.06 mL, 1.70 mmol) was added dropwise to a solution of 9-tris(trimethylsilyl)silylfluorene (0.70 g, 1.70 mmol) in 10 mL of THF at −68 °C. The solution was stirred at this temperature for 1 h and slowly turned orange. Thereafter the solution was warmed slowly to room temperature, and the solvents were removed. The sticky orange product was washed with 10 mL of hexane and dissolved in a mixture of warm benzene (10 mL) and THF (2 mL). Cooling to room temperature overnight afforded bright-red, plate-like crystals of the title compound (98%, 0.94 g). ^1H NMR (250 MHz, [D_6]benzene): δ = 0.48 [s, 27 H, $(Me_3Si)_3Si$], 1.03 (m, 8 H, THF), 2.67 (m, 8 H, THF), 7.07 (dd, *J* = 7.2 Hz, 2 H, fluorenyl), 7.39 (dd, *J* = 7.5 Hz, 2 H, fluorenyl), 8.12 (d, *J* = 8.3 Hz, 2 H, fluorenyl), 8.28 (d, *J* = 7.8 Hz, 2 H, fluorenyl) ppm. $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 4.0 [$(Me_3Si)_3Si$], 25.2 (THF), 67.4 (THF), 87.2 (fluorenyl), 114.4 (fluorenyl), 119.9 (fluorenyl), 121.2 (fluorenyl), 122.2 (fluorenyl), 124.4 (fluorenyl), 141.7 (fluorenyl) ppm.

[K(hSi-Flu)(THF)]: *n*-Butyllithium (1.6 M in hexane, 2.27 mL, 3.63 mmol) was added dropwise to a mixture of 9-tris(trimethylsilyl)silylfluorene (1.50 g, 3.63 mmol) and potassium 3-methyl-3-pentanolate in 30 mL of THF at −68 °C. The solution was stirred at this temperature for about one hour and slowly turned red. Thereafter the solution was warmed slowly to room temperature and the solvents were removed. The orange residue was washed five times with 10 mL portions of hexane and was dissolved in a mixture of warm benzene (10 mL) and THF (2 mL). Cooling to 20 °C overnight yielded orange-red needles of a benzene solvate of the title compound (85%, 1.85 g) which can be freed from THF and benzene under vacuum. ^1H NMR (250 MHz, [D_6]benzene/[D_8]THF 10:1): δ = 0.44 [s, 27 H, $(Me_3Si)_3Si$], 1.43 (m, 4 H, THF), 3.56 (m, 4 H, THF), 6.90 (dd, *J* = 7.6 Hz, 2 H, fluorenyl), 7.28 (dd, *J* = 7.1 Hz, 2 H, fluorenyl), 7.64 (d, *J* = 8.3 Hz, 2 H, fluorenyl), 8.19 (d, *J* = 7.7 Hz, 2 H, fluorenyl) ppm. $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 3.6 [$(Me_3Si)_3Si$], 25.8 (THF), 67.8 (THF), 83.0 (fluorenyl), 111.1 (fluorenyl), 119.0 (fluorenyl), 120.2 (fluorenyl), 120.3 (fluorenyl), 125.9 (fluorenyl), 144.0 (fluorenyl) ppm.

[Ca(hSi-Flu)$_2$(THF)$_2$]: A mixture of THF-free K(hSi-Flu)$_2$ (0.80 g, 1.77 mmol) and CaI_2 (0.27 g, 0.92 mmol) in 20 mL of THF was stirred for two days at room temperature. The THF solvent was then evaporated and the remaining residue was extracted with two 10 mL portions of dry benzene. Evaporation of the solvent from these combined extracts resulted in a red solid, which was crystallized from 12 mL of warm hexane. Cooling to 4 °C yielded red needles of a benzene solvate of the title compound in 49% yield (0.47 g). ^1H NMR (250 MHz, [D_6]benzene): δ = 0.37 [s, 54 H, $(Me_3Si)_3Si$], 1.01 (m, 8 H, THF), 2.77 (m, 8 H, THF), 6.80 (dd, *J* = 7.2 Hz, 4 H, fluorenyl), 7.10 (dd, *J* = 7.6 Hz, 4 H, fluorenyl), 7.86 (dd, *J* = 7.1 Hz, 8 H, fluorenyl) ppm. $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 3.3 [$(Me_3Si)_3Si$], 26.1 (THF), 70.4 (THF), 83.1 (fluorenyl), 113.5 (fluorenyl), 120.7 (fluorenyl), 121.9 (fluorenyl), 122.6 (fluorenyl), 124.6 (fluorenyl), 142.8 (fluorenyl) ppm.

[Sr(hSi-Flu)$_2$(THF)$_2$]: A mixture of THF-free K(hSi-Flu)$_2$ (1.50 g, 3.33 mmol) and SrI_2 (0.58 g, 1.70 mmol) in 20 mL of THF was stirred for three days at room temperature. The THF solvent was evaporated and the remaining residue was extracted with two 10 mL portions of dry benzene. Evaporation of the solvent from these combined extracts resulted in a red solid, which was crystallized from 30 mL of warm hexane. Cooling to 20 °C yielded dark-red blocks of the title compound in 72% yield (1.27 g). ^1H NMR (250 MHz, [D_6]benzene): δ = 0.40 [s, 54 H, $(Me_3Si)_3Si$], 1.05 (m, 8 H, THF), 2.62 (m, 8 H, THF), 6.82 (dd, *J* = 7.2 Hz, 4 H, fluorenyl), 7.18 (dd, *J* = 7.5 Hz, 4 H, fluorenyl), 7.83 (d, *J* = 7.6 Hz, 4 H, fluorenyl), 7.91 (d, *J* = 8.3 Hz, 4 H, fluorenyl) ppm. $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 3.6 [$(Me_3Si)_3Si$], 25.1 (THF), 68.4 (THF), 80.5 (fluorenyl), 112.9 (fluorenyl), 120.5 (fluorenyl), 121.6 (fluorenyl), 122.1 (fluorenyl), 126.0 (fluorenyl), 143.2 (fluorenyl) ppm.

[K(hSi-Cp)(THF)]: A solution of tris(trimethylsilyl)silyl chloride (1.00 g, 3.55 mmol) and cyclopentadienylsodium (0.30 g, 3.40 mmol) in 15 mL of THF was stirred for 16 hours at room temperature. The THF solvent was evaporated and the remaining residue was extracted with two 10 mL portions of dry diethyl ether. Potassium bis(trimethylsilyl)amide (0.60 g, 3.00 mmol) dissolved in 15 mL of THF was added to the combined ether extracts of [tris(trimethylsilyl)silyl]cyclopentadiene and the resulting solution was stirred for 15 hours at room temperature. The solvent was evaporated and the remaining white residue was crystallized from 30 mL of hot THF. Cooling to −30 °C yielded crystalline [K(hSi-Cp)(THF)] in the form of white needles (98%, 1.25 g, 2.95 mmol) which can be freed from THF under vacuum. ^1H NMR (250 MHz, [D_8]THF): δ = 0.17 [s, 27 H, $(Me_3Si)_3Si$], 1.78 (m, 4 H, THF), 3.63 (m, 4 H, THF), 5.88 (dd, *J* = 1.9 Hz, 2 H, Cp), 5.89 (dd, *J* = 1.9 Hz, 2 H, Cp) ppm. $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 2.0 [$(Me_3Si)_3Si$], 25.3 (THF), 67.4 (THF), 98.8 (Cp), 109.0 (Cp), 116.6 (Cp) ppm.

[Ca(hSi-Cp)$_2$(THF)]: A mixture of THF-free K(hSi-Cp) (0.70 g, 2.00 mmol) and CaI_2 (0.30 g, 1.02 mmol) in 50 mL of THF was stirred for two days at room temperature. The THF solvent was evaporated and the remaining residue was extracted with two 20 mL portions of dry benzene. Evaporation of the solvent from these combined extracts resulted in a white solid, which was crystallized from a mixture of warm toluene (10 mL) and THF (1 mL). Cooling to −80 °C yielded colourless crystals of [Ca(hSi-Cp)$_2$(THF)] in 60% yield (0.44 g). ^1H NMR (250 MHz, [D_6]benzene/[D_8]THF 10:1): δ = 0.36 [s, 54 H, $(Me_3Si)_3Si$, 1.43 (m, 4 H, THF), 3.56 (m, 4 H, THF), 6.20 (dd, *J* = 2.3 Hz, 4 H, Cp), 6.39 (dd, *J* = 2.3 Hz, 4 H, Cp) ppm. $^{13}C\{^1H\}$ NMR ([D_8]THF): δ = 1.9 [$(Me_3Si)_3Si$], 25.8 (THF), 67.8 (THF), 104.8 (Cp), 111.0 (Cp), 120.1 (Cp) ppm.

[Ca(DMAT)(hSi-Flu)(THF)$_x$]: [Ca(DMAT)$_2$(THF)$_2$] (7.1 mg, 12 μmol) and [Ca(hSi-Flu)$_2$(THF)$_2$] (12 mg, 12 μmol) were mixed in an NMR tube and dissolved in [D_6]benzene (0.5 mL). Heating to 60 °C immediately resulted in the quantitative formation of [Ca(DMAT)(hSi-Flu)(THF)$_x$] (*x* = 1 or 2). Evaporation of the solvent and drying under vacuum yielded the complex [Ca(DMAT)(hSi-Flu)(THF)]. Upon redissolving this complex in [D_6]benzene the constant of the Schlenk equilibrium is approximately 20. NMR spectra before and after removal of one equivalent of THF are similar and show maximum chemical shift differences of 0.02 ppm. ^1H NMR (600 MHz, [D_6]benzene): δ = 0.34 [s, 27 H, $(Me_3Si)_3Si$], 0.42 (s, 9 H, Me_3Si-benzyl), 0.74 [s, 1 H, $CH(SiMe_3)$], 1.06 (m, 4 H, THF), 1.93 (s, 3 H, Me_2N), 2.04 (s, 3 H, Me_2N), 2.71 (m, 4 H, THF), 6.14 (dd, *J* = 7.0 Hz, 1 H, benzyl), 6.31 (d, *J* = 7.8 Hz, 1 H, benzyl), 6.63 (dd, *J* = 7.3 Hz, 1 H, benzyl), 6.85 (d, *J* = 7.9 Hz, 1 H, benzyl), 6.99 (dd, *J* = 8.3 Hz, 1 H, fluorenyl), 7.02 (dd, *J* = 8.3 Hz, 1 H, fluorenyl), 7.27 (dd, *J* = 7.1 Hz, 1 H, fluorenyl), 7.30

(dd, J = 7.6 Hz, 1 H, fluorenyl), 8.00 (d, J = 8.0 Hz, 1 H, fluorenyl), 8.04 (d, J = 7.7 Hz, 1 H, fluorenyl), 8.21 (d, J = 7.5 Hz, 1 H, fluorenyl), 8.21 (d, J = 7.5 Hz, 1 H, fluorenyl) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene): δ = 2.6 (Me$_3$Si-benzyl), 3.5 [(Me$_3$Si)$_3$Si-fluorenyl], 24.9 (THF), 41.9 (Me$_2$N), 45.0 (Me$_2$N), 47.6 [CH(Me$_3$Si)], 68.9 (THF), aromatics: 81.6, 113.3, 115.0, 115.7, 119.4, 121.6, 121.9, 122.2, 122.3, 123.4, 123.9, 124.9, 125.5, 126.5, 128.2, 135.2, 142.3, 143.4 147.4 ppm.

[Sr(DMAT)(hSi-Flu)(THF)$_x$]: [Sr(DMAT)$_2$(THF)$_2$] (10.5 mg, 16 μmol) and [Sr(hSi-Flu)$_2$(THF)$_2$] (16 mg, 16 μmol) were mixed in an NMR tube and dissolved in [D$_6$]benzene (0.5 mL). Heating to 60 °C immediately resulted in the formation of the heteroleptic strontium complex as the major product. Only traces of the homoleptic starting materials were detected (Schlenk equilibrium $K \approx$ 800). Evaporation of the solvent and drying under vacuum yielded the complex [Sr(DMAT)(hSi-Flu)(THF)]. NMR spectra and the constant of the Schlenk equilibrium of this compound are similar as with two equivalents of THF. ^1H NMR (600 MHz, [D$_6$]benzene): δ = 0.39 [s, 27 H, (Me$_3$Si)$_3$Si], 0.44 (s, 9 H, Me$_3$Si-benzyl), 0.76 [s, 1 H, CH(SiMe$_3$)], 1.18 (m, 4 H, THF), 2.05 (s, 3 H, Me$_2$N), 2.15 (s, 3 H, Me$_2$N), 3.00 (m, 4 H, THF), 6.10 (dd, J = 7.2 Hz, 1 H, benzyl), 6.36 (d, J = 7.8 Hz, 1 H, benzyl), 6.67 (dd, J = 7.3 Hz, 1 H, benzyl), 6.91 (d, J = 8.0 Hz, 1 H, benzyl), 7.02 (t, broad, 2 H, fluorenyl), 7.34 (t, broad, 2 H, fluorenyl), 8.04 (d, J = 6.9 Hz, 2 H, fluorenyl), 8.15 (d, broad, 2 H, fluorenyl) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]benzene): δ = 2.8 (Me$_3$Si-benzyl), 3.6 [(Me$_3$Si)$_3$Si-fluorenyl], 25.2 (THF), 41.8 (Me$_2$N), 43.7 (Me$_2$N), 50.2 [CH(Me$_3$Si)], 68.2 (THF), aromatics: 85.2, 111.2, 113.8, 120.0, 120.8, 121.6, 122.4, 123.5, 126.3 128.3, 134.3, 143.4, 147.3 ppm.

X-ray Crystallographic Studies: Crystals protected with a layer of dry paraffin oil were mounted in the cold nitrogen stream (−90 °C) on an Enraf−Nonius CAD4 diffractometer. Structures were solved with SHELXL-97[18] and the PLATON program package[19] (the latter was also used for geometrical calculations and illustrations). All crystal data are summarized in Table 1. CCDC entries 205469−205473 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the BASF AG (Ludwigshafen, Germany) for financing this project. Prof. Dr. H.-H. Brintzinger (Konstanz) and Dr. K. Knoll (Ludwigshafen) are kindly acknowledged for helpful discussions. Mrs. A. Friemel is thanked for measuring 600 MHz spectra.

Structural Studies of Lithium Telluro- and Seleno-Phosphorus Compounds

Robert P. Davies,*[a] M. Giovanna Martinelli,[a] Andrew E. H. Wheatley,[b] Andrew J. P. White,[a] and David J. Williams[a]

Dedicated to the memory of Ron Snaith

Keywords: Lithium / Selenium / Solid-state structures / Tellurium

Lithium tellurophosphinite $[Ph_2PTe][Li(TMEDA)_{1.33}(THF)_{1.33}]$ (**4**), ditellurophosphinate, $[Ph_2PTe_2][Li(THF)_{3.5}(TMEDA)_{0.25}]$ (**5**), and selenotellurophosphinate $[Ph_2P(Se)Te][Li(THF)_2(TMEDA)]$ (**6**) complexes have been prepared from the insertion/oxidation reactions of lithiated secondary phosphanes with elemental chalcogens and characterised by X-ray crystallography. Compounds **4**–**6** contain no tellurium–lithium bonding interactions in the solid state, instead existing as ion-separated species with THF/TMEDA-solvated lithium cations. Reaction of dilithiated primary phosphanes with more than three equivalents of elemental selenium gives $[\{(c\text{-}C_6H_{11})P(Se)(SeLi)\}_2\cdot 2TMEDA]$ (**7**) via a phosphorus-phosphorus coupling reaction. Solid state characterisation of **7** reveals the organo groups in the tetradentate tetraselenohypodisphosphinate ligand to be in an anti conformation to one another and each lithium atom to be coordinated by two selenium atoms, one from each of the diselenophosphinate groups. Multinuclear NMR spectroscopic data are consistent with retention of the solid-state structures of **4**–**7** in solution.

Introduction

Thiophosphorus ligands, in particular dithiophosphates and -phosphinates, have been reported extensively in the literature[1] and have found many applications including as lubricant oil additives[1,2] and as extraction agents for separation procedures.[3] In addition they have been shown to exhibit a broad variety of coordination patterns leading to a wide range of molecular and supramolecular structures.[1] However, the chemistry of the heavier group 16 homologues, the seleno- and telluro-phosphorus ligands, is less well documented. This is despite the growing interest in using selenolates and tellurolates as precursors to semiconducting metal selenides and tellurides,[4] and also as new reagents for the synthesis of selenium- and tellurium-containing organics.[5] Furthermore, triorganophosphane tellurides have been employed as more reactive sources of tellurium than elemental tellurium metal itself in, for example, the low-temperature synthesis of transition metal tellurium clusters and nanoclusters.[6] We have been interested in the synthesis and characterisation of new selenolate and tellurolate complexes utilising the insertion reaction of elemental chalcogens into carbon−lithium[7] or heteroatom−lithium bonds[8] and have recently reported the synthesis and structural characterisation of a lithium selenophosphinite, $[Ph_2PSeLi\cdot TMEDA]_2$ **1** [TMEDA = $(Me_2NCH_2)_2$], a lithium diselenophosphinate, $[Ph_2PSe_2Li\cdot THF\cdot TMEDA]$ **2**, and a dilithium triselenophosphonate, $[(c\text{-}C_6H_{11})PSe_3Li_2\cdot 2TMEDA]$ **3** (Figure 1).[8] In these systems the ligands were shown to exhibit a variety of novel coordination modes to the lithium centres which differed from those exhibited by their thio-phosphorus counterparts. This observation has now led us to turn our attention to the corresponding tellurium and mixed selenium/tellurium analogues.

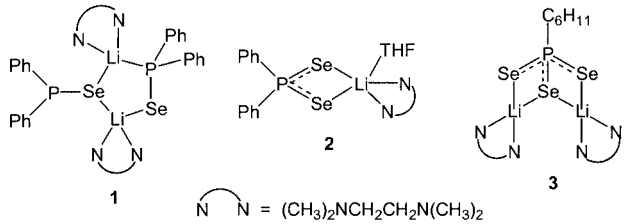

Figure 1. Lithium seleno-phosphorus complexes **1**, **2**, and **3**

Although the syntheses of ditellurophosphinates and selenotellurophosphinates have been reported previously by Sladky and Bildstein[9] there are to date no solid-state

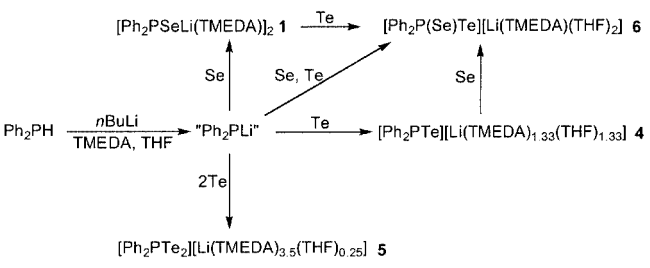
characterisations of these species. Indeed, a search of the Cambridge Structural Database[10] reveals fewer than twenty structures containing any form of phosphorus−tellurium bond, and of these the only metal-containing examples are the triorganophosphane telluride complexes $[(CO)_5WTeP{t}Bu_3]$[11] and $[(HgTeP{n}Bu_3)_3Br_5]_2$-$[Hg_2Br_6]$,[12] the tellurobisphosphane complex $[(CO)_4Cr(\mu$-$P{t}Bu_2)_2Te]$,[13] a 1,2,4-telluradiphosphole ring complex $[W(CO)_5(P_2TeC_2{t}Bu_2)]$,[14] a binuclear iron species $[Fe_2(CO)_6(\mu_2$-TeMes$)\{\mu_2$-P(iPr)TeMes$\}]$[15] and, most recently, a magnesium cyclodiphosphazane monotelluride $[{t}BuN(Te)P(\mu$-NtBu$)_2PN{t}Bu\cdot Mg(THF)_2]$.[16]

We present here the first solid-state characterisations of anionic telluro-phosphorus ligands, namely a tellurophosphinite $[Ph_2PTe][Li(TMEDA)_{1.33}(THF)_{1.33}]$ (**4**), a ditellurophosphinate $[Ph_2PTe_2][Li(THF)_{3.5}(TMEDA)_{0.25}]$ (**5**), and a mixed chalcogen selenotellurophosphinate $[Ph_2P(Se)Te]$-$[Li(THF)_2(TMEDA)]$ (**6**). In addition we report on the reactions of dilithiated primary phosphanes with an excess of selenium. It has been shown previously that reaction of dilithio organylphosphides, $RPLi_2$, with elemental tellurium leads, via a series of phosphorus-phosphorus coupling reactions, to the formation of cyclic organylpolyphosphanes $(RP)_n$.[9] In contrast, reaction of $RPLi_2$ with three equivalents of selenium leads to formation of the dilithio triselenophosphonate **3**.[8] We now report how reaction of (c-C_6H_{11})PLi_2 with an excess (>3.2 equivalents) of selenium results in a single phosphorus-phosphorus coupling reaction to yield the novel tetraselenohypodiphosphonate complex $[\{(c$-$C_6H_{11})P(Se)(SeLi)\}_2\cdot 2TMEDA]$ (**7**).

Results and Discussion

Using a synthetic route analogous to that employed to prepare the seleno-phosphorus compounds **1** and **2**,[8] and also in accordance with literature procedures,[9] reaction of one equivalent of elemental tellurium with lithium diphenylphosphide in THF gave insertion of the tellurium into the phosphorus-lithium bond to yield the tellurophosphinite, $[Ph_2PTe][Li(TMEDA)_{1.33}(THF)_{1.33}]$ (**4**). Reaction of $LiPPh_2$ with two equivalents of elemental tellurium gave insertion followed by oxidation to yield the ditellurophosphinate $[Ph_2PTe_2][Li(THF)_{3.5}(TMEDA)_{0.25}]$ (**5**). A mixed selenotellurophosphinate $[Ph_2P(Se)Te][Li(THF)_2$-$(TMEDA)]$ (**6**) was prepared from reaction of lithium diphenylphosphide with elemental selenium and tellurium in a one-pot reaction, although we were also able to prepare **6** from reaction of **1** or **4** with one equivalent of tellurium or selenium respectively (Scheme 1). All of these tellurium-containing compounds (**4**−**6**) are much more reactive than their selenium analogues (**1**, **2**), being highly air, moisture, and light sensitive, and readily decompose to deposit amorphous tellurium.



Scheme 1

X-ray structural analysis of $[Ph_2PTe][Li(TMEDA)_{1.33}(THF)_{1.33}]$ (**4**) shows it to crystallise as an ion-separated species consisting of the tellurophosphinite anion $[Ph_2PTe]^-$ and a solvated lithium cation (Figure 2); two different lithium cations are present in the crystal lattice, $[(TMEDA)(THF)_2Li]^+$ (67% occupancy, depicted in Figure 2) and $[(TMEDA)_2Li]^+$ (33% occupancy). The tellurophosphinite anion contains a distorted pyramidal phosphorus atom with angles of 97.8(1), 105.8(1) and 107.6(1)° (Table 1), the most "acute" corresponding to the Ph−P−Ph angle (i.e. between the two least sterically demanding substituents). The P−Te bond length of 2.447(1) Å is slightly shorter than previously reported P−Te single bonds: 2.565 Å (av.) in $[(i$Pr$)_2P]_2Te$;[17] 2.481(1) and 2.491(1) Å in $[(CO)_4Cr(\mu$-PtBu$_2)_2Te]$;[13] 2.4728(9) and 2.4790(5) Å in the phosphorus-tellurium cage $P_6C_4{t}Bu_4Te$.[18] This shortening suggests that the species exists predominately as its Ph_2P-Te^- tautomer with a P−Te single bond and the negative charge localised on the tellurium centre, with possibly some minor contribution from the $Ph_2P(=Te)^-$ tautomer resulting in a slight shortening of the P−Te bond. Given the weakness of phosphorus−tellurium double bonds[1c] it is perhaps not unexpected that the equilibrium lies well on the side of the Ph_2P-Te^- tautomer and this is also in agreement with our observations with the selenium analogue **1**, which also exists in a similar tautomeric form.[8] The ^{31}P NMR spectrum of **4** consists of a single peak with ^{125}Te satellites ($^1J_{P,Te}$ = 747 Hz). As expected the coupling constant is approximately two to three times larger than the corresponding P−Se coupling constants in **1**, and is also at the top end of the range of values expected for P−Te single bonds (reflecting the slightly shorter P−Te distance), for example 451 Hz in $({t}Bu_2P)_2Te$.[19] It is interesting to note the absence of any Te−Li or P−Li bonding interactions in the solid-state structure of **4**, especially when compared to the analogous Se complex **1** where two distinct coordination modes were observed: end-on bridging from Se to two Li and side-on bridging from Se to one Li and P to another Li.[8] Low-temperature ^{31}P NMR spectroscopic studies were carried out on **4**, but even at −70 °C we were unable to verify the existence of any metal−tellurophosphinite bonding, there being only one constant peak observed as the temperature was lowered (cf. **1**[8]). Although lithium−tellurium bonds are expected to be weak due to the size mismatch of the atoms, Li−Te bonds have previously been reported in both Si−Te−Li[20] and C−Te−Li systems[7,20d,21] and, to the best of our knowledge, the only example of an ion-separated lithium tellurolate is $[(Me_3Si)_3$-$SiTe][Li(12\text{-crown-}4)_2]$ where the lithium cation is stabilised by crown ether ligands. It therefore seems likely that stabil-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

isation of the negative charge on the tellurium by the phosphorus in **4** is responsible for the lack of Te−Li bonding, presumably due to the $Ph_2P(=Te)^-$ tautomer formed from donation of a lone pair in a p orbital on the tellurium into an empty d orbital on the phosphorus. However, it is also possible that overlap of the p orbitals on tellurium with σ* orbitals on the Ph_2P moiety is occurring, similar to that previously reported for triorganophosphane tellurides.[6,22] Both of these interactions would result in a shortening of the P−Te bond as observed in the solid state and in solution.

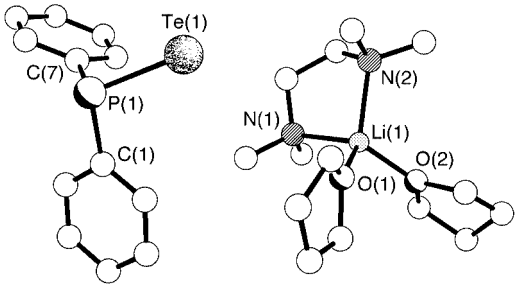


Figure 2. The molecular structure of $[Ph_2PTe][Li(TMEDA)_{1.33}(THF)_{1.33}]$ (**4**) showing the major occupancy $[(TMEDA)(THF)_2Li]^+$ cation

The solid-state characterisation of dark red crystals of $[Ph_2PTe_2][Li(THF)_{3.5}(TMEDA)_{0.25}]$ (**5**) reveals an ion-separated species comprising a $[Ph_2PTe_2]^-$ anion and a combination of $[(THF)_4Li]^+$ (75%) and $[(TMEDA)(THF)_2Li]^+$ (25%) solvated lithium cations. The crystals contain two crystallographically independent cation-anion pairs in the asymmetric unit (see Figure 3 and Figure S1 (Supporting Information, see footnote on page 1 of this article); selected bond lengths and angles for the major component are given in Table 1). The phosphorus atoms in both of the independent anions in **5** are distorted tetrahedral with Te−P−Te angles of 118.6(2) and 117.3(2)°, and Ph−P−Ph angles of 100.6(5) and 101.8(6)°; the Ph−P−Te angles range between 107.9(4) and 110.3(5)°. The four P−Te bond lengths (av. 2.391 Å) do not differ significantly, ranging between 2.380(4) and 2.399(3) Å. These values are concordant with delocalisation of the negative charge throughout the ditellurophosphinate group and would suggest a formal bond order of 1.5 for each of the P−Te bonds, analogous to the bonding observed in lithium diselenophosphinates and di-

thiophosphinates.[1,8] However, although these phosphorus−tellurium bonds are shorter than, for example, the P−Te single bond observed in **4** [2.447(1) Å], they do not differ considerably in length from formal "double" bonds [such as those in triorganophosphane tellurides, $TePR_3$, i.e. 2.368 Å in $TeP{t}Bu_3$,[23] 2.365 Å in $TeP{i}Pr_3$,[24] and 2.371 Å in $t{Bu}_2P(Te)NH(C_6H_{11})$[25]]. There has been considerable debate in the literature concerning the nature of the multiple bonding in phosphorus-tellurium compounds,[6] particularly the triorganophosphane tellurides, with ^{125}Te NMR and Mössbauer spectroscopy being interpreted as showing no P−Te multiple bonding in these compounds,[26] whereas density functional theory calculations have shown contributions from resonance structures consistent with substantial multiple bonding.[22] The P−Te bonds in **5** are the first crystallographically characterised P−Te bonds with a "formal" bond order of 1.5 (assuming complete delocalisation of the negative charge throughout the ditellurophosphinate) and therefore allow us speculate that, due to the similarity in bond lengths, the correct bond order for triorganophosphane tellurides is also 1.5. This conclusion agrees with the calculations carried out by Sandblom, Ziegler and Chivers.[22] It is also worthwhile noting that the ^{31}P NMR spectrum of **5** has a $^1J_{P,Te}$ coupling constant of 1530 Hz which is close to the range observed elsewhere for triorganophosphane tellurides (1548−1743 Hz),[19] indicating that the P−Te bonds in these two species are of similar length both in solution and in the solid-state ($^1J_{P,Te}$ coupling constants are known to correlate very strongly with bond lengths[19]).

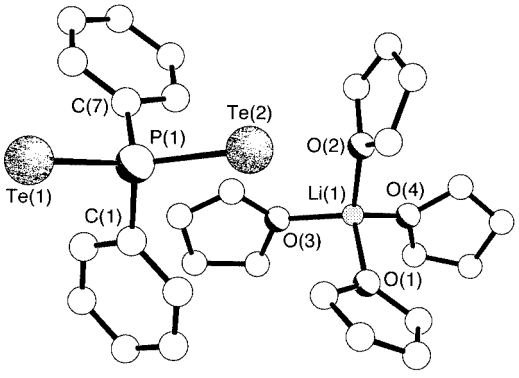

Figure 3. The molecular structure of one of the crystallographically independent cation:anion pairs present in the crystals of $[Ph_2PTe_2][Li(THF)_{3.5}(TMEDA)_{0.25}]$ (**5**) showing the major occupancy $[(THF)_4Li]^+$ cation

Crystals of $[Ph_2P(Se)Te][Li(THF)_2(TMEDA)]$ (**6**) were shown by X-ray analysis to contain a mixed chalcogen selenotellurophosphinate anion (Figure 4). The positions of the Te(1) and Se(1) centres are sometimes reversed (ca. 63:37, see Figure S2), and this disorder means that the possibility of a certain amount of the diseleno and ditellurophosphinate species also being present in the crystal cannot be ruled out, though NMR spectroscopic data (see later) suggests that any contribution from these species is likely to be minor. Again the species is ion separated, this time containing a $[Li(THF)_2(TMEDA)]^+$ cation. The geometry at phosphorus is distorted tetrahedral with, for the major occupancy atoms, a Ph−P−Ph angle of 99.8(2)° and a Te−P−Se angle of 116.8(2)°; the other angles are in the range 106.7(3)−111.0(2)° (Table 1). The P−Se bond lengths of 2.137(6) to Se(1), and 2.136(8) Å to Se(1′), are similar in length to those observed in the diselenophosphinate **2** [2.141(1) and 2.147(1) Å][8] and the P−Te bonds of 2.379(3) to Te(1), and 2.378(6) Å to Te(1′), are similar to those observed in the ditellurophosphinate **4** (av. 2.391 Å). Together these bond lengths point to delocalisation of the negative charge over the selenotellurophosphinate group to give P−Se and P−Te bonds of order 1.5. This interpretation is further supported by ^{31}P NMR spectroscopy (Figure 5) which shows one main phosphorus peak ($\delta = -43.0$ ppm) with both ^{77}Se and ^{125}Te satellites and coupling constants similar to those observed in the dichalcogenophosphinates **2** and **5**; $^1J_{P,Se} = -635$ Hz and $^1J_{P,Te} = 1485$ Hz in **6** cf. $^1J_{P,Se} = -585$ Hz in **2** and $^1J_{P,Te} = 1585$ Hz in **5**. Small peaks (< 10%) can also be seen in the ^{31}P NMR spectra at $\delta = 24.0$ and -121.8 ppm due to the presence of the dichalcogenophosphinate species **2** and **5** respectively, which are present in equilibrium with the asymmetric species **6**.[9] Low temperature ^{31}P NMR spectroscopy of this mixture shows the signals at $\delta = 24$ and -122 ppm to increase in size (20% at −70 °C) due to the equilibrium being shifted more towards the symmetrical chalcogenophosphinates **2** and **5** at lower temperatures.

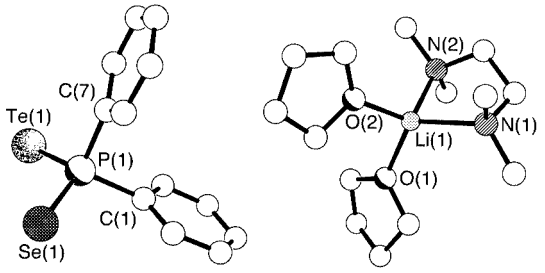

Figure 4. The molecular structure of $[Ph_2P(Se)Te][Li(THF)_2(TMEDA)]$ (**6**) showing the major occupancy orientation of the $[Ph_2PSeTe]^-$ anion

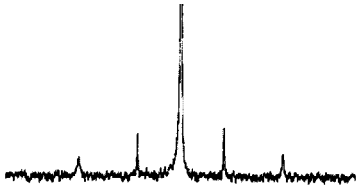

Figure 5. ^{31}P NMR spectrum of **6** showing the main truncated peak at $\delta = -43.0$ ppm with ^{77}Se and ^{125}Te satellites

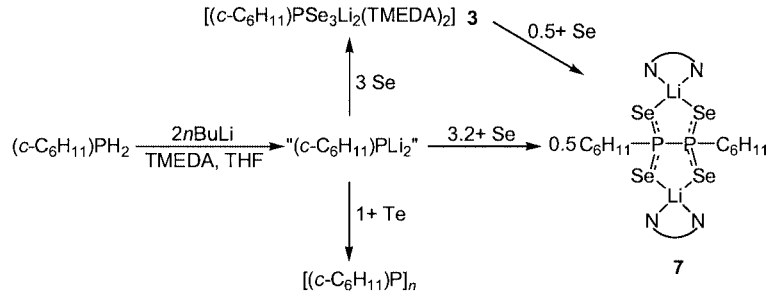
Previously we have shown how reaction of dilithiated primary phosphanes, $RPLi_2$, with three equivalents of elemental selenium gives triselenophosphonates such as **3**. However, similar attempts to prepare tritellurophosphonates from reaction of $RPLi_2$ with elemental Te failed, instead forming cyclic poylphosphanes $(RP)_n$ and lithium telluride

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 2

(Li_2Te_n) (Scheme 2). We therefore turned our attention to the reaction of $CyPLi_2$ and a greater than threefold excess of selenium powder to see if similar phosphorus-phosphorus coupling reactions[27] would occur. Indeed, reaction of $CyPLi_2$ with a greater than threefold excess of selenium was observed to give the dilithium tetraselenohypodiphosphonate complex [{(*c*-C_6H_{11})P(Se)(SeLi)}$_2$·2TMEDA] **7** via reduction of **3** with concomitant elimination of Li_2Se_n (Scheme 2), as well as some cyclic phosphane by-products. It also proved possible to prepare **7** by direct reaction of the triselenophosphonate **3** with 0.5 equivalents of selenium verifying that **3** is indeed an intermediate in this reaction. Further tests showed the reaction to proceed from (*c*-C_6H_{11})PLi_2 to **7** with between three (with reflux) and six equivalents of selenium, although the best yields with least contamination from cyclic polyphosphanes (<5% by ^{31}P NMR spectroscopy) were achieved with 3.2 equivalents of selenium at room temperature. There is only one other published example of a tetraselenohypodiphosphonate, that of the diphenyl analogue formed from the reaction of LiP(Ph)$SnPh_3$ (itself prepared from the reaction of PPh_5 with $LiSnPh_3$) with four equivalents of selenium, although no solid-state characterisation was reported and there was significant contamination with cyclic phosphanes (57%).[28]

X-ray structural characterisation of [{(*c*-C_6H_{11})P(Se)(SeLi)}$_2$·2TMEDA] (**7**, Figure 6) showed it to be disordered about a crystallographic C_{2h} position (with the twofold axis passing along the Li···LiA vector and the mirror pane bisecting the two Se−P−Se angles). As a consequence only the phosphorus, lithium, and nitrogen centres are ordered. In particular, each of the selenium centres is disordered over two 50% occupancy sites (shown in Figure S3, see Supporting Information) so that there are two distinctly different P−Se bond lengths [2.072(2) and 2.229(2) Å]; by contrast, all of the Li−Se distances are the same (Table 1). The 50:50 nature of this disorder means that for each of the two phosphorus centres it is crystallographically impossible to distinguish between i) the disorder of a single PSe_2 unit having one "short" and one "long" P−Se linkage, and ii) the superimposition of two different PSe_2 units, one that has two "short" P−Se linkages and one in which both bonds are "long". Although the presence of this disorder precludes an in-depth analysis of the bond lengths and angles, the structure clearly shows two lithium coordination sites on either side of the phosphorus-phosphorus backbone with each lithium bonding to two selenium atoms (one from each of the diselenophosphinate groups) and a TMEDA molecule, whilst the two cyclohexyl groups are in an *anti* conformation to one another. The two P−Se bond lengths are very disparate (differing by ca. 0.16 Å) with the longer bond [2.229(2) Å] being close to the length expected for a P−Se single bond [cf. P−Se bond lengths of 2.233(1) and 2.200(8) in **1**][8] and the shorter [2.072(16) Å] being within the range expected for a P−Se double bond.[29] This therefore suggests disorder of type i) with one selenium singly and one doubly bonded to each phosphorus atom and no, or very little, charge delocalisation occurring within the diselenophosphinate moieties. This behaviour therefore contrasts with that observed for the dichalcogenophosphinate groups in **2**, **5**, and **6** where complete charge delocalisation was present. The P−P bond, 2.252(2) Å, is in the range expected for a single bond (2.20 to 2.35 Å);[27] the Li−Se distances are all equal at 2.561(4) Å and are similar to previously reported Li−Se bond lengths in lithium seleno-phosphorus complexes.[8] Characterisation in solution by ^{31}P NMR spectroscopy showed just one predominate phosphorus signal (δ = 53.4 ppm) with satellites exhibiting AA′X splitting (where A is ^{31}P and X is ^{77}Se) due to the 23.9% abundant ^{77}Se isotopomer (Figure 7, a). ^{77}Se NMR spectroscopy also reveals an AA′X splitting pattern due to the same isotopomer (Figure 7, c). These ^{31}P and ^{77}Se NMR spectra correlate very accurately with compu-

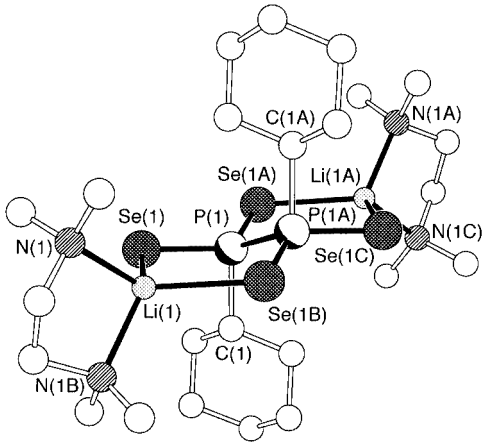


Figure 6. The molecular structure of [{(*c*-C_6H_{11})-P(Se)(SeLi)}$_2$·2TMEDA] (**7**)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tationally simulated spectra (Figure 7, b and d) with assignment iterated coupling constants of $^1J_{P,Se} = -623.2$, $^1J_{P,P} = -175.2$ and $^3J_{P,Se} = 2.0$ Hz (± 0.2 Hz).[30] The value of the $^1J_{P,Se}$ coupling constant is indicative of a phosphorus-selenium bond of order 1.5 and is similar to the $^1J_{P,Se}$ values observed for **2** (−585 Hz) and **6** (−635 Hz). Therefore, in contrast to the behaviour observed for **7** in the solid state, in solution all P−Se bonds are of equal length (on the NMR time scale), signifying that charge delocalisation within the diselenophosphinate groups is now taking place. The P-P NMR coupling constant is within the range expected for a single bond.[27]

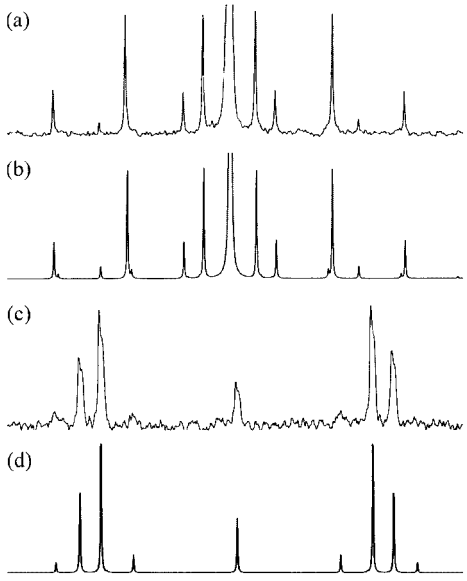

Figure 7. (a) ^{31}P NMR spectrum of **7** in C_6H_6; (b) Computationally simulated[30] ^{31}P NMR spectrum of **7**; (c) ^{77}Se NMR spectrum of **7** in C_6H_6; (d) Computationally simulated[30] ^{77}Se NMR spectrum of **7**

Conclusion

In summary, we have shown the first solid-state characterisations of a tellurophosphinite complex **4**, a ditellurophosphinate complex **5** and a mixed chalcogen selenotellurophosphinate complex **6**. Although these compounds are all ion-separated species with solvated lithium cations and therefore do not exhibit such a range of coordination modes with lithium as observed for their selenium or sulfur analogues, they do provide some valuable and rare structural insights into phosphorus tellurium multiple bonding. We are now investigating the coordination chemistry of these ligands with a range of transition metal centres as it is envisaged that stronger ligand-metal coordination will render these ligands more stable, and such complexes would be of potential use as chemical vapour deposition (CVD) precursors to metal chalcogenolides.[4] Related phosphinotellurgenoic amidato complexes [M{tBu$_2$P(Te)NR}$_2$] (M = Fe, Mn, and Co) have already shown promise is this area as suitable agents for the gas-phase deposition of metal chalcogenolide films.[31]

In addition we have demonstrated a new, clean synthetic route to a tetraselenohypodiphosphonate complex by reaction of dilithiated primary phosphanes with greater than three equivalents of elemental selenium, and have presented the first full characterisation of such a species. The tetradentate nature of these ligands should allow them to form wide range of coordination compounds and we are currently investigating their transmetallation reactions.

Experimental Section

General Procedures: All reactions and manipulations were carried out under an inert atmosphere of dry nitrogen or argon using standard double manifold and glove-box techniques. Purification and drying of the solvents were done using standard methods.[32] Ph_2PH and $CyPH_2$ were purchased from Strem and all other chemicals from Lancaster.

NMR spectra were recorded on either a Bruker DPX400 (^{1}H and ^{31}P) or a Joel EX270 Delta Upgrade (^{77}Se and low temperature ^{31}P) spectrometer. External standards used were TMS (^{1}H, ^{13}C), 85% H_3PO_4 (^{31}P) or Me_2Se (^{77}Se). Melting points were measured in sealed capillaries under argon.

Synthesis of [Ph$_2$PTe][Li(TMEDA)$_{1.33}$(THF)$_{1.33}$] (4): nBuLi (1.6 M in hexanes, 3.2 mL, 5 mmol) was added to Ph_2PH (0.86 mL, 5 mmol) and TMEDA (1.0 mL, 6.7 mmol) in 5 mL THF. The resulting solution was then transferred onto powdered Te (0.64 g, 5 mmol) in 3 mL of toluene at −78 °C and allowed to warm slowly to room temperature to give a dark red solution which was filtered through celite and left at −30 °C for 48 h to yield red crystals of **4** (1.52 g, 54%). M.p. 76−78 °C. Note that 0.66 THF was lost from **4** during the isolation procedure in the glove-box, so all spectroscopic characterisation is for [Ph$_2$PTe][Li(TMEDA)$_{1.33}$(THF)$_{0.67}$]. ^{1}H NMR (250 MHz, [D$_6$]DMSO, 25 °C): δ = 1.74 (m, 2.7 H, THF), 2.09 (s, 16 H, TMEDA), 2.25 (s, 5.3 H, TMEDA), 3.59 (m, 2.7 H, THF), 6.97−7.63 (m, 10 H, Ph_2P-) ppm. ^{13}C NMR (101 MHz, [D$_6$]DMSO, 25 °C): δ = 145.7, 134.0, 126.9, 125.7 (Ph_2P-), 67.1 (THF), 57.3, 45.6 (TMEDA), 25.2 (THF) ppm.^{31}P NMR (162 MHz, [D$_6$]DMSO, 25 °C): δ = −32.5 (s + d satellites, $^1J_{P,Te}$ = 747 Hz) ppm. $C_{22.66}H_{36.66}LiN_{2.66}O_{0.66}PTe$ (522.7): calcd. C 52.08, H 7.07, N 7.15; found C 51.99, H 6.98, N 7.18.

Synthesis of [Ph$_2$PTe$_2$][Li(THF)$_{3.5}$(TMEDA)$_{0.25}$] (5): nBuLi (1.6 M in hexanes, 1.6 mL, 2.5 mmol) was added to Ph_2PH (0.43 mL, 2.5 mmol) in 5 mL of THF. The resulting solution was then reacted with a suspension of powdered Te (0.64 g, 5 mmol) in 5 mL of THF at −78 °C followed by further stirring for 12 h at room temperature to give a dark red-brown solution. This solution was filtered through celite and reduced in volume to 5 mL in vacuo. Highly air- and moisture-sensitive dark-red crystals of **5** grew from this solution on storage at −30 °C over 72 h. Due to the extreme air, moisture and thermal instability of **5** we were unable to isolate it as a stable solid long enough to achieve full characterisation. Therefore ^{31}P NMR was carried out on a 1 mL aliquot of the reaction mixture to show qualitative production of **5**. ^{31}P NMR (162 MHz, THF, 25 °C): δ = −123.8 (s + d satellites, $^1J_{P,Te}$ = 1530 Hz) ppm.

Synthesis of [Ph$_2$P(Se)Te][Li(THF)$_2$(TMEDA)] (6): nBuLi (1.6 M in hexanes, 1.6 mL, 2.5 mmol) was added to Ph_2PH (0.43 mL, 2.5 mmol) and TMEDA (0.37 mL, 2.5 mmol) in 2 mL of toluene/2 mL of THF to give a clear yellow solution. This solution was then transferred onto a mixed suspension of Te powder (0.64 g,

5 mmol) and Se powder (0.40 g, 5 mmol) in 5 mL of THF at −78 °C, allowed to warm to room temperature slowly and stirred for a further 12 h. Orange crystals of **2** grew from this solution at room temperature over 72 h in 42% yield (1.39 g). M.p. 95−98 °C. ^{1}H NMR (250 MHz, [D$_6$]DMSO, 25 °C): δ = 1.75 (m, 8 H, THF), 2.10 (s, 12 H, TMEDA), 2.27 (s, 4 H, TMEDA), 3.60 (m, 8 H, THF), 7.21−8.00 (m, 10 H, Ph$_2$P) ppm. ^{13}C NMR (101 MHz, [D$_6$]DMSO, 25 °C): 142.0, 132.4, 128.5, 126.8 (Ph$_2$P-), 67.1 (THF), 57.3, 45.7 (TMEDA), 25.2 (THF) ppm. ^{31}P NMR (162 MHz, [D$_6$]DMSO, 25 °C): δ = 24.0 (5%, s + d satellites, $^1J_{P,Se}$ = −647; **2**), −43.0 (90%, s +2 × d satellites, $^1J_{P,Se}$ = −635, $^1J_{P,Te}$ = 1485 Hz; **6**), −121.8 (5%, s + d satellites, $^1J_{P,Te}$ = 1510; **5**) ppm. Due to contamination of **6** by small amounts of **2** and **5** we were unable to obtain satisfactory elemental analyses.

Synthesis of [{(*c*-C$_6$H$_{11}$)P(Se)(SeLi)}$_2$·2TMEDA] (7): *n*BuLi (1.6 M in hexanes, 3.2 mL, 5 mmol) was added to CyPH$_2$ (0.33 mL, 2.5 mmol) and TMEDA (0.75 mL, 5 mmol) in 4 mL of toluene/6 mL of THF at −78 °C. The resulting solution was then slowly warmed to room temperature and then transferred onto powdered grey Se (0.635 g, 8 mmol) and stirred for 15 min. Colourless crystals of **4** grew from the solution after 3 days at −27 °C 0.71 g, 72% yield). M.p. 166−168 °C. ^{1}H NMR (270 MHz, [D$_6$]DMSO, 25 °C): δ = 0.82−2.10 (m, 11 H, C$_6$H$_{11}$), 2.12 (s, 4 H, TMEDA), 2.28 (s, 12 H, TMEDA) ppm. ^{13}C NMR (101 MHz, [D$_6$]DMSO, 25 °C): δ = 57.3, 45.7 (TMEDA), 44.9, 27.3, 26.7, 26.5, 26.4, 26.3, 26.0 (*c*-C$_6$H$_{11}$) ppm. ^{31}P (109 MHz, [D$_6$]DMSO, 25 °C): δ = 53.4 (m) ppm. ^{77}Se (51.5 MHz, [D$_6$]DMSO, 25 °C): δ = −504 (m) ppm. $C_{24}H_{54}Li_2N_4P_2Se_4$ (790.4): calcd. C 36.47, H 6.89, N 7.09; found C 38.46, H 7.00, N 7.07.

X-ray Structure Determinations of 4−7: Table 2 provides a summary of the crystallographic data for compounds **4**−**7**. Data were collected on Nonius Kappa CCD (compounds **4**−**6**) and Siemens P4/RA (compound **7**) diffractometers, and the structures were refined based on F^2 using the SHELXTL and SHELX-97 program systems.[33] The crystals of **4** contain two different cations, there being a ca. 67:33 mixture of [(TMEDA)(THF)$_2$Li]$^+$ and [(TMEDA)$_2$Li]$^+$. A similar situation is seen in the crystals of **5**, though here the two cations [(THF)$_4$Li]$^+$ and [(TMEDA)(THF)$_2$Li]$^+$ are present in a ca. 75:25 ratio. In the structure of **6** the positions of the Te(1) and Se(1) centres are occasionally reversed (ca. 63:37). The structure of **7** is substantially disordered about the crystallographic C_{2h} position (refinement in lower symmetry space groups does not remove the disorder) such that only the P(1), Li(1), and N(1) positions are ordered.

CCDC-208127−208130 (**4**−**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

This work was supported by a studentship from the Dept of Chemistry, Imperial College, London (M.G.M), a CRF grant from the University of London and a Royal Society Research Grant. The authors also wish to thank Dr J. Davies, University of Cambridge, for his assistance in the collection of the X-ray crystallographic data on compounds **4**−**6**.

Homo- and Heteroleptic Hypersilylcuprates — Valuable Reagents for the Synthesis of Molecular Compounds with a Cu−Si Bond

Karl W. Klinkhammer,*[a] Jan Klett,[a] Yun Xiong,[a] and Shenglai Yao[a]

Dedicated to the memory of Ron Snaith

Keywords: Copper / Silicon / Silylcuprates / Si ligands

Unsolvated hypersilanides MHyp [Hyp = $Si(SiMe_3)_3$] of the heavier alkali metals (M^I = Na, K, Cs) react with copper *tert*-butoxide in toluene to yield crystalline heteroleptic cuprates [M^I(toluene)][*t*BuOCuHyp]. These cuprates proved to be valuable sources for pure hypersilylcopper and other cuprates bearing hypersilyl ligands such as the di(hypersilyl)-cuprates $M^I[CuHyp_2]$.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

Molecular compounds with a Cu−Si bond are very important reagents in modern organic chemistry.[1] However, since they are usually prepared in situ for this purpose, only limited information about their composition and molecular structures is available. This information has mainly been derived from NMR experiments.[2] Only very few structural data for pure compounds are available to date.[3−8] This is partially related to the low kinetic stability of these cuprates and/or the fact that the reaction mixtures often contain various additives to get better regiospecificity and stereoselectivity. The first report of a crystal structure came from Cowley et al. in 1988 , who succeeded in preparing a kinetically stabilized triphenylphosphane complex of a neutral silylcopper complex and determined its structure by X-ray diffraction.[3] All efforts to isolate the pure silylcopper complex in the absence of any stabilizing donor failed however. A few years later Stalke et al. synthesized two silylcuprates as crystalline materials.[4,5] The yields were low, however, and in spite of the bulky hypersilyl substituent employed one of these cuprates, a polynuclear chlorocuprate, is extremely kinetically unstable and decomposes below −20 °C. Until 1999 when we finally succeeded in preparing the first kinetically stable unsolvated silylcopper complex as well as stable lithium cuprates in very good yields,[6,7] a few further reports were published concerning the synthesis of pure Cu^I compounds bearing silyl groups.[9−11] To the best of our knowledge, no detailed structural information about such species had been provided with the exception of two cuprates synthesized very recently by Lerner et al. by a procedure similar to the one used by Stalke.[8] We again used the mentioned hypersilyl group, but in contrast to Stalke and Lerner avoided the presence of halide anions which are thought to have a destabilizing influence on related copper derivatives with hydrocarbyl substituents. As alternative copper(I) source we used either copper *tert*-butoxide or a very bulky arylcopper derivative.

$$7\ LiHyp + 6\ CuO\mathit{t}Bu \longrightarrow [Li_7(O\mathit{t}Bu)_6][Cu_7Hyp_3] + 4\ CuHyp \quad (1)$$

$$9\ LiHyp + 6\ CuO\mathit{t}Bu \longrightarrow [Li_7(O\mathit{t}Bu)_6][Cu_2Hyp_3] + 2\ LiCu_2Hyp_3 \quad (2)$$

$$11\ LiHyp + 6\ CuO\mathit{t}Bu \longrightarrow [Li_7(O\mathit{t}Bu)_6][Cu_2Hyp_3] + 4\ LiCuHyp_2 \quad (3)$$

$$PbHyp_2 + CuAr \longrightarrow CuHyp + Pb(Ar)Hyp \quad (4)$$

The employed silanide nucleophiles were unsolvated hypersilanides of lithium [Equations (1)−(3)] and lead(II) [Equation (4)], respectively. Both reaction types, however, are not suitable for preparing large quantities of pure silylcopper derivatives. We now report the synthesis of novel hypersilyl complexes of Cu^I, the heteroleptic *tert*-butoxy(hypersilyl)cuprates of the heavier alkali metals M^I[*t*BuOCuHyp], which are easily accessible in high quantities and excellent yields. They are fairly stable under controlled conditions and, as will be seen below, have proved to be valuable starting compounds for other silyl derivatives of Cu^I.

Results and Discussion

Potassium hypersilanide [KHyp; Hyp = -Si(SiMe$_3$)$_3$][12] readily reacts with copper *tert*-butoxide in toluene to give a pale yellow solution from which, on cooling to −20 °C, colorless crystals precipitate. The NMR spectroscopic data indicate that the toluene solvate of heteroleptic potassium *tert*-butoxy(hypersilyl)cuprate [K(toluene)][*t*BuOCuHyp] (**1**) had formed quantitatively [Equation (5)]. This assumption was verified by an X-ray diffraction experiment on a single crystal (Table 1 and 2). Whereas in the crystalline state cuprate **1** may be stored for several months, in solution

it decomposes slowly even at −20 °C with precipitation of a black powder within a few weeks; this process is even faster when the solution is exposed to ambient light.

$$M^{I}Hyp + CuO\mathit{t}Bu \xrightarrow[-20°C]{\text{toluene}} [M^{I}(\text{toluene})][\mathit{t}BuOCuHyp]$$

M^{I} = Na (**2**), K (**1**), Cs (**3**) (5)

In the solid state the heterocuprate **1** consists of centrosymmetric dimers (Figure 1), where two *tert*-butoxy(hypersilyl)cuprate anions with almost linear Si−Cu−O backbones [171.70(7)°] are linked via two $[K(\text{toluene})]^{+}$ cations, thus forming planar K_2O_2 rings with alternating short and long K−O distances of 259.1(3) and 266.0(2) pm, respectively. The coordination sphere of each alkali cation is completed by an η^6-bonded toluene molecule. Due to twofold disordering of the toluene ligand the K···C distances cannot be determined to a great accuracy, but observed values between 315 and 352 pm lie in the expected range. An intriguing feature of the cuprate anion is a very short Cu−Si bond of 222.59(12) pm, which is thus far the shortest among all structurally characterized compounds with Cu−Si bonds (Table 3). The Cu−O distance, on the other hand, is comparatively long, giving rise to the description of cuprate **1** as a *loose* Lewis-acid/base adduct of hypersilylcopper and potassium *tert*-butoxide. Replacing the relatively hard Lewis base *tert*-butoxide for a softer one such as a second hypersilanide anion, or neutral ligands such as phosphanes, leads to substantial lengthening of the Cu−Si bond. We were able to synthesize and structurally characterize di(hypersilyl)cuprates with Na, K and Cs as countercations and therein found Cu−Si distances of about 230 ± 1 pm (see below).

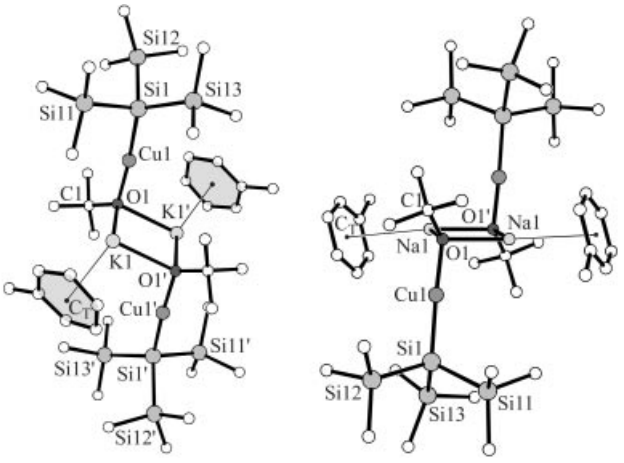

Figure 1. Molecular structures of heterocuprates **1** (left) and **2** (right); slightly differing orientations have been chosen for better illustrating the structural details; atoms are represented by spheres of arbitrary radii; the centroids of the aromatic rings are denoted by C_T; selected structural parameters are given in Table 2

Replacing K^{+} for Na^{+} or Cs^{+} does not significantly change the basicity and availability of the butoxide anion. The respective heterocuprates **2** and **3** again form dimers in the solid state (Figure 1 and 2) and in spite of different crystal structures display very similar molecular structures to the potassium derivative **1**. The observed differences such as different M^{I}−O bond lengths and different M^{I}···C distances (Table 2) can all be related to the strongly differing ionic radii of the alkali metals. Due to the much larger radius of Cs^{+} the cesium cuprate **3** exhibits — other than its relatives **1** and **2** — further aggregation in the solid state. This is accomplished by a Cs···CH_3 agostic interaction with methyl groups of neighboring cuprate dimers [Cs···C122′ 372.8(6) pm] and finally leads to one-dimensional coordination polymers (Figure 2). The cesium cuprate also differs in the fact that the solvating toluene, again bonded in an η^6-fashion, is now well ordered.

Replacing potassium for lithium, i.e. reacting lithium hypersilanide with copper *tert*-butoxide, dramatically changes the type of products obtained. Lithium *tert*-butoxide, which is presumably formed at first, doesn't give any isolable adduct with hypersilylcopper. Instead it catches Li^{+} cations from excess lithium hypersilanide to give the unique cation $[Li_7(O\mathit{t}Bu)_6]^{+}$, and — with simultaneously generated hypersilylcopper — gives rise to the formation of different homocuprates [Equations (1) − (3)], details of which have been published in a previous paper.[7]

The structural parameters of the hypersilyl group present in the cuprates **1**, **2** and **3** differ only slightly. Relatively short Si−Si bonds and Si−Si−Si angles significantly smaller than ideal tetrahedral values indicate negative charge accumulation on the hypersilyl group. An almost complete charge transfer is expected, and found, for the parent alkali metal silanides. Consequently, Si−Si bond lengths of 233 pm and Si−Si−Si angles down to 102° are observed for these compounds, whereas almost ideal tetrahedral angles are found for the derivatives of elements with a similar electronegativity as silicon (e.g. $HgHyp_2$ [13]). A relatively high negative charge of about −0.5 is verified by NBO analysis of the density derived from ab initio or DFT calculations, and is in agreement with the position of the ^{29}Si NMR resonance for the central silicon atom, which is observed at high field (δ = −147 ppm) for all cuprates **1**−**3**.

Next we discuss preliminary results for the utilization of the heterocuprates **1**−**3** in the synthesis of other cuprates. From the outcome of the reaction of lithium hypersilanide with copper *tert*-butoxide, we assumed that in the presence of (unsolvated) Li^{+} cations *tert*-butoxide anions usually do not bind to a Cu−SiR_3 moiety to form heterocuprates. Therefore we supposed that the addition of lithium salt might lead to substitution of the *tert*-butoxide ligand for the co-anion of lithium [Equation (6)].

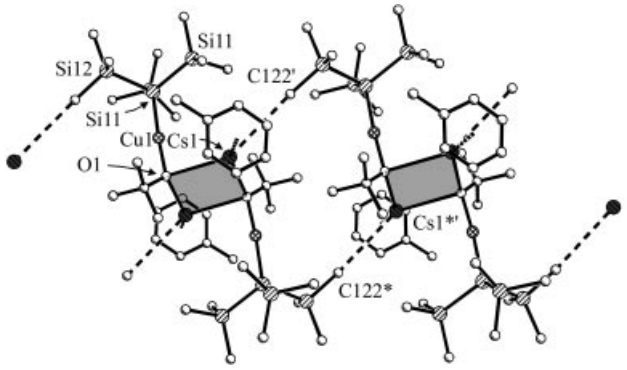

Figure 2. Molecular and crystal structure of heterocuprate **3**; intermolecular contacts are symbolized as dashed lines; atoms are represented by spheres of arbitrary radii; selected structural parameters are given in Table 2

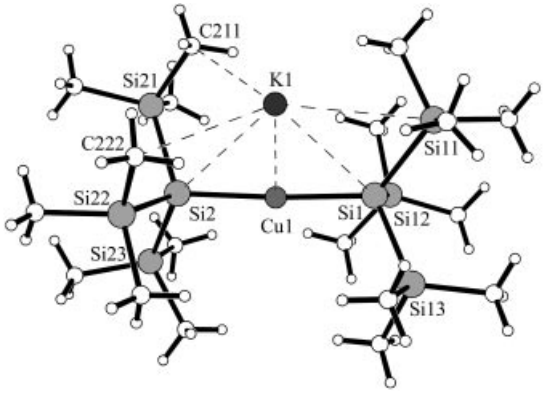

Figure 3. Molecular structure of potassium di(hypersilyl)cuprate (**4**); atoms are represented by spheres of arbitrary radii; dashed lines are used to symbolize interatomic distances markedly smaller than the sum of the corresponding van der Waals radii; selected structural parameters are given in Table 2

At first we investigated the reaction of unsolvated lithium hypersilanide with toluene solutions of the heterocuprates **1**−**3**. In the course of all these reactions the heterocuprates are fully consumed and one very soluble compound, probably unsolvated lithium *tert*-butoxide, is detected as a major product. The ^1H NMR spectra of the non-volatile products reveal the presence of at least one novel species present in all three reaction mixtures, in each case giving a resonance near $\delta = 0.38$ ppm (C_6D_6). The same resonances are found if pure hypersilylcopper is reacted with solvated or unsolvated lithium or potassium hypersilanide in a 1:1 molar ratio. Only for potassium has the respective product — potassium di(hypersilyl)cuprate $K[CuHyp_2]$ (**4**) — been isolated almost pure and in high yields after crystallization from pentane/toluene mixtures [according to Equation (6) with X = Hyp] as a colorless crystalline compound that could be fully characterized by X-ray diffraction (Table 1 and 4; Figure 3 and 4) and NMR spectroscopy.

The colorless solid material from the reaction of heterocuprate **2** contains at least three different compounds. Beside the desired $Na[CuHyp_2]$ (**5**), which again could be structurally characterized, varying amounts of crystalline sodium hypersilanide and one further unidentified product are present in the recrystallized material; from the reaction of cesium derivative **3**, solid mixtures of the desired $Cs[CuHyp_2]$ (**6**), cesium hypersilanide, hypersilylcopper, $Si(SiMe_3)_4$ and at least one other unidentified product are obtained. We concentrate here on the discussion of solid-state structures for the di(hypersilyl)cuprates **4** and **5** which could be determined from single crystals. A thorough comparison of molecular structures and spectroscopic data for all three dihypersilyl cuprates **4**−**6** will be discussed in a later paper, since only during the writing of the present report were we able to isolate the di(hypersilyl)cuprates **5** and **6** as pure compounds from direct reactions of hypersilylcopper and the appropriate alkali metal hypersilanide.[14]

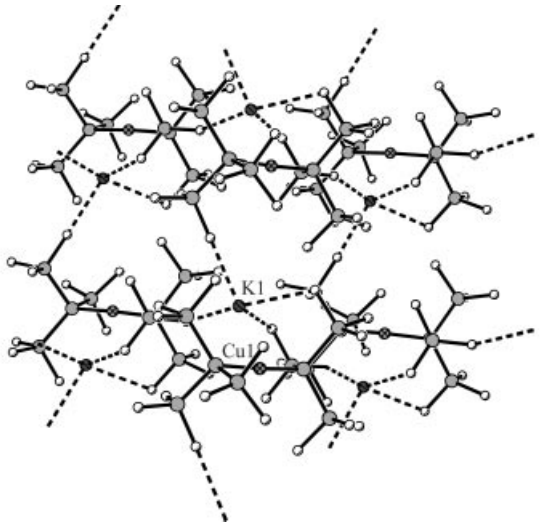

Figure 4. View parallel to [001] of the puckered two-dimensional coordination polymer of cuprate **4**; dashed lines indicate agostic-type intermolecular K···C contacts

The colorless crystal needles of potassium di(hypersilyl)-cuprate (**4**) comprise discrete molecules (Figure 3) interlinked weakly by agostic-type interactions (Figure 4). The potassium ion is located above the center of the dumbbell-like di(hypersilyl)cuprate fragment, thus giving short K−Si distances to the central silicon atoms of the hypersilyl groups of nearly equal length (380 pm), and a short K−Cu distance of 305 pm. The copper atom is slightly bent away from the potassium atom giving a Si−Cu−Si angle of about 176.4°. We assume the most adequate description of the molecule to be as an intimate ion-pair with a predominantly ionic binding mode between the K^+ cation and the cuprate anion. The anion is isoelectronic with di(hypersilyl)-zinc and, in spite of the additional K^+ ion present in **4**, adopts an almost ideal staggered conformation (approximate local D_{3d} symmetry) and has similar structural parameters.[15] According to the somewhat larger atomic radius of zinc the Cu−Si bonds found in the cuprate **4** (2 × 230 pm) are slightly shorter (by 4 pm) than the corresponding Zn−Si bonds in di(hypersilyl)zinc (2 × 234 pm).

The only structural differences between the cuprate anion and di(hypersilyl)zinc worth mentioning are markedly widened Cu−Si−Si angles to those trimethylsilyl groups in the neighborhood of the intruding K^+ cation (Table 4). The electrostatic bond between the K^+ cation and $[Hyp_2Cu]^-$ anion is further amended by agostic-type interaction to two methyl groups within the molecular unit [K···CH_3: 331.2(6) and 336.0(5) pm]. Two further, but intermolecular, K···CH_3 contacts of 321.8(5) and 342.1(5) pm complete the coordination of the K^+ cation, leading to puckered infinite two-dimensional coordination polymers (Figure 4).

The structural parameters of the related sodium di(hypersilyl)cuprate (**5**) are very similar (Table 4). Significant differences occur only for the location and coordination of the markedly smaller Na^+ cation. Other than the K^+ ion in compound **5**, which is located above the center of the dumbbell anion, the Na^+ ion is statistically disordered about two positions. The sites are located on opposite sites of the $CuSi_2$ dumbbell and slightly displaced from the center of the dumbbell in opposite directions (Figure 5). Again, due to the smaller ionic radius of Na^+, the sodium derivative **5** does not form coordination polymers but only dimers, as illustrated in Figure 6.

Very recently the synthesis of related sodium di(supersilyl)cuprates Na[Cu(Si*t*Bu$_3$)$_2$] was reported by Lerner et al.[8] They were obtained as THF solvates from CuCl and sodium supersilanide in tetrahydrofuran at −78 °C. However, similar to the findings of Stalke the overall yields were relatively low (47%), perhaps again due to the presence of halide. Interestingly two *different* solvates were isolated from the reaction mixture. The first, [Na(THF)$_4$][Cu(Si*t*Bu$_3$)$_2$], consists of separated ions, whereas the second, [Na(THF)$_2$][Cu(Si*t*Bu$_3$)$_2$], displays similar structural features to potassium di(hypersilyl)cuprate, i.e. contact ion-pairs, but now with two additional THF molecules coordinated to the sodium cation.

Unexpectedly, the Cu−Si bonds shorten markedly from ca. 236 pm to 231 pm on going from the contact ion-pair to

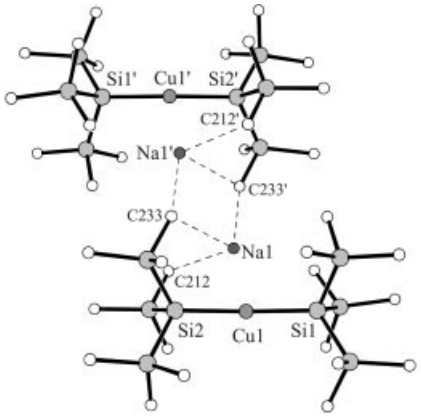

Figure 6. Coordination dimer of cuprate **5**; dashed lines indicate intra- and intermolecular agostic-type Na···C contacts

the separated anion, although we do not see a comparable shortening of the Cu−Si bonds on going from the contact ion-pair in cuprate **4** to separated ions in $[K(THF)_6][CuHyp_2]$, which is obtained by reaction of potassium hypersilanide with copper *tert*-butoxide in tetrahydrofuran (Table 3).[16]

It should be noted, finally, that a mixture of lithium hypersilanide and other lithium silanides may be used as a reactant in the reaction with the heterocuprates **1**−**3**, leading to cuprates with two different silyl ligands. In some cases mixed bis(silyl)cuprates may be isolated, whereas in other cases ligand redistribution takes place and the two symmetric species are formed. Detailed investigations are currently in progress.

Finally, we report a rational synthesis of large amounts of pure hypersilylcopper[6] — a compound ideal for the study of prototypic reactions of the Cu−Si bond towards organic or inorganic substrates — and for which no straightforward synthesis is known to date. Since the cuprates **1**, **2**, and **3** in turn are very easily accessible, we looked for a possible transformation of those cuprates into the neutral silylcopper complex. We finally succeeded with the reaction of the cuprates with chlorotrimethylsilane in toluene or pentane at low temperatures [Equation (7)].

$$\underset{(\mathbf{1})}{[K(\text{toluene})][t\text{BuOCuHyp}]} + Me_3SiCl \longrightarrow CuHyp + KCl + Me_3SiO t\text{Bu} + \text{toluene} \quad (7)$$

At ambient temperature both nucleophiles — the *tert*-butoxide and the hypersilanide anion — are stripped simultaneously from the heterocuprate anion leading to mixtures of hypersilylcopper and undesired non-volatile side-products such as copper *tert*-butoxide, the mixed tetramers $Cu_4Hyp_2(OtBu)_2$ (**7**) and $Cu_4Hyp_3(OtBu)$ (**8**) as well as tetrakis(trimethylsilyl)silane [Equation (8) and (9)]. At temperatures below −20 °C solutions of almost pure hypersilylcopper are obtained, however, from which crystalline material is obtained after removing all volatile components in vacuo and subsequent crystallization of the residue from toluene. To get very clean hypersilylcopper the cuprate **1** should be recrystallized before use and the ratio of the reactants should be as close as possible to 1:1. The mixed tetramers **7** and **8**, which are found as major side-products if the temperature chosen is too high, represent the first *heteroleptic* neutral Cu^I species bearing silyl substituents. A rational synthesis, spectroscopic data and structural details will be discussed in a subsequent paper.

$$\underset{(\mathbf{1})}{[K(\text{toluene})][t\text{BuOCuHyp}]} + Me_3SiCl \longrightarrow CuOtBu + KCl + Me_3SiHyp + \text{toluene} \quad (8)$$

$$x\ CuOtBu + y\ CuHyp \longrightarrow Cu_4(OtBu)_xHyp_y \quad [x = 2, y = 2\ (\mathbf{7}); x = 1, y = 3\ (\mathbf{8})] \quad (9)$$

Conclusion

We have shown that copper *tert*-butoxide reacts with the hypersilanides of the heavier alkali metals Na, K, and Cs in toluene solution to yield heterocuprates of the type $M^I[t$-BuOCuHyp] (**1**−**3**). They form dimers in the solid state and contain the shortest Cu−Si bond ever determined for molecular compounds. These cuprates can be used as valuable sources for the parent hypersilylcopper complex and other silylcopper reagents. Due to the fact that Li^+ cations bind to the *tert*-butoxide anion very strongly, reactions of cuprates **1**−**3** with lithium salts often leads to a replacement of the *tert*-butoxide anion for the counteranion of the employed salt. Therefore di(hypersilyl)cuprates, or even unsymmetrically substituted bis(silyl)cuprates, are obtained if the heterocuprates **1**−**3** are treated with a mixture of lithium hypersilanide and other lithium silanides. If the *tert*-butoxide anion is completely removed from the heterocuprate anion pure hypersilylcopper is obtained.

Experimental Section

General Remarks: All experiments were carried out under dry oxygen-free argon using standard Schlenk techniques. Solvents were freshly distilled under Ar from $LiAlH_4$ prior to use. NMR: Bruker AM 200 and AC 250 instruments and referenced to solvent resonances.

$[M^I(C_7H_8)][t$BuOCuSi(SiMe$_3$)$_3$] [M^I = K (1), Na (2), Cs(3)]: In a typical experiment unsolvated $M^ISi(SiMe_3)_3$ (2 mmol) dissolved in toluene (10 mL) was slowly added to a well-stirred solution of CuO*t*Bu (0.27 g, 2 mmol) in toluene (20 mL) at −20 °C. The reaction mixture was stirred for 30 min at −20 °C and then rapidly heated for a few minutes to about 40 °C. After filtration from small amounts of copper powder the now pale-yellow solution was concentrated under dynamic vacuum to a volume of about 20 mL and cooled to −60 °C for 24 h. The cuprates **1**−**3** were obtained as colorless (**1** and **2**) or pale-yellow (**3**) crystalline toluene solvates. Some more crystalline material was obtained after subsequent concentration and crystallization at −60 °C. Typical yields lie between 85 and 96%.

1: $C_{40}H_{88}Cu_2K_2O_2Si_8$ (1031.10): calcd. C 46.59, H 8.6; found C 46.23, H 8.52. ^{1}H NMR (C_6D_6): δ = 0.49 (s, 27 H, $SiMe_3$) 1.12 [s, 9 H, Me (O*t*Bu)] ppm. ^{13}C NMR (C_6D_6): δ = 5.53 ($SiMe_3$, $^1J_{C,Si}$ = 42.1 Hz), 37.4 [C(*C*H$_3$)], 70.1 [*C*(CH$_3$)] ppm. ^{29}Si NMR: δ = −7.40 [Si(*Si*Me$_3$)$_3$], 141.2 [*Si*(SiMe$_3$)$_3$] ppm.

2: $C_{40}H_{88}Cu_2Na_2O_2Si_8$ (998.88): calcd. C 48.09, H 8.88; found C 47.92, H 8.91. ^{1}H NMR (C_6D_6): δ = 0.49 (s, 27 H, $SiMe_3$) 1.06 [s, 9 H, Me (O*t*Bu)] ppm. ^{13}C NMR (C_6D_6): δ = 5.43 ($SiMe_3$, $^1J_{C,Si}$ = 42.0 Hz), 37.4 [C(*C*H$_3$)], 69.8 [*C*(CH$_3$)] ppm. ^{29}Si NMR: δ = −7.60 [Si(*Si*Me$_3$)$_3$, $^1J_{Si,Si}$ = 47.3 Hz), 139.6 [*Si*(SiMe$_3$)$_3$] ppm.

3: $C_{40}H_{88}Cu_2Cs_2O_2Si_8$ (1218.72): calcd. C 39.42, H 7.28; found C 39.12, H 7.24. ^{1}H NMR (C_6D_6): δ = 0.48 (s, 27 H, $SiMe_3$) 1.13 [s, 9 H, Me (O*t*Bu)] ppm. ^{13}C NMR (C_6D_6): δ = 6.20 ($SiMe_3$, $^1J_{C,Si}$ = 41.4 Hz), 36.5 [C(*C*H$_3$)], 70.4 [*C*(CH$_3$)] ppm. ^{29}Si NMR: δ = −7.40 [Si(*Si*Me$_3$)$_3$], 141.5 [*Si*(SiMe$_3$)$_3$] ppm.

KCu[Si(SiMe$_3$)$_3$]$_2$ (4): Unsolvated lithium hypersilanide (2.5 g, 9.82 mmol) dissolved in toluene (10 mL) was added to a solution of cuprate **1** [5.06 g, 4.91 mmol (dimer)] in toluene (20 mL) at −20 °C and stirred for 30 min at this temperature, then warmed to room temperature and stirred for another 20 min. The volatiles were removed at 25 °C/10^{-2} Torr and the oily residue extracted with 3 × 10 mL of *n*-pentane. The pentane solution was concentrated under dynamic vacuum at 20 °C until a few colorless crystals appeared and then placed at −60 °C for 24 h. The cuprate **4** was obtained in 65% yield as colorless crystal blocks. $C_{18}H_{54}CuKSi_8$ (597.97): calcd. C 36.15, H 9.10; found C 35.95, H 9.13. ^{1}H NMR (C_6D_6): δ = 0.38 (s, 27 H, $SiMe_3$) ppm. ^{13}C NMR (C_6D_6): δ = 6.1 ($SiMe_3$, $^1J_{C,Si}$ = 41.6 Hz) ppm. ^{29}Si NMR: δ = −7.5 [Si(*Si*Me$_3$)$_3$], 147.5 [*Si*(SiMe$_3$)$_3$].

NaCu[Si(SiMe$_3$)$_3$]$_2$ (5): Unsolvated lithium hypersilanide (2.5 g, 9.82 mmol) dissolved toluene (10 mL) was added to a solution of cuprate **2** [4.90 g, 4.91 mmol (dimer)] in toluene (20 mL) at −20 °C and stirred for 30 min at this temperature, then warmed to room temperature and stirred for another 20 min. The volatiles were removed at 25 °C/10^{-2} Torr and the oily residue extracted with 3 × 10 mL of *n*-pentane. The pentane solution was concentrated to 5 mL and then placed at −60 °C for several days. The cuprate **5** was obtained as a solid mixture with sodium hypersilanide and one unidentified product. ^{1}H NMR (C_6D_6): δ = 0.38 (s, 27 H, $SiMe_3$) ppm. ^{13}C NMR (C_6D_6): δ = 5.9 ($SiMe_3$, $^1J_{C,Si}$ = 41.7 Hz) ppm. ^{29}Si NMR: δ = −7.3 [Si(*Si*Me$_3$)$_3$], 147.3 [*Si*(SiMe$_3$)$_3$] ppm.

Synthesis of Hypersilylcopper [CuSi(SiMe$_3$)$_3$] from [K(C$_7$H$_8$)][*t*BuOCuSi(SiMe$_3$)$_3$] (1): A solution of Me_3SiCl (0.466 g, 4.29 mmol) in toluene (20 mL) was added dropwise to a stirred solution of cuprate **1** [2.21 g, 2.14 mmol (dimer)] in the same solvent (15 mL) at −20 °C. The solution was slowly warmed to room temperature and stirred for 0.5 h. Then all volatiles were removed at 25 °C/10^{-2} Torr. After addition of 25 mL of *n*-pentane to the residue, the resulting suspension was filtered through a glass filter. The solution was concentrated in dynamic vacuum to approximately 5 mL and cooled to −30 °C for 24 h. Hypersilylcopper was obtained as colorless crystal plates or needles in about 80% yield. The yield may be improved by another 5−10% by subsequent cooling of the mother liquor to −60 °C for several days. The identity and purity of the product were verified by comparison with published NMR spectroscopic data.

X-ray Crystallographic Study: Diffraction data for compounds **1**−**5** were collected on a Siemens P4 four-circle diffractometer using monochromated Mo-K_α radiation (λ = 0.71073 Å) at 173 K. Crystals were covered with nujol, placed on the tip of a glass fiber and mounted on the diffractometer under a stream of cold nitrogen gas. The cell dimensions were determined from the positions of 35−52 selected reflections ($20 < 2\theta < 25°$). The structures were solved by direct methods and refined against all F^2 using the SHELXTL-PC 5.03 program package on a local PC. Anisotropic thermal parameters were included for all non-hydrogen atoms. Hydrogen atoms were placed at ideal positions using appropriate HFIX procedures and refined with riding models. The isotropic displacement parameters were constrained to 1.5 (aliphatic) or 1.2 (aromatic) times the U_{eq} of the connected carbon atom. Further details can be found in Table 1.

CCDC-213800 (**1**), -213801 (**2**), -213802 (**3**), -213803 (**4**), and -213804 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Fluorite-Related Phases in the System Li-Pt-Sn: Synthesis and Structures of Li_2PtSn, $Li_3Pt_2Sn_3$, $Li_{2.27}Pt_2Sn_{3.73}$ and $Li_{2.43}Pt_2Sn_{3.57}$

Rolf-Dieter Hoffmann,[a] Zhiyun Wu,[a] and Rainer Pöttgen*[a]

In memory of Ron Snaith

Keywords: Lithium / Tin / Platinum / Intermetallic phases

The intermetallic compounds Li_2PtSn, $Li_3Pt_2Sn_3$, $Li_{2.27}Pt_2Sn_{3.73}$ and $Li_{2.43}Pt_2Sn_{3.57}$ were synthesised by reaction of the elements in sealed tantalum tubes. They were investigated by X-ray diffraction on powders and single crystals: $F\bar{4}3m$, a = 626.0(1) pm, $wR2$ = 0.0834, 70 F^2 values, 7 variables for Li_2PtSn; $Ia\bar{3}$, a = 1264.3(1) pm, $wR2$ = 0.0340, 416 F^2 values, 23 variables for $Li_3Pt_2Sn_3$; $Ia\bar{3}$, a = 1269.7(1) pm, $wR2$ = 0.1130, 521 F^2 values, 24 variables for $Li_{2.27(1)}Pt_2Sn_{3.73(1)}$; $Ia\bar{3}$, a = 1266.6(1) pm, $wR2$ = 0.1094, 620 F^2 values, 25 variables for $Li_{2.43(1)}Pt_2Sn_{3.57(1)}$. The latter refinement was based on a crystal twinned by merohedry. Li_2PtSn crystallises with an ordered variant of the BiF_3 type. The other stannides adopt a superstructure of the fluorite type where all three subcell axes are doubled. In $Li_3Pt_2Sn_3$ the platinum atoms are located on the calcium sites while the tin and 1/3 of the lithium atoms are ordered on the fluorine site. The remaining lithium atoms fill octahedral voids of the *fcc* arrangement of platinum. The superstructure is discussed on the basis of a group-subgroup scheme and experimental evidence is given for a solid solution $Li_{3-x}Pt_2Sn_{3+x}$.

Introduction

The binary fluoride BiF_3[1] has three crystallographic positions, Bi on the Wyckoff site 4*a*, F1 at 4*b*, and F2 at 8*c*. This structure type may be described as a filled fluorite variant with F1 in the octahedral voids or as a filled blende-type structure with half of the F2 atoms in the remaining tetrahedral voids and the F1 atoms in the octahedral voids. A variety of intermetallic lithium compounds adopt BiF_3-related structures. According to the different Wyckoff positions, the compositions Li_2TX, LiT_2X and $LiTX_2$ (T = late transition metal; X = *p*-block element of the 3rd or 4th group) are possible. Indeed, examples are known for all of them.[2] A large variety of such intermetallics were synthesised in the groups of Schuster[3,4] and Weiss[5] 30 years ago. Most of these intermetallics, however, have only been characterised on the basis of X-ray powder diffraction data.

Depending on the composition as well as on the T and X components, the compounds Li_2TX, LiT_2X and $LiTX_2$ have different electron counts, leading to a variety of interesting physical properties. Susceptibility and resistivity measurements reveal metallic behaviour and Pauli paramagnetism.[3,6] One of the most interesting properties of these intermetallics is the intrinsic colour,[3,6,7] which varies with the valence electron concentration. To give an example, in the solid solution $Li_{2-x}Mg_xPdSn$, the colour changes from brass yellow via copper red to red violet with increasing x.[7] The optical constants have been determined from reflection spectroscopic data.[3,6,7] At least some of the Li_2TX, LiT_2X and $LiTX_2$ compounds show lithium mobility.[8,9] Chemical bonding in various Li_2TX and $LiTX_2$ (T = Rh, Pd, Ir, Pt; X = Al, Ga, In) intermetallics has been investigated by X-ray photoelectron and X-ray excited Auger spectroscopy paralleled by DFT electronic structure calculations.[10,11]

In the course of our systematic studies on structure/property relation of Li-*T*-Sn stannides,[12–14] we have investigated the ternary system lithium-platinum-tin in more detail. It turned out that a large solid solution $Li_{3-x}Pt_2Sn_{3+x}$ (x = 0–1) exists with a fluorite subcell structure. $PtSn_2$ [15] crystallises with a fluorite structure and Li_2PtSn has a fluorite type subcell as well. In the superstructure with the ideal formula $Li_3Pt_2Sn_3$ the lithium and tin atoms are well ordered in a 2 × 2 × 2 cubic supercell. The process of lithium filling and Sn/Li substitution is formally done in two steps. At first the octahedral sites in $PtSn_2$ are filled to get "$LiPtSn_2$" and secondly tin is substituted by lithium on the tetrahedral sites up to Li_2PtSn.[16,17] The synthesis and crystal chemistry of these stannides is reported herein.

Results

A fluorite-type arrangement heavily governs the structural chemistry in the ternary system Li-Pt-Sn. The binary stannide $PtSn_2$ crystallises in the CaF_2 type. From the literature it is not known whether $PtSn_2$ has a noticeable range of homogeneity. This is also suggested by our own phase-analytical investigations within this work.

In the ternary compounds Li_2PtSn and $Li_3Pt_2Sn_3$ (better formulated as $Li_{3-x}Pt_2Sn_{3+x}$ with $x = 0-1$) the *ccp* arrangement of platinum atoms remains fixed, while lithium fills the octahedral voids and in addition substitutes tin atoms on the tetrahedral sites (Table 1 and 2, Figure 1). This filling is done in two steps. First, the octahedral sites are filled and then the Sn/Li substitution sets in. This conclusion can be drawn from Figure 2. For comparison reasons the lattice parameters of $PtSn_2$ and Li_2PtSn have been doubled to compare to the supercell of $Li_3Pt_2Sn_3$ (Table 3). Binary $PtSn_2$ has the largest lattice parameter, leading to a Sn−Sn distance of 321 pm which nicely matches the distance in elemental tin: 4×302 and 2×318 pm in β-Sn.[18] The Pt−Sn contacts are 278 pm comparing well to the sum of Pauling's single bond radii.[19] Incorporation of lithium at octahedral voids lets the lattice parameter sharply drop by about 16 pm resulting in shorter Pt−Sn distances (Table 4) than those in binary $PtSn_2$. The excess electrons from the lithium atoms, therefore, presumably fill bonding Pt−Sn states. The ideal structure $LiPtSn_2$, where only octahedral voids are filled by lithium, was not obtained. The extrapolated lattice parameter is indicated by an open circle in Figure 2. The composition with the lowest lithium content was $Li_{1.11}PtSn_{1.89}$ with 5.5% lithium on the tin site, whereas the highest lithium content in the superstructure was 25% corresponding to the ideal composition $Li_3Pt_2Sn_3$.

Table 1. Crystal data and structure refinement parameters for Li_2PtSn, $Li_3Pt_2Sn_3$, $Li_{2.43}Pt_2Sn_{3.57}$ and $Li_{2.27}Pt_2Sn_{3.73}$

[a] The displacement parameters are constrained to be equal and the sum of Li1 and Sn2 are set to 100% occupancy.

Thus, the content of lithium can be increased further. This is done by substitution of tin at the tetrahedral sites by lithium atoms. Gradually the lithium content can be increased from $LiPtSn_2$ to $Li_3Pt_2Sn_3$, where 2/8 of the tin atoms are replaced. The general formula of the new ternary compound may be written as $Li_{octahedra}[Pt(Sn_{1.5+x}Li_{tetrahedra\ 0.5-x})]$ with $x = 0-0.5$ for the fluorite-type subcell i.e. $Li_2[Pt_2(Sn_{3+x}Li_{1-x})]$ with $x = 0-1$ for the superstructure.

Seven single crystals were refined and their lattice parameters found to correlate nicely with the amount of lithium on the tetrahedral sites (Figure 2). Decreasing the tin content lets the lattice parameter drop mainly because the smaller lithium atoms substitute the larger tin atoms (123 pm and 140 pm for lithium and tin, respectively).[19] Along with this substitution the intensities of the superstructure reflections increase in intensity to reach a maximum at the ideal composition for the superstructure of $Li[Pt(Sn_{1.5}Li_{0.5})]$ i.e. $Li_3Pt_2Sn_3$.

The following discussion reflects on the consequences of the ordered arrangement of lithium and tin for the near neighbour environment (Figure 3). The filling of octahedral sites by lithium in a fluorite-type subcell increases the coordination numbers (CN) of platinum and tin and lithium as well. CNs of 8, 9 and 10 are found for Pt1, Pt2 and Sn, respectively. The CNs for the lithium atoms are 14, 8 and 9 for Li1, Li2 and Li3, respectively. The high CN of Li1 can be explained as follows. The lithium atom Li1 replaces 2/8 of the tin positions of the subcell. This would lead to CN 8 i.e. four tetrahedrally oriented platinum atoms and four lithium atoms on octahedral sites. In the superstructure, however, shorter Pt−Sn distances of 270−276 pm (Table 4) occur as compared to those in binary $PtSn_2$ (278 pm). This shrinkage allows extra atoms to be in contact with the Li1 atoms. Due to the additional lithium on octahedral voids of the *fcc* arrangement of the platinum atoms and the order of tin and lithium on tetrahedral voids, all near-neighbour environments are basically strongly distorted cubes with six additional atoms on faces and edges increasing the CN.

In Li_2PtSn the lithium content seems to reach the maximum possible, where 4/8 of the tin positions are occupied by lithium atoms. The lattice parameter fits well in the *a* vs. *portion Li* plot of Figure 2, indicating again that the drop of the lattice parameter is due to the size difference of Li/Sn of 123/140 pm (Pauling's radii).

Li_2PtSn constitutes the second ordered superstructure in the large range of fluorite-related structures in the Li-Pt-Sn system. It derives from the binary BiF_3 (a filled fluorite type) where bismuth forms a *fcc* arrangement and the two different fluoride sites occupy the tetrahedral and octahedral voids on 4*b* and 8*c* in $Fm\bar{3}m$, respectively (Figure 1). As compared to CaF_2, the Li2 atoms replace 4/8 of the fluoride positions in an ordered manner. This leads to a reduction in symmetry. The structure becomes non-centro-

The crystal structures of $Li_3Pt_2Sn_3$ and Li_2PtSn; the lithium, platinum and tin atoms are drawn as grey, filled and open circles, respectively; at the top the $2 \times 2 \times 2$ supercell of $Li_3Pt_2Sn_3$ is shown; one subcell of $Li_3Pt_2Sn_3$ is outlined in the middle; note that in the solid solution $Li_{3-x}Pt_2Sn_{3+x}$ the Li1 position is additionally occupied by tin atoms; the similarity of the subcell with the ternary ordered BiF_3-type Li_2PtSn is emphasised below

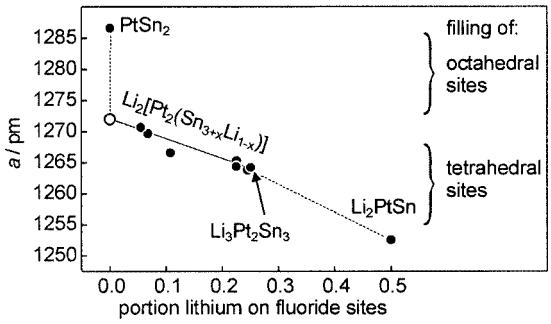

Figure 2. Course of the cubic lattice parameter of the solid solution $Li_{3-x}Pt_2Sn_{3+x}$, $PtSn_2$ and Li_2PtSn; for the latter two compounds the lattice parameters are doubled for comparison; the open circle marks the composition with the lowest lithium content possible of the solid solution where no tin/lithium mixing on the tetrahedral sites occur; the different filling mechanisms by lithium atoms are indicated on the right hand side of the drawing; filling of tetrahedral sites corresponds to a replacement of tin atoms

symmetric and it crystallises in the space group $F\bar{4}3m$, a *translationengleiche* subgroup of index 2 of $Fm\bar{3}m$ (Figure 4, upper right-hand side). The indide $LiPdIn_2$[12] actually crystallises in $Fm\bar{3}m$ representing a ternary ordered version of BiF_3. In Figure 4 the substitution of tin by lithium can be seen by the splitting of the 8*c* site of $Fm\bar{3}m$ into two fourfold sites 4*c* and 4*d* of $F\bar{4}3m$.

There is no direct group-subgroup relation between $F\bar{4}3m$ and $Ia\bar{3}$ because $F\bar{4}3m$ is non-centrosymmetric and one cannot gain symmetry. In addition, following the Bärnighausen formalism strictly,[20,21] filled structures are also excluded from a symmetry tree. Li_2PtSn and $Li_3Pt_2Sn_3$ have the same aristotype (BiF_3), but both are situated on different branches.

BiF_3 is a filled CaF_2 type. For clarity the empty octahedral sites are left out on the CaF_2 branch (left hand side of Figure 4). Within the CaF_2 branch it is improbable that the interim AX_2 phases exist, and in actual fact they do not have to. So far no intermetallics with the symmetry $Pm\bar{3}m$ or $Pm\bar{3}$ and the atomic positions given in Figure 4 are known. One might speculate that a ternary stannide with two different transition metals on the sites 1*a* (A1) and 3*c* (A′2) of $Pm\bar{3}m$ exists. The necessary distortions are already

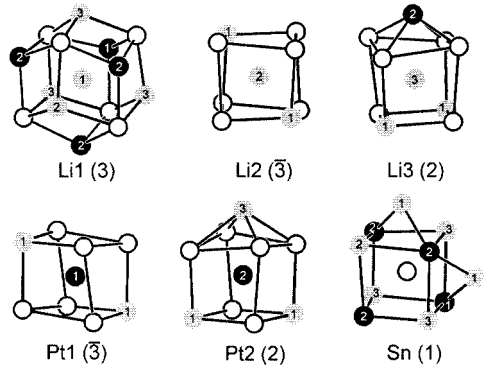

Figure 3. Near neighbour environment in the structure of $Li_3Pt_2Sn_3$; the lithium, platinum and tin atoms are drawn as grey, filled and open circles, respectively; the numbers correspond to the atom designations; the site symmetries are given in parentheses

taken care of by the extra parameter x of the X (Sn) position in 8*g*. Nevertheless, at this point the two different platinum sites of $Li_3Pt_2Sn_3$ already come into play. Both have different average distances to lithium and tin (Table 4).

The gain of the next *klassengleiche* symmetry reduction of index 4 (doubling in all three directions) is the most important one. It allows ordering of the tin and lithium atoms in the ratio 3:1. This was the key in solving the superstructure. It also means that this reduction is a one-way direction. The tin/lithium ratio on the tetrahedral sites is now fixed to 3:1 and cannot be changed unless further symmetry reductions occur. The consequence of this is that there is no solid solution between $Li_3Pt_2Sn_3$ and Li_2PtSn, because Li_2PtSn crystallises with a higher symmetry. Nevertheless, as Figure 2 suggests, the different volume increments of tin/lithium determine the course of the lattice parameters of $Li_3Pt_2Sn_3$ and Li_2PtSn.

To sum up, the crystal chemical relation between the different ternary lithium stannides is nicely depicted by the symmetry tree given in Figure 4. There are different mechanisms of establishing a certain lithium/tin ratio by filling octahedral and tetrahedral voids with lithium and lithium/tin mixtures, respectively, in the *fcc* arrangement of platinum.

Experimental Section

General: Starting materials for the preparation of the lithium-platinum-stannides were lithium rods (Merck, >99%), platinum powder (Degussa-Hüls, 200 mesh, >99.9%) and a tin bar (Heraeus, 99.9%). The lithium rods were cut into smaller pieces under dry paraffin oil and subsequently washed with *n*-hexane. The paraffin oil and *n*-hexane were previously dried over sodium wire. The lithium pieces were kept in Schlenk tubes under argon prior to the reactions. Argon was purified over titanium sponge (900 K), silica gel and molecular sieves.

The lithium pieces were mixed with cold-pressed pellets of platinum powder and pieces of the tin bar in the respective atomic ratios and sealed in tantalum ampoules under an argon pressure of about 800 mbar in an arc-melting apparatus.[22] The tantalum tubes were then sealed in evacuated silica tubes to prevent oxidation, rapidly heated at 1070 K and held at this temperature for between three hours and one day. The temperature was then lowered to 720 K or 820 K within four days followed by slow cooling to room temperature by switching off the furnace. The samples could be readily separated from the tubes. No reaction with the container material was observed. The light grey, polycrystalline compounds are stable in air over several weeks. Single crystals exhibit a metallic lustre.

X-ray investigations

The samples were characterised from Guinier patterns or powder diffractograms (Stoe StadiP) using Cu-$K\alpha_1$ radiation and silicon (a = 543.07 pm) as external standard or α-quartz (a = 491.30 pm, c = 540.46 pm) as internal standard. The cubic lattice parameters (Table 1) were obtained from least-squares fits of the powder data. The correct indexing of the patterns was facilitated by intensity calculations[23] taking the atomic positions from the structure refinements. The lattice parameters determined from the powders and the single crystals agreed well.

Several silvery, irregularly shaped single crystals of the solid solution were isolated from the annealed samples by mechanical fragmentation. They were examined on a Buerger precession camera equipped with an image plate system (Fujifilm BAS-2500 and -1800) in order to establish suitability for intensity data collection.

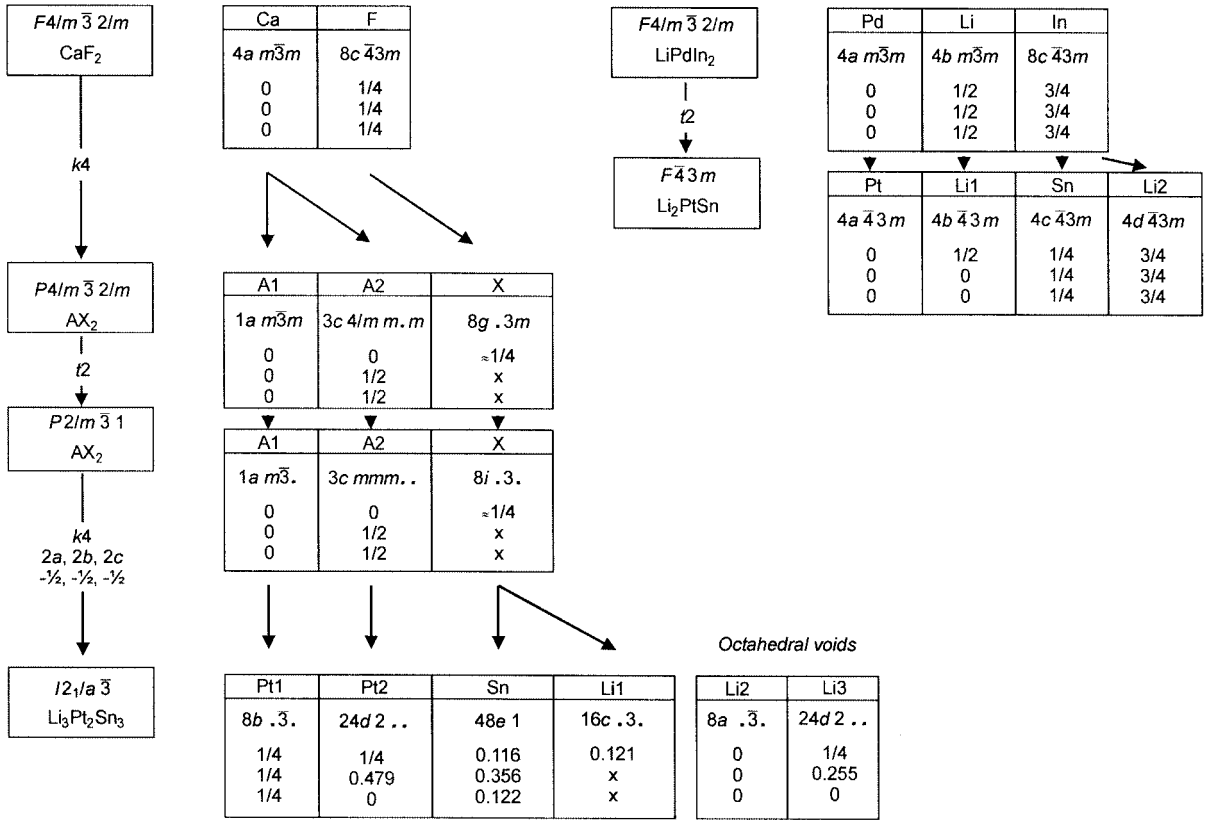

Figure 4. Group-subgroup relation in the Bärnighausen formalism[20,21] for the structures of CaF_2, $Li_3Pt_2Sn_3$, $LiPdIn_2$ and Li_2PtSn; the indices of the *klassengleiche* (k) and *translationengleiche* (t) transitions, the unit cell transformations with origin shifts and the evolution of the atomic parameters are given; the octahedral voids in CaF_2 and the interim structures are left out for clarity; $LiPdIn_2$ constitutes a ternary ordered version of BiF_3, which is a filled fluorite type

Single-crystal intensity data were collected at room temperature by use of a four-circle diffractometer (CAD4) with graphite-monochromated Mo-K_α radiation (71.073 pm) and a scintillation counter with pulse height discrimination. The scans were performed in the $\omega/2\theta$ mode. Empirical absorption corrections were applied on the basis of Ψ-scan data. Some data sets were collected on a Stoe IPDS-I and IPDS-II diffractometer with graphite monochromated Mo-K_α radiation. All relevant crystallographic data and experimental details for the data collections are listed in Table I.

Structure Refinements

The starting atomic parameters for the platinum and tin atoms were deduced from automatic interpretations of direct methods with SHELXS-97.[24] The lithium positions were determined from subsequent difference Fourier analyses. The structures were then refined using SHELXL-97 (full-matrix least-squares on F_o^2)[25] with anisotropic atomic displacement parameters for tin and platinum while isotropic refinement was carried out for the lithium atoms.

Refinement of Li_2PtSn

The determination of the space group for Li_2PtSn was carried out as follows. Reciprocal space revealed only the extinction conditions for a cubic face centred lattice. No extra extinctions were observed. Therefore, $Fm\bar{3}m$ was chosen as the highest symmetry space group possible. The refinement went smoothly to low R values ($R1$ = 0.032) assuming a fluorite-type structure with platinum occupying the calcium sites and a 1:1 mixture of tin and lithium on the fluoride sites. The drawback of this refinement, of course, is the mixed Sn/Li occupancy and that the occupation of additional octahedral sites by lithium could not be detected in a difference Fourier synthesis. However, the subgroup $F\bar{4}3m$ of $Fm\bar{3}m$ allows ordering of the tin/lithium atoms on the fluoride positions. This refinement yielded a reasonable R value, but not as low as the refinement in $Fm\bar{3}m$. In addition, a final difference Fourier synthesis revealed the occupancy of the octahedral voids leading to the composition Li_2PtSn. Careful inspection of the displacement parameters and the difference Fourier synthesis suggested a slight mixing of tin and lithium on the octahedral sites resulting in the composition $Li_{1.96(2)}PtSn_{1.04(2)}$. Despite the fact that the final R value is actually higher than the refinement in $Fm\bar{3}m$, the structure is correctly described in $F\bar{4}3m$. This is also undermined by the refined Flack parameter of 0.01(6), indicating the correct absolute orientation. In addition, the Flack parameter is expected to be 0.5 in the case where $Fm\bar{3}m$ is the correct space group.

$Li_{3-x}Pt_2Sn_{3+x}$: Refinement of $Li_3Pt_2Sn_3$, $Li_{2.27}Pt_2Sn_{3.73}$ and $Li_{2.43}Pt_2Sn_{3.57}$

The strongly dominating subcell of $Li_3Pt_2Sn_3$ with $a' = 1/2a$ belongs to a fluorite type as does Li_2PtSn. Indeed, the atomic positions of the binary fluorite phase $PtSn_2$ served as a starting point. Both lithium and tin occupy the fluoride positions with a refined ratio of approximately 3:1. The difference Fourier synthesis indicated additional occupation of octahedral voids by lithium, but in the subcell those positions were not refinable. This is due to the high cubic symmetry and parameter correlations. However, these correlations were nicely resolved in the superstructure.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

All three lattice parameters are doubled in the superstructure. This means in terms of symmetry reduction that one has to decentre the *F*-lattice first to get a primitive lattice and subsequently double a', b' and c'. The extinction conditions of the many weak superstructure reflections were compatible with a body centred lattice and showed the presence of an *a*-glide plane. Only one cubic space group was possible, $Ia\bar{3}$, in which the superstructure was refined successfully. Also, $Ia\bar{3}$ allows ordering of the lithium and tin atoms on the fluoride positions of the subcell in the ratio 1:3.

The ternary stannide follows the general formula $Li_{3-x}Pt_2Sn_{3+x}$. To cover the whole range of homogeneity a total of seven single crystals were refined for which x varied between $x = 0$ and $x = 0.78$. The crystals originated from samples with four different starting compositions, Li:Pt:Sn = 1:1:4, 1:1:2, 1:1:1 and 3:2:3.

The lattice parameters were refined from powder data as well and matched those obtained for the single crystal. We did not obtain pure samples in all cases as the starting compositions suggest. Therefore the lattice parameters obtained from the single crystal were taken to calculate atomic distances for the various structures refined. Apparently inhomogeneity with respect to the composition $Li_{3-x}Pt_2Sn_{3+x}$ could not be avoided as additional shoulders next to the strongest reflections suggested. Nevertheless, the lattice parameters in a single powder sample were within a narrow range and smaller than the variation of the lattice parameters over the whole range of homogeneity.

Two of the seven data sets were collected from crystals that showed twinning by merohedry. This twinning is suggested by the *translationengleiche* symmetry reduction t2 i.e. losing the high Laue symmetry. Consequently the twin matrix is 0 1 0, 1 0 0, 0 0 −1. Only three refinements are reported here, corresponding to the compositions, $Li_3Pt_2Sn_3$, $Li_{2.27}Pt_2Sn_{3.73}$ and $Li_{2.43}Pt_2Sn_{3.57}$. The other four data sets were refined to similar results, but give only redundant information.

The course of the structure refinement will be discussed for $Li_3Pt_2Sn_3$ as an example. The platinum and tin positions were calculated in going from the subcell positions to the supercell positions according to the symmetry reductions given in a Bärnighausen scheme[20,21] (Figure 4). The three lithium positions were clearly revealed by a difference Fourier synthesis. For the ideal composition $Li_3Pt_2Sn_3$ no remaining electron density on the lithium sites was observed and the displacement parameters of the lithium atoms behaved well. This occurred quite differently within the solid solution. Here, large difference Fourier peaks on the lithium site 16*c* could be observed. The only explanation, supported by the varying lattice parameters, was a mixed occupancy by tin atoms. The 16*c* site was occupied by Li1 and additional Sn2 atoms assuming that the sum was 100% (Table 2). The atomic positions and displacement parameters were constrained to be equal. Thus, the refinement of the lithium content was riding on the larger scattering power of tin on the site 16*c*, even though increasing tin/lithium mixing lets the intensity of the superstructure reflections gradually diminish.

Final difference Fourier syntheses revealed no significant residual peaks (see Table 1). The positional parameters of the refinements are listed in Table 2. Table 3 contains additional information regarding the range of homogeneity. In Table 4 the interatomic distances of the ideal structures are listed. Listings of the observed and calculated structure factors are available.
Further details of the crystal-structure investigation(s) may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number(s) CSD-413190 (Li_2PtSn), -413187 ($Li_3Pt_2Sn_3$), -413188 ($Li_{2.27}Pt_2Sn_{3.73}$) and -413189 ($Li_{2.43}Pt_2Sn_{3.57}$).

Keywords: N ligands / Calcium / O ligands / Ring-opening polymerization / Tin

The equimolar reaction of calcium bis[bis(trimethylsilyl)-amide] with 2,2,6,6-tetramethylheptane-3,5-dione (Htmhd) in THF yields liquid mononuclear [Ca(tmhd){N-$(SiMe_3)_2$}$(THF)_3$] (**1**). A similar reaction in toluene with a stoichiometric ratio of 2:3 gives the dinuclear complex [{$(THF)Ca\}_2(tmhd)_2$(μ-tmhd){μ-$N(SiMe_3)_2$}] (**2**). The calcium atoms of these complexes are in a distorted octahedral environment. In **2** the complex consists of two octahedra connected by a common face of one nitrogen base and two oxygen atoms; the bridging Ca–N bond lengths are extremely large. The metalation of the tetradentate Jacobsen reagent with calcium bis[bis(trimethylsilyl)amide] in 1,2-dimethoxyethane (DME) gives the corresponding calcium complex **3**, nearly quantitatively, as its DME adduct. The calcium atom is in an unusual trigonal prismatic coordination sphere. The metathesis reaction of **3** with tin(II) chloride yields the corresponding yellow tin(II) complex with the metal atom in a distorted square-pyramidal environment. Complexes **2** and **3** show catalytic reactivity in the ring-opening polymerization of cyclic esters such as lactones and lactides.

Introduction

The expectations that organocalcium chemistry might have a wide variety of applications[1] has led to intensive research efforts on this topic. Organocalcium compounds have been investigated for use as combustion improvers and smoke inhibitors, and as an additive for diesel fuels and fuel oils.[2] Another field of interest is the MOCVD (*M*etal *O*rganic *C*hemical *V*apour *D*eposition) process to produce, for example, thin films of calcium sulfide[3] or titanate.[4] There are also investigations on these compounds as sol-gel precursors.[5] Another important application for organocalcium compounds focuses on their use as initiators for the anionic ring-opening polymerization of cyclic esters and lactones.[6] These arbitrarily chosen examples illustrate the wide spectrum of interest in these compounds. Whereas for the MOCVD processes the main requirements of these compounds are volatility and thermal stability, the demands for ring-opening polymerization concern their reactivity towards cyclic esters and their solubility in common organic solvents such as ethers and hydrocarbons.

Due to the lack of redox reactivity, which is the key step in many catalytic cycles with transition metals, the alkaline-earth metals always show the oxidation state of +2. For their use as polymerization initiators and catalysts the organocalcium complexes should therefore have vacant coordination sites, which can be filled by weakly bonding ligands, or have unusual or distorted coordination spheres at the metal center. Furthermore, we have to design organocalcium compounds in a special reactivity range to have sufficient reactivity for the ring opening of cyclic esters but to prevent side reactions with the already formed polymer or with the solvent (such as ether cleavage reactions).

Polymeric cyclic esters such as D,L-lactide or ε-caprolactone are used for tissue engineering and as materials for surgical sutures. Orthopedic applications as well as the use for controlled-release systems for pharmaceuticals are also under investigation. The demand for these materials is extremely high with respect to toxicity and immunogenic, allergic and thrombogenic reactions. Furthermore, the polymeric materials should be sterilizable and have suitable mechanical properties.[7] Polylactides are amongst the most important biodegradable polymers. Due to the fact that the anionic polymerization initiator remains in the polymeric material, organometallic compounds based on calcium are the ideal starting materials for ring-opening polymerization.

For the purpose of investigating organocalcium compounds with respect to ring-opening polymerization we have chosen heteroleptic β-diketonates of calcium with reactive bis(trimethylsilyl)amide ligands. Homoleptic calcium

bis(tetramethylheptane-3,5-dionate) was prepared from calcium diethoxide and tetramethylheptane-3,5-dione (Htmhd) and crystallized as a dimeric bis(ethanol) complex or as a solvent-free trimer.[8] This trimer was monomerized by addition of strong mono- or bidentate N-donors.[9]

Results and Discussion

Synthesis

Until now the synthesis of β-diketonato complexes of calcium started from the alkoxides. However, the soluble and readily accessible {by transmetalation of $Sn[N(SiMe_3)_2]_2$} bis(tetrahydrofuran)calcium bis[bis(trimethylsilyl)-amide][10,11] is a more reactive metalation reagent. The equimolar reaction of $Ca[N(SiMe_3)_2]_2$ with Htmhd in tetrahydrofuran yielded the liquid, mononuclear complex tris-(tetrahydrofuran)(2,2,6,6-tetramethylheptane-3,5-dionato)-calcium bis(trimethylsilyl)amide (**1**) according to Equation (1) with a surprisingly low melting point of 4 °C. The prolonged exposure of this complex to vacuum gave a brown and nearly insoluble oil. The metalation of Htmhd with $[Ca\{N(SiMe_3)_2\}_2(THF)_2]$ in a stoichiometric ratio of 3:2 in toluene gave binuclear bis[(tetrahydrofuran)calcium]-tris(2,2,6,6-tetramethylheptane-3,5-dionato)bis(trimethylsilyl)amide (**2**) according to Equation (2) in good yield. This complex reacts in THF with alcohols such as methanol, ethanol and 2-propanol by substitution of the amide ligand by an alkoxide anion. However, recrystallization from toluene gave the homoleptic dismutation product $[Ca(tmhd)_2]_3$ and a mixture of alkoxide-rich complexes of yet unknown composition. However, the structure of **2** was maintained upon alcoholysis with sterically demanding alcohols such as 2,6-di(*tert*-butyl)phenol and 1-phenylethanol, and compounds of the type $[(THF)Ca]_2(tmhd)_3OR$ were isolated.

(2) **2**

The different coordination spheres of the nitrogen atoms of the bis(trimethylsilyl)amido ligands is clearly shown by the $^{29}Si\{^1H\}$ NMR chemical shifts.[12] For **1** the $N(SiMe_3)_2$ substituent with a triply coordinated nitrogen atom shows a chemical shift of $\delta = -15.9$ ppm which is a characteristic value for a terminally bonded amido group. The low-field shifted $^{29}Si\{^1H\}$ NMR resonance of **2** at $\delta = -8.0$ ppm proves the bridging position of the bis(trimethylsilyl)amido ligand. Similar characteristic shifts have been found for the calcium bis[bis(trimethylsilyl)amides].[12]

In order to investigate the reactive coordination sites of the calcium-containing complexes the molecular structures of **1** and **2** were determined (see below). We have already shown that **2** shows catalytic activity in anionic ring opening polymerization of cyclic esters.[13]

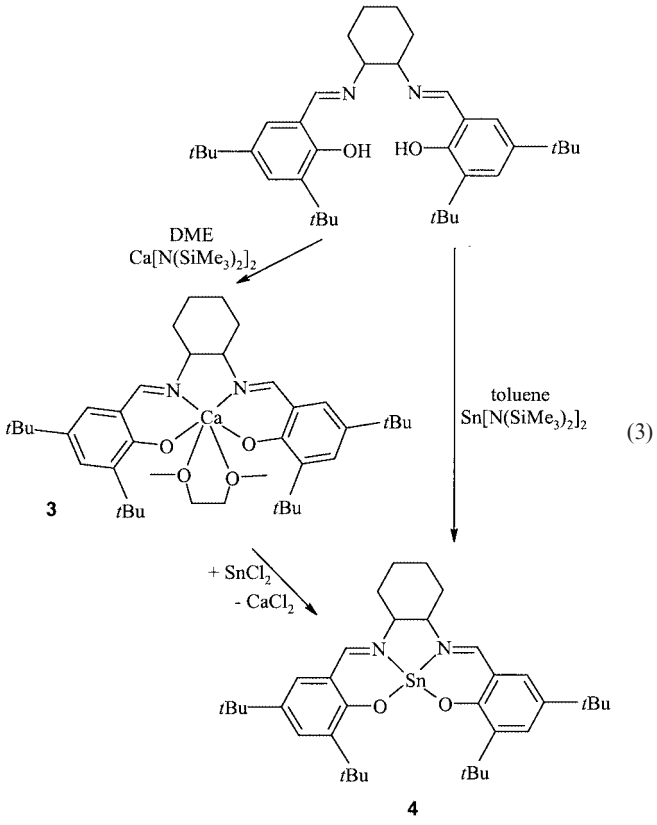
Another possibility to enhance the reactivity of organocalcium compounds is to embed the calcium center in an unusual coordination sphere. Vacant coordination sites at the Lewis-acid metal center lead immediately to coordination of Lewis bases such as ethers or to a dimerization of the calcium-containing compound. Therefore, the unusual coordination sphere has to be fixed by employing a multidentate ligand which shows very restricted flexibility and enforces a non-octahedral coordination sphere of the calcium atom.

In order to investigate the coordination sphere the Jacobsen ligand[14] was chosen due to its nearly square-planar tetradentate N_2O_2 coordination site and its dianionic charge to ensure a stable complex with *tert*-butyl groups at the periphery to ensure solubility in common organic solvents such as ethers. The metalation of the Jacobsen reagent with calcium bis[bis(trimethylsilyl)amide] in 1,2-dimethoxyethane (DME) yielded (1,2-dimethoxyethane-*O*,*O*′)calcium (*R*,*R*)-(−)-*N*,*N*′-bis[3,5-di(*tert*-butyl)salicylate]-1,2-cyclohexenediimine (**3**) according to Equation (3).

In order to investigate the suitability of the calcium complex **3** for metathesis reactions a well-known tin(II) complex was prepared. Compound **3** was reacted with tin dichloride to give nearly quantitatively the corresponding yellow tin(II) (*R*,*R*)-(−)-*N*,*N*′-bis[3,5-di(*tert*-butyl)salicylate]-1,2-cyclohexenediimine (**4**) according to Equation (3). The $^{119}Sn\{^1H\}$ NMR chemical shift of $\delta = -536.0$ ppm is similar to the published value ($\delta = -524.5$ ppm[15]). This compound was prepared earlier by metalation of the Jacobsen reagent with $Sn[N(SiMe_3)_2]_2$, however, only the oxidation product with 3,5-di(*tert*-butyl)-1,2-benzoquinone[15] and the addition products to metal carbonyl fragments[16] were characterized by X-ray crystallography. The metal centers of organometallic tin(II) compounds usually display coordination numbers of two and three. Monomeric molecules such as $Sn[N(SiMe_3)_2]_2$ are bent due to the lone pair at the metal center.[17] The dimeric molecules can either form a tin-tin bond in a trans-bent fashion, as for example observed for $[Sn\{CH(SiMe_3)_2\}_2]_2$,[18] or can exhibit a Sn_2X_2 cycle, as for example in $[RSn(\mu\text{-}Cl)_2SnR][R = N(SiMe_3)_2, N(CMe_2CH_2)_2CH_2]$.[19] In all compounds with a triply coordinated tin(II) atom the metal atoms show a strongly pyramidal coordination sphere because stannanediyls of the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

type SnR_2 are Lewis acids as well as Lewis bases.[20] Due to the geometry of the Jacobsen ligand the formation of a distorted tetragonal pyramid has to be expected, as found for a similar complex.[21] The molecular structure of **4** was determined by X-ray crystallography.



Molecular Structures

Due to their low melting point single crystals of **1** have to be handled at temperatures below −20 °C during isolation from the mother liquor and mounting on the diffractometer. The molecular structure of **1** and the numbering scheme is represented in Figure 1. Selected structural parameters are summarized in Table 1. The calcium center is in a distorted octahedral environment with a meridional arrangement of the three anionic donors.

The Ca−O distances of the anionic diketonate ligand are approximately 12 pm smaller than those of the THF molecules. The Ca−N bond length of 237.7 pm is rather large in comparison to Ca−N bonds of terminally bonded bis(trimethylsilyl)amido substituents in $[Ca\{N(SiMe_3)_2\}_2(THF)_2]$ (230 pm[11]) and $[Ca\{N(SiMe_3)_2\}_2(DME)]$ (227 pm[22]).

The distortion of the octahedral coordination sphere of the calcium atom is caused by the bite of the β-diketonate ligand, with an O1···O2 distance of 278.8 pm, which gives an O1−Ca1−O2 angle of only 74.2°. The anionic charge is delocalized within the planar diketonate fragment. Therefore, average C−O and C−C bond lengths of 128 and 139 pm, respectively, are observed.

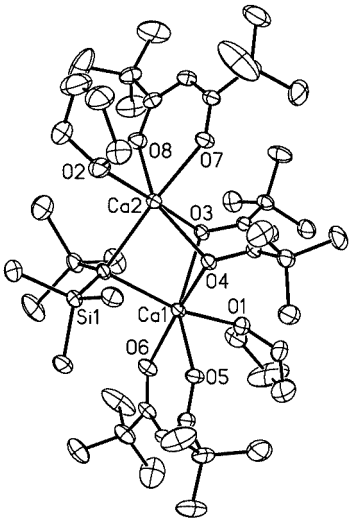

Figure 2. Molecular structure of **2**; the ellipsoids represent a probability of 40%; the hydrogen atoms are omitted for clarity; selected bond lengths (pm): Ca1−N 246.5(2), Ca1−O1 243.7(2), Ca1−O3 248.1(2), Ca1−O4 243.7(2), Ca1−O5 226.4(2), Ca1−O6 229.2(2), Ca2−N 251.2(2), Ca2−O2 241.8(2), Ca2−O3 244.8(2), Ca2−O4 239.7(2), Ca2−O7 231.5(2), Ca2−O8 225.9(2), Ca1···Ca2 337.46(7)

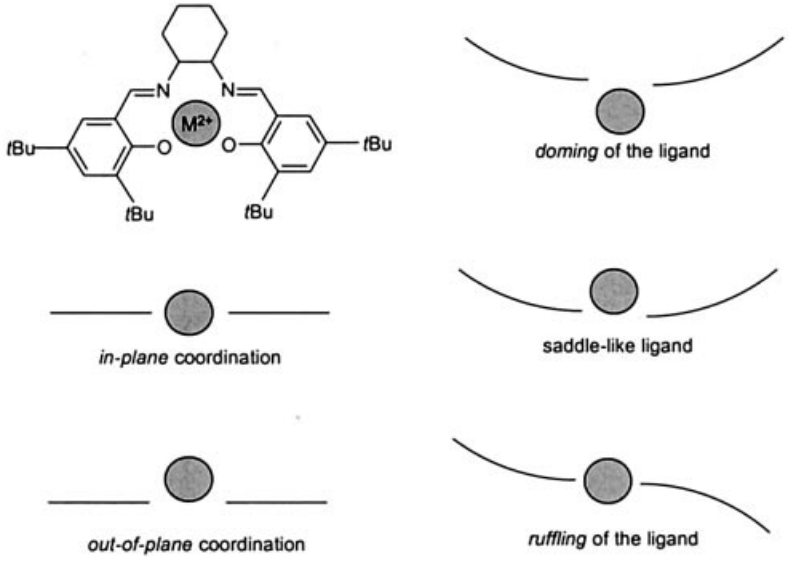
leads to coordination numbers of four for the nitrogen atom and three for the bridging oxygen atoms O3 and O4.

The Ca−N bonds, with an average length of 249 pm, are extraordinarily long. Likewise, the bridging Ca−O bonds have an average length of 244 pm, which is even slightly larger than the distance between the metal centers and the THF molecules. The terminally bonded β-diketonate ligands display much shorter Ca−O bonds, with an average value of 228 pm. These Ca−O distances are the smallest due to the electrostatic attraction and the small coordination numbers of the oxygen atoms. The N−Si distances, with a mean value of 172 pm, are in the expected region found for other calcium bis[bis(trimethylsilyl)amides] and do not support an ionic picture where extremely short N−Si bonds are to be expected, as, for example, for barium bis[bis(trimethylsilyl)amide].[12]

For multidentate ligands with a fixed arrangement of the Lewis donors several possibilities of coordination behaviour are possible (Scheme 1). Depending on the ratio of the radii of the metal atoms and the coordination gap an in-plane or out-of-plane coordination is realized. Furthermore, doming of the ligand is often observed, with the metal atom on the outside, or a saddle-like arrangement, with the metal on the inside of the ligand. Sometimes a twisting or ruffling of the multidentate base is also observed. To enhance the reactivity, a doming of the ligand with the metal center bonded from the outside is necessary.

The Jacobsen ligand retains its stereochemical centers and therefore centrosymmetric space groups have been excluded during the structure determination and refinement procedures of the calcium complex **3**. The geometry of the unit cell and the reflection conditions lead to the acentric orthorhombic space group $P2_12_12_1$. Surprisingly, other authors have found centrosymmetric space groups for solid-state structures of complexes of the Jacobsen ligand with divalent metals such as zinc,[23] even though the synthesis was performed with a stereochemically pure starting material.

The molecular structure of the calcium compound **3** with the Jacobsen ligand is shown in Figure 3. Here also the alkaline-earth metal center displays a coordination number of six, although the calcium atom is in an unusual distorted trigonal prismatic environment. The Ca−O distances of 219 pm to the alkoxide groups are extremely small due to the anionic charge, whereas in **2** the anionic charge on the oxygen atoms is reduced because it is delocalized within the β-diketonate fragment. In Figure 3 the doming of the Jacobsen ligand can clearly be seen.



Scheme 1. Coordination behaviour of potentially multidentate ligands with reference to the flexibility of compounds **3** (M^{2+} = Ca·DME) and **4** (M^{2+} = Sn)

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

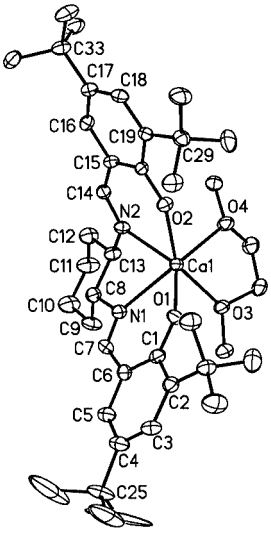


Figure 3. Molecular structure of **3**; the ellipsoids show a probability of 40%; the hydrogen atoms are omitted for clarity

The square-planar fragment is slightly distorted, as can be seen from the widening of the O1−Ca1−O2 angle (104.5°), whereas the other (endocyclic) angles are much smaller (O1−Ca1−N1 75.8°, N1−Ca1−N2 67.6°, N2−Ca1−O2 74.8°). However, the smallest angle is observed to the bidentate DME ligand. The calcium atom is larger than the O_2N_2 gap, and therefore it is located above the plane containing O1, O2, N1, and N2. Furthermore, the Jacobsen ligand is not planar but arched. Nevertheless, the nitrogen atoms are coordinated in a trigonal planar manner by two carbon atoms and the alkaline earth metal dication. The Ca1−O1−C1 and Ca1−O2−C20 fragments are bent (average 142.2°). The cyclohexane backbone shows the favoured chair conformation with a slightly elongated C8−C13 bond (154.3 pm) compared to the other C−C bonds of the cyclohexane moiety (average value of 152 pm).

The distances between the calcium center and the oxygen atoms of the DME molecule are approximately 25 pm longer than those to the alkoxide anions. In solution exchange reactions with solvent molecules are observed. Dissolving **3** in tetrahydrofuran immediately leads to the THF adduct, which can be isolated as a powder after standard workup procedures. Another coordination sphere of this molecule which contains monodentate Lewis bases has to expected. Atwood and co-workers[24] found a heptacoordinate calcium center for [Ca(*t*Bu-salen)(HOEt)$(THF)_2$] with a distorted pentagonal bipyramidal coordination. The use of a bidentate ligand is necessary to enforce the trigonal prismatic environment of the alkaline-earth metal atom. This easily exchangeable DME molecule offers the possibility of creating a coordination vacancy for the initial step of the polymerization reaction namely the coordination of the cyclic ester such as lactide or ε-caprolactone. Detailed studies of the polymerization process are under investigation and will be published elsewhere.

Compound **4** (M.p. 291−293 °C) crystallizes in the acentric orthorhombic space group $P2_12_12_1$ with two crystallographically independent molecules which are distinguished by the letters A and B. The molecular structure of molecule A is shown in Figure 4. Both the molecules show nearly identical structural parameters. Therefore, the discussion of this structure is limited to molecule A; however, in Table 1 selected bond lengths and angles of both molecules are listed together with the data of the calcium complex **3**.

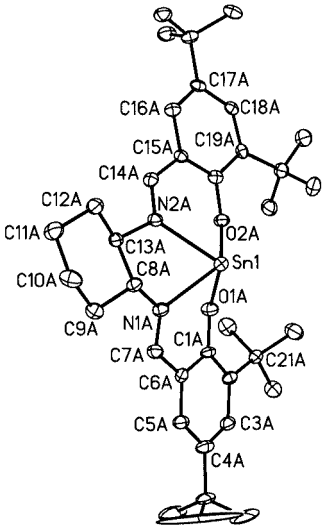

Figure 4. Molecular structure of **4**; the ellipsoids show a probability of 40%; the hydrogen atoms are omitted for clarity

The tin atom is bonded above the N_2O_2 plane with Sn−O bond lengths of 209.6 and 211.9 pm which are larger than in tin(II) bis[2,6-di(*tert*-butyl)phenolate] (200.3 and 204.4 pm[25]) and tin(II) bis[2,6-di(*tert*-butyl)-4-methylphenolate] (200.8 pm[26]). In dimeric Sn(O*t*Bu)$_2$, with a central Sn_2O_2 ring, endocyclic and exocyclic Sn−O bonds of 214.7 (average) and 200.9 pm, respectively, were found.[27] The Sn−N distances are coordinative bonds with large values of 235.0 and 236.1 pm. The Sn−O−C angles display an average value of 127°. The oxidation of tin(II) to tin(IV) leads to a drastic contraction of the bonding parameters, even though the enhancement of the coordination number to six is realized in an octahedral environment of the tin(IV) atom.[15] Also, the Sn−N bonds show a smaller average length of 218.3 pm, with the Sn−O bonds having average values of 201.8 pm. The Jacobsen ligands of **2** and **3** display nearly the same orientation and structural features. This observation shows that an inflexible ligand can enforce unusual coordination spheres at the metal atoms, namely a trigonal prism for the calcium center and the tin(II) atom being the apex of a distorted square pyramid.

Perspective

The catalytic reactivity of **2** was tested towards the polymerization of lactide and ε-caprolactone in THF solution. A fast gel formation as a sign of polymerization was observed. The polymeric materials show high molecular weights of approximately 1.67×10^5 g·mol^{-1} and a broad mass distribution. The substitution of the bis(trimethylsilyl)-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

amide by an alkoxide substituent, or the polymerization in the presence of an alcohol, leads to a living polymerization. The preparative details of the ring-opening polymerization and the concept that labile anionic ligands support the catalytic activity of this polymerization reaction will be presented in detail elsewhere. The preformed coordination gap by enforcing a trigonal prismatic coordination sphere at the calcium atom as realized in **3** is also a promising working hypothesis. Usually an octahedral environment of the alkaline earth metal atoms is preferred, and therefore the 1,2-dimethoxyethane ligand is immediately substituted by monodentate ligands, which is the first step in the polymerization process. On the other hand, the liquid complex **1** also loses neutral coligands very easily at room temperature during handling under an inert gas atmosphere or in hydrocarbons; a brown, nearly insoluble oil forms which separates from solution. Therefore, it is not recommended to use this calcium compound as an initiator or catalyst for the anionic polymerization of lactones and lactides. In a short communication Chisholm[28] has reported calcium compounds with four-coordinate calcium centers which can be used as catalysts for the ring-opening polymerization of lactides.

The advantage of the catalytically active complexes **2** and **3** in comparison to the already investigated calcium bis[bis(trimethylsilyl)amide][6,29] lies in the reduced sensitivity towards air and moisture and, therefore, an easier handling outside of a glove box seems to be possible during the polymerization experiments. Preliminary experiments support the expectation that these compounds are valuable initiators for the anionic polymerization of lactones and other cyclic ester.

Experimental Section

General Remarks: All experiments and manipulations were carried out under an atmosphere of argon. Reactions were performed using standard Schlenk techniques and dried, thoroughly deoxygenated solvents. Calcium bis[bis(trimethylsilyl)amide] was prepared according to a literature procedure.[10,11] NMR spectra were recorded on Jeol spectrometers GSX270 and EX400. A Nicolet 520 FT-IR spectrophotometer was used to record the IR spectra; solid substances were measured in nujol between KBr plates (vs very strong, s strong, m medium strong, w weak, vw very weak, sh shoulder).

Tris(tetrahydrofuran)(2,2,6,6-tetramethylheptane-3,5-dionato)-calcium Bis(trimethylsilyl)amide (1): A solution of [Ca{N-$(SiMe_3)_2$}$_2$$(THF)_2$] (2.40 g, 4.76 mmol) in 20 mL of THF was cooled to 0 °C. Then 2,2,6,6-tetramethylheptane-dione (0.99 mL, 4.76 mmol) was added. After stirring for an additional hour the solution was warmed to room temperature and the volume reduced to a few milliliters. After cooling to approximately −20 °C 1.74 g of colorless crystals of **1** (yield 66%) were collected. M.p. 4 °C. ^{1}H NMR ([D$_6$]benzene/THF mixture): δ = 0.19 ($SiMe_3$), 1.13 (*t*Bu), 5.68 (CH), 1.51 and 3.57 (THF) ppm. ^{13}C{^{1}H} NMR ([D$_6$]benzene/THF mixture): δ = 5.42 ($SiMe_3$), 28.46 (C*Me*$_3$), 40.69 (*C*Me$_3$), 89.00 (CH), 199.29 (CO), 25.40 and 67.65 (THF) ppm. ^{29}Si{^{1}H} NMR ([D$_6$]benzene/THF mixture): δ = −15.9 (NSi_2) ppm. IR: $\tilde{\nu}$ = 1693 m, 1660 s, 1562 w, 1538 m, 1505 s, 1480 w, 1450 w, 1417 s, 1390 m, 1360 m, 1250 m, 1224 w, 1183 w, 1131 w, 956 w, 932 m, 881 w, 867 m, 841 m, 794 w, 479 w, 403 w. $C_{25}H_{45}CaNO_4Si_2$ (527.95) [bis(THF) complex due to loss of THF during handling and combustion]: calcd. C 57.76, H 8.72, N 2.69; found C 57.48, H 8.71, N 2.69.

Bis[(tetrahydrofuran)calcium] Tris(2,2,6,6-tetramethylheptane-3,5-dionate) Bis(trimethylsilyl)amide (2): A solution of [Ca{N$(SiMe_3)_2$}$_2$$(THF)_2$] (4.41 g, 8.74 mmol) in 50 mL of toluene was cooled to 0 °C and then 2,2,6,6-tetramethylheptane-3,5-dione (1.82 mL, 8.74 mmol) was added. After warming to room temperature the solution was stirred for an additional 12 hours. All volatile materials were removed under vacuum and the residue redissolved in 50 mL of *n*-pentane. The remaining solid materials were removed and the volume of the solution reduced to 10 mL. At −30 °C 3.25 g of colorless crystals of **2** (yield 80%) precipitated. Dec. 74 °C (without melting). ^{1}H NMR ([D$_6$]benzene): δ = 0.53 ($SiMe_3$), 1.26 (*t*Bu), 5.89 (CH), 1.37 and 3.63 (THF) ppm. ^{13}C{^{1}H} NMR ([D$_6$]benzene): δ = 5.12 ($SiMe_3$), 28.63 (C*Me*$_3$), 41.11 (*C*Me$_3$), 91.24 (CH), 200.84 (CO), 28.63 and 68.09 (THF) ppm. ^{29}Si{^{1}H} NMR ([D$_6$]benzene): δ = −8.0 (NSi_2) ppm. IR: $\tilde{\nu}$ = 1693 m, 1660 s, 1562 w, 1537 m, 1505 s, 1450 w, 1419 s, 1390 m, 1360 m, 1249 w, 1224 w, 1183 w, 1131 w, 933 m, 867 m, 843 w, 793 w, 479 w. $C_{47}H_{91}Ca_2NO_8Si_2$ (934.57): calcd. C 60.40, H 9.80, N 1.50; found C 60.38, H 9.81, N 1.41.

(1,2-Dimethoxyethane-*O*,*O*′)calcium (*R*,*R*)-(−)-*N*,*N*′-bis[3,5-di(*tert*-butyl)salicylate]-1,2-cyclohexenediimine (3): A solution of Htmhd (1.08 g, 1.98 mmol) in 10 mL of toluene was added to a solution of (1,2-dimethoxyethane-*O*,*O*′)calcium bis[bis(trimethylsilyl)amide] (1.07 g, 1.98 mmol) in 10 mL of toluene. The yellow solution was stirred for one day at room temperature and then all volatile materials were removed under vacuum. The yellow residue was redissolved in a few milliliters of toluene. At 5 °C 0.82 g of yellow plates of **3** (1.2 mmol, 61%) precipitated. X-ray Structure Determinations of 1−4: Data were collected on a Siemens P4 diffractometer with a Siemens SMART-CCD area detector using oil-coated rapidly cooled single crystals.[30,31] Graphite monochromated Mo-K_α radiation (λ = 71.073 pm) was used. Crystallographic parameters, details of data collection and refinement procedures are summarized in Table 2. The structures were solved by direct methods and refined with the software packages SHELXL-93 and SHELXL-97.[33] Neutral scattering factors were taken from Cromer and Mann[34] and for the hydrogen atoms from Stewart et al.[35] The non-hydrogen atoms were refined anisotropically. The H-atoms were considered with a riding model under restriction of ideal symmetry at the corresponding carbon atoms or refined isotropically. Crystallographic details can be obtained from the Cambridge Crystallographic Data Centre quoting the CCDC numbers given in Table 2.[36] One of the *tert*-butyl groups of **3** and **4** shows a rotatory disordering which was not resolved by split-positions of the corresponding atoms because neither the *R*

Polar Molecular Precursors for Alkali and Alkaline Earth Metal Clusters and Low-Dimensional Polymer Structures: the Solid-State Structures of $[CaI(dme)_3]I$, and *cis*-$[SrI_2(diglyme)_2]$ (dme = $CH_3OC_2H_4OCH_3$; diglyme = $CH_3(OC_2H_4)_2OCH_3$)

Katharina M. Fromm*[a] and William Maudez[a]

Keywords: Alkaline earth metals / Calcium / Halides / Polar compounds / Strontium

Two new alkaline earth metal halide adducts with oxygen-donor polyether ligands are described. One of them, *cis*-$[SrI_2(diglyme)_2]$, features two terminally bonded anions in vicinal positions, and at an angle of ca. 90°. The low bond valence sum of ca. 1.9 indicates how well the cation is shielded by its ligands in the solid state, and that ligand exchange can be expected in solution and upon reaction. The second compound, $[CaI(dme)_3]I$, consists of an ion pair formed by the cationic complex $[CaI(dme)_3]^+$ with one anion in terminal position, and one iodide. Both compounds possess a strong dipole moment at the molecular level, but crystallize in centrosymmetric space groups.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

We are interested in molecular compounds, especially oxygen donor adducts of alkaline earth metal iodides, because they are used as starting materials in the synthesis of low-dimensional polymeric compounds, including clusters.[1−10] The latter are used in the low-cost synthesis of superconductors and other oxide materials by the sol-gel technique, or as volatile precursors in CVD processes.[2,10] Furthermore, alkaline earth metal iodides complexed with polyether ligands have also been shown to have a dramatic effect on the dealkylation reactions of phosphinic esters.[11] We have also started to investigate the synthesis of polar materials for possible applications in NLO, for instance second harmonic generation. We became interested in these compounds because we wished to understand how they were formed and discover whether polar molecules can be forced to crystallize in polar space groups.

Compounds that have so far been isolated in the class of molecular species are, for instance, the zero-dimensional compounds *trans*-$[CaI_2(THF)_4]$[12] or *trans*-$[MI_2(THF)_5]$ (M = Sr,[13] Ba[1]), in which the metal cation is always surrounded in a linear or quasi-linear fashion by the two anions, whereas the THF ligands are found in the equatorial positions of a square or pentagonal bipyramid. They are commonly used as starting materials for substitution reactions of at least one iodide. Other compounds can also be molecular, but without any direct M−I contacts left to be reactive. Instead, the halide ions are replaced in the first coordination sphere by neutral water or polyether oxygen donor ligands for instance, leading to compounds such as $[Ba(OH_2)(triglyme)_2]I_2$ [triglyme = $CH_3(OC_2H_4)_3OCH_3$],[7] in which the anions are linked to the cationic complex by hydrogen bonding to the protons of the water molecules remaining in a second coordination sphere.

We now present some new exceptional molecular compounds that possess either two M−I bonds in *cis*-positions or only one M−I bond, leading in both cases to polar molecular precursors of alkaline earth metal iodides.

Results and Discussion

When SrI_2 is dissolved and re-crystallised from freshly dried and distilled diglyme ($CH_3OC_2H_4OC_2H_4OCH_3$), only the compound *cis*-$[SrI_2(diglyme)_2]$ (**1**) is obtained. Compound **1** crystallises in the monoclinic space group $P2_1/c$ with two independent molecules A and B per asymmetric unit (Figure 1).[14] Both molecules consist of a strontium cation to which two diglyme ligands and two anions are directly linked, with Sr−I distances between 3.314(3) and 3.335(3) Å, the shorter bonds being found in the first molecule A with Sr1. They are 0.11 Å longer than the Sr−I bonds in other molecular strontium iodide adducts, firstly due to the higher coordination number in **1** (eight instead of seven), and secondly due to the intra-ionic repulsion between the iodides in the *cis*-positions.[10,13] On the other hand, they are shorter than the bonds in compounds where iodide plays the role of a μ-bridging ligand between two strontium cations.[10] The I1−Sr1−I2 angle is, at 91.26(9)°, slightly smaller than that in the second molecule,

I3−Sr2−I4 [91.78(9)°]. In addition to the anions, each alkaline earth metal cation is surrounded by two diglyme ligands, their oxygen atoms coordinating to the strontium ion with distances ranging between 2.614(7) and 2.731(8) Å. This results in a severely distorted square antiprismatic coordination sphere around the cation in each molecule. In molecule A, the bite angles of the diglyme ligand are 58.6(7)° and 60.8(7)° for the first, and 58.8(6)° and 60.6(6)° for the second ligand. In molecule B, the corresponding values are 61.1(7)°, 60.3(7)°, 60.7(6)° and 59.2(6)°, slightly larger than in molecule A. The O−Sr−O angles closest to linear are O1−Sr1−O6 [166.9(7)°] and O9−Sr2−O12 [165.6(7)°]. The other angles between the two diglyme ligands of each molecule are 74.3(6)° and 74.3(7)° for O1−Sr1−O4 and O3−Sr1−O6, respectively, and 80.9(3)° for O3−Sr1−O4 in molecule A, and 74.1(7)°, 74.3(7)° and 81.2(7)° for O9−Sr2−O10, O7−Sr2−O12 and O7−Sr2−O10, respectively, in molecule B. The C−O and C−C bonds are normal at 1.42 and 1.55 Å, respectively, on average, but with the general tendency of being slightly longer in molecule B than in molecule A. The molecules A and B can be considered as isolated as there aren't any close contacts between, for instance, the iodide of one molecule and hydrogen atoms of a neighbouring unit (>3 Å). Only one intramolecular H-bond can be found in molecule B, with a I3−H24B distance of 2.958(6) Å. There are no contacts between the iodides of one unit and the strontium cations of another, as the cation is completely protected by the organic ligands and its own anions. Thus, the shortest distance between the anions of one molecule and the cation of another is greater than 6 Å. Although there is some similarity between the two molecules A and B of **1**, no correlation matrix was found linking the two in order to indicate a higher symmetry. Furthermore, careful analysis of the X-ray data gave no hints for the presence of a higher symmetry. The relatively high *R* value is due to slight disorder in the polyether ligands as well as — and more importantly — to strong absorption effects, which could unfortunately not be corrected. This is not unusual for structures containing heavy elements such as iodine, and residual electron density as high as three electrons close to the anions in **1** has also been reported in other structures.[1]

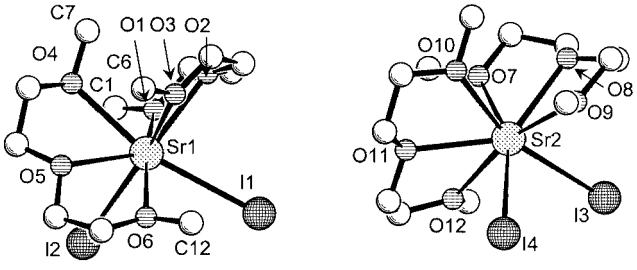

Figure 1. Two independent molecules of **1**; H atoms not shown

The coordination number of eight for the strontium cation is common. Generally, the strontium cation usually behaves more like barium than calcium as far as coordination numbers are concerned. Examples are found with a coordination number of seven in the compounds *trans*-$[MI_2(THF)_5]$ (M = Sr, Ba) whereas the corresponding calcium compound possesses a coordination number of six in *trans*-$[CaI_2(THF)_4]$, or for coordination number five as in $[IM(OtBu)_4(Li\{thf\})_4(OH)]$ for M = Sr and Ba, whereas the corresponding Ca compound has not been reported.[6,10] Barium compounds with sterically similar polyether ligands exist, and they all show a coordination number of nine for the alkaline earth metal cation, the corresponding bond valence sums being greater than two to satisfy the charge requirements.[7] In **1**, however, we observe a coordination number of eight for the strontium cation, and, more importantly, a bond valence sum of 1.95 and 1.91 for Sr1 and Sr2, respectively, which is obviously less than two.[15] This means that the cation is not sufficiently coordinated and would therefore be an excellent starting material for further synthesis, as it would tend to complete its coordination sphere by exchanging ligands for instance. However, the space-filling model of molecule A (Figure 2) shows how well the cation is shielded by its ligands, explaining why the bond valence sum remains below two.

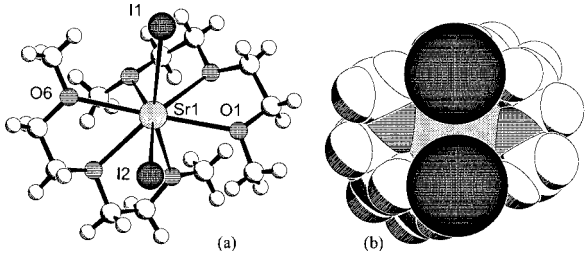

Figure 2. Molecule A of **1**: Sr1 and its coordination sphere as ball-and-stick model (a) and as space-filling representation (b)

The most intriguing fact about this structure is the fact that both anions occupy vicinal positions. This has never been observed before in a molecular species of the heavier alkaline earth metal halides, but only in two- or three-dimensional compounds with H-bonding involved,[5,7,16] or forming polymers or dimers with other anions of the neighbouring units.[1,17,18] For small alkaline earth metal cations, like Mg, with a coordination number of four, two anions are automatically in the vicinal positions, although with a larger angle between the anions than in **1**.[19] In general, to obtain such structures with the anions in *cis*-positions a sterically important ligand, which shields one side of the cation, such as slightly too small crown ethers, is required.[16] In these cases the X−M−X angles are usually much larger, the M−X bonds are longer than in **1**, and the anions are involved in H-bonding to build up a polymeric structure. Compound **1** is therefore the first example of a polar molecular alkaline earth metal iodide precursor. The strongly bent I−Sr−I feature in this structure is reminiscent of the alkaline earth metal halides, especially the heavier ones with strontium, barium and iodide as counterions, in the gas phase. Indeed, experimental as well as theoretical data show bent structures for the molecules in the gas

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

phase.[20] So, **1** could be compared to a gas phase species stabilised by oxygen donor ligands. The bent structure is also reminiscent of the cyclopentadienyl derivatives of the alkaline earth metals. They have bent structures as well, although in the solid state they form polymers via contacts to neighbouring units. The THF-solvated cyclopentadienyl species are more similar to **1**.[21] More generally, other neutral complexes of alkaline earth metal cations, with coordination numbers greater than or equal to six, where two anions, such as halides or bulky amides for instance, are directly linked to the cation, preferentially show the anions organised in *trans*-positions. If the anions and further coordinating ligands are sterically more demanding, a distortion from the quasi-linear arrangement is observed, although it never reaches as small angles between the anions as in **1**.[17−19,22] Unfortunately, the polarity of the molecules of **1** is not maintained in the overall solid state as the compound crystallizes in a centrosymmetric space group.

The second compound presented here, $[CaI(dme)_3]I$ (**2**), was obtained by crystallizing CaI_2 from freshly dried and distilled DME.[14] It is built up from two independent cationic molecules A and B per asymmetric unit, each consisting of a calcium cation, Ca1 and Ca2, to which one iodide and three DME ligands are bonded terminally via both oxygen atoms, with two separate iodides as counterions (Figure 3). Thus, the cation reaches a coordination number of seven, that is, between six and eight, which are the most common coordination numbers for the calcium atom in general. The coordination geometry can roughly be described as a distorted pentagonal bipyramid with one iodide and an oxygen atom in axial positions. The corresponding I−Ca−O angle is, however, far from linear with an average value of 155°. This is due to the bite angles of the DME ligands, which vary from 63.7(4)° to 68.8(3)°. Of the five oxygen atoms in equatorial positions, one is clearly more out of the mean plane (formed by Ca and the five oxygen atoms) than the other four oxygen atoms, as has been described for a calcium compound with a similar coordination sphere.[9,23] The Ca−O bonds vary between 2.375(11) and 2.496(11) Å, the shorter bonds on average being found in molecule A around Ca1. The Ca−I bond is 3.120(3) Å and 3.121(3) Å for Ca1 and Ca2, respectively. This gives a cationic species for each molecule, the counterions I2 and I4 not being bonded at all to the cationic unit since all further Ca−I contacts are larger than 5.8 Å. In fact, there are no H−I contacts to I2 and I4 of less than 3.7 Å. Therefore, these anions can be considered as independent and not H-bonded to the cationic units. A similar compound can be obtained by replacing the three DME ligands of **2** by two, larger diglyme molecules. The number of oxygen atoms then remains identical, and so does their arrangement around the cation. The compound which is then obtained can be written as $[CaI(diglyme)_2]I$.[24] Unfortunately, crystals of both polar compounds are difficult to grow, as mentioned by Rogers et al.,[25] and the single crystal data is not yet of sufficient quality for publication. However, we have shown before that small polyether molecules (such as DME) can easily be replaced by larger ones (diglyme or triglyme for instance), as long as the number of oxygen atoms remains constant, without changes in the structure except for higher symmetries.[7]

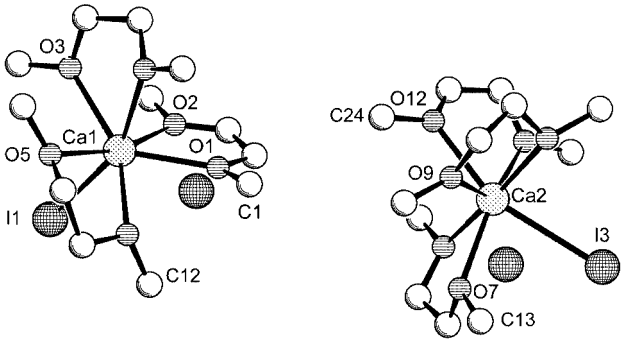

Figure 3. Two independent molecules of **2**; H atoms omitted for clarity

A heavier analogue to **2** with pseudo-halides is $[Sr(NO_3)(EO3)_2](NO_3)$ (EO3 = triethylene glycol)[25] where one anion is directly bonded to the cation whereas the other is weakly linked via H-bonds to an OH group of one of the polyglycols. In contrast to **2**, the H-bonding allows connections between anions and cationic units to form an overall threedimensional network. This is not observed in **2**.

The $[CaI(dme)_3]^+$ cations of **2** possess a strong dipole moment along the Ca−I bond vector, as can be seen from Figure 4. Such polar species are scarce: in the literature, only one example with calcium and iodide has been described so far to the best of our knowledge, $[CaI(THF)_5]^+$,[26] in which the cation possesses a coordination number of six, the counterion being an extremely bulky phosphonium diylide. The bond lengths in **2** are generally longer than in $[CaI(THF)_5]^+$, which is readily explained by the larger coordination number. In fact, the bond-valence sums for the calcium cations in **2** are, at 2.227 and 2.266, larger than the charge of the cation, indicating a more than satisfying bonding situation. The cation is indeed well wrapped up by its ligands, as shown in the space-filling model (Figure 4). Other polar compounds of alkaline earth metal cations linked to one halide and other neutral ligands can only be achieved when one coordination side of the cation is efficiently shielded by a sterically bulky ligand.[18,27] In some cases, formation of dimers occurs when

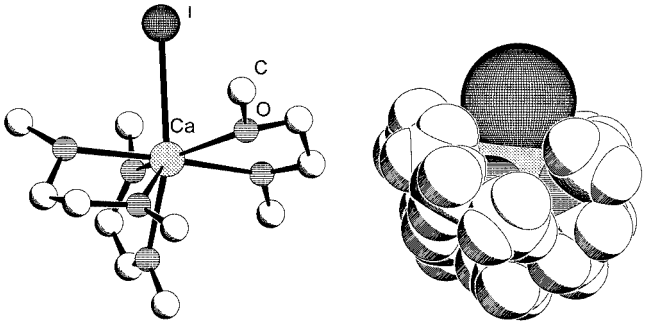

Figure 4. Cationic unit A $[CaI(dme)_3]^+$ of **2** and its space filling model

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coordination sites on the cation remain empty, in order to avoid single polar units,[28,29] whereas other complexes form infinite polymer structures via H-bonding of the neutral ligands toward both of the linked and free anions.[24,30]

Conclusions

We have synthesised two adducts of alkaline earth metal halides, one of which carries both anions connected to the cation in mutual *cis*-positions, and the other with only one iodide bound to the cation with the second anion showing no interaction with the cationic units. Both compounds possess a strong dipole moment at the molecular level, although this vanishes in the overall solid-state structure as both crystallize in centrosymmetric space groups. Both type of species are rare in the chemistry of the heavier alkaline earth metal halides, and could therefore be useful alternatives for precursors in new substitution reactions as have been described in the literature on *trans*-alkaline earth metal iodide adducts.[10,12,13,17] In all of the examples cited above, the polarity remains a local phenomenon, whereas the compounds crystallize in centrosymmetric space groups, so that the dipole moment vanishes in the solid state. We are now investigating the possibilities of crystallizing these compounds, **1** and **2**, in polar space groups, relying on the presence of polar ion pairs in solution.

Experimental Section

General: All experiments were carried out under an inert nitrogen atmosphere, using Schlenk techniques. The solvents DME and diglyme (diethylene glycol dimethyl ether) were dried over Na/benzophenone and distilled under nitrogen prior to use. IR spectra were carried out on a Perkin−Elmer Spectrum One IR spectrometer.

1: SrI_2 (0.174 g, 0.51 mmol) was dried for 30 min under vacuum at 300 °C and then dissolved in 30 mL of freshly dried and distilled diglyme, heating to reflux. The solution was filtered while hot and was then left to stand at room temperature. After two days, colourless single crystals grow in a yield of 78% with respect to SrI_2. $C_{24}H_{56}I_4O_{12}Sr_2$ (1219.6): calcd C 23.64, H 4.63; found C 25.97, H 5.27. The differences between found and calculated values are due to solvent, which remains on the crystals as they can't be dried under vacuum, and decompose rapidly if left in air. IR (nujol, CsI plates): $\tilde{\nu}$ = 2849 cm^{-1} (Nujol), 2077(w), 1971(w), 1939(w), 1605, 1459(Nujol), 1380(m), 1354(Nujol), 1286(m), 1269(w), 1249(vs), 1203(vs), 1129(s, sh), 944(m), 870(s), 839(s), 723(Nujol), 559(s), 489(w), 461(m), 367(w)

2: CaI_2 (0.24 g, 0.817 mmol) was dried under vacuum for half an hour at 300 °C, and then dissolved in 30 mL of freshly dried and distilled DME by heating to reflux for 15 minutes. The solution was filtered while hot, and colourless single crystals of **2** formed within one day at room temperature. Out of the mother liquor, crystals quickly lose solvent, as can be observed under the microscope, where they turn from clear colourless to opaque. The yield has therefore been estimated at 70% with reference to CaI_2. The lower evaporation temperature of DME compared to diglyme explains the values found for elemental analysis, where values are generally too low. $C_{24}H_{60}Ca_2I_4O_{12}$ (1128.5): calcd. C 25.54, H 5.36; found C 21.47, H 4.9. IR (nujol, CsI plates): $\tilde{\nu}$ = 863 cm^{-1} (Nujol), 2059(w), 1915(w), 1622(m), 1465(Nujol), 1374(Nujol), 1285(s), 1247(s), 1192(s), 1123(w, sh), 937(w), 859(vs), 721(Nujol), 569(m), 387(s)

Structural Diversity in Lewis-Base Complexes of Lithium Triflamide

Matthew G. Davidson,*[a] Paul R. Raithby,*[a] Andrew L. Johnson,[a] and Philip D. Bolton[a]

Dedicated to the memory of Dr Ron Snaith

Keywords: Lithium / Solid-state structures / Aggregation / Crystal engineering / Anions

Complexation of the salt lithium triflamide [$LiNTf_2$; NTf_2 = $N(SO_2CF_3)_2$], with a range of nitrogen donor ligands results in the formation of a series of coordination complexes [$(Tf_2N)Li{\cdot}N(H)PPh_2Me$] (**1**), [$(Tf_2N)Li{\cdot}N(H)PPh_3$] (**2**), [$(Tf_2N)Li{\cdot}TMEDA$] (**3**), [$(Tf_2N)Li{\cdot}PMDTEA$] (**4**) and [$(Bz\text{-}TAC)_2\text{-}Li][NTf_2$] (**5**). The molecular structures of **1**, **3**, **4** and **5** have been determined by single-crystal X-ray diffraction. The resulting solvated structures are discussed in terms of solvent-separated ion pairs, contact ion pairs and higher aggregates, with the degree of aggregation and ion contact being dependent on the relative coordinating abilities and steric demands of the donor ligand and the anion, and provide an insight into the possible structures of lithium aggregates present in complex systems such as polymer electrolytes and synthetic reaction media.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2003)

Introduction

The structural chemistry of organolithium compounds has attracted significant and sustained interest, primarily because of their extensive use as reagents in synthetic chemistry and the perceived close relationship between structure and reactivity.[1−6] Principles such as ring stacking and laddering[2,3] have been developed to explain the structural types of organolithiums that are found in the gas phase,[4] the solid state[5] and in solution.[6] Furthermore, these structures have been useful in accounting for the observed reactivity of even quite complex systems.[6] In contrast, the systematic study of simple inorganic lithium salts has attracted considerably less attention. The development of "in situ" synthetic routes (in particular the so-called "ammonium salt route")[7] has provided facile and high yielding methodologies for the controlled synthesis of hydrocarbon-soluble molecular complexes of inorganic lithium salts. However, these methodologies have yet to be fully exploited in terms of providing well-defined materials with specific reactivities and/or material properties.

Two areas of research that may benefit from systematic structural studies of inorganic lithium salts are polymer electrolytes[8] and Lewis acid-mediated organic synthesis.[1,9] Both of these areas utilise inorganic lithium salts containing weakly coordinating anions, such as $LiPF_6$, $LiClO_4$, $LiBF_4$ and $LiAsF_6$.

In order to understand more fully the role of these weakly coordinated lithium salts in complex environments (such as in homogeneous liquid-phase reactions or a coordinating polymer electrolyte) it is useful to investigate systems in the solid state in which we can more easily and unambiguously assign the coordination geometry about the lithium ion and extrapolate these studies to "real" systems.

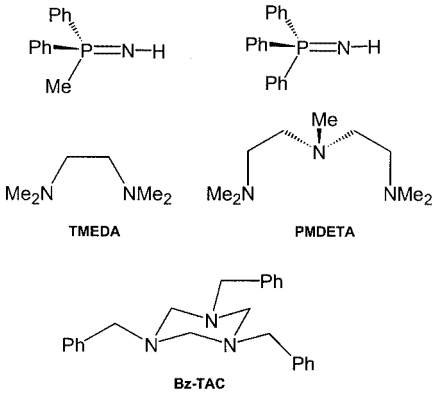
Of late, studies in these areas have begun to focus on salts that incorporate much more stable, larger and more weakly coordinating anions such as $CF_3SO_3^-$ (OTf^-, triflate), $[N(SO_2CF_3)_2]^-$ (NTf_2^-, triflamide), $[HC(SO_2CF_3)_2]^-$ and $[C(SO_2CF_3)_3]^-$, all of which show remarkable chemical and electrochemical stability, and provide alternatives to potentially dangerous salts such as $LiClO_4$.

In this context, we report herein a systematic study of the coordination chemistry of lithium triflamide. Although structural studies of the parent salt, $LiNTf_2$,[10] and its hydrate, $LiNTf_2{\cdot}H_2O$,[11] have been performed, this work represents the first systematic structural study of $LiNTf_2$ in the presence of a range of nitrogen-donor ligands, with the aim of investigating the extent and range of anion binding within these systems and their more general structural diversity.

Results and Discussion

In order to study the coordination chemistry between $LiNTf_2$ and donor ligand systems, and the extent of anion-cation contact in the presence of strongly competing donor ligands, we first chose specific donor ligands that could provide a varied number of coordination environments from

mono- to polydentate in order to mimic the possible coordination environments in systems such as conducting polymer electrolytes. The nitrogen-based ligands, selected on the basis of their synthetic utility and availability, are shown below.



All lithium complexes **1**−**5** were initially synthesised using the "ammonium-salt route",[7] in which ammonium triflamide, $[NH_4][NTf_2]$, and the ligand are combined in toluene and a stoichiometric amount of *n*-butyllithium is added. The ammonium triflamide was prepared by passing ammonia gas through a toluene solution of the parent acid, Tf_2NH (see Exp. Sect.).

In some scenarios, the "ammonium-salt route" is the only rigorous method of synthesis for complexes of lithium salts, e.g. halides.[7] However, direct methods, whereby solid salts are treated with the Lewis base (donor ligand), either neat or in hydrocarbon solution, can be applied to more soluble lithium salts, such as lithium triflamide. Both direct and in situ methods of lithium complex preparation were employed in our investigation in order to reveal any differences between the products formed by the two methods, i.e. stoichiometries, different ligand coordination modes, different polymorphs, etc.

Our investigation has shown that for the compounds discussed here, both methodologies (Scheme 1) are equally effective, and for comparable experiments, the products were found to be identical by multinuclear NMR spectroscopy, elemental analysis, melting point analysis and unit cell determination.

In solution, ^{1}H, ^{13}C, ^{19}F and ^{31}P NMR experiments performed on complexes **1**−**5** indicate that, in all cases, on the NMR timescale, the lithium ion appears to remain coordinated to the nitrogen donor ligand in solution, as indicated by the moderate change in ^{1}H and ^{13}C NMR chemical shift between free and ligated nitrogen-donor ligand. As with the closely related triflate anions $[OTf]^-$, ^{19}F NMR experiments on **1**−**5** provide little information about the coordination state of the triflamide anion, $[NTf_2]^-$, in the solution state.[12]

Compound **1** was found to have the empirical formula $[(Tf_2N)Li{\cdot}N(H)PPh_2Me]$. Crystallisation of the complex from hot toluene resulted in the formation of colourless crystals. Single crystal X-ray diffraction experiments reveal the asymmetric unit cell of **1** to consist of a central lithium cation coordinated by both the nitrogen atom of the iminophosphorane ligand and one oxygen atom of the triflamide

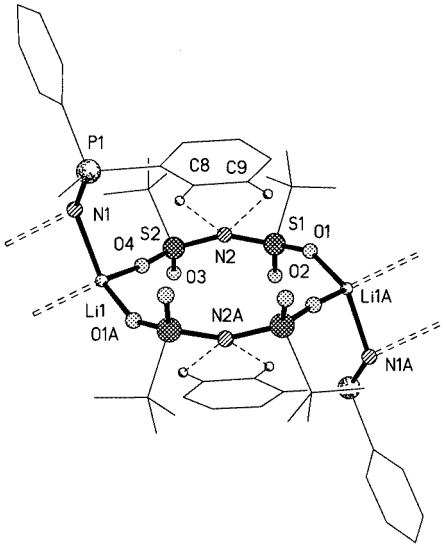


Figure 1. Molecular structure of (**1**), highlighting the weak N···H−C hydrogen bonding interaction between the C−H of a iminophosphorane bound phenyl group and the central nitrogen atom of the triflamide anion; CF_3 groups on the triflamide anion and the iminophosphorane ligand are shown as wire frames and hydrogen atoms omitted for clarity; symmetry transformations used to generate equivalent atoms: $(-x, -y+1, -z+2)$, $(x+1, y, z)$ and $(x-1, y, z)$; selected bond lengths (Å): Li(1)−N(1) 2.036(13), Li(1)−N(1A) 2.051(12), Li(1)−O(4) 1.980(13), Li(1)−O(1A) 1.934(12), O(1)−S(1) 1.427(5), O(2)−S(1) 1.415(5), S(1)−N(2) 1.562(6), N(1)−S(2) 1.573(5), S(2)−O(3), 1.424(5), S(2)−O(4) 1.429(5), P(1)−N(1) 1.589(6), P(1)−C(15) 1.782(7), P(1)−C(1) 1.806(7), P(1)−C(7) 1.805(7), C(8)−H(8) 0.93, N(2)−H(8) 2.79, C(8)−N(2) 3.465(9), C(9)−H(9) 0.93, N(2)−H(9) 2.96, C(9)−N(2) 3.541(9); selected bond angles (°): Li(1)−N(1)−Li(1A) 80.6(5), N(1)−Li(1)−N(1A) 99.4(5), O(4)−Li(1)−O(1A) 119.2(6), S(1)−N(2)−S(2) 127.5(3), C(15)−P(1)−N(1) 109.7(3) C(8)−H(8)−N(2) 130.7, C(9)−H(9)−N(2) 122.3

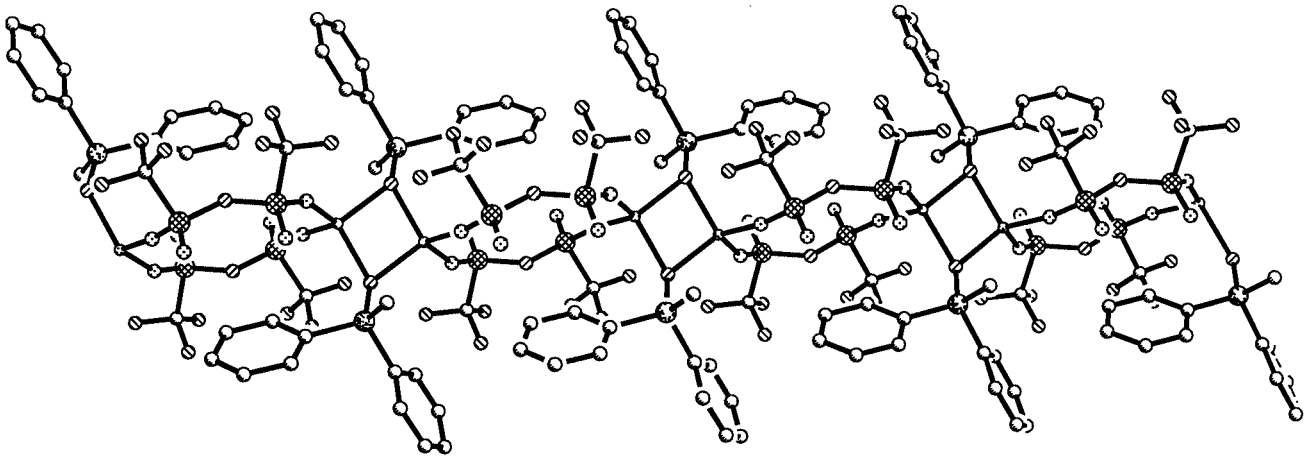

Figure 2. View of the polymeric chain in **1**

anion. Crystallographic symmetry renders the asymmetric unit part of an infinite polymeric chain, in which each lithium triflamide unit forms one half of a twelve-membered ring system (Figure 1). Each twelve-membered ring is subsequently linked by lithium-bridging iminophosphorane groups to propagate the polymeric chain through alternate, and approximately orthogonal, corner-sharing twelve-membered and four-membered rings (Figure 2).

Searches of the literature and the Cambridge Structural Database reveal this twelve-membered ring system to be unique in terms of both its composition and as a bonding mode for the triflamide anion.[13] The CF_3 groups of each NTf_2^- anion within the dimer are found to be mutually *cisoid* with respect to the twelve-membered ring, whereas those of different anions are mutually *transoid*. This unexpected conformation allows a close approach between one of the iminophosphorane-based phenyl groups and the lone pair of the central nitrogen atom of the triflamide anion, facilitating the formation of two C−H···N···H−C hydrogen bonds [C(8)···N(2): 3.464(9) Å; H(8)···N(2): 2.77 Å; C(8)−H(8)···N(2): 130.3°; and C(9)···N(2): 3.540(9) Å; H(9)···N(2): 2.94 Å; C(9)−H(9)···N(2), 122.0°; Figure 1].[14]

Neutral iminophosphorane ligands, which are isoelectronic with phosphane oxides,[15] have been observed previously as ligands to s-block metals.[15,16] The iminophosphorane P−N bond length [P(1)−N(1): 1.589(6) Å] is little changed on coordination to Li from that of the parent ligand,[17] [P−N: 1.563(4)], and in the solid state the ligands are arranged *trans* to each other across the $[Li_2N_2]$ core. Whilst the Li−N bond lengths in **1** [Li(1)−N(1): 2.036(13) Å; Li(1)−N(1A): 2.051(12) Å] are fairly typical of Li−N bonds in a wide range of compounds, the Li−O bonds [Li(1)−O(1): 1.934(12) Å; Li(1)−O(4): 1.980(13) Å] are longer than generally observed in systems containing oxygen-based anions, such as lithium aryloxides,[18] and are closer to typical bond lengths for Li···THF and Li···OEt_2 contacts, implying rather weak anion-cation interactions. The binding of triflamide to the lithium atoms via the oxygen atoms, and not the nitrogen, would suggest that the centre of electronegativity does not reside solely at the nitrogen centre, and close inspection of the bond lengths and bond angles in the triflamide anion reveals only a small degree of asymmetry.

We believe that the preference for Li−O rather than Li−N coordination is electronic in nature rather than steric. This theory is supported by both the structural characterisation of bulkier bis(fluorobenzylsuphonyl)imido systems, $[N(SO_2C_6H_4F)_2]^-$,[19] which possess M−N interactions and the observation by others that strong electron-withdrawing effects of the -CF_3 groups result in a large degree of pπ-dπ bonding within the N−S backbone, resulting in charge delocalisation over the whole of the anion.[20,21]

Compound **2**, $[(Tf_2N)Li{\cdot}N(H)PPh_3]_n$, was prepared in an identical manner to **1** using triphenyliminophosphorane as the nitrogen donor ligand. Characterisation by multinuclear NMR spectroscopy and elemental analysis showed **2** to have the empirical formula $[(Tf_2N)Li{\cdot}N(H)PPh_3]$. Single-crystal X-ray diffraction studies were not undertaken on **2**, but the complex is assumed to be isostructural with the methyldiphenyliminophosphorane complex **1**.

In order to examine further the coordination chemistry of the triflamide anion we reasoned that addition of a bidentate N-donor ligand would enable us to isolate and characterise a single dimeric $[Li_2(NTf_2)_2]$ twelve-membered ring system. Indeed, reaction of TMEDA with $LiNTf_2$ in toluene (or reaction of $[NH_4][NTf_2]$ with *n*BuLi in the presence of TMEDA) results in the isolation of the complex **3**, which has been shown by X-ray diffraction studies to be a discrete dimeric lithium species, $[(Tf_2N)Li{\cdot}TMEDA]_2$, as predicted (Figure 3).

The asymmetric unit of **3** contains half of the dimer, the second half being generated by a crystallographic centre of symmetry that lies at the centre of the twelve-membered $[Li_2(NTf_2)_2]$ ring such that the two lithium centres are bridged by two triflamide ligands as in **1**. However, unlike in **1**, distortion of the twelve-membered ring results in increased cation-anion contact, such that a secondary coordination of the triflamide ligand results, and the geometry about each lithium ion in **3** is pseudo-trigonal bipyramidal rather than the pseudo-tetrahedral geometry observed in **1**.

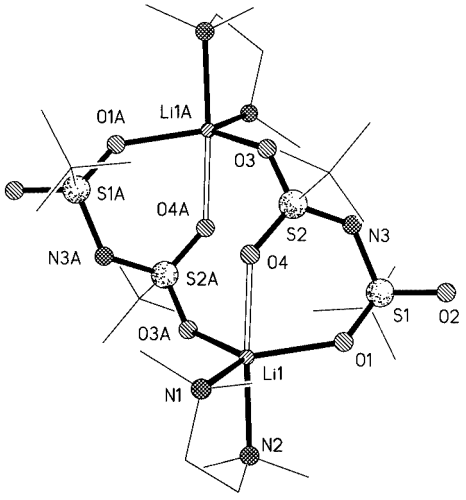

Figure 3. Molecular structure of **3**; symmetry transformations used to generate equivalent atoms: ($-x$, $-y$, $-z$); CF_3 groups and the TMEDA ligands are shown as wire frames and hydrogen atoms omitted for clarity; selected bond lengths (Å): Li(1)−N(1) 2.077(3), Li(1)−N(2) 2.175(3), Li(1)−O(1) 2.070(3), Li(1)−O(3A) 2.008(3), Li(1)−O(4) 2.230(3), O(1)−S(1) 1.4382(13), S(2)−O(3) 1.4332(12), S(2)−O(4) 1.4326(13), S(1)−N(3) 1.5779(15), S(2)−N(3) 1.5628(15); selected bond angles (°): N(1)−Li(1)−N(2) 86.63(12), O(1)−Li(1)−O(4) 79.66(12) O(1)−Li(1)−O(3A) 126.33(16), O(1)−Li(1)−N(1) 118.71(16), O(3A)−Li(1)−N(1) 113.68(15), N(2)−Li(1)−O(4) 175.53(17), S(1)−N(3)−S(2) 124.74(10)

The nitrogen atoms of the TMEDA ligand occupy equatorial and axial positions [Li(1)−N(1): 2.077(3) Å; Li(1)−N(2): 2.175(3) Å], with the axial Li−N bond being the longer. Each lithium centre within the dimer is also coordinated by two oxygen atoms of separate triflamide anions, creating the twelve-membered ring. These oxygen atoms occupy equatorial positions about the lithium ion [Li(1)−O(1): 2.007(3) Å; Li(1)−O(3A): 2.008(3) Å], leaving the axial position available for secondary coordination by an oxygen atom from one of the two bound triflamide anions. This axial Li−O distance [Li(1)−O(4): 2.230(3) Å] is significantly longer than any of the other interactions with lithium, implying a significantly weaker ligation compared to other Li−O contacts. These observations are in contrast to the related complex $[(Tf_2N)Li{\cdot}DME]_\infty$ [22] (DME = dimethoxyethane) in which the central lithium possesses a five-coordinate square-based pyramidal geometry with both the DME ligand and triflamide anion coordinating in an η^2-fashion to the lithium ion. The fifth coordination about the lithium ion site is filled by a long Li−O interaction from a neighbouring η^2-bound triflamide ligand. This bonding motif continues throughout the complex forming a polymeric chain of $[(Tf_2N)Li{\cdot}DME]$ units.[22]

In contrast to **1** the central nitrogen atom of the triflamide anion does not participate in any hydrogen bonding in the absence of suitable acidic C−H donor groups, and it is unclear whether the change in NTf_2^- coordination mode between **1** and **3** is a result of the lack of suitable hydrogen-bonding interactions or due to the steric differences in the N-donor ligands. The different conformations of the twelve-membered rings found in **1** and **3** are highlighted in Figure 4.

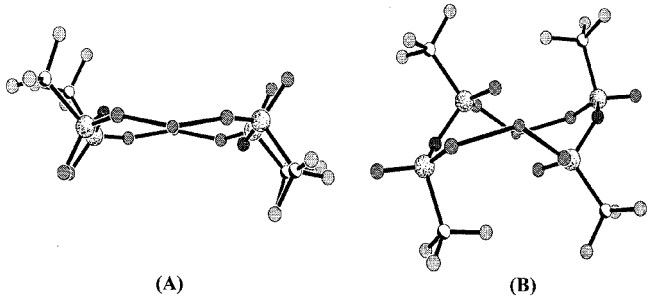

Figure 4. Structure of the central twelve-membered rings found in **1** (**A**) and **3** (**B**)

On changing the nitrogen donor ligand from bidentate TMEDA to the tridentate ligand PMDETA (pentamethyldiethylenetriamine), the aggregation state of the lithium triflamide is further reduced with the formation of a monomeric complex $[(Tf_2N)Li{\cdot}PMDETA]$ (**4**). The central lithium cation in this monomeric species possesses a five-coordinate pseudo-trigonal bipyramidal geometry as in **3** with the PMDETA ligand and the triflamide anion bound to the lithium centre in a tridentate and bidentate fashion, respectively. The molecular structure of **4** is shown in Figure 5.

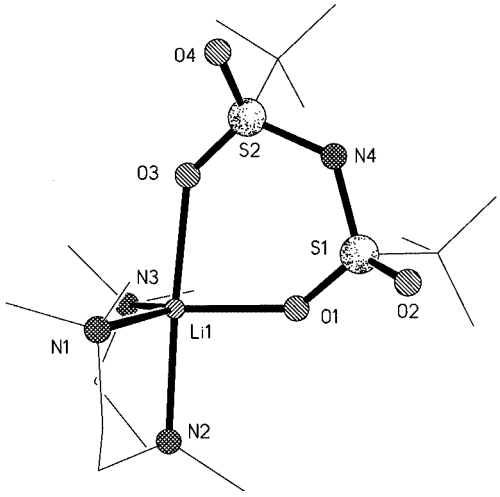

Figure 5. Molecular structure of **4** highlighting the coordination geometry about the central lithium ion; hydrogen atoms have been omitted and selected groups (PMDETA and CF_3) are shown as wire frames for clarity; selected bond lengths (A): Li(1)−N(1) 2.118(4), Li(1)−N(2) 2.173(4), Li(1)−N(3) 2.132(4) Li(1)−O(1) 1.997(4), Li(1)−O(3) 2.151(4), O(1)−S(1) 1.4251(17), S(2)−O(3) 1.4322(15), S(1)−N(4) 1.5705(17), S(2)−N(4) 1.5658(17); selected bond angles (°): O(1)−L(1)−O(3) 83.84(13), N(1)−Li(1)−N(3) 123.62(17), N(1)−Li(1)−N(2) 86.23(13), N(1)−Li(1)−N(3) 84.12(13), N(1)−Li(1)−O(1) 110.06(17), O(1)−Li(1)−N(3) 125.98(17), N(2)−Li(1)−O(3) 175.04(18), S(1)−N(4)−S(2) 126.99(11)

The distortion away from an ideal trigonal bipyramidal geometry in **4** is manifest in the axial-equatorial bond angles and is presumably the result of constrained bite angles within the PMDETA ligand and the triflamide anion [N(1)−Li(1)−N(2): 86.32(13)°; N(2)−Li(1)−N(3): 84.12(13)°; O(1)−Li(1)−O(3): 83.84(13)°]. However the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

O−Li−N angle is close to linear [N(2)−Li(1)−O(3): 175.04(18)°].

The PMDETA ligand binds to the lithium in a facial configuration, with three Li−N contacts, two of which correspond to the outer nitrogen atoms [Li(1)−N(1): 2.118(4) Å; Li(1)−N(3): 2.132(4) Å] and lie in the equatorial plane of the trigonal bipyramid. The third nitrogen atom, which is the central nitrogen of the PMDETA ligand, occupies an axial position with a comparatively longer Li−N contact [Li(1)−N(2): 2.173(4) Å]. The triflamide anion, which binds to the lithium in an η^2-fashion [Li(1)−O(1): 1.997(4) Å; Li(1)−O(3): 2.151(4) Å] fills the remaining two coordination sites about the lithium ion, with the longer of the two Li−O contacts in the axial position. In the absence of any further intra- or intermolecular bonding the CF_3 groups of the triflamide anion maintain the *cis*- conformation observed in **1**.

It is noteworthy when considering the conceptual deaggregation of a dimeric complex containing a bidentate donor ligand, such as **3**, to a monomeric complex containing a tridentate donor ligand, such as **4**, that it is the short Li−O bond [Li(1)−O(3A) in **3**] that generates the dimer that is replaced rather than the longer (secondary) Li−O interaction [Li(1)−O(4) in **3**].

Finally, we wished to investigate the effect of variation in the nature of the tridentate donor ligand by synthesising complexes of *N*-tribenzyltriazocyclohexane (Bz-TAC). Although both PMDETA and Bz-TAC contain three donor atoms we expected the more compact ligand set of Bz-TAC relative to PMDETA to influence the nature of NTf_2^- coordination to the lithium ion.[23]

Attempted synthesis of the Bz-TAC analogues of **4**, using the direct addition of ligand to $LiNTf_2$ in toluene, were unsuccessful, with all stoichiometries of starting materials resulting in the isolation of the ion-separated bis-ligand complex $[(Bz\text{-}TAC)_2Li][NTf_2]$, (**5**), in which each lithium ion is coordinated by two TAC ligands.

Complex **5** was characterised by single-crystal X-ray diffraction (Figure 6). The asymmetric unit cell contains two independent half $[\eta^3\text{-}(Bz\text{-}TAC)_2Li]^+$ cations, with the Li atom in each case sitting on a centre of symmetry. The asymmetric unit is completed by one non-coordinating NTf_2^- anion. For both cations all Li−N distances are similar, spanning a small range [2.2411(15) to 2.3031(15) Å].

The six benzyl groups of the $[(Bz\text{-}TAC)_2Li]^+$ cation wrap around the central lithium ion and participate in an intricate *ortho*-(C−H···π) arene hydrogen bonding motif, in which each benzyl group is hydrogen bonded to its nearest neighbour on the other Bz-TAC ligand (Figure 7). The two ligands are thus interlocked in a paddlewheel motif about the central lithium ion.

$[(R\text{-}TAC)_2Li]^+$ cations, where R = Bz[24] or R = Me,[24,25] have been characterised previously, although the hydrogen-bonding network that is present in the benzyl system has not been commented upon. The presence of two TAC ligands around the lithium ion provides sufficient steric protection to preclude any cation-anion interactions in **5**.

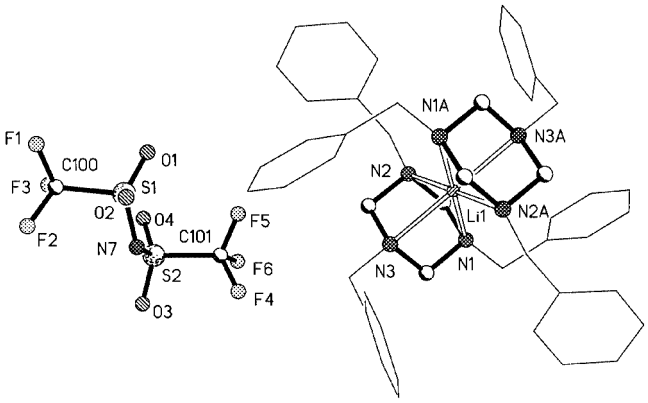

Figure 6. Molecular structure of one of the two centrosymmetric $[Li(Bz\text{-}TAC)_2]^+$ cations and an NTf_2^- anion in (**5**); symmetry transformations used to generate equivalent atoms: (x, y, z), & ($-x$, $-y$, $-z$); benzyl groups of the $[Li(Bz\text{-}TAC)_2]^+$ cation are shown as wire frames and hydrogen atoms omitted for clarity; selected bond lengths (Å): Li(1)−N(1) 2.2411(15), Li(1)−N(2) 2.2602(15), Li(1)−N(3) 2.2471(16), S(1)−N(7) 1.5731(17), S(2)−N(7) 1.5736(18), S(1)−O(1) 1.4259(16), S(1)−O(2) 1.4239(15), S(2)−O(3) 1.4286(15), S(2)−O(4) 1.4223(15); selected bond angles (°): N(1)−Li(1)−N(2) 63.64(6), N(1)−Li(1)−N(3) 63.53(6), N(2)−Li(1)−N(3) 63.06(6), S(1)−N(7)−S(2) 125.41(11)

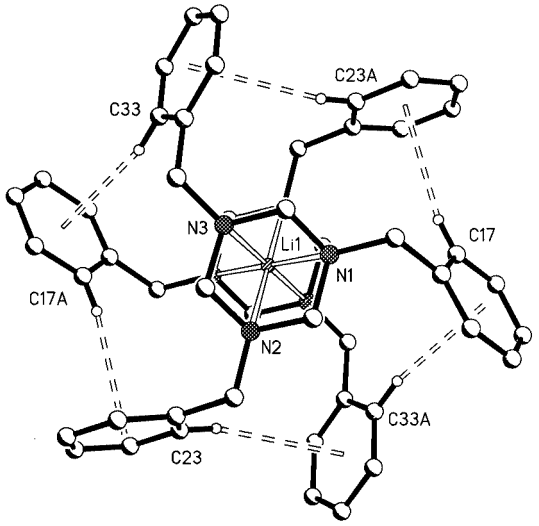

Figure 7. Diagram highlighting the C−H···π arene hydrogen-bonding network within one of the two centrosymmetric cations in **5**; hydrogen atoms not involved in the hydrogen-bonding network omitted for clarity; C−(H)···X distances (where X = centroid of the relevant aryl ring) (Å): C(17)−X 3.802, C(23)−X 3.956, C(33)−X 3.593; selected C−(H)···X angles (°): C(17)−H(17)−X 167, C(23)−H(23)−X 155, C(33)−H(33)−X 166

Close inspection of the bond lengths and angles about the NTf_2^- anion in **5** (Figure 6), shows a remarkable similarity to the coordinated anions in $[(Tf_2N)Li{\cdot}N(H)Ph_2Me]$, $[(Tf_2N)Li{\cdot}TMEDA]$, $[(Tf_2N)Li{\cdot}PMDETA]$, and other non-coordinated anions in complexes such as $[Li(12\text{-}C\text{-}4)_2][NTf_2]$,[26] $[Li(C\text{-}2,2,2)][NTf_2]$,[26] $[Mg(H_2O)_6][NTf_2]_2$,[27] $[Im][NTf_2]$,[28] $[R_4N][NTf_2]$[29] and $[Me_3NH][NTf_2]$.[30]

It is noteworthy that even using the high degree of control provided by the ammonium salt route, it has not been possible to isolate mono Bz-TAC complexes, such as [(*i*Pr-

TAC)Li·BH_4]$_2$,[24] highlighting the high stability of the [(Bz-TAC)$_2$Li]$^+$ cation.

Conclusions

The single crystal structures of the four lithium triflamide salts have been determined. The resulting solvated structures can be thought of in terms of solvent-separated ion pairs, contact ion pairs and higher aggregates (Figure 8), with the degree of aggregation and ion contact being dependent on the relative coordinating abilities and steric demands of the donor ligand and the anion. These results provide an insight into the possible structures of lithium aggregates present in complex systems such as polymer electrolytes and synthetic reaction media.

The degree to which lithium ions will engage in intimate contact with the triflamide anions has little effect on the electronic structure of the anion, which remains reasonably impassive. However, conformational changes within the very flexible anion are observed.

The observation of ion separation in lithium triflamide salts contrasts directly with more coordinating (less delocalised) anions such as triflate, $CF_3SO_3^-$, in which contact between anion and cation persists to the extent that the coordination number of the metal cation is expanded rather than loss of contact with the anion.

Experimental Section

General Remarks: All manipulations were carried out under an atmosphere of dry argon using standard Schlenk and glove-box techniques. Solvents were purified by conventional procedures and distilled prior to use. $LiNTf_2$ was purchased from Aldrich and used as received, without further purification. The ligand systems were prepared using standard literature techniques or purchased from Aldrich.

Solution ^{1}H, ^{19}F and ^{31}P NMR experiments were performed at ambient temperature using a Varian 400 or a Bruker Advance-300 Spectrometer. ^{1}H NMR chemical shifts are referenced to $SiMe_4$, and ^{31}P NMR shifts relative to 85% H_3PO_4. All chemical shifts (δ) are in ppm and coupling constants in Hz.

[NH_4][NTf_2]: Ammonia gas was bubbled through an ethereal solution (50 mL) of bis(trifluoromethylsulfonyl)amine (Tf_2NH; 10 mmol, 2.8 g) for 10 min. The solvent was then allowed to evaporate at room temperature, yielding a white crystalline material which was isolated and washed with hexane (3 × 5 mL). Yield: 2.9 g (98%). Colourless blocks. $C_2H_4F_6N_2O_4S_2$ (298.2): calcd. C 8.1, H 1.4, N 9.4; found C 8.1, H 1.3, N 9.9.

The lithium complexes **1**−**5** were prepared using standard procedures for both the direct and in situ synthesis, examples of both procedures are given below.

[(Tf_2N)Li·N(H)Ph_2Me] (1). (in situ Method): Methyldiphenyliminophosphorane (0.22 g, 1 mmol) was added to a suspension of ammonium trifluoromethanesulfonimide (0.30 g, 1 mmol) in 5 mL of toluene. The mixture was stirred for 20 min at room temperature, and then cooled to −78 °C. One mole-equivalent of *n*BuLi (0.63 mL, 1.6 M) was then added to the cooled suspension. Warming to room temperature caused the solution to undergo several colour changes, and a fine colourless precipitate to be deposited on the walls of the vessel. The precipitate was re-dissolved by heating, and the solution was left to cool to room temperature to yield a crop of crystals, which where isolated by filtration and washed with 5 mL of cold hexane and dried in vacuo. Yield: 0.30 g (60%). Colourless blocks. Mp: 120−122 °C. $C_{15}H_{14}F_6LiN_2O_4P_1S_2$ (502.3): calcd. C 35.9, H 2.8, N 5.6; found C 36.2, H 3.2, N 4.9. ^{1}H NMR (400 MHz, 23 °C, C_6D_6): δ = 1.11 (s, 1 H, N*H*), 1.45 (d, $^2J_{P,H}$ = 13.3 Hz, 3 H, P−CH_3), 6.8−7.0 (m, 6 H, *m*- & *p*- aromatic C*H*), 7.1−7.3 (m, 4 H, *o*-aromatic C*H*) ppm. ^{19}F NMR (376 MHz, 23 °C, C_6D_6): δ = −79.9 (s, CF_3) ppm. ^{31}P NMR (162 MHz, 23 °C, C_6D_6): δ = 33.7 (s, Ph_2Me*P*NH) ppm.

(Direct Method): A toluene solution (2 mL) of methyldiphenyliminophosphorane (0.22 g, 1 mmol) was added to a sample of *N*-lithiotrifluoromethanesulfonimide (0.29 g, 1 mmol) in 2 mL of toluene. The reaction was stirred for 1 h under an argon atmosphere and a further 3 mL of toluene was added. The mixture was then heated to reflux, to aid dissolution, and the solution left to crystallise at room temperature to yield a crop of crystals suitable for X-ray analysis, which where isolated by filtration and washed with 5 mL of cold hexane and dried in vacuo. Yield: 0.36 g (71%). Analysis showed the product to be identical to that prepared by the in situ method.

[(Tf_2N)Li·N(H)PPh_3] (2): Triphenyliminophosphorane (0.28 g, 1 mmol). in situ method: yield 0.30 g (60%); direct method: yield 0.37 g (73%). Colourless blocks. Mp: 85−87 °C. $C_{20}H_{16}F_6Li_1N_2O_4P_1S_2$ (564.4): calcd. C 42.5, H 2.9, N 5.0; found C 43.2, H 3.34, N 4.8. ^{1}H NMR (400 MHz, 23 °C, C_6D_6): δ = 1.35 (s, 1 H, N*H*), 7.0−7.2 (m, 9 H, *m*- & *p*- aromatic C*H*), 7.4−7.6 (m, 6 H, *o*-aromatic C*H*) ppm. ^{19}F NMR (376 MHz, 23 °C, C_6D_6): δ = −79.7 (s, CF_3) ppm. ^{31}P NMR (162 MHz, 23 °C, C_6D_6): δ = 33.0 (s, Ph_3*P*NH) ppm.

C 23.6, H 4.0, N 10.9. ^{1}H NMR (400 MHz, 23 °C, C_6D_6): δ = 1.8 (br. s, 4 H, NCH_2CH_2N), 1.9 (br. s, 12 H, N−CH_3) ppm. ^{19}F NMR (376 MHz, 23 °C, C_6D_6): δ = −80.0 (s, CF_3) ppm.

$[(Tf_2N)Li{\cdot}PMDETA]$ (4): *N*,*N*,*N*′,*N*′′,*N*′′-Pentamethyldiethylenetriamine (0.20 mL, 0.17 g, 1 mmol); in situ method: yield 0.34 g (74%); direct method: yield 0.38 g (83%). Colourless blocks. Mp: 122−123.5 °C. $C_{11}H_{23}F_6LiN_4O_4S_2$ (460.4): calcd. C 28.7, H 5.0, N 12.2; found C 28.8, H 5.1, N 12.3. ^{1}H NMR (400 MHz, 23 °C, C_6D_6): δ = 2.19 (s, 12 H, NMe_2), 2.23 (s, 3 H, N*Me*), 2.28−2.56 [br. m, 8 H, (Me_2NCH_2CH_2)NMe] ppm. ^{19}F NMR (376 MHz, 23 °C, C_6D_6): δ = −78.9 (s, CF_3) ppm.

$[(Bz\text{-}TAC)_2Li][NTf_2]$(5): *N*-tribenzyltriazocyclohexane (0.36 g, 1 mmol); in situ method: yield 0.36 g (36% with respect to Li); direct method: yield 0.48 g (48% with respect to Li). Colourless blocks. Mp: 141−143 °C. $C_{50}H_{54}F_6Li_1N_7O_4S_2$ (1002.1): calcd. C 59.9, H 5.4, N 9.8; found C 59.9, H 5.6, N 9.8. ^{1}H NMR (400 MHz, 23 °C, $CDCl_3$): δ = 3.32 (br. s, 12 H, N−CH_2-N), 3.46 (br. s, 12 H, N−CH_2-Ph), 7.1−7.4 (br. m, 30 H, aromatic-C*H*) ppm. ^{19}F NMR (376 MHz, 23 °C, $CDCl_3$): δ = −78.8 (s, CF_3) ppm.

X-ray Crystallographic Study: Suitable single crystals of $[NH_4][NTf_2]$ and compounds **1**, **3**, **4** and **5** were mounted on glass fibres using perfluoroether oil. Data collections were carried out on an Enraf Nonius Kappa CCD diffractometer, equipped with a Oxford Cryosystems cooling device, and graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å). Data were corrected for Lorentz and polarisation effects and for absorption. The structures were solved by direct methods, and refined using full-matrix least-squares on F^2 with all non-hydrogen atoms assigned anisotropic displacement parameters. Hydrogen atoms were included at calculated positions throughout and refined using a riding model, with U_{iso} set to 1.2-times (1.5-times for methyl-H) U_{equiv} of the carrier atom, with the exception of the nitrogen-bound hydrogen atoms in $[NH_4][NTf_2]$. In the final stages of refinement a weighting scheme was introduced and refinement continued until convergence was achieved. Programs used were SHELXS-86[31] and SHELXL-97.[32] Experimental data relating to all the structure determinations are presented in Table 1.

CCDC-212575−212579 ($[NH_4][NTf_2]$, **1**, **3**, **4** and **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Syntheses and Crystal Structures of Highly Diastereomerically Enriched Lithiated Benzylsilanes in the Presence of External Donor Molecules: Experiment and Theory

Carsten Strohmann,*[a] Daniel H. M. Buchold,[a] Timo Seibel,[a] Kerstin Wild,[a] and Daniel Schildbach[a]

In memory of Ron Snaith

Keywords: Silanes / Lithium / Diastereomers / Quantum-chemical calculations / Stereochemistry

The solid-state structures of the lithiated (aminomethyl)benzylsilanes $Me_2Si[(R)$-(CHPhLi·0.5TMEDA)$](CH_2SMP)$ [{(*R*,*S*)-**2**}$_2$·TMEDA] and $Me_2Si[(R)$-(CHPhLi·DABCO)$](CH_2SMP)$ [(*R*,*S*)-**2**·DABCO] [CH_2SMP = (*S*)-2-(methoxymethyl)pyrrolidinomethyl] and the absolute configurations at the stereogenic metallated carbon centres of these compounds were determined by single-crystal X-ray diffraction methods. The crystal structures of the TMEDA-bridged dimer [(*R*,*S*)-**2**]$_2$·TMEDA and monomeric (*R*,*S*)-**2**·DABCO were compared to that of the parent compound (*R*,*S*)-**2**, a coordination polymer. By computational methods [B3LYP/6–31+G(d)], the mechanism of the deprotonation of the starting compound, (aminomethyl)benzylsilane [(*S*)-**1**], as well as the stability of configuration of the lithiated derivatives of (*R*,*S*)-**2**, were examined. For the highly diastereoselective substitution reactions of the derivatives of (*R*,*S*)-**2** with iodomethane, inversion of the configuration at the metallated carbon centre was observed and correlated with the results of the quantum-chemical studies.

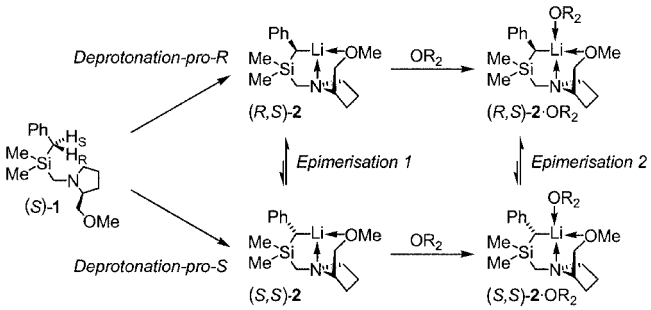
Introduction

The synthesis of enantiomerically or diastereomerically enriched[1] alkyllithium compounds, in which the metallated carbon centre is the stereogenic centre, has been intensively studied for the last 20 years.[2] Among these compounds are several enantiomerically enriched benzyllithium reagents.[2–5] Stereogenic metallated carbon centres are usually generated by deprotonation using alkyllithium bases, like *tert*-butyllithium. The stereochemical information can be introduced *prior* to the deprotonation reaction by using enantiomerically enriched C–H acidic precursors bearing only one proton at the stereogenic carbon centre. In contrast, methods for the introduction of the stereochemical information *during* the deprotonation reaction are either *inter*molecular by chiral auxiliaries, like (–)-sparteine, or *intra*molecular by the side-arm donation of chiral substituents, like the (*S*)-2-(methoxymethyl)pyrrolidinomethyl substituent (CH_2SMP). This latter method is used in our laboratory.

Two different reaction conditions for the synthesis of the studied diastereomerically enriched benzyllithium compounds are applicable. *Kinetically controlled synthesis:* Diastereotopos-differentiating deprotonation at low temperatures, mostly observed in non-polar solvents (e.g. in toluene, *n*-pentane); *Thermodynamically controlled synthesis:* Epimerisation between two diastereomeric alkyllithiums at higher temperatures, mostly observed in polar solvents (e.g. in THF) (Scheme 1). Kinetically controlled deprotonation and thermodynamically controlled epimerisation will be discussed in detail in the section "Quantum-Chemical Studies".



Scheme 1. Relevant deprotonation reactions and epimerisation equilibria starting from (*S*)-**1**

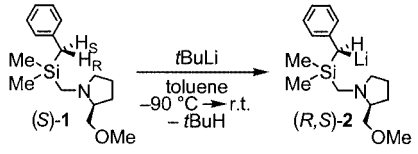
The focus of this article will be particularly on the lithiated (aminomethyl)benzylsilane (*R*,*S*)-**2** in the presence of external coordinating donor molecules. The synthesis, the stability of configuration at the metallated carbon centre and further transformations (stereochemical course) have been investigated thoroughly.

The lithiation of [(benzyldimethylsilyl)methyl]-(*S*)-2-(methoxymethyl)pyrrolidine [(*S*)-**1**] with *sec*-butyllithium in THF and selective substitution reactions with alkyl halides, which showed very high diastereomeric ratios (*dr*), were first reported by Chan and co-workers.[4a] A significant solvent effect on the diastereomeric ratios of the transformations with iodomethane was observed when the reaction was carried out in THF (*dr* = 75:25) and diethyl ether (*dr* ≥ 98:2). Thus, it was of great interest to determine the solid-state structure (and the absolute configuration) of lithiated organosilane (*R*,*S*)-**2** in the crystal,[6] especially since only very few enantiomerically pure alkyllithiums have been investigated in the solid state up to now.[2a,3d,3g,3h,7–9]

The lithiation of (aminomethyl)benzylsilane [(*S*)-**1**] was carried out with *tert*-butyllithium at −90 °C in a toluene/*n*-pentane mixture (Scheme 2). At −30 °C, yellow needles of the metallated product (*R*,*S*)-**2** could be isolated as single crystals in 80% yield. The result of the single-crystal X-ray diffraction study is shown in Figure 1.[6]



Scheme 2

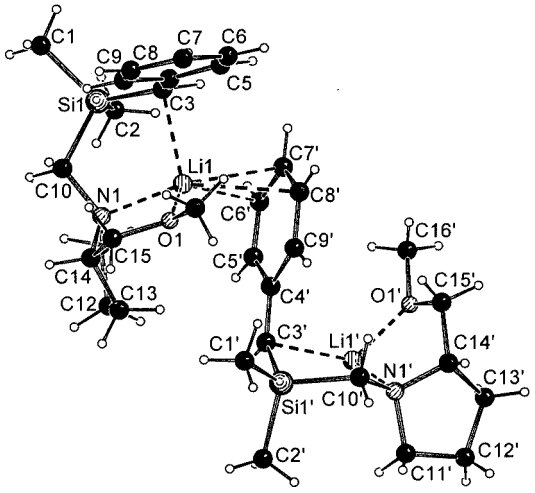


Figure 1. Molecular structure and numbering scheme of compound (*R*,*S*)-**2** in the crystal (Schakal plot);[10] selected bond lengths (Å) and angles (°): Si(1)−C(3) 1.797(7), Li(1)−C(3) 2.269(14), C(3)−C(4) 1.419(9), N(1)−Li(1) 2.183(12); C(3)−Si(1)−C(10) 107.9(3)

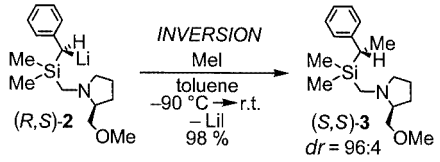
For the substitution reaction of (*R*,*S*)-**2** with iodomethane in toluene/*n*-pentane, inversion of the configuration at the metallated carbon centre was observed with a high diastereoselectivity (*dr* = 96:4). The absolute configuration of methylated (aminomethyl)benzylsilane (*S*,*S*)-**3** was determined by X-ray structural analysis of the corresponding ammonium iodide (Scheme 3).[6]



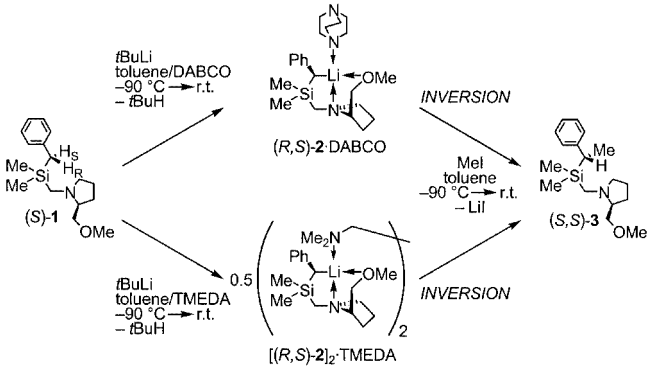
Scheme 3

Due to the difference in the stereoselectivities of the mentioned substitution reactions, when switching from non-polar solvents to polar solvents, the molecular structures of (*R*,*S*)-**2** with external (intermolecularly) coordinating molecules, blocking a potential vacant coordination site at the lithium centre, were to be examined. Therefore, the solid-state molecular structures of the two donor-stabilised adducts (*R*,*S*)-**2**·DABCO and [(*R*,*S*)-**2**]$_2$·TMEDA are presented, as well as the results of substitution reactions with the electrophile iodomethane. The stereochemical aspects of these transformations will be explained by quantum-chemical studies.

Results and Discussion

Synthesis of the Diastereomerically Enriched Alkyllithiums

[(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO were generated by lithiation with *tert*-butyllithium in a toluene/*n*-pentane mixture in the presence of the corresponding diamine ligand at low temperatures. After warming to room temperature, single crystals of both compounds were obtained that were suitable for X-ray structural analysis. According to this, a monomeric molecular structure was observed for (*R*,*S*)-**2**·DABCO, with only one nitrogen centre coordinating to one lithium centre, while a dimeric structure was determined for [(*R*,*S*)-**2**]$_2$·TMEDA with the diamine in a bridging mode [both molecular structures, with an (*R*) configuration at the lithiated carbon centre, will be discussed]. The bridged dimer [(*R*,*S*)-**2**]$_2$·TMEDA is formed indepen-



Scheme 4

dently of the molar ratio between the alkyllithium compound and TMEDA (1:1 or 2:1), and the use of half an equivalent of DABCO (molar ratio of 2:1) does not force this ligand into a bridging position (Scheme 4).

After dissolving the solids of [(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO in toluene, the trapping reactions with iodomethane were carried out at −90 °C and the reaction mixture was subsequently warmed to room temperature. Methylated silane (*S*,*S*)-**3**/(*R*,*S*)-**3** was formed in maximum yields of 98%. Higher diastereomeric ratios were observed when the substitution reactions with iodomethane were carried out in the coordinating solvent diethyl ether (*dr* > 98:2), than for the corresponding reactions in a toluene/*n*-pentane mixture (*dr* = 96:4). Surprisingly, THF as a solvent gave only poor diastereomeric ratios (*dr* = 75:25).[4a,6] Unfortunately, no single-crystals of (*R*,*S*)-**2** from the two ethereal solvents have been obtained up to now. Thus, the absolute configurations at the lithiated carbon centres of compounds of the formal type (*R*,*S*)-**2**·OR$_2$ (OR$_2$ = THF, Et$_2$O) have not been confirmed for these two solvents. Due to the difference in the stereoselectivities of the substitution reaction with iodomethane in the two ethereal solvents, different reaction conditions for the methylation were applied and the diastereomeric ratios studied. The results are summarised in Table 1.

Table 1. Diastereoselectivities of substitution reactions with iodomethane in different solvents

Compound	Solvent	*dr* [(*S*,*S*)-**3**:(*R*,*S*)-**3**]
[(*R*,*S*)-**2**]$_2$·TMEDA	toluene	>98:2
(*R*,*S*)-**2**·DABCO	toluene	>98:2
(*R*,*S*)-**2**	toluene +1 equiv. THF *before* metallation	>98:2
(*R*,*S*)-**2**	toluene +1 equiv. THF *after* metallation	>98:2
(*R*,*S*)-**2**	Et$_2$O	>98:2
[(*R*,*S*)-**2**]$_2$·TMEDA	THF	69:31
(*R*,*S*)-**2**·DABCO	THF	62:38
(*R*,*S*)-**2**	THF	75:25

For the reactions of the defined donor adducts [(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO as well as for reactions where the external donor molecule is added stoichiometrically (THF), high diastereoselectivities were observed. In contrast to the methylation in the solvent diethyl ether, methylations of (*R*,*S*)-**2**, [(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO in THF as a solvent give only poor diastereoselectivities. Obviously, the high selectivities of reactions of (*R*,*S*)-**2** are only diminished by the highly polar environment of THF as a solvent, while reactions of defined mixtures/adducts of (*R*,*S*)-**2** with external coordinating donor molecules in less or non-polar solution give high diastereomeric ratios. Moreover, the stereochemical course of the transformations with the lithiated (aminomethyl)benzylsilanes is not affected by crystallisation and isolation of these compounds; reactions starting with the lithium compound as prepared and maintained in solution gave the same *dr* values.

Discussion of the X-ray Structural Analyses of [(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO

The alkyllithium compound [(*R*,*S*)-**2**]$_2$·TMEDA crystallised from a toluene/*n*-pentane mixture in the orthorhombic crystal system, space group $P2_12_12_1$ (see also Table 2). The asymmetric unit of [(*R*,*S*)-**2**]$_2$·TMEDA contains one molecule, representing a TMEDA-bridged dimer, where each nitrogen centre of the bidentate diamine ligand coordinates to one lithium centre of a silane unit (Figure 2). (Due to the similarity of the structural parameters of these two bridged silane units, only one unit is discussed; selected bond lengths are given in Table 3).

The lithium centre, with a distorted tetrahedral coordination sphere, has contacts to the metallated carbon centre C(3), to the oxygen centre O(1) and the nitrogen centre N(1) of the SMP substituent, as well as to N(3) of the TMEDA ligand. The metallated carbon centre C(3) is slightly pyramidalised: the sum of the angles at the "carbanionic" unity, consisting of Si(1), C(3), C(4) and H(3), is 354°. Nevertheless, the tetracoordinate C(3) is a stereogenic centre with the (*R*) configuration due to the Li(1)−C(3) contact; the Li(1)−C(3) distance is 2.254(4) Å. The *intra*molecular nitrogen-lithium contact [N(1)−Li(1) = 2.185(4) Å] and the *inter*molecular nitrogen-lithium contact [N(3)−Li(1) = 2.171(4) Å] are equal within the margin of error. As a consequence of the stabilisation effect of silicon centres on vicinal metallated carbon centres (polarisability of the silicon centre in addition to the stabilisation effect by the phenyl substituent), the Si(1)−C(3) bond length [1.817(2) Å] is significantly shorter than the Si(1)−C(10) bond [1.916(2) Å]. Moreover, when the C−C distances in the phenyl ring are compared to a similar (aminomethyl)-(lithiomethyl)benzylsilane that is not lithiated at the benzyl position, the influence of the metallation at C(3) is noticeable. Thus, the C−C distances between the *ipso*- and the two *ortho* carbon centres are longer [C(4)−C(5) = 1.419(4) and C(4)−C(9) = 1.427(3) Å] than the values found previously [1.378(4) and 1.390(4) Å].[11,12]

The related alkyllithium compound (*R*,*S*)-**2**·DABCO crystallised from a toluene/*n*-pentane mixture in the monoclinic crystal system, space group $P2_1$. The asymmetric unit of (*R*,*S*)-**2**·DABCO contains one molecule of the alkyllithium as well as one molecule of toluene from the solvent (due to the lack of interactions between the alkyllithium compound and the toluene, the solvent molecule is omitted in Figure 3). In contrast to the TMEDA adduct [(*R*,*S*)-**2**]$_2$·TMEDA, the bidentate DABCO ligand does not bridge two silane units, but coordinates to the lithium centre Li through the nitrogen centre N(2), while the nitrogen centre N(3) remains in a non-coordinating mode [the shortest intermolecular distance N(3)···H(10a) is 2.678(7) Å]. The reason for this is probably the lack of flexibility of the more rigid DABCO, compared to the TMEDA ligand; steric interactions between bridged silane units would be the consequence. The distorted tetrahedral coordination sphere of the lithium centre is built up by one contact to the metallated carbon centre C(3), as well as to O(1) of the meth-

Molecular structure and numbering scheme of compound [(*R*,*S*)-**2**]$_2$·TMEDA in the crystal (Schakal plot);[10] selected bond lengths (Å) and angles (°): Si(1)–C(3) 1.817(2), Li(1)–C(3) 2.254(4), C(3)–C(4) 1.430(3), N(1)–Li(1) 2.185(4), N(3)–Li(1) 2.171(4), O(1)–Li(1) 1.993(4); C(3)–Si(1)–C(10) 110.19(10), Li(1)–C(3)–Si(1)–C(4) 96.5(2), Si(2)–C(19) 1.809(2), Li(2)–C(19) 2.254(5), C(19)–C(20) 1.437(3), N(2)–Li(2) 2.185(4), N(4)–Li(2) 2.161(4), O(2)–Li(2) 2.013(4), C(19)–Si(2)–C(26) 109.75(12)

oxymethyl substituent and two lithium-nitrogen contacts to nitrogen centres N(1) and N(2) of the SMP substituent and the DABCO ligand. In (*R*,*S*)-**2**·DABCO, the metallated carbon centre C(3) is also slightly pyramidalised: At the "carbanionic" unit, consisting of Si(1), C(3), C(4) and H(3), a sum of the angles of 358° is found. The tetracoordinate metallated carbon centre C(3), a stereogenic centre due to the Li(1)–C(3) contact, has an (*R*) configuration; the Li(1)–C(3) distance is 2.279(9) Å. The two nitrogen-lithium distances are slightly shorter than in the TMEDA adduct [(*R*,*S*)-**2**]$_2$·TMEDA, but equal within the margin of error [N(1)–Li(1) = 2.138(9) Å (*intra*molecular), N(2)–Li(1) = 2.102(9) Å (*inter*molecular)]. As a consequence of the stabilizing effect of the silicon centre on metallated C(3) (in addition to the stabilisation of the phenyl substituent), the Si–C(3) distance, which amounts to 1.814(5) Å, is significantly shorter than the Si(1)–C(10) distance, which is 1.895(5) Å. In a related non-chiral lithiated benzyl(piperidinomethyl)silane, whose synthesis and crystal structure were reported previously,[11,12] the corresponding Si(1)–C(3) bond length [1.821(3) Å] is of a similar value, indicating an analogous stabilising effect by the silicon centre of this molecule. The C–C bonds between the *ipso*- and both *ortho* carbon centres [C(4)–C(5) = 1.419(7) and C(4)–C(9) = 1.425(7) Å] are longer than the previously reported values [1.378(4) and 1.390(4) Å].[11,12]

All three lithiated (aminomethyl)benzylsilanes [(*R*,*S*)-**2**, (*R*,*S*)-**2**·DABCO and [(*R*,*S*)-**2**]$_2$·TMEDA] are metallated at the benzyl position; the benzylic carbon centre, being the stereogenic metallated carbon centre, has an (*R*) configura-

tion in all three cases. The carbon-lithium distances of the three compounds are equal within the margin of error. This fact underlines — especially in the case of the two *inter*molecularly coordinated compounds [(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO — that these compounds do not have the properties of lithium-carbanion pairs. The lithium centre is not separated from the metallated carbon centre, either by the DABCO or by the strongly chelating TMEDA ligand. In the case of compound (*R*,*S*)-**2**, which is only *intra*molecularly coordinated by donor centres, the ''carbanionic'' unit is planar (sum of the angles of 360°), thus the adjoining centres H(3), C(4) and Si are coplanar with C(3). The two externally coordinated compounds [(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO are slightly pyramidalised at C(3) (sum of the angles of 354° and 358° respectively), although the sums of the angles should not be overvalued. The torsion angles, incorporating the lithium, the silicon, the metallated carbon and the *ipso* carbon centres, are in the range of 96.5(2)° and 104.1(7)° and demonstrate that the lithium centres are located almost orthogonal to the planes of the ''carbanionic'' units. Moreover, the periplanar conformation of the C(3)−C(4) bond shows that this ''carbanionic'' unit is in the same plane as the aromatic ring system. The most important structural parameters of the three alkyllithium compounds (*R*,*S*)-**2**,[6] [(*R*,*S*)-**2**]$_2$·TMEDA and (*R*,*S*)-**2**·DABCO are summarised in Table 3.

An investigation of the molecular structures of (*R*,*S*)-**2**, (*R*,*S*)-**2**·DABCO and [(*R*,*S*)-**2**]$_2$·TMEDA in solution by low-temperature NMR techniques is not possible due to the poor solubility of the compounds in the essential non-polar solvents at reduced temperatures. At room temperature, no carbon-lithium coupling was observed, although this is not a reliable probe for the carbon-lithium distance.

Quantum-Chemical Studies

Kinetically Controlled Deprotonation

An insight into the deprotonation reaction of (*S*)-**1** with *tert*-butyllithium can be gained by computational methods.[13] Experimentally, this reaction is effected at very low temperatures (−70 to −90 °C) under kinetically controlled conditions. Under these conditions, the reaction will proceed via the energetically more stable transition state. Two reaction paths are possible, resulting in the formation of the two possible epimers (*R*,*S*)-**2** and (*S*,*S*)-**2** (Scheme 1). Each of these reaction paths will be considered separately. With the implication of the complex induced proximity effect (CIPE),[14] the reaction is believed to start with a pre-coordinated *tert*-butyllithium molecule, whose lithium centre is coordinated by the oxygen and nitrogen atoms of the SMP ligand. From the specific conformation of the Si−C bond in **MIN-1**, the *pro*-R hydrogen atom (H_R) is being abstracted in the deprotonation reaction, proceeding via the transition state **TS-1**, in which the carbon-lithium contact is formed simultaneously with the carbon-hydrogen bond cleavage. The reaction products (metallated silane and *tert*-

(a) Relative-energy profile of stationary points **MIN-1**, **TS-1** and **MIN-2** for the deprotonation reaction towards the (*R*,*S*)-epimer, deprotonation-*pro*-*R*, B3LYP/6−31+G(d); (b) relative-energy profile of stationary points **MIN-3**, **TS-2** and **MIN-4** for the deprotonation reaction towards the (*S*,*S*)-epimer, deprotonation-*pro*-*S*, B3LYP/6−31+G(d)

butane) form the stationary point **MIN-2** (Deprotonation-*pro*-R; Scheme 1, Figure 4a, Table 4). The results of this calculation, together with the analogous deprotonation reaction, where the abstraction of the *pro*-*S* hydrogen atom (H_S) gives the other epimer **MIN-4** (deprotonation-*pro*-*S*; Scheme 1, Figure 4b, Table 4), are summarised in Table 4.

Table 4. Calculated energies for the stationary points **MIN-1** to **MIN-4**, **TS-1** and **TS-2** of the deprotonation reactions towards the (*R*,*S*)/(*S*,*S*)-epimer, B3LYP/6−31+G(d) (ZPVE = Zero-Point Vibrational Energy)

Deprotonation reaction towards (*R*,*S*)-/(*S*,*S*)-epimer		Electronic Energy relative to **MIN-1**	
		corrected by ZPVE	uncorrected
Deprotonation 1 **MIN-1** → **MIN-2**	**MIN-1**	0	0
	TS-1	55	65
	MIN-2	−100	−102
Deprotonation 2 **MIN-3** → **MIN-4**	**MIN-3**	0	0
	TS-2	61	71
	MIN-4	−85	−88

The energies of the two conformers **MIN-1** and **MIN-3** are equal within the margin of error of the DFT method used.[15] On the reasonable assumption of an equilibrium between **MIN-1** and **MIN-3**, the stereoselectivity of the reaction would be influenced by the difference between the two activation barriers of the potential energy surface of deprotonation-*pro*-*R* and deprotonation-*pro*-*S*. This activation barrier for deprotonation-*pro*-*R* is 6 kJ/mol smaller than the one for the abstraction of the *pro*-*S* hydrogen atom. This reflects the trend of the kinetically controlled experiment, where the epimer with the (*R*)-configured metallated centre is highly enriched (Scheme 2).[16] After the deprotonation reaction, two equilibria (epimerisations 1 and 2 in Scheme 1) can influence the distribution of the stereoisomers. This will be examined in the following subsection.

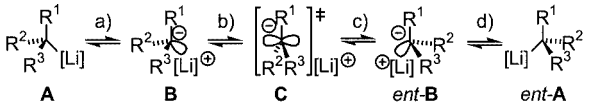
Thermodynamically Controlled Epimerisation — Stability of Configuration

In general, "carbanions" have a low barrier of inversion (they are isoelectronic with tertiary amines). Therefore, un-

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

substituted systems of this type lose their stereochemical information even at low temperatures. For the racemisation, the following process is assumed (Scheme 5), where the two enantiomeric alkyllithiums **A** and *ent*-**A** are interconverting by separation/fixation of the lithium centre (steps a and d) and the inversion of the configuration via the planar transition state **C** (steps b and c):

The two equilibria (epimerisations 1 and 2 in Scheme 1) can influence the distribution of the stereoisomers after the deprotonation reaction. The situations in non-polar and polar solution are, of course, different. While it is reasonable to imply a vacant coordination site at the lithium centre for non-polar solvents (Figure 5a, see also crystal structure in Figure 1), a polar solvent molecule, like diethyl ether, will complete the coordination sphere of the metal centre. This has been demonstrated in the case of amines by the X-ray structural analyses of $[(R,S)\text{-}\mathbf{2}]_2$·TMEDA and (*R*,*S*)-**2**·DABCO. Thus, the energies of the stationary points of the epimerisation were calculated with a three-coordinate lithium centre (epimerisation 1, Scheme 1; Figure 5a, Table 5) and a four-coordinate lithium centre with an additionally coordinated dimethyl ether and DABCO molecule (epimerisation 2, Scheme 1; Figure 5b and Figure 6, Table 5), to take this into account.



Scheme 5. Proposed racemisation process of enantiomerically enriched alkyllithiums: a) separation of the Li fragment; b) and c) inversion of the "carbanion" via a planar transition state; d) fixation of the Li centre

The two reaction products (*R*,*S*)-**2** and (*S*,*S*)-**2** (equivalent to **MIN-5** and **MIN-6**, epimerisation 1, Scheme 1; Figure 5a, Table 5) might be involved in an equilibrium process of interconversion. This process, which is undesirable for the kinetically controlled synthesis, is required for the

	MIN-8	9	9
DABCO *Epimerisation 3* DABCO **MIN-9** ⇌ **MIN-10**	**MIN-9**	0	0
	TS-5	76	79
	MIN-10	6	6

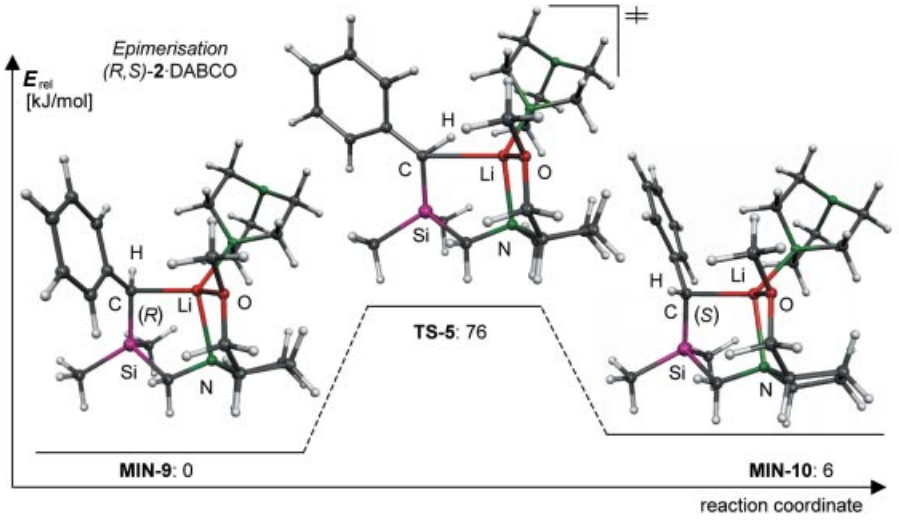

Figure 6. Relative-energy profile of stationary points **MIN-9**, **TS-5** and **MIN-10** for the epimerisation reaction (DABCO molecule coordinated) between epimers (*R*,*S*)- and (*S*,*S*)-**2**·DABCO, B3LYP/6-31+G(d)

thermodynamically controlled route, where typically a polar solvent is added.

Previous calculations and experimental NMR studies[5] have shown that the energies for removing the intramolecularly coordinating ligands from the lithium centre and for removing the lithium centre from the metallated carbon centre, are much higher than the energies discussed in Table 4 and 5. Therefore, it is reasonable to exclude a racemisation proceeding via dimeric structures or carbanions.

The energy differences of the stationary points **MIN-5**, **TS-3** and **MIN-6** (Figure 5a, Table 5) indicate that an epimerisation process at room temperature is unlikely to occur in a non-polar solvent. In this model system for (*R*,*S*)-**2** in that type of solvent with a vacant coordination site at the lithium centre, the activation barrier on the potential energy surface of epimerisation 1 is 93 kJ/mol.

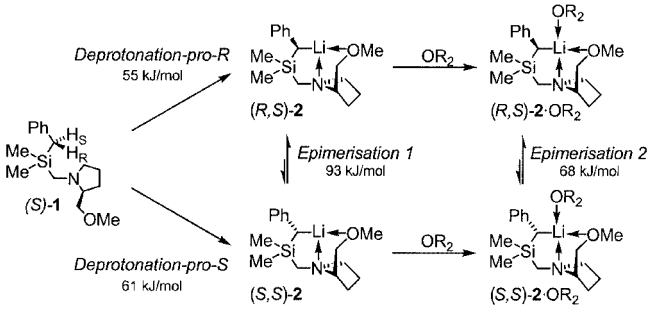
In the model system for (*R*,*S*)-**2** in a polar solvent with a coordinating dimethyl ether molecule at the lithium centre (epimerisation 2 in Scheme 1), the energy difference between **MIN-7** and **TS-4** is smaller by 25 kJ/mol. Furthermore, in contrast to the described non-polar case, there is an energy difference of 9 kJ/mol between both diastereomeric minimum structures **MIN-7** and **MIN-8**. Concluding these studies, in an ethereal solution, highly diastereomerically enriched (*R*,*S*)-**2** should be obtained by epimerisation at room temperature, while a diastereotopos-differentiating deprotonation without noticeable epimerisation should be possible in non-polar solution (under the described reaction conditions).

For (*R*,*S*)-**2**·DABCO, the corresponding calculations have been performed and lead to similar results. [Although a slightly increased inversion barrier is calculated for this

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compound, compared to the results with dimethyl ether, the energy difference between both epimers (*R*,*S*)-**2**·DABCO and (*S*,*S*)-**2**·DABCO decreases slightly]. For this experimentally accessible compound, the more stable epimer (*R*,*S*)-**2**·DABCO is the stereoisomer found in the solid state. Thus, experimental structural information can be correlated with the results of selective transformations and the corresponding quantum-chemical investigations.

The experiments with coordinating amine ligands and potentially coordinating ether molecules that have been described in the previous section show very high diastereoselectivities for substitution reactions in non-polar solvents. These results are supported by the quantum-chemical calculations applied on systems of this type (Scheme 6). The poor selectivities of reactions carried out in highly polar solvents, like THF, might not be explained by the calculation of gas-phase structures, since more polar structures are stabilised by the polar solvent environment. Phenomena like this do have an obvious impact on the equilibria and inversion barriers involved and could in an extreme case lead to a change in the reaction mechanism (e.g. orbital control, CIPE control, ionic reaction mechanisms).



Scheme 6. Relevant deprotonation reactions and epimerisation equilibria starting from (*S*)-**1** (including the quantum chemically calculated activation barriers for R = Me)

Stereochemical Course

The literature reveals that both retention and inversion of the configuration have been observed for the reactions of lithiated benzylic and related systems with various electrophiles.[17,3a,3e] In most cases no solid-state structure of the corresponding alkyllithium could be determined to support the absolute configuration of the stereogenic metallated carbon centre. The stereochemical course (inversion of the configuration) of the reaction of our alkyllithiums with the electrophile iodomethane in toluene can be understood on the basis of the solid-state structure of compound (*R*,*S*)-**2**·DABCO (crystallised from the same solvent as was used in the substitution reaction with the alkyl iodide) in combination with the computational studies.

The modelling of monomeric (*R*,*S*)-**2**·DABCO [B3LYP/6−31+G(d)] indicates that the highest occupied molecular orbital (HOMO) is chiefly located at the metallated carbon centre and the aromatic ring system (Figure 7). It can be deduced from the calculated orbital coefficients that both inversion and retention of the configuration are almost equally likely to result from electrophilic attack. Only the fact that the site opposite to the lithium centre is sterically accessible to attack by electrophiles makes it possible for (*R*,*S*)-**2**·DABCO to react selectively with inversion of configuration at C(3) under kinetic control in non-polar solvents.

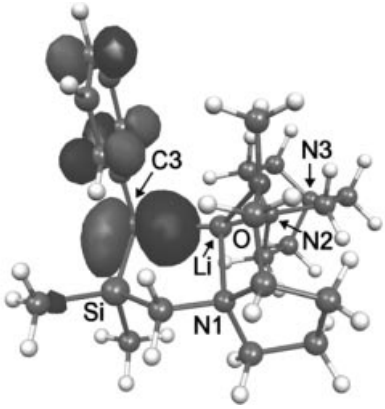


Figure 7. B3LYP/6−31+G(d)-optimised structure of monomeric (*R*,*S*)-**2**·DABCO and visualisation of the highest occupied molecular orbital (HOMO) (Molekel plot;[18] numbering scheme adopted from Figure 3)

Outlook

In a recent review article by Basu and Thayumanavan, the following quote on the main challenges in this research field can be found: "We believe that the first of these challenges is the development of a systematic structure-function relationship for the stereochemical behaviour of organolithium compounds. There have only been a few instances in which structural information about organolithium aggregates have been used as the starting point for the design of stereoselective lithiation/substitution sequences."[2a]

It is hoped that the correlation of experimental data, like stereoselectivities and the stereochemical pathways — especially results from solid-state structural analyses — will lead to a deeper understanding of the transformations of (highly diastereomerically enriched) alkyllithium compounds. It must always be of general interest to determine whether the results of such investigations may be of use in understanding the reaction pathways of alkyllithium systems, or if studies of systems like (*R*,*S*)-**2** and its derivatives are too specialised to set up common rules for the stereochemistry of this class of compounds.[19]

Experimental Section

Experimental Procedures: All reactions were carried out under an argon atmosphere using Schlenk tubes that had been flame-dried in vacuo. The solvents, including the NMR solvents, were dried according to common procedures. All NMR spectra were measured on a Bruker DRX-300 NMR spectrometer. Assignment of the signals was supported by DEPT135 and C,H-COSY experiments and

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the relative intensities of the resonance signals. Crystal structure determination of [(*R*,*S*)-**2**]$_2$·TMEDA: Stoe IPDS diffractometer (Stoe & Cie GmbH); data collection: Expose (Stoe & Cie, 1997); cell determination and refinement: Cell (Stoe & Cie, 1997); integration: Integrate (Stoe & Cie, 1999); numerical absorption correction: Faceit (Stoe & Cie, 1997). Crystal structure determination of (*R*,*S*)-**2**·DABCO: Bruker APEX-CCD (D8 three-circle goniometer) (Bruker AXS); data collection, cell determination and refinement: Smart version 5.622 (Bruker AXS, 2001); integration: SaintPlus version 6.02 (Bruker AXS, 1999); empirical absorption correction: Sadabs version 2.01 (Bruker AXS, 1999). The determination of the absolute configurations at the metallated stereogenic carbon centres of both compounds is unambiguous due to the fixed (*S*) configuration at the SMP substituent; for the achieved crystal quality of (*R*,*S*)-**2**·DABCO, the lack of a heavier atom than silicon does not allow a refinement of the absolute structure factor (Flack parameter) better than 0.2(2), indicating yet the overall refinement of the correct stereoisomer. The crystals of both compounds were mounted at −100 °C (N_2 stream), using the X-TEMP 2 device.[20] Both structures were solved applying direct and Fourier methods, using SHELXS-90[21] and SHELXL-97.[22] CCDC-210324 {[(*R*,*S*)-**2**]$_2$·TMEDA} and CCDC-210325 [(*R*,*S*)-**2**·DABCO] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; Fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Computational Methods: All calculations were carried out on gas-phase structures. Structure optimisations at the B3LYP/6−31+G(d) level were performed using GAUSSIAN 98.[13] The basis for the starting structures were the coordinates of the X-ray structural analyses of (*R*,*S*)-**2** and (*R*,*S*)-**2**·DABCO; different starting conformers [C(3)−C(4) bond] were also investigated. Selected bond lengths [Å] and angles [°] of the optimised structure (*R*,*S*)-**2**·DABCO: Si−C(3) 1.832, Si−C(10) 1.941, Li−C(3) 2.211, Li−N(1) 2.206, Li−N(2) 2.170, Li−O 2.047, C(3)−C(4) 1.451, C(3)−Si−C(10) 108.5. For all transition states, only one imaginary frequency was found. For the deprotonation reactions, the vibrational modes corresponding to the imaginary frequency were in the direction of the C(3)−H bond dissociation. For the epimerisation reactions, the vibrational modes corresponding to the imaginary frequency were in the direction of the inversion of the configuration at C(3). IRC calculations (intrinsic reaction coordinate) were performed at the HF/3−21G level of theory.

[(*R*,*S*)-2]$_2$·TMEDA: A solution of (aminomethyl)benzylsilane [(*S*)-**1**; 450 mg, 1.62 mmol] and TMEDA (94.0 mg, 810 μmol) in *n*-pentane was combined with 950 μL (1.62 mmol) of a solution of *t*BuLi in *n*-pentane (1.7 M) at −90 °C. Upon warming to room temp. the lithium compound [(*R*,*S*)-**2**]$_2$·TMEDA was obtained as a microcrystalline orange powder. Whilst stirring at room temp., toluene was added dropwise until a solution was obtained. The yellow solution was kept at −30 °C. After 14 days at −30 °C [(*R*,*S*)-**2**]$_2$·TMEDA was obtained as orange-coloured single-crystals suitable for X-ray structural analysis (yield: 509 mg, 745 μmol, 92%). ^{1}H NMR (300.1 MHz, $C_6D_5CD_3$): δ = 0.27 (s, 6 H, SiCH_3), 0.31 (s, 6 H, SiCH_3), 1.29−1.58 (m, 8 H, CH_2), 1.82 [br, 2 H, SiC(*H*)Li], 1.89−2.04 (m, 18 H, NCH_3, NCH_2C, NC*H*), 2.11−2.28 (m, 4 H, NCH_2CH_2N), 1.45, 2.56 (AB-System, $^2J_{A,B}$ = 14.3 Hz, 2 H, SiCH_2N), 2.64 (ABX-System, unresolved, 2 H, CH_2O), 2.67 (s, 6 H, OCH_3), 3.03−3.19 (m, 2 H, CH_2), 3.24 (ABX-System, unresolved, 2 H, CH_2O), 6.19−6.23 (m, 2 H, aromat. H), 6.64−6.67 (m, 4 H, aromat. H), 6.90−6.97 (m, 4 H, aromat. H) ppm. ^{7}Li{^{1}H} NMR (116.6 MHz, $C_6D_5CD_3$): δ = 0.46 ppm. ^{13}C{^{1}H} NMR (75.5 MHz, $C_6D_5CD_3$): δ = −1.6 (2C, Si*C*H$_3$), 0.9 (2C, Si*C*H$_3$), 22.1 (2C, *C*H$_2$), 26.6 (2C, *C*H$_2$), 36.7 (2C) [Si*C*(H)Li], 45.8 (4C, N*C*H$_3$), 47.8 (2C, Si*C*H$_2$N), 57.1 (2C, N*C*H$_2$*C*H$_2$N), 57.8 (2C, N*C*H$_2$C), 58.7 (2C, O*C*H$_3$), 67.3 (2C, N*C*H), 70.8 (2C, *C*H$_2$O), 108.6 (2C, *C*-p), 119.9 (4C, *C*-m or *C*-o), 137.4 (4C, *C*-o or *C*-m), 157.3 (2C, *C*-i) ppm. ^{29}Si{^{1}H} NMR (59.6 MHz, $C_6D_5CD_3$): δ = −13.2 ppm.

(*R*,*S*)-2·DABCO: A solution of (aminomethyl)benzylsilane [(*S*)-**1**; 440 mg, 1.59 mmol] and DABCO (179 mg, 1.59 mmol) in *n*-pentane was combined with 935 μL (1.59 mmol) of a solution of *t*BuLi in *n*-pentane (1.7 M) at −90 °C. Upon warming to room temp. lithium compound (*R*,*S*)-**2**·DABCO was obtained as a microcrystalline yellow powder. Whilst stirring at room temp., toluene was added dropwise until a solution was obtained. The yellow solution was kept at −30 °C. After 21 days at −30 °C (*R*,*S*)-**2**·DABCO was obtained as yellow single-crystals suitable for X-ray structural analysis (yield: 744 mg, 1.53 mmol, 96%). ^{1}H NMR (300.1 MHz, $C_6D_5CD_3$): δ = 0.24 (s, 3 H, SiCH_3), 0.41 (s, 3 H, SiCH_3), 1.19−1.41 (m, 4 H, CH_2), 1.43, 2.60 (AB-System, $^2J_{A,B}$ = 14.2 Hz, 2 H, SiCH_2N), 1.78 [br, 1 H, SiC(*H*)Li], 1.85−2.07 (m, 2 H, NC*H*, NCH_2), 2.42 (s, 12 H, NCH_2CH_2N), 2.60 (s, 3 H, OCH_3), 2.97−3.00 (ABX-System, unresolved, 1 H, CH_2O), 2.97−3.06 (m, 1 H, NCH_2), 3.33−3.39 (ABX-System, unresolved, 1 H, CH_2O), 6.31−6.36 (m, 1 H, aromat. H), 6.69−6.72 (m, 2 H, aromat. H), 7.10−7.19 (m, 2 H, aromat. H) ppm. ^{7}Li{^{1}H} NMR (116.6 MHz, $C_6D_5CD_3$): δ = 0.45 ppm. ^{13}C{^{1}H} NMR (75.5 MHz, $C_6D_5CD_3$): δ = −2.2 (br., Si*C*H$_3$), 0.7 (Si*C*H$_3$), 22.8 (*C*H$_2$), 26.6 (*C*H$_2$), 34.5 [Si*C*(H)Li], 47.8 (6C, N*C*H$_2$*C*H$_2$N), 48.1 (Si*C*H$_2$N), 57.9 (N*C*H$_2$), 58.8 (O*C*H$_3$), 67.7 (N*C*H), 70.3 (*C*H$_2$O), 108.6 (*C*-p), 124.3 (2C, *C*-m or *C*-o), 128.9 (2C, *C*-o or *C*-m), 157.5 (*C*-i) ppm. ^{29}Si{^{1}H} NMR (59.6 MHz, $C_6D_5CD_3$): δ = −13.6 ppm.

Absolute electronic energies [B3LYP/6−31+G(d)] including ZPVE correction (uncorrected values in brackets): **MIN-1** −1210.329989 (−1210.85396686), **MIN-2** −1210.367902 (−1210.89273147), **TS-1** −1210.309066 (−1210.82931116), **MIN-3** −1210.330119 (−1210.85397884), **MIN-4** −1210.362321 (−1210.88757733), **TS-2** −1210.306980 (−1210.82688289), **MIN-5** −1052.035771 (−1052.42846659), **MIN-6** −1052.035924 (−1052.42849744), **TS-3** −1052.000391 (−1052.39218728), **MIN-7** −1207.002773 (−1207.47727275), **MIN-8** −1206.999447 (−1207.47375891), **TS-4** −1206.973602 (−1207.44687856), **MIN-9** −1397.204510 (1397.78271366), **MIN-10** −1397.202535 (−1397.78059515), **TS-5** −1397.175908 (−1397.75282437).

Acknowledgments

We are grateful to the Institut für Anorganische Chemie der Universität Würzburg, the Deutsche Forschungsgemeinschaft (DFG), the Sonderforschungsbereich 347, the Graduiertenkolleg 690, and the Fonds der Chemischen Industrie (FCI) for financial support. D. S. and K. W. thank the FCI for the grant of two scholarships. Furthermore we acknowledge Wacker-Chemie GmbH for providing us with special chemicals.

[1] Remark: In general, we speak of *enantiomerically enriched* metal alkyls when we focus our interest on the stereogenic metallated carbon centre, whereas these molecules are almost always *diastereomerically enriched* metal alkyls, due to the presence of more stereogenic centres than only the metallated one.

[15] All corrected and uncorrected electronic energies are given relative to **MIN-1**.

[16] At this point, the influence of the indispensable correction of all optimised structures by the *zero-point vibrational energy* (ZPVE) becomes obvious, since it decreases the absolute energies of the transition states more than those the minimum structures. This, and the computational method itself, significantly affect the electronic part of the activation energy. Thus, conclusions, deriving from too accurate comparisons of calculations with experimental data have to be drawn very carefully but can be found in the literature time and time again.

Keywords: Solid-state structures / Lithium / N ligands / Carbanions

The hemi-solvated C_2-symmetric 1,3-diamidolithium *l*-[$CMe_2\{CHMeN(R)\}_2Li_2\cdot OEt_2$] has been crystallographically characterized. It reacts with oxygen to form the N-N ring-closed pyrazolidine *l*-[$(RNCHMe)_2CMe_2$]. The slightly bulkier C_s-symmetric amidolithium *u*-[$CMe_2\{CHMeN(R')\}_2\cdot Li_2$] forms an unsolvated 1:2 heterocubane complex with *n*BuLi in the solid state and in solution, as determined by X-ray crystallography and multinuclear NMR spectroscopy (R = 2-*i*Pr-C_6H_4; R′ = 2,6-*i*Pr$_2$-C_6H_3).

Introduction

The basis for the solid-state study of the aggregation behaviour of secondary amidolithium and organolithium compounds was set in two major reviews some years ago.[1,2] Given the massive growth of interest in the intervening years, it comes as little surprise that investigation of mixed aggregates containing each of these two key weapons in the modern arsenal of synthetic chemistry has developed rapidly. There are now a good number of mixed lithium aggregates containing both carbanions and secondary amido groups. Seminal solution-phase studies[3] have been augmented by theory[4] and by a number of X-ray crystallographically characterized examples. The solution-phase studies indicate that a complicated, equilibrating mixture, containing some unmixed homo-aggregate of one or both components, is commonly in existence, such that attempts to crystallise components of the mixture offer no guarantee of isolation of a mixed aggregate. Most crystallographic studies circumvent this problem by placing the carbanion and nitrogen-anion centres on the same covalent framework.[5] There are only a very small number of solid-state studies not invoking such C/N dianions in order to isolate mixed species.[6] We present here an additional example, different in a number of key respects from those reported previously. We have isolated this first solid-sate unsolvated 2:2 amido/organolithium tetralithium cluster by lithiation of a new class of diamine ligand. Diamines,[7] including, as in our examples, 1,3-diamines,[8] have also enjoyed much previous interest from lithium structural chemists, but ours differ from almost all previous structurally characterized examples in that they are C_2 or C_s symmetric, as opposed to the common C_{2v} case, and incorporate a higher degree of substitution into the chain linking the two amido centres than has previously been the case. There is but a single precedent for a crystallographically characterized C_2-symmetric dilithiodiamide.[7c] We report a hemi-solvated dilithiated diamine, and its novel oxidative ring-closure reaction to yield a C_2-symmetric pyrazolidine. The isolation of this product has implications for the mechanism of formation of the remarkable "inverse crown ether" class of compounds developed by Mulvey and co-workers.[9]

In addition to the above-cited precedents in organo/amido mixed aggregates, there are increasing numbers of examples where *n*BuLi is incorporated into P-N, As-N, Al-N and other main-group cluster species.[10] These have yet to mirror the synthetic utility of more conventional secondary amidolithiums, though,[3d,4b,11] and so it is secondary amidolithium compounds which remain our focus.

Results and Discussion

Lithiation in hexane of *l*-(2-*i*Pr-$C_6H_4NHCHMe)_2CMe_2$, an amine derived from a diastereoselective hydroboration[12] of a 1,3-diimine,[13] produced a pale cream precipitate, which would only redissolve upon addition of a coordinating solvent. From a solution containing diethyl ether, crystals of *l*-[(2-*i*Pr-$C_6H_4NHCHMe)_2CMe_2Li_2{\cdot}OEt_2$] (**1**·$OEt_2$), deposited. Its structure was determined by X-ray crystallography, and is depicted in Figure 1; selected geometric parameters are listed in Table 1.

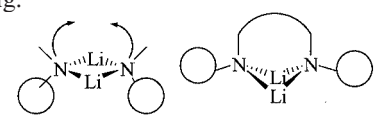
Only a single diethyl ether molecule is incorporated into the structure, which is comprised of a single diamido unit with a central Li_2N_2 ring. This most common motif[1] is in this case rather puckered [torsion angle Li(1)−N(3)−Li(2)−N(1) = −34°]. This butterfly conformation is characteristic of *di*amides,[7,8] where the linking group draws together the two N-vertices of the Li_2N_2 ring, pushing the lithium atoms downwards as shown below. Also apparent from this scheme is the reason that cyclic diamidolithium complexes often defy the ring-laddering prediction, since the projection of one of the substituents of the secondary amine into an axial position, which prevents ring stacking, thus favouring ring laddering,[1] is converted into an equatorial projection by the constraint of the diamido ring.



Evident from a comparison of the structures of **1**·OEt_2 and its protonated secondary amine precursor[12] is the fact that the conformational preferences of the organic portion are dominant. The organic portions of the structures map closely, since in the diamine, an H-bonded ring is present. The N−N distance of 2.89 Å in **1**·OEt_2 matches that of 2.84 Å in the NH precursor.[12] Because of the two lithium atoms bonded to each nitrogen atom, the ring in **1** can at once be described as both a boat and a chair. The axial/equatorial arrangement of the methyls attached to the two chiral centres is also identical in metallated and unmetallated forms. Crystallographic symmetry generates the molecule of opposite polarity in this racemic crystal. In the only other dilithiated C_2-symmetric diamine,[7c] the 1,2 diamidolithium *l*-[Li{*t*BuN$(CHMe)_2$N*t*Bu}Li], which, like most dilithiated diamines, defies Snaith's laddering principle by adopting a stacked, dimeric structure, disorder of both enantiomers confused the issue of conformation, and of whether in its dimeric structure, like or unlike enantiomers aggregated. It was synthesised by the rather different route of diastereoselective double carbolithiation[7c] of the parent 1,2-diimine *t*BuN$(CH)_2$N*t*Bu. The parent 1,3-diimines from which **1** is derived do not undergo similar carbolithiation or carbozincation reactivity.[14]

Included in the previous examples of stacked diamidolithium structures is a case involving a 1,3-diamine linkage: [Li{$Me_3SiN(CH_2)_3NSiMe_3$}Li]$_2$ was obtained as an unsolvated stack, reminiscent of the 1,2 cases discussed above.[8b] Complex **1** differs from all of these cases in the fact that it precipitates as an insoluble (presumably polymeric) powder from hexane. In this behaviour, it mimics the less-bulky amides which gave rise to the ring laddering principle.[1] The possibility that **1** aggregates in a ladder form is supported by close inspection of its structure. Unusually for an arylamidolithium,[15] the aryls are almost coplanar with the CNC planes (dihedral angles of −16.4° on the side bearing the equatorial methyl, and 2.1° on the axial methyl side). This facilitates π-interaction of the amido density into the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

aromatic ring, as shown by the relatively short (aryl)C−N bonds (mean 1.38 Å, cf. 1.43 Å for orthogonal rings; see later). This coplanarity is optimal for lateral packing (laddering), while both isopropyl groups are in a position which would make stacking difficult. This perhaps explains the insolubility of **1** in non-donor solvents, despite its relative bulk.

Nevertheless, **1** crystallizes with only a single molecule of diethyl ether coordinated to Li(2), rendering it three-coordinate, while Li(1) remains merely two-coordinate. A fairly close CH···Li interaction is present across the boat-ring. This sort of interaction is quite frequently found to low-coordination number lithium atoms,[16] but it is more usually a C_α or C_β interaction, as in [(*n*BuLi)$_6$], for example (see later).[17] To find a C···Li distance of 2.49 Å to a C_δ carbon is without precedent.[16] However, we tend toward the view that the short "δ-agostic" interaction is a consequence of the high degree of puckering of the boat conformation in the C_2N_2Li ring, rather than a cause of it. The hemisolvated nature of the Li_2N_2 ring has some precedent; in [$C_{10}H_6$(N{Li(THF)}$SiMe_3$){N(Li)$SiMe_3$}], also a 1,3-diamidolithium, though one with a planar aromatic core, a single lithium is coordinated by THF, while the other engages in π-interactions with a neighbouring molecule.[8a] Similar situations obtain in doubly lithium-reduced diazadiene complexes.[7e] In **1**, the only such stabilizing interaction is the aforementioned "δ-agostic" one.

The exposed nature of the low-coordinate lithium may be a factor in the reactivity of compound **1**. Interestingly, a similarly exposed, bent two-coordinate lithium is present in [LiMg{N($SiMe_3$)$_2$}$_3$],[9a] which has been shown to be extremely sensitive to traces of oxygen, generating the first case of the remarkable oxo-centred "inverse crown ether" cluster class.[9b] It has, however, never been established without doubt that the oxo-centre of the clusters was a result of reduction of dioxygen, because it was not possible to unambiguously identify the partner product of oxidation, the presumed substituted hydrazine {N($SiMe_3$)$_2$}$_2$, in the reaction mixtures.

We find the opposite scenario to pertain for **1**: significant amounts of the stable, crystalline product of oxidative N-N ring closure, the substituted pyrazolidine **2**, were found in aged solutions of **1**, and in reaction products where **1** was employed as an intermediate, whereas we have not isolated oxide-containing aggregates. It was subsequently shown that exposure of solutions of **1** to dry oxygen generated significant yields of **2**. While we have yet to identify oxo-centred lithium clusters in our products, this first clear proof of oxidative N-N coupling of secondary amidolithium compounds is strong indirect evidence supporting the mechanism proposed by Mulvey and co-workers for the generation of inverse crown ethers.[9]

Normal routes to pyrazolidines involve additions across an N−N π-bond.[18] In 1994, Nelsen et al. reported a curious reaction in which two molar equivalents of *t*BuLi were reacted with a polycyclic secondary bis(chloroamine) to yield an N−N bonded species,[19] but in this case the rings formed in the ring closure were four- and six-membered. The mechanism of this reaction was not discussed. It seems that our route to pyrazolidines is new. Structurally (see Figure 2), there is little remarkable in **2**; the conformation and bonding parameters (Table 2) are as expected; an approximate C_2 axis passes through the mid-point of the N−N bond and the C(3) atom. C(2), C(3), and C(4) are coplanar; the ring puckers above and below this plane at the pyramidalized N(1) and N(2) centres, in which the neighbouring lone pairs adopt an antiperiplanar arrangement.[19] This allows both methyls on the chiral carbon to adopt equatorial positions. The crystals are racemic.

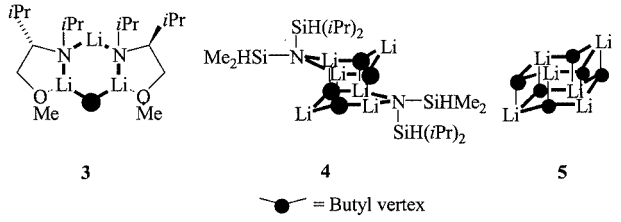
Turning now to mixed aggregates containing amido units akin to **1**, by far the most common means of achieving mixed carbanion/N-aggregation in the solid state is to tie both anionic centres together in the same molecule, i.e. to use heterodentate C/N dianions.[5a−5e] Rather less common are genuine mixed aggregates of independent carbanion and amido anion, where the thermodynamic balance between homo-aggregates and mixed aggregates is often a fine one, as evidenced by the observance of mixtures in solution.[3] The enthalpy-neutrality of the formation of mixed dimer

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

over homodimer has been demonstrated computationally for simple amido and carbanion groups.[4a] However, by appropriate choice of ancillary donor atoms and/or steric bulk, it has proven possible in a few cases to isolate heterocomponent amidolithium/*n*-butyllithium aggregates.[6] In addition, there are two examples where C/N dianions are co-aggregated with Ph_2N monoanions and/or *n*-butyl carbanions in a large cluster,[5f,5g] and another example where an anti-fluorite-like cluster of $(C_6H_5C_6H_4)NLi_2$ is stabilized by a methanide anion.[20] All of these are ether-solvated.

We restrict our discussion to simple cases of solid-state co-aggregation of secondary amidolithium species with organolithium species. In this category there are only two structural types in existence (see below), **3** and **4**.[6] Isostructural analogues of **3** containing *sec*- and *tert*-butyllithium are also known.[6a] The structure of the homoaggregate, $[(n\text{BuLi})_6]$ (**5**) is shown for comparison.[17]



Use of an excess of *n*BuLi in the metallation of the bulkier, C_s-symmetric *u*-(2,6-$i\text{Pr}_2$-C_6H_3NHCHMe)$_2$$CMe_2$ in hexane afforded a solution from which the mixed organo/amidolithium compound **6** crystallized. Its structure (Table 3 and Figure 3) is that of a heterocubane, in which a dimer of *n*BuLi stacks with a diamidodilithium unit similar to that in **1**. The incorporation of bulk in both *ortho* positions on the phenyl rings, and the *u*-(*meso*) diastereochemistry of the diamide, results in conformational differences: both of the chiral carbons can now direct their methyl substituents into equatorial positions while maintaining the dual boat/chair character of the ring. This forces both aryls to pack in an approximately orthogonal disposition with respect to the average plane of the $N_2C_3Li_2$ pair of rings. In turn, this facilitates a stacked packing arrangement. However, key to the isolation of a mixed organo-amido complex is the fact that the extreme bulk of the 2,6-diisopropylphenyl substituents still precludes such a stacking arrangement in a homo-aggregate of amidolithium units; in order to relieve steric strain, it is the less demanding *n*BuLi units which are pressed into service to complete the stable, heterocubane arrangement. Looking from the other perspective, this is a case where the extra bulk of the amido unit forces *n*BuLi to adopt a role in a tetrameric aggregate, whereas in a homo-aggregate of *n*BuLi a hexameric stack of two trimeric rings is preferred.[17]

Unfortunately, attempts to isolate a homoaggregate of the 1,3-diamido unit in **6** resulted only in isolation of oils, though a similar 1,2-diamidolithium, with identical 2,6-diisopropylphenyl substituents, has been characterized.[7b] It is a rare example of an unsolvated four-runged step-ladder (the extreme bulk limits growth of the ladder in this case),

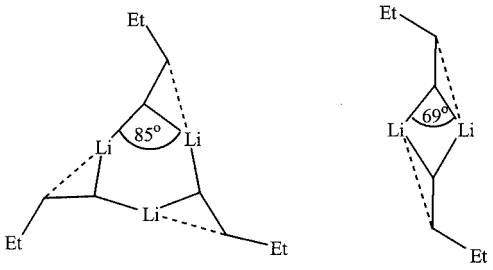
and it seems reasonable to assume a similar arrangement would occur for the 1,3 analogue. In such an aggregation mode, only two lithiums attain three coordination, the other two having to limit themselves to two-coordination, augmented by aryl-Li interactions. Just such a situation occurs

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in an arched unsolvated limited ladder attained by lithiation of a trimethylsilyl-substituted benzyldiamine.[8c] Incorporation of *n*BuLi into the aggregate **6** allows for more stabilizing electrostatic interactions, all four lithium atoms attaining three coordination. The energetic cost of this to the *n*BuLi fragment is modest. It finds itself in a very similar arrangement to that of its homoaggregate, capping a triangular face of lithium atoms, to use the traditional terminology for the description of organolithium structures.[17] In this mode of description, **5** is viewed as an octahedral array of lithium atoms with six of its faces capped by butyl anions. In the same way, the mixed aggregate **4** is described as an octahedron in which four faces are capped by butyl anions, and two edges are capped by amido anions. We prefer to describe the structures on the basis of the electrostatic interaction which hold them together, rather than the Li−Li framework, which has been shown not to be involved in bonding.[21] Re-examination of **5** in this way reveals a view of it as a stack of cyclic trimers. The inter-trimer distances are systematically longer than the intra-trimer ones.[22] Each six-membered ring adopts a flattened chair conformation. The extra bulk of the amido groups in **4** is inconsistent with stacking, but they can be accommodated without distorting the structure unduly simply by flipping one corner of each six-membered ring, so that each is in a boat, rather than a chair, conformation. This generates room for all four butyl groups to direct their secondary interaction to the two lithium atoms that are left two-coordinate by the cleavage of the two stacking interactions. Further stabilization through SiH−Li interactions help to favour the mixed aggregate **5**, despite the fact that the stoichiometry employed in its preparation was far from 1:2.[6b] In the synthesis of **6**, we originally employed a 2:1 N:*n*Bu ratio, hoping to isolate unsolvated versions of compound **3**, but in our hands also, there was no stoichiometric control over the product identity. This is generally true of all mixed aggregate syntheses in s-block chemistry. The key to the unusual stoichiometry of **3** is clearly in the internal solvation and high degree of bulk, which destabilize the homoamide aggregate in favour of incorporation of a single unit of organolithium.[6a] All of these factors must be considered for the successful isolation of solid state mixed aggregates. Though in ether solutions, cubic amido-organoaggregates similar to **6** have been previously characterized by NMR spectroscopy,[3b,3c,3e] they are generally components of mixtures. Synthetic studies have shown that incorporation of *n*BuLi into the mixed aggregates often increases its reactivity, and where the amidolithium unit is chiral, asymmetric induction can be observed in additions of *n*BuLi across carbonyl bonds.[11]

This might be partially explained by a closer inspection of the structure of **6**. It has a δ-agostic interaction between C(7) and Li(1) even shorter (2.40 Å) than that in **1**, possibly as a result of flattening of the butterfly (torsion = −31°, a decrease of 3° with respect to **1**·OEt_2) by the steric influence of the $(n\text{BuLi})_2$ ring, and a more conventional β-agostic interaction between C(33) and Li(4), separated by 2.33 Å. This is longer than the β-agostic distances in **5** (2.28 Å on average), because all those distances in **5** involved interactions *within* each trimeric ring.[17] The Li−C−Li angles at the bridging carbons in the trimeric rings of **5** average 85°, whereas those in the dimeric ring found in **6** average 69°. Lithium-β-carbon distances are therefore trigonometrically predetermined to be longer in tetramers (stacks of dimers) than in hexamers (stacks of trimers), as shown schematically below. This may be linked to higher reactivity.



Similar β-agostic distances to that in **6** are found in $[(n\text{BuLi})_4(t\text{BuOLi})_4]$, in which $(n\text{BuLi})_2$ units cap either end of a folded (*t*BuOLi) octagon.[23] In fact, there is only a single conventional β-agostic interaction in **6**, shown in Figure 4. The other butyl chain is excluded by the bulky substituents, a result of the C_s symmetry of the backbone, telegraphed via the conformation of the aryl rings, and the δ-agostic interaction to C(7) differentiating either side of the $(n\text{BuLi})_2$ unit. Aryl-Li interactions are probably more important in stabilizing the structure of **6**: *ipso*-C(aryl)···Li distances of 2.318(3) and 2.369(3) Å are in the normal range for such interactions.[7b] Despite the fact that in all structures the hydrogen atoms were freely refined, no statistically meaningful systematic lengthening of C−H bonds is seen for hydrogens with short H···Li contacts.[16]

The above discussion presupposes that **6** can be rationalized as a stack of amidolithium dimers with butyllithium dimers. The Li−N distances support this view, those within the Li_2N_2 butterfly [1.977(3)−2.041(3) Å] being systematically shorter than the stacking N−Li distances [2.180(3) and 2.182(3) Å].[1] However, the Li−C distances involving the carbanionic centres of the $(n\text{BuLi})_2$ unit are in the range 2.178(3)−2.224(3) Å, and the stacking interactions lie within the *lower* part of that range [2.182(3) and 2.185(3) Å]. There is, therefore, little basis for viewing the $(n\text{BuLi})_2$ unit as an independent entity within the cluster. Rather, the molecule is an integrated whole. The rather longer-than-expected C−Li distances within the $(n\text{BuLi})_2$ "dimer" might be explained by a slight elongation of the Li(3)···Li(4) distance {2.506(4) Å, cf 2.42 Å in $[(n\text{BuLi})_4(t\text{BuOLi})_4]$ and 2.43 Å in **5** for the equivalent distances}[17,23] in order for those two lithium atoms to engage most effectively in the stacking interactions with N(1) and N(2).

Given the extent of previous interest in the solution-phase behaviour of mixed amidolithium/butyllithium aggregates,[3] and the fact that reactions of such aggregates have hitherto been performed only in solution,[11] a limited NMR investigation of **6** was undertaken. The signals in the NMR spectra are broad at room temperature. The best-

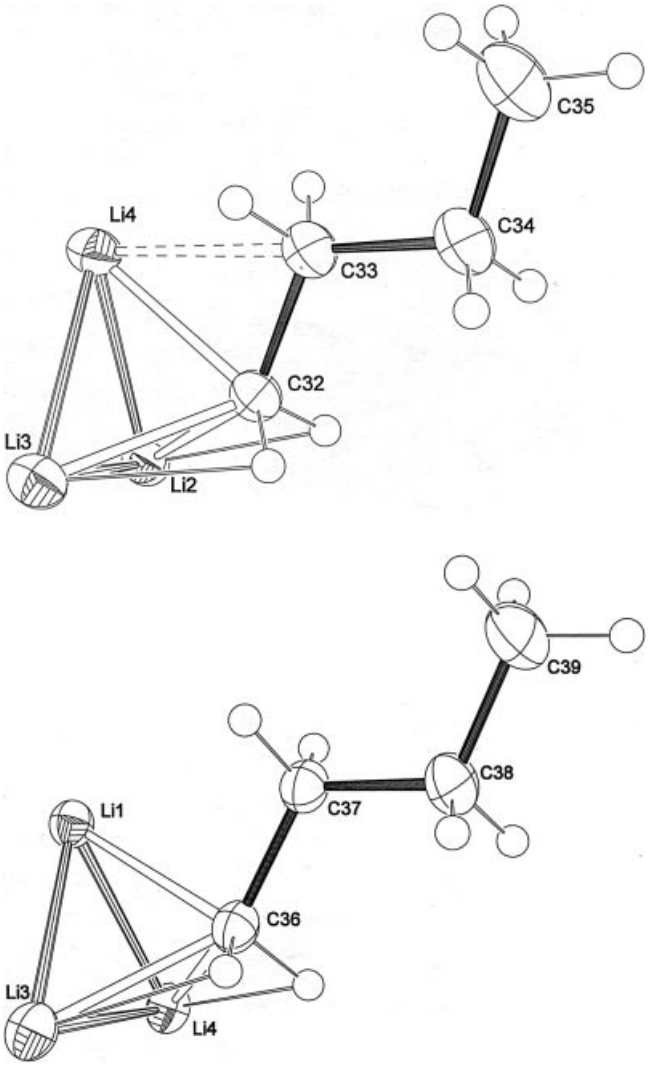

Figure 4. Views of the two butyl anions (top) including normal Cβ interaction to the lithium with shortest bond to Cα and (bottom) lacking Cβ interaction due to steric effect of C(7)

resolved data were obtained at −40 °C. It is reasonable to assume that the puckering of the central $C_3N_2Li_2$ ring is maintained, since flexing into the alternative conformation [C(7) equatorial] would place a total of three methyl groups and one lithium atom, as well as the isopropyl substituents on each aryl, into axial positions. It is deemed highly unlikely that this conformation would be populated to any appreciable extent. Therefore, the environments of Li(1) and Li(2) should remain well-distinguished. Li(3) and Li(4), being related by the approximate molecular C_s symmetry plane, are less likely to exhibit distinct chemical shifts. At −40 °C a ^{7}Li NMR spectrum consistent with this model, i.e. three signals in the ratio 1:1:2, is observed. In the ^{1}H NMR spectrum at −40 °C, two high-field signals in the *n*BuLi C_α region are observed. Both show a characteristic non-first-order envelope which has previously been associated with restricted rotation about the $C_\alpha-C_\beta$ bond of the butyl anions.[24] It is observed here at significantly higher temperature than in the other studies, which were performed in ether solvents.[3,24] It may be that the bulky amide substituents help to hinder such rotation. In any case, the presence of two types of butyl is consistent with the molecular symmetry of **6**. The other butyl signals are partially obscured by the methyl region, but the integrals of the resolved peaks match for two distinct α-carbons for each amido ligand, of which there is only one type. The observance of two distinct isopropyl methine resonances in the ratio 1:1 shows that the aryl-N bonds are fixed. An interesting feature of the ^{1}H NMR spectrum is the observance of a quintet at δ = 0.2 ppm. This is tentatively assigned (attempts at ^{1}H-^{1}H COSY failed for these broad, weak peaks) to the β-carbon of an atypical butyl group. For **5** in toluene, and for $(n\text{BuLi})_4$ in THF, this proton environment resonates around δ = 1.5 ppm. The marked shift in what must either be the β- or the γ-proton environment into a region which is silent in all other observed spectra of *n*BuLi fragments suggests an unusual situation.[3,24] Given that close β-C(H)···Li contacts are reported in all other *n*BuLi fragments discussed above, but are absent in one of the butyls in **6**, we tentatively ascribe the anomalous shift to the absence of the agostic-type interaction. More normal β, γ and δ environments were also observable, but not all eight expected butyl peaks could be identified due to crowding in the δ = 0.9−1.7 ppm region. The different butyl environments were less-easily distinguished in the ^{13}C NMR spectrum, but such resonances as could be discerned were consistent with the maintenance of the structure **6** in solution. It should be stressed, however, that alternative models of behaviour, such as expulsion of one *n*BuLi unit from **6** to form one sixth of an equivalent of **5** (matching of some of the butyl resonances to **5** in toluene was quite close, but not identical), and reversion of the remaining cluster to a structure analogous to **3**,[6a] cannot be ruled out. There was fluxionality evident (e.g. coalescence of the different butyl environments at 0 °C), but detailed solution studies lie outside the scope of this predominantly solid-state investigation.

Unfortunately, the *l*-diastereomer of the bulkier amine used in **6** is inaccessible due to the difficulty in deboronating the hydroboration intermediate,[12] but, given the encouraging results that have been obtained by others in enantioselective syntheses using mixed aggregates of chiral amines,[11] we feel justified in pressing on with resolution of the amine used in **1**, and its employment in mixed aggregate synthesis. There may yet prove to be a role for the C_s-symmetric amine used in **6** in the promotion of syndiotacticity in alkene polymerization, where titanium complexes of 1,3-diamido ligands identical to that in **6** but for the de-symmetrizing methylene backbone substituents, have shown promise.[25]

Experimental Section

All manipulations were carried out under a protective argon blanket, either in a double manifold argon/vacuum line or argon-filled recirculating glovebox. Argon was dried over phosphorus pentoxide supported on vermiculite. Toluene and diethyl ether were used freshly distilled under argon from sodium-benzophenone ketyl; in the case of hexane, approximately 5% tetraglyme was added in order to dissolve the sodium-benzophenone ketyl. $CDCl_3$, C_6D_6,

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

C_7D_8 and [D_8]THF were stored over freshly activated 4 Å molecular sieves. The hexane solution of *n*BuLi was used as received and standardised using *N*-benzylbenzamide.[26] *u*-*N*,*N*′-bis(2,6-diisopropylphenyl)-3,3′-dimethylpentane-2,4-diamine and *l*-*N*,*N*′-bis(2-isopropylphenyl)-3,3′-dimethylpentane-2,4-diamine were prepared by literature methods.[12] All other reagents were obtained from standard commercial vendors and used as received.

Melting points were determined in sealed glass capillaries under argon. Elemental analyses were performed by the microanalytical group in the Chemistry Department at UMIST.

Chemical shifts are given in ppm and referenced to residual solvent shifts for ^{13}C and ^{1}H; ^{7}Li spectra were referenced to 0.1 M LiCl in D_2O. Assignments were made with the aid of DEPT and HMQC experiments. Infrared spectra were recorded on a Nicolet Nexus-FTIR/Raman spectrometer using NaCl plates and nujol mulls.

***l*-[(2-*i*Pr-C_6H_4NCHMe)$_2$CMe$_2$Li$_2$·OEt$_2$] (1·OEt$_2$):** *n*BuLi (16.0 mL of a 1.51 M hexane solution, 24.16 mmol) was added to a stirring solution of *l*-[(2-*i*Pr-C_6H_4NHCHMe)$_2$CMe$_2$ (4.03 g, 11.0 mmol) in hexane (30 mL) at room temperature. Initially, a pale orange solution was obtained, but over a stirring period of 5 minutes, a cream precipitate deposited. Heating to boiling did not induce re-dissolution. To the cream precipitate was added diethyl ether (65 mL, in 5 mL volumes) over a 10 minute period until the precipitate had dissolved. The resulting dark orange solution was cooled to −45 °C yielding crystals of dilithiated amido complex **1**·OEt$_2$. Isolation by filtration in vacuo resulted in a decrease in crystal quality, associated with loss of coordinated diethyl ether. Isolated material (2.84 g, 57% based on the formulation [2-*i*Pr-C_6H_4NCHMe)$_2$CMe$_2$Li$_2$.OEt$_2$]) was poorly soluble in deuterobenzene. M.p. 160−163 °C dec. $C_{29}H_{46}Li_2N_2O$ (452.6): calcd. C 77.0, H 10.2, N 6.2; found C 79.0, H 10.1, N 6.6. Poor agreement due to diethyl ether loss. ^{1}H NMR (300 MHz; [D_8]THF, 35 °C): δ = 1.08 [br. s, 6 H, NCHMeC(*Me*)$_2$CHMeN],1.12 (d, 6 H, *Me*CHMe), 1.17 [d, 6 H, NCH*Me*C(Me)$_2$CH*Me*N], 1.31 (d, 6 H, MeCH*Me*), 2.69 (sept., 2 H, MeC*H*Me), 3.96 [q, 2 H, NC*H*MeC(Me)$_2$C*H*MeN], 7.00 (dd, 2 H), 7.10 (td, 2 H), 7.20 (td, 2 H) and 7.35 (dd, 2 H, aromatic C*H*) ppm. ^{13}C NMR (75 MHz; [D_8]THF, 35 °C): δ = 15.6 [NCH*Me*C(Me)$_2$CH*Me*N], 21.3 [NCHMeC(*Me*)$_2$CHMeN, broad; accidental coincidence], 23.4 and 24.6 [CH(*Me*)$_2$], 29.8 [*C*H(Me)$_2$], 42.7 [NCHMe*C*(Me)$_2$CHMeN], 65.3 [N*C*HMeC(Me)$_2$*C*HMeN], 114.0, 118.4, 127.2 and 129.1 (aromatic CH), 133.2 (*C*-N, aromatic C), 151.9 {*C*[CH(Me)$_2$], aromatic C}. Peaks due to free Et$_2$O could also be observed at substoichiometric levels.

1,2-(2-Isopropylphenyl)-3,4,4,5-tetramethylpyrazolidine (2): *n*BuLi (1.6 mL of a 1.51 M hexane solution, 2.42 mmol) was added to a stirring solution of *l*-[(2-*i*Pr-C_6H_4NHCHMe)$_2$CMe$_2$] (0.40 g, 1.1 mmol) in hexane (5 mL) at room temperature. The suspension was vented to the atmosphere via a drying tube freshly charged with anhydrous $CaCl_2$, and stirred for 12 h. Removal of solvent yielded a brown oil. Its NMR spectrum was dominated by peaks listed below, but contained some other unidentified impurities. Flash column chromatography on silica (eluting with hexane) yielded **2** as the major fraction, R_f = 0.7. Large colourless crystals of 1,2-(2-isopropylphenyl)-3,4,4,5-tetramethyl pyrazolidine (**2**) were grown from a hexane solution at −25 °C. M.p.: 118−120 °C. Yield: 0.19 g, 48%. ^{1}H NMR (300 MHz. $CDCl_3$): δ = 0.97 (d, $^{3}J_{H,H}$ = 6.8 Hz, 6 H, *Me*CHMe), 0.91 [d, $^{3}J_{H,H}$ = 6.8 Hz, 6 H, NCH*Me*C(Me$_2$)CH*Me*N], 1.10 [s, 6 H, NCHMeC(*Me*$_2$)CHMeN], 1.19 (d, $^{3}J_{H,H}$ = 6.8 Hz, 6 H, MeCH*Me*), 2.80 [q, $^{3}J_{H,H}$ = 6.8 Hz, 2 H, NC*H*MeC(Me$_2$)C*H*MeN], 3.94 (septet, $^{3}J_{H,H}$ = 6.8 Hz, 2 H, MeC*H*Me), 6.96−7.11 and 7.76−7.82 (8 H, non-first-order m, aromatic protons) ppm. ^{13}C NMR (75 MHz; C_6D_6): δ = 14.4 [NCH*Me*C(Me$_2$)CH*Me*N], 24.3 [NCHMeC(*Me*$_2$)CHMeN], 24.4 (*Me*CHMe), 25.5 (MeCH*Me*), 25.9 (Me*C*HMe), 42.6 [NCHMe*C*-(Me$_2$)CHMeN], 73.7 [N*C*HMeC(Me$_2$)*C*HMeN], 125.6, 126.1, 126.2 and 126.4 (aromatic CH), 147.4 and 147.8 {*C*-N, aromatic C and *C*[CH(Me$_2$)]}. $C_{25}H_{36}N_2$ (364.6): calcd. C 82.4, H 10.0, N 7.7; found C 82.7, H 10.2, N 7.8. IR: $\tilde{\nu}$ = 1521 cm^{-1}, 1485 cm^{-1} and 1445 cm^{-1} (s, aromatic C−C stretch), 1345 cm^{-1} [s, ν(C−N)].

{*N*,*N*′-Bis(2,6-diisopropylphenyl)-3,3′-dimethylpentane-2,4-diamido}dibutyltetralithium (6): *n*BuLi (4.2 mL of a 1.58 M hexane solution, 6.7 mmol) was added dropwise to a stirring solution of *N*,*N*′-bis(2,6-diisopropylphenyl)-3,3′-dimethylpentane-2,4-diamine (1.00 g, 2.2 mmol) in toluene (20 mL) at 22 °C and the solution was stirred for 2 h. Large, colourless crystals were grown overnight from the solution at −4 °C. The crystals were filtered from the solution and dried under vacuum. Yield: 0.42 g, 32%. M.p. 80−83 °C dec. The UMIST microanalysis facility could not handle this extremely sensitive compound; results indicated hydrolysis. Large crystal size and reproducibility and purity of NMR spectroscopic data indicated acceptable sample purity and homogeneity. ^{1}H NMR (200 MHz; [D_8]toluene, −40 °C): δ = −1.6 [br. m, 2 H, CH$_3$(CH$_2$)$_2$C*H*$_2$Li], −0.9 [br. m, 2 H, CH$_3$(CH$_2$)$_2$C*H*$_2$Li], 0.2 (br. quint., 2 H, CH$_3$CH$_2$C*H*$_2$CH$_2$Li or CH$_3$C*H*$_2$CH$_2$CH$_2$Li), 0.75 [t, $^{3}J_{H,H}$ = 7.2 Hz, 3 H, C*H*$_3$(CH$_2$)$_2$CH$_2$Li], 1.0 [two broad d overlapped, 6 H +6 H, NCH*Me*C(Me$_2$)CH*Me*N and *Me*C$_A$HMe], 1.1 [s, 3 H +3 H, unresolved NCHMeC(*Me*$_2$)CHMeN], 1.31 (br. d, 6 H, MeC$_B$H*Me*), 1.45 (apparent br. d, two d overlapped, 6 H +6 H, *Me*C$_A$HMe and MeC$_B$H*Me*), 1.75 [non-first-order br. m, 4 H, CH$_3$(C*H*$_2$)$_2$CH$_2$Li], 3.01 (br. septet, 2 H, MeC$_A$*H*Me), 3.89 [br. q, $^{3}J_{H,H}$ = 6.8 Hz, 2 H, NC*H*MeC(Me$_2$)C*H*MeN], 4.16 (br septet, 2 H, MeC$_B$*H*Me), 7.02−7.22 (non-first-order br. m, 6 H, aromatic protons) ppm. ^{7}Li NMR (78 MHz, [D_8]toluene, −40 °C): δ = 1.0 (br. s, 2 Li), 2.6 (br. s, 1 Li), 3.3 (br. s, 1 Li) ppm. ^{13}C NMR (75 MHz; C_6D_6, 22 °C): δ = 10 [br. overlapped m, Me(CH$_2$)$_2$*C*H$_2$Li], 14.2 [NCHMeC(*Me*$_2$)CHMeN], 20.4 [NCH*Me*C(Me$_2$)CH*Me*N], 25.6, 26.5 and 30.8 (*Me*CH*Me*), 27.1 and 31.2 (Me*C*HMe), 32 [br. overlapped m, Me(*C*H$_2$)$_2$CH$_2$Li], 44.1 [NCHMe*C*(Me$_2$)CHMeN], 69.7 [N*C*HMeC(Me$_2$)*C*HMeN], 123.2, 126.0 and 128.0 (aromatic CH), 145.6, 149.1 and 151.4 [*C*(CHMe$_2$) and *C*-N, aromatic C] ppm.

X-ray Structure Determinations: Low-temperature X-ray diffraction data for **1**·OEt$_2$, **2** and **6** were recorded from perfluoropolyether-coated crystals on a Nonius KappaCCD instrument fitted with an Oxford Instruments Cryostream (**1**·OEt$_2$ and **6**), or a Nonius MACH 3 diffractometer (**2**) fitted with a liquid-nitrogen boil-off device. Collection and solution methods and programs have been detailed elsewhere.[14] All hydrogens were found in difference maps and freely refined. Collection and refinement summaries are shown in Table 4. CCDC-212782 (**1**·OEt$_2$), -212783 (**2**) and -212784 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are indebted to the EPSRC for studentships (RJW, JEW) and NMR and X-ray diffraction equipment grants, to the Royal Society (FSM) for small equipment and consumables, and to Creators Ltd for Total Technology support (JEW).

Synthesis, Structures and Characterization of the Calcium Pyrrolates [Ca{(2-(dimethylaminomethyl)pyrrolyl}$_2$ donor$_n$] (donor = THF and pyridine, n = 2; DME and TMEDA, n = 1) as Potential Precursors for Solid-State Applications

Wilda Vargas[a] and Karin Ruhlandt-Senge*[a]

In memory of the late Ron Snaith

Keywords: Calcium / N ligands / Chemical vapor deposition / Transamination / Metallation / Intramolecular donation

The synthesis and characterization of novel alkaline earth metal pyrrolyl derivatives is described. The target molecules were synthesized using transamination and metallation protocols, involving either the treatment of calcium bis[bis(trimethylsilyl)]amide with two equivalents of 2-(dimethylaminomethyl)pyrrole (2-DMAMP) or the reaction of elemental calcium with two equivalents of 2-DMAMP. Different donors, namely THF, pyridine (py), DME (dimethoxyethane), and TMEDA (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine) were utilized to study their influence on the structural chemistry of the target compounds. In order to compare the influence of the metal coordination on the pyrrole ligand, we included the crystal structure of the free 2-DMAMP ligand. All new compounds were characterized using ^{1}H, ^{13}C NMR and IR spectroscopy in addition to X-ray crystallography**.** Crystal data with Mo-K_α radiation (λ = 0.71073 Å) are as follows: **1**: [Ca(2-DMAMP)$_2$(THF)$_2$], a = 15.440(2) Å, b = 14.992(2) Å, c = 10.175(1) Å, β = 94.9(3)°,V= 2346.6(6) Å^3, Z = 4, monoclinic, space group $P2_1/c$, $R1$(all data) = 0.0981; **2**: [Ca(2-DMAMP)$_2$(py)$_2$], a = 9.168(6) Å, b = 10.418(7) Å, c = 13.329(8) Å, α = 85.9(1)°, β = 72.9(1)°, γ = 86.2(1)°, V = 1212.2(1) Å^3, Z = 2, triclinic, space group $P\bar{1}$, $R1$ (all data) = 0.0711; **3**: [Ca(2-DMAMP)$_2$(DME)], a = 10.814(1) Å, b = 12.907(1) Å, c = 15.170(1) Å, V = 2117.3(3) Å^3, Z = 4, orthorhombic, space group $P2_12_12_1$, $R1$ (all data) = 0.0729; **4**: [Ca(2-DMAMP)$_2$(TMEDA)], a = 9.403(6) Å, b = 15.810(1) Å, c = 15.417(1) Å, V = 2292.0(3) Å^3, Z = 4, orthorhombic, space group $Pbcn$, $R1$ (all data) = 0.0997; **5**: 2-DMAMP, a = 10.8820(7) Å, b = 15.2186(10) Å, c = 9.7578(6) Å, β = 109.736(2)°,V = 1521.05(17) Å^3, Z = 2, monoclinic, space group Cc, $R1$ (all data) = 0.0382.

Introduction

Calcium-containing solid-state materials showing huge negative resistance or colossal magnetoresistance (CMR) have become prominent not only for fundamental physics but also for their possibilities in device applications.[1] Amongst these materials, the doped manganates $A_{1-x}Ca_xMnO_3$ (A = rare earth metals) are especially interesting for their potential employment in the development of magnetic recording heads.[2,3] The production of these materials by CVD procedures requires precursors with a high volatility. The well-established β diketonate[4] derivatives decompose cleanly, but their volatility is not sufficient for these applications. Conventional means to improve the volatility by -$SiMe_3$ or -CF_3 substitution are not applicable since small amounts of fluorine or silicon impurities are detrimental to electronic applications.[5]

Nitrogen-based precursors are ideally suited for the production of a wide array of solid-state materials. In addition, the structural flexibility of the ligand system, since two not one organic groups (as in oxygen-based precursors) are linked to a monoanionic, secondary amido ligand, significantly increases ligand design opportunities. The most intensively studied nitrogen-based calcium derivatives carry the sterically demanding hexamethyldisilazane ligand in conjunction with various mono and bidentate donors. A number of donor-containing monomers in addition to a donor-free dimer have been reported and recently summarized in an excellent review article.[6] However, the promise of the calcium bis[bis(trimethylsilyl)]amides as potential precursor materials has not been fulfilled due to the facile acid-promoted cleavage of the N−Si bonds[7] and consequent silicon contamination of the final products. Derivatives of the hexamethyldisilazane ligand replacing one trimethylsilyl group by a bulky aromatic substituent display a reduced

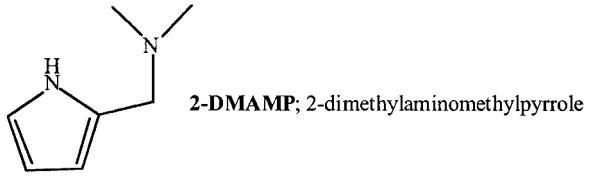
tendency towards N−Si bond cleavage and have partially fulfilled the aim for volatile precursors.[8] Still, advanced amido-based precursors would avoid the presence of silyl groups altogether, but synthetic difficulties have so far precluded the preparation of these highly reactive materials.[9]

Volatile precursor materials will likely consist of monomeric compounds. However, heavy alkaline earth metal derivatives exhibit a pronounced tendency towards oligomerization due to their large ionic radii.[10] Multiple strategies exist to prevent the formation of oligomers, most prominently the use of sterically demanding ligands, and application of donors and intramolecularly coordinating ligands. Since the use of bulky ligands alone does not ensure the presence of monomeric molecules,[11] a combined approach of multiple strategies is advantageous. As an added incentive, intramolecular coordination is likely to increase the solubility of the target compounds in common organic solvent systems, thus facilitating the delivery of the target compounds in CVD applications.

Amongst the array of nitrogen ligands with intramolecular stabilization capabilities, we identified the monoanionic bidentate pyrrole derivative 2-(dimethylaminomethyl)pyrrole (2-DMAMP), as shown in Scheme 1, as being ideally suited for our purpose, with the $(CH_3)_2NCH_2$- linker providing the desired intramolecular stabilization to allow for the isolation of monomeric species.



2-DMAMP; 2-dimethylaminomethylpyrrole

Scheme 1. Schematic drawing of the 2-DMAMP ligand

Although first reported in the 1940′s,[12] 2-DMAMP has received little attention as a ligand system. In fact, well-characterized main group derivatives are limited to aluminum,[13] gallium and indium[14] in addition to some recently published mixed magnesium cyclopentadienide/amido derivatives.[15] Other metal complexes bearing DMAMP-type ligands include titanium,[16] tungsten,[16] zirconium,[17−19] vanadium,[19] thallium,[20] chromium,[19] molybdenum,[21] cobalt[19] and nickel.[19]

Pyrrolylcalcium and -strontium derivatives with two *tert*-butyl substituents have been reported.[22] This sterically demanding ligand disfavors the η^1-type bonding observed in the 2-DMAMP compounds; instead, π-bonding involving an η^5 arrangement is observed. A related metal geometry is also observed in a calcium porphyrinogen derivative. Here, four pyrrolyl rings are arranged in a macrocycle, each binding in an η^3 fashion to calcium.[23] If, instead, calcium is coordinated to a pyrollyl ring in a porphyrin system, η^1 binding is ensured by the planar nature of the macrocycle.[24] Studies focusing on the unsubstituted pyrrole ligand in conjunction with the heavier alkaline earth metals have been limited to the gas-phase synthesis of the monopyrrolylcalcium and -strontium free radicals.[25]

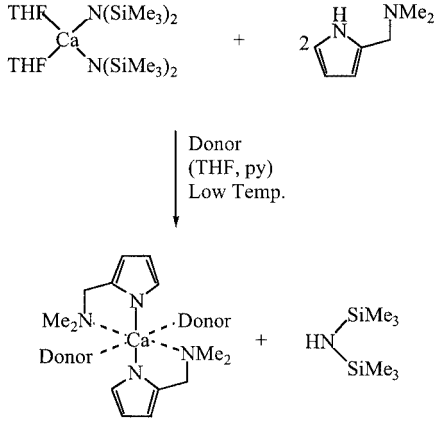
We report here on a group of monomeric pyrrolylcalcium derivatives carrying the 2-(dimethylaminomethyl)pyrrolyl ligand (2-DMAMP), in addition to mono- and bidentate donors, namely $[Ca(2\text{-DMAMP})_2(THF)_2]$ (**1**), $[Ca(2\text{-DMAMP})]_2(py)_2]$ (**2**), $[Ca(2\text{-DMAMP})]_2(DME)]$ (**3**), and $[Ca(2\text{-DMAMP})_2(TMEDA)]$ (**4**). The crystal structure of the free 2-DMAMP ligand **5** is also reported.

Results and Discussion

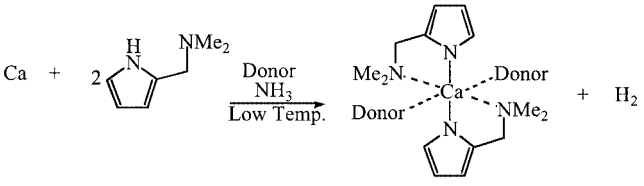
Synthetic Aspects and Reactivity

Multiple synthetic methods were probed to identify the most facile route that allows the production of the target compounds in a simple and efficient manner. The initial starting point was salt elimination, used successfully for the preparation of amidocalcium derivatives.[6,8] Following a similar procedure, we obtained an inseparable precipitate containing the pyrrolyl target compound and potassium iodide. A change in reaction conditions did not improve this result.

Two reaction schemes, transamination[26] (Scheme 2) and metallation[27] (Scheme 3) were identified as viable alternatives, since both have been used successfully to prepare a host of alkaline earth metal derivatives. Limitations of the transamination scheme are based on the required pK_a difference between the liberated amine and the reagent, and only substrates with a higher acidity than the secondary amine may be successfully utilized. If, on the other hand, the acidity would be too high, as for example observed in aromatic thiols, consumption of acid, with protonation of the liberated amine and formation of primary amine and silylated substrate, is observed.[7]



Scheme 2. The synthesis of calcium pyrrolates by transamination



Scheme 3. The synthesis of calcium pyrrolates by direct metallation

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Compounds **1** and **2** were prepared using transamination (Scheme 2), although the purity of the resulting products was not consistently high. A common technique to obtain high quality products by transamination is the removal of $HN(SiMe_3)_2$ in vacuo to shift the equilibrium to the product side and assure the quantitative release of $HN(SiMe_3)_2$.[26c] Still, elimination of amine was occasionally incomplete as evidenced by ^1H NMR analysis. Attempts to remove the amine at elevated temperature and under vacuum resulted in the removal of the donor and consequent formation of insoluble precipitates. This was also observed if the acid and the amide were combined too rapidly, or donors were omitted, despite the use of very dilute solutions and low reaction temperatures.

Metallation, used successfully to prepare the target compounds in a facile, reproducible manner, requires the activation of calcium since the oxide layer in commercially available calcium effectively passivates the metal. Several methods are available to activate the metal. Westerhausen et al. successfully use the distillation of the metals for this purpose,[28] while recent collaborative work between the Deacon group and our group showed mercury activation, as used frequently for the rare earth metals, to be effective.[29] Alternatively, dissolving the metals in anhydrous, liquid ammonia followed by addition of acid, as shown with the preparation of a selection of alkaline earth metal derivatives, is also a viable method.[27] As an example, the preparation of the barium amide $[Ba\{N(SiMe_3)_2\}_2(THF)_2]$ by metallation in the presence of ammonia proceeds smoothly,[30] whereas no product is observed if ammonia is omitted. Since the reactivity of the alkaline earth metals increases upon descending the group, metallation is most efficient for barium, whereas no reaction, even after extended reflux in liquid ammonia (dry-ice condenser), is observed for calcium.

With these parameters in mind, we proceeded by dissolving calcium in anhydrous, condensed ammonia, followed by addition of the acid and extended reflux of the reaction mixture. Consistently, the reaction mixture turned dark, and intractable, insoluble solids were obtained. If, however, a small amount of ammonia is condensed onto the reaction mixture to dissolve the metal (as indicated by the formation of deep-blue solutions), followed by the evaporation of most of the ammonia and brief heating, the reaction proceeds smoothly, as evidenced by the vigorous evolution of gas. This method produces the target compounds in excellent yield and purity.

The initially surprising fact that compounds **1**−**4** may be prepared in good yields and purity, while the reaction of calcium metal with $HN(SiMe_3)_2$ does not yield the amide, may be explained by the lower pK_a of the pyrrole vs. the amine, its reduced steric demand and the pyrrole's capability for intramolecular stabilization yielding a thermodynamically favored five-membered ring.

Spectroscopic Studies

The ^1H NMR spectra of compounds **1**−**4** show a consistent change from the spectrum of the free 2-DMAMP ligand **5**. Due to limited solubility of the target compounds, all NMR spectra were recorded in $[D_8]$THF. The most prominent difference is observed for the proton in the 5-position, which shifts from δ = 6.57 ppm in the free ligand **5** to δ = 6.63−6.67 ppm in compounds **1**−**4**. The protons in the 3- and 4-positions in the free ligand lie very close together at δ = 5.90 and 5.85 ppm. In **1**−**4** these signals are shifted slightly upfield, moving even closer together; they are observed at δ = 5.79 and 5.78 ppm. In the free ligand the CH_2 and $N(Me)_2$ protons are observed as singlets at δ = 3.31 and 2.13 ppm, respectively. Upon deprotonation both signals experience a slight downfield shift to δ = 3.46 and

2.25 ppm. These values are in good agreement with literature data.[13−15]

Structural Aspects

Crystallographic information and data collection parameters for compounds **1**−**4** are summarized in Table 1 and the Exp. Sect. A compilation of selected geometrical parameters for the compounds is given in Table 2 and 3, while Figures 1−5 illustrate the structural principles displayed in compounds **1**−**5**. Compounds **1** and **2**, bearing the monodentate donors THF and pyridine, and **3** and **4**, carrying bidentate donors DME and TMEDA, display very similar structural features and will be described together.

[Ca(2-DMAMP)$_2$(THF)$_2$] (1) and [Ca(2-DMAMP)$_2$(py)$_2$] (2): Compounds **1** (Figure 1) and **2** (Figure 2) exhibit monomeric six-coordinate calcium centers. The two independent metal centers in compounds **1** and **2** are located on inversion centers, thus, two half molecules are located in each asymmetric unit, of which only one is shown. The coordination geometry around calcium is distorted octahedral with a center of symmetry requiring a linear geometry of the trans oriented ligands and donors. The distortion from octahedral geometry stems from the narrow bite angles within the intramolecularly coordinating ligand, with values of 75.22(2)° for **1** and 75.71(8)° for **2**. Ca−N(pyrrolate) and Ca−N(NMe$_2$) distances in **1** are 2.386(6) Å and 2.523(6) Å, respectively, with closely related values [2.394(2) Å and 2.532(2) Å] for **2**. The Ca−O(THF) distances in **1** are 2.372(4) Å, while the Ca−N(pyridine) distances in **2** are 2.524(2) Å.

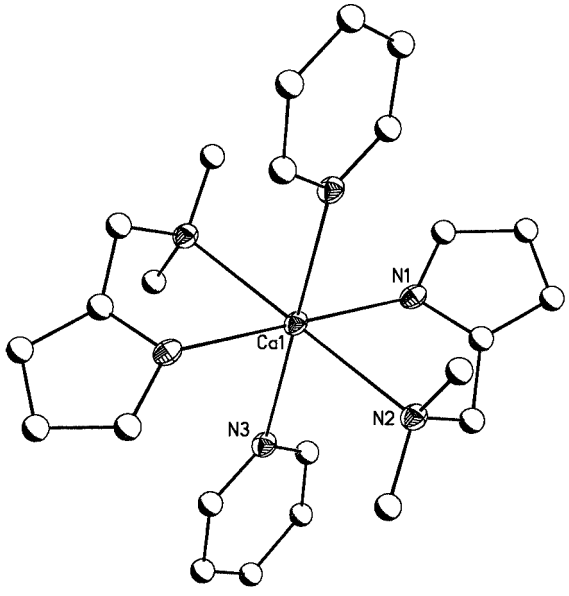

Figure 2. Computer-generated plot of **2** with anisotropic displacement parameters depicting 30% probability for all non-carbon atoms; the hydrogen atoms have been omitted for clarity

[Ca(2-DMAMP)$_2$(DME)] (3) and [Ca(2-DMAMP)$_2$-(TMEDA)] (4): Compounds **3** and **4,** represented in Figures 3 and 4, respectively, feature monomeric, six-coordinate metal centers with two 2-DMAMP ligands and one DME or TMEDA donor. In compound **4** the metal center is located on a twofold axis, generating the second half of the

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

molecule. In both **3** and **4** the 2-DMAMP ligands adopt a *cisoid* conformation to accommodate the bidentate donors, resulting in a significant distortion from ideal octahedral geometry, as reflected in N1−Ca1−N1A, N2−Ca1−N2A and O1−Ca1−O2 angles of 112.35(1)°, 166.65(1)° and 67.82(8)°, respectively, in **3**, and N1−Ca1−N3, N2−Ca1−N4 and N5−Ca1−N6 angles of 115.95(5)°, 142.23(5)° and 69.38(6)°, respectively, in **4**. The calcium center and the 2-DMAMP ligand form five-membered rings with N−Ca−N angles of 73.22(2)° in **3**, and 72.59(4)° in **4**, which are in part responsible for the distortion from octahedral geometry. The Ca−N(pyrrolate) and Ca−N(NMe_2) distances are 2.378(6) Å and 2.522(6) in **3** and 2.384(6) Å and 2.523(6) Å in **4**, respectively. The calcium-oxygen bond lengths in **3** average 2.378(4) Å, while Ca−N(TMEDA) contacts in **4** are 2.595(1) Å.

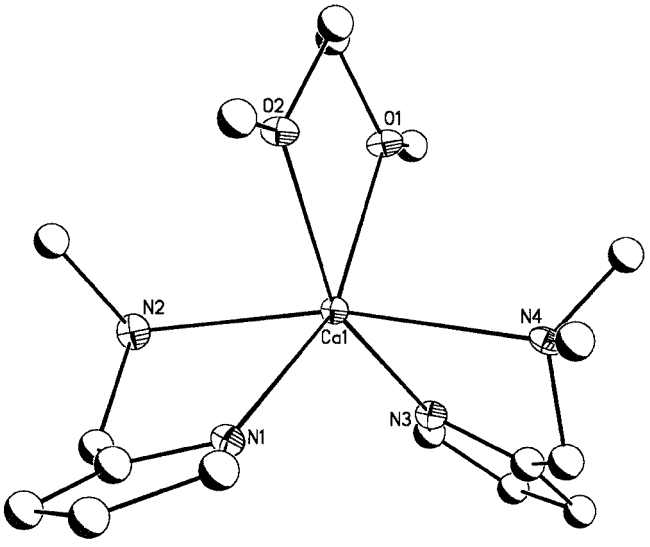

Figure 3. Computer-generated plot of **3** with anisotropic displacement parameters depicting 30% probability for all non-carbon atoms; the hydrogen atoms have been omitted for clarity

DMAMP-2 (5): The free ligand is depicted in Figure 5; pertinent bond lengths and angles are summarized in Table 3. Compound **5** crystallizes with two independent molecules per asymmetric unit which are connected through a hydrogen bond (2.024 Å) involving the pyrrole hydrogen atom on one molecule and the dimethylamine fragment on the second pyrrole. The geometrical parameters in the two independent molecules are very similar, therefore only one is described. Pyrrole nitrogen-carbon bond lengths are observed at 1.370(2) Å, the C−C bond lengths between carbons 2 and 3 and 4 and 5 are slightly shorter, at 1.356(3) and 1.361(2) Å, while the C−C bond between carbons 3 and 4 is the longest, at 1.422(2) Å. This is consistent with the location of the double bonds. The angle at nitrogen is 108.81(16)°. The (CH_2)NMe_2 linker is attached to carbon 2, with a C2−C6 bond length of 1.497(2) Å.

The observed calcium-pyrrolate binding mode in **1**−**4** is a sigma-type η^1-bond through the nitrogen atom on the pyrrole ring. η^5 Coordination, as observed for di-*tert*-butyl-substituted pyrrolates of calcium and strontium,[22] or calcium porphyrinogen,[23] is not observed. The differences in coordination mode can be explained by the steric bulk of the di-*tert*-butyl-substituted pyrrolate, or the arrangement of pyrrolyl groups in the macrocycle, which effectively block the σ-type Ca−N(pyrrolyl) bonding observed here. In addition, the formation of a thermodynamically favored five-membered ring utilizing the intramolecularly coordinating $(CH_3)_2NCH_2$- linker also favors the σ-type bonding observed in compounds **1**−**4**.

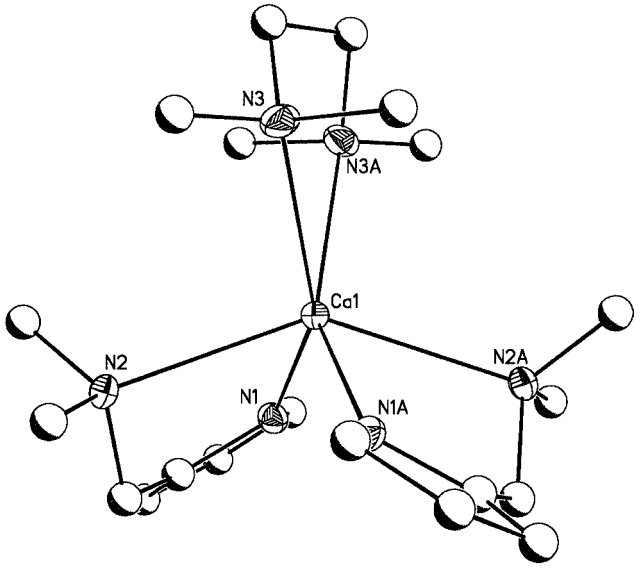

Figure 4. Computer-generated plot of **4** with anisotropic displacement parameters depicting 30% probability for all non-carbon atoms; the hydrogen atoms have been omitted for clarity

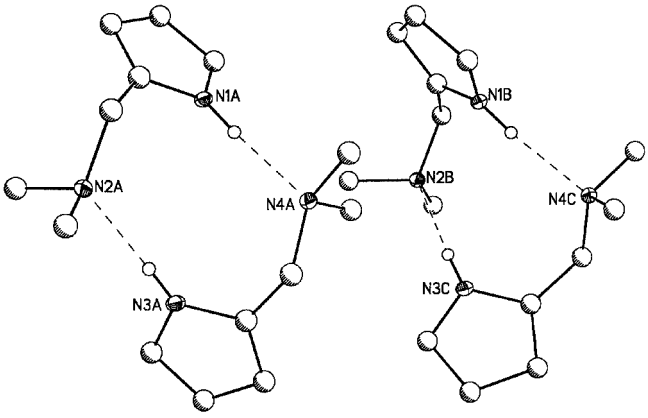

Figure 5. Computer-generated plot of **5** with anisotropic displacement parameters depicting 30% probability for all non-carbon atoms; the hydrogen atoms, except on the pyrrole nitrogen have been omitted for clarity

In compounds **1** and **2** the two 2-DMAMP ligands occupy the equatorial plane, with the two monodentate donors occupying the axial positions. In the case of the bidentate donors DME and TMEDA, this arrangement is no longer possible, since the donor bite angle prevents the coordination to both axial positions. Instead, a *cisoid* ligand arrangement is observed.

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Calcium-pyrrolyl nitrogen bond lengths in **1**−**4** lie in a narrow range [2.378(6)−2.404(1) Å], as do the calcium-nitrogen [Ca−N(CH_3)$_2$] contacts involving the intramolecular linker [2.522(2)−2.584(1) Å]. As expected, the Ca−N bond lengths to the anionic pyrrolyl ligand are significantly shorter than to those to the neutral -N(CH_3)$_2$ donor. The Ca−N(pyrrolyl) values compare favorably with the four-coordinate calcium amides [Ca{N($SiMe_3$)$_2$}$_2$(THF)$_2$] [2.301(6) Å],[31] and [Ca{N($SiMe_3$)(2,6-*i*Pr$_2$$C_6H_3$)}$_2(THF)_2$] [2.326(8) Å],[8] despite the lower coordination number observed in these compounds. The only marginally longer Ca−N(pyrrolyl) bond lengths in compounds **1**−**4** are an expression of the larger steric demand of the amido ligands as compared to the pyrrolyl system. The ligand size is based on the narrow N(pyrrolyl)−Ca−N[N(CH_3)$_2$] bite angle [72.59(4) to 75.71(8)°], effectively reducing the steric bulk of the ligand. The Ca−N(pyrrolyl) bond lengths also compare favorably with the seven coordinate tris-pyridine solvated calcium porphyrin with Ca−N(pyrrolyl) distances of 2.382(4)−2.416(3) Å.[23]

Metal binding has only a negligible influence on the overall features of the pyrrolyl ring, and the structural parameters of **1**−**4** are within standard deviations compared to the free 2-DMAMP ligand **5**. Compounds **1**−**4** may be compared with a family of furfurylsilylamides, of which the magnesium compound is closest to the calcium species presented here.[32] In this ligand system, a furan ring is connected in the 2-position to a methyltrimethylsilylamine linker. This linker is deprotonated yielding an amido function with the opportunity for intramolecular furan coordination. In the presence of non-coordinating solvents, both the furan oxygen and the amido function are coordinated to the magnesium. If, however, donating solvents such as THF are utilized, only the amide coordinates to the metal. In the pyrrole system presented here, the intramolecular coordinating ability of the ligand is used in all cases, even in the presence of strong or multidentate donors such as pyridine, TMEDA or DME, with analogous results for a series of magnesium compounds.[33] Clearly then, without relying on silyl substitution, the 2-DMAMP ligand displays excellent capabilities to stabilize monomeric heavy alkaline earth metal derivatives, as needed for solid-state applications.

Solid-State Studies

Compounds **1**−**4** were analyzed for their capacity as CVD precursor molecules. To this effect, TGA and sublimation studies were conducted. Remarkably, the compounds involving nitrogen donation by either pyridine (compound **2**) or TMEDA (compound **4**) show a clean decomposition pattern in the TGA, whereas **1** and **3** display a complex decomposition behavior, with a significant amount of residue remaining at 450 °C. The TGA pattern for compound **4** is shown in Figure 6, indicating a clean decomposition process at low temperatures. To confirm the usefulness of the material as a CVD precursor, extended sublimation studies were conducted with the most promising material, the TMEDA adduct **4**. It was shown that compound **4** sublimes cleanly into a uniform calcium-containing solid-state species, demonstrating the potential of these compounds as precursor materials.

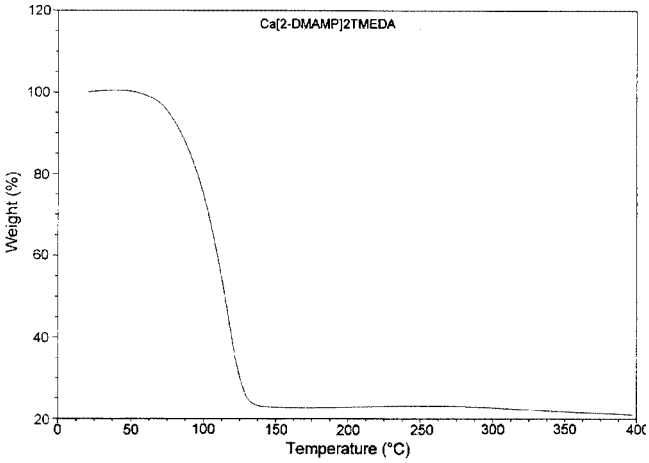

Figure 6. TGA profile for compound **4**

Conclusion

Four new calcium pyrrolates containing intramolecularly coordinating linkers were synthesized and characterized. The compounds exhibit monomeric structures in the solid state as shown by X-ray crystallography. Extended studies involving TGA and sublimation showed that compounds **2** and **4** show considerable promise as precursor materials for the production of calcium-containing solid-state materials. This result is especially important in the light of desirable silicon-free calcium source material.

We have probed salt-elimination, transamination, and metallation procedures and found that calcium pyrrolate derivatives are most conveniently accessible by metallation. This method also holds the greatest promise of a facile large-scale preparation.

Experimental Section

General Procedures: All reactions were performed using standard procedures using a purified nitrogen atmosphere by utilizing either modified Schlenk techniques and/or a Braun Labmaster 100 dry box. Pyridine, THF, DME, TMEDA, hexamethyldisilazane and pyrrole were distilled prior to use from CaH_2 or Na/K alloy. Ca[N($SiMe_3$)$_2$]$_2$$THF_2$ [31] and 2-DMAMP[12] were synthesized according to literature procedures. Formaldehyde and dimethylamine hydrochloride were obtained from commercial sources and used as received. Anhydrous ammonia was further dried by condensing over sodium metal. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker DPX-300 or -500 spectrometer. Spectra were recorded in deuterated THF and are referenced to residual solvent resonances. Use of C_6D_6 or $CD_3C_6D_5$ as NMR solvents did not allow for the dissolution of the target compounds, precluding the recording of quality spectra. Infrared spectra were recorded as Nujol mulls between NaBr plates on a Perkin−Elmer PE 1600 FI-IR spectrometer. Thermogravimetric analysis (TGA) was performed on

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

vacuum dried samples kept under inert conditions and loaded manually onto a Auto TGA2950HR thermogravimetric analyzer. The TGA experiments were performed under an N_2 atmosphere using a heating rate of 10 °C /min. Reliable elemental analyses could not be obtained, even when glove-box handling was attempted, due to the high moisture and oxygen sensitivity of all compounds reported. Repeated elemental analysis of high quality samples with clean ^{1}H NMR spectra and perfect integration afforded large deviations between duplicate runs, even when V_2O_5 was added as a combustion aid. This is a well-known problem in alkaline earth metal chemistry.[34]

Procedure A, Transamination: In a typical experiment, a Schlenk tube was charged with one equivalent of $[Ca\{N(SiMe_3)_2\}_2(THF)_2]$ (typically 3.6 mmol), dissolved in 40 mL of donor solvent (THF, pyridine or DME) and stirred at low temperature for half an hour. To this, a solution of two equivalents of 2-DMAMP in 20 mL of the same solvent was added dropwise with vigorous stirring. The resulting clear solution was stirred for three hours at low temperature, −78 °C (acetone/dry ice) for THF or DME, or −40 °C (acetonitrile/dry-ice) for the pyridine reactions, due to the higher melting point of pyridine. The clear, yellow solution was slowly warmed to room temperature before being filtered through a fine filter frit. The filtrate was reduced in volume to about 30 mL, followed by storage at −23 °C.

Procedure B, Metallation: In a typical experiment, a Schlenk tube was charged with calcium metal (typically 1 mmol) and two equivalents of 2-DMAMP. To this, about 60 mL of solvent (THF, pyridine or a toluene/TMEDA (10:1 v/v mixture) was added and stirred at −78 °C (THF, DME or toluene/TMEDA), or at −40 °C if pyridine was utilized. Into this mixture approximately 20 mL of ammonia was condensed. The solution was then removed from the cold bath and allowed to warm up to room temperature. After most of the ammonia had evaporated, the presence of ammoniates was indicated by a characteristic bronze color. Heat was applied briefly, initiating vigorous bubbling. The evolution of gas persisted for several minutes. After the formation of bubbles had ceased, the homogeneous clear solution was filtered through a fine filter frit. The volume of the filtrate was reduced to about 30 mL followed by storage at −23 °C (unless otherwise noted).

[Ca(2-DMAMP)$_2$(THF)$_2$] (1). Procedure A: $[Ca\{N(SiMe_3)_2\}_2(THF)_2]$ (1.89 g, 3.6 mmol) in 40 mL of THF and 2-DMAMP (0.93 g, 7.5 mmol) in 20 mL of THF stirred at −78 °C. Within a week colorless block-shaped crystals suitable for X-ray crystallography studies formed. Yield: 47% (0.73 g, 1.70 mmol).

Procedure B: Calcium metal (0.04 g, 1 mmol) and 2-DMAMP (0.25 g, 2 mmol), stirred at −78 °C. Within a day colorless block-shaped crystals suitable for X-ray crystallography studies formed. Yield: 65% (0.28 g, 0.65 mmol).

$C_{22}H_{38}CaN_4O_2$ (430.64): calcd. C 61.36, H 8.89, Ca 9.31, N 13.01; found C 54.88, H 8.24, Ca 10.34, N 18.41. M.p.: turns opaque at 80 °C (presumably loss of donor solvent), turns dark above 135 °C. ^{1}H NMR ([D]$_8$THF): δ = 1.80 (m, 4 H), 2.25 (s, 12 H), 3.46 (s, 4 H), 3.64 (m, 4 H), 5.79 (s, 4 H), 6.63 (s, 2 H) ppm. ^{13}C NMR ([D]$_8$THF): δ = 23.63 (THF), 45.70 (NMe_2), 57.63 (CH_3), 62.25 (CH_2), 68.28 (THF), 106.34 (CH), 107.77 (CH), 127.21 (CH) ppm. IR (Nujol): $\tilde{\nu}$ = 3084.4 cm^{-1}, 1353.3, 1294.5, 1261.8, 1160, 1136, 1086, 1037, 767.2, 623.5.

[Ca(2-DMAMP)$_2$(py)$_2$] (2). Procedure A: $[Ca\{N(SiMe_3)_2\}_2(THF)_2]$ (1.89 g, 3.6 mmol) in 40 mL of pyridine and 2-DMAMP (0.93 g, 7.5 mmol) in 20 mL of pyridine (−40 °C). The solution turned cloudy and was removed from the cold bath and warmed to room temperature upon which it turned clear. Within a week, colorless block-shaped crystals suitable for X-ray crystallography studies formed. Yield: 55% (0.88 g, 1.97 mmol).

Procedure B: Calcium metal (0.04 g, 1 mmol) and 2-DMAMP (0.25 g, 2 mmol). Stirred at −40 °C. Yield: 72% (0.32 g, 0.72 mmol).

$C_{24}H_{32}CaN_6$ (444.64): calcd. C 64.82, H 7.25, Ca 9.01, N 18.90; found C 55.20, H 7.63, Ca 9.88, N 18.00.. M. p.: turns opaque at 95 °C (presumably loss of donor solvent), turns dark above 120 °C, sublimes above 200 °C. ^{1}H NMR ([D]$_8$THF): δ = 2.25 (s, 12 H), 3.46 (s, 4 H), 5.79 (s, 4 H), 6.68 (s, 2 H), 7.25 (m, 4 H), 7.66 (t, 2 H), 8.53 (d, 4 H) ppm. ^{13}C NMR ([D]$_8$THF): δ = 45.82 (NMe_2), 62.36 (CH_2), 106.3 (CH), 106.4(CH), 124.5 (py), 127 (CH), 136.4 (py), 151 (py) ppm. IR (Nujol): $\tilde{\nu}$ = 2723.1 cm^{-1}, 1591.9, 1345.6, 1169.6, 1021, 947.8, 729.4, 627.9.

[Ca(2-DMAMP)$_2$(DME)] (3). Procedure A: $[Ca\{N(SiMe_3)_2\}_2(THF)_2]$ (1.89 g, 3.6 mmol) in 40 mL of DME and 2-DMAMP (0.93 g, 7.5 mmol) in 20 mL of dimethoxyethane stirred at −78 °C. The solution turned cloudy and was removed from the cold bath, first warmed up to room temperature and subsequently heated to reflux temperature. On reaching reflux temperature, the solution turned clear. Upon cooling to room temperature, colorless needle-shaped crystals suitable for X-ray crystallography studies formed. Yield: 44% (0.59 g, 1.56 mmol).

$C_{18}H_{32}CaN_4O_2$ (376.56): M.p.: turns opaque at 80 °C (presumably loss of donor solvent), turns dark above 155 °C. ^{1}H NMR ([D]$_8$THF): δ = 2.25 (s, 12 H), 3.27 (s, 6 H), 3.43 (s, 4 H), 3.60 (s, 4 H), 5.79 (s, 4 H), 6.68 (s, 2 H), 7.25 (m, 4 H) ppm. ^{13}C NMR ([D]$_8$THF): δ = 45.40 (NMe_2), 57.63 (CH_3), 59.00 (CH_2), 72.83 (OCH_2), 107.6 (CH), 107.8(CH), 127 (CH) ppm. IR (Nujol): $\tilde{\nu}$ = 1261.2 cm^{-1}, 1242.9, 1224, 1172.4, 11.38.2, 1100.8, 1069.6, 1025.9, 992.9, 827.9.

[Ca(2-DMAMP)$_2$(TMEDA)] 4. Procedure B: Calcium (0.04 g, 1 mmol) and 2-DMAMP (0.25 g) in 5 mL of TMEDA and 50 mL of toluene (−78 °C). Block-shaped crystals suitable for X-ray crystallography formed within 24 hours. Yield: 67% (0.17 g, 0.44 mmol).

$C_{20}H_{38}CaN_6$ (402.64): calcd. C 59.65, H 9.51, Ca 9.95, N 20.89; found C 51.82, H 8.30, Ca 12.35, N 21.24. M.p.: turns opaque at 85 °C (presumably loss of donor solvent), turns dark above 145 °C, sublimes above 200 °C. ^{1}H NMR ([D]$_8$THF): δ = 1.73 (s, 12 H), 3.27 (s, 6 H), 3.30 (s, 4 H), 3.45 (s, 4 H), 5.79 (s, 4 H), 6.68 (s, 2 H), 7.25 (m, 4 H), 7.66 (t, 2 H), 8.53 (d, 4 H) ppm. ^{13}C NMR ([D]$_8$THF): δ = 45.50 (TMEDA, NMe_2), 45.82 (NMe_2), 57.73 (TMEDA, CH_2), 62.03 (CH_2), 106.29 (CH), 106.45(CH), 127.4 (CH) ppm. IR (Nujol): $\tilde{\nu}$ = 3361.8 cm^{-1}, 1506.1, 1376.4, 1096.0, 1027.2, 947.8, 714.1.

X-ray Crystallographic Study: X-ray quality crystals for all compounds were grown as described in the Exp. Sect. The crystals were removed from the Schlenk tube under a stream of N_2 and immediately covered with a layer of viscous hydrocarbon oil (Infineum). A suitable crystal was selected with the aid of a microscope, attached to a glass fiber, and immediately placed in the low temperature N_2 stream of the diffractometer.[35] The intensity data sets for all compounds were collected using a Siemens SMART system, complete with three-circle goniometer and CCD detector operating at −54 °C. Data for compounds **1** and **2** were collected at 93(2)K and for **3**, **4** and **5** at 87(2), 85(2) and 96(2) K, respectively, using a custom-built low temperature device from Professor H. Hope (UC Davis). In all cases graphite-monochromated Mo-K_α radiation (λ = 0.71073Å) was employed. The data collections nominally covered a hemisphere of reciprocal space utilizing a combination of three

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sets of exposures, each with a different angle, and each exposure covering 0.3° in φ. Crystal decay was monitored by repeating the initial frames at the end of the data collection and analyzing the duplicate reflections. In all cases, no decay was observed. An absorption correction was applied for all compounds utilizing the program SADABS.[36] The crystal structures of all compounds were solved by Direct Methods, as included in the SHELXTL-Plus program package.[37] Missing atoms were located in subsequent difference Fourier maps and included in the refinement. The structures of all compounds were refined by full-matrix least-squares refinement on F^2 (SHELX-93). Hydrogen atoms were placed geometrically and refined using a riding model, including free rotation about C−C bonds for methyl groups with U_{iso} constrained at 1.2 for non-methyl groups, and 1.5 for methyl groups times U_{eq} of the carrier C atom. The crystallographic programs used for structure refinement and solution were installed on a PC clone. Scattering factors were those provided with the SHELX program system. All non-hydrogen atoms were refined anisotropically.

CCDC-210044−210047 (**1**−**4**) and -217175 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internet.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Acknowledgments

We are grateful for support from the National Science Foundation (CHE-9702246 and CHE-0108098), SHARP Corporation of North America and Syracuse University. Purchase of the X-ray diffractometer was made possible with grants from NSF (CHE-9527898), the W. M. Keck Foundation and Syracuse University. We thank Professor W. Winter (SUNY ESF, Syracuse) for his help in obtaining TGA analyses.

Influence of the Crystallization Solvent on Molecular and Supramolecular Structures of Silver(I) Tris(3-Phenylpyrazolyl)methane Complexes

Daniel L. Reger,*[a] Radu F. Semeniuc,[a] and Mark D. Smith[a]

Keywords: N ligands / Solvent effects / Noncovalent interactions / Silver / Supramolecular chemistry

The compound [{HC(3-Phpz)$_3$}Ag](BF$_4$) (pz = pyrazolyl ring) has been prepared and shown to crystallize in four different forms depending on the solvent. Vapor-phase diffusion of diethyl ether into nitromethane solutions of the complex produces two polymorphs, an orthorhombic form (**1**) and triclinic form (**2**). Both polymorphs are coordination polymers constructed by a κ^2–κ^1 coordination of the tris(3-Phpz)methane units and have similar, but different, supramolecular structures. In **1** there are two independent chains linked by C–H···π interactions. In **2** only one type of chain is present, with a different internal structure than in **1**. Non-covalent forces, mainly C–H···π interactions, organize the chains into sheets and the sheets into a final 3-D supramolecular structure in the case of **1**, while in the case of **2** only a 2-D supramolecular structure forms. In contrast, vapor-phase diffusion of diethyl ether into acetonitrile or acetone solutions produces [{HC(3-Ph-pz)$_3$}Ag{(CH$_3$)$_2$CO}](BF$_4$) (**3**) and [{HC(3-Phpz)$_3$}-Ag{CH$_3$CN}](BF$_4$) (**4**). In these compounds, the ligand shows tripodal coordination to a single silver center and coordination of one solvent molecule to the metallic center. Both compounds form 3-D supramolecular structures organized by both C–H···π interactions and weak C–H···F hydrogen bonds and in the case of **4** π–π stacking.

Introduction

In 1966 Trofimenko introduced the tripodal hydrotris(pyrazolyl)borate family of ligands. They remain an important class of N_3 tripodal ligands in many fields of coordination chemistry, supramolecular chemistry, and catalysis.[1−5] Substituted hydrotris(pyrazolyl)borates, especially in the 3-position of the pyrazolyl ring, offer the possibility of controlling steric factors, making them suitable ligands in various enzyme models.[6−9] We have recently been investigating the isoelectronic tris(pyrazolyl)methane ligands and wish to demonstrate the ability of these neutral ligands to control the coordination chemistry of various metals through careful choice of substituents on the pyrazolyl rings.[10−15] With silver(I), we have reported the solid-state structures of [{HC(3,5-Me$_2$pz)$_3$}$_2$Ag](O$_3$SCF$_3$), [{HC(3-Butpz)$_3$}Ag](O$_3$SCF$_3$), and [{HC(3-Butpz)$_3$}Ag(CNBut)](O$_3$SCF$_3$).[12] Recently, others reported a series of silver derivatives of simple tris(pyrazolyl)methane ligands[16] and structures based on linking pyrazolyl rings with organic spacers.[17,18]

We have expanded the chemistry of simple tris(pyrazolyl)-methane ligands with the synthesis of a new class of multitopic ligands of the general formula C_6H_{6-n}[CH$_2$OCH$_2$C(3-Rpz)$_3$]$_n$, (R = H or Ph, n = 2, 4). These ligands are based on semi-rigid organic spacers that link two or more tris(pyrazolyl)methane units in a single molecule.[19−25] We have shown that metal complexes of these ligands form an array of unusual supramolecular structures supported by a multitude of non-covalent interaction, such as weak hydrogen bonds,[19−22] intermolecular[20,25] or intramolecular[22,24] π−π stacking, and C−H···π interactions.[20,24,25] This versatility is a consequence of the presence of the aromatic pyrazolyl rings and linking arene rings that can act as acceptors in C−H···π interactions or participate in π−π stacking. Another factor is that the hydrogen atoms within the pyrazolyl rings are acidic enough to be involved in weak hydrogen bonds. Additional structural diversity is derived from the ability of the tris(pyrazolyl)methane units to act as (a) a κ^3-tripodal ligand, (b) a κ^2-ligand, with the third pyrazolyl not coordinated to a metal, and (c) a bridge between two metals in a $\kappa^2-\kappa^1$ coordination mode, see Scheme 1. We defined these ligands as *structurally adaptive*.[24,25] A structurally adaptive ligand can adjust its shape to maximize covalent and non-covalent interactions and the overall structure of the supramolecular array will be the resultant of the interplay amongst all forces. While rigid ligands allow a better prediction of the overall structure, shape and porosity of the resulting array,[26,27] these semi-rigid, structurally adaptive ligands offer new insights into the self-assembly process. For example, [*o*-C$_6$H$_4${CH$_2$OCH$_2$C(3-Phpz)$_3$}$_2$Ag$_2$(BF$_4$)$_2$]$_n$ forms a 1-D organometallic coordination polymer that contains two different types of silver(I) cations arranged in bimetallic units. The bimetallic units show three different types of bridging

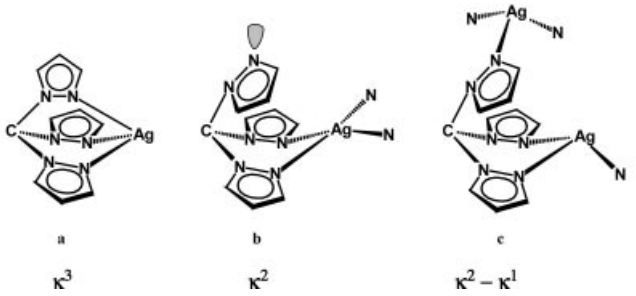
interactions, including a $\kappa^2-\kappa^1$ coordination mode of a tris(3-Ph-pyrazolyl)methane unit, a silver η^2-bonded to a phenyl group and $\pi-\pi$ stacking interactions.[23]



Scheme 1. Observed coordination modes of the $[HC(pz)_3]$ unit in silver(I) chemistry: a) κ^3 — tripodal; b) κ^2 — chelating one metal with the third pyrazolyl ring not coordinated; c) $\kappa^2-\kappa^1$ — bridging two metallic centers

In an attempt to elucidate the intimate processes that lead to the formation of these supramolecular species containing multitopic tris(pyrazolyl)methane ligands, we focused our attention back on simple tris(pyrazolyl)methane ligands, ligands that have the same potential to enter into non-covalent interactions and poses the same structural diversity in the modes of covalent bonding, to study the molecular and supramolecular structures of complexes of the tris(pyrazolyl)methane unit without the organizational feature of the linking, semi-rigid organic spacer. We have shown that $[\{HC(pz)_3\}CuPPh_3](NO_3)$ and $[\{HC(3\text{-}Phpz)_3\}CuPPh_3](NO_3)$ form a two dimensional supramolecular network of dimeric units.[28] Reported here are the synthesis and spectral characterization of $[\{HC(3\text{-}Phpz)_3\}_2Ag](BF_4)$, and the solid state structures of four different crystallographic forms of the complex with emphasis on the importance of the crystallization solvent and the role played by the counterion in influencing the types of covalent and non-covalent forces that organize the supramolecular networks.

Results and Discussion

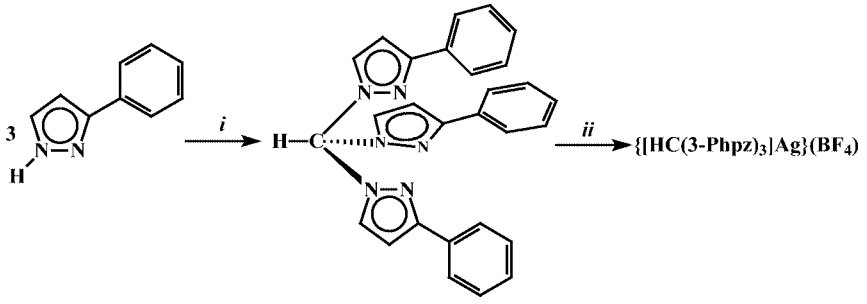
Syntheses and Characterization

$HC(3\text{-}Phpz)_3$ was prepared in high yield using a modified procedure of the published preparation[13] that avoids the chromatography step. The compound $[\{HC(3\text{-}Phpz)_3\}Ag](BF_4)$ (Scheme 2) was prepared by mixing a THF solution of the ligand with a THF solution of $AgBF_4$ in a 1:1 ratio. The same product is formed in a reaction using a 1:2 metal to ligand ratio, with one equivalent of the ligand recovered from the filtrate. The compound is an air and light stable solid. It is soluble in acetone, acetonitrile, and nitromethane but insoluble in halogenated solvents, water, or alcohols.

The ^1H NMR spectrum of the solid in CD_3CN shows that the acetonitrile completely replaces the ligand in solution; the spectrum of the compound in CD_3CN is the same as the free ligand in this solvent. However, the ^1H NMR spectra of the compound in deuterated acetone or nitromethane are clearly different from the free ligand, showing the coordination of the ligand to the silver(I) in these solutions. Although the X-ray structures of all crystalline forms of $[\{HC(3\text{-}Phpz)_3\}Ag](BF_4)$ show that in the solid state the pyrazolyl rings are non-equivalent (vide infra), the NMR spectra of $[\{HC(3\text{-}Phpz)_3\}Ag](BF_4)$ and similar complexes of silver containing the $[C(pz)_3]$ unit[20,21,23,25] all show equivalent rings, presumably because of fast exchange of the ligands and metals on the NMR timescale. This fast exchange process is maintained even at low temperatures.

An interesting solvent dependence was observed in the chemical shifts of the hydrogen atoms of the silver complex when they were compared with their initial position in the free ligand. In deuterated acetone the resonances that corresponds to the methine hydrogen and the 5-H (pz) were shifted ca. 0.4 ppm while the other resonances [the 4-H(pz) and phenyl hydrogens] were found at almost the same positions as in the free ligand. In deuterated nitromethane the only peak that was found shifted significantly was the 5-H(pz) with a shift of ca. 0.25 ppm. The greater shifts in acetone are likely due to hydrogen bonding of the acetone with the acidic methine hydrogen, an effect that has been observed previously.[29,30]

Electrospray mass spectroscopy (ES/MS) has emerged as a technique for investigating solution aggregation of covalent and noncovalent species. In the case of coordination polymers, ES/MS was used to probe the aggregation between the ligands and silver(I) salts in solution, aggregates that might be related to the building blocks and subsequently to the final supramolecular structure of the coordination polymers.[31] We performed the ES/MS experiment in three different solvents to establish such a connection,



Scheme 2. Preparation of $[\{HC(3\text{-}Phpz)_3\}Ag](BF_4)$: i: $HCCl_3$, Na_2CO_3, nBu_4NBr; ii: $AgBF_4$, THF

especially given the important influence the crystallization solvent has over the solid state structures (vide infra).

In nitromethane, four peaks were identified at 551, 610, 991, and 1187 *m*/*z*, corresponding to $[LAg]^+$, $[LAg(nitromethane)]^+$, $[L_2Ag]^+$, and $[L_2Ag_2(BF_4)]^+$ respectively. The spectrum is presented in Figure 1. The most abundant peak is the one that corresponds to $[LAg]^+$ species. The least abundant peak corresponds to the species that contains two ligands, two silver(I) ions and one BF_4^-, a peak that presumably arises from a species related to the presence of a coordination polymer in solution. When acetone was used, three peaks were identified at 551, 607, and 991 *m*/*z*, corresponding to $[LAg]^+$, $[LAg(acetone)]^+$, and $[L_2Ag]^+$ respectively. In this case the most abundant peak is the one that corresponds to the $[LAg(acetone)]^+$ species. The same situation was observed when acetonitrile was used as solvent. Three peaks at 551, 590, and 991 *m*/*z* were observed, corresponding to $[LAg]^+$, $[LAg(acetonitrile)]^+$, and $[L_2Ag]^+$ respectively. Interestingly, the most abundant species observed here is the one that corresponds to $[L_2Ag]^+$ species. These $[L_2Ag]^+$ species in all solvents could indicate individual species with a metal to ligand ratio of 1:2 in solution, but given that such species have only been observed for $[\{\kappa^3\text{-HC(3,5-Me}_2\text{pz)}_3\}_2\text{Ag}]^+$ [12] they more likely arise from solution coordination polymers. While the observation of $[L_2Ag_2(BF_4)]^+$ in the spectrum taken from the non-coordinating solvent nitromethane almost certainly arises from a solution coordination polymer, further studies are needed to definitively establish the relationship between ES/MS results and solution aggregation. What is clear from the NMR and ES/MS studies and the fact that coordination compounds of the ligand crystallize from acetonitrile and acetone (vide infra) is that in solutions of coordinating solvents a complicated series of equilibria take place between $[LAg]^+$ species (either aggregated or not), and species in which the solvent has partially or completely displaced the ligands.

Solid-State Studies

Given the versatility of the tris(3-Ph-pyrazolyl)methane ligand (L) we determined the solid state structure of the free ligand for comparison purposes. The molecular structure of the ligand together with the crystallographic and structure refinement data and selected bond lengths and angles are presented as supplementary information (Figure S1 and Tables S1 and S2, Supporting Information, see footnote on page 1 of this article). The ligand structure consists of discrete molecules without significant intermolecular associations. The orientation of the three pyrazolyl rings is a propeller arrangement with only one of the donor nitrogen atoms oriented toward the potential bonding "pocket" of the ligand. The pyrazolyl and phenyl rings are not in the same plane, the N(*n*1)−C(*n*1)−C(*n*4)−C(*n*5) (where *n* denotes the ring number) torsion angles between the rings ranging from 155 to 172 degrees.

We have grown crystals of $[\{HC(3\text{-Phpz})_3\}Ag](BF_4)$ from vapor phase diffusion of diethyl ether into nitromethane, acetonitrile, and acetone solutions of the complex in order

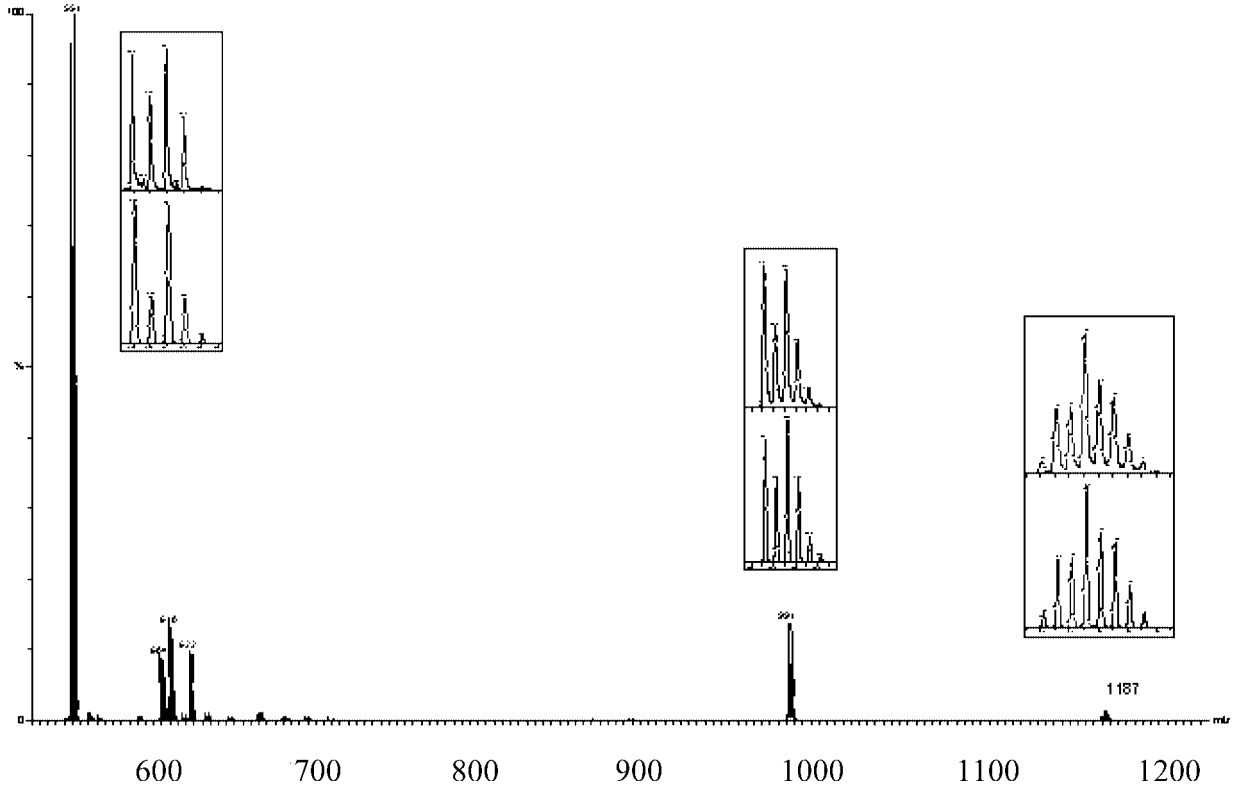

Figure 1. Portion of ES/MS spectra of $[\{HC(3\text{-Phpz})_3\}Ag](BF_4)$ in nitromethane; the insets show the observed (top) and calculated (bottom) isotopic patterns

to ascertain the effects of non-coordinating and coordinating solvents on molecular and the subsequent supramolecular structures. When nitromethane was used, two polymorphs were found, an orthorhombic form (**1**) and triclinic form (**2**). Both polymorphs are coordination polymers constructed by a κ^2-κ^1 coordination of the tris(3-Ph-pyrazolyl)methane units, with a metal to ligand ratio of 1:1. In contrast, when acetonitrile or acetone was used, two new discrete compounds were obtained, with the same metal to tris(pyrazolyl)methane ligand ratio, of the formula [{HC(3-Phpz)$_3$}Ag{$(CH_3)_2CO$}](BF_4) (**3**) and [{HC(3-Phpz)$_3$}Ag{CH_3CN}](BF_4) (**4**). In these compounds, the ligand shows tripodal coordination to a single silver center. In addition one solvent molecule is coordinated to the metallic center. The metrical parameters for all four compounds (bond lengths and angles) are given in Table 1.

The two crystallographically independent [{HC(3-Phpz)$_3$}Ag]$^+$ units and two BF_4^- anions of **1** are pictured in Figure 2 (a and b) together with their partial crystallographic numbering scheme (for a full crystallographic numbering scheme see the ORTEP representation of **1** in the Supplementary Information, Figure S2). Each ligand is κ^2-κ^1 coordinated to silver(I) centers. The polyhedra about Ag(1) and Ag(2) atoms are flattened trigonal pyramids [sum of the N−Ag−N bond angles = 332° for Ag(1) and 341° for Ag(2)], with a large distortion caused by the restricted bite angle [82.55(11)° for Ag(1) and 84.11(10)° for Ag(2)] of the κ^2-bonded ligand. The BF_4^- anions are located along the polymeric strand in the vicinity of the silver atoms. There are several close contacts between the silver and fluorine atoms in both chains, interactions that are best described as secondary bonds.[32] The Ag···F distances, shown as blue dotted lines in Figure 2, are listed in Table 2, together with other non-covalent parameters for **1**.[33−37] Interestingly, in **1** the BF_4^- anions are not involved in the organization of the extended structure, a structural feature frequently observed with other similar complexes.[21,23,25] There are several C−H···F weak hydrogen bonds (see Table 2), but they are interstrand only and pictured in Figure 2 (a and b) also as blue dotted lines. The H···F distances are all well below the sum of van der Waals radii for hydrogen and fluorine and are typical for this type of hydrogen bonding.

There are two crystallographically independent chains (Figure 2, c and e), that run along the *a* axis, associated with the independent atoms Ag(1) and Ag(2). As pictured in Figure 2 (c), the chain associated with Ag(1) has an intrastrand π−π stacking interaction (black double dotted lines) between the [N(31)−N(32)−C(31)−C(32)−C(33)] pyrazole ring that is κ^1 coordinated to silver(I) and the [C(14)−C(15)−C(16)−C(17)−C(18)−C(19)] phenyl ring attached to the [N(11)−N(12)−C(11)−C(12)−C(13)] pyrazolyl ring that is κ^2 coordinated to the same silver. The two rings are parallel displaced, resulting in a centroid−centroid distance of 3.83 Å, but with a perpendicular distance between the rings of 3.47 Å. These values are typical for a π−π stacking interaction.[35] There is no similar interaction in the chains associated with Ag(2). Figure 2 (d and f) show a view of both chains along the *a* axis, illustrating the overall similarity in the chains, where the only important difference is the orientation of the phenyl rings involved in the π−π stacking in the Ag(1) chain.

These non-covalent forces appear to be correlated with a twisting of the pyrazolyl rings. For maximum overlap with the lone pair on the donor nitrogen atoms the metal would lie in the plane of each pyrazole ring. Any deviation where the metal lies out of this plane can be measured by the Ag−N(*n*1)−N(*n*2)−C(*n*1) (where *n* denotes the ring number) torsion angle, an angle that is 180° for a metal located in the same plane as the ring. We have shown[38] that these deviations are related to the size of the metal when the tris(pyrazolyl)methane ligand is tripodal. For **1**, where the ligand is not tripodal, the angles associated with the Ag(1) chain are 160°, 145°, and 122° and those associated with Ag(2) chain are 165°, 143°, and 134° respectively. The greatest value (least twisting) in this series (165°) is correlated with a pyrazolyl and its associated phenyl ring that are *not*

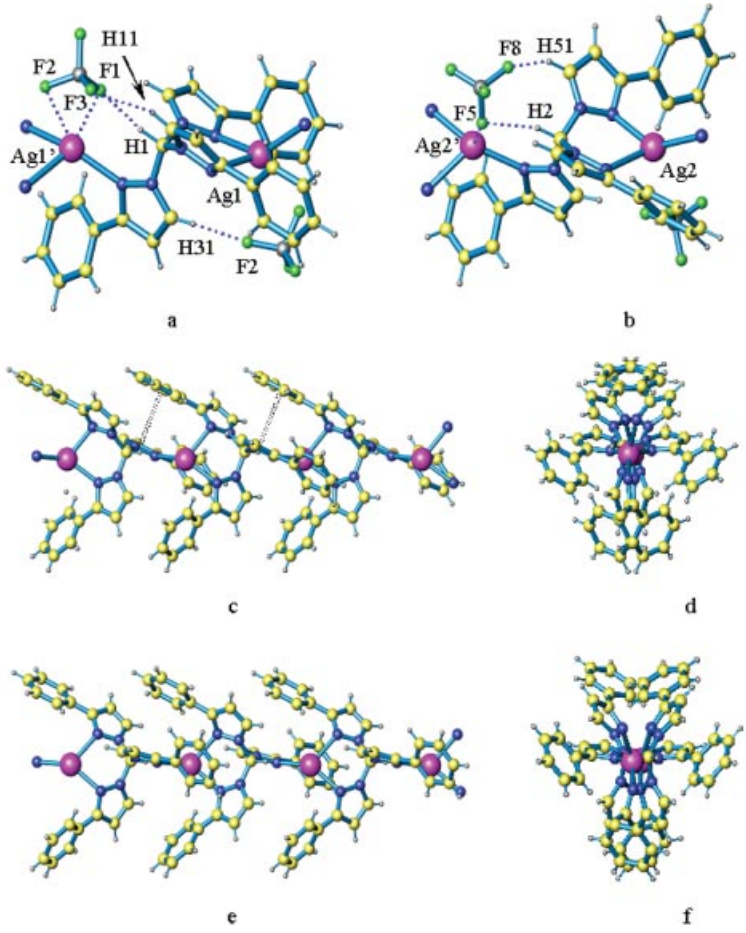

Figure 2. a, b) Formation of the two independent chains in **1** based on the κ^2-κ^1 coordination mode of the HC(3-Phpz)$_3$ ligand; secondary Ag···F bonds and C−H···F weak hydrogen bonds are shown as blue dotted lines; color scheme: silver purple, carbon yellow, nitrogen blue, fluorine green; c) Ag(1) chain with the π−π stacking between pyrazolyl and phenyl rings showed as black double dotted lines; d) end-on view of the same chain; e) Ag(2) chain, with no intrastrand interactions; f) view down the Ag(2) chain

involved in any non-covalent interaction. In contrast, the smallest value in this series (122°) is related to the [N(11)−N(12)−C(11)−C(12)−C(13)] pyrazolyl ring that has its associated phenyl ring involved in the intrachain π−π stacking as showed above. Furthermore, this pyrazolyl ring participates in a C−H···F hydrogen bond, see Figure 2 (a).

The non-equivalent chains of **1** are organized into a 3-D supramolecular structure by C−H···π interactions. The chains are organized into corrugated sheets by two interactions of this type, with phenyl rings acting as both donors and acceptors. The sheets are situated in the *ab* plane of the crystal. Further, the sheets are held together by another C−H···π interaction, with a pyrazolyl ring acting as donor and a phenyl ring acting as acceptor. The metrical parameters for these interactions are given in Table 2 and are represented by red dotted lines in Figure 3, which shows partial views of two of the sheets down the polymer chains.

Compound **2** is also a coordination polymer, built by the same κ^2−κ^1 coordination mode of the HC(3-Phpz)$_3$ ligand. Figure 4 (a) shows a portion of this coordination polymer together with the partial numbering scheme (for a full crystallographic numbering scheme see the ORTEP representation of **2** in the Supplementary Information, Figure S3). Selected bond lengths and angles are summarized in Table 1. The polyhedra around the silvers are again flattened trigonal pyramids [sum of the N−Ag−N bond angles = 339° for Ag(1) and 343° for Ag(2)], with a large distortion caused by the restricted bite angle [86.08(9)° for Ag(1) and 85.17(9)° for Ag(2)] of the κ^2-bonded ligand. The difference between **1** and **2** is that in **2** there is only one independent chain containing two independent silver atoms, while in **1** there are two independent chains, associated with two independent silver atoms. A similarity with **1** is that the BF_4^- anions are located along the polymeric strand in the vicinity of silver atoms, leading to close contacts between the silver and fluorine atoms along the chain. The Ag···F distances (blue dotted lines) are listed in Table 2, together with other non-covalent parameters for **2**. Another similarity between **1** and **2** is that the BF_4^- anions are not involved in the organization of the supramolecular structure and all the C−H···F weak hydrogen bonds are intrastrand. They are pictured in Figure 4 (a) as blue dotted lines and their metrical parameters are given in Table 2.

In the case of **2** there are several additional non-covalent interactions within the polymeric strands, also represented

in Figure 4 (a). There are two π−π stacking interactions involving both pyrazolyl and phenyl rings. One interaction (shown as black double dotted line) involves one of the κ^2 bonded pyrazolyl ring [N(21)−N(22)−C(21)−C(22)−C(23)] and the phenyl ring associated with one of the κ^1 bonded pyrazolyl ring [containing N(61)] with a perpendicular distance between the rings of 3.73 Å. Another π−π interaction involves the second κ^1 bonded pyrazolyl ring [N(31)−N(32)−C(31)−C(32)−C(33)] and a phenyl ring attached to another κ^2 bonded pyrazolyl ring [containing N(51)] with a perpendicular distance between the rings of 3.63 Å. This interaction is shown in Figure 4 (a) by two black arrows pointing toward where the respective group would be located if more of the strand were shown. There are additional C−H···π interactions within the strand (red dotted lines) with the metrical parameters listed in Table 2.

There is substantial tilting of the pyrazolyl rings from the ideal value of 180°. The torsion angles around the Ag(1) atom are 164°, 144°, and 124° and those around the Ag(2) atom are 170°, 151°, and 118°, respectively. As in **1**, these angles are correlated to the non-covalent interactions within the strand. For example, the Ag(1)−N(11)−N(12)−C(11) angle of 124° is related to a C−H···π interaction formed by the [N(11)−N(12)−C(11)−C(12)−C(13)] ring, acting as acceptor, with one of the phenyl rings involved in the π−π stacking interaction. The associated phenyl ring acts also as the acceptor in another C−H···π interaction where the donor is the [N(41)−N(42)−C(41)−C(42)−

C(43)] pyrazolyl ring. The Ag(2)−N(51)−N(52)−C(51) torsion angle of 118° is influenced by four non-covalent interactions. The pyrazolyl ring associated with the largest angle is not involved in any non-covalent interactions.

The supramolecular structure of **2** is only 2-D and is again organized by C−H···π interactions, Table 2. A pair of these interactions organizes the strands into dimers that are oriented in the direction of the *c* axis. A third interaction organizes the dimers into sheets placed parallel to the *ab* plane of the crystal. Figure 4 (b) depicts a 2-D sheet built up from three dimers with the C−H···π interactions represented by red dotted lines.

The replacement of nitromethane with acetone or acetonitrile as the crystallization solvent leads to a dramatic change in the structure of the compound. The coordination of one molecule of solvent to the silver atom, together with a tripodal, κ^3-coordination of the (3-Ph-pyrazolyl)methane ligand leads to the formation of discrete complexes of the formula $[\{HC(3\text{-}Phpz)_3\}Ag\{(CH_3)_2CO\}](BF_4)$ (**3**) and $[\{HC(3\text{-}Phpz)_3\}Ag\{CH_3CN\}](BF_4)$ (**4**).

The crystal structure of **3** contains two symmetry independent units of virtually identical conformation about the silver(I) (see Table 1), but which have different supramolecular contacts. The two units and their partial numbering schemes are represented in Figure 5 (a and b) (for a full crystallographic numbering scheme see the ORTEP representation of **3** in the Supplementary Information, Figure S4; see also footnote on the first page of this article). The silver atoms have a distorted tetrahedral arrangement. For the first unit the average Ag(1)−N distance is 2.37 Å with a corresponding N−Ag(1)−N average angle of 80.64°. The Ag(1)−O distance is 2.231(3) Å, with an average N−Ag(1)−O angle of 131.25°. For the second unit the average Ag(2)−N distance is the same as for the first, 2.37 Å, but with a corresponding N−Ag(2)−N average angle of 81.29°. The Ag(2)−O distance is 2.172(4) Å with the corresponding average N−Ag(2)−O angle of 130.9°.

In contrast with **1** and **2**, where the counterions interacted with the silvers and were not involved in interchain interactions, the cations in **3** are organized into a 3-D structure using both weak C−H···F hydrogen bonds and C−H···π interactions (Table 2). The unit containing the Ag(1) atom is organized into chains via C−H···F hydrogen bonds, Figure 5 (c). The BF_4^- counterion makes two hydrogen bonds, shown as blue dotted lines, one with the methine hydrogen H(101) and another with H(138), a hydrogen situ-

ated on one of the phenyl rings. The (C)H···F distances to H(101) and H(138) are 2.33 and 2.39 Å with the corresponding C−H−F angles of 150 and 148°. Both these distances are below the sum of van der Waals radii for hydrogen and fluorine[33,34] and are typical for this type of hydrogen bonding.[39,40] These interactions build up chains that run along *c* axis of the unit cell. The chains are arranged into sheets by means of C−H···π interactions, as can be seen also in Figure 5 (c) as red dotted lines. One hydrogen atom from a phenyl group in one cationic unit is pointed toward a pyrazolyl ring within another chain thus generating a sheet in the *bc* plane of the unit cell.

The unit containing the Ag(2) atom has a different supramolecular organization, based again on both C−H···π interactions and weak C−H···F hydrogen bonds. One C−H···π interaction is between H(217), located in a phenyl ring and the pi cloud of a phenyl ring on an adjacent silver(I) unit, Figure 5 (d). The hydrogen to centroid distance is 2.90 Å with the corresponding C−H-centroid angle of 149° see also Table 2. This distance is typical for C−H···π interactions.[36,37] A pair of these interactions, showed as red dotted lines, links two Ag(2) units forming a dimer.

The BF_4^- ions connect these dimers into a 2-D supramolecular network (see Table 2 for metrical parameters) via C−H···F hydrogen bonds. Figure 5 (e) shows seven dimeric assemblies viewed in the same orientation as in Figure 5 (d), connected by the BF_4^- anions. At the corners of each square shaped dimeric unit, each dimer is bonded to four other dimers arranged in a square around it through four BF_4^- anions. The two "outside" dimers in Figure 5 (e) are not connected to the central dimer but to the two dimeric units above and below them in the figure.

The sheets associated with Ag(1) and Ag(2) are arranged in a 3-D architecture again by weak C−H···F hydrogen bonds and C−H···π interactions, Figure 6. One fluorine atom that is part of the BF_4^- anion involved in the organization of the Ag(2) units in chains makes a close contact with a hydrogen located on an acetone molecule coordinated to an Ag(1) unit. The H···F contact is 2.26 Å (C···F contact of 3.22 Å) with a corresponding C−H−F angle of 165°. A second interaction holding the sheets together is a C−H···π interactions formed between a hydrogen atom situated on a phenyl ring within the Ag(1) unit and another phenyl ring that is part of Ag(2) unit. The H···centroid distance is 2.90 Å and the C···centroid distance of 3.78 Å, with the corresponding C−H-centroid angle of 153°.

When acetone was replaced with acetonitrile in the crystallization procedure, the structures of the two silver(I) units of the resulting compound (**4**) are similar to those of **3**. The crystal structure of **4** contains two symmetry independent units of virtually identical conformation but which have different supramolecular contacts. The two units and their partial numbering schemes are represented in Figure 7 (for a full crystallographic numbering scheme see the ORTEP representation of **4** in the Supplementary Information, Figure S5). The silver atoms again have a distorted tetrahedral arrangement. For the first unit the average $Ag(1)-N_{pz}$ distance is 2.36 Å with a corresponding $N_{pz}-Ag-N_{pz}$ average angle of 80.06°. The Ag(1)−N(101) distance is 2.137(2) Å, with an average $N_{pz}-Ag(1)-N(101)$ angle of 132.03°. For the second unit the average $Ag(2)-N_{pz}$ distance is 2.37 Å, with a corresponding $N_{pz}-Ag-N_{pz}$ average angle of 80.78°. The Ag(2) − N(201) distance in this case is 2.149(2) Å with the corresponding average $N_{pz}-Ag(2)-N(201)$ angle of 131.19°. For further details on the bond lengths and angles see Table 1. The BF_4^- counterions make hydrogen bonds with the hydrogen atoms attached to the central methine carbon atoms. The BF_4^- anion associated with Ag(1) was found to be disordered over two closely spaced positions so further discussions about its role in the extended structure of **4** are precluded; Figure 7 (a) pictures one component of the disordered counterion, but in further discussions this counterion will not be mentioned.

The units containing the Ag(1) silver atoms are organized in chains running along the *b* axis by means of two C−H···π interactions (see Table 2 for details). In both cases, two pyrazolyl rings act as acceptors and two phenyl rings as hydrogen donors. Figure 8 (a) illustrates three chains, that are further connected in a 2-D network, again through C−H···π interactions, with pyrazolyl rings acting as acceptors and phenyl rings as hydrogen donors. The interactions responsible for the formation of the chains and sheets are pictured as red dotted lines in Figure 8 (part a). Figure 8 (part b) is a view end-on of the Figure 8 (part a), showing the orientation of the sheets in the *bc* plane of the unit cell.

The units containing the Ag(2) atoms are arranged in a different way. A double π−π/C−H···π interaction organizes these units in dimers, as pictured in Figure 9. The metrical

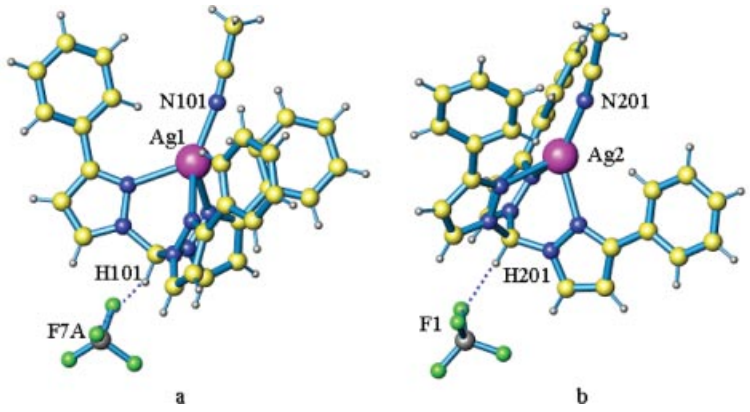

Figure 7. Two silver(I) building blocks in **4** with the BF_4^- counterions positioned close to the methine hydrogen; the BF_4^- anion in (a) is disordered over two positions; only one component is shown here

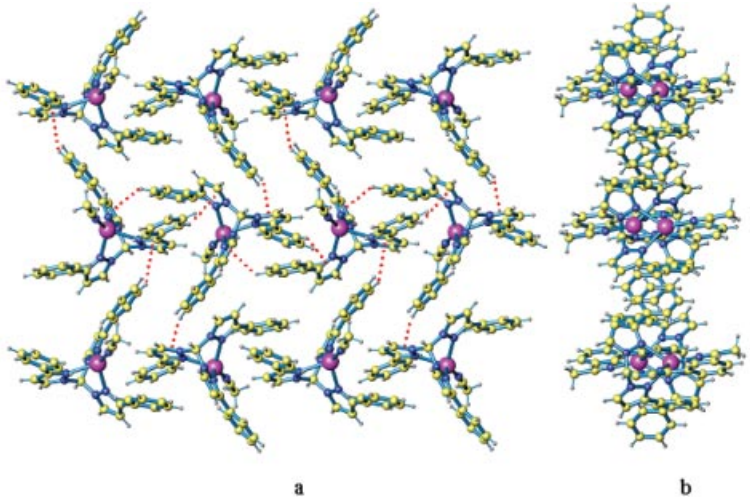

Figure 8. Formation of Ag(1) sheets in **4**: a) view perpendicular to the sheet, illustrating three interconnected chains; the C−H···π interactions that form the chains are represented only within the middle chain; b) end-on view of the same sheet in the *bc* plane of the unit cell

parameters for these non-covalent interactions are listed in Table 2. The π−π stacking is between two phenyl rings that also act as hydrogen donors in the C−H···π interaction, with two other phenyl rings acting as acceptors. The stacked phenyl rings are parallel, but displaced in order to maximize the C−H···π interaction, the angle formed by the centroid−centroid vector with the ring normal being 30°. The centroid−centroid distance is 3.9 Å and the perpendicular distance between the planes is 3.4 Å.[35] There is also a shift from an ideal geometric arrangement for the C−H···π interaction. The presence of the π−π stacking between the parallel displaced phenyl rings leads to a rather long H···centroid distance of 3.02 Å, but the perpendicular distance from the hydrogen atom to the acceptor phenyl planes is 2.7 Å, with the corresponding C−H−centroid angle of 171°.[36,37]

These two units are arranged into a supramolecular structure by the means of weak (C)H···F hydrogen bonds. The ordered BF_4^- counterion act as a bridge between one Ag(1) chain and one Ag(2) dimer, Figure 10 (a). The F(3) atom within the BF_4^- counterion is involved in a bifurcated hydrogen bond with two hydrogen atoms located on the fifth carbon atom of the pyrazolyl rings. As it can be seen in Table 2, the H···F contacts are short, with C−H−F angles approaching to linearity. The resultant architecture is further connected into a 3-D network by the non-covalent C−H···π interactions that connects the Ag(1) chains into sheets, as pictured in Figure 10 (b). There is no non-coval-

ent interaction holding the dimers associated with Ag(2) together. The sheets in Figure 10 (b) are in the same orientation as in Figure 8 (b).

Comparison of Molecular and Supramolecular Structures

Our systematic X-ray crystallographic studies reveal that a coordinating solvent dramatically changes the molecular structures and/or the supramolecular structures of the four forms of [{HC(3-Phpz)$_3$}Ag](BF_4) studied here. In the absence of a coordinating solvent, the tris(3-phenyl-pyrazolyl)methane ligand bridges two silver atoms in the κ^2-κ^1 bonding mode forming coordination polymers arranged in argentachains. This arrangement of the ligands allows room for the BF_4^- counterion to be located in the vicinity of the silver atoms, with close silver−fluorine contacts (see Table 2 and Figure 2, a, b and Figure 4, a). This secondary interaction between the silver and fluorine atoms completes the fourth coordination site and prevents the anions from participating in the organization of the subsequent supramolecular structures of the polymeric chains. Two polymorphs with the same basic κ^2-κ^1 coordinating mode have been crystallized that have different supramolecular structures based on similar types of non-covalent interactions. In compound **1** there are two independent chains having different shapes (Figure 2, d and f) and in **2** only one type of chain is present, with a different internal structure than in **1**. Noncovalent forces organize the chains into sheets and the sheets into a final 3-D supramolecular structure in the case of **1**, while in the case of **2** only a 2-D supramolecular structure forms (compare Figures 3 and 4, b).

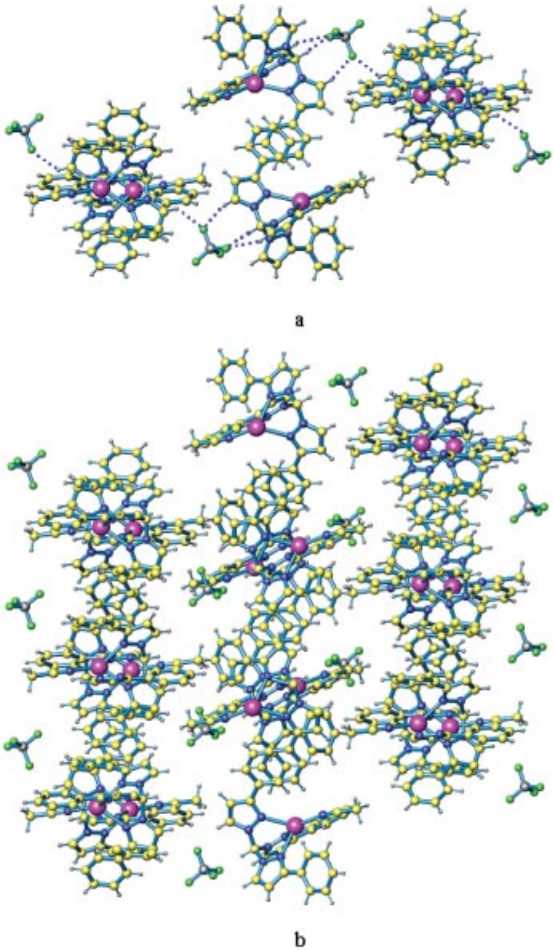

Figure 10. a) Two Ag(1) chains and one Ag(2) dimer in **4** bridged by the counterions, with the C−H···F hydrogen bonds shown as blue dotted lines; one fluorine atom makes a bifurcated hydrogen bond with hydrogen atoms situated on the fifth position of pyrazolyl rings; b) the extended 3-D structure of **4**, showing six Ag(1) chains in two Ag(1) sheets (left and right, view down the chains) and three Ag(2) dimers (middle) bridged by six BF_4^- counterions

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The structures of the same complex crystallized from the coordinating solvents acetone and acetonitrile are very different from **1** and **2**. The structures feature a κ^3 tripodal coordination mode of the tris(3-phenylpyrazolyl)methane ligand with the fourth coordination site on the silver filled with the solvent, thus generating the discrete compounds **3** (Figure 5, a, b) and **4** (Figure 7) rather than coordination polymers. In both cases the structures of the silver cationic units are very similar. Their asymmetric units contain two chemically similar but crystallographically independent [HC(3-Phpz)$_3$Ag(solvent)] cations. The coordination environment around the silver atom is also similar − a distorted tetrahedron.

The supramolecular structures of **3** and **4** are also similar. In both cases one type of silver(I) unit associates in chains and then in sheets (Figure 5, c, and Figure 8). The second type of silver(I) forms dimeric units (Figure 5, d, and Figure 9). Association between the sheets and dimers leads in both cases to a 3-D supramolecular structure. However, the connection pattern and the resulting extended structures are different. In the case of **3** the chains are supported by weak H···F hydrogen bonds with the BF_4^- counterion acting as a bridge between the cationic units, whereas in **4** the chains are formed only by the means of C−H···π interactions with phenyl rings acting as hydrogen donors and pyrazolyl rings acting as acceptors. The sheets that result from the association of the chains are in both cases supported by C−H···π interactions where the phenyl rings are the donors and pyrazolyl rings are the acceptors.

The mode of formation of the dimeric units in each structure is also different. The self-assembly of the dimeric units in **3** are supported by C−H···π interactions with phenyl rings acting as hydrogen donors and acceptors, while in **4** there is an additional π−π stacking between the phenyl rings that are the hydrogen donors in the C−H···π interaction. The shape of the acetone molecule (two methyl groups, see Figure 5, d) prevents the donor phenyl rings involved in the C−H···π interaction from getting close enough for the additional π−π stacking observed in the case of **4**, where an acetonitrile molecule (one methyl group, see Figure 9) does not have such a pronounced steric effect.

The role of the dimers is also different. In **3**, the dimers are arranged in chains by the non-covalent forces, forming a 2-D array of dimers (Figure 5, e) and the association of these sheets forms the overall supramolecular structure pictured in Figure 6. In contrast, in **4** the dimers are not arranged into an extended structure, their contribution to the 3-D supramolecular structure is that they act, together with the BF_4^- anions, as a bridge between two sheets, as shown in Figure 10 (a).

Conclusion

An important conclusion of this work is that in silver(I) chemistry the non-linked, tris(pyrazolyl)methane ligand HC(3-Phpz)$_3$ supports complex supramolecular structures using the same types of covalent and non-covalent forces observed in the silver(I) complexes of the linked multitopic ligands studied earlier. In the absence of a coordinating solvent, [{HC(3-Phpz)$_3$}Ag](BF$_4$) forms two polymorphs with structures dominated by polymeric argentachains that are constructed from the κ^2-κ^1 bonding mode of each ligand, a bonding mode that is frequently observed in the structures of the linked ligands.[20,21,25] In these structures, the weakly coordinating counterion BF_4^- bonds to the silvers completing the coordination spheres. This interaction removes the BF_4^- groups from the ability to support the supramolecular structure through weak H···F hydrogen bonds with the acid hydrogen atoms located on the ligands of different cationic units.

When [{HC(3-Phpz)$_3$}Ag](BF$_4$) is crystallized from coordinating solvents, the solvent bonds directly to silver. The presence of the coordinating solvent changes the bonding mode of the HC(3-Phpz)$_3$ ligand to tripodal. Even in the absence of a coordination polymer formed by either the κ^2-κ^1 coordinating mode or from the linking component of the multitopic ligands, complex supramolecular structures form from an interesting array of non-covalent interactions. In these structures, the BF_4^- does not interact with the metal, but contributes to the supramolecular structures through weak H···F hydrogen bonds.

Tris(pyrazolyl)methane ligands, whether monotopic or multitopic, clearly contain functionality that supports 2D and 3D supramolecular structures organized by weak hydrogen bonds, π−π stacking, and C−H···π interactions. Their ability to act as (a) κ^3 tripodal, (b) κ^2 bonded to a single metal with the third pyrazolyl not coordinated, and (c) κ^2-κ^1 bonded bridging two metals adds to the structural diversity observed for silver(I) complexes of these ligands. The 3-phenyl substituents on the pyrazolyls add to the structural diversity of HC(3-Phpz)$_3$ complexes in comparison to those of the parent HC(pz)$_3$ ligand.

An understanding of how the covalent and non-covalent forces organize the supramolecular self-assembly process is a prerequisite for the progress of crystal engineering. This study shows that although the same types of forces are involved in building the supramolecular structures of **1**−**4**, differences were found when the extended structures of even similar building blocks were compared. A good example is given by the formation of the dimeric units of **3** and **4** and their role in the extended structures. In one case they are formed only by a C−H···π interaction and in the other there is an additional π−π stacking as a supporting interaction. Also, each has a different role in the resulting supramolecular structure. Further studies are clearly needed in order to ascertain the influence of *all* factors on the outcome of a supramolecular arrays if one hopes to fully understand/control the self-assembly process.

Experimental Section

General Remarks: All manipulations involving uncomplexed silver tetrafluoroborate were carried out either in a Vacuum Atmospheres HE-493 dry box under a N_2 atmosphere or by using standard

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Schlenk techniques. After complexation of the silver salt by the ligand no precautions were taken to exclude moisture or oxygen. All solvents were dried using conventional procedures and distilled prior to use. The ^{1}H NMR spectra were recorded on a Varian AM300 spectrometer using a broad-band probe. Proton chemical shifts are reported in ppm vs. internal Me_4Si. Mass spectroscopic data were recorded on a MicroMass QTOF spectrometer. Clusters assigned to specific ions show appropriate isotopic patterns as calculated for the atoms present. Robertson Microlit Laboratories, Inc. (Madison, NJ) performed the elemental analyses. Silver tetrafluoroborate and 3-Ph-pyrazole (3-PhpzH) were used as purchased from Aldrich. Samples for melting point determinations were contained in flame sealed capillaries and the reported temperatures are uncorrected.

HC(3-Phpz)$_3$: Distilled water (400 mL) was added to a 1000 mL flask containing a mixture of 3-phenylpyrazole (28.8 g, 0.20 mol) and tetra-*n*-butylammonium bromide (3.2 g, 9.9 mmol). With vigorous stirring, sodium carbonate (127 g, 1.2 mol) was added gradually to the reaction mixture. Then chloroform (150 mL) was added and the flask was equipped with a reflux condenser. This mixture was heated at reflux for 3 days over which time it became a dark yellow emulsion. The mixture was allowed to cool to room temp. and filtered to remove the solid Na_2CO_3. The organic layer was separated from the aqueous layer and the latter extracted with diethyl ether (3 × 75 mL). The combined organic layers were washed with distilled water (2 × 150 mL) and dried over sodium sulfate. The solution was filtered and the solvent was removed by rotary evaporation. The resulting off-white solid containing 3/5-substituted isomers was then dissolved in the minimum required amount of boiling toluene and poured into a 100 mL flask containing a small amount of *p*-toluenesulfonic acid monohydrate (ca. 0.1 g). The golden solution was heated at reflux temperature overnight. After it had cooled to room temp., an off-white precipitate appeared that was filtered with suction. The moist powder was taken into a beaker and 200 mL of distilled water added. After 2 hours of stirring the suspension was filtered (suction), washed twice with water and once with hexanes, to afford 15 g (52%) of pure HC(3-Phpz)$_3$ as a white powder. M.p. 125−126 °C. ^{1}H NMR ([D$_6$]acetone): δ = 8.86 (s, 1 H, *H*C), 8.10 (d, *J* = 2.1 Hz, 3 H, 5-H *pz*), 7.90 (m, 6 H, *o*-H *Ph*), 7.42 (m, 6 H, *m*-H *Ph*), 7.35 (m, 3 H, *p*-H *Ph*), 6.90 (d, *J* = 2.1 Hz, 3 H, 4-H *pz*) ppm. ^{1}H NMR ([D$_3$]nitromethane): δ = 8.64 (s, 1 H, *H*C), 7.95 (d, *J* = 2.7 Hz, 3 H, 5-H *pz*), 7.87 (m, 6 H, *o*-H *Ph*), 7.42 (m, 9 H, *m*-H, *p*-H *Ph*), 6.86 (d, *J* = 2.7 Hz, 3 H, 4-H *pz*) ppm.

[{HC(3-Phpz)$_3$}Ag](BF$_4$): *Reaction A (1:1 metal to ligand ratio):* Silver tetrafluoroborate, $AgBF_4$ (0.195 g, 1.0 mmol) was dissolved in dry THF (15 mL). To this solution was added via syringe a solution of HC(3-Phpz)$_3$ (0.442 g, 1.0 mmol) in THF (15 mL). After stirring the reaction mixture overnight, hexanes were added (75 mL) and a white precipitate appeared. The mixture was kept 1 hour at −20 °C, and then quickly filtered to afford 0.592 g (93%) of a white powder identified by elemental analysis as [{HC(3-Phpz)$_3$}Ag](BF$_4$): $C_{28}H_{22}AgBF_4N_6$ calcd. C 52.79, H 3.45, N 13.18%, found C 52.43, H 3.65, N 13.09%. *Reaction B (1:2 metal to ligand ratio):* The second procedure involved the same steps as procedure A, using 0.097 g of $AgBF_4$ (0.50 mmol) and 0.442 g of HC(3-Phpz)$_3$ (1.0 mmol). The white compound obtained was identified by elemental analysis as [{HC(3-Phpz)$_3$}Ag](BF$_4$): $C_{28}H_{22}AgBF_4N_6$ calcd. C 52.79, H 3.45, N 13.18, found C 52.93, H 3.36, N 12.79. In addition, 0.5 mol of the ligand was recovered from the filtrate. The ^{1}H NMR spectra of the two samples were identical and they are listed below [D$_6$]acetone: δ = 9.30 (s, 1 H, *H*C), 8.42 (d, *J* = 2.4 Hz, 3 H, 5-H *pz*), 7.92 (m, 6 H, *o*-H *Ph*), 7.43 (m, 9 H, *m*-H, *p*-H *Ph*), 6.98 (d, *J* = 2.4 Hz, 3 H, 4-H *pz*) ppm; [D$_3$] nitromethane: δ 8.67 (s, 1 H, *H*C), 8.19 (d, *J* = 2.4 Hz, 3 H, 5-H *pz*), 7.83 (m, 6 H, *o*-H *Ph*), 7.41 (m, 9 H, *m*-H, *p*-H *Ph*), 6.87 (d, *J* = 2.7 Hz, 3 H, 4-H *pz*) ppm.

X-ray Crystallographic Study: Suitable colorless single crystals of **1**−**4** were selected and mounted onto thin glass fibers. Low-temperature X-ray intensity data were measured on a Bruker SMART APEX CCD-based diffractometer (Mo-*Kα* radiation, λ = 0.71073 Å). After preliminary crystal quality and unit cell parameter determination, a full sphere (**1**, **2**) or hemisphere (**3**, **4**) of raw frame data was collected. Raw data frame integration was performed with SAINT+,[41] which also applied corrections for Lorentz and polarization effects. Analysis of each data set showed negligible crystal decay during data collection. Empirical absorption corrections were applied to each data set (SADABS)[41] in the case of **1**, **2**, and **4**, while in the case of **3** no correction for absorption was applied. The reported final unit cell parameters are based on the least-squares refinement of all reflections from each data set with $I > 5\sigma(I)$. The structures were solved by a combination of direct methods and difference Fourier syntheses and refined by full-matrix least-squares against F^2 (SHELXTL).[42] Non-hydrogen atoms in each structure were refined with anisotropic displacement parameters; hydrogen atoms were placed in idealized positions and included as riding atoms. For **1** systematic absences in the intensity data were consistent with the space groups *Pcam* and *Pca*2$_1$; intensity statistics indicated acentricity. The structure was solved in the polar space group *Pca*2$_1$. Upon successful solution and refinement in *Pca*2$_1$, a check for missed symmetry using the ADDSYM program in PLATON[43] verified the space group choice. All atoms reside on positions of general crystallographic symmetry. The structure contains two crystallographically independent polymeric chains, associated with the independent atoms Ag(1) and Ag(2). At the end of the refinement, the Flack parameter was 0.24(2), indicating that both orientations of the polar axis are present and the crystal is an inversion twin. Refinement of the data accounting for the twinning[42] yielded twin fractions of 0.76/0.24. Compound **2** crystallizes in the triclinic system. The space group $P\bar{1}$ was assumed and confirmed by the successful solution and refinement of the structure. The asymmetric unit contains two ligands, two silver atoms and two BF_4^- counterions with all of them residing on positions of general crystallographic symmetry. Systematic absences in the data sets for **3** and **4** were consistent with the space group $P2_1/c$, and the structures were readily solved in this space group. The asymmetric unit of **3** contains two chemically similar but crystallographically independent [{HC(3-Phpz)$_3$Ag}(CH$_3$)$_2$CO]$^+$ cations, two BF_4^- anions and one acetone molecule of crystallization. All atoms reside on positions of general crystallographic symmetry. The asymmetric unit of **4** contains two chemically similar but crystallographically independent [{HC(3-Phpz)$_3$Ag}(CH$_3$CN)]$^+$ cations, two BF_4^- anions, and one diethyl ether molecule of crystallization. All atoms reside on positions of general crystallographic symmetry. One BF_4^- anion is disordered over two closely spaced positions; a total of 30 geometric restraints (SHELX SAME) were used to assist in modeling the disorder. Crystal data and structure refinement for all compounds are presented in Table 3. CCDC 203781−203784 (**1**−**3**) and -205526 (**4**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Synthesis and Characterization of the Very Bulky Phenols Ar*OH and Ar′OH (Ar* = C_6H_3-2,6-$Trip_2$, Trip = C_6H_2-2,4,6-*i*Pr_3; Ar′ = C_6H_3-2,6-$Dipp_2$, Dipp = C_6H_3-2,6-*i*Pr_2) and Their Lithium and Sodium Derivatives $(LiOAr')_2$ and $(NaOAr^*)_2$

Corneliu Stanciu,[a] Marilyn M. Olmstead,[a] Andrew D. Phillips,[a] Matthias Stender,[a] and Philip P. Power*[a]

Dedicated to the memory of Ron Snaith, a pioneer in alkali metal chemistry

Keywords: Phenol / Phenoxide / Terphenyl / Alkali metals

The very bulky phenols Ar*OH (**1**) and Ar′OH (**2**), where Ar* = C_6H_3-2,6-$Trip_2$ (Trip = C_6H_2-2,4,6-*i*Pr_3) and Ar′ = C_6H_3-2,6-$Dipp_2$ (Dipp = C_6H_3-2,6-*i*Pr_2), as well as their lithium and sodium derivatives $(LiOAr^*)_2$ (**3**), $(LiOAr')_2$ (**4**) and $(NaOAr^*)_2$ (**5**) have been synthesized and characterized. The terphenols **1** and **2** were obtained by the reaction of the aryllithium reagents with nitrobenzene and were isolated in *ca.* 70% yield. The lithium or sodium salts **3**–**5** were isolated by the reaction of **1** or **2** with *n*BuLi or sodium metal. All compounds were characterized spectroscopically, and by X-ray crystallography in the case of **1**, **2**, **4** and **5**. The large terphenyl substituents prevent hydrogen-bonded association of the phenols **1** and **2**. Instead, the O–H hydrogens interact with the π-electron cloud on one of the flanking Trip or Dipp rings. The dimeric structures of **4** and **5** are relatively rare examples of structurally characterized alkali metal phenoxides that are unsolvated by internal electron pair donors or classical Lewis bases such as ethers or amines.

Introduction

The continuing interest in sterically encumbered phenols is mainly due to use of their deprotonated derivatives (aryloxides) as protecting ligands for a large variety of metallic and non-metallic reactive centers.[1] Such ligands have been extensively used to stabilize low coordinate compounds,[1,2] persistent odd-electron species[3] and heavier main group compounds with multiple bonds.[4] Aryloxides have been used as supporting ligands in metal catalysts as exemplified by the employment of Zn^{II} and Cd^{II} aryloxide derivatives in the copolymerization of epoxides and carbon dioxide.[5] In addition, aryloxide ligands have been employed to synthesize bowl-shaped Lewis acid host molecules as in $Al\{OC_6H_3$-2,6-$Ph_2\}_3$ which can encapsulate Lewis base guests and protect and accelerate chemical reactions with various substrates.[6] The most common, currently used, sterically hindered aryloxides are those that employ either *t*Bu or Ph substituents at the ortho positions of the phenoxide aryl ring. Some members of these ligand classes are commercially available as illustrated by the examples 1-HOC_6H_2-2,4,6-*t*Bu_3 and 1-HOC_6H_3-2,6-Ph_2. In both of these ligands, however, the ortho *t*Bu or Ph groups are susceptible to activation either to form oxametallacycle rings, or dehydrogenation can occur in the alkyl-substituted species. For the phenyl-substituted -OC_6H_3-2,6-Ph_2 activation of the ortho phenyls by close approach of the phenyl CH groups to the reactive center can occur by rotation of the ortho phenyl ring so that it is almost coplanar with the central phenoxide moiety. Recent work by Rothwell and coworkers has shown that when large meta substituents are also present at the central ring, as in -OC_6H-2,6-Ph_2-3,5-*t*Bu_2,[7] resistance or immunity to the cyclometallation reaction is induced because the ortho phenyl rings cannot become coplanar with the central ring due to the steric effects of the *t*Bu substituents. In related work we have pursued the use of very bulky terphenyl ligands in the stabilization of several new compound classes.[8] In these ligands, bulky substituents have been introduced on the flanking aryl rings [e.g., *i*Pr groups in -C_6H_3-2,6-*i*Pr_2(Dipp) or -C_6H_2-2,4,6-*i*Pr_3(Trip)] to prevent them from becoming coplanar with the central phenyl ring. In this way an approximately perpendicular orientation of the flanking rings is maintained which protects the wedge shaped cavity containing the reactive center. In much of this work the terphenyl ligand has been attached directly to the reactive center. However, we have also shown that several derivatives of terphenyl ligands (or their precursors) can be synthesized by attachment of

-NH_2,[9] PH_2,[9] AsH_2,[9] SbH_2,[9] -SH,[10] or SeH[10] groups to the central phenyl ring at the C-1 position to give very bulky terphenylamines, phosphanes, thiols, etc. A notable omission from this list are the corresponding phenol derivatives. Their absence can be partially explained on the basis of synthetic difficulties due to steric hindrance and solubility effects. In seeking a route to such compounds we have examined several synthetic routes to the two bulky terphenols and show that they can be synthesized in good yield and that they readily form alkali metal salts in essentially quantitative yields.

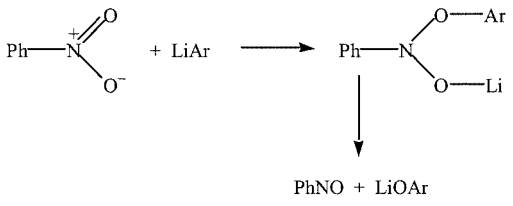
Results and Discussion

Synthesis

There exist several methods for the synthesis of phenols on a laboratory scale.[11] Among the most prominent of these are the diazotization of arylamines followed by hydrolysis, conversion of halides to phenols in the presence of concentrated KOH or NaOH, and the sulfonation-alkaline melting process. The synthesis of the bulky phenols **1** and **2** was attempted by each of these methods. None afforded yields that were useful. It seems likely that the steric effects of the flanking aryl rings and the low solubility of the aryl halide precursors in aqueous phases prevent efficient reactions in these cases. There are other routes to terphenols in the literature[12,13] but since we already had terphenyllithium reagents to hand, we were drawn to the, apparently little used, anhydrous route,[14] which involves the reaction between nitrobenzene and an aryllithium derivative and afforded as products the nitrosobenzene and the lithium aryloxide salt as depicted below.



It may be noted that the addition of the bulky aryl group, Ar, to nitrogen is disfavored for steric reasons, although it seems likely that products in which the Ar group is bound to nitrogen will be obtained under appropriate reaction conditions. Quenching of the reaction with a methanol/water mixture affords ArOH in ca. 70% yield for both of the very bulky aryl substituents Ar = Ar* and Ar′. The above route was discovered in 1966−67[14] during the investigation of the reactions of various substituted benzenes with organolithium compounds. The reaction of *o*-nitrobromobenzene with phenyllithium readily afforded the expected *o*-nitrophenyllithium.[15] However, it was found that for pure nitrobenzene the nitro group rather than the aryl ring was attacked. Investigations showed that the addition of one equivalent of phenyllithium to nitrobenzene in THF, with cooling to ca. −95 °C, afforded nitrosobenzene and lithium phenoxide in good yield. We found that a similar reaction result is obtained upon treatment of nitrobenzene with the very bulky lithium reagents LiAr*[11] or LiAr′[12] which afford nitrosobenzene and LiOAr* or LiOAr′ which can then be hydrolysed to give the terphenols **1** and **2**. The terphenols may then be readily converted into their lithium or sodium salts by reaction with *n*BuLi or sodium metal.

Structures

The main feature of the structures of **1** (Figure 1) and **2** (Figure 2) is that they are monomers and contain no inter-

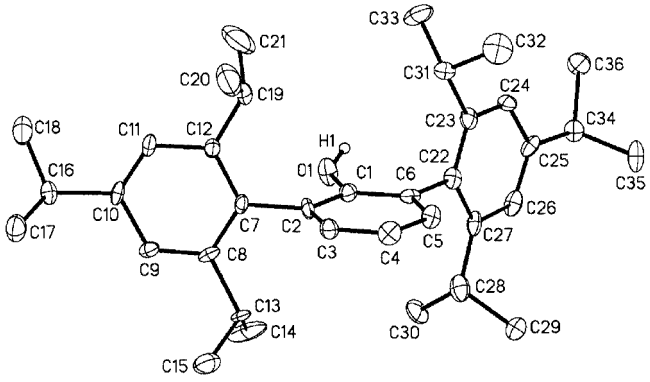


Figure 1. Thermal ellipsoid (35%) plot of **1**. H atoms (except O−H) are not shown; selected bond lengths and angles are given in Table 2

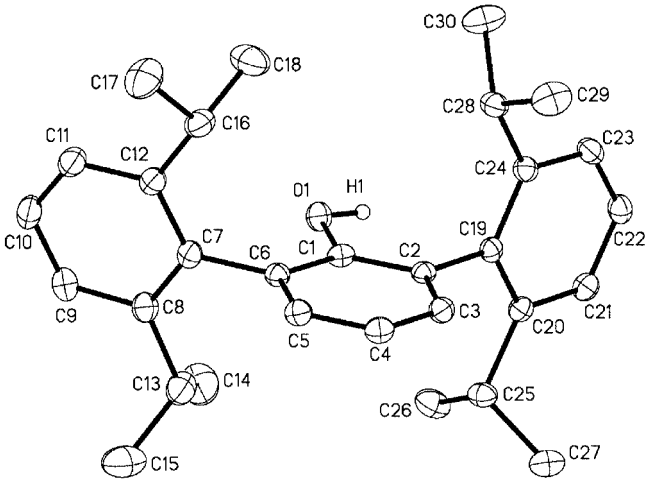

Figure 2. Thermal ellipsoid (35%) plot of **2**. H atoms (except O−H) are not shown; selected bond lengths and angles are given in Table 2

molecular hydrogen bonding. Although alcohols and phenols are prone to intermolecular hydrogen bonding, this is prevented in **1** and **2** by the steric effects of the ortho Trip or Dipp substituents. Instead, the structures of **1** and **2** show evidence of interaction between the O−H hydrogens and the π-electrons of an ortho phenyl ring. The coordination planes of the O(1) atom and the central aryl ring plane are essentially coincident in each molecule. In **1** the H(1)···C(22) distance is 2.64 Å and in **2** the corresponding H(2)···C(19) separation is 2.39 Å. In addition there is a long H(2) to Dipp(centroid) contact of 3.30 Å to a Dipp ring in an adjacent molecule in **2**, although an interaction of this length may not be significant. The intramolecular O−H···Ar distances resemble those found in the structure of 2,6-diphenylphenol [2.40(4) and 2.43 Å].[16] The O−H stretching frequencies observed in **1** and **2** (3520 and 3530 cm^{-1}) also support the existence of an O−H···π interaction since they are red shifted by 70−80 cm^{-1} in comparison to the O−H stretching frequency observed for phenol in dilute CCl_4 solution.[17] However, there is no clear pattern in the angles and distances surrounding the O(1), C(1), C(2) and C(6) atoms in the molecules that suggests that the O−H···π interaction has any systematic effect on the geometry in the remainder of the molecule. A previous publication has noted that the O−C(1)−C(ortho) angle on the side of the hydroxyl group is wider.[16] While this is true for **2** [120.8(1) vs. 117.1(1)°], the opposite is the case for **1** [116.9(5) vs. 120.7(5)°]. The internal angle at the ipso−C(1) atom exceeds the idealized 120° value by ca. 2° and this is consistent with previous structures of phenols,[16,18,19] and the fact that the very electronegative oxygen substituent removes electron density from C(1) toward itself, thereby permitting a widening of the C(2)−C(1)−C(6) angle. The C−O bond lengths in **1** and **2** are similar to those observed in other sterically encumbered phenols.[14,16,17] As in most structures with bulky terphenyl ligands[8] the flanking aryl rings subtend almost vertical angles (83.1−85.7°) with the central ring and this is maintained in solution, as evidenced by the observation of two sets of methyl doublets for the *i*Pr groups.

Both **1** and **2** react immediately with *n*BuLi to form the lithium salts LiOAr* (**4**) or LiOAr′ (**5**). However, only crystals of the LiOAr′ species were suitable for X-ray crystallography. These proved to exist as dimers, as shown in Figure 3. This structure is a relatively rare example of an alkali metal aryloxide unsolvated[20−24] by internal Lewis base donors or molecules such as Et_2O, THF or pyridine. It consists of centrosymmetric dimers in which the lithiums bridge two OAr′ groups. The lower degree of aggregation in **5** may be contrasted with the trimer structure observed for (Li-OC_6H-2,6-Ph_2-3,5-$t Bu_2$)$_3$ [24] which has the less crowded phenyl substituents in the ortho positions. The planar Li_2O_2 rhombic core features two different Li−O distances of 1.807(3) and 1.979(3) Å and LiOLi and OLiO angles of 81.2(1)° and 98.8(1)°. These distances lie near the lower and upper extremities of the known Li−O range for dimeric solvated and unsolvated LiOR species.[18−25] Each lithium further interacts with the ipso (Li−C = 2.39 Å) and ortho carbons (Li−C = 2.54 and 2.65 Å) of a flanking Dipp ring. The Ar′ groups are tilted toward the side which interacts with the lithiums as indicated by the ca. 22° difference between the LiOC angles. The oxygen atoms have almost stanar coordination. The O−C bond length of 1.335(2) is 0.05−0.07 Å shorter than the corresponding distances in **1** and **2** probably as a result of the increased ionic contribution to the O−C bond strength when hydrogen is replaced by lithium. The flanking aryl rings subtend angles of 88.3° (C7 ring) and 82.8° (C19 ring) with respect to the central ring. A notable difference between the structure of $(LiOAr')_2$ and **1** and **2** concerns the internal angle at the ipso carbon of the central aryl ring of the terphenyl substituent. The much more negative character of the oxygen in the lithium salt means that, relatively speaking, it is less electronegative than the oxygens in **1** and **2**. This is reflected in the C(2)−C(1)−C(6) angle, which, at 117.55(14)°, is ca. 4.5° narrower than the corresponding angle in **2**.

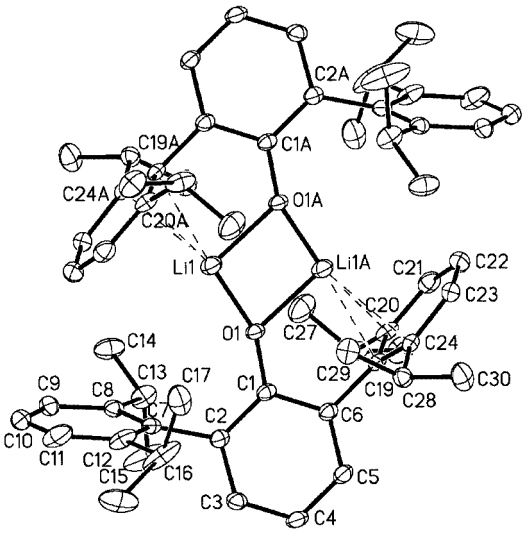

Figure 3. Thermal ellipsoid (35%) plot of **5**. H atoms are not shown; selected bond lengths and angles are given in Table 2

The structure of NaOAr* (**4**; Figure 4) is a relatively rare example of a structurally characterized unsolvated (by internal or external Lewis base donors) sodium phenolate. It crystallizes as two slightly different sodium-bridged dimeric units. One dimer incorporates a twofold rotational axis along the Na···Na [Na(1) and Na(2)] vector, whereas the other involves a twofold rotational axis along the O···O [O(2) and O(3)] vector. The planar Na_2O_2 cores are very similar in each molecule, having Na−O−Na angles near 94.5° and O−Na−O angles near 85.5°. The Na−O bonds are in the narrow range 2.221(2)−2.237(2) Å. The sodiums also display close interactions to the ipso carbons of the flanking Trip rings in the range 2.995(3)−3.076(3) Å. The Na−O−C(ipso) angles are symmetric and lie within the narrow limits 132.1(2)−132.78(6)°.

The unassociated dimeric structural motif in **4** provides a good illustration of the disruption of the stacking of dimeric units[26] in the polymeric structures of $(NaOPh)_n$ [22,23] or $(NaOC_6H_4$-4-$Me)_n$.[20] The Na−O bond lengths in

 © 2003 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

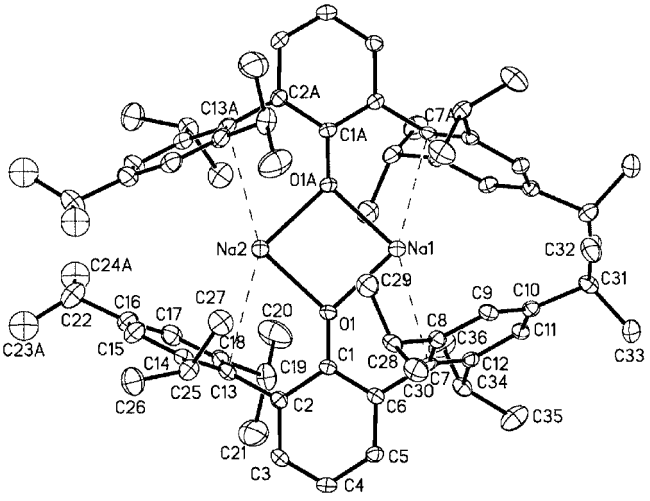

Figure 4. Thermal ellipsoid (35%) plot of one of the molecules in the asymmetric unit of **4**. H atoms are not shown; selected bond lengths and angles are given in Table 2

4 are at the shorter end of the range previously observed in species such as $(NaOC_6H_4\text{-}4\text{-}Me)_n$,[20] $[(MeOCH_2CH_2O\text{-}Me)NaOC_6H_4\text{-}4\text{-}Me]_4$ [18] or $(NaOPh)_n$.[22,23] The Na···C interactions are similar to the average Na−C(arene) distance of 2.94(11) Å observed in $(NaOC_6H_4\text{-}4\text{-}Me)_n$ [20] and 3.05(8) Å in $(NaOPh)_n$.[23] The basic structural motif in **4** resembles that observed for the dimer $(NaSAr^*)_2$.[10] However, in the latter species the sodium displays unequal and weaker interactions with the aryl rings. Apparently, the Na^+ ions are a better fit for the cavity generated by the flanking aryl rings in the case of **4**. As in the structure of **5**, and for the same reasons, the internal angles at the ipso carbons of the central aryl rings [117.6(3) and 117.7(4)°] are less than the idealized 120° and the flanking aryl rings subtend high angles with respect to the central aryl ring.

Conclusions

The reaction of LiAr* or LiAr′ with nitrobenzene at low temperature, followed by hydrolysis, is an effective, high-yield route to very bulky terphenols from their lithium terphenyl precursors. The latter are available in essentially quantitative yield from the reaction of terphenyl iodide with *n*BuLi thereby permitting the terphenols to be isolated in *ca*. 70% from the terphenyl iodide starting material.

Experimental Section

General Procedures: All manipulations were carried out (except where otherwise noted) by using modified Schlenk techniques under an atmosphere of Ar or N_2 or in Vacuum Atmospheres HE-43 or NEXUS dryboxes. All solvents were distilled from molten Na/K alloy and degassed prior to use. Nitrobenzene was distilled off P_2O_5 and stored over molecular sieves. The lithium compounds $Et_2O{\cdot}LiC_6H_3\text{-}2,6\text{-}Trip_2$ (LiAr*)[27] and $LiC_6H_3\text{-}2,6\text{-}Dipp_2$ (LiAr′)[28] were prepared as described previously. The ^1H and ^{13}C NMR spectra were recorded on a Varian 300 or 400 MHz spectrometer and referenced to known standards. Melting points were recorded in glass capillaries under N_2 and are uncorrected. Infrared spectra were recorded as Nujol mulls between CsI plates on a Perkin−Elmer-1430 spectrometer.

1-HOC_6H_3-2,6-$Trip_2$ (Ar*OH, 1): $Et_2O{\cdot}$LiAr* (1.7 g, 3.0 mmol) was dissolved in diethyl ether (20 mL) with rapid stirring. This solution was cooled in a CH_2Cl_2/liquid N_2 slush bath, and nitrobenzene (1.5 mL, ca. 15 mmol) was added dropwise by syringe. A red solution was formed immediately upon the addition of nitrobenzene, and after stirring for ca. 5 min, methanol (20 mL) was added with a syringe. The resulting amber colored mixture was warmed to room temperature and water (25 mL) was added to afford a solution with two layers. The upper layer was separated and the aqueous alcohol layer was acidified with concentrated HCl (1.0 mL), extracted with 2 × 20 mL portions of diethyl ether and combined with the upper layer. The combined organic layers were washed with 2 × 100 mL portions of water and 2 × 100 mL saturated NaCl/H_2O solution. The ethereal layer was separated, dried over $MgSO_4$, filtered and concentrated to ca. 10 mL. Column chromatography on silica gel with use of pentane eluent afforded, upon concentration to ca. 10 mL, large orange-yellow crystals of the crude product upon standing overnight. These were purified by recrystallization from diethyl ether to afford colorless crystals of **1**. Yield: 1.12 g, 2.25 mmol, (75%), m.p. 148−150 °C. The crystals proved suitable for X-ray crystallographic studies. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 1.21 [d, $^3J_{H,H}$ = 7.50 Hz, 12 H, *o*-CH(CH_3)$_2$], 1.24 [d, $^3J_{H,H}$ = 6.60 Hz, 12 H, *o*-CH(CH_3)$_2$], 1.27 [d, $^3J_{H,H}$ = 6.90 Hz, 12 H, *p*-CH(CH_3)$_2$], 2.82 [sept, $^3J_{H,H}$ = 6.90 Hz, 2 H, *p*-*CH*(CH_3)$_2$], 3.02 [sept, $^3J_{H,H}$ = 6.90 Hz, 4 H, *o*-*CH*(CH_3)$_2$], 4.57 [s, 1 H, −OH], 6.89 [t, $^3J_{H,H}$ = 7.50 Hz, 1 H, *p*-Ph], 7.06 [d, $^3J_{H,H}$ = 7.50 Hz, 2 H, *m*-Ph], 7.23 [s, 4 H, *m*-Trip] ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 24.36 [*o*-CH(CH_3)$_2$], 24.43 [*o*-CH(CH_3)$_2$], 24.69 [*p*-CH(CH_3)$_2$], 31.04 [*o*-*CH*(CH_3)$_2$], 34.65 [*p*-*CH*(CH_3)$_2$], 120.07 (*p*-Ph), 121.29 (m-Trip), 126.64 (i-Trip), 130.23 (*o*-Ph), 131.02 (p-Trip), 147.79 (*m*-Ph), 148.83 (o-Trip), 150.96 (i-Ph) ppm. IR (Nujol): $\tilde{\nu}$ = 3520 cm^{-1} (ν_{OH}, sharp).

1-HOC_6H_3-2,6-$Dipp_2$ (Ar′OH, 2): In a similar manner to that described for **1**, nitrobenzene (3.5 mL, ca. 35 mmol) was syringed into a rapidly stirred solution of LiAr′ (2.93 g, 7.0 mmol) dissolved in diethyl ether (20 mL) with cooling to ca. −95 °C. Quenching with MeOH (20 mL), followed by warming to room temperature, and water addition, afforded two layers, which were worked up as described for **1**, to yield colorless crystals of **2**. Yield: 2.0 g, 4.83 mmol (69%); m.p. 164−166 °C. ^1H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.08 [d, $^3J_{H,H}$ = 6.9 Hz, 12 H, *o*-CH(CH_3)$_2$], 1.13 [d, $^3J_{H,H}$ = 6.9 Hz, 12 H, *o*-CH(CH_3)$_2$], 2.72 [sept, $^3J_{H,H}$ = 6.9 Hz, 4 H, *o*-*CH*(CH_3)$_2$], 4.46 [s, 1 H, −O*H*], 7.03−7.09 [m, 2 H, *p*-Ph and *p*-Dipp], 7.25 [d, $^3J_{H,H}$ = 7.5 Hz, 4 H, *m*-Dipp], 7.37 [d, $^3J_{H,H}$ = 7.8 Hz, 2 H, *m*-Ph] ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 24.14 [*o*-CH(CH_3)$_2$], 24.50 [*o*-CH(CH_3)$_2$], 30.86 [*o*-*CH*(CH_3)$_2$], 120.08 (*p*-Ph), 123.10 (m-Dipp), 126.36 (i-Dipp), 128.76 (p-Dipp), 129.91 (*m*-Ph), 133.36 (0-Ph), 147.97 (o-Dipp), 150.86 (i-Ph) ppm. IR (Nujol): $\tilde{\nu}$ = 3530 cm^{-1} (ν_{OH}, sharp).

LiOAr* (3): MeLi (1.1 mmol, 0.65 mL, 1.6 M in ether) was added from a syringe to a well-stirred solution of **1** (0.5 g, *ca*. 1 mmol) in diethyl ether (20 mL) at room temperature. After 10 minutes, the solution became a pale red and the reaction was stirred for another 4 h. The diethyl ether was pumped off and hexane (20 mL) was added. The volume of the clear red solution was reduced to ca. 10 mL under reduced pressure and the flask was placed in a ca. −20 °C freezer overnight. Colorless crystals (stable up to 260 °C) had formed after 24 h, but they were found to be unsuitable for X-

ray crystallography. Several efforts were made to grow crystals from other solvents without success. The isolated yield of **3** was 0.465 g, 0.92 mmol (92%). ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.92 [d, $^3J_{H,H}$ = 11.1 Hz, 12 H, *o*-CH(*CH*$_3$)$_2$], 1.10 [d, $^3J_{H,H}$ = 11.1 Hz, *o*-CH(*CH*$_3$)$_2$], 1.40 [d, $^3J_{H,H}$ = 11.1 Hz, 12 H, *p*-CH(*CH*$_3$)$_2$], 3.00 [m, 6 H, o+*p*-*CH*(CH$_3$)$_2$], 6.61 [t, J_{ortho} = 8.1 Hz, 1 H, *p*-Ph], 6.73 [d, J_{ortho} = 10.5 Hz, 2 H, *m*-Ph], 7.16 (s, 4 H, *m*-Tripp) ppm. ^{13}C NMR (300 MHz, C_6D_6, 25 °C): δ = 24.10 [*o*-CH(*CH*$_3$)$_2$], 24.40 [*o*-CH(*CH*$_3$)$_2$], 24.85 [*p*-*CH*(CH$_3$)$_2$], 31.02 [*o*-*CH*(CH$_3$)$_2$], 34.41 [*p*-*CH*(CH$_3$)$_2$], 115.05 (*p*-Ph), 121.91 (m-Trip), 126.51 (i-Trip), 131.04 (p-Trip), 137.38 (*o*-Ph), 147.11 (*m*-Ph), 147.25 (o-Trip), 161.41 (i-Ph) ppm.

NaOAr* (4): A solution of Ar*OH (**1**; 0.5 g, 1 mmol) in toluene was added via cannula to sodium metal 0.050 g (ca. 2 mmol) suspended in toluene (5 mL). The mixture was refluxed overnight. The red solution obtained was pumped to dryness and the residue was extracted in diethyl ether (15 mL) and the resultant solution allowed to settle. The clear, red supernatant solution was decanted off, and pumped down to ca. 5 mL, and stored in a ca. −20 °C freezer. After three weeks, colorless crystals of **4** were formed which were suitable for X-ray analysis. Yield: 0.45 g, 0.86 mmol (86%). m.p. 230−232 °C. ^{1}H NMR (300 MHz, C_6D_6, CD_3, 25 °C): δ = 1.01 [d, $^3J_{H,H}$ = 6.0 Hz, 12 H, *o*-CH(*CH*$_3$)$_2$], 1.20 [d, $^3J_{H,H}$ = 6.0 Hz, 12 H, *o*-CH(*CH*$_3$)$_2$], 1.47 [d, $^3J_{H,H}$ = 6.0 Hz, 12 H, *p*-CH(*CH*$_3$)$_2$], 3.17 [s broad, 6 H, o+*p*-*CH*(CH$_3$)$_2$], 6.61 [s, 1 H, *p*-Ph], 6.83 [s, 2 H, *m*-Ph], 7.19 [s, 4 H, *m*-Trip] ppm. ^{13}C NMR (300 MHz, [D$_8$]toluene, 25 °C): δ = 23.87 [*o*-CH(*CH*$_3$)$_2$], 24.14 [*o*-CH(*CH*$_3$)$_2$], 24.75 [*p*-CH(*CH*$_3$)$_2$], 30.56 [*o*-*CH*(CH$_3$)$_2$], 33.96 [*p*-*CH*(CH$_3$)$_2$], 111.97 (*p*-Ph), 120.92 (m-Trip), 128.55 (i-Trip), 130.26 (p-Trip), 138.67 (*o*-Ph), 146.53 (o-Trip), 147.27 (*m*-Ph), 166.02 (i-Ph) ppm.

LiOAr′ (5): Ar′OH (**2**; 0.36 g, 0.86 mmol) was dissolved in diethyl ether (15 mL) and the resulting solution was cooled to 0 °C. *n*-Butyllithium (0.6 mL, 0.96 mmol, 12% excess of a 1.6 M solution in hexane) was slowly added with a syringe. Evolution of gas (*n*BuH) was seen during addition. The solution was stirred at room temperature for an additional 2 h, the diethyl ether was pumped off, and hexane (*ca*. 20 mL) was added. The resulting yellow solution was concentrated to about 10 mL and let stand in a ca. −20 °C freezer. After three days small, colorless crystals were obtained. They were suitable for X-ray analysis. Yield: 0.334 g, 0.79 mmol (92%). M.p. 198−200 °C. ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.92 [d, $^3J_{H,H}$ = 6.9 Hz, 12 H, *o*-CH(*CH*$_3$)$_2$], 1.02 [d, $^3J_{H,H}$ = 6.9 Hz, 12 H, *o*-CH(*CH*$_3$)$_2$], 2.89 [sept, $^3J_{H,H}$ = 6.9 Hz, 4 H, *o*-*CH*(CH$_3$)$_2$], 6.67 [t, $^3J_{H,H}$ = 6.3 Hz, 1 H, *p*-Ph], 6.84 [d, $^3J_{H,H}$ = 7.5 Hz, 2 H, *m*-Ph], 7.03 [d, $^3J_{H,H}$ = 7.5 Hz, 4 H, *m*-Dipp], 7.14 [t, $^3J_{H,H}$ = 6.3 Hz, 2 H, *p*-Dipp] ppm. ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): δ = 24.54 [*o*-CH(*CH*$_3$)$_2$], 24.62 [*o*-CH(*CH*$_3$)$_2$], 30.71 [*o*-*CH*(CH$_3$)$_2$], 114.76 (*p*-Ph), 124.30 (*m*-Dipp), 128.57 (*p*-Dipp), 129.17 (i-Dipp), 130.26 (*m*-Ph), 139.17 (*o*-Ph), 146.71 (*o*-Dipp), 161.13 (i-Ph) ppm.

X-ray Crystallographic Studies: Sample preparation consisted of removing the crystal from the Schlenk tube under a rapid flow of Argon and immediately submerging it in hydrocarbon oil. A suitable crystal was selected, attached to a glass fiber, mounted on a copper pin and rapidly placed in the cold stream of N_2 of the diffractometer for data collection.[29] Data were collected at 293 K (**1**), 130 K (**2**) or 90 K (**4**) and (**5**) with Mo-K_α (λ = 0.71073Å) radiation (**1**, **4** and **5**) or Cu-K_α (λ = 1.54178Å) (**2**) on a Bruker SMART 1000 (**1**, **4** and **5**) or Siemens P4 (**2**) diffractometers. Data collection and processing were performed using the Bruker programs SMART and SAINT (**1**, **4** and **5**) or Siemens P3-PC (**2**). Empirical absorption corrections were applied using SADABS,[30a] XABS.[30b] The crystal structures were solved using either direct methods or the Patterson option in SHELXS program and refined by the full-matrix least-squares procedure in the SHELXL program.[31] All non-hydrogen atoms were refined anisotropically while hydrogen atoms (with the exception of those attached to oxygen in **1** and **2** which were located) were placed at calculated positions and included in refinement using a riding model. Some details of the data collection and refinement are given in Table 1. Further details can be found in the supporting information.

CCDC-218873 (**1**), -218874 (**2**) -218875 (**4**) and -218876 (**5**) contain the supplementary crystallographic data for this paper. These data

COVER PICTURE

The cover picture shows, as one representative out of the carbene-analogue family, a novel heteroleptic lead(II) compound containing an O,C,O-coordinating pincer-type ligand. Details are discussed in the article by K. Jurkschat et al. on p. 3563 ff.

Palladium-Catalyzed Cyanation of Aryl Halides: Recent Developments and Perspectives

Mark Sundermeier,[a][‡] Alexander Zapf,[a] and Matthias Beller*[a]

Keywords: Palladium / Cyanation / Benzonitriles / Homogeneous catalysis

The palladium-catalyzed cyanation of aryl halides is an elegant method for the preparation of benzonitriles. Since its discovery in 1973, this reaction has been the topic of several investigations. Nevertheless, the general methodology is still somewhat underdeveloped compared to other palladium-catalyzed coupling reactions. Here, we summarize important developments from 1997 until 2003 in this area. Recent contributions from our group include the development of palladium/phosphane/amine catalyst systems for the cyanation of aryl chlorides, the successful cyanation of aryl halides with acetone cyanohydrin and trimethylsilyl cyanide as cyanation reagents, and a general improvement of catalyst efficiency by using a continuous dosage of cyanide sources.

Introduction

Benzonitriles are of considerable interest for organic chemistry as an integral part of dyes, herbicides, agrochemicals, pharmaceuticals, and natural products. The nitrile group also serves as an important intermediate structure for a multitude of possible transformations into other functional groups. As an example the synthesis of Fluvoxamine is shown in Scheme 1. Here, 4-(trifluoromethyl)-

Fort Collins, CO 80523, Colorado, USA

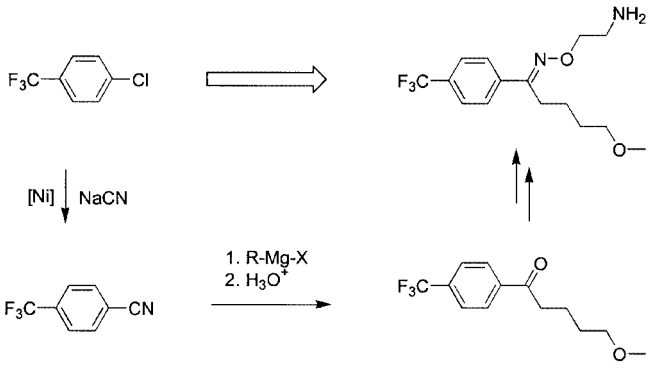
Mark Sundermeier was born in Herford, Germany in 1972. He studied chemistry at the Friedrich-Schiller-University in Jena, where he has done his diploma thesis in 1998 under directions of Prof. R. Beckert on the field of 1,2-dioxetanes and their luminescence. Under the supervision of Prof. M. Beller he started his PhD studies in 1998 on the field of palladium-catalyzed cyanation of aryl−X derivatives at the Leibniz-Institut für Organische Katalyse in Rostock, where he completed his PhD degree in 2002. He focused his research on the cyanation of aryl chlorides and bromides. Since 2003 he is a postdoctoral fellow at the Colorado State University in the group of Prof. T. Rovis working on the field of asymmetric O→C rearrangements.

Alexander Zapf was born in Coburg, Germany, in 1970. After studying chemistry at the Technical University of Munich he worked on his PhD thesis in the area of Heck and Suzuki reactions under the supervision of Prof. M. Beller until 1998. Then he joined the Leibniz-Institut für Organische Katalyse in Rostock, where he became the project leader of "Ar−X activation" in 1999. Pd-catalyzed coupling reactions of aryl chlorides and bromides are the subject of most of the projects, which are mainly worked on in cooperation with industry. Alexander has been a fellow of the Studienstiftung des deutschen Volkes and the Max-Buchner-Forschungsstiftung.

Matthias Beller, born 1962 in Gudensberg, Germany, studied chemistry at the University of Göttingen and obtained his doctorate in 1989 under the guidance of Prof. L. F. Tietze. After postdoctoral studies (1990) with Prof. K. B. Sharpless at Massachussetts Institute of Technology (USA) funded with a Liebig scholarship of the Verband der Chemischen Industrie, he became a research chemist in the Central Research of Hoechst AG in Frankfurt, Germany. In 1993 he became group leader of "Organometallic chemistry - catalysis" and in 1994 project leader of "Homogeneous catalysis" at Hoechst AG. From 1996 to 1998 he was Associate Professor for Inorganic Chemistry at the Technical University of Munich and since June 1998 he is Director of the Leibniz-Institut für Organische Katalyse (IfOK) aligned with a full professorship "Catalysis" at the University of Rostock. His research topics cover the development of a wide range of practical catalytic methodologies. Special attention is given to selective and environmentally benign transformations. More specifically he is interested in palladium-catalyzed coupling reactions, carbonylation reactions, catalytic amination of olefins and oxidations of olefins using air or molecular oxygen as the final oxidant. His scientific work has been published in more than 140 original publications and review articles. In addition 70 patent applications have been filed in the last decade. Together with Prof. Carsten Bolm he has edited a book on the use of "Transition Metals for Organic Synthesis". Matthias Beller is married since 1992 to Dr. Anja Fischer-Beller and they have two sons (Marc-Philipp and Jan-Niclas).

MICROREVIEWS: This feature introduces the readers to the author's research through a concise overview of the selected topic. Reference to important work from others in the field is included.

benzonitrile, which is available from 4-chloro(trifluoromethyl)benzene by nickel-catalyzed cyanation on ton-scale, serves as an intermediate.[1−3]



Scheme 1. 4-(Trifluoromethyl)benzonitrile, a key intermediate in the synthesis of Fluvoxamine

Benzonitriles themselves are also of significant interest, for example as substructures in biologically active agents. In Figure 1 selected examples of pharmaceuticals containing an aromatic nitrile as integral part of the molecule are shown along with their names, producers, and effects.[4] In the case of biologically active benzonitrile derivatives another aspect is worth noting. By applying transition-metal-catalyzed cyanation of aryl halides using $K^{11}CN$, $K^{13}CN$ or $K^{14}CN$ isotopically labeled compounds are easily accessible.[5−9] The resulting products are used in pharmacokinetic studies and investigations on the metabolism of pharmaceuticals.

Clearly, benzonitriles can be prepared in numerous ways.[10−14] Most often they are synthesized by the Rosenmund-von Braun reaction[15−19] from aryl halides or diazotization of anilines and subsequent Sandmeyer reaction[20−22] on a laboratory as well as on an industrial scale. On a ton-scale the method of choice in industry is ammoxidation, whereby the corresponding toluene derivatives are reacted with oxygen and ammonia at 300−550 °C in the presence of heterogeneous fixed-bed catalysts.[23−25]

A drawback of the Rosenmund-von Braun and the Sandmeyer reactions is the use of stoichiometric amounts of copper(I) cyanide as cyanating agent, which leads to equimolar amounts of heavy metal waste. Other disadvantages of the Rosenmund-von Braun reaction are the relatively high temperature (150−250 °C) and the low reactivity of aryl chlorides and bromides (in general the use of expensive aryl iodides is required). The ammoxidation is restricted to simpler substrates because of the high temperature, high pressure, and the large excess of ammonia required. Furthermore, only a limited number of toluene derivatives are available on a larger scale. Hence, this procedure is applied for products such as benzonitrile, terephthalodinitrile, and chlorobenzonitriles.[26,27]

A useful alternative for the preparation of substituted benzonitriles is the transition-metal-catalyzed cyanation of aryl−X compounds (X = Cl, Br, I, OTf etc.) with cheap and readily available cyanation agents like sodium or potassium cyanide (Scheme 2).[28−31] The order of reactivity of the aryl−X derivatives is opposite to the bond-dissociation energy of the C−X bond (reactivity: I ≈ OTf > Br > Cl).[32,33] Electron-withdrawing substituents on the aryl ring increase the reactivity, while electron-donating substituents decrease reactivity. Most common catalysts for coupling of aryl halides or triflates with cyanide are transition metal complexes of the platinum group, especially palladium or nickel complexes. Palladium catalysts tolerate a wider vari-

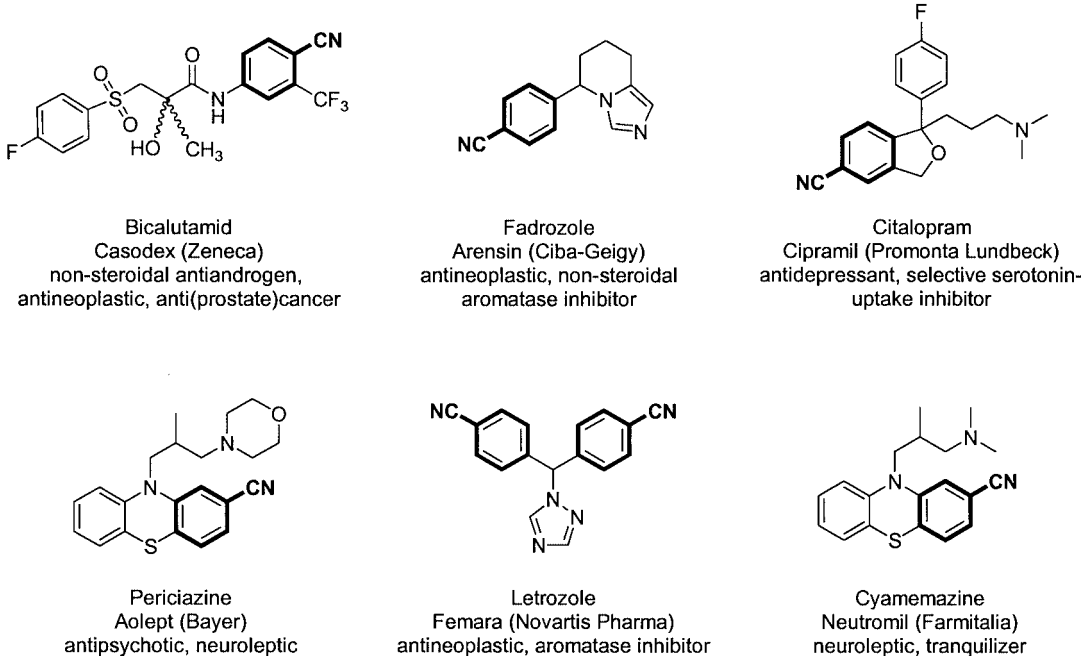


Figure 1. Examples of pharmaceutically active benzonitriles

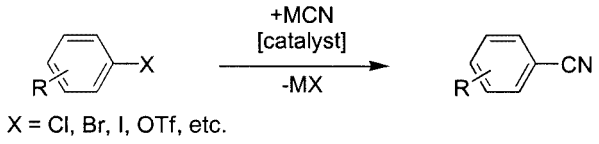
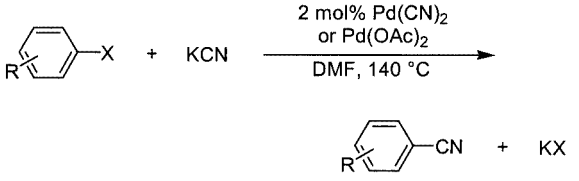
ety of functional groups and are less sensitive to air and humidity than nickel catalysts.



Scheme 2. Transition-metal-catalyzed cyanation of aryl halides

The first palladium-catalyzed cyanation of aryl−X derivatives has been introduced in 1973 by Takagi and co-workers using aryl bromides and iodides with potassium cyanide as the cyanating agent (Scheme 3).[34] Palladium(II) cyanide or palladium(II) acetate served as the catalyst without additional ligands present. Typical reaction conditions were DMF as solvent, 140−150 °C and 2−12 h reaction time.



Scheme 3. First palladium-catalyzed cyanation of aryl bromides and iodides

Early mechanistic studies by Takagi and co-workers[35] led to the mechanistic proposal shown in Scheme 4. The mechanism consists of two cycles, one representing the typical cycle for a palladium-catalyzed cross-coupling reaction with oxidative addition and reductive elimination, and a second prior cycle, where palladium species act as cyanide carriers. It was pointed out that an excess of cyanide ions inhibits the catalytic cycle. This deactivation was explained by the reaction of cyanide with palladium(II) species, forming inactive palladium(II) cyano compounds, which cannot be reduced to catalytically active palladium(0) species.

Potassium tetracyanopalladate(II) and palladium(II) cyanide were shown to be almost inactive in the cyanation reaction, and a dramatic solvent effect was described which can be explained by the influence of the cyanide solubility in different reaction media. The higher the solubility of the cyanide salt, the lower the reaction outcome. Another finding of this work is the positive effect of co-catalysts like potassium hydroxide, sodium ethoxide, potassium carbonate, or sodium phenoxide, which facilitate the reduction of palladium(II) species.[36,37]

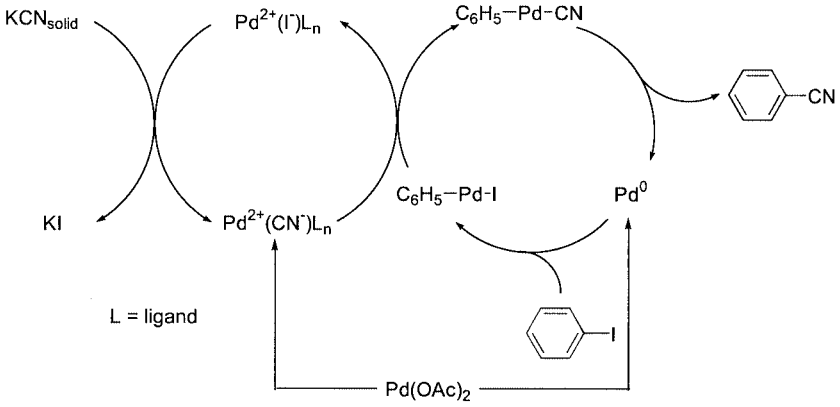
The reaction conditions have subsequently been optimized and the substrate scope of the method has been considerably enhanced by different groups. In Table 1 the different conditions of palladium-catalyzed cyanation reactions of aryl halides known prior to 1997 are summarized. In general the cyanation of aryl bromides and iodides has been performed in the presence of an excess of KCN in dipolar aprotic solvents. In addition, NaCN, Me_3SiCN, nBu_3SnCN and $Zn(CN)_2$ were employed in selected examples as cyanide sources. Apparently there is no difference in applying palladium(II) or palladium(0) pre-catalysts. In a few cases the cyanation of chloroarenes was also performed. However, in all these examples highly reactive heteroaryl chlorides have been used.

Table 1 demonstrates that the palladium-catalyzed cyanation of aryl bromides and iodides works with different palladium catalysts and cyanide sources. However, the described catalyst productivity was always quite low (turnover numbers (TON) are in general 10−50). Furthermore, many systems need additives or a special cyanide source to enable good product yields. In the last five years new approaches have been made by us and other groups which will be discussed below.

Results and Discussion

Recent Developments in the Palladium-Catalyzed Cyanation of Aryl Bromides and Iodides

Due to the low catalyst efficiency realized with KCN in the palladium-catalyzed cyanation of aryl halides, some recent publications focused on the development of alternative cyanation agents. A somewhat unusual cyanide source are alkyl nitriles, which represent common solvents. In this re-



Scheme 4. Proposed mechanism of the palladium-catalyzed cyanation according to Takagi et al.

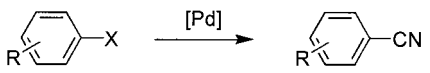

Scheme 5. Palladium-catalyzed cyanation of aryl halides

an overstoichiometric amount of zinc powder as additive (4 equiv.). Thus, this protocol might be a viable alternative only for a limited number of benzonitriles. The unusual reaction mechanism is, however, worth mentioning, as it is completely different from the general mechanism for the palladium-catalyzed cyanations. As shown in Scheme 6 the

gard it is interesting to note that Luo et al. have shown that a transfer of the nitrile function from acetonitrile to aryl halides is possible at high temperature (160 °C).[50] Table 2 presents a summary of the obtained results. In contrast to most other cyanation protocols good yields of 2-substituted benzonitriles and even 2,6-disubstituted benzonitriles are obtained.

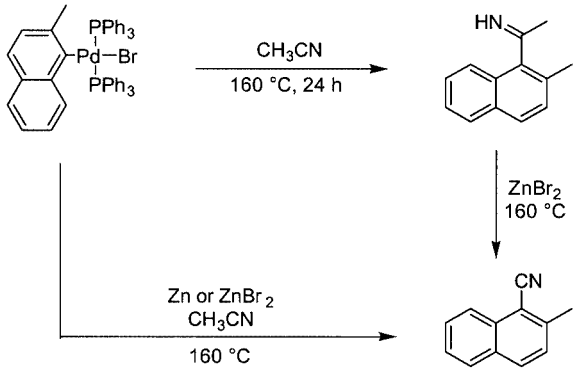
7			$[PdCl_2(PBu_3)_2]$	32
8			$[PdCl_2(PPh_3)_2]$/8 PPh_3	30 (28)[c]

[a] General conditions: 5 mmol aryl bromide, 10 mol % Pd-catalyst, 4 equiv. Zn-powder, 30 mL acetonitrile, 160 °C, 24 h.[b] Yields determined by ^1H NMR using $HCONEt_2$ as internal standard.[c] Isolated yield in parentheses.

Unfortunately, this transformation requires high catalyst concentration (10 mol %), high temperature (160 °C) and

oxidative addition product of the aryl halide and palladium(0) first gives the corresponding imine, which is then degraded by Lewis acid catalysis to the desired nitrile. Stoichiometric amounts of zinc(II) salts are formed during the reaction.



Scheme 6. Mechanism of the palladium-catalyzed cyanation using acetonitrile as cyanating agent

Surprisingly, copper(I) cyanide, the typical cyanating agent in the Rosenmund-von Braun and the Sandmeyer reaction, was not described as a cyanide source in palladium-catalyzed reactions of aryl halides until recently. Hence, the first palladium-catalyzed Rosenmund-von Braun reaction was developed by Sakamoto and Ohsawa in 1999 (Scheme 7).[51]

This protocol is useful for the transformation of electron-rich and electron-poor aryl bromides. Also *N*-heteroaryl iodides and bromides [e.g., *N*-(phenylsulfonyl)indoles, pyrrols, quinolines] give the corresponding nitriles in good

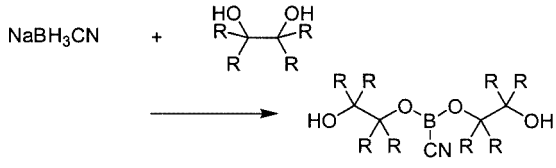
Scheme 7. Palladium-catalyzed Rosenmund-von Braun reaction

yield. A comparison of the palladium-catalyzed variant and the noncatalytic reaction shows that the palladium catalyst leads to higher yields. Nevertheless, the use of copper(I) cyanide leads to no improvement of the palladium catalyst efficiency compared to other cyanating agents. A comparatively high catalyst concentration (8 mol % Pd), an overstoichiometric amount of copper(I) cyanide (4 equiv.) and a stoichiometric amount of an additive (Et_4NCN) are still required for successful reactions.

Based on the knowledge of the well-established palladium-catalyzed cross-coupling of aryl halides with organoboron compounds (Suzuki reaction), Jiang et al. used dialkyl cyanoboronates as the cyanide source.[52] Dialkyl cyanoboronates are easily prepared by the reaction of sodium cyanoborohydride and 1,2-diols (Scheme 8). As shown in Table 3, the cyanation of aryl bromides, iodides and strongly activated chlorides is possible under these conditions.



Scheme 8. Dialkyl cyanoboronates — new cyanating agents

Apart from variations of the cyanide source the optimization of co-catalysts and ligands was studied in order to improve the palladium-catalyzed cyanation of aryl halides in efficiency and scope. For example Okano et al. introduced a new class of phase-transfer-type phosphane ligands for this reaction. Here, the known positive effect of a phase-transfer catalyst (PTC) was introduced in the phosphane ligand in order to control the reactivity of the palladium catalyst. Several ligands, containing crown ether, sulfonic acid, carbonic acid or ammonium salts, or similar substructures were tested (Figure 2).[53,54] The best results were obtained in the presence of PPh_2(bc-5) and PPh_2(ms) as ligand (Table 4 and 5).

As shown in Table 4, when using PPh_2(bc-5) as ligand the cyanation of bromo- and iodoarenes is possible in the presence of a comparatively low catalyst concentration (0.33 mol %). Here, no further additives are necessary, but
